5. Properties of the discrete functional. In this section we consider properties of the discrete functional in the 1-D and 2-D cases within the framework of the three-point model of adaptation. It will be shown that if the coefficient c_a is larger than some critical value, minimization of the functional leads the right cell of the two-cell grid to collapse. In order to get a convex functional in the 1-D case, i.e., to provide the unique solution of the minimization problem, we use a regularized functional. The improved functional holds an infinite barrier preventing the right cell from collapsing to any extent of grid nodes condensation. In the 2-D case, the meaning of the minimization procedure to the functional can be lost due to absence of a solution in the minimization problem. Nevertheless, we shall demonstrate the iterative procedure allows us to condense significantly the grid lines towards the discontinuity and guarantee the grid is unfolded.

First, consider the 1-D case. In assumptions of section 4 the approximation (3.3) to the functional on the two-cell grid reads (we set $\triangle\xi = 1$) as

$$I^h = \frac{1}{x} + \frac{1}{(L-x)\sqrt{1 + c_a^2\triangle u^2/(L-x)^2}}, \tag{5.1}$$

where $\triangle u = |u_3 - u_2|/2 = |u_r - u_l|/2$. To minimize the one-parametric functional I^h we apply the Newton method

$$x^{p+1} = x^p - \tau\frac{\partial I^h}{\partial x}\left[\frac{\partial^2 I^h}{\partial x^2}\right]^{-1}, \tag{5.2}$$

where the iterative parameter $\tau \le 1$, the first derivatives is

$$\frac{\partial I^h}{\partial x} = -\frac{1}{x^2} + \frac{1}{(L-x)^2\left[1 + c_a^2\triangle u^2/(L-x)^2\right]^{3/2}},$$

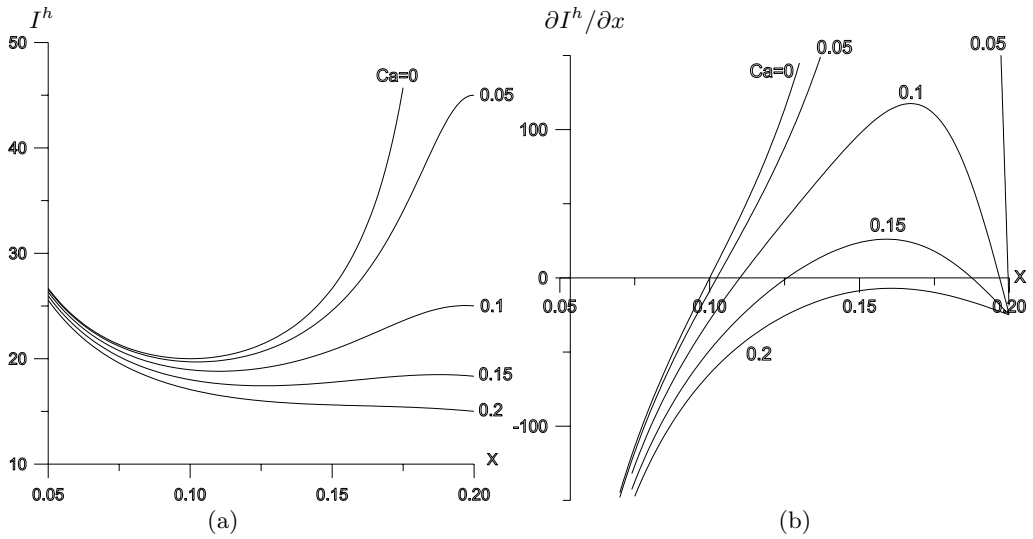

FIG. 4. *Dependence of distribution for the functional* I^h (a) *and* $\partial I^h/\partial x$ (b) *on* c_a *within the interval* $(0, L)$, *where* $L = 2h = 0.2$. *Here the part of the interval* $(0, 0.05)$ *is cut off since it is out of interest. At* $c_a > 0.185$ *there is no minimum of the functional* (*see the curve* $c_a = 0.2$), *and minimization of* I^h *causes the right cell to collapse.*

and the second derivative is derived from the first one.

In Figure 4 the distributions of I^h and $\partial I^h/\partial x$ are presented for several values of c_a at $u_l = 2, u_r = 1$, and initial uniform spacing $h = 0.1$. One can see at $c_a = 0$ the functional I^h has the minimum at $x = 0.1$ which corresponds to the point's equidistribution or a uniform mesh. When $c_a > 0$ the functional I^h loses convexity in the interval $(0, L)$ and besides the minimum there appears a maximum to the left of point 3. Therefore, the solution of the problem on finding its extremum becomes nonunique. When increasing c_a on one hand the value $x_{\min}$, where I^h reaches the minimum in $(0, L)$, shifts to the right corresponding to point 2 moving towards point 3 or grid clustering (see Figure 4(b)). On the other hand, $x_{\max}$, where I^h reaches the maximum in $(0, L)$, shifts to the left from point 3 causing grid rarefaction. In 2-D problems it can cause harsh displacements of the mesh nodes due to jumps of the solution from the minimum to maximum and vice versa during iterations, i.e., grid lines overlap and instability in the solution of the flow problem. Furthermore, for some critical value c_a^{crt}, both extrema merge at the point x^{crt}. To find c_a^{crt} it is required that we solve the system of two equations $\partial I^h/\partial x = 0$ and $\partial^2 I^h/\partial x^2 = 0$ about c_a^{crt} and x^{crt}. For the above parameters $c_a^{crt} \simeq 0.185$, $x^{crt} \simeq 0.159$. When $c_a > c_a^{crt}$ there is no extremum and minimization of I^h causes the right cell to collapse; see the curve $c_a = 0.2$ in Figure 4(b). Consequently, significant mesh clustering is impossible.

Let us write the discrete functional to the left half of the mesh including $0.5 i_{\max}$ intervals

$$I^h = \frac{(0.5 i_{\max} - 1)^2}{x} + \frac{1}{(L - x)\sqrt{1 + c_a^2 \triangle u^2/(L - x)^2}}; \tag{5.3}$$

here $L = 0.5 i_{\max} h$. The functional (5.3) is also one-parametric since all intervals except that on the right have the same length. Note the larger $i_{\max}$ is the smaller c_a^{crt} is. For example, at $i_{\max} = 100$ the value $c_a^{crt} = 0.126$, which reduces the possibility of condensing the mesh towards discontinuity.

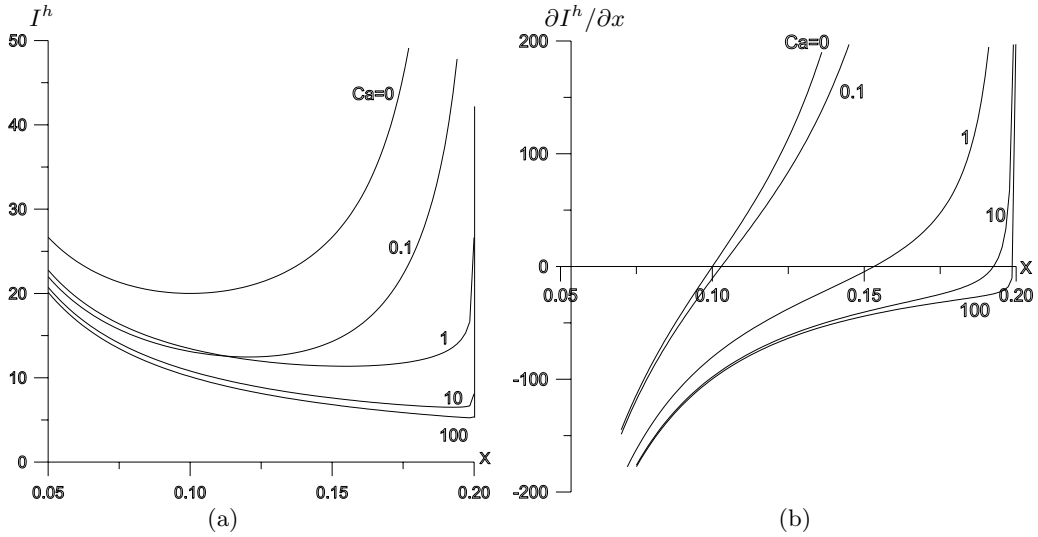

FIG. 5. *Dependence of distribution for* I_1^h (a) *and* $\partial I_1^h/\partial x$ (b) *on* c_a. *Functional* I_1^h *is convex within the interval* $(0, L)$ *for any* c_a *that guarantees existence of a unique solution of the minimization problem. The infinite barrier prevents the right cell from collapsing.*

In order to preserve convexity of the discrete functional we assume, when varying x, the derivative of the control function f_x in (3.3) (i.e., u_x in our case) remains fixed (invariable metric) as it was used in [24]. Assuming in (5.1) the derivative $(u_x)_{i+1/2}$ does not depend on x, we obtain the derivative of a new functional I_1^h:

$$\frac{\partial I_1^h}{\partial x} = -\frac{1}{x^2} + \frac{1}{(L-x)^2\sqrt{1 + c_a^2 \triangle u^2/(L-x)^2}}. \tag{5.4}$$

To obtain an explicit expression for I_1^h, referred to as the regularized functional, we integrate (5.4) and get

$$I_1^h = \frac{1}{x} + \frac{1}{c_a \triangle u} \ln\left[\frac{c_a \triangle u}{L-x} + \sqrt{1 + \frac{c_a^2 \triangle u^2}{(L-x)^2}}\right]. \tag{5.5}$$

Distributions of I_1^h and $\partial I_1^h/\partial x$, presented in Figure 5, illustrate three important properties of this new class of functionals:

1. *The functional* I_1^h *is convex within the interval* $(0, L)$ *for any* c_a.
2. *When* $c_a \to \infty$ *the position of* $x_{\min}$ *for* I_1^h *tends to* L *from the left.*
3. *There is an infinite barrier preventing the right cell from collapsing.*

The first property guarantees existence and uniqueness of the solution of the minimization problem within the interval $(0, L)$. According to the second one, point 2 can approach point 3 to within any small distance. The third one states that the infinite barrier keeps the mesh nondegenerate. The infinite barrier allows the clustering of the mesh in the vicinity of the discontinuity up to any small size. When modeling a flow with shock waves it allows the accuracy to increase significantly, since the error caused by shock wave smearing, in the integral norms L_1 or L_2, is proportional to the shock thickness. A corollary is that two adjacent cells, one located in the shock zone and the other in the domain of smooth flow, with sizes differing by

orders of magnitude, do not degrade the accuracy of the solution. Thus, the mesh can be sharply clustered within one cell towards discontinuity. Those properties hold in the case of a mesh with any number of intervals $i_{\max}$ as well.

Note, when adapting with using the regularized functional (5.5), the velocity of grid nodes condensing, defined by dependence of the node 2 position on c_a at fixed L and $\triangle u$, is reduced in comparison with the case of the functional (5.1). It can be shown that at small c_a the ratio of the velocities to the functionals (5.1) and (5.5) equal 3. It leads one to have to perform a greater number of mesh iterations to obtain necessary degree of nodes condensing. We can increase the velocity of condensing by raising the expression under the square root in (5.4) to the power of $1 - 1/2^m$ (here substitution $m = 1$ gives (5.4)), and such a functional will be referred to as I^h_m. In practice $m = 2$ can be used as well.

Now we turn to a special case of constructing the 2-D adaptive mesh when the discrete functional can be reduced to be one-parametric. Suppose the control function f in (2.3) depends only on the variable x. Therefore, when seeking the mapping of the parametric square onto the domain Ω we have $x = x(\xi)$, $y = a\eta$ ($a = \text{const}$), and $f_y = x_\eta = y_\xi = 0$. Then the harmonic functional (2.3) reads (we set $a = 1$) as

$$I = \int_0^1 \int_0^1 \frac{x_\xi^2(1 + c_a^2 f_x^2) + 1}{x_\xi \sqrt{1 + c_a^2 f_x^2}} d\xi d\eta = \int_0^1 \frac{x_\xi^2(1 + c_a^2 f_x^2) + 1}{x_\xi \sqrt{1 + c_a^2 f_x^2}} d\xi. \tag{5.6}$$

The functional (5.6) differs from (2.4) by the additional term $\int x_\xi \sqrt{1 + c_a^2 f_x^2} d\xi$ expressing the curve $c_a f$ length in a cross-section $y = \text{const}$. This term defines the difference in properties of the 1-D and 2-D regularized discrete functionals.

We follow assumptions of section 4 when approximating (5.6) on the two-cell grid

$$I^h = x + \frac{1}{x} + (L - x)\sqrt{1 + c_a^2 \triangle u^2/(L - x)^2} + \frac{1}{(L - x)\sqrt{1 + c_a^2 \triangle u^2/(L - x)^2}}.$$

This discrete functional possesses properties similar to (5.1). Within the interval $(0, L)$ at $c_a < c_a^{crt}$ there are a maximum and minimum of I^h which disappear at $c_a > c_a^{crt}$. Here the value of c_a^{crt} differs a bit from the one in the 1-D case.

To regularize I^h we again fix the metric when deriving the first derivative. Derivative of a new functional reads as

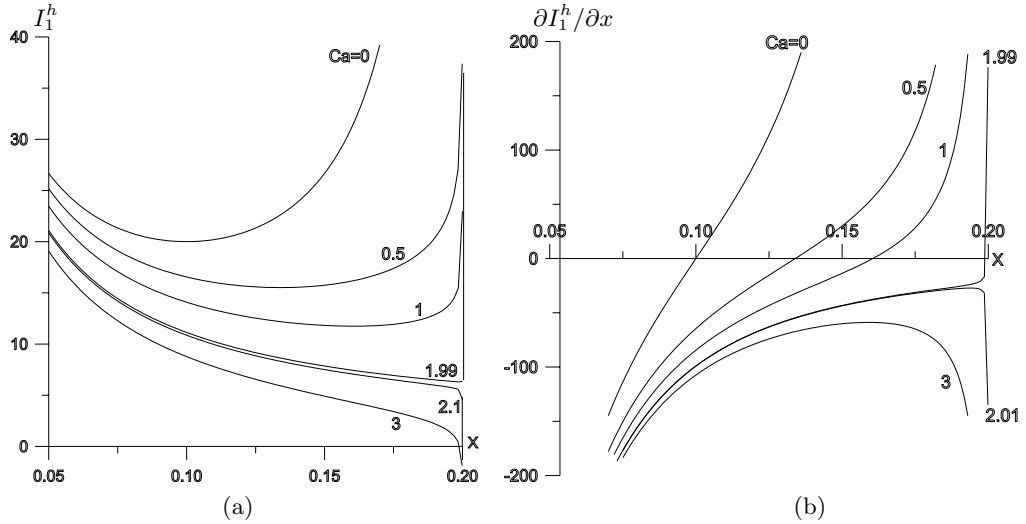
$$\frac{\partial I_1^h}{\partial x} = 1 - \frac{1}{x^2} - \sqrt{1 + c_a^2 \triangle u^2/(L - x)^2} + \frac{1}{(L - x)^2 \sqrt{1 + c_a^2 \triangle u^2/(L - x)^2}}.$$

Integrating it we get the regularized functional

$$I_1^h = \frac{1}{x} + x + \sqrt{(L - x)^2 + c_a^2 \triangle u^2} + \frac{1}{c_a \triangle u}(1 - c_a^2 \triangle u^2) \ln \left[\frac{c_a \triangle u}{L - x} + \sqrt{1 + \frac{c_a^2 \triangle u^2}{(L - x)^2}} \right].$$

Distributions of I_1^h and $\partial I_1^h / \partial x$ are presented in Figure 6. We see as soon as the term $1 - c_a^2 \triangle u^2$ becomes negative, in the above case at $c_a > 1/\triangle u = 2$, that the functional loses convexity. First, it seems to lead the right cell to collapse when finding the minimum of I_1^h via the iterative procedure (5.2). In practice it does not happen for the following reason. Derive the second derivative of I_1^h:

$$\frac{\partial^2 I_1^h}{\partial x^2} = \frac{1}{x^3} + \frac{2(L - x)^2 + c_a^2 \triangle u^2}{(L - x)^2 \sqrt{(L - x)^2 + c_a^2 \triangle u^2}} \left[\frac{1}{(L - x)^2 + c_a^2 \triangle u^2} + 1 \right].$$



(a) (b)

FIG. 6. 1-*D approach to* 2-*D functional* (2.3). *Dependence of distribution for* I_1^h (a) *and* $\partial I_1^h/\partial x$ (b) *on* c_a. *At* $c_a > 2$ *the functional loses convexity.*

When point 2 tends to point 3, i.e., x to L, and consequently we have $L - x \ll c_a \triangle u$, the ratio of the derivatives in (5.2) gives

$$\frac{\partial I_1^h}{\partial x} : \frac{\partial^2 I_1^h}{\partial x^2} \approx (L - x^p) \frac{1 - c_a^2 \triangle u^2}{1 + c_a^2 \triangle u^2}.$$

Since $1 - c_a^2 \triangle u^2 < 0$ at every iteration x^p gets an increment being smaller than the distance to the right node 3. The length of the right cell remains greater than zero within the truncation error or prescribed accuracy of calculation at any c_a. Thus, although it can turn out beginning from some value of c_a that the regularized functional will not have a minimum, nevertheless the iterative procedure (5.2) allows us to condense significantly the grid lines towards the discontinuity and to guarantee the grid to be unfolded.

The approach of the three-point model can also be applied in the general case of computing real 2-D flows with shocks. In the neighborhood of any point of discontinuity we introduce a local Cartesian system of coordinates with axis y directed along the tangent line towards the discontinuity at the point considered. Then, to a first approximation, we assume $x = x(\xi)$, $y = a\eta$, neglect the small terms in (2.3), i.e., f_x, x_η, y_ξ, and get (5.6). On the other hand, the presence of these small terms in the functional causes the nodes "to wander" permanently along some trajectory about an average position keeping strong grid lines condensing in the vicinity of shocks. Further, for the sake of simplicity, we shall refer the iterative procedure (quasi-Newton method in a real 2-D case, see section 7.2) as a minimization of the discrete functional independent of whether there is a solution of the minimization problem or not.

Performed analysis of the properties to the 1-D and 2-D functionals shows that these functionals are inconsistent, i.e., nodes clustering towards the discontinuity are performed in a different manner inside the domain Ω via minimization of the 2-D functional and on the boundary $\partial\Omega$ via the 1-D functional. The necessity arises in consistent redistribution of the grid nodes in Ω and on $\partial\Omega$. This matter will be considered in section 8.

6. Another method of adaptation. Let us see what the use of the functional (2.5) to the direct mapping or Euler–Lagrange equation (2.6) gives to constructing the adaptive mesh.

Consider the problem of minimizing the Dirichlet functional to the direct mapping of the domain $\Omega(x)$ onto ξ. Approximation of (2.5) on the two-cell mesh gives the discrete functional

$$I^h = x^2 + (L-x)^2 + c_a^2 \triangle u^2.$$

Its derivative

$$\frac{\partial I^h}{\partial x} = 4x - 2L$$

vanishes at $x = L/2$. Thus, independently on c_a the minimum of I^h reaches on the set of uniform meshes and grid clustering is not performed towards discontinuity.

Approximation of the Euler–Lagrange equation (2.6) is given

$$x = (L-x)\sqrt{1 + c_a^2 \triangle u^2/(L-x)^2}$$

and from it we obtain

$$x_{\min} = \frac{L}{2} + \frac{c_a^2 \triangle u^2}{2L}.$$

Consequently, at $c_a \triangle u = L$ the right cell collapses. In this case there is no barrier and in multidimensional problems, when grid lines are strongly bent near the shock wave, the derivative of a control function f towards the normal of the shock changes from one cell to another. In some cells we will not get enough condensation of grid lines and the other cells will have already been folded.

7. Optimization method and coupled algorithm.

7.1. 1-D case. We use the approximation (3.3) of the functional (2.4) and seek the minimum of I_m^h $(m = 1, 2)$ applying the Newton method (5.2) when $x = (x_1, \ldots, x_{i_{\max}+1})$. Using the approximations (3.4) to $(x_\xi)_{i+1/2}$ and $(f_x)_{i+1/2}$, fixing $(f_x)_{i+1/2}$ and setting $\triangle\xi = 1$ we get the first derivative

$$\frac{\partial I_m^h}{\partial x_i} = \frac{-1}{(x_i - x_{i-1})^2 \left[1 + c_a^2 (f_x)_{i-1/2}^2\right]^{1-2^{-m}}} + \frac{1}{(x_{i+1} - x_i)^2 \left[1 + c_a^2 (f_x)_{i+1/2}^2\right]^{1-2^{-m}}}.$$

The Hessian is a diagonal matrix with components $\mathcal{H}_{ii} = \partial^2 I_m^h / \partial x_i^2$. As above we fix $(f_x)_{i+1/2}$ while deriving the second derivative

$$\frac{\partial^2 I_m^h}{\partial x_i^2} = \frac{2}{(x_i - x_{i-1})^3 \left[1 + c_a^2 (f_x)_{i-1/2}^2\right]^{1-2^{-m}}} + \frac{2}{(x_{i+1} - x_i)^3 \left[1 + c_a^2 (f_x)_{i+1/2}^2\right]^{1-2^{-m}}}.$$

Here the case $m = 2$ is used to increase the velocity of grid nodes condensing.

If we need to perform adaptation along the curve, e.g., boundary $\partial\Omega$ of the domain Ω, the 1-D functional (2.4) can be written in the parametric form [31, 32]

$$I = \int_0^1 \frac{1}{t_\xi \sqrt{1 + c_a^2 f_t^2}} d\xi, \tag{7.1}$$

where the control function $f = f(t)$, parameter t defines the length of the boundary $\partial\Omega$. Then the Newton method (5.2) of minimization can be applied.

7.2. 2-D case. We use the optimization algorithm suggested in [12, 24]. Approximation of the functional (2.3) is performed on the mesh of quadrilaterals and is given by (3.1). If the set of convex grids is not empty, the system of algebraic equations (3.2) has at least one solution which is the convex mesh. Assuming the grid to be convex at the pth step of the iterative procedure we find the coordinates of the ith node at the $p+1$st step using the quasi-Newton method in the sense that the Hessian is a diagonal matrix (see [4, 12, 24] for details):

$$
\begin{aligned}
x_i^{p+1} &= x_i^p - \tau \left(R_x \frac{\partial R_y}{\partial y_i} - R_y \frac{\partial R_x}{\partial y_i} \right) \left(\frac{\partial R_x}{\partial x_i}\frac{\partial R_y}{\partial y_i} - \frac{\partial R_y}{\partial x_i}\frac{\partial R_x}{\partial y_i} \right)^{-1}, \\
y_i^{p+1} &= y_i^p - \tau \left(R_y \frac{\partial R_x}{\partial x_i} - R_x \frac{\partial R_y}{\partial x_i} \right) \left(\frac{\partial R_x}{\partial x_i}\frac{\partial R_y}{\partial y_i} - \frac{\partial R_y}{\partial x_i}\frac{\partial R_x}{\partial y_i} \right)^{-1};
\end{aligned}
\tag{7.2}
$$

here τ is the iterative parameter.

Note when finding the first and second derivatives of the functional (3.1) we fix the metric (derivatives f_x and f_y in (2.3)) and it is referred to as I_1^h.

To increase the velocity of grid nodes condensing in the discrete functional instead of $\sqrt{1+f_x^2+f_y^2}$ we use the term

$$
\left[1+(f_x)^2+(f_y)^2\right]^{1-2^{-m}},
$$

where $m = 1, 2$, and as in the 1-D case such a discrete functional will be referred to as I_m^h.

If a flow solver gives the values of the control function in the cell's center, it is required that we update them to the nodes. It can be done by interpolation and it is sufficient to use a first-order interpolation formula, e.g., to the ith node (except boundary nodes) which is surrounded by four cells; we have

$$
f_i = c_a \sum_{l=1}^{4} f_l^c A_l \Bigg/ \sum_{l=1}^{4} A_l,
$$

where f_l^c is the value in the lth cell center, A_l is the area of the triangle, one vertex of which is the ith node and two others are adjacent vertexes of the lth cell.

The coefficient of adaptation can depend on the node position, i.e., $c_a = c_a(x, y)$.

7.3. Coupled algorithm. One time step to solve the 1-D or 2-D equations of gas dynamics with grid adaptation contains the following steps:

1. Generate the mesh at the next time level $n+1$.
2. Compute the gas dynamics values at time t^{n+1}.
3. Make one iteration step and compute the new values of $(x, y)_i$ at t^{n+1} by formulas (5.2) or (7.2).
4. Repeat starting with step 2 to convergence or within given number of iterations p_{iter}.
5. Compute the final gas dynamics values at t^{n+1}.

The matter of preparing an initial quasi-uniform mesh, including the procedure of untangling the initial prepared folded mesh, is considered in [12, 24].

We now consider how to select c_a. As shown in section 5 the present method generates an unfolded mesh at any c_a and L_1- or L_2-errors depend on the shock thickness. Besides, used here the Godunov-type solver smears the shocks within 2 to

3 cells. Theoretically the thinner the discontinuity (i.e., the larger c_a) is, the higher is the accuracy we get. Therefore, there are no grounds for an automatic choice of c_a in contrast to, for instance, [37], where a smoothing of the solution and variation of the number of grid points in the shock zone are used. In practical computations, however, definition of c_a should satisfy some reasonable requirements. On the one hand c_a must not be too large, otherwise the mesh begins "to feel" weak compression and rarefaction waves that leads to undesirable and useless distortion of the cells. Besides, the larger the value of c_a, the less iterative the parameter τ needs to be in order not to leave the admissible set of convex grids (see Tables 10.1 and 10.2), and the more number of iterations p_{iter} we have to perform. On the other hand, if c_a is too small, then the mesh cannot be condensed in the vicinity of shocks of interest. Thus, we should choose c_a so that we avoid these lacks in mesh adaptation. Further, as it will be shown in section 10, on the one hand to get a substantial win in accuracy we need to have very strong grid lines condensing near the shocks. On the other hand, in gas dynamics calculations at strong grid lines clustering the admissible time step $\triangle t$ becomes rather small. It is not burdensome to steady flows. But when computing unsteady flows too small a $\triangle t$ will cause the overall time of modeling to increase significantly. To avoid a too large running time in [4, 5] the basic calculation of the 2-D unsteady flow was performed with not very large c_a when $\triangle t \approx 0.1 \triangle t_u$, where $\triangle t_u$ is the step on the quasi-uniform mesh. At some time before the control time c_a is increased so that $\triangle t \approx 0.01 \triangle t_u$. And such a technique gave very high resolution of the shocks and contact discontinuity. One more reason not to set c_a too large is that by controlling cell sizes we can eliminate only the errors caused by shock smearing; see sections 10.3 and 10.4. There also exist the errors gained throughout the domains of smooth flow. And it is useless to try to reduce the first type of error to zero.

Numerical experiments have shown that to get a suitable mesh it is sufficient to define c_a to be a constant, linear, or piecewise linear function along some distinctive direction in Ω, and its values are within the interval $0.05 \le c_a \le 0.5$.

The above discussion shows that both in theory and in practice the parameter c_a is free and the user should find an optimal solution taking into account the particularity of the concrete problem.

As it was shown in section 5 in the 2-D case, it may happen that the iteration procedure (7.2) will not converge, and we define the number of iterations p_{iter} at every time step. In real 2-D flow computations one should set $p_{\text{iter}} = 8$ to 10 for the rapidly developing unsteady flows and $p_{\text{iter}} = 1$ to 2 for the nearly steady flows [5].

8. Redistribution of nodes along the boundary curve. There are several ways to redistribute the grid nodes along the boundary $\partial\Omega$ during adaptation. The simplest one is a fixed position of every point on $\partial\Omega$, referred to as "fixed position." When moving the interior nodes towards a discontinuity, some instability in mesh generation and, consequently, in the flow near the points where the discontinuity joins $\partial\Omega$ can arise. In the next method the boundary nodes are treated as interior and the vectors of shift are projected onto $\partial\Omega$ [26]; we call it "unconstrained minimization." This way can be used only if the discontinuity is nearly orthogonal to $\partial\Omega$. If not, then, when condensing, the boundary nodes overlap, adjacent cells degenerate, and modeling breaks. The next method consists of using the 1-D functional (7.1) [12] referred to as "1-D minimization." It is more robust than the two methods discussed above and can usually be used at adaptation. However, as it has been shown in section 5, the 1-D and 2-D functionals are inconsistent. By this reason the parameters of adaptation c_a and τ should be selected separately. It requires additional work

and is particularly cumbersome when modeling unsteady flows. Sometimes we get undesirable displacement of the boundary nodes up to their overlap.

It is required that we perform redistribution of the interior and boundary nodes consistently. In the suggested method we perform constrained minimization of the discrete functional (3.1) under constraints defining $\partial\Omega$, referred to as "constrained minimization." Constrained minimization on $\partial\Omega$ has been also applied in [29]. We minimize the functional [3]

$$\tilde{I}_1^h = \sum_{i=1}^{i_{\max}} \sum_{k=1}^{4} \frac{1}{4} [F_k]_i + \sum_{l\in\mathcal{L}} \lambda_l G_l = I_1^h + \sum_{l\in\mathcal{L}} \lambda_l G_l, \tag{8.1}$$

where the constraints $G_l = G(x_l, y_l) = 0$ define $\partial\Omega$, λ_l are the Lagrange multipliers, and $\mathcal{L}$ is the set of the boundary nodes. Since the function $G(x, y)$ is assumed piecewise differentiable, the functional $\tilde{I}_1^h$ holds the infinite barrier on the boundary of the set of convex grids as I_1^h does if $f \in C^1$. If f is of the class of discontinuous functions, then the analysis from section 5 can be applied here.

If the set of convex grids is not empty, the system of algebraic equations has at least one solution that is the convex mesh

$$R_x = \frac{\partial I_1^h}{\partial x_i} + \lambda_i \frac{\partial G_i}{\partial x_i} = 0, \quad R_y = \frac{\partial I_1^h}{\partial y_i} + \lambda_i \frac{\partial G_i}{\partial y_i} = 0; \quad G_i = 0; \tag{8.2}$$

here $\lambda_i = 0$ if $i \notin \mathcal{L}$ and constraints are defined for the boundary nodes $i \in \mathcal{L}$.

Consider the method of minimizing the functional (8.1) assuming the grid to be convex at the pth step of the iterative procedure. We use the quasi-Newton procedure to find the coordinates x_i^{p+1}, y_i^{p+1} of the ith node from the system (8.2)

$$\begin{aligned}
&\tau R_x + \frac{\partial R_x}{\partial x_i}(x_i^{p+1} - x_i^p) + \frac{\partial R_x}{\partial y_i}(y_i^{p+1} - y_i^p) + \frac{\partial R_x}{\partial \lambda_i}(\lambda_i^{p+1} - \lambda_i^p) = 0,\\
&\tau R_y + \frac{\partial R_y}{\partial x_i}(x_i^{p+1} - x_i^p) + \frac{\partial R_y}{\partial y_i}(y_i^{p+1} - y_i^p) + \frac{\partial R_y}{\partial \lambda_i}(\lambda_i^{p+1} - \lambda_i^p) = 0,\\
&\tau G_i + \frac{\partial G_i}{\partial x_i}(x_i^{p+1} - x_i^p) + \frac{\partial G_i}{\partial y_i}(y_i^{p+1} - y_i^p) = 0,
\end{aligned} \tag{8.3}$$

where

$$\begin{aligned}
&\frac{\partial R_x}{\partial x_i} = \frac{\partial^2 I_1^h}{\partial x_i^2} + \lambda_i \frac{\partial^2 G_i}{\partial x_i^2}, \quad \frac{\partial R_x}{\partial y_i} = \frac{\partial^2 I_1^h}{\partial x_i \partial y_i} + \lambda_i \frac{\partial^2 G_i}{\partial x_i \partial y_i}, \quad \frac{\partial R_x}{\partial \lambda_i} = \frac{\partial G_i}{\partial x_i},\\
&\frac{\partial R_y}{\partial x_i} = \frac{\partial^2 I_1^h}{\partial x_i \partial y_i} + \lambda_i \frac{\partial^2 G_i}{\partial x_i \partial y_i}, \quad \frac{\partial R_y}{\partial y_i} = \frac{\partial^2 I_1^h}{\partial y_i^2} + \lambda_i \frac{\partial^2 G_i}{\partial y_i^2}, \quad \frac{\partial R_y}{\partial \lambda_i} = \frac{\partial G_i}{\partial y_i}.
\end{aligned}$$

Resolving the last equation of (8.3) about $y_i^{p+1} - y_i^p$ and substituting it in the two remaining equations, we get the system

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \begin{pmatrix} x_i^{p+1} - x_i^p \\ \lambda_i^{p+1} - \lambda_i^p \end{pmatrix} = \begin{pmatrix} a_{13} \\ a_{23} \end{pmatrix},$$

where

$$\begin{aligned}
a_{11} &= \frac{\partial R_x}{\partial x_i} - \frac{\partial R_x}{\partial y_i}\frac{\partial G_i}{\partial x_i} \Big/ \frac{\partial G_i}{\partial y_i}, \quad a_{12} = \frac{\partial G_i}{\partial x_i}, \quad a_{13} = \tau \left[\frac{\partial R_x}{\partial y_i} G_i \Big/ \frac{\partial G_i}{\partial y_i} - R_x \right],\\
a_{21} &= \frac{\partial R_y}{\partial x_i} - \frac{\partial R_y}{\partial y_i}\frac{\partial G_i}{\partial x_i} \Big/ \frac{\partial G_i}{\partial y_i}, \quad a_{22} = \frac{\partial G_i}{\partial y_i}, \quad a_{23} = \tau \left[\frac{\partial R_y}{\partial y_i} G_i \Big/ \frac{\partial G_i}{\partial y_i} - R_y \right].
\end{aligned}$$

Denoting

$$\triangle = a_{11}a_{22} - a_{12}a_{21}, \quad \triangle_1 = a_{13}a_{22} - a_{23}a_{12}, \quad \triangle_2 = a_{11}a_{23} - a_{21}a_{13},$$

we obtain

$$x_i^{p+1} = x_i^p + \triangle_1/\triangle, \quad \lambda_i^{p+1} = \lambda_i^p + \triangle_2/\triangle, \tag{8.4}$$

and y_i^{p+1} is determined from the third equation of (8.3). If the constraints are resolved about y in the form $G(x, y) = y - g(x) = 0$, then

$$\frac{\partial G_i}{\partial x_i} = -\frac{\partial g_i}{\partial x_i}, \quad \frac{\partial G_i}{\partial y_i} = 1,$$

and above formulas are simplified. Constraints can be resolved about x in the form $G(x, y) = x - \tilde{g}(y) = 0$ and then (here it is better to resolve the third equation of (8.3) about $x_i^{p+1} - x_i^p$)

$$\frac{\partial G_i}{\partial x_i} = 1, \quad \frac{\partial G_i}{\partial y_i} = -\frac{\partial \tilde{g}_i}{\partial y_i}.$$

These two forms of $G(x, y)$ can substitute for each other. For example, on the part of $\partial\Omega$ that is nearly parallel to the axis x the boundary should be defined in the form $y = g(x)$, and where $\partial\Omega$ is nearly parallel to the axis y it should be defined as $x = \tilde{g}(y)$.

If $\partial\Omega$ is given by parametric functions $x = x(t)$, $y = y(t)$ or tabular values $(x, y)_i$, the following algorithm can be used. When calculating the coordinates of the ith node, in the interval (x_{i-1}, x_{i+1}) we construct an interpolating parabola $t = t(x)$ using the values in three nodes $i - 1, i, i + 1$. From (8.4) we compute an intermediate value $\tilde{x}_i^{p+1}$, further from the interpolation formula we determine $t_i = t(\tilde{x}_i^{p+1})$ and final values x_i^{p+1}, y_i^{p+1} from the parametric formulas.

Another way of redistributing the nodes along $\partial\Omega$, given as parametric functions or by tabular values, employs an unconstrained minimization of the functional in parametric form and is based on solving the following system of algebraic equations [3], referred to as "parametric minimization,"

$$R_t = R_x \frac{\partial x_i}{\partial t_i} + R_y \frac{\partial y_i}{\partial t_i} = 0,$$

via the quasi-Newton procedure

$$\tau R_t + \frac{\partial R_t}{\partial t_i}(t_i^{p+1} - t_i^p) = 0. \tag{8.5}$$

Here

$$\frac{\partial R_t}{\partial t_i} = \frac{\partial R_x}{\partial x_i}\left(\frac{\partial x_i}{\partial t_i}\right)^2 + \frac{\partial R_y}{\partial y_i}\left(\frac{\partial y_i}{\partial t_i}\right)^2 + \left(\frac{\partial R_x}{\partial y_i} + \frac{\partial R_y}{\partial x_i}\right)\frac{\partial x_i}{\partial t_i}\frac{\partial y_i}{\partial t_i}$$
$$+ R_x \frac{\partial^2 x_i}{\partial t_i^2} + R_y \frac{\partial^2 y_i}{\partial t_i^2}, \quad R_x = \frac{\partial I_1^h}{\partial x_i}, \quad R_y = \frac{\partial I_1^h}{\partial y_i}.$$

To the analytical control functions constrained and parametric minimization give similar results. Real-world 2-D flow computations have shown it is better to perform adaptation along the boundary using constrained minimization (8.3), (8.4) since the procedure (8.5) does not always ensure consistent redistribution of the nodes in Ω and on $\partial\Omega$.

9. Flow solver. In this section we briefly describe the Godunov linear flux correction (GLFC) scheme [2] to compute the 2-D gas flow in the Euler approach.

Equations of gas dynamics are written in the integral form which can be derived by transformation of the volume integrals in the space x-y-t to the surface integrals by virtue of Gauss's theorem as shown below for the law of conservation of mass:

$$\iiint_V \left[\frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \boldsymbol{V})\right] dV = \oiint_{\partial V} \rho dxdy + \rho u dydt + \rho v dtdx = 0;$$

here V is an arbitrary control volume, homeomorphic sphere in space x-y-t, ∂V is the boundary of V.

Hence, the laws of conservation of mass, momentum, and total energy, can be written in the integral form, or generalized formulation [20], as follows:

$$\oiint_{\partial V} \boldsymbol{\sigma} dxdy + \boldsymbol{a} dydt + \boldsymbol{b} dtdx = \boldsymbol{0}, \tag{9.1}$$

where

$$\boldsymbol{\sigma} = \begin{bmatrix} \rho \\ \rho u \\ \rho v \\ E \end{bmatrix}, \quad \boldsymbol{a} = \begin{bmatrix} \rho u \\ \rho u^2 + p \\ \rho uv \\ u(E+p) \end{bmatrix}, \quad \boldsymbol{b} = \begin{bmatrix} \rho v \\ \rho uv \\ \rho v^2 + p \\ v(E+p) \end{bmatrix}.$$

Here u and v are the velocity components, p and ρ are the pressure and density. The total energy $E = \rho[e + 0.5(u^2 + v^2)]$; e is the specific internal energy. The equation of state is $p = (\gamma - 1)\rho e$, where γ is the ratio of specific heats. Denote the vector-valued unknown functions as $\boldsymbol{f} = (u, v, p, \rho)^T$. The conservation laws (9.1) hold for any parameters $\boldsymbol{f}$, both smooth and discontinuous, governing a real gas flow.

We introduce the curvilinear moving grid in space x-y-t and consider the hexahedral computing cell; see Figure 7. The bottom face of the cell (or control volume) is taken at time level n and the top face at level $n+1$; four lateral faces generally form ruled surfaces rather than simple planes.

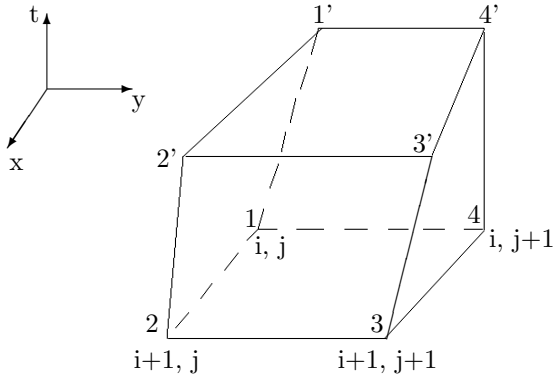


FIG. 7. *Computing cell.*

Integrating (9.1) over the oriented surface, being the boundary ∂V of the computing cell, we obtain a cell-centered finite-volume discretization of the governing equations

$$\boldsymbol{\sigma}^{n+1} A^{n+1} - \boldsymbol{\sigma}^n A^n + \boldsymbol{Q}_{411'4'} + \boldsymbol{Q}_{233'2'} + \boldsymbol{Q}_{122'1'} + \boldsymbol{Q}_{344'3'} = \boldsymbol{0}, \tag{9.2}$$

where $\boldsymbol{\sigma}^{n+1}$ and $\boldsymbol{\sigma}^n$ are the average values at time t^{n+1} and t^n in the center of the top and bottom faces, A^{n+1} and A^n are the areas of these faces. Each of four vector values $\boldsymbol{Q}_{411'4'}$, $\boldsymbol{Q}_{233'2'}$, $\boldsymbol{Q}_{122'1'}$, and $\boldsymbol{Q}_{344'3'}$ is an average flux of mass, momentum, and energy through the corresponding intercell surface in the direction of the outward normal vector. Unlike the original Godunov scheme [20] where the fluxes in (9.2) are taken at time t^n, in the present scheme those values are computed at $t^{n+1/2}$ that provides it with the second-order accuracy in time.

For example, at the face $122'1'$ the value $\boldsymbol{Q}_{122'1'}$ has the following structure:

$$\boldsymbol{Q}_{122'1'} = \boldsymbol{\sigma}^{n+1/2}A^{xy} + \boldsymbol{a}^{n+1/2}A^{yt} + \boldsymbol{b}^{n+1/2}A^{tx}, \tag{9.3}$$

where A^{xy}, A^{yt}, A^{tx} are the areas of projections of the face $122'1'$ onto the coordinate planes x-y, y-t, and t-x, respectively, given by

$$A^{xy} = \iint_{122'1'} dxdy = \frac{1}{2}[(x_{2'} - x_1)(y_{1'} - y_2) - (x_{1'} - x_2)(y_{2'} - y_1)],$$
$$A^{yt} = \iint_{122'1'} dydt = \frac{1}{2}\triangle t(y_{2'} + y_2 - y_1 - y_{1'}),$$
$$A^{tx} = \iint_{122'1'} dtdx = -\frac{1}{2}\triangle t(x_{2'} + x_2 - x_1 - x_{1'}),$$

which are obtained from the formula for the quadrangle 1234

$$A_{1234} = A(x_1, y_1; x_2, y_2; x_3, y_3; x_4, y_4) = \frac{1}{2}[(x_3 - x_1)(y_4 - y_2) - (x_4 - x_2)(y_3 - y_1)]$$

when running along its contour in an anticlockwise manner, time step $\triangle t = t^{n+1} - t^n$.

The values $\boldsymbol{f}^{n+1}$ are updated by two stages using time splitting. In the first stage, predictor, via (9.2) we compute the intermediate values $\tilde{\boldsymbol{f}}^{n+1}$. Here we apply the piecewise linear interpolation along each curvilinear coordinate line ξ, passing through the center of cells $j + 1/2 = \text{const}$, and η, passing through the center of cells $i + 1/2 = \text{const}$; i.e., determine the derivatives $\boldsymbol{f}_\xi$ and $\boldsymbol{f}_\eta$ in every cell to get the fluxes via (9.3) on the lateral faces with the second-order accuracy in space but still at t^n. To suppress spurious oscillations in the vicinity of discontinuities a monotonicity algorithm is applied [2]. At the second stage, corrector, using $\boldsymbol{f}^n$, $\tilde{\boldsymbol{f}}^{n+1}$ and derivatives $\boldsymbol{f}_\xi$, $\boldsymbol{f}_\eta$ at t^n, we get prewave values on both sides of each of four lateral faces of the cell at $t^{n+1/2}$. After solving the Riemann problem we obtain $\boldsymbol{f}^{n+1/2}$, the values at each of four lateral faces, and again calculate the fluxes from (9.3). Then, via (9.2), we compute the final values $\boldsymbol{f}^{n+1}$.

In the $(i + 1/2, j + 1/2)$th cell the admissible time step $\triangle t_{i+1/2,j+1/2}$ is defined via [20] as

$$\triangle t_{i+1/2,j+1/2} = \frac{\triangle t' \ \triangle t''}{\triangle t' + \triangle t''},$$

where

$$\triangle t' = \frac{h'}{\max(d^{II}_{41} - w_{41}; -d^{I}_{23} - w_{23})}, \qquad \triangle t'' = \frac{h''}{\max(d^{II}_{12} - w_{12}; -d^{I}_{34} - w_{34})},$$
$$h' = \frac{A_{1234}}{0.5\sqrt{(x_4 + x_3 - x_1 - x_2)^2 + (y_4 + y_3 - y_1 - y_2)^2}},$$
$$h'' = \frac{A_{1234}}{0.5\sqrt{(x_3 + x_2 - x_4 - x_1)^2 + (y_3 + y_2 - y_4 - y_1)^2}}.$$

Here $\triangle t^{'}$ and $\triangle t^{''}$ are the admissible time steps to the 1-D schemes in the ξ and η directions, respectively, $h^{'}, h^{''}$ are the "average heights" of the bottom face A_{1234}, w is the velocity of the corresponding cell edge, e.g., w_{12} is the velocity of the edge 12 which defines inclination of the face $122'1'$; see Figure 7. Next, d_{12}^{II} and d_{41}^{II} are the "extreme right wave" speeds defined from solving the Riemann problem to the faces $122'1'$ and $11'4'4$, respectively; d_{23}^{I} and d_{34}^{I} are the "extreme left wave" speeds to the faces $233'2'$ and $344'3'$, respectively.

As an admissible time step we take the minimal of all cells

$$\triangle t = \nu \min_{i,j} \triangle t_{i+1/2,j+1/2}.$$

The coefficient ν is less than 1 (usually $0.5 \le \nu \le 0.9$) and it is introduced as a correction to the nonlinearity of the problem. Note that the time step depends on both postwave values and the velocity of every intercell face. In computations the value of $\triangle t$, obtained at the preceding time step, is used for the next time step. By this reason, in the case of essentially nonstationary processes, the coefficient ν should be greatly decreased.

The GLFC scheme is of second-order accuracy in time and space in the domains of smooth flow. We get the values $\boldsymbol{f}^{n+1}$ directly on the moving mesh and need not perform interpolation at t^{n+1} from one mesh to the other.

10. Examples of modeling.

10.1. Analytical control function. First we demonstrate a simple test illustrating the inconsistency of redistributing the boundary and interior nodes when using various methods from section 8 and vice versa, i.e., their consistency when using another.

The 50×50 adaptive mesh is generated in the unit square $0 < x, y < 1$ when the control function is defined to be

$$f(x,y) = \begin{cases} 1 & \text{if} \quad y < 0.5, \\ 0 & \text{if} \quad y \ge 0.5. \end{cases}$$

Fragments of the adapted meshes in the vicinity of the discontinuity are presented in Figure 8. In the first case the coefficient $c_a = 0.1$; see Figure 8(a)–(c). When we apply fixed position and 1-D minimization methods of redistributing the boundary nodes (see Figure 8(a)–(b)), the horizontal grid lines are not parallel and in the case of the other 3 methods they are parallel. In the next case the coefficient $c_a = 0.15$; see Figure 8(d)–(f). To the fixed position method the coordinate lines become more bent; see Figure 8(d). Using 1-D minimization leads the boundary nodes to overlap (see Figure 8(e)), i.e., the mesh to fold. This happens due to the inconsistency of the nodes' redistribution in Ω and on $\partial\Omega$ despite the fact that 1-D and 2-D algorithms separately provide unfolded grid generation. In this test unconstrained minimization gives the same result as constrained and parametric minimization due to the discontinuity is orthogonal to $\partial\Omega$ and here the horizontal lines almost merge near the discontinuity and remain parallel, keeping the mesh unfolded; see Figure 8(f).

