Define the map from the space of $n \times s$ matrices to order-k symmetric tensors,

$$f : \mathbb{C}^{n \times s} \to \mathsf{S}^k(\mathbb{C}^n),$$
$$[\mathbf{y}_1, \dots, \mathbf{y}_s] \mapsto \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}.$$

It is clear that f takes $\mathbb{C}^{n \times s}$ *onto* $\mathcal{Y}_s$ (i.e., $f(\mathbb{C}^{n \times s}) = \mathcal{Y}_s$). We let E_0 and E_1 be the subsets of rank-deficient and full-rank matrices in $\mathbb{C}^{n \times s}$, respectively. Thus we have the disjoint union

$$E_0 \cup E_1 = \mathbb{C}^{n \times s}, \quad E_0 \cap E_1 = \varnothing.$$

Recall that the full-rank matrices are generic in $\mathbb{C}^{n \times s}$. Recall also that E_0 is an algebraic set in $\mathbb{C}^{n \times s}$ defined by the vanishing of all $s \times s$ principal minors. By the previous lemma, $f(E_1) \subseteq \mathcal{Z}_s$. The set of symmetric tensors

$$\sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}$$

in $\mathcal{Z}_s$ for which $\{\mathbf{y}_1, \dots, \mathbf{y}_s\}$ is linearly dependent, i.e., $[\mathbf{y}_1, \dots, \mathbf{y}_s]$ is rank deficient, is simply

$$\mathcal{Z}_s \cap f(E_0).$$

Since f is a polynomial map and E_0 is a nontrivial algebraic set, we conclude that $f(E_1)$ is generic in $\mathcal{Z}_s$. □

PROPOSITION 5.3. *Let* $A \in \mathsf{S}^k(\mathbb{C}^n)$. *If* $\operatorname{rank}_{\mathsf{S}}(A) \leq n$, *then* $\operatorname{rank}(A) = \operatorname{rank}_{\mathsf{S}}(A)$ *generically.*

Proof. Let $r = \operatorname{rank}(A)$ and $s = \operatorname{rank}_{\mathsf{S}}(A)$. There exist decompositions

$$\sum\nolimits_{j=1}^{r} \mathbf{x}_j^{(1)} \otimes \cdots \otimes \mathbf{x}_j^{(k)} = A = \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}. \tag{5.3}$$

By Lemma 5.2, we may assume that for a generic $A \in \mathcal{Z}_s$, the vectors $\mathbf{y}_1, \dots, \mathbf{y}_s$ are linearly independent. As in the proof of Lemma 5.1, we may find a set of covectors $\varphi_1, \dots, \varphi_s \in (\mathbb{C}^n)^*$ that are dual to $\mathbf{y}_1, \dots, \mathbf{y}_s$, i.e.,

$$\varphi_i(\mathbf{y}_j) = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

Contracting both sides of (5.3) in the first $k-1$ modes with $\varphi_i^{\otimes(k-1)} \in \mathsf{S}^{k-1}((\mathbb{C}^n)^*)$, we get

$$\sum\nolimits_{j=1}^{r} \alpha_{ij} \mathbf{x}_j^{(k)} = \mathbf{y}_i,$$

where $\alpha_{ij} = \varphi_i(\mathbf{x}_j^{(1)}) \cdots \varphi_i(\mathbf{x}_j^{(k-1)})$, $j = 1, \dots, r$. Since this holds for each $i = 1, \dots, s$, it implies that the s linearly independent vectors $\mathbf{y}_1, \dots, \mathbf{y}_s$ are contained in $\operatorname{span}\{\mathbf{x}_1^{(k)}, \dots, \mathbf{x}_r^{(k)}\}$. Hence we must have $r \geq s$. On the other hand, it is clear that $r \leq s$. Thus we must have equality. □

We will see below that we could have $\operatorname{rank}(A) = \operatorname{rank}_{\mathsf{S}}(A)$ even when the constituting vectors $\mathbf{y}_1, \dots, \mathbf{y}_s$ are not linearly independent. The authors would like to thank David Gross for his help in correcting an error in the original proof.

PROPOSITION 5.4. *Let* $\mathbf{y}_1, \dots, \mathbf{y}_s \in \mathbb{C}^n$ *be pariwise linearly independent. If* k *is sufficiently large, then the symmetric tensor defined by*

$$A := \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}$$

satisfies $\operatorname{rank}(A) = \operatorname{rank}_{\mathsf{S}}(A)$ *generically.*

Proof. Let $r = \operatorname{rank}(A)$ and $s = \operatorname{rank}_{\mathsf{S}}(A)$. So there exist decompositions

$$\sum\nolimits_{j=1}^{r} \mathbf{x}_j^{(1)} \otimes \cdots \otimes \mathbf{x}_j^{(k)} = A = \sum\nolimits_{i=1}^{s} \mathbf{y}_i^{\otimes k}. \tag{5.4}$$

Note that the left-hand side may be written $\sum_{i=1}^{s} \mathbf{y}_i^{\otimes k/2} \otimes \mathbf{y}_i^{\otimes k/2}$, where we have assumed, without loss of generality, that k is even. By Proposition 4.3, when k is sufficiently large, the order-$(k/2)$ tensors $\mathbf{y}_1^{\otimes k/2}, \dots, \mathbf{y}_s^{\otimes k/2}$ are generically linearly independent. Hence we may find functionals $\Phi_1, \dots, \Phi_s \in \mathsf{S}^{k/2}(\mathbb{C}^n)^*$ that are dual to $\mathbf{y}_1^{\otimes k/2}, \dots, \mathbf{y}_s^{\otimes k/2} \in \mathsf{S}^{k/2}(\mathbb{C}^n)$, i.e.,

$$\Phi_i(\mathbf{y}_j^{\otimes k/2}) = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{if } i \neq j. \end{cases}$$

Contracting both sides of (5.4) in the first $k/2$ modes with Φ_i, we get

$$\sum\nolimits_{j=1}^{r} \alpha_{ij} \mathbf{x}_j^{(k/2+1)} \otimes \cdots \otimes \mathbf{x}_j^{(k)} = \mathbf{y}_i^{\otimes k/2},$$

where $\alpha_{ij} = \Phi_i(\mathbf{x}_j^{(1)} \otimes \cdots \otimes \mathbf{x}_j^{(k/2)})$, $j = 1, \ldots, r$. Since this holds for each $i = 1, \ldots, s$, it implies that the s linearly independent vectors $\mathbf{y}_1, \ldots, \mathbf{y}_s$ are contained in $\operatorname{span}\{\mathbf{x}_1^{(k/2+1)} \otimes \cdots \otimes \mathbf{x}_1^{(k)}, \ldots \mathbf{x}_r^{(k/2+1)} \otimes \cdots \otimes \mathbf{x}_r^{(k)}\}$. Hence we must have $r \geq s$. On the other hand, it is clear that $r \leq s$. Thus we must have equality. ∎

PROPOSITION 5.5. *Let* $A \in \mathsf{S}^k(\mathbb{C}^n)$. *If* $\operatorname{rank}_{\mathsf{S}}(A) = 1$ *or* 2, *then* $\operatorname{rank}(A) = \operatorname{rank}_{\mathsf{S}}(A)$.

Proof. If $\operatorname{rank}_{\mathsf{S}}(A) = 1$, then $\operatorname{rank}(A) = 1$ clearly. If $\operatorname{rank}_{\mathsf{S}}(A) = 2$, then

$$A = \mathbf{y}_1^{\otimes k} + \mathbf{y}_2^{\otimes k}$$

for some $\mathbf{y}_1, \mathbf{y}_2 \in \mathbb{C}^n$. It is clear that $\mathbf{y}_1$ and $\mathbf{y}_2$ must be linearly independent or otherwise $\mathbf{y}_2 = \alpha \mathbf{y}_1$ implies that

$$A = (\beta \mathbf{y}_1)^{\otimes k}$$

for any $\beta = (1 + \alpha^k)^{1/k}$, contradicting $\operatorname{rank}_{\mathsf{S}}(A) = 2$. It follows from the argument in the proof of Proposition 5.3 with $s = 2$ that $\operatorname{rank}(A) = 2$. ∎

The following result will be useful later.

PROPOSITION 5.6. *Let* $\mathbf{v}_1$ *and* $\mathbf{v}_2$ *be two linearly independent vectors in* $\mathbb{C}^n$. *Then for any* $k > 1$, *the order-*k *symmetric tensor*

$$\begin{aligned}(5.5)\quad &\mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \mathbf{v}_2 \otimes \cdots \otimes \mathbf{v}_2 + \mathbf{v}_2 \otimes \mathbf{v}_1 \otimes \mathbf{v}_2 \otimes \cdots \otimes \mathbf{v}_2 \\ &\quad + \mathbf{v}_2 \otimes \mathbf{v}_2 \otimes \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_2 + \cdots + \mathbf{v}_2 \otimes \mathbf{v}_2 \otimes \mathbf{v}_2 \otimes \cdots \otimes \mathbf{v}_1\end{aligned}$$

is of symmetric rank k.

Proof. It is not hard to check that the symmetric tensor in (5.5) is associated with the quantic $p(z_1, z_2) = z_1 z_2^{k-1}$ up to a constant multiplicative factor (where z_1, z_2 are the first two coordinate variables in $(z_1, \ldots, z_n)$).

To prove that this quantic is of symmetric rank k, we are going to show that $p(z_1, z_2)$ can be decomposed into a sum of powers of linear forms as

$$(5.6)\qquad p(z_1, z_2) = \sum\nolimits_{i=1}^{k} \lambda_i (\alpha_i z_1 + \beta_i z_2)^k.$$

There are infinitely many possibilities of choosing coefficients (α_i, β_i) but we need to provide just one solution. Take $\alpha_1 = \cdots = \alpha_r = 1$ and $\beta_1, \ldots, \beta_k$ distinct such that

$$(5.7)\qquad \sum\nolimits_{i=1}^{k} \beta_i = 0.$$

First we express all quantics in terms of the canonical basis scaled by the binomial coefficients:

$$\{z_1^k, k z_1^{k-1} z_2, \ldots, k z_1 z_2^{k-1}, z_2^k\}.$$

In this basis, the monomial $k z_1 z_2^{k-1}$ can be represented by a $(k+1)$-dimensional vector containing only one nonzero entry. The quantic $(z_i + \beta_i z_2)^k$ is then represented by the vector

$$[1, \beta_i, \beta_i^2, \ldots, \beta_i^k] \in \mathbb{C}^{k+1}.$$

The existence of coefficients $\lambda_1, \dots, \lambda_k$ such that we have the decomposition (5.6) is equivalent to the vanishing of the $(k+1) \times (k+1)$ determinant

$$\begin{vmatrix} 0 & 0 & \cdots & 1 & 0 \\ 1 & \beta_1 & \cdots & \beta_1^{k-1} & \beta_1^k \\ \vdots & \vdots & & \vdots & \vdots \\ 1 & \beta_k & \cdots & \beta_k^{k-1} & \beta_k^k \end{vmatrix}. \tag{5.8}$$

An explicit computation shows that this determinant is $\pm(\sum_{i=1}^k \beta_i) V_k(\beta_1, \dots, \beta_k)$, where $V_k(\beta_1, \dots, \beta_k)$ is the Vandermonde determinant of degree $k-1$ of $\beta_1, \dots, \beta_k$. Thus by (5.7), the determinant in (5.8) vanishes.

This proves that the symmetric rank of $z_1 z_2^k$ is $\leq k$. Note that the symmetric rank cannot be smaller than k because removing any row of the matrix of (5.8) still yields a matrix of rank k if the β_i are distinct (see also Proposition 4.3). □

This proof is constructive and gives an algorithm to compute a symmetric outer product decomposition of any binary symmetric tensor of the form (5.5). For example, the reader can check out that the decompositions below may be obtained this way.

Example 5.7. The quantics $48 z_1^3 z_2$ and $60 z_1^4 z_2$ are associated with the symmetric tensors of maximal rank A_{31} and A_{41}, respectively. Their symmetric outer product decompositions are given by

$$\begin{aligned} A_{31} &= 8(\mathbf{v}_1 + \mathbf{v}_2)^{\otimes 4} - 8(\mathbf{v}_1 - \mathbf{v}_2)^{\otimes 4} - (\mathbf{v}_1 + 2\mathbf{v}_2)^{\otimes 4} + (\mathbf{v}_1 - 2\mathbf{v}_2)^{\otimes 4}, \\ A_{41} &= 8(\mathbf{v}_1 + \mathbf{v}_2)^{\otimes 5} - 8(\mathbf{v}_1 - \mathbf{v}_2)^{\otimes 5} - (\mathbf{v}_1 + 2\mathbf{v}_2)^{\otimes 5} + (\mathbf{v}_1 - 2\mathbf{v}_2)^{\otimes 5} + 48\mathbf{v}_1^{\otimes 5}. \end{aligned}$$

The maximal symmetric rank achievable by symmetric tensors of order k and dimension $n = 2$ is k, i.e., $R_{\mathsf{S}}(k, 2) = k$. One can say that such symmetric tensors lie on a tangent line to the Veronese variety of symmetric rank-1 tensors. In [13], an algorithm was proposed to decompose binary forms when their rank is not larger than $k/2$; however, this algorithm would not have found the decompositions above since the symmetric ranks of A_{31} and A_{41} exceed $4/2$ and $5/2$, respectively.

6. Generic symmetric rank and typical symmetric ranks. For given order and dimension, define the following subsets of symmetric tensors $\mathcal{Y}_r := \{A \in \mathsf{S}^k(\mathbb{C}^n) \mid \operatorname{rank}_{\mathsf{S}}(A) \leq r\}$ and $\mathcal{Z}_r := \{A \in \mathsf{S}^k(\mathbb{C}^n) \mid \operatorname{rank}_{\mathsf{S}}(A) = r\}$. Also, denote the corresponding Zariski closures by $\overline{\mathcal{Y}}_r$ and $\overline{\mathcal{Z}}_r$, respectively. Recall that the Zariski closure [18] of a set $\mathcal{S}$ is simply the smallest variety containing $\mathcal{S}$. For every $r \in \mathbb{N}$, we clearly have

$$\mathcal{Y}_{r-1} \cup \mathcal{Z}_r = \mathcal{Y}_r \quad \text{and} \quad \underbrace{\mathcal{Y}_1 + \cdots + \mathcal{Y}_1}_{r \text{ copies}} = \mathcal{Y}_r.$$

The quantities $\overline{R}_{\mathsf{S}}(k, n)$ and $R_{\mathsf{S}}(k, n)$ may now be formally defined by

$$\overline{R}_{\mathsf{S}}(k, n) := \min\{r \mid \overline{\mathcal{Y}}_r = \mathsf{S}^k(\mathbb{C}^n)\} \quad \text{and} \quad R_{\mathsf{S}}(k, n) := \min\{r \mid \mathcal{Y}_r = \mathsf{S}^k(\mathbb{C}^n)\}.$$

By definition, we have $\overline{R}_{\mathsf{S}}(k, n) \leq R_{\mathsf{S}}(k, n)$. We shall prove in this section that a generic symmetric rank always exists in $\mathsf{S}^k(\mathbb{C}^n)$, i.e., there is an r such that $\overline{\mathcal{Z}}_r = \mathsf{S}^k(\mathbb{C}^n)$, and that it is equal to $\overline{R}_{\mathsf{S}}(k, n)$, thus justifying our naming $\overline{R}_{\mathsf{S}}(k, n)$ the *generic* symmetric rank in section 5.

An integer r is not a *typical rank* if $\mathcal{Z}_r$ has zero volume, which means that $\mathcal{Z}_r$ is contained in a nontrivial closed set. This definition is somewhat unsatisfactory since

any mention of "volume" necessarily involves a choice of measure, which is really irrelevant here. A better definition is as follows.

DEFINITION 6.1. *An integer r is a typical rank if $\mathcal{Z}_r$ is dense with the Zariski topology, i.e., if $\overline{\mathcal{Z}}_r = \mathsf{S}^k(\mathbb{C}^n)$. When a typical rank is unique, it may be called generic.*

We used the wording "typical" in agreement with previous terminologies [9, 56, 58]. Since two dense algebraic sets always intersect over $\mathbb{C}$, there can be only one typical rank over $\mathbb{C}$, and hence it is generic. In the remainder of this section, we will write $\overline{R}_{\mathsf{S}} = \overline{R}_{\mathsf{S}}(k,n)$ and $R_{\mathsf{S}} = R_{\mathsf{S}}(k,n)$. We can then prove the following.

PROPOSITION 6.2. *The varieties $\overline{\mathcal{Z}}_r$ can be ordered by inclusion as follows. If*

$$r_1 < r_2 < \overline{R}_{\mathsf{S}} < r_3 \leq R_{\mathsf{S}},$$

then

$$\overline{\mathcal{Z}}_{r_1} \subsetneq \overline{\mathcal{Z}}_{r_2} \subsetneq \overline{\mathcal{Z}}_{\overline{R}_{\mathsf{S}}} \supsetneq \overline{\mathcal{Z}}_{r_3}.$$

Before proving this proposition, we state two preliminary results. Recall that an algebraic variety is *irreducible* if it cannot be decomposed as the union of proper subvarieties (cf. [27, pp. 51] and [49, pp. 34]). In algebraic geometry, it is known that the secant varieties of any irreducible variety are irreducible. Nevertheless, we will give a short proof of the following lemma for the sake of completeness.

LEMMA 6.3. *The sets $\overline{\mathcal{Y}}_r$, $r \geq 1$, are irreducible algebraic varieties.*

Proof. For $r \geq 1$, the variety $\overline{\mathcal{Y}}_r$ is the closure of the image $\mathcal{Y}_r$ of the map

$$\begin{aligned} \varphi_r : \mathbb{C}^{n\times r} &\to \mathsf{S}^k(\mathbb{C}^n), \\ [\mathbf{u}_1, \ldots, \mathbf{u}_r] &\mapsto \sum\nolimits_{i=1}^{r} \mathbf{u}_i^{\otimes k}. \end{aligned}$$

Consider now two polynomials f, g such that $fg \equiv 0$ on $\overline{\mathcal{Y}}_r$. As $\overline{\mathcal{Y}}_r$ is the Zariski closure of $\mathcal{Y}_r$, this is equivalent to $fg \equiv 0$ on $\mathcal{Y}_r$ or

$$(fg) \circ \varphi_r = (f \circ \varphi_r)(g \circ \varphi_r) \equiv 0.$$

Thus either $f \equiv 0$ or $g \equiv 0$ on $\mathcal{Y}_r$ or equivalently on $\overline{\mathcal{Y}}_r$, which proves that $\overline{\mathcal{Y}}_r$ is an irreducible variety. For more details on properties of parameterized varieties, see [18]. See also the proof of [52, 9] for third order tensors. ∎

LEMMA 6.4. *We have $\overline{R}_{\mathsf{S}} = \min\{r \mid \overline{\mathcal{Y}}_r = \overline{\mathcal{Y}}_{r+1}\}$.*

Proof. Suppose that there exists $r < \overline{R}_{\mathsf{S}}$ such that $\overline{\mathcal{Y}}_r = \overline{\mathcal{Y}}_{r+1}$. Then since $\overline{\mathcal{Y}}_r \subseteq \overline{\mathcal{Y}}_r + \mathcal{Y}_1 \subseteq \overline{\mathcal{Y}}_{r+1} = \overline{\mathcal{Y}}_r$, we have

$$\overline{\mathcal{Y}}_r = \overline{\mathcal{Y}}_r + \mathcal{Y}_1 = \overline{\mathcal{Y}}_r + \mathcal{Y}_1 + \mathcal{Y}_1 = \cdots = \overline{\mathcal{Y}}_r + \mathcal{Y}_1 + \cdots + \mathcal{Y}_1.$$

As the sum of R_{S} copies of $\mathcal{Y}_1$ is $\mathsf{S}^k(\mathbb{C}^n)$, we deduce that $\overline{\mathcal{Y}}_r = \mathsf{S}^k(\mathbb{C}^n)$ and thus $r \geq \overline{R}_{\mathsf{S}}$, which contradicts our hypothesis. By definition, $\overline{\mathcal{Y}}_{\overline{R}_{\mathsf{S}}} = \overline{\mathcal{Y}}_{\overline{R}_{\mathsf{S}}+1} = \mathsf{S}^k(\mathbb{C}^n)$, which proves the lemma. See also the proof of [52] for the asymmetric case. ∎

We are now in a position to prove Proposition 6.2.

Proof of Proposition 6.2. By Lemma 6.4, we deduce that for $r < \overline{R}_{\mathsf{S}}$,

$$\overline{\mathcal{Y}}_r \neq \overline{\mathcal{Y}}_{r+1}.$$

As $\overline{\mathcal{Y}}_r$ is an irreducible variety, we have $\dim(\overline{\mathcal{Y}}_r) < \dim(\overline{\mathcal{Y}}_{r+1})$. As $\mathcal{Y}_r \cup \mathcal{Z}_{r+1} = \mathcal{Y}_{r+1}$, we deduce that

$$\overline{\mathcal{Y}}_r \cup \overline{\mathcal{Z}}_{r+1} = \overline{\mathcal{Y}}_{r+1},$$

which implies by the irreducibility of $\overline{\mathcal{Y}}_{r+1}$, that $\overline{\mathcal{Z}}_{r+1} = \overline{\mathcal{Y}}_{r+1}$. Consequently, for $r_1 < r_2 < \overline{R}_{\mathsf{S}}$, we have

$$\overline{\mathcal{Z}}_{r_1} = \overline{\mathcal{Y}}_{r_1} \subsetneq \overline{\mathcal{Z}}_{r_2} = \overline{\mathcal{Y}}_{r_2} \subsetneq \overline{\mathcal{Z}}_{\overline{R}_{\mathsf{S}}} = \overline{\mathcal{Y}}_{\overline{R}_{\mathsf{S}}} = \mathsf{S}^k(\mathbb{C}^n).$$

Let us prove now that if $\overline{R}_{\mathsf{S}} < r_3$, we have $\overline{\mathcal{Z}}_{r_3} \subsetneq \mathsf{S}^k(\mathbb{C}^n)$. Suppose that $\overline{\mathcal{Z}}_{r_3} = \mathsf{S}^k(\mathbb{C}^n)$, then $\mathcal{Z}_{r_3}$ is dense in $\mathsf{S}^k(\mathbb{C}^n)$ as well as $\mathcal{Z}_{\overline{R}_{\mathsf{S}}}$ in the Zariski topology. This implies that $\mathcal{Z}_{r_3} \cap \mathcal{Z}_{\overline{R}_{\mathsf{S}}} \neq \varnothing$, which is false because a tensor cannot have two different ranks. Consequently, we have $\overline{\mathcal{Z}}_{r_3} \subsetneq \mathsf{S}^k(\mathbb{C}^n)$. ∎

PROPOSITION 6.5. *If $1 \leq r \leq R_{\mathsf{S}}$, then $\mathcal{Z}_r \neq \overline{\mathcal{Z}}_r$.*

Proof. Let $r > 1$ and $A \in \mathcal{Z}_r$. Then by definition of $\mathcal{Y}_r$, there exists $A_0 \in \mathcal{Y}_{r-1}$ and $A_1 \in \mathcal{Y}_1$ such that $A = A_0 + A_1$. As $A_0 \notin \mathcal{Y}_{r-2}$ (otherwise $A \in \mathcal{Y}_{r-1}$) we have $A_0 \in \mathcal{Z}_{r-1}$. For $\varepsilon \neq 0$, define $A_\varepsilon = A_0 + \varepsilon A_1$. We have that $A_\varepsilon \in \mathcal{Z}_r$ for all $\varepsilon \neq 0$ and $\lim_{\varepsilon \to 0} A_\varepsilon = A_0$. This shows that $A_0 \in \overline{\mathcal{Z}}_r - \mathcal{Z}_r$ and consequently that $\mathcal{Z}_r \neq \overline{\mathcal{Z}}_r$. ∎

The above proposition is about the set of symmetric tensors of symmetric rank *exactly* r. But what about those of symmetric rank *at most* r? While $\mathcal{Y}_1$ is closed as a determinantal variety, we will see from Examples 6.6 and 6.7 as well as Proposition 6.8 that $\mathcal{Y}_r$ is generally not closed for $r > 1$. This is another major difference from matrices, for which all $\mathcal{Y}_r$ are closed sets.

Example 6.6. In dimension $n \geq 2$, and for any order $k > 2$, $\mathcal{Y}_2$ is not closed. In fact, take two independent vectors $\mathbf{x}_i$ and $\mathbf{x}_j$ and define the sequence of symmetric tensors

$$A_\varepsilon(i,j) := \frac{1}{\varepsilon}\left[(\mathbf{x}_i + \varepsilon \mathbf{x}_j)^{\otimes k} - \mathbf{x}_i^{\otimes k}\right]. \tag{6.1}$$

For any $\varepsilon \neq 0$, $A_\varepsilon(i,j)$ is of symmetric rank 2, but converges in the limit as $\varepsilon \to 0$ to a symmetric tensor of symmetric rank k. In fact, the limiting symmetric tensor is easily seen to be a sum of k rank-1 tensors,

$$\mathbf{x}_i \otimes \mathbf{x}_j \otimes \cdots \otimes \mathbf{x}_j + \mathbf{x}_j \otimes \mathbf{x}_i \otimes \cdots \otimes \mathbf{x}_j + \cdots + \mathbf{x}_j \otimes \mathbf{x}_j \otimes \cdots \otimes \mathbf{x}_i,$$

which has symmetric rank k by Proposition 5.6.

Example 6.7. Let $n = 3$ and $k = 3$. Then $\mathcal{Y}_5 \subset \overline{\mathcal{Y}}_3$, whereas $3 < \overline{R}_{\mathsf{S}}$. In fact, take the symmetric tensor associated with the ternary cubic $p(x,y,z) = x^2y - xz^2$. According to [16, 47], this tensor has rank 5. On the other hand, it is the limit of the sequence $p_\varepsilon(x,y,z) = x^2y - xz^2 + \varepsilon z^3$ as ε tends to zero. According to a result in [16], the latter polynomial is associated with a rank-3 tensor since the determinant of its Hessian is equal to $8x^2(x - 3\varepsilon z)$ and hence contains two distinct linear forms as long as $\varepsilon \neq 0$.

It is easy to show that this lack of closeness extends in general to $r > \overline{R}_{\mathsf{S}}$ or for $r \leq n$, as stated in the two propositions below.

PROPOSITION 6.8. *If $\overline{R}_{\mathsf{S}} < r$, then for all $k > 2$, $\mathcal{Y}_r \neq \overline{\mathcal{Y}}_r$.*

Proof. If $\overline{R}_{\mathsf{S}} < r$, then $\mathcal{Y}_{\overline{R}_{\mathsf{S}}} \subsetneq \mathcal{Y}_r$. By the definition of generic symmetric rank, $\overline{\mathcal{Y}}_{\overline{R}_{\mathsf{S}}} = \mathsf{S}^k(\mathbb{C}^n) = \overline{\mathcal{Y}}_r$. Hence $\mathcal{Y}_r \subsetneq \overline{\mathcal{Y}}_r = \mathsf{S}^k(\mathbb{C}^n)$. ∎

PROPOSITION 6.9. *If $1 < r \leq n$, then for any $k > 2$, $\mathcal{Y}_r \neq \overline{\mathcal{Y}}_r$.*

Proof. Take n linearly independent vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$. Then the symmetric tensors $\mathbf{x}_1^{\otimes k}, \ldots, \mathbf{x}_n^{\otimes k}$ are linearly independent as well, and $\sum_{i=1}^r \mathbf{x}_i^{\otimes k}$ is of symmetric rank r for every $r \leq n$ by Lemma 5.1. Now for $r > 2$ and any $\varepsilon \neq 0$, define the symmetric tensor

$$A_\varepsilon = \frac{1}{\varepsilon}\left[(\mathbf{x}_1 + \varepsilon \mathbf{x}_2)^{\otimes k} - \mathbf{x}_1^{\otimes k}\right] + \sum\nolimits_{i=3}^{r} \mathbf{x}^{\otimes k}.$$

A_ε is again of symmetric rank r for every $\varepsilon \neq 0$, but tends to a symmetric rank $r+1$ tensor (see also section 8.1). For $r = 2$, the same reasoning applies with

$$A_\varepsilon = \frac{1}{\varepsilon}\left[(\mathbf{x}_1 + \varepsilon \mathbf{x}_2)^{\otimes k} - \mathbf{x}_1^{\otimes k}\right].$$

This shows that $\mathcal{Y}_r$ is not closed. ∎

Based on these two propositions, we conjecture the stronger statement that for order $k > 2$, the set of symmetric tensors of symmetric rank at most r is never closed, even for $r = n+1, \ldots, R_{\mathsf{S}} - 1$.

CONJECTURE 6.10. *Assume $k > 2$ and $n \geq 2$. Then $\mathcal{Y}_r \neq \overline{\mathcal{Y}}_r$ for any r such that $1 < r < R_{\mathsf{S}}$.*

Up to this point, our study has been based on the Zariski topology [49, 18]. However it is useful from a practical point of view to be able to apply these results to other topologies, for example, the Euclidean topology. Since the $\mathcal{Y}_r$ are parameterized and are thus algebraic constructible sets [49], and since the closure of an algebraic constructible set for the Euclidean topology and the Zariski topology are the same, the results in this paper holds true for many other topologies. We have in particular the following result.

COROLLARY 6.11. *Let μ be a measure on Borel subsets of $\mathsf{S}^k(\mathbb{C}^n)$ with respect to the Euclidean topology on $\mathsf{S}^k(\mathbb{C}^n)$. Let $\overline{R}_{\mathsf{S}}$ be the generic symmetric rank in $\mathsf{S}^k(\mathbb{C}^n)$. If μ is absolutely continuous with respect to the Lebesgue measure on $\mathsf{S}^k(\mathbb{C}^n)$, then*

$$\mu(\{A \in \mathsf{S}^k(\mathbb{C}^n) \mid \operatorname{rank}_{\mathsf{S}}(A) \neq \overline{R}_{\mathsf{S}}\}) = 0.$$

In particular, this corollary tells us that $\mathcal{Z}_{\overline{R}_{\mathsf{S}}}$ is also dense in $\mathsf{S}^k(\mathbb{C}^n)$ with respect to the Euclidean topology. It also tells us that the rank of a tensor whose entries are drawn randomly according to an absolutely continuous distribution (e.g., Gaussian) is $\overline{R}_{\mathsf{S}}$ with probability 1. This is useful in signal processing, for instance, where cumulant tensors are estimated from actual data and are asymptotically Gaussian distributed [6, 44].

These statements extend previous results [3] and prove that there can be only *one* subset $\mathcal{Z}_r$ of nonempty interior and that the latter is dense in $\mathsf{S}^k(\mathbb{C}^n)$; this result, however, requires that we work over an algebraically closed field such as $\mathbb{C}$.

The results of this section are indeed not generally valid over $\mathbb{R}$. We refer the reader to section 8 for further discussions concerning the real field.

7. Values of the generic symmetric rank. In practice, it would be useful to be able to compute the symmetric rank of any given symmetric tensor, or at least to know the maximal values of the symmetric rank, given its order and dimensions. Unfortunately, these problems are far from resolved.

The corresponding problem for the generic values of the symmetric rank, however, has seen enormous progress due to the work of Alexander and Hirschowitz described in section 7.1. In fact, even before their breakthrough, bounds on the generic symmetric rank have been known for decades [3, 47, 48]:

$$\left\lceil \frac{1}{n}\binom{n+k-1}{k} \right\rceil \leq \overline{R}_{\mathsf{S}}(k,n) \leq \binom{n+k-2}{k-1}.$$

It is known that the lower bound is often accurate but the upper bound is not tight [16]. Furthermore, exact results are known in the case of binary quantics ($n = 2$) and ternary cubics ($k = 3$) [22, 16, 48, 35].

7.1. Alexander–Hirschowitz theorem. It was not until the work [1] of Alexander and Hirschowitz in 1995 that the generic symmetric rank problem was completely settled. Nevertheless, the relevance of their result has remained largely unknown in the applied and computational mathematics communities. One reason is that the connection between our problem and the *interpolating polynomials* discussed in [1] is not at all well known in the aforementioned circles. So for the convenience of our readers, we will state the result of Alexander and Hirschowitz in the context of the symmetric outer product decomposition below.

THEOREM 7.1 (Alexander–Hirschowitz). *For $k > 2$, the generic symmetric rank of an order-k symmetric tensor of dimension n over $\mathbb{C}$ is always equal to the lower bound*

$$\overline{R}_{\mathsf{S}}(k,n) = \left\lceil \frac{1}{n}\binom{n+k-1}{k} \right\rceil \tag{7.1}$$

except for the following cases: $(k,n) \in \{(3,5),(4,3),(4,4),(4,5)\}$, where it should be increased by 1.

This theorem is extremely complicated to prove, and the interested reader should refer to the two papers by Alexander and Hirschowitz [1, 2]. Simplifications to this proof have also been recently proposed in [12]. It is worth noting that these results have been proved in terms of multivariate polynomials and interpolation theory, not in terms of symmetric tensors. The exception $(k,n) = (4,3)$ has been known since 1860; in fact, Sylvester referred to it as the Clebsch theorem in his work [53]. It is not hard to guess the formula in (7.1) by a degrees-of-freedom argument. The difficulty of proving Theorem 7.1 lies in establishing the fact that the four given exceptions to the expected formula (7.1) are the only ones. Table 7.1 lists a few values of the generic symmetric rank.

TABLE 7.1
Values of the generic symmetric rank $\overline{R}_{\mathsf{S}}(k,n)$ for various orders k and dimensions n. Values appearing in bold are the exceptions outlined by the Alexander–Hirschowitz theorem.

k \ n	2	3	4	5	6	7	8	9	10
3	2	4	5	**8**	10	12	15	19	22
4	3	**6**	**10**	**15**	21	30	42	55	72
5	3	7	14	26	42	66	99	143	201
6	4	10	21	42	77	132	215	334	501

7.2. Uniqueness. Besides the exceptions pointed out in Theorem 7.1, the number of solutions for the symmetric outer product decomposition has to be finite if the rank r is smaller than or equal to $\frac{1}{n}\binom{n+k-1}{k}$. This occurs, for instance, for all cases of degree $k = 5$ in Table 7.1, except for $n = 5$ and $n = 10$. Hence we may deduce the following.

COROLLARY 7.2. *Suppose $(k,n) \notin \{(3,5),(4,3),(4,4),(4,5)\}$. Let $A \in \mathsf{S}^k(\mathbb{C}^n)$ be a generic element and let the symmetric outer product decomposition of A be*

$$A = \sum\nolimits_{i=1}^{\overline{R}_{\mathsf{S}}} \mathbf{v}_i^{\otimes k}. \tag{7.2}$$

Then (7.2) *has a finite number of solutions if and only if*

$$\frac{1}{n}\binom{n+k-1}{k} \in \mathbb{N}.$$

TABLE 7.2
Generic dimension $F(k,n)$ of the fiber of solutions.

k \ n	2	3	4	5	6	7	8	9	10
3	0	2	0	**5**	4	0	0	6	0
4	1	**3**	**5**	**5**	0	0	6	0	5
5	0	0	0	4	0	0	0	0	8
6	1	2	0	0	0	0	4	3	5

Actually, one may easily check the generic dimension of the fiber of solutions by computing the number of remaining free parameters [16]:

$$F(k,n) = n\overline{R}_{\mathsf{S}}(k,n) - \binom{n+k-1}{k}.$$

This is summarized in Table 7.2. When the dimension of the fiber is nonzero, there are infinitely many symmetric outer product decompositions.

Our technique is different from the reduction to simplicity proposed by ten Berge [56, 59] but also relies on the calculation of dimensionality.

8. Examples. We will present a few examples to illustrate our discussions in the previous sections.

8.1. Lack of closeness. It has been shown [16, 35] that symmetric tensors of order 3 and dimension 3 have a generic rank $\overline{R}_{\mathsf{S}}(3,3) = 4$ and a maximal rank $R_{\mathsf{S}}(3,3) = 5$. From the results of section 6, this means that only $\mathcal{Z}_4$ is dense in $\overline{\mathcal{Y}}_4 = \overline{\mathcal{Y}}_5$ and that $\mathcal{Z}_3$ and $\mathcal{Z}_5$ are not closed by Proposition 6.5. On the other hand, $\mathcal{Z}_1$ is closed.

To make this statement even more explicit, let us now define a sequence of symmetric tensors, each of symmetric rank 2, that converges to a symmetric tensor of symmetric rank 3. This will be a simple demonstration of the lack of closure of $\mathcal{Y}_r$ for $r > 1$ and $k > 2$, already stated in Proposition 6.8. For this purpose, let $\mathbf{x}, \mathbf{y}$ be two noncollinear vectors. Then the order-3 symmetric tensor

$$A_\varepsilon = \varepsilon^2(\mathbf{x} + \varepsilon^{-1}\mathbf{y})^{\otimes 3} + \varepsilon^2(\mathbf{x} - \varepsilon^{-1}\mathbf{y})^{\otimes 3} \tag{8.1}$$

is of symmetric rank 2 for any scalar $\varepsilon \neq 0$, and it converges, as $\varepsilon \to 0$, to the following symmetric tensor:

$$A_0 = 2\left(\mathbf{x}\otimes\mathbf{y}\otimes\mathbf{y} + \mathbf{y}\otimes\mathbf{x}\otimes\mathbf{y} + \mathbf{y}\otimes\mathbf{y}\otimes\mathbf{x}\right).$$

This limiting symmetric tensor is of symmetric rank 3. In fact, one may show [14] that it admits the following symmetric outer product decomposition:

$$A_0 = (\mathbf{x}+\mathbf{y})^{\otimes 3} - (\mathbf{x}-\mathbf{y})^{\otimes 3} - 2\mathbf{y}^{\otimes 3}.$$

Now let $\mathbf{x}_i, \mathbf{y}_i$ be linearly independent vectors.

By adding two terms of the form (8.1), a similar example can be given in dimension $n = 4$, where we get a sequence of symmetric tensors of symmetric rank 4 converging to a limit of symmetric rank 6.

We will give two more illustrations of Conjecture 6.10.

Example 8.1. If the dimension is $n = 3$, we can take three linearly independent vectors, say, $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$. Then the sequence of symmetric tensors $A_\varepsilon + \mathbf{z}^{\otimes 3}$ is of symmetric rank 3 and converges toward a symmetric rank-4 tensor.

In dimension 3, it is somewhat more tricky to build a sequence converging toward a symmetric tensor of symmetric rank 5. Note that 5 is the maximal rank for $k = 3$ and $n = 3$.

Example 8.2. Consider the sequence below as ε tends to zero:

$$\frac{1}{\varepsilon}\left[(\mathbf{x}+\varepsilon\mathbf{y})^{\otimes 3} - \mathbf{x}^{\otimes 3} + (\mathbf{z}+\varepsilon\mathbf{x})^{\otimes 3} - \mathbf{z}^{\otimes 3}\right]. \tag{8.2}$$

It converges to the following symmetric tensor, which we expressed as a sum of six (asymmetric) rank-1 terms:

$$\mathbf{x}\otimes\mathbf{x}\otimes\mathbf{y} + \mathbf{x}\otimes\mathbf{y}\otimes\mathbf{x} + \mathbf{y}\otimes\mathbf{x}\otimes\mathbf{x} + \mathbf{z}\otimes\mathbf{z}\otimes\mathbf{x} + \mathbf{z}\otimes\mathbf{x}\otimes\mathbf{z} + \mathbf{x}\otimes\mathbf{z}\otimes\mathbf{z}.$$

This has symmetric rank 5 since it can be associated with quantic $x^2y + xz^2$, which is the sum of (at least) five cubes.

In terms of algebraic geometry, this example admits a simple geometric interpretation. The limiting tensor is the sum of a point in the tangent space to $\mathcal{Y}_1$ at $\mathbf{x}^{\otimes 3}$ and a point in the tangent space to $\mathcal{Y}_1$ at $\mathbf{z}^{\otimes 3}$.

Note that the same kind of example can be constructed in the asymmetric case:

$$\mathbf{x}_1\otimes\mathbf{x}_2\otimes(\mathbf{x}_3 - \varepsilon^{-1}\mathbf{y}_3) + (\mathbf{x}_1+\varepsilon\mathbf{y}_1)\otimes(\mathbf{x}_2+\varepsilon\mathbf{y}_2)\otimes\varepsilon^{-1}\mathbf{y}_3.$$

Further discussions of the lack of closeness of $\mathcal{Y}_r$ and the ill-posedness of the best rank-r approximation problem in the asymmetric case can be found in [21].

8.2. Symmetric outer product decomposition over the real field. We now turn our attention to real symmetric tensors. We are interested in the symmetric outer product decomposition of $A \in \mathsf{S}^k(\mathbb{R}^n)$ over $\mathbb{R}$, i.e.,

$$A = \sum\nolimits_{i=1}^{r} \lambda_i \mathbf{v}_i \otimes \mathbf{v}_i \otimes \cdots \otimes \mathbf{v}_i, \tag{8.3}$$

where $\lambda_i \in \mathbb{R}$ and $\mathbf{v}_i \in \mathbb{R}^n$ for all $i = 1, \dots, r$. First note that unlike the decomposition over $\mathbb{C}$ in Lemma 4.2, we can no longer drop the coefficients $\lambda_1, \dots, \lambda_r$ in (8.3) since the kth roots of λ_i may not exist in $\mathbb{R}$.

Since $\mathsf{S}^k(\mathbb{R}^n) \subset \mathsf{S}^k(\mathbb{C}^n)$, we may regard A as an element of $\mathsf{S}^k(\mathbb{C}^n)$ and seek its symmetric outer product decomposition over $\mathbb{C}$. It is easy to see that we will generally need more terms in (8.3) to decompose A over $\mathbb{R}$ than over $\mathbb{C}$ and so

$$\operatorname{rank}_{\mathsf{S},\mathbb{C}}(A) \le \operatorname{rank}_{\mathsf{S},\mathbb{R}}(A). \tag{8.4}$$

This inequality also holds true for the outer product rank of asymmetric tensors. For $k = 2$, i.e., matrices, we always have equality in (8.4), but we will see in the examples below that strict inequality can occur when $k > 2$.

Example 8.3. Let $A \in \mathsf{S}^3(\mathbb{R}^2)$ be defined by

$$A = \left[\begin{array}{cc|cc} -1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{array}\right].$$

It is of symmetric rank 3 over $\mathbb{R}$,

$$A = \frac{1}{2}\begin{bmatrix}1\\1\end{bmatrix}^{\otimes 3} + \frac{1}{2}\begin{bmatrix}1\\-1\end{bmatrix}^{\otimes 3} - 2\begin{bmatrix}1\\0\end{bmatrix}^{\otimes 3},$$

whereas it is of symmetric rank 2 over $\mathbb{C}$,

$$A = \frac{\jmath}{2}\begin{bmatrix}-\jmath\\1\end{bmatrix}^{\otimes 3} - \frac{\jmath}{2}\begin{bmatrix}\jmath\\1\end{bmatrix}^{\otimes 3}, \quad \text{where } \jmath := \sqrt{-1}.$$

Hence we see that $\operatorname{rank}_{\mathsf{S},\mathbb{C}}(A) \neq \operatorname{rank}_{\mathsf{S},\mathbb{R}}(A)$.

These decompositions may be obtained using the algorithm described in [16], for instance. Alternatively, this tensor is associated with the homogeneous polynomial in two variables $p(x, y) = 3xy^2 - x^3$, which can be decomposed over $\mathbb{R}$ into

$$p(x, y) = \frac{1}{2}(x + y)^3 + \frac{1}{2}(x - y)^3 - 2x^3.$$

In the case of $2 \times 2 \times 2$ symmetric tensors, or equivalently in the case of binary cubics, the symmetric outer product decomposition can always be computed [16]. Hence, the symmetric rank of any symmetric tensor can be calculated, even over $\mathbb{R}$. In this case, it can be shown that the generic symmetric rank over $\mathbb{C}$ is 2, whereas there are *two typical symmetric ranks* over $\mathbb{R}$, which are 2 and 3.

In fact, in the $2 \times 2 \times 2$ case, there are two 2×2 matrix slices, which we can call A_1 and A_2. Since the generic symmetric rank over $\mathbb{C}$ is 2, the outer product decomposition may be obtained via the eigenvalue decomposition of the matrix pencil (A_1, A_2), which generically exists and whose eigenvalues are those of $A_1 A_2^{-1}$. By generating (four) independent real Gaussian entries with zero mean and unit variance, it can be easily checked out with a simple computer simulation that one gets real eigenvalues in 52% of the cases. This means that the real rank is 3 in 48% of the remaining cases. This is the simplest example demonstrating that a generic rank can be lacking over $\mathbb{R}$. So the concept of typical rank is essential to studying symmetric tensors over $\mathbb{R}$.

For asymmetric tensors, the same kind of computer simulation would yield (by generating eight independent real Gaussian entries) typical ranks of 2 and 3, 78% and 22% of the time, respectively, leading to the same qualitative conclusions. This procedure is not new [54, pp. 13] and was proposed in the past to illustrate the existence of several typical ranks for asymmetric tensors [37, 56]. An interesting result obtained by ten Berge [57] is that $p \times p \times 2$ real asymmetric tensors have typical ranks $\{p, p + 1\}$.

The problems pertaining to rank and decompositions of real symmetric tensors have not received as much attention as their complex counterparts. However, a moderate amount of work has been done [37, 48, 56, 59, 58], and we refer the reader to these for further information.

8.3. Open questions. Most of the results that we have presented so far are limited to symmetric tensors over the complex field. The case of general asymmetric tensors is currently being addressed with the same kind of approach. As pointed out earlier, decompositions over the real field are more complicated to handle with algebraic geometric tools. In addition, while the problem of determining the generic symmetric rank has been resolved thanks to the Alexander–Hirschowitz theorem, the maximal symmetric rank is known only for particular values of order and dimensions (e.g., dimension 2); only very rough upper bounds are known for general values. Lastly, the computation of an explicit symmetric outer product decomposition for a symmetric tensor is computationally expensive, and the conditions (dimension, order) under which this can be executed within a polynomial time are not yet clearly known. These are problems that we hope will be addressed in future work, either by ourselves or by interested readers.

Acknowledgments. The authors would like to thank the anonymous reviewers for their helpful comments. This work is a result of collaboration initiated at the 2004 Workshop on Tensor Decomposition held at the American Institute of Mathematics, Palo Alto, California, and continued in the 2005 Workshop on Tensor Decomposition

and Its Applications held at Centre International de Rencontres Mathématiques, Luminy, France.

TOWARDS A BACKWARD PERTURBATION ANALYSIS FOR DATA LEAST SQUARES PROBLEMS*

X.-W. CHANG†, G. H. GOLUB‡, AND C. C. PAIGE†

Abstract. Given an approximate solution to a data least squares (DLS) problem, we would like to know its minimal backward error. Here we derive formulas for what we call an "extended" minimal backward error, which is at worst a lower bound on the minimal backward error. When the given approximate solution is a good enough approximation to the exact solution of the DLS problem (which is the aim in practice), the extended minimal backward error is the actual minimal backward error, and this is also true in other easily assessed and common cases. Since it is computationally expensive to compute the extended minimal backward error directly, we derive a lower bound on it and an asymptotic estimate for it, both of which can be evaluated less expensively. Simulation results show that for reasonable approximate solutions, the lower bound has the same order as the extended minimal backward error, and the asymptotic estimate is an excellent approximation to the extended minimal backward error.

Key words. data least squares, backward errors, numerical stability, perturbation analysis, asymptotic estimate, iterative methods, stopping criteria

1. Introduction.

Given an approximate solution to a problem, the aim of backward perturbation analysis is to find a minimum size perturbation in the data such that the approximate solution is an exact solution of the perturbed problem. In the analysis one tries to find a formula for, or good bounds on, the size of the minimal perturbation (to be referred to as the minimal backward error) and design an efficient algorithm to evaluate or estimate the formula or the bounds. If the relative minimal backward error (i.e., the size of the minimal perturbation divided by an acceptable measure of the size of the data) is of the order of the unit roundoff, then we say that the approximate solution is a (normwise) backward stable solution. Backward perturbation analyses are useful in practice. Sometimes we may not know if an algorithm for solving a problem is numerically stable, e.g., the backward numerical stability of some fast algorithms for structured matrix problems is unknown. But if we know that a computed solution of a specific problem is a backward stable solution, we are satisfied with this computed solution. Also when we solve a large-scale problem by an iterative algorithm, the results of a backward perturbation analysis can often be used to design effective stopping criteria; see, for example, [1], [20], and [25].

There has been a lot of work on the backward perturbation analysis of linear systems, especially in recent years. For example, for consistent linear systems, see [14], [25], [30], [31], [32], [34], [36]; for unconstrained least squares problems, see [9],

[12], [17], [18], [19], [26], [27], [28], [29], [30], [35]; and for constrained least squares problems, see [4], [18], and [19].

The main purpose of this paper is to give a normwise backward perturbation analysis for the general linear data least squares (DLS) problem. As a result, the structure of the matrix and magnitudes of individual elements of the matrix in the DLS problem will not be considered. We derive formulas for an "extended" minimal backward error in section 2. This extended minimal backward error is at worst a lower bound on the minimal backward error. But we show that when the given approximate solution is a good enough approximation to the exact solution of the DLS problem (which is the aim in practice), the extended minimal backward error is the actual minimal backward error. Section 2.1 deals with perturbations in both A and b, while section 2.2 considers perturbations in A alone and shows how these are limiting cases of those in section 2.1. Since computing the extended minimal backward error directly is time consuming, in section 3 we derive a lower bound on, and in section 4 an asymptotic estimate for, this extended minimal backward error. We give numerical examples in section 5. Finally a summary is given in section 6.

We use $I=[e_1,\ldots,e_n]$ to denote the unit matrix. For any matrix $B\in\mathbb{R}^{m\times n}$, its column range is denoted by $\mathcal{R}(B)$, its Moore–Penrose generalized inverse is denoted by $B^\dagger$, its smallest singular value (the pth largest singular value, with $p=\min\{m,n\}$) by $\sigma_{\min}(B)$, and its condition number in the 2-norm is denoted by $\kappa_2(B)$. For any matrix $B=[b_1,\ldots,b_n]$ $\mathtt{vec}(B)=[b_1^T,\ldots,b_n^T]^T$. For any symmetric $B\in\mathbb{R}^{n\times n}$, its eigenvalues are labeled in nondecreasing order: $\lambda_{\min}=\lambda_1\le\lambda_2\le\cdots\le\lambda_n$, but when only $\lambda_{\min}$ is of interest we will write $\lambda=\lambda_{\min}$. For any vector $v\in\mathbb{R}^n$, its Moore–Penrose generalized inverse is

$$v^\dagger\equiv\begin{cases}0 & \text{if } v=0,\\ v^T/\|v\|_2^2 & \text{if } v\neq 0,\end{cases}\qquad \|v\|_2\equiv(v^Tv)^{\frac{1}{2}}.$$

Note that $vv^\dagger$ is the orthogonal projector onto $\mathcal{R}(v)$, and $I-vv^\dagger$ is the orthogonal projector onto the orthogonal complement of $\mathcal{R}(v)$.

2. Backward perturbation analysis. Given $A\in\mathbb{R}^{m\times n}$ and $b\in\mathbb{R}^m$, the DLS problem defined by DeGroat and Dowling [5] is

$$\sigma_{\scriptscriptstyle D}\equiv\min_{E,x}\|E\|_F\quad\text{subject to}\quad(A+E)x=b,\qquad \|E\|_F\equiv\left[\operatorname{trace}\left(E^TE\right)\right]^{\frac{1}{2}}. \tag{2.1}$$

See also, for example, [21], [22]. The purpose of the DLS problem is to find the optimal x. For applications of the DLS method to some signal processing problems, see [5]. Let $\mathcal{U}_{\min}(A)$ be the left singular vector subspace of A corresponding to its minimum singular value $\sigma_{\min}(A)$. In [21] it was explained that a satisfactory condition for building the theory for the DLS problem (2.1) is the condition that we will now assume holds:

$$A \text{ has full column rank, and } b\not\perp\mathcal{U}_{\min}(A). \tag{2.2}$$

With this condition, the solution to (2.1) must exist and be unique. From $(A+E)x=b$ we have $Ex=b-Ax$. Thus the minimal E must satisfy

$$E=(b-Ax)x^\dagger. \tag{2.3}$$

But (2.2) implies that $b\neq 0$, so the solution x must be nonzero, and this allows us to eliminate E and reformulate the DLS problem (2.1) as

$$\sigma_{\scriptscriptstyle D}\equiv\min_x\|(b-Ax)x^\dagger\|_F=\min_x\frac{\|b-Ax\|_2}{\|x\|_2}. \tag{2.4}$$

From [21, equations (5.14)–(5.17)], $\hat{x}$ solves the DLS problem (2.1) if and only if

$$A^T(b - A\hat{x}) = -\hat{x}\frac{\|b - A\hat{x}\|_2^2}{\|\hat{x}\|_2^2}, \tag{2.5}$$

$$\frac{\|b - A\hat{x}\|_2}{\|\hat{x}\|_2} < \sigma_{\min}(A). \tag{2.6}$$

Differentiating the objective function in (2.4) and setting the result to zero gives (2.5), corresponding to a stationary point. The global minimum also satisfies (2.6).

The DLS formulation is designed for problems where the right-hand side b is accurately known, but the matrix A is only known approximately. Given a nonzero approximate solution $y \in \mathbb{R}^n$ to $Ax \approx b$, two questions are of particular interest here:

Q1: Is y a feasible (not necessarily DLS) solution, given the accuracy of the data?

Q2: Is y a backward stable solution to the DLS problem for the given data A, b?

Q1 will often be easy to check: for example, if it is known that the given data matrix A approximates an unknown ideal matrix $\hat{A}$ to within $\|A - \hat{A}\|_{\{F \text{ or } 2\}} \le \alpha$ while b is accurately known, then from (2.3) we need only check that $\|b - Ay\|/\|y\| \le \alpha$. If the answer to Q1 is positive and we are not interested in the DLS solution, we might accept y. But then in practice there will be an infinite set of y satisfying Q1, and we will often seek some additional criterion, for example, "Does y make sense physically?"—a difficult question we might ask of an ill-posed problem. Here we consider the more generally approachable question Q2, since if we can answer this affirmatively, we will know that y is a desirable [illegible] solution to (2.1). Even if the answer to Q1 is "no," we might still check Q2, since it is possible for y to satisfy Q2 but not Q1 in that y can be a DLS solution for $A + \Delta A$, $b + \Delta b$ for very small ΔA and Δb, but the minimal norm E in $(A + \Delta A + E)y = b + \Delta b$ can be too large for Q1. This would indicate that there are difficulties with the data.

To answer Q2 we would like to solve the minimal backward error problem:

$$\min_{\Delta A, \Delta b} \|[\Delta A, \Delta b\, \theta]\|_F \quad \text{subject to} \quad y = \arg\min_x \frac{\|b + \Delta b - (A + \Delta A)x\|_2}{\|x\|_2}; \tag{2.7}$$

see (2.4), where the chosen scalar $\theta \ge 0$ allows a different emphasis on each data error.

From (2.5) and (2.6) we see that $[\Delta A, \Delta b]$ is a backward perturbation for the DLS problem with the given solution y if and only if it is in the set $\mathcal{C}_{A,b}$, where

$$\mathcal{C}^+_{A,b} \equiv \left\{ [\Delta A, \Delta b] : \ (A+\Delta A)^T[b+\Delta b - (A+\Delta A)y] = -y\frac{\|b+\Delta b - (A+\Delta A)y\|_2^2}{\|y\|_2^2} \right\}, \tag{2.8}$$

$$\mathcal{C}_{A,b} \equiv \left\{ [\Delta A, \Delta b] : \ [\Delta A, \Delta b] \in \mathcal{C}^+_{A,b} \ \& \ \frac{\|b+\Delta b - (A+\Delta A)y\|_2}{\|y\|_2} < \sigma_{\min}(A+\Delta A) \right\}. \tag{2.9}$$

The inequality in (2.9) makes it difficult to derive a general expression for $[\Delta A, \Delta b] \in \mathcal{C}_{A,b}$, so we initially ignore it and consider the larger set $\mathcal{C}^+_{A,b}$, which we will show is also useful. The following result from Theorem 5.1 of [3] characterizes $[\Delta A, \Delta b] \in \mathcal{C}^+_{A,b}$.

LEMMA 2.1. [illegible] $A \in \mathbb{R}^{m\times n}$, $b \in \mathbb{R}^m$, [illegible] $y \in \mathbb{R}^n$ [illegible] $[\Delta A, \Delta b] \in \mathcal{C}^+_{A,b}$ [illegible] (2.8) [illegible] $w \in \mathbb{R}^n$ [illegible] $Z \in \mathbb{R}^{m\times n}$ [illegible]

$$A + \Delta A = (b + \Delta b - w)y^\dagger + \left(I - ww^\dagger\right) Z \left(I - yy^\dagger\right), \quad (b + \Delta b)^T w = 0. \tag{2.10}$$

2.1. Allowing backward perturbations in A and b. Based on Lemma 2.1 we will first find a computable expression for $\mu_F(y,\theta)$ in the following "extended" minimal backward error problem:

$$\mu_F(y,\theta) \equiv \min_{[\Delta A,\Delta b]\in\mathcal{C}^+_{A,b}} \|[\Delta A, \Delta b\,\theta]\|_F \quad \text{for } \mathcal{C}^+_{A,b} \text{ in (2.8).} \tag{2.11}$$

We call $\mu_F(y,\theta)$ the extended minimal backward error because we minimize over the extended set $\mathcal{C}^+_{A,b}$, giving at worst a lower bound on the minimal backward error.

If $b=0$, the DLS problem (2.1) has the solution $\hat{x}=0$; if $y=0$, then it cannot be the DLS solution of any problem with $b\neq 0$. We do not need to consider these cases further. For the remainder of this paper we will assume the conditions and notation of the following theorem.

The following will simplify the presentation:

$$\rho \equiv 1/\left(1+\theta^2\|y\|_2^2\right) \quad \text{so that} \quad \rho\theta^2\|y\|_2^2 = 1-\rho \quad \text{and} \quad 0\le\rho\le 1. \tag{2.12}$$

THEOREM 2.2. [illegible] $A\in\mathbb{R}^{m\times n}$, $b\in\mathbb{R}^m$, [illegible] $y\in\mathbb{R}^n$, $\theta\ge 0$ [illegible] (2.2) [illegible] $r\equiv b-Ay$, $\rho\equiv 1/(1+\theta^2\|y\|_2^2)$ [illegible]

$$N \equiv N(\theta) \equiv \left[A\left(I-yy^\dagger\right), \rho^{\frac{1}{2}}\theta\|r\|_2\left(I-rr^\dagger\right), b\,\theta\right], \tag{2.13}$$

$$M \equiv M(\theta) \equiv A\left(I-yy^\dagger\right)A^T - r\rho\theta^2 r^T + b\,\theta^2 b^T = NN^T - \rho\theta^2\|r\|_2^2 I. \tag{2.14}$$

[illegible] $M(\theta)$ [illegible] $\mu_F(y,\theta)$ [illegible] (2.11) [illegible]

$$\mu_F^2(y,\theta) = \begin{cases} \rho\theta^2\|r\|_2^2 & \text{if } \lambda_{\min}(M(\theta))\ge 0, \\ \rho\theta^2\|r\|_2^2 + \lambda_{\min}(M(\theta)) = \sigma_{\min}^2(N(\theta)) & \text{if } \lambda_{\min}(M(\theta))<0. \end{cases} \tag{2.15}$$

[illegible] $\mu_F(y,\theta)$ [illegible] $\widehat{\Delta A}$ [illegible] $\widehat{\Delta b}$.

$$A+\widehat{\Delta A} = \begin{cases} A+r(1-\rho)y^\dagger & \text{if } \lambda_{\min}(M(\theta))\ge 0, \\ \left(I-w_\theta w_\theta^\dagger\right)[A+r(1-\rho)y^\dagger]+w_\theta w_\theta^\dagger Ayy^\dagger & \text{if } \lambda_{\min}(M(\theta))<0, \end{cases} \tag{2.16}$$

$$b+\widehat{\Delta b} = \begin{cases} b-r\rho & \text{if } \lambda_{\min}(M(\theta))\ge 0, \\ \left(I-w_\theta w_\theta^\dagger\right)(b-r\rho) & \text{if } \lambda_{\min}(M(\theta))<0, \end{cases} \tag{2.17}$$

[illegible] w_θ [illegible] ($\lambda_{\min}(M(\theta))<0$) [illegible] $M(\theta)$ [illegible] $\lambda_{\min}(M(\theta))$ [illegible] $N(\theta)$ [illegible] $\sigma_{\min}(N(\theta))$ [illegible] $A(I-yy^\dagger)A^T+b\,\theta^2 b^T$ is nonnegative definite, so from [15, Theorem 4.3.4(b)] with $k=1$, $M(\theta)$ has at most one negative eigenvalue.

Now we want to determine the optimal w, Z, ΔA, and Δb in (2.10) to minimize $\|\Delta A, \Delta b\,\theta\|_F$. In the following we discuss two cases separately.

[illegible] 1: The optimal $w=0$. Let $Y=[y/\|y\|_2, Y_2]\in\mathbb{R}^{n\times n}$ be an orthogonal matrix. From (2.10) we have $(b+\Delta b)^T w=0$ automatically, and

$$\begin{aligned} \Delta A Y &= (b+\Delta b)y^\dagger[y/\|y\|_2, Y_2] + Z\left(I-yy^\dagger\right)[y/\|y\|_2, Y_2] - A[y/\|y\|_2, Y_2] \\ &= [(b+\Delta b)/\|y\|_2, 0] + [0, ZY_2] - [Ay/\|y\|_2, AY_2] \\ &= [(r+\Delta b)/\|y\|_2, (Z-A)Y_2]. \end{aligned}$$

It follows that

$$\|[\Delta A, \Delta b\,\theta]\|_F^2 = \|\Delta A Y\|_F^2 + \theta^2\|\Delta b\|_2^2 = \frac{1}{\|y\|_2^2}\left\|\begin{bmatrix} I \\ \theta\|y\| I\end{bmatrix}\Delta b + \begin{bmatrix} r \\ 0\end{bmatrix}\right\|_2^2 + \|(Z-A)Y_2\|_F^2.$$

Thus $\|[\Delta A, \Delta b\,\theta]\|_F$ is minimized when

$$\Delta b = \widehat{\Delta b} \equiv -\begin{bmatrix} I \\ \theta\|y\| I\end{bmatrix}^{\dagger}\begin{bmatrix} r \\ 0\end{bmatrix} = -r\rho, \quad Z = \widehat{Z} \equiv A, \tag{2.18}$$

and from (2.10) we see that the optimal ΔA must satisfy

$$\Delta A = \widehat{\Delta A} \equiv (b - r\rho)y^{\dagger} + A\left(I - yy^{\dagger}\right) - A = r(1-\rho)y^{\dagger}, \tag{2.19}$$

$$\|[\widehat{\Delta A}, \widehat{\Delta b}\,\theta]\|_F^2 = (1-\rho)^2\|ry^{\dagger}\|_2^2 + \rho^2\theta^2\|r\|_2^2 = \rho\theta^2\|r\|_2^2. \tag{2.20}$$

In Case 2 we will show that if $\lambda_{\min}(M) \geq 0$, then $w = 0$ is optimal.

2: The optimal $w \neq 0$. Let Y be as in Case 1, and $W = [w/\|w\|_2, W_2] \in \mathbb{R}^{m\times m}$ be an orthogonal matrix. Since $w^T(b + \Delta b) = 0$, we can write

$$b + \Delta b = W_2 s \quad \text{for some } s \in \mathbb{R}^{m-1}. \tag{2.21}$$

From (2.10) we have

$$\begin{aligned} W^T\Delta A Y &= \begin{bmatrix} w^T/\|w\|_2 \\ W_2^T\end{bmatrix}\left[(b + \Delta b - w)y^{\dagger} + \left(I - ww^{\dagger}\right)Z\left(I - yy^{\dagger}\right) - A\right][y/\|y\|_2, Y_2] \\ &= \left[\begin{array}{c|c} -\|w\|_2/\|y\|_2 - w^TAy/(\|w\|_2\|y\|_2) & -w^TAY_2/\|w\|_2 \\ \hline s/\|y\|_2 - W_2^TAy/\|y\|_2 & W_2^TZY_2 - W_2^TAY_2\end{array}\right]. \end{aligned}$$

Thus the objective function can be written as five additive nonnegative terms:

$$\begin{aligned} \|[\Delta A, \Delta b\,\theta]\|_F^2 = &\left[\|w\|_2/\|y\|_2 + w^TAy/(\|w\|_2\|y\|_2)\right]^2 + \|w^TAY_2\|_2^2/\|w\|_2^2 \\ &+ \|s - W_2^TAy\|_2^2/\|y\|_2^2 + \|W_2^T(Z-A)Y_2\|_F^2 + \theta^2\|W_2 s - b\|_2^2. \end{aligned} \tag{2.22}$$

To minimize this we take $Z = \widehat{Z} \equiv A$ and note the sum of terms involving s is

$$\begin{aligned} \phi(s) &\equiv \|s - W_2^TAy\|_2^2/\|y\|_2^2 + \theta^2\|W_2 s - b\|_2^2 \\ &= \left[\left\|W^T(W_2 s - Ay)\right\|_2^2 - \left(w^TAy\right)^2/\|w\|_2^2 + \theta^2\|y\|_2^2\|W_2 s - b\|_2^2\right]/\|y\|_2^2 \\ &= \frac{1}{\|y\|_2^2}\left\|\begin{bmatrix} I \\ \theta\|y\|_2 I\end{bmatrix}W_2 s - \begin{bmatrix} Ay \\ b\,\theta\|y\|_2\end{bmatrix}\right\|_2^2 - \left(\frac{w^TAy}{\|w\|_2\|y\|_2}\right)^2. \end{aligned} \tag{2.23}$$

The normal equations for $\hat{s}$, the optimal s, give $(1 + \theta^2\|y\|_2^2)\hat{s} = W_2^T(Ay + b\,\theta^2\|y\|_2^2)$. Therefore

$$\hat{s} = W_2^T[Ay\rho + b(1-\rho)] = W_2^T(b - r\rho). \tag{2.24}$$

Substituting this in the first line of (2.23) gives with $W_2W_2^T = I - ww^{\dagger}$

$$\begin{aligned} \phi(\hat{s}) &= \left\|W_2^T r(1-\rho)\right\|_2^2/\|y\|_2^2 + \theta^2\left\|ww^{\dagger}b + W_2W_2^T r\rho\right\|_2^2 \\ &= \rho\theta^2\left\|\left(I - ww^{\dagger}\right)r\right\|_2^2 + \theta^2\left\|ww^{\dagger}b\right\|_2^2. \end{aligned}$$

Then from (2.22), we obtain

$$\min_{[\Delta A,\Delta b]\in\mathcal{C}^+_{A,b}} \|[\Delta A, \Delta b\,\theta]\|_F^2 = \min_w [\psi_1(w) + \psi_2(w)], \tag{2.25}$$

$$\psi_1(w) \equiv \left[\|w\|_2/\|y\|_2 + w^T Ay/(\|w\|_2\|y\|_2)\right]^2, \tag{2.26}$$

$$\psi_2(w) \equiv \left\|w^T AY_2\right\|_2^2/\|w\|_2^2 + \rho\theta^2 \left\|(I - ww^\dagger)r\right\|_2^2 + \theta^2 \left\|ww^\dagger b\right\|_2^2. \tag{2.27}$$

We will minimize $\psi_2(w)$, which is a function of $w/\|w\|_2$ alone, and then show that we can set $\psi_1(w)$ to zero by scaling w, leading to the optimal w. Since $Y_2Y_2^T = I - yy^\dagger$,

$$\begin{aligned}\psi_2(w) &= \frac{w^T A\left(I - yy^\dagger\right)A^T w}{w^T w} + \rho\theta^2\|r\|_2^2\frac{w^T\left(I - rr^\dagger\right)w}{w^T w} + \theta^2\frac{w^T bb^T w}{w^T w} \\ &= \frac{w^T NN^T w}{w^T w} = \rho\theta^2\|r\|_2^2 + \frac{w^T Mw}{w^T w},\end{aligned} \tag{2.28}$$

whose minimum is $\rho\theta^2\|r\|_2^2 + \lambda_{\min}(M)$ given by $w = w_\theta\alpha$ for any nonzero $\alpha \in \mathbb{R}$ and w_θ satisfying $Mw_\theta = w_\theta\lambda_{\min}(M)$, $\|w_\theta\|_2 = 1$, since we assumed $w \neq 0$.

If $\lambda_{\min}(M) \geq 0$, the above with (2.20) in Case 1 show that $w = 0$ is optimal for minimizing $\|[\Delta A, \Delta b\,\theta]\|_F^2$, giving the minimum value $\rho\theta^2\|r\|_2^2$. So from (2.18), (2.19), and (2.20) we see that the top equalities in each of (2.15), (2.16), and (2.17) hold. Only when $\lambda_{\min}(M) < 0$ do we need to consider the possibility that $w \neq 0$.

Assume that $\lambda_{\min}(M) < 0$. It is easy to verify that $\psi_1(\hat{w}) = 0$ if

$$\hat{w} \equiv -w_\theta\left(w_\theta^T Ay\right) \neq 0. \tag{2.29}$$

Suppose $w_\theta^T Ay = 0$, then from $w_\theta^T Mw_\theta = \lambda_{\min}(M) < 0$ and (2.14),

$$0 > \lambda_{\min}(M) = w_\theta^T AA^T w_\theta - \left(w_\theta^T r\right)^2\rho\theta^2 + \left(w_\theta^T b\right)^2\theta^2 = w_\theta^T AA^T w_\theta + \left(w_\theta^T b\right)^2(1-\rho)\theta^2,$$

which is impossible since the right-hand side is nonnegative; see (2.12), proving that the inequality in (2.29) holds. Therefore from (2.25) we see that when $\lambda_{\min}(M) < 0$, the extended minimal backward error $\mu_F(y,\theta)$ satisfies the two bottom equalities in (2.15). The bottom equality in (2.17) follows immediately from (2.21) and (2.24), and substituting this with $Z = A$ and (2.29) in (2.10) gives

$$\begin{aligned}A + \Delta A &= \left[\left(I - w_\theta w_\theta^\dagger\right)(b - r\rho) + w_\theta\left(w_\theta^T Ay\right)\right]y^\dagger + \left(I - w_\theta w_\theta^\dagger\right)A\left(I - yy^\dagger\right) \\ &= \left(I - w_\theta w_\theta^\dagger\right)\left[A + (b - r\rho - Ay)y^\dagger\right] + w_\theta\left(w_\theta^T Ay\right)y^\dagger \\ &= \left(I - w_\theta w_\theta^\dagger\right)\left[A + r(1-\rho)y^\dagger\right] + w_\theta\left(w_\theta^T Ay\right)y^\dagger\end{aligned}$$

to prove the bottom equation in (2.16). ∎

2.1. The criterion $\lambda_{\min}(M(\theta)) \geq 0$ appears in (2.15)–(2.17). But if, as is usual, $m > n+1$, then $M(\theta)$ has at least $m-n-1$ zero eigenvalues corresponding to eigenvectors spanning $\mathcal{R}([A,b])^\perp$. The eigenvalues of a parameterized matrix that are zero independent of the parameter (here θ) will be called "trivial zero eigenvalues." Because they remain zero, their limiting behavior is trivial.

2.2. Allowing a backward perturbation in *A* alone. In DLS problems only the matrix A is assumed to have uncertainty, so it is also important to consider the

case where there is a backward perturbation in A alone. Then the corresponding minimal backward error problem becomes

$$\min_{\Delta A\in\mathcal{C}_A}\|\Delta A\|_F, \qquad \text{where}$$

$$\mathcal{C}_A^+ \equiv \left\{\Delta A : (A+\Delta A)^T[b-(A+\Delta A)y] = -y\frac{\|b-(A+\Delta A)y\|_2^2}{\|y\|_2^2}\right\}, \tag{2.30}$$

$$\mathcal{C}_A \equiv \left\{\Delta A :\ \Delta A\in\mathcal{C}_A^+ \ \&\ \frac{\|b-(A+\Delta A)y\|_2}{\|y\|_2} < \sigma_{\min}(A+\Delta A)\right\}, \tag{2.31}$$

and these two sets are just $\mathcal{C}_{A,b}^+$ and $\mathcal{C}_{A,b}$ in (2.8) and (2.9) with $\Delta b = 0$, so that $\Delta A\in\mathcal{C}_A^+ \Rightarrow [\Delta A, 0]\in\mathcal{C}_{A,b}^+$. We can force $\Delta b = 0$ by taking the limit as $\theta\to\infty$ in (2.11), giving for the [illegible] minimal backward error in this more limited case

$$\mu_F(y) \equiv \min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_F = \lim_{\theta\to\infty}\mu_F(y,\theta). \tag{2.32}$$

Here we have abused the notation a little by using both $\mu_F(\cdot)$ and $\mu_F(\cdot,\cdot)$. The proof using $\theta\to\infty$ (we use $\varepsilon\equiv\theta^{-2}\searrow 0$) is made possible by a beautiful classical result.

LEMMA 2.3 (Rellich [24, pp. 29–37]; see also Kato [16, pp. 121–122]). [illegible] $\varepsilon\in\mathbb{R}$ [illegible] $H(\varepsilon) = H(\varepsilon)^T\in\mathbb{R}^{n\times n}$ [illegible] $\varepsilon = 0$ [illegible] $\varepsilon = 0$

We need some more results to prepare for Theorem 2.6.

LEMMA 2.4. [illegible] $M = SWS^T$ [illegible] $S\in\mathbb{R}^{m\times n}$, $W = W^T\in\mathbb{R}^{n\times n}$, $m\ge n$, [illegible]

(a) M [illegible] ([illegible]) [illegible] W

(b) [illegible] $W = I - y\alpha y^\dagger$, [illegible] M [illegible]

[illegible]. Part (a) was proven in [15, section 4.5.11] for the case $m = n$. For $m > n$ writing $M = [S,0]\,\mathrm{diag}(W,0)[S,0]^T$ with square $[S,0]$ proves that (a) still holds. Since $I - y\alpha y^\dagger$ has eigenvalues 1 when $y = 0$, and $1-\alpha, 1, \ldots, 1$ when $y\ne 0$, (b) follows from (a). ∎

To make later analysis easier, we use ε to replace θ^{-2}. From (2.12)

$$\rho = \varepsilon/\left(\varepsilon+\|y\|_2^2\right), \qquad \varepsilon+\rho\|y\|_2^2 = \varepsilon(2-\rho), \qquad \varepsilon\equiv\theta^{-2}. \tag{2.33}$$

In our limits we consider only $\varepsilon\ge 0$, so $\varepsilon\to 0$ will always mean $\varepsilon\searrow 0$.

THEOREM 2.5. [illegible] (2.33), [illegible] $A\in\mathbb{R}^{m\times n}$, $0\ne y\in\mathbb{R}^n$, $0\ne b\in\mathbb{R}^m$, $r\equiv b-Ay$,

$$H(\varepsilon)\equiv\varepsilon A(I-yy^\dagger)A^T - r\rho r^T + bb^T,\ \varepsilon\in\mathbb{R},\ H(\varepsilon)w(\varepsilon) = w(\varepsilon)\lambda(\varepsilon),\ w(\varepsilon)\in\mathbb{R}^m, \tag{2.34}$$

$m\ge 2$, [illegible] $\lambda(0)\equiv\lambda_{\min}(H(0))$ [illegible] $\varepsilon\ge 0$ [illegible] $\lambda(\varepsilon)$ [illegible] $w(\varepsilon)$ [illegible]

$$\lambda(\varepsilon) = \lambda_1\varepsilon+\lambda_2\varepsilon^2+\cdots,\ w(\varepsilon) = w_0+w_1\varepsilon+w_2\varepsilon^2+\cdots,\ b^Tw_0 = 0,\ \|w(\varepsilon)\|_2 = 1. \tag{2.35}$$

$$T(\varepsilon)\equiv\varepsilon^{-1}P_b^\perp H(\varepsilon)P_b^\perp, \text{ [illegible] } T(0)\equiv\lim_{\varepsilon\to 0}T(\varepsilon) = P_b^\perp A\left(I-y2y^\dagger\right)A^TP_b^\perp. \tag{2.36}$$

[illegible] $\lambda_*(0)\equiv\lambda_{\min}(T(0))$ [illegible] $\varepsilon\ge 0$ [illegible] $\lambda_*(\varepsilon)$ [illegible] $w_*(\varepsilon)$ [illegible]

$$T(\varepsilon)w_*(\varepsilon) = w_*(\varepsilon)\lambda_*(\varepsilon), \qquad w_*(\varepsilon)\in\mathbb{R}^m, \quad \|w_*(\varepsilon)\|_2 = 1. \tag{2.37}$$

[illegible] $\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)$ [illegible] (2.35)) [illegible] $\lambda_*(0)$ [illegible] $w_*(0)$. (2.37)

$$\lim_{\varepsilon\to 0} b^T w(\varepsilon)=0, \qquad \lim_{\varepsilon\to 0}\varepsilon^{-\frac{1}{2}} b^T w(\varepsilon)=0, \qquad \lim_{\varepsilon\to 0}\varepsilon^{-1} b^T w(\varepsilon)=b^T w_1; \tag{2.38}$$

$$\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)<0 \;\Rightarrow\; \lambda_*(0)<0 \;\Rightarrow\; \lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=\lambda_*(0) \;\;\&\;\; w(0)=\pm w_*(0); \tag{2.39}$$

$$\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)\geq 0 \;\Leftrightarrow\; \lambda_*(0)=0; \tag{2.40}$$

$$\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=0 \Rightarrow \lambda_*(0)=0 \;\&\; \begin{cases}\{\exists x \text{ [illegible] } b=Ax \;\&\; \angle(x,y)=\pm\pi/4\},\\ \{\varepsilon^{-1}\lambda(\varepsilon)=0 \text{ [illegible] } \varepsilon=0\}.\end{cases} \tag{2.41}$$

[illegible]. The expression for $T(0)$ in (2.36) follows from (2.34) and (2.33), and then

$$T(\varepsilon)=T(0)+P_b^{\perp}Ay\rho y^{\dagger}A^T P_b^{\perp} = P_b^{\perp}A\left[I-y(2-\rho)y^{\dagger}\right]A^T P_b^{\perp}. \tag{2.42}$$

Clearly $H(\varepsilon)$ and $T(\varepsilon)$ are analytic about $\varepsilon=0$, so $w(\varepsilon)$, $\lambda(\varepsilon)$, $w_*(\varepsilon)$, and $\lambda_*(\varepsilon)$ can be chosen to be analytic, with $\|w(\varepsilon)\|_2=\|w_*(\varepsilon)\|_2=1$; see Lemma 2.3. Also $H(\varepsilon)$ can have at most one negative eigenvalue, see the start of the proof of Theorem 2.2, so from Lemma 2.4 $T(\varepsilon)$ can have at most one negative eigenvalue. Since $m\geq 2$, $H(0)=bb^T$ has minimum eigenvalue $\lambda(0)=0$, proving the first part of (2.35). Since $bb^T w(0)=w(0)\lambda(0)=0$, we must have $b^T w(0)=b^T w_0=0$, proving the rest of (2.35). Next (2.35) proves (2.38), and we have

$$\begin{aligned}\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon) &= \lim_{\varepsilon\to 0}\varepsilon^{-1}w(\varepsilon)^T H(\varepsilon)w(\varepsilon) = \lim_{\varepsilon\to 0}\varepsilon^{-\frac{1}{2}}w(\varepsilon)^T P_b^{\perp}H(\varepsilon)P_b^{\perp}w(\varepsilon)\varepsilon^{-\frac{1}{2}}\\ &= \lim_{\varepsilon\to 0} w(\varepsilon)^T T(\varepsilon)w(\varepsilon) = w(0)^T T(0)w(0)\geq \lambda_*(0)=\lambda_{\min}(T(0)),\end{aligned} \tag{2.43}$$

so $\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)<0 \Rightarrow \lambda_*(0)<0$. When $\lambda_*(0)<0$, it is a singleton; see Lemma 2.4, so for small enough ε, $\lambda_*(\varepsilon)<0$; then $b^T w_*(\varepsilon)=0$ from (2.37) and (2.36), giving

$$\lambda_*(\varepsilon)=\varepsilon^{-1}w_*(\varepsilon)^T P_b^{\perp}H(\varepsilon)P_b^{\perp}w_*(\varepsilon)=\varepsilon^{-1}w_*(\varepsilon)^T H(\varepsilon)w_*(\varepsilon). \tag{2.44}$$

Taking the limit as $\varepsilon\to 0$ and using (2.43), with $\|w(\varepsilon)\|_2=\|w_*(\varepsilon)\|_2=1$ gives

$$\begin{aligned}\lambda_*(0) &= \lim_{\varepsilon\to 0}\varepsilon^{-1}w_*(\varepsilon)^T H(\varepsilon)w_*(\varepsilon)\geq \lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=w(0)^T T(0)w(0)\\ &\geq \lambda_*(0)=w_*(0)^T T(0)w_*(0),\end{aligned}$$

proving equality throughout, so that $\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=\lambda_*(0)$ when $\lambda_*(0)<0$. Also $w(0)^T T(0)w(0)=w_*(0)^T T(0)w_*(0)$ is a minimum of $w^T T(0)w$ over $w^T w=1$ with unique minimizer (up to sign) when $\lambda_*(0)$ is a singleton, completing the proof of (2.39). Since $T(\varepsilon)b=0$, we see that $\lambda_*(0)\leq 0$, and (2.40) follows using (2.39).

Now assume that $\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=0$, ($\lambda_1=0$ in (2.35)). Then $\lambda_*(0)=0$ in (2.41) follows from (2.40). If $[A,b]$ has rank s, then $\varepsilon^{-1}H(\varepsilon)$ has m–s trivial zero eigenvalues. If in the limit as $\varepsilon\to 0$ there are only trivial zero eigenvalues, then by continuity, $\varepsilon^{-1}\lambda(\varepsilon)=0$ in some neighborhood of $\varepsilon=0$. Next assume that there is a nontrivial zero eigenvalue, that is, an eigenpair of the form (2.35), with $\lambda_1=0$ and $A^T w_0\neq 0$. But $\lambda_*(0)=0$ shows that $T(0)$ is positive semidefinite, and $0=\lim_{\varepsilon\to 0}\varepsilon^{-1}\lambda(\varepsilon)=$

$\lim_{\varepsilon\to 0} w_0^T\varepsilon^{-1}H(\varepsilon)w_0 = \lim_{\varepsilon\to 0} w_0^T T(\varepsilon)w_0$; see (2.36), so $0 = w_0^T T(0)w_0 = w_0^T A(I - y2y^\dagger)A^T w_0$. Here $I - y2y^\dagger$ is a Householder reflection. Thus

$$\left\|A^T w_0\right\|_2^2 = 2\left(w_0^T Ay\right)^2/\|y\|_2^2, \qquad 0 = T(0)w_0 = P_b^\perp A\left(I - y2y^\dagger\right)A^T w_0, \tag{2.45}$$

and $A(I-y2y^\dagger)A^T w_0 = bb^\dagger A(I-y2y^\dagger)A^T w_0 \neq 0$; see (2.2). Then $Ax\nu = b\nu$, where

$$x\nu = \left(I - y2y^\dagger\right)A^T w_0, \quad \nu \equiv b^T A\left(I - y2y^\dagger\right)A^T w_0/b^T b \neq 0.$$

From this $y^T x\nu = -y^T A^T w_0$, and with (2.45) $x^T x\nu^2 = \|A^T w_0\|_2^2 = 2(w_0^T Ay)^2/\|y\|_2^2 = 2(y^T x)^2\nu^2/\|y\|_2^2$. This gives $2(y^T x)^2 = y^T y \cdot x^T x$, so $\angle(x,y) = \pm\pi/4$, proving (2.41). □

2.2. In (2.41) the case $b = Ax$ & $\angle(x,y) = \pm\pi/4$ is extremely unlikely (it has "probability zero"), requiring $b \in \mathcal{R}(A)$ (a highly unlikely situation when we are solving DLS problems) and y to be a terrible approximation to the unique x for which $b = Ax$, giving $\angle(x,y) = \pm\pi/4$.

We can now obtain the equivalent of Theorem 2.2 for a backward perturbation restricted to A alone.

THEOREM 2.6. $A \in \mathbb{R}^{m\times n}$, $m \geq 2$, $b \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, (2.2) $r \equiv b - Ay$

$$N_\infty \equiv \left[\left(I-bb^\dagger\right)A\left(I-yy^\dagger\right), \frac{\|r\|_2}{\|y\|_2}\left(I-bb^\dagger\right), \frac{b}{\|b\|_2}\frac{\|r\|_2}{\|y\|_2}\right], \tag{2.46}$$

$$M_\infty = M_\infty(y) \equiv \left(I-bb^\dagger\right)A\left(I-y2y^\dagger\right)A^T\left(I-bb^\dagger\right) = N_\infty N_\infty^T - \|r\|_2^2/\|y\|_2^2\, I. \tag{2.47}$$

$\lambda_{\min}(M_\infty) \leq 0$ M_∞ $\mu_F(y)$ (2.32)

$$\mu_F^2(y) = \frac{\|r\|_2^2}{\|y\|_2^2} + \lambda_{\min}(M_\infty) = \sigma_{\min}^2(N_\infty). \tag{2.48}$$

$\mu_F(y)$

$$\widehat{\Delta A} = \begin{cases} ry^\dagger & \lambda_{\min}(M_\infty) = 0, \\ ry^\dagger - w_* w_*^\dagger A(I - y2y^\dagger) & \lambda_{\min}(M_\infty) < 0, \end{cases} \tag{2.49}$$

w_* M_∞ $\lambda_{\min}(M_\infty) < 0$ N_∞ $\sigma_{\min}(N_\infty)$ $\lambda_{\min}(M_\infty) < 0$. (2.47) $\lambda_{\min}(M_\infty) = \lim_{\theta\to\infty}\lambda_{\min}(M(\theta))$. (2.14) (2.48)–(2.49) (2.15)–(2.16) $\theta\to\infty$ 2.2 $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta)) = 0$. 2.1

. Since (2.47) follows from (2.46), the results on N_∞ follow trivially from those on M_∞. Since $M_\infty b = 0$, $\lambda_{\min}(M_\infty) \leq 0$. From Lemma 2.4 M_∞ has at most one negative eigenvalue. In fact M_∞ in (2.47) is identical to $T(0)$ in (2.36), so with $w_* \equiv w_*(0)$, $\lambda_* \equiv \lambda_{\min}(M_\infty) \equiv \lambda_*(0)$ in (2.37), $M_\infty w_* = w_*\lambda_*$. From (2.14) and (2.34)

$$M(\theta) \equiv A\left(I-yy^\dagger\right)A^T - r\rho\theta^2 r^T + b\,\theta^2 b^T = \varepsilon^{-1}H(\varepsilon), \quad \text{with } \varepsilon \equiv \theta^{-2}. \tag{2.50}$$

Since $M(\theta)$ can have at most one negative eigenvalue, when $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta)) < 0$, $\lambda_{\min}(M(\theta))$ is the unique minimum eigenvalue for large enough θ, and w_θ in (2.16)

can be taken as $w(\varepsilon)$ in Theorem 2.5. This, and noting that $\lambda(\theta^2 H(\theta^{-2}))$ is equal to $\lambda_{\min}(M(\theta))$ for large enough θ, gives from (2.38)–(2.41)

$$\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))<0 \;\Rightarrow\; \begin{cases} \lambda_{\min}(M_\infty)=\lim_{\theta\to\infty}\lambda_{\min}(M(\theta)), \\ \;\&\;\; w_*=\pm\lim_{\theta\to\infty}w_\theta \;\;\&\;\; \lim_{\theta\to\infty}\theta w_\theta^T b=0; \end{cases}$$

$$\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))\geq 0 \;\Leftrightarrow\; \lambda_*\equiv\lambda_{\min}(M_\infty)=0;$$

$$\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))=0 \;\Rightarrow\; \lambda_{\min}(M_\infty)=0 \;\&\; \begin{cases} \{\exists x \;:\; b=Ax \;\&\; \angle(x,y)=\pm\pi/4\}, \\ \text{or } \{\exists\theta_1 \;:\; \lambda_{\min}(M(\theta))=0 \;\forall\theta>\theta_1\}. \end{cases}$$

But from (2.12) $\lim_{\theta\to\infty}\rho=0$ and $\lim_{\theta\to\infty}\rho\theta^2=\|y\|_2^{-2}$, so that (2.48) is the limiting value of both cases of (2.15) as $\theta\to\infty$. If $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))\neq 0$, it can also be seen that in the limit the two criteria in (2.16) become the respective criteria in (2.49), where if $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))<0$, $b^T w_*=\lim_{\theta\to\infty}b^T w_\theta=0$, so that in the limit the two expressions for $\widehat{\Delta A}$ in (2.16) become the respective expressions in (2.49). If $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))=0$ and this corresponds to trivial zero eigenvalues only, the top row of (2.49) is clearly once again the correct limit. Only the probability zero case of $\lim_{\theta\to\infty}\lambda_{\min}(M(\theta))=0$ with $b=Ax$, $\angle(x,y)=\pm\pi/4$, allows the possibility that $\lambda_{\min}(M(\theta))<0$ for arbitrarily large θ, and since in this case $\lambda_{\min}(M_\infty)=0$, this suggests that (2.16) could fail to give the correct limiting perturbation in (2.49). That is, although (2.49) is correct, until proven otherwise there remains the possibility that taking the limit in (2.16) could lead to $\widehat{\Delta A}=ry^\dagger-w_*w_*^\dagger A(I-y2y^\dagger)$ rather than $ry^\dagger$ in this one strange case; see (2.49). □

Deriving $\mu_F(y)$ directly as we did for $\mu_F(y,\theta)$ also leads to the results down to the sentence including (2.49). But Theorem 2.5 describes the limiting behavior as well.

To parallel the remark given in [13, section 20.7] for some formulas for the minimal backward error of ordinary least squares problems, computing and adding the eigenvalue in (2.15) or (2.48) is not wise computationally. Catastrophic cancellation may occur when it is negative. Furthermore, the computed value may have very poor accuracy even using well-known software such as MATLAB 7.4, e.g., in (2.48) the computed value of $\lambda_{\min}(M_\infty)$ may be smaller than $-\|r\|_2^2/\|y\|_2^2$. The singular value is much more reliable for computation. If we computed that using the Golub–Reinsch singular value decomposition algorithm, it would need about $8/3m^3+4mn^2$ flops, but one point of this paper is that we can use cheaper lower bounds or estimates instead.

In Theorem 2.2 we have either $\lambda_{\min}(M(\theta))<0$ or $\lambda_{\min}(M(\theta))\geq 0$, while in Theorem 2.6 we have either $\lambda_{\min}(M_\infty)<0$ or $\lambda_{\min}(M_\infty)=0$. By substituting the resulting perturbations in the relevant inequalities, it is straightforward to see that the inequality in (2.9) is satisfied when $\lambda_{\min}(M(\theta))\geq 0$ and $\operatorname{rank}(A+r(1-\rho)y^\dagger)=n$, and the inequality in (2.31) is satisfied when $\lambda_{\min}(M_\infty)=0$ and $\operatorname{rank}(A+ry^\dagger)=n$. It follows that, in these two special cases, the extended minimal backward error is actually the true minimal backward error and that nothing was lost by using the "supersets" $\mathcal{C}_{A,b}^+$ and $\mathcal{C}_A^+$. We will supply further justification for the use of these supersets later.

The following result indicates that the extended minimal backward error $\mu_F(y)$ is continuous at $y=\hat{x}$, where $\hat{x}$ is the DLS solution in (2.5)–(2.6), where of course $\mu_F(\hat{x})=0$. In order to save space, here and in the rest of the paper we will only consider the case where A is perturbed, but all of the results could be extended to the more general case where both A and b are perturbed.

COROLLARY 2.7. [illegible] 2.6 [illegible] $\hat{x}$ [illegible] (2.5)–(2.6) [illegible] $\hat{M}_\infty\equiv M_\infty(\hat{x})$ ([illegible] (2.47)) [illegible] $\hat{r}\equiv b-A\hat{x}$ [illegible]

... (2.15)

$$\lim_{y\to\hat{x}} \mu_F(y) = \mu_F(\hat{x}) = \left(\frac{\|\hat{r}\|_2^2}{\|\hat{x}\|_2^2} + \lambda_{\min}\left(\hat{M}_\infty\right)\right)^{1/2} = 0.$$

... First we see that (2.5) just says

$$A^T\hat{r} = A^T(b - A\hat{x}) = -\hat{x}\|b - A\hat{x}\|_2^2/\|\hat{x}\|_2^2 = -\hat{x}\|\hat{r}\|_2^2/\|\hat{x}\|_2^2,$$

and multiplying this on the left by $\hat{x}^T$ shows that

$$0 = (b - A\hat{x})^T(b - A\hat{x}) + (A\hat{x})^T(b - A\hat{x}) = b^T(b - A\hat{x}) = b^T\hat{r} \tag{2.51}$$

so that $(I - bb^\dagger)\hat{r} = \hat{r}$. Since $\hat{M}_\infty = M_\infty(\hat{x}) = (I - bb^\dagger)A(I - 2\hat{x}\hat{x}^\dagger)A^T(I - bb^\dagger)$, the above give

$$\begin{aligned}\hat{M}_\infty\hat{r} &= \left(I - bb^\dagger\right) A \left(I - 2\hat{x}\hat{x}^\dagger\right) A^T\hat{r} = -\left(I - bb^\dagger\right) A \left(I - 2\hat{x}\hat{x}^\dagger\right)\hat{x}\|\hat{r}\|_2^2/\|\hat{x}\|_2^2 \\ &= \left(I - bb^\dagger\right) A\hat{x}\|\hat{r}\|_2^2/\|\hat{x}\|_2^2 = \left(I - bb^\dagger\right)(A\hat{x} - b)\|\hat{r}\|_2^2/\|\hat{x}\|_2^2 \\ &= -\hat{r}\|\hat{r}\|_2^2/\|\hat{x}\|_2^2.\end{aligned}$$

Thus by Lemma 2.4, $-\|\hat{r}\|_2^2/\|\hat{x}\|_2^2$ is the only negative eigenvalue of $\hat{M}_\infty$, and $\mu_F(\hat{x}) = 0$. Clearly when $y \to \hat{x}$, we have $r = b - Ay \to \hat{r}$, $M_\infty \to \hat{M}_\infty$, and by the continuity of the eigenvalues of M_∞ in (2.47), $\lambda_{\min}(M_\infty) \to \lambda_{\min}(\hat{M}_\infty)$, completing the proof. □

Since in (2.32) $\mathcal{C}_A \subseteq \mathcal{C}_A^+$,

$$\mu_F(y) \equiv \min_{\Delta A\in\mathcal{C}_A^+} \|\Delta A\|_F \le \min_{\Delta A\in\mathcal{C}_A} \|\Delta A\|_F,$$

i.e., $\mu_F(y)$ is a lower bound on the minimal backward error. However we have found computationally, see section 5, that when y is a reasonable approximation to the exact solution of the DLS problem (2.1), the minimal perturbation $\widehat{\Delta A}$ usually satisfies the inequality in (2.31). Therefore in such cases $\mu(y)$ is actually the minimal backward error. The following result partially justifies this finding.

THEOREM 2.8. ... $A \in \mathbb{R}^{m\times n}$ ... $b \in \mathbb{R}^m$ ... (2.2) ... $\hat{x}$ ... (2.1) ... $\epsilon > 0$ ... $\|y - \hat{x}\|_2 < \epsilon$, ... $\mu_F(y)$ ...

... For any given y, Theorem 2.6 shows that $\widehat{\Delta A}$ satisfying (2.49) is the minimizer of (2.32). Notice that when $y \to \hat{x}$, we have from Corollary 2.7 that $\widehat{\Delta A} \to 0$. Thus

$$\lim_{y\to\hat{x}} \left(\frac{\left\|b - \left(A + \widehat{\Delta A}\right) y\right\|_2}{\|y\|_2} - \sigma_{\min}\left(A + \widehat{\Delta A}\right)\right) = \frac{\|b - A\hat{x}\|_2}{\|\hat{x}\|_2} - \sigma_{\min}(A).$$

Since $\frac{\|b-A\hat{x}\|_2}{\|\hat{x}\|_2} - \sigma_{\min}(A) < 0$, there must exist $\epsilon > 0$ such that when $\|y - \hat{x}\|_2 < \epsilon$,

$$\frac{\left\|b - \left(A + \widehat{\Delta A}\right) y\right\|_2}{\|y\|_2} - \sigma_{\min}\left(A + \widehat{\Delta A}\right) < 0.$$

Therefore $\widehat{\Delta A} \in \mathcal{C}_A$ and $\mu_F(y) = \min_{\Delta A\in\mathcal{C}_A} \|\Delta A\|_F$, i.e., when $\|y - \hat{x}\|_2 < \epsilon$, $\mu_F(y)$ is the true minimal backward error. □

3. A lower bound on $\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_2$. Since computing $\mu_F(y)$ directly is expensive, in this section we suggest a good lower bound which can be estimated easily.

First we give the following result, which is analogous to Theorem 3.1 in [35] for ordinary least squares problems.

THEOREM 3.1. [illegible] 2.6 [illegible] $\mathcal{C}_A^+$ [illegible] (2.30) [illegible] $\mu_2(y)\equiv\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_2$ [illegible] $\mu_F(y)$ [illegible] (2.32),

$$\frac{1}{\sqrt{2}}\mu_F(y)\le\mu_2(y)\le\mu_F(y). \tag{3.1}$$

[illegible] For any $\Delta A\in\mathcal{C}_A^+$, we see from Lemma 2.1 that there exist w satisfying $b^Tw=0$ and $Z\in\mathbb{R}^{m\times n}$ such that

$$\begin{aligned}\Delta A&=(b-w)y^\dagger+\left(I-ww^\dagger\right)Z\left(I-yy^\dagger\right)-A\\&=\left[\left(I-ww^\dagger\right)b-w\right]y^\dagger+\left(I-ww^\dagger\right)Z\left(I-yy^\dagger\right)\\&\quad-\left(I-ww^\dagger\right)Ayy^\dagger-ww^\dagger Ayy^\dagger-\left(I-ww^\dagger\right)A\left(I-yy^\dagger\right)-ww^\dagger A\left(I-yy^\dagger\right)\\&=\left[\left(I-ww^\dagger\right)(b-Ay)-w-ww^\dagger Ay\right]y^\dagger-ww^\dagger A\left(I-yy^\dagger\right)\\&\quad+\left(I-ww^\dagger\right)(Z-A)\left(I-yy^\dagger\right).\end{aligned}$$

Denote $\Delta A_1=[(I-ww^\dagger)(b-Ay)-w-ww^\dagger Ay]y^\dagger$, $\Delta A_2=-ww^\dagger A(I-yy^\dagger)$, and $\Delta A_3=(I-ww^\dagger)(Z-A)(I-yy^\dagger)$. Since $\Delta A_1\Delta A_2^T=0$, $\Delta A_1\Delta A_3^T=0$ and $\Delta A_2^T\Delta A_3=0$ and ΔA_1 and ΔA_2 are rank 1 matrices,

$$\begin{aligned}\|\Delta A\|_2^2&=\|\Delta A_1+\Delta A_2+\Delta A_3\|_2^2=\|(\Delta A_1+\Delta A_2+\Delta A_3)(\Delta A_1+\Delta A_2+\Delta A_3)^T\|_2\\&=\left\|\Delta A_1\Delta A_1^T+(\Delta A_2+\Delta A_3)(\Delta A_2+\Delta A_3)^T\right\|_2\\&\ge\max\left\{\left\|\Delta A_1\Delta A_1^T\right\|_2,\|(\Delta A_2+\Delta A_3)(\Delta A_2+\Delta A_3)^T\|_2\right\}\\&\ge\frac{1}{2}\left(\|\Delta A_1\|_2^2+\|\Delta A_2+\Delta A_3\|_2^2\right)\\&=\frac{1}{2}\left(\|\Delta A_1\|_2^2+\|(\Delta A_2+\Delta A_3)^T(\Delta A_2+\Delta A_3)\|_2\right)\\&=\frac{1}{2}\left(\|\Delta A_1\|_2^2+\left\|\Delta A_2^T\Delta A_2+\Delta A_3^T\Delta A_3\right\|_2\right)\ge\frac{1}{2}\left(\|\Delta A_1\|_2^2+\|\Delta A_2\|_2^2\right)\\&=\frac{1}{2}\left(\|\Delta A_1\|_F^2+\|\Delta A_2\|_F^2\right)=\frac{1}{2}\|\Delta A_1+\Delta A_2\|_F^2\ge\frac{1}{2}\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_F^2,\end{aligned}$$

where the last inequality is due to the fact that $\Delta A_1+\Delta A_2\in\mathcal{C}_A^+$ (take $Z=A$). Therefore

$$\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_2^2\ge\frac{1}{2}\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_F^2,$$

leading to the first inequality in (3.1). The second inequality in (3.1) is easy to prove. In fact, if $\widehat{\Delta A}$ is a minimal solution to (2.32), then

$$\mu_F(y)=\left\|\widehat{\Delta A}\right\|_F\ge\left\|\widehat{\Delta A}\right\|_2\ge\mu_2(y).\qquad\square$$

Now we give a lower bound on $\mu_2(y)\equiv\min_{\Delta A\in\mathcal{C}_A^+}\|\Delta A\|_2$.

THEOREM 3.2. [illegible] 2.6 [illegible] $\mu_2(y) \equiv \min_{\Delta A \in \mathcal{C}_A^+} \|\Delta A\|_2$ [illegible] $\mathcal{C}_A^+$ [illegible] (2.30)

$$\mu_2(y) \geq \mu_2^{\mathrm{lb}}(y) \equiv \frac{2\beta_0}{\beta_1 + \sqrt{\beta_1^2 + 4\beta_0}}, \tag{3.2}$$

[illegible]

$$\beta_0 \equiv \frac{\left\|(A^T r\|y\|_2^2 + y\|r\|_2^2)\right\|_2}{2\|y\|_2^3}, \quad \beta_1 \equiv \frac{\|y\|_2^3\|A\|_2 + 3\|y\|_2^2\|r\|_2}{2\|y\|_2^3}. \tag{3.3}$$

[illegible]. For any $\Delta A \in \mathcal{C}_A^+$, from (2.30) we obtain

$$(A + \Delta A)^T (r - \Delta A y)\|y\|_2^2 + y\|r - \Delta A y\|_2^2 = 0.$$

Thus we have

$$\begin{aligned} A^T r\|y\|_2^2 + y\|r\|_2^2 = A^T \Delta A y\|y\|_2^2 - \Delta A^T r\|y\|_2^2 + y2\left(r^T \Delta A y\right) \\ + \Delta A^T \Delta A y\|y\|_2^2 - y\|\Delta A y\|_2^2. \end{aligned}$$

Then taking the 2-norm on both sides of this equation, we obtain the inequality

$$\left\|\left(A^T r\|y\|_2^2 + y\|r\|_2^2\right)\right\|_2 \leq \left(\|y\|_2^3\|A\|_2 + 3\|y\|_2^2\|r\|_2\right)\|\Delta A\|_2 + 2\|y\|_2^3\|\Delta A\|_2^2,$$

that is, with (3.3), the quadratic inequality in terms of $\xi \equiv \|\Delta A\|_2$:

$$\beta_0 \leq \beta_1 \xi + \xi^2.$$

Since ξ and β_1 are nonnegative, $\xi \geq \xi_+$, where ξ_+ is the positive root of $\beta_0 = \beta_1 \xi + \xi^2$, so

$$\xi \geq \xi_+ = \left(\sqrt{\beta_1^2 + 4\beta_0} - \beta_1\right)/2 = 2\beta_0 / \left(\sqrt{\beta_1^2 + 4\beta_0} + \beta_1\right),$$

giving (3.2). ∎

The lower bound in (3.2) can usually be evaluated in $\mathcal{O}(mn)$ flops, since $\|A\|_2$ can usually be estimated by a standard norm estimator in $O(mn)$ flops; see [13, section 15.2]. In fact a good estimate of $\|A\|_2$ might already be available from whatever method is used for obtaining y, and the cost will essentially be the $4mn$ flops for computing $A^T(b - Ay)$.

Also $\mu_2^{\mathrm{lb}}(\hat{x}) = \mu_2(\hat{x}) = \mu_F(\hat{x}) = 0$ as desired; see (2.5), Corollary 2.7, and (3.1).

4. An asymptotic estimate for $\mu_F(y)$. Computing $\mu_F(y)$ directly is expensive, and the lower bound (3.2) may not be very tight. In this section we would like to give an asymptotic estimate by following the general approach given in [9].

Let $f(A, y) \equiv (b - Ay)^T(b - Ay)y + (y^T y)A^T(b - Ay) = \|r\|_2^2 y + \|y\|_2^2 A^T r$. Note that $f(A, \hat{x}) = 0$ (see (2.5)). The extended minimal backward perturbation ΔA is the matrix satisfying $f(A + \Delta A, y) = 0$ and $\mu_F(y) = \|\Delta A\|_F$. But by Taylor's expansion, for small enough $E \in \mathbb{R}^{m \times n}$,

$$f(A + E, y) \approx f(A, y) + \mathcal{J}_A f(A, y)\mathtt{vec}(E),$$

where $\mathcal{J}_A f(A,y) \in \mathbb{R}^{n\times mn}$ is the Jacobian matrix of f with respect to $\mathtt{vec}(A)$. Thus an approximation to ΔA is that E giving the minimum 2-norm solution to

$$f(A,y) + \mathcal{J}_A f(A,y)\mathtt{vec}(E) = 0, \tag{4.1}$$

that is, E such that

$$\mathtt{vec}(E) = -[\mathcal{J}_A f(A,y)]^\dagger f(A,y), \quad \tilde{\mu}_F(y) \equiv \|E\|_F = \|[\mathcal{J}_A f(A,y)]^\dagger f(A,y)\|_2. \tag{4.2}$$

THEOREM 4.1. [illegible] 2.6, $\tilde{\mu}_F(y)$ [illegible] (4.2) [illegible] $\mu_F(y)$ [illegible] (2.32) [illegible] $\hat{x}$ [illegible] (2.1),

$$\lim_{y\to\hat{x}} \frac{\tilde{\mu}_F(y)}{\mu_F(y)} = 1.$$

[illegible]. By Taylor's expansion,

$$0 = f(A+\Delta A, y) = f(A,y) + \mathcal{J}_A f(A,y)\mathtt{vec}(\Delta A) + O\left(\|\Delta A\|_F^2\right). \tag{4.3}$$

Thus from (4.2),

$$\mathtt{vec}(E) = -[\mathcal{J}_A f(A,y)]^\dagger f(A,y) = [\mathcal{J}_A f(A,y)]^\dagger \mathcal{J}_A f(A,y)\mathtt{vec}(\Delta A) + O\left(\|\Delta A\|_F^2\right).$$

Taking the 2-norm and noticing $[\mathcal{J}_A f(A,y)]^\dagger \mathcal{J}_A f(A,y)$ is an orthogonal projection matrix, we obtain

$$\tilde{\mu}_F(y) \le \mu_F(y) + O\left(\|\Delta A\|_F^2\right),$$

which, with Corollary 2.7, leads to $\lim_{y\to\hat{x}} \tilde{\mu}_F(y)/\mu_F(y) \le 1$.

On the other hand, from (4.1) and (4.3) we can obtain

$$\mathcal{J}_A f(A,y)\mathtt{vec}(\Delta A) = \mathcal{J}_A f(A,y)\left[\mathtt{vec}(E) + O\left(\|\Delta A\|_F^2\right)\right].$$

Since ΔA is a matrix satisfying the above equality with minimum F-norm, we must have

$$\|\mathtt{vec}(\Delta A)\|_2 \le \left\|\mathtt{vec}(E) + O\left(\|\Delta A\|_F^2\right)\right\|_2 \le \|\mathtt{vec}(E)\|_2 + O\left(\|\Delta A\|_F^2\right),$$

which, with Corollary 2.7, leads to $\lim_{y\to\hat{x}} \tilde{\mu}_F(y)/\mu_F(y) \ge 1$, completing the proof. □

Theorem 4.1 is similar to [9, Corollary 3.4], where a general minimal backward error problem was considered, and applying the corollary to our case will result in the asymptotic estimate $\|[\mathcal{J}_A f(A,\hat{x})]^\dagger f(A,y)\|_2$. We thank the referee who pointed out that a general version of Theorem 4.1 was given in [10] (with no formal proof).

In the following we will consider computing or estimating $\tilde{\mu}_F(y)$. First we would like to obtain an explicit expression for it. If $f = (f_i)$ and $g = (g_i)$ are column vectors, then we define the matrix $\partial f/\partial g^T \equiv (\partial f_i/\partial g_j)$. Write $m \times n$ $A = [a_1, \ldots, a_n]$, $y^T = (\eta_1, \ldots, \eta_n)$, then $\partial r/\partial a_j^T = \partial(b - Ay)/\partial a_j^T = -\eta_j I$, $\partial(r^T r)/\partial a_j^T = 2r^T \partial r/\partial a_j^T = -2\eta_j r^T$ and if $i \ne j$, $\partial(a_i^T r)/\partial a_j^T = -\eta_j a_i^T$, while $\partial(a_j^T r)/\partial a_j^T = r^T - \eta_j a_j^T$, from

which we see that

$$\begin{aligned}
&\mathcal{J}_A f(A,y) \equiv \partial f(A,y)/\partial \mathtt{vec}(A)^T = \left[\partial f(A,y)/\partial a_1^T, \ldots, \partial f(A,y)/\partial a_n^T\right],\\
&\partial f(A,y)/\partial a_j^T = \partial\left(r^T r y + y^T y A^T r\right)/\partial a_j^T = -2\eta_j y r^T + y^T y e_j r^T - \eta_j y^T y A^T,\\
&\mathcal{J}_A f(A,y)\cdot[\mathcal{J}_A f(A,y)]^T = \sum_{j=1}^{n}\left[\partial f(A,y)/\partial a_j^T\right]\cdot\left[\partial f(A,y)/\partial a_j^T\right]^T\\
&= \sum_{j=1}^{n}\left(-2\eta_j y r^T + y^T y e_j r^T - \eta_j y^T y A^T\right)\left(-2\eta_j y r^T + y^T y e_j r^T - \eta_j y^T y A^T\right)^T\\
&= \|y\|_2^6\left[A^T A + A^T r y^\dagger + \left(y^\dagger\right)^T r^T A + \left(\|r\|_2^2/\|y\|_2^2\right) I\right]\\
&= \|y\|_2^6\begin{bmatrix} A + r y^\dagger \\ \left(\|r\|_2/\|y\|_2\right)\left(I - y y^\dagger\right)\end{bmatrix}^T\begin{bmatrix} A + r y^\dagger \\ \left(\|r\|_2/\|y\|_2\right)\left(I - y y^\dagger\right)\end{bmatrix}. \qquad (4.4)
\end{aligned}$$

Here the matrix $\begin{bmatrix} A+ry^\dagger \\ (\|r\|_2/\|y\|_2)(I-yy^\dagger)\end{bmatrix}$ has full column rank. In fact, if it does not, then there exists nonzero $x \in \mathbb{R}^n$ such that

$$\left(A + r y^\dagger\right) x = 0, \quad \left(I - y y^\dagger\right) x = 0,$$

and it follows that $Ay + r = 0$, so $b = 0$, contradicting our assumption (2.2). Therefore $\mathcal{J}_A f(A,y)$ has full row rank. Then from (4.2),

$$\begin{aligned}
\tilde{\mu}_F(y) &= \left\|[\mathcal{J}_A f(A,y)]^T\left\{\mathcal{J}_A f(A,y)\cdot[\mathcal{J}_A f(A,y)]^T\right\}^{-1} f(A,y)\right\|_2\\
&= \left\|\left\{\mathcal{J}_A f(A,y)\cdot[\mathcal{J}_A f(A,y)]^T\right\}^{-1/2} f(A,y)\right\|_2, \qquad (4.5)
\end{aligned}$$

where the second equality can easily be proved by using the SVD of $\mathcal{J}_A f(A,y)$.

Define

$$B \equiv \begin{bmatrix} A + r y^\dagger \\ \left(\|r\|_2/\|y\|_2\right)\left(I - y y^\dagger\right)\end{bmatrix}, \quad c \equiv \begin{bmatrix} r \\ 0\end{bmatrix} \in \mathbb{R}^{m+n}. \qquad (4.6)$$

Note that

$$f(A,y) = \|y\|_2^2\left(A^T r + \|r\|_2^2\left(y^\dagger\right)^T\right) = \|y\|_2^2 B^T c. \qquad (4.7)$$

Then from (4.5) with (4.4) and (4.7), it follows that

(4.8)

$$\tilde{\mu}_F(y) = \frac{\|\left(B^T B\right)^{-1/2} B^T c\|_2}{\|y\|_2} = \frac{[c^T B\left(B^T B\right)^{-1} B^T c]^{1/2}}{\|y\|_2} = \frac{\|B\left(B^T B\right)^{-1} B^T c\|_2}{\|y\|_2}.$$

Note that $B(B^TB)^{-1}B^T$ is an orthogonal projector onto $\mathcal{R}(B)$.

The asymptotic estimate $\tilde{\mu}_F(y)$ is analogous to an estimate for the minimal backward error for ordinary least squares problems whose various forms have been studied in [9], [11], [12], and [17]. One method for computing $\tilde{\mu}_F(y)$ is to use the QR factorization. If $B = QR$ where $Q \in \mathbb{R}^{(m+n)\times n}$ satisfies $Q^TQ = I_n$ and R is upper triangular, then we see that

$$\tilde{\mu}_F(y) = \left\|Q^T c\right\|_2 / \|y\|_2. \qquad (4.9)$$

If we use Householder QR factorization, this method will cost $2(m + 2/3n^2)n^2$ flops. The other method is to use the moment method (see, e.g., [6]) by following [27, Part I]. For brevity, we will not give details here.

5. Numerical tests. In section 2 we gave an extended minimal backward error $\mu_F(y)$, which is a lower bound on the minimal backward error. But if the inequality in (2.31) holds for the extended minimal backward perturbation $\widehat{\Delta A}$ given in (2.49), then $\mu_F(y)$ is in fact the minimal backward error. Our numerical tests indicate that if the given vector y is a reasonable approximation to the true DLS solution, the inequality in (2.31) holds, where ΔA is the minimal $\widehat{\Delta A}$ given in (2.16). We will give some examples in this section to illustrate this. In section 3 we gave a lower bound $\mu_2^{\mathrm{lb}}(y)$ on $\mu_2(y)$, which is also a lower bound on $\mu_F(y)$ (since $\mu_2(y) \le \mu_F(y)$). In section 4 we presented an asymptotic estimate $\tilde{\mu}_F(y)$ of $\mu_F(y)$. We will give numerical examples to show how good $\mu_2^{\mathrm{lb}}(y)$ and $\tilde{\mu}_F(y)$ are as approximations to $\mu_F(y)$. We carried out computations using MATLAB 7.4 on a MacBook running Mac OS X 10.4.11.

In our numerical tests the data was constructed as follows (`randn` and `rand` are two MATLAB built-in functions for generating random matrices with normal and uniform distributions, respectively):

- We use two types of test matrix for A:
  Type 1: $A = \tilde{A}/\|\tilde{A}\|_F$, $\tilde{A} = \mathtt{randn}(100, 40)$. Typically $\kappa_2(A) \le 10$.
  Type 2: $A = \tilde{A}/\|\tilde{A}\|_F$, $\tilde{A} = U\Sigma V^T$, 40×40 $\Sigma = \mathrm{diag}(\sigma_i)$, $\sigma_i = 10^{-4(i-1)/39}$, $U \in \mathbb{R}^{100\times 40}$ and $V \in \mathbb{R}^{40\times 40}$ are the Q-factors of the QR factorizations of two random matrices $\mathtt{randn}(100, 40)$ and $\mathtt{randn}(40, 40)$, respectively. Note that $\kappa_2(A) = 10^4$.
- $b = (A + E)x$, $x = [1, \ldots, 1]^T \in \mathbb{R}^{40}$, $E = \frac{\delta_A}{\sqrt{100\times 40}}\mathtt{rand}(100, 40)$ (note that $\|E\|_F \le \delta_A$), $\delta_A = 10^{-7}, 10^{-6}, \ldots, 10^{-1}$ for Type 1 matrices A, $\delta_A = 10^{-7}, 10^{-6}, 10^{-5}, 10^{-4}$ for Type 2 matrices A. The DLS estimate usually has no accurate digits compared with x if δ_A is taken to be larger.
- $y = \hat{x} + \frac{1}{\sqrt{40}}\delta_{\hat{x}}\|\hat{x}\|_2\,\mathtt{rand}(40, 1)$, $\hat{x}$ is the computed solution to the DLS problem (2.1), and $\delta_{\hat{x}} = 0, 10^{-7}, 10^{-6}, \ldots, 10^{-1}$.
- For each pair of δ_A and $\delta_{\hat{x}}$ and each type of matrix, we generated 1000 sample problems.

The solution $\hat{x}$ to the DLS problem satisfies (see [5])

$$\hat{x} = \frac{b^T b}{b^T A v_{_D}} v_{_D}, \tag{5.1}$$

where $v_{_D}$ is the right singular vector corresponding to the smallest singular value of $(I - bb^\dagger)A$. The equality (5.1) can also be obtained from [21, section 9], which suggests a way to compute $\hat{x}$. In our numerical tests we used the MATLAB built-in function `svd` to find $v_{_D}$ and then computed $\hat{x}$. To compute the asymptotic estimate $\tilde{\mu}_F(y)$, we first computed the QR factorization of B (see (4.6)) to find the Q-factor and then used (4.9).

In our numerical tests single precision was used to generate the data A, b, and y and to compute the DLS solution $\hat{x}$; both single precision and double precision were used to compute both sides of the inequality in (2.31) (where ΔA gives the minimum). The number of failures to satisfy the inequality for each case by single (S) and double (D) precision is reported in Table 5.1 for Type 1 matrices, and in Table 5.2 for Type 2 matrices. When δ_A is small or $\delta_{\hat{x}}$ is large, we see that the computed version of the inequality by single precision sometimes fails. In particular, for ill-conditioned Type 2 matrices, when $\delta_A = 10^{-7}$ or $\delta_{\hat{x}} = 10^{-1}$, the failure percentage is very large. However, the computed version of the inequality by double precision holds for these test cases. This shows that these failures were due to rounding errors in the single precision computed version of the inequality, and for these test

cases the extended minimal backward error is actually the true minimal backward error. The reason that single precision rounding errors caused some tests to fail is almost certainly the following: in each failed case the gap between the smallest and the second smallest singular values of N_∞ was small, making the computation of the singular vector w_* (see (2.49)) inaccurate (see, e.g., [2, Theorem 1.2.8] or [8, Theorem 8.6.5] for perturbation results concerning the singular vectors). Indeed we noticed that, for the failed cases, w_* computed by single precision was very inaccurate compared with the one computed by double precision, leading to a large computational error in $\widehat{\Delta A}$, where this is needed for checking the inequality in (2.31).

In Figures 5.1 to 5.8 we give the plots corresponding to eight extreme cases in Tables 5.1 and 5.2 which exhibit $\mu_F(y)$ (as abscissa) versus $\mu_2^{\mathrm{lb}}(y)$ in (3.2), and $\mu_F(y)$ (as abscissa) versus $\tilde{\mu}_F(y)$ in (4.2) and (4.9), represented by the points $\cdot$ (blue) for $\mu_2^{\mathrm{lb}}(y)$, and $*$ (green) for $\tilde{\mu}_F(y)$. The diagonal (red) is plotted for reference. In these figures the above quantities were computed by double precision. But we can see no difference between these figures and the corresponding ones obtained by single precision.

From Figures 5.1, 5.2, 5.5, and 5.6, where each y is the computed DLS solution $\hat{x}$, we see that the minimal backward error $\mu_F(\hat{x}) \approx 10^{-7}$, which is close to the unit roundoff for single precision so that each computed $\hat{x}$ is a backward stable solution. It is interesting to see from Figures 5.3, 5.4, 5.7, and 5.8 that $\mu_F(y)$ is about one or two orders of magnitude smaller than $\delta_{\hat{x}}$. This phenomenon also holds for other test cases.

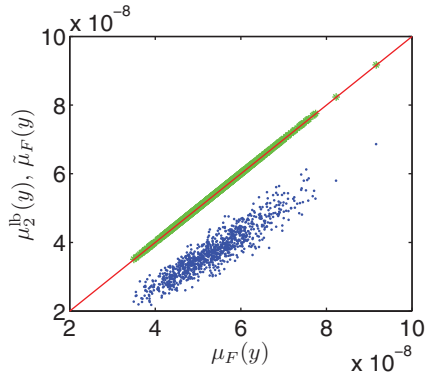

FIG. 5.1. *Type* 1 A, $\delta_A = 10^{-7}$, $\delta_{\hat{x}} = 0$.

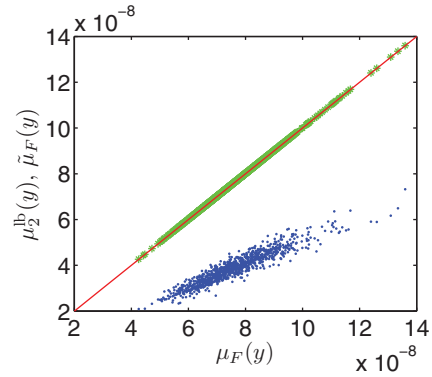

FIG. 5.2. *Type* 1 A, $\delta_A = 10^{-1}$, $\delta_{\hat{x}} = 0$.

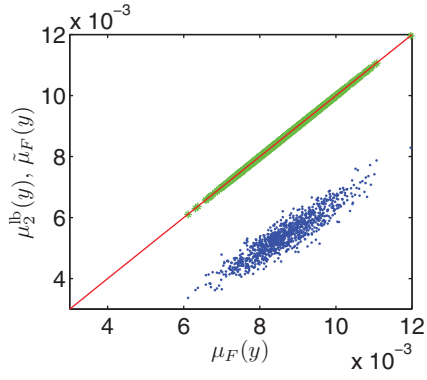

FIG. 5.3. *Type* 1 A, $\delta_A = 10^{-7}$, $\delta_{\hat{x}} = 10^{-1}$.

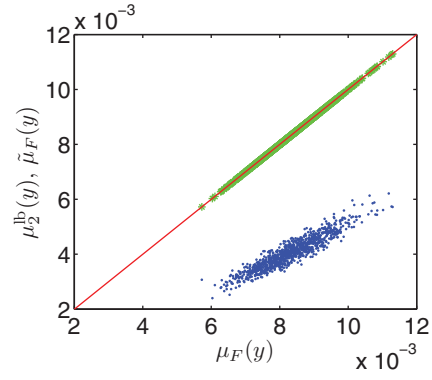

FIG. 5.4. *Type* 1 A, $\delta_A = 10^{-1}$, $\delta_{\hat{x}} = 10^{-1}$.

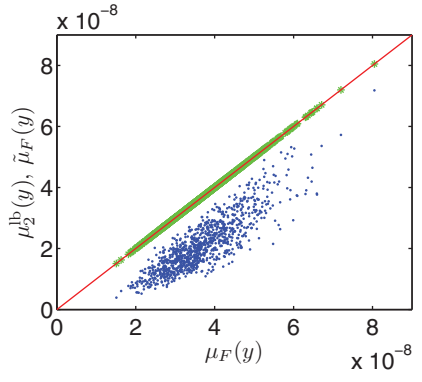

FIG. 5.5. *Type* 2 A, $\delta_A = 10^{-7}$, $\delta_{\hat{x}} = 0$.

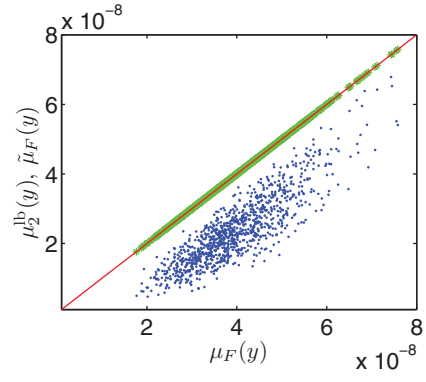

FIG. 5.6. *Type* 2 A, $\delta_A = 10^{-4}$, $\delta_{\hat{x}} = 0$.

All of these figures and the figures we did not display here indicate that the lower bound $\mu_2^{\rm lb}(y)$ is a reasonable approximation to the minimal backward error $\mu_F(y)$ in the sense that these two always had the same order of magnitude, although the case for Type 1 matrices is worse than the case for Type 2 matrices. We also see that the asymptotic estimate $\tilde{\mu}_F(y)$ is an excellent approximation to $\mu_F(y)$, even when y is not close to the DLS solution $\hat{x}$; see Figures 5.3, 5.4, 5.7, and 5.8, where $\delta_{\hat{x}} = 10^{-1}$.

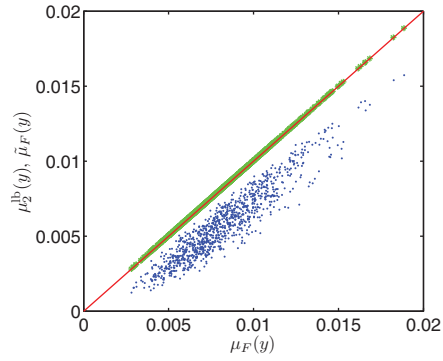

FIG. 5.7. *Type* 2 A, $\delta_A = 10^{-7}$, $\delta_{\hat{x}} = 10^{-1}$.

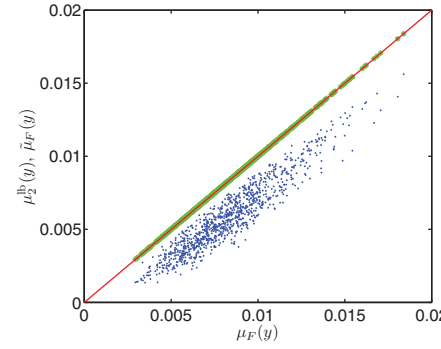

FIG. 5.8. *Type* 2 A, $\delta_A = 10^{-4}$, $\delta_{\hat{x}} = 10^{-1}$.

6. Summary and future work. For a given approximate solution y to the DLS problem (2.1), we first presented formulas (2.15) in Theorem 2.2 for an extended minimal backward error $\mu_F(y, \theta)$ for the case where backward perturbations in both A and b are allowed. Then by taking $\theta \to \infty$, we obtained the corresponding formulas (2.48) in Theorem 2.6 for an extended minimal backward error $\mu_F(y)$ for the case where only backward perturbations in A are allowed—this is the case we considered later in the paper. In theory $\mu_F(y)$ is a lower bound on the minimal backward error, but if the inequality in (2.31) is satisfied for the optimal perturbation $\widehat{\Delta A}$ given in (2.49), it is, in fact, the the minimal backward error. Our simulations showed that if y is a reasonable approximation to the exact DLS solution (that is, having a relative error in y of less than 10^{-1} for our test cases), then apparently the inequality in (2.31) holds in the absence of rounding errors in checking the inequality. Thus we believe in practice that $\mu_F(y)$ can usually be used as the minimal backward error. Since the formula (2.48) for $\mu_F(y)$ involves the minimum singular value of a matrix, it is expensive to compute directly. In order to overcome this problem, we derived a lower bound $\mu_2^{\mathrm{lb}}(y)$ (see (3.2)) and an asymptotic estimate $\tilde{\mu}_F(y)$ (see (4.6), (4.8), and (4.9)). These can be computed or estimated more efficiently. For our numerical test cases, $\mu_2^{\mathrm{lb}}(y)$ always had the same order of magnitude as $\mu_F(y)$, and $\tilde{\mu}_F(y)$ was an excellent approximation to $\mu_F(y)$. Since the computation of $\mu_2^{\mathrm{lb}}(y)$ is so inexpensive, it would seem to give a simple and effective indicator.

Several problems need to be investigated in the future. To check if the extended minimal backward error is the actual minimal backward error, we need an efficient and reliable way to test the inequality in (2.31) (or the inequality in (2.9) when perturbations in both A and b are allowed). The relationships between $\mu_F(y)$ and $\tilde{\mu}_F(y)$ needs to be studied further. We would also like to incorporate the results obtained in this paper to design effective stopping criteria for iterative algorithms for solving the DLS problem and extend the results here to total least squares problems (see [7] and [33]) and scaled total least squares problems (see [23] and [21]).

Acknowledgments. The first author is indebted to the second author and to Michael Saunders for their hospitality when he was on sabbatical at Stanford University where part of this research was done. He is also grateful to Zheng Su for helpful discussions. We also thank Pete Stewart and Nick Trefethen for improving our understanding of eigensystems of analytic Hermitian matrices. Two referees made many helpful suggestions, some of which were very demanding but led to necessary and sub-

stantial expansions of this paper. One referee also suggested the form of Theorem 2.8 in order to give a clearer exposition of our thinking.

OUT-OF-CORE IMPLEMENTATIONS OF CHOLESKY FACTORIZATION: LOOP-BASED VERSUS RECURSIVE ALGORITHMS*

NATACHA BÉREUX†

Abstract. We compare, in the same framework, out-of-core implementations of the Cholesky factorization algorithm. The candidate implementations are the classical blocked left-looking variant and a more recent recursive formulation. Both have been implemented for real positive definite matrices: the former in the parallel out-of-core linear algebra package (POOCLAPACK) library and the latter in the scalable out-of-core linear algebra computations (SOLAR) library. We perform a theoretical analysis of the amount of input/output (I/O) operations required by each variant. We consider alternatives for the left-looking algorithm: the one-tile and two-tiles approaches. We show that when main memory is restricted, the one-tile approach yields less I/O volume. We then show that the left-looking implementation requires less I/O volume than the recursive variant. We have implemented all for complex matrices, and we report on numerical experiments.

Key words. Cholesky factorization, out-of-core algorithms

DOI. 10.1137/06067256X

1. Introduction.

Large, dense, and complex valued linear systems occur in industrial applications of the boundary element method (BEM). Using the disk through an out-of-core solver is an effective way to overcome memory limitations. The aim of this paper is to compare recursive and loop-based implementations of an out-of-core Cholesky solver.

1.1. Motivation.

The BEM, which is widely used in electromagnetic or acoustic scattering, consists of transforming the original scattering problem set in an unbounded domain into an integral equation set on the boundary of the scatterer [19]. In many situations, a symmetric formulation of the integral equation is preferred (such as the electric field integral equation in electromagnetism [6, 9]). The discretization of such an integral equation, e.g., by finite element methods leads to a linear system of equations:

$$A\,X = B, \tag{1.1}$$

where the coefficient matrix A of order N is dense, complex valued, symmetric but non-Hermitian, and the right-hand side B is a given complex valued matrix of size $N \times M$. It is observed that, for complex symmetric matrices issued from the discretization of boundary integral equations (BIE), pivoting is not required: thus, a Cholesky factorization can be used [7, 5]. Note that this special property is strongly linked to the underlying BIE problem. For general complex symmetric matrices, the Cholesky algorithm is unstable and may even breakdown.

For very large problems (e.g., $N \geq 100000$), direct solvers are too costly, and preconditioned iterative algorithms are preferred [8, 10]. For intermediate size problems where the matrix is too large to fit in-core, an out-of-core solver is very effective.

1.2. State of the art. The limited size of the memory is a major bottleneck for solving large industrial problems, e.g., in electromagnetics. Therefore, out-of-core implementation, which performs linear algebra operations on matrices stored on the disk, is still an active resarch field. We refer to [24] for an extensive survey of trends in out-of-core algorithms and to [1] for recent developments related to sparse out-of-core parallel solvers. The Cholesky factorization is one of the classical linear algebra operations supported, for example, by linear algebra package (LAPACK) library [4].

The parallel extension of LAPACK, scalable linear algebra package (ScaLAPACK) provides a parallel out-of-core implementation of Cholesky factorization [11]: the matrix is partitioned into column panels and a left-looking variant of Cholesky factorization is chosen.

The parallel linear algebra package (PLAPACK) is a library infrastructure for coding linear algebra algorithms at a high level of abstraction [25]. Its parallel out-of-core linear algebra package extension (POOCLAPACK) provides a parallel out-of-core implementation of Cholesky factorization: the matrix is partitioned into tiles and is factorized by a left-looking variant [15]. The tile approach is more scalable than the panel approach used in ScaLAPACK. Two slightly different tile variants have been proposed in POOCLAPACK: the one-tile variant [26] and the two-tiles variant [21], depending on the number of full tiles allowed to reside in the memory simultaneously.

The scalable out-of-core linear algebra computations (SOLAR) library [22] is based on recursive formulations of linear algebra algorithms. It is designed to be portable across various architectures (personal, shared-memory, distributed memory computers) thanks to a portability layer, the matrix input output subroutines, which manages the data transfers to and from the disk. Matrices are partitioned into primary blocks. A primary block is the basic unit of the matrix, stored contiguously on the disk. In SOLAR's Cholesky factorization routine, the matrix is recursively split. At each level, the solution of a large system with a triangular matrix is computed, and a large symmetric rank-k update (SYRK) is performed through calls to the out-of-core basic linear algebra subroutines (BLAS). At the leaf level, the matrix is factorized by an in-core Cholesky routine (from LAPACK or ScaLAPACK). The recursion is stopped when the matrix size is equal to a predefined blocksize (for instance, when the matrix consists of 2×2 or 4×4 primary blocks). Experiments with the recursive Cholesky algorithm show that a significant amount of I/O operations is hidden by the computations. The recursive formulation of LU decomposition with partial pivoting drastically outperforms the left- and right-looking formulations.

Recursion is mainly thought to improve the locality of reference: in-core implementations perform fewer cache misses, and out-of-core implementations incur a smaller I/O volume. This feature is demonstrated for LU decomposition in [23]. Recursive data structures have also been developed in [3, 2]. Recently, a sparse Cholesky solver based on a recursive formulation of the Cholesky algorithm, at the sparse and at the dense level, combined with a recursive layout of the data has been proposed in [17]. This solver is part of the library of sparse linear solvers TAUCS. We refer to [13] for a complete survey on recursion as a key for designing high-performance linear algebra libraries.

1.3. Aim. We seek to compute the Cholesky decomposition of large dense matrices, stored on disk, on a computer with a limited amount of available memory. We focus on sequential algorithms. We survey several variants and memory layouts for computing this decomposition. Then, we propose a theoretical comparison of the re-

sulting implementations, substantiated by experiments, to find out the most effective implementation.

The paper is organized as follows. Section 2 describes two variants of the Cholesky algorithm: the left-looking variant and the recursive variant. Then, out-of-core implementations of these variants are detailed in section 3. We describe, in particular, the one-tile and the two-tiles approaches, which correspond to different memory layout. These out-of-core implementations rely on out-of-core BLAS, which are described in section 4. A theoretical analysis of the data volume from the disk to the memory is performed in section 5 for the left-looking variant and in section 6 for the recursive variant. Experiments are conducted in section 7. Our conclusions are presented in section 8.

2. The Cholesky factorization. We recall the definition of the Cholesky decomposition of a symmetric matrix A, along with assumptions and notations used throughout the paper. Then, two algorithms for the computation of the Cholesky factor L are reviewed: a loop-based algorithm (the left-looking Cholesky algorithm) and a recursive algorithm. A loop-based algorithm is based on nested do-loops, whereas a recursive algorithm is based on a recursive splitting of the matrix.

2.1. Definitions and notations.

2.1.1. Definition. Let A be a symmetric matrix, admitting the decomposition:

$$A = L\,L^T, \tag{2.1}$$

where L is a lower triangular matrix. This decomposition exists and may be computed in a stable way by the so-called Cholesky algorithm when A is a real definite positive matrix, or when A is a complex symmetric matrix encountered by the BEM [5, 7].

In the following, chol denotes a generic routine for the computation of the lower triangular Cholesky factor. Depending on the context, chol stands for a variant of the algorithm or for an optimized computational kernel.

2.1.2. Partitioned algorithms. All variants of the Cholesky algorithm considered in this paper are partitioned algorithms. The matrices A and L are partitioned into tiles. Basic operations are matrix-matrix operations on these tiles, such as multiply, add.... These operations are provided by the level 3 BLAS and are known to enjoy a high level of data-reuse [12]. Therefore, partitioned algorithms built on calls to level 3 BLAS benefit from this high level of data-reuse, which is critical for an efficient out-of-core implementation [24].

2.1.3. Notations. The matrix A is a real or complex symmetric matrix of size $n \times n$, partitioned into $p \times p$ tiles of size $t \times t$ each. The dimension p, in tiles, is approximately equal to n/t. The dimension of A, in tiles, is sometimes denoted by $p(A)$, to avoid an ambiguity.

2.2. A loop-based algorithm: The left-looking variant. We follow the formalism embraced in [20] to recap the left-looking variant of the Cholesky algorithm. Let A and L be partitioned into quadrants with square diagonal blocks:

$$A = \begin{pmatrix} A_{TL} & \star \\ A_{BL} & A_{BR} \end{pmatrix}, \quad L = \begin{pmatrix} L_{TL} & 0 \\ L_{BL} & L_{BR} \end{pmatrix}.$$

Here, A_{TL} and L_{TL} are square, and the diagonal blocks of L, L_{TL}, and L_{BL} are lower triangular. The $\star$ indicates that the corresponding part of the matrix is not referenced (due to symmetry).

Algorithm: $[A] := \text{LLT}(A)$

Partition $A \rightarrow \left(\begin{array}{c|c} A_{TL} & \star \\ \hline A_{BL} & A_{BR} \end{array}\right)$
where A_{TL} is 0×0

until A_{BR} is 0×0 **do**
Repartition

$$\left(\begin{array}{c|c} A_{TL} & \star \\ \hline A_{BL} & A_{BR} \end{array}\right) \rightarrow \left(\begin{array}{c|c|c} A_{00} & \star & \star \\ \hline A_{10} & A_{11} & \star \\ \hline A_{20} & A_{21} & A_{22} \end{array}\right)$$

where A_{11} is $b \times b$

$$\begin{array}{ll} \mathbf{1} & A_{11} := A_{11} - A_{10}\, A_{10}^T \\ \mathbf{2} & A_{11} := L_{11} = \text{CHOL}\,(A_{11}) \\ \mathbf{3} & A_{21} := A_{21} - A_{20}\, A_{10}^T \\ \mathbf{4} & A_{21} := A_{21}\, L_{11}^{-T} \end{array}$$

Continue with

$$\left(\begin{array}{c|c} A_{TL} & A_{TR} \\ \hline A_{BL} & A_{BR} \end{array}\right) \leftarrow \left(\begin{array}{c|c|c} A_{00} & \star & \star \\ \hline A_{10} & A_{11} & A_{12} \\ \hline A_{20} & A_{21} & A_{22} \end{array}\right)$$

enddo

FIG. 2.1. *Loop-based, partitioned, left-looking variant of the Cholesky algorithm.*

Using the partitionings in (2.1), we obtain

$$\begin{pmatrix} A_{TL} & \star \\ A_{BL} & A_{BR} \end{pmatrix} = \begin{pmatrix} L_{TL}\, L_{TL}^T & \star \\ L_{BL}\, L_{TL}^T & L_{BL}\, L_{BL}^T + L_{BR}\, L_{BR}^T \end{pmatrix}. \tag{2.2}$$

This equality must hold when the factorization is completed. A possible choice for the content of A at an intermediate step of the factorization is

$$A := \begin{pmatrix} L_{TL} & \star \\ A_{BL}\, L_{TL}^{-T} & A_{BR} \end{pmatrix}. \tag{2.3}$$

The bottom-right part of the matrix A_{BR} is not changed. The loop-invariant (2.3) yields the so-called left-looking variant, described in Figure 2.1.

2.3. A recursive algorithm. Observe that

$$\mathsf{chol}\,(A) := \begin{pmatrix} L_{TL} & \star \\ L_{BL} & L_{BR} \end{pmatrix},$$

where

$$\begin{aligned} L_{TL} &= \mathsf{chol}\,(A_{TL}), \\ L_{BL} &= A_{BL}\, L_{TL}, \\ L_{BR} &= \mathsf{chol}\,(A_{BR} - L_{BL}\, L_{BL}^T). \end{aligned}$$

The diagonal blocks are computed by recursive calls to the chol decomposition, yielding a natural recursive description of Cholesky decomposition [13], based on a recursive splitting of A, until the subblocks consist of a single tile. The main steps of this variant are described in Figure 2.2. In [23], Toledo shows that a recursive formulation of LU decomposition improves the locality of reference. The recursive algorithm is thus not only more concise but also more efficient than the classical right-looking variant of LAPACK. Recursive blocked algorithms have been introduced for several dense and sparse linear algebra operations, e.g., Cholesky decomposition [2, 16, 3, 17, 22].

Algorithm: $[A] := \text{RLLT}(A)$

if $p(A) > 1$ **do**

Partition $A \rightarrow \left(\begin{array}{c|c} A_{TL} & \star \\ \hline A_{BL} & A_{BR} \end{array}\right)$

where $p(A_{TL}) = p(A)/2$

1 $A_{TL} := L_{TL} = \text{RLLT}(A_{TL})$

2 $A_{BL} := A_{BL}\, L_{TL}^{-T}$

3 $A_{BR} := A_{BR} - A_{BL} A_{BL}^{T}$

4 $A_{BR} := L_{BR} = \text{RLLT}(A_{BR})$

else

$A := L = \text{CHOL}(A)$

endif

FIG. 2.2. *A recursive variant of the Cholesky algorithm. The dimension of matrix A, in tiles, is denoted by* $p(A)$.

3. Out-of-core implementations. From now on, the matrix is assumed to reside on disk. We describe the data layout and then detail the implementation of a left-looking variant and of a recursive variant of the Cholesky algorithm. Two implementations of a Cholesky left-looking variant are sketched: a two-tiles and a one-tile, depending on the number of tiles (respectively two and one) allowed to reside in memory simultaneously.

3.1. Data layout. We follow the tile approach already implemented in POOCLAPACK [15, 26].

3.1.1. Matrix tiling. We use two types of partitioning of the matrix:

- a **recursive** partitioning: the interval $[1, n]$ is recursively halved until the size of the subintervals is less than or equal to t.
- an **arithmetic** partitioning: the interval $[1, n]$ is partitioned into subintervals of size t, except possibly for the first subinterval.

Examples of partitioning are shown in Figure 3.1. In the arithmetic partitioning, the larger subintervals are the last ones: the tiles updated by more computation lay

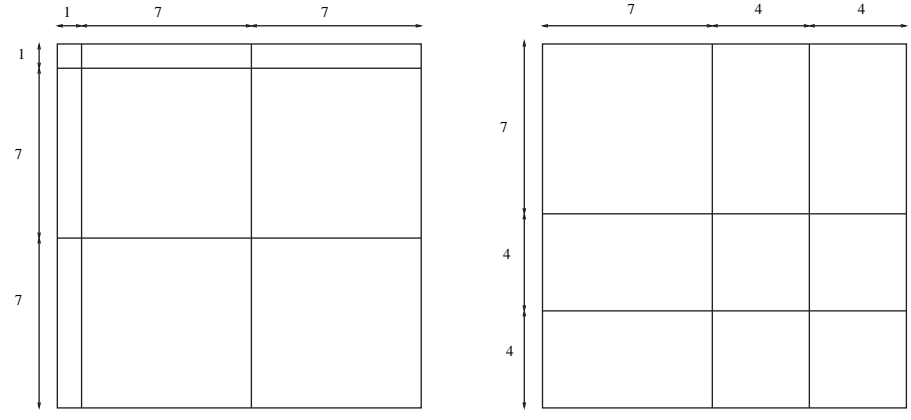

FIG. 3.1. *A matrix of size* 15×15 *is partitioned using an arithmetic partitioning (on the left) and using a recursive partitioning (on the right). In both cases, the tile size* t *is equal to* 7*: it represents the default block size in the arithmetic partitioning and the maximum size of the leaves in the recursion tree for the recursive partitioning.*

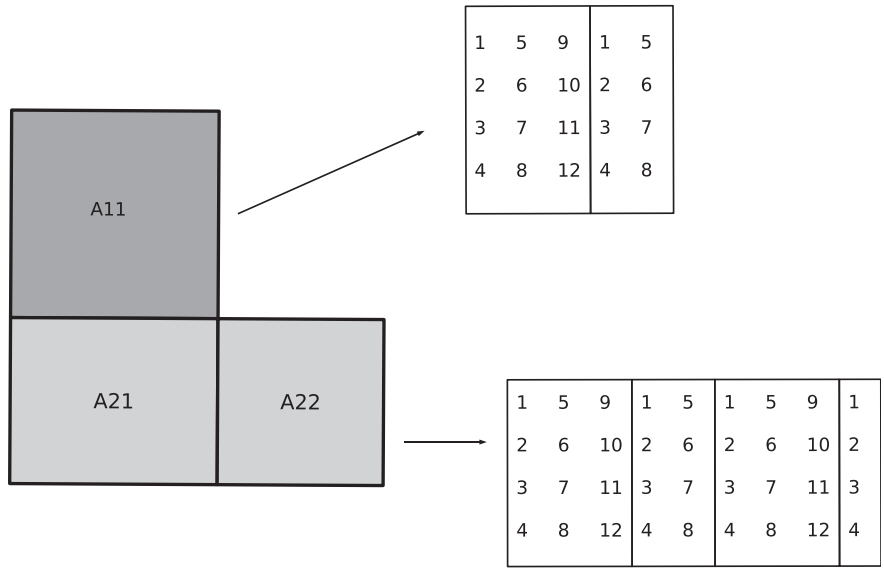

FIG. 3.2. *An example of a matrix out-of-core storage. The matrix of size* 9×9 *is recursively partitioned into tiles of size* $t \times t$*, with* $t = 5$*. The matrix is stored on the disk by block-rows. Hence, two direct-access files are needed: one contains the tile* A_{11}*, and the other the tiles* A_{21} *and* A_{22}*. Each tile is stored as a collection of records, where each record corresponds to a block of size* $t \times b$ *(*$b = 3$*), stored in column-major order.*

indeed at the bottom-right part of the matrix, and it is better to have them as large as possible to increase the operations-to-I/O ratio.

The recursive variants of Cholesky algorithms are based on a recursive partitioning of the matrix. The left-looking variants are usually based on an arithmetic partitioning.

The size of the main memory constrains the size of the tile, but p can be very large (it is only constrained by the size of the disk). Hence, this approach is well-adapted to large out-of-core matrices.

Another choice is made in the out-of-core parallel implementation of Cholesky factorization in ScaLAPACK: the matrix is partitioned into slabs of columns (possibly of variable width), instead of tiles. But this approach is known to lack scalability [24, 18].

3.1.2. Storage details. The partitioned matrix is decomposed in block-rows of height t. Each row is stored tile by tile. We will assume that each tile itself is stored in column-major order.

In practical, each block-row is stored as a collection of records in a direct-access file. In this file, each record corresponds to a primary block, stored contiguously on disk. The storage is illustrated by Figure 3.2. We distinguish between a block and a tile. A [illegible] corresponds to a physical record in the direct-access file storing a block-row of the matrix: it is the smallest unit in which the matrix is stored. A [illegible] corresponds to an element of the logical partitioning of the matrix. A tile is split on disk into several blocks of size $t \times b$, with $b \leq t$. In the following, blocks are called [illegible], since they generally have fewer columns than rows. Note that if $b = t$, a tile is identical to a block.

3.2. I/O scheme. The I/O scheme is a simple synchronous scheme, based on the standard read/write subroutines. Narrow blocks are stored as records in direct-

access files. These records are explicitly read from (and written back to) the disk when needed. No prefetching (overlapping of I/O with computation) is employed.

3.3. Implementations of the left-looking variant. We describe two implementations of the left-looking variant for the computation of the Cholesky factor of matrix A:

- In the [illegible] approach, two tiles are allowed to reside in-core simultaneously [15].
- In the [illegible] approach, there is only one tile in-core [26]. Therefore, this tile may be larger, and the implementation benefits from a better ratio between computations and I/O operations.

In both approaches, two extra buffers are needed for the in-core storage of two narrow blocks.

3.3.1. Two-tiles approach. We strictly follow the sequential implementation stated in [15]. Two tiles simultaneously reside in the main memory. One contains the diagonal tile A_{11}, and the other contains the current tile of column A_{21}. We recap the main steps and refer to [15] and [21] for further details:

- [illegible] 1: Tile A_{11} is read from disk and updated as $A_{11} := A_{11} - A_{10}A_{10}^T$ by a sequence of narrow out-of-core symmetric rank-k updates (routine OOC_TILE_SYRK).
- [illegible] 2: Tile A_{11} is factored by an in-core factorization routine. Then, tile A_{11} is written back on disk, but the corresponding in-core buffer is kept in memory.
- [illegible] 3 [illegible] 4: The update of block-column A_{21}, $A_{21} := (A_{21} - A_{20}\,A_{10}^T)L_{11}^{-T}$ is performed tile by tile. Each tile of A_{21} is brought in turn into memory, updated by a sequence of narrow out-of-core multiply and adds (routine OOC_TILE_GEMM), and next, by solving (in-core) a multiple right-hand side triangular system of matrix A_{11}^T. Then, the current tile of A_{21} is written back on disk, the buffer containing A_{11} is flushed, and the next tile is read.

To optimize data transfers, tile A_{11} remains in-core for Steps 1 to 4. Therefore, we define mixed BLAS OOC_TILE_SYRK and OOC_TILE_GEMM, whose arguments are an in-core tile and out-of-core tiles:

- OOC_TILE_SYRK overwrites the (in-core) tile C of size $t \times t$ with $C - A\,A^T$, where the tile A is stored on disk.
- OOC_TILE_GEMM overwrites the (in-core) tile C of size $t \times t$ with $C + A\,B^T$, where A and B are out-of-core tiles.

These operations can be implemented as sequences of operations on narrow matrices, as advocated in [15]. The narrow block technique analyzed in section 5.5 allows us to increase the ratio of computation over I/O operations.

3.3.2. One-tile approach. The motivation of the one-tile approach introduced in [26] is to increase the size of the current tile, which is read and written. We briefly state the differences with the two-tiles implementation, for each step of the algorithm:

- Steps 1 and 2 are not changed.
- Tile A_{11} no longer remains in-core after Step 2. It is replaced in-core by the current tile of A_{21}. Then the routine OOC_TILE_GEMM is used to update A_{21}.
- For Step 4, a new mixed BLAS is needed for the solution of the triangular system with matrix A_{11}: OOC_TILE_TRSM. This routine overwrites the (in-core) tile A_{21} with the solution X of $X\,A_{11}^T = A_{21}$, where the triangular tile A_{11} is stored on disk. Tile A_{11} is read narrow block by narrow block in one of the two extra buffers provided.

This implementation uses a larger current tile and benefits from a better flops-to-I/O-operations ratio for the mixed BLAS, as we will see. Nevertheless, tile A_{11} has to be read twice.

3.4. Implementations of the recursive variant. Let us now consider the out-of-core implementation of the recursive factorization sketched in Algorithm 2.2. A similar implementation is reported in [22], in the framework of the SOLAR project.

3.4.1. Basic implementation. The main features of the factorization are the following:

- [illegible] of the matrix until the matrix consists of a single tile.
- [illegible] 1: At the leaf level, tile A_{11} is brought into memory, factored by an in-core Cholesky routine, and written back to the disk. At another level, the factorization is called recursively.
- [illegible] 2 consists in solving a triangular linear system with matrix L_{TL}. At the leaf level, this operation is performed by an in-core routine (for instance, the BLAS routine TRSM), after reading the tile L_{TL}. If the matrices are larger, an out-of-core routine OOC_TRSM is called.
- [illegible] 3 is a symmetric update operation. It is performed either by calling an in-core routine (for instance, the BLAS routine SYRK) or an out-of-core routine OOC_SYRK.

The recursive implementation calls two out-of-core BLAS, whose arguments are all out-of-core matrices:

- OOC_SYRK overwrites the out-of-core matrix C of size $n \times n$ with $C - A\,A^T$, where A is an out-of-core matrix of size $n \times k$. If $n = t$, A and C are brought into memory, and an in-core routine is called.
- OOC_TRSM overwrites the out-of-core matrix B of size $m \times n$ by the solution X of $X\,A^T = B$, where A is a triangular out-of-core matrix of size $n \times n$. When $m = n = t$, both arguments are brought into memory, and an in-core routine is called.

So, out-of-core routines switch to in-core routine as soon as the arguments are matrices consisting of a single tile.

3.4.2. Optimization: A (two-tiles) hybrid variant. Observe the factorization of a matrix of 2×2 tiles:

$$A = \begin{pmatrix} A_{11} & \star \\ A_{21} & A_{22} \end{pmatrix}.$$

The recursive procedure starts by splitting the matrix. Then the computation with a two-tiles implementation requires reading 5 tiles and writing 3 tiles. The following (also two-tiles) schedule avoids reading a tile immediately after it has been written:

- read, factorize A_{11};
- read, update A_{21};
- write A_{11} on disk and read A_{22},
- update A_{22}, write A_{21}, factorize and write A_{22}.

It involves only reading and writing 3 tiles. So it is proposed to stop the recursion when the matrix has 2×2 tiles and to switch to this schedule. The total gain in I/O volume is evaluated in section 6.5.

4. Out-of-core BLAS. The recursive schedule of Cholesky factorization stated in section 3.4 calls out-of-core BLAS, for the out-of-core computation of the following:

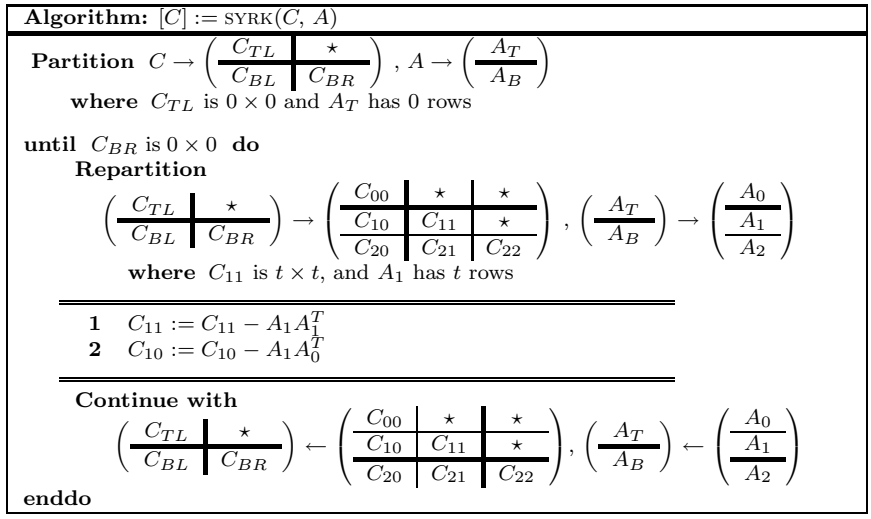

FIG. 4.1. *Blocked, loop-based algorithm for the computation of the SYRK, $C := C - A\,A^T$.*

- A symmetric rank-k update, OOC_SYRK, $C - A\,A^T$, where A is a $n \times k$ matrix and C is a $k \times k$ matrix (see Figure 4.1).
- The solution X of $X\,A^T = B$, OOC_TRSM, where A is a triangular matrix of size $n \times n$ and X overwrites B (of size $m \times n$); see Figure 4.2.

Out-of-core BLAS may be based on recursive algorithms or on loop-based algorithms. Some tests were conducted with recursive implementations but the performance was quite disappointing. So, we do not take the recursive option here and restrict (as in [22]) to loop-based algorithms. One-tile and two-tiles implementations of the out-of-core BLAS are needed as building blocks for the one-tile and two-tiles implementations of the recursive Cholesky algorithm. We briefly recall these implementations for OOC_SYRK and OOC_TRSM (see Chapter 8 and Chapter 16 of [14]).

4.1. Out-of-core SYRK. We recap the (one-tile) block down-right moving variant of the symmetric rank-k update SYRK:

- Tile C_{11} is brought into the main memory.
- [illegible] 1 is performed by applying a sequence of narrow rank-k updates through a call to OOC_TILE_SYRK. Then, C_{11} is written back on the disk.
- [illegible] 2 is performed tile by tile. Each tile of C_{10} is read, updated by a call to OOC_TILE_GEMM, and written back on disk.

4.2. Out-of-core TRSM. The solution of $X\,L^T = B$ is computed by the blocked right-moving variant of the triangular solver TRSM. The main steps of the out-of-core two-tiles implementation are

- Tile L_{11} is brought into memory.
- Column B_1 is replaced tile by tile by the corresponding column of tiles of the solution. The current tile of B_1 is read, updated by calling the routine OOC_TILE_GEMM. Then, the linear system with matrix L_{11}^T is solved in-core, and the current tile of B_1 is written back to the disk.

In the one-tile implementation, the tile L_{11} does not stay in-core. For every tile of B_1, the mixed BLAS OOC_TILE_TRSM is called instead of the in-core TRSM.

Algorithm: $[B] := \text{TRSM}(L, B)$

Partition $L \rightarrow \left(\begin{array}{c|c} L_{TL} & \star \\ \hline L_{BL} & L_{BR} \end{array}\right)$, $B \rightarrow \left(\begin{array}{c|c} B_L & B_R \end{array}\right)$

where L_{TL} is 0×0 and B_L has 0 columns

until L_{BR} is 0×0 **do**

Repartition

$$\left(\begin{array}{c|c} L_{TL} & \star \\ \hline L_{BL} & L_{BR} \end{array}\right) \rightarrow \left(\begin{array}{c|c|c} L_{00} & \star & \star \\ \hline L_{10} & L_{11} & \star \\ \hline L_{20} & L_{21} & L_{22} \end{array}\right), \left(\begin{array}{c|c} B_T & B_B \end{array}\right) \rightarrow \left(\begin{array}{c|c|c} B_0 & B_1 & B_2 \end{array}\right)$$

where L_{11} is $t \times t$, and B_1 has t columns

$B_1 := (B_1 - B_0 L_{10}^T)\, L_{11}^{-T}$

Continue with

$$\left(\begin{array}{c|c} L_{TL} & \star \\ \hline L_{BL} & L_{BR} \end{array}\right) \leftarrow \left(\begin{array}{c|c|c} L_{00} & \star & \star \\ \hline L_{10} & L_{11} & \star \\ \hline L_{20} & L_{21} & L_{22} \end{array}\right), \left(\begin{array}{c|c} B_L & B_R \end{array}\right) \leftarrow \left(\begin{array}{c|c|c} B_0 & B_1 & B_2 \end{array}\right)$$

enddo

5. Analysis of the I/O costs of the left-looking variant. This section presents a theoretical analysis of data transfers between the disk and the main memory in left-looking Cholesky algorithms.

We compare the number of tiles read and written by the two-tiles and one-tile implementations of the left-looking Cholesky variant. Assuming that the main memory is limited, we obtain a simple criterion for choosing one or the other approach, when one wishes to minimize the I/O volume during the factorization. We then investigate the impact of using narrow blocks in terms of I/Os.

5.1. Notations. We follow a systematic naming scheme. The number of tiles read (respectively written) during the factorization of the matrix A is denoted by Tr (respectively, Tw). The number of matrix elements read (respectively written) is similarly denoted by Nr (respectively, Nw). A subscript characterizes the variant (LLT for the left-looking variant), and a superscript characterizes the implementation ((1T) for the one-tile implementation and (2T) for the two-tiles implementation). Their dependence with respect to (p, n, t, b) is made explicit when necessary.

For the sake of simplicity, we assume that n is a multiple of t, and thus $p = p(n, t) = n/t$.

The main memory is limited to M words. A narrow block is a subtile of size $t \times b$.

5.2. Two-tiles approach. We analyze the data transfers performed by the schedule described in section 3.3.1. Suppose that $k-1$ columns of the tiles of A have already been factored. Matrix A is partitioned as

$$\left(\begin{array}{c|c|c} A_{00} & \star & \star \\ \hline A_{10} & A_{11} & \star \\ \hline A_{20} & A_{21} & A_{22} \end{array}\right), \tag{5.1}$$

where A_{11} is a tile and A_{22} is a matrix of $(p-k) \times (p-k)$ tiles.
During the kth iteration, the following I/O operations are performed:

- Read A_{11}, A_{10} (k tiles).
- Write A_{11} (1 tile).
- Read A_{21} tile by tile ($p-k$ tiles).

- For each tile of A_{21}, read A_{10} and $k-1$ tiles of A_{20} ($2 \times (k-1)$ tiles).
- Write A_{21} ($p-k$ tiles).

Hence, the total number of tiles read $\mathrm{Tr}_{\mathrm{LLT}}^{(2\mathrm{T})}(p)$ is

$$\mathrm{Tr}_{\mathrm{LLT}}^{(2\mathrm{T})}(p) = \sum_{k=1}^{p} p + 2\,(k-1)\;(p-k) = \frac{p}{3}\;\left(p^2+2\right).$$

The total number of tiles written $\mathrm{Tw}_{\mathrm{LLT}}^{(2\mathrm{T})}$ is

$$\mathrm{Tw}_{\mathrm{LLT}}^{(2\mathrm{T})}(p) = \sum_{k=1}^{p} k = \frac{p}{2}\,(p+1).$$

5.3. One-tile approach. We examine the number of tiles read and written during the kth iteration of the one-tile approach described in section 3.3.2. Matrix A is partitioned as in (5.1).

The tile A_{11} does not stay in memory for the whole iteration: it has to be read for each tile of A_{21}, which results in $p-k$ extra tiles to read. In the end, the number of tiles read $\mathrm{Tr}_{\mathrm{LLT}}^{(1\mathrm{T})}(p)$ is

$$\mathrm{Tr}_{\mathrm{LLT}}^{(1\mathrm{T})}(p) = \mathrm{Tr}_{\mathrm{LLT}}^{(2\mathrm{T})}(p) + \sum_{k=1}^{p}(p-k) = \frac{p}{6}\;\left(2p^2+3p+1\right),$$

and the number of tiles written $\mathrm{Tw}_{\mathrm{LLT}}^{(1\mathrm{T})}(p)$ is

$$\mathrm{Tw}_{\mathrm{LLT}}^{(1\mathrm{T})}(p) = \mathrm{Tw}_{\mathrm{LLT}}^{(2\mathrm{T})}(p) = \frac{p}{2}\;(p+1).$$

5.4. One-tile versus two-tiles implementation. We compare the two-tiles and one-tile implementations from the point of view of I/O volume.

The number of matrix elements read by the two-tiles and one-tile implementations, respectively, are given by,

$$\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}(n,t) = \mathrm{Tr}_{\mathrm{LLT}}^{(2\mathrm{T})}\left(p=\frac{n}{t}\right) \times t^2 = \frac{n}{3\,t}\;\left(\left(\frac{n}{t}\right)^2+2\right), \tag{5.2}$$

$$\mathrm{Nr}_{\mathrm{LLT}}^{(1\mathrm{T})}(n,t) = \mathrm{Tr}_{\mathrm{LLT}}^{(1\mathrm{T})}\left(p=\frac{n}{t}\right) \times t^2 = \frac{n}{6\,t}\;\left(2\left(\frac{n}{t}\right)^2+3\left(\frac{n}{t}\right)+1\right). \tag{5.3}$$

The available main memory is partitioned into two-tiles of size $t=\sqrt{M/2}$ or one tile of size $t=\sqrt{M}$, respectively. Here, we neglect the two extra buffers needed for the storage in-core of two narrow blocks. The number of terms read with the two-tiles and the one-tile approach are equal to

$$\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}\left(n,t=\sqrt{M/2}\right) = \frac{n\,\sqrt{M}}{3}\;\sqrt{2}\;\left(\frac{n^2}{M}+1\right),$$

$$\mathrm{Nr}_{\mathrm{LLT}}^{(1\mathrm{T})}\left(n,t=\sqrt{M}\right) = \frac{n\,\sqrt{M}}{3}\;\left(\frac{n^2}{M}+\frac{3}{2}\frac{n}{\sqrt{M}}+1\right).$$

For large values of n, the one-tile implementation requires less I/O operations than the two-tiles.

5.5. Narrow blocks. Some basic linear algebra operations, e.g., SYRK and matrix multiply and add (GEMM) can be implemented using the narrow block technique. The matrix operands that are left unchanged on exit of these operations are partitioned into narrow blocks. Hence, a GEMM

$$C \leftarrow C - AB^T$$

is implemented as a sequence of narrow multiply and adds: $C - \sum_i A_i B_i^T$, where A_i and B_i are narrow subblocks of A and B of width b.

This scheduling does not change the I/O volume for a fixed tile size. It improves the I/O volume when the memory size is limited. A two-tiles implementation actually uses two tiles and two narrow blocks in-core, that is, $2\,tb + 2\,t^2$ words. If b is small, t can increase up to the asymptotic value $\sqrt{M/2}$. On the opposite, if $b = t$, the maximum tile size is $t = \sqrt{M/4}$. The ratio of the number of matrix elements read in both situations is

$$\frac{\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}\left(n, t = \sqrt{M/2}\right)}{\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}\left(n, t = \sqrt{M/4}\right)} \simeq \frac{1}{\sqrt{2}}, \tag{5.4}$$

which is a quantitative estimate of the potential gain when using narrow blocks. The numerical experiments reported in section 7.1 confirm these asymptotic I/O savings.

A similar analysis is conducted for the one-tile variant. One tile and two narrow blocks reside in memory, consisting of $t^2 + 2tb$ words of memory. If b is small, the tile size goes to $\sqrt{M/2}$, whereas if $b = t$, t equals $\sqrt{M/3}$. The ratio of the number of elements read is asymptotically

$$\frac{\mathrm{Nr}_{\mathrm{LLT}}^{(1\mathrm{T})}\left(n, t = \sqrt{M/2}\right)}{\mathrm{Nr}_{\mathrm{LLT}}^{(1\mathrm{T})}\left(n, t = \sqrt{M/3}\right)} \simeq \frac{\sqrt{3}}{2\sqrt{2}}. \tag{5.5}$$

6. Analysis of the I/O costs of the recursive variant. In this section, we analyze the memory behavior of the two-tiles implementation of the recursive variant of the Cholesky factorization. We first estimate the number of I/Os for the out-of-core BLAS OOC_TRSM and OOC_SYRK. Then, in section 6.3, we combine these estimates to obtain the number of tiles read and written by the recursive variant of Cholesky factorization, when the number of tiles of the matrix A is a power of two.

6.1. Notations. Notations are similar to the notations introduced in section 5.1.

The subscripts RLLT, HLLT, SYRK, and TRSM, respectively, refer to the recursive variant of the Cholesky algorithm, the hybrid variant proposed in section 3.4.2, and the out-of-core BLAS OOC_SYRK and OOC_TRSM. Unless stated, implementations are two-tiles, and superscript (2T) is omitted.

6.2. Analysis of the out-of-core BLAS. We analyze the data transfer performed by an out-of-core (two-tiles) implementation of OOC_SYRK and OOC_TRSM. The operands of these routines are out-of-core matrices partitioned into tiles of size $t \times t$.

6.2.1. Out-of-core SYRK. Let A be a symmetric matrix of $p \times k$ tiles, and let C be a matrix of $p \times p$ tiles. The number of tiles read during the computation of $C - AA^T$ (see Figure 4.1) is

$$\mathrm{Tr}_{\mathrm{SYRK}}(p,k) = \sum_{j=1}^{p} 1 + k + (j-1)(2k+1) = k\,p^2 + \frac{p}{2}\,(p+1)\,. \tag{6.1}$$

The number of tiles written $\mathrm{Tw}_{\mathrm{SYRK}}(p,k)$ is

$$\mathrm{Tw}_{\mathrm{SYRK}}(p,k) = \frac{p}{2}\,(p+1). \tag{6.2}$$

6.2.2. Out-of-core TRSM. Let A be a lower triangular matrix of $p \times p$ tiles, and let B be a matrix of $m \times p$ tiles. The number of tiles read during the computation of the solution of $X\,A^T = B$ (see Figure 4.2) is

$$\mathrm{Tr}_{\mathrm{TRSM}}(m,p) = \sum_{k=1}^{p} 1 + m\,(1 + 2(k-1)) = m\,p^2 + p. \tag{6.3}$$

The number of tiles written $\mathrm{Tw}_{\mathrm{TRSM}}(m,p)$ is

$$\mathrm{Tw}_{\mathrm{TRSM}}(m,p) = \sum_{k=1}^{p} m = mp. \tag{6.4}$$

6.3. Analysis of the recursive variant. This subsection presents an analysis of the data transfers associated to the recursive variant of Cholesky factorization (see Figure 2.2). We assume that $p = 2^l$ for some integer l.

Let us compute $\mathrm{Tr}_{\mathrm{RLLT}}(2^l)$ and $\mathrm{Tw}_{\mathrm{RLLT}}(2^l)$ by induction.

If $k = 0$, the matrix A is reduced to a single tile, and the factorization is computed by the in-core Cholesky factorization routine. Hence,

$$\mathrm{Tr}_{\mathrm{RLLT}}(1) = 1, \quad \mathrm{Tw}_{\mathrm{RLLT}}(1) = 1.$$

Let $k \geq 1$. The number of tiles read at level k satisfies the following recurrence:

$$\mathrm{Tr}_{\mathrm{RLLT}}\left(2^k\right) = 2\,\mathrm{Tr}_{\mathrm{RLLT}}\left(2^{k-1}\right) + \mathrm{Tr}_{\mathrm{TRSM}}\left(2^{k-1}, 2^{k-1}\right) + \mathrm{Tr}_{\mathrm{SYRK}}\left(2^{k-1}, 2^{k-1}\right). \tag{6.5}$$

Hence, we have, for the factorization of a matrix of 2^l tiles,

$$\begin{aligned} \mathrm{Tr}_{\mathrm{RLLT}}\left(2^l\right) = 2^l\,\mathrm{Tr}_{\mathrm{RLLT}}(1) &+ \sum_{k=1}^{l} 2^{k-1}\,\mathrm{Tr}_{\mathrm{TRSM}}\left(2^{l-k}, 2^{l-k}\right) \\ &+ \sum_{k=1}^{l} 2^{k-1}\,\mathrm{Tr}_{\mathrm{SYRK}}\left(2^{l-k}, 2^{l-k}\right). \end{aligned} \tag{6.6}$$

Hence, using (6.1) and (6.3) in (6.6), we obtain the number of tiles read:

$$\mathrm{Tr}_{\mathrm{RLLT}}(2^l) = \frac{2^{3l}}{3} + \frac{2^{2l}}{4} + 2^l \left(\frac{3l}{4} + \frac{5}{12}\right). \tag{6.7}$$

The number of tiles written also satisfies relation (6.5). Using (6.2) and (6.4), we obtain

$$\mathrm{Tw}_{\mathrm{RLLT}}(2^l) = \frac{3}{4}\,2^{2l} + 2^l \left(\frac{l+1}{4}\right). \tag{6.8}$$

If p is not a power of two, we obtain an approximate value of $\mathrm{Tr}_{\mathrm{RLLT}}(p)$ and $\mathrm{Tw}_{\mathrm{RLLT}}(p)$ by replacing 2^l with p and l with $\log_2(p)$:

$$\mathrm{Tr}_{\mathrm{RLLT}}(p) \approx \frac{p^3}{3} + \frac{p^2}{4} + p \left(\frac{3}{4}\log_2(p) + \frac{5}{12}\right),$$
$$\mathrm{Tw}_{\mathrm{RLLT}}(p) \approx \frac{3p^2}{4} + \frac{p}{4}\left(\log_2(p) + 1\right).$$

6.4. A one-tile implementation. A one-tile implementation of the recursive variant of Cholesky factorization is easily obtained by calling a one-tile implementation of OOC_TRSM instead of the two-tiles implementation analyzed in section 6.2.2. The number of tiles read by OOC_TRSM is slightly increased:

$$\mathrm{Tr}^{(1T)}_{\mathrm{TRSM}}(m,p) = m\,p^2 + m\,p,$$

whereas the number of tiles written is not modified. Finally, the number of tiles read by a one-tile recursive factorization of a matrix with 2^l tiles is

$$\mathrm{Tr}^{(1T)}_{\mathrm{RLLT}}\left(2^l\right) = \frac{2^{3l}}{3} + \frac{3}{4}\,2^{2l} + 2^l \left(\frac{l}{4} - \frac{1}{12}\right).$$

6.5. The hybrid recursive/left-looking approach. We investigate the hybrid implementation proposed in section 3.4.2. Assume that $p = 2^l$. This hybrid variant is very close to the fully recursive variant analyzed in section 6.3.

The recursive partitioning of the matrix is stopped at level $l-1$ (instead of l) when the matrix has 2×2 tiles.

The read operations corresponding to the level l are avoided. This results in 3×2^l tiles less to read. At level $l-1$, $3 \times 2^{l-1}$ additional tiles are read (for the factorization of the 2^{l-1} blocks of 2×2 tiles). Finally,

$$\mathrm{Tr}_{\mathrm{HLLT}}(p) = \mathrm{Tr}_{\mathrm{RLLT}}(p) - 3 \times 2^l + 3 \times 2^{l-1} = \frac{2^{3l}}{3} + \frac{2^{2l}}{4} + 2^l \left(\frac{3l}{4} - \frac{13}{12}\right).$$

This variant avoids to write 2^{l-1} tiles. Hence,

$$\mathrm{Tw}_{\mathrm{HLLT}}(p) = \mathrm{Tw}_{\mathrm{RLLT}}(p) - 2^{l-1} = \frac{3}{4}\,2^{2l} + 2^l \left(\frac{l-1}{4}\right).$$

The hybrid variant slightly improves the number of tiles read and written. Nevertheless, it does not affect the dominant terms.

TABLE 6.1
The number of tiles read and written during the factorization of an out-of-core matrix A partitioned into $p \times p$ tiles for the left-looking and the recursive variants of the Cholesky algorithm. For each variant, the one-tile and two-tiles implementation are considered.

	Left-looking algorithm	
Implementation	One-tile	Two-tiles
Tiles read	$\frac{p^3}{3} + \frac{p^2}{2} + \frac{p}{6}$	$\frac{p^3}{6} + \frac{2\,p}{3}$
Tiles written	$\frac{p}{2}(p+1)$	

	Recursive algorithm	
Implementation	One-tile	Two-tiles
Tiles read	$\frac{p^3}{3} + \frac{3}{4}p^2 + p\left(\frac{\log_2(p)}{4} - \frac{1}{12}\right)$	$\frac{p^3}{3} + \frac{p^2}{4} + p\left(\frac{3}{4}\log_2(p) + \frac{5}{12}\right)$
Tiles written	$\frac{3\,p^2}{4} + \frac{p}{4}(\log_2(p)+1)$	

6.6. Conclusion of the analysis. The number of tiles read from and written to the disk during the factorization of an out-of-core matrix A partitioned into $p \times p$ tiles is gathered in Table 6.1 for the left-looking and the recursive variants of the Cholesky algorithm. For each variant, the one-tile and two-tiles implementations are considered. The conclusion of this analysis is that the recursive variant reads and writes more tiles. Therefore, when one tries to minimize the number of tiles read and written, the left-looking variant is more appropriate.

7. Performance experiments. We present experiments for the different variants of the out-of-core Cholesky factorization. All variants were implemented in Fortran 90, compiled with Intel's Fortran compiler `ifort` with `-fast` optimization, and run on a Pentium 4 XEON based biprocessor running RedHat Linux 3.2.2-5. The 2 CPUs have a clock cycle of 3.05 GHz, 2GB of Ram, and a cache size of 512 KB. We use a small computer system interface (SCSI) disk for the out-of-core storage of matrices. We use Intel's optimized implementation of BLAS, the math kernel library. Experiments are performed in simple precision complex arithmetic with matrices generated by the discretization of boundary element formulation of the electromagnetic scattering by an object.

7.1. Narrow blocks. We present a preliminary study which aims at optimizing the width of narrow blocks.

We first verify the estimate (5.4) (estimate (5.5) is similarly verified). We consider the factorization of a matrix A of size $n = 12000$, arithmetically partitioned into tiles of size $t \times t$, by the two-tiles implementation of the Cholesky factorization. The memory is limited to 10^6 words. We compare the ratio of the number of terms read with two extreme choices:

- b minimum ($b = 1$), t maximum ($t = 707$): $\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}(b = 1)$,
- b maximum, equal to t ($b = t = 500$): $\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}(b = t = 500)$,

to the predicted value $1/\sqrt{2}$ and obtain a good agreement:

$$\frac{\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}(b = 500)}{\mathrm{Nr}_{\mathrm{LLT}}^{(2\mathrm{T})}(b = 1)}\sqrt{2} = \frac{824\,10^6 \times \sqrt{2}}{1156\,10^6} = 1.0080.$$

But, when $b = 1$, the factorization takes 1858 seconds, against 398 seconds, when $b = t = 500$. When $b = 1$, the bulk of the computation is, namely, in level 2 BLAS, which explains this poor performance.

TABLE 7.1

I/O time (in seconds) for the factorization of a matrix of size $N = 48000$, partitioned into tiles of size $t \times t$, for different values of t. An "empty" factorization (with read/write operations but without computation) is performed. The elapsed time for the "empty" factorization roughly corresponds to the I/O time for the real factorization.

	Left-looking algorithm		Recursive algorithm		Hybrid algorithm	
t	One-tile	Two-tiles	One-tile	Two-tiles	One-tile	Two-tiles
750	4704	4951	5039	5125	5052	5122
1500	2727	2512	2900	2756	2841	2778
3000	1499	1543	1695	1713	1672	1625

We then follow [15] and choose b such that it optimizes an out-of-core SYRK. We compute $C - A\,A^T$, where matrices C and A consist of a single tile. We perform two sets of experiments: one with $t = 2535$, and the other with $t = 5880$. For each set, several values of b are tested (from $b = 128$ to $b = t/2$). The value $b = 256$ is a good compromise between speed and memory. This value is fixed throughout the following experiments.

7.2. Performance characteristics of the different variants. In this paragraph, we compare the performance characteristics of the left-looking, the recursive, and the hybrid variant of the Cholesky algorithm. The test case is a matrix of size $n = 48000$, partitioned in tiles of size 750, 1500, and 3000. For these tile sizes, arithmetic and recursive partitioning of the matrix are identical. One-tile and two-tiles implementations are experienced for each variant.

7.2.1. Evaluation of the time taken by the I/Os. The time taken by the I/Os is shown on Table 7.1. It is evaluated for each variant and each tile size by running an "empty" factorization of the matrix: the tiles are read and written according to the algorithmic schedule but no computation is made (all of the BLAS calls are turned off). The elapsed time gives an estimate of the time taken by the I/Os.

. . . 1. As mentioned in subsection 3.2, I/O operations are performed through standard read/write. But the operating system (OS) may cache pages in memory. Therefore, I/O timings may not be reliable. In this work, the specifier `BUFFERED='NO'` is used in the `OPEN` statements: this specifier is available in the Intel Fortran compiler, and it should ensure that records are not accumulated in a buffer instead of being read or written on disk. Nevertheless, the experimental timings presented here may be inaccurate, due to OS caching.

7.2.2. Performances of the different variants. Table 7.2 shows the performances of all of the variants. The elapsed time for completing the factorization is presented, along with the flops rate attained. The number of tiles read and written is measured, and this measure confirms the previous analysis of the I/O costs. The main result of these experiments is that the loop-based algorithm outperforms the others: it reads and writes less tiles, and it achieves the factorization faster than the other candidates. The recursive variant, although promising, does not seem to be well suited for an out-of-core decomposition. The I/O cost is higher than for the loop-based variant, and the better data locality provided by the recursive schedule does not compensate this drawback. The hybrid algorithm performs fewer I/O operations than the fully recursive one, but it does not perform better: the total time taken by the factorization is the same.

For a fixed given tile size, the two-tiles implementation is always faster than the one-tile implementation (for the three variants considered here). This is not a surprise:

TABLE 7.2

Factorization of a matrix of size $N = 48000$, partitioned into tiles of size $t \times t$, for different values of t. We compare one-tile and two-tiles implementations of the left-looking, recursive, and hybrid Cholesky factorization. For the hybrid algorithm, the recursive splitting of the matrix is stopped when the matrix has 2×2 tiles. Then, the algorithm switches in one case to the optimized (two-tiles) left-looking algorithm presented in section 3.4.2 and in the other case to the standard one-tile left-looking algorithm. We measure the number of tiles read and written during the factorization and the total time elapsed. Times are reported in seconds.

a one-tile implementation performs better than a two-tiles implementation when the memory size (and not the tile size) is fixed.

8. Conclusion and perspectives. This paper analyses and compares out-of-core implementations of the partitioned Cholesky factorization algorithm. The same partitioning of the matrix to factorize is used for all variants, to allow a fair comparison. Our theoretical analysis shows that the amount of I/O operations is lower when a left-looking algorithm is used. Our numerical experiments confirm this result. Moreover, in our tests, the two-tiles implementation of the left-looking algorithm is the fastest variant, when tile size is fixed. It is the equivalent in complex arithmetic of the (sequential) POOCLAPACK routine for the Cholesky decomposition of real positive definite matrices [15]. Some improvements could still be added to this solver, such as prefetching the tiles, to overlap I/O operations and computation, as is performed in [22].

OPTIMAL SCALING OF GENERALIZED AND POLYNOMIAL EIGENVALUE PROBLEMS*

T. BETCKE†

Abstract. Scaling is a commonly used technique for standard eigenvalue problems to improve the sensitivity of the eigenvalues. In this paper we investigate scaling for generalized and polynomial eigenvalue problems (PEPs) of arbitrary degree. It is shown that an optimal diagonal scaling of a PEP with respect to an eigenvalue can be described by the ratio of its normwise and componentwise condition number. Furthermore, the effect of linearization on optimally scaled polynomials is investigated. We introduce a generalization of the diagonal scaling by Lemonnier and Van Dooren to PEPs that is especially effective if some information about the magnitude of the wanted eigenvalues is available and also discuss variable transformations of the type $\lambda = \alpha\mu$ for PEPs of arbitrary degree.

Key words. polynomial eigenvalue problem, balancing, scaling, condition number, backward error

AMS subject classifications. 65F15, 15A18

DOI. 10.1137/070704769

1. Introduction.

Scaling of standard eigenvalue problems $Ax = \lambda x$ is a well-established technique that is implemented in the LAPACK routine `xGEBAL`. It goes back to work by Osborne [14] and Parlett and Reinsch [15]. The idea is to find a diagonal matrix D that scales the rows and columns of $A \in \mathbb{C}^{n\times n}$ in a given norm such that

$$\|D^{-1}ADe_i\| = \|e_i^*D^{-1}AD\|, \quad i = 1, \ldots, n,$$

where e_i is the ith unit vector. This is known as balancing. LAPACK uses the 1-norm. Balancing matrix rows and columns can often reduce the effect of rounding errors on the computed eigenvalues. However, as Watkins demonstrated [19], there are also cases in which balancing can lead to a catastrophic increase of the errors in the computed eigenvalues.

For generalized eigenvalue problems (GEPs) $Ax = \lambda Bx$, a scaling technique proposed by Ward [18] is implemented in the LAPACK routine `xGGBAL`. Its aim is to find diagonal matrices D_1 and D_2 such that the elements of D_1AD_2 and D_1BD_2 are scaled as equal in magnitude as possible.

A different approach for the scaling of GEPs is proposed by Lemonnier and Van Dooren [11]. In section 5 we will come back to this. It is interesting to note that the default behavior of LAPACK (and also of MATLAB) is to scale nonsymmetric standard eigenvalue problems but not to scale GEPs.

In this paper we discuss the scaling of polynomial eigenvalue problems (PEPs) of the form

$$P(\lambda)x := (\lambda^\ell A_\ell + \cdots + \lambda A_1 + A_0)x = 0, \quad A_k \in \mathbb{C}^{n\times n},\ A_\ell \neq 0,\ \ell \geq 1. \tag{1.1}$$

Every $\lambda \in \mathbb{C}$ for which there exists a solution $x \in \mathbb{C}^n\backslash\{0\}$ of $P(\lambda)x = 0$ is called an

eigenvalue of P with associated right eigenvector x. We will also need left eigenvectors $y \in \mathbb{C}^n \backslash \{0\}$ defined by $y^* P(\lambda) = 0$.

In section 2 we review the definition of condition numbers and backward errors for the PEP (1.1). Then in section 3 we investigate diagonal scalings of (1.1) of the form $D_1 P(\lambda) D_2$, where D_1 and D_2 are diagonal matrices in the set

$$\mathcal{D}_n := \{D : \ D \in \mathbb{C}^{n \times n} \text{ is diagonal and } \det(D) \neq 0\}.$$

We show that the minimal achievable normwise condition number of an eigenvalue by diagonal scaling of $P(\lambda)$ can be bounded by its componentwise condition number. This gives easily computable conditions on whether the condition number of eigenvalues can be improved by scaling. The results of that section can be applied to generalized linear and higher degree polynomial problems.

The most widely used technique to solve PEPs of degree $\ell \geq 2$ is to convert the associated matrix polynomial into a linear pencil, the process of linearization, and then solve the corresponding GEP. In section 4 we investigate the difference between scaling before or after linearizing the matrix polynomial. Then in section 5 we introduce a heuristic scaling strategy for PEPs that generalizes the idea of Lemonnier and Van Dooren. It is applicable to arbitrary polynomials of degree $\ell \geq 1$ and includes a weighting factor that, given some information about the magnitude of the wanted eigenvalues, can crucially improve the normwise condition numbers of eigenvalues after scaling.

Fan, Lin and Van Dooren [3] propose a transformation of variables of the form $\lambda = \alpha\mu$ for some parameter α for quadratic polynomials whose aim is to improve the backward stability of numerical methods for quadratic eigenvalue problems (QEPs) that are based on linearization. In section 6 we extend this variable transformation to matrix polynomials of arbitrary degree $\ell \geq 2$.

Numerical examples illustrating our scaling algorithms are presented in section 7. We conclude with practical remarks on how to put the results of this paper into practice.

Scaling routines for standard and generalized eigenvalue problems often include a preprocessing step that attempts to remove isolated eigenvalues by permutation of the matrices. This is, for example, implemented in the LAPACK routines `xGBAL` and `xGGBAL`. Since the permutation algorithm described in [18] can be easily adapted for matrix polynomials, we will not discuss this further in this paper. But nevertheless, it is advisable to use this preprocessing step also for PEPs to reduce the problem dimension if possible.

All notation is standard. For a matrix A, we denote by $|A|$ the matrix of absolute values of the entries of A. Similarly, $|x|$ for a vector x denotes the absolute values of the entries of x. The vector of all ones is denoted by e; that is, $e = \begin{bmatrix} 1, 1, \ldots, 1 \end{bmatrix}^T \in \mathbb{R}^n$.

2. Normwise and componentwise error bounds. An important tool to measure the quality of an approximate eigenpair $(\tilde{x}, \tilde{\lambda})$ of the PEP $P(\lambda)x = 0$ is its normwise backward error. With $\Delta P(\lambda) = \sum_{k=0}^{\ell} \lambda^k \Delta A_k$ it is defined for the 2-norm by

$$\eta_P\left(\tilde{x}, \tilde{\lambda}\right) := \min\left\{\epsilon : \ \left(P\left(\tilde{\lambda}\right) + \Delta P\left(\tilde{\lambda}\right)\right)\tilde{x} = 0, \ \|\Delta A_k\|_2 \leq \epsilon \|A_k\|_2, \ k = 0 : \ell\right\}.$$

Tisseur [17] shows that

$$\eta_P\left(\tilde{x}, \tilde{\lambda}\right) = \frac{\|r\|_2}{\tilde{\alpha}\|\tilde{x}\|_2},$$

where $r = P(\tilde{\lambda})\tilde{x}$ and $\tilde{\alpha} = \sum_{k=0}^{\ell} |\tilde{\lambda}|^k \|A_k\|_2$. The normwise backward error $\eta(\tilde{\lambda})$ of a computed eigenvalue $\tilde{\lambda}$ is defined as

$$\eta_P\left(\tilde{\lambda}\right) = \min_{\substack{x \in \mathbb{C}^n \\ x \neq 0}} \eta_P\left(x, \tilde{\lambda}\right).$$

It follows immediately [17, Lemma 3] that $\eta_P(\tilde{\lambda}) = (\tilde{\alpha}\|P(\tilde{\lambda})^{-1}\|_2)^{-1}$.

The sensitivity of an eigenvalue is measured by the condition number. It relates the forward error, that is, the error in the computed eigenvalue $\tilde{\lambda}$, and the backward error $\eta_P(\tilde{\lambda})$. To first order (meaning up to higher terms in the backward error) one has

$$\text{forward error} \leq \text{backward error} \times \text{condition number}. \tag{2.1}$$

The condition number of a simple, finite, nonzero eigenvalue $\lambda \neq 0$ is defined by

$$\kappa_P(\lambda) := \lim_{\epsilon \to 0} \sup \left\{ \frac{|\Delta\lambda|}{\epsilon|\lambda|} \ : \ \big(P(\lambda+\Delta\lambda) + \Delta P(\lambda+\Delta\lambda)\big)(x+\Delta x) = 0, \right.$$
$$\left. \|\Delta A_k\|_2 \leq \epsilon \|A_k\|_2, \ k = 0:\ell \right\}.$$

Let x be a right eigenvector and y be a left eigenvector associated with the eigenvalue λ of P. Then $\kappa_P(\lambda)$ is given by [17, Theorem 5]

$$\kappa_P(\lambda) = \frac{\|y\|_2 \|x\|_2 \alpha}{|y^* P'(\lambda) x||\lambda|}, \quad \alpha = \sum_{k=0}^{\ell} |\lambda|^k \|A_k\|_2. \tag{2.2}$$

Backward error and condition number can also be defined in a componentwise sense. The componentwise backward error of an eigenpair $(\tilde{x}, \tilde{\lambda})$ is

$$\omega_P\left(\tilde{x}, \tilde{\lambda}\right) := \min\left\{\epsilon : \ \left(P\left(\tilde{\lambda}\right) + \Delta P\left(\tilde{\lambda}\right)\right)\tilde{x} = 0; |\Delta A_k| \leq \epsilon |A_k|, \ k = 0:\ell\right\}. \tag{2.3}$$

The componentwise condition number of a simple, finite, nonzero eigenvalue λ is defined as

$$\operatorname{cond}_P(\lambda) := \lim_{\epsilon \to 0} \sup \left\{ \frac{|\Delta\lambda|}{\epsilon|\lambda|} \ : \ \big(P(\lambda+\Delta\lambda) + \Delta P(\lambda+\Delta\lambda)\big)(x+\Delta x) = 0, \right.$$
$$\left. |\Delta A_k| \leq \epsilon |A_k|, \ k = 0:\ell \right\}. \tag{2.4}$$

The following theorem gives explicit expressions for these quantitites.

THEOREM 2.1. [illegible] $(\tilde{x}, \tilde{\lambda})$ [illegible]

$$\omega_P(\tilde{x}, \tilde{\lambda}) = \max_i \frac{|r_i|}{\left(\widetilde{A}|\tilde{x}|\right)_i}, \quad \widetilde{A} := \sum_{k=0}^{\ell} |\tilde{\lambda}|^k |A_k|, \tag{2.5}$$

r_i ith $P(\tilde{\lambda})\tilde{x}$ λ y x

$$\text{cond}_P(\lambda) = \frac{|y|^*A|x|}{|\lambda||y^*P'(\lambda)x|}, \quad A := \sum_{k=0}^{\ell} |\lambda|^k |A_k|. \tag{2.6}$$

. The proof is a slight modification of the proofs of [5, Theorems 3.1 and 3.2] along the lines of the proof of [17, Theorem 1]. ∎

Surveys of componentwise error analysis are contained in [8, 9]. The componentwise backward error and componentwise condition number are invariant under multiplication of $P(\lambda)$ from the left and the right with nonsingular diagonal matrices. In the next section we will use this property to characterize optimally scaled eigenvalue problems.

3. Optimal scalings. In this section we introduce the notion of an optimal scaling with respect to a certain eigenvalue and give characterizations of it.

Ultimately, we are interested in computing eigenvalues to as many digits as possible. Hence, we would like to find a scaling that leads to small forward errors. If we assume that we use a backward stable algorithm, that is, the backward error is only a small multiple of the machine precision, then it follows from (2.1) that we can hope to compute an eigenvalue to many digits of accuracy by finding a scaling that minimizes the condition number.

In the following we define what we mean by a scaling of a matrix polynomial $P(\lambda)$.

DEFINITION 3.1. $P(\lambda) \in \mathbb{C}^{n\times n}$ $P(\lambda)$ $D_1P(\lambda)D_2$ $D_1, D_2 \in \mathcal{D}_n$

It is immediately clear that the eigenvalues of a matrix polynomial $P(\lambda)$ are invariant under scaling. Furthermore, if (y, x, λ) is an eigentriplet of $P(\lambda)$ with eigenvalue λ and left and right eigenvector y and x, respectively, then an eigentriplet of the scaling $D_1P(\lambda)D_2$ is $(D_1^{-*}y, D_2^{-1}x, \lambda)$.

The following definition defines an optimal scaling of $P(\lambda)$ with respect to a given eigenvalue λ in terms of minimizing the condition number of λ.

DEFINITION 3.2. λ $P(\lambda)$ $P(\lambda)$ λ

$$\kappa_P(\lambda) = \inf_{D_1, D_2 \in \mathcal{D}_n} \kappa_{D_1PD_2}(\lambda).$$

This definition of optimal scaling depends on the eigenvalue λ. We cannot expect that an optimal scaling for one eigenvalue also gives an optimal scaling for another eigenvalue. The following theorem states that a PEP is almost optimally scaled with respect to an eigenvalue λ, if the componentwise and normwise condition numbers of λ are close to each other. Furthermore, it gives explicit expressions for scaling matrices $D_1, D_2 \in \mathcal{D}_n$ that achieve an almost optimal scaling.

THEOREM 3.3. λ $n \times n$ $P(\lambda)$ y x

$$\frac{1}{\sqrt{n}}\,\text{cond}_P(\lambda) \le \inf_{D_1, D_2 \in \mathcal{D}_n} \kappa_{D_1PD_2}(\lambda) \le n\,\text{cond}_P(\lambda). \tag{3.1}$$

y x

$$D_1 = \text{diag}(|y|), \quad D_2 = \text{diag}(|x|),$$

$$\kappa_{D_1PD_2}(\lambda) \leq n \operatorname{cond}_P(\lambda). \tag{3.2}$$

. Let $A := \sum_{k=0}^{\ell} |\lambda|^k |A_k|$ and $\alpha := \sum_{k=0}^{\ell} |\lambda|^k \|A_k\|_2$. Using $\||B|\|_2 \leq \sqrt{n}\|B\|_2$ [9, Lemma 6.6] for any matrix $B \in \mathbb{C}^{n\times n}$, the lower bound follows from

$$\operatorname{cond}_P(\lambda) = \frac{|y|^*A|x|}{|\lambda||y^*P'(\lambda)x|} \leq \frac{\|y\|_2\|x\|_2\|A\|_2}{|\lambda||y^*P'(\lambda)x|} \leq \frac{\sqrt{n}\alpha\|y\|_2\|x\|_2}{|\lambda||y^*P'(\lambda)x|} = \sqrt{n}\kappa_P(\lambda),$$

and the fact that the componentwise condition number is invariant under diagonal scaling. For $\epsilon > 0$ define the vectors $\tilde{y}$ and $\tilde{x}$ by

$$\tilde{y}_i = \begin{cases} y_i, & y_i \neq 0 \\ \epsilon, & y_i = 0 \end{cases} \qquad \tilde{x}_i = \begin{cases} x_i, & x_i \neq 0 \\ \epsilon, & x_i = 0 \end{cases}$$

and consider the diagonal matrices

$$D_1 = \operatorname{diag}(|\tilde{y}|), \quad D_2 = \operatorname{diag}(|\tilde{x}|).$$

Using $\|B\|_2 \leq e^*|B|e$ for any matrix $B \in \mathbb{C}^{n\times n}$ [9, Table 6.2], we have

$$\kappa_{D_1PD_2}(\lambda) = \frac{\|D_1^{-1}y\|_2\|D_2^{-1}x\|_2 \left(\sum_{k=0}^{\ell} |\lambda|^k \|D_1A_kD_2\|_2\right)}{|\lambda||y^*P'(\lambda)x|} \leq \frac{n\left(\sum_{k=0}^{\ell} |\lambda|^k e^*|D_1A_kD_2|e\right)}{|\lambda||y^*P'(\lambda)x|}$$

$$= \frac{n\left(\sum_{k=0}^{\ell} |\lambda|^k \cdot |\tilde{y}|^* \cdot |A_k| \cdot |\tilde{x}|\right)}{|\lambda||y^*P'(\lambda)x|} \longrightarrow n \operatorname{cond}_P(\lambda) \text{ as } \epsilon \to 0. \tag{3.3}$$

The upper bounds in (3.1) and (3.2) follow immediately. ∎

Theorem 3.3 is restricted to finite and nonzero eigenvalues. Assume that $\lambda = 0$ is an eigenvalue. Then we have to replace relative componentwise and normwise condition numbers by the absolute condition numbers

$$\kappa_P^{(a)}(\lambda) = \frac{\|y\|_2\|x\|_2\alpha}{|y^*P'(\lambda)x|}, \quad \operatorname{cond}_P^{(a)}(\lambda) = \frac{|y|^*A|x|}{|y^*P'(\lambda)x|}.$$

With these condition numbers Theorem 3.3 is also valid for zero eigenvalues. If $P(\lambda)$ has an infinite eigenvalue, the reversal $\operatorname{rev} P(\lambda) := \lambda^\ell P(1/\lambda)$ has a zero eigenvalue, and we can apply Theorem 3.3 using absolute condition numbers to $\operatorname{rev} P(\lambda)$.

While Theorem 3.3 applies to generalized linear and polynomial problems, it does not immediately apply to standard problems of the form $Ax = \lambda x$. The crucial difference is that for standard eigenvalue problems we assume the right-hand side identity matrix to be fixed and only allow scalings of the form $D^{-1}AD$ that leave the identity unchanged. However, if λ is an eigenvalue of A with associated left and right eigenvectors y and x that have nonzero entries, we can still define $D_1 = \operatorname{diag}(|y|)$ and $D_2 = \operatorname{diag}(|x|)$ to obtain the generalized eigenvalue problem

$$D_1AD_2v = \lambda D_1D_2v, \tag{3.4}$$

where $x = D_2v$. Since D_1D_2 has positive diagonal entries there exists $\hat{D}$ such that $\hat{D}^2 = D_1D_2$. We then obtain from (3.4) the standard eigenvalue problem

$$\hat{D}^{-1}D_1AD_2\hat{D}^{-1}\tilde{x} = \lambda\tilde{x}, \tag{3.5}$$

where $\tilde{x} = \hat{D}D_2^{-1}x$ and $|\tilde{x}| = \left[\sqrt{|y_1||x_1|}, \ldots, \sqrt{|y_n||x_n|}\right]^T$. For the scaled left eigenvector $\tilde{y}$ we have $\tilde{y} = \hat{D}D_1^{-1}y$ and $|\tilde{y}| = |\tilde{x}|$. If we define the normwise condition number $k_A(\lambda)$ and the componentwise condition number $c_A(\lambda)$ for the eigenvalue λ of a standard eigenvalue problem by[1]

$$k_A(\lambda) = \frac{\|y\|_2\|x\|_2}{|\lambda||y^Tx|}, \quad c_A(\lambda) = \frac{|y|^T|x|}{|\lambda||y^Tx|},$$

it follows for the scaling $D^{-1}AD$, where $D = D_2\hat{D}^{-1} = D_1^{-1}\hat{D}$ that

$$c_A(\lambda) = k_{D^{-1}AD}(\lambda).$$

But this scaling is not always useful as $\|D^{-1}AD\|_2$ can become large if x or y contain tiny entries.

There is a special case in which the scaling (3.5) also minimizes $\|D^{-1}AD\|_2$. If λ is the Perron root of an irreducible and nonnegative matrix A, the corresponding left and right eigenvectors y and x can be chosen to have positive entries. After scaling by D as described above, we have $k_{D^{-1}AD}(\lambda) = 1$ and $\|D^{-1}AD\|_2 = \lambda$. This was investigated by Chen and Demmel in [2] who proposed a weighted balancing which is identical to the scaling described above for nonnegative and irreducible A.

Theorem 3.3 gives us an easy way to check whether a matrix polynomial P is nearly optimally scaled with respect to an eigenvalue λ. We only need to compute the ratio

$$\frac{\kappa_P(\lambda)}{\operatorname{cond}_P(\lambda)} = \frac{\|y\|_2\|x\|_2 \sum_{k=0}^{\ell} |\lambda|^k \|A_k\|_2}{|y|^* \left(\sum_{k=0}^{\ell} |\lambda|^k |A_k|\right) |x|} \tag{3.6}$$

after computing the eigenvalues and eigenvectors. If an eigensolver already returns normwise condition numbers, this is only a little extra effort. If $\frac{\kappa_P(\lambda)}{\operatorname{cond}_P(\lambda)} \gg n$ the eigensolver can give a warning to the user that the problem is badly scaled and that the error in the computed eigenvalue λ is likely to become smaller by rescaling P. Furthermore, from Theorem 3.3 it follows that a polynomial is nearly optimally scaled if the entries of the left and right eigenvectors have equal magnitude. This motivates a heuristic scaling algorithm, which is discussed in section 5.

At the end we would like to emphasize that a diagonal scaling which improves the condition numbers of the eigenvalues needs not necessarily be a good scaling for eigenvectors. An example is the generalized linear eigenvalue problem $L(\lambda)x = 0$, where

$$L(\lambda) = \lambda \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{bmatrix} + \begin{bmatrix} 0 & 1 + 2 \cdot 10^{-8} & 2 \\ 2 & 10^{-8} & 1 \\ 1 & 1 + 10^{-8} & -1 \end{bmatrix}.$$

One eigenvalue is $\lambda = 1$ with associated right eigenvector $x = \begin{bmatrix} 1 & -1 & 10^{-8} \end{bmatrix}^T$ and left eigenvector $y = \begin{bmatrix} \frac{1}{3} & \frac{1}{3} & -1 \end{bmatrix}^T$. The condition number[2] of the eigenvector x before scaling is approximately 33.1. After scaling with $D_1 = \operatorname{diag}(|y|)$ and $D_2 = \operatorname{diag}(|x|)$, it increases to $1.70 \cdot 10^9$. For the corresponding eigenvalue $\lambda = 1$ we have $\kappa_L(1) \approx 21.8$ and after scaling $\kappa_{D_1LD_2}(1) \approx 19.6$. However, in most of our experiments we could not observe an increase of the eigenvector condition number after scaling.

[1] Choose $E = I$, $F = 0$, and $B = I$ in Theorems 2.5 and 3.2 of [5].

[2] The condition number of the eigenvector was computed using Theorem 2.7 from [5] with the normalization vector $g = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}^T$.

4. Scalings and linearizations. The standard way to solve the PEP (1.1) of degree $\ell \geq 2$ is to convert $P(\lambda)$ into a linear pencil

$$L(\lambda) = \lambda X + Y$$

having the same spectrum as $P(\lambda)$ and then solve the eigenproblem for L. Formally, $L(\lambda)$ is a linearization if

$$E(\lambda)L(\lambda)F(\lambda) = \begin{bmatrix} P(\lambda) & 0 \\ 0 & I_{(\ell-1)n} \end{bmatrix}$$

for some unimodular $E(\lambda)$ and $F(\lambda)$ [4, section 7.2]. For example,

$$C_1(\lambda) = \lambda \begin{bmatrix} A_\ell & 0 & \cdots & 0 \\ 0 & I_n & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & I_n \end{bmatrix} + \begin{bmatrix} A_{\ell-1} & A_{\ell-2} & \cdots & A_0 \\ -I_n & 0 & \cdots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ 0 & \cdots & -I_n & 0 \end{bmatrix} \tag{4.1}$$

is a linearization of $P(\lambda)$, called the first companion form. In [12] Mackey, Mackey, Mehl, and Mehrmann identified two vector spaces of pencils that are potential linearizations of $P(\lambda)$. Let $\Lambda := [\lambda^{\ell-1}, \lambda^{\ell-2}, \ldots, 1]^T$. Then these spaces are defined by

$$\begin{aligned} \mathbb{L}_1(P) &= \left\{ L(\lambda) : L(\lambda)(\Lambda \otimes I_n) = v \otimes P(\lambda),\ v \in \mathbb{C}^\ell \right\}, \\ \mathbb{L}_2(P) &= \left\{ L(\lambda) : (\Lambda^T \otimes I_n)L(\lambda) = \tilde{v}^T \otimes P(\lambda),\ \tilde{v} \in \mathbb{C}^\ell \right\}. \end{aligned}$$

The first companion linearization belongs to $\mathbb{L}_1(P)$ with $v = e_1$. Furthermore, the pencils in $\mathbb{L}_1(P)$ and $\mathbb{L}_2(P)$ that are not linearizations form a closed nowhere dense subset of measure zero in these spaces [12, Theorem 4.7].

Another important space of potential linearizations is given by

$$\mathbb{DL}(P) := \mathbb{L}_1(P) \cap \mathbb{L}_2(P).$$

In [12, Theorem 5.3] it is shown that each pencil $L(\lambda) \in \mathbb{DL}(P)$ is uniquely defined by a vector $v \in \mathbb{C}^\ell$ such that

$$L(\lambda)(\Lambda \otimes I_n) = v \otimes P(\lambda), \quad \left(\Lambda^T \otimes I_n\right) L(\lambda) = v^T \otimes P(\lambda).$$

There is a well-defined relationship between the eigenvectors of linearizations $L(\lambda) \in \mathbb{DL}(P)$ and eigenvectors of $P(\lambda)$; namely, for finite eigenvalues λ x is a right eigenvector of $P(\lambda)$ if and only if $\Lambda \otimes x$ is a right eigenvector of $L(\lambda)$ and y is a left eigenvector of $P(\lambda)$ if and only if $\overline{\Lambda} \otimes y$ is a left eigenvector of $L(\lambda)$ [12, Theorems 3.8 and 3.14].

A simple observation is that scaling $P(\lambda)$ leads to a scaling of $L(\lambda)$ within the same space of potential linearizations.

LEMMA 4.1. *If $L(\lambda) \in \mathbb{S}(P)$ for some v, then $\mathbb{S}(P) = \mathbb{L}_1(P)$, $\mathbb{L}_2(P)$, $\mathbb{DL}(P)$ and $(I_n \otimes D_1)L(\lambda)(I_n \otimes D_2) \in \mathbb{S}(D_1 P D_2)$ for some v, $D_1, D_2 \in \mathbb{C}^{n \times n}$.*

Proof. The statements follow immediately from the identities

$$(I \otimes D_1)L(\lambda)(I \otimes D_2)(\Lambda \otimes I_n) = v \otimes D_1 P(\lambda) D_2$$

and

$$\left(\Lambda^T \otimes I_n\right)(I \otimes D_1)L(\lambda)(I \otimes D_2) = \tilde{v}^T \otimes D_1 P(\lambda) D_2$$

for matrices $D_1, D_2 \in \mathbb{C}^{n\times n}$. ∎

Hence, if we solve a PEP by a linearization in $\mathbb{L}_1(P)$, $\mathbb{L}_2(P)$, or $\mathbb{DL}(P)$, scaling of the original polynomial $P(\lambda)$ with matrices D_1 and D_2 is just a special scaling of the linearization $L(\lambda)$ with scaling matrices $(I \otimes D_1)$ and $(I \otimes D_2)$. If preserving structure of the linearization is not an issue, we can scale the linearization $L(\lambda)$ directly with diagonal scaling matrices $\widetilde{D}_1$ and $\widetilde{D}_2$ that have $2\ell n$ free parameters compared to the $2n$ free parameters in D_1 and D_2. The following theorem gives a worst case bound on the ratio between the optimal condition numbers with the two different scaling strategies (i.e., scaling and then linearizing or linearizing and then scaling).

THEOREM 4.2. [illegible] P [illegible] $L(\lambda) \in \mathbb{DL}(P)$ [illegible] v [illegible]

$$\inf_{D_1, D_2 \in \mathcal{D}_n} \kappa_{\widetilde{L}}(\lambda; v; D_1 P D_2) \le \begin{cases} \ell^{1/2} n^{3/2} \left(\frac{|\lambda|^{2\ell}-1}{|\lambda|^2-1}\right) \inf\limits_{\tilde{D}_1, \tilde{D}_2 \in \mathcal{D}_{\ell n}} \kappa_{\tilde{D}_1 L \tilde{D}_2}(\lambda) & \text{if } |\lambda| \ge 1, \\ \frac{\ell^{1/2} n^{3/2}}{|\lambda|^{2(\ell-1)}} \left(\frac{|\lambda|^{2\ell}-1}{|\lambda|^2-1}\right) \inf\limits_{\tilde{D}_1, \tilde{D}_2 \in \mathcal{D}_{\ell n}} \kappa_{\tilde{D}_1 L \tilde{D}_2}(\lambda) & \text{if } |\lambda| < 1, \end{cases}$$

[illegible] $\kappa_{\widetilde{L}}(\lambda; v; D_1 P D_2)$ [illegible] λ [illegible] $\widetilde{L}(\lambda) \in \mathbb{DL}(D_1 P D_2)$ [illegible] v

[illegible]. Let y and x be left and right eigenvectors of $P(\lambda)$ associated with the eigenvalue λ. Since $L(\lambda) = \lambda X + Y \in \mathbb{DL}(P)$, its left and right eigenvectors associated with λ are $\overline{\Lambda} \otimes y$ and $\Lambda \otimes x$. Assume that y and x have no zero entries. The case of zero entries follows by a limit process similar to that in the proof of Theorem 3.3. Define $D_1 = \operatorname{diag}(|y|)$ and $D_2 = \operatorname{diag}(|x|)$. Since $\|\overline{\Lambda} \otimes (D_1^{-1} y)\|_2 = \|\Lambda\|_2 \|D_1^{-1} y\|_2$ and $\|\Lambda \otimes (D_2^{-1} x)\|_2 = \|\Lambda\|_2 \|D_2^{-1} x\|_2$, we have

$$\begin{aligned} &\kappa_{\widetilde{L}}(\lambda; v; D_1 P D_2) \\ &= \frac{\|\Lambda\|_2^2 \|D_1^{-1} y\|_2 \|D_2^{-1} x\|_2 (|\lambda| \|(I \otimes D_1) X (I \otimes D_2)\|_2 + \|(I \otimes D_1) Y (I \otimes D_2)\|_2)}{|\lambda| \left|\left(\overline{\Lambda} \otimes y\right)^* X (\Lambda \otimes x)\right|}, \end{aligned}$$

and therefore by using $\|B\|_2 \le e^* |B| e$ for any $B \in \mathbb{C}^{n\times n}$

$$\kappa_{\widetilde{L}}(\lambda; v; D_1 P D_2) \le \frac{\|\Lambda\|_2^2 n \hat{e}^* (|\lambda| |(I \otimes D_1) X (I \otimes D_2)| + |(I \otimes D_1) Y (I \otimes D_2)|) \hat{e}}{|\lambda| \left|\left(\overline{\Lambda} \otimes y\right)^* X (\Lambda \otimes x)\right|}$$

for $\hat{e} = \begin{bmatrix} 1 & \dots & 1 \end{bmatrix}^T \in \mathbb{R}^{\ell n}$. Assume that $|\lambda| \ge 1$. Since componentwise $\hat{e} \le |\Lambda| \otimes e = |\overline{\Lambda}| \otimes e$ and

$$\left(|\overline{\Lambda}| \otimes e\right)^* (I \otimes D_1) = |\overline{\Lambda} \otimes y|^*, \quad (I \otimes D_2)(|\Lambda| \otimes e) = |\Lambda \otimes x|,$$

we obtain

$$\kappa_{\widetilde{L}}(\lambda; v; D_1 P D_2) \le n \frac{\|\Lambda\|_2^2 |\overline{\Lambda} \otimes y|^* (|\lambda| |X| + |Y|) |\Lambda \otimes x|}{|\lambda| \left|\left(\overline{\Lambda} \otimes y\right)^* X (\Lambda \otimes x)\right|} = n \|\Lambda\|_2^2 \operatorname{cond}_L(\lambda). \tag{4.2}$$

It holds that

$$\|\Lambda\|_2^2 = \left(\frac{|\lambda|^{2\ell} - 1}{|\lambda|^2 - 1}\right). \tag{4.3}$$

Furthermore, from Theorem 3.3 we know that

$$\frac{1}{\sqrt{\ell n}}\mathrm{cond}_L(\lambda) \leq \inf_{\tilde{D}_1,\tilde{D}_2\in\mathcal{D}_{\ell n}} \kappa_{\tilde{D}_1 L \tilde{D}_2}(\lambda). \tag{4.4}$$

Combining (4.2), (4.3), and (4.4), the proof for the case $|\lambda| \geq 1$ follows. The proof for $|\lambda| < 1$ is similar. The only essential difference is that now componentwise $\hat{e} \leq \frac{|\Lambda|}{|\lambda|^{\ell-1}} \otimes e$. ∎

Theorem 4.2 suggests that for eigenvalues that are large or small in magnitude first linearizing and then scaling can in the worst case be significantly better than first scaling and then linearizing. However, if we first linearize and then scale, the special structure of the linearization is lost.

How sharp are these bounds? In the following we discuss the case $|\lambda| \geq 1$. For the case $|\lambda| < 1$ analogous arguments can be used. Consider the QEP $Q(\lambda) = \lambda^2 A + \lambda B + C$, where

$$A = \begin{bmatrix} -0.6 & -0.1 \\ 2 & 0.1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & -0.1 \\ 0.6 & -0.8 \end{bmatrix}, \quad C = \begin{bmatrix} 3\cdot 10^7 & 7\cdot 10^7 \\ -1\cdot 10^8 & 1.6\cdot 10^8 \end{bmatrix}, \tag{4.5}$$

and its linearization in $\mathbb{DL}(Q)$

$$L(\lambda) = \lambda X + Y := \lambda \begin{bmatrix} A & 0 \\ 0 & -C \end{bmatrix} + \begin{bmatrix} B & C \\ C & 0 \end{bmatrix},$$

which corresponds to the vector $v = \begin{bmatrix} 1 & 0 \end{bmatrix}^T$. One eigenvalue of this pencil is $\lambda \approx 4.105\cdot 10^4$. If we first scale Q using the left and right eigenvectors associated with λ and then linearize, this eigenvalue has the condition number $1.2\cdot 10^9$ for the linearization. If we first linearize the QEP and then scale the pencil $L(\lambda)$ using the left and right eigenvectors of λ for the linearization, this eigenvalue has the condition number 5.2. The ratio between the condition numbers is in magnitude what we would expect from applying Theorem 4.2.

However, Theorem 4.2 can be a large overestimate. Assume that $P(\lambda)$ is already almost optimally scaled in the sense of Theorem 3.3, that is, $|y| = |x| = e$ for the left and right eigenvectors y and x associated with the simple finite eigenvalue λ of P. Let $L(\lambda) = \lambda X + Y$ be a linearization of P and let D_1 and D_2 be scaling matrices for L such that $|D_1^{-*}\tilde{y}| = |D_2^{-1}\tilde{x}| = e$ for the left and right eigenvectors $\tilde{y}$ and $\tilde{x}$ of L associated with the eigenvalue λ. The ratio of the condition numbers of the eigenvalue λ for the two pencils L and $D_1 L D_2$ is given by

$$\frac{\kappa_L(\lambda)}{\kappa_{D_1 L D_2}(\lambda)} = \frac{\|\tilde{x}\|_2\|\tilde{y}\|_2}{\|D_1^{-*}\tilde{y}\|_2\|D_2^{-1}\tilde{x}\|_2} \frac{|\lambda|\|X\|_2 + \|Y\|_2}{|\lambda|\|D_1 X D_2\|_2 + \|D_1 Y D_2\|_2}. \tag{4.6}$$

If $L(\lambda) \in \mathbb{DL}(P)$ (4.6) simplifies to

$$\frac{\kappa_L(\lambda)}{\kappa_{D_1 L D_2}(\lambda)} = \frac{1}{\ell}\left(\frac{|\lambda|^{2\ell}-1}{|\lambda|^2-1}\right) \frac{|\lambda|\|X\|_2 + \|Y\|_2}{|\lambda|\|D_1 X D_2\|_2 + \|D_1 Y D_2\|_2}$$

since $|\tilde{x}| = |\tilde{y}| = |\Lambda \otimes e|$. This shows that for $|\lambda| > 1$ the upper bound in Theorem 4.2 can be attained only if

$$\frac{|\lambda|\|X\|_2 + \|Y\|_2}{|\lambda|\|D_1 X D_2\|_2 + \|D_1 Y D_2\|_2} =: \tau(\lambda) \tag{4.7}$$

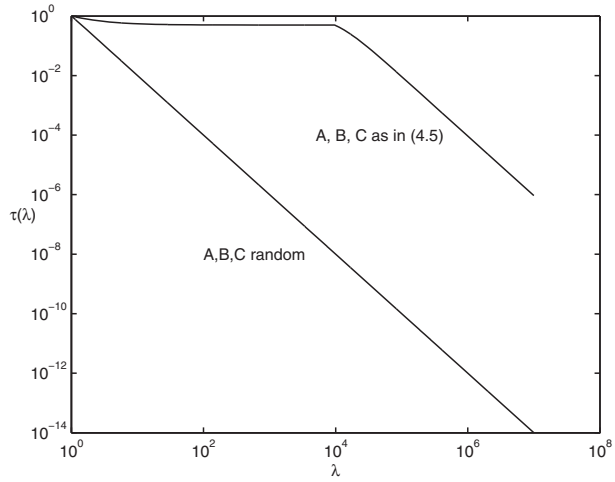

FIG. 4.1. *The function $\tau(\lambda)$ for a large range of values in the case of a random 2×2 QEP and the QEP from* (4.5).

is approximately constant in the range of the eigenvalues in which we are interested. For $L(\lambda) \in \mathbb{DL}(P)$ the matrices D_1 and D_2 are given as

$$D_1 = D_2 = \begin{bmatrix} |\lambda|^{\ell-1} I & & \\ & \ddots & \\ & & I \end{bmatrix} = \operatorname{diag}(|\Lambda|) \otimes I.$$

It follows that for $|\lambda|$ large enough

$$\tau(\lambda) \sim \gamma |\lambda|^{2-2\ell} \tag{4.8}$$

for some constant $\gamma > 0$ and therefore

$$\frac{\kappa_L(\lambda)}{\kappa_{D_1 L D_2}(\lambda)} \sim \frac{\gamma}{\ell}$$

in that case.

In particular, if the upper left $n \times n$ block of X is in norm comparable or larger than the other $n \times n$ subblocks of X, we expect a good agreement of the asymptotic in (4.8) for all $|\lambda| > 1$, where γ is not much larger than 1. Only if the $n \times n$ subblocks of X and Y are of widely varying norm it is possible that $\tau(\lambda)$ is approximately constant for a large range of values of λ, leading to the worst case bound in (4.2) being attained.

The situation is demonstrated in Figure 4.1. For a random 2×2 QEP $\tau(\lambda)$ decays like $\gamma |\lambda|^{-2}$, where $\gamma \approx 1$. For the QEP from (4.5) the function $\tau(\lambda)$ is almost constant for a long time, leading to the worst case bound of Theorem 4.2 being attained in these range of values. Then at about 10^4 it starts decaying like $\gamma |\lambda|^{-2}$, where this time γ is in the order of 10^8.

One of the most frequently used linearizations for unstructured problems is the companion form (4.1). Unfortunately, we cannot immediately apply the previous results to it since the companion form is not in $\mathbb{DL}(P)$ but only in $\mathbb{L}_1(P)$. However, we can still compare the ratio in (4.6). Consider the QEP $Q(\lambda) = \lambda^2 A + \lambda B + C$.

The companion linearization takes the form

$$C_1(\lambda) = \lambda \begin{bmatrix} A & \\ & I \end{bmatrix} + \begin{bmatrix} B & C \\ -I & 0 \end{bmatrix}.$$

We assume that for the left and right eigenvectors y and x associated with the eigenvalue λ of Q we have $|y| = |x| = e$. Furthermore, let D_1 and D_2 again be chosen such that $|D_1^{-*}\tilde{y}| = |D_2^{-1}\tilde{x}| = e$, where $\tilde{y}$ and $\tilde{x}$ are the corresponding left and right eigenvectors for the eigenvalue λ of the companion linearization $C_1(\lambda) = \lambda X + Y$. The relationship between the eigenvectors of C_1 and the eigenvectors of P associated with a finite nonzero eigenvalue λ is given by

$$\tilde{x} = \Lambda \otimes x, \quad \tilde{y} = \begin{bmatrix} y \\ -\frac{1}{\lambda} C^* y \end{bmatrix}.$$

The formula for the left eigenvector is a consequence of [6, Theorem 3.2]. It follows that

$$\frac{\kappa_{C_1}(\lambda)}{\kappa_{\tilde{D}_1 C_1 \tilde{D}_2}(\lambda)} = \frac{1}{2n^{1/2}} \left(\frac{|\lambda|^4 - 1}{|\lambda|^2 - 1} \right)^{1/2} \left(n + \frac{1}{|\lambda|^2} \|C^* y\|_2^2 \right)^{1/2} \tau(\lambda).$$

If $|\lambda| \gg 1$ this simplifies to

$$\frac{\kappa_{C_1}(\lambda)}{\kappa_{\tilde{D}_1 C_1 \tilde{D}_2}(\lambda)} \approx \frac{1}{2} |\lambda| \tau(\lambda),$$

which differs by a factor of $|\lambda|$ from the corresponding case using a $\mathbb{DL}(P)$ linearization. Asymptotically, we have

$$\tau(\lambda) \sim \gamma |\lambda|^{-1}, \quad |\lambda| \gg 1$$

for some factor γ and therefore $\frac{\kappa_{C_1}(\lambda)}{\kappa_{\tilde{D}_1 C_1 \tilde{D}_2}(\lambda)} \sim \frac{\gamma}{2}$, where again we expect this asymptotic to hold approximately for all $|\lambda| > 1$ with a value of γ that is not much larger than 1 if the $n \times n$ subblocks of X and Y do not differ too widely in norm.