In the next example the discontinuity is not orthogonal to $\partial\Omega$. The control function is defined as

$$f(x,y) = \begin{cases} 1 & \text{if} \quad y > 5x - 2, \\ 0 & \text{if} \quad y \le 5x - 2. \end{cases}$$

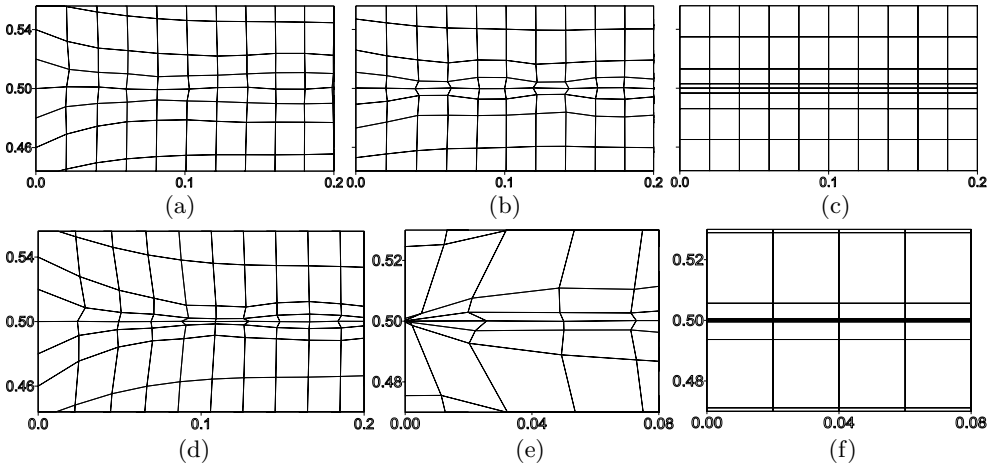

FIG. 8. *Fragment of the adapted mesh. The boundary nodes are redistributed using fixed position* (a), (d), 1-*D minimization* (b), (e), *and unconstrained or constrained or parametric minimization* (c), (f). *Coefficient* $c_a = 0.1$ *in the cases* (a)–(c) *and* $c_a = 0.15$ *in the cases* (d)–(f); *iterative parameter* $\tau = 0.15$.

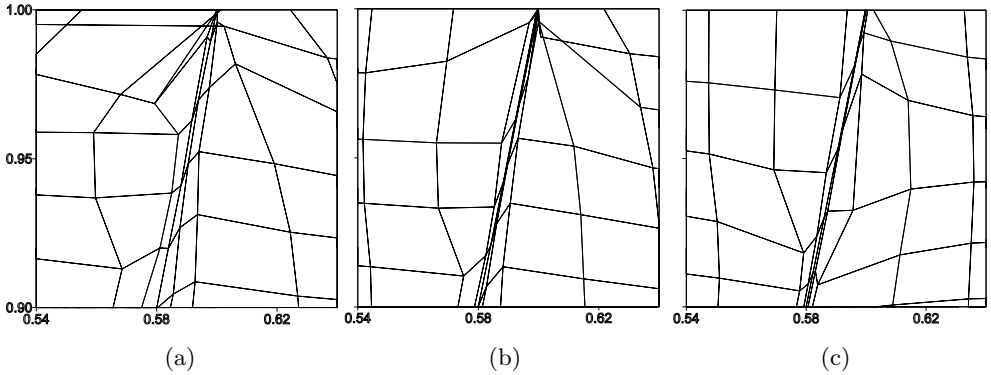

FIG. 9. *Fragment of the adapted mesh. The boundary nodes are redistributed using unconstrained* (a), 1-*D* (b), *and constrained or parametric minimization* (c) *methods. Coefficient* $c_a = 0.3$; *iterative parameter* $\tau = 0.1$.

Fragments of the adapted meshes near the top boundary are presented in Figure 9. Here using unconstrained and 1-D minimization leads the boundary nodes to overlap in several tenths of mesh iterations (see Figure 9(a)–(b)), respectively. Constrained and parametric minimization maintain an unfolded mesh; see Figure 9(c). To the analytical control functions constrained and parametric minimization give similar results.

10.2. Contact discontinuity. To observe how the adaptive procedure handles the contact discontinuities the Cauchy problem for the 1-D linear advection equation has been computed with the Godunov scheme; see Godunov and Ryaben'kii [19]. Adaptation is executed via (5.2). It appears that once the grid points have been condensed towards the contact discontinuity the thickness of discontinuity smeared increases with time proportionally to $\sqrt{t}$ as the theoretical estimation gives on the

uniform fixed mesh.

10.3. Inviscid Burger's equation. Consider the IVP (4.1) with initial values $u_l = 2$, $u_l = 1$. The initial uniform mesh has spacing $h = 0.1$ and zones number $i_{\max} = 50$. The boundary nodes are fixed. Calculations are performed up to $t = 1$ using the first-order Godunov scheme (4.4) and second-order GLFC scheme [2]. In this case the mesh structure differs a bit from the one in section 4. The shock smears over 3 cells with approximately similar length $h_{\min}$. To the left and right of those 3 cells there is a cell with intermediate length and the remaining 45 cells are similar (if a sufficient number of mesh iterations are provided). In computations, presented in Table 10.1, every time step includes $p_{\text{iter}} = 100$ mesh iterations.

The data of Table 10.1 show that increasing the coefficient of adaptation c_a from 0 to 16 decreases the thickness of smearing, equal approximately to $3h_{\min}$, by 478 times for the Godunov scheme and by 369 times for the GLFC scheme; that leads the accuracy to increase by factors of 4335 and 362 for those schemes, respectively. We see if on the uniform mesh the second-order scheme delivers a higher accuracy than the first-order one, on the strongly compressed mesh the situation changes. Moreover, to the GLFC scheme the accuracy is not increased at $c_a > 2$. This can be explained by the presence of spurious oscillations near the discontinuity to the second-order scheme.

10.4. Shock tube problem. Consider the 1-D flow of ideal gas with initial parameters $(u, p, \rho)_l = (2.253928, 2.296074, 1.7811378)$ in the left 3 cells and $(u, p, \rho)_r = (1.5, 1, 1)$ selected in such a way that at $t > 0$ these two domains are divided by the shock wave, moving from the left to the right. The ratio of specific heats $\gamma = 1.4$. Initial uniform mesh is as in section 10.3 and calculations are performed up to $t = 1$ with the same schemes. Every time step includes $p_{\text{iter}} = 100$ mesh iterations.

The data of Table 10.2 show that increasing the coefficient of adaptation c_a from 0 to 4 decreases thickness of the shock smeared, equal approximately $3h_{\min}$, by 80 times and accuracy increases by the factor of 194 and 138 for the Godunov and GLFC schemes, respectively. The second-order scheme gives the lesser error $||Er||_{L_1}$ estimated by the density. Further increase of c_a does not deliver a higher accuracy since the error, caused by shock smearing, becomes much less than the error gained throughout the other cells. If on the uniform mesh $c_a = 0$ the second-order scheme provides a higher accuracy than the first-order one by a factor of 3.1, at $c_a = 4$ the ratio of errors falls to 2.2. The last column shows $\triangle\rho$, the amplitude of spurious

TABLE 10.2

Shock tube problem. Adaptation is performed by minimization of I_1^h except the last row where I_2^h is used. Here $h_{\min}$ is the smallest interval, n is the number of time steps, τ is the iterative parameter, $||Er||_{L_1}$ is the error estimated by ρ, $\triangle\rho$ is the amplitude of spurious oscillations.

oscillations to the density in the vicinity of the shock computed with the GLFC scheme. We see adaptation allows us to reduce significantly $\triangle\rho$ from 1.1% down to 0.01%. Using the functional I_2^h causes strong grid nodes clustering at rather small c_a and, consequently, $||Er||_{L_1}$ to reduce.

Note in the two examples above p_{iter} at every time step was equal to 100 to get similar cell spacings in the shock zone and domains of constant flow parameters to see what adaptation provides in the limit at the extreme large values of c_a. In Table 10.3 we present two computations of this problem with the GLFC scheme when $p_{\text{iter}} = 10$ and 100 with parameters $\tau = 0.5$, $c_a = 1$. The spacings $h_{i+1/2}$, values of $\rho_{i+1/2}$, and exact values of $\rho^{\text{exact}}_{i+1/2}$ in the segments center are shown in the vicinity of the shock. It can be seen that in the first case the value of p_{iter} is insufficient and nodes did not manage to come to their "final" positions judging by the values of $h_{i+1/2}$. Spacings before and behind the shock differ by a factor of 3. By this reason $h_{\min}$ is larger by a factor of ≈ 2.7 than the one in the second case, and therefore the L_1-error is too large. Thus, in the second case, by winning in accuracy we lose in the number of iterations p_{iter}.

10.5. Flow in a channel. The following test demonstrates the capability of the grid adaptation technique to reduce computer costs while obtaining the same accuracy as on the fixed quasi-uniform mesh. Into the channel, shown in Figure 10, from the

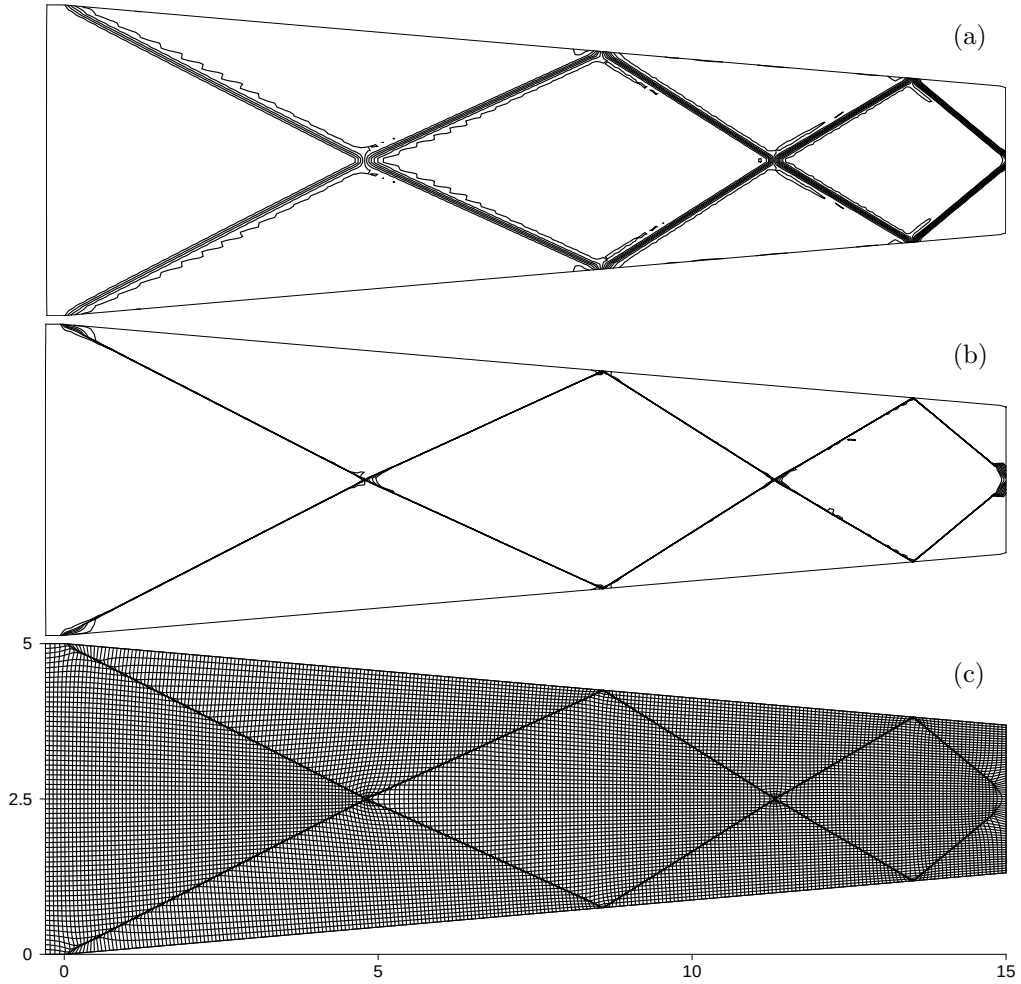

FIG. 10. *Supersonic flow in the channel.* ρ *is used as a control function. Density contours* (*from* 1 *to* 2.7 *with* $\triangle\rho = 0.05$) *computed on the quasi-uniform* (a) *and adapted* (b) *meshes* 264×64; *adapted mesh* 264×64 (c).

left is introduced an ideal gas with $M_\infty = 2.5$. There are two edges in the top and bottom with inclination of 5°. The steady flow has the following structure: two shock waves attached to the top of wedges intersect each other, reflect from the walls, again intersect, etc., dividing the domain into a set of subdomains which contain constant flow parameters.

The problem is calculated with the GLFC scheme on the successively refined grids with 64×16, 128×32, 256×64, and 512×128 zones number. At the first stage the calculation on the quasi-uniform mesh is performed until the solution achieves its steady state. Then, at the second stage, we switch to the adaptive procedure. ρ is used as a control function. At every time step we perform one mesh iteration, i.e., $p_{\text{iter}} = 1$. To provide the best accuracy of computations c_a is selected so to get similar grid clustering towards the shocks within the whole flow and this is achieved by defining a linear/(piecewise linear) dependence of c_a on the x-coordinate.

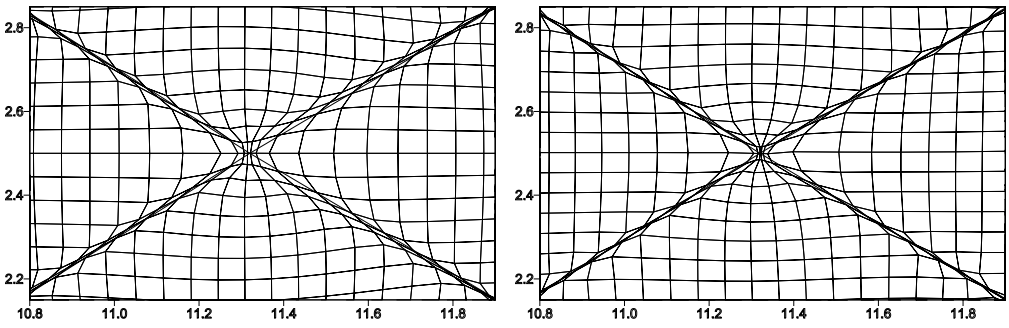

FIG. 11. *Fragments of adapted mesh in* 200 *time steps* (a) *and final mesh* (b). *Two diagonal straight-lines indicate position of shocks for the exact solution.*

TABLE 10.4

Dependence of error, estimated by ρ, *on zones number computed to quasi-uniform and adaptive meshes.*

	Error $\|\|Er\|\|_{L_1}$	
Zones number	Quasi-uniform mesh	Adaptive mesh
64×16	1.5598	0.4070
128×32	0.8274	0.1666
256×64	0.4290	0.0846
512×128	0.2207	0.0444

Figure 10 shows the density contours, when modeling on the quasi-uniform and adapted meshes 256×64 and adapted mesh. Here the first stage, to get a steady state on the quasi-uniform mesh by $t = 15$, takes 1739 time steps. Applying adaptation we get strong grid lines condensing in 200 time steps and a gain in accuracy by a factor of 2. The coefficient of adaptation is defined to be $c_a = 0.2 - 0.15(15 - x)/15$; iterative parameter $\tau = 0.3$. But condensed grid lines are still far from the shock location in the exact solution; see Figure 11(a). We have to perform 2000 time steps more to obtain maximal accuracy. After this rather long shocks "capturing" by the grid lines we get an additional gain in accuracy by a factor of 2.5; see the final mesh in Figure 11(b). To increase the grid velocity we use the functional I_2^h, and this reduces the time of shocks capturing by a factor of 1.7. Nevertheless, during the last 300 steps we use the functional I_1^h, since I_2^h does not provide very strong grid nodes condensing. Note that using I_2^h on the rough mesh 64×16 does not provide an increase of the grid velocity. In real computing the steady problems, when the exact solution is not known, the user shall watch whether the location of a shock changes with time; if yes, using the functional I_2^h can increase the grid velocity; if no, one should at once apply I_1^h. In Figure 11(a)–(b) it can be seen that the shock waves are smeared over three cells as in the 1-D case. Near the shocks the cells are very narrow and the maximal aspect ratio reaches 40. As for the 1-D case, due to adaptation, the amplitude of oscillations in the solution is reduced by many factors of ten.

Knowing the exact solution, one can estimate the error; see Table 10.4. We see adaptation allows us to increase the accuracy by a factor of 4 to 5. Keeping in mind that doubling the points in each space direction on the quasi-uniform mesh causes the accuracy to increase by a factor of 2, we can estimate that adaptation in the last three variants is equivalent to the mesh refinement by a factor of 5. Thus, adaptation allows us to gain in CPU memory by a factor of 25 and running time by a factor of

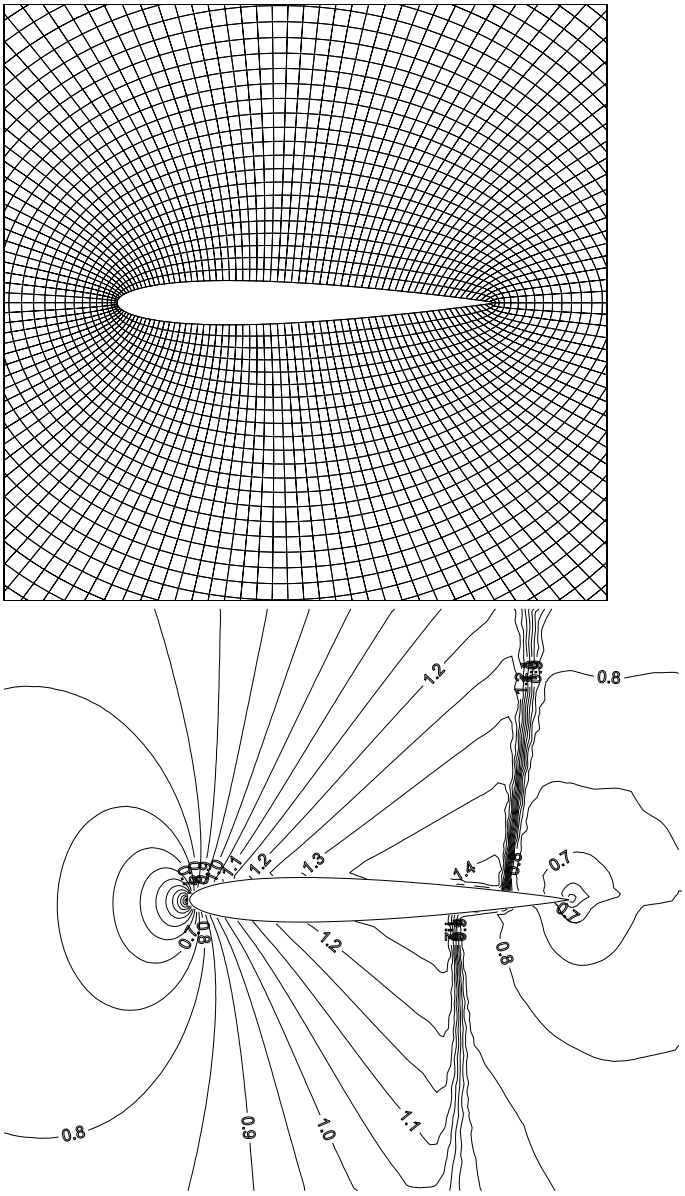

FIG. 12. *Transonic flow around NACA*0012 *airfoil. Quasi-uniform mesh* (a) *and Mach number contours* (b).

50 to 60 taking into account the additional time steps required at adaptation.

10.6. Flow over an airfoil. The GLFC scheme with an adaptive procedure is applied to calculating transonic and supersonic Euler flow over an NACA0012 airfoil. The first test is a transonic case with $M_\infty = 0.85$ and angle of attack $\alpha = 1^\circ$. Figure 12 presents the quasi-uniform O-mesh 140×80 and plots the Mach number contours. We see that shock waves, one (stronger) on the upper side of the airfoil and the other (weaker) on the low side, are rather thick. Figure 13 presents the adapted mesh and

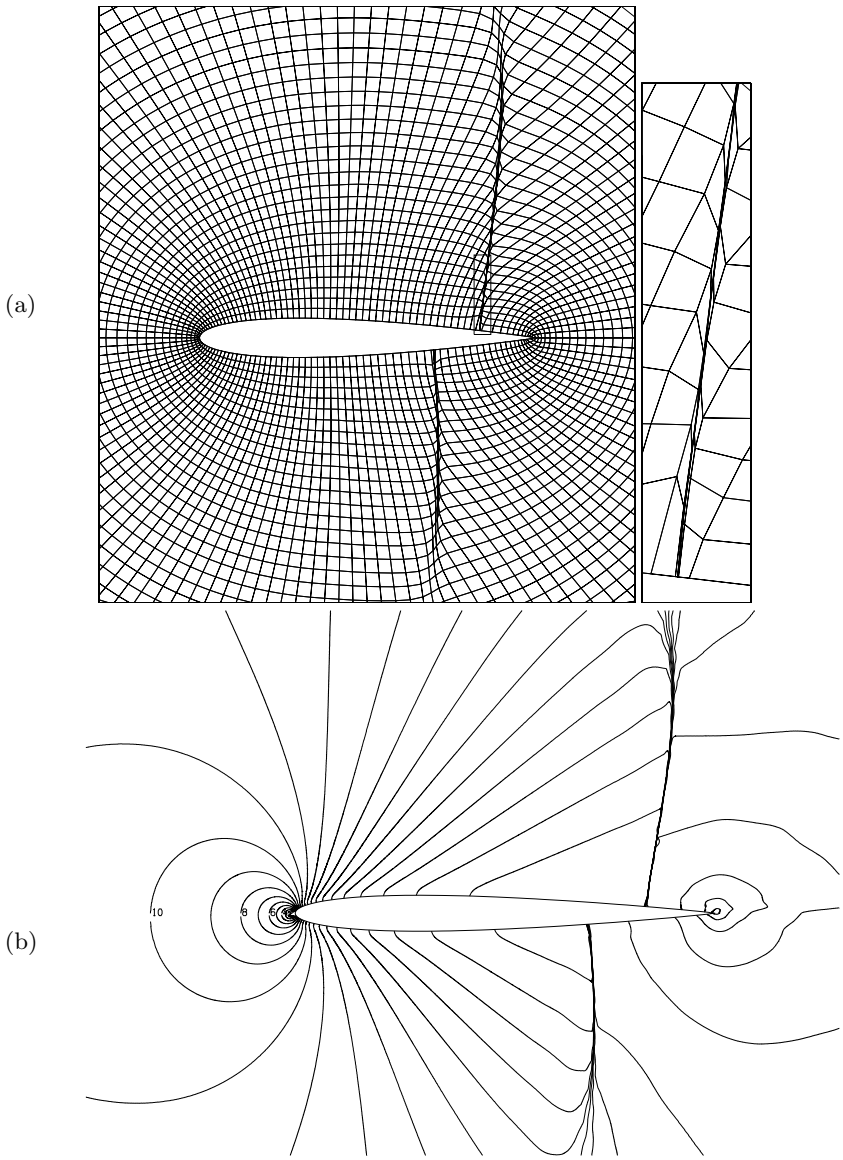

FIG. 13. *Transonic flow around NACA*0012 *airfoil. Adapted mesh* (a) *and Mach number contours* (b).

Mach number contours calculated on this grid. As a control function we use ρ. The coefficient of adaptation c_a is defined to be

$$c_a = \begin{cases} c_{\min} + (c_{\max} - c_{\min})|y|/0.8 & \text{if } |y| \le 0.8, \\ c_{\max} & \text{if } |y| > 0.8, \end{cases}$$

$$c_{\min} = 0.1, \quad c_{\max} = \begin{cases} 0.2 & \text{if } y < 0, \\ 0.15 & \text{if } y > 0. \end{cases}$$

A linear dependence of c_a on y is used to strengthen adaptation in the domains where the shocks grow weaker. Around the leading edge where there are rarefaction

waves we switch off adaptation by setting $c_a = 0$ to exclude cells distortion. Iterative parameter $\tau = 0.3$; the number of iterations at every time step $p_{\text{iter}} = 1$. Constrained minimization is applied to redistribute the boundary nodes along the airfoil contour and along the line $y = 0$ passing from the trailing edge which the boundaries of the parametric square $\xi = 0, 1$ correspond to. Using 1-D or parametric minimization with the same parameters c_a, τ on $\partial\Omega$ as in Ω leads the boundary nodes to overlap in the vicinity of the shocks. Thickness of the shocks is reduced by 50 times in comparison with the nonadapted mesh that provides us with capturing the discontinuities very accurately. The first stage takes 7345 time steps to compute by $t = 20$; adaptation does 150 steps that is about 4% of the first stage time.

Another test is a supersonic flow over the same airfoil with $M_\infty = 1.3$ and $\alpha = 0°$. Figure 14 plots the Mach number contours computed on the quasi-uniform and adapted O-meshs 120×50. As can be seen in Figure 14(a), a strong bow shock wave appears in front of the airfoil leading edge and two weak shocks emanate from the trailing edge. Using adaptation provides us with a very strong reduction in the bow shock thickness and a rather strong reduction in the trailing edge shocks thickness that is demonstrated by the both Mach number contours in Figure 14(b) and adapted grid in Figure 15. The coefficient of adaptation c_a is defined to be

$$c_a = \begin{cases} c_{\min} + (c_{\max} - c_{\min})|y|/1.5 & \text{if } |y| \le 1.5, \\ c_{\max} & \text{if } |y| > 1.5, \end{cases}$$

$$c_{\min} = \begin{cases} 0.05 & \text{if } x \le 0.6, \\ 0.1 & \text{if } x > 0.6, \end{cases} \qquad c_{\max} = 0.15,$$

and as above we set $c_a = 0$ near the airfoil leading edge. Parameters $\tau = 0.3$, $p_{\text{iter}} = 1$.

Grid points clustering allows us to hope that we nearly eliminated the errors caused by shock waves smearing and increased significantly the accuracy of computations. The first stage takes 5882 time steps to compute by $t = 5$; adaptation does 200 steps, which is about 7% of the first stage time. In both tests we use only minimization of the functional I_1^h.

11. Concluding remarks. Results of computations presented show adaptive-harmonic grid generation significantly increases the accuracy of calculations in comparison with modeling on quasi-uniform meshes due to reducing the thickness of smearing to the shock waves, while keeping the same simple grid structure and requiring less computer costs.

Theoretical analysis based on the three-point model of adaptation has shown minimization of the regularized discrete functional in the 1-D and 2-D cases delivers strong grid lines compression towards the discontinuities, while keeping the mesh unfolded. The errors of computations can be conditionally divided into two kinds. The first kind of errors are gained in the vicinity of the shock waves and the second throughout the subdomains of smooth flow. The value of the first in the integral norms L_1 or L_2 is proportional to the thickness of the shocks smeared and, consequently, grid clustering enables us to eliminate those errors or, at least, provides that their magnitude is insignificant in comparison with the second type errors, the value of which depends on the numerical scheme accuracy.

Constrained minimization leads to consistent redistribution of the boundary and interior mesh nodes that increases the reliability of the adaptive procedure and modeling.

In 2-D tests, presented in sections 10.5 and 10.6, the mesh with strong grid lines compression looks like a set of subdomains into which the flow is smooth and the

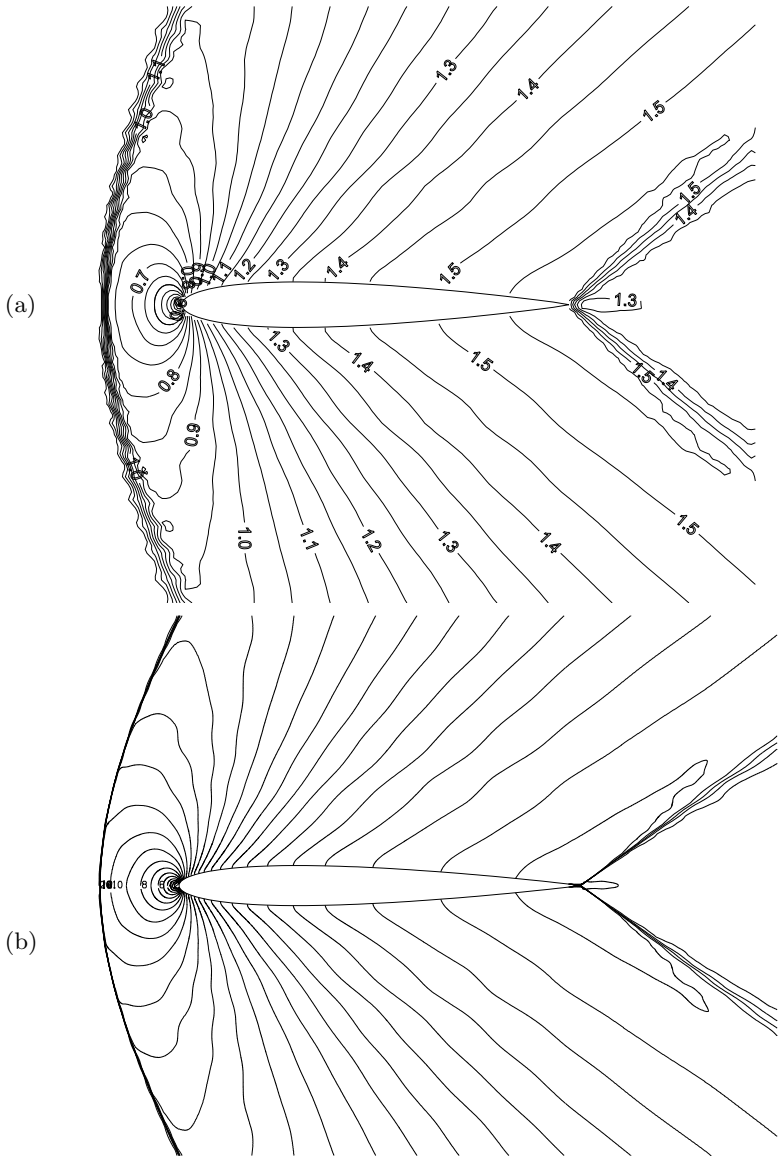

FIG. 14. *Supersonic flow around NACA*0012 *airfoil. Mach number contours computed on quasi-uniform* (a) *and adapted* (b) *grids.*

mesh is quasi-uniform. Boundaries of those subdomains coincide with the shocks and are built automatically by the condensed grid lines. If we draw a closed contour along the shock, one side to the left of the discontinuity and another to the right, and direct the contour width to zero, from the system of conservation laws, written in the integral form (9.1), we get in the limit the Rankine–Hugoniot conditions across the shock [33]. The line passing through the centers of narrow cells, stretched along the shocks, looks like that contour. To draw such a limiting contour we need two adjacent narrow cells in the shock zone as the three-point model of adaptation provides. In real computations (see sections 10.5 and 10.6) the shocks are smeared over 2 to 3

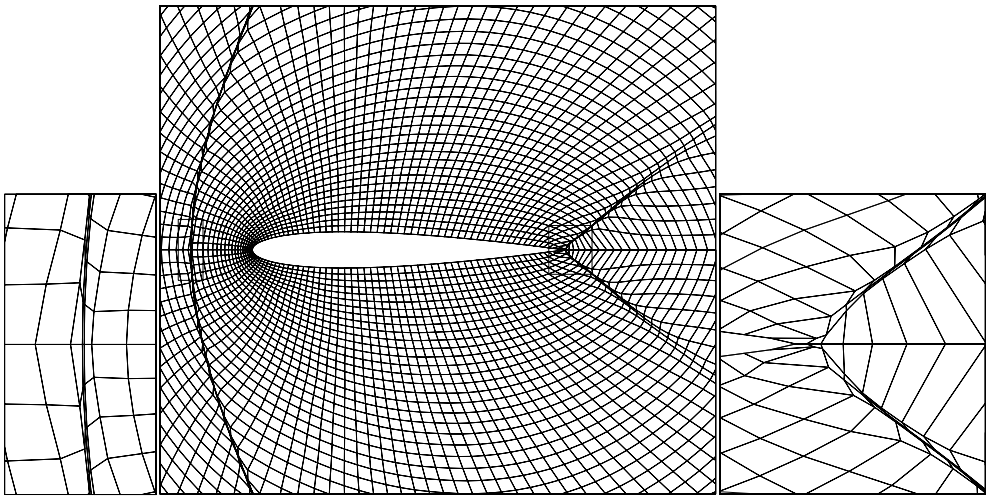

FIG. 15. *Mesh around NACA*0012 *airfoil after adaptation for supersonic flow calculations.*

cells and this is nearly the same as what we would like to have in the ideal case, when the shocks are treated using the Rankine–Hugoniot conditions with a special "shock-fitting" procedure and the subdomains of smooth flow are computed using the numerical scheme. The adaptive procedure, changing the cells width in the shock zone, adjusts automatically the flow solver to those two kinds of computations that increases significantly accuracy of modeling.

Performed in section 5, theoretical analysis shows, in contrast to the boundary layers or shocks smeared in viscous flows, that in the vicinity of the shocks in the hyperbolic problems that the adjacent cells, one located in the shock zone and the other in the domain of smooth solution, with sizes in the direction of normal towards the shock differing by orders of magnitude, do not deteriorate the accuracy of the solution. Therefore, it is not necessary to change the cells' size gradually when passing across the shock. If to apply a numerical scheme using an artificial viscosity, the shock is smeared over several cells and we get a mesh clustered gradually towards the shock. But when decreasing the artificial viscosity and tending the smooth solution to discontinuous, the mesh will come to the above described structure when cell size changes sharply while approaching the shock. From this point of view when computing on the adaptive grids the flow solvers, using piecewise polynomial approximation of the functions, especially Godunov-type schemes, have some advantages over the others based on continuous distribution of the flow parameters.

From the above we can state, probably, that the adapted meshes to the Euler and Navier–Stokes flows must have a different structure and be generated in a different way.

Acknowledgments. The author thanks Dr. Sergey Ivanenko for his attention to the work and fruitful discussions.

ON A NUMERICAL LIAPUNOV–SCHMIDT SPECTRAL METHOD AND ITS APPLICATION TO BIOLOGICAL PATTERN FORMATION*

K. BÖHMER†, C. GEIGER‡, AND J. D. RODRIGUEZ‡

Abstract. Spectral expansions are used to provide a basis which preserves continuous symmetries. We show that spectral methods satisfy the conditions for convergence of numerical Liapunov–Schmidt methods. An explicit algorithm for the calculation of stationary bifurcation scenarios near primary instabilities in general continuous symmetric equations is given. The above convergence is extended to Γ-equivalent discrete and original bifurcation scenarios. The method is applied to a biologically motivated reaction-diffusion system with spherical symmetry forming patterns. A specific singularity of a generic steady state bifurcation is investigated in detail.

1. Introduction.

We discuss numerical Liapunov–Schmidt spectral methods for a symmetric bifurcation problem $G(x) = G(u, \lambda) = 0$ of the form

$$G : \mathcal{D}(G) \subset \mathcal{X} = \mathcal{E} \times \mathbf{R}^q \to \hat{\mathcal{E}}, \qquad \mathcal{E} \subseteq \hat{\mathcal{E}} \text{ are Hilbert spaces,} \tag{1.1}$$

$\hat{\mathcal{E}}$ w.r.t. $\langle \cdot, \cdot \rangle$, and $\mathcal{E}$ w.r.t. a usually stronger norm $\langle \cdot, \cdot \rangle_{\mathcal{E}}$. G transforms equivariantly w.r.t. an (infinite) dimensional representation γ of a symmetry group Γ, i.e., $\gamma G(u, \lambda) = G(\gamma u, \lambda)$, and $\langle \cdot, \cdot \rangle$ is invariant w.r.t. Γ, i.e., $\langle \gamma u, \gamma v \rangle = \langle u, v \rangle \ \forall \ \ \gamma \in \Gamma$, $\forall\ u, v \in \hat{\mathcal{E}}$. We study G near a bifurcation point $x_0 = (u_0, \lambda_0)$ with rank-deficient Jacobian G':

$$G(x_0) = 0,\ G'_0 = G'(x_0) = (G^0_u, G^0_\lambda),\ \dim \mathcal{N}(G'_0) = \mu + q > q. \tag{1.2}$$

Here $\mathcal{N}(G'_0)$ denotes the kernel of G'_0. Let x_0 be a fully symmetric solution of (1.2), i.e., $\gamma x_0 = (\gamma u_0, \lambda_0) = x_0\ \forall \gamma \in \Gamma$. We assume G'_0 to be a Fredholm operator and $\langle \cdot . \cdot \rangle$ to be Γ-invariant; see [27]. For most realistic applications analytical approaches become intractable and discretization methods must be used. However, near the singularity conventional discretization methods fail for several reasons, loss of stability being the most important. Also, consistency inappropriately relates only the original operator to its discretization but not to its derivatives. Finally, discretization methods act as a perturbation and will therefore destroy all generic and nongeneric symmetric bifurcation scenarios; see, e.g., [34, 7, 16, 17, 35, 30, 36, 44, 33, 18]. Comprehensive discussions of general discretization methods in bifurcation theory, using difference methods and finite element methods for both asymmetric and discrete symmetric cases, have been recently provided in [8, 13, 1, 2, 9, 4]. In the presence of continuous

symmetries a symmetry preserving discretization can only be obtained with spectral methods. Another attractive feature of spectral methods is their high accuracy. Nice presentations of spectral methods are given in [29, 19, 5].

History of numerical bifurcation. The earlier results on numerical bifurcation theory do not include spectral methods in general. Specifically, de-aliasing techniques, as well as many important operators, are not discussed. The two most advanced approaches are given in [16, 17] and [30]; see [18] as well. In both papers very restrictive conditions have been used: Assuming an application of inverse operators they require $G : \hat{\mathcal{E}} \times \mathbf{R}^q \to \hat{\mathcal{E}}$, $G(u, \lambda) = u + T(u, \lambda)$ with compact T. This is problematic, since analytically equivalent numerical methods may behave very differently. Then, using convergent approximation operators $P^N : \hat{\mathcal{E}} \to \hat{\mathcal{E}}^N \subset \hat{\mathcal{E}}$, they study discretizations of the form

$$G^N(u, \lambda) = u + P^N T(u, \lambda) = 0 \text{ with } P^N T = T P^N. \tag{1.3}$$

These assumptions allow very elegant convergence proofs of discrete bifurcation scenarios. However, the condition (1.3) excludes many important discretization methods as well as many physically relevant operators, e.g., Navier–Stokes equations.

To cover all these problems and to allow a direct discretization of (1.1), (1.2), the *numerical Liapunov–Schmidt method* has been introduced in [8, 13, 4, 15, 9, 10]. Since the bifurcation effects are determined by an interplay of kernels, ranges, and complements of linear operators and nonlinear terms, we have to make sure that the discrete version of the original nonlinear problem indeed reproduces these effects. To achieve this goal we need the concepts of consistent differentiability and the stability of the bordered systems. Consistent differentiability requires consistency for G and its derivatives as well. In [8] stability for bordered systems was proved by referring to [40, 41]. [14] presents an independent proof, which is valid for spectral methods and for Navier–Stokes equations as well.

The purpose of this paper is to show that the numerical Liapunov–Schmidt spectral method reproduces, under physically appropriate conditions, the bifurcation, stability, and symmetry properties of the original problem. For general discretization methods only convergence of the scenarios exists [15]. In section 2 we show that the concepts of consistent differentiability and stability for the bordered systems hold for a numerical Liapunov–Schmidt spectral method based on spectral approximations. We introduce an efficient algorithm for the numerical reduction of bifurcation problems. Explicit expressions for the calculation of n-determined bifurcation equations are given. In section 3 we introduce a three dimensional reaction-diffusion equation posed on a spherical domain which arises in biological pattern formation. This example is very instructive since it models all possible complications: The symmetry group of the model, $O(3)$, is continuous and non-Abelian. It also requires the splitting of the domain into a periodic and a bounded nonperiodic part. Due to the importance of the $O(3)$-symmetry group, the bifurcation structure of a number of instabilities has been previously investigated [21, 26, 25, 24, 28]. Using these results we can completely classify the bifurcation structure in our examples once the bifurcation equations have been derived by the numerical Liapunov–Schmidt algorithm. This demonstrates another strength of combining symmetry preserving reduction, numerical Liapunov–Schmidt methods, and equivariant local bifurcation theory. If a classification for a bifurcation problem with a given symmetry has been obtained once, the results are universal and can be applied to any physical problem with this specific symmetry. We then apply the numerical Liapunov–Schmidt spectral method to the $l = 3$ instability of the model equations in section 4.

2. Numerical Liapunov–Schmidt methods.

2.1. Definitions and notations. Even a brief introduction into spectral methods would be beyond the scope of this paper. Therefore, we refer the reader to the competent presentations of spectral methods given in [29, 19, 5, 23, 42]. An extended version of this section can be found in [11]. We start with the introduction of spectral approximating spaces and projection operators. Let $\mathcal{E} \subset H^n_w(\Omega), \hat{\mathcal{E}} \subset L^2_w(\Omega), \Omega \subset \mathbf{R}^d$; $H^n_w(\Omega)$ are Sobolev spaces w.r.t. a weight function w. We assume a fixed weight function w and, hence, do not indicate it any more. Let

$$\{\varphi_k\}_{k\in\mathbf{Z}^d_0\subset\mathbf{Z}^d} \text{ be a complete orthogonal basis for } \mathcal{E},\ \hat{\mathcal{E}} \tag{2.1}$$

for $\hat{\mathcal{E}}$ w.r.t. $\langle\cdot,\cdot\rangle$, and for $\mathcal{E}$ w.r.t. $\langle\cdot,\cdot\rangle_{\mathcal{E}}$. The $\varphi_k(x)$ are real- or complex-valued functions. We define finite dimensional approximating spaces

$$\mathcal{E}^N = \operatorname{span}\{\varphi_k\}_{k\in\mathbf{K}^N} \subset \mathcal{E} \subseteq \hat{\mathcal{E}} \text{ with } u^N \in \mathcal{E}^N, \tag{2.2}$$

where $k = (k_1, \dots, k_d) \in \mathbf{K}^N$ is a d dimensional multi-index in a finite subset $\mathbf{K}^N \subset \mathbf{Z}^d_0$, and $k \in \mathbf{K}^N$ with $|k_i| \le N_i$ and $N = (N_1, \dots, N_d) \in \mathbf{N}^d_0$, $\hat{N} := |\mathbf{K}^N|$, $\tilde{N} := \min\{N_1, \dots, N_d\}$. The usage of multi-index notation is important since it appropriately reflects the structure of the basis functions $\varphi_k(x)$. This structure is certainly a consequence of the symmetry of (1.1). The structure of $\varphi_k(x)$ and the values of N can be determined using the theory of symmetric spaces. For a very instructive introduction to this theory see [6]. In section 3 we give the explicit form of $\varphi_k(x)$ for $O(3)$-symmetric spaces. Now, every $u \in \mathcal{E}$ (or $\hat{\mathcal{E}}$) is, alternatively, *approximated by truncation* $T^N u$ as

$$T^N u = T^N \left(\sum_{k\in\mathbf{Z}^d_0} \hat{a}_k \varphi_k \right) := \sum_{k\in\mathbf{K}^N} \hat{a}_k \varphi_k \in \mathcal{E}^N$$

or by (unique) *interpolation* in distinct points $y_j \in \Omega$, j are multi-indices, with

$$I^N : \mathcal{E} \to \mathcal{E}^N \text{ unique by } (I^N u - u)|_{y_j} = 0, \qquad j \in \mathbf{J}^N \subset \mathbf{Z}^d, \quad |\mathbf{J}^N| = \hat{N} = |\mathbf{K}^N|.$$

Sometimes, we use the notations $T^N = T(\mathcal{E}^N)$ and $I^N = I(\mathcal{E}^N)$. Now, $\langle\cdot,\cdot\rangle$ is approximated by the (Gaussian) quadrature rule defined as

$$\langle u, v\rangle^N := \sum_{j\in\mathbf{J}^N} u(y_j)\bar{v}(y_j)w_j, \quad (\|u\|^N_0)^2 := \langle u, u\rangle^N. \tag{2.3}$$

$\langle u, v\rangle$, $\langle u, v\rangle^N$ are Γ-invariant, and the operators $T^N, I^N : \mathcal{E}, \hat{\mathcal{E}} \to \mathcal{E}^N$ are Γ-equivariant and are orthogonal projectors w.r.t. $\langle\cdot,\cdot\rangle$ and $\langle\cdot,\cdot\rangle^N$; hence the corresponding error functions $T^N u - u$ and $I^N u - u$ satisfy

$$T^N u - u \perp \mathcal{E}^N \text{ and } I^N u - u \perp^N \mathcal{E}^N. \tag{2.4}$$

In general, different symmetry preserving boundary conditions $B_1(u) = 0, B_2(z) = 0$ are imposed on (1.1), (1.2). Therefore, we must replace $\mathcal{E}$ and $\hat{\mathcal{E}}$ by spaces of appropriate ansatz- and test-functions

$$\mathcal{V}^N_1 := \{u \in \mathcal{E}^N : B_1(u) = 0\} \text{ and } \mathcal{V}^N_2 := \{z \in \hat{\mathcal{E}}^N : B_2(z) = 0\}$$

with $\dim \mathcal{V}_1^N = \dim \mathcal{V}_2^N$. Now we define Γ-equivariant orthogonal projectors $P_i^N, \tilde{P}_i^N : \mathcal{E} \to \mathcal{V}_i^N$ such that

$$\langle P_i^N u - u, v^N\rangle,\ \langle \tilde{P}_i^N u - u, v^N\rangle^N = 0 \quad \forall\ v^N \in \mathcal{V}_i^N, \qquad i = 1, 2, \tag{2.5}$$

where $\tilde{P}_i^N, i = 1, 2$, are well defined whenever $u(y_j), v^N(y_j)$ are known. Obviously, for $\mathcal{E}_1^N = \mathcal{V}_1^N, \mathcal{E}_2^N = \mathcal{V}_2^N$ it follows that $P_i^N = T(\mathcal{E}_i^N),\ \tilde{P}_i^N = I(\mathcal{E}_i^N),\ i = 1, 2$. Applying the projections to our bifurcation problem (1.2) we get the following two discrete problems: With $x_0^N = (u_0^N,\ \lambda_0) \in \mathcal{V}_1^N \times \mathbf{R}^q$

$$\text{determine } x_0^N \text{ such that } \ P_2^N G(x_0^N) = 0 \text{ or } G(x_0^N) \perp \mathcal{V}_2^N, \tag{2.6}$$

$$\text{determine } x_0^N \text{ such that } \ \tilde{P}_2^N G(x_0^N) = 0 \text{ or } G(x_0^N) \perp^N \mathcal{V}_2^N. \tag{2.7}$$

Remark. Often $G(u^N)$ is replaced by an approximate operator $\tilde{G}^N(u^N)$ (in particular, if the nonlinear parts of G are evaluated in pseudospectral and collocation methods or with de-aliasing techniques; see, e.g., (2.11), (2.16)). In fact, collocation methods are perturbed Galerkin methods: They are obtained by choosing in (2.5), (2.7) the v^N for $\tilde{P}_2^N$ as the Lagrange basis $v_i^N(y_j) = \delta_{i,j}, i, j \in \mathbf{J}^N$.

The equivariant *interpolation, truncation*, and *projection operators* have the following properties. They hold for smooth $u \in H_w^m(\Omega), 0 \le n \le m$, with $\ell = 0$ and n corresponding to the norms in $\hat{\mathcal{E}}$ and $\mathcal{E}$, respectively,

$$\|T^N u - u\|_\ell \le \|I^N u - u\|_\ell, \|P_i^N u - u\|_\ell, \|\tilde{P}_i^N u - u\|_\ell = \mathcal{O}(\tilde{N}^{-m+\iota^K(\ell)}\|u\|_\ell), \tag{2.8}$$

and $K = F, C, L$ indicate Fourier (or exponential), Chebyshev-, and Legendre-approximations in (2.2), with $\iota^F(n) = n, \iota^C(n) = 2n, \iota^L(n) = 2n + d/2$. If different variables for multivariate u require different approximations, we replace $\iota^K(n)$ by the maximal value. For quadrature approximations with Gauss–Lobatto points we use the equiboundedness of $\|T^{N-\nu}u - u\|_\ell / \|T^N u - u\|_\ell$ for fixed ν, usually $\nu = 1$. Therefore, only the interpolation errors in (2.8) have to be considered.

2.2. Consistent differentiability. To avoid too many technicalities, we assume (1.1) in the form

$$\begin{aligned} G(x) = G(u, \lambda) = L_0 u + \lambda R(u) &= L_0 u + \lambda R_e\left(u, \nabla u, \int_{\Omega_0} u\right) \\ &= L_0 u + \lambda\left(u^2 + \nabla u\left(u + \int_{\Omega_0} u\right) + g\right) \end{aligned} \tag{2.9}$$

with $u_0 = 0$ and a bounded linear operator $L_0 = G_u(x_0)$ and a nonlinear operator R. For the general case see [11]. Now we evaluate (2.9) for spectral and collocation methods indicated by an indices s and c, respectively. In the spectral approach $x_0^N \in \mathcal{V}_1^N \times \mathbf{R}$ are determined as

$$\begin{aligned} \tilde{G}_s^N(x_0^N) :&= P_2^N \tilde{G}^N(x_0^N) = P_2^N T^N G(x_0^N) = 0, \quad \text{or} \\ \tilde{G}_s^N(x_0^N) &= T^N G(x_0^N) \perp \mathcal{V}_2^N. \end{aligned} \tag{2.10}$$

For collocation methods we need point evaluations in (2.9) (see (2.13)):

$$\begin{aligned} G^N(u^N, \lambda)(y_j) &:= (L_0^N u^N)(y_j) + \lambda R^N(u^N)(y_j), \\ L_0^N u^N &:= T^N\ (L_0) u^N = L_0(u^N), \end{aligned} \tag{2.11}$$

$$\begin{aligned} R^N(u^N)(y_j) := &((u^N)^2(y_j) + (\nabla u^N)(y_j)) \\ &\times (u^N(y_j) + Q^N u^N + g(y_j)), \qquad j \in \mathbf{J}^N. \end{aligned} \tag{2.12}$$

In spectral approach terms like $(L_0(u^N))(y_j), (\nabla u^N)(y_j)$ and integrals are not evaluated directly but via some linear approximation operators, e.g., the Fourier collocation derivative (see [19]) or quadrature formulas, $Q^N u^N$; see (2.13). We denote these approximate *linear operators and functionals* (evaluated in y_j) as

$$\begin{aligned} &(L_0^N u^N)(y_j) \approx (L_0 u^N)(y_j), \\ &(L_1^N u^N)(y_j) \approx (\nabla u^N)(y_j), \text{ and } Q^N u^N = \sum_{i \in \mathbf{J}^N} u^N(y_i) w_i, \end{aligned} \tag{2.13}$$

the quadrature approximation. We introduce the restriction operator

$$\rho^N : C(\Omega) \to \mathbf{R}^{\hat{N}}, (\rho^N(u))(y_j) := u(y_j), \quad j \in \mathbf{J}^N, \tag{2.14}$$

where $C(\Omega)$ denotes continuous scalar functions on Ω. Then we re-interpret the approximated $G^N(x^N)$ in (2.11) (see (2.9)) as

$$\begin{aligned} G_c^N(x^N) &:= \rho^N \tilde{G}_c^N(x^N) := \rho^N L_0^N(u^N) + \lambda \rho^N R^N(u^N) \\ &:= \rho^N L_0^N(u^N) + \lambda \rho^N R_e^N(u^N, L_1^N u^N, Q^N u^N). \end{aligned} \tag{2.15}$$

We insert the $L_i^N u^N$, $i = 0, 1$, in (2.13) into R_e. To reveal the structure of $R^N(u^N)$, note that

$$\begin{aligned} \rho^N R^N(u^N) &:= R_e(\rho^N u^N, \rho^N(L_1 u^N), Q^N u^N) \\ &= \rho^N R_e(u^N, L_1^N u^N, Q^N u^N) + \mathcal{O}(\|I^N R(u^N) - R(u^N)\|_0) \\ &= \rho^N R(u^N) + \mathcal{O}(\|I^N R(u^N) - R(u^N)\|_0), \end{aligned} \tag{2.16}$$

and there may possibly be other approximations such as Fourier collocation derivatives or de-aliasing techniques into R to obtain an R_e or even an approximation $R_a \approx R_e$. Corresponding relations hold for the partial derivatives of R, R^N. It is possible to include de-aliasing techniques into this formalism (see [11]) as well. With the equivalent definition of $\tilde{P}_z^N u$ for smooth u via functions and point evaluations (see (2.5)) we formulate the collocation equations as follows: Determine $x_0^N \in \mathcal{V}_1^N \times \mathbf{R}$ such that

$$\tilde{P}_2^N G_c^N(x_0^N) = \tilde{P}_2^N \rho^N \tilde{G}_c^N(x_0^N) = 0 \text{ or } G_c^N(x_0^N) \perp^N \mathcal{V}_2^N. \tag{2.17}$$

THEOREM 2.1. *Let, for the nonlinear operator $G \in C^r(\mathcal{D}(G))$, $G(x_0) = 0$, $\|x_0 - x\|_n$ be small. Let its spectral approximation $G^N = G_s^N$ or G_c^N, with or without de-aliasing (see* (2.11)*), satisfy* (2.16)*. Then the spectral operator G^N is* consistent *and* r-times consistently differentiable *with G, that is, for $j = 1, \dots, r, 0 \le n \le m$,*

$$\begin{aligned} &\|G^N(P_1^N x) - P_2^N G x\|_0 = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)} \|x\|_m), \\ &\|(G^N)^{(j)}(P_1^N x) P_1^N x_1 \cdot \dots \cdot P_1^N x_j - P_2^N G^{(j)}(x) x_1 \cdot \dots \cdot x_j\|_0 \\ &\quad = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)} \|x_1\|_m \cdot \dots \cdot \|x_j\|_m (1 + \|x\|_m)) \end{aligned} \tag{2.18}$$

for $x = (u, \lambda), x_j = (u_j, \mu_j) \in \mathcal{X} = \mathcal{E} \times \mathbf{R}^q$, and $u, u_1, \dots, u_j \in H_w^m(\Omega) \cap \mathcal{E}$. Analogous results hold for the $\tilde{P}_1^N, \tilde{P}_2^N$ and G, G^N combinations. All these operators, derivatives, and $\mathcal{O}$-terms are Σ-equivariant for $u_j \in$ Fix$(\mathcal{E}^\Sigma)$ (see (2.30)*) for $\Sigma = \Gamma$ or a subgroup $\Sigma \subseteq \Gamma$.*

Proof. The estimates (2.8) imply for $u \in H^m_w(\Omega) \cap \mathcal{E}$, similarly in $\hat{\mathcal{E}}$,

$$\|I_N x - x\|_n + \|P_1^N x - x\|_n + \|\tilde{P}_1^N x - x\|_n = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m). \tag{2.19}$$

With $G(u,\lambda) \in H^{m-n}_w(\Omega)$ and (2.9), (2.16), we obtain for both cases

$$\begin{aligned} &\|G_s^N(P_1^N x) - P_2^N G(x)\|_0,\ \|G_c^N(\tilde{P}_1^N x) - \tilde{P}_2^N G(x)\|_0 \\ &\qquad = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m), \end{aligned} \tag{2.20}$$

with all terms Σ-equivariant. The $\tilde{P}_1^N, \tilde{P}_2^N$, and $\tilde{G}^N$ results are obtained here and below in a full analogy.

We prove (2.18)(ii) only for the more complicated case of G_c^N. We have $v_i = x_i = (u_i, \lambda_i)$ or $v_i = u_i$:

$$(L_i v_1)^{(j)}(v_2) = \delta_{1j} L_i v_2, \quad (L_i^N v_1^N)^{(j)}(v_2^N) = \delta_{1j} L_i^N v_2^N \tag{2.21}$$

for $i = 0, 1$ and for $j \geq 1$. (2.9), (2.16) for the partials imply with the partials $\partial_i R$ that

$$\begin{aligned} \big(G_c^N\big)'\big(\tilde{P}_1^N x\big)\tilde{P}_1^N x_1 &= \rho^N(T^N L_0)\tilde{P}_1^N x_1 \\ &\quad +\lambda\rho^N(\partial_1 R^N(\tilde{P}_1^N x), \partial_2 R^N(\tilde{P}_1^N x), \partial_3 R^N(\tilde{P}_1^N x)) \\ &\quad \cdot(\tilde{P}_1^N x_1, L_1^N \tilde{P}_1^N x_1, Q^N \tilde{P}_1^N x_1)^T \\ &= \rho^N(L_0, (\partial_1 R(x), \partial_2 R(x), \partial_3 R(x))(1 + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m))) \\ &\quad \cdot((x_1, L_1 x_1, l x_1) + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x_1\|_m))^T \\ &= \rho^N(G'(x)(1 + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m))) \\ &\quad \cdot(x_1 + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x_1\|_m)) \\ &= \tilde{P}_2^N(G'(x)(1 + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m))) \\ &\quad \cdot(x_1 + \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x_1\|_m)). \end{aligned}$$

So, we have proved (2.18)(ii) for $j = 1$. This holds for G_s^N and the higher derivatives as well. ∎

Consistent differentiability and stability for bordered systems imply convergent bifurcation scenarios for numerical Liapunov–Schmidt methods [15]. In [14] we have proved this stability for a large class of discretization methods and operator equations, including spectral methods for elliptic and Navier–Stokes operators.

2.3. Bifurcation equations and truncated Liapunov–Schmidt methods. Without loss of generality we have distinguished one specific parameter λ as a bifurcation parameter. So, for the remainder of the paper we assume $\lambda \in \mathbf{R}^1$. We want to identify the bifurcation scenario for the bifurcation equation from its truncated discretizations. First we review an iterative Liapunov–Schmidt method that generates the jets (truncated Taylor series) of the bifurcation equation up to the required order. Let $E^\nu_{m,1}$ denote the module of germs [27, 28] at $(0,0)$ of C^∞ vector or matrix-valued functions $\mathbf{R}^m \times \mathbf{R} \to \mathbf{R}^\nu$, over the ring $E^1_{m,1}$. We study Γ-equivariant bifurcation problems

$$\mathcal{F}_\Gamma := \{f \in E^m_{m,1} \ :\ f(0,0) = 0,\ Df(0,0) = 0,\ \gamma f(u,\lambda) = f(\gamma u, \lambda)\ \forall\ \gamma \in \Gamma\}.$$

We identify elements in $f, g \in \mathcal{F}_\Gamma$ that are merely deformations of each other and denote them to be Γ-equivalent (we write $f \overset{\Gamma}{\sim} g$); see [28]. We write $j_k g$ for the truncated Taylor expansion of g w.r.t. all its arguments up to order k (the so called

k-jet). If $j_k g \sim g$, for minimal $k \in \mathbf{N}$, then g is said to be k-determined. We define a pseudonorm

$$\|g\|_k^0 = \sum_{|i|+j\le k} \left| \frac{\partial^{|i|+j} g}{\partial u^i \partial \lambda^j}(0,0) \right|. \tag{2.22}$$

Here we consider $g \in \mathcal{F}_\Gamma$ to be structurally stable, i.e., there exists $\varepsilon > 0$ such that all perturbations $f \in \mathcal{F}_\Gamma$ with $\|f-g\|_k^0 < \varepsilon$ satisfy $f \sim g$. As a consequence Γ must be absolutely irreducibly represented on $\mathbf{R}^m$; see [28]. Structural stability of g guarantees that qualitative results of bifurcation theory can be observed in the underlying physical model.

We consider the 1-parameter Γ-equivariant operator equation (2.9) with the singularity in $x_0 = (0,0)$:

$$G(0,0) = 0,\ G_0' := \partial G(0,0) = (\partial_u G(0,0), \partial_\lambda G(0,0)) =: L =: (\partial_u G_0, \partial_\lambda G_0),$$

G_0' is a Γ-equivariant Fredholm operator of index 1 with a kernel of dimension $m+1$, $m \ge 1$. Note that by the definitions $R(x) = O(\|x\|^2)$. $\mathcal{F}_\Gamma$ excludes turning point bifurcations, i.e., we assume the existence of a trivial solution from which the nontrivial branches bifurcate. Using the Fredholm condition we split into Γ-invariant orthogonal subspaces

$$\mathcal{X} = \mathcal{E} \times \mathbf{R} = \mathcal{N}(G_0') \oplus \operatorname{im}(G_0'^*), \quad \hat{\mathcal{E}} = \mathcal{N}(G_0'^*) \oplus \operatorname{im}(G_0'), \quad \operatorname{im}(G_0'^*) \subset \mathcal{E} \times \{0\},$$

with * always indicating the adjoint operator. We define Γ-equivariant projections (see, e.g., [43, 27])

$$\begin{aligned} &\mathcal{Q} : \mathcal{E} \times \mathbf{R} \to \operatorname{im}(G_0'^*),\ \ \mathcal{N}(\mathcal{Q}) = \mathcal{N}(G_0') = \mathcal{N}(\partial_u G_0) \times \mathbf{R}; \\ &\hat{\mathcal{Q}} : \hat{\mathcal{E}} \to \operatorname{im}(G_0'),\ \mathcal{N}(\hat{\mathcal{Q}}) = \mathcal{N}(G_0'^*),\ \text{e.g., } \hat{\mathcal{Q}}\hat{u} := \hat{u} - \textstyle\sum_{i=1}^{\mu} \langle \hat{\psi}_i, \hat{u} \rangle \hat{\psi}_i. \end{aligned} \tag{2.23}$$

Let $x = x_{\mathcal{N}} + w$ with $x_{\mathcal{N}} \in \mathcal{N}(G_0')$, $w \in \operatorname{im}(G_0'^*)$, and note that $G(x) = 0$ if and only if

$$\hat{\mathcal{Q}} G(x_{\mathcal{N}} + w) = G_0' w + \hat{\mathcal{Q}} R(x_{\mathcal{N}} + w) = 0 \ \text{ and} \tag{2.24}$$

$$(I - \hat{\mathcal{Q}}) G(x_{\mathcal{N}} + w) \ = (I - \hat{\mathcal{Q}}) R(x_{\mathcal{N}} + w) = 0. \tag{2.25}$$

The bordered system (2.24) is uniquely solvable (for small $x_{\mathcal{N}}$) yielding $w(x_{\mathcal{N}}) = w \in \operatorname{im}(G_0'^*)$. This is substituted into (2.25) to give the Γ-equivariant *bifurcation equation*:

$$B(x_{\mathcal{N}}) := (I - \hat{\mathcal{Q}}) G(x_{\mathcal{N}} + w(x_{\mathcal{N}})) = (I - \hat{\mathcal{Q}}) R(x_{\mathcal{N}} + w(x_{\mathcal{N}})) = 0. \tag{2.26}$$

For the following iteration method, theorem, and modification, see [28] and [3].

ALGORITHM 1 (truncated Liapunov–Schmidt method). Let $w_1(x_{\mathcal{N}}) = 0$.

Iteration. For $k = 2, 3, \ldots$ until determinacy do

Define the truncated bifurcation equation of order k,

$$B_k : \mathcal{N}(G_0') \to \mathcal{N}(G_0'^*), \quad B_k(x_{\mathcal{N}}) := (I - \hat{\mathcal{Q}}) j_k R(x_{\mathcal{N}} + w_{k-1}(x_{\mathcal{N}})). \tag{2.27}$$

We usually identify $x_{\mathcal{N}} \in \mathcal{N}(G_0')$ with $(\alpha, \lambda) \in \mathbf{R}^{m+1}$, $\mathcal{N}(G_0'^*)$ with $\mathbf{R}^m$, and maintain the equivariance for α. Generate the next w_k by

$$G_0' w_k(x_{\mathcal{N}}) := \hat{\mathcal{Q}} j_k R(x_{\mathcal{N}} + w_{k-1}(x_{\mathcal{N}})), \qquad w_k \in \operatorname{im}(G_0'^*). \tag{2.28}$$

THEOREM 2.2. *For the iteration defined in* (2.28), *we have*

$$w_k(x_{\mathcal{N}}) = j_k w(x_{\mathcal{N}}), \text{ and } B_k(x_{\mathcal{N}}) = j_k B(x_{\mathcal{N}}).$$

The truncated bifurcation equations (2.27) will transform equivariantly under a finite dimensional representation of the symmetry group of (2.26).

2.4. Equivariant numerical Liapunov–Schmidt methods. To guarantee that the *discretization of* (1.1) *and of all introduced projection operators inherit the* Γ*-equivariance, we need* to reflect this in the discretization method and in $\langle\cdot,\cdot\rangle^N$. In particular, $\mathcal{E}^N$, $\hat{\mathcal{E}}^N$ and $\mathcal{V}_1^N, \mathcal{V}_2^N$ need to be closed under the action of Γ, and $G^N, \tilde{G}^N$, and all the above discrete operators, e.g., T^N, have to be Γ-equivariant, and

$$\begin{aligned} &G^N(\gamma u^N, \lambda) = \gamma G^N(u^N, \lambda) \text{ and, e.g., } T^N \gamma u^N = \gamma T^N u^N, \text{ and} \\ &\langle u^N, v^N\rangle^N = \langle \gamma u^N, \gamma v^N\rangle^N \ \forall \gamma \in \Gamma \text{ and } u^N, v^N \in \mathcal{E}^N. \end{aligned} \tag{2.29}$$

In particular, Γ-invariant approximating subspaces have to be chosen such that (2.29) is satisfied. For spectral methods this is achieved by the finite dimensional bases which provide a representation of, e.g., the spherical symmetries. We assume that the symmetry group acts only in the periodic direction; hence the radial dependence of the functions has no symmetry properties. Therefore, the full problem will be discretized by a product-ansatz with a harmonic basis in the periodic directions and a basis of orthogonal polynomials in the inhomogeneous directions. For other methods, the so-called *symmetry respecting bases* are studied in [22, 2]. Fixed point spaces within $\mathcal{E}^N$ and $\hat{\mathcal{E}}^N$ are defined for subgroups $\Sigma \subseteq \Gamma$ in the usual way:

$$\begin{aligned} &\mathcal{E}^{N,\Sigma} := \mathrm{Fix}^{\Sigma}(\mathcal{E}^N) := \{u^N \in \mathcal{E}^N \ : \ u^N = \sigma u^N \ \forall\ \sigma \in \Sigma\}, \\ &\mathcal{X}^{N,\Sigma} := \mathcal{E}_0^{N,\Sigma} \times \mathbf{R}. \end{aligned} \tag{2.30}$$

For the discrete problem $G^N(x^N)$ on fixed point spaces (2.30) we have

$$G^{N,\Sigma} := G^N|_{\mathcal{X}^{N,\Sigma}} : \mathcal{X}^{N,\Sigma} \to \hat{\mathcal{E}}^{N,\Sigma},$$

G^N and its derivatives (and remainder terms) evaluated at x^N are Σ_{x^N}-equivariant; $\Sigma_{x^N} = \{\gamma \in \Gamma, \gamma x_N = x_N\}$ is the isotropy subgroup of x^N. If G^N is stable or r-times consistently differentiable, the same is true for $G^{N,\Sigma}$.

Throughout we have assumed that we study the singularity of the original problem at $(0,0) = x_0$, i.e., $G(0,0) = G(x_0) = 0$ with

$$\begin{aligned} &\partial_\lambda G(0,0) = 0, \ \mathcal{N}(G_0'^*) = \text{span}\,\{\hat{\psi}_1, \dots, \hat{\psi}_\mu\} \quad \text{and} \\ &\mathcal{N}(G_0') = \mathcal{N}(\partial_u G(0,0)) \times \mathbf{R} = \text{span}\,\{\psi_1, \dots, \psi_\mu\} \times \mathbf{R}. \end{aligned} \tag{2.31}$$

Let

$$G^N(x_0^N) = 0, \quad x_0^N \approx (0,0) \text{ and } x_0^N \in \mathrm{Fix}^{\Gamma}(\mathcal{E}^N) = \mathcal{E}^{N,\Gamma}. \tag{2.32}$$

For a simple bifurcation point of G ($\mu = 1$ in (2.31)) and for bifurcation from a trivial solution it has been shown in [17] that G^N has a bifurcation point in $x_0^N = (0,0) + \mathcal{O}(h^p)$. The general problem is studied in [8, 13, 15]. We introduce

$$\hat{G}^N(x^N) := G^N(x_0^N + x^N), \quad (\hat{G}^N)^{(j)}(x^N) = (G^N)^{(j)}(x^N), \qquad j \geq 1, \tag{2.33}$$

and drop the $\hat{}$ below without violating Theorem 2.1. Thus, without loss of generality, $(0,0)$ is also a singular point of G^N. For higher singularities of G it has been shown in [1] and [8] that for $\partial_\lambda G^N(0,0)=0$ there exist $\psi_i \approx \psi_i^N$ and $\hat{\psi}_i \approx \hat{\psi}_i^N$ such that $\psi_i^N \notin \mathcal{N}(G_0'), \hat{\psi}_i^N \notin \mathcal{N}(G_0'^*)$. These approximations for the kernels of $\partial_u G_0$ and $(\partial_u G_0)^*$ allow the application of the generalized Liapunov–Schmidt methods. Using the equivariance of the bifurcation problem and its discretization we can assume the following generic form:

$$
\begin{aligned}
&\partial_\lambda G^N(0,0)=0,\\
&\mathcal{N}(G_0^{N\prime}) = \mathcal{N}(\partial_{u^N} G^N(0,0)) \times \mathbf{R} = \operatorname{span}\{\psi_1^N,\dots,\psi_\mu^N\}\times\mathbf{R} =: \mathcal{N}^N,\\
&\mathcal{N}(G_0^{N\prime *}) = \operatorname{span}\{\hat{\psi}_1^N,\dots,\hat{\psi}_\mu^N\} =: \hat{\mathcal{N}}^N \quad \text{with again} \qquad (2.34)\\
&\|\psi_i^N - T^N\psi_i\|_n = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|\psi_i\|_m),\\
&\|\hat{\psi}_i^N - \hat{T}^N\hat{\psi}_i\|_n = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|\hat{\psi}_i\|_m), \qquad i=1,\dots,\mu=\dim\mathcal{N}(G_0'^*).
\end{aligned}
$$

We assume Γ-invariant pairings and

$$
\langle T^N u, T^N v\rangle^N = \langle u,v\rangle + \mathcal{O}(N^{-m+\iota^K(n)}\|u\|_m\|v\|_m). \tag{2.35}
$$

With the systematic replacement of the original operators, bilinear forms, projectors, spaces, and functions by their respective discrete version (labeled by N), we translate Algorithm 1 and Theorem 2.2 into their discrete counterparts.

ALGORITHM 2 (numerical truncated Liapunov–Schmidt spectral method).

Iteration. For $k=2,3,\dots$ until determinacy perform the two steps:

$$
B_k^N : \mathcal{N}(G_0^{N\prime}) \to \mathcal{N}(G_0'^*), \quad B_k^N(x_\mathcal{N}^N) := (I-\hat{\mathcal{Q}}^N) j_k R^N(x_\mathcal{N}^N + w_{k-1}^N(x_\mathcal{N}^N)), \tag{2.36}
$$

$$
G_0^{N\prime} w_k^N(x_\mathcal{N}^N) := \hat{\mathcal{Q}}^N j_k R^N(x_\mathcal{N}^N + w_{k-1}^N(x_\mathcal{N}^N)), \qquad w_k^N \in \operatorname{im}(G_0'^*). \tag{2.37}
$$

THEOREM 2.3. *Let G and its discretization G^N satisfy the following (natural) conditions:*

1. *G and G^N are r-times continuously and consistently differentiable (see (2.18)), $r \ge k$, the determinacy of the problem.*
2. *The original and discrete kernels are related via (2.31) and (2.34).*
3. *The original problem is a Γ-equivariant bifurcation problem (see (1.1) and (1.2)) and satisfies (2.31).*
4. *G^N is a spectral, pseudospectral, or collocation method with or without dealiasing; hence it is a Γ-equivariant discretization of G, that is, G^N is based on the Γ-invariant subspaces and pairings (see (2.35)) and Γ-equivariant operators, projectors, and $\mathcal{O}$-terms (see (2.2), (2.16), (2.2)) which are related, e.g., $0 \le n \le m$, by*

$$
T^N\mathcal{Q}x - \mathcal{Q}^N T^N x = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x\|_m) \quad \text{for} \quad x=(u,\lambda),\ u\in H^m(\Omega).
$$

Then, similarly to (2.8), the exact, discrete, and truncated results are related as

$$
\begin{aligned}
&w_k^N(x_\mathcal{N}) = j_k w^N(x_\mathcal{N}) \ \text{ and } \ B_k^N(x_\mathcal{N}) = j_k B^N(x_\mathcal{N}),\\
&\|w_k^N(T^N x_\mathcal{N}) - T^N w_k(x_\mathcal{N})\|_n = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x_\mathcal{N}\|_m), \qquad (2.38)\\
&\|B_k^N(T^N x_\mathcal{N}) - T^N B_k(x_\mathcal{N})\|_k^0 = \mathcal{O}(\tilde{N}^{-m+\iota^K(n)}\|x_\mathcal{N}\|_m),
\end{aligned}
$$

with Γ*-equivariant* $B_k^N(T^N x_{\mathcal{N}}), B_k(x_{\mathcal{N}})$ *determining* Γ*-equivalent bifurcation scenarios, since* B_k *and* B_k^N *are elements in* $\mathcal{F}_\Gamma$*. As norms for* w_k^N *we use* (2.37)*; for* B_k^N *we use* (2.22)*. Without the* Γ*-invariant and equivariant conditions,* $\partial_\lambda G^N(0,0) = 0$, (2.34)*, and* (2.22)*, we still obtain convergence of the discrete to the exact bifurcation scenarios.*

Proof. Since all the error-terms $\mathcal{O}$ are Γ-equivariant, the bordered system is stable, the discretization is r-times consistently differentiable, and the problem is structurally stable w.r.t. the seminorm (2.22), the results of this theorem are immediate consequences of the given conditions. ∎

The validity of the stability assumption for the number of bordering conditions can be monitored by comparing results for different values of N.

ALGORITHM 3 (symmetric Liapunov–Schmidt method).

Initiation. For harmonic spectral expansions the harmonic component of the critical eigenvector consists of a reducible representation of the symmetry group Γ. Let the dimension of the critical eigenspace be N_0; then the spectral space $\mathcal{E}^{N_0}$ is of dimension N_0 with maximum wave number l_{N_0}. The nonlinear interactions in the k-jet $j_k R^N(u)$ generate wave numbers of order kl_{N_0}.

Iteration. Remove aliasing errors by padded transforms of the nonlinear operator R (see [19, 11]), where $N_1 \geq (k+1)l_{N_0}/2-1$ for one dimensional trigonometric Fourier transforms and $N_{lon,1} \geq (2k+1)l_{N_0}+1$, $N_{lat,1} \geq \big((2k+1)l_{N_0}+1\big)/2$ for spherical harmonic transforms. Remove the truncation error by the projection $\hat{T}^{N_1}, \hat{T}^{N_{k-1}}$; then

$$j_2 R^N(u) : \mathcal{E}^{N_0} \to \mathcal{E}^{N_1}, \quad j_k R^N(u) : \mathcal{E}^{N_{k-2}} \to \mathcal{E}^{N_{k-1}}.$$

Repeat until determinacy. Thereby one generates the sequence of approximating spaces $\mathcal{E}^{N_m}$ with $\mathcal{E}^{N_0} \subset \mathcal{E}^{N_1} \subset \cdots \subset \mathcal{E}^{N_m}$.

3. Application to a reaction-diffusion system in biology.

3.1. The model equations. We consider a coupled system of nonlinear reaction-diffusion equations. The specific model we chose was originally suggested in [39]:

$$\frac{\partial c_1}{\partial t} = D_1 \nabla^2 c_1 + 1 - c_1 c_2^\alpha, \tag{3.1}$$

$$\frac{\partial c_2}{\partial t} = D_2 \nabla^2 c_2 + \beta\big(c_1 c_2^\alpha - c_2\big). \tag{3.2}$$

It is defined on a spherical domain in $\mathbf{R}^3$ of radius R. We abbreviate it in the form

$$\frac{\partial c}{\partial t} = G(c,\beta) := \tilde{L}(\beta)c + \tilde{N}(c,\beta), \quad \frac{\partial c}{\partial r} = 0 \text{ at } r = R \text{ and bounded at } r = 0, \tag{3.3}$$

with a two-component mixture $c = \{c_1, c_2\}$. These problems arise in the context of mathematical biology, e.g., in Turing's theory of pattern formation [31]. In the specific model [39] we choose, with α and λ related as in subsection 3.3,

$$\tilde{L}(\beta) = \begin{pmatrix} D_1\nabla^2 - 1 & -\alpha \\ \beta & D_2\nabla^2 + \beta(\alpha - 1) \end{pmatrix} \quad \text{with } \tilde{L} := \tilde{L}(\beta_c),$$

$$G_0' = (\tilde{L}, 0),\ \mathcal{N}(G_0') = \mathcal{N}(\tilde{L}) \times \mathbf{R}, \tag{3.4}$$

satisfying (2.31), and the nonlinear part is $\tilde{N}(c,\beta) = (-c_1 c_2^\alpha, \beta c_1 c_2^\alpha)^T$. Following [39] we assume a fixed effective Hill constant $\alpha = 3$ and the diffusion constants as

$D_1 = 0.15$ and $D_2 = 0.015$. The distinguished bifurcation parameter β represents a rate constant measuring the level of enzyme activity. The isotropy of the model induces the $O(3)$-equivariance of the model equations. We discuss stationary solutions.

3.2. Computation of the linearized eigenvalue problem. The concentration vector yields the homogeneous solution $c_1 = c_2 = 1$ for arbitrary β, $G_0 = G(c_1 = c_2 = 1, \beta) = 0$. With $\partial_\lambda G_0 = 0$, $\mathcal{N}(G_0')$ satisfies (2.31). For an extended study, see [12]. A linear stability calculation shows that $c_1 = c_2 = 1$ is stable for small β. Instabilities or bifurcation occur whenever an eigenvalue σ of $\tilde{L}v = \sigma v$ crosses the imaginary axis. We solve the eigenvalue problem with boundary conditions from (3.3) for the $f_l(r)$ and $f_l^N(r)$ below, via

$$v = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} f_l(r) Y_{lm}(\theta, \phi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} (f_{l1}(r), f_{l2}(r))^T Y_{lm}(\theta, \phi) \in \mathcal{E}. \tag{3.5}$$

With $\nabla^2 Y_{lm} = -l(l+1) Y_{lm}$, $(Y_{km}, Y_{ln})_2 = \delta_{kl} \cdot \delta_{mn}$, the linear eigenvalue problem $\tilde{L}v = \sigma v$ can be split and reduced to the radial eigenvalue problem

$$\tilde{L} f_l Y_{lm} = Y_{lm} \tilde{L}_l f_l = Y_{lm} \sigma_l f_l, \text{ and reduced to } \tilde{L}_l f_l = \sigma_l f_l \text{ for fixed } l; \tag{3.6}$$

here σ_l is an eigenvalue of multiplicity $2l+1$ and 1 for $\tilde{L}$ and $\tilde{L}_l$, respectively, and

$$d_l^2 = \frac{d^2}{dr^2} + \frac{2d}{rdr} - \frac{l(l+1)}{r^2} \text{ replaces } \nabla^2 \text{ in (3.4) to define } \tilde{L}_l. \tag{3.7}$$

(3.6) may be solved exactly in terms of spherical Bessel functions [20], or numerically by a Chebyshev-tau or Chebyshev-collocation method with the Gauss–Radau points applied to the ansatz $f_l^N(r) = \sum_{n=0}^{N-1} \hat{f}_n \; T_n(r), \hat{f}_n \in \mathbf{R}^2$ for the $\hat{f}_n \in \mathbf{R}^2$. Mind that this transition from $f_l(r)$ to $f_l^N(r)$ causes the discretization errors discussed below. The critical or stability curves $\beta = \beta_l(R)$ in the (β, R) plane for each value of the wave number l satisfy $\Re\{\sigma_l\} = 0 = \sigma_l$, since for the parameter range of our interest the eigenvalues are always real. The minimal β_l selects the critical wave number l_0 and determines the critical rate constant $\beta_c(R) = \min_l \beta_l(R)$. The critical curves $\beta(R)$ are shown in Figure 3.1 for the $l = 1, 2$, and 3 spherical harmonics. Generically, there is a unique l for each R. However, when the critical value of β_c occurs at the intersection point of two stability curves, e.g., for $l_{0,1} = 1$ and $l_{0,2} = 2$ in $R \approx 0.83$, the dimension of the kernel is equal to $2(l_{0,1} + l_{0,2} + 1)$. Moreover, two radial eigenvectors corresponding to a single irreducible representation, l_0, may be simultaneously unstable with a resulting kernel of dimension $4l_0 + 2$. For the parameter values in Figure 3.1 that does not appear at criticality.

3.3. Application of the Liapunov–Schmidt reduction. For the Liapunov–Schmidt procedure and a given shell radius R the minimal critical curve occurs generically for a single $l = l_0$; see section 4 for $l = l_0 = 3$. Redefining $\lambda := \beta - \beta_c$, $u = (u_1, u_2)^T := c - (1,1)^T$ the critical value is transformed to $\lambda_c = \lambda = 0$ with $\Re\{\sigma_{l_0}\} = 0 = \sigma_{l_0}$. This allows the standard form for (3.3) as

$$G : \mathcal{X} = \mathcal{E} \times \mathbf{R} \to \hat{\mathcal{E}}, \; G(u, \lambda) = \tilde{L}u + R(u, \lambda), \; G_0' = (\tilde{L}, 0), \; \tilde{L} = \partial_u G(0, 0); \tag{3.8}$$

$\tilde{L}$ is a Fredholm operator of index 0, $R(\cdot, \cdot)$ is the nonlinear operator

$$R(u, \lambda) = \begin{pmatrix} -\alpha u_1 u_2 - (u_1 + 1)\mathcal{R}(u_2) \\ (\lambda + \beta_c)(\alpha u_1 u_2 + (u_1 + 1)\mathcal{R}(u_2)) + \lambda(u_1 + (\alpha - 1)u_2) \end{pmatrix}, \tag{3.9}$$

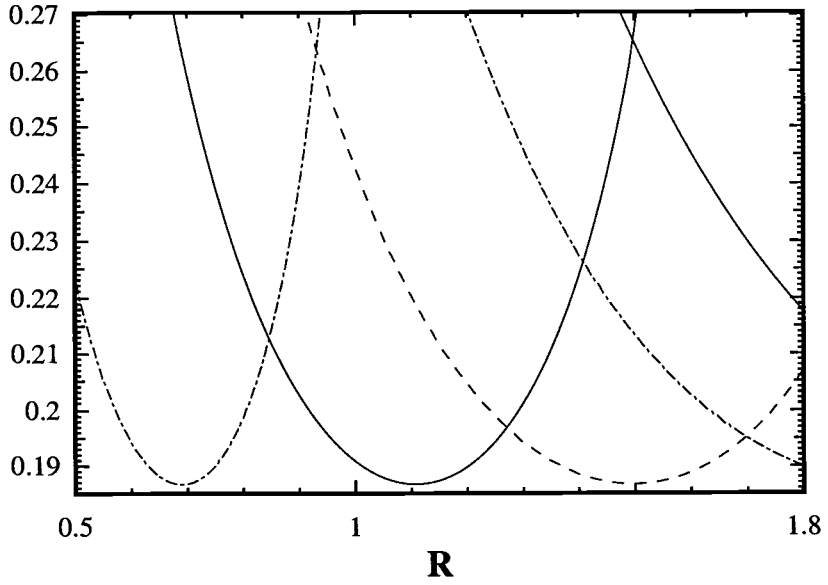

FIG. 3.1. *Linear stability diagram, β versus R, for $l = 1, 2$, and $= 3$ (dot-dashed, solid, and dashed lines, resp.). For $l = 1, 2$ two dot-dashed and solid lines are shown for different radial modes.*

and α is an integer. The Taylor expansions for $\mathcal{R}(u_2)$ and $R(u, \lambda)$ are given as

$$\mathcal{R}(u_2) \equiv \sum_{k=2}^{\alpha} \frac{\alpha!}{k!(\alpha-k)!} u_2^k, \quad R(u,\lambda) = \sum_{i=1} \sum_{j=0} R_{ij}(u)\lambda^j, \tag{3.10}$$

with $R_{ij}(u)$ an i-linear operator in u and $R_{10} = 0$; see (3.9) and (3.10). We restrict ourselves to steady state solutions of (3.8) and obtain

$$\begin{aligned} \mathcal{N} \equiv \mathcal{N}\big(\partial_u G(0,0)\big) = \mathcal{N}(\tilde{L}) = \operatorname{span}\{\psi_{l_0 -l_0}, \dots, \psi_{l_0 l_0}\} \\ = \operatorname{span}\{f^0_{l_0} Y_{l_0 -l_0}, \dots, f^0_{l_0} Y_{l_0 l_0}\}, \quad \mathcal{N}\big(G_0'\big) = \mathcal{N} \times \mathbf{R}, \quad \tilde{L}_{l_0} f^0_{l_0} = 0, \end{aligned} \tag{3.11}$$

$f^0_{l_0} = (f^0_{l_0 1}, f^0_{l_0 2})^T$, and $\dim \mathcal{N}(\tilde{L}) = \mu = 2l_0 + 1$.

Bifurcating branches may then be determined by the truncated Liapunov–Schmidt reduction. For $v \in \mathcal{N} = \mathcal{N}(\tilde{L}) = \mathcal{N}(\tilde{L}^*)$ (see (3.4)) we have

$$\begin{aligned} v = z\psi = (v_j)_{j=1}^2 = \left(\sum_{m=-l_0}^{l_0} z_m f^0_{l_0 j}(r) Y_{l_0 m}(\vartheta, \phi) \right)_{j=1}^2 \\ \in \mathcal{N} = \mathcal{N}(\tilde{L}) = \mathcal{N}(\tilde{L}^*). \end{aligned} \tag{3.12}$$

$z_m \in \mathbf{C}$, $z = (z_{-l_0}, \dots, z_{l_0})^T \in \mathbf{C}^{2l_0+1}$ satisfy the reality condition $z_{-m} = (-1)^m \bar{z}_m$.

Since $\tilde{L} = \tilde{L}^*$ is self-adjoint, the above algorithms can be simplified: We split a solution $(u, \lambda) \in \mathcal{E} \times \mathbf{R}$ of (3.8) into $u = v + w$, with $v \in \mathcal{N}(\tilde{L}) = \mathcal{N}$ and $w \in \mathcal{M} \equiv \operatorname{im}(G_0'^*) = \operatorname{im}(\tilde{L}^*) = \operatorname{im}(\tilde{L})$, i.e., $\mathcal{M}$ is the orthogonal complement of $\mathcal{N}$ in (3.11). In (2.23) we had defined the Γ-equivariant projectors $\mathcal{Q}, \hat{\mathcal{Q}}$. Using the same operator $\mathcal{P}$

in $\mathcal{E}$ and $\hat{\mathcal{E}}$, we want to slightly change the notation into

$$\mathcal{P} : \hat{\mathcal{E}} \to \mathcal{N} = \mathcal{N}(\tilde{L}) = \mathcal{N}(\tilde{L}^*) \text{ and hence } \mathcal{Q} \equiv I - \mathcal{P} = \hat{\mathcal{Q}} : \hat{\mathcal{E}} \to \mathcal{M}, \tag{3.13}$$

with complementary orthogonal projectors $\mathcal{P}, \mathcal{Q}$, and for $u \in \mathcal{E}$ or $u \in \hat{\mathcal{E}}$

$$\mathcal{P}u = \sum_{m=-l_0}^{l_0} \langle u, \psi_{l_0 m} \rangle \psi_{l_0 m}, \quad \mathcal{Q}u = (I - \mathcal{P})u = u - \mathcal{P}u, \quad \mathcal{P}(u, \lambda) = (\mathcal{P}u, \lambda). \tag{3.14}$$

The $O(3)$-symmetry of (3.8) leads to the equivariance of G w.r.t. an infinite dimensional representation T_γ, i.e., $T_\gamma G(u, \lambda) = G(T_\gamma u, \lambda)\ \forall \gamma \in O(3)$. T_γ induces the finite dimensional irreducible representation $T_{l_0,\gamma}$ on the five dimensional subspace $\mathcal{N}$ (see (3.12)) spanned by the critical spherical harmonics for l_0 via

$$T_\gamma v = T_\gamma \sum_{m=-l_0}^{l_0} z_m f_{l_0}^0 Y_{l_0 m} = T_\gamma z\psi = \sum_{m=-l_0}^{l_0} z_m f_{l_0}^0 T_\gamma Y_{l_0 m} = \sum_{m=-l_0}^{l_0} (T_{l_0,\gamma} z)_m f_{l_0}^0 Y_{l_0 m}.$$

This implies the relation $T_\gamma z\psi = (T_{l_0,\gamma} z, \psi)$ for an element $z\psi = v \in \mathcal{N}$. It also follows that $T_\gamma \mathcal{P}u = \mathcal{P}T_\gamma u$ and $T_\gamma \mathcal{Q}u = \mathcal{Q}T_\gamma u$. The bifurcation equations (2.26) are obtained by projecting (3.8) with $\mathcal{P}$ ($\mathcal{P}^*$ for the non-self-adjoint case) onto $\mathcal{N}$ to get

$$B(z, \lambda) = \mathcal{P}R(z\psi + w(z, \lambda)). \tag{3.15}$$

The successive approximations to the bifurcation equations are calculated as a Taylor series in z and in λ until determinacy. From (2.27) and (3.10) we get

$$\begin{aligned} B_k(z, \lambda) &= \mathcal{P} j_k R(z\psi + w_{k-1}(z\psi, \lambda), \lambda) \\ &= \mathcal{P} j_k \sum_{i=2} R_{i0}(z\psi + w_{k-1}(z, \lambda), \lambda) + \lambda \mathcal{P} j_{k-1} \sum_{i=1} R_{i1}(z\psi + w_{k-1}(z, \lambda), \lambda). \end{aligned} \tag{3.16}$$

Using the theory of invariants, it can be shown that the equivariance property permits the series expansion (3.16) to be decomposed at each order i in z into a finite set of m_l^i-equivariant homogeneous polynomials $Z_{lm}^{ij}(z)$ of degree i which are independent over $\mathbf{R}$ $(1 \le j \le m_l^i)$ [21, 28]. The polynomials $Z_{lm}^{ij}(z)$ have the equivariance property that $T_{l,\gamma} Z_{lm}^{ik}(z) = Z_l^{ik}(T_{l_0,\gamma} z)$ where $T_{l,\gamma}\ l \in \mathbf{N}_0$ are the irreducible representations of $O(3)$ where l is the order of the spherical harmonics Y_{lm}. This will be exemplified in section 4.1 for second order terms (cf. (4.4)). Since m_l^i is small for lower orders this results in a dramatic simplification of the Taylor series. Since in previous investigations a complete classification of all the generic singularities with $l < 5$ has been achieved [21, 24], we can directly apply these results to our examples. This is because a given singularity is independent from its physical origin, i.e., it depends only on the specific degeneracy, the symmetry group, and the representation of the symmetry group. Then a local bifurcation analysis yields three important pieces of information: the determinacy of the bifurcation problem and the corresponding normal form, the universal unfolding of the normal form, and the local solution structure of the bifurcation equations. Consequently, from the results of [21, 24] we know not only the determinacy of the problem but also which of the terms of the Taylor expansion in the bifurcation equations need to be calculated. Furthermore, once we calculate the required terms, we can apply the results of the local analysis again in order to determine the qualitative branching behavior. In cases in which a complete classification of the local branching behavior of a given singularity does not exist, the determinacy of the problem can be also determined numerically [15, 38].

4. Generic bifurcations in the $l = 3$ representation.

4.1. Calculation of the bifurcation equations. If we fix the radius of the sphere to $R = 1.55$, then in (cf. section 3.2) the minimal critical curve occurs for $l_0 = 3$ and therefore $\dim\mathcal{N} = 5$ and $z = (z_{-3}, \dots, z_3)^T$, $B_k = (B_{k,-3}, \dots, B_{k,3})^T \in \mathcal{N}$. Because generic bifurcations with $l = 3$ critical are three-determined [28] we must compute only up to third order terms.