5. A heuristic scaling strategy. For standard eigenvalue problems the motivation of scaling algorithms is based on the observation that in floating point arithmetic computed eigenvalues of a matrix A can be expected to be at least perturbed by an amount of the order of $\epsilon_{mach}\|A\|$. Hence, by reducing $\|A\|$ one hopes to reduce the inaccuracies in the computed eigenvalues.

One way of minimizing $\|A\|$ is to find a nonsingular diagonal matrix D such that the rows and columns of A are balanced in the sense that

$$\|D^{-1} A D e_i\| = \|e_i^* D^{-1} A D\|, \quad i = 1, \ldots, n. \tag{5.1}$$

Osborne [14] shows that if A is irreducible and $\|\cdot\|$ is the 2-norm in (5.1), then for this D it holds that

$$\left\| D^{-1} A D \right\|_F = \inf_{\hat{D} \in \mathcal{D}_n} \left\| \hat{D}^{-1} A \hat{D} \right\|_F.$$

A routine that attempts to find a matrix D that balances the row and column norms of A is built into LAPACK under the name `xGEBAL`. It uses the 1-norm in the balancing condition (5.1). A description of the underlying algorithm is contained in [15].

For generalized eigenvalue problems $Ax = \lambda Bx$, Ward [18] proposes to find nonsingular diagonal scaling matrices D_1 and D_2 such that the elements of the scaled matrices D_1AD_2 and D_1BD_2 would have absolute values close to unity. Then the relative perturbations in the matrix elements caused by computational errors would be of similar magnitude. To achieve this Ward proposes to minimize the function

$$\sum_{i,j=1}^{n} (r_i + c_j + \log|A_{ij}|)^2 + (r_i + c_j + \log|B_{ij}|)^2,$$

where the r_i and c_j are the logarithms of the absolute values of the diagonal entries of D_1 and D_2. The scaling by Ward can fail if the matrices A and B contain tiny entries that are not due to bad scaling [10, Example 2.16].

A different strategy for generalized eigenvalue problems is proposed by Lemonnier and Van Dooren [11]. By introducing the notion of generalized normal pencils they motivate a scaling strategy that aims to find nonsingular diagonal matrices D_1 and D_2 such that

$$\|D_1AD_2e_j\|_2^2 + \|D_1BD_2e_j\|_2^2 = \|e_i^*D_1AD_2\|_2^2 + \|e_i^*D_1BD_2\|_2^2 = 1, \quad i,j = 1,\dots,n. \tag{5.2}$$

The scaling condition (5.2) can be generalized in a straightforward way to matrix polynomials of higher degree by

$$\sum_{k=0}^{\ell} \omega^{2k}\|D_1A_kD_2e_i\|_2^2 = 1, \quad \sum_{k=0}^{\ell} \omega^{2k}\|e_j^*D_1A_kD_2\|_2^2 = 1, \quad i,j = 1,\dots,n \tag{5.3}$$

for some $\omega > 0$ that is chosen in magnitude close to the wanted eigenvalues. The intuitive idea behind (5.3) is to balance rows and columns of the coefficient matrices A_k while taking into account the weighting of the coefficient matrices induced by the eigenvalue parameter; that is, for very large eigenvalues the rows and columns of A_ℓ dominate and for very small eigenvalues the rows and columns of A_0 dominate. This also reflects the result of Theorem 3.3 that the optimal scaling matrices are dependent on the wanted eigenvalue. In section 7 we show that including the estimate ω can greatly improve the results of scaling.

In [11] Lemonnier and Van Dooren introduced a linearly convergent iteration to obtain matrices D_1 and D_2 consisting of powers of 2 that approximately satisfy (5.2). The idea in their code is to alternatively update D_1 and D_2 by first normalizing all rows of $\begin{bmatrix} A & B \end{bmatrix}$ and then all columns of $\begin{bmatrix} A \\ B \end{bmatrix}$. The algorithm repeats this operation until (5.2) is approximately satisfied. This iteration can easily be extended to weighted scaling of matrix polynomials. This is done in Algorithm 1. The main difference to the MATLAB code in [11] is the definition of the variable M in line 6 that now accommodates matrix polynomials and the weighting parameter ω.

If we do not have any estimate for the magnitude of the wanted eigenvalues, a possible choice is to set $\omega = 1$ in (5.3). In that case all coefficient matrices have the same weight in that condition.

6. Transformations of the eigenvalue parameter. In the previous sections we investigated how diagonal scaling of $P(\lambda)$ by multiplication of $P(\lambda)$ with left and right scaling matrices $D_1, D_2 \in \mathcal{D}_n$ can improve the condition number of the eigenvalues. In this section we consider scaling a PEP by transforming the eigenvalue parameter λ. This was proposed by Fan, Lin, and Van Dooren for quadratics in

ALGORITHM 1 Diagonal scaling of $P(\lambda) = \lambda^\ell A_\ell + \cdots + \lambda A_1 + A_0$.

Require: $A_0, \ldots, A_\ell \in \mathbb{C}^{n\times n}$, $\omega > 0$.
1: $M \leftarrow \sum_{k=0}^{\ell} |\lambda|^{2k} |A_k|.^2$, $D_1 \leftarrow I$, $D_2 \leftarrow I$ ($|A_k|.^2$ is entry-wise square)

[3] (see also [6]). Let $Q(\lambda) := \lambda^2 A_2 + \lambda A_1 + A_0$. Define the quadratic polynomial $\widetilde{Q}(\mu) = \mu^2 \widetilde{A}_2 + \mu \widetilde{A}_1 + \widetilde{A}_0$ as

$$\widetilde{Q}(\mu) := \beta Q(\alpha\mu) = \beta\mu^2\alpha^2 A_2 + \beta\mu\alpha A_1 + \beta A_0.$$

The parameters $\beta > 0$ and $\alpha > 0$ are chosen such that the 2-norms of the new coefficient matrices $\widetilde{A}_2 := \beta\alpha^2 A_2$, $\widetilde{A}_1 := \beta\alpha A_1$, and $\widetilde{A}_0 := \beta A_0$ are as close to 1 as possible; that is, we need to solve

$$\min_{\alpha>0,\beta>0} \max\left\{|\beta\alpha^2\|A_2\|_2 - 1|, |\beta\alpha\|A_1\|_2 - 1|, |\beta\|A_0\|_2 - 1|\right\}. \tag{6.1}$$

It is shown in [3] that the unique solution of (6.1) is given by

$$\alpha = \left(\frac{\|A_0\|_2}{\|A_2\|_2}\right)^{\frac{1}{2}}, \quad \beta = \frac{2}{\|A_0\|_2 + \|A_1\|_2\alpha}.$$

Hence, after scaling we have $\|\widetilde{A}_0\|_2 = \|\widetilde{A}_2\|_2$. The motivation behind this scaling is that solving a QEP by applying a backward stable algorithm to solve (4.1) is backward stable if $\|A_0\|_2 = \|A_1\|_2 = \|A_2\|_2$ [17, Theorem 7]. For matrix polynomials of arbitrary degree ℓ it is shown in [7] that with

$$\rho := \frac{\max_i \|A_i\|_2}{\min(\|A_0\|_2, \|A_\ell\|_2)} \geq 1$$

one has

$$\frac{2\sqrt{\ell}}{\ell+1}\frac{1}{\rho} \leq \frac{\inf_v \kappa_L(\lambda; v; P)}{\kappa_P(\lambda)} \leq \ell^2\rho,$$

where $\kappa_L(\lambda; v; P)$ is the condition number of the eigenvalue λ for the linearization $L(\lambda) \in \mathbb{DL}(P)$ with vector v. Hence, if $\rho \approx 1$ then there is $L(\lambda) \in \mathbb{DL}(P)$ such that $\kappa_L(\lambda; v; P) \approx \kappa_P(\lambda)$. For backward errors analogous results were shown in [6]. The aim is therefore to find a transformation of λ such that ρ is minimized. For the transformation $\lambda = \alpha\mu$ the solution is given in the following theorem.

THEOREM 6.1. [illegible] $P(\lambda)$ [illegible] ℓ [illegible]

$$\rho(\alpha) := \frac{\max_{0\le i\le \ell} \alpha^i \|A_i\|_2}{\min(\|A_0\|_2, \alpha^\ell \|A_\ell\|_2)}$$

[illegible] $\alpha > 0$ [illegible] $\rho(\alpha)$ [illegible] $\alpha_{opt} = (\|A_0\|_2/\|A_\ell\|_2)^{\frac{1}{\ell}}$ [illegible]. The function $\rho(\alpha)$ is continuous. Furthermore, for $\alpha \to 0$ and $\alpha \to \infty$ we have $\rho(\alpha) \to \infty$. Hence, there must be at least one minimium in $(0, \infty)$. Let $\tilde{\alpha}$ be a local minimizer. Now assume that $\|A_0\|_2 < \tilde{\alpha}^\ell \|A_\ell\|_2$. Then

$$\rho(\alpha) = \frac{1}{\|A_0\|_2} \max(\alpha\|A_1\|_2, \ldots, \alpha^\ell \|A_\ell\|_2)$$

in a neighborhood of $\tilde{\alpha}$. But this function is strictly increasing in this neighborhood. Hence, $\tilde{\alpha}$ cannot be a minimizer. Similarly, the assumption $\|A_0\|_2 > \tilde{\alpha}^\ell \|A_\ell\|_2$ at the minimum leads to

$$\rho(\alpha) = \frac{1}{\alpha^\ell \|A_\ell\|_2} \max\left(\|A_0\|_2, \ldots, \alpha^{\ell-1}\|A_{\ell-1}\|_2\right),$$

in a neighborhood of this minimum, which is strictly decreasing. A necessary condition for a minimizer is therefore given as $\|A_0\|_2 = \alpha^\ell \|A_\ell\|_2$, which has the unique solution $\alpha_{opt} = (\|A_0\|_2/\|A_\ell\|_2)^{\frac{1}{\ell}}$ in $(0, \infty)$. Since there must be at least one minimum of $\rho(\alpha)$ in $(0, \infty)$, it follows that α_{opt} is the unique minimizer there. ∎

We emphasize that the variable transformation $\lambda = \alpha\mu$ does not change condition numbers or backward errors of the original polynomial problem. It affects only these quantities for the linearization $L(\lambda)$.

For the special case $\ell = 2$, this leads to the same scaling as proposed by Fan, Lin, and Van Dooren [3]. If $\|A_0\|_2 = \|A_\ell\|_2$, then $\alpha_{opt} = 1$ and we cannot improve ρ with the transformation $\lambda = \alpha\mu$. In that case one might consider more general Möbius transformations of the type

$$\widetilde{P}(\mu) := (c\mu + d)^\ell P\left(\frac{a\mu + b}{c\mu + d}\right), \quad a, b, c, d \in \mathbb{C}.$$

However, it is still unclear how to choose the parameters a, b, c, d in order to improve ρ for a specific matrix polynomial.

7. Numerical examples. We first present numerical experiments on sets of randomly generated PEPs. The test problems are created by defining $A_k := F_1^{(k)} \tilde{A}_k F_2^{(k)}$, where the entries of $\tilde{A}_k$ are $N(0, 1)$ distributed random numbers and the entries of $F_1^{(k)}$ and $F_2^{(k)}$ are jth powers of $N(0, 1)$ distributed random numbers obtained from the `randn` function in MATLAB. As j increases these matrices become more badly scaled and ill-conditioned. This is a similar strategy to create test matrices as was used in [11]. In our experiments we choose the parameter $j = 6$.

In Figure 7.1(a) we show the ratio of the normwise and componentwise eigenvalue condition numbers of the eigenvalues for 100 quadratic eigenvalue problems of

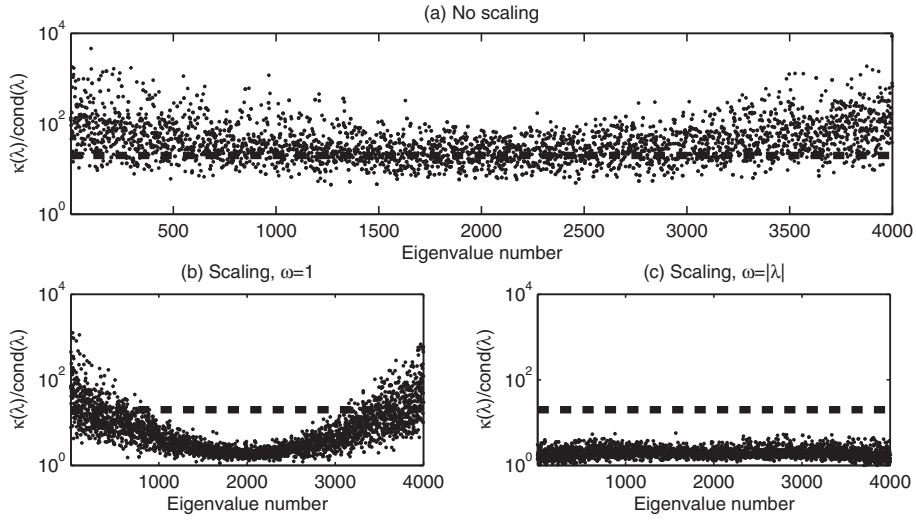

FIG. 7.1. (a) *The ratio of the normwise and componentwise condition numbers for the eigenvalues of* 100 *randomly created quadratic test problems of dimension* $n = 20$ *before scaling.* (b) *The same test set but now after scaling with* $\omega = 1$. (c) *Eigenvalue dependent scaling with* $\omega = |\lambda|$.

dimension $n = 20$. The eigenvalues range in magnitude from 10^{-8} to 10^{8} and are sorted in ascending magnitude. According to Theorem 3.3 the ratio of normwise and componentwise condition number is smaller than n (shown by the dotted line) if the problem is almost optimally scaled for the corresponding eigenvalue. But only a few eigenvalues satisfy this condition. Hence, we expect that scaling will improve the normwise condition numbers of the eigenvalues in these test problems. In Figure 7.1(b) the test problems are scaled using Alg. 1 with the fixed parameter $\omega = 1$. Apart from the extreme ones, all eigenvalues are now almost optimally scaled. In Figure 7.1(c) an eigenvalue dependent scaling is used; that is, $\omega = |\lambda|$ for each eigenvalue λ. Now all eigenvalues are almost optimally scaled. This demonstrates that having some information about the magnitude of the wanted eigenvalues can greatly improve the results of scaling.

The source of badly scaled eigenvalue problems often lies in a nonoptimal choice of units in the modelling process, which can lead to all coefficient matrices A_k being badly scaled in a similar way. In that case it is not necessary to provide any kind of weighting. This is demonstrated by the example in Figure 7.2. The left plot in that figure shows the ratio of the normwise and componentwise condition numbers of the eigenvalues of another set of eigenvalue problems. Again, we choose $n = 20$ and $\ell = 2$. However, this time the matrices $F_1^{(k)}$ and $F_2^{(k)}$ in the definition $A_k := F_1^{(k)} \tilde{A}_k F_2^{(k)}$ are kept constant for all $k = 0, \ldots, \ell$. They vary only between different eigenvalue test problems. The right plot in Figure 7.2 shows the ratio of normwise and componentwise condition number after scaling using $\omega = 1$. Now all eigenvalue condition numbers are almost optimal.

Let us now consider the example of a 4th order PEP $(\lambda^4 A_4 + \lambda^3 A_3 + \lambda^2 A_2 + \lambda A_1 + A_0)x = 0$ derived from the Orr–Sommerfeld equation [16]. The matrices are created with the NLEVP benchmark collection [1]. To improve the scaling factor ρ, we substitute $\lambda = \mu\alpha_{opt}$, where $\alpha_{opt} \approx 8.42 \cdot 10^{-4}$. This reduces ρ from $1.99 \cdot 10^{12}$ to 4.86. The ratio $\kappa_P(\mu)/\mathrm{cond}_P(\mu)$ for the unscaled problem is shown in Figure 7.3(a).

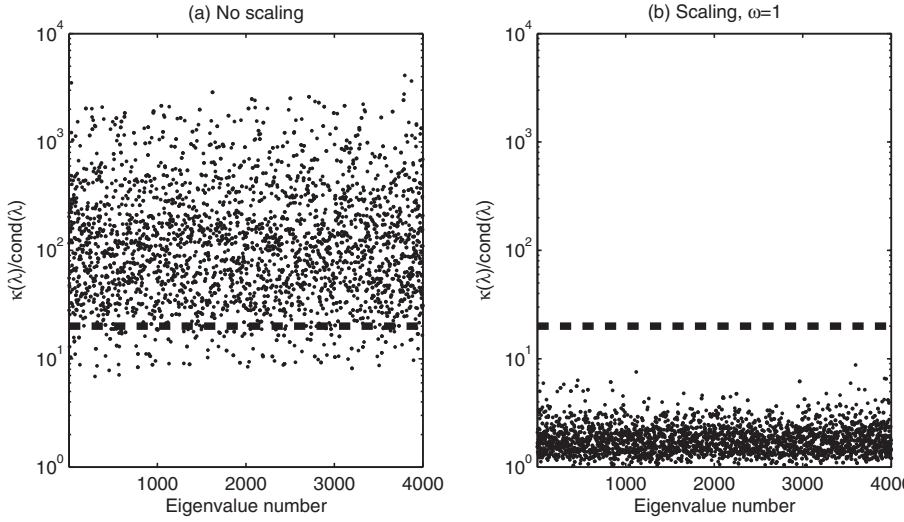

FIG. 7.2. *In this test all coefficient matrices of an eigenvalue problem are badly scaled in a similar way.* (a) *Ratio of normwise and componentwise condition condition numbers before scaling.* (b) *The same ratio after scaling with* $\omega = 1$.

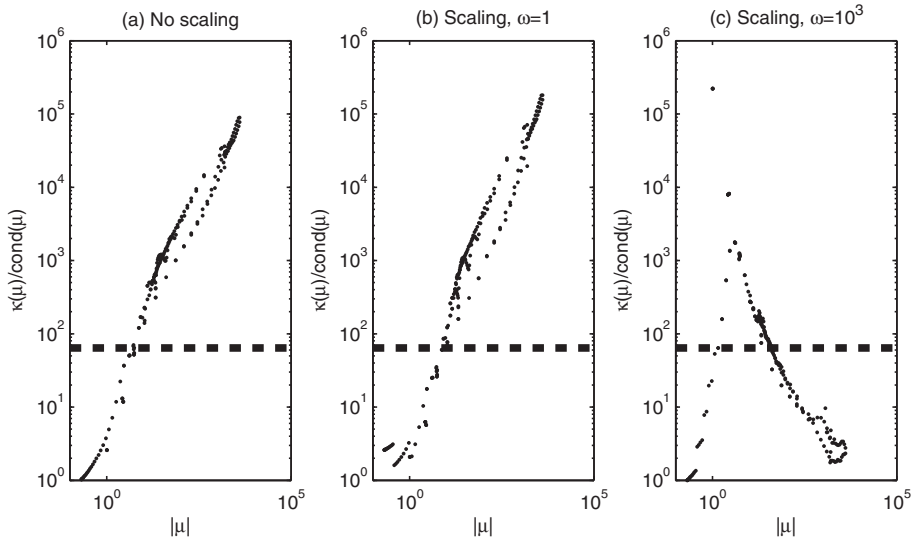

FIG. 7.3. *Scaling of a 4th order PEP.* (a) $\kappa(\mu)/\mathrm{cond}(\mu)$ *for the unscaled PEP.* (b) *The same ratio after scaling with* $\omega = 1$. (c) *Scaling with* $\omega = 10^3$. *The horizontal lines denote the dimension* $n = 64$ *of the PEP.*

The x-axis denotes the absolute value $|\mu|$ of an eigenvalue μ. The horizontal line shows the dimension $n = 64$ of the problem. The large eigenvalues in this problem are far away from being optimally scaled. In Figure 7.3(b) we use Alg. 1 with the weighting parameter $\omega = 1$. This has almost no effect on the normwise condition numbers of the eigenvalues. In Figure 7.3(c) we use $\omega = 10^3$. Now the larger eigenvalues are almost optimally scaled while the normwise condition numbers of some of the smaller eigenvalues have become worse. Hence, in this example the right choice of

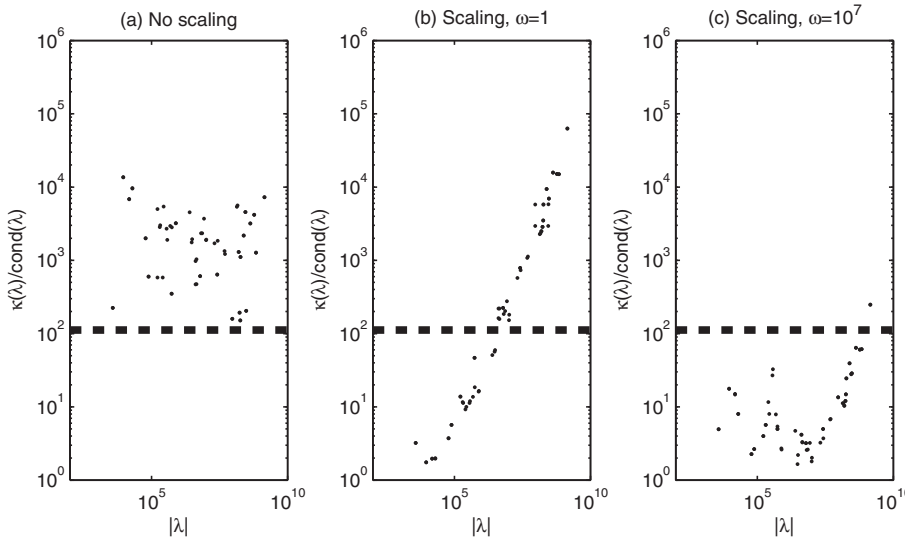

FIG. 7.4. *Scaling of the GEP $Kx = \lambda Mx$, where K and M are the matrices BCSSTK*03 *and BCSSTM*03 *from Matrix Market* [13]. *The best overall results are obtained with $\omega = 10^7$ (see right graph). The horizontal lines denote the dimension $n = 112$ of the GEP.*

the weighting parameter ω is crucial. If we want to improve the scaling of the large eigenvalue, we need to choose ω as approximately the magnitude of these values to obtain good results. By diagonal scaling with D_1 and D_2 the scaling factor ρ might increase again. In this example, after diagonal scaling using the weight $\omega = 10^3$, ρ increases to $1.8 \cdot 10^5$. However, we can reduce this again by another variable transformation of the form $\mu = \tilde{\alpha}_{opt}\tilde{\mu}$. From Theorem 6.1 it follows that $\tilde{\alpha}_{opt} \approx 13.9$, and after this variable transformation ρ reduces to 67.6. Hence, at the end the condition numbers of the largest eigenvalues have decreased by a factor of about 10^5, while the scaling factor ρ has increased only by a factor of about 10.

Not only for polynomial problems can a weighted scaling significantly improve the condition numbers compared to unweighted scaling. In Figure 7.4 we show the results of scaling for the GEP $Kx = \lambda Mx$, where K and M are the matrices BCSSTK03 and BCSSTM03 from Matrix Market [13]. The dimension of the GEP is 112. While unweighted scaling improves the condition number of the smaller eigenvalues, the best result is obtained by using the weighting parameter $\omega = 10^7$. Then the condition number of all eigenvalues is improved considerably.

8. Some remarks about scaling in practice. In this concluding section we want to give some suggestions for practical scaling algorithms based on the results of this paper.

1. [illegible] $\kappa(\lambda)$ [illegible] $\mathrm{cond}(\lambda)$ [illegible] At the moment eigensolvers often return a normwise condition number if desired by the user. It is only a little more effort to additionally compute the ratio $\kappa(\lambda)/\mathrm{cond}(\lambda)$. From Theorem 3.3 it follows that a polynomial is almost optimally scaled for a certain eigenvalue if $\kappa(\lambda)/\mathrm{cond}(\lambda) \leq n$. If this condition is violated, the user may decide to rescale the eigenvalue problem and then to recompute the eigenvalues in order to improve their accuracy.

2. [illegible] The numerical examples in section 7 show that the results of scaling can be greatly improved if ω is chosen to be of the magnitude of

the wanted eigenvalues. In many applications this information is available from other considerations. If no information about the eigenvalues is available, a reasonable choice is to set $\omega = 1$.

3. [illegible] The results in section 4 show that one can obtain a smaller condition number if one scales after linearizing the polynomial $P(\lambda)$. If the eigenvalues of the linearization $L(\lambda)$ are computed without taking any special structure of $L(\lambda)$ into account, this is therefore the preferable way. However, if the eigensolver uses the special structure of the linearization $L(\lambda)$, then one should scale the original polynomial $P(\lambda)$ and then linearize in order not to destroy this structure.

4. [illegible] $\lambda = \alpha\mu$ [illegible] ρ This technique, which was introduced by Fan, Lin, and Van Dooren [3] for quadratics and generalized in Theorem 6.1, often reduces the ratio of the condition number of an eigenvalue λ between the linearization and the original polynomial. In practice we would compute α using the Frobenius or another cheaply computable norm.

The first two suggestions also apply to generalized linear eigenvalue problems and can be easily implemented to current standard solvers for them. Further research is needed for the effect of scaling on the backward error. Bounds on the backward error after scaling are difficult to obtain since the computed eigenvalues change after scaling and this change depends on the eigensolver.

Acknowledgments. The author would like to thank Nick Higham and Françoise Tisseur for their support and advice on this work. Furthermore, the author would like to thank the anonymous referees whose comments improved the paper.

EXPLICIT SOLUTIONS FOR A RICCATI EQUATION FROM TRANSPORT THEORY*

VOLKER MEHRMANN† AND HONGGUO XU‡

In memoriam of Gene H. Golub

Abstract. We derive formulas for the minimal positive solution of a particular nonsymmetric Riccati equation arising in transport theory. The formulas are based on the eigenvalues of an associated matrix. We use the formulas to explore some new properties of the minimal positive solution and to derive fast and highly accurate numerical methods. Some numerical tests demonstrate the properties of the new methods.

Key words. nonsymmetric Riccati equation, secular equation, eigenvalues, minimal positive solution, Cauchy matrix, transport theory, quadrature formula

1. Introduction.

We consider nonsymmetric matrix Riccati equations of the special form

$$XA + DX - XBX - C = 0, \tag{1.1}$$

with

$$A = \Gamma - pe^T, \quad D = \Delta - ep^T, \quad B = pp^T, \quad C = ee^T,$$

where

$$\Gamma := \operatorname{diag}(\gamma_1, \ldots, \gamma_n), \quad \Delta := \operatorname{diag}(\delta_1, \ldots, \delta_n),$$
$$p = [p_1, \ldots, p_n]^T, \quad e = [1, \ldots, 1]^T,$$

and $\gamma_n > \cdots > \gamma_1 > 0$, $\delta_n > \cdots, \delta_1 > 0$, and $p_1, \ldots, p_n > 0$.

Such Riccati equations arise in Markov models [28] and in nuclear physics [8, 18, 22]. In the latter application, to study the transport of particles, one introduces integral equations of the form

$$\left[\frac{1}{x+\alpha} + \frac{1}{y-\alpha}\right] T(x,y) = \beta \left[1 + \frac{1}{2}\int_{-\alpha}^{1} \frac{T(t,y)}{t+\alpha} dt\right] \left[1 + \frac{1}{2}\int_{\alpha}^{1} \frac{T(x,t)}{t-\alpha} dt\right], \tag{1.2}$$

where the unknown function $T(x,y) : [-\alpha, 1] \times [\alpha, 1] \mapsto \mathbb{R}^+$ is called the [illegible], $\alpha \in [0, 1)$ is an angular shift, and $\beta \in [0, 1]$ is the average of the total

number of particles emerging from a collision. (Here $\mathbb{R}^+$ denotes the set of positive real numbers.)

To solve this integral equation numerically, one approximates the integrals via classical quadrature formulas [29]. For this the function $T(x, y)$ is approximated via a matrix $X = [x_{ij}]$, where x_{ij} is an approximation of $T(\mu_i, \nu_j)$ with μ_i, ν_j being the ith and jth nodes of the quadrature formula on $[-\alpha, 1]$ and $[\alpha, 1]$, respectively; see, e.g., [18].

In this discretization the matrix X has to satisfy the matrix Riccati equation (1.1) with coefficient matrices

$$\gamma_j = \frac{1}{\beta(1-\alpha)\omega_j}, \quad \delta_j = \frac{1}{\beta(1+\alpha)\omega_j}, \quad p_j = \frac{c_j}{2\omega_j}, \tag{1.3}$$

for $j = 1, 2, \ldots, n$, where $\{c_j\}_{j=1}^n$, $\{w_j\}_{j=1}^n$ are the sets of weights and nodes of the specific quadrature rule that is used on the interval [0, 1]. These typically satisfy

$$c_1, \ldots, c_n > 0, \quad \sum_{j=1}^{n} c_j = 1; \qquad 1 > \omega_1 > \cdots > \omega_n > 0. \tag{1.4}$$

In [20] it is shown that the Riccati equation (1.1) has two entrywise positive solutions $X = [x_{ij}], Y = [y_{ij}] \in \mathbb{R}^{n,n}$, which satisfy $X \leq Y$, where we use the notation that $X \leq Y$ if $x_{ij} \leq y_{ij}$ for all $i, j = 1, \ldots, n$.

In the applications from transport theory, only X, the smaller of the two positive solutions, is of interest. Therefore, in this paper we consider only the computation of the minimal positive solution X. The computation of this minimal solution has been investigated in several publications. Various direct and iterative methods [1, 2, 12, 13, 14, 15, 16, 17, 18, 19, 25] have been proposed by either directly solving the Riccati equation or by computing specific invariant subspaces of the $2n \times 2n$ matrix

$$H = \begin{bmatrix} A & -B \\ C & -D \end{bmatrix} \tag{1.5}$$

that is formed from the coefficient matrices.

In [20] even an explicit solution formula has been derived that is based on the eigenvalues H. Motivated by this result, we derive different explicit formulas, one of which is mathematically equivalent to the one in [20], but of a much simpler form. We will use these formulas to derive both entrywise and normwise bounds for the solution matrix and show that the entries of the solution have a graded entry property. We will also use the formulas to develop fast and highly accurate numerical algorithms for the minimal positive solution of (1.1).

This paper is organized as follows. In section 2, we will reformulate the associated eigenvalue problem via an appropriate balancing strategy. We use the associated secular function to derive some properties of the eigenvalues of H. In section 3, we then derive four formulas for the minimal positive solution based on the eigenvalues. Entrywise and normwise bounds for the minimal positive solution are provided in section 4. Numerical algorithms and an error analysis are presented in section 5 and some numerical examples are shown in section 6. A conclusion is given in section 7.

Throughout this paper, $\lambda(A)$ denotes the spectrum of a square matrix A, and I_n (or simply I) is the $n \times n$ identity matrix. The norm used in this paper is the spectral norm.

2. Spectral properties of the matrix H. In this section we analyze the spectral properties of the matrix H in (1.5) defined by the coefficient matrices of (1.1).

In order for all of the eigenvalues of H to be real, we assume that the condition

$$1 - \sum_{j=1}^{n} p_j \left(\frac{1}{\gamma_j} + \frac{1}{\delta_j} \right) \geq 0 \tag{2.1}$$

holds. The transport problem with the coefficients defined in (1.3) and (1.4) is a special case where this assumption is satisfied.

The first step in our analysis is a balancing of the coefficient matrices. Since the entries of the vector p are positive, we may define

$$\Phi := \operatorname{diag}(\sqrt{p_1}, \ldots, \sqrt{p_n}), \qquad \phi := [\sqrt{p_1}, \ldots, \sqrt{p_n}]^T.$$

Using Φ to scale the Riccati equation (1.1) via

$$\begin{aligned}
\tilde{X} &= \Phi X \Phi, \\
\tilde{A} &= \Phi^{-1} A \Phi = \Gamma - \phi\phi^T, \\
\tilde{D} &= \Phi D \Phi^{-1} = \Delta - \phi\phi^T, \\
\tilde{B} &= \Phi^{-1} B \Phi^{-1} = \phi\phi^T, \\
\tilde{C} &= \Phi C \Phi = \phi\phi^T = \tilde{B},
\end{aligned}$$

we obtain the equivalent Riccati equation

$$\tilde{X}\tilde{A} + \tilde{D}\tilde{X} - \tilde{X}\tilde{B}\tilde{X} - \tilde{B} = 0, \tag{2.2}$$

and obviously, X is a solution to (1.1) if and only if $\tilde{X} = \Phi X \Phi$ is a solution to (2.2). For the associated matrix formed from the coefficients we then have

$$\begin{aligned}
\tilde{H} &= \begin{bmatrix} \Phi^{-1} & 0 \\ 0 & \Phi \end{bmatrix} H \begin{bmatrix} \Phi & 0 \\ 0 & \Phi^{-1} \end{bmatrix} \\
&= \begin{bmatrix} \tilde{A} & -\tilde{B} \\ \tilde{B} & -\tilde{D} \end{bmatrix} = \begin{bmatrix} \Gamma & 0 \\ 0 & -\Delta \end{bmatrix} - \begin{bmatrix} \phi \\ -\phi \end{bmatrix} \begin{bmatrix} \phi \\ \phi \end{bmatrix}^T, \qquad (2.3)
\end{aligned}$$

and we see that $\tilde{H}$ is similar to H and is a rank-one modification of a diagonal matrix, which is analogous to the real symmetric rank-one updating problem discussed in [9]. It follows that the eigenvalues of $\tilde{H}$ can be obtained cheaply and accurately via the solution of secular equations by using a method similar to the one discussed in [10, section 8.5].

Furthermore, it is well known (see, e.g., [23]) that $\tilde{X}$ is a solution to (2.2) if and only if $\tilde{X}$ satisfies the invariant subspace equation

$$\tilde{H} \begin{bmatrix} I \\ \tilde{X} \end{bmatrix} = \begin{bmatrix} I \\ \tilde{X} \end{bmatrix} (\tilde{A} - \tilde{B}\tilde{X}).$$

In [20] it was shown (for the original solution X) that $\tilde{X}$ is the minimal positive solution if and only if all of the eigenvalues of $\tilde{A} - \tilde{B}\tilde{X}$ are nonnegative.

In order to analyze the properties of the matrix $\tilde{H}$ and thus also of the similar matrix H, we first derive some properties of the eigenvalues of $\tilde{H}$.

Consider the rational function

$$\chi(\lambda) = 1 + \sum_{j=1}^{n} \frac{p_j}{\lambda - \gamma_j} - \sum_{j=1}^{n} \frac{p_j}{\lambda + \delta_j}. \tag{2.4}$$

Then, since

$$\det(\lambda I - \tilde{H}) = \chi(\lambda) \left(\prod_{j=1}^{n} (\lambda - \gamma_j)(\lambda + \delta_j) \right), \tag{2.5}$$

it follows that the eigenvalues of $\tilde{H}$ are just the roots of the [illegible] $\chi(\lambda) = 0$, and thus the computation of the spectrum of $\tilde{H}$ can be carried out very efficiently by solving the secular equation; see [11, 27]. Furthermore, we have the following interlacing properties.

LEMMA 2.1. [illegible] $\tilde{H}$ [illegible] (2.2) [illegible] (2.1) [illegible] $\tilde{H}$ [illegible] $2n$ [illegible] $-\nu_n < \cdots < -\nu_1 \le 0$, $0 \le \lambda_1 < \cdots < \lambda_n$ [illegible]

$$0 \le \nu_1 < \delta_1 < \nu_2 < \delta_2 < \cdots < \nu_{n-1} < \delta_{n-1} < \nu_n < \delta_n$$

[illegible]

$$0 \le \lambda_1 < \gamma_1 < \lambda_2 < \gamma_2 < \cdots < \lambda_{n-1} < \gamma_{n-1} < \lambda_n < \gamma_n.$$

[illegible]

1. $\nu_1 = 0$ [illegible] $\lambda_1 > 0$, [illegible] $\chi(0) = 0$ [illegible] $\chi'(0) > 0$
2. $\nu_1 > 0$ [illegible] $\lambda_1 = 0$, [illegible] $\chi(0) = 0$ [illegible] $\chi'(0) < 0$
3. $\nu_1 = \lambda_1 = 0$, [illegible] $\chi(0) = \chi'(0) = 0$ [illegible] $\tilde{H}$ [illegible] 2×2 [illegible] 0

[illegible]. The proof is basically given already in [20] based on the properties of the secular function $\chi(\lambda)$. Note that assumption (2.1) implies that $\chi(0) \ge 0$.

The second part of the third case has already been shown in [12] in a more general setting. □

[illegible] 2.2. Suppose the quadrature formula that is used to discretize the integral equation (1.2) is of order greater than or equal to 3; i.e.,

$$\sum_{j=1}^{n} c_j w_j^k = \frac{1}{k+1}, \qquad k = 0, 1, 2, 3.$$

With (1.3) it is easily verified that

$$\chi(0) = 1 - \sum_{j=1}^{n} \left(\frac{p_j}{\gamma_j} + \frac{p_j}{\delta_j} \right) = 1 - \beta \sum_{j=1}^{n} c_j = 1 - \beta,$$

$$\chi'(0) = \sum_{j=1}^{n} \left(-\frac{p_j}{\gamma_j^2} + \frac{p_j}{\delta_j^2} \right) = 2\alpha\beta^2 \sum_{j=1}^{n} c_j w_j = \alpha\beta^2,$$

$$\chi''(0) = -2 \sum_{j=1}^{n} \left(\frac{p_j}{\gamma_j^3} + \frac{p_j}{\delta_j^3} \right) = -2(1+3\alpha^2)\beta^3 \sum_{j=1}^{n} c_j w_j^2 = -\frac{2}{3}(1+3\alpha^2)\beta^3,$$

$$\chi'''(0) = 6 \sum_{j=1}^{n} \left(-\frac{p_j}{\gamma_j^4} + \frac{p_j}{\delta_j^4} \right) = 24\alpha(1+\alpha^2)\beta^4 \sum_{j=1}^{n} c_j w_j^3 = 6\alpha(1+\alpha^2)\beta^4.$$

Since $\chi'(0) \geq 0$, we have that case 1 in Lemma 2.1 happens when $\beta = 1$ and $\alpha > 0$ and case 3 happens when $\beta = 1$ and $\alpha = 0$. Case 2 will never happen.

3. Formulas for the minimal positive solution. In this section we will derive explicit formulas for the minimal positive solution of (1.1) in terms of the eigenvalues $-\nu_1, \ldots, -\nu_n, \lambda_1, \ldots, \lambda_n$ of H (or $\tilde{H}$). For this we need the following lemma.

LEMMA 3.1. [illegible] $\tilde{X} \in \mathbb{R}^{n,n}$ [illegible]

(a) $\tilde{X}$ [illegible] (2.2)

(b) $\tilde{X}$ [illegible]

$$\tilde{H} \begin{bmatrix} I_n \\ \tilde{X} \end{bmatrix} = \begin{bmatrix} I_n \\ \tilde{X} \end{bmatrix} \tilde{R}_1,$$

[illegible] $\tilde{R}_1 = \tilde{A} - \tilde{B}\tilde{X}$ [illegible] $\sigma(\tilde{R}_1) = \{\lambda_1, \ldots, \lambda_n\}$.

(c) $\tilde{X}^T$ [illegible]

$$\tilde{Y}\tilde{D} + \tilde{A}\tilde{Y} - \tilde{Y}\tilde{B}\tilde{Y} - \tilde{B} = 0. \tag{3.1}$$

(d) $\tilde{X}$ [illegible]

$$\tilde{H} \begin{bmatrix} \tilde{X}^T \\ I_n \end{bmatrix} = \begin{bmatrix} \tilde{X}^T \\ I_n \end{bmatrix} \tilde{R}_2, \tag{3.2}$$

[illegible] $\tilde{R}_2 = -(\tilde{D} - \tilde{B}\tilde{X}^T)$ [illegible] $\sigma(\tilde{R}_2) = \{-\nu_1, \ldots, -\nu_n\}$.

[illegible]. The equivalence of (a) and (b) is given in [20]. The equivalence between (a) and (c) is obvious by taking the transpose on both sides of (2.2) or (3.1). The equivalence between (c) and (d) is shown in [12]. □

With formulas for $\tilde{R}_1, \tilde{R}_2$ as in Lemma 3.1 and the formulas for $\tilde{A}$, $\tilde{D}$ and $\tilde{B}$, it follows that the minimal positive solution $\tilde{X}$ of (2.2) satisfies the following relations:

$$\Gamma - \phi\tilde{\xi}^T = \tilde{R}_1, \qquad \sigma(\tilde{R}_1) = \{\lambda_1, \ldots, \lambda_n\}, \tag{3.3}$$

$$\Delta - \phi\tilde{\eta}^T = -\tilde{R}_2, \qquad \sigma(-\tilde{R}_2) = \{\nu_1, \ldots, \nu_n\}, \tag{3.4}$$

$$\tilde{X}\Gamma + \Delta\tilde{X} = \tilde{\eta}\tilde{\xi}^T, \tag{3.5}$$

where

$$\tilde{\xi} = (I + \tilde{X}^T)\phi, \qquad \tilde{\eta} = (I + \tilde{X})\phi.$$

The last equation is a reformulation of (2.2). It thus follows that if the vectors $\tilde{\xi}$ and $\tilde{\eta}$ can be determined, then $\tilde{X}$ can be easily formulated based on the simple Sylvester equation (3.5).

The following result shows that $\tilde{\xi}$ and $\tilde{\eta}$ can be determined based on the relations (3.3) and (3.4).

PROPOSITION 3.2 (see [26]). A, B $A = \operatorname{diag}(a_1, \ldots, a_n)$ $a_1, \ldots, a_n \in \mathbb{R}$ $B \in \mathbb{R}^{n,n}$ $\lambda(B) = \{b_1, \ldots, b_n\}$ $b_1, \ldots, b_n \in \mathbb{R}$ $q_1, q_2, \ldots, q_n \in \mathbb{R} \setminus \{0\}$

$$q = [q_1, q_2, \ldots, q_n]^T, \quad Q = \operatorname{diag}(q_1, q_2, \ldots, q_n)$$

$$f = \left[\frac{\prod_{j=1}^{n}(a_1 - b_j)}{\prod_{j\neq 1}(a_1 - a_j)}, \ldots, \frac{\prod_{j=1}^{n}(a_k - b_j)}{\prod_{j\neq k}(a_k - a_j)}, \ldots, \frac{\prod_{j=1}^{n}(a_n - b_j)}{\prod_{j\neq n}(a_n - a_j)} \right]^T.$$

$z \in \mathbb{R}^n$ $A - qz^T = B$

$$z = Q^{-1} f = \left[\frac{f_1}{q_1}, \ldots, \frac{f_n}{q_n} \right]^T. \tag{3.6}$$

Using (3.6), (3.3), (3.4), and (3.5), we obtain the following explicit formulas for X.

THEOREM 3.3. (1.1). $k = 1, \ldots, n$

$$\xi_k = \frac{\prod_{j=1}^{n}(\gamma_k - \lambda_j)}{\prod_{j\neq k}(\gamma_k - \gamma_j)}, \quad \eta_k = \frac{\prod_{j=1}^{n}(\delta_k - \nu_j)}{\prod_{j\neq k}(\delta_k - \delta_j)}, \quad \kappa_k = \frac{\prod_{j=1}^{n}(\gamma_k + \delta_j)}{\prod_{j=1}^{n}(\gamma_k + \nu_j)}, \quad \epsilon_k = \frac{\prod_{j=1}^{n}(\delta_k + \gamma_j)}{\prod_{j=1}^{n}(\delta_k + \lambda_j)},$$

$$\begin{aligned} \xi &= [\xi_1, \ldots, \xi_n]^T, & \Xi &= \operatorname{diag}(\xi_1, \ldots, \xi_n), \\ \eta &= [\eta_1, \ldots, \eta_n]^T, & E &= \operatorname{diag}(\eta_1, \ldots, \eta_n), \\ \kappa &= [\kappa_1, \ldots, \kappa_n]^T, & K &= \operatorname{diag}(\kappa_1, \ldots, \kappa_n), \\ \epsilon &= [\epsilon_1, \ldots, \epsilon_n]^T, & \mathcal{E} &= \operatorname{diag}(\epsilon_1, \ldots, \epsilon_n), \end{aligned} \tag{3.7}$$

$$\Theta = \left[\frac{1}{\delta_i + \gamma_j} \right].$$

$$P = \operatorname{diag}(p_1, \dots, p_n),$$

p_i (1.1). (1.1):

$$X = P^{-1} E \Theta \Xi P^{-1}, \tag{3.8}$$

$$X = P^{-1} E \Theta K, \tag{3.9}$$

$$X = \mathcal{E} \Theta \Xi P^{-1}, \tag{3.10}$$

$$X = \mathcal{E} \Theta K. \tag{3.11}$$

. To prove the formulas, we apply Proposition 3.2 to (3.3) and obtain

$$\tilde{\xi} = \Phi^{-1} \xi,$$

where ξ is defined in (3.7). Similarly, from (3.4) we obtain

$$\tilde{\eta} = \Phi^{-1} \eta,$$

where η is defined in (3.7). By solving the Sylvester equation (3.4) we obtain

$$\tilde{X} = \Phi^{-1} E \Theta \Xi \Phi^{-1},$$

with E, Ξ as in (3.7). Then, (3.8) follows by using $X = \Phi^{-1} \tilde{X} \Phi^{-1}$ and $P = \Phi^2$.

In order to get the other formulas we need only show that $\Xi = PK$ and $E = P\mathcal{E}$.

Since $-\nu_1, \dots, -\nu_n, \lambda_1, \dots, \lambda_n$ are the eigenvalues of $\tilde{H}$, it follows from (2.5) that

$$\prod_{j=1}^{n} (\lambda - \lambda_j) \prod_{j=1}^{n} (\lambda + \nu_j) = \sum_{m=1}^{n} p_m \prod_{j \neq m} (\lambda - \gamma_j) \prod_{j=1}^{n} (\lambda + \delta_j)$$

$$- \sum_{m=1}^{n} p_m \prod_{j=1}^{n} (\lambda - \gamma_j) \prod_{j \neq m} (\lambda + \delta_j) + \prod_{j=1}^{n} (\lambda - \gamma_j) \prod_{j=1}^{n} (\lambda + \delta_j). \tag{3.12}$$

By inserting $\lambda = \gamma_k$, we obtain

$$\prod_{j=1}^{n} (\gamma_k - \lambda_j) \prod_{j=1}^{n} (\gamma_k + \nu_j) = p_k \prod_{j \neq k} (\gamma_k - \gamma_j) \prod_{j=1}^{n} (\gamma_k + \delta_j),$$

which implies that

$$\xi_k = p_k \kappa_k, \quad k = 1, 2, \dots, n.$$

We then have $\Xi = PK$.

Similarly, by inserting $\lambda = -\delta_k$ in (3.12) we get

$$\eta_k = p_k \epsilon_k, \quad k = 1, \dots, n,$$

and thus $E = P\mathcal{E}$. Then the other formulas follow. □

Note that formula (3.9) needs only the eigenvalues $-\nu_1, \dots, -\nu_n$, while formula (3.10) needs only the eigenvalues $\lambda_1, \dots, \lambda_n$. Numerically, these two formulas provide very cheap procedures to compute the minimal solution X of (1.1).

3.4. In [20] an explicit formula for the minimal solution of (1.1) was already given that is equivalent to (3.10). However, there a different expression for ϵ_k was introduced as

$$\epsilon_k = 1 + \sum_{m=1}^{n} \frac{1}{\delta_k + \lambda_m} \frac{\prod_{j=1}^{n}(\gamma_j - \lambda_m)}{\prod_{j\neq m}(\lambda_j - \lambda_m)}.$$

This expression is less compact and its evaluation has a higher complexity than the expression in Theorem 3.3.

In this section we have derived new explicit formulas for the minimal solution X of (1.1) and we will use them in the next section to derive some further properties of X.

4. Properties and bounds for the minimal positive solution. The simple expressions of the quantities $\xi_k, \kappa_k, \eta_k, \epsilon_k$ in the explicit formulas (3.8)–(3.11) and the eigenvalue interlacing property for the eigenvalues of $\tilde{H}$ allow one to derive further properties of the minimal positive solution of (1.1). For this we first prove the following lemma.

LEMMA 4.1. *ffi… γ_k, δ_k… (1.1),… $-\nu_k, \lambda_k$… $\tilde{H}$… (2.3),… $\xi_k, \eta_k, \kappa_k, \epsilon_k$, $k = 1, \ldots, n$… (3.7)…*

1.

$$0 < a_k < \eta_k < \delta_k - \nu_1 \le \delta_k, \qquad 0 < b_k < \xi_k < \gamma_k - \lambda_1 \le \gamma_k,$$

$$1 < \epsilon_k < \frac{\delta_k + \gamma_n}{\delta_k + \lambda_1} \le \frac{\delta_k + \gamma_n}{\delta_k}, \qquad 1 < \kappa_k < \frac{\gamma_k + \delta_n}{\gamma_k + \nu_1} \le \frac{\gamma_k + \delta_n}{\gamma_k},$$

…

$$a_k = \begin{cases} \frac{(\delta_k - \nu_k)(\nu_{k+1} - \delta_k)}{\delta_n - \delta_k}, & 1 \le k < n, \\ \delta_n - \nu_n, & k = n, \end{cases}$$

$$b_k = \begin{cases} \frac{(\gamma_k - \lambda_k)(\lambda_{k+1} - \gamma_k)}{\gamma_n - \gamma_k}, & 1 \le k < n, \\ \gamma_n - \lambda_n, & k = n. \end{cases}$$

2.

$$1 < \epsilon_n < \epsilon_{n-1} < \cdots < \epsilon_1, \qquad 1 < \kappa_n < \kappa_{n-1} < \cdots < \kappa_1.$$

…. To prove the first part, we use the interlacing property in Lemma 2.1 and obtain

$$0 < \frac{\delta_k - \nu_j}{\delta_k - \delta_{j-1}} < 1, \quad 1 < j \le k; \qquad \frac{\delta_k - \nu_j}{\delta_k - \delta_j} > 1, \quad 1 \le j < k,$$

and

$$0 < \frac{\delta_k - \nu_j}{\delta_k - \delta_j} < 1, \quad k < j \le n; \qquad \frac{\delta_k - \nu_{j+1}}{\delta_k - \delta_j} > 1, \quad k < j < n.$$

For $1 \le k < n$

$$\eta_k = \frac{(\delta_k - \nu_k)(\delta_k - \nu_{k+1})}{\delta_k - \delta_n} \prod_{j=1}^{k-1} \frac{\delta_k - \nu_j}{\delta_k - \delta_j} \prod_{j=k+1}^{n-1} \frac{\delta_k - \nu_{j+1}}{\delta_k - \delta_j} > a_k,$$

and

$$\eta_k = (\delta_k - \nu_1) \prod_{j=1}^{k-1} \frac{\delta_k - \nu_{j+1}}{\delta_k - \delta_j} \prod_{j=k+1}^{n} \frac{\delta_k - \nu_j}{\delta_k - \delta_j} < \delta_k - \nu_1 \le \delta_k.$$

Finally, for $k = n$ we obtain

$$\eta_n = (\delta_n - \nu_n) \prod_{j=1}^{n-1} \frac{\delta_n - \nu_j}{\delta_n - \delta_j} > \delta_n - \nu_n =: a_n$$

and

$$\eta_n = (\delta_n - \nu_1) \prod_{j=1}^{n-1} \frac{\delta_n - \nu_{j+1}}{\delta_n - \delta_j} < \delta_n - \nu_1 \le \delta_n.$$

This proves the inequalities for the η_k, and clearly we have $a_k > 0$ for $k = 1, \ldots, n$.

The inequalities for the ξ_k can be derived in the same way by using the interlacing property for the eigenvalues $\lambda_1, \ldots, \lambda_n$. This interlacing property also gives

$$\epsilon_k = \prod_{j=1}^{n} \frac{\delta_k + \gamma_j}{\delta_k + \lambda_j} > 1$$

and

$$\epsilon_k = \frac{\delta_k + \gamma_n}{\delta_k + \lambda_1} \prod_{j=1}^{n-1} \frac{\delta_k + \gamma_j}{\delta_k + \lambda_{j+1}} < \frac{\delta_k + \gamma_n}{\delta_k + \lambda_1} \le \frac{\delta_k + \gamma_n}{\delta_k}.$$

Similarly, one can prove the inequalities for κ_k.

To prove part 2 we consider the function

$$\psi(t) = \prod_{j=1}^{n} \frac{t + \gamma_j}{t + \lambda_j} = \prod_{j=1}^{n} \left(1 + \frac{\gamma_j - \lambda_j}{t + \lambda_j}\right).$$

Since $\gamma_j - \lambda_j \ge 0$ for $j = 1, \ldots, n$, it follows that $\psi(t)$ is decreasing as t increases. Since $\psi(\delta_k) = \epsilon_k$ for $k = 1, \ldots, n$, and $\delta_1 < \cdots < \delta_n$, we thus have

$$\epsilon_1 > \epsilon_2 > \cdots > \epsilon_n.$$

Obviously $\psi(t) > 1$ for any $t > 0$, and hence $\epsilon_n = \psi(\delta_n) > 1$.

The monotonicity $\kappa_1 > \cdots > \kappa_n > 1$ follows in the same way. □

With the help of Lemma 4.1 we can now prove the following entrywise monotonicity property of the minimal positive solution X of (1.1).

THEOREM 4.2. [illegible] $X = [x_{ij}] \in \mathbb{R}^{n,n}$ [illegible] (1.1). [illegible] $i \ge k$ [illegible] $j \ge l$ [illegible] $(i,j) \ne (k,l)$ [illegible] X [illegible]

$$x_{ij} > x_{kl}.$$

[illegible]. Since

$$0 < \gamma_1 < \cdots < \gamma_n, \quad 0 < \delta_1 < \cdots < \delta_n,$$

and by Lemma 4.1,

$$1 < \epsilon_n < \cdots < \epsilon_1, \quad 1 < \kappa_n < \cdots < \kappa_1,$$

with (3.11), for $1 \le i, j \le n$, if $i < n$, it follows that

$$x_{ij} = \frac{\epsilon_i \kappa_j}{\delta_i + \gamma_j} > \frac{\epsilon_{i+1} \kappa_j}{\delta_{i+1} + \gamma_j} = x_{i+1,j}.$$

If $j < n$, then

$$x_{ij} = \frac{\epsilon_i \kappa_j}{\delta_i + \gamma_j} > \frac{\epsilon_i \kappa_{j+1}}{\delta_i + \gamma_{j+1}} = x_{i,j+1}. \qquad \square$$

The quantities in Lemma 4.1 also provide upper and lower bounds for the entries of the minimal positive solution X of (1.1).

THEOREM 4.3. [illegible] $X = [x_{ij}] \in \mathbb{R}^{n,n}$ [illegible] (1.1).

$$\frac{w_{ij}}{\delta_i + \gamma_j} < x_{ij} < \frac{W_{ij}}{\delta_i + \gamma_j},$$

[illegible]

$$w_{ij} = \max\left\{ \frac{a_i b_j}{p_i p_j},\ \frac{a_i}{p_i},\ \frac{b_j}{p_j},\ 1 \right\},$$

$$W_{ij} = \min\left\{ \frac{\delta_i \gamma_j}{p_i p_j},\ \frac{\delta_i(\gamma_j + \delta_n)}{p_i \gamma_j},\ \frac{(\delta_i + \gamma_n)\gamma_j}{\delta_i p_j},\ \frac{(\delta_i + \gamma_n)(\gamma_j + \delta_n)}{\delta_i \gamma_j} \right\}.$$

[illegible]. The bounds follow from the formulas (3.8)–(3.11) and the inequalities given in the first part of Lemma 4.1. $\square$

COROLLARY 4.4. [illegible] $X = [x_{ij}] \in \mathbb{R}^{n,n}$ [illegible] (1.1) [illegible] w_{ij}, W_{ij} [illegible] 4.3. [illegible]

$$\frac{w_{nn}}{\delta_n + \gamma_n} < x_{nn} \le x_{ij} \le x_{11} < \frac{W_{11}}{\delta_1 + \gamma_1}$$

[illegible] $i, j = 1, \ldots, n$

[illegible]. The inequalities follow from Theorems 4.2 and 4.3. $\square$

By taking advantage of the scaled equation (2.2), we also obtain a bound for the spectral norm of the minimal positive solution X of (1.1).

THEOREM 4.5. [illegible] $\tilde{X} \in \mathbb{R}^{n,n}$ [illegible] (2.2). [illegible]

$$\|\tilde{X}\| \le 1,$$

[illegible] $\|\tilde{X}\| = 1$, [illegible] $\chi(0) = 0$ [illegible] $\chi'(0) = 0$ [illegible] X [illegible] (1.1) [illegible]

$$\|X\| \le \frac{1}{\min_j p_j}.$$

[illegible]. Let $\tilde{X}_+ \ge \tilde{X}$ be another positive solution of (2.2) [20]. Since both $\tilde{X}$ and $\tilde{X}_+$ are positive, it is easily verified that

$$\|\tilde{X}\|^2 = \rho(\tilde{X}^T \tilde{X}) \le \rho(\tilde{X}^T \tilde{X}_+),$$

where $\rho(Z)$ is the spectral radius of Z. Lemma 3.1 shows that $\tilde{X}^T$ is the minimal positive solution of the dual equation (3.1). By Lemma 12 of [7], $\rho(\tilde{X}^T\tilde{X}_+) \le 1$. Hence $\|\tilde{X}\| \le 1$, and $\|\tilde{X}\| = 1$ if and only if $\tilde{X}_+ = \tilde{X}$. The last equality holds if and only if 0 is a double eigenvalue of $\tilde{H}$, which is equivalent to the conditions $\chi(0) = 0$ and $\chi'(0) = 0$, by Lemma 2.1.

The upper bound for $\|X\|$ follows from the relation $X = \Phi^{-1}\tilde{X}\Phi^{-1}$. □

Various lower bounds for $\|X\|$ can also be derived by using the inequalities for the entries of X, but we will not pursue this topic here.

At the end of this section we also provide a formula for the inverse of X.

THEOREM 4.6. [illegible] $X = [x_{ij}]$ [illegible] (1.1) [illegible] P, Θ [illegible] 3.3, [illegible]

$$X^{-1} = PQ\Theta^T GP,$$

[illegible]

$$Q = \operatorname{diag}(q_1, \dots, q_n), \qquad G = \operatorname{diag}(g_1, \dots, g_n),$$

[illegible]

$$q_k = \prod_{j=1}^{n} \frac{\gamma_k + \delta_j}{\gamma_k - \lambda_j}, \qquad g_k = \prod_{j=1}^{n} \frac{\delta_k + \gamma_j}{\delta_k - \nu_j},$$

[illegible] $k = 1, \dots, n$ [illegible]. Since $\gamma_n > \cdots > \gamma_1 > 0$ and $\delta_n > \cdots > \delta_1 > 0$, it follows (see, e.g., [6]) that the Cauchy matrix Θ is invertible and

$$\Theta^{-1} = \hat{Q}\Theta^T\hat{G},$$

where

$$\hat{Q} = \operatorname{diag}(\hat{q}_1, \dots, \hat{q}_n), \quad \hat{G} = \operatorname{diag}(\hat{g}_1, \dots, \hat{g}_n),$$

with

$$\hat{q}_k = \frac{\displaystyle\prod_{j=1}^{n}(\gamma_k + \delta_j)}{\displaystyle\prod_{j\ne k}(\gamma_k - \gamma_j)}, \qquad \hat{g}_k = \frac{\displaystyle\prod_{j=1}^{n}(\delta_k + \gamma_j)}{\displaystyle\prod_{j\ne k}(\delta_k - \delta_j)},$$

for $k = 1, \dots, n$. Since all of the diagonal matrices in (3.8) are invertible, it follows that X is also invertible and the formula for X^{-1} follows from (3.8) using Θ^{-1}. □

5. Numerical algorithms. The formulas given in section 3 can be used to develop the following numerical algorithms for computing the minimal positive solution of (1.1).

ALGORITHM 5.1. For the Riccati equation (1.1) this algorithm computes the minimal positive solution.

1. Compute the eigenvalues $-\nu_1, \dots, -\nu_n, \lambda_1, \dots, \lambda_n$ of $\tilde{H}$ in (2.3) by applying a root finding solver to the secular equation $\chi(\lambda) = 0$ given by (2.4).
2. Use either of the formulas (3.8) or (3.11) to compute the minimal positive solution X of (1.1).

We can also use either of the formulas (3.9) or (3.10).

ALGORITHM 5.2. For the Riccati equation (1.1) this algorithm computes the minimal positive solution.

1. Compute the eigenvalues $-\nu_1, \ldots, -\nu_n$ of $\tilde{H}$ in (2.3) by applying a root finding solver to the secular equation $\chi(\lambda) = 0$ given by (2.4).
2. Use formula (3.9) to compute the minimal positive solution X of (1.1).

ALGORITHM 5.3. For the Riccati equation (1.1) this algorithm computes the minimal positive solution.

1. Compute the eigenvalues $\lambda_1, \ldots, \lambda_n$ of $\tilde{H}$ in (2.3) by applying a secular equation solver to $\chi(\lambda) = 0$.
2. Use formula (3.10) to compute the minimal positive solution X of (1.1).

Note that Algorithms 5.2 and 5.3 need only compute half of the eigenvalues.

The success of these three algorithms depends on how fast and accurately the eigenvalues can be computed and how sensitive the evaluation of the formulas (3.8)–(3.11) is. This requires an efficient and reliable secular equation solver. The osculatory interpolation methods of [3, 24] that were developed in the context of the divide-and-conquer eigenvalue methods ([10, section 8.5], [4, 5, 9]) may not be applicable directly, since the secular function $\chi(\lambda)$ has quite different properties than the secular equation derived in the symmetric divide-and-conquer method. For this reason we propose the following hybrid method for the computation of roots of the secular function. We consider only the case for computing the eigenvalues λ_k as the method for computing the eigenvalues ν_k is analogous. Our approach treats λ_1 differently from the other eigenvalues $\lambda_2, \ldots, \lambda_n$, because of the different properties that λ_1 has.

5.1. Computation of λ_k with $k > 1$.

1. Initial guess. To compute an initial guess, we basically follow the procedure suggested in [24]. We first evaluate $\chi(m_k)$, where m_k is the midpoint of the interval (γ_{k-1}, γ_k). Because $\chi(\lambda)$ has only one root in (γ_{k-1}, γ_k), and since $\lim_{\lambda \to \gamma_{k-1}^+} \chi(\lambda) = \infty$, and $\lim_{\lambda \to \gamma_k^-} \chi(\lambda) = -\infty$, based on the sign of $\chi(m_k)$, we can easily determine in which half of the interval λ_k is located. Simple geometry shows that if $\chi(m_k) > 0$, then λ_k is closer to γ_k, and if $\chi(m_k) < 0$, then λ_k is closer to γ_{k-1}. We then consider the equation

$$\frac{p_{k-1}}{\lambda - \gamma_{k-1}} + \frac{p_k}{\lambda - \gamma_k} + r_k = 0,$$

with $r_k = \chi(m_k) - p_{k-1}/(m_k - \gamma_{k-1}) - p_k/(m_k - \gamma_k)$, which can be obtained during the evaluation of $\chi(m_k)$ without any extra cost. We then take the root of this equation in (γ_{k-1}, γ_k) as our initial guess z_k^0. It is easily verified that z_k^0 and λ_k are in the same half interval. We also choose an initial interval so that the χ values on endpoints have opposite signs (which guarantees that λ_k is in this interval). If $\chi(m_k)\chi(z_k^0) < 0$, then we use m_k, z_k^0 for the interval. Otherwise, we use the asymptotic properties of χ to find another λ value to replace m_k. Let us denote the resulting interval by $[u_0, v_0]$.

2. Iteration step. For a current approximation z_k^j, we first evaluate $\chi'(z_k^j)$ and use one step of Newton's method to determine the next approximate z_k^{j+1}. If z_k^{j+1} is inside the current interval $[u_j, v_j]$, then we evaluate $\chi(z_k^{j+1})$. We then replace one of u_j, v_j and its corresponding χ value with z_k^{j+1} and $\chi(z_k^{j+1})$ based on the sign of $\chi(z_k^{j+1})$ and move on to the next iteration. If z_k^{j+1} is outside $[u_j, v_j]$ (maybe even outside of (γ_{k-1}, γ_k)), then we apply one step of

the secant method with u_j, v_j and their corresponding χ values to get z_k^{j+1}. We then evaluate $\chi(z_k^{j+1})$, update $[u_j, v_j]$, and continue. If this z_k^{j+1} is still outside of $[u_j, v_j]$, then we use one step of the bisection method with u_j, v_j to get z_k^{j+1}.

When the iterates z_k^j get close to the root λ_j, then, due to rounding errors, it becomes more difficult to compute a reliable value of $\chi(z_k^j)$. (This happens typically for small roots.) This may cause the sign of χ to alternate between positive and negative values in the Newton iteration and the secant iteration, which may have the effect that the sequence $\{z_k^j\}$ does not converge. If we observe such a behavior and the function values for χ are also small in absolute value, then we run a step of the bisection method. This procedure has turned out to be very successful during our numerical tests.

3. Stopping criterion. In order to compute the root λ_k accurately, we actually use the shift $s = \lambda - \gamma_{k-1}$ or $s = \lambda - \gamma_k$ initially, depending on whether λ_k is closer to γ_{k-1} or γ_k. The iteration step is then applied to the new variable s to generate a sequence of approximate values $s_0, s_1, \ldots, s_j, \ldots$. The iteration can be written as

$$s_{j+1} = s_j + \Delta s_j,$$

where Δs_j is the jth correction.

We use the stopping criterion

$$|\Delta s_j| < c\varepsilon_M |s_{j+1}|, \tag{5.1}$$

where ε_M is the machine epsilon and c is a modest constant (which is set to 48 in our tests).

The procedure for the computation of ν_k $(k = 2, \ldots, n)$ is analogous.

5.2. Computation of λ_1.

1. Initial guess. The strategy for choosing starting values z_1^0 and starting intervals $[u_0, v_0]$ is slightly different than in the case of the other eigenvalues. Since we know that $\lambda_1 \in [0, \gamma_1)$, we first evaluate $\chi(m_1)$, where $m_1 = \gamma_1/2$. We use the sign of $\chi(m_1)$ to determine if λ_1 is closer to 0 or γ_1. We then use the root $z_1^0 \in [0, \gamma)$ of the equation

$$\frac{p_1}{\lambda - \gamma_1} + r_1 = 0,$$

with $r_1 = \chi(m_1) - p_1/(m_1 - \gamma_1)$, as the initial starting value.

If $\chi(m_1), \chi(z_1^0) < 0$, then we use m_1, z_1^0 to form the initial interval $[u_0, v_0]$. If $\chi(m_1), \chi(z_1^0) > 0$, then we replace m_1 by another value such that the corresponding χ value is negative, by using the fact $\lim_{\lambda \to \gamma_1^-}(\lambda) = -\infty$. In the case that $\chi(m_1), \chi(z_1^0) < 0$, if $\chi(0) > 0$, we replace m_1 with 0. If $\chi(0) = 0$, we still need to check the sign of $\chi'(0)$. If $\chi'(0) > 0$, we may use it to find a small positive number such that its corresponding χ is positive. We then replace m_1 with this number. If $\chi'(0) \leq 0$, we simply set $\lambda_1 = 0$, and no iteration is required.

Note that for the transport theory problem, $\chi(0)$ and $\chi'(0)$ can be easily determined by the formulas given in Remark 2.2.

2. Iteration step. We first use the same iteration steps as described for the eigenvalues λ_k, $k \geq 2$, to an approximation of λ_1. This usually works well for $\lambda_1 > c_1\sqrt{\varepsilon_M}$ with some positive constant c_1. If, however, λ_1 is too small, then it is difficult to get accurate function values for χ and χ', which then may cause convergence problems. In order to overcome this difficulty, once we observe that the jth approximate z_1^j satisfies $z_1^j < c_1\sqrt{\varepsilon_M}$ (we used $c_1 = 100$ in our tests), we evaluate $\chi(z_1^j)$ and $\chi'(z_1^j)$ by using their corresponding Taylor polynomials at 0, given by

$$\chi(z_1^j) \approx \chi(0) + z_1^j\chi'(0) + \frac{(z_1^j)^2}{2}\chi''(0),$$

$$\chi'(z_1^j) \approx \chi'(0) + z_1^j\chi''(0) + \frac{(z_1^j)^2}{2}\chi'''(0),$$

and use these values in the next step of the Newton iteration. If $\chi'(z_1^j)$ is also very small in modulus, then we approximate $\chi''(z_1^j)$ by

$$\chi''(z_1^j) \approx \chi''(0) + z_1^j\chi'''(0).$$

We then use the approximations for $\chi(z_1^j)$, $\chi'(z_1^j)$, $\chi''(z_1^j)$ to construct the second degree Taylor polynomial for χ at z_1^j and use one of the roots of this polynomial (if it exists) as our next iterate z_1^{j+1}.
For a general secular equation, the computation of $\chi(0)$, $\chi'(0)$, $\chi''(0)$, and $\chi'''(0)$ requires extra cost and it is not clear if the values can be evaluated accurately. In the secular equation from the transport problem, however, this computation is essentially cost-free since we may use the formulas in Remark 2.2, and because of the simple formulations the values can be computed accurately.

3. Stopping criterion. We use again the stopping criterion (5.1) (with $\gamma_0 := 0$).

The procedure for the computation of ν_1 is analogous.

5.3. Costs. The main cost in Algorithms 5.1–5.3 is the evaluation of χ and χ' during each iteration step. In order to evaluate $\chi(\lambda)$ and $\chi'(\lambda)$, we first compute $\lambda - \gamma_j$, $\lambda + \delta_j$ for $j = 1, \ldots, n$. We then compute $p_j/(\lambda - \gamma_j)$ and $p_j/(\lambda + \delta_j)$. After this $\chi(\lambda)$ can be evaluated. We continue to compute $[p_j/(\lambda - \gamma_j)]/(\lambda - \gamma_j)$ and $[p_j/(\lambda+\delta_j)]/(\lambda+\delta_j)]$, which costs one extra flop for each term, and then evaluate $\chi'(\lambda)$. So if the Newton iteration is used in the iteration step, then the cost per iteration step and per eigenvalue is about $10n$ flops. If the average number of iterations is M, then the cost for Algorithm 5.1 is about $(20M + 9)n^2$ flops, and the cost for Algorithms 5.2 and 5.3 is about $(10M + 9)n^2$ flops. Note that it requires $3n^2$ flops to compute each set of the values $\xi_k, \eta_k, \kappa_k, \epsilon_k$, and it requires another $3n^2$ flops to compute the components of X. Note also that in these complexity estimates we did not count the cost for the computation of the initial values.

5.4. Error analysis. To analyze the computational errors in the described procedures, we first estimate the errors in the computed eigenvalues; see also [30]. We assume that the iteration for each eigenvalue stops when (5.1) holds, and the computed sequence satisfies the conditions in the following lemma observed by Kahan (see, e.g., [24]).

LEMMA 5.4. $\{x_j\}_{j=1}^{\infty}$ $\lim_{j\to\infty} x_j = x^*$ $\frac{|x_{j+1}-x_j|}{|x_j-x_{j-1}|}$ $j \geq k$, $\frac{|x_{k+1}-x_k|}{|x_k-x_{k-1}|} < 1$

$$|x_{k+1} - x^*| < \frac{|x_{k+1} - x_k|^2}{|x_k - x_{k-1}| - |x_{k+1} - x_k|}.$$

Let λ_j, ν_j be the exact eigenvalues of H, and let $\hat{\lambda}_j$, $\hat{\nu}_j$ be the corresponding computed eigenvalues. With the discussed properties of the eigenvalues, the presented procedures, and Lemma 5.4, it is reasonable to assume that the computed eigenvalues satisfy

$$|\lambda_j - \hat{\lambda}_j| < C_{\lambda_j}\varepsilon_M \min\{\gamma_j - \lambda_j,\, \lambda_j - \gamma_{j-1}\}, \tag{5.2}$$

$$|\nu_j - \hat{\nu}_j| < C_{\nu_j}\varepsilon_M \min\{\delta_j - \nu_j,\, \nu_j - \delta_{j-1}\}, \tag{5.3}$$

for $j = 1, \ldots, n$, where $\gamma_0 = \delta_0 = 0$ and C_{λ_j}, C_{ν_j} are some modest constants. We then have the following lemma.

LEMMA 5.5. $\hat{\lambda}_j$, $-\hat{\nu}_j$, H (1.5) (5.2) (5.3). $\hat{\xi}_k$, $\hat{\eta}_k$, $\hat{\epsilon}_k$, $\hat{\kappa}_k$ 3.3.

$$\hat{\xi}_k = \xi_k(1 + nC_{\xi_k}\varepsilon_M), \quad \hat{\eta}_k = \eta_k(1 + nC_{\eta_k}\varepsilon_M),$$

$$\hat{\kappa}_k = \kappa_k(1 + nC_{\kappa_k}\varepsilon_M), \quad \hat{\epsilon}_k = \epsilon_k(1 + nC_{\epsilon_k}\varepsilon_M),$$

$k = 1, \ldots, n$, C_{ξ_k}, C_{η_k}, C_{κ_k}, C_{ϵ_k} . For the proof we just consider the first order error.

Note that $\hat{\xi}_k$ is actually computed by the formula

$$\prod_{j=1}^{n}(\gamma_k - \hat{\lambda}_j) / \prod_{j\neq k}(\gamma_k - \gamma_j);$$

i.e., λ_j is replaced with $\hat{\lambda}_j$. We then have

$$|\gamma_k - \hat{\lambda}_j| = |(\gamma_k - \lambda_j) + (\lambda_j - \hat{\lambda}_j)| = |\gamma_k - \lambda_j|\left|1 + \frac{\lambda_j - \hat{\lambda}_j}{\gamma_k - \lambda_j}\right| =: |\gamma_k - \lambda_j||1 + \tilde{C}_{kj}\varepsilon_M|,$$

for $j = 1, \ldots, n$, where by (5.2) and the interlacing property of the eigenvalues

$$|\tilde{C}_{kj}| = \frac{1}{\varepsilon_M}\left|\frac{\lambda_j - \hat{\lambda}_j}{\gamma_k - \lambda_j}\right| < C_{kj}\frac{\min\{\gamma_j - \lambda_j,\, \lambda_j - \gamma_{j-1}\}}{|\gamma_k - \lambda_j|} \leq C_{kj}.$$

With this relation, it is not difficult to obtain that

$$\hat{\xi}_k = \xi_k(1 + nC_{\xi_k}\varepsilon_M),$$

where C_{ξ_k} is a constant. The corresponding relations for the other terms follow in the same way. □

Using this lemma we obtain the following relative errors for the components of the minimal positive solution computed by the formulas given in section 3.

THEOREM 5.6. $X = [x_{ij}]$ (1.1) (3.8)–(3.11) (5.2) (5.3) $\hat{X} = [\hat{x}_{ij}]$

$$\frac{|\hat{x}_{ij} - x_{ij}|}{x_{ij}} = D_{ij} n \varepsilon_M, \qquad i, j = 1, \ldots, n$$

D_{ij} . The relative error estimates follow from Lemma 5.5. □

6. Numerical examples. In this section we present some numerical test results for the problems from transport theory; see [20, 21]. The weights $c_1, \ldots, c_n$ and nodes $\omega_1, \ldots, \omega_n$ are generated from the composite four-node Gauß–Legendre quadrature formula on [0, 1] with $n/4$ equally spaced subintervals; see, e.g., [29]. All the numerical examples were tested in MATLAB version 7.1.0 with machine precision $\varepsilon_M \approx 2.22e-16$. We solved the problem for various numbers of the parameters α and β and the size n. We used all four formulas to compute the minimal positive solution, with a secular equation solver as described in section 5.

The computed minimal positive solutions via formulas (3.8)–(3.11) are denoted by $X^{(1)}, X^{(2)}, X^{(3)}, X^{(4)}$, respectively. In the following we display the test results. We present one table for each pair (α, β) and various values of n. (The used norm is always the spectral norm.) In each of Tables 6.1–6.6, we list the following results:

- Maximum residual:

$$R = \max_{j \in \{1,2,3,4\}} \|X^{(j)}\Gamma + \Delta X^{(j)} - (e + X^{(j)}p)(e^T + p^T X^{(j)})\|.$$

- Maximum and minimum entrywise relative errors:

$$RE_{\max} = \max_{\substack{i,j \in \{1,2,3,4\} \\ i \neq j}} \max_{k,l \in \{1,\ldots,n\}} \frac{|x_{kl}^{(i)} - x_{kl}^{(j)}|}{\min\{x_{kl}^{(i)}, x_{kl}^{(j)}\}},$$

$$RE_{\min} = \min_{\substack{i,j \in \{1,2,3,4\} \\ i \neq j}} \max_{k,l \in \{1,\ldots,n\}} \frac{|x_{kl}^{(i)} - x_{kl}^{(j)}|}{\min\{x_{kl}^{(i)}, x_{kl}^{(j)}\}}.$$

- Largest entry x_{11} (determined by one of the four solutions).
- Smallest entry x_{nn} (determined by one of the four solutions).
- Norm $\|X\|$ (X is one of the four solutions). Note that we have proved that $\|\tilde{X}\| \leq 1$, which translates to $\|X\| \leq 1/\min p_j$.
- Number of iterations for ν_1: N_-.
- Number of iterations for λ_1: N_+.
- Average of the number of iterations for all $2n$ eigenvalues: N.

We also give the eigenvalues $-\nu_1, \lambda_1$ in the caption.

We can summarize the numerical results as follows.

1. The values of R in the tables are usually the residual of $X^{(1)}$. The other residuals are basically the same, but some can be one order smaller.
2. Since we do not know the exact solution, we use $RE_{\max}$ and $RE_{\min}$ to detect if high relative accuracy can actually be achieved. The values of $RE_{\max}$ and $RE_{\min}$ do support the high relative accuracy result. (Note that x_{nn} is small in all examples.)

3. The number of iterations for ν_1 and λ_1 increases as $\alpha \to 0$ and $\beta \to 1$. This shows the numerical difficulty when the eigenvalues $-\nu_1$ and λ_1 are getting close to each other. However, our computed values of ν_1, λ_1 are much more accurate than those obtained by running the MATLAB code .. on $\tilde{H}$.
4. Our MATLAB implementation of the root finder based on the secular equation is still not very robust. In general, about .5% of the eigenvalues need 100 iterations, the maximum iteration number used in our experimental code. Some further improvement could enhance these convergence properties.

7. Conclusion. We have presented four formulas for the minimal positive solution of the nonsymmetric Riccati equation (1.1) that depend on the eigenvalues of the associated matrix. With the help of the formulas we have given some properties and entrywise bounds for the minimal positive solution. We have used the formulas to develop fast numerical algorithms for computing the minimal positive solution. If the eigenvalues can be computed accurately, then the computed minimal positive solution has high relative accuracy.

Acknowledgments. We thank an anonymous referee for suggestions that helped to improve this paper. Hongguo Xu wishes to gratefully acknowledge the hospitality of TU Berlin, where part of this research was carried out.

A NOTE ON BACKWARD ERROR ANALYSIS OF THE GENERALIZED SINGULAR VALUE DECOMPOSITION*

XIAO-SHAN CHEN† AND WEN LI†

Abstract. In terms of the generalized singular value decomposition, we define the generalized singular matrix sets and their backward errors. The explicit expressions of backward errors are derived, which extend a result of Sun [*SIAM J. Matrix Anal. Appl.*, 22 (2000), pp. 323–341]. The results are illustrated by a numerical example.

Key words. generalized singular matrix set, backward error, spectral norm, Frobenius norm

1. Introduction.

The generalized singular value decomposition (GSVD) of two matrices having the same number of columns, first proposed by Van Loan [13], is a very useful tool in many matrix computation problems. Numerical methods and perturbation analysis of the GSVD have been developed (e.g., see [1, 2, 4, 8, 9, 10, 12]). In this paper, we discuss the backward errors for the GSVD and derive their explicit expressions.

Throughout this paper, we always use the following notations. Let $\mathcal{C}^{m\times n}$ be the set of $m \times n$ complex matrices, and let $\mathcal{C}^m = \mathcal{C}^{m\times 1}$ and $\mathcal{C} = \mathcal{C}^1$. The symbol I_p stands for the identity matrix of order p. By A^T, A^*, and $A^\dagger$ we denote the transpose, conjugate transpose, and Moore–Penrose inverse of a matrix A, respectively. $P_A = AA^\dagger$ is the orthogonal projection onto the column space of A and $P_A^\perp = I - P_A$. We use $\|\cdot\|_2, \|\cdot\|_F$, and $\|\cdot\|_\infty$ for the Euclidean vector norm and the spectral norm, Frobenius norm, and ∞-norm, respectively.

Let $A \in \mathcal{C}^{m\times n}$ and $B \in \mathcal{C}^{p\times n}$. The matrix pair $\{A, B\}$ is called an (m, p, n)-Grassmann matrix pair (GMP) if $\operatorname{rank}(A^T, B^T) = n$. In [6] Paige and Saunders obtained the following GSVD of the (m, p, n)-GMP.

THEOREM 1.1. $\{A, B\}$ (m, p, n) $U \in \mathcal{R}^{m\times m}, V \in \mathcal{R}^{p\times p}$ $X \in \mathcal{R}^{n\times n}$

$$U^*AX = \begin{pmatrix} D_\alpha & & \\ & 0_{(m-r-s)\times(n-r-s)} & \end{pmatrix}, \quad V^*BX = \begin{pmatrix} 0_{(p+r-n)\times r} & & \\ & & D_\beta \end{pmatrix}, \tag{1.1}$$

$0_{k\times l}$ $k \times l$

$$D_\alpha = \operatorname{diag}(\alpha_1, \ldots, \alpha_{r+s}), \quad D_\beta = \operatorname{diag}(\beta_{r+1}, \ldots, \beta_n) \tag{1.2}$$

$$1 = \alpha_1 = \cdots = \alpha_r > \alpha_{r+1} \geq \cdots \geq \alpha_{r+s} > \alpha_{r+s+1} = \cdots = \alpha_n = 0, \tag{1.3}$$

$$0 = \beta_1 = \cdots = \beta_r < \beta_{r+1} \leq \cdots \leq \beta_{r+s} < \beta_{r+s+1} = \cdots = \beta_n = 1, \tag{1.4}$$

$$\alpha_j^2 + \beta_j^2 = 1 \quad \forall j. \tag{1.5}$$

Let $\{A, B\}$ be an (m, p, n)-GMP with the GSVD given by (1.1)–(1.5). Then $\{(\alpha_j, \beta_j)\}_{j=1}^n$ are the generalized singular values (GSVs) of $\{A, B\}$, and every column x_j of the matrix X of (1.1) is a right generalized singular vector of $\{A, B\}$ associated with (α_j, β_j).

Let l be a natural number satisfying $\max\{n-p, 0\} < l < \min\{m, n\}$. From (1.1)–(1.5) we obtain formally

$$A(X_1, X_2) = (U_1, U_2)\begin{pmatrix} A_{11} & 0 \\ 0 & A_{22} \end{pmatrix}, \quad B(X_1, X_2) = (V_1, V_2)\begin{pmatrix} B_{11} & 0 \\ 0 & B_{22} \end{pmatrix} \tag{1.6}$$

and

$$A^*(U_1, U_2) = (Y_1, Y_2)\begin{pmatrix} A_{11}^* & 0 \\ 0 & A_{22}^* \end{pmatrix}, \quad B^*(V_1, V_2) = (Y_1, Y_2)\begin{pmatrix} B_{11}^* & 0 \\ 0 & B_{22}^* \end{pmatrix}, \tag{1.7}$$

where $A_{11} \in \mathcal{C}^{l\times l}$, $B_{11} \in \mathcal{C}^{(p+l-n)\times l}$, and the matrices $(U_1, U_2) \in \mathcal{C}^{m\times m}$, $(V_1, V_2) \in \mathcal{C}^{p\times p}$ with $U_1 \in \mathcal{C}^{m\times l}$, $V_1 \in \mathcal{C}^{p\times(p+l-n)}$ are unitary, and $X = (X_1, X_2) \in \mathcal{C}^{n\times n}$, $Y = X^{-*} = (Y_1, Y_2)$ with X_1, $Y_1 \in \mathcal{C}^{n\times l}$ are nonsingular.

From the relations (1.6) and (1.7) we have

$$\begin{aligned} &AX_1 = U_1A_{11}, \quad BX_1 = V_1B_{11}, \quad A^*U_1 = Y_1A_{11}^*, \quad B^*V_1 = Y_1B_{11}^*, \\ &Y_1^*X_1 = U_1^*U_1 = I_l, \quad V_1^*V_1 = I_{p+l-n}. \end{aligned} \tag{1.8}$$

The matrix set $\{X_1, Y_1, U_1, V_1\}$ of (1.8) is called a generalized singular matrix set of $\{A,\ B\}$ associated with the $(l, p+l-n, l)$-GMP $\{A_{11}, B_{11}\}$.

Let $\{\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ be an approximate generalized singular matrix set of $\{A,\ B\}$ associated with an approximate $(l, p+l-n, l)$-GMP $\{\widetilde{A}_{11}, \widetilde{B}_{11}\}$; that is, the matrices $\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1$ and $\widetilde{V}_1$ satisfy

$$\begin{aligned} &A\,\widetilde{X}_1 \approx \widetilde{U}_1\widetilde{A}_{11}, \quad B\,\widetilde{X}_1 \approx \widetilde{V}_1\widetilde{B}_{11}, \quad A^*\,\widetilde{U}_1 \approx \widetilde{Y}_1\widetilde{A}_{11}^*, \quad B^*\,\widetilde{V}_1 \approx \widetilde{Y}_1\widetilde{B}_{11}^*, \\ &\widetilde{Y}_1^*\widetilde{X}_1 = \widetilde{U}_1^*\widetilde{U}_1 = I_l, \quad \widetilde{V}_1^*\widetilde{V}_1 = I_{p+l-n}. \end{aligned}$$

We always assume that γ_A and γ_B are positive parameters.

Now we define the set $\mathcal{E}_1$ by

$$\mathcal{E}_1 = \left\{ \begin{pmatrix} E \\ F \end{pmatrix} : \begin{array}{ll} (A+E)\,\widetilde{X}_1 = \widetilde{U}_1\widetilde{A}_{11}, & (A+E)^*\,\widetilde{U}_1 = \widetilde{Y}_1\widetilde{A}_{11}^*, \\ (B+F)\,\widetilde{X}_1 = \widetilde{V}_1\widetilde{B}_{11}, & (B+F)^*\,\widetilde{V}_1 = \widetilde{Y}_1\widetilde{B}_{11}^* \end{array} \right\}, \tag{1.9}$$

and define the backward errors $\eta_2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$ and $\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$ of $\{A,\ B\}$ with respect to the approximate generalized singular matrix set $\{\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ associated with the approximate $(l, p+l-n, l)$-GMP $\{\widetilde{A}_{11}, \widetilde{B}_{11}\}$ by

$$\eta_2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = \min_{\left(\begin{smallmatrix} E \\ F \end{smallmatrix}\right) \in \mathcal{E}_1} \left\| \left(\frac{\|E\|_2}{\gamma_A}, \frac{\|F\|_2}{\gamma_B} \right) \right\|_\infty \tag{1.10}$$

and

$$\eta_F(\{\widetilde{A}_{11},\widetilde{B}_{11}\},\widetilde{X}_1,\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)=\min_{\left(\begin{smallmatrix}E\\F\end{smallmatrix}\right)\in\mathcal{E}_1}\left\|\left(\frac{E}{\gamma_A},\ \frac{F}{\gamma_B}\right)\right\|_F, \tag{1.11}$$

respectively.

In some applications (e.g., investigating the generalized singular subspace group [4, 8, 10]) we only need an approximate matrix set $\{\widetilde{X}_1,\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1\}$, while $\{\widetilde{A}_{11},\widetilde{B}_{11}\}$ is not available. Hence we define the backward error $\eta_F(\widetilde{X}_1,\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)$ of $\{A,\ B\}$ with respect to the approximate generalized singular matrix set $\{\widetilde{X}_1,\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1\}$ by

$$\eta_F(\widetilde{X}_1,\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)=\min_{\left(\begin{smallmatrix}E\\F\end{smallmatrix}\right)\in\mathcal{E}_2}\left\|\left(\frac{E}{\gamma_A},\frac{F}{\gamma_B}\right)\right\|_F, \tag{1.12}$$

where

$$\mathcal{E}_2=\left\{\begin{pmatrix}E\\F\end{pmatrix}:\ \begin{array}{ll}(A+E)\ \widetilde{X}_1=\widetilde{U}_1\widetilde{A}_1, & (A+E)^*\ \widetilde{U}_1=\widetilde{Y}_1\widetilde{A}_1^*,\\ (B+F)\ \widetilde{X}_1=\widetilde{V}_1\widetilde{B}_1, & (B+F)^*\ \widetilde{V}_1=\widetilde{Y}_1\widetilde{B}_1^*,\\ \{\widetilde{A}_1,\widetilde{B}_1\}\text{ is an }(l,p+l-n,l)\text{-GMP}\end{array}\right\}. \tag{1.13}$$

It is well known that numerical algorithms for computing the GSVD do not produce the factors X_1 and Y_1 simultaneously (e.g., see [1, 5]). So, one needs to invert Y^* in order to get X_1. Hence if Y is very ill-conditioned, this inversion will introduce additional errors. Hence we also define the backward error $\eta_F(\{\widetilde{A}_{11},\widetilde{B}_{11}\},\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)$ with respect to an approximate generalized singular matrix set $\{\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1\}$ associated with an approximate $(l,p+l-n,l)$-GMP $\{\widetilde{A}_{11},\widetilde{B}_{11}\}$ by

$$\eta_F(\{\widetilde{A}_{11},\widetilde{B}_{11}\},\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)=\min_{\left(\begin{smallmatrix}E\\F\end{smallmatrix}\right)\in\mathcal{E}_3}\left\|\left(\frac{E}{\gamma_A},\frac{F}{\gamma_B}\right)\right\|_F, \tag{1.14}$$

where

$$\mathcal{E}_3=\left\{\begin{pmatrix}E\\F\end{pmatrix}:\ (A+E)^*\ \widetilde{U}_1=\widetilde{Y}_1\widetilde{A}_{11}^*,\quad (B+F)^*\ \widetilde{V}_1=\widetilde{Y}_1\widetilde{B}_{11}^*\right\}. \tag{1.15}$$

Similarly to (1.12) we also define the backward error $\eta_F(\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)$ of $\{A,B\}$ with respect to the approximate generalized singular matrix set $\{\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1\}$ by

$$\eta_F(\widetilde{Y}_1,\widetilde{U}_1,\widetilde{V}_1)=\min_{\left(\begin{smallmatrix}E\\F\end{smallmatrix}\right)\in\mathcal{E}_4}\left\|\left(\frac{E}{\gamma_A},\frac{F}{\gamma_B}\right)\right\|_F, \tag{1.16}$$

where

$$\mathcal{E}_4=\left\{\begin{pmatrix}E\\F\end{pmatrix}:\ \begin{array}{ll}(A+E)^*\ \widetilde{U}_1=\widetilde{Y}_1\widetilde{A}_1^*, & (B+F)^*\ \widetilde{V}_1=\widetilde{Y}_1\widetilde{B}_1^*,\\ \{\widetilde{A}_1,\widetilde{B}_1\}\text{ is an }(l,p+l-n,l)\text{-GMP}\end{array}\right\}. \tag{1.17}$$

1.1. Taking $\gamma_A = \gamma_B = 1$, the above errors are called the absolute backward errors; and taking $\gamma_A = \|A\|_F$ and $\gamma_B = \|B\|_F$ in (1.11), (1.12), (1.14), and (1.16), and taking $\gamma_A = \|A\|_2$ and $\gamma_B = \|B\|_2$ in (1.10), the above errors are called the relative backward errors.

1.2. By definitions of $\mathcal{E}_1, \mathcal{E}_2, \mathcal{E}_3$, and $\mathcal{E}_4$, it is easy to see that

$$\mathcal{E}_1 \subset \mathcal{E}_2, \quad \mathcal{E}_3 \subset \mathcal{E}_4, \quad \mathcal{E}_1 \subset \mathcal{E}_3, \quad \mathcal{E}_2 \subset \mathcal{E}_4.$$

Hence we have

$$\eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \le \eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1),$$

$$\eta_F(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \le \eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1),$$

$$\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \le \eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1),$$

and

$$\eta_F(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \le \eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1).$$

From the definitions of the backward errors, we know that a small backward error means that the approximate solution of a problem is the exact one of a slightly perturbed problem. For example, a small $\eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$ means that the approximate generalized singular matrix set $\{\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ is the exact generalized singular matrix set of a slightly perturbed $\{\widetilde{A}, \widetilde{B}\}$ of $\{A, B\}$. Consequently, a computable formula of the backward error may be useful for assessing the numerical quality of a computed GSVD and for testing the backward stability of algorithms for the computation of the GSVD.

The rest of this paper is organized as follows. In section 2, we shall derive explicit expressions of the backward errors of $\eta_2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$, $\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$, $\eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$, $\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{U}_1, \widetilde{V}_1)$, and $\eta_F(\widetilde{X}_1, \widetilde{U}_1, \widetilde{V}_1)$, respectively. We extend a result of Sun [12] to the generalized singular matrix set. In section 3, the results are illustrated by a numerical example.

2. Expressions of backward errors. In order to obtain the explicit expressions of backward errors for the GSVD, we need the following lemmas.

LEMMA 2.1 (see [12]). Let $A \in \mathcal{C}^{k\times m}, B \in \mathcal{C}^{n\times l}$, and $C \in \mathcal{C}^{k\times l}$. Define

$$\mathcal{E} = \{E \in \mathcal{C}^{m\times n} : \ AEB = C\}.$$

Then $\mathcal{E} \neq \emptyset$ (i.e., the matrix equation $AEB = C$ is consistent) for any A, B, and C if and only if

$$P_A C P_{B^*} = C,$$

where P_A and P_{B^*} denote the orthogonal projections onto the range of A and the range of B^*, respectively. In this case, the general solution of $AEB = C$ can be expressed as

$$E = A^\dagger C B^\dagger + Z - P_{A^*} Z P_B, \quad Z \in \mathcal{C}^{m\times n}.$$

LEMMA 2.2. Let $A \in \mathcal{C}^{m\times n}, U_1 \in \mathcal{C}^{m\times l}, A_1 \in \mathcal{C}^{l\times r}$, and $X_1, Y_1 \in \mathcal{C}^{n\times r}$ with $U_1^* U_1 = I_l, \operatorname{rank}(X_1) = r$. Then

$$\mathcal{G} = \left\{E \in \mathcal{C}^{m\times n} : \ (A+E)X_1 = U_1 A_1, \quad (A+E)^* U_1 = Y_1 A_1^*\right\}. \tag{2.1}$$

$X_1 = W_1 H$ X_1 $W_1^* W_1 = I_r$ H $U_2 \in \mathcal{C}^{m\times(m-l)}$, $W_2 \in \mathcal{C}^{n\times(n-r)}$ $U = (U_1, U_2)$ $W = (W_1, W_2)$ $\mathcal{G} \neq \emptyset$ $E \in \mathcal{G}$

$$E = U \begin{pmatrix} U_1^*(U_1A_1 - AX_1)H^{-1} & (A_1Y_1^* - U_1^*A)W_2 \\ -U_2^*AW_1 & U_2^*LW_2 \end{pmatrix} W^*, \quad L \in \mathcal{C}^{m\times n}. \tag{2.2}$$

. From (2.1), we know that $E \in \mathcal{G}$ if and only if E satisfies

$$EX_1 = U_1A_1 - AX_1, \quad E^*U_1 = Y_1A_1^* - A^*U_1. \tag{2.3}$$

Applying Lemma 2.1 to the first equation of (2.3), it is easy to see that the equation is solvable and any solution E can be expressed as

$$E = (U_1A_1 - AX_1)X_1^\dagger + Z(I - X_1X_1^\dagger), \quad Z \in \mathcal{C}^{m\times n}. \tag{2.4}$$

Since $X_1^\dagger = H^{-1}W_1^*$ and $X_1X_1^\dagger = W_1W_1^*$, (2.4) can be written as

$$E = (U_1A_1 - AX_1)H^{-1}W_1^* + ZW_2W_2^*, \tag{2.5}$$

which together with the second equation of (2.3) gives

$$W_1H^{-1}(U_1A_1 - AX_1)^*U_1 + W_2W_2^*Z^*U_1 = Y_1A_1^* - A^*U_1.$$

Multiplying the above equation by W_2^* on the left-hand side yields

$$U_1^*ZW_2 = (Y_1A_1^* - A^*U_1)^*W_2. \tag{2.6}$$

By Lemma 2.1, (2.6) is solvable, and any solution Z can be expressed as

$$Z = U_1(A_1Y_1^* - U_1^*A)W_2W_2^* + L - U_1U_1^*LW_2W_2^*, \quad L \in \mathcal{C}^{m\times n}. \tag{2.7}$$

Substituting (2.7) into (2.5) gives

$$E = (U_1A_1 - AX_1)H^{-1}W_1^* + U_1(A_1Y_1^* - U_1^*A)W_2W_2^* + U_2U_2^*LW_2W_2^*, \quad L \in \mathcal{C}^{m\times n},$$

from which (2.2) follows immediately. □

Sun [11] provided the following lemma, which can be found in [7].

LEMMA 2.3 (see [11]). . $F \in \mathcal{C}^{p\times m}, G \in \mathcal{C}^{n\times q}, and\ K \in \mathcal{C}^{p\times q}$ $X_* = F^\dagger KG^\dagger$.

$$\min_{X\in\mathcal{C}^{m\times n}} \|FXG - K\|_F = \|FX_*G - K\|_F.$$

LEMMA 2.4 (see [3]). .

$$f(X) = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & X \end{pmatrix}$$

$A_{11} \in \mathcal{C}^{k\times k}$ $A_{21}, A_{12}^T \in \mathcal{C}^{l\times k}$.

$$\min_{X\in\mathcal{C}^{l\times l}} \|f(X)\|_2 = \max\left\{ \left\| \begin{pmatrix} A_{11} \\ A_{21} \end{pmatrix} \right\|_2, \ \|(A_{11},\ A_{12})\|_2 \right\}.$$

The following theorem gives explicit expressions of $\eta_2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$ and $\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$.

THEOREM 2.1. $\widetilde{U}_1 \in \mathcal{C}^{m\times l}, \widetilde{V}_1 \in \mathcal{C}^{p\times(p+l-n)}, \widetilde{X}_1, \widetilde{Y}_1 \in \mathcal{C}^{n\times l}, \widetilde{A}_{11} \in \mathcal{C}^{l\times l}$, $\widetilde{B}_{11} \in \mathcal{C}^{(p+l-n)\times l}$ $\widetilde{X}_1^* \widetilde{Y}_1 = \widetilde{U}_1^* \widetilde{U}_1 = I_l, \widetilde{V}_1^* \widetilde{V}_1 = I_{p+l-n}$. $\{\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ (m, p, n) $\{A, B\}$ $\{\widetilde{A}_{11}, \widetilde{B}_{11}\}$

$$\eta_2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \tag{2.8}$$
$$= \max\left\{ \frac{1}{\gamma_A} \max\left\{ \left\| R_1 \widetilde{X}_1^\dagger \right\|_2, \|R_3\|_2 \right\}, \frac{1}{\gamma_B} \max\left\{ \left\| R_2 \widetilde{X}_1^\dagger \right\|_2, \|R_4\|_2 \right\} \right\}$$

$$\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \tag{2.9}$$
$$= \sqrt{\begin{aligned} &\frac{1}{\gamma_A^2}\left(\|R_3\|_F^2 + \left\| R_1 \widetilde{X}_1^\dagger \right\|_F^2 - \left\| \widetilde{U}_1^* R_1 \widetilde{X}_1^\dagger \right\|_F^2 \right) \\ &\quad + \frac{1}{\gamma_B^2}\left(\|R_4\|_F^2 + \left\| R_2 \widetilde{X}_1^\dagger \right\|_F^2 - \left\| \widetilde{V}_1^* R_2 \widetilde{X}_1^\dagger \right\|_F^2 \right), \end{aligned}}$$

$$\begin{aligned} R_1 &= \widetilde{U}_1 \widetilde{A}_{11} - A \widetilde{X}_1, R_2 = \widetilde{V}_1 \widetilde{B}_{11} - B \widetilde{X}_1, \\ R_3 &= \widetilde{Y}_1 \widetilde{A}_{11}^* - A^* \widetilde{U}_1, \text{and } R_4 = \widetilde{Y}_1 \widetilde{B}_{11}^* - B^* \widetilde{V}_1. \end{aligned} \tag{2.10}$$

. From (1.9), we know that $\binom{E}{F} \in \mathcal{E}_1$ if and only if E and F satisfy

$$(A + E)\widetilde{X}_1 = \widetilde{U}_1 \widetilde{A}_{11}, \quad (A + E)^* \widetilde{U}_1 = \widetilde{Y}_1 \widetilde{A}_{11}^* \tag{2.11}$$

and

$$(B + F)\widetilde{X}_1 = \widetilde{V}_1 \widetilde{B}_{11}, \quad (B + F)^* \widetilde{V}_1 = Y_1 B_{11}^*. \tag{2.12}$$

Let $\widetilde{X}_1 = \widetilde{W}_1 \widetilde{H}$ be the polar decomposition of $\widetilde{X}_1$, where $\widetilde{W}_1^* \widetilde{W}_1 = I_r$ and $\widetilde{H}$ is a Hermitian positive definite matrix, and choose $\widetilde{U}_2 \in \mathcal{C}^{m\times(m-l)}, \widetilde{W}_2 \in \mathcal{C}^{n\times(n-l)}$, and $\widetilde{V}_2 \in \mathcal{C}^{p\times(n-l)}$ so that $\widetilde{U} = (\widetilde{U}_1, \widetilde{U}_2), \widetilde{W} = (\widetilde{W}_1, \widetilde{W}_2)$, and $\widetilde{V} = (\widetilde{V}_1, \widetilde{V}_2)$ are unitary. By (2.10) we have

$$\widetilde{U}_2^* R_1 \widetilde{H}^{-1} = -\widetilde{U}_2^* A \widetilde{W}_1 \quad \text{and} \quad \widetilde{V}_2^* R_2 \widetilde{H}^{-1} = -\widetilde{V}_2^* A \widetilde{W}_1.$$

Thus applying Lemma 2.2 to (2.11) and (2.12) gives

$$E = \widetilde{U} \begin{pmatrix} \widetilde{U}_1^* R_1 \widetilde{H}^{-1} & R_3^* \widetilde{W}_2 \\ \widetilde{U}_2^* R_1 \widetilde{H}^{-1} & \widetilde{U}_2^* L \widetilde{W}_2 \end{pmatrix} \widetilde{W}^* \equiv E(L), \quad L \in \mathcal{C}^{m\times n}, \tag{2.13}$$

and

$$F = \widetilde{V}\begin{pmatrix} \widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1} & R_4^*\, \widetilde{W}_2 \\ \widetilde{V}_2^*\, R_2\, \widetilde{H}^{-1} & \widetilde{V}_2^*\, N\, \widetilde{W}_2 \end{pmatrix} \widetilde{W}^* \equiv F(N), \quad N \in \mathcal{C}^{p\times n}, \tag{2.14}$$

respectively, where R_1, R_2, R_3, and R_4 are given by (2.10). From Lemma 2.4 and (2.13) and (2.14), we obtain

$$\min_{L\in\mathcal{C}^{m\times n}} \frac{1}{\gamma_A}\|E(L)\|_2 = \frac{1}{\gamma_A}\max\left\{\left\|\begin{pmatrix} \widetilde{U}_1^*\, R_1\, \widetilde{H}^{-1} \\ \widetilde{U}_2^*\, R_1\, \widetilde{H}^{-1} \end{pmatrix}\right\|_2, \quad \left\|\left(\widetilde{U}_1^*\, R_1\, \widetilde{H}^{-1},\, R_3^*\, \widetilde{W}_2\right)\right\|_2\right\} \tag{2.15}$$

and

$$\min_{N\in\mathcal{C}^{p\times n}} \frac{1}{\gamma_B}\|F(N)\|_2 = \frac{1}{\gamma_B}\max\left\{\left\|\begin{pmatrix} \widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1} \\ \widetilde{V}_2^*\, R_2\, \widetilde{H}^{-1} \end{pmatrix}\right\|_2, \quad \left\|\left(\widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1},\, R_4^*\, \widetilde{W}_2\right)\right\|_2\right\}. \tag{2.16}$$

The equations $\widetilde{X}_1 = \widetilde{W}_1\widetilde{H}$ and $\widetilde{Y}_1^*\widetilde{X}_1 = I$ imply that $\widetilde{X}_1\widetilde{H}^{-1} = \widetilde{W}_1$ and $\widetilde{H}^{-1} = \widetilde{Y}_1^*\widetilde{W}_1$, which together with (2.10) gives

$$\widetilde{U}_1^*\, R_1\, \widetilde{H}^{-1} = R_3^*\, \widetilde{W}_1, \quad \widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1} = R_4^*\, \widetilde{W}_1. \tag{2.17}$$

Clearly,

$$\left\|R_1\, \widetilde{H}^{-1}\right\|_2 = \left\|R_1\, \widetilde{X}_1^{\dagger}\right\|_2, \quad \left\|R_2\, \widetilde{H}^{-1}\right\|_2 = \left\|R_2\, \widetilde{X}_1^{\dagger}\right\|_2. \tag{2.18}$$

Combining (1.10) with (2.15)–(2.18) yields (2.8).

Now we prove (2.9). By (1.11), (2.13), (2.14), and (2.17) we have

$$\begin{aligned}
&\eta_F^2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \\
&\quad = \min_{L\in\mathcal{C}^{m\times n}} \frac{1}{\gamma_A^2}\,\|E(L)\|_F^2 + \min_{N\in\mathcal{C}^{p\times n}} \frac{1}{\gamma_B^2}\,\|F(N)\|_F^2 \\
&\quad = \frac{1}{\gamma_A^2}\left(\left\|\widetilde{U}_1^*\, R_1\, \widetilde{H}^{-1}\right\|_F^2 + \left\|\widetilde{U}_2^*\, R_1\, \widetilde{H}^{-1}\right\|_F^2 + \left\|R_3^*\, \widetilde{W}_2\right\|_F^2\right) \\
&\qquad + \frac{1}{\gamma_B^2}\left(\left\|\widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1}\right\|_F^2 + \left\|\widetilde{V}_2^*\, R_2\, \widetilde{H}^{-1}\right\|_F^2 + \left\|R_4^*\, \widetilde{W}_2\right\|_F^2\right) \\
&\quad = \frac{1}{\gamma_A^2}\left(\left\|R_1\, \widetilde{H}^{-1}\right\|_F^2 + \|R_3\|_F^2 - \left\|\widetilde{U}_1^*\, R_1\, \widetilde{H}^{-1}\right\|_F^2\right) \\
&\qquad + \frac{1}{\gamma_B^2}\left(\left\|R_2\, \widetilde{H}^{-1}\right\|_F^2 + \|R_4\|_F^2 - \left\|\widetilde{V}_1^*\, R_2\, \widetilde{H}^{-1}\right\|_F^2\right),
\end{aligned}$$

from which (2.9) follows immediately. □

2.1. It is noted that the result of Sun [12] can be derived from (2.8). Let $(\widetilde{\alpha},\ \widetilde{\beta}) \neq (0,\ 0)$ with $\widetilde{\alpha}, \widetilde{\beta} \geq 0$ be an approximate GSV of an (m,p,n)-GMP$\{A,\ B\}$, and let $\{\widetilde{x}, \widetilde{y}, \widetilde{u}, \widetilde{v}\}$ be an associated approximate generalized singular vector set, that is, the vectors $\widetilde{x}, \widetilde{y} \in \mathcal{C}^n, \widetilde{u} \in \mathcal{C}^m$, and $\widetilde{v} \in \mathcal{C}^p$ satisfy

$$A\ \widetilde{x} \approx \widetilde{\alpha}\widetilde{u}, \quad B\ \widetilde{x} \approx \widetilde{\beta}\widetilde{v}, \quad A^*\ \widetilde{u} \approx \widetilde{\alpha}\widetilde{y}, \quad B^*\ \widetilde{v} \approx \widetilde{\beta}\widetilde{y},$$

$$\widetilde{y}^*\widetilde{x} = 1, \quad \|\ \widetilde{u}\ \|_2 = \|\ \widetilde{v}\ \|_2 = 1.$$

Let

$$r_1 = \widetilde{\alpha}\widetilde{u} - A\ \widetilde{x}, \qquad r_2 = \widetilde{\beta}\widetilde{v} - B\ \widetilde{x},$$

$$r_3 = \widetilde{\alpha}\widetilde{y} - A^*\ \widetilde{u}, \qquad r_4 = \widetilde{\beta}\widetilde{y} - B^*\ \widetilde{v}.$$

Then by (2.8) and (2.9) we can obtain

$$\eta_2((\widetilde{\alpha},\widetilde{\beta}),\widetilde{x},\widetilde{y},\widetilde{u},\widetilde{v})$$

$$= \max\left\{\frac{1}{\gamma_A}\max\left\{\frac{\|r_1\|_2}{\|\ \widetilde{x}\ \|_2},\ \|r_3\|_2\right\}, \frac{1}{\gamma_B}\max\left\{\frac{\|r_2\|_2}{\|\ \widetilde{x}\ \|_2},\ \|r_4\|_2\right\}\right\},$$

which was proved by Sun [12] and

$$\eta_F((\widetilde{\alpha},\widetilde{\beta}),\widetilde{x},\widetilde{y},\widetilde{u},\widetilde{v})$$

$$= \sqrt{\frac{1}{\gamma_A^2}\left(\|r_3\|_2^2 + \frac{\|r_1\|_2^2}{\|\ \widetilde{x}\ \|_2^2} - \frac{|\ \widetilde{u}^*\ r_1|^2}{\|\ \widetilde{x}\ \|_2^2}\right) + \frac{1}{\gamma_B^2}\left(\|r_4\|_2^2 + \frac{\|r_2\|_2^2}{\|\ \widetilde{x}\ \|_2^2} - \frac{|\ \widetilde{v}^*\ r_2|^2}{\|\ \widetilde{x}\ \|_2^2}\right)},$$

respectively.

Next we give the expression of $\eta_F(\ \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\ )$.

THEOREM 2.2. $\widetilde{U}_1 \in \mathcal{C}^{m\times l}, \widetilde{V}_1 \in \mathcal{C}^{p\times(p+l-n)}$ $\widetilde{X}_1, \widetilde{Y}_1 \in \mathcal{C}^{n\times l}$ $\widetilde{U}_1^*\widetilde{U}_1 = \widetilde{X}_1^*\widetilde{Y}_1 = I_l$ $\widetilde{V}_1^*\widetilde{V}_1 = I_{p+l-n}$ $\{\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ (m,p,n) $GMP\{A,\ B\}$ $\{\widetilde{U}_1^*\ A\ \widetilde{Y}_1^{\dagger *},\ \widetilde{V}_1^*\ B\ \widetilde{Y}_1^{\dagger *}\}$ $(l, p+l-n, l)$

$$\eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) \tag{2.19}$$

$$= \sqrt{\frac{1}{\gamma_A^2}\left(\left\|P_{\widetilde{U}_1}^{\perp} A P_{\widetilde{X}_1}\right\|_F^2 + \left\|P_{\widetilde{U}_1} A P_{\widetilde{Y}_1}^{\perp}\right\|_F^2\right) + \frac{1}{\gamma_B^2}\left(\left\|P_{\widetilde{V}_1}^{\perp} B P_{\widetilde{X}_1}\right\|_F^2 + \left\|P_{\widetilde{V}_1} B P_{\widetilde{Y}_1}^{\perp}\right\|_F^2\right)}.$$

. From (1.13), we know that $\binom{E}{F} \in \mathcal{E}_2$ if and only if there exists an $(l, p+l-n, l)$-GMP $\{\widetilde{A}_1,\ \widetilde{B}_1\}$ such that

$$(A+E)\ \widetilde{X}_1 = \widetilde{U}_1\widetilde{A}_1, \quad (A+E)^*\ \widetilde{U}_1 = \widetilde{Y}_1\widetilde{A}_1^* \tag{2.20}$$

and

$$(B+F)\,\widetilde{X}_1=\widetilde{V}_1\widetilde{B}_1,\quad (B+F)^*\,\widetilde{V}_1=\widetilde{Y}_1\widetilde{B}_1^*\,. \tag{2.21}$$

Applying Lemma 2.2 to (2.20) and (2.21) gives

$$\begin{aligned} E &= \widetilde{U}\begin{pmatrix} \widetilde{U}_1^*\,(\widetilde{U}_1\widetilde{A}_1-A\,\widetilde{X}_1)\,\widetilde{H}^{-1} & (\widetilde{A}_1\widetilde{Y}_1^*-\widetilde{U}_1^*\,A)\,\widetilde{W}_2 \\ -\,\widetilde{U}_2^*\,A\,\widetilde{W}_1 & \widetilde{U}_2^*\,L\,\widetilde{W}_2 \end{pmatrix}\widetilde{W}^* \\ &\equiv E\left(\widetilde{A}_1,\ L\right),\quad L\in\mathcal{C}^{m\times n}, \end{aligned} \tag{2.22}$$

and

$$\begin{aligned} F &= \widetilde{V}\begin{pmatrix} \widetilde{V}_1^*\,(\widetilde{V}_1\widetilde{B}_1-B\,\widetilde{X}_1)\,\widetilde{H}^{-1} & (\widetilde{B}_1\widetilde{Y}_1^*-\widetilde{V}_1^*\,B)\,\widetilde{W}_2 \\ -\,\widetilde{V}_2^*\,B\,\widetilde{W}_1 & \widetilde{V}_2^*\,N\,\widetilde{W}_2 \end{pmatrix}\widetilde{W}^* \\ &\equiv F\left(\widetilde{B}_1,N\right),\quad N\in\mathcal{C}^{p\times n}, \end{aligned} \tag{2.23}$$

respectively, where $\widetilde{U}=(\widetilde{U}_1,\widetilde{U}_2),\widetilde{V}=(\widetilde{V}_1,\widetilde{V}_2),\widetilde{W}=(\widetilde{W}_1,\widetilde{W}_2)$, and $\widetilde{H}$ are given by the proof in Theorem 2.1. From (2.22) and (2.23), we have

$$\begin{aligned} \min_{\widetilde{A}_1\in\mathcal{C}^{l\times l},\ L\in\mathcal{C}^{m\times n}}\left\|E\left(\widetilde{A}_1,\ L\right)\right\|_F^2 = \min_{\widetilde{A}_1\in\mathcal{C}^{l\times l}}\Bigg(&\left\|\widetilde{U}_1^*\left(\widetilde{U}_1\widetilde{A}_1-A\,\widetilde{X}_1\right)\widetilde{H}^{-1}\right\|_F^2 \\ &+\left\|\left(\widetilde{A}_1\widetilde{Y}_1^*-\widetilde{U}_1^*\,A\right)\widetilde{W}_2\right\|_F^2\Bigg)+\left\|\widetilde{U}_2^*\,A\,\widetilde{W}_1\right\|_F^2 \end{aligned} \tag{2.24}$$

and

$$\begin{aligned} \min_{\widetilde{B}_1\in\mathcal{C}^{(p+l-n)\times l},\ N\in\mathcal{C}^{p\times n}}\left\|F\left(\widetilde{B}_1,\ L\right)\right\|_F^2 = \min_{\widetilde{B}_1\in\mathcal{C}^{(p+l-n)\times l}}\Bigg(&\left\|\widetilde{V}_1^*\left(\widetilde{V}_1\widetilde{B}_1-B\,\widetilde{X}_1\right)\widetilde{H}^{-1}\right\|_F^2 \\ &+\left\|\left(\widetilde{B}_1\widetilde{Y}_1^*-\widetilde{V}_1^*\,B\right)\widetilde{W}_2\right\|_F^2\Bigg)+\left\|\widetilde{V}_2^*\,B\,\widetilde{W}_1\right\|_F^2. \end{aligned} \tag{2.25}$$

It is easy to see that

$$\left\|\widetilde{U}_2^*\,A\,\widetilde{W}_1\right\|_F=\left\|P_{\widetilde{U}_1}^{\perp}\,AP_{\widetilde{X}_1}\right\|_F,\quad \left\|\widetilde{V}_2^*\,B\,\widetilde{W}_1\right\|_F=\left\|P_{\widetilde{V}_1}^{\perp}\,BP_{\widetilde{X}_1}\right\|_F. \tag{2.26}$$

Similarly to (2.17), we have

$$\widetilde{U}_1^*\left(\widetilde{U}_1\widetilde{A}_1-A\,\widetilde{X}_1\right)\widetilde{H}^{-1}=\left(\widetilde{A}_1\widetilde{Y}_1^*-\widetilde{U}_1^*\,A\right)\widetilde{W}_1, \tag{2.27}$$

$$\widetilde{V}_1^*\left(\widetilde{V}_1\widetilde{B}_1-B\,\widetilde{X}_1\right)\widetilde{H}^{-1}=\left(\widetilde{B}_1\widetilde{Y}_1^*-\widetilde{V}_1^*\,B\right)\widetilde{W}_1\,. \tag{2.28}$$

Hence from (2.27) and (2.28) we obtain

$$\left\|\widetilde{U}_1^*\,(\widetilde{U}_1\widetilde{A}_1 - A\,\widetilde{X}_1)\,\widetilde{H}^{-1}\right\|_F^2 + \left\|(\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\,A)\,\widetilde{W}_2\right\|_F^2 = \left\|\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\,A\right\|_F^2, \tag{2.29}$$

$$\left\|\widetilde{V}_1^*\,(\widetilde{V}_1\widetilde{B}_1 - B\,\widetilde{X}_1)\,\widetilde{H}^{-1}\right\|_F^2 + \left\|(\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\,B)\,\widetilde{W}_2\right\|_F^2 = \left\|\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\,B\right\|_F^2. \tag{2.30}$$

Applying Lemma 2.3 to (2.29) and (2.30) gives

$$\min_{\widetilde{A}_1\in\mathcal{C}^{l\times l}}\left\|\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\,A\right\|_F = \left\|\widetilde{U}_1^*\,A\,\widetilde{Y}_1^{*\dagger}\,\widetilde{Y}_1^* - \widetilde{U}_1^*\,A\right\|_F = \left\|P_{\widetilde{U}_1}AP_{\widetilde{Y}_1}^{\perp}\right\|_F \tag{2.31}$$

and

$$\min_{\widetilde{B}_1\in\mathcal{C}^{(p+l-n)\times l}}\left\|\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\,B\right\|_F = \left\|\widetilde{V}_1^*\,B\,\widetilde{Y}_1^{*\dagger}\,\widetilde{Y}_1^* - \widetilde{V}_1^*\,B\right\|_F = \left\|P_{\widetilde{V}_1}BP_{\widetilde{Y}_1}^{\perp}\right\|_F, \tag{2.32}$$

respectively. Notice that $\{\widetilde{U}_1^*\,A\,\widetilde{Y}_1^{\dagger *}, \widetilde{V}_1^*\,B\,\widetilde{Y}_1^{\dagger *}\}$ is an $(l, p+l-n, l)$-GMP. Combining (1.12) with (2.24)–(2.26) and (2.29)–(2.32) shows the formula (2.19). The proof is complete. □

The following two results give computable formulae of the backward errors $\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$ and $\eta_F(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)$.

THEOREM 2.3. $\widetilde{U}_1\in\mathcal{C}^{m\times l}, \widetilde{V}_1\in\mathcal{C}^{p\times(p+l-n)}, \widetilde{Y}_1\in\mathcal{C}^{n\times l}$, $\widetilde{A}_{11}\in\mathcal{C}^{l\times l}$, $\widetilde{B}_{11}\in\mathcal{C}^{(p+l-n)\times l}$, $\widetilde{U}_1^*\widetilde{U}_1 = I_l, \widetilde{V}_1^*\widetilde{V}_1 = I_{p+l-n}$. $\{\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ (m, p, n) $\{A, B\}$ $\{\widetilde{A}_{11}, \widetilde{B}_{11}\}$

$$\eta_F(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = \sqrt{\frac{1}{\gamma_A^2}\,\|R_3\|_F^2 + \frac{1}{\gamma_B^2}\,\|R_4\|_F^2}, \tag{2.33}$$

R_3 R_4 (2.10).

. From (1.15) and (2.10), we see that $\binom{E}{F}\in\mathcal{E}_3$ if and only if E and F satisfy

$$E^*\,\widetilde{U}_1 = R_3, \quad F^*\,\widetilde{V}_1 = R_4. \tag{2.34}$$

Applying Lemma 2.1 to (2.34) gives

$$E^* = R_3\,\widetilde{U}_1^* + Z_1(I_m - \widetilde{U}_1\widetilde{U}_1^*), \quad F^* = R_4\,\widetilde{V}_1^* + Z_2(I_p - \widetilde{V}_1\widetilde{V}_1^*),$$

where $Z_1\in\mathcal{C}^{m\times n}$ and $Z_2\in\mathcal{C}^{p\times n}$. From the above equations and (1.14), it is easy to see that

$$\begin{aligned}
&\eta_F^2(\{\widetilde{A}_{11}, \widetilde{B}_{11}\}, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1)\\
&= \frac{1}{\gamma_A^2}\min_{Z_1\in\mathcal{C}^{m\times n}}\left\|R_3\,\widetilde{U}_1^* + Z_1(I_m - \widetilde{U}_1\widetilde{U}_1^*)\right\|_F^2 + \frac{1}{\gamma_B^2}\min_{Z_2\in\mathcal{C}^{p\times n}}\left\|R_4\,\widetilde{V}_1^* + Z_2(I_n - \widetilde{V}_1\widetilde{V}_1^*)\right\|_F^2\\
&= \frac{1}{\gamma_A^2}\|R_3\|_F^2 + \frac{1}{\gamma_B^2}\|R_4\|_F^2,
\end{aligned}$$

which implies (2.33). The proof is complete. □

THEOREM 2.4. $\widetilde{U}_1 \in \mathcal{C}^{m\times l}, \widetilde{V}_1 \in \mathcal{C}^{p\times(p+l-n)}$ $\widetilde{Y}_1 \in \mathcal{C}^{n\times l}$ $\widetilde{U}_1^*\widetilde{U}_1 = I_l$, $\widetilde{V}_1^*\widetilde{V}_1 = I_{p+l-n}$ $\{\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1\}$ (m,p,n) $\{A,\ B\}$ $\{\widetilde{U}_1^*\ A\ \widetilde{Y}_1^{\dagger *},\ \widetilde{V}_1^*\ B\ \widetilde{Y}_1^{\dagger *}\}$ $(l, p+l-n, l)$

$$\eta_F(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = \sqrt{\frac{1}{\gamma_A^2}\left\|P_{\widetilde{U}_1} A P^{\perp}_{\widetilde{Y}_1}\right\|_F^2 + \frac{1}{\gamma_B^2}\left\|P_{\widetilde{V}_1} B P^{\perp}_{\widetilde{Y}_1}\right\|_F^2}. \tag{2.35}$$

. By definition (1.17), $\binom{E}{F} \in \mathcal{E}_4$ if and only if there is an $(l, p+l-n, l)$-GMP $\{\widetilde{A}_1, \widetilde{B}_1\}$ such that

$$E^*\ \widetilde{U}_1 = \widetilde{Y}_1\widetilde{A}_1^* - A^*\ \widetilde{U}_1, \quad F^*\ \widetilde{V}_1 = \widetilde{Y}_1\widetilde{B}_1^* - B^*\ \widetilde{V}_1\ .$$

By Lemma 2.1, we know that the above two equations are solvable and E and F are expressed by

$$E = \widetilde{U}_1\ (\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\ A) + (I_m - \widetilde{U}_1\widetilde{U}_1^*)Z_1,$$
$$F = \widetilde{V}_1\ (\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\ B) + (I_p - \widetilde{V}_1\widetilde{V}_1^*)Z_2,$$

where $Z_1 \in \mathcal{C}^{m\times n}, Z_2 \in \mathcal{C}^{p\times n}$. From (1.16) and the above two equalities we have

$$\begin{aligned}
\eta_F^2(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) &= \frac{1}{\gamma_A^2} \min_{\widetilde{A}_1\in\mathcal{C}^{l\times l}, Z_1\in\mathcal{C}^{m\times n}} \left\|\widetilde{U}_1\ (\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\ A) + (I_m - \widetilde{U}_1\widetilde{U}_1^*)Z_1\right\|_F^2 \\
&\quad + \frac{1}{\gamma_B^2} \min_{\widetilde{B}_1\in\mathcal{C}^{(p+l-n)\times l}, Z_2\in\mathcal{C}^{p\times n}} \left\|\widetilde{V}_1\ (\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\ B) + (I_p - \widetilde{V}_1\widetilde{V}_1^*)Z_2\right\|_F^2 \\
&= \frac{1}{\gamma_A^2} \min_{\widetilde{A}_1\in\mathcal{C}^{m\times n}} \left\|\widetilde{A}_1\widetilde{Y}_1^* - \widetilde{U}_1^*\ A\right\|_F^2 + \frac{1}{\gamma_B^2} \min_{\widetilde{B}_1\in\mathcal{C}^{(p+l-n)\times l}} \left\|\widetilde{B}_1\widetilde{Y}_1^* - \widetilde{V}_1^*\ B\right\|_F^2.
\end{aligned} \tag{2.36}$$

From Lemma 2.3 and (2.36) we have

$$\eta_F^2(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = \frac{1}{\gamma_A^2}\left\|\widetilde{U}_1^*\ A(I - \widetilde{Y}_1\widetilde{Y}_1^{\dagger})\right\|_F^2 + \frac{1}{\gamma_B^2}\left\|\widetilde{V}_1^*\ B(I - \widetilde{Y}_1\widetilde{Y}_1^{\dagger})\right\|_F^2. \tag{2.37}$$

Notice that $\{\widetilde{U}_1^*\ A\ \widetilde{Y}_1^{\dagger *},\ \widetilde{V}_1^*\ B\ \widetilde{Y}_1^{\dagger *}\}$ is an $(l, p+l-n, l)$-GMP. Then (2.35) follows from (2.37). The proof is complete. □

3. A numerical example. In this section we use a simple example to illustrate the results of the previous section. All computations were performed by using MATLAB 6.5. The relative machine precision is 2.22×10^{-16}.

3.1. Consider the (3,3,3)-GMP $\{A, B\}$ with

$$A = \begin{pmatrix} \frac{7}{2} & 3 & -3 \\ 2\sqrt{2} & 4\sqrt{2}(1+10^{-14}) & -4\sqrt{2} \\ -\frac{1}{2} & 3 & -3 \end{pmatrix}, \quad B = \begin{pmatrix} -\frac{1}{2} & 1 & -1 \\ \frac{\sqrt{2}}{2} & \sqrt{2}(1+10^{-14}) & -\sqrt{2} \\ \frac{3}{2} & 1 & -1 \end{pmatrix}.$$

By using function **[U,V,Y,C,S] = gsvd(A,B)** in MATLAB 6.5, we get the computed GSVD $A = UCY^T$ and $B = VSY^T$, where

$$U = \begin{pmatrix} 0.72882766003858 & -0.68439687422507 & -0.02027709332328 \\ -0.01691197215049 & 0.01161155660932 & -0.99978955633228 \\ -0.68448829585368 & -0.72901720851024 & 0.00311167724380 \end{pmatrix},$$

$$V = \begin{pmatrix} -0.69179597797044 & -0.72206709187087 & 0.00611879898952 \\ -0.00818050022115 & -0.00063616783742 & -0.99996633678670 \\ 0.72204667735546 & -0.69182274473136 & -0.00546677165349 \end{pmatrix},$$

$$Y = \begin{pmatrix} 3.18138671232003 & -2.10966551430603 & -2.98799096458163 \\ 0.04176115800505 & -4.40778386049074 & -5.87960010926594 \\ -0.04176115800505 & 4.40778386049074 & 5.87960010926588 \end{pmatrix},$$

$$C = \operatorname{diag}(0.89436052092627, 0.94708758346252, 0.97067146447266),$$

and

$$S = \operatorname{diag}(0.44734691080692, 0.32097524710033, 0.24040987512682).$$

By using the function **inv** in MATLAB 6.5, we obtain

$$X = Y^{-T} = \begin{pmatrix} 0.31622982070089 & 0.00507812500000 & -0.00156084661164 \\ -9.288469999189297e+11 & 2.251799813685225e+13 & -1.688775709899456e+13 \\ -9.288469999187793e+11 & 2.251799813685248e+13 & -1.688775709899456e+13 \end{pmatrix}.$$

Let

$$\widetilde{A}_{11} = C(1:2,1:2), \quad \widetilde{B}_{11} = S(1:2,1:2), \quad \widetilde{\alpha}_3 = C(3,3), \quad \widetilde{\beta}_3 = S(3,3),$$

$$\widetilde{U}_1 = U(1:3,1:2), \quad \widetilde{u}_3 = U(1:3,3), \quad \widetilde{V}_1 = V(1:3,1:2), \quad \widetilde{v}_3 = V(1:3,3),$$

$$\widetilde{Y}_1 = Y(1:3,1:2), \quad \widetilde{y}_3 = Y(1:3,3), \quad \widetilde{X}_1 = X(1:3,1:2), \quad \widetilde{x}_3 = X(1:3,3),$$

where $K(i:j,k:l)$ is the submatrix of K with entries having row and column indices in the ranges i through j and k through l, respectively. Taking $\gamma_A = \|A\|_F$ and $\gamma_B = \|B\|_F$ we get the relative backward errors

$$\eta_F((\widetilde{A}_{11}, \widetilde{B}_{11}), \widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = 0.00185341925320, \tag{3.1}$$

$$\eta_F((\widetilde{\alpha}_3, \widetilde{\beta}_3), \widetilde{x}_3, \widetilde{y}_3, \widetilde{u}_3, \widetilde{v}_3) = 8.724097354653458e-16, \tag{3.2}$$

$$\eta_F(\widetilde{X}_1, \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = 0.00203991762337, \tag{3.3}$$

$$\eta_F(\widetilde{x}_3, \widetilde{y}_3, \widetilde{u}_3, \widetilde{v}_3) = 4.300498624031868e-16, \tag{3.4}$$

$$\eta_F((\widetilde{A}_{11}, \widetilde{B}_{11}), \widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = 1.322954207342138e-15, \tag{3.5}$$

$$\eta_F((\widetilde{\alpha}_3, \widetilde{\beta}_3), \widetilde{y}_3, \widetilde{u}_3, \widetilde{v}_3) = 8.710521422021934e-16, \tag{3.6}$$

$$\eta_F(\widetilde{Y}_1, \widetilde{U}_1, \widetilde{V}_1) = 2.516175515362349e-16, \tag{3.7}$$

and

$$\eta_F(\widetilde{y}_3, \widetilde{u}_3, \widetilde{v}_3) = 4.255419420330271e-16. \tag{3.8}$$

The results (3.5)–(3.8) show that the computation of the GSVD by using function **gsvd** in MATLAB 6.5 has proceeded stably. But since Y is very ill-conditioned, in fact, $\mathrm{cond}_2(Y) = \|Y\|_2\|Y^{-1}\|_2 = 4.360846260436090e+014$, inverting Y to get X will introduce additional errors. This means that the backward errors of (3.1)–(3.4) may not be very small.

Acknowledgment. The authors would like to thank the anonymous referees for their valuable comments.

A GRAPH BASED APPROACH TO THE CONVERGENCE OF ONE LEVEL SCHWARZ ITERATIONS FOR SINGULAR M-MATRICES AND MARKOV CHAINS*

STEFAN BOROVAC†

Abstract. We study the convergence of additive and multiplicative Schwarz iterations applied to singular M-matrices and Markov chains. We do our investigations in order to solve consistent linear systems or to calculate a probability distribution vector of a Markov chain. It turns out that for a certain set of equations we are able to prove convergence for both methods with a reliable degree of freedom concerning the overlap. These new convergence theorems are based on a graph theoretical approach and represent the main results of this paper. Other applications of the introduced theory are also discussed.

Key words. linear systems, M-matrices, Markov chains, singular matrices, iterative methods, block methods, additive Schwarz, multiplicative Schwarz, domain decomposition methods, overlap, graph theory

1. Introduction.

Schwarz methods are mainly used for the numerical solution of partial differential equations and can be classified as domain decomposition methods [22, 27, 30]. Another common application of these methods is to use them as a preconditioner for Krylov subspace methods. But recently, these methods have also been proposed to solve symmetric [20] and nonsymmetric [8, 16] Markov chains iteratively. To this purpose, an algebraic formulation was developed which is partly recapitulated in section 4; see also [3, 8, 13, 16, 19, 20].

In this paper we analyze Schwarz methods for the iterative solution of consistent linear systems of the form

$$Ax = b. \tag{1.1}$$

Here, either A is a square singular M-matrix or, as a special case, $A = I - B$, I the identity matrix and B a square column stochastic matrix [28]. We assume that (1.1) is consistent; i.e., b lies in the range of A.

We do not tackle the system (1.1) in the most general setting but introduce some restrictions concerning the null space of A. We assume that

$$\mathcal{N}(A) = \{x \in \mathbb{R}^n : Ax = 0\} = \operatorname{span}\{z\} \text{ for some positive vector } z. \tag{1.2}$$

This assumption allows us to construct convergent additive and multiplicative Schwarz iterations to solve (1.1). Whereas the convergence is not too hard to prove, the consistency of the convergence process takes considerable effort, and a lot of the theory developed here is to obtain consistency.

The theory presented can be applied to reducible nonsymmetric matrices A which satisfy (1.2). In [20] only symmetric semidefinite systems are considered. In [8] an

†Fachbereich Mathematik und Naturwissenschaften, Universität Wuppertal, D-42097 Wuppertal, Germany (borovac@math.uni-wuppertal.de).

alternative to our ansatz is studied, but there only certain cases of overlap are considered. The approach in [16] appears to be more general than ours but relies on an assumption of consistency which is actually not known to hold.

Our theory is based on properties of the nonzero pattern of A which must necessarily exist if A satisfies (1.2) (cf. section 3). We use this in a graph based approach to construct convergent Schwarz iterations which are also consistent in the sense that we converge to a reliable solution. For one level multiplicative Schwarz we do this in two steps. First we present the basic idea (section 5.1) and prove, as an intermediate result, the convergence of the Gauss–Seidel iteration. In sections 5.2 and 5.3 we extend our theory to multiplicative Schwarz iterations. For our type of problem the Schwarz decomposition has to be somehow compatible with the graph of A.

In section 6 we consider a damped (relaxed) version of multiplicative Schwarz. It turns out that this variant converges for virtually any type of decomposition so that compatibility with the graph of A is not required.

Additive Schwarz iterations are studied in section 7. We will see that the theory developed in this paper can be directly applied to obtain new convergence results.

In section 8 we give an overview of other results and generalizations which can be obtained using our theory.

2. Definitions and auxiliary results. In this section we recall some definitions and preliminaries. If not stated otherwise, they can be found in [4]. The basic definitions concerning graphs are taken from [25].

2.1. Basics. Let $A = (a_{ij}) \in \mathbb{R}^{m\times n}$ be given. We assume that the reader is familiar with the concept of *nonnegativity* ($A \geq 0$) and positivity ($A > 0$); see, e.g., [4, 31].

For a given matrix $A \in \mathbb{R}^{n\times n}$ and sets $V_1, V_2 \subset \{1, \ldots, n\}$ the matrix $A[V_1, V_2]$ consists of a_{ij} satisfying $i \in V_1$ and $j \in V_2$. By $A[V_1]$ we denote the *principal minor* of A with respect to V_1.

For $A \in \mathbb{R}^{n\times n}$ we denote by $\mathcal{R}(A), \mathcal{N}(A), \sigma(A)$, and $\rho(A)$ the range, the null space, the spectrum, and the spectral radius of A, respectively. The term $\mathrm{ind}_\lambda(A)$ identifies the index of an eigenvalue λ of A. Finally, we define

$$\gamma(A) := \max\{|\lambda| : \lambda \in \sigma(A) \text{ and } \lambda \neq \rho(A)\}.$$

$A \in \mathbb{R}^{n\times n}$ is an *M-matrix* if $A = \beta I - B,\ B \geq 0$, and $\rho(B) \leq \beta$. If $\rho(B) = \beta$, the matrix A is singular; otherwise, it is nonsingular. A matrix $A \in \mathbb{R}^{n\times n}$ is a nonsingular M-matrix if and only if $A^{-1} \geq 0$. When A is a nonsingular M-matrix, each principal minor is a nonsingular M-matrix.

2.2. Graph theory. It is assumed that the basics from graph theory are known to the reader; see, e.g., [11].

Let $\Gamma_1 = (V, E_1)$ and $\Gamma_2 = (V, E_2)$ be directed graphs with identical vertex sets V. The union $\Gamma_1 \cup \Gamma_2$ is defined to be the union of the edge sets. The product graph $\Gamma_1\Gamma_2 = (V, E)$ is defined by $(u, w) \in E$ if there is a $v \in V$ such that $(u, v) \in E_1$ and $(v, w) \in E_2$. We write $\Gamma^2 = \Gamma\Gamma$ and $\Gamma^{k+1} = \Gamma^k\Gamma$. If V is a given vertex set, the graph $\Delta = (V, E)$ with $E := \{(v, v) : v \in V\}$ denotes the diagonal graph of V.

The *reflexive transitive closure* $\overline{\Gamma}$ of a graph Γ is defined to be

$$\overline{\Gamma} = \Delta \cup \Gamma \cup \Gamma^2 \cup \ldots.$$

Therefore, $u \in V$ has access to $w \in V$ in Γ if and only if (u, w) is an edge of $\overline{\Gamma}$.

For $A \in \mathbb{R}^{n\times n}$, we denote by $\Gamma(A) = (V(A), E(A))$ the corresponding directed graph. Now the vertices are also called *states* or *indices*.

LEMMA 2.1. *Let $A, B \in \mathbb{R}^{n\times n}$ be nonnegative, and let $\alpha \in \mathbb{R}$ be positive. Then*

$$\Gamma(\alpha A) = \Gamma(A), \quad \Gamma(A+B) = \Gamma(A) \cup \Gamma(B), \quad \textit{and} \quad \Gamma(AB) = \Gamma(A)\Gamma(B).$$

If A is a nonsingular M-matrix, then $\Gamma(A^{-1}) = \overline{\Gamma(A)}$.

2.3. Classification of vertices and eigenvectors. Let a graph Γ be given. Equivalence classes of Γ are always to be understood with respect to the communication relation. If $A \in \mathbb{R}^{n\times n}$ is some matrix, then A is called *irreducible* if $\Gamma(A)$ is strongly connected; i.e., there is only one equivalence class. Otherwise, A is called *reducible*.

THEOREM 2.2. *Let $A \in \mathbb{R}^{n\times n}$ be an irreducible M-matrix.*

(1) *If A is nonsingular, then $A^{-1} > 0$.*

(2) *If A is singular, then each proper principal minor of A is a nonsingular M-matrix.*

For an $A \in \mathbb{R}^{n\times n}$, the *classes* of A are the equivalence classes of $\Gamma(A)$. A class is called *final* if none of its vertices has access to another class. A class α is called *basic* if $\rho(A[\alpha]) = \rho(A)$; otherwise, α is called *nonbasic*.

We will need the following result on the relation between graphs of nonnegative matrices, positive eigenvectors, and their index. A proof can be found in [24].

THEOREM 2.3. *Let $B \in \mathbb{R}^{n\times n}$ be nonnegative, and let $\mathcal{N}((\rho(B)I - B)^k)$ with $k = \operatorname{ind}_{\rho(B)}(B)$ be the* algebraic eigenspace. *Assume that B has m basic classes $\alpha_1, \ldots, \alpha_m$. Then the algebraic eigenspace corresponding to $\rho(B)$ contains nonnegative vectors $v^{(1)}, \ldots, v^{(m)}$, such that $v_j^{(i)} > 0$ if and only if the index j has access to α_i in $\Gamma(B)$. Furthermore, any such collection is a basis of the algebraic eigenspace.*

THEOREM 2.4. *Let $B \in \mathbb{R}^{n\times n}$ be nonnegative; then there is a positive eigenvector z corresponding to the spectral radius if and only if the basic classes of B are exactly its final ones.*

2.4. Semiconvergence. For a given $T \in \mathbb{R}^{n\times n}$ we say that T is *semiconvergent* if $\lim_{k\longrightarrow\infty} T^k = T^*$ exists and, additionally, $T^* \neq 0$. This concept is used to analyze stationary iterations

$$x^{k+1} = Tx^k + c, \qquad k = 0, 1, 2, \ldots, \tag{2.1}$$

which are known to converge for every initial guess x^0 if $c \in \mathcal{R}(I - T)$ and T is semiconvergent.

A square matrix T is semiconvergent if and only if T satisfies the following three conditions (see [4, Lemma 7.6.9]):

$$(1)\ 1 \in \sigma(T), \quad (2)\ \gamma(T) < 1, \quad \text{and} \quad (3)\ \mathcal{R}(I-T) \oplus \mathcal{N}(I-T) = \mathbb{R}^n.$$

Furthermore, $T^* = \lim_{k\longrightarrow\infty} T^k$ is a projection onto $\mathcal{N}(I - T)$ along $\mathcal{R}(I - T)$.

Note that condition (3) states that there are no generalized eigenvectors to the eigenvalue 1. This is equivalent to $\operatorname{ind}_1(T) = 1$ and automatically fulfilled if $Tz = z$ for some positive vector z; see [4, 31]. If $T \geq 0$, then condition (2) can be replaced by T having all its diagonal elements positive [1] or, in the case that T is irreducible, it suffices to have one positive diagonal element; see [4, Corollary 2.2.28].

3. The model problem *MP*. In this section we present our model problem which represents the class of singular systems which we consider. We will see that the model problem exposes a nice graph structure which allows us to construct convergent Schwarz iterations.

Assume that for $A \in \mathbb{R}^{n\times n}$ there holds

$$A = I - B, \quad B \geq 0, \quad \rho(B) = 1. \tag{3.1}$$

For a given $b \in \mathcal{R}(A)$, the problem to be solved is to find a solution $x^* \in \mathbb{R}^n$ of

$$Ax = b \Leftrightarrow x = Bx + b \tag{3.2}$$

for $x \in \mathbb{R}^n$.

Equation (3.2) will not be considered in its greatest generality; only in the following case.

DEFINITION 3.1. *The model problem* MP *is to find a solution* x^* *of* (3.2) *satisfying* (3.1) *in the case that* $\mathcal{N}(A) = \operatorname{span}\{z\}$ *for a positive vector* z.

We now characterize $\mathcal{N}(A) = \operatorname{span}\{z\}$ with $z > 0$ via the graph structure of A. We say that a directed graph $\Gamma = (V, E)$ contains a directed *spanning tree* $\mathcal{T} = (V_\mathcal{T}, E_\mathcal{T})$ (see, e.g., [9]) if

$$(1)\ \mathcal{T} \text{ is a directed tree}, \quad (2)\ V_\mathcal{T} = V, \quad \text{and} \quad (3)\ E_\mathcal{T} \subset E.$$

As we discuss only directed graphs, the term "directed" will be omitted in the rest of the paper.

DEFINITION 3.2. *Let* $B \in \mathbb{R}^{n\times n}$ *be such that* $B \geq 0$, $\rho(B) = 1$, *and let* $\Gamma(B) = (V(B), E(B))$ *be the corresponding graph. Then* B *is said to be an* ST-matrix *(ST for "spanning tree") if the following hold:*

(1) $\Gamma(B^T)$ *contains a spanning tree* $\mathcal{T}_B$,

(2) *if the index* $i_0 \in V(B)$ *is the root of* $\mathcal{T}_B$, *then* i_0 *has access to some* $j_0 \in V(B)$ *via* $(i_0, j_0) \in \Gamma(B)$, *and*

(3) *each class of* B *is final if and only if it is basic.*

The index j_0 *defined above will be called the* guard index.

Remark 3.1. Note that it might happen that the root i_0 communicates only with itself via $(i_0, i_0) \in \Gamma(B)$. As this leads to some problems when using Schwarz iterations, we will always assume $j_0 \neq i_0$ if not stated otherwise.

The following lemma characterizes ST-matrices. The results can directly be deduced from Theorems 2.3 and 2.4 and the theory of Markov chains [4, 26].

LEMMA 3.3. *Let* B *be an ST-matrix; then there is a permutation matrix* Π *such that*

$$\Pi B \Pi^T = \begin{pmatrix} D & 0 \\ E & F \end{pmatrix}. \tag{3.3}$$

Furthermore, the following hold:

(1) D *is square and irreducible.*

(2) *If* B *is irreducible, then* $\Pi = I$ *and* $B = D$.

(3) *If* i_0 *is the root index of any tree in* $\Gamma(B^T)$, *then* i_0 *resides in the index set belonging to* D.

(4) $\rho(B) = \rho(D) = 1$.

(5) $\rho(F) < 1$.

(6) *There exists a vector* $z > 0$ *such that* $Bz = z$, $\mathcal{N}(I - B) = \operatorname{span}\{z\}$, *and* $\operatorname{ind}_1(B) = 1$.

Remark 3.2. Note that the representation (3.3) can be efficiently calculated with the algorithm of Tarjan [29].

Now we state a few corollaries of Lemma 3.3.

COROLLARY 3.4. *Let $B \in \mathbb{R}^{n\times n}$ be an ST-matrix and let α be the set of indices of the final class of B. Then $\Gamma(B^T)$ contains at least $|\alpha|$ spanning trees with corresponding guard indices; i.e., each index in α might act as a root.*

Proof. It is easy to see that every index $i_0 \in \alpha$ has access to all other indices in $\Gamma(B^T)$. ∎

COROLLARY 3.5. *Let $B \in \mathbb{R}^{n\times n}$ be an irreducible ST-matrix. Then $\Gamma(B^T)$ contains at least n spanning trees with corresponding guard indices; i.e., every index can act as a root.*

COROLLARY 3.6. *If $B \in \mathbb{R}^{n\times n}$ is a symmetric ST-matrix, then B is irreducible.*

COROLLARY 3.7. *Consider a nonnegative matrix $B \in \mathbb{R}^{n\times n}$, $\rho(B) = 1$, and a positive vector $z > 0$ such that $Bz = z$. If B contains a spanning tree and a guard index, then B is an ST-matrix.*

If the final classes are exactly the basic ones and there is only one such class, then the existence of a spanning tree is not only sufficient but also necessary.

THEOREM 3.8. *Let $B \in \mathbb{R}^{n\times n}$ be nonnegative, and let $\rho(B) = 1$. Then B is an ST-matrix if and only if the final classes of B are exactly its basic ones and there is only one such class.*

Proof. The sufficiency is given in Lemma 3.3. The necessity is shown now. Assume that B has exactly one final class which is also the only basic class.

There is a permutation matrix Π such that (3.3) holds; then

$$C^T = \begin{pmatrix} D^T & E^T \\ 0 & F^T \end{pmatrix} \tag{3.4}$$

and D is irreducible, satisfying $\rho(D) = 1$ and $\rho(F) < 1$. Additionally, there exists a positive vector $z > 0$ such that $Bz = z$ (cf. Theorem 2.4). Let the index set $\{1, \dots, n\}$ be split with respect to (3.4) into sets V_1 and V_2, where V_1 corresponds to the indices of D. It remains to show that each index in V_2 is accessible from V_1 in $\Gamma(B^T)$. If this is proven, the existence of a spanning tree is obvious because any index belonging to D then has access to every other index in $\Gamma(B^T)$ (cf. Corollary 3.4).

Assume that there is a nonempty subset W_2 of V_2 containing all the indices that are not accessible from V_1. Then there is another permutation matrix $\tilde{\Pi}$ acting on V_2 such that

$$\tilde{\Pi}C\tilde{\Pi}^T = \begin{pmatrix} D & 0 & 0 \\ E_1 & F_{11} & F_{12} \\ E_2 & F_{21} & F_{22} \end{pmatrix} \text{ and } \tilde{\Pi}^T C^T \tilde{\Pi} = \begin{pmatrix} D^T & E_1^T & E_2^T \\ 0 & F_{11}^T & F_{21}^T \\ 0 & F_{12}^T & F_{22}^T \end{pmatrix}. \tag{3.5}$$

Here F_{22} corresponds to the index set $W_2 \subset V_2$ of all nonaccessible indices, while F_{11} corresponds to the indices $W_1 = V_2 \setminus W_2$.

Since each $j \in W_2$ is not accessible from V_1, one gets $E_2^T = 0$, whereas $E_1^T \neq 0$. But then $F_{21}^T = 0$, since all indices in W_1 are accessible from V_1; hence $F_{21}^T \neq 0$ would imply that an index $i \in V_1$ has access to some $j \in W_2$ via a $k \in W_1$. Thus

$$\tilde{\Pi}C\tilde{\Pi}^T = \begin{pmatrix} D & 0 & 0 \\ E_1 & F_{11} & F_{12} \\ 0 & 0 & F_{22} \end{pmatrix}.$$

If z is split into (z_1, z_2, z_3) with respect to V_1, W_1, and W_2, then $F_{22}z_3 = z_3 > 0$. Consequently, F_{22} is a final and basic class, contradicting the assumptions. As there is only one final and basic class, z is a basis for $\mathcal{N}(A)$. ∎

In order to give an alternative characterization of our model problem, we define the following class of singular M-matrices.

DEFINITION 3.9. *A matrix $A \in \mathbb{R}^{n\times n}$ is called an* STM-matrix *(STM for "spanning tree monotone") if $A = I - B$ and B is an ST-matrix.*

An STM-matrix naturally fulfills the requirements of the model problem. On the other hand, each matrix $A = I - B$ having a positive vector $z > 0$ such that $Az = 0$ and $\dim \mathcal{N}(A) = 1$ is an STM-matrix by Theorem 3.8. Thus, the model problem can be restated as follows.

Given an STM-matrix $A \in \mathbb{R}^{n\times n}$ and $b \in \mathcal{R}(A)$, find a solution $x^* \in \mathbb{R}^n$ of

$$Ax = b,\ x \in \mathbb{R}^n.$$

4. Schwarz methods. We give a brief introduction to algebraic Schwarz methods following, e.g., [3, 8, 13, 16, 19, 20]. For technical reasons we will distinguish between partitionings and decompositions.

Let the finite set $S = \{1, \dots, n\}$ be given. The nonempty sets $S_1, \dots, S_p$ are a *decomposition* of S if

$$\bigcup_{i=1}^{p} S_i = S.$$

If an index $j \in S$ appears in more than one set, we speak of overlap. The measure of overlap is the maximum number of sets any index $j \in S$ belongs to, i.e.,

$$q = \max_{j=1,\dots,n} |\{i : j \in S_i\}|. \tag{4.1}$$

We have $q = 1$ if and only if no overlap occurs; see, e.g., [3]. In the latter case we say that $S_1, \dots, S_p$ form a *partitioning*.

If $A \in \mathbb{R}^{n\times n}$, then a partitioning or a decomposition $S_1, \dots, S_p$ of $\{1, \dots, n\}$ is called *regular* (with respect to A) if $A[S_i]$ is invertible for every $i = 1, \dots, p$. Note that it is impossible to find a regular decomposition of an STM-matrix if the basic class consists only of one index.

For a given $A \in \mathbb{R}^{n\times n}$ and a regular decomposition $S_1, \dots, S_p$ we define restriction operators $R_i \in \mathbb{R}^{|S_i|\times n}$ by the rows of the identity matrix corresponding to the indices in S_i; e.g., if $n = 6$ and $S_1 = \{1, 3, 2\}$, then

$$R_1 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

With the above restriction operators, a projection onto the subspace associated with S_i is given by

$$P_i := R_i^T (R_i A R_i^T)^{-1} R_i A. \tag{4.2}$$

A *(one level) multiplicative Schwarz method* for an initial vector x^0 is given by the stationary iteration (2.1) with

$$T = T_\mu := (I - P_1) \cdot (I - P_2) \cdots (I - P_p). \tag{4.3}$$

The *(damped) additive Schwarz method* is also defined by (2.1), but now

$$T = T_\theta := I - \theta \sum_{i=1}^{p} P_i = I - \theta \sum_{i=1}^{p} R_i^T (R_i A R_i^T)^{-1} R_i A \tag{4.4}$$

and $\theta \in (0, 1)$ is a damping factor.

Note that the usage of partitionings instead of decompositions puts (4.3) into a block Gauß–Seidel and (4.4) into a damped block Jacobi operator.

The following proposition is easy to prove and summarizes the properties of the operators defined above. The proof for the semiconvergence of T_θ can be found in [8]. The rest is easy to obtain.

PROPOSITION 4.1. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix and let $S_1, \dots, S_p$ be a regular decomposition of $\{1, \dots, n\}$. Let $z \in \mathbb{R}^n$ be the positive vector satisfying $Az = 0$. Then, with operators as given in* (4.2) *and* (4.3)*:*

(1) $I - P_i \geq 0,\ i = 1, \dots, p,$
(2) $(I - P_i)z = z,\ i = 1, \dots, p,$
(3) $\rho(I - P_i) = 1,\ i = 1, \dots, p,$
(4) $\mathrm{ind}_1(I - P_i) = 1,\ i = 1, \dots, p,$
(5) $T_\mu \geq 0,$
(6) $T_\mu z = z,$
(7) $\rho(T_\mu) = 1,$
(8) $\mathrm{ind}_1(T_\mu) = 1.$

If T_θ is defined by (4.4) *and $\theta \in (0, 1/q)$, where q is the measure of overlap, then assertions* (5)–(8) *apply verbatim to T_θ. Moreover, T_θ has all its diagonal elements positive, and therefore T_θ is semiconvergent.*

Comparing Proposition 4.1 with the conditions of semiconvergence stated in section 2.4, we see that they match directly except for multiplicative Schwarz. But a closer look on the iterations reveals that, for both additive and multiplicative Schwarz, consistency is nontrivial; i.e., it is not clear that

$$\mathcal{N}(I - T_\mu) = \mathcal{N}(I - T_\theta) = \mathcal{N}(A) \tag{4.5}$$

holds for an STM-matrix A.

Indeed, consider the STM-matrix

$$A = \begin{pmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & -1 \\ 0 & 0 & -1/2 & 0 & 1 & 0 & -1/2 \\ 0 & 0 & 0 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & -1 & 0 & 1 \end{pmatrix},$$

and put $S_1 = \{1, 2, 3\}, S_2 = \{4, 5, 7\}$, and $S_3 = \{6, 7\}$. Then

$$T_\mu := (I - P_1)(I - P_2)(I - P_3) = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{pmatrix}.$$

This is a rank two semiconvergent matrix. Thus

$$\mathcal{N}(I - T_\mu) = \mathrm{span}\{(1, \dots, 1)^T, e_6\} \neq \mathcal{N}(A) = \mathrm{span}\{(1, \dots, 1)^T\},$$

and the iteration might fail to converge against a desired solution. In what follows, we therefore have to investigate consistency and semiconvergence for multiplicative Schwarz, whereas for additive Schwarz we have only to consider consistency.

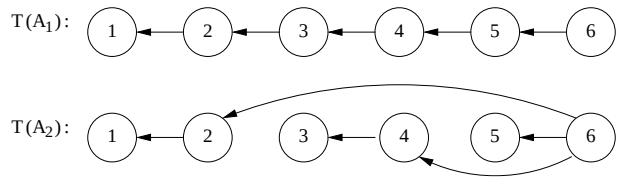

FIG. 5.1. *Trees of A_1 and A_2.*

Note that a consistency problem cannot occur if we use partitions instead of decompositions, i.e., we use block Jacobi or block Gauß–Seidel iterations. This is not hard to see.

5. Convergence of multiplicative Schwarz for *MP*. In this section we define decompositions for an STM-matrix which allows us to prove that a corresponding operator of the form (4.3) is semiconvergent and consistent. As the basic ideas can be derived from simple Gauß–Seidel iterations, we will start with partitionings consisting of singletons.

5.1. The basic idea. Consider the following STM-matrices $A_i = I - B_i,\ B_i \geq 0$ (we show only the nonzero entries):

$$A_1 = \begin{pmatrix} 1 & -1 & & & & \\ & 1 & -1 & & & \\ & & 1 & -1 & & \\ & & & 1 & -1 & \\ & & & & 1 & -1 \\ -1 & & & & & 1 \end{pmatrix}, A_2 = \begin{pmatrix} 1 & -1 & & & & \\ & 1 & & & & -1 \\ & & 1 & -1 & & \\ & & & 1 & & -1 \\ & & & & 1 & -1 \\ -1 & & & & & 1 \end{pmatrix}.$$

We assume a multiplicative Schwarz iteration for the partitioning $S_1, \ldots, S_6$, where $S_i = \{i\}$; i.e., we consider a Gauß–Seidel iteration. Then the projection $I - P_3$, e.g., for A_2, becomes

$$I - P_3 = \begin{pmatrix} 1 & & & & & \\ & 1 & & & & \\ & & 0 & 1 & & \\ & & & 1 & & \\ & & & & 1 & \\ & & & & & 1 \end{pmatrix}.$$

It is easy to see that, for both matrices A_1 and A_2, the operator

$$T_\mu = (I - P_1) \cdots (I - P_6)$$

has a positive first column. And this can be explained by considering the spanning trees of the respective matrices (see Figure 5.1) and multiplying the B_i by an appropriate vector: Consider a vector $x = (\xi, 0, 0, 0, 0, 0)^T, \xi > 0$, and the product $B_i x$ for some B_i. Then the initial value ξ is stored in state 6, the root. Another application of B_i to $B_i x$ reveals that ξ is carried to the states which are direct children of the root, and so on. Hence ξ "flows" through the tree, until it reaches the leaves. The product operator T_μ combines this transport into a single step; i.e., it can be interpreted as introducing a shortcut. The most important property of T_μ is given in the following theorem.

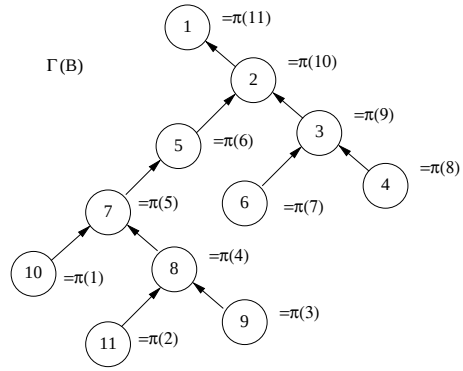

FIG. 5.2. *A flow compatible numbering.*

THEOREM 5.1. *Let $B \in \mathbb{R}^{n\times n}$ be nonnegative with $\rho(B) = 1$. Assume that B has a positive column and there exists $z > 0$ such that $Bz = z$. Then $\gamma(B) < 1$; i.e., B is semiconvergent and $\mathcal{N}(I - B) = \operatorname{span}\{z\}$.*

The above result has been used and proved in [15] and [26]. But it is easy to prove it in the ST-matrix context.

Proof. Let column i_0 of B be positive. Then B contains a spanning tree of height one with the root index i_0 (it is exactly the column i_0 and here we allow the root to coincide with the guard index; cf. Remark 3.1). Since $Bz = z$ for a some z, it follows from Corollary 3.7 that B is an ST-matrix and from section 2.4 that $\rho(B) = 1$ and $\operatorname{ind}_1 B = 1$. By Lemma 3.3, there is a permutation matrix Π such that (3.3) holds, where $\rho(F) < 1$, $\rho(D) = 1$, and D is irreducible. The existence of a positive column is invariant under symmetric permutation. Hence D has a positive diagonal element. But then, $\gamma(D) < 1$ from section 2.4. Thus $\gamma(B) < 1$ and the semiconvergence follows. ∎

Theorem 5.1 gives us the direction we need. If we can characterize decompositions which lead us to operators having a positive column, then the iteration is both semiconvergent and consistent. The example above gives us a hint how to obtain such operators—simply by respecting the above-mentioned "flow." As we will see, the "flow" can be generalized to decompositions and is the key concept behind our investigations.

Based on this idea, we are looking for decompositions such that we have a mapping from the set of STM-matrices (original matrix) into the set of consistent semiconvergent ST-matrices (operator of the multiplicative Schwarz iteration).

DEFINITION 5.2. *Let A be an STM-matrix (or ST-matrix), and let $\mathcal{T}$ be an arbitrary spanning tree in $\Gamma(A^T)$ with some guard index. A* flow compatible numbering (or permutation) *of the vertices of $\mathcal{T}$ is a permutation $\pi : \{1,\dots,n\} \longrightarrow \{1,\dots,n\}$ such that if there is a path from $\pi(i)$ to $\pi(j)$ in $\mathcal{T}$, then $i > j$ for each $1 \le i, j \le n$, $i \ne j$. Any such permutation is also called* flow compatible *(with respect to $\mathcal{T}$).*

Figure 5.2 shows a flow compatible numbering for an ST-matrix B (guard edges have been left out). The example defines a permutation $(10, 11, 9, 8, 7, 5, 6, 4, 3, 2, 1)$, but note that the permutation $(9, 11, 8, 4, 6, 3, 10, 7, 5, 2, 1)$ is also flow compatible.

Remark 5.1. Note that a flow compatible numbering can easily be calculated using a simple depth first search strategy [9] if we start within the strongly connected component (cf. Remark 3.2 and [5, section 4.3]).

We now have the following theorem, which also gives a proof for the classical Gauß–Seidel iteration for STM-matrices.

THEOREM 5.3. *Let $A = I - B \in \mathbb{R}^{n\times n}$ be an STM-matrix, and let π be a flow compatible permutation with respect to some tree $\mathcal{T} \subset \Gamma(B^T)$. Assume that the regular partitioning $S_1, \dots, S_n$ is such that $S_i = \{i\}$, and let P_i be the corresponding projections given by* (4.3) *for $i = 1, \dots, n$. Then*

$$(I - P_{\pi(1)}) \cdot (I - P_{\pi(2)}) \cdots (I - P_{\pi(n)})$$

has at least one positive column and is therefore semiconvergent.

Proof. We prove the theorem using a straightforward calculation of the matrix product.

Since the node $\pi(n)$ is always the root of a tree $\mathcal{T}$ in $\Gamma(B^T)$ (cf. Definition 5.2), there is a guard index j_0 such that $(I - P_{\pi(n)})_{\pi(n),j_0} > 0$. It will first be shown that

$$((I - P_{\pi(k)}) \cdot (I - P_{\pi(k+1)}) \cdots (I - P_{\pi(n)}))_{\pi(k),j_0} > 0$$

for an arbitrary $k \in \{1, \dots, n\}$. As the proposition is obvious for $k = n$, let $1 \le k < n$ be arbitrary but fixed.

Case 1. $(\pi(k), \pi(k+1)) \in \Gamma(B)$. In this case, the node $\pi(k+1)$ represents the parent of $\pi(k)$ in $\mathcal{T}$. Thus we have $(I - P_{\pi(k)})_{\pi(k),\pi(k+1)} > 0$, and there is an index $l \in \mathbb{N},\ k < l \le n$, such that $(I - P_{\pi(k+1)})_{\pi(k+1),\pi(l)} > 0$. The latter holds, since there is a path from $\pi(k+1)$ to $\pi(n)$ in $\mathcal{T}$. But then

$$((I - P_{\pi(k)}) \cdot (I - P_{\pi(k+1)}))_{\pi(k),\pi(l)} > 0.$$

Case 2. $(\pi(k), \pi(k+1)) \notin \Gamma(B)$. In this case, the index $\pi(k)$ must have access to $\pi(l)$ for some $l \in \mathbb{N},\ k+1 < l \le n$, since there is again a path from $\pi(k)$ to $\pi(n)$ in $\mathcal{T}$. The construction of the operators implies that $(I - P_{\pi(k+1)})_{\pi(l),\pi(l)} > 0$ because $\pi(l) \notin S_{k+1}$; thus

$$((I - P_{\pi(k)}) \cdot (I - P_{\pi(k+1)}))_{\pi(k),\pi(l)} > 0.$$

A simple induction leads to

$$((I - P_{\pi(k)}) \cdots (I - P_{\pi(n-1)}))_{\pi(k),\pi(l)} > 0$$

for some $l \in \mathbb{N},\ n-1 < l \le n$, i.e., $l = n$. But $(I - P_{\pi(n)})_{\pi(n),j_0} > 0$, and there holds

$$((I - P_{\pi(k)}) \cdots (I - P_{\pi(n)}))_{\pi(k),j_0} > 0.$$

To finish the proof of the theorem observe that $(I - P_{\pi(j)})_{\pi(k),\pi(k)} > 0$ follows for all $1 \le j < k$ from the construction of $(I - P_{\pi(j)})$. Hence

$$((I - P_{\pi(1)}) \cdot (I - P_{\pi(2)}) \cdots (I - P_{\pi(n)}))_{\pi(k),j_0} > 0.$$

This is the theorem since k was arbitrary. ∎

Theorem 5.3 gives us information about the order of row updates to be used in the Gauß–Seidel iteration. As the proof shows, if the matrix is full, any order works.

COROLLARY 5.4. *Let $A = I - B \in \mathbb{R}^{n\times n}$. If $B > 0$ and $\rho(B) = 1$, then the Gauß–Seidel iteration converges.*

5.2. Block operators. We now extend the concept of flow compatibility to block operators. We start with an investigation of the structure of a single projection.

The following lemma is fundamental, but we need additional notation. To this purpose, let A be an STM-matrix, and let $\mathcal{T}$ be any spanning tree in $\Gamma(A^T)$.

We say a vertex i has *access to a vertex* j *along* $\mathcal{T}$ if there is a path $(j = l_1, l_2, \ldots, l_k = i)$ in $\mathcal{T}$. This is denoted by $i \to_{\mathcal{T}} j$.

Remark 5.2.

(1) If $i \to_{\mathcal{T}} j$, then $(i = l_k, l_{k-1}, \ldots, l_1 = j)$ is a path in $\Gamma(A)$.

(2) The access relation *along* $\mathcal{T}$ is useful, because $\mathcal{T}$ represents a minimal structure of positive elements needed to determine for which decompositions multiplicative Schwarz iterations converge. All other positive elements of A can be ignored.

LEMMA 5.5. *Let A be an STM-matrix, and let $\mathcal{T}$ be an arbitrary spanning tree in $\Gamma(A^T)$. Let π be a flow compatible permutation corresponding to $\mathcal{T}$. Let the tuple*

$$V := (\pi(k), \pi(k+1), \ldots, \pi(l)), \quad 1 \le k < l \le n, \; l - k < n - 1,$$

be chosen in such a way that $A[V]^{-1}$ exists and denote by Π the permutation matrix corresponding to π. According to (4.2)*, let the matrix $I - P$ be defined through*

$$\Pi(I-P)\Pi^T = \begin{pmatrix} I & 0 & 0 \\ M^{-1}N_L & 0 & M^{-1}N_R \\ 0 & 0 & I \end{pmatrix}, \tag{5.1}$$

where $N_L = -A[V, (\pi(1), \ldots, \pi(k-1))]$, $N_R = -A[V, (\pi(l+1), \ldots, \pi(n))]$, and $M = A[V]$. Then for each index j_0, $k \le j_0 \le l$, one of the following three conditions holds:

(1) *If $j_0 = n$, then there exists a node $\pi(i_0) \notin V$ such that $\pi(n) \to \pi(i_0)$ in $\Gamma(A)$ and $(\pi(n), \pi(i_0)) \in \Gamma(I - P)$.*

(2) *If $j_0 \neq n$ and $(\pi(i_0), \pi(j_0)) \in \mathcal{T}$ for some node $\pi(i_0) \notin V$, then $(\pi(j_0), \pi(i_0)) \in \Gamma(I - P)$.*

(3) *If $j_0 \neq n$ and $(\pi(h), \pi(j_0)) \in \mathcal{T}$ for some node $\pi(h) \in V$, then there exists $\pi(i_0) \notin V$ such that $\pi(j_0) \to_{\mathcal{T}} \pi(i_0)$. For any such $\pi(i_0)$ we have $(\pi(j_0), \pi(i_0)) \in \Gamma(I - P)$.*

Furthermore, the node $\pi(i_0)$ in (1)*,* (2)*, and* (3) *satisfies the following:*

(4) *If $l < n$, then $i_0 > l$.*

(5) *If $l = n$, then $i_0 < k$ and i_0 is given by assertion* (1) *(with $j_0 = l$).*

In case (4) *i_0 is unique (with respect to $\mathcal{T}$). In case* (5) *i_0 depends on the chosen guard.*

Before we prove the lemma, we provide a few explanations.

Remark 5.3. The lemma has an easy interpretation if we consider the representation (5.1).

(i) The case $\pi(n) \in V$ plays a special role. Assertion (1) states that there exists a path in $\Gamma(A)$ starting at $\pi(n)$, which leads out of V, and this path is replaced by an edge in $\Gamma(I - P)$, which resides in $M^{-1}N_L$ (note that N_R is empty).

(ii) Assertion (2) says that if $\pi(j_0) \in V$ has direct access to $\pi(i_0) \notin V$ along $\mathcal{T}$ (i.e., $(\pi(j_0), \pi(i_0)) \in \Gamma(A)$), then this edge is still in $\Gamma(I-P)$; i.e., connections leading out of V are preserved.

(iii) Assertion (3) says that if $\pi(j_0) \in V$ has direct access to some element in V along $\mathcal{T}$, then there is a path in V along $\mathcal{T}$ leading to some $\pi(i_0) \notin V$. Furthermore, for each such path there will be an edge in $\Gamma(I - P)$. We can interpret this as that a multiplication with M^{-1} introduces a shortcut in $\mathcal{T}$, with the flow itself being preserved.

(iv) Assertion (4) states that the edges of interest lie in $M^{-1}N_R$ except in the case in which the root is in V, which is considered in assertion (5). Then, since each vertex has access to the root, access to some vertex outside V is guaranteed by assertion (1).

Figure 5.3 describes the situation for an STM-matrix $A = I - B$. The figure shows the graph of A and the tuple $V = (\pi(4), \pi(5), \pi(6), \pi(7)) = (8, 7, 5, 6)$. The graph $\Gamma(I - P)$ is the graph of P given by (5.1) with respect to V. Note that the dashed edges in $\Gamma(I - P)$ are shortcuts of paths existing in $\Gamma(A)$. The diagonal edges and the guard edges in $\Gamma(A)$ are not shown.

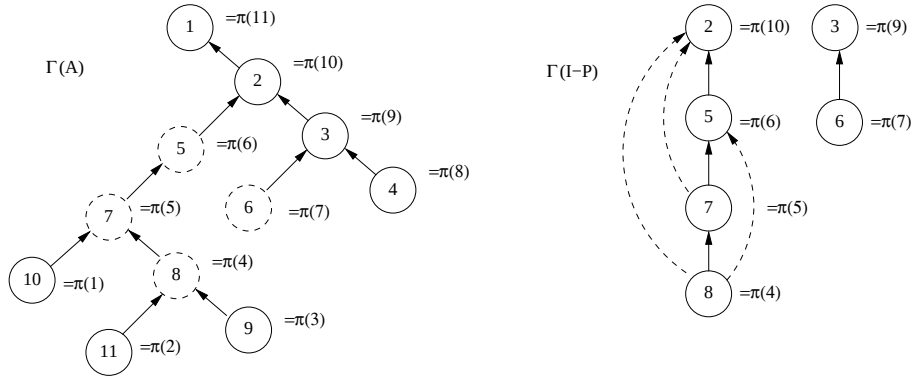

FIG. 5.3. *Graph of a matrix and of a corresponding projection.*

Proof. The proof of Lemma 5.5 is a bit technical and is therefore split into several parts.

Part 1: *Classification of vertices in* V. Define boundary, inner, and outer vertices $B(V), I(V), O(V)$, respectively, by

$$\begin{aligned} B(V) &:= \{v \in V : \text{ there exist } w \notin V \text{ such that } (w, v) \in \mathcal{T}\}, \\ I(V) &:= \{v \in V : \text{ there exist } u \in V \text{ such that } (u, v) \in \mathcal{T}\}, \\ O(V) &:= V \setminus (B(V) \cup I(V)). \end{aligned}$$

Taking the set V from Figure 5.3, we have $B(V) = \{\pi(6), \pi(7)\} = \{5, 6\}$, $I(V) = \{\pi(4), \pi(5)\} = \{8, 7\}$, and $O(V) = \emptyset$.

Now we have

(i) $B(V) \cap I(V) = \emptyset$,
(ii) $B(V) \cup O(V) \cup I(V) = V$,
(iii) $O(V) \neq \emptyset \Rightarrow O(V) = \{\pi(n)\}$, and
(iv) $B(V) = \emptyset \Leftrightarrow O(V) \neq \emptyset$.

To prove this let $v \in V$ be arbitrary. Assume there exists a w such that $(w, v) \in \mathcal{T}$. Then w is unique since $\mathcal{T}$ is tree. If $w \in V$, then $v \in I(V)$; else $v \in B(V)$. If there exists no w satisfying $(w, v) \in \mathcal{T}$, then $v = \pi(n)$ and obviously $\pi(n) \in O(V)$. Since the root is unique, this proves (i)–(iii).

Suppose $B(V) = \emptyset$. Every vertex, except the root, has a parent, but no vertex $v \in V$ has an adjacent vertex $w \notin V$ in $\mathcal{T}$. Thus, every vertex $v \in V$ has an adjacent vertex in V along $\mathcal{T}$ (except the root), and therefore $\pi(n) \in V$ holds necessarily.

Now assume $O(V) \neq \emptyset$; then $O(V) = \{\pi(n)\}$ by (iii) and $l = n$ by the flow compatibility and the definition of V. If there is a $v \in B(V)$, then there exists a

$w \notin V$ satisfying $(w, v) \in \mathcal{T}$. Additionally, there are numbers $k_1, k_2 \in \{1, \dots, n\}$ such that $v = \pi(k_1)$ and $w = \pi(k_2)$. Since π is flow compatible, $k \le k_1 < k_2 \le n$. But then $w = \pi(k_2) \in V$, which is a contradiction, and (iv) follows.

Part 2: *The case* $\pi(n) \in V$. Here we prove the existence of the index i_0 as stated in assertion (1) and (i) in Remark 5.3. We have

$$V := (\pi(k), \pi(k+1), \dots, \pi(n)), \quad 1 < k < n,$$

and $\pi(j_0) = \pi(n)$. Now we show that there is always a path in $\Gamma(A[V]) = \Gamma(M)$ starting at $\pi(n)$ which leads us to some $\pi(i_0)$ not in V.

As A is an STM-matrix, there is a guard index $k_0 \in \{1, \dots, n\}$ such that $(A)_{\pi(j_0),\pi(k_0)} > 0$. If $\pi(k_0) \notin V$, we have found the path and choose $i_0 := k_0$.

Hence assume $\pi(k_0) \in V$. Let α be the final and basic class of A. Denote $\tilde{\alpha} = \pi(\alpha)$. Then there is an index $\pi(i_0) \in \tilde{\alpha}$ which fulfills $\pi(i_0) \notin V$. Otherwise, the strongly connected class $\tilde{\alpha}$ would be a subset of V and because $0 \in \sigma(A[\tilde{\alpha}])$ we also have $0 \in \sigma(A[V])$ (cf. Lemma 3.3). The latter is impossible because $M^{-1} = A[V]^{-1}$ exists by assumption.

Now there exist $\pi(i_0) \in \tilde{\alpha} \backslash V$ and a path $(\pi(n) = \pi(i_k), \dots, \pi(i_1), \pi(i_0))$ from $\pi(n)$ to $\pi(i_0)$ in $\Gamma(A)$. We can choose the path such that $(\pi(i_k), \dots, \pi(i_1)) \subset \Gamma(A[V]) = \Gamma(M)$. Then $(\pi(i_1), \pi(i_0)) \in \Gamma(A)$ and, by the construction, $\pi(i_0) \notin V$ and $i_0 < k < l = n$; i.e., we have found a path leading outside V.

Additionally, by Lemma 2.1, $\Gamma(M^{-1}) = \overline{\Gamma(M)}$; thus there is an edge $(\pi(n), \pi(i_1)) \in \Gamma(M^{-1})$. We will see that this part of the path will be cut short in the final operator (we give an example of this situation later).

Part 3: *Inner vertices.* Now we analyze inner vertices as mentioned in (iii) in Remark 5.3. Let $v \in I(V)$; then there exists exactly one vertex $w \in V$ such that $(w, v) \in \mathcal{T}$. If $w \in I(V)$, we continue inductively until a vertex $u \notin I(V)$. Then $u \in B(V)$ or $u = \pi(n)$ (part 1, (iv)). In either case there is a unique path $p = (u = \pi(i_k), \pi(i_{k-1}), \dots, \pi(i_1) = v)$ in $\mathcal{T}$; i.e., $v \to_{\mathcal{T}} u$. Furthermore, $l \ge i_k > i_{k-1} > \cdots > i_1 \ge k$ and $p^T = (\pi(i_1), \dots, \pi(i_k))$ is a path in $\Gamma(M)$. As in part 2, we have $\Gamma(M^{-1}) = \overline{\Gamma(M)}$, i.e., $(v, u) \in \Gamma(M^{-1})$. So the path in $\mathcal{T}$ will be cut short in $\Gamma(M^{-1})$ by the vertex $(v, u) = (\pi(i_1), \pi(i_k))$. Additionally, we have $i_k > i_1$.

Part 4: *Proving the assertions.* Now we use the results from the previous parts to prove the assertions for an arbitrary but fixed j_0 with $k \le j_0 \le l$. Write $I - P$ as follows:

$$\Pi(I - P)\Pi^T = \begin{pmatrix} I & 0 & 0 \\ 0 & M^{-1} & 0 \\ 0 & 0 & I \end{pmatrix} \begin{pmatrix} I & 0 & 0 \\ N_L & 0 & N_R \\ 0 & 0 & I \end{pmatrix} =: M_n^{-1} N_n.$$

By Lemma 2.1

$$\Gamma(M_n^{-1} N_n) = \Gamma(M_n^{-1})\Gamma(N_n) = \overline{\Gamma(M_n)}\Gamma(N_n). \tag{5.2}$$

Case (a) $\pi(j_0) \in B(V)$. There exists exactly one $\pi(i_0)$ satisfying $(\pi(j_0), \pi(i_0))_{\mathcal{T}}$ and $\pi(i_0) \notin V$. But then $(\pi(j_0), \pi(i_0)) \in \Gamma(N_R)$ since $i_0 > j_0$ by the flow compatibility.

With $\Delta \subset \overline{\Gamma(M_n)}$ and (5.2) the relation $(\pi(j_0), \pi(i_0)) \in \Gamma(I - P)$ follows. Hence, assertion (2) combined with (4) is proven.

Case (b) $\pi(j_0) \in I(V)$ *and* $B(V) \neq \emptyset$. In view of part 3 there exists exactly one $\pi(h) \in B(V)$ such that $(\pi(j_0), \pi(h)) \in \overline{\Gamma(M_n)}$ and $h > j_0$. Applying case (a) to h instead of j_0, we see that there is exactly one edge $(\pi(h), \pi(i_0)) \in \Gamma(N_R)$. From (5.2) we again get $(\pi(j_0), \pi(i_0)) \in \Gamma(I-P)$, and $i_0 > h > j_0$. This is assertion (3) combined with (4).

Case (c) $\pi(j_0) = \pi(n)$. By part 2 there are vertices $\pi(i_0) \notin V$ and $\pi(j_1) \in V$ such that $(\pi(j_1), \pi(i_0)) \in \Gamma(A)$ and $(\pi(j_0), \pi(j_1)) \in \Gamma(M^{-1})$. But $i_0 < k < l = n$; thus $(\pi(j_1), \pi(i_0)) \in \Gamma(N_L)$, and again by (5.2), $(\pi(j_0), \pi(i_0)) \in \Gamma(I-P)$. This is assertion (1) combined with (5).

Case (d) $\pi(j_0) \in I(V)$ *and* $\pi(n) \in V$. By part 1, $B(V) = \emptyset$. Part 3 implies that there exists an edge $(\pi(j_0), \pi(n)) \in \overline{\Gamma(M_n)}$ which is unique in $\mathcal{T}$. Applying case (c) shows the existence of edges $(\pi(j_1), \pi(i_0)) \in \Gamma(N_L)$ and $(\pi(j_0), \pi(j_1)) \in \overline{\Gamma(M_n)}$. This implies $(\pi(j_0), \pi(i_0)) \in \Gamma(I-P)$ and $j_0 \geq k > i_0$. Hence, assertion (2) combined with (5) is proven.

This finishes the proof of the lemma. ∎

Remark 5.4. The lemma also holds for the projection P instead of $I - P$.

The proof shows that Lemma 5.5 holds independently of the order within V; hence, V can be interpreted as a set rather than a tuple.

DEFINITION 5.6. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix, and let π be a flow compatible numbering of a spanning tree $\mathcal{T} \subset \Gamma(A^T)$. A regular partitioning $S_1, \ldots, S_p$ of $(\pi(1), \ldots, \pi(n))$ is termed a* block flow compatible *partitioning if for $1 \leq k < l \leq p$ we have*

$$\max\{j : \pi(j) \in S_k\} < \min\{j : \pi(j) \in S_l\}.$$

We will use Lemma 5.5 and Definition 5.6 to prove the convergence of multiplicative Schwarz iterations. Before we start with this, we consider some other applications of the results presented so far. The first application concerns the block Jacobi iteration operator and will be used to motivate the approach in section 6.

COROLLARY 5.7. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix, and let π be a flow compatible numbering of a spanning tree $\mathcal{T} \subset \Gamma(A^T)$. Consider a block flow compatible partitioning $S_1, \ldots, S_p$ and define $M_i := A[S_i]$, $M = \operatorname{diag}(M_1, \ldots, M_p)$, and $N = M - A$. Then $M^{-1}N$ is an ST-matrix.*

Proof. Since the partitioning is regular, each M_i is invertible. By Lemma 5.5, each index $u \in S_i, i < p$ has access to some $v \in S_j, j > i$, in $\Gamma(M^{-1}N)$. Therefore, each index $u \in \{1, \ldots, n\} \setminus S_p$ has access to some $v \in S_p$. Furthermore, each index $v \in S_p$ has access to a single index $w \notin S_p$, which is the guard index of $\pi(n) \in S_p$. Hence $\Gamma((M^{-1}N)^T)$ contains a spanning tree. Since $w \notin S_p$, we have $w \in S_i$ for some $i < p$ and w has access to some index in $S_j, j > i$. Hence there is a path from w to itself in $\Gamma(M^{-1}N)$. The vertex w can be considered as the root, and there must exist a guard index, since there is a path from w to itself. The ST-matrix property follows now from Corollary 3.7. ∎

COROLLARY 5.8. *With the assumptions of Corollary* 5.7 *there exists a spanning tree $\widetilde{\mathcal{T}}$ in $M^{-1}N$ of height at most p.*

To give an example to illustrate Corollary 5.7 and Lemma 5.5, consider the STM-matrix $A = I - B$, where the graph of B is given by Figure 5.3 and the guard index of the root index 1 is index 3. Then

$$A = \begin{pmatrix}
1 & & -1 & & & & & & & & \\
-1 & 1 & & & & & & & & & \\
 & -1 & 1 & & & & & -1 & & & \\
 & & -1 & 1 & & & & & & & \\
 & -1 & & & 1 & & & & & & \\
 & & -1 & & & 1 & & & & & \\
 & & & & -1 & & 1 & & & & \\
 & & & & & & -1 & 1 & & & \\
 & & & & & & -1 & & & 1 & \\
 & & & & & & & -1 & & & 1
\end{pmatrix}.$$

Applying the flow compatible permutation given in Figure 5.3, A becomes

$$\Pi A \Pi^T = \left(\begin{array}{ccc|ccc|ccc|ccc}
1 & & & & -1 & & & & & & & \\
 & 1 & & -1 & & & & & & & & \\
 & & 1 & -1 & & & & & & & & \\
\hline
 & & & 1 & -1 & & & & & & & \\
 & & & & 1 & -1 & & & & & & \\
 & & & & & 1 & & & & -1 & & \\
 & & & & & & 1 & & -1 & & & \\
\hline
 & & & & & & & 1 & -1 & & & \\
 & & & -1 & & & & & 1 & -1 & & \\
 & & & & & & & & & 1 & -1 & \\
 & & & & & & & & -1 & & & 1
\end{array}\right).$$

Now consider the (permuted) partition $S_1 = \{1, 2, 3\}, S_2 = \{4, 5, 6, 7\}$, and $S_3 = \{8, 9, 10, 11\}$. To give an example for the proof of Lemma 5.5 note that

(i) S_1 consists of only boundary nodes,

(ii) S_2 consists of both boundary and inner nodes,

(iii) S_3 has one outer node (the root) and some inner nodes, and

(iv) the guard index of the root lies within S_3; thus S_3 is an example as discussed in part 2 of the proof of Lemma 5.5.

To illustrate Corollary 5.7, the block Jacobi iteration matrix becomes

$$M^{-1}N = \left(\begin{array}{ccc|ccc|ccc|ccc}
 & & & & 1 & & & & & & & \\
 & & & 1 & & & & & & & & \\
 & & & 1 & & & & & & & & \\
\hline
 & & & & & & & & & 1 & & \\
 & & & & & & & & & 1 & & \\
 & & & & & & & & & 1 & & \\
 & & & & & & & & 1 & & & \\
\hline
 & & & 1 & & & & & & & & \\
 & & & 1 & & & & & & & & \\
 & & & 1 & & & & & & & & \\
 & & & 1 & & & & & & & &
\end{array}\right).$$

The matrix $M^{-1}N$ is obviously an ST-matrix with the root index $4 = \pi^{-1}(8)$ and the guard index $10 = \pi^{-1}(2)$. Note that $M^{-1}N$ is not semiconvergent.

Now let $(I - P_1), (I - P_2)$, and $(I - P_3)$ be the operators given by (5.1) with respect to $S_i, i = 1, 2, 3$. Then the nontrivial block row of $I - P_i$ corresponds to the ith block row of $M^{-1}N$. Additionally, a short computation shows that the product $(I - P_1) \cdot (I - P_2) \cdot (I - P_3)$ has a positive fourth column and is thus semiconvergent.

This is not very surprising because now the block rows behave like single states and the order of the projections in the product can be interpreted as a flow compatible numbering of a (block) spanning tree of height 3 (cf. Corollary 5.8). In the general case, the following result holds.

THEOREM 5.9. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix and $S_1, \dots, S_p$ be a block flow compatible partitioning. Let $(I - P_i)$ be given by* (5.1)*; then the product*

$$P := (I - P_1) \cdots (I - P_p)$$

has at least one positive column and is semiconvergent.

Proof. This theorem is a special case of Theorem 5.13 to be proven later. □

Theorem 5.9 has a corollary which has the same meaning as Corollary 5.4 has for Theorem 5.3.

COROLLARY 5.10. *Let $A = I - B \in \mathbb{R}^{n\times n}$. Assume $B > 0$ and $\rho(B) = 1$; then the block Gauß–Seidel iteration converges for every regular partitioning $S_1, \dots, S_p$.*

To prepare our convergence theorem for the overlapping case, we must adapt flow compatibility to decompositions rather than partitionings. The following definition is a natural extension of block flow compatibility for partitionings (cf. Definition 5.6) to decompositions.

DEFINITION 5.11. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix, and let π be a flow compatible numbering of a spanning tree $\mathcal{T} \subset \Gamma(A^T)$. A regular decomposition $S_1, \dots, S_p$ of $(\pi(1), \dots, \pi(n))$ is said to be* ms-compatible *(ms for "multiplicative Schwarz") if there exists a block flow compatible partitioning $\tilde{S}_1, \dots, \tilde{S}_p$ such that $\tilde{S}_i \subseteq S_i$ for all $i = 1, \dots, p$ and if, in addition, $\pi(n) \notin S_j$ for $j = 1, \dots, p-1$.*

The restriction for the root residing in just one set will be discussed after the next theorem. As a preparation, we need the following corollary to Lemma 5.5 for the case that $V \subset \{1, \dots, n\}$ is arbitrary.

COROLLARY 5.12. *Let V be any subset of $\{\pi(1), \dots, \pi(n)\}$ such that $M^{-1} = A[V]^{-1}$ exists.*

(1) *If $\pi(n) \notin V$, then the assertions* (2), (3), *and* (4) *of Lemma* 5.5 *hold.*

(2) *If $\pi(n) \in V$, define $\mathcal{T}_V := \mathcal{T} \cap \Gamma(M^T)$:*

$$V_{\mathcal{T}} := \{\pi(k) \in V : \pi(k) \to_{\mathcal{T}_V} \pi(n)\} \cup \{\pi(n)\},$$
$$V_{\neg\mathcal{T}} := V \setminus V_{\mathcal{T}}.$$

(i) *Then the assertions* (2), (3), *and* (4) *of Lemma* 5.5 *hold for $V_{\neg\mathcal{T}}$, and*

(ii) *the assertions* (1), (3), *and* (5) *of Lemma* 5.5 *hold for $V_{\mathcal{T}}$ with an index $i_0 \in \{1, \dots, n\}$ satisfying $i_0 < n$.*

Proof. Assertion (1) follows as in the proof of Lemma 5.5. As $\pi(n) \notin V_{\neg T}$, there is also nothing to prove for $V_{\neg T}$, i.e., for assertion 2, part (i).

To prove assertion 2, part (ii), consider the guard index $\pi(j_0)$ of $\pi(n) \in V_{\mathcal{T}}$. If $\pi(j_0) \notin V$, then Lemma 5.5 applies directly to $V_{\mathcal{T}}$ with $i_0 = j_0$. Thus assume $\pi(j_0) \in V$. Then an argument analogous to part (2) of the proof of Lemma 5.5 can be used which gives the proposition for some i_0 satisfying $i_0 < n$ and $\pi(i_0) \notin V$. □

THEOREM 5.13. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix, π a flow compatible numbering of a spanning tree $\mathcal{T} \subset \Gamma(A^T)$, and $S_1, \dots, S_p$ an ms-compatible decomposition. Let $(I - P_i)$ be given by* (4.2)*. Then the product*

$$P := (I - P_1) \cdots (I - P_p)$$

has at least one positive column.

Proof. Let $\tilde{S}_1, \ldots, \tilde{S}_p$ be the corresponding partitioning according to Definition 5.11, and set

$$\bar{S}_j := \bigcup_{l=j}^{p} \tilde{S}_l, \quad j = 1, \ldots, p.$$

Put

$$\mathcal{P}_j := (I - P_j) \cdots (I - P_p).$$

By induction we now show that for $j = p, \ldots, 1$

(5.3) there is an l_0 such that for all $\pi(k) \in \bar{S}_j$ there holds $(\pi(k), \pi(l_0)) \in \Gamma(\mathcal{P}_j)$.

Note that $\bar{S}_p = \tilde{S}_p$ and $\tilde{S}_p = \{\pi(k_p), \pi(k_p + 1), \ldots, \pi(n)\}$ for $k_p < n$. Corollary 5.12 implies that there is an index $l_0 < n$ such that $(\pi(j), \pi(l_0)) \in \Gamma(I - P_p) = \Gamma(\mathcal{P}_p)$ for all $j = k_p, \ldots, n$.

Let $p > j > 1$ and assume that (5.3) holds for some j. The inductive step has two parts.

Increasing number of positive elements. Let $\tilde{S}_{j-1} = \{\pi(k_{j-1}), \pi(k_{j-1} + 1), \ldots, \pi(k_{j-1} + l)\}$ for some $l \in \mathbb{N}_0$. Due to Lemma 5.5, there exists for each $i = 0, \ldots, l$ an index $l_i > k_{j-1} + i$ such that $(\pi(k_{j-1} + i), \pi(l_i)) \in \Gamma(I - P_{j-1})$. Since $\pi(n) \notin S_{j-1}$ one gets $l_i > k_{j-1} + l$ for all $i = 0, \ldots, l$. But $k_{j-1} + l = k_j - 1$ and thus $n \geq l_i \geq k_j$ for all $i = 0, \ldots, l$. By the induction hypothesis there is an edge $(\pi(l_i), \pi(l_0)) \in \Gamma(\mathcal{P}_j)$ for all $i = 0, \ldots, l$. Since $\Gamma(\mathcal{P}_{j-1}) = \Gamma(I - P_{j-1})\Gamma(\mathcal{P}_j)$, the relation $(\pi(k_{j-1} + i), \pi(l_0)) \in \Gamma(\mathcal{P}_{j-1})$ follows for all $i = 0, \ldots, l$.

Positivity preservation. Let $\pi(k_0) \in \bar{S}_j = \{\pi(k_j), \ldots, \pi(n)\}$ be arbitrary but fixed. Then by the induction hypothesis $(\pi(k_0), \pi(l_0)) \in \Gamma(\mathcal{P}_j)$. There are two possible cases.

In the case $\pi(k_0) \notin S_{j-1}$, there is an edge $(\pi(k_0), \pi(k_0)) \in \Gamma(I - P_{j-1})$ by the construction of P_{j-1}. But then $(\pi(k_0), \pi(l_0)) \in \Gamma(\mathcal{P}_{j-1})$ as the positive diagonal element in $I - P_{j-1}$ preserves the entry. In the case $\pi(k_0) \in S_{j-1}$, Lemma 5.5 implies that there is an edge $(\pi(k_0), \pi(l_1)) \in \Gamma(I - P_{j-1})$, and $l_1 > k_0$. Consequently, $\pi(l_1) \in \bar{S}_j$. By the induction hypothesis there is an edge $(\pi(l_1), \pi(l_0)) \in \Gamma(\mathcal{P}_j)$, and therefore $(\pi(k_0), \pi(l_0)) \in \Gamma(\mathcal{P}_{j-1})$.

We have thus shown that (5.3) holds for $j = p, \ldots, 1$.

Taking $j = 1$, $\bar{S}_1 = \{\pi(1), \ldots, \pi(n)\}$ and $(\pi(j), \pi(l_0)) \in \Gamma(\mathcal{P}_1)$ for all $j = 1, \ldots, n$. Hence the theorem is proven. ∎

The condition $\pi(n) \notin S_j$ for $j \neq p$ in Definition 5.11 appears to be restrictive. It cannot, however, be omitted when general overlap is allowed. This has been shown by the example from section 4. There are alternative conditions for which we can prove Theorem 5.13 holds. For a given regular decomposition $S_1, \ldots, S_p$, these conditions are as follows.

(1) Every set S_i containing the root can be written as $S_i = \{\pi(k_i), \pi(k_i + 1), \ldots, \pi(n)\}$ for an index $1 \leq k_i \leq n$; i.e., the sets have no gap.

(2) All sets $S_{i_1}, \ldots, S_{i_k}$ containing the root have access to the same index in $\Gamma(A)$; i.e., there exists an index $\pi(i_0) \notin S_{i_j}$ for $j = 1, \ldots, k$, such that $\pi(n) \longrightarrow \pi(i_0)$ in $\Gamma(A)$.

Results based on these conditions are not presented here. Note that neither condition is satisfied in the example from section 4.

5.3. Application to multiplicative Schwarz. Now we have elements in place to prove the convergence of multiplicative Schwarz to a solution of the model problem *MP*; cf. Definition 3.1.

THEOREM 5.14. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix and let $S_1, \dots, S_p$ be an ms-compatible decomposition. Then the one level multiplicative Schwarz iteration* (2.1) *using T_μ given by* (4.3) *converges to a solution of $Ax = b$ for every given $x^0 \in \mathbb{R}^n$ whenever $b \in \mathcal{R}(A)$.*

Proof. The operator T_μ has a positive column by Theorem 5.13. Hence, Corollary 3.7 implies that it is an ST-matrix and the semiconvergence follows from Theorem 5.1. Theorem 5.1 implies also that $\dim \mathcal{N}(I - T_\mu) = 1$. Thus one gets $\mathcal{N}(I - T_\mu) = \mathcal{N}(A)$ and the iteration is consistent. ∎

6. Damped projections. Now we investigate multiplicative Schwarz iterations for damped projections; i.e., for an STM-matrix A we consider the operator

$$T_{\mu,\eta} := (I - \eta P_1) \cdots (I - \eta P_p) \tag{6.1}$$

for a regular decomposition $S_1, \dots, S_p$ and some $\eta \in (0, 1)$. We choose $\eta \in (0, 1)$ since we can view this as introducing under relaxation because

$$I - \eta P_i = (1 - \eta)I + \eta(I - P_i)$$

for all $i = 1, \dots p$.

Proposition 4.1 applies verbatim to $T_{\mu,\eta}$. Trivially, since $\eta \in (0, 1)$, it follows that $T_{\mu,\eta}$ has a positive diagonal; thus it is semiconvergent. Hence, it remains only to prove consistency.

We will show that $T_{\mu,\eta}$ is an ST-matrix. Then we are done, because the ST property implies consistency. We need the following lemma, which transforms the question of consistency from a multiplicative problem into an additive one and follows in a straightforward manner from Lemma 2.1.

LEMMA 6.1. *Consider nonnegative square matrices $L_1, \dots, L_p$ and assume that the diagonal of each L_i is positive. Then for any permutation $\sigma : \{1, \dots, p\} \longrightarrow \{1, \dots, p\}$,*

$$\Gamma\left(\sum_{j=1}^{p} L_{\sigma(j)}\right) = \bigcup_{j=1}^{p} \Gamma(L_{\sigma(j)}) \subset \Gamma(L_{\sigma(1)} \cdots L_{\sigma(p)}).$$

We can now prove the desired result.

THEOREM 6.2. *Suppose $A \in \mathbb{R}^{n\times n}$ is an STM-matrix, α is the final and basic class of A, and $i_0 \in \alpha$ is arbitrary. Let $S_1, \dots, S_p$ be a regular decomposition such that i_0 is contained in exactly one set S_j. Then*

$$T^{(\sigma)}_{\mu,\eta} := (I - \eta P_{\sigma(1)}) \cdots (I - \eta P_{\sigma(p)})$$

is a semiconvergent ST-matrix for any permutation $\sigma : \{1, \dots, p\} \longrightarrow \{1, \dots, p\}$ and $\eta \in (0, 1)$.

Proof. By Lemma 6.1 and the nonnegativity of the damped projections, it suffices to show that the "flow" given by $\mathcal{T}$ is preserved, i.e., that the graph of

$$\sum_{j=1}^{p} (I - \eta P_j)$$

contains a spanning tree with a guard.

To prove this let $\mathcal{T} \subset \Gamma(A^T)$ be an arbitrary spanning tree with root i_0 (cf. Corollary 3.4). Consider a flow compatible numbering π of $\mathcal{T}$; then $i_0 = \pi(n)$. Assume w.l.o.g. that $\pi(n) \in S_p$ and define

$$\tilde{S}_p := \{\pi(j) \in S_p : \pi(j) \to_{\mathcal{T}} \pi(n)\} \cup \{\pi(n)\}. \tag{6.2}$$

By Corollary 5.12 there exists an index j_0 such that $j_0 < n$ and each $\pi(j) \in \tilde{S}_p$ has access to $\pi(j_0) \notin \tilde{S}_p$ in $\Gamma(I - \eta P_p)$. Thus, it remains to show that each $\pi(l) \in \{1, \ldots, n\} \setminus \tilde{S}_p$ has access to some $\pi(j) \in \tilde{S}_p$ in

$$\Gamma\left(\sum_{j=1}^{p}(I - \eta P_j)\right). \tag{6.3}$$

Therefore, we let $\pi(l_0) \in \{1, \ldots, n\} \setminus \tilde{S}_p$ be arbitrary but fixed. Then $\pi(l_0) \in S_{k_0} \setminus \tilde{S}_p$ for some $k_0 \in \{1, \ldots, p\}$. It follows from Lemma 5.5 that $\pi(l_0)$ has access to some $\pi(l_1)$ in $\Gamma(I - \eta P_{k_0})$ and $l_1 > l_0$. If $\pi(l_1) \notin \tilde{S}_p$, then $\pi(l_1)$ has access to some $\pi(l_2)$ in $\Gamma(I - \eta P_{k_1})$ for some $k_1 \in \{1, \ldots, p\}$ and $l_2 > l_1$. So, inductively, after a maximum of $n-1$ steps, it follows that $\pi(l_0)$ has access to some $\pi(j) \in \tilde{S}_p$ in the graph from (6.3).

Consequently, each $\pi(j) \in \{1, \ldots, n\}$ has access to $\pi(j_0)$ and since $\pi(j_0) \in \{1, \ldots, n\} \setminus \tilde{S}_p$, $\pi(j_0)$ must have access to itself; i.e. the graph (6.3) contains a spanning tree with a guard index. Lemma 6.1 implies that this also holds for $T_{\mu,\eta}^{(\sigma)}$. As $T_{\mu,\eta}^{(\sigma)} z = z$ for the positive vector $z \in \mathcal{N}(A)$, we have from Corollary 3.7 that $T_{\mu,\eta}^{(\sigma)}$ is an ST-matrix. Additionally, the diagonals of $T_{\mu,\eta}^{(\sigma)}$ are positive; thus $T_{\mu,\eta}^{(\sigma)}$ is semiconvergent. □

Remark 6.1. We do not know whether one could dispense with the condition that one index from α is contained in just one set S_j. In the case of an irreducible matrix, this condition reduces to having one variable which has no overlap, which will usually be fulfilled.

DEFINITION 6.3. *Let $A = I - B \in \mathbb{R}^{n\times n}$ be an STM-matrix and denote by α its basic class. A regular decomposition $S_1, \ldots, S_p$ with respect to A is said to be* root preserving *if there exists an $i_0 \in \alpha$ such that $|\{j : i_0 \in S_j\}| = 1$.*

The following theorem is a simple application of Theorem 6.2 and gives us the convergence of the damped Schwarz iteration for *MP*.

THEOREM 6.4. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix, and let $S_1, \ldots, S_p$ be a root preserving decomposition. Then the damped one level multiplicative Schwarz iteration, i.e., iteration* (2.1) *using $T_{\mu,\eta}$ given by* (6.1)*, converges to the solution of $Ax = b$ for every given $x^0 \in \mathbb{R}^n$ whenever $b \in \mathcal{R}(A)$ and $\eta \in (0, 1)$.*

7. Convergence of additive Schwarz for *MP*. Finally, we investigate the convergence of additive Schwarz iterations for the model problem *MP* given by the iteration (2.1) and (4.4). This is now quite simple using the theory already developed.

Let us consider a root preserving decomposition $S_1, \ldots, S_p$ from the last section. We know that

$$\sum_{j=1}^{p}(I - \eta P_j) = pI - \eta P_1 - \cdots - \eta P_p \tag{7.1}$$

is a semiconvergent ST-matrix by the proof of Theorem 6.2. Comparing (7.1) and (4.4) reveals that T_θ is also an ST-matrix because

$$\Gamma(T_\theta) = \Gamma\left(\sum_{j=1}^{p}(I - \eta P_j)\right).$$

The semiconvergence of T_θ has been considered in Proposition 4.1. Thus we have the following theorem (which obviously applies to MP).

THEOREM 7.1. *Let $A \in \mathbb{R}^{n\times n}$ be an STM-matrix and let $S_1, \ldots, S_p$ be a root preserving decomposition. Then the one level additive Schwarz iteration, i.e., iteration* (2.1) *using T_θ given by* (4.4)*, converges to the solution of $Ax = b$ for every given $x^0 \in \mathbb{R}^n$ whenever $b \in \mathcal{R}(A)$ and $\theta \in (0, 1/q)$, where q is the measure of overlap.*

8. Concluding remarks and outlook. In this paper we introduce a graph theoretical approach and prove new convergence theorems for the classical one level multiplicative Schwarz iteration, the damped one level multiplicative Schwarz iteration, and the one level additive Schwarz method when applied to singular M-matrices.

The major ingredient is a compatibility condition between a spanning tree embedded in the graph of the matrix and the sets defining the Schwarz decomposition. In the case of overlap, additional conditions had to be imposed on the root of the tree. It is not possible to completely ignore these conditions, as we have shown in a counterexample.

Several generalizations are possible [5]. We can weaken condition (1.2) to

$$Az = 0 \quad \text{for some positive vector } z;$$

i.e., we allow the dimension of the null space of A to be larger than one. Indeed, the results presented here carry over with only minor restrictions to this new situation. Additionally, within our framework we can also obtain convergence results of Schwarz methods for two-stage (see, e.g., [6, 17, 21]) and partially asynchronous (see, e.g., [2, 7, 14, 12]) variants. These results are presented in a future companion paper.

Finally we mention that the graph based approach used here is quite different from those in [10, 18, 23, 25]. In those references, only splittings of a singular M-matrix without overlap are discussed.

NEW CRITERIA FOR THE FEASIBILITY OF THE CHOLESKY METHOD WITH INTERVAL DATA*

G. ALEFELD† AND G. MAYER‡

Dedicated to Prof. Dr. Ulrich Kulisch of the University of Karlsruhe on the occasion of his 75th birthday

Abstract. We present some new criteria for the feasibility of the interval Cholesky method. In particular, we relate this feasibility to that of the interval Gaussian algorithm.

Key words. linear interval equations, Cholesky method, interval Cholesky algorithm, Gaussian algorithm, interval Gaussian algorithm, linear system of equations, criteria of feasibility

AMS subject classifications. 65G20, 65G30

DOI. 10.1137/070711232

1. Introduction.

In [2] we introduced the interval Cholesky method in order to enclose the symmetric solution set

$$S_{\text{sym}} = \{x \in \mathbb{R}^n |\ Ax = b,\ A = A^T \in [A] = [A]^T,\ b \in [b]\},$$

where $[A] = [\underline{A}, \overline{A}]$ is a given $n \times n$ interval matrix and $[b]$ is a corresponding interval vector. The algorithm uses the formulae of the classical Cholesky method, replacing the real entries and arithmetic by interval ones. It terminates with an interval vector $[x]^C = \text{ICh}([A], [b])$ which encloses S_{sym} but not necessarily the general solution set

$$S = \{x \in \mathbb{R}^n |\ Ax = b,\ A \in [A],\ b \in [b]\},$$

which also contains the solutions of linear systems with unsymmetric matrices from $[A]$. A criterion necessary for $[x]^C$ to exist is the positive definiteness of all symmetric matrices in $[A]$—independently of any right-hand side $[b]$. Unfortunately, this property is not sufficient as Reichmann's example in [13] shows which originally was constructed for a different situation. This example caused the necessity of criteria which guarantee the existence of $[x]^C$ or, equivalently, the feasibility of the interval Cholesky method for arbitrary right-hand interval sides. In [2] we proved that $[x]^C$ exists for a variety of structured matrices, among them H-matrices, M-matrices, diagonal dominant matrices, and tridiagonal ones, all with appropriate additional properties. In [3] we extended these criteria of feasibility by perturbation results analogously to those in [11]. In [15] further results of feasibility were presented for block variants of the algorithm which were introduced there. It is the purpose of the present paper to add others. In particular, we will show that the feasibility of the interval Gaussian algorithm [1] implies the existence of $[x]^C$ provided that $[A]$ contains at least one positive definite element matrix. Based on this crucial result a

great deal of criteria for the interval Gaussian algorithm carries over to the interval Cholesky method. Unfortunately, the feasibility of the interval Cholesky method does not necessarily imply that of the interval Gaussian algorithm. We will illustrate this phenomenon by an example. It was unexpected, since we can show that the existence of $[x]^C$ for each *symmetric* matrix $\tilde{A} \in [A]$ implies the feasibility of the Gaussian algorithm for *any* matrix $A \in [A]$ and not only for the symmetric ones.

We have organized this paper as follows: In section 2 we recall the formulae for the algorithm and a recursive representation. In addition we introduce our notation and some basic facts that are used later on. In section 3 we state and prove our new results illustrating them by examples.

2. Preliminaries. By $\mathbb{R}^n, \mathbb{R}^{n\times n}, \mathbb{IR}, \mathbb{IR}^n, \mathbb{IR}^{n\times n}$ we denote the set of real vectors with n components, the set of real $n\times n$ matrices, the set of intervals, the set of interval vectors with n components, and the set of $n \times n$ interval matrices, respectively. By "interval" we always mean a real compact interval. We write interval quantities in brackets with the exception of point quantities (i.e., degenerate interval quantities) which we identify with the element they contain. Examples are the zero matrix O, the identity matrix I, and the vector $e = (1, 1, \ldots, 1)^T$. We use the notation $[A] = [\underline{A}, \overline{A}] = ([a]_{ij}) = ([\underline{a}_{ij}, \overline{a}_{ij}]) \in \mathbb{IR}^{n\times n}$ simultaneously without further reference, and we proceed similarly for the elements of $\mathbb{R}^n, \mathbb{R}^{n\times n}, \mathbb{IR}$, and $\mathbb{IR}^n$. We also mention the standard notation from interval analysis ([1], [11]),

$$\check{a} = \operatorname{mid}([a]) = (\underline{a} + \overline{a})/2 \qquad \text{(midpoint)},$$

$$|[a]| = \max\{|\tilde{a}| \mid \tilde{a} \in [a]\} = \max\{|\underline{a}|, |\overline{a}|\} \qquad \text{(absolute value)},$$

$$\langle [a] \rangle = \min\{|\tilde{a}| \mid \tilde{a} \in [a]\} = \begin{cases} \min\{|\underline{a}|, |\overline{a}|\} & \text{if } 0 \notin [a], \\ 0 & \text{otherwise} \end{cases} \qquad \text{(minimal absolute value)}$$

for intervals $[a]$. For $[A] \in \mathbb{IR}^{n\times n}$ we obtain $|[A]| \in \mathbb{R}^{n\times n}$ by applying the operator $|\cdot|$ entrywise, and we define the comparison matrix $\langle [A] \rangle = (c_{ij}) \in \mathbb{R}^{n\times n}$ by setting

$$c_{ij} = \begin{cases} -|[a]_{ij}| & \text{if } i \neq j, \\ \langle [a]_{ii} \rangle & \text{if } i = j. \end{cases}$$

Since real numbers can be viewed as degenerate intervals, $|\cdot|$ and $\langle\cdot\rangle$ can also be used for them. In this case they coincide with their well known real counterpart.

By $A \geq O$ we denote a nonnegative $n \times n$ matrix, i.e., $a_{ij} \geq 0$ for $i, j = 1, \ldots, n$. Analogously, we define $x \geq 0$ for $x \in \mathbb{R}^n$. We call $x \in \mathbb{R}^n$ positive writing $x > 0$ if $x_i > 0$, $i = 1, \ldots, n$. We use $Z^{n\times n}$ for the set of real $n \times n$ matrices with nonpositive off-diagonal entries. Trivially, $Z^{n\times n}$ contains the $n \times n$ matrix $\langle A \rangle$. As usual we call $A \in \mathbb{R}^{n\times n}$ an M-matrix if A is nonsingular with $A^{-1} \geq O$ and $A \in Z^{n\times n}$. It is an H-matrix if $\langle A \rangle$ is an M-matrix.

An interval matrix $[A] \in \mathbb{IR}^{n\times n}$ is defined to be an M-matrix if each element $\tilde{A} \in [A]$ is an M-matrix. In the same way the term "H-matrix" can be extended to $\mathbb{IR}^{n\times n}$. It is easy to verify that $[A] \in \mathbb{IR}^{n\times n}$ is an M-matrix if and only if $\underline{A}$ is an M-matrix and $\overline{a}_{ij} \leq 0$ for $i \neq j$, and that $[A] \in \mathbb{IR}^{n\times n}$ is an H-matrix if and only if $\langle [A] \rangle$ is an M-matrix.

We call $[A] \in \mathbb{IR}^{n\times n}$ irreducible if $\langle [A] \rangle$ is irreducible. In the same way we define $[A]$ to be diagonally dominant, strictly diagonally dominant, and irreducibly

diagonally dominant, respectively. If there is a positive vector x such that

$$\langle [A] \rangle x \geq 0 \tag{2.1}$$

holds, then we call $[A]$ generalized diagonally dominant. Moreover, we define $[A]$ to be generalized strictly diagonally dominant if strict inequality holds in (2.1). Analogously, a generalized irreducibly diagonally dominant matrix $[A]$ is irreducible and generalized diagonally dominant with $(\langle [A] \rangle x)_i > 0$ in (2.1) for at least one component i. It is well known that generalized strictly diagonally dominant matrices are H-matrices and vice versa.

We equip $\mathbb{IR}, \mathbb{IR}^n, \mathbb{IR}^{n \times n}$ with the usual real interval arithmetic as described in [1], [11]. We assume that the reader is familiar with the basic properties of this arithmetic. For $[a] \in \mathbb{IR}$ we define

$$\sqrt{[a]} = \{\sqrt{a} \mid a \in [a]\} \text{ for } 0 \leq \underline{a}$$

and

$$[a]^2 = \{a^2 \mid a \in [a]\}. \tag{2.2}$$

Instead of $\sqrt{[a]}$ we also write $[a]^{1/2}$.

Then the interval Cholesky method reads as follows.

Given $[A] = [A]^T \in \mathbb{IR}^{n \times n}$ and $[b] \in \mathbb{IR}^n$, define the lower triangular matrix $[L]$ and the vectors $[y], [x]^C = ([x]_i^C) = \mathrm{ICh}([A], [b]) \in \mathbb{IR}^n$ by

$$[l]_{jj} = \left([a]_{jj} - \sum_{k=1}^{j-1} [l]_{jk}^2 \right)^{1/2},$$

$$[l]_{ij} = \left([a]_{ij} - \sum_{k=1}^{j-1} [l]_{ik}[l]_{jk} \right) / [l]_{jj}, \quad i = j+1, \ldots, n,$$

$$j = 1, \ldots, n,$$

$$[y]_i = \left([b]_i - \sum_{j=1}^{i-1} [l]_{ij}[y]_j \right) / [l]_{ii}, \qquad i = 1, \ldots, n,$$

$$[x]_i^C = \left([y]_i - \sum_{j=i+1}^{n} [l]_{ji}[x]_j^C \right) / [l]_{ii}, \quad i = n, n-1, \ldots, 1.$$

Sums with an upper bound smaller than the lower one are defined to be zero; the squares in the first formula are evaluated by applying the interval square function (2.2).

Apparently $[x]^C$ exists if and only if $0 < \underline{l}_{ii}$, $i = 1, \ldots, n$. In this case we call the algorithm feasible. Note that this feasibility does not depend on the choice of $[b]$. For the interval Cholesky method we assume, without loss of generality, $[A]$ to be symmetric, i.e., $[A] = [A]^T$. (In the case $[A] \neq [A]^T$ we replace $[A]$ by the largest interval matrix $[B] \subseteq [A]$ which satisfies $[B] = [B]^T$ and rename $[B]$ to $[A]$.) By the overestimation of the interval arithmetic only

$$[A] \subseteq [L][L]^T$$

can be guaranteed; cf. [2] for details. Nevertheless the pair $([L],[L]^T)$ is called the Cholesky decomposition of $[A]$. This decomposition can also be defined in a recursive way. To this end write $[A] \in \mathbb{IR}^{n\times n}$ as

$$[A] = \begin{pmatrix} [a]_{11} & [c]^T \\ [c] & [A]' \end{pmatrix}$$

and use its Schur complement $\Sigma^C_{[A]} = [A]' - [c][c]^T/[a]_{11}$ if $n > 1$, $0 \notin [a]_{11}$, where $[c]_i[c]_i$ is evaluated as $[c]_i^2$.

DEFINITION 2.1 (equivalent definition of $([L],[L]^T)$). *The pair $([L],[L]^T)$ is called the Cholesky decomposition of $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ if $0 < \underline{a}_{11}$ and if either $n = 1$, $[L] = (\sqrt{[a]_{11}})$, or if $n > 1$ and*

$$[L] = \begin{pmatrix} \sqrt{[a]_{11}} & 0 \\ [c]/\sqrt{[a]_{11}} & [L]' \end{pmatrix}, \tag{2.3}$$

where $([L]',([L]')^T)$ is the Cholesky decomposition of $\Sigma^C_{[A]}$. If $0 \in [a]_{11}$, then the Cholesky decomposition does not exist.

In [2] we showed that the matrix $[L]$ in Definition 2.1 is the same as that defined by the interval Cholesky method. In particular, the existence of the Cholesky decomposition is equivalent to the feasibility of the interval Cholesky method. We will exploit this fact later. It is a basic fact of matrix analysis that the existence of the Cholesky decomposition of a symmetric point matrix $A \in \mathbb{R}^{n\times n}$ is equivalent to A being positive definite, to A having only positive eigenvalues, and to A having only positive leading principal minors; cf., for instance, [7].

Directly from the formulae of the interval Cholesky method we obtain the following result which corresponds to Lemma 3.1 (b) in [8].

LEMMA 2.1. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$, $[b] \in \mathbb{IR}^n$, and let $[x]^C = \mathrm{ICh}([A],[b])$ exist. If $D = \mathrm{diag}(d_1,\ldots,d_n) \in \mathbb{R}^{n\times n}$ has positive entries d_i, $i = 1,\ldots,n$, in the diagonal, then $[\tilde{x}]^C = \mathrm{ICh}([D[A]D, D[b])$ exists and satisfies $[\tilde{x}]^C = D^{-1}[x]^C$.*

Proof. Denote by a tilde all items which belong to $[\tilde{x}]^C$. Then, by induction, the formulae of the interval Cholesky method yield $[\tilde{L}] = D[L]$, hence $[\tilde{y}] = [y]$ and $[\tilde{x}]^C = D^{-1}[x]^C$. ∎

We continue by recalling some results from [2].

THEOREM 2.1. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ be an H-matrix with $0 < \underline{a}_{ii}$, $i = 1,\ldots,n$. Then the following statements hold.*

(a) *The vector $[x]^C$ exists, and $[L]$ is again an H-matrix.*

(b) *Each symmetric matrix $\tilde{A} \in [A]$ is positive definite.*

From Theorem 2.1 we easily get the following corollary.

COROLLARY 2.1. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ be an H-matrix. Then the following statements are equivalent.*

(i) *The vector $[x]^C$ exists.*

(ii) *The sign condition $\underline{a}_{ii} > 0$, $i = 1,\ldots,n$, holds.*

(iii) *The matrix $[A]$ contains at least one symmetric and positive definite element $\tilde{A} \in [A]$.*

Proof. (i) ⇒ (ii). Since $\langle[A]\rangle$ is an M-matrix we have $\langle[a]_{ii}\rangle > 0$, $i = 1,\ldots,n$, whence $0 \notin [a]_{ii}$. The existence of $[x]^C$ then implies $\underline{a}_{ii} > 0$.

The implications (ii) ⇒ (i) and (ii) ⇒ (iii) follow directly from Theorem 2.1.

(iii) ⇒ (ii). As in the first implication above, one gets $0 \notin [a]_{ii}$, and the sign condition for $\underline{a}_{ii}$ follows from the positive definiteness of $\tilde{A}$. ∎

THEOREM 2.2. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ be a tridiagonal matrix, and let $\tilde{A} \in [A]$ be any symmetric matrix which satisfies $\langle \tilde{A}\rangle = \langle [A]\rangle$ and is positive definite. Then $[A]$ is an H-matrix; in particular, all symmetric matrices $A \in [A]$ are positive definite, and $[x]^C$ exists.*

THEOREM 2.3. *Let*

$$A = \begin{pmatrix} a_{11} & c^T \\ c & A' \end{pmatrix} \in \mathbb{R}^{n\times n}$$

be symmetric and positive definite. Then the Schur complement $\Sigma_A^C = A' - cc^T/a_{11}$ of A is symmetric and positive definite.

Proof. Use $0 < x^T Ax = (x')^T \Sigma_A^C x'$ for $x = \left(-c^T x'/a_{11},\, (x')^T\right)^T$ and any nonzero vector $x' \in \mathbb{R}^{n-1}$. □

Since we will also use results of the interval Gaussian algorithm we will recall its formulae, too.

Given $[A] \in \mathbb{IR}^{n\times n}$ and $[b] \in \mathbb{IR}^n$, define $[A]^{(k)} = ([a]_{ij}^{(k)}) \in \mathbb{IR}^{n\times n}$, $[b]^{(k)} = ([b]_i^{(k)}) \in \mathbb{IR}^n$, $k = 1,\dots,n$, and $[x]^G = ([x]_i^G) = \mathrm{IGA}([A],[b]) \in \mathbb{IR}^n$ by

$$[A]^{(1)} = [A], \quad [b]^{(1)} = [b],$$

$$[a]_{ij}^{(k+1)} = \begin{cases} [a]_{ij}^{(k)}, & i = 1,\dots,k,\ j = 1,\dots,n, \\ [a]_{ij}^{(k)} - \dfrac{[a]_{ik}^{(k)} \cdot [a]_{kj}^{(k)}}{[a]_{kk}^{(k)}}, & i = k+1,\dots,n,\ j = k+1,\dots,n, \\ 0 & \text{otherwise}, \end{cases}$$

$$[b]_i^{(k+1)} = \begin{cases} [b]_i^{(k)}, & i = 1,\dots,k, \\ [b]_i^{(k)} - \dfrac{[a]_{ik}^{(k)}}{[a]_{kk}^{(k)}} \cdot [b]_k^{(k)}, & i = k+1,\dots,n, \end{cases}$$

$$k = 1,\dots,n-1,$$

$$[x]_i^G = \left([b]_i^{(n)} - \sum_{j=i+1}^{n} [a]_{ij}^{(n)} [x]_j^G\right) \Big/ [a]_{ii}^{(n)}, \quad i = n, n-1,\dots,1.$$

For $i = n$ the sum is set equal to zero.