Following section 3 we derive the bifurcation equation near critical rate constant. For odd values of l the action of the reflective component of $O(3)$ is nontrivial and the equivariants of even order vanish identically. Therefore we can immediately turn to the calculation of the third order terms. Note that this requires the computation of the function $w_2 = w_2(v, \lambda) = w_2(z\psi, \lambda)$ (cf. Algorithms 1–3 and (2.28) ff.), which we start now:

$$G_0' w_2(z\psi, \lambda) = \mathcal{Q} j_2 R(z\psi, \lambda), \quad j_2 R(z\psi, \lambda) = \lambda R_{11}(z\psi) + R_{20}(z\psi). \tag{4.1}$$

The term R_{11} will induce a term of order $\mathcal{O}(\lambda\|z\|^2)$ and $\mathcal{O}(\lambda^2\|z\|)$ in the bifurcation equations. From the classification in [21, 24] we know that these terms do not appear in the normal form and therefore do not effect the local branching behavior. Therefore we use (3.9), (3.10), (3.12) and simplify

$$j_2 R(z\psi, \lambda) = R_{20}(v = z\psi) = q \sum_{m', m''=-3}^{3} z_{m'} z_{m''} Y_{3m'} Y_{3m''}, \tag{4.2}$$

with $q = q(r) := (-1, \beta_c)^T \alpha (f_{31}^0(r) f_{32}^0(r) + \frac{\alpha-1}{2}(f_{32}^0(r))^2)$. With

$$c_{m'm''m}^{l'l''l} := \int_0^{2\pi} \int_0^{\pi} Y_{l'm'} Y_{l''m''} \bar{Y}_{lm} \, \sin\theta d\theta \, d\phi$$

we get

$$\mathcal{Q} R_{20}(z\psi) = R_{20}(z\psi) - \int_0^R q(r) f_3^0 dr \sum_{m=3}^{3} \left(\sum_{m', m''=-3}^{3} c_{m'm''m}^{333} z_{m'} z_{m''} \right) Y_{3m} = R_{20}(z\psi),$$

since the sum over the $c_{m'm''m}^{333} z_{m'} z_{m''}$ vanishes for all $m = -3, \dots, 3$. From (4.1) we get the reduced equation

$$\begin{aligned} G_0' w_2(z\psi) &= q \sum_{m'm''=-3}^{3} z_{m'} z_{m''} Y_{3m'} Y_{3m''} = q \sum_{l=0}^{\infty} \sum_{-l}^{l} Z_{lm}^{21} \\ &= q \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sum_{m'm''=-3}^{3} c_{m'm''m}^{333} z_{m'} z_{m''} Y_{lm} = q \sum_{l=0,2,4,6} \sum_{-l}^{l} Z_{lm}^{21}. \end{aligned} \tag{4.3}$$

The linearity and $O(3)$-equivariance of (4.3) w_2 admits a product-ansatz

$$w_2(r, \theta, \phi) = \sum_{l=0,2,4,6} f_l^{21}(r) \sum_{m=-l}^{l} Z_{lm}^{21} Y_{lm}(\theta, \phi) \perp \mathcal{N}. \tag{4.4}$$

With this ansatz and (4.3) we get a differential equation (see (3.6), (3.7)),

$$G_0' w_2 = \tilde{L} w_2(r, \theta, \phi) = \sum_{l=0,2,4,6} (\tilde{L}_l f_l^{21}) \sum_{m=-l}^{l} Z_{lm}^{21} Y_{lm} = q(r) \sum_{l=0,2,4,6} \sum_{m=-l}^{l} Z_{lm}^{21} Y_{lm}.$$

Hence we solve instead the better uniquely solvable equations for $l = 0, 2, 4, 6$.

$$\tilde{L}_l f_l^{21}(r) = q(r), \quad l = 0, 2, 4, 6, \text{ where } f_l^{21} = (f_{l1}^{21} f_{l2}^{21})^T, \tag{4.5}$$

for the above boundary conditions; see (3.3). The solutions f_l^{21} depend only on l, r and not on m. The solution w_2 is a second order polynomial in z. The projection of (3.8) onto $\mathcal{N}$ finally yields the bifurcation equations. They are given to order $\mathcal{O}(|z|^3)$, $\mathcal{O}(|z|\lambda)$, and $\mathcal{O}(|z|^2\lambda)$ (see (3.9), (3.10), (3.13), (3.14)) as

$$\begin{aligned}
B_3(z,\lambda) &= \lambda \mathcal{P} R_{11}(z\psi) + \mathcal{P} R_{20}(z\psi + w_2(z\psi,\lambda)) + \mathcal{P} R_{30}(z\psi),\\
B_{3,m}(z,\lambda) &= B_{2,m}(z,\lambda) + \langle R_{30}(z\psi), \psi_m\rangle\\
&= \lambda \langle R_{11}(z\psi), \psi_m\rangle + \langle R_{20}(z\psi + w_2(z\psi,\lambda)), \psi_m\rangle + \langle R_{30}(z\psi), \psi_m\rangle\\
&= \lambda b_1 z_m + b_2 \sum_{m'm''=-3}^{3} c^{333}_{m'm''m} z_{m'} z_{m''}\\
&\quad + \sum_{l'} \tilde{b}_{3l'} \sum_{m'm''=-3}^{3} c^{l'33}_{m'm''m} Z^{21}_{l'm'} z_{m''}\\
&\quad + \tilde{b}_{30} \sum_{m'm''m'''=-3}^{3} z_{m'} z_{m''} z_{m'''} \int_0^{\pi}\int_0^{2\pi} Y_{3m'} Y_{3m''} Y_{3m'''} \bar{Y}_{3m} \sin\theta d\theta\, d\phi,
\end{aligned} \tag{4.6}$$

with

$$b_2 = \int_0^R \alpha\big(f_{31}^0 f_{32}^0 + (\alpha-1)(f_{32}^0)^2/2\big)\big(\beta_c f_{32}^0 - f_{31}^0\big)\, r^2 dr\,,$$

$$\tilde{b}_{3l} = \int_0^R \frac{\alpha}{2}\big(f_{l1}^{21} f_{32}^0 + f_{l2}^{21} f_{31}^0 + (\alpha-1) f_{l2}^{21} f_{32}^0\big)\big(\beta_c f_{32}^0 - f_{31}^0\big)\, r^2 dr\,,$$

$$\tilde{b}_{30} = \int_0^R \frac{\alpha(\alpha-1)}{2}\big(f_{31}^0 (f_{32}^0)^2 + (\alpha-2)(f_{32}^0)^3/3\big)\big(\beta_c f_{32}^0 - f_{31}^0\big)\, r^2 dr.$$

For the calculation at third order there are 7^3 terms per component of z and thus 7^3 undetermined coefficients. Using invariant theory, it can be shown that all coefficients can be expressed in terms of the two third order coefficients b_{31} and b_{32}. More precisely, the three-jet of the bifurcation equations B_3 can then be decomposed into only two equivariant polynomials. These two polynomials are given by linear combinations of the third order terms in (4.6).

4.2. Approximation errors. The approximation errors for the N-term Chebyshev spectral approximant yielding the critical rate constant β_c^N and the coefficient b_1^N are shown in Table 4.1. The converged values $\beta_c^N = \beta_c^\infty, b_1 = b_1^\infty$ (with errors $\approx 10^{-12}$) occur for $N - 1 = 18$. The numerical computation of the radial function is realized through the approximant B_3^N. Here N refers to the $(N+1)$-term Chebyshev expansion in the radial direction. The dependence of the linear operator on the angular variables (θ, ϕ) is eliminated by a discretization to a collocation grid chosen to eliminate aliasing error and is therefore exact. For cubic polynomials the elimination of aliased terms requires that $N_{lon} \geq 4l_0 + 1 = 13$ and $N_{lat} \geq (4l_0 + 1)/2 = 13/2$. We therefore choose $N_{lon} = 16$ and $N_{lat} = 8$ to allow the use of the FFT. The integrals

defining the projection operator $\mathcal{P}$ are then approximated as summations over the collocation grid points. The resulting third order coefficients b_{31} and b_{32} and the approximation error for increasing numbers of terms N of the Chebyshev expansion are shown in Table 4.2. Since our computations have been designed to preserve equivariance we are thus assured by the arguments presented in section 3 that a one-to-one

correspondence exists between the discretized solutions $x^N \in \mathcal{E}^N \times \mathbf{R}$ and solutions $x \in \mathcal{E} \times \mathbf{R}$ with $\|x - x^N\| = \mathcal{O}(N^{-m+n}\|x\|_m)$.

4.3. Solution branches. Given the computation of the Taylor series coefficients the bifurcation equations are completely specified:

$$B_{3,m}(z, \lambda) = 0, \quad m = -3, \ldots, 3 \tag{4.7}$$

with $B_{3,m}$ given in (4.6). Stability and symmetry of bifurcating solution branches of (4.7) have been completely classified in [21]. Nevertheless, in order to apply the results of the Liapunov–Schmidt reduction we must present the result of [21] in an explicit form suitable to our analysis. The solutions of (4.7) can be ordered by their symmetries of the lattice of isotropy subgroup (cf. Figure 4.1). For an exact definition for the isotropy subgroups groups of Figure 4.1, c.f. [32, 28]. In [21] it is shown that in the generic case there are only solutions with symmetries of the maximal isotropy subgroups. We now restrict $B_{3,m}(z, \lambda)$ to each of the fixed point subspaces in Figure 4.1. Then a solution of the bifurcation equations can be written in the form $\lambda = -(c_{1k}b_{31} + c_{2k}b_{32})x_k^2/b_1$ with $k = 0$ for the octahedral symmetric (O^-) branch, $k = 2$ for the axisymmetric $O(2)^-$ branch, and $k = 3$ for the dihedral symmetric ($D(6)^d$) branch, respectively, and coefficients $c_{10} = 1$, $c_{20} = 9/(121\pi)$, $c_{12} = 2$, $c_{22} = 42/(121\pi)$, $c_{13} = 2$, $c_{23} = (9/242\pi)$. With the values for b_{31} and b_{32} we get three subcritical bifurcation branches. We also determine the stability of the three nontrivial branches in the full 7 dimensional $l = 3$ representation space. The result is shown in the bifurcation digram of Figure 4.2 where the sign of the eigenvalues of the Jacobian along the bifurcation branches as well as the symmetry of the branches is indicated. All the solution branches are unstable. The branches with discrete symmetry have three zero eigenvalues in the direction of the continuous group orbits. The solution with octahedral symmetry has only two distinct eigenvalues, one of which is of multiplicity three and is negative. The second eigenvalue is of multiplicity one

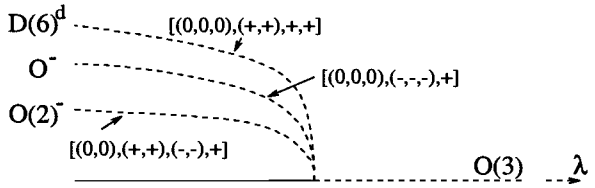

FIG. 4.2. *Bifurcation diagram for generic bifurcations in the $l = 3$ case: The sign of the eigenvalues of the Jacobian along each solution branch is given. Multiple eigenvalues are collected into parentheses.*

and is positive. This solution can be expected to stabilize in a saddle node bifurcation at finite amplitudes.

Acknowledgments. We want to thank the referees for their constructive reports, Prof. B. Schmitt for helpful discussions, and Mrs. Muth for her patient typing.

A NUMERICAL SCHEME FOR IMPACT PROBLEMS I: THE ONE-DIMENSIONAL CASE*

LAETITIA PAOLI† AND MICHELLE SCHATZMAN‡

Abstract. We consider a mechanical system with impact and one degree of freedom. The system is not necessarily Lagrangian. The representative point is subject to the constraint $u(t) \in \mathbb{R}^+$ for all t. We assume that, at impact, the velocity is reversed and multiplied by a given coefficient of restitution $e \in [0,1]$. We define a numerical scheme which enables us to approximate the solutions of the Cauchy problem: this is an ad hoc scheme which does not require a systematic search for the times of impact. We prove the convergence of this numerical scheme to a solution. Many of the features of this proof will be reused in the nonconvex, multidimensional case, written in generalized coordinates, given in the companion paper [L. Paoli and M. Schatzman, *SIAM J. Numer. Anal.*, 40 (2002), pp. 734–768]. We present some numerical results obtained with the scheme for a spring-dashpot system and we compare them to the results obtained by impact detection and penalization.

Key words. impact, coefficient of restitution, numerical scheme, convergence, local existence, global existence

1. Introduction.

We study in this article a numerical approximation of dynamics with impact with one degree of freedom when the representative point u is subject to the constraint

$$u \in K = [0, \infty).$$

Let f be a continuous function from $[0,T] \times \mathbb{R} \times \mathbb{R}$ to $\mathbb{R}$ which is locally Lipschitz continuous with respect to its last two arguments.

The free dynamics of the system are written as

$$\ddot{u} = f(\cdot, u, \dot{u}). \tag{1.1}$$

This system is more general than the system obtained in Lagrangian mechanics, since we want to include possible dissipative terms in the dynamics of the problem under discussion. There is no need for a mass matrix: in the one degree of freedom case, the velocity is always proportional to the impulsion, and an obvious change of variable enables us to forget about any other metric other than the Euclidean one.

Let us describe now the system satisfied by the problem with impact: we replace (1.1) with

$$\ddot{u} = \mu + f(\cdot, u, \dot{u}), \tag{1.2}$$

and since we cannot expect to have global solutions in general, μ is an unknown nonnegative measure on $[t_0, t_0 + \overline{\tau}]$ which describes the reaction of the constraints; μ

†UMR 5585 CNRS Analyse Numérique, Faculté des Sciences, Université Jean Monnet, 23 Rue du Docteur Paul Michelon, 42023 Saint-Etienne Cedex 2, France (paoli@anumsun1.univ-st-etienne.fr).
‡UMR 5585 CNRS Analyse Numérique, Université Lyon 1, 69622 Villeurbanne Cedex, France (schatz@maply.univ-lyon1.fr).

has the following properties:

$$\operatorname{supp}(\mu) \subset \{t \in [t_0, t_0 + \overline{\tau}] : u(t) = 0\}, \tag{1.3a}$$

$$\mu \geq 0. \tag{1.3b}$$

We require the following functional properties for u:

$$u \text{ is a continuous nonnegative function on } [t_0, t_0 + \overline{\tau}], \tag{1.4a}$$

$$\dot{u} \text{ is of bounded variation over } [t_0, t_0 + \overline{\tau}]. \tag{1.4b}$$

We have to make a supplementary assumption in order to have a complete description of the impact; we choose a constitutive law of the impact using a coefficient of restitution. Thus we will assume that there exists $e \in [0, 1]$ such that $\dot{u}(t + 0)$ is equal to $-e$ times $\dot{u}(t - 0)$. In other words, we have

$$\dot{u}(t + 0) = -e\dot{u}(t - 0). \tag{1.5}$$

The set of admissible initial data $\mathbb{D}$ will be

$$\mathbb{D} = \big\{(t_0, u_0, v_0) \in [0, T) \times K \times \mathbb{R} : \text{if } u_0 = 0, \text{ then } v_0 \geq 0\big\}.$$

This choice is equivalent to the convention that there is no impact at the initial time t_0.

Given initial conditions $(t_0, u_0, v_0) \in \mathbb{D}$, we require that the following Cauchy data be satisfied:

$$u(t_0) = u_0 \tag{1.6}$$

and

$$\dot{u}(t_0) = v_0. \tag{1.7}$$

For all initial data $(t_0, u_0, v_0) \in \mathbb{D}$ we will obtain the existence of a local solution to (1.2), (1.3a), (1.3b), and (1.5) belonging to the functional class defined by (1.4a) and (1.4b) and satisfying the initial conditions (1.6) and (1.7).

The existence of this local solution is obtained by defining a numerical scheme, whose convergence will be shown in appropriate functional spaces; the limit of the approximation will be a solution of our problem. The projection on K is given by

$$P_K(x) = \max(x, 0) = x^+. \tag{1.8}$$

Given two positive numbers $h^* \leq 1$ and T, assume that F is a continuous function from $[0, T] \times \mathbb{R} \times \mathbb{R} \times \mathbb{R} \times [0, h^*]$ to $\mathbb{R}$, which is locally Lipschitz continuous with respect to its second, third, and fourth arguments. Assume, moreover, that F is consistent with f, i.e., that for all $t \in [0, T]$, for all u and v in $\mathbb{R}$,

$$F(t, u, u, v, 0) = f(t, u, v). \tag{1.9}$$

We approximate the solution of (1.2), (1.3a), (1.3b), and (1.4a), (1.4b), (1.5), (1.6), (1.7) by the following numerical scheme: the initial values y^0 and y^1 are given by the initial position

$$y^0 = u_0, \tag{1.10}$$

and the position at the first time step

$$y^1 = u_0 + hv_0 + hz(h), \tag{1.11}$$

where $z(h)$ tends to 0 as h tends to 0.

Henceforth, we will systematically use the notation

$$t^m = t_0 + mh.$$

Given y^{m-1} and y^m, y^{m+1} is defined by the relations

$$y^{m+1} = -ey^{m-1} + \left(2y^m - (1-e)y^{m-1} + h^2F^m\right)^+ \tag{1.12}$$

and

$$F^m = F\left(t^m, y^m, y^{m-1}, \frac{y^{m+1} - y^{m-1}}{2h}, h\right). \tag{1.13}$$

The reader should be aware at this point that, given y^{m-1} and y^m, the existence of y^{m+1} is an easy consequence of the strict contraction theorem; but we might be in trouble here, since F is locally Lipschitz continuous and we are not sure about the existence of a solution on a finite time interval. This existence is not a trivial question and it depends on estimates which are at the heart of our subject.

A commentary on the construction of this scheme from the point of view of convex analysis will be useful here. We refer to the book of Rockafellar [25] for more information on the basic ideas in convex analysis to be used below.

Recall that the indicator function ψ_K of the closed convex set K is defined by

$$\psi_K(x) = \begin{cases} 0 & \text{if } x \in K, \\ +\infty & \text{otherwise,} \end{cases} \tag{1.14}$$

and its subdifferential $\partial\psi_K$ is a function from K to the set of closed convex sets given by

$$\partial\psi_K(x) = \begin{cases} \{0\} & \text{if } x \in \text{int}(K), \\ \mathbb{R}^- & \text{if } x \in \partial K. \end{cases} \tag{1.15}$$

For all $\lambda > 0$, the multivalued equation

$$x + \lambda\partial\psi_K(x) \ni f \tag{1.16}$$

has a unique solution given by

$$x = P_K f. \tag{1.17}$$

In the announcement [22], we assumed that the set of constraints K was convex and the geometry was Euclidean and d-dimensional, and we had defined a numerical scheme by the multivalued equation

$$\frac{y^{m+1} - 2y^m + y^{m-1}}{h^2} + \partial\psi_K\left(\frac{y^{m+1} + ey^{m-1}}{1+e}\right) \ni F^m. \tag{1.18}$$

We may rewrite (1.18) as

$$\begin{aligned} &\frac{y^{m+1}+ey^{m-1}}{1+e}+\frac{h^2}{1+e}\partial\psi_K\left(\frac{y^{m+1}+ey^{m-1}}{1+e}\right) \\ &\quad\ni \frac{2y^m-(1-e)y^{m-1}+h^2F^m}{1+e}, \end{aligned} \tag{1.19}$$

which reduces, thanks to (1.16), (1.17), and (1.8), to relation (1.12). In contrast with the original proof of convergence of this scheme, as written in [19], the proof presented here is written in such a way that many of its features can be reused in the nonconvex, multidimensional case, written in generalized coordinates. This more general proof will be given in the companion paper [20].

Let us outline now the structure of the article and of the proofs. The main estimates are given by Lemma 2.1 in section 2.

Then we find two constants A and τ such that for initial data given by (1.10)–(1.11), and for all small enough h and all $m \le \tau/h$, the discrete velocity is bounded:

$$\sup \left|(y^{m+1}-y^m)/h\right| \le A.$$

In sections 4, 5, 6, and 7, we prove estimates on the discrete acceleration, we establish the variational properties of the limit of the numerical scheme, and we study the transmission of energy at impact, as well as the passage to the limit for the initial conditions. All these results are obtained under the assumption that on a certain time interval starting at t_0, the discrete velocity is bounded independently of the time step.

As a preliminary to the global existence proof, we give a priori estimates on problem (1.2)–(1.7) in section 8, which is completely independent from the remainder of the article.

In section 9, we establish a very weak semicontinuity for the supremum of the local norm of the discrete velocities; this result enables us to obtain a global existence and convergence theorem.

This article contains theoretical results and reports also on some of the numerical implementations.

The existence result obtained here is a generalization of [26], [2], [24], [19], [17]. The numerical scheme has been implemented in the one-dimensional case, and the results were reported in [19], [18], [23]. In all these articles, we compared the performances of this scheme with those of a method based on the detection of impact. When the impact times are isolated, the algorithm by detection of impacts is more precise than the present scheme. As soon as the restitution coefficient is strictly less than one, we find systematically nonisolated impact times. In all cases, the present scheme is substantially faster. Since the phenomena that we want to approximate are highly nonlinear and often very sensitive to the initial data, the issue of precision is not necessarily crucial. Our numerical experiments show that the performance of the present numerical scheme is quite satisfactory from the point of view of qualitative conclusions.

The aforementioned references also concern the multidimensional case.

Let us remark that many articles have been devoted to the problem treated here under the assumption of inelasticity, i.e., a situation where the normal component of the impulsion vanishes after the impact. Moreau applied Gauss's principle of least constraint to unilateral problems in order to justify his choice of inelastic impact

[11], which eventually led him to sweeping processes [14], followed by [12], [13]. Dry friction enters in Moreau's work as [15]; frictionless inelastic impact starts as [16], and the mathematical theory is tackled by M. Monteiro Marques in a series of articles: his main contributions are [9] for the general theory of differential inclusions, [10] for one-dimensional dynamics with friction, and [5] which adds percussion to the previous framework; this work is improved as [6], where dynamics of n particles on a plane with normal friction are considered. The discretization approach has been taken up by Kunze and Monteiro Marques in [4], but most significantly by Stewart and Trinkle: they use that approach in [27], [29], and [30]. The real coronation is the beautiful and difficult article of Stewart [28], which concludes the study of dynamics with friction and inelastic impact for a finite number of degrees of freedom and one constraint; his results are not quite so precise in the case of many constraints but are still very important.

The philosophy of this long list of works is somewhat different from ours: we feel that not all impacts are inelastic, and we were originally motivated by continuous media; thus, we wanted to develop methods which work well for stiff systems of ordinary differential equations. From this point of view, any method which has to calculate with some precision the impact times is doomed to failure. On the other hand, the precision of the method presented here needs improvement, and globally it would make sense to agree on benchmarks which would enable the end-user to decide between different numerical methods.

Our approach is not the only possible one. In particular, in recent work, Mabrouk in [7] and [8] defines a numerical scheme for vibro-impact as a tool for proving existence of dynamics with impact; he allows for elastic, partially elastic, or inelastic impact. In his work, the mass matrix is assumed to be scalar, and therefore the metric is Euclidean. The idea is to discretize Moreau's formulation which describes the constraint in terms of velocity instead of describing it in terms of position, as we do here.

From a practical point of view a nice property of Mabrouk's scheme is that the velocity is reversed immediately upon impact. However, the number of steps during which the representative point of the system is outside of the set of constraints can be very large. For $e = 0$, the representative point of the system can even leave for ever the set of constraints, while remaining close to it.

Therefore, numerical simulations will probably decide which of all these numerical schemes gives the most reliable simulations of dynamics with impact. It may well be that a future scheme will conciliate the two distinct approaches and perform better than them: the road is open to researchers to try their ingenuity on these challenging problems.

2. The heart of the estimates. In the one-dimensional case, the main estimate on the numerical scheme is described in the following lemma; we recall the definition

$$r^+ = \max(r, 0).$$

LEMMA 2.1. *Let the real-valued sequence* $\left(y^m\right)_m$ *satisfy the following recurrence relation for all* $m \geq 1$*:*

$$y^{m+1} = -ey^{m-1} + \left(2y^m - (1-e)y^{m-1}\right)^+ + h^2\lambda^m. \tag{2.1}$$

Then, for all $m \geq 2$*, the discrete velocity*

$$\eta^m = \left(y^{m+1} - y^m\right)/h \tag{2.2}$$

satisfies the estimate

$$|\eta^m| \le \max\bigl(|\eta^{m-1}|, e\,|\eta^{m-2}|\bigr) + h\,|\lambda^m| + h\,|\lambda^{m-1}|. \tag{2.3}$$

Proof. Assume first that $2y^m-(1-e)y^{m-1}$ is nonnegative, and substitute $y^{m+1} = y^m + h\eta^m, y^{m-1} = y^m - h\eta^{m-1}$ into (2.1); we obtain

$$\eta^m = \eta^{m-1} + h\lambda^m$$

so that

$$|\eta^m| \le |\eta^{m-1}| + h\,|\lambda^m|. \tag{2.4}$$

Assume now that $2y^m - (1-e)y^{m-1}$ is strictly negative. On the one hand, (2.1) implies the relation

$$\eta^m = e\eta^{m-1} - \frac{1+e}{h}y^m + h\lambda^m;$$

the assumption on the sign of $2y^m - (1-e)y^{m-1}$ is equivalent to

$$\frac{(1+e)y^m}{h} < -(1-e)\eta^{m-1},$$

and therefore

$$\eta^m > \eta^{m-1} + h\lambda^m. \tag{2.5}$$

On the other hand, we subtract from the relation

$$y^{m+1} + ey^{m-1} = h^2\lambda^m$$

the inequality implied by (2.1) with m substituted by $m-1$:

$$y^m + ey^{m-2} \ge h^2\lambda^{m-1},$$

and we infer that

$$\eta^m \le -e\eta^{m-2} + h\bigl(\lambda^m - \lambda^{m-1}\bigr). \tag{2.6}$$

When we summarize (2.4), (2.5), and (2.6), we find (2.3). ∎

3. Existence of a discrete solution and estimates on the discrete velocity. We systematically use the floor and ceiling notations: when r is a real number, the floor $\lfloor r\rfloor$ of r is the largest integer at most equal to r, and the ceiling $\lceil r\rceil$ is the smallest integer at least equal to r. In this section we prove that for h and τ small enough, relations (1.12) and (1.13) uniquely define a numerical solution while $(m+1)h \le \tau$; moreover the discrete velocity of this solution is bounded independently of h.

The idea of this result is to show the existence by the Brouwer fixed point argument and the uniqueness by local considerations.

We say that a pair of numbers y^0 and y^1 satisfy the property $P(a,h)$ if the following conditions are true:

$$|y^0| \le a, \quad |y^1| \le a, \tag{3.1a}$$

$$|y^1 - y^0| \le ah, \tag{3.1b}$$

$$\begin{cases} \text{There exists } y^2 \text{ such that } |y^2 - y^1| \le ah \\ \text{and } y^2 + ey^0 - \bigl(2y^1 - (1-e)y^0 + h^2F(t^1, y^0, y^1, (y^2-y^0)/2h, h)\bigr)^+ = 0. \end{cases} \tag{3.1c}$$

THEOREM 3.1. *For all $a > 0$ and for all $A > a$, there exists $\tau > 0$ such that, for all $t_0 \in [0,T)$ and for all y^0 and y^1 satisfying property $P(a,h)$, there exists a numerical solution of the scheme* (1.12) *and* (1.13) *for $0 \le mh \le \tau$, which satisfies, moreover, the estimate*

$$\forall m \in \{0,\dots,\lfloor \tau/h \rfloor - 1\}, \quad |y^{m+1} - y^m| \le Ah. \tag{3.2}$$

Proof. Define

$$C_1 = \sup\{|F(t,u,u',0,h)| : 0 \le t \le T, \quad |u| \le a, \quad |u'| \le a, \quad 0 \le h \le h^*\}.$$

Let L be the local Lipschitz constant of F defined by

$$\begin{aligned} &\forall (t,u_i,u_i',v_i,h) \in [0,T] \times [-a-AT, a+AT]^2 \times [-A,A] \times [0,h^*], \quad i = 1,2, \\ &|F(t,u_1,u_1',v_1,h) - F(t,u_2,u_2',v_2,h)| \le L\big(|u_1-u_2| + |u_1'-u_2'| + |v_1-v_2|\big). \end{aligned}$$

Choose $\tau > 0$ such that

$$2\tau\big(C_1 + LA + 2LA\tau\big) \le A - a. \tag{3.3}$$

We will apply a Brouwer fixed point argument; we choose y^2 according to (3.1c), and we define a compact convex set B_h by

$$\begin{aligned} B_h = \big\{ \widehat{y} = \big(\widehat{y}^m\big)_{0 \le mh \le \tau} : \widehat{y}^0 = y^0, \widehat{y}^1 = y^1, \widehat{y}^2 = y^2, \\ \forall m \in \{1,\dots,\lfloor \tau/h \rfloor - 1\} : |\widehat{y}^{m+1} - \widehat{y}^m| \le Ah \big\}. \end{aligned}$$

Assuming that $\widehat{y}$ belongs to B_h, we define $\widehat{F}$ by

$$\widehat{F}^m = F(t^m, \widehat{y}^m, \widehat{y}^{m-1}, (\widehat{y}^{m+1} - \widehat{y}^{m-1})/2h, h), \quad m \in \{1,\dots,\lfloor \tau/h \rfloor - 1\}.$$

We now write the numerical scheme

$$y^{m+1} + ey^{m-1} - \big(2y^m - (1-e)y^{m-1} + h^2\widehat{F}^m\big)^+ = 0, \tag{3.4}$$

which can be put under the form (2.1), provided that we define

$$h^2\lambda^m = \big(2y^m - (1-e)y^{m-1} + h^2\widehat{F}^m\big)^+ - \big(2y^m - (1-e)y^{m-1}\big)^+. \tag{3.5}$$

It should be remarked that (3.4) possesses a unique solution, since it is explicit in y^{m+1}, and that if the mapping $\widehat{y} \mapsto y$ possesses a fixed point, this fixed point is precisely the numerical solution sought here. We estimate the discrete velocity η^m thanks to Lemma 2.1: the number λ^m is estimated by

$$\begin{aligned} &|\lambda^m| \le |\widehat{F}^m| \\ &\le |F(t^m, y^0, y^0, 0, h)| + L\big(|\widehat{y}^m - y^0| + |\widehat{y}^{m-1} - y^0| + |\widehat{\eta}^m|/2 + |\widehat{\eta}^{m-1}|/2\big), \end{aligned}$$

and the assumption $\widehat{y} \in B_h$ guarantees that

$$|\lambda^m| \le C_1 + 2LA\tau + LA. \tag{3.6}$$

Estimate (2.3) implies

$$|\eta^m| \le \max\big(|\eta^0|, |\eta^1|\big) + 2\big(C_1 + 2LA\tau + LA\big)mh$$

by discrete integration. We may conclude now that for $(m+1)h \le \tau$,

$$|\eta^m| \le a + 2\big(C_1 + 2LA\tau + LA\big)\tau,$$

and thanks to assumption (3.3), y also belongs to B_h. This mapping is clearly continuous, which implies the existence of a fixed point thanks to Brouwer's fixed point theorem. □

There remains two easy lemmas; the first one settles for h small the question of the uniqueness of the numerical solution.

LEMMA 3.2. *Under the hypotheses of Theorem* 3.1*, there exists* $h_1 > 0$ *such that for all* $h \in (0, h_1]$*, for all* y^0 *and* y^1 *satisfying condition* $P(a,h)$*, the numerical solution of* (1.12) *and* (1.13) *satisfying estimate* (3.2) *is unique.*

Proof. Given y^{m-1} and y^m, the discrete velocity η^m is a fixed point of the mapping

$$\begin{aligned}\eta \mapsto h^{-1}\Big(&-ey^{m-1} - y^m \\ &+ \big(2y^m - (1-e)y^{m-1} + h^2F(t^m, y^m, y^{m-1}, (\eta+\eta^{m-1})/2, h)\big)^+\Big).\end{aligned} \tag{3.7}$$

Let L be the Lipschitz constant of the mapping

$$z \mapsto F(t, y, y', z, h)$$

for $t \in [0,T]$, y and y' in $[-a-TA, a+TA]$, $|z| \le A$, and $0 \le h \le h^*$. Then the Lipschitz constant of the mapping (3.7) is $hL/2$, and therefore, if $h_1 < 2/M$, the uniqueness of η^m is guaranteed and the lemma is proved. □

The second lemma establishes that under conditions (1.10) and (1.11), property $P(a,h)$ holds.

LEMMA 3.3. *Assume that* $y^0 = u_0$ *and* $y^1 = u_0 + hv_0 + ho(h)$ *as in* (1.11)*; then there exists* $h_1 > 0$ *such that for all* $h \in (0, h_1]$*, there exists a unique* y^2 *such that*

$$y^2 + ey^0 - \big(2y^1 - (1-e)y^0 + h^2F(t^1, y^0, y^1, (y^2 - y^0)/2h, h)\big)^+ = 0$$

and

$$\max(|y^1 - y^0|, |y^2 - y^1|) \le (3|v_0| + 1)h.$$

Proof. Define a mapping

$$z \mapsto h^{-1}\Big(\big((1+e)y^0 + 2\eta^0 h + h^2F(t^1, y^0, y^1, z/2, h)\big)^+ - (1+e)y^0\Big), \tag{3.8}$$

which is slightly different from the mapping (3.7), since its fixed point will be $(y^2 - y^0)/h$. Standard arguments show that it is possible to find $h_1 > 0$ such that for all $h \in (0, h_1]$ and all y^1 in $[y^0 - 1, y^0 + 1]$, the mapping (3.8) is a strict contraction from the ball of radius $2|v_0| + 1/2$ to itself. We set $y^2 = y^0 + hz$, where z is the fixed point of the above mapping. Then it is clear that for h small enough,

$$|\eta^2| = |(y^2 - y^1)/h| \le |z| + |\eta^0|,$$

and the lemma is proved. □

As a consequence of Theorem 3.1 and Lemma 3.2, we have the following result.

PROPOSITION 3.4. *For all* $(t_0, u_0, v_0) \in \mathbb{D}$*, there exists* $A > 0$*,* $\tau \in (0, T - t_0]$*, and* $h_1 \in (0, h^*]$ *such that for all* $m \in \{0, \dots, \lfloor \tau/h \rfloor\}$*,* y^m *is uniquely defined by* (1.10)*,* (1.11)*, and the recursive formulas* (1.12)*,* (1.13) *and satisfies the estimate*

$$\forall m \in \big\{0, \dots, \lfloor \tau/h \rfloor - 1\big\}, \quad |y^{m+1} - y^m| \le Ah.$$

Proof. The main observation is that we have to choose A as a function of the initial data. Thanks to Lemma 3.3, it suffices to take

$$A \ge \max\big(3|v_0| + 1, |u_0| + 1\big);$$

the remainder of the argument is clear. ∎

4. Estimates on the discrete acceleration. In this section and the three following ones, we assume that there exist strictly positive numbers τ, A, and h_1 and a subsequence of time steps to which correspond solutions of the numerical scheme defined by (1.10), (1.11), (1.12), and (1.13), which satisfy the estimate, for all $h \le h_1$,

$$\forall l \in \{0, \dots, P - 1\}, \quad \big|y^{l+1} - y^l\big| \le Ah, \tag{4.1}$$

where

$$P = \lfloor \tau/h \rfloor.$$

Here we estimate the discrete total variation of the sequence $\big(\eta^m\big)_m$.

THEOREM 4.1. *Under assumption* (4.1)*, there exists a constant* C_2 *such that for all* $h \le h_1$

$$\sum_{m=1}^{P-1} \big|\eta^m - \eta^{m-1}\big| \le C_2. \tag{4.2}$$

Proof. The constant C_3 is taken as a majorant of $|F^m|$; we can take it as equal to

$$\begin{aligned} C_3 = \max\big\{|F(t, y, y', z, h)| : t \in [0, T], |y - u_0| \le AT, \\ |y' - u_0| \le AT, |z| \le A, 0 \le h \le h^*\big\}. \end{aligned} \tag{4.3}$$

We put the numerical scheme under the form (2.1) by defining λ^m through

$$h^2\lambda^m = \big(2y^m - (1 - e)y^{m-1} + h^2F^m\big)^+ - \big(2y^m - (1 - e)y^{m-1}\big)^+, \tag{4.4}$$

which differs slightly from (3.5), since it involves F^m instead of $\widehat{F}^m$. The number λ^m is estimated by

$$|\lambda^m| \le |F^m| \le C_3.$$

We observe that

$$\eta^m - \eta^{m-1} = h\lambda^m + (2y^m - (1 - e)y^{m-1})^-/h. \tag{4.5}$$

Therefore, by the triangle inequality,

$$|\eta^m - \eta^{m-1}| \le hC_3 + (2y^m - (1 - e)y^{m-1})^-/h.$$

Using (4.5) again, we obtain

$$|\eta^m - \eta^{m-1}| \le 2hC_3 + \eta^m - \eta^{m-1}. \tag{4.6}$$

We observe that we have the elements of a telescoping sum: we sum (4.6) for m varying from 1 to $P-1$ and we get

$$\sum_{m=1}^{P-1} |\eta^m - \eta^{m-1}| \le 2hC_3P + \eta^{P-1} - \eta^0 \le 2C_3\tau + 2A. \qquad \square$$

5. Variational properties of the limit of the numerical scheme. In this section, we work under the assumption (4.1). We define a function u_h by affine interpolation, as follows:

$$\begin{cases} u_h(t) = y^m + (t - t_0 - mh)\dfrac{y^{m+1} - y^m}{h} \\ \qquad\qquad \text{for } t - t_0 \in [mh, (m+1)h), \ 0 \le m \le P-1, \\ u_h(t) = y^P \quad \text{for } t - t_0 \in [Ph, \tau]. \end{cases} \tag{5.1}$$

We also define a measure F_h as the following sum of Dirac masses:

$$F_h(t) = \sum_{m=1}^{P-1} hF^m \delta(t - t_0 - mh). \tag{5.2}$$

In this section we prove that the sequence $(u_h)_h$ converges in an appropriate sense to a function u which satisfies (1.2) to (1.4b) with τ instead of $\overline{\tau}$. We delay the proof of (1.5), the transmission condition at impacts, to a later section.

There are three steps in the convergence proof: the first is to prove that the limit u exists in an appropriate sense and takes its values in K; in the second step, we show that $\dot{u}_h$ is of bounded variation uniformly in h and that F_h converges to $f(\cdot, u, \dot{u})$ weakly in the space of $\mathbb{R}$-valued measures. The last step is the characterization of the measure $\mu = \ddot{u} - f(\cdot, u, \dot{u})$: there we show that μ satisfies conditions (1.3a) and (1.3b).

LEMMA 5.1. *From all sequence of functions $(u_h)_h$ indexed by a sequence h tending to 0, it is possible to extract a subsequence, still denoted by $(u_h)_h$, such that*

$$u_h \to u \quad \textit{in } C^0([t_0, t_0+\tau]) \textit{ strong}, \tag{5.3}$$

$$\dot{u}_h \to \dot{u} \quad \textit{in } L^\infty([t_0, t_0+\tau]) \textit{ weak } *. \tag{5.4}$$

The function u takes its values in K.

Proof. Thanks to assumption (4.1), we know that $(u_h)_{0<h\le h_1}$ is uniformly Lipschitz continuous over $[t_0, t_0+\tau]$. Therefore, we may extract a subsequence, still denoted by u_h, such that (5.3) and (5.4) hold. Thus u belongs to $W^{1,\infty}([t_0, t_0+\tau]) \cap C^0([t_0, t_0+\tau])$, which means that u is a Lipschitz continuous function [1]. For all m belonging to $\{1, \dots, P-1\}$, we have that

$$\frac{y^{m+1} + ey^{m-1}}{1+e} = y^m + h\frac{\eta^m - e\eta^{m-1}}{1+e} \ge 0. \tag{5.5}$$

It follows that, for all $m \in \{1, \dots, P-1\}$, the Euclidean distance between y^m and K can be estimated as follows:

$$(y^m)^- \le h\left|\eta^m - e\eta^{m-1}\right| / (1+e) \le hA. \tag{5.6}$$

Thanks to the definition (5.1), we can see that for all $t \in [t_0, t_0+\tau]$ the Euclidean distance between $u_h(t)$ and K is estimated by $2hA$. This allows us to pass to the limit when h tends to 0 and to conclude. □

The next lemma describes the convergence of the measures involved in our problem; we denote by $M^1\big((t_0,t_0+\tau)\big)$ the space of bounded measures over $(t_0,t_0+\tau)$.

LEMMA 5.2. *The measures $\ddot{u}_h$ and F_h converge weakly $*$ in $M^1\big((t_0,t_0+\tau)\big)$ to $\ddot{u}$ and $f(\cdot,u,\dot{u})$, respectively.*

Proof. The measure $\ddot{u}_h$ is a sum of Dirac measures on $(t_0,t_0+\tau)$; more precisely, we have

$$\ddot{u}_h(t) = \sum_{m=1}^{P-1} (\eta^m - \eta^{m-1})\delta(t-t_0-mh) - \eta^{P-1}\delta(t-t_0-Ph),$$

and the total variation of $\dot{u}_h$ on $(t_0,t_0+\tau)$ is estimated by

$$TV(\dot{u}_h) \le \sum_{m=1}^{P-1} \left|\eta^m - \eta^{m-1}\right| + \left|\eta^{P-1}\right|.$$

Theorem 4.1 implies that $(\dot{u}_h)_{0<h\le h_1}$ is a bounded family in $BV\big((t_0,t_0+\tau)\big)$, the space of functions of bounded variation over $(t_0,t_0+\tau)$. Using Helly's theorem, we can extract another subsequence $\big(\dot{u}_h\big)_h$ which converges, except perhaps on a countable set of points, to a function of bounded variation. Hence

$$\dot{u} \in BV\big((t_0,t_0+\tau)\big).$$

Moreover,

$$\ddot{u}_h \to \ddot{u} \quad \text{ weakly } * \text{ in } M^1\big((t_0,t_0+\tau)\big).$$

Lebesgue's theorem implies that $\dot{u}_h$ converges to $\dot{u}$ in $L^1\big(t_0,t_0+\tau\big)$. We extend $\dot{u}_h$ and $\dot{u}$ to $\mathbb{R}$ by 0 outside of $(t_0,t_0+\tau)$ and still denote the respective extensions by $\dot{u}_h$ and $\dot{u}$. The set $\{\dot{u}_h : h \in (0,h_1]\} \cup \{\dot{u}\}$ is a compact subset of $L^1(\mathbb{R})$. The classical characterization of compact subsets of $L^1(\mathbb{R})$ [3] implies that

$$\lim_{\theta\to 0} \sup_{0<h\le h_1} \int_{\mathbb{R}} |\dot{u}_h(t-\theta) - \dot{u}_h(t)|\, dt = 0.$$

Letting $\theta = h$, we can see that $\dot{u}_h(\cdot - h)$ converges to $\dot{u}$ in $L^1\big(\mathbb{R}\big)$. Let us define an approximate velocity v_h on $\mathbb{R}$ by

$$v_h(t) = \frac{\dot{u}_h(t-h+0) + \dot{u}_h(t+0)}{2}.$$

The sequence v_h converges to $\dot{u}$ in $L^1\big(\mathbb{R}\big)$. Moreover, for all $t \in [t^m, t^{m+1})$ and for all $m \in \{1,\dots,P-1\}$, we have the identity

$$v_h(t) = \frac{\eta^m + \eta^{m-1}}{2}.$$

We immediately have the following estimates for all $t \in (t_0,t_0+\tau)$ and all $h \in (0,h_1]$:

$$|v_h(t)| \le A, \quad |u_h(t) - u_0| \le A(t-t_0) \le A\tau. \tag{5.7}$$

Let ψ be a continuous function over $[0,T]$ with compact support included in $(t_0, t_0+\tau)$. For all small enough h, the support of ψ is included in $[t_0+h, t_0+(P-1)h]$. The duality product $\langle F_h, \psi\rangle$ has the expression

$$\langle F_h, \psi\rangle = \sum_{m=1}^{P-1} h\psi(t_0+mh)F^m. \tag{5.8}$$

We wish to compare the expression (5.8) to

$$\int_{t_0}^{t_0+\tau} \psi f(\cdot, u, \dot{u})\, dt. \tag{5.9}$$

We compare the right-hand side of (5.8) which is basically a numerical quadrature by the formula of rectangles to an appropriate integral. Let us rewrite the individual terms of the right-hand side of (5.8) as

$$h\psi(t^m)F^m = \int_{t^m}^{t^{m+1}} \psi(t)F^m\, dt + \int_{t^m}^{t^{m+1}} \big(\psi(t^m)-\psi(t)\big)F^m\, dt. \tag{5.10}$$

Consider now the second term on the right-hand side of (5.10). Recalling estimate (4.3),

$$\max_{0\le m\le n} |F^m| \le C_3, \tag{5.11}$$

and denoting by ω_ψ the modulus of continuity of ψ we can see that

$$\left| \int_{t^m}^{t^{m+1}} \big(\psi(t^m)-\psi(t)\big)F^m\, dt \right| \le C_3\omega_\psi(h)h. \tag{5.12}$$

We consider now the first term on the right-hand side of (5.10), which we would like to compare to expression (5.9). Thanks to the consistency assumption (1.9) we have the following inequalities, for all $t\in[t^m, t^{m+1})$ and all $m\in\{1,\dots,P-1\}$:

$$\begin{aligned}
&\big|F^m - f\big(t, u_h(t), v_h(t)\big)\big| \\
&\quad\le \big|F\big(t^m, y^m, y^{m-1}, v_h(t^m), h\big) - F\big(t^m, u_h(t), u_h(t), v_h(t^m), h\big)\big| \\
&\quad+ \big|F\big(t^m, u_h(t), u_h(t), v_h(t^m), h\big) - F\big(t^m, u_h(t), u_h(t), v_h(t), 0\big)\big| \\
&\quad+ \big|f\big(t^m, u_h(t), v_h(t)\big) - f\big(t, u_h(t), v_h(t)\big)\big|.
\end{aligned}$$

Denote by $\mathcal{D}$ the set

$$\begin{aligned}
\mathcal{D} = \big\{(t,u_1,u_2,v,h) : 0\le t\le T,\quad &|u_1-u_0|\le AT, \\
&|u_2-u_0|\le AT,\quad |v|\le A,\quad 0\le h\le h^*\big\}.
\end{aligned}$$

Let L be the Lipschitz constant of $(u_1,u_2)\mapsto F(t,u_1,u_2,v,h)$ restricted to $\mathcal{D}$ and let ω_F be the modulus of continuity of F on $\mathcal{D}$. With these notations, we can see that

$$\begin{aligned}
&\big|F^m - f\big(t, u_h(t), v_h(t)\big)\big| \\
&\quad\le L\big(|y^m-u_h(t)| + \big|y^{m-1}-u_h(t)\big|\big) + 2\omega_F(h).
\end{aligned} \tag{5.13}$$

Since $(u_h)_h$ converges strongly in $C^0([t_0, t_0+\tau])$ and $(v_h)_h$ converges strongly to $\dot{u}$ in $L^1(\mathbb{R})$ and almost everywhere on $(t_0, t_0+\tau)$, we see that $f(\cdot, u_h, v_h)$ tends to $f(\cdot, u, \dot{u})$ strongly in $L^1(t_0, t_0+\tau)$ and almost everywhere on $(t_0, t_0+\tau)$. We summarize relations (5.12) and (5.13) together with the above convergence result, and we find that

$$\begin{aligned}
&\left| \langle F_h, \psi \rangle - \int_{t_0}^{t_0+\tau} \psi f(\cdot, u, \dot{u})\, dt \right| \\
&\leq \int_{t_0}^{t_0+\tau} \left| f\big(\cdot, u_h, v_h\big) - f\big(\cdot, u, \dot{u}\big) \right| |\psi|\ dt \\
&\quad + C_3 \omega_\psi(h)\tau + (3LAh + 2\omega_F(h)) \int_{t_0}^{t_0+\tau} |\psi|\ dt,
\end{aligned}$$

which concludes the proof. □

Let us prove now that the measure μ has the required variational properties.

LEMMA 5.3. *The measure μ satisfies properties* (1.3a) *and* (1.3b).