Note that $[x]^G$ is defined without permuting rows or columns. The algorithm is feasible if and only if $0 \notin [a]_{kk}^{(k)}$, $k = 1,\dots,n$, where again the feasibility does not depend on the choice of $[b]$. Define the lower triangular matrix $[\hat{L}]$ by $[\hat{l}]_{ii} = 1$, $[\hat{l}]_{ij} = [a]_{ij}^{(j)}/[a]_{jj}^{(j)}$ for $i > j$, and the upper triangular matrix $[\hat{U}]$ by $[\hat{u}]_{ij} = [a]_{ij}^{(n)}$ for $i \le j$. According to [11] the pair $([\hat{L}],[\hat{U}])$ is called the triangular decomposition of $[A]$.

Similar to Definition 2.1 there is an equivalent recursive definition of that decomposition. It uses the partition

$$[A] = \begin{pmatrix} [a]_{11} & [c]^T \\ [d] & [A]' \end{pmatrix}$$

and its Schur complement $\Sigma^G_{[A]} = [A]' - [d][c]^T/[a]_{11}$ if $n > 1$, $0 \notin [a]_{11}$. Note that for $[A] = [A]^T$ we have $[c] = [d]$. In this case we assume that $[c]_i[c]_i$ in the product $[d][c]^T = [c][c]^T$ is evaluated as a product of intervals and not as in (2.2). This implies

$$\Sigma^C_{[A]} \subseteq \Sigma^G_{[A]}, \tag{2.4}$$

where both matrices may differ from each other. For symmetric *point matrices* $A \equiv [A]$, however, equality always holds in (2.4), provided that $a_{11} > 0$.

DEFINITION 2.2 (equivalent definition of $([\hat{L}], [\hat{U}])$). *The pair* $([\hat{L}], [\hat{U}])$ *is called triangular decomposition of* $[A] \in \mathbb{IR}^{n\times n}$ *if* $0 \notin [a]_{11}$ *and if either* $n = 1$, $[\hat{L}] = 1$, $[\hat{U}] = ([a]_{11})$, *or if* $n > 1$ *and*

$$[\hat{L}] = \begin{pmatrix} 1 & 0 \\ [d]/[a]_{11} & [\hat{L}]' \end{pmatrix}, \qquad [\hat{U}] = \begin{pmatrix} [a]_{11} & [c]^T \\ 0 & [\hat{U}]' \end{pmatrix},$$

where $([\hat{L}]', [\hat{U}]')$ *is the triangular decomposition of* $\Sigma^G_{[A]}$. *If* $0 \in [a]_{11}$, *then the triangular decomposition does not exist.*

In what follows we will use the notation of section 2 without further reference.

3. New results. In this section we will present some new criteria for the feasibility of the interval Cholesky method. Since neither the existence of $[x]^C$ nor that of $[x]^G$ depends on the right-hand side $[b]$, we do not refer to $[b]$ in our results.

Assume now that $A \in \mathbb{R}^{n\times n}$ is symmetric and positive definite. Then from the Cholesky decomposition (L, L^T) of A we define the diagonal matrix $D = \mathrm{diag}(l_{11}, \ldots, l_{nn})$. It is well known that D has positive diagonal entries. Hence $A = LL^T = (LD^{-1})(DL^T)$ yields the unique $(\hat{L}, \hat{U})$-decomposition of A with $\hat{L} = LD^{-1}$ and $\hat{U} = DL^T$. Conversely, from the $(\hat{L}, \hat{U})$-decomposition of a symmetric matrix $A \in \mathbb{R}^{n\times n}$ with positive diagonal entries $\hat{u}_{ii}$, $i = 1, \ldots, n$, one easily verifies positive definiteness of A and hence the existence of the Cholesky decomposition. Therefore, the question arises at once whether a similar result also holds in the interval case. In one direction the answer is positive.

THEOREM 3.1. *Let* $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ *contain a symmetric and positive definite matrix* $\tilde{A}$. *If* $[x]^G$ *exists, then* $[x]^C$ *exists, too.*

Proof. Since $\tilde{A} \in [A]$ is symmetric and positive definite we have $\tilde{a}_{11} > 0$. Moreover, since by assumption $[x]^G$ exists we obtain $\underline{a}_{11} > 0$. We now proceed by induction on the dimension of $[A]$.

If $n = 1$, then the assertion is obvious. If $n > 1$, then let it hold for dimensions less than n, and let

$$[A] = \begin{pmatrix} [a]_{11} & [c]^T \\ [c] & [A'] \end{pmatrix}.$$

From $\underline{a}_{11} > 0$, the Schur complements

$$\Sigma^C_{[A]} = [A]' - [c][c]^T/[a]_{11} \quad (\text{with } [c]_i[c]_i \text{ being evaluated as } [c]_i^2)$$

for the Cholesky method and

$$\Sigma^G_{[A]} = [A]' - [c][c]^T/[a]_{11} \supseteq \Sigma^C_{[A]}$$

(with $[c]_i[c]_i$ being evaluated as a product of two intervals) for the Gaussian algorithm exist. Since, by assumption, the interval Gaussian algorithm is feasible for $\Sigma^G_{[A]}$

and since this interval matrix contains the symmetric and positive definite matrix $\Sigma^G_{\tilde{A}} = \Sigma^C_{\tilde{A}}$ (cf. Theorem 2.3), the induction hypothesis applies for $\Sigma^G_{[A]}$. Therefore, the Cholesky decomposition exists for this interval matrix and thus exists for the (possibly proper) subset $\Sigma^C_{[A]}$, too. □

We will prove now a result on point matrices which originally increased our hope for a converse of Theorem 3.1.

THEOREM 3.2. *Let all symmetric matrices $\tilde{A} \in [A] = [A]^T \in \mathbb{IR}^{n\times n}$ be positive definite. Then the Gaussian algorithm is feasible without pivoting for all matrices $A \in [A]$ (and not only for the symmetric ones).*

Proof. Let $A \in [A]$. Then the symmetric part[1] $A_{\mathrm{sym}} = (A + A^T)/2$ of A is contained in $[A]$, and hence it is positive definite by assumption. For $x \neq 0$ we have

$$0 < x^T A_{\mathrm{sym}} x = (x^T Ax + x^T A^T x)/2 = x^T Ax, \tag{3.1}$$

where we used $x^T A^T x = (x^T A^T x)^T = x^T Ax$. From (3.1) we immediately get $\det A \neq 0$. Since this implication applies also to all leading submatrices of A the assertion follows from Theorem 9.1.2 in [12]. □

Despite this positive result the converse of Theorem 3.1 does not hold. This is illustrated by the following example.

Example 3.1. Consider the matrix

$$[A] = \begin{pmatrix} 1 & [-1,1] & 0 & 0 \\ [-1,1] & 2 & 1 & 2 \\ 0 & 1 & 2 & 2 \\ 0 & 2 & 2 & 5+\varepsilon \end{pmatrix}$$

with a positive parameter ε which will be chosen below. Then for the interval Cholesky method we get

$$[L] = \begin{pmatrix} 1 & 0 & 0 & 0 \\ [-1,1] & [1,\sqrt{2}] & 0 & 0 \\ 0 & [1/\sqrt{2},1] & [1,\sqrt{3/2}] & 0 \\ 0 & [2/\sqrt{2},2] & [0,1] & [\sqrt{\varepsilon},\sqrt{3+\varepsilon}] \end{pmatrix},$$

i.e., $[x]^C$ exists for any positive value of ε. On the other hand we obtain

$$[\hat{U}] = [A]^{(4)} = \begin{pmatrix} 1 & [-1,1] & 0 & 0 \\ 0 & [1,3] & 1 & 2 \\ 0 & 0 & [1,5/3] & [0,4/3] \\ 0 & 0 & 0 & [\varepsilon - 7/9, \varepsilon + 11/3] \end{pmatrix}$$

for the upper triangular matrix of the interval Gaussian algorithm. Choosing $\varepsilon = 1/3$ results in the interval $[a]^{(4)}_{44} = [-4/9, 4]$ which contains zero. Hence $[x]^G$ does not exist although $[x]^C$ does. In particular, the assumptions of Theorem 3.2 are fulfilled. Therefore, the Gaussian algorithm is feasible for any matrix $\tilde{A} \in [A]$, and our example is also a counterexample for the interval Gaussian algorithm.

[1] We thank Prof. M. Plum of the University of Karlsruhe for his suggestion to apply the symmetric part of A, which made our original proof more elementary.

The dimension $n = 4$ in Example 3.1 is minimal for a counterexample. This can be seen from our next result.

THEOREM 3.3. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ contain a symmetric and positive definite matrix $\tilde{A}$, and let $n \le 3$. Then $[x]^C$ exists if and only if $[x]^G$ exists.*

Proof. By virtue of Theorem 3.1 we must only show that the existence of $[x]^C$ implies that of $[x]^G$. Therefore, from now on we assume that $[x]^C$ exists. In particular, $0 < \underline{a}_{11}$ holds, which immediately guarantees the existence of $[x]^G$ in the case $n = 1$.

$n = 2$: By Theorem 3.2 no matrix $\tilde{A} \in [A] \in \mathbb{IR}^{2\times 2}$ is singular, hence $[x]^G$ exists by Proposition 4.5.4 in [11].

$n = 3$: From $\underline{a}_{11} > 0$ we know that $\Sigma^G_{[A]}$ exists. Since any interval $[c]$ satisfies

$$[c]^2 \subseteq [c] \cdot [c] = [c]^2 + [-d, 0]$$

with an appropriate nonnegative number d, we obtain

$$\Sigma^G_{[A]} = \Sigma^C_{[A]} + [D] \quad \text{with } [D] = \operatorname{diag}([0, d_1], [0, d_2], [0, d_3]),$$

where d_1, d_2, d_3 are appropriate nonnegative real numbers. Note that $\min(\Sigma^G_{[A]})_{11} = \min(\Sigma^C_{[A]})_{11} > 0$. Choose $x \in \mathbb{R}^2\backslash\{0\}$ and $\tilde{\Sigma}^G = (\tilde{\Sigma}^G)^T \in \Sigma^G_{[A]}$. Then $\tilde{\Sigma}^G$ can be written as $\tilde{\Sigma}^G = \tilde{\Sigma}^C + \tilde{D}$ with $\tilde{\Sigma}^C = (\tilde{\Sigma}^C)^T \in \Sigma^C_{[A]}$ and $O \le \tilde{D} \in [D]$, whence

$$x^T\tilde{\Sigma}^G x = x^T\tilde{\Sigma}^C x + x^T\tilde{D}x \ge x^T\tilde{\Sigma}^C x > 0. \tag{3.2}$$

Thus any symmetric matrix $\tilde{\Sigma}^G \in \Sigma^G_{[A]}$ is positive definite, and Theorem 3.2 applies to $\Sigma^G_{[A]}$. Therefore, no matrix $\Sigma \in \Sigma^G_{[A]}$ is singular, and $[x]^G \in \mathbb{IR}^3$ exists again by virtue of Proposition 4.5.4 in [11] applied to $\Sigma^G_{[A]} \in \mathbb{IR}^{2\times 2}$. □

Another interesting negative result can be seen from Example 3.1: For symmetric and positive definite matrices $\tilde{A} \in \mathbb{R}^{n\times n}$, one proves similarly as for $\tilde{\Sigma}^G$ in (3.2) that $\tilde{A} + \tilde{D}$ with $\tilde{D} \ge O$ is positive definite, hence the Cholesky method is feasible for $\tilde{A} + \tilde{D}$, too. For interval matrices $[A] + [O, D]$, $D \ge O$, an analogous result does not hold if one merely knows that $[x]^C$ exists for $[A]$. Otherwise apply this result to $\Sigma^G_{[A]} = \Sigma^C_{[A]} + [O, D]$; it would guarantee that $\Sigma^G_{[A]}$ has a Cholesky decomposition if $[A]$ has one, and an inductive argument would show that Theorem 3.1 has a converse. This contradicts Example 3.1.

There are more classes of matrices for which one can prove the converse of Theorem 3.1. In order to characterize some of them we use the concept of an undirected graph of a real matrix $A \in \mathbb{R}^{n\times n}$ with the nodes $1, \ldots, n$ and the edges $\{i, j\}$ whenever $|a_{ij}| + |a_{ji}| \ne 0$; cf. for instance [6]. We call j a neighbor of the node i ($\ne j$) if i and j are connected by an edge. The number of neighbors of i are the degree of i in the underlying graph. Let G_k denote the kth elimination graph of $[A]$, i.e., the undirected graph of $|[A]^{(k)}|$ in which the nodes $1, \ldots, k-1$ and the corresponding edges have been removed and for which we assume that $[a]^{(k-1)}_{ij} \ne 0$ implies $[a]^{(k)}_{ij} \ne 0$, $i, j \ge k$ (no accidental zeros!); cf. [6]. If in G_k the node k has the smallest degree and if this holds for all $k = 1, \ldots, n$, then we say that $[A]$ is ordered by minimum degree. If the graph of such a matrix has tree structure (i.e., it is a connected graph with no cycles of length ≥ 3; cf. [4]), then the following result holds.

THEOREM 3.4. *Let $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ contain a symmetric and positive definite matrix $\tilde{A}$. If the undirected graph of $\langle[A]\rangle$ is a tree and if it is ordered by minimum degree, then the following statements are equivalent.*

(i) *The vector* $[x]^G$ *exists.*
(ii) *The vector* $[x]^C$ *exists.*
(iii) *Each symmetric matrix in* $[A]$ *is positive definite.*

Proof. (i) $\Rightarrow$ (ii) follows from Theorem 3.1.
(ii) $\Rightarrow$ (iii) is trivial.
(iii) $\Rightarrow$ (i) follows from Theorem 3.2 and Theorem 4 in [4]. □

For a variant of the interval Cholesky method, Theorem 3.4 was proved in [4]. Note that symmetric tridiagonal interval matrices and symmetric arrowhead interval matrices [14] belong to the class of matrices characterized in Theorem 3.4 (provided that they contain a symmetric and positive definite matrix $\tilde{A}$).

Example 3.2. Consider the arrowhead matrix

$$[A] = \begin{pmatrix} 2 & 0 & [-1,1] \\ 0 & 2 & [-1,1] \\ [-1,1] & [-1,1] & 2 \end{pmatrix}.$$

Then Gerschgorin's theorem shows that the eigenvalues of each symmetric matrix $\tilde{A} \in [A]$ are nonnegative. They are even positive as can be seen in most cases by the same theorem. For the remaining cases $\tilde{A}$ is irreducibly diagonally dominant and thus an H-matrix. Since such a matrix is regular it cannot have zero as an eigenvalue. Therefore, each symmetric matrix $\tilde{A} \in [A]$ is positive definite, and $[x]^C$ exists for $[A]$ by Theorem 3.4.

In order to formulate our next result we need the extended sign matrix S' which we define recursively as in [8].

DEFINITION 3.1 (sign matrix S and extended sign matrix S' for $[A]$). *Let* $[A] \in \mathbb{IR}^{n\times n}$. *Then we have the following.*

(a) *The matrix* $S \in \mathbb{R}^{n\times n}$ *with* $s_{ij} = \operatorname{sign}\check{a}_{ij}$ *is called the sign matrix of* $[A]$.
(b) *With* S *from (a) the extended sign matrix* S' *is defined as follows:*

$S' = S$
for $k = 1 : (n-1)$
  for $i = (k+1) : n$
    for $j = (k+1) : n$
      if $s'_{ij} == 0$ *then* $s'_{ij} = -s'_{ik} s'_{kk} s'_{kj}$.

Note that the values of s'_{ij} depend only on S. Any other matrix $[\hat{A}]$ with the same sign matrix S as $[A]$ yields the same extended sign matrix S'.

THEOREM 3.5. *Let* $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ *be irreducible and generalized diagonally dominant with* $0 < \underline{a}_{ii}$, $i = 1, \ldots, n$. *Moreover, let* S' *be the extended sign matrix of* $[A]$ *defined in Definition* 3.1. *Then the following statements are equivalent.*

(i) *The vector* $[x]^C$ *exists.*
(ii) *The vector* $[x]^G$ *exists.*
(iii) *The matrix* $[A]$ *is generalized irreducibly diagonally dominant or the sign condition*

$$s'_{ij}\, s'_{ik}\, s'_{kj}\, s'_{kk} = \begin{cases} 1 & \text{if } i \neq j, \\ -1 & \text{if } i = j \end{cases} \tag{3.3}$$

holds for some triple (i, j, k) *with* $k < i, j$.

(iv) *The matrix* $[A]$ *is generalized irreducibly diagonally dominant or the sign condition*

$$s'_{ij}\, s'_{ik}\, s'_{kj} = 1 \tag{3.4}$$

holds for some triple (i, j, k) *with* $k < j < i$.

Proof. The case $n = 1$ is trivial since $\underline{a}_{11} > 0$. Therefore, from now on we assume $n > 1$.

(ii) $\Leftrightarrow$ (iii) holds by virtue of Theorem 4.7 in [8].

(iii) $\Leftrightarrow$ (iv). From the general assumptions of the theorem we get $s_{ii} = 1 = s'_{ii}$, $i = 1, \ldots, n$, and $S = S^T$, whence $S' = (S')^T$. Therefore,

$$s'_{ii}\, s'_{ik}\, s'_{ki}\, s'_{kk} = (s'_{ik})^2 \neq -1$$

holds, i.e., the second sign condition in (3.3) can never be fulfilled. Moreover, a factor $s'_{kk} = 1$ can always be added in (3.4) which results in the first sign condition in (3.3). Hence the existence of some triple (i, j, k) as required in (iii) is equivalent to the existence of some triple as required in (iv).

(ii) $\Rightarrow$ (i). Since $[x]^G$ exists by assumption, each matrix $\tilde{A} \in [A]$ is regular. Consider the matrix $[A] + \varepsilon I$, $\varepsilon > 0$. Since $\underline{a}_{ii} > 0$, $i = 1, \ldots, n$, we get $\langle [A] + \varepsilon I \rangle = \langle [A] \rangle + \varepsilon I$ which shows that $[A] + \varepsilon I$ is generalized strictly diagonally dominant. Therefore, it is an H-matrix by Theorem 4.4 (a) in [8] and Theorem 2.1 guarantees that $\tilde{A} + \varepsilon I$ is positive definite for each symmetric matrix $\tilde{A} \in [A]$. Hence $\tilde{A} + \varepsilon I$ has only positive real eigenvalues which remain positive in the limit $\varepsilon \to 0$ since $\tilde{A}$ is regular and since the eigenvalues behave continuously when changing the entries of a matrix continuously. Therefore, $\tilde{A}$ is positive definite for each symmetric matrix $\tilde{A} \in [A]$. In particular, $[A]$ contains at least one such matrix, and Theorem 3.1 finishes the proof.

(i) $\Rightarrow$ (ii). Let $[x]^C$ exist and assume that $[x]^G$ does not exist. Then $[A]$ cannot be an H-matrix; in particular, by Theorem 4.4 (b) in [8] it cannot be generalized irreducibly diagonally dominant. However, since it is generalized diagonally dominant by assumption, there must exist a positive vector x such that $\langle [A] \rangle x = 0$. Without loss of generality, we can assume $x = e$, i.e.,

$$\langle [A] \rangle\, e = 0. \tag{3.5}$$

Otherwise consider the matrix $D[A]D$ with $D = \operatorname{diag}(x_1, \ldots, x_n) \in \mathbb{R}^{n \times n}$. This matrix has the same extended sign matrix S' as $[A]$, is irreducible and diagonally dominant, but not irreducibly diagonally dominant. Moreover, it fulfills (3.5), and by Lemma 2.1 the interval Cholesky method is feasible for it since it is for $[A]$ by assumption.

Since we assumed that $[x]^G$ does not exist, the equivalence of (ii) and (iii) shows that the sign condition (3.3) does not hold. Choose $k = 1$ for the moment and let S be the sign matrix of $[A]$. If $s_{ij} \neq s'_{ij}$, then s_{ij} must be zero by the construction of S' in Definition 3.1. (Note that at the beginning of this definition we have $S' = S$. Later s'_{ij} is changed only if it was equal to zero.) Therefore, $s_{ij} = s'_{ij}$ or $s_{ij} = 0$. Hence (3.3) does not hold if s'_{ij} is replaced there by s_{ij}. By Lemma 2.1 in [9] this implies

$$\left| [a]_{ij} - \frac{[a]_{i1} \cdot [a]_{1j}}{[a]_{11}} \right| = |[a]_{ij}| + \frac{|[a]_{i1}| \cdot |[a]_{1j}|}{\langle [a]_{11} \rangle} \quad \text{if } i \neq j \text{ and } i, j > 1. \tag{3.6}$$

Next we remark that the equality $|[a]^2| = |[a]|^2 = |[a] \cdot [a]|$ holds for any interval $[a]$. Since $\underline{a}_{ii}$ is positive and since $[x]^C$ exists we have $0 < \underline{l}_{ii}$ and

$$0 < (\underline{l}_{ii})^2 = \underline{a}_{ii} - \sum_{k=1}^{i-1} |[l]_{ik}^2| \le \underline{a}_{ii} - |[l]_{i1}^2| = \underline{a}_{ii} - \left| \left(\frac{[a]_{i1}}{[l]_{11}} \right)^2 \right| = \langle [a]_{ii} \rangle - \left| \frac{[a]_{i1}^2}{[a]_{11}} \right|$$

$$= \langle [a]_{ii} \rangle - \frac{|[a]_{i1}^2|}{\langle [a]_{11} \rangle} = \langle [a]_{ii} \rangle - \frac{|[a]_{i1}|^2}{\langle [a]_{11} \rangle}, \qquad i > 1.$$

In particular, $\langle [a]_{ii} \rangle > \dfrac{|[a]_{i1}|^2}{\langle [a]_{11} \rangle}$ holds, and Lemma 2.1(b) in [9] implies

$$\left\langle [a]_{ii} - \frac{[a]_{i1}^2}{[a]_{11}} \right\rangle = \left\langle [a]_{ii} - \frac{[a]_{i1} \cdot [a]_{i1}}{[a]_{11}} \right\rangle = \langle [a]_{ii} \rangle - \frac{|[a]_{i1}|^2}{\langle [a]_{11} \rangle}, \qquad i > 1. \tag{3.7}$$

From (3.6) and (3.7) we directly get

$$\langle \Sigma_{[A]}^C \rangle = \Sigma_{\langle [A] \rangle}^C = \Sigma_{\langle [A] \rangle}^G = \langle \Sigma_{[A]}^G \rangle \tag{3.8}$$

although $\Sigma_{[A]}^C \subsetneqq \Sigma_{[A]}^G$ may hold. In fact, by construction both matrices can differ at most in the diagonal because $[c]_i^2 \subsetneqq [c]_i \cdot [c]_i$ can occur. Since $[x]^C$ exists the diagonal entries of $\Sigma_{[A]}^C$ are positive; hence the sign matrices of $\Sigma_{[A]}^C$ and $\Sigma_{[A]}^G$ coincide and the same holds for the extended sign matrices.

With $e = \begin{pmatrix} 1 \\ e' \end{pmatrix}$ and (3.5) we obtain

$$\left(\langle \Sigma_{[A]}^C \rangle e' \right)_i = \left(\Sigma_{\langle [A] \rangle}^C e' \right)_i = \left(\langle [a]_{ii} \rangle - \frac{|[a]_{i1}|^2}{\langle [a]_{11} \rangle} \right) - \sum_{\substack{j=2 \\ j \ne i}}^{n} \left(|[a]_{ij}| + \frac{|[a]_{i1}| \cdot |[a]_{j1}|}{\langle [a]_{11} \rangle} \right)$$

$$= \left\{ \langle [a]_{ii} \rangle - \sum_{\substack{j=1 \\ j \ne i}}^{n} |[a]_{ij}| \right\} + \frac{|[a]_{i1}|}{\langle [a]_{11} \rangle} \left\{ \langle [a]_{11} \rangle - \sum_{j=2}^{n} |[a]_{j1}| \right\}$$

$$= \left(\langle [A] \rangle e \right)_i + \frac{|[a]_{i1}|}{\langle [a]_{11} \rangle} \left(\langle [A] \rangle e \right)_1 = 0, \qquad i = 2, \ldots, n.$$

Hence

$$\langle \Sigma_{[A]}^C \rangle e' = \Sigma_{\langle [A] \rangle}^C e' = \Sigma_{\langle [A] \rangle}^G e' = \langle \Sigma_{[A]}^G \rangle e' = 0.$$

Moreover, from (3.8) together with Lemma 3.3 in [5] we know that $\Sigma_{[A]}^C$ is irreducible provided that $n \ge 3$.

Since we assumed that $[x]^G$ does not exist, the interval Gaussian algorithm cannot be feasible for $\Sigma_{[A]}^G$. Therefore, (3.3) cannot hold when formulated for the extended sign matrix of $\Sigma_{[A]}^G$. (In fact, deleting the first row and column of S' for $[A]$ results in the corresponding extended sign matrix for the Schur complement.) Since we already showed that $\Sigma_{[A]}^C$ and $\Sigma_{[A]}^G$ have the same extended sign matrices the equivalence of (ii) and (iii) implies that the interval Gaussian algorithm is not feasible for $\Sigma_{[A]}^C$. Thus the assumptions of Theorem 3.5 for $[A]$ are also fulfilled for $\Sigma_{[A]}^C = (\Sigma_{[A]}^C)^T$. Therefore, the previous conclusions can be repeated up to the dimension $n = 2$ for

$\Sigma^C_{[A]}$. (Note that the restriction of the dimension n concerns only the irreducibility.) For ease of notation assume that $[A]$ plays the role of $\Sigma^C_{[A]}$ if $n = 2$, i.e., it is an irreducible symmetric 2×2 interval matrix satisfying $\langle [A] \rangle e = 0$. As before we obtain $\langle \Sigma^C_{[A]} \rangle e' = 0$, i.e., $0 \in \Sigma^C_{[A]} \in \mathbb{IR}^{1\times 1}$, which contradicts the feasibility of the interval Cholesky method and which finally shows that (3.3) must hold for some triple (i, j, k) unless $[A] \in \mathbb{IR}^{n\times n}$ is generalized irreducibly diagonally dominant. (In this case the sign condition (3.3) may be hurt as the example $[A] = \left(\begin{smallmatrix} 2 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ shows.) □

Example 3.3.

(a) Let

$$[A]_\alpha = \begin{pmatrix} 4 & [\alpha, 2] & [\alpha, 2] \\ [\alpha, 2] & 4 & 2 \\ [\alpha, 2] & 2 & 4 \end{pmatrix}, \qquad -2 \le \alpha \le 2.$$

Then $\langle [A]_\alpha \rangle e = 0$. For $-2 < \alpha \le 2$ we obtain $S = ee^T = S'$. Thus (3.4) is fulfilled with $(i, j, k) = (3, 2, 1)$, and $[x]^C$ exists.

If $\alpha = -2$, then things change. Here

$$S = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{pmatrix} = S'$$

and (3.4) does not hold as one can easily check. Thus $[x]^C$ does not exist. In fact, $[A]_{-2}$ contains the singular matrix

$$\tilde{A} = \begin{pmatrix} 4 & 2 & -2 \\ 2 & 4 & 2 \\ -2 & 2 & 4 \end{pmatrix}.$$

(b) Let

$$[A] = \begin{pmatrix} 4 & 0 & [0, 2] & [-2, 0] \\ 0 & 4 & [0, 2] & [0, 2] \\ [0, 2] & [0, 2] & [6, 9] & [-2, 2] \\ [-2, 0] & [0, 2] & [-2, 2] & [6, 9] \end{pmatrix}.$$

Then $[A]$ is irreducible and diagonally dominant. In particular, it satisfies the assumptions of Theorem 3.5. Moreover, we have

$$S = \begin{pmatrix} 1 & 0 & 1 & -1 \\ 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 \\ -1 & 1 & 0 & 1 \end{pmatrix} \neq S' = \begin{pmatrix} 1 & 0 & 1 & -1 \\ 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ -1 & 1 & 1 & 1 \end{pmatrix}$$

with (3.4) for $(i, j, k) = (4, 3, 2)$. Hence $[x]^C$ exists.

It is easy to see by Example 3.3 (b) that (3.4) does not hold if the entries of S' are replaced there by the corresponding entries of S. Doing so, nevertheless, yields a sufficient criterion analogously to Theorem 5.3 in [5]. We state this result as a corollary which follows directly from Theorem 3.5(iv) since (3.9) below can be written as (3.4).

COROLLARY 3.1. *Let* $[A] = [A]^T \in \mathbb{IR}^{n\times n}, n \geq 3$, *be irreducible and generalized diagonally dominant with* $0 < \underline{a}_{ii}$, $i = 1, \ldots, n$. *Moreover, let* S *be the sign matrix of* $[A]$ *defined in Definition* 3.1. *If*

$$s_{ij}\, s_{ik}\, s_{kj} = 1 \tag{3.9}$$

for some triple (i, j, k) *with* $k < j < i$, *then* $[x]^C$ *exists.*

Now we consider tridiagonal matrices.

THEOREM 3.6. *Let* $[A] = [A]^T \in \mathbb{IR}^{n\times n}$ *be tridiagonal. Then the following statements are equivalent.*

(i) *The vector* $[x]^G$ *exists and* $[A]$ *contains at least one symmetric and positive definite matrix.*
(ii) *The vector* $[x]^C$ *exists.*
(iii) *Each symmetric matrix* $\tilde{A} \in [A]$ *is positive definite.*

Proof. (i) $\Rightarrow$ (ii) follows from Theorem 3.1.

(ii) $\Rightarrow$ (iii) follows from the feasibility of the Cholesky method for each symmetric matrix $\tilde{A} \in [A]$.

(iii) $\Rightarrow$ (i) follows from Theorem 2.2 and the feasibility of the interval Gaussian algorithm for H-matrices; cf. [1] or [11]. ∎

Example 3.4. Let $[A] = \text{tridiag}([-1, 1], 2, [-1, 1]) \in \mathbb{IR}^{n\times n}$. Then Gershgorin's theorem shows that the eigenvalues of each symmetric matrix $\tilde{A} \in [A]$ are nonnegative. Since $\tilde{A}$ is either irreducibly diagonally dominant or consists of blocks of such matrices, it is an H-matrix. Therefore, no eigenvalue can be zero, each symmetric matrix $\tilde{A} \in [A]$ is positive definite, and $[x]^C$ exists for $[A]$ by Theorem 3.6.

Our final result deals with matrices of the form $[A] = I + [-R, R]$, which at first glance look very specific. However, preconditioning any regular interval matrix by its midpoint inverse $\check{A}^{-1}$ finally results in such a matrix.

THEOREM 3.7. *Let* $[A] = I + [-R, R]$ *with* $O \leq R = R^T \in \mathbb{R}^{n\times n}$ *and* $0 < \underline{a}_{ii}$, $i = 1, \ldots, n$. *Then the following statements are equivalent.*

(i) *The vector* $[x]^G$ *exists.*
(ii) *The vector* $[x]^C$ *exists.*
(iii) *The spectral radius of* R *is less than one.*
(iv) *The matrix* $[A]$ *is an* H*-matrix.*

Proof. The equivalence of (i), (iii), and (iv) is contained in Theorem 3.1 of [10]; cf. also Theorem 4.2 in [8]. The implication (iv) $\Rightarrow$ (ii) follows from Theorem 2.1. For the implication (ii) $\Rightarrow$ (iv), let $[x]^C$ exist. Then the Cholesky method is feasible for $\tilde{A} = I - R = \langle [A] \rangle \in [A]$, hence $\tilde{A}$ is symmetric and positive definite. Moreover, it is an M-matrix whence $[A]$ is an H-matrix. ∎

CHARACTERIZING MATRICES THAT ARE CONSISTENT WITH GIVEN SOLUTIONS*

X.-W. CHANG†, C. C. PAIGE†, AND D. TITLEY-PELOQUIN†

Abstract. For given vectors $b \in \mathbb{C}^m$ and $y \in \mathbb{C}^n$ we describe a unitary transformation approach to deriving the set $\mathcal{F}$ of all matrices $F \in \mathbb{C}^{m\times n}$ such that y is an exact solution to the compatible system $Fy = b$. This is used for deriving minimal backward errors E and f such that $(A+E)y = b+f$ when possibly noisy data $A \in \mathbb{C}^{m\times n}$ and $b \in \mathbb{C}^m$ are given, and the aim is to decide if y is a satisfactory approximate solution to $Ax = b$. The approach might be different, but the above results are not new. However, we also prove the apparently new result that two well-known approaches to making this decision are theoretically equivalent and discuss how such knowledge can be used in designing effective stopping criteria for iterative solution techniques. All these ideas generalize to the following formulations. We extend our constructive approach to derive a superset $\mathcal{F}_{STLS+}$ of the set $\mathcal{F}_{STLS}$ of all matrices $F \in \mathbb{C}^{m\times n}$ such that y is a scaled total least squares solution to $Fy \approx b$. This is a new general result that specializes in two important ways. The ordinary least squares problem is an extreme case of the scaled total least squares problem, and we use our result to obtain the set $\mathcal{F}_{LS}$ of all matrices $F \in \mathbb{C}^{m\times n}$ such that y is an exact least squares solution to $Fy \approx b$. This complements the original less-constructive derivation of Waldén, Karlson, and Sun [*Numer. Linear Algebra Appl.*, 2 (1995), pp. 271–286]. We do the equivalent for the data least squares problem—the other extreme case of the scaled total least squares problem. Not only can the results be used as indicated above for the compatible case, but the constructive technique we use could also be applicable to other backward problems—such as those for underdetermined systems, the singular value decomposition, and the eigenproblem.

1. Introduction.

We will study a class of "backward" problems for linear systems $Fy \approx b$. Specifically, given two vectors y and b we want to find the sets of all matrices F such that y is the exact solution (i.e., $Fy = b$), the least squares (LS) solution, the data least squares (DLS) solution, and the scaled total least square (STLS) solution. We will propose a unified unitary transformation approach to handling these problems.

Some of these problems have been investigated before. The result for the compatible case is well known, and the result for the least squares case was obtained elegantly by Waldén, Karlson, and Sun in [31]. But while [31] presents, then proves, the least squares result, our approach shows how to derive a more general result in a fairly simple way, and we suspect that this constructive approach is not only easier to comprehend for non-mathematicians, but perhaps easier to apply to other problems.

Thus the technique we use is widely applicable and an important part of this paper: it is to transform the unknown matrices F from the left and right by certain theoretical unitary matrices related to the given vectors b and y. These are designed

so that the constraints, such as $Fy = b$ in the compatible case, reveal the structure of the set of possible matrices F.

One of the main uses for finding sets of matrices consistent with given approximate solutions is to find minimal backward errors; see, for example, section 2.2 here. If the normwise relative backward error is of the order of the unit roundoff, then we say that the approximate solution is a (normwise) backward stable solution. This is useful in practice, for sometimes we do not know if an algorithm for solving a problem is numerically stable—but if we know that a computed solution of a specific problem is a backward stable solution, we are usually satisfied with this computed solution. Also, when we solve a problem by an iterative algorithm, the minimal backward error can often be used to design effective stopping criteria. There has been a lot of work on backward error problems, especially in recent years. For example, for consistent linear systems (including structured problems), see [10], [12], [19], [24], [25], [26], [30], [32]; for unconstrained least squares problems, see [6], [8], [11], [12], [13], [14], [20], [21], [22], [23], [31]; for constrained least squares problems, see [3], [13], [14]; and for data least squares problems, see [2].

To illustrate the basic ideas and techniques of our approach and the uses of the results, we start with the simplest compatible case in section 2. In section 3 we find a useful superset $\mathcal{F}_{STLS+}$ of the set $\mathcal{F}_{STLS}$ of matrices consistent with given STLS solutions. The STLS problem is a generalization of the ordinary LS and DLS problems. From the results for the STLS problem we obtain the set $\mathcal{F}_{LS}$ of consistent matrices for the LS problem and a superset $\mathcal{F}_{DLS+}$ of the set $\mathcal{F}_{DLS}$ of consistent matrices for the DLS problem. The results are given in sections 4 and 5. We have not been able to find simple and practical representations of $\mathcal{F}_{DLS}$ and $\mathcal{F}_{STLS}$, but we discuss in section 6 how the sets $\mathcal{F}_{STLS+}$ and $\mathcal{F}_{DLS+}$ can be just as useful.

In problems which have known structure we will sometimes be interested only in those matrices with that structure; see, for example, several papers in [27], [28] for total least squares problems. We have not looked at such problems, but one approach might be to start with the sets we derive here and then consider the subsets of these with the desired structures.

We will use $I = [e_1, \ldots, e_n]$ to denote the unit matrix; $\|x\|^2 \equiv x^H x$; $\|B\|_2 \equiv \sigma_{\max}(B)$, the maximum singular value of B; $\|B\|_F^2 \equiv \operatorname{trace}(B^H B)$. We will use $B^\dagger$ to represent the Moore–Penrose generalized inverse of B. For any complex vector v,

$$v^\dagger \equiv \begin{cases} 0 & \text{if } v = 0, \\ v^H/\|v\|^2 & \text{if } v \neq 0, \end{cases}$$

and $P_{v^\perp} = I - vv^\dagger$ is always the projector onto the orthogonal complement of range(v). We will regularly use the following: if $v \in \mathbb{C}^n$ and $V_2 \in \mathbb{C}^{n\times(n-1)}$, then

$$V_2 V_2^H = I - vv^\dagger \quad \Leftrightarrow \quad V \equiv [v/\|v\|, V_2] \in \mathbb{C}^{n\times n} \quad \text{is unitary.} \tag{1.1}$$

2. The compatible case. Our analysis for known results for compatible linear systems $Ax = b$ will provide the basic ideas and techniques used throughout this paper. The useful Lemma 2.1 and an apparently new result Corollary 2.3 will be given.

2.1. The set of consistent matrices F for $Fy = b$. The backward problem is the following: given $b \in \mathbb{C}^m$ and $y \in \mathbb{C}^n$ we wish to characterize all $F \in \mathbb{C}^{m\times n}$ such that y is the exact solution to $Fy = b$. We can write

$$\mathcal{F} = \mathcal{F}(b, y) \equiv \left\{ F \in \mathbb{C}^{m\times n} : \; Fy = b \right\}. \tag{2.1}$$

An explicit expression for $\mathcal{F}$ can be used in various problems such as finding optimal such F, structured such F, etc. We now obtain such an explicit characterization of all $F \in \mathcal{F}$. Note that if $y = 0$, then every $F \in \mathbb{C}^{m\times n}$ will do if $b = 0$, but none will do if $b \neq 0$, and we now consider only $y \neq 0$.

LEMMA 2.1. $b \in \mathbb{C}^m$ $y \in \mathbb{C}^n$

$$\begin{aligned} \mathcal{F} &\equiv \{F \in \mathbb{C}^{m\times n} : \ Fy = b\}, \\ \mathcal{N} &\equiv \left\{by^\dagger + Z\left(I - yy^\dagger\right) : \ Z \in \mathbb{C}^{m\times n}\right\}. \end{aligned} \tag{2.2}$$

$\mathcal{F} = \mathcal{N}$ $F \in \mathcal{F}$

$$F = by^\dagger + G_2 Y_2^H, \quad G_2 \in \mathbb{C}^{m\times(n-1)}, \quad Y_2 Y_2^H = I - yy^\dagger. \tag{2.3}$$

. In the theory of generalized inverses, any solution X of $XA = B$ can be written as $X = BA^\dagger + Z(I - AA^\dagger)$, so $\mathcal{F} = \mathcal{N}$ follows immediately. However, the following constructive derivation provides the useful representation (2.3) and can be extended to solve other backward problems such as those in sections 3, 4, and 5.

Note in (2.3) that Y_2 has $n-1$ columns, so from (1.1) we see that $Y = [y/\|y\|, Y_2]$ is unitary. Such unitary matrices are the tools we use in our constructive derivations of sets such as those above. For any $F \in \mathcal{F}$, let Y be any unitary matrix of the form $Y = [y/\|y\|, Y_2]$, so that $Y^H y = e_1\|y\|$. In order to describe our sets, we introduce an unknown matrix G. Specifically we define $G \equiv FY \in \mathbb{C}^{m\times n}$ so that the constraint $Fy = b$ can be rewritten as

$$Fy = FYY^H y = Ge_1\|y\| = b. \tag{2.4}$$

We will show how (2.4) limits the possible G. Express G as $G \equiv [g_1, G_2]$ for some vector g_1. Then (2.4) gives $g_1\|y\| = b$, so that $g_1 = b/\|y\|$ and $F = GY^H = by^\dagger + G_2 Y_2^H$, proving (2.3). Here G_2, and only G_2, is independent of the constraint $Fy = b$.

We can replace $G_2 Y_2^H$ by $ZY_2 Y_2^H$ as follows. For any $Z \in \mathbb{C}^{m\times n}$ define $G_2 \equiv ZY_2$, so that $G_2 Y_2^H = ZY_2 Y_2^H$. Conversely, for any G_2 we can define $Z \equiv G_2 Y_2^H$ so that $G_2 Y_2^H = G_2 Y_2^H Y_2 Y_2^H = ZY_2 Y_2^H$. Thus we can use (1.1) to rewrite any F in (2.3) as

$$F = by^\dagger + ZY_2 Y_2^H = by^\dagger + Z\left(I - yy^\dagger\right)$$

for some totally unknown $Z \in \mathbb{C}^{m\times n}$. Thus $F \in \mathcal{F} \Rightarrow F \in \mathcal{N}$, and so $\mathcal{F} \subseteq \mathcal{N}$. But if $F \in \mathcal{N}$, then clearly $Fy = b$, so $F \in \mathcal{F}$, proving $\mathcal{N} \subseteq \mathcal{F}$, and thus $\mathcal{F} = \mathcal{N}$. ∎

If $y = 0$ and $b = 0$, it is easy to see that $\mathcal{F} = \mathcal{N}$ still holds, but (2.3) does not since no such Y_2 can exist.

Notice that, although (2.2) is a compact explicit representation of all possible matrices F such that $Fy = b$, the equivalent (2.3) shows there are other representations. The most useful representation will depend on the problem being solved.

Compatible linear systems are a distinct and important special case of each of the later problems we examine. It is helpful to continue this introduction by applying Lemma 2.1 to give some well-known results and an interesting corollary. These illustrate how these set representations might be used in general.

2.2. Minimal backward errors and acceptable solutions. In this section we will consider only the matrix 2- and F-norms and use one description for both. Thus $\eta_{2,F}$ etc. will indicate that one can use either the matrix 2-norm throughout or the F-norm throughout.

Given $A \in \mathbb{C}^{m\times n}$, $b \in \mathbb{C}^m$, and nonzero $y \in \mathbb{C}^n$, suppose we wish to find the smallest (in some sense) perturbations E and f in A and b such that $(A+E)y = b+f$. One approach proposed by Rigal and Gaches [19, section 3.1] is to essentially solve

$$\eta_{2,F} \equiv \min_{\eta,E,f}\{\eta :\ \|E\|_{2,F} \le \eta\alpha\|A\|_{2,F},\ \|f\| \le \eta\beta\|b\|,\ (A+E)y = b+f\} \tag{2.5}$$

for given $\alpha \ge 0$ and $\beta \ge 0$ (not both zero). See Remark 2.1 for comments on $\eta_{2,F}$. Another well-known approach (see, for example, [9, Problem 7.8]) is to solve

$$\zeta \equiv \min_{E,f}\{\|[E, f\theta]\|_F :\ (A+E)y = b+f\} \tag{2.6}$$

for some given real scalar $\theta \ge 0$.

Although the solutions are known for the above two approaches, these are apparently not compared in the literature. We prove in Corollary 2.3 that for the 2- and F-norms the two approaches are, in fact, theoretically equivalent.

THEOREM 2.2. $A \in \mathbb{C}^{m\times n}$, $b \in \mathbb{C}^m$, $y \in \mathbb{C}^n$, α, β ( ), $\theta \ge 0$

$$r \equiv b - Ay, \quad \mu_{2,F} \equiv \frac{\beta\|b\|}{\alpha\|A\|_{2,F}\|y\| + \beta\|b\|}, \quad \nu \equiv \frac{1}{1+\theta^2\|y\|^2}, \tag{2.7}$$

(2.5)

$$\eta_{2,F} = \frac{\|r\|}{\alpha\|A\|_{2,F}\|y\| + \beta\|b\|}, \tag{2.8}$$

$$\hat{E} = r(1-\mu_{2,F})y^\dagger, \quad \hat{f} = -r\mu_{2,F}, \tag{2.9}$$

(2.6)

$$\zeta = \left(\frac{\theta^2\|r\|^2}{1+\theta^2\|y\|^2}\right)^{1/2}, \tag{2.10}$$

$$\hat{E} = r(1-\nu)y^\dagger, \quad \hat{f} = -r\nu. \tag{2.11}$$

. The quickest proof is to follow the approach of Higham [9, Theorem 7.1]: for each of (2.8) and (2.10) it is straightforward to show that the right-hand side is a lower bound on the minimand and that the stated optimal values give the lower bound.

But for possible future work it is useful to see how the actual solutions can be via Lemma 2.1. Using the notation of Lemma 2.1 we see from (2.1) and (2.3) that, for any given f, any E satisfying the constraint $(A+E)y = b+f$ has the form

$$E = (b+f)y^\dagger + G_2Y_2^H - A, \qquad Y_2Y_2^H = I - yy^\dagger,$$

for some $G_2 \in \mathbb{C}^{m\times(n-1)}$. Therefore with unitary Y of the form $Y = [y/\|y\|, Y_2]$,

$$\begin{aligned}\|E\|_{2,F}^2 = \|EY\|_{2,F}^2 &= \|[(b+f)y^\dagger + G_2Y_2^H - A][y/\|y\|, Y_2]\|_{2,F}^2 \\ &= \|[(b+f-Ay)/\|y\|, G_2 - AY_2]\|_{2,F}^2 \\ &\ge \|r+f\|^2/\|y\|^2.\end{aligned}$$

The last inequality becomes an equality if $G_2 = AY_2$, which is independent of f. Thus $G_2 = AY_2$ is optimal for both (2.5) and (2.6), and so with this G_2 we have $E = (b+f)y^\dagger - Ayy^\dagger = (r+f)y^\dagger$ for both problems.

Note that we can always write $f = -r\mu + u$ for some (possibly complex) scalar μ and some $u \in \mathbb{C}^m$ such that $u^H r = 0$, so

$$\|f\|^2 = \|r\|^2|\mu|^2 + \|u\|^2, \qquad \|r+f\|^2 = \|r\|^2|1-\mu|^2 + \|u\|^2.$$

But $\|E\|_{2,F} = \|r+f\|/\|y\|$, from which we can see that the minima in both (2.5) and (2.6) require $u = 0$ and μ real, since for a given real part $\mu_{\mathcal{R}}$, both $|\mu|$ and $|1-\mu|$ are minimized by taking $\mu = \mu_{\mathcal{R}}$. This gives $f = -r\mu$, $E = r(1-\mu)y^\dagger$.

The theorem is obvious when $r = 0$, so assume $r \neq 0$. For (2.5) we solve

$$\min_\mu \{\eta : |1-\mu|\cdot\|r\| \le \eta\alpha\|A\|_{2,F}\|y\|,\ |\mu|\cdot\|r\| \le \eta\beta\|b\|\},$$

from which we can see that if $\alpha = 0$, then $\mu = 1$; if $\beta = 0$, then $\mu = 0$; otherwise, the minimum occurs when

$$\eta = \frac{|1-\mu|\cdot\|r\|}{\alpha\|A\|_{2,F}\|y\|} = \frac{|\mu|\cdot\|r\|}{\beta\|b\|}, \quad 0 < \mu < 1,$$

giving $\mu = \beta\|b\|/(\alpha\|A\|_{2,F}\|y\| + \beta\|b\|) = \mu_{2,F}$ in all cases, so that the optimal $\eta = \eta_{2,F}$, proving (2.8) with its minimizers (2.9).

In (2.10)

$$\|[E, f\theta]\|_F^2 = \left[(1-\mu)^2 + \mu^2\theta^2\|y\|^2\right]\|r\|^2/\|y\|^2,$$

which is minimized by $\mu = (1+\theta^2\|y\|^2)^{-1} = \nu$, $1-\mu = \nu\theta^2\|y\|^2$, proving (2.10) with its minimizers (2.11) and completing this longer but constructive proof. ∎

Rigal and Gaches [19, section 3.1] essentially proved (2.8), while the result (2.10) is well known; see, for example, [9, Problem 7.8]. Here we relate these two results.

Corollary 2.3. [illegible] 2.2 [illegible] θ [illegible] (2.6) [illegible]

$$\theta_{2,F} \equiv \begin{cases} \left(\dfrac{\alpha\|A\|_{2,F}}{\beta\|b\|\cdot\|y\|}\right)^{1/2} & \beta > 0, \\ \infty & \beta = 0 \end{cases} \tag{2.12}$$

[illegible] $\hat{E}$ [illegible] $\hat{f}$ [illegible] (2.10) [illegible] $\hat{E}$ [illegible] $\hat{f}$ [illegible] (2.8) [illegible]. From Theorem 2.2 we see that the optimal $\hat{E}$ and $\hat{f}$ have the same forms $E = r(1-\mu)y^\dagger$ and $f = -r\mu$, where the only differences are in the values of μ. The values of μ become the same by choosing θ so that $\nu = \mu_{2,F}$; that is,

$$\nu^{-1} = 1 + \theta^2\|y\|^2 = \mu_{2,F}^{-1} = (\alpha\|A\|_{2,F}\|y\| + \beta\|b\|)/\beta\|b\|,$$

giving $\theta = \theta_{2,F}$ in (2.12) when $\beta > 0$. If $\beta = 0$, then taking $\theta = \infty$ results in $\nu = \mu_{2,F} = 0$, which forces $f = 0$; cf. the DLS case in section 5. ∎

Thus in order to define optimal backward perturbations in these cases, it does not matter which of the theoretical approaches (2.8) or (2.10) we take, as long as we choose α and β, or θ, according to (2.12).

The quantity $\eta_{2,F}$ can be used to check if an approximate solution to $Ax = b$ is an [illegible]. Most practical problems contain uncertainties in the data, and, instead of solving $Ax = b$ with ideal data A and b, we solve some system

$$(A+\delta A)\tilde{x} = b + \delta b, \quad \text{where} \quad \|\delta A\|_{2,F} \le \alpha\|A\|_{2,F},\ \|\delta b\| \le \beta\|b\| \tag{2.13}$$

for some hopefully approximately known $\alpha \geq 0$ and $\beta \geq 0$. Notice that the given y solves a problem within the range of uncertainty in the data (2.13) if and only if $\eta_{2,F} \leq 1$, so that if $\eta_{2,F} \leq 1$ we can conclude that the given y is an acceptable solution to the compatible system $Ax = b$, and this can be used as a stopping criterion for iterative methods such as the modified Gram-Schmidt GMRES method (MGS-GMRES).

2.1. If $\alpha = \beta = 1$ in (2.5), then from (2.8) $\eta_{2,F}$ becomes the normwise relative backward error (NRBE) $\|r\|/(\|A\|_{2,F}\|y\|+\|b\|)$ in [9, p. 120]. This is excellent for plotting the performance of an iterative solution of equations algorithm and can be used in the stopping criterion $\eta_{2,F} \leq O(\epsilon)$ for a numerically stable algorithm. To handle $\alpha \neq \beta$ in (2.13) we chose $\eta_{2,F}$ as in (2.5). This is then neither a NRBE nor a direct measure of backward error, and it has to be used with the very different stopping criterion $\eta_{2,F} \leq 1$. But in this case it is easy to define and compute the two NRBEs—that in A: $\eta_{2,F}\alpha = \|\hat{E}\|_{2,F}/\|A\|_{2,F}$ and that in b: $\eta_{2,F}\beta = \|\hat{f}\|/\|b\|$.

A knowledge of the uncertainties will usually suggest rough values for α and β. If we do not know such values, or want maximum accuracy in a normwise backward sense, we can use a backward stable algorithm and take $\alpha = \beta = O(\epsilon)$, where ϵ is the floating point arithmetic unit roundoff and $O(\epsilon)$ depends on the algorithm. For example, it was shown in [15, sections 1 and 8.2] that, for sufficiently nonsingular $n \times n$ A in the real problem $Ax = b$, for MGS-GMRES we would use the F-norm and might take $\alpha = \beta = 100kn\epsilon$ at step k if we wanted to be unrealistically careful, or more sensibly $\alpha = \beta = 10n\epsilon$, where experience suggests we can usually obtain even better accuracy than this.

Sometimes we will have only an estimate of the α/β ratio or of the equivalent θ satisfying (2.12). For example, we might know only that the relative error in b can be about ten times that in A. If we have no idea of the individual α and β values, we do not have a clear acceptance criterion. For certainty we could assume that α and β were very small, and in the case $\beta/\alpha \geq 1$ we could set $\alpha = O(\epsilon)$ and $\beta = (\beta/\alpha)O(\epsilon)$. For example, when using MGS-GMRES, if we know that the relative error in b is about ten times that in A, we might set $\alpha = 10n\epsilon$, $\beta = 100n\epsilon$.

If only θ, or the ratio α/β, is available, the quantity ζ in (2.6) is sometimes referred to as a normwise backward error; see, for example, [9, Problem 7.8]. But it is important to be aware that this quantity can be a poor measure of backward error for small θ. This is because $\zeta \to 0$ as $\theta \to 0$ (see (2.10)) while (2.6) shows that the optimal $E \to 0$, $f \to Ay - b = -r$ as $\theta \to 0$, so that if $r \neq 0$, then ζ will be an inappropriate measure when θ is small. A generally more appropriate measure of backward error for the $\|[E, f\theta]\|_F$ approach might be $\|[\hat{E}, \hat{f}]\|_F^2$, where with (2.11) and (2.7)

$$\left\| \left[\hat{E}, \hat{f}\right] \right\|_F^2 = \frac{1 + \theta^4\|y\|^2}{(1 + \theta^2\|y\|^2)^2}\|r\|^2. \tag{2.14}$$

Note that this quantity is equal to ζ when $\theta = 1$ and in the limit as $\theta \to \infty$ but tends to the desired $\|r\|^2$ as $\theta \to 0$. Thus, although for a given θ we minimize $\|[E, f\theta]\|_F$, a more meaningful measure of the backward error might be $\|[\hat{E}, \hat{f}]\|_F$.

Finally for fixed $\|y\|$ and $\|r\|$ the minimum of (2.14) is given by $\theta^2 = 1$. This is one argument for taking $\theta = 1$ if we have no reasonable a priori idea of α/β or θ.

3. The scaled total least squares problem. Given $A \in \mathbb{C}^{m\times n}$, $b \in \mathbb{C}^m$, and $\gamma \in (0, \infty)$, the STLS problem was formulated in [18] as finding $\hat{E}$, $\hat{f}$, and $\hat{x}$, which

solve

$$\sigma_S \equiv \min_{E,f,x} \|[E, f\gamma]\|_F \quad \text{subject to} \quad (A+E)x = b+f. \tag{3.1}$$

By taking $g = f\gamma$, (3.1) was reformulated in [16, equation (5.1)] as

$$\sigma_S \equiv \min_{E,g,x} \|[E, g]\|_F \quad \text{subject to} \quad (A+E)x\gamma = b\gamma + g. \tag{3.2}$$

The scalar σ_S is called the STLS distance, and $\hat{x} = \hat{x}(\gamma)$ the STLS solution. The formulation (3.1) is closely related to the minimal backward error problem for compatible systems (2.6), while (3.2) has the advantage of being an unscaled total least squares problem, for which codes are easily available.

Let $\mathcal{U}_{\min}$ be the left singular vector subspace of A corresponding to its minimum singular value $\sigma_{\min}(A)$. In [16] it was shown that a satisfactory condition for building the theory for the STLS problem is the condition that we will now assume holds:

$$\text{the } m \times n \text{ matrix } A \text{ has rank } n, \text{ and } b \not\perp \mathcal{U}_{\min}. \tag{3.3}$$

Under this condition the solution to (3.2) must exist and be unique.

The STLS solution reduces to the ordinary least squares solution in the limit as $\gamma \to 0$ (so $E = 0$), to the unscaled total least squares solution when $\gamma = 1$, and to the data least squares solution in the limit as $\gamma \to \infty$ (so $f = 0$); see, for example, [16].

It was shown in [4] for the real case, and in [16, equation (5.9)] for the complex case, that the STLS solution $\hat{x}$ solves

$$\sigma_S^2 = \min_x \left\{ \sigma_S^2(x) \equiv \frac{\|b - Ax\|^2}{\gamma^{-2} + \|x\|^2} \right\}. \tag{3.4}$$

If we differentiate the real version of $\sigma_S^2(x)$ in (3.4) with respect to x and equate the result to zero, we see that $\hat{x}$ satisfies the real version of

$$A^H(b - A\hat{x}) = -\hat{x}\frac{\|b - A\hat{x}\|^2}{\gamma^{-2} + \|\hat{x}\|^2} = -\hat{x}\sigma_S^2(\hat{x}).$$

This is a necessary optimality condition, but it is not sufficient since the function $\sigma_S^2(x)$ is not convex. In fact, it can be proven (see [29, Theorem 2.7], [16, section 6]) that when (3.3) holds, $\hat{x}$ solves (3.2) if and only if

$$A^H(b - A\hat{x}) = -\hat{x}\sigma_S^2, \quad \sigma_S^2 \equiv \frac{\|b - A\hat{x}\|^2}{\gamma^{-2} + \|\hat{x}\|^2} < \sigma_{\min}^2(A). \tag{3.5}$$

Given $b \in \mathbb{C}^m$ and nonzero $y \in \mathbb{C}^n$, the backward STLS problem is then to characterize the set $\mathcal{F}_{STLS}$ of all $F \in \mathbb{C}^{m\times n}$ such that y is the exact STLS solution to $Fy \approx b$; see (3.1). From (3.4) and (3.5), the sets $\mathcal{F}_{STLS}$ and $\mathcal{F}_{STLS+}$ can be defined as follows:

$$\mathcal{F}_{STLS} \equiv \left\{ F \in \mathbb{C}^{m\times n} : \ \frac{\|b - Fy\|^2}{\gamma^{-2} + \|y\|^2} = \min_{x\in\mathbb{C}^n} \frac{\|b - Fx\|^2}{\gamma^{-2} + \|x\|^2} \right\} \tag{3.6}$$

$$\equiv \left\{ F \in \mathbb{C}^{m\times n} : F^H(b - Fy) = -y\frac{\|b - Fy\|^2}{\gamma^{-2} + \|y\|^2}, \ \frac{\|b - Fy\|^2}{\gamma^{-2} + \|y\|^2} < \sigma_{\min}^2(F) \right\} \tag{3.7}$$

$$\subseteq \mathcal{F}_{STLS+} \equiv \left\{ F \in \mathbb{C}^{m\times n} : \ F^H(b - Fy) = -y\frac{\|b - Fy\|^2}{\gamma^{-2} + \|y\|^2} \right\}. \tag{3.8}$$

There might be elements of $\mathcal{F}_{STLS+}$ which do not satisfy the inequality in (3.7). In other words, there might be $F \in \mathcal{F}_{STLS+}$ for which the given y is not the minimizer, but merely a stationary point, of the right-hand side in (3.6). In the use of such sets, optimizing over $\mathcal{F}_{STLS}$ would be difficult, so in practice we would usually choose to use the more amenable $\mathcal{F}_{STLS+}$. One reason for this is that any particular element found in $\mathcal{F}_{STLS+}$ could be tested to see if it also satisfied (3.7). A more important reason is that in all the problems we can imagine we would be given a y that is a reasonable approximation to $\hat{x}$, and use this to find an $F \in \mathcal{F}_{STLS+}$ which is as close as possible to A. It can be seen from (3.5) that if $y = \hat{x}$ then the closest F in any measure would be A itself, so that F [illegible] satisfy (3.7). If we only had $y \approx \hat{x}$ then finding F as close as possible to A would tend to force (3.7) to hold. A good example of this is in [2] which deals with the minimum backward error for an approximate solution y to the DLS problem, see section 5. Using the notation in (5.4), in [2] we used

$$\mu_F(y) \equiv \min_{A+\Delta A \in \mathcal{F}_{DLS+}} \|\Delta A\|_F \quad \text{in order to find} \quad \hat{\mu}_F(y) \equiv \min_{A+\Delta A \in \mathcal{F}_{DLS}} \|\Delta A\|_F,$$

and proved in [2, Theorem 2.8] that if $\hat{x}$ is the DLS solution to $Ax \approx b$ then there exists an $\epsilon > 0$ such that if $\|y - \hat{x}\|_2 < \epsilon$ then $\mu_F(y) = \hat{\mu}_F(y)$. So that for a good approximation y nothing is lost by using $\mathcal{F}_{DLS+}$ instead of $\mathcal{F}_{DLS}$. In fact, in the thousands of numerical tests in [2, Section 5], no example was found where using $\mathcal{F}_{DLS+}$ gave the wrong answer, where the y were chosen to have relative errors up to 10^{-1}. Since $\mathcal{F}_{DLS}$ is a limiting case of $\mathcal{F}_{STLS}$, we suspect that in many practical cases $\mathcal{F}_{STLS+}$ will also be a useful and usable replacement for $\mathcal{F}_{STLS}$.

To develop an explicit expression for all $F \in \mathcal{F}_{STLS+}$, we will use the following lemma as a guide.

LEMMA 3.1. $F \in \mathbb{C}^{m\times n}$, $b \in \mathbb{C}^m$, [illegible] $y \in \mathbb{C}^n$, [illegible] $\gamma \in (0,\infty)$, [illegible]

$$F^H(b - Fy) = -y\|b - Fy\|^2 / \left(\gamma^{-2} + \|y\|^2\right) \tag{3.9}$$

$$\iff w = b - Fy, \quad \left(I - yy^\dagger\right) F^H w = 0, \quad b^H w = \frac{\|w\|^2}{1 + \gamma^2\|y\|^2} \tag{3.10}$$

$$\iff w = b - Fy, \quad \left(F^H + y\gamma^2 b^H\right) w = 0. \tag{3.11}$$

[illegible]. Define $w \equiv b - Fy$, and then

$$\|w\|^2 = b^H w - y^H F^H w. \tag{3.12}$$

Suppose that (3.9) holds. Multiplying (3.9) on the left by y^H gives

$$y^H F^H w = -\|y\|^2\|w\|^2 / \left(\gamma^{-2} + \|y\|^2\right),$$

which with (3.12) leads to the last equality in (3.10):

$$b^H w = \|w\|^2 / \left(1 + \gamma^2\|y\|^2\right). \tag{3.13}$$

The second equality in (3.10) can be obtained immediately by multiplying (3.9) on the left by $I - yy^\dagger$. Thus (3.10) holds. From (3.9) and (3.13) we obtain

$$F^H w = -y\|w\|^2 / \left(\gamma^{-2} + \|y\|^2\right) = -y\gamma^2 b^H w,$$

leading to (3.11).

Conversely if (3.10) holds, then using its second, first, and third equalities we have

$$F^H w = \frac{y\left(y^H F^H w\right)}{\|y\|^2} = \frac{y\left(b^H w - w^H w\right)}{\|y\|^2} = \frac{y\left(\frac{\|w\|^2}{1+\gamma^2\|y\|^2} - \|w\|^2\right)}{\|y\|^2} = -y\frac{\|w\|^2}{\gamma^{-2}+\|y\|^2},$$

so that (3.9) holds. Finally if (3.11) holds, then from its two equalities we obtain

$$\|w\|^2 = b^H w - y^H F^H w = b^H w - y^H\left(-y\gamma^2 b^H w\right) = \left(1+\gamma^2\|y\|^2\right) b^H w.$$

Therefore the second equality in (3.11) can be rewritten as

$$F^H w = -y\gamma^2 b^H w = -y\gamma^2\|w\|^2/\left(1+\gamma^2\|y\|^2\right),$$

so that (3.9) holds. ∎

We now obtain two new characterizations of all matrices $F \in \mathcal{F}_{STLS+}$ in (3.8).

THEOREM 3.2. $b \in \mathbb{C}^m$, $y \in \mathbb{C}^n$, $\gamma \in (0,\infty)$,

$$\mathcal{F}_{STLS+} \equiv \left\{ F \in \mathbb{C}^{m\times n} : F^H(b-Fy) = -y\frac{\|b-Fy\|^2}{\gamma^{-2}+\|y\|^2} \right\}, \tag{3.14}$$

$$\mathcal{N}_{STLS+} \equiv \left\{ (b-w)y^\dagger + \left(I-ww^\dagger\right) Z \left(I-yy^\dagger\right) : \right.$$
$$\left. w \in \mathbb{C}^m,\, b^H w = \frac{\|w\|^2}{1+\gamma^2\|y\|^2},\, Z \in \mathbb{C}^{m\times n} \right\}, \tag{3.15}$$

$$\widetilde{\mathcal{N}}_{STLS+} \equiv \left\{ -\tilde{w}\tilde{w}^\dagger b\gamma^2 y^H + \left(I-\tilde{w}\tilde{w}^\dagger\right)\left[by^\dagger + Z\left(I-yy^\dagger\right)\right] : \right.$$
$$\left. \tilde{w} \in \mathbb{C}^m, Z \in \mathbb{C}^{m\times n} \right\}. \tag{3.16}$$

$\mathcal{F}_{STLS+} = \mathcal{N}_{STLS+} = \widetilde{\mathcal{N}}_{STLS+}$, F w (3.15) $w = b - Fy$ $\tilde{w}$ (3.16) . In order to show that $\mathcal{F}_{STLS+} \subseteq \mathcal{N}_{STLS+}$ and $\mathcal{F}_{STLS+} \subseteq \widetilde{\mathcal{N}}_{STLS+}$, consider any $F \in \mathcal{F}_{STLS+}$ so that by Lemma 3.1

$$w \equiv b - Fy, \quad \left(F^H + y\gamma^2 b^H\right) w = 0. \tag{3.17}$$

If $w = 0$, then $Fy = b$, so from Lemma 2.1 we see that $F \in \mathcal{F} = \mathcal{N}$. But obviously $\mathcal{N} \subseteq \mathcal{N}_{STLS+}$ and $\mathcal{N} \subseteq \widetilde{\mathcal{N}}_{STLS+}$; thus $F \in \mathcal{N}_{STLS+}$ and $F \in \widetilde{\mathcal{N}}_{STLS+}$. Now assume $w \neq 0$. Write $\hat{w} \equiv w/\|w\|$, $\hat{y} \equiv y/\|y\|$, and let $W = [\hat{w}, W_2] \in \mathbb{C}^{m\times m}$ and $Y = [\hat{y}, Y_2] \in \mathbb{C}^{n\times n}$ be unitary matrices, so that $Y^H y = e_1\|y\|$ and $W^H w = e_1\|w\|$. Define $G \equiv W^H F Y \in \mathbb{C}^{m\times n}$, so $F = WGY^H$. The restrictions in (3.17) can then be written as

$$Ge_1\|y\| = W^H(b-w), \quad G^H e_1\|w\| = -e_1\left(\|y\|\gamma^2 b^H w\right). \tag{3.18}$$

We will now show how (3.18) limits the possible G. Write

$$m \times n \;\; G = \begin{bmatrix} g_{11} & g_1^H \\ g_2 & G_{22} \end{bmatrix}, \;\; \text{with} \;\; (m-1)\times(n-1) \;\; G_{22}.$$

Then from (3.18) we obtain

$$\begin{bmatrix} g_{11} \\ g_2 \end{bmatrix} \|y\| = \begin{bmatrix} \hat{w}^H(b-w) \\ W_2^H b \end{bmatrix}, \quad \begin{bmatrix} g_{11}^H \\ g_1 \end{bmatrix} \|w\| = \begin{bmatrix} -\|y\|\gamma^2 b^H w \\ 0 \end{bmatrix},$$

leading to

$$g_1 = 0, \quad g_2 = W_2^H b/\|y\|, \quad g_{11} = \hat{w}^H(b-w)/\|y\| = -\|y\|\gamma^2 \hat{w}^H b. \tag{3.19}$$

From these it follows that

$$\begin{aligned} F = WGY^H &= (\hat{w}g_{11} + W_2 g_2)\hat{y}^H + W_2 G_{22} Y_2^H \\ &= ww^\dagger(b-w)y^\dagger + W_2 W_2^H b y^\dagger + W_2 G_{22} Y_2^H \qquad (3.20) \\ &= -ww^\dagger b\gamma^2 y^H + W_2 W_2^H b y^\dagger + W_2 G_{22} Y_2^H. \qquad (3.21) \end{aligned}$$

Similarly to what we did in the proof of Lemma 2.1, we can replace $W_2 G_{22} Y_2^H$ in (3.20) and (3.21) by $W_2 W_2^H Z Y_2 Y_2^H$ for some totally unknown $Z \in \mathbb{C}^{m\times n}$. Then using (1.1) we have from (3.20) and (3.21) that

$$\begin{aligned} F &= ww^\dagger(b-w)y^\dagger + \left(I - ww^\dagger\right) b y^\dagger + \left(I - ww^\dagger\right) Z \left(I - yy^\dagger\right) \\ &= (b-w)y^\dagger + \left(I - ww^\dagger\right) Z \left(I - yy^\dagger\right) \qquad (3.22) \\ &= -ww^\dagger b\gamma^2 y^H + \left(I - ww^\dagger\right)\left[b y^\dagger + Z\left(I - yy^\dagger\right)\right]. \qquad (3.23) \end{aligned}$$

From (3.22) and (3.10) it follows that $F \in \mathcal{N}_{STLS+}$, so $\mathcal{F}_{STLS+} \subseteq \mathcal{N}_{STLS+}$; and from (3.23) it follows that $F \in \widetilde{\mathcal{N}}_{STLS+}$, and therefore $\mathcal{F}_{STLS+} \subseteq \widetilde{\mathcal{N}}_{STLS+}$.

Conversely suppose that $F \in \mathcal{N}_{STLS+}$, so that

$$F = (b-w)y^\dagger + \left(I - ww^\dagger\right) Z \left(I - yy^\dagger\right)$$

for some Z and some w satisfying $b^H w = \|w\|^2/(1+\gamma^2\|y\|^2)$. Then it follows that

$$Fy = b - w, \quad \left(I - yy^\dagger\right) F^H w = 0. \tag{3.24}$$

Therefore by Lemma 3.1 and (3.14), $F \in \mathcal{F}_{STLS+}$, and thus $\mathcal{N}_{STLS+} \subseteq \mathcal{F}_{STLS+}$, proving that $\mathcal{N}_{STLS+} = \mathcal{F}_{STLS+}$. Finally suppose that $F \in \widetilde{\mathcal{N}}_{STLS+}$, so that

$$F = -\tilde{w}\tilde{w}^\dagger b\gamma^2 y^H + \left(I - \tilde{w}\tilde{w}^\dagger\right)\left[b y^\dagger + Z\left(I - yy^\dagger\right)\right]$$

for some Z and $\tilde{w}$. Then $\tilde{w}^H F = -\tilde{w}^H b\gamma^2 y^H$, so $(F^H + y\gamma^2 b^H)\tilde{w} = 0$, and

$$Fy = -\tilde{w}\tilde{w}^\dagger b\gamma^2\|y\|^2 + \left(I - \tilde{w}\tilde{w}^\dagger\right) b = b - \tilde{w}\tilde{w}^\dagger b\left(1 + \gamma^2\|y\|^2\right).$$

This gives an expression for w defined by

$$w \equiv b - Fy = \tilde{w}\left[\tilde{w}^\dagger b\left(1 + \gamma^2\|y\|^2\right)\right]. \tag{3.25}$$

We see by Lemma 3.1 and (3.14) that $F \in \mathcal{F}_{STLS+}$, and thus $\widetilde{\mathcal{N}}_{STLS+} \subseteq \mathcal{F}_{STLS+}$, proving that $\mathcal{F}_{STLS+} = \widetilde{\mathcal{N}}_{STLS+}$. The first equality in (3.24) and (3.25) indicates that w in (3.15) is a scalar multiple of $\tilde{w}$ in (3.16) for the same matrix F. ∎

Here we make two remarks. Unlike the expression for $\mathcal{N}_{STLS+}$ in (3.15), the expression for $\widetilde{\mathcal{N}}_{STLS+}$ in (3.16) does not involve any constraint and so is easier to use. But if we want to consider $\gamma \to \infty$, it is easier to use $\mathcal{N}_{STLS+}$; see section 5.

The condition (3.3) does not necessarily hold for every $F \in \mathcal{F}_{STLS+}$—an example is the rank-1 matrix $by^\dagger \in \mathcal{F}_{STLS+}$ in (3.8) which does not have full column rank if $n > 1$ nor need it hold for every $F \in \mathcal{F}_{STLS}$. This knowledge needs to be taken into account in the use of these sets, but at least we know that, for every $F \in \mathcal{F}_{STLS+}$, y gives a stationary point of $\|b - Fx\|^2/(\gamma^{-2} + \|x\|^2)$; see (3.4).

This completes our theory for the general STLS formulation. We will now use Theorem 3.2 to characterize matrices consistent with given approximate solutions for its two extreme cases: the least squares and data least squares problems.

4. The least squares problem. Given $A \in \mathbb{C}^{m\times n}$ and $b \in \mathbb{C}^m$, the ordinary LS problem is defined as

$$\sigma_{LS} \equiv \min_{f,x} \|f\| \quad \text{subject to} \quad Ax = b + f.$$

It is well known that $\hat{x}$ is the LS solution if and only if it satisfies the normal equations:

$$A^H(b - A\hat{x}) = 0.$$

See, for example, [1] or [5] for useful background.

Given $b \in \mathbb{C}^m$ and nonzero $y \in \mathbb{C}^n$, the backward LS problem is then to characterize the set $\mathcal{F}_{LS}$ of all $F \in \mathbb{C}^{m\times n}$ such that y is the exact LS solution to $Fy \approx b$. Obviously we have

$$\begin{aligned}\mathcal{F}_{LS} &\equiv \left\{F \in \mathbb{C}^{m\times n} : \|b - Fy\|^2 = \min_{x\in\mathbb{C}^n} \|b - Fx\|^2\right\} \\ &= \left\{F \in \mathbb{C}^{m\times n} : F^H(b - Fy) = 0\right\}.\end{aligned}$$

We now give an alternative derivation to that in [31] of an explicit representation for all $F \in \mathcal{F}_{LS}$.

THEOREM 4.1. [illegible] $b \in \mathbb{C}^m$ [illegible] $y \in \mathbb{C}^n$, [illegible]

$$\mathcal{F}_{LS} \equiv \left\{F \in \mathbb{C}^{m\times n} : \ \|b - Fy\|^2 = \min_{x\in\mathbb{C}^n} \|b - Fx\|^2\right\}$$

$$= \left\{F \in \mathbb{C}^{m\times n} : \ F^H(b - Fy) = 0\right\}, \tag{4.1}$$

$$\widetilde{\mathcal{N}}_{LS} \equiv \left\{\left(I - \tilde{w}\tilde{w}^\dagger\right)\left[by^\dagger + Z\left(I - yy^\dagger\right)\right] : \ \tilde{w} \in \mathbb{C}^m, Z \in \mathbb{C}^{m\times n}\right\}. \tag{4.2}$$

[illegible] $\mathcal{F}_{LS} = \widetilde{\mathcal{N}}_{LS}$ [illegible] F [illegible] $w \equiv b - Fy$ [illegible] $\tilde{w}$ [illegible] (4.2) [illegible]. This theorem could be proved by the same approach as that used in proving Theorem 3.2. But we can obtain the results directly from Theorem 3.2. Notice from (3.14) and (4.1) that

$$\mathcal{F}_{LS} = \lim_{\gamma\to 0} \mathcal{F}_{STLS+}.$$

Now since $\mathcal{F}_{STLS+} = \widetilde{\mathcal{N}}_{STLS+}$ from Theorem 3.2, it follows that

$$\begin{aligned}\mathcal{F}_{LS} &= \lim_{\gamma\to 0} \mathcal{F}_{STLS+} = \lim_{\gamma\to 0} \widetilde{\mathcal{N}}_{STLS+} \\ &= \left\{\left(I - \tilde{w}\tilde{w}^\dagger\right)\left[by^\dagger + Z\left(I - yy^\dagger\right)\right] : \tilde{w} \in \mathbb{C}^m, Z \in \mathbb{C}^{m\times n}\right\} = \widetilde{\mathcal{N}}_{LS}.\end{aligned}$$

The conclusion that $w = b - Fy$ is a scalar multiple of $\tilde{w}$ still holds. In fact, this can be seen from (3.25) by taking $\gamma \to 0$. ∎

In [31] Waldén, Karlson, and Sun gave the original and elegant proof that $\mathcal{F}_{LS} = \widetilde{\mathcal{N}}_{LS}$, and used the result to find the minimal backward error for the LS problem. It is not the intent of this paper to find minimal backward errors, and we will now specialize the general result of Theorem 3.2 to DLS problems.

5. The data least squares problem. Given $A \in \mathbb{C}^{m\times n}$ and $b \in \mathbb{C}^m$, the DLS problem is defined as (see [7] and, for example, [16], [17]):

$$\sigma_{D} \equiv \min_{E,x} \|E\|_F \quad \text{subject to} \quad (A+E)x = b. \tag{5.1}$$

When $\gamma \to \infty$, the STLS problem (3.1) becomes the DLS problem (5.1); see [16]. The condition (3.3) is still needed for building the theory for the DLS problem.

It is easy to show that (5.1) is equivalent to (see, e.g., [16])

$$\sigma_{D}^2 = \min_{x} \frac{\|b-Ax\|^2}{\|x\|^2}. \tag{5.2}$$

From [16, equations (5.14)–(5.17)], when (3.3) holds, $\hat{x}$ solves (5.1) if and only if

$$A^H(b-A\hat{x}) = -\hat{x}\sigma_{D}^2, \quad \sigma_{D}^2 \equiv \frac{\|b-A\hat{x}\|^2}{\|\hat{x}\|^2} < \sigma_{\min}^2(A). \tag{5.3}$$

Both (5.2) and (5.3) can also be obtained by taking $\gamma \to \infty$ in (3.4) and (3.5).

Given $b \in \mathbb{C}^m$ and nonzero $y \in \mathbb{C}^n$, the backward DLS problem is then to characterize the set $\mathcal{F}_{DLS}$ of all $F \in \mathbb{C}^{m\times n}$ such that y is the exact DLS solution to $Fy \approx b$. As in the STLS problem, the sets $\mathcal{F}_{DLS}$ and $\mathcal{F}_{DLS+}$ can be defined as follows:

$$\begin{aligned} \mathcal{F}_{DLS} &\equiv \left\{ F \in \mathbb{C}^{m\times n} : \ \frac{\|b-Fy\|^2}{\|y\|^2} = \min_{x\in\mathbb{C}^n} \frac{\|b-Fx\|^2}{\|x\|^2} \right\} \\ &\subseteq \mathcal{F}_{DLS+} \equiv \left\{ F \in \mathbb{C}^{m\times n} : \ F^H(b-Fy) = -y\frac{\|b-Fy\|^2}{\|y\|^2} \right\}. \end{aligned} \tag{5.4}$$

Comments paralleling those given after (3.8) and Theorem 3.2 apply here as well.

We now obtain an explicit characterization for all $F \in \mathcal{F}_{DLS+}$.

THEOREM 5.1. [illegible] $b \in \mathbb{C}^m$ [illegible] $y \in \mathbb{C}^n$, [illegible]

$$\mathcal{F}_{DLS+} \equiv \left\{ F \in \mathbb{C}^{m\times n} : \ F^H(b-Fy) = -y\frac{\|b-Fy\|^2}{\|y\|^2} \right\},$$

$$\mathcal{N}_{DLS+} \equiv \left\{ (b-w)y^\dagger + \left(I-ww^\dagger\right) Z \left(I-yy^\dagger\right) : w \in \mathbb{C}^m,\, b^Hw = 0,\, Z \in \mathbb{C}^{m\times n} \right\}. \tag{5.5}$$

[illegible] $\mathcal{F}_{DLS+} = \mathcal{N}_{DLS+}$, [illegible] $F \in \mathcal{N}_{DLS+}$, [illegible] w [illegible] (5.5) [illegible] $w = b - Fy$ [illegible]. We could prove this theorem by using a constructive derivation similar to that used in proving Theorem 3.2. Instead we obtain the results by taking the limit $\gamma \to \infty$ for the results in Theorem 3.2. In fact, we have

$$\begin{aligned} \mathcal{F}_{DLS+} &= \lim_{\gamma\to\infty} \mathcal{F}_{STLS+} = \lim_{\gamma\to\infty} \mathcal{N}_{STLS+} \\ &= \left\{ (b-w)y^\dagger + \left(I-ww^\dagger\right) Z \left(I-yy^\dagger\right) : \ b^Hw = 0,\ Z \in \mathbb{C}^{m\times n} \right\} \\ &= \mathcal{N}_{DLS+}. \end{aligned}$$

The conclusion that w in (5.5) satisfies $w = b - Fy$ still holds and can also be verified by forming Fy for any $F \in \mathcal{N}_{DLS+}$. ∎

The result of Theorem 5.1 is used in [2] for the backward perturbation analysis for the DLS problem.

6. Summary and comments. Given $b \in \mathbb{C}^m$ and $y \in \mathbb{C}^n$ we have presented a unitary transformation approach to finding sets, or supersets, of all matrices $F \in \mathbb{C}^{m\times n}$ such that y is the solution to $Fy \approx b$ for some common classes of approximation problems.

Our approach is constructive and easy to follow. We have used the well-known compatible case $Fy = b$ to illustrate this approach in its simplest setting, as well as to illustrate one of the uses of such sets—finding minimal backward errors. In doing so we have shown the equivalence of two often used problem formulations for such errors—an apparently new result.

We then applied this approach to finding new and useful supersets of matrices consistent with the STLS solution to $Fy \approx b$. From (3.1) or (3.5) the STLS solution becomes the LS solution as $\gamma \to 0$ and becomes the DLS solution as $\gamma \to \infty$; see, for example, [16, section 6]. Based on these facts, we derived the results for the LS and DLS problems using the results of Theorem 3.2 directly, although we could have separately given a full constructive derivation for these two problems, similar to that in Theorem 3.2.

We summarize the different problems and sets we have obtained as follows:

- the STLS problem; see (3.8) and Theorem 3.2:

$$\begin{aligned}
\mathcal{F}_{STLS} &\equiv \left\{ F \in \mathbb{C}^{m\times n} : \frac{\|b-Fy\|^2}{\gamma^{-2}+\|y\|^2} = \min_{x\in\mathbb{C}^n} \frac{\|b-Fx\|^2}{\gamma^{-2}+\|x\|^2} \right\} \\
\subseteq \mathcal{F}_{STLS+} &\equiv \left\{ F \in \mathbb{C}^{m\times n} : F^H(b-Fy) = -y\frac{\|b-Fy\|^2}{\gamma^{-2}+\|y\|^2} \right\} \\
= \mathcal{N}_{STLS+} &\equiv \Big\{ (b-w)y^\dagger + \left(I-ww^\dagger\right) Z \left(I-yy^\dagger\right) : \\
&\qquad w \in \mathbb{C}^m,\ w^H b = \frac{\|w\|^2}{1+\gamma^2\|y\|^2},\ Z \in \mathbb{C}^{m\times n} \Big\} \\
= \widetilde{\mathcal{N}}_{STLS+} &\equiv \left\{ -\tilde{w}\tilde{w}^\dagger b\gamma^2 y^H + \left(I-\tilde{w}\tilde{w}^\dagger\right)\left[by^\dagger + Z\left(I-yy^\dagger\right)\right] : \right. \\
&\qquad \left. \tilde{w} \in \mathbb{C}^m, Z \in \mathbb{C}^{m\times n} \right\}.
\end{aligned}$$

- compatible systems; see Lemma 2.1:

$$\begin{aligned}
\mathcal{F} &\equiv \{F \in \mathbb{C}^{m\times n} : Fy = b\} \\
= \mathcal{N} &\equiv \left\{ by^\dagger + Z\left(I-yy^\dagger\right) :\ Z \in \mathbb{C}^{m\times n} \right\}.
\end{aligned}$$

- the LS problem; see Theorem 4.1:

$$\begin{aligned}
\mathcal{F}_{LS} &\equiv \{F \in \mathbb{C}^{m\times n} : \|b-Fy\| = \min_{x\in\mathbb{C}^n} \|b-Fx\|\} \\
&= \{F \in \mathbb{C}^{m\times n} :\ F^H(b-Fy) = 0\} \\
= \widetilde{\mathcal{N}}_{LS} &\equiv \left\{ \left(I-\tilde{w}\tilde{w}^\dagger\right)\left[by^\dagger + Z\left(I-yy^\dagger\right)\right] :\ \tilde{w} \in \mathbb{C}^m,\ Z \in \mathbb{C}^{m\times n} \right\}.
\end{aligned}$$

- the DLS problem; see Theorem 5.1:

$$\begin{aligned}
\mathcal{F}_{DLS} &\equiv \left\{ F \in \mathbb{C}^{m\times n} : \frac{\|b-Fy\|^2}{\|y\|^2} = \min_{x\in\mathbb{C}^n} \frac{\|b-Fx\|^2}{\|x\|^2} \right\} \\
\subseteq \mathcal{F}_{DLS+} &\equiv \left\{ F \in \mathbb{C}^{m\times n} : F^H(b-Fy) = -y\frac{\|b-Fy\|^2}{\|y\|^2} \right\} \\
= \mathcal{N}_{DLS+} &\equiv \left\{ (b-w)y^\dagger + \left(I-ww^\dagger\right) Z \left(I-yy^\dagger\right) : b^H w = 0, w \in \mathbb{C}^m, Z \in \mathbb{C}^{m\times n} \right\}.
\end{aligned}$$

The sets $\mathcal{F}_{STLS+}$ and $\mathcal{F}_{DLS+}$ are supersets of $\mathcal{F}_{STLS}$ and $\mathcal{F}_{DLS}$, respectively. But some theoretical arguments and numerical experiments given in [2] have shown that, when y is a reasonable approximation to the solution of the DLS problem for $Ax \approx b$, the set $\mathcal{N}_{DLS+}$ can usually be used with no further constraints to obtain the minimal backward errors for the DLS problem. This is probably true for the STLS problem as well. However, since such behavior is problem-dependent, we will not discuss it further here, except to state that for many practical uses $\mathcal{N}_{STLS+}$ or $\widetilde{\mathcal{N}}_{STLS+}$ can be used in place of $\mathcal{F}_{STLS}$, and $\mathcal{N}_{DLS+}$ can be used in place of $\mathcal{F}_{DLS}$.

The constructive technique we use could also be applicable to other backward problems, e.g., finding a matrix whose partial eigenvalues and eigenvectors are known.

Acknowledgment. We would like to thank the referees for their helpful comments.

A NOTE ON EIGENVALUES OF MATRICES WHICH ARE SELF-ADJOINT IN SYMMETRIC BILINEAR FORMS*

ZHI-HAO CAO†

Abstract. In this note we discuss the eigenvalue properties of matrices which are self-adjoint in symmetric bilinear forms and point out that an assertion given by Stoll and Wathen in [*SIAM J. Matrix Anal. Appl.*, 30 (2008), pp. 582–608] is not true.

Key words. eigenvalues, symmetric bilinear forms, symmetric indefinite matrices

AMS subject classifications. 65F10, 65F15

DOI. 10.1137/080728068

Let $\mathcal{H} \in \mathcal{R}^{n,n}$ be a symmetric matrix. The symmetric bilinear form $< \cdot, \cdot >_{\mathcal{H}}$ defined by $\mathcal{H}$ is

$$< x, y >_{\mathcal{H}} :\equiv \ x^T \mathcal{H} y.$$

The fact that a matrix $\mathcal{A} \in \mathcal{R}^{n,n}$ is self-adjoint in the symmetric bilinear form $< \cdot, \cdot >_{\mathcal{H}}$ means that

$$x^T \mathcal{A}^T \mathcal{H} y =< \mathcal{A}x, y >_{\mathcal{H}} =< x, \mathcal{A}y >_{\mathcal{H}} = x^T \mathcal{H}\mathcal{A} y \, \forall x, y \in \mathcal{R}^n,$$

which is equivalent to

$$\mathcal{A}^T \mathcal{H} = \mathcal{H}\mathcal{A}; \tag{1}$$

i.e., $\mathcal{H}\mathcal{A}$ is symmetric. Thus, the fact that the matrix $\mathcal{A}$ is self-adjoint in the symmetric bilinear form $< \cdot, \cdot >_{\mathcal{H}}$ can also be defined by (1), and we say $\mathcal{A}$ is $\mathcal{H}$ [illegible].

It is well known that if $\mathcal{A}$ is I-symmetric, i.e., $\mathcal{A}^T = \mathcal{A}$, then $\mathcal{A}$ has real eigenvalues. In [3, p. 587], Stoll and Wathen discuss eigenvalues of matrices which are self-adjoint in symmetric bilinear forms, as follows.

Assume that a matrix $\mathcal{A} \in \mathcal{R}^{n,n}$ is $\mathcal{H}$ [illegible], where $\mathcal{H} \in \mathcal{R}^{n,n}$ is symmetric; i.e., $\mathcal{A}^T \mathcal{H} = \mathcal{H}\mathcal{A}$ holds and (λ, v) is a given eigenpair of $\mathcal{A}$. Thus

$$\mathcal{A}v = \lambda v, \quad v \neq 0. \tag{2}$$

Multiplying (2) from the left by $v^* \mathcal{H}$, where v^* is the conjugate transpose of v, gives

$$v^* \mathcal{H}\mathcal{A} v = \lambda v^* \mathcal{H} v. \tag{3}$$

From (3), Stoll and Wathen claim that λ must be real. Thus, they [3, p. 587, lines 29–30] state: "Note that the above arguments establish that there is no symmetric bilinear form in which $\mathcal{A}$ is self-adjoint unless $\mathcal{A}$ has real eigenvalues."

However, the assertion above is not true as the following example shows.

†School of Mathematical Sciences and Laboratory of Mathematics for Nonlinear Sciences, Fudan University, Shanghai 200433, People's Republic of China (zcao@fudan.edu.cn, zhcao@cableplus.com.cn).

EXAMPLE.

$$\mathcal{A} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \qquad \mathcal{H} = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}.$$

$\mathcal{A}$ $\pm i$ $\mathcal{H}$

$$\mathcal{H}\mathcal{A} \equiv \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & -1 \\ -1 & -1 \end{pmatrix} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \equiv \mathcal{A}^T\mathcal{H}.$$

$\mathcal{A}$ $< \cdot, \cdot >_{\mathcal{H}}$

(λ, v) $\mathcal{A}$ $\lambda = i$ $v^* = [1, i]$

(2)

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} \begin{pmatrix} 1 \\ -i \end{pmatrix} = i \begin{pmatrix} 1 \\ -i \end{pmatrix}.$$

$v^*\mathcal{H}$ (3)

$$v^*\mathcal{H}\mathcal{A}v \equiv [1, i] \begin{pmatrix} 1 & -1 \\ -1 & -1 \end{pmatrix} \begin{pmatrix} 1 \\ -i \end{pmatrix} = 0 = i[1, i] \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} 1 \\ -i \end{pmatrix} \equiv \lambda v^*\mathcal{H}v.$$

λ

We can revise the assertion of Stoll and Wathen as follows.

PROPOSITION A1. $\mathcal{A} \in \mathcal{R}^{n,n}$ $\mathcal{H}$-symmetric $\mathcal{H} \in \mathcal{R}^{n,n}$ $v^*\mathcal{H}v \neq 0$ $\mathcal{A}$ $\mathcal{A}$ $\mathcal{H}$ $\mathcal{A}$ $\mathcal{H}$ $\mathcal{A}$

It should be noted that Benzi and Simoncini in [1] investigated spectral properties of the block 2×2 matrix of the form

$$\mathcal{M}_- = \begin{pmatrix} A & B^T \\ -B & C \end{pmatrix},$$

where $A \in \mathcal{R}^{n,n}$ is symmetric positive definite, $B \in \mathcal{R}^{m,n}$ with $m \leq n$, and $C \in \mathcal{R}^{m,m}$ is symmetric positive semidefinite. Let

$$\mathcal{J} = \begin{pmatrix} I_n & \\ & -I_m \end{pmatrix},$$

which is symmetric indefinite. Then it is easy to see that

$$\mathcal{J}\mathcal{M}_- = \mathcal{M}_-^T\mathcal{J};$$

i.e., $\mathcal{M}_-$ is $\mathcal{J}$. The eigenvalues of the matrix $\mathcal{M}_-$ are usually not all real (cf. [1, section 2]).

Finally, we point out that an important related result is given by Gohberg, Lancaster, and Rodman (cf. [2, Corollary 5.2]).

PROPOSITION A2. $\mathcal{A}$ $\mathcal{H}$-symmetric $\mathcal{H}$ $\mathcal{H}$ $\mathcal{A} = \mathcal{H}^{-1}\mathcal{A}^T\mathcal{H}$

Comment from Stoll and Wathen. This short note by Professor Cao gives an important correction to some incorrect statements in our SIAM Journal on Matrix Analysis and Applications paper

Martin Stoll and Andy Wathen,

SIAM J. Matrix Anal. Appl., 30 (2008), pp. 582–608.

Precisely on page 587, the one-sentence paragraph before Lemma 3.8 should say "Note that the above arguments establish that there is no inner product in which $\mathcal{A}$ is self-adjoint unless $\mathcal{A}$ has real eigenvalues," the preceding paragraph should have the ammended sentence "On the right-hand side $v^*\mathcal{H}v$ is also real since $\mathcal{H}$ is real symmetric, therefore the eigenvalue must be real unless $v^*\mathcal{H}v = 0$," and the final sentence in that paragraph is not relevant.

The case when $v^*\mathcal{H}v = 0$ for some eigenvector v of $\mathcal{A}$ is more important than we had realized and Professor Cao significantly points out that for real square matrix $\mathcal{A}$ there is a real symmetric matrix $\mathcal{H}$ such that $\mathcal{H}\mathcal{A} = \mathcal{A}^T\mathcal{H}$; i.e., that for real square matrix there is a symmetric bilinear form in which it is self-adjoint.

These corrections do not affect any of the other results and statements in our paper as far as we are aware.

FAST COMPUTATION OF MINIMAL FILL INSIDE A GIVEN ELIMINATION ORDERING*

PINAR HEGGERNES† AND BARRY W. PEYTON‡

Abstract. Minimal elimination orderings were introduced by Rose, Tarjan, and Lueker in 1976, and during the last decade they have received increasing attention. Such orderings have important applications in several different fields, and they were first studied in connection with minimizing fill in sparse matrix computations. Rather than computing any minimal ordering, which might result in fill that is far from minimum, it is more desirable for practical applications to start from an ordering produced by a fill-reducing heuristic and then compute a minimal fill that is a subset of the fill produced by the given heuristic. This problem has been addressed previously, and there are several algorithms for solving it. The drawback of these algorithms is that either there is no theoretical bound given on their running time, although they might run fast in practice, or they have a good theoretical running time, but they have never been implemented, or they require a large machinery of complicated data structures to achieve the good theoretical time bound. In this paper, we present an algorithm called MCS-ETree for solving the mentioned problem in $O(nm\,\mathrm{A}(m,n))$ time, where m and n are, respectively, the number of edges and vertices of the graph corresponding to the input sparse matrix and $\mathrm{A}(m,n)$ is the very slowly growing inverse of Ackerman's function. A primary strength of MCS-ETree is its simplicity and its straightforward implementation details. We present run time test results to show that our algorithm is fast in practice. Thus our algorithm is the first that both has a provably good running time with easy implementation details and is fast in practice.

Key words. sparse matrix computations, minimal fill, elimination trees, composite tree rotations, maximum cardinality search (MCS), minimal triangulation

1. Introduction.

Consider the Cholesky factorization $A = LL^T$ of an $n \times n$ symmetric positive definite sparse matrix A. Elements $l_{ij} \neq 0$, where $a_{ij} = 0$, are called *fill* elements. It is well known that finding a good permutation matrix P and computing the Cholesky factor of PAP^T rather than the Cholesky factor of A can give much less fill and is an essential operation in sparse matrix computations. The matrix A is conveniently interpreted as a graph G, where G has a vertex v_i for each row (or equivalently column) i of A and $\{v_i, v_j\}$ is an edge in G if and only if $a_{ij} \neq 0$. Similarly, the *filled graph* G^+ is the graph of $L + L^T$, and the fill elements of L correspond to the *fill edges* of G^+. Any permutation matrix P for A corresponds to an elimination ordering α on G such that G_α is the graph of PAP^T, and the number of fill edges in G_α^+ is entirely dependent on α. Thus we refer to the fill edges of G_α^+ as the fill *produced by* α. (Definitions and notation are detailed in section 2.)

For sparse matrix computations [26] and in many other fields [7, 16, 27], one would like to find orderings that produce the minimum possible fill. This problem was shown to be NP-hard by Yannakakis in 1981 [28]. Already in 1976, Rose, Tarjan, and Lueker [25] conjectured the NP-hardness of this problem. They also introduced the notion of *minimal elimination orderings* and *minimal fill*, and they presented an algorithm for computing both in $O(nm)$ time in the same paper. An ordering α is a minimal elimination ordering if there is no ordering β such that G_β^+ is a strict subgraph

of G_α^+. For any ordering α, the filled graph G_α^+ is a chordal graph [10] and is called a *triangulation* of G. If α is a minimal elimination ordering, then G_α^+ is a minimal triangulation. One reason that minimal elimination orderings are highly desirable in sparse matrix computations is that they ensure that subsequent equivalent reorderings do not change the space allocation requirements [5]. In the field of graph algorithms, minimal elimination orderings and minimal triangulations are very important and well studied [13], as they include the set of triangulations that correspond to widely studied graph parameters, like *minimum fill* and *treewidth*, and thus provide a tool to compute these by approximation algorithms [21] or exact (fast) exponential time algorithms [9].

A minimal triangulation can contain fill that is far from minimum fill. Consequently, for practical applications, it is more appropriate to start with a good triangulation produced by a common heuristic algorithm, like Minimum Degree [1, 17] or Nested Dissection [11], and then compute a minimal triangulation that is a subgraph of the initial triangulation [6]. This problem, sometimes called the *minimal triangulation sandwich problem*, was first posed and solved by Blair, Heggernes, and Telle in 1996 [5], and they presented an algorithm with running time $O(mf + f^2)$, where f is the number of fill edges in the initial triangulation. For small f, this algorithm is fast in practice; however, its running time is heavily dependent on f, which might be $O(n^2)$, giving an $O(n^4)$ time algorithm in the worst case. Later, Dahlhaus solved the same problem with an algorithm of running time $O(nm)$ [8], but this algorithm has never been implemented to our knowledge. A more recent algorithm by Berry et al. solves the same problem in $O(nm)$ time [3]; however, a heavy machinery of complicated data structures is necessary to achieve this time bound. In addition to these, two algorithms based on iterations were given without running time analysis separately by Peyton [24] and by Berry, Heggernes, and Simonet [4]. The algorithm of Peyton is documented to run fast in practice,[1] whereas the latter algorithm is of less practical and more theoretical interest [22].

In this paper, we present an algorithm called MCS-ETree that takes as input a graph G and an initial ordering β and produces as output a minimal elimination ordering α such that G_α^+ is a subgraph of G_β^+ (i.e., G_α^+ is *sandwiched* between G and G_β^+). The running time of our algorithm is $O(nm\,\mathrm{A}(m,n))$, where $\mathrm{A}(m,n)$ is the very slowly growing inverse of Ackerman's function. Hence, our theoretical running time is very close to the best known theoretical running time $O(nm)$ for solving this problem. Compared to $O(nm)$ algorithms solving the same problem, MCS-ETree has the advantage of being both fast in practice and easy to implement, while not relying on complicated data structures; it uses basic operations and data structures commonly used in practice in sparse matrix computations, with modest adaptations for use by the algorithm. In addition, in practical tests our algorithm is usually faster than the previous algorithm with the fastest running time.

This paper is organized as follows. Section 2 introduces most of the background, terminology, and notation. Section 3 gives some background on composite elimination tree rotations [19], which are used by our new algorithm in a slightly modified form. Section 4 presents the new algorithm MCS-ETree, which computes minimal orderings and solves the above-mentioned sandwich problem. This section also proves that the algorithm is correct. Section 5 discusses some of the implementation issues and shows that the running time is $O(nm\,\mathrm{A}(m,n))$. Also, section 5 both presents a straightforward implementation and discusses how to enhance the implementation in

[1] In fact, the algorithm of Peyton [24] is the fastest in practice of all mentioned algorithms.

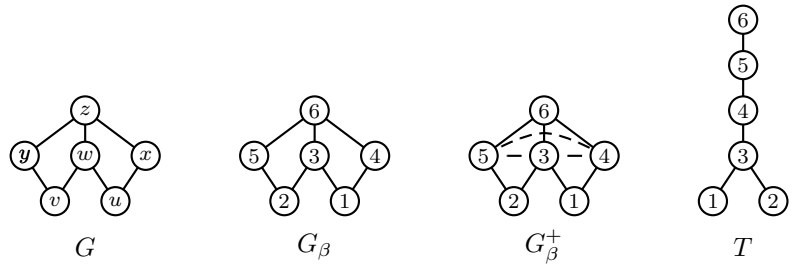

FIG. 2.1. *For the given graph G and its ordering β, the Elimination Game results in the filled graph G_β^+. The three fill edges are dashed lines. Also pictured is the elimination tree produced by the ordering.*

ways that dramatically improve the performance in our tests. Section 6 reports the results of these tests. Finally, section 7 gives some concluding remarks.

2. Background and notation. A graph $G = (V, E)$ consists of a set V of n vertices and a set E of m edges. For a given graph G, we denote the set of its vertices by $V(G)$ and the set of its edges by $E(G)$. When $\{u, v\}$ is an edge, we say that u and v are *adjacent* or *neighbors*. For a vertex v of G, $\mathrm{adj}_G(v)$ denotes the set of vertices adjacent to v, also called the *adjacency* or *neighborhood* of v, and $\mathrm{adj}_G[v] = \mathrm{adj}_G(v) \cup \{v\}$. For a set of vertices $X \subseteq V$, $\mathrm{adj}_G(X) = \bigcup_{x \in X} \mathrm{adj}_G(x) \setminus X$ and $\mathrm{adj}_G[X] = \mathrm{adj}_G(X) \cup X$. An *ordering* α of G is a bijective function $\alpha : V \to \{1, 2, \ldots, n\}$, and we will sometimes write $\alpha = (v_1, v_2, \ldots, v_n)$, meaning that $\alpha(v_i) = i$ for $1 \le i \le n$ (we will call i the *number* of v_i). When an ordering α is given, the ordered graph is denoted by G_α. In this case, $\mathrm{hadj}_{G_\alpha}(v_i) = \mathrm{adj}_{G_\alpha}(v_i) \cap \{v_{i+1}, v_{i+2}, \ldots, v_n\}$ is the set of higher-numbered neighbors of v_i, and $\mathrm{ladj}_{G_\alpha}(v_i) = \mathrm{adj}_{G_\alpha}(v_i) \cap \{v_1, v_2, \ldots, v_{i-1}\}$ is the set of lower-numbered neighbors of v_i.

If two graphs G and H have the same vertex set, then G is a *subgraph* of H if $E(G) \subseteq E(H)$, and G is a *proper subgraph* of H if $E(G) \subset E(H)$. A subgraph of G *induced* by a vertex set $X \subseteq V$ will be denoted by $G(X)$. An induced subgraph $G(X)$ contains every edge of G with both endpoints in X. A set $X \subseteq V$ of vertices is a *clique* if every pair of vertices in X is adjacent in G. A *maximal clique* is any clique whose vertex set is maximal with respect to subset inclusion for this property. A *path* is a sequence of distinct vertices $x_1 - x_2 - \cdots - x_k$ such that x_i is adjacent to x_{i+1} for $1 \le i < k$. A *chord* on a path is an edge between two nonconsecutive vertices of the path. A *cycle* is a path where the first vertex is the same as the last vertex. A graph is *chordal* if it contains no chordless cycle on four or more vertices.

The following simple algorithm is called the *Elimination Game* [23], and it simulates (on graphs) the Cholesky factorization of matrices. With input graph G and ordering α, repeatedly pick the smallest numbered vertex, add edges to make its set of neighbors a clique, and remove this vertex and the edges incident upon it from the graph until the graph is empty. The set of edges that are added during the algorithm is called *fill*, and the *filled graph* G_α^+ is obtained by adding to G this fill. Figure 2.1 shows a graph G, an ordering β of the graph (G_β), and the filled graph G_β^+ associated with the ordering. This graph and initial ordering will be used throughout the paper to illustrate algorithms and other points as needed.

The following lemma, which we will use in our proofs, characterizes the edges in a filled graph G_α^+.

LEMMA 2.1 (see [25]). *Given a graph G and an ordering $\alpha = (v_1, v_2, \ldots, v_n)$, an edge $\{v_i, v_j\}$, with $i < j$ is present in G_α^+ if and only if $\{v_i, v_j\}$ is an edge of G or there is a path between v_i and v_j in G containing only vertices from the set $\{v_1, v_2, \ldots, v_{i-1}\}$.*

A path between v_i and v_j containing only vertices that all have smaller numbers in α than the smaller of i and j will be called a *fill path*.

If G_α^+ contains no fill edges, then α is called a *perfect elimination ordering (peo)*. Fulkerson and Gross showed that chordal graphs are exactly the class of graphs that have perfect elimination orderings [10]. Thus for every graph G and ordering α, the filled graph G_α^+ is chordal, and G_α^+ is a triangulation of G. In a chordal graph, the vertices of any maximal clique can be ordered last by some peo in any arbitrary internal order [27].

Any ordering β of G that is a peo of G_α^+ is an *equivalent reordering* of G with respect to α. An equivalent reordering introduces no new fill, that is, G_β^+ is a subgraph of G_α^+. If there exists no ordering β for which G_β^+ is a proper subgraph of G_α^+, then α is called a *minimal elimination ordering (meo)*, and G_α^+ is a *minimal triangulation*. Computing an meo is equivalent to computing a minimal triangulation, as every peo of a minimal triangulation gives the same filled graph when applied to the original graph [5, 25]. The following is a characterization of minimal triangulations that we will use in the proof that our new algorithm is correct.

THEOREM 2.2 (see [25]). *A given triangulation H of a graph G is a minimal triangulation if and only if every fill edge added to G to obtain H is the unique chord of a 4-cycle in H.*

Given a graph G and an ordering α, the filled graph G_α^+ defines a structure called an *elimination tree* T as follows: vertex v_j is the parent of vertex v_i in T if v_j is the smallest numbered vertex in $\mathrm{hadj}_{G_\alpha^+}(v_i)$. The elimination tree associated with the filled graph in Figure 2.1 is included in Figure 2.1. Due to Lemma 2.1, the elimination tree corresponding to α can be computed directly from G and α without computing G_α^+ explicitly [20]. A *topological ordering* of T is any ordering that numbers each child with a number smaller than that of its parent. The ordering in Figure 2.1 is a topological ordering of T. Any topological ordering of T is an equivalent ordering of G with respect to α. Consequently, we will talk about equivalent orderings with respect to an ordering and with respect to an elimination tree interchangeably. Liu [20] provides a thorough examination of elimination trees. Note also that if G has more than one connected component, then one obtains an elimination forest with one tree for each connected component.

In a rooted tree, an *ancestor* of a vertex v is any vertex that is on the unique path between v and the root, including the root; a *descendant* of v is any vertex of which v is an ancestor. Let $T[v]$ be the subtree of an elimination tree T that is rooted at v and consists of v and every descendant of v in T; such subtrees will be called *elimination subtrees*. It is well known that $\mathrm{hadj}_{G_\alpha^+}(v) = \mathrm{adj}_G(V(T[v]))$ [20], and we will make use of this fact throughout the paper. As an illustration, note that in Figure 2.1 we have

$$\begin{aligned}\mathrm{adj}_G(V(T[v_3])) &= \mathrm{adj}_G(\{v_1, v_2, v_3\})\\ &= \{v_4, v_5, v_6\}\\ &= \mathrm{adj}_{G_\beta^+}(v_3).\end{aligned}$$

Finally, we let $\mathrm{anc}_T(v)$ be the set of ancestors of v in T, where v is *not* included in the set; we also write $\mathrm{anc}_T[v] = \mathrm{anc}_T(v) \cup \{v\}$.

Algorithm Change_Root(G, T, u)
Input: A graph $G = (V, E)$, an elimination tree T of G, and a vertex $u \in V$.
Output: A reordering γ of G that is equivalent with respect to T,
where u is numbered last.

```
Number u last in γ and mark u as already numbered;
z ← u;
while z is not the root of T do
    Order the unnumbered vertices of adj_G(V(T[z])) last in γ, but
    before those that are already numbered by γ;
    Mark the newly numbered vertices as already numbered;
    z ← the parent of z in T;
end while;
Number in γ the vertices in V \ anc_T[u] using their original
relative order in T;
```

end Change_Root;

FIG. 3.1. *An algorithm for changing the root of an elimination tree with an equivalent reordering (see Algorithm* 3.2 *Composite_Rotations in Liu* [19]).

3. Changing the root of an elimination subtree. In our new algorithm MCS-ETree, we will need to reorder an elimination subtree $T[v]$ in such a way that a particular vertex $u \in V(T[v])$ is numbered last by this reordering, and the corresponding reordering of $G(V(T[v]))$ is equivalent to any given topological ordering of $T[v]$. Since u is numbered last among the vertices in $V(T[v])$ by the reordering, it will be the root of the new elimination subtree associated with the new equivalent reordering. A trivial modification of the composite elimination tree rotations algorithm in Liu [19] will perform this task.

For a given graph G and a given ordering β, let T be the elimination tree associated with the filled graph G^+_β, and let $u \in V(G)$. Algorithm 3.2 (Composite_Rotations) from [19] reorders G with a peo γ of G^+_β such that the vertices of $\mathrm{adj}_G(V(T[u]))$ are numbered last in γ. (Recall that γ is an equivalent reordering of G with respect to β.) Notice that there might be ancestors of u in T that do not belong to $\mathrm{adj}_G(V(T[u]))$, and hence u will often become closer to the root of the resulting new elimination tree corresponding to γ and will never be further away than it is in T. The algorithm Change_Root in Figure 3.1 adds a single first line to Liu's Composite_Rotations algorithm in order to number u last and also modifies the last line to number the vertices in $V \setminus \mathrm{anc}_T[u]$ so that u is not also numbered there. These are the only modifications to the original algorithm. Consequently, the rest of the vertices are numbered in the same order as in Composite_Rotations, that is, the vertices of $\mathrm{adj}_G(V(T[u]))$ are ordered next-to-last and so on. The elimination tree obtained from the ordering produced by Change_Root clearly is rooted at vertex u.

In Figure 3.2, we illustrate a run of Change_Root on the graph and elimination tree in Figure 2.1. The elimination tree in Figure 3.2 is the same as that in Figure 2.1 with the numbers replaced by the appropriate letters. The vertex u has been chosen to become the new root. The algorithm first numbers u last with the number 6. The main loop then processes the ancestors of u in ascending order. When u is processed, the unnumbered neighbors of $V(T[u])$, namely, w and x, are numbered next-to-last in front of u with numbers 4 and 5, respectively. When w is processed next, the unnumbered neighbors of $V(T[w])$, namely, z and y, are numbered last in front of the previously numbered vertices with numbers 2 and 3, respectively. When y and

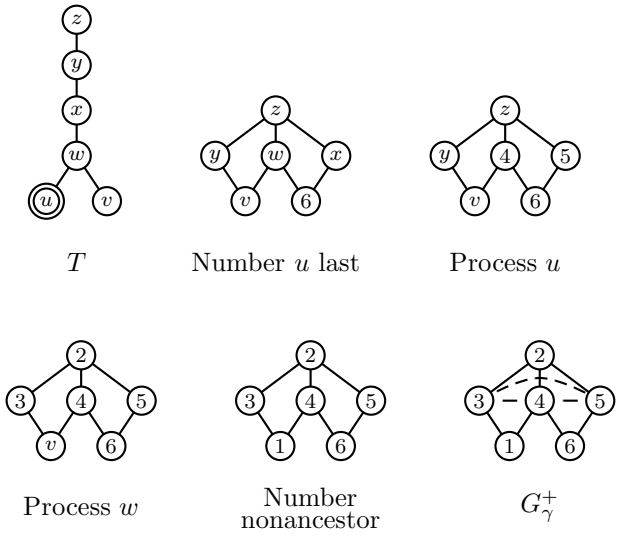

FIG. 3.2. *The algorithm Change_Root is run on the graph and elimination tree shown in Figure* 2.1. *The new root is to be vertex u.*

z are processed, no vertices receive their numbers. Finally, when the main loop is finished, the single nonancestor of u, namely v, receives the number 1. Note that G^+_γ in Figure 3.2 is identical to G^+_β in Figure 2.1 so that γ is an equivalent reordering with respect to β, as required. Note also that u will be the root of the new elimination tree, as desired.

The following lemma shows that Change_Root produces an ordering equivalent to the input ordering.

LEMMA 3.1. *Let β be an ordering of a graph G, and let T be the elimination tree associated with G^+_β. Choose $u \in V(G)$. Any ordering γ produced by Change_Root(G, T, u) is equivalent with respect to β.*

Proof. The desired property is inherited directly from Composite_Rotations, as we will see. Consider the ordering γ' produced by Composite_Rotations that corresponds as closely as possible to the ordering γ produced by Change_Root. It is known from Liu [19] that γ' is equivalent with respect to β. The ordering γ' matches the ordering γ except for the placement of u. The ordering γ numbers u at the end of the ordering; the ordering γ' numbers u before the vertices of $\mathrm{adj}_G(V(T[u]))$ and after the vertices of $V(T[u]) \setminus \{u\}$. The lowest numbered vertex of $\mathrm{adj}_G(V(T[u]))$ will be the parent of u in the elimination tree T' associated with γ'. Note then that the set $\{u\} \cup \mathrm{adj}_G(V(T[u]))$ is a clique in $G^+_{\gamma'}$ and forms a chain in T' from u to the root of the tree. A new topological ordering of T' can be obtained by ordering the vertices of $\{u\} \cup \mathrm{adj}_G(V(T[u]))$ last (consistent with γ') and then ordering the rest earlier, but consistent with γ'. The key observation is that when we change this ordering so that u is moved to the end (i.e., u is ordered last, but the vertices of $\mathrm{adj}_G(V(T[u]))$ remain ordered consistent with γ'), we obtain a topological ordering of the elimination tree associated with the ordering γ. Since we have merely changed the order of the vertices in the highest-numbered clique, clearly, γ is equivalent with respect to γ'. Since γ' is equivalent with respect to β, we have γ is equivalent with respect to β, as desired. □

We will use Change_Root to process elimination subtrees. Choose a vertex $v \in V(T)$ and consider the elimination subtree $T[v]$. Observe that $T[v]$ is the elimination

tree one obtains by applying a topological ordering of $T[v]$ to the induced subgraph $H = G(V(T[v]))$. This follows because any topological ordering of an elimination tree will produce the same elimination tree. Let $u \in V(T[v])$. When we execute Change_Root(H, $T[v]$, u), we obtain an equivalent reordering of H with respect to $T[v]$, where u is numbered last and hence will become the root of the new elimination subtree. When this new subtree is glued to the old elimination tree with the old parent of v now becoming the new parent of u, a revised elimination tree for the entire graph is obtained.

4. Algorithm MCS-ETree and its proof of correctness. In this section, we present a new algorithm MCS-ETree that solves the minimal triangulation sandwich problem. Given an original ordering β and graph G, this algorithm generates a minimal ordering α such that G_α^+ is a subgraph of G_β^+. The algorithm generates α by numbering the vertices from n down to 1, and the key feature is the selection at each step of a vertex of "maximum cardinality" to receive the next number. Hence the algorithm resembles a minimal triangulation algorithm called MCS-M [2], and its proof of correctness uses the same technique used there. In section 5, we will show that it can be implemented to run in $O(nm\,\mathrm{A}(m,n))$ time and can be implemented so that it does not compute any filled graphs explicitly.

Our new algorithm is given in Figure 4.1. First the algorithm computes the elimination tree T^* obtained when β is used as an elimination order on G. The set of elimination subtrees remaining to be processed (i.e., numbered) is $Trees$. Initially $Trees$ contains the single member $T^* = T^*[x]$, where x is the root of T^*. We have assumed that G is a connected graph so that we have an elimination tree rather than an elimination forest. If we had an elimination forest, then we would place each tree of the forest in $Trees$.

4.1. Executing MCS-ETree on an example. Figure 4.2 walks step-by-step through an execution of MCS-ETree on the example introduced in Figure 2.1. In Figure 4.2, the filled graph G_β^+ is the same as that pictured in Figure 2.1. The initialization step computes the elimination tree T^* of G with respect to β. This is shown next in the figure. The elimination subtree $T^*[x]$ is placed in $Trees$, the set of elimination subtrees yet to receive their α-numbers. The set of vertices that have received their α-numbers, namely L, is initially empty. The set L is listed above the heavy horizontal line above T^*. The counter k used to assign the next α-number is initially 6.

The algorithm then enters the main *while* loop. There is only one unnumbered elimination subtree to process, which is referred to as $T = T[v]$ by the algorithm. Now, $T = T^*$ at this stage in the example. Since $L = \emptyset$, the cardinalities referred to next in the algorithm are all zero. In the figure, these zero cardinalities are written beside each vertex. A vertex of maximum cardinality, with no descendant of maximum cardinality, will have to be a leaf in this case. The algorithm chooses vertex 1 as the maximum cardinality vertex.

The algorithm next uses Change_Root to reorder the subtree and change the root to vertex 1. Precisely this operation was illustrated in Figure 3.2. The ordering shown in the first graph of Figure 4.2, labeled G_γ^+, is precisely the same as the final ordering shown in Figure 3.2.

The algorithm next computes the elimination subtree for the new reordering. This new elimination tree T' rooted at the vertex now numbered 6 by γ appears next in the figure. At the bottom of the *while* loop, the root vertex receives its α-number 6. It is removed and added to the set of α-numbered vertices L. The unnumbered elimination

FIG. 4.1. *Algorithm MCS-ETree, which finds a minimal ordering and solves the minimal triangulation sandwich problem.*

subtree rooted at the sole child of vertex 6 (i.e., vertex 5) is also added to $Trees$ to be processed later.

At the top of the next iteration of the *while* loop, the unnumbered subtree $T'[c]$, where c is the vertex numbered 5 by the current ordering γ, is chosen to be processed next. Note that in the previously filled graph, only vertices 5 and 4 are neighbors of the vertex that received α-number 6. The cardinalities of vertices 4 and 5 then are both 1, while the cardinalities of the rest of the vertices in the subtree are 0, as indicated in the figure. The vertex with γ-number 4 is the maximum cardinality vertex with no descendants of maximum cardinality.

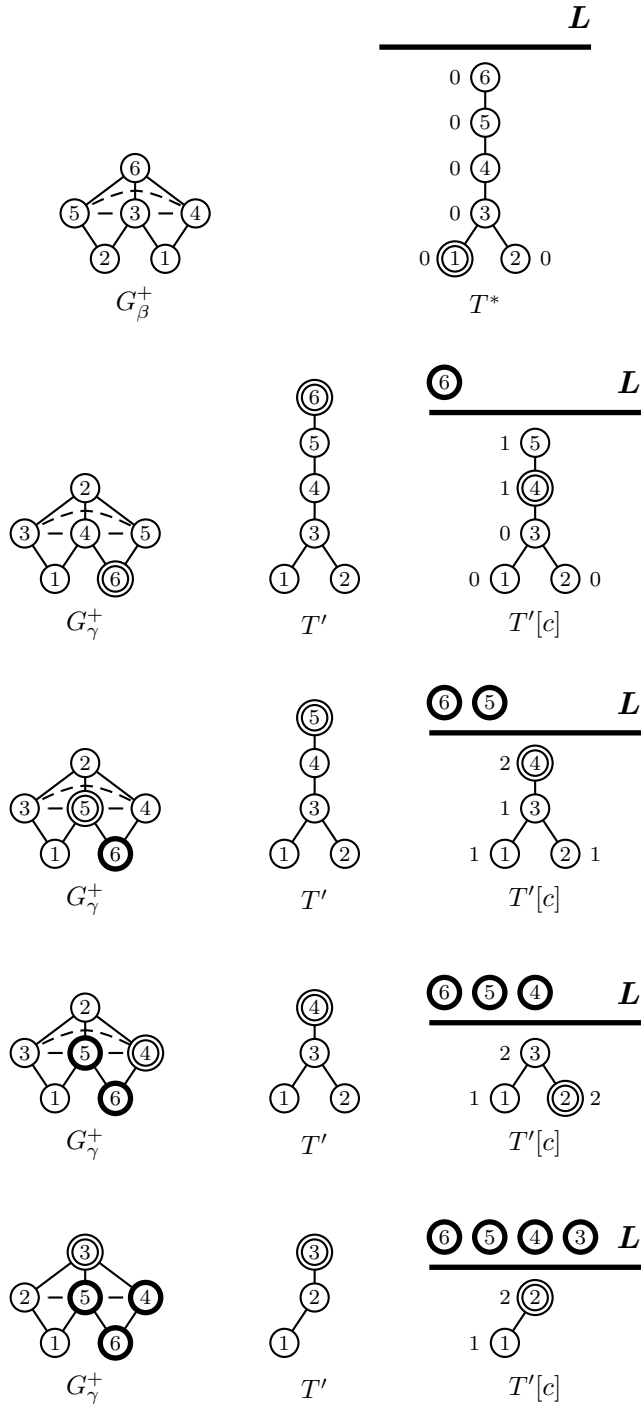

FIG. 4.2. *An execution of Algorithm MCS-ETree on the example introduced in Figure* 2.1.

We leave it for the reader to walk through the remaining steps of MCS-ETree on our example shown in Figure 4.2. Observe that in the final filled graph G^+_γ, the fill edge that once joined current vertices 2 and 4 has disappeared. In the unfilled graph, vertices 1, 5, 3, and 2 form an unchorded 4-cycle and so do vertices 6, 4, 3, and 5 (using the current γ-numbers). No single fill edge will suffice to chord both cycles, so any minimum fill set will have two fill edges—one to chord each cycle. It follows that the last filled graph pictured has minimum fill, and hence minimal fill. We leave it for the reader to verify that the final ordering α produced by the algorithm is the same as that shown in the last graph G^+_γ shown at the bottom of the figure. Hence the final ordering α is a minimal ordering.

4.2. Proving the algorithm correct. In this subsection, we will show that the algorithm is correct. The following simple loop invariant is needed to verify the integrity of the elimination subtrees.

LEMMA 4.1. *The following is a loop invariant of algorithm MCS-ETree:*

$$adj_G(V(T)) \subseteq L \text{ for each elimination subtree } T \in Trees.$$

Proof. The statement is clearly true before the first iteration of the *while* loop. Suppose that it is true at the beginning of an iteration. Then, for the elimination subtree $T = T[v]$ chosen to be processed and removed from $Trees$, we have $\mathrm{adj}_G(V(T)) \subseteq L$, where L is the set of vertices already numbered by the eventual meo α. The next step in the iteration chooses a vertex $u \in V(T)$ of maximum cardinality. As in the MCS-M ordering [2], the cardinality is determined by the number of neighbors in the filled graph that have received their number in α. Subsequently, the iteration reorders the connected component $H = G(V(T))$ so that u is numbered last. Next, the iteration computes the new elimination subtree $T' = T'[u]$ obtained when the computed reordering is applied to H. The vertex u is the root of this new elimination subtree. Then u is ordered next by MCS-ETree and added to L. From the basic properties of elimination trees [20] and the fact that the loop invariant holds at the beginning of the iteration, we have the following for each elimination subtree $T'[c]$ added to $Trees$:

$$\begin{aligned}\mathrm{adj}_G(V(T'[c])) &\subseteq \{u\} \cup \mathrm{adj}_G(V(T'[u])) \\ &= \{u\} \cup \mathrm{adj}_G(V(T')) \\ &= \{u\} \cup \mathrm{adj}_G(V(T)) \\ &\subseteq L.\end{aligned}$$

The result then follows. ∎

At the beginning or end of any iteration, a *current ordering* γ is implicitly associated with the algorithm, as follows. For each vertex $x \in L$, we let $\gamma(x) = \alpha(x)$. The vertices in $V \setminus L$ are numbered from 1 to $n - |L|$ so that each child in an elimination subtree in $Trees$ receives a smaller number than that assigned to its parent. Then, at the beginning or end of any iteration, the *current filled graph* implicitly associated with the algorithm is G^+_γ.

Lemma 4.1 says that there are no edges in G joining two vertices from different elimination subtrees in $Trees$ at any point during the algorithm. It follows that the elimination subtrees generated throughout the algorithm will maintain their integrity, with no pair of elimination subtrees merged into a single elimination subtree by a current ordering γ associated with the algorithm. In other words, every elimination tree in $Trees$ is an elimination subtree of the elimination tree with respect to γ.

The key step within each iteration of the algorithm selects the vertex to receive the highest α-number among the vertices in the elimination subtree $T = T[v]$. For any vertex $x \in V(T)$, the set of vertices in L adjacent to x in the current filled graph G_γ^+ is $\text{hadj}_{G_\gamma^+}(x) \cap L$. What MCS-ETree requires is a maximum cardinality vertex in T with no descendants that are maximum cardinality vertices. That is, choose a vertex $u \in V(T)$ for which $|\text{hadj}_{G_\gamma^+}(u) \cap L| = |\text{hadj}_{G_\gamma^+}(v)|$ and for which $|\text{hadj}_{G_\gamma^+}(w) \cap L| < |\text{hadj}_{G_\gamma^+}(u) \cap L|$ for every descendant w of u. Since $\text{hadj}_{G_\gamma^+}(x) \cap L = \text{adj}_G(V(T[x])) \cap L$ for every vertex $x \in V(T)$, the algorithm equivalently chooses a vertex $u \in V(T)$ for which $|\text{adj}_G(V(T[u])) \cap L| = |\text{adj}_G(V(T))|$ and for which $|\text{adj}_G(V(T[w])) \cap L| < |\text{adj}_G(V(T[u])) \cap L|$ for every descendant w of u. Notice that such a vertex u always exists, since $\text{adj}_G(V(T[v])) \cap L = \text{adj}_G(V(T))$, and hence v can be chosen as u if no descendant x of v satisfies $|\text{adj}_G(V(T[x])) \cap L| = |\text{adj}_G(V(T))|$. Furthermore, if every descendant x of v satisfies $|\text{adj}_G(V(T[x])) \cap L| = |\text{adj}_G(V(T))|$, then u is chosen to be a leaf of T.

A second important step within each iteration uses algorithm Change_Root to compute a new peo of the filled graph of induced subgraph $H = G(V(T))$ under a topological ordering of T. This is instrumental in causing G_α^+ to be a subgraph of G_β^+.

LEMMA 4.2. *If γ is a current ordering for the algorithm at the beginning of an iteration and γ' is a current ordering for the algorithm at the end of the same iteration, then $E(G_{\gamma'}^+) \subseteq E(G_\gamma^+)$.*

Proof. Let $\{x, y\}$ be a fill edge in $E(G_{\gamma'}^+)$ at the end of the iteration. Let L be the set of numbered vertices at the beginning of the iteration. (Vertex u is added to L at the end of the iteration.) If both x and y belong to L, then by Lemma 2.1, we have $\{x, y\} \in E(G_\gamma^+)$. If either x or y is a vertex in one of the unnumbered elimination subtrees other than $T = T[v]$, then $\{x, y\} \in E(G_\gamma^+)$ because the subtree is ordered topologically by both γ and γ'. If both x and y are vertices in $V(T)$, then $\{x, y\} \in E(G_\gamma^+)$ because $H = G(V(T))$ is renumbered by algorithm Change_Root with a peo of the filled graph $H_{\gamma_1}^+$, where γ_1 is a topological ordering of T. Finally, the only case remaining is where $x \in V(T)$ and $y \in L$. If $x \notin \text{anc}_T[u]$, then from algorithm Change_Root, we have $T'[x] = T[x]$, so by Lemma 2.1, we have $\{x, y\} \in E(G_\gamma^+)$. If $x \in \text{anc}_T[u]$, then by the choice of u in the algorithm and the simple properties of elimination trees [20],

$$\begin{aligned}
\text{adj}_{G_{\gamma'}^+}(x) \cap L &= \text{adj}_G(V(T'[x])) \cap L \\
&\subseteq \text{adj}_G(V(T')) \\
&= \text{adj}_G(V(T)) \\
&= \text{adj}_G(V(T[u])) \cap L \\
&\subseteq \text{adj}_G(V(T[x])) \cap L \\
&= \text{adj}_{G_\gamma^+}(x) \cap L.
\end{aligned}$$

This completes the proof. □

Observe that Lemma 4.2 holds for the sequence of filled graphs associated with the sequence of current orderings in Figure 4.2. Observe also that in the final filled graph in Figure 4.2, fill edge $\{4, 5\}$ is the sole chord of a 4-cycle joining vertices 3, 5, 6, and 4, and fill edge $\{2, 5\}$ is the sole chord of a 4-cycle joining vertices 1, 5, 3, and 2. In our proof of correctness, we will show that every fill edge in the final filled graph G_α^+ generated by MCS-ETree is the sole chord of a 4-cycle and then use Theorem 2.2 to argue the result.

THEOREM 4.3. *Given a graph G and an ordering β of G, algorithm MCS-ETree generates an meo α of G such that G^+_α is a subgraph of G^+_β.*

Proof. From Lemma 4.2 and the definition of current orderings γ within the algorithm, it follows that G^+_α is a subgraph of G^+_β. If there are no fill edges in G^+_α, then G is chordal and α is a peo of G. It follows that α is an meo of G, and hence we have the result in this case. Assume therefore that G^+_α has at least one fill edge. Let $\{u, w\}$ be a fill edge in G^+_α. We will find a 4-cycle in G^+_α for which $\{u, w\}$ is the only chord. The minimality of the ordering α will then follow by Theorem 2.2.

Without loss of generality, assume that $\alpha(u) < \alpha(w)$. Let $T = T[v]$ be the elimination subtree that the algorithm is processing when u is chosen by the algorithm to receive its α-number. Let γ be a current ordering for the algorithm at the beginning of this iteration. By Lemma 4.2, since $\{u, w\}$ is a fill edge in G^+_α, $\{u, w\}$ is also a fill edge in the current filled graph G^+_γ. By Lemma 2.1, there is a fill path $u - x_1 - \cdots - x_r - w$ ($r \geq 1$) in G through vertices x_i that are the descendants of u in T. Notice that u therefore cannot be a leaf of T. The vertices x_i come from one (and only one) of the subtrees rooted at a child of u in T, say, $T[c]$. Let x_t be the vertex among the x_i that is eventually numbered highest by the algorithm. Then there are fill paths (or direct edges) in G from x_t to u and from x_t to w under the final ordering α generated by the algorithm. So $\{x_t, u\}$ and $\{x_t, w\}$ are edges in the final filled graph G^+_α.

By Lemma 2.1, we know that $\text{hadj}_{G^+_\gamma}(c) \cap L \subseteq \text{hadj}_{G^+_\gamma}(u) \cap L$ for each child c of u in T. From the choice of u, we can conclude that $\text{hadj}_{G^+_\gamma}(c) \cap L \subset \text{hadj}_{G^+_\gamma}(u) \cap L$ (proper subset). Let $y \in (\text{hadj}_{G^+_\gamma}(u) \cap L) \setminus (\text{hadj}_{G^+_\gamma}(c) \cap L)$, which is not empty. By Lemma 2.1, none of the vertices x_i is adjacent to y in G^+_γ (including x_t). By Lemma 4.2, $\{x_t, y\}$ is not an edge in the final filled graph G^+_α.

Finally, the set $\text{hadj}_{G^+_\gamma}(u) \cap L = \text{hadj}_{G^+_\gamma}(v)$ is the higher adjacency set of u in the final filled graph G^+_α, since u receives its number at this step, and all vertices that are numbered higher than u in α have already received their numbers. So $\text{hadj}_{G^+_\gamma}(u) \cap L = \text{hadj}_{G^+_\alpha}(u)$, and recall that $\text{hadj}_{G^+_\alpha}(u) \cup \{u\}$ is a clique in G^+_α. Note that both y and w belong to $\text{hadj}_{G^+_\alpha}(u)$. It follows that $\{u, y\}$ and $\{w, y\}$ are both edges in G^+_α. This completes a 4-cycle $x_t - u - y - w - x_t$ in G^+_α for which $\{u, w\}$ is the only chord.

Since every fill edge is the only chord of such a 4-cycle, the final filled graph G^+_α is a minimal chordal supergraph by Theorem 2.2, and the final ordering, which is a peo of G^+_α, is an meo of G. ∎

5. Implementation details and running time analysis. We can adapt basic tools from sparse matrix computations to obtain a time bound of $O(nm\,\text{A}(m, n))$ for algorithm MCS-ETree.

THEOREM 5.1. *The running time of algorithm MCS-ETree is $O(nm\,A(m, n))$.*

Proof. Let us consider the three major tasks the algorithm must perform as it goes through a single iteration of the *while* loop. Let γ be a current ordering at the beginning of the iteration, and let $T = T[v]$ be the elimination subtree chosen to be processed.

First, the algorithm needs the values $|\text{hadj}_{G^+_\gamma}(x) \cap L| = |\text{adj}_G(V(T[x])) \cap L|$ for every vertex $x \in V(T)$. One option is to compute and work directly with the filled graph G^+_γ, but this leads to $O(nm')$ total work for this task (summed over all iterations of the *while* loop), where m' is the number of edges in the initial filled graph G^+_β. It also requires the storage of filled graphs rather than just the original graph G. We have not implemented this option. Gilbert, Ng, and Peyton [12] introduced a fast algorithm for computing the number of nonzeros in each row and each column of a sparse Cholesky factor. Hence a second, and better, option is to modify the

algorithm in [12] for column nonzero counts to compute the values $|\text{hadj}_{G_\gamma^+}(x) \cap L|$ for every vertex $x \in V(T)$. This option leads to $O(nm\ \text{A}(m,n))$ total work for this task, summed over all iterations of the *while* loop. It does not involve or require the computation of any filled graphs explicitly.

The algorithm in [12] is geared to compute $|\text{ladj}_{G_\gamma^+}(x) \cup \{x\}|$ (the "row count") and $|\text{hadj}_{G_\gamma^+}(x) \cup \{x\}|$ (the "column count") for every vertex $x \in V(G)$. In adapting for use by MCS-ETree, the computation is restricted in three different ways. First, none of the computation connected with row counts is carried out. Second, the computation can be restricted to the elimination subtree $T = T[v]$ processed by the current iteration of the algorithm rather than the entire elimination tree associated with a current ordering γ. And third, the counts must be restricted to compute $|\text{hadj}_{G_\gamma^+}(x) \cap L|$ rather than $|\text{hadj}_{G_\gamma^+}(x) \cup \{x\}|$. It is straightforward to adapt the implementation in Gilbert, Ng, and Peyton [12, page 1085] to incorporate these restrictions. Note also that a postordering of the elimination subtree T is required by our adaptation of the algorithm. This requirement is inherited from the original algorithm.

Second, MCS-ETree uses algorithm Change_Root to reorder the vertices of T so that u becomes the new root and there is no additional fill under the new current ordering. To implement Change_Root, we initially reorder the vertices of T by a postordering that numbers each vertex in $\text{anc}_T[u]$ before any of its siblings. The ordering and marking process can then be performed as the vertices are visited in this postorder. The total work spent on this task over all iterations of the outer loop is $O(nm)$.

Third, the algorithm needs to recompute the elimination subtree for the new ordering of $H = G(V(T))$. The elimination subtree can be computed with a single sweep of the full adjacency lists of the vertices of T and the required disjoint set union operations. It is trivial to adapt the standard algorithm [20] for computing the entire elimination tree to compute the elimination subtrees needed here. The total work for this task over all iterations of the outer loop is $O(nm\ \text{A}(m,n))$. This concludes the proof. □

5.1. Basic implementation. We have implemented these three steps in the most straightforward way possible, with no attempt at avoiding redundant work. The object with the first implementation was to make it as simple as possible. We have called this first implementation the *basic* implementation.

With the basic implementation established, we sought to enhance the implementation by avoiding redundant work. There is much redundant work to be avoided in all three of the major steps within each iteration. Getting rid of this redundant work does not reduce the overall provable time bound of the algorithm, but it results in a much faster implementation in practice, as the test results will show in the next section.

5.2. Enhanced implementation. Consider again the computation of the values $|\text{hadj}_{G_\gamma^+}(x) \cap L|$ for every vertex $x \in V(T[v])$. A key part of the algorithm in [12] is the recognition of and reduction to the so-called *skeleton adjacency sets* [18] associated with the current ordering. If these sets are known and stored ahead of the computation, then they can be traversed rather than using full adjacency sets. Let $z \in L$, and let $T[v]$ be the current elimination subtree. Let $T_r[z,v]$ denote the *row subtree* of z in $T[v]$. That is, $V(T_r[z,v])$ is the set of the vertices of $T[v]$ that are adjacent to z in the current filled graph G_γ^+. We say that z is in the *skeleton adjacency set* of $x \in V(T[v])$ if x is a leaf of $T_r[z,v]$. Note that our skeleton adjacency set of $x \in V(T[v])$ is limited

to vertices in L. To ultimately improve efficiency, we store the skeleton adjacency sets of all vertices $x \in V(T[v])$ as the values $|\text{hadj}_{G^+_\gamma}(x) \cap L|$ are computed. The skeleton adjacency sets come as a natural by-product of the computation.

In Figure 4.2, consider the point where the vertex of maximum cardinality is chosen from the unnumbered elimination subtree $T'[c]$, whose root has current γ-number 4. The skeleton adjacency sets of vertices 1, 2, 3, and 4 are $\{5\}$, $\{5\}$, $\emptyset$, and $\{6\}$, respectively. These skeleton adjacency sets suffice to compute the needed cardinalities.

Again, let $T = T[v]$. For each vertex $x \in \text{anc}_T[u]$, it is possible that $T'[x] \neq T[x]$ because of the reordering obtained from algorithm Change_Root (if $u \neq v$). So the vertices in the skeleton adjacency set of x cannot safely be used during the next step that processes the subtree containing x. The entire adjacency set of x must be used during the next step that processes the subtree containing x. But in the case where $x \in V(T) \setminus \text{anc}_T[u]$, we have $T'[x] = T[x]$ because of the reordering obtained from algorithm Change_Root. The descendants of x remain precisely the same, so the skeleton adjacency set of x does not change, except for the possible addition of the new root u. We take care of the update with u and process the old abbreviated skeleton adjacency set during the next step that processes the subtree containing x.

So in summary, we process abbreviated skeleton adjacency sets, many of which are in practice empty, for vertices that at the most recent relevant step were in $V(T) \setminus \text{anc}_T[u]$; we process full adjacency sets for vertices that at the most recent relevant step were in $\text{anc}_T[u]$. To store the skeleton adjacency sets requires another vector large enough to store the full adjacency structure of G. But this technique promises to improve run times appreciably.

Consider again how to implement algorithm Change_Root for computing a reordering of an elimination tree T so that $u \in V(T)$ becomes the new root and no new fill is introduced. As before, we reorder the vertices of T with a postordering for which every vertex in $\text{anc}_T[u]$ is numbered before any of its siblings. The procedure Change_Root2 in Figure 5.1 can then be used to perform the reordering. The prescribed postordering is input as γ_1, which is, of course, a topological ordering of T. Unlike our earlier implementation of algorithm Change_Root, the only adjacency sets that algorithm Change_Root2 traverses are those for vertices in $\text{anc}_T[u]$. This also promises to improve run times appreciably.

Consider the recomputation of the elimination subtree, replacing $T = T[v]$ with $T' = T'[u]$. Again, the subtrees rooted at vertices in $V(T) \setminus \text{anc}_T[u]$ remain unchanged as MCS-ETree goes forward to the next iteration. So there is no need to recompute these portions of the elimination subtree. The new subtree can be patched together with an enhanced implementation that traverses the adjacency sets of the vertices of $\text{anc}_T[u]$ only.

These enhancements do not change the time complexity of the algorithm; it remains $O(nm\,\text{A}(m,n))$. We call the improved implementation of the algorithm the *enhanced* implementation. Because the components of the work of lower time complexity have greater relative influence on performance after these enhancements are incorporated, there are other improvements implemented in marking processes and initializations. These are not described here.

5.3. Blocked implementation. Finally, there is one further enhancement of a completely different sort to incorporate into the code. For this last version, we first include all of the enhancements described thus far, then we add the following. When $T = T[v]$ is processed and vertex u is to be numbered, we can often detect other

```
procedure Change_Root2(G, T, γ1, u, γ2)
Input: A graph G, an elimination tree T of G with respect to γ1,
       a prescribed postordering γ1 of T, and a vertex u ∈ V(T).
Output: An equivalent reordering γ2 of G with respect to γ1,
        where u is numbered last.
  for i ∈ [0, 1, ..., |V(T)|]; B(i) ← ∅; end for;
  j ← 0;
  for x ∈ V(T) in the prescribed postorder γ1
    if x ∈ V(T) \ anc_T[u] then
      j ← j + 1; γ2(x) ← j;
    end if;
  end for;
  B(0) ← B(0) ∪ {u};
  for x ∈ anc_T(u)
    j ← |V(T)|;
    for y ∈ adj_G(x)
      j ← min(j, γ1(y));
    end for;
    B(j) ← B(j) ∪ {x};
  end for;
  j ← |V(T)|;
  for i ∈ [0, 1, ..., |V(T)|] in order
    for x ∈ B(i)
      γ2(x) ← j;
      j ← j − 1;
    end for;
  end for;
end Change_Root2;
```

FIG. 5.1. *An enhanced variant of algorithm Change_Root for the second step in the main loop of MCS-ETree.*

vertices among the vertices of $\mathrm{anc}_T(u)$ that can be numbered in a block along with u and removed with no further processing. There are two cases to consider. First, consider the case where u has descendants in T. Let $c_1, \ldots, c_r$ be the children of u in T. If a vertex $x \in \mathrm{anc}_T(u)$ is adjacent to each subtree $T[c_1], \ldots, T[c_r]$ and the adjacency set of x contains every vertex that is in the skeleton adjacency set of u (again, limited to skeleton neighbors in L), then x can be ordered in a block along with u (see Lemma 5.2). Having possession of the skeleton adjacency sets is crucial here for implementing detection of this condition. These are available only after our enhancement for the computation of cardinalities.

In Figure 4.2, consider the unnumbered elimination subtree $T'[c]$, whose root has γ-number 5. There, the maximum cardinality vertex chosen is vertex 4. The sole member of the skeleton adjacency set of vertex 4 is vertex 6. Since vertex 5 is adjacent in G to vertex 6 and also adjacent in G to the subtree rooted at vertex 3, it follows that vertex 5 can be ordered in a block along with vertex 4.

Second, consider the case where u has no descendants in T. If a vertex $x \in \mathrm{anc}_T(u)$ is adjacent to u and every vertex in $\mathrm{adj}_G(u)$ (except x, of course), then x can be ordered in a block along with u (see Lemma 5.3).

LEMMA 5.2. *Let u be a vertex of maximum cardinality chosen at some iteration of algorithm MCS-ETree such that u has descendants in $T = T[v]$. Let X be the set*

comprised of u and any vertex $x \in anc_T(u)$ adjacent to all of the subtrees rooted at children of u and adjacent to all of the members of u's skeleton adjacency set. Our algorithm can be modified so that it numbers next as a block the vertices in X in the current iteration.

Proof. Let the algorithm be modified so that it numbers the vertices of X next as a block in the current iteration. Let L be the set of numbered vertices before the vertices of X are numbered. Note first that by the choice of u, the definition of X, and Lemma 2.1, every vertex of X will be adjacent to every vertex of $\mathrm{adj}_G(V(T))$ in the final filled graph. Choose $x \in X$, and let $\{x, w\}$ be a fill edge, where w is numbered higher than x by the ordering. (Note that x may be u.) For our first case, suppose that $w \in L$. Note that w is not in u's skeleton adjacency set, otherwise w would be in x's adjacency set, and hence we would not have a fill edge. This means that w is adjacent to one of the subtrees rooted at a child c of u. Since x is adjacent to every vertex of $\mathrm{adj}_G(V(T))$ in the final fill graph and x is also adjacent to $T[c]$, this means that we can argue, just as in the proof of correctness, the existence of a 4-cycle that has the fill edge $\{x, w\}$ as its sole chord.

For our second case, suppose that $w \in X$. Since both x and w are adjacent to all subtrees rooted at children of u, we can again argue, as above and in the proof of correctness, the existence of a 4-cycle that has the fill edge $\{x, w\}$ as its sole chord. □

LEMMA 5.3. *Let u be a vertex of maximum cardinality chosen at some iteration of MCS-ETree such that u has no descendants in $T = T[v]$. Any vertex $x \in anc_T(u)$ that is adjacent to u and every vertex in $adj_G(u)$ (except x) can be ordered in a block along with u.*

Proof. In this case, there is no fill edge incident to x and a higher-numbered vertex, so the result follows. □

Based on Lemma 5.2, we modified MCS-ETree to number all vertices of any block X described by the lemma at the end of the current iteration. Based on Lemma 5.3, we also modified MCS-ETree to number all vertices of any block described by the lemma at the end of the current iteration. We call our implementation that includes all of the previous enhancements and this capability to number blocks of vertices the *blocked* implementation. The detection of the blocks is implemented by additional code within the Change_Root2 procedure that does not require any further traversal of adjacency sets. The vertices of a block are placed in the set $B(0)$, where they are labeled last by ordering γ_2 among the vertices of the current elimination subtree.

6. Test results. We have coded the *basic*, *enhanced*, and *blocked* implementations discussed in section 5. For test results in an earlier technical report [15], we ran these implementations on a set of test problems taken from the Harwell–Boeing collection of sparse matrices. The initial orderings used in [15] were approximate minimum degree (AMD) [1] orderings and random orderings. As reported in earlier work [5, 24], minimum degree orderings are so close to minimal in practice that there is very little extraneous fill to remove. Consequently, the practical impact of MCS-ETree is extremely limited when AMD initial orderings are used. But our timing results in [15] indicate that the best implementation of MCS-ETree is very efficient on AMD initial orderings. A full set of tables and a discussion of results on AMD and random initial orderings can be found in our technical report [15].

In this paper, we run our three implementations of MCS-ETree on a set of test problems taken from the sparse matrix collection of Tim Davis. A greater variety of stuctural analysis problems are included, along with a number of problems from optimization and other application areas. The structural analysis problems include

TABLE 6.1
The number of vertices in each graph, the number of edges in each filled graph, and the number of factorization operations when the initial ordering is ND.

BCSSTK17, BCSSTK25, SRBEDDY, CRYSTK02, CRYSTK03, nasasrb, pkustk01, pwt, shuttle_eddy, skirt, tandem_dual, and pli. The optimization problems include ex3sta1, fxm4_6, gupta1, minsurfo, and pfinan512. Also included are Helmholtz equations on a unit cube (helm3d01), a CFD problem (Pres_Poisson), a quantum chemistry problem (nemeth02), a thermoelasticity problem (ted_B), and an acoustics problem (vibrobox).

Also, we look at nested dissection (ND) initial orderings only. For ND initial orderings, there is sometimes a significant amount of extraneous fill to remove; hence MCS-ETree is tested in a more demanding setting and gives results of more practical consequence. We also run a code that implements the algorithm from Peyton [24] for solving the same problem and compare our algorithm with this algorithm, since it has the fastest documented practical running time. We remind the reader that the theoretical running time bound of the algorithm of [24] is not known.

Table 6.1 reports the number of vertices in each graph and the number of edges in the filled graphs for the ND orderings and the minimal orderings obtained from the *blocked* implementation of MCS-ETree. Also shown are the number of factorization operations that result from the ND orderings and the minimal orderings. The percent decrease in edges is less than 2% for 12 of the 22 problems. It is greater than 5% for 6 of the 22 problems. For matrix ted_B, which comes from coupled linear thermoelasticity equations, the decrease is 17%. For nemeth02, which comes from a Newton–Schultz iteration for a chemistry problem, the decrease is 52%. The latter is a long "path-like" problem for which nested dissection is inappropriate unless one seeks to exploit parallelism during the factorization.

Looking at the reductions in factorization operations gives us more matrices where MCS-ETree has some practical impact. Nonetheless, the reduction is less than 5%

TABLE 6.2

CPU seconds to compute the ND initial orderings and the minimal orderings using the algorithm of [24] *and the three implementations of MCS-ETree.*

for 12 of the 22 problems. For three of the structural analysis matrices used also in our technical report [15], namely, BCSSTK17, BCSSTK25, and SRBEDDY, the decreases are roughly 15%, 18%, and 19.5%, respectively. Two structural analysis matrices added to our problem set for this paper, namely, nasasrb and shuttle_eddy, have decreases of roughly 14% and 19%, respectively. The two matrices with the largest fill reductions, namely, ted_B and nemeth02, have decreases of roughly 29% and 76%, respectively.

Table 6.2 reports the CPU time in seconds for the ND orderings, for each of the three implementations of algorithm MCS-ETree, and for the algorithm of [24]. The tests were run on a PC with a Pentium 4 processor running at 2.66 GHz with 0.99 GB RAM available. The code was written in Fortran and executed under the Linux operating system. We used the Metis software package available from the University of Minnesota to compute nested dissection orderings.

The basic implementation of MCS-ETree has much larger run times than the ND code and is clearly too inefficient for practical sparse matrix computations. The enhanced implementation of MCS-ETree is much faster than the basic implementation in every case. Often it is ten times faster, or close to ten times faster, than the basic implementation. But comparing run times for the enhanced implementation with the ND ordering times, it is obvious that the enhanced implementation is also too inefficient for practical sparse matrix computations, despite its improvements.

Our timings, however, improve dramatically for most problems as we move to the blocked implementation, which includes the blocking technique along with all of the enhancements employed by the enhanced implementation. For 17 of the 22 problems, the blocked implementation runs more than ten times faster than the enhanced im-

plementation. For 13 of the 22 problems, the blocked implementation runs more than 100 times faster than the basic implemenation.

The three problems for which the reduction in time from the basic implementation to the blocked implementation is smallest are gupta1, nemeth02, and ted_B. For each of these problems, the number of blocks detected by the blocked implementation is unusually large relative to the number of vertices in the graph. For gupta1, there are 31,198 blocks and 31,802 vertices; for nemeth02, there are 7,619 blocks and 9506 vertices; for ted_B, there are 8,750 blocks and 10,605 vertices. For nemeth02, the reduction from the enhanced implementation to the blocked implementation is very small—from 2.082 seconds to 1.859 seconds. The matrix gupta1, which arises in a linear programming problem, presents the greatest difficulties to all of the algorithms we have looked at. For gupta1, the reduction from the basic implementation to the blocked implementation is from 38.178 seconds to 6.876 seconds—a reduction of only 82%. The time for the ND ordering of gupta1 is also greater than the ND ordering time for any other matrix. The matrices nemeth02 and ted_B have, by far, the greatest percent reduction in edges, and it may be natural to pay more in time to remove a greater percentage of edges.

The algorithm of Peyton [24] runs reasonably fast for ND initial orderings (except on the matrix gupta1). It is not as fast as the blocked implementation of MCS-ETree for any test matrix when ND initial orderings are used; however, there are a few instances where it is faster when AMD initial orderings are used [15]. In fairness, the implementation of the algorithm of [24] has not been improved to the extent that the blocked implementation of MCS-ETree has been improved. It would be interesting to see if the implementation of the algorithm of [24] could be improved to the extent that it would prove more competitive than the blocked implementation of MCS-ETree for ND initial orderings.

The algorithm of [24] takes an exhorbitant amount of time (4.76 hours) to compute the minimal ordering for the matrix gupta1. It became clear to us what was going on when we saw that the AMD ordering time for gupta1 is 52.2 seconds, which is extremely large. It was shown in Heggernes et al. [14] that AMD is an $O(nm)$ algorithm and that there exist examples to which this worst-case time complexity applies. The algorithm of [24] relies on the iteration of a restricted version of the minimum degree algorithm with exact degrees. The time complexity of minimum degree with exact degrees is $O(n^2m)$ [14]. This interesting test matrix fully reveals the vulnerability of the algorithm of [24].

Finally, run times for the blocked implementation are reduced to the point that MCS-ETree is fast enough to be considered for sparse matrix computations. For 16 of 22 problems, the time required by the blocked implementation of MCS-ETree is less than that required by the ND algorithm. For only two of the 22 problems, the ratio of the time for the blocked implementation to the time for the ND ordering is greater than three; for gupta1 the ratio is 4.09, and for nemeth02, the ratio is 8.50.

7. Concluding remarks. We have introduced a new algorithm MCS-ETree for computing a minimal ordering whose minimal fill lies inside the fill of any given initial ordering. The $O(nm\,\mathrm{A}(m,n))$ running time complexity is virtually as good as the best known time complexity of $O(nm)$. In practical tests, our algorithm performs better than the previous fastest algorithm of [24] and has the advantage of having a provably good theoretical running time as well. Algorithm MCS-ETree explicitly deals with a current ordering and the structure associated with that ordering, at the cost of disjoint set union operations that lead to the extremely slowly growing $\mathrm{A}(m,n)$ term

in its running time complexity. By explicitly computing and exploiting elimination subtrees and partial Cholesky column nonzero counts, one obtains a relatively simple algorithm whose proof of correctness is also relatively simple. The new algorithm is based on selecting a special vertex of maximum cardinality at each step and resembles, in this regard, the algorithm MCS-M introduced in [2].

The algorithm can be implemented in $O(nm\ \mathrm{A}(m,n))$ time by adapting three commonly used sparse matrix algorithms that date from the mid-1980's to the mid-1990's:

1. An $O(m\ \mathrm{A}(m,n))$ algorithm for computing the number of nonzeros in each column of a Cholesky factor [12];
2. An $O(m)$ algorithm for computing equivalent reorderings [19]; and
3. An $O(m\ \mathrm{A}(m,n))$ algorithm for computing an elimination tree [20].

We were able to improve the *basic* implementation to obtain much faster implementations. The first set of enhancements are straightforward programming-level improvements that greatly limit the number of times adjacency lists are traversed or shorten those lists to abbreviated skeleton adjacency lists. The other improvement allows blocks of vertices to be numbered by a single iteration of the algorithm, and this is based closely on the idea of indistinguishable vertex sets in elimination graphs exploited so successfully by the implementations of the minimum degree algorithm [17].

We coded in Fortran the *basic*, *enhanced*, and *blocked* implementations, and our timing results show that the blocked implementation is fast enough to be considered for use in sparse matrix computations. The best implementation of the algorithm could prove useful when the initial orderings are nested dissection orderings, because sometimes the fill and factorization operations can be significantly reduced by removing extraneous fill.

Acknowledgments. The authors thank the referees for their many helpful suggestions. We also thank Vince Postell for his help in gaining access to Linux and PSTricks.

A FAMILY OF RATIONAL ITERATIONS AND ITS APPLICATION TO THE COMPUTATION OF THE MATRIX pTH ROOT*

BRUNO IANNAZZO†

Abstract. Matrix fixed-point iterations $z_{n+1} = \psi(z_n)$ defined by a rational function ψ are considered. For these iterations a new proof is given that matrix convergence is essentially reduced to scalar convergence. It is shown that the principal Padé family of iterations for the matrix sign function and the matrix square root is a special case of a family of rational iterations due to Ernst Schröder. This characterization provides a family of iterations for the matrix pth root which preserve the structure of a group of automorphisms associated with a bilinear or a sesquilinear form. The first iteration in that family is the Halley method for which a convergence result is proved. Finally, new algorithms for the matrix pth root based on the Newton and Halley iterations are designed using the idea of the Schur–Newton method of Guo and Higham.

Key words. Halley's method, matrix iteration, matrix root, matrix function, Newton's method, rational iterations, structure-preserving

1. Introduction.

The study of rational iterations, which have the form $x_{k+1} = \varphi(x_k)$, where $\varphi(z)$ is a rational function, is a topic of great interest in computation, particularly for the design and analysis of root-finding algorithms. The local convergence at a fixed point z_*, such that $z_* = \varphi(z_*)$, is related to the properties of the derivatives of φ at z_*. A study of the global convergence is very difficult: the sets of initial values for which the sequence generated by a rational iteration converges to a fixed point are bounded by the so-called Julia sets which in most cases are fractals [1].

The generalization to the matrix case appears in the study of matrix equations and in the computation of matrix functions [9]. It raises problems somehow new: it is not straightforward how to define a rational matrix iteration; there can be infinite fixed points, the lack of commutativity in finite arithmetic can have effects on the convergence, and so on.

In this paper we provide a general convergence result for rational matrix iterations, and then we prove some properties of specific classes of rational iterations.

General results concern the case where the iterates are rational functions of a matrix A, say, $s_k(A)$. We prove that the uniform convergence of $s_k(z)$ on a compact neighborhood of the spectrum of A implies the matrix convergence. Then we show that if the iteration is of the type $x_{k+1} = \varphi(x_k)$, where φ is a rational function, then the pointwise convergence of $s_k(\lambda)$ to attractive fixed points for each eigenvalue λ of A implies the uniform convergence on a compact neighborhood of the spectrum of A and thus the matrix convergence. This extends in part a result of Higham [9, Thm. 4.15].

Concerning specific classes, we first consider the principal Padé family introduced in [17] and discussed in [8, 10, 11, 4]. We prove that the family can be obtained by the König root-finding method applied to the polynomial x^2-1, which goes back to a work of Schröder in 1870 [20]. Second, using the characterization given above, we extend to the König family for the polynomial x^p-1 a result of Higham et al. [10] concerning the property of a part of the principal Padé family of preserving the structure of group of automorphisms associated with a bilinear or a sesquilinear form. Third, we show that the Halley method, which belongs to the König family, for the computation of the principal pth root of a matrix preserves the structure described above, and we prove a result on the convergence of that method. Finally, we show that the idea of the Schur–Newton method proposed by Guo and Higham in [6] for the inverse Newton iteration for the computation of the principal pth root of a matrix can be applied to the direct Newton iteration and to the Halley method, providing new algorithms with good numerical properties.

We recall that the principal pth root of a matrix A having no nonpositive real eigenvalues is the unique solution X of the matrix equation $X^p - A = 0$, such that the eigenvalues of X have argument less in modulus than π/p.

The paper is organized as follows: in section 2 we define the class of pure rational matrix iterations and we discuss their convergence; in section 3 we show the equivalence between the principal Padé iterations and the König iterations for x^2-1; in section 4 we generate a König family of matrix iterations preserving the structure of a group of automorphisms; in sections 5 and 6 we prove convergence results for the Newton and Halley method, and we extend the idea of the Schur–Newton method of Guo and Higham to them.

2. Pure rational matrix iterations. Given a rational function φ, the iteration

$$\begin{cases} z_0 \in \mathbb{C}, \\ z_{k+1} = \varphi(z_k), \quad k = 0, 1, 2, \dots, \end{cases} \tag{2.1}$$

is called a rational iteration. The function φ can have poles, so that the sequence is not necessarily well defined for each z_0. We use the notation $\varphi^{\circ k}$ to denote the kth iterate of the function φ, i.e., $\varphi^{\circ 1} = \varphi$ and $\varphi^{\circ k+1} = \varphi \circ \varphi^{\circ k}$. A fixed point z_* of (2.1) is such that $\varphi(z_*) = z_*$ and is said to be *attractive* if $|\varphi'(z_*)| < 1$. For an attractive fixed point z_*, the *basin of attraction* is the set $\mathcal{B} = \{z_0 \in \mathbb{C} : z_k \to z_*\}$; the *immediate basin* is the connected component of $\mathcal{B}$ which contains z_*.

We state a useful lemma on the basin of attraction which is a special case of Theorem 6.3.1 of [1].

LEMMA 2.1. *Let z_* be an attractive fixed point of iteration* (2.1). *The sequence $\varphi^{\circ k}(z)$ converges locally uniformly to z_* for each z_0 belonging to the basin of z_*. In other words, z_0 has a neighborhood in which $\varphi^{\circ k}$ converges uniformly to z_*.*

Proof. Since $|\varphi'(z_*)| < 1$, there exists a closed disk D centered at z_* and such that $|\varphi(z) - z_*| \leqslant M|z - z_*|$ for a positive constant $M < 1$ and for each $z \in D$, and thus $\varphi^{\circ k}$ converges uniformly on the compact sets of D.

Let z_0 belong to the basin of attraction of z_*. There exists m such that $\varphi^{\circ m}(z_0)$ belongs to the interior of D. Since $\varphi^{\circ m}$ is continuous, there exists a compact neighborhood K of z_0 such that $\varphi^{\circ m}(z)$ is a compact set fully contained in the interior of D, and thus $\varphi^{\circ k}(z)$ converges uniformly to z_* for each $z \in K$. ∎

In the matrix case, a formula like (2.1) would give an iteration of the form

$$\begin{cases} Z_0 \in \mathbb{C}^{n\times n}, \\ Z_{k+1} = \varphi(Z_k), \quad k = 0, 1, 2, \dots, \end{cases} \tag{2.2}$$

where $\varphi(z)$ is a rational function and $\varphi(Z)$, where Z is a square matrix, is defined by substituting Z for z and replacing scalar numbers by multiples of the identity and arithmetic operations by matrix operations. That procedure leads to the usual definition of function of a matrix [12, 5, 9]. We call an iteration defined by a function, as in (2.2), a *pure rational matrix iteration*.

The class of pure rational matrix iterations is not suitable to approximate generic matrix functions, since, as we will explain in Remark 2.5, there hold strong conditions on the limits of such sequences.

A larger class of iterations than the pure rational matrix iterations can be studied with similar techniques. An iteration in this larger class can be written in the form

$$\left\{ \begin{array}{l} Z_0 = p(A), \\ Z_{k+1} = \psi(Z_k, A), \quad k = 0, 1, 2, \ldots, \end{array} \right. \tag{2.3}$$

where A is a square matrix, $\psi = \psi(t, z)$ is a two-variable rational function, and p is a polynomial. In that case, for each A, the sequence Z_k defines the same sequence of rational functions $s_k(z)$ such that $s_k(A) = \psi(s_{k-1}(A), A) = Z_k$ and $s_0(A) = p(A)$. That class contains the pure rational matrix iterations as a special case if p is the identity function and the formula for ψ does not contain A.

Consider an iteration of the class (2.3) described above. Let Z_k be the kth iterate, so that $Z_k = s_k(A)$, with $s_k(z)$ being a rational function. Using the Jordan canonical form of A, say, $M^{-1}AM = J_1 \oplus \cdots \oplus J_r$, one has $M^{-1}Z_kM = s_k(J_1) \oplus \cdots \oplus s_k(J_r)$ for each k. Therefore, by means of similarity M, the iteration can be uncoupled into r iterations involving only functions of the Jordan blocks. The study of the convergence is thus restricted to the case in which A is a Jordan block of arbitrary size for the eigenvalue λ, which will be denoted by J.

Moreover, in view of the formula for a function of a Jordan block [5, Thm. 11.1.1],

$$f(J) = \begin{bmatrix} f(\lambda) & f'(\lambda) & \ldots & \frac{f^{(k-1)}(\lambda)}{(k-1)!} \\ & f(\lambda) & \ddots & \vdots \\ & & \ddots & f'(\lambda) \\ \bigcirc & & & f(\lambda) \end{bmatrix}, \tag{2.4}$$

each of the iterates is upper triangular.

A question arises naturally: if the sequence $s_k(\lambda)$, with $s_0(\lambda) = p(\lambda)$, converges for each eigenvalue of A, what can be said about the convergence of $s_k(A)$? The following easy example shows that, in general, scalar convergence does not imply matrix convergence.

Example 2.2. Consider the rational iteration $z_{k+1} = \varphi(z_k)$, where $\varphi(z) = z^2$. The sequence $\varphi^{\circ k}(1)$ converges to 1, but it fails to converge uniformly on any neighborhood of the point 1. Consider the matrix iteration $Z_{k+1} = Z_k^2$ and the starting point $Z_0 = \left[\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right]$; the iterates are $Z_k = \left[\begin{smallmatrix} 1 & 2^k \\ 0 & 1 \end{smallmatrix}\right]$, and the sequence fails to converge. For this iteration and Z_0 being a Jordan block of size n for the eigenvalue 1, there is matrix convergence only for $n = 1$, that is, in the scalar case.

A sufficient condition for the convergence of the matrix sequence, given the scalar convergence, is stated in Lemma 2.3, in which the notation $\|f(z)\|_K = \sup_{x \in K} |f(x)|$ is used for a function f defined on a compact set K. This approach generalizes a proof of matrix convergence in [15]. A different approach for the matrix convergence has been used in [17] and generalized in [9, Thm. 4.15], where it is proved that the matrix

convergence follows from the scalar convergence of the eigenvalues to attracting fixed points.

LEMMA 2.3. *If $s_k(z)$ is a sequence of rational functions that converges uniformly in a compact neighborhood K of λ to the function $f(z)$, then $s_k(J)$ converges to $f(J)$, where J is a Jordan block of arbitrary size n relative to the eigenvalue λ. Moreover, there exists a function $c = c(n)$, independent of k, such that*

$$\|s_k(J) - f(J)\|_\infty \leqslant c\|s_k(z) - f(z)\|_K. \tag{2.5}$$

Proof. The function f is holomorphic on K since it is the uniform limit on a compact set of holomorphic functions.

From formula (2.4), the matrix sequence converges if the sequence $s_k(z)$ and its derivatives up to the order $n-1$ converge. Consider a small circle γ of radius R, centered at λ and fully contained in K. Using the Cauchy formula, for $p = 0, 1, \ldots, n-1$, it holds that

$$\left|\frac{s_k^{(p)}(\lambda)}{p!} - \frac{f^{(p)}(\lambda)}{p!}\right| = \left|\frac{1}{2\pi i}\oint_\gamma \frac{s_k(z) - f(z)}{(z-\lambda)^{p+1}}dz\right| \leqslant \frac{1}{R^p}\|s_k(z) - f(z)\|_K.$$

The previous relation provides the convergence of the sequence $s_k(J)$ to $f(J)$, since the latter term tends to zero as k tends to ∞ by the uniform convergence assumption. It also provides the proof of (2.5), since from formula (2.4) it follows that

$$\|s_k(J) - f(J)\|_\infty = \sum_{p=0}^{n-1}\left|\frac{s_k^{(p)}(\lambda)}{p!} - \frac{f^{(p)}(\lambda)}{p!}\right| \leqslant \|s_k(z) - f(z)\|_K \sum_{p=0}^{n-1}\frac{1}{R^p}. \tag{2.6}$$ ∎

In summary, if the sequence $s_k(z)$ converges uniformly on a compact neighborhood of the spectrum of A, then the sequence $s_k(A)$ converges, and formula (2.6) can be used to provide an upper bound for the convergence of the matrix sequence. If the scalar convergence is not uniform, then the matrix iteration may fail to converge, as Example 2.2 shows.

We have turned the problem from matrix convergence to uniform scalar convergence on a compact neighborhood of the spectrum. This does not seem at first sight an advantage, but its benefit is clear in the case of pure rational iterations; in fact, Lemma 2.1 shows that if the sequence $s_k(\lambda)$ converges, for each eigenvalue λ of A, to an attractive fixed point λ_*, then the sequence $s_k(z)$ converges uniformly to λ_* on a neighborhood of λ. We have the following result.

THEOREM 2.4. *Let $Z_{k+1} = \varphi(Z_k)$ be a pure rational matrix iteration. If for each eigenvalue λ of Z_0 the scalar sequence $z_{k+1} = \varphi(z_k)$, $z_0 = \lambda$, converges to an attractive fixed point λ_*, then there exists a locally constant function $f(z)$ such that for each initial value Z in a neighborhood of Z_0 the matrix iteration converges to $f(Z)$. Moreover, $f(Z)$ is diagonalizable.*

Proof. Lemma 2.1 guarantees that the scalar iteration converges uniformly in a compact neighborhood K of spectrum of Z_0 to a locally constant function $f(z)$. Lemma 2.3 provides the matrix convergence for the Jordan blocks relative to eigenvalues belonging to the interior of K. Since the eigenvalues of a matrix are continuous functions of the entries, there exists a neighborhood V of Z_0 in the space of square matrices such that for each matrix Z of V, the eigenvalues of Z belong to the interior of K, so the matrix iteration converges to $f(Z)$.

The diagonalizability follows from the fact that f is locally constant and thus its derivatives are 0: By formula (2.4), $f(J)$ is a diagonal matrix for each Jordan block J. ∎

Remark 2.5. Theorem 2.4 states that the limit of a pure rational matrix iteration is a (scalar) locally constant function of the initial value, and it is diagonalizable provided that the convergence of the scalar sequence on the eigenvalues of Z_0 is to attractive fixed points (a scalar locally constant function need not be locally constant if applied to matrices; consider, for instance, the matrix sign function). A consequence is that only (scalar) locally constant functions can be the limit of a pure rational matrix iteration, which explains why in the literature the sole matrix functions computed using pure rational matrix iterations are the matrix sign function and the matrix sector function, which are (scalar) locally constant.

On the other hand, Theorem 2.4 shows that a function which is not (scalar) locally constant cannot be the limit of a pure rational matrix iteration; thus there is no hope to find, for instance, a pure rational matrix iteration converging to the matrix pth root, logarithm or exponential.

We note that Theorem 2.4 implies that a matrix function defined as the limit of a pure rational iteration is diagonalizable, which in particular gives another proof of the diagonalizability of the matrix sign function.

Remark 2.6. A convergence result for iterations of the type (2.3) is given by Higham [9, Thm. 4.15], generalizing a result for the matrix sign function in [17, Lem. 5.1]. His result guarantees matrix convergence if the scalar eigenvalue sequences converge to attractive fixed points. When [9, Thm. 4.15] is specialized to the case of pure rational matrix iterations, it gives a result similar to, but weaker than, Theorem 2.4. Theorem 2.4, together with Lemma 2.3, has the advantage of specifying the limit to which the matrix sequence converges as a matrix function, provides a bound for the matrix convergence, and can be further extended to the case $|\varphi'(\lambda^*)| = 1$ using, for instance, the Leau–Fatou theorem [1].

3. Equivalence between the König family and the principal Padé iterations family. In the paper [17] Kenney and Laub derive a family of rational iterations for the computation of the matrix sign function. The derivation is based on the theory of Padé approximations and exploits the relation

$$\operatorname{sign}(z) = \frac{z}{\sqrt{z^2}} = \frac{z}{\sqrt{1-(1-z^2)}} = \frac{z}{\sqrt{1-\xi}},$$

where $\xi = 1 - x^2$. They consider the approximants of the function

$$h(\xi) = (1-\xi)^{-1/2},$$

which are well known.

Given $p_{mn}(\xi)/q_{mn}(\xi)$, the (m,n) Padé approximant to h, the recurrence

$$x_{k+1} = f_{mn}(x_k) = x_k \frac{p_{mn}(1-x_k^2)}{q_{mn}(1-x_k^2)},$$

defines a family of iterations for the matrix sign function.

The iterations with $m = n-1$ and $m = n$ are globally convergent and have been called *principal Padé iterations* [9]. For these values of m and n one can define

$$g_r(x) = f_{mn}(x) \text{ for } r = m+n+1, \tag{3.1}$$

for which we have the following result [17].

THEOREM 3.1. *For the function* (3.1) *it holds that*

1. *for each nonimaginary* x_0*, the iteration* $x_{k+1} = g_r(x_k)$ *is convergent to* $\operatorname{sign}(x_0)$*, with order of convergence* r*; and*
2. $g_r(x) = \frac{(1+x)^r-(1-x)^r}{(1+x)^r+(1-x)^r}$.

Higham [9] noticed that these families were essentially derived by Howland [14]; though for even r the iteration functions of Howland are the reciprocal of those of Kenney and Laub.

In fact, the family of principal Padé iterations is a particular case of iterations going back to Schröder in his monumental paper of 1870 [20] (an English translation is available in [21]). This family was studied by Householder [13] and many other authors, who called it the König family [3] or the basic family [16].

The König method of order σ, applied to the function f, is defined by the formula [3]

$$K_{f,\sigma}(z) = z + (\sigma-1)\frac{(1/f(z))^{(\sigma-2)}}{(1/f(z))^{(\sigma-1)}}, \tag{3.2}$$

where $(1/f)^{(k)}$ is the kth derivative of $1/f$. It can be proved that the method converges to simple roots of f with order at least σ. For $\sigma = 2$ the König method is the Newton method, while for $\sigma = 3$ it is the so-called Halley method.

If f is a polynomial, then $K_{f,\sigma}$ is a rational function. Let us define $K_{p,\sigma}$ as the König family applied to the polynomial $f = x^p - 1$.

THEOREM 3.2. *For the König rational functions relative to the polynomial* x^2-1 *it holds that* $K_{2,r}(x) = \frac{(x+1)^r+(x-1)^r}{(x+1)^r-(x-1)^r}$. *Thus,* $K_{2,r}$ *coincides with* g_r *of* (3.1) *for odd* r *and with the reciprocal of* g_r *for even* r.

Proof. From

$$\frac{d^n}{dx^n}\left(\frac{1}{x^2-1}\right) = \frac{1}{2}\frac{d^n}{dx^n}\left(\frac{1}{x-1}-\frac{1}{x+1}\right)$$
$$= \frac{(-1)^n n!}{2}\left(\frac{1}{(x-1)^{n+1}}-\frac{1}{(x+1)^{n+1}}\right) = \frac{(-1)^n n!}{2}\left(\frac{(x+1)^{n+1}-(x-1)^{n+1}}{(x^2-1)^{n+1}}\right),$$

it follows that

$$K_{2,r}(x) = x - (x^2-1)\frac{(x+1)^{r-1}-(x-1)^{r-1}}{(x+1)^r-(x-1)^r} = \frac{(x+1)^r+(x-1)^r}{(x+1)^r-(x-1)^r}. \qquad \square$$

4. Structure-preserving algorithms in the König family. It has been proved in [11, Thm. 3.13] that an iteration of the form

$$z\frac{q(z)}{\operatorname{rev} q(z)}, \tag{4.1}$$

where $\operatorname{rev} q(z) = z^d q(1/z)$ for a real polynomial $q(z)$ of degree d, preserves the structure of group of automorphisms associated with

- a bilinear form on $\mathbb{R}^n$ or $\mathbb{C}^n$ and
- a sesquilinear form on $\mathbb{C}^n$.

To ease the notation we call *structure-preserving* an iteration with the form (4.1), recalling that the rational functions preserving bilinear or sesquilinear forms (fully characterized in [11, Thm. 3.13]) are more general.

The principal Padé iterations and, in view of Theorem 3.2, the $K_{2,\sigma}$ iterations for odd σ are iterations for the matrix sign function which are structure-preserving [11]; this is a case of a more general theorem.

THEOREM 4.1. *If $n \equiv 3 \pmod p$, then the function $K_{p,n}$, namely, the König method for the polynomial $x^p - 1$, has the form*

$$z\frac{q(z^p)}{\operatorname{rev} q(z^p)}, \tag{4.2}$$

where q is a real polynomial, and so in particular it is structure-preserving.

Proof. The proof is obtained by deriving a formula for the derivatives of $1/(x^p-1)$ and, from it, an explicit elementary formula for the König function from which we deduce the theorem. Let $p \geqslant 3$; the case $p = 2$ follows easily from Theorem 3.2.

Let $\omega = \cos(2\pi/p) + \mathbf{i}\sin(2\pi/p)$ and $\varphi(x) = (x^p-1)/(x-1) = \sum_{k=0}^{p-1} x^k$. Observe that $\varphi(\omega^k) = 0$ for $k \not\equiv 0 \pmod p$.

It holds that

$$\frac{1}{x^p-1} = \frac{1}{p}\sum_{k=0}^{p-1}\frac{\omega^k}{x-\omega^k};$$

in fact,

$$\begin{aligned}\sum_{k=0}^{p-1}\frac{\omega^k}{x-\omega^k} &= \frac{1}{x^p-1}\sum_{k=0}^{p-1}\frac{1}{\bar\omega^k}\frac{x^p-1}{x-\omega^k} = \frac{1}{x^p-1}\sum_{k=0}^{p-1}\frac{(\bar\omega^k x)^p-1}{\bar\omega^k x-1}\\ &= \frac{1}{x^p-1}\sum_{k=0}^{p-1}\varphi(\bar\omega^k x) = \frac{1}{x^p-1}\sum_{k=0}^{p-1}\sum_{r=0}^{p-1}(\bar\omega^k x)^r = \frac{1}{x^p-1}\sum_{r=0}^{p-1}x^r\sum_{k=0}^{p-1}\bar\omega^{kr} = \frac{p}{x^p-1}.\end{aligned}$$

Now,

$$\begin{aligned}\frac{d^n}{dx^n}\left(\frac{1}{x^p-1}\right) &= \frac{1}{p}\sum_{k=0}^{p-1}\frac{d^n}{dx^n}\frac{\omega^k}{x-\omega^k} = \frac{(-1)^n n!}{p}\sum_{k=0}^{p-1}\frac{\omega^k}{(x-\omega^k)^{n+1}}\\ &= \frac{(-1)^n n!}{p(x^p-1)^{n+1}}\sum_{k=0}^{p-1}\bar\omega^{kn}\varphi^{n+1}(\bar\omega^k x) = \frac{(-1)^n n!}{p(x^p-1)^{n+1}}\sum_{k=0}^{p-1}\omega^{kn}\varphi^{n+1}(\omega^k x),\end{aligned}$$

and defining $\psi_n(x) = \frac{1}{p}\sum_{k=0}^{p-1}\omega^{k(n-1)}\varphi^n(\omega^k x)$ yields the explicit formula

$$K_{p,n} = x - (x^p-1)\frac{\psi_{n-1}}{\psi_n} = \frac{x\psi_n - (x^p-1)\psi_{n-1}}{\psi_n}.$$

The denominator of $K_{p,n}$, namely, $\psi_n(x)$, is formed by the terms of $\varphi^n(x)$ in which the exponent of x is congruent to $(1-n)$ modulo p; in fact, if $\varphi^n(x) = \sum a_r x^r$, then

$$\psi_n(x) = \frac{1}{p}\sum_{k=0}^{p-1}\omega^{k(n-1)}\sum_r a_r\omega^{kr}x^r = \frac{1}{p}\sum_r\left(a_r x^r\sum_{k=0}^{p-1}\omega^{k(n+r-1)}\right) = \sum_{r\equiv 1-n} a_r x^r.$$

The numerator of $K_{p,n}$, namely, $x\psi_n(x)-(x^p-1)\psi_{n-1}(x)$, is formed by the terms of $\varphi^n(x)$ in which the exponent of x is congruent to $(2-n)$ modulo p; in fact,

$$x\psi_n(x)-(x^p-1)\psi_{n-1}(x) = \frac{1}{p}\sum_{k=0}^{p-1}\left(\omega^{k(n-1)}x\varphi^n(\omega^k x)-\omega^{k(n-2)}(x^p-1)\varphi^{n-1}(\omega^k x)\right)$$

$$= \frac{1}{p}\sum_{k=0}^{p-1}\left(\omega^{k(n-1)}x\varphi^n(\omega^k x)-\omega^{k(n-2)}(\omega^k x-1)\varphi^n(\omega^k x)\right) = \frac{1}{p}\sum_{k=0}^{p-1}\omega^{k(n-2)}\varphi^n(\omega^k x)$$

$$= \frac{1}{p}\sum_{k=0}^{p-1}\omega^{k(n-2)}\sum_r a_r\omega^{kr}x^r = \frac{1}{p}\sum_r\left(a_r x^r\sum_{k=0}^{p-1}\omega^{k(n+r-2)}\right) = \sum_{r\equiv 2-n} a_r x^r,$$

where we have used the identity $x^p-1=(\omega^k x-1)\varphi(\omega^k x)$ for any k.

Let $a_{\alpha_1},\dots,a_{\alpha_\nu}$ be the coefficients of $\varphi^n(x)$ relative to exponents congruent to $1-n$ modulo p, and let $a_{\beta_1},\dots,a_{\beta_\mu}$ be the coefficients of $\varphi^n(x)$ relative to exponents congruent to $2-n$ modulo p, so that

$$K_{p,n} = \frac{a_{\beta_1}x^{\beta_1}+\cdots+a_{\beta_\mu}x^{\beta_\mu}}{a_{\alpha_1}x^{\alpha_1}+\cdots+a_{\alpha_\nu}x^{\alpha_\nu}}.$$

To conclude the proof, it is enough to prove that, for $n\equiv 3 \pmod p$, it holds that $\mu=\nu$ and $a_{\alpha_1}=a_{\beta_\mu}, a_{\alpha_2}=a_{\beta_{\mu-1}},\dots,a_{\alpha_\nu}=a_{\beta_1}$.

Let $N=\deg\varphi^n(x)=np-n$. To prove the equality $\mu=\nu$ observe that μ and ν are the numbers of solutions of the congruences $r\equiv 1-n \pmod p$ and $r\equiv 2-n \pmod p$, respectively, such that $0\leqslant r\leqslant N$. For $n\equiv 3 \pmod p$ there exists an integer γ such that $N=\gamma p-3$; thus the number of solutions of the two congruences $r\equiv 1-n\equiv -2 \pmod p$ and $r\equiv 2-n\equiv -1 \pmod p$ such that $0\leqslant r\leqslant N$ is the same.

Observe that since $N=np-n$, then $\beta_\mu=N+2-p$, and observe that $\varphi^n(x)=\operatorname{rev}\varphi^n(x)$, namely, $a_r=a_{N-r}$ for each $r=0,1,\dots$. For $n\equiv 3 \pmod p$, it holds that $\alpha_1=p-2$, and thus $a_{\alpha_1}=a_{p-2}=a_{N+2-p}=a_{\beta_\mu}$.

The equalities $a_{\alpha_{i+1}}=a_{\beta_{\mu-i}}$ for $i=1,2,\dots$ follow from the fact that if $n\equiv 3 \pmod p$, then $\alpha_{i+1}=(i+1)p-2=N-(N+2-p-ip)=N-\beta_{\mu-i}$.

Simplifying the common factors gives the required form for $K_{p,n}$. □

By the properties of the König method [3], the iteration $z_{k+1}=K_{p,n}(z_k)$ converges locally, with order of convergence at least n, to the roots of the polynomial x^p-1. It is easy to see, by an induction argument, that the iteration

$$x_{k+1}=\zeta K_{p,n}(\zeta^{-1}x_k), \tag{4.3}$$

where ζ is any pth root of the nonzero scalar a, for $x_0=\zeta z_0$, is such that $x_k=\zeta z_k$ and thus converges locally to the roots of $x^p-a=0$.

Iteration (4.3) does not seem effective for computing the pth roots of a, since it uses ζ, but for $n\equiv 3 \pmod p$; in view of Theorem 4.1, the iteration for x_k has the form

$$x_{k+1}=x_k\frac{q(a^{-1}x_k^p)}{\operatorname{rev}q(a^{-1}x_k^p)}=x_k\frac{\widehat{q}(x_k^p)}{\operatorname{rev}\widehat{q}(x_k^p)}, \tag{4.4}$$

where $\widehat{q}$ is obtained by multiplying q by a suitable power of a. In this way, an effective iteration is obtained to approximate with high precision the pth roots of a given complex number.

A difficulty in the use of iteration (4.4) is the global convergence. We will not investigate further the global convergence of (4.4), but in section 5 we will give a convergence proof for the case $n = 3$, which is a structure-preserving iteration for each p, in view of Theorem 4.1.

Remark 4.2. Theorem 4.1 has a perhaps surprising application to the theory of root-finding algorithms. Following McMullen [19], a rational iterative root-finding algorithm is said to be *generally convergent* if it converges to a root for almost every initial guess and for almost every polynomial (where the Lebesgue measure on the complex plane and on the space of coefficients is considered).

It is known that the Newton method is generally convergent for quadratic polynomials, but not for cubics. In fact, the Newton iteration for the polynomial $p(z) = z^3 - 2z + 2$ does not converge to any root for initial values in a suitable set of measure greater than zero.

McMullen constructed in [19] a generally convergent algorithm for cubic polynomials and proved that there does not exist a generally convergent algorithm for polynomials of degree greater than 3.

Using the results of McMullen, Hawkins proved that any generally convergent root-finding algorithm is generated by a root-finding algorithm for the polynomial $x^3 - 1$ of the form (4.2) [7]. Thus, Theorem 4.1 could be used to construct generally convergent algorithms for a cubic polynomial of an arbitrarily high order of convergence.

5. Nice properties of the Halley method. The König method of order 3 is the so-called Halley method, which, for the equation $x^p - 1 = 0$, is

$$x_{k+1} = x_k \frac{(p-1)x_k^p + (p+1)}{(p+1)x_k^p + (p-1)}, \quad x_0 \in \mathbb{C}. \tag{5.1}$$

Here we considered a matrix generalization of the Halley method for computing the principal pth root of a matrix A.

A very nice feature of the Halley method for the equation $x^p - 1 = 0$ is that the basin of attraction for the fixed point 1 is somewhat *nicer* than that of the Newton method (see Figure 5.1 for a comparison in the case $p = 4$). It was proved [15] that for the Newton method applied to the equation $x^p - 1 = 0$ the basin of attraction for the fixed point 1 contains the set

$$\mathcal{T}_{2p} = \{z \in \mathbb{C} \setminus \{0\} \,:\, -\pi/(2p) < \arg(z) < \pi/(2p), |z| \geqslant 1\}, \tag{5.2}$$

while for the Halley method there holds the following result.

THEOREM 5.1. *The immediate basin of attraction for the fixed point* 1 *of the rational iteration* (5.1) *contains the sector*

$$\mathcal{S}_{2p} = \{z \in \mathbb{C} \setminus \{0\} \,:\, -\pi/(2p) < \arg(z) < \pi/(2p)\}. \tag{5.3}$$

Proof. Let us define

$$\varphi(z) = \frac{(p-1)z^p + (p+1)}{(p+1)z^p + (p-1)};$$

iteration (5.1) can be written as $z_{k+1} = z_k\varphi(z_k)$. The sector $\mathcal{S}_{2p}$ contains the fixed point $z = 1$ and is an open connected set, and, by Lemma 5.2, if $z \in \mathcal{S}_{2p}$, then $z\varphi(z) \in \mathcal{S}_{2p}$. Thus, the set $\mathcal{S}_{2p}$ belongs to the immediate basin of the fixed point $z = 1$. In fact, given a rational iteration $x_{k+1} = \psi(x_k)$ of degree greater than 1,

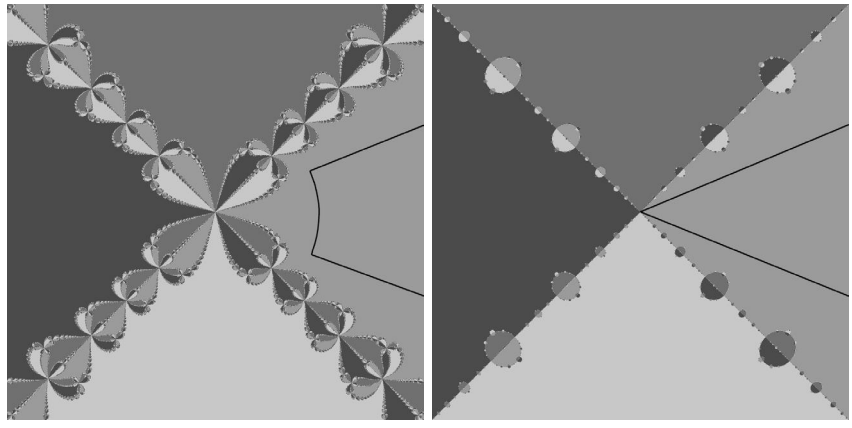

FIG. 5.1. *Comparison of the basins of attraction for the Newton method (left) and the Halley method (right) for the equation* $x^4 - 1$ *in the set* $[-2,2] \times [-2,2] \subset \mathbb{C}$. *The sets* $\mathcal{T}_{2p}$ *of* (5.2) *and* $\mathcal{S}_{2p}$ *of* (5.3) *are highlighted.*

any connected open set $\mathcal{U}$ such that $\psi(\mathcal{U}) \subset \mathcal{U}$ and containing only a fixed point z_* belongs to the immediate basin of z_* (compare with [1, Thm. 4.2.5]). □

LEMMA 5.2. *For each* $z \in \mathcal{S}_{2p}$, *it holds that* $|\arg(z\varphi(z))| \leqslant |\arg(z)|$ *and the equality holds if and only if* z *is real.*

Proof. If z is real, then $\varphi(z)$ is real. Let us consider the case $\arg(z) > 0$; since $\arg(z\varphi(z)) = \arg(z) + \arg(\varphi(z))$, it is enough to prove that

$$-2\arg(z) < \arg(\varphi(z)) < 0. \tag{5.4}$$

Removing real positive constants, it holds that

$$\arg(\varphi(z)) = \arg\big(((p-1)z^p + (p+1)) \cdot ((p+1)\bar{z}^p + (p-1))\big).$$

Using the decomposition $z = r(\cos\vartheta + \mathbf{i}\sin\vartheta)$, one has

$$\arg(\varphi(z)) = \arg\big((p^2-1)(|r|^{2p}+1) + 2(p^2+1)r^p\cos(p\vartheta) - 4\mathbf{i}pr^p\sin(p\vartheta)\big).$$

Applying the tangent trigonometric function to the inequalities (5.4), we obtain the equivalent

$$-\frac{\sin(2\vartheta)}{\cos(2\vartheta)} < \frac{-4pr^p\sin(p\vartheta)}{(p^2-1)(r^{2p}+1) + 2(p^2+1)r^p\cos(p\vartheta)} < 0. \tag{5.5}$$

The latter inequality is evident from $0 < \vartheta < \pi/(2p)$. The former needs a bit more work; it can be rewritten as

$$\begin{aligned}(p^2-1)\sin(2\vartheta)r^{2p} + 2\big((p^2+1)\cos(p\vartheta)\sin(2\vartheta) - 2p\sin(p\vartheta)\cos(2\vartheta)\big)r^p \\ + (p^2-1)\sin(2\vartheta) > 0\end{aligned} \tag{5.6}$$

and can be seen as a quadratic inequality on the variable $x = r^p$. The quadratic has the form $\gamma(x) = ax^2 + 2bx + a$, where $a = (p^2-1)\sin(2\vartheta)$ and $b = (p^2+1)\cos(p\vartheta)\sin(2\vartheta) - 2p\sin(p\vartheta)\cos(2\vartheta)$. Since $a > 0$, the inequality $\gamma(x) > 0$ is true if the equation $\gamma(x) = 0$ has no solution. Observe that if $\gamma(x) = 0$, then $\gamma(1/x) = 0$, and if $\gamma(1) > 0$, there exists no positive solution.

Using the inequalities $(\vartheta - \vartheta^3/6) \leqslant \sin\vartheta \leqslant \vartheta$ for $0 < \vartheta < \pi/p$ and $\sin((p-2)\vartheta) = \sin(p\vartheta)\cos(2\vartheta) - \sin(2\vartheta)\cos(p\vartheta)$, one can see that

$$\frac{1}{2}\gamma(1) \geqslant (p^2-1)\sin(2\vartheta) - 2p\sin((p-2)\vartheta) > (p^2-1)\left(2\vartheta - \frac{4}{3}\vartheta^3\right) - 2p(p-2)\vartheta$$
$$= \frac{2}{3}\vartheta\left(6p - 3 - 2(p^2-1)\vartheta^2\right);$$

the last expression is positive if $\vartheta^2 \leqslant \frac{6p-3}{2p^2-2}$, and this is true since $\vartheta \leqslant \pi/(2p)$. ∎

It is worth giving a corollary of Theorem 5.1 which could be used for the computation of the scalar pth root.

COROLLARY 5.3. *Consider the Halley method for the equation* $x^p - a = 0$,

$$x_{k+1} = x_k \frac{(p-1)x_k^p + (p+1)a}{(p+1)x_k^p + (p-1)a}, \quad x_0 \in \mathbb{C}. \tag{5.7}$$

The principal basin for the initial value $x_0 = 1$ *contains the set* $\mathbb{C}_> = \{z \in \mathbb{C} : \operatorname{Re} z > 0\}$.

Theorem 2.4 guarantees the convergence of the pure matrix iteration

$$Y_{k+1} = Y_k((p-1)Y_k^p + (p+1)I)((p+1)Y_k^p + (p-1)I)^{-1} \tag{5.8}$$

to the identity matrix I for each Y_0 having eigenvalues in $\mathcal{S}_{2p}$, particularly for $Y_0 = A^{-1/p}$, where A has eigenvalues in the open right half complex plane, which will be denoted by $\mathbb{C}_>$. Iteration (5.8) is strictly related to

$$X_{k+1} = X_k((p-1)X_k^p + (p+1)A)((p+1)X_k^p + (p-1)A)^{-1}; \tag{5.9}$$

in fact, if A has eigenvalues in $\mathbb{C}_>$, $Y_0 = A^{-1/p}$, and $X_0 = I$, then it can be shown that $X_k = Y_k A^{1/p}$ for each k (the proof follows by an induction argument and using the fact that X_k and Y_k are functions of A and so commute with A and $A^{1/p}$).

COROLLARY 5.4. *The sequence* X_k *obtained by iteration* (5.9) *with* $X_0 = I$ *converges to* $A^{1/p}$ *for each* A *having eigenvalues in* $\mathbb{C}_>$.

Moreover, for what we have proved in section 4, iteration (5.8) is structure-preserving. If A belongs to a group of automorphisms as in section 4, so does $A^{1/p}$; thus, each of the iterates obtained by (5.9) belongs to that group.

Iteration (5.9) cannot be used directly to approximate the principal pth root. In fact, using the same idea as in [15], one can prove that iteration (5.9) is *not stable in a neighborhood of* $A^{1/p}$; i.e., a perturbation on the value of X_k is amplified in the following steps preventing the convergence in a finite arithmetic computation.

This problem can be overridden using another algorithm which provides the same sequence but which is stable in a neighborhood of $A^{1/p}$—for instance,

$$\begin{cases} X_0 = I, \quad N_0 = A, \\ X_{k+1} = X_k((p+1)I + (p-1)N_k)^{-1}((p-1)I + (p+1)N_k), \\ N_{k+1} = N_k\left(((p+1)I + (p-1)N_k)^{-1}((p-1)I + (p+1)N_k)\right)^{-p}, \end{cases} \tag{5.10}$$

where $N_k \to I$ and $X_k \to A^{1/p}$. If the pth power is computed using the binary powering technique [5, Alg. 11.2.2], the computational cost of iteration (5.10) is $2(5 + \vartheta\log_2 p)n^3$ arithmetic operations (ops) per step, where $1 \leqslant \vartheta \leqslant 2$.

6. New algorithms for the matrix *p*th root. A family of iterations for computing the principal pth root of a matrix A is

$$X_{k+1} = \frac{(p-1)X_k + AX_k^{1-p}}{p}, \tag{6.1}$$

which coincides with the Newton method for the equation $X^p - A = 0$, when the latter is well defined and X_0 commutes with A [22]; this is the reason why iteration (6.1) is referred to, somehow improperly, as the Newton method.

In [22] it was proved that this iteration is not stable in a neighborhood of $A^{1/p}$. A stable variant, for $X_0 = I$,

$$\begin{cases} Y_0 = I, \quad N_0 = A, \\ Y_{k+1} = Y_k \left(\dfrac{(p-1)I + N_k}{p} \right), \\ N_{k+1} = \left(\dfrac{(p-1)I + N_k}{p} \right)^{-p} N_k, \end{cases} \tag{6.2}$$

was proposed in [15], where it was proved that (Y_k, N_k) converges quadratically to $(A^{1/p}, I)$ for each A having eigenvalues in the set

$$\mathcal{D} = \{z \in \mathbb{C} : \operatorname{Re} z > 0, |z| \leqslant 1\}. \tag{6.3}$$

This leads to an algorithm for computing the principal pth root.

Algorithm 1 (a Newton method for $A^{1/p}$ [15]). Given are $A \in \mathbb{C}^{n\times n}$ with no nonpositive real eigenvalues, an integer $p > 2$, and an algorithm for computing the square root.

1. Compute B, the principal square root of A;
2. set $C = B/\|B\|$ for a suitable norm; the eigenvalues of C belong to the set $\mathcal{D}$ of (6.3);
3. by means of iteration (6.2),
   - if p is even, compute $S = C^{2/p}$, the $(p/2)$th root of C, and set $X = S\|B\|^{2/p}$;
   - if p is odd, compute $S = C^{1/p}$, the pth root of C, and set $X = \left(S\|B\|^{1/p}\right)^2$.

Iteration (6.2) of Algorithm 1 has a computational cost of $2(3+\vartheta \log_2 p)n^3$ ops per step, where $1 \leqslant \vartheta \leqslant 2$. The initial square root can be obtained by forming the Schur decomposition of A, without affecting the complexity order with respect to p. An observation of Guo and Higham is that the Schur decomposition gives the eigenvalues of A, and that information is not exploited in Algorithm 1.

Since the number of steps to achieve the required accuracy in the numerical computation depends on the localization of the eigenvalues of the matrix whose pth root is required, a smarter preprocessing could reduce the number of steps needed for the expensive iteration (6.2) (or other similar iterations) to verify a suitable stopping criterion. In order to give a better localization of the eigenvalues, one could perform a small number of initial square roots without affecting the order of complexity of the overall algorithm. Moreover, multiplying the preprocessed matrix by a scalar parameter could further reduce the number of steps needed for convergence.

The *Schur–Newton method*, an algorithm of Guo and Higham [6], is based on these ideas. The algorithm does not use iteration (6.2) but an iteration which generalizes

the scalar Newton method for the equation $x^{-p} - a = 0$. The iteration, introduced in [2], is

$$X_{k+1} = \frac{1}{p}\left((p+1)X_k - X_k^{p+1}A\right), \quad X_0 = I, \tag{6.4}$$

which converges to $A^{-1/p}$, and for which in [6] is constructed a convergence region for the eigenvalues of A: if the spectrum of A belongs to that region, then $X_k \to A^{-1/p}$. From iteration (6.4) can be obtained a stable iteration [15, 18, 6]

$$\begin{cases} Y_0 = \dfrac{1}{c}I, \quad N_0 = \dfrac{1}{c^p}A, \\ Y_{k+1} = Y_k\left(\dfrac{(p+1)I - N_k}{p}\right), \\ N_{k+1} = \left(\dfrac{(p+1)I - N_k}{p}\right)^p N_k, \end{cases} \tag{6.5}$$

such that $Y_k \to A^{-1/p}$ and $N_k \to I$. Setting $X_k = Y_k^{-1}$ gives the iteration [6]

$$\begin{cases} X_0 = cI, \quad N_0 = \dfrac{1}{c^p}A, \\ X_{k+1} = \left(\dfrac{(p+1)I - N_k}{p}\right)^{-1} X_k, \\ N_{k+1} = \left(\dfrac{(p+1)I - N_k}{p}\right)^p N_k, \end{cases} \tag{6.6}$$

for which $X_k \to A^{1/p}$. The computational costs of iterations (6.5) and (6.6) are $2(2 + \vartheta \log_2 p)n^3$ and $2(3 + \vartheta \log_2 p)n^3$ ops per step, respectively, where $1 \leqslant \vartheta \leqslant 2$.

Algorithm 2 (Schur–Newton algorithm for $A^{1/p}$ using (6.5) and (6.6) [6]). Given are $A \in \mathbb{C}^{n\times n}$ with no nonpositive real eigenvalues and an integer $p = 2^{k_0}q$ with $k_0 \geqslant 0$ and q odd.

1. Compute the Schur decomposition of $A = QRQ^T$;
2. if $q = 1$, then $k_1 = k_0$; else choose $k_1 \geqslant k_0$ such that $\arg(\lambda_i^{1/2^{k_1}}) \in (-\pi/8, \pi/8)$ for each i and $|\lambda_1/\lambda_n|^{1/2^{k_1}} \leqslant 2$, where the eigenvalues of A are ordered $|\lambda_n| \leqslant \cdots \leqslant |\lambda_1|$;
3. compute $B = R^{1/2^{k_1}}$ by taking the square root k_1 times; if $q = 1$, then $X = QBQ^T$; else continue;
4. let $\mu_1 = |\lambda_1|^{1/2^{k_1}}$, $\mu_n = |\lambda_n|^{1/2^{k_1}}$;
   - if the λ_i are all real, if $\mu_1 \neq \mu_n$, determine $c = \left(\frac{\alpha^{1/q}\mu_1 - \mu_n}{(\alpha^{1/q}-1)(p+1)}\right)^{1/q}$ with $\alpha = \mu_1/\mu_n$; else $c = \mu_n^{1/q}$;
   - if some λ_i is complex, then $c = \left(\frac{\mu_1+\mu_n}{2}\right)^{1/q}$;
5. compute $C = B^{1/q}$ by (6.6); $X = QC^{2^{k_1-k_0}}Q^T$ (or compute $C = B^{-1/q}$ by (6.5), $X = Q(C^{2^{k_1-k_0}})^{-1}Q^T$).

The initial square roots computation, in certain cases, may dramatically reduce the number of steps needed by the iteration, but each square root in preprocessing corresponds to a squaring at the final step of the algorithm. The cost of a square root and a squaring is less than the cost of one step of the iteration, but a large number of initial square roots may result in a waste of computation if there is no saving in the number of iteration steps.

A little extension of the region of convergence D of (6.3) allows one to use the ideas of Algorithm 2 also for iteration (6.2). The proof will be given in section 6.1 and is based on the proof of Theorem 2.3 of [15].

THEOREM 6.1. *The immediate basin of attraction for the fixed point* 1 *of the iteration*

$$x_{k+1} = \frac{(p-1)x_k + x_k^{1-p}}{p} \tag{6.7}$$

contains the set

$$\mathcal{E} = \left\{ z \in \mathbb{C} : |z| \geqslant \frac{1}{2^{1/p}}, |\arg(z)| < \pi/(4p) \right\}.$$

Observe that iteration (6.1) with $X_0 = I$ converges to $A^{1/p}$ if and only if the iteration

$$X_{k+1} = \frac{(p-1)X_k + X_k^{1-p}}{p}, \quad X_0 = A^{-1/p}, \tag{6.8}$$

converges to the identity matrix. This fact and Theorem 2.4 give the following result.

COROLLARY 6.2. *Iteration* (6.1) *converges for each A having eigenvalues in*

$$D_+ = \{z \in \mathbb{C} : |z| \leqslant 2, |\arg(z)| < \pi/4\}. \tag{6.9}$$

Corollary 6.2 leads to an analogue of Algorithm 2 using iteration (6.2).

Algorithm 3 (Schur–Newton algorithm using (6.2)). Given are $A \in \mathbb{C}^{n\times n}$ with no nonpositive real eigenvalues and an integer $p = 2^{k_0}q$ with $k_0 \geqslant 0$ and q odd.

1. Compute the Schur decomposition of $A = QRQ^T$;
2. if $q = 1$, then $k_1 = k_0$; else choose $k_1 \geqslant k_0$ such that there exists a positive number s such that for each eigenvalue λ of A, $s\lambda^{1/2^{k_1}} \in \mathcal{D}$, where $\mathcal{D}$ is the disk of center 6/5 and radius 3/4;
3. compute $B = R^{1/2^{k_1}}$ by taking the square root k_1 times; if $q = 1$, then $X = QBQ^T$; else continue;
4. compute $C = (B/s)^{1/q}$ by (6.2); $X = Q(Cs^{1/q})^{2^{k_1-k_0}}Q^T$.

The convergence of Algorithm 3 is guaranteed by Corollary 6.2; in fact, iteration (6.2) is applied to a matrix having eigenvalues in the set $\mathcal{D}$, which is a subset of D_+ of (6.9). The set $\mathcal{D}$ is chosen heuristically in order to need at most 5 steps of the Newton iteration in the scalar case.

Step 2 of Algorithm 3 can be performed in an inexpensive way. For $m \geqslant k_0$ and for each eigenvalue λ of A, one looks for an interval $[t_1(\lambda), t_2(\lambda)]$ such that $t_1(\lambda) > 0$ and $t\lambda^{1/2^m}$ lies in $\mathcal{D}$ for $t \in [t_1(\lambda), t_2(\lambda)]$; if such an interval exists for each λ and the intersection is not void, then s can be any point of the intersection; else increase m.

In Figure 6.1 we have constructed experimentally the *level sets of convergence* for iterations (6.1) and (6.4) applied to scalar numbers. Given the tolerance $\varepsilon = 10^{-15}$, a point x_0 of the region $[-1, 5] \times [-3, 3]$ of the complex plane has been colored by a tonality of grey if convergence up to ε occurs in less than 10 steps. Each tonality of grey corresponds to a different number of iterations needed: the lighter one corresponds to the points for which convergence up to ε occurs in 9 steps. The black contour encloses the sets in which the eigenvalues of the matrix preprocessed by Algorithms 3 and 2 lie; observe that in the examples in Figure 6.1 the scalar iteration with an initial value

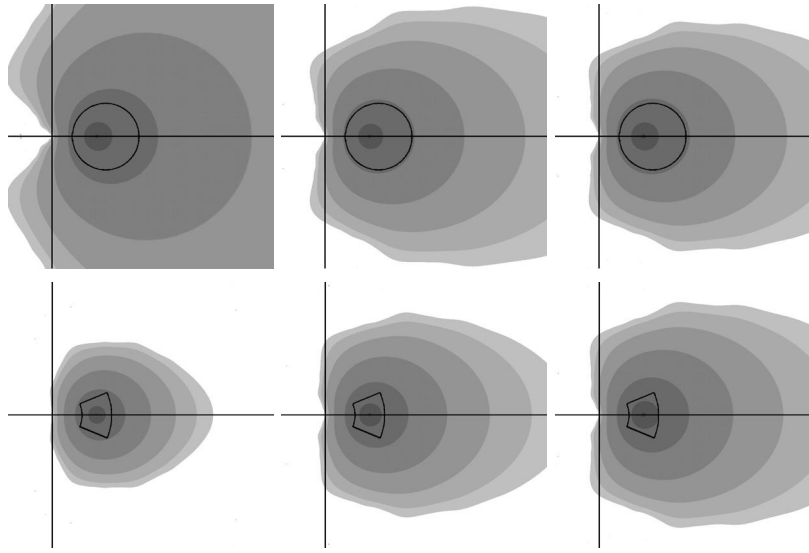

FIG. 6.1. *Comparison of the* level sets of convergence *for the Newton method (first row) and the inverse Newton method (second row) for* $p = 4$ *(first column),* $p = 20$ *(second column), and* $p = 200$ *(last column). The black contour encloses the regions in which lie the eigenvalues of the preprocessed matrices to which is applied the iterative step of Algorithms* 3 *(first row) and* 2 *(second row).*

inside the bordered regions needs at most five iterations. The expected number for the matrix iteration is the same, unless the matrix is nondiagonalizable.

In practice, due to the larger level sets of convergence (see Figure 6.1), Algorithm 3 is likely to obtain the same number of iteration steps as Algorithm 2 with a slightly milder condition on step 2, which could save a couple of square roots in preprocessing.

From the stable version of Halley's iteration (5.10) and Corollary 5.4, we obtain another algorithm.

Algorithm 4 (Schur–Halley algorithm using (5.10)). Given are $A \in \mathbb{C}^{n\times n}$ with no nonpositive real eigenvalues and an integer $p = 2^{k_0}q$ with $k_0 \geqslant 0$ and q odd.

1. Compute the Schur decomposition of $A = QRQ^T$;
2. if $q = 1$, then $k_1 = k_0$; else choose $k_1 \geqslant k_0$ such that there exists a positive number s such that for each eigenvalue λ of A, $s\lambda^{1/2^{k_1}} \in \mathcal{D}$, where $\mathcal{D}$ is the disk of center 8/5 and radius 1;
3. compute $B = R^{1/2^{k_1}}$ by taking the square root k_1 times; if $q = 1$, then $X = QBQ^T$; else continue;
4. compute $C = (B/s)^{1/q}$ by (5.10); $X = Q(Cs^{1/q})^{2^{k_1-k_0}}Q^T$.

The convergence of Algorithm 4 is guaranteed by Corollary 5.4; in fact, iteration (5.10) is applied to a matrix having eigenvalues in the set $\mathbb{C}_>$.

Once again, the choice of $\mathcal{D}$ is heuristic and is based on the observation of the experimental regions of convergence. With this preprocessing the iteration usually needs three steps to converge.

Algorithms 3 and 4 do not have the disadvantages of Algorithm 1, described in [6], i.e., a large number of steps or a possible instability in certain cases. They do have the same excellent numerical behavior of Algorithm 2; moreover, in most cases, they can save some square roots in preprocessing.

TABLE 6.1

Results for the 15th root of a 3-by-3 matrix A with real eigenvalues and condition number $\kappa_2(A) \approx 10^{10}$.

Algorithm 2 iteration (6.5)	Algorithm 3 iteration (6.2)	Algorithm 4 iteration (5.10)
$\text{err} = 2.7\text{e-}8$	$\text{err} = 2.7\text{e-}8$	$\text{err} = 2.7\text{e-}8$
$\rho_A(\widetilde{X}) = 5.0\text{e-}17$	$\rho_A(\widetilde{X}) = 8.1\text{e-}18$	$\rho_A(\widetilde{X}) = 1.5\text{e-}17$
iter=5, $k_1 = 5$	iter=5, $k_1 = 4$	iter=3, $k_1 = 4$

To compare the algorithms, we use the criterion used in [6], considering the *relative residual*

$$\rho_A(\widetilde{X}) \doteq \frac{\|A - \widetilde{X}^p\|}{\|\widetilde{X}\| \left\| \sum_{i=0}^{p-1} \left(\widetilde{X}^{p-1-i}\right)^T \otimes \widetilde{X}^i \right\|},$$

where $\widetilde{X}$ is the computed matrix and where the norm used is the infinity norm, and the algorithms are stopped when $\|N_k - I\| < 100nu$, where n is the size of A and u is the machine precision.

As a first test, the 5th root of a random nonnormal matrix constructed as described in [6] is computed with Algorithms 2, 3, and 4. This example was used in [6] to show the better behavior of Algorithm 2 with respect to Algorithm 1. In Table 6.1 we compare the results in terms of relative residual, number of steps (iter), and number of square roots in preprocessing (k_1).

A second test is performed considering the nonnormal matrix

$$S = \begin{bmatrix} -1 & -2 & 2 \\ -4 & -6 & 6 \\ -4 & -16 & 13 \end{bmatrix},$$

whose eigenvalues are $\{1, 2, 3\}$, and computing the 15th root of $A \doteq S^{15}$, which is formed exactly. The condition number $\kappa_2(A) = \|A\|_2\|A^{-1}\|_2$ of the matrix A is about 10^{10}. In Table 6.2 the algorithms are compared in terms of the relative residual and the relative error of the computed solution $\widetilde{X}$, namely, $\text{err} = \|\widetilde{X} - S\|/\|S\|$, where the Frobenius norm is used.

Observe that Algorithm 3 gives the same numerical results as Algorithm 2, with fewer square roots in preprocessing. Algorithm 4 requires, in general, fewer square roots in preprocessing and a minor number of steps since it has cubic convergence, though the computational cost per step is higher than in the other two. An advantage of Algorithm 4 is that it is structure-preserving.

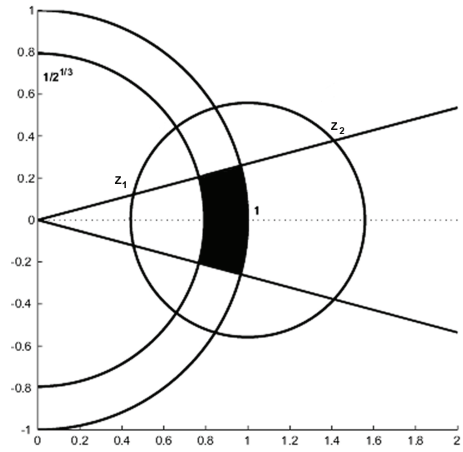

FIG. 6.2. *In black the region $\mathcal{E}$ of the proof of Theorem* 6.1 *for $p = 3$.*

6.1. Proof of Theorem 6.1. It is enough to prove that the set $\mathcal{E} \cap \{|z| < 1\}$ belongs to the immediate basin of attraction; in fact, the case $|z| \geqslant 1$ is a corollary of Theorem 2.3 of [15].

In Lemma 2.4 of [15], it is proved that a disk centered at $z = 1$ and with radius R_p is contained in the basin of 1, where $R_p = 1 - s_p$ and s_p is the unique real solution of the equation $(2p-1)s^p - 2p\,s^{p-1} + 1 = 0$ in the interval $(0, 1)$. In Lemma 2.8 of [15], it is proved that $R_p \geqslant \alpha_0/p$ for each $p > 1$, where $\alpha_0 > 1.256$.

To achieve the proof it is enough to show that the half line forming an angle of $\pi/(4p)$ with the real axis meets the circle $|z - 1| = R_p$ at two points z_1 and z_2 such that

$$r_1 < \frac{1}{\sqrt[p]{2}} < 1 < r_2,$$

where $r_1 = |z_1|$ and $r_2 = |z_2|$. That would imply that the set $\mathcal{E}$ (the black set in Figure 6.2) belongs to the disk $|z-1| \leqslant R_p$ and then to the basin of attraction of the fixed point 1.

The equation that gives the two points of intersection is $|re^{\mathbf{i}\pi/(4p)} - 1| = R_p$, which can be rewritten as

$$\gamma(r) \doteq r^2 - 2r\cos(\pi/(4p)) + 1 - R_p^2 = 0.$$

The function $\gamma(r)$ is quadratic; to prove that $r_2 > 1$, observe that

$$\gamma(1) = 2 - R_p^2 - 2\cos\left(\frac{\pi}{4p}\right) \leqslant \frac{1}{p^2}\left(\frac{\pi^2}{16} - \alpha_0^2\right) < 0.$$

The inequality $r_1 < 1/\sqrt[p]{2}$ can be written as

$$\cos(\pi/(4p)) - \sqrt{\cos^2(\pi/(4p)) - 1 + R_p^2} < \frac{1}{\sqrt[p]{2}},$$

which follows from

$$\sqrt{\cos^2(\pi/(4p)) - 1 + R_p^2} \geqslant \frac{\sqrt{\alpha_0^2 - \pi^2/16}}{p} > 0 > \frac{\log 2}{p} \geqslant \cos(\pi/(4p)) - \frac{1}{\sqrt[p]{2}},$$

where we have used the following inequalities: $\cos^2(\pi/(4p)) - 1 \geqslant -\pi^2/(16p^2)$, $R_p^2 \geqslant \alpha_0^2/p^2$, $1/\sqrt[p]{2} > 1 - \log(2)/p$, and $\cos(\pi/(4p)) < 1$. ∎

Acknowledgments. The author would like to thank Prof. Dario A. Bini, Prof. Nicholas J. Higham, and an anonymous referee whose pertinent and detailed suggestions considerably improved the presentation and the correctness of the paper.

THE QUADRATIC ARNOLDI METHOD FOR THE SOLUTION OF THE QUADRATIC EIGENVALUE PROBLEM*

KARL MEERBERGEN†

Abstract. The quadratic Arnoldi algorithm is a Krylov method for the solution of the quadratic eigenvalue problem, that exploits the structure of the Krylov vectors. This allows us to reduce the memory requirements by about a half. The method is an alternative to the second order Arnoldi (SOAR) method. In the SOAR method it is not clear how to perform an implicit restart. We discuss various choices of linearizations in $\mathbb{L}_1$ and $\mathbb{DL}$. We also explain how to compute a partial Schur form of the underlying linearization with respect to the structure of the Schur vectors. We also formulate some open problems.

Key words. quadratic eigenvalue problem, Arnoldi method, SOAR method, Schur decomposition

1. Introduction.

The goal is to solve the quadratic eigenvalue problem

$$Q(\lambda)u = 0 \quad \text{with} \quad Q(\lambda) = K + \lambda C + \lambda^2 M. \tag{1.1}$$

The matrices K, $-iC$, and $-M$ are the stiffness, damping, and mass matrices, respectively, and arise from the Fourier transformation of the spatial discretization by finite elements of the equation of motion. The matrices are large $n \times n$ matrices and usually sparse. Equation (1.1) is solved when the engineer is interested in the eigenfrequencies (resonance frequencies) and damping properties of the mode shapes (i.e., the eigenvectors). Krylov methods for the solution of quadratic eigenvalue problems have been studied by Parlett and Chen [20], Saad [21], and Mehrmann and Watkins [18]. The quadratic eigenvalue problem and solution methods are reviewed by Tisseur and Meerbergen [25].

Standard methods cannot be used directly to efficiently solve (1.1) because of the quadratic term in λ. Instead, (1.1) can be "linearized" into a problem of the form

$$(A - \lambda B) \begin{pmatrix} \lambda u \\ u \end{pmatrix} = 0, \tag{1.2}$$

where A and B will be defined in section 2. Since we are interested in the eigenvalues near zero, we usually solve the inverted problem

$$S \begin{pmatrix} u \\ \theta u \end{pmatrix} = \theta \begin{pmatrix} u \\ \theta u \end{pmatrix} \tag{1.3}$$

with $S = A^{-1}B$ and $\theta = \lambda^{-1}$. There are three disadvantages to the Arnoldi method: first, the doubling of the size of the problem increases the memory cost by a factor of

two; second, the typical structure of the eigenvectors of the linearization is lost; and finally, the Ritz values are computed from a small Hessenberg matrix and not from a small quadratic eigenvalue problem.

All these disadvantages can be overcome by the second order Arnoldi (SOAR) method [4]. However, the SOAR method is not the preferred method for computing a Schur form of the linearization. As a consequence, classical implicit restarting [22, 19] is no longer possible.

In this document, we propose a method that is close to the SOAR method. We call it Q-Arnoldi, where Q stands for "quadratic." It exploits the structure of the linear problem to reduce the storage cost of the Arnoldi method roughly by a factor of two. We propose a locking procedure of converged Schur vectors that do keep the structure of the exact Schur vectors.

Both the SOAR method [4] and the Q-Arnoldi method compute the same subspace of the linearized problem. Q-Arnoldi performs a projection that does not produce a quadratic eigenvalue problem: the Ritz pairs are computed from the Arnoldi recurrence relation, which allows for the computation of a Schur form. Exploiting the Schur form of the linearization in the SOAR method for restarting purposes is not trivial and is, to date, an open question. See [15] for exploiting the Schur form in the inverse residual iteration and Jacobi–Davidson methods. The difficulty is that the Schur vectors, computed by the SOAR method, cannot, in general, be mapped in a Krylov recurrence relation.

Nevertheless, some results in this paper also have consequences concerning the SOAR method. We devote some time to the choice of linearization in $\mathbb{L}_1$ and $\mathbb{DL}$ [13], which is also useful for the SOAR method.

Note that $B^{-1}A$ can be used as an alternative to $A^{-1}B$. In applications this is usually less effective than using $A^{-1}B$ when the eigenvalues near zero are wanted. Many applications are not extremely large, i.e., smaller than 100,000 degrees of freedom, which allows the use of a direct linear system solver for applying A^{-1}.

The fact that the Krylov vectors belong to $\mathbb{C}^{2n}$ instead of $\mathbb{C}^n$ may limit their practical use, especially when the Arnoldi method [1, 12, 3] is used when a large number of vectors need to be stored: k iterations of the Arnoldi method require the storage of the order of $(2k+2)n$ floating point numbers (real or complex). The Q-Arnoldi scheme exploits the structure of S to reduce the memory requirements to $(k+2)n$ floating point numbers. Similar tricks can be used for reducing the storage cost for partial reorthogonalization in the Lanczos method. Although the Lanczos method [9, 10] can be used to keep the storage requirements low, the Arnoldi method is usually preferred for eigenvalue computations. This memory reduction trick is also used in the SOAR algorithm.

The eigenvectors of (1.1) appear twice in the eigenvectors of (1.2). When the linearized problems are solved in a Krylov subspace, however, the two computed solutions are, in general, different. Therefore, we address which one of the two should be returned as an approximate solution vector of (1.1).

The paper is organized as follows. In section 2, we introduce linearizations for (1.1). In section 3, we review the Arnoldi method for (1.2) and present a modification of Arnoldi's method that saves memory. We call this the Q-Arnoldi algorithm, where Q stands for "quadratic." We discuss various issues including the choice of linearization, some thoughts on computations in finite precision arithmetic, and the choice of component of the Ritz vectors. Section 4 shows how to exploit the structure of (1.2) in the computation of Schur vectors. In section 5 we show a numerical example from applications. We conclude with some remarks in section 6.

Throughout the paper, we use x^* to denote the Hermitian transpose, x^*y for the inner product of two vectors, and $\|x\| = \sqrt{x^*x}$ for the induced two-norm. We also use $\|\cdot\|$ to denote the two-norm of a matrix. The matrix Frobenius norm is denoted by $\|\cdot\|_F$.

2. Linearization via the first companion form. By linearization, we mean the transformation of (1.1) into (1.2) by a suitable choice of A and B so that there is a one-to-one correspondence between eigenpairs of (1.1) and the $A - \lambda B$ pencil [24, 14, 13]. The linearization should be chosen so that the application of $S = A^{-1}B$ is efficient and accurate. We therefore assume that A and so K are invertible. The motivation for using linearizations other than the classical companion forms lies in respecting the structure of the eigenvalue problem. In this section, we show that this structure is lost in the shift-and-invert Arnoldi method for the linearizations from [14, 13], meaning that the structure is not respected by the Arnoldi method.

The fact that K has no factor λ in (1.1) suggests that K should appear in A. A straightforward choice is

$$A = \begin{bmatrix} D & \\ & K \end{bmatrix}, \quad B = \begin{bmatrix} & D \\ -M & -C \end{bmatrix}, \quad y = \begin{pmatrix} \lambda x \\ x \end{pmatrix}, \tag{2.1}$$

where D can be any nonsingular matrix. It is easy to see that

$$S = A^{-1}B = \begin{bmatrix} & I \\ -K^{-1}M & -K^{-1}C \end{bmatrix}, \tag{2.2}$$

from which D disappears.

LEMMA 2.1. *The pencil $A-\lambda B$ with* (2.1) *is a linearization iff D is nonsingular.*

Proof. If D is nonsingular, $A - \lambda B$ is a linearization. If D were singular, $\lambda = 0$ is an eigenvalue of $A - \lambda B$ but not of (1.1). Also, $\lambda = \infty$ is an eigenvalue even if it is not an eigenvalue of (1.1). In addition, it is no longer guaranteed that all eigenvectors have the form (1.2), so $A - \lambda B$ is not a linearization. ∎

An alternative to (2.1) is the first companion form

$$B = \begin{bmatrix} -M & \\ & D \end{bmatrix}, \quad A = \begin{bmatrix} C & K \\ D & \end{bmatrix}, \quad y = \begin{pmatrix} \lambda x \\ x \end{pmatrix}, \tag{2.3}$$

which also produces (2.2).

The matrix used in [18] for the skew-Hamiltonian/Hamiltonian eigenvalue problem does not have the form (2.2).

The linearization can be chosen so that A and B respect the special structures of K, C, and M. For example, if all matrices are symmetric and M is nonsingular, one could use $D = -M$. Although $A^{-1}B$ is independent of D, the choice of D may help build the Krylov subspace more efficiently. We discuss this in more detail in section 3.2.

3. The Arnoldi method. Let $N = 2n$. The Arnoldi method applied to $S \in \mathbb{C}^{N\times N}$ and $b \in \mathbb{C}^N$ produces the Krylov subspace

$$\mathcal{K}_k(S, b) = \operatorname{span}\{b, Sb, S^2b, \ldots, S^{k-1}b\}.$$

It computes the $N \times k$ matrix $\mathbf{V}_k = [\mathbf{v}_1, \ldots, \mathbf{v}_k]$ of iteration vectors, the upper Hessenberg matrix H_k, and the residual term $\mathbf{v}_{k+1}\beta_k$ so that

$$\begin{aligned} S\mathbf{V}_k - \mathbf{V}_k H_k &= \mathbf{v}_{k+1}\beta_k e_k^*, \\ S\mathbf{V}_k - \mathbf{V}_{k+1}\underline{H}_k &= 0, \end{aligned} \tag{3.1}$$

where $\mathbf{V}_{k+1}^*\mathbf{V}_{k+1} = I$. Equation (3.1) is called the Arnoldi recurrence relation. An algorithm for computing $\mathbf{V}_k$ and H_k is now given.

ALGORITHM 3.1 (Arnoldi method).

1. *Set the initial vector* $\mathbf{v}_1$ *so that* $\|\mathbf{v}_1\|_2 = 1$.
2. *For* $j = 1, \ldots, k$ *do*
   - 2.1. *Compute* $\hat{\mathbf{v}}_j = S\mathbf{v}_j$.
   - 2.2. *Compute the Arnoldi coefficients* $h_j = \mathbf{V}_j^*\hat{\mathbf{v}}_j$.
   - 2.3. *Update* $\tilde{\mathbf{v}}_j = \hat{\mathbf{v}}_j - \mathbf{V}_j h_j$.
   - 2.4. *Get the scalar* $\beta_j = \|\tilde{\mathbf{v}}_j\|_2$ *and compute* $\mathbf{v}_{j+1} = \tilde{\mathbf{v}}_j/\beta_j$.

   End for

Steps 2.2–2.4 orthonormalize $S\mathbf{v}_j$ against $\mathbf{v}_1, \ldots, \mathbf{v}_j$ into $\mathbf{v}_{j+1}$. The coefficients h_j form the jth column of H_j, and β_j is the $(j+1, j)$th element of $\underline{H}_k$. Roughly speaking, k iterations cost about $2N(k+3)k$ flops, excluding the cost for Step 2.1, where one flop is the cost for an addition or a multiplication.

3.1. The Q-Arnoldi algorithm. We now discuss how we can make Algorithm 3.1 more efficient for S from (2.2). We decompose the jth Arnoldi vectors into

$$\mathbf{v}_j = \begin{pmatrix} v_j \\ w_j \end{pmatrix},$$

with $v_j, w_j \in \mathbb{C}^n$. The Arnoldi recurrence relation (3.1) for the linearization (2.1) can now be written as

$$\begin{bmatrix} I \\ -K^{-1}M & -K^{-1}C \end{bmatrix} \begin{pmatrix} V_k \\ W_k \end{pmatrix} - \begin{pmatrix} V_k \\ W_k \end{pmatrix} H_k = \beta_k \begin{pmatrix} v_{k+1} \\ w_{k+1} \end{pmatrix} e_k^*, \tag{3.2}$$

from which we deduce that

$$W_k = V_{k+1}\underline{H}_k. \tag{3.3}$$

This implies that we have only to store the vectors V_k, v_{k+1}, and w_{k+1} to evaluate the recurrence relation, which contain $(2+k)n$ floating point numbers. Storing only V_k, v_{k+1}, and w_{k+1} results in an important reduction of the memory cost compared to Algorithm 3.1. The following algorithm implements this idea.

ALGORITHM 3.2 (Q-Arnoldi).

1. *Let* v_1 *and* w_1 *be chosen so that* $\|v_1\|_2^2 + \|w_1\|_2^2 = 1$.
2. *For* $j = 1, \ldots, k$ *do*
   - 2.1. *Compute* $\hat{w}_j = -K^{-1}(Mv_j + Cw_j)$ *and* $\hat{v}_j = w_j$.
   - 2.2. *Compute the Arnoldi coefficients*

$$h_j = \begin{bmatrix} V_{j-1}^*\hat{v}_j + \underline{H}_{j-1}^*(V_j^*\hat{w}_j) \\ v_j^*\hat{v}_j + w_j^*\hat{w}_j \end{bmatrix}.$$

   - 2.3. *Update*

$$\tilde{v}_j = \hat{v}_j - V_j h_j,$$
$$\tilde{w}_j = \hat{w}_j - [V_j \;\; w_j]\left(\begin{bmatrix} \underline{H}_{j-1} & 0 \\ 0 & 1 \end{bmatrix} h_j\right).$$

   - 2.4. *Normalize* $v_{j+1} = \tilde{v}_j/\beta_j$ *and* $w_{j+1} = \tilde{w}_j/\beta_j$ *with* $\beta_j = (\|\tilde{v}_j\|^2 + \|\tilde{w}_j\|^2)^{1/2}$.
   - 2.5. *Set the* j*th column of* $\underline{H}_j$ *as* $[h_j^T \;\; \beta_j]^T$.

   End for

The difference between Algorithm 3.1 and Algorithm 3.2 is only in Steps 2.2–2.3, where W_{j-1} is replaced by $V_j \underline{H}_{j-1}$. The cost for computing $\underline{H}_{j-1}^*(V_j^* \hat{w}_j)$ in Step 2.2 is $2(nj+j(j-1))$ flops, so that the total cost for Step 2.2 is $2(2nj+n+j(j-1))$ flops. The cost for computing $\tilde{w}_j$ in Step 2.3 is $2((j-1)j+n(j+1))$, and the computation of $\tilde{v}_j$ requires $2nj$ flops. Step 2.4 costs $8n$ flops, as for Algorithm 3.1. The total cost for Steps 2.2–2.4 is $8nj + 12n + 4j(j-1)$. For k iterations the cost is of the order of $4nk^2 + 16nk + \frac{4}{3}(k-1)k(k+1)$ flops. Algorithm 3.1 requires $4n(k+1)k$ flops. So, when k is significantly smaller than n (which is usually the case; otherwise the Arnoldi method is not suitable anyway), Steps 2.2–2.4 of Algorithms 3.1 and 3.2 have a cost of approximately $4nk^2$. Note that only $v_1, \ldots, v_{j+1}$ and w_{j+1} need to be stored on iteration j so that the memory requirements for the storage of the Arnoldi vectors for k iterations is limited to $n(k+2)$ with the Q-Arnoldi method. The storage for the Arnoldi method is of the order of $2n(k+1)$. Although Q-Arnoldi is slightly more expensive in computation time, the extra cost is usually small compared to the computation of $A^{-1}B\mathbf{v}_j$.

3.2. Other linearizations. In this section, we study the use of linearizations other than the companion form in (2.3). These are introduced for respecting special structures in the eigenvalues. Consider the vectorspace of linearizations [14] of the form

$$\mathbb{L}_1(Q) = \left\{ A - \lambda B : (A - \lambda B) \begin{pmatrix} \lambda \\ 1 \end{pmatrix} = \begin{pmatrix} \eta_1 Q(\lambda) \\ \eta_2 Q(\lambda) \end{pmatrix}, \eta_{1,2} \in \mathbb{C} \right\}, \tag{3.4}$$

where Q is defined in (1.1). From (3.4), we have

$$A = \begin{bmatrix} A_{11} & \eta_1 K \\ A_{21} & \eta_2 K \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} -\eta_1 M & A_{11} - \eta_1 C \\ -\eta_2 M & A_{21} - \eta_2 C \end{bmatrix},$$

where A_{11}, A_{21}, η_1, and η_2 can be freely chosen.

THEOREM 3.1. *Let A and B be defined following* (3.4)*, and let K be invertible. Then $A - \lambda B$ is a linearization of* (1.1) *iff A is invertible. In addition,* (2.2) *holds, and applying the Arnoldi method to $A^{-1}B$ produces Arnoldi vectors with the structure* (3.3).

Proof. Let

$$S = A^{-1}B = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix}.$$

From $B = AS$, i.e.,

$$\begin{bmatrix} -\eta_1 M & A_{11} - \eta_1 C \\ -\eta_2 M & A_{21} - \eta_2 C \end{bmatrix} = \begin{bmatrix} A_{11} & \eta_1 K \\ A_{21} & \eta_2 K \end{bmatrix} \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix},$$

it is easy to verify (2.2).

Formally, A does not need to be invertible for $AS = B$ to be true. If both $\eta_1 = \eta_2 = 0$, then $\det(A - \lambda B) = 0$ for all λ's, so $A - \lambda B$ is not a linearization. Suppose $\eta_1 \neq 0$. If we multiply the first block of A and B by η_2 and the second block row by η_1, we find the pencil $\tilde{A} - \tilde{B}$ with the same eigenvalues and eigenvectors, where

$$\tilde{A} = \begin{bmatrix} A_{11} & \eta_1 K \\ \eta_2 A_{11} - \eta_1 A_{21} & 0 \end{bmatrix}, \quad \tilde{B} = \begin{bmatrix} -\eta_1 M & A_{11} - \eta_1 C \\ 0 & \eta_2 A_{11} - \eta_1 A_{21} \end{bmatrix}.$$

Since K is nonsingular, A can be singular only when

$$\eta_2 A_{11} - \eta_1 A_{21}$$

is singular. Following Lemma 2.1, the pencil $\tilde{A} - \tilde{B}$ can only be a linearization when $\eta_2 A_{11} - \eta_1 A_{21}$ is nonsingular. In other words, A should be invertible for $A - \lambda B$ being a linearization of (1.1).

Since $A^{-1}B$ is the same matrix for all linearizations of this form, the Arnoldi method produces the same recurrence relation, which finishes the proof. ∎

One example that fits into this framework is the solution of palindromic eigenvalue problems [13]. Let $K = M^T$ and $C = C^T$; then (1.1) is called T-palindromic. If (λ, x) is an eigenpair to (1.1) and the associated left eigenvector is y so that $y^* Q(\lambda) = 0$, then λ^{-1} also is an eigenvalue with (right) eigenvector $\bar{y}$ and left eigenvector $\bar{x}$. In [13], methods that produce eigenvalue approximates that respect this spectral structure are advocated. They therefore introduce the linearization with $B = -A^T$ in (3.4) of the form

$$A = \begin{bmatrix} K & K \\ C - M & K \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} -M & K - C \\ -M & -M \end{bmatrix}.$$

This corresponds to $\eta_1 = \eta_2 = 1$, $A_{11} = K$, and $A_{21} = C - M$. A is invertible when K and $C - M - K$ are invertible, i.e., 0 and -1 are not eigenvalues of (1.1). The linearized pencil $A + \lambda(-B)$ is T-palindromic, since $(-B) = A^T$. Using $A^{-1}B$ in the Arnoldi method requires the inverse of K and $C - M - K = C - K - K^T$. However, note that the Ritz values from Arnoldi's method do not necessarily come in pairs of the form λ, λ^{-1}.

The generalization of the second companion form is given by

$$\mathbb{L}_2(Q) = \{A - \lambda B : (\lambda I \quad I)(A - \lambda B) = (\tilde{\eta}_1 Q(\lambda) \quad \tilde{\eta}_2 Q(\lambda)), \tilde{\eta}_{1,2} \in \mathbb{C}\}.$$

Similarly to $\mathbb{L}_1$, we can show that A and B take the form

$$A = \begin{bmatrix} A_{11} & A_{12} \\ \tilde{\eta}_1 K & \tilde{\eta}_2 K \end{bmatrix} \quad \text{with} \quad B = \begin{bmatrix} -\tilde{\eta}_1 M & -\tilde{\eta}_2 M \\ A_{11} - \tilde{\eta}_1 C & A_{12} - \tilde{\eta}_2 C \end{bmatrix}$$

and

$$BA^{-1} = \begin{bmatrix} 0 & -MK^{-1} \\ I & -CK^{-1} \end{bmatrix}.$$

Note that $A^{-1}B$ depends on A_{11}, A_{12}, and $\tilde{\eta}_{1,2}$.

The intersection of $\mathbb{L}_1$ and $\mathbb{L}_2$ is denoted by $\mathbb{DL}(Q)$ [14]. Its general form is

$$A = \begin{bmatrix} \eta_1 C - \eta_2 M & \eta_1 K \\ \eta_1 K & \eta_2 K \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} -\eta_1 M & -\eta_2 M \\ -\eta_2 M & -\eta_2 C + \eta_1 K \end{bmatrix}.$$

The common cases for symmetric K, C, and M are $\eta_{1,2} = \{0, 1\}$ and $\eta_{1,2} = \{1, 0\}$. Note that A is invertible iff

$$\eta_1 \eta_2 C - \eta_2^2 M - \eta_1^2 K$$

is invertible, i.e., $-\eta_2/\eta_1$ is not an eigenvalue of (1.1). Although working with pencils in $\mathbb{DL}$ does not seem important for the Arnoldi method, it might be of interest when using the Lanczos method; see [20, 2]. The pseudo-Lanczos method [20] is the Lanczos method applied to $A^{-1}B$ using the B pseudo-inner product; i.e., the Lanczos vectors are orthogonal with respect to B, where A and B are chosen in $\mathbb{DL}$. Using the B inner product $x^T B y$ rather than the Euclidean inner product $x^* y$ produces a tridiagonal H_k.

3.3. Applying a shift. In this section, we review ideas for shifting the eigenvalue problem, which is a key element in the shift-and-invert Arnoldi method. We first apply a shift to (1.1) in section 3.3.1, and then to the linearization (2.1) in section 3.3.2.

3.3.1. Shifting the quadratic equation. The convergence of eigenvalues near σ can be improved [21, 3] by shifting the eigenvalue problem (1.1) into

$$(\tilde{K} + (\lambda - \sigma)\tilde{C} + (\lambda - \sigma)^2\tilde{M})u = 0, \tag{3.5}$$

with

$$\tilde{K} = K + \sigma C + \sigma^2 M, \quad \tilde{C} = C + 2\sigma M, \quad \tilde{M} = M.$$

Without loss of generality, we can assume that $\sigma = 0$, by replacing K, C, and M by $\tilde{K}$, $\tilde{C}$, and $\tilde{M}$, respectively, and $\lambda - \sigma$ by λ.

3.3.2. Shifting the linearization. We can also shift (2.1) into

$$(A - \sigma B)^{-1}(A - \lambda B)y(\lambda) = 0.$$

The recurrence relation for $(A - \sigma B)^{-1}B$ becomes

$$\begin{bmatrix} A_{11} + \sigma\eta_1 M & \eta_1 K - \sigma A_{11} + \sigma\eta_1 C \\ A_{21} + \sigma\eta_2 M & \eta_2 K - \sigma A_{21} + \sigma\eta_2 C \end{bmatrix}^{-1} \begin{bmatrix} -\eta_1 M & A_{11} - \eta_1 C \\ -\eta_2 M & A_{21} - \eta_2 C \end{bmatrix} \begin{pmatrix} V_k \\ W_k \end{pmatrix}$$

$$= \begin{pmatrix} V_{k+1} \\ W_{k+1} \end{pmatrix} \underline{H}_k.$$

With $\tilde{A}_{j1} = A_{j1} + \sigma\eta_j M$ this becomes

$$\begin{bmatrix} \tilde{A}_{11} & \eta_1\tilde{K} - \sigma\tilde{A}_{11} \\ \tilde{A}_{21} & \eta_2\tilde{K} - \sigma\tilde{A}_{21} \end{bmatrix}^{-1} \begin{bmatrix} -\eta_1 M & \tilde{A}_{11} - \eta_1\tilde{C} + \eta_1\sigma M \\ -\eta_2 M & \tilde{A}_{21} - \eta_2\tilde{C} + \eta_2\sigma M \end{bmatrix} \begin{pmatrix} V_k \\ W_k \end{pmatrix}$$

$$= \begin{pmatrix} V_{k+1} \\ W_{k+1} \end{pmatrix} \underline{H}_k.$$

The pencil $(A - \sigma B) - \mu B$ does not lie in $\mathbb{L}_1(Q(\lambda - \sigma))$. However, when we introduce $Z_{k+1} = V_{k+1} - \sigma W_{k+1}$, we have

$$\begin{bmatrix} \tilde{A}_{11} & \eta_1\tilde{K} \\ \tilde{A}_{21} & \eta_2\tilde{K} \end{bmatrix}^{-1} \begin{bmatrix} -\eta_1 M & \tilde{A}_{11} - \eta_1\tilde{C} \\ -\eta_2 M & \tilde{A}_{21} - \eta_2\tilde{C} \end{bmatrix} \begin{pmatrix} Z_k \\ W_k \end{pmatrix} = \begin{pmatrix} Z_{k+1} \\ W_{k+1} \end{pmatrix} \underline{H}_k,$$

which is exactly the same as (3.2) with $V_{k+1} = Z_{k+1}$, where $\tilde{K}$, $\tilde{C}$, and M are related to the shifted problem (3.5). We compute $W_k = Z_{k+1}\underline{H}_k$ and $V_k = Z_{k+1} + \sigma W_k$.

3.4. Numerical stability. A few words about numerical stability are in order. In this section, we perform a traditional rounding error analysis on Algorithms 3.1 and 3.2.

The fact that we compute W_k from (3.3) changes the Arnoldi method in finite precision arithmetic. In this section, we show that, under certain conditions, the

Q-Arnoldi method is as backward stable for the recurrence relation as the Arnoldi method. More specifically, we shall give bounds to

$$\tau_R = \|W_k - V_{k+1}\underline{H}_k\|_F, \tag{3.6}$$

where $\mathbf{V}_{k+1}$ and $\underline{H}_k$ are computed by either the Arnoldi method or the Q-Arnoldi method.

The reader is referred to Higham [8, Chapter 3] for more details on computations with finite precision arithmetic. We denote by u the machine precision. We introduce the symbol $\lesssim$ to denote

$$\alpha \lesssim \beta \Leftrightarrow \alpha \leq c\beta + \mathcal{O}(u),$$

where c is a u independent constant. We also bound $\||X|\cdot|Y|\|_F \leq \|X\|_F \cdot \|Y\|_F$.

We define the error matrices F_j and G_j on the recurrence relation (3.1):

$$\hat{V}_j - V_{j+1}\underline{H}_j = F_j, \tag{3.7a}$$

$$\hat{W}_j - W_{j+1}\underline{H}_j = G_j. \tag{3.7b}$$

3.5. Analysis for the Arnoldi algorithm. We first show two lemmas that will help us to make a statement on the backward stability of the Arnoldi method.

LEMMA 3.2. *For all $j = 1, \ldots, k$ we have*

$$\|v_{j+1}\beta_j - \tilde{v}_j\| \lesssim u\|\tilde{v}_j\| \lesssim u\|v_{j+1}\|\beta_j, \tag{3.8a}$$

$$\|w_{j+1}\beta_j - \tilde{w}_j\| \lesssim u\|\tilde{w}_j\| \lesssim u\|w_{j+1}\|\beta_j, \tag{3.8b}$$

$$\left\|\begin{pmatrix} v_{j+1} \\ w_{j+1}\end{pmatrix}\beta_j - \begin{pmatrix} \tilde{v}_j \\ \tilde{w}_j\end{pmatrix}\right\| \lesssim u\left\|\begin{pmatrix} \tilde{v}_j \\ \tilde{w}_j\end{pmatrix}\right\| \lesssim u\beta_j. \tag{3.8c}$$

We also have

$$\|V_j\|_F^2 + \|W_j\|_F^2 = j + \mathcal{O}(u). \tag{3.9}$$

Proof. The proofs of (3.8a), (3.8b), and (3.8c) follow from the fact that v_{j+1} and w_{j+1} are computed as $v_{j+1} = \tilde{v}_j/\beta_j$ and $w_{j+1} = \tilde{w}_j/\beta_j$. The proof of (3.9) follows from [8, Theorem 18.2] with $m = 1$ for $\|v_j\|^2 + \|w_j\|^2 = 1 + \mathcal{O}(u)$. ∎

LEMMA 3.3. *In finite precision arithmetic, Algorithm* 3.1 *produces V_{j+1}, W_{j+1}, and $\underline{H}_j$ so that* (3.7) *holds with*

$$\|F_j\|_F \lesssim u\||V_{j+1}|\cdot|\underline{H}_j|\|_F \lesssim u\|V_{j+1}\|_F\|\underline{H}_j\|_F, \tag{3.10a}$$

$$\|G_j\|_F \lesssim u\||W_{j+1}|\cdot|\underline{H}_j|\|_F \lesssim u\|W_{j+1}\|_F\|\underline{H}_j\|_F, \tag{3.10b}$$

$$\left\|\begin{pmatrix} \hat{V}_j - V_{j+1}\underline{H}_j \\ \hat{W}_j - W_{j+1}\underline{H}_j\end{pmatrix}\right\|_F \lesssim u\|\underline{H}_j\|_F. \tag{3.10c}$$

In addition, we have

$$\left\|h_j - \begin{pmatrix} V_j \\ W_j\end{pmatrix}^* \begin{pmatrix} \hat{v}_j \\ \hat{w}_j\end{pmatrix}\right\| \lesssim u\left\|\begin{pmatrix} \hat{v}_j \\ \hat{w}_j\end{pmatrix}\right\|. \tag{3.11}$$

Proof. Recall that we can omit constant factors from error bounds using the notation $\lesssim$. We first prove (3.10a). We define

$$\tilde{f}_j = \hat{v}_j - V_j h_j - \tilde{v}_j, \tag{3.12}$$

where $\tilde{v}_j$ is computed in Step 2.3 of Algorithm 3.1. We have

$$\|\tilde{f}_j\| \lesssim u(\|\hat{v}_j\| + \||V_j| \cdot |h_j|\|).$$

Denote by f_j the last column of F_j:

$$f_j = \hat{v}_j - V_j h_j - v_{j+1}\beta_j = \tilde{f}_j + (\tilde{v}_j - v_{j+1}\beta_j), \tag{3.13}$$

where v_{j+1} and β_j are computed from Step 2.4. The application of Lemma 3.2 on Step 2.4 of Algorithm 3.1 readily produces

$$\|f_j\| \lesssim u(\|\hat{v}_j\| + \||V_j| \cdot |h_j|\| + \|v_{j+1}\|\beta_j) \lesssim u \left\| |V_{j+1}| \cdot \left| \begin{pmatrix} h_j \\ \beta_j \end{pmatrix} \right| \right\|,$$

using $\|\hat{v}_j\| \lesssim \||V_j||h_j|+|v_{j+1}|\beta_j\|$. Accumulating f_j in $F_j = [f_1, \ldots, f_j]$ proves (3.10a). The proofs for (3.10b) and (3.10c) are similar. We use (3.9) to bound (3.10c).

The proof of (3.11) readily follows from standard rounding error analysis. ∎

3.6. Analysis for the Q-Arnoldi algorithm. We define

$$\delta_j = \|V_j\|_F, \tag{3.14}$$

$$\gamma_j = \|[|V_j| \cdot |\underline{H}_{j-1}| \quad w_j]\|_F, \tag{3.15}$$

$$\tilde{\gamma}_{j+1} = \|[|V_j| \cdot |\underline{H}_{j-1}| \quad w_j \quad w_{j+1}]\|_F. \tag{3.16}$$

For the Q-Arnoldi algorithm, $W_j z$ and $\begin{pmatrix} V_j \\ W_j \end{pmatrix}^* \begin{pmatrix} \hat{v}_j \\ \hat{w}_j \end{pmatrix}$ are computed as

$$[V_j \underline{H}_{j-1} \quad w_j]z \quad \text{and} \quad \begin{pmatrix} \underline{H}_{j-1}^*(V_j^* \hat{w}_j) \\ w_j^* \hat{w}_j \end{pmatrix} + V_j^* \hat{v}_j, \tag{3.17}$$

respectively. The componentwise errors on the computation of (3.17) are of the order

$$u[|V_j| \cdot |\underline{H}_{j-1}| \quad |w_j|]|z| \quad \text{and} \quad u \left| \begin{pmatrix} |\underline{H}_{j-1}|^*(|V_j|^*|\hat{w}_j|) \\ |w_j|^*|\hat{w}_j| \end{pmatrix} + |V_j|^*|\hat{v}_j| \right|, \tag{3.18}$$

respectively. The normwise error bounds are

$$u\gamma_j\|z\| \quad \text{and} \quad u(\gamma_j + \delta_j) \left\| \begin{pmatrix} \hat{v}_j \\ \hat{w}_j \end{pmatrix} \right\|, \tag{3.19}$$

respectively.

We extend Lemma 3.3 to the Q-Arnoldi algorithm.

LEMMA 3.4. *In finite precision arithmetic, Algorithm* 3.2 *produces* V_{j+1}, W_{j+1}, *and* $\underline{H}_j$ *so that* (3.7) *holds with*

$$\|F_j\|_F \lesssim u\delta_{j+1}\|\underline{H}_j\|_F, \tag{3.20a}$$

$$\|G_j\|_F \lesssim u\gamma_{j+1}\|\underline{H}_j\|_F, \tag{3.20b}$$

$$\left\| \begin{pmatrix} \hat{V}_j - V_{j+1}\underline{H}_j \\ \hat{W}_j - W_{j+1}\underline{H}_j \end{pmatrix} \right\|_F \lesssim u\sqrt{\gamma_{j+1}^2 + \delta_{j+1}^2}\|\underline{H}_j\|_F. \tag{3.20c}$$

Proof. Similar to the proof of (3.10a), we find for the componentwise analysis that

$$|F_j| = |W_j - V_{j+1}\underline{H}_j| \lesssim u|V_{j+1}| \cdot |\underline{H}_j|,$$

which proves (3.20a).

We now prove (3.20b). We define

$$\tilde{g}_j = \hat{w}_j - [V_j \underline{H}_{j-1} \quad w_j] h_j - \tilde{w}_j, \tag{3.21}$$

where $\tilde{w}_j$ is computed in Step 2.3 of Algorithm 3.2. We have

$$\|\tilde{g}_j\| \lesssim u(\|\hat{w}_j\| + \left\| \left[\begin{array}{cc} |V_j| \cdot |\underline{H}_{j-1}| & |w_j| \end{array} \right] |h_j| \right\|).$$

Let

$$g_j = \hat{w}_j - W_j h_j - w_{j+1}\beta_j, \tag{3.22}$$

$$= \tilde{g}_j + (\tilde{w}_j - w_{j+1}\beta_j) + ([V_j \underline{H}_{j-1} \quad w_j] - W_j)h_j, \tag{3.23}$$

where w_{j+1} and β_j are computed from Step 2.4. Using Lemma 3.2, we find that

$$\begin{aligned} \|g_j\| &\lesssim u(\|\hat{w}_j\| + \|[|V_j| \cdot |\underline{H}_{j-1}| \quad |w_j|]|h_j|\| + \|w_{j+1}\|\beta_j + \|[|V_j| \cdot |\underline{H}_{j-1}| \quad 0]|h_j|\|) \\ &\lesssim u \left\| [|V_j| \cdot |\underline{H}_{j-1}| \quad |w_j| \quad |w_{j+1}|] \left| \begin{pmatrix} h_j \\ \beta_j \end{pmatrix} \right| \right\|. \end{aligned}$$

Accumulating g_j in $G_j = [g_1, \ldots, g_j]$ and noting that $\tilde{\gamma}_{j+1} \leq \gamma_{j+1}$ proves (3.20b). The proof for (3.20c) is similar. ∎

Let $\sigma_{\min}$ and $\sigma_{\max}$ denote the smallest and largest singular values, respectively. Define

$$\xi_{j,\min} = \sqrt{\sigma_{\min}\left(\underline{H}_{j-1}\right)^2 + 1}, \tag{3.24}$$

$$\xi_{j,\max} = \sqrt{\sigma_{\max}\left(\underline{H}_{j-1}\right)^2 + 1}. \tag{3.25}$$

Note that $\xi_{j,\min} \leq 1 \leq \xi_{j,\max}$. For vibration problems, S usually has small eigenvalues, usually leading to $\xi_{j,\min} \approx 1$. The choice of pole σ (see section 3.3) may influence the large singular values of S. It is common practice not to pick the pole close to an eigenvalue when several eigenvalues are wanted [7, 16]. In this case, $\xi_{j,\max}$ is not large.

THEOREM 3.5. *In exact arithmetic,*

$$\left\| \begin{pmatrix} V_{j-1} \\ |V_j| \cdot |\underline{H}_{j-1}| \end{pmatrix} \right\|_2 \leq \frac{\xi_{j,\max}}{\xi_{j,\min}}.$$

Proof. First,

$$\sigma_{\min}\left(\begin{pmatrix} I_{j-1} \\ \underline{H}_{j-1} \end{pmatrix} \right) = \lambda_{\min}^{1/2}(I + \underline{H}_{j-1}^* \underline{H}_{j-1}) = \sqrt{\sigma_{\min}\left(\underline{H}_{j-1}\right)^2 + 1} = \xi_{j,\min}.$$

Similarly,

$$\sigma_{\max}\left(\begin{pmatrix} I_{j-1} \\ \underline{H}_{j-1} \end{pmatrix} \right) = \xi_{j,\max}.$$

From

$$\begin{pmatrix} V_{j-1} \\ V_j \underline{H}_{j-1} \end{pmatrix} = \begin{bmatrix} V_j & 0 \\ 0 & V_j \end{bmatrix} \begin{pmatrix} \underline{I}_{j-1} \\ \underline{H}_{j-1} \end{pmatrix}$$

and

$$\left\| \begin{pmatrix} V_{j-1} \\ V_j \underline{H}_{j-1} \end{pmatrix} \right\|_2 = 1,$$

we have that

$$\xi_{j,\max}^{-1} \leq \|V_j\|_2 \leq \xi_{j,\min}^{-1}.$$

The proof follows from

$$\left\| \begin{bmatrix} V_j & 0 \\ 0 & V_j \end{bmatrix} \begin{pmatrix} \underline{I}_{j-1} \\ \underline{H}_{j-1} \end{pmatrix} \right\| \leq \xi_{j,\min}^{-1} \xi_{j,\max}. \qquad \square$$

The conclusion from this section is that a loss of precision is possible in the computation of $\underline{H}_k$ (see (3.11) and (3.19)) and the recurrence relation in the Q-Arnoldi process when $\xi_{k,\max}/\xi_{k,\min}$ is large.

4. The solution of the quadratic eigenvalue problem. To simplify, we write S, defined in (2.2), in the form

$$S = \begin{bmatrix} & I \\ S_1 & S_2 \end{bmatrix}.$$

The solution of the quadratic eigenvalue problem by the shift-and-invert Arnoldi method is the objective of this section. For the computation of a number of eigenvalues of a non-Hermitian linear problem, we usually compute a partial Schur form. The idea is that we want the computed Schur vectors to have the structure of the exact Schur vectors, i.e., the form

$$\begin{pmatrix} U_k \\ U_k S_k \end{pmatrix}, \tag{4.1}$$

where S_k is the (upper-triangular) Schur matrix. The Schur vectors from the Arnoldi method do not have the form (4.1). It turns out that when we force the Schur vectors to satisfy the structure (4.1), we can keep the structure of the Krylov vectors in the form (3.3). In addition, implicit restarting also maintains the structure of the Krylov vectors.

We first introduce the notion of the Q-Arnoldi triple.

4.1. Definition and properties of Q-Arnoldi triples.

DEFINITION 4.1. *$\mathcal{Q} = \{V_{k+1}, \underline{H}_k, w_{k+1}\}$ is a Q-Arnoldi triple associated with S iff $V_{k+1} \in \mathbb{C}^{n\times(k+1)}$, $w_{k+1} \in \mathbb{C}^n$, $\underline{H}_k \in \mathbb{C}^{(k+1)\times k}$, and for*

$$\mathbf{V}_k = \begin{pmatrix} V_k \\ V_{k+1}\underline{H}_k \end{pmatrix} \quad \text{and} \quad \mathbf{V}_{k+1} = \begin{pmatrix} V_k & v_{k+1} \\ V_{k+1}\underline{H}_k & w_{k+1} \end{pmatrix}, \tag{4.2}$$

1. *the Arnoldi recurrence relation* (3.1) *holds, and*
2. *the Arnoldi vectors are orthogonal:*

$$\|I - \mathbf{V}_{k+1}^* \mathbf{V}_{k+1}\| = 0. \tag{4.3}$$

DEFINITION 4.2. *We denote by $\mathbf{Q}_k(S)$ the set of all Q-Arnoldi triples associated with S.*

4.1.1. Inexact Q-Arnoldi triples. In practice, we may allow a small error on (3.1) and (4.3) so that

$$S\mathbf{V}_k - \mathbf{V}_{k+1}\underline{H}_k = F_k \tag{4.4}$$

and

$$\left\|I - \mathbf{V}_{k+1}^*\mathbf{V}_{k+1}\right\| = \gamma_k, \tag{4.5}$$

where F_k can be considered a backward error on S.

DEFINITION 4.3. *The set of inexact Q-Arnoldi triples*

$$\mathbf{Q}_k(S, \eta, \rho)$$

consists of $\{V_{k+1}, \underline{H}_k, w_{k+1}\}$ *that satisfy* (4.4), (4.5), *and* (4.2) *with* $\|F_k\| \leq \eta$ *and* $\gamma_k \leq \rho$.

4.1.2. Transformations of (inexact) Q-Arnoldi triples.

DEFINITION 4.4. *Let* Z *be a full column rank* $k+1 \times p+1$ *matrix of the form* $Z = \left(\begin{smallmatrix} Z_1 & z \\ 0 & \zeta \end{smallmatrix}\right)$ *with* Z_1 *a* $k \times p$ *matrix and* $k \geq p$. *We define the transformation*

$$\mathcal{T}_Z\ \{V_{k+1}, \underline{H}_k, w_{k+1}\} = \{V_{k+1}Z, Z^\dagger \underline{H}_k Z_1, V_{k+1}\underline{H}_k z + w_{k+1}\zeta\},$$

where $Z^\dagger$ *is the generalized inverse, i.e.,* $Z^\dagger Z = I$.

The following theorem characterizes the transformation of an (inexact) Q-Arnoldi triple.

THEOREM 4.5. *Let* $\mathcal{Q} \in \mathbf{Q}_k(S, \eta, \rho)$. *Let* $\mathcal{T}_Z$ *be a transformation as defined by Definition* 4.4. *If*

$$ZZ^\dagger \underline{H}_k Z_1 = \underline{H}_k Z_1,$$

then

$$\mathcal{T}_Z\mathcal{Q} \in \mathbf{Q}_p(S, \eta\|Z_1\|, \|Z\|^2\rho + \|I - Z^*Z\|).$$

Proof. Let $\mathcal{Q} = \{V_{k+1}, \underline{H}_k, w_{k+1}\} \in \mathbf{Q}_k(S, \eta, \rho)$. Under the condition of the theorem, the elements of $\mathcal{T}_Z\mathbf{Q}_k(S)$ respect the structure (4.2). Multiplication of (4.4) on the right by Z_1 proves that the error on the recurrence relation of the transformed triple is bounded by $\|Z_1\|\eta$. Finally, we have that

$$I - Z^*\mathbf{V}_{k+1}^*\mathbf{V}_{k+1}Z = Z^*(I - \mathbf{V}_{k+1}^*\mathbf{V}_{k+1})Z + (I - Z^*Z),$$

which proves the theorem. ∎

When Z is square, Theorem 4.5 always holds. When, in addition to the conditions of Theorem 4.5, $Z^*Z = I$, $\mathcal{T}_Z\mathbf{Q}_k(S) \subset \mathbf{Q}_p(S)$.

4.1.3. Modification of the vectors of a Q-Arnoldi triple. Let $\{V_{k+1}, \underline{H}_k, w_{k+1}\} \in \mathbf{Q}_k(S)$. Suppose we modify the second block of the Arnoldi vectors as follows: $\tilde{W}_k = W_k + v_{k+1}g^*$. Not surprisingly, (4.2), (3.1), and (4.3) are broken. With $\tilde{\mathbf{V}}_k = \left(\begin{smallmatrix} V_k \\ \tilde{W}_k \end{smallmatrix}\right)$, we have that the recurrence relation becomes

$$S\tilde{\mathbf{V}}_k - \tilde{\mathbf{V}}_{k+1}\underline{H}_k = G_k := \begin{pmatrix} v_{k+1}g^* \\ S_2 v_{k+1}g^* - v_{k+1}g^*H_k \end{pmatrix},$$

where

$$\|G_k\| \leq (\|S_2 v_{k+1}\| + \|v_{k+1}\|\|H_k\| + 1)\|g\|. \tag{4.6}$$

The structure of the vectors (4.2) can be restored by modifying $\underline{\tilde{H}}_k = \underline{H}_k + e_{k+1}g^*$. The recurrence relation for the new $\underline{H}_k$ becomes

$$S\tilde{\mathbf{V}}_k - \tilde{\mathbf{V}}_{k+1}\underline{\tilde{H}}_k = \tilde{G}_k := \begin{pmatrix} 0 \\ S_2 v_{k+1}g^* - v_{k+1}g^* H_k - w_{k+1}g^* \end{pmatrix}. \tag{4.7}$$

The upper bound (4.6) also holds for $\tilde{G}_k$. The orthogonality of $\tilde{V}_k$ is restored by applying $\mathcal{T}_{Z^{-1}}$ to the Q-Arnoldi triple, where Z is upper-triangular and so that $\tilde{\mathbf{V}}_k^* \tilde{\mathbf{V}}_k = Z^* Z$, which can be computed by a Cholesky factorization.

Suppose we modify the first block of the Arnoldi vectors as follows: $\hat{V}_k = V_k + v_{k+1}g^*$; then (4.2) is restored by modifying $\underline{\hat{H}}_k = \underline{H}_k - e_{k+1}g^* H_k$. With $\hat{\mathbf{V}}_k = \left(\begin{smallmatrix} \hat{V}_k \\ W_k \end{smallmatrix}\right)$, we have that the recurrence relation for the new vectors becomes

$$S\hat{\mathbf{V}}_k - \hat{\mathbf{V}}_{k+1}\underline{\hat{H}}_k = \begin{pmatrix} 0 \\ S_1 v_{k+1}g^* - w_{k+1}g^* H_k \end{pmatrix}. \tag{4.8}$$

The orthogonality can be restored in the same way as for $\tilde{\mathbf{V}}_k$.

4.2. Computing Ritz vectors and Schur vectors.

4.2.1. Ritz vectors. The Ritz vectors corresponding to Ritz value θ have the form $x = \left(\begin{smallmatrix} x_1 \\ x_2 \end{smallmatrix}\right) = \left(\begin{smallmatrix} V_k z \\ V_{k+1}\underline{H}_k z \end{smallmatrix}\right)$, where $H_k z = \theta z$. When (θ, x) is an eigenpair of S, $x_2 = \theta x_1$. As a Ritz vector of (1.1), we can return x_2/θ or x_1.

In this section, we study which of these is the best choice. Let the residual of the Ritz pair computed by the Arnoldi method be

$$\begin{pmatrix} r_1 \\ r_2 \end{pmatrix} = \begin{bmatrix} 0 & I \\ S_1 & S_2 \end{bmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} - \theta \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} x_2 - \theta x_1 \\ S_1 x_1 + S_2 x_2 - \theta x_2 \end{pmatrix}. \tag{4.9}$$

If we use x_1 as a Ritz vector for (1.1), the Ritz vector for the linearization is then

$$\tilde{x} = \begin{pmatrix} x_1 \\ \theta x_1 \end{pmatrix}. \tag{4.10}$$

The residual is

$$\begin{bmatrix} 0 & I \\ S_1 & S_2 \end{bmatrix} \begin{pmatrix} x_1 \\ \theta x_1 \end{pmatrix} - \theta \begin{pmatrix} x_1 \\ \theta x_1 \end{pmatrix} = \begin{pmatrix} 0 \\ -(S_2 - \theta I)r_1 + r_2 \end{pmatrix}.$$

If we use x_2/θ as a Ritz vector for (1.1), the Ritz vector for the linearization is then

$$\hat{x} = \begin{pmatrix} \theta^{-1} x_2 \\ x_2 \end{pmatrix}. \tag{4.11}$$

The residual is

$$\begin{bmatrix} 0 & I \\ S_1 & S_2 \end{bmatrix} \begin{pmatrix} \theta^{-1} x_2 \\ x_2 \end{pmatrix} - \theta \begin{pmatrix} \theta^{-1} x_2 \\ x_2 \end{pmatrix} = \begin{pmatrix} 0 \\ \theta^{-1} S_1 r_1 + r_2 \end{pmatrix}.$$

The conclusion from this analysis is that for large θ there may be an advantage in using x_2/θ and for small θ in using x_1. From (4.10) and (4.11), we derive that if x is

close enough to an eigenvector, $\|\tilde{x}\| \approx \|\hat{x}\|$. Alternatively, the norms $\|S_1\|$ and $\|S_2\|$ may also play a role in the decision to make the choice.

Related to the choice of the first or second component is the difference $x_2 - \theta x_1$. If this difference is small, it probably does not make much difference which component we take.

THEOREM 4.6. *Recall* (3.24). *Let* $x_1 = V_k z$ *and* $x_2 = W_k z$ *with* $H_k z = \theta z$ *and* $\|z\| = 1$ *and define* $\rho = \beta_k |e_k^* z|$.

$$\|x_2 - \theta x_2\|_1 \leq \xi_{k,\min}^{-1} \rho.$$

Proof. From (4.9), we have that

$$\|x_2 - \theta x_1\|_2 = \beta_k \|v_{k+1}\|_2 e_k^* z. \qquad \square$$

We conclude that $\|x_2 - \theta x_1\|_2$ is at most ρ but can be smaller. Recall that

$$\xi_{k,\min} = \sqrt{1 + \sigma_{\min}^2(\underline{H}_k)} > 1,$$

which is large when the singular values of $\underline{H}_k$ are large.

4.2.2. Schur decomposition. The eigenvectors usually do not form an orthogonal set of vectors and are not even guaranteed to exist (in the defective case). The Schur vectors always form an orthogonal basis and a Schur decomposition always exists.

For the linearized quadratic eigenvalue problem, the Schur decomposition of S is

$$S \begin{pmatrix} U \\ UT \end{pmatrix} = \begin{pmatrix} U \\ UT \end{pmatrix} T.$$

The diagonal elements of T are the Ritz values. (In the case of real matrices, T is in pseudo–upper-triangular form when a Ritz value is complex. For the details, see [6, section 7.4].)

Let $H_k Z_k = Z_k T_k$ be the Schur decomposition of H_k. Define the residual $r_k^* = \beta_k e_k^* Z_k$. The Schur vectors computed from a Q-Arnoldi triple have the form

$$\mathbf{U}_k = \mathbf{V}_k Z_k = \begin{pmatrix} V_k Z_k \\ V_k Z_k T_k + v_{k+1} r_k^* \end{pmatrix}. \tag{4.12}$$

The structure in the Schur vectors is lost in the Krylov subspace for the same reasons as in the case of the Ritz vectors. However, we can similarly select the upper or lower components as Schur vectors. When we do this, we not only add an error in the recurrence relation but also perturb the orthogonality of the basis vectors. We study this problem in detail in section 4.4.

4.3. Implicit restarting. When k gets large, the storage and computational costs of the Arnoldi method can become unacceptably high. Therefore, some form of restarting or reduction of the basis is desirable. The idea is to reduce the Krylov subspace by throwing away a part of the spectrum we are not interested in.

Implicit restarting in Arnoldi's method was first introduced by Sorensen [22]. Sorensen uses implicit QR steps. Variations on this theme have been proposed where the Schur form of the Hessenberg matrix is truncated [26, 23]. This is mathematically equivalent to [22] using exact shifts.

4.3.1. Implicit QR step. One way to perform such a reduction is called implicit restarting and was proposed by Sorensen [22]. Also see [22, 19, 11, 12, 17]. The idea is to apply an orthogonal transformation to H_k that pushes the p desired Ritz values of H_k to the principle $p \times p$ block. The orthogonal transformation produces a reduction of the subspace of dimension $k+1$ to $p+1$ keeping the p desired Ritz values.

When Z results from the QR factorization $\underline{H}_k - \mu \underline{I}$, we have that

$$\underline{Z}_k^* \underline{H}_k = R_k + \mu \underline{Z}_k^* \underline{I},$$

and so

$$\underline{Z}_k \underline{Z}_k^* \underline{H}_k \underline{Z}_{k-1} = \underline{Z}_k \left(R_k \underline{Z}_{k-1} + \mu I \right) = \underline{H}_k \underline{Z}_{k-1}.$$

So, if $\mathcal{Q} = \{V_{k+1}, \underline{H_k}, w_{k+1}\} \in \mathbf{Q}_k(S)$, following Theorem 4.5, $\mathcal{T}_Z \mathcal{Q} \in \mathbf{Q}_{p=k-1}(S)$.

4.3.2. Purging. Another way to reduce the subspace dimension is purging [11]. The idea here is to purge the undesired part of the Schur factorization of H_k.

Recall the definitions of T_k, Z_k, and r_k from section 4.2.2. By multiplying on the right by Z_k, the Arnoldi recurrence relation (3.1) can be written in terms of Schur vectors as follows:

$$S\mathbf{V}_k Z_k - \mathbf{V}_k Z_k T_k = \mathbf{v}_{k+1} r_k^*. \tag{4.13}$$

Let the Schur form be ordered so that the last $k-p$ diagonal elements in T_k are unwanted Ritz values. The idea of purging is to keep the first p Schur vectors in the basis. Removing the last $k-p$ columns from (4.13) produces

$$S\mathbf{V}_k Z_p - [\mathbf{V}_k Z_p \;\; \mathbf{v}_{k+1}] \begin{pmatrix} T_p \\ r_p^* \end{pmatrix} = 0, \tag{4.14}$$

where Z_p are the first p columns of Z, T_p is the leading $p \times p$ block of T_k, and r_p are the first p elements of r_k. There exists a unitary U_p so that

$$\underline{\tilde{H}}_p = \begin{pmatrix} U_p & 0 \\ 0 & 1 \end{pmatrix}^* \begin{pmatrix} T_p \\ r_p^* \end{pmatrix} U_p$$

is $p+1 \times p$ upper Hessenberg [6].

Let $\mathcal{T}$ have transformation matrix $\left(\begin{smallmatrix} Z_p U_p & 0 \\ 0 & 1 \end{smallmatrix}\right)$ (Definition 4.4). From

$$\underline{H}_k Z_p = \begin{bmatrix} Z_p & 0 \\ 0 & 1 \end{bmatrix} \begin{pmatrix} T_p \\ r_p^* \end{pmatrix},$$

we derive that

$$\begin{bmatrix} Z_p & \\ & 1 \end{bmatrix} \begin{bmatrix} Z_p & \\ & 1 \end{bmatrix}^* \underline{H}_k Z_p = \underline{H}_k Z_p,$$

and so

$$\begin{bmatrix} Z_p U_p & \\ & 1 \end{bmatrix} \begin{bmatrix} Z_p U_p & \\ & 1 \end{bmatrix}^* \underline{H}_k Z_p U_p = \underline{H}_k Z_p U_p.$$

We conclude that $\mathcal{T}\{V_{k+1}, \underline{H}_k, w_{k+1}\} \in \mathbf{Q}_p(S)$.

4.4. Locking. Suppose that the first l elements in r_k are smaller than a convergence tolerance. The idea of locking is to set these small elements explicitly to zero assuming that the Schur vectors are exact. Decompose $r_k^* = [r_l^* \;\; r_{k-l}^*]$. Locking introduces an error in the recurrence relation:

$$S\mathbf{U}_k - [\mathbf{U}_k \;\; \mathbf{v}_{k+1}] \begin{pmatrix} T_k \\ [0 \;\; r_{k-l}^*] \end{pmatrix} = \mathbf{v}_{k+1}(r_l^* \;\; 0). \tag{4.15}$$

This can be considered a backward error on the solution. The corresponding Q-Arnoldi triple is in $\mathbf{Q}(S, \|r_l\|, 0)$. Reasons for the use of locking in eigenvalue codes are the reduction of the dimension of the Krylov subspace and the computation of multiple eigenvalues without the need of block methods.

For linear problems it is accepted that the recurrence relation of Arnoldi's method has a small error. The residual term in the right-hand side of (4.15) is usually considered a backward error on S. The Bauer–Fike theorem [21, Theorem 3.6] shows an upper bound to the perturbation of the eigenvalues that is proportional to $\|r_l\|$ and that is small when the eigenvectors associated with different eigenvalues are almost orthogonal. The Schur vectors form an orthogonal set, so the orthogonality is preserved. In the following, we aim to preserve the structure of the Schur vectors (4.12). As we will see, this modifies the error on the recurrence relation and destroys the orthogonality. The goal of this section is to restore the orthogonality and analyze the impact on the recurrence relation using the results from section 4.1.3.

When we use the upper component as Schur vectors of the quadratic eigenvalue problem, the Schur vectors obtain the form

$$\tilde{\mathbf{U}}_k = \begin{pmatrix} V_k Z_l & U_{1,k-l} \\ V_k Z_l T_l & U_{2,k-l} \end{pmatrix} = \mathbf{U}_k - \begin{pmatrix} 0 & 0 \\ v_{k+1} r_l^* & 0 \end{pmatrix}. \tag{4.16}$$

Following (4.7) with $g^* = -[r_l^* \;\; 0]$, we find

$$\underline{\tilde{H}}_k = \begin{pmatrix} T_k \\ [0 \;\; r_{k-l}^*] \end{pmatrix}.$$

This is precisely the matrix we want to have with locking. Recall that $\|\tilde{G}_k\| \simeq \|G_k\| \sim \|r_l\|$ is small. The new basis can be orthogonalized by applying an appropriate transformation.

Similarly, we can use the lower part of $\mathbf{U}_k$ as Schur vectors. Decompose

$$Z_k = [Z_l \;\; Z_{k-l}] \quad \text{and} \quad T_k = \begin{bmatrix} T_l & T_{l,k-l} \\ & T_{k-l} \end{bmatrix}.$$

Now define Schur vectors using the lower part of $\mathbf{U}_l$:

$$\hat{\mathbf{U}}_k = \begin{pmatrix} V_k Z_l + v_{k+1} r_l^* T_l^{-1} & U_{1,k-l} \\ V_k Z_l T_l + v_{k+1} r_l^* & U_{2,k-l} \end{pmatrix} = \mathbf{U}_k - \begin{pmatrix} v_{k+1} r_l^* T_l^{-1} & 0 \\ 0 & 0 \end{pmatrix}. \tag{4.17}$$

This assumes that T_l is nonsingular. With $g^* = -[r_l^* T_l^{-1} \;\; 0]$, following (4.8), the structure of the vectors is restored by using

$$\underline{\hat{H}}_k = \begin{pmatrix} T_k \\ [0 \;\; \hat{r}_{k-l}^*] \end{pmatrix},$$

with $\hat{r}_{k-l}^* = r_{k-l}^* - r_l^* T_l^{-1} T_{l,k-l}$. The most important point is that the residual term corresponding to the first l Ritz values is set equal to zero. The residual terms of the remaining Ritz values are modified. This is not the case when $\tilde{\mathbf{U}}_k$ is used as the Schur basis. The error on the recurrence relation is again proportional to $\|r_l\|$.

TABLE 5.1
Illustration of instabilities in the Q-Arnoldi method. $\gamma_\perp = \|I - \mathbf{V}_{k+1}^* \mathbf{V}_{k+1}\|_F$ is the deviation of orthogonality, and γ_R is the error on the recurrence relation.

ζ	1		10^4		10^6	
$\kappa(\underline{H}_k)$	30.0		$1 \cdot 10^8$		$1 \cdot 10^{12}$	
$\|\underline{H}_k\|_2$	1.6		$1 \cdot 10^8$		$1 \cdot 10^{12}$	
$\frac{\sqrt{\gamma_k^2+\delta_k^2+1.0}}{\sqrt{k+1}}$	1.03		$3.66\,10^6$		$1.66\,10^{10}$	
	$\gamma_\perp$	γ_R	$\gamma_\perp$	γ_R	$\gamma_\perp$	γ_R
Arnoldi	$1 \cdot 10^{-13}$	$1 \cdot 10^{-16}$	$5 \cdot 10^{-14}$	$1 \cdot 10^{-16}$	$2 \cdot 10^{-13}$	$2 \cdot 10^{-16}$
Q-Arnoldi	$3 \cdot 10^{-13}$	$1 \cdot 10^{-16}$	$4 \cdot 10^{-10}$	$6 \cdot 10^{-12}$	3.0	$4 \cdot 10^{-6}$

5. Numerical examples.

5.1. Illustration of numerical instabilities in Q-Arnoldi. From section 3.4, we can see that the Q-Arnoldi method may lose stability when γ_k is large. This is possible only when $\|\underline{H}_k\|_2$ and $\kappa(\underline{H}_k)$ are large.

We have run $k = 10$ iterations of the Arnoldi method for a problem of dimension $n = 10,000$ with $K = I$, $C = \zeta I$, and $M = \zeta \mathrm{diag}(\mu_1, \ldots, \mu_n)$, where $\mu_j = 1/j$ for three values of ζ. Table 5.1 illustrates the numerical behavior of the Arnoldi and Q-Arnoldi algorithms for this example. The Q-Arnoldi algorithm is sensitive to large ζ's. The example illustrates that scaling the matrices may help improve the numerical stability of the Q-Arnoldi algorithm: indeed, the eigenvectors are the same for all cases, independent of ζ, and the eigenvalues of (1.1) are divided by ζ, but when $\zeta = 1$, K, C, and M have norms around one.

5.2. Selection of component of Ritz vectors. Consider the quadratic eigenvalue problem (1.1) with $K = I$, $M = \mathrm{diag}(\mu_1, \ldots, \mu_n)$, and $C = 0.01M$ with $\mu_j = 1/j$ for $n = 10,000$. We have run 10 steps of the Arnoldi method with an initial vector with equal components. Let $(\theta, x = \left(\begin{smallmatrix} x_1 \\ x_2 \end{smallmatrix}\right))$ be a Ritz vector returned by the Arnoldi method. Define

$$\begin{aligned} \rho &= \|A^{-1}(\theta A - B)x\|, \\ \rho_1 &= \|K^{-1}(\theta^2 K + \theta C + M)x_1\|, \\ \rho_2 &= \|K^{-1}(\theta^2 K + \theta C + M)x_2\|. \end{aligned}$$

Table 5.2 shows the Ritz values and the corresponding residual norms. For this example, x_2 shows to be a better Ritz vector than x_1 for the large Ritz values.

5.3. Quadratic eigenvalue problem for an acoustic box. In this section we study the problem of an acoustic box with walls covered with carpet with dimensions 0.54m × 0.54m × 0.55m. The material has a complex speed of sound $340 + i3.4$, and the density is 1.225kg/m^3. The box is discretized with 64,710 hexahedral elements.

The matrices are produced by ACTRAN [5]. The problem to be solved has the form (1.1) and $n = 13,623$. We want to compute the 50 eigenvalues with imaginary part larger than 600. We applied the shift $\sigma = 600i$; see section 3.3. We used the following algorithm.

ALGORITHM 5.1 (restarted Q-Arnoldi method).

1. *Choose* $\mathbf{v}_1$ *randomly and normalize.*
2. *Until the wanted eigenvalues have converged, do:*
   2.1. *Build a Krylov subspace of dimension* k.

TABLE 5.2
Comparison of Ritz vectors.

TABLE 5.3
$\sqrt{\gamma_k^2 + \delta_k^2}$ for the different restarts in the solution of the quadratic eigenvalue problem of the box.

Before restart	2.14777
First restart	1.93901
Second restart	1.73840
Third restart	1.69189

2.1. *Compute Ritz values, Ritz vectors, and residual norms.*
2.2. *Order the Ritz values in increasing distance to σ.*
2.3. *Purge the last $m - p$ columns of the recurrence relation.*

We solved the problem using the Arnoldi method with $k = 100$ and $p = 50$. The first iteration costs $k = 100$ products with S. In Step 2.3, the purging operation keeps p iteration vectors with Ritz values corresponding to the Ritz values nearest σ. The goal of the next iterations is to improve these values. The next call to Step 2.1 requires only $k - p$ additional iterations to obtain a subspace of dimension k. After three restarts, 50 Ritz values were computed with residual norms smaller than 10^{-8}. The computations were carried out on a Linux PC. The final loss of orthogonality in the Q-Arnoldi algorithm was

$$\|I - \mathbf{V}_{k+1}^* \mathbf{V}_{k+1}\|_F \simeq 3.1\, 10^{-13}.$$

For the Arnoldi algorithm we also had

$$\|I - \mathbf{V}_{k+1}^* \mathbf{V}_{k+1}\|_F \simeq 3.1\, 10^{-13}.$$

Table 5.3 shows $\sqrt{\gamma_k^2 + \delta_k^2}$ for the different restarts. For all restarts, $\sqrt{\gamma_k^2 + \delta_k^2}$ is small, so we do not expect numerical difficulties. This is no surprise since the shift $\sigma = 600i$ is not close to an eigenvalue of (1.1), so $\|\underline{H}_k\|_2 \leq \|S\|_2$ is small.

6. Conclusions. The Q-Arnoldi algorithm is a memory efficient implementation of the Arnoldi method for specific choices of linearization of the quadratic eigenvalue problem.

We have proposed an algorithm that preserves the structure of the Schur vectors and that shows that implicit restarting, purging, and locking similarly preserve the structure of the Arnoldi vectors.

As for the choice of linearization, due to A^{-1}, the Arnoldi method produces the same results for any linearization in $\mathbb{L}_1$. The same conclusion holds for the SOAR

method. This also implies (as we already knew) that the Arnoldi method in its standard form is not able to preserve structure.

An important conclusion lies in the influence of $\xi_{\min}$ and $\xi_{\max}$. The ratio should not be far away from one in order to reduce the chance of cancelation in the numerical computations. In addition, the components of the Ritz vectors lie in the same direction when $\xi_{\min}$ is large. However, as we mentioned earlier, for the shift-and-invert transformation, $\xi_{\min}$ usually lies close to one. We have some freedom in choosing the pole σ to keep $\xi_{\max}$ low. The derivation of scalings of S_1 and S_2 is still an open problem. Note that S_1 and S_2 are known only in factored forms $-K^{-1}C$ and $-K^{-1}M$, respectively.

The conclusion is not that the SOAR method is useless when more than one eigenvalue needs to be computed or restarting the Arnoldi process is required. The Q-Arnoldi algorithm produces a Krylov subspace, whereas the SOAR method projects K, C, and M on V_{k+1}. This is still possible in a postprocessing step in the Q-Arnoldi algorithm in order to improve the Ritz values or impose spectral structure.

The extension to higher order polynomials,

$$(A_0 + \lambda A_1 + \cdots + \lambda^p)u = 0,$$

is straightforward and leads to a similar algorithm with similar conclusions.

HOW TO MAKE SIMPLER GMRES AND GCR MORE STABLE*

PAVEL JIRÁNEK†, MIROSLAV ROZLOŽNÍK‡, AND MARTIN H. GUTKNECHT§

Abstract. In this paper we analyze the numerical behavior of several minimum residual methods which are mathematically equivalent to the GMRES method. Two main approaches are compared: one that computes the approximate solution in terms of a Krylov space basis from an upper triangular linear system for the coordinates, and one where the approximate solutions are updated with a simple recursion formula. We show that a different choice of the basis can significantly influence the numerical behavior of the resulting implementation. While Simpler GMRES and ORTHODIR are less stable due to the ill-conditioning of the basis used, the residual basis is well-conditioned as long as we have a reasonable residual norm decrease. These results lead to a new implementation, which is conditionally backward stable, and they explain the experimentally observed fact that the GCR method delivers very accurate approximate solutions when it converges fast enough without stagnation.

1. Introduction.

In this paper we consider certain methods for solving a system of linear algebraic equations

$$Ax = b, \qquad A \in \mathbb{R}^{N\times N}, \qquad b \in \mathbb{R}^N, \tag{1.1}$$

where A is a large and sparse nonsingular matrix that is, in general, nonsymmetric. For solving such systems, Krylov subspace methods are very popular. They build a sequence of iterates x_n $(n = 0, 1, 2, \ldots)$ such that $x_n \in x_0 + \mathcal{K}_n(A, r_0)$, where $\mathcal{K}_n(A, r_0) \equiv \mathrm{span}\{r_0, Ar_0, \ldots, A^{n-1}r_0\}$ is the nth Krylov subspace generated by the matrix A from the residual $r_0 \equiv b - Ax_0$ that corresponds to the initial guess x_0. Many approaches for defining such approximations x_n have been proposed; see, e.g., the books by Greenbaum [9], Meurant [16], and Saad [22]. In particular, due to their smooth convergence behavior, minimum residual methods satisfying

$$\|r_n\| = \min_{\widetilde{x}\in x_0+\mathcal{K}_n(A,r_0)} \|b - A\widetilde{x}\|, \qquad r_n \equiv b - Ax_n, \tag{1.2}$$

are widely used; see, e.g., the GMRES algorithm of Saad and Schultz [23]. We recall that the minimum residual property (1.2) is equivalent to the orthogonality condition

$$r_n \perp A\mathcal{K}_n(A, r_0),$$

where $\perp$ is the orthogonality relation induced by the Euclidean inner product $\langle \cdot, \cdot \rangle$.

The classical implementation of GMRES [23] makes use of a nested sequence of orthonormal bases of the Krylov subspaces $\mathcal{K}_n(A, r_0)$. These bases are generated by the Arnoldi process [2], and the approximate solution x_n satisfying the minimum residual property (1.2) is constructed from the transformed least squares problem with an upper Hessenberg matrix. This problem is solved via its recursive QR factorization, updated by applying Givens rotations. Once the norm of the residual is small enough, which can be seen without explicitly solving the least squares problem, the triangular system with the computed R-factor is solved, and the approximate solution x_n is computed. In [3, 11, 18] it was shown that this "classical" version of the GMRES method is backward stable provided that the Arnoldi process is implemented using the modified Gram–Schmidt algorithm or Householder reflections.

In this paper we deal with a different approach. Instead of building an orthonormal basis of $\mathcal{K}_n(A, r_0)$, we look for an orthonormal basis $V_n \equiv [v_1, \ldots, v_n]$ of $A\mathcal{K}_n(A, r_0)$. We will also consider a basis $Z_n \equiv [z_1, \ldots, z_n]$ of $\mathcal{K}_n(A, r_0)$ and assume in our analysis that the vectors Z_n have unit lengths, but they need not be orthogonal. The orthonormal basis V_n of $A\mathcal{K}_n(A, r_0)$ is obtained from the QR factorization of the image of Z_n:

$$AZ_n = V_n U_n. \tag{1.3}$$

Since $r_n \in r_0 + A\mathcal{K}_n(A, r_0) = r_0 + \mathcal{R}(V_n)$ and $r_n \perp \mathcal{R}(V_n)$, the residual $r_n = (I - V_n V_n^T) r_0$ is just the orthogonal projection of r_0 onto the orthogonal complement of $\mathcal{R}(V_n)$, which can be computed recursively as

$$r_n = r_{n-1} - \alpha_n v_n, \qquad \alpha_n \equiv \langle r_{n-1}, v_n \rangle \tag{1.4}$$

($\mathcal{R}(V_n)$ denotes the range of the matrix V_n). Let $R_{n+1} \equiv [r_0, \ldots, r_n]$, let $D_n \equiv \mathrm{diag}(\alpha_1, \ldots, \alpha_n)$, and let $L_{n+1,n} \in \mathbb{R}^{(n+1)\times n}$ be the bidiagonal matrix with 1's on the main diagonal and -1's on the first subdiagonal; then the recursion (1.4) can be cast into a matrix relation

$$R_{n+1} L_{n+1,n} = V_n D_n. \tag{1.5}$$

Since the columns of Z_n form a basis of $\mathcal{K}_n(A, r_0)$, we can represent x_n in the form

$$x_n = x_0 + Z_n t_n, \tag{1.6}$$

so that $r_n = r_0 - AZ_n t_n = r_0 - V_n U_n t_n$. Due to $r_n \perp \mathcal{R}(V_n)$, it follows that

$$U_n t_n = V_n^T r_0 = [\alpha_1, \ldots, \alpha_n]^T. \tag{1.7}$$

Hence, once the residual norm is small enough, we can solve this upper triangular system and compute the approximate solution $x_n = x_0 + Z_n t_n$. We call this approach the *generalized simpler approach*. Its pseudocode is given in Figure 1.1. It includes, as a special case, Simpler GMRES, which was proposed by Walker and Zhou [30], where $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$. We will be also interested in the case of the residual basis $Z_n = \widetilde{R}_n \equiv [\frac{r_0}{\|r_0\|}, \ldots, \frac{r_{n-1}}{\|r_{n-1}\|}]$; we will call this case RB-SGMRES (Residual-based Simpler GMRES). Recently this method was also derived and implemented by Yvan Notay [17].

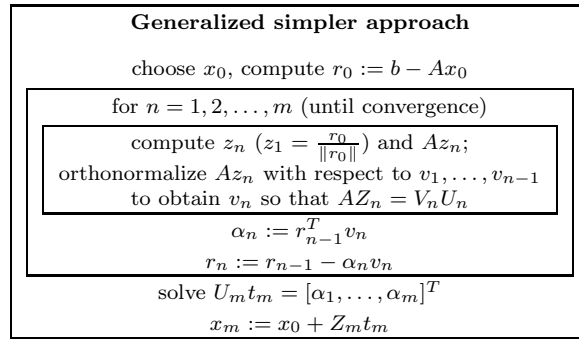

FIG. 1.1. *Pseudocode of the generalized simpler approach.*

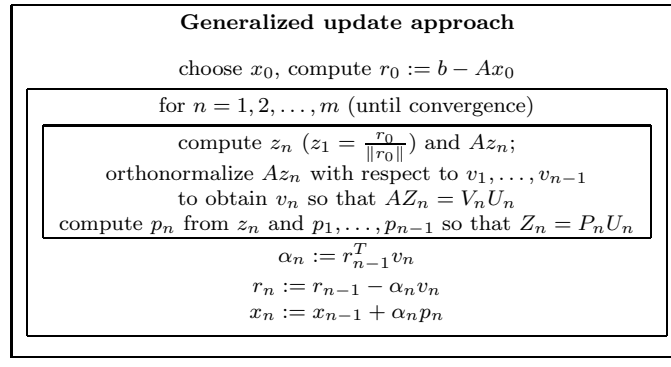

FIG. 1.2. *Pseudocode of the generalized update approach.*

Recursion (1.4) reveals the connection between the generalized simpler approach and yet another minimum residual approach. Let us set $p_k \equiv A^{-1}v_k$ $(k = 1, \ldots, n)$ and $P_n \equiv [p_1, \ldots, p_n]$. Then, left-multiplying (1.4) by A^{-1} yields

$$x_n = x_{n-1} + \alpha_n p_n \tag{1.8}$$

or, in matrix form, $X_{n+1}L_{n+1,n} = -P_nD_n$ with $X_{n+1} \equiv [x_0, \ldots, x_n]$. So, instead of computing the coordinates t_n of $x_n - x_0$ with respect to the basis Z_n, we can directly update x_n from x_{n-1}. However, this requires that we construct the direction vectors P_n forming an A^TA-orthogonal basis of $\mathcal{K}_n(A, r_0)$. Since U_n is known from (1.3), the recursion for p_n can be extracted from the formula

$$Z_n = P_nU_n. \tag{1.9}$$

Note that two recursions (1.3) and (1.9) can be run in the same loop, and we have to store all the direction vectors in P_n and all the orthonormal basis vectors in V_n. We will use the terminology *generalized update approach* for this case. Its pseudocode is given in Figure 1.2. The case $Z_n \equiv [\frac{r_0}{\|r_0\|}, V_{n-1}]$ of this method was proposed in [20] under the name A^TA-variant of GMRES, and up to the normalization of the vectors V_n in (1.3) it is equivalent to the ORTHODIR algorithm due to Young and Jea [33, 7]. Likewise, the case $Z_n = [r_0, \ldots, r_{n-1}]$ corresponds to the GCR (or full ORTHOMIN) method of Elman, Eisenstat, and Schultz [6, 5] (the orthogonal vectors v_n are unnormalized in the original implementation), and it is identical to

TABLE 1.1
Computational costs (without the cost of $m+1$ matrix-vector products) and storage requirements (without the storage of A) of the generalized simpler and update approaches after m iteration steps.

	Computational costs	Storage requirements
Generalized simpler approach	$(2N+\frac{1}{2})m^2+(9N-\frac{1}{2})m+4N$	$(2N+\frac{3}{2})m+\frac{1}{2}m^2+2N+1$
Generalized update approach	$(3N-\frac{1}{2})m^2+(9N-\frac{1}{2})m+4N$	$(2N+1)m+2N+2$

the GMRESR method [28] of van der Vorst and Vuik (with the choice $u_n^{(0)} = r_n$). Without normalization it was also treated in [33]. As we have already mentioned, here we will analyze the choice $Z_n = \widetilde{R}_n$. The importance of normalizing Z_n before the orthogonalization in (1.3) will be seen later.

In Table 1.1 we summarize the computational costs and storage requirements of performing m iteration steps in the generalized simpler approach and the generalized update approach, where we have excluded the storage for A and the cost of $m+1$ matrix-vector products. In both approaches we have to store two sets of vectors—the bases V_m and Z_m (the generalized simpler approach) or V_m and P_m (the generalized update approach)—making these schemes comparable to FGMRES [21], the (flexible) preconditioned variant of the standard GMRES method [23]. This remains true also in the case of preconditioned versions of our algorithms, but we do not treat these explicitly here. In contrast to the generalized simpler approach, we do not need to store the triangular $m \times m$ matrix of orthogonalization coefficients U_m in the generalized update approach, but we have to compute the additional set of vectors P_m. Some savings are possible in special cases, as in Simpler GMRES with the particular choice of the basis $Z_m = [\frac{r_0}{\|r_0\|}, V_{m-1}]$, where the last $m-1$ columns of Z_m need not to be stored and normalized again. Simpler GMRES is in terms of work and storage competitive to the GMRES method, which in addition was shown to be backward stable and in this context should clearly be the method of choice when preconditioning is not considered.

The paper is organized as follows. In section 2 we analyze first the maximum attainable accuracy of the generalized simpler approach based on (1.6) and (1.7). Then we turn to the generalized update approach based on (1.9) and (1.8). To keep the text readable, we assume rounding errors only in selected, most relevant parts of the computation. The bounds presented in Theorems 2.1 and 2.3 show that the conditioning of the matrix Z_n plays an important role in the numerical stability of these schemes. Both theorems give bounds on the maximum attainable accuracy measured by the normwise backward error. We also formulate analogous statements for the residual norm in terms of the condition number of the matrix U_n. While for the generalized simpler approach these bounds do not depend on the conditioning of A, the bound for the generalized update approach is proportional to $\kappa(A)$ (as we will show in our constructed numerical example, the bound is attained). However, the additional factor of $\kappa(A)$ in the generalized update approach is usually an overestimate; in practice, both approaches behave almost equally well for the same choice of basis. This is especially true for the relative errors of the computed approximate solutions, where we have essentially the same upper bound. The situation is completely analogous to results for the MINRES method [19] given by Sleijpen, van der Vorst, and Modersitzki in [25].

In section 3 we derive particular results for two choices of the basis Z_n—first for $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$, leading to Simpler GMRES by Walker and Zhou [30] and to ORTHODIR, and then for $Z_n = \widetilde{R}_n$, which leads to RB-SGMRES and to a variant of GCR, respectively. It turns out that the two choices lead to a truly different behavior in the condition number of U_n, which governs the stability of the considered schemes. Since all these methods converge in a finite number of iterations, we fix the iteration index n such that $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$; that is, the exact solution has not yet been reached. Based on this we give conditions on the linear independence of the basis Z_n. It is known that the residuals are linearly dependent (or even identical) when the GMRES method stagnates (a breakdown occurs in GCR as well as in RB-SGMRES), while this does not happen for $[\frac{r_0}{\|r_0\|}, V_{n-1}]$ (Simpler GMRES and ORTHODIR are breakdown-free). On the other hand, we show that while the choice $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$ leads to inherently unstable or numerically less stable schemes, the second selection $Z_n = \widetilde{R}_n$ gives rise to conditionally stable implementations provided that we have some reasonable residual decrease. In particular, we show that the RB-SGMRES implementation is conditionally backward stable. Our theoretical results are illustrated by selected numerical experiments. In section 4 we draw conclusions and give directions for future work.

Throughout the paper, we denote by $\|\cdot\|$ the Euclidean vector norm and the induced matrix norm and by $\|\cdot\|_F$ the Frobenius norm. Moreover, for $B \in \mathbb{R}^{N\times n}$ $(N \geq n)$ of rank n, $\sigma_1(B) \geq \sigma_n(B) > 0$ are the extremal singular values of B, and $\kappa(B) = \sigma_1(B)/\sigma_n(B)$ is the spectral condition number. By I we denote the unit matrix of a suitable dimension and by e_k $(k = 1, 2, \ldots)$ its kth column, and we let $e \equiv [1, \ldots, 1]^T$. We assume the standard model of finite precision arithmetic with the unit roundoff u (see Higham [13] for details). In our bounds, instead of distinguishing between several constants (which are in fact low-degree polynomials in N and n that can differ from place to place), we use the generic name c for constants.

2. Maximum attainable accuracy of the generalized simpler and update approaches. In this section we analyze the final accuracy level of the generalized simpler and update approaches formulated in the previous section. In order to make our analysis readable, we assume that only the computations performed in (1.3), (1.7), and (1.9) are affected by rounding errors.

Different orthogonalization techniques for computing the columns of V_n can be applied in the QR factorization (1.3). Here we focus on such implementations where the computed R-factor U_n has been obtained in a backward stable way; i.e., there exists an orthonormal matrix $\hat{V}_n$ so that $\hat{V}_n$ and V_n satisfy

$$AZ_n = \hat{V}_n U_n + E_n, \qquad \|E_n\| \leq cu\|A\|\|Z_n\|, \tag{2.1}$$

$$AZ_n = V_n U_n + F_n, \qquad \|F_n\| \leq cu\|A\|\|Z_n\|. \tag{2.2}$$

This is certainly true for the implementation based on Householder reflections [32], the modified Gram–Schmidt process [18], or the Gram–Schmidt process with full reorthogonalization [3]. For details we refer the reader to [13, 8]. From [31, 13] we have for the computed solution $\hat{t}_n$ of (1.7) that

$$(U_n + \Delta U_n)\hat{t}_n = D_n e, \qquad |\Delta U_n| \leq cu|U_n|, \tag{2.3}$$

where the absolute value and inequalities are understood componentwise. The approximation $\hat{x}_n$ to x is then computed as

$$\hat{x}_n = x_0 + Z_n\hat{t}_n. \tag{2.4}$$

The crucial quantity for the analysis of the maximum attainable accuracy is the gap between the true residual $b - A\hat{x}_n$ of the computed approximation and the updated residual r_n obtained from the update formula (1.4) describing the projection of the previous residual; see [9, 12]. In fact, once the updated residual becomes negligible compared to the true one (and in all algorithms considered here it ultimately will), the gap will be equal to the true residual divided by $\|A\|\|\hat{x}_n\|$, which therefore can be thought of as the normwise backward error of the ultimate approximate solution $\hat{x}_n$ (after suitable normalization). Here is our basic result on this gap for the generalized simpler approach.

THEOREM 2.1. *In the generalized simpler approach, if* $cu\kappa(A)\kappa(Z_n) < 1$*, the gap between the true residual* $b - A\hat{x}_n$ *and the updated residual* r_n *satisfies*

$$\frac{\|b - A\hat{x}_n - r_n\|}{\|A\|\|\hat{x}_n\|} \leq cu\kappa(Z_n)\left(1 + \frac{\|x_0\|}{\|\hat{x}_n\|}\right).$$

Proof. From (2.4), (2.2), and (2.3) we have $b - A\hat{x}_n = r_0 - AZ_n\hat{t_n} = r_0 - (V_nU_n + F_n)(U_n + \Delta U_n)^{-1}D_ne$, and (1.4) gives $r_n = r_0 - V_nD_ne$. It is clear from (2.1) and (2.3) that the assumption $cu\kappa(A)\kappa(Z_n) < 1$ implies the invertibility of the perturbed matrix $U_n + \Delta U_n$. Using the identity $I - U_n(U_n + \Delta U_n)^{-1} = \Delta U_n(U_n + \Delta U_n)^{-1}$ and the relation $Z_n(U_n + \Delta U_n)^{-1}D_ne = Z_n\hat{t}_n = \hat{x}_n - x_0$ following from (2.4) and (2.3), we can express the gap between $b - A\hat{x}_n$ and r_n as

$$\begin{aligned}
b - A\hat{x}_n - r_n &= (V_n - (V_nU_n + F_n)(U_n + \Delta U_n)^{-1})D_ne \\
&= (V_n(I - U_n(U_n + \Delta U_n)^{-1}) - F_n(U_n + \Delta U_n)^{-1})D_ne \\
&= (V_n\Delta U_n - F_n)(U_n + \Delta U_n)^{-1}D_ne \\
&= (V_n\Delta U_n - F_n)Z_n^{\dagger}Z_n(U_n + \Delta U_n)^{-1}D_ne \\
&= (V_n\Delta U_n - F_n)Z_n^{\dagger}(\hat{x}_n - x_0).
\end{aligned}$$

Taking the norm, considering (2.1), and noting that the terms in $V_n\Delta U_n$ and F_n can be subsumed into the generic constant c, we get $\|V_n\Delta U_n - F_n\| \leq cu\|A\|\|Z_n\|$ and

$$\|b - A\hat{x}_n - r_n\| \leq cu\|A\|\kappa(Z_n)\|\hat{x}_n - x_0\|.$$

Using the triangle inequality and division by $\|A\|\|\hat{x}_n\|$ concludes the proof. ∎

In the previous theorem we have expressed the residual gap using the difference between the actual and initial approximations $\hat{x}_n$ and x_0, respectively. However, its norm is strongly influenced by the conditioning of the upper triangular matrix U_n. As shown in section 3, the matrix U_n can be ill-conditioned for the particular case $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$, thus leading to an inherently unstable scheme, whereas (under some assumptions) the scheme with $Z_n = \widetilde{R}_n$ gives rise to a well-conditioned triangular matrix U_n. In the following corollary we give a bound for the residual gap in terms of the minimal singular values of the matrices Z_k and norms of the updated residuals r_{k-1}, $k = 1, \ldots, n$.

COROLLARY 2.2. *In the generalized simpler approach, if* $cu\kappa(A)\kappa(Z_n) < 1$*, the gap between the true residual* $b - A\hat{x}_n$ *and the updated residual* r_n *satisfies*

$$\|b - A\hat{x}_n - r_n\| \leq \frac{cu\kappa(A)}{1 - cu\kappa(A)\kappa(Z_n)} \sum_{k=1}^{n} \frac{\|r_{k-1}\|}{\sigma_k(Z_k)}.$$

Proof. The gap between the true residual $b-A\hat{x}_n$ and the updated residual r_n can be expressed as $b-A\hat{x}_n-r_n=(V_n\Delta U_n-F_n)(U_n+\Delta U_n)^{-1}D_ne$. Since $e_k^TD_ne_k=\alpha_k$ and $|\alpha_k|=\sqrt{\|r_{k-1}\|^2-\|r_k\|^2}\le\sqrt{2}\|r_{k-1}\|$, the norm of the term $(U_n+\Delta U_n)^{-1}D_ne$ can be estimated as follows:

$$\begin{aligned}\|(U_n+\Delta U_n)^{-1}D_ne\| &\le \sum_{k=1}^{n}\|(U_n+\Delta U_n)^{-1}D_ne_k\| \\ &\le \sqrt{2}\sum_{k=1}^{n}\frac{\|r_{k-1}\|}{\sigma_k([U_n+\Delta U_n]_{1:k,1:k})},\end{aligned} \tag{2.5}$$

where $[U_n+\Delta U_n]_{1:k,1:k}$ denotes the principal $k\times k$ submatrix of $U_n+\Delta U_n$. Owing to (2.4), we can estimate the perturbation of $[U_n]_{1:k,1:k}=U_k$ as $\|[\Delta U_n]_{1:k,1:k}\|\le cu\|U_k\|$. Perturbation theory of singular values (see, e.g., [14]) shows that

$$\sigma_k([U_n+\Delta U_n]_{1:k,1:k})\ge\sigma_k(U_k)-cu\|U_k\|\ge\sigma_k(AZ_k)-cu\|A\|\|Z_k\| \tag{2.6a}$$

$$\ge\sigma_N(A)\sigma_k(Z_k)-cu\|A\|\|Z_k\|, \tag{2.6b}$$

which together with (2.5) concludes the proof. ∎

The estimates (2.5) and (2.6a) given in the previous proof that involve the minimum singular values of U_k $(k=1,\dots,n)$ are quite sharp. However, the estimate (2.6b) relating the minimum singular values of U_k to those of Z_k can be a large underestimate, as also observed in our numerical experiments in section 3.

Next we analyze the maximum attainable accuracy of the generalized update approach. We assume that in finite precision arithmetic the computed direction vectors satisfy

$$Z_n=P_nU_n+G_n,\qquad \|G_n\|\le cu\|P_n\|\|U_n\|. \tag{2.7}$$

This follows from the standard rounding error analysis of the recursion for vectors P_n. Note that the norm of the matrix G_n cannot be bounded by $cu\|A\|\|Z_n\|$ as it can in the case of the QR factorization (2.2). We update then the approximate solution $\hat{x}_n$ according to (1.8):

$$\hat{x}_n=\hat{x}_{n-1}+\alpha_np_n. \tag{2.8}$$

THEOREM 2.3. *In the generalized update approach, if $cu\kappa(A)\kappa(Z_n)<1$, the gap between the true residual $b-A\hat{x}_n$ and the updated residual r_n satisfies*

$$\frac{\|b-A\hat{x}_n-r_n\|}{\|A\|\|\hat{x}_n\|}\le\frac{cu\kappa(A)\kappa(Z_n)}{1-cu\kappa(A)\kappa(Z_n)}\left(1+\frac{\|x_0\|}{\|\hat{x}_n\|}\right).$$

Proof. From (2.8), (1.4), (2.2), and (2.7), $\hat{x}_n=x_0+P_nD_ne=x_0+(Z_n-G_n)U_n^{-1}D_ne$ and $r_n=r_0-V_nD_ne=r_0-(AZ_n-F_n)U_n^{-1}D_ne$, we have that

$$b-A\hat{x}_n-r_n=(AG_n-F_n)U_n^{-1}D_ne, \tag{2.9}$$

and from (2.7) and (2.1) we get $P_n=A^{-1}\hat{V}_n+A^{-1}E_nU_n^{-1}-G_nU_n^{-1}$. The norm of the matrix G_n in (2.7) can hence be bounded by

$$\|G_n\|\le cu\kappa(A)\|Z_n\|. \tag{2.10}$$

Owing to (2.8), we have the identity $U_n^{-1}D_n e = U_n^{-1}P_n^{\dagger}P_n D_n e = (P_nU_n)^{\dagger}(\hat{x}_n - x_0)$, where $\|(P_nU_n)^{\dagger}\| \le [1 - cu\kappa(A)\kappa(Z_n)]^{-1}\|Z_n^{\dagger}\|$, as follows from (2.7). Thus we obtain

$$\|U_n^{-1}D_n e\| \le \frac{\|Z_n^{\dagger}\|}{1 - cu\kappa(A)\kappa(Z_n)}\|\hat{x}_n - x_0\|, \tag{2.11}$$

which together with (2.9), (2.10), and (2.2) leads to

$$\|b - A\hat{x}_n - r_n\| \le \frac{cu\|A\|\kappa(A)\kappa(Z_n)}{1 - cu\kappa(A)\kappa(Z_n)}\|\hat{x}_n - x_0\|.$$

The proof is concluded using the triangle inequality and dividing by $\|A\|\|\hat{x}_n\|$. ∎

In the following we formulate an analogous corollary for the residual gap as in the case of the generalized simpler approach.

COROLLARY 2.4. *In the generalized update approach, if* $cu\kappa(A)\kappa(Z_n) < 1$, *the gap between the true residual* $b - A\hat{x}_n$ *and the updated residual* r_n *satisfies*

$$\|b - A\hat{x}_n - r_n\| \le \frac{cu\kappa^2(A)}{1 - cu\kappa(A)\kappa(Z_n)}\sum_{k=1}^{n}\frac{\|r_{k-1}\|}{\sigma_k(Z_k)}.$$

Proof. Considering (2.2), (2.7), and (2.10) the norm of the term $AG_n - F_n$ in (2.9) can be bounded as $\|AG_n - F_n\| \le cu\|A\|\kappa(A)$, while the term $U_n^{-1}D_n e$ can be treated as in Corollary 2.2. ∎

The bound on the ultimate backward error given in Theorem 2.3 is worse than the one in Theorem 2.1. We see that for the generalized simpler approach the normwise backward error is of the order of the roundoff unit, whereas for the generalized update approach we have an upper bound proportional to the condition number of A. Similarly, the bounds on the ultimate relative residual norms given in Corollaries 2.2 and 2.4 indicate that the relative residuals in the generalized simpler approach will reach the level which is approximately equal to $u\kappa(A)$, while in the generalized update approach this level becomes $u\kappa^2(A)$.

In the previous text we have given bounds in terms of the true residual $b - A\hat{x}_n$ and the updated residual r_n. It should be noted that the true residual is not available in practical computations, but for verification or for other purposes it can be estimated by the explicit evaluation of $\mathrm{fl}(b - A\hat{x}_n)$. It is clear from $\|\mathrm{fl}(b - A\hat{x}_n) - (b - A\hat{x}_n)\| \le cu(\|b\| + \|A\|\|\hat{x}_n\|) \le cu\|A\|(\|x\| + \|\hat{x}_n\|)$ that the error in the evaluation of the true residual (if needed) is significantly smaller than other quantities involved in our analysis.

In Theorems 2.1 and 2.3 we have estimated the attainable level of the normwise backward error of both generalized simpler and update approaches. The resulting bound is in general worse for the generalized update approach. However, as shown below, it appears that *the generalized update approach leads to an approximate solution whose forward error is essentially on the same accuracy level as the generalized simpler approach.* A similar phenomenon was also observed by Sleijpen, van der Vorst, and Modersitzki [25] in the symmetric case for two different implementations (called GMRES and MINRES in their paper).

COROLLARY 2.5. *If* $cu\kappa(A)\kappa(Z_n) < 1$, *the gap between the error* $x - \hat{x}_n$ *and the vector* $A^{-1}r_n$ *in both the generalized simpler and update approaches satisfies*

$$\frac{\|(x - \hat{x}_n) - A^{-1}r_n\|}{\|x\|} \le \frac{cu\kappa(A)\kappa(Z_n)}{1 - cu\kappa(A)\kappa(Z_n)}\frac{\|\hat{x}_n\| + \|x_0\|}{\|x\|}.$$

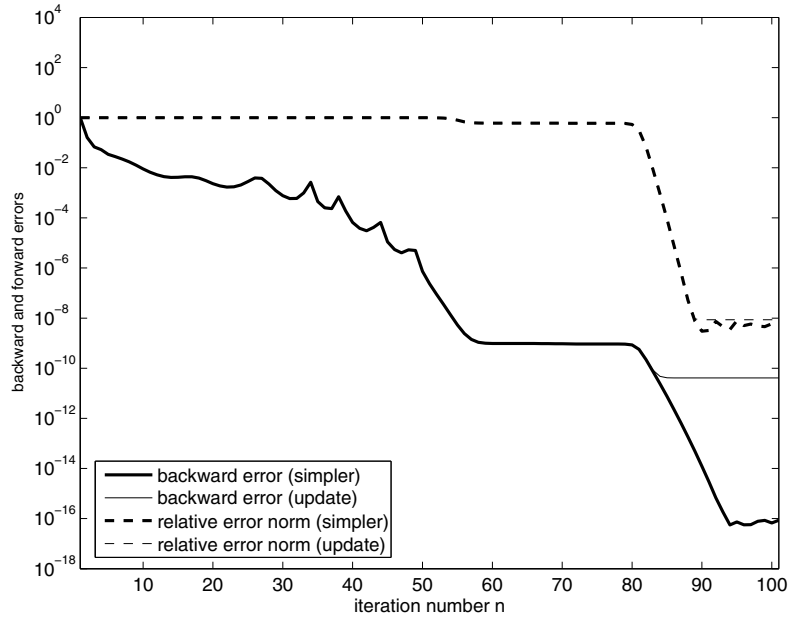

FIG. 2.1. *The test problem solved by the generalized simpler and update approaches with the almost orthonormal basis Z_n satisfying $\kappa(Z_n) \approx 1$.*

Proof. For the generalized simpler approach, the result follows directly from Theorem 2.1. For the generalized update approach, using (2.9) we have

$$(x - \hat{x}_n) - A^{-1}r_n = (-A^{-1}F_n + G_n)U_n^{-1}D_n e,$$

and the statement follows from (2.2), (2.10), and (2.11). ∎

Theorems 2.1 and 2.3 indicate that *as soon as the backward error of the approximate solution in the generalized simpler approach gets below $cu\kappa(A)\kappa(Z_n)$, the difference between the backward errors in the generalized simpler and update approaches may become visible and can be expected to be up to the order of $\kappa(A)$.* Based on our experience it is difficult to find an example where this difference is significant. Similarly to Sleijpen, van der Vorst, and Modersitzki [25], we use here a model example, where $A = G_1 D G_2^T \in \mathbb{R}^{100\times 100}$ with $D = \mathrm{diag}(10^{-8}, 2\cdot 10^{-8}, 3, 4, \ldots, 100)$ and with G_1 and G_2 being Givens rotations over the angle of $\frac{\pi}{4}$ in the $(1, 10)$-plane and the $(1, 100)$-plane, respectively; finally, $b = e$. The numerical experiments were performed in MATLAB using double precision arithmetic ($u \approx 10^{-16}$) and $x_0 = 0$. In Figure 2.1 we have plotted the normwise backward errors $\|b - A\hat{x}_n\|/(\|A\|\|\hat{x}_n\|)$ (thin and thick solid lines), and the relative 2-norms of the errors $\|x - \hat{x}_n\|/\|x\|$ (thin and thick dash-dotted lines). In all our experiments the basis V_n in (1.3) is computed with the modified Gram–Schmidt orthogonalization process, where the upper triangular factor U_n is obtained in a backward stable way satisfying (2.1). In order to ensure that the difference is not affected by a possibly high condition number of Z_n, we use the implementation where the basis Z_n is computed with the modified Gram–Schmidt Arnoldi process so that $\kappa(Z_n) \approx 1$. We see that the actual backward errors are close to each other until they stagnate: for the generalized update approach this happens approximately at a level approaching $u\kappa(A)$, while for the generalized simpler

approach we have stagnation on the roundoff unit level u. Similar observations could be made for the relative true residual norms (for better readability they are not shown in Figure 2.1); in the case of the generalized simpler approach the final level of the relative 2-norm of the true residual is on the level of $u\kappa(A)$, while for the generalized update approach this level is approximately one factor of $\kappa(A)$ higher. In contrast, the 2-norms of the errors stagnate on the $u\kappa(A)$ level in both approaches considered.

3. Choice of basis and stability. In this section we discuss the two main particular choices for the matrix Z_n leading to different algorithms for the generalized simpler and update approaches. For the sake of simplicity, we assume exact arithmetic here. The conditioning of Z_n plays an important role in our analysis. The effect of scaling the columns on the condition number has been analyzed by van der Sluis in [27], who showed that the normalization of columns is a nearly optimal strategy producing the condition number within the factor $\sqrt{n}$ of the minimum 2-norm condition number achievable by column scaling.

First, we choose $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$, which leads to the Simpler GMRES method of Walker and Zhou [30] and to ORTHODIR by Young and Jea [33]. Hence, we choose $\{\frac{r_0}{\|r_0\|}, v_1, \ldots, v_{n-1}\}$ as a basis of $\mathcal{K}_n(A, r_0)$. To be sure that such a choice is adequate, we state the following simple lemma.

LEMMA 3.1. *Let $v_1, \ldots, v_{n-1}$ be an orthonormal basis of $A\mathcal{K}_{n-1}(A, r_0)$, $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$. Then the vectors $\frac{r_0}{\|r_0\|}, v_1, \ldots, v_{n-1}$ form a basis of $\mathcal{K}_n(A, r_0)$.*

Proof. The result follows easily from the assumption $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$. ∎

Note that if $r_0 \in A\mathcal{K}_n(A, r_0)$, then the condition (1.2) yields $x_n = A^{-1}b$, $r_n = 0$, and any implementation of a minimum residual method will terminate. Lemma 3.1 ensures that it makes sense to build an orthonormal basis V_n of $A\mathcal{K}_n(A, r_0)$ by the successive orthogonalization of the columns of the matrix $A[\frac{r_0}{\|r_0\|}, V_{n-1}]$ via (1.3). It reflects the fact that, for any initial residual r_0, both Simpler GMRES and ORTHODIR converge (in exact arithmetic) to the exact solution; see [33]. However, as observed by Liesen, Rozložník, and Strakoš [15], this choice of the basis is not very suitable from the stability point of view. This shortcoming is reflected by the unbounded growth of the condition number of $[\frac{r_0}{\|r_0\|}, V_{n-1}]$ discussed next. The upper bound we recall here was also derived in [30].

THEOREM 3.2. *Let $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$. Then the condition number of $[\frac{r_0}{\|r_0\|}, V_{n-1}]$ satisfies*

$$\frac{\|r_0\|}{\|r_{n-1}\|} \le \kappa([\tfrac{r_0}{\|r_0\|}, V_{n-1}]) \le 2\frac{\|r_0\|}{\|r_{n-1}\|}.$$

Proof. Since $r_{n-1} = (I - V_{n-1}V_{n-1}^T)r_0$, it is easy to see that r_{n-1} is the residual of the least squares problem $V_{n-1}y \approx r_0$. The statement therefore follows from [15, Theorem 3.2]. ∎

The conditioning of $[\frac{r_0}{\|r_0\|}, V_{n-1}]$ is thus related to the convergence of the method; in particular, it is inversely proportional to the actual relative norm of the residual. Small residuals lead to the ill-conditioning of the matrices $A[\frac{r_0}{\|r_0\|}, V_{n-1}]$ and U_n, and this negatively affects the accuracy of computed approximate solutions. This essentially means that, after some initial residual reduction, Simpler GMRES and ORTHODIR can behave unstably, which makes our analysis on maximum attainable accuracy inapplicable.

As a remedy, we now turn to the second choice, $Z_n = \widetilde{R}_n$, which leads to RB-SGMRES (proposed here as a more stable counterpart of Simpler GMRES) and to a

version of GCR due to Eisenstat, Elman, and Schultz [6, 5] (see also [29]). Hence, we choose normalized residuals $r_0, \ldots, r_{n-1}$ as the basis of $\mathcal{K}_n(A, r_0)$. To make sure that such a choice is adequate, we state the following result.

LEMMA 3.3. *Let $v_1, \ldots, v_{n-1}$ be an orthonormal basis of $A\mathcal{K}_{n-1}(A, r_0)$, $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$, and $r_k = (I - V_k V_k^T) r_0$, where $V_k \equiv [v_1, \ldots, v_k]$, $k = 1, 2, \ldots, n-1$. Then the following statements are equivalent:*

1. *$\|r_k\| < \|r_{k-1}\|$ for all $k = 1, \ldots, n-1$,*
2. *$r_0, \ldots, r_{n-1}$ are linearly independent.*

Proof. Since $r_0 \notin A\mathcal{K}_{n-1}(A, r_0) = \mathcal{R}(V_{n-1})$, we have $r_k \neq 0$ for all $k = 0, 1, \ldots, n-1$. It is clear that $\|r_k\| < \|r_{k-1}\|$ if and only if $\langle r_{k-1}, v_k \rangle \neq 0$. If that holds for all $k = 1, \ldots, n-1$, the diagonal matrix D_{n-1} is nonsingular. Using the relation (1.5), we find that $R_n[L_{n,n-1}, e_n] = [V_{n-1} D_{n-1}, r_{n-1}]$. Since $r_{n-1} \perp V_{n-1}$, the matrix $[V_{n-1} D_{n-1}, r_{n-1}]$ has orthogonal nonzero columns, and hence its rank equals n. Moreover, $\operatorname{rank}([L_{n,n-1}, e_n]) = n$, and thus $\operatorname{rank}(R_n) = n$; i.e., $r_0, \ldots, r_{n-1}$ are linearly independent. Conversely, from the same matrix relation we find that if $r_0, \ldots, r_{n-1}$ are linearly independent, then $\operatorname{rank}([V_{n-1} D_{n-1}, r_{n-1}]) = n$, and hence D_{n-1} is nonsingular, which proves that $\|r_k\| < \|r_{k-1}\|$ for all $k = 1, \ldots, n-1$. ∎

Therefore, if the method does not stagnate, i.e., if the 2-norms of the residuals $r_0, \ldots, r_{n-1}$ are strictly monotonously decreasing, then $r_0, \ldots, r_{n-1}$ are linearly independent. In this case, we can build an orthonormal basis V_n of $A\mathcal{K}_n(A, r_0)$ by the successive orthogonalization of the columns of $A\widetilde{R}_n$ via (1.3). If $r_0 \in A\mathcal{K}_{n-1}(A, r_0)$, we have an exact solution of (1.1), and the method terminates with $x_{n-1} = A^{-1} b$.

Several conditions for the nonstagnation of the minimum residual method have been given in the literature. For example, Eisenstat, Elman, and Schultz [5, 6] show that GCR (and hence any minimum residual method) does not stagnate if the symmetric part of A is positive definite, i.e., if the origin is not contained in the field of values of A. See also Greenbaum and Strakoš [10] for a different proof and Eiermann and Ernst [4]. Several other conditions can be found in Simoncini and Szyld [24] and the references therein. If stagnation occurs, the residuals are no longer linearly independent, and thus the method prematurely breaks down. In particular, if $0 \in \mathcal{F}(A)$, choosing x_0 such that $\langle A r_0, r_0 \rangle = 0$ leads to a breakdown in the first step. This was first pointed out by Young and Jea [33] with a simple 2×2 example.

However, as shown in the following theorem, when the minimum residual method does not stagnate, the columns of $\widetilde{R}_n$ are a reasonable choice for the basis of $\mathcal{K}_n(A, r_0)$.

THEOREM 3.4. *If $r_0 \notin A\mathcal{K}_{n-1}(A, r_0)$ and $\|r_k\| < \|r_{k-1}\|$ for all $k = 1, \ldots, n-1$, the condition number of $\widetilde{R}_n$ satisfies*

$$1 \leq \kappa(\widetilde{R}_n) \leq \sqrt{n}\, \gamma_n, \qquad \gamma_n \equiv \sqrt{1 + \sum_{k=1}^{n-1} \frac{\|r_{k-1}\|^2 + \|r_k\|^2}{\|r_{k-1}\|^2 - \|r_k\|^2}}. \tag{3.1}$$

Proof. From (1.5) it follows that

$$\widetilde{R}_n[\widetilde{L}_{n,n-1}, e_n] = \left[V_{n-1}, \frac{r_{n-1}}{\|r_{n-1}\|} \right], \quad \widetilde{L}_{n,n-1} \equiv \operatorname{diag}(\|r_0\|, \ldots, \|r_{n-1}\|) L_{n,n-1} D_{n-1}^{-1}.$$

Since $[V_{n-1}, \frac{r_{n-1}}{\|r_{n-1}\|}]$ is an orthonormal matrix, we have from [14, Theorem 3.3.16]

$$\begin{aligned} 1 = \sigma_n \left(\left[V_{n-1}, \frac{r_{n-1}}{\|r_{n-1}\|} \right] \right) &\leq \sigma_n(\widetilde{R}_n) \|[\widetilde{L}_{n,n-1}, e_n]\| \\ &\leq \sigma_n(\widetilde{R}_n) \|[\widetilde{L}_{n,n-1}, e_n]\|_F. \end{aligned}$$

The value of $\|[\widetilde{L}_{n,n-1}, e_n]\|_F$ can be directly computed as

$$\|[\widetilde{L}_{n,n-1}, e_n]\|_F = \sqrt{1 + \sum_{k=1}^{n-1} \frac{\|r_{k-1}\|^2 + \|r_k\|^2}{\|r_{k-1}\|^2 - \|r_k\|^2}} = \gamma_n$$

since $\alpha_k^2 = \|r_{k-1}\|^2 - \|r_k\|^2$. The statement then follows using $\|\widetilde{R}_n\| \leq \|\widetilde{R}_n\|_F \leq \sqrt{n}$. □

We define the quantity γ_n in (3.1) as the *stagnation factor*. The conditioning of $\widetilde{R}_n$ is thus related to the convergence of the method, but in contrast to the conditioning of $[\frac{r_0}{\|r_0\|}, V_{n-1}]$, it is related to the intermediate decrease of the residual norms and not to the residual decrease with respect to the initial residual. A different bound for the conditioning of the matrix $\widetilde{R}_n$ in terms of the residual norms of GMRES and FOM could be derived using the approach in [26].

We illustrate our theoretical results by two numerical examples using the ill-conditioned matrices FS1836 ($\|A\| \approx 1.2 \cdot 10^9$, $\kappa(A) \approx 1.5 \cdot 10^{11}$) and STEAM1 ($\|A\| \approx 2.2 \cdot 10^7$, $\kappa(A) \approx 3 \cdot 10^7$) obtained from the Matrix Market [1] with the right-hand side $b = Ae$ and with the initial guess $x_0 = 0$. In Figures 3.1, 3.2, 3.4, and 3.5 we show the normwise backward error $\|b - Ax_n\|/(\|A\|\|x_n\|)$, the relative norm of the residual $\|b - Ax_n\|/\|b\|$ and $\|r_n\|/\|b\|$, and the relative norms of the error $\|x - x_n\|/\|x\|$ for the choice $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$ that corresponds to Simpler GMRES and ORTHODIR (Figures 3.1 and 3.4), and for $Z_n = \widetilde{R}_n$ corresponding to RB-SGMRES and GCR (Figures 3.2 and 3.5), respectively. In Figures 3.3 and 3.6 we report the condition numbers of the system matrix A, the basis Z_n, and the triangular matrix U_n multiplied by the unit roundoff u. We see that the backward errors, residual norms, and error norms are almost identical for corresponding implementations of the generalized simpler and update approaches. This can be observed in most cases: the differences between Simpler GMRES and ORTHODIR, and RB-SGMRES and GCR, respectively, are practically negligible. Figures 3.1 and 3.4 illustrate our theoretical considerations and show that, after some initial reduction, *the backward error of Simpler GMRES and ORTHODIR may stagnate at a significantly higher level than the backward error of RB-SGMRES or GCR, which stagnates at a level proportional to the roundoff units*, as shown in Figures 3.2 and 3.5. Due to Theorem 3.2, after some initial phase, the norms of the errors start to diverge in Simpler GMRES and ORTHODIR, while for RB-SGMRES and GCR we have a stagnation on a level approximately proportional to $u\kappa(A)$. The difference is clearly caused by the choice of the basis Z_n, which has an effect on the conditioning of the matrix U_n. We see that $\widetilde{R}_n$ remains well-conditioned up to the very end of the iteration process, while the conditioning of $[\frac{r_0}{\|r_0\|}, V_{n-1}]$ is linked to the convergence of Simpler GMRES and may lead to a very ill-conditioned triangular matrix U_n. Consequently, the approximate solution x_n computed from (1.7) becomes inaccurate, and its error starts to diverge. This problem does not occur in the RB-SGMRES method and GCR, since the matrix U_n remains well-conditioned due to the low stagnation factor. These two implementations behave almost equally to the backward stable MGS-GMRES method. For numerical experiments with MGS-GMRES on the same examples, we refer the reader to [11] and [15].

4. Conclusions. In this paper we have studied the numerical behavior of several minimum residual methods mathematically equivalent to GMRES. Two general formulations have been analyzed: the generalized simpler approach that does not require an upper Hessenberg factorization and the generalized update approach which

is based on generating a sequence of appropriately computed direction vectors. It has been shown that for the generalized simpler approach our analysis leads to an upper bound for the backward error proportional to the roundoff unit, whereas for the generalized update approach the same quantity can be bounded by a term proportional to the condition number of A. Although our analysis suggests that the difference between both may be up to the order of $\kappa(A)$, in practice they behave very similarly, and it is very difficult to find a concrete example with a significant difference in the limiting accuracy measured by the normwise backward error of the approximate solutions x_n. Our first test problem displayed in Figure 2.1 is such a rare example. Moreover, when looking at the errors, we note that both approaches lead essentially to the same accuracy of x_n.

We have indicated that the choice of the basis Z_n is the most important issue for the stability of the considered schemes. Our analysis supports the well-known fact that, even when implemented with the best possible orthogonalization techniques, Simpler GMRES and ORTHODIR are inherently less stable due to the choice $Z_n = [\frac{r_0}{\|r_0\|}, V_{n-1}]$ for the basis. The situation becomes significantly better when we use the residual basis $Z_n = \widetilde{R}_n$. This choice leads to the popular GCR (ORTHOMIN, GMRESR) method, which is widely used in applications. Assuming some reasonable residual decrease (which happens almost always in finite precision arithmetic), we have shown that this scheme is quite efficient, and we have proposed a conditionally backward stable variant RB-SGMRES. Our theoretical results in a sense justify the use of the GCR method in practical computations. In this paper we studied only the unpreconditioned implementations. The implications for the preconditioned GCR scheme will be discussed elsewhere.

Acknowledgments. We would like to thank Julien Langou, Yvan Notay, Kees Vuik, and Gérard Meurant for valuable discussions during the preparation of the paper. We also thank the referees for their comments, which helped to improve the presentation of our results.

ANALYSIS OF THE TRUNCATED SPIKE ALGORITHM*

CARL CHRISTIAN KJELGAARD MIKKELSEN† AND MURAT MANGUOGLU†

Abstract. The truncated SPIKE algorithm is a parallel solver for linear systems which are banded and strictly diagonally dominant by rows. There are machines for which the current implementation of the algorithm is faster and scales better than the corresponding solver in ScaLAPACK (PDDBTRF/PDDBTRS). In this paper we prove that the SPIKE matrix is strictly diagonally dominant by rows with a degree no less than the original matrix. We establish tight upper bounds on the decay rate of the spikes as well as the truncation error. We analyze the error of the method and present the results of some numerical experiments which show that the accuracy of the truncated SPIKE algorithm is comparable to LAPACK and ScaLAPACK.

Key words. direct methods, banded, and row diagonally dominant linear systems

AMS subject classification. 65F05

DOI. 10.1137/080719571

1. Introduction.

A matrix $A = [a_{ij}]$ is diagonally dominant by rows if

$$\sum_{i \neq j} |a_{ij}| \leq |a_{ii}| \tag{1.1}$$

for all i. If the inequality is sharp, then A is *strictly* diagonally dominant by rows.

The truncated SPIKE algorithm is a parallel solver for linear systems which are banded and strictly diagonally dominant by rows. Polizzi and Sameh demonstrated [10], [11] that there are parallel machines for which the algorithm is faster and scales better than the algorithm which is implemented in ScaLAPACK (PDDBTRF/PDDBTRS) [1]. We present the algorithm in section 2 and prove certain key properties of the truncated SPIKE algorithm in section 3. We analyze the error in section 4. We present the results of some experiments which supplement our theoretical analysis, and we compare the accuracy of the truncated SPIKE algorithm and ScaLAPACK in section 5.

The SPIKE algorithms are designed to solve banded systems on a parallel machine. The basic idea was introduced by Sameh and Kuck [12] who considered the tridiagonal case and Chen, Kuck, and Sameh [2] who studied the triangular case. Lawrie and Sameh [8] applied the algorithm to the symmetric positive definite systems, while Dongarra and Sameh [4] considered the strictly diagonally dominant case. Variations of the SPIKE algorithms for tridiagonal systems were introduced by Sun, Zhang, and Ni [13], who also analyzed the truncation error for tridiagonal systems which are evenly diagonally dominant. The truncation error for tridiagonal Toeplitz systems, which are also strictly diagonally dominant, as well as symmetric or skew symmetric was considered by Sun [14]. Another variation of the SPIKE algorithm for strictly diagonally dominant systems was studied by Larriba-Pey, Jorba, and Navarro

[7]. Polizzi and Sameh have extended the SPIKE algorithms to the general banded case, and they developed the SPIKE package.

If A is nonsingular and diagonally dominant by rows, then the diagonal entries are nonzero and the dominance factor [5] ϵ is defined as follows:

$$\epsilon = \max_i \left\{ \frac{\sum_{i \neq j} |a_{ij}|}{|a_{ii}|} \right\}. \tag{1.2}$$

If $\epsilon > 0$, then the degree of diagonal dominance d is given by

$$d = \epsilon^{-1}. \tag{1.3}$$

The degree of diagonal dominance is central to the analysis of the truncated SPIKE algorithm.

2. The algorithm. Consider the nonsingular linear system

$$Ax = f,$$

where A is a n by n banded matrix which is strictly diagonally dominant by rows.

We assume that the number of superdiagonals k is equal to the number of subdiagonals and that the matrix is narrow banded, i.e., $k \ll n$. Let p denote the number of processors. We assume for simplicity that p divides n. Let the system be partitioned into the block diagonal form shown below

$$Ax = \begin{bmatrix} A_1 & \overline{B}_1 & & & \\ \overline{C}_2 & A_2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & \overline{B}_{p-1} \\ & & & \overline{C}_p & A_p \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ \vdots \\ x_p \end{bmatrix} = \begin{bmatrix} f_1 \\ f_2 \\ \vdots \\ \vdots \\ f_p \end{bmatrix}, \tag{2.1}$$

where $A_i, i = 1, 2, \ldots, p$ is a banded matrix of order $\mu = n/p$ and bandwidth $2k + 1$ (just like A),

$$\overline{B}_i = \begin{bmatrix} 0 & 0 \\ B_i & 0 \end{bmatrix}, \quad \text{and} \quad \overline{C}_{i+1} = \begin{bmatrix} 0 & C_{i+1} \\ 0 & 0 \end{bmatrix}, \quad i = 1, 2, \ldots p-1,$$

in which B_i and C_i are lower and upper triangular matrices, respectively, each of order k. Let D denote the main block diagonal D, i.e.,

$$D = \text{diag}\{A_1, A_2, \ldots, A_p\}.$$

The matrix D is nonsingular because A is strictly diagonally dominant. If we premultiply both sides of (2.1) by D^{-1}, we obtain a system $Sx = g$ of the form

$$\begin{bmatrix} I_\mu & \overline{V}_1 & & & \\ \overline{W}_2 & I_\mu & \overline{V}_2 & & \\ & \ddots & \ddots & \ddots & \\ & & \overline{W}_{p-1} & I_\mu & \overline{V}_{p-1} \\ & & & \overline{W}_p & I_\mu \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{p-1} \\ x_p \end{bmatrix} = \begin{bmatrix} g_1 \\ g_2 \\ \vdots \\ g_{p-1} \\ g_p \end{bmatrix}, \tag{2.2}$$

where

$$\overline{V}_i = \begin{bmatrix} V_i & 0 \end{bmatrix}, \quad \text{and} \quad \overline{W}_i = \begin{bmatrix} 0 & W_i \end{bmatrix},$$

in which V_i and W_i are matrices with k columns given by

$$V_i = A_i^{-1} \begin{bmatrix} 0 \\ B_i \end{bmatrix}, \quad \text{and} \quad W_i = A_i^{-1} \begin{bmatrix} C_i \\ 0 \end{bmatrix},$$

and will in general be full. Let the tall and narrow matrices V_i and W_i be partitioned, in turn, as follows

$$V_i = \begin{bmatrix} V_i^{(t)} \\ V_i^{(m)} \\ V_i^{(b)} \end{bmatrix}, \quad \text{and} \quad W_i = \begin{bmatrix} W_i^{(t)} \\ W_i^{(m)} \\ W_i^{(b)} \end{bmatrix},$$

where $V_i^{(t)}$, $V_i^{(b)}$, $W_i^{(t)}$, and $W_i^{(b)} \in \mathbb{R}^{k \times k}$. The superscripts t, m, and b are abbreviations of the words top, middle, and bottom, respectively. Let x_i and g_i be partitioned conformally, i.e.,

$$x_i = \begin{bmatrix} x_i^{(t)} \\ x_i^{(m)} \\ x_i^{(b)} \end{bmatrix}, \quad \text{and} \quad g_i = \begin{bmatrix} g_i^{(t)} \\ g_i^{(m)} \\ g_i^{(b)} \end{bmatrix}.$$

As an illustration we show the system (2.2) for $p = 3$, where $\nu = \mu - 2k$,

$$\begin{bmatrix} I_k & & & V_1^{(t)} & & & & & \\ & I_\nu & & V_1^{(m)} & & & & & \\ & & I_k & V_1^{(b)} & & & & & \\ & & W_2^{(t)} & I_k & & & V_2^{(t)} & & \\ & & W_2^{(m)} & & I_\nu & & V_2^{(m)} & & \\ & & W_2^{(b)} & & & I_k & V_2^{(b)} & & \\ & & & & & W_3^{(t)} & I_k & & \\ & & & & & W_3^{(t)} & & I_\nu & \\ & & & & & W_3^{(t)} & & & I_k \end{bmatrix} \begin{bmatrix} x_1^{(t)} \\ x_1^{(m)} \\ x_1^{(b)} \\ x_2^{(t)} \\ x_2^{(m)} \\ x_2^{(b)} \\ x_3^{(t)} \\ x_3^{(m)} \\ x_3^{(b)} \end{bmatrix} = \begin{bmatrix} g_1^{(t)} \\ g_1^{(m)} \\ g_1^{(b)} \\ g_2^{(t)} \\ g_2^{(m)} \\ g_2^{(b)} \\ g_3^{(t)} \\ g_3^{(m)} \\ g_3^{(b)} \end{bmatrix}.$$

It is from these narrow block columns or spikes extending from the main diagonal that the algorithm has derived its name. We will frequently refer to the V_i as the superdiagonal spikes and to the W_i as the subdiagonal spikes, and call the matrix S the SPIKE matrix.

Observe that the union of the k equations above and the k equations below the $p-1$ partition lines forms an independent subsystem of order $2k(p-1)$. We shall refer to this system as the "reduced" system and write $Rx_r = g_r$. It has the form

$$\begin{bmatrix} E_1 & F_1 & & & \\ G_2 & E_2 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & \ddots & F_{p-2} \\ & & & G_{p-2} & E_{p-1} \end{bmatrix} \begin{bmatrix} x_{r,1} \\ x_{r,2} \\ \vdots \\ x_{r,p-1} \end{bmatrix} = \begin{bmatrix} g_{r,1} \\ g_{r,2} \\ \vdots \\ g_{r,p-1} \end{bmatrix}, \tag{2.3}$$

where

$$E_i = \begin{bmatrix} I_k & V_i^{(b)} \\ W_{i+1}^{(t)} & I_k \end{bmatrix}, \quad F_i = \begin{bmatrix} 0 & 0 \\ 0 & V_{i+1}^{(t)} \end{bmatrix}, \quad \text{and} \quad G_i = \begin{bmatrix} W_i^{(b)} & 0 \\ 0 & 0 \end{bmatrix},$$

and

$$x_{r,i} = \begin{bmatrix} x_i^{(b)} \\ x_{i+1}^{(t)} \end{bmatrix}, \quad \text{and} \quad g_{r,i} = \begin{bmatrix} g_i^{(b)} \\ g_{i+1}^{(t)} \end{bmatrix}.$$

The subscript r is an abbreviation of the word "reduced". Dongarra and Sameh [4] noted that the reduced system is strictly diagonally dominant by rows and solved the reduced system using a parallel implementation of the Jacobi iteration. In Theorem 3.3 we show that the reduced system is strictly diagonally dominant by rows with a degree no less than the original matrix.

Once the reduced system has been solved

$$z_i = g_i - W_i x_{i-1}^{(b)} - V_i x_{i+1}^{(t)},$$

where x_0, x_{p+1}, W_1, and V_p are undefined and should be taken to zero in this equation. If the calculations are carried out using exact arithmetic, then z is the solution of $Ax = f$.

In general the reduced system is block tridiagonal. However, Polizzi and Sameh [10] noted that the off diagonal blocks are often negligible and can be dropped, yielding a truncated reduced system $Tx_{tr} = g_r$, which is block diagonal,

$$\begin{bmatrix} E_1 & & & & \\ & E_2 & & & \\ & & \ddots & & \\ & & & \ddots & \\ & & & & E_{p-1} \end{bmatrix} \begin{bmatrix} x_{tr,1} \\ x_{tr,2} \\ \vdots \\ x_{tr,p-1} \end{bmatrix} = \begin{bmatrix} g_{r,1} \\ g_{r,2} \\ \vdots \\ g_{r,p-1} \end{bmatrix}. \tag{2.4}$$

The subscript tr is an abbreviation of the words "truncated" and "reduced". In Theorem 3.8 we establish a tight upper bound on the size of the off diagonal blocks in terms of the degree of diagonal dominance of the original matrix and the size of the partitions. Polizzi and Sameh [10] showed that it is possible to compute the truncated reduced system without assembling the entire SPIKE system. Let $\mathcal{A}$ denote one of the diagonal blocks and consider the problem of computing the bottom $\mathcal{V}^{(b)}$ of the corresponding spike $\mathcal{V}$, given by

$$\mathcal{A}\mathcal{V} = \begin{bmatrix} 0 \\ \mathcal{B} \end{bmatrix}, \tag{2.5}$$

where $\mathcal{B}$ is a k by k dense matrix. It is not important here that $\mathcal{B}$ is lower triangular. We can exploit the remaining structure as follows. Let $\mathcal{A} = LU$ be the LU factorization of $\mathcal{A}$. Partition L and Y conformally with the right-hand side,

$$\begin{bmatrix} L_{11} & 0 \\ L_{21} & L_{22} \end{bmatrix} \begin{bmatrix} Y_1 \\ Y_2 \end{bmatrix} = \begin{bmatrix} 0 \\ \mathcal{B} \end{bmatrix},$$

where L_{22} is a k by k lower unit triangular matrix. Since $L_{11}Y_1 = 0$, we have $Y_1 = 0$, and the problem reduces to solving $L_{22}Y_2 = \mathcal{B}$. Then we solve $U\mathcal{V} = Y$. Partition U and $\mathcal{V}$ conformally with Y and the right-hand side,

$$\begin{bmatrix} U_{11} & U_{12} \\ 0 & U_{22} \end{bmatrix} \begin{bmatrix} \mathcal{V}_1 \\ \mathcal{V}_2 \end{bmatrix} = \begin{bmatrix} Y_1 \\ Y_2 \end{bmatrix}.$$

Since U is upper triangular we can compute $\mathcal{V}^{(b)} = \mathcal{V}_2 = U_{22}^{-1}Y_2$ without computing $\mathcal{V}_1$. Similarly if $A_i = U_i'L_i'$ is a UL factorization of A_i, then it is possible to extract the top of the subdiagonal spikes without computing the entire spike.

Polizzi and Sameh [10] found experimentally that it is faster to extract the truncated reduced system using the LU/UL combinations than it is to compute the entire SPIKE matrix using the LU factorizations only. This is true on machines where arithmetic operations require much less time than memory references. The UL/LU strategy has greater data locality: computing the spikes is a BLAS2 operation, whereas computing the LU/UL factorizations is a BLAS3 operation.

The original equation is equivalent to

$$A_i x_i = f_i - C_i x_{i-1}^{(b)} - B_i x_{i+1}^{(t)}, \quad i = 1, 2, \ldots p, \tag{2.6}$$

where $x_0^{(b)}$, $x_{p+1}^{(t)}$, C_1, and B_p are undefined and should be taken to zero in this equation.

These observations led to the truncated SPIKE algorithm by Polizzi and Sameh [10]. The algorithm consist of four stages.

Stage 1. Processor i computes the LU/UL factorizations

$$A_i = L_i U_i \quad \text{and} \quad A_i = U_i' L_i', \quad i = 1, 2, \ldots p.$$

Stage 2. Processor i solves

$$A_i g_i = f_i, \quad i = 1, 2, \ldots p,$$

using the LU factorization. Processor i computes $V_i^{(b)}$ using (L_i, U_i), $i = 1, 2, \ldots p-1$. Processor i computes $W_i^{(t)}$ using (U_i', L_i') , $i = 2, 3 \ldots p$.

Stage 3. Processor $i+1$ sends $W_{i+1}^{(t)}$ and $g_{i+1}^{(t)}$ to processor i, $i = 1, 2, \ldots p-1$. Processor i solves one block of the truncated reduced system, specifically

$$\begin{bmatrix} I_k & V_i^{(b)} \\ W_{i+1}^{(t)} & I_k \end{bmatrix} \begin{bmatrix} x_i^{(b)} \\ x_{i+1}^{(t)} \end{bmatrix} = \begin{bmatrix} g_i^{(b)} \\ g_{i+1}^{(t)} \end{bmatrix}, \quad i = 1, 2, \ldots p-1,$$

using Gaussian elimination without pivoting.

Stage 4. Processor i sends $x_i^{(b)}$ to processor $i+1$, for $i = 1, 2, \ldots, p-1$, and processor i sends $x_i^{(t)}$ to processor $i-1$ for $i = 2, 3, \ldots, p$. Then processor i solves

$$A_i y_i = f_i - C_i x_{i-1}^{(b)} - B_i x_{i+1}^{(t)}, \quad i = 1, 2, \ldots, p$$

using the LU factorization, where $x_0^{(b)}$, $x_{p+1}^{(t)}$, C_1, and B_p are undefined and should be taken to zero in this equation. The vector y is an approximation of the solution to $Ax = f$.

3. The matrices S, R, and T. In this section we prove that the matrices S, R, and T in (2.2), (2.3), and (2.4) are strictly diagonally dominant by rows with degree no less than A, and we establish an upper bound on their condition number. The degree of diagonal dominance is defined by (1.3). We bound the truncation error, i.e., the difference between R and T, and show that all our bounds are tight.

The general estimates for the decay rates of the inverse of a banded matrix discovered by Demko, Moss, and Smith [3] are not suitable in our situation because it is necessary to exploit the relationship between the matrices and the right-hand sides which determine the spikes, in order to obtain estimates which are tight.

LEMMA 3.1. *Let $n \le m$ and let A be any n by m matrix which is strictly diagonally dominant by rows with degree $d > 1$. Let $A = LU$ be the LU factorization which is obtained by applying Gaussian elimination without pivoting to A. Then U is strictly diagonally dominant by rows with degree no less than d.*

Proof. Gaussian elimination produces a chain of matrices $A^{(j)}$, where the first $j-1$ columns of $A^{(j)}$ are lower triangular, $A = A^{(1)}$ and $A^{(n)} = U$. Due to the recursive nature of Gaussian elimination, it suffices to consider the transition from $A = A^{(1)}$ to $B = A^{(2)}$. Let $B = [b_{ij}]$. We must show the following equalities

$$|b_{kk}| \ge d \sum_{j \notin \{1,k\}} |b_{k,j}|, \quad k = 2, 3, \ldots, m.$$

Now, since $d \ge 1$ and $|a_{11}| \ge d \sum_{j=2}^{m} |a_{1j}|$ we have

$$\begin{aligned} |a_{kk}| &\ge d \sum_{j \ne k} |a_{kj}| \ge |a_{k1}| + d \sum_{j \notin \{1,k\}} |a_{kj}| \\ &\ge |a_{k1}| \frac{d \sum_{j=2}^{m} |a_{1j}|}{|a_{11}|} + d \sum_{j \notin \{1,k\}} |a_{kj}| \\ &\ge |a_{k1}| \frac{|a_{1k}|}{|a_{11}|} + d \sum_{j \notin \{1,k\}} \left(|a_{kj}| + \frac{|a_{k1}|}{|a_{11}|} |a_{1j}| \right). \end{aligned}$$

Now, since

$$b_{ij} = a_{ij} - \frac{a_{i1}}{a_{11}} a_{1j}, \quad i = 2, 3, \ldots, n, \quad j = 2, 3, \ldots, m,$$

the previous inequality implies

$$|b_{kk}| \ge |a_{kk}| - \frac{|a_{k1}|}{|a_{11}|} |a_{1k}| \ge d \sum_{j \notin \{1,k\}} \left(|a_{kj}| + \frac{|a_{k1}|}{|a_{11}|} |a_{1j}| \right) \ge d \sum_{j \notin \{1,k\}} |b_{kj}|. \qquad \square$$

COROLLARY 3.2. *Let A be an n by n matrix, and let F be an n by m matrix. If the matrix $\begin{bmatrix} A, & F \end{bmatrix}$ is strictly diagonally dominant by rows with degree $d > 1$, then the matrix $\begin{bmatrix} I, & A^{-1}F \end{bmatrix}$ is strictly diagonally dominant by rows with degree no less than d.*

Proof. We use Gaussian elimination without pivoting to reduce the n by $n+m$ matrix $\begin{bmatrix} A, & F \end{bmatrix}$ to upper triangular form, $U = [u_{ij}]$. By Lemma 3.1, U is diagonally dominant by rows with degree no less than d, and using back substitution we have a formula for the entries g_{ij} of the n by m matrix $G = A^{-1}F$, namely,

$$g_{n-t,j} = \frac{1}{u_{n-t,n-t}} \left(u_{n-t,n+j} - \sum_{s=n-t+1}^{n} u_{n-t,s} g_{s,j} \right),$$

for $j = 1, 2, \dots m$ and $t = 0, 1, 2 \dots n-1$. Let $\epsilon = d^{-1}$ and let $\Omega \subseteq \{0, 1, \dots n-1\}$ be given by

$$t \in \Omega \Leftrightarrow \sum_{j=1}^{m} |g_{n-t,j}| \leq \epsilon.$$

We will prove that $\Omega = \{0, 1, \dots n-1\}$. First, $0 \in \Omega$ because U is strictly diagonally dominant by rows with degree no less than d, and if $\{0, 1, 2, \dots t-1\} \subset \Omega$ with $t < n$, then

$$\begin{aligned}
\sum_{j=1}^{m} |g_{n-t,j}| &\leq \frac{1}{|u_{n-t,n-t}|} \sum_{j=1}^{m} \left(|u_{n-t,n+j}| + \sum_{s=n-t+1}^{n} |u_{n-t,s}||g_{s,j}| \right) \\
&= \frac{1}{|u_{n-t,n-t}|} \left(\sum_{j=1}^{m} |u_{n-t,n+j}| + \sum_{s=n-t+1}^{n} |u_{n-t,s}| \sum_{j=1}^{m} |g_{s,j}| \right) \\
&\leq \frac{1}{|u_{n-t,n-t}|} \left(\sum_{j=1}^{m} |u_{n-t,n+j}| + \sum_{s=n-t+1}^{n} |u_{n-t,s}|\epsilon \right) \leq \epsilon,
\end{aligned}$$

which implies $t \in \Omega$. Therefore $\Omega = \{0, 1, 2 \dots n-1\}$ and the proof is complete. ∎

THEOREM 3.3. *Let A be strictly diagonally dominant by rows with degree $d > 1$. Then the matrices S, R, and T are strictly diagonally dominant by rows with degree no less than d, specifically*

$$d \leq d(S) \leq d(R) \leq d(T),$$

with equality possible. The condition numbers share a common bound, namely

$$\max\{\, \kappa_\infty(S),\, \kappa_\infty(R),\, \kappa_\infty(T)\} \leq \frac{d+1}{d-1},$$

with the possibility of

$$\kappa_\infty(S) = \kappa_\infty(R) = \kappa_\infty(T) = \frac{d+1}{d-1}.$$

Proof. If S is strictly diagonally dominant by rows, then it is clear that T and R are strictly diagonally dominant by rows and $d(S) \leq d(R) \leq d(T)$. By applying Lemma 3.2 to the matrices $\begin{bmatrix} A_i, & F_i \end{bmatrix}$ where

$$F_1 = \begin{bmatrix} 0 \\ B_1 \end{bmatrix}, \quad F_i = \left[\begin{bmatrix} 0 \\ B_i \end{bmatrix}, \begin{bmatrix} C_i \\ 0 \end{bmatrix} \right], \; i = 2, \dots p-1, \quad \text{and} \quad F_p = \begin{bmatrix} C_p \\ 0 \end{bmatrix},$$

we see that S is strictly diagonally dominant by rows with degree no less than d. Since $S_{ii} = 1$, we have $\|S - I\|_\infty \leq \epsilon < 1$ which allows us to treat S as a small perturbation of the identity matrix and estimate

$$\|S^{-1}\|_\infty \leq \frac{1}{1-\epsilon}, \quad \text{and} \quad \kappa_\infty(S) \leq \frac{1+\epsilon}{1-\epsilon} = \frac{d+1}{d-1},$$

and similarly for R and T.

It remains to be seen that our bounds are tight. To this end we consider a special case of the original problem, (2.1), where the diagonal blocks satisfy $A_i = I_\mu$ and the off-diagonal blocks are given by

$$\overline{B}_i = \begin{bmatrix} 0 & 0 \\ \epsilon J_k & 0 \end{bmatrix}, \quad \text{and} \quad \overline{C}_{i+1} = \begin{bmatrix} 0 & \epsilon J_k \\ 0 & 0 \end{bmatrix}, \quad i = 1, 2, \ldots p-1,$$

where J_k is the k by k antidiagonal identity matrix, and $\epsilon \in (0, 1)$. The matrix A is diagonally dominant by rows with degree $d = \epsilon^{-1}$. The upper and the lower bandwidths are equal to k. The main block diagonal is equal to the identity matrix, which implies $A = S$. The reduced system is block diagonal which implies $T = R$. It follows that

$$d(T) = d(R) = d(S) = d.$$

Computing S^{-1} reduces to inverting the 2 by 2 matrix $\left[\begin{smallmatrix} 1 & \epsilon \\ \epsilon & 1 \end{smallmatrix}\right]$. Direct computation establishes that

$$\kappa_\infty(T) = \kappa_\infty(R) = \kappa_\infty(S) = \frac{1+\epsilon}{1-\epsilon} = \frac{d+1}{d-1}. \qquad \square$$

We now study the truncation error, i.e., $\|R - T\|_\infty$. Let $\mathcal{A}$ denote one of the diagonal blocks of A, and let $\mathcal{V}$ be the corresponding superdiagonal spike given by (2.5). We are especially interested in the size of the elements at the top of the spike, i.e., the submatrix $\mathcal{V}^{(t)}$, which is given by

$$\mathcal{V}^{(t)} = \mathcal{V}(1:k, 1:k).$$

There is no loss of generality in limiting the analysis to the first diagonal block, rather there is a slight notational advantage, because the numbering of the elements of A and $\mathcal{A}$ coincide. We will use μ to denote the size of the first diagonal block.

We begin by estimating the size of the elements located in the bottom of $\mathcal{V}$; i.e., the submatrix $\mathcal{V}^{(b)}$ given by

$$\mathcal{V}^{(b)} = \mathcal{V}(\mu - k + 1 : \mu, 1 : k).$$

LEMMA 3.4. *Let A be strictly diagonally dominant by rows with degree $d > 1$. Let $\mathcal{V}$ be a superdiagonal spike. Then the submatrix $\mathcal{V}^{(b)}$ satisfies*

$$\|\mathcal{V}^{(b)}\|_\infty \leq \epsilon,$$

where $\epsilon = d^{-1}$.

Proof. Reduce the first μ by n block row to upper triangular form U. Since Gaussian elimination without pivoting preserves the upper bandwidth and does not decrease the degree of diagonal dominance, we have the following set of inequalities

$$\sum_{j=1}^{k} |u_{\mu-t,\mu-t+j}| \leq \epsilon |u_{\mu-t,\mu-t}|, \qquad t = 0, 1, \ldots k-1. \tag{3.1}$$

Our goal is to show that $\|\mathcal{V}^{(b)}\|_\infty \leq \epsilon$ or equivalently

$$\sum_{j=1}^{k} |v_{\mu-t,j}| \leq \epsilon, \quad t = 0, 1, \ldots k-1. \tag{3.2}$$

To this end we define the set $\Omega \subseteq \{0, 1, 2, \ldots, k-1\}$ by

$$t \in \Omega \Leftrightarrow \sum_{j=1}^{k} |v_{n-t,j}| \leq \epsilon.$$

We claim that $\Omega = \{0, 1, 2, \ldots, k-1\}$. Clearly $0 \in \Omega$, because

$$\sum_{j=1}^{k} |u_{\mu,\mu+j}| \leq \epsilon |u_{\mu,\mu}|, \quad \text{and} \quad v_{\mu,j} = \frac{u_{\mu,\mu+j}}{u_{\mu,\mu}}, \quad j = 1, 2, \ldots k.$$

Now suppose $\{0, 1, 2, \ldots t-1\} \subset \Omega$ with $t < k$. We wish to show that $t \in \Omega$. By back substitution we find that

$$v_{\mu-t,j} = \frac{1}{u_{\mu-t,\mu-t}} \left(u_{\mu-t,\mu+j} - \sum_{s=1}^{t} u_{\mu-t,\mu-t+s} v_{\mu-t+s,j} \right), \quad j = 1, 2, \ldots, (k-t),$$

and

$$v_{\mu-t,j} = -\frac{1}{u_{\mu-t,\mu-t}} \sum_{s=1}^{t} u_{\mu-t,\mu-t+s} v_{\mu-t+s,j}, \quad j = (k-t)+1, \ldots, k.$$

It follows that

$$\begin{aligned}
\sum_{j=1}^{k} |v_{\mu-t,j}| &\leq \frac{1}{|u_{\mu-t,\mu-t}|} \left(\sum_{j=1}^{k-t} |u_{\mu-t,\mu+j}| + \sum_{j=1}^{k} \sum_{s=1}^{t} |u_{\mu-t,\mu-t+s} v_{\mu-t+s,j}| \right) \\
&= \frac{1}{|u_{\mu-t,\mu-t}|} \left(\sum_{j=1}^{k-t} |u_{\mu-t,\mu+j}| + \sum_{s=1}^{t} |u_{\mu-t,\mu-t+s}| \sum_{j=1}^{k} |v_{\mu-t+s,j}| \right) \\
&\leq \frac{1}{|u_{\mu-t,\mu-t}|} \left(\sum_{j=1}^{k-t} |u_{\mu-t,\mu+j}| + \epsilon \sum_{s=1}^{t} |u_{\mu-t,\mu-t+s}| \right) \\
&\leq \frac{1}{|u_{\mu-t,\mu-t}|} \sum_{j=1}^{k} |u_{\mu-t,\mu-t+j}| \leq \epsilon,
\end{aligned}$$

which implies $t \in \Omega$. It follows that $\Omega = \{0, 1, 2, \ldots k-1\}$ and $\|\mathcal{V}^{(b)}\|_\infty \leq \epsilon$. ∎

We continue with the following lemma which relates the size of the elements in a specific row of $\mathcal{V}$ to the infinity norm of the k by k submatrix which lies directly below the row.

LEMMA 3.5. *Let μ denote the dimension of the diagonal block $\mathcal{A}$ and let $i \geq \mu - k$. Then*

$$\sum_{j=1}^{k} |v_{i,j}| \leq \epsilon \|\mathcal{V}(i+1 : i+k, 1 : k)\|_\infty.$$

Proof. We have

$$\mathcal{V} = \mathcal{A}^{-1} \begin{bmatrix} 0 \\ \mathcal{B} \end{bmatrix}$$

for the appropriate k by k matrix $\mathcal{B}$. We use Gaussian elimination without pivoting to reduce the matrix

$$\begin{bmatrix} \mathcal{A}, & \begin{bmatrix} 0 \\ \mathcal{B} \end{bmatrix} \end{bmatrix},$$

to upper triangular form $U = [u_{ij}]$. By Lemma 3.2 U is strictly diagonally dominant by rows with degree no less than d. Since the original matrix A was banded and no pivoting was applied, it follows that $u_{ij} = 0$ for all i and j such that $j > \mu$ and $i \geq \mu - k$. It follows by back substitution that

$$v_{i,j} = -\frac{1}{u_{i,i}} \sum_{s=i+1}^{i+k} u_{i,s} v_{s,j},$$

which implies

$$\sum_{j=1}^{k} |v_{i,j}| \leq \frac{1}{|u_{i,i}|} \sum_{s=i+1}^{i+k} |u_{i,s}| \sum_{j=1}^{k} |v_{s,j}|.$$

By definition

$$\max_{s=i+1,\ldots i+k} \sum_{j=1}^{k} |v_{s,j}| = \|\mathcal{V}(i+1:i+k, 1:k)\|_\infty,$$

and since U is strictly diagonally dominant by rows with degree no less than d, we have

$$\frac{1}{|u_{i,i}|} \sum_{s=i+1}^{i+k} |u_{i,s}| \leq \epsilon,$$

which completes the proof. □

The following corollary is an immediate consequence.

COROLLARY 3.6. *Let $\mathcal{V}'$ and $\mathcal{V}''$ be two k by k submatrices of the superdiagonal spike $\mathcal{V}$, such that $\mathcal{V}'$ lies directly on top of $\mathcal{V}''$. Then*

$$\|\mathcal{V}'\|_\infty \leq \epsilon \|\mathcal{V}''\|_\infty.$$

This corollary establishes a chain of inequalities leading from the bottom to the top of the spike which together with Lemma 3.4 implies the following theorem.

THEOREM 3.7. *Let d denote the degree of diagonal dominance of A, let μ denote the dimension of one of the diagonal blocks, and $q = \lfloor \mu/k \rfloor$ is the largest integer less than or equal to μ/k. The top of the corresponding superdiagonal spike $\mathcal{V}$ satisfies the inequality*

$$\|\mathcal{V}^{(t)}\|_\infty \leq \epsilon^q.$$

Is this estimate for the decay rate of the spikes tight or not? Let $\epsilon \in (0,1)$ and consider the upper triangular matrix A given by $a_{ii} = 1$, $a_{ij} = \epsilon$ for $i = j - k$, and $a_{ij} = 0$ in all other cases. Now consider a partition of a certain size μ. Write $\mu = qk + r$, where $q = \lfloor \mu/k \rfloor$, and the remainder r satisfies $0 \leq r < k$. If $r > 0$, then by back substitution we find that the corresponding spike is given by

$$\mathcal{V} = \begin{bmatrix} \mathcal{V}_{q+1}^T & \mathcal{V}_q^T & \ldots & \mathcal{V}_1^T \end{bmatrix}^T,$$

where

$$V_j = (-1)^{j-1}\epsilon^j I_k \quad \text{for } j = 1, 2, \ldots, q,$$

and $V_{q+1} = (-1)^q \epsilon^{q+1} E_r$, where I_k is the k by k identity matrix and E_r consists of the last r rows of I_k. If $r = 0$, then the term V_{q+1} does not appear. Regardless of the value of the remainder r, we have

$$\left\|\mathcal{V}^{(t)}\right\|_\infty = \epsilon^q.$$

In short, if we limit ourselves to matrices A which are strictly diagonally dominant by rows with degree d and upper bandwidth k, then the estimate given in Theorem 3.7 is tight.

The following theorem is an immediate consequence of Theorem 3.7.

THEOREM 3.8. *Let A be a n by n narrow banded matrix with upper and lower bandwidth k, and strictly diagonally dominant by rows with degree d. Then the truncation error satisfies*

$$\|R - T\|_\infty \leq \max_{i=1,\ldots p} d^{-q_i},$$

where $q_i = \lfloor \mu_i / k \rfloor$, and μ_i is the size of the ith partition.

A better bound exists in the special case in which A is a tridiagonal, evenly diagonally dominant matrix [13], or when A is a tridiagonal Toeplitz matrix, which is also strictly diagonally dominant, as well as symmetric or skew symmetric [14].

Now, consider for the sake of simplicity, the case when the partitions have the same size μ. Then Theorem 3.8 reduces to the statement

$$\|R - T\|_\infty \leq d^{-q},$$

where $q = \lfloor \mu / k \rfloor$. Let S_T denote the matrix obtained by eliminating the tips of the spikes from the spike matrix S. Then the reduced system matrix for S_T is equal to T. The truncation error effectively replaces A with the matrix $A_T = DS_T$, for which we have

$$\|A - A_T\|_\infty \leq \|D\|_\infty \|S - S_T\|_\infty \leq \|A\|_\infty \|R - T\|_\infty \leq d^{-q}\|A\|_\infty, \tag{3.3}$$

or equivalently $A_T = A + \Delta A$, where $\|\Delta A\|_\infty \leq d^{-q}\|A\|_\infty$. We see that the effect of the truncation is to introduce a normwise relative backward error which is bounded by d^{-q}.

We have already seen that the estimate of Theorem 3.8 is tight, but which matrices exhibit the slowest possible decay rate? We can answer this question for tridiagonal matrices.

THEOREM 3.9. *Let $\{(a_i, b_i, c_i)\}_{i=1}^n$ be a finite sequence, such that $a_i \neq 0$, and*

$$\max_{i=1,\ldots,n} \frac{|b_i| + |c_i|}{|a_i|} = \epsilon < 1.$$

If the vector $x = (x_1, x_2, \ldots, x_n)^T$ given by

$$\begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} a_1 & b_1 & & \\ c_2 & \ddots & \ddots & \\ & \ddots & & b_{n-1} \\ & & c_n & a_n \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ \vdots \\ 0 \\ b_n \end{bmatrix}$$

exhibits the smallest possible decay rate, i.e., if $|x_1| = \epsilon^n, \epsilon = d^{-1}$, *then* $c_i = 0$, *for* $i = 1, 2, 3, \ldots, n$ *and* $|b_i| = \epsilon |a_i|$ *for* $i = 1, 2, \ldots n$.

Proof. Mikkelsen [9] gives a direct proof. □

4. Error analysis. In this section we do an error analysis of the truncated SPIKE algorithm. We begin by deriving a few results on Gaussian elimination for systems which are strictly diagonally dominant by rows with degree $d > 1$.

We assume that the original problem has been scaled by rows such that $a_{ii} = 1$. Such a scaling preserves the degree of diagonal dominance, and allows us to estimate

$$\|A_i\|_\infty \leq 1 + d^{-1}, \quad \|A_i^{-1}\|_\infty \leq \frac{1}{1 - d^{-1}}, \quad \text{and} \quad \kappa_\infty(A_i) \leq \frac{d+1}{d-1}.$$

Let u denote the unit roundoff error on the machine, and following Higham [6], we define

$$\gamma_j = \frac{ju}{1 - ju}, \tag{4.1}$$

when $ju < 1$. If A is any matrix, then $B = |A|$ is the matrix given by $b_{ij} = |a_{ij}|$. If A, B are matrices of the same dimension, then we write $A \leq B$, if $a_{ij} \leq b_{ij}$ for all i and j.

If A is a banded matrix with upper and lower bandwidth k, which is diagonally dominant by rows, and if Gaussian elimination runs to completion, then the computed solution $\hat{x}$ to $Ax = f$ satisfies

$$(A + \Delta A)\hat{x} = f, \quad |\Delta A| \leq \gamma_{3k+2} |\hat{L}||\hat{U}|,$$

where $\hat{L}$ and $\hat{U}$ are the computed LU factors.

Now, how large is $\|\Delta A\|_\infty$? If A is any n by n matrix and if $A = LU$ is the exact LU factorization, then

$$|L||U| = |AU^{-1}||U| \leq |A||U^{-1}||U|.$$

If U is diagonally dominant by rows, then by Lemma 8.8 [6]

$$\| |U^{-1}||U| \|_\infty \leq (2n - 1). \tag{4.2}$$

This estimate is tight. However, if A is strictly diagonally dominant by rows with degree $d > 1$, then we may be able to improve upon it. By Theorem 3.1 U is strictly diagonally dominant by rows with degree no less than d. Write $U = DV$, where D is the main diagonal of U, then

$$|U^{-1}||U| = |V^{-1}D^{-1}||DV| = |V^{-1}||V|,$$

which allows us to estimate

$$\| |U^{-1}||U| \|_\infty \leq \frac{d+1}{d-1}, \tag{4.3}$$

because $\|I - V\|_\infty \leq d^{-1} < 1$.

It is important to realize that neither (4.2) nor (4.3) need apply to the computed LU factorization, because, while $\hat{L}\hat{U}$ is the exact LU factorization of the matrix $A + \Delta A$, this matrix need not be diagonally dominant! However, since $\hat{L} \to L$, and $\hat{U} \to U$

as $u \to 0$, then $A + \Delta A$ will be strictly diagonally dominant by rows with degree close to d, for u sufficiently small, and then we may estimate

$$\|\Delta A\|_\infty \leq \gamma_{3k+2} \||\hat{L}||\hat{U}|\|_\infty \lesssim \gamma_{3k+2} \frac{d+1}{d-1} \|A\|_\infty.$$

In the following we assume that we may estimate

$$\|\Delta A\|_\infty \leq \gamma_{3k+2} \frac{d+1}{d-1} \|A\|_\infty.$$

Now, what can be said about the solution $\hat{X}$ to the equation $AX = F$ where X and F have m columns? We have

$$(A + \Delta A_j)\hat{x}_j = f_j, \quad |\Delta A_j| \leq \gamma_{3k+2} |\hat{L}||\hat{U}|, \quad j = 1, 2, \dots m,$$

where the perturbations ΔA_j depend on j, but share a common bound which is independent of j. Now, if the unit roundoff error is sufficiently small, specifically if

$$\alpha = \gamma_{3k+2} \left(\frac{d+1}{d-1} \right)^2 < 1, \tag{4.4}$$

then $I + A^{-1}\Delta A_j$ and $I + \Delta A_j A^{-1}$ are both invertible and we may write

$$\hat{x}_j = \sum_{i=0}^{\infty} \left(-A^{-1}\Delta A_j \right)^i x_j = A^{-1} \sum_{i=0}^{\infty} \left(-(\Delta A_j)A^{-1} \right)^i f_j,$$

from which it follows immediately that

$$|\hat{x}_j - x_j| \leq E_1 |x_j|, \quad E_1 = \sum_{i=1}^{\infty} \left(\gamma_{3k+2} |A^{-1}||\hat{L}||\hat{U}| \right)^i,$$
$$|A\hat{x}_j - f_j| \leq E_2 |f_j|, \quad E_2 = \sum_{i=1}^{\infty} \left(\gamma_{3k+2} |\hat{L}||\hat{U}||A^{-1}| \right)^i,$$

which implies

$$|\hat{X} - X| \leq E_1 |X|, \quad \text{and} \quad |A\hat{X} - F| \leq E_2 |F|.$$

The two operators, E_1 and E_2, share a common bound, namely,

$$\|E_1\|_\infty \leq \frac{\alpha}{1-\alpha}, \quad \text{and} \quad \|E_2\|_\infty \leq \frac{\alpha}{1-\alpha},$$

where α is defined by (4.4). It follows that

$$\|\hat{X} - X\|_\infty \leq \frac{\alpha}{1-\alpha} \|X\|_\infty, \quad \text{and} \quad \|A\hat{X} - F\|_\infty \leq \frac{\alpha}{1-\alpha} \|F\|_\infty. \tag{4.5}$$

Stage 1 Each matrix A_i has dimension μ and is strictly diagonally dominant by rows. The computed LU factorization satisfies

$$A_i + \Delta A_i = \hat{L}_i \hat{U}_i, \quad |\Delta A_i| \leq \gamma_{k+1} \left| \hat{L}_i \right| \left| \hat{U}_i \right|,$$

where

$$\left\|\left|\hat{L}_i\right|\left|\hat{U}_i\right|\right\|_\infty \lesssim \frac{d+1}{d-1}\|A_i\|_\infty,$$

when the unit roundoff error u is sufficiently small. We have the same type of estimate for the computed UL factorizations.

Stage 2 In the truncated SPIKE algorithm, we do not compute the entire SPIKE matrix but stop substituting as soon as the truncated reduced system matrix has been computed. However, in order to estimate the error, it is convenient to consider the computation of the entire SPIKE matrix S.

By applying (4.5) repeatedly to the individual block rows we find

$$\|\hat{S}-S\|_\infty \le \frac{2\alpha}{1-\alpha}\|S-I\|_\infty, \quad \left\|D\hat{S}-A\right\|_\infty \le \frac{2\alpha}{1-\alpha}\|A-D\|_\infty.$$

The extra factor of 2 is introduced because we have to treat the superdiagonal and the subdiagonal spikes separately.

Similarly we find for the computation of the modified right-hand side that

$$\|\hat{g}-g\|_\infty \le \frac{\alpha}{1-\alpha}\|g\|_\infty, \quad \text{and} \quad \left\|D\hat{g}-f\right\|_\infty \le \frac{\alpha}{1-\alpha}\|f\|_\infty.$$

It is clear that since $\hat{T}-T$ is a submatrix of $\hat{S}-S$ we have

$$\left\|\hat{T}-T\right\|_\infty \le \left\|\hat{S}-S\right\|_\infty \le \frac{2\alpha}{1-\alpha}\|S-I\|_\infty \le \frac{2\alpha}{1-\alpha}d^{-1}.$$

Stage 3 By Theorem 3.8 the truncated reduced system is a good approximation of the reduced system if d is not too close to 1 and if the partitions are not too small. By Theorem 3.3 the truncated reduced system is strictly diagonally dominant by rows with a degree no less than the original system. It consists of $p-1$ independent systems which are of dimension $2k$. By Theorem 9.3 [6] it follows that if Gaussian elimination runs to completion, then the computed solution $\hat{x}_{tr}$ of the computed truncated reduced system $\hat{T}x_{tr}=\hat{g}_r$ satisfies

$$\left(\hat{T}+\Delta\hat{T}\right)\hat{x}_{tr}=\hat{g}_r, \quad \left|\Delta\hat{T}\right| \le \gamma_{6k}\left|\hat{L}_t\right|\left|\hat{U}_t\right|,$$

where $\hat{L}_t\hat{U}_t$ is the computed LU factorization of the computed truncated reduced system matrix $\hat{T}$. It follows that

$$\|\hat{x}_{tr}-x_{tr}\|_\infty \le \frac{\beta}{1-\beta}\|x_{tr}\|_\infty \quad \text{and} \quad \left\|\hat{T}\hat{x}_{tr}-\hat{g}_r\right\| \le \frac{\beta}{1-\beta}\|\hat{g}_r\|_\infty,$$

provided the unit round off error is so small that

$$\beta = \gamma_{6k}\left(\frac{d+1}{d-1}\right)^2 < 1.$$

Stage 4 Adjusting the original right-hand side, i.e., computing

$$h_i = f_i - C_i x_{i-1}^{(b)} - B_i x_{i+1}^{(t)},$$

introduces a small forward error. Notice that C_i affects only the top of f_i and B_i affects only the bottom of f_i. The componentwise relative forward error is no more than

$$|\hat{h}_i - h_i| \le \gamma_{k+1}\left(|f_i| + |C_i||x_{i-1}^{(b)}| + |B_i||x_{i+1}^{(t)}|\right),$$

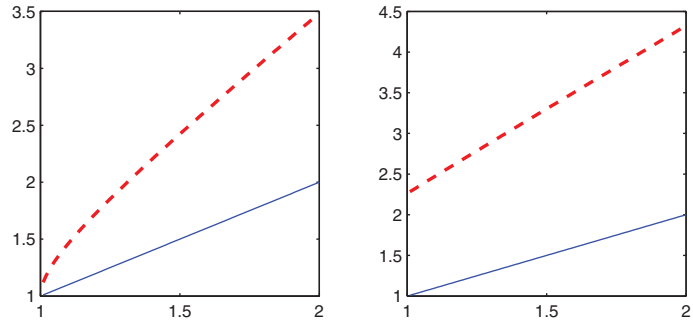

FIG. 5.1. *The degree of diagonal dominance for the matrix $S^{(k)}$ as a function of the degree of diagonal dominance of the original matrices: $A^{(k)}$ (left), and $B^{(k)}$ (right). The matrices are defined by equation* (5.1). *The red dotted line is the experimental result and the solid blue line is the theoretical lower bound.*

regardless of the order in which the scalar products are evaluated. This is an overestimate which does not take into account that the central components of f_i are not changed at all. The solution of the final set of linear equations is identical to stage 2 and generates a normwise relative residual of at most $\frac{\alpha}{1-\alpha}$, as well as a normwise relative forward error of at most $\frac{\alpha}{1-\alpha}$; cf. (4.5).

In short, if d is not too close to 1 and if the partitions are not too small, then the errors at every stage of the algorithm are small. We found that the simplest way to evaluate the overall error was to calculate the residual and estimate

$$\|x-y\|_\infty \leq \|A^{-1}\|_\infty \|f-Ay\|_\infty \leq \frac{1}{1-d^{-1}}\|f-Ay\|_\infty,$$

which turned out to be fairly effective as long as d is not too close to 1.

5. Numerical experiments. We ran experiments to verify the main results of this paper as well as compare the accuracy of the truncated SPIKE algorithm with the algorithm implemented in ScaLAPACK.

5.1. The matrices S, R, and T. We wanted to verify that the degree of diagonal dominance of the SPIKE matrix S was no less than that of the original matrix A. We selected two sequences of matrices with $(n, k_u, k_l) = (10^6, 5, 5)$:

$$A_{ij}^{(k)} = \begin{cases} 1+0.01k & \text{for } i=j \\ -0.1 & \text{for } 0<|i-j|\leq 5, \\ 0 & \text{otherwise} \end{cases} \qquad B_{ij}^{(k)} = \begin{cases} 1+0.01k & \text{for } i=j \\ 0.1 & \text{for } 0<|i-j|\leq 5, \\ 0 & \text{otherwise} \end{cases} \tag{5.1}$$

for $k = 1, 2, \ldots, 100$. We selected $p = 8$ partitions and a uniform block size of $1.25 \cdot 10^5$. We explicitly computed the entire SPIKE matrix S and the excess $\|S-I\|_\infty$ for each of these 200 matrices, from which we determined the degree of diagonal dominance as $d(S) = 1/\|S-I\|_\infty$. Our results are displayed in Figure 5.1. We found that not only is the degree of diagonal dominance preserved, i.e., $d(S) \geq d(A)$, but there can be a substantial increase in diagonal dominance as well.

We extracted the truncated reduced system matrix T from each of the 200 matrices and computed the condition number in the infinity norm by explicitly inverting T and calculating $\|T^{-1}\|_\infty$. We then plotted the condition number of T as a function of the degree of diagonal dominance of A. The results are displayed in Figure 5.2.

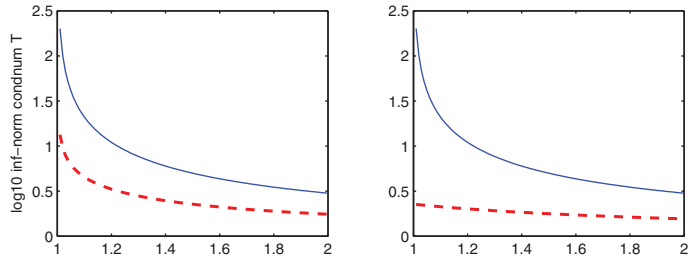

FIG. 5.2. *The condition number of the truncated reduced system as a function of the degree of diagonal dominance of the original system matrices: $A^{(k)}$ (left), and $B^{(k)}$ (right). The matrices are defined by equation* (5.1). *The dotted red line is the experimental result and the solid blue line is the theoretical upper bound.*

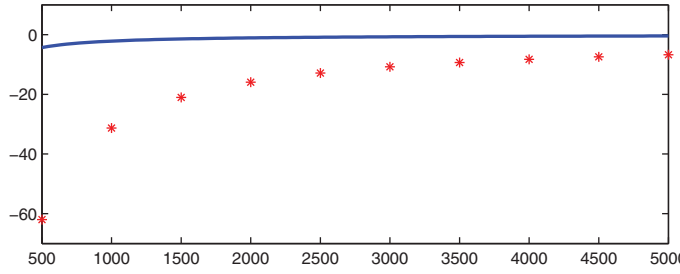

FIG. 5.3. *The infinity norm of the truncation error as a function of the number of partitions. Solid blue line is the theoretical upper bound, while red dots are experimental results. The matrix has $d = 1.01$ and is tridiagonal.*

The theoretical upper bound is given by $\frac{d+1}{d-1}$ where $d = d(A)$ is the degree of diagonal dominance of A. We found that the truncated reduced system was even better conditioned than expected.

We wanted to investigate the size of the truncation error as a function of the degree of diagonal dominance of the original matrix A and the number of partitions p. We selected a tridiagonal Toeplitz matrix with $n = 5 \cdot 10^5$ and 1.01 on the main diagonal and 0.5 on the off-diagonal elements. We choose $p = 500j$, for $j = 1, 2, \ldots, 10$ and computed the truncation error explicitly. The theoretical upper bound is given by d^{-q} where $d = 1.01$ and $q = \lfloor 5 \cdot 10^5/p \rfloor$. The results are displayed in Figure 5.3. The truncation error is much smaller than the theoretical upper bound and it is smaller than the unit roundoff error $u = 2^{-53} \approx 1.1 \cdot 10^{-16}$ as long as $p \leq 2000$.

5.2. The error analysis. We wanted to verify the bounds presented in section 4. We constructed matrices which were diagonally dominant by rows with different degrees and ran them through our implementation of the truncated SPIKE algorithm. The matrices all had $(n, k_l, k_u) = (10^6, 10, 10)$ with every diagonal entry equal to 1. The nonzero, off-diagonal entries where positive and constant for each matrix, such that the degree of diagonal dominance varied from 1.1 for the first matrix to 2.0 for the last matrix, with steps of 0.1. The right-hand side side was generated from the solution which was selected as $x = (1, 1, \ldots, 1)^T$. Our results are listed as Table 5.1 and Table 5.2. The bounds were computed as follows:

1. The modified right-hand side,

$$\|D\hat{g} - f\|_\infty \leq \frac{\alpha}{1-\alpha}\|f\|_\infty.$$

TABLE 5.1

2. The SPIKE matrix,

$$\left\|D\hat{S} - A\right\|_\infty \leq 2\frac{\alpha}{1-\alpha}d^{-1}.$$

3. The computed truncated reduced system,

$$\left\|\hat{T}\hat{x}_{tr} - \hat{g}_r\right\|_\infty \leq \gamma_{6k}\frac{d+1}{d-1}\|\hat{x}_{tr}\|_\infty.$$

4. The overall error,

$$\|\hat{x} - x\|_\infty \leq \frac{1}{1-d^{-1}}\|A\hat{x} - f\|_\infty.$$

We see that the modified right-hand side g is computed with a small residual and that the bound becomes increasingly accurate as d becomes larger. The SPIKE matrix is computed with a very small residual and the bound is between 10^3 and 10^5 times too large. The computed reduced system is solved with a very small residual and the bound is between 10^2 and 10^3 times larger. Finally we see that using the residual to estimate the error is very reliable, leading to estimates that are accurate within one order of magnitude.

5.3. Comparisons with ScaLAPACK. We began by comparing the errors in the truncated SPIKE algorithm to ScaLAPACK (PDDBTRF/PDDBTRS) for four

TABLE 5.3

The 2-norm of the absolute error for ScaLAPACK (Sca) (PDDBTRF/PDDBTRS) and the truncated SPIKE (T.S) algorithm for four different banded matrices and different numbers of partitions. The results from LAPACK (DGBTRF/DGBTRS) are listed at the bottom of the table.

different matrices with

$$(n, k_l, k_u) \in \left\{ \left(2.0 \cdot 10^4, 10, 10\right), \left(10^5, 10, 10\right), \left(10^5, 50, 50\right), \left(10^6, 10, 10\right) \right\}.$$

Every diagonal entry was 1 and all other entries within the band were 10^{-2}. The right-hand side was constructed from the solution which was selected as $(1, 2, \ldots, n)^T$. The number of partitions were 2, 4, 8, 16, 24, 32, 48, 64, 128, and 256. The calculations were carried out in IEEE double precision arithmetic. We measured the 2-norm of the absolute error. Our results are displayed in Table 5.3. In our experiments ScaLAPACK did slightly better than the truncated SPIKE algorithm, but the difference between the two algorithms decreased, as the problems became larger. We would like to draw attention to the case of $p = 256$. In this case ScaLAPACK cannot be applied to the first matrix where $n = 20{,}000$, because the matrix is too small and the bandwidth is large compared to the number of partitions, and the routine issues the appropriate error message. The truncated SPIKE algorithm had a large error for the first and the third matrix. This is due to the fact that the infinity norm of the truncation error was very large: for the first matrix it was $1.62 \cdot 10^{-12}$, while for the third matrix it was $1.52 \cdot 10^{-7}$. In all other cases we found that the infinity norm of the truncation error was either less than machine ϵ or much smaller than the unit round off error u. The experiments with $p = 256$ emphasize the fact that the truncated SPIKE algorithm should not be applied to problems where the partitions are either too small or where the diagonal blocks are not diagonally dominant enough. The first matrix is diagonally dominant with degree $d = 5$, and for $p = 256$ the dimension of the smallest partition was 78. In this case Theorem 3.7 gives an upper bound for the infinity norm of the truncations error of $5^{-7} \approx 1.28 \cdot 10^{-5}$. In other words, we knew in advance that the result might not be accurate. Theorem 3.7 does not apply to the third matrix, which is not strictly diagonally dominant.

We found nine matrices that were diagonally dominant at Matrix Market. They were all quite small, with dimensions no larger than 5000. We extracted narrow banded matrices from these matrices by choosing $k = \lceil 0.01n \rceil$. We ran the examples through LAPACK (DGBTRF/DGBTRS), ScaLAPACK (PDDBTRF/PDDBTRS), our own implementation of the truncated SPIKE algorithm, as well as the SPIKE package itself (TU0). The matrices were scaled such that the main diagonals were 1

and the right-hand side was generated from the solution which was selected as $x = (1, 1, \ldots, 1)^T$. We measured the 2-norm of the absolute error. Our results are listed in Table 5.4 and Table 5.5. We found no substantial difference in the accuracy of the four different routines.

6. Conclusion. We have shown that the SPIKE matrix is diagonally dominant by rows with a degree no less than that of the original matrix. We have derived a tight upper bound on the truncation error for the general case. We showed that the error committed at each stage is small, and we found that our bounds are probably pessimistic. We compared the truncated SPIKE algorithm to the corresponding algorithm in ScaLAPACK (PDDBTRF/PDDBTRS) and found no substantial difference between the accuracy of the two methods. The advantage of the truncated SPIKE algorithm is that if the matrix is diagonally dominant by rows with degree $d > 1$ and the partitions are sufficiently large, then the reduced system is essentially block diagonal and can be solved with a constant amount of communication, with all but one processor contributing equally to the solution of the reduced system. In ScaLAPACK (PDDTRS) the reduced system is solved recursively with the number of active processors being cut in half at each iteration.

SYMBOLIC AND EXACT STRUCTURE PREDICTION FOR SPARSE GAUSSIAN ELIMINATION WITH PARTIAL PIVOTING*

LAURA GRIGORI†, JOHN R. GILBERT‡, AND MICHEL COSNARD§

Abstract. In this paper we consider two structure prediction problems of interest in Gaussian elimination with partial pivoting of sparse matrices. First, we consider the problem of determining the nonzero structure of the factors L and U during the factorization. We present an exact prediction of the structure that identifies some numeric cancellations appearing during Gaussian elimination. The numeric cancellations are related to submatrices of the input matrix A that are structurally singular, that is, singular due to the arrangements of their nonzeros, and independent of their numerical values. Second, we consider the problem of estimating upper bounds for the structure of L and U prior to the numerical factorization. We present tight exact bounds for the nonzero structure of L and U of Gaussian elimination with partial pivoting $PA = LU$ under the assumption that the matrix A satisfies a combinatorial property, namely, the Hall property, and that the nonzero values in A are algebraically independent of each other. This complements existing work showing that a structure called the row merge graph represents a tight bound for the nonzero structure of L and U under a stronger combinatorial assumption, namely, the strong Hall property. We also show that the row merge graph represents a tight symbolic bound for matrices satisfying only the Hall property.

Key words. sparse LU factorization, partial pivoting, structure prediction, characterization of fill

1. Introduction.

In this paper we consider the problem of structure prediction when solving a linear system $Ax = b$ by Gaussian elimination with partial pivoting, where A is an $n \times n$ sparse, nonsingular, and nonsymmetric matrix and b is an n-vector. This elimination, also called LU factorization, involves explicit factorization of the matrix A into the product of L and U, where L is a unit lower triangular matrix and U is an upper triangular matrix.

One of the main characteristics of the sparse LU factorization is the notion of fill. "Fill" denotes a nonzero entry in the factors that was a zero in matrix A. When Gaussian elimination without pivoting is used, the nonzero structure of the factors can be computed without referring to the numerical values of the matrix and is determined before performing the numerical computation of the factors themselves. Knowledge of this structure is used to allocate memory, set up data structures, schedule parallel tasks, and save time [16] by avoiding operations on zeros. When pivoting is used for numerical stability [13], the structure of L and U depends not only on the structure of A but also on the row interchanges. As the row interchanges are determined while doing the numerical factorization, the computation of the structure of the factors has to be interleaved with the computation of the numerical values of the factors. Prior to the numerical factorization, only upper bounds of the structure of L and U can be determined.

We discuss in this paper two structure prediction problems. The first problem considers the computation of the nonzero structure of the factors during Gaussian elimination with row interchanges. The second problem is to obtain tight bounds of the structure of L and U prior to the numerical factorization. For both problems, we study relations between the combinatorial properties of the nonzero structure of the matrix A and the LU factorization.

Two kinds of structure prediction and two combinatorial properties of the input matrix are usually considered for these problems. The two structure predictions are called *symbolic* and *exact* [11]. *Symbolic* structure prediction assumes that the addition or subtraction of two nonzero results always yields a nonzero result. It ignores possible numeric cancellations occurring during the LU factorization. *Exact* structure prediction assumes that the nonzero values in A are algebraically independent from each other; in other words, it assumes that any computed zero is due to combinatorial properties of the nonzero structure. The two combinatorial properties of the input matrix are called the *strong Hall* property and the *Hall* property. The *strong Hall* property is an irreducibility condition. The *Hall* property is a weaker combinatorial assumption and is related to matrices with full-column rank. We will define these two properties in more detail later in the paper. A matrix that satisfies the Hall property can be decomposed using the Dulmage–Mendelsohn decomposition [2, 17, 18] into a block upper triangular form such that every block on the diagonal satisfies the strong Hall property. However, in practice this decomposition is not always used, and hence it is interesting to understand the structure prediction for matrices satisfying either the strong Hall property or the Hall property.

Much of the research has been aimed at predicting the structure and bounds of the factors L and U as tightly as possible [9, 10, 11, 12, 20]. The existing results for determining the nonzero structure of L and U during Gaussian elimination with partial pivoting $PA = LU$ are symbolic [20]. Under several additional conditions, this structure prediction is exact [11]. But in general it ignores possible numeric cancellations during the factorization for matrices satisfying the strong Hall property or only the Hall property. For the problem of predicting bounds for the structure of L and U prior to the numerical factorization, the existing results in the literature assume that A satisfies the strong Hall property. The results assume the LU factorization with partial pivoting is seen as

$$A = P_1 L_1 P_2 L_2 \dots P_{n-1} L_{n-1} U,$$

where P_i is an $n \times n$ elementary permutation matrix identifying the row interchanges at step i. L_i is an $n \times n$ elementary lower triangular matrix whose ith column contains the multipliers at step i. U is an $n \times n$ upper triangular matrix. $\widetilde{L}$ is the $n \times n$ matrix whose ith column is the ith column of L_i so that $\widetilde{L} - I = \sum_i (L_i - I)$. Note that this $\widetilde{L}$ is not the same as the factor L obtained from the factorization $PA = LU$. Both matrices are unit lower triangular, and they contain the same nonzero values but in different positions. The factor L has its rows in the order described by the entire row permutations. The factor $\widetilde{L}$ has the rows of its ith column in the order described by only the first i row interchanges. George and Ng [9] predict an upper bound of the nonzero structure of $\widetilde{L}$ and U, called the row merge graph, that contains the nonzeros in $\widetilde{L}$ and U for all possible row permutations which can later appear in the numerical factorization due to pivoting. Gilbert and Ng [11] showed that this is a tight exact bound for a square matrix with nonzero diagonal which satisfies the strong Hall property.

In this paper we provide answers to several open questions related to the two structure prediction problems considered here. For the first problem, we identify the exact structure prediction of L and U during LU factorization with partial pivoting. For the second problem, we describe the exact bounds of the factors obtained from the factorization $PA = LU$, when the matrix A satisfies only the Hall property. These exact bounds are not symbolic bounds. Then we show that the row merge graph represents symbolic bounds for the structure of $\widetilde{L}$ and U.

The exact structure prediction is based on the following approach: all of the elements of the factors L and U can be computed using the determinants of two submatrices of the input matrix A (see, for example, Gantmacher [8]). Consider, for example, the element in position (i, j) of U, where i and j are two indices with $i \leq j$. Let A_{i-1} be the submatrix of A formed by the first $(i-1)$ columns and the first $(i-1)$ rows of A. Let K be the $i \times i$ submatrix of A that includes the first i rows, the first $i-1$ columns, and column j of A. Then the value in position (i, j) of the factor U is given by the quotient of the determinant of K and the determinant of A_{i-1}. A similar relation exists for the elements of L. Our new results identify when the submatrix K is structurally singular, that is, singular due to the arrangements of its nonzeros, and independent of the numerical values. In exact arithmetic, the determinant of K is zero, and hence the element in position (i, j) corresponds to a numeric cancellation. This numeric cancellation is identified in our new results on exact structure prediction. However, in a backward stable factorization $A + E = \hat{L}\hat{U}$, the computed factors $\hat{L}$ and $\hat{U}$ are not necessarily close to the exact $A = LU$ factors, even though the norm of E is small. In particular, a zero in L or U may, in principle, be large in $\hat{L}$ or $\hat{U}$, so rounding it to zero may cause backward instability.

The rest of the paper is organized as follows. In section 2 we present background and several new results used throughout the paper. In section 3 we consider the problem of determining the nonzero structure of the factors L and U during Gaussian elimination with partial pivoting. We present new results that give an exact characterization of the fill occurring in the LU factorization. We show how the theoretical results can be used in an algorithm for computing fill-ins.

In sections 4 and 5 we consider the problem of predicting bounds for the structure of L and U prior to the numerical factorization. In section 4 we present an exact analysis for matrices that satisfy the Hall property. We present tight exact bounds for the nonzero structure of L and U of Gaussian elimination with partial pivoting $PA = LU$. In section 5 we present a symbolic analysis, and we show that the row merge graph is a lower symbolic bound for the factors $\widetilde{L}$ and U of the factorization $A = P_1 L_1 P_2 L_2 \dots P_{n-1} L_{n-1} U$. In other words, for every edge of the row merge graph of a Hall matrix, there is a permutation such that this edge corresponds to a symbolic nonzero in $\widetilde{L}$ or U. By a simple counterexample, we will show that the row merge graph is not a tight bound for the factors L and U in the exact sense. These results are of practical interest since the row merge graph is used by several solvers implementing the sparse LU factorization with partial pivoting. In solvers like the sequential and shared memory versions of SuperLU [5, 6], the row merge graph is used to estimate the memory needs prior to the LU factorization. In solvers proposed in [9, 21], the numerical computation of the factors L and U is performed on the row merge graph, and some operations involve zero elements. Finally, section 6 presents concluding remarks.

2. Graphs of matrices and their properties. In this section we provide the necessary notions to study the structure prediction of the sparse LU factorization

with partial pivoting. We give definitions, previously published results, and two new results (Lemmas 2.6 and 2.7) that are needed by our subsequent proofs.

Let A be a sparse $n \times n$ matrix. A_{ij} denotes the element at row i and column j of A. We refer to the determinant of matrix A as $\det(A)$. We denote the submatrix of A formed by elements of row indices from i to j and column indices from d to e as $A(i\colon j, d\colon e)$. When the indices are not consecutive, we use the following notation: $A([i\colon j, k], d\colon e)$ denotes the submatrix of A formed by elements of row indices from i to j and k and column indices from d to e. We refer to the submatrix $A(1\colon i, 1\colon i)$ as the principal minor of order i of A.

Two graphs are used to predict the nonzero structure of the factors L and U from the structure of A. The first graph is the directed graph of A and is denoted by $G(A)$. This graph has n vertices and an edge $\langle i, j\rangle$ for each nonzero element A_{ij}. We say that the edge $\langle i, j\rangle$ is incident on the vertices i and j.

The second graph is the bipartite graph of A, denoted by $H(A)$. This graph is undirected and has n row vertices, n column vertices, and an edge $\langle i', j\rangle$ if and only if the element A_{ij} is nonzero. Note that whenever possible, we use prime to distinguish between row vertices and column vertices in a bipartite graph. Also we use i, j, k, d, and e to denote a vertex of H for which it is known if it is a column or a row vertex. That is, i' stands for a row vertex and i for a column vertex. We use v and w to denote a generic vertex of H, that is, a vertex that can be a row vertex or a column vertex.

A *path* is a sequence of distinct vertices $\mathcal{Q} = (v_0, v_1, \ldots, v_{q-1}, v_q)$ such that for each two consecutive vertices v_i, v_{i+1} there is an edge from v_i to v_{i+1}. The length of this path is q. The vertices $v_1, \ldots, v_{q-1}$ are called intermediate vertices.

Let H be a bipartite graph with m row vertices and n column vertices. A matching M on H is a set of edges, no two of which are incident on the same vertex. A vertex is covered or matched by M if it is an end point of an edge of M. A matching is called column-complete if it has n edges, row-complete if it has m edges, and perfect if $m = n$ and it is both row- and column-complete. Given a graph H and a column vertex i, we denote by $H - i$ the subgraph of H induced by all of the row vertices and all of the column vertices except i.

The next lemma identifies a matching in the bipartite graph H of A such that if the edges of M become the diagonal elements, the values chosen make the permuted matrix strongly diagonally dominant. It will be used in section 4 to prove our results on exact structure prediction for Hall matrices.

LEMMA 2.1 (Gilbert and Ng [11]). *Suppose the bipartite graph H has a perfect matching M. Let A be a matrix with $H(A) = H$ such that $A_{ij} > n$ for $\langle i', j\rangle \in M$ and $0 < A_{ij} < 1$ for $\langle i', j\rangle \notin M$. If A is factored by Gaussian elimination with partial pivoting, then the edges of M will be the pivots.*

If M is a matching on H, an alternating path with respect to M is a path on which every second edge is an element of M. A c-alternating path is a path that follows matching edges from rows to columns. An r-alternating path is a path that follows matching edges from columns to rows. Suppose the last vertex of one c-alternating path is the first vertex of another c-alternating path. The path obtained by their concatenation is also a c-alternating path. The same result holds for r-alternating paths. Suppose $\mathcal{Q}$ is an alternating path from an unmatched vertex v to a different vertex w. If the last vertex w on $\mathcal{Q}$ is unmatched or the last edge on $\mathcal{Q}$ belongs to M, then a new matching M_1 can be obtained from M by alternating along path $\mathcal{Q}$. The set of edges of M_1 is given by $M \oplus \mathcal{Q} = (M \cup \mathcal{Q}) - (M \cap \mathcal{Q})$. If w is matched by M, then v is matched and w is unmatched by M_1 and $|M_1| = |M|$. If w is unmatched

by M, then both v and w are matched by M_1, $|M_1| = |M| + 1$, and $\mathcal{Q}$ is called an augmenting path with respect to M.

2.1. Hall and strong Hall graphs. We briefly review the Hall and the strong Hall properties and related results. For a detailed description of Hall and strong Hall matrices and their properties, the reader is directed to [2, 3, 11].

A bipartite graph with m rows and n columns has the *Hall property* if every set of k column vertices is adjacent to at least k row vertices, for all $1 \leq k \leq n$. The next theorem and corollary relate the Hall property to column-complete matchings and matrices with full-column rank. In Corollary 2.3 [11] it is shown that if H is Hall and given a matrix A with $H = H(A)$, then the set of ways to fill in its values to make it singular has measure zero. Hence almost all matrices A with $H = H(A)$ have full-column rank.

THEOREM 2.2 (Hall's theorem). *A bipartite graph has a column-complete matching if and only if it has the Hall property.*

COROLLARY 2.3 (Gilbert and Ng [11]). *If a matrix A has full-column rank, then $H(A)$ is Hall. Conversely, if H is Hall, then almost all matrices A with $H = H(A)$ have full-column rank.*

Known results in structure prediction were obtained under an additional assumption, called the strong Hall property. A bipartite graph with m rows and $n \leq m$ columns satisfies the *strong Hall property* if

(i) $m = n > 1$ and every set of k column vertices is adjacent to *more than* k row vertices, for all $1 \leq k < n$, or

(ii) $m > n$ and every set of k column vertices is adjacent to *more than* k row vertices, for all $1 \leq k \leq n$.

LEMMA 2.4 (Gilbert and Ng [11]). *If H is strong Hall and has more nonzero rows than columns and M is any column-complete matching on H, then from every row or column vertex v of H there is a c-alternating path to some unmatched row vertex i' (which depends on v and M).*

The next theorem relates alternating paths and matchings in strong Hall graphs. This theorem was used in several structure prediction results, in the context of sparse LU factorization by Gilbert and Ng in [11], as well as in the sparsity analysis of QR factorization by Coleman, Edenbrandt, and Gilbert in [4] and Hare et al. in [15]. In this paper we will use it in Lemma 2.6 to derive a new result on alternating paths and matchings in strong Hall graphs.

THEOREM 2.5 (alternating paths, Gilbert [12]). *Let H be a strong Hall graph with at least two rows, let i be a column vertex of H, and let v be any row or column vertex of H such that a path exists from i to v. Then H has a column-complete matching for which there exists a c-alternating path from i to v (or, equivalently, an r-alternating path from v to i).*

The next lemma is new. Given a path in a bipartite graph H between a column vertex and a row vertex or between two row vertices, the lemma shows that there is an alternating path with respect to a column-complete matching of H which excludes a row vertex at the extremity of the path. We will use it in sections 3 and 4 to estimate the nonzero structure of the factors L and U.

LEMMA 2.6. *Let H be a strong Hall graph with more nonzero rows than columns, let v be a row or column vertex of H, and let i' be any row vertex of H such that a path exists from v to i'. Then H has a column-complete matching which excludes vertex i' and for which there exists a c-alternating path from v to i'.*

Proof. We distinguish two different cases.

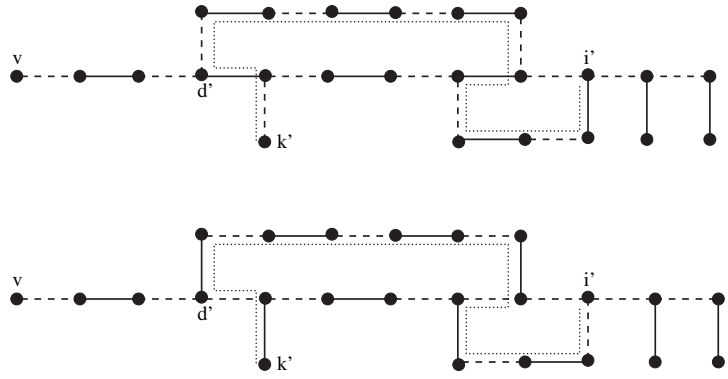

FIG. 2.1. *Case* 1 *of Lemma* 2.6. *In the upper graph, the solid edges are the matching* M*; path* $\mathcal{P}$ *is the horizontal path from* v *to* i'*; path* $\mathcal{Q}$ *is the light dotted line from* i' *to* k'*. In the lower graph, the solid edges are the matching* M_1*. The path obtained by concatenating* $\mathcal{P}[v\colon d']$ *and* $\mathcal{Q}[d'\colon i']$ *is c-alternating with respect to* M_1*.*

Case 1 (v is a column vertex). By hypothesis, there is a path from v to i'. As H is strong Hall, the alternating path Theorem 2.5 applies and says that H has a column-complete matching M for which there exists a c-alternating path $\mathcal{P}$ from v to i'. If i' is not covered by M, then M is the column-complete matching searched. Otherwise, Lemma 2.4 implies that there is an unmatched row vertex k' and a c-alternating path $\mathcal{Q}$ from i' to k'. Now obtain matching M_1 from M by alternating along path $\mathcal{Q}$, where i' is unmatched in M_1.

If $\mathcal{P}$ and $\mathcal{Q}$ have no vertices in common (except row vertex i'), then $\mathcal{P}$ is still c-alternating from v to i' with respect to M_1. If the only vertex in common for $\mathcal{P}$ and $\mathcal{Q}$ (except row vertex i') is column vertex v, then let e' be the row vertex matched by M to v that belongs to the path $\mathcal{Q}$. The path formed by $\langle v, e'\rangle$ followed by $\mathcal{Q}[e'\colon i']$ is c-alternating with respect to M_1.

If $\mathcal{P}$ and $\mathcal{Q}$ have intermediate vertices in common, let d' be the first (row) vertex of $\mathcal{P}$ (starting from v) which belongs to $\mathcal{Q}$. The path obtained by the concatenation of $\mathcal{P}[v\colon d']$ and $\mathcal{Q}[d'\colon i']$ is c-alternating with respect to M_1, and this ends the proof for this case. This case is illustrated in Figure 2.1.

Case 2 (v is a row vertex). We denote the row vertex v as v'. By hypothesis, there is a path from v' to i'. Suppose $v' \neq i'$; otherwise there is nothing to prove. Let d be the first column vertex on this path, that is, the next vertex after v'. H is a strong Hall graph that has a path from column vertex d to row vertex i'. The first case of this theorem, that we have just proved, says that there is a column-complete matching M that excludes vertex i' and for which there exists a c-alternating path $\mathcal{P}$ from d to i'. We distinguish four cases.

Case 2.1 (v' is not matched by M). Let e' be the row vertex matched by M to the column vertex d. We obtain a new matching M_1 by unmatching row vertex e' and matching row vertex v' to row vertex d. The path formed by $\langle v', d\rangle$ followed by $\mathcal{P}$ is c-alternating from v' to i' with respect to M_1. Note that M_1 excludes row vertex i', and this is the path searched.

Case 2.2 (v' is matched by M to the column vertex d). The path obtained by $\langle v', d\rangle$ followed by $\mathcal{P}$ is c-alternating from v' to i' with respect to the matching M, and the matching M excludes row vertex i'.

Case 2.3 (v' is matched by M and belongs to the path $\mathcal{P}$). Then $\mathcal{P}[v'\colon i']$ is a c-alternating path with respect to the matching M.

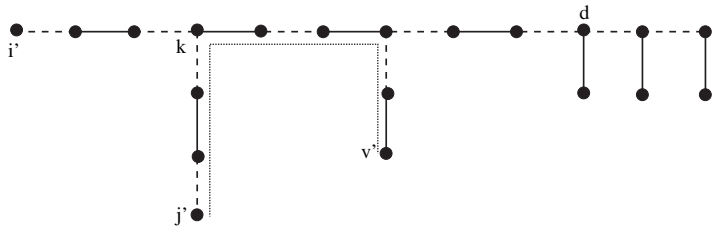

FIG. 2.2. *Case* 2.4 *of Lemma* 2.6. *The solid edges are the matching* M*; path* $\mathcal{P}$ *is the horizontal path from* i' *to* d*; path* $\mathcal{R}$ *is the light dotted line from* v' *to* j'*. Here,* $\mathcal{P}$ *and* $\mathcal{R}$ *have at least one common vertex. Vertex* k *is the last vertex on* $\mathcal{P}$ *(starting from* d*) that belongs to* $\mathcal{R}$*. The path obtained by concatenating* $\mathcal{R}[v':k]$ *and* $\mathcal{P}[k:i']$ *is c-alternating with respect to* M*, and* M *excludes row vertex* i'*.*

Case 2.4 (v' is matched by M to a different column vertex than d and does not belong to the path $\mathcal{P}$). Lemma 2.4 applies and says that there is an unmatched row vertex j' and a c-alternating path $\mathcal{R}$ from v' to j'.

If $\mathcal{P}$ and $\mathcal{R}$ have no vertices in common, then obtain matching M_1 from M by alternating along path $\mathcal{R}$. As v' is matched in M, then v' is unmatched in M_1 and j' is matched in M_1. From here we proceed as in Case 2.1, and we obtain a matching that excludes vertex i' and with respect to which there is a c-alternating path from v' to i'.

If $\mathcal{P}$ and $\mathcal{R}$ have at least one vertex in common, then let k be the last vertex of $\mathcal{P}$ (starting from d) which belongs to $\mathcal{R}$. Note that k has to be a column vertex. The path obtained by concatenating $\mathcal{R}[v':k]$ and $\mathcal{P}[k:i']$ is c-alternating with respect to M, M excludes the row vertex i', and this ends the proof. This case is illustrated in Figure 2.2. □

2.2. Hall sets and their properties. For a bipartite graph H with m row vertices and $n \leq m$ column vertices, a set of k column vertices, $1 \leq k \leq n$, forms a *Hall set* if these columns are adjacent to exactly k rows [15].

Under the assumption that A satisfies the Hall property, the union of two Hall sets is a Hall set, so there exists a unique Hall set of maximum cardinality in any given set of columns. The set of maximum cardinality might be empty. Let C_j be the Hall set of maximum cardinality in the first j columns; we define $C_0 = \emptyset$. Let R_j be the set of all row indices covered by the columns of C_j; thus C_j and R_j have the same cardinality. Note that if we assume all diagonal entries of A are nonzero, then $R_j = \{i' : 1 \leq i \leq j \text{ and } i \in C_j\}$.

The Hall sets of maximum cardinality are useful to partition a Hall graph into two subgraphs: one that satisfies the Hall property and another one that satisfies the strong Hall property. Let H be a bipartite graph with m row vertices and $n < m$ column vertices that satisfies the Hall property. Let C be the Hall set of maximum cardinality in H, and let R be the set of row vertices covered by column vertices of C. The first subgraph $\widetilde{H}$ is induced by all of the row vertices in R and all of the column vertices in C. This subgraph satisfies the Hall property. The second subgraph $\widehat{H}$ is induced by all of the row vertices except those in R and all of the column vertices except those in C. This subgraph is strong Hall because its Hall set of maximum cardinality is empty.

In a similar way, we can partition the edges of a column-complete matching M of H into edges belonging to the graph $\widetilde{H}$ and edges belonging to the graph $\widehat{H}$. This is expressed in a more general way in the following lemma.

LEMMA 2.7. *Let A be an $m \times n$ Hall matrix, $m \geq n$. Let C be a Hall set of cardinality p in A, where $p \leq n$, and let R be the set of all row indices covered by the columns of C. Suppose M is a column-complete matching in the bipartite graph $H(A)$. Then each column vertex j of C is matched by M to a row vertex i' of R.*

Proof. The proof is immediate. □

3. Nonzero structure of L and U during Gaussian elimination with partial pivoting. Let A be an $n \times n$ nonsingular matrix. In this section we consider the problem of determining the nonzero structure of the factors L and U during Gaussian elimination with partial pivoting. In the first part of this section we consider the LU factorization without pivoting. We first present a brief overview of several well-known results described in the literature. Then we describe why these results ignore numeric cancellations related to submatrices of A that are structurally singular. In section 3.1 we present new results that identify some numeric cancellation occurring during Gaussian elimination and caused by submatrices of A that are structurally singular. In section 3.2 we describe how the new results can be used in the Gaussian elimination with partial pivoting. We also present an algorithm that uses the new results to compute the nonzero structure of the factors L and U.

The main result in the structure prediction of Gaussian elimination without pivoting is the fill path Lemma 3.1. This lemma relates paths in the directed graph $G(A)$ and the nonzero elements that appear in the factors L and U, represented in the so-called filled graph $G^+(A)$.

LEMMA 3.1 (fill path (Rose and Tarjan [20])). *Let G be a directed or undirected graph whose vertices are the integers 1 through n, and let G^+ be its filled graph. Then $\langle i, j\rangle$ is an edge of G^+ if and only if there is a path in G from i to j whose intermediate vertices are all smaller than $\min(i, j)$.*

The filled graph $G^+(A)$ represents a symbolic bound for the factors L and U; that is, it ignores possible numeric cancellation during the factorization. The next lemma represents an example of conditions under which this structure prediction is exact, by taking into account the values of the nonzeros in the matrix. In this lemma, a square Hall submatrix of A denotes a square submatrix of A which satisfies the Hall property and which is formed by a subset of rows and columns of A that can be different and noncontiguous.

LEMMA 3.2 (Gilbert and Ng [11]). *Suppose A is square and nonsingular and has a triangular factorization $A = LU$ without pivoting. Suppose also that all of the diagonal elements of A, except possibly the last one, are nonzero and that every square Hall submatrix of A is nonsingular. Then $G(L + U) = G^+(A)$; that is, every nonzero predicted by the filled graph of A is actually nonzero in the factorization.*

We are interested in fill when the diagonal may contain zeros (perhaps due to pivoting), but Lemma 3.2 does not hold in this case. An example showing this was given by Brayton, Gustavson, and Willoughby [1]. We give a slightly different example in Figure 3.1, where we display a matrix A, its bipartite graph $H(A)$, and its directed graph $G(A)$. Note that $H(A)$ satisfies the strong Hall property. Since there is a path from 5 to 4 through lower numbered vertices in $G(A)$, the edge $\langle 5, 4\rangle$ belongs to the filled graph $G^+(A)$, but $L_{54} = 0$ regardless of the nonzero values of A. That is because after the first step of elimination, the elements in column positions 2 and 4 of the rows 2 and 5 are linearly dependent. At the second step of elimination the element L_{54} is zeroed.

A simpler way of understanding this numeric cancellation is to consider the two submatrices $A([1\colon 3, 5], 1\colon 4)$ and $A(1\colon 3, 1\colon 3)$ and their determinants that determine

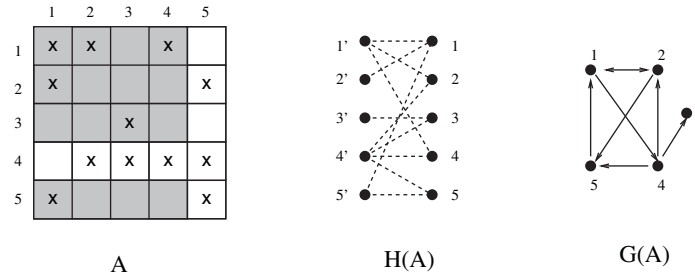

FIG. 3.1. *Example showing that the fill path Lemma* 3.2 *does not predict exactly the nonzero structure of* L *and* U *when factorizing without pivoting the strong Hall matrix* A*. Details are given in the text following Lemma* 3.1.

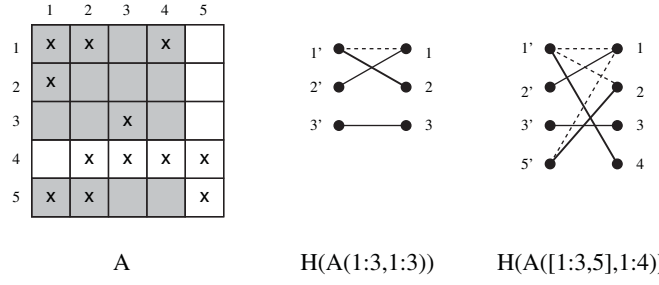

FIG. 3.2. *Example for Theorem* 3.4 $(1 \to 2)$*. Consider the strong Hall matrix* A *and the matrix* $B = A([1\colon 3, 5], 1\colon 4)$ *displayed in patterned gray. The Hall set of maximum cardinality of* $H(A([1\colon 3, 5], 1\colon 3))$ *is* $C_{35} = \{3\}$ *and* $R_{35} = \{3'\}$*. Suppose element* L_{54} *is nonzero. The perfect matching* M_k *of matrix* $A_k = A(1\colon 3, 1\colon 3)$ *is formed by the edges* $\langle 1', 2\rangle$*,* $\langle 2', 1\rangle$*, and* $\langle 3', 3\rangle$*. The perfect matching* M_B *of* B *is formed by the edges* $\langle 1', 4\rangle$*,* $\langle 2', 1\rangle$*,* $\langle 3', 3\rangle$*, and* $\langle 5', 2\rangle$*. Form a path by starting at* $5'$ *and by following one edge in* M_B *and one edge in* M_k*. This yields the path* $(5', 2, 1', 4)$*.*

the value of L_{54}. The submatrix $A([1\colon 3, 5], 1\colon 4)$ (displayed in light gray in Figure 3.1) has three columns (2, 3, and 4) with nonzero elements in only two rows (1 and 3). This submatrix does not satisfy the Hall property, and its determinant is zero. This is the approach we use to identify some numeric cancellations in the LU factorization.

The following lemma describes the above observation. Assuming that the LU factorization exists, this lemma relates the value of an element of the factors L and U to the singularity of a submatrix of A.

LEMMA 3.3 (Gilbert and Ng [11]). *Suppose* A *is square and nonsingular and has a triangular factorization* $A = LU$ *without pivoting. Let* i *be a row index and* j *a column index of* A*, and let* B *be the submatrix of* A *consisting of rows* 1 *through* $\min(i, j) - 1$ *and* i*, and columns* 1 *through* $\min(i, j) - 1$ *and* j*. Then* $(L + U)_{ij}$ *is zero if and only if* B *is singular.*

3.1. New results. Theorem 3.4 is the first new result of this section and provides necessary and sufficient conditions, in terms of paths in the bipartite graph $H(A)$ for a fill element to occur in exact arithmetic during Gaussian elimination. It is illustrated in Figures 3.2 and 3.3. Consider the nonzero structure of L. Suppose that the factorization exists until the step $j - 1$ of factorization; that is, the principal minor of order $j - 1$ is nonzero. The theorem uses the fact that L_{ij} is nonzero if and only if the determinant of the submatrix $A([1\colon j - 1, i], 1\colon j)$ is nonzero.

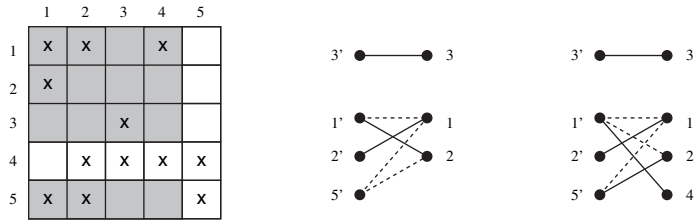

FIG. 3.3. *Example for Theorem* 3.4 ($3 \rightarrow 1$). *Consider the strong Hall matrix* A *as in Figure* 3.2, *the matrix* $B = A([1\colon 3, 5], 1\colon 4)$, $C_{35} = \{3\}$, *and* $R_{35} = \{3'\}$. *Consider the path* $\mathcal{Q} = (5', 1, 1', 4)$ *that has no vertex in* $C_{35} \cup R_{35}$. *The graph* $H(A([1\colon 3, 5], 1\colon 3))$ *is partitioned into two subgraphs. The subgraph induced by column vertex* 3 *and row vertex* $3'$ *satisfies the Hall property, and it has a perfect matching* $\widetilde{M} = \{\langle 3', 3\rangle\}$. *The subgraph induced by column vertices* $\{1, 2\}$ *and row vertices* $\{1', 2', 5'\}$ *satisfies the strong Hall property and has a column-complete matching* $\widehat{M} = \{\langle 1', 2\rangle, \langle 2', 1\rangle\}$ *for which there is a c-alternating path* $\mathcal{R} = (1', 2, 5')$. *The matching* M *is formed by the edges of* $\widetilde{M}$ *and* $\widehat{M}$ *and is presented by solid edges in the graph* $H(A([1\colon 3, 5], 1\colon 3))$. *The matching obtained by alternating along path* $\mathcal{R}$ *is a perfect matching of* $H(B)$ *and is presented at the right of the figure.*

THEOREM 3.4. *Let* A *be an* $n \times n$ *nonsingular matrix that has a triangular factorization* $A = LU$. *Suppose that every square Hall submatrix of* A *is nonsingular. Let* i *be a row of* A, j *be a column of* A, *and* $k = \min(i, j) - 1$. *Let* M_k *be a perfect matching of* $A(1\colon k, 1\colon k)$. *Let* C_{ki} *be the Hall set of maximum cardinality in* $H(A([1\colon k, i], 1\colon k))$ *and* R_{ki} *be the set of all row indices covered by columns of* C_{ki}. *Then the following three statements are equivalent:*

1. $(L + U)_{ij}$ *is nonzero.*
2. *There is an r-alternating path in the bipartite graph* $H(A)$ *from row vertex* i' *to column vertex* j *with respect to the matching* M_k.
3. *There is a path in the bipartite graph* $H(A)$ *from* i' *to* j *whose intermediate vertices are smaller than or equal to* k *and that has no vertex in* $C_{ki} \cup R_{ki}$.

Proof. Let A_k be the leading $(k \times k)$ principal submatrix of A and $\det(A_k)$ be its determinant. As we suppose the factorization exists, $\det(A_k)$ is nonzero. This implies that A_k satisfies the Hall property and has a perfect matching M_k. The matching M_k also represents a column-complete matching in the graph $H(A([1\colon k, i], 1\colon k))$. Lemma 2.7 applies with respect to the graph $H(A([1\colon k, i], 1\colon k))$ and the Hall set C_{ki} and says that each row vertex of R_{ki} has to be matched by M_k to one of the column vertices in C_{ki}. Since i' is not a row vertex matched by M_k, then $i' \notin R_{ki}$.

Let B be the submatrix of A consisting of columns 1 through k and j and rows 1 through k and row i. Suppose edge $\langle i', j\rangle$ does not belong to $H(A)$; otherwise the proof is trivial. We will prove now that the three statements are equivalent.

$1 \rightarrow 2$. As $(L+U)_{ij}$ is nonzero by hypothesis, then Lemma 3.3 applies and shows that B is a nonsingular matrix. Hence its bipartite graph $H(B)$ satisfies the Hall property, and there is a perfect matching M_B in $H(B)$.

Consider now the row vertex i' in the bipartite graph $H(A)$. Recall we assume that edge $\langle i', j\rangle$ does not belong to $H(A)$. Row vertex i' is matched by M_B to column vertex j_0. Since $i' \notin R_{ki}$, we can deduce that $j_0 \notin C_{ki}$. Column vertex j_0 is matched by M_k to some row vertex i'_0, where $i'_0 \neq i'$ since i' is not matched by M_k. Also we have that $i'_0 \notin R_{ki}$. Row vertex i'_0 is matched by M_B to some column vertex j_1, where $j_1 \neq j_0$ since j_0 is matched in M_B to i'. If $j_1 = j$, then we stop. Otherwise, we continue our reasoning. For each row vertex we consider its matched column vertex by M_B;

then for each column vertex we consider its matched row vertex by M_k. Continuing inductively, we arrive at vertex j. The vertices followed during our reasoning are vertices $i', j_0, i'_0, j_1, i'_1, \ldots, i'_t, j$. Edge $\langle i', j_0\rangle$ and edges $\langle i'_q, j_{q+1}\rangle$ are edges of $H(B)$ which belong to the perfect matching M_B. Edge $\langle i'_t, j\rangle$ and edges $\langle j_q, i'_q\rangle$ are edges of $H(A_k)$ which belong to the perfect matching M_k. This yields a path in $H(A)$ from row vertex i' to column vertex j that is r-alternating with respect to the matching M_k.

$2 \rightarrow 3$. Consider the r-alternating path $(i', j_0, i'_0, j_1, i'_1, \ldots, i'_t, j)$ from i' to j with respect to the matching M_k. All of the intermediate vertices on this path are smaller than or equal to k. Because $i' \notin R_{ki}$, we can deduce that $j_0 \notin C_{ki}$. Continuing inductively, we can deduce that this path does not include any vertex in $C_{ki} \cup R_{ki}$.

$3 \rightarrow 1$. Let d' be the last row vertex on $\mathcal{Q}$, that is, the vertex just before j on $\mathcal{Q}$. We partition the graph $H(A([1\colon k, i], 1\colon k))$ into two subgraphs. The first subgraph, induced by the row vertices in R_{ki} and the column vertices in C_{ki}, satisfies the Hall property and has a perfect matching $\widehat{M}$. The second subgraph, induced by the row vertices $1, \ldots k'$ and i', except row vertices in R_{ki}, and the column vertices 1 through k, except column vertices in C_{ki}, is strong Hall. Lemma 2.6 says that there is a column-complete matching $\widehat{M}$ which excludes row vertex i' and for which there exists a c-alternating path $\mathcal{R}$ from d' to i'.

Let the matching M be formed by the edges of $\widehat{M}$ and the edges of $\widetilde{M}$. This matching represents a column-complete matching in $H(A([1\colon k, i], 1\colon k))$. We now show that the graph $H(B)$ satisfies the Hall property. Recall that column vertex j and row vertex i' are not matched by the matching M. Consider path $\mathcal{R}$ from d' to i' that is c-alternating with respect to matching M. Obtain a new matching $M \oplus \mathcal{R}$ from M by alternating along path $\mathcal{R}$. As i' is not matched in M and d' is matched in M, then i' is matched in $M \oplus \mathcal{R}$ and d' is not matched in $M \oplus \mathcal{R}$. Add to matching $M \oplus \mathcal{R}$ the edge $\langle d', j\rangle$.

Thus we obtain a perfect matching in $H(B)$; that is, $H(B)$ satisfies the Hall property. By hypothesis, every square Hall submatrix of A is nonsingular, and thus B is nonsingular and its determinant is nonzero. Therefore $(L+U)_{ij}$ is nonzero. ∎

The next theorem uses Hall sets of maximum cardinality associated with subsets of columns of A to restrict paths corresponding to nonzero elements of L and U. In this paper we use this theorem in section 4 to determine upper bounds for the factorization $PA = LU$, where the matrix A satisfies only the Hall property. Note that for a matrix satisfying the strong Hall property, the Hall set of maximum cardinality of a subset of columns is always empty. Thus Theorem 3.5 is relevant to matrices satisfying only the Hall property. This theorem can also be useful in the algorithm described in section 3.2. The Hall sets involved can be computed prior to the factorization using an algorithm as, for example, the one proposed in [15].

THEOREM 3.5. *Let A be an $n \times n$ nonsingular matrix that is factored by Gaussian elimination as $A = LU$. Suppose that $(L+U)_{ij}$ is nonzero. Let $k = min(i, j) - 1$, and let C_k be the Hall set of maximum cardinality in the first k columns and R_k be the set of all row indices covered by columns of C_k. Then there is a path in the bipartite graph $H(A)$ from row vertex i' to column vertex j whose intermediate vertices are smaller than or equal to k and that has no vertex in $C_k \cup R_k$.*

Proof. Let C_{ki} be the Hall set of maximum cardinality in $H(A([1\colon k, i], 1\colon k))$ and R_{ki} be the set of all row indices covered by columns of C_{ki}. It can be easily shown that $C_k \subseteq C_{ki}$ and $R_k \subseteq R_{ki}$. The third statement of Theorem 3.4 implies that this theorem holds. ∎

Note that Theorem 3.5 provides only a necessary condition for fill to occur during the elimination. Figure 3.4 (as well as Theorem 3.4) shows that the condition is

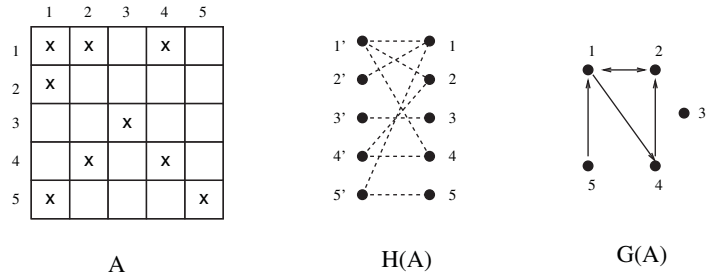

FIG. 3.4. *Example showing that the converse of Theorem* 3.5 *is not true.*

not sufficient. Consider the Hall matrix A in Figure 3.4. The Hall set of maximum cardinality is $C_3 = \{3\}$, and it covers the row index $R_3 = \{3'\}$. The Hall set of maximum cardinality in $H(A([1\!:\!3, 5], 1\!:\!3))$ is $C_{35} = \{2, 3\}$, and it covers the row indices $R_{35} = \{1', 3'\}$. There is a path $(5', 1, 1', 4)$ in $H(A)$ that has no vertex in C_3. However, the element $L_{54} = 0$ because of numeric cancellation.

3.2. Computing the nonzero structure of the factors L and U during Gaussian elimination with partial pivoting. In this section we present an algorithm that uses the results of the previous section to compute the nonzero structure of the factors L and U during the LU factorization with partial pivoting. The algorithm computes one column of L and one row of U at a time.

First, we present Theorem 3.6 that describes explicitly how Theorem 3.4 can be used during the LU factorization with partial pivoting of a matrix A. This theorem supposes that the first $j-1$ steps of the LU factorization exist, and it gives the necessary results to compute the structure of column j of L and of row j of U at the jth step of factorization.

THEOREM 3.6. *Let A be an $n \times n$ nonsingular matrix that is to be decomposed using LU factorization with partial pivoting. Suppose that the first $j-1$ steps of LU factorization with partial pivoting of A exist and have been executed. Let $P_{J-1} = P_{j-1}P_{j-2}\dots P_1$ be the permutations performed during the first $j-1$ steps of elimination, and let M_{j-1} be a perfect matching of $(P_{J-1}A)(1\!:\!j-1, 1\!:\!j-1)$. Suppose that every square Hall submatrix of A is nonsingular. At the jth step of decomposition, the element L_{ij} is nonzero if and only if there is a c-alternating path in the bipartite graph $H(P_{J-1}A)$ from column vertex j to row vertex i' with respect to the matching M_{j-1}. The element U_{ji} is nonzero if and only if there is an r-alternating path in the bipartite graph $H(A)$ from row vertex j' to column vertex i with respect to the matching M_{j-1}.*

Proof. The proof is similar to the proof of Theorem 3.4. □

Algorithm 1 uses Theorem 3.6 and sketches the factorization $PA = LU$, where $P = P_{n-1}\dots P_1$ and each P_j reflects the permutation of two rows at step j of factorization. At each step j, the structure of column j of L is determined, and then its numerical values are computed. The element of maximum magnitude in column j of L is chosen as the pivot. Let L_{kj} be this element. The algorithm interchanges rows k and j of L and rows k and j of A. Then the structure of row j of U is determined, followed by the computation of its numerical values.

The structure of column j of L is computed by finding all of the c-alternating paths with respect to M_{j-1} from column vertex j to some row vertex i'. This can be achieved in a similar way to the augmenting path technique, used in finding maximum matchings in bipartite graphs and described, for example, in [7]. This technique

ensures that each edge of the bipartite graph of A is traversed at most once. The structure of row i of U is computed in a similar way. Since the jth diagonal element corresponds to a nonzero, Theorem 3.4 ensures that there is a c-alternating path $\mathcal{Q}$ from column vertex j to row vertex j' with respect to the matching M_{j-1}. During the computation of the structure of column j of L, we store for each row vertex i' the column vertex just before i' on a c-alternating path with respect to M_{j-1} from j to i'. This allows us to retrace $\mathcal{Q}$. The algorithm computes a new matching M_j by alternating along path $\mathcal{Q}$.

The overall complexity of computing the structure of L and the structure of U in Algorithm 1 is hence bounded by $O(n \cdot nnz(A))$, where n is the order and $nnz(A)$ is the number of nonzeros of matrix A.

ALGORITHM 1. LU factorization with partial pivoting, aware of some cancellations

$M_0 = \emptyset$
for $j := 1$ to n **do**
  if $j < n$ **then**
    1. Compute structure of $L(j\colon n, j)$. This is formed by all row vertices $i' \geq j$ such that there is a c-alternating path in $H(A)$ with respect to M_{j-1} from column vertex j to row vertex i'.
    2. Compute numerical values of $L(j\colon n, j)$.
    3. Find k such that $|L_{kj}| = \max |L(j\colon n, j)|$. Let $v = L_{kj}$.
    4. Interchange $L(j, :)$ with $L(k, :)$ and $A(j, :)$ with $A(k, :)$. Let $\mathcal{Q}[j\colon j']$ be the c-alternating path in $H(A)$ with respect to M_{j-1} that corresponds to L_{jj}.
    5. Scale: $L(:, j) = L(:, j)/v$.
  end if
  6. Compute structure of $U(j, j+1\colon n)$. This is formed by all column vertices $i \geq j$ such that there is an r-alternating path in $H(A)$ from row vertex j' to column vertex i with respect to the matching M_{j-1}.
  7. Compute numerical values of $U(j, j+1\colon n)$. Let $U_{jj} = v$.
  if $j = 1$ **then**
    $M_1 = \mathcal{Q}$
  else
    $M_j = M_{j-1} \oplus \mathcal{Q}$
  end if
end for

Several aspects need to be investigated and remain as open questions. The first important aspect is related to the practical interest of using this algorithm, which depends on the utility of identifying numeric cancellations and on the number of numeric cancellations that appear in real world applications. The second aspect is related to the complexity of Algorithm 1, which is equivalent to the complexity of one of the first algorithms for computing the structure of the factors L and U, denoted as the FILL2 algorithm in [20]. The algorithms proposed more recently for computing fill-ins [10] are faster in practice than FILL2. Since we expect Algorithm 1 to have a similar run time to FILL2, further investigation is required to make it competitive with respect to the new algorithms.

4. Tight exact bounds for the structure prediction of $PA = LU$, when A satisfies only the Hall property. Let A be an $n \times n$ matrix that satisfies the Hall property. Suppose A is factored by Gaussian elimination with row interchanges

as $PA = LU$. In this section we discuss the problem of predicting bounds for the factors L and U prior to the numerical factorization. We consider exact results; that is, the upper bounds do not include elements that correspond to numeric cancellations due to submatrices of A structurally singular.

The next three theorems give tight exact bounds for the nonzero structure of the factors L and U. Theorem 4.1 gives upper bounds for the structure of L and U in terms of paths in the bipartite graph $H(A)$. Theorems 4.2 and 4.3 show that this bound is the tightest possible for Gaussian elimination with row interchanges of a matrix that satisfies the Hall property. That is, for every predicted element of the upper bound, there is a permutation and a choice of the values of matrix A such that this element corresponds to a nonzero in the factors L or U.

THEOREM 4.1. *Let A be an $n \times n$ nonsingular matrix that is factored by Gaussian elimination with row interchanges as $PA = LU$. Let i be an index, j be a column index, and $q = \min(i, j) - 1$. Let C_q be the Hall set of maximum cardinality in the first q columns and R_q be the set of all row indices covered by columns of C_q. If L_{ij} is nonzero, then there is a path in the bipartite graph $H(A)$ from row vertex k' to column vertex j whose intermediate column vertices are all in $\{1, \ldots, q\}$ and that has no vertex in $C_q \cup R_q$, where k is the row of A that corresponds to row i of PA. If U_{ij} is nonzero, then there is a path in the bipartite graph $H(A)$ from column vertex i to column vertex j whose intermediate column vertices are all in $\{1, \ldots, q\}$ and that has no vertex in $C_q \cup R_q$.*

Proof of Case 1 ($i \geq j$ (*structure of* L)). Due to Theorem 3.5, there is a path $\mathcal{Q}$ in $H(A)$ from row vertex k' to column vertex j whose intermediate column vertices are all in $\{1, \ldots, j-1\}$ and that has no vertex in $C_{j-1} \cup R_{j-1}$. This is the path searched in the theorem. □

Proof of Case 2 ($i < j$ (*structure of* U)). According to Theorem 3.5, there is a path $\mathcal{Q}$ in $H(A)$ from row vertex k' to column vertex j whose intermediate column vertices are all in $\{1, \ldots, i-1\}$ and that has no vertex in $C_{i-1} \cup R_{i-1}$.

By hypothesis, the factorization exists; thus the ith diagonal element of PA is nonzero. Theorem 3.5 applies with respect to this element and says that there is a path $\mathcal{R}$ in $H(A)$ from column vertex i to row vertex k' whose intermediate column vertices are all in $\{1, \ldots, i-1\}$ and that has no vertex in $C_{i-1} \cup R_{i-1}$.

Using the path $\mathcal{R}$ and the path $\mathcal{Q}$, we can form a path in $H(A)$ from column vertex i to column vertex j whose intermediate column vertices are all in $\{1, \ldots, i-1\}$ and that has no vertex in $C_{i-1} \cup R_{i-1}$. This is the path searched in the theorem. □

The next two theorems show that the upper bound defined in Theorem 4.1 for the structure of L and U is tight. First, Theorem 4.2 shows that the bound for the structure of L is tight, and it is illustrated in Figure 4.1. Second, Theorem 4.3 shows that the bound for U is tight, and it is illustrated in Figure 4.2.

The bound for L depends on the row permutations of A. It considers every row i of the original matrix A. The bound identifies all column indices j that correspond to elements of row i that can become potentially nonzeros during the factorization through permutations. The bound for U is independent of row permutations of A. It identifies potential nonzeros U_{ij} using paths that relate column vertex i to column vertex j in the bipartite graph of A. None of the results assumes that the input matrix A has a zero-free diagonal.

THEOREM 4.2. *Let H be the structure of a square Hall matrix. Let j be a column vertex, C_{j-1} be the Hall set of maximum cardinality in the first $j-1$ columns, R_{j-1} be the set of row indices covered by columns in C_{j-1}, and i' be any row vertex not in R_{j-1}. Suppose that H contains a path from i' to j whose intermediate column*

Proof. By hypothesis, there is a path in H from i' to j whose intermediate column vertices are all at most j. Consider H_{j-1} the subgraph of H induced by all row vertices and all column vertices from 1 to $j-1$. The graph H satisfies the Hall property, and hence H_{j-1} also satisfies the Hall property. We obtain a column-complete matching M_{j-1} in this graph which will induce the pivoting order for the first $j-1$ steps of elimination. We partition the graph H_{j-1} into two subgraphs. The first subgraph $\widetilde{H}_{j-1}$ satisfies the Hall property and is induced by all of the row vertices in R_{j-1} and all of the column vertices in C_{j-1}. Let $\widetilde{M}_{j-1}$ be a perfect matching in this subgraph. The second subgraph $\widehat{H}_{j-1}$ satisfies the strong Hall property and is induced by all of the row vertices except row vertices in R_{j-1} and all of the column vertices 1 through $j-1$ except column vertices in C_{j-1}. Let $\widehat{M}_{j-1}$ be a column-complete matching in this subgraph.

We distinguish two cases to determine $\widehat{M}_{j-1}$, depending on if $\langle i', j\rangle$ is an edge of $H(A)$ or not. First, assume that $\langle i', j\rangle$ is an edge of $H(A)$. Lemma 2.4 says that for any column-complete matching M of $\widehat{H}_{j-1}$ there is a c-alternating path $\mathcal{R}$ from i' to some unmatched row vertex. We denote by $\widehat{M}_{j-1}$ the matching obtained from

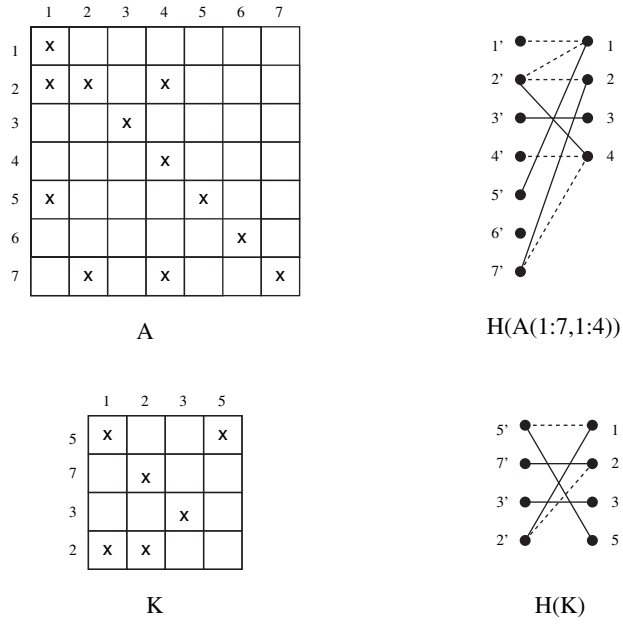

FIG. 4.2. *Example for Theorem* 4.3 *showing the construction that makes element* U_{45} *nonzero for the Hall matrix* A *at the top left. The Hall set of maximum cardinality in the first three columns is* $C_3 = \{3\}$, $R_3 = \{3'\}$. *Consider the path* $\mathcal{Q} = (5, 5', 1, 2', 4)$ *satisfying the conditions in Theorem* 4.3 ($k' = 5'$ *and* $e' = 2'$). *The graph* $\widehat{H}_4$, *presented at the top right, is the subgraph of* H *induced by column vertices* 1 *through* $i = 4$ *and all of the row vertices. The solid edges represent a column complete-matching* M_4 *that is formed by the edge* $\langle 2', 4\rangle$, *the matching* $\widehat{M}_3$ *(formed by the edges* $\langle 5', 1\rangle, \langle 7', 2\rangle, \langle 2', 4\rangle$*), and the matching* $\widetilde{M}_3$ *(formed by the edge* $\langle 3', 3\rangle$*). This matching determines the pivoting order for the first four steps of elimination. With respect to the matching* $\widehat{M}_3$ *there is a c-alternating path* $\mathcal{R} = (5', 1, 2')$. *Consider the matrix* $K = A([5', 7', 3', 2'][1\colon 3, 5])$ *presented at the bottom left and its graph presented at the bottom right. The perfect matching* M *is presented by solid edges in the graph* $H(K)$. *Since* K *satisfies the Hall property and the minor of order-*3 *of* PA *is nonzero, then the element* U_{45} *is nonzero.*

M by alternating along path $\mathcal{R}$. With this choice, row vertex i' is not covered by the matching $\widehat{M}_{j-1}$. Second, assume that $\langle i', j\rangle$ is not an edge of $H(A)$. Let e' be the last row vertex on the path between i' and j, that is, the vertex just before j. Therefore Lemma 2.6 applies and says that there is a column-complete matching $\widehat{M}_{j-1}$ which excludes vertex i' and for which there exists a c-alternating path $\mathcal{R}$ from e' to i'.

Let the column-complete matching M_{j-1} be formed by the edges of $\widehat{M}_{j-1}$ and the edges of $\widetilde{M}_{j-1}$. We choose the values of A such that every square submatrix of A that is Hall, including A itself, is nonsingular. We can say that this is possible by using an argument as the one described in [11] (the determinant of a Hall submatrix is a polynomial in its nonzero values, not identically zero, since the Hall property implies a perfect matching). We choose the values of the nonzeros of A corresponding to edges of M_{j-1} to be larger than n and the values of the other nonzeros of A to be between 0 and 1. With this choice, Lemma 2.1 says that the first $j-1$ steps of elimination of A pivot on nonzeros corresponding to edges of M_{j-1}. Let P be the permutation matrix that describes these row interchanges.

Note that with our choice of M_{j-1}, row vertex i' is not covered by the matching M_{j-1}. Thus, after the first $j-1$ steps of elimination, row i of A was moved to a row in position k of PA, where $k \geq j$. We prove that this choice makes L_{kj} nonzero. If $\langle i', j\rangle$

is an edge of $H(A)$, then L_{kj} is nonzero. Otherwise, let K be the $j \times j$ submatrix of A that includes the first j columns and the rows 1 to $j-1$ in corresponding positions of PA and row i of A (that is, row k of PA). Thus the columns of K are those numbered 1 through j in $H(A)$. The first $j-1$ columns are matched by M_{j-1}, while the last column j is not matched by M_{j-1}. The first $j-1$ rows of K are those matched to columns 1 through $j-1$ of $H(A)$ by M_{j-1}. The last row of K is row number i of A.