Proof. Define

$$\mu_h = \ddot{u}_h - F_h;$$

μ_h is a sum of Dirac measures on $(t_0, t_0+\tau)$. More precisely

$$\begin{aligned}
\mu_h = &\sum_{m=1}^{P-1} \big(\eta^m - \eta^{m-1} - hF^m\big)\delta(t - t_0 - mh) \\
&- \eta^{P-1}\delta(t - t_0 - Ph).
\end{aligned}$$

With all the previous results, we know that μ_h converges to $\mu = \ddot{u} - f(\cdot, u, p)$ weakly * in $M^1\big((t_0, t_0+\tau)\big)$. Let us prove property (1.3a). Assume that τ_0 is a point of $(t_0, t_0+\tau)$ such that $u(\tau_0) > 0$. Then, by continuity of u, there exist $\varepsilon > 0$ and $\rho > 0$ such that

$$\forall t \in (\tau_0 - \varepsilon, \tau_0 + \varepsilon), \quad u(t) \geq 3\rho.$$

Since the sequence $(u_h)_h$ converges uniformly to u as h tends to 0, we can decrease h_1 so that

$$\forall h \in (0, h_1], \quad \forall t \in (\tau_0 - \varepsilon, \tau_0 + \varepsilon), \quad u_h(t) \geq 2\rho.$$

Replacing y^{m-1} by $y^m - h\eta^{m-1}$, we have

$$2y^m - (1-e)y^{m-1} + h^2F^m = (1+e)y^m + (1-e)h\eta^{m-1} + h^2F^m,$$

and relations (4.3) and (4.1) imply that

$$2y^m - (1-e)y^{m-1} + h^2F^m \geq (1+e)y^m - (1-e)hA - h^2C_3.$$

Possibly decreasing h_1, we have

$$\forall h \in (0, h_1], \quad \forall t^m \in (\tau_0 - \varepsilon, \tau_0 + \varepsilon), \quad 2y^m - (1-e)y^{m-1} + h^2F^m \geq \rho,$$

and thus

$$\forall h \in (0, h_1], \quad \forall t^m \in (\tau_0 - \varepsilon, \tau_0 + \varepsilon), \quad \eta^m - \eta^{m-1} - hF^m = 0.$$

This proves that, for h small enough, the support of μ_h does not intersect the open set $(\tau_0 - \varepsilon, \tau_0 + \varepsilon)$ and therefore relation (1.3a). In order to conclude the proof, we observe that

$$\eta^m - \eta^{m-1} - hF^m = \frac{1}{h}(2y^m - (1-e)y^{m-1} + h^2F^m)^- \geq 0.$$

Thus, for all $\tau' \in (0, \tau)$, the measure μ_h is nonnegative on $(t_0, t_0 + \tau')$ for h small enough, which implies by a straightforward passage to the limit that μ is nonnegative. This concludes the proof of the lemma. □

6. Transmission of energy during impact. The basic assumption is still the one made at the beginning of section 4.

Let $\overline{\tau} \in (0, \tau)$ be such that $u(t_0 + \overline{\tau})$ vanishes. Write $\overline{t} = t_0 + \overline{\tau}$.

We will prove the relation

$$\dot{u}(\overline{t} + 0) = -e\dot{u}(\overline{t} - 0)$$

by performing a precise analysis of the transmission of the energy by the scheme.

Possibly decreasing h_1, there exists a nonempty interval $[\tau_{-5}, \tau_2]$ containing $\overline{\tau}$ and included in $[h, (P-1)h]$. The apparently strange notations τ_{-5} and τ_2 have been chosen in view of the upcoming construction of Lemmas 6.1 and 6.2, where we will consider relative times

$$\tau_{-5} < \cdots < \tau_{-1} < \overline{\tau} < \tau_1 < \tau_2.$$

Define

$$P = \lceil \tau_{-5}/h \rceil + 1 \text{ and } Q = \lfloor \tau_2/h \rfloor - 1.$$

The measure $\ddot{u}_h$ is a sum of Dirac measures on $(t_0 + \tau_{-5}, t_0 + \tau_2)$. We define two measures ω_h and λ_h on $(t_0 + \tau_{-5}, t_0 + \tau_2)$ by

$$\omega_h(t) = \sum_{m=P}^{Q} \frac{\big(-2y^m + (1-e)y^{m-1}\big)^+}{h} \delta(t - t_0 - mh)$$

and

$$\lambda_h(t) = \sum_{m=P}^{Q} h\lambda^m \delta(t - t_0 - mh).$$

We have

$$\ddot{u}_h = \omega_h + \lambda_h,$$

and it is obvious that ω_h is a nonnegative measure.

Since the real numbers λ^m are bounded independently of h and m, the measure by $|\lambda_h|$ of any subinterval $[a, b]$ of $(t_0 + \tau_{-5}, t_0 + \tau_2)$ is bounded by $C_3(b - a + h)$, and it is clear therefore that there exists a function $\lambda \in L^\infty(t_0 + \tau_{-5}, t_0 + \tau_2)$ and a subsequence λ_h converging to λ in the weak * topology of $M^1\big((t_0 + \tau_{-5}, t_0 + \tau_2)\big)$.

The measure ω_h converges in the weak * topology of $M^1\big((t_0 + \tau_{-5}, t_0 + \tau_2)\big)$ to a nonnegative measure ω and in the limit

$$\ddot{u} = \omega + \lambda, \tag{6.1}$$

while

$$|\lambda|_{L^\infty} \leq C_3. \tag{6.2}$$

Since u is nonnegative on $(t_0+\tau_{-5}, t_0+\tau_2)$ and $u(\bar t)$ vanishes, we must have

$$\dot u(\bar t+0) \geq 0, \quad \dot u(\bar t-0) \leq 0.$$

On the other hand, $\dot u(\bar t+0) - \dot u(\bar t-0)$ is equal to $\omega(\{\bar t\})$; if $\omega(\{\bar t\})$ vanishes, we have

$$\dot u(\bar t+0) = \dot u(\bar t-0) = 0,$$

and the identity

$$\dot u(\bar t+0) = -e\dot u(\bar t-0)$$

holds. Therefore, the only interesting case is when

$$\omega(\{\bar t\}) > 0. \tag{6.3}$$

The following two lemmas enable us to prove in two steps that the velocity is reversed according to the law described by (1.5). Lemma 6.1 shows that if ω has a Dirac mass at $\bar t$, then the left velocity at $\bar t$ is outgoing; Lemma 6.2 indeed shows that (1.5) holds.

LEMMA 6.1. *If $\omega(\{\bar t\})$ is strictly positive, then $\dot u(\bar t-0)$ is strictly negative.*

Proof. The idea of the proof is to find two successive times $t^{m-1} \leq t^m < \bar t$ for which we can write down an estimate on the discrete velocities and then to use Lemma 2.1 to perform a discrete integration and to obtain a contradiction. We must deal with the fact that $\dot u_h$ does not converge uniformly to $\dot u$.

Without loss of generality, we may assume that $\dot u$ is continuous on the right and that for all $h \leq h_1$, $\dot u_h$ is also continuous from the right. According to Helly's theorem, there exists a countable set D such that

$$\dot u_h(t) \to \dot u(t) \quad \forall t \text{ such that } t-\bar t \in (\tau_{-5}, \tau_2) \setminus D.$$

Assume that $\dot u(\bar t-0)$ vanishes; therefore, $\dot u(\bar t+0)$ is strictly positive. Choose $\alpha = \dot u(\bar t+0)/4$, and let τ_{-4} and τ_1 be such that

$$\begin{aligned} &\tau_{-5} \leq \tau_{-4} < \overline{\tau} < \tau_1 \leq \tau_2, \\ &6C_3\big(\tau_1 - \tau_{-4}\big) \leq \alpha, \end{aligned} \tag{6.4}$$

and

$$\omega\big([t_0+\tau_{-4}, \bar t)\big) \leq \alpha, \quad \omega\big((\bar t, t_0+\tau_1]\big) \leq \alpha. \tag{6.5}$$

An integration of (6.1) on appropriate intervals yields

$$\forall t \in (t_0+\tau_{-4}, \bar t), \quad |\dot u(t \pm 0)| \leq \alpha + C_3(\bar t - t), \tag{6.6}$$

$$\forall t \in (\bar t, t_0+\tau_1), \quad \dot u(t \pm 0) \geq 2\omega\big(\{\bar t\}\big) - \alpha - C_3(t-\bar t). \tag{6.7}$$

Choose $\tau_{-3} \in (\tau_{-4}, \overline{\tau}) \setminus D$ and $\tau_{-1} \in (\tau_{-3}, \overline{\tau}) \setminus D$; since ω_h is a nonnegative measure, we have the following inequality for all $\tau' \in (\tau_{-3}, \tau_{-1})$ and all $\tau'' \in (\tau', \tau_{-1})$:

$$\begin{aligned} |\dot u_h(t_0+\tau') - \dot u_h(t_0+\tau'')| &\leq \omega_h((t_0+\tau', t_0+\tau'']) + C_3(\tau''-\tau'+h) \\ &\leq \omega_h([t_0+\tau_{-3}, t_0+\tau_{-1}]) + C_3(\tau''-\tau'+h). \end{aligned}$$

We integrate $\omega_h - \omega$ on the interval $\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]$; since the measures ω and ω_h do not charge $t_0+\tau_{-3}$ and $t_0+\tau_{-1}$, we find that

$$\begin{aligned}&\omega_h\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big) - \omega\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big)\\ &\quad = \dot u_h\big(t_0+\tau_{-1}\big) - \dot u_h\big(t_0+\tau_{-3}\big) - \dot u\big(t_0+\tau_{-1}\big) + \dot u\big(t_0+\tau_{-3}\big)\\ &\quad + \lambda\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big) - \lambda_h\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big),\end{aligned}$$

and therefore

$$\begin{aligned}&\omega_h\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big)\\ &\quad \le \omega\big(\big[t_0+\tau_{-3}, t_0+\tau_{-1}\big]\big) + |\dot u_h(t_0+\tau_{-1}) - \dot u(t_0+\tau_{-1})|\\ &\quad + |\dot u_h(t_0+\tau_{-3}) - \dot u(t_0+\tau_{-3})| + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big)+h\big).\end{aligned}$$

Choose now $\tau_{-2} \in \big(\tau_{-3}, \tau_{-1}\big) \setminus D$; then, for h small enough, $t^m = h\lfloor \tau_2/h\rfloor$ and $t^{m-1} = t^m - h$ belong to the interval (τ_{-3}, τ_{-1}), and therefore

$$\big|\dot u_h(t^m) - \dot u_h(t^{m-1})\big| \le \alpha + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big)+3h\big) + \varepsilon_h, \tag{6.8}$$

where ε_h tends to 0 as h tends to 0. On the other hand, $\dot u_h(t_0+\tau_{-2})$ tends to $\dot u(t_0+\tau_{-2})$ and therefore, thanks to relation (6.6), there exists a family ε'_h such that

$$|\dot u_h(t_0+\tau_{-2})| = |\dot u_h(t^m)| \le \alpha + C_3\big(\overline\tau - \tau_{-2}\big) + \varepsilon'_h,$$

which is equivalent to

$$|\eta^m| \le \alpha + C_3\big(\overline\tau - \tau_{-2}\big) + \varepsilon'_h; \tag{6.9}$$

we infer from (6.8) and (6.9) that

$$\big|\eta^{m-1}\big| \le 2\alpha + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big) + \overline\tau - \tau_{-2} + 3h\big) + \varepsilon_h + \varepsilon'_h.$$

Thus, for all $n \ge m$ we infer from Lemma 2.1 that

$$\begin{aligned}|\eta^n| \le{}& 2\alpha + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big) + 3h\\ &+ \overline\tau - \tau_{-2} + 2\big(t^n - t^m\big)\big) + \varepsilon_h + \varepsilon'_h.\end{aligned}$$

Therefore, in the limit, for all $t \ge t_0 + \tau_{-2}$

$$|\dot u(t)| \le 2\alpha + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big) + \overline\tau - \tau_{-2} + 2\big(t - t_0 - \tau_{-2}\big)\big),$$

and for all $t \in [t_0+\tau_{-2}, t_0+\tau_1]$

$$|\dot u(t)| \le 2\alpha + C_3\big(2\big(\tau_{-1}-\tau_{-3}\big) + \overline\tau - \tau_{-2} + 2\big(\tau_1 - \tau_{-2}\big)\big). \tag{6.10}$$

On the other hand, relation (6.7) implies that for all $t \in (\overline t, t_0+\tau_1)$,

$$|\dot u(t)| \ge 3\alpha - C_3\big(\tau_1 - \overline\tau\big). \tag{6.11}$$

Under assumption (6.4), relation (6.11) contradicts relation (6.10). □

We can conclude now the local study of the reflection of the velocity by the following lemma.

LEMMA 6.2. *If* $\omega\big(\{\overline{t}\}\big)$ *is strictly positive, then*

$$\dot{u}(\overline{t}) = -e\dot{u}(\overline{t}-0). \tag{6.12}$$

Proof. Since $\dot{u}(\overline{t}-0)$ is strictly negative, there exists a real number τ_{-3} such that $u(t)$ is strictly positive on $[t_0+\tau_{-3},\overline{t}) \subset [t_0+\tau_{-5},\overline{t})$. For all $\tau_{-2} \in (\tau_{-3},\overline{\tau})$, there exists $\tau_{-1} \in (\tau_{-2},\overline{\tau})$ and $h_1 > 0$ such that

$$\forall h \in (0,h_1], \quad \forall t \in [t_0+\tau_{-2}, t_0+\tau_{-1}), \quad u_h(t) \geq \frac{u(t_0+\tau_{-2})}{2}. \tag{6.13}$$

We prove now that there exists a maximal integer

$$m \in \{\lfloor \tau_{-3}/h \rfloor, \dots, \lfloor (\tau_2)/h \rfloor\}$$

such that

$$\forall l \in \big\{\lfloor \tau_{-3}/h \rfloor, \dots, m-1\big\}, \quad 2y^l - (1-e)y^{l-1} \geq 0, \tag{6.14}$$

and denoting

$$\rho_h = t^{m-1} - t_0, \tag{6.15}$$

the time ρ_h satisfies

$$\lim_{h\to 0} \rho_h = \overline{\tau}. \tag{6.16}$$

Let us first observe that for all small enough h and all t_l belonging to $[t_0+\tau_{-2}, t_0+\tau_{-1})$ we have

$$2y^l - (1-e)y^{l-1} \geq 0. \tag{6.17}$$

Indeed,

$$\begin{aligned} 2y^l - (1-e)y^{l-1} &= (1+e)y^l + (1-e)h\eta^{l-1} \\ &\geq \frac{1+e}{2}u(t_0+\tau_{-2}) - h(1-e)A, \end{aligned}$$

and if $2A(1-e)h \leq (1+e)u(t_0+\tau_{-2})$, we can see that (6.17) holds. Therefore m exists and

$$\liminf \rho_h \geq \overline{\tau}.$$

On the other hand, if there existed $\tau_1 > \overline{\tau}$ such that for all $t^m \in [t_0+\tau_{-3}, t_0+\tau_1]$ we had (6.17), then ω_h would vanish on $(t_0+\tau_{-3}, t_0+\tau_1)$, which contradicts assumption (6.3). Therefore, we have shown that

$$\limsup \rho_h \leq \overline{\tau},$$

i.e., (6.16). We integrate (4.4) discretely, and we find that for $t \in \big[t_0+\tau_{-3}, t_0+\rho_h\big]$

$$\begin{aligned} u_h(t) =& u_h(t_0+\rho_h) - (t_0+\rho_h-t)\dot{u}_h(t_0+\rho_h) \\ &+ \int_t^{t_0+\rho_h} \lambda_h((s, t_0+\rho_h])\, ds. \end{aligned} \tag{6.18}$$

In the limit we have

$$u(t) = u(t_0+\overline{\tau}) - (\overline{\tau}+t_0-t)\lim_{h\downarrow 0}\dot{u}_h(t_0+\rho_h+0) + \int_t^{t_0+\overline{\tau}}\int_s^{t_0+\overline{\tau}}\lambda(r)\,dr\,ds. \tag{6.19}$$

The comparison of (6.18) and (6.19) shows that

$$\lim_{h\downarrow 0}\dot{u}_h(t_0+\rho_h+0) = \lim_{h\downarrow 0}\eta^{m-1} = \dot{u}(\overline{t}-0). \tag{6.20}$$

Our purpose now is to obtain very precise estimates on the behavior of y_h beyond $t_0+\rho_h$. Thanks to the maximality of m, we have the relation

$$y^{m+1} = -ey^{m-1} + h^2\lambda^m; \tag{6.21}$$

let us estimate $2y^{m+1}-(1-e)y^m$. We substitute the value of y^{m+1} given by (6.21) into this expression, and we also use (4.4) with m replaced by $m-1$; we find that

$$\begin{aligned} &2y^{m+1}-(1-e)y^m \\ &\quad = -\bigl[2y^{m-1}-(1-e)y^{m-2}\bigr] - (1-e)h^2\lambda^{m-1} + 2h^2\lambda^m. \end{aligned}$$

We apply relation (2.1) for $n=m+1$ and we find that

$$\begin{aligned} \eta^{m+1}+e\eta^{m-1} &= h\bigl(\lambda^{m+1}-\lambda^m\bigr) \\ &\quad + \bigl\{-\bigl[2y^{m-1}-(1-e)y^{m-2}\bigr]h^{-1} - (1-e)h\lambda^{m-1} + 2h\lambda^m\bigr\}^+. \end{aligned}$$

Therefore, we have

$$\eta^{m+1}+e\eta^{m-1} \geq -2hC_3.$$

On the other hand, if $\xi = -\bigl[2y^{m-1}-(1-e)y^{m-2}\bigr]h^{-1} - (1-e)h\lambda^{m-1} + 2h\lambda^m$ is less than or equal to 0,

$$\bigl|\eta^{m+1}+e\eta^{m-1}\bigr| \leq 2hC_3;$$

if ξ is positive, then the sign condition on $2y^{m-1}-(1-e)y^{m-2}$ implies that

$$\eta^{m+1}+e\eta^{m-1} \leq h\bigl(\lambda^{m+1}+\lambda^m\bigr) - (1-e)h\lambda^{m-1}.$$

Thus, we have shown that

$$\bigl|\eta^{m+1}+e\eta^{m-1}\bigr| \leq 3C_3h. \tag{6.22}$$

If e is strictly positive, then for all small enough h,

$$\eta^{m+1} \geq e\,\bigl|\dot{u}(\overline{t}-0)\bigr|\,/2.$$

Let us estimate now the expression $2y^{m+2}-(1-e)y^{m+1}$: we have

$$2y^{m+2}-(1-e)y^{m+1} = -e\bigl[2y^m-(1-e)y^{m-1}\bigr] + O(h^2).$$

If $2y^{m+2}-(1-e)y^{m+1}$ is nonnegative, then

$$y^{m+3} = 2y^{m+2} - y^{m+1} + h^2\lambda^{m+2}.$$

We must estimate $2y^{m+3} - (1-e)y^{m+2}$:

$$\begin{aligned} &2y^{m+3} - (1-e)y^{m+2} - 2y^{m+2} + (1-e)y^{m+1} \\ &= h\big(2\eta^{m+2} - (1-e)\eta^{m+1}\big) \\ &= h(1+e)\eta^{m+1} + 2h^2\lambda^{m+2}, \end{aligned}$$

and therefore $2y^{m+3} - (1-e)y^{m+2}$ is nonnegative for all small enough h; the repetition of the argument shows that there exists $\theta > 0$ such that for all small enough h and all $n \in \{m+2, \dots, m + \lfloor \theta/h \rfloor\}$, the expression $2y^{n+1} - (1-e)y^n$ is nonnegative, and thus we have the relations

$$y^n = y^{m+1} + h(n-m-1)\eta^{m+1} + \sum_{j=m+2}^{n-1} \big(n-j\big)h^2\lambda^j.$$

On the other hand, if $2y^{m+2} - (1-e)y^{m+1}$ is negative, we must have

$$y^m = -\frac{(1-e)h\eta^{m-1}}{1+e} + O(h^2),$$

and therefore

$$y^{m-1} = -\frac{2h\eta^{m-1}}{1+e} + O(h^2).$$

These relations and the assumption on the sign of $2y^{m+2} - (1-e)y^{m+1}$ imply that

$$2y^{m+3} - (1-e)y^{m+2} = -\frac{\big(4e^2 + e(1-e)^2\big)h\eta^{m-1}}{1+e} + O(h^2), \tag{6.23}$$

which is strictly positive for h small enough. But now, we can see that

$$y^{m+3} - y^{m+2} = -eh\eta^{m-1} + O(h^2),$$

which is strictly positive for small enough h, and therefore $2y^{m+4} - (1-e)y^{m+3}$ is strictly positive for h small enough, since

$$2y^{m+4} - (1-e)y^{m+3} \geq -he(1+e)\eta^{m-1} + O(h^2);$$

the same argument as above shows now that there exists $\theta > 0$ such that for all $n \in \{m+3, \dots, m + \lfloor \theta/h \rfloor\}$,

$$y^n = y^{m+2} + h(n-m-2)\eta^{m+2} + \sum_{j=m+3}^{n-1} \big(n-j\big)h^2\lambda^j.$$

If we let $\rho'_h = t^{m+1} - t_0$ in the first case and $\rho'_h = t^{m+2} - t_0$ in the second case, we have now for $\rho'_h \leq t - t_0 \leq \rho'_h + \theta - h$

$$u_h(t) = u_h(t_0 + \rho'_h) + (t - \rho'_h - t_0)\dot{u}_h(t_0 + \rho'_h) + \int_{t_0+\rho'_h}^{t} \lambda_h((s,t])\, ds \tag{6.24}$$

and

$$u_h(t_0 + \rho'_h) = O(h), \quad \dot{u}_h(t_0 + \rho'_h) = -e\eta^{m-1} + O(h). \tag{6.25}$$

Passing to the limit in (6.24), we can see that

$$\dot{u}(\bar{t}+0) = -e\dot{u}(\bar{t}-0).$$

If we assume now that e vanishes, relation (6.22) implies

$$\eta^{m+1} = O(h).$$

We observe that Lemma 2.1 implies that for all n

$$|\eta^n| \leq \left|\eta^{n-1}\right| + 2C_3 h,$$

which implies immediately that for $n \geq m+1$

$$|\eta^n| \leq \left|\eta^{m+1}\right| + 2hC_3(n-m-1),$$

which proves by a straightforward passage to the limit that

$$\dot{u}(\bar{t}+0) = 0.$$

This completes the proof of the lemma. □

7. Initial conditions. In this section we prove that the solution that we have constructed satisfies the initial conditions; we work under the hypotheses stated at the beginning of section 4.

LEMMA 7.1. *The function u satisfies the initial conditions*

$$u(t_0) = u_0, \quad \dot{u}(t_0+0) = v_0.$$

Proof. By uniform convergence of u_h to u, it is clear that $u(t_0)$ is equal to u_0. There remains to show that the initial condition on the velocity is satisfied.

Assume first $u_0 > 0$; then there exist $h_1 > 0$ and $\tau_1 > 0$ such that for all $h \in (0, h_1]$ and for all $t - t_0 \in [0, \tau_1]$

$$u_h(t) \geq u_0/2.$$

Then, for all $t^m - t_0 \in (0, \tau_1]$, $2y^m - (1-e)y^{m-1} + h^2F^m$ belongs to K for h small enough; we indeed have

$$\begin{aligned} 2y^m - (1-e)y^{m-1} + h^2F^m &\geq (1+e)y^m - (1-e)hA - h^2C_3 \\ &\geq (1+e)u_0/2 - (1-e)hA - h^2C_3, \end{aligned}$$

which is strictly positive for h small enough. Thus the constraints are not active for $t_0 \leq t^m \leq t_0 + \tau_1$ and the convergence is clear.

In the second case, u_0 vanishes; we have taken admissible initial conditions, so that

$$v_0 \geq 0.$$

Let us show that

$$\dot{u}(t_0+0) = v_0,$$

considering two cases: $v_0 > 0$ and $v_0 = 0$. When v_0 vanishes, we have

$$y^1 = y^0 + hv_0 + O(h^2) = O(h^2)$$

and

$$\begin{aligned} y^2 &= -ey^0 + \big(2y^1 - (1-e)y^0\big)^+ + h^2\lambda^1 \\ &= 2\big(y^1\big)^+ + h^2\lambda^1 = O(h^2). \end{aligned}$$

Thus,

$$\eta^0 = O(h), \quad \eta^1 = O(h),$$

and relation (2.3) implies

$$|\eta^m| \le O(h) + 2C_3h(m-1);$$

therefore, a passage to the limit immediately gives

$$\dot{u}(t_0 + 0) = 0.$$

If, on the other hand, v_0 is strictly positive, then

$$2y^1 - (1-e)y^0 = 2y^1 = 2hv_0 + O(h^2),$$

which is strictly positive if h is small enough. Let $\{1, \dots, m\}$ be the maximal interval such that

$$2y^n - (1-e)y^{n-1} > 0 \quad \text{if } n \le m.$$

Then, for all $n \in \{1, \dots, m\}$,

$$\eta^n - \eta^{n-1} = h\lambda^n,$$

which implies by discrete integration that

$$\eta^n \ge \eta^0 - hnC_3,$$

as long as n belongs to $\{1, \dots, m\}$. Moreover, if we choose any $\tau_1 < v_0/(2C_3)$ and if n is at most equal to $\min\big(m, \lfloor \tau_1/h \rfloor\big)$, we can see that

$$y^n = y_0 + h\big(\eta^0 + \cdots + \eta^{n-1}\big) \ge \frac{hnv_0}{2}$$

for all small enough values of h.

In particular, for all $n \le \min\big(m, \lfloor \tau_1/h \rfloor\big)$,

$$2y^n - (1-e)y^{n-1} \ge \frac{(1+e)hnv_0}{2} - (1-e)hA,$$

which proves that m is at least equal to $\lfloor \tau_1/h \rfloor$. Therefore, ω_h vanishes on the interval $(t_0, t_0 + \tau_1 - h)$; in the limit, ω vanishes on $(t_0, t_0 + \tau_1)$ and therefore

$$\dot{u}(t_0 + 0) = v_0,$$

which completes the proof of the lemma. □

8. A priori estimates. In this section we prove that solutions of the problem (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), and (1.7) satisfy an a priori estimate on an interval with nonempty interior.

LEMMA 8.1. *Let R be strictly larger than $|v_0|$. Then there exists $\tau(R) > 0$ such that for all solution u of* (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), *and* (1.7) *defined on $[t_0, t_0 + \tau]$, the following estimates hold:*

$$\forall t \in [t_0, t_0 + \min(\tau, \tau(R))], \quad |u(t) - u_0| \le R, \quad |\dot u(t)| \le R. \tag{8.1}$$

Proof. The measure μ appearing in (1.3b) can be decomposed in the sum of an atomic part μ_a and a diffuse part μ_d. There might be a continuous singular part in the measure μ, and it is convenient to see μ as the sum of the derivative of a jump function and of the derivative of a continuous function. At each point of the support of μ_a we have

$$|\dot u(t+0)| \le |\dot u(t-0)| \tag{8.2}$$

thanks to relation (1.5). On any interval (t_1, t_2) which does not intersect the support of μ_a, we multiply relation (1.2) by $\dot u$, and we find that

$$\frac{d}{dt}\frac{1}{2}|\dot u|^2 = \dot u f(\cdot, u, \dot u). \tag{8.3}$$

Define

$$z = |\dot u|.$$

Relations (8.2) and (8.3) imply that in the sense of measures

$$z\dot z \le \dot u f(\cdot, u, \dot u). \tag{8.4}$$

Our purpose now is to transform (8.4) into a differential inequality. We write

$$\dot u f(t, u, \dot u) = \dot u\big[f(t, u, \dot u) - f(t, u_0, 0) + f(t, u_0, 0)\big].$$

Define

$$g(t) = |f(t, u_0, 0)|,$$

fix $R > |v_0|$, and let $\omega(R)$ be the Lipschitz constant of $(u, v) \mapsto f(t, u, v)$ for $t \in [0, T]$ and $\max(|u - u_0|, |v|) \le R$. By construction, ω is continuous and it is an increasing function of R.

If $t_0 \le t \le t_0 + \tau$ and if $\max(|u(t) - u_0|, |\dot u(t)|) \le R$ on $[t_0, t_0 + \tau]$, we have the inequality

$$z\dot z \le |\dot u f(\cdot, u, \dot u)| \le z\big(g + \omega(R)(|u - u_0| + |\dot u|)\big).$$

But we can estimate $u(t) - u_0$:

$$|u(t) - u_0| \le \int_{t_0}^{t} |\dot u(s)|\, ds \le \int_{t_0}^{t} z\, ds.$$

Therefore we have the estimate

$$|\dot u f(\cdot, u, \dot u)| \le zg + z\omega(R)\left(\int_{t_0}^{t} z\, ds + z\right),$$

and we conclude that z satisfies the differential inequality

$$\dot{z} \leq g + \omega(R) \left[\int_{t_0}^{t} z \, ds + z \right].$$

Let $\widehat{z}$ be the solution of the integro-differential equation

$$\frac{d\widehat{z}}{dt} = g + \omega(R) \left[\int_{t_0}^{t} \widehat{z} \, ds + \widehat{z} \right], \quad \widehat{z}(t_0) = |v_0|.$$

Such a $\widehat{z}$ exists and is unique, by very classical arguments, and it is also a majorant of z. Let $\tau(R)$ be the largest number in $(0, T - t_0]$ such that

$$\forall t \in [t_0, t_0 + \tau(R)], \quad \widehat{z}(t) \leq R, \quad \int_{t_0}^{t} \widehat{z}(s) \, ds \leq R.$$

Such a number exists since $\widehat{z}(t_0)$ is strictly inferior to R. On the interval $[t_0, t_0 + \min(\tau, \tau(R))]$ we have the desired estimate. □

9. Global results. We summarize the results obtained so far in the following proposition.

PROPOSITION 9.1. *Assume that there exist strictly positive numbers τ, A, and $h_1 > 0$ and a sequence of solutions of the numerical scheme defined by* (1.10), (1.11), (1.12), *and* (1.13), *which satisfies the estimate* (4.1). *Then it is possible to extract from the sequence u_h defined by* (5.1) *a subsequence which converges to a solution of* (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), *and* (1.7). *The convergence holds in the following sense: u_h converges uniformly to u_h on $[t_0, t_0 + \tau]$; $\dot{u}_h$ converges to $\dot{u}$ in $L^\infty(t_0, t_0 + \tau)$ weakly $*$ and almost everywhere on $[t_0, t_0 + \tau]$; and $\ddot{u}_h$ converges to $\ddot{u}$ in the weak $*$ topology of measures. Moreover, for all $\overline{\tau} \in (0, \tau]$, we have the following convergence:*

$$\begin{aligned} &\limsup_{h \downarrow 0} \, \sup \big\{ |\eta^m| : t_0 \leq t^m \leq t_0 + \overline{\tau} \big\} \\ &\qquad \leq \operatorname{ess\,sup} \big\{ |\dot{u}(t)| : t_0 \leq t \leq t_0 + \overline{\tau} \big\}. \end{aligned} \tag{9.1}$$

Proof. The only statement which deserves a proof is the last one; if it is not true, there exists $\gamma > 0$, a sequence of time steps still denoted by h, and a sequence of integers $m(h)$ such that

$$\left| \eta^{m(h)} \right| \geq \operatorname{ess\,sup} \big\{ |\dot{u}(t)| : t_0 \leq t \leq t_0 + \overline{\tau} \big\} + \gamma. \tag{9.2}$$

Without loss of generality, we may assume that $hm(h)$ tends to $\tau_2 \in [0, \overline{\tau}]$.

First, τ_2 cannot be equal to 0: we have learnt in section 7 that there exists a constant C_4 and a time τ_1 such that for all $h \leq h_1$ and all $m \leq \tau_1/h$,

$$\left| \eta^m - \eta^0 \right| \leq C_4 mh.$$

In particular, this estimate implies that

$$\left| \eta^{m(h)} \right| = |v_0| + O(mh);$$

but $|v_0|$ is at most equal to $\operatorname{ess\,sup} \big\{ |\dot{u}(t)| : t_0 \leq t \leq t_0 + \tau \big\}$, which contradicts (9.2). In the same fashion, we cannot have $u(t_0 + \tau_2) > 0$; if it were the case, we could find an

interval $[\tau_1, \tau_3]$ containing τ_2 and $h_1 > 0$ such that for all $h \in (0, h_1]$, $u_h([\tau_1, \tau_3])$ belongs to the interior of K. But, in this case, $\dot{u}_h$ converges uniformly to $\dot{u}$ in $C^0([\tau_1, \tau_3])$ and this contradicts again (9.2).

Thus, we assume that τ_2 is strictly positive and that $u(t_0 + \tau_2)$ vanishes.

We infer from (2.3) that

$$|\eta^{m+1}| \leq \max\bigl(|\eta^m|, |\eta^{m-1}|\bigr) + 2C_3 h.$$

We now use (9.2). We can see that for all $m \leq m(h)$,

$$|\eta^{m(h)}| \leq \max\bigl(|\eta^m|, |\eta^{m-1}|\bigr) + 2C_3\bigl(m(h) - m\bigr)h,$$

so that

$$\max\bigl(|\eta^m|, |\eta^{m-1}|\bigr) \geq |\eta^{m(h)}| - 2C_3\bigl(m(h) - m\bigr)h.$$

If $\tau_4 < \tau_2$ is such that

$$\tau_2 - \tau_4 \leq \gamma/4C_3,$$

we can see that for all $m \in \{\lceil \tau_4/h \rceil, \ldots, m(h)\}$, the following estimate holds:

$$\max\bigl(|\eta^m|, |\eta^{m-1}|\bigr) \geq \operatorname{ess\,sup}\bigl\{|\dot{u}(t)| : t_0 \leq t \leq t_0 + \overline{\tau}\bigr\} + \gamma/2. \tag{9.3}$$

But the function $|\dot{u}_h|$ converges almost everywhere on $[t_0, t_0 + \tau]$ to $|\dot{u}|$, and so does $\max(|\dot{u}_h(\cdot - h)|, |\dot{u}_h|)$. Therefore, in the limit, relation (9.3) leads to

$$\begin{aligned}\liminf_{h \downarrow 0} \operatorname{ess\,sup}\bigl\{|\dot{u}_h(t)| : t \in [t_0 + \tau_4, t_0 + \tau_2]\bigr\}\\ \geq \operatorname{ess\,sup}\bigl\{|u(t)| : t_0 \leq t \leq t_0 + \overline{\tau}\bigr\} + \gamma/2,\end{aligned}$$

which is a contradiction. □

A corollary can be inferred imediately from this proposition and Proposition 3.4.

COROLLARY 9.2. *For all admissible initial conditions (t_0, u_0, p_0), there exists $\tau > 0$ and a solution of* (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), *and* (1.7) *defined on $[t_0, t_0 + \tau]$.*

We have proved above the existence of a nonempty interval on which the numerical scheme converges to a solution of (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), and (1.7). On the other hand, Lemma 8.1 gives a priori estimates on the solution of such a problem.

We couple now the a priori estimates with the local convergence result to obtain a global result.

THEOREM 9.3. *Let R be strictly larger than $|v_0|$, and let $\tau(R)$ be given as in Lemma* 8.1. *Then, for all small enough h, the solution y^m of the numerical scheme* (1.10), (1.11), (1.12), (1.13) *is defined on a discrete interval $\{0, \ldots, m(h)\}$ such that*

$$\liminf_{h \to 0} hm(h) \geq \tau(R);$$

moreover, the approximation u_h converges to a solution u of the continuous time equation, i.e., (1.2), (1.3a), (1.3b), (1.4a), (1.4b), (1.5), (1.6), *and* (1.7), *which is defined on $[t_0, t_0 + \tau(R)]$.*

Proof. Let A be given by

$$A = \max\bigl(3R+1, u_0 + T(3R+1)\bigr).$$

Let $\{0, \dots, m(h)\}$ be the maximal discrete time interval for which the numerical scheme (1.10), (1.11), (1.12), (1.13) has a solution satisfying the estimate

$$\forall m \in \bigl\{0, \dots, m(h)-1\bigr\}, \quad |y^{m+1} - y^m| \leq Ah.$$

Let

$$\tau_1 = \liminf_{h \to 0} hm(h).$$

We know from Proposition 3.4 that τ_1 is at least equal to some number $\tau > 0$. Assume that τ_1 is strictly inferior to $\tau(R)$. Proposition 9.1 implies in particular that for all $\varepsilon > 0$

$$\begin{aligned}\limsup_{h \to 0} \bigl\{\sup|\eta^m| : t_0 \leq t^m \leq t_0 + \tau_1 - \varepsilon\bigr\} \\ \leq \operatorname{ess\,sup}\bigl\{|\dot{u}(t)| : t_0 \leq t \leq t_0 + \tau_1 - \varepsilon\bigr\} \leq R,\end{aligned}$$

thanks to the a priori estimates proved in Lemma 8.1. Since the above inequalities hold for all $\varepsilon > 0$, we see that

$$\limsup_{h \to 0} \bigl\{\sup|\eta^m| : t_0 \leq t^m \leq t_0 + \tau_1\bigr\} \leq R.$$

Let

$$a = \max\bigl(R + 1/2, u_0 + T(R+1/2)\bigr);$$

Theorem 3.1 implies the existence of $\tau_2 > 0$ such that if $\widehat{y}^0$ and $\widehat{y}^1$ satisfy property $P(a,h)$, and $\widehat{t}_0$ is any time in $[0,T)$, then there exists a numerical solution of (1.12), (1.13) which satisfies

$$\forall m \in \{0, \dots, \lfloor \tau_2/h \rfloor\}, \quad \bigl|\widehat{y}^{m+1} - \widehat{y}^m\bigr| \leq Ah.$$

We denote

$$l(h) = \lfloor (\tau_1 - \tau_2/2)/h \rfloor,$$

and we initialize with the following choices:

$$\widehat{t}_0 = t_0 + hl(h), \quad \widehat{y}^0 = y^{l(h)}, \quad \widehat{y}^1 = y^{l(h)+1}.$$

With these data, we know that $\widehat{y}^m$ exists for $0 \leq mh \leq \tau_2$, so that the numerical solution y^m is extended up to $\lfloor (\tau_1 + \tau_2/2)/h \rfloor - 1$, and therefore,

$$\liminf_{h \to 0} hm(h) \geq \tau_1 + \tau_2/2,$$

which is a contradiction. ∎

10. Numerical experiments. In this section, we report about the numerical implementation of our scheme and of the impact detection method; we compare these results to results obtained for a penalized version of our model, using a freely available scientific computation package.

In view of its practical importance and of its ease of programming, we have limited ourselves to vibro-impact, i.e.,

$$f(t,u,\dot{u}) = a\cos\omega t - u - 2\alpha\dot{u}$$

with constraint set

$$K = [u_{\min}, +\infty).$$

The following numerical values are kept constant throughout the numerical experiments:

$$\alpha = 0.5, \quad a = 1, \quad \omega = 50, \quad e = 0.5.$$

Observe that $u_{\min}/a$ is the relevant parameter. We have observed in previous work [17], [19], [18] that if we systematically choose

$$u(0) = u_{\min}, \quad \dot{u}(0) = 0.1,$$

the variation of the parameter $u_{\min}$ triggers a variety of dynamical behaviors: periodic solutions, period doubling, and chaotic attractors.

All the penalty computations presented here have been implemented as `SCILAB` programs, a free high level scientific computation software developed and distributed by INRIA (http://www-rocq.inria.fr/scilab). Some of the other computations have been performed in FORTRAN.

10.1. Implementation particulars. The impact detection scheme goes as follows: starting from initial data t_j, $u(t_j) = u_{\min}$, $\dot{u}(t_j)$, the solution of the linear problem

$$\ddot{u} + 2\alpha\dot{u} + u = a\cos\omega t$$

is found explicitly; a nonlinear solver finds the first zero $t_{j+1} > t_j$ of $t \mapsto u(t) - u(t_j)$ and this instant is called t_{j+1}. We let

$$u(t_{j+1} + 0) = -eu(t_{j+1} - 0),$$

and we restart the process.

The foregoing description is slightly too rough: if there is an accumulation of impact instants, we have to define a threshold of velocity at t_j, under which we set the solution equal to $u_{\min}$, as long as $\cos\omega t$ remains negative. Observe that the detection method is potentially accurate to machine precision, since the nonlinear solvers for a scalar function are extremely precise, and the threshold velocity can be taken very small.

The numerical scheme is implemented as follows:

$$\begin{aligned} y^{n+1} &= -ey^{n-1} + \max\bigl((1+e)u_{\min}, x^n\bigr), \\ x^n &= \frac{h^2 a}{1+\alpha h}\cos(\omega t_n) + \frac{2-h^2}{1+\alpha h}y^n - \frac{(1-e)-\alpha h(1+e)}{1+\alpha h}y^{n-1}. \end{aligned}$$

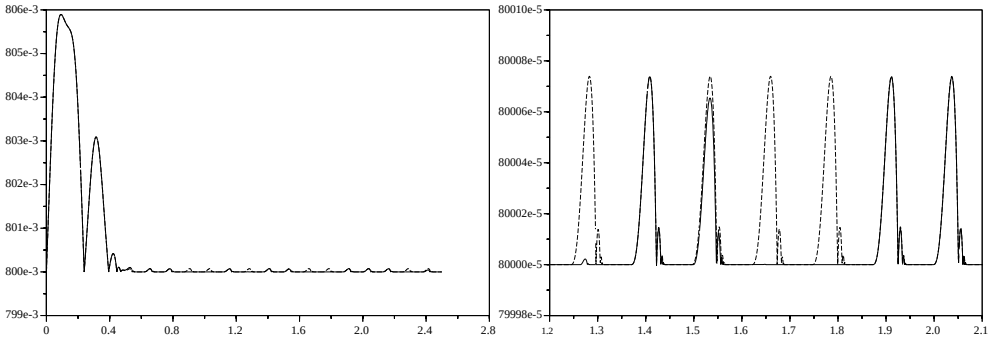

FIG. 10.1. *The penalized solution on the left and its zoom on the right for time step* $h = 1.25\,10^{-5}$ *and* $\varepsilon = 10^{-6}/256$.

The reader will check that this form is equivalent to (1.12) and (1.13); one of the advantages of this numerical scheme is that it is absolutely trivial to program.

For the penalty method, we applied the `SCILAB` function `ode` with the option `stiff` to the ordinary differential system

$$\begin{aligned} &\dot u = v,\\ &\dot v = a\cos\omega t - u - 2\alpha v + \frac{(u-u_{\min})^-}{\varepsilon} + 2\frac{\beta\,\mathrm{sign}^-\,(u-u_{\min})}{\sqrt{\varepsilon}}, \end{aligned} \tag{10.1}$$

where

$$r^- = -\min(r,0), \quad \mathrm{sign}^-\,(r) = \begin{cases} -1 & \text{if } r<0,\\ 0 & \text{otherwise.}\end{cases}$$

The parameter β is defined in terms of the restitution coefficient e by

$$\beta = -\frac{\ln e}{\sqrt{\pi^2 + (\ln e)^2}}.$$

It has been proved in [21] that the solution of (10.1) converges to a solution of (1.2), (1.3a), (1.3b), (1.4a), (1.4b), and (1.5). The choice of β is also justified in that reference.

10.2. Periodic solution: $u_{\min} = 0.8$. The solution obtained by the scheme and impact detection agree satisfactorily: they both converge as time increases to a periodic solution, with an infinite number of impacts per period—of which we calculate only a finite number, of course!

The penalized approximation is satisfactory for not too small values of the penalty parameter, but for very small values of the parameter, it completely misses some of the periods (see Figure 10.1). The choice of parameters corresponds to $\sqrt{\varepsilon}/h = 5$, which is quite sufficient for a good numerical approximation of the rebound.

As a matter of comparison we show in Figure 10.2 that the scheme and the detection method coincide very precisely.

We cannot offer much in the way of the explanations, since we did not go into the details of the `SCILAB` code to understand its inner workings; though it is an open package, with freely accessible code, we treated it as a black box.

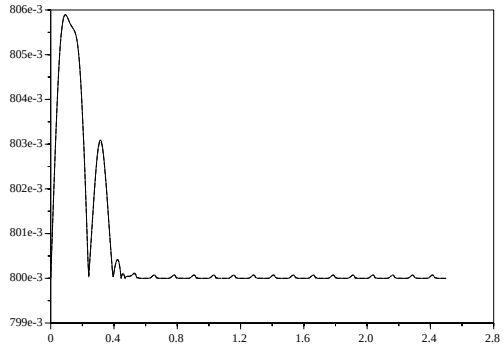

FIG. 10.2. *The scheme for* $h = 0.0003125$ *superposed to the solution by detection.*

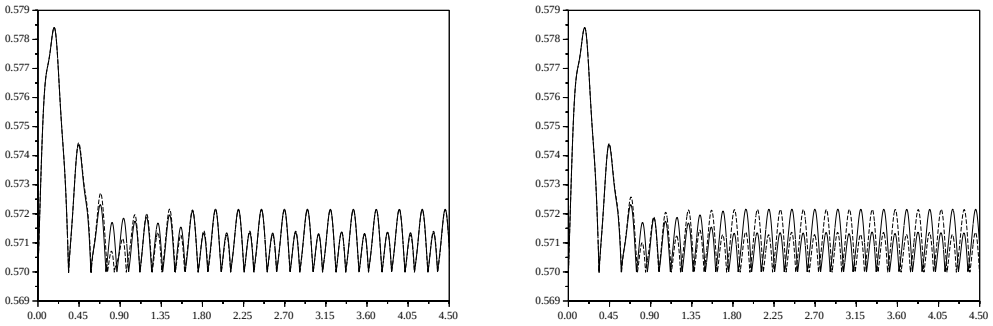

FIG. 10.3. *On the left: detection (solid) and scheme (dotted); on the right: detection (solid) and penalty (dotted).*

10.3. Period doubling: $u_{\min} = 0.57$. We observe period doubling slightly above this value, and the scheme continues to agree satisfactorily with the detection method.

The penalty method gives also period doubling, but, depending on ε and the time step, we may obtain either a good approximation of the period doubled solution obtained by the previous two approaches or its translate by a half (doubled) period, i.e., $2\pi/\omega$.

For instance, Figure 10.3 shows the results of the calculation with the detection scheme, our ad hoc scheme with a time step $h = 5\,10^{-4}$, and the penalty method for $\varepsilon = 10^{-7}$ with a time step $h = 2\,10^{-5}$.

The results of the numerical scheme do not seem to depend on the time step, once convergence is experimentally achieved; see Figure 10.4, left, where the solution is significantly improved by decreasing the time step from $6.25\,10^{-4}$ to $5.\,10^{-4}$. In contrast, on the right, decreasing the time step with the same penalty parameter $\varepsilon = 10^{-6}$ does not give a significant improvement: for the larger time parameter, the beginning of the numerical solution is bad, and for the smaller one, we hit a phase shifted solution.

The penalized solution is also very sensitive to the choice of the penalty parameter; see Figure 10.5, with the same time step of $2\,10^{-5}$ and penalty parameters of 10^{-7} and 10^{-8}.

The results of the penalty method keep depending on the choice of the time step and ε (see Figures 10.4, right, and 10.5), and we have not been able to establish the

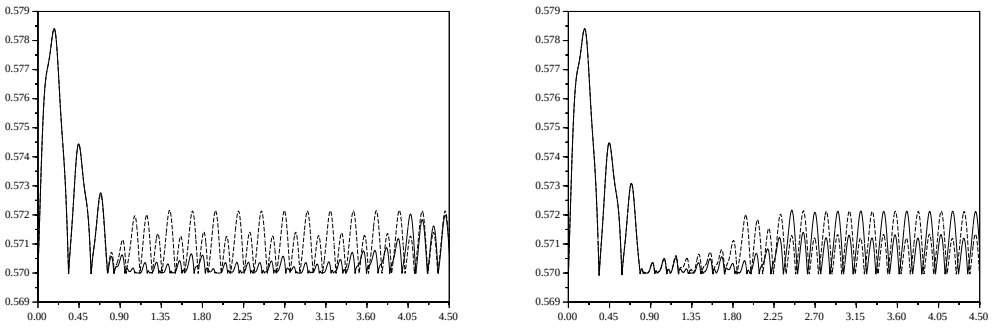

FIG. 10.4. *Left: the scheme with* $h = 6.25\,10^{-4}$ *(solid line) and with* $h = 5\,10^{-4}$ *(dashed line); right: the penalty method with* $h = 2\,10^{-5}, \varepsilon = 10^{-6}$ *(solid line) and with* $h = 10^{-4}, \varepsilon = 10^{-6}$ *(dashed line).*

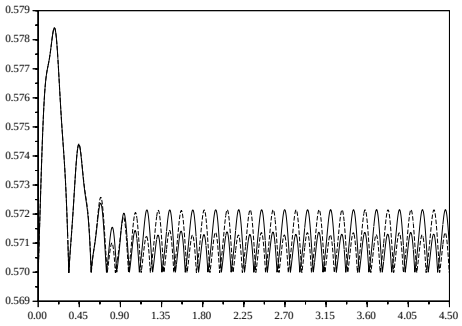

FIG. 10.5. *The penalty method with* $h = 2\,10^{-5}, \varepsilon = 10^{-8}$ *(solid line) and with* $h = 2\,10^{-5}, \varepsilon = 10^{-7}$ *(dashed line).*

pattern of dependency.

10.4. Strange attractor: $u_{\min} = 0.54$. We picture a stroboscopic view of the attractors by displaying the sequences

$$\big(u((2k+1)\pi/\omega), \dot{u}((2k+1)\pi/\omega)\big)$$

for 1989 values of k.

Figure 10.6 displays a superposition of the computation by the detection method and the scheme, in FORTRAN double precision. Figure 10.7 displays a superposition of the `SCILAB` computation by the penalty method and by the scheme; it is somewhat surprising to see so few points of the scheme in this last computation, while the sizes of vectors are identical: k varies from 1 to 1989, corresponding to a final time of 250 (and not to the bicentennial of the French Revolution). We believe that this phenomenon may be due to a bad control in `SCILAB` of the format of the numbers.

Nevertheless, these figures show a very satisfactory agreement between the three methods.

10.5. Numerical conclusion. We would like to stress the qualitative properties of numerical schemes in a dynamical systems framework: this scientific program has been started by several authors, and we refer to [31] for an overview of the subject. However, the methods of analysis rely heavily on a smoothness assumption which is not satisfied here, and therefore, they do not apply. Thus, at the present moment, we

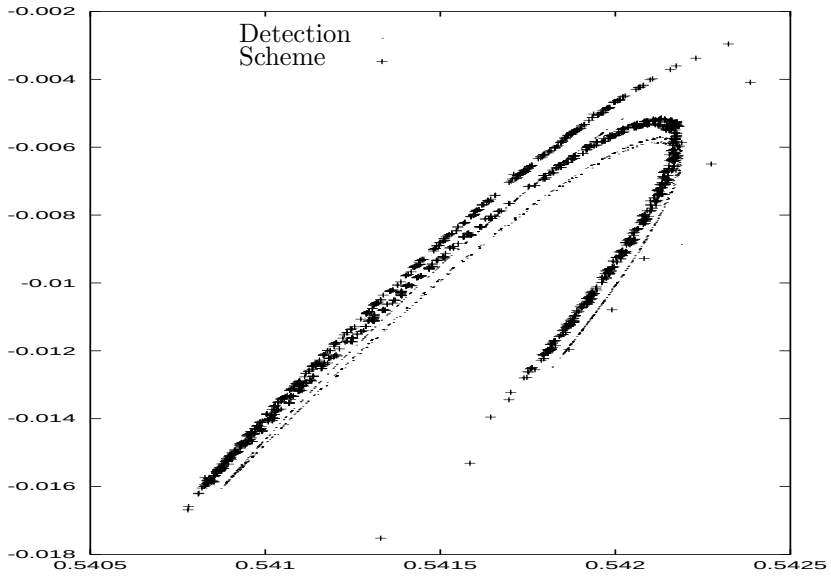

FIG. 10.6. *A superposition of the stroboscopic pictures of the attractor obtained by the detection method (dots) and the scheme (points):* `FORTRAN` *calculation with time step* 510^{-4}.

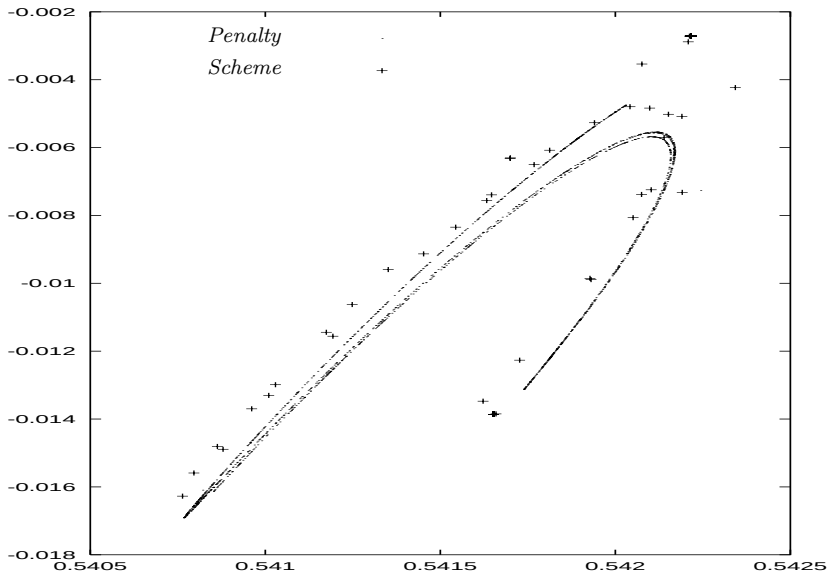

FIG. 10.7. *A superposition of the stroboscopic pictures of the attractor obtained by the penalty method (dots) and the scheme (points):* `SCILAB` *calculation with time step* $\pi/2500$.

are reduced to experimental numerics, but we should keep in mind a rational approach to the numerical analysis of dynamical systems, focusing not only on the accuracy of a given method for finite time intervals but also on the qualitative properties of the method for long time ranges. The provisional conclusion for our one-dimensional case is that the penalty method performs reasonably well, but it misses details, while the

detection method enables us to benchmark our ad hoc scheme and to certify that it does not miss details. Our scheme is quite easy to implement, and it contains no black box; however, it is still missing some bells and whistles, such as time step control. In any case, our scheme is of very low order: order one with respect to the position and order zero with respect to the velocity. The reason is that the velocity is discontinuous and the numerical impact times are usually distinct from their limit. Schemes with a better order of convergence should approximate very precisely the impact times, but one cannot but wonder whether it is really necessary to do so.

A NUMERICAL SCHEME FOR IMPACT PROBLEMS II: THE MULTIDIMENSIONAL CASE*

LAETITIA PAOLI† AND MICHELLE SCHATZMAN‡

Abstract. We consider a mechanical system with impact and n degrees of freedom, written in generalized coordinates. The system is not necessarily Lagrangian. The representative point is subject to a constraint: it must stay inside a closed set K with boundary of class C^3. We assume that, at impact, the tangential component of the impulsion is conserved, while its normal coordinate is reflected and multiplied by a given coefficient of restitution $e \in [0,1]$: the mechanically relevant notion of orthogonality is defined in terms of the local metric for the impulsions (local cotangent metric). We define a numerical scheme which enables us to approximate the solutions of the Cauchy problem: this is a generalization of the scheme presented in the companion paper [L. Paoli and M. Schatzman, *SIAM J. Numer. Anal.*, 40 (2002), pp. 702–733]. We prove the convergence of this numerical scheme to a solution, which also yields an existence result. Without any a priori estimates, the convergence and the existence are local; with some a priori estimates, the convergence and the existence are proved on intervals depending exclusively on these estimates. The technique of proof uses a localization of the scheme close to the boundary of K; this idea is classical for a differential system studied in the framework of flows of a vector field. It is much more difficult to implement here because finite differences schemes are only approximately local: straightening the boundary creates quadratic terms which cause all the difficulties of the proof.

Key words. impact, coefficient of restitution, numerical scheme, convergence, local existence, global existence

1. Introduction.

In this article we study a numerical approximation of dynamics with impact with a finite number of degrees of freedom and a smooth constraint.

The set of constraints is denoted K and satisfies the following assumptions:

(1.1a) K is a closed subset of $\mathbb{R}^d$ with a nonempty interior;

(1.1b) $\begin{cases} \text{the boundary } \partial K \text{ of } K \text{ is an embedded submanifold} \\ \text{of class } C^3 \text{ of } \mathbb{R}^d; \end{cases}$

(1.1c) K lies on only one side of ∂K.

It is possible to find a function ϕ of class C^3 such that

$$K = \{u \in \mathbb{R}^d : \phi(u) \geq 0\}$$

and the differential $d\phi$ does not vanish on $\partial K = \{u \in \mathbb{R}^d : \phi(u) = 0\}$.

Let f be a continuous function from $[0,T]\times\mathbb{R}^d\times\mathbb{R}^d$ to $\mathbb{R}^d$ which is locally Lipschitz continuous with respect to its last two arguments, and let $M(u)$ be the mass matrix:

$u \mapsto M(u)$ is a mapping of class C^3 from $\mathbb{R}^d$ to the set of symmetric positive definite matrices.

The free dynamics of the system are written in generalized coordinates as

$$M(u)\ddot{u} = f(\cdot, u, p), \quad p = M(u)\dot{u}. \tag{1.2}$$

This system is more general than the system obtained in Lagrangian mechanics, since we want to include possible dissipative terms in the dynamics of the problem under discussion.

Let us give the few geometric notations which are absolutely necessary here, since we use a Riemannian metric: the cotangent bundle $T^*\mathbb{R}^d$ is identified with $\mathbb{R}^d \times \mathbb{R}^d$, and its elements are denoted as pairs (u, ξ); at each point u of $\mathbb{R}^d$ the metric tensor for tangent vectors is defined by the matrix $M(u)$, and the metric tensor for cotangent vectors is defined by the matrix $M(u)^{-1}$. The scalar product of two vectors x and y in the tangent space at u is denoted by $\langle x, y\rangle_u$; coordinatewise it can be expressed as $x^T M(u) y$, where x and y are column vectors. The scalar product of two vectors ξ and η in the cotangent space at u is denoted by $\langle \xi, \eta\rangle_u^*$ and coordinatewise it is equal to $\xi^T M(u)^{-1}\eta$. The corresponding norms of vectors and covectors are denoted, respectively, by $|x|_u$ and $|\xi|_u^*$.

Therefore, a cotangent vector (u, ξ) belonging to $T^*\mathbb{R}^d$ is orthogonal to the cotangent vector (u, η) iff $\langle \xi, \eta\rangle_u^*$ vanishes.

With these notations, if the velocity of the system is $\dot{u}$, the generalized impulsion is $M(u)\dot{u} = p$ and (u, p) belongs to the cotangent space $T^*\mathbb{R}^d$. Whenever we take the orthogonal of a vector or a vector subspace of the tangent or the cotangent space at u, we always use the relevant metric tensor; therefore it is important to know which of the vectors under consideration are cotangent and which are tangent. Of course, all the differential forms are cotangent vectors.

Let us describe now the system satisfied by the problem with impact: we replace (1.2) by

$$M(u)\ddot{u} = \mu + f(\cdot, u, p), \tag{1.3}$$

and since we cannot expect to have global solutions in general, μ is an unknown measure on $[t_0, t_0 + \overline{\tau}]$ with values in $\mathbb{R}^d$ which describes the reaction of the constraints and has the following properties: if $d\phi$ denotes the differential of ϕ, then

$$\operatorname{supp}(\mu) \subset \{t \in [t_0, t_0 + \overline{\tau}] : \phi(u(t)) = 0\}, \tag{1.4a}$$

$$\mu = \lambda d\phi(u), \tag{1.4b}$$

$$\lambda \geq 0 \quad |d\phi(u)| \text{ almost everywhere on } [t_0, t_0 + \overline{\tau}]. \tag{1.4c}$$

We require the following functional properties for u:

$$\begin{cases} u \text{ is a continuous function taking its values in } K \\ \forall\ t \in [t_0, t_0 + \overline{\tau}], \end{cases} \tag{1.5a}$$

$$\dot{u} \text{ is of bounded variation over } [t_0, t_0 + \overline{\tau}]. \tag{1.5b}$$

If $\dot{u}$ is of bounded variation, p is also of bounded variation. Assume that $u(t)$ belongs to ∂K; we decompose $p(t-0)$ and $p(t+0)$ on $\mathbb{R}d\phi(u(t)) \oplus d\phi(u(t))^\perp$; here the $\perp$ sign means the orthogonality with respect to the local cotangent metric. We integrate (1.3) on a small neighborhood of t, and relation (1.4b) implies that the component of $p(t-0)$ on $d\phi(u(t))^\perp$ is conserved.

Therefore, we have to make a supplementary assumption in order to have a complete description of the impact; we choose a constitutive law of the impact using a coefficient of restitution. Thus we will assume that there exists $e \in [0,1]$ such that the component of $p(t+0)$ along $\mathbb{R}d\phi(u)$ is equal to $-e$ times the component of $p(t-0)$ on $\mathbb{R}d\phi(u)$. In other words, we have

$$p(t+0) = p(t-0) - (1+e)\frac{\langle d\phi(u(t)), p(t-0)\rangle^*_{u(t)}}{\langle d\phi(u(t)), d\phi(u(t))\rangle^*_{u(t)}} d\phi(u(t)). \tag{1.6}$$

The set of admissible initial data $\mathbb{D}$ will be

$$\begin{aligned}\mathbb{D} = \Big\{ &(t_0, u_0, p_0) \in [0,T) \times K \times \mathbb{R}^d : \\ &\text{if } u_0 \in \partial K, \text{ then } \langle p_0, d\phi(u_0)\rangle^*_{u_0} \geq 0 \Big\}.\end{aligned} \tag{1.7}$$

This choice is equivalent to the convention that there is no impact at the initial time t_0.

Given initial conditions $(t_0, u_0, p_0) \in \mathbb{D}$, we require that the following Cauchy data be satisfied:

$$u(t_0) = u_0 \tag{1.8}$$

and

$$p(t_0) = p_0. \tag{1.9}$$

For all initial data $(t_0, u_0, p_0) \in \mathbb{D}$ we will obtain the existence of a local solution to (1.3), (1.4a), (1.4b), (1.4c), and (1.6) belonging to the functional class defined by (1.5a) and (1.5b) and satisfying the initial conditions (1.8) and (1.9).

The existence of this local solution is obtained by defining a numerical scheme, whose convergence will be shown in appropriate functional spaces; the limit of the approximation will be a solution of our problem.

The distance on $\mathbb{R}^d$ is defined with the help of the Riemannian metric: if $s \mapsto u(s)$ is a C^1 mapping from $[a,b]$ to $\mathbb{R}^d$, the Riemannian length of the image of u is

$$\ell(u) = \int_a^b |\dot{u}(s)|_{u(s)}\, ds.$$

This curve length is invariant by a diffeomorphic change of parameter. Therefore, we may assume that $a = 0$ and $b = 1$. The distance from x to y is the lower bound of the length of the curves from x to y, or in other words

$$\operatorname{dist}(x,y) = \inf\{\ell(u) : \quad u \in C^1([0,1]), \quad u(0) = x, \quad u(1) = y\}.$$

It is classical that the lower bound is attained on the geodesics for the given Riemannian metric; it is also known that for each point x there exists $r > 0$ such that, if $\operatorname{dist}(x,y) \leq r$, there is only one geodesic from x to y.

We denote by $\operatorname{dist}(x,E)$ the Riemannian distance of a point x to a set E.

Under assumptions (1.1), a projection on ∂K can be defined uniquely on an appropriate neighborhood of ∂K; more precisely, for all compact $\mathcal{C} \subset \partial K$, there exists a neighborhood of $\mathcal{C}$ on which the projection $P_{\partial K}$ is uniquely defined, and

there exists a unique geodesic joining a point of this neighborhood to its projection. This projection $P_{\partial K}$ is characterized by the relation

$$\forall y \in \partial K, \quad \operatorname{dist}(P_{\partial K} x, x) \leq \operatorname{dist}(y, x). \tag{1.10}$$

This projection is of class C^2.

For all x in ∂K, denote by $N(x)$ the interior unit normal vector: this means that $|N(x)|_x$ is equal to 1 and that it is orthogonal to the tangent space at $P_{\partial K} x$ with respect to the scalar product in the tangent space; i.e., for all y such that $d\phi(x)y$ vanishes, $\langle y, N(x)\rangle_x = 0$. The smoothness of ∂K implies that the mapping $z \mapsto N(z)$ is of class C^2.

When the geodesic from x to $P_{\partial K} x$ is unique it is tangent at $P_{\partial K} x$ to $N(P_{\partial K} x)$.

Starting from this projection on ∂K, we can define a projection on K as follows: for each compact $\mathcal{C}$ included in K, there exists a relatively compact neighborhood $\mathcal{U}$ of $\mathcal{C}$ on which P_K is defined by

$$P_K(x) = \begin{cases} P_{\partial K}(x) & \text{if } x \notin K, \\ x & \text{otherwise.} \end{cases} \tag{1.11}$$

The reader will check that P_K is Lipschitz continuous over $\mathcal{U}$ and that $P_K x$ realizes the minimum of the distance from x to K.

Given two positive numbers $h^* \leq 1$ and T, assume that F is a continuous function from $[0,T] \times \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}^d \times [0, h^*]$ to $\mathbb{R}^d$, which is locally Lipschitz continuous with respect to its second, third, and fourth arguments; assume, moreover, that F is consistent with f, i.e., that for all $t \in [0,T]$, for all u and v in $\mathbb{R}^d$

$$F(t, u, u, v, 0) = M(u)^{-1} f(t, u, M(u)v). \tag{1.12}$$

We approximate the solution of (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.8), (1.9) by the following numerical scheme: the initial values U^0 and U^1 are given by the initial position

$$U^0 = u_0, \tag{1.13}$$

and the position at the first time step

$$U^1 = u_0 + hM(u_0)^{-1} p_0 + hz(h), \tag{1.14}$$

where $z(h)$ tends to 0 as h tends to 0.

We will systematically use, henceforth, the notation

$$t_m = t_0 + mh. \tag{1.15}$$

Given U^{m-1} and U^m, U^{m+1} is defined by the relations

$$U^{m+1} = -eU^{m-1} + (1+e) P_K \left(\frac{2U^m - (1-e)U^{m-1} + h^2 F^m}{1+e} \right) \tag{1.16}$$

and

$$F^m = F\left(t_m, U^m, U^{m-1}, \frac{U^{m+1} - U^{m-1}}{2h}, h \right) \tag{1.17}$$

provided that U^{m+1} is unique in a neighborhood of U^m. Definition (1.16) and (1.17) is the obvious generalization of (1.12) and (1.13) of [9].

In the announcement [11], where we assumed that the set of constraints K was convex and the geometry was Euclidean, we had defined the numerical scheme by relation (1.16), where P_K was the Euclidean projection on the convex set K.

The boundary ∂K is smooth, and as we expect that for small h, the U^m's will stay close to K, we still have a projection of $(2U^m - (1-e)U^{m-1} + h^2F^m)/(1+e)$ on K, and thus we start from (1.16) to define the numerical scheme.

Let us define

$$W^m = \frac{2U^m - (1-e)U^{m-1} + h^2F^m}{1+e}, \tag{1.18}$$

which will be used in many places in the upcoming proofs. With this definition, (1.16) is rewritten as

$$U^{m+1} = -eU^{m-1} + (1+e)P_K(W^m).$$

Hence, if we define

$$Z^m = \frac{U^{m+1} + eU^{m-1}}{1+e}, \tag{1.19}$$

we find that

$$Z^m = P_K(W^m). \tag{1.20}$$

Another way of writing (1.16) is to define the discrete velocity V^m by

$$V^m = \frac{U^{m+1} - U^m}{h}. \tag{1.21}$$

Then, (1.16) can be rewritten as

$$V^m - V^{m-1} - hF^m = \frac{(1+e)(Z^m - W^m)}{h}. \tag{1.22}$$

A strict contraction argument in $\mathbb{R}^d$ gives the existence of a unique U^m for small values of m and h. As the projections on K and F are only Lipschitz continuous, the iteration of a fixed point argument might request smaller and smaller bounds on the time step h, and there is no guarantee that we could integrate numerically on a time interval bounded from below, for any initial time step size.

Let us outline now the structure of the article and of the proofs. In section 2, we will straighten the boundary, a natural geometrical idea.

While the system (1.3)–(1.6) is nicely transformed under a diffeomorphism, the numerical scheme (1.13), (1.14), (1.16), and (1.17) does not behave well under diffeomorphisms. The reason is that a numerical scheme is not a local object: when we define a discrete velocity by subtracting U^m from U^{m+1}, we use locally a vector structure which is not intrinsic from the point of view of differential geometry. In particular, if we apply a diffeomorphism to the numerical scheme, we will find another numerical scheme which will look much more complicated than the previous one, since it will contain a number of small term which show the lack of an intrinsic description of the scheme. After a very technical proof, we find two constants C_3 and

τ such that for initial data in a neighborhood of a compact subset of the admissible set, and for all small enough h and all $m \leq \tau/h$, the discrete velocity is bounded:

$$\sup |V^m| \leq C_3.$$

Since uniqueness is not true in general [2], [16], and hypotheses of analyticity are often but not always used for the proof of uniqueness [13], [15], [17], [4], [1], the proof of convergence of the numerical approximation is delicate also for this reason.

However, there is a bonus: all the effort made to prove the local convergence of the numerical scheme provides us with a local existence proof for our problem. In section 3 we prove estimates on the discrete acceleration; then in section 4 we establish the variational properties of the limit of the numerical scheme. Sections 5 and 6 are devoted to the study of the transmission of energy at impact and the passage to the limit for the initial conditions. All these results are obtained under the assumption that on a certain time interval starting at t_0, the discrete velocity is bounded independently of the time step.

As a preliminary to the global existence proof, we give a priori estimates on problem (1.3)–(1.9) in section 7, which is completely independent from the remainder of the article.

In section 8, we establish a very weak semicontinuity for the supremum of the local norm of the discrete velocities; this result enables us to obtain a global existence and convergence theorem.

A note on the strategy of proof seems necessary here: an essential device is the straightening of the boundary of K. However, it is not always convenient to work in the straightened coordinates; in particular, whenever we need very precise estimates involving P_K, the physical coordinates are better. This seeming inconsistency in the redaction of our proofs is a compromise whereby we tried to save space without losing clarity.

We present some numerical simulations in section 9: we simulated the dropped bar experiment of Stoianovici and Hurmuzlu [18], using generalized coordinates and therefore a nontrivial mass matrix. We compared the results of our ad hoc scheme to an impact detection method; the reader is referred to the original article [18] for a comparison with the experiments. Much more information on our simulations has been given in [12].

The numerical scheme analyzed here has been implemented in the case of a trivial mass matrix in [8], [7]. Our ad hoc scheme is substantially faster than an impact detection method.

The existence result obtained here is a generalization of [16], [3], [14], [8], [10], and of [6] and [5], who also constructs a solution with the help of a numerical method; however, he does not consider a nonconstant mass matrix.

We refer the reader to the introduction of [9] for more bibliographical references.

2. Existence of $(U^m)_{0 \leq m \leq \lfloor \tau/h \rfloor}$ for some $\tau > 0$. We systematically use the floor and ceiling notations: when r is a real number, the floor $\lfloor r \rfloor$ of r is the largest integer at most equal to r, and the ceiling $\lceil r \rceil$ is the smallest integer at least equal to r.

The main result of this section is the existence of a number $\tau > 0$ such that for all small enough h and all $m \leq \lfloor \tau/h \rfloor$ there exists indeed a discrete solution of (1.16) and (1.17), whose discrete velocity is bounded independently of h. In fact, we prove a stronger result: provided that the first two discrete velocities are bounded, we find a uniform lower bound on τ when the initial position belongs to a neighborhood of a

compact subset of K. As in the one dimensional case [9], the idea is to show the existence by Brouwer's fixed point argument and the uniqueness by local considerations. However, the proof is longer and much more technical: the cost of straightening the boundary is the appearance of a host of supplementary terms of geometrical origin that we have to control. At a crucial point of the proof, we use Lemma 2.1 of [9] to estimate the normal component of the velocity, thereby effectively reducing the N dimensional problem to the one dimensional case.

We say that U^0 and U^1 satisfy condition $E\big(\overline{u}, r_0, C_2, h\big)$ if

$$\big|U^0 - \overline{u}\big| \le r_0, \quad \big|U^1 - \overline{u}\big| \le r_0, \quad \big|U^1 - U^0\big| \le C_2 h, \tag{2.1}$$

and that, moreover, U^2 is uniquely defined in $B(\overline{u}, r_0)$ by

$$\frac{U^2 + eU^0}{1+e} = P_K\left(\frac{2U^1 - (1-e)U^0 + h^2 F^1}{1+e}\right), \tag{2.2}$$

and the following inequalities are satisfied:

$$\big|U^2 - \overline{u}\big| \le r_0, \quad \big|U^2 - U^1\big| \le C_2 h. \tag{2.3}$$

When $\overline{u}$ belongs to ∂K, we need local coordinates in which the projection P_K is particularly simple. They are defined in the following fashion: we choose a coordinate frame in $\mathbb{R}^d$ such that

- $\overline{u} = 0$;
- the tangent hyperplane to ∂K at 0 is the hyperplane of the first $d-1$ coordinates;
- the positive direction of the dth coordinate axis points inside K.

For a d dimensional vector x, we will use the notation

$$x' = (x_1, \dots, x_{d-1}).$$

Locally, ∂K is a graph over the hyperplane of the first $d-1$ coordinates, and it can be parameterized as

$$\chi(x') = \begin{pmatrix} x' \\ H(x') \end{pmatrix},$$

where x' belongs to $\mathbb{R}^{d-1}$, H is of class C^3, and $DH(0)$ vanishes. Let $s \mapsto \psi(s,z)$ be the parameterization of the geodesic starting at $z \in \partial K$ with an initial velocity equal to $-N(z)$ which satisfies

$$\left|\frac{\partial \psi}{\partial s}(s,z)\right|_{\psi(s,z)} = 1. \tag{2.4}$$

Let Ψ be defined by

$$\Psi(x', y) = \psi(-y, \chi(x')); \tag{2.5}$$

the function Ψ is of class C^2 in a neighborhood of 0; its derivative at 0 has the block representation

$$D\Psi(0,0) = \left(\begin{array}{c|c} \mathbf{1}_{d-1} & N(0) \\ 0 & \end{array}\right); \tag{2.6}$$

it is invertible, since $N(0)$ does not belong to the tangent plane at 0 to ∂K. Thus Ψ is a local diffeomorphism from a neighborhood $\mathcal{U}$ of 0 to a neighborhood $\Psi(\mathcal{U})$ of 0. In particular, we may assume that $\mathcal{U}$ contains a compact neighborhood of 0 of the form $\overline{\mathcal{O}} \times [-r_1, r_1]$, where $\mathcal{O}$ is an open neighborhood of 0 in $\mathbb{R}^{d-1}$.

The inverse diffeomorphism of Ψ is denoted by Φ, and we decompose it as

$$\Phi(x) = \begin{pmatrix} S(x) \\ Y(x) \end{pmatrix}, \tag{2.7}$$

where S takes its values in $\mathbb{R}^{d-1}$ and Y takes its values in $\mathbb{R}$. If x belongs to

$$\mathcal{F} = \Psi(\overline{\mathcal{O}} \times [-r_1, r_1]),$$

the projection $P_K(x)$ is given by

$$P_K(x) = \Psi \begin{pmatrix} S(x) \\ Y(x)^+ \end{pmatrix}. \tag{2.8}$$

With these preparations, we are able to prove the main local estimates.

THEOREM 2.1. *For all $\overline{u} \in K$, for all $C_2 > 0$, there exist two positive numbers, $r_1 < r_2$ and three numbers $\tau > 0$, $h_1 > 0$, and $C_3 < \infty$ such that for all $h \in (0, h_1]$ and all $t_0 \in [0, T)$, for all U^0 and U^1, satisfying the condition $E\big(\overline{u}, r_1, C_2, h\big)$, U^m is uniquely defined in $B(\overline{u}, r_2)$, for all $m \le \lfloor \min(\tau, T - t_0)/h \rfloor$, and $|V^m|$ is bounded by C_3 independently of h for $0 \le m \le \lfloor \min(\tau, T - t_0)/h \rfloor - 1$.*

Proof. The theorem decomposes into an easy part and a difficult part. The easy part is when $\overline{u}$ belongs to the interior of K.

First case: $\overline{u} \in \mathbf{int}(K)$. We choose $r_0 > 0$ such that the ball of center $\overline{u}$ and radius $2r_0$ is included in K. Let C_3 be greater than C_2. We define the numbers C_1 and L by

$$\begin{aligned} C_1 = \sup\big\{ |F(t, u, u', 0, h)| : t \in [0, T],\ |u - \overline{u}| \le 2r_0, \\ |u' - \overline{u}| \le 2r_0,\ h \in [0, h^*]\big\}, \end{aligned} \tag{2.9}$$

$$\begin{aligned} L = \sup\Bigg\{ \frac{|F(t, u, u', v, h) - F(t, u, u', v', h)|}{|v - v'|} : t \in [0, T],\ |u - \overline{u}| \le 2r_0, \\ |u' - \overline{u}| \le 2r_0, |v| \le C_3,\ |v'| \le C_3,\ h \in [0, h^*],\ v \ne v' \Bigg\}. \end{aligned} \tag{2.10}$$

We choose $r_1 = r_0/2$ and $r_2 = r_0$. Assume that τ satisfies the following inequalities:

$$\begin{aligned} &\tau\big(C_1 + LC_3 + 2LC_3\tau\big) < C_3 - C_2, \\ &\tau C_3 \le \frac{r_0}{2}, \quad 0 < \tau < T - t_0. \end{aligned} \tag{2.11}$$

Let h_1 be a nonnegative number such that

$$\frac{2h_1 C_3}{1 + e} + \frac{h_1^2}{1 + e}\big(C_1 + LC_3 + 2LC_3\tau\big) < r_0. \tag{2.12}$$

Let U^0, U^1 satisfy the condition $E\big(\overline{u}, r_1, C_2, h\big)$. We claim that for all $h \in (0, h_1]$ we can find a solution of

$$U^{m+1} - 2U^m + U^{m-1} = h^2 F\left(t_m, U^{m-1}, U^m, \big(V^m + V^{m-1}\big)/2, h\right) \tag{2.13}$$

for all $m \in \{1, \dots, \lfloor \tau/h \rfloor - 1\}$ which satisfies the estimates

$$\forall m \in \{0, \dots, \lfloor \tau/h \rfloor\}, \quad |U^m - \overline{u}| \leq r_2, \tag{2.14}$$

$$\forall m \in \{0, \dots, \lfloor \tau/h \rfloor - 1\}, \quad |V^m| \leq C_3. \tag{2.15}$$

In this construction, we seek a solution without considering the constraints, and we prove eventually that they are satisfied.

We will apply Brouwer's fixed point argument in order to prove the existence of a solution of (2.13). Let $h \in (0, h_1]$ and define a compact convex set B_h by

$$B_h = \Big\{ \widehat{U} = (\widehat{U}^m)_{0 \leq m \leq \lfloor \tau/h \rfloor} : \widehat{U}^0 = U^0, \widehat{U}^1 = U^1, \widehat{U}^2 = U^2, \\ \forall m \in \{1, \dots, \lfloor \tau/h \rfloor - 1\}, \quad \left| \widehat{U}^{m+1} - \widehat{U}^m \right| \leq C_3 h \Big\}.$$

Assuming that $\widehat{U}$ belongs to B_h, we define $\widehat{F}$ by

$$\forall m \in \{1, \dots, \lfloor \tau/h \rfloor - 1\}, \qquad \widehat{F}^m = F\left(t_m, \widehat{U}^m, \widehat{U}^{m-1}, \frac{\widehat{U}^{m+1} - \widehat{U}^{m-1}}{2h}, h \right).$$

We write now the numerical scheme

$$\forall m \in \{2, \dots, \lfloor \tau/h \rfloor - 1\}, \qquad U^{m+1} - 2U^m + U^{m-1} = h^2 \widehat{F}^m.$$

Since $\widehat{U}$ belongs to B_h, we estimate $\left| \widehat{F}^m \right|$ by

$$\left| \widehat{F}^m \right| \leq \left| F(t_m, \widehat{U}^0, \widehat{U}^0, 0, h) \right| + L \left(\left| \widehat{U}^m - \widehat{U}^0 \right| + \left| \widehat{U}^{m-1} - \widehat{U}^0 \right| + \left| \frac{\widehat{U}^{m+1} - \widehat{U}^{m-1}}{2h} \right| \right) \\ \leq C_1 + 2LC_3\tau + LC_3.$$

By definition of V^m we have

$$|V^m| = \left| V^{m-1} + h\widehat{F}^m \right| \leq \left| V^{m-1} \right| + h \left| \widehat{F}^m \right|,$$

and by discrete integration

$$|V^m| \leq \left| V^0 \right| + \tau\big(C_1 + 2LC_3\tau + LC_3\big) \leq C_3,$$

thanks to (2.11) and (2.1). Hence U belongs to B_h and the mapping $\widehat{U} \mapsto U$ is clearly continuous, which implies the existence of a fixed point in B_h thanks to Brouwer's fixed point theorem. This fixed point is a solution of (2.13) satisfying (2.15). Moreover, for all $m \in \{0, \dots, \lfloor \tau/h \rfloor\}$ we have

$$|U^m - \overline{u}| \leq \sum_{p=0}^{m-1} h\,|V^p| + \left| U^0 - \overline{u} \right| \leq C_3\tau + r_0/2 \leq r_0$$

thanks to (2.11), and thus (2.14) holds.

Let us prove that the vector W^m defined by (1.18) belongs to K: since

$$W^m - \overline{u} = U^{m-1} + \frac{2h}{1+e} V^{m-1} + \frac{h^2 F^m}{1+e} - \overline{u},$$

we have the estimate

$$|W^m - \overline{u}| \le r_0 + \frac{2hC_3}{1+e} + \frac{h^2}{1+e}\big(C_1 + LC_3 + 2L\tau C_3\big).$$

With (2.12) we infer that W^m belongs to K, and the sequence U^m satisfies (1.16)–(1.17).

Second case: $\overline{u} \in \partial K$. We define on $\mathbb{R}^d$ a norm denoted by $\|\ \|$ as follows:

$$x = \begin{pmatrix} x' \\ x_d \end{pmatrix}, \quad \|x\| = \max\big(|x'|\,, |x_d|\big).$$

Pick $R_1 > 0$ such that Ψ is a diffeomorphism from a closed neighborhood

$$\mathcal{B} = \big\{x : \|x - \Phi(\overline{u})\| \le R_1\big\}$$

to its image and such that $\Psi(\mathcal{B})$ is included in an Euclidean ball $B(\overline{u}, r_0)$ such that P_K is Lipschitz continuous on $B(\overline{u}, 2r_0)$; denote by γ the Lipschitz constant of P_K on $B(\overline{u}, 2r_0)$.

Define Λ by

$$\Lambda = \max\left\{\sup\left\{\frac{|D\Psi(x)x_1|}{\|x_1\|} : x \in \mathcal{B}, x_1 \ne 0\right\}, \sup\left\{\frac{|D\Phi(u)u_1|}{\|u_1\|} : u \in \Psi(\mathcal{B}), u_1 \ne 0\right\}\right\}$$

and

$$C_4 = \max\left\{\sup\left\{\frac{\big|D^2\Psi(x)x_1 \otimes x_2\big|}{2\,\|x_1\|\,\|x_2\|} : x \in \mathcal{B}, x_1 \ne 0, x_2 \ne 0\right\}, \sup\left\{\frac{\big|D^2\Phi(u)u_1 \otimes u_2\big|}{2\,\|u_1\|\,\|u_2\|} : u \in \Psi(\mathcal{B}), u_1 \ne 0, u_2 \ne 0\right\}\right\}.$$

A continuity argument shows that the compact set $\Psi(\mathcal{B})$ contains the ball of radius R_1/Λ about $\overline{u}$.

We will give now a description of the scheme (1.16), (1.17) in the new coordinates. We define

$$X^m = \Phi(U^m).$$

Assume, therefore, that

$$U^{m+1},\ U^m,\ U^{m-1},\ W^m, \text{ and } \frac{U^m + eU^{m-1}}{1+e} \text{ belong to } \Psi(\mathcal{B}). \tag{2.16}$$

We know that (1.16) is equivalent to

$$\frac{U^{m+1} + eU^{m-1}}{1+e} = P_K(W^m). \tag{2.17}$$

We map (2.17) by Φ, and we calculate the Taylor expansion of either side of (2.17) around U^m. The left-hand side of (2.17) can be rewritten as

$$U^m + h\frac{V^m - eV^{m-1}}{1+e},$$

and therefore

$$\Phi\left(U^m + h\frac{V^m - eV^{m-1}}{1+e}\right) = \Phi(U^m) + D\Phi(U^m)h\frac{V^m - eV^{m-1}}{1+e} + I^m, \tag{2.18}$$

where

$$\|I^m\| \le C_4 \left|\frac{h\big(V^m - eV^{m-1}\big)}{1+e}\right|^2.$$

But $U^{m+1} = U^m + hV^m$, so that another Taylor expansion gives

$$\Phi\big(U^{m+1}\big) = \Phi(U^m) + D\Phi(U^m)hV^m + \widehat{I}^m$$

with

$$\left\|\widehat{I}^m\right\| \le C_4 \left|hV^m\right|^2.$$

Thus

$$D\Phi(U^m)hV^m = \Phi(U^{m+1}) - \Phi(U^m) - \widehat{I}^m. \tag{2.19}$$

A similar calculation gives

$$-D\Phi(U^m)hV^{m-1} = \Phi(U^{m-1}) - \Phi(U^m) - \widetilde{I}^m, \tag{2.20}$$

with

$$\left\|\widetilde{I}^m\right\| \le C_4 \left|hV^{m-1}\right|^2.$$

If we substitute (2.19) and (2.20) into (2.18), we find that

$$\Phi\big((U^{m+1} + eU^{m-1})/(1+e)\big) = \frac{X^{m+1} + eX^{m-1}}{1+e} - \frac{\overline{I}^m}{1+e},$$

where

$$\overline{I}^m = \widehat{I}^m + e\widetilde{I}^m - (1+e)I^m,$$

and we have the estimate

$$\left\|\overline{I}^m\right\| \le C_4 h^2\big(|V^m|^2 + e\left|V^{m-1}\right|^2 + (1+e)^{-1}\left|V^m - eV^{m-1}\right|^2\big). \tag{2.21}$$

Consider now the right-hand side of (2.17). By definition of V^{m-1}, we have the identity

$$W^m = U^m + \frac{(1-e)hV^{m-1} + h^2F^m}{1+e}, \tag{2.22}$$

and a Taylor expansion gives

$$\Phi(W^m) = \Phi(U^m) + D\Phi(U^m)\frac{(1-e)hV^{m-1} + h^2F^m}{1+e} + J^m, \tag{2.23}$$

with

$$\|J^m\| \le C_4 \left| \frac{(1-e)hV^{m-1} + h^2 F^m}{1+e} \right|^2.$$

We substitute (2.20) into (2.23), and we obtain

$$\Phi(W^m) = \frac{2X^m - (1-e)X^{m-1} + h^2 D\Phi(U^m)F^m}{1+e} + \frac{\overline{J}^m}{1+e},$$

where

$$\overline{J}^m = (1+e)J^m + (1-e)\widetilde{I}^m,$$

so that

$$\left\|\overline{J}^m\right\| \le C_4 \left[\frac{\left|(1-e)hV^{m-1} + h^2 F^m\right|^2}{1+e} + (1-e)h^2 \left|V^{m-1}\right|^2 \right].$$

We have to estimate $\|\overline{I}^m\| + \|\overline{J}^m\|$; by elementary inequalities,

$$\left\|\overline{I}^m\right\| + \left\|\overline{J}^m\right\| \le C_4 h^2 \left[\frac{2(1-e)^2 \left|V^{m-1}\right|^2 + 2h^2 \left|F^m\right|^2}{1+e} \right.$$
$$\left. + (1-e)\left|V^{m-1}\right|^2 + \left|V^m\right|^2 + e\left|V^{m-1}\right|^2 + \frac{2\left|V^m\right|^2 + 2e^2\left|V^{m-1}\right|^2}{1+e} \right].$$

The coefficient of $\left|V^{m-1}\right|^2$ in the above bracket is

$$\frac{2(1-e)^2}{1+e} + 1 + \frac{2e^2}{1+e},$$

and since for $e \in [0,1]$, $(1-e)^2 \le 1-e^2$, this coefficient is at most equal to 3. The coefficient of $|V^m|^2$ in the same bracket is equal to $1+2/(1+e)$, which is also at most equal to 3. Therefore

$$\left\|\overline{I}^m\right\| + \left\|\overline{J}^m\right\| \le C_4 h^2 \left[3\left|V^m\right|^2 + 3\left|V^{m-1}\right|^2 + 2h^2\left|F^m\right|^2\right]. \tag{2.24}$$

Thanks to the properties of P_K,

$$\Phi\left(\frac{U^{m+1} + eU^{m-1}}{1+e}\right) = \Phi(P_K W^m) = \begin{pmatrix} S(W^m) \\ Y(W^m)^+ \end{pmatrix}. \tag{2.25}$$

Define

$$s^m = S(U^m) = \left[X^m\right]', \quad y^m = Y(U^m) = X_d^m.$$

In these new coordinates, we have

$$s^{m+1} - 2s^m + s^{m-1} = h^2 \kappa^m, \tag{2.26}$$

$$y^{m+1} + ey^{m-1} - \left(2y^m - (1-e)y^{m-1}\right)^+ = h^2 \lambda^m, \tag{2.27}$$

and κ^m and λ^m are given by

$$\begin{aligned} h^2\kappa^m &= \left[h^2 D\Phi(U^m)F^m + \overline{I}^m + \overline{J}^m\right]', \\ h^2\lambda^m &= \left[2y^m - (1-e)y^{m-1} + \left(h^2 D\Phi(U^m)F^m + \overline{J}^m\right)_d\right]^+ \\ &\qquad - \left(2y^m - (1-e)y^{m-1}\right)^+ + \overline{I}^m_d. \end{aligned}$$

Therefore, we have the estimates:

$$\max\left(|\kappa^m|, |\lambda^m|\right) \le \Lambda |F^m| + C_4\left(3|V^m|^2 + 3\left|V^{m-1}\right|^2 + 2h^2|F^m|^2\right). \tag{2.28}$$

We define ξ^m and ζ^m by

$$\xi^m = \begin{pmatrix} \sigma^m \\ \eta^m \end{pmatrix} = \frac{X^{m+1} - X^m}{h}, \quad \zeta^m = \begin{pmatrix} \kappa^m \\ \lambda^m \end{pmatrix}.$$

Now let q be a number which satisfies

$$q > \Lambda C_2.$$

Let $C_3 = \Lambda q$, and let C_1 and L be, respectively, as in (2.9) and (2.10). If we assume beyond (2.16) that

$$\max\left(\left|V^{m-1}\right|, |V^m|\right) \le C_3, \tag{2.29}$$

we have the estimate

$$|F^m| \le C_1 + L\left(|V^m| + \left|V^{m-1}\right|\right)/2;$$

by elementary inequalities,

$$|F^m|^2 \le 2C_1^2 + L^2\left(|V^m|^2 + \left|V^{m-1}\right|^2\right),$$

and therefore, if we define

$$C_5 = \frac{\Lambda}{2} + C_1^2\left(\Lambda + 4h_1^2 C_4\right), \quad C_6 = \left(\left(\frac{\Lambda}{2} + 2h_1^2 C_4\right)L^2 + 3C_4\right)\Lambda^2,$$

we have shown that under assumptions (2.16) and (2.29), the following inequality holds:

$$\|\zeta^m\| \le C_5 + C_6\left(\|\xi^m\|^2 + \left\|\xi^{m-1}\right\|^2\right). \tag{2.30}$$

Let τ be a number which satisfies the following inequalities:

$$\begin{aligned} &\Lambda C_2 + 2\tau(C_5 + 2C_6 q^2) < q, \\ &\tau q < R_1/3\Lambda^2, \quad 0 < \tau < T - t_0. \end{aligned} \tag{2.31}$$

Let h_1 be a nonnegative number such that

$$\max\left(\frac{1-e}{1+e}\Lambda q h_1 + \frac{h_1^2}{1+e}(C_1 + L\Lambda q), h_1 q\right) < \frac{R_1}{3\Lambda}. \tag{2.32}$$

We will prove that, for all $h \in (0, h_1]$ and all $t_0 \in [0, T)$, for all U^0, U^1 satisfying the condition $E\big(\overline{u}, r_1, C_2, h\big)$ with $r_1 = R_1/3\Lambda^3$, U^m is uniquely defined in $B(\overline{u}, r_2)$, for all $m \le \lfloor \tau/h \rfloor$ with $r_2 = 2R_1/3\Lambda$, and $|V^m|$ is bounded by C_3 for $0 \le m \le \lfloor \tau/h \rfloor - 1$.