To show that L_{kj} is nonzero, we still need to show that K satisfies the Hall property. Recall that column vertex j and row vertex i' are not matched by the matching M_{j-1} in $H(K)$. Consider path $\mathcal{R}$ from e' to i' that is c-alternating with respect to matching M_{j-1}. Obtain a new matching $M_{j-1} \oplus \mathcal{R}$ from M_{j-1} by alternating along path $\mathcal{R}$. As i' is not matched in M_{j-1} and e' is matched in M_{j-1}, then i' is matched in $M_{j-1} \oplus \mathcal{R}$ and e' is not matched in $M_{j-1} \oplus \mathcal{R}$. Add to matching $M_{j-1} \oplus \mathcal{R}$ the edge $\langle e', j \rangle$, and thus we get a perfect matching in $H(K)$; that is, $H(K)$ satisfies the Hall property. By our choice of values, every submatrix that satisfies the Hall property is nonsingular. Therefore element L_{kj} is nonzero. □

THEOREM 4.3. *Let H be the structure of a square Hall matrix. Let i and j be two column vertices, $i < j$, let C_{i-1} be the Hall set of maximum cardinality in the first $i-1$ columns, and let R_{i-1} be the row vertices covered by columns in C_{i-1}. Suppose that H contains a path from j to i whose intermediate column vertices are all in $\{1, \ldots, i-1\}$ and that has no vertex in $C_{i-1} \cup R_{i-1}$. There exists a nonsingular matrix A with $H(A) = H$ and a permutation matrix P such that if A is factored by Gaussian elimination with row interchanges as $PA = LU$, then U_{ij} is nonzero.*

Proof. By hypothesis, there is a path $\mathcal{Q}$ in $H(A)$ from column vertex j to column vertex i whose intermediate column vertices are all at most $i-1$. Let k' be the first row vertex on $\mathcal{Q}$, that is, the vertex just after j on $\mathcal{Q}$. Let e' be the last row vertex on $\mathcal{Q}$, that is, the vertex just before i on $\mathcal{Q}$. Note that e' can be equal to k'.

Let $\widehat{H}_{i-1}$ be the strong Hall subgraph of H induced by all of the row vertices except row vertices in R_{i-1} and all of the column vertices 1 through $i-1$ except column vertices in C_{i-1}. Lemma 2.6 says that there is a column-complete matching $\widehat{M}_{i-1}$ which excludes e' and for which there exists a c-alternating path $\mathcal{R}$ from k' to e'. (If $k' = e'$, then $\mathcal{R}$ is empty.) Let $\widetilde{H}_{i-1}$ be the subgraph of $H(A)$ induced by all of the row vertices in R_{i-1} and all of the column vertices in C_{i-1}. The graph $\widetilde{H}_{i-1}$ satisfies the Hall property, and Lemma 2.6 says that there is a perfect matching $\widetilde{M}_{i-1}$ in $\widetilde{H}_{i-1}$.

Consider H_i the subgraph of H induced by all of the row vertices and all of the column vertices 1 through i. The matching M_i formed by the edge $\langle e', i \rangle$, all of the edges of $\widehat{M}_{i-1}$, and all of the edges of $\widetilde{M}_{i-1}$ is a column-complete matching in H_i . We choose the values of A such that every square submatrix of A that is Hall, including A itself, is nonsingular. We set the values of the nonzeros of A corresponding to edges of M_i to be larger than n and the values of the other nonzeros of A to be between 0 and 1. With this choice the first i steps of elimination of A pivot on nonzeros corresponding to edges of M_i (Lemma 2.1). Let P be the permutation matrix that describes these row interchanges.

We prove that this pivoting choice makes U_{ij} nonzero. Let K be the submatrix $PA(1{:}\,i, [1{:}\,i-1, j])$. To show that U_{ij} is nonzero, we need to show that the graph $H(K)$ satisfies the Hall property. For this, consider again the matching $\widehat{M}_{i-1}$ and the c-alternating path $\mathcal{R}$ from k' to e'. Consider the path formed by the edge $\langle j, k' \rangle$ followed by $\mathcal{R}$, and consider the matching M obtained by alternating along this path. Since k' is matched by $\widehat{M}_{i-1}$ and j is unmatched by $\widehat{M}_{i-1}$, then both k' and j are matched by M, and its cardinality is $|\widehat{M}_{i-1}| + 1$. We add to matching M the edges of

$\widetilde{M}_{i-1}$. Thus M is a perfect matching in $H(K)$; that is, this matrix satisfies the Hall property, and its determinant is nonzero. This shows that U_{ij} is nonzero. □

We make one final note on the similarities between the exact structure prediction presented in this section and the sparsity analysis of the QR factorization for square matrices satisfying the Hall property. The structure prediction for the QR factorization of matrices satisfying only the Hall property was studied by Hare et al. in [15] and Pothen in [19]. It can be easily shown that the structure of Q represents a tight exact bound for the structure of L of the factorization $PA = LU$ and that the structure of R is a tight exact bound for the structure of U obtained from Gaussian elimination with row interchanges.

5. The row merge graph and structure prediction for $A = P_1L_1 \dots P_{n-1}L_{n-1}U$. Let A be an $n \times n$ matrix with nonzero diagonal that satisfies the Hall property. Suppose A is factored by Gaussian elimination with row interchanges as $A = P_1L_1P_2L_2 \dots P_{n-1}L_{n-1}U$ and $\widetilde{L}$ is the union of the L_i. An upper bound for the nonzero structure of $\widetilde{L}$ and U was proposed by George and Ng [9]. This upper bound, called the row merge graph, contains the nonzeros in the factors for all possible row permutations that can later appear in the numerical factorization due to pivoting. In this section we discuss the row merge graph as an upper bound for the nonzero structure of the factors $\widetilde{L}$ and U when the matrix A satisfies only the Hall property. Thus we extend the work of Gilbert and Ng who showed in [11] that the row merge graph is a tight upper bound for Gaussian elimination with row permutations of strong Hall matrices.

First, we consider an exact analysis; that is, we assume only that the nonzero values in A are algebraically independent of each other. By a simple counterexample we show that for matrices satisfying only the Hall property, the row merge graph is not a tight bound for the factors $\widetilde{L}$ and U in the exact sense. This means that the row merge graph predicts as nonzero elements of $\widetilde{L}$ and U that during the actual factorization are zeroed. Second, we relax the condition on the numerical values of the nonzeros of A by considering a symbolic analysis. This is a weaker analysis than the exact analysis performed in section 4, since we ignore the possibility of numeric cancellation during the factorization. With this assumption, we show that the row merge graph is a tight bound for the factors $\widetilde{L}$ and U. In other words, for every edge of the row merge graph of a Hall matrix, there is a permutation such that this edge corresponds to a symbolic nonzero in the factors $\widetilde{L}$ or U.

5.1. Existing results. The row merge graph was proposed by George and Ng [9] as an upper bound for the nonzero structure of $\widetilde{L}$ and U and is obtained as follows: at each step of elimination an upper bound of the structure of $\widetilde{L}$ and U is computed. Consider step i and all of the rows that are candidates to pivoting at this step. An upper bound of their structure is given by the union of their structures. Thus the structure of each row candidate to pivoting is replaced by this union. The bipartite graph that contains all of the edges of the upper bound of $\widetilde{L}$ and U is called the *row merge graph*, denoted by $H^{\times}(A)$. The matrix containing a nonzero element for each edge of $H^{\times}(A)$ is referred to as the row merge matrix of A, denoted as $A^{\times}$. Several results in the literature use a directed version of the row merge graph, denoted as $G^{\times}(A)$ or $G^{\times}(H)$. This graph has n vertices and an edge for each nonzero of $A^{\times}$. The next theorem proves the claim that the row merge graph is an upper bound for the structure of $\widetilde{L}$ and U.

THEOREM 5.1 (George and Ng [9]). *Let A be a nonsingular square matrix with nonzero diagonal. Suppose Gaussian elimination with row interchanges is performed*

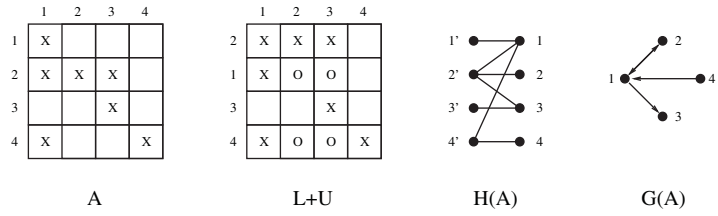

FIG. 5.1. *Example matrix A showing that the row merge graph is not an exact tight bound. The nonzero elements of A are denoted by* x*, and the fill elements of the factors $\widetilde{L}$ and U (corresponding to edges of $G^+(PA)$) are denoted by* o.

as $A = P_1 L_1 \dots P_{n-1} L_{n-1} U$, and let $\widetilde{L}$ be the union of the L_i. Then

$$G(L+U) \subseteq G^{\times}(A).$$

When the matrix satisfies the strong Hall property, Gilbert and Ng [11] showed that this graph represents a tight exact bound for the structure of $\widetilde{L}$ and U. That is, having a strong Hall graph H, for every edge $\langle i', j\rangle$ in its row merge graph $H^{\times}$, there exists a nonsingular matrix A (depending on i' and j) with $H(A) = H$ such that the element in position (i, j) of $L+U$ is nonzero. Nothing is known for the case when the matrix satisfies only the Hall property, and this question is the subject of this section.

5.2. The row merge graph and counterexample for tight exact bounds. In Figure 5.1 we give a counterexample showing that the row merge graph is not tight in the exact sense. The edge $\langle 4', 3\rangle$ is an edge of the row merge graph $H^{\times}(A)$. We present a permutation that makes the entry in position $(4, 3)$ nonzero in the factor $\widetilde{L}$. At the first step of elimination we pivot on the element at position $(2, 1)$, while at the next steps of elimination we pivot on the diagonal. Let P be the matrix describing these permutations. The directed graph $G(PA)$ has a path $(4, 1, 3)$; therefore the element in position $(4, 3)$ fills in. Then the $\langle 4, 3\rangle$ entry in $G^+(PA)$ is nonzero, but $\widetilde{L}_{43} = 0$, regardless of the nonzero values of A. Note that there is no choice of pivot at the first step of elimination that fills the element at position $(4, 3)$. We conclude that there is no permutation that makes the element $\widetilde{L}_{43}$ nonzero.

5.3. The row merge graph as a tight symbolic bound. We now discuss a symbolic analysis; that is, we ignore the possibility of numeric cancellation during the factorization. With this assumption, we show that the row merge graph is a tight bound for the factors $\widetilde{L}$ and U.

An example of the construction of the row merge matrix is presented in Figure 5.2. At the first step of elimination, rows 1, 4, and 5 are candidates to pivoting. The union of their structure is formed, and it replaces the structure of each one of these rows. This is repeated at each step on the trailing matrix.

Row merge fill elements refer to elements that are zero in the original matrix A but are nonzero in the row merge matrix $A^{\times}$. Similarly, *row merge fill edges* refer to those edges that don't belong to $H(A)$ but belong to the row merge graph $H^{\times}(A)$. The row merge fill edges in the row merge graph $H^{\times}(A)$ are related to paths in the bipartite graph $H(A)$ by Definition 5.2 and Theorem 5.3.

DEFINITION 5.2 (Gilbert and Ng [11]). *A path $\mathcal{Q} = (i', j_1, i'_1, j_2, i'_2, \dots, j_t, i'_t, j)$ in $H(A)$ is a row merge fill path for LU elimination with partial pivoting if either*

FIG. 5.2. *Example to illustrate the construction of a row merge matrix* $A^{\times}$, *Theorems* 5.4 *and* 5.5. *The nonzero elements of* A *are denoted by* x, *and the row merge fill elements are denoted by* o.

$t = 0$ *or the following conditions are satisfied:*

1. $j_k < j$ *and* $j_k \leq i'$ *for all* $1 \leq k \leq t$.
2. *Let* j_p *be the largest* j_k. *Then there is some* q *with* $p \leq q \leq t$, $j_p \leq i'_q \leq n$, *and the three paths* $\mathcal{Q}[i' : j_p]$, $\mathcal{Q}[j_p : i'_q]$, *and* $\mathcal{Q}[i'_q : j]$ *are also row merge fill paths in* $H(A)$.

The next theorem due to Gilbert and Ng gives a necessary and sufficient condition for fill to occur in the row merge graph $H^{\times}(A)$.

THEOREM 5.3 (Gilbert and Ng [11]). *For two vertices* i', j *of the bipartite graph* $H(A)$, *the edge* $\langle i', j \rangle$ *is an edge of* $H^{\times}(A)$ *if and only if there is a row merge fill path joining* i' *and* j *in* $H(A)$.

We present two algorithms that use Definition 5.2 to decompose a row merge fill path in paths and edges of the bipartite graph $H(A)$. Algorithm 2 decomposes the row merge fill path $\mathcal{Q}[i' : j]$ in subpaths by recursively applying Definition 5.2. The recursivity is stopped when a path is reduced to an edge. Its aim is to record for each intermediate column vertex j_p its corresponding row vertex of the middle path $\mathcal{Q}[j_p : i'_q]$ (that is, $MC[j_p] = i'_q$). Note that the vertices belonging to $\mathcal{Q}[i' : j]$ are distinct, and hence each intermediate vertex belongs to one and only one middle path.

ALGORITHM 2. Decomposition in subpaths

Input $\mathcal{Q} = (i', j_1, i'_1, \ldots, j_t, i'_t, j)$
Output MC **array updated**
if $t \neq 0$ **then**
1. decompose $\mathcal{Q}[i' : j]$ in $\mathcal{Q}[i' : j_p]$, $\mathcal{Q}[j_p : i'_q]$, and $\mathcal{Q}[i'_q : j]$ such that j_p is the largest j_k, where $1 \leq k \leq t$ and $j_p \leq i'_q \leq n$ and the three paths are also row merge fill paths (Definition 5.2).
2. $MC[j_p] = i'_q$.
3. decompose each of the three paths (which is not an edge) in sub-fill paths.
end if

Algorithm 3 decomposes the row merge fill path $\mathcal{Q}[i' : j]$ in an alternating sequence of edges and middle paths that we refer to as $ASEM$. It is easy to check that this algorithm returns the sequence $ASEM = \{\langle i', k_1 \rangle, \mathcal{Q}[k_1 : MC[k_1]], \langle MC[k_1], k_2 \rangle, \mathcal{Q}[k_2 : MC[k_2]], \ldots, \mathcal{Q}[k_u : MC[k_u]], \langle MC[k_u], j \rangle\}$, where $u \leq t$ and $k_1 = j_1$.

Consider an edge of the row merge graph $\langle i', j \rangle$ and its associated row merge fill path $\mathcal{Q} = (i', j_1, i'_1, \ldots, j_t, i'_t, j)$. We define a pivoting strategy relative to this path. At each elimination step k, if column vertex k is an intermediate vertex of

ALGORITHM 3. Decomposition in alternating sequence of edges and middle paths

Input $\mathcal{Q} = (i', j_1, i'_1, \ldots, j_t, i'_t, j)$
Output alternating sequence $ASEM$
if $t \neq 0$ **then**
1. decompose $\mathcal{Q}[i' \colon j]$ in $\mathcal{Q}[i' \colon j_p]$, $\mathcal{Q}[j_p \colon i'_q]$ and $\mathcal{Q}[i'_q \colon j]$ such that j_p is the largest j_k, $j_p \leq i'_q \leq n$, and the three paths are also row merge fill paths (Definition 5.2).
2. decompose $\mathcal{Q}[i' \colon j_p]$ in an alternating sequence and assign it to $ASEM$.
3. add the middle sub-fill path $\mathcal{Q}[j_p \colon i'_q]$ at the end of the sequence $ASEM$.
4. decompose $\mathcal{Q}[i'_q \colon j]$ in an alternating sequence and add it at the end of the sequence $ASEM$.
5. return the sequence $ASEM$.
else
6. return the edge $\langle i', j \rangle$.
end if

the path $\mathcal{Q}[i' \colon j]$, then we pivot on the element in position $(MC[k], k)$, and P_k is the elementary permutation matrix that describes this pivoting. If column vertex k is not an intermediate vertex of $\mathcal{Q}[i' \colon j]$, then we pivot on the diagonal element; that is, the elementary permutation matrix P_k is the identity. We call this strategy of pivoting the middle correspondent pivoting strategy with respect to the path $\mathcal{Q}[i' \colon j]$. In the next theorem we prove that such a strategy is valid; that is, the LU factorization exists in a symbolic sense.

LEMMA 5.4. *Let A be a square matrix with nonzero diagonal that satisfies the Hall property. Let $\langle i', j \rangle$ be an edge of the row merge graph $H^{\times}(A)$ and $\mathcal{Q}[i' \colon j]$ be its corresponding fill path in $H(A)$. Let $P = P_{n-1} \ldots P_2 P_1$ be the permutation matrix describing the middle correspondent pivoting strategy relative to $\mathcal{Q}[i' \colon j]$. Gaussian elimination $A = P_1 L_1 \ldots P_{n-1} L_{n-1} U$ exists in the symbolic sense.*

Proof. If the fill path $\mathcal{Q}[i' \colon j]$ corresponds to an edge of $H(A)$, then we choose P to be the identity matrix. As we assume the matrix A has a nonzero diagonal, the Gaussian elimination exists in the symbolic sense. In the rest of the proof, we assume that $\langle i', j \rangle$ is not an edge of $H(A)$.

As the case $j = 1$ is trivial, we will assume that $j > 1$. We will prove this by induction. At the first step of elimination, if row vertex $1'$ and column vertex 1 do not belong to $\mathcal{Q}[i' \colon j]$, then we pivot on the element in position $(1, 1)$. If the column vertex 1 belongs to $\mathcal{Q}[i' \colon j]$, then consider the fill path $\mathcal{Q}[1 \colon k']$, where $k' = MC[1]$ and $k' \geq 1$. We can see that $\mathcal{Q}[1 \colon k']$ is an edge of $H(A)$, and thus we can pivot on the element A_{k1}. Note that according to Definition 5.2, we cannot have that row vertex $1'$ belongs to $\mathcal{Q}[i' \colon j]$ and column vertex 1 does not belong to $\mathcal{Q}[i' \colon j]$.

Consider the kth step of elimination, where $k < n$. Suppose that at each elimination step prior to k, the middle correspondent pivoting strategy was valid; that is, the diagonal elements of the permuted matrix are nonzero. We show that at this step k we can apply the same pivoting strategy. Let P_{K-1} be the permutation matrix that describes the first $k-1$ row interchanges, that is, $P_{K-1} = P_{k-1} \ldots P_1$. Let A_k be the $k \times k$ principal submatrix of $P_{K-1}A$ that includes the first k columns and the rows in corresponding positions of $P_{K-1}A$. The columns of A_k are those numbered 1 through k in $H(A)$; the rows of A_k are those given by the permutation matrix P_{K-1}. We add to the matrix A_k all of the diagonal elements, except the last one, nonzero by our hypothesis. In the directed graph $G(A_k)$ we will number the vertices from 1 to k.

First, we will prove that the kth diagonal element of the permuted matrix $P_{K-1}A$ is nonzero. This corresponds to the last diagonal element of A_k. If k' is not an intermediate row vertex of the path $\mathcal{Q}[i'\colon j]$, then during the first $k-1$ steps of elimination row k was not permuted, and the last diagonal element of A_k is nonzero by our hypothesis. If k' is an intermediate row vertex on the path $\mathcal{Q}[i'\colon j]$, then row k was permuted during the first $k-1$ steps of elimination. We denoted by d the row that at the kth step of elimination is in position k of matrix A_k. We now trace the pivoting process to discover where row d comes from. Let k_1 be the middle correspondent vertex of k' ($MC[k_1] = k', k_1 \leq k'$). If $k_1 = k$, then $d' = k'$. Otherwise, according to our pivoting choice, the element in position (k', k_1) was used as the pivot at step k_1, and thus row k was interchanged with the row in position k_1. At this point, either row vertex k'_1 does not belong to $\mathcal{Q}[i'\colon j]$, and then $d = k_1$, or else it belongs, and then row k_1 was used as the pivot in some column k_2, where it was interchanged with some row $k_2 < k_1$. Extending the induction, we arrive at a row vertex $k'_q = d'$, which is not an intermediate row vertex of $\mathcal{Q}[i'\colon j]$. The vertices in $H(A)$ followed while tracing the pivoting process form the path $(k, k', k_1, k'_1, k_2, k'_2, \ldots, k_q, d')$. On this path, the edge $\langle k', k_1\rangle$ and the edges $\langle k'_p, k'_{p+1}\rangle$, with $1 \leq p < q$, correspond to diagonal elements of A_k. Hence this path can be transformed into the path $(k, k_1, \ldots, k_q, k)$ in $G(A_k)$. As $k > k_1 > \cdots > k_q$, according to Theorem 3.1 this path is a fill path in the directed graph $G(A_k)$, and the kth diagonal element of $P_{K-1}A$ corresponds to a symbolic nonzero.

Second, we show that at elimination step k we can apply the middle correspondent pivoting strategy. We distinguish two cases.

Case 1 (column vertex k is not an intermediate column vertex of $\mathcal{Q}[i'\colon j]$). We have just proved that the kth diagonal element of $P_{K-1}A$ is an edge of the filled graph $G^+(A_k)$. We use as the pivot the diagonal element.

Case 2 (column vertex k is an intermediate column vertex of $\mathcal{Q}[i'\colon j]$). Let e' be the middle path correspondent vertex of k, that is, $MC[k] = e'$ and $k \leq e'$. Let $\mathcal{Q}[e'\colon k]$ be the fill path between e' and k which is a subpath of our initial path $\mathcal{Q}[i'\colon j]$.

If $e' = k'$ (that is, $MC[k] = k'$), then row k' was not involved in any row permutation. We use as the pivot the diagonal element. If $e' > k$, then let K be the $(k+1) \times (k+1)$ submatrix of $P_{K-1}A$ that includes the first k columns and the rows in corresponding positions of $P_{K-1}A$ and column e and row e' of $P_{K-1}A$. We add to matrix K the first k diagonal elements, which correspond to symbolic nonzeros by our hypothesis. The vertices of the directed graph $G(K)$ are the vertices 1 through k and vertex e.

In the following, we want to show that $\langle e, k\rangle$ is an edge of the directed graph $G^+(K)$. If path $\mathcal{Q}[e'\colon k]$ is simply an edge, then $\langle e, k\rangle$ is an edge of $G^+(K)$. Otherwise, we decompose path $\mathcal{Q}[e'\colon k]$ into an alternating sequence of edges and middle paths using Algorithm 3. The following sequence is obtained: $\{\langle e', e_1\rangle, \mathcal{Q}[e_1\colon MC[e_1]], \langle MC[e_1], e_2\rangle, \mathcal{Q}[e_2\colon MC[e_2]], \ldots, \mathcal{Q}[e_q\colon MC[e_q]], \langle MC[e_q], k\rangle\}$. We can rewrite the sequence as a directed path from vertex e to vertex k of $G(K)$: $(e, e_1, e_2, \ldots, e_q, k)$. The intermediate vertices on this path are less than both e and k, because of the row merge fill paths Definition 5.2. Therefore $\langle e, k\rangle$ is an edge of $G^+(K)$, and thus it corresponds to a symbolic nonzero. This shows that we can choose as the pivot the element in position (e, k) at this step of elimination, and this ends our proof. □

The next theorem shows that the row merge graph represents a tight bound for the nonzero structure of $\widetilde{L}$ and U, in the symbolic sense. It is illustrated in Figures 5.3, 5.4, 5.5, and 5.6.

THEOREM 5.5. *Let A be a square matrix with nonzero diagonal that satisfies the Hall property. Let $\langle i', j\rangle$ be an edge of the row merge graph $H^{\times}(A)$. There is a*

Proof. According to Theorem 5.3 there is a row merge fill path in $H(A)$ from row vertex i' to column vertex j. Let $\mathcal{Q}[i'\colon j]$ be formed by the vertices $(i', j_1, i'_1, \dots, j_t, i'_t, j)$. Assume that $t \neq 0$. At each step of elimination we pivot following the middle correspondent pivoting strategy with respect to the path $\mathcal{Q}[i'\colon j]$, as described in Lemma 5.4.

Assume now that we are at the jth step of elimination. Let P_{J-1} be the permutation matrix that describes the first $j-1$ row interchanges. Let K be the principal submatrix of $P_{J-1}A$ that includes the first j columns and column i and the rows in corresponding positions of PA (that is, if $i' \leq j$, then K is a $j \times j$ matrix; otherwise K is a $(j+1) \times (j+1)$ matrix). In matrix K we add diagonal elements, with $1 \leq i \leq j$, which are nonzero by our hypothesis. When $i > j$, we also add diagonal element (i', i) (row i was not permuted). The vertices of the directed graph $G(K)$ are numbered 1 through j and i.

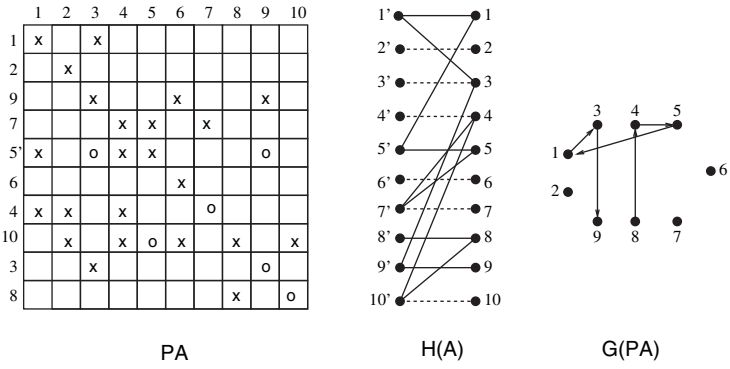

FIG. 5.5. *Example illustrating Theorem* 5.5 *and showing that* U_{89} *is nonzero for the row merge matrix presented in Figure* 5.2. *The row merge fill path* $Q[8':9] = (8', 8, 10', 4, 7', 5, 5', 1, 1', 3, 9', 9)$ *is displayed by solid edges in the bipartite graph* $H(A)$. *Figure* 5.6 *presents the decomposition of path* $Q[8':9]$ *by Algorithms* 2 *and* 3. *First, the path* $\mathcal{Q}[8':9]$ *is decomposed using Algorithm* 2, *and the following middle paths are obtained:* $\mathcal{Q}[8:10']$, $\mathcal{Q}[4:7']$, $\mathcal{Q}[5:5']$, $\mathcal{Q}[9':3]$, *and* $\mathcal{Q}[1:1']$. *This decomposition gives us the pivoting strategy, illustrated in the permuted matrix at the top left of Figure* 5.5. *Algorithm* 3 *decomposes the fill path* $\mathcal{Q}[8':9]$ *in an alternating sequence of edges and middle paths. This allows us to obtain the path* $(8, 4, 5, 1, 3, 9)$ *which is a fill path in the directed graph of the permuted matrix* PA.

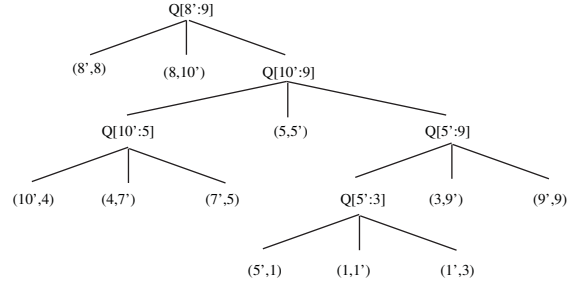

FIG. 5.6. *Example of the application of Algorithms* 2 *and* 3 *on the path* $\mathcal{Q}[8':9] = (8', 8, 10', 4, 7', 5, 5', 1, 1', 3, 9', 9)$ *from Figure* 5.5. *Both algorithms return the same result.*

Case 1 ($i > j$ (structure of $\widetilde{L}$)). The proof is similar to the proof of Lemma 5.4, in which a middle path becomes an edge of the filled graph of A, and we omit the details here.

Case 2 ($i < j$ (structure of U)). Consider row merge fill path $\mathcal{Q}[i':j] = (i', j_1, i'_1, \ldots, j_t, i'_t, j)$. We distinguish two cases. If column vertex i is not a vertex of path $\mathcal{Q}[i':j]$, then row i of A is not permuted during our pivoting strategy, and the proof is similar to the $\widetilde{L}$ case. If column vertex i is a vertex of path $\mathcal{Q}[i':j]$, Definition 5.2 decomposes this path in the following three paths: $\mathcal{Q}[i':i]$, $\mathcal{Q}[i:k']$, and $\mathcal{Q}[k':j]$ such that $i < k' \leq n$, and the three paths are also row merge fill paths in $H^{\times}(A)$. Our pivoting strategy interchanges rows i and k of A at the ith step of elimination. We use Algorithm 3 to decompose the path $\mathcal{Q}[k':j]$ in an alternating sequence of edges and middle paths. This sequence is transformed into a path from i to j in the graph $G(K)$ which has all of the intermediate column vertices smaller than i. This corresponds to an edge in the filled graph $G^{+}(K)$. Thus the element U_{ij} corresponds to a symbolic nonzero, and this ends our proof. ∎

We make one note about the structure prediction of $A = P_1L_1 \ldots P_{n-1}L_{n-1}\, U$. The tight bound of U obtained for the structure prediction of $PA = LU$ (Theorem 4.3) also represents a tight bound for U obtained in $A = P_1L_1 \ldots P_{n-1}L_{n-1}\, U$. But there does not seem to be a simple way to express tight exact bounds for $\widetilde{L}$, where $\widetilde{L}$ is the union of the L_i obtained from $A = P_1L_1 \ldots P_{n-1}L_{n-1}U$.

6. Concluding remarks. In this paper we have discussed two aspects of interest in the structure prediction problem of sparse LU factorization with partial pivoting of a matrix A. The first aspect considers the computation of the nonzero structure of the factors during Gaussian elimination with row interchanges. We have presented new results that provide an exact structure prediction for matrices that satisfy the strong Hall property or only the Hall property. We then have used the theoretical results to derive an algorithm for computing fill-ins. The second aspect is to estimate tight bounds of the structure of L and U prior to the numerical factorization. We have introduced tight exact bounds for the nonzero structure of L and U of Gaussian elimination with partial pivoting $PA = LU$, under the assumption that the matrix A satisfies the Hall property. We have also shown that the row merge graph represents a tight symbolic bound for the structure of the factors $\widetilde{L}$ and U obtained from the factorization $A = P_1L_1 \ldots P_{n-1}L_{n-1}U$.

The practical usage of the exact structure prediction presented in this paper remains an open problem. Several aspects are of interest. One important question is to understand if rounding to zero elements that correspond to numeric cancellation in exact arithmetic leads to instability in the Gaussian elimination. A different aspect is to analyze on real world matrices how many numeric cancellations, that Theorem 3.4 identifies, occur during Gaussian elimination. Another aspect is to compare experimentally the bounds presented in this paper with the bounds provided by the row merge graph, knowing that the latter can be efficiently computed [14].

Acknowledgments. The authors thank the anonymous reviewers for their helpful comments and suggestions to improve the presentation of the paper.

ERROR ESTIMATES FOR POLYNOMIAL KRYLOV APPROXIMATIONS TO MATRIX FUNCTIONS*

FASMA DIELE†, IGOR MORET‡, AND STEFANIA RAGNI§

Abstract. In this paper we are interested in the polynomial Krylov approximations for the computation of $\varphi(A)v$, where A is a square matrix, v represents a given vector, and φ is a suitable function which can be employed in modern integrators for differential problems. Our aim consists of proposing and analyzing innovative a posteriori error estimates which allow a good control of the approximation procedure. The effectiveness of the results we provide is tested on some numerical examples of interest.

Key words. Krylov methods, matrix functions, exponential-like functions, error estimates

1. Introduction.

Krylov subspace methods are commonly used for evaluating $y = \varphi(A)v$ in the case when φ is a suitable function, A represents a large sparse matrix, and v is a given vector. The simplest Krylov approach provides polynomial approximations achieved in the Krylov subspaces generated by A and v. Its application to the exponential matrix operator and, more in general, to functions representing differential problem solutions has received wide attention in the literature; among others, we quote [7], [22], [31], [17], [26], [23], where different a priori error estimates have been proposed. We notice that these estimates are usually obtained by employing some minimal information concerning the matrix A, such as the spectrum size or the numerical range; therefore, they often turn out to be pessimistic and not so useful in the error-control procedure due to their inability of adaption to the spectrum. Thus, obtaining adaptive a posteriori error bounds represents an interesting task which, in our knowledge, has not been developed yet.

In this framework our aim consists of proposing a posteriori error estimates employed in the computation of a specific class of functions represented in integral form. In particular, we refer to exponential-like operators that are considered as the basis for constructing exponential integrators widely used in modern methods for solving differential problems (see, e.g., [19], [20], [18], [21], [25], [2]); moreover, we also analyze the case of trigonometric functions which are involved in the solution of second order differential systems (see [15]).

In this respect, the paper is organized in the following way. In section 2 we provide some general results related to polynomial Krylov approximations for matrix functions represented by some general integral forms. We specify and extend the results dealing with the cases of both the exponential-like functions and the trigonometric ones, in the specific of *cos* and *sinc* functions, in section 3. Moreover, some numer-

ical experiments are shown in section 4 with the aim of testing the effectiveness of the proposed estimates. Our bounds are compared with the best a priori error estimates already known in the literature (see [7] and [17]) since, up to our knowledge, a posteriori ones have never been provided so far.

2. Polynomial Krylov methods. We are going to sketch important and well-known features of polynomial Krylov methods; in particular, we provide and prove some results concerning their application in computing specific matrix functions represented in integral form. With this aim, in the sequel $\|\cdot\|$ represents the vector and matrix Euclidean norm and Π_k is the set of all the algebraic polynomials with degree equal or less than k ($k \in \mathbb{N}$).

Let A be a given $N \times N$ matrix; we denote the spectrum by $\sigma(A)$ and the *numerical range* by $W(A)$, i.e.,

$$W(A) = \left\{ \frac{\langle x, Ax \rangle}{\langle x, x \rangle},\ x(\neq 0) \in \mathbb{C}^N \right\},$$

where $\langle \cdot, \cdot \rangle$ represents the Euclidean inner product. We consider a given vector v with $\|v\| = 1$, and we focus on the Krylov subspaces

$$K_m(A, v) = span\left\{v, Av, \ldots, A^{m-1}v\right\}$$

related to A and v; thus, we suppose that $\{v_1, v_2, \ldots, v_j, \ldots\}$ is an ordered system of vectors providing a basis for each Krylov subspace, that is

$$K_m(A, v) = span\left\{v_1, v_2, \ldots, v_m\right\}$$

for every m. Moreover, under the assumption that

$$Av_j = \sum_{i=1}^{j+1} h_{i,j} v_i, \tag{1}$$

where $h_{i,j}$'s are suitable coefficients with $h_{j+1,j} \neq 0$ for $1 \leq j \leq m-1$, we denote by H_m the $m \times m$ upper Hessenberg matrix having its entries given by the values $h_{i,j}$ ($1 \leq i, j \leq m$). It follows that

$$AV_m = V_m H_m + h_{m+1,m} v_{m+1} e_m^T, \tag{2}$$

where V_m=$(v_1, v_2, \ldots, v_m)$ and each e_j represents the jth column of the $m \times m$ unit matrix.

It is possible to prove that for any $q_{m-1} \in \Pi_{m-1}$ it holds that

$$q_{m-1}(A)v = V_m q_{m-1}(H_m) e_1. \tag{3}$$

Different choices for the previous basis $\{v_1, v_2, \ldots, v_m\}$, generated via relationships like (1), have been proposed in the literature: for instance, it is possible to adopt classical, full, or incomplete (IOM) Arnoldi's algorithm, Lanczos biorthogonalization, Chebyshev or Faber polynomials ([26]), quasi-kernel polynomials ([27]), or Leja sequences ([4]). Furthermore, throughout the paper we assume exact arithmetic (anyway, we refer to the recent survey [24] and the references therein concerning the treatment of problems related to finite precision arithmetic in the field of Krylov methods).

As already pointed out, our aim consists of evaluating

$$y = \varphi(A)v$$

under the assumption that φ is a function representable in the general integral form

$$\varphi(A) = \int_\Gamma g(\lambda)(\lambda I + A)^{-1} d\lambda, \tag{4}$$

where Γ and g are a suitable curve in the complex plane and a scalar function, respectively. We notice that every function analytic in a domain including $\sigma(A)$ can be written in this integral form due to the well-known Dunford–Taylor theorem. We remark also that a specific example in the class of functions (4) consists of the discrete counterpart given by the partial fraction forms. They may arise by applying any quadrature to evaluate integral representation (4), as it is shown in some applications in [3], [6], [21]. Moreover, linear partial fractions can give raise to some computational advantages when they are adopted for representing rational functions; in this respect, we quote the recent paper [23], where the convergence of the polynomial Krylov method is investigated as what concerns Padé or Chebyshev approximations of the exponential function.

Assume that $\sigma(A) \cup \sigma(H_m)$ is included in a given domain G; furthermore let φ be analytic in G itself and continuous on its closure. Then the mth polynomial approximation (related to (2)) for the computation of y is defined by

$$y_m = V_m \varphi(H_m) e_1.$$

We recall that, in particular, if $\{v_j\}_{j=1,2,\ldots}$ are generated by means of the full Arnoldi's algorithm, they are orthonormal vectors and the resulting approach is referred to as the Polynomial Arnoldi (PA) method. More in general, from (2) and the relationship

$$y - y_m = \int_\Gamma g(\lambda) \left((\lambda I + A)^{-1} v - V_m (\lambda I + H_m)^{-1} e_1 \right) d\lambda, \tag{5}$$

it follows that for any polynomial Krylov scheme we have

$$y - y_m = \int_\Gamma g(\lambda) \xi_m(\lambda) (\lambda I + A)^{-1} v_{m+1} d\lambda, \tag{6}$$

where

$$\xi_m(\lambda) = -h_{m+1,m} \left(e_m^T (\lambda I + H_m)^{-1} e_1 \right).$$

By exploiting (6) it is possible both to obtain error estimates and to put a restart procedure right; indeed the error formulation is featured by the same form of function φ (different approaches of restarting Krylov methods for matrix functions can be found in [5] and [8]).

We are going to propose another error representation which generalizes a result already given in [17] and [32] for the Arnoldi's method. With this aim we set

$$\overline{H}_{\lambda,m} = \begin{pmatrix} \lambda I + H_m \\ h_{m+1,m} e_m^T \end{pmatrix} \in \mathbb{C}^{(m+1)\times(m+1)};$$

thus from (2) we obtain

$$(\lambda I + A) V_m = V_{m+1} \overline{H}_{\lambda,m}. \tag{7}$$

In the sequel, $\overline{e}_1$ represents the first column of the $(m+1)\times(m+1)$ unit matrix and $\{U_j\}_{j=1,2,\ldots}$ is a sequence of $N\times j$ matrices which satisfy the relationships $U_j^H V_j = I$ and $U_j^H v_{j+1} = 0$; using these notations, in the following lemma (see [17] for its proof) a further error formula is given.

LEMMA 1. *For each $p_m \in \Pi_m$ with $p_m(-\lambda) = 1$, it holds that*

$$y - y_m = \int_\Gamma g(\lambda)\left((\lambda I + A)^{-1} - V_m(\lambda I + H_m)^{-1}U_m^H\right) p_m(A)v\, d\lambda.$$

Moreover, for every $x \in \mathbb{C}^m$ the error formula is given in the equivalent form

$$y - y_m = \int_\Gamma g(\lambda)\left((\lambda I + A)^{-1} - V_m(\lambda I + H_m)^{-1}U_m^H\right) V_{m+1}(\overline{e}_1 - \overline{H}_{\lambda,m}x)\, d\lambda.$$

In the sequel, for any $m \geq 0$, we will denote

$$\mu_m(\lambda, A) = \min_{p_m\in\Pi_m,\ p_m(-\lambda)=1} \|p_m(A)v\|$$

and

$$\nu_m(\lambda, A) = \min_{x\in\mathbb{C}^m} \left\|\overline{e_1} - \overline{H}_{\lambda,m}x\right\|.$$

Using (7) it is not so difficult to verify that

$$\left\|U_{m+1}^H\right\|^{-1} \nu_m(\lambda, A) \leq \mu_m(\lambda, A) \leq \|V_{m+1}\|\, \nu_m(\lambda, A).$$

In particular, when the PA method is applied ($U_m = V_m$), Lemma 1 yields

$$\|y - y_m\| \leq \int_\Gamma |g(\lambda)| \left(\left\|(\lambda I + A)^{-1}\right\| + \left\|(\lambda I + H_m)^{-1}\right\|\right) \mu_m(\lambda, A)\, |d\lambda|. \tag{8}$$

For our purposes we set $\delta_m = 1 + h_{m+1,m}^2 \|(\lambda I + H_m)^{-H} e_m\|^2$ and consider $\overline{H}_{\lambda,m}$ partitioned in the form

$$\overline{H}_{\lambda,m} = \begin{pmatrix} d_{\lambda,m}^H \\ T_{\lambda,m} \end{pmatrix}, \tag{9}$$

where $d_{\lambda,m}^H$ represents the first row of $\overline{H}_{\lambda,m}$ itself and $T_{\lambda,m}$ is an $m\times m$ upper triangular matrix with diagonal entries given by the $h_{j+1,j}$'s ($j = 1,\ldots,m$).

LEMMA 2. *For every $\lambda \notin \sigma(A)$ it holds that*

$$\nu_m(\lambda, A) = \frac{1}{\sqrt{1 + \left\|T_{\lambda,m}^{-H} d_{\lambda,m}\right\|^2}} \tag{10}$$

or, equivalently,

$$\nu_m(\lambda, A) = \delta_m^{-1/2}\, |\xi_m(\lambda)| \tag{11}$$

where

$$|\xi_m(\lambda)| = \left|\det(\lambda I + H_m)^{-1} \prod_{j=1}^m h_{j+1,j}\right|. \tag{12}$$

Moreover, for $m > 1$, an upper bound is given by

$$\nu_m(\lambda, A) \leq h_{m+1,m} \left\| U_m(\lambda I + H_m)^{-H} e_m \right\| \delta_m^{-1/2} \mu_{m-1}(\lambda, A). \tag{13}$$

Proof. Identity (10) can be proved using the same arguments as employed in [33], Proposition 4.1. Moreover it is possible to verify that

$$\langle e_m, p_{m-2}(H_m) e_1 \rangle = 0 \tag{14}$$

for every $p_{m-2} \in \Pi_{m-2}$. Therefore, exploiting the Cayley–Hamilton theorem, (12) follows. Furthermore, we point out that $\overline{H}_{\lambda,m}^H \overline{H}_{\lambda,m} = d_{\lambda,m} d_{\lambda,m}^H + T_{\lambda,m}^H T_{\lambda,m}$, and thus we obtain

$$\prod_{j=1}^{m} h_{j+1,j}^2 = \det\left(T_{\lambda,m}^H T_{\lambda,m}\right) = \det\left(\overline{H}_{\lambda,m}^H \overline{H}_{\lambda,m}\right) \left(1 + \left\| T_{\lambda,m}^{-H} d_{\lambda,m} \right\|^2\right)^{-1} \tag{15}$$

and $\det(\overline{H}_{\lambda,m}^H \overline{H}_{\lambda,m}) = \delta_m \det((\lambda I + H_m)^H (\lambda I + H_m))$. In this way, once (10) is proved, we have

$$\nu_m(\lambda, A) = \delta_m^{-1/2} \left| \prod_{j=1}^{m} h_{j+1,j} \det((\lambda I + H_m))^{-1} \right|,$$

and then (11) follows from (12). Furthermore, due to (14) we obtain

$$\nu_m(\lambda, A) = \delta_m^{-1/2} \left| h_{m+1,m} \langle e_m, ((\lambda I + H_m)^{-1} + p_{m-2}(H_m)) e_1 \rangle \right|$$

for every $p_{m-2} \in \Pi_{m-2}$ ($m \geq 2$). Thus, when we consider any $p_{m-1} \in \Pi_{m-1}$ with $p_{m-1}(-\lambda) = 1$, we have

$$\nu_m(\lambda, A) = \delta_m^{-1/2} \left| h_{m+1,m} \langle e_m, (\lambda I + H_m)^{-1} p_{m-1}(H_m) e_1 \rangle \right|.$$

Due to this inequality and to (3) it follows that (13) is proved. ∎

In the remaining part of the section we suppose that the full Arnoldi method is employed in the construction of the Krylov subspaces; of course, in this case, it holds that $\mu_m(\lambda, A) = \nu_m(\lambda, A)$. Moreover, the results in Lemma 2 point out the $h_{j+1,j}$'s role in the Krylov procedure. It is well known that $h_{j+1,j} \geq 0$ for each j and the following relationship can be proved (see [34, p. 269])

$$\prod_{j=1}^{m} h_{j+1,j} = \min_{q_m \in \Pi_m^{(0)}} \|q_m(A) v\| \tag{16}$$

with $\Pi_m^{(0)}$ being the set of all the monic polynomials with degree m. Recall that (16) is useful for developing a priori bounds for $\prod_{j=1}^{m} h_{j+1,j}$ by means of known classical results. For instance, if A is self-adjoint with spectrum in an interval of length 4γ, then by suitable bounds for Chebyshev polynomials it is possible to verify that (see [13, p. 91])

$$\prod_{j=1}^{m} h_{j+1,j} \leq 2\gamma^m. \tag{17}$$

A further upper bound can be obtained assuming that the distinct eigenvalues of A are arranged in decreasing order

$$0 \leq \cdots < \lambda_j(A) < \lambda_{j-1}(A) < \cdots < \lambda_2(A) < \lambda_1(A)$$

and choosing $p_m(\lambda) = \prod_{j=1}^{m}(\lambda - \lambda_j(A))$ in (16); indeed, under this assumption we have

$$\prod_{j=1}^{m} h_{j+1,j} \leq \max_{k>m} \prod_{j=1}^{m} (\lambda_j(A) - \lambda_k(A)). \tag{18}$$

More in general, for any scalar α we consider the singular values of $\alpha I + A$ given by

$$\sigma_1(\alpha I + A) \geq \sigma_2(\alpha I + A) \geq \cdots \geq \sigma_j(\alpha I + A) \geq \cdots$$

Since $V_m V_m^H$ is an orthogonal projection, from (15) and (10) it is possible to obtain (see [14, p. 128])

$$\begin{aligned} \Pi_{j=1}^{m} h_{j+1,j} &= \mu_m(\alpha, A) \sqrt{\det\left(V_m^H \left(\alpha I + A^H\right)(\alpha I + A) V_m\right)} \\ &\leq \mu_m(\alpha, A) \prod_{j=1}^{m} \sigma_j(\alpha I + A). \end{aligned}$$

Assuming $\alpha I + A$ to be a compact operator in a Hilbert space with $q > 0$ summable singular values (i.e., $\sum_{j=1}^{+\infty} \sigma_j^q < +\infty$), then by the geometric-arithmetic mean inequality we have

$$\prod_{j=1}^{m} \sigma_j(\alpha I + A) \leq \left(\frac{1}{m} \sum_{j=1}^{m} (\sigma_j(\alpha I + A))^q \right)^{m/q}. \tag{19}$$

In particular, for Hilbert–Schmidt operators, in correspondence with $q = 2$, it holds that

$$\begin{aligned} \prod_{j=1}^{m} \sigma_j(\alpha I + A) &\leq \left(\frac{1}{m} \sum_{j=1}^{m} (\sigma_j(\alpha I + A))^2 \right)^{m/2} \\ &\leq \left(\frac{1}{m} \|\alpha I + A\|_F^2 \right)^{m/2} \end{aligned}$$

with $\|\cdot\|_F$ being the Frobenius norm.

3. Application to specific functions. We are interested in applying the results we have just provided in the previous section to specific cases. More precisely, we first consider the so-called *φ-functions* which are widely used in modern methods for solving differential problems; then we account for trigonometric functions, like *cos* and *sinc* ones, that are involved in the construction of several numerical integrators for solving second-order differential systems. We consider the PA method (anyway, the use of other bases can be taken into account by developing similar arguments).

3.1. The case of exponential-like functions. It is well known that *φ-functions* are exponential-like ones defined as

$$\varphi_0(-tz) = \exp(-tz),$$
$$\varphi_k(-tz) = \frac{1}{(k-1)!t^k}\int_0^t \exp(-(t-s)z)s^{k-1}ds, \qquad k = 1, 2, \ldots,$$

and they satisfy the recursive formula

$$\varphi_{k+1}(u) = \frac{\varphi_k(u) - \frac{1}{k!}}{u}, \quad \varphi_k(0) = \frac{1}{k!}, \qquad k = 0, 1, 2, \ldots \tag{20}$$

With the aim of evaluating

$$y(k;t) = \varphi_k(-tA)v, \qquad t > 0, \tag{21}$$

we recall that $W(H_m) \subseteq W(A)$ holds for each m and we denote by

$$y_m(k;t) = V_m\varphi_k(-tH_m)e_1$$

the mth approximation to $y(k;t)$. We would like to remark that, as pointed out by other authors (see, e.g., [21], [25], [2]), the computation of these functions may be affected by some difficulties. Concerning the different approaches carried out in the literature, we quote the one related to Padè approximants discussed in [2].

For $a \geq 0$ and $0 \leq \vartheta \leq \pi/2$ let us define the set

$$\Sigma_{\vartheta,a} = \{\lambda \in \mathbb{C} : |\arg(\lambda - a)| \leq \vartheta\}$$

and assume that

$$W(A) \subset \Sigma_{\vartheta,a}. \tag{22}$$

It is well known that this assumption holds in important applications such as parabolic partial differential equations.

As we already mentioned, our aim consists of introducing novel error estimates, which will be compared with other results already provided in the literature. In this respect we remark that a priori error bounds can be found in [7], [22], [31], [17], [26], [23]. For instance, we refer to the following results given in [17].

PROPOSITION 3. *Under the assumption that A is Hermitian with eigenvalues in the interval $[0, 4\gamma]$, an error estimate for the PA approximation is given by*

$$\|y(0;t) - y_m(0;t)\| \leq \left(12\frac{\gamma t}{m^2} + 8\frac{\sqrt{\gamma t}}{m}\right)\exp\left(\frac{-\beta m^2}{4\gamma t}\right), \tag{23}$$

for $\sqrt{4\gamma t} \leq m \leq 2\gamma t$, where $\beta > 0.92$ is a suitable parameter, and

$$\|y(0;t) - y_m(0;t)\| \leq \left(\frac{5}{\gamma t} + 3\sqrt{\frac{\pi}{\gamma t}}\right)\exp\left(\frac{(\gamma t)^2}{m}\right)\exp(-2\gamma t)\left(\frac{\exp(1)\gamma t}{m}\right)^m, \tag{24}$$

for $m > 2\gamma t$.

Moreover, assuming A is skew-Hermitian with eigenvalues in an interval of the imaginary axis with length 4γ, then the PA approximation error is bounded by

$$\|y(0;t) - y_m(0;t)\| \leq \frac{1}{3}\left(\frac{4}{\gamma t} + \frac{11}{\sqrt{\gamma t}}\right)\exp\left(\frac{-(\gamma t)^2}{m}\right)\left(\frac{\exp(1)\gamma t}{m}\right)^m, \tag{25}$$

for $m \geq 2\gamma t (\gamma t > \frac{1}{2})$.

Moreover, we take into account also the following a priori error bounds which can be obtained by the argument developed in [7]. In several cases, these estimates reveal sharper than the previous ones as we show in the numerical tests.

PROPOSITION 4. *Let A be symmetric with eigenvalues in the interval $[0, 4\gamma]$; then, an upper bound for the error in the PA approximation is obtained as*

$$\|y(0;t) - y_m(0;t)\| \leq 4\exp(-2t\gamma)\sum_{k=m}^{+\infty} I_k(2t\gamma), \tag{26}$$

where I_k represents the modified Bessel function of the first kind. Moreover, under the assumption that A is skew-Hermitian with eigenvalues in an interval of the imaginary axis with length 4γ, then the PA approximation error is bounded by

$$\|y(0;t) - y_m(0;t)\| \leq 4\sum_{k=m}^{+\infty} |J_k(2t\gamma)|, \tag{27}$$

where J_k is the Bessel function of the first kind.

Our analysis is based on the integral representation (cfr. [9, p. 234] and [29, pp. 28–29])

$$y(k;t) = \frac{1}{t^k}\lim_{n\to\infty}\frac{1}{2\pi i}\int_{\epsilon-in}^{\epsilon+in}\exp(t\lambda)\lambda^{-k}(\lambda I + A)^{-1}v d\lambda, \quad k = 0, 1, 2, \ldots,$$

which, under our assumptions, holds for every $\varepsilon > 0$ with uniform convergence when t is chosen in compact intervals of $(0, +\infty)$. More precisely, in [9] and [29], this representation is proved for $k = 0, 1, 2$, but it is possible to verify that it can be extended also for $k > 2$ by noting that

$$\lim_{n\to\infty}\frac{1}{2\pi i}\int_{\epsilon-in}^{\epsilon+in}\lambda^{-k}(\lambda I + A)^{-1}v d\lambda = 0.$$

Given $\varepsilon > 0$, we set $\lambda = \varepsilon + i\rho$, and then we obtain

$$y(k;t) = \frac{1}{t^k}\exp(t\varepsilon)\lim_{n\to\infty}\frac{1}{2\pi}\int_{-n}^{+n}\exp(it\rho)(\varepsilon + i\rho)^{-k}((\varepsilon + i\rho)I + A)^{-1}v d\rho. \tag{28}$$

In the sequel we suppose A and v to be real, and then we consider $\mu_j = a_j + ib_j$ $(j = 1, 2, \ldots, m)$ the eigenvalues of matrix H_m arranging them as $\mu_1, \ldots, \mu_{m_1}$ the real ones and $\mu_{m_1+1}, \ldots, \mu_m$ the complex conjugate ones. Moreover we set

$$r_j = |\mu_j| = \left((\varepsilon + a_j)^2 + b_j^2\right)^{1/2} \quad \text{for } j = 1, \ldots, m,$$

$$R = \max_{1\leq j\leq m} r_j$$

and

$$\omega_m(\varepsilon) = \prod_{j=1}^{m}(r_j(\varepsilon + a_j))^{1/2}. \tag{29}$$

For convenience we also define the functions

$$\beta_m(\rho) = \prod_{j=1}^{m_1}\left(1 + \rho^2/r_j^2\right)^{1/2}\prod_{j=m_1+1}^{m}\left(1 + \rho^2/r_j^2\right)^{1/4} \tag{30}$$

and

$$d_m(\rho) = \frac{\prod_{j=1}^{m} h_{j+1,j}}{\omega_m(\varepsilon)\beta_m(\rho)}.$$

Under these assumptions, applying (8) we will prove the following result.

PROPOSITION 5. *Consider an arbitrary value $\varepsilon > 0$ and suppose $m + m_1 + 2k \geq 4$. Then, for the PA method the following error bound holds:*

$$\|y(k;t) - y_m(k;t)\| \leq c_{k,m} \int_0^\infty \frac{\left(1 + \rho^2/\varepsilon^2\right)^{-k/2}}{\beta_m(\rho)\sqrt{1 + d_m(\rho)^2}} d\rho \tag{31}$$

where

$$c_{k,m} = \frac{2\exp(t\varepsilon)\prod_{j=1}^{m} h_{j+1,j}}{\pi\omega_m(\varepsilon)(\varepsilon + a)(t\varepsilon)^k}. \tag{32}$$

Proof. For $\rho \geq 0$ we have

$$\begin{aligned} |\det((\varepsilon + i\rho)I + H_m)| &= \prod_{j=1}^{m} |(\varepsilon + i\rho) + \mu_j| \\ &= \prod_{j=1}^{m} \left({r_j}^2 + \rho^2 + 2\rho b_j\right)^{1/2}. \end{aligned}$$

We claim that

$$|\det((\varepsilon + i\rho)I + H_m)| \geq \omega_m(\varepsilon)\beta_m(\rho). \tag{33}$$

Indeed, when $m_1 = m$ then the previous relationship clearly holds; otherwise, since H_m is real, there are $(m - m_1)/2$ couples of conjugate eigenvalues. For each of them, say $\mu^{\pm} = \overline{a} \pm i\overline{b}$ ($\overline{b} > 0$), we have

$$\begin{aligned} |(\varepsilon + i\rho) + \mu^+|\,|(\varepsilon + i\rho) + \mu^-| &= \left(\left((\varepsilon + \overline{a})^2 + (\rho + \overline{b})^2\right)\left((\varepsilon + \overline{a})^2 + (\rho - \overline{b})^2\right)\right)^{1/2} \\ &\geq \left((\varepsilon + \overline{a})^2 + \overline{b}^2 + \rho^2\right)^{1/2} (\varepsilon + \overline{a}); \end{aligned}$$

hence (33) follows. Using the same arguments, we obtain (33) also for $\rho < 0$. Therefore, due to (12) we have

$$|\xi_m(\varepsilon + i\rho)| \leq d_m(\rho). \tag{34}$$

Moreover we account for the following bound

$$\max\left(\left\|((\varepsilon + i\rho)I + A)^{-1}\right\|, \left\|((\varepsilon + i\rho)I + H_m)^{-1}\right\|\right) \leq (\varepsilon + a)^{-1}, \tag{35}$$

which arises from the well-known inequality $\|(\lambda I + A)^{-1}\| \leq dist(-\lambda, W(A))^{-1}$ and by assumption (22). Then, referring to representation (28), we consider error formula (8). From (11) and (13) ($U_m = V_m$) we obtain

$$|\xi_m(\lambda)| \leq h_{m+1,m} \left\|(\lambda I + H_m)^{-H} e_m\right\| \mu_{m-1}(\lambda, A).$$

Thus, due to $\mu_{m-1}(\lambda, A) \leq \|v\| = 1$, from (11) it follows that

$$\mu_m(\lambda, A) \leq \frac{|\xi_m(\lambda)|}{\sqrt{1 + |\xi_m(\lambda)|^2}}. \tag{36}$$

As a consequence, by means of (34) and (35), we have

$$\|y(k;t) - y_m(k;t)\| \leq \frac{2\exp(t\varepsilon)}{\pi(\varepsilon + a)t^k} \int_0^\infty \frac{d_m(\rho)d\rho}{(\varepsilon^2 + \rho^2)^{k/2}\sqrt{1 + d_m(\rho)^2}}.$$

Thus (31) is proved. We notice that if $m + m_1 + 2k \geq 4$, then the integral in (31) converges. □

We would like to point out that by (31) we can recognize the well-known superlinear convergence of the method; indeed, setting $\varepsilon = m/t$, for a suitable constant C, we obtain

$$\|y(k;t) - y_m(k;t)\| \leq \frac{Ct}{m^{k+1}} \left(\frac{t\exp(1)(\prod_{j=1}^m h_{j+1,j})^{1/m}}{m} \right)^m,$$

which stresses the dependence on the term $t(\prod_{j=1}^m h_{j+1,j})^{1/m}$. A further speed-factor may be added and a consequent *super-super linear* convergence is reached when the product $\prod_{j=1}^m h_{j+1,j}$ rapidly decreases; but, unfortunately, this does not occur in the case of approximating parabolic problem solution, where A represents the discretization of an elliptic operator and its spectrum enlarges as the mesh is refined. Anyway, in order to overcome this drawback, we mention the use of a rational Krylov method recently adopted in [28] and [10] (numerical comparisons can be found also in the recent paper [30]). Moreover, though a priori information on the behavior of $\prod_{j=1}^m h_{j+1,j}$ can be provided by (17), (18), (19), and (2), in our experiments this product is directly evaluated in the PA process.

The result we give below aims to avoid the use of a quadrature rule for evaluating the integral in (31).

PROPOSITION 6. *Let $\varepsilon > 0$ and assume $m + m_1 \geq 4$. Referring to the previous notations, the approximation error obtained by applying the PA method is bounded by*

$$\|y(k;t) - y_m(k;t)\| \leq c_{k,m} C_m \tag{37}$$

where we set

$$C_m = \frac{\sqrt{\pi}}{2\sqrt{(1 + d_m(\varepsilon)^2)\, S_m^{(1)}}} + \frac{\exp\left(-\varepsilon^2 S_m^{(2)}\right)}{\sqrt{1 + d_m(R)^2}}(R - \varepsilon) + \left(\frac{\varepsilon}{\sqrt{\varepsilon^2 + R^2}}\right)^k \frac{R\pi}{2^{\left(\frac{m+m_1}{4}+1\right)}}$$

with

$$S_m^{(1)} = \frac{k}{4\varepsilon^2} + \frac{1}{2}\sum_{i=1}^{m_1} \frac{1}{r_j^2 + \varepsilon^2} + \frac{1}{4}\sum_{i=m_1+1}^{m} \frac{1}{r_j^2 + \varepsilon^2}$$

and

$$S_m^{(2)} = \frac{k}{2(\varepsilon^2 + R^2)} + \frac{1}{2}\sum_{i=1}^{m_1} \frac{1}{r_j^2 + R^2} + \frac{1}{4}\sum_{i=m_1+1}^{m} \frac{1}{r_j^2 + R^2}.$$

Proof. Setting

$$\Psi_m(\rho) = \frac{(1+\rho^2/\varepsilon^2)^{-k/2}}{\beta_m(\rho)},$$

we approximate the integral in (31), exploiting the relationship

$$\Psi_m(\rho) \le \exp\left(-\rho^2\left(\frac{k}{2(\varepsilon^2+\rho^2)} + \frac{1}{2}\sum_{i=1}^{m}\frac{1}{r_j^2+\rho^2} + \frac{1}{4}\sum_{i=m_1+1}^{m}\frac{1}{r_j^2+\rho^2}\right)\right), \tag{38}$$

which comes from $1-x \le \exp(-x)$, $0 \le x \le 1$. At first we have

$$\int_0^\varepsilon \frac{\Psi_m(\rho)}{\sqrt{1+d_m(\rho)^2}}d\rho \le \frac{1}{\sqrt{1+d_m(\varepsilon)^2}}\int_0^\varepsilon \Psi_m(\rho)d\rho.$$

Thanks to (38), using formulae 7.1.1 and 7.1.2 in [1], we get

$$\begin{aligned}\int_0^\varepsilon \Psi_m(\rho)d\rho &\le \int_0^\varepsilon \exp\left(-\rho^2 S_m^{(1)}\right)d\rho = \frac{1}{\sqrt{S_m^{(1)}}}\int_0^{\varepsilon\sqrt{S_m^{(1)}}} \exp\left(-x^2\right)dx \\ &\le \frac{\sqrt{\pi}}{2\sqrt{S_m^{(1)}}}.\end{aligned}$$

Furthermore (38) yields

$$\int_\varepsilon^R \frac{\Psi_m(\rho)}{\sqrt{1+d_m(\rho)^2}}d\rho \le \frac{\int_\epsilon^R \exp\left(-\rho^2 S_m^{(2)}\right)d\rho}{\sqrt{1+d_m(R)^2}} \le \frac{\exp\left(-\varepsilon^2 S_m^{(2)}\right)(R-\varepsilon)}{\sqrt{1+d_m(R)^2}}.$$

Finally it is not so difficult to verify that, for $m+m_1 \ge 4$, it holds

$$\begin{aligned}\int_R^{+\infty} \frac{\Psi_m(\rho)}{\sqrt{1+d_m(\rho)^2}}d\rho &\le \int_R^{+\infty}\Psi_m(\rho)d\rho \\ &\le \left(\frac{\varepsilon}{\sqrt{\varepsilon^2+R^2}}\right)^k \int_R^{+\infty}\frac{1}{(1+\rho^2/R^2)^{\frac{m+m_1}{4}}}d\rho \\ &\le \left(\frac{\varepsilon}{\sqrt{\varepsilon^2+R^2}}\right)^k \frac{\pi R}{2^{\left(\frac{m+m_1}{4}+1\right)}}.\end{aligned}$$

This completes the proof. □

Concerning the choice of ε, of course a suitable value is the one minimizing the bound. In practice ε can be chosen by trying to reach the minimum value of a significant part of it: for instance, we can find $\varepsilon > 0$ which minimizes

$$\frac{\exp(t\varepsilon)}{(\varepsilon+a)\omega_m(\varepsilon)\varepsilon^k} \tag{39}$$

or, when the b_j's are negligible with respect to the a_j's, simply

$$\frac{\exp(t\varepsilon)}{(\varepsilon+a)\prod_{j=1}^m(\varepsilon+a_j)\varepsilon^k}. \tag{40}$$

Remark 7. After some computations, it is possible to prove that the following inequality holds:

$$\max\left(\left\|((\varepsilon+i\rho)I+A)^{-1}\right\|,\left\|((\varepsilon+i\rho)I+H_m)^{-1}\right\|\right)\leq\kappa(\varepsilon,\rho,\vartheta)^{-1}$$

where

$$\kappa(\varepsilon,\rho,\vartheta)=\sqrt{(\varepsilon+a)^2+\rho^2},\ \text{if}\ |\rho|\tan\theta\leq\varepsilon+a$$

and

$$\kappa(\varepsilon,\rho,\vartheta)=\frac{(\varepsilon+a)\tan\theta+|\rho|}{\sqrt{1+\tan^2\vartheta}},\ \text{if}\ |\rho|\tan\theta>\varepsilon+a.$$

This bound could be employed instead of (35); yet, in practice its use does not influence substantially the error estimates.

At the end of this subsection we account for the computation of

$$y^+(k;t)=\varphi_k(-itA)v,\quad t>0$$

under the assumption that A is symmetric and positive semidefinite; as it is well known this problem is related to the solution of the Schrödinger equation (see, for instance, [16]). In this respect, we refer to (2) and consider the mth PA-approximation

$$y_m^+(k;t)=V_m\varphi_k(-itH_m)e_1. \tag{41}$$

Denoting by μ_j $(j=1,2,\dots m)$ the eigenvalues of the Hermitian and positive semidefinite matrix H_m, we set

$$r_j^2=\left(\varepsilon^2+\mu_j^2\right)\quad\text{for } 1\leq j\leq m,\quad R=\max_{1\leq j\leq m}r_j,$$
$$\omega_m^+(\varepsilon)=\prod_{j=1}^m r_j\quad\text{and}\quad G_m=\prod_{j=1}^m(1-\mu_j/r_j)^{1/2}.$$

Furthermore we define

$$\beta_m^+(\rho)=\prod_{j=1}^m\left(1+\rho^2/{r_j}^2\right)^{1/2}\quad\text{and}\quad d_m^+(\rho)=\frac{\prod_{j=1}^m h_{j+1,j}}{\omega_m^+(\varepsilon)\beta_m^+(\rho)}.$$

Under these notations we will prove the following result.

PROPOSITION 8. *Let us consider an arbitrary $\varepsilon>0$. Supposing $m+k\geq 2$, the PA approximation* (41) *yields the error estimate*

$$\left\|y^+(k;t)-y_m^+(k;t)\right\|\leq c_{k,m}C_m \tag{42}$$

where we set

$$c_{k,m}=\frac{\exp(t\varepsilon)\prod_{j=1}^m h_{j+1,j}}{\pi\varepsilon\omega_m^+(\varepsilon)(t\varepsilon)^k}\left(1+\frac{1}{G_m}\right),$$

$$C_m=\frac{\sqrt{\pi}}{2\sqrt{\left(1+d_m^+(\varepsilon)^2\right)S_m^{(1)}}}+\frac{\exp\left(-\varepsilon^2S_m^{(2)}\right)}{\sqrt{1+d_m^+(R)^2}}(R-\varepsilon)+\left(\frac{\varepsilon}{\sqrt{\varepsilon^2+R^2}}\right)^k\frac{R\pi}{2^{\left(\frac{m}{2}+1\right)}}$$

with

$$S_m^{(1)} = \frac{k}{4\varepsilon^2} + \frac{1}{2}\sum_{j=1}^{m} \frac{1}{r_j^2 + \varepsilon^2} \quad \textit{and} \quad S_m^{(2)} = \frac{k}{2(\varepsilon^2 + R^2)} + \frac{1}{2}\sum_{j=1}^{m} \frac{1}{r_j^2 + R^2}.$$

Proof. It is similar to the proof of Propositions 5 and 6 with slight modifications due to the different structure of the spectra of matrices iH_m and H_m. We replace A by iA in (28) and H_m by iH_m in (12); thus, we obtain

$$|\xi_m(\varepsilon + i\rho)| = \frac{\prod_{j=1}^{m} h_{j+1,j}}{|\det((\varepsilon + i\rho)I + iH_m)|}.$$

Then, for $\rho \geq 0$ we have

$$\begin{aligned} |\det((\varepsilon + i\rho)I + iH_m)| &= \prod_{j=1}^{m} \left(\varepsilon^2 + (\rho + \mu_j)^2\right)^{1/2} = \prod_{j=1}^{m} \left({r_j}^2 + \rho^2 + 2\rho\mu_j\right)^{1/2} \\ &\geq \omega_m^+(\varepsilon)\beta_m^+(\rho), \end{aligned}$$

while for $\rho < 0$ we get

$$\begin{aligned} |\det((\varepsilon + i\rho)I + iH_m)| &= \prod_{j=1}^{m} \left(r_j^2 + \rho^2\right)^{1/2} \left(1 - \frac{2\mu_j\,|\rho|}{r_j^2 + \rho^2}\right)^{1/2} \\ &\geq \prod_{j=1}^{m} \left(r_j^2 + \rho^2\right)^{1/2} \left(1 - \frac{\mu_j}{r_j}\right)^{1/2} = \omega_m^+(\varepsilon)\beta_m^+(\rho)G_m. \end{aligned}$$

Hence, for $\rho > 0$ it holds $|\xi_m(\varepsilon + i\rho)| \leq d_m^+(\rho)$ and $|\xi_m(\varepsilon - i\rho)| \leq d_m^+(\rho)/G_m$. Therefore, due to (35) which holds for $a = 0$, arguing as in Proposition 5, from (6) and (36) by easy computations it follows that

$$\left\|y^+(k;t) - y_m^+(k;t)\right\| \leq c_{k,m} \int_0^\infty \frac{\left(1 + \rho^2/\varepsilon^2\right)^{-k/2}}{\beta_m^+(\rho)\sqrt{1 + d_m^+(\rho)^2}} d\rho.$$

By the same arguments as in the proof of Proposition 6, we obtain the bound

$$\int_0^{+\infty} \frac{\left(1 + \rho^2/\varepsilon^2\right)^{-k/2}}{\beta_m^+(\rho)\sqrt{1 + d_m^+(\rho)^2}} d\rho \leq C_m$$

and we prove the whole result. ∎

3.2. The case of trigonometric functions. Our interest is now focused on $\varphi(x) = \cos(t\sqrt{x})$ and the so-called *sinc* function defined as $\varphi(x) = \sin(t\sqrt{x})/\sqrt{x}$ which arise in the solution of second-order problems (see [15], [12], [7]). In particular, concerning the solution of hyperbolic equations, we account for the computation of

$$y^{(c)}(t) = \cos\left(t\sqrt{A}\right) v \quad t > 0 \tag{43}$$

under the assumption that A is real symmetric and positive semidefinite. In this respect, [7] provides the following error estimate.

PROPOSITION 9. *Let the eigenvalues of matrix A lie in the interval $[0, 4\gamma]$; then, an upper bound for the error in the PA approximation*

$$y_m^{(c)}(t) = V_m \cos\left(t\sqrt{H_m}\right) e_1$$

is given by

$$\left\| y^{(c)}(t) - y_m^{(c)}(t) \right\| \leq 4 \sum_{k=m}^{+\infty} |J_{2k}(2t\sqrt{\gamma})|, \tag{44}$$

where each J_k represents the Bessel function of the first kind.

In the sequel, we add the assumption that A is positive definite with spectrum in the interval $[a, +\infty)$ $(a > 0)$. Then, according to [11], we recall the representation

$$y^{(c)}(t) = \cos\left(t\sqrt{A}\right) v = \lim_{n\to\infty} \frac{1}{2\pi i} \int_{\epsilon-in}^{\epsilon+in} \exp(t\lambda)\lambda \left(\lambda^2 I + A\right)^{-1} v d\lambda$$

holds for every $\varepsilon > 0$ and $t \in (0, +\infty)$. In this way we have

$$y^{(c)}(t) = \exp(t\varepsilon) \lim_{n\to\infty} \frac{1}{2\pi} \int_{-n}^{n} \exp(it\rho)(\varepsilon + i\rho) \left((\varepsilon + i\rho)^2 I + A\right)^{-1} v \, d\rho, \tag{45}$$

and we provide the following result concerning the PA approximation.

PROPOSITION 10. *Suppose $m \geq 2$ and set*

$$R = \max_{1\leq j\leq m} \left(\varepsilon^2 + \mu_j\right),$$

where μ_j's are the eigenvalues of matrix H_m. Then, the error estimate

$$\left\| y^{(c)}(t) - y_m^{(c)}(t) \right\| \leq \frac{\exp(t\varepsilon)R}{2\sqrt{2}\varepsilon^{m+2}} \prod_{j=1}^{m} \frac{h_{j+1,j}}{(\varepsilon^2 + \mu_j)^{1/2}} \tag{46}$$

holds for each $\varepsilon > 0$ and $t > 0$.

Proof. We use the error representation (6). Thanks to the following relationship

$$\left\| \left((\varepsilon + i\rho)^2 I + A\right)^{-1} \right\| = \min_{x\in\sigma(A)} \left| \left((\varepsilon^2 - \rho^2) + x\right) + 2i\varepsilon\rho)^{-1} \right|$$

it is not so difficult to verify that

$$\left\| \left((\varepsilon + i\rho)^2 I + A\right)^{-1} \right\| \leq \left(\left(\varepsilon^2 + \rho^2\right)^2 + a^2 + 2a\left(\varepsilon^2 - \rho^2\right)\right)^{-1/2}, \text{ if } \rho^2 \leq \varepsilon^2 + a \tag{47}$$

and

$$\left\| \left((\varepsilon + i\rho)^2 I + A\right)^{-1} \right\| \leq (2\varepsilon|\rho|)^{-1}, \text{ if } \rho^2 > \varepsilon^2 + a. \tag{48}$$

From (47) we have

$$\left\| \left((\varepsilon + i\rho)^2 I + A\right)^{-1} \right\| \leq \left(\varepsilon^2 + \rho^2 + a\right)^{-1} \left(1 - \frac{a}{\varepsilon^2 + a}\right)^{-1/2} = \frac{\sqrt{\varepsilon^2 + a}}{\varepsilon(\varepsilon^2 + \rho^2 + a)}$$

when $\rho^2 \leq \varepsilon^2 + a$. Therefore, for any ρ we find that

$$\sqrt{\varepsilon^2+\rho^2}\left\|\left((\varepsilon+i\rho)^2 I + A\right)^{-1}\right\| \leq \frac{1}{\varepsilon}.$$

In order to evaluate

$$\left|\xi_m\left((\varepsilon+i\rho)^2\right)\right| = \prod_{j=1}^{m} \frac{h_{j+1,j}}{\left|\left(\left(\varepsilon^2-\rho^2\right)+\mu_j\right)+2i\varepsilon\rho\right)\right|},$$

we notice that

$$\begin{aligned}
\left|\left(\left(\left(\varepsilon^2-\rho^2\right)+\mu_j\right)+2i\varepsilon\rho\right)\right|^2 &= \left(\varepsilon^2+\rho^2\right)^2+\mu_j^2+2\mu_j\left(\varepsilon^2-\rho^2\right) \\
&= \left(\varepsilon^4+\rho^4+2\left(\varepsilon^2-\mu_j\right)\rho^2+\mu_j^2+2\mu_j\varepsilon^2\right) \\
&\geq \left(\varepsilon^4+\rho^4+2\varepsilon^2\rho^2+\mu_j^2+2\mu_j\varepsilon^2\right)\left(1-\frac{\mu_j}{\left(\varepsilon^2+\mu_j\right)}\right) \\
&= \left(\left(\varepsilon^2+\mu_j\right)^2+\rho^2\left(\rho^2+2\varepsilon^2\right)\right)\left(\frac{\varepsilon^2}{\varepsilon^2+\mu_j}\right) \\
&= \varepsilon^2\left(\varepsilon^2+\mu_j\right)\left(1+\frac{\rho^2\left(\rho^2+2\varepsilon^2\right)}{\left(\varepsilon^2+\mu_j\right)^2}\right).
\end{aligned}$$

As a consequence, due to (6) and (45), an upper bound for the error $\|y^{(c)}(t)-y_m^{(c)}(t)\|$ is given by the quantity

$$\begin{aligned}
&\frac{\exp(t\varepsilon)}{\varepsilon\pi}\prod_{j=1}^{m}\frac{h_{j+1,j}}{\varepsilon\left(\varepsilon^2+\mu_j\right)^{1/2}}\int_0^\infty\prod_{j=1}^{m}\left(1+\frac{\rho^2\left(\rho^2+2\varepsilon^2\right)}{\left(\varepsilon^2+\mu_j\right)^2}\right)^{-1/2}d\rho \\
&\leq \frac{\exp(t\varepsilon)}{\varepsilon^{m+1}\pi}\prod_{j=1}^{m}\frac{h_{j+1,j}}{\left(\varepsilon^2+\mu_j\right)^{1/2}}\int_0^\infty\prod_{j=1}^{m}\left(1+\frac{2\rho^2\varepsilon^2}{\left(\varepsilon^2+\mu_j\right)^2}\right)^{-1/2}d\rho \\
&\leq \frac{\exp(t\varepsilon)}{\varepsilon^{m+1}\pi}\prod_{j=1}^{m}\frac{h_{j+1,j}}{\left(\varepsilon^2+\mu_j\right)^{1/2}}\frac{R}{\varepsilon\sqrt{2}}\int_0^\infty\left(1+x^2\right)^{-1}d\rho \\
&\leq \frac{\exp(t\varepsilon)}{\varepsilon^{m+1}\pi}\prod_{j=1}^{m}\frac{h_{j+1,j}}{\left(\varepsilon^2+\mu_j\right)^{1/2}}\frac{R\pi}{2\varepsilon\sqrt{2}},
\end{aligned}$$

which is the desired result. □

Also in this case, in practice further improvement can be reached by choosing the value for ε which minimizes

$$\frac{\exp(t\varepsilon)}{\varepsilon^{m+2}\prod_{j=1}^{m}(\varepsilon^2+\mu_j)^{1/2}}. \tag{49}$$

Moreover, since H_m is symmetric positive definite, $\cos(t\sqrt{H_m})e_1$ can be computed by diagonalization of H_m.

Finally, as what concerns the computation of the *sinc* function

$$y^{(s)}(t) = \left(\sqrt{A}\right)^{-1}\sin\left(t\sqrt{A}\right)v, \quad t>0,$$

we notice that the relationship

$$y^{(s)}(t) = \int_0^t \cos\left(\tau\sqrt{A}\right) v d\tau$$

holds for each $t > 0$ so that, by integrating (46), the error bound

$$\left\| y^{(s)}(t) - y_m^{(s)}(t) \right\| \leq \frac{(\exp(t\varepsilon) - 1)R}{2\sqrt{2}\varepsilon^{m+3}} \prod_{j=1}^{m} \frac{h_{j+1,j}}{(\varepsilon^2 + \mu_j)^{1/2}}$$

is obtained for the corresponding PA approximation.

4. Numerical experiments. In order to provide some numerical results aiming to test the effectiveness of the previous error estimates, we account for some matrices which arise from the discretization of classical partial differential operators. Precisely we consider

$$L = -\frac{\partial^2}{\partial x^2} - \frac{\partial^2}{\partial y^2} + c_1 \frac{\partial}{\partial x} + c_2 \frac{\partial}{\partial y}, \quad c_1, c_2 \in \mathbb{R}, \tag{50}$$

where homogeneous Dirichlet boundary conditions are enforced on the unit square $(0,1) \times (0,1)$. The spatial discretization of this partial differential operator is carried out by central differences with uniform steplength $\delta = 1/(n+1)$ along both directions (i.e., $N = n^2$).

We provide several numerical results in order to compare the estimates given in Propositions 6, 8, and 10 with the true error norm and with a priori error estimates already known in the literature (in the case when they are available according to Propositions 3, 4, and 9). We implement bounds (23), (24), and (25) provided in [17] for $\beta = 1$. In the sequel we define the vector v by

$$v = (1, 1, \ldots, 1)^T / n \in \mathbb{R}^N \tag{51}$$

or, as an alternative, by the normalized discretization of the following function

$$v(x, y) = x(1 - x)y(1 - y). \tag{52}$$

Figures 1 and 2 refer to cases concerned with Proposition 6. We account for the φ_0-function applied to the matrix $A = B - \lambda_{\min} I$ where B is symmetric (given by setting $c_1 = c_2 = 0$ and discretizing (50)) and $\lambda_{\min}$ represents its minimum eigenvalue; under this assumption, it is possible to compare estimates (23)–(24), (26), and (37) as it is shown in Figure 1 (on the left) where we have set $n = 50$, $t = 0.005$, and defined v by (52) (normalized). As another test, we consider the skew-symmetric matrix defined as

$$A = \begin{pmatrix} O & B \\ -B & O \end{pmatrix},$$

where B is the symmetric block which arises from the discretization of (50) setting $c_1 = c_2 = 0$ and $n = 30$; in Figure 1 (on the right) we provide the numerical results obtained in correspondence with $\varphi_0(-tA)\overline{v}$ where $t = 0.001$ and $\overline{v} = (v, v)^T / (\|(v, v)\|)$ with v defined by (52). It is evident that, in both cases, our approach is in agreement with the true error norm and it outperforms the a priori bounds given in Propositions 3 and 4.

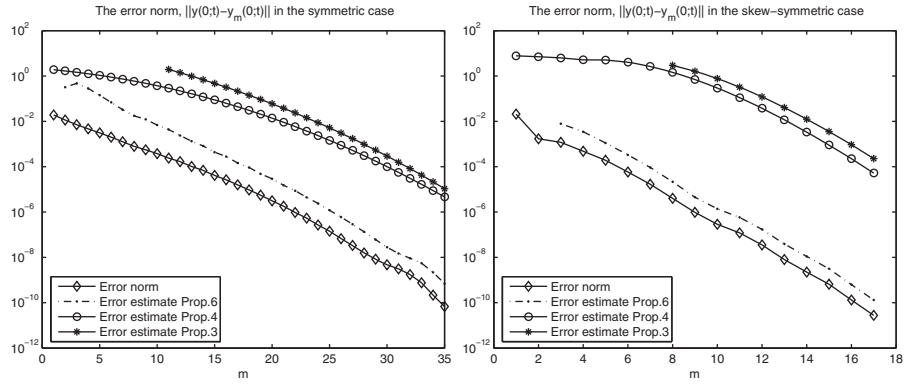

FIG. 1. *The error estimates for the φ_0-function related to Propositions* 3, 4, *and* 6 *compared with the true error norm. On the left: the case when A is symmetric (i.e., $c_1 = c_2 = 0$). On the right: the case when A is skew-symmetric.*

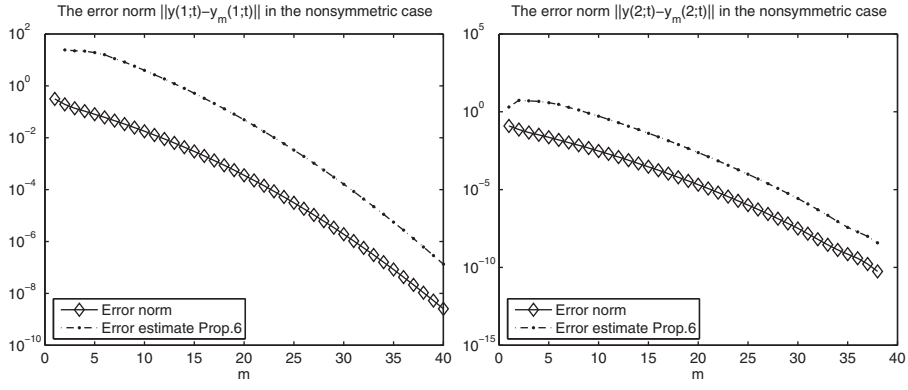

FIG. 2. *The error estimates for the φ_k-function (on the left: $k = 1$; on the right: $k = 2$) related to Proposition* 6 *compared with the true error norm in the case when A is nonsymmetric (i.e., $c_1 = 5$ and $c_2 = 10$).*

Moreover, we are interested in investigating the effectiveness of the estimates we provided concerning the φ_k-functions for $k \geq 1$ in the case of nonsymmetric matrices; for instance, concerning $k = 1, 2$ in Figure 2 we give the results related to the nonsymmetric matrix A obtained by the spatial discretization of (50) where we have set $c_1 = 5$, $c_2 = 10$, $n = 50$, taking $t = 0.005$ and v defined by (51). So far, in all the numerical experiments related to Proposition 6 the parameter ε has been chosen by minimizing quantity (40) except for the skew-symmetric case where ε is set equal to m/t.

In the following, we add further tests: concerning Proposition 8, in Figure 3 we compare estimates (25), (27), and (42) with the true error referring to $\varphi_0(-itA)v$ where $t = 0.001$, v is defined by (52), and A is the symmetric matrix obtained by discretizing (50) with $c_1 = c_2 = 0$, $n = 50$. In Figure 4 we show the results of two experiments concerning $\cos(t\sqrt{A})v$, where we compare the a posteriori estimate of Proposition 10 with the a priori bound of Proposition 9. In both cases we suppose $n = 50$, $t = 0.05$, and v defined by (51). On the left we give the results related

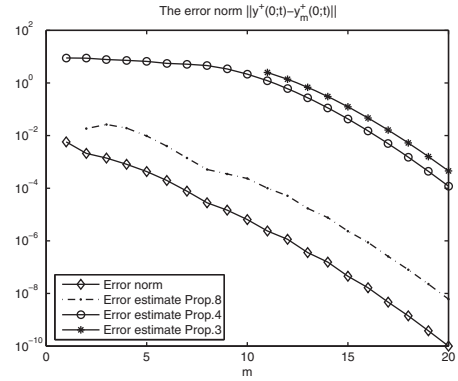

FIG. 3. *The error estimates for the φ_0-function related to Propositions* 3, 4, *and* 8 *compared with the true error norm.*

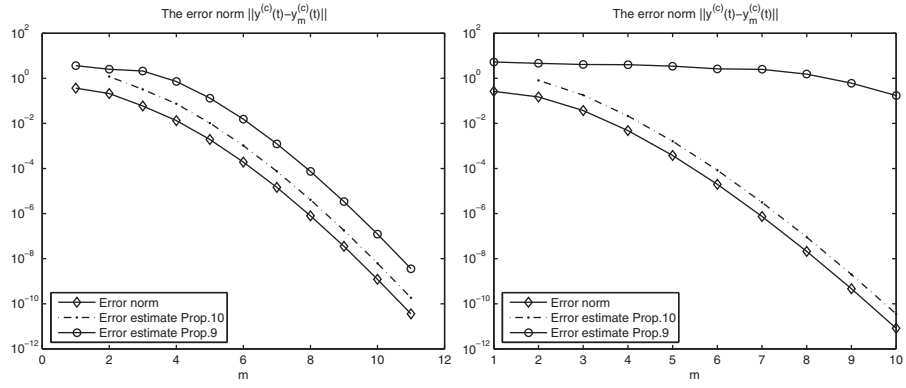

FIG. 4. *The error estimates for the cosine function related to Propositions* 9 *and* 10 *compared with the true error norm.*

to the symmetric matrix A obtained by (50) where $c_1 = c_2 = 0$; while on the right we consider A obtained by using finite differences in order to discretize the following operator

$$L = -\frac{\partial^2}{\partial x^2} - 10\frac{\partial^2}{\partial y^2}$$

on the square $(0,1) \times (0,1)$ with homogeneous Dirichlet conditions in x and homogeneous Neumann conditions in y. In both cases ε is taken by minimizing (49). We notice that in the first case both the estimates match well with the true error; but, in the second test, the a priori bound turns out to be too pessimistic and it is not able to detect the fast convergence of the method, as the a posteriori one does.

We would like to point out that we have found similar results when testing the effectiveness of the proposed estimates on other examples such as the matrices arising from the discretization of the three-dimensional Laplacian operator.

All the numerical experiments have been performed in a MatLab environment, and every value $\varphi(H_m)$ has been computed by means of diagonalization (when it has been possible) or by built-in functions (`expm` or more in general `funm`).

Acknowledgments. The authors would like to thank the referees for advising us to perform comparison with the estimates provided in [7] which helped in the improvement of the numerical part.

STRUCTURE-PRESERVING ALGORITHMS FOR PALINDROMIC QUADRATIC EIGENVALUE PROBLEMS ARISING FROM VIBRATION OF FAST TRAINS*

TSUNG-MING HUANG†, WEN-WEI LIN‡, AND JIANG QIAN§

Abstract. In this paper, based on Patel's algorithm (1993), we propose a structure-preserving algorithm for solving palindromic quadratic eigenvalue problems (QEPs). We also show the relationship between the structure-preserving algorithm and the URV-based structure-preserving algorithm by Schröder (2007). For large sparse palindromic QEPs, we develop a generalized $\top$-skew-Hamiltonian implicitly restarted shift-and-invert Arnoldi algorithm for solving the resulting $\top$-skew-Hamiltonian pencils. Numerical experiments show that our proposed structure-preserving algorithms perform well on the palindromic QEP arising from a finite element model of high-speed trains and rails.

Key words. palindromic quadratic eigenvalue problem, $\top$-symplectic pencil, $\top$-skew-Hamiltonian pencil

DOI. 10.1137/080713550

1. Introduction.

In this paper, we consider the palindromic quadratic eigenvalue problem (QEP) of the form

$$\mathcal{P}(\lambda)x \equiv (\lambda^2 A_1^\top + \lambda A_0 + A_1)x = 0, \tag{1.1}$$

where $\lambda \in \mathbb{C}$, $x \in \mathbb{C}^n \backslash \{0\}$ and $A_1, A_0 \in \mathbb{C}^{n\times n}$ with $A_0^\top = A_0$. Note that the superscript "$\top$" denotes the complex transpose. The scalar λ and the nonzero vector x in (1.1) are the eigenvalue and the associated eigenvector of $\mathcal{P}(\lambda)$, respectively. The underlying matrix polynomial $\mathcal{P}(\lambda)$ has the property that reversing the order of the coefficients, followed by taking the transpose, leads back to the original matrix polynomial, which explains the word "palindromic." Consequently, taking the transpose of (1.1), we easily see that the eigenvalues of $\mathcal{P}(\lambda)$ satisfy the "symplectic" property; that is, they are paired with respect to the unit circle, containing both an eigenvalue λ and its reciprocal $1/\lambda$ (with 0 and ∞ considered to be reciprocal).

The palindromic QEP (1.1) was first raised in the study of the vibration in the structural analysis for fast trains in Germany [3, 4], associated with the company SFE GmbH in Berlin. Existing fast train systems, like the Japanese Shinkansen, the French TGV, and the German ICE, are being modernized and expanded. Vibration is produced from the interaction between the wheels of a train and the rails underneath. Due to the ever increasing speed (currently up to 300 km/hr) of modern trains, the study of its vibration becomes an important task. Research does not only contribute

towards the increased comfort of passengers, in terms of lower noise and vibration levels. More importantly, the safety in the operation of the trains will be improved, and the operational and construction costs will be optimized [4, 5, 12, 13]. In addition, innovative designs of railway bridges, embedded rail structures, and train suspension systems require accurate resolution of the vibration.

A standard approach for solving the palindromic QEP (1.1) is to transform it into a $2n \times 2n$ linear eigenvalue problem

$$\begin{bmatrix} 0 & I \\ A_1 & A_0 \end{bmatrix} \begin{bmatrix} x \\ \lambda x \end{bmatrix} = \lambda \begin{bmatrix} I & 0 \\ 0 & -A_1^\top \end{bmatrix} \begin{bmatrix} x \\ \lambda x \end{bmatrix} \tag{1.2}$$

and compute its generalized Schur form (see [23]). However, the symplectic property of the eigenvalues of (1.1) is not preserved by computation, generally, producing large numerical errors ([5]). Recently, some pioneering work [4, 12, 13] proposed a good linearization which linearizes the palindromic QEP (1.1) into the form $\lambda Z^\top + Z$, which preserves symplecticity to some extent, and suggested some structure-preserving solution methods. This leads to a vast improvement over previous approaches. Later, a QR-like algorithm [19] and a Jacobi-type method [4] combined with the Laub trick, a preprocessing step of the generalized Schur form [11], have been developed for solving the palindromic linear pencil $\lambda Z^\top + Z$. However, the latter method works well, only if there are no eigenvalues near ± 1. The Jacobi method typically needs about $O(n^3 \log(n))$ flops and the QR-like algorithm is of $O(n^4)$ flops. Recently, a URV-decomposition-based structured method of cubic complexity was developed in [20] to solve the palindromic linear pencil $\lambda Z^\top + Z$, producing eigenvalues which are paired to working precision. In section 3, we will show that the URV-based method [20] is mathematically equivalent to applying the structure-preserving algorithm in section 2 to the enlarged $2n \times 2n$ palindromic quadratic pencil $\zeta^2 Z^\top + \zeta 0 + Z$ (with $\zeta^2 = \lambda$). On the other hand, a structure-preserving doubling algorithm was developed in [1] via the computation of a solvent of a nonlinear matrix equation associated with (1.1). The numerical results show much promise but the convergence theory holds only when the algorithm does not break down.

As mentioned before, the linearization (1.2) generally cannot preserve the symplectic structure. Fortunately, the special linearization for (1.1) (see [1] or [10])

$$(\mathcal{M} - \lambda \mathcal{L})z \equiv \left(\begin{bmatrix} A_1 & 0 \\ -A_0 & -I \end{bmatrix} - \lambda \begin{bmatrix} 0 & I \\ A_1^\top & 0 \end{bmatrix} \right) \begin{bmatrix} x \\ y \end{bmatrix} = 0 \tag{1.3}$$

obtained by setting $y = \frac{1}{\lambda} A_1 x$ and multiplying the second equation of (1.3) by λ satisfies

$$\mathcal{M} \mathcal{J} \mathcal{M}^\top = \mathcal{L} \mathcal{J} \mathcal{L}^\top, \tag{1.4}$$

where $\mathcal{J} \equiv \mathcal{J}_{2n}$ is the $2n \times 2n$ matrix $\left[\begin{smallmatrix} 0 & I_n \\ -I_n & 0 \end{smallmatrix} \right]$. In other words, the pencil $\mathcal{M} - \lambda \mathcal{L}$ or the matrix pair $(\mathcal{M}, \mathcal{L})$ in (1.3) preserves the symplectic structure of (1.4) and is said to be $\top$-symplectic.

For a real matrix pair $(\mathcal{M}, \mathcal{L})$ satisfying (1.4), a structure-preserving $(\mathcal{S} + \mathcal{S}^{-1})$-transform for the computation of all its eigenvalues is proposed by [9] and a numerically stable algorithm for reducing the transformed pair to a block triangular condensed form by using only orthogonal transformations was developed by Patel [16]. It is perfectly suitable for the $\top$-symplectic pair, but not applicable to the complex conjugate

symplectic pair (i.e., $\mathcal{M}\mathcal{J}\mathcal{M}^H = \mathcal{L}\mathcal{J}\mathcal{L}^H$). In this paper, we adapt Patel's approach to solve the $\top$-symplectic pencil in (1.3) resulting from the palindromic QEP (1.1). Only unitary transformations are used and the symplectic structure is fully preserved, which make the method attractive. It is worth mentioning that the $(\mathcal{S}+\mathcal{S}^{-1})$-transform is, in general, a nonlinear transform as in solving the discrete-time optimal control problem [9, 16]. However, the special form in (1.3) leads to a linear $(\mathcal{S}+\mathcal{S}^{-1})$-transform without involving any matrix multiplication.

In some applications, the matrices A_1 and A_0 in (1.1) (and hence $\mathcal{M}$ and $\mathcal{L}$ in (1.3)) can be large and sparse and only the eigenvalues in a specified region are required. To accomplish this, the shift-and-invert (implicitly restarted) Arnoldi algorithm [7, 17, 21] is one of the most widely used standard techniques for computing selected eigenvalues of the large sparse matrix pencil $\mathcal{M}-\lambda\mathcal{L}$. In this approach, the corresponding shifted and inverted matrix is reduced to a Hessenberg form which no longer has the desirable symplectic structure.

Mehrmann and Watkins [15] developed a structure-preserving skew-Hamiltonian, isotropic, implicitly restarted shift-and-invert Arnoldi algorithm (SHIRA) for the computation of eigenpairs of a large sparse real skew-Hamiltonian/Hamiltonian pencil by transforming the pencils to a skew-Hamiltonian operator. In fact, SHIRA can be straightforwardly extended to solve a skew-Hamiltonian/Hamiltonian pencil in the complex transpose case (not in the complex conjugate case), referred to as $\top$SHIRA. We first transform the $\top$-symplectic pencil to a $\top$-skew-Hamiltonian eigenvalue problem by using the $(\mathcal{S}+\mathcal{S}^{-1})$-transform, then $\top$SHIRA is applied to the resulting $\top$-skew-Hamiltonian matrix. On the other hand, to avoid explicitly forming the $\top$-skew-Hamiltonian matrix in the above transformation, we also develop a generalized $\top$-skew-Hamiltonian implicitly restarted shift-and-invert Arnoldi algorithm (G$\top$SHIRA) for solving the $\top$-skew-Hamiltonian pencil resulting from the $(\mathcal{S}+\mathcal{S}^{-1})$-transform of the symplectic pencil $\mathcal{M}-\lambda\mathcal{L}$.

We introduce some definitions that will be used frequently in this paper.

DEFINITION 1.1.

(i) *A matrix $\mathcal{A}\in\mathbb{C}^{n\times n}$ is called $\top$-symmetric or $\top$-skew-symmetric if it satisfies $\mathcal{A}^\top=\mathcal{A}$ or $\mathcal{A}^\top=-\mathcal{A}$, respectively.*

(ii) *A matrix $\mathcal{U}\in\mathbb{C}^{2n\times 2n}$ is called $\top$-symplectic if $\mathcal{U}^\top\mathcal{J}\mathcal{U}=\mathcal{J}$; a pencil $\mathcal{M}-\lambda\mathcal{L}\in\mathbb{C}^{2n\times 2n}$ or the matrix pair $(\mathcal{M},\mathcal{L})$ is called $\top$-symplectic if $\mathcal{M}\mathcal{J}\mathcal{M}^\top=\mathcal{L}\mathcal{J}\mathcal{L}^\top$.*

(iii) *A matrix $\mathcal{H}\in\mathbb{C}^{2n\times 2n}$ is called $\top$-Hamiltonian or $\top$-skew-Hamiltonian if it satisfies $(\mathcal{H}\mathcal{J})^\top=\mathcal{H}\mathcal{J}$ or $(\mathcal{H}\mathcal{J})^\top=-\mathcal{H}\mathcal{J}$, respectively.*

(iv) *A pencil $\mathcal{K}-\lambda\mathcal{N}\in\mathbb{C}^{2n\times 2n}$ or the matrix pair $(\mathcal{K},\mathcal{N})$ is called $\top$-skew-Hamiltonian if $\mathcal{K}$ and $\mathcal{N}$ are $\top$-skew-Hamiltonian.*

(v) *Let $X,Y\in\mathbb{C}^{2n\times m}(1\le m\le n)$; X is called $\top$-isotropic if $X^\top\mathcal{J}X=0_m$; and X and Y are called $\top$-bi-isotropic if $X^\top\mathcal{J}Y=0_m$.*

Throughout this paper, $A^\top$ and A^H denote the transpose and conjugate transpose of a matrix A, respectively. We denote the $m\times n$ zero matrix by $0_{m,n}$, and the zero and identity matrices of order n by 0_n and I_n, respectively. The ith column of I_n is denoted by e_i. We adopt the following MATLAB notations: $v(i:j)$ denotes the subvector of the vector v that consists of the ith to the jth entries of v. $A(i:j,k:\ell)$ denotes the submatrix of the matrix A that consists of the intersection of the rows i to j and the columns k to ℓ. $A(i:j,:)$ and $A(:,k:\ell)$ select the rows i to j and the columns k to ℓ, respectively, of A.

The paper is organized as follows. In section 2, we briefly present the structure-preserving algorithm based on Patel's method [16] for solving palindromic QEPs. In

section 3, we show the relationship between the structure-preserving algorithm and the URV-based structured method proposed by Schröder [20]. In section 4, based on the SHIRA developed in [15], we introduce the $\top$-skew-Hamiltonian implicitly-restarted shift-and-invert Arnoldi algorithm ($\top$SHIRA) for solving the resulting $\top$-skew-Hamiltonian matrix. In section 5, a generalized $\top$-skew-Hamiltonian implicitly-restarted shift-and-invert Arnoldi algorithm (G$\top$SHIRA) for solving the resulting $\top$-skew-Hamiltonian pencils is developed. We present some numerical results of the proposed algorithms, using examples from a finite element model of fast trains [1], in section 6. Conclusions are given in section 7.

2. Structure-preserving algorithm I. We adapt Patel's algorithm [16] applying to the $(\mathcal{S}+\mathcal{S}^{-1})$-transform of a $\top$-symplectic matrix pair for the computation of all its eigenpairs. Let $(\mathcal{M},\mathcal{L})$ be a $\top$-symplectic pair. The $(\mathcal{S}+\mathcal{S}^{-1})$-transform $(\mathcal{M}_s,\mathcal{L}_s)$ of $(\mathcal{M},\mathcal{L})$ is defined by (see [9])

$$\mathcal{M}_s \equiv \mathcal{M}\mathcal{J}\mathcal{L}^\top + \mathcal{L}\mathcal{J}\mathcal{M}^\top, \qquad \mathcal{L}_s \equiv \mathcal{L}\mathcal{J}\mathcal{L}^\top. \tag{2.1}$$

We first give the relationship between eigenpairs of a $\top$-symplectic pencil and its $(\mathcal{S}+\mathcal{S}^{-1})$-transform.

THEOREM 2.1. *Let $(\mathcal{M},\mathcal{L})$ be a $\top$-symplectic pair and $(\mathcal{M}_s,\mathcal{L}_s)$ be its $(\mathcal{S}+\mathcal{S}^{-1})$-transform. Then*

(i) *μ is a double eigenvalue of $(\mathcal{M}_s,\mathcal{L}_s)$ if and only if $\nu,\frac{1}{\nu}$ are eigenvalues of $(\mathcal{M},\mathcal{L})$, where $\nu,\frac{1}{\nu}$ are two roots of the quadratic equation $\lambda+\frac{1}{\lambda}=\mu$.*

(ii) *Let x and y be linearly independent eigenvectors of $(\mathcal{L}^\top,\mathcal{M}^\top)$ corresponding to ν and $\frac{1}{\nu}$, respectively, i.e., $(\mathcal{L}^\top-\nu\mathcal{M}^\top)x=0$ and $(\mathcal{L}^\top-\frac{1}{\nu}\mathcal{M}^\top)y=0$. Then x and y are two linearly independent eigenvectors of $(\mathcal{M}_s,\mathcal{L}_s)$ corresponding to $\mu=\nu+\frac{1}{\nu}$.*

(iii) *Furthermore, from* (ii)*, if $z_s=\alpha x+\beta y$ (with $\alpha\beta\neq 0$) is an eigenvector of $(\mathcal{M}_s,\mathcal{L}_s)$ corresponding to $\mu=\nu+\frac{1}{\nu}$ ($\mu\neq\pm 2$), i.e., $(\mathcal{M}_s-\mu\mathcal{L}_s)z_s=0$, then $\mathcal{J}(\mathcal{L}^\top-\frac{1}{\nu}\mathcal{M}^\top)z_s$ and $\mathcal{J}(\mathcal{L}^\top-\nu\mathcal{M}^\top)z_s$ are the eigenvectors of $(\mathcal{M},\mathcal{L})$ corresponding to ν and $\frac{1}{\nu}$, respectively.*

Proof.

(i) As in [9], since $\mathcal{M}\mathcal{J}\mathcal{M}^\top=\mathcal{L}\mathcal{J}\mathcal{L}^\top$, by (2.1) it holds that

$$\begin{aligned}\mathcal{M}_s-\mu\mathcal{L}_s &= \mathcal{M}\mathcal{J}\mathcal{L}^\top+\mathcal{L}\mathcal{J}\mathcal{M}^\top-\left(\nu+\frac{1}{\nu}\right)\mathcal{L}\mathcal{J}\mathcal{L}^\top\\ &= (\mathcal{M}-\nu\mathcal{L})\mathcal{J}\left(\mathcal{L}^\top-\frac{1}{\nu}\mathcal{M}^\top\right)\\ &= \left(\mathcal{M}-\frac{1}{\nu}\mathcal{L}\right)\mathcal{J}(\mathcal{L}^\top-\nu\mathcal{M}^\top).\end{aligned} \tag{2.2}$$

Hence (i) follows.

(ii) From the last two equations of (2.2), it follows that

$$(\mathcal{M}_s-\mu\mathcal{L}_s)\,x=\left(\mathcal{M}-\frac{1}{\nu}\mathcal{L}\right)\mathcal{J}(\mathcal{L}^\top-\nu\mathcal{M}^\top)\,x=0,$$

and

$$(\mathcal{M}_s-\mu\mathcal{L}_s)\,y=(\mathcal{M}-\nu\mathcal{L})\mathcal{J}\left(\mathcal{L}^\top-\frac{1}{\nu}\mathcal{M}^\top\right)y=0.$$

(iii) By applying the last two equations of (2.2) again, it remains to show only that $\mathcal{J}(\mathcal{L}^\top - \frac{1}{\nu}\mathcal{M}^\top)z_s \neq 0$ and $\mathcal{J}(\mathcal{L}^\top - \nu\mathcal{M}^\top)z_s \neq 0$. From (ii) we have

$$\mathcal{J}\left(\mathcal{L}^\top - \frac{1}{\nu}\mathcal{M}^\top\right)z_s = \mathcal{J}\left(\mathcal{L}^\top - \frac{1}{\nu}\mathcal{M}^\top\right)(\alpha x + \beta y) = \alpha\mathcal{J}\left(\mathcal{L}^\top - \frac{1}{\nu}\mathcal{M}^\top\right)x \neq 0.$$

Similarly,

$$\mathcal{J}(\mathcal{L}^\top - \nu\mathcal{M}^\top)z_s = \mathcal{J}(\mathcal{L}^\top - \nu\mathcal{M}^\top)(\alpha x + \beta y) = \beta\mathcal{J}(\mathcal{L}^\top - \nu\mathcal{M}^\top)y \neq 0. \qquad \square$$

THEOREM 2.2. *Let $(\mathcal{M}, \mathcal{L})$ be the $\top$-symplectic pair as in (1.3) and $(\mathcal{M}_s, \mathcal{L}_s)$ be its $(\mathcal{S} + \mathcal{S}^{-1})$-transform. If $z_s = [z_1^\top, z_2^\top]^\top$ with $z_1, z_2 \in \mathbb{C}^n$ is an eigenvector of $(\mathcal{M}_s, \mathcal{L}_s)$ corresponding to $\mu = \nu + \frac{1}{\nu}$ $(\mu \neq \pm 2)$, then $z_1 + \frac{1}{\nu}z_2$ and $z_1 + \nu z_2$ are eigenvectors of $\mathcal{P}(\lambda)$ in (1.1) corresponding to ν and $\frac{1}{\nu}$, respectively.*

Proof. From (iii) of Theorem 2.1 we compute

(2.3)
$$\left(\mathcal{J}\left(\mathcal{L}^\top - \frac{1}{\nu}\mathcal{M}^\top\right)z_s\right)(1:n) = z_1 + \frac{1}{\nu}z_2, \quad (\mathcal{J}(\mathcal{L}^\top - \nu\mathcal{M}^\top)z_s)(1:n) = z_1 + \nu z_2.$$

Then, from (1.3) and (2.3), it follows that $\mathcal{P}(\nu)(z_1 + \frac{1}{\nu}z_2) = 0$ and $\mathcal{P}(\frac{1}{\nu})(z_1 + \nu z_2) = 0$. $\square$

Note that from (1.3), we have

$$\begin{aligned}(\mathcal{M}_s, \mathcal{L}_s) &= (\mathcal{M}\mathcal{J}\mathcal{L}^\top + \mathcal{L}\mathcal{J}\mathcal{M}^\top, \mathcal{L}\mathcal{J}\mathcal{L}^\top) \\ &= \left(\begin{bmatrix} A_1 - A_1^\top & A_0 \\ -A_0 & A_1 - A_1^\top \end{bmatrix}, \begin{bmatrix} 0 & -A_1 \\ A_1^\top & 0 \end{bmatrix}\right) \\ &= \left(\begin{bmatrix} A_0 & A_1^\top - A_1 \\ A_1 - A_1^\top & A_0 \end{bmatrix}, \begin{bmatrix} -A_1 & 0 \\ 0 & -A_1^\top \end{bmatrix}\right)\mathcal{J} \\ &\equiv (\mathcal{K}, \mathcal{N})\mathcal{J}. \qquad (2.4)\end{aligned}$$

From (2.4), if z is an eigenvector of $(\mathcal{K}, \mathcal{N})$ corresponding to μ, then $z_s = \mathcal{J}^\top z$ is the eigenvector of $(\mathcal{M}_s, \mathcal{L}_s)$ corresponding to the same μ.

Remark 2.1.

(i) The $(\mathcal{S} + \mathcal{S}^{-1})$-transform $(\mathcal{M}_s, \mathcal{L}_s)$ in (2.1) of a $\top$-symplectic pair, in general, is a nonlinear (quadratic) transformation. For instance, the $(\mathcal{S} + \mathcal{S}^{-1})$-transform of the symplectic pair of the form $(\mathcal{M}, \mathcal{L}) \equiv ([\begin{smallmatrix} A & 0 \\ -H & I \end{smallmatrix}], [\begin{smallmatrix} I & G \\ 0 & A^\top \end{smallmatrix}])$ with $H = H^\top$ and $G = G^\top$ arisen from discrete-time optimal control problems produces a quadratic $(\mathcal{S} + \mathcal{S}^{-1})$-transform which involves matrix multiplications and is not backward stable. However, the special form of the $\top$-symplectic pair $(\mathcal{M}, \mathcal{L})$ in (1.3) leads to a linear $(\mathcal{S} + \mathcal{S}^{-1})$-transform as in (2.4) and does not involve any matrix multiplication.

(ii) The eigenvectors of $\mathcal{P}(\lambda)$ corresponding to ν and $1/\nu$ can be obtained from the eigenvectors of $(\mathcal{K}, \mathcal{N})$ directly (see Theorem 2.2), not requiring us to solve any linear system or perform any matrix-vector multiplications.

It is easily seen that $\mathcal{K}$ and $\mathcal{N}$ in (2.4) are both $\top$-skew-Hamiltonian. Patel [16] introduced two types of transformations that preserve the skew-Hamiltonian structure. The first type involves similarity transformations on $\mathcal{K}$ and $\mathcal{N}$, respectively, using Given rotations $G_0(i, c, \bar{s}) := G(i, n + i, c, \bar{s})$. The second type involves equivalence transformations on $\mathcal{K}$ and $\mathcal{N}$, respectively, by the left transformation $Q_0^\top := (U^\top \oplus V^\top)$ and the right transformation $Z_0 := (V \oplus U)$, where the unitary

$U, V \in \mathbb{C}^{n\times n}$ represent the application of Givens rotations. One can easily verify that the new transforming $\mathcal{K}$ and $\mathcal{N}$ are still $\top$-skew-Hamiltonian.

Based on Patel's approach [16] with these two types of transformations, we may reduce $(\mathcal{K}, \mathcal{N})$ to a block triangular structure; that is,

$$\mathcal{K} := Q^\top \mathcal{K} Z = \begin{bmatrix} K_{11} & K_{12} \\ 0 & K_{11}^\top \end{bmatrix}, \qquad \mathcal{N} := Q^\top \mathcal{N} Z = \begin{bmatrix} N_{11} & N_{12} \\ 0 & N_{11}^\top \end{bmatrix}, \tag{2.5}$$

where $K_{11} \in \mathbb{C}^{n\times n}$ is upper Hessenberg, $N_{11} \in \mathbb{C}^{n\times n}$ is upper triangular, and Q, Z are unitary satisfying

$$Q = \mathcal{J}^\top Z \mathcal{J}. \tag{2.6}$$

From (2.5), we see that the pair (K_{11}, N_{11}) contains half of the eigenvalues of $(\mathcal{K}, \mathcal{N})$. We then apply the QZ algorithm to (K_{11}, N_{11}) for computing all eigenpairs $\{(\mu_i, y_i)\}_{i=1}^n$. Consequently, $\{(\mu_i, Z[\begin{smallmatrix} y_i \\ 0 \end{smallmatrix}])\}_{i=1}^n$ are n eigenpairs of $(\mathcal{K}, \mathcal{N})$. From (2.4), $\{(\mu_i, z_i(\equiv \mathcal{J}^\top Z[\begin{smallmatrix} y_i \\ 0 \end{smallmatrix}]))\}_{i=1}^n$ are eigenpairs of $(\mathcal{M}_s, \mathcal{L}_s)$. Finally, we compute all eigenvalues and the associated eigenvectors of $\mathcal{P}(\lambda)$ by Theorem 2.2.

ALGORITHM 2.1 (structure-preserving algorithm I (SA_I)).

Input: *A palindromic quadratic pencil* $\mathcal{P}(\lambda) \equiv \lambda^2 A_1^\top + \lambda A_0 + A_1$ *with* $A_0, A_1 \in \mathbb{C}^{n\times n}$ *and* $A_0^\top = A_0$.

Output: *All eigenvalues and eigenvectors of* $\mathcal{P}(\lambda)$.

Step 1. *Form the pair* $(\mathcal{K}, \mathcal{N})$ *as in* (2.4)*;*

Step 2. *Reduce* $(\mathcal{K}, \mathcal{N})$ *to block upper triangular forms in* (2.5) *using unitary transformations. (See a pseudocode in Appendix* A.1.*);*

Step 3. *Compute eigenpairs* $\{(\mu_i, y_i)\}_{i=1}^n$ *of* (K_{11}, N_{11}) *defined in* (2.5) *by using the QZ algorithm;*

Step 4. *Compute* $z_i = \mathcal{J}^\top Z[\begin{smallmatrix} y_i \\ 0 \end{smallmatrix}] \equiv [\begin{smallmatrix} z_{i1} \\ z_{i2} \end{smallmatrix}], i = 1, 2, \ldots, n;$

Step 5. *Compute eigenvalues* ν_i *and* $\frac{1}{\nu_i}$ *of* $\mathcal{P}(\lambda)$ *by solving* $\nu^2 - \mu_i \nu + 1 = 0$*; Compute eigenvectors* $x_{i1} \equiv z_{i1} + \frac{1}{\nu_i} z_{i2}$, $x_{i2} \equiv z_{i1} + \nu_i z_{i2}$ *corresponding to* $\nu_i, \frac{1}{\nu_i}$, *respectively, for* $i = 1, 2, \ldots, n$.

Remark 2.2. The SA_I requires approximately $27n^3$ flops for the eigenvalues, and an additional $23n^3$ flops for the eigenvectors. While the QZ algorithm is applied to $(\mathcal{M}, \mathcal{L})$ directly, it requires approximately $120n^3$ flops for the eigenvalues and an additional $\frac{260}{3}n^3$ flops for the eigenvectors. Here and hereafter a flop is a floating point multiplication and addition for complex numbers, which involves 6 real flops.

3. Structure-preserving algorithm II vs. URV-based method. Recently in [4, 12, 13], a "good" linearization of the palindromic quadratic pencil (1.1) was proposed:

$$\lambda Z^\top + Z \equiv \lambda \begin{bmatrix} A_1^\top & A_0 - A_1 \\ A_1^\top & A_1^\top \end{bmatrix} + \begin{bmatrix} A_1 & A_1 \\ A_0 - A_1^\top & A_1 \end{bmatrix}. \tag{3.1}$$

This preserves the "symplecticity" of the eigenvalues. In order to solve the palindromic linear eigenvalue problem of (3.1), we rewrite it into a new palindromic quadratic pencil

$$\mathcal{Q}(\zeta) \equiv \zeta^2 Z^\top + \zeta 0_{2n} + Z \tag{3.2}$$

with $\zeta^2 = \lambda$. We then apply the SA_I algorithm proposed in section 2 to solve the palindromic QEP of (3.2). As in (2.4), we form

$$\widetilde{\mathcal{K}} = \begin{bmatrix} 0 & Z^\top - Z \\ Z - Z^\top & 0 \end{bmatrix}, \quad \widetilde{\mathcal{N}} = \begin{bmatrix} -Z & 0 \\ 0 & -Z^\top \end{bmatrix}. \tag{3.3}$$

By (2.5) there are unitary $\mathcal{U}_a, \mathcal{V}_a \in \mathbb{C}^{4n\times 4n}$ with $\mathcal{U}_a = \mathcal{J}_{4n}^\top \mathcal{V}_a \mathcal{J}_{4n}$ such that

$$\mathcal{U}_a^\top \widetilde{\mathcal{K}} \mathcal{V}_a = \begin{bmatrix} K_{11}^a & K_{12}^a \\ 0 & (K_{11}^a)^\top \end{bmatrix}, \quad \mathcal{U}_a^\top \widetilde{\mathcal{N}} \mathcal{V}_a = \begin{bmatrix} N_{11}^a & N_{12}^a \\ 0 & (N_{11}^a)^\top \end{bmatrix}, \tag{3.4}$$

where $K_{11}^a \in \mathbb{C}^{2n\times 2n}$ is upper Hessenberg with $\{0, 2, \ldots, 2n-2\}$-diagonals being zeros, $N_{11}^a \in \mathbb{C}^{2n\times 2n}$ is upper triangular with $\{1, 3, \ldots, 2n-1\}$-diagonals being zeros, and K_{12}^a and $N_{12}^a \in \mathbb{C}^{2n\times 2n}$ are skew symmetric with $\{1, -1, \ldots, 2n-1, -(2n-1)\}$-diagonals and with $\{2, -2, \ldots, 2n-2, -(2n-2)\}$-diagonals, respectively, being zeros. Here the ℓ-diagonal of a matrix $A \equiv [a_{ij}]_{i,j=1}^n$ consists of the entries $\{a_{ij}\}$ with $j - i = \ell$. Note that the extra zeros in K_{11}^a, N_{11}^a, K_{12}^a, and N_{12}^a are obtained by performing some suitable permutations on the special forms of (3.3) without any calculation. (See Appendix A.2 for details.) Denote

$$\mathcal{P}_{2n} = [e_1, e_{n+1}, e_2, e_{n+2}, \ldots, e_n, e_{2n}]. \tag{3.5}$$

Let

$$\mathcal{U}^\top = \begin{bmatrix} \mathcal{P}_{2n}^\top & 0 \\ 0 & \mathcal{P}_{2n}^\top \end{bmatrix} \mathcal{U}_a^\top, \quad \mathcal{V} = \mathcal{V}_a \begin{bmatrix} \mathcal{P}_{2n} & 0 \\ 0 & \mathcal{P}_{2n} \end{bmatrix}. \tag{3.6}$$

Then we have

$$\mathcal{U}^\top \widetilde{\mathcal{K}} \mathcal{V} = \left[\begin{array}{cc|cc} 0 & R_1 & T_1 & 0 \\ R_2 & 0 & 0 & -T_2 \\ \hline 0 & 0 & 0 & R_2^\top \\ 0 & 0 & R_1^\top & 0 \end{array}\right], \tag{3.7a}$$

$$\mathcal{U}^\top \widetilde{\mathcal{N}} \mathcal{V} = \left[\begin{array}{cc|cc} R_3 & 0 & 0 & -T_3 \\ 0 & R_4 & T_3^\top & 0 \\ \hline 0 & 0 & R_3^\top & 0 \\ 0 & 0 & 0 & R_4^\top \end{array}\right], \tag{3.7b}$$

where $R_1 \in \mathbb{C}^{n\times n}$ is upper Hessenberg, $R_2, R_3, R_4 \in \mathbb{C}^{n\times n}$ are upper triangular, $T_1, T_2 \in \mathbb{C}^{n\times n}$ are skew symmetric, and $T_3 \in \mathbb{C}^{n\times n}$. From (3.7), we see that in order to compute the eigenvalues and the eigenvectors of $(\widetilde{\mathcal{K}}, \widetilde{\mathcal{N}})$ it suffices to compute those of the matrix pair

$$(R_1 R_4^{-1} R_2, R_3). \tag{3.8}$$

We apply the periodic QZ algorithm [2, 18] to the matrix pair in (3.8) without forming the product explicitly, which gives the n eigenpairs $\{(\gamma_i, y_i)\}_{i=1}^n$, where $y_i \in \mathbb{C}^n$. Let $\mu_i = \sqrt{\gamma_i}$ (one branch of the square root of γ_i), $\eta_i := \mu_i R_1^{-1} R_3 y_i$, and $\widetilde{y}_i = [y_i^\top, \eta_i^\top]^\top$. It follows that $\{(\mu_i, \widetilde{z}_i (\equiv \mathcal{V}\begin{bmatrix} \widetilde{y}_i \\ 0 \end{bmatrix}))\}_{i=1}^n$ are n eigenpairs of $(\widetilde{\mathcal{K}}, \widetilde{\mathcal{N}})$. Write $\widetilde{z}_i = [\widetilde{z}_{i1}^\top, \widetilde{z}_{i2}^\top]^\top$ and solve ν_i and $\frac{1}{\nu_i}$ for $\nu^2 + (2 - \mu_i^2)\nu + 1 = 0$. By Theorem 2.2 and (3.1), we compute the eigenvectors

$$x_{i1} = \widetilde{x}_{i1}(1:n) + \widetilde{x}_{i1}(n+1:2n), \quad x_{i2} = \widetilde{x}_{i2}(1:n) + \widetilde{x}_{i2}(n+1:2n) \tag{3.9a}$$

of $\mathcal{P}(\lambda)$ corresponding to ν_i and $\frac{1}{\nu_i}$, respectively, where

$$\widetilde{x}_{i1} := \widetilde{z}_{i2} - \frac{1}{\sqrt{\nu_i}}\widetilde{z}_{i1}, \quad \widetilde{x}_{i2} := \widetilde{z}_{i2} - \sqrt{\nu_i}\widetilde{z}_{i1}. \tag{3.9b}$$

ALGORITHM 3.1 (structure-preserving algorithm II (SA_II)).

Input: *A palindromic quadratic pencil* $\mathcal{P}(\lambda) \equiv \lambda^2 A_1^\top + \lambda A_0 + A_1$ *with* $A_0, A_1 \in \mathbb{C}^{n\times n}$ *and* $A_0^\top = A_0$.

Output: *All eigenvalues and eigenvectors of* $\mathcal{P}(\lambda)$.

Step 1. *Form the pair* $(\widetilde{\mathcal{K}}, \widetilde{\mathcal{N}})$ *as in* (3.3);

Step 2. *Reduce* $(\widetilde{\mathcal{K}}, \widetilde{\mathcal{N}})$ *to block upper triangular forms as in* (3.7) *using unitary transformations of* (3.4)–(3.6);

Step 3. *Compute eigenpairs* $\{(\gamma_i, y_i)\}_{i=1}^n$ *of* $(R_1 R_4^{-1} R_2, R_3)$ *in* (3.8) *by the periodic QZ algorithm* [18];

Step 4. *Compute* $\widetilde{z}_i = \mathcal{V}\left[\begin{smallmatrix}\widetilde{y}_i\\ 0\end{smallmatrix}\right] \equiv \left[\begin{smallmatrix}\widetilde{z}_{i1}\\ \widetilde{z}_{i2}\end{smallmatrix}\right]$, *where* $\widetilde{y}_i = \left[\begin{smallmatrix} I_n \\ \sqrt{\gamma_i} R_1^{-1} R_3\end{smallmatrix}\right] y_i$ *for* $i = 1, 2, \ldots, n$;

Step 5. *Compute* ν_i *and* $\frac{1}{\nu_i}$ *by solving* $\nu^2 + (2 - \gamma_i)\nu + 1 = 0$; *Compute eigenvectors* x_{i1} *and* x_{i2} *of* $\mathcal{P}(\lambda)$ *as in* (3.9a) *corresponding to* $\nu_i, \frac{1}{\nu_i}$, *respectively, for* $i = 1, 2, \ldots, n$.

Remark 3.1.

(i) In Step 3, since R_1, R_4, R_2, and R_3 are already in Hessenberg-triangular form, the first step in the periodic QZ algorithm is not needed.

(ii) The SA_II requires $62n^3$ flops for the eigenvalues, and an additional $23n^3$ flops for the eigenvectors.

Recently a URV-decomposition-based structured method was proposed in [20] for solving the palindromic linear pencil (3.1). From [20] there are unitary $U, V \in \mathbb{C}^{2n\times 2n}$ such that

$$U^\top Z V = \begin{bmatrix} 0 & \widehat{R}_4^\top \Pi_n \\ \Pi_n \widehat{R}_3 & \Pi_n \widehat{T}_3 \Pi_n \end{bmatrix}, \quad V^\top (Z - Z^\top) V = \begin{bmatrix} 0 & -\widehat{R}_2^\top \Pi_n \\ \Pi_n \widehat{R}_2 & \Pi_n \widehat{T}_2 \Pi_n \end{bmatrix} \tag{3.10a}$$

and

$$U^\top (Z^\top - Z) U = \begin{bmatrix} 0 & -\widehat{R}_1^\top \Pi_n \\ \Pi_n \widehat{R}_1 & \Pi_n \widehat{T}_1 \Pi_n \end{bmatrix}, \tag{3.10b}$$

where $\Pi_n = [e_n, \ldots, e_1]$, $\widehat{R}_1 \in \mathbb{C}^{n\times n}$ is upper Hessenberg, $\widehat{R}_2, \widehat{R}_3, \widehat{R}_4 \in \mathbb{C}^{n\times n}$ are upper triangular, $\widehat{T}_1, \widehat{T}_2 \in \mathbb{C}^{n\times n}$ are skew symmetric, and $\widehat{T}_3 \in \mathbb{C}^{n\times n}$. Define

$$\mathcal{U}_0^\top := \left[\begin{array}{cc|cc} 0 & \Pi_n & 0 & 0 \\ 0 & 0 & 0 & \Pi_n \\ \hline 0 & 0 & I_n & 0 \\ -I_n & 0 & 0 & 0 \end{array}\right] \begin{bmatrix} U^\top & 0 \\ 0 & V^\top \end{bmatrix}, \quad \mathcal{V}_0 := \mathcal{J}_{4n}^\top \mathcal{U}_0 \mathcal{J}_{4n}. \tag{3.11}$$

Then it is easily seen that $\mathcal{U}_0^H \widetilde{\mathcal{K}} \mathcal{V}_0$ and $\mathcal{U}_0^H \widetilde{\mathcal{N}} \mathcal{V}_0$ have the same forms as in (3.7) with "\hat" being over all submatrices. Furthermore, if we define

$$\mathcal{U}_b^\top = \begin{bmatrix} \mathcal{P}_{2n} & 0 \\ 0 & \mathcal{P}_{2n} \end{bmatrix} \mathcal{U}_0^\top, \quad \mathcal{V}_b := \mathcal{J}_{4n}^\top \mathcal{U}_b \mathcal{J}_{4n}, \tag{3.12}$$

then we have

$$\mathcal{U}_b^H \widetilde{\mathcal{K}} \mathcal{V}_b = \begin{bmatrix} K_{11}^b & K_{12}^b \\ 0 & (K_{11}^b)^\top \end{bmatrix}, \quad \mathcal{U}_b^H \widetilde{\mathcal{N}} \mathcal{V}_b = \begin{bmatrix} N_{11}^b & N_{12}^b \\ 0 & (N_{11}^b)^\top \end{bmatrix}, \tag{3.13}$$

where $K_{11}^b, K_{12}^b, N_{11}^b$, and N_{12}^b are of the same forms as in (3.4).

THEOREM 3.1. *If K_{11}^a and K_{11}^b are unreduced, and N_{11}^a and N_{11}^b are nonsingular (see* (3.4) *and* (3.13)*), then the SA_II is mathematically equivalent to the URV-based structured method.*

Proof. Denote $\mathcal{V}_a := [\mathcal{V}_1^a, \mathcal{V}_2^a]$ with $\mathcal{V}_i^a \in \mathbb{C}^{4n\times 2n} (i = 1, 2)$. Since $\mathcal{U}_a = \mathcal{J}_{4n}^\top \mathcal{V}_a \mathcal{J}_{4n}$, it holds that $\mathcal{U}_a = [\mathcal{J}_{4n}\mathcal{V}_2^a, -\mathcal{J}_{4n}\mathcal{V}_1^a]$. From (3.4), it follows that

$$\widetilde{\mathcal{K}} \mathcal{V}_1^a = \mathcal{J}_{4n} \mathcal{V}_2^a K_{11}^a, \quad \widetilde{\mathcal{N}} \mathcal{V}_1^a = \mathcal{J}_{4n} \mathcal{V}_2^a N_{11}^a. \tag{3.14}$$

This implies that

$$\widetilde{\mathcal{K}} \mathcal{V}_1^a = \widetilde{\mathcal{N}} \mathcal{V}_1^a (N_{11}^a)^{-1} K_{11}^a. \tag{3.15}$$

Since the first columns of $\mathcal{V}_1^a$ and $\mathcal{V}_1^b$ ($\mathcal{V}_b \equiv \left[\mathcal{V}_1^b, \mathcal{V}_2^b\right]$) are both e_1, by applying the implicit Q-theorem to (3.15), the matrices $\mathcal{U}_a$ and $\mathcal{V}_a$ are uniquely determined, and $\mathcal{U}_a = \mathcal{U}_b$ and $\mathcal{V}_a = \mathcal{V}_b$. ∎

4. $\top$-skew-Hamiltonian Arnoldi method. Based on SHIRA [15], in this section we briefly introduce the structure-preserving $\top$-skew-Hamiltonian Arnoldi algorithm to compute the desired eigenpairs of a $\top$-skew-Hamiltonian $\mathcal{B}$.

As in (2.4), using the $(\mathcal{S} + \mathcal{S}^{-1})$-transform, we transform $\mathcal{M} - \lambda\mathcal{L}$ of (1.3) into a $\top$-skew-Hamiltonian pencil $\mathcal{K} - \mu\mathcal{N}$ by

$$\mathcal{K} - \mu\mathcal{N} \equiv \left[(\mathcal{L}\mathcal{J}\mathcal{M}^\top + \mathcal{M}\mathcal{J}\mathcal{L}^\top) - \mu\mathcal{L}\mathcal{J}\mathcal{L}^\top\right] \mathcal{J}^\top. \tag{4.1}$$

Next, we derive the shift-invert transformation of $\mathcal{K} - \mu\mathcal{N}$. Let $\lambda_0 \notin \sigma(\mathcal{M}, \mathcal{L})$. Then, from Theorem 2.2(i), we have $\mu_0 \equiv \lambda_0 + \frac{1}{\lambda_0} \notin \sigma(\mathcal{K}, \mathcal{N})$. Define the shift-invert transformation $\widehat{\mathcal{K}} - \widehat{\mu}\widehat{\mathcal{N}}$ for $\mathcal{K} - \mu\mathcal{N}$ with $\widehat{\mu} = \frac{1}{\mu - \mu_0}$ and

$$\widehat{\mathcal{K}} \equiv -\lambda_0\mathcal{N} = -\lambda_0\mathcal{L}\mathcal{J}\mathcal{L}^\top\mathcal{J}^\top = \lambda_0 \begin{bmatrix} A_1^\top & 0 \\ 0 & A_1 \end{bmatrix}, \tag{4.2a}$$

$$\widehat{\mathcal{N}} \equiv -\lambda_0(\mathcal{K} - \mu_0\mathcal{N}) = -\lambda_0(\mathcal{L}\mathcal{J}\mathcal{M}^\top + \mathcal{M}\mathcal{J}\mathcal{L}^\top - \mu_0\mathcal{L}\mathcal{J}\mathcal{L}^\top)\mathcal{J}^\top. \tag{4.2b}$$

Substituting $\mu_0 = \lambda_0 + \frac{1}{\lambda_0}$ into (4.2b), $\widehat{\mathcal{N}}$ can be factorized as

$$\begin{aligned} \widehat{\mathcal{N}} &= -\lambda_0 \left(\mathcal{L}\mathcal{J}\mathcal{M}^\top + \mathcal{M}\mathcal{J}\mathcal{L}^\top - \left(\lambda_0 + \frac{1}{\lambda_0}\right) \mathcal{L}\mathcal{J}\mathcal{L}^\top\right) \mathcal{J}^\top \\ &= (\mathcal{M} - \lambda_0\mathcal{L})\, \mathcal{J} \left(\mathcal{M}^\top - \lambda_0\mathcal{L}^\top\right) \mathcal{J}^\top \equiv \mathcal{N}_1\mathcal{N}_2, \end{aligned} \tag{4.3}$$

where

$$\mathcal{N}_1 = \mathcal{M} - \lambda_0\mathcal{L}, \quad \mathcal{N}_2 = \mathcal{J}(\mathcal{M}^\top - \lambda_0\mathcal{L}^\top)\mathcal{J}^\top \tag{4.4}$$

are nonsingular and satisfy $\mathcal{N}_2^\top \mathcal{J} = \mathcal{J}\mathcal{N}_1$. The generalized eigenvalue problem $\widehat{\mathcal{K}} z = \widehat{\mu}\widehat{\mathcal{N}} z$ is then equivalent to the eigenvalue problem $\mathcal{B}y = \widehat{\mu} y$, where $y = \mathcal{N}_2 z$ and

$$\mathcal{B} \equiv \mathcal{N}_1^{-1} \widehat{\mathcal{K}} \mathcal{N}_2^{-1}. \tag{4.5}$$

Using the facts that $\widehat{\mathcal{K}}\mathcal{J} = \mathcal{J}\widehat{\mathcal{K}}^\top$ and $\mathcal{N}_2^\top \mathcal{J} = \mathcal{J}\mathcal{N}_1$, we find that $\mathcal{B}$ satisfies

$$\mathcal{J}\mathcal{B}^\top = \mathcal{J}\mathcal{N}_2^{-\top}\widehat{\mathcal{K}}^\top\mathcal{N}_1^{-\top} = \mathcal{N}_1^{-1}\mathcal{J}\widehat{\mathcal{K}}^\top\mathcal{N}_1^{-\top} = \mathcal{N}_1^{-1}\widehat{\mathcal{K}}\mathcal{J}\mathcal{N}_1^{-\top} = \mathcal{N}_1^{-1}\widehat{\mathcal{K}}\mathcal{N}_2^{-1}\mathcal{J} = \mathcal{B}\mathcal{J},$$

and hence $\mathcal{B}$ is again $\top$-skew-Hamiltonian.

We now define the Krylov matrix with respect to u_1 and j $(1 \le j \le n)$ by

$$K_j \equiv K_j[\mathcal{B}, u_1] = [u_1, \mathcal{B}u_1, \ldots, \mathcal{B}^{j-1}u_1] \tag{4.6}$$

and state two useful theorems from [15]. Note that these theorems are slightly different from the originals, but the proofs are almost identical to the ones in [15].

THEOREM 4.1 (see [15]). *Let $\mathcal{B} \in \mathbb{C}^{2n\times 2n}$ be $\top$-skew-Hamiltonian and $K_j \equiv K_j[\mathcal{B}, u_1]$ $(1 \le j \le n)$ be a Krylov matrix with rank$(K_j) = j$. Then span(K_j) is $\top$-isotropic and if $K_j = U_j\widehat{R}_j$ is a QR-factorization, then*

$$\mathcal{B}U_j = U_j\widehat{H}_j + \widehat{u}_{j+1}e_j^\top, \tag{4.7}$$

where $\widehat{H}_j \in \mathbb{C}^{j\times j}$ is unreduced upper Hessenberg, $U_j \in \mathbb{C}^{2n\times j}$ is orthonormal and $\top$-isotropic, and $\widehat{u}_{j+1} \in \mathbb{C}^{2n}$ is a suitable vector such that

$$U_j^H\widehat{u}_{j+1} = 0 \quad \textit{and} \quad U_j^\top\mathcal{J}\widehat{u}_{j+1} = 0. \tag{4.8}$$

THEOREM 4.2 (see [15]). *Let $\mathcal{B} \in \mathbb{C}^{2n\times 2n}$ be $\top$-skew-Hamiltonian. If rank $(K_n[\mathcal{B}, u_1]) = n$, then there is a unitary $\top$-symplectic matrix $\mathcal{U}$ with $\mathcal{U}e_1 = u_1$ such that*

$$\mathcal{U}^H\mathcal{B}\mathcal{U} = \begin{bmatrix} \widehat{H}_n & \widehat{N}_n \\ 0 & \widehat{H}_n^\top \end{bmatrix}, \tag{4.9}$$

where $\widehat{H}_n$ is unreduced upper Hessenberg and $\widehat{N}_n$ is $\top$-skew-symmetric.

Based on Theorem 4.2, the jth step of the Arnoldi process is given by

$$\widehat{h}_{j+1,j}u_{j+1} = \mathcal{B}u_j - \sum_{i=1}^{j}\widehat{h}_{ij}u_i, \tag{4.10}$$

where $\widehat{h}_{ij} = u_i^H\mathcal{B}u_j$, $i = 1, \ldots, j$, and $\widehat{h}_{j+1,j} > 0$ is chosen so that $\|u_{j+1}\|_2 = 1$. In order to ensure that the space span$\{u_1, \ldots, u_{j+1}\}$ is $\top$-isotropic to working precision, the jth step of the $\top$-isotropic Arnoldi process is modified by

$$\widehat{h}_{j+1,j}u_{j+1} = \mathcal{B}u_j - \sum_{i=1}^{j}\widehat{h}_{ij}u_i - \sum_{i=1}^{j}\widehat{t}_{ij}\mathcal{J}\bar{u}_i, \tag{4.11}$$

where $\widehat{h}_{ij} = u_i^H\mathcal{B}u_j$, $\widehat{t}_{ij} = -u_i^\top\mathcal{J}\mathcal{B}u_j$, $i = 1, \ldots, j$, and $\widehat{h}_{j+1,j} > 0$ is chosen so that $\|u_{j+1}\|_2 = 1$. We present the $\top$SHIRA-method.

ALGORITHM 4.1 ($\top$SHIRA).

Input: $\top$*-skew-Hamiltonian matrix* $\mathcal{B}$ *with starting vector* u_1.
Output: U_ℓ *and upper Hessenberg matrix* $\widehat{H}_\ell$ *with* $\mathcal{B}U_\ell = U_\ell\widehat{H}_\ell$, $U_\ell^H U_\ell = I_\ell$ *and* $U_\ell^\top \mathcal{J} U_\ell = 0$.
Use (4.11) *with starting vector* u_1 *to generate the* ℓ*th step of the* $\top$*-isotropic Arnoldi factorization:*

$$\mathcal{B}U_\ell = U_\ell\widehat{H}_\ell + \widehat{h}_{\ell+1,\ell}u_{\ell+1}e_\ell^\top.$$

For $k = 1, 2, \ldots,$ *until wanted* ℓ *eigenpairs of* $\mathcal{B}$ *are convergent,*
Use (4.11) *to extend the* ℓ*th step of the* $\top$*-isotropic Arnoldi factorization to the* $(\ell+p)$*th step of the* $\top$*-isotropic Arnoldi factorization:*

$$\mathcal{B}U_{\ell+p} = U_{\ell+p}\widehat{H}_{\ell+p} + \widehat{h}_{\ell+p+1,\ell+p}u_{\ell+p+1}e_{\ell+p}^\top.$$

Use standard implicitly restarted step for the Arnoldi algorithm [8] *to reform a new* ℓ*th step of the* $\top$*-isotropic Arnoldi factorization.*
End

Remark 4.1.

(i) $\widehat{h}_{\ell+1,\ell}$ is set to zero if $|\widehat{h}_{\ell+1,\ell}| < tol(|\widehat{h}_{\ell,\ell}| + |\widehat{h}_{\ell+1,\ell+1}|)$ for some stopping tolerance "tol."

(ii) Let (θ_i, v_i) be an eigenpair of $\widehat{H}_\ell$, i.e., $\widehat{H}_\ell v_i = \theta_i v_i$. Let $y_i = U_\ell v_i$ be the Ritz vector of $\mathcal{B}$ corresponding to the Ritz value θ_i. Then from (4.7) and (4.8), we have

$$\begin{aligned}
&\|\mathcal{B}y_i - \theta_i y_i\|_2 = \|\mathcal{B}U_\ell v_i - \theta_i U_\ell v_i\|_2 \\
&= \|(U_\ell\widehat{H}_\ell + \widehat{u}_{\ell+1,\ell}e_\ell^\top)v_i - \theta_i U_\ell v_i\|_2 \\
&= \|U_\ell(\widehat{H}_\ell v_i - \theta_i v_i) + \widehat{h}_{\ell+1,\ell}(e_\ell^\top v_i)u_{\ell+1}\|_2 \\
&= |\widehat{h}_{\ell+1,\ell}||e_\ell^\top v_i|.
\end{aligned}$$

5. Generalized $\top$-skew-Hamiltonian Arnoldi method. We now consider the generalized eigenvalue problem $\widehat{\mathcal{K}}z = \widehat{\mu}\widehat{\mathcal{N}}z$, where $\widehat{\mathcal{K}}$ and $\widehat{\mathcal{N}}$ are $\top$-skew-Hamiltonian given in (4.2). Based on the reduction method [16], $\widehat{\mathcal{K}} - \widehat{\mu}\widehat{\mathcal{N}}$ can be reduced to block triangular condensed forms

$$\mathcal{V}^\top(\widehat{\mathcal{K}} - \widehat{\mu}\widehat{\mathcal{N}})\mathcal{U} = \begin{bmatrix} K_{11} & K_{12} \\ 0 & K_{11}^\top \end{bmatrix} - \widehat{\mu}\begin{bmatrix} N_{11} & N_{12} \\ 0 & N_{11}^\top \end{bmatrix}, \tag{5.1}$$

where $K_{11}, N_{11} \in \mathbb{C}^{n\times n}$ are, respectively, upper Hessenberg and upper triangular, and $\mathcal{V}$ and $\mathcal{U} \in \mathbb{C}^{2n\times 2n}$ are unitary satisfying

$$\mathcal{V} = \mathcal{J}^\top\mathcal{U}\mathcal{J}. \tag{5.2}$$

In order to solve a large sparse product or a periodic eigenvalue problem, recently, a product (or a periodic) Arnoldi process and a product Krylov process were, respectively, proposed by Kressner's book [6, section 4.2.5] and Watkins' book [24, section 9.10]. Using the result of Theorem 4.1, we adopt the idea of the periodic Arnoldi process [6, section 4.2.5] to develop a generalized $\top$-skew-Hamiltonian algorithm which preserves the structure of (5.1) for the computation of the desired eigenpairs of $\widehat{\mathcal{K}}z = \widehat{\mu}\widehat{\mathcal{N}}z$.

THEOREM 5.1. *Let* $\mathcal{B} \equiv \mathcal{N}_1^{-1}\widehat{\mathcal{K}}\mathcal{N}_2^{-1}$ *be* $\top$*-skew-Hamiltonian defined in* (4.5). *Let* $\widehat{\mathcal{N}} = \mathcal{N}_1\mathcal{N}_2$ *and* $K_j \equiv K_j[\mathcal{B}, u_1]$ *be the Krylov matrix with rank*$(K_j) = j$. *If*

$$\mathcal{N}_2^{-1}K_j = Z_j R_{2,j} \quad \text{and} \quad \mathcal{N}_1 K_j = Y_j R_{1,j} \tag{5.3}$$

are QR-factorizations, where $Z_j, Y_j \in \mathbb{C}^{2n\times j}$ are orthonormal and $R_{2,j}, R_{1,j}$ are nonsingular upper triangular, then we have

$$\widehat{\mathcal{K}} Z_j = Y_j H_j + \widehat{y}_{j+1} e_j^\top \tag{5.4}$$

and

$$\widehat{\mathcal{N}} Z_j = Y_j R_j, \tag{5.5}$$

where $H_j \in \mathbb{C}^{j\times j}$ is unreduced upper Hessenberg, $R_j \in \mathbb{C}^{j\times j}$ is nonsingular upper triangular, and Y_j and Z_j are $\top$-bi-isotropic such that

$$Y_j^H \widehat{y}_{j+1} = 0 \quad \text{and} \quad Z_j^\top \mathcal{J} \widehat{y}_{j+1} = 0 \tag{5.6}$$

for a suitable $\widehat{y}_{j+1} \in \mathbb{C}^{2n}$.

Proof. Let $K_j = U_j \widehat{R}_j$ be the QR-factorization of K_j with $\widehat{R}_j$ being nonsingular upper triangular. From Theorem 4.1, it follows that

$$\mathcal{N}_1^{-1} \widehat{\mathcal{K}} \mathcal{N}_2^{-1} U_j = U_j \widehat{H}_j + \widehat{u}_{j+1} e_j^\top. \tag{5.7}$$

Substituting (5.3) into (5.7) we obtain

$$\begin{aligned}
\widehat{\mathcal{K}} Z_j &= \widehat{\mathcal{K}} \mathcal{N}_2^{-1} K_j R_{2,j}^{-1} = \widehat{\mathcal{K}} \mathcal{N}_2^{-1} U_j \widehat{R}_j R_{2,j}^{-1} \\
&= (\mathcal{N}_1 U_j \widehat{H}_j + \mathcal{N}_1 \widehat{u}_{j+1} e_j^\top) \widehat{R}_j R_{2,j}^{-1} \\
&= Y_j (R_{1,j} \widehat{R}_j^{-1} \widehat{H}_j \widehat{R}_j R_{2,j}^{-1}) + \gamma_j Y_j Y_j^H \mathcal{N}_1 \widehat{u}_{j+1} e_j^\top + \gamma_j (I - Y_j Y_j^H) \mathcal{N}_1 \widehat{u}_{j+1} e_j^\top \\
&= Y_j H_j + \widehat{y}_{j+1} e_j^\top, \qquad (5.8)
\end{aligned}$$

where $\gamma_j = e_j^\top \widehat{R}_j R_{2,j}^{-1} e_j$,

$$H_j = R_{1,j} \widehat{R}_j^{-1} \widehat{H}_j \widehat{R}_j R_{2,j}^{-1} + \gamma_j Y_j^H \mathcal{N}_1 \widehat{u}_{j+1} e_j^\top, \tag{5.9}$$

and

$$\widehat{y}_{j+1} = \gamma_j (I - Y_j Y_j^H) \mathcal{N}_1 \widehat{u}_{j+1}. \tag{5.10}$$

Since $\widehat{R}_j$, $R_{1,j}$, and $R_{2,j}$ are nonsingular upper triangular, and $\widehat{H}_j$ is unreduced upper Hessenberg, from (5.9) it follows that H_j is unreduced upper Hessenberg. Clearly, it holds that $Y_j^H \widehat{y}_{j+1} = 0$ by (5.10).

On the other hand, from (5.3), we also have

$$\widehat{\mathcal{N}} Z_j = \mathcal{N}_1 \mathcal{N}_2 Z_j = \mathcal{N}_1 K_j R_{2,j}^{-1} = Y_j R_{1,j} R_{2,j}^{-1} \equiv Y_j R_j,$$

where $R_j = R_{1,j} R_{2,j}^{-1}$ is nonsingular and upper triangular.

We now show that Y_j and Z_j are $\top$-bi-isotropic. By the fact that $\mathcal{N}_2^\top \mathcal{J} = \mathcal{J} \mathcal{N}_1$ and (5.3), it holds that

$$Y_j^\top \mathcal{J} Z_j = R_{1,j}^{-\top} K_j^\top (\mathcal{N}_1^\top \mathcal{J} \mathcal{N}_2^{-1}) K_j R_{2,j}^{-1} = R_{1,j}^{-\top} K_j^\top \mathcal{J} K_j R_{2,j}^{-1} = 0. \tag{5.11}$$

From (5.8) and (5.10), we have

$$Z_j^\top \mathcal{J} \widehat{y}_{j+1} e_j^\top = Z_j^\top \mathcal{J} (\widehat{\mathcal{K}} Z_j - Y_j H_j) = Z_j^\top \mathcal{J} \widehat{\mathcal{K}} Z_j,$$

which is $\top$-skew-symmetric. This implies that $Z_j^\top \mathcal{J} \widehat{y}_{j+1} = 0$. ∎

THEOREM 5.2. *Let* $\mathcal{B} = \mathcal{N}_1^{-1}\widehat{\mathcal{K}}\mathcal{N}_2^{-1}$ *be* $\top$*-skew-Hamiltonian defined in* (4.5) *and* $\widehat{\mathcal{N}} = \mathcal{N}_1\mathcal{N}_2$. *If rank*$(K_n[\mathcal{B}, u_1]) = n$, *then there are unitary matrices* $\mathcal{U}$ *and* $\mathcal{V}$ *satisfying* (5.2) *and* $\mathcal{V}e_1 = \mathcal{N}_1u_1/\|\mathcal{N}_1u_1\|_2$ *such that*

$$\mathcal{V}^\top\widehat{\mathcal{K}}\mathcal{U} = \begin{bmatrix} H_n & S_n \\ 0 & H_n^\top \end{bmatrix}, \quad \mathcal{V}^\top\widehat{\mathcal{N}}\mathcal{U} = \begin{bmatrix} R_n & T_n \\ 0 & R_n^\top \end{bmatrix}, \tag{5.12}$$

where H_n *is unreduced upper Hessenberg,* R_n *is nonsingular upper triangular, and* S_n *and* T_n *are* $\top$*-skew-symmetric.*

Proof. Applying Theorem 5.1 for $j = n$, we have $\widehat{y}_{n+1}$ being orthogonal to Y_n and $\mathcal{J}\bar{Z}_n$. This implies that $\widehat{y}_{n+1} = 0$. Then (5.4) and (5.5) become

$$\widehat{\mathcal{K}}Z_n = Y_nH_n \quad \text{and} \quad \widehat{\mathcal{N}}Z_n = Y_nR_n, \tag{5.13}$$

where H_n is unreduced upper Hessenberg and R_n is nonsingular upper triangular. Let $\mathcal{U} \equiv \begin{bmatrix} Z_n & -\mathcal{J}\bar{Y}_n \end{bmatrix}$, $\mathcal{V} \equiv \begin{bmatrix} Y_n & -\mathcal{J}\bar{Z}_n \end{bmatrix}$. Clearly,

$$Z_n^HZ_n = I_n, \quad Y_n^HY_n = I_n, \quad \text{and} \quad Y_n^\top\mathcal{J}Z_n = 0_n. \tag{5.14}$$

Then $\mathcal{U}$ and $\mathcal{V}$ satisfy (5.2). Since $\widehat{\mathcal{K}}\mathcal{J}$ and $\widehat{\mathcal{N}}\mathcal{J}$ are $\top$-skew symmetric, from (5.13)–(5.14), (5.12) follows. ∎

Based on Theorem 5.2, we now introduce a generalized $\top$-isotropic Arnoldi process which produces $\top$-bi-isotropic matrices Z_j and Y_{j+1} at the jth step.

By the recursive definition of j, let us first assume that the $\top$-bi-isotropic matrices Z_{j-1} and Y_j satisfy (5.4) and (5.5) with $j := j - 1$. That is, the $(j-1)$th step of the generalized $\top$-isotropic Arnoldi process generates

$$\widehat{\mathcal{N}}Z_{j-1} = Y_{j-1}R_{j-1}. \tag{5.15}$$

Now, we compare the jth columns of both sides in (5.5) which give

$$\widehat{\mathcal{N}}z_j = \sum_{i=1}^{j-1} r_{ij}y_i + r_{jj}y_j. \tag{5.16}$$

With (5.15), (5.16) it can be rewritten as

$$r_{jj}^{-1}z_j = \widehat{\mathcal{N}}^{-1}y_j - \sum_{i=1}^{j-1}\widehat{r}_{ij}z_i, \tag{5.17}$$

where

$$[\widehat{r}_{1j}, \ldots, \widehat{r}_{j-1,j}]^\top := -r_{jj}^{-1}R_{j-1}^{-1}[r_{1j}, \ldots, r_{j-1,j}]^\top. \tag{5.18}$$

Since $Z_j^HZ_j = I_j$, the coefficient $\widehat{r}_{ij}$ in (5.17) can be evaluated by

$$\widehat{r}_{ij} = z_j^H\widehat{\mathcal{N}}^{-1}y_j, \quad i = 1, \ldots, j-1, \tag{5.19}$$

and r_{jj} in (5.17) is chosen so that $\|z_j\|_2 = 1$. Substituting $[\widehat{r}_{1j}, \ldots, \widehat{r}_{j-1,j}]^\top$ of (5.19) into (5.18), we obtain the coefficient vector $[r_{1j}, \ldots, r_{j-1,j}]^\top$.

In exact arithmetic, z_j is orthogonal to $\mathcal{J}\bar{Y}_j$ automatically. As before, round-off errors cause $z_j^\top \mathcal{J} y_i$, $i = 1, \ldots, j$, to be tiny values. Thus, the jth step of the generalized $\top$-isotropic Arnoldi process for z_j should be modified by

$$r_{jj}^{-1} z_j = \widehat{\mathcal{N}}^{-1} y_j - \sum_{i=1}^{j-1} \widehat{r}_{ij} z_i - \sum_{i=1}^{j} s_{ij} \mathcal{J} \bar{y}_i, \tag{5.20a}$$

where

$$s_{ij} = y_i^\top \mathcal{J}^\top \left(\widehat{\mathcal{N}}^{-1} y_j - \sum_{i=1}^{j-1} \widehat{r}_{ij} z_i \right), \quad i = 1, \ldots, j. \tag{5.20b}$$

From (5.4), similar to (4.11), the jth step of the generalized $\top$-isotropic Arnoldi process for y_{j+1} is given by

$$h_{j+1,j} y_{j+1} = \widehat{\mathcal{K}} z_j - \sum_{i=1}^{j} h_{ij} y_i - \sum_{i=1}^{j} t_{ij} \mathcal{J} \bar{z}_i, \tag{5.21a}$$

where

$$h_{ij} = y_i^H \widehat{\mathcal{K}} z_j, \quad t_{ij} = z_i^\top \mathcal{J}^\top \widehat{\mathcal{K}} z_j, \quad i = 1, \ldots, j, \tag{5.21b}$$

and $h_{j+1,j} > 0$ is chosen so that $\|y_{j+1}\|_2 = 1$. Combing (5.20) and (5.21), we state the jth step of the generalized $\top$-isotropic Arnoldi process.

ALGORITHM 5.1 (the jth generalized $\top$-isotropic Arnoldi step).

Input: $\top$*-skew-Hamiltonian* $\widehat{\mathcal{K}}$ *and* $\widehat{\mathcal{N}}$*, upper triangular* $R(1:j-1, 1:j-1)$*,* $Y_j = [y_1, \ldots, y_j]$ *and* $Z_{j-1} = [z_1, \ldots, z_{j-1}]$ *with* $Y_j^H Y_j = I_j$*,* $Z_{j-1}^H Z_{j-1} = I_{j-1}$*, and* $Y_j^\top \mathcal{J} Z_{j-1} = 0$*.*

Output: $[h_{1,j}, \ldots, h_{j+1,j}]$*,* $R(1:j, 1:j)$*,* y_{j+1}*, and* z_j*.*

Compute z_j *in* (5.20) *by using the modified Gram–Schmidt step:*

End

5.1. Implicitly restart. We now derive the implicitly restarted step for the $(\ell+p)$th step of the generalized $\top$-isotropic Arnoldi process. Suppose we have computed the $(\ell+p)$th step of the generalized $\top$-isotropic Arnoldi factorization:

$$\widehat{\mathcal{K}} Z_{\ell+p} = Y_{\ell+p} H_{\ell+p} + h_{\ell+p+1,\ell+p} y_{\ell+p+1} e_{\ell+p}^\top, \tag{5.22}$$

$$\widehat{\mathcal{N}} Z_{\ell+p} = Y_{\ell+p} R_{\ell+p}. \tag{5.23}$$

Let $\{\lambda_1, \ldots, \lambda_\ell, \lambda_{\ell+1}, \ldots, \lambda_{\ell+p}\}$ be the eigenvalues of the matrix pair $(H_{\ell+p}, R_{\ell+p})$, where $\{\lambda_1, \ldots, \lambda_\ell\}$ are the wanted eigenvalues. Let Q_k and V_k for $k = 1, \ldots, p$ be unitary matrices computed by the implicit-QZ step [22, p. 147] for $(H_{\ell+p}, R_{\ell+p})$ with the single shift $\lambda_{\ell+k}$.

Let $\widehat{H}_{\ell+p} := Q_p^H \cdots Q_1^H H_{\ell+p} V_1 \cdots V_p$, $\widehat{R}_{\ell+p} := Q_p^H \cdots Q_1^H R_{\ell+p} V_1 \cdots V_p$, $\widehat{Y}_{\ell+p} := Y_{\ell+p} Q_1 \cdots Q_p$, and $\widehat{Z}_{\ell+p} := Z_{\ell+p} V_1 \cdots V_p$. Then $\widehat{H}_{\ell+p}$ and $\widehat{R}_{\ell+p}$ are upper Hessenberg and upper triangular, respectively, and $\widehat{Y}_{\ell+p}$ and $\widehat{Z}_{\ell+p}$ satisfy $\widehat{Y}_{\ell+p}^\top \mathcal{J} \widehat{Z}_{\ell+p} = 0$ because of $Y_{\ell+p}^\top \mathcal{J} Z_{\ell+p} = 0$. Multiplying (5.22) and (5.23) by $V_1 \cdots V_p$, we get

$$\widehat{\mathcal{K}} \widehat{Z}_{\ell+p} = \widehat{Y}_{\ell+p} \widehat{H}_{\ell+p} + h_{\ell+p+1,\ell+p} y_{\ell+p+1} e_{\ell+p}^\top V_1 \cdots V_p, \tag{5.24}$$

$$\widehat{\mathcal{N}} \widehat{Z}_{\ell+p} = \widehat{Y}_{\ell+p} \widehat{R}_{\ell+p}. \tag{5.25}$$

Since

$$e_{\ell+p}^\top V_1 = \alpha_{\ell+p} e_{\ell+p-1}^\top + \beta_{\ell+p} e_{\ell+p}^\top,$$

by induction, the first $\ell - 1$ entries of $e_{\ell+p}^\top V_1 \cdots V_p$ are zero. Hence a new ℓth step of the generalized $\top$-isotropic Arnoldi factorization can be obtained by equating the first ℓ columns of (5.24) and (5.25):

$$\widehat{\mathcal{K}} \widehat{Z}_\ell = \widehat{Y}_\ell \widehat{H}_\ell + \widehat{h}_{\ell+p+1,\ell+p} y_{\ell+p+1} e_\ell^\top,$$
$$\widehat{\mathcal{N}} \widehat{Z}_\ell = \widehat{Y}_\ell \widehat{R}_\ell.$$

We summarize the above processes in Algorithm 5.2.

ALGORITHM 5.2 (generalized implicitly restarted step).

Input: given $(Y_{\ell+p}, y_{\ell+p+1}, Z_{\ell+p}, H_{\ell+p}, h_{\ell+p+1,\ell+p}, R_{\ell+p})$;
Output: $(Y_\ell, y_{\ell+1}, Z_\ell, H_\ell, h_{\ell+1,\ell}, R_\ell)$ formed a new ℓth step of the generalized $\top$-isotropic Arnoldi factorization. The best ℓ eigenvalues are locked in (H_ℓ, R_ℓ).
  Sort the eigenvalues of $(H_{\ell+p}, R_{\ell+p})$ from best to worst according to the sorting criterion and take $\{\lambda_{\ell+1}, \ldots, \lambda_{\ell+p}\}$ to be the p worst eigenvalues.
  Set $v := h_{\ell+p+1,\ell+p} e_{\ell+p}$;
  For $k = 1, \ldots, p$,
    Compute unitary matrices Q_k and V_k by the implicit-QZ step for $(H_{\ell+p}, R_{\ell+p})$ with the single shift $\lambda_{\ell+k}$ so that $Q_k^H H_{\ell+p} V_k$ and $Q_k^H R_{\ell+p} V_k$ are upper Hessenberg and upper triangular, respectively;
    Update $Y_{\ell+p} := Y_{\ell+p} Q_k$, $Z_{\ell+p} := Z_{\ell+p} V_k$, $H_{\ell+p} := Q_k^H H_{\ell+p} V_k$, $R_{\ell+p} := Q_k^H R_{\ell+p} V_k$, $v := Z_k^H v$;
  End
  Set $H_\ell = H_{\ell+p}(1:\ell, 1:\ell)$, $h_{\ell+1,\ell} := e_\ell^\top v$, $R_\ell = R_{\ell+p}(1:\ell, 1:\ell)$, $Y_\ell := Y_{\ell+p}(:, 1:\ell)$, $y_{\ell+1} := y_{\ell+p+1}$, $Z_\ell := Z_{\ell+p}(:, 1:\ell)$.

We now present the G⊤SHIRA.

ALGORITHM 5.3 (G⊤SHIRA).

Input: $\top$*-skew-Hamiltonian matrices* $\widehat{\mathcal{K}}$ *and* $\widehat{\mathcal{N}}$ *with starting vector* y_1.
Output: Z_ℓ, Y_ℓ, *upper Hessenberg* H_ℓ, *and upper triangular* R_ℓ *with*
$\widehat{\mathcal{K}}Z_\ell = Y_\ell H_\ell$, $\widehat{\mathcal{N}}Z_\ell = Y_\ell R_\ell, Y_\ell^H Y_\ell = I_\ell$, $Z_\ell^H Z_\ell = I_\ell$, *and* $Y_\ell^\top \mathcal{J} Z_\ell = 0$.
Use Algorithm 5.1 *with starting vector* y_1 *to generate an* ℓ*th step of the generalized* $\top$*-isotropic Arnoldi factorization:*

$$\widehat{\mathcal{K}}Z_\ell = Y_\ell H_\ell + h_{\ell+1,\ell} y_{\ell+1} e_\ell^\top,$$
$$\widehat{\mathcal{N}}Z_\ell = Y_\ell R_\ell.$$

For $k = 1, 2, \ldots,$ *until wanted* ℓ *eigenpairs of* $(\widehat{\mathcal{K}}, \widehat{\mathcal{N}})$ *are convergent,*
Use Algorithm 5.1 *to extend the* ℓ*th step of the generalized* $\top$*-isotropic Arnoldi factorization to the* $(\ell+p)$*th step of the generalized* $\top$*-isotropic Arnoldi factorization:*

$$\widehat{\mathcal{K}}Z_{\ell+p} = Y_{\ell+p} H_{\ell+p} + h_{\ell+p+1,\ell+p} y_{\ell+p+1} e_{\ell+p}^\top,$$
$$\widehat{\mathcal{N}}Z_{\ell+p} = Y_{\ell+p} R_{\ell+p}.$$

Use Algorithm 5.2 *to reform a new* ℓ*th step of the generalized* $\top$*-isotropic Arnoldi factorization.*
End

Remark 5.1.

(i) $h_{\ell+1,\ell}$ is set to zero if $|h_{\ell+1,\ell}| < tol(|h_{\ell,\ell}| + |h_{\ell+1,\ell+1}|)$ for some stopping tolerance "*tol*."

(ii) Let (θ_i, v_i) be an eigenpair of (H_ℓ, R_ℓ), i.e., $H_\ell v_i = \theta_i R_\ell v_i$, and let $z_i = Z_\ell v_i$ be a Ritz vector of the eigenproblem $\widehat{\mathcal{K}}z = \mu\widehat{\mathcal{N}}z$ corresponding to the Ritz value θ_i. Then from (5.4) and (5.5), we have

$$\begin{aligned}
&\|\widehat{\mathcal{K}}z_i - \theta_i\widehat{\mathcal{N}}z_i\|_2 = \|\widehat{\mathcal{K}}Z_\ell v_i - \theta_i\widehat{\mathcal{N}}Z_\ell v_i\|_2 \\
&= \|(Y_\ell H_\ell + h_{\ell+1,\ell} y_{\ell+1} e_\ell^\top)v_i - \theta_i Y_\ell R_\ell v_i\|_2 \\
&= \|Y_\ell(H_\ell v_i - \theta_i R_\ell v_i) + h_{\ell+1,\ell}(e_\ell^\top v_i) y_{\ell+1}\|_2 \\
&= \|h_{\ell+1,\ell}(e_\ell^\top v_i) y_{\ell+1}\|_2 = |h_{\ell+1,\ell}||e_\ell^\top v_i|.
\end{aligned}$$

6. Numerical study: Vibration of fast trains. In this section, we shall study the resonance phenomena of a railway track under high frequent excitation forces. We present numerical results of the vibration of fast trains to illustrate the performance of the proposed structure-preserving algorithms in sections 2–5. All numerical experiments are carried out using MATLAB 2006b with the machine precision $eps \approx 2.22 \times 10^{-16}$.

Research in the vibration of fast trains contributes to the safety of operations of high-speed trains as well as new designs of train bridges, embedded rail structures (ERS), and train suspension systems. Recently, the dynamic response of the vehicle-rail-bridge interaction system under different train speed was studied in [25] and a procedure for designing an optimal ERS was proposed in [14]. In both papers, the accurate numerical estimation to the resonance frequencies of the rail plays an important role. However, as mentioned by Ipsen in [5], the classical finite element packages fail to deliver correct resonance frequency for such problems. In this section, we would like to use our structure-preserving algorithms to solve the palindromic QEP (1.1) arising from the spectral modal analysis of rails under periodic excitation forces.

In the model of vibration of fast trains, we assume that the rail sections between

consecutive sleeper bays are identical, the distance between consecutive wheels is the same, and the wheel loads are equal. The rail between two sleepers is modeled by a three-dimensional isotropic elastic solid with linear isoparametric tetrahedron finite elements. Figure 6.1 shows a three-dimensional rail model (see [1] for details).

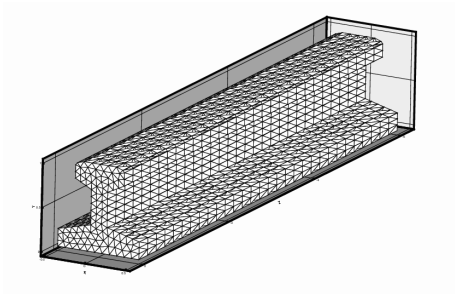

FIG. 6.1. *A three-dimensional rail model.*

Based on the ERS design [14], the external force is assumed to be periodic and the displacements of two boundary cross sections of the modeled rail are assumed to have a ratio λ, which is dependent on the excitation frequency of the external force. From the virtual work principle and strain-stress relationship, the governing equation for the displacement vector q involving viscous damping can be formulated by $Kq + D\dot{q} + M\ddot{q} = f(t)$, where K, D, and M from the finite element discretization on a uniform mesh satisfy the given boundary conditions. These matrices have the form

$$\begin{bmatrix} E_{11} & \widetilde{E}_{1,2:m-1}^{\top} & \frac{1}{\lambda}E_{m,m+1} \\ \widetilde{E}_{1,2:m-1} & \widetilde{E}_{2:m-1} & \widetilde{E}_{2:m-1,m}^{\top} \\ \lambda E_{m,m+1}^{\top} & \widetilde{E}_{2:m-1,m} & E_{m,m} \end{bmatrix}$$

in which $\widetilde{E}_{1,2:m-1}^{\top} = [E_{12}^{\top}, 0_n, \ldots, 0_n]$, $\widetilde{E}_{2:m-1,m} = [0_n, \ldots, 0_n, E_{m-1,m}]$, and $\widetilde{E}_{2:m-1} = \operatorname{tridiag}\big(E_{i-1,i}, E_{i,i}, E_{i,i+1}^{\top}\big)_{i=2}^{m-1}$ with $E_{ij} \in \mathbb{R}^{n\times n}$, $i, j = 1, \ldots, m+1$. (See [1] for details.) Furthermore, from the spectral modal analysis, we consider $q = \widetilde{x}e^{i\omega t}$, where ω is the frequency of the external force and $\widetilde{x}$ is the corresponding eigenmode. Consequently, we get the palindromic QEP

$$\left(\lambda^2 \widetilde{A}_1^{\top} + \lambda \widetilde{A}_0 + \widetilde{A}_1\right)\widetilde{x} = 0, \tag{6.1}$$

where

$$\left[\widetilde{A}_1\right]_{ij} = \begin{cases} K_{m,m+1} + i\omega D_{m,m+1} - \omega^2 M_{m,m+1} & (\text{if } \ i = m, j = 1), \\ 0 & \text{otherwise}, \end{cases}$$

$$\left[\widetilde{A}_0\right]_{ij} = \begin{cases} K_{i,j} + i\omega D_{i,j} - \omega^2 M_{i,j} & (\text{if } \ i-1 \le j \le i+1), \\ 0 & \text{otherwise}. \end{cases}$$

By consulting the preprocessing procedure (see [4] or [1]) for the deflation of all trivial zero and infinite eigenvalues of (6.1), we arrive to the deflated palindromic QEP

$$\left(\lambda^2 A_1^{\top} + \lambda A_0 + A_1\right) x = 0. \tag{6.2}$$

Example 6.1. We first consider the deflated palindromic QEP (6.2) for high-speed trains and rails. The size of A_0 and A_1 after deflation is $n = 303$, and the excitation frequency ω is chosen as 1000. The absolute values of the eigenvalues vary from 10^{-20} to 10^{20}.

We compute all eigenpairs of Example 6.1 by the SA_I, SA_II, and QZ algorithm. Note that as shown in section 3, SA_II and the URV-based method [20] are mathematically equivalent. In practice, we compare the backward error (relative residual (RRes)) of (1.1) by SA_II and the SKURV software [18]. Since SKURV gives only the eigenvalues, the associated eigenvectors are computed from (3.9) and (3.10) by inverse iteration. Numerical results show that the backward errors obtained by SA_II and SKURV for Example 6.1 are slightly different. Therefore, in the following computation, we adapt SA_II instead of the URV-method.

To measure the accuracy of an approximate eigenpair (λ, x) for (6.2), we use the RRes

$$\text{RRes} \equiv \frac{\|\lambda^2 A_1^\top x + \lambda A_0 x + A_1 x\|_2}{(|\lambda^2|\|A_1\|_F + |\lambda|\|A_0\|_F + \|A_1\|_F)\|x\|_2}. \tag{6.3}$$

As mentioned before, theoretically, the eigenvalues of (6.2) appear in pairs $(\lambda, \frac{1}{\lambda})$. So, if we sort the eigenvalues in the ascending order by modulus, the product of the ith and $(2n + 1 - i)$th sorted eigenvalues should be one. Therefore, we define the reciprocities of computed eigenvalues by

$$|\lambda_i \lambda_{2n+1-i} - 1|, \ i = 1, \ldots, n. \tag{6.4}$$

The RRes of the computed eigenpairs by the SA_I, SA_II, and QZ algorithm for the eigenvalues with absolute values in $[10^{-20}, 10^{20}]$ and $\omega = 1000$ are shown in Figure 6.2. For eigenvalues with small modulus, the SA_I performs much better than the SA_II and the QZ algorithm. For eigenvalues near the unit circle or with large modulus, all three algorithms have similar accuracy.

The important reciprocity property of eigenvalues is shown in Figure 6.3. Clearly, SA_I and SA_II preserve the essential reciprocity property as expected, while the QZ algorithm has only less than 12 pairs of computed eigenvalues near the unit circle with reciprocity near zero ($\approx 1.17 \times 10^{-12}$). The average and maximal values of all reciprocities are 0.220 and 1.006, respectively.

Next, we apply the SA_I, SA_II, and QZ algorithm to the palindromic QEP with various excitation frequency ω. Figure 6.4 shows the RRes of all computed eigenpairs with eigenvalues in $[10^{-20}, 10^{20}]$ by the three algorithms for 100 different ω's uniformly chosen from 50 to 5000. We see that the RRes of the SA_I are better than those of the SA_II and the QZ algorithm for all ω's.

Example 6.2. *We now consider the palindromic QEP* (6.1) *for high-speed trains and rails, with n, the size of* A_0 *and* A_1*, being* 5757.

Computational cost. Before showing our numerical results computed by the $\top$SHIRA and G$\top$SHIRA, we compare the computational costs of one step of the $\top$-isotropic Arnoldi process and the implicitly restarted step in each algorithm.

In one step of the $\top$SHIRA, it requires one matrix-vector product for $\mathcal{B}$, and $3j$ inner products and saxpy operations with vector length $2n$. Since $\mathcal{B} = \mathcal{N}_1^{-1}\widetilde{\mathcal{K}}\mathcal{N}_2^{-1}$, by the definitions of $\widetilde{\mathcal{K}}$ and $(\mathcal{N}_1, \mathcal{N}_2)$ in (4.2a) and (4.4), the matrix-vector of $\mathcal{B}$ requires solving 2 linear systems, 4 and 2 matrix-vector products for A_1 and A_0, respectively, and 6 saxpy operations with vector length n.

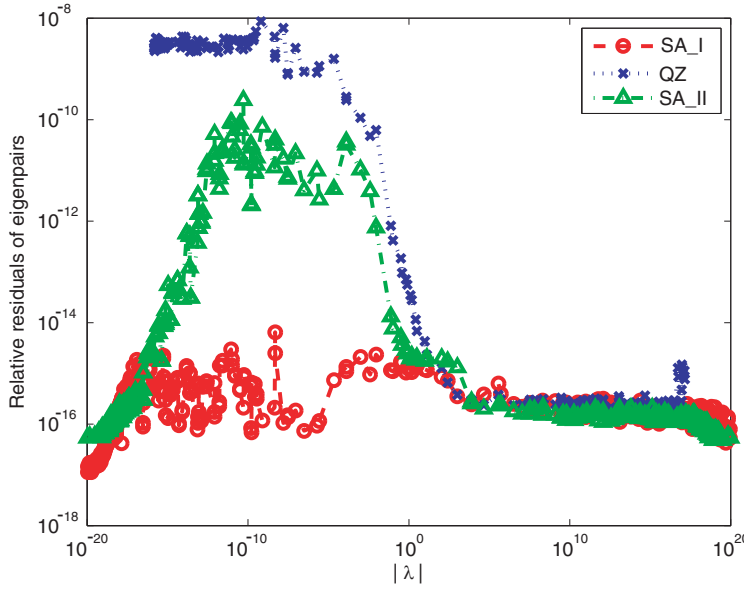

FIG. 6.2. *RRes of Example* 6.1 *($\omega = 1000$).*

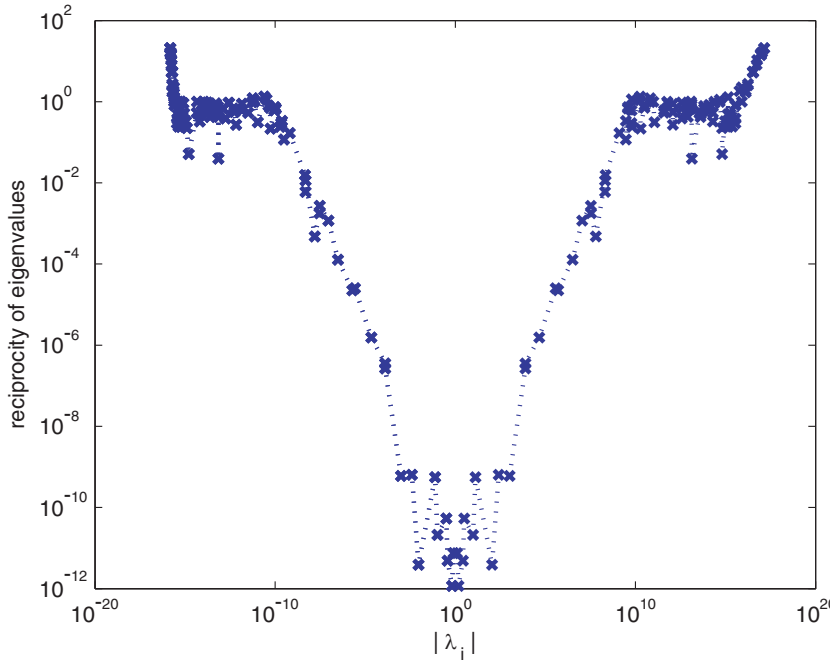

FIG. 6.3. *Reciprocities of computed eigenvalues produced by the QZ algorithm ($\omega = 1000$).*

In one step of the G⊤SHIRA, solving $\widetilde{z}_j$ requires solving 2 linear systems, 2 matrix-vector products of A_0 and A_1, and 6 saxpy operations with vector length n; computing z_j requires $2j - 1$ inner products and saxpy operations with vector length $2n$;

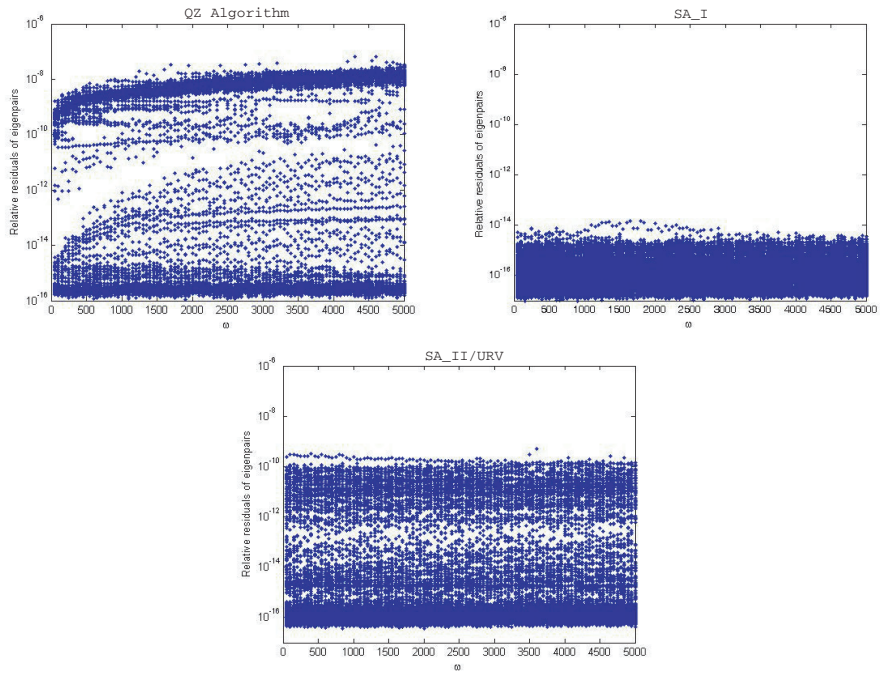

FIG. 6.4. *The RRes of eigenvalues vs. ω.*

TABLE 6.1
Computational cost of one step of the ⊤-isotropic Arnoldi process in the ⊤SHIRA and G⊤SHIRA algorithms.

	⊤SHIRA	G⊤SHIRA
Solving linear system	2	2
Matrix-vector product for A_1	4	4
Matrix-vector product for A_0	2	2
Inner products	$6j$	$8j-2$
Saxpy operations	$6j+6$	$8j+4$

computing y_{j+1} requires 2 matrix-vector products for A_1, and $2j$ inner products and saxpy operations with vector length $2n$.

We summarize the above computational costs in Table 6.1. The vector length of the inner products and saxpy operations in Table 6.1 is equal to n. On the other hand, the implicitly restarted steps in the ⊤SHIRA and G⊤SHIRA require $2(\ell+p-1)p$ and $4(\ell+p-1)p$ saxpy operations with vector length $2n$, respectively. Comparing one ⊤-isotropic Arnoldi step with one implicitly restarted step, the G⊤SHIRA algorithm is slightly more expensive than the ⊤SHIRA algorithm.

Accuracy of eigenpairs. We now compare the numerical results computed by the ⊤SHIRA and G⊤SHIRA algorithms. Here, $\lambda_{\omega,1},\ldots,\lambda_{\omega,10}$ denote target eigenvalues, and we set $\ell=10$, $p=20$ in the implicitly restarted step for each algorithm.

The RRes of $(\lambda_{\omega,i},x_i)$ and $(\frac{1}{\lambda_{\omega,i}},\widetilde{x}_i)$ for $i=1,\ldots,10$ are shown in Figure 6.5, where x_i and $\widetilde{x}_i$ are the corresponding computed eigenvectors. In (a) and (b) of Figure 6.5, we show those RRes for frequency $\omega=50$ and $\omega=2000$, respectively. The notations "Δ" and "$\times$" denote the results computed by the ⊤SHIRA and G⊤SHIRA

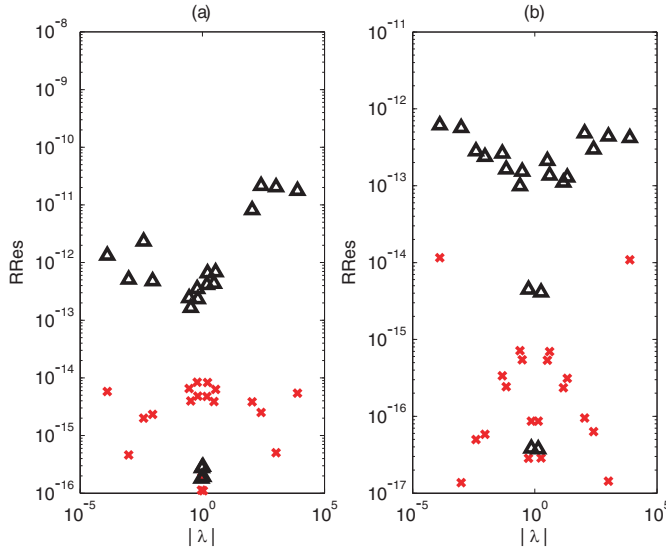

FIG. 6.5. *The RRes of the eigenpairs computed by the ⊤SHIRA and G⊤SHIRA algorithms. The notations "Δ" and "×" denote the results computed by the ⊤SHIRA and G⊤SHIRA algorithms, respectively. In* (a) *and* (b)*, the frequency ω is equal to* 50 *and* 2000*, respectively.*

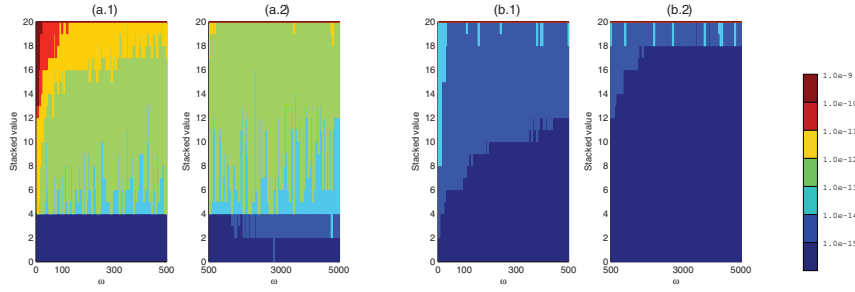

FIG. 6.6. *The stacked bars of $\ell_{\omega,k}$ for $k = 1, \ldots, 7$ with different ω. For each ω, all $\ell_{\omega,k}$ for $k = 1, \ldots, 7$ are stacked to form a vertical bar with ordering $\ell_{\omega,1}, \ell_{\omega,2}, \ldots, \ell_{\omega,7}$. Each bar is multicolored and the color corresponds to distinct $\ell_{\omega,k}$. The color bar in the right position shows the relationship between color and interval I_k, which corresponds to $\ell_{\omega,k}$. The results in* (a) *and* (b) *are computed by the ⊤SHIRA and G⊤SHIRA algorithms, respectively.*

algorithms, respectively. From these results, we see that the reciprocity property of the eigenvalues are preserved in both algorithms, but the accuracy of the eigenpairs computed by the G⊤SHIRA algorithm is obviously better than that by the ⊤SHIRA algorithm.

In order to give an overall comparison between the two algorithms, we compute the eigenpairs $(\lambda_{\omega,i}, x_i)$ and $(\frac{1}{\lambda_{\omega,i}}, \widetilde{x}_i)$ for $i = 1, \ldots, 10$ with $\omega = 5, 10, 15, \ldots, 500$ and $\omega = 550, 600, 650, \ldots, 5000$. We analyze the distribution of the corresponding 20 RRes with respect to ω. We partition the interval $(0, 10^{-9})$ into seven subintervals $\mathcal{I}_1 = (0, 10^{-15}]$, $\mathcal{I}_2 = (10^{-15}, 10^{-14}], \ldots, \mathcal{I}_7 = (10^{-10}, 10^{-9})$. For fixed ω, let $\ell_{\omega,k}$ be the number of the RRes which belongs to the interval $\mathcal{I}_k$ for $k = 1, \ldots, 7$. In Figure 6.6, for each ω, all $\ell_{\omega,k}$, $k = 1, \ldots, 7$, are stacked to form a vertical bar with ordering

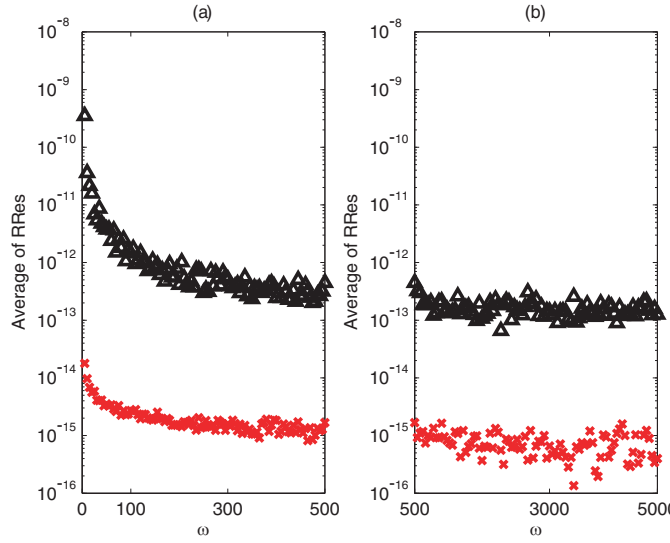

FIG. 6.7. *The average of RRes for the twelve eigenpairs computed by the* ⊤*SHIRA and G*⊤*SHIRA algorithms. The notations "*Δ*" and "*$\times$*" denote the results computed by the* ⊤*SHIRA and G*⊤*SHIRA algorithms, respectively.*

$\ell_{\omega,1}, \ell_{\omega,2}, \ldots, \ell_{\omega,7}$. The bar height is 20 which is the sum of $\ell_{\omega,1}, \ldots, \ell_{\omega,7}$. Each bar is multicolored and the color corresponds to distinct $\ell_{\omega,k}$. The color bar in the right bottom position of Figure 6.6 shows the relationship between colors and intervals $\mathcal{I}_k$ corresponding to $\ell_{\omega,k}$. All stacked bars of $\ell_{\omega,k}$ $(k = 1, \ldots, 7)$ with $\omega = 5, 10, 15, \ldots, 500$ are shown in (a.1) and (b.1) of Figure 6.6 and those with $\omega = 550, 600, 650, \ldots, 5000$ are shown in (a.2) and (b.2) of Figure 6.6. The results in (a) and (b) of Figure 6.6 are computed by the ⊤SHIRA and the G⊤SHIRA algorithms, respectively.

In the above paragraph, we show the distribution of the RRes for different ω for the comparison of the accuracy of the target eigenpairs. From another point of view, we show the average of the RRes for the target eigenpairs with each ω in Figure 6.7. The notations "Δ" and "$\times$" in Figure 6.7 denote the results computed by the ⊤SHIRA and G⊤SHIRA algorithms, respectively. From Figures 6.6 and 6.7, we can summarize that the accuracy of the eigenpairs computed by the G⊤SHIRA algorithm are obviously better than that of the ⊤SHIRA algorithm for all ω in $(0, 5000]$.

We now try to explain the different accuracies of the two algorithms. One important reason is that the ⊤SHIRA algorithm needs to solve a linear system in the extraction method of eigenvectors, while the G⊤SHIRA algorithm needs only vector additions. The accuracy of the extracted eigenvector will be reduced if the condition number of the linear system is large. On the other hand, Theorem A.1 in Appendix A.3 may help explain this phenomenon from the viewpoint of the minimal residual. The accuracy of the eigenpair computed by the G⊤SHIRA algorithm is better than that by the ⊤SHIRA algorithm, since the G⊤SHIRA algorithm is a generalized Arnoldi algorithm for $\widehat{\mathcal{K}}z = \widehat{\mu}\widehat{\mathcal{N}}z$, while the ⊤SHIRA algorithm is an Arnoldi algorithm for $\mathcal{N}_1^{-1}\widehat{\mathcal{K}}\mathcal{N}_2^{-1}y = \widehat{\mu}y$.

7. Conclusions. In this paper, we first transform a palindromic QEP to a ⊤-skew-Hamiltonian pencil by the $(S + S^{-1})$-transform. Then, we extend Patel's ap-

proach to solve the $\top$-skew-Hamiltonian pencil efficiently. We have also developed a structure-preserving generalized $\top$-skew-Hamiltonian implicitly restarted Arnoldi method (G$\top$SHIRA) for solving the large sparse $\top$-skew-Hamiltonian pencil. Numerical results show that the accuracy of desired eigenpairs computed by the G$\top$SHIRA is better than that computed by the classical $\top$SHIRA. The standard algorithms proposed in this paper are numerically stable for solving palindromic QEPs. In the future, we are motivated to develop structure-preserving algorithms for solving the antipalindromic QEP $\lambda^2 A_1^\top + \lambda A_0 - A_1$ with $A_0^\top = -A_0$, efficiently.

Appendix.

A.1. In this section we list pseudocodes of Step 2 in Algorithm 2.1.

In the following, $\mathsf{givensl}(\alpha,\beta,\mathsf{i})$ returns a Givens rotation G such that $G[\begin{smallmatrix}\alpha\\ \beta\end{smallmatrix}] = \gamma e_i$ with $\gamma \in \mathbb{C}$; $\mathsf{givensr}(\alpha,\beta,\mathsf{i})$ returns a Givens rotation G such that $[\alpha\ \beta]G = \gamma e_i^\top$ with $\gamma \in \mathbb{C}$. The functions $\mathsf{qr}(\mathsf{A})$ and $\mathsf{ql}(\mathsf{A})$ perform the standard QR and QL factorizations.

Step 2 *in Algorithm* 2.1. function $[\mathcal{K},\mathcal{N},Q,Z] = \mathsf{rbutf}(\mathcal{K},\mathcal{N})$

Input: Matrices $\mathcal{K},\mathcal{N}$ in the form (2.4).

Output: Unitary Q, Z and $\mathcal{K},\mathcal{N}$ of the form (2.5), where $\mathcal{K}$ and $\mathcal{N}$ are overwritten by $Q\mathcal{K}Z$ and $Q\mathcal{N}Z$, respectively.

$[Q_1, R] \leftarrow \mathsf{qr}(\mathcal{N}(1:n, 1:n))$
$Q \leftarrow \mathrm{diag}(\mathrm{Q_1^H},\ \mathrm{I_n})$
$Z \leftarrow \mathrm{diag}(\mathrm{I_n},\ \bar{\mathrm{Q}}_1)$
$\mathcal{K} \leftarrow Q\mathcal{K}Z$
$\mathcal{N} \leftarrow Q\mathcal{N}Z$
for $j = 1 : n-2$
  for $k = j+1 : n-1$
    % *annihilate* $\mathcal{K}(n+k, j)$ *by Givens rotation in* $(n+k, n+k+1)$ *plane*
    $G \leftarrow \mathsf{givensl}(\mathcal{K}(n+k, j), \mathcal{K}(n+k+1, j), 2)$
    $Q(n+k : n+k+1, :) \leftarrow GQ(n+k : n+k+1, :)$
    $\mathcal{K}(n+k : n+k+1, :) \leftarrow G\mathcal{K}(n+k : n+k+1, :)$

A.2. To show the extra zeros of the subdiagonals of the submatrices in (3.4), let $\mathbb{H}_k$ and $\mathbb{T}_k$ be the sets of $k\times k$ upper Hessenberg and triangular matrices, respectively, and let $\mathbb{S}_{2k}$ be the set of $2k\times 2k$ $\top$-skew symmetric matrices. Denote

$$\text{(A2.1)}\quad \mathbb{A}_{2k} = \left\{ A\in\mathbb{C}^{2k\times 2k} \middle| A \equiv P_{2k}^\top \left[\begin{array}{c|c} 0_k & \diagdown \\ \hline \diagup & 0_k \end{array}\right] P_{2k} \ \text{ with } \diagdown\in\mathbb{H}_k \ \text{ and } \diagup\in\mathbb{T}_k \right\},$$

where $P_{2k} = [e_1, e_{k+1}, e_2, e_{k+2}, \ldots, e_k, e_{2k}]$,

$$\text{(A2.2)}\qquad \mathbb{R}_{2k} = \left\{ R\in\mathbb{C}^{2k\times 2k} \middle| R \equiv P_{2k}^\top \left[\begin{array}{c|c} 0_k & \diagup \\ \hline \diagup & 0_k \end{array}\right] P_{2k} \ \text{ with } \diagup\in\mathbb{T}_k \right\},$$

$$\text{(A2.3)}\quad \mathbb{B}_{2m,2k} = \{B\in\mathbb{C}^{2m\times 2k} | Be_1 = Be_3 = \cdots = Be_{2k-1} = 0\},$$

$$\text{(A2.4)}\quad \widehat{\mathbb{B}}_{2m,2k} = \{\widehat{B}\in\mathbb{C}^{2m\times 2k} | \widehat{B}e_2 = \widehat{B}e_4 = \cdots = \widehat{B}e_{2k} = 0\},$$

$$\text{(A2.5)}\quad \mathbb{C}_{2m\times 2k} = \{C\in\mathbb{C}^{2m\times 2k} | c_{ij} = 0, i = 1,\ldots,2m, j = 1,\ldots,2k \ \text{ and } \ (i,j)\neq(1,2k)\},$$

$$\text{(A2.6)}\quad \mathbb{D}_{2k} = \{D\in\mathbb{C}^{2k\times 2k} | D\in\mathbb{S}_{2k} \ \text{ with } \ \{1,-1,3,-3,\ldots,2k-1,-(2k-1)\} \text{ – diagonals being zeros}\},$$

$$\text{(A2.7)}\quad \widehat{\mathbb{D}}_{2k} = \{\widehat{D}\in\mathbb{C}^{2k\times 2k} | \widehat{D}\in\mathbb{S}_{2k} \ \text{ with } \ \{2,-2,4,-4,\ldots,2k-2,-(2k-2)\} \text{ – diagonals being zeros}\}.$$

After performing the first and second steps of the SA_I (i.e., Steps 07–50 in section A.1, for $j = 1$ and 2) on $(\widetilde{\mathcal{K}}, \widetilde{\mathcal{N}})$, it produces

$$\text{(A2.8a)}\quad K_{11}^{(2)} := \left[\begin{array}{cc|ccc} 0 & \times & 0 & \cdots & 0 \\ \times & 0 & \times & \cdots & \times \\ \hline 0 & \times & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \cdots & 0 \end{array}\right],\quad K_{12}^{(2)} := \left[\begin{array}{cc|ccc} 0 & 0 & \times & \cdots & \times \\ 0 & 0 & 0 & \cdots & 0 \\ \hline \times & 0 & & & \\ \vdots & \vdots & & G_{2n-2} & \\ \times & 0 & & & \end{array}\right],$$

$$\text{(A2.8b)}\qquad K_{21}^{(2)} := \left[\begin{array}{cc|ccc} 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \hline 0 & 0 & & & \\ \vdots & \vdots & & H_{2n-2} & \\ 0 & 0 & & & \end{array}\right],\ K_{22}^{(2)} := (K_{11}^{(2)})^{\top},$$

and

$$\text{(A2.9a)}\ N_{11}^{(2)} := \left[\begin{array}{cc|ccc} \times & 0 & \times & \cdots & \times \\ 0 & \times & 0 & \cdots & 0 \\ \hline 0 & 0 & & & \\ \vdots & \vdots & & T_{2n-2} & \\ 0 & 0 & & & \end{array}\right],\ N_{12}^{(2)} := \left[\begin{array}{cc|ccc} 0 & \times & 0 & \cdots & 0 \\ \times & 0 & \times & \cdots & \times \\ \hline 0 & \times & & & \\ \vdots & \vdots & & 0_{2n-2} & \\ 0 & \times & & & \end{array}\right],$$

$$\text{(A2.9b)}\qquad N_{21}^{(2)} := 0_{2n},\quad N_{22}^{(2)} := (N_{11}^{(2)})^{\top},$$

where G_{2n-2} and $H_{2n-2} \in \mathbb{S}_{2n-2}$ and $T_{2n-2} \in \mathbb{T}_{2n-2}$. Let $m = n - k$. Suppose after $2k$ steps (for $j = 1, 2, \ldots, 2k$) the SA_I gives

$$\text{(A2.10a)}\ K_{11}^{(2k)} := \begin{bmatrix} A_{2k} & B_{2m,2k}^{\top} \\ C_{2m,2k} & 0_{2m} \end{bmatrix},\quad K_{12}^{(2k)} := \begin{bmatrix} D_{2k} & \widehat{B}_{2m,2k}^{\top} \\ \widehat{B}_{2m,2k} & G_{2m} \end{bmatrix},$$

$$\text{(A2.10b)}\ K_{21}^{(2k)} := \begin{bmatrix} 0_{2k} & 0_{2m,2k}^{\top} \\ 0_{2m,2k} & H_{2m} \end{bmatrix},\quad K_{22}^{(2k)} := (K_{11}^{(2k)})^{\top},$$

and

$$\text{(A2.11a)}\quad N_{11}^{(2k)} := \begin{bmatrix} R_{2k} & \widehat{E}_{2m,2k}^{\top} \\ 0_{2m,2k} & T_{2m} \end{bmatrix},\ N_{12}^{(2k)} := \begin{bmatrix} \widehat{D}_{2k} & E_{2m,2k}^{\top} \\ E_{2m,2k} & 0_{2m} \end{bmatrix},$$

$$\text{(A2.11b)}\qquad N_{21}^{(2k)} := 0_{2n},\quad N_{22}^{(2k)} := (N_{11}^{(2k)})^{\top},$$

where $A_{2k} \in \mathbb{A}_{2k}$, $R_{2k} \in \mathbb{R}_{2k}$, $C_{2m,2k} \in \mathbb{C}_{2m,2k}$, $B_{2m,2k}$, $E_{2m,2k} \in \mathbb{B}_{2m,2k}$, $\widehat{B}_{2m,2k}$, $\widehat{E}_{2m,2k} \in \widehat{\mathbb{B}}_{2m,2k}$, $D_{2k} \in \mathbb{D}_{2k}$, $\widehat{D}_{2k} \in \widehat{\mathbb{D}}_{2k}$, $G_{2m}, H_{2m} \in \mathbb{S}_{2m}$, and $T_{2m} \in \mathbb{T}_{2m}$.

By letting $k' = k+1$ and $m' = m-1$, we perform the SA_I for $j = 2k+1, 2k+1$ and obtain

$$\text{(A2.12a)}\ K_{11}^{(2k')} := \begin{bmatrix} A_{2k'} & B_{2m',2k'}^{\top} \\ C_{2m',2k'} & 0_{2m'} \end{bmatrix},\quad K_{12}^{(2k')} := \begin{bmatrix} D_{2k'} & \widehat{B}_{2m',2k'}^{\top} \\ \widehat{B}_{2m',2k'} & G_{2m'} \end{bmatrix},$$

$$\text{(A2.12b)}\ K_{21}^{(2k')} := \begin{bmatrix} 0_{2k'} & 0_{2m',2k'}^{\top} \\ 0_{2m',2k'} & H_{2m'} \end{bmatrix},\quad K_{22}^{(2k')} := (K_{11}^{(2k')})^{\top},$$

and

$$\text{(A2.13a)}\ N_{11}^{(2k')} := \begin{bmatrix} R_{2k'} & \widehat{E}_{2m',2k'}^{\top} \\ 0_{2m',2k'} & T_{2m'} \end{bmatrix},\ N_{12}^{(2k')} := \begin{bmatrix} \widehat{D}_{2k'} & E_{2m',2k'}^{\top} \\ E_{2m',2k'} & 0_{2m'} \end{bmatrix},$$

$$\text{(A2.13b)}\qquad N_{21}^{(2k')} := 0_{2n},\quad N_{22}^{(2k')} := (N_{11}^{(2k')})^{\top},$$

where the subblocks in (A2.12)–(A2.13) have the same forms as in (A2.10)–(A2.11) by replacing k and m by k' and m', respectively, and satisfy

$$A_{2k} = \Phi_{2k}^{\top} A_{2k'} \Phi_{2k}, \quad D_{2k} = \Phi_{2k}^{\top} D_{2k} \Phi_{2k}, \tag{A2.14a}$$

$$R_{2k} = \Phi_{2k}^{\top} R_{2k'} \Phi_{2k}, \quad \widehat{D}_{2k} = \Phi_{2k}^{\top} \widehat{D}_{2k'} \Phi_{2k}, \tag{A2.14b}$$

where $\Phi_{2k} = [e_1, \ldots, e_{2k}]$ with $e_i \in \mathbb{C}^{2k'}, i = 1, \ldots, 2k$. By the inductive process above, (3.4) holds with $k' = n$ in (A2.12)–(A2.13) and with the superscript "a" in (3.4) being $(2n)$. ∎

A.3. THEOREM A.1. *Let $V \in \mathbb{C}^{n\times r}$ be a unitary matrix and $A, B \in \mathbb{C}^{n\times n}$. Then*

$$\|AV - BVC\|_2 \geq \|AV - BVP\|_2 \qquad \text{for all } C \in \mathbb{C}^{r\times r},$$

where $P = (V^H B^H BV)^{-1}(V^H B^H AV)$, or equivalently, $P = (U^H BV)^{-1}(U^H AV)$, where $BV = US$ is the QR factorization of BV.

Proof. Since

$$\begin{aligned} -C^H V^H B^H BVP &= -C^H V^H B^H BV(V^H B^H BV)^{-1}(V^H B^H AV) \\ &= -C^H V^H B^H AV, \end{aligned}$$

it follows that

$$\begin{aligned} &(V^H A^H - C^H V^H B^H)(AV - BVC) \\ &= V^H A^H AV - C^H V^H B^H AV - V^H A^H BVC + C^H V^H B^H BVC \\ &= V^H A^H AV + (P^H - C^H)V^H B^H BV(P - C) - P^H V^H B^H BVP \\ &= (V^H A^H - P^H V^H B^H)(AV - BVP) + (P^H - C^H)V^H B^H BV(P - C). \end{aligned}$$

Obviously, $(P^H - C^H)V^H B^H BV(P - C)$ is semidefinite. Then by Weyl's theorem, we have

$$\lambda_j((AV - BVC)^H(AV - BVC)) \geq \lambda_j((AV - BVP)^H(AV - BVP)),\ j = 1, \ldots, n.$$

Hence

$$\|AV - BVC\|_2 \geq \|AV - BVP\|_2,$$

since $\|G\|_2^2 = \lambda\max(G^H G)$. ∎

DETECTING AND SOLVING HYPERBOLIC QUADRATIC EIGENVALUE PROBLEMS*

CHUN-HUA GUO†, NICHOLAS J. HIGHAM‡, AND FRANÇOISE TISSEUR‡

Abstract. Hyperbolic quadratic matrix polynomials $Q(\lambda) = \lambda^2 A + \lambda B + C$ are an important class of Hermitian matrix polynomials with real eigenvalues, among which the overdamped quadratics are those with nonpositive eigenvalues. Neither the definition of overdamped nor any of the standard characterizations provides an efficient way to test if a given Q has this property. We show that a quadratically convergent matrix iteration based on cyclic reduction, previously studied by Guo and Lancaster, provides necessary and sufficient conditions for Q to be overdamped. For weakly overdamped Q the iteration is shown to be generically linearly convergent with constant at worst 1/2, which implies that the convergence of the iteration is reasonably fast in almost all cases of practical interest. We show that the matrix iteration can be implemented in such a way that when overdamping is detected a scalar $\mu < 0$ is provided that lies in the gap between the n largest and n smallest eigenvalues of the $n \times n$ quadratic eigenvalue problem (QEP) $Q(\lambda)x = 0$. Once such a μ is known, the QEP can be solved by linearizing to a definite pencil that can be reduced, using already available Cholesky factorizations, to a standard Hermitian eigenproblem. By incorporating an initial preprocessing stage that shifts a hyperbolic Q so that it is overdamped, we obtain an efficient algorithm that identifies and solves a hyperbolic or overdamped QEP maintaining symmetry throughout and guaranteeing real computed eigenvalues.

Key words. quadratic eigenvalue problem, hyperbolic, overdamped, weakly overdamped, quadratic matrix polynomial, quadratic matrix equation, solvent, cyclic reduction, doubling algorithm

1. Introduction.

The quadratic eigenvalue problem (QEP) is to find scalars λ and nonzero vectors x and y satisfying $Q(\lambda)x = 0$ and $y^*Q(\lambda) = 0$, where

$$Q(\lambda) = \lambda^2 A + \lambda B + C, \quad A, B, C \in \mathbb{C}^{n\times n} \tag{1.1}$$

is a quadratic matrix polynomial. The vectors x and y are right and left eigenvectors, respectively, corresponding to the eigenvalue λ. The many applications of the QEP, as well as its theory and algorithms for solving it, are surveyed by Tisseur and Meerbergen [27].

Our interest in this work is in Hermitian quadratic matrix polynomials—those with Hermitian A, B, and C—and more specifically those that are *hyperbolic*. Hyperbolic quadratics, and the subclass of overdamped quadratics, are defined as follows. For Hermitian X and Y we write $X > Y$ ($X \geq Y$) if $X - Y$ is positive definite (positive semidefinite).

DEFINITION 1.1. *$Q(\lambda)$ is hyperbolic if A, B, and C are Hermitian, $A > 0$, and*

$$(x^*Bx)^2 > 4(x^*Ax)(x^*Cx) \quad \textit{for all nonzero } x \in \mathbb{C}^n. \tag{1.2}$$

DEFINITION 1.2. *$Q(\lambda)$ is overdamped if it is hyperbolic with $B > 0$ and $C \geq 0$.*

Overdamped quadratics arise in overdamped systems in structural mechanics [22, section 7.6].

Any eigenpair of Q satisfies $x^*Q(\lambda)x = 0$ and hence

$$\lambda = \frac{-x^*Bx \pm \sqrt{(x^*Bx)^2 - 4(x^*Ax)(x^*Cx)}}{2x^*Ax}. \tag{1.3}$$

Therefore the eigenvalues of a hyperbolic Q are real and those of an overdamped Q are real and nonpositive. Both classes of quadratics have other important spectral properties, which we summarize in section 2.

We have two aims. The first is to devise an efficient and reliable numerical test for hyperbolicity or overdamping of a given Hermitian quadratic. The second aim is to build upon an affirmative test result an efficient algorithm for solving the QEP that exploits hyperbolicity and in particular that guarantees real computed eigenvalues in floating point arithmetic.

Part of the motivation for testing overdamping concerns the stability of gyroscopic systems. It is known that a gyroscopic system $G(\lambda) = \lambda^2 A_g + \lambda B_g + C_g$ with $A_g, C_g > 0$ and B_g Hermitian indefinite and nonsingular is stable whenever the quadratic $Q_g(\lambda) = \lambda^2 A_g + \lambda|B_g| + C_g$ is overdamped [9]. Here $|B_g|$ is the Hermitian positive definite square root of B_g^2 (i.e., the Hermitian polar factor of the Hermitian matrix B_g) [12].

Checking the hyperbolicity condition (1.2) is a nontrivial task, and plausible sufficient conditions for hyperbolicity may be incorrect. For example, it is claimed in [21] that when $A = I$, $B > 0$, and $C \geq 0$, Q is hyperbolic if $B > 2C^{1/2}$. That this claim is false has been shown by Barkwell and Lancaster [1].

Guo and Lancaster [9] propose testing overdamping by using a matrix iteration based on cyclic reduction to compute two solvents (solutions) of the quadratic matrix equation

$$Q(X) = AX^2 + BX + C = 0 \tag{1.4}$$

and then computing an extremal eigenvalue of each solvent. A definiteness test on Q evaluated at the average of the two extremal eigenvalues finally determines whether Q is overdamped. We show that the same iteration can be used to test overdamping in a much more efficient way that does not necessarily require the iteration to be run to convergence, even for a positive test result. Our test is based on a more complete understanding of the behavior of the matrix iteration, developed in section 3.

In section 4 we extend the convergence analysis to weakly overdamped quadratics, for which the strict inequality in (1.2) is replaced by a weak inequality ($\geq$). The key idea is to use an interpretation of the matrix iteration as a doubling algorithm. We show that for weakly overdamped Q with equality in (1.2) for some nonzero x, the iteration is linearly convergent with constant at worst $1/2$ in the generic case. A reasonable speed of convergence can therefore be expected in almost all practically important cases.

In section 5 we turn to algorithmic matters. We first show how a hyperbolic Q can be shifted to make it overdamped. Then we specify our test for overdamping, which

requires only the building blocks of Cholesky factorization, matrix multiplication, and the solution of triangular systems. We then show how after a successful test the eigensystem of an overdamped Q can be efficiently computed in a way that exploits the symmetry and definiteness and guarantees real computed eigenvalues.

Veselić [28] and Higham, Tisseur, and Van Dooren [19] have previously shown that every hyperbolic quadratic can be reformulated as a definite pencil $L(\lambda) = \lambda X + Y$ of twice the dimension, and this connection is explored in detail and in more generality by Higham, Mackey, and Tisseur [16]. However, the algorithm developed here is the first practical procedure for arranging that X or Y is a definite matrix and hence allowing symmetry and definiteness to be fully exploited.

Section 6 concludes the paper with a numerical experiment that provides further insight into the theory and algorithms.

2. Preliminaries. We first recall the definition of a definite pencil.

DEFINITION 2.1. *A Hermitian pencil $L(\lambda) = \lambda X + Y$ is definite (or, equivalently, the matrices X, Y form a definite pair) if $(z^*Xz)^2 + (z^*Yz)^2 > 0$ for all nonzero $z \in \mathbb{C}^n$.*

Definite pairs have the desirable properties that they are simultaneously diagonalizable under congruence and, in the associated eigenproblem $L(\lambda)x = 0$, the eigenvalues are real and semisimple.[1]

The next result gives three conditions each equivalent to the condition (1.2) in the definition of hyperbolic quadratic.

THEOREM 2.2. *Let the $n \times n$ quadratic $Q(\lambda) = \lambda^2 A + \lambda B + C$ be Hermitian with $A > 0$ and let*

$$\gamma = \min_{\|x\|_2=1} [(x^*Bx)^2 - 4(x^*Ax)(x^*Cx)]. \tag{2.1}$$

The following statements are equivalent:

(a) *Q is hyperbolic.*

(b) *$\gamma > 0$.*

(c) *$x^*Q(\lambda)x = 0$ has two distinct real zeros for all nonzero $x \in \mathbb{C}^n$.*

(d) *$Q(\mu) < 0$ for some $\mu \in \mathbb{R}$.*

Proof. (a) $\Leftrightarrow$ (b) $\Leftrightarrow$ (c) is immediate. (c) $\Leftrightarrow$ (d) follows from Markus [25, Lemma 31.15]. ∎

Hyperbolic quadratics have many interesting properties [25, section 31].

THEOREM 2.3. *Let the $n \times n$ quadratic $Q(\lambda) = \lambda^2 A + \lambda B + C$ be hyperbolic.*

(a) *The $2n$ eigenvalues of $Q(\lambda)$ are all real and semisimple.*

(b) *There is a gap between the n largest and n smallest eigenvalues, that is, the eigenvalues can be ordered $\lambda_1 \geq \cdots \geq \lambda_n > \lambda_{n+1} \geq \cdots \geq \lambda_{2n}$.*

(c) *$Q(\mu) < 0$ for all $\mu \in (\lambda_{n+1}, \lambda_n)$ and $Q(\mu) > 0$ for all $\mu \in (-\infty, \lambda_{2n}) \cup (\lambda_1, \infty)$.*

(d) *There are n linearly independent eigenvectors associated with the n largest eigenvalues and likewise for the n smallest eigenvalues.*

(e) *The quadratic matrix equation $Q(X) = 0$ in (1.4) has a solvent $S^{(1)}$ with eigenvalues $\lambda_1, \ldots, \lambda_n$ and a solvent $S^{(2)}$ with eigenvalues $\lambda_{n+1}, \ldots, \lambda_{2n}$. Moreover,*

$$Q(\lambda) = \big(\lambda I - S^{(2)^*}\big) A (\lambda I - S^{(1)}) = \big(\lambda I - S^{(1)^*}\big) A (\lambda I - S^{(2)}).$$

The n largest eigenvalues of a hyperbolic quadratic are called the primary eigenvalues and the n smallest eigenvalues are the secondary eigenvalues. The solvents

[1] An eigenvalue of a matrix polynomial $P(\lambda) = \sum_{k=0}^{\ell} \lambda^k P_k$ is semisimple if it appears only in 1×1 Jordan blocks in a Jordan triple for P [7].

$S^{(1)}$ and $S^{(2)}$ having as their eigenvalues the primary eigenvalues and the secondary eigenvalues, respectively, are referred to as the *primary* and *secondary solvents*.

Hyperbolicity can also be defined for matrix polynomials P of arbitrary degree [25, section 31]. The notion has recently been extended in [16] by replacing the assumption of a positive definite leading coefficient matrix with $P(\omega) > 0$ for some $\omega \in \mathbb{R} \cup \{\infty\}$.

The next result gives some characterizations of an overdamped quadratic. First, we need a simple lemma.

LEMMA 2.4. *Let $Q(\lambda) = \lambda^2 A + \lambda B + C$ be Hermitian and let $\mu > 0$. Then $Q(-\mu) < 0$ if and only if $B > \mu A + \mu^{-1} C$.*

Proof. The proof is immediate from $Q(-\mu) = \mu^2 A - \mu B + C < 0 \Leftrightarrow \mu A - B + \mu^{-1} C < 0$. ∎

THEOREM 2.5. *Let $Q(\lambda) = \lambda^2 A + \lambda B + C$ be Hermitian with $A > 0$. Then the following statements are equivalent:*

(a) *$Q(\lambda)$ is overdamped.*

(b) *$Q(\lambda)$ is hyperbolic and all of its eigenvalues are real and nonpositive.*

(c) *$B > 0$, $C \geq 0$, and $B > \mu A + \mu^{-1} C$ for some $\mu > 0$.*

Proof. (a) $\Leftrightarrow$ (b) is proved in [9, Theorem 5]. (b) $\Rightarrow$ (c): By Theorem 2.3(c), $Q(\widetilde{\mu}) < 0$ for some $\widetilde{\mu} < 0$; (c) follows on invoking Lemma 2.4. (c) $\Rightarrow$ (a): $B > \mu A + \mu^{-1} C$ with $\mu > 0$ implies $Q(-\mu) < 0$ by Lemma 2.4, which implies Q is hyperbolic by Theorem 2.2(d) and hence overdamped since $B > 0$ and $C \geq 0$. ∎

It follows from (b) in Theorem 2.5 that if we know an upper bound, say, θ, on the largest eigenvalue λ_1 of a hyperbolic quadratic Q then, with $\lambda = \mu + \theta$, the quadratic Q_θ defined by

$$\begin{aligned} Q(\lambda) = Q(\mu + \theta) &= \mu^2 A + \mu(B + 2\theta A) + C + \theta B + \theta^2 A \\ &= \mu^2 A_\theta + \mu B_\theta + C_\theta \\ &=: Q_\theta(\mu) \end{aligned} \tag{2.2}$$

is overdamped. Thus any hyperbolic quadratic can be transformed into an overdamped quadratic by an appropriate shifting of the eigenvalues. Hence for the purposes of testing hyperbolicity and overdamping it suffices to consider overdamping. We make this restriction in the next two sections and consider in section 5 how to implement the shifting in practice.

3. An iteration for testing overdamping. Suppose we have a Hermitian quadratic $Q(\lambda) = \lambda^2 A + \lambda B + C$, where we assume throughout this section that $A > 0$, $B > 0$, and $C \geq 0$. The challenge is how to test the hyperbolicity (or, equivalently, the overdamping) condition (1.2) or, equivalently, condition (c) in Theorem 2.5.

The primary and secondary solvents $S^{(1)}$ and $S^{(2)}$ of an overdamped quadratic can be found efficiently by applying an iteration based on cyclic reduction [2], [9]. The iteration is

$$\begin{aligned} &S_0 = B, \quad A_0 = A, \quad B_0 = B, \quad C_0 = C, \\ &S_{k+1} = S_k - A_k B_k^{-1} C_k, \\ &A_{k+1} = A_k B_k^{-1} A_k, \\ &B_{k+1} = B_k - A_k B_k^{-1} C_k - C_k B_k^{-1} A_k, \\ &C_{k+1} = C_k B_k^{-1} C_k. \end{aligned} \tag{3.1}$$

The next theorem summarizes properties of the iteration proved in [9, Lemma 6, Theorem 7 and proof].

THEOREM 3.1. *Let $Q(\lambda) = \lambda^2 A + \lambda B + C$ be an $n \times n$ overdamped quadratic with eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n > \lambda_{n+1} \geq \cdots \geq \lambda_{2n}$. Consider iteration* (3.1) *and any matrix norm $\|\cdot\|$.*

(a) *The iterates satisfy $A_k > 0$, $C_k \geq 0$, and $B_k > 0$ for all $k \geq 0$.*

(b) *$\|A_k\|\,\|C_k\|$ converges quadratically to zero with*

$$\limsup_{k\to\infty} \sqrt[2^k]{\|A_k\|\,\|C_k\|} \leq \frac{\lambda_n}{\lambda_{n+1}} < 1.$$

(c) *S_k converges quadratically to a nonsingular matrix $\widehat{S}$ with*

$$\limsup_{k\to\infty} \sqrt[2^k]{\|S_k - \widehat{S}\|} \leq \frac{\lambda_n}{\lambda_{n+1}} < 1. \tag{3.2}$$

(d) *The primary and secondary solvents of $Q(X)$, $S^{(1)}$ and $S^{(2)}$, respectively, are given by*

$$S^{(1)} = -\widehat{S}^{-1}C, \quad S^{(2)} = -A^{-1}\widehat{S}^*. \tag{3.3}$$

The next lemma reveals a crucial property of iteration (3.1) for overdamped quadratics. The "only if" part of the result is [9, Lemma 6].

LEMMA 3.2. *Let $\mu > 0$ and assume $A_k > 0$ and $C_k \geq 0$. In* (3.1)*, $B_k > \mu^{2^k} A_k + \mu^{-2^k} C_k$ if and only if $A_{k+1} > 0$, $C_{k+1} \geq 0$, and $B_{k+1} > \mu^{2^{k+1}} A_{k+1} + \mu^{-2^{k+1}} C_{k+1}$.*

Proof. "$\Rightarrow$": We have

$$\begin{aligned} B_{k+1} &= B_k - A_k B_k^{-1} C_k - C_k B_k^{-1} A_k \\ &= B_k - \big(\mu^{2^k} A_k + \mu^{-2^k} C_k\big) B_k^{-1} \big(\mu^{2^k} A_k + \mu^{-2^k} C_k\big) \\ &\qquad + \mu^{2^{k+1}} A_k B_k^{-1} A_k + \mu^{-2^{k+1}} C_k B_k^{-1} C_k \\ &> \mu^{2^{k+1}} A_k B_k^{-1} A_k + \mu^{-2^{k+1}} C_k B_k^{-1} C_k, \end{aligned}$$

where we have used the fact that $X - YX^{-1}Y > Y - YY^{-1}Y = 0$ when $X > Y > 0$. Clearly, $A_{k+1} > 0$ and $C_{k+1} \geq 0$ since $B_k^{-1} > 0$.

"$\Leftarrow$": As in the first part we have

$$B_{k+1} = B_k - F_k B_k^{-1} F_k + F_{k+1}, \tag{3.4}$$

where $F_k = \mu^{2^k} A_k + \mu^{-2^k} C_k$. Now if $B_{k+1} > \mu^{2^{k+1}} A_{k+1} + \mu^{-2^{k+1}} C_{k+1} = F_{k+1}$ then (3.4) gives $B_k - F_k B_k^{-1} F_k > 0$. Note that $B_k - F_k B_k^{-1} F_k$ is the Schur complement of $B_k > 0$ in

$$T = \begin{bmatrix} B_k & F_k \\ F_k & B_k \end{bmatrix}.$$

So we have $T > 0$, and it follows that $B_k - F_k > 0$ (for example, by looking at the $(1,1)$ block of the congruence $\left[\begin{smallmatrix} I & -I \\ 0 & I \end{smallmatrix}\right] T \left[\begin{smallmatrix} I & 0 \\ -I & I \end{smallmatrix}\right]$). Therefore $B_k > F_k = \mu^{2^k} A_k + \mu^{-2^k} C_k$. ∎

In view of Theorem 2.5(c), Lemma 3.2 implies that Q is overdamped *if and only if* any one of the quadratics

$$Q_k(\lambda) = \lambda^2 A_k + \lambda B_k + C_k \tag{3.5}$$

generated during the iteration is overdamped, assuming that $A_k > 0$ and $C_k \geq 0$ for all k. Note that the latter assumption holds if $B_k > 0$ for all k.

COROLLARY 3.3. *Let Q be a Hermitian quadratic with $A, B > 0$ and $C \geq 0$. For iteration* (3.1) *and any fixed $m \geq 0$, if $B_k > 0$ for $k = 1\colon m-1$ and*

$$B_m > \mu^{2^m} A_m + \mu^{-2^m} C_m \tag{3.6}$$

for some $\mu > 0$, then $B > \mu A + \mu^{-1} C$ and Q is overdamped.

Intuitively, we can think of the scalars μ^{2^m} and μ^{-2^m} in (3.6) as trying to balance A_m and C_m. This suggests that (3.6) could be replaced by $B_m > \widetilde{A}_m + \widetilde{C}_m$ if the iteration is scaled so that $\widetilde{A}_m$ and $\widetilde{C}_m$ are balanced. Normwise balancing is included in the following scaled version of (3.1), introduced in [9]; it generates iterates $\widetilde{A}_k$, B_k (unchanged from (3.1)), and $\widetilde{C}_k$ according to

$$\begin{aligned}
&\alpha_0 = \sqrt{\|C\|/\|A\|},\\
&\widetilde{A}_0 = \alpha_0 A, \quad B_0 = B, \quad \widetilde{C}_0 = \alpha_0^{-1} C,\\
&A_{k+1} = \widetilde{A}_k B_k^{-1} \widetilde{A}_k,\\
&B_{k+1} = B_k - \widetilde{A}_k B_k^{-1} \widetilde{C}_k - \widetilde{C}_k B_k^{-1} \widetilde{A}_k,\\
&C_{k+1} = \widetilde{C}_k B_k^{-1} \widetilde{C}_k,\\
&\alpha_{k+1} = \sqrt{\|C_{k+1}\|/\|A_{k+1}\|},\\
&\widetilde{A}_{k+1} = \alpha_{k+1} A_{k+1}, \quad \widetilde{C}_{k+1} = \alpha_{k+1}^{-1} C_{k+1}.
\end{aligned} \tag{3.7}$$

Here we have assumed that $C \neq 0$ (the overdamping condition holds for the trivial case $C = 0$ by (1.2)); thus $\alpha_k > 0$ for each $k \geq 0$. The scaling procedure ensures that $\|\widetilde{A}_k\| = \|\widetilde{C}_k\|$ and $\|\widetilde{A}_k\|\,\|\widetilde{C}_k\| = \|A_k\|\,\|C_k\|$.

The next result describes the behavior of the scaled iteration.

THEOREM 3.4. *A Hermitian quadratic Q with $A, B > 0$ and $0 \neq C \geq 0$ is overdamped if and only if in* (3.7)

$$B_k > 0 \text{ for all } k, \quad \lim_{k\to\infty} \widetilde{A}_k = 0, \quad \lim_{k\to\infty} \widetilde{C}_k = 0, \quad \lim_{k\to\infty} B_k > 0, \tag{3.8}$$

and in this case

$$\limsup_{k\to\infty} \sqrt[2^k]{\|\widetilde{A}_k\|} = \limsup_{k\to\infty} \sqrt[2^k]{\|\widetilde{C}_k\|} \leq \left(\frac{\lambda_n}{\lambda_{n+1}}\right)^{1/2}, \tag{3.9}$$

$$\limsup_{k\to\infty} \sqrt[2^k]{\|B_k - \widehat{B}\|} \leq \frac{\lambda_n}{\lambda_{n+1}}, \tag{3.10}$$

with $\widehat{B} = A(S^{(1)} - S^{(2)})$.

Proof. Assume that the conditions in (3.8) hold. Then $B_m > \widetilde{A}_m + \widetilde{C}_m$ for some $m \geq 0$. It is easy to see that the iterates $\widetilde{A}_k$ and $\widetilde{C}_k$ defined in (3.7) are related to A_k and C_k in (3.1) by

$$\widetilde{A}_k = \alpha_0^{2^k} \alpha_1^{2^{k-1}} \dots \alpha_{k-1}^2 \alpha_k A_k, \quad \widetilde{C}_k = \alpha_0^{-2^k} \alpha_1^{-2^{k-1}} \dots \alpha_{k-1}^{-2} \alpha_k^{-1} C_k, \quad k \geq 0.$$

So $B_m > \widetilde{A}_m + \widetilde{C}_m$ implies $B_m > \mu^{2^m} A_m + \mu^{-2^m} C_m$ with $\mu = \alpha_0 \alpha_1^{2^{-1}} \alpha_2^{2^{-2}} \dots \alpha_m^{2^{-m}}$, which implies Q is overdamped by Corollary 3.3.

TABLE 3.1
Number of iterations m to verify that the quadratic defined by (3.11) *is overdamped.*

β	1	0.62	0.61	0.53	0.52	0.5197	0.519616	0.51961525	0.5196152423
m	0	0	1	1	2	3	5	8	12

TABLE 3.2
Number of iterations m to verify that the quadratic defined by (3.11) *is* not *overdamped.*

β	0.36	0.47	0.50	0.51	0.5196	0.519615	0.51961524	0.5196152422
m	1	2	3	4	8	11	15	17

Now assume the QEP is overdamped. Then, from Theorem 3.1(a), $B_k > 0$ for each $k \geq 0$, while, since $\|\widetilde{A}_k\| = \|\widetilde{C}_k\| = (\|A_k\|\|C_k\|)^{1/2}$, Theorem 3.1(b) implies $\lim \widetilde{A}_k = \lim \widetilde{C}_k = 0$ and that (3.9) holds. To show the convergence of B_k, we note that from (3.1), $B_{k+1} = B_k - (S_k - S_{k+1}) - (S_k - S_{k+1})^*$, which implies

$$B_k = B_0 - (S_0 - S_k) - (S_0 - S_k)^* = -B + S_k + S_k^*.$$

In view of (3.2), (3.3), and $B_k > 0$, (3.10) holds with $\widehat{B} = -B + \widehat{S} + \widehat{S}^* = A(S^{(1)} - S^{(2)}) \geq 0$. Since the sequence $\{\|B_k^{-1}\|\}$ is known to be bounded (see the proof of [9, Theorem 7]), we have $\widehat{B} > 0$. ∎

The next result confirms that μ can be removed from (3.6) for the scaled iteration. It follows readily from Theorem 3.4 and its proof.

COROLLARY 3.5. *A Hermitian quadratic Q with $A, B > 0$ and $0 \neq C \geq 0$ is overdamped if and only if, for some $m \geq 0$, $B_k > 0$ for $k = 1\colon m-1$ in* (3.7) *and $B_m > \widetilde{A}_m + \widetilde{C}_m$.*

The corollary is important for two reasons. First, it provides a basis for an elegant, practical test for overdamping, as definiteness of a matrix is easily tested numerically. Second, in the case of an affirmative test result a μ with $Q(-\mu) < 0$ can be identified, and such a μ is very useful when we go on to solve the QEP, as we will show in section 5.

From a numerical point of view it is preferable to work with the original data as much as possible. The following variant of Corollary 3.5 tests the overdamping condition using the original quadratic Q and will be the basis of the algorithm in section 5. It follows readily from Corollary 3.3 and Theorem 3.4 and its proof.

COROLLARY 3.6. *A Hermitian quadratic Q with $A, B > 0$ and $0 \neq C \geq 0$ is overdamped if and only if, for some $m \geq 0$, $B_k > 0$ for $k = 1\colon m-1$ in* (3.7) *and $Q(-\mu_m) < 0$, where $\mu_m = \alpha_0 \alpha_1^{2^{-1}} \alpha_2^{2^{-2}} \cdots \alpha_m^{2^{-m}} > 0$ and the α_k are defined in* (3.7).

Usually, only a few iterations of the cyclic reduction algorithm (3.7) will be necessary. To illustrate, we consider a quadratic $Q(\lambda)$ of dimension $n = 100$ defined by

$$(3.11)\quad A = I,\ B = \beta \begin{bmatrix} 20 & -10 & & & \\ -10 & 30 & \ddots & & \\ & \ddots & \ddots & \ddots & \\ & & \ddots & 30 & -10 \\ & & & -10 & 20 \end{bmatrix},\ C = \begin{bmatrix} 15 & -5 & & \\ -5 & 15 & \ddots & \\ & \ddots & \ddots & -5 \\ & & -5 & 15 \end{bmatrix},$$

where $\beta > 0$ is a real parameter. This example, which comes from a damped mass-spring system, is used in [13] with $\beta = 1$. We use the 1-norm in (3.7). Tables 3.1 and 3.2 report the number of iterations required to demonstrate that Q is over-

damped, through verification of the conditions in Corollary 3.6, or that it is not overdamped, through generation of a non-positive definite iterate B_m. Note that when Q is "strongly" overdamped and when Q is far from being overdamped, the overdamping condition is shown to hold or not after just a few iterations.

4. Convergence analysis for weakly overdamped quadratics. For the example at the end of section 3 and some $\beta_0 \in (0.5196152422, 0.5196152423)$, the inequality (1.2) holds as a weak inequality with equality attained for some nonzero x. We have seen that the overdamping test requires a very small number of iterations when β is not close to β_0. When $\beta \approx \beta_0$, the number of iterations increases but is still under 20 in our experiments. The purpose of this section is to explain this behavior by showing that the convergence of iteration (3.1) is reasonably fast even when the QEP is weakly overdamped in the sense defined as follows.

DEFINITION 4.1. *$Q(\lambda)$ is weakly hyperbolic if A, B, and C are Hermitian, $A > 0$, and*

$$\gamma = \min_{\|x\|_2=1} [(x^*Bx)^2 - 4(x^*Ax)(x^*Cx)] \geq 0. \tag{4.1}$$

DEFINITION 4.2. *$Q(\lambda)$ is weakly overdamped if it is weakly hyperbolic with $B > 0$ and $C \geq 0$.*

The eigenvalues of a weakly hyperbolic Q are real and those of a weakly overdamped Q are real and nonpositive. The following result collects further properties of a weakly overdamped quadratic [25, section 31].

THEOREM 4.3. *Let $Q(\lambda) = \lambda^2 A + \lambda B + C$ be a weakly overdamped $n \times n$ quadratic.*

(a) *If $\gamma = 0$ in (4.1), then $Q(\lambda)$ has $2n$ real eigenvalues that can be ordered $\lambda_1 \geq \cdots \geq \lambda_n = \lambda_{n+1} \geq \cdots \geq \lambda_{2n}$. The partial multiplicities[2] of λ_n are at most 2, and the eigenvalues other than λ_n are semisimple.*

(b) *$Q(\lambda_n) \leq 0$.*

(c) *The quadratic matrix equation $Q(X) = 0$ in (1.4) has a solvent $S^{(1)}$ with eigenvalues $\lambda_1, \ldots, \lambda_n$ and a solvent $S^{(2)}$ with eigenvalues $\lambda_{n+1}, \ldots, \lambda_{2n}$.*

In the overdamped case considered in the previous section, convergence results for the iteration (3.1) are established using matrix identities obtained from the cyclic reduction method. Those identities do not contain enough information about (3.1) to allow a proof of convergence for weakly overdamped quadratics with $\gamma = 0$, for which $\lambda_{n+1} = \lambda_n$. We now study this critical case and thereby obtain a better understanding of the convergence of the iteration for overdamped QEPs with $\lambda_n \approx \lambda_{n+1}$. The next lemma shows that (3.1) remains well defined in the critical case, which is the setting for the rest of this section.

LEMMA 4.4. *For a weakly overdamped quadratic $Q(\lambda) = \lambda^2 A + \lambda B + C$ with $\gamma = 0$ in (4.1), there is a positive real number μ such that for the iteration (3.1)*

$$A_k > 0, \quad C_k \geq 0, \quad B_k \geq \mu^{2^k} A_k + \mu^{-2^k} C_k \tag{4.2}$$

for all $k \geq 0$.

Proof. We have $\lambda_n \leq \lambda_1 \leq 0$. If $\lambda_n = 0$ then, from Theorem 4.3, $C = Q(\lambda_n) \leq 0$. Since $C \geq 0$ we must have $C = 0$. However, $\gamma > 0$ for the trivial case $C = 0$. Therefore $\lambda_n < 0$ since $\gamma = 0$. It then follows from $Q(\lambda_n) \leq 0$ that $B \geq \mu A + \mu^{-1} C$

[2]The partial multiplicities of an eigenvalue of Q are the sizes of the Jordan blocks in which it appears in a Jordan triple for Q [7].

for $\mu = -\lambda_n > 0$. The inequalities in (4.2) are then proved inductively using the technique from the proof of the first part of Lemma 3.2. ∎

Lin and Xu [24] recently showed that Meini's iterations based on cyclic reduction for the matrix equation $X + A^*X^{-1}A = Q$ [26] can also be derived from a structure-preserving doubling algorithm. Following their approach we show that the iteration (3.1) is related to a doubling algorithm, and we use this observation to study the convergence of (3.1) for weakly overdamped quadratics. The rate of convergence will be shown to be at least linear with constant 1/2 in the generic case, which is the case where $\lambda_n = \lambda_{n+1}$ is a multiple eigenvalue with partial multiplicities all equal to 2 (that is, λ_n occurs only in 2×2 Jordan blocks). This rate and constant are to be expected in view of the results of Guo in [8].

LEMMA 4.5. *Let* $X = \left[\begin{smallmatrix} A & 0 \\ H & -I \end{smallmatrix}\right]$ *and* $Y = \left[\begin{smallmatrix} G & I \\ C & 0 \end{smallmatrix}\right]$ *be block* 2×2 *matrices with* $n \times n$ *blocks. When* $H + G$ *is nonsingular there exist* $2n \times 2n$ *matrices* $\widetilde{X}$ *and* $\widetilde{Y}$ *such that* (a) $\widetilde{X}Y = \widetilde{Y}X$ *and* (b) $\widetilde{X}X$, $\widetilde{Y}Y$ *have the same zero and identity blocks as* X *and* Y, *respectively.*

Proof. Applying block row permutations and block Gaussian elimination to $\left[\begin{smallmatrix} X \\ Y \end{smallmatrix}\right]$ yields $P\left[\begin{smallmatrix} X \\ Y \end{smallmatrix}\right] = \left[\begin{smallmatrix} U \\ 0 \end{smallmatrix}\right]$, where $U = \left[\begin{smallmatrix} G & I \\ G+H & 0 \end{smallmatrix}\right]$ and

$$P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix} = \left[\begin{array}{cc|cc} 0 & 0 & I & 0 \\ 0 & I & I & 0 \\ \hline I & -A(G+H)^{-1} & -A(G+H)^{-1} & 0 \\ 0 & C(G+H)^{-1} & C(G+H)^{-1} & -I \end{array}\right].$$

Since $\left[\begin{smallmatrix} P_{21} & P_{22} \end{smallmatrix}\right]\left[\begin{smallmatrix} X \\ Y \end{smallmatrix}\right] = 0$, the required equality $\widetilde{Y}X = \widetilde{X}Y$ is satisfied with $\widetilde{X} := -P_{22}$ and $\widetilde{Y} := P_{21}$. Furthermore,

$$\widetilde{X}X = \begin{bmatrix} A(G+H)^{-1}A & 0 \\ H - C(G+H)^{-1}A & -I \end{bmatrix}, \qquad \widetilde{Y}Y = \begin{bmatrix} G - A(G+H)^{-1}C & I \\ C(G+H)^{-1}C & 0 \end{bmatrix}. \qquad \blacksquare$$

Lemma 4.5 and its proof suggest the recurrence

$$X_{k+1} = \widetilde{X}_k X_k, \quad Y_{k+1} = \widetilde{Y}_k Y_k, \qquad k \geq 0, \tag{4.3}$$

with

$$X_k = \begin{bmatrix} A_k & 0 \\ H_k & -I \end{bmatrix}, \quad Y_k = \begin{bmatrix} G_k & I \\ C_k & 0 \end{bmatrix} \tag{4.4}$$

and

$$\widetilde{X}_k = \begin{bmatrix} A_k(G_k+H_k)^{-1} & 0 \\ -C_k(G_k+H_k)^{-1} & I \end{bmatrix}, \quad \widetilde{Y}_k = \begin{bmatrix} I & -A_k(G_k+H_k)^{-1} \\ 0 & C_k(G_k+H_k)^{-1} \end{bmatrix},$$

which leads to

$$\begin{aligned} A_{k+1} &= A_k(G_k+H_k)^{-1}A_k, \\ G_{k+1} &= G_k - A_k(G_k+H_k)^{-1}C_k, \\ H_{k+1} &= H_k - C_k(G_k+H_k)^{-1}A_k, \\ C_{k+1} &= C_k(G_k+H_k)^{-1}C_k. \end{aligned} \tag{4.5}$$

With

$$A_0 = A, \quad C_0 = C, \quad G_0 = 0, \quad H_0 = B, \tag{4.6}$$

the iteration (3.1) is recovered from (4.5) by letting $B_k = G_k + H_k$ and $S_k = H_k^*$. By Lemma 4.4, $B_k > 0$ for all $k \geq 0$. Therefore with the starting matrices (4.6), iteration (4.5) is well defined. Note that X_k in (4.4) is nonsingular for all $k \geq 0$ and, from (4.3) and the property that $\widetilde{X}_k Y_k = \widetilde{Y}_k X_k$,

$$X_{k+1}^{-1} Y_{k+1} = (\widetilde{X}_k X_k)^{-1} \widetilde{Y}_k Y_k = X_k^{-1} \widetilde{X}_k^{-1} \widetilde{Y}_k Y_k = X_k^{-1} Y_k X_k^{-1} Y_k = (X_k^{-1} Y_k)^2. \tag{4.7}$$

It follows from (4.7) that for all $k \geq 0$,

$$X_k^{-1} Y_k = \left(X_0^{-1} Y_0\right)^{2^k}. \tag{4.8}$$

The identity (4.8) is what we need to prove the convergence of (4.5) with (4.6) and hence the convergence of (3.1).

The next result describes the convergence behavior in the generic case.

THEOREM 4.6. *Let $Q(\lambda)$ be weakly overdamped with eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n = \lambda_{n+1} \geq \cdots \geq \lambda_{2n}$, and assume that the partial multiplicities of λ_n are all equal to 2. Let $S^{(1)}$ and $S^{(2)}$ be the primary and secondary solvents of $Q(X) = 0$, respectively, and assume that λ_n is a semisimple eigenvalue of $S^{(1)}$ and $S^{(2)}$. Then the iterates G_k, H_k, A_k, and C_k defined by* (4.5) *and* (4.6) *satisfy*

$$\limsup_{k\to\infty} \sqrt[k]{\|G_k - AS^{(1)}\|} \leq \frac{1}{2}, \quad \limsup_{k\to\infty} \sqrt[k]{\|H_k + AS^{(2)}\|} \leq \frac{1}{2},$$
$$\limsup_{k\to\infty} \sqrt[k]{\|A_k\|\|C_k\|} \leq \frac{1}{4}.$$

Proof. We start by making the change of variables (or scaling) $\lambda = \mu\theta$, where $\theta = |\lambda_n| > 0$ (see the proof of Lemma 4.4) so that $\mu_n = \mu_{n+1} = -1$, and we define $\widehat{Q}(\mu) = \mu^2 \widehat{A} + \mu \widehat{B} + \widehat{C}$ with $(\widehat{A}, \widehat{B}, \widehat{C}) = (\theta A, B, \theta^{-1} C)$. For this triple denote the iterates of (4.5) by $\widehat{A}_k$, $\widehat{G}_k$, $\widehat{H}_k$, and $\widehat{C}_k$. It is easy to see that for all $k \geq 0$, $\widehat{G}_k = G_k$, $\widehat{H}_k = H_k$, $\widehat{A}_k = \theta^{2^k} A_k$, and $\widehat{C}_k = \theta^{-2^k} C_k$ so that $\|A_k\|\,\|C_k\| = \|\widehat{A}_k\|\,\|\widehat{C}_k\|$. The primary and secondary solvents of $\widehat{A}S^2 + \widehat{B}S + \widehat{C} = 0$ are $\widehat{S}^{(1)} = \theta^{-1} S^{(1)}$ and $\widehat{S}^{(2)} = \theta^{-1} S^{(2)}$, respectively. Note that $\widehat{A}\widehat{S}^{(i)} = AS^{(i)}$, $i = 1, 2$. To avoid notational clutter, we omit the hats on matrices in the rest of the proof.

We now consider the iterations for the block 2×2 matrices X_k and Y_k in (4.4). With $A_0 = A$, $C_0 = C$, $G_0 = 0$, and $H_0 = B$, the pencil

$$\mu X_0 + Y_0 = \mu \begin{bmatrix} A & 0 \\ B & -I_n \end{bmatrix} + \begin{bmatrix} 0 & I_n \\ C & 0 \end{bmatrix} \tag{4.9}$$

is a linearization of $Q(\mu)$ [7]. Hence $-X_0^{-1} Y_0$ and $Q(\mu)$ have the same eigenvalues, with the same partial multiplicities. Suppose there are r 2×2 Jordan blocks associated with eigenvalues equal to $\mu_n = -1$, where $r \geq 1$ by assumption. Rearranging the Jordan canonical form of $X_0^{-1} Y_0$ appropriately yields

$$V^{-1}(X_0^{-1} Y_0) V = \begin{bmatrix} D_2 \oplus I_r & 0 \oplus I_r \\ 0 & D_1 \oplus I_r \end{bmatrix} =: D_V, \tag{4.10}$$

$$W^{-1}(X_0^{-1} Y_0) W = \begin{bmatrix} D_2 \oplus I_r & 0 \\ 0 \oplus I_r & D_1 \oplus I_r \end{bmatrix} =: D_W, \tag{4.11}$$

where V and W are nonsingular, D_1 and D_2 are $(n-r) \times (n-r)$ diagonal matrices containing the (semisimple) eigenvalues less than 1 and greater than 1 in modulus,

respectively, and $M \oplus N$ denotes $\left[\begin{smallmatrix} M & 0 \\ 0 & N \end{smallmatrix}\right]$. Now partition V and W as block 2×2 matrices with $n \times n$ blocks

$$V = \begin{bmatrix} V_1 & V_3 \\ V_2 & V_4 \end{bmatrix}, \qquad W = \begin{bmatrix} W_1 & W_3 \\ W_2 & W_4 \end{bmatrix},$$

and note from (4.10)–(4.11) that

$$X_0^{-1}Y_0 \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} (D_2 \oplus I_r), \qquad X_0^{-1}Y_0 \begin{bmatrix} W_3 \\ W_4 \end{bmatrix} = \begin{bmatrix} W_3 \\ W_4 \end{bmatrix} (D_1 \oplus I_r). \tag{4.12}$$

By Theorem 4.3 and our assumption on $S^{(1)}$ and $S^{(2)}$ there exist nonsingular U_1 and U_2 such that

$$-S^{(1)} = U_1(D_1 \oplus I_r)U_1^{-1}, \qquad -S^{(2)} = U_2(D_2 \oplus I_r)U_2^{-1}. \tag{4.13}$$

Since $S^{(i)}$, $i = 1, 2$, is a solution of $Q(X) = 0$, from (4.9) we obtain

$$X_0^{-1}Y_0 \begin{bmatrix} I_n \\ -AS^{(i)} \end{bmatrix} = \begin{bmatrix} I_n \\ -AS^{(i)} \end{bmatrix} (-S^{(i)}), \quad i = 1, 2.$$

On comparing with the invariant subspaces in (4.12) and using (4.13) we deduce that

$$\begin{bmatrix} V_1 \\ V_2 \end{bmatrix} = \begin{bmatrix} U_2 \\ -AS^{(2)}U_2 \end{bmatrix} Z_1, \qquad \begin{bmatrix} W_3 \\ W_4 \end{bmatrix} = \begin{bmatrix} U_1 \\ -AS^{(1)}U_1 \end{bmatrix} Z_2,$$

with Z_1 and Z_2 nonsingular, where we have also used the fact that there are exactly r eigenvectors of $X_0^{-1}Y_0$ corresponding to the eigenvalue 1. Hence V_1 and W_3 are nonsingular and

$$-AS^{(2)} = V_2V_1^{-1}, \quad -AS^{(1)} = W_4W_3^{-1}. \tag{4.14}$$

By (4.8)–(4.11) we have $V^{-1}(X_k^{-1}Y_k)V = D_V^{2^k}$ and $W^{-1}(X_k^{-1}Y_k)W = D_W^{2^k}$, so that

$$Y_kV = X_kVD_V^{2^k}, \quad Y_kW = X_kWD_W^{2^k}. \tag{4.15}$$

On equating blocks using (4.4) this yields

$$G_kV_1 + V_2 = A_kV_1(D_2^{2^k} \oplus I_r), \tag{4.16}$$

$$G_kV_3 + V_4 = A_kV_1(0 \oplus 2^kI_r) + A_kV_3(D_1^{2^k} \oplus I_r), \tag{4.17}$$

$$C_kV_1 = (H_kV_1 - V_2)(D_2^{2^k} \oplus I_r), \tag{4.18}$$

$$C_kV_3 = (H_kV_1 - V_2)(0 \oplus 2^kI_r) + (H_kV_3 - V_4)(D_1^{2^k} \oplus I_r) \tag{4.19}$$

and

$$G_kW_1 + W_2 = A_kW_1(D_2^{2^k} \oplus I_r) + A_kW_3(0 \oplus 2^kI_r), \tag{4.20}$$

$$G_kW_3 + W_4 = A_kW_3(D_1^{2^k} \oplus I_r), \tag{4.21}$$

$$C_kW_1 = (H_kW_1 - W_2)(D_2^{2^k} \oplus I_r) + (H_kW_3 - W_4)(0 \oplus 2^kI_r), \tag{4.22}$$

$$C_kW_3 = (H_kW_3 - W_4)(D_1^{2^k} \oplus I_r). \tag{4.23}$$

By (4.22) and (4.23) we have

$$C_k(W_3 - W_1(0 \oplus 2^{-k} I_r)) = (H_k W_3 - W_4)(D_1^{2^k} \oplus 0) - (H_k W_1 - W_2)(0 \oplus 2^{-k} I_r). \tag{4.24}$$

By (4.18) we have

$$H_k = V_2 V_1^{-1} + C_k V_1 (D_2^{-2^k} \oplus I_r) V_1^{-1}. \tag{4.25}$$

Inserting (4.25) in (4.24) we obtain

$$\begin{aligned} C_k \Big(W_3 - W_1(0 \oplus 2^{-k} I_r) - V_1 (D_2^{-2^k} \oplus I_r) V_1^{-1} \big(W_3 (D_1^{2^k} \oplus 0) - W_1 (0 \oplus 2^{-k} I_r) \big) \Big) \\ = (V_2 V_1^{-1} W_3 - W_4)(D_1^{2^k} \oplus 0) - (V_2 V_1^{-1} W_1 - W_2)(0 \oplus 2^{-k} I_r), \end{aligned}$$

from which it follows, since D_1 and D_2 are diagonal with diagonal elements of magnitude less than 1 and greater than 1, respectively, that

$$C_k = O(2^{-k}); \tag{4.26}$$

the latter notation means that $\|C_k\| = O(2^{-k})$. It then follows from (4.25) and (4.14) that

$$H_k + AS^{(2)} = H_k - V_2 V_1^{-1} = O(2^{-k}). \tag{4.27}$$

By (4.20) and (4.21),

$$G_k W_3 + W_4 - (G_k W_1 + W_2)(0 \oplus 2^{-k} I_r) = A_k (W_3 (D_1^{2^k} \oplus 0) - W_1 (0 \oplus 2^{-k} I_r)). \tag{4.28}$$

By (4.16),

$$A_k = (G_k V_1 + V_2)(D_2^{-2^k} \oplus I_r) V_1^{-1}. \tag{4.29}$$

Inserting (4.29) in (4.28) we obtain

$$G_k W_3 + W_4 - (G_k W_1 + W_2)(0 \oplus 2^{-k} I_r) = (G_k V_1 + V_2) M_k,$$

with $M_k = O(2^{-k})$. Thus

$$-G_k \big(W_3 - W_1 (0 \oplus 2^{-k} I_r) - V_1 M_k \big) = W_4 - W_2 (0 \oplus 2^{-k} I_r) - V_2 M_k.$$

It follows from (4.14) that

$$G_k - AS^{(1)} = G_k + W_4 W_3^{-1} = O(2^{-k}). \tag{4.30}$$

Postmultiplying (4.16) by $D_2^{-2^k} \oplus 0$ gives

$$(G_k V_1 + V_2)(D_2^{-2^k} \oplus 0) = A_k V_1 (I_r \oplus 0), \tag{4.31}$$

while postmultiplying (4.17) by $0 \oplus 2^{-k} I_r$ gives

$$(G_k V_3 + V_4)(0 \oplus 2^{-k} I_r) = A_k V_1 (0 \oplus I_r) + A_k V_3 (0 \oplus 2^{-k} I_r). \tag{4.32}$$

Adding (4.31) and (4.32) we get

$$A_k (V_1 + V_3 (0 \oplus 2^{-k} I_r)) = (G_k V_1 + V_2)(D_2^{-2^k} \oplus 0) + (G_k V_3 + V_4)(0 \oplus 2^{-k} I_r).$$

It follows that

$$A_k = O(2^{-k}), \tag{4.33}$$

since $\{G_k\}$ has been shown to be bounded. Equations (4.26), (4.27), (4.30), and (4.33) yield the required convergence results. ∎

For S_k and B_k in iteration (3.1) we obtain the following convergence result.

COROLLARY 4.7. *Under the conditions of Theorem* 4.6*, the iterates* S_k *and* B_k *in* (3.1) *satisfy*

$$\limsup_{k\to\infty} \sqrt[k]{\|S_k - \widehat{S}\|} \le \frac{1}{2}, \qquad \limsup_{k\to\infty} \sqrt[k]{\|B_k - \widehat{B}\|} \le \frac{1}{2},$$

where $\widehat{S} = -S^{(2)^*}A$ *is nonsingular and* $\widehat{B} = A(S^{(1)} - S^{(2)}) \ge 0$ *is singular.*

Proof. The convergence results follow from Theorem 4.6 by noting $B_k = H_k + G_k$ and $S_k = H_k^*$. By (4.27) and (4.30), $\widehat{B} = A(S^{(1)} - S^{(2)})$. We have $\widehat{B} \ge 0$ since $B_k > 0$ for each k, by Lemma 4.4. We now show that $\widehat{B}$ is singular. Using (4.9) it is easy to check that

$$(-X_0^{-1}Y_0)\begin{bmatrix} I & I \\ -AS^{(1)} & -AS^{(2)} \end{bmatrix} = \begin{bmatrix} I & I \\ -AS^{(1)} & -AS^{(2)} \end{bmatrix}(S^{(1)} \oplus S^{(2)}), \tag{4.34}$$

and $S^{(1)} \oplus S^{(2)}$ is diagonalizable. Now $-X_0^{-1}Y_0$ is not diagonalizable, by assumption, since it has at least one eigenvalue of partial multiplicity 2. Thus (4.34) can only hold if $\left[\begin{smallmatrix} I & I \\ -AS^{(1)} & -AS^{(2)} \end{smallmatrix}\right]$ is singular. Thus the Schur complement $\widehat{B} = A(S^{(1)} - S^{(2)})$ is singular. ∎

In the generic case for a weakly overdamped Q with $\gamma = 0$, in which all of the partial multiplicities of λ_n are 2, Q is in some sense irreducible or coupled. The next example shows that this condition is necessary for the conclusions in Theorem 4.6 and Corollary 4.7 (and at the same time answers an open question from [9, section 4]). Consider

$$Q(\lambda) = \lambda^2 A + \lambda B + C = \lambda^2 \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + \lambda \begin{bmatrix} 3 & 0 \\ 0 & 1 \end{bmatrix} + \begin{bmatrix} 2 & 0 \\ 0 & 0 \end{bmatrix}.$$

It is easy to see that $\gamma = 0$, so $Q(\lambda)$ is weakly overdamped with eigenvalues $\{0, -1, -1, -2\}$ with $\lambda_2 = \lambda_3 = -1$ semisimple. In (3.1) and (4.5), (4.6),

$$\lim_{k\to\infty} A_k = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad \lim_{k\to\infty} B_k = I_2, \quad \lim_{k\to\infty} C_k = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix},$$
$$\lim_{k\to\infty} G_k = \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix}, \quad \lim_{k\to\infty} H_k = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}.$$

Neither A_k nor C_k converges to zero. We also note that the convergence is quadratic for B_k, G_k, and H_k. Moreover, B_k converges to a nonsingular matrix. This does not come as a surprise, since $Q(\lambda)$ can be decomposed into the direct sum of two scalar quadratics

$$Q_1(\lambda) = \lambda^2 + 3\lambda + 2, \qquad Q_2(\lambda) = \lambda^2 + \lambda.$$

It is readily seen that Q_1 is overdamped with eigenvalues $-1, -2$ and that Q_2 is overdamped with eigenvalues $0, -1$. Thus the convergence of B_k to a positive definite matrix is guaranteed by Theorem 3.4 applied to each component of the direct sum.

5. Algorithm for the detection and numerical solution. Let $Q(\lambda) = \lambda^2 A + \lambda B + C$ be Hermitian with $A > 0$. We develop in this section an efficient algorithm that checks if Q is hyperbolic and, if it is, computes some or all of the eigenvalues and associated eigenvectors, exploiting the symmetry and hyperbolicity and thereby preserving the spectral properties.

Our algorithm consists of three steps:

1. *Preprocessing.* This step forms $Q_\theta(\lambda) \equiv Q(\lambda + \theta) = \lambda^2 A_\theta + \lambda B_\theta + C_\theta$ with θ such that $B_\theta > 0$ and $C_\theta \geq 0$ or concludes that Q is not hyperbolic and terminates the algorithm.
2. *Overdamping test.* This step checks the overdamping condition for Q_θ. If Q_θ is overdamped, a $\mu \in \mathbb{R}$ such that $Q_\theta(\mu) = Q(\mu + \theta) < 0$ is also computed; otherwise the algorithm terminates.
3. *Solution.* The quadratic Q_θ is converted into a definite pencil $\lambda X + Y \in \mathbb{C}^{2n\times 2n}$ with $X > 0$ or $Y > 0$. The eigenvalues and eigenvectors of $Q(\lambda)$ are then obtained from the eigendecomposition of a $2n \times 2n$ Hermitian matrix obtained by transforming $\lambda X + Y$ and exploiting the definiteness of X or Y and the block structure of X and Y.

We now detail each of these three steps and compare the cost and stability of our solution process with that of three alternative ways of solving the QEP: The QZ algorithm applied to a linearization of $Q(\lambda)$, the J-orthogonal Jacobi algorithm [28] also applied to a linearization of $Q(\lambda)$, and the method of computing the eigenpairs of the primary and secondary solvents obtained via the cyclic reduction method [9].

At different stages our algorithm needs to test the (semi)definiteness of a matrix. This is done by attempting a Cholesky factorization, with complete pivoting in the case of semidefinitiness: Completion of the factorization means the matrix is (semi)definite. This is a numerically stable test, as shown in [10].

5.1. Preprocessing step. The preprocessing step aims to eliminate, by simple tests, quadratics that are not hyperbolic and to produce, if possible, a shifted quadratic $Q_\theta(\lambda) = Q(\lambda+\theta)$ (with $\theta = 0$ is possible) for which the necessary condition

$$B > 0, \quad C \geq 0 \tag{5.1}$$

for overdamping is satisfied.

If B is singular then, by (1.2), Q cannot be hyperbolic. Assume now that B is nonsingular but not positive definite or C is not positive semidefinite. Since $A > 0$, for $\theta > 0$ large enough the matrices

$$B_\theta = B + 2\theta A, \quad C_\theta = C + \theta B + \theta^2 A$$

defining the shifted quadratic $Q_\theta(\lambda) = Q(\lambda+\theta)$ with $A_\theta = A$ (see (2.2)) satisfy (5.1). To avoid numerical instability in the formation of B_θ and C_θ (due to the possibly large variation in $\|A\|$, $\|B\|$, and $\|C\|$) we would ideally like to choose θ close to

$$\theta_{\mathrm{opt}} = \inf\{\theta \in \mathbb{R} : \ B + 2\theta A > 0, \ C + \theta B + \theta^2 A \geq 0\}.$$

Rather than solving this optimization problem we choose θ to be an upper bound on the modulus of λ_1, the right-most eigenvalue of Q. With such a shift, all of the eigenvalues of Q_θ lie in the left half plane. When Q is hyperbolic, Q_θ is also hyperbolic with real and nonpositive eigenvalues. Thus $B_\theta > 0$ and $C_\theta \geq 0$ by Theorem 2.5. Therefore if $B_\theta \not> 0$ or $C_\theta \not\geq 0$ we can conclude that Q is not hyperbolic. If $B_\theta > 0$ and $C_\theta \geq 0$ we proceed to step 2.

TABLE 5.1
Operation count for the preprocessing step. Matrices are assumed real and of dimension n.

Operations		Cost (flops)
Cholesky factorization of B and C to check definiteness.		$2n^3/3$ or less
Computation of θ when B and/or C not positive definite:		
Cholesky factorization of A.		$n^3/3$
$\|A^{-1}\|$ (1-norm estimation [11, section 15.3], typically 4 solves).		$4n^2$
Form $B_\theta = B + 2\theta A$, $C_\theta = C + \theta B + \theta^2 A$.		$6n^2$
Cholesky factorizations of B_θ and C_θ.		$2n^3/3$ or less
	Total	$5n^3/3$ or less

To construct the shift θ we use the following strategy: let

$$a = \|A\|, \quad b = \|B\|, \quad c = \|C\|,$$

where $\|\cdot\|$ is any consistent matrix norm. Then, from [18, Lemmas 3.1 and 4.1], for every eigenvalue λ of Q we have

$$|\lambda| \le \frac{1}{2}\|A^{-1}\|\left(b + \sqrt{b^2 + 4c/\|A^{-1}\|}\right) =: \sigma_1, \tag{5.2}$$

$$|\lambda| \le \left(1 + \|A^{-1}\|\right)\max(c^{1/2}, b) =: \sigma_2. \tag{5.3}$$

We take the 1-norm and set $\sigma = \min(\sigma_1, \sigma_2)$. Since σ must greatly overestimate $|\lambda_1|$ when $|\lambda_n| \gg |\lambda_1|$, we carry on one step further and form the shifted quadratic $Q_{-\sigma/2}(\lambda) = Q(\lambda - \sigma/2)$ for which (5.2)–(5.3) give two new bounds τ_1 and τ_2 (and A is unchanged, so $\|A^{-1}\|$ can be reused). We then take $\theta = \min(\sigma, \tau - \frac{1}{2}\sigma)$, where $\tau = \min(\tau_1, \tau_2)$.

As shown by Theorem 3.4, the speed of convergence of iteration (3.7) for overdamped Q depends on the ratio λ_n/λ_{n+1}. An unnecessarily large shift of the spectrum to the left can make this ratio very close to 1, potentially causing slow convergence of the iteration. However, we showed in section 4 that for the generic case of weakly overdamped Q with $\lambda_n = \lambda_{n+1}$ the convergence is at least linear with constant $1/2$, so convergence of the iteration cannot be unduly delayed by a conservative choice of shift.

Table 5.1 details the computations and their cost. (Costs of all the operations used here are summarized in [12, Appendix C].) Preprocessing requires at most $\frac{5}{3}n^3$ flops.

5.2. Overdamping test. The following algorithm is based on Corollary 3.6. It runs the scaled iteration (3.7) until either a non-positive definite B_k or a negative definite $Q(\mu_k)$ is detected, signaling that Q is not overdamped or is overdamped, respectively. The algorithm terminates on one of these conditions or because of possible nonconvergence of the iteration for a non-overdamped Q. It is intended to be applied to Q_θ from the preprocessing step.

ALGORITHM 5.1 (overdamping test). *This algorithm tests whether a quadratic $Q(\lambda) = \lambda^2 A + \lambda B + C$ with $A, B > 0$ and $0 \ne C \ge 0$ is overdamped and, if it is, computes $\mu < 0$ such that $Q(\mu) < 0$. Input parameters are the maximum number of iterations $k_{\max}$ and a convergence tolerance $\epsilon > 0$.*

1 Set $A_0 = A$, $B_0 = B$, $C_0 = C$.
2 Set $\alpha_0 = \|C_0\|_1/\|A_0\|_1$, $\mu_0 = -\alpha_0^{1/2}$, $k = 0$.
3 if $Q(\mu_0) < 0$, $Q(\lambda)$ is (hyperbolic and hence) overdamped, $\mu = \mu_0$, quit, end

4 while $k < k_{\max}$
5 $B_{k+1} = B_k - A_k B_k^{-1} C_k - C_k B_k^{-1} A_k$
6 if $\|B_{k+1} - B_k\|_1 / \|B_{k+1}\|_1 \le \epsilon$, goto line 15, end
7 if $B_{k+1} \not> 0$, Q is not overdamped, quit, end
8 $A_{k+1} = \alpha_k A_k B_k^{-1} A_k$
9 $C_{k+1} = \alpha_k^{-1} C_k B_k^{-1} C_k$
10 $\alpha_{k+1} = \|C_{k+1}\|_1 / \|A_{k+1}\|_1$
11 $\mu_{k+1} = \mu_k \alpha_{k+1}^{1/2^{k+2}}$
12 if $Q(\mu_{k+1}) < 0$, Q is overdamped, $\mu = \mu_{k+1}$, quit, end
13 $k = k + 1$
14 end
15 Q is not overdamped. % See the discussion below.

Note that the crucial definiteness test on line 12 of Algorithm 5.1 is carried out on Q and not on Q_k in (3.5). Hence a positive test can be interpreted irrespective of rounding errors in the iteration: The only errors are in forming $Q(\mu_{k+1})$ and in computing its Cholesky factor. For a non-overdamped Q, it is possible that $B_k > 0$ for all k (see the example at the end of section 4). However, if convergence of the B_k is detected on line 6 then Q is declared not overdamped because by this point an overdamped Q would have been detected, while if $k_{\max}$ is large enough (say, $k_{\max} = 20$) and this iteration limit is reached then Q can reasonably be declared not overdamped in view of the fast (quadratic) convergence of (3.7) for an overdamped Q.

The implementation details of Algorithm 5.1 and the cost per iteration are described in Table 5.2. The total cost for m iterations is $\frac{1}{3}n^3$ flops for $m = 0$ and roughly $\frac{20}{3}mn^3$ flops for $m \ge 1$.

Guo and Lancaster's test for overdamping is based on iteration (3.1), scaled as in (3.7). For the computation of $\widehat{S}$, $\frac{19}{3}\ell n^3$ flops are required, where ℓ is the number of iterations for convergence of (3.1). An extra $5n^3$ flops is needed to form the two solvents $S^{(1)}$ and $S^{(2)}$ (which are nonsymmetric in general) via (3.3). Then the smallest eigenvalue λ_n of $S^{(1)}$ and the largest eigenvalue λ_{n+1} of $S^{(2)}$ need to be computed and the definiteness of $Q((\lambda_n + \lambda_{n+1})/2)$ tested. The total cost is $(\frac{19}{3}\ell + \frac{16}{3})n^3$ flops plus the cost of finding λ_n and λ_{n+1}. Since $m \le \ell$, Algorithm 5.1 is clearly the more efficient, possibly significantly so.

We mention two alternative ways to test hyperbolicity. Both are based on the fact that a Hermitian Q with $A > 0$ is hyperbolic if and only if a certain $2n \times 2n$ pair

$(\mathcal{A},\mathcal{B})$ is definite [19, Theorem 3.6]. The first approach is to apply the J-orthogonal Jacobi algorithm of Veselić [28] to $(\mathcal{A},\mathcal{B})$, since the algorithm breaks down when applied to an indefinite pair. Drawbacks of this approach are that the algorithm uses hyperbolic transformations, and so is potentially unstable, and that it must be run to completion to check whether the problem is overdamped, though of course upon completion it has computed the eigenvalues. It requires an initial $\frac{11}{3}n^3$ flops followed by $12sn^3$ flops, where s is the number of sweeps performed. The second approach is to apply to $(\mathcal{A},\mathcal{B})$ an algorithm of Crawford and Moon [4] for detecting definiteness of Hermitian matrix pairs. Although only linearly convergent, this algorithm usually terminates within 30 iterations with a message of "definite," "indefinite," or "fail" (denoting failure of the algorithm to make a determination). The number 30 here is for difficult problems, for which our algorithm may also need 20 iterations. For easy problems, the Crawford–Moon algorithm needs about 3 iterations, while our algorithm needs 0 or 1 iterations. Since the Crawford–Moon algorithm requires one Cholesky factorization per iteration, here of a $2n \times 2n$ matrix, it needs $\frac{8}{3}n^3$ flops per iteration, and this can be reduced to $\frac{1}{3}n^3$ flops per iteration by working directly with the $n \times n$ quadratic Q through the use of a congruence transformation, as given in the proof of [19, Theorem 3.6], for example. Since our algorithm needs $\frac{20}{3}n^3$ flops per iteration, it is often more efficient than the Crawford–Moon algorithm applied to the pair $(\mathcal{A},\mathcal{B})$ and is often less efficient than the Crawford–Moon algorithm working on Q via the congruence. However, the Crawford–Moon algorithm with or without the congruence is numerically unreliable, as we now explain.

We use a MATLAB translation of the Fortran code PDFIND from [3] and also modify it so that it exploits the congruence to work only with the quadratic Q. For the quadratic (3.11), we found that for $\beta \in (0.5196152422, 0.5196152423)$ (which is a small interval in which Q changes from being not overdamped to overdamped—see Tables 3.1 and 3.2) both codes often return with a "fail" message when Algorithm 5.1 correctly diagnoses (non) overdamping. We then considered a scaling of the problem $A \leftarrow \alpha^2 A,\ B \leftarrow \alpha B$, with $\alpha > 0$, which has no effect on the overdamping or on Algorithm 5.1. However, as α decreases, PDFIND becomes more unreliable, due to the increasing ill conditioning of the congruence transformation with decreasing α. To be more specific, we take $\alpha = 10^{-7}$. First, consider $\beta = 0.5157\colon 0.0001\colon 0.5197$. For $\beta = 0.5197$ our algorithm detects overdamping in 3 iterations, and for other values our algorithm detects nonoverdamping in at most 8 iterations. PDFIND, using the congruence, incorrectly detects nonoverdamping for $\beta = 0.5197$ and fails for $\beta = 0.5157$, 0.5177–0.5181, 0.5188, 0.5189, 0.5194. Next, we take $\beta = 0.51965\colon 0.00001\colon 0.51971$. Our algorithm detects overdamping in at most 5 iterations. PDFIND without the congruence incorrectly detects nonoverdamping for 0.51965, 0.51967, 0.51968 and fails for 0.51966, 0.51969, 0.51970. The conclusion is that PDFIND is numerically unreliable whether the congruence is used or not, and when it gives the wrong answer there is no warning. The poor performance of PDFIND when working with the pair is due to the fact that the ill-conditioned congruence transformation is implicitly present in the equivalence between Q being hyperbolic and $(\mathcal{A},\mathcal{B})$ being definite.

For our algorithm, instability could potentially arise if B_k is ill-conditioned. However, we know from [2, p. 40, line 10] that B_k is well-conditioned if $B_0 = B$ is well-conditioned (which is verifiable right from the beginning) and if λ_n/λ_{n+1} is not too close to 1. When λ_n/λ_{n+1} is extremely close to 1, B_k is known to be ill-conditioned for large k. However, B_k appears in our algorithm only in terms like $A_k B_k^{-1} C_k$, and A_k and C_k converge to 0, so the ill-conditioning of B_k has only a limited effect on our algorithm. Indeed, instability has not been observed in any of our tests.

5.3. Solving hyperbolic QEPs via definite linearizations. Recall that the scalar μ computed by Algorithm 5.1 applied to Q_θ is such that $Q(\mu+\theta) = Q_\theta(\mu) < 0$. Hence with $\omega = \mu + \theta$ we have

$$\begin{aligned}\widetilde{Q}(t) = Q(t+\omega) &= t^2 A + t(B + 2\omega A) + C + \omega B + \omega^2 A \\ &= t^2 \widetilde{A} + t\widetilde{B} + \widetilde{C},\end{aligned}$$

with $\widetilde{C} = Q(\omega) < 0$ and $\widetilde{A} = A > 0$. The pencils

$$L_1(\lambda) = \lambda \begin{bmatrix} \widetilde{A} & 0 \\ 0 & -\widetilde{C} \end{bmatrix} + \begin{bmatrix} \widetilde{B} & \widetilde{C} \\ \widetilde{C} & 0 \end{bmatrix}, \quad L_2(\lambda) = \lambda \begin{bmatrix} 0 & \widetilde{A} \\ \widetilde{A} & \widetilde{B} \end{bmatrix} + \begin{bmatrix} -\widetilde{A} & 0 \\ 0 & \widetilde{C} \end{bmatrix}$$

are both Hermitian definite linearizations of $\widetilde{Q}$ with a positive definite leading coefficient of L_1 and a negative definite trailing coefficient of L_2. They share the same eigenvalues as $\widetilde{Q}$, and the eigenvectors of $\widetilde{Q}$ are easy to recover from those of L_1 or L_2. The sensitivity and stability of these linearizations have recently been studied in [14], [15], [17]. It is shown therein that the scaling of Fan, Lin and Van Dooren [6] should be applied to $\widetilde{Q}$ before linearizing. The choice between L_1 and L_2 should be guided by the fact that, in terms of conditioning and backward error, they favor large and small eigenvalues, respectively. However, if $\widetilde{C}$ or $\widetilde{A}$ is well-conditioned and $\|\widetilde{B}\|/(\|\widetilde{A}\|\,\|\widetilde{C}\|)^{1/2}$ is not much bigger than 1 then L_1 or L_2, respectively, can safely be used to stably obtain all of the eigenpairs. For more details on conditioning and backward error for L_1 and L_2, see [14], [15], [17].

Using Cholesky factorizations $\widetilde{A} = L_A L_A^T$ and $-\widetilde{C} = L_C L_C^T$, the definite generalized eigenvalue problem $L_1(\lambda)z = 0$ or $L_2(\lambda)z = 0$ is transformed to a Hermitian (or real symmetric) standard eigenvalue problem [5]. For example, $L_1(\lambda)$ reduces to

$$\lambda I + \begin{bmatrix} L_A^{-1} \widetilde{B} L_A^{-T} & -L_A^{-1} L_C \\ -L_C^T L_A^{-T} & 0 \end{bmatrix}. \tag{5.4}$$

As Table 5.3 explains, this phase requires about $13n^3$ flops, giving a grand total of $(\frac{20}{3}m + 13)n^3$ flops.

Guo and Lancaster's solution algorithm has a total cost of $(\frac{19}{3}\ell + 25)n^3$ flops, assuming the eigenvalues of $S^{(1)}$ and $S^{(2)}$ (which are the eigenvalues of Q) are computed by the QR algorithm. In practice this is significantly more than the cost of our algorithm given that $m \le \ell$ is usually small.

The most common way of solving the QEP is to apply the QZ algorithm or a Krylov method to a linearization L of Q. The QZ algorithm applied to the $2n \times 2n$ L costs $240n^3$ flops for the computation of the eigenvalues.

Our algorithm has two important advantages over that of Guo and Lancaster and QZ applied to a linearization, besides its more favorable operation count. First, it works entirely with symmetric matrices, which reduces the storage requirement. Second, it guarantees to produce real eigenvalues in floating point arithmetic; the other two approaches cannot do so because they invoke the QZ algorithm and the nonsymmetric QR algorithm.

6. Numerical experiment. We describe an experiment that illustrates the behavior of our algorithm for testing overdamping. More extensive testing of this algorithm, and of the preprocessing and solving procedures described in section 5, will be presented in a future publication. Our experiments were performed in MATLAB 7.4 (R2007a), for which the unit roundoff is $u = 2^{-53} \approx 1.1 \times 10^{-16}$. We took $k_{\max} = 30$ and $\epsilon = u$ in Algorithm 5.1.

We first describe a useful technique for generating symmetric quadratic matrix polynomials with prescribed eigenvalues and eigenvectors and positive definite coefficient matrices.

Let (λ_k, v_k), $k = 1\colon 2n$, be a set of given real eigenpairs such that, with

$$\begin{aligned} \Lambda &= \operatorname{diag}(\lambda_1, \dots, \lambda_{2n}) =: \Lambda_1 \oplus \Lambda_2, && \Lambda_1, \Lambda_2 \in \mathbb{R}^{n\times n}, \\ V &:= [\, v_1, \dots, v_{2n} \,] =: [\, V_1 \quad V_2 \,], && V_1, V_2 \in \mathbb{R}^{n\times n}, \end{aligned}$$

V_1 and V_2 are nonsingular, and

$$V_1 V_1^T = V_2 V_2^T, \qquad V_1 \Lambda_1 V_1^T - V_2 \Lambda_2 V_2^T =: \Gamma \text{ is nonsingular.} \tag{6.1}$$

Then the symmetric quadratic polynomial defined by the matrices

$$A = \Gamma^{-1}, \quad B = -A(V_1 \Lambda_1^2 V_1^T - V_2 \Lambda_2^2 V_2^T)A, \tag{6.2a}$$

$$C = -A(V_1 \Lambda_1^3 V_1^T - V_2 \Lambda_2^3 V_2^T)A + B\Gamma B \tag{6.2b}$$

has eigenpairs (λ_k, v_k), $k = 1\colon 2n$ (see [23] for example). We now show how to generate a potentially overdamped quadratic.

LEMMA 6.1. *Assume that* $0 > \lambda_1 \geq \cdots \geq \lambda_n > \lambda_{n+1} \geq \cdots \geq \lambda_{2n}$. *Then* Γ *is nonsingular and the matrices generated by* (6.2) *satisfy* $A > 0$, $B > 0$, *and* $C > 0$.

Proof. It follows from Weyl's theorem [20, p. 181] that $\Gamma > 0$ and hence that $A > 0$. All matrices V_2 that satisfy the first constraint in (6.1) can be written as $V_1 U$ for some orthogonal U. Hence we can write

$$B = -AV_1(\Lambda_1^2 - U\Lambda_2^2 U^T)V_1^T A = -AV_1(H_1^2 - H_2^2)V_1^T A,$$

where $H_1 = \Lambda_1$ and $H_2 = U\Lambda_2 U^T$, and again Weyl's theorem guarantees that $B > 0$.

It is known that (V, Λ, PV^T), where $P = \operatorname{diag}(I_n, -I_n)$, forms a self-adjoint triple for $Q(\lambda)$ [7, section 10.2]. Since Q has no zero eigenvalues, C is nonsingular and a formula for its inverse is easily obtained from the resolvent form of $Q(\lambda)$: For $\lambda \neq \lambda_i$,

$$Q(\lambda)^{-1} = V(\lambda I_{2n} - \Lambda)^{-1} PV^T.$$

TABLE 6.1
Minimum, average, and maximum number of iterations performed by Algorithm 5.1 *and percentage of overdamped problems, for each* n *and matrix type.*

n	type 1		type 2		type 3	
5	0.0, 2.4, 6.0	100%	0.0, 0.8, 3.0	100%	0.0, 2.4, 5.0	25%
10	0.0, 3.6, 10.0	100%	0.0, 0.5, 3.0	100%	2.0, 2.7, 4.0	5%
50	0.0, 4.2, 11.0	100%	0.0, 2.1, 4.0	100%	2.0, 2.1, 3.0	0%
100	3.0, 6.2, 10.0	100%	0.0, 2.6, 4.0	100%	2.0, 2.0, 2.0	0%
250	2.0, 6.0, 11.0	100%	2.0, 3.0, 4.0	100%	2.0, 2.0, 2.0	0%
500	3.0, 7.5, 11.0	100%	2.0, 3.0, 4.0	100%	2.0, 2.0, 2.0	0%

Setting $\lambda = 0$ in the above expression gives

$$C^{-1} = -V\Lambda^{-1}PV^T = -V_1(H_1^{-1} - H_2^{-1})V_1^T,$$

and once again Weyl's theorem guarantees that C^{-1}, and therefore also C, is positive definite. ∎

We use the following eigenvalue distributions:

type 1: λ_k, $k = 1\colon 2n$, is uniformly distributed in $[-100, -1]$.

type 2: λ_k is uniformly distributed in $[-100, -6]$ for $k = n+1\colon 2n$ and $[-5, -1]$ for $k = 1\colon n$.

type 3: λ_k is uniformly distributed in $[-100, 20]$. B and C are then shifted as in (2.2) with $\theta = 1.1\lambda_1$ to ensure that the eigenvalues are all negative.

We took $V_1 = U_1$ and $V_2 = V_1U_2$, where U_1 and U_2 are random orthogonal matrices from the Haar distribution [11, section 28.3]. For types 1 and 2, A, B, and C are all positive definite by construction; for type 3 nothing can be said about the definiteness of A, B, and C. Table 6.1 shows the minimum, average, and maximum number of iterations for Algorithm 5.1 over 20 quadratics for each of several values of n, along with the percentage of Q found to be overdamped for each n and matrix type. In all cases where Q was deemed overdamped, the computed μ was verified to lie in $(\lambda_{n+1}, \lambda_n)$.

We make several observations:

- For all three eigenvalue distributions, Algorithm 5.1 is quick to terminate, especially for types 2 and 3, with only very occasional need for more than 10 iterations. The gap between λ_n and λ_{n+1} is larger for type 2 than type 1, which explains the greater number of iterations for type 1.
- With V_1 orthogonal the coefficients matrices A, B, and C are well-conditioned, with 2-norm condition numbers of order 10^2. If instead we take V_1 as a random matrix with 2-norm condition number 10^4 (computed in MATLAB as `gallery('randsvd',n,1e4,...)`, the condition numbers of A, B, and C are of order 10^8 and the number of iterations of the algorithm increases, though only slightly: The maximum number of iterations over all tests is 13, and the largest average over all n rises to 7.8, 3.1, and 3.2 for types 1, 2, and 3, respectively.
- After detecting overdamping an average of 6–9 more iterations are needed for convergence of the block cyclic iteration. Recall that the algorithm of Guo and Lancaster [9] needs to iterate to convergence in order to show overdamping.

Acknowledgments. This work was started while the first author visited MIMS in the School of Mathematics at the University of Manchester in 2005; he thanks the School for its hospitality. We thank Qiang Ye for helpful comments concerning the algorithm of Crawford and Moon.

A METHOD TO AVOID DIVERGING COMPONENTS IN THE CANDECOMP/PARAFAC MODEL FOR GENERIC $I \times J \times 2$ ARRAYS*

ALWIN STEGEMAN† AND LIEVEN DE LATHAUWER‡

Abstract. Computing the Candecomp/Parafac (CP) solution of R components (i.e., the best rank-R approximation) for a generic $I \times J \times 2$ array may result in diverging components, also known as "degeneracy." In such a case, several components are highly correlated in all three modes, and their component weights become arbitrarily large. Evidence exists that this is caused by the nonexistence of an optimal CP solution. Instead of using CP, we propose to compute the best approximation by means of a generalized Schur decomposition (GSD), which always exists. The obtained GSD solution is the limit point of the sequence of CP updates (whether it features diverging components or not) and can be separated into a nondiverging CP part and a sparse Tucker3 part or into a nondiverging CP part and a smaller GSD part. We show how to obtain both representations and illustrate our results with numerical experiments.

Key words. canonical decomposition, parallel factors analysis, low-rank tensor approximations, degenerate Parafac solutions, diverging components

1. Introduction.

Hitchcock [16, 17] introduced a generalized rank and related decomposition of a multiway array or tensor. The same decomposition was proposed independently by Carroll and Chang [3] and Harshman [13] for component analysis of three-way data arrays. They named it Candecomp and Parafac, respectively. We denote the Candecomp/Parafac (CP) model, i.e., the decomposition with a residual term, as

$$\underline{\mathbf{Z}} = \sum_{h=1}^{R} \omega_h \, (\mathbf{a}_h \otimes \mathbf{b}_h \otimes \mathbf{c}_h) + \underline{\mathbf{E}}, \tag{1.1}$$

where $\underline{\mathbf{Z}}$ is an $I \times J \times K$ data array, ω_h is the weight of component h, $\otimes$ denotes the outer product, and $\|\mathbf{a}_h\| = \|\mathbf{b}_h\| = \|\mathbf{c}_h\| = 1$ for $h = 1, \ldots, R$, with $\|\cdot\|$ denoting the Frobenius norm. To find the R components $\mathbf{a}_h \otimes \mathbf{b}_h \otimes \mathbf{c}_h$ and the weights ω_h, an iterative algorithm is used which minimizes the Frobenius norm of the residual

array $\underline{\mathbf{E}}$. For an overview and comparison of CP algorithms, see Hopke et al. [18] and Tomasi and Bro [45].

The rank of a three-way array $\underline{\mathbf{Z}}$ is defined in the usual way, i.e., the smallest number of rank-1 arrays whose sum equals $\underline{\mathbf{Z}}$. A three-way array has rank 1 if it is the outer product of three vectors, i.e., $\mathbf{a} \otimes \mathbf{b} \otimes \mathbf{c}$. We denote three-way rank as $\text{rank}_{\otimes}(\underline{\mathbf{Z}})$. It follows that the CP model tries to find a best rank-R approximation to the three-way array $\underline{\mathbf{Z}}$.

The real-valued CP model, i.e., where $\underline{\mathbf{Z}}$ and the model parameters are real-valued, was introduced in psychometrics (Carroll and Chang [3]) and phonetics (Harshman [13]). Later on, it was also applied in chemometrics and the food industry (Bro [1] and Smilde, Bro, and Geladi [37]). For other applications of CP in psychometrics, see Kroonenberg [25]. Complex-valued applications of CP occur in signal processing, especially wireless telecommunications; see Sidiropoulos, Giannakis, and Bro [35], Sidiropoulos, Bro, and Giannakis [36], and De Lathauwer and Castaing [9]. Also, CP describes the basic structure of fourth-order cumulants of multivariate data on which a lot of algebraic methods for independent component analysis are based (Comon [4], De Lathauwer, De Moor, and Vandewalle [5], and Hyvärinen, Karhunen, and Oja [20]). In this paper, we consider the real-valued CP model. All occurrences of three-way rank are assumed to be over the real field.

For later use, we mention that the CP model (1.1) is a special case of the Tucker3 model of Tucker [46]. The latter is defined as

$$\underline{\mathbf{Z}} = \sum_{h=1}^{R} \sum_{i=1}^{P} \sum_{j=1}^{Q} g_{hij} \, (\mathbf{a}_h \otimes \mathbf{b}_i \otimes \mathbf{c}_j) + \underline{\mathbf{E}}. \tag{1.2}$$

Clearly, the case with $R = P = Q$ and $g_{hij} = 0$ if $(h, i, j) \neq (h, h, h)$ yields (1.1). The $R \times P \times Q$ array $\underline{\mathbf{G}}$ with entries g_{hij} is referred to as the core array. The matrices $[\mathbf{a}_1| \ldots |\mathbf{a}_R]$, $[\mathbf{b}_1| \ldots |\mathbf{b}_P]$, and $[\mathbf{c}_1| \ldots |\mathbf{c}_Q]$ are called the component matrices.

A matrix notation of the CP model (1.1) is as follows. Let $\mathbf{Z}_k$ $(I \times J)$ and $\mathbf{E}_k$ $(I \times J)$ denote the kth slices of $\underline{\mathbf{Z}}$ and $\underline{\mathbf{E}}$, respectively. Then (1.1) can be written as

$$\mathbf{Z}_k = \mathbf{A}\, \mathbf{C}_k\, \mathbf{B}^T + \mathbf{E}_k, \qquad k = 1, \ldots K, \tag{1.3}$$

where the component matrices $\mathbf{A}$ $(I \times R)$ and $\mathbf{B}$ $(J \times R)$ have the vectors $\mathbf{a}_h$ and $\mathbf{b}_h$ as columns, respectively, and $\mathbf{C}_k$ $(R \times R)$ is the diagonal matrix with the kth elements of the vectors $\omega_h \mathbf{c}_h$ on its diagonal. The model part of the CP model is characterized by $(\mathbf{A}, \mathbf{B}, \mathbf{C})$, where component matrix $\mathbf{C}$ $(K \times R)$ has the vectors $\mathbf{c}_h$ as columns. Hence, it is assumed that the weights ω_h are absorbed by the matrix $\mathbf{C}$.

The most attractive feature of CP is its uniqueness property. Kruskal [26] has shown that, for fixed residuals $\underline{\mathbf{E}}$, the vectors $\mathbf{a}_h$, $\mathbf{b}_h$, and $\mathbf{c}_h$ and the weights ω_h are unique up to sign changes and a reordering of the summands in (1.1) if

$$k_{\mathbf{A}} + k_{\mathbf{B}} + k_{\mathbf{C}} \geq 2\, R + 2, \tag{1.4}$$

where $k_{\mathbf{A}}$, $k_{\mathbf{B}}$, $k_{\mathbf{C}}$ denote the k-ranks of the component matrices. The k-rank of a matrix is the largest number x such that every subset of x columns of the matrix is linearly independent. If a CP solution is unique up to these indeterminacies, it is called *essentially unique*. Two CP solutions which are identical up to the essential uniqueness indeterminacies will be called *equivalent*.

In case one of the component matrices $\mathbf{A}$, $\mathbf{B}$, and $\mathbf{C}$ has full column rank, a weaker uniqueness condition than (1.4) has been derived by Jiang and Sidiropoulos [22] and De Lathauwer [7]. See also Stegeman, Ten Berge, and De Lathauwer [41].

The practical use of CP has been hampered by the occurrence of diverging CP components, also known as "degeneracy." In such cases, convergence of a CP algorithm is extremely slow, and some components display the following pattern. Let the model parameters of the nth update of a CP algorithm be denoted by a superscript (n). For the diverging components, the weights $\omega_h^{(n)}$ become arbitrarily large in magnitude, and the corresponding columns in $\mathbf{A}^{(n)}$, $\mathbf{B}^{(n)}$, and $\mathbf{C}^{(n)}$ become nearly linearly dependent. Although the individual diverging components may diverge in nearly opposite directions, their sum still contributes to a better fit of the CP model. Diverging CP components are a problem to the analysis of three-way arrays, since the obtained CP solution is hardly interpretable. The occurrence of diverging components can be avoided by imposing orthogonality constraints on the components matrices; see Krijnen, Dijkstra and Stegeman [24], but this will come with some loss of fit. Lim [29] shows that diverging components do not occur for nonnegative $\underline{\mathbf{Z}}$ under the restriction of nonnegative component matrices.

The first case of diverging CP components was reported in Harshman and Lundy [14]. Contrived examples are given by Ten Berge, Kiers, and De Leeuw [43] and Paatero [33]. Kruskal, Harshman, and Lundy [27] have argued that diverging CP components occur due to the fact that the array $\underline{\mathbf{Z}}$ has no best rank-R approximation, i.e., CP has no optimal solution. They reason that every sequence of CP updates, of which the objective value is approaching the infimum of the CP objective function, must fail to converge and displays a pattern of a diverging CP components. This has recently been proven by Krijnen, Dijkstra, and Stegeman [24].

De Silva and Lim [10] give results on the existence of a best rank-R approximation of N-way arrays with $N \geq 3$. For the three-way CP model, [10] shows that for $R = 1$, an optimal CP solution always exists, while for any $I, J, K \geq 2$ and any $R \in \{2, \ldots, \min(I, J, K)\}$, a rank-$(R+1)$ array $\underline{\mathbf{Z}}$ exists which has no optimal CP solution. Also, [10] shows that all $2 \times 2 \times 2$ arrays of rank 3 (a set of positive volume in $\mathbb{R}^{2\times 2\times 2}$) have no optimal CP solution for $R = 2$ and that, for any $I, J, K \geq 2$, the set of arrays in $\mathbb{R}^{I\times J\times K}$, which have no optimal CP solution for $R = 2$ has positive volume.

Stegeman [38, 40] has mathematically analyzed diverging CP components occurring for generic $I \times J \times 2$ arrays $\underline{\mathbf{Z}}$ and all values of R. In these cases, diverging components occur if the sequence of CP updates converges to a limit point $\underline{\mathbf{X}}$, which has rank larger than R. Formally, these occurrences of diverging components can be described as follows. There exist disjoint index sets $D_1, \ldots, D_r \subset \{1, \ldots, R\}$ such that

$$|\omega_h^{(n)}| \to \infty, \qquad \text{for all } h \in D_j, \quad j = 1, \ldots, r, \tag{1.5}$$

$$\text{while} \quad \left\| \sum_{h \in D_j} \omega_h^{(n)} \left(\mathbf{a}_h^{(n)} \otimes \mathbf{b}_h^{(n)} \otimes \mathbf{c}_h^{(n)}\right) \right\| \qquad \text{is bounded}, \quad j = 1, \ldots, r. \tag{1.6}$$

Stegeman [38, 40] gives a complete characterization of the diverging components (1.5)–(1.6) in terms of properties of the limit point of the sequence of CP updates. Also, [40] provides a link between diverging CP components and results from the theory of matrix pencils and algebraic complexity theory.

The only mathematically analyzed cases of diverging CP components so far are the contrived examples in Ten Berge, Kiers, and De Leeuw [43] and Paatero [33], generic $I \times J \times 2$ arrays in Stegeman [38, 40], and generic $5 \times 3 \times 3$ and $8 \times 4 \times 3$ arrays, and generic $3 \times 3 \times 4$ and $3 \times 3 \times 5$ arrays with symmetric slices in Stegeman [39].

A numerical example of diverging CP components is the following. Let $\underline{\mathbf{Z}}$ be a $4 \times 4 \times 2$ array with slices

$$\mathbf{Z}_1 = \begin{bmatrix} -0.5 & -1.2 & 0.3 & -0.6 \\ -1.7 & 1.1 & 0.1 & 2.1 \\ 0.1 & 1.1 & -0.2 & -0.2 \\ 0.2 & -0.1 & 0.7 & 0.1 \end{bmatrix} \quad \text{and} \quad \mathbf{Z}_2 = \begin{bmatrix} 0.8 & 1.1 & -1.7 & -0.9 \\ 0.7 & -1.3 & 0.2 & 0.5 \\ 1.2 & -0.1 & -1.1 & 0.2 \\ 0.6 & -0.2 & 1.4 & -1.0 \end{bmatrix}. \tag{1.7}$$

This array was randomly generated such that $\text{rank}_{\otimes}(\underline{\mathbf{Z}}) = 5$. Next, we try to fit the CP model with $R = 4$ components using the multilinear engine of Paatero [32]. For a convergence criterion of `1e-15`, the algorithm terminates after 162055 iterations with an objective value of 0.051204 and final CP update

$$\mathbf{A} = \begin{bmatrix} 0.6787 & 0.1278 & 0.6767 & -0.6778 \\ -0.6642 & -0.7946 & -0.6735 & 0.6693 \\ -0.1189 & -0.5895 & -0.1464 & 0.1320 \\ -0.2898 & 0.0690 & -0.2590 & 0.2746 \end{bmatrix}, \tag{1.8}$$

$$\mathbf{B} = \begin{bmatrix} -0.6870 & -0.8259 & -0.6919 & -0.6895 \\ -0.2365 & -0.0386 & -0.2609 & -0.2481 \\ -0.0509 & 0.4005 & -0.0080 & -0.0298 \\ 0.6852 & 0.3949 & 0.6732 & 0.6800 \end{bmatrix}, \tag{1.9}$$

$$\mathbf{C} = \begin{bmatrix} 1454 & -2.8913 & 1443 & 2895 \\ 789 & 4.4617 & 634 & 1426 \end{bmatrix}, \tag{1.10}$$

where the columns of $\mathbf{A}$ and $\mathbf{B}$ are normalized to length 1. It can be seen that columns 1, 3, and 4 in $\mathbf{A}$ and $\mathbf{B}$ are nearly identical up to a sign change. Also, these columns have large magnitudes in $\mathbf{C}$. Hence, CP components 1, 3, and 4 appear to be diverging. The multilinear engine terminates with nearly the same CP update for all tried random starting values. The alternating least squares CP algorithm gives the same results.

Since diverging CP components cannot be interpreted, one may wonder whether they can be avoided. However, the discussion above shows that for some array sizes and some values of R, there is no best rank-R approximation and, hence, trying to fit the CP model results in diverging components. To ensure the existence of a best rank-R approximation, De Silva and Lim [10] propose to consider the closure of the set of arrays with at most rank R instead. For each array size and value of R, this involves characterizing the boundary arrays of this set. These are the limit points of the sequences of CP updates featuring diverging CP components. De Silva and Lim [10] show that for $R = 2$, these limit points have rank 3 with the following decomposition into rank-1 terms:

$$\underline{\mathbf{X}} = \mathbf{x}_1 \otimes \mathbf{x}_2 \otimes \mathbf{y}_3 + \mathbf{x}_1 \otimes \mathbf{y}_2 \otimes \mathbf{x}_3 + \mathbf{y}_1 \otimes \mathbf{x}_2 \otimes \mathbf{x}_3. \tag{1.11}$$

In this paper, we apply the idea of De Silva and Lim [10] to the CP model for generic $I \times J \times 2$ arrays $\underline{\mathbf{Z}}$. Apart from the results in Stegeman [39], this is the only class of arrays for which the analysis of diverging components is nearly complete. Instead of fitting the CP model, we propose to find the best approximation of $\underline{\mathbf{Z}}$ in terms of the generalized Schur decomposition (GSD), which was considered in De Lathauwer, De Moor, and Vandewalle [6]. The GSD model is the same as (1.3) except that $\mathbf{A}$ and

$\mathbf{B}$ are columnwise orthonormal and $\mathbf{C}_k$ are upper triangular $k = 1, 2$. We show that an optimal solution to the GSD model always exists. Moreover, for $I \times J \times 2$ arrays, the set of feasible GSD solutions equals the closure of the set of feasible CP solutions. Hence, the optimal GSD solution, if it is unique, is the limit point of the sequence of CP updates, whether the latter features diverging components or not.

Next, we show how to write the obtained GSD solution in several alternative forms. First, using the Jordan normal form, the GSD solution may be written as the sum of the nondiverging CP components and a sparse Tucker3 part. Here, each of the m sets of diverging CP components in (1.5)–(1.6) forms one block in the Tucker3 part. We call this the CP+Jordan form. Although this is not a decomposition into rank-1 terms, it is an essentially unique decomposition, and its blocks may be interpretable to the researcher. Second, the obtained GSD solution may be written as the sum of the nondiverging CP components and a smaller GSD part. We call this the CP+GSD form. If one is only interested in obtaining the nondiverging CP components, this is a fast way to get them. Third, using the CP+Jordan form, the GSD solution may also be written as a sum of rank-1 terms where the number of terms equals the rank of the solution array. However, this rank-revealing decomposition is not essentially unique. During the computation of the GSD solution, the problems of diverging CP components do not arise, neither during the computation of the mentioned alternative forms for the GSD solution.

As explained above, the analyzed cases of diverging CP components most likely occur because the CP model has no optimal solution. Hence, modified CP algorithms designed to avoid diverging components (e.g., Rayens and Mitchell [34], Cao et al. [2]) are no remedy here. With our method for $I \times J \times 2$ arrays, the problems of diverging CP components are avoided without imposing additional constraints.

Note that the occurrences of diverging CP components we consider do not include cases where $\text{rank}_{\otimes}(\underline{\mathbf{Z}}) \leq R$ and either its full CP decomposition resembles a case of diverging components or where diverging components occur due to an unlucky choice of the starting position of the CP algorithm. Examples of these cases can be found in Mitchell and Burdick [30] and Paatero [33]. We will assume instead that $\text{rank}_{\otimes}(\underline{\mathbf{Z}}) > R$.

This paper is organized as follows. We discuss the analysis of diverging CP components for typical $I \times I \times 2$ arrays $\underline{\mathbf{Z}}$ of rank $I + 1$ and $R = I$ in section 3. For this, we need results on the rank of $I \times I \times 2$ arrays. These are presented in section 2. In section 4 we discuss the simultaneous GSD model. In section 5, we consider the GSD model for $I \times I \times 2$ arrays and show how it is related to the CP model. In section 6, we show how to obtain the CP+Jordan and CP+GSD representations of the GSD solution. In section 7, we discuss the extension of our analysis for $I \times I \times 2$ arrays and $R = I$ to $I \times J \times 2$ arrays and general R. Section 8 contains numerical experiments which illustrate our results. Finally, section 9 provides a discussion.

2. The rank of $I \times I \times 2$ arrays. For an array $\underline{\mathbf{Y}} \in \mathbb{R}^{I \times I \times 2}$, we denote its $I \times I$ frontal slices by $\mathbf{Y}_k$, $k = 1, 2$. Let

$$\mathcal{R}_I = \{\underline{\mathbf{Y}} \in \mathbb{R}^{I \times I \times 2} : \det(\mathbf{Y}_k) \neq 0\,,\ k = 1, 2\}. \tag{2.1}$$

The following result on the rank of arrays in $\mathcal{R}_I$ is due to Ja' Ja' [21]. For later use, we also give its proof as formulated in Stegeman [38].

LEMMA 2.1. *For $\underline{\mathbf{X}} \in \mathcal{R}_I$, the following statements hold:*

(i) *If $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues and is diagonalizable, then $\underline{\mathbf{X}}$ has rank I.*

(ii) *If* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *has at least one pair of complex eigenvalues, then* $\underline{\mathbf{X}}$ *has at least rank* $I+1$.

(iii) *If* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *has* I *real eigenvalues but is not diagonalizable, then* $\underline{\mathbf{X}}$ *has at least rank* $I+1$.

Proof. If (i) holds, then $\mathbf{X}_2\mathbf{X}_1^{-1}$ has an eigendecomposition $\mathbf{K}\,\mathbf{\Lambda}\,\mathbf{K}^{-1}$, where $\mathbf{\Lambda}$ is the $I \times I$ diagonal matrix of eigenvalues and $\mathbf{K}$ contains the associated eigenvectors. Taking

$$\mathbf{A} = \mathbf{K}, \qquad \mathbf{B}^T = \mathbf{K}^{-1}\,\mathbf{X}_1, \qquad \mathbf{C}_1 = \mathbf{I}_I, \qquad \mathbf{C}_2 = \mathbf{\Lambda}, \tag{2.2}$$

yields a full rank-I decomposition of $\underline{\mathbf{X}}$ as in (1.3).

The proof of (ii)–(iii) is as follows. Since its $I \times I$ slices are nonsingular, it follows that $\underline{\mathbf{X}}$ has at least rank I. Suppose $\underline{\mathbf{X}}$ has rank I. Then there exist nonsingular matrices $\mathbf{A}$ and $\mathbf{B}$ and nonsingular diagonal matrices $\mathbf{C}_1$ and $\mathbf{C}_2$ such that $\mathbf{X}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$, $k = 1, 2$. But then $\mathbf{X}_2\mathbf{X}_1^{-1} = \mathbf{A}\,\mathbf{C}_2\,\mathbf{C}_1^{-1}\,\mathbf{A}^{-1}$ is an eigendecomposition with I real eigenvalues and I linearly independent eigenvectors, which contradicts (ii)–(iii). Hence, the rank of $\underline{\mathbf{X}}$ is at least $I+1$. ∎

If $\underline{\mathbf{X}}$ satisfies (iii) of Lemma 2.1, the rank of $\underline{\mathbf{X}}$ can be deduced from the Jordan normal form of $\mathbf{X}_2\mathbf{X}_1^{-1}$. This is stated in the following result, also due to Ja' Ja' [21].

LEMMA 2.2. *Let* $\underline{\mathbf{X}} \in \mathcal{R}_I$ *and suppose* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *has* I *real eigenvalues. Let the Jordan normal form of* $\mathbf{X}_2\mathbf{X}_1^{-1}$ *be given by* $\operatorname{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$, *where* $\mathbf{J}_{m_j}(\mu_j)$ *denotes an* $m_j \times m_j$ *Jordan block with diagonal elements equal to* μ_j *and* $m_j \geq 2$. *Then*

$$\operatorname{rank}_{\otimes}(\underline{\mathbf{X}}) = I + r. \tag{2.3}$$

For an eigenvalue λ_j of an $I \times I$ matrix $\mathbf{G}$, we define the *algebraic multiplicity* of λ_j as the multiplicity of λ_j as root of the characteristic polynomial $\det(\mathbf{G} - \lambda\mathbf{I}_I)$, and the *geometric multiplicity* of λ_j as the maximum number of linearly independent eigenvectors of $\mathbf{G}$ associated with λ_j (i.e., the dimensionality of the eigenspace of λ_j). Let $\mathbf{G} = \operatorname{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$, with $m_j \geq 2$ for $j = 1, \ldots, r$. Then the eigenvalues of $\mathbf{G}$ are $\lambda_1, \ldots, \lambda_p, \mu_1, \ldots, \mu_r$ (not necessarily distinct), and each Jordan block $\mathbf{J}_{m_j}(\mu_j)$ adds m_j to the algebraic multiplicity of μ_j and 1 to the geometric multiplicity of μ_j. This establishes a relation between the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ and the rank of the array $\underline{\mathbf{X}}$ in Lemma 2.2. In particular, if $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues and is diagonalizable, then $\underline{\mathbf{X}}$ has rank I, which is case (i) of Lemma 2.1.

When $I \times I \times 2$ arrays are randomly drawn from a continuous distribution, they have rank I or $I+1$, both with positive probability; see Ten Berge and Kiers [44]. Their *typical rank* is said to be $\{I, I+1\}$. A typical array $\underline{\mathbf{X}}$ of rank I satisfies (i) of Lemma 2.1, and $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I distinct real eigenvalues. A typical array $\underline{\mathbf{X}}$ of rank $I+1$ satisfies (ii) of Lemma 2.1, and the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ are again distinct.

If a three-way array of size $I \times J \times K$ has a one-valued typical rank, this is called its *generic rank*. In this case, a generic $I \times J \times K$ array has rank equal to its generic rank.

3. Diverging CP components for $I \times I \times 2$ arrays of rank $I+1$ and $R = I$. Here, we discuss the analysis of Stegeman [38] that shows how diverging CP components occur for typical $I \times I \times 2$ arrays of rank $I+1$ and $R = I$. Let

$$\mathcal{S}_I = \{\underline{\mathbf{Y}} \in \mathcal{R}_I : \underline{\mathbf{Y}} \text{ has rank at most } I\}. \tag{3.1}$$

Hence, the set $\mathcal{S}_I$ consists of the arrays in $\mathcal{R}_I$ which satisfy (i) of Lemma 2.1. Note that $\mathcal{S}_I$ contains only arrays of rank I, and not less than I, due to its restriction to $\mathcal{R}_I$.

Let $\underline{\mathbf{Z}} \in \mathcal{R}_I$ be typical and have rank $I+1$. Then $\underline{\mathbf{Z}}$ satisfies (ii) of Lemma 2.1. We consider the following CP problem:

$$\begin{aligned} &\text{Minimize} \|\underline{\mathbf{Z}} - \underline{\mathbf{Y}}\|^2 \\ &\text{subject to } \underline{\mathbf{Y}} \in \mathcal{S}_I. \end{aligned} \tag{3.2}$$

If problem (3.2) has an optimal solution $\underline{\mathbf{X}}$, then $\underline{\mathbf{X}}$ is a boundary point of $\mathcal{S}_I$. The following result defines the interior points and boundary points of $\mathcal{S}_I$ in $\mathcal{R}_I$ and is due to Stegeman [38].

LEMMA 3.1. *For $\underline{\mathbf{X}} \in \mathcal{R}_I$, the following statements hold:*

(a) *$\underline{\mathbf{X}}$ is an interior point of $\mathcal{S}_I$ if and only if $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I distinct real eigenvalues.*

(b) *$\underline{\mathbf{X}}$ is a boundary point of $\mathcal{S}_I$ in $\mathcal{R}_I$ if and only if $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues but not all distinct.*

The boundary points in (b) can have rank I or rank $\geq I+1$, depending on whether $\mathbf{X}_2\mathbf{X}_1^{-1}$ is diagonalizable (type I) or not (type II); see Lemma 2.1. Hence, the set $\mathcal{S}_I$ is not a closed subset of $\mathcal{R}_I$, and the existence of an optimal solution for problem (3.2) is not guaranteed. If problem (3.2) has an optimal solution $\underline{\mathbf{X}}$, then it is a boundary point of type I.

Remark 3.2. For a typical $\underline{\mathbf{Z}}$ of rank $I+1$, problem (3.2) does not seem to have an optimal solution in practice. We conjecture the following explanation for this. For $m \geq 2$, define the sets of matrices

$$\begin{aligned} \mathcal{B}(\lambda_0, m) &= \{\mathbf{Y} \in \mathbb{R}^{I \times I} : \ \mathbf{Y} \text{ has eigenvalue } \lambda_0 \text{ with algebraic multiplicity } m\} \\ &= \mathcal{B}_1(\lambda_0, m) \cup \cdots \cup \mathcal{B}_m(\lambda_0, m), \end{aligned}$$

with

$$\mathcal{B}_l(\lambda_0, m) = \{\mathbf{Y} \in \mathcal{B}(\lambda_0, m) : \ \text{rank}(\mathbf{Y} - \lambda_0 \mathbf{I}_I) = I - l\}, \qquad l = 1, \ldots, m.$$

Due to the upper-semicontinuity of matrix rank, the set $\mathcal{B}_l(\lambda_0, m)$ lies dense in $\mathcal{B}_l(\lambda_0, m) \cup \cdots \cup \mathcal{B}_m(\lambda_0, m)$. For a boundary point $\underline{\mathbf{X}}$ of $\mathcal{S}_I$, all eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ are real and $\mathbf{X}_2\mathbf{X}_1^{-1} \in \mathcal{B}(\lambda_0, m)$ for some eigenvalue λ_0 and $m \geq 2$ (see Lemma 3.1 (b)). For a boundary point of type I (with rank I), it holds that $\mathbf{X}_2\mathbf{X}_1^{-1} \in \mathcal{B}_m(\lambda_0, m)$ for all multiple eigenvalues λ_0 of $\mathbf{X}_2\mathbf{X}_1^{-1}$. For a boundary point of type II (with rank at least $I+1$), it holds that $\mathbf{X}_2\mathbf{X}_1^{-1} \in \mathcal{B}_l(\lambda_0, m)$, with $l < m$ for some multiple eigenvalue λ_0 of $\mathbf{X}_2\mathbf{X}_1^{-1}$. From these observations, it follows that the set of boundary points of type II lies dense on the boundary of the set $\mathcal{S}_I$. As stated above, if problem (3.2) has an optimal solution, then it is a boundary point of type I. We conjecture that this implies that, for a typical array $\underline{\mathbf{Z}}$ of rank $I+1$, problem (3.2) has no optimal solution.

If problem (3.2) does not have an optimal solution, then the sequence of CP updates $\underline{\mathbf{Y}}^{(n)}$ converges to a boundary point $\underline{\mathbf{X}}$ of type II (i.e., with $\mathbf{X}_2\mathbf{X}_1^{-1}$ having I real eigenvalues and not diagonalizable) such that $\|\underline{\mathbf{Z}} - \underline{\mathbf{X}}\|^2$ equals the infimum of $\|\underline{\mathbf{Z}} - \underline{\mathbf{Y}}\|^2$ over $\mathcal{S}_I$. Stegeman [38] shows that when $\underline{\mathbf{Y}}^{(n)}$ converges to $\underline{\mathbf{X}}$, the sequence $\underline{\mathbf{Y}}^{(n)}$ features diverging components. This can be seen as follows. The boundary point $\underline{\mathbf{X}}$ satisfies (iii) of Lemma 2.1, and its rank, which is at least $I+1$, is given by Lemma 2.2. We assume $\underline{\mathbf{Y}}^{(n)}$ to be interior points of $\mathcal{S}_I$, i.e., $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ has I distinct real eigenvalues. Then $\underline{\mathbf{Y}}^{(n)}$ has a rank-I decomposition of the form (2.2). Moreover, for the k-ranks we have $k_{\mathbf{A}^{(n)}} = k_{\mathbf{B}^{(n)}} = I$ and $k_{\mathbf{C}^{(n)}} = 2$, and

Kruskal's condition (1.4) yields that the decomposition is essentially unique. By continuity, $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ converges to $\mathbf{X}_2\mathbf{X}_1^{-1}$. Denote the eigendecomposition of $\mathbf{Y}_2^{(n)}(\mathbf{Y}_1^{(n)})^{-1}$ by $\mathbf{K}^{(n)}\mathbf{\Lambda}^{(n)}(\mathbf{K}^{(n)})^{-1}$. The matrix $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues but is not diagonalizable, and we have $\mathbf{A}^{(n)} = \mathbf{K}^{(n)}$, $\mathbf{B}^{(n)} = ((\mathbf{K}^{(n)})^{-1}\mathbf{Y}_1^{(n)})^T$, $\mathbf{C}_1^{(n)} = \mathbf{I}_I$, and $\mathbf{C}_2^{(n)} = \mathbf{\Lambda}^{(n)}$. Let λ be an eigenvalue of $\mathbf{X}_2\mathbf{X}_1^{-1}$ with algebraic multiplicity strictly larger than its geometric multiplicity, and associated Jordan block of size $m \times m$. Then m columns of $\mathbf{A}^{(n)}$ converge to the same eigenvector (up to a sign change) of λ, the corresponding m columns of $\mathbf{B}^{(n)}$ tend to linear dependency and large magnitudes, and the m corresponding columns of $\mathbf{C}^{(n)}$ become nearly identical to $(1 \quad \lambda)^T$. The pattern of the m CP components is such that their sum does not blow up. Clearly, this is a case of diverging CP components as defined by (1.5)–(1.6).

The diverging CP components are related to the Jordan form of $\mathbf{X}_2\mathbf{X}_1^{-1}$ in the way described above. Hence, based on Lemma 2.2, one may conclude that the number of groups of diverging CP components equals the rank of the boundary array $\underline{\mathbf{X}}$ minus I.

To illustrate the phenomenon of diverging CP components as described above, we return to the example in (1.7). For this randomly sampled $4 \times 4 \times 2$ array $\underline{\mathbf{Z}}$, the matrix $\mathbf{Z}_2\mathbf{Z}_1^{-1}$ has one pair of complex eigenvalues. Hence, $\underline{\mathbf{Z}}$ is a typical $4 \times 4 \times 2$ array of rank 5. Trying to fit the CP model with $R = 4$, results in three diverging components, as shown in (1.8)–(1.10). Next, we compute the array $\underline{\mathbf{Y}}$ corresponding to the final CP update, i.e., $\mathbf{Y}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$ for $k = 1, 2$. This $\underline{\mathbf{Y}}$ is an approximation of the optimal boundary array $\underline{\mathbf{X}}$. For the eigenvalues of $\mathbf{Y}_2\mathbf{Y}_1^{-1}$, we get

$$-1.5431, \qquad 0.4395, \qquad 0.4925, \qquad 0.5427. \tag{3.3}$$

Hence, three eigenvalues are close together. This corresponds to the three diverging components in (1.8)–(1.10) as discussed above.

4. A simultaneous GSD. Here, we introduce the simultaneous GSD (SGSD) model for $I \times I \times K$ arrays and show that it always has an optimal solution. We also discuss a relation between the CP model and the SGSD model as presented in De Lathauwer, De Moor, and Vandewalle [6]. In matrix notation, the SGSD model for an array $\underline{\mathbf{Z}}$ is

$$\mathbf{Z}_k = \mathbf{Q}_a\,\mathbf{R}_k\,\mathbf{Q}_b^T + \mathbf{E}_k, \qquad k = 1, \ldots K, \tag{4.1}$$

where $\mathbf{Q}_a$ and $\mathbf{Q}_b$ are $I \times I$ orthonormal and $\mathbf{R}_k$ are $I \times I$ upper triangular $k = 1, \ldots, K$. The matrices $\mathbf{Q}_a$, $\mathbf{Q}_b$, and $\mathbf{R}_k$ are determined by minimizing the sum-of-squares of the residuals $\mathbf{E}_k$, $k = 1, \ldots, K$. For this purpose, a Jacobi-type algorithm is presented in [6], and Van der Veen and Paulraj [47] developed an extended QZ algorithm. Like the CP model, we consider the real-valued SGSD model.

Next, we show that the SGSD model, contrary to the CP model, always has an optimal solution. Our approach is analogous to Krijnen [23]. We make use of the following lemma, which can be found in Ortega and Rheinboldt [31, p. 104].

LEMMA 4.1. *Let $g : D \subset \mathbb{R}^q \to \mathbb{R}$, where D is unbounded. Then all level sets of g are bounded if and only if $g(\boldsymbol{\theta}_n) \to \infty$ whenever $\{\boldsymbol{\theta}_n\} \subset D$ and $\|\boldsymbol{\theta}_n\| \to \infty$.*

We define the parameter vector of the SGSD model as

$$\boldsymbol{\theta} = \mathrm{vec}(\mathrm{vec}(\mathbf{Q}_a), \mathrm{vec}(\mathbf{Q}_b), \mathrm{vec}(\mathbf{R}_1), \ldots, \mathrm{vec}(\mathbf{R}_K)).$$

Let $f(\boldsymbol{\theta})$ be the sum-of-squares of the residuals of the SGSD model. Since f is continuous, the level sets $L(\gamma) = \{\boldsymbol{\theta} : \ f(\boldsymbol{\theta}) \leq \gamma\}$ are closed. We have the following result.

PROPOSITION 4.2. *All level sets of f are bounded, and the SGSD model has an optimal solution.*

Proof. We have $\|\boldsymbol{\theta}\|^2 = 2I + \sum_{k=1}^{K} \|\mathbf{R}_k\|^2$. Hence, $\|\boldsymbol{\theta}_n\| \to \infty$ implies that $\|\mathbf{R}_k\| \to \infty$ for at least one k. Moreover,

$$f(\boldsymbol{\theta})^{1/2} = \sum_{k=1}^{K} \|\mathbf{Z}_k - \mathbf{Q}_a \mathbf{R}_k \mathbf{Q}_b^T\| \geq \sum_{k=1}^{K} \Big| \|\mathbf{Z}_k\| - \|\mathbf{Q}_a \mathbf{R}_k \mathbf{Q}_b^T\| \Big| = \sum_{k=1}^{K} \Big| \|\mathbf{Z}_k\| - \|\mathbf{R}_k\| \Big|,$$

which implies that $f(\boldsymbol{\theta}_n) \to \infty$ whenever $\|\boldsymbol{\theta}_n\| \to \infty$. From Lemma 4.1, it follows that all level sets of f are bounded. Since the level sets are also closed, f attains its infimum on any nonempty level set. This completes the proof. ∎

Next, we present a relation between the CP model and the SGSD model, which was partly proven by De Lathauwer, De Moor, and Vandewalle [6]. We have the following result.

LEMMA 4.3. *Let $\underline{\mathbf{X}} \in \mathbb{R}^{I \times I \times K}$. The following statements hold:*

(i) *If $\underline{\mathbf{X}}$ has a full CP decomposition with $R = I$, then $\underline{\mathbf{X}}$ has a full SGSD.*

(ii) *Suppose $\mathbf{X}_1$ is nonsingular. Then $\underline{\mathbf{X}}$ has a full CP decomposition with $R = I$ if and only if $\mathbf{X}_k \mathbf{X}_1^{-1}$, $k = 1, \ldots, K$ have a simultaneous eigendecomposition with only real eigenvalues. Moreover, the full CP decomposition of $\underline{\mathbf{X}}$ is essentially unique if and only if $k_{\mathbf{C}} \geq 2$.*

(iii) *Suppose $\mathbf{X}_1$ is nonsingular. If $\underline{\mathbf{X}}$ has an essentially unique full CP decomposition with $R = I$, then the indeterminacies in the full SGSD of $\underline{\mathbf{X}}$ are only due to the indeterminacies in the full CP decomposition of $\underline{\mathbf{X}}$.*

Proof. First, we show (i). We have $\mathbf{X}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$, $k = 1, \ldots, K$; see (1.3). Let $\mathbf{A} = \mathbf{Q}_a \mathbf{R}_a$ be a QR-decomposition of $\mathbf{A}$, with $\mathbf{Q}_a$ orthonormal and $\mathbf{R}_a$ upper triangular. Analogously, let $\mathbf{B} = \mathbf{Q}_b \mathbf{L}_b$ be a QL-decomposition of $\mathbf{B}$, with $\mathbf{Q}_b$ orthonormal and $\mathbf{L}_b$ lower triangular. Then $\mathbf{X}_k = \mathbf{Q}_a\,(\mathbf{R}_a \mathbf{C}_k \mathbf{L}_b^T)\,\mathbf{Q}_b^T$, $k = 1, \ldots, K$ is a full SGSD for $\underline{\mathbf{X}}$.

The first part of the proof of (ii) is due to De Lathauwer, De Moor, and Vandewalle [6]. Suppose $\underline{\mathbf{X}}$ has a full CP decomposition with $R = I$. Then we have $\mathbf{X}_k \mathbf{X}_1^{-1} = \mathbf{A}\,\mathbf{C}_k\,\mathbf{C}_1^{-1}\,\mathbf{A}^{-1}$, which is an eigendecomposition with real eigenvalues and shows that $\mathbf{X}_k \mathbf{X}_1^{-1}$, $k = 1, \ldots, K$ have a simultaneous eigendecomposition. Next, suppose $\mathbf{X}_k \mathbf{X}_1^{-1} = \mathbf{A}\,\mathbf{C}_k\,\mathbf{A}^{-1}$ for diagonal matrices $\mathbf{C}_k$, $k = 2, \ldots, K$. Then $\mathbf{X}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{A}^{-1}\,\mathbf{X}_1$. Taking $\mathbf{C}_1 = \mathbf{I}_I$ and $\mathbf{B}^T = \mathbf{A}^{-1}\,\mathbf{X}_1$ now yields a full CP decomposition of $\underline{\mathbf{X}}$ with $R = I$.

In the CP decomposition of $\underline{\mathbf{X}}$, we have $k_{\mathbf{A}} = k_{\mathbf{B}} = I$. Hence, Kruskal's condition (1.4) for essential uniqueness is equivalent to $k_{\mathbf{C}} \geq 2$. See also Leurgans, Ross, and Abel [28]. Moreover, $k_{\mathbf{C}} \geq 2$ is also necessary for uniqueness as is shown in Stegeman and Sidiropoulos [42].

Next, we show (iii). From (ii), it follows that $\mathbf{X}_k \mathbf{X}_1^{-1} = \mathbf{A}\,\mathbf{C}_k\,\mathbf{A}^{-1}$, $k = 2, \ldots, K$, and $k_{\mathbf{C}} \geq 2$. From the full SGSD of $\underline{\mathbf{X}}$, we obtain that also $\mathbf{Q}_a^T \mathbf{X}_k \mathbf{X}_1^{-1} \mathbf{Q}_a = \mathbf{R}_k \mathbf{R}_1^{-1}$, $k = 2, \ldots, K$ have a simultaneous eigendecomposition $\mathbf{R}_a \mathbf{C}_k \mathbf{R}_a^{-1}$, with $\mathbf{R}_a$ upper triangular up to a column permutation. From Kruskal's condition (1.4), it follows that $\mathbf{R}_k = \mathbf{R}_a \mathbf{C}_k \mathbf{R}_b$, with $\mathbf{R}_b = \mathbf{R}_a^{-1} \mathbf{R}_1$ and $\mathbf{C}_1 = \mathbf{I}_I$, is an essentially unique full CP decomposition. Thus we have $\mathbf{X}_k \mathbf{X}_1^{-1} = \mathbf{Q}_a \mathbf{R}_a \mathbf{C}_k \mathbf{R}_a^{-1} \mathbf{Q}_a^T = \mathbf{A} \mathbf{C}_k \mathbf{A}^{-1}$, $k = 2, \ldots, K$, which implies $\mathbf{Q}_a \mathbf{R}_a = \mathbf{A}$ (since $k_{\mathbf{C}} \geq 2$). Looking at $\mathbf{X}_1^{-1} \mathbf{X}_k$, we get equivalently $\mathbf{Q}_b \mathbf{R}_b^T = \mathbf{B}$. Hence, there are no other indeterminacies in the full SGSD of $\underline{\mathbf{X}}$ than those implied by CP essential uniqueness. This completes the proof. ∎

From the proof of Lemma 4.3, it follows that a CP decomposition of $\underline{\mathbf{X}}$ (if it exists) can be obtained from its full SGSD by computing the simultaneous eigendecomposi-

tion of $\mathbf{R}_k\mathbf{R}_1^{-1}$, $k = 2, \ldots, K$. This method is analogous to the one proposed in De Lathauwer, De Moor, and Vandewalle [6]. For the case $I \leq K$ a different method is given in Van der Veen and Paulraj [47].

5. The GSD model for $I \times I \times 2$ arrays. Here, we consider the SGSD model for $I \times I \times 2$ arrays and discuss its relation with the CP model. Since a (complex-valued) SGSD for two slices ($K = 2$) is known as a GSD (see Golub and Van Loan [12]), we will use the abbreviation GSD. Next, we show which of the arrays in Lemma 2.1 have a full (real-valued) GSD.

LEMMA 5.1. *For $\underline{\mathbf{X}} \in \mathcal{R}_I$, the following statements hold:*

(i) *If $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues and is diagonalizable, then $\underline{\mathbf{X}}$ has a full GSD.*
(ii) *If $\mathbf{X}_2\mathbf{X}_1^{-1}$ has at least one pair of complex eigenvalues, then $\underline{\mathbf{X}}$ does not have a full GSD.*
(iii) *If $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues but is not diagonalizable, then $\underline{\mathbf{X}}$ has a full GSD.*

Proof. If (i) holds, then $\underline{\mathbf{X}}$ has a full CP decomposition with $R = I$ of the form (2.2). Hence, $\underline{\mathbf{X}}$ also has a full GSD. Next, suppose (ii) holds, and $\underline{\mathbf{X}}$ has a full GSD. Then $\mathbf{X}_2\mathbf{X}_1^{-1} = \mathbf{Q}_a\mathbf{R}_2\mathbf{R}_1^{-1}\mathbf{Q}_a^T$, and

$$\det(\mathbf{X}_2\mathbf{X}_1^{-1} - \lambda\,\mathbf{I}_I) = \det(\mathbf{Q}_a^T\mathbf{X}_2\mathbf{X}_1^{-1}\mathbf{Q}_a - \lambda\,\mathbf{I}_I) = \det(\mathbf{R}_2\mathbf{R}_1^{-1} - \lambda\,\mathbf{I}_I).$$

Since $\mathbf{R}_2\mathbf{R}_1^{-1}$ is upper triangular and has only real eigenvalues, it follows that also $\mathbf{X}_2\mathbf{X}_1^{-1}$ has only real eigenvalues. But this contradicts (ii). Therefore, $\underline{\mathbf{X}}$ has no full GSD if (ii) holds.

Next, suppose (iii) holds. Then $\mathbf{X}_2\mathbf{X}_1^{-1} = \mathbf{P}\,\mathbf{J}\,\mathbf{P}^{-1}$, where $\mathbf{J}$ is the Jordan normal form. Let $\mathbf{P} = \mathbf{Q}_a\mathbf{R}_a$ be a QR-decomposition of $\mathbf{P}$, and let $\mathbf{X}_1^T\mathbf{Q}_a = \mathbf{Q}_b\mathbf{L}_b$ be a QL-decomposition of $\mathbf{X}_1^T\mathbf{Q}_a$. Then

$$\text{(5.1)}\quad \mathbf{X}_2 = \mathbf{Q}_a\mathbf{R}_a\mathbf{J}\mathbf{R}_a^{-1}\mathbf{Q}_a^T\mathbf{X}_1 = \mathbf{Q}_a\,(\mathbf{R}_a\mathbf{J}\mathbf{R}_a^{-1}\mathbf{L}_b^T)\,\mathbf{Q}_b^T \quad \text{and} \quad \mathbf{X}_1 = \mathbf{Q}_a\,\mathbf{L}_b^T\,\mathbf{Q}_b^T$$

is a full GSD of $\underline{\mathbf{X}}$. This completes the proof. ∎

Note that a full GSD requires $\mathbf{R}_1$ and $\mathbf{R}_2$ to be upper triangular. This is not the same as the generalized real Schur decomposition (see Golub and Van Loan [12]), which always exists for two $I \times I$ matrices and which has $\mathbf{R}_1$ upper quasi-triangular.

As we see from Lemma 5.1, the arrays satisfying (iii) do not have a full CP decomposition with $R = I$ but do have a full GSD. Note that the CP decomposition of arrays satisfying (i) is essentially unique if and only if the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ are distinct; see (ii) of Lemma 4.3.

Since (iii) of Lemma 4.3 does not apply to the GSD in (5.1), one may wonder what the uniqueness properties of (5.1) are. The Jordan form $\mathbf{J} = \operatorname{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$ is unique up to the order of the Jordan blocks. If $\lambda_1, \ldots, \lambda_p, \mu_1, \ldots, \mu_r$ are distinct, then the columns of $\mathbf{P}$ are unique up to the same ordering and up to scaling. Suppose there is a second GSD, i.e., $\mathbf{X}_k = \widetilde{\mathbf{Q}}_a\,\widetilde{\mathbf{R}}_k\,\widetilde{\mathbf{Q}}_b^T$, $k = 1, 2$. Then there holds $\widetilde{\mathbf{R}}_2\,\widetilde{\mathbf{R}}_1^{-1} = (\widetilde{\mathbf{Q}}_a^T\mathbf{P})\,\mathbf{J}\,(\widetilde{\mathbf{Q}}_a^T\mathbf{P})^{-1}$. In fact, we have $\widetilde{\mathbf{Q}}_a^T\mathbf{P} = \widehat{\mathbf{R}}\,\mathbf{\Pi}$, with $\widehat{\mathbf{R}}$ upper triangular and $\mathbf{\Pi}$ a permutation. Then $\widetilde{\mathbf{R}}_2\,\widetilde{\mathbf{R}}_1^{-1} = \widehat{\mathbf{R}}\,(\mathbf{\Pi}\,\mathbf{J}\,\mathbf{\Pi}^T)\,\widehat{\mathbf{R}}$ is a Jordan form with a different ordering of the Jordan blocks. Hence, the GSD in (5.1) is unique up to the indeterminacies of the Jordan form of $\mathbf{X}_2\mathbf{X}_1^{-1}$.

6. Using the GSD model to avoid diverging CP components. Here, we show how the relation between the GSD and CP models for $I \times I \times 2$ arrays can be used to avoid the problems of diverging CP components discussed in section 3.

First, we establish a relation between the set of $I \times I \times 2$ arrays that have a full CP decomposition with $R = I$, i.e., the set $\mathcal{S}_I$ in (3.1), and the set of arrays that have a full GSD. Let

$$\mathcal{P}_I = \{\underline{\mathbf{Y}} \in \mathcal{R}_I : \underline{\mathbf{Y}} \text{ has a full GSD}\}. \tag{6.1}$$

Hence, the set $\mathcal{P}_I$ consists of the arrays satisfying either (i) or (iii) in Lemma 5.1. From Lemmas 2.1 and 5.1, it follows that $\mathcal{S}_I \subset \mathcal{P}_I$. Moreover, Lemmas 3.1 and 5.1 show that $\mathcal{P}_I$ is the closure of $\mathcal{S}_I$ in $\mathcal{R}_I$ and has the same interior points and boundary points as $\mathcal{S}_I$. For the boundary points $\underline{\mathbf{X}}$ of $\mathcal{P}_I$ and $\mathcal{S}_I$, the matrix $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues which are not all distinct; see Lemma 3.1. As explained in Remark 3.2, the boundary points $\underline{\mathbf{X}}$ of type II, i.e., with $\mathbf{X}_2\mathbf{X}_1^{-1}$ not diagonalizable, lie dense on the boundary of $\mathcal{P}_I$.

Let $\underline{\mathbf{Z}}$ be a typical $I \times I \times 2$ array of rank $I+1$, i.e., $\underline{\mathbf{Z}}$ satisfies (ii) of Lemma 5.1. Recall that the CP problem (3.2) for $\underline{\mathbf{Z}}$ usually does not have an optimal solution (see Remark 3.2). We define the analogue GSD problem as

$$\begin{aligned} &\text{Minimize} \|\underline{\mathbf{Z}} - \underline{\mathbf{Y}}\|^2 \\ &\text{subject to } \underline{\mathbf{Y}} \in \mathcal{P}_I. \end{aligned} \tag{6.2}$$

From the analysis in Stegeman [38], it follows that $\mathcal{P}_I$ is a closed subset of $\mathcal{R}_I$. Hence, the GSD problem (6.2) has an optimal solution, and a GSD algorithm finds an optimal solution $\underline{\mathbf{X}}$ of problem (6.2) in terms of its full GSD. We will assume that the optimal solution $\underline{\mathbf{X}}$ obtained for the GSD problem (6.2) is a boundary point of $\mathcal{P}_I$ of type II, i.e., $\mathbf{X}_2\mathbf{X}_1^{-1}$ has I real eigenvalues but is not diagonalizable. We conjecture (see Remark 3.2) that this is true almost everywhere for typical $\underline{\mathbf{Z}}$ of rank $I+1$.

From the observations above and our discussion in section 3, it follows that the optimal solution $\underline{\mathbf{X}}$ of the GSD problem (6.2), if it is unique, is the limit point of the sequence of CP updates (featuring diverging components) which attempts to converge to the (nonexisting) optimal solution of the CP problem (3.2).

Next, we show how to extract the nondiverging CP components from the optimal GSD solution. The limit point of the diverging CP components can be obtained from the optimal GSD solution as a Tucker3 part from the Jordan form of $\mathbf{X}_2\mathbf{X}_1^{-1}$ or as a smaller GSD part. These CP+Jordan and CP+GSD representations will be discussed in sections 6.1 and 6.3, respectively. In section 6.2, we show how the GSD solution can be decomposed into rank-1 terms using the CP+Jordan representation. Here, the number of rank-1 terms equals the rank of the solution array.

6.1. Optimal GSD solution in CP+Jordan form. Let $\underline{\mathbf{X}}$ be the optimal solution of the GSD problem (6.2). As explained above, we assume that $\mathbf{X}_2\mathbf{X}_1^{-1}$ has only real eigenvalues but is not diagonalizable. Next, we show how to obtain the nondiverging CP components from $\underline{\mathbf{X}}$ and write the limit points of the groups of diverging CP components in Jordan form. We have $\mathbf{X}_k = \mathbf{Q}_a\,\mathbf{R}_k\,\mathbf{Q}_b^T$, $k = 1, 2$ from a GSD algorithm. Since $\underline{\mathbf{X}} \in \mathcal{R}_I$, the matrices $\mathbf{R}_k$, $k = 1, 2$ are nonsingular. Let the Jordan normal form $\mathbf{P}\,\mathbf{J}\,\mathbf{P}^{-1}$ of $\mathbf{R}_2\mathbf{R}_1^{-1}$ be given by $\mathbf{J} = \text{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$, where $\mathbf{J}_{m_j}(\mu_j)$ denotes an $m_j \times m_j$ Jordan block with $m_j \geq 2$, and $r \geq 1$. Note that the Jordan form $\mathbf{J}$ of $\mathbf{R}_2\mathbf{R}_1^{-1}$ is also the Jordan form of $\mathbf{X}_2\mathbf{X}_1^{-1}$. Hence, $\mathbf{R}_2\mathbf{R}_1^{-1}$ also has only real eigenvalues but is not diagonalizable.

Now the following decomposition of $\underline{\mathbf{X}}$ can be obtained. Let $\mathbf{C}_1 = \mathbf{I}_p$, $\mathbf{C}_2 = \text{diag}(\lambda_1, \ldots, \lambda_p)$, and let $\mathbf{A}$ contain the corresponding columns of $\mathbf{Q}_a\mathbf{P}$ and $\mathbf{B}^T$ the corresponding rows of $\mathbf{P}^{-1}\mathbf{R}_1\mathbf{Q}_b^T$. For the r Jordan blocks $\mathbf{J}_{m_j}$, let $\mathbf{K}_j$ contain the corresponding columns of $\mathbf{Q}_a\mathbf{P}$ and $\mathbf{L}_j^T$ the corresponding rows of $\mathbf{P}^{-1}\mathbf{R}_1\mathbf{Q}_b^T$. Then

$$\mathbf{X}_2 = \mathbf{A}\,\mathbf{C}_2\,\mathbf{B}^T + \sum_{j=1}^{r} \mathbf{K}_j\,\mathbf{J}_{m_j}\,\mathbf{L}_j^T, \tag{6.3}$$

$$\mathbf{X}_1 = \mathbf{A}\,\mathbf{C}_1\,\mathbf{B}^T + \sum_{j=1}^{r} \mathbf{K}_j\,\mathbf{I}_{m_j}\,\mathbf{L}_j^T. \tag{6.4}$$

Hence, we have decomposed the optimal GSD solution $\underline{\mathbf{X}}$ into a nondiverging CP part and r parts with a Jordan block $\mathbf{J}_{m_j}$ instead of a diagonal matrix. In this way, diverging CP components are avoided, i.e., the components $\mathbf{A}, \mathbf{K}_1, \ldots, \mathbf{K}_r$ are linearly independent (since they are columns of $\mathbf{Q}_a\mathbf{P}$), the components $\mathbf{B}, \mathbf{L}_1, \ldots, \mathbf{L}_r$ are linearly independent (since they are the rows of $\mathbf{P}^{-1}\mathbf{R}_1\mathbf{Q}_b^T$), and none of the elements in the decomposition tends to infinity. Note that each part of the decomposition (6.3)–(6.4) can be written in GSD form by using QR- and QL-decompositions as in the proof of (i) of Lemma 4.3.

If the eigenvalues $\lambda_1, \ldots, \lambda_p$ are distinct, then the CP-part of the representation (6.3)–(6.4) is essentially unique. Indeed, we have p components and k-ranks $k_{\mathbf{A}} = k_{\mathbf{B}} = p$ and $k_{\mathbf{C}} = 2$, and essential uniqueness follows from Kruskal's condition (1.4). From the uniqueness properties of the Jordan form of $\mathbf{R}_2\mathbf{R}_1^{-1}$ it follows that if $\mu_1, \ldots, \mu_r$ are distinct, then the representation of the non-CP part of (6.3)–(6.4) is unique up to the order of the Jordan blocks $\mathbf{J}_{m_j}$ and the scaling of the principal vectors in $\mathbf{P}$.

Although the decomposition (6.3)–(6.4) features not only rank-1 terms, it is essentially unique and may be interpretable to the researcher. From a computational as well as a practical point of view, this is a considerable improvement with respect to facing diverging CP components.

In practice, the matrix $\mathbf{R}_2\mathbf{R}_1^{-1}$ of the corresponding optimal GSD solution obtained from a GSD algorithm does not have exactly identical eigenvalues. To be able to "recognize" the identical eigenvalues of $\mathbf{R}_2\mathbf{R}_1^{-1}$ and their geometric multiplicities, the GSD algorithm must have a sufficiently small stopping criterion. The identical eigenvalues can then be estimated as the average of the ones which are "close together." The Jordan normal form of $\mathbf{R}_2\mathbf{R}_1^{-1}$ can be estimated by using, e.g., the method proposed in Golub and Wilkinson [11]. Below, we present the algorithm to obtain representation (6.3)–(6.4). The algorithm is formulated for general R (instead of $R = I$) in order to make it applicable to the $I \times J \times 2$ case as well (see section 7).

ALGORITHM FOR CP+JORDAN REPRESENTATION OF OPTIMAL GSD SOLUTION.

Input: Optimal GSD solution $\mathbf{X}_k = \mathbf{Q}_a\,\mathbf{R}_k\,\mathbf{Q}_b^T$, $k = 1, 2$, where $\mathbf{R}_2\mathbf{R}_1^{-1}$ has only real eigenvalues but is not diagonalizable.

Output: CP+Jordan representation (6.3)–(6.4).

1. Calculate the Jordan form $\mathbf{P}\,\mathbf{J}\,\mathbf{P}^{-1}$ of $\mathbf{R}_2\mathbf{R}_1^{-1}$, where $\mathbf{J} = \operatorname{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$. Here, $\mathbf{J}_{m_j}(\mu_j)$ denotes an $m_j \times m_j$ Jordan block with $m_j \geq 2$, and $r \geq 1$.
2. Set $\mathbf{C}_1 = \mathbf{I}_p$, $\mathbf{C}_2 = \operatorname{diag}(\lambda_1, \ldots, \lambda_p)$. For eigenvalues $\lambda_1, \ldots, \lambda_p$, let $\mathbf{A}$ contain the corresponding columns of $\mathbf{Q}_a\mathbf{P}$ and $\mathbf{B}^T$ the corresponding rows of $\mathbf{P}^{-1}\mathbf{R}_1\mathbf{Q}_b^T$.
3. For Jordan block $\mathbf{J}_{m_j}$, let $\mathbf{K}_j$ contain the corresponding columns of $\mathbf{Q}_a\mathbf{P}$ and $\mathbf{L}_j^T$ the corresponding rows of $\mathbf{P}^{-1}\mathbf{R}_1\mathbf{Q}_b^T$, $j = 1, \ldots, r$.
4. The CP+Jordan representation (6.3)–(6.4) follows, with p nondiverging CP components in $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}_1$, $\mathbf{C}_2$ and r limit points of groups of diverging CP components (see section 3).

The following result states that (6.3)–(6.4) can be written as a Tucker3 model (1.2).

PROPOSITION 6.1. *Let the Jordan form of* $\mathbf{R}_2\mathbf{R}_1^{-1}$ *be given by* $\operatorname{diag}(\lambda_1,\ldots,\lambda_p, \mathbf{J}_{m_1}(\mu_1),\ldots,\mathbf{J}_{m_r}(\mu_r))$, *where* $\mathbf{J}_{m_j}(\mu_j)$ *denotes an* $m_j \times m_j$ *Jordan block with* $m_j \geq 2$. *Set* $M = p + r + 1$. *The decomposition* (6.3)–(6.4) *can be written as a Tucker*3 *model with an* $I \times I \times M$ *core array and component matrices*

$$[\mathbf{A} \,|\, \mathbf{K}_1 \,|\, \ldots \,|\, \mathbf{K}_r], \quad [\mathbf{B} \,|\, \mathbf{L}_1 \,|\, \ldots \,|\, \mathbf{L}_r], \quad \begin{bmatrix} 1 & \ldots & 1 & 0 & 1 & \ldots & 1 \\ \lambda_1 & \ldots & \lambda_p & 1 & \mu_1 & \ldots & \mu_r \end{bmatrix}. \tag{6.5}$$

The number of nonzeros in the core array equals $2I - (p + r)$.

Proof. The first p columns of the component matrices in (6.5) follow from the CP part in (6.3)–(6.4). Next, we consider a Jordan block $\mathbf{J}_m(\mu)$, with $m \geq 2$. The corresponding part in (6.3)–(6.4) can be written as

$$\sum_{i=1}^{m} \mathbf{k}_i \otimes \mathbf{l}_i \otimes \begin{pmatrix} 1 \\ \mu \end{pmatrix} + \sum_{i=1}^{m-1} \mathbf{k}_i \otimes \mathbf{l}_{i+1} \otimes \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \tag{6.6}$$

where $\mathbf{k}_i$ and $\mathbf{l}_i$ are the columns of the corresponding matrices $\mathbf{K}$ and $\mathbf{L}$, respectively. Hence, (6.6) uses the corresponding columns of the component matrices in (6.5) and adds $m + (m-1)$ nonzeros to the Tucker3 core array.

Since the CP part adds p nonzeros to the Tucker3 core array, the total number of nonzeros equals

$$p + \sum_{j=1}^{r}(2m_j - 1) = p - r + 2\sum_{j=1}^{r} m_j = p - r + 2(I - p) = 2I - (p + r). \tag{6.7}$$

This completes the proof. ∎

Note that the restricted Tucker3 model in Proposition 6.1 is unique up to the indeterminacies in the CP+Jordan representation (6.3)–(6.4).

The result of Proposition 6.1 is in line with Harshman [15], who explains diverging CP components for $2 \times 2 \times 2$ arrays as "Parafac trying to model Tucker variation." Paatero [33] also noticed that his constructed sequences of diverging CP components have a limit that can be written in Tucker3 form.

The decomposition (6.3)–(6.4) of $\underline{\mathbf{X}}$ into p rank-1 terms and r rank-$(m_j, m_j, 2)$ terms (i.e., the ranks of the vectors in the three modes are m_j, m_j, and 2) is an example of the *block-term decomposition* introduced in De Lathauwer [8].

Remark 6.2. Note that it is not our goal to find a CP+Tucker3 representation of $\underline{\mathbf{Z}}$, for which $\mathbf{Z}_2\mathbf{Z}_1^{-1}$ has some complex eigenvalues. Such a representation exists if the eigenvalues of $\mathbf{Z}_2\mathbf{Z}_1^{-1}$ are distinct and can be obtained from the transformation

$$\mathbf{Z}_2\mathbf{Z}_1^{-1} = \mathbf{K}\,\mathbf{\Lambda}\,\mathbf{K}^{-1}, \tag{6.8}$$

where $\mathbf{\Lambda} = \operatorname{diag}(\lambda_1,\ldots,\lambda_s,\mathbf{\Gamma}_1,\ldots,\mathbf{\Gamma}_t)$ and $\mathbf{\Gamma}_i$ is 2×2 and corresponds to a pair of complex eigenvalues of $\mathbf{Z}_2\mathbf{Z}_1^{-1}$; see, e.g., Horn and Johnson [19]. Instead, it is our goal to find the limit point $\underline{\mathbf{X}}$ of the sequence of CP updates featuring diverging components, and (6.3)–(6.4) is a representation of that point $\underline{\mathbf{X}}$.

Next, we illustrate the CP+Jordan algorithm by revisiting the $4 \times 4 \times 2$ example in (1.7)–(1.10) that was also discussed at the end of section 3. Using the Jacobi algorithm of De Lathauwer, De Moor, and Vandewalle [6] with $R = 4$ and a convergence criterion

of `1e-9`, we obtain the following optimal GSD solution for $\underline{\mathbf{Z}}$ in (1.7):

$$\mathbf{Q}_a = \begin{bmatrix} 0.1279 & 0.8039 & -0.5519 & 0.1813 \\ -0.7946 & -0.1776 & -0.2749 & 0.5113 \\ -0.5895 & 0.3628 & 0.1606 & -0.7037 \\ 0.0690 & -0.4367 & -0.7708 & -0.4588 \end{bmatrix}, \tag{6.9}$$

$$\mathbf{Q}_b = \begin{bmatrix} -0.6328 & 0.3387 & -0.0964 & -0.6896 \\ 0.6382 & 0.5502 & -0.4778 & -0.2486 \\ 0.1774 & 0.5110 & 0.8406 & -0.0294 \\ -0.4011 & 0.5670 & -0.2363 & 0.6795 \end{bmatrix}, \tag{6.10}$$

$$\mathbf{R}_1 = \begin{bmatrix} -1.1875 & -1.3604 & 1.1724 & -1.5430 \\ 0 & -1.0758 & 0.4567 & -0.3733 \\ 0 & 0 & -0.9103 & -0.7889 \\ 0 & 0 & 0 & 1.5915 \end{bmatrix}, \tag{6.11}$$

$$\mathbf{R}_2 = \begin{bmatrix} 1.8323 & 0.0832 & 0.0009 & -0.0168 \\ 0 & -0.5285 & -2.5802 & -0.9022 \\ 0 & 0 & -0.4472 & 1.4516 \\ 0 & 0 & 0 & 0.7818 \end{bmatrix}. \tag{6.12}$$

The GSD algorithm terminated after 24 sweeps with an error sum-of-squares of 0.051016. The latter is less than the value of 0.051204 obtained by the CP algorithm in section 1, indicating that the GSD solution is closer to $\underline{\mathbf{Z}}$ than the final CP update. The sum-of-squares distance between the GSD solution $\mathbf{X}_k = \mathbf{Q}_a\,\mathbf{R}_k\,\mathbf{Q}_b^T$, $k = 1, 2$ and the final CP update $\mathbf{Y}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$, $k = 1, 2$ is only 3.2144e-7. For the GSD solution, the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ are

$$-1.5430, \qquad 0.4912, \qquad 0.4912, \qquad 0.4912. \tag{6.13}$$

Hence, for the final CP update, the three eigenvalues of $\mathbf{Y}_2\mathbf{Y}_1$ that were close together in (3.3) have become identical in the limit point $\underline{\mathbf{X}}$.

Next, we apply the CP+Jordan algorithm to the obtained GSD solution above. For the CP-part, we obtain

$$\mathbf{A} = \begin{bmatrix} 0.1279 \\ -0.7946 \\ -0.5895 \\ 0.0690 \end{bmatrix}, \qquad \mathbf{B} = \begin{bmatrix} 0.8259 \\ 0.0385 \\ -0.4005 \\ -0.3950 \end{bmatrix}, \qquad \mathbf{C} = \begin{bmatrix} 2.8918 \\ -4.4621 \end{bmatrix}, \tag{6.14}$$

where the columns of $\mathbf{A}$ and $\mathbf{B}$ are normalized to length 1. Comparing this to the final CP-update in (1.8)–(1.10), we see that (6.14) is the nondiverging CP component of the final CP update. For the non-CP part of the CP+Jordan representation, we obtain

$$\mathbf{K} = \begin{bmatrix} -0.6779 & -0.0194 & -0.0500 \\ 0.6690 & -0.0900 & -0.1191 \\ 0.1326 & -0.2662 & 0.1248 \\ 0.2744 & 0.3003 & 0.1064 \end{bmatrix}, \quad \mathbf{L} = \begin{bmatrix} 0.8879 & -2.6832 & 5.3125 \\ 1.7433 & -2.6564 & 1.9149 \\ -0.7556 & 3.1066 & 0.2265 \\ 1.0387 & 1.3806 & -5.2348 \end{bmatrix}, \tag{6.15}$$

$$\mathbf{J} = \begin{bmatrix} 0.4912 & 1 & 0 \\ 0 & 0.4912 & 1 \\ 0 & 0 & 0.4912 \end{bmatrix}. \tag{6.16}$$

Hence, the limit point of the three diverging CP components is represented as (6.15)–(6.16).

6.2. A rank-revealing decomposition of the optimal GSD solution. Here we discuss how one may obtain a decomposition into rank-1 terms of the optimal GSD solution, where the number of rank-1 terms equals the rank of the solution array $\underline{\mathbf{X}}$. We make use of the CP+Jordan representation (6.3)–(6.4). The Tucker3 representation of $\underline{\mathbf{X}}$ in Proposition 6.1 decomposes $\underline{\mathbf{X}}$ into $2I-(p+r)$ rank-1 terms. Lemma 2.2 states that $\underline{\mathbf{X}}$ has rank $I+r$. Hence, the number of rank-1 terms in the Tucker3 representation is equal to $\text{rank}_{\otimes}(\underline{\mathbf{X}}) = I+r$ if and only if $I = p+2r$. That is, if all Jordan blocks $\mathbf{J}_{m_j}(\mu_j)$ have size $m_j = 2$. In this case, (6.3)–(6.4) itself is a rank-revealing decomposition of $\underline{\mathbf{X}}$. From (6.6), it follows that for $p = 0$, $r = 1$, and $m = 2$, the representation has the form (1.11) of De Silva and Lim [10] with $\mathbf{x}_1 = \mathbf{k}_1$, $\mathbf{x}_2 = \mathbf{l}_2$, $\mathbf{x}_3 = \binom{1}{\mu}$, $\mathbf{y}_1 = \mathbf{k}_2$, $\mathbf{y}_2 = \mathbf{l}_1$, and $\mathbf{y}_3 = \binom{0}{1}$. For general p and r and $m_j = 2$ for $j = 1, \ldots, r$, the representation (1.11) can be generalized to

$$\underline{\mathbf{X}} = \sum_{i=1}^{p} \mathbf{z}_1^{(i)} \otimes \mathbf{z}_2^{(i)} \otimes \mathbf{z}_3^{(i)} + \sum_{j=1}^{r} (\mathbf{x}_1^{(j)} \otimes \mathbf{x}_2^{(j)} \otimes \mathbf{y}_3 + \mathbf{x}_1^{(j)} \otimes \mathbf{y}_2^{(j)} \otimes \mathbf{x}_3^{(j)} + \mathbf{y}_1^{(j)} \otimes \mathbf{x}_2^{(j)} \otimes \mathbf{x}_3^{(j)}). \tag{6.17}$$

If there is a Jordan block $\mathbf{J}_{m_j}(\mu_j)$ with size $m_j \geq 3$, then the number of rank-1 terms in the decomposition (6.3)–(6.4) is larger than $\text{rank}_{\otimes}(\underline{\mathbf{X}}) = I+r$. However, a method to obtain a decomposition into $I+r$ rank-1 terms from (6.3)–(6.4) can be found in Ja' Ja' [21]. Consider the $m \times m \times 2$ array consisting of the slices $\mathbf{I}_m$ and $\mathbf{J}_m(\mu)$, with $m \geq 2$. From Lemma 2.2, it follows that this array has rank $m+1$. Let $\mathbf{w} = (w_0\ w_1\ \ldots w_{m-1})^T$, and let $\mathbf{e}_m$ denote the mth column of $\mathbf{I}_m$. Then $\mathbf{J}_m(\mu) - \mathbf{e}_m\,\mathbf{w}^T$ has characteristic polynomial $f(\lambda - \mu)$, with

$$f(x) = w_0 + w_1\,x + \cdots + w_{m-1}\,x^{m-1} - x^m. \tag{6.18}$$

It follows that we can pick $\mathbf{w}$ such that $f(x)$ has m distinct real roots. By Lemma 2.1, the $m \times m \times 2$ array with slices $\mathbf{I}_m$ and $\mathbf{J}_m(\mu) - \mathbf{e}_m\,\mathbf{w}^T$ has rank m, and a rank-m decomposition can be obtained from an eigendecomposition of its second slice. Since we have subtracted the rank-1 slice $\mathbf{e}_m\,\mathbf{w}^T$, this gives us a rank-$(m+1)$ decomposition of the array with $\mathbf{I}_m$ and $\mathbf{J}_m(\mu)$.

Applying this procedure to each Jordan block in (6.3)–(6.4) yields a decomposition of $\underline{\mathbf{X}}$ into $p + \sum_{j=1}^{r}(m_j+1) = I+r$ rank-1 terms. Since we have freedom in choosing the vector $\mathbf{w}$, this decomposition is not essentially unique (also for $m_j = 2$).

6.3. Optimal GSD solution in CP+GSD form. Since the Jordan form has a discontinuous transition from diagonalizable to nondiagonalizable matrices, it is numerically unstable, and the obtained Jordan form is extremely sensitive to tolerances for "recognizing" identical eigenvalues; see the discussion in Golub and Van Loan [12]. It follows from (6.3)–(6.4) that the complete non-CP part may also be represented in a full GSD of size $I-p$. For this, one only has to determine the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ with algebraic multiplicity equal to 1, which is numerically more stable. Here, we show how the CP part and the GSD of the non-CP part can be computed without first computing the Jordan representation (6.3)–(6.4). Also, if one is only interested in obtaining the nondiverging CP components, computing the CP-part of the CP+GSD representation is an efficient way.

We assume that the optimal GSD solution $\underline{\mathbf{X}}$ has been obtained from a GSD algorithm and the GSD $\mathbf{X}_k = \mathbf{Q}_a \mathbf{R}_k \mathbf{Q}_b^T$, $k = 1, 2$ is known. Let the Jordan form of $\mathbf{R}_2\mathbf{R}_1^{-1}$ be given by $\mathbf{J} = \text{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$, where $\mathbf{J}_{m_j}(\mu_j)$ denotes an $m_j \times m_j$ Jordan block with $m_j \geq 2$, and $r \geq 1$. The eigenvalues and the Jordan form $\mathbf{J}$ of $\mathbf{R}_2\mathbf{R}_1^{-1}$ are the same as those of $\mathbf{X}_2\mathbf{X}_1^{-1}$ and those of $\mathbf{R}_1^{-1}\mathbf{R}_2$. As mentioned above, we assume that $\mathbf{R}_2\mathbf{R}_1^{-1}$ has only real eigenvalues but is not diagonalizable. In the following, we assume that the eigenvalues $\lambda_1, \ldots, \lambda_p$ are known. For this, it is not necessary to compute the complete Jordan form $\mathbf{J}$.

First, we show how to obtain the CP-part of (6.3)–(6.4). For simplicity, we assume that none of the eigenvalues μ_j is equal to a λ_i. Let $\mathbf{R}_a$ have as columns the eigenvectors of $\mathbf{R}_2\mathbf{R}_1^{-1}$ corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_p$. From the discussion in section 6.1, it follows that $\mathbf{A} = \mathbf{Q}_a \mathbf{R}_a$. Next, we find $\mathbf{B}$. If $\mathbf{R}_2\mathbf{R}_1^{-1} = \mathbf{P}\,\mathbf{J}\,\mathbf{P}^{-1}$, then $\mathbf{R}_1^{-1}\mathbf{R}_2 = (\mathbf{R}_1^{-1}\mathbf{P})\,\mathbf{J}\,(\mathbf{R}_1^{-1}\mathbf{P})^{-1}$. Let $\mathbf{R}_b$ have as rows the left eigenvectors of $\mathbf{R}_1^{-1}\mathbf{R}_2$ corresponding to the eigenvalues $\lambda_1, \ldots, \lambda_p$, i.e., $\mathbf{R}_b\,\mathbf{R}_1^{-1}\mathbf{R}_2 = \text{diag}(\lambda_1, \ldots, \lambda_p)\,\mathbf{R}_b$. Then we have $\mathbf{B} = \mathbf{Q}_b\,\mathbf{R}_b^T$ (see section 6.1). Since $\mathbf{R}_2\mathbf{R}_1^{-1}$ and $\mathbf{R}_1^{-1}\mathbf{R}_2$ are upper triangular, the columns of $\mathbf{R}_a$ and the rows of $\mathbf{R}_b$ are the columns and rows, respectively, of an $I \times I$ upper triangular matrix. We normalize the rows of $\mathbf{R}_b$ such that the first nonzero element becomes 1, and we normalize the columns of $\mathbf{R}_a$ such that the last nonzero element becomes 1. Let $\mathbf{C}_k$ be the $p \times p$ diagonal matrix containing the diagonal elements of $\mathbf{R}_k$ corresponding to the locations of $\lambda_1, \ldots, \lambda_p$ on the diagonal of $\mathbf{R}_2\mathbf{R}_1^{-1}$. It now follows that the CP-part in (6.3)–(6.4) is equal (up to scaling/rescaling and a joint permutation of the p CP components) to $\mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$, $k = 1, 2$.

Note that the eigenvalues $\lambda_1, \ldots, \lambda_p$ may appear anywhere on the diagonal of $\mathbf{R}_2\mathbf{R}_1^{-1}$. Hence, unlike the ordering in the Jordan form $\mathbf{J}$, the eigenvalues λ_j do not need to appear as the first p diagonal elements of $\mathbf{R}_2\mathbf{R}_1^{-1}$. This is due to the permutation indeterminacy of the GSD solution. See also the discussion at the end of section 5.

Next, we show how to obtain the GSD of the non-CP part of (6.3)–(6.4). Define $\mathbf{T}_k = \mathbf{R}_k - \mathbf{R}_a\,\mathbf{C}_k\,\mathbf{R}_b$, $k = 1, 2$. Then $\mathbf{Y}_k = \mathbf{Q}_a\,\mathbf{T}_k\,\mathbf{Q}_b^T$, $k = 1, 2$ is the non-CP part of (6.3)–(6.4). From (6.3)–(6.4), it follows that $\mathbf{Y}_1 = \mathbf{K}\,\mathbf{I}_{I-p}\,\mathbf{L}^T$ and $\mathbf{Y}_2 = \mathbf{K}\,\tilde{\mathbf{J}}\,\mathbf{L}^T$ for $I \times (I-p)$ matrices $\mathbf{K}$ and $\mathbf{L}$ of full column rank and an $(I-p) \times (I-p)$ Jordan form $\tilde{\mathbf{J}}$. This implies that $\mathbf{Y}_1$ and $\mathbf{Y}_2$ have rank $I-p$ and identical column and row spaces. These properties of $\mathbf{Y}_1$ and $\mathbf{Y}_2$ also hold for $\mathbf{T}_1$ and $\mathbf{T}_2$. Moreover, by definition, $\mathbf{T}_k$ is upper triangular and has zeros on the diagonal corresponding to the locations of $\lambda_1, \ldots, \lambda_p$ on the diagonal of $\mathbf{R}_2\mathbf{R}_1^{-1}$. From the I locations on the diagonal of $\mathbf{R}_2\mathbf{R}_1^{-1}$, let $1 \leq i_1 < i_2 < \cdots < i_{I-p} \leq I$ be those not containing $\lambda_1, \ldots, \lambda_p$. Let $\widetilde{\mathbf{T}}_k$ contain the columns $i_1, i_2, \ldots, i_{I-p}$ of $\mathbf{T}_k$, in the same order as they appear in $\mathbf{T}_k$, $k = 1, 2$. Then each of these columns has a nonzero diagonal element in $\mathbf{T}_k$, and since $\mathbf{T}_k$ is upper triangular, $\widetilde{\mathbf{T}}_k$ has rank $I-p$. Since $\mathbf{T}_k$ also has rank $I-p$, it follows that the column spaces of $\widetilde{\mathbf{T}}_k$ and $\mathbf{T}_k$ are identical. Also, the column spaces of $\widetilde{\mathbf{T}}_1$ and $\widetilde{\mathbf{T}}_2$ are identical. We write $\mathbf{T}_k = \widetilde{\mathbf{T}}_k\,\mathbf{H}_k^T$, where $\mathbf{H}_k = \mathbf{T}_k^T\,\widetilde{\mathbf{T}}_k\,(\widetilde{\mathbf{T}}_k^T\widetilde{\mathbf{T}}_k)^{-1}$, $k = 1, 2$. We need the following lemmas.

LEMMA 6.3. *There holds* $\widetilde{\mathbf{T}}_k = \widetilde{\mathbf{Q}}\,\widetilde{\mathbf{R}}_k$ *for some* $I \times (I-p)$ *columnwise orthonormal* $\widetilde{\mathbf{Q}}$ *and some* $(I-p) \times (I-p)$ *upper triangular* $\widetilde{\mathbf{R}}_k$, $k = 1, 2$.

Proof. Let $\widetilde{\mathbf{T}}_k$ contain columns $i_1, \ldots, i_{I-p}$ of $\mathbf{T}_k$, with $1 \leq i_1 < i_2 < \cdots < i_{I-p} \leq I$. Let $\mathbf{t}_{i_n}^{(k)}$ denote column i_n of $\mathbf{T}_k$, which is column n of $\widetilde{\mathbf{T}}_k$, $k = 1, 2$. Then $\mathbf{t}_{i_n}^{(k)}$ has the last $I - i_n$ elements equal to zero and element i_n nonzero. We obtain $\widetilde{\mathbf{Q}}$ and $\widetilde{\mathbf{R}}_1$ from a QR-decomposition of $\widetilde{\mathbf{T}}_1$ by means of the Gram–Schmidt process.

Let

$$\mathbf{v}_1 = \mathbf{t}_{i_1}^{(1)} \qquad \text{and} \qquad \mathbf{v}_n = \mathbf{t}_{i_n}^{(1)} - \sum_{j=1}^{n-1} \text{proj}_{\mathbf{v}_j}\, \mathbf{t}_{i_n}^{(1)}, \qquad n = 2, \ldots, I-p, \tag{6.19}$$

where $\text{proj}_{\mathbf{v}}\, \mathbf{t} = (\mathbf{t}^T\mathbf{v})/(\mathbf{v}^T\mathbf{v})\, \mathbf{v}$ denotes the orthogonal projection of $\mathbf{t}$ onto $\mathbf{v}$. The columns of $\widetilde{\mathbf{Q}}$ are the unit length versions of $\mathbf{v}_1, \ldots, \mathbf{v}_{I-p}$, and the elements of $\widetilde{\mathbf{R}}_1$ follow from (6.19).

The columns of $\widetilde{\mathbf{Q}}$ form an orthonormal basis for the column space of $\widetilde{\mathbf{T}}_1$ and, hence, also for the column space of $\widetilde{\mathbf{T}}_2$. This implies that for every column $\mathbf{t}_{i_n}^{(2)}$, there is a vector $\mathbf{w}$ such that

$$\mathbf{t}_{i_n}^{(2)} = \widetilde{\mathbf{Q}}\, \mathbf{w}. \tag{6.20}$$

From (6.19), it follows that column j of $\widetilde{\mathbf{Q}}$ has the last $I - i_j$ elements equal to zero and element i_j nonzero, $j = 1, \ldots, I-p$. Since $\mathbf{t}_{i_n}^{(2)}$ has the last $I - i_n$ elements equal to zero, (6.20) implies that $\mathbf{t}_{i_n}^{(2)}$ lies in the space spanned by the first n columns of $\widetilde{\mathbf{Q}}$. Hence, $\mathbf{w}$ in (6.20) has the last $I - p - n$ elements equal to zero. It follows that $\widetilde{\mathbf{T}}_2 = \widetilde{\mathbf{Q}}\, \widetilde{\mathbf{R}}_2$ for some $(I-p) \times (I-p)$ upper triangular $\widetilde{\mathbf{R}}_2$. Since $\widetilde{\mathbf{Q}}$ has full column rank, the matrix $\widetilde{\mathbf{R}}_2$ is uniquely determined. This completes the proof. ∎

Recall that, since the column spaces of $\widetilde{\mathbf{T}}_k$ and $\mathbf{T}_k$ are identical, we may write $\mathbf{T}_k = \widetilde{\mathbf{T}}_k\, \mathbf{H}_k^T$, $k = 1, 2$.

LEMMA 6.4. *Let* $\mathbf{H}_k$ *satisfy* $\mathbf{T}_k = \widetilde{\mathbf{T}}_k\, \mathbf{H}_k^T$, $k = 1, 2$. *Then* $\mathbf{H}_1 = \mathbf{H}_2$.

Proof. Since $\widetilde{\mathbf{T}}_k$ contains columns $i_1, \ldots, i_{I-p}$ of $\mathbf{T}_k$, it follows that rows $i_1, \ldots, i_{I-p}$ of $\mathbf{H}_k$ are equal to rows $1, \ldots, I-p$ of $\mathbf{I}_{I-p}$, $k = 1, 2$. Let the row permutation $\mathbf{\Pi}$ be such that $\mathbf{\Pi}\, \mathbf{H}_k = \begin{bmatrix} \mathbf{I}_{I-p} \\ \widetilde{\mathbf{H}}_k \end{bmatrix}$.

Since $\mathbf{H}_k$ has full column rank, $\text{rank}(\mathbf{T}_k) = I - p$, and $\mathbf{T}_k^T = \mathbf{H}_k\, \widetilde{\mathbf{T}}_k^T$, the column space of $\mathbf{H}_k$ is identical to the column space of $\mathbf{T}_k^T$. Moreover, since the row spaces of $\mathbf{T}_1$ and $\mathbf{T}_2$ are identical, the column spaces of $\mathbf{H}_1$ and $\mathbf{H}_2$ are also identical. It follows that each column of $\mathbf{\Pi}\, \mathbf{H}_1$ must lie in the column space of $\mathbf{\Pi}\, \mathbf{H}_2$. Since both matrices have $\mathbf{I}_{I-p}$ as their first $I-p$ rows, this yields that $\mathbf{\Pi}\, \mathbf{H}_1 = \mathbf{\Pi}\, \mathbf{H}_2$. Hence, $\mathbf{H}_1 = \mathbf{H}_2$, which completes the proof. ∎

Using Lemmas 6.3 and 6.4, the GSD of the non-CP part of (6.3)–(6.4) can be computed as follows. From a QR-decomposition of $\widetilde{\mathbf{T}}_1$, we obtain $\widetilde{\mathbf{T}}_1 = \widetilde{\mathbf{Q}}\, \widetilde{\mathbf{R}}_1$. The matrix $\widetilde{\mathbf{R}}_2$ in Lemma 6.3 follows from $\widetilde{\mathbf{R}}_2 = \widetilde{\mathbf{Q}}^T \widetilde{\mathbf{T}}_2$. The matrix $\mathbf{H} = \mathbf{H}_1 = \mathbf{H}_2$ in Lemma 6.4 is obtained as $\mathbf{H} = \mathbf{T}_1^T\, \widetilde{\mathbf{T}}_1\, (\widetilde{\mathbf{T}}_1^T \widetilde{\mathbf{T}}_1)^{-1}$. Next, let $\mathbf{H} = \widehat{\mathbf{Q}}\, \widehat{\mathbf{R}}^T$ be a QL-decomposition of $\mathbf{H}$ with an $I \times (I-p)$ columnwise orthonormal $\widehat{\mathbf{Q}}$ and an $(I-p) \times (I-p)$ upper triangular $\widehat{\mathbf{R}}$. It follows that

$$\mathbf{Y}_k = \mathbf{Q}_a\, \mathbf{T}_k\, \mathbf{Q}_b^T = \mathbf{Q}_a\, \widetilde{\mathbf{T}}_k\, \mathbf{H}^T\, \mathbf{Q}_b^T = (\mathbf{Q}_a\, \widetilde{\mathbf{Q}})\, (\widetilde{\mathbf{R}}_k\, \widehat{\mathbf{R}})\, (\mathbf{Q}_b\, \widehat{\mathbf{Q}})^T, \qquad k = 1, 2 \tag{6.21}$$

is a full GSD of size $I-p$ of the non-CP part of (6.3)–(6.4). Below, we present the algorithm to obtain a CP+GSD representation of the optimal GSD solution $\underline{\mathbf{X}}$. The algorithm is formulated for general R (instead of $R = I$) in order to make it applicable to the $I \times J \times 2$ case as well (see section 7).

ALGORITHM FOR CP+GSD REPRESENTATION OF OPTIMAL GSD SOLUTION.

Input: Optimal GSD solution $\mathbf{X}_k = \mathbf{Q}_a\,\mathbf{R}_k\,\mathbf{Q}_b^T$, $k = 1, 2$, where $\mathbf{R}_2\mathbf{R}_1^{-1}$ has only real eigenvalues but is not diagonalizable.

Output: CP+GSD representation $\mathbf{X}_k = \mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T + \mathbf{Q}_1\,\mathbf{R}_k^{(0)}\,\mathbf{Q}_2^T$, $k = 1, 2$.

1. Calculate the eigenvalues $\lambda_1, \ldots, \lambda_p$ of $\mathbf{R}_2\mathbf{R}_1^{-1}$ with algebraic multiplicity 1. Set $\mathbf{\Lambda} = \mathrm{diag}(\lambda_1, \ldots, \lambda_p)$.
2. Determine $\mathbf{R}_a$ $(R \times p)$ as $\mathbf{R}_2\mathbf{R}_1^{-1}\,\mathbf{R}_a = \mathbf{R}_a\,\mathbf{\Lambda}$. Normalize the columns of $\mathbf{R}_a$ such that the last nonzero element becomes 1. Determine $\mathbf{R}_b$ $(p \times R)$ as $\mathbf{R}_b\,\mathbf{R}_1^{-1}\mathbf{R}_2 = \mathbf{\Lambda}\,\mathbf{R}_b$. Normalize the rows of $\mathbf{R}_b$ such that the first nonzero element becomes 1.
3. Set $\mathbf{A} = \mathbf{Q}_a\mathbf{R}_a$ and $\mathbf{B} = \mathbf{Q}_b\mathbf{R}_b^T$. Let $\mathbf{C}_k$ be the diagonal matrix containing the diagonal elements of $\mathbf{R}_k$ corresponding to the locations of $\lambda_1, \ldots, \lambda_p$ on the diagonal of $\mathbf{R}_2\mathbf{R}_1^{-1}$, $k = 1, 2$. The p nondiverging CP components are now obtained as $\mathbf{A}\,\mathbf{C}_k\,\mathbf{B}^T$, $k = 1, 2$.
4. Set $\mathbf{T}_k = \mathbf{R}_k - \mathbf{R}_a\,\mathbf{C}_k\,\mathbf{R}_b$, $k = 1, 2$. Let $\widetilde{\mathbf{T}}_k$ contain the $R - p$ columns of $\mathbf{T}_k$ with a nonzero diagonal element, in the same order as they appear in $\mathbf{T}_k$, $k = 1, 2$.
5. Compute the QR-decomposition $\widetilde{\mathbf{T}}_1 = \widetilde{\mathbf{Q}}\,\widetilde{\mathbf{R}}_1$ and set $\widetilde{\mathbf{R}}_2 = \widetilde{\mathbf{Q}}^T\widetilde{\mathbf{T}}_2$.
6. Set $\mathbf{H} = \mathbf{T}_1^T\,\widetilde{\mathbf{T}}_1\,(\widetilde{\mathbf{T}}_1^T\widetilde{\mathbf{T}}_1)^{-1}$ and compute the QL-decomposition $\mathbf{H} = \widehat{\mathbf{Q}}\,\widehat{\mathbf{R}}^T$.
7. Set $\mathbf{Q}_1 = \mathbf{Q}_a\,\widetilde{\mathbf{Q}}$, $\mathbf{Q}_2 = \mathbf{Q}_b\,\widehat{\mathbf{Q}}$ and $\mathbf{R}_k^{(0)} = \widetilde{\mathbf{R}}_k\,\widehat{\mathbf{R}}$, $k = 1, 2$. The size-$(R - p)$ GSD representation of the limit point of the diverging CP components is now obtained as $\mathbf{Q}_1\,\mathbf{R}_k^{(0)}\,\mathbf{Q}_2^T$, $k = 1, 2$.

To illustrate the CP+GSD algorithm, we return once again to the $4\times4\times2$ example in (1.7)–(1.10) that was also discussed at the end of sections 3 and 6.1. We apply the CP+GSD algorithm to the optimal GSD solution (6.9)–(6.12) for $\underline{\mathbf{Z}}$ in (1.7). For the CP-part, we obtain

$$\mathbf{R}_a = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \quad \mathbf{R}_b^T = \begin{bmatrix} 1.0000 \\ 0.3111 \\ 0.8314 \\ 2.0353 \end{bmatrix}, \quad \mathbf{C}_1 = -1.1875, \quad \mathbf{C}_2 = 1.8323. \tag{6.22}$$

Up to scaling/rescaling, the CP-part $\mathbf{A} = \mathbf{Q}_a\mathbf{R}_a$, $\mathbf{B} = \mathbf{Q}_b\mathbf{R}_b^T$, $\mathbf{C}_1$, $\mathbf{C}_2$ in (6.22) is equal to the CP-part (6.14) of the CP+Jordan representation. For the GSD-part, we obtain

$$\mathbf{Q}_1 = \begin{bmatrix} -0.6779 & -0.0470 & 0.2357 \\ 0.6690 & -0.2187 & 0.5479 \\ 0.1326 & -0.6466 & -0.6812 \\ 0.2744 & 0.7293 & -0.4244 \end{bmatrix}, \quad \mathbf{Q}_2 = \begin{bmatrix} 0.3387 & -0.0964 & -0.6896 \\ 0.5502 & -0.4778 & -0.2486 \\ 0.5110 & 0.8406 & -0.0294 \\ 0.5670 & -0.2363 & 0.6795 \end{bmatrix}, \tag{6.23}$$

$$\mathbf{R}_1^{(0)} = \begin{bmatrix} 1.4627 & -1.7991 & -0.3176 \\ 0 & 1.5699 & 1.1872 \\ 0 & 0 & 1.5963 \end{bmatrix}, \quad \mathbf{R}_2^{(0)} = \begin{bmatrix} 0.7185 & 2.9293 & 3.2016 \\ 0 & 0.7712 & -2.5885 \\ 0 & 0 & 0.7841 \end{bmatrix}. \tag{6.24}$$

Hence, the limit point of the three diverging CP components is represented as (6.23)–(6.24).

TABLE 7.1
Conjectures of Stegeman [40] on the occurrence of diverging CP components for a generic $I \times J \times 2$ array $\underline{\mathbf{Z}}$. Here, $I \geq J \geq 2$ and $R \geq 2$.

Case	$\underline{\mathbf{Z}} \in \mathbb{R}^{I \times J \times 2}$	$\text{Rank}_{\otimes}(\underline{\mathbf{Z}})$	R	Diverging CP components
2	$I = J$	$I+1$	$R = I$	almost everywhere
3	$I = J$	$I+1$	$R < I$	positive volume
5	$I = J$	I	$R < I$	positive volume
8	$I > J$	$\min(I, 2J)$	$R = J$	positive volume
9	$I > J$	$\min(I, 2J)$	$R < J$	positive volume

7. Extension to $I \times J \times 2$ arrays and general R. Stegeman [40] has mathematically analyzed the cases of diverging CP components occurring for generic $I \times J \times 2$ arrays and all values of R. The cases in which diverging components occur are listed in Table 7.1, as well as the conjectures of Stegeman [40] on the frequency of their occurrence. A generic $I \times J \times 2$ array $\underline{\mathbf{Z}}$ has rank $\min(I, 2J)$ if $I > J$, and rank I or $I+1$ (both on a set of positive volume) if $I = J$; see Ten Berge and Kiers [44].

It is shown in [40] that the cases of diverging CP components in Table 7.1 can be transformed to Case 2 (with $I = J = R$), which we have considered so far. Next, we extend our results in the previous sections by showing that in all cases in Table 7.1, the GSD approach may be used to avoid the problem of diverging CP components. Analogous to our previous results, the optimal GSD solution is the limit point of the sequence of CP updates (whether it features diverging components or not) and may be decomposed into a nondiverging CP-part and a Jordan part or into a nondiverging CP-part and a smaller GSD part.

The GSD model for an $I \times J \times 2$ array $\underline{\mathbf{Z}}$ is

$$\mathbf{Z}_k = \mathbf{Q}_a \, \mathbf{R}_k \, \mathbf{Q}_b^T + \mathbf{E}_k, \qquad k = 1, 2, \tag{7.1}$$

where $\mathbf{Q}_a$ ($I \times R$) and $\mathbf{Q}_b$ ($J \times R$) are columnwise orthonormal and $\mathbf{R}_k$ are $R \times R$ upper triangular, $k = 1, 2$. Without loss of generality, we assume $I \geq J$. Also, we assume $R \leq J$ (and $R \leq I$) and $R < \text{rank}_{\otimes}(\underline{\mathbf{Z}})$. From Table 7.1, it can be seen that this includes all cases. Finding $\mathbf{Q}_a$, $\mathbf{Q}_b$, $\mathbf{R}_1$, and $\mathbf{R}_2$, which minimize the sum-of-squares of the residuals in (7.1), can be achieved by a modification of the Jacobi algorithm of De Lathauwer, De Moor, and Vandewall [6]. This will be explained in section 7.1 below.

The proof of Proposition 4.2 can be used to show that the GSD model (7.1) for $I \times J \times 2$ arrays always has an optimal solution. Analogous to (6.1)–(6.2), we define

$$\mathcal{P}_{(I,J,R)} = \{\underline{\mathbf{Y}} \in \mathbb{R}^{I \times J \times 2} : \underline{\mathbf{Y}} \text{ has a full GSD (7.1) with } \mathbf{R}_1 \text{ and } \mathbf{R}_2 \text{ nonsingular}\} \tag{7.2}$$

and the GSD problem

$$\begin{aligned} &\text{Minimize} \quad \|\underline{\mathbf{Z}} - \underline{\mathbf{Y}}\|^2 \\ &\text{subject to} \underline{\mathbf{Y}} \in \mathcal{P}_{(I,J,R)}. \end{aligned} \tag{7.3}$$

From the analysis in Stegeman [40], it follows that the set $\mathcal{P}_{(I,J,R)}$ is closed, and hence, problem (7.3) always has an optimal solution. In Cases 3, 5, 8, and 9 of Table 7.1, the boundary of $\mathcal{P}_{(I,J,R)}$ is the set $\mathcal{P}_{(I,J,R)}$ itself, and the optimal solution $\underline{\mathbf{X}}$ of the GSD problem (7.3) has $\mathbf{R}_2 \mathbf{R}_1^{-1}$ with only real eigenvalues, some of which are identical. The problem of diverging CP components occurs if $\mathbf{R}_2 \mathbf{R}_1^{-1}$ is not diagonalizable; see [40]. In this case, the GSD of $\underline{\mathbf{X}}$ cannot be fully transformed to a CP representation, and

sequences of CP updates converging to $\underline{\mathbf{X}}$ feature diverging components. As in Case 2 of Table 7.1, two alternatives are a CP+Jordan or a CP+GSD representation. These can be obtained by using the algorithms in sections 6.1 and 6.3, respectively. As explained in section 6.2, a decomposition of $\underline{\mathbf{X}}$ into $\text{rank}_{\otimes}(\underline{\mathbf{X}})$ terms of rank 1 can be obtained from the CP+Jordan representation of $\underline{\mathbf{X}}$ using the method of Ja' Ja' [21].

If, in Cases 3, 5, 8, and 9 of Table 7.1, the optimal GSD solution $\underline{\mathbf{X}}$ has a GSD with $\mathbf{R}_2\mathbf{R}_1^{-1}$ diagonalizable, then the GSD can be transformed into a full CP representation of $\underline{\mathbf{X}}$, and the problems of diverging components do not occur. That is, $\underline{\mathbf{X}}$ is also an optimal solution of the CP problem. The CP representation of $\mathbf{R}_1$ and $\mathbf{R}_2$ can be obtained from the eigendecomposition of $\mathbf{R}_2\mathbf{R}_1^{-1}$ analogous to (2.2). Premultiplying by $\mathbf{Q}_a$ and postmultiplying by $\mathbf{Q}_b^T$ then yields the full CP representation for $\mathbf{X}_1$ and $\mathbf{X}_2$.

7.1. The Jacobi algorithm for the GSD problem of $I \times J \times 2$ arrays. Here, we show how the Jacobi algorithm of De Lathauwer, De Moor, and Vandewalle [6] for solving the GSD problem (6.2) can be modified to the case of $I \times J \times 2$ arrays and all values of R not larger than I and J. That is, the modified Jacobi algorithm can be used to solve the more general class of GSD problems (7.3).

Let $I = J = R$. The Jacobi algorithm of [6] sets out to find $(\mathbf{Q}_a, \mathbf{Q}_b, \mathbf{R}_1, \mathbf{R}_2)$ such that $\mathbf{Q}_a^T\mathbf{Z}_k\mathbf{Q}_b$, $k = 1, 2$ are as upper triangular as possible. Their upper triangular parts are then the estimates of $\mathbf{R}_k$, $k = 1, 2$. The estimates $(\mathbf{Q}_a, \mathbf{Q}_b, \mathbf{R}_1, \mathbf{R}_2)$ are updated by applying Givens rotations to the rows and columns of $\mathbf{Q}_a^T\mathbf{Z}_k\mathbf{Q}_b$, $k = 1, 2$, as follows. Let $\mathbf{G}_{ij}$ be equal to $\mathbf{I}_I$ except for the entries $(\mathbf{G}_{ij})_{ii} = (\mathbf{G}_{ij})_{jj} = \cos\alpha$ and $(\mathbf{G}_{ij})_{ji} = -(\mathbf{G}_{ij})_{ij} = \sin\alpha$, where α is the rotation angle. Let $\widetilde{\mathbf{G}}_{ij}$ be defined as $\mathbf{G}_{ij}$ for a rotation angle β. One sweep of the Jacobi algorithm determines for each (i, j) with $1 \le i < j \le I$, the optimal rotation angles α and β such that $\mathbf{G}_{ij}\mathbf{Q}_a^T\mathbf{Z}_k\mathbf{Q}_b\widetilde{\mathbf{G}}_{ij}^T$, $k = 1, 2$ are as upper triangular as possible. The updated estimates of $(\mathbf{Q}_a, \mathbf{Q}_b, \mathbf{R}_1, \mathbf{R}_2)$ are given by $\mathbf{Q}_a\mathbf{G}_{ij}^T$, $\mathbf{Q}_b\widetilde{\mathbf{G}}_{ij}^T$, and $\mathbf{G}_{ij}\mathbf{R}_k\widetilde{\mathbf{G}}_{ij}^T$, $k = 1, 2$.

Next, consider the general case where possibly $I \neq J$ and $R \le I$, $R \le J$. In the modified Jacobi algorithm, we have the orthonormal variables $\widetilde{\mathbf{Q}}_a$ $(I \times I)$ and $\widetilde{\mathbf{Q}}_b$ $(J \times J)$. The modified Jacobi algorithm maximizes the sum-of-squares of the upper triangular parts of the first R rows and columns of $\widetilde{\mathbf{R}}_k = \widetilde{\mathbf{Q}}_a^T\mathbf{Z}_k\widetilde{\mathbf{Q}}_b$, $k = 1, 2$. These $R \times R$ upper triangular parts are then the estimates of $\mathbf{R}_k$, $k = 1, 2$. The estimates of $\mathbf{Q}_a$ and $\mathbf{Q}_b$ are the first R columns of $\widetilde{\mathbf{Q}}_a$ and $\widetilde{\mathbf{Q}}_b$, respectively. Each sweep of the algorithm consists of two phases. In the first phase, the Givens rotations $\mathbf{G}_{ij}$ $(I \times I)$ and $\widetilde{\mathbf{G}}_{ij}$ $(J \times J)$ are determined as above for each (i, j) with $1 \le i < j \le R$. Within the first R rows and columns of $\widetilde{\mathbf{R}}_k$, $k = 1, 2$, these rotations make the structure as upper triangular as possible.

In the second phase, rotations $\mathbf{G}_i$, $1 \le i \le R$ are determined such that they transfer as much energy as possible from rows $R + 1, \ldots, I$ of $\widetilde{\mathbf{R}}_k$ to row i of (the upper triangular part of) $\widetilde{\mathbf{R}}_k$, $k = 1, 2$. Independently, rotations $\widetilde{\mathbf{G}}_j$, $1 \le i \le R$ are determined such that they transfer as much energy as possible from columns $R + 1, \ldots, J$ of $\widetilde{\mathbf{R}}_k$ to column j of (the upper triangular part of) $\widetilde{\mathbf{R}}_k$, $k = 1, 2$. We first show how to obtain $\mathbf{G}_i$. Let

$$\hat{\mathbf{R}}_i = \begin{bmatrix} (\widetilde{\mathbf{R}}_1)_{ii} & \ldots & (\widetilde{\mathbf{R}}_1)_{iR} & (\widetilde{\mathbf{R}}_2)_{ii} & \ldots & (\widetilde{\mathbf{R}}_2)_{iR} \\ (\widetilde{\mathbf{R}}_1)_{R+1,i} & \ldots & (\widetilde{\mathbf{R}}_1)_{R+1,R} & (\widetilde{\mathbf{R}}_2)_{R+1,i} & \ldots & (\widetilde{\mathbf{R}}_2)_{R+1,R} \\ \vdots & & \vdots & \vdots & & \vdots \\ (\widetilde{\mathbf{R}}_1)_{I,i} & \ldots & (\widetilde{\mathbf{R}}_1)_{I,R} & (\widetilde{\mathbf{R}}_2)_{I,i} & \ldots & (\widetilde{\mathbf{R}}_2)_{I,R} \end{bmatrix} = \mathbf{S}\,\mathbf{D}\,\mathbf{V}^T \tag{7.4}$$

be the singular value decomposition (SVD) of $\hat{\mathbf{R}}_i$. Then $\mathbf{S}^T\hat{\mathbf{R}}_i$ is an orthogonal rotation of the rows of $\hat{\mathbf{R}}_i$ such that its first row has maximum sum-of-squares. The square root of this is equal to the dominant singular value of $\hat{\mathbf{R}}_i$. From $\mathbf{S}^T$, the rotation $\mathbf{G}_i$ can be obtained.

The computation of $\widetilde{\mathbf{G}}_j$ is analogous. Let

$$\bar{\mathbf{R}}_j = \begin{bmatrix} (\widetilde{\mathbf{R}}_1)_{1j} & (\widetilde{\mathbf{R}}_1)_{1,R+1} & \dots & (\widetilde{\mathbf{R}}_1)_{1,J} \\ \vdots & \vdots & & \vdots \\ (\widetilde{\mathbf{R}}_1)_{jj} & (\widetilde{\mathbf{R}}_1)_{j,R+1} & \dots & (\widetilde{\mathbf{R}}_1)_{j,J} \\ (\widetilde{\mathbf{R}}_2)_{1j} & (\widetilde{\mathbf{R}}_2)_{1,R+1} & \dots & (\widetilde{\mathbf{R}}_2)_{1,J} \\ \vdots & \vdots & & \vdots \\ (\widetilde{\mathbf{R}}_2)_{jj} & (\widetilde{\mathbf{R}}_2)_{j,R+1} & \dots & (\widetilde{\mathbf{R}}_2)_{j,J} \end{bmatrix} = \mathbf{S}\,\mathbf{D}\,\mathbf{V}^T \tag{7.5}$$

be the SVD of $\bar{\mathbf{R}}_j$. Then $\bar{\mathbf{R}}_j\mathbf{V}$ is an orthogonal rotation of the columns of $\bar{\mathbf{R}}_j$ such that its first column has maximum sum-of-squares. The square root of this is equal to the dominant singular value of $\bar{\mathbf{R}}_j$. The rotation $\widetilde{\mathbf{G}}_j$ can be obtained from $\mathbf{V}$.

Below, we present the steps of one sweep of the modified Jacobi algorithm.

ONE SWEEP OF THE MODIFIED JACOBI ALGORITHM FOR THE GSD PROBLEM.

Input: $I \times J \times 2$ array $\underline{\mathbf{Z}}$ with $I \times J$ slices $\mathbf{Z}_k$, $k = 1, 2$.
Previous GSD update: $\widetilde{\mathbf{Q}}_a$ $(I \times I)$ and $\widetilde{\mathbf{Q}}_b$ $(J \times J)$ orthonormal, and $\widetilde{\mathbf{R}}_k$ $(I \times J)$, $k = 1, 2$.
Output: New GSD update $\widetilde{\mathbf{Q}}_a$, $\widetilde{\mathbf{Q}}_b$, and $\widetilde{\mathbf{R}}_k$, $k = 1, 2$.

1. (Do for $1 \leq i < j \leq R$.) Let $\mathbf{G}_{ij}$ be equal to $\mathbf{I}_I$ except for the entries $(\mathbf{G}_{ij})_{ii} = (\mathbf{G}_{ij})_{jj} = \cos\alpha$ and $(\mathbf{G}_{ij})_{ji} = -(\mathbf{G}_{ij})_{ij} = \sin\alpha$, where α is the rotation angle. Let $\widetilde{\mathbf{G}}_{ij}$ be equal to $\mathbf{I}_J$ and analogous to $\mathbf{G}_{ij}$ for a rotation angle β. Using the Jacobi algorithm of [6], determine α and β such that the sum-of-squares of the upper triangular part of the first R rows and columns of $\mathbf{G}_{ij}\widetilde{\mathbf{R}}_k\mathbf{G}_{ij}^T$, $k = 1, 2$ are maximal.
   Update $\widetilde{\mathbf{Q}}_a \to \widetilde{\mathbf{Q}}_a\mathbf{G}_{ij}^T$, $\widetilde{\mathbf{Q}}_b \to \widetilde{\mathbf{Q}}_b\widetilde{\mathbf{G}}_{ij}^T$, and $\widetilde{\mathbf{R}}_k \to \mathbf{G}_{ij}\widetilde{\mathbf{R}}_k\widetilde{\mathbf{G}}_{ij}^T$, $k = 1, 2$.
2. (Do for $1 \leq i \leq R$.) Compute the SVD (7.4) and let s_{mn} denote the elements of $\mathbf{S}$. Let $\mathbf{G}_i$ be equal to $\mathbf{I}_I$ except $(\mathbf{G}_i)_{ii} = s_{11}$, $(\mathbf{G}_i)_{i,R+m} = s_{1,m+1}$ for $m = 1, \dots, I-R$, $(\mathbf{G}_i)_{R+m,i} = s_{m+1,1}$ for $m = 1, \dots, I-R$, and $(\mathbf{G}_i)_{mn} = s_{m-R+1,n-R+1}$ for $R+1 \leq m, n \leq I$.
   Update $\widetilde{\mathbf{Q}}_a \to \widetilde{\mathbf{Q}}_a\mathbf{G}_i^T$ and $\widetilde{\mathbf{R}}_k \to \mathbf{G}_i\widetilde{\mathbf{R}}_k$, $k = 1, 2$.
3. (Do for $1 \leq j \leq R$.) Compute the SVD (7.5) and let v_{mn} denote the elements of $\mathbf{V}^T$. Let $\mathbf{G}_j$ be equal to $\mathbf{I}_J$ except $(\mathbf{G}_j)_{jj} = v_{11}$, $(\mathbf{G}_j)_{j,R+m} = v_{1,m+1}$ for $m = 1, \dots, I-R$, $(\mathbf{G}_j)_{R+m,j} = v_{m+1,1}$ for $m = 1, \dots, I-R$, and $(\mathbf{G}_j)_{mn} = v_{m-R+1,n-R+1}$ for $R+1 \leq m, n \leq I$.
   Update $\widetilde{\mathbf{Q}}_b \to \widetilde{\mathbf{Q}}_b\mathbf{G}_j^T$ and $\widetilde{\mathbf{R}}_k \to \widetilde{\mathbf{R}}_k\widetilde{\mathbf{G}}_j^T$, $k = 1, 2$.

8. Numerical experiments. Here, we illustrate the GSD method to avoid diverging CP components for generic $I \times J \times 2$ arrays. For each of the cases in Table 7.1, we randomly generate 50 arrays $\underline{\mathbf{Z}}$ of a chosen size. For each such $\underline{\mathbf{Z}}$, we use the (modified) Jacobi algorithm of De Lathauwer, De Moor, and Vandewall [6] to compute the optimal solution $\underline{\mathbf{X}}$ of the GSD problem (7.3), in terms of its full GSD representation $(\mathbf{Q}_a, \mathbf{Q}_b, \mathbf{R}_1, \mathbf{R}_2)$. The stopping criterion of the (modified) Jacobi algorithm is set to

TABLE 8.1

Types of optimal solutions encountered when solving the GSD problem (7.3) for randomly generated arrays $\underline{\mathbf{Z}}$ in the cases of Table 7.1. For each case, the value of (I, J, R), the number of runs, and the average time to compute the GSD solution and the Jordan form of $\mathbf{R}_2\mathbf{R}_1^{-1}$ (on a Pentium 4 PC) are given. In all runs, the matrix $\mathbf{R}_2\mathbf{R}_1^{-1}$ has distinct eigenvalues $\lambda_1, \ldots, \lambda_p, \mu_1, \ldots, \mu_r$, where λ_j has algebraic multiplicity 1 and μ_i has algebraic multiplicity larger than 1 and geometric multiplicity 1. For each case, the number of solutions with the same (p, r) value are given.

`1e-9`. Next, the Jordan normal form of $\mathbf{R}_2\mathbf{R}_1^{-1}$ is computed, which we denote as $\mathbf{J} = \text{diag}(\lambda_1, \ldots, \lambda_p, \mathbf{J}_{m_1}(\mu_1), \ldots, \mathbf{J}_{m_r}(\mu_r))$, where $\mathbf{J}_{m_j}(\mu_j)$ denotes an $m_j \times m_j$ Jordan block, with $m_j \geq 2$. Numerically, we treat two eigenvalues μ_1 and μ_2 as identical if $|\mu_1 - \mu_2| < 0.01$. The multiple eigenvalue μ is then estimated as the mean of all "identical" eigenvalues. The geometric multiplicity of an eigenvalue μ is determined as the number of singular values s_j of $(\mathbf{R}_2\mathbf{R}_1^{-1} - \mu\,\mathbf{I}_I)$ that satisfy $|s_j| < 0.0001$.

In the (modified) Jacobi algorithm, we use the following initial values for $(\mathbf{Q}_a, \mathbf{Q}_b, \mathbf{R}_1, \mathbf{R}_2)$. In Case 2 in Table 7.1, these are obtained from the "generalized real Schur decomposition" (GRSD) of $\mathbf{Z}_1$ and $\mathbf{Z}_2$, which is computed by means of the QZ-method; see Golub and Van Loan [12]. In the other cases, the slices are first transformed to $\mathbf{U}_R^T\mathbf{Z}_k\mathbf{V}_R$, $k = 1, 2$, where $\mathbf{U}_R$ contains the R dominant left singular vectors of $[\mathbf{Z}_1|\mathbf{Z}_2]$ and $\mathbf{V}_R$ contains the R dominant right singular vectors of $\begin{bmatrix}\mathbf{Z}_1\\ \mathbf{Z}_2\end{bmatrix}$. The initial values are then obtained from $\mathbf{U}_R$, $\mathbf{V}_R$ and the GRSD of $\mathbf{U}_R^T\mathbf{Z}_k\mathbf{V}_R$, $k = 1, 2$.

Table 8.1 summarizes the results of computing the optimal solutions $\underline{\mathbf{X}}$ of the GSD problem (7.3) and the Jordan forms of $\mathbf{R}_2\mathbf{R}_1^{-1}$. As can be seen, a wide variety of values (p, r) is encountered among the optimal solutions $\underline{\mathbf{X}}$. In a few of the 50 runs per case, some identical eigenvalues were not recognized. These runs do not appear in Table 8.1. In all runs in Table 8.1, the estimated eigenvalues $\lambda_1, \ldots, \lambda_p, \mu_1, \ldots, \mu_r$ are distinct. Hence, each μ_i has algebraic multiplicity larger than 1 and geometric multiplicity 1. As observed in Remark 3.2, this is probably due to the fact that the set of these arrays lies dense on the boundary of the set $\mathcal{P}_{(I,J,R)}$. For the solutions with $r \geq 1$, diverging CP components occur, and the GSD of the solution cannot be fully transformed into a CP solution. The solutions with $r = 0$ can be transformed into a nondiverging CP solution, i.e., diverging CP components do not occur.

As can be seen from Table 8.1, all runs in Cases 2, 3, and 8 have a solution with $r \geq 1$. For Case 2, this is in line with the conjecture of Stegeman [40] in Table 7.1. For Cases 3 and 8, this does not seem to support the conjectures of Stegeman [40] in Table 7.1, which state that diverging CP components occur on a set of positive volume (and not almost everywhere). However, trying different values of R in Case 3 yields 15 solutions with $r = 0$ (out of 50) for $R = 4$ and 3 solutions with $r = 0$ (out of 50) for $R = 6$. Hence, it seems that nondiverging CP solutions occur less frequently as R is increased. The same holds for Case 8, where we get 13 solutions with $r = 0$ (out of 50) for $R = J = 4$ and 5 solutions with $r = 0$ (out of 50) for $R = J = 6$. For Cases 5 and 9, there are both solutions with $r = 0$ as well as solutions with $r \geq 1$, which is in line with the conjectures of Stegeman [40] in Table 7.1.

Also listed in Table 8.1 are the average computational times (on a Pentium 4 PC) for the (modified) Jacobi algorithm to terminate and for the computation of the Jordan form of $\mathbf{R}_1\mathbf{R}_1^{-1}$. For Case 2, this is 58 seconds. For comparison, we tried finding an approximate solution to the CP problem (3.2) for random $\underline{\mathbf{Z}}$ as in Case 2, by using the multilinear engine of Paatero [32]. For a convergence criterion of `1e-15` over 1000 consecutive iterations, the algorithm terminated after 40 minutes. However, for the obtained approximate solution $\underline{\mathbf{X}}$, the eigenvalues of $\mathbf{X}_2\mathbf{X}_1^{-1}$ are all clearly distinct. On the other hand, running the Jacobi algorithm on the same $\underline{\mathbf{Z}}$ yields a solution with two groups of identical eigenvalues within 1 minute. Hence, to obtain an equally accurate estimate of the solution $\underline{\mathbf{X}}$ using a CP algorithm requires a very small stopping criterion and takes prohibitively long. This shows the spectacular improvement in efficiency when using the Jacobi GSD algorithm instead.

9. Discussion. We have proposed, analyzed, and demonstrated a method to avoid diverging components when trying to fit the CP model for generic $I \times J \times 2$ arrays and $R \leq I, J$ components. Instead of fitting the CP model, we fit the GSD model. The problems of diverging CP components are likely to occur because the CP model has no optimal solution in these cases. We showed that the GSD model always has an optimal solution. Moreover, the optimal GSD solution is the limit point of the sequence of CP updates, whether it features diverging components or not. Hereby we assume that the GSD model has a unique optimal solution (up to trivial indeterminacies) which is always satisfied in our numerical experiments. Also, we showed that the optimal GSD solution can be represented as the sum of the nondiverging CP components and a sparse Tucker3 part (CP+Jordan form) or as the sum of the nondiverging CP components and a smaller GSD part (CP+GSD form). The CP+Jordan form is essentially unique and sparse. Although it is not an outer-product decomposition, it may still be interpretable to the researcher. From the CP+Jordan representation, we can obtain a rank-revealing decomposition of the optimal GSD solution using the method of Ja' Ja' [21]. However, this decomposition is not essentially unique. The CP+GSD representation is numerically more stable and suitable if only the nondiverging CP components are of interest.

The GSD method not only yields an accurate solution, it is also much faster than trying to fit CP in the case of diverging components. Hence, to compute the CP solution for generic $I \times J \times 2$ arrays, it is advisable to compute the GSD solution instead and then transfer the nondiverging part of the solution into CP components. We may conclude that from a computational as well as a practical point of view, our method is a considerable improvement with respect to facing diverging CP components.

Our analysis is confined to arrays in the sets $\mathcal{R}_I$ in (2.1) and $\mathcal{P}_{(I,J,R)}$ in (6.1). For a given array size, these sets are dense in the space of all arrays. The results

of our numerical experiments and those in Stegeman [38, 40], together with the fact that we consider generic arrays $\underline{\mathbf{Z}}$ to be approximated, lead us to conclude that this confinement is justified in practice. However, from a theoretical point of view, this leaves open the question whether the complement set of $\mathcal{R}_I$ or $\mathcal{P}_{(I,J,R)}$ can contain all best rank-R approximations of a generic $I \times J \times 2$ array.

Stegeman [39] has mathematically analyzed diverging CP components occurring for several generic $I \times J \times 3$ arrays. Whether the SGSD method can also be used for arrays with three slices is currently under investigation.

COMPUTING THE FRÉCHET DERIVATIVE OF THE MATRIX EXPONENTIAL, WITH AN APPLICATION TO CONDITION NUMBER ESTIMATION*

AWAD H. AL-MOHY† AND NICHOLAS J. HIGHAM†

Abstract. The matrix exponential is a much-studied matrix function having many applications. The Fréchet derivative of the matrix exponential describes the first-order sensitivity of e^A to perturbations in A and its norm determines a condition number for e^A. Among the numerous methods for computing e^A the scaling and squaring method is the most widely used. We show that the implementation of the method in [N. J. Higham, *The scaling and squaring method for the matrix exponential revisited*, SIAM J. Matrix Anal. Appl., 26 (2005), pp. 1179–1193] can be extended to compute both e^A and the Fréchet derivative at A in the direction E, denoted by $L(A, E)$, at a cost about three times that for computing e^A alone. The algorithm is derived from the scaling and squaring method by differentiating the Padé approximants and the squaring recurrence, reusing quantities computed during the evaluation of the Padé approximant, and intertwining the recurrences in the squaring phase. To guide the choice of algorithmic parameters, an extension of the existing backward error analysis for the scaling and squaring method is developed which shows that, modulo rounding errors, the approximations obtained are $e^{A+\Delta A}$ and $L(A + \Delta A, E + \Delta E)$, with the same ΔA in both cases, and with computable bounds on $\|\Delta A\|$ and $\|\Delta E\|$. The algorithm for $L(A, E)$ is used to develop an algorithm that computes e^A together with an estimate of its condition number. In addition to results specific to the exponential, we develop some results and techniques for arbitrary functions. We show how a matrix iteration for $f(A)$ yields an iteration for the Fréchet derivative and show how to efficiently compute the Fréchet derivative of a power series. We also show that a matrix polynomial and its Fréchet derivative can be evaluated at a cost at most three times that of computing the polynomial itself and give a general framework for evaluating a matrix function and its Fréchet derivative via Padé approximation.

1. Introduction.

The sensitivity of a matrix function $f : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ to small perturbations is governed by the Fréchet derivative. The Fréchet derivative at a point $A \in \mathbb{C}^{n\times n}$ is a linear mapping

$$\begin{array}{rcl} \mathbb{C}^{n\times n} & \stackrel{L(A)}{\longrightarrow} & \mathbb{C}^{n\times n} \\ E & \longmapsto & L(A, E) \end{array}$$

such that for all $E \in \mathbb{C}^{n\times n}$,

$$f(A + E) - f(A) - L(A, E) = o(\|E\|), \tag{1.1}$$

and it therefore describes the first-order effect on f of perturbations in A. If we need to show the dependence of L on f we will write $L_f(A, E)$.

It is desirable to be able to evaluate efficiently both $f(A)$ and the Fréchet derivative in order to obtain sensitivity information or to apply an optimization algorithm requiring derivatives. However, while the numerical computation of matrix functions is quite well developed, fewer methods are available for the Fréchet derivative, and the existing methods for $L(A,E)$ usually do not fully exploit the fact that $f(A)$ is being computed [6].

The norm of the Fréchet derivative yields a condition number [6, Theorem 3.1]:

$$\operatorname{cond}(f,A) := \lim_{\epsilon\to 0} \sup_{\|E\|\le\epsilon\|A\|} \frac{\|f(A+E)-f(A)\|}{\epsilon\|f(A)\|} = \frac{\|L(A)\|\,\|A\|}{\|f(A)\|}, \tag{1.2}$$

where

$$\|L(A)\| := \max_{Z\neq 0} \frac{\|L(A,Z)\|}{\|Z\|} \tag{1.3}$$

and the norm is any matrix norm. When evaluating $f(A)$ we would like to be able to efficiently estimate $\operatorname{cond}(f,A)$; (1.3) shows that to do so we need to approximately maximize the norm of $L(A,Z)$ over all Z of unit norm.

The main aim of this work is to develop an efficient algorithm for simultaneously computing e^A and $L(A,E)$ and to use it to construct an algorithm for computing e^A along with an estimate of $\operatorname{cond}(\exp,A)$. The need for such algorithms is demonstrated by a recent paper in econometrics [8] in which the authors state that "One problem we did discover, that has not been accentuated in the literature, is that altering the stability properties of the coefficient matrix through a change in just one parameter can dramatically alter the theoretical and computed matrix exponential." If $A = A(t)$ depends smoothly on a vector $t \in \mathbb{C}^p$ of parameters then the change in e^A induced by small changes θh in t ($\theta \in \mathbb{C}$, $h \in \mathbb{C}^p$) is approximated by $\theta L(A, \sum_{i=1}^p h_i \partial A(t)/\partial t_i)$, since

$$\begin{aligned} f(A(t+\theta h)) &= f\left(A + \theta \sum_{i=1}^p \frac{\partial A(t)}{\partial t_i} h_i + O(\theta^2)\right) \\ &= f(A) + L\left(A, \theta \sum_{i=1}^p \frac{\partial A(t)}{\partial t_i} h_i + O(\theta^2)\right) + o(\theta) \\ &= f(A) + \theta L\left(A, \sum_{i=1}^p \frac{\partial A(t)}{\partial t_i} h_i\right) + o(\theta). \end{aligned}$$

Thus a single Fréchet derivative evaluation with $h = e_j$ (the jth unit vector) provides the information that the authors of [8] needed about the effect of changing a single parameter t_j.

We begin in section 2 by recalling a useful connection between the Fréchet derivative of a function and the same function evaluated at a certain block triangular matrix. We illustrate how this relation can be used to derive new iterations for computing $L(A,E)$ given an iteration for $f(A)$. Then in section 3 we show how to efficiently evaluate the Fréchet derivative when f has a power series expansion, by exploiting a convenient recurrence for the Fréchet derivative of a monomial. In section 4 we show that under reasonable assumptions a matrix polynomial and its Fréchet derivative can both be evaluated at a cost at most three times that of evaluating the polynomial itself. Then in section 5 we show how to evaluate the Fréchet derivative of a

rational function and give a framework for evaluating f and its Fréchet derivative via Padé approximants. In section 6 we apply this framework to the scaling and squaring algorithm for e^A [14], [17], and in particular to the implementation of Higham [5], which is the basis of MATLAB's `expm` function. We extend Higham's analysis to show that, modulo rounding errors, the approximations obtained from the new algorithm are $e^{A+\Delta A}$ and $L(A+\Delta A, E+\Delta E)$, with the *same* ΔA in both cases—a genuine backward error result. The computable bounds on $\|\Delta A\|$ and $\|\Delta E\|$ enable us to choose the algorithmic parameters in an optimal fashion. The new algorithm is shown to have significant advantages over existing ones. In section 7 we combine the new algorithm for $L(A,E)$ with an existing matrix 1-norm estimator to develop an algorithm for computing both e^A and an estimate of its condition number, and we show experimentally that the condition estimate can provide a useful guide to the accuracy of the scaling and squaring algorithm. Some concluding remarks are given in section 8.

2. Fréchet derivative via function of block triangular matrix. The following result shows that the Fréchet derivative appears as the $(1,2)$ block when f is evaluated at a certain block triangular matrix. Let $\mathcal{D}$ denote an open subset of $\mathbb{R}$ or $\mathbb{C}$.

THEOREM 2.1. *Let f be $2n-1$ times continuously differentiable on $\mathcal{D}$ and let the spectrum of X lie in $\mathcal{D}$. Then*

$$f\left(\begin{bmatrix} X & E \\ 0 & X \end{bmatrix}\right) = \begin{bmatrix} f(X) & L(X,E) \\ 0 & f(X) \end{bmatrix}. \tag{2.1}$$

Proof. See Mathias [13, Theorem 2.1] or Higham [6, section 3.1]. The result is also proved by Najfeld and Havel [15, Theorem 4.11] under the assumption that f is analytic. ∎

The significance of Theorem 2.1 is that given a smooth enough f and any method for computing $f(A)$, we can compute the Fréchet derivative by applying the method to the $2n \times 2n$ matrix in (2.1). The doubling in size of the problem is unwelcome, but if we exploit the block structure the computational cost can be reduced. Moreover, the theorem can provide a simple means to derive, and prove the convergence of, iterations for computing the Fréchet derivative.

To illustrate the use of the theorem we consider the principal square root function, $f(A) = A^{1/2}$, which for $A \in \mathbb{C}^{n\times n}$ with no eigenvalues on $\mathbb{R}^-$ (the closed negative real axis) is the unique square root X of A whose spectrum lies in the open right half-plane. The Denman–Beavers iteration

$$\begin{aligned} X_{k+1} &= \frac{1}{2}\left(X_k + Y_k^{-1}\right), \qquad X_0 = A, \\ Y_{k+1} &= \frac{1}{2}\left(Y_k + X_k^{-1}\right), \qquad Y_0 = I \end{aligned} \tag{2.2}$$

is a Newton variant that converges quadratically with [6, section 6.3]

$$\lim_{k\to\infty} X_k = A^{1/2}, \qquad \lim_{k\to\infty} Y_k = A^{-1/2}. \tag{2.3}$$

It is easy to show that if we apply the iteration to $\widetilde{A} = \left[\begin{smallmatrix} A & E \\ 0 & A \end{smallmatrix}\right]$ then iterates $\widetilde{X}_k$ and $\widetilde{Y}_k$ are produced for which

$$\widetilde{X}_k = \begin{bmatrix} X_k & F_k \\ 0 & X_k \end{bmatrix}, \qquad \widetilde{Y}_k = \begin{bmatrix} Y_k & G_k \\ 0 & Y_k \end{bmatrix},$$

where

$$\begin{aligned} F_{k+1} &= \frac{1}{2}\left(F_k - Y_k^{-1} G_k Y_k^{-1}\right), \qquad F_0 = E, \\ G_{k+1} &= \frac{1}{2}\left(G_k - X_k^{-1} F_k X_k^{-1}\right), \qquad G_0 = 0. \end{aligned} \tag{2.4}$$

By applying (2.3) and Theorem 2.1 to $\widetilde{A}$ we conclude that

$$\lim_{k\to\infty} F_k = L_{x^{1/2}}(A,E), \qquad \lim_{k\to\infty} G_k = L_{x^{-1/2}}(A,E). \tag{2.5}$$

Moreover, scaling strategies for accelerating the convergence of (2.2) [6, section 6.5] yield corresponding strategies for (2.4).

The next result shows quite generally that differentiating a fixed point iteration for a matrix function yields a fixed point iteration for the Fréchet derivative.

THEOREM 2.2. *Let f and g be $n-1$ times continuously differentiable on $\mathcal{D}$. Suppose that for any matrix $X \in \mathbb{C}^{n\times n}$ whose spectrum lies in $\mathcal{D}$, g has the fixed point $f(X)$, that is, $f(X) = g(f(X))$. Then for any such X, L_g at $f(X)$ has the fixed point $L_f(X,E)$ for all E.*

Proof. Applying the chain rule to $f(X) \equiv g(f(X))$ gives the relation $L_f(X,E) = L_g(f(X), L_f(X,E))$, which is the result. ∎

The iteration (2.4) for computing the Fréchet derivative of the square root function is new, and other new iterations for the Fréchet derivative of the matrix square root and related functions can be derived, and their convergence proved, in the same way, or directly by using Theorem 2.2. In the case of the Newton iteration for the matrix sign function this approach yields an iteration for the Fréchet derivative proposed by Kenney and Laub [10, Theorem 3.3] (see also [6, Theorem 5.7]) and derived using Theorem 2.1 by Mathias [13].

In the rest of this paper we consider the situation in which the underlying method for computing $f(A)$ is based on direct approximation rather than iteration, and we develop techniques that are more sophisticated than a direct application of Theorem 2.1.

3. Fréchet derivative via power series. When f has a power series expansion the Fréchet derivative can be expressed as a related series expansion.

THEOREM 3.1. *Suppose f has the power series expansion $f(x) = \sum_{k=0}^{\infty} a_k x^k$ with radius of convergence r. Then for $A, E \in \mathbb{C}^{n\times n}$ with $\|A\| < r$, the Fréchet derivative*

$$L_f(A,E) = \sum_{k=1}^{\infty} a_k \sum_{j=1}^{k} A^{j-1} E A^{k-j}. \tag{3.1}$$

Proof. See [6, Problem 3.6]. ∎

The next theorem gives a recurrence that can be used to evaluate (3.1).

THEOREM 3.2. *Under the assumptions of Theorem* 3.1*,*

$$L_f(A,E) = \sum_{k=1}^{\infty} a_k M_k, \tag{3.2}$$

where $M_k = L_{x^k}(A,E)$ satisfies the recurrence

$$M_k = M_{\ell_1} A^{\ell_2} + A^{\ell_1} M_{\ell_2}, \qquad M_1 = E, \tag{3.3}$$

with $k = \ell_1 + \ell_2$ and ℓ_1 and ℓ_2 positive integers. In particular,

$$M_k = M_{k-1}A + A^{k-1}M_1, \qquad M_1 = E. \tag{3.4}$$

In addition,

$$\|f(A)\| \le \widetilde{f}(\|A\|), \qquad \|L_f(A)\| \le \widetilde{f}'(\|A\|), \tag{3.5}$$

where $\widetilde{f}(x) = \sum_{k=0}^{\infty} |a_k| x^k$.

Proof. Since the power series can be differentiated term-by-term within its radius of convergence, we have

$$L_f(A,E) = \sum_{k=1}^{\infty} a_k M_k, \qquad M_k = L_{x^k}(A,E).$$

One way to develop the recurrence (3.3) is by applying Theorem 2.1 to the monomial $x^k = x^{\ell_1+\ell_2}$. A more direct approach is to use the product rule for Fréchet derivatives [6, Theorem 3.3] to obtain

$$M_k = L_{x^k}(A,E) = L_{x^{\ell_1}}(A,E)A^{\ell_2} + A^{\ell_1}L_{x^{\ell_2}}(A,E) = M_{\ell_1}A^{\ell_2} + A^{\ell_1}M_{\ell_2}.$$

Taking $\ell_1 = k-1$ and $\ell_2 = 1$ gives (3.4). It is straightforward to see that $\|f(A)\| \le \widetilde{f}(\|A\|)$. Taking norms in (3.1) gives

$$\|L_f(A,E)\| \le \|E\| \sum_{k=1}^{\infty} k|a_k| \|A\|^{k-1} = \|E\| \widetilde{f}'(\|A\|),$$

and maximizing over all nonzero E gives $\|L_f(A)\| \le \widetilde{f}'(\|A\|)$. ∎

The recurrence (3.3) will prove very useful in the rest of the paper.

4. Cost analysis for polynomials. Practical methods for approximating $f(A)$ may truncate a Taylor series to a polynomial or use a rational approximation. Both cases lead to the need to evaluate both a polynomial and its Fréchet derivative at the same argument. The question arises "what is the extra cost of computing the Fréchet derivative?" Theorem 3.2 does not necessarily answer this question because it only describes one family of recurrences for evaluating the Fréchet derivative. Moreover, the most efficient polynomial evaluation schemes are based on algebraic rearrangements that avoid explicitly forming all the matrix powers. Does an efficient evaluation scheme for a polynomial p also yield an efficient evaluation scheme for L_p?

Consider schemes for evaluating $p_m(X)$, where p_m is a polynomial of degree m and $X \in \mathbb{C}^{n\times n}$, that consist of s steps of the form

$$q_1^{(k)}(X) = q_2^{(k-1)}(X)\, q_3^{(k-1)}(X) + q_4^{(k-1)}(X), \qquad k = 1\colon s, \tag{4.1a}$$

$$\deg q_i^{(k)} < m, \quad i = 1\colon 4,\ k < s, \qquad \deg q_i^{(k)} \ge 1, \quad i = 2\colon 3, \tag{4.1b}$$

where the q_i are polynomials, $q_i^{(k)}$, $i = 2\colon 4$, is a linear combination of $q_1^{(1)}, \dots, q_1^{(k-1)}$, and $p_m(X) = q_1^{(s)}(X)$. This class contains all schemes of practical interest, which include Horner's method, evaluation by explicit powers, and the Paterson and Stockmeyer method [16] (all of which are described in [6, section 4.2]), as well as more ad hoc schemes such as those described below. We measure the cost of the scheme by the

number of matrix multiplications it requires. The next result shows that the overhead of evaluating the Fréchet derivative is at most twice the original cost.

THEOREM 4.1. *Let p be a polynomial and let π_p denote the cost of evaluating $p(X)$ by any scheme of the form* (4.1). *Let σ_p denote the extra cost required to compute $L_p(X,E)$ by using the scheme obtained by differentiating the scheme for $p(X)$. Then $\sigma_p \le 2\pi_p$.*

Proof. The proof is by induction on the degree m of the polynomial. For $m = 1$, $p_1(x) = b_0 + b_1 x$ and the only possible scheme is the obvious evaluation $p_1(X) = b_0 I + b_1 X$ with $\pi_1 = 0$. The corresponding Fréchet derivative scheme is $L_{p_1}(X,E) = b_1 E$ and $\sigma_1 = 0$, so the result is trivially true for $m = 1$. Suppose the result is true for all polynomials of degree at most $m-1$ and consider a polynomial p_m of degree m. By (4.1) the last stage of the scheme can be written $p_m(X) = q_2^{(s-1)}(X) q_3^{(s-1)}(X) + q_4^{(s-1)}(X)$, where the polynomials $q_i \equiv q_i^{(s-1)}$, $i = 2\colon 4$ are all of degree less than m. Note that $\pi_{p_m} = \pi_{q_2} + \pi_{q_3} + \pi_{q_4} + 1$ and by the inductive hypothesis, $\sigma_{q_i} \le 2\pi_{q_i}$, $i = 2\colon 4$. Now $L_{p_m}(X,E) = L_{q_2}(X,E) q_3(X) + q_2(X) L_{q_3}(X,E) + L_{q_4}(X,E)$ by the product rule and so

$$\sigma_{p_m} \le \sigma_{q_2} + \sigma_{q_3} + \sigma_{q_4} + 2 \le 2(\pi_{q_2} + \pi_{q_3} + \pi_{q_4} + 1) = 2\pi_{p_m},$$

as required. This proof tacitly assumes that there are no dependencies between the $q_i^{(k)}$ that reduce the cost of evaluating p, for example, $q_2^{(s-1)} = q_3^{(s-1)}$. However, any dependencies equally benefit the L_p evaluation and the result remains valid. ∎

To illustrate the theorem, consider the polynomial $p(X) = I + X + X^2 + X^3 + X^4 + X^5$. Rewriting it as

$$p(X) = I + X\left(I + X^2 + X^4\right) + X^2 + X^4,$$

we see that $p(X)$ can be evaluated in just three multiplications via $X_2 = X^2$, $X_4 = X_2^2$, and $p(X) = I + X(I + X_2 + X_4) + X_2 + X_4$. Differentiating gives

$$\begin{aligned} L_p(X,E) &= L_{x(1+x^2+x^4)}(X,E) + M_2 + M_4 \\ &= E(I + X_2 + X_4) + X(M_2 + M_4) + M_2 + M_4, \end{aligned}$$

where $M_2 = XE + EX$ and $M_4 = M_2 X_2 + X_2 M_2$ by (3.3). Hence the Fréchet derivative can be evaluated with six additional multiplications, and the total cost is nine multiplications.

5. Computational framework. For a number of important functions f, such as the exponential, the logarithm, and the sine and cosine, successful algorithms for $f(A)$ have been built on the use of Padé approximants: a Padé approximant r_m of f of suitable degree m is evaluated at a transformed version of A and the transformation is then undone. Here, $r_m(x) = p_m(x)/q_m(x)$ with p_m and q_m polynomials of degree m such that $f(x) - r_m(x) = O(x^{2m+1})$ [2]. It is natural to make use of this Padé approximant by approximating L_f by the Fréchet derivative L_{r_m} of r_m. The next result shows how to evaluate L_{r_m}.

LEMMA 5.1. *The Fréchet derivative L_{r_m} of the rational function $r_m(x) = p_m(x)/q_m(x)$ satisfies*

$$q_m(A) L_{r_m}(A,E) = L_{p_m}(A,E) - L_{q_m}(A,E) r_m(A). \tag{5.1}$$

Proof. Applying the Fréchet derivative product rule to $q_m r_m = p_m$ gives

$$L_{p_m}(A,E) = L_{q_m r_m}(A,E) = L_{q_m}(A,E)r_m(A) + q_m(A)L_{r_m}(A,E),$$

which rearranges to the result. ∎

We can now state a general framework for simultaneously approximating $f(A)$ and $L_f(A,E)$ in a way that reuses matrix multiplications from the approximation of f in the approximation of L_f.

1. Choose a suitable Padé degree m and transformation function g and set $A \leftarrow g(A)$.
2. Devise efficient schemes for evaluating $p_m(A)$ and $q_m(A)$.
3. Fréchet differentiate the schemes in the previous step to obtain schemes for evaluating $L_{p_m}(A,E)$ and $L_{q_m}(A,E)$. Use the recurrences (3.3) and (3.4) as necessary.
4. Solve $q_m(A)r_m(A) = p_m(A)$ for $r_m(A)$.
5. Solve $q_m(A)L_{r_m}(A,E) = L_{p_m}(A,E) - L_{q_m}(A,E)r_m(A)$ for $L_{r_m}(A,E)$.
6. Apply the appropriate transformations to $r_m(A)$ and $L_{r_m}(A,E)$ that undo the effect of the initial transformation on A.

In view of Theorem 4.1, the cost of this procedure is at most $(3\pi_m + 1)M + 2D$, where $\pi_m M$ is the cost of evaluating both $p_m(A)$ and $q_m(A)$, and M and D denote a matrix multiplication and the solution of a matrix equation, respectively.

If we are adding the capability to approximate the Fréchet derivative to an existing Padé-based method for $f(A)$ then our attention will focus on step 1, where we must reconsider the choice of m and transformation to ensure that both f and L_f are approximated to sufficient accuracy.

In the next section we apply this framework to the matrix exponential.

6. Scaling and squaring algorithm for the exponential and its Fréchet derivative. The scaling and squaring method for computing the exponential of $A \in \mathbb{C}^{n\times n}$ is based on the relation

$$e^A = \left(e^{2^{-s}A}\right)^{2^s}. \tag{6.1}$$

For suitably chosen nonnegative integers s and m, this method approximates $e^{2^{-s}A}$ by $r_m(2^{-s}A)$, where r_m is the $[m/m]$ Padé approximant to e^x, and it takes $e^A \approx (r_m(2^{-s}A))^{2^s}$. A choice of the parameters s and m with a certain optimality property is given in the following algorithm from [5], [6, Algorithm 10.20], which forms the basis of MATLAB's `expm` function.

ALGORITHM 6.1 (scaling and squaring algorithm for exponential). *This algorithm evaluates the matrix exponential $X = e^A$ of $A \in \mathbb{C}^{n\times n}$ using the scaling and squaring method. It uses the parameters θ_m given in Table* 6.1. *The algorithm is intended for IEEE double precision arithmetic.*

```
1  for m = [3 5 7 9]
2      if ||A||_1 ≤ θ_m, evaluate X = r_m(A) using (6.11) and (6.14), quit, end
3  end
4  A ← 2^{-s}A with s = ⌈log_2(||A||_1/θ_13)⌉
5  Evaluate r_13(A) using (6.14) and the preceding equations.
6  X = r_13(A)^{2^s} by repeated squaring.
```

Cost: $(\pi_m + s)M + D$, where m is the degree of Padé approximant used and π_m (tabulated in [5, Table 2.2]) is the cost of evaluating p_m and q_m.

Our aim is now to adapt this algorithm to compute $L_{\exp}(A,E)$ along with e^A.

TABLE 6.1
Maximal values ℓ_m of $\|2^{-s}A\|$ such that the backward error bound (6.10) *does not exceed $u = 2^{-53}$, along with maximal values θ_m such that a bound for $\|\Delta A\|/\|A\|$ does not exceed u.*

m	1	2	3	4	5	6	7	8	9	10
θ_m	3.65e-8	5.32e-4	1.50e-2	8.54e-2	2.54e-1	5.41e-1	9.50e-1	1.47e0	2.10e0	2.81e0
ℓ_m	2.11e-8	3.56e-4	1.08e-2	6.49e-2	2.00e-1	4.37e-1	7.83e-1	1.23e0	1.78e0	2.42e0

m	11	12	13	14	15	16	17	18	19	20
θ_m	3.60e0	4.46e0	5.37e0	6.33e0	7.34e0	8.37e0	9.44e0	1.05e1	1.17e1	1.28e1
ℓ_m	3.13e0	3.90e0	4.74e0	5.63e0	6.56e0	7.52e0	8.53e0	9.56e0	1.06e1	1.17e1

A recurrence for the Fréchet derivative of the exponential can be obtained by differentiating (6.1). Note first that differentiating the identity $e^A = (e^{A/2})^2$ using the chain rule [6, Theorem 3.4] along with $L_{x^2}(A,E) = AE + EA$ gives the relation

$$\begin{aligned} L_{\exp}(A,E) &= L_{x^2}\big(e^{A/2}, L_{\exp}(A/2,E/2)\big) \\ &= e^{A/2}L_{\exp}(A/2,E/2) + L_{\exp}(A/2,E/2)e^{A/2}. \end{aligned} \tag{6.2}$$

Repeated use of this relation leads to the recurrence

$$\begin{aligned} \widetilde{L}_s &= L_{\exp}(2^{-s}A, 2^{-s}E), \\ \widetilde{L}_{i-1} &= e^{2^{-i}A}\widetilde{L}_i + \widetilde{L}_i e^{2^{-i}A}, \qquad i = s\colon -1\colon 1 \end{aligned} \tag{6.3}$$

for $\widetilde{L}_0 = L_{\exp}(A,E)$. Our numerical method replaces $L_{\exp}$ by L_{r_m} and $e^{2^{-i}A}$ by $r_m(2^{-s}A)^{2^{s-i}}$, producing approximations L_i to $\widetilde{L}_i$:

$$\begin{aligned} X_s &= r_m(2^{-s}A), \\ L_s &= L_{r_m}(2^{-s}A, 2^{-s}E), \\ \left.\begin{aligned} L_{i-1} &= X_i L_i + L_i X_i \\ X_{i-1} &= X_i^2 \end{aligned}\right\} & \quad i = s\colon -1\colon 1. \end{aligned} \tag{6.4}$$

The key question is what can be said about the accuracy or stability of L_0 relative to that of the approximation $X_0 = (r_m(2^{-s}A))^{2^s}$ to e^A. To answer this question we recall the key part of the error analysis from [5] (see also [6, section 10.3]), which is summarized in the following result. We denote by log the principal logarithm of $A \in \mathbb{C}^{n\times n}$, which is defined for A with no eigenvalues on $\mathbb{R}^-$ and is the unique logarithm whose eigenvalues all have imaginary parts in $(-\pi,\pi)$.

THEOREM 6.2. *Suppose that*

$$\|e^{-A}r_m(A) - I\| < 1, \qquad \|A\| < \min\{\,|t| : q_m(t) = 0\,\} \tag{6.5}$$

for some consistent matrix norm, so that $g_m(A) = \log(e^{-A}r_m(A))$ is guaranteed to be defined. Then $r_m(A) = e^{A+g_m(A)}$ and $\|g_m(A)\| \le -\log(1 - \|e^{-A}r_m(A) - I\|)$. In particular, if (6.5) *is satisfied with $A \leftarrow 2^{-s}A$ then*

$$r_m(2^{-s}A) = e^{2^{-s}A + g_m(2^{-s}A)}, \tag{6.6}$$

so that $r_m(2^{-s}A)^{2^s} = e^{A + 2^s g_m(2^{-s}A)}$, where

$$\frac{\|2^s g_m(2^{-s}A)\|}{\|A\|} \le \frac{-\log(1 - \|e^{-2^{-s}A}r_m(2^{-s}A) - I\|)}{\|2^{-s}A\|}. \tag{6.7}$$

∎

Differentiating (6.6) gives, using the chain rule,

$$\begin{aligned} L_s &= L_{r_m}(2^{-s}A, 2^{-s}E) \\ &= L_{\exp}\bigl(2^{-s}A + g_m(2^{-s}A), 2^{-s}E + L_{g_m}(2^{-s}A, 2^{-s}E)\bigr). \end{aligned} \tag{6.8}$$

From (6.4), (6.6), and (6.8),

$$\begin{aligned} L_{s-1} &= r_m(2^{-s}A)L_s + L_s r_m(2^{-s}A) \\ &= e^{2^{-s}A+g_m(2^{-s}A)}\, L_{\exp}\bigl(2^{-s}A + g_m(2^{-s}A), 2^{-s}E + L_{g_m}(2^{-s}A, 2^{-s}E)\bigr) \\ &\quad + L_{\exp}\bigl(2^{-s}A + g_m(2^{-s}A), 2^{-s}E + L_{g_m}(2^{-s}A, 2^{-s}E)\bigr)\, e^{2^{-s}A+g_m(2^{-s}A)} \\ &= L_{\exp}\bigl(2^{-(s-1)}A + 2g_m(2^{-s}A), 2^{-(s-1)}E + L_{g_m}(2^{-s}A, 2^{-(s-1)}E)\bigr), \end{aligned}$$

where we have used (6.2) and the fact that L is linear in its second argument. Continuing this argument inductively, and using

$$X_i = X_s^{2^{s-i}} = \bigl(e^{2^{-s}A+g_m(2^{-s}A)}\bigr)^{2^{s-i}} = e^{2^{-i}A+2^{s-i}g_m(2^{-s}A)},$$

we obtain the following result.

THEOREM 6.3. *If* (6.5) *is satisfied with* $A \leftarrow 2^{-s}A$ *then* L_0 *from* (6.4) *satisfies*

$$L_0 = L_{\exp}\bigl(A + 2^s g_m(2^{-s}A), E + L_{g_m}(2^{-s}A, E)\bigr). \tag{6.9}$$ □

Theorem 6.3 is a backward error result: it says that L_0 is the exact Fréchet derivative for the exponential of a perturbed matrix in a perturbed direction. We emphasize that the backward error is with respect to the effect of truncation errors in the Padé approximation, not to rounding errors, which for the moment are ignored.

Theorems 6.2 and 6.3 show that $X_0 = e^{A+\Delta A}$ and $L_0 = L_{\exp}(A + \Delta A, E + \Delta E)$ with the *same* $\Delta A = 2^s g_m(2^{-s}A)$. We already know from the analysis in [5] how to choose s and m to keep ΔA acceptably small. It remains to investigate the norm of $\Delta E = L_{g_m}(2^{-s}A, E)$.

Let $\widetilde{g}_m(x) = \sum_{k=2m+1}^{\infty} c_k x^k$ be the power series resulting from replacing the coefficients of the power series expansion of the function $g_m(x) = \log(e^{-x} r_m(x))$ by their absolute values. Using the second bound in (3.5) we have

$$\frac{\|\Delta E\|}{\|E\|} = \frac{\|L_{g_m}(2^{-s}A, E)\|}{\|E\|} \le \|L_{g_m}(2^{-s}A)\| \le \widetilde{g}_m{}'(\theta), \tag{6.10}$$

where $\theta = \|2^{-s}A\|$. Define $\ell_m = \max\{\, \theta : \widetilde{g}_m{}'(\theta) \le u \,\}$, where $u = 2^{-53} \approx 1.1 \times 10^{-16}$ is the unit roundoff for IEEE double precision arithmetic. Using MATLAB's Symbolic Math Toolbox we evaluated ℓ_m, $m = 1\colon 20$, by summing the first 150 terms of the series symbolically in 250 decimal digit arithmetic. Table 6.1 shows these values along with analogous values θ_m calculated in [5], which are the maximal values of θ such that a bound on $\|\Delta A\|/\|A\|$ obtained from (6.7) does not exceed u. In every case $\ell_m < \theta_m$, which is not surprising given that we are approximating L_{r_m} by an approximation chosen for computational convenience rather than its approximation properties, but

the ratio θ_m/ℓ_m is close to 1. For each m, if $\theta \le \ell_m$ then we are assured that

$$X_0 = e^{A+\Delta A}, \quad L_0 = L_{\exp}(A+\Delta A, E+\Delta E), \quad \|\Delta A\| \le u\|A\|, \quad \|\Delta E\| \le u\|E\|;$$

in other words, perfect backward stability is guaranteed for such θ.

In order to develop an algorithm we now need to look at the cost of evaluating $r_m = p_m/q_m$ and L_{r_m}, where r_m is the $[m/m]$ Padé approximant to e^x. Higham [5] shows how to efficiently evaluate $p_m(A)$ and $q_m(A)$ by using one type of scheme for $m \le 11$ and another for $m \ge 12$; the number of matrix multiplications, π_m, required to compute $p_m(A)$ and $q_m(A)$ is given in [5, Table 2.2]. As Theorem 4.1 suggests, the Fréchet derivatives L_{p_m} and L_{q_m} can be calculated at an extra cost of $2\pi_m$ multiplications by differentiating the schemes for p_m and q_m. We now give the details.

We consider the odd degree Padé approximants to the exponential function. Analogous techniques apply to the even degree approximants (which, as in Algorithm 6.1, it will turn out we do not need). For $m = 3, 5, 7, 9$, we decompose $p_m = \sum_{i=0}^m b_i x^i$ into its odd and even parts:

$$p_m(x) = x \sum_{k=0}^{(m-1)/2} b_{2k+1} x^{2k} + \sum_{k=0}^{(m-1)/2} b_{2k} x^{2k} =: u_m(x) + v_m(x). \tag{6.11}$$

It follows that $q_m(x) = -u_m(x) + v_m(x)$ since $q_m(x) = p_m(-x)$, and hence

$$L_{p_m} = L_{u_m} + L_{v_m}, \qquad L_{q_m} = -L_{u_m} + L_{v_m}.$$

We obtain $L_{u_m}(A,E)$ and $L_{v_m}(A,E)$ by differentiating u_m and v_m, respectively:

$$L_{u_m}(A,E) = A \sum_{k=1}^{(m-1)/2} b_{2k+1} M_{2k} + E \sum_{k=0}^{(m-1)/2} b_{2k+1} A^{2k} \tag{6.12}$$

$$L_{v_m}(A,E) = \sum_{k=1}^{(m-1)/2} b_{2k} M_{2k}. \tag{6.13}$$

The $M_k = L_{x^k}(A,E)$ are computed using (3.3).

For $m = 13$ it is more efficient to use the odd-even splitting $p_{13} = u_{13} + v_{13}$, where

$$\begin{aligned} u_{13}(x) &= xw(x), \quad w(x) = x^6 w_1(x) + w_2(x), \quad v_{13}(x) = x^6 z_1(x) + z_2(x), \\ w_1(x) &= b_{13}x^6 + b_{11}x^4 + b_9 x^2, \quad w_2(x) = b_7 x^6 + b_5 x^4 + b_3 x^2 + b_1, \\ z_1(x) &= b_{12}x^6 + b_{10}x^4 + b_8 x^2, \quad z_2(x) = b_6 x^6 + b_4 x^4 + b_2 x^2 + b_0. \end{aligned}$$

Differentiating these polynomials yields

$$\begin{aligned} L_{u_{13}}(A,E) &= AL_w(A,E) + Ew(A), \\ L_{v_{13}}(A,E) &= A^6 L_{z_1}(A,E) + M_6 z_1(A) + L_{z_2}(A,E), \end{aligned}$$

where

$$\begin{aligned} L_w(A,E) &= A^6 L_{w_1}(A,E) + M_6 w_1(A) + L_{w_2}(A,E), \\ L_{w_1}(A,E) &= b_{13}M_6 + b_{11}M_4 + b_9 M_2, \\ L_{w_2}(A,E) &= b_7 M_6 + b_5 M_4 + b_3 M_2, \\ L_{z_1}(A,E) &= b_{12}M_6 + b_{10}M_4 + b_8 M_2, \\ L_{z_2}(A,E) &= b_6 M_6 + b_4 M_4 + b_2 M_2. \end{aligned}$$

TABLE 6.2
Number of matrix multiplications, ω_m, required to evaluate $r_m(A)$ and $L_{r_m}(A,E)$, and measure of overall cost C_m in (6.17).

m	1	2	3	4	5	6	7	8	9	10
ω_m	1	4	7	10	10	13	13	16	16	19
C_m	25.5	12.5	8.5	6.9	5.3	5.2	4.4	4.7	4.2	4.7

m	11	12	13	14	15	16	17	18	19	20
ω_m	19	19	19	22	22	22	22	25	25	25
C_m	4.4	4.0	3.8	4.5	4.3	4.1	3.9	4.7	4.6	4.5

Then $L_{p_{13}} = L_{u_{13}} + L_{v_{13}}$ and $L_{q_{13}} = -L_{u_{13}} + L_{v_{13}}$. We finally solve for $r_m(A)$ and $L_{r_m}(A,E)$ the equations

$$(-u_m + v_m)(A)r_m(A) = (u_m + v_m)(A), \tag{6.14}$$

$$(-u_m + v_m)(A)L_{r_m}(A,E) = (L_{u_m} + L_{v_m})(A,E) + (L_{u_m} - L_{v_m})(A,E)r_m(A). \tag{6.15}$$

We are now in a position to choose the degree m and the scaling parameter s. Table 6.2 reports the total number of matrix multiplications, $\omega_m = 3\pi_m + 1$, necessary to evaluate r_m and L_{r_m} for a range of m, based on [5, Table 2.2] and the observations above. In evaluating the overall cost we need to take into account the squaring phase. If $\|A\| > \ell_m$ then in order to use the $[m/m]$ Padé approximant we must scale A by 2^{-s} so that $\|2^{-s}A\| \le \ell_m$, that is, we need $s = \lceil \log_2(\|A\|/\ell_m) \rceil$. From the recurrence (6.4), we see that $3s$ matrix multiplications are added to the cost of evaluating r_m and L_{r_m}. Thus the overall cost in matrix multiplications is

$$\omega_m + 3s = 3\pi_m + 1 + 3\max(\lceil \log_2 \|A\| - \log_2 \ell_m \rceil, 0). \tag{6.16}$$

To minimize the cost we therefore choose m to minimize the quantity

$$C_m = \pi_m - \log_2 \ell_m, \tag{6.17}$$

where we have dropped the constant terms and factors in (6.16). Table 6.2 reports the C_m values. The table shows that $m = 13$ is the optimal choice, just as it is for the scaling and squaring method for the exponential itself [5]. The ω_m values also show that only $m = 1, 2, 3, 5, 7, 9$ need be considered if $\|A\| < \ell_{13}$. As in [5] we rule out $m = 1$ and $m = 2$ on the grounds of possible loss of significant figures in floating point arithmetic.

It remains to check that the evaluation of L_{p_m}, L_{q_m}, and L_{r_m} is done accurately in floating point arithmetic. The latter matrix is evaluated from (6.15), which involves solving a matrix equation with coefficient matrix $q_m(A)$, just as in the evaluation of r_m, and the analysis from [5] guarantees that $q_m(A)$ is well conditioned for the scaled A. It can be shown that for our schemes for evaluating L_{p_m} we have

$$\|L_{p_m}(A,E) - fl(L_{p_m}(A,E))\|_1 \le \widetilde{\gamma}_{n^2} p'_m(\|A\|_1)\|E\|_1 \approx \widetilde{\gamma}_{n^2} e^{\|A\|_1/2}\|E\|_1,$$

where we have used the facts that p_m has positive coefficients and $p_m(x) \approx e^{x/2}$. Here, $\widetilde{\gamma}_k = cku/(1-cku)$, where c denotes a small integer constant. At least in an absolute sense, this bound is acceptable for $\|A\| \le \ell_{13}$. An entirely analogous bound can be obtained for L_{q_m}, since $q_m(x) = p_m(-x)$.

We now state the complete algorithm.

ALGORITHM 6.4 (scaling and squaring algorithm for exponential and Fréchet derivative). *Given $A, E \in \mathbb{C}^{n\times n}$ this algorithm computes $R = e^A$ and $L = L_{\exp}(A, E)$ by a scaling and squaring algorithm. It uses the parameters ℓ_m listed in Table* 6.1. *The algorithm is intended for IEEE double precision arithmetic.*

Cost: $(\omega_m + 3s)M + 2D$, where m is the degree of Padé approximant used and ω_m is given in Table 6.2. The linear systems at lines 26 and 27 have the same coefficient matrix, so an LU factorization can computed once and reused.

Since $L_{\exp}(A, \alpha E) = \alpha L_{\exp}(A, E)$, an algorithm for computing $L_{\exp}(A, E)$ should not be influenced in any significant way by $\|E\|$, and this is the case for Algorithm 6.4. Najfeld and Havel [15] propose computing $L_{\exp}(A, E)$ using their version of the scaling and squaring method for the exponential in conjunction with (2.1). With this approach E affects the amount of scaling, and overscaling results when $\|E\| \gg \|A\|$, while how to scale E to produce the most accurate result is unclear.

To assess the cost of Algorithm 6.4 we compare it with Algorithm 6.1 and with a "Kronecker–Sylvester scaling and squaring algorithm" of Kenney and Laub [11], which is based on a Kronecker sum representation of the Fréchet derivative. In the form detailed in [6, section 10.6.2], this latter algorithm scales to obtain $\|2^{-t}A\| \le 1$, evaluates the [8/8] Padé approximant to $\tanh(x)/x$ at the scaled Kronecker sum, and then uses the recurrence (6.4) or the variant (6.3) that explicitly computes $X_i = e^{2^{-i}A}$

in each step. It requires one matrix exponential, $(17 + 3t)M$, and the solution of 8 Sylvester equations if (6.4) is used, or s matrix exponentials, $(18 + 2t)M$, and the same number of Sylvester equation solutions if (6.3) is used.

To compare the algorithms, assume that the Padé degree $m = 13$ is used in Algorithms 6.1 and 6.4. Then Algorithm 6.4 costs $(19+3s)M+2D$ and Algorithm 6.1 costs $(6+s)M+D$. Two conclusions can be drawn. First, Algorithm 6.4 costs about three times as much as just computing e^A. Second, since the cost of solving a Sylvester equation is about $60n^3$ flops, which is the cost of 30 matrix multiplications, the Kronecker–Sylvester algorithm is an order of magnitude more expensive than Algorithm 6.4. To be more specific, consider the case where $\|A\| = 9$, so that $s = 1$ in Algorithms 6.1 and 6.4 and $t = 4$, and ignore the cost of computing the matrix exponential in the less expensive "squaring" variant of the Kronecker–Sylvester algorithm. Then the operation counts in flops are approximately $48n^3$ for Algorithm 6.4 (e^A and $L_{\exp}(A, E)$), $16n^3$ for Algorithm 6.1 (e^A only), and $538n^3$ for the Kronecker–Sylvester algorithm ($L_{\exp}(A, E)$ only). A further drawback of the Kronecker–Sylvester algorithm is that it requires complex arithmetic, so the effective flop count is even higher.

Other algorithms for $L_{\exp}(A, E)$ are those of Kenney and Laub [9] and Mathias [12] (see also [6, section 10.6.1]), which apply quadrature to an integral representation of the Fréchet derivative. These algorithms are intended only for low accuracy approximations and do not lend themselves to combination with Algorithm 6.1.