We will apply once again Brouwer's fixed point argument. Let $h \in (0, h_1]$ and define a compact convex set B_h by

$$B_h = \Big\{ \widehat{X} = (\widehat{X}^m)_{0 \le m \le \lfloor \tau/h \rfloor} : \widehat{X}^0 = \Phi(U^0), \widehat{X}^1 = \Phi(U^1), \widehat{X}^2 = \Phi(U^2), \\ \forall m \in \{1, \dots, \lfloor \tau/h \rfloor - 1\}, \quad \Big\| \widehat{X}^{m+1} - \widehat{X}^m \Big\| \le qh \Big\}.$$

Let $\widehat{X}$ be in B_h. Since $\Lambda \ge 1$ and U^0, U^1 satisfy the condition $E\big(\overline{u}, r_1, C_2, h\big)$, we have

$$\{U^0, U^1, U^2\} \subset B(\overline{u}, r_1) \subset B(\overline{u}, R_1/\Lambda) \subset \Psi(\mathcal{B}),$$

and for all $m \in \{3, \dots, \lfloor \tau/h \rfloor\}$ we have

$$\begin{aligned} \Big\| \widehat{X}^m - \Phi(\overline{u}) \Big\| &\le \Big\| \widehat{X}^m - \widehat{X}^0 \Big\| + \Big\| \widehat{X}^0 - \Phi(\overline{u}) \Big\| \\ &\le \tau q + \Lambda \big| U^0 - \overline{u} \big| \le \frac{2R_1}{3\Lambda^2} < R_1. \end{aligned} \tag{2.33}$$

It follows that $\widehat{X}^m$ belongs to $\mathcal{B}$ for all $m \in \{0, \dots, \lfloor \tau/h \rfloor\}$. For all $m \in \{3, \dots, \lfloor \tau/h \rfloor\}$ we define

$$U^m = \Psi(\widehat{X}^m).$$

We clearly have $U^m \in \Psi(\mathcal{B})$ for all $m \in \{0, \dots, \lfloor \tau/h \rfloor\}$ and

$$\big| U^{m+1} - U^m \big| = \Lambda \Big\| \widehat{X}^{m+1} - \widehat{X}^m \Big\| \le \Lambda q h \le C_3 h.$$

Hence we have the following estimate:

$$|F^m| \le C_1 + \frac{L}{2} \big(|V^m| + \big| V^{m-1} \big| \big) \le C_1 + L\Lambda q.$$

Using (2.22) we infer that

$$\begin{aligned} |W^m - \overline{u}| &\le |U^m - \overline{u}| + \left| \frac{(1-e)hV^{m-1} + h^2 F^m}{1+e} \right| \\ &\le \Lambda \Big\| \widehat{X}^m - \Phi(\overline{u}) \Big\| + \frac{(1-e)h}{1+e} \Lambda q + \frac{h^2}{1+e} (C_1 + L\Lambda q) \le \frac{R_1}{\Lambda}, \end{aligned}$$

thanks to (2.32) and (2.33). Moreover,

$$\left| \frac{U^{m+1} + eU^{m-1}}{1+e} - \overline{u} \right| \le |U^m - \overline{u}| + h \left| \frac{V^m - eV^{m-1}}{1+e} \right|$$

and (2.32) and (2.33) also imply that

$$\left| \frac{U^{m+1} + eU^{m-1}}{1+e} - \overline{u} \right| \le \Lambda \Big\| \widehat{X}^m - \Phi(\overline{u}) \Big\| + hq \le \frac{R_1}{\Lambda}.$$

Consequently assumption (2.16) is satisfied and we define I^m, $\widehat{I}^m$, $\widetilde{I}^m$, and J^m as in (2.18), (2.19), (2.20), and (2.23). We now write the numerical scheme (2.26)–(2.27) and define $(X^m)_{0\leq m\leq \lfloor \tau/h\rfloor}$ by

$$X^0=\widehat{X}^0,\ X^1=\widehat{X}^1,\ X^2=\widehat{X}^2,\quad \text{and,}\quad \text{for } 3\leq m\leq \lfloor \tau/h\rfloor,\quad X^m=\begin{pmatrix} s^m\\ y^m\end{pmatrix}.$$

It should be remarked that if the mapping $\widehat{X}\mapsto X$ possesses a fixed point X in B_h, then $U=\Psi(X)$ is precisely the numerical solution sought here. Using (2.30) we have the following estimate:

$$\|\zeta^m\|\leq C_5+C_6\left(\left\|\widehat{\xi}^m\right\|^2+\left\|\widehat{\xi}^{m-1}\right\|^2\right)\leq C_5+2C_6q^2.$$

Let us estimate now the discrete velocity $\|\xi^m\|$. By definition of σ^m we have

$$|\sigma^m|\leq \left|\sigma^{m-1}\right|+h\left\|\zeta^m\right\|.$$

For the normal component η^m, we apply Lemma 2.1 of the companion paper [9] and get

$$|\eta^m|\leq \max\left(\left|\eta^{m-1}\right|,e\left|\eta^{m-2}\right|\right)+h\left\|\zeta^m\right\|+h\left\|\zeta^{m-1}\right\|.$$

It follows that

$$\|\xi^m\|\leq \max\left(\left\|\xi^{m-1}\right\|,e\left\|\xi^{m-2}\right\|\right)+h\left\|\zeta^m\right\|+h\left\|\zeta^{m-1}\right\| \tag{2.34}$$

and thus

$$\|\xi^m\|\leq \max\left(\left\|\xi^{m-1}\right\|,\left\|\xi^{m-2}\right\|\right)+2h(C_5+2C_6q^2).$$

By discrete integration we obtain

$$\|\xi^m\|\leq \max\left(\left\|\xi^{1}\right\|,\left\|\xi^{0}\right\|\right)+2\tau(C_5+2C_6q^2),$$

and we have

$$\max\left(\left\|\xi^{1}\right\|,\left\|\xi^{0}\right\|\right)\leq \Lambda\max\left(\left|\frac{U^1-U^0}{h}\right|,\left|\frac{U^2-U^1}{h}\right|\right)\leq \Lambda C_2.$$

Hence (2.31) implies that X belongs to B_h. The mapping $\widehat{X}\mapsto X$ is clearly continuous and Brouwer's fixed point theorem implies the existence of a fixed point in B_h.

We prove uniqueness in both cases by local considerations. Given U^{m-1} and U^m, the discrete velocity V^m is a fixed point of the mapping

$$\begin{aligned} v\mapsto h^{-1}\Bigg[&-eU^{m-1}-U^m\\ &+(1+e)P_K\left(\frac{2U^m-(1-e)U^{m-1}+h^2F(t_m,U^m,U^{m-1},(v+V^{m-1})/2h,h)}{1+e}\right)\Bigg].\end{aligned}$$

The Lipschitz constant of this mapping is $h\gamma L/2$, and therefore if $h_1<2/(\gamma L)$, the uniqueness of V^m is guaranteed. ∎

The next lemma establishes the existence of U^2 under appropriate assumptions on U^0 and U^1.

LEMMA 2.2. *For all $(t_0, u_0, p_0) \in \mathbb{D}$, define $v_0 = M(u_0)^{-1}p_0$; then for all U^1 satisfying* (1.14) *and for all small enough h, there exists a unique solution U^2 of* (1.16) *for $m = 1$ satisfying*

$$\left|U^2 - U^1\right|_{u_0} \leq 3|v_0|_{u_0}h + h.$$

Proof. Let $r > 0$ be such that P_K is Lipschitz continuous on

$$B_{u_0}(u_0, r) = \left\{u \in \mathbb{R}^d : |u - u_0|_{u_0} \leq r\right\}.$$

Define $\widetilde{C}_1$ by

$$\widetilde{C}_1 = \max\Big\{ |F(t, u, u', 0, h)|_{u_0} : t \in [0, T],\ |u - u_0|_{u_0} \leq r,\\ |u' - u_0|_{u_0} \leq r,\ h \in [0, h^*]\Big\},$$

and let $\widetilde{L}$ be the Lipschitz constant defined by

$$\widetilde{L} = \sup\left\{ \frac{|F(t, u, u', v, h) - F(t, u, u', v', h)|_{u_0}}{|v - v'|_{u_0}} : |u' - u_0|_{u_0} \leq r,\ |u' - u_0|_{u_0} \leq r,\right.\\ \left. |v|_{u_0} \leq 2\,|v_0|_{u_0} + 1,\ |v'|_{u_0} \leq 2\,|v_0|_{u_0} + 1,\ v \neq v',\ h \in [0, h^*]\right\}.$$

Finally, let $\widetilde{\gamma}$ be the Lipschitz constant of P_K defined by

$$\widetilde{\gamma} = \sup\left\{ \frac{|P_K u - P_K u'|_{u_0}}{|u - u'|_{u_0}} : |u - u_0|_{u_0} \leq r,\ |u - u_0|_{u_0} \leq r,\ u \neq u' \right\}.$$

There exists a function $z(t)$ which is bounded in a neighborhood of 0 such that for small positive values of t

$$P_K(u_0 + tv_0) = u_0 + tv_0 + t^2 z(t); \tag{2.35}$$

indeed, if v_0 vanishes, or if u_0 belongs to $\mathrm{int}(K)$, or if u_0 belongs to ∂K and the scalar product $\langle v_0, N(u_0)\rangle_{u_0}$ is strictly positive, z vanishes; if u_0 belongs to ∂K and $\langle v_0, N(u_0)\rangle_{u_0}$ vanishes, while v_0 does not vanish, (2.35) is a consequence of the smoothness of $P_{\partial K}$ in a neighborhood of u_0. For the values of t for which $u_0 + tv_0$ belongs to K, z vanishes; for the values of t for which $u_0 + tv_0$ does not belong to K, a Taylor expansion shows that

$$P_{\partial K}(u_0 + tv_0) = u_0 + tv_0 + O(t^2)$$

and hence (2.35). With the change of variable $v = (U^2 - U^0)/h$, (1.16) is equivalent to $v = G(v)$, where the function G is defined by

$$G(v) = \frac{1 + e}{h}\left[P_K\left(U^0 + \frac{2h}{1 + e}V^0 + \frac{h^2}{1 + e}F\left(t_1, U^1, U^0, v, h\right)\right) - U^0\right].$$

Let us check that G is a strict contraction on $B_{u_0}\big(0, 2\,|v_0|_{u_0} + 1/2\big)$. If $|v|_{u_0} \leq 2\,|v_0|_{u_0} + 1/2$, for h small enough, we can use the definitions of $\widetilde{L}$ and $\widetilde{C}_1$:

$$\left|F\left(t_1, U^1, U^0, v, h\right)\right|_{u_0} \leq \widetilde{C}_1 + \widetilde{L}\big(2\,|v_0|_{u_0} + 1/2\big). \tag{2.36}$$

We estimate $G(v)$ as follows: by the triangle inequality and the Lipschitz condition on P_K,

$$|G(v)|_{u_0} \leq \frac{1+e}{h}\widetilde{\gamma}\left|\frac{2h\big(V^0-v_0\big)}{1+e}+\frac{h^2}{1+e}F^1\right|_{u_0}+\frac{1+e}{h}\left|P_K\left(u_0+\frac{2hv_0}{1+e}\right)-U^0\right|_{u_0}.$$

We apply (2.35), (1.14), and (2.36), and we find that

$$|G(v)|_{u_0} \leq \widetilde{\gamma}\Big[2\,|z(h)|_{u_0}+h\big(\widetilde{C}_1+2\widetilde{L}\,|v_0|_{u_0}+\widetilde{L}\big)\Big]+2\,|v_0|_{u_0}+\frac{4h}{1+e}\left|z\left(\frac{2hv_0}{1+e}\right)\right|_{u_0}.$$

Therefore, for h small enough, G maps $B_{u_0}\big(0,2\,|v_0|_{u_0}+1/2\big)$ to itself. Moreover, the Lipschitz constant of G on this ball is at most equal to $\widetilde{\gamma}\widetilde{L}h$. This proves that G has a fixed point in $B_{u_0}\big(0,2\,|v_0|_{u_0}+1/2\big)$ for small enough values of h. We set $U^2=U^0+hv$, where v is the fixed point of G in $B_{u_0}\big(0,2\,|v_0|_{u_0}+1/2\big)$. Then it is clear that, for h small enough,

$$\big|(U^2-U^1)/h\big|_{u_0} \leq 2|v_0|_{u_0}+1/2+\big|(U^1-U^0)/h\big|_{u_0},$$

and the lemma is proved. □

If we put together Theorem 2.1 and Lemma 2.2, we obtain a local existence result for the scheme.

THEOREM 2.3. *For all $(t_0,u_0,M(u_0)v_0)\in\mathbb{D}$, for all U^1 satisfying* (1.14)*, there exist $\tau>0$, $C_3<\infty$, and $h_1>0$ such that for all $h\in(0,h_1]$, there exists a unique solution of* (1.16) *and* (1.17) *for all $m\leq\lfloor\tau/h\rfloor-1$, which satisfies the estimate*

$$\forall l\leq\lfloor\tau/h\rfloor,\quad \big|V^l\big|\leq C_3. \tag{2.37}$$

Proof. Let us check that U^0 and U^1 satisfy condition $E(u_0,r_1,C_2,h)$. Lemma 2.2 and assumption (1.14) on U^1 imply that

$$\big|U^1-u_0\big|_{u_0}\leq h\big(|z(h)|_{u_0}+|v_0|_{u_0}\big)$$

and

$$\big|U^2-u_0\big|_{u_0}\leq h\big(2\,|v_0|_{u_0}+1/2\big).$$

Choose $C_2\geq\big(3\,|v_0|_{u_0}+2\big)\,\big\|M(u_0)^{-1/2}\big\|$; U^0 and U^1 satisfy condition $E(u_0,r_1,C_2,h)$ for small enough values of h. Then it is clear that Theorem 2.1 applies. □

It is convenient to give a uniformized version of Theorem 2.1.

THEOREM 2.4. *For all compact subsets $\mathcal{C}$ of K, for all $C_2>0$, there exist positive numbers r_1, $r_2>r_1$, τ, C_3, and h_1 such that for all $t_0\in[0,T)$, for all $\overline{u}\in\mathcal{C}$, for all $h\leq h_1$, and for all U^0 and U^1 satisfying condition $E(\overline{u},r_1,C_2,h)$, relations* (1.16) *and* (1.17) *define uniquely in the ball $B(\overline{u},r_2)$ under condition* (2.37) *the vectors U^m for $2\leq m\leq\lfloor\min(\tau,T-t_0)/h\rfloor$.*

Proof. Let C_2 be a strictly positive number. Any element u of $\mathcal{C}$ is included in an open ball $\mathrm{int}(B(u,r_1(u)))$ such that Theorem 2.1 holds. We cover $\mathcal{C}$ by a finite number of balls $\mathrm{int}(B(u_j,r_1(u_j)/2))$ with associated numbers $r_2(u_j)$, $\tau(u_j)$, $h_1(u_j)$, and $C_3(u_j)$. If we let

$$r_1=\frac{1}{2}\min\{r_1(u_j):1\leq j\leq J\},$$

then any $\overline{u} \in \mathcal{C}$ belongs to a ball $B(u_j, r_1(u_j)/2)$, and in particular $B(\overline{u}, r_1)$ is included in $B(u_j, r_1(u_j))$. If we take

$$\tau = \min_j \tau(u_j),\ r_2 = \max_j r_2(u_j), \quad h_1 = \min_j h_1(u_j),\ C_3 = \max_j C_3(u_j),$$

it is immediate that the theorem holds, thanks to Theorem 2.1. □

3. Estimates on the acceleration. In this section and the three following ones, we assume that there exist strictly positive numbers τ, C_3, and h_1, and a subsequence of time steps to which correspond solutions of the numerical scheme defined by (1.13), (1.14), (1.16), and (1.17), which satisfy the estimate, for all $h \le h_1$,

$$\forall l \in \{0, \dots, P-1\}, \quad \left|U^{l+1} - U^l\right| \le C_3 h, \tag{3.1}$$

where $P = \lfloor \min(\tau, T - t_0)/h \rfloor$. Here we estimate the discrete total variation of the sequence $\left(V^m\right)_m$. It is also convenient to define the function $w_h(t)$ on $[t_0, t_0 + \tau]$ by

$$\begin{aligned} &w_h(t_m) = W^m, \quad w_h \text{ is continuous and it is affine} \\ &\text{on each interval } [t_m, t_{m+1}) \text{ and constant on } [t_P, t_0 + \tau]. \end{aligned}$$

THEOREM 3.1. *Under assumption* (3.1)*, there exists a constant* C_7 *such that for all* $h \le h_1$

$$\sum_{m=1}^{P-1} \left|V^m - V^{m-1}\right| \le C_7. \tag{3.2}$$

Proof. The idea of the proof is exactly the same as in section 4 of [9], up to geometric complications.

Let $\mathcal{C}$ be the compact set $K \cap B(u_0, C_3\tau)$ and let r_1 be as in Theorem 2.4; cover $\mathcal{C}$ with a finite number of balls $B(u_j, r_1/4)$; observe that, thanks to the Ascoli–Arzelá theorem, the set $\mathcal{W}$ of functions $(w_h)_{0<h_1\le h}$ is relatively compact in $C^0([t_0, t_0 + \tau])$. The set of limit points of $(w_h)_{0<h\le h_1}$ as h tends to 0 is also a compact set, which we shall denote by $\mathcal{W}_\infty$. There exists a finite subset $w^1, \dots, w^I$ of $\mathcal{W}_\infty$ such that

$$\forall w \in \mathcal{W}_\infty \quad \inf\{\|w - w^i\|_{C^0[t_0, t_0+\tau]} : 1 \le i \le I\} \le r_1/4.$$

For each $i \in \{1, \dots, I\}$, it is possible to find a finite increasing sequence of times

$$0 = \tau(i,0) < \cdots < \tau(i,k) < \cdots < \tau(i, \kappa(i)) = \tau$$

such that

$$w^i([t_0 + \tau(i,k), t_0 + \tau(i,k+1)]) \subset B\big(u_{j(i,k)}, r_1/4\big).$$

Thus, for all $w \in \mathcal{W}_\infty$, there exists $i \in \{1, \dots, I\}$ such that for all $k \in \{0, \dots, \kappa(i) - 1\}$,

$$w([t_0 + \tau(i,k), t_0 + \tau(i,k+1)]) \subset B\big(u_{j(i,k)}, r_1/2\big).$$

Therefore, we can decrease h_1 so that

$$\begin{aligned} &\forall h \in (0, h_1], \quad \exists i \in \{1, \dots, I\}, \quad \forall k \in \{1, \dots, \kappa(i) - 1\}, \\ &\forall t \in [t_0 + \tau(i,k), t_0 + \tau(i,k+1)] \quad w_h(t) \in B\big(u_{j(i,k)}, 3r_1/4\big), \end{aligned}$$

and thanks to (2.22) and to (3.1), we can decrease h_1 such that

$$\forall h \in (0, h_1], \quad \exists i \in \{1, \dots, I\}, \quad \forall k \in \{1, \dots, \kappa(i) - 1\},$$
$$\forall l \in \{\lfloor \tau(i,k)/h \rfloor, \dots, \lfloor \tau(i,k+1)/h \rfloor\}, \quad U^l \in B\big(u_{j(i,k)}, r_1\big).$$

We simplify the notations by letting

$$P = \lfloor \tau(i,k)/h \rfloor, \quad Q = \lfloor \tau(i,k+1)/h \rfloor,$$

and we take C_1 as in (2.9), where $\overline{u}$ is set equal to $u_{j(i,k)}$, r_0 is set equal to r_1, and C_3 is set equal to C_3.

Now, we have to consider two cases.

First case: $B(\overline{u}, r_1) \cap \partial K = \emptyset$. We have the inequality

$$|F^m| \le C_1 + LC_3; \tag{3.3}$$

hence, thanks to (1.16), we have the inequality

$$\big|V^m - V^{m-1}\big| \le h\big(C_1 + LC_3\big),$$

and therefore

$$\sum_{m=P+1}^{Q} \big|V^m - V^{m-1}\big| \le \big(\tau(i,k+1) + 2h - \tau(i,k)\big)\big(C_1 + LC_3\big). \tag{3.4}$$

Second case: $B(\overline{u}, r_1) \cap \partial K \neq \emptyset$. We observe that, thanks to (2.30), we have the estimate

$$\forall m \in \{P+1, \dots, Q-1\}, \quad \max\big(|\kappa^m|, |\lambda^m|\big) \le C_9, \tag{3.5}$$

where

$$C_9 = C_5 + 2C_6\Lambda^2 C_3^2.$$

The estimates on the first $d-1$ components of the velocity in the straightened coordinates are immediate:

$$\sum_{m=P+1}^{Q-1} \left| \frac{s^{m+1} - s^m}{h} - \frac{s^m - s^{m-1}}{h} \right| \le \big(\tau(i,k+1) + 2h - \tau(i,k)\big)C_9. \tag{3.6}$$

In order to estimate the last coordinate we use the same idea as in the one dimensional case (see Theorem 3.1 [9]). We observe that

$$\eta^m - \eta^{m-1} = h\lambda^m + \big(2y^m - (1-e)y^{m-1}\big)^-/h \tag{3.7}$$

and therefore, by the triangle inequality,

$$\big|\eta^m - \eta^{m-1}\big| \le hC_9 + \big(2y^m - (1-e)y^{m-1}\big)^-/h,$$

and using (3.7) again,

$$\big|\eta^m - \eta^{m-1}\big| \le 2hC_9 + \eta^m - \eta^{m-1}.$$

We have the elements of a telescoping sum and we obtain

$$\sum_{m=P+1}^{Q-1} \left|\eta^m - \eta^{m-1}\right| \leq 2C_9 h(Q-P) + 2C_3\Lambda.$$

Summarizing this relation with (3.6), we can see that

$$\sum_{m=P+1}^{Q} \left|V^m - V^{m-1}\right| \leq \Lambda C_9\big(3\tau(i,k+1) - 3\tau(i,k) + 6h\big) + 2C_3\Lambda^2. \tag{3.8}$$

Relations (3.4) and (3.8) do not depend on $h \leq h_1$; since we have only a finite number of these estimates, the theorem is proved. □

4. Variational properties of the limit of the numerical scheme. In this section, we work under the assumption (3.1). Recall that $P = \lfloor \tau/h \rfloor$. We define a function u_h by affine interpolation as follows:

$$\begin{cases} u_h(t) = U^m + (t - t_0 - mh)\dfrac{U^{m+1} - U^m}{h} \\ \qquad\qquad \text{for } t - t_0 \in [mh, (m+1)h\big),\ 0 \leq m \leq P-1, \\ u_h(t) = U^P \quad \text{for } t - t_0 \in [Ph, \tau]. \end{cases} \tag{4.1}$$

We also define a measure F_h as the following sum of Dirac masses:

$$F_h(t) = \sum_{m=1}^{P-1} hF^m \delta(t - t_0 - mh). \tag{4.2}$$

In this section we prove that the sequence $(u_h)_h$ converges in an appropriate sense to a function u which satisfies (1.3) to (1.5b) with τ instead of $\overline{\tau}$. We delay the proof of (1.6), the transmission condition at impacts, to a later section.

As in the one dimensional case there are three steps in the convergence proof: the first is to prove that the limit u exists in an appropriate sense and takes its values in K; in the second step, we show that $\dot{u}_h$ is of bounded variation uniformly in h and that F_h converges to $M(u)^{-1} f(\cdot, u, M(u)\dot{u})$ weakly in the space of $\mathbb{R}^d$-valued measures. The last step is the characterization of the measure $\mu = M(u)\ddot{u} - f(\cdot, u, M(u)\dot{u})$: there we show that μ satisfies conditions (1.4a), (1.4b), and (1.4c). The main ideas of the proofs are the same as in the one dimensional case; we will essentially give the differences in the proofs.

LEMMA 4.1. *From all sequence of functions $(u_h)_h$ indexed by a sequence h tending to 0, it is possible to extract a subsequence, still denoted by $(u_h)_h$ such that*

$$u_h \to u \quad \textit{in } C^0([t_0, t_0+\tau]) \textit{ strong}, \tag{4.3}$$

$$\dot{u}_h \to \dot{u} \quad \textit{in } L^\infty([t_0, t_0+\tau]) \textit{ weak } *. \tag{4.4}$$

The function u takes its values in K.

Proof. We generalize the proof of Lemma 5.1 of [9], as follows: instead of (5.5), we have for all m belonging to $\{1, \ldots, P-1\}$

$$Z^m = \frac{U^{m+1} + eU^{m-1}}{1+e} = U^m + h\frac{V^m - eV^{m-1}}{1+e}; \tag{4.5}$$

hence $U^m = Z^m - h(V^m - eV^{m-1})/(1+e)$. By definition of the scheme, we have $Z^m = P_K(W^m)$ (see (1.20)), and thus Z^m belongs to K. It follows that, for all $m \in \{1, \dots, P-1\}$, the Euclidean distance between U^m and K can be estimated as follows:

$$\min\big\{|U^m - u| : u \in K\big\} \le h\left|V^m - eV^{m-1}\right|/(1+e) \le hC_3. \qquad \square \tag{4.6}$$

The next lemma describes the convergence of the measures involved in our problem; we denote by $M^1\big((t_0, t_0+\tau)\big)$ the space of bounded measures over $(t_0, t_0+\tau)$ with values in $\mathbb{R}^d$.

LEMMA 4.2. *The measures $\ddot{u}_h$ and F_h converge weakly $*$ in $M^1\big((t_0, t_0+\tau)\big)$, respectively, to $\ddot{u}$ and $M(u)^{-1}f(\cdot, u, M(u)\dot{u})$.*

Proof. The proof is a direct generalization of the proof of Lemma 5.2 of [9]; the only modifications are the following: η^m is replaced by V^m and $f(t, u, \dot{u})$ is replaced by $M(u)^{-1}f(t, u, M(u)\dot{u})$. $\square$

Let us prove now that the measure μ has the required variational properties.

LEMMA 4.3. *The measure μ satisfies properties* (1.4a), (1.4b), *and* (1.4c).

Proof. The measure

$$\mu_h = M(u_h)\big(\ddot{u}_h - F_h\big)$$

is a sum of Dirac measures on $(t_0, t_0+\tau)$ given by

$$\mu_h = \sum_{m=1}^{P-1} M(U^m)\big(V^m - V^{m-1} - hF^m\big)\delta(t - t_0 - mh) - M\big(U^P\big)V^{P-1}\delta(t - t_0 - Ph)$$

and it converges to $\mu = M(u)\ddot{u} - f(\cdot, u, p)$ weakly $*$ in $M^1\big((t_0, t_0+\tau)\big)$. The proof of property (1.4a) is analogous to the proof of property (1.3a) of the companion paper (Lemma 5.3. of [9]).

The foregoing proof is precisely the one where one would be tempted to use straightened coordinates; however, this is an inefficient choice, because of the simplicity of (1.22) in the original coordinates.

Assume now that $u_1 = u(t_1)$ belongs to ∂K, and let $B(u_1, r_1)$ be a ball having the properties of Theorem 2.1; assume that the image of (τ_1, τ_2) by u_h and w_h is included in this ball for all small enough h. We rewrite conditions (1.4b) and (1.4c) as follows: for all continuous function ψ with compact support included in $(t_0, t_0+\tau)$ and taking its values in $\mathbb{R}^d$ the following implication holds:

$$\forall t \in (t_0, t_0+\tau), \quad d\phi(u(t))\psi(t) \ge 0 \Longrightarrow \langle \mu, \psi \rangle \ge 0. \tag{4.7}$$

The reader will check the equivalence of (1.4b) and (1.4c) with (4.7). We infer from relation (4.6) that

$$|Y(U^m)| \le \Lambda h C_3;$$

therefore, there exists a constant C_{10} such that

$$|Y(W^m)| \le hC_{10}.$$

Since (4.7) is local, it is enough to check it in the neighborhood of any $t_1 \in (t_0, t_0+\tau)$. Let

$$P = \lceil \tau_1/h \rceil, \quad Q = \lfloor \tau_2/h \rfloor,$$

and

$$\mathcal{P} = \big\{ m \in \{P, \dots, Q\} : W^m \notin K \big\}, \quad \mathcal{P}' = \{P, \dots, Q\} \setminus \mathcal{P}.$$

We observe that if m belongs to $\mathcal{P}'$, then

$$V^m - V^{m-1} - hF^m = 0.$$

Therefore, we have the identity

$$\begin{aligned} &\sum_{m=P}^{Q} \langle V^m - V^{m-1} - hF^m, \psi(t_m) \rangle_{U^m} \\ &\quad = \sum_{m \in \mathcal{P}} \langle V^m - V^{m-1} - hF^m, \psi(t_m) \rangle_{U^m}. \end{aligned}$$

We recall relation (1.22). Relation (2.25) implies that

$$\Phi(Z^m) - \Phi(W^m) = \begin{pmatrix} 0 \\ Y(W^m)^- \end{pmatrix},$$

and therefore

$$\left| Z^m - W^m - D\Phi(W^m) \begin{pmatrix} 0 \\ Y(W^m)^- \end{pmatrix} \right| \le C_4 \, |Z^m - W^m|^2 \, \Lambda^2. \tag{4.8}$$

On the other hand, the definition of Ψ is such that the dth column of $D\Psi(Z^m)$ is equal to $N(Z^m)$; therefore

$$\begin{aligned} &\left| D\Psi(W^m) \begin{pmatrix} 0 \\ Y(W^m)^- \end{pmatrix} - N(Z^m) Y(W^m)^- \right| \\ &\quad \le 2C_4 \, |Z^m - W^m| \, Y(W^m)^-. \end{aligned} \tag{4.9}$$

We combine (4.8) and (4.9) to get

$$\begin{aligned} &\big| Z^m - W^m - Y(W^m)^- N(Z^m) \big| \\ &\quad \le C_4 \big(2Y(W^m)^- + \Lambda^2 \, |Z^m - W^m| \big) \, |Z^m - W^m| \\ &\quad \le \frac{C_4 C_{10} \big(2 + \Lambda^3\big) h^2}{1+e} \big| V^m - V^{m-1} - hF^m \big|, \end{aligned}$$

and thus there exists C_{11} such that for all $m \in \mathcal{P}$

$$\big| Z^m - W^m - Y(W^m)^- N(Z^m) \big| \le h^2 C_{11} \big| V^m - V^{m-1} - hF^m \big|.$$

We now can see that

$$\begin{aligned}
&\sum_{m\in\mathcal{P}} \langle V^m - V^{m-1} - hF^m, \psi(t_m)\rangle_{U^m} \\
&= \frac{1+e}{h} \sum_{m\in\mathcal{P}} \langle Z^m - W^m, \psi(t_m)\rangle_{U^m} \\
&\geq \frac{1+e}{h} \sum_{m\in\mathcal{P}} Y(W^m)^- \langle N(Z^m), \psi(t_m)\rangle_{U^m} \\
&\quad - C_{11}h(1+e) \max_{P\leq m\leq Q} \big(\|M(U^m)\|\,|\psi(t_m)|\big) \sum_{m\in\mathcal{P}} \left|V^m - V^{m-1} - hF^m\right|,
\end{aligned}$$

which implies by a straightforward passage to the limit that $\langle \mu, \psi\rangle$ is nonnegative. This concludes the proof of the lemma. ∎

5. Transmission of energy during impact. The basic assumption is still the one made at the beginning of section 3.

Let $\overline{\tau} \in (0,\tau)$ be such that $u(t_0+\overline{\tau})$ belongs to ∂K. Write $\overline{t} = t_0 + \overline{\tau}$. We decompose $p(\overline{t}\pm 0)$ into a normal component $p_N(\overline{t}\pm 0)$ belonging to $\mathbb{R}d\phi(u(\overline{t}))$ and a tangential part $p_T(\overline{t}\pm 0)$ belonging to the orthogonal of $d\phi(u(\overline{t}))$ in the cotangent metric at $u(\overline{t})$.

In this section, we shall prove that

$$p_T(\overline{t}+0) = p_T(\overline{t}-0) \text{ and } p_N(\overline{t}+0) = -ep_N(\overline{t}-0), \tag{5.1}$$

where e is the restitution coefficient of the problem.

The conservation of the tangential component of the impulsion is proved in next lemma.

LEMMA 5.1. *Assume that $\overline{\tau} \in (0,\tau)$ is such that $u(\overline{\tau})$ belongs to ∂K. Then*

$$p_T(\overline{t}+0) = p_T(\overline{t}-0).$$

Proof. Thanks to Lemma 4.3, we know that

$$M(u)\ddot{u} = \mu + f(\cdot, u, p) \tag{5.2}$$

and that there exists a nonnegative measure λ such that

$$\mu = \lambda d\phi(u). \tag{5.3}$$

We take the measure of the set $\{\overline{t}\}$ by the two sides of (5.2), and we find that

$$M(u(\overline{t}))\big(\dot{u}(\overline{t}+0) - \dot{u}(\overline{t}-0)\big) = \mu(\{\overline{t}\}),$$

which immediately implies that $p(\overline{t}+0) - p(\overline{t}-0)$ is parallel to $d\phi(u(\overline{t}))$ and proves the lemma. ∎

Let $\overline{u} = u(\overline{t})$ and let $B(\overline{u}, r_1)$ and $B(\overline{u}, r_2)$ have the properties of Theorem 2.1. There exists an interval $[\tau_-, \tau_+]$ containing $\overline{\tau}$ in its interior such that for all small enough h, $u_h\big([t_0+\tau_-, t_0+\tau_+]\big)$ is included in $B(\overline{u}, r_1)$.

Define

$$P = \lceil \tau_-/h \rceil + 1, \quad Q = \lfloor \tau_+/h \rfloor - 1,$$

and let x_h be obtained from the X^m by affine interpolation, for $P \le m \le Q$. We infer from estimates (3.1) and (3.2) the estimates

$$\max_{P\le m\le Q}\left|\frac{X^{m+1}-X^m}{h}\right| \le \Lambda C_3,$$
$$\sum_{m=P}^{Q}\left|\frac{X^{m+1}-X^m}{h}-\frac{X^m-X^{m-1}}{h}\right| \le \Lambda C_7.$$

Therefore, we have the following convergences:

$$x_h \to x \text{ strongly in } C^0\big([t_0+\tau_-,t_0+\tau_+]\big);$$
$$\dot{x}_h \to \dot{x} \text{ except on a countable set and weakly } * \text{ in } L^\infty\big([t_0+\tau_-,t_0+\tau_+]\big);$$
$$\ddot{x}_h \to \ddot{x} \text{ weakly in } M^1\big([t_0+\tau_-,t_0+\tau_+]\big).$$

Write for all $h \le h_1$

$$x_h = \begin{pmatrix} s_h \\ y_h \end{pmatrix}, \quad x = \begin{pmatrix} s \\ y \end{pmatrix},$$

where the s_h's and s take their values in $\mathbb{R}^{d-1}$ and the y_h's and y are real valued functions. We do not have $x_h = \Phi(u_h)$, because x_h is a linear interpolation of the sequence $X^m = \Phi(U^m)$, and $\Phi(u_h)$ is the image of the linear interpolation of the sequence U^m. However, we can estimate the difference $x_h - \Phi(u_h)$.

LEMMA 5.2. *For all $t \in [t_0+\tau_-, t_0+\tau_+]$ belonging to $[t_m, t_{m+1}]$, we have*

$$x_h(t) - \Phi\big(u_h(t)\big) \le 2C_4C_3^2 h \min(t-t_m, t_{m+1}-t).$$

Proof. We observe that $x_h(t_m) = X^m$ and that

$$\left|\frac{d}{dt}\big[x_h(t)-\Phi\big(u_h(t)\big)\big]\ \big|_{t=t_m+0}\right| = \left|\frac{\Phi(U^{m+1})-\Phi(U^m)-hD\Phi(U^m)V^m}{h}\right| \le hC_3^2C_4.$$

Moreover, for all $t \in [t_m, t_{m+1})$

$$\left|\frac{d^2}{dt^2}\Big[x_h(t)-\Phi\big(u_h(t)\big)\Big]\right| = \big|D^2\Phi\big(U^m+(t-t_m)V^m\big)V^m\otimes V^m\big| \le 2C_3^2C_4.$$

Therefore, a straightforward integration yields

$$\big|x_h(t)-\Phi\big(u_h(t)\big)\big| \le C_3^2C_4\big(h(t-t_m)+(t-t_m)^2\big),$$

which implies

$$\big|x_h(t)-\Phi\big(u_h(t)\big)\big| \le 2C_3^2C_4h(t-t_m).$$

We can write the analogous estimate on the interval $[t, t_{m+1})$, which concludes the proof. ∎

As a consequence of Lemma 5.2 we obtain

$$\forall t \in [t_0+\tau_-, t_0+\tau_+], \quad x(t) = \Phi\big(u(t)\big)$$

and

$$\forall t \in (t_0+\tau_-, t_0+\tau_+), \quad \dot{x}(t\pm 0) = D\Phi\big(u(t)\big)\dot{u}(t\pm 0).$$

By virtue of relation (2.6),

$$\dot{u}(\bar{t}\pm 0) = \begin{pmatrix} \dot{s}(\bar{t}\pm 0) \\ 0 \end{pmatrix} + \dot{y}(\bar{t}\pm 0)N(\overline{u}).$$

We can rewrite this relation in terms of p_N and p_T:

$$p_T(\bar{t}\pm 0) = M(\overline{u})\begin{pmatrix} \dot{s}(\bar{t}\pm 0) \\ 0 \end{pmatrix}, \quad p_N(\bar{t}\pm 0) = \dot{y}(\bar{t}\pm 0)M(\overline{u})N(\overline{u}).$$

Lemma 5.1 implies $\dot{s}(\bar{t}+0) = \dot{s}(\bar{t}-0)$. In order to achieve the proof of relation (5.1), it remains to prove the scalar relation

$$\dot{y}(\bar{t}+0) = -e\dot{y}(\bar{t}-0). \tag{5.4}$$

But this relation is an immediate consequence of the precise analysis of the transmission of energy performed in the one dimensional case in [9] (see section 6).

6. Initial conditions. In this section we prove that the solution that we have constructed satisfies the initial conditions; we work under the hypotheses stated at the beginning of section 3.

LEMMA 6.1. *The function u satisfies the initial conditions*

$$u(t_0) = u_0, \quad p(t_0+0) = p_0.$$

Proof. By uniform convergence of u_h to u, it is clear that $u(t_0)$ is equal to u_0. There remains to show that the initial condition on the impulsion is satisfied.

First assume that u_0 belongs to the interior of K; then there exist $h_1 > 0$ and $\tau_1 > 0$ such that for all $h \in (0, h_1]$ and for all $t - t_0 \in [0, \tau_1]$

$$|u_h(t) - u_0| \le \frac{1}{2}\inf\{|u_0 - y| : y \notin K\}.$$

Then for all $t_m - t_0$ belonging to $(0, \tau_1]$, $\big(2U^m - (1-e)U^{m-1} + h^2F^m\big)/(1+e)$ belongs to K for h small enough; we have indeed

$$\begin{aligned}\left|\frac{2U^m - (1-e)U^{m-1} + h^2F^m}{1+e} - u_0\right| \\ \le \frac{1-e}{1+e}hC_3 + \frac{1}{2}\inf\{|u_0 - y| : y \notin K\} + \frac{h^2}{1+e}C_8,\end{aligned}$$

which is strictly inferior to $\inf\{|u_0 - y| : y \notin K\}$ for h small enough. Thus the constraints are not active for $0 \le t_m \le \tau_1$ and the convergence is a classical result.

In the second case, assume that u_0 belongs to ∂K; we have taken admissible initial conditions so that

$$\langle p_0, d\phi(u_0)\rangle^*_{u_0} \ge 0.$$

We use the construction and notations of section 2: Φ, Ψ, X^m, s^m, y^m, and ζ^m have the same signification as there.

Taylor's formula yields

$$\xi^0 = \frac{X^1 - X^0}{h} = D\Phi(u_0)\frac{U^1 - u_0}{h} + O(h),$$

and the definition (1.14) of U^1 gives

$$\xi^0 = D\Phi(u_0)M(u_0)^{-1}p_0 + O(h). \tag{6.1}$$

Write

$$\begin{pmatrix}\sigma_0\\ \eta_0\end{pmatrix} = D\Phi(u_0)M(u_0)^{-1}p_0.$$

Then the normal and tangential components of the impulsion are given by

$$p_{0T} = M(u_0)\begin{pmatrix}\sigma_0\\ 0\end{pmatrix} \text{ and } p_{0N} = \eta_0 M(u_0)N(u_0).$$

We wish to prove $p(t_0+0) = p_0$, which is equivalent to

$$\dot{x}(t_0+0) = \begin{pmatrix}\dot{s}(t_0+0)\\ \dot{y}(t_0+0)\end{pmatrix} = \begin{pmatrix}\sigma_0\\ \eta_0\end{pmatrix}.$$

We recall relation (2.26). Relation (6.1) implies that

$$\sigma^0 = \big(D\Phi(u_0)M(u_0)^{-1}p_0\big)' + O(h),$$

and together with (2.26), we obtain in the limit

$$\dot{s}(t) = \big(D\Phi(u_0)M(u_0)^{-1}p_0\big)' + O(t-t_0),$$

i.e., $\dot{s}(t_0+0) = \sigma_0$. Finally, using the same arguments as in the one dimensional case (see Lemma 7.1 in [9]), we obtain

$$\dot{y}(t_0+0) = \eta_0,$$

which concludes the proof. □

7. A priori estimates. In this section we prove that solutions of the problem (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), and (1.9) satisfy an a priori estimate on an interval with a nonempty interior.

LEMMA 7.1. *Let R be strictly larger than $|p_0|^*_{u_0}$. Then there exists $\tau(R) > 0$ such that for all solution u of* (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), *and* (1.9) *defined on $[t_0, t_0+\tau]$, the following estimates hold:*

$$\forall t \in [t_0, t_0 + \min(\tau, \tau(R))], \quad |u(t) - u_0| \le R, \quad |p(t)|^*_{u(t)} \le R. \tag{7.1}$$

Proof. Once again, the main ideas of the proof are the same as in the one dimensional case, but the estimates are more complex. The measure λ appearing in (1.4b) can be decomposed in the sum of an atomic part λ_a and a diffuse part λ_d. At each point of the support of λ_a we have

$$|p(t+0)|^*_{u(t)} \le |p(t-0)|^*_{u(t)} \tag{7.2}$$

thanks to relation (1.6). On any interval (t_1, t_2) which does not intersect the support of λ_a, we multiply relation (1.3) by $\dot{u}^T$ on the left, and we find that

$$\frac{d}{dt}\frac{1}{2}\dot{u}^T M(u)\dot{u} = \dot{u}^T f(\cdot, u, p) + \frac{1}{2}\dot{u}^T (DM(u)\dot{u})\dot{u}. \tag{7.3}$$

Define

$$E(u,p) = \frac{1}{2}\langle p, p\rangle_u^*, \quad z = |p|_u^*.$$

It is convenient to recall that

$$|p|_u^* = |M(u)^{-1/2} p| = |M(u)^{1/2}\dot{u}|.$$

Relations (7.2) and (7.3) imply that in the sense of measures

$$z\dot{z} = \dot{E} \le \dot{u}^T f(\cdot, u, p) + \frac{1}{2}\dot{u}^T \big(DM(u)\dot{u}\big)\dot{u}. \tag{7.4}$$

Our purpose now is to transform (7.4) into a differential inequality. Let $\chi(u)$ be the norm of the bilinear mapping

$$(v_1, v_2) \mapsto M(u)^{-1/2}(DM(u)M(u)^{-1/2}v_1)M(u)^{-1/2}v_2.$$

With this definition,

$$\big|\dot{u}^T \big(DM(u)\dot{u}\big)\dot{u}\big| \le \chi(u) z^3.$$

We write now

$$\begin{aligned}\dot{u}^T f(t,u,p) &= \dot{u}^T M(u)^{1/2} M(u)^{-1/2} f(t,u,p)\\ &= \dot{u}^T M(u)^{1/2}\big[M(u)^{-1/2} f(t,u,p) - M(u_0)^{-1/2} f(t,u_0,0) + M(u_0)^{-1/2} f(t,u_0,0)\big].\end{aligned}$$

Define

$$g(t) = |M(u_0)^{-1/2} f(t, u_0, 0)|.$$

Fix $R > |p_0|_{u_0}^*$ and let $\omega(R)$ be the Lipschitz constant of $(u,p) \mapsto M(u)^{-1/2} f(t,u,p)$ for $t \in [0,T]$ and $\max(|u-u_0|, |p|_u^*) \le R$; more precisely,

$$\begin{aligned}\omega(R) = \sup\Bigg\{ &\frac{|M(u_1)^{-1/2} f(t,u_1,p_1) - M(u_2)^{-1/2} f(t,u_2,p_2)|}{|u_1-u_2| + |p_1-p_2|} : 0 \le t \le T,\\ &\max(|u_1-u_0|, |u_2-u_0|, |p_1|_{u_1}^*, |p_2|_{u_2}^*) \le R, u_1 \ne u_2 \text{ or } p_1 \ne p_2\Bigg\}.\end{aligned}$$

By construction, ω is continuous and is an increasing function of τ and R.

If $t_0 \le t \le t_0 + \tau$ and if $\max(|u(t)-u_0|, |p(t)|_{u(t)}^*) \le R$ on $[t_0, t_0+\tau]$, we have the inequality

$$\big|\dot{u}^T f(\cdot, u, p)\big| \le z\big(g + \omega(R)(|u-u_0| + |p|)\big).$$

But we can estimate $u(t) - u_0$:

$$|u(t) - u_0| \le \int_{t_0}^{t} |\dot{u}(s)|\, ds \le \int_{t_0}^{t} \|M(u)^{-1/2}\| z\, ds.$$

Therefore we have the estimate

$$|\dot{u}^T f(\cdot, u, p)| \le zg + z\omega(R)\left(\int_{t_0}^{t} \|M(u)^{-1/2}\| z\, ds + \|M(u)^{1/2}\| z\right),$$

and we conclude that z satisfies the differential inequality

$$\dot{z} \le g + \omega(R)\left[\int_{t_0}^{t} \|M(u)^{-1/2}\| z\, ds + \|M(u)^{1/2}\| z\right] + \frac{1}{2}\chi(u) z^2.$$

Set

$$\alpha = \sup\big\{\|M(u)^{1/2}\| : |u - u_0| \le R\big\}, \tag{7.5}$$

$$\beta = \sup\big\{\|M(u)^{-1/2}\| : |u - u_0| \le R\big\}, \tag{7.6}$$

$$\gamma = 2\sup\big\{\chi(u) : |u - u_0| \le R\big\}.$$

While $t \le t_0 + \tau$ and $\max(|u(t) - u_0|, |p(t)|^*_{u(t)}) \le R$, z satisfies the following differential inequality:

$$\dot{z} \le g + \omega(R)\left[\beta \int_{t_0}^{t} z\, ds + \alpha z\right] + \gamma z^2. \tag{7.7}$$

Consider the integrodifferential equation

$$\dot{y} = g + \omega(R)\left(\beta \int_{t_0}^{t} y\, ds + \alpha y\right) + \gamma |y|^2, \tag{7.8}$$

with the initial condition $y(t_0) = z(t_0)$. It has a unique maximal solution which blows up in finite time, as soon as γ is strictly positive and $\sup|g|$ is strictly positive. Let $\tau(R) \in (0, T - t_0]$ be the largest time for which

$$\forall t \in [t_0, t_0 + \tau(R)], \quad y(t) \le R, \quad \beta \int_{t_0}^{t} y\, ds \le R.$$

Such a number exists since $y(t_0) < R$. Then we can compare the solution z of (7.7) and the solution y of (7.8), and we find immediately that

$$\forall t \in \big[t_0, t_0 + \min\big(\tau, \tau(R)\big)\big], \quad z(t) \le y(t). \tag{7.9}$$

This concludes the proof of the lemma. □

8. Global results. We summarize the results obtained so far in the following proposition.

PROPOSITION 8.1. *Assume that there exist strictly positive numbers τ, C_3, and $h_1 > 0$, and a sequence of solutions of the numerical scheme defined by* (1.13), (1.14), (1.16), *and* (1.17), *which satisfies the estimate* (3.1). *Then it is possible to extract from the sequence u_h defined by* (4.1) *a subsequence which converges to a solution of* (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), *and* (1.9). *The convergence*

holds in the following sense: u_h converges uniformly to u on $[t_0, t_0+\tau]$; $\dot{u}_h$ converges to $\dot{u}$ in $L^\infty(t_0, t_0+\tau)$ weakly $*$ and almost everywhere on $[t_0, t_0+\tau]$; and $\ddot{u}_h$ converges to $\ddot{u}$ in the weak $*$ topology of measures. Moreover, for all $\bar{\tau} \in (0, \tau]$, we have the following convergence:

$$\begin{aligned} &\limsup_{h\downarrow 0} \sup\big\{|V^m|_{U^m} : t_0 \le t_m \le t_0 + \bar{\tau}\big\} \\ &\quad \le \operatorname{ess\,sup}\big\{|\dot{u}(t)|_{u(t)} : t_0 \le t \le t_0 + \bar{\tau}\big\}. \end{aligned} \tag{8.1}$$

Proof. The proof of this theorem is for the most part identical to the proof of Proposition 9.1 of [9]; assume the last statement to be false; then there exist $\tau_2 > 0$, $\gamma > 0$, and a sequence of time steps h and a sequence of integers $m(h)$ such that $hm(h)$ converges to τ_2 and

$$\Big|V^{m(h)}\Big|^2_{U^{m(h)}} \ge \operatorname{ess\,sup}\big\{|\dot{u}(t)|^2_{u(t)} : t_0 \le t \le t_0 + \bar{\tau}\big\} + \gamma. \tag{8.2}$$

Moreover, $u(t_0 + \tau_2)$ belongs to ∂K.