We describe a numerical experiment, modeled on that in [5], that tests the accuracy of Algorithm 6.4. We took 74 test matrices, which include some from MATLAB (in particular, from the `gallery` function), some from the Matrix Computation Toolbox [3], and test matrices from the e^A literature; most matrices are 10×10, with a few having smaller dimension. We evaluated the normwise relative errors of the computed Fréchet derivatives $L_{\exp}(A, E)$, using a different E, generated as `randn(n)`, for each A. The "exact" Fréchet derivative is obtained using (2.1) with the exponential evaluated at 100 digit precision via MATLAB's Symbolic Math Toolbox. Figure 6.1 displays

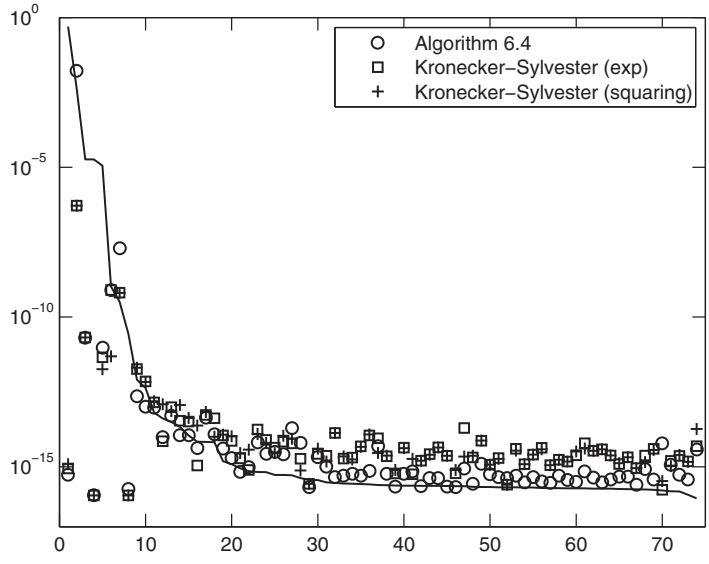

FIG. 6.1. *Normwise relative errors in Fréchet derivatives* $L_{\exp}(A, E)$ *computed by Algorithm* 6.4 *and two variants of the Kronecker–Sylvester algorithm for* 74 *matrices* A *with a different random* E *for each* A*, along with estimate of* $\mathrm{cond}(L_{\exp}, A)u$ (*solid line*).

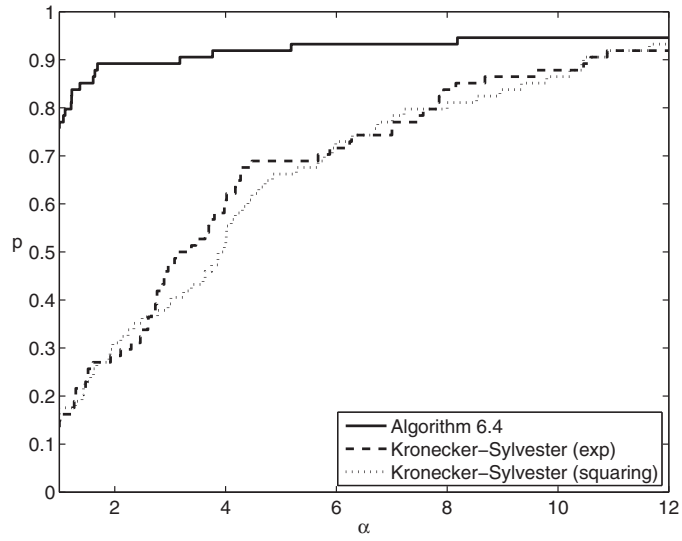

FIG. 6.2. *Same data as in Figure* 6.1 *presented as a performance profile.*

the Frobenius norm relative errors for Algorithm 6.4 and for the Kronecker–Sylvester algorithm in both "squaring" and "exponential" variants. Also shown is a solid line representing a finite difference approximation to $\mathrm{cond}(L_{\exp}, A)u$, where $\mathrm{cond}(L_{\exp}, A)$ is a condition number defined in terms of the Jacobian of the map L regarded as a function of A and E (we use (1.2) with a small, random E); this line indicates the accuracy we would expect from a forward stable algorithm for computing the Fréchet derivative. Figure 6.1 shows that all the methods are performing in a reasonably forward stable manner but does not clearly reveal differences between the methods.

Figure 6.2 plots the same data as a performance profile: for a given α the corresponding point on each curve indicates the fraction p of problems on which the method had error at most a factor α times that of the smallest error over all three methods. The results show clear superiority of Algorithm 6.4 over the Kronecker–Sylvester algorithm in terms of accuracy, for both variants of the latter algorithm. Since Algorithm 6.4 is also by far the more efficient, as explained above, it is clearly the preferred method.

7. Condition number estimation. We now turn our attention to estimating the condition number of the matrix exponential, which from (1.2) is

$$\kappa_{\exp}(A) = \frac{\|L_{\exp}(A)\|\,\|A\|}{\|e^A\|}.$$

Algorithm 6.4 can compute $L_{\exp}(A, E)$ for any direction E, but to obtain the norm $\|L_{\exp}(A)\|$ we need to maximize $L_{\exp}(A, E)$ over all E of unit norm.

For the moment we will consider general f. We can write

$$\mathrm{vec}(L(A, E)) = K(A)\mathrm{vec}(E), \tag{7.1}$$

where $K(A) \in \mathbb{C}^{n^2 \times n^2}$ is independent of E and $\mathrm{vec}(E) \in \mathbb{C}^{n^2}$ denotes the vector comprising the columns of E strung one on top of the other from first to last. We refer to $K(A)$ as the Kronecker form of the Fréchet derivative. From (7.1) we have

$\|L(A,E)\|_F = \|K(A)\mathrm{vec}(E)\|_2$, and on dividing by $\|E\|_F = \|\mathrm{vec}(E)\|_2$ and maximizing over all E it follows that

$$\|L(A)\|_F = \|K(A)\|_2. \tag{7.2}$$

Therefore we can compute $\|L(A)\|_F$ exactly by forming $K(A)$, whose columns are $\mathrm{vec}(L(A, e_i e_j^T))$ for $i,j = 1\colon n$, and then taking the 2-norm. This is a prohibitively expensive computation, typically requiring $O(n^5)$ flops. However, in practice only an estimate of the correct order of magnitude is needed. For this purpose it is appropriate to use matrix norm estimation techniques.

The following algorithm is essentially the usual power method applied to $K(A)$, and exploits the relation (7.2) [6, section 3.4], [9].

ALGORITHM 7.1 (power method on Fréchet derivative). *Given $A \in \mathbb{C}^{n\times n}$ and the Fréchet derivative L of a function f, this algorithm uses the power method to produce an estimate $\eta \le \|L(A)\|_F$.*

```
1  Choose a nonzero starting matrix Z_0 ∈ C^{n×n}.
2  for k = 0: ∞
3        W_{k+1} = L(A, Z_k)
4        Z_{k+1} = L*(A, W_{k+1})
5        η_{k+1} = ||Z_{k+1}||_F / ||W_{k+1}||_F
6        if converged, η = η_{k+1}, quit, end
7  end
```

Here, $\star$ denotes the adjoint, and for the exponential, $L^{\star}_{\exp}(A,W) \equiv L_{\exp}(A^*, W)$.

We do not specify Algorithm 7.1 in any more detail because we prefer a 1-norm variant of the power method. For the 1-norm there is no analogue of (7.2), but the next lemma shows how $\|K(A)\|_1$ compares with $\|L(A)\|_1$.

LEMMA 7.2 ([6, Lemma 3.18]). *For $A \in \mathbb{C}^{n\times n}$ and any function f,*

$$\frac{\|L(A)\|_1}{n} \le \|K(A)\|_1 \le n\|L(A)\|_1. \qquad \square \tag{7.3}$$

The following algorithm, which again needs the ability to evaluate $L(A,E)$ and $L^{\star}(A,E)$, is essentially [6, Algorithm 3.22]; it employs a block 1-norm estimation algorithm of Higham and Tisseur [7], which for an $n \times n$ matrix carries out a 1-norm power iteration whose iterates are $n \times t$ matrices, where t is a parameter.

ALGORITHM 7.3 (block 1-norm estimator for Fréchet derivative). *Given a matrix $A \in \mathbb{C}^{n\times n}$ this algorithm uses a block 1-norm estimator to produce an estimate η of $\|L(A)\|_1$. More precisely, $\eta \le \|K(A)\|_1$, where $\|K(A)\|_1$ satisfies* (7.3).

1 Apply Algorithm 2.4 from Higham and Tisseur [7] with parameter $t = 2$ to the Kronecker matrix representation $B := K(A)$ of $L(A)$, noting that $By \equiv \mathrm{vec}(L(A,E))$ and $B^*y \equiv \mathrm{vec}(L^{\star}(A,E))$, where $\mathrm{vec}(E) = y$.

Key properties of Algorithm 7.3 are that it typically requires about $4t$ Fréchet derivative evaluations and it almost invariably produces an estimate of $\|K(A)\|_1$ correct to within a factor 3. A factor n of uncertainty is added when we take η as an estimate of $\|L(A)\|_1$, but just changing the norm from the 1-norm to the ∞-norm can introduce such a factor, so it is not a serious weakness. Overall, the algorithm is a very reliable means of estimating $\|L(A)\|_1$ to within a factor $3n$.

Returning to the exponential, our interest is in how to combine Algorithms 6.4 and 7.3 in the most efficient manner. We need to evaluate $L(A,E)$ and $L(A^*,E)$ for a fixed A and several different E, without knowing all the E at the start of the

TABLE 7.1
Matrices that must be computed and stored during the initial e^A evaluation, to be reused during the Fréchet derivative evaluations. "LU fact" stands for LU factorization of $-u_m + v_m$, and $B = A/2^s$.

computation. To do so we will store matrices accrued during the initial computation of e^A and reuse them in the Fréchet derivative evaluations. This of course assumes the availability of extra storage, but in modern computing environments ample storage is usually available.

In view of the evaluation schemes (6.11)–(6.13) and (6.15), for $m \in \{3, 5, 7, 9\}$ we need to store A^{2k}, $k = 1\colon d_{(m-1)/2}$, where $d = [0\ 1\ 2\ 2]$, along with $W_m(A) = \sum_{k=0}^{(m-1)/2} b_{2k+1}A^{2k}$, $r_m(A)$, and the LU factorization of $(-u_m + v_m)(A)$. For $m = 13$, the matrix A needs to be scaled, to $B = A/2^s$. According to the scheme used in Algorithm 6.4 we need to store B^{2k}, $k = 1\colon 3$, $W \equiv w(B)$, the LU factorization of $(-u_m + v_m)(B)$, and $r_m(B)^{2^i}$, $i = 0\colon s-1$. Table 7.1 summarizes the matrices that need to be stored for each m.

The following algorithm computes the matrix exponential and estimates its condition number. Since the condition number is not needed to high accuracy we use the parameters θ_m in Table 6.1 (designed for e^A) instead of ℓ_m (designed for $L(A, E)$). The bound in (6.10) for the Fréchet derivative backward error $\|\Delta E\|/\|E\|$ does not exceed $28u$ for $m \le 13$ when we use the θ_m, so the loss in backward stability for the Fréchet derivative evaluation is negligible. If the condition estimate is omitted, the algorithm reduces to Algorithm 6.1. The algorithm exploits the relation $L_f(A^*, E) = L_f(A, E^*)^*$, which holds for any f with a power series expansion with real coefficients, by (3.1).

ALGORITHM 7.4 (scaling and squaring algorithm for the matrix exponential with 1-norm condition estimation). *Given $A \in \mathbb{C}^{n\times n}$ this algorithm computes $X = e^A$ by the scaling and squaring method (Algorithm 6.1) and an estimate $\gamma \approx \kappa_{\exp}(A)$ using the block 1-norm estimator (Algorithm 7.1). It uses the values θ_m listed in Table 6.1. The algorithm is intended for IEEE double precision arithmetic.*

37 $L_u = AL_w + EW$
38 $L_v = A_6L_{z_1} + M_6Z_1 + L_{z_2}$
39 Solve $(-U + V)L = L_u + L_v + (L_u - L_v)X_s$ for L.
40 for $i = s\colon -1\colon 1$
41 $L \leftarrow X_iL + LX_i$
42 end
..... To compute $L^\star_{\exp}(\widetilde{A}, E)$ for a given E:
43 Execute lines 30–42 with E replaced by its conjugate transpose and take the conjugate transpose of the result.
44 $\gamma = \eta\alpha/\|X\|_1$

The cost of Algorithm 7.4 is the cost of computing e^A plus the cost of about 8 Fréchet derivative evaluations, so obtaining e^A and the condition estimate multiplies the cost of obtaining just e^A by a factor of about 17. This factor can be reduced to 9 if the parameter t in the block 1-norm power method is reduced to 1, at a cost of slightly reduced reliability.

In our MATLAB implementation of Algorithm 7.4 we invoke the function `funm_condest1` from the Matrix Function Toolbox [4], which interfaces to the MATLAB function `normest1` that implements the block 1-norm estimation algorithm of [7].

With the same matrices as in the test of the previous section we used Algorithm 7.4 to estimate $\|K(A)\|_1$ and also computed $\|K(A)\|_1$ exactly by forming $K(A)$ as described at the start of this section. Figure 7.1 plots the norms and the estimates.

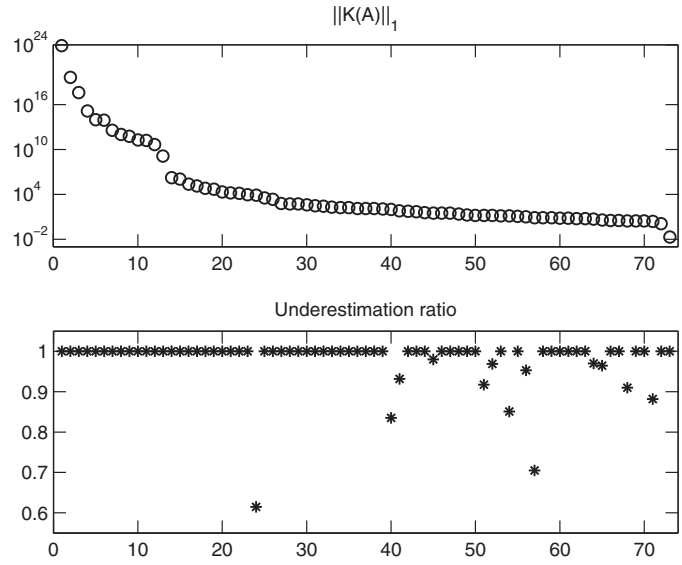

FIG. 7.1. $\|K(A)\|_1$ *and underestimation ratio* $\eta/\|K(A)\|_1$*, where* η *is the estimate of* $\|K(A)\|_1$ *produced by Algorithm* 7.4.

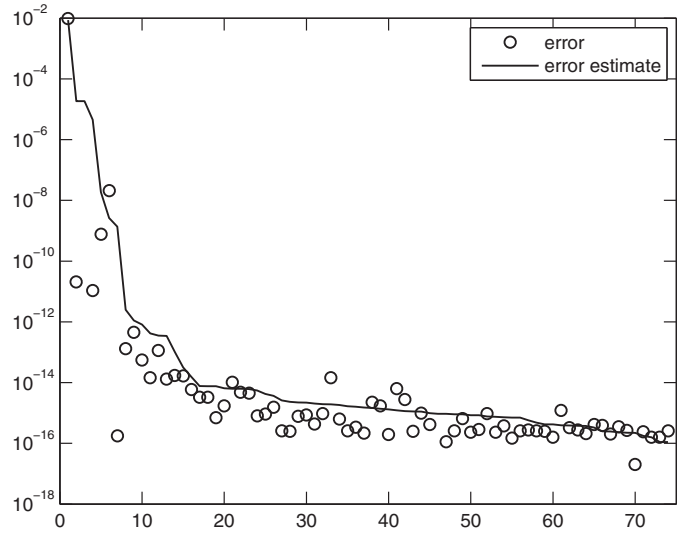

FIG. 7.2. *Normwise relative error for computed exponential and error estimate comprising condition number estimate times unit roundoff.*

The worst underestimation ratio is 0.61, so the estimates are all within a factor 2 of the true 1-norm.

Finally, we invoked Algorithm 7.4 on the same set of test matrices and computed the "exact" exponential in 100 digit precision. Figure 7.2 plots the error in the computed exponential along with the quantity γu: the condition estimate multiplied by the unit roundoff, regarded as an error estimate. If the scaling and squaring algorithm were forward stable and the condition estimate reliable we would expect

the error to be bounded by $\phi(n)\gamma u$ for some low degree polynomial ϕ. The overall numerical stability of the scaling and squaring algorithm is not understood [6], but our experience is that the method usually does behave in a forward stable way. Figure 7.2 indicates that the condition estimate from Algorithm 7.4 provides a useful guide to the accuracy of the computed exponential from the algorithm.

8. Concluding remarks. The LAPACK Users' Guide states [1, p. 77] that "Our goal is to provide error bounds for most quantities computed by LAPACK." This is a desirable goal for any numerical algorithm, and in order to achieve it error analysis must be developed that yields a reasonably sharp error bound that can be efficiently estimated. For matrix function algorithms a complete error analysis is not always available, and for the forward error a bound of the form $\mathrm{cond}(f, A)u$ is the best we can expect in general. To date relatively little attention has been paid to combining evaluation of $f(A)$ with computation of the Fréchet derivative $L(A, E)$ and estimation of the condition number $\mathrm{cond}(f, A)$. We are currently applying and extending the ideas developed here to other transcendental functions such as the logarithm and the sine and cosine and will report on this work in a future paper.

Acknowledgment. We thank Bruno Iannazzo for his helpful comments on a draft of this paper.

FAST CONDITION ESTIMATION FOR A CLASS OF STRUCTURED EIGENVALUE PROBLEMS*

A. J. LAUB† AND J. XIA‡

Abstract. We present a fast condition estimation algorithm for the eigenvalues of a class of structured matrices. These matrices are low rank modifications to Hermitian, skew-Hermitian, and unitary matrices. Fast structured operations for these matrices are presented, including Schur decomposition, eigenvalue block swapping, matrix equation solving, compact structure reconstruction, etc. Compact semiseparable representations of matrices are used in these operations. We use these operations in a new, improved version of the statistical condition estimation method for eigenvalue problems. The estimation algorithm costs $O(n^2)$ flops for all eigenvalues, instead of $O(n^3)$ as in traditional algorithms, where n is the order of the matrix. The algorithm provides reliable condition estimates for both eigenvalues and eigenvalue clusters. The proposed structured matrix operations are also useful for additional eigenvalue problems and other applications. Numerical examples are used to illustrate the reliability and efficiency of the algorithm.

1. Introduction.

The condition number of an eigenvalue or eigenvalue cluster measures the sensitivity of the eigenvalue or eigenvalue cluster to small changes in the input matrix, and it may be used to bound the error in the computed approximation. For a general order-n matrix, it usually costs $O(n^3)$ flops or more to estimate the sensitivity of all its eigenvalues, for example, by considering separations of eigenvalues, considering angles between left eigenvectors and right eigenvectors, and other methods [1], [6], [19], [21], [28]. For structured eigenvalue problems, on the one hand, it is important to capture the structures [13]. We can take advantage of the structures to obtain fast condition estimation. The development of new fast structured algorithms for these matrices in recent years makes it possible to obtain fast condition estimation. In this paper, we consider condition estimation for the eigenvalues of a class of structured matrices, and we present a reliable estimation scheme which costs only $O(n^2)$ flops. This class of matrices has the following structures:

1. Low rank modifications to Hermitian and skew-Hermitian matrices. Examples include Frobenius matrices, diagonal plus rank one matrices, and arrowhead matrices which arise in applications such as bidiagonal SVD, divide-and-conquer algorithms for some eigenvalue problems [18], etc.
2. Low rank modifications to unitary matrices such as companion matrices, which are closely related to the problems of finding polynomial roots and solving certain differential equations.

Any such matrix $C \in \mathbb{R}^{n\times n}$ is a low rank perturbation to a *rank symmetric* matrix [3] (a matrix $\hat{C}$ is said to be rank symmetric if for any 2×2 block partition of

$\hat{C} = \begin{bmatrix} \hat{C}_{11} & \hat{C}_{12} \\ \hat{C}_{21} & \hat{C}_{22} \end{bmatrix}$ with $\hat{C}_{11}$ and $\hat{C}_{22}$ square, the ranks of $\hat{C}_{12}$ and $\hat{C}_{21}$ are equal). That is,

$$C = \hat{C} + xy^T, \tag{1.1}$$

where $x, y \in \mathbb{C}^{n\times k}$ with $k \ll n$, and $\hat{C}$ is rank symmetric. Some fast methods for finding the eigenvalues of these matrices have been proposed in recent years (see, e.g., [3], [4], [5], [11], [16]). These methods exploit certain rank structure of the QR iterates when using QR iterations to find the eigenvalues. In this paper we show that the rank structure can also be used to accelerate the condition estimation of the eigenvalues.

As an example, the companion matrix

$$C = \begin{bmatrix} -a_{n-1} & -a_{n-2} & \cdots & -a_0 \\ 1 & 0 & \cdots & 0 \\ & \ddots & \ddots & \vdots \\ 0 & & 1 & 0 \end{bmatrix} \tag{1.2}$$

can be written as

$$C = \begin{bmatrix} 0 & \cdots & 0 & \pm 1 \\ 1 & 0 & \cdots & 0 \\ & \ddots & \ddots & \vdots \\ 0 & & 1 & 0 \end{bmatrix} - \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \begin{bmatrix} a_{n-1} & a_{n-2} & \cdots & a_0 \mp 1 \end{bmatrix}.$$

To quickly find the eigenvalues of (1.2), the fast structured QR iteration algorithm in [11] computes structured QR iterates which are unitarily similar to C. The iterations are done via the Q and R factors of the QR iterates. It can be shown that the QR iterates have small off-diagonal ranks [3], [5], [11]. Thus the Q and R factors can be efficiently represented by rank structures called *sequentially semiseparable* (SSS) matrix forms, proposed in [7], [8], [9]. An SSS matrix looks like

$$\begin{bmatrix} \mathcal{D}_1 & \mathcal{U}_1\mathcal{V}_2^T & \mathcal{U}_1\mathcal{W}_2\mathcal{V}_3^T & \mathcal{U}_1\mathcal{W}_2\mathcal{W}_3\mathcal{V}_4^T \\ \mathcal{P}_2\mathcal{Q}_1^T & \mathcal{D}_2 & \mathcal{U}_2\mathcal{V}_3^T & \mathcal{U}_2\mathcal{W}_3\mathcal{V}_4^T \\ \mathcal{P}_3\mathcal{R}_2\mathcal{Q}_1^T & \mathcal{P}_3\mathcal{Q}_2^T & \mathcal{D}_3 & \mathcal{U}_3\mathcal{V}_4^T \\ \mathcal{P}_4\mathcal{R}_3\mathcal{R}_2\mathcal{Q}_1^T & \mathcal{P}_4\mathcal{R}_3\mathcal{Q}_2^T & \mathcal{P}_4\mathcal{Q}_3^T & \mathcal{D}_4 \end{bmatrix}, \tag{1.3}$$

where the matrices $\{\mathcal{D}_i\}$, $\{\mathcal{U}_i\}$, $\{\mathcal{W}_i\}$, $\{\mathcal{V}_i\}$, $\{\mathcal{P}_i\}$, $\{\mathcal{R}_i\}$, $\{\mathcal{Q}_i\}$ are called (SSS) generators. SSS structures are useful for problems where the off-diagonal blocks have small ranks (see, e.g., [10], [11]). When the off-diagonal ranks of an SSS matrix are small and the sizes of $\{\mathcal{W}_i\}$ and $\{\mathcal{R}_i\}$ are close to the off-diagonal ranks, the matrix is said to be in *compact* SSS form. In such a situation, the matrix can be represented by only a linear amount of data, and operations on the compact SSS matrices are very efficient. For example, it costs only linear time to solve compact SSS linear systems and to multiply two compact SSS matrices with the same partition. More details can be found in [7], [8], [9], [10], [11]. The use of compact SSS matrices in the algorithm in [11] provides an $O(n^2)$ cost eigensolver for companion matrices (and polynomial root problems).

1.1. Main results. This paper shows that we can also exploit the rank structure of the above class of eigenvalue problems (1.1) to provide efficient condition estimation

for the eigenvalues. We use the *statistical condition estimation* (SCE) method by Kenney and Laub [23]. In [19], a perturbation analysis for the *average eigenvalues* of a general matrix based on SCE has been given, and an SCE condition estimator is provided. The cost is $O(n^3)$ flops for all eigenvalues. Here, we first improve the estimator in [19] from various points of view. Then we take into account the rank structure of the above class of matrices in SCE and extend the estimator in [19] to all the eigenvalues or eigenvalue clusters of these matrices. Given the facts that the related matrix computations become structured, and that SCE is good at respecting matrix structures, we can reduce the total condition estimation cost for all eigenvalues to $O(n^2)$.

We present the main idea based on the companion matrix (1.2). For convenience, we consider only real matrices and maintain real arithmetic in this paper. Similar techniques can be easily extended to other matrices in the above class. This is discussed in section 4. In this paper, the following structured matrix algorithms are used or developed:

1. Use the existing algorithm in [11] to compute a compact SSS Schur decomposition of C in $O(n^2)$ flops. Improve the algorithm so that the maximum generator size is smaller than the original one in [11] (see the next item).
2. Preserve *quasi-triangular* (a block upper triangular matrix with 1×1 and/or 2×2 diagonal blocks) Schur form when bringing any desired eigenvalue or eigenvalue cluster to any other position. This is done by swapping the contiguous 1×1 or 2×2 diagonal blocks of the Schur form in structured form. Quickly update the initial Schur form to recover a new compact Schur form. A recovery procedure in [11] is improved (with even less cost) so that it also works for quasi-triangular matrices, and the computational rank result is consistent with the theoretical prediction as well. The total cost for all eigenvalues is $O(n^2)$ flops.
3. Represent certain Sylvester equations in structured forms. Quickly solve a structured Sylvester equation for each eigenvalue so that the total cost for all eigenvalues is $O(n^2)$ instead of $O(n^3)$.
4. Use structured perturbation in SCE and evaluate all the condition estimates in $O(n^2)$ flops by taking advantage of matrix structures. Efficiently reconstruct certain invariant subspaces.

Our estimator works for both simple or multiple eigenvalues or eigenvalue clusters. The paper [26] presents some similar work. However, [26] requires that the eigenvalues of C all be distinct. The new operations here are more general, more efficient, and even simpler to implement than those in [26]. For example, after the diagonal block swapping, [26] uses SSS matrix multiplications to get the SSS representation of the new Schur form. But when the matrix has multiple eigenvalues, many SSS multiplications may be needed and the SSS Schur form may not be compact anymore. Instead, here we use a recovery strategy which always guarantees that the SSS Schur form is compact. As another example, here we simplify the reconstruction of the invariant subspace corresponding to an eigenvalue or eigencluster after the diagonal block swapping.

Similar techniques can also speed up the condition estimation for the eigenvectors of (1.1). We emphasize that the structured matrix operations in this paper are also useful in many other problems, in addition to condition estimation. Condition estimation for the eigenvalues of a companion matrix C can be used to assess the accuracy of polynomial roots including multiple or clustered roots.

1.2. Overview and notation. The rest of this paper is organized as follows. Section 2 reviews SCE for general eigenvalue problems and gives some new improvements. The fast structured condition estimation scheme is presented in section 3 in detail. Related matrix algorithms are derived. We also briefly discuss the extension of the techniques to general matrices (1.1) in the above class. Section 4 provides the algorithm, together with detailed flop counts, and shows some numerical examples. We draw some concluding remarks in section 6.

The following notation is used in this paper:

- The ith row (or block row) and the jth column (or block column) of $A \equiv (A_{ij})_{n\times n}$ are denoted by $A_{i,:}$ and $A_{:,j}$, respectively. Similarly, $A_{1:i,1:j}$ denotes the submatrix of A at (block) rows 1 through i and (block) columns 1 through j.
- $\mathrm{vec}(A)$ denotes the column vector formed by stacking the columns of A from left to right.
- If A is an SSS matrix, $\mathcal{D}_i(A)$, $\mathcal{U}_i(A)$, etc. represent its SSS generators as in (1.3).
- δA means the product of a small scalar δ with A.
- If a vector u is selected uniformly and randomly from the unit n-sphere S_{n-1}, we write $u \in \mathrm{U}(S_{n-1})$.

2. Condition estimation for general eigenvalue problems.

2.1. General SCE scheme for average (mean) eigenvalues. For a general $n \times n$ real matrix C, Gudmundsson, Kenney, and Laub derived an SCE condition estimator for its average or mean eigenvalues in the following way [19]. Assume we have a block Schur decomposition of C,

$$C = UTU^T, \quad U = [U_1, U_c], \quad T = \begin{bmatrix} T_1 & H \\ 0 & T_c \end{bmatrix}, \tag{2.1}$$

where U is orthogonal and T_1 and T_c have orders n_1 and $n - n_1$, respectively. The average eigenvalue of T_1 is defined to be [1], [19]

$$\mu(T_1) = \frac{\mathrm{trace}(T_1)}{n_1}.$$

If the spectra of T_1 and T_c are well separated [22], [31], then the sensitivity of $\mu(T_1)$ is well defined. A condition number κ for $\mu(T_1)$ is given in [19].

In SCE, a condition estimate for $\mu(T_1)$ can be obtained by perturbing C to $C + \delta E$ with a relative perturbation matrix δE, where δ is a small number, and $E = (C_{ij}Z_{ij})_{n\times n}$ with $Z = (Z_{ij})_{n\times n}$ satisfying $\mathrm{vec}(Z) \in \mathrm{U}(S_{n^2-1})$. Accordingly, $\mu(T_1)$ is perturbed to [19]

$$\mu(\tilde{T_1}) \approx \mu(T_1 + \delta B) = \mu(T_1) + \delta\mu(B), \tag{2.2}$$

where

$$B = U_1^T E U_1 + Y U_c^T E U_1, \tag{2.3}$$

and Y is an $n_1 \times (n - n_1)$ matrix satisfying a Sylvester equation

$$T_1 Y - Y T_c = H. \tag{2.4}$$

Based on (2.2), SCE leads to a relative condition estimate to $\mu(T_1)$ in the following form:

$$\nu = \frac{1}{\omega_p |\mu(T_1)|} |\mu(B)|, \tag{2.5}$$

where p is the number of parameters that define C (for a general $n \times n$ matrix, $p = n^2$; for the companion matrix (1.2), $p = n$), and ω_p is the Wallis factor which can be approximated by [23]

$$\omega_p \approx \sqrt{\frac{2}{\pi(p - \frac{1}{2})}}.$$

The expected value of the estimate $\mathrm{E}(\nu)$ is equal to the exact condition number κ [19].

Multiple samples of Z can be used to increase the accuracy of the estimation. For example, assume we use m samples of Z, denoted $Z^{(i)},\ i = 1, 2, \ldots, m$, which are properly orthonormalized [23], and accordingly, T_1 is perturbed to $T_1 + \delta B^{(i)},\ i = 1, 2, \ldots, m$. Then the m-sample condition estimator is defined as

$$\nu^{(m)} = \frac{1}{\omega_p |\mu(T_1)|} \sqrt{[\mu(B^{(1)})]^2 + \cdots + [\mu(B^{(m)})]^2}.$$

The accuracy of this estimator is given by [19]

$$\Pr\left(\frac{\kappa}{\gamma} \le \nu^{(m)} \le \gamma\kappa\right) \ge 1 - \frac{1}{m!}\left(\frac{2m}{\gamma\pi}\right)^m + \mathrm{O}\left(\frac{1}{\gamma^{m+1}}\right), \qquad \gamma > 1.$$

For example, with $m = 2$, the probability of $\nu^{(m)}$ being within a factor of $\gamma = 10$ of the exact condition number κ is greater than 0.9919. Even with only one sample, this probability is greater than 0.9363.

2.2. Improvements. We make several improvements over Gudmundsson, Kenney, and Laub's general SCE estimator for average eigenvalues. First, for simple real eigenvalues and complex eigenpairs, more specific forms based on (2.3) and (2.5) can be derived. When T_1 is a 1×1 block (eigenvalue), B in (2.3) is reduced to a scalar which can be calculated by using Y (a vector) and the first row and the first column of U. When T_1 is a 2×2 block, T_1 has a conjugate pair of complex eigenvalues. The condition number of this eigenpair is generally different from the condition number of their average. Thus, (2.5) may not precisely reflect the sensitivity of this eigenpair. In fact, by assuming

$$T_1 \equiv \begin{bmatrix} t_{11} & t_{12} \\ t_{21} & t_{22} \end{bmatrix}, \qquad B \equiv \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix},$$

we can derive a more accurate estimator for the actual condition of the eigenpair [26]

$$\nu = \frac{1}{\omega_p \sqrt{\det(T_1)}} \sqrt{\frac{\alpha^2 \det(T_1) - \alpha\beta \mathrm{trace}(T_1) + \beta^2}{[\mathrm{trace}(T_1)]^2 - 4\det(T_1)}},$$

where $\alpha = b_{11} + b_{22},\ \beta = t_{11}b_{22} + t_{22}b_{11} - t_{12}b_{21} - t_{21}b_{12}$.

The second improvement is that, for average eigenvalues corresponding to a diagonal block T_i other than T_1, we can employ diagonal block swapping techniques as in

[1], [12], [27] to obtain a new Schur decomposition such that T_i (in its similar form) appears in the leading (upper left) position of the new Schur form

$$\tilde{T} = GTG^T, \tag{2.6}$$

where G is an orthogonal transformation matrix.

Another improvement is to rewrite (2.3) as

$$\begin{aligned} B &= \begin{bmatrix} I_{n_1} & Y \end{bmatrix} U^T E U_1 \\ &= \begin{bmatrix} I_{n_1} & Y \end{bmatrix} (U^T E U) \begin{bmatrix} I_{n_1} \\ 0 \end{bmatrix}, \end{aligned} \tag{2.7}$$

where E is isolated from Y. The new representation (2.7) indicates that the operations involving E can be independent of different eigenvalues. In order to compute B for different eigenvalues, we can precompute the matrix $U^T E U$ just once. Then for different eigenvalues we need only solve for Y and then compute the trace of the left $n_1 \times n_1$ submatrix of

$$\hat{B} = \begin{bmatrix} I_{n_1} & Y \end{bmatrix} (U^T E U), \tag{2.8}$$

where appropriate transformations may be applied to $U^T E U$ (see section 4). On the other hand, if multiple samples of E are used, then we can reuse the matrices Y and U. This will be further discussed in section 4.

Finally, for structured matrices C, the perturbation matrix E may also be structured, and it is also possible to compute Y and B quickly by taking advantage of the structure of C. The total cost of the condition estimation can then be less than $O(n^3)$. This is the actual situation for the class of matrices (1.1) where only $O(n^2)$ flops are needed. We elaborate on this in the rest of this paper.

Remark 2.1. The algorithm in this paper can be used to estimate the condition of polynomial roots. For the companion matrix (1.2), it can be shown that the exact condition number κ for $\mu(T_1)$ is actually the condition number defined in [14], [15] for the roots of the polynomial $\sum_{i=0}^{n} a_i x^i$ (with $a_n \equiv 1$) when all roots are distinct [26].

3. Fast structured condition estimation. For a structured matrix C in (1.1), the perturbation matrix E generally corresponds to the low rank modifications (see, e.g., [18] for an error analysis based on perturbing the low rank part of a diagonal plus rank one matrix). In such a situation, the relative perturbation matrix E has the form

$$E = xE_2^T + E_1 y^T = \begin{bmatrix} x & E_1 \end{bmatrix} \begin{bmatrix} E_2^T \\ y^T \end{bmatrix} \equiv \hat{x}\hat{y}^T, \tag{3.1}$$

where $E_1 = (x_{ij} Z_{ij}^x)_{n\times k}$, $E_2 = (y_{ij} Z_{ij}^y)_{n\times k}$ with Z^x and Z^y random matrices satisfying $\mathrm{vec}([Z^x, Z^y]) \in \mathrm{U}(S_{2nk-1})$. For the example of the companion matrix (1.2), E can be further simplified to

$$E = \begin{bmatrix} e^T \\ 0 \end{bmatrix} \begin{matrix} 1 \\ n-1 \end{matrix}, \tag{3.2}$$

where $e^T = [-a_{n-1}z_{n-1}, -a_{n-2}z_{n-2}, \ldots, -(a_0 \mp 1)z_0]$ and $[z_{n-1}, \ldots, z_0]^T \in \mathrm{U}(S_{n-1})$. This is because, usually, $a_{n-1}, a_{n-2}, \ldots, a_0$ are the parameters of interest.

The special structure of E saves the cost of computing B. Moreover, based on the rank structure of C and its similarity transformations, all the major steps in the SCE scheme can be quickly done by structured matrix computations. They include

1. structured Schur decomposition in (2.1),
2. structured diagonal block swapping in (2.6),
3. structured Sylvester equation solution for (2.4), and
4. evaluation of $\mu(B)$ in (2.5) using the low rank structure.

We discuss the details in the following subsections.

3.1. Structured Schur decomposition. We can find a structured Schur decomposition of C by using the fast structured eigensolver in [11]. The traditional Hessenberg QR iterations for the eigenvalues of C are

$$C^{(0)} = C,$$
$$C^{(k)} = Q^{(k)}R^{(k)},\ C^{(k+1)} = R^{(k)}Q^{(k)}, \qquad k = 0, 1, 2, \ldots.$$

Clearly, any $C^{(k)}$ is a rank one update to an orthogonal matrix since C is. The QR algorithm in [11] is based on the result that each $C^{(k)}$ actually has small off-diagonal ranks.

THEOREM 3.1 (see [3], [4], [11]). *The ranks of all off-diagonal blocks* $C^{(k)}_{1:j,j+1:n}$, $j = 1, \ldots, n-1$, *of* $C^{(k)}$ *are no larger than* 3.

The algorithm in [11] uses a sequence of Givens matrices for $Q^{(k)}$ and an SSS form $R^{(k)}$. When the algorithm converges, it yields a quasi-triangular Schur form T. Appropriate Givens matrices form an orthogonal matrix U such that $C = UTU^T$, which is a structured form of (2.1). That is, U is a product of $\mathrm{O}(n^2)$ Givens matrices in general, and T is an SSS matrix.

Clearly, T also has off-diagonal ranks bounded by 3. However, we can compute the QR factorization $T = QR$, where Q is a block diagonal matrix with 1×1 or 2×2 diagonal blocks and R is also a rank one update to an orthogonal matrix. The matrix R has maximum off-diagonal rank bounded by 2 with a proof similar to that of Theorem 3.1 [3], [11]. The application of Q to R does not increase this rank. Thus, we have the following result.

THEOREM 3.2. *For any quasi-triangular matrix orthogonally similar to* C, *its maximum off-diagonal rank is no larger than* 2.

The algorithm in [11] can be used to obtain a compact SSS form of T with maximum generator size 3. This algorithm can be improved by using the techniques in subsection 3.3.2 so that the maximum generator size of T is 2.

3.2. Structured Sylvester equation solver. The Sylvester equation (2.4) can be solved in different ways. It can be converted into a linear system using Kronecker products. Alternatively, since T_1 and T_c are quasi triangular, the Bartels–Stewart algorithm [2] can be applied conveniently. However, both methods cost $\mathrm{O}(O(n_1(n-n_1)^2 + n_1^2(n-n_1)))$ if T_1 and T_c are general quasi-triangular matrices. This makes the total condition estimation cost as large as $\mathrm{O}(n^3)$. Notice that T_1 and T_c are also SSS matrices. We can reduce the Sylvester equation solution cost to $\mathrm{O}(n_1(n-n_1))$ by a structured form of the Bartels–Stewart algorithm. This consists of three parts: making one coefficient matrix lower quasi triangular, quickly formulating certain (simpler) linear or Sylvester systems in the Bartels–Stewart algorithm, and quickly solving those systems.

3.2.1. Transforming the Sylvester equation. We first make one of the two coefficient matrices lower quasi triangular. Since T_1 is block upper triangular, we employ a permutation matrix P such that

$$L \equiv PT_1P^T$$

is lower quasi triangular. The matrix P is simply the anti-identity matrix

$$P = \begin{bmatrix} 0 & & 1 \\ & \iddots & \\ 1 & & 0 \end{bmatrix}.$$

Then (2.4) can be written as

$$L(PY) - (PY)T_c = PH. \tag{3.3}$$

It is clear that the SSS generators of L can be obtained directly from those of T_1 as follows:

$$\mathcal{D}_i(L) = \mathcal{D}_i(T_1)^T, \quad \mathcal{P}_i(L) = \mathcal{V}_i(T_1), \quad \mathcal{Q}_i(L) = \mathcal{U}_i(T_1), \quad \mathcal{R}_i(L) = \mathcal{W}_i(T_1)^T.$$

For notational convenience, we write (3.3) as the SSS Sylvester equation

$$LX - XR = K, \tag{3.4}$$

where L is a block lower triangular compact SSS matrix with generators $\{\mathcal{D}_i(L) \equiv L_{ii}\}_1^{l_1}$, $\{\mathcal{P}_i\}_2^{l_1}$, $\{\mathcal{Q}_i\}_1^{l_1-1}$, and $\{\mathcal{R}_i\}_2^{l_1-1}$, and R is a block upper triangular compact SSS matrix with generators $\{\mathcal{D}_i(R) \equiv R_{ii}\}_1^{l_2}$, $\{\mathcal{U}_i\}_1^{l_2-1}$, $\{\mathcal{V}_i\}_2^{l_2}$, and $\{\mathcal{W}_i\}_2^{l_2-1}$. Here, $l_1 + l_2 = l$ is the total number of diagonal blocks (eigenvalue clusters) in T.

3.2.2. Formulating (simpler) systems in the Bartels–Stewart algorithm. Next, we apply the Bartels–Stewart algorithm to (3.4). Since H is an off-diagonal block of T, we assume $K = PH$ has the form

$$\begin{aligned} K &= \begin{bmatrix} K_{:,1} & K_{:,2} & \cdots & K_{:,l_2} \end{bmatrix} \\ &= \begin{bmatrix} u_1 w_2 \cdots w_{l_1} v_{l_1+1}^T & u_1 w_2 \cdots w_{l_1+1} v_{l_1+2}^T & \cdots & u_1 w_2 \cdots w_{l-1} v_l^T \\ \vdots & \vdots & & \vdots \\ u_{l_1-1} w_{l_1} v_{l_1+1}^T & u_{l_1-1} w_{l_1} w_{l_1+1} v_{l_1+2}^T & \cdots & u_{l_1-1} w_{l_1} \cdots w_{l-1} v_l^T \\ u_{l_1} v_{l_1+1}^T & u_{l_1} w_{l_1+1} v_{l_1+2}^T & \cdots & u_{l_1} w_{l_1+1} \cdots w_{l-1} v_l^T \end{bmatrix}. \end{aligned} \tag{3.5}$$

We also assume that all the matrices in (3.4) have conformal partitions. When we get the solution X of (3.4), the solution of (2.4) can be simply obtained by $Y = P^T X$.

The Bartels–Stewart algorithm solves (3.4) by successively solving

$$\begin{aligned} L_{ii} X_{ij} - X_{ij} R_{jj} = K_{ij} - \sum_{k=1}^{i-1} L_{ik} X_{kj} + \sum_{k=1}^{j-1} X_{ik} R_{kj}, \\ i = 1, 2, \ldots, l_1, \qquad j = 1, 2, \ldots, l_2, \end{aligned}$$

where L_{ii} and R_{jj} are 1×1 or 2×2 blocks, and X_{ij} denotes the (i, j) block of X, which is partitioned conformally according to the blocks of L and R. These equations can be rewritten as a set of linear equations or (simpler) Sylvester equations

$$\begin{aligned} LX_{:,j} - X_{:,j} R_{jj} = \hat{K}_j, \\ j = 1, 2, \ldots, l_2, \end{aligned} \tag{3.6}$$

where $\hat{K}_j = K_{:,j} + X_{:,1:j-1} R_{1:j-1,j}$, and $X_{:,j}$ has one or two columns. Since L is an $n_1 \times n_1$ SSS matrix and R_{jj} is a 1×1 or 2×2 block, we can solve (3.6) for each j in

$O(n_1)$ flops, provided that the right-hand side $\hat{K}_j$ can be evaluated in $O(n_1)$ flops. In fact, the evaluation of both $K_{:,j}$ and $X_{:,1:j-1}R_{1:j-1,j}$ for all $j = 1, \ldots, l_2$ can be done successively as follows (when $j = 1$, let $X_{:,1:j-1}R_{1:j-1,j} \equiv 0$).

For $K_{:,j}$, $j = 1, \ldots, l_2$ in (3.5), introduce auxiliary matrices Ω_k defined by

$$\Omega_{l_1} = I,\ \Omega_k = w_{k+1}\Omega_{k+1}, \qquad k = l_1 - 1,\ l_1 - 2, \ldots, 2, 1. \tag{3.7}$$

Then compute each block K_{kj} by

$$K_{kj} = u_k \Omega_k v_j^T, \qquad k = 1, 2, \ldots, l_1. \tag{3.8}$$

After the calculation of each $K_{:,j}$, replace all Ω_k by

$$\hat{\Omega}_k = \Omega_k w_{l_1+j}. \tag{3.9}$$

For $X_{:,1:j-1}R_{1:j-1,j}$, $j = 1, \ldots, l_2$, notice that the block column $R_{1:j-1,j}$ has the following form:

$$\begin{bmatrix} \mathcal{U}_1\mathcal{W}_2\cdots\mathcal{W}_{j-1}\mathcal{V}_j^T \\ \vdots \\ \mathcal{U}_{j-2}\mathcal{W}_{j-1}\mathcal{V}_j^T \\ \mathcal{U}_{j-1}\mathcal{V}_j^T \end{bmatrix}.$$

Introduce auxiliary matrices Φ_j defined by

$$\Phi_0 = 0,\ \Phi_j = \Phi_{j-1}\mathcal{W}_j + X_{:,j}\mathcal{U}_j, \qquad j = 1, 2, \ldots, l_2 - 1. \tag{3.10}$$

Then clearly,

$$X_{:,1:j-1}R_{1:j-1,j} = \Phi_{j-1}\mathcal{V}_j^T, \qquad j = 1, 2, \ldots, l_2. \tag{3.11}$$

It can be shown that the cost of evaluating $\hat{K}_j$ in (3.6) for each j by (3.7)–(3.11) is $O(n_1)$.

3.2.3. Solving (3.6). Finally, we consider the solution of (3.6). For each j, when R_{jj} is a scalar, (3.6) is an order-n_1 lower triangular SSS system

$$(L - R_{jj})X_{:,j} = \hat{K}_j^T.$$

The coefficient matrix $L - R_{jj}$ has the same generators as L except that the $\mathcal{D}_i$ generators are replaced by $L_{ii} - R_{jj}$ or $L_{ii} - R_{jj}I_2$, depending on the size of L_{ii}. This system can be solved in linear time by the fast SSS system solver in [9], and the details are shown in [26].

When R_{jj} is 2×2, (3.6) is a simple Sylvester equation, which can be converted into an order-$2n$ lower triangular SSS system. Note that for this situation, the Bartels–Stewart algorithm does not apply to (3.6) anymore since we want to maintain real arithmetic and R_{jj} does not have a real Schur form. However, we can rewrite (3.6) as a Sylvester equation in terms of $X_{:,j}^T$ as follows:

$$-R_{jj}^T X_{:,j}^T + X_{:,j}^T L^T = \hat{K}_j^T.$$

This equation can be converted into a lower triangular SSS system

$$(L \otimes I_2 - I_{n_1-2} \otimes R_{jj}^T)\mathrm{vec}(X_{:,j}^T) = \mathrm{vec}(\hat{K}_j^T).$$

The SSS generators of the coefficient matrix are given by those of $L \otimes I_2$, except the diagonal generators are $\mathcal{D}_i(L \otimes I_2) - R_{jj}^T$ or $\mathcal{D}_i(L \otimes I_2) - I_2 \otimes R_{jj}^T$, depending on whether the order of $\mathcal{D}_i(L)$ is 1 or 2. The generators of $L \otimes I_2$ are listed in Table 3.1.

For both cases, the solution of (3.6) costs $O(n_1)$ for each j.

TABLE 3.1

SSS generators of $L\otimes I_2$ in terms of the generators of L, where $\mathcal{P}_i(L) \equiv \begin{bmatrix} \mathcal{P}_{i,1}(L) \\ \mathcal{P}_{i,2}(L) \end{bmatrix}$ and $\mathcal{Q}_i(L) \equiv \begin{bmatrix} \mathcal{Q}_{i,1}(L) \\ \mathcal{Q}_{i,2}(L) \end{bmatrix}$.

Order of $\mathcal{D}_i(L)$	$\mathcal{D}_i(L\otimes I_2)$	$\mathcal{P}_i(L\otimes I_2)$	$\mathcal{Q}_i(L\otimes I_2)$	$\mathcal{R}_i(L\otimes I_2)$
1	$\mathcal{D}_i(L)\otimes I_2$	$I_2\otimes\mathcal{P}_i(L)$	$I_2\otimes\mathcal{Q}_i(L)$	$I_2\otimes\mathcal{R}_i(L)$
2	$\mathcal{D}_i(L)\otimes I_2$	$\begin{bmatrix} I_2\otimes\mathcal{P}_{i,1}(L) \\ I_2\otimes\mathcal{P}_{i,2}(L) \end{bmatrix}$	$\begin{bmatrix} I_2\otimes\mathcal{Q}_{i,1}(L) \\ I_2\otimes\mathcal{Q}_{i,2}(L) \end{bmatrix}$	$I_2\otimes\mathcal{R}_i(L)$

3.3. Swapping the diagonal blocks of the Schur form T. In order to use (2.5) to evaluate the condition of any eigenvalue cluster corresponding to diagonal blocks other than T_1, we can use a swapping procedure to bring those blocks to the leading upper left position of T. Assume that the eigenvalue cluster of interest corresponds to the diagonal blocks $\{T_{i_1}, T_{i_2}, \ldots, T_{i_k}\}$ of T. The matrix T will be transformed into $\tilde{T}$ in (2.6), for which we will derive a new compact SSS form.

3.3.1. Swapping procedure for contiguous blocks. We make use of a fundamental swapping procedure in [1], [12], [27] for two diagonal blocks of a matrix

$$\begin{bmatrix} T_i & H_i \\ 0 & T_j \end{bmatrix},$$

where T_i and T_j have orders n_i and n_j, respectively, and T_i and T_j have no eigenvalue in common. The swapping procedure in [1], [12], [27] finds an orthogonal matrix G_i, which is the product of some Givens matrices such that

$$G_i \begin{bmatrix} T_i & H_i \\ 0 & T_j \end{bmatrix} G_i^T = \begin{bmatrix} M_j T_j M_j^{-1} & \bar{H}_i \\ 0 & M_i T_i M_i^{-1} \end{bmatrix},$$

where M_i and M_j are approximate invertible matrices. Thus T_i and T_j have been swapped.

In order to preserve the quasi-triangular form of T, we apply this swapping procedure to contiguous 1×1 or 2×2 diagonal blocks of T, even if T may have multiple eigenvalues. The details are as follows. To bring the 1×1 or 2×2 blocks $\{T_{i_1}, T_{i_2}, \ldots, T_{i_k}\}$ of an eigencluster to the leading position, we partition T as

$$T = \begin{bmatrix} \hat{T}_1 & \hat{H}_1 & \cdots \\ 0 & \hat{T}_2 & \cdots \\ 0 & 0 & \ddots \end{bmatrix},$$

where $\hat{T}_2$ has diagonal blocks $\{T_{i_1}, T_{i_2}, \ldots, T_{i_k}\}$. If we directly apply the above swapping procedure to $\begin{bmatrix} \hat{T}_1 & \hat{H}_1 \\ 0 & \hat{T}_2 \end{bmatrix}$ to bring $\hat{T}_2$ to the leading position, then the quasi-triangular form of T may be destroyed, and also the structures of the related matrices and matrix equations are hard to explore.

Thus, instead, we apply the above procedure to contiguous 1×1 or 2×2 diagonal blocks of T and bring each T_i in $\{T_{i_1}, T_{i_2}, \ldots, T_{i_k}\}$ to the leading position in one round of swapping. After each round of swapping, T is transformed into a new quasi-triangular matrix $\tilde{T} = GTG^T$ as in (2.6), where G is a product of Givens matrices. (The current structure of this $\tilde{T}$ needs to be compressed. See the next subsection.) The number of Givens matrices depends on the size of T_i. If T_i is 1×1, then $k_i - 1$

Givens matrices are needed, where k_i is the row or column index of T_i in T. The matrix G has the form

$$G = \prod_{j=1}^{k_i-1} \operatorname{diag}\left[I_{j-1}, \begin{bmatrix} c_j & s_j \\ -s_j & c_j \end{bmatrix}, I_{n-j-1}\right], \tag{3.12}$$

which is upper Hessenberg. If T_i is 2×2, then $2(k_i - 1)$ Givens matrices are needed, where k_i is the row or column index of the leading entry of T_i in T. Some of these Givens matrices commute, and after reordering the matrices, we have $G = G_1 G_2$, where each of G_1 and G_2 has the form (3.12). The details of the generation of G are similar to those in [26]. Clearly, G in (3.12) is an SSS matrix, with its generators given in Table 3.2 in terms of its Schur parameters $\{c_i, s_i\}$ [11].

TABLE 3.2
SSS generators of G in (3.12).

$\mathcal{D}_j(G)$	$\mathcal{U}_j(G)$	$\mathcal{V}_j(G)$	$\mathcal{W}_j(G)$	$\mathcal{P}_j(G)$	$\mathcal{Q}_j(G)$	$\mathcal{R}_j(G)$
$c_{j-1}c_j$	$c_{j-1}s_j$	c_j	s_j	1	$-s_j$	0

The matrix $\tilde{T}$ is then still quasi triangular. We can get its SSS form by multiplying three SSS matrices in (2.6) using the formulas for SSS matrix multiplications in [8]. This is the method used in [26] for the situation of distinct eigenvalues. Notice that the off-diagonal generator sizes increase accumulatively with the multiplications in (2.6). If the $\mathcal{W}_i(T)$ generators have size 2, then the $\mathcal{W}_i(\tilde{T})$ generators have size up to 6, since the $\mathcal{W}_i$ generators of G and G^T have size 1 or 2.

3.3.2. Recovery of compact SSS representation of $\tilde{T}$. Since here we are considering general eigenclusters instead of simple distinct eigenvalues, the matrix multiplication technique in [26] is inefficient. For example, if the swapping process is applied to an eigencluster which has k multiple eigenvalues or eigenpairs, then $\tilde{T}$ needs to be multiplied by up to $\mathrm{O}(kn)$ Givens matrices, and the off-diagonal generator sizes of $\tilde{T}$ increase significantly. Therefore, $\tilde{T}$ is generally not compact anymore. On the other hand, the actual off-diagonal ranks of $\tilde{T}$ do not increase, according to Theorem 3.2. Thus, we use a recovery strategy similar to the one in [11] to reconstruct a compact SSS form for $\tilde{T}$. The recovery strategy in [11] is designed for certain strictly triangular matrices with maximum off-diagonal rank 2 such that their generator sizes are bounded by 3. Here we improve the strategy such that it works for the quasi-triangular matrix $\tilde{T}$, and furthermore, the generators sizes are bounded by 2, which is consistent with the maximum off-diagonal rank. This also saves one SSS matrix multiplication.

The matrix T is orthogonally similar to C and is obviously orthogonal plus rank one, which we assume to be $T \equiv P + uv^T$. Also, assume that $\tilde{T}$ has a QR factorization $\tilde{T} = \tilde{Q}\tilde{R}$. The matrix $\tilde{Q}$ is a block diagonal matrix with 1×1 or 2×2 diagonal blocks, since $\tilde{T}$ is quasi triangular. We have

$$\begin{aligned} \tilde{R} &= \tilde{Q}^T \tilde{T} = \tilde{Q}^T G(P + uv^T)G^T \\ &= \tilde{Q}^T GPG^T + (\tilde{Q}^T Gu)(Gv)^T \equiv \tilde{P} + \tilde{u}\tilde{v}^T. \end{aligned}$$

There exists an orthogonal upper Hessenberg matrix P_1 which is a product of Givens matrices such that

$$P_1 \tilde{u} = ||\tilde{u}||_2 e_1, \tag{3.13}$$

TABLE 3.3

Upper SSS generators of $P_1^T P_2$ in terms of the Schur parameters of P_1 and P_2, where $\rho_{i-1} \equiv \prod_{k=1}^{i-1} s_k \tilde{s}_k + \sum_{j=1}^{i-1} (c_j \tilde{c}_j \prod_{k=j+1}^{i-1} s_k \tilde{s}_k)$. Other generators can be obtained by symmetry in the structure.

$D_i(P_1^T P_2)$	$U_i(P_1^T P_2)$	$V_i(P_1^T P_2)$	$W_i(P_1^T P_2)$
$c_i \tilde{c}_i \rho_{i-1} + s_i \tilde{s}_i$	$c_i \tilde{s}_i \rho_{i-1} - s_i \tilde{c}_i$	$\tilde{c}_i$	$\tilde{s}_i$

TABLE 3.4

SSS generators of $\tilde{u}\tilde{v}^T$.

$\mathcal{D}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{U}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{V}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{W}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{P}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{Q}_i(\tilde{u}\tilde{v}^T)$	$\mathcal{R}_i(\tilde{u}\tilde{v}^T)$
$\tilde{u}_i \tilde{v}_i^T$	$\tilde{u}_i$	$\tilde{v}_i$	1	$\tilde{u}_i$	$\tilde{v}_i$	1

where e_1 is the first unit vector. Then we have that $P_1 \tilde{P} = P_1 \tilde{R} - ||\tilde{u}||_2 e_1 \tilde{v}^T$ is orthogonal and also upper Hessenberg. Thus, there exists another orthogonal upper Hessenberg matrix P_2 such that

$$P_2 = P_1 \tilde{P} = P_1 \tilde{R} - ||\tilde{u}||_2 e_1 \tilde{v}^T, \tag{3.14}$$

$$\tilde{R} = P_1^T P_2 + ||\tilde{u}||_2 P_1^T e_1 \tilde{v}^T = P_1^T P_2 + \tilde{u}\tilde{v}^T, \tag{3.15}$$

$$\tilde{T} = \tilde{Q}\tilde{R} = \tilde{Q}(P_1^T P_2 + \tilde{u}\tilde{v}^T). \tag{3.16}$$

Both P_1 and P_2 are orthogonal upper Hessenberg and have maximum off-diagonal rank one, and $||\tilde{u}||_2 P_1^T e_1 \tilde{v}^T$ is a rank one matrix. Therefore, if SSS multiplication and addition formulas are used as in [11], the SSS form of $\tilde{R}$ has maximum generator size 3. However, a more compact form of $\tilde{R}$ is available.

THEOREM 3.3. *For any orthogonal upper Hessenberg matrices P_1 and P_2, the matrix $P_1^T P_2$ has maximum off-diagonal rank one.*

Proof. Denote a submatrix $P_1(1:i, 1:i+1)$ by $P_{1;(1:i,1:i+1)}$. An upper off-diagonal block of $P = P_1^T P_2$ is given by

$$P_{1:i,i+1:n} = P_{1;(1:i+1,1:i)}^T P_{2;(1:i+1,i+1:n)}.$$

The submatrix $P_{2;(1:i+1,i+1:n)}$ has rank one, since all its rows are multiples of

$$[\tilde{c}_i,\ \tilde{s}_i \tilde{c}_{i+1},\ \ldots,\ \tilde{s}_i \cdots \tilde{s}_{n-1} \tilde{c}_n],$$

where $\{\tilde{c}_i, \tilde{s}_i\}$ are the Schur parameters of P_2. (See Table 3.2.) Thus, $P_{1:i,i+1:n}$ has rank one also. ∎

The SSS form of $P_1^T P_2$ in (3.16) is given in Table 3.3 in terms of the Schur parameters $\{c_i, s_i\}$ and $\{\tilde{c}_i, \tilde{s}_i\}$ of P_1 and P_2, respectively. The generators can be obtained in O(n) complexity by computing $\rho_{i-1} = \prod_{k=1}^{i-1} s_k \tilde{s}_k + \sum_{j=1}^{i-1} \left(c_j \tilde{c}_j \prod_{k=j+1}^{i-1} s_k \tilde{s}_k \right) \equiv \alpha_{i-1} + \beta_{i-1}$ recursively as follows:

$$\begin{aligned} &\alpha_0 = 1,\ \alpha_i = (s_i \tilde{s}_i)\alpha_{i-1}, \qquad i = 1, 2, \ldots, n-1, \\ &\beta_0 = 0,\ \beta_i = (s_i \tilde{s}_i)\beta_{i-1} + c_i \tilde{c}_i, \qquad i = 1, 2, \ldots, n-1. \end{aligned}$$

The SSS form of $\tilde{u}\tilde{v}^T$ is given in Table 3.4. Then one SSS addition gives an SSS form for $\tilde{R}$ whose maximum generator size is 2.

The left multiplication of $\tilde{R}$ by $\tilde{Q}$ does not increase the off-diagonal block ranks because $\tilde{Q}$ is a block diagonal matrix with 1×1 or 2×2 diagonal blocks. Thus, $\tilde{T}$ has

maximum generator size 2. This construction process provides an alternative way of proving Theorem 3.2.

Therefore, we can use (3.14)–(3.16) to recover a compact SSS form for $\tilde{T}$. After each round of swapping to bring a single eigenvalue or eigenpair to a desired position, we apply the recovery procedure to $\tilde{T}$. First, we form the redundant SSS form of $\tilde{T}$ in (2.6) by SSS matrix multiplications, and then we compute the QR factorization $\tilde{Q}\tilde{R}$ for $\tilde{T}$. The matrix $\tilde{Q}$ can be obtained by computing the Givens QR factorization

$$\tilde{T}_i = \tilde{Q}_i \tilde{R}_i \tag{3.17}$$

for any 2×2 diagonal block $\tilde{T}_i$ of T. The block diagonal matrix $\tilde{Q}$ has each diagonal block being either 1 or $\tilde{Q}_i$. The matrix $\tilde{R}$ is still an SSS matrix with the same generators as $\tilde{T}$ except that for any i corresponding to a 2×2 diagonal block,

$$\mathcal{D}_i(\tilde{R}) = \tilde{R}_i,\ \mathcal{U}_i(\tilde{R}) = \tilde{Q}_i^T \mathcal{U}_i(\tilde{T}). \tag{3.18}$$

Note that the Schur parameters of P_2 are obtained by updating only certain SSS generators of $P_1\tilde{R}$. With $P_1^T P_2$ and $\tilde{u}\tilde{v}^T$ available in SSS forms, a new compact SSS form of $\tilde{T}$ is straightforward according to (3.17) and (3.18). This improved recovery procedure requires about $14i_1$ operations, as compared with the $40i_1$ cost in [11]. In addition, the SSS generators have maximum size 2 instead of 3, which reduces the cost for later operations also.

3.4. Computing the condition estimate (2.5). The major work in evaluating ν in (2.5) is to compute $\mu(B)$, where B is given by (2.3). In general, for companion matrices we can compute (2.5) using the method which will be presented in section 4. But since E has a special form (3.2) with only one nonzero row, an alternative method is to use (2.3) directly.

We first find $U_{1,:}$. Note that the fast eigensolver in [11] provides U in the form of a sequence of $O(n^2)$ Givens rotation matrices. Thus, the application of these matrices on the right to e_1^T, the first unit vector of length n, yields the initial $U_{1,:}$. This costs $O(n^2)$ operations. Later, for each cluster of diagonal blocks with size n_i, the row $U_{1,:}$ needs to be updated when T is updated by the swapping process. According to the previous subsection, U is updated to $\tilde{U} = UG^T$, where G is also represented by Givens rotation matrices. Thus, the updated vector is

$$\tilde{U}_{1,:} = U_{1,:}G^T. \tag{3.19}$$

The computation of EU_1 in (2.3) can be done by considering EU. (If the diagonal blocks of T are swapped, then we compute $E\tilde{U}$ similarly.) Since U is represented by $O(n^2)$ Givens matrices, the cost for computing EU is $O(n^2)$. The matrix EU_1 has only one nonzero row, which we assume to be u_1^T. Also, let $U_{1,:} = \begin{bmatrix} U_{1:n_1,:} \\ U_{n_1+1:n,:} \end{bmatrix}$. Then we have

$$B = U_{1,1:n_1}^T u_1^T + (YU_{1,n_1+1:n}^T)u_1^T,$$

which is the sum of two rank one matrices. We first evaluate $YU_{1,n_1+1:n}^T$ and then compute the diagonal entries of B.

4. The case of general C in (1.1). For a general C in (1.1), which is a low rank modification to a symmetric, skew-symmetric, or orthogonal matrix, the main operations in previous sections are similar. For example, we can quickly get an SSS

form Schur decomposition. A major difference is that the computation of the condition estimate (2.5) can be done in a more general way.

For C in (1.1), the perturbation matrix E has the form (3.1). We can precompute

$$U^T E U = (U^T \hat{x})(U^T \hat{y})^T \equiv \tilde{x}\tilde{y}^T.$$

The computations of $\tilde{x}$ and $\tilde{y}$ cost $O(n^2)$ flops, since U is a product of $O(n^2)$ Givens rotation matrices and both $\tilde{x}$ and $\tilde{y}$ have a finite number of columns.

The direct computation of the trace of $\hat{B}$ in (2.8) is thus straightforward. Since $\hat{B} = \left(\begin{bmatrix} I_{n_1} & Y \end{bmatrix}\tilde{x}\right)\tilde{y}^T$, we first form $\begin{bmatrix} I_{n_1} & Y \end{bmatrix}\tilde{x}$ and then compute the trace of the left $n_1 \times n_1$ submatrix of $\hat{B}$. For different eigenvalues, permutations are applied to U, and $\hat{B}$ now has the form

$$\hat{B} = \begin{bmatrix} I_{n_1} & Y \end{bmatrix} (G\tilde{x})(G\tilde{y})^T, \tag{4.1}$$

where G is a product of Givens rotation matrices. (Here, Y should also be different, but the same notation is used for convenience.) We form $G\tilde{x}$ and $G\tilde{y}$ first, and the rest of the computations are similar.

5. Algorithm, flop counts, and numerical experiments. We outline the major steps in the following algorithm in terms of a companion matrix C.

ALGORITHM 1 (condition estimation for the eigenvalues/eigenclusters of C).

1. Compute an initial structured Schur decomposition $C = UTU^T$.
2. Choose a perturbation matrix E as in (3.2) or (3.1). Precompute $U^T E U$ as in section 4.
3. Repeat for each eigenvalue cluster i corresponding to $\{T_{i_1}, T_{i_2}, \ldots\}$.
   (a) If $i > 1$, use the swapping technique in subsection 3.3 to bring cluster i to the leading position, one block T_{i_j} per round.
   (b) Solve the Sylvester equation (2.4) as in subsection 3.2.
   (c) Compute the condition estimate (2.5) via the diagonal entries of $\hat{B}$ in (4.1).
4. If additional samples of E are used, repeat steps 2 and 3(c).

5.1. Flop counts. To obtain detailed flop counts for a companion matrix C, we make the following assumptions:

- The number of iterations required for the Hessenberg QR iteration to converge is cn^2, where c is a constant (c is usually small).
- Each compact SSS matrix A has maximum off-diagonal rank p which is 2 for T and 1 for an orthogonal upper Hessenberg matrix. All $\mathcal{W}_i$ and $\mathcal{R}_i$ generators of A have dimension p.
- A simplified problem is considered, where all diagonal blocks T_i of T are 1×1.
- The matrix T has m eigenvalue clusters and the ith cluster has n_i eigenvalues $\{T_{i_1}, T_{i_2}, \ldots\}$.

Step 1 costs about the same as the structured eigensolver in [11], and we do not discuss the details here. Step 2 costs about $6cn^2$ flops. The cost of computing the condition estimate of each cluster i in step 3 is as follows.

1. In step 3(a), the operations and the required flops are given by the following:
   (a) Swapping the diagonals of T to bring T_{i_j} to the leading position and computing a redundant SSS form for $\tilde{T}$ cost
   $$(80p^3 + 122p^2 + 130p + 81)(i_j - j),$$
   where we have used the result that it costs at most $40p^3(i_j - j)$ flops to multiply two order-$(i_j - j)$ SSS matrices whose maximum off-diagonal ranks are p [8].
   (b) Recovery of a compact SSS form for $\tilde{T}$ approximately costs
   $$(47p^3 + 242p^2 + 464p + 374)(i_j - j),$$
   where, for simplicity, the cost for a general rank p recovery process is mainly counted based on SSS multiplications, although it is possible to extend the idea in subsection 3.3.2 to further reduce the cost.

   The total cost for the entire cluster i is thus
   $$(127p^3 + 364p^2 + 594p + 455)\sum_{j=1}^{n_i}(i_j - j).$$
2. The cost for step 3(b) using the Bartels–Stewart algorithm is
   $$(2p^3 + 8p^2 + 11p + 2)n_i(n - n_i).$$
3. Step 3(c) costs
   $$2n_i(n - n_i) + 2n_i + 12\sum_{j=1}^{n_i}(i_j - j).$$

Therefore, the cost for all the eigenvalue clusters is

$$(127p^3 + 364p^2 + 594p + 467)\sum_{i=2}^{m}\sum_{j=1}^{n_i}(i_j - j)$$
$$+ (2p^3 + 8p^2 + 11p + 4)\sum_{i=1}^{m} n_i(n - n_i) + 2\sum_{i=1}^{m} n_i.$$

Since $\sum_{i=1}^{m} n_i = n$, we have

$$\sum_{i=2}^{m}\sum_{j=1}^{n_i}(i_j - j) = \sum_{i=2}^{m} n_i(i_1 - 1) \le n\sum_{i=2}^{m} n_i \le n^2,$$
$$\sum_{i=1}^{m} n_i(n - n_i) \le n\sum_{i=1}^{m} n_i = n^2.$$

The total cost is thus approximately bounded by

$$(129p^3 + 372p^2 + 605p + 471)n^2. \tag{5.1}$$

This bound can highly overestimate the cost. For example, when there are only two eigenvalue clusters with equal size $n/2$, the cost is bounded by

$$\left(33p^3 + 95p^2 + 154p + 119\right)n^2.$$

If multiple samples are used, we need only repeat steps 2 and 3(c), and the results from other steps can be reused. Since the total cost for steps 2 and 3(c) is bounded by $26n^2$, which is much smaller than (5.1), the amount of work required for each additional sample of SCE is insignificant.

5.2. Numerical examples. A MATLAB implementation of Algorithm 1 is available at http://www.math.purdue.edu/~xiaj/work/sceeig.

We apply it to some companion matrices and demonstrate the efficiency and accuracy. Note that [26] also includes some results with a different algorithm which requires all the eigenvalues to be distinct.

Example 5.1. Consider a companion matrix C whose eigenvalues are $\lambda_i = i,\ i = 1, 2, \ldots, n$. These eigenvalues are the roots of the Wilkinson polynomial. According to [26], the SCE estimator (2.5) is an estimate of the following exact condition number for λ_i:

$$\kappa_i = ||(k_{i,1}, k_{i,2}, \ldots, k_{i,n})^T||_2,\ \kappa_{i,j} = \left| \frac{a_j \lambda_i^{j-1}}{\prod_{k \neq i} (\lambda_i - \lambda_k)} \right|, \tag{5.2}$$

where a_j is the coefficient of the λ^j term of the polynomial (see (1.2)).

For $n = 15$, we calculate the exact condition numbers κ_i, their 1-sample SCE estimates, and the estimates by the MATLAB routine `condeig`, which computes the reciprocals of the cosines of the angles between the left and right eigenvectors of C. According to Figure 5.1, SCE provides favorable estimates, while `condeig` gives large estimates for nearly all eigenvalues except the first one.

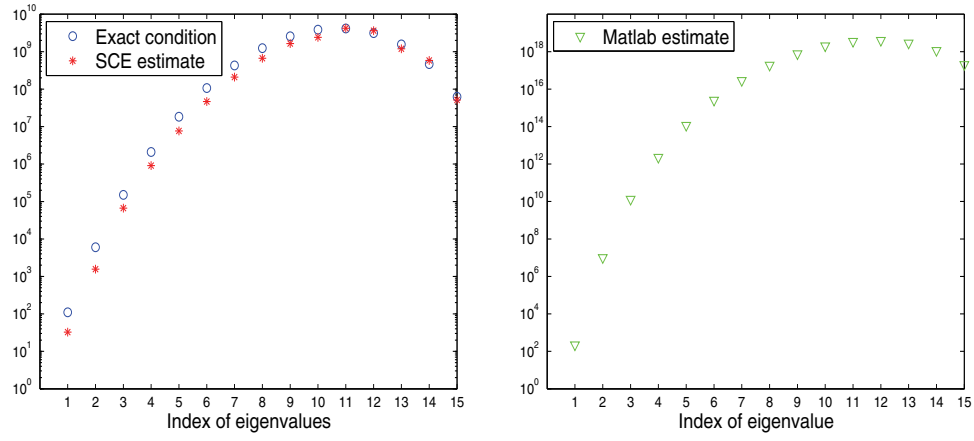

FIG. 5.1. *Condition numbers and their estimates for Example* 5.1.

Example 5.2. We show the quadratic complexity of the estimator with an example where C in (1.2) has $a_0 = 1$ and $a_i = 0,\ i = 1, \ldots, n-1$. We report only the flop counts of our preliminary MATLAB implementation of the algorithm.

This companion matrix has eigenvalues at the roots of unity. The eigenvalues are all well conditioned, with κ_i in (5.2) given by $1/n$ [15]. Our SCE estimator also reflects this fact. We run our algorithm for n ranging from 32 to 1024 and count the flops, denoted flops_n. Then we compute the flop ratios $\frac{\text{flops}_n}{\text{flops}_{n/2}}$. The numerical results

TABLE 5.1
SCE for Example 5.2 *with different* n.

n	32	64	128	256	512	1024
κ_{exact}	0.0313	0.0156	0.0078	0.0039	0.0020	0.0010
κ_{SCE}	0.0432	0.0268	0.0124	0.0083	0.0009	0.0007
$\frac{\text{flops}_n}{\text{flops}_{n/2}}$	4.9	4.4	4.2	4.1	4.0	4.0

TABLE 5.2
SCE for Example 5.4 *with multiplicity* $m = 2$.

n	32	64	128	256	512	1024
$\frac{\text{flops}_n}{\text{flops}_{n/2}}$	4.8	4.4	4.2	4.1	4.0	4.0

show that the ratios are close to 4, which is consistent with the $O(n^2)$ complexity. See Table 5.1.

Example 5.3. We consider a companion matrix C with multiple eigenvalues $\{2^{-i}, 2^{-i}\}$, $i = 1, 2, \ldots, n/2$.

For $n = 10$, SCE gives five estimates for the five eigenvalue clusters $\{2^{-i}, 2^{-i}\}$: $2.5E2$, $9.9E2$, $6.4E1$, $3.4E2$, $4.7E1$. We see that the eigenvalue clusters are still well conditioned. This somehow is consistent with the result that multiple roots of polynomials may be well conditioned if the multiplicities are preserved on a proper pejorative manifold [22], [32].

However, for large problems with multiple eigenvalues, eigensolvers such as the one in [11] give inaccurate results. Thus, it is not clear if SCE with those eigensolvers accurately reflects the condition. With multiplicity preserving eigensolvers, it is possible to further explore the potential of SCE. This remains an open problem. Therefore, in the following example, we report only the complexity results.

Example 5.4. Consider a companion matrix C whose eigenvalues are the roots of unity with different multiplicities m. (We chose this example because its nonzero entries are relatively easy to compute accurately.) Tables 5.2 shows the flop ratios $\frac{\text{flops}_n}{\text{flops}_{n/2}}$ for $m = 2$. Very similar results can be observed for m to be a fraction of n such as $\frac{n}{4}$. Thus we omit them.

6. Conclusions. We develop a condition estimation scheme for the eigenvalues of a class of matrices which are low rank perturbations to rank symmetric matrices. Rank structures of these matrices are exploited and fast structured matrix operations are presented, such as Schur decomposition, matrix equation solution, Schur form update, compact semiseparable form reconstruction, etc. These operations may be used in the condition estimation of other structured matrices and more general problems such as invariant subspace computations.

Similar techniques can also be used to estimate the condition of the eigenvectors. The information in the condition estimation for the eigenvalues can be reused. It is also possible to derive a condition estimate for the average eigenvalue of the block T_c in (2.1). In this way, we can save about 3/4 of the diagonal swapping work, on average, for all the eigenvalues. We also notice that the cost for the structured Sylvester solver can be possibly reduced further, since K in (3.4) is a low rank matrix.

ORDINAL RANKING FOR GOOGLE'S PAGERANK*

REBECCA S. WILLS† AND ILSE C. F. IPSEN‡

Abstract. We present computationally efficient criteria that can guarantee correct ordinal ranking of Google's PageRank scores when they are computed with the power method (ordinal ranking of a list consists of assigning an ordinal number to each item in the list). We discuss the tightness of the ranking criteria, and illustrate their effectiveness for top k and bucket ranking. We present a careful implementation of the power method, combined with a roundoff error analysis that is valid for matrix dimensions $n < 10^{14}$. To first order, the roundoff error depends neither on n nor on the iteration count, but only on the maximal number of inlinks and the dangling nodes. The applicability of our ranking criterion is limited by the roundoff error from a single matrix vector multiply. Numerical experiments suggest that our criteria can effectively rank the top PageRank scores. We also discuss how to implement ranking for extremely large practical problems, by curbing roundoff error, reducing the matrix dimension, and using faster converging methods.

Key words. ranking distance, power method, stochastic matrix, PageRank, Google matrix, ordinal rank, roundoff error

1. Introduction.

Google founders Larry Page and Sergey Brin developed the PageRank algorithm primarily for ranking Web pages. In addition to its continued use in many Google Web search tools [1], the PageRank algorithm reaches beyond the Web to many other applications involving directed graphs such as social networks and semantic networks [2, 9, 11, 14, 19, 30, 33, 37, 45], as well as genomics [34], and identifying sources of hospital infections [41]. In fact, Hilgers and Langville recently identified the PageRank algorithm as one of the five greatest applications of Markov Chains [44].

The Google PageRank vector π is the stationary distribution of a $n \times n$ stochastic matrix G

$$\pi^T G = \pi^T, \qquad \pi \geq 0, \qquad \|\pi\|_1 = 1. \tag{G}$$

Each component of π measures the importance of a web page [8, 36]. If $\pi_i > \pi_j$, then web page i has higher PageRank than web page j, and page i may be displayed ahead of page j among the search results.

The matrix G is a convex combination of two stochastic matrices, $G \equiv \alpha S + (1 - \alpha)\mathbf{1}v^T$. Here $0 < \alpha < 1$ is a scalar, which was originally set to .85 [8, section 2.1.1]; S is an $n \times n$ stochastic matrix; $\mathbf{1}$ is the column vector of all ones; and $v \geq 0$ is a column vector with $\|v\|_1 = 1$. Because $\alpha < 1$ and $\mathbf{1}$ is a right eigenvector of S, the eigenvalue one of G is algebraically simple [13, 20, 40], which implies that π is unique.

Row i of S contains the outgoing links from web page i to other pages, while column i contains the incoming links from other pages to page i. A web page without

any outgoing links (such as a pdf, image, or audio file) is called a *dangling node*. Zero rows corresponding to dangling nodes are replaced by a *dangling node vector* that has nonnegative elements summing to one.

In their 1998 paper [36, section 2.6] Google founders Brin and Page computed PageRank with the power method.

Power method applied to G. Let $x^{(0)} \geq 0$ with $\|x^{(0)}\|_1 = 1$. Repeat

$$[x^{(k+1)}]^T = [x^{(k)}]^T G, \qquad k \geq 0, \tag{P}$$

until some termination criterion is satisfied. Although numerous, possibly faster, methods have been proposed since 1998 [4, 31, 32], the power method retains many advantages:

1. It is simple to implement, especially in a parallel computing environment [17].
2. It requires a minimum of storage.
3. It has a robust and predictable convergence behavior that is insensitive to changes in the matrix. The convergence rate depends only on α, and is not sensitive to the underlying Web graph represented by S, the personalization vector v, the dangling node vector, or the starting vector $x^{(0)}$ [17].
4. It is numerically stable. All operations are numerically well conditioned. If $1 - \alpha$ is precomputed, then no subtractions are necessary to compute the iterates of (P). There is no danger of overflow since, in exact arithmetic, $\|x^{(k)}\|_1 = 1$.

The power method (P) as well as most iterative methods for computing PageRank compare successive iterates, based on their geometric distance or ranking distance. Once such a distance is small enough, the most recent iterate is judged to be a sufficiently good approximation to π. But the question is: Is the induced ranking of the iterate correct?

Overview. In section 2 we answer the previous question with "no." In section 3 we present the main idea of our paper, a ranking criterion for the elements of an iterate $x^{(k)}$:

If $x_i^{(k)} > x_j^{(k)} + \beta$, then $\pi_i > \pi_j$.

Here β is an upper bound for the error $\|x^{(k)} - \pi\|_1$. We show how this criterion can be used for exact, top k, and bucket ranking. In section 4 we derive several classes of computationally efficient bounds β based on geometric distances between iterates. In section 5 we present a careful implementation of the power method and derive roundoff error bounds for the iterates $x^{(k)}$. Numerical experiments in section 6 demonstrate that our criterion can identify the ranking of the top PageRank scores. We conclude with a discussion of how to solve extremely large problems in section 7.

Notation. All matrices are $n \times n$ matrices, and all vectors are $n \times 1$ column vectors. The $n \times n$ identity matrix is I, with ith column e_i. The transpose of a vector v is v^T, the elements of v are v_i, and inequalities like $v \geq 0$ and $|v| \geq 0$ are to be interpreted componentwise. The one norm $\|\cdot\|_1$ is the maximal column sum, and the infinity norm $\|\cdot\|_\infty$ the maximal row sum. In particular, if x is a column vector, then

$$\|x\|_1 = \sum_i |x_i| = \|x^T\|_\infty, \qquad \|x\|_\infty = \max_i |x_i| = \|x^T\|_1.$$

2. Existing termination criteria do not produce correct rankings. The two most frequently mentioned termination criteria for PageRank computation are based on geometric distance and ranking distance [6, section 4.2.1].

Geometric distance. The traditional convergence criterion terminates the power method once some norm of the residual is sufficiently small. Since the power method iteration (P) contains no normalization, the residual equals the difference between successive iterates, $[x^{(k)}]^T - [x^{(k)}]^T G = [x^{(k)} - x^{(k+1)}]^T$. The power method (P) is terminated once $\|x^{(k)} - x^{(k+1)}\|$ is sufficiently small in the one, two, or infinity norms. The residual norm of (P) can be interpreted as a distance between two vectors, and has thus been classified as a *geometric distance* [6, section 4.2.1], in contrast to the *ranking distance* below.

Ranking distance. We specify the position of an element in an ordered list through its *ordinal rank*, which is defined below first for a single element and then for a whole vector (the ordinal rank bears no relation to the numerical rank).

DEFINITION 2.1 (ordinal rank). *Let* $x = \begin{pmatrix} x_1 & \dots & x_n \end{pmatrix}^T$ *be a real vector, and* σ *a permutation that orders the elements of* x *in decreasing order,* $x_{\sigma(1)} \geq \dots \geq x_{\sigma(n)}$. *Then the ordinal rank of an individual element is* $\mathrm{Orank}(x_i) \equiv \sigma(i)$, $1 \leq i \leq n$, *and the ordinal rank of the whole vector is* $\mathrm{Orank}(x) \equiv \begin{pmatrix} \mathrm{Orank}(x_1) & \dots & \mathrm{Orank}(x_n) \end{pmatrix}$.

If the elements of x are distinct, and if $x_j = \max_i x_i$, then $\mathrm{Orank}(x_j) = 1$; and if $x_j = \min_i x_i$, then $\mathrm{Orank}(x_j) = n$. If x contains identical elements, then the ordinal ranking is not unique, because the permutation σ in Definition 2.1 is not unique and is not required to preserve the relative order of the elements (i.e., σ does not have to be stable in the sense of sorting). In contrast to other ranking schemes, no two items receive the same ordinal rank, even when they are equal. The concept of ordinal rank leads to the particular ranking distance below, which is known as *Kendall's* τ *distance* [6, section 4.2.2] [27, section 1.13].

DEFINITION 2.2 (ranking distance). *The ranking distance between real vectors* x *and* y, *each with distinct elements, is* $\sum_i \sum_j \delta_{xy}(i,j)$, *where*

$$\delta_{xy}(i,j) \equiv \begin{cases} 1 & \mathrm{Orank}(x_i) < \mathrm{Orank}(x_j) \text{ and } \mathrm{Orank}(y_i) > \mathrm{Orank}(y_j) \\ 0 & \text{otherwise} \end{cases}.$$

Ranking distances have been used as termination criteria in iterative methods for computing PageRank [3, 10, 25, 28, 38, 39, 46]. Because the matrix G is large, computing the ranking distance for entire vectors is too expensive. To reduce computation time, one can focus on the top k rankings [15, 25, 26]. Experiments in [26] suggest that termination based on the top k rankings tends to produce rankings that resemble those produced by a termination criterion based on the one norm of the residual.

Incorrect ranking. Simple examples, such as those described in [47, section 4.2] for the directed ring[1] graph with n vertices, illustrate that geometric and ranking distances between successive iterates of the power method (P) can fail to produce correct rankings. In addition, the examples demonstrate that (1) correct ranking can be achieved in some iteration and destroyed in the next, (2) a small residual norm does not guarantee correct ranking, (3) zero ranking distance between successive iterates does not guarantee correct ranking, and (4) successive iterates can be correctly ranked before the residual norm is small.

3. Ranking. Since geometric and ranking distances between successive iterates of the power method (P) do not ensure correct ranking, we consider instead the

[1] In a directed ring graph with n vertices, vertex i links to vertex $i+1$, $1 \leq i \leq n-1$, and vertex n links back to vertex 1.

ranking distance between an iterate $x^{(k)}$ and the desired PageRank vector π. We obtain information about the ranking distance from the geometric distance, and show how the resulting ranking criterion can be used to perform exact, top k, and bucket ranking.

We use a consequence of an inequality from [21, Corollary 2.4(a)] which relates the one norm and infinity norm of a vector whose elements sum to zero: If y is a column vector with $y^T\mathbf{1} = 0$, then

$$\|y\|_\infty \leq \|y\|_1/2. \tag{3.1}$$

The main idea of our paper is to gather information about relative ranking based on an approach by Kirkland [29, Corollaries 3.9-3.12], which we present below in a more general context.

THEOREM 3.1 (ranking criterion). *Let $x \geq 0$ with $\|x\|_1 = 1$ be an approximation to π in* (G)*, and $\beta \geq \|x - \pi\|_1$. If $x_i > x_j + \beta$, then $\pi_i > \pi_j$.*

Proof. If $x = \pi$, then $\beta = 0$ and the result holds trivially. Assuming $\beta > 0$ gives $(x_i - \pi_i) - (x_j - \pi_j) \leq |x_i - \pi_i| + |x_j - \pi_j| \leq 2\|x - \pi\|_\infty$. Since $(x - \pi)^T\mathbf{1} = 0$, (3.1) implies $\|x - \pi\|_\infty \leq \|x - \pi\|_1/2$. Hence $(x_i - \pi_i) - (x_j - \pi_j) \leq \|x - \pi\|_1 \leq \beta$, and $x_i - (x_j + \beta) \leq \pi_i - \pi_j$. Therefore, $0 < x_i - (x_j + \beta)$ implies $0 < \pi_i - \pi_j$. ∎

Consequently, if two elements of $x^{(k)}$ are well-separated (compared to the geometric distance between $x^{(k)}$ and π), then we can say something about the relative rankings of the corresponding PageRank scores. Because the ranking criterion in Theorem 3.1 applies only to well-separated elements, it can, in general, determine only a partial ranking of the PageRank scores.

Kirkland [29, section 3] expresses the quantity β in Theorem 3.1 as a function of the lengths of shortest cycles on which vertices i and j are situated in the graph of S. However, it is not clear how to efficiently compute shortest cycle lengths for all vertices.

Exact, top k, and bucket ranking. The bucket ranking criteria below are motivated by Google's Toolbar PageRank scores, which are integers from 0 (low) to 10 (high). Our ranking criteria determine a topological (or partial) order for the PageRank scores.

Let $x \geq 0$ with $\|x\|_1 = 1$ be an approximation to π in (G) and $\beta \geq \|x - \pi\|_1$. Let Q be a permutation that orders the elements of x in decreasing magnitude, i.e.,

$$\tilde{x} \equiv Qx = \begin{pmatrix} \tilde{x}_1 & \dots & \tilde{x}_n \end{pmatrix}^T, \qquad \tilde{x}_1 \geq \dots \geq \tilde{x}_n, \qquad \tilde{\pi} \equiv Q\pi = \begin{pmatrix} \tilde{\pi}_1 & \dots & \tilde{\pi}_n \end{pmatrix}^T.$$

In contrast to the elements of $\tilde{x}$, those of $\tilde{\pi}$ are, in general, not ordered in decreasing magnitude.

First we show that if element k of $\tilde{x}$ is well separated from element $k + 1$, then elements $1, \dots, k$ approximate the top k PageRank scores.

LEMMA 3.2 (top k). *If $\tilde{x}_k > \tilde{x}_{k+1} + \beta$, then* $\text{Orank}(\tilde{\pi}_i) \leq k$ *for $1 \leq i \leq k$, and* $\text{Orank}(\tilde{\pi}_j) \geq k + 1$ *for $k + 1 \leq j \leq n$.*

Proof. From $\tilde{x}_k > \tilde{x}_{k+1} + \beta$ follows $\tilde{\pi}_k > \tilde{\pi}_{k+1}$, according to Theorem 3.1. The descending ordering implies $\tilde{x}_k > \tilde{x}_{k+1} + \beta \geq \dots \geq \tilde{x}_n + \beta$, so that $\tilde{\pi}_k > \tilde{\pi}_{k+1}, \dots, \tilde{\pi}_n$. The descending ordering also implies $\tilde{x}_1 \geq \dots \geq \tilde{x}_k > \tilde{x}_{k+1} + \beta$, so that $\tilde{\pi}_1, \dots, \tilde{\pi}_k > \tilde{\pi}_{k+1}$. Combining the two sets of inequalities yields $\tilde{\pi}_1, \dots, \tilde{\pi}_k > \tilde{\pi}_{k+1}, \dots, \tilde{\pi}_n$. Therefore $\text{Orank}(\tilde{\pi}_i) \leq k$ for $1 \leq i \leq k$, and $\text{Orank}(\tilde{\pi}_j) \geq k + 1$ for $k + 1 \leq j \leq n$. ∎

Now we present a criterion for finding the "exact" rank (here "exact" does not refer to finite precision accuracy but to the fact that we can assign a number, rather

than an interval, to the rank). If element $k+1$ of $\tilde{x}$ is well separated from elements k and $k+2$, then element $k+1$ of $\tilde{x}$ approximates the $(k+1)$st PageRank score.

LEMMA 3.3 (exact rank). *If* $\tilde{x}_k > \tilde{x}_{k+1} + \beta$ *and* $\tilde{x}_{k+1} > \tilde{x}_{k+2} + \beta$, *then* $\mathrm{Orank}(\tilde{\pi}_{k+1}) = k+1$.

Proof. This follows from Lemma 3.2. Condition $\tilde{x}_k > \tilde{x}_{k+1}+\beta$ implies $\tilde{\pi}_1, \ldots, \tilde{\pi}_k > \tilde{\pi}_{k+1}$; hence $\mathrm{Orank}(\tilde{\pi}_{k+1}) \geq k+1$. Condition $\tilde{x}_{k+1} > \tilde{x}_{k+2} + \beta$ implies $\tilde{\pi}_{k+1} > \tilde{\pi}_{k+2}, \ldots, \tilde{\pi}_n$; hence $\mathrm{Orank}(\tilde{\pi}_{k+1}) \leq k+1$. ∎

Often it is not possible to determine the exact PageRank, but we can still try to assign PageRank scores to a "bucket". This is done in the next lemma, which represents an extension of Lemma 3.3 to intervals.

LEMMA 3.4 (bucket). *If* $\tilde{x}_k > \tilde{x}_{k+i} + \beta$ *and* $\tilde{x}_{k+i} > \tilde{x}_{k+i+j} + \beta$ *for* $i, j \geq 1$ *then* $k+1 \leq \mathrm{Orank}(\tilde{\pi}_{k+i}) \leq k+i+j-1$.

Proof. This follows from Lemma 3.2. The condition $\tilde{x}_k > \tilde{x}_{k+i} + \beta$ implies $\tilde{\pi}_1, \ldots, \tilde{\pi}_k > \tilde{\pi}_{k+i}$, so that $\mathrm{Orank}(\tilde{\pi}_{k+i}) \geq k+1$. The condition $\tilde{x}_{k+i} > \tilde{x}_{k+i+j} + \beta$ implies $\tilde{\pi}_{k+i} > \tilde{\pi}_{k+i+j}, \ldots, \tilde{\pi}_n$ so that $\mathrm{Orank}(\tilde{\pi}_{k+i}) \leq k+i+j-1$. ∎

Lemma 3.4 assigns PageRank score $\tilde{x}_{k+i}$ to a bucket that represents ranks $k+1, \ldots, k+i+j-1$. If $i = j = 1$ then the bucket consists of a single number and Lemma 3.4 reduces to Lemma 3.3. The top k ranking in Lemma 3.2 is a special case of bucket ranking with two buckets: One for ranks $1, \ldots, k$ and another one for ranks $k+1, \ldots, n$. In contrast to bucket sorting the buckets are not specified beforehand; they emerge during the execution of the power method (P).

4. Error bounds for the power method. We present four classes of computable bounds for the error $\|x^{(k)} - \pi\|_1$ and for the quantity β used in the ranking criteria in section 3. The four classes consist of the following types of bounds: simple (section 4.1), backward looking (section 4.2), forward looking (section 4.3), and two-level forward looking (section 4.4). We use the following facts for stochastic matrices S: $\|S^i\|_\infty = 1$, $i \geq 0$, and

$$\|S^i(I - \alpha^j S^j)^{-1}\|_\infty = \frac{1}{1-\alpha^j}, \qquad i \geq 0, \quad j \geq 1. \tag{4.1}$$

The last expression follows from the fact that $(I - \alpha^j S^j)^{-1}$ is nonnegative, and $\|(I - \alpha^j S^j)^{-1}\|_\infty = (1-\alpha^j)^{-1}$ [32, section 7.1].

First we justify why the ranking of the iterates in (P) can converge under a criterion like the one in Theorem 3.1. The inequalities below relate two corresponding components of two different iterates and show that the distance between the components changes less and less as the iterations progress.

THEOREM 4.1 (component distances stabilize).

$$|x_i^{(k-1)} - x_j^{(k-1)}| - \alpha^{k-1}\gamma \leq |x_i^{(k)} - x_j^{(k)}| \leq |x_i^{(k-1)} - x_j^{(k-1)}| + \alpha^{k-1}\gamma, \qquad k \geq 1,$$

where $\gamma \equiv 2\|x^{(1)} - x^{(0)}\|_1$.

Proof. As in [7, Property 7] one shows $[x^{(k)}]^T = \alpha^k [x^{(0)}]^T S^k + (1-\alpha)\sum_{l=0}^{k-1} \alpha^l v^T S^l$. Hence the difference between two components equals

$$\begin{aligned} x_i^{(k)} - x_j^{(k)} &= \alpha^k \left[x^{(0)}\right]^T S^k (e_i - e_j) + (1-\alpha)\sum_{l=0}^{k-1} \alpha^l v^T S^l (e_i - e_j) \\ &= \left(x_i^{(k-1)} - x_j^{(k-1)}\right) + \alpha^{k-1}\left[x^{(1)} - x^{(0)}\right]^T S^{k-1}(e_i - e_j). \end{aligned}$$

The Hölder inequality and (4.1) imply

$$\left|[x^{(1)} - x^{(0)}]^T S^{k-1}(e_i - e_j)\right| \leq \|x^{(1)} - x^{(0)}\|_1 \|S^{k-1}(e_i - e_j)\|_\infty \leq 2\|x^{(1)} - x^{(0)}\|_1. \quad \square$$

The idea behind the bounds for $\|x^{(k)} - \pi\|_1$ is to extend the residual, which is a difference of successive iterates $[x^{(k)}]^T - [x^{(k)}]^T G = [x^{(k)} - x^{(k+1)}]^T$, to differences between nonsuccessive iterates $[x^{(k-j)} - x^{(k)}]^T$. The derivations in subsequent sections are based on the following recursions.

LEMMA 4.2 (recursions).

$$\begin{aligned} \text{Error :} \quad & [x^{(k+1)} - \pi]^T = \alpha[x^{(k)} - \pi]^T S, \qquad k \geq 0 \\ \text{Iterate difference :} \quad & [x^{(k-j+1)} - x^{(k+1)}]^T = \alpha[x^{(k-j)} - x^{(k)}]^T S, \qquad 1 \leq j \leq k. \end{aligned}$$

Proof. The recursions follow from $[x^{(k+1)}]^T = [x^{(k)}]^T G$, $G = \alpha S + (1-\alpha)\mathbf{1}v^T$, and $[x^{(k)} - \pi]^T \mathbf{1} = 0$.

Note that the statements also follow from the properties of splitting methods [43, section 3.6]. This is because π is the solution of the linear system $\pi^T(I - \alpha S) = (1-\alpha)v^T$, and the power method $[x^{(k+1)}]^T = [x^{(k)}]^T G$ is mathematically equivalent to a splitting method $[x^{(k+1)}]^T M = [x^{(k)}]^T N + (1-\alpha)v^T$, where $M = I$ and $N = \alpha S$. $\square$

The second recursion in Lemma 4.2 is an extension of the one derived for $j = 1$ in [29, Proof of Corollary 3.11].

4.1. Simple bound. The recursions in Lemma 4.2 lead immediately to a simple normwise error bound that depends only on α and k.

THEOREM 4.3 (simple bound). $\|x^{(k)} - \pi\|_1 \leq \alpha^k \|x^{(0)} - \pi\|_1 \leq 2\alpha^k$, $k \geq 0$.

Proof. Lemma 4.2 implies $[x^{(k)} - \pi]^T = \alpha^k [x^{(0)} - \pi]^T S^k$, and (4.1) implies

$$\|x^{(k)} - \pi\|_1 = \|[x^{(k)} - \pi]^T\|_\infty \leq \alpha^k \|[x^{(0)} - \pi]^T\|_\infty \|S^k\|_\infty = \alpha^k \|x^{(0)} - \pi\|_1.$$

The second upper bound follows from the triangle inequality and $\|x^{(0)}\|_\infty = \|\pi\|_\infty = 1$. $\square$

The bounds in Theorem 4.3 first appeared in [5, Theorem 5.1] and [24, section 4]. In the special case $x^{(0)} = v$, when the starting vector equals the personalization vector, the power of α can be increased by one, $\|x^{(k)} - \pi\|_1 \leq \alpha^{k+1}\|v - S^T\pi\|_1 \leq 2\alpha^{k+1}$; see also [7, Property 9]. The simple bound in Theorem 4.3 can be used as a ranking criterion in the power method (P) as follows.

COROLLARY 4.4 (ranking with the simple bound). *If* $x_i^{(k)} > x_j^{(k)} + 2\alpha^k$, $k \geq 1$, *then* $\pi_i > \pi_j$.

Proof. Follows from Theorem 4.3 and setting $\beta = 2\alpha^k$ in Theorem 3.1. $\square$

4.2. Backward-looking bounds. Backward-looking bounds are constructed from previous iterates.

THEOREM 4.5 (backward-looking bounds). $\|x^{(k)} - \pi\|_1 \leq \frac{\alpha^j}{1-\alpha^j}\|x^{(k-j)} - x^{(k)}\|_1$, $1 \leq j \leq k$.

Proof. Lemma 4.2 implies

$$\begin{aligned} \alpha^j [x^{(k-j)} - x^{(k)}]^T S^j &= [x^{(k)} - x^{(k+j)}]^T = [x^{(k)} - \pi]^T - [x^{(k+j)} - \pi]^T \\ &= [x^{(k)} - \pi]^T - \alpha^j [x^{(k)} - \pi]^T S^j = [x^{(k)} - \pi]^T (I - \alpha^j S^j). \end{aligned}$$

Hence $\left[x^{(k)} - \pi\right]^T = \alpha^j \left[x^{(k-j)} - x^{(k)}\right]^T S^j (I - \alpha^j S^j)^{-1}$. Take norms

$$\|x^{(k)} - \pi\|_1 = \|[x^{(k)} - \pi]^T\|_\infty \leq \alpha^j \|[x^{(k-j)} - x^{(k)}]^T\|_\infty \|S^j (I - \alpha^j S^j)^{-1}\|_\infty$$

and use (4.1). $\square$

The bound for $j = 1$ in Theorem 4.5 was already derived in [29, (3.1)] for general approximations, not limited to just power method iterates. Note that for a fixed step length j, a full backward look is not possible in early iterations as long as $k < j$. Experiments indicate that no bound is always the tightest. We can distinguish two types of backward-looking bounds: Those where j is fixed and those where j is a function of k. Among the fixed step bounds, the $j = 1$ bound is preferable for several reasons: It tends to be competitive in the long-term since $\|x^{(k)} - \pi\|_1 \leq \alpha\|x^{(k-1)} - \pi\|_1 \leq \alpha^2\|x^{(k-2)} - \pi\|_1 \leq \ldots$. It takes effect immediately starting with iteration 1 – in contrast to other bounds which require a startup of j iterations before the full backward look is possible. It performs well in our experiments in later iterations. At last, it keeps storage requirements low, because bounds with fixed j need to store j or more vectors. Among the bounds where j is a function of k, the simplest one is $j = k$,

$$\|x^{(k)} - \pi\|_1 \leq \frac{\alpha^k}{1-\alpha^k}\|x^{(0)} - x^{(k)}\|_1.$$

This bound has low storage requirements as well, it is effective immediately, starting with iteration 1, and in our experiments it tends to do well in early iterations. However, the $j = k$ bound does not do as well in later iterations. This is because it depends on the initial error $\|x^{(0)} - \pi\|_1$ which remains constant throughout the iterations, while for bounds with a fixed step length j, the error $\|x^{(k-j)} - \pi\|_1$ approaches zero as k increases. Applied to the power method (P), the backward-looking bounds in Theorem 4.5 can be used for ranking as follows.

COROLLARY 4.6 (ranking with backward-looking bounds). *If* $x_i^{(k)} > x_j^{(k)} + \frac{\alpha^l}{1-\alpha^l}\|x^{(k-l)} - x^{(k)}\|_1$, $1 \leq l \leq k$, *then* $\pi_i > \pi_j$.

4.3. Forward-looking bounds. Forward-looking bounds are constructed from future iterates. The derivation is similar to the one in Theorem 4.5.

THEOREM 4.7 (forward-looking bounds). $\|x^{(k)} - \pi\|_1 \leq \frac{\|x^{(k+j)} - x^{(k)}\|_1}{1-\alpha^j}$, $k \geq 0$, $j \geq 1$.

The forward-looking bound for $j = 1$ was derived in [7, Property 12]. Looking farther ahead can lead to better estimates for the error at the current iteration k. This is to be expected because future iterates can be more accurate. Comparing the bounds in Theorem 4.7 for $j = 1$ and $j > 1$ shows that looking several steps ahead can result in tighter bounds than just looking a single step ahead,

$$\frac{\|x^{(k+j)} - x^{(k)}\|_1}{1-\alpha^j} \leq \frac{\|x^{(k+1)} - x^{(k)}\|_1}{1-\alpha}, \qquad k \geq 0, \quad j \geq 1.$$

Applied to the power method (P), the forward-looking bounds in Theorem 4.7 can be used for ranking as follows.

COROLLARY 4.8 (ranking with forward-looking bounds). *If* $x_i^{(k)} > x_j^{(k)} + \frac{\|x^{(k+l)} - x^{(k)}\|_1}{1-\alpha^l}$, $k \geq 0$, $l \geq 1$, *then* $\pi_i > \pi_j$.

4.4. Two-level, forward-looking bounds. Another type of forward bound looks forward in two stages.

THEOREM 4.9 (two-level, forward-looking bounds).

$$\|x^{(k)} - \pi\|_1 \leq \|x^{(k+j)} - x^{(k)}\|_1 + \frac{\|x^{(k+j+i)} - x^{(k+j)}\|_1}{1-\alpha^i}, \qquad k \geq 0, \quad j, i \geq 1.$$

COROLLARY 4.10 (ranking with two-level, forward-looking bounds). *If*

$$x_i^{(k)} > x_j^{(k)} + \|x^{(k+l)} - x^{(k)}\|_1 + \frac{\|x^{(k+l+h)} - x^{(k+l)}\|_1}{1-\alpha^h}, \qquad k \geq 0, \quad l,h \geq 1,$$

then $\pi_i > \pi_j$.

5. Finite precision computation. We present error bounds for perturbed power method iterates in section 5.1, a floating point implementation of the power method in section 5.2, and bounds for ranking in floating point arithmetic in section 5.3.

5.1. Perturbation bounds. In a finite precision context, the ranking criterion in Theorem 3.1 must be applied to perturbed power method iterates $\hat{x}^{(k)}$. That is, if $\hat{x}_i^{(k)} > \hat{x}_j^{(k)} + \|\hat{x}^{(k)} - \pi\|_1$, then $\pi_i > \pi_j$. We assume that the perturbed iterates are nonnegative, have unit norm, and incur an error during each iteration. The error bounds for $\|\hat{x}^{(k)} - \pi\|_1$ below are simple and easy to compute.

THEOREM 5.1 (finite precision error bounds). *Let* $\hat{x}^{(0)} = x^{(0)}$, *and* $[\hat{x}^{(k+1)}]^T = [\hat{x}^{(k)}]^T G + g_k^T$, $k \geq 0$, *be such that* $\hat{x}^{(k)} \geq 0$ *and* $\|\hat{x}^{(k)}\|_1 = 1$, $k \geq 0$.

1. *Simple bound:*

$$\|\hat{x}^{(k)} - \pi\|_1 \leq 2\alpha^k + \frac{1-\alpha^k}{1-\alpha} \max_{0\leq i\leq k-1} \|g_{k-i}\|_1, \qquad k \geq 1.$$

2. *Backward-looking bounds:*

$$\|\hat{x}^{(k)} - \pi\|_1 \leq \frac{\alpha^j}{1-\alpha^j}\|\hat{x}^{(k-j)} - \hat{x}^{(k)}\|_1 + \frac{1-\alpha^j}{1-\alpha} \max_{0\leq i\leq j-1} \|g_{k-i}\|_1, \qquad 0 \leq j < k.$$

3. *Forward-looking bounds:*

$$\|\hat{x}^{(k)} - \pi\|_1 \leq \frac{\|\hat{x}^{(k+j)} - \hat{x}^{(k)}\|_1}{1-\alpha^j} + \frac{1-\alpha^j}{1-\alpha} \max_{1\leq i\leq j} \|g_{k+i}\|_1, \qquad k \geq 0, \quad j \geq 1.$$

4. *Two-level, forward-looking bounds:*

$$\|\hat{x}^{(k)} - \pi\|_1 \leq \|\hat{x}^{(k+j)} - \hat{x}^{(k)}\|_1 + \frac{\|\hat{x}^{(k+j+i)} - \hat{x}^{(k+j)}\|_1}{1-\alpha^i} + \frac{1-\alpha^i}{1-\alpha} \max_{1\leq l\leq i} \|g_{k+j+l}\|_1,$$

where $k \geq 0$, $j,i \geq 1$.

Proof. First we derive an expression for the absolute error in the perturbed iterates. From $\hat{x}^{(k)} \geq 0$, $x^{(k)} \geq 0$, $\|\hat{x}^{(k)}\|_1 = \|x^{(k)}\|_1 = 1$ follows $g_k^T\mathbf{1} = f_k^T\mathbf{1} = 0$. With $f_0 \equiv 0$ this implies

$$\hat{x}^{(k)} = x^{(k)} + f_k, \qquad f_k^T \equiv \alpha^j f_{k-j}^T S^j + \sum_{i=0}^{j-1} \alpha^i g_{k-i}^T S^i, \qquad 1 \leq j \leq k. \tag{5.1}$$

We use (5.1) to derive each of the four finite precision bounds.

1. Simple bound: This follows from $[\hat{x}^{(k)} - \pi]^T = [x^{(k)} - \pi]^T + f_k^T$ and (5.1).
2. Backward-looking bounds: As in the proof of Theorem 4.5 one shows

$$[\hat{x}^{(k)} - \pi]^T(I - \alpha^j S^j) = \alpha^j[\hat{x}^{(k-j)} - \hat{x}^{(k)}]^T S^j + f_k^T - \alpha^j f_{k-j}^T S^j.$$

Then (5.1) implies $f_k^T - \alpha^j f_{k-j}^T S^j = \sum_{i=0}^{j-1} \alpha^i g_{k-i}^T S^i$.

3. Forward-looking bounds: As in the proof of Theorem 4.7 one shows

$$[\hat{x}^{(k)} - \pi]^T (I - \alpha^j S^j) = [\hat{x}^{(k)} - \hat{x}^{(k+j)}]^T + f_{k+j}^T - \alpha^j f_k^T S^j.$$

From (5.1) follows $f_{k+j}^T - \alpha^j f_k^T S^j = \sum_{i=0}^{j-1} \alpha^i g_{k+j-i}^T S^i$.

4. Two-level, forward-looking bounds: As in the proof of Theorem 4.9, one shows that $[\pi - \hat{x}^{(k)}]^T$ is equal to

$$[\hat{x}^{(k+j)} - \hat{x}^{(k)}]^T - [\hat{x}^{(k+j)} - \hat{x}^{(k+j+i)}]^T (I - \alpha^i S^i)^{-1} - f_{k+j}^T - [f_{k+j+i} - f_{k+j}]^T (I - \alpha^i S^i)^{-1}.$$

Hence (5.1) implies for the error term

$$-f_{k+j}^T - [f_{k+j+i} - f_{k+j}]^T (I - \alpha^i S^i)^{-1} = -\sum_{l=0}^{i-1} \alpha^l g_{k+j+i-l}^T S^l (I - \alpha^i S^i)^{-1}. \qquad \square$$

The term g_k takes care of finite precision errors incurred in iteration k, including those from matrix vector multiplication, as well as explicit normalization of the iterates if necessary. Theorem 5.1 shows that the bounds are affected only by the error in a single iteration, and do not suffer from accumulation of errors.

5.2. Power method implementation. We discuss the implementation of the power method in floating point arithmetic.

As already mentioned in section 1, the matrix S is derived from the webgraph and zero rows corresponding to dangling nodes (i.e., web pages without outlinks) are modified to ensure that S is stochastic. Computationally, though, it is more efficient to keep the webgraph part separated from the dangling node fix so that one can take advantage of the latter's low rank [32, section 8.1]. It turns out that this separation also limits accumulation of roundoff error in a matrix vector multiplication with S. Therefore it is necessary to discuss the construction of S in more detail.

The web graph is represented by a $n \times n$ *substochastic* matrix H. That is, the elements of H are nonnegative, and each row is either zero, or else its elements sum to one. The zero rows correspond to dangling nodes, which are web pages without outlinks. To obtain the stochastic matrix S, one can replace each zero row by the same dangling node vector w^T, where w is a column vector with $w \geq 0$ and $\|w\|_1 = 1$. The resulting Google matrix is $G = \alpha S + (1 - \alpha)\mathbf{1}v^T$, where $S = H + dw^T$ and d is a column vector of zeros and ones. An element of d is equal to 1 if the corresponding row in H is zero; otherwise this element of d is equal to zero. The following floating point implementation of the power method (P) exploits the fact that dw^T and $\mathbf{1}v^T$ have rank one.

Floating point implementation of (P). Let $\hat{x}^{(0)} \geq 0$ with $\|\hat{x}^{(0)}\|_1 = 1$, and $\alpha_1 \equiv 1 - \alpha$. Repeat

$$\text{(FP)} \qquad [y^{(k+1)}]^T := \text{fl}\left(\alpha([\hat{x}^{(k)}]^T H + ([\hat{x}^{(k)}]^T d)w^T) + \alpha_1 v^T\right)$$
$$\hat{x}^{(k+1)} := \text{fl}\left(y^{(k+1)}/\|y^{(k+1)}\|_1\right)$$

until some termination criterion is satisfied.

The explicit normalization of the iterates in (FP) is necessary to ensure that iterate norms remain close to unity in a finite precision environment. Figure 5.1 illustrates why this is necessary. The norms of the unnormalized iterates $y^{(k)}$ deviate much further from 1 than the norms of the normalized iterates $\hat{x}^{(k)}$. The ratios

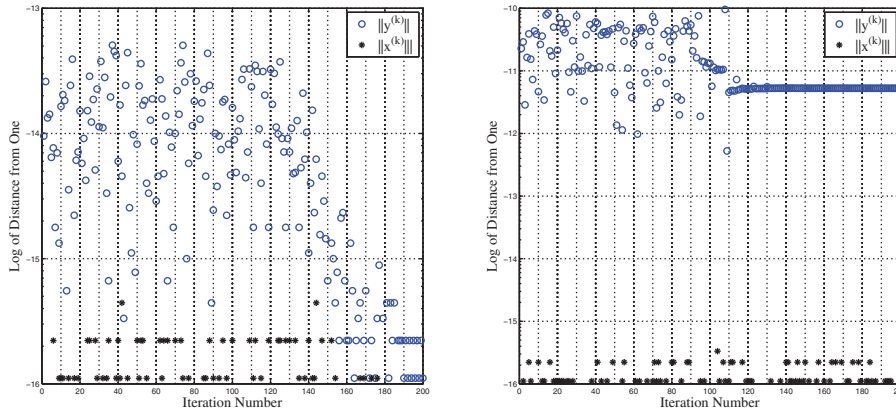

FIG. 5.1. $|1 - \|\hat{x}^{(k)}\|_1|$ *and* $|1 - \|y^{(k)}\|_1|$ *for iterates of the Power Method* (FP) *applied to the matrices* G_S *(left) and* G_L *(right) in section* 6.

$|1 - \|y^{(k)}\|_1|$ can approach 10^{-13} for the small matrix G_S and hover around 10^{-11} for the larger matrix G_L. The analysis in the proof of Theorem 5.2 explains this: In IEEE double precision the unit roundoff is $\epsilon \approx 10^{-16}$, so that the error in the matrix vector multiplication $[\hat{x}^{(k)}]^T G_L$ is about $m\epsilon \approx 4 \cdot 10^{-11}$, where $m = 168,685$ is the maximal number of nonzero elements in any column of H_L. For the smaller matrix G_S, the computation of $x^T d$ dominates, leading to an error of $\|d\|_1 \epsilon \approx 7 \cdot 10^{-12}$, since d has 2,861 elements equal to one. In contrast, the norms of the normalized iterates are almost perfect. In all iterations k the deviation $|\|\hat{x}^{(k)}\|_1 - 1|$ is either ϵ, $\epsilon/2$, or 0. Note that Figure 5.1 shows merely the effect of a single missing normalization; the accumulated damage from failing to normalize over many iterations is much worse.

5.3. Floating point bounds. We bound the roundoff error g_k incurred in iteration k of the power method (FP). Existing roundoff error bounds for the power method and stationary iterative methods [22, sections 17, 18], [42] do not seem to be applicable here, because they require knowledge of the condition number of a diagonalizing transformation, or assume that the spectral radius of the iteration matrix is strictly less than one.

We assume the standard model for the elementary floating point arithmetic operations with unit roundoff ϵ [22, section 2.2]. If a and b are floating point numbers, then

$$\mathrm{fl}(a \text{ op } b) = (a \text{ op } b)(1 + \delta), \qquad |\delta| \leq \epsilon, \quad \text{op} = +, -, *, /.$$

We exploit the fact that the iterations in (FP) execute no subtractions, and that all operations are well conditioned. The norms are computed by *compensated summation* [22, section 4.3], [35] so that the dominant part of the roundoff error $\|g_k\|_1$ does not depend on the matrix dimension n, but only on the sparsity of the matrix. The analysis below holds for matrices of order $n < 10^{14}$, in IEEE double precision with unit roundoff $\epsilon \equiv 10^{-16}$.

THEOREM 5.2 (floating point bounds). *Assume that* $n\epsilon < .01$, *and*

1. *The scalars* α *and* $\alpha_1 \equiv 1 - \alpha$, *and the elements of* H, v, w, *and* $\hat{x}^{(0)} = x^{(0)}$ *are floating point numbers.*
2. *The iterates* $\hat{x}^{(k)}$ *are computed according to* (FP).
3. *The norms* $\|y^{(k+1)}\|_1$ *in* (FP) *are computed by compensated summation.*

4. *H has at most m nonzeros per column, and $\|d\|_1$ zero rows.*
Then

$$\|g_{k+1}\|_1 \le \frac{2\epsilon(3.03 + c\alpha M)}{1 - \epsilon(3.03 + c\alpha M)} + \mathcal{O}(n\epsilon^2), \qquad k \ge 0$$

where $M \equiv \max\{m, \|d\|_1 + 1\}$, and $c \equiv 1.01(1 + 3.03\epsilon)$.

Proof. Abbreviate $x \equiv \hat{x}^{(k)}$, $y \equiv y^{(k+1)}$, and $\delta \equiv \|d\|_1 + 1$.

1. Since H has at most m nonzero elements per column, the elements of S and x are nonnegative, and $m\epsilon \le .01$ we obtain with [22, (3.2) and Lemma 3.4] $\mathrm{fl}(x^T H) = x^T H + h_1^T$, where $|h_1^T| \le 1.01 m\epsilon\,(x^T H)$.

2. Similarly, since α and the elements of d and x are nonnegative, we obtain for the second summand in $\alpha x^T S$, $\mathrm{fl}(\alpha x^T d) = \alpha x^T d + h_2$, where $|h_2| \le 1.01\delta\epsilon\,(\alpha x^T d)$.

3. For the computation of $y^T = \mathrm{fl}(x^T G)$ abbreviate $z^T \equiv \alpha\,\mathrm{fl}(x^T H) + \mathrm{fl}(\alpha x^T d) w^T + \alpha_1 v^T$ so that $y^T = \mathrm{fl}(z^T) = z^T + h_3^T$, where $|h_3^T| \le 3.03\epsilon\, z^T$. From $z^T = x^T G + \alpha h_1^T + h_2 w^T$ follows

$$\begin{aligned} |h_3^T| &\le 3.03\epsilon\, \left(x^T G + 1.01 m\epsilon\,(x^T H) + 1.01\delta\epsilon\,(\alpha x^T d w^T)\right) \\ &\le 3.03\epsilon\, \left(x^T G + 1.01 M\epsilon\,(\alpha x^T S)\right). \end{aligned}$$

In order to express y^T in terms of $x^T G$, write $y^T = z^T + h_3^T = x^T G + \alpha h_1^T + h_2 w^T + h_3^T$. Then $y^T = x^T G + h_4^T$, where $h_4^T \equiv \alpha h_1^T + h_2 w^T + h_3^T$. Hence

$$\begin{aligned} |h_4^T| &\le 1.01 m\epsilon\,(\alpha x^T H) + 1.01\delta\epsilon\,(\alpha x^T d w^T) + 3.03\epsilon\, \left(x^T G + 1.01 M\epsilon\,(\alpha x^T S)\right) \\ &\le 1.01 M\epsilon\,(\alpha x^T S) + 3.03\epsilon\, \left(x^T G + 1.01 M\epsilon\,(\alpha x^T S)\right) \\ &\le \epsilon\left(3.03\, x^T G + 1.01 M(1 + 3.03\epsilon)\,(\alpha x^T S)\right). \end{aligned}$$

4. Now comes the computation of $\|y\|_1$. Since $n\epsilon < .01$, and the additions in $\|y\|_1$ involve only nonnegative numbers, a compensated summation gives [22, (4.8)] $\eta \equiv \mathrm{fl}(\|y\|_1) = \|y\|_1(1 + h_5)$, where $|h_5| \le 2\epsilon + \mathcal{O}(n\epsilon^2)$. It is more convenient to write instead $\eta = \|y\|_1/(1 + h_6)$, where $|h_6| \le 2\epsilon + \mathcal{O}(n\epsilon^2)$.

5. A final division completes the normalization,

$$\hat{x}^{(k+1)} = \mathrm{fl}\left(\frac{y}{\eta}\right) = \frac{y^T}{\eta} + h_7^T, \qquad \text{where} \quad |h_7^T| \le \epsilon\,\frac{y^T}{\eta}.$$

To express $\hat{x}^{(k+1)}$ in terms of $x^T G$ write

$$\hat{x}^{(k+1)} = \frac{y^T}{\|y\|_1} + \frac{y^T}{\|y\|_1} h_6 + h_7^T = \frac{x^T G + h_4}{\|y\|_1} + \frac{y^T}{\|y\|_1} h_6 + h_7^T = x^T G + g_{k+1}^T,$$

where

$$g_{k+1}^T = \frac{(1 - \|y\|_1) x^T G + h_4^T}{\|y\|_1} + \frac{y^T}{\|y\|_1} h_6 + h_7^T.$$

Apply $\|y\|_1 \ge 1 - \|h_4\|_1$ twice to get

$$\|g_{k+1}\|_1 \le \frac{2\|h_4\|_1}{1 - \|h_4\|_1} + |h_6| + \|h_7\|_1.$$

From $\|h_7\|_1 \le \epsilon(1 + |h_6|)$ and $|h_6| \le 2\epsilon + \mathcal{O}(n\epsilon^2)$ follows

$$\|g_{k+1}\|_1 \le \frac{2\|h_4\|_1}{1 - \|h_4\|_1} + 3\epsilon + \mathcal{O}(n\epsilon^2).$$

At last use $\|h_4\|_1 \le \epsilon(3.03 + c\alpha M)$. ∎

TABLE 5.1
Range of parameter values for experiments in section 6.

Unit roundoff	$\epsilon \approx 10^{-16}$
Damping factor	$\alpha = .85$
Dimension of H, S, G	$n \leq 4 \cdot 10^6$
Max # nonzeros in columns of H	$m \leq 2 \cdot 10^5$
Max # iterations	$k \leq 200$

Theorem 5.2 implies that the roundoff error in an iteration of the power method (FP) is bounded approximately by

$$\|g_k\|_1 \lessapprox \frac{2\alpha M\epsilon}{1-\alpha M\epsilon} \leq 4\alpha M\epsilon \qquad \text{if} \quad \alpha M\epsilon \leq 1/2.$$

Because we assume use of compensated summation, the roundoff error $\|g_k\|_1$ does not depend, to first order, on the matrix dimension n. It also does not depend on the iteration count k. The roundoff error is more or less constant, and the same for all iterations. It represents the error caused by a single matrix vector multiply, and is determined, for the most part, by the maximal number of nonzeros m in any column of H (i.e., the maximal number of inlinks into any web page) and the number of dangling nodes $\|d\|_1$, whichever is larger. The discussion relating to Figure 5.1 in section 5.2 indicates that the bounds in Theorem 5.2 are realistic, and not too pessimistic.

The only error we did not capture effectively in Theorem 5.2 consists of the higher order effects $\mathcal{O}(n\epsilon^2)$ in the compensated summation. Higher order effects can be completely avoided with *doubly compensated summation* [22, Algorithm 4.3] for applications of PageRank for matrices with dimensions not exceeding $n \leq 2^{13} = 8192$.

COROLLARY 5.3 (floating point version of error bounds). *With the assumptions in Theorem* 5.2*, the bounds in Theorem* 5.1 *hold with*

$$\|g_k\|_1 \leq \frac{2\epsilon(3.03 + c\alpha M)}{1-\epsilon(3.03+c\alpha M)} + \mathcal{O}(n\epsilon^2), \qquad k \geq 1,$$

where $M \equiv \max\{m, \|d\|_1 + 1\}$ *and* $c \equiv 1.01(1 + 3.03\epsilon)$.

Corollary 5.3 implies that the floating point error in the bounds is independent of the iteration count. The error is caused essentially by the matrix vector multiply and can be assumed to be constant. Moreover, the contribution of the floating point error to the different types of bounds is essentially the same, so that all bounds incur more or less the same floating point error.

We examine the ramifications of the above analysis when the power method (FP) is applied to the data matrices in section 6, whose parameter ranges are listed in Table 5.1. The simple bound in Theorem 4.3 and the roundoff error bound in Theorem 5.2 amount to $2\alpha^k \geq 10^{-14}$ and $\|g_k\|_1 \leq 4 \cdot 10^{-11}$. The roundoff error dominates the ranking bounds in later iterations, so that the bounds remain essentially constant from then on. Since the iterates can still change, though, one could continue the power method (FP) as long as the ranking criteria in Theorem 5.1 collect new ranking information. Note that the ranking criteria do not care whether the errors are due to finite termination or roundoff. For illustration purposes we execute 200 iterations of the power method in the experiments in section 6. A suitable termination criterion would stop the iterations once $\log(2\alpha^k) < \log(\|g_k\|_1)$.

TABLE 6.1
Properties of the data matrices (n = matrix dimension, m = maximal number of nonzeros in any column, $M = \max\{m, \text{dangling nodes} + 1\}$, and g = roundoff error).

Matrix	n	Nonzeros	m	Dangling nodes		M	g
H_S	9,914	36,854	340	2,861	29%	2,862	10^{-12}
H_L	3,148,440	39,383,235	168,685	91,462	3%	168,685	10^{-10}

The higher order effects $\mathcal{O}(n\epsilon^2)$ from the compensated summation are not likely to be of any consequence for the experiments in section 6 because $n\epsilon^2 \leq 10^{-25}$, which is negligible compared to $2\alpha^k \geq 10^{-14}$.

6. Numerical experiments. We present numerical experiments on data matrices from web crawls to compare the finite precision error bounds in section 5 and assess the performance of the ranking criterion. We describe the data matrices in section 6.1, and compare the bounds with respect to tightness in section 6.2 and with regard to ranking performance in section 6.3.

6.1. Data matrices. We present numerical experiments with two matrices that are obtained from web crawls and available on David Gleich's web page [16].

The properties of the two matrices are listed in Table 6.1. The small matrix H_S of dimension 9,914 represents a 2001 crawl [16, Webbase subgraph cs.stanford.edu], while the larger matrix H_L of dimension 3,148,440 represents a 2006 crawl [16, Wikipedia 2006-11-04]. Although the matrix H_S is small and dates from an older crawl, its larger percentage of dangling nodes is more representative of web graphs than that of H_L.

We choose the most popular values for the parameters of the Google matrix: $\alpha = .85$ for the amplification factor; and the uniform vector for personalization, dangling node, and starting vectors, $x^{(0)} = v = w = \frac{1}{n}\mathbf{1}$. The two data matrices for our experiments are

$$G_S \equiv \alpha(H_S + dw^T) + (1-\alpha)\mathbf{1}v^T, \qquad G_L \equiv \alpha(H_L + dw^T) + (1-\alpha)\mathbf{1}v^T.$$

The quantity g in Table 6.1 denotes the roundoff error from Corollary 5.3,

$$g \equiv \frac{2\epsilon(3.03 + c\alpha M)}{1 - \epsilon(3.03 + c\alpha M)}, \qquad M \equiv \max\{m, \|d\|_1 + 1\}, \qquad c \equiv 1.01(1 + 3.03\epsilon).$$

Note that the number of dangling nodes in G_S exceeds the maximal number of inlinks. Hence the dominant amplification factor M for the roundoff error of G_S is determined by the number of dangling nodes; see Theorem 5.2. This may reflect more what happens in practice when the nondangling nodes can be outnumbered by the dangling nodes, especially when applied to web graphs, since dangling nodes are part of the ever increasing web frontier. All experiments are performed in Matlab. We did not compute the norms with compensated summation because Matlab's accuracy appears to be sufficient for small problems with $n \leq 10^7$.

6.2. Tightness of the bounds. We compare bounds for the error $\|\hat{x}^{(k)} - \pi\|_1$ in iteration k. Since the roundoff error is essentially the same for all bounds and constant in each iteration, see Corollary 5.3, it suffices to compare the exact bounds. We assume that storage for 3 iterates is available, and that no overwriting takes place, so that successive iterates $\hat{x}^{(k-1)}$ and $\hat{x}^{(k)}$ require different storage locations. Among the resulting seven bounds below we included the k-step backward bound to illustrate the behavior of a bound where j is a function of k.

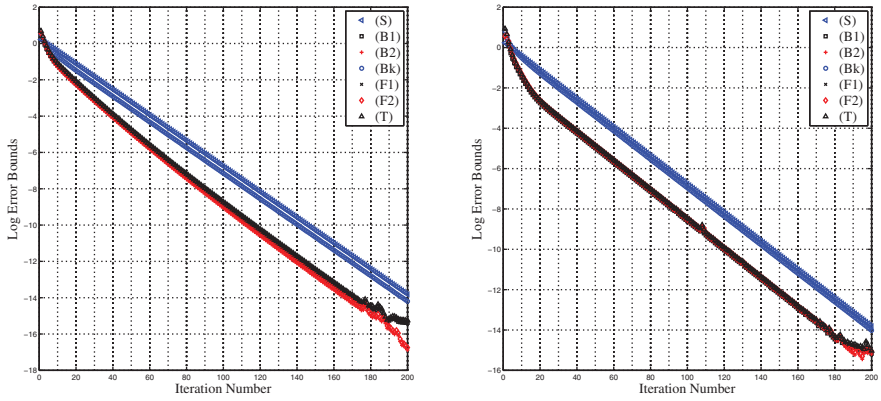

FIG. 6.1. *Error bounds for power method* (FP) *applied to the matrices G_S (left) and G_L (right).*

(S) Simple bound: $2\alpha^k$

(B1) Backward looking 1-step bound: $\frac{\alpha}{1-\alpha}\|\hat{x}^{(k-1)} - \hat{x}^{(k)}\|_1$

(B2) Backward looking 2-step bound: $\frac{\alpha^2}{1-\alpha^2}\|\hat{x}^{(k-2)} - \hat{x}^{(k)}\|_1$

(Bk) Backward looking k-step bound: $\frac{\alpha^k}{1-\alpha^k}\|x^{(0)} - \hat{x}^{(k)}\|_1$

(F1) Forward looking 1-step bound: $\frac{\|\hat{x}^{(k+1)} - \hat{x}^{(k)}\|_1}{1-\alpha}$

(F2) Forward looking 2-step bound: $\frac{\|\hat{x}^{(k+2)} - \hat{x}^{(k)}\|_1}{1-\alpha^2}$

(T) Two level 1-1-step bound: $\|\hat{x}^{(k+1)} - \hat{x}^{(k)}\|_1 + \frac{\|\hat{x}^{(k+2)} - \hat{x}^{(k+1)}\|_1}{1-\alpha}$

Figure 6.1 shows the above bounds for the matrices G_S and G_L. The bounds fall into two groups. The first group, consisting of (S) and (Bk), is less tight than the second group, which comprises the remaining bounds. There is little difference among the bounds in the second group. The straight lines in the context of the vertical logarithmic axis suggest that the geometric distances between iterates decrease at the same rate.

6.3. Ranking performance. Due to the lack of difference among the bounds in the competitive second group, we choose only (B1) for ranking, because it is the cheapest. The floating point version of the corresponding ranking criterion from Theorem 5.1 is as follows: If $\hat{x}_i^{(k)} > \hat{x}_j^{(k)} + \beta_B$, then $\pi_i > \pi_j$, where

$$\text{(B1-FP)} \qquad \beta_B \equiv \frac{\alpha}{1-\alpha}\|\hat{x}^{(k-1)} - \hat{x}^{(k)}\|_1 + g.$$

Applicability. Let Q_j be a permutation that orders the elements of $\hat{x}^{(j)}$ in decreasing order. That is, $\tilde{x}^{(j)} \equiv Q_j\hat{x}^{(j)}$ where $\tilde{x}_1^{(j)} \geq \ldots \geq \tilde{x}_n^{(j)}$. We count the number of pairs to which the criterion (B1-FP) applies. That is, we count the number of distinct pairs for which $\tilde{x}_i^{(j)} > \tilde{x}_{i+1}^{(j)} + \beta_B$ in iterations $1, \ldots, j$. Figure 6.2 shows this number for each iteration with the matrix G_S (due to memory limitations we were not able to collect this information for the large matrix G_L in every iteration). The line in the upper half represents the number of pairs of identical elements $\tilde{x}_i^{(j)} = \tilde{x}_{i+1}^{(j)}$ in each iterate. For instance, if $\tilde{x}_1^{(j)} = \tilde{x}_2^{(j)} = \tilde{x}_3^{(j)}$, then we count the two pairs $(1, 2)$ and $(2, 3)$. Since the ranking criterion cannot be applied to $\tilde{x}_1$ and $\tilde{x}_2$, the number of identical element pairs puts a natural limit on the performance of any ranking criterion that does not rely on additional criteria.

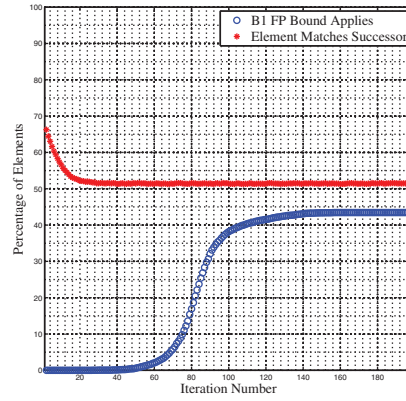

FIG. 6.2. *Applicability of ranking criterion* (B1-FP) *applied to the small matrix* G_S.

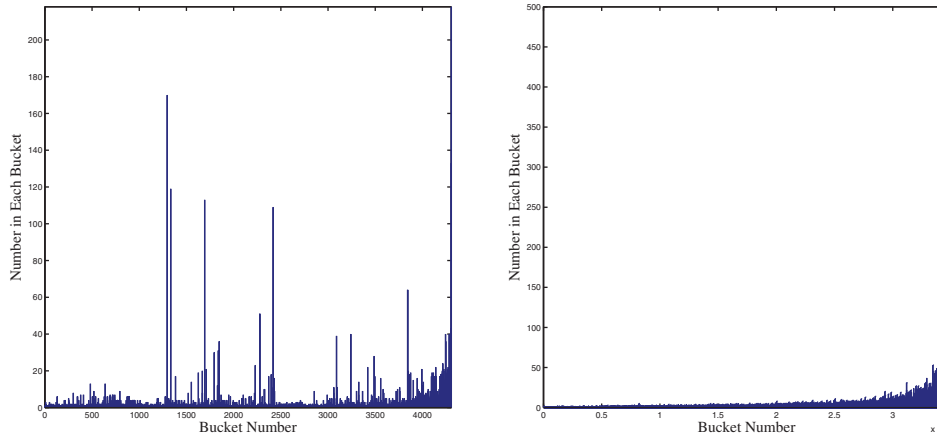

FIG. 6.3. *Buckets for ranking criterion* (B1-FP) *applied to iteration* 200 *with matrices* G_S *(left) and* G_L *(right).*

Figure 6.2 suggests that over 50% of the elements in most iterates are identical to another element. After about 100 iterations, criterion (B1-FP) applies to more than 40% of the elements. This means that only less than 10% of the elements remain unranked. The collection of new ranking information seems to level off after about 140 iterations. We can explain this as follows. The simple ranking bound $2\alpha^k$ is dominated by the roundoff error $\|g_k\|_1$ after about 170 iterations. Since the (B1) bound is tighter than the simple bound, the roundoff error dominates earlier. This is another justification for a termination criterion of the type already mentioned in section 5.3: Terminate the power method (FP) as soon as $\beta_B \approx g$.

Bucket ranking. Figure 6.3 gives an idea of how many different elements can be ranked and how big the buckets are. The histograms refer to the last iteration and depict the number of elements per bucket. To prevent distortion of the vertical axis and to assure better visibility for the top-ranked buckets, we omit the rightmost buckets (a single bucket in case of G_S and many buckets in case of G_L), which are the largest and contain the smallest elements.

Table 6.2 gives detailed information about the number and size of the buckets. The number of buckets represents *distinct* ranks that have been identified. For both

TABLE 6.2
Number and size of buckets for the matrices G_S (top) and G_L (bottom). The last two columns list the number of elements in the first and last buckets, respectively.

n	# Buckets	First bucket	Last bucket	
9,914	4,307	1	699	7%
3,148,440	34,911	1	2,996,646	95%

TABLE 6.3
Ranking information for the matrices G_S (top) and G_L (bottom). The second column lists the number of elements with exact rank, the third column the number of exactly ranked elements among the top 100 elements, and the last column lists the lowest rank that could be distinguished.

n	Exact ranking		Exact top 100	Lowest rank
9,914	3,177	32%	79	9,215
3,148,440	24,120	0.76%	100	151,794

matrices the ranking criterion (B1-FP) isolates the highest ranked PageRank score, because the first bucket contains only a single element. For the small matrix G_S, 7% of the smallest elements cannot be ranked, while for the large matrix G_L this number increases to 95%.

Table 6.3 gives detailed information about the ranking. It shows how many elements are ranked exactly, how many elements among the top 100 are exactly ranked, and the lowest rank that could be identified. Since the lowest identified rank for the matrix G_S is 9,215, the smallest bucket contains $n - 9,215 = 699$ elements, as shown in Table 6.2. The preceding information illustrates that the ranking criteria are able to identify the PageRanks of the top-ranked elements.

7. Extremely large matrices. As stated in Theorem 3.1, the main idea of our paper is the following ranking criterion: Let $x \geq 0$ with $\|x\|_1 = 1$ be any approximation to the PageRank vector π, and $\beta \geq \|x - \pi\|_1$.

(C) $$\text{If } x_i > x_j + \beta, \text{ then } \pi_i > \pi_j.$$

In the preceding sections we discussed the performance of (C) for matrices of dimension $n \leq 4 \cdot 10^6$, and for many applications of PageRank this is sufficient. However, the indexed web comprises hundreds of billions of web pages. Below are several suggestions for how to apply the criterion to matrices of extreme dimension.

7.1. Curbing roundoff error. The subsequent discussions are based on the roundoff error analysis in Theorem 5.2, which is valid for matrix dimensions $n < 10^{14}$ in IEEE double precision. Our experiments suggest that these roundoff error bounds are accurate and not at all pessimistic.

1. Computation of iterate norms. To prevent first-order dependence of the roundoff error on n, the iterates must be normalized on a regular basis, and the norms computed with compensated summation. However, even with compensated summation the higher order terms of the roundoff error can reach $n\epsilon^2 = 10^{-18}$ for $n = 10^{14}$ in IEEE double precision, which is large enough to be of concern for the ranking bound (C). Doubly compensated summation, or cascaded compensated summation [35, Algorithm 4.8], may be able to reduce higher order effects.

2. Matrix vector multiplications. Theorem 5.2 shows that with accurate computation of the iterate norms, the roundoff error is mainly due to a single matrix vector multiplication. In particular, it is determined by the maximal number of nonzeros in any column of the web matrix H (maximal number of inlinks) and the number of

dangling nodes (web pages without outlinks), whichever is larger. Since the dangling nodes are part of the increasing web frontier, they can easily outnumber the inlinks [12, section 2] and contribute substantially to the roundoff error. In section 7.2 we indicate how to reduce the influence of the dangling nodes.

3. Termination criteria. In later iterations the ranking bound β in (C) is dominated by roundoff error. Once this happens no new ranking information seems to be available. One may want to terminate the power method as soon as β is on the order of the roundoff error. The bound β is computed from geometric differences between iterates, that is, expressions of the form $\|\hat{x}^{(k+j)} - \hat{x}^{(k)}\|_1$. Catastrophic cancellation may damage the accuracy of these norms. This can be circumvented by resorting to the simple bound $2\alpha^k$ in Theorem 4.3. However, this bound is the least tight among all the bounds and requires the most iterations. A practical approach might be to just iterate until β is on the order of the roundoff error, so that accuracy in the computation of $\|\hat{x}^{(k+j)} - \hat{x}^{(k)}\|_1$ becomes less important, and collect ranking information only in the very last iteration.

7.2. Reducing matrix dimension. There are at least two advantages in reducing the matrix dimension: Faster computation and smaller roundoff error. Two easy approaches involve eliminating unreferenced pages (pages without inlinks) and dangling nodes (pages without outlinks). After such a reduction, the computation time depends only on the number of nondangling referenced pages, and the roundoff error depends only on the maximal number of inlinks to nondangling nodes.

1. Unreferenced pages. Suppose, as is likely in applications of PageRank to web graphs, that the dangling nodes outnumber the unreferenced pages, and that we have reordered the web matrix H so that the unreferenced pages are numbered last,

$$QHQ^T = \begin{pmatrix} H_1 & H_2 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix},$$

where the diagonal blocks are square and Q is a permutation matrix. If one sets the trailing block of the dangling node vector equal to zero $w^TQ^T = \begin{pmatrix} w_1^T & w_2^T & 0 \end{pmatrix}$ so that the dangling nodes do not add new inlinks to the unreferenced pages, then the last block column of S is also zero. If we partition the personalization vector conformally, $v^TQ^T = \begin{pmatrix} v_1^T & v_2^T & v_3^T \end{pmatrix}$. Then $\pi^T = \pi^T G$ implies that the PageRank of the unreferenced pages is simply $(1-\alpha)v_3$. Furthermore, setting $v_3 = 0$ forces the PageRank of the unreferenced pages to be zero, so that they automatically receive the lowest ranking. Therefore, by keeping the dangling node vector positions associated with unreferenced pages zero, one can compute the PageRank of the remaining pages from the smaller matrix $\left(\begin{smallmatrix} H_1 & H_2 \\ 0 & 0 \end{smallmatrix}\right)$.

2. Dangling nodes. One can further reduce the matrix dimension by lumping all dangling nodes into a single node. The resulting lumped matrix $S_l \equiv \left(\begin{smallmatrix} H_1 & H_2\mathbf{1} \\ w_1^T & w_2^T\mathbf{1} \end{smallmatrix}\right)$ is stochastic and its dimension is equal to one plus the number of nondangling nodes [23]. One can rank the nondangling nodes by applying the power method (FP) and the ranking criterion (C) to $G_l \equiv \alpha S_l + (1-\alpha)\mathbf{1}v_l^T$, where $v_l^T \equiv \begin{pmatrix} v_1^T & v_2^T\mathbf{1} \end{pmatrix}$. The PageRanks of the dangling nodes can be recovered with a single matrix vector multiplication [23].

7.3. Ranking with faster converging methods. The ranking criterion (C) is not tied to any computational method. To apply it to a method other than the power method, one first needs rigorous bounds on the forward error $\|x - \pi\|_1$ that also

take into account roundoff error. This may be hard to do for methods with involved decision processes and intricate and possibly worse conditioned matrix operations.

Instead it may be easier to compute an approximation to PageRank with a fast converging method, such as a Krylov space method [17, 18], and then use this approximation as a restart for a single power method iteration to rank the nondangling nodes. Here is a more detailed description.

1. Apply a fast method to compute an approximation z to the PageRank of the lumped matrix G_l, and terminate when the residual norm is less than g_l. Here

$$g_l \equiv \frac{2\epsilon(3.03 + c\alpha m_l)}{1 - \epsilon(3.03 + c\alpha m_l)}, \qquad c \equiv 1.01(1 + 3.03\epsilon)$$

is the roundoff error in a single iteration of the power method, and m_l is the maximal number of nonzeros in any column of S_l.

2. Execute a single iteration of the power method (FP) with $\hat{x}^{(0)} := z/\|z\|_1$ as the starting vector. That is, $[y^{(1)}]^T := [\hat{x}^{(0)}]^T G_l$, $\hat{x}^{(1)} := y^{(1)}/\|y^{(1)}\|_1$, and compute $\|z\|_1$ and $\|y^{(1)}\|_1$ by a cacaded compensated summation method [35] or by doubly compensated summation [22, Algorithm 4.3].

3. Determine the ranking bound (B1-FP) from section 6.3, $\beta_l := \|\hat{x}^{(1)} - \hat{x}^{(0)}\|_1 + g_l$, where $\|\hat{x}^{(1)} - \hat{x}^{(0)}\|_1$ is computed by doubly compensated summation. Use the ranking criterion: If $\hat{x}_i^{(1)} > \hat{x}_j^{(1)} + \beta_l$, then $\pi_i > \pi_j$, and construct buckets according to the rules in section 3.

Acknowledgments. We thank Steve Kirkland for many helpful discussions, and David Gleich for sharing his data so generously and patiently. We are also grateful to Nick Higham for suggesting the use of compensated summation.

VALIDATED SOLUTIONS OF SADDLE POINT LINEAR SYSTEMS*

TAKUMA KIMURA† AND XIAOJUN CHEN‡

Abstract. We propose a fast verification method for saddle point linear systems where the (1,1) block is singular. The proposed verification method is based on an algebraic analysis of a block diagonal preconditioner and rounding mode controlled computations. Numerical comparison of several verification methods with various block diagonal preconditioners is given.

Key words. saddle point matrix, numerical verification, block preconditioning

1. Introduction.

We consider the system of saddle point linear systems

$$\mathcal{H}u = b \equiv \begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} c \\ d \end{pmatrix}, \tag{1.1}$$

where A is an $n \times n$ symmetric positive semidefinite matrix and B is an $n \times m$ matrix, with $m \leq n$. We denote $l = n + m$. We assume that the coefficient matrix $\mathcal{H}$ is nonsingular, which implies that B has full-column rank.

In recent years, saddle point problems have received considerable attention. A large amount of work has been devoted to developing efficient algorithms for solving saddle point problems. In a recent comprehensive survey [1], Benzi, Golub, and Liesen discussed a large selection of numerical methods for saddle point problems. We are aware that it is very important to verify the accuracy of approximate solutions obtained by the numerical methods. However, there is little discussion on validated solutions of saddle point problems by taking all possible effects of rounding errors into account.

Standard validation methods for the solution of a system of linear equations use an approximation of the inverse of the coefficient matrix. These methods are not efficient for the saddle point problem (1.1) when the dimension l is large or the condition number of $\mathcal{H}$ is large, due to the indefiniteness of $\mathcal{H}$ and the singularity of A.

In [2], a numerical validation method is proposed for verifying the accuracy of approximation solutions of the saddle point problem (1.1) without using an approximation of the inverse $\mathcal{H}^{-1}$, under the assumption that A is symmetric positive definite. The method uses the special structure of the saddle point problem to represent the variable x by the inverse of A and the variable y. For the case that A is singular and the size of the problem is large, it is a significant challenge to compute a rigorous upper bound for the norm $\|\mathcal{H}^{-1}\|$ without using an approximation of the inverse $\mathcal{H}^{-1}$. In this paper, we present a fast method to compute rigorous error bounds for the

saddle point problem (1.1) where A is symmetric positive semidefinite. In particular, we present a fast method to compute a constant α such that

$$\|u^* - u\|_2 \le \alpha \|b - \mathcal{H}u\|_2 \quad \text{for } u \in R^l, \tag{1.2}$$

where u^* is the exact solution of (1.1). This method is based on an algebraic analysis of a block diagonal preconditioner for saddle point systems studied in a recent paper [6] by Golub, Greif, and Varah. Instead of approximating the inverse of the $l \times l$ indefinite matrix $\mathcal{H}$, we use approximations of inverses of two symmetric positive definite matrices in $R^{n\times n}$ and $R^{m\times m}$ to define the constant α in the error bound (1.2). Moreover, we present fast methods to estimate upper bounds for the norms of inverses of the two symmetric positive definite matrices based on fast validated matrix computation by Oishi and Rump [8].

In section 2, we define the error constant α. In section 3, we discuss how to compute an upper bound of α efficiently and accurately by taking all possible effects of rounding errors into account. In section 4, we compare our verification method with the Krawczyk method [13], the LU decomposition method [8], the verifylss function of INTLAB, and a block component verification method proposed in [2] using examples from CUTEr [6], optimal surface fitting [3, 10], mixed finite element discretization of the Stokes equations [1], and image restoration [5, 15].

2. A new error bound. Let W be an $m \times m$ symmetric positive semidefinite matrix such that

$$M(W) = A + BWB^T$$

is a symmetric positive definite matrix. Note that BWB^T is singular for any symmetric positive definite matrix W when $m < n$. However, if W is symmetric positive definite, we can show that $M(W)$ is symmetric positive definite under the conditions that A is positive semidefinite and $\mathcal{H}$ is nonsingular. To see it, let $\bar{x} \neq 0$ be a solution of $M(W)\bar{x} = 0$. Then we have

$$\bar{x}^T A\bar{x} + \bar{x}^T BWB^T\bar{x} = 0.$$

Since A and BWB^T are positive semidefinite, we obtain

$$\bar{x}^T A\bar{x} = 0 \quad \text{and} \quad \bar{x}^T BWB^T\bar{x} = 0,$$

which implies

$$A\bar{x} = 0 \quad \text{and} \quad B^T\bar{x} = 0.$$

Therefore, we find that $\mathcal{H}z = 0$ with $z = (\bar{x}, 0)$. This contradicts that $\mathcal{H}$ is nonsingular.

Recently, Golub, Greif, and Varah [6] performed an algebraic study of the block diagonal positive definite preconditioner

$$\mathcal{M}(W) = \begin{pmatrix} M(W) & 0 \\ 0 & B^T M(W)^{-1} B \end{pmatrix}. \tag{2.1}$$

They showed that $\mathcal{M}(W)$ has the attractive property that the eigenvalues of the associated preconditioned matrix $\mathcal{M}(W)^{-1}\mathcal{H}$ are bounded in a small range.

LEMMA 2.1 (see [6]). *The eigenvalues of the preconditioned matrix $\mathcal{M}(W)^{-1}\mathcal{H}$ are bounded within the two intervals*

$$\left[-1, \frac{1-\sqrt{5}}{2}\right] \cup \left[1, \frac{1+\sqrt{5}}{2}\right].$$

Lemma 2.1 makes it possible for us to present rigorous error bounds for the saddle point problem (1.1).

THEOREM 2.1. *Let u^* be the exact solution of* (1.1). *For any $u \in R^l$, we have*

$$\|u^* - u\|_2 \le \frac{2}{\sqrt{5}-1} \max\left(\left\|M(W)^{-1}\right\|_2, \|M(W)\|_2 \left\|\left(B^T B\right)^{-1}\right\|_2 \right) \|b - \mathcal{H}u\|_2. \tag{2.2}$$

Proof. Obviously, we have

$$\|u^* - u\|_2 \le \left\|\mathcal{H}^{-1}\right\|_2 \|b - \mathcal{H}u\|_2.$$

Now, we use Lemma 2.1 to give an upper bound of $\|\mathcal{H}^{-1}\|_2$. Let $\mathcal{L}$ be a nonsingular matrix such that $\mathcal{L}\mathcal{L}^T = \mathcal{M}(W)$, and let

$$\mathcal{S} = \mathcal{L}^{-1}\mathcal{H}\mathcal{L}^{-T}. \tag{2.3}$$

Then the inverse $\mathcal{H}^{-1}$ can be given as

$$\mathcal{H}^{-1} = \mathcal{L}^{-T}\mathcal{S}^{-1}\mathcal{L}^{-1}.$$

Since $\mathcal{H}$ and $\mathcal{S}$ are symmetric, we have

$$\begin{aligned}
\left\|\mathcal{H}^{-1}\right\|_2 &= \max_{\substack{v \in R^l \\ v \neq 0}} \left| \frac{v^T \mathcal{L}^{-T}\mathcal{S}^{-1}\mathcal{L}^{-1} v}{v^T v} \right| \\
&= \max_{\substack{v \in R^l \\ v \neq 0}} \left| \frac{v^T \mathcal{L}^{-T}\mathcal{S}^{-1}\mathcal{L}^{-1} v}{v^T \mathcal{L}^{-T}\mathcal{L}^{-1} v} \frac{v^T \mathcal{L}^{-T}\mathcal{L}^{-1} v}{v^T v} \right| \\
&\le \max_{\substack{w \in R^l \\ w \neq 0}} \left| \frac{w^T \mathcal{S}^{-1} w}{w^T w} \right| \max_{\substack{v \in R^l \\ v \neq 0}} \left| \frac{v^T \mathcal{M}(W)^{-1} v}{v^T v} \right| \\
&= \left\|\mathcal{S}^{-1}\right\|_2 \left\|\mathcal{M}(W)^{-1}\right\|_2. \qquad (2.4)
\end{aligned}$$

From (2.3) and $\mathcal{L}\mathcal{L}^T = \mathcal{M}(W)$, we have

$$\mathcal{L}^T \mathcal{M}(W)^{-1} \mathcal{H}\mathcal{L}^{-T} = \mathcal{S}.$$

Hence $\mathcal{S}$ and $\mathcal{M}(W)^{-1}\mathcal{H}$ have the same eigenvalues.

By Lemma 2.1, the eigenvalues of $\mathcal{S}$ are bounded within the two intervals

$$\left[-1, \frac{1-\sqrt{5}}{2}\right] \cup \left[1, \frac{1+\sqrt{5}}{2}\right].$$

Hence all eigenvalues of $\mathcal{S}^{-1}$ satisfy

$$|\lambda_i| \le \frac{2}{\sqrt{5}-1}, \quad i = 1, 2, \ldots, l.$$

From (2.4), we obtain

$$\left\|\mathcal{H}^{-1}\right\|_2 \le \frac{2}{\sqrt{5}-1} \left\|\mathcal{M}(W)^{-1}\right\|_2.$$

Moreover, from (2.1), we have

$$\begin{aligned}\left\|\mathcal{M}(W)^{-1}\right\|_2 &\le \max\left(\left\|M(W)^{-1}\right\|_2, \left\|\left(B^T M(W)^{-1} B\right)^{-1}\right\|_2\right)\\ &\le \max\left(\left\|M(W)^{-1}\right\|_2, \|M(W)\|_2 \left\|\left(B^T B\right)^{-1}\right\|_2\right),\end{aligned}$$

where the last inequality uses

$$\begin{aligned}\lambda_{\min}\left(B^T M(W)^{-1} B\right) &= \min_{\substack{y\in R^m\\ y\neq 0}} \frac{\left(M(W)^{-1}By, By\right)}{(By, By)} \frac{\left(B^T By, y\right)}{(y, y)}\\ &\ge \lambda_{\min}\left(M(W)^{-1}\right)\lambda_{\min}(B^T B). \qquad \square\end{aligned}$$

Theorem 2.1 shows that an upper bound of the inverse $\|\mathcal{H}^{-1}\|_2$ can be obtained by computing upper bounds for the norm of inverses of two symmetric positive definite matrices with sizes of $n \times n$ and $m \times m$. When n and/or m are large, the number of its flops is much less than the methods working on the $(n+m) \times (n+m)$ matrix $\mathcal{H}$. For example, the LU decomposition method for (1.1) requires $O((n+m)^3)$ flops, but estimating $\|M(W)^{-1}\|_\infty$ and $\|(B^T B)^{-1}\|_\infty$ requires only $O(n^3) + O(m^3)$ flops, which will save $O(n^2 m + nm^2)$ flops computational cost. Moreover, since the two matrices are symmetric, we can replace $\|\cdot\|_2$ by $\|\cdot\|_\infty$ for the matrix norm in (2.2) and have

$$\|u^* - u\|_2 \le \frac{2}{\sqrt{5}-1} \max\left(\left\|M(W)^{-1}\right\|_\infty, \|M(W)\|_\infty \left\|\left(B^T B\right)^{-1}\right\|_\infty\right) \|b - \mathcal{H}u\|_2. \tag{2.5}$$

In general, (2.5) is easier to implement than (2.2).

3. Verification methods. When we apply Theorem 2.1 and other verification methods to verify the accuracy of an approximate solution of (1.1) on a computer, it is necessary to consider rounding error. The IEEE 754 arithmetic standard [4] defines the rounding modes for double precision floating point numbers. Since Intel's CPU follows this standard, the rounding modes can be used on most personal computers (PCs) and workstations. We use rounding downwards, rounding upwards, and rounding nearest to compute rigorous error bounds for (2.5). We also apply these rounding modes to the following three verification methods.

Krawczyk method [11, 13].

$$\begin{aligned}K(U) &:= u - \mathcal{R}(\mathcal{H}u - b) + (I - \mathcal{R}\mathcal{H})(U - u),\\ K(U) \subset \mathrm{int}(U) &\Rightarrow u^* \in K(U) \Rightarrow \|u^* - u\|_\infty \le \|\mathrm{radius}(U)\|_\infty,\end{aligned}$$

where $\mathcal{R}$ is an approximate inverse of $\mathcal{H}$ and U is an interval vector whose center is u.

LU decomposition method [8]. Let $\mathcal{L}\mathcal{U}$ be an approximate LU factorization of $\mathcal{H}$, that is, $\mathcal{H} \approx \mathcal{L}\mathcal{U}$.

$$\|u^* - u\|_\infty \le \frac{\left\|\mathcal{U}^{-1}\mathcal{L}^{-1}(b - \mathcal{H}u)\right\|_\infty}{1 - \left\|\mathcal{U}^{-1}\mathcal{L}^{-1}\mathcal{H} - \mathcal{I}\right\|_\infty}.$$

Block component verification method [2]. Let $u^* = (x^*, y^*)$, $r_1 = Ax + By - c$, and $r_2 = B^T x - d$.

$$\begin{aligned}\|u^* - u\|_\infty &\le \max(\|x^* - x\|_\infty, \|y^* - y\|_\infty),\\ \|x^* - x\|_\infty &\le \|A^{-1}\|_\infty (\|r_1\|_\infty + \|B\|_\infty \|y^* - y\|_\infty),\\ \|y^* - y\|_\infty &\le \|A\|_\infty \left\|\left(B^T B\right)^{-1}\right\|_\infty \left(\|r_2\|_2 + \sqrt{\left\|BB^T\right\|_\infty \left\|A^{-1}\right\|_\infty} \|r_1\|_2\right).\end{aligned}$$

verifylss of INTLAB [14].

$$U = \mathsf{verifylss}(\mathcal{H}, b),$$
$$\|u - u^*\|_\infty \le 2\|\mathrm{radius}(U)\|_\infty \quad \text{for} \quad u \in U.$$

Note that when A is singular, the block component verification method cannot be applied to (1.1) directly but to the equivalent system

$$\begin{pmatrix} A + BWB^T & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} c + BWd \\ d \end{pmatrix}. \tag{3.1}$$

Obviously, the error bounds depend on the choice of W. We tested the error bounds with various W. In this paper, we consider two types of choices

$$W_1(\gamma) = \gamma / \left\|B^T B\right\|_2 I$$

and

$$W_2(\gamma) = \gamma \left(B^T B\right)^{-1}$$

if A is singular. We set $W = 0$ if A is nonsingular.

4. Numerical experiment. The numerical testing was carried out on an IBM PC (3.0 GHz Pentium 4 processor, 1GB of memory) with the use of MATLAB 7.0 and INTLAB (Version 5.4) [12, 14]. We use the function setround in INTLAB [14] to compute the error bound. The function setround allows the rounding mode of the processor to be changed between round nearest (setround(0)), round down (setround(-1)), round up (setround(1)), and round towards zero (setround(2)). To compute $\|M(W)^{-1}\|_\infty$, we first use setround(0) to compute an approximate inverse R of $M(W)$. Next we use

```
S=intval(R),
beta=abss(norm(S,inf)/(1-norm(S*M(W)-I)))
```

to get an upper bound β for $\|M(W)^{-1}\|_\infty$ as

$$\left\|M(W)^{-1}\right\|_\infty \le \frac{\|R\|_\infty}{1 - \|RM(W) - I\|_\infty} \le \beta.$$

Similarly, we apply the function setround to (2.5) to get an upper bound Γ by taking all possible effects of rounding errors into account such that

$$\|u^* - u\|_2 \le \Gamma. \tag{4.1}$$

We compare the error bound (2.5) with the Krawczyk method, the LU decomposition method, the block component verification method, and the function verifylss of INTLAB using examples from CUTEr [6], optimal surface fitting [3, 10], mixed finite element discretization of the Stokes equations [1], and image restoration [5, 15].

Example 4.1 (CUTEr matrices). We used two test problems genhs28 and gouldqp3 from the CUTEr collection [7], which were used in [6].

The genhs28 is an $(n+m)\times(n+m)$ saddle point matrix, where A is an $n \times n$ tridiagonal matrix with 2, 4, 2 along its superdiagonal, main diagonal, and subdiagonal, respectively, except $A_{1,1} = A_{n,n} = 2$. The rank of A is $n-1$. B is $n \times m$ with values 1, 2, 3 along its main diagonal, first subdiagonal, and second subdiagonal, respectively.

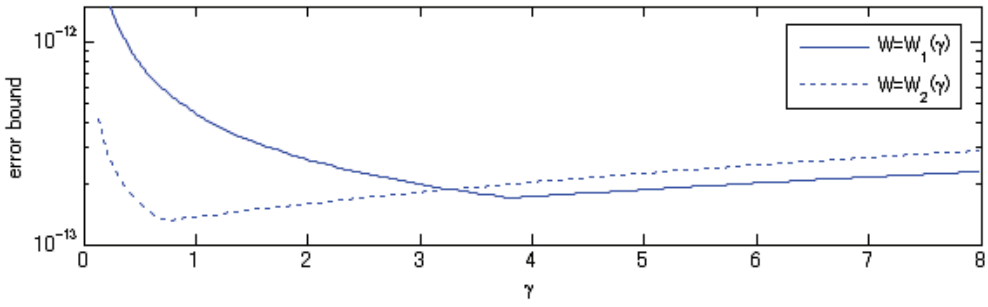

FIG. 1. *Error bounds* (2.5) *for genhs*28 *with different* W. $(n, m) = (500, 498)$, $\|A\|_2 \approx 8.0$, $\|B^T B\|_2 \approx 36.0$, *and* $\|(B^T B)^{-1}\|_2 \approx 0.38$.

The gouldqp3 is an $(n + m) \times (n + m)$ saddle point matrix, where A is an $n \times n$ matrix with rank$(A) = n - 2$.

We set the exact solution u^* and right-hand side vector b as

$$u^* = (1, \ldots, 1)^T, \qquad b = \mathcal{H}u^*.$$

Figure 1 shows the error bounds for genhs28 with $(n, m) = (500, 498)$ as γ changes from $\min(\|A\|_2, 1/\|A\|_2)$ to $\max(\|A\|_2, 1/\|A\|_2)$. In Tables 1–2, we report numerical results with $W_1(1)$ and $W_2(1)$.

Example 4.2 (surface fitting problem). Let $\Omega \subset R^2$ be a convex bounded domain, $p_i = (p_i^1, p_i^2) \in \Omega$ be the measurement points, and q_i be the corresponding real values $(i = 1 \ldots k)$. We consider the following surface fitting problem [3, 10]

$$\min \quad \sum_{i=1}^{k} (f(p_i) - q_i)^2 + \mu |f|^2_{H^2(\Omega)} \tag{4.2}$$

over all functions f in the Sobolev space $H^2(\Omega)$. Here μ is a fixed parameter.

[1] In Tables 1–5, "Fail" means out of the memory; [ ] shows CPU time (sec.).

We apply a finite element approximation with uniform triangular meshes to (4.2) and obtain a convex optimization problem in R^{4m+1} [3]:

$$\begin{aligned} &\min \|Nx_1 + \mu e_k - q\|_2^2 + \mu \left(x_2^T G x_2 + x_3^T G x_3\right) \\ &\text{subject to (s.t.) } Gx_1 = B_1 x_2 + B_2 x_3, \\ &\qquad\qquad e_k^T N x_1 = 0, \end{aligned} \tag{4.3}$$

where $N \in R^{k\times m}$ and $B_1, B_2, G \in R^{m\times m}$. Here G is a symmetric positive semidefinite matrix. The problem (4.3) is equivalent to the following saddle point system:

$$\left(\begin{array}{ccc|cc} N^TN & & & G & N^Te_k \\ & \mu G & & -B_1^T & \\ & & \mu G & -B_2^T & \\ \hline G & -B_1 & -B_2 & & \\ e_k^TN & & & & \end{array}\right) \left(\begin{array}{c} x_1 \\ x_2 \\ x_3 \\ \hline y_1 \\ y_2 \end{array}\right) = \left(\begin{array}{c} 2N^T(q - \mu e_k) \\ 0 \\ 0 \\ \hline 0 \\ 0 \end{array}\right), \tag{4.4}$$

where y_1 and y_2 are the Lagrange multipliers. In many applications, $k < m$, which results in the matrix N^TN being singular; i.e., the $(1,1)$ block of the saddle point matrix in (4.4) is singular.

In this example, we use real data of the 2006 average temperature in the Aomori region from the Japan Meteorological Agency. We choose $k = 47$, $n = 3m + 1$, and rank$(A) = 2m+47$ and set $\mu =$1.0e−5 in (4.4). Numerical results of the error estimate with various m, n are given in Table 3.

Example 4.3 (the Stokes equation). We consider the saddle point system arising from the mixed finite element discretization of the stationary Stokes equation:

$$\begin{cases} -\nu\Delta u + \nabla p = \varphi & \text{in} \quad \Omega, \\ -\operatorname{div} u = 0 & \text{in} \quad \Omega, \\ u = 0 & \text{on} \quad \partial\Omega, \end{cases} \tag{4.5}$$

where $\Omega = (0,1) \times (0,1)$, $\partial\Omega$ is the boundary of Ω, $\nu > 0$ is the kinematic viscosity coefficient, $\varphi = (\varphi_1, \varphi_2)$ is a given force field, $u : \Omega \to R^2$ is a velocity field, and

$p : \Omega \to R$ is a pressure field. We apply a mixed finite element approximation with uniform triangular meshes and obtain a saddle point linear system (1.1) where the velocity is approximated by the standard piecewise quadratic basis functions and the pressure is approximated by piecewise linear basis functions.

In this example, A is nonsingular and $A^{-1} \geq 0$. We use Theorem 2 in [9] to get a upper bound of $\|A^{-1}\|_\infty$, i.e.,

$$\left\|A^{-1}\right\|_\infty \leq \frac{\|\tilde{w}\|_\infty}{1-\|s\|_\infty},$$

where $\tilde{w}$ is an approximate solution of $Aw = e_n$, $s = A\tilde{w} - e_n$, and $e_n = (1,1,\ldots,1)^T \in R^n$.

In this example, $\|(B^TB)^{-1}\|_2 = O(h^{-2})$, where h is the mesh size. To avoid using $\|(B^TB)^{-1}\|_2$ for small h, we consider a preconditioned system. Let L be an $m \times m$ nonsingular matrix such that $L^TL \approx B^TB$. Let

$$\mathcal{P} = \begin{pmatrix} I & \\ & L^{-1} \end{pmatrix}, \quad \tilde{\mathcal{H}} = \mathcal{P}^T\mathcal{H}\mathcal{P} = \begin{pmatrix} A & \tilde{B} \\ \tilde{B}^T & 0 \end{pmatrix}, \quad \tilde{b} = \mathcal{P}^Tb,$$
$$\tilde{B} = BL^{-1}, \quad \tilde{M}(W) = A + \tilde{B}W\tilde{B}^T.$$

Applying Theorem 2.1 to the preconditioned system

$$\tilde{\mathcal{H}}\mathcal{P}^{-1}u = \tilde{b},$$

we obtain

$$\begin{aligned}\|u-u^*\|_\infty &\leq \|\mathcal{P}\|_\infty \left\|\mathcal{P}^{-1}(u^*-u)\right\|_\infty \leq \|\mathcal{P}\|_\infty \left\|\mathcal{P}^{-1}(u^*-u)\right\|_2 \\ &\leq \frac{2\|\mathcal{P}\|_\infty}{\sqrt{5}-1} \max\left(\left\|\tilde{M}(W)^{-1}\right\|_2, \|\tilde{M}(W)\|_2 \left\|\left(\tilde{B}^T\tilde{B}\right)^{-1}\right\|_2\right) \|\mathcal{P}^T(b-\mathcal{H}u)\|_2 \\ &\leq \frac{2\max\left(1, \left\|L^{-1}\right\|_\infty\right)}{\sqrt{5}-1} \max\left(\left\|\tilde{M}(W)^{-1}\right\|_\infty, \|\tilde{M}(W)\|_\infty \left\|L\left(B^TB\right)^{-1}L^T\right\|_\infty\right) \\ &\quad \times \left\|\mathcal{P}^T(b-\mathcal{H}u)\right\|_2. \qquad (4.6)\end{aligned}$$

TABLE 4
The preconditioned error bounds for Example 4.3*, Stokes equation.* $rank(A) = n$.

(n, m)	(882,144)	(2738,400)	(9522,1296)	(20402,2704)
$\mathrm{cond}(\mathcal{H})$	4.11e+05	1.21e+06	4.09e+06	8.66e+06
$\|b - \mathcal{H}u\|_2$	1.58e−15	2.56e−15	5.04e−15	7.32e−15
(4.7)	1.10e−11 [0.078]	9.24e−11 [1.001]	1.14e−09 [19.312]	5.11e−09 [149.383]
Preconditioned block component	7.24e−11 [0.078]	6.06e−10 [1.002]	7.46e−09 [19.295]	4.59e−08 [149.352]
LU	7.04e−16 [15.780]	1.53e−15 [430.490]	Fail	Fail

verifylss	1.11e−16 [5.202]	2.22e−16 [124.224]	Fail	Fail

We call (4.6) a preconditioned error bound. From $\|L^{-1}\|_\infty \approx \sqrt{\|(B^TB)^{-1}\|_\infty} = O(h^{-1})$, the preconditioned error bound is expected to be sharper than (2.5) for the Stokes equation. Similarly, we can get a preconditioned block component verification method as Method 2 in [2].

Numerical results of the preconditioned error bounds for Example 4.3 with $\nu = 1$ are given in Table 4.

Example 4.4 (image restoration). Suppose the discretized scenes have $p = p_1 \times p_2$ pixels. Let $f \in R^p, g \in R^q$ be the underlying image and the observed image, respectively. Let $H \in R^{q\times p}$ be the corresponding blurring matrix of block Toeplitz with Toeplitz blocks. Restoration of f is an ill-conditioned problem. We consider the linear least squares problem with Tikhonov's regularization [5, 15]

$$\min_f \|Hf - g\|_2^2 + \alpha\|Df\|_2^2, \tag{4.7}$$

where α is a regularization parameter and $D \in R^{(2p-p_1-p_2)\times p}$ is a regularization matrix of a first order finite difference operator

$$D = \begin{pmatrix} \Delta_{(p_1-1)\times p_1} \otimes I_{p_2\times p_2} \\ I_{p_1\times p_1} \otimes \Delta_{(p_2-1)\times p_2} \end{pmatrix} \quad \text{with} \quad \Delta = \begin{pmatrix} 1 & -1 & & \\ & 1 & -1 & \\ & & \ddots & \ddots \\ & & & 1 \quad -1 \end{pmatrix}.$$

Problem (4.7) can be rewritten as a quadratic programming

$$\begin{aligned} \min \quad & \frac{1}{2}x^TAx + c^Tx \\ \text{s.t.} \quad & B^Tx = 0, \end{aligned} \tag{4.8}$$

where

$$x = \begin{pmatrix} f \\ v \end{pmatrix}, \quad A = \begin{pmatrix} 2H^TH & 0 \\ 0 & \alpha I \end{pmatrix} \in R^{(3p-p_1-p_2)\times(3p-p_1-p_2)},$$
$$B^T = \begin{pmatrix} D & -I \end{pmatrix} \in R^{(2p-p_1-p_2)\times(3p-p_1-p_2)}, \quad c = \begin{pmatrix} -2H^Tg \\ 0 \end{pmatrix}.$$

The optimal condition for (4.8) is a saddle point problem

$$\begin{pmatrix} A & B \\ B^T & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} -c \\ 0 \end{pmatrix},$$

where y is the Lagrange multiplier vector for the constraints $B^T x = 0$. In this problem, A is a positive semidefinite matrix and B has full-column rank.

We generate an original image of the cameraman as shown in Figure 2(a). The image is blurred by a Gaussian function

$$h(i,j) = e^{-(i^2+j^2)/18},$$

truncated such that the function has a support of 7×7, and then pixels are contaminated by Gaussian noise with the standard deviation of 0.05. The blurred and noisy image is shown in Figure 2(b). We solve the saddle point problem to find a restored image, which is shown in Figure 2(c). In the saddle point matrix, A has rank(A)=$2p - p_1 - p_2 + [p_1/2][p_2/2]$. Here $[\cdot]$ denotes the nearest integer.

Numerical results of the error bounds for the restored image are given in Table 5.

To end this section, we use a 3×3 block ill-conditioned saddle matrix to show that the error bound (2.5) is tight.

Example 4.5. We consider the following problem:

$$\mathcal{H} = \begin{pmatrix} \epsilon I & 0 & 0 \\ 0 & 0 & B \\ 0 & B^T & 0 \end{pmatrix}, \quad b = \begin{pmatrix} b_1 \\ b_2 \\ b_3 \end{pmatrix},$$

where $b_1, b_2, b_3 \in R^m, I, B \in R^{m\times m}$, and B is nonsingular. It is easy to find the inverse and the solution

$$\mathcal{H}^{-1} = \begin{pmatrix} \frac{1}{\epsilon} I & 0 & 0 \\ 0 & 0 & B^{-T} \\ 0 & B^{-1} & 0 \end{pmatrix}, \quad u^* = \begin{pmatrix} \frac{1}{\epsilon} b_1 \\ B^{-T} b_3 \\ B^{-1} b_2 \end{pmatrix}.$$

Consider $0 < \epsilon \leq 1$ and $\|B\|_\infty \geq 1$. The condition number of $\mathcal{H}$ satisfies

$$\|\mathcal{H}\|_\infty \left\|\mathcal{H}^{-1}\right\|_\infty \geq \epsilon^{-1} \|B\|_\infty.$$

When $\epsilon \to 0$, the condition number will go to ∞.

Using (2.2) or (2.5) with $W = B^{-1}B^{-T}$, we obtain

$$M(W) = \begin{pmatrix} \epsilon I & 0 \\ 0 & I \end{pmatrix}$$

and

$$\|u^* - u\|_2 \leq \frac{2}{\epsilon(\sqrt{5}-1)} \|b - \mathcal{H}u\|_2 \tag{4.9}$$

for $0 < \epsilon \leq 1/\|(B^TB)^{-1}\|_\infty$. Furthermore, the equality holds in (4.9) when $B = \frac{\epsilon(\sqrt{5}-1)}{2} I$ and $u = (\frac{1}{\epsilon} b_1, u_2, u_3)$.

5. Final remark. Using the algebraic analysis of a block diagonal preconditioner in [6], we proposed a fast verification method for saddle point linear systems where the $(1, 1)$ block may be singular. The method was implemented by using INTLAB [14] and taking all possible effects of rounding errors into account. Numerical results show that the method is efficient.

Acknowledgments. We are grateful to the two referees for their very helpful comments and suggestions. We wish to thank Prof. T. Yamamoto for carefully reading this paper and giving us helpful comments.

ON THE TENSOR SVD AND THE OPTIMAL LOW RANK ORTHOGONAL APPROXIMATION OF TENSORS*

JIE CHEN† AND YOUSEF SAAD†

Abstract. It is known that a higher order tensor does not necessarily have an optimal low rank approximation, and that a tensor might not be orthogonally decomposable (i.e., admit a tensor SVD). We provide several sufficient conditions which lead to the failure of the tensor SVD, and characterize the existence of the tensor SVD with respect to the higher order SVD (HOSVD). In the face of these difficulties to generalize standard results known in the matrix case to tensors, we consider the low rank orthogonal approximation of tensors. The existence of an optimal approximation is theoretically guaranteed under certain conditions, and this optimal approximation yields a tensor decomposition where the diagonal of the core is maximized. We present an algorithm to compute this approximation and analyze its convergence behavior. Numerical experiments indicate a linear convergence rate for this algorithm.

Key words. multilinear algebra, singular value decomposition, tensor decomposition, low rank approximation

1. Introduction.

There has been renewed interest in studying the properties and decompositions of tensors (also known as N-way arrays or multidimensional arrays) in numerical linear algebra in recent years [30, 13, 12, 43, 17, 9, 28, 29, 15, 11]. The tensor approximation techniques have been fruitfully applied in various areas which include, among others, chemometrics [38, 4], signal processing [10, 8], vision and graphics [41, 42], and network analysis [31, 1]. From the point of view of practical applications, the matrix SVD and the optimal rank-r approximation of matrices (a.k.a. the Eckart–Young theorem [18]) are of particular interest, and it would be nice if these properties could be directly generalized to higher order tensors. However, for any order $N \geq 3$, de Silva and Lim [17] showed that the problem of optimal low rank approximation of higher order tensors is ill-posed for many ranks r, and that this ill-posedness is not rare for order-3 tensors. Furthermore, Kolda presented numerous examples to illustrate the difficulties of orthogonal tensor decompositions [28, 29]. These studies revealed many aspects of the dissimilarities between tensors and matrices, in spite of the fact that higher order tensors are multidimensional generalizations of matrices.

The most commonly used generalization of the matrix SVD to higher order tensors to date is the *higher order singular value decomposition* (HOSVD) [12]. The HOSVD decomposes an order-N tensor into a core tensor that has the same size as the original tensor together with N orthogonal[1] side-matrices. Although this decomposition preserves many nice aspects of the matrix SVD (e.g., the core has the all-orthogonality

[1]Throughout this paper, a matrix $A \in \mathbb{R}^{m \times n}$, $m \geq n$, is said to be *orthogonal* if $A^T A = I$. This generalizes the definition for square matrices.

property and the ordering property), a notable difference is that the core is in general not diagonal. Hence, in contrast with the matrix SVD, the HOSVD cannot be written as a sum of a few orthogonal outer-product terms.[2]

There exist three well-known approximations to higher order tensors: (1) the rank-1 approximation [13, 43, 27]; (2) the rank-$(r_1, r_2, \ldots, r_N)$ approximation with a full core and N orthogonal side-matrices (in the *Tucker/HOOI* fashion) [40, 13]; and (3) the approximation using r outer-product terms (in the *CANDECOMP/PARAFAC* fashion) [6, 19]. Note that the approximated tensor in case (3) might have rank less than r. Among these approximations, the rank-1 approximation [17] and the rank-$(r_1, r_2, \ldots, r_N)$ approximation are theoretically guaranteed to have a global optimum. In practical applications, the three approximations are generally computed using an alternating least squares (ALS) method [33, 3, 25] (the so-called workhorse algorithm [30]), although many other methods have also been proposed [34, 37, 43, 28, 15, 11]. The convergence behavior of the ALS method is theoretically unknown except under a few strong conditions [32]. Besides, it has long been observed that the ALS method for the PARAFAC model may converge extremely slowly if at all [36, 26]. An illustration of this phenomenon is given in the appendix.

Kolda [28] investigated several orthogonal decompositions of tensors related to different definitions of orthogonality, including *orthogonal rank decomposition*, *complete orthogonal rank decomposition*, and *strong orthogonal rank decomposition*. These decompositions might not be unique, or even exist. Among these definitions, only the *complete orthogonality* gives a situation which parallels that of the matrix SVD. This approach demands that the side-matrices all be orthogonal, in which case we use the term *tensor singular value decomposition* (tensor SVD; see Definition 4.1) in this paper. Zhang and Golub [43] proved that for all tensors of order $N \geq 3$, the tensor SVD is unique (up to signs) if it exists, and that the incremental rank-1 approximation approach will compute this decomposition.

The following contributions are made in this paper:

1. Sufficient conditions indicating which tensors fail to have a tensor SVD are given. These conditions are related to the rank, the order, and the dimensions of the tensor, and hence can be viewed as generalizations of results given in the literature with specific examples. Furthermore, the existence of the tensor SVD can be characterized by the diagonality of the core in the HOSVD of the tensor.
2. A form of low rank approximations—one that requires a diagonal core and orthogonal side-matrices—is discussed. Theoretically the global optimum of this approximation can be attained for any (appropriate) rank. We present an iterative algorithm to compute this approximation and analyze its convergence behavior.
3. The proposed approximation at the maximally possible rank leads to a decomposition of the tensor, where the diagonal of the core is maximized. This "maximal diagonality" for symmetric order-3 [14] and order-4 [7] tensors and for general order-3 tensors [15, 24, 35] has been previously investigated and Jacobi algorithms were used in the cited papers, but our discussion is in a more general context and the proposed algorithm is not of a Jacobi type.

2. Tensor algebra. In this section, we briefly review some concepts and notions that are used throughout the paper. A *tensor* is a multidimensional array of data whose elements are referred by using multiple indices. The number of indices required

[2]For discussions of orthogonality, see section 2.4.

is called the *order* of a tensor. We use

$$\mathcal{A} = (a_{i_1,i_2,\ldots,i_N}) \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$$

to denote a tensor $\mathcal{A}$ of order N. For $n = 1, 2, \ldots, N$, d_n is the nth *dimension* of $\mathcal{A}$. As a special case, a vector is an order-1 tensor and a matrix is an order-2 tensor.

2.1. Unfoldings and mode-n products. It is hard to visualize tensors of order $N > 3$. They can be flexibly represented when "unfolded" into matrices. The *unfolding* of a tensor along *mode* n is a matrix of dimension $d_n \times (d_{n+1} \cdots d_N d_1 \cdots d_{n-1})$. We denote the mode-$n$ unfolding of tensor $\mathcal{A}$ by $A_{(n)}$. Each column of $A_{(n)}$ is a column of $\mathcal{A}$ along the nth mode.

An important operation for a tensor is the *tensor-matrix multiplication*, also known as *mode-n product*. Given a tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ and a matrix $M \in \mathbb{R}^{c_n \times d_n}$, the mode-$n$ product is a tensor

$$\mathcal{B} = \mathcal{A} \times_n M \in \mathbb{R}^{d_1 \times \cdots \times d_{n-1} \times c_n \times d_{n+1} \cdots \times d_N},$$

where

$$b_{i_1,\ldots,i_{n-1},j_n,i_{n+1},\ldots,i_N} := \sum_{i_n=1}^{d_n} a_{i_1,\ldots,i_{n-1},i_n,i_{n+1},\ldots,i_N} m_{j_n,i_n}$$

for $j_n = 1, 2, \ldots, c_n$. In matrix representation, this is

$$B_{(n)} = M A_{(n)}. \tag{2.1}$$

2.2. Inner products and tensor norms. The *inner product* of two tensors $\mathcal{A}$ and $\mathcal{B}$ of the same size is defined by

$$\langle \mathcal{A}, \mathcal{B} \rangle_F := \sum_{i_N=1}^{d_N} \cdots \sum_{i_1=1}^{d_1} a_{i_1,\ldots,i_N} b_{i_1,\ldots,i_N},$$

and the *norm* induced from this inner product is

$$\|\mathcal{A}\|_F := \sqrt{\langle \mathcal{A}, \mathcal{A} \rangle_F}.$$

We say that $\mathcal{A}$ is a *unit tensor* if $\|\mathcal{A}\|_F = 1$. When $N = 2$, $\|\mathcal{A}\|_F$ is the Frobenius norm of matrix $\mathcal{A}$. The norm of a tensor is equal to the Frobenius norm of the unfolding of the tensor along any mode:

$$\|\mathcal{A}\|_F = \|A_{(n)}\|_F \quad \text{for } n = 1, \ldots, N.$$

2.3. Tensor products and outer products of vectors. The *tensor product* of an order-N tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ and an order-N' tensor $\mathcal{B} \in \mathbb{R}^{c_1 \times c_2 \times \cdots \times c_{N'}}$ is an order-$(N + N')$ tensor

$$\mathcal{C} = \mathcal{A} \otimes \mathcal{B} \in \mathbb{R}^{d_1 \times \cdots \times d_N \times c_1 \times \cdots \times c_{N'}},$$

where

$$c_{i_1,\ldots,i_N,j_1,\ldots,j_{N'}} := a_{i_1,\ldots,i_N} b_{j_1,\ldots,j_{N'}}.$$

Note that the operator $\otimes$ for tensor products unfortunately coincides with the one used to denote the Kronecker product of two matrices. In particular, the tensor product of two matrices (order-2 tensors) is an order-4 tensor, while the Kronecker product of two matrices is again a matrix. The reader shall not be confused by this notation since in this paper Kronecker products are not involved.

The *outer product* of N (column) vectors, which generalizes the standard outer product of two vectors (a rank-1 matrix), is a special case of tensor products. The outer product of N vectors $x^{(n)} \in \mathbb{R}^{d_n}$ is an order-N tensor of dimension $d_1 \times d_2 \times \cdots \times d_N$:

$$\mathcal{X} = x^{(1)} \otimes x^{(2)} \otimes \cdots \otimes x^{(N)}.$$

The $(i_1, i_2, \ldots, i_N)$-entry of $\mathcal{X}$ is $\prod_{n=1}^{N} (x^{(n)})_{i_n}$, where $(x^{(n)})_{i_n}$ denotes the i_nth entry of vector $x^{(n)}$. The tensor $\mathcal{X}$ is also called a *rank*-1 *tensor*. The *rank* of a tensor is defined in section 3.

It can be verified that the mode-n product of a rank-1 tensor $\mathcal{X}$ with a matrix M can be computed as follows:

$$\mathcal{X} \times_n M = x^{(1)} \otimes \cdots \otimes x^{(n-1)} \otimes \left(M x^{(n)}\right) \otimes x^{(n+1)} \cdots \otimes x^{(N)},$$

and it can be verified that the inner product of $\mathcal{X}$ with a general tensor $\mathcal{A}$ is

$$\begin{aligned} \langle \mathcal{A}, \mathcal{X} \rangle_F &= \left\langle \mathcal{A}, x^{(1)} \otimes x^{(2)} \otimes \cdots \otimes x^{(N)} \right\rangle_F \\ &= \mathcal{A} \times_1 x^{(1)^T} \times_2 x^{(2)^T} \times \cdots \times_N x^{(N)^T}. \end{aligned}$$

If $\mathcal{U} = u^{(1)} \otimes u^{(2)} \otimes \cdots \otimes u^{(N)}$ and $\mathcal{V} = v^{(1)} \otimes v^{(2)} \otimes \cdots \otimes v^{(N)}$ are two rank-1 tensors, then

$$\langle \mathcal{U}, \mathcal{V} \rangle_F = \prod_{n=1}^{N} \left\langle u^{(n)}, v^{(n)} \right\rangle,$$

where $\langle \cdot, \cdot \rangle$ denotes the standard Euclidean inner product of two vectors. A consequence of the above relation is that $\|\mathcal{U}\|_F$ is the product of the 2-norms of the vectors $u^{(n)}$'s.

2.4. Orthogonality of tensors. Two tensors $\mathcal{A}$ and $\mathcal{B}$ of the same size are *F-orthogonal* (*Frobenius orthogonal*) if their inner product is zero, i.e.,

$$\langle \mathcal{A}, \mathcal{B} \rangle_F = 0.$$

For rank-1 tensors $\mathcal{U} = u^{(1)} \otimes u^{(2)} \otimes \cdots \otimes u^{(N)}$ and $\mathcal{V} = v^{(1)} \otimes v^{(2)} \otimes \cdots \otimes v^{(N)}$, the above definition implies that they are F-orthogonal if

$$\prod_{n=1}^{N} \left\langle u^{(n)}, v^{(n)} \right\rangle = 0.$$

This leads to other options for defining orthogonality for two rank-1 tensors. The paper [28] discussed two cases:

1. Complete orthogonality: $\left\langle u^{(n)}, v^{(n)} \right\rangle = 0$ for all $n = 1, \ldots, N$.
2. Strong orthogonality: For all n, either $\left\langle u^{(n)}, v^{(n)} \right\rangle = 0$ or $u^{(n)}$ and $v^{(n)}$ are collinear, but there is at least one ℓ such that $\left\langle u^{(\ell)}, v^{(\ell)} \right\rangle = 0$.

In this paper we will simply use the term *orthogonal* for two outer products that are completely orthogonal (case 1).

2.5. Tensor decompositions. A *decomposition* of a tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ is of the form

$$\mathcal{A} = \mathcal{B} \times_1 S^{(1)} \times_2 S^{(2)} \times \cdots \times_N S^{(N)},$$

where $\mathcal{B} \in \mathbb{R}^{c_1 \times c_2 \times \cdots \times c_N}$ is called the *core tensor*, and $S^{(n)} \in \mathbb{R}^{d_n \times c_n}$ for $n = 1, \ldots, N$ are called *side-matrices*. An illustration is given in Figure 2.1.

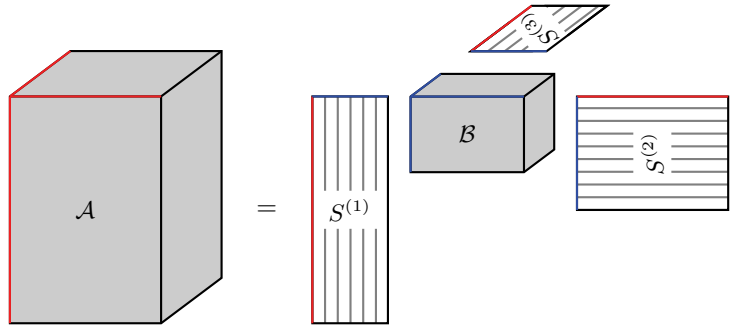

FIG. 2.1. *A decomposition of an order-3 tensor* $\mathcal{A}$ *as* $\mathcal{B} \times_1 S^{(1)} \times_2 S^{(2)} \times_3 S^{(3)}$.

Let $s_i^{(n)}$ be the ith column of $S^{(n)}$. The decomposition of $\mathcal{A}$ can equivalently be written as a linear combination of rank-1 tensors:

$$\mathcal{A} = \sum_{i_N=1}^{c_N} \cdots \sum_{i_1=1}^{c_1} b_{i_1,i_2,\ldots,i_N} s_{i_1}^{(1)} \otimes s_{i_2}^{(2)} \otimes \cdots \otimes s_{i_N}^{(N)}. \tag{2.2}$$

In particular, if $\mathcal{B}$ is diagonal, i.e., $b_{i_1,i_2,\ldots,i_N} = 0$ except when $i_1 = i_2 = \cdots = i_N$, then

$$\mathcal{A} = \sum_{i=1}^{r} b_{ii\ldots i} s_i^{(1)} \otimes s_i^{(2)} \otimes \cdots \otimes s_i^{(N)}, \tag{2.3}$$

where $r = \min\{c_1, \ldots, c_N\}$.

In the literature, the term "decomposition" is often used when "approximation" is meant instead. The *Tucker*3 *decomposition* is an approximation in the form of the right-hand side of (2.2), for given dimensions $c_1, c_2, \ldots, c_N$. Usually, it is required that c_n is less than the rank of $A_{(n)}$ for all n; otherwise the problem is trivial. The HOOI approach computes this approximation with an additional property that all the $S^{(n)}$'s are orthogonal matrices. The *CANDECOMP/PARAFAC decomposition* is an approximation in the form of the right-hand side of (2.3), for a prespecified r. Usually, r is smaller than the smallest dimension of all modes of $\mathcal{A}$, although requiring a larger r is also possible in the ALS and other algorithms. As will be discussed in the next section, the smallest r that satisfies equality (2.3) is the rank of the tensor $\mathcal{A}$.

3. Tensor ranks. The rank of a tensor causes difficulties when attempting to generalize matrix properties to tensors. There are several possible generalizations of the notion of rank. The *n-rank* of a tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$, for $n = 1, \ldots, N$, denoted by $\operatorname{rank}_n(\mathcal{A})$, is the rank of the unfolding $A_{(n)}$:

$$\operatorname{rank}_n(\mathcal{A}) := \operatorname{rank}(A_{(n)}).$$

The *(outer-product) rank* of $\mathcal{A}$, denoted by $\operatorname{rank}(\mathcal{A})$, is defined as

$$\operatorname{rank}(\mathcal{A}) := \min\left\{ r \,\middle|\, \exists\, x_i^{(n)} \in \mathbb{R}^{d_n},\ \ i = 1, \ldots, r,\ \ n = 1, \ldots, N, \right.$$
$$\left. \text{s.t. } \mathcal{A} = \sum_{i=1}^{r} x_i^{(1)} \otimes x_i^{(2)} \otimes \cdots \otimes x_i^{(N)} \right\}.$$

Hence, a tensor is the outer product of N vectors if and only if it has rank one, and the rank of a general tensor $\mathcal{A}$ is the minimum number of rank-1 tensors that sum to $\mathcal{A}$.

There are a few notable differences between the notion of rank for matrices and that for tensors:

1. For $N = 2$, i.e., when $\mathcal{A}$ is a matrix, $\operatorname{rank}_1(\mathcal{A})$ is the row rank, $\operatorname{rank}_2(\mathcal{A})$ is the column rank, and $\operatorname{rank}(\mathcal{A})$ is the outer-product rank, and they are all equal. However, for higher order tensors ($N > 2$), in general, the n-ranks are different for different modes n, and they are different from $\operatorname{rank}(\mathcal{A})$ [12]. Furthermore, the rank of a matrix A cannot be larger than the smallest dimension of both modes of A, but for tensors this is no longer true; i.e., the rank can be larger than the smallest dimension of the tensor [12].

2. The matrix SVD yields one possible way of writing a matrix as a sum of outer-product terms, and the number of nonzero singular values is equal to the rank of the matrix. However, a tensor SVD does not always exist (see section 4), but if it indeed does, it is unique up to signs [34, 43] and the number of singular values is equal to the rank of the tensor (see Definition 4.1 and Proposition 4.2).

3. It is well known that the optimal rank-r approximation of a matrix is simply its truncated SVD. However, some tensors may fail to have an optimal rank-r approximation [17]. If such an approximation exists, then it is unclear whether it can be written in the form of a diagonal core multiplied by orthogonal side-matrices.

Next are some lemmas and a theorem related to tensor ranks, which were also given in [17]. They are useful in deriving the results in section 4. The first lemma indicates that the rank of a tensor cannot be smaller than any of its n-ranks.

LEMMA 3.1. *Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ be an order-N tensor. Then*

$$\operatorname{rank}_n(\mathcal{A}) \leq \min\{\operatorname{rank}(\mathcal{A}), d_n\} \quad \textit{for } n = 1, 2, \ldots, N.$$

The next lemma illustrates a way to construct higher order tensors while preserving the rank.

LEMMA 3.2. *Let $\mathcal{A}$ be a tensor and x be a nonzero vector. Then*

$$\operatorname{rank}(\mathcal{A}) = \operatorname{rank}(\mathcal{A} \otimes x).$$

The following lemma indicates that given any dimension $d_1 \times d_2 \times \cdots \times d_N$, we can construct a tensor of arbitrary rank $R \leq \min\{d_1, d_2, \ldots, d_N\}$.

LEMMA 3.3. *For $n = 1, \ldots, N$, let $x_1^{(n)}, \ldots, x_R^{(n)} \in \mathbb{R}^{d_n}$ be linearly independent. Then the tensor*

$$\mathcal{A} = \sum_{i=1}^{R} x_i^{(1)} \otimes x_i^{(2)} \otimes \cdots \otimes x_i^{(N)}$$

has rank R.

The next theorem is due to JáJá and Takche [23]. They showed that if $\mathcal{A}$ and $\mathcal{B}$ are order-3 tensors and at least one of them is a "stack" of two matrices, then the rank of their direct sum is equal to the sum of their ranks.

THEOREM 3.4 (JáJá–Takche). *Let* $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ *and* $\mathcal{B} \in \mathbb{R}^{c_1 \times c_2 \times c_3}$. *If* $2 \in \{d_1, d_2, d_3, c_1, c_2, c_3\}$, *then*

$$\operatorname{rank}(\mathcal{A} \oplus \mathcal{B}) = \operatorname{rank}(\mathcal{A}) + \operatorname{rank}(\mathcal{B}).$$

3.1. The ill-posedness of the optimal low rank approximation problem. de Silva and Lim [17] proved that for any order $N \geq 3$ and dimensions $d_1, \ldots, d_N \geq 2$, there exists a rank-$(r+1)$ tensor that has no optimal rank-r approximation, for any $r = 2, \ldots, \min\{d_1, \ldots, d_N\}$. This result was further generalized to an arbitrary rank gap, i.e., there exists a rank-$(r+s)$ tensor that has no optimal rank-r approximation, for some r's and s's.

Essentially, this ill-posedness of the optimal approximation problem is illustrated by the fact that the tensor

$$\mathcal{E} := e_2 \otimes e_1 \otimes e_1 + e_1 \otimes e_2 \otimes e_1 + e_1 \otimes e_1 \otimes e_2 \in \mathbb{R}^{2\times 2\times 2},$$

where e_i is the ith column of the identity matrix, has rank 3 but can be approximated arbitrarily closely by rank-at-most-2 tensors. Hence $\mathcal{E}$ does not have an optimal rank-2 approximation. Then according to Theorem 3.4 and Lemma 3.2, the ill-posedness of the problem can be generalized to arbitrary rank and order, by constructing higher rank and higher order tensors using direct sums and tensor products. We restate one of the results of [17] in the following theorem. For details of the proof, see the original paper.

THEOREM 3.5. *For* $N \geq 3$ *and* $d_1, d_2, \ldots, d_N \geq 2$, *there exists a tensor* $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ *of rank* $r+s$ *that has no optimal rank-*r *approximation, for any* r *and* $s \geq 1$ *satisfying* $2s \leq r \leq \min\{d_1, d_2, \ldots, d_N\}$.

4. The tensor SVD and its (non-)existence. The definition used for the SVD of a tensor generalizes the matrix SVD from the angle of an expansion of outer product matrices, which becomes an expansion into a sum of rank-1 tensors.

DEFINITION 4.1. *If a tensor* $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ *can be written in the form*

$$\mathcal{A} = \sum_{i=1}^{R} \sigma_i u_i^{(1)} \otimes u_i^{(2)} \otimes \cdots \otimes u_i^{(N)}, \tag{4.1}$$

where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_R > 0$ *and* $\langle u_j^{(n)} u_k^{(n)} \rangle = \delta_{jk}$ *(Kronecker delta) for* $n = 1, 2, \ldots, N$, *then* (4.1) *is said to be the* tensor singular value decomposition (tensor SVD) *of* $\mathcal{A}$. *The* σ_i*'s are* singular values *and the* $u_i^{(n)}$*'s for* $i = 1, \ldots, R$ *are the mode-*n singular vectors.

We also call (4.1) the *SVD* of tensor $\mathcal{A}$ for short where there is no ambiguity about tensors and matrices. In fact, when $N = 2$, i.e., $\mathcal{A}$ is a matrix, the tensor SVD of $\mathcal{A}$ boils down to the matrix SVD. Expression (4.1) can equivalently be written in the form

$$\mathcal{A} = \mathcal{D} \times_1 U^{(1)} \times_2 U^{(2)} \times \cdots \times_N U^{(N)}, \tag{4.2}$$

where $\mathcal{D} \in \mathbb{R}^{R \times R \times \cdots \times R}$ is the diagonal *core tensor* with $\mathcal{D}_{ii\ldots i} = \sigma_i$, and

$$U^{(n)} = \left[u_1^{(n)}, u_2^{(n)}, \ldots, u_R^{(n)} \right] \in \mathbb{R}^{d_n \times R} \tag{4.3}$$

are orthogonal matrices for $n = 1, 2, \ldots, N$. The following proposition indicates that the tensor SVD is rank revealing.

PROPOSITION 4.2. *If a tensor $\mathcal{A}$ has the SVD as* (4.1)*, then* $\operatorname{rank}(\mathcal{A}) = R$.

Proof. This follows from Lemma 3.3. ∎

Trivially, if a tensor is constructed as in (4.1), then its SVD exists. However, in general, a tensor of order $N \geq 3$ may fail to have such a decomposition. In this section, we identify some of these situations.

To begin with, note that the orthogonality of each $U^{(n)}$ implies that $R \leq d_n$ for each n, i.e., $R \leq \min\{d_1, d_2, \ldots, d_N\}$. This leads to the following simple result.

PROPOSITION 4.3. *A tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ with* $\operatorname{rank}(\mathcal{A}) > \min\{d_1, d_2, \ldots, d_N\}$ *does not admit a tensor SVD.*

Proof. The existence of a tensor SVD such as in (4.1) would trivially lead to a contradiction since the tensor in (4.1) has rank R with $R \leq \min\{d_1, d_2, \ldots, d_N\}$. ∎

Note that Theorem 3.5 guarantees that the condition of Proposition 4.3 is not vacuously satisfied, for any order $N \geq 3$ and dimensions $d_1, d_2, \ldots, d_N \geq 2$.

COROLLARY 4.4. *Given a tensor $\mathcal{A}$ satisfying the condition in Proposition* 4.3*, any tensor of the form*

$$\mathcal{A} \otimes x^{(N+1)} \otimes \cdots \otimes x^{(N+\ell)},$$

where $\ell \geq 1$ and $x^{(N+1)}, \ldots, x^{(N+\ell)}$ are nonzero vectors, does not admit a tensor SVD.

Proof. This follows from Proposition 4.3 and Lemma 3.2. ∎

COROLLARY 4.5. *A tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ does not admit a tensor SVD if there exists at least one mode n such that* $\operatorname{rank}_n(\mathcal{A}) > \min\{d_1, d_2, \ldots, d_N\}$.

Proof. This follows from Proposition 4.3 and Lemma 3.1. ∎

PROPOSITION 4.6. *There exists a tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ which does not admit a tensor SVD whenever*

$$d := \max_n\{d_n\} > \min_n\{d_n\} \quad \text{and} \quad d^2 \leq \prod_{n=1}^{N} d_n.$$

Proof. Without loss of generality, assume that $d = d_1 \geq d_2 \geq \cdots \geq d_N$ and let $d' = d_2 \times \cdots \times d_N$. Since $d \leq d'$, for an arbitrary set of orthonormal vectors $\{a_i \in \mathbb{R}^{d'} \mid i = 1, \ldots, d\}$, we can construct a tensor $\mathcal{A}$ whose unfolding $A_{(1)} = [a_1, a_2, \ldots, a_d]^T$. Then $\operatorname{rank}_1(\mathcal{A}) = d$. By Corollary 4.5, $\mathcal{A}$ does not admit a tensor SVD. ∎

Note that when $N = 2$, i.e., for the matrix case, it is impossible for d_1 and d_2 to satisfy the condition in the proposition.

In closing this section, we provide a necessary and sufficient condition to characterize the existence of the tensor SVD.[3] This is related to the HOSVD proposed by [12]. The essential relation underlying the theorem is that the mode-n singular vectors of $\mathcal{A}$, when its SVD exists, are also the left singular vectors of the unfolding $A_{(n)}$.

THEOREM 4.7. *A tensor $\mathcal{A}$ admits an SVD if and only if there exists an HOSVD of $\mathcal{A}$ such that the core is diagonal.*

Proof. The sufficient condition is obvious. Consider the necessary condition. If $\mathcal{A}$ can be written in the form (4.1), then define the tensor

$$\mathcal{W}_i^{(n)} := u_i^{(n+1)} \otimes \cdots \otimes u_i^{(N)} \otimes u_i^{(1)} \otimes \cdots \otimes u_i^{(n-1)},$$

[3] As pointed out by a referee, the provided relation may have long been recognized in other fields of research, such as signal processing, at least in the case of distinct singular values.

and let $w_i^{(n)}$ be the vectorization of $\mathcal{W}_i^{(n)}$. Then the unfolding of $\mathcal{A}$ along mode n is

$$A_{(n)} = \sum_{i=1}^{R} \sigma_i u_i^{(n)} \otimes w_i^{(n)}.$$

Since $\langle u_j^{(n)} u_k^{(n)} \rangle = \delta_{jk}$ for all n, we have $\langle w_j^{(n)} w_k^{(n)} \rangle = \delta_{jk}$. Hence the above form is the SVD of matrix $A_{(n)}$. In other words, the vectors $u_1^{(n)}, \ldots, u_R^{(n)}$ are the left singular vectors of $A_{(n)}$. From the construction of the HOSVD, (4.2) is a valid HOSVD for $\mathcal{A}$.[4] □

The proof of the above theorem indicates that if the SVD of a tensor $\mathcal{A}$ exists, then its singular values coincide with the nonzero mode-n singular values in its HOSVD. However, the HOSVD of a tensor may not be unique, since the SVD of the unfoldings $A_{(n)}$'s are not guaranteed to be unique. Hence even if a tensor is constructed as in (4.1), its HOSVD will not necessarily recover this form. This is the reason why in the above theorem we use the phase "... if there exists ...."

It is interesting to note again that the nonuniqueness of matrix SVD is caused by duplicate singular values; however, the tensor SVD is unique (if it exists) even when some of the singular values are the same [43, Theorem 3.2].

5. The optimal low rank orthogonal approximation. The problem addressed by tensor analysis is to approximate some tensor $\mathcal{A}$ by a linear combination of tensors $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_r$ that have "special" structures, e.g., rank-1 tensors, orthogonal tensors, or simple tensors.[5] For this it is desirable to minimize

$$\left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F$$

for a given r. Without loss of generality, we assume that $\|\mathcal{T}_i\|_F = 1$ for all i. As discussed in section 3.1, if the $\mathcal{T}_i$'s are rank-1 tensors, then the infimum of the above expression might not necessarily be attained. The following proposition reveals some properties when the infimum is indeed achieved.

PROPOSITION 5.1. *Given a tensor $\mathcal{A}$ and a positive integer r, consider a set of linear combinations of tensors of the form*

$$\mathcal{T} := \sum_{i=1}^{r} \sigma_i \mathcal{T}_i, \tag{5.1}$$

where the $\mathcal{T}_i$'s are arbitrary unit tensors. If $\inf \|\mathcal{A} - \mathcal{T}\|_F$ is reached on this set, then for the optimal $\mathcal{T}$ and $\mathcal{T}_i$'s,

$$\langle \mathcal{A} - \mathcal{T}, \mathcal{T}_i \rangle_F = 0 \quad \text{for } i = 1, 2, \ldots, r.$$

Furthermore, if the $\mathcal{T}_i$'s are required to be mutually F-orthogonal, then the optimal σ_i's are related to the optimal $\mathcal{T}_i$'s by

$$\sigma_i = \langle \mathcal{A}, \mathcal{T}_i \rangle_F \quad \text{for } i = 1, 2, \ldots, r. \tag{5.2}$$

[4] In order to strictly conform to the definition of the HOSVD defined in [12], in (4.2) the size of $\mathcal{D}$ should be enlarged from $R \times R \times \cdots \times R$ to $d_1 \times d_2 \times \cdots \times d_N$ by padding zeros, and the $U^{(n)}$'s should be padded with orthogonal columns to make square shapes.

[5] A tensor is simple if it is the tensor product of two tensors.

In this situation,

$$\|\mathcal{T}\|_F = \sqrt{\sum_{i=1}^{r} \sigma_i^2} \qquad \textit{and} \qquad \|\mathcal{A} - \mathcal{T}\|_F^2 = \|\mathcal{A}\|_F^2 - \|\mathcal{T}\|_F^2 . \tag{5.3}$$

Proof. If the infimum is attained by a certain set of σ_i's and $\mathcal{T}_i$'s, and if there is a j such that $\langle \mathcal{A} - \mathcal{T}, \mathcal{T}_j \rangle_F = \epsilon \neq 0$, then

$$\begin{aligned}
&\left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i - \epsilon \mathcal{T}_j \right\|_F^2 \\
&= \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F^2 - 2\epsilon \left\langle \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i, \mathcal{T}_j \right\rangle_F + \epsilon^2 \|\mathcal{T}_j\|_F^2 \\
&= \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F^2 - \epsilon^2 < \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F^2 ,
\end{aligned}$$

which contradicts the assumption.

If the unit tensors $\mathcal{T}_i$'s are mutually F-orthogonal, then

$$0 = \left\langle \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i, \mathcal{T}_j \right\rangle_F = \langle \mathcal{A}, \mathcal{T}_j \rangle_F - \sigma_j \langle \mathcal{T}_j, \mathcal{T}_j \rangle_F = \langle \mathcal{A}, \mathcal{T}_j \rangle_F - \sigma_j .$$

Also,

$$\|\mathcal{T}\|_F^2 = \langle \mathcal{T}, \mathcal{T} \rangle_F = \sum_{i,j=1}^{r} \langle \sigma_i \mathcal{T}_i, \sigma_j \mathcal{T}_j \rangle_F = \sum_{i=1}^{r} \sigma_i^2$$

and

$$\begin{aligned}
\left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F^2 &= \|\mathcal{A}\|_F^2 - \sum_{i=1}^{r} 2\sigma_i \langle \mathcal{A}, \mathcal{T}_i \rangle_F + \sum_{i=1}^{r} \sigma_i^2 \\
&= \|\mathcal{A}\|_F^2 - \sum_{i=1}^{r} \sigma_i^2 = \|\mathcal{A}\|_F^2 - \|\mathcal{T}\|_F^2 . \qquad \square
\end{aligned}$$

The last part of the proof indicates that the equalities in (5.3) follow from the orthogonality of the $\mathcal{T}_i$'s and the relations (5.2). They do not require optimality.

In this section, we will see that if the $\mathcal{T}_i$'s are mutually orthogonal rank-1 tensors, then the infimum in the proposition can be attained. Formally, we will prove that the problem

$$\begin{aligned}
&\min \quad E := \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i u_i^{(1)} \otimes u_i^{(2)} \otimes \cdots \otimes u_i^{(N)} \right\|_F \\
&\text{s.t.} \quad \left\langle u_j^{(n)}, u_k^{(n)} \right\rangle = \delta_{jk}, \quad \text{for } n = 1, 2, \ldots, N,
\end{aligned} \tag{5.4}$$

has a solution for any $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}$ and any $r \leq \min\{d_1, d_2, \ldots, d_N\}$. The solution for the case $r = \min\{d_1, d_2, \ldots, d_N\}$ leads to a decomposition of $\mathcal{A}$ where the diagonal of the core is maximized.

5.1. Existence of the global optimum. Let

$$\mathcal{T}_i := u_i^{(1)} \otimes u_i^{(2)} \otimes \cdots \otimes u_i^{(N)} \quad \text{for } i = 1, \ldots, r, \tag{5.5}$$

and let σ_i's be defined as in (5.2); then, according to Proposition 5.1 (see comments following the proof),

$$E^2 = \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i \mathcal{T}_i \right\|_F^2 = \|\mathcal{A}\|_F^2 - \sum_{i=1}^{r} \sigma_i^2.$$

Hence minimizing E is equivalent to maximizing $\sum_{i=1}^{r} \sigma_i^2$; i.e., the optimization problem (5.4) is equivalent to the following:

$$\begin{aligned} \max \quad & E' := \sum_{i=1}^{r} \left(\mathcal{A} \times_1 u_i^{(1)^T} \times_2 u_i^{(2)^T} \times \cdots \times_N u_i^{(N)^T} \right)^2 \\ \text{s.t.} \quad & \left\langle u_j^{(n)}, u_k^{(n)} \right\rangle = \delta_{jk} \quad \text{for } n = 1, 2, \ldots, N. \end{aligned} \tag{5.6}$$

Let

$$U^{(n)} = \left[u_1^{(n)}, u_2^{(n)}, \ldots, u_r^{(n)} \right] \in \Omega^{(n)}, \tag{5.7}$$

where

$$\Omega^{(n)} := \{ W \in \mathbb{R}^{d_n \times r} \mid W^T W = I \} \tag{5.8}$$

for $n = 1, 2, \ldots, N$. The problem (5.6) can be interpreted as that of maximizing E' within the feasible region

$$\Omega := \Omega^{(1)} \times \Omega^{(2)} \times \cdots \times \Omega^{(N)}. \tag{5.9}$$

Since for each n the set $\Omega^{(n)}$ is compact (see, e.g., [22, p. 69]), by the Tychonoff theorem, the feasible region Ω is compact. Under the continuous mapping E', the image $E'(\Omega)$ is also compact. Hence it has a maximum. This proves the following theorem.

THEOREM 5.2. *There exists a solution to the problem* (5.6) *(or equivalently* (5.4) *with σ_i defined in* (5.2)*) for any $r \leq \min\{d_1, d_2, \ldots, d_N\}$.*

5.2. Relation to tensor decompositions. Let $U^{(n)}$, $n = 1, \ldots, N$, be the solution to the problem (5.4) with $r = \min\{d_1, d_2, \ldots, d_N\}$ and σ_i be defined in (5.2). Also for $n = 1, \ldots, N$, let $U^{(n)^\perp}$ be a $d_n \times (d_n - r)$ matrix such that the square matrix

$$\tilde{U}^{(n)} := \left[U^{(n)}, U^{(n)^\perp} \right] \in \mathbb{R}^{d_n \times d_n} \tag{5.10}$$

is orthogonal. Further, define the tensor

$$\mathcal{S} := \mathcal{A} \times_1 \tilde{U}^{(1)^T} \times_2 \tilde{U}^{(2)^T} \times \cdots \times_N \tilde{U}^{(N)^T} \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N}. \tag{5.11}$$

Then the equality

$$\mathcal{A} = \mathcal{S} \times_1 \tilde{U}^{(1)} \times_2 \tilde{U}^{(2)} \times \cdots \times_N \tilde{U}^{(N)} \tag{5.12}$$

holds. This decomposition of $\mathcal{A}$ has the following two properties:

(i) The side-matrices $\tilde{U}^{(n)}$'s are orthogonal.
(ii) The (squared) norm of the diagonal of the core $\mathcal{S}$

$$\sum_{i=1}^{\min\{d_1,\ldots,d_N\}} s_{ii\ldots i}^2 = \sum_{i=1}^{r} \left(\mathcal{A} \times_1 u_i^{(1)^T} \times_2 u_i^{(2)^T} \times \cdots \times_N u_i^{(N)^T} \right)^2 = \sum_{i=1}^{r} \sigma_i^2$$

is maximized among all choices of the orthogonal side-matrices. This is known as *maximal diagonality* in [12].

5.3. First order condition. The Lagrangian of (5.6) is

$$L = \sum_{i=1}^{r} \sigma_i^2 - \sum_{j,k=1}^{r} \sum_{n=1}^{N} \mu_{j,k}^n \left(\left\langle u_j^{(n)}, u_k^{(n)} \right\rangle - \delta_{jk} \right), \tag{5.13}$$

where

$$\sigma_i = \mathcal{A} \times_1 u_i^{(1)^T} \times_2 u_i^{(2)^T} \times \cdots \times_N u_i^{(N)^T} \tag{5.14}$$

and the $\mu_{j,k}^n$'s are Lagrange multipliers. Define the vector

$$\begin{aligned} v_i^{(n)} &:= \mathcal{A} \times_1 u_i^{(1)^T} \times \cdots \times_{n-1} u_i^{(n-1)^T} \times_{n+1} u_i^{(n+1)^T} \times \cdots \times_N u_i^{(N)^T} \\ &\in \mathbb{R}^{1\times\cdots\times 1\times d_n\times 1\cdots\times 1}. \end{aligned} \tag{5.15}$$

(Here we abuse the use of notation "=." More precisely, $v_i^{(n)}$ should be the mode-n unfolding of the tensor on the right-hand side of (5.15).) It is not hard to see that

$$\left\langle u_i^{(n)}, v_i^{(n)} \right\rangle = \sigma_i$$

for all n and i, and $v_i^{(n)}$ is the partial derivative of σ_i with respect to $u_i^{(n)}$.

The partial derivative of the Lagrangian with respect to $u_i^{(n)}$ is

$$\frac{\partial L}{\partial u_i^{(n)}} = 2\sigma_i v_i^{(n)} - \sum_{j=1}^{r} \mu_{j,i}^n u_j^{(n)} - \sum_{k=1}^{r} \mu_{i,k}^n u_k^{(n)}$$

for any n and i. By setting the partial derivatives to 0 and putting all equations related to the same n in matrix form, we obtain the following equations:

$$\begin{bmatrix} v_1^{(n)} & \cdots & v_r^{(n)} \end{bmatrix} \begin{bmatrix} \sigma_1 & & \\ & \ddots & \\ & & \sigma_r \end{bmatrix} = \begin{bmatrix} u_1^{(n)} & \cdots & u_r^{(n)} \end{bmatrix} \begin{bmatrix} \frac{\mu_{1,1}^n + \mu_{1,1}^n}{2} & \cdots & \frac{\mu_{1,r}^n + \mu_{r,1}^n}{2} \\ \vdots & \ddots & \vdots \\ \frac{\mu_{r,1}^n + \mu_{1,r}^n}{2} & \cdots & \frac{\mu_{r,r}^n + \mu_{r,r}^n}{2} \end{bmatrix} \tag{5.16}$$

for all $n = 1, 2, \ldots, N$. Let

$$V^{(n)} := \left[v_1^{(n)}, v_2^{(n)}, \ldots, v_r^{(n)} \right], \tag{5.17}$$

$$\Sigma := \operatorname{diag}(\sigma_1, \ldots, \sigma_r), \tag{5.18}$$

and let $M^{(n)}$ be the second term on the right-hand side of (5.16). Then (5.16) is compactly represented as

$$V^{(n)}\Sigma = U^{(n)}M^{(n)}, \quad n = 1, 2, \ldots, N. \tag{5.19}$$

In summary, the necessary condition of an extremum of the Lagrangian is (5.19), where $V^{(n)}$ is defined in (5.17), Σ is defined in (5.18), $U^{(n)}$ is defined in (5.7), and $M^{(n)}$ is symmetric, for all $n = 1, 2, \ldots, N$.

5.4. Algorithm: LROAT. We seek orthogonal matrices $U^{(n)}$'s and symmetric matrices $M^{(n)}$'s which satisfy the system (5.19). (The Σ and $V^{(n)}$'s are computed from the $U^{(n)}$'s.) Note that the pair $U^{(n)}, M^{(n)}$ happens to be the polar decomposition of the matrix $V^{(n)}\Sigma$. Hence the system can be solved in an iterative fashion: We begin with an initial guess of the set of orthogonal matrices $\{U^{(1)}, U^{(2)}, \ldots, U^{(N)}\}$, which can be obtained, say, by the HOSVD of $\mathcal{A}$. For each n, we compute $V^{(n)}$ and Σ, and update $U^{(n)}$ as an orthogonal polar factor of $V^{(n)}\Sigma$. This procedure is iterated until convergence is observed. Algorithm 1 (LROAT) summarizes this idea.

ALGORITHM 1. Low Rank Orthogonal Approximation of Tensors (LROAT)

Input: Tensor $\mathcal{A}$, rank r, orthogonal matrices $U^{(1)}, \ldots, U^{(N)}$ as initial guess
Output: $\sigma_1, \ldots, \sigma_r$, $U^{(1)}, \ldots, U^{(N)}$

```
repeat
  for n ← 1, ..., N do
    Compute V^(n) = [v_1^(n), ..., v_r^(n)] according to (5.15)
    Compute Σ = diag(σ_1, ..., σ_r) according to (5.14)
    [Q^(n), H^(n)] ← polar-decomp(V^(n)Σ)
    Update U^(n) ← Q^(n)
  end for
until convergence
```

Note that when $r = 1$, the matrix $V^{(n)} = [v_1^{(n)}]$ and $U^{(n)} = [u_1^{(n)}]$, which means that for each iteration $u_1^{(n)}$ is updated as the normalized $v_1^{(n)}$. This indicates that the LROAT algorithm for $r = 1$ boils down to the ALS method [43] (or the so-called higher order power method [13, 27]) for computing the optimal rank-1 approximation. Hence, it is not unexpected to see in the numerical experiments that in general LROAT converges linearly. We also comment that LROAT is not an ALS method (except for the case $r = 1$) by the nature of the update of $U^{(n)}$.

5.5. Convergence analysis. LROAT employs an alternating procedure (iterating through $U^{(1)}$, $U^{(2)}, \ldots,$ $U^{(N)}$), where in each step all but one of the $(U^{(n)})$ parameters are fixed. In general, algorithms of this type, including ALS, are not guaranteed to converge. Specifically, the objective function may converge but not the parameters. (See, for example, [32] for some discussions.) For LROAT, we are also unable yet to prove the global convergence, though empirically it appears to hold. However, in this section, we will prove the following: (1) the iterations monotonically increase the objective value E' (Theorem 5.4); (2) under a mild condition, of the generated parameter sequence, every converging subsequence converges to a stationary point of the objective function (Theorem 5.7); and (3) in a neighborhood of a local maximum, the parameter sequence converges to this stationary point (Theorem 5.9).

Before analyzing the convergence behavior of LROAT, we index all of the iterates. The outer loop is indexed by p and the overall iterations are indexed by idx, which is equal to $n+(p-1)N$. In other words, Algorithm 1 is rewritten as follows. In particular, the numbered lines correspond to the lines in Algorithm 1.

---

for $p \leftarrow 1, 2, \ldots$ **do**
  for $n \leftarrow 1, \ldots, N$ **do**
    $idx = n + (p-1)N$
    For all i, compute $\sigma_i^{(idx)}$ according to $U_{(p+1)}^{(1)}, \ldots, U_{(p+1)}^{(n-1)}, U_{(p)}^{(n)}, U_{(p)}^{(n+1)}, \ldots, U_{(p)}^{(N)}$
    Objective $E'^{(idx)} = \sum_{i=1}^{r} \left(\sigma_i^{(idx)}\right)^2$
3: Compute $V_{(p)}^{(n)}$ from $U_{(p+1)}^{(1)}, \ldots, U_{(p+1)}^{(n-1)}, U_{(p)}^{(n+1)}, \ldots, U_{(p)}^{(N)}$
4: Assign $\Sigma^{(idx)} = \operatorname{diag}\left(\sigma_1^{(idx)}, \ldots, \sigma_r^{(idx)}\right)$
5: Polar decomposition $V_{(p)}^{(n)}\Sigma^{(idx)} = Q_{(p)}^{(n)}H_{(p)}^{(n)}$
6: Update $U_{(p+1)}^{(n)} = Q_{(p)}^{(n)}$
  end for
end for

The following lemma, which is well known when the matrix A is square, reveals the trace maximizing property that is important for the convergence analysis of LROAT.

LEMMA 5.3. *Let matrix $A \in \mathbb{R}^{m\times n}$, $m \geq n$, have the polar decomposition $A = QH$, where $Q \in \mathbb{R}^{m\times n}$ is the orthogonal polar factor and $H \in \mathbb{R}^{n\times n}$ is the symmetric positive semidefinite factor; then*

$$\max_{P\in\mathbb{R}^{m\times n},\, P^TP=I} \operatorname{tr}(P^TA)$$

is attained when $P = Q$.

Proof. Any P can be written as ZQ, where $Z \in \mathbb{R}^{m\times m}$ is orthogonal. Then

$$\operatorname{tr}(P^TA) = \operatorname{tr}(Q^TZ^TQH) = \operatorname{tr}(Z^TQHQ^T).$$

Since QHQ^T is symmetric positive semidefinite, $\max \operatorname{tr}(Z^TQHQ^T)$ is attained when $Z = I$. ∎

Since $U_{(p+1)}^{(n)}$ is the orthogonal polar factor of $V_{(p)}^{(n)}\Sigma^{(idx)}$, by Lemma 5.3,

$$\sum_{i=1}^{r}\left(\sigma_i^{(idx)}\right)^2 = \operatorname{tr}\left(U_{(p)}^{(n)^T}V_{(p)}^{(n)}\Sigma^{(idx)}\right) \leq \operatorname{tr}\left(U_{(p+1)}^{(n)^T}V_{(p)}^{(n)}\Sigma^{(idx)}\right) = \sum_{i=1}^{r}\sigma_i^{(idx+1)}\sigma_i^{(idx)}.$$

Then, by the Cauchy–Schwarz inequality,

$$\sum_{i=1}^{r}\left(\sigma_i^{(idx)}\right)^2 \leq \sum_{i=1}^{r}\sigma_i^{(idx+1)}\sigma_i^{(idx)} \leq \sum_{i=1}^{r}\left(\sigma_i^{(idx+1)}\right)^2, \tag{5.20}$$

and

$$\sum_{i=1}^{r}\left(\sigma_i^{(idx)}\right)^2 = \sum_{i=1}^{r}\left(\sigma_i^{(idx+1)}\right)^2 \quad \text{iff} \quad \sigma_i^{(idx)} = \sigma_i^{(idx+1)} \text{ for all } i. \tag{5.21}$$

Inequality (5.20) means that each update of $U^{(n)}$ increases the value of the objective function E', i.e.,

$$E'^{(idx)} \leq E'^{(idx+1)}.$$

Since E' is bounded from above (existence of the maximum; see Theorem 5.2), the sequence $\{E'^{(idx)}\}_{idx=1}^{\infty}$ converges. Note that the convergence does not depend on the initial guess input to the algorithm. Formally, we have established the following theorem.

THEOREM 5.4. *Given any initial guess, the iterations of Algorithm* 1 *monotonically increase the objective function E' defined in* (5.6) *to a limit.*

The convergence of the objective function does not necessarily imply that the function parameters will converge. However, in our case, since the parameters $U^{(n)}$'s are bounded, they admit converging subsequences. Next we will show that every such subsequence converges to a stationary point of E'. For this, the following lemma uses a helper function f.

LEMMA 5.5. *Let $T : \Theta \to \Theta$ be a continuous mapping and a sequence $\{\theta_n \in \Theta\}_{n=1}^{\infty}$ be generated from the fixed point iteration $\theta_{n+1} = T(\theta_n)$. If there exists a continuous function $f : \Theta \to \mathbb{R}$ satisfying that*

(i) *the sequence $\{f(\theta_n)\}_{n=1}^{\infty}$ converges, and*
(ii) *for $\theta \in \Theta$, if $f(T(\theta)) = f(\theta)$, then $T(\theta) = \theta$,*

then every converging subsequence of $\{\theta_n\}_{n=1}^{\infty}$ converges to a fixed point of T.

Proof. Let $\{\theta_{s_n}\}_{n=1}^{\infty}$ be a converging subsequence of $\{\theta_n\}_{n=1}^{\infty}$, where $\theta_{s_n} \to \theta^*$. Also let f^* be the limit of $f(\theta_n)$. Then $f(\theta_{s_n}) \to f(\theta^*)$; therefore $f(\theta^*) = f^*$. Meanwhile, from the continuity of T and f, we have $T(\theta_{s_n}) \to T(\theta^*)$ and $f(\theta_{s_n+1}) = f(T(\theta_{s_n})) \to f(T(\theta^*))$, which implies that $f(T(\theta^*)) = f^*$. Condition (ii) of the lemma now implies that $\theta^* = T(\theta^*)$. ∎

Our objective function E' is just one such helper function f, and the orthogonal polar factor function plays the role of the mapping T in the above lemma. The following lemma establishes the fact that the orthogonal polar factor function is continuous.

LEMMA 5.6. *The orthogonal polar factor function $g : A \to Q$ defined on the set of matrices with full column rank is continuous. Here Q is the orthogonal polar factor of $A \in \mathbb{R}^{m \times n}$, $m \geq n$.*

Proof. First, function g is well defined, since the orthogonal polar factor of a full rank matrix exists and is unique [21]. When Q and Q' are the orthogonal polar factors of A and A', respectively, Sun and Chen [39] have shown that

$$\|Q - Q'\|_F \leq \frac{2}{\|A^+\|_2} \|A - A'\|_F,$$

where $^+$ means pseudoinverse. Hence if $A_1, A_2, \ldots$ converges to A^*, then $g(A_1)$, $g(A_2), \ldots$ converges to $g(A^*)$. ∎

Now we are ready to prove the following result.

THEOREM 5.7. *Every converging subsequence of $\{U_{(p)}^{(1)}, \ldots, U_{(p)}^{(N)}\}_{p=1}^{\infty}$ generated by Algorithm* 1 *converges to a stationary point of the objective function E' defined in* (5.6)*, provided the matrices $V^{(n)}$ in line* 3 *of the algorithm do not become rank-deficient throughout the iterations.*

Proof. For convenience, let U denote the side-by-side concatenation of the $U^{(n)}$'s; i.e., at iteration number p we write $U_{(p)} := [U_{(p)}^{(1)}, \ldots, U_{(p)}^{(N)}]$. For each iteration, $V_{(p)}^{(n)}\Sigma^{(idx)}$ is computed from $U_{(p)}$ and polar factorized, and $U_{(p)}^{(n)}$ is updated. Let

T be the composite of all of these iterations running n from 1 to N. That is, $U_{(p+1)} = T(U_{(p)})$. It is not hard to see that T is continuous by Lemma 5.6. The objective function E' taking parameter $U_{(p)}$ has been previously shown such that the sequence $\{E'(U_{(p)})\}_{p=1}^{\infty}$ is monotonically converging.

Hence by Lemma 5.5, in order to prove this theorem, it will suffice to show that $E'(T(U)) = E'(U)$ implies $T(U) = U$. Then every converging subsequence of $\{E'(U_{(p)})\}_{p=1}^{\infty}$ converges to a fixed point, which satisfies the first order condition (5.19); i.e., it is also a stationary point of E'.

If $E'(T(U)) = E'(U)$, then formula (5.21) indicates that the σ_i values have not changed after the iteration. In particular, for any n, the update of $U^{(n)}$ has not changed $\mathrm{tr}({U^{(n)}}^T V^{(n)}\Sigma)$. Since the orthogonal polar factor of $V^{(n)}\Sigma$ is unique when $V^{(n)}$ is not rank-deficient, this means that $U^{(n)}$ has not changed. This in turn means that U is a fixed point of the mapping T. ∎

The condition in the theorem is not a strong requirement in general. Of course, the columns $v_i^{(n)}$ of the matrix $V^{(n)}$, as computed from (5.15), will be linearly dependent if the n-rank of $\mathcal{A}$ is less than r. For practical applications, the tensor usually has full n-ranks for all n, so this does not hamper the applicability of the theorem.

Though the global convergence of $\{U_{(p)}\}$ is not determined, when localized, it is possible that this parameter sequence converges. The following lemma and theorems consider this situation.

LEMMA 5.8. *If a sequence $\{\theta_n\}_{n=1}^{\infty}$ is bounded, and all of its converging subsequences converge to θ^*, then $\theta_n \to \theta^*$.*

Proof (by contradiction). If $\{\theta_n\}_{n=1}^{\infty}$ does not converge to θ^*, then there is an $\epsilon > 0$ such that there exists a subsequence $S = \{\theta_{s_n}\}_{n=1}^{\infty}$, where $\|\theta_{s_n} - \theta^*\| \geq \epsilon$ for all n. Since S is bounded, it has a converging subsequence S'. Then S' as a subsequence of $\{\theta_n\}_{n=1}^{\infty}$ converges to a limit other than θ^*. ∎

THEOREM 5.9. *Let $U_* = [U_*^{(1)}, \ldots, U_*^{(N)}]$ be a local maximum of the objective function E' defined in* (5.6)*. If the sequence $\{U_{(p)} := [U_{(p)}^{(1)}, \ldots, U_{(p)}^{(N)}]\}_{p=1}^{\infty}$ generated by Algorithm* 1 *lies in a neighborhood of U_*, where U_* is the only stationary point in that neighborhood, and if the full rank requirement in Theorem* 5.7 *is satisfied, then the sequence $\{U_{(p)}\}_{p=1}^{\infty}$ converges to U_*.*

Proof. This immediately follows from Theorem 5.7 and Lemma 5.8. ∎

Note that since the starting elements of a sequence have no effect on its convergence behavior, the above theorem holds whenever the tailing subsequence, starting from a sufficiently large p, lies within the neighborhood.

A weaker, but simpler, result is the following corollary.

COROLLARY 5.10. *Let $U_* = [U_*^{(1)}, \ldots, U_*^{(N)}]$ be a local maximum of the objective function E' defined in* (5.6)*. If this local maximum is unique and if the full rank requirement in Theorem* 5.7 *is satisfied, then the sequence $\{U_{(p)} := [U_{(p)}^{(1)}, \ldots, U_{(p)}^{(N)}]\}_{p=1}^{\infty}$ generated by Algorithm* 1 *converges to U_*.*

5.6. LROAT for symmetric tensors. An order-N tensor $\mathcal{A} \in \mathbb{R}^{d \times d \times \cdots \times d}$, whose dimensions of all modes are the same, is *symmetric* if, for all permutations π,

$$a_{i_1, i_2, \ldots, i_N} = a_{i_{\pi(1)}, i_{\pi(2)}, \ldots, i_{\pi(N)}}.$$

For symmetric tensors, usually the approximation problem (5.4) has an additional constraint that the side-matrices $U^{(n)}$'s are the same for all n; i.e., the problem

becomes

$$\begin{aligned} \min \quad & E = \left\| \mathcal{A} - \sum_{i=1}^{r} \sigma_i u_i \otimes u_i \otimes \cdots \otimes u_i \right\|_F \\ \text{s.t.} \quad & \langle u_j, u_k \rangle = \delta_{jk}. \end{aligned} \tag{5.22}$$

Applying similar arguments to those in section 5.1, it is easily seen that (5.22) is equivalent to the following problem:

$$\begin{aligned} \max \quad & E' = \sum_{i=1}^{r} \left(\mathcal{A} \times_1 u_i^T \times_2 u_i^T \times \cdots \times_N u_i^T \right)^2 \\ \text{s.t.} \quad & \langle u_j, u_k \rangle = \delta_{jk}. \end{aligned} \tag{5.23}$$

The supremum of E' can be attained. Further, the "maximal-diagonality" decomposition of $\mathcal{A}$ (cf. (5.12)) has an additional property that the core $\mathcal{S}$ is symmetric. Also, the first order condition (5.19) is simplified to

$$V\Sigma = UM.$$

Hence, there are two approaches to compute the approximation for the symmetric tensor $\mathcal{A}$. The first approach is to directly apply LROAT on $\mathcal{A}$. Theorems in the above section guarantee the convergence under mild assumptions, but the side-matrices might no longer be the same, though in the next section an experiment indicates that they indeed converge to the same matrix. The second approach is to only use a single initial guess U and omit the for-loop on n (line 2 of Algorithm 1). We call this the *symmetric variant of LROAT*. In this case Theorem 5.4 no longer holds, i.e., the iterations might not monotonically increase the objective value E' defined in (5.23), since the for-loop on n is omitted. An experiment in the next section shows an oscillating phenomenon, which is similar to the one indicated in Figure 4.1 of [27], for the objective value E'.

6. Numerical experiments. This section will show a few experiments to illustrate the convergence behavior and the approximation quality of LROAT. For comparisons see the ALS methods for Tucker and PARAFAC, whose implementations are based on the codes from the MATLAB Tensor Toolbox developed by Bader and Kolda [2]. We use the major left singular vectors of the unfoldings as the initial guess input for all of the algorithms compared. When it comes to the quality of the final approximation, experience shows that compared with random orthonormal vectors, singular vectors as initial guesses do not offer any advantage. It has been argued that running the algorithms several times using different sets of random initial guess enhances the probability of hitting the global optimum. We use singular vectors here only for repeatability.

6.1. Convergence of LROAT. In the first experiment, we test LROAT (and the symmetric variant of LROAT mentioned in section 5.6) on a few tensors listed in Table 6.1. The results are shown in Figures 6.1 and 6.2. Each row of the figures is one test on a tensor. The left plot shows the objective value E' (the same as the norm of the approximated tensor $\mathcal{T}$) for each iteration p, while the right plot shows the convergence history of the $U^{(n)}$'s. Since the optima are unknown, we plot the values $\|U_{(p)}^{(n)} - U_{(p-1)}^{(n)}\|_F$ to indicate the convergence of the sequence $\{U_{(p)}^{(n)}\}_{p=1,2,\ldots}$. Since

these values are plotted on logarithmic scales, if the curves are bounded from above by a straight decreasing line, then it is indicated that the convergence of the sequence is at least linear.

TABLE 6.1
The tensors used for the first experiment. The value r is the rank input to LROAT; it is not the rank of the tensor.

Tensor	Dimensions	r	Notes
$\mathcal{A}_1$	$20 \times 16 \times 10 \times 32$	5	random tensor
$\mathcal{A}_2$	$20 \times 16 \times 10 \times 32$	5	rank-5 tensor + Gaussian noise
$\mathcal{A}_3$	$10 \times 10 \times 10$	5	the (i,j,k)-entry $= 1/(i^2+j^2+k^2)$
$\mathcal{A}_4$	$3 \times 3 \times 3 \times 3$	2	see [27, Example 1]

Figures 6.1 and 6.2 show a total of five tests. The first test (Figure 6.1(a)) uses a randomly generated tensor $\mathcal{A}_1$. The second test (Figure 6.1(b)) uses a low-rank-plus-Gaussian-noise tensor

$$\mathcal{A}_2 = \mathcal{B}_1 + \rho\mathcal{B}_2,$$

where the low rank tensor $\mathcal{B}_1$ is in the form (2.3) with $r = 5$, the Gaussian noise tensor $\mathcal{B}_2$ has normally distributed elements, and $\rho = 0.1 \|\mathcal{B}_1\|_F / \|\mathcal{B}_2\|_F$. In these two tests the two tensors are applied to the LROAT algorithm. The third test (Figure 6.1(c)) uses a symmetric tensor $\mathcal{A}_3$ with entries

$$(\mathcal{A}_3)_{ijk} = \frac{1}{i^2+j^2+k^2}.$$

In this test $\mathcal{A}_3$ is applied to the symmetric variant of LROAT. All three tests show a linear convergence rate. The fourth (Figure 6.2(a)) and the fifth (Figure 6.2(b)) tests use a symmetric tensor $\mathcal{A}_4$ introduced in [27, Example 1]:

$$\begin{aligned}
&(\mathcal{A}_4)_{1111} = 0.2883, && (\mathcal{A}_4)_{1112} = -0.0031, && (\mathcal{A}_4)_{1113} = 0.1973,\\
&(\mathcal{A}_4)_{1112} = -0.2485, && (\mathcal{A}_4)_{1123} = -0.2939, && (\mathcal{A}_4)_{1133} = 0.3847,\\
&(\mathcal{A}_4)_{1222} = 0.2972, && (\mathcal{A}_4)_{1223} = 0.1862, && (\mathcal{A}_4)_{1233} = 0.0919,\\
&(\mathcal{A}_4)_{1333} = -0.3619, && (\mathcal{A}_4)_{2222} = 0.1241, && (\mathcal{A}_4)_{2223} = -0.3420,\\
&(\mathcal{A}_4)_{2233} = 0.2127, && (\mathcal{A}_4)_{2333} = 0.2727, && (\mathcal{A}_4)_{3333} = -0.3054.
\end{aligned}$$

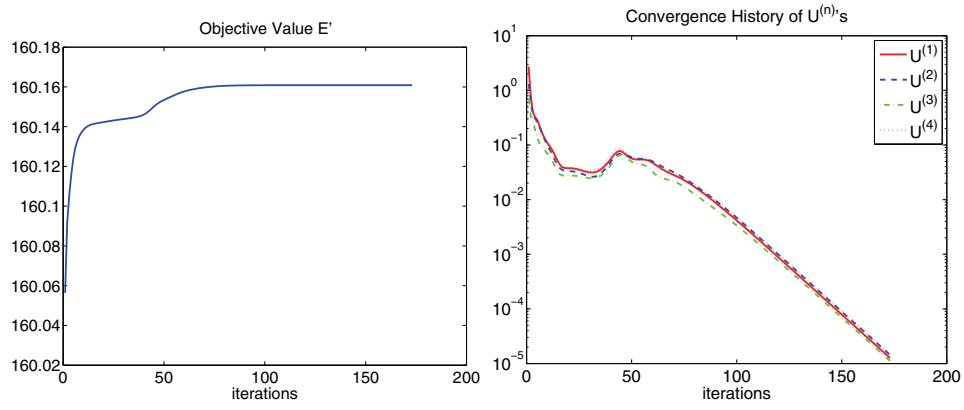
In [27], the symmetric higher order power method for computing the optimal rank-1 approximation of $\mathcal{A}_4$ is shown to be nonconverging. We experiment with this tensor with $r = 2$ on LROAT and the symmetric variant of LROAT. Figure 6.2(a) shows that when applied to LROAT, the approximation to $\mathcal{A}_4$ indeed linearly converges, and what is more, all of the side-matrices converge to the same result. The approximation computed by LROAT is

$$\mathcal{A}_4 \approx \sigma_1 u^{(1)} \otimes u^{(1)} \otimes u^{(1)} \otimes u^{(1)} + \sigma_2 u^{(2)} \otimes u^{(2)} \otimes u^{(2)} \otimes u^{(2)}$$

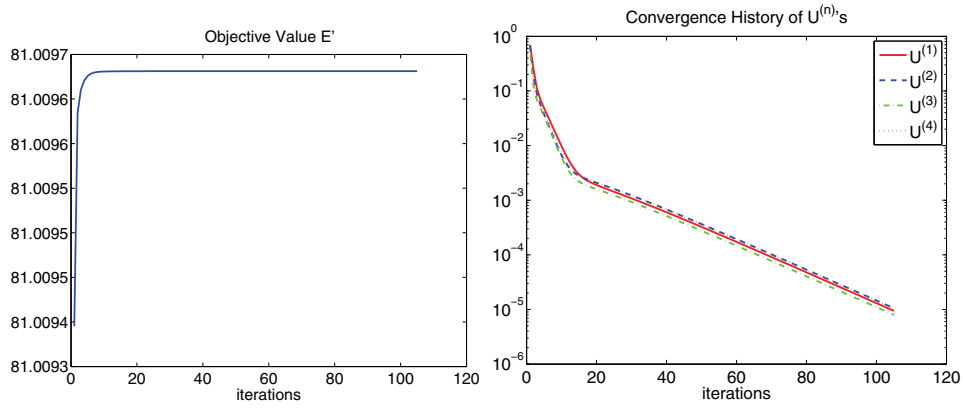
with

$$\begin{aligned}
&\sigma_1 = -1.0939, && u^{(1)} = \begin{bmatrix} -0.5946 & 0.7503 & 0.2890 \end{bmatrix}^T,\\
&\sigma_2 = -0.55594, && u^{(2)} = \begin{bmatrix} 0.1947 & -0.2144 & 0.9572 \end{bmatrix}^T.
\end{aligned}$$

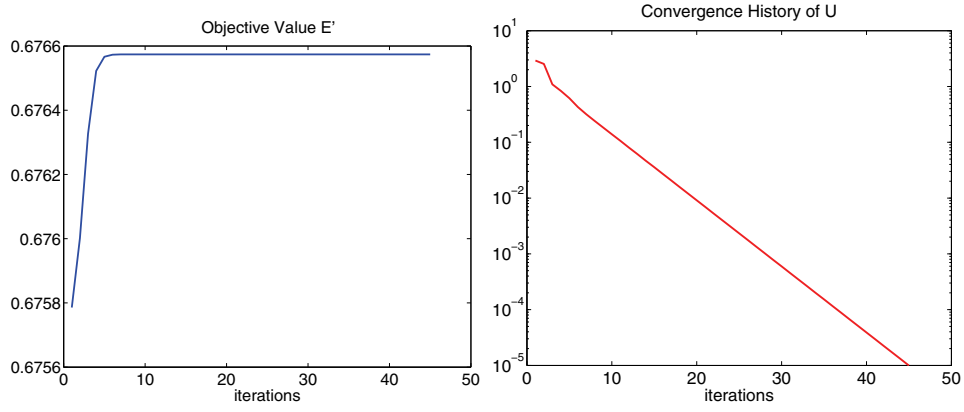
On the other hand, Figure 6.2(b) shows that the symmetric variant of LROAT fails to converge.



(a) Tensor $\mathcal{A}_1$: Randomly generated.

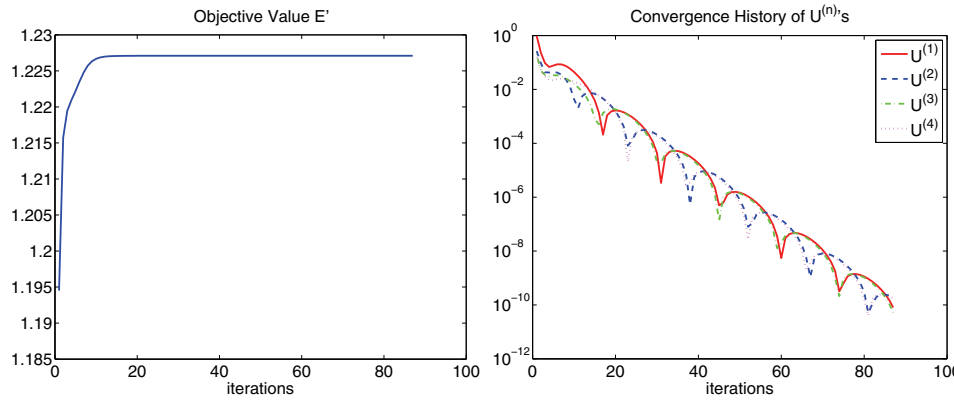


(b) Tensor $\mathcal{A}_2$: Low rank plus Gaussian noise.

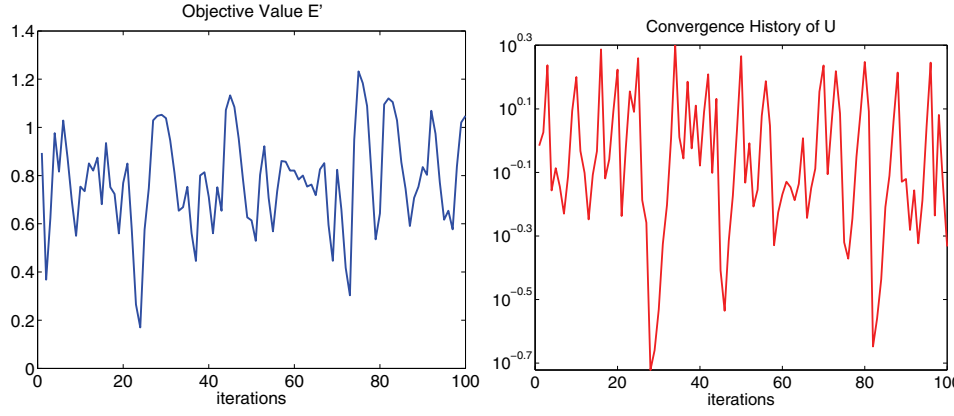


(c) Tensor $\mathcal{A}_3$: $(\mathcal{A}_3)_{ijk} = 1/(i^2 + j^2 + k^2)$.

FIG. 6.1. *Experiment* 1*: Convergence tests for LROAT.*



(a) Tensor $\mathcal{A}_4$ directly applied to LROAT.



(b) Tensor $\mathcal{A}_4$ applied to the symmetric variant of LROAT.

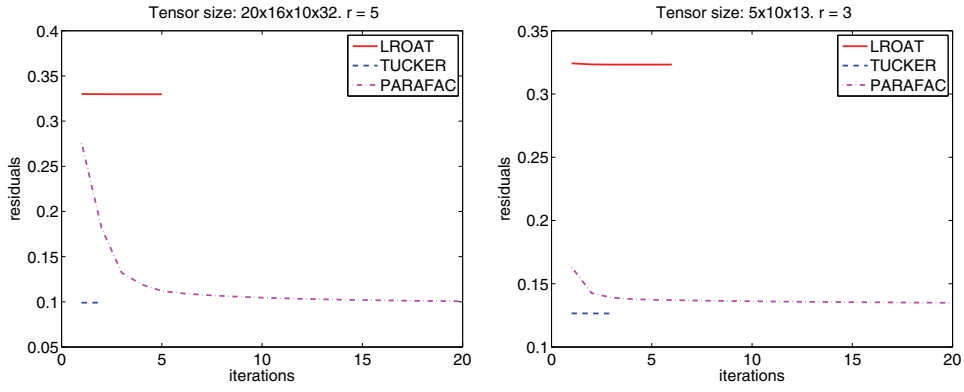
FIG. 6.2. *Experiment* 1 *(continued): Convergence tests for LROAT.*

6.2. Low rank orthogonal approximation compared with Tucker and PARAFAC. In the second experiment, we compare the approximation quality of three different models: low rank orthogonal approximation (without confusion in this section, we call this model "LROAT," which happens to be the name of the algorithm, for short), Tucker, and PARAFAC. See Figure 6.3. We experiment with two tensors: a low-rank-plus-Gaussian-noise tensor which is generated the same way as $\mathcal{A}_2$ and a real-life tensor. The latter is obtained from a problem in acoustics [20], and the data can be downloaded from [16]. The residual norms

$$res(p) := \frac{\left\|\mathcal{A} - \mathcal{T}_{(p)}\right\|_F}{\|\mathcal{A}\|_F}$$

over all of the iterations p are plotted.

Figure 6.3 indicates three facts: (1) the three models approximate the data tensor well to some extent (less than 35% of the information is lost due to approximation); (2) PARAFAC is usually slow to converge; (3) the residual norm for LROAT is larger than those of Tucker and PARAFAC. The last fact is not unexpected since LROAT can be considered a special case of Tucker and of PARAFAC: The Tucker model has a



(a) Low-rank-plus-Gaussian-noise tensor. (b) Real-life tensor.

FIG. 6.3. *Experiment 2: Comparison of LROAT, Tucker, and PARAFAC.*

full core while the core for LROAT is diagonal, and unlike LROAT the side-matrices in the PARAFAC model are not restricted to be orthogonal.

6.3. An application. In the blind source separation (BSS) problem [5], the cumulant tensor of order 4 is a rank-R tensor:

$$\sum_{i=1}^{R} \sigma_i u_i \otimes u_i \otimes u_i \otimes u_i, \tag{6.1}$$

where R is the number of sources and u_i is the ith column of the mixing matrix. In the prewhitening approach for the BSS problem, the u_i's become the columns of the composite of the whitening matrix and the mixing matrix; that is, the u_i's are length-R vectors and are orthonormal. Hence, this prewhitening approach reduces to computing the tensor SVD of the cumulant tensor. Since in practice this tensor is estimated from a finite data set, it is not exact. Thus, the low rank orthogonal approximation becomes a suitable tool to recover the u_i's.

In an experiment, we let $R = 3$ and generate a data tensor

$$\mathcal{A}_5 = \mathcal{B}_3 + \rho \mathcal{B}_4,$$

where $\mathcal{B}_3$ is as (6.1), $\mathcal{B}_4$ is a symmetric tensor with normally distributed elements, and $\rho = 0.05 \|\mathcal{B}_3\|_F / \|\mathcal{B}_4\|_F$. The σ_i's are

$$\sigma_1 = 0.7942, \quad \sigma_2 = 0.5678, \quad \sigma_3 = 0.4611,$$

and the u_i's are

$$U = [u_1, u_2, u_3] = \begin{bmatrix} 0.0974 & 0.4049 & 0.9092 \\ 0.9918 & -0.1154 & -0.0548 \\ 0.0827 & 0.9071 & -0.4128 \end{bmatrix}.$$

We use four methods to compute the rank-R (or rank-(R, R, R)) approximations to $\mathcal{A}_5$: LROAT, incremental rank-1 approximation, PARAFAC, and Tucker. All four

methods return same side-matrices for all modes. They are

$$U_{\text{LROAT}} = \begin{bmatrix} 0.0937 & 0.3822 & 0.9193 \\ 0.9918 & -0.1164 & -0.0527 \\ 0.0869 & 0.9167 & -0.3899 \end{bmatrix}, \quad U_{\text{inc}} = \begin{bmatrix} 0.0841 & 0.3795 & 0.9162 \\ 0.9929 & -0.1282 & -0.0745 \\ 0.0846 & 0.9163 & -0.3938 \end{bmatrix},$$

$$U_{\text{PARAFAC}} = \begin{bmatrix} 0.0841 & 0.3795 & 0.9162 \\ 0.9929 & -0.1282 & -0.0745 \\ 0.0846 & 0.9163 & -0.3938 \end{bmatrix},$$

$$U_{\text{Tucker}} = \begin{bmatrix} 0.0627 & 0.3707 & 0.9266 \\ 0.9952 & -0.0937 & -0.0298 \\ 0.0758 & 0.9240 & -0.3748 \end{bmatrix}.$$

Observations are as follows:

1. The U_{inc} and U_{PARAFAC} are not orthogonal.
2. Compared with Tucker, LROAT gives better approximations to the vectors u_i's:

$$\|U - U_{\text{LROAT}}\| = 0.0252, \quad \|U - U_{\text{Tucker}}\| = 0.0527.$$

3. In terms of approximation quality, the residual norms (in percentage of the norm of $\mathcal{A}_5$), are

$$res_{\text{LROAT}} = 3.07\%, \quad res_{\text{inc}} = 1.36\%, \quad res_{\text{PARAFAC}} = 1.36\%, \quad res_{\text{Tucker}} = 0\%.$$

7. Concluding remarks. In the present paper we studied the tensor SVD and characterized its existence in relation to the HOSVD. Similar to the concept of rank, the SVD of higher order tensors exhibits a quite different behavior and characteristics from those of matrices. Thus, the SVD of a matrix is guaranteed to exist, though it may have different representations due to orthogonal transformations of singular vectors corresponding to the same singular value. On the other hand, there are many ways in which a tensor can fail to have an SVD (see the results in section 4), but when it exists, this decomposition is unique up to signs.

We have also discussed a new form of optimal low rank approximation of tensors, where orthogonality is required. This approximation is inspired by the constraints of the Tucker model and the PARAFAC model. In some applications, the proposed approximation model may be favored, since it results in N sets of orthonormal vectors or, equivalently, r mutually orthogonal unit rank-1 tensors with different weights. Among the advantages of this approximation over the Tucker model is the fact that it requires far fewer entries to represent the core, and that it is easier to interpret. Also, compared with the PARAFAC model, the orthogonality of vectors may be useful in some cases. Further, the LROAT algorithm for computing the proposed approximation does not seem to exhibit the well-known slow convergence from which the ALS algorithm for PARAFAC suffers.

A major restriction of the proposed model is that the number of terms r can not exceed the smallest dimension of all modes of the tensor. A consequence is that the approximation may still be very different from the original tensor even when the maximum r is employed. However, we note that when performing data analysis, the

interpretation of the vectors and the core tensor might be more important than how much is lost when the data is approximated.

A nice aspect of the proposed approximation is that the optimum of the objective function can theoretically be attained, in contrast to the PARAFAC model which is ill-posed in a strict mathematical sense. We presented an algorithm to compute this approximation, but the computed result is optimal only in a local neighborhood. It will be interesting to study for what tensors or what initial guesses the LROAT algorithm converges to the global optimum, or to devise a new algorithm to solve this optimization problem. It is an open problem how fast LROAT converges, although empirically convergence is observed to be linear. We also discussed the symmetric variant of LROAT and pointed out the possibility of its nonconvergence. Hence the convergence properties of this variant, and the observed phenomenon that the original LROAT algorithm can yield same side-matrices for symmetric tensors, remain to be investigated.

Appendix. Does the ALS algorithm for PARAFAC converge? It has been pointed out that the ALS algorithm for computing the PARAFAC model may converge very slowly due to degenerate solutions or multicollinearities, and many alternatives have been proposed to address this problem [36, 37, 26]. During iterations, the objective value monotonically decreases by the nature of the ALS procedure, and since the sequence is bounded, it converges. However, a proof of the convergence of the parallel factors is lacking. In general it is assumed that these factors converge, but may take a very large number of iterations. In this section, we discuss an experiment showing that the general concept of convergence is unclear in this context. Though only one example is given, we note that the exhibited behavior is not rare for randomly generated tensors. (On the other hand it may be argued that tensors in real applications are far from being filled with random entries.)

We generate an order-3 tensor $\mathcal{A} \in \mathbb{R}^{3\times3\times3}$ and run the ALS algorithm on $r = 2$, i.e., to compute the approximation

$$\mathcal{A} \approx \lambda_1 u_1^{(1)} \otimes u_1^{(2)} \otimes u_1^{(3)} + \lambda_2 u_2^{(1)} \otimes u_2^{(2)} \otimes u_2^{(3)}.$$

The MATLAB code which generates the tensor $\mathcal{A}$ is as follows:

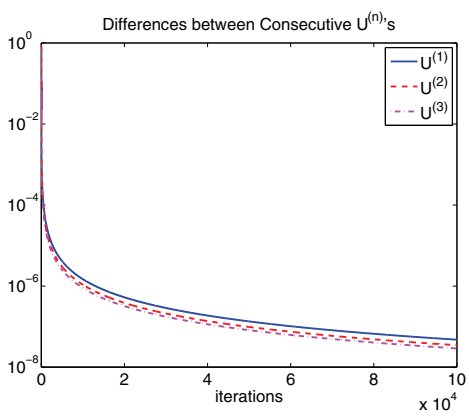
```
A(:,:,1) = [.99 .29 .08; .44 .69 .19; .00 .49 .97];
A(:,:,2) = [.36 .64 .10; .13 .73 .89; .01 .02 .76];
A(:,:,3) = [.58 .55 .98; .68 .77 .04; .96 .61 .98];
```

We use $u_i^{(n)} = e_i$, where $n = 1, 2, 3$ and e_i is the ith column of the identity matrix, as the initial guess.

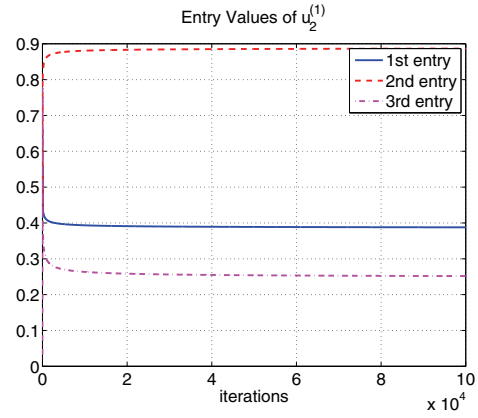
Denote $U^{(n)} = [u_1^{(n)}, u_2^{(n)}]$ for $n = 1, 2, 3$. Two plots are shown after running 10^5 iterations (see Figure A.1). Figure A.1(a) shows the "convergence" history for each $U^{(n)}$. The curves represent $\|U_{(p)}^{(n)} - U_{(p-1)}^{(n)}\|$, where p is the index of the iterations. A necessary condition for convergence to occur is that all three curves decrease to zero. However, we see from the figure that this may not be the case. To test the conjecture that each of the curves tends to a nonzero value, we use the expression

$$\log_{10} y = \frac{a}{(10^{-4}x)^{1/\alpha}} + b$$

to fit the tailing part of the curves (starting from the 2×10^4th iteration). Table A.1 gives the fitting results for different α's. When the number of iterations tends to



(a) Differences of the $U^{(n)}$'s between consecutive iterations.



(b) Entry values of the parallel factor $u_2^{(1)}$.

FIG. A.1. *Slow convergence or nonconvergence of ALS for PARAFAC.*

TABLE A.1

Curve fitting for the three curves in Figure A.1(a) *using different* α *values. The error is measured as the quadratic mean of fitting errors in logarithmic scales, i.e., the RMS of* $|\log_{10} y - \log_{10} y_{fit}|$. *It will be easier to understand this error by noticing that the vertical axis of Figure* A.1(a) *has a length* 8 *(after taking logarithm).*

	α	1	2	3	4	5
$U^{(1)}$	a	2.8407	2.7925	3.2657	3.8359	4.4404
	b	−7.5060	−8.1549	−8.8047	−9.4544	−10.1042
	error	0.0595	0.0301	0.0201	0.0151	0.0121
$U^{(2)}$	a	2.8408	2.7926	3.2658	3.8360	4.4406
	b	−7.6428	−8.2917	−8.9415	−9.5913	−10.2411
	error	0.0595	0.0301	0.0201	0.0151	0.0121
$U^{(3)}$	a	2.8411	2.7930	3.2662	3.8365	4.4411
	b	−7.7219	−8.3709	−9.0208	−9.6707	−10.3205
	error	0.0595	0.0301	0.0201	0.0151	0.0121

infinity, the value 10^b will show the limit of the differences between two consecutive $U^{(n)}$'s.

It is still difficult to conclude for this example that the iterations do not converge since rounding has not been taken into account. However, it makes no practical difference for this case whether the sequence actually converges or whether it is exceedingly slow to converge. The result, if convergence holds, will be an inordinate number of iterations to reach a desirable level of convergence, and the cost will be too high in practice. This can be made evident by examining Figure A.1(b), which plots the parallel factor $u_2^{(1)}$ over all iterations: The 3rd entry of $u_2^{(1)}$ decreases from 0.2540 at the 5×10^4th iteration to 0.2517 at the 10^5th iteration.

STATE FEEDBACK DECOUPLING PROBLEM WITH STABILITY FOR (A, B, C, D) QUADRUPLES*

DELIN CHU†, M. MALABRE‡, AND ROGER C. E. TAN†

Abstract. The state feedback decoupling problem with stability for general proper systems described by (A, B, C, D) quadruples has been studied for a long time. But, it is still an open problem in the sense that there is still a lack of numerically verifiable solvability conditions and numerically implementable methods for solving it in the existing literature. In this paper numerically verifiable solvability conditions and a numerical method for solving this open problem are developed. The proposed method is based on orthogonal transformations and hence can be implemented in a numerically reliable manner.

1. Introduction.

Decoupling is a fundamental objective in control theory [6, 11, 12, 16]. It is easy for an operator to control a system if each input of the system can affect only one of the outputs. Usually, a given multivariable system has couplings. A strategy is then to design a controller such that the resulting control system has no couplings between the inputs and the outputs. Decoupling control is popular not only because it can simplify multivariable system design and control but also because it is a desired feature in many practical applications, at least in process and chemical industry [6, 11, 12]. Although the exact decoupling is not always possible to achieve, it has been pointed out in [23, p. 796] that the state feedback decoupling (namely, the diagonal decoupling by state feedback in [23]) is likely to be feasible for a wide variety of general proper systems of the form (1.1) below. Moreover, the decoupling technique has found applications not only in process and chemical industry [6, 11, 12, 20] but also in industrial robots [16, 17, 28, 33, 36], and it has been studied extensively in the last three decades; see [6, 8, 11, 12, 15, 16, 18, 23, 24, 25, 26, 28, 29, 35, 39, 41, 44, 45, 46, 47, 48, 49, 50] and the references therein. Hence, decoupling is of importance in systems design and control.

Consider a proper multivariable system described by an (A, B, C, D) quadruple:

$$\begin{cases} \dot{x} = Ax + Bu, \\ y = Cx + Du, \end{cases} \tag{1.1}$$

where $A \in \mathbf{R}^{n\times n}$, $B \in \mathbf{R}^{n\times m}$, $C \in \mathbf{R}^{m\times n}$, $D \in \mathbf{R}^{m\times m}$, D is the direct feedthrough matrix, $x \in \mathbf{R}^n$ is the state, $u \in \mathbf{R}^m$ is the control input, and $y \in \mathbf{R}^m$ is the output. If we apply the state feedback of the form

$$u = Fx + Hv \tag{1.2}$$

to (1.1), then the closed-loop system becomes

$$\begin{cases} \dot{x} = (A + BF)x + BHv, \\ y = (C + DF)x + DHv. \end{cases} \tag{1.3}$$

The transfer matrix from output y to input v in (1.3) is $(C+DF)(sI-A-BF)^{-1}BH+DH$. The state feedback decoupling problem (i.e., row by row decoupling problem) with stability studied in this paper can be formulated mathematically as follows.

DEFINITION 1.1. *The state feedback decoupling problem with stability for proper system* (1.1) *is solvable if there exist matrices* $F \in \mathbf{R}^{m\times n}$ *and* $H \in \mathbf{R}^{m\times m}$ *such that*

$$(C + DF)(sI - A - BF)^{-1}BH + DH \text{ is nonsingular and diagonal}, \tag{1.4}$$

and $A+BF$ *is stable (i.e., all eigenvalues of* $A+BF$ *are on the open left half complex plane* $\mathbf{C}^-$*).*

Up to now, many important contributions have been made to the study of the state feedback decoupling problem with stability for the strictly proper system

$$\begin{cases} \dot{x} = Ax + Bu, \\ y = Cx, \end{cases} \tag{1.5}$$

which has no direct feedthrough matrix; in particular, we have the following:

• Solvability conditions have been established in [49, 50]. In [49, 50], the class of all feedback matrices which decouple the system (1.5) and the number of closed-loop poles which can be assigned are characterized. But, as pointed out in [4, p. 34], the conditions given in [49, 50] are difficult to apply.

• Solvability conditions have also been given in [24, 25, 26, 47] based on the geometric/structural approaches.

• Solvability conditions have also been given in [21] based on a polynomial equations approach; these conditions are implicit and valid only for system (1.5) satisfying that the maximal (A, B)-controllability subspace lying in $\mathrm{Ker}(C)$ is the same as the maximal (A, B)-invariant subspace contained in $\mathrm{Ker}(C)$ [39], which implies that there is no extra difficulty in requiring internal stability of the decoupled closed-loop system.

• The family of all attainable transfer function matrices for the decoupled closed-loop system has been characterized in [4] under the assumption that the solvability conditions in [25] are satisfied; that is, system (1.5) is decouplable by a state feedback of the form (1.2). Based on the results in [4], a numerical algorithm has been developed in [7] for computing a desired feedback matrix pair (F, H). The main steps of this algorithm include the following:

(1) Compute the global and row infinite zeros, and global and row invariant finite zeros of system (1.5);

(2) compute the last invariant polynomial $z_i(s)$ of the matrix $\left[\begin{smallmatrix} sI-A & B \\ c_i & 0 \end{smallmatrix}\right]$ with c_i being the ith row of C $(i = 1, \ldots, m)$, and then define

$$W_1(s) = \begin{bmatrix} k_1 \frac{z_1(s)}{a_1(s)} & & \\ & \ddots & \\ & & k_m \frac{z_m(s)}{a_m(s)} \end{bmatrix},$$

where $k_1, \ldots, k_m$ are real numbers, for $i = 1, \ldots, m$, $a_i(s)$ is a monic polynomial with arbitrary roots and satisfying

$$\deg(a_i(s)) - \deg(z_i(s)) = n_i,$$

and $n_1, \ldots, n_m$ are the row infinite zero orders of the system (1.5);

(3) let $Q(s) = \left(C(sI - A)^{-1}B\right)^{-1} W_1(s)$, compute $G = \lim_{s\to\infty} Q(s)$, and then compute a basis for the left constant kernel of the matrix

$$\begin{bmatrix} (sI - A)^{-1}B \\ I - GQ^{-1}(s) \end{bmatrix}$$

via computing the left constant kernel of the matrix

$$\begin{bmatrix} \det(Q(s))\mathrm{adj}(sI - A)B \\ \det(sI - A)(\det(Q)I - G\mathrm{adj}(Q)) \end{bmatrix}.$$

But, (i) infinite zeros of system (1.5) are very sensitive to the perturbations including rounding errors to matrices A, B, and C; thus, the computation of the global and row infinite zeros of system (1.5) must be avoided if possible; and (ii) the computations of the last invariant polynomials $z_i(s)$ $(i = 1, \ldots, m)$, basis for the left constant kernel of the matrix

$$\left[(sI - A)^{-1}BI - GQ^{-1}(s)\right],$$

and the matrix

$$[\det(Q(s))\mathrm{adj}(sI - A)B\det(sI - A)(\det(Q)I - G\mathrm{adj}(Q))]$$

and its left constant kernel are very difficult and very expensive, and thus, the computational complexity of the algorithm in [7] is too high.

• A numerically reliable method, which does not compute the finite/infinite structures of system (1.5) explicitly, has been developed in [9] based on orthogonal transformations for solving this decoupling problem.

However, to the best of our knowledge, the results in [4, 7, 9, 21, 24, 25, 26, 47, 49, 50] cannot be generalized easily to the state feedback decoupling problem with stability for general proper systems of the form (1.1). In addition, the state feedback decoupling problem *without stability* for descriptor systems of the form

$$\begin{cases} E\dot{x} = Ax + Bu, \\ y = Cx, \end{cases} \tag{1.6}$$

with E *singular* has also been investigated in [2]. But, the state feedback decoupling problem *with stability* is not considered and still remains an open problem in [2].

The solvability condition for the state feedback decoupling problem *without stability* for general proper systems of the form (1.1) has been available in [23, 37], which is included in the following lemma.

LEMMA 1.2 (cf. [23, 37]). *Given $A \in \mathbf{R}^{n\times n}, B \in \mathbf{R}^{n\times m}, C \in \mathbf{R}^{m\times n}, D \in \mathbf{R}^{m\times m}$, let the matrix $L \in \mathbf{R}^{m\times m}$ be defined as follows: If the ith row of the matrix D is nonzero, this becomes the ith row of the matrix L, and set $l_i = 0$; otherwise, find the lowest positive integer l_i, for which the ith row of $CA^{l_i-1}B$ is nonzero; this then becomes the ith row of the matrix L. Then there exist matrices $F \in \mathbf{R}^{m\times n}$ and $H \in \mathbf{R}^{m\times m}$ such that* (1.4) *holds (i.e., $(C + DF)(sI - A - BF)^{-1}BH + DH$ is nonsingular and diagonal) if and only if the matrix L is nonsingular.*

The state feedback decoupling problem with stability for general proper systems of the form (1.1) is much more complicated than the state feedback decoupling problem without stability and has been considered in [23, 37, 41, 44, 46]. In [41, 46] only

sufficient conditions are given, while the necessary and sufficient conditions in [44] are based on the existence of some particular but unknown invariant subspaces of system (1.1) and some particular but also unknown solutions of the state feedback decoupling problem *without stability* for system (1.1); hence, the conditions given in [44] are not numerically verifiable. Furthermore, the results in [41, 44, 46] cannot give any direction to establish a numerically implementable method for solving the underlying problem in the general setting. In [23, 37], an algorithm for the state feedback decoupling problem for system (1.1) is presented. This algorithm can be summarized as follows:

• First, define the matrix L and the integers $\{l_i\}$ as those in Lemma 1.2, and let

$$\hat{T}(s) = \begin{bmatrix} p_1(s) & & \\ & \ddots & \\ & & p_m(s) \end{bmatrix},$$

where $p_i(s)$ $(i = 1, \ldots, m)$ are properly selected stable monic polynomials of degree l_i, i.e.,

$$p_i(s) = s^{l_i} + \text{lower} - \text{degree terms},$$

such that $\lim_{s\to\infty} \hat{T}(s)[C(sI - A)^{-1}B + D] = L$ and that $\{A, B, \hat{C}, L\}$ is a realization of $\hat{T}(s)[C(sI - A)^{-1}B + D]$ for some matrix $\hat{C}$.

• Next, if L is nonsingular, and if we take $F = -L^{-1}\hat{C},\ H = L^{-1}$, then

$$(1.7)\quad (C + DF)(sI - A - BF)^{-1}BH + DH = \hat{T}^{-1}(s) = \begin{bmatrix} p_1^{-1}(s) & & \\ & \ddots & \\ & & p_m^{-1}(s) \end{bmatrix}.$$

However, (i) as addressed in [9], the explicit computation of the matrix L above is ill-conditioned and should be avoided; and (ii) it is pointed out in [23, p. 797, lines 1, 2, 3 below (50.5)] that "the closed-loop eigenvalues are at the assumed stable zeros of $T(s)$ (i.e., $C(sI - A)^{-1}B + D$) and at the selected stable zeros of the polynomials $p_i(s)$." But, if the ith row of D is nonzero for some i, then $l_i = 0$, and $p_i(s) =$ constant, which has no stable zeros, so, if the zeros of $C(sI - A)^{-1}B + D$ are not stable and/or $D \neq 0$, then $A + BF$ is not necessarily stable, and thus, the (F, H) above cannot solve the state feedback decoupling problem with stability for system (1.1) when $D \neq 0$. Hence, the results in [23, 37] also cannot give any direction for establishing a numerically implementable method for solving the state feedback decoupling problem with stability for general proper systems of the form (1.1) with $D \neq 0$.

Based on the above observations, we can conclude that the state feedback decoupling problem with stability for general proper systems of the form (1.1) is still an open problem from both theoretical and numerical points of view. The main purpose of this paper is to develop a numerically reliable method based on a numerical linear algebra technique to solve this open problem.

2. Main results. In this section we will develop a numerical method for solving the state feedback decoupling problem with stability for general proper systems of the form (1.1). Our main idea lies in decomposing the underlying problem into the following two subproblems:

(a) decoupling of a reduced system without a feedthrough matrix, and

(b) simultaneous decoupling and disturbance decoupling of a reduced system with a nonsingular feedthrough term that is further reduced to an "unusual" problem of decoupling.

The obtained solutions are then transformed back to get a solution to the original problem. Our approach is very technical and consists of the following four different stages:

(1) The state feedback decoupling problem with stability for system (1.1) is much more difficult than that for system (1.5). Stage 1 is to eliminate the singularity of matrix D and reduce the underlying problem for system (1.1) into (i) a state feedback decoupling problem with stability for a reduced system without direct feedthrough matrix; and (ii) a simultaneous problem of state feedback decoupling with stability and disturbance decoupling for a reduced system with *nonsingular* direct feedthrough matrix.
(2) The state feedback decoupling problem with stability for a system without direct feedthrough matrix can be solved using the numerical method in [9]; thus, in Stage 2, we consider only the simultaneous problem of state feedback decoupling with stability and disturbance decoupling arising in Stage 1. This simultaneous problem will be reduced to an "unusual" state feedback decoupling problem with stability for a reduced system with *nonsingular* direct feedthrough matrix.
(3) In Stage 3 we first derive a useful reduction property of the "unusual" state feedback decoupling problem with stability produced in Stage 2 and then present a numerically reliable algorithm for solving this "unusual" decoupling problem with stability.
(4) Stage 4 consists of back-transformations of the results in Stages 1, 2, and 3 to the desired solution for the original decoupling problem with stability. An outline of the overall algorithm is given in this stage.

The following auxiliary lemma will be used frequently in this section.

LEMMA 2.1 (cf. [13, 14]). *Given* $E, A \in \mathbf{R}^{n\times n}$, $B \in \mathbf{R}^{n\times m}$, $C \in \mathbf{R}^{p\times n}$, $D \in \mathbf{R}^{p\times m}$ *with* $\operatorname{rank}(E) = n$,

(i) *the following three statements are equivalent:*

$$\begin{array}{ll} [(a)] & C(sE-A)^{-1}B + D = 0; \\ [(b)] & \max_{s\in\mathbf{C}} \operatorname{rank}\left[\begin{smallmatrix} sE-A & B \\ C & -D \end{smallmatrix}\right] = n; \\ [(c)] & D = 0, \max_{s\in\mathbf{C}} \operatorname{rank}\left[\begin{smallmatrix} sE-A & B \\ C & 0 \end{smallmatrix}\right] = n; \end{array}$$

(ii) *if* $\operatorname{rank}\left[\begin{array}{cc} sE-A & B \end{array}\right] = n$ *for all* $s \in \mathbf{C}$, *then* $\max_{s\in\mathbf{C}} \operatorname{rank}\left[\begin{smallmatrix} sE-A & B \\ C & 0 \end{smallmatrix}\right] = n$ *if and only if* $C = 0$.

2.1. Stage 1—elimination of the singularity of matrix D. The state feedback decoupling problem with stability for systems of the form (1.5) has been studied in [9]. Hence, the results in [9] are used as a bridge to achieve the purpose of Stage 1 in this subsection.

LEMMA 2.2 (cf. [13, 14, 43]). *Given* $A \in \mathbf{R}^{n\times n}, B \in \mathbf{R}^{n\times m}, C \in \mathbf{R}^{m\times n}$, *and* $D \in \mathbf{R}^{m\times m}$, *there exist orthogonal matrices* $V_1 \in \mathbf{R}^{n\times n}$ *and* $W \in \mathbf{R}^{m\times m}$ *and a*

permutation matrix $P \in \mathbf{R}^{m\times m}$ *such that*

$$\begin{cases} V_1AV_1^T = \begin{matrix} \\ \\ \\ \end{matrix}\begin{matrix} n_1 & n_2 & n_3 \end{matrix} \\ \qquad\qquad \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ A_{21} & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \\ \}n_3 \end{matrix}, \\ PCV_1^T = \begin{matrix} \\ \\ \end{matrix}\begin{matrix} n_1 & n_2 & n_3 \end{matrix} \\ \qquad\qquad \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ 0 & C_{22} & C_{23} \end{bmatrix} \begin{matrix} \}m_0 \\ \}m-m_0 \end{matrix}, \end{cases} \quad \begin{cases} V_1BW = \begin{matrix} \\ \\ \\ \end{matrix}\begin{matrix} m_0 & m-m_0 \end{matrix} \\ \qquad\qquad \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \\ 0 & 0 \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \\ \}n_3 \end{matrix}, \\ PDW = \begin{matrix} \\ \\ \end{matrix}\begin{matrix} m_0 & m-m_0 \end{matrix} \\ \qquad\qquad \begin{bmatrix} D_{11} & 0 \\ D_{21} & 0 \end{bmatrix} \begin{matrix} \}m_0 \\ \}m-m_0 \end{matrix}, \end{cases}$$

(2.1)

where

(2.2)

$$\operatorname{rank}(D_{11}) = m_0,\ \operatorname{rank}\begin{bmatrix} B_{21} & B_{22} \end{bmatrix} = n_2,\ \max_{s\in\mathbf{C}} \operatorname{rank}\begin{bmatrix} -A_{32} & sI-A_{33} \\ C_{22} & C_{23} \end{bmatrix} = n_2+n_3,$$

(2.3)

$$\operatorname{rank}\begin{bmatrix} sI-A_{11} & B_{11} & B_{12} \\ -A_{21} & B_{21} & B_{22} \end{bmatrix} = n_1+n_2 \quad \forall s\in\mathbf{C}.$$

Some important information about the state feedback decoupling for system (1.1) can be read directly from the form (2.1).

LEMMA 2.3. *Given* $A\in\mathbf{R}^{n\times n}, B\in\mathbf{R}^{n\times m}, C\in\mathbf{R}^{m\times n}$, *and* $D\in\mathbf{R}^{m\times m}$, *assume the factorization* (2.1) *has been determined. If there exist* $F\in\mathbf{R}^{m\times n}$ *and* $H\in\mathbf{R}^{m\times m}$ *such that* (1.4) *holds (i.e.,* $(C+DF)(sI-A-BF)^{-1}BH+DH$ *is nonsingular and diagonal), then*

$$D_{21}=0, \quad n_2 = m-m_0 = \operatorname{rank}(B_{22}). \tag{2.4}$$

Proof. First, (2.2) implies that $n_2+n_3 = \max_{s\in\mathbf{C}} \operatorname{rank}\begin{bmatrix} -A_{32} & sI-A_{33} \\ C_{22} & C_{23} \end{bmatrix} \le n_3+(m-m_0)$, so

$$n_2 \le m-m_0. \tag{2.5}$$

Next, note that $\operatorname{rank}\begin{bmatrix} B_{21} & B_{22} \end{bmatrix} = n_2$ and that there exist $\mathcal{F}_{11}\in\mathbf{R}^{m_0\times n_1}$ and $\mathcal{F}_{21}\in\mathbf{R}^{(m-m_0)\times n_1}$ such that

$$A_{21} + \begin{bmatrix} B_{21} & B_{22} \end{bmatrix}\begin{bmatrix} \mathcal{F}_{11} \\ \mathcal{F}_{21} \end{bmatrix} = 0.$$

Let

$$\mathcal{F} = W^TFV_1^T - \begin{bmatrix} \mathcal{F}_{11} & 0 & 0 \\ \mathcal{F}_{21} & 0 & 0 \end{bmatrix}, \qquad \mathcal{H} = W^THP^T,$$

$$\begin{aligned} \mathcal{A} = V_1AV_1^T + (V_1BW)\begin{bmatrix} \mathcal{F}_{11} & 0 & 0 \\ \mathcal{F}_{21} & 0 & 0 \end{bmatrix} &= \begin{bmatrix} A_{11}+\sum_{i=1}^2 B_{1i}\mathcal{F}_{i1} & A_{12} & A_{13} \\ 0 & A_{22} & A_{23} \\ 0 & A_{32} & A_{33} \end{bmatrix} \\ &=: \begin{bmatrix} A_{11}+\sum_{i=1}^2 B_{1i}\mathcal{F}_{i1} & \mathcal{A}_{12} \\ 0 & \mathcal{A}_{22} \end{bmatrix}, \\ \mathcal{C} = PCV_1^T + PDW\begin{bmatrix} \mathcal{F}_{11} & 0 & 0 \\ \mathcal{F}_{21} & 0 & 0 \end{bmatrix} &= \begin{bmatrix} C_{11}+D_{11}\mathcal{F}_{11} & C_{12} & C_{13} \\ D_{21}\mathcal{F}_{11} & C_{22} & C_{23} \end{bmatrix} \\ &=: \begin{bmatrix} C_{11}+D_{11}\mathcal{F}_{11} & \mathcal{C}_{12} \\ D_{21}\mathcal{F}_{11} & \mathcal{C}_{22} \end{bmatrix}, \end{aligned}$$

$$\mathcal{B} = V_1 BW = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \\ 0 & 0 \end{bmatrix}, \quad \mathcal{D} = PDW = \begin{bmatrix} D_{11} & 0 \\ D_{21} & 0 \end{bmatrix},$$

and define the integers $\{l_i\}$ and matrix L as follows: If the ith row of the matrix $\mathcal{D}$ is nonzero, this becomes the ith row of the matrix L, and set $l_i = 0$; otherwise, find the lowest positive integer l_i, for which the ith row of $\mathcal{C}\mathcal{A}^{l_i-1}\mathcal{B}$ is nonzero, this then becomes the ith row of the matrix L. It is clear by using $\mathcal{D} = \left[\begin{smallmatrix} D_{11} & 0 \\ D_{21} & 0 \end{smallmatrix}\right]$, where D_{11} is nonsingular, that L is of the form $L = \left[\begin{smallmatrix} D_{11} & 0 \\ L_{21} & L_{22} \end{smallmatrix}\right]$, and if the ith row of $\begin{bmatrix} D_{21} & 0 \end{bmatrix}$ is nonzero, then it is the ith row of $\begin{bmatrix} L_{21} & L_{22} \end{bmatrix}$. Since $(C+DF)(sI-A-BF)^{-1}BH+DH$ is nonsingular and diagonal, and P is a permutation matrix, thus,

$$(\mathcal{C}+\mathcal{D}\mathcal{F})(sI-\mathcal{A}-\mathcal{B}\mathcal{F})^{-1}\mathcal{B}\mathcal{H}+\mathcal{D}\mathcal{H} = P\left((C+DF)(sI-A-BF)^{-1}BH+DH\right)P^T$$

is also nonsingular and diagonal; consequently, by Lemma 1.2, L is nonsingular. Hence, $D_{21} = 0$, and further,

$$L_{22} = \begin{bmatrix} c_{m_0+1}\mathcal{A}^{l_{m_0+1}-1} \\ \vdots \\ c_m\mathcal{A}^{l_m-1} \end{bmatrix} \begin{bmatrix} B_{12} \\ B_{22} \\ 0 \end{bmatrix} = \begin{bmatrix} \hat{c}_{m_0+1}\mathcal{A}_{22}^{l_{m_0+1}-1} \\ \vdots \\ \hat{c}_m\mathcal{A}_{22}^{l_m-1} \end{bmatrix} \begin{bmatrix} B_{22} \\ 0 \end{bmatrix}$$

is nonsingular, where c_{m_0+k} and $\hat{c}_{m_0+k}$ are the kth rows of $\mathcal{C}$ and $\mathcal{C}_{22}$, respectively, $k = 1, \ldots, m-m_0$. Thus,

$$\operatorname{rank}(B_{22}) = \operatorname{rank}\begin{bmatrix} B_{22} \\ 0 \end{bmatrix} = m - m_0, \tag{2.6}$$

which, together with (2.5) and $B_{22} \in \mathbf{R}^{n_2\times(m-m_0)}$, yields that $n_2 = m - m_0 = \operatorname{rank}(B_{22})$. □

Let orthogonal matrix

$$U_1 := \begin{matrix} \\ \end{matrix} \begin{matrix} n_1 & n_2 \end{matrix} \\ \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \end{matrix}$$

be such that

$$U_1 \begin{bmatrix} B_{12} \\ B_{22} \end{bmatrix} = \begin{bmatrix} 0 \\ R_B \end{bmatrix} \begin{matrix} \}n_1 \\ \}n_2 \end{matrix}. \tag{2.7}$$

Define

(2.8)

$$\begin{cases} \tilde{A}_{11} = \begin{bmatrix} U_{11} & U_{12} \end{bmatrix} \begin{bmatrix} A_{11} \\ A_{21} \end{bmatrix}, \quad \tilde{A}_{12} = \begin{bmatrix} U_{11} & U_{12} \end{bmatrix} \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} U_{21}^T \\ U_{22}^T \end{bmatrix}, \\ \tilde{A}_{13} = \begin{bmatrix} U_{11} & U_{12} \end{bmatrix} \begin{bmatrix} A_{13} \\ A_{23} \end{bmatrix}, \quad \tilde{A}_{22} = \begin{bmatrix} A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} U_{21}^T \\ U_{22}^T \end{bmatrix}, \\ \tilde{A}_{32} = \begin{bmatrix} 0 & A_{32} \end{bmatrix} \begin{bmatrix} U_{21}^T \\ U_{22}^T \end{bmatrix}, \\ \tilde{B}_{11} = \begin{bmatrix} U_{11} & U_{12} \end{bmatrix} \begin{bmatrix} B_{11} \\ B_{21} \end{bmatrix}, \quad \tilde{C}_{12} = \begin{bmatrix} C_{11} & C_{12} \end{bmatrix} \begin{bmatrix} U_{21}^T \\ U_{22}^T \end{bmatrix}, \\ \tilde{C}_{22} = \begin{bmatrix} 0 & C_{22} \end{bmatrix} \begin{bmatrix} U_{21}^T \\ U_{22}^T \end{bmatrix}, \end{cases}$$

and

$$Q_L = \begin{bmatrix} U_{11} & U_{12} & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix}, \qquad Q_R = \begin{bmatrix} I & 0 & 0 \\ U_{21} & U_{22} & 0 \\ 0 & 0 & I \end{bmatrix}. \tag{2.9}$$

LEMMA 2.4. *Assume that condition* (2.4) *holds. Then*
(i) U_{11} *and* U_{22} *are nonsingular.*
(ii)

$$\begin{cases} Q_L V_1 A V_1^T Q_R^T = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} & \tilde{A}_{13} \\ A_{21} & \tilde{A}_{22} & A_{23} \\ 0 & \tilde{A}_{32} & A_{33} \end{bmatrix}, \quad Q_L Q_R^T = \begin{bmatrix} U_{11} & 0 & 0 \\ 0 & U_{22}^T & 0 \\ 0 & 0 & I \end{bmatrix}, \\ Q_L V_1 B W = \begin{bmatrix} \tilde{B}_{11} & 0 \\ B_{21} & B_{22} \\ 0 & 0 \end{bmatrix}, \qquad PCV_1^T Q_R^T = \begin{bmatrix} C_{11} & \tilde{C}_{12} & C_{13} \\ 0 & \tilde{C}_{22} & C_{23} \end{bmatrix}, \end{cases} \tag{2.10}$$

and

$$\operatorname{rank} \begin{bmatrix} sU_{11} - A_{11} & \tilde{B}_{11} \end{bmatrix} = n_1 \quad \forall s \in \mathbf{C}, \tag{2.11}$$

$$\max_{s \in \mathbf{C}} \operatorname{rank} \begin{bmatrix} -\tilde{A}_{32} & sI - A_{33} \\ \tilde{C}_{22} & C_{23} \end{bmatrix} = n_2 + n_3. \tag{2.12}$$

Proof. Part (i) has been proved in [1, 5, 10, 19, 32], and part (ii) follows from a simple calculation. □

Transformations Q_L and Q_R have been used in [1, 5, 10, 19, 32], where many numerical examples have shown that such transformations formed based on orthogonal transformations are numerically reliable, in contrast to the (block) Gaussian elimination without pivoting.

Lemmas 2.2 and 2.4 offer a springboard to the objective of this subsection.

THEOREM 2.5. *The state feedback decoupling problem with stability for system* (1.1) *is solvable if and only if the condition* (2.4) *holds as follows:*

$$\operatorname{rank} \begin{bmatrix} \tilde{A}_{32} & sI - A_{33} \end{bmatrix} = n_3, \quad \forall s \in \mathbf{C} \backslash \mathbf{C}^-. \tag{2.13}$$

Furthermore,

(a) *there exist* $F_{22} \in \mathbf{R}^{n_2 \times n_2}$, $F_{23} \in \mathbf{R}^{n_2 \times n_3}$, *and* $H_{22} \in \mathbf{R}^{n_2 \times n_2}$ *solving the following state feedback decoupling problem with stability:*

$$\text{The pencil } \left(\begin{bmatrix} U_{22}^T & 0 \\ 0 & I \end{bmatrix}, \begin{bmatrix} \tilde{A}_{22} + B_{22}F_{22} & A_{23} + B_{22}F_{23} \\ \tilde{A}_{32} & A_{33} \end{bmatrix} \right) \text{ is stable,} \tag{2.14}$$

$$\begin{bmatrix} \tilde{C}_{22} & C_{23} \end{bmatrix} \begin{bmatrix} sU_{22}^T - \tilde{A}_{22} - B_{22}F_{22} & -A_{23} - B_{22}F_{23} \\ -\tilde{A}_{32} & sI - A_{33} \end{bmatrix}^{-1} \begin{bmatrix} B_{22} \\ 0 \end{bmatrix} H_{22} \tag{2.15}$$

is nonsingular and diagonal.

(b) *there exist matrices* $F_{11} \in \mathbf{R}^{m_0\times n_1}$, $F_{12} \in \mathbf{R}^{m_0\times n_2}$, $F_{13} \in \mathbf{R}^{m_0\times n_3}$, *and* $H_{11} \in \mathbf{R}^{m_0\times m_0}$ *solving the following simultaneous problem of state feedback decoupling with stability and disturbance decoupling:*

(2.16) *The pencil* $(U_{11}, \tilde{A}_{11} + \tilde{B}_{11}F_{11})$ *is stable,*

$D_{11}H_{11}+(C_{11}+D_{11}F_{11})(sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11})^{-1}\tilde{B}_{11}H_{11}$ *is nonsingular and diagonal,*
(2.17)

$$\tilde{C}_{12}+D_{11}F_{12}+\begin{bmatrix} C_{11}+D_{11}F_{11}C_{13}+D_{11}F_{13} \end{bmatrix} \times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ 0 & sI-A_{33} \end{bmatrix}^{-1} \begin{bmatrix} \tilde{A}_{12}+\tilde{B}_{11}F_{12} \\ \tilde{A}_{32} \end{bmatrix} = 0.$$
(2.18)

Proof. Necessity. Let (F, H) solve the state feedback decoupling problem with stability for system (1.1). Then the condition (2.4) follows directly from Lemma 2.3.

With the condition (2.4) we have the factorization (2.10). Denote

$$(2.19)\quad \begin{cases} \begin{bmatrix} I & 0 \\ B_{21} & B_{22} \end{bmatrix} W^T F V_1^T Q_R^T = \begin{bmatrix} I & 0 \\ 0 & B_{22} \end{bmatrix} \begin{matrix} \\ \begin{bmatrix} F_{11} & F_{12} & F_{13} \\ F_{21} & F_{22} & F_{23} \end{bmatrix} \end{matrix} \begin{matrix} \\ \}m_0 \\ \}n_2 \end{matrix}, \\ \begin{bmatrix} I & 0 \\ B_{21} & B_{22} \end{bmatrix} W^T H P^T = \begin{bmatrix} I & 0 \\ 0 & B_{22} \end{bmatrix} \begin{matrix} \\ \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \end{matrix} \begin{matrix} \\ \}m_0 \\ \}n_2 \end{matrix}. \end{cases}$$

As $D_{21} = 0$, we have

$$(2.20)\quad \begin{cases} Q_L V_1 (sI - A - BF) V_1^T Q_R^T \\ \quad = \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}, \\ Q_L V_1 B H P^T = \begin{bmatrix} \tilde{B}_{11}H_{11} & \tilde{B}_{11}H_{12} \\ B_{22}H_{21} & B_{22}H_{22} \\ 0 & 0 \end{bmatrix}, \quad P D H P^T = \begin{bmatrix} D_{11}H_{11} & D_{11}H_{12} \\ 0 & 0 \end{bmatrix}, \\ P(C+DF)V_1^T Q_R^T = \begin{bmatrix} C_{11}+D_{11}F_{11} & \tilde{C}_{12}+D_{11}F_{12} & C_{13}+D_{11}F_{13} \\ 0 & \tilde{C}_{22} & C_{23} \end{bmatrix}. \end{cases}$$

Thus, condition (2.13) follows since $A + BF$ is stable.

Note that $DH + (C + DF)(sI - A - BF)^{-1}BH$ is nonsingular and diagonal, P is a permutation matrix, and so

$$P[DH + (C + DF)(sI - A - BF)^{-1}BH]P^T =: \begin{matrix} \\ \begin{bmatrix} T_{11}(s) & T_{12}(s) \\ T_{21}(s) & T_{22}(s) \end{bmatrix} \end{matrix} \begin{matrix} \\ \}m_0 \\ \}n_2 \end{matrix}$$

is also nonsingular and diagonal; i.e.,

$$\begin{cases} T_{12}(s) = D_{11}H_{12} + \begin{bmatrix} C_{11}+D_{11}F_{11} & \tilde{C}_{12}+D_{11}F_{12} & C_{13}+D_{11}F_{13} \end{bmatrix} \\ \qquad \times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}^{-1} \\ \qquad \times \begin{bmatrix} \tilde{B}_{11}H_{12} \\ B_{22}H_{22} \\ 0 \end{bmatrix} = 0, \\ T_{21}(s) = \begin{bmatrix} 0 & \tilde{C}_{22} & C_{23} \end{bmatrix} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}^{-1} \\ \qquad \times \begin{bmatrix} \tilde{B}_{11}H_{11} \\ B_{22}H_{21} \\ 0 \end{bmatrix} = 0, \end{cases} \tag{2.21}$$

$$\begin{aligned} T_{11}(s) = D_{11}H_{11} &+ \begin{bmatrix} C_{11}+D_{11}F_{11} & \tilde{C}_{12}+D_{11}F_{12} & C_{13}+D_{11}F_{13} \end{bmatrix} \\ &\times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}^{-1} \\ &\times \begin{bmatrix} \tilde{B}_{11}H_{11} \\ B_{22}H_{21} \\ 0 \end{bmatrix} \end{aligned}$$

and

$$\begin{aligned} T_{22}(s) = \begin{bmatrix} 0 & \tilde{C}_{22} & C_{23} \end{bmatrix} &\times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}^{-1} \\ &\times \begin{bmatrix} \tilde{B}_{11}H_{12} \\ B_{22}H_{22} \\ 0 \end{bmatrix} \end{aligned}$$

are nonsingular and diagonal.

By applying Lemma 2.1(i) to (2.21) we have that

$$\begin{cases} D_{11}H_{12} = 0, \\ n_1+n_2+n_3 = \max\limits_{s\in\mathbf{C}} \operatorname{rank} \\ \times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} & \tilde{B}_{11}H_{12} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} & B_{22}H_{22} \\ 0 & -\tilde{A}_{32} & sI-A_{33} & 0 \\ C_{11}+D_{11}F_{11} & \tilde{C}_{12}+D_{11}F_{12} & C_{13}+D_{11}F_{13} & 0 \end{bmatrix}, \\ n_1+n_2+n_3 = \max\limits_{s\in\mathbf{C}} \operatorname{rank} \\ \times \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} & \tilde{B}_{11}H_{11} \\ -A_{21}-B_{22}F_{21} & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} & B_{22}H_{21} \\ 0 & -\tilde{A}_{32} & sI-A_{33} & 0 \\ 0 & \tilde{C}_{22} & C_{23} & 0 \end{bmatrix}, \end{cases}$$

which, together with (2.12) and the nonsingularity of D_{11}, B_{22}, and H, yields that

$$\begin{cases} H_{12}=0,\ H_{11} \text{ and } H_{22} \text{ are nonsingular,} \\ \max\limits_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \\ C_{11}+D_{11}F_{11} & \tilde{C}_{12}+D_{11}F_{12} & C_{13}+D_{11}F_{13} \end{bmatrix} = n_1+n_3, \\ \max\limits_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & \tilde{B}_{11}H_{11} \\ -A_{21}-B_{22}F_{21} & B_{22}H_{21} \end{bmatrix} = n_1. \end{cases} \tag{2.22}$$

Since the property (2.11) and the nonsingularity of H_{11} imply that

$$\operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & \tilde{B}_{11}H_{11} \end{bmatrix} = \operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11} & \tilde{B}_{11} \end{bmatrix} = n_1 \quad \forall s\in\mathbf{C},$$

we have further by applying Lemma 2.1 to (2.22) that

$$\begin{cases} H_{12}=0, \\ \max\limits_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} \\ 0 & sI-A_{33} & -\tilde{A}_{32} \\ C_{11}+D_{11}F_{11} & C_{13}+D_{11}F_{13} & \tilde{C}_{12}+D_{11}F_{12} \end{bmatrix} = n_1+n_3, \\ B_{22}H_{21}=0,\ -A_{21}-B_{22}F_{21}=0, \end{cases}$$

which with the nonsingularity of B_{22} gives that

$$H_{12}=0,\ H_{21}=0, \quad B_{22}F_{21}=-A_{21}, \tag{2.23}$$

and

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} & \tilde{A}_{12}+\tilde{B}_{11}F_{12} \\ 0 & sI-A_{33} & \tilde{A}_{32} \\ C_{11}+D_{11}F_{11} & C_{13}+D_{11}F_{13} & -(\tilde{C}_{12}+D_{11}F_{12}) \end{bmatrix} = n_1+n_3. \tag{2.24}$$

Consequently, (2.24) and Lemma 2.1(i) give (2.18). Moreover, we obtain

$$\begin{aligned} &Q_L V_1 (sI-A-BF) V_1^T Q_R^T \\ &= \begin{bmatrix} sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11} & -\tilde{A}_{12}-\tilde{B}_{11}F_{12} & -\tilde{A}_{13}-\tilde{B}_{11}F_{13} \\ 0 & sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ 0 & -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}, \end{aligned}$$

$$\begin{cases} T_{11}(s) = D_{11}H_{11} + (C_{11}+D_{11}F_{11})(sU_{11}-\tilde{A}_{11}-\tilde{B}_{11}F_{11})^{-1}\tilde{B}_{11}H_{11}, \\ T_{22}(s) = \begin{bmatrix} \tilde{C}_{22} & C_{23} \end{bmatrix} \begin{bmatrix} sU_{22}^T-\tilde{A}_{22}-B_{22}F_{22} & -A_{23}-B_{22}F_{23} \\ -\tilde{A}_{32} & sI-A_{33} \end{bmatrix}^{-1} \begin{bmatrix} B_{22} \\ 0 \end{bmatrix} H_{22}. \end{cases}$$

Now, $A+BF$ is stable, and $T_{11}(s)$ and $T_{22}(s)$ are nonsingular and diagonal. Hence, (2.14)–(2.17) hold.

Sufficiency. Assume that the conditions (2.4) and (2.13) hold, and that F_{11}, F_{12}, F_{13}, F_{22}, F_{23}, H_{11} and H_{22} satisfy (2.14)–(2.18). Define F_{21}, H_{12}, and H_{21} by (2.23) and determine F and H by (2.19). Then a simple calculation yields that the matrix $A+BF$ is stable, and that $(C+DF)(sI-A-BF)^{-1}BH+DH$ is nonsingular and diagonal. Hence, (F,H) solves the state feedback decoupling problem with stability for the system (1.1). □

Remark 2.6. Problem (2.18) is called a disturbance decoupling problem [39].

The feedthrough matrices in the state feedback decoupling problems (2.15) and (2.17) are zero and nonsingular, respectively. By this feature the problems (2.15) and (2.17) are easier to solve than the original problem (1.4), as shown in the next subsections.

2.2. Stage 2—rejection of the disturbance in (2.5)–(2.18). Since the problem of (2.14) and (2.15) has been solved in [9], in this subsection we shall study only the simultaneous problem of (2.5), (2.17), and (2.18). We will reject the disturbance and consequently transform the simultaneous problem of (2.5), (2.17), and (2.18) into a single problem like that of (2.5) and (2.17).

LEMMA 2.7 (cf. [27, 30, 43]). *Assume that the factorizations* (2.1) *and* (2.10) *have been determined. There exist orthogonal matrices* $U_2 \in \mathbf{R}^{(n_1+n_3+m_0)\times(n_1+n_3+m_0)}$ *and* $V_2 \in \mathbf{R}^{(n_1+n_3)\times(n_1+n_3)}$ *such that*

$$U_2 \left[\begin{array}{ccc|cc} -D_{11} & -C_{11} & -C_{13} & \tilde{C}_{12} & I \\ -\tilde{B}_{11} & sU_{11}-\tilde{A}_{11} & -\tilde{A}_{13} & \tilde{A}_{12} & 0 \\ 0 & 0 & sI-A_{33} & \tilde{A}_{32} & 0 \end{array}\right] \left[\begin{array}{ccc} I_{m_0} & 0 & 0 \\ 0 & V_2 & 0 \\ 0 & 0 & I \end{array}\right]^T$$

$$= \begin{array}{c} \begin{array}{ccccccc} m_0 & n_1+n_3-\tau-\nu & \tau & \nu & n_2 & m_0 & \end{array} \\ \left[\begin{array}{ccccccc} \mathcal{D}_{11} & \star & \star & \star & \star & \star & \}m_0 \\ 0 & s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13} & \Delta & \tilde{\Psi} & \}n_1+n_3-\tau-\nu \\ 0 & 0 & s\Theta-\Phi & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23} & 0 & \Psi & \}\tau \\ 0 & 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} & 0 & 0 & \}\nu \end{array}\right] \end{array}, \tag{2.25}$$

where $\star$ *denotes subblocks that we are not interested in;* $\tilde{\Theta}_{11}$, Θ, *and* $\tilde{\Theta}_{33}$ *are nonsingular; and*

$$\operatorname{rank}\left[\begin{array}{cc} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & \Delta \end{array}\right] = n_1+n_3-\tau-\nu \quad \forall s \in \mathbf{C}, \tag{2.26}$$

$$\operatorname{rank}\left[\begin{array}{cc} s\Theta-\Phi & \Psi \end{array}\right] = \tau \quad \forall s \in \mathbf{C}. \tag{2.27}$$

Proof. By computing the QR factorization of $\left[\begin{smallmatrix} D_{11} \\ \tilde{B}_{11} \end{smallmatrix}\right]$ first and then computing the controllability staircase form [27, 30, 43] of the pair

$$\left(\mathcal{N}^T \left[\begin{array}{ccc} -D_{11} & -C_{11} & -C_{13} \\ -\tilde{B}_{11} & sU_{11}-\tilde{A}_{11} & -\tilde{A}_{13} \\ 0 & 0 & sI-A_{33} \end{array}\right] \left[\begin{array}{c} 0 \\ I_{n_1+n_3} \end{array}\right]\right), \quad \left(\mathcal{N}^T \left[\begin{array}{cc} \tilde{C}_{12} & I \\ \tilde{A}_{12} & 0 \\ \tilde{A}_{32} & 0 \end{array}\right]\right),$$

we get the factorization (2.25). Here $\mathcal{N}$ is a column orthogonal matrix whose columns span the null space of $\left[\begin{smallmatrix} D_{11} \\ \tilde{B}_{11} \end{smallmatrix}\right]^T$. ∎

THEOREM 2.8. *Assume that the conditions* (2.4) *and* (2.13) *hold and the factorization* (2.25) *has been determined. Then the simultaneous problem of* (2.5), (2.17), *and* (2.18) *is solvable if and only if*

$$\sigma(\tilde{\Theta}_{11},\ \tilde{\Phi}_{11}) \backslash \mathbf{C}^- = \sigma(A_{33}) \backslash \mathbf{C}^-, \tag{2.28}$$

and there exists a $\mathcal{K} \in \mathbf{R}^{m_0\times\tau}$ *satisfying the following "unusual" state feedback decoupling with stability:*

(2.29) *The pencil* $(\Theta, \Phi+\Psi\mathcal{K})$ *is stable,* $\mathcal{K}(s\Theta-\Phi-\Psi\mathcal{K})^{-1}\Psi$ *is diagonal.*

Moreover, if (2.28) *and* (2.29) *hold with* $\mathcal{K} \in \mathbf{R}^{m_0\times\tau}$, *then* (2.5), (2.17), *and* (2.18) *hold with* F_{11}, F_{12}, F_{13}, *and* H_{11} *determined by*

$$D_{11}\begin{bmatrix} F_{11} & F_{13}\end{bmatrix} = -\begin{bmatrix} 0 & \mathcal{K} & \hat{\mathcal{K}}\end{bmatrix}V_2 - \begin{bmatrix} C_{11} & C_{13}\end{bmatrix}, \quad D_{11}F_{12} = -\tilde{C}_{12},$$

$$D_{11}H_{11} \text{ is nonsingular and diagonal,}$$

where $\hat{\mathcal{K}} \in \mathbf{R}^{m_0\times\nu}$ *is arbitrary.*

In the above, for any square matrices N *and* M, $\sigma(N,M)$ *denotes the finite spectrum of the pencil* (N,M), *and* $\sigma(M) = \sigma(I,M)$.

Proof. First, the factorization (2.25) and the properties (2.11) and (2.13) yield

$$\begin{aligned}
&\operatorname{rank}\begin{bmatrix} \mathcal{D}_{11} & \star & \star & \star & \star & \star \\ 0 & s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13} & \Delta & \tilde{\Psi} \\ 0 & 0 & s\Theta-\Phi & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23} & 0 & \Psi \\ 0 & 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} & 0 & 0 \end{bmatrix} \\
&= \operatorname{rank}\begin{bmatrix} -D_{11} & -C_{11} & -C_{13} & \tilde{C}_{12} & I \\ -\tilde{B}_{11} & sU_{11}-\tilde{A}_{11} & -\tilde{A}_{13} & \tilde{A}_{12} & 0 \\ 0 & 0 & sI-A_{33} & \tilde{A}_{32} & 0 \end{bmatrix} = n_1+n_3+m_0 \quad \forall s \in \mathbf{C}\backslash\mathbf{C}^-,
\end{aligned}$$

and thus, the pencil $(\tilde{\Theta}_{33}, \tilde{\Phi}_{33})$ is stable.

Next, the property (2.27) holds, so there exists a $\mathcal{K}_0$ such that the pencil $(\Theta, \Phi + \Psi\mathcal{K}_0)$ is stable [39]. Let

$$\begin{bmatrix} \mathcal{F}_1^{(0)} & \mathcal{F}_3^{(0)}\end{bmatrix} = -\begin{bmatrix} \overset{n_1+n_3-\tau-\nu}{0} & \overset{\tau}{\mathcal{K}_0} & \overset{\nu}{0}\end{bmatrix}V_2.$$

Then

$$\begin{aligned}
&U_2\begin{bmatrix} -D_{11} & -C_{11}+\mathcal{F}_1^{(0)} & -C_{13}+\mathcal{F}_3^{(0)} \\ -\tilde{B}_{11} & sU_{11}-\tilde{A}_{11} & -\tilde{A}_{13} \\ 0 & 0 & sI-A_{33} \end{bmatrix}\begin{bmatrix} I_{m_0} & 0 \\ 0 & V_2 \end{bmatrix}^T \\
&= \begin{bmatrix} \mathcal{D}_{11} & \star & \star & \star \\ 0 & s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13} \\ 0 & 0 & s\Theta-\Phi & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23} \\ 0 & 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} \end{bmatrix} - \begin{bmatrix} \star \\ \tilde{\Psi} \\ \Psi \\ 0 \end{bmatrix}\begin{bmatrix} 0 & 0 & \mathcal{K}_0 & 0 \end{bmatrix} \\
&= \begin{bmatrix} \mathcal{D}_{11} & \star & \star & \star \\ 0 & s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K}_0 & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13} \\ 0 & 0 & s\Theta-\Phi-\Psi\mathcal{K}_0 & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23} \\ 0 & 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} \end{bmatrix},
\end{aligned}$$

so, by using the stability of the pencils $(\Theta, \Phi+\Psi\mathcal{K}_0)$ and $(\tilde{\Theta}_{33}, \tilde{\Phi}_{33})$ we obtain

(2.30)

$$\begin{aligned}
\sigma(A_{33})\backslash\mathbf{C}^- &\subseteq \sigma\left(\begin{bmatrix} 0 & 0 & 0 \\ 0 & U_{11} & 0 \\ 0 & 0 & I \end{bmatrix}, \begin{bmatrix} D_{11} & C_{11}-\mathcal{F}_1^{(0)} & C_{13}-\mathcal{F}_3^{(0)} \\ \tilde{B}_{11} & \tilde{A}_{11} & \tilde{A}_{13} \\ 0 & 0 & A_{33} \end{bmatrix}\right)\backslash\mathbf{C}^- \\
&= \sigma\left(\begin{bmatrix} \tilde{\Theta}_{11} & \tilde{\Theta}_{12} & \tilde{\Theta}_{13} \\ 0 & \Theta & \tilde{\Theta}_{23} \\ 0 & 0 & \tilde{\Theta}_{33} \end{bmatrix}, \begin{bmatrix} \tilde{\Phi}_{11} & \tilde{\Phi}_{12}+\tilde{\Psi}\mathcal{K}_0 & \tilde{\Phi}_{13} \\ 0 & \Phi+\Psi\mathcal{K}_0 & \tilde{\Phi}_{23} \\ 0 & 0 & \tilde{\Phi}_{33} \end{bmatrix}\right)\backslash\mathbf{C}^- \\
&= \sigma(\tilde{\Theta}_{11}, \tilde{\Phi}_{11})\backslash\mathbf{C}^-.
\end{aligned}$$

For any $F_{1i} \in \mathbf{R}^{m_0 \times n_i}$ $(i = 1, 2, 3)$ and $H_{11} \in \mathbf{R}^{m_0 \times m_0}$, define

$$\begin{cases} \mathcal{F}_1 = C_{11} + D_{11}F_{11}, \quad \mathcal{F}_2 = \tilde{C}_{12} + D_{11}F_{12}, \quad \mathcal{F}_3 = C_{13} + D_{11}F_{13}, \quad \mathcal{H} = D_{11}H_{11}, \\ \qquad\qquad\qquad\qquad n_1 + n_3 - \tau - \nu \quad \tau \quad \nu \\ \left[\begin{array}{cc} \mathcal{F}_1 & \mathcal{F}_3 \end{array}\right] V_2^T = -\left[\begin{array}{ccc} \tilde{\mathcal{K}} & \mathcal{K} & \hat{\mathcal{K}} \end{array}\right]. \end{cases}$$

We have that

$$U_2 \left[\begin{array}{ccc} -D_{11} & -C_{11} + \mathcal{F}_1 & -C_{13} + \mathcal{F}_3 \\ -\tilde{B}_{11} & sU_{11} - \tilde{A}_{11} & -\tilde{A}_{13} \\ 0 & 0 & sI - A_{33} \end{array}\right] \left[\begin{array}{cc} I_{m_0} & 0 \\ 0 & V_2 \end{array}\right]^T$$

$$= \left[\begin{array}{cccc} \mathcal{D}_{11} & \star & \star & \star \\ 0 & s\tilde{\Theta}_{11} - \tilde{\Phi}_{11} - \tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12} - \tilde{\Phi}_{12} - \tilde{\Psi}\mathcal{K} & s\tilde{\Theta}_{13} - \tilde{\Phi}_{13} - \tilde{\Psi}\hat{\mathcal{K}} \\ 0 & -\Psi\tilde{\mathcal{K}} & s\Theta - \Phi - \Psi\mathcal{K} & s\tilde{\Theta}_{23} - \tilde{\Phi}_{23} - \Psi\hat{\mathcal{K}} \\ 0 & 0 & 0 & s\tilde{\Theta}_{33} - \tilde{\Phi}_{33} \end{array}\right],$$

$$\begin{aligned} &\sigma\ (U_{11},\ \tilde{A}_{11} + \tilde{B}_{11}F_{11}) = \sigma(U_{11},\ \tilde{A}_{11} + \tilde{B}_{11}D_{11}^{-1}(\mathcal{F}_1 - C_{11})) \\ &= \sigma\left(\left[\begin{array}{cc} 0 & 0 \\ 0 & U_{11} \end{array}\right], \left[\begin{array}{cc} D_{11} & C_{11} - \mathcal{F}_1 \\ \tilde{B}_{11} & \tilde{A}_{11} \end{array}\right]\right) \\ &= \sigma\left(\left[\begin{array}{ccc} 0 & 0 & 0 \\ 0 & U_{11} & 0 \\ 0 & 0 & I \end{array}\right], \left[\begin{array}{ccc} D_{11} & C_{11} - \mathcal{F}_1 & C_{13} - \mathcal{F}_3 \\ \tilde{B}_{11} & \tilde{A}_{11} & \tilde{A}_{13} \\ 0 & 0 & A_{33} \end{array}\right]\right) \backslash \sigma(A_{33}) \\ &= \sigma\left(\left[\begin{array}{cccc} 0 & \star & \star & \star \\ 0 & \tilde{\Theta}_{11} & \tilde{\Theta}_{12} & \tilde{\Theta}_{13} \\ 0 & 0 & \Theta & \tilde{\Theta}_{23} \\ 0 & 0 & 0 & \tilde{\Theta}_{33} \end{array}\right], \left[\begin{array}{cccc} -\mathcal{D}_{11} & \star & \star & \star \\ 0 & \tilde{\Phi}_{11} + \tilde{\Psi}\tilde{\mathcal{K}} & \tilde{\Phi}_{12} + \tilde{\Psi}\mathcal{K} & \tilde{\Phi}_{13} + \tilde{\Psi}\hat{\mathcal{K}} \\ 0 & \Psi\tilde{\mathcal{K}} & \Phi + \Psi\mathcal{K} & \tilde{\Phi}_{23} + \Psi\hat{\mathcal{K}} \\ 0 & 0 & 0 & \tilde{\Phi}_{33} \end{array}\right]\right) \backslash \sigma(A_{33}), \end{aligned}$$

$$\begin{aligned} &D_{11}H_{11} + (C_{11} + D_{11}F_{11})(sU_{11} - \tilde{A}_{11} - \tilde{B}_{11}F_{11})^{-1}\tilde{B}_{11}H_{11} \\ &= \mathcal{H} + \mathcal{F}_1(sU_{11} - \tilde{A}_{11} - \tilde{B}_{11}D_{11}^{-1}(\mathcal{F}_1 - C_{11}))^{-1}\tilde{B}_{11}D_{11}^{-1}\mathcal{H} \\ &= \mathcal{H} + \left[\begin{array}{ccc} 0 & \mathcal{F}_1 & \mathcal{F}_3 \end{array}\right] \left[\begin{array}{ccc} -D_{11} & -C_{11} + \mathcal{F}_1 & -C_{13} + \mathcal{F}_3 \\ -\tilde{B}_{11} & sU_{11} - \tilde{A}_{11} & -\tilde{A}_{13} \\ 0 & 0 & sI - A_{33} \end{array}\right]^{-1} \left[\begin{array}{c} -\mathcal{H} \\ 0 \\ 0 \end{array}\right] \\ &= \mathcal{H} + \left[\begin{array}{ccc} \tilde{\mathcal{K}} & \mathcal{K} & \hat{\mathcal{K}} \end{array}\right] \left[\begin{array}{ccc} s\tilde{\Theta}_{11} - \tilde{\Phi}_{11} - \tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12} - \tilde{\Phi}_{12} - \tilde{\Psi}\mathcal{K} & s\tilde{\Theta}_{13} - \tilde{\Phi}_{13} - \tilde{\Psi}\hat{\mathcal{K}} \\ -\Psi\tilde{\mathcal{K}} & s\Theta - \Phi - \Psi\mathcal{K} & s\tilde{\Theta}_{23} - \tilde{\Phi}_{23} - \Psi\hat{\mathcal{K}} \\ 0 & 0 & s\tilde{\Theta}_{33} - \tilde{\Phi}_{33} \end{array}\right]^{-1} \\ &\qquad \times \left[\begin{array}{c} \tilde{\Psi}\mathcal{H} \\ \Psi\mathcal{H} \\ 0 \end{array}\right], \end{aligned}$$

and

$$\begin{aligned} &\tilde{C}_{12} + D_{11}F_{12} + \left[\begin{array}{cc} C_{11} + D_{11}F_{11} & C_{13} + D_{11}F_{13} \end{array}\right] \\ &\quad \times \left[\begin{array}{cc} sU_{11} - \tilde{A}_{11} - \tilde{B}_{11}F_{11} - \tilde{A}_{13} - \tilde{B}_{11}F_{13} & \\ 0 & sI - A_{33} \end{array}\right]^{-1} \left[\begin{array}{c} \tilde{A}_{12} + \tilde{B}_{11}F_{12} \\ \tilde{A}_{32} \end{array}\right] \\ &= \mathcal{F}_2 + \left[\begin{array}{cc} \mathcal{F}_1 & \mathcal{F}_3 \end{array}\right] \left[\begin{array}{cc} sU_{11} - \tilde{A}_{11} - \tilde{B}_{11}D_{11}^{-1}(\mathcal{F}_1 - C_{11}) & -\tilde{A}_{13} - \tilde{B}_{11}D_{11}^{-1}(\mathcal{F}_3 - C_{13}) \\ 0 & sI - A_{33} \end{array}\right]^{-1} \\ &\qquad \times \left[\begin{array}{c} \tilde{A}_{12} + \tilde{B}_{11}D_{11}^{-1}(\mathcal{F}_2 - \tilde{C}_{12}) \\ \tilde{A}_{32} \end{array}\right] \end{aligned}$$

$$= \mathcal{F}_2 + \begin{bmatrix} 0 & \mathcal{F}_1 & \mathcal{F}_3 \end{bmatrix} \begin{bmatrix} -D_{11} & -C_{11}+\mathcal{F}_1 & -C_{13}+\mathcal{F}_3 \\ -\tilde{B}_{11} & sU_{11}-\tilde{A}_{11} & -\tilde{A}_{13} \\ 0 & 0 & sI-A_{33} \end{bmatrix}^{-1} \begin{bmatrix} \tilde{C}_{12}-\mathcal{F}_2 \\ \tilde{A}_{12} \\ \tilde{A}_{32} \end{bmatrix}$$

$$= \mathcal{F}_2 + \begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} & \hat{\mathcal{K}} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13}-\tilde{\Psi}\hat{\mathcal{K}} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23}-\Psi\hat{\mathcal{K}} \\ 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} \end{bmatrix}^{-1} \times \begin{bmatrix} \tilde{\Psi}\mathcal{F}_2-\Delta \\ \Psi\mathcal{F}_2 \\ 0 \end{bmatrix}.$$

As a result, we get by using Lemma 2.1, factorization (2.25), and the stability of the pencil $(\tilde{\Theta}_{33}, \tilde{\Phi}_{33})$ that (2.5)–(2.18) hold as follows:

$$\Longleftrightarrow \begin{cases} \sigma\left(\begin{bmatrix} \tilde{\Theta}_{11} & \tilde{\Theta}_{12} & \tilde{\Theta}_{13} \\ 0 & \Theta & \tilde{\Theta}_{23} \\ 0 & 0 & \tilde{\Theta}_{33} \end{bmatrix}, \begin{bmatrix} \tilde{\Phi}_{11}+\tilde{\Psi}\tilde{\mathcal{K}} & \tilde{\Phi}_{12}+\tilde{\Psi}\mathcal{K} & \tilde{\Phi}_{13}+\tilde{\Psi}\hat{\mathcal{K}} \\ \Psi\tilde{\mathcal{K}} & \Phi+\Psi\mathcal{K} & \tilde{\Phi}_{23}+\Psi\hat{\mathcal{K}} \\ 0 & 0 & \tilde{\Phi}_{33} \end{bmatrix}\right) \backslash \mathbf{C}^- = \sigma(A_{33}) \backslash \mathbf{C}^-, \\ \mathcal{H} + \begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} & \hat{\mathcal{K}} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13}-\tilde{\Psi}\hat{\mathcal{K}} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23}-\Psi\hat{\mathcal{K}} \\ 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} \end{bmatrix}^{-1} \\ \qquad \times \begin{bmatrix} \tilde{\Psi}\mathcal{H} \\ \Psi\mathcal{H} \\ 0 \end{bmatrix} \text{ is nonsingular and diagonal}, \\ \mathcal{F}_2 + \begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} & \hat{\mathcal{K}} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} & s\tilde{\Theta}_{13}-\tilde{\Phi}_{13}-\tilde{\Psi}\hat{\mathcal{K}} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} & s\tilde{\Theta}_{23}-\tilde{\Phi}_{23}-\Psi\hat{\mathcal{K}} \\ 0 & 0 & s\tilde{\Theta}_{33}-\tilde{\Phi}_{33} \end{bmatrix}^{-1} \\ \qquad \times \begin{bmatrix} \tilde{\Psi}\mathcal{F}_2-\Delta \\ \Psi\mathcal{F}_2 \\ 0 \end{bmatrix} = 0 \end{cases}$$

$$\Longleftrightarrow \begin{cases} \sigma\left(\begin{bmatrix} \tilde{\Theta}_{11} & \tilde{\Theta}_{12} \\ 0 & \Theta \end{bmatrix}, \begin{bmatrix} \tilde{\Phi}_{11}+\tilde{\Psi}\tilde{\mathcal{K}} & \tilde{\Phi}_{12}+\tilde{\Psi}\mathcal{K} \\ \Psi\tilde{\mathcal{K}} & \Phi+\Psi\mathcal{K} \end{bmatrix}\right) \backslash \mathbf{C}^- = \sigma(A_{33}) \backslash \mathbf{C}^-, \\ \mathcal{H} \text{ is nonsingular and diagonal}, \\ \begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} \end{bmatrix}^{-1} \begin{bmatrix} \tilde{\Psi} \\ \Psi \end{bmatrix} \text{ is diagonal}, \\ \mathcal{F}_2 = 0, \quad \begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} \end{bmatrix}^{-1} \begin{bmatrix} \Delta \\ 0 \end{bmatrix} = 0. \end{cases} \tag{2.31}$$

Because Lemma 2.1 implies that

$$\begin{bmatrix} \tilde{\mathcal{K}} & \mathcal{K} \end{bmatrix} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} \end{bmatrix}^{-1} \begin{bmatrix} \Delta \\ 0 \end{bmatrix} = 0$$

$$\Longleftrightarrow \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11}-\tilde{\Psi}\tilde{\mathcal{K}} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12}-\tilde{\Psi}\mathcal{K} & \Delta \\ -\Psi\tilde{\mathcal{K}} & s\Theta-\Phi-\Psi\mathcal{K} & 0 \\ \tilde{\mathcal{K}} & \mathcal{K} & 0 \end{bmatrix} = n_1+n_3-\nu$$

$$\Longleftrightarrow \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & s\tilde{\Theta}_{12}-\tilde{\Phi}_{12} & \Delta \\ 0 & s\Theta-\Phi & 0 \\ \tilde{\mathcal{K}} & \mathcal{K} & 0 \end{bmatrix} = n_1+n_3-\nu$$

$$\iff \max_{s\in\mathbf{C}} \operatorname{rank}\begin{bmatrix} s\tilde{\Theta}_{11}-\tilde{\Phi}_{11} & \Delta \\ \tilde{\mathcal{K}} & 0 \end{bmatrix} = (n_1+n_3)-\tau-\nu$$

(since $\Theta \in \mathbf{R}^{\tau\times\tau}$ is nonsingular and thus $\max_{s\in\mathbf{C}} \operatorname{rank}(s\Theta-\Phi)=\tau$)

$$\iff \tilde{\mathcal{K}} = 0 \qquad \text{(since (2.26) holds)},$$

we obtain by using (2.31) that

$$(2.5)-(2.18)\text{ hold} \iff \begin{cases} \mathcal{F}_2 = 0, \quad \tilde{\mathcal{K}} = 0, \\ \mathcal{K}(s\Theta-\Phi-\Psi\mathcal{K})^{-1}\Psi \text{ is diagonal}, \\ (\sigma(\tilde{\Theta}_{11},\ \tilde{\Phi}_{11})\cup\sigma(\Theta,\ \Phi+\Psi\mathcal{K}))\backslash\mathbf{C}^- = \sigma(A_{33})\backslash\mathbf{C}^-, \end{cases}$$

$$\iff \begin{cases} \mathcal{F}_2 = 0, \quad \tilde{\mathcal{K}} = 0, \\ \mathcal{K}(s\Theta-\Phi-\Psi\mathcal{K})^{-1}\Psi \text{ is diagonal}, \\ \sigma(\tilde{\Theta}_{11},\ \tilde{\Phi}_{11})\backslash\mathbf{C}^- = \sigma(A_{33})\backslash\mathbf{C}^-,\ \sigma(\Theta,\ \Phi+\Psi\mathcal{K}) \subseteq \mathbf{C}^- \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{(since (2.30) holds)} \end{cases}$$

$$\iff \begin{cases} \mathcal{F}_2 = 0, \quad \tilde{\mathcal{K}} = 0, \\ \mathcal{K}(s\Theta-\Phi-\Psi\mathcal{K})^{-1}\Psi \text{ is diagonal}, \\ \sigma(\tilde{\Theta}_{11},\ \tilde{\Phi}_{11})\backslash\mathbf{C}^- = \sigma(A_{33})\backslash\mathbf{C}^-,\ \text{pencil } (\Theta, \Phi+\Psi\mathcal{K}) \text{ is stable}. \end{cases}$$

Hence, Theorem 2.8 holds. □

2.3. Stage 3—a numerical solution to Problem (2.29). The main difference between the problem (2.29) and the usual state feedback decoupling problem is that the problem (2.29) does not require the nonsingularity of the transfer function $\mathcal{K}(s\Theta-\Phi-\Psi\mathcal{K})^{-1}\Psi$. To our knowledge, the problem (2.29) has not been studied yet, and our attempts to characterize its solvability conditions by extending the results in [24, 25, 26, 39] have failed. We will develop a numerically reliable algorithm in this subsection for solving the problem (2.29).

The following result is trivial.

COROLLARY 2.9. *Assume that the factorization* (2.25) *has been determined and that* $m_0 = 1$*; then the problem* (2.29) *is always solvable and all its solutions are given by all matrices* $\mathcal{K}$ *satisfying that the pencil* $(\Theta, \Phi+\Psi\mathcal{K})$ *is stable.*

In the following we consider the case that $m_0 > 1$.

THEOREM 2.10. *Assume that the factorization* (2.25) *has been determined and that* $m_0 > 1$*. There exist nonnegative integers* τ_i *(*$i = 1, \ldots, 5$*), a permutation matrix* $\mathcal{P} \in \mathbf{R}^{m_0\times m_0}$*, and orthogonal matrices* $\mathcal{U}_1, \mathcal{U}_2, \mathcal{V}_1, \mathcal{V}_2 \in \mathbf{R}^{\tau\times\tau}$*,* $\mathcal{U}_3, \mathcal{V}_3 \in \mathbf{R}^{(\tau_1+\tau_2+\tau_3)\times(\tau_1+\tau_2+\tau_3)}$ *with partitioning,*

$$\mathcal{U}_2 = \begin{array}{c} \begin{matrix} \sum_{i=1}^3 \tau_i & \tau_4+\tau_5 \end{matrix} \\ \begin{bmatrix} \mathcal{U}_{11} & \mathcal{U}_{12} \\ \mathcal{U}_{21} & \mathcal{U}_{22} \end{bmatrix} \begin{matrix} \}\sum_{i=1}^3 \tau_i \\ \}\tau_4+\tau_5 \end{matrix} \end{array}, \quad \mathcal{V}_2 = \begin{array}{c} \begin{matrix} \sum_{i=1}^3 \tau_i & \tau_4+\tau_5 \end{matrix} \\ \begin{bmatrix} \mathcal{V}_{11} & \mathcal{V}_{12} \\ \mathcal{V}_{21} & \mathcal{V}_{22} \end{bmatrix} \begin{matrix} \}\sum_{i=1}^3 \tau_i \\ \}\tau_4+\tau_5 \end{matrix} \end{array},$$

such that $\operatorname{rank}(\mathcal{U}_{11}) = \sum_{i=1}^{3} \tau_i$, $\operatorname{rank}(\mathcal{V}_{22}) = \tau_4 + \tau_5$, *and*

$$
\begin{cases}
\begin{bmatrix} \mathcal{U}_3 & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} \mathcal{U}_{11} & \mathcal{U}_{12} \\ 0 & I \end{bmatrix} \mathcal{U}_1 (s\Theta - \Phi) \left(\begin{bmatrix} \mathcal{V}_3 & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} I & 0 \\ \mathcal{V}_{21} & \mathcal{V}_{22} \end{bmatrix} \mathcal{V}_1 \right)^T \\
\qquad = \begin{array}{c} \begin{matrix} \tau_1 & \tau_2 & \tau_3 & \tau_4 & \tau_5 \end{matrix} \\ \begin{bmatrix} s\Theta_{11} - \Phi_{11} & 0 & 0 & 0 & 0 \\ s\Theta_{21} - \Phi_{21} & s\Theta_{22} - \Phi_{22} & 0 & 0 & 0 \\ s\Theta_{31} - \Phi_{31} & s\Theta_{32} - \Phi_{32} & s\Theta_{33} - \Phi_{33} & 0 & -\Phi_{35} \\ 0 & 0 & 0 & s\Theta_{44} - \Phi_{44} & s\Theta_{45} - \Phi_{45} \\ 0 & 0 & 0 & s\Theta_{54} - \Phi_{54} & s\Theta_{55} - \Phi_{55} \end{bmatrix} \end{array} \begin{matrix} \}\tau_1 \\ \}\tau_2 \\ \}\tau_3 \\ \}\tau_5 \\ \}\tau_4 \end{matrix}, \\
\begin{bmatrix} \mathcal{U}_3 & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} \mathcal{U}_{11} & \mathcal{U}_{12} \\ 0 & I \end{bmatrix} \mathcal{U}_1 \Psi \mathcal{P}^T = \begin{array}{c} \begin{matrix} m_1 & \tau_5 & m_0 - m_1 - \tau_5 \end{matrix} \\ \begin{bmatrix} \Psi_{11} & 0 & 0 \\ \Psi_{21} & 0 & \Psi_{23} \\ \Psi_{31} & 0 & \Psi_{33} \\ 0 & \Psi_{42} & \Psi_{43} \\ 0 & 0 & 0 \end{bmatrix} \end{array} \begin{matrix} \}\tau_1 \\ \}\tau_2 \\ \}\tau_3 \\ \}\tau_5 \\ \}\tau_4 \end{matrix},
\end{cases}
\tag{2.32}
$$

where

$$
0 < m_1 < m_0, \quad 0 \le \tau_5 \le 1, \tag{2.33}
$$

$$
\text{if } \tau_5 = 0, \text{ then } \tau_3 = \tau_4 = 0, \tag{2.34}
$$

(2.35)

$$
\operatorname{rank} \begin{bmatrix} s\Theta_{11} - \Phi_{11} & 0 & 0 & \Psi_{11} \\ s\Theta_{21} - \Phi_{21} & s\Theta_{22} - \Phi_{22} & 0 & \Psi_{21} \\ s\Theta_{31} - \Phi_{31} & s\Theta_{32} - \Phi_{32} & s\Theta_{33} - \Phi_{33} & \Psi_{31} \end{bmatrix} = \tau_1 + \tau_2 + \tau_3 \quad \forall s \in \mathbf{C},
$$

(2.36)

$$
\operatorname{rank} \begin{bmatrix} s\Theta_{22} - \Phi_{22} & \Psi_{23} \end{bmatrix} = \tau_2 \quad \forall s \in \mathbf{C},
$$

and furthermore, if $\tau_5 = 1$, *we also have*

$$
\Psi_{42} \neq 0, \tag{2.37}
$$

$$
\operatorname{rank} \begin{bmatrix} s\Theta_{33} - \Phi_{33} & \Phi_{35} \end{bmatrix} = \tau_3, \quad \operatorname{rank}(s\Theta_{54} - \Phi_{54}) = \tau_4 \quad \forall s \in \mathbf{C}. \tag{2.38}
$$

Proof. The constructive proof of Theorem 2.10 is given in [3]. □

Similarly to the factorization (2.10), the factorization (2.32) is also numerically reliable.

We are now ready to derive a useful reduction property of the problem (2.29) using the factorization (2.32).

THEOREM 2.11. *Assume that factorizations* (2.25) *and* (2.32) *have been determined. Then the problem* (2.29) *is solvable if and only if*

$$
\text{pencils } (\Theta_{22}, \Phi_{22}) \text{ and } (\Theta_{33}, \Phi_{33}) \text{ are stable}, \tag{2.39}
$$

$$
\text{the pencil } \left(\begin{bmatrix} \Theta_{44} & \Theta_{45} \\ \Theta_{54} & \Theta_{55} \end{bmatrix}, \begin{bmatrix} \Phi_{44} & \Phi_{45} \\ \Phi_{54} & \Phi_{44} \end{bmatrix} \right) \text{ is stable if } \Psi_{43} \neq 0, \tag{2.40}
$$

and there exists a matrix $\mathcal{K}_{11} \in \mathbf{R}^{m_1 \times \tau_1}$ *such that*

(2.41)
$$\text{pencil } (\Theta_{11}, \Phi_{11} + \Psi_{11}\mathcal{K}_{11}) \text{ is stable}, \quad \mathcal{K}_{11}(s\Theta_{11} - \Phi_{11} - \Psi_{11}\mathcal{K}_{11})^{-1}\Psi_{11} \text{ is diagonal.}$$

Moreover, if (2.39), (2.40), *and* (2.41) *hold, then one solution* $\mathcal{K}$ *of the problem* (2.29) *is given by*

$$\mathcal{K}\left(\begin{bmatrix} \mathcal{V}_3 & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} I & 0 \\ \mathcal{V}_{21} & \mathcal{V}_{22} \end{bmatrix}\mathcal{V}_1\right)^T = \mathcal{P}^T \begin{array}{c} \begin{matrix} \tau_1 & \tau_2 & \tau_3 & \tau_4 & \tau_5 \end{matrix} \\ \begin{bmatrix} \mathcal{K}_{11} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mathcal{K}_{24} & \mathcal{K}_{25} \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \end{array} \begin{matrix} \}m_1 \\ \}\tau_5 \\ \}m_0 - m_1 - \tau_5, \end{matrix}$$

(2.42)

where

(2.43)
$$\begin{bmatrix} \mathcal{K}_{24} & \mathcal{K}_{25} \end{bmatrix} = 0 \text{ if } \Psi_{43} \neq 0,$$

(2.44)
$$\text{the pencil } \left(\begin{bmatrix} \Theta_{44} & \Theta_{45} \\ \Theta_{54} & \Theta_{55} \end{bmatrix}, \begin{bmatrix} \Phi_{44} & \Phi_{45} \\ \Phi_{54} & \Phi_{55} \end{bmatrix} + \begin{bmatrix} \Psi_{42} \\ 0 \end{bmatrix}\begin{bmatrix} \mathcal{K}_{24} & \mathcal{K}_{25} \end{bmatrix}\right)$$
is stable if $\Psi_{43} = 0$.

Proof. Denote

$$\mathcal{Q}_{\mathcal{L}} = \begin{bmatrix} \mathcal{U}_3 & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} \mathcal{U}_{11} & \mathcal{U}_{12} \\ 0 & I \end{bmatrix}\mathcal{U}_1, \quad \mathcal{Q}_{\mathcal{R}} = \begin{bmatrix} \mathcal{V}_3 & 0 \\ 0 & I \end{bmatrix}\begin{bmatrix} I & 0 \\ \mathcal{V}_{21} & \mathcal{V}_{22} \end{bmatrix}\mathcal{V}_1,$$

(2.45)
$$\mathcal{Q}_{\mathcal{L}}\Psi\mathcal{P}^T =: \begin{array}{c} \begin{matrix} m_1 & \tau_5 & m_0 - m_1 - \tau_5 \end{matrix} \\ \begin{bmatrix} \Psi_1 & \Psi_2 & \Psi_3 \end{bmatrix} \end{array},$$
$$\text{i.e., } \Psi_1 := \begin{bmatrix} \Psi_{11} \\ \Psi_{21} \\ \Psi_{31} \\ 0 \\ 0 \end{bmatrix}, \ \Psi_2 := \begin{bmatrix} 0 \\ 0 \\ 0 \\ \Psi_{42} \\ 0 \end{bmatrix}, \ \Psi_3 := \begin{bmatrix} 0 \\ \Psi_{23} \\ \Psi_{33} \\ \Psi_{43} \\ 0 \end{bmatrix}.$$

For any $\mathcal{K} \in \mathbf{R}^{m_0 \times \tau}$, let

$$\mathcal{P}\mathcal{K}\mathcal{Q}_{\mathcal{R}}^T =: \begin{array}{c} \begin{matrix} \tau_1 & \tau_2 & \tau_3 & \tau_4 & \tau_5 \end{matrix} \\ \begin{bmatrix} \mathcal{K}_{11} & \mathcal{K}_{12} & \mathcal{K}_{13} & \mathcal{K}_{14} & \mathcal{K}_{15} \\ \mathcal{K}_{21} & \mathcal{K}_{22} & \mathcal{K}_{23} & \mathcal{K}_{24} & \mathcal{K}_{25} \\ \mathcal{K}_{31} & \mathcal{K}_{32} & \mathcal{K}_{33} & \mathcal{K}_{34} & \mathcal{K}_{35} \end{bmatrix} \end{array} \begin{matrix} \}m_1 \\ \}\tau_5 \\ \}m_0 - m_1 - \tau_5 \end{matrix} = \begin{bmatrix} \mathcal{K}_1 \\ \mathcal{K}_2 \\ \mathcal{K}_3 \end{bmatrix} \begin{matrix} \}m_1 \\ \}\tau_5 \\ \}m_0 - m_1 - \tau_5. \end{matrix}$$

Necessity. Assume that (2.29) holds with $\mathcal{K} \in \mathbf{R}^{m_0 \times \tau}$. Since $\mathcal{K}(s\Theta - \Phi - \Psi\mathcal{K})^{-1}\Psi$ is diagonal, so $\mathcal{P}\mathcal{K}\mathcal{Q}_{\mathcal{R}}^T(\mathcal{Q}_{\mathcal{L}}(s\Theta - \Phi)\mathcal{Q}_{\mathcal{R}}^T - \mathcal{Q}_{\mathcal{L}}\Psi\mathcal{P}^T\mathcal{P}\mathcal{K}\mathcal{Q}_{\mathcal{R}}^T)^{-1}\mathcal{Q}_{\mathcal{L}}\Psi\mathcal{P}^T$ is also diagonal; i.e.,

$$\begin{bmatrix} \mathcal{K}_1 \\ \mathcal{K}_2 \\ \mathcal{K}_3 \end{bmatrix}(\mathcal{Q}_{\mathcal{L}}(s\Theta - \Phi)\mathcal{Q}_{\mathcal{R}}^T - \Psi_1\mathcal{K}_1 - \Psi_2\mathcal{K}_2 - \Psi_3\mathcal{K}_3)^{-1}\begin{bmatrix} \Psi_1 & \Psi_2 & \Psi_3 \end{bmatrix} \text{ is diagonal.}$$

Thus, we have

$$\begin{aligned}
&\mathcal{K}_3(\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3)^{-1}\begin{bmatrix}\Psi_1 & \Psi_2\end{bmatrix}=0,\\
&\mathcal{K}_1(\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3)^{-1}\begin{bmatrix}\Psi_2 & \Psi_3\end{bmatrix}=0,\\
&\mathcal{K}_2(\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3)^{-1}\Psi_1=0,\\
&\mathcal{K}_2(\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3)^{-1}\Psi_3=0.
\end{aligned}$$

By using Lemma 2.1(i) we obtain

$$\begin{aligned}
\tau&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3 & \Psi_1 & \Psi_2\\ \mathcal{K}_3 & 0 & 0\end{bmatrix}\\
&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T & \Psi_1 & \Psi_2\\ \mathcal{K}_3 & 0 & 0\end{bmatrix},
\end{aligned}\tag{2.46}$$

$$\begin{aligned}
\tau&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3 & \Psi_2 & \Psi_3\\ \mathcal{K}_1 & 0 & 0\end{bmatrix}\\
&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T & \Psi_2 & \Psi_3\\ \mathcal{K}_1 & 0 & 0\end{bmatrix}\\
&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}
s\Theta_{11}-\Phi_{11} & 0 & 0 & 0 & 0 & 0 & 0\\
s\Theta_{21}-\Phi_{21} & s\Theta_{22}-\Phi_{22} & 0 & 0 & 0 & 0 & \Psi_{23}\\
s\Theta_{31}-\Phi_{31} & s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & 0 & -\Phi_{35} & 0 & \Psi_{33}\\
0 & 0 & 0 & s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{42} & \Psi_{43}\\
0 & 0 & 0 & s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 & 0\\
\mathcal{K}_{11} & \mathcal{K}_{12} & \mathcal{K}_{13} & \mathcal{K}_{14} & \mathcal{K}_{15} & 0 & 0
\end{bmatrix},
\end{aligned}\tag{2.47}$$

$$\begin{aligned}
\tau&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_3\mathcal{K}_3 & \Psi_1\\ \mathcal{K}_2 & 0\end{bmatrix}\\
&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_3\mathcal{K}_3 & \Psi_1\\ \mathcal{K}_2 & 0\end{bmatrix},
\end{aligned}\tag{2.48}$$

$$\begin{aligned}
\tau&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1-\Psi_2\mathcal{K}_2-\Psi_1\mathcal{K}_1 & \Psi_3\\ \mathcal{K}_2 & 0\end{bmatrix}\\
&=\max_{s\in\mathbf{C}}\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1 & \Psi_3\\ \mathcal{K}_2 & 0\end{bmatrix}.
\end{aligned}\tag{2.49}$$

In (2.32), we have

$$\operatorname{rank}\begin{bmatrix}\mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T & \Psi_1 & \Psi_2\end{bmatrix}=\tau\quad\forall s\in\mathbf{C},$$

which, with (2.46) and Lemma 2.1(ii), gives that

$$\mathcal{K}_3=0,\ \text{i.e.,}\ \begin{bmatrix}\mathcal{K}_{31} & \mathcal{K}_{32} & \mathcal{K}_{33} & \mathcal{K}_{34} & \mathcal{K}_{35}\end{bmatrix}=0.\tag{2.50}$$

Note that

$$\operatorname{rank}\begin{bmatrix}
s\Theta_{22}-\Phi_{22} & 0 & 0 & 0 & 0 & \Psi_{23}\\
s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & 0 & -\Phi_{35} & 0 & \Psi_{33}\\
0 & 0 & s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{42} & \Psi_{43}\\
0 & 0 & s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 & 0
\end{bmatrix}=\tau-\tau_1\quad\forall s\in\mathbf{C},$$

and (2.47) yields that

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\Theta_{22}-\Phi_{22} & 0 & 0 & 0 & 0 & \Psi_{23} \\ s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & 0 & -\Phi_{35} & 0 & \Psi_{33} \\ 0 & 0 & s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{42} & \Psi_{43} \\ 0 & 0 & s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 & 0 \\ \mathcal{K}_{12} & \mathcal{K}_{13} & \mathcal{K}_{14} & \mathcal{K}_{15} & 0 & 0 \end{bmatrix} = \tau-\tau_1;$$

thus, it follows from Lemma 2.1(ii) that

$$\begin{bmatrix} \mathcal{K}_{12} & \mathcal{K}_{13} & \mathcal{K}_{14} & \mathcal{K}_{15} \end{bmatrix} = 0. \tag{2.51}$$

Next, (2.50) is true, and (2.48) is reduced to

$$\begin{aligned} \tau &= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} \mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T & \Psi_1 \\ \mathcal{K}_2 & 0 \end{bmatrix} \\ &= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\Theta_{11}-\Phi_{11} & 0 & 0 & 0 & 0 & \Psi_{11} \\ s\Theta_{21}-\Phi_{21} & s\Theta_{22}-\Phi_{22} & 0 & 0 & 0 & \Psi_{21} \\ s\Theta_{31}-\Phi_{31} & s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & 0 & -\Phi_{35} & \Psi_{31} \\ 0 & 0 & 0 & s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & 0 \\ 0 & 0 & 0 & s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 \\ \mathcal{K}_{21} & \mathcal{K}_{22} & \mathcal{K}_{23} & \mathcal{K}_{24} & \mathcal{K}_{25} & 0 \end{bmatrix}, \end{aligned}$$

i.e.,

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\Theta_{11}-\Phi_{11} & 0 & 0 & \Psi_{11} \\ s\Theta_{21}-\Phi_{21} & s\Theta_{22}-\Phi_{22} & 0 & \Psi_{21} \\ s\Theta_{31}-\Phi_{31} & s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & \Psi_{31} \\ \mathcal{K}_{21} & \mathcal{K}_{22} & \mathcal{K}_{23} & 0 \end{bmatrix} = \tau_1+\tau_2+\tau_3,$$

which, with (2.36) and Lemma 2.1(ii), gives

$$\begin{bmatrix} \mathcal{K}_{21} & \mathcal{K}_{22} & \mathcal{K}_{23} \end{bmatrix} = 0. \tag{2.52}$$

Now, (2.51) and (2.52) hold, so (2.49) is reduced to

$$\begin{aligned} \tau &= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} \mathcal{Q}_{\mathcal{L}}(s\Theta-\Phi)\mathcal{Q}_{\mathcal{R}}^T-\Psi_1\mathcal{K}_1 & \Psi_3 \\ \mathcal{K}_2 & 0 \end{bmatrix} \\ &= \max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\Theta_{11}-\Phi_{11}-\Psi_{11}\mathcal{K}_{11} & 0 & 0 & 0 & 0 & 0 \\ s\Theta_{21}-\Phi_{21}-\Psi_{21}\mathcal{K}_{11} & s\Theta_{22}-\Phi_{22} & 0 & 0 & 0 & \Psi_{23} \\ s\Theta_{31}-\Phi_{31}-\Psi_{31}\mathcal{K}_{11} & s\Theta_{32}-\Phi_{32} & s\Theta_{33}-\Phi_{33} & 0 & -\Phi_{35} & \Psi_{33} \\ 0 & 0 & 0 & s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{43} \\ 0 & 0 & 0 & s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 \\ 0 & 0 & 0 & \mathcal{K}_{24} & \mathcal{K}_{25} & 0 \end{bmatrix}, \end{aligned}$$

which gives

$$\max_{s\in\mathbf{C}} \operatorname{rank} \begin{bmatrix} s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{43} \\ s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 \\ \mathcal{K}_{24} & \mathcal{K}_{25} & 0 \end{bmatrix} = \tau_4+\tau_5. \tag{2.53}$$

If $\Psi_{43}=0$, then (2.53) is always true. Otherwise, if $\Psi_{43}\neq 0$, then $\tau_5=1$ and

$$\operatorname{rank} \begin{bmatrix} s\Theta_{44}-\Phi_{44} & s\Theta_{45}-\Phi_{45} & \Psi_{43} \\ s\Theta_{54}-\Phi_{54} & s\Theta_{55}-\Phi_{55} & 0 \end{bmatrix} = \tau_4+\tau_5 \quad \forall s\in\mathbf{C}. \tag{2.54}$$

In this case, it follows from (2.53), (2.54), and Lemma 2.1(ii) that

$$\begin{bmatrix} \mathcal{K}_{24} & \mathcal{K}_{25} \end{bmatrix} = 0. \tag{2.55}$$

We have shown above that (2.42) and (2.43) hold. Therefore, (2.39), (2.40), and (2.41) follow directly from (2.50), (2.51), (2.52), and (2.55).

Sufficiency. If $\Psi_{43} = 0$, then, since

$$\operatorname{rank} \begin{bmatrix} s\Theta_{44} - \Phi_{44} & s\Theta_{45} - \Phi_{45} & \Psi_{42} \\ s\Theta_{54} - \Phi_{54} & s\Theta_{55} - \Phi_{55} & 0 \end{bmatrix} = \tau_4 + \tau_5 \quad \forall s \in \mathbf{C},$$

there always exist matrices $\mathcal{K}_{24}$ and $\mathcal{K}_{25}$ such that (2.44) holds [30]. Let $\mathcal{K} \in \mathbf{R}^{m_0 \times \tau}$ be given by (2.42), (2.43), and (2.44). Because (2.39), (2.40), and (2.41) hold, a simple calculation yields that the pencil $(\Theta, \Phi + \Psi\mathcal{K})$ is stable, and $\mathcal{P}\mathcal{K}\mathcal{Q}_{\mathcal{R}}^T(\mathcal{Q}_{\mathcal{L}}(s\Theta - \Phi)\mathcal{Q}_{\mathcal{R}}^T - \mathcal{Q}_{\mathcal{L}}\Psi\mathcal{P}^T\mathcal{P}\mathcal{K}\mathcal{Q}_{\mathcal{R}}^T)^{-1}\mathcal{Q}_{\mathcal{L}}\Psi\mathcal{P}^T$ is diagonal, i.e., $\mathcal{K}(s\Theta - \Phi - \Psi\mathcal{K})^{-1}\Psi$ is diagonal. □

Theorem 2.11 and Corollary 2.9 lead to the following algorithm, which is based only on orthogonal transformations and solutions of some linear systems of equations for solving the problem (2.29).

ALGORITHM 1.

Input: $\Theta, \Phi \in \mathbf{R}^{\tau \times \tau}$, $\Psi \in \mathbf{R}^{\tau \times m_0}$ *satisfying* (2.27).

Output: $\mathcal{K} \in \mathbf{R}^{m_0 \times \tau}$ *(if possible) solving the problem* (2.29).

Step 0. *Set* $K := \emptyset$, $M := I_{m_0}$, $N := I_\tau$, $l := 0$.

Step 1. *If* $m_0 = 1$, *compute* $\mathcal{K}$ *such that the pencil* $(\Theta, \Phi + \Psi\mathcal{K})$ *is stable, and set* $K := \left[\begin{smallmatrix} \mathcal{K} & 0 \\ 0 & K \end{smallmatrix}\right]$, *then go to Step* 3. *Otherwise, if* $m_0 > 1$, *go to Step* 2.

Step 2. *Compute the factorization* (2.32). *If* (2.39) *or* (2.40) *fails, print "The problem* (2.29) *is not solvable" and stop. Otherwise, compute* $\begin{bmatrix} \mathcal{K}_{24} & \mathcal{K}_{25} \end{bmatrix}$ *based on* (2.43) *and* (2.44). *Set*

$$K := \begin{array}{c} \begin{matrix} \tau_2 & \tau_3 & \tau_4 & \tau_5 & \end{matrix} \\ \begin{bmatrix} 0 & 0 & \mathcal{K}_{24} & \mathcal{K}_{25} & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & K \end{bmatrix} \end{array} \begin{array}{l} \}\tau_5 \\ \}m_0 - m_1 - \tau_5 \\ l \end{array},$$

$$M := M \begin{bmatrix} \mathcal{P}^T & 0 \\ 0 & I \end{bmatrix}, \quad N := N \begin{bmatrix} \mathcal{Q}_{\mathcal{R}}^T & 0 \\ 0 & I \end{bmatrix},$$

$$\Theta := \Theta_{11}, \ \Phi := \Phi_{11}, \ \Psi := \Psi_{11}, \ l = l + m_0 - m_1, \ \tau = \tau_1, \ m_0 := m_1.$$

Go to Step 1.

Step 3. *Compute* $\mathcal{K}$ *by solving the linear system*

$$\mathcal{K}N = MK. \tag{2.56}$$

Output $\mathcal{K}$.

2.4. Stage 4—an overall algorithm. The results in subsections 2.1, 2.2, and 2.3 can be combined to provide an overall algorithm for solving the state feedback decoupling problem with stability for general proper systems of the form (1.1) as follows.

ALGORITHM 2.

Input: $A \in \mathbf{R}^{n \times n}$, $B \in \mathbf{R}^{n \times m}$, $C \in \mathbf{R}^{m \times n}$, *and* $D \in \mathbf{R}^{m \times m}$.

Output: *Matrices* $F \in \mathbf{R}^{m\times n}$ *and* $H \in \mathbf{R}^{m\times m}$ *(if possible) such that* $A+BF$ *is stable and* (1.4) *holds.*

Step 1. *Compute the factorization* (2.1)*. If the condition* (2.4) *is not true, print "The studied problem is not solvable" and stop. Otherwise, compute the factorization* (2.10)*. If the condition* (2.13) *is not true, print "The studied problem is not solvable" and stop.*

Step 2. *Solve the problem of* (2.14) *and* (2.15) *by the algorithm in* [9]*. If it is not solvable, print "The studied problem is not solvable" and stop. Otherwise, compute* $(\begin{bmatrix} F_{22} & F_{23} \end{bmatrix}, H_{22})$ *such that* (2.14) *and* (2.15) *hold.*

Step 3. *Compute the staircase form* (2.25)*. If the condition* (2.28) *does not hold, print "The studied problem is not solvable" and stop. Otherwise, perform Algorithm* 1 *without Step* 3 *to get matrices* M*,* N*, and* K*.*

Step 4. *Solve* (2.56) *to get* $\mathcal{K}$ *and then solve the following linear systems of equations to get* F *and* H*:*

$$\begin{bmatrix} D_{11} & 0 \\ B_{21} & B_{22} \end{bmatrix} W^T F V_1^T Q_R^T = -\begin{bmatrix} C_{11}+E_1 & \tilde{C}_{12} & C_{13}+E_3 \\ A_{21} & -B_{22}F_{22} & -B_{22}F_{23} \end{bmatrix},$$

$$\begin{bmatrix} D_{11} & 0 \\ B_{21} & B_{22} \end{bmatrix} W^T H P^T = \begin{bmatrix} \Lambda & 0 \\ 0 & B_{22}H_{22} \end{bmatrix},$$

where Λ *is an arbitrary nonsingular and diagonal matrix, and*

$$\begin{bmatrix} E_1 & E_3 \end{bmatrix} = \begin{bmatrix} n_1+n_3-\tau-\nu & \tau & \nu \\ 0 & \mathcal{K} & 0 \end{bmatrix} \mathcal{V}_2.$$

Output F *and* H*.*

Note that Algorithm 2 has the following features:

- The factorizations (2.1), (2.10), (2.25), and (2.32) are numerically reliable.[1]
- Steps 1 and 3 are implemented based on only orthogonal transformations, in which the condition (2.13) is equivalent to that the pair $(A_{33}, \tilde{A}_{32})$ is stabilizable and thus it can be verified easily [43].
- Step 2 is implemented based on the algorithm in [9] which is numerically reliable.
- Linear systems of equations in Steps 3 and 4 can be solved efficiently by the SVD method [22].

Hence, Algorithm 2 can be implemented in a numerically reliable manner.

In the following, we apply Algorithm 2 to an example generated by MATLAB 7.0.

EXAMPLE 2.12. *Let*

$$A(:,1:3) = \begin{bmatrix} -134.7151815770 & 684.5200688479 & -252.4858402416 \\ 2965.6910031615 & 2968.6795856120 & 3127.3190640174 \\ 2496.6636879933 & 5313.7625190612 & 2258.0418588501 \\ -224.6817995288 & 1986.6127660631 & -532.3798160083 \\ -37.1081164625 & -3118.1270598251 & 369.5187260686 \\ 1410.6906971850 & 2447.1024041232 & 1348.3759688211 \end{bmatrix},$$

[1] The computations of the factorizations (2.1), (2.10), (2.25), and (2.32) require the usage of the notion *numerical rank* of a matrix. The most reliable method for deciding the rank of a matrix $M \in \mathbf{R}^{m\times n}$, $m \geq n$, is as follows: Compute the singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_n$ of M, as in [27], and consider a singular value σ_j to be zero if $\sigma_j \leq \epsilon\sigma_1$, where ϵ bounds the relative error in M. The number of remaining nonzero singular values is then taken to be the (numerical) rank of the matrix.

$$A(:,\,4\,:\,6) = \begin{bmatrix} 316.6433509627 & 300.0280484275 & -10.467634805 \\ 1276.6140059526 & 1011.4552055403 & 820.772696295 \\ 2365.7472100096 & 2039.6108213012 & 784.077193552 \\ 916.7671233048 & 857.0012773342 & 10.752404856 \\ -1430.5834820660 & -1313.1753655886 & -112.512294456 \\ 1080.7385716405 & 918.0951249252 & 424.352681385 \end{bmatrix},$$

$$B = \begin{bmatrix} 425.29217463199 & -80.88171998499 & -145.72982759769 \\ 3982.20690197082 & 3016.72330542203 & 3062.57237309851 \\ 5436.32609118648 & 2736.92286843590 & 2560.48573537041 \\ 1335.34779570743 & -74.51223868009 & -247.07435777624 \\ -2331.54633119938 & -255.18364603148 & -20.55480073218 \\ 2660.00572592472 & 1506.16763608974 & 1448.73127764291 \end{bmatrix},$$

$$C(:,\,1\,:\,3) = \begin{bmatrix} 0.4447033643532 & 0.9218129707448 & 0.4057062130621 \\ 0.6154323481001 & 0.7382072458107 & 0.9354696991076 \\ 0.7919370374270 & 0.1762661444946 & 0.9169044399134 \end{bmatrix},$$

$$C(:,\,4\,:\,6) = \begin{bmatrix} 0.4102702069910 & 0.3528681322170 & 0.1388908819570 \\ 0.8936495309135 & 0.8131664973038 & 0.2027652185603 \\ 0.0578913047843 & 0.0098613006609 & 0.1987217426615 \end{bmatrix},$$

$$D = \begin{bmatrix} 0.95012928514718 & 0.48598246870930 & 0.45646766516834 \\ 0.23113851357429 & 0.89129896614890 & 0.01850364324822 \\ 0.60684258354179 & 0.76209683302739 & 0.82140716429525 \end{bmatrix}.$$

By using Algorithm 2, *we get a solution* (F, H) *of the state feedback decoupling problem with stability for the proper system described by the* (A, B, C, D) *quadruple as follows:*

$$F(:,\,1\,:\,3) = \begin{bmatrix} 13.213245245439 & 6.533314996605 & -7.120728173265 \\ -5.071573120781 & -1.923440437567 & 0.236601849708 \\ 45.978278670010 & -28.856343706120 & 26.995864311313 \end{bmatrix},$$

$$F(:,\,4\,:\,6) = \begin{bmatrix} -5.266769113169 & -7.409085032473 & -3.479842456999 \\ 1.574115104850 & 1.054592476902 & 0.489990507618 \\ -58.329243480873 & -2.194096577547 & 8.908103088096 \end{bmatrix},$$

$$H = \begin{bmatrix} 1.67404446726824 & -0.11964439680952 & -0.92759516260175 \\ -0.41647243581381 & 1.17375817197623 & 0.20499869641804 \\ -0.85035677245799 & -1.00061468473081 & 1.71251901466682 \end{bmatrix}.$$

It has been verified that $A + BF$ *is stable with eigenvalues*

$$\sigma(A + BF) = \{-2368.44594880864, -1583.30208404670, -0.46317761699,$$

$$-0.00497367650, -0.00764132113, -0.11009271581\},$$

and $DH + (C + DF)(sI - A - BF)^{-1}BH$ *is nonsingular. It has also been verified that* $DH + (C + DF)(sI - A - BF)^{-1}BH$ *is diagonal as follows:*

- *Compute the transfer function* $T_f(s) = DH + (C + DF)(sI - A - BF)^{-1}BH$ *by* MATLAB 7.0

  $$T_f(s) = tf(\mathrm{ss}(A + B * F, B * H, C + D * F, D * H)).$$

  Let $(T_f(s))_{diag}$ *be a diagonal matrix that satisfies that all diagonal elements of* $T_f(s) - (T_f(s))_{diag}$ *are zeros.*

- *Calculate the peak gain of the frequency responses (as measured by the largest singular value) of* $T_f(s)$ *and* $T_f(s) - (T_f(s))_{diag}$ *using the code* $\mathrm{norm}(\cdot, \mathrm{inf})$ *of* MATLAB 7.0 *to get*

$$\frac{\mathrm{norm}(T_f(s) - (T_f(s))_{diag}, \mathrm{inf})}{\mathrm{norm}(T_f(s), \mathrm{inf})} = O(10^{-13}).$$

Therefore, under the measure of the peak gain of the frequency responses, the off-diagonal elements of $T_f(s)$ *are tiny relative to its diagonal elements, and thus* $T_f(s)$ *is diagonal.*

3. Conclusions. We have derived numerically verifiable solvability conditions and developed a numerical algorithm, Algorithm 2, to compute a solution for the state feedback decoupling problem with stability for general proper systems described by (A, B, C, D) quadruples. Algorithm 2 involves only orthogonal transformations and the solutions of several linear systems of equations, and thus it can be implemented in a numerically reliable manner.

Acknowledgments. We would like to thank the anonymous referees and Professor Peter Benner for their helpful suggestions and comments on an early version of this paper.

INTERVAL GAUSSIAN ELIMINATION WITH PIVOT TIGHTENING*

JÜRGEN GARLOFF†

Abstract. We present a method by which the breakdown of the interval Gaussian elimination caused by division of an interval containing zero can be avoided for some classes of matrices. These include the inverse nonnegative matrices, the totally nonnegative matrices, and the inverse M-matrices—all classes with identically signed inverses. The approach consists of a tightening of the interval pivot by determining the exact range of the pivot over the matrix interval.

Key words. interval Gaussian elimination, inverse nonnegative matrix, totally nonnegative matrix, inverse M-matrix

1. Introduction.

Systems of linear interval equations arise when the entries of the coefficient matrix and the right-hand side of a system of linear equations are varying between given bounds; cf. [20, sect. 3.4]. The *solution set* of such a system

$$[A]x = [b],$$

where $[A] = [\underline{A}, \overline{A}]$ is a given n-by-n matrix interval and $[b] = [\underline{b}, \overline{b}]$ is a given vector interval w.r.t. the usual entrywise partial order, is the set

$$\Sigma([A],[b]) := \{x \in \mathbf{R}^n \mid Ax = b,\ A \in [A],\ b \in [b]\}. \tag{1.1}$$

We will assume here throughout that all $A \in [A]$ are nonsingular. We denote the hull of $\Sigma([A],[b])$, i.e., the smallest vector interval containing $\Sigma([A],[b])$, by $[A]^H[b]$. A method to enclose $[A]^H[b]$ is interval Gaussian elimination, which is obtained from the usual (termed *ordinary* henceforth) Gaussian elimination by replacing the real numbers by the related intervals and the real operations by the respective interval operations; see, e.g., [1, Chap. 15], [20, sect. 4.5]. However, interval Gaussian elimination may fail due to division by an interval pivot containing zero, even when ordinary Gaussian elimination works for all matrices $A \in [A]$. There are some classes of interval matrices for which interval Gaussian elimination cannot fail, e.g., the H-matrices; cf. [17].

If ordinary Gaussian elimination is applied without pivoting, the pivots can be represented as the quotient of two successive leading principal minors. This property is used in [18] to modify the interval Gaussian elimination by tightening the interval pivots, and it is shown that the breakdown of interval Gaussian elimination can be avoided in some cases. However, this tightening is obtained by bounding the range of the two leading principal minors independently and then forming the quotient of both enclosures (in addition, the resulting interval is intersected with the ordinary interval

pivot). This often causes an overestimation of the range of the pivot. In this paper, we show that for some classes of matrices the exact range of the pivot can be given. As a consequence of the inclusion isotonicity of the interval arithmetic operations, this further tightening of the interval pivot has the additional advantage that the resulting enclosure of $[A]^H[b]$ is not larger than the one obtained by the method of [18] and it is often smaller. Moreover, the range of the pivots can be obtained by running a few ordinary Gaussian elimination procedures in parallel.

The organization of the paper is as follows: In the next section we introduce our notation and recall the interval Gaussian elimination. In section 3 we present pivot tightening. This is applied in section 4 to inverse nonnegative matrices, to totally nonnegative matrices, and to inverse M-matrices. In sections 5 and 6 we show that analogous results can be obtained for a related determinantal function and some algorithms for the solution of structured systems of linear interval equations. We conclude with some remarks in section 7.

2. Notation and interval Gaussian elimination. By $\mathbf{R}^n$, $\mathbf{R}^{n\times n}$, $\mathbf{IR}$, $\mathbf{IR}^n$, and $\mathbf{IR}^{n\times n}$ we denote the set of real vectors with n components, the set of real n-by-n matrices, the set of the compact and nonempty intervals, the set of the intervals of real vectors with n components, and the set of the intervals of real n-by-n matrices, respectively. We also regard vector intervals as interval vectors and matrix intervals as interval matrices, i.e., as vectors and matrices over $\mathbf{IR}$, respectively, and consequently represent them as $[b] = [\underline{b}, \overline{b}] = ([b_i])_{i=1}^n = ([\underline{b}_i, \overline{b}_i])_{i=1}^n$ and $[A] = [\underline{A}, \overline{A}] = ([a_{ij}])_{i,j=1}^n = ([\underline{a}_{ij}, \overline{a}_{ij}])_{i,j=1}^n$. We identify a degenerate interval (vector, matrix) with the (only) real number (vector, matrix) it contains.

We equip $\mathbf{IR}$, $\mathbf{IR}^n$, $\mathbf{IR}^{n\times n}$ with the usual real interval arithmetic; see, e.g., [1, Chap. 10], [20, Chap. 1]. We assume that the reader is familiar with the basic properties of this arithmetic. For a function $f : \mathbf{R}^{n\times n} \to \mathbf{R}$ we denote the range of f over the matrix interval $[A]$ by $f([A])$, i.e.,

$$f([A]) := \{f(A) \mid A \in [A]\}.$$

The interval Gaussian elimination (without pivoting) reads as follows.

Given $[A] \in \mathbf{IR}^{n\times n}$, $[b] \in \mathbf{IR}^n$, define $[A]^{(k)} = ([a_{ij}]^{(k)}) \in \mathbf{IR}^{n\times n}$, $[b]^{(k)} = ([b_i]^{(k)}) \in \mathbf{IR}^n$, $k = 1, \ldots, n$, and $[x]^G = ([x_i]^G) \in \mathbf{IR}^n$ by

$$[A]^{(1)} = [A], \quad [b]^{(1)} = [b],$$

$$[a_{ij}]^{(k+1)} = \begin{cases} [a_{ij}]^{(k)}, & i = 1, \ldots, k,\ j = 1, \ldots, n, \\ [a_{ij}]^{(k)} - \frac{[a_{ik}]^{(k)} \cdot [a_{kj}]^{(k)}}{[a_{kk}]^{(k)}}, & i = k+1, \ldots, n,\ j = k+1, \ldots, n, \\ 0 & \text{otherwise}, \end{cases} \tag{2.1}$$

$$[b_i]^{(k+1)} = \begin{cases} [b_i]^{(k)}, & i = 1, \ldots, k, \\ [b_i]^{(k)} - \frac{[a_{ik}]^{(k)}}{[a_{kk}]^{(k)}} \cdot [b_k]^{(k)}, & i = k+1, \ldots, n, \end{cases}$$

$$k = 1, \ldots, n-1,$$

$$[x_i]^G = \left([b_i]^{(n)} - \sum_{j=i+1}^{n} [a_{ij}]^{(n)} [x_j]^G \right) / [a_{ii}]^{(n)}, \quad i = n, n-1, \ldots, 1,$$

where $\sum_{j=n+1}^{n} \ldots = 0$. Note that no rows or columns are permuted. The algorithm is feasible if and only if $0 \notin [a_{kk}]^{(k)}$, $k = 1, \ldots, n$.

For a survey on results on this algorithm the reader is referred to [17]. Since we are interested only in the feasibility of the algorithm we consider here only the formulae in (2.1) which provide the transformation of $[A]$ into triangular form.

We further adopt standard notation from matrix analysis. For any n-by-n matrix A, we denote the submatrix lying in rows indexed from α and columns indexed from β (both in increasing order) by $A[\alpha \,|\, \beta]$, where $\alpha, \beta \subseteq \{1, 2, \ldots, n\}$. If $\alpha = \beta$, the principal submatrix $A[\alpha \,|\, \alpha]$ is abbreviated as $A[\alpha]$. In particular, when $\alpha = \{1, \ldots, k\}$, $k = 1, \ldots, n$, we call $A[\alpha]$ a *leading* principal submatrix and put $A' := A[\{1, 2, \ldots, n-1\}]$. We denote by A_{ij} the submatrix of A which is obtained by the deletion of row i and column j in A. We call A a *P-matrix* if all its principal minors are positive, *inverse nonnegative*[1] if it is nonsingular and its inverse is entrywise nonnegative, and an M-matrix if it is inverse nonnegative and all its off-diagonal entries are nonpositive. If π is a certain property of a matrix, then we call a matrix interval $[A] = [\underline{A}, \overline{A}]$ a π matrix interval if all $A \in [A]$ possess property π. For example, $[A]$ is an inverse M-matrix interval if all $A \in [A]$ are inverse M-matrices. Often it is of interest to know whether such a property of a matrix interval can be inferred from a certain subset of the *vertex matrices* $A = (a_{ij})$ with $a_{ij} \in \{\underline{a}_{ij}, \overline{a}_{ij}\}$, for all i,j. Examples are given in section 4.

3. Interval pivot tightening. Interval Gaussian elimination breaks down when an interval pivot $[a_{kk}]^{(k)}$ (henceforth termed *ordinary* interval pivot) contains zero. This can occur even though all matrices $A \in [A]$ have nonvanishing leading principal minors [22]. For ordinary Gaussian elimination, the pivot $a_{kk}^{(k)}$ can be represented as the quotient of two succeeding leading principal minors (e.g., [5, p. 26]),

$$a_{kk}^{(k)} = \frac{\det A[\{1, 2, \ldots, k\}]}{\det A[\{1, 2, \ldots, k-1\}]}. \tag{3.1}$$

This property is used in [18] to tighten the ordinary interval pivot $[a_{kk}]^{(k)}$: Let D_k denote an enclosure for $\det A[\{1, 2, \ldots, k\}]$ for all $A \in [A]$, where $D_0 := 1$. If

$$0 \notin D_k, \quad k = 1, 2, \ldots, n, \tag{3.2}$$

then $[a_{kk}]^{(k)}$ in (2.1) is replaced by

$$[a_{kk}]^{(k)} \cap \frac{D_k}{D_{k-1}}. \tag{3.3}$$

In general, this approach does not have any advantage over the ordinary interval pivot because finding an enclosure for the range of a determinant is as difficult as the original problem of solving a system of linear interval equations. However, for some classes of interval matrices presented in section 4 the exact range of principal minors can be given (only by using two specified vertex matrices) and (3.2) is satisfied. Then, when (3.3) is used as the interval pivot the breakdown of interval Gaussian elimination can be avoided. As a welcome side effect, the enclosure of the solution set may be tighter compared to the one which is obtained when the ordinary interval pivot is

[1] This is often also called *inverse positive*; since we use the terminology *totally nonnegative* instead of *totally positive* (cf. subsection 4.2), we consequently prefer *inverse nonnegative*.

used; at least it will not be larger. This is a consequence of the inclusion isotonicity of the interval arithmetic operations.

However, by enclosing the ranges of the two principal minors in (3.1) independently some overestimation is introduced into the computation. In the following, we identify some classes of matrices for which the range of the pivot $a_{kk}^{(k)}$ for all $A \in [A]$ can be given exactly such that forming the intersection in (3.3) is not necessary. Again, as a side effect, this further tightening may result in a further shrinking of the enclosure of the solution set (1.1).

The classes of matrices we will discuss in the next section have the property that any of their leading principal submatrices are in the same class (of lower order). Therefore, the discussion can be restricted to

$$p(A) := \frac{\det A}{\det A'}. \tag{3.4}$$

PROPOSITION 3.1. *The partial derivative of* $p(A) = \det A / \det(A')$ *w.r.t. the entry* a_{ij} *is given by*

$$\frac{\partial p(A)}{\partial a_{ij}} = (-1)^{i+j} \frac{\det A_{nj} \det A_{in}}{(\det A')^2}, \quad i,j = 1,\ldots,n. \tag{3.5}$$

Proof. By Laplacian expansion along row i, we obtain

$$\frac{\partial p(A)}{\partial a_{ij}} = \begin{cases} (-1)^{i+j} \frac{\det A_{ij} \det A' - \det A'_{ij} \det A}{(\det A')^2} & \text{if } i,j < n, \\ (-1)^{i+j} \frac{\det A_{ij}}{\det A'} & \text{if } i = n \text{ or } j = n. \end{cases} \tag{3.6}$$

To show (3.5) for $i,j < n$ we make use of a special case of Sylvester's determinantal identity (e.g., [12, p. 22]): Let $C \in \mathbf{R}^{n\times n}$, $\alpha \subseteq \{1,2,\ldots,n\}$ be a fixed set of cardinality $n-2$, and let $\{1,2,\ldots,n\} \setminus \alpha = \{i,j\}$ with $i < j$. Define the 2-by-2 matrix B by

$$\begin{aligned} b_{11} &:= \det C\,[\alpha \cup \{i\}], \\ b_{12} &:= \det C\,[\alpha \cup \{i\},\, \alpha \cup \{j\}], \\ b_{21} &:= \det C\,[\alpha \cup \{j\},\, \alpha \cup \{i\}], \\ b_{22} &:= \det C\,[\alpha \cup \{j\}]. \end{aligned}$$

Then it holds that

$$\det B = \det C[\alpha] \det C. \tag{3.7}$$

Now, we interchange in A rows 1 and i and columns 1 and j and apply (3.7) to the resulting matrix denoted by C with $\alpha = \{2,3,\ldots,n-1\}$. Since

$$\begin{aligned} \det C[\alpha] &= (-1)^{i+j} \det A'_{ij}, \\ \det C[\{1,\ldots,n-1\}] &= \det A', \\ \det C[\{2,\ldots,n\}] &= (-1)^{i+j} \det A_{ij}, \\ \det C[\{1,\ldots,n-1\} \,|\, \{2,\ldots,n\}] &= (-1)^{j-1} \det A_{nj}, \\ \det C[\{2,\ldots,n\} \,|\, \{1,\ldots,n-1\}] &= (-1)^{i-1} \det A_{in}, \end{aligned}$$

formula (3.7) yields

$$\det A'_{ij} \det A = \det A_{ij} \det A' - \det A_{nj} \det A_{in}.$$

Combining with (3.6), we obtain (3.5) for $i, j < n$. □

Note that $\det A_{nj}$ and $\det A_{in}$ appear in the cofactor form of the inverse of A. Therefore, we consider in the following section sets of matrices with identically signed inverses.

4. Applications.

4.1. Inverse nonnegative matrices. We will make use of the following property of the inverse nonnegative matrices.

PROPOSITION 4.1 (see [16]). *Let $[A] = [\underline{A}, \overline{A}]$ be a matrix interval and $\underline{A}$ and $\overline{A}$ be inverse nonnegative. Then $[A]$ is inverse nonnegative and $\overline{A}^{-1} \leq \underline{A}^{-1}$.*

For results on properties of inverse nonnegative matrix intervals the reader is referred to [23] and for the construction of $[A]^H[b]$ in this case to [21] and the references therein. We will focus here on the applicability of the interval Gaussian elimination. It is known that interval Gaussian elimination may break down for inverse nonnegative interval matrices; see, e.g., [20, p. 160]. We apply the pivot tightening approach from section 3.

We assume now that each $A \in [A]$ has the property that all its leading principal submatrices are inverse nonnegative. By [19, p. 24] this is equivalent to the property that A allows a factorization $A = LDU$, where L and U are inverse nonnegative lower and upper triangular matrices, respectively, whose diagonal entries are all one, and D is a diagonal matrix with positive diagonal entries. According to Proposition 4.1 the condition on $[A] = [\underline{A}, \overline{A}]$ is fulfilled if all leading principal submatrices of $\underline{A}$ and $\overline{A}$ are inverse nonnegative.

THEOREM 4.2. *If all leading principal submatrices of $[A] = [\underline{A}, \overline{A}]$ are inverse nonnegative, then the range of $p(A)$ over $[A]$ is given by*

$$p([A]) = [p(\underline{A}), p(\overline{A})]. \tag{4.1}$$

Proof. For $\underline{A} \leq A \leq \overline{A}$ it follows from Proposition 4.1 that

$$(\overline{A}^{-1})_{nn} \leq (A^{-1})_{nn} \leq (\underline{A}^{-1})_{nn}. \tag{4.2}$$

Formula (4.1) is now a consequence of $(A^{-1})_{nn} = \frac{1}{p(A)}$. □

The practical application of (4.1) requires running in parallel to the interval Gaussian elimination two instances of ordinary Gaussian elimination applied to $\underline{A}$ and $\overline{A}$. In the kth step, both pivots span the interval given on the right-hand side of (4.1).

4.2. Totally nonnegative matrices. A matrix $A \in \mathbf{R}^{n \times n}$ is called *totally nonnegative* or *totally positive* if all its minors are nonnegative or positive, respectively. These matrices appear in mechanics and in many branches of mathematics. If A is nonsingular and totally nonnegative, then so too is each leading principal submatrix and A is a P-matrix. For further properties of these matrices the reader is referred to [3].

A suitable partial order for the totally nonnegative matrices is the *checkerboard order*. For $A, B \in \mathbf{R}^{n \times n}$ define

$$A \leq^* B := (-1)^{i+j} a_{ij} \leq (-1)^{i+j} b_{ij}, \quad i, j = 1, 2, \ldots, n.$$

This partial order is related to the usual entrywise partial order by

$$A \leq^* B \Leftrightarrow A^* \leq B^*, \text{ where } A^* := SAS,\ S := \operatorname{diag}(1, -1, \ldots, (-1)^{n+1}),$$

is the checkerboard transformation.

A matrix interval $[\underline{A}, \overline{A}]$ w.r.t. the usual entrywise partial order can be represented as an interval $[\downarrow A, \uparrow A]^*$ w.r.t. the checkerboard order, where

$$(\downarrow A)_{ij} := \begin{cases} \underline{a}_{ij} & \text{if } i+j \text{ is even,} \\ \overline{a}_{ij} & \text{if } i+j \text{ is odd,} \end{cases}$$

$$(\uparrow A)_{ij} := \begin{cases} \overline{a}_{ij} & \text{if } i+j \text{ is even,} \\ \underline{a}_{ij} & \text{if } i+j \text{ is odd.} \end{cases}$$

It is conjectured in [7][2] that if $\downarrow A$ and $\uparrow A$ are nonsingular and totally nonnegative, then the whole matrix interval $[\downarrow A, \uparrow A]^*$ is nonsingular and totally nonnegative. This conjecture is settled for the totally positive and nonsingular tridiagonal totally nonnegative matrices [7], almost totally positive matrices [10], and interval matrices $[A]$ for which the index sum $i+j$ of all degenerate entries $[a_{ij}]$ has the same parity [7]. In [9] a subset of cardinality of at most 2^{2n-1} vertex matrices is given, from which the total nonnegativity of the entire matrix interval can be inferred.

Note that if A is nonsingular and totally nonnegative, then $0 \leq^* A^{-1}$ and, therefore, $0 \leq (A^{-1})^* = (A^*)^{-1}$. Since A^* is inverse nonnegative, all results for inverse nonnegative matrices carry over to the totally nonnegative matrices by the checkerboard transformation; e.g., if A and B are nonsingular and totally nonnegative, then it follows that $A \leq^* B \Rightarrow B^{-1} \leq^* A^{-1}$. For results on the calculation of $[A]^H[b]$ under special sign conditions posed on $[b]$, cf. [6].

In [6] it was shown that the interval Gaussian elimination may fail if it is applied to a nonsingular totally nonnegative interval matrix. As the most important application of the approach presented in [18], the pivot tightening (3.3) was employed for these interval matrices using the fact that the range of the determinant on such an interval matrix is given by

$$\det A([\downarrow A, \uparrow A]^*) = [\det(\downarrow A), \det(\uparrow A)]. \tag{4.3}$$

However, inspection of (3.5) or the use of the results in subsection 4.1 and application of the checkerboard transformation shows that even the exact range of the pivot of ordinary Gaussian elimination can be given.

COROLLARY 4.3. *If* $[A] = [\downarrow A, \uparrow A]^*$ *is nonsingular and totally nonnegative, then the range of* $p(A)$ *over* $[A]$ *is given by*

$$p([\downarrow A, \uparrow A]^*) = [p(\downarrow A), p(\uparrow A)]. \tag{4.4}$$

Example 4.4. We consider the example in [6], also treated in [18]. Let

$$[A] := \begin{pmatrix} [4,5] & [2,3] & 1 \\ [2,3] & 4 & [2,3] \\ 1 & [2,3] & [4,5] \end{pmatrix}.$$

[2]Note that Theorem 1 in [6] is not correct.

Taking (4.3) into account, it is easily checked that $[A]$ is nonsingular and totally nonnegative. Interval Gaussian elimination results in the interval

$$[a_{33}]^{(3)} = \left[-\frac{79}{700}, \frac{5519}{1280}\right],$$

which contains zero, and breaks down.[3] Using (4.3) the pivot tightening approach from [18] gives for this entry $[a_{33}]^{(3)} \cap \frac{[6,64]}{[7,16]} = [\frac{3}{8}, \frac{5519}{1280}]$, whereas (4.4) results in the smaller interval $[\frac{6}{7}, 4]$.

4.3. Inverse M-matrices. A matrix $A \in \mathbf{R}^{n\times n}$ is called an *inverse M-matrix* if it is the inverse of an M-matrix. Inverse M-matrices are entrywise nonnegative and P-matrices; each leading principal submatrix is likewise an inverse M-matrix. For further properties of these matrices the reader is referred to [13]. Sufficient conditions for a real matrix to be an inverse M-matrix and applications of these matrices can be found in [25].

We will make use of the following proposition.

PROPOSITION 4.5 (see [15]). *A matrix interval is an inverse M-matrix interval if and only if all its vertex matrices are inverse M-matrices.*

Example 4.7 below shows that interval Gaussian elimination may fail if it is applied to such a matrix interval. Pivot tightening here is more involved than in (4.1) and (4.4).

THEOREM 4.6. *If $[A] \in \mathbf{IR}^{n\times n}$ is an inverse M-matrix interval, then the range of $p(A)$ over $[A]$ is given by*

$$p([A]) = \left[p(A^l), p(A^u)\right], \quad \textit{where}$$

$$A^l := \begin{pmatrix} \underline{a}_{11} & \cdots & \underline{a}_{1,n-1} & \overline{a}_{1n} \\ \vdots & & \vdots & \vdots \\ \underline{a}_{n-1,1} & \cdots & \underline{a}_{n-1,n-1} & \overline{a}_{n-1,n} \\ \overline{a}_{n1} & \cdots & \overline{a}_{n,n-1} & \underline{a}_{nn} \end{pmatrix},$$

$$A^u := \begin{pmatrix} \overline{a}_{11} & \cdots & \overline{a}_{1,n-1} & \underline{a}_{1n} \\ \vdots & & \vdots & \vdots \\ \overline{a}_{n-1,1} & \cdots & \overline{a}_{n-1,n-1} & \underline{a}_{n-1,n} \\ \underline{a}_{n1} & \cdots & \underline{a}_{n,n-1} & \overline{a}_{nn} \end{pmatrix}.$$

Proof. According to the sign condition that the inverse of an inverse M-matrix A must have positive diagonal entries and all of its off-diagonal entries must be nonpositive, we obtain

$$\begin{aligned} &0 < \det A_{ii}, \quad i = 1, \ldots, n, \\ &\operatorname{sgn}(\det A_{ij}) \in \{0, (-1)^{i+j+1}\}, \quad i, j = 1, \ldots, n,\ i \neq j. \end{aligned} \tag{4.5}$$

Consider in Proposition 3.1 first the case $i = n$ or $j = n$. It follows that the partial derivative of p w.r.t. the entries in the last row or column is nonpositive (note that

[3] It should be noted that the interval Gaussian elimination would not fail, were $[a_{22}]$ chosen as the first pivot. The same applies to Example 4.7.

$0 < \det A'$) with the exception of a_{nn} for which the partial derivative is positive. In the case $i, j < n$, note that $\operatorname{sgn}(\det A_{nj} \det A_{in}) \in \{0, (-1)^{i+j}\}$. Therefore, the partial derivative of p w.r.t. an entry of A' is always nonnegative. □

Remark 4.6.1. An alternative proof in the case $i, j < n$ is as follows:[4] By permutation similarity of the inverse M-matrices it suffices to consider only entry a_{12}. The inequality

$$\det A_{12} \det A' \leq \det A'_{12} \det A$$

follows from the inequality [14, Theorem 2.1(ii)]

$$(A[\alpha])^{-1} \leq A^{-1}[\alpha]$$

which is valid for inverse M-matrices by choosing $\alpha = \{1, \ldots, n-1\}$.

Example 4.7. Let

$$[A] := \begin{pmatrix} [1,4] & [\frac{1}{2}, \frac{\sqrt{2}}{2}] & \frac{\sqrt{2}}{2} \\ \frac{\sqrt{2}}{2} & 1 & [\frac{1}{2}, \frac{\sqrt{2}}{2}] \\ \frac{1}{2} & \frac{\sqrt{2}}{2} & 1 \end{pmatrix}.$$

It is easily checked that all eight vertex matrices are inverse M-matrices, and by Proposition 4.5 it follows that $[A]$ is an inverse M-matrix interval. Interval Gaussian elimination results in the interval

$$[a_{33}^{(3)}] = \left[-\frac{4\sqrt{2}+1}{64}, 1 - \frac{\sqrt{2}}{16} \right],$$

which contains zero, and breaks down. By Theorem 4.6 this pivot can be tightened to $[\frac{1}{2}, 1 - \frac{\sqrt{2}}{4}] = [0.5, 0.6464\ldots]$.

If pivot tightening is applied in all steps, the computation of $p(A^l)$ (and similarly of $p(A^u)$) requires running in parallel to the interval Gaussian elimination an extension of ordinary Gaussian elimination. The elimination algorithm is applied to the submatrices of $[A]$ in the order indicated in Figure 4.1. The part which is recomputed or newly computed is inside the shaded area.

5. A related determinantal function. In a similar way we can determine monotonicity of the related determinantal function

$$d(A) := \det A \det A',$$

which appears, e.g., in the matricial description of the Cholesky decomposition [5, p. 38].

THEOREM 5.1. *Let* $[A] \in \mathbf{IR}^{n \times n}$.

(i) *If* $[A]$ *fulfills the assumption of Theorem* 4.2*, then the range of* $d(A)$ *over* $[A]$ *is given by*

$$d([A]) = [d(\underline{A}), d(\overline{A})].$$

[4] This was pointed out to us by Professor Charles R. Johnson.

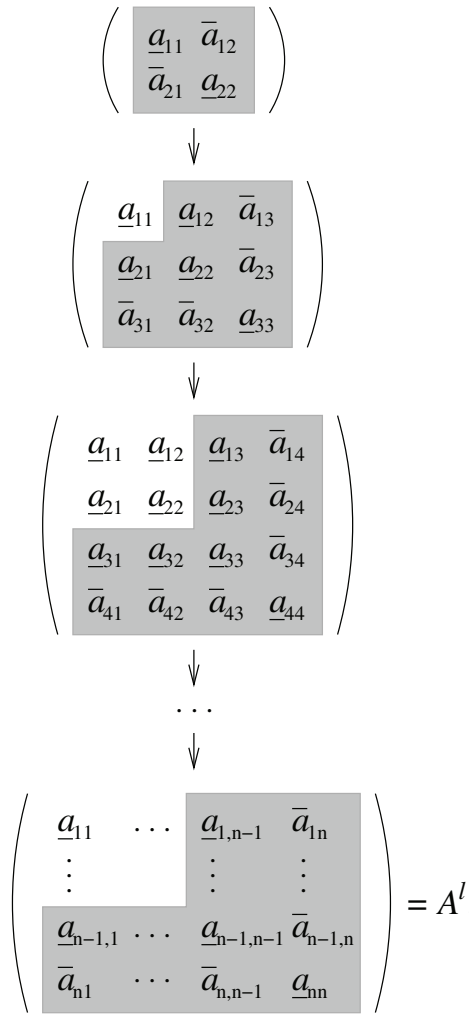

FIG. 4.1. *Elimination algorithm applied to submatrices of* $[A]$.

(ii) *If* $[A]$ *is an inverse* M*-matrix interval, it holds that*

$$d([A]) = [d(A^1), d(A^2)],$$

where

$$A^1 := \begin{pmatrix} \underline{a}_{11} & \overline{a}_{12} & \cdots & \overline{a}_{1n} \\ \overline{a}_{21} & \underline{a}_{22} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \overline{a}_{n-1,n} \\ \overline{a}_{n1} & \cdots & \overline{a}_{n,n-1} & \underline{a}_{nn} \end{pmatrix},$$

$$A^2 := \begin{pmatrix} \overline{a}_{11} & \underline{a}_{12} & \cdots & \underline{a}_{1n} \\ \underline{a}_{21} & \overline{a}_{22} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \underline{a}_{n-1,n} \\ \underline{a}_{n1} & \cdots & \underline{a}_{n,n-1} & \overline{a}_{nn} \end{pmatrix}.$$

Proof. Similarly as in (3.6) we obtain

$$\frac{\partial d(A)}{\partial a_{ij}} = \begin{cases} (-1)^{i+j}(\det A_{ij} \det A' + \det A'_{ij} \det A) & \text{if } i,j < n, \\ (-1)^{i+j} \det A_{ij} \det A' & \text{if } i = n \text{ or } j = n. \end{cases}$$

Let $[A]$ first fulfill the assumption of Theorem 4.2. From the sign condition for the inverse B of an inverse nonnegative matrix A, $B = A^{-1}$, we obtain

$$0 \le b_{ij} = (-1)^{i+j} \frac{\det A_{ji}}{\det A};$$

in particular for $i = j = n$,

$$0 < b_{nn} = \frac{\det A'}{\det A},$$

whence

$$\operatorname{sgn}(\det A) = \operatorname{sgn}(\det A').$$

If $i, j < n$ and $B' := (A')^{-1}$, it follows that

$$\frac{\partial d(A)}{\partial a_{ij}} = (b_{ji} + b'_{ji}) \det A' \det A \geqq 0.$$

If $i = n$ or $j = n$, the proof of the nonnegativity of the partial derivative of d w.r.t. a_{ij} is similar. Therefore, d is monotone increasing. This proves (i).

If $[A]$ is an inverse M-matrix interval, we obtain from the sign condition (4.5) that d is monotone increasing w.r.t. the diagonal entries and monotone decreasing w.r.t. the off-diagonal entries. This proves (ii). ∎

6. Methods for structured systems. The results for interval Gaussian elimination apply to some algorithms for the solution of structured systems of linear interval equations. Interval variants for the respective ordinary methods are obtained by replacing the real numbers by the related intervals and the real operations by the respective interval operations.

If $[A]$ is *symmetric*, i.e., $[A] = [A]^T$, then the *symmetric solution set*

$$\Sigma_{\mathrm{sym}}([A],[b]) := \{x \in \mathbf{R}^n \mid Ax = b,\ A = A^T,\ A \in [A],\ b \in [b]\}$$

is considered. The interval Cholesky method [2] can be used to enclose this set. Each step requires the division by an interval which may contain zero even if all symmetric matrices $A \in [A]$ are positive definite; an example is provided by Example 4.4. For each step of the ordinary Cholesky method, the divisor can be represented as the square root of the quotient of two succeeding leading principal minors as in (3.4) (cf. [5, p. 38]), so that the result for the interval Gaussian elimination applies.

Let $[A]$ be a *Toeplitz* interval matrix (of order $n+1$), i.e., there are intervals $[a_i]$, $i = -n, \ldots, n$, such that $[a_{ij}] = [a_{j-i}]$, $i, j = 1, \ldots, n+1$, and define by $[A]_T$ the set of all real Toeplitz matrices contained in $[A]$. Then one restricts the solution set (1.1) to the *Toeplitz solution set*

$$\Sigma_T([A], [b]) := \{x \in \mathbf{R}^n \mid Ax = b,\ A \in [A]_T, b \in [b]\}.$$

Interval variants of the elimination procedure of Bareiss [4] and of the recurrence relations for the inverse of a Toeplitz matrix [24], [26] are investigated in [8]. Even if all matrices $A \in [A]_T$ have only nonzero leading principal minors, these interval algorithms may break down due to division by an interval containing zero. An example is the interval matrix in [22]. For the ordinary (real) version of both algorithms the divisor can be represented as quotient of two successive leading principal minors (cf. Corollary 1 in [4] and [26, p. 276]), so that for both algorithms the results for the interval Gaussian elimination also apply.

If pivot tightening is used in the symmetric case, then for the three classes of matrix intervals considered in section 4, the respective vertex matrices are symmetric. In the Toeplitz case, the two vertex matrices are Toeplitz matrices in the case of an inverse nonnegative or nonsingular totally nonnegative matrix interval, but in general not in the case of an inverse M-matrix interval.

An elimination process very well suited for totally nonnegative matrices is Neville elimination [11]. Here, zeros in a column below the main diagonal of an n-by-n matrix are produced by adding to each row an appropriate multiple of the previous one (instead of using a fixed row with a fixed pivot as in Gaussian elimination). Lemma 2.6 in [11] shows that all the pivots of Neville elimination are nonzero if and only if the column-initial minors $\det A[\alpha \mid \{1, \ldots, k\}]$, where α is a subset of k successive elements of $\{1, \ldots, n\}$, are nonzero, $k = 1, \ldots, n$. Moreover, in this case, Neville elimination can be carried out without row interchanges. This suggests that the column-initial minors play a role in Neville elimination similar to that of the leading principal minors in Gaussian elimination. Formula (2.8) in [11] shows that the pivots in the kth step of Neville elimination are just the quotients of a column-initial minor of order k and its leading principal minor which is column-initial of order $k-1$. So we can apply Proposition 3.1 and the results from subsection 4.2.

7. Conclusions. We have shown how for some classes of interval matrices the interval pivots in the performance of the interval Gaussian elimination can be tightened such that the shrunken interval does not contain zero, thereby avoiding a breakdown of the algorithm. As a positive side effect, the tightening often leads to a smaller enclosure of the solution set, so that the approach is recommended not only merely for avoiding a breakdown. The extra computational effort consists of two or four instances of ordinary Gaussian elimination, depending on the class of matrices under consideration. However, to obtain verified results, these parallel runs of Gaussian elimination should be performed in interval arithmetic, too. The approach easily extends to some algorithms for solving structured systems of linear interval equations and may be applied to other classes of matrices with identically signed inverses.

Acknowledgments. We thank Professor Charles R. Johnson for his comments on the case of inverse M-matrices and Andrew P. Smith for his careful reading of the manuscript.

ON THE CONVERGENCE OF THE SELF-CONSISTENT FIELD ITERATION FOR A CLASS OF NONLINEAR EIGENVALUE PROBLEMS*

CHAO YANG†, WEIGUO GAO‡, AND JUAN C. MEZA†

Abstract. We investigate the convergence of the self-consistent field (SCF) iteration used to solve a class of nonlinear eigenvalue problems. We show that for the class of problems considered, the SCF iteration produces a sequence of approximate solutions that contain two convergent subsequences. These subsequences may converge to two different limit points, neither of which is the solution to the nonlinear eigenvalue problem. We identify the condition under which the SCF iteration becomes a contractive fixed point iteration that guarantees its convergence. This condition is characterized by an upper bound placed on a parameter that weighs the contribution from the nonlinear component of the eigenvalue problem. We derive such a bound for the general case as well as for a special case in which the dimension of the problem is 2.

Key words. nonlinear eigenvalue problem, self-consistent field iteration polynomial

1. Introduction.

We are concerned with the convergence of a numerical method for solving the following type of nonlinear eigenvalue problem:

$$H(X)X = X\Lambda_k, \tag{1}$$

where $X \in \mathbb{R}^{n\times k}$, $X^TX = I_k$, $H(X) \in \mathbb{R}^{n\times n}$ is a matrix that has a special structure to be defined below, and $\Lambda_k \in \mathbb{R}^{k\times k}$ is a diagonal matrix consisting of the k smallest eigenvalues of $H(X)$. This type of problem arises in electronic structure calculations [10, 6]. The nonlinearity simply refers to the dependency of the matrix H on the eigenvector X to be computed. This dependency is expressed through a vector $\rho(X)$ that corresponds to the *charge density* of electrons in an electronic structure calculation. This vector is defined as

$$\rho(X) \equiv \mathrm{diag}(XX^T), \tag{2}$$

where $\mathrm{diag}(A)$ denotes the vector containing the diagonal elements of the matrix A.

Given $\rho(X)$, the matrix $H(X)$ that we will consider in this paper is defined as

$$H(X) = L + \alpha \mathrm{Diag}(L^{-1}\rho(X)), \tag{3}$$

where L is a discrete Laplacian, $\mathrm{Diag}(x)$ (with an uppercase D) denotes a diagonal matrix with x on its diagonal, and α is some known constant. In electronic structure calculations, $H(X)$ is often referred to as a single-particle Hamiltonian.

The solution of (1) is also a global minimizer of the constrained minimization problem

$$\begin{array}{ll} \min & E(X) \\ \text{s.t.} & X^T X = I_k, \end{array} \tag{4}$$

where the objective function $E(X)$ is defined by

$$E(X) = \frac{1}{2}\text{trace}(X^T L X) + \frac{\alpha}{4}\rho(X)^T L^{-1}\rho(X). \tag{5}$$

In fact, it is not difficult to show that (1) and the orthonormality constraint $X^T X = I_k$ form the first order necessary conditions for (4) [7].

The nonlinear eigenvalue problem defined by (1) and (3) is a simplification of the Hartree–Fock (HF) and Kohn–Sham (KS) equations in electronic structure calculations [10, 6]. In particular, it contains a parameterized Hartree term $\rho^T L^{-1}\rho$ that is present in both the HF and KS equations. But it does not contain the exchange term in the HF model [10] or the exchange-correlation term in the KS model [6]. Although our analysis is performed on this simplified model, the main results reveal some of the fundamental properties of this type of problem and how the behavior of the algorithm used to solve this type of problem changes with respect to the amount of nonlinearity measured by the parameter α in (3).

The numerical method we will analyze is called the *self-consistent field* (SCF) iteration. It is currently the most widely used algorithm for solving the HF and KS equations. In each SCF iteration, one computes approximations to a few of the smallest eigenvalues and the corresponding eigenvectors of a fixed Hamiltonian constructed from the previous approximation to X; the computed eigenvector approximations are used to update the Hamiltonian. When the difference between Hamiltonians constructed in two consecutive iterations is negligible, the SCF procedure is terminated, and the eigenvectors of the last Hamiltonian are said to be self-consistent.

It is well known that the simplest version of SCF iteration, which we will carefully describe in the next section, often fails to converge [5]. For certain types of Hamiltonians (e.g., HF and the one defined in (3)), the SCF iteration may eventually oscillate between two limit points, neither of which satisfies (1). The convergence failure of the SCF iteration is partially explained in [11] by viewing the SCF iteration as an indirect minimization procedure that seeks the minimum of (4) by minimizing a sequence of quadratic surrogates. Although the arguments and numerical examples presented in [11] demonstrated that $E(X)$ may not decrease monotonically in an SCF iteration, they do not reveal the asymptotic convergence behavior of the SCF iteration.

In this paper, we will take a closer look at the SCF iteration and analyze its convergence when used to solve (1). A brief overview of the algorithm is given in section 2 along with a simple example that illustrates the convergence failure of the SCF iteration for some choices of α used in (3). In section 3, we show that when the SCF iteration fails to converge, the approximate eigenvectors $X^{(i)}$ produced in the SCF iteration contain two subsequences that converge to two distinct limit points. Neither of these limit points is a solution to (1). Our proof of this result is similar to an earlier proof given by Cancès and Le Bris in [2]. We made a number of simplifications to make it easier to follow. However, the subsequence convergence result does not give the conditions under which the two subsequences are guaranteed to converge to the solution of (1). Such a condition is identified in section 4. We will show that for $n = 2$, the SCF iteration is guaranteed to converge when $\alpha < 3$. For the more general case,

SCF Iteration

Input: A discrete Laplacian $L \in \mathbb{R}^{n\times n}$; an initial guess $X^{(0)}$ for the eigenvector $X \in \mathbb{R}^{n\times k}$;

Output: $X \in \mathbb{R}^{n\times k}$ such that $X^*X = I_k$ and $H(X)X = X\Lambda_k$, where Λ_k contains the k smallest eigenvalues of $H(X)$.

1. For $i = 1, 2, \ldots$ until convergence
2. construct $H^{(i)} = H(X^{(i-1)})$ using (3);
3. compute $X^{(i)}$ such that $H^{(i)}X^{(i)} = X^{(i)}\Lambda^{(i)}$, and $\Lambda^{(i)}$ contains the k smallest eigenvalues of $H^{(i)}$;
4. end for

FIG. 1. *The SCF iteration.*

our main result provides an upper bound for α that depends on the minimum gap between the kth and the $k+1$st eigenvalues of $H(X)$, the dimension of the problem, and the norm of L^{-1}.

Throughout this paper, we will use $\|\cdot\|_p$ to denote the p-norm [3] of either a vector or a matrix. The Frobenius norm of a matrix is denoted by $\|\cdot\|_F$.

2. The SCF iteration. In this section, we describe the SCF iteration and show how it fails when it is applied to a 2×2 Hamiltonian (3) with a particular choice of α.

The basic idea of an SCF iteration is to reduce the nonlinear eigenvalue problem (1) to a sequence of linear eigenvalue problems that can be solved efficiently using existing tools. Figure 1 shows the main steps of this procedure. The convergence of the iteration can be monitored by computing the difference between charge densities $\rho(X)$ obtained in two consecutive iterations. The following example shows that the simplest version of the SCF iteration fails to converge. In this example, we set

$$L = \begin{pmatrix} 2 & -1 \\ -1 & 2 \end{pmatrix}, \tag{6}$$

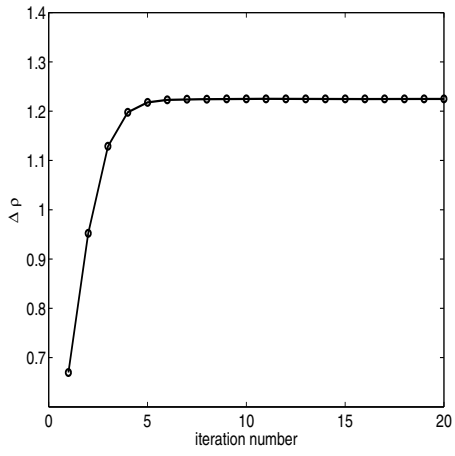
$\alpha = 12$, and $k = 1$. As a result, $X = (x_1 \;\; x_2)^T$ with $x_1, x_2 \in \mathbb{R}$ such that $x_1^2 + x_2^2 = 1$, and $\rho(X) = (x_1^2 \;\; x_2^2)^T$.

Due to the convexity and symmetry of $E(x)$ (i.e., interchanging x_1 and x_2 does not change the problem), the solution to the minimization problem (4), and hence the nonlinear eigenvalue problem (1), must satisfy $x_1 = x_2 = \sqrt{2}/2$ or $x_1 = x_2 = -\sqrt{2}/2$.

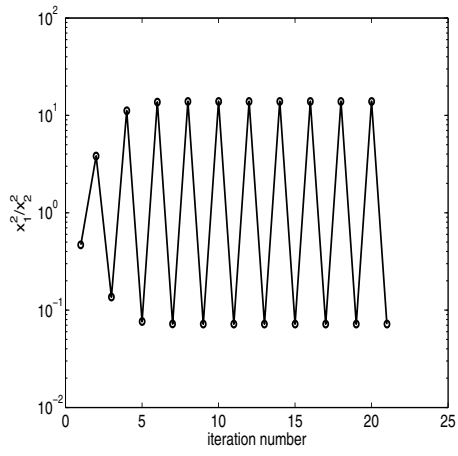
However, when the initial guess of the desired eigenvector is chosen to be, for example,

$$X^{(0)} = \begin{pmatrix} 0.1389 \\ 0.2028 \end{pmatrix}, \tag{7}$$

the difference between the charge densities computed in two consecutive SCF iterations does not converge to zero, as we can clearly see in Figure 2(a). Furthermore, Figure 2(b) shows that the ratio between two components of $\rho(X^{(i)})$ does not converge to 1.



(a) The change in charge density $\Delta\rho^{(i)} \equiv \|\rho(X^{(i+1)}) - \rho(X^{(i)})\|_2$ fails to converge to zero.



(b) The ratio between x_1^2 and x_2^2 oscillates around one, but does not converge to one.

FIG. 2. *The SCF iteration fails to converge when* $\alpha = 12$ *in* (3).

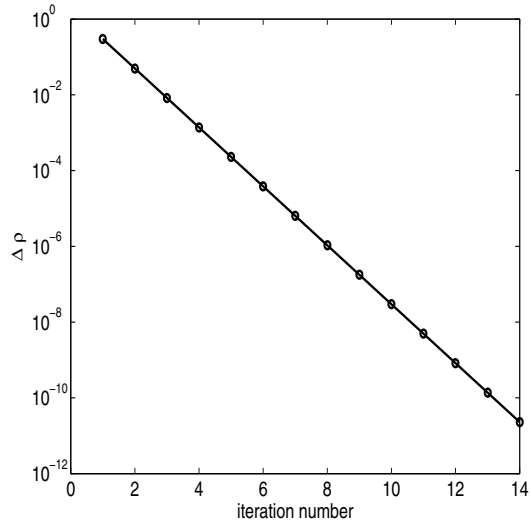


FIG. 3. *When* $\alpha = 1.0$, $\Delta\rho^{(i)}$ *converges rapidly to* 0.

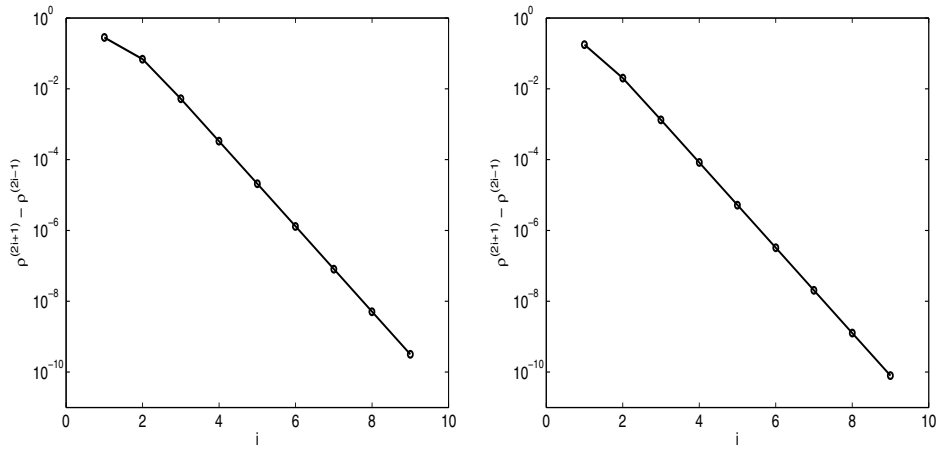
If we reduce α to 1, then SCF converges from any starting guess. Figure 3 shows that the difference between charge densities computed in two consecutive SCF iterations decreases rapidly towards zero in this case when (7) is used as the starting guess. In section 4, we will show that for this 2×2 example, the convergence of SCF can be guaranteed if $\alpha < 3$.

3. Subsequence convergence in the SCF iteration. When the SCF iteration fails to converge to the solution of (1), it produces a sequence of approximations



(a) Odd iterations (b) Even iterations

FIG. 4. *When $\alpha = 12$, the charge density converges to two different limit points in odd and even SCF iterations.*

$\{X^{(i)}\}$ that do not become self-consistent as i increases. We have already seen this phenomenon in Figure 2(a), where we plotted the norm of the change in $\rho(X^{(i)})$ between two consecutive SCF iterations. In this case, it is clear that $\|\Delta\rho(X^{(i)})\|_2$ does not converge to zero as i increases.

However, if we examine the subsequences $\{X^{(2i-1)}\}$ and $\{X^{(2i)}\}$ $(i = 1, 2, \ldots)$ produced in the SCF iteration, we will see that they both converge to subspaces that become self-consistent in every other iteration. Figure 4 shows that both

$$\Delta\rho^{(i)}_{\text{odd}} \equiv \|\rho(X^{(2i+1)}) - \rho(X^{(2i-1)})\|_2 \quad \text{and} \quad \Delta\rho^{(i)}_{\text{even}} \equiv \|\rho(X^{(2i+2)}) - \rho(X^{(2i)})\|_2$$

converge to zero as i increases, although neither $X^{(2i+1)}$ nor $X^{(2i+2)}$ becomes a minimizer of $E(X)$, as we can clearly see in Figure 2(b).

In [1] and [2] it was shown that such a phenomenon occurs in a more general setting; i.e., when SCF fails to converge to the solution of the HF equation, the odd and even subsequences of the approximations converge to two distinct limit points. This analysis, which we will reproduce here with some modification, is based on examining the convergence of the density matrix $D(X) = XX^T$. It relies on the assumption that there exists a gap δ between the kth and $k+1$st eigenvalues of $H(X)$ for all valid X, an assumption that is referred to in [1] as the *uniformly well posed* (UWP) property. The major result of [1] asserts that

$$\sum_{i=\ell}^{\infty} \|D(X^{(i+2)}) - D(X^{(i)})\|_F^2 < \infty$$

for any finite $\ell \geq 0$. Therefore, $\|D(X^{(i+2)}) - D(X^{(i)})\|_F$ must converge to zero as i increases.

In the analysis we present next, the subsequence convergence of the SCF iteration is measured by the distance between two subspaces spanned by columns of $X \in \mathbb{R}^{n\times k}$ and $Y \in \mathbb{R}^{n\times k}$. We will use the standard distance measure defined in

[3, Theorem 2.6.1, p. 76]; i.e., if $X^TX = Y^TY = I_k$,

$$\text{dist}(X, Y) \equiv \|Z^TY\|_2,$$

where $Z \in \mathbb{R}^{n\times(n-k)}$ is the orthogonal complement to X and $Z^TZ = I_{n-k}$.

The following lemma, which is a block version of Lemma 11-9-8 in [8], shows that $\text{dist}(X, Y)$ can, in general, be bounded in terms of $\text{trace}(Y^THY) - \text{trace}(X^THX)$ and the gap between the kth and $k+1$st eigenvalues of H if columns of X consist of eigenvectors associated with the k smallest eigenvalues of H and $Y \in \mathbb{R}^{n\times k}$ satisfies $Y^TY = I_k$.

LEMMA 1. *Let $\lambda_1 \le \lambda_2 \le \cdots \le \lambda_n$ be eigenvalues of a symmetric matrix $H \in \mathbb{R}^{n\times n}$, and let columns of X be eigenvectors associated with $\lambda_1, \lambda_2, \ldots, \lambda_k$. If $\lambda_{k+1} = \lambda_k + \delta$ for some $\delta > 0$, then*

$$\text{dist}^2(X, Y) \le \frac{\text{trace}(Y^THY) - \text{trace}(X^THX)}{\delta} \tag{8}$$

for any $Y \in \mathbb{R}^{n\times k}$ such that $Y^TY = I_k$.

Proof. Let columns $Z \in \mathbb{R}^{n\times(n-k)}$ be eigenvectors associated with $\lambda_{k+1}, \lambda_{k+2}, \ldots, \lambda_n$, and define $\Lambda_k = \text{Diag}(\lambda_1, \lambda_2, \ldots, \lambda_k)$ and $\Lambda_{n-k} = \text{Diag}(\lambda_{k+1}, \lambda_{k+2}, \ldots, \lambda_n)$. It follows from the spectral decomposition of H that

$$\text{trace}(Y^THY) = \text{trace}[(Y^TX)\Lambda_k(X^TY)] + \text{trace}[(Y^TZ)\Lambda_{n-k}(Z^TY)].$$

Since $\lambda_{k+1} = \lambda_k + \delta$, we have $\lambda_i \ge \lambda_k + \delta$ for $i \ge k+1$. Thus,

$$\text{trace}[(Y^TZ)\Lambda_{n-k}(Z^TY)] \ge (\lambda_k + \delta)\|Z^TY\|_F^2.$$

Consequently,

$$\text{trace}(Y^THY) \ge \text{trace}[(Y^TX)\Lambda_k(X^TY)] + \lambda_k\|Z^TY\|_F^2 + \delta\|Z^TY\|_F^2. \tag{9}$$

Because $W = (X, Z)$ defines an orthogonal transformation, we have

$$\|W^TY\|_F^2 = \|Y\|_F^2 = k.$$

Hence

$$\|Z^TY\|_F^2 = \|W^TY\|_F^2 - \|X^TY\|_F^2 = k - \|X^TY\|_F^2. \tag{10}$$

Substituting (10) into (9) and setting $S = X^TY$ yields

$$\begin{aligned}
\text{trace}(Y^THY) &\ge \text{trace}(S\Lambda_kS^T) + \lambda_k(k - \|S\|_F^2) + \delta\|Z^TY\|_F^2 \\
&= \lambda_k k + \text{trace}[S(\Lambda_k - \lambda_kI)S^T] + \delta\|Z^TY\|_F^2 \\
&= \text{trace}(\Lambda_k) + \text{trace}(\lambda_kI - \Lambda_k) + \text{trace}[(\Lambda_k - \lambda_kI)SS^T] + \delta\|Z^TY\|_F^2 \\
&= \text{trace}(X^THX) + \text{trace}[(\lambda_kI - \Lambda_k)(I - SS^T)] + \delta\|Z^TY\|_F^2.
\end{aligned}$$

Because $X^TX = Y^TY = I_k$, the diagonal elements of SS^T are all less than or equal to one. Hence

$$\text{trace}[(\lambda_kI - \Lambda_k)(I - SS^T)] \ge 0.$$

Therefore, we can now conclude that

$$\begin{aligned}\operatorname{trace}(Y^T HY) &\geq \operatorname{trace}(X^T HX) + \delta\|Z^T Y\|_F^2 \\ &\geq \operatorname{trace}(X^T HX) + \delta\|Z^T Y\|_2^2 \\ &= \operatorname{trace}(X^T HX) + \delta \operatorname{dist}^2(X, Y).\end{aligned}$$

Rearranging terms in the above inequality yields (8). ∎

Our analysis of the subsequence convergence will make use of the auxiliary function

$$\hat{E}(X, Y) = \operatorname{trace}(X^T LX) + \operatorname{trace}(Y^T LY) + \alpha\rho(X)^T L^{-1}\rho(Y). \tag{11}$$

This function is similar to the one used in [1], which is defined in terms of density matrices $D(X)$ and $D(Y)$.

It is easy to verify that

$$\rho(X)^T L^{-1}\rho(Y) = \operatorname{trace}(X^T \operatorname{Diag}[L^{-1}\rho(Y)]X) = \operatorname{trace}(Y^T \operatorname{Diag}[L^{-1}\rho(X)]Y).$$

Thus, $\hat{E}(X, Y)$ is clearly symmetric, i.e., $\hat{E}(X, Y) = \hat{E}(Y, X)$, and it can be expressed alternatively as

$$\begin{aligned}\hat{E}(X, Y) &= \operatorname{trace}(X^T H(Y)X) + \operatorname{trace}(Y^T LY) \\ &= \operatorname{trace}(Y^T H(X)Y) + \operatorname{trace}(X^T LX).\end{aligned} \tag{12}$$

We are now ready to show the main result, which we state formally in the following theorem.

THEOREM 1. *Let $X^{(0)} \in \mathbb{R}^{n\times k}$ be the initial guess to the solution of the nonlinear eigenvalue problem* (1) *that satisfies ${X^{(0)}}^T X^{(0)} = I_k$. If columns of $X^{(i)} \in \mathbb{R}^{n\times k}$ contain eigenvectors associated with the smallest k eigenvalues of $H(X^{(i-1)})$, as we would obtain when applying the SCF iteration to* (1)*, and if the gap between the kth and the $k+1$st eigenvalues of $H(X^{(i)})$ is greater than or equal to $\delta > 0$ for all i, then*

$$\sum_{i=0}^{m} \operatorname{dist}^2(X^{(i+2)}, X^{(i)}) \leq \frac{\hat{E}(X^{(0)}, X^{(1)}) - \hat{E}(X^{(m+1)}, X^{(m+2)})}{\delta}, \tag{13}$$

where $\hat{E}(\cdot, \cdot)$ is the auxiliary function defined in (11)*.*

Proof. The proof we give here is similar to that presented in [2]. To simplify notation, we will denote $H(X^{(i+1)})$ by H. Because $X^{(i+2)}$ contains eigenvectors associated with the smallest k eigenvalues of H, it follows from Lemma 1 that

$$\operatorname{trace}({X^{(i+2)}}^T H X^{(i+2)}) + \delta \operatorname{dist}^2(X^{(i+2)}, X^{(i)}) \leq \operatorname{trace}({X^{(i)}}^T H X^{(i)}).$$

Adding $\operatorname{trace}({X^{(i+1)}}^T L X^{(i+1)})$ to both sides of the inequality above and invoking (12) yields

$$\hat{E}(X^{(i+1)}, X^{(i+2)}) + \delta \operatorname{dist}^2(X^{(i+2)}, X^{(i)}) \leq \hat{E}(X^{(i)}, X^{(i+1)}).$$

Rearranging terms in the above inequality yields

$$\operatorname{dist}^2(X^{(i+2)}, X^{(i)}) \leq \frac{\hat{E}(X^{(i)}, X^{(i+1)}) - \hat{E}(X^{(i+1)}, X^{(i+2)})}{\delta}.$$

Summing over i yields the inequality (13). ∎

Because $\hat{E}(X^{(m+1)}, X^{(m+2)})$ can be bounded by a constant for any m, and the left-hand side of (13) is an increasing series, $\operatorname{dist}(X^{(i+2)}, X^{(i)})$ must converge to zero as $i \to \infty$.

4. The convergence of SCF. Although the subsequence convergence analysis characterizes what would happen when the SCF iteration fails to converge, it does not give the conditions under which both the even and odd subsequences are guaranteed to converge to the solution of (1). On the other hand, the numerical examples presented in section 2 appear to indicate that the convergence of SCF for the 2×2 problem depends on the value of α, which weighs the contribution of the nonlinear term $\mathrm{Diag}(L^{-1}\rho(X))$ in the Hamiltonian (3). In this section, we will provide a formal proof that this is indeed true. We will prove that the SCF iteration is guaranteed to converge to the solution of (1) from any starting point when $\alpha < \alpha_{\max}$ for some upper bound $\alpha_{\max}$.

Before we state and derive a general bound for α, we will first examine the convergence of the 2×2 problem shown in section 2 because this problem is relatively easy to analyze and because we can obtain a much tighter upper bound on α in this special case.

In section 4.2, we will use a more sophisticated technique to derive an upper bound for α that is more general but somewhat pessimistic.

4.1. The 2×2 case. Before we get to the main result, we will first show that the ratio between the two components of the charge density oscillates around 1 regardless of the choice of α. We will later show that the magnitude of the oscillation decreases to zero when α is sufficiently small.

LEMMA 2. *Let $y = (y_1 \;\; y_2)^T$ be the eigenvector associated with the smallest eigenvalue of $H(X)$ defined in* (3)*, where $X = (x_1 \;\; x_2)^T$ with $|x_1| > |x_2|$. If $\alpha > 0$ in* (3)*, then $|y_2| > |y_1|$.*

Proof. It is straightforward to write down the inverse of L defined in (6) and show that

$$L^{-1}\rho(X) = \frac{1}{3}\begin{pmatrix} 2x_1^2 + x_2^2 \\ x_1^2 + 2x_2^2 \end{pmatrix}.$$

Consequently, the two diagonal elements in the second term of $H(X)$ in (3) are simply

$$\beta_1 = \frac{\alpha}{3}(2x_1^2 + x_2^2) \quad \text{and} \quad \beta_2 = \frac{\alpha}{3}(x_1^2 + 2x_2^2). \tag{14}$$

Suppose λ is an eigenvalue of $H(X)$; then

$$\det\begin{pmatrix} 2+\beta_1-\lambda & -1 \\ -1 & 2+\beta_2-\lambda \end{pmatrix} = (2+\beta_1-\lambda)(2+\beta_2-\lambda) - 1 = 0. \tag{15}$$

If we let $\phi(\lambda) = (2+\beta_1-\lambda)(2+\beta_2-\lambda)$, then eigenvalues of H are solutions to the equation $\phi(\lambda) = 1$.

It is easy to see from (14) that

$$\beta_1 - \beta_2 = \frac{\alpha}{3}(x_1^2 - x_2^2) > 0, \tag{16}$$

since $|x_1| > |x_2|$. Therefore, the two eigenvalues of $H(X)$, which are distinct roots of the quadratic equation $\phi(\lambda) = 1$, must satisfy

$$\lambda_1 < 2 + \beta_2 < 2 + \beta_1 < \lambda_2. \tag{17}$$

Let $y = (y_1 \;\; y_2)^T$ be the eigenvector associated with λ_1. It follows from $H(X)y = \lambda_1 y$ that

$$(2 + \beta_1 - \lambda_1)y_1 = y_2. \tag{18}$$

Because (17) implies $0 < 2 + \beta_2 - \lambda_1 < 2 + \beta_1 - \lambda_1$, it follows from (15) that

$$2 + \beta_1 - \lambda_1 > 1.$$

Consequently, we can deduce from (18) that $|y_2| > |y_1| > 0$. □

Lemma 3 confirms the observation we made in Figure 2(b), namely, that the ratio between the first and second components of ρ oscillates around 1 in the SCF iteration. The convergence of x_1 and x_2 to the optimal solution can be easily proved if we can show that

$$\frac{|y_2|}{|y_1|} < \frac{|x_1|}{|x_2|} \quad \text{when} \quad |x_1| > |x_2|, \tag{19}$$

or

$$\frac{|y_1|}{|y_2|} < \frac{|x_2|}{|x_1|} \quad \text{when} \quad |x_2| > |x_1|. \tag{20}$$

Without loss of generality, we will establish the condition under which (19) holds. However, before we do that, let us first express y_2/y_1 as a function of $\beta_1 - \beta_2$.

LEMMA 3. *If β_1 and β_2 are defined by* (14)*, then*

$$\frac{y_2}{y_1} = \frac{(\beta_1 - \beta_2) + \sqrt{(\beta_1 - \beta_2)^2 + 4}}{2}, \tag{21}$$

where $y = (y_1, y_2)^T$ is the eigenvector associated with the smallest eigenvalue of $H(X)$.

Proof. Let $\delta = y_2/y_1 = 2 + \beta_1 - \lambda_1$. It is easy to show that

$$2 + \beta_2 - \lambda_1 = \delta - (\beta_1 - \beta_2).$$

Hence, it follows from (15) that

$$\delta^2 - (\beta_1 - \beta_2)\delta - 1 = 0. \tag{22}$$

Solving (22) for δ and taking the positive root yields (21). □

Note that if $x_1 = x_2 = \sqrt{2}/2$, then $\beta_1 - \beta_2 = 0$. In this case, it follows from (21) that $y_2/y_1 = 1$, which matches our intuitive expectation that the SCF iteration should converge right away when the initial guess is the solution to (1).

The following theorem establishes the condition that guarantees the monotonic convergence of the SCF iteration when the initial guess is not the solution to (1).

THEOREM 2. *Let $X = (x_1 \;\; x_2)^T$ be an initial guess of the solution to* (1)*, where $H(X)$ is defined by* (3)*, and let $(y_1 \;\; y_2)^T$ be the eigenvector associated with the smallest eigenvalue of $H(X)$. If $|x_1| > |x_2|$, then*

$$\left|\frac{y_2}{y_1}\right| < \left|\frac{x_1}{x_2}\right| \tag{23}$$

when the parameter α in (3) *satisfies*

$$0 < \alpha \leq 3. \tag{24}$$

Proof. Applying the inequality $\sqrt{(\beta_1 - \beta_2)^2 + 4} \leq (\beta_1 - \beta_2) + 2$ to (21) yields

$$\frac{y_2}{y_1} \leq \beta_1 - \beta_2 + 1.$$

If $|x_1| = 1$ and $x_2 = 0$, then $|y_2/y_1| < \infty = |x_1/x_2|$ for any choice of $\alpha > 0$. Thus (23) certainly holds when α satisfies (24).

If $x_2 \neq 0$, it follows from (16) that

$$\begin{aligned}
\frac{y_2}{y_1} - 1 &\leq \frac{\alpha}{3}(x_1^2 - x_2^2) \\
&= \frac{\alpha}{3}(|x_1| - |x_2|)(|x_1| + |x_2|) \\
&= \frac{\alpha}{3}\left[|x_2|(|x_1| + |x_2|)\right]\left(\left|\frac{x_1}{x_2}\right| - 1\right) \\
&\leq \frac{\alpha}{3}\left(\frac{x_1^2 + x_2^2}{2} + x_2^2\right)\left(\left|\frac{x_1}{x_2}\right| - 1\right) \\
&= \frac{\alpha}{6}(1 + 2x_2^2)\left(\left|\frac{x_1}{x_2}\right| - 1\right).
\end{aligned}$$

Since $x_1^2 + x_2^2 = 1$ and $|x_1| > |x_2|$, x_2^2 must be less than $1/2$. Consequently,

$$\frac{y_2}{y_1} - 1 < \frac{\alpha}{3}\left(\left|\frac{x_1}{x_2}\right| - 1\right).$$

Thus (23) holds if $\alpha \leq 3$. □

The upper bound for α established in Theorem 2 is slightly pessimistic because our experiments show that the SCF iteration converges for α as large as 6.0. However, it is not terribly loose because our experiments also show that convergence failure occurs when $\alpha = 6.5$.

4.2. The more general case. Our analysis of the SCF iteration for the 2×2 problem relies heavily on the symmetry property of the problem and the fact that the solution to the nonlinear eigenvalue problem satisfies $|x_1| = |x_2|$. It is difficult to apply this approach to the more general case in which $n > 2$ and $k > 1$.

Instead of tracking how eigenvectors of $H(X)$ vary from one iteration to another, we will focus in this section on the change in charge density $\rho(X)$. We will use a technique developed in [9] to characterize the mapping between the input charge density used to construct $H(X)$ in (3) and the output charge density obtained directly from the desired eigenvectors of $H(X)$ via (2). We will show that under certain conditions this mapping becomes a contraction when $\alpha < \alpha_{\max}$ for some $\alpha_{\max}$ that depends on the minimum gap between the kth and the $k+1$st eigenvalues of $H(X)$, the norm of L^{-1}, and the problem size n.

We will again assume that there is a gap between the kth and $k+1$st eigenvalues of $H(X)$ for all $X \in \mathbb{R}^{n\times k}$ that satisfies $X^T X = I_k$, and this gap is larger than some lower bound $\delta > 0$. (This is the UWP condition defined in [1].) The significance of this gap will become clear in the following.

Suppose the eigenvalues of $H(X)$ are

$$\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_k < \lambda_{k+1} \leq \cdots \leq \lambda_n,$$

for a given X that satisfies $X^T X = I_k$, and the corresponding eigenvectors are $y_1, y_2, \ldots, y_n$. By definition, the density matrix associated with $Y = (y_1, y_2, \ldots, y_k)$ is

$$D(Y) = YY^T.$$

An alternative way to represent this density matrix is

$$D = Z\Omega Z^T,$$

where $Z = (y_1, y_2, \ldots, y_n)$ and $\Omega = \mathrm{Diag}(\underbrace{1, 1, \ldots, 1}_{k}, 0, \ldots, 0)$.

Because $\lambda_k < \lambda_{k+1}$, we can construct a filter function $\phi(\lambda)$ that satisfies

$$\phi(\lambda) = \begin{cases} 1 & \text{for } \lambda = \lambda_1, \lambda_2, \ldots, \lambda_k, \\ 0 & \text{for } \lambda = \lambda_{k+1}, \lambda_{k+2}, \ldots, \lambda_n. \end{cases} \tag{25}$$

If $\phi(\lambda)$ is continuous and differentiable, then we can represent the charge density, which is normally defined as

$$\rho(Y) = \mathrm{diag}(D(Y)),$$

in an alternative form given by

$$\rho = \mathrm{diag}(\phi(H)).$$

If H is constructed from the charge density ρ_{in}, then

$$\rho_{\mathrm{out}} = \mathrm{diag}[\phi(H(\rho_{\mathrm{in}}))]$$

defines a mapping η from ρ_{in} to ρ_{out}, and this is the mapping implicitly constructed at each SCF iteration.

We would like to identify the condition under which η becomes a contraction. Such a condition will ensure that the SCF iteration converges to a fixed point of η that is the solution to our nonlinear eigenvalue problem.

To seek such a condition, we will show that

$$\|\eta(\rho_1) - \eta(\rho_2)\|_1 < \gamma \|\rho_1 - \rho_2\|_1 \tag{26}$$

for any ρ_1 and ρ_2 that satisfy the standard definition (2), and identify the requirement under which $\gamma < 1$.

Constructing a proper filter function is the key to proving (26). We will choose $\phi(t)$ to be a Fermi–Dirac distribution [4] of the form

$$\phi(t) = f_\mu(t) = \frac{1}{1 + e^{\beta(t-\mu)}}, \tag{27}$$

where μ is implicitly determined by the input matrix argument to $\phi(t)$ and $\beta > 0$ is a constant. To be specific, μ is the solution of the equation

$$\mathrm{trace}(\phi(H)) = \mathrm{trace}(f_\mu(H)) = k. \tag{28}$$

Because $\sum_{i=1}^{n} f_\mu(\lambda_i)$ is monotonic with respect to μ for a fixed β, the solution to (28) is unique for any choice of β and H. Figure 5 shows how Fermi–Dirac distributions look with different β values and $\mu = 0$. Notice that a larger β value leads to a sharper drop-off of $\phi(t)$ from 1 to 0.

If the UWP condition holds, then there exists a constant β sufficiently large so that (25) is fulfilled in finite precision arithmetic.

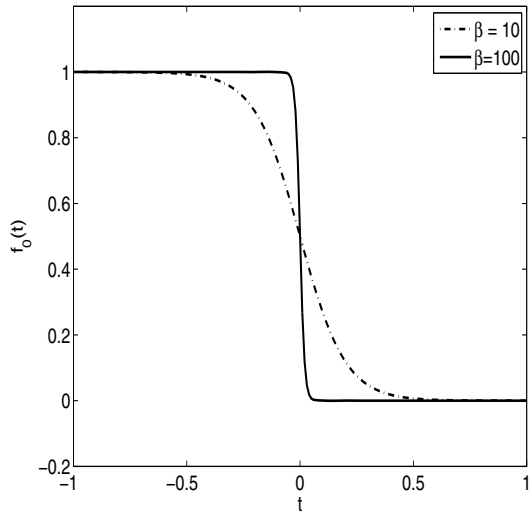


FIG. 5. *Fermi–Dirac distribution* $f_\mu(t) = \frac{1}{1+e^{\beta(t-\mu)}}$ *for* $\mu = 0$.

Let H_1 and H_2 be Hamiltonians constructed from the charge densities ρ_1 and ρ_2, respectively. It is easy to see that

$$\begin{aligned} \|\eta(\rho_1) - \eta(\rho_2)\|_1 &= \|\mathrm{diag}[f_{\mu_1}(H_1)] - \mathrm{diag}[f_{\mu_2}(H_2)]\|_1 \\ &\le \|\mathrm{diag}[f_{\mu_1}(H_1) - f_{\mu_2}(H_1)]\|_1 + \|\mathrm{diag}[f_{\mu_2}(H_1) - f_{\mu_2}(H_2)]\|_1. \end{aligned} \tag{29}$$

Without loss of generality, let us assume $\mu_1 \ge \mu_2$. As a result, $f_{\mu_1}(t) \ge f_{\mu_2}(t)$ for any t. Hence

$$\begin{aligned} \|\mathrm{diag}[f_{\mu_1}(H_1) - f_{\mu_2}(H_1)]\|_1 &= \mathrm{trace}[f_{\mu_1}(H_1) - f_{\mu_2}(H_1)] \\ &= \mathrm{trace}[f_{\mu_1}(H_1)] - \mathrm{trace}[f_{\mu_2}(H_1)]. \end{aligned} \tag{30}$$

Since $\mathrm{trace}[f_{\mu_1}(H_1)] = \mathrm{trace}[f_{\mu_2}(H_2)] = k$, it is easy to see that

$$\begin{aligned} \mathrm{trace}[f_{\mu_1}(H_1)] - \mathrm{trace}[f_{\mu_2}(H_1)] &= \mathrm{trace}[f_{\mu_2}(H_2)] - \mathrm{trace}[f_{\mu_2}(H_1)] \\ &= \mathrm{trace}[f_{\mu_2}(H_2) - f_{\mu_2}(H_1)] \\ &\le \|\mathrm{diag}[f_{\mu_2}(H_2) - f_{\mu_2}(H_1)]\|_1. \end{aligned} \tag{31}$$

Consequently, it follows from (29), (30), and (31) that

$$\begin{aligned} \|\eta(\rho_1) - \eta(\rho_2)\|_1 &\le 2\|\mathrm{diag}[f_{\mu_2}(H_2) - f_{\mu_2}(H_1)]\|_1 \\ &\le 2n\|f_{\mu_2}(H_2) - f_{\mu_2}(H_1)\|_1. \end{aligned} \tag{32}$$

Now to show (26) and to derive an upper bound for α, all we need to do is show that

$$\|f_{\mu_2}(H_2) - f_{\mu_2}(H_1)\|_1 < \frac{\gamma}{2n}\|\rho_1 - \rho_2\|_1$$

for some γ that is proportional to α. Before we do that, we will first prove the following lemma, which allows us to establish a desirable relationship between $f_{\mu_2}(H_2) - f_{\mu_2}(H_1)$ and $H_2 - H_1$.

LEMMA 4. *Let $A, B \in \mathbb{R}^{n\times n}$ be two symmetric matrices, and let $f(t)$ be the Fermi–Dirac distribution defined in* (27). *Suppose $A = V_A D_A V_A^T$ and $B = V_B D_B V_B^T$ are the spectral decompositions of A and B, respectively, i.e., $V_A^T V_A = V_B^T V_B = I$ and*

$$D_A = \begin{pmatrix} \lambda_1^A & & & \\ & \lambda_2^A & & \\ & & \ddots & \\ & & & \lambda_n^A \end{pmatrix}, \quad D_B = \begin{pmatrix} \lambda_1^B & & & \\ & \lambda_2^B & & \\ & & \ddots & \\ & & & \lambda_n^B \end{pmatrix}.$$

Then the identity

$$f(A) - f(B) = V_A(C \odot \Delta)V_B^T$$

holds, where $\Delta = V_A^T(A - B)V_B$, the (j,k)th entry of the matrix C is defined by

$$C_{j,k} = \begin{cases} \frac{f(\lambda_j^A) - f(\lambda_k^B)}{\lambda_j^A - \lambda_k^B} & \text{if } \lambda_j^A \neq \lambda_k^B, \\ f'(\lambda) & \text{if } \lambda_j^A = \lambda_k^B = \lambda, \end{cases}$$

and $C \odot \Delta$ denotes the Hadamard product of C and Δ.

Proof. It follows from the matrix version of the Cauchy integral formula [3] that

$$f(A) - f(B) = \frac{1}{2\pi i} \oint_\Gamma f(z) \Big[(zI - A)^{-1} - (zI - B)^{-1} \Big] dz, \tag{33}$$

where Γ is a closed contour that contains the spectra of both A and B.

Using the identity

$$(zI - A)^{-1} - (zI - B)^{-1} = (zI - A)^{-1}(A - B)(zI - B)^{-1},$$

we can express the right-hand side of (33) as

$$\begin{aligned} &\frac{1}{2\pi i} \oint_\Gamma f(z) V_A (zI - D_A)^{-1} V_A^T (A - B) V_B (zI - D_B)^{-1} V_B^T dz \\ &\quad = \frac{1}{2\pi i} \oint_\Gamma f(z) V_A [(w_A(z) w_B(z)^T) \odot \Delta] V_B^T dz, \end{aligned} \tag{34}$$

where $w_A = \mathrm{diag}[(zI - D_A)^{-1}]$, $w_B = \mathrm{diag}[(zI - D_B)^{-1}]$.

Since the only term in (34) that contains z is $w_A(z)w_B(z)^T$, it follows that

$$f(A) - f(B) = V_A \left[\left(\frac{1}{2\pi i} \oint_\Gamma f(z) w_A(z) w_B(z)^T dz \right) \odot \Delta \right] V_B^T.$$

Let

$$C = \frac{1}{2\pi i} \oint_\Gamma f(z) w_A(z) w_B(z)^T dz.$$

It is easy to verify that the (j,k)th entry of C can be expressed as

$$C_{j,k} = \frac{1}{2\pi i} \oint_\Gamma \frac{f(z)}{(z - \lambda_j^A)(z - \lambda_k^B)} dz. \tag{35}$$

If $\lambda_j^A \neq \lambda_k^B$, the expression above can be evaluated as

$$C_{j,k} = \frac{1}{2\pi i}\frac{1}{\lambda_j^A - \lambda_k^B}\oint_\Gamma \left(\frac{f(z)}{z-\lambda_j^A} - \frac{f(z)}{z-\lambda_k^B}\right)dz. \tag{36}$$

If $\lambda_j^A = \lambda_k^B = \lambda$, (35) becomes

$$C_{j,k} = \frac{1}{2\pi i}\oint_\Gamma \frac{f(z)}{(z-\lambda)^2}dz. \tag{37}$$

Invoking the scalar version of the Cauchy integral formula in both (36) and (37), we then obtain

$$C_{j,k} = \begin{cases} \frac{f(\lambda_j^A)-f(\lambda_k^B)}{\lambda_j^A-\lambda_k^B} & \text{if } \lambda_j^A \neq \lambda_k^B, \\ f'(\lambda) & \text{if } \lambda_j^A = \lambda_k^B = \lambda. \end{cases} \qquad \square$$

Suppose $H_1 = X_1\Lambda_1 X_1^T$ and $H_2 = X_2\Lambda_2 X_2^T$ are the spectral decompositions of H_1 and H_2, respectively. A direct application of Lemma 4 to H_1 and H_2 yields

$$\begin{aligned} \|f_{\mu_2}(H_2) - f_{\mu_2}(H_1)\|_1 &= \|X_2[C \odot (X_2^T(H_2-H_1)X_1)]X_1^T\|_1 \\ &\leq n\|C \odot (X_2^T(H_2-H_1)X_1)\|_1 \\ &\leq n^2\|C\|_1\|H_2-H_1\|_1 \\ &\leq \alpha n^2\|C\|_1\|L^{-1}\|_1\|\rho_2-\rho_1\|_1. \end{aligned} \tag{38}$$

To establish an upper bound for $\|C\|_1$, we can use the mean value theorem and the fact that

$$|f'_\mu(t)| = \left|\frac{-\beta e^{\beta(t-\mu)}}{(1+e^{\beta(t-\mu)})^2}\right| \leq \frac{\beta}{4}$$

to first show that

$$\max_{j,k}|C_{j,k}| \leq \beta/4.$$

It follows immediately that

$$\|C\|_1 \leq n\beta/4. \tag{39}$$

Combining (32), (38), and (39), we obtain

$$\|\eta(\rho_2) - \eta(\rho_1)\|_1 \leq \frac{\alpha n^4\beta\|L^{-1}\|_1}{2}\|\rho_2-\rho_1\|_1.$$

We can easily see that η is a contraction if α satisfies

$$\alpha < \frac{2}{n^4\beta\|L^{-1}\|_1}. \tag{40}$$

It may seem surprising that the upper bound that ensures $\eta(\rho)$ becomes a contraction depends on a parameter β that is present in neither the original eigenvalue problem (1) nor the description of the SCF iteration. However, if we go back to Figure 5 and recall that the choice of β is dictated by the smallest gap between $\lambda_k(H)$ and

$\lambda_{k+1}(H)$ for all valid H matrices, then it becomes clear that the dependency of (40) on β simply says that for problems in which the gap between $\lambda_k(H)$ and $\lambda_{k+1}(H)$ is small, a smaller upper bound of α is required to ensure that the SCF iteration converges from any starting point.

We should point out that the bound established in (40) is pessimistic. In particular, the n^4 factor on the denominator, which is introduced by the use of a loose inequality in (32) and the use of 1-norms to bound the norms of the orthogonal matrices X_1 and X_2 in (38), is rather conservative. In our numerical experiments, we observed that the SCF iteration may converge for α values that are much larger than the right-hand side of (40). However, the qualitative behavior of the SCF iteration seems to be correctly characterized by (40). Table 1 shows both the experimentally observed largest α values (α_1) for which the SCF iteration converges and the experimentally observed smallest α values (α_2) for which the SCF iteration fails to converge for problems with different choices of n and k. The optimal bound lies within the interval (α_1, α_2). We can clearly see that the optimal bound for α decreases as n increases. For the same value of n, changing the value of k in Table 1 results in a change of the gap $\lambda_{k+1} - \lambda_k$. For each combination of n and k, the smallest gap among the various choices of α's that we experimented with is shown in Table 1. The last two rows of Table 1 clearly indicate that for the same n, a smaller $\lambda_{k+1} - \lambda_k$, which corresponds to a larger β value in (40), leads to a more restrictive choice of α for which the SCF iteration is guaranteed to converge.

TABLE 1

Observation from numerical experiments performed to determine the optimal bound for α. In these experiments, the L matrix in (3) *is constructed as the one-dimensional discrete Laplacian with* 2 *on the diagonal and* -1 *on the sub- and sup-diagonals. The dimension of the matrix is n. We look for k smallest eigenvalues and the corresponding eigenvectors. The SCF iteration converges for $\alpha \leq \alpha_1$ and fails to converge for $\alpha \geq \alpha_2$. This implies that the optimal bound for α lies in (α_1, α_2). The spectral gap $\lambda_{k+1} - \lambda_k$ listed here is smallest among all gaps associated with the different choices of α values that we experimented with. These gaps were computed using a trust-region enabled SCF iteration discussed in* [11].

n	k	$\lambda_{k+1} - \lambda_k$	$\|L^{-1}\|_1$	α_1	α_2
2	1	2.0	1.0	6.0	6.5
10	2	0.37	15.0	0.8	0.9
100	10	0.02	1275.0	0.05	0.06
100	4	0.0087	1275.0	0.002	0.0025

In general, the minimum gap between $\lambda_k(H)$ and $\lambda_{k+1}(H)$ is not known a priori. However, when α is sufficiently small, we can estimate such a gap by calculating the difference between the kth and $k+1$st eigenvalues of L. Such an estimate can in turn be used to derive a suitable β value that would allow (27) to achieve the filtering effect (25) in finite precision arithmetic.

5. Concluding remarks. We examined the convergence of the self-consistent field (SCF) iteration used to solve a class of nonlinear eigenvalue problems defined in (1). Our analysis shows that for this type of problem the SCF iteration produces a sequence of approximate solutions $X^{(i)}$ that contain two convergent subsequences. However, the limit points associated with these convergent subsequences may be different, as we demonstrated in a numerical example. We identified the condition under which the SCF iteration becomes a contractive fixed point iteration that will converge to the solution of the nonlinear eigenvalue problem. Our main result suggests that this condition can be characterized by an upper bound placed on the parameter α in (1).

In the most general case, the upper bound we derived characterizes the qualitative behavior of the SCF iteration, although the bound itself is somewhat pessimistic. When the dimension of the problem is 2×2, we can give a much tighter bound using a completely different technique. To generalize such a bound for the Hartree–Fock (HF) or the Kohn–Sham (KS) problem, we need to analyze the relative contribution of the exchange and exchange-correlation terms to the HF and KS Hamiltonians, respectively. We will pursue such analysis in future research.

Acknowledgments. We would like to thank the anonymous referees and the associate editor for careful reading and helpful comments.