Choose a coordinate system such that the origin is at $u(t_0 + \tau_2)$; let Ψ be the diffeomorphism defined at (2.5). In this case, $D\Psi(0)$ is given by (2.6). Define

$$\beta^m = \big(\xi^m\big)^T D\Psi(0)^T M(0) D\Psi(0) \xi^m.$$

Let us compare β^m to $|V^m|^2_{U^m}$; it is convenient to define

$$\widetilde{V}^m = D\Psi(0)\xi^m;$$

then

$$\begin{aligned} |V^m|^2_{U^m} - \beta^m &= \big(V^m\big)^T M(U^m) V^m - \big(\widetilde{V}^m\big)^T M(0) \widetilde{V}^m \\ &= \big(V^m\big)^T \big(M(U^m) - M(0)\big) V^m - \big(V^m - \widetilde{V}^m\big) M(0) \big(V^m - \widetilde{V}^m\big) \\ &\quad + 2\big(V^m - \widetilde{V}^m\big)^T M(0) V^m. \end{aligned}$$

We observe that

$$|U^m| \le \|u_h - u\| + C_3 \left|mh - \tau_2\right|, \quad \|X^m\| \le \Lambda \|U^m\|$$

and that

$$\left|V^m - \widetilde{V}^m\right| \le C_4 \|\xi^m\| \left[2\Lambda \|X^m\| + \left\|X^m - X^{m-1}\right\|\right].$$

These observations enable us to estimate the difference: there exists a constant C_{12} such that

$$\left||V^m|^2_{U^m} - \beta^m\right| \le C_{12}\big(h + \|u - u_h\|_{C^0([t_0, t_0+\tau])} + |mh - \tau_2|\big).$$

We infer from (2.34) that there exists a constant C_{13} such that

$$\beta^{m+1} \le \min\big(\beta^m, \beta^{m-1}\big) + C_{13} h.$$

We now use (8.2): we can see that for all $m \le m(h)$,

$$\beta^{m(h)} \le \max\big(\beta^m, \beta^{m-1}\big) + C_{13}\big(m(h) - m\big)h,$$

so that

$$\max\bigl(|V^m|^2_{U^m}, |V^{m-1}|^2_{U^{m-1}}\bigr) \geq \beta^{m(h)} - C_{13}\bigl(m(h)-m\bigr)h - C_{12}\bigl(h + \|u-u_h\|_{C^0([t_0,t_0+\tau])} + |mh-\tau_2|\bigr).$$

If $\tau_4 < \tau_2$ is such that

$$\tau_2 - \tau_4 \leq \gamma/(4C_{13}),$$

and if

$$C_{12}\bigl(h + \|u-u_h\|_{C^0([t_0,t_0+\tau])} + |mh-\tau_2|\bigr) \leq \gamma/4,$$

we can see that for all small enough h and all $m \in \{\lceil \tau_4/h\rceil, \dots, m(h)\}$ the following estimate holds:

$$\max\bigl(|V^m|_{U^m}, |V^{m-1}|_{U^{m-1}}\bigr) \geq \operatorname{ess\,sup}\bigl\{|\dot u(t)|^2_{u(t)} : t_0 \leq t \leq t_0+\overline{\tau}\bigr\} + \gamma/4. \tag{8.3}$$

But the function v_h defined by

$$v_h(t) = |V^m|^2_{U^m} \text{ if } t \in [mh, (m+1)h)$$

converges almost everywhere on $[t_0, t_0+\tau]$ to $|\dot u(t)|^2_{u(t)}$; so does $\max(v_h(t-h), v_h(t))$. Therefore, in the limit, relation (8.3) leads to

$$\liminf_{h\downarrow 0} \operatorname*{ess\,sup}_{t\in[t_0+\tau_4, t_0+\tau_2]} v_h(t) \geq \operatorname{ess\,sup}\bigl\{|\dot u(t)|^2_{u(t)} : t_0 \leq t \leq t_0+\overline{\tau}\bigr\} + \gamma/4,$$

which is a contradiction.

Once again, we have been tempted to work in straightened coordinates; but it does not shorten the proof, and it introduces more notations. Therefore, it was hardly worth the effort. □

A corollary can be inferred immediately from this proposition and Theorem 2.3.

COROLLARY 8.2. *For all admissible initial conditions u_0 and p_0, there exists $\tau > 0$ and a solution of* (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), *and* (1.9) *defined on $[t_0, t_0+\tau]$.*

Above we have proved the existence of a nonempty interval on which the numerical scheme converges to a solution of (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), and (1.9). On the other hand, Lemma 7.1 gives a priori estimates on the solution of such a problem.

We couple now the a priori estimates with the local convergence result to obtain a global result.

THEOREM 8.3. *Let R be strictly larger than $|p_0|^*_{u_0}$, and let $\tau(R)$ be given as in Lemma* 7.1. *Then, for all small enough h, the solution U^m of the numerical scheme* (1.13), (1.14), (1.16), (1.17) *is defined on a discrete interval $\{0, \dots, m(h)\}$, such that*

$$\liminf_{h\to 0} hm(h) \to \tau(R);$$

moreover, the approximation u_h converges to a solution u of the continuous time equation, i.e., (1.3), (1.4a), (1.4b), (1.4c), (1.5a), (1.5b), (1.6), (1.8), *and* (1.9), *which is defined on $[t_0, t_0+\tau(R)]$.*

Proof. Let C_2 be given by

$$C_2 = \max\left\{ (3\,|v_0|_{u_0} + 2) \left\| M(u_0)^{-1/2} \right\|, 1 + R \max\left\{ \left\| M(u)^{-1/2} \right\| ; |u - u_0| \le R \right\} \right\}.$$

We know from Theorem 2.4 that there exist nonnegative numbers r_1, τ_2, C_3, and h_1 such that for all $\widehat{t}_0 \in [0,T)$, for all $\overline{u} \in K \cap B(u_0, R+1)$, and for all $h \in (0, h_1]$, if $\widehat{U}^0$, $\widehat{U}^1$ satisfy the condition $E(\overline{u}, r_1, C_2, h)$, then the numerical scheme (1.16)–(1.17) has a unique solution which satisfies the estimate

$$\forall m \in \{0, \dots, \lfloor \tau_2/h \rfloor\} \quad \left| \widehat{U}^{m+1} - \widehat{U}^m \right| \le C_3 h.$$

Let $\{0, \dots, m(h)\}$ be the maximal discrete time interval for which the numerical scheme (1.13), (1.14), (1.16), (1.17) has a solution satisfying

$$|V^m| \le C_3.$$

Let

$$\tau_1 = \liminf_{h \to 0} h m(h).$$

From Theorem 2.1 we know that τ_1 is at least equal to some number $\tau > 0$. Assume that τ_1 is strictly inferior to $\tau(R)$. Proposition 8.1 and the a priori estimates proved in Lemma 7.1 imply that, for h small enough and for all $\varepsilon > 0$,

$$\begin{aligned} &\forall t_m \in [t_0, t_0 + \tau_1 - \varepsilon], \qquad U^m \in B(u_0, R+1), \\ &\text{and } |V^m|^2_{U^m} \le \operatorname{ess\,sup}\left\{ |\dot{u}(t)|^2_{u(t)} : t_0 \le t_m \le t_0 + \tau_1 - \varepsilon \right\} \le R^2 + 1. \end{aligned}$$

Since the above estimates hold for all $\varepsilon > 0$, we see that

$$\begin{aligned} &\forall t_m \in [t_0, t_0 + \tau_1], \qquad U^m \in B(u_0, R+1), \\ &\text{and } |V^m|^2 \le 1 + R \max\left\{ \left\| M(u)^{-1/2} \right\| : |u - u_0| \le R \right\}. \end{aligned}$$

We denote

$$\ell(h) = \lfloor (\tau_1 - \tau_2/2)/h \rfloor$$

and we re-initialize with the following choices:

$$\widehat{t}_0 = t_0 + \ell(h) h, \quad \widehat{U}^0 = U^{\ell(h)}, \quad \widehat{U}^1 = U^{\ell(h)+1}.$$

With these data, we know that $\widehat{U}^m$ exists for $0 \le mh \le \tau_2$, so that the numerical solution U^m is extended up to $\lfloor (\tau_1 + \tau_2/2)/h \rfloor - 1$, and therefore

$$\liminf_{h \to 0} h m(h) \ge \tau_1 + \tau_2/2,$$

which is a contradiction. ∎

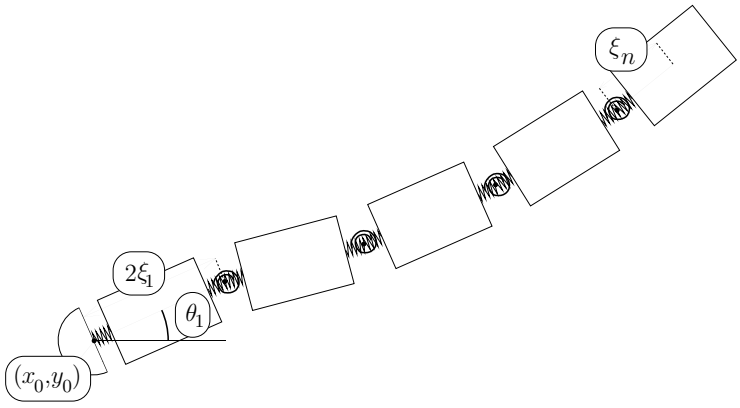

FIG. 9.1. *The discretization of the bar and the generalized coordinates.*

9. A numerical experiment: The dropped bar of Stoianovici and Hurmuzlu. In a recent paper [18], D. Stoianovici and Y. Hurmuzlu report experiments on the dynamics of a slender impacting bar, where they performed measurements of the apparent restitution coefficient of the bar.

The experiments consisted of dropping a bar on a rigid horizontal massive support: the velocity vanished initially and the bar initially made an angle θ with respect to the horizontal. This angle was varied in the experiments. The main conclusion of [18] was that the apparent coefficient of restitution, calculated by taking the ratio of the normal velocity of the impacting point after impact to the normal velocity of the impacting point before impact, varied as a function of θ.

We use a mechanical model of a bar with a finite number of degrees of freedom: the bar is discretized by a finite number n of identical cylindrical segments (of circular section) and a half-sphere at the impacting end; the nearest segment to the impacting half-sphere is joined by a linear spring; every other segment is joined to its neighbors by three springs and an articulation; see Figure 9.1.

Let θ_i be the angle between the ith segment and the horizontal; let $2\xi_i$ be the length of the ith segment plus the springs, except for the nth segment, where the convention is displayed on Figure 9.1. Denote by (x_0, y_0) the coordinates of the center of the impacting hemisphere. With these notations, the center of gravity of the ith segment has coordinates

$$x_i = x_0 + 2\sum_{j=1}^{i-1} \xi_j \cos\theta_j + \xi_i \cos\theta_i, \quad y_i = y_0 + 2\sum_{j=1}^{i-1} \xi_j \sin\theta_j + \xi_i \sin\theta_i.$$

We have made the following choice of generalized coordinates:

$$u = \big(x_0, y_0, \theta_1, \ldots, \theta_n, \xi_1, \ldots, \xi_n\big).$$

Whenever convenient, we will denote by u_i the ith coordinate of u.

The kinetic energy and the potential energy are defined, respectively, by

$$T = \frac{\mu}{2}\left(\dot{x}_0^2 + \dot{y}_0^2\right) + \frac{m}{2}\sum_{i=1}^{n}\left(\dot{x}_i^2 + \dot{y}_i^2\right) + \frac{J\dot{\theta}_1^2}{2} + \frac{I}{2}\sum_{i=1}^{n}\dot{\theta}_i^2,$$

$$U = \mu g y_0 + mg\sum_{i=1}^{n} y_i + k\sum_{i=1}^{n-1}\left(\xi_i - L\right)^2 + \frac{k}{2}\left(\xi_n - L\right)^2 + \frac{\Gamma}{2}\sum_{i=1}^{n-1}\left(\theta_i - \theta_{i+1}\right)^2.$$

Here m is the mass of each segment, μ is the mass of the end hemisphere, and I and J are appropriate moments of inertia.

We use all the physical constants chosen by the authors of [18], and the length of the bar is 200 mm. Our discretization used $n = 9$ segments, i.e., 20 degrees of freedom.

The set of constraints is

$$K = \{u \in \mathbb{R}^{2n+2} : \phi(u) = y_0 - R \geq 0\}.$$

Let e_2 be the second vector of the canonical basis of $\mathbb{R}^{2n+2}$; let

$$v(u) = M(u)^{-1}e_2,$$

and denote by $v_i(u)$ the ith component of $v(u)$. With these notations, the transmission law at impact is given for all $i = 1, \ldots, 2n+2$ by

$$\dot{u}_i(t+0) = \dot{u}_i(t-0) - (1+e)\frac{v_i(u)}{v_2(u)}\dot{u}_2(t-0).$$

For $i = 2$, we find

$$\dot{u}_2(t+0) = -e\dot{u}_2(t-0),$$

which is precisely Newton's law for the impacting degree of freedom.

In the practical implementation of the scheme, we freeze the metric at U^n, and therefore we utilize the projection P_K^n onto K with respect to the metric defined by $M(U^n)$; at each step of the scheme we solve

$$\frac{U^{n+1} + eU^{n-1}}{1+e} = P_K^n\left(\frac{2U^n - (1-e)U^{n-1} + h^2F^n}{1+e}\right)$$

by Newton's method. Observe that in our experiments we took $e = 1$.

In order to compare our ad hoc scheme to methods whose reliability is known, we set up a detection method: we integrate the free flight by a Newmark scheme, and we seek the impact time by looking for zeros of the parabolic interpolation of $y_0 - R$.

In Figure 9.2, we show the apparent restitution coefficient obtained by our two methods. There are many microimpacts; the apparent coefficient of restitution is the ratio of the vertical velocity of the impacting point after all the microimpacts to the vertical velocity before impact; we plot this ratio as a function of θ. In this simulation, the ad hoc scheme is approximately 40% faster than the detection scheme.

We checked that numerically the total energy is conserved; the result plotted here implies that a significant part of the global kinetic energy is transferred to the continuous medium modes.

The reader is referred to [18] for a comparison with the experimental results.

A LOCAL DISCONTINUOUS GALERKIN METHOD FOR KdV TYPE EQUATIONS*

JUE YAN† AND CHI-WANG SHU†

Abstract. In this paper we develop a local discontinuous Galerkin method for solving KdV type equations containing third derivative terms in one and two space dimensions. The method is based on the framework of the discontinuous Galerkin method for conservation laws and the local discontinuous Galerkin method for viscous equations containing second derivatives; however, the guiding principle for intercell fluxes and nonlinear stability is new. We prove L^2 stability and a cell entropy inequality for the square entropy for a class of nonlinear PDEs of this type in both one and multiple space dimensions, and we give an error estimate for the linear cases in the one-dimensional case. The stability result holds in the limit case when the coefficients to the third derivative terms vanish; hence the method is especially suitable for problems which are "convection dominated," i.e., those with small second and third derivative terms. Numerical examples are shown to illustrate the capability of this method. The method has the usual advantage of local discontinuous Galerkin methods, namely, it is extremely local and hence efficient for parallel implementations and easy for *h-p* adaptivity.

Key words. discontinuous Galerkin method, KdV equation, stability, error estimate

1. Introduction.

In this paper we develop a local discontinuous Galerkin method for solving KdV type equations containing third derivative terms in one and multiple space dimensions. An example of such a PDE is the original KdV equation [20],

$$U_t + (\alpha U + \beta U^2)_x + \sigma U_{xxx} = 0, \tag{1.1}$$

where α, β, and σ are constants. In this paper we use capital letters such as U, V, Q, etc. to denote the solutions to the PDEs and use lowercase letters to denote the numerical solutions. Our scheme can be designed and proven stable for more general nonlinearities, namely,

$$U_t + f(U)_x + (r'(U)g(r(U)_x)_x)_x = 0 \tag{1.2}$$

in one space dimension for arbitrary (smooth) functions f, g, and r, and

$$U_t + \sum_{i=1}^{d} f_i(U)_{x_i} + \sum_{i=1}^{d} \left(r_i'(U) \sum_{j=1}^{d} g_{ij}(r_i(U)_{x_i})_{x_j} \right)_{x_i} = 0 \tag{1.3}$$

in multiple space dimensions for arbitrary (smooth) functions f_i, g_{ij}, and r_i, $i, j = 1, \ldots, d$.

KdV type equations describe the propagation of waves in a variety of nonlinear, dispersive media and appear often in applications. See, e.g., [1]. Various numerical methods have been proposed and used in practice to solve this type of equation; see, e.g., [4, 5, 19]. However, in many situations, such as in quantum hydrodynamic models of semiconductor device simulations [16] and in the dispersive limit of conservation laws [21], the third derivative terms might have small or even zero coefficients in some parts of the domain. We will call such cases "convection dominated." The design of stable, efficient, and high order methods, especially those for the "convection dominated" cases, i.e., when the third derivative terms are small ($|\sigma| \ll 1$ in (1.1)), remains a challenge, as the success of such methods depends crucially on correct treatment of this singular limit. The situation is similar to convection diffusion problems. While a large class of methods suitable for parabolic problems also works for convection diffusion problems when diffusion dominates, these methods may not work well when convection dominates.

The discontinuous Galerkin method is a class of finite element methods using completely discontinuous piecewise polynomial space for the numerical solution and the test functions. One certainly needs to use more degrees of freedom because of the discontinuities at the element boundaries; however, this also gives one room to design suitable interelement boundary treatments (the so-called fluxes) to obtain highly accurate and stable methods in many difficult situations.

The first discontinuous Galerkin method was introduced in 1973 by Reed and Hill [24] in the framework of neutron transport (steady state linear hyperbolic equations). Convergence for such methods was proven in, e.g., [22]. A major development of the discontinuous Galerkin method was carried out by Cockburn et al. in a series of papers [11, 10, 8, 12] in which a framework was established to easily solve *nonlinear* time dependent hyperbolic conservation laws (i.e., (1.2) and (1.3) without the third derivative terms) using explicit, nonlinearly stable high order Runge–Kutta time discretizations [26] and discontinuous Galerkin discretization in space with exact or approximate Riemann solvers as interface fluxes and TVB (total variation bounded) nonlinear limiters [25] to achieve nonoscillatory properties for strong shocks. See also [17] for a discontinuous Galerkin method with additional "shock capturing" terms.

The discontinuous Galerkin method has found rapid applications in such diverse areas as aeroacoustics, electromagnetism, gas dynamics, granular flows, magnetohydrodynamics, meteorology, modeling of shallow water, oceanography, oil recovery simulation, semiconductor device simulation, transport of contaminant in porous media, turbomachinery, turbulent flows, viscoelastic flows, and weather forecasting, among many others. Good references for the discontinuous Galerkin method and its recent development include the survey paper [9], other papers therein, and the review paper [14].

The original discontinuous Galerkin method was designed to solve first order hyperbolic problems. A simple example to illustrate its essential ideas is the linear transport equation

$$U_t + U_x = 0. \tag{1.4}$$

Let's denote the mesh by $I_j = [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}]$ for $j = 1, \ldots, N$, with the center of the cell denoted by $x_j = \frac{1}{2}(x_{j-\frac{1}{2}} + x_{j+\frac{1}{2}})$ and the size of each cell by $\Delta x_j = x_{j+\frac{1}{2}} - x_{j-\frac{1}{2}}$. We will denote $\Delta x = \max_j \Delta x_j$. If we multiply (1.4) by an arbitrary test function

$V(x)$, integrate over the interval I_j, and integrate by parts, we get

$$\int_{I_j} U_t V dx - \int_{I_j} U V_x dx + U(x_{j+\frac{1}{2}}, t)V(x_{j+\frac{1}{2}}) - U(x_{j-\frac{1}{2}}, t)V(x_{j-\frac{1}{2}}) = 0. \tag{1.5}$$

This is the starting point for designing the discontinuous Galerkin method. We replace both the solution U and the test function V by piecewise polynomials of degree at most k and denote them by u and v. That is, $u, v \in \mathcal{V}_{\Delta x}$, where

$$\mathcal{V}_{\Delta x} = \{v : \ v \text{ is a polynomial of degree at most } k \text{ for } x \in I_j, \ \ j = 1, \ldots, N\}. \tag{1.6}$$

When U and V in (1.5) are replaced by u and v, there is ambiguity in the last two terms of (1.5) involving the boundary values at $x_{j\pm\frac{1}{2}}$, as both the solution u and the test function v are *discontinuous* exactly at these boundary points. The idea is to treat these terms with an upwinding mechanism (information from characteristics) borrowed from successful high resolution finite volume schemes. Thus u at the interfaces $x_{j\pm\frac{1}{2}}$ is given by a single valued numerical flux $\hat{u}_{j\pm\frac{1}{2}} = u^-_{j\pm\frac{1}{2}}$, determined from upwinding, and the v's at the interfaces $x_{j\pm\frac{1}{2}}$ are given by the values taken from inside the cell I_j, namely, $v^-_{j+\frac{1}{2}}$ and $v^+_{j-\frac{1}{2}}$. Notice that we use v^- and v^+ to denote the left and right limits of v, respectively, at the interface where v is discontinuous. For more general nonlinear fluxes $f(u)$, the only difference is that the single valued flux $\hat{f}_{j+\frac{1}{2}}$ would be taken as a monotone flux depending on both $u^-_{j+\frac{1}{2}}$ and $u^+_{j+\frac{1}{2}}$ (exact or approximate Riemann solvers in the system case). The resulting method of the method-of-lines ODE is then discretized by the nonlinearly stable high order Runge–Kutta time discretizations [26]. Nonlinear TVB limiters [25] may be used if the solution contains strong discontinuities. The scheme thus obtained, for solving hyperbolic conservation laws ((1.2) and (1.3) without the third derivative terms), has the following attractive properties:

1. It can be easily designed for any order of accuracy. In fact, the order of accuracy can be locally determined in each cell, thus allowing for efficient p adaptivity.
2. It can be used on arbitrary triangulations, even those with hanging nodes, thus allowing for efficient h adaptivity.
3. It is extremely local in data communications. The evolution of the solution in each cell needs to communicate only with the immediate neighbors, regardless of the order of accuracy, thus allowing for efficient parallel implementations. See, e.g., [3].
4. It has excellent provable nonlinear stability. One can prove a strong L^2 stability and a cell entropy inequality for the square entropy, for the general nonlinear cases, for any orders of accuracy on arbitrary triangulations in any space dimension, without the need for nonlinear limiters [18]. See also [17] for a nonlinear stability result of a discontinuous Galerkin method with extra "shock capturing" terms.

In [13] these discontinuous Galerkin methods were generalized to solve convection diffusion problems containing second derivative terms. This generalization was motivated by the successful numerical experiments of Bassi and Rebay [2] for the compressible Navier–Stokes equations. The idea can be illustrated with the simple heat equation

$$U_t - U_{xx} = 0 \tag{1.7}$$

which we rewrite into a first order system

$$U_t - Q_x = 0, \qquad Q - U_x = 0. \tag{1.8}$$

We can then *formally* use the same discontinuous Galerkin method for the convection equation to solve (1.8), resulting in the following scheme: Find $u, q \in \mathcal{V}_{\Delta x}$ such that, for all test functions $v, w \in \mathcal{V}_{\Delta x}$,

$$\begin{aligned} &\int_{I_j} u_t v dx + \int_{I_j} q v_x dx - \hat{q}_{j+\frac{1}{2}} v^-_{j+\frac{1}{2}} + \hat{q}_{j-\frac{1}{2}} v^+_{j-\frac{1}{2}} = 0, \\ &\int_{I_j} q w dx + \int_{I_j} u w_x dx - \hat{u}_{j+\frac{1}{2}} w^-_{j+\frac{1}{2}} + \hat{u}_{j-\frac{1}{2}} w^+_{j-\frac{1}{2}} = 0. \end{aligned} \tag{1.9}$$

However, there is no longer an upwinding mechanism or characteristics to guide the design of the fluxes $\hat{u}_{j+\frac{1}{2}}$ and $\hat{q}_{j+\frac{1}{2}}$. The crucial part in designing a stable and accurate algorithm (1.9) is a correct design of these fluxes. In [13], criteria are given for these fluxes to guarantee stability, convergence, and a suboptimal error estimate of order k in the L^2 norm for piecewise polynomials of degree k. The (most natural) central fluxes

$$\hat{u}_{j+\frac{1}{2}} = \frac{1}{2}\left(u^-_{j+\frac{1}{2}} + u^+_{j+\frac{1}{2}}\right), \qquad \hat{q}_{j+\frac{1}{2}} = \frac{1}{2}\left(q^-_{j+\frac{1}{2}} + q^+_{j+\frac{1}{2}}\right) \tag{1.10}$$

would satisfy these criteria and give a scheme which is indeed suboptimal in the order of accuracy for odd k (i.e., the accuracy is order k rather than the expected order $k+1$ for odd k). This deficiency, however, is easily removed by a clever choice of fluxes, proposed in [13]:

$$\hat{u}_{j+\frac{1}{2}} = u^-_{j+\frac{1}{2}}, \qquad \hat{q}_{j+\frac{1}{2}} = q^+_{j+\frac{1}{2}}; \tag{1.11}$$

i.e., we alternatively take the left and right limits for the fluxes in u and q (we could of course also take the pair $u^+_{j+\frac{1}{2}}$ and $q^-_{j+\frac{1}{2}}$ as the fluxes). Notice that the evaluation of (1.11) is simpler than that of the central fluxes in (1.10), and this easily generalizes to multispace dimensions on arbitrary triangulations. The accuracy now becomes the optimal order $k+1$ for both even and odd k; see [6] for a proof of this in the general h-p context. Notice that this alternating way of choosing fluxes may render the resulting system nonsymmetric except for the P^0 case, although it still will be positive definite. This is not a problem if the method is discretized explicitly in time or if an implicit time discretization is solved by an iterative method suitable for positive definite matrices.

The schemes thus designed for the heat equation (1.7), or in fact for the most general multidimensional nonlinear convection diffusion equations (nonlinear in both the first derivative convection part and the second derivation diffusion part), retain *all* four nice properties listed above for the method used on convection equations. Moreover, the appearance of the auxiliary variable q is superficial: when a local basis is chosen in cell I_j, q is eliminated and the actual scheme for u takes a form similar to that for convection alone. This is a major advantage of the scheme over the traditional "mixed methods," and it is the reason that the scheme is termed *local* discontinuous Galerkin method in [13]. Even though the auxiliary variable q can be locally eliminated, it does approximate the derivative of the solution u to the same order of accuracy, thus matching the advantage of traditional "mixed methods" on this.

The purpose of this paper is to develop a similar local discontinuous Galerkin method for the KdV type equations (1.1), (1.2), and (1.3) containing third derivative terms. Our objective is to design a method retaining again all four nice properties listed above for the method used on convection and convection diffusion equations, plus having the feature of being local, namely, the auxiliary variables introduced to approximate the first and second derivatives of the solution could be locally eliminated.

The organization of the paper is as follows. In subsection 1.1 we give a short "preview" of the proposed method on a simple linear equation to motivate the ideas. In section 2 we describe the method for the one-dimensional case and prove its nonlinear L^2 stability and a cell entropy inequality, as well as an error estimate for the linear case. In section 3 the multiple space dimension case is considered, where the nonlinear stability is given for the general triangulations. In section 4 we provide several numerical examples to illustrate the capability of the method. Concluding remarks and remarks about future work are given in section 5.

1.1. A preview of the method. We will give a "preview" of the method on the simple linear equation

$$U_t + U_{xxx} = 0 \tag{1.12}$$

which we again rewrite into a first order system

$$U_t + P_x = 0, \quad P - Q_x = 0, \quad Q - U_x = 0. \tag{1.13}$$

We can then *formally* use the same discontinuous Galerkin method for the convection equation to solve (1.13), resulting in the following scheme: Find $u, p, q \in \mathcal{V}_{\Delta x}$ such that, for all test functions $v, w, z \in \mathcal{V}_{\Delta x}$,

$$\begin{aligned}
&\int_{I_j} u_t v dx - \int_{I_j} p v_x dx + \hat{p}_{j+\frac{1}{2}} v^-_{j+\frac{1}{2}} - \hat{p}_{j-\frac{1}{2}} v^+_{j-\frac{1}{2}} = 0,\\
&\int_{I_j} p w dx + \int_{I_j} q w_x dx - \hat{q}_{j+\frac{1}{2}} w^-_{j+\frac{1}{2}} + \hat{q}_{j-\frac{1}{2}} w^+_{j-\frac{1}{2}} = 0,\\
&\int_{I_j} q z dx + \int_{I_j} u z_x dx - \hat{u}_{j+\frac{1}{2}} z^-_{j+\frac{1}{2}} + \hat{u}_{j-\frac{1}{2}} z^+_{j-\frac{1}{2}} = 0.
\end{aligned} \tag{1.14}$$

However, the fluxes $\hat{p}_{j+\frac{1}{2}}$, $\hat{q}_{j+\frac{1}{2}}$, and $\hat{u}_{j+\frac{1}{2}}$ must be designed based on guiding principles different than the first order convection or second order diffusion cases. The crucial part in designing a stable and accurate algorithm (1.14) is again a correct design of these fluxes. It turns out that the simple choices

$$\hat{p}_{j+\frac{1}{2}} = p^+_{j+\frac{1}{2}}, \quad \hat{q}_{j+\frac{1}{2}} = q^+_{j+\frac{1}{2}}, \quad \hat{u}_{j+\frac{1}{2}} = u^-_{j+\frac{1}{2}}, \tag{1.15}$$

which are partially motivated by upwinding (a simple wave solution to (1.12) moves from right to left), would guarantee stability and convergence, as will be proven later in this paper and also clearly seen in Example 4.1 in section 4.

We remark that the choice for the fluxes (1.15) is not unique. In fact, the crucial part is to take $\hat{p}$ and $\hat{u}$ from opposite sides and to take $\hat{q}$ from the right. Thus

$$\hat{p}_{j+\frac{1}{2}} = p^-_{j+\frac{1}{2}}, \quad \hat{q}_{j+\frac{1}{2}} = q^+_{j+\frac{1}{2}}, \quad \hat{u}_{j+\frac{1}{2}} = u^+_{j+\frac{1}{2}}$$

would also work.

2. The local discontinuous Galerkin method for the one-dimensional case. In this section, we present and analyze the local discontinuous Galerkin method for the following one-dimensional nonlinear problem:

$$U_t + f(U)_x + (r'(U)g(r(U)_x)_x)_x = 0, \qquad 0 \le x \le 1, \tag{2.1}$$

with an initial condition

$$U(x,0) = U^0(x), \qquad 0 \le x \le 1, \tag{2.2}$$

and periodic boundary conditions. Here $f(U)$, $r(U)$, and $g(Q)$ (with Q defined by (2.3) below) are arbitrary (smooth) nonlinear functions. Notice that the assumption of periodic boundary conditions is for simplicity only and is not essential: the method can be easily designed for nonperiodic boundary conditions. Also notice that both the linear equation (1.12) and the KdV equation (1.1) are special cases of (2.1).

To define the local discontinuous Galerkin method, we first introduce the new variables

$$Q = r(U)_x, \qquad P = g(Q)_x \tag{2.3}$$

and rewrite (2.1) as a first order system:

$$U_t + (f(U) + r'(U)P)_x = 0, \quad P - g(Q)_x = 0, \quad Q - r(U)_x = 0. \tag{2.4}$$

The local discontinuous Galerkin method is obtained by discretizing the above system with the discontinuous Galerkin method. This is achieved by multiplying the three equations in (2.4) by three test functions v, w, z, respectively, integrating over the interval I_j, and integrating by parts. We also need to pay special attention to the boundary terms resulting from the procedure of integration by parts, as mentioned in the previous section. Thus we seek piecewise polynomial solutions $u, p, q \in \mathcal{V}_{\Delta x}$, where $\mathcal{V}_{\Delta x}$ is defined in (1.6) and consists of piecewise polynomials of degree up to k in each cell I_j such that for all test functions $v, w, z \in \mathcal{V}_{\Delta x}$ we have, for $1 \le j \le N$,

$$\begin{aligned}
&\int_{I_j} u_t v dx - \int_{I_j} (f(u) + r'(u)p) v_x dx + \left(\hat{f} + \widehat{r'}\hat{p}\right)_{j+\frac{1}{2}} v^-_{j+\frac{1}{2}} - \left(\hat{f} + \widehat{r'}\hat{p}\right)_{j-\frac{1}{2}} v^+_{j-\frac{1}{2}} = 0,\\
&\int_{I_j} p w dx + \int_{I_j} g(q) w_x dx - \hat{g}_{j+\frac{1}{2}} w^-_{j+\frac{1}{2}} + \hat{g}_{j-\frac{1}{2}} w^+_{j-\frac{1}{2}} = 0,\\
&\int_{I_j} q z dx + \int_{I_j} r(u) z_x dx - \hat{r}_{j+\frac{1}{2}} z^-_{j+\frac{1}{2}} + \hat{r}_{j-\frac{1}{2}} z^+_{j-\frac{1}{2}} = 0.
\end{aligned} \tag{2.5}$$

The only ambiguity in the algorithm (2.5) now is the definition of the numerical fluxes (the "hats"), which should be designed based on guiding principles different than the first order convection or second order diffusion cases to ensure stability. It turns out that we can take the following simple choices (we omit the subscripts $j \pm \frac{1}{2}$ in the definition of the fluxes, as all quantities are evaluated at the interfaces $x_{j\pm\frac{1}{2}}$):

$$\hat{f} = \hat{f}(u^-, u^+), \quad \widehat{r'} = \frac{r(u^+) - r(u^-)}{u^+ - u^-}, \quad \hat{p} = p^+, \quad \hat{g} = \hat{g}(q^-, q^+), \quad \hat{r} = r(u^-), \tag{2.6}$$

where $\hat{f}(u^-, u^+)$ is a monotone flux for $f(u)$, namely, $\hat{f}(u^-, u^+)$ is a Lipschitz continuous function in both arguments u^- and u^+, is consistent with $f(u)$ in the sense that

$\hat{f}(u,u) = f(u)$, and is a nondecreasing function in u^- and a nonincreasing function in u^+. Likewise, $-\hat{g}(q^-,q^+)$ is a monotone flux for $-g(q)$, namely, $\hat{g}(q^-,q^+)$ is a Lipschitz continuous function in both arguments q^- and q^+, is consistent with $g(q)$ in the sense that $\hat{g}(q,q) = g(q)$, and is a nonincreasing function in q^- and a nondecreasing function in q^+. Examples of monotone fluxes which are suitable for discontinuous Galerkin methods can be found in, e.g., [11]. We could, for example, use the simple Lax–Friedrichs flux

$$\hat{f}(u^-,u^+) = \frac{1}{2}\left(f(u^-) + f(u^+) - \alpha(u^+ - u^-)\right), \qquad \alpha = \max_u |f'(u)|, \tag{2.7}$$

where the maximum is taken over a relevant range of u. The algorithm is now well defined.

We remark that the choice for the fluxes (2.6) is not unique. In fact, the crucial part is to take $\hat{p}$ and $\hat{r}$ from opposite sides. Thus

$$\hat{f} = \hat{f}(u^-,u^+), \quad \widehat{r'} = \frac{r(u^+) - r(u^-)}{u^+ - u^-}, \quad \hat{p} = p^-, \quad \hat{g} = \hat{g}(q^-,q^+), \quad \hat{r} = r(u^+)$$

would also work. Since information for the third order equation (2.1) flows in preferred directions, the choice of monotone fluxes above is heuristically justified based on upwind considerations. Of course, the rigorous justification for the choice of fluxes comes from the stability results to be proven in Proposition 2.1 below.

We also remark that the algorithm (2.5)–(2.6) is very easy for numerical implementation. Given u, one first uses the third equation in (2.5) to obtain q. This is achieved locally: q in I_j can be obtained with the information of u in the cells I_j and I_{j-1}. The second equation in (2.5) is then used to obtain p locally: p in I_j can be obtained with the information of q in (at most) the cells I_j, I_{j-1}, and I_{j+1}. Finally, the update of the solution u is obtained using the first equation in (2.5), again locally, namely, the update of u in I_j can be obtained with the information of u in (at most) the cells I_j, I_{j-1}, and I_{j+1} and that of p in the cells I_j and I_{j+1}.

We have the following "cell entropy inequality" for the scheme (2.5)–(2.6). This is a generalization of the cell entropy inequality obtained in [18] for the discontinuous Galerkin method applied to hyperbolic conservation laws ((2.1) with $g(q) = 0$).

PROPOSITION 2.1 (cell entropy inequality). *There exist numerical entropy fluxes $\hat{H}_{j+\frac{1}{2}}$ such that the solution to the scheme* (2.5)–(2.6) *satisfies*

$$\frac{d}{dt}\int_{I_j}\left(\frac{u^2(x,t)}{2}\right)dx + \left(\hat{H}_{j+\frac{1}{2}} - \hat{H}_{j-\frac{1}{2}}\right) \le 0. \tag{2.8}$$

Proof. We sum up the three equalities in (2.5) and introduce the notation

$$\begin{aligned} B_j(u,p,q;v,w,z) = &\int_{I_j} u_t v dx - \int_{I_j}(f(u) + r'(u)p)v_x dx + \left(\hat{f} + \widehat{r'}\hat{p}\right)_{j+\frac{1}{2}} v^-_{j+\frac{1}{2}} \\ &- \left(\hat{f} + \widehat{r'}\hat{p}\right)_{j-\frac{1}{2}} v^+_{j-\frac{1}{2}} + \int_{I_j} pw dx + \int_{I_j} g(q)w_x dx - \hat{g}_{j+\frac{1}{2}} w^-_{j+\frac{1}{2}} \\ &+ \hat{g}_{j-\frac{1}{2}} w^+_{j-\frac{1}{2}} + \int_{I_j} qz dx + \int_{I_j} r(u)z_x dx - \hat{r}_{j+\frac{1}{2}} z^-_{j+\frac{1}{2}} + \hat{r}_{j-\frac{1}{2}} z^+_{j-\frac{1}{2}}. \end{aligned} \tag{2.9}$$

Clearly, the solutions u, p, q of the scheme (2.5)–(2.6) satisfy

$$B_j(u,p,q;v,w,z) = 0 \tag{2.10}$$

for all $v, w, z \in \mathcal{V}_{\Delta x}$. We then take

$$v = u, \quad w = q, \quad z = -p$$

to obtain, after some algebraic manipulations,

$$0 = B_j(u, p, q; u, q, -p) = \frac{d}{dt} \int_{I_j} \left(\frac{u^2(x,t)}{2} \right) dx + \left(\hat{H}_{j+\frac{1}{2}} - \hat{H}_{j-\frac{1}{2}} \right) + \Theta_{j-\frac{1}{2}}$$

with the numerical entropy flux $\hat{H}$ defined by

$$\hat{H} = -F(u^-) + G(q^-) - r(u^-)p^- + \left(\hat{f} + \widehat{r'}\hat{p} \right) u^- - \hat{g}q^- + \hat{r}p^- \tag{2.11}$$

and the extra term Θ given by

$$\Theta = [F(u) - G(q) + r(u)p] - \left(\hat{f} + \widehat{r'}\hat{p} \right) [u] + \hat{g}[q] - \hat{r}[p].$$

Here

$$F(u) = \int^u f(u)du, \qquad G(q) = \int^q g(q)dq,$$

and

$$[v] = v^+ - v^-$$

denotes the jump of v. Notice that we have dropped the subscripts about the location $j - \frac{1}{2}$ or $j + \frac{1}{2}$, as all these quantities are defined at a single interface and depend only on the left and right values at that interface. Now all we need to do is verify $\Theta \geq 0$. To this end, we notice that, with the definition (2.6) of the numerical fluxes and with simple algebraic manipulations, we easily obtain

$$[r(u)p] - \widehat{r'}\hat{p}[u] - \hat{r}[p] = 0,$$

and hence

$$\begin{aligned} \Theta &= [F(u)] - \hat{f}[u] - [G(q)] + \hat{g}[q] \\ &= \int_{u^-}^{u^+} \left(f(s) - \hat{f}(u^-, u^+) \right) ds - \int_{q^-}^{q^+} \left(g(s) - \hat{g}(q^-, q^+) \right) ds \\ &\geq 0, \end{aligned} \tag{2.12}$$

where the last inequality follows from the monotonicity of the fluxes $\hat{f}$ and $-\hat{g}$. This finishes the proof. ∎

Now the L^2 stability of the method is a trivial corollary as follows.

COROLLARY 2.2 (L^2 stability). *The solution to the scheme* (2.5)–(2.6) *satisfies the L^2 stability*

$$\frac{d}{dt} \int_0^1 \left(\frac{u^2(x,t)}{2} \right) dx \leq 0. \tag{2.13}$$

Proof. For the proof, we simply add up (2.8) over j. ∎

Regarding time discretizations, if we denote the semidiscrete local discontinuous Galerkin method (2.5)–(2.6) by

$$u_t = R(u),$$

then the following implicit θ scheme:

$$\frac{u^{n+1}-u^n}{\Delta t} = R(u^{n+\theta}), \qquad u^{n+\theta} = (1-\theta)u^n + \theta u^{n+1} \tag{2.14}$$

also will satisfy the same cell entropy inequality and L^2 stability as long as $\frac{1}{2} \le \theta \le 1$. Notice that this includes the first order backward Euler and second order Crank–Nicholson implicit time discretizations as special cases. See [18] for the purely hyperbolic case.

PROPOSITION 2.3 (implicit time discretization). *The cell entropy inequality and the L^2 stability also hold for the time discretization* (2.14) *with $\frac{1}{2} \le \theta \le 1$ for the scheme* (2.5)–(2.6). *That is,*

$$\int_{I_j} \left(\frac{(u^{n+1}(x))^2 - (u^n(x))^2}{2\Delta t} \right) dx + \hat{H}^{n+\theta}_{j+\frac{1}{2}} - \hat{H}^{n+\theta}_{j-\frac{1}{2}} \le 0 \tag{2.15}$$

and

$$\int_0^1 (u^{n+1}(x))^2 dx \le \int_0^1 (u^n(x))^2 dx. \tag{2.16}$$

Proof. If we take the test functions at $n+\theta$, e.g., $v = u^{n+\theta}$ given by (2.14), we obtain, just as before,

$$\int_{I_j} \frac{u^{n+1}(x) - u^n(x)}{\Delta t} u^{n+\theta} dx + \hat{H}^{n+\theta}_{j+\frac{1}{2}} - \hat{H}^{n+\theta}_{j-\frac{1}{2}} \le 0,$$

which can be rewritten as

$$\int_{I_j} \left(\frac{(u^{n+1}(x))^2 - (u^n(x))^2}{2\Delta t} \right) dx + \hat{H}^{n+\theta}_{j+\frac{1}{2}} - \hat{H}^{n+\theta}_{j-\frac{1}{2}} + \left(\theta - \frac{1}{2}\right) \int_{I_j} \left(\frac{(u^{n+1}(x) - u^n(x))^2}{\Delta t} \right) dx \le 0.$$

Thus, a sufficient condition for obtaining the cell entropy inequality (2.15) is just $\theta \ge \frac{1}{2}$. Again, (2.16) is obtained simply by adding up (2.15) over j. ∎

The stability result obtained here can be used to get an error estimate in L^2 for the numerical solution u when (2.1) is linear. Without loss of generality, we may take $f(U) = U$, $g(Q) = Q$, and $r(U) = U$, resulting in the equation

$$U_t + U_x + U_{xxx} = 0. \tag{2.17}$$

We have the following result, where C here and below denotes a generic constant which may be of different values at different locations.

PROPOSITION 2.4 (error estimate). *The error for the scheme* (2.5)–(2.6) *applied to the linear PDE* (2.17) *satisfies*

$$\sqrt{\int_0^1 \left(U(x,t) - u(x,t)\right)^2 dx} \le C\Delta x^{k+\frac{1}{2}}, \tag{2.18}$$

where the constant C depends on the first $k+3$ derivatives of U and time t.

Proof. First, we notice that, in this linear case, most monotone fluxes simply become upwinding,

$$\hat{f}(u^-, u^+) = u^-, \qquad \hat{g}(q^-, q^+) = q^+,$$

and this is what we will assume. It is then easy to work out the exact form of Θ in (2.12) for the cell entropy inequality to be

$$\Theta = \frac{1}{2}\left([u]^2 + [q]^2\right). \tag{2.19}$$

We now notice that the exact solution of the PDE (2.17), U, $Q = U_x$, and $P = U_{xx}$ clearly satisfies

$$B_j(U, P, Q; v, w, z) = 0$$

for all $v, w, z \in \mathcal{V}_{\Delta x}$, where B_j is defined by (2.9). Taking the difference between the above equality and (2.10), we obtain the *error equation*

$$B_j(U - u, P - p, Q - q; v, w, z) = 0 \tag{2.20}$$

for all $v, w, z \in \mathcal{V}_{\Delta x}$. As usual, this error equation is the basic starting point of error estimates.

We now take

$$v = \mathcal{S}U - u, \quad w = \mathcal{P}Q - q, \quad z = p - \mathcal{P}P \tag{2.21}$$

in the error equation (2.20). Here $\mathcal{P}$ is the standard L^2 projection into $\mathcal{V}_{\Delta x}$; that is, for each j,

$$\int_{I_j} (\mathcal{P}r(x) - r(x))s(x)dx = 0 \quad \forall s \in P^k,$$

where P^k denotes the space of all polynomials of degree at most k. In other words, the difference between the projection $\mathcal{P}r$ and the original function r is orthogonal to all polynomials of degree up to k in each interval. $\mathcal{S}$ is a special projection into $\mathcal{V}_{\Delta x}$ which satisfies, for each j,

$$\int_{I_j} (\mathcal{S}r(x) - r(x))s(x)dx = 0 \quad \forall s \in P^{k-1} \quad \text{and} \quad \mathcal{S}r(x^-_{j+1/2}) = r(x^-_{j+1/2});$$

in other words, the difference between the projection $\mathcal{S}r$ and the original function r is orthogonal to all polynomials of degree up to $k-1$ in each interval, and the projection agrees with the function at the right boundary in each interval. This special projection is needed for U because we have no control over the jumps of p in the cell entropy inequality; see (2.19). Substituting (2.21) into the error equation (2.20) and moving terms, we obtain

$$B_j(v, -z, w; v, w, z) = B_j(v^e, -z^e, w^e; v, w, z), \tag{2.22}$$

where v, w, z are given by (2.21), and v^e, w^e, z^e are given by

$$v^e = \mathcal{S}U - U, \quad w^e = \mathcal{P}Q - Q, \quad z^e = P - \mathcal{P}P. \tag{2.23}$$

By the same argument as that used for the cell entropy inequality, the left-hand side of (2.22) becomes

$$B_j(v,-z,w;v,w,z)=\frac{d}{dt}\int_{I_j}\left(\frac{v^2}{2}\right)dx+\left(\hat{H}_{j+\frac{1}{2}}-\hat{H}_{j-\frac{1}{2}}\right)+\Theta_{j-\frac{1}{2}}, \tag{2.24}$$

where, by (2.19),

$$\Theta_{j-\frac{1}{2}}=\frac{1}{2}\left([v]^2_{j-\frac{1}{2}}+[w]^2_{j-\frac{1}{2}}\right). \tag{2.25}$$

The right-hand side of (2.22) can be written out as

$$B_j(v^e,-z^e,w^e;v,w,z)=\mathcal{I}+\mathcal{II}+\mathcal{III}+\mathcal{IV}, \tag{2.26}$$

where

$$\mathcal{I}=\int_{I_j}v_t^e v dx, \tag{2.27}$$

$$\mathcal{II}=-\int_{I_j}z^e w dx+\int_{I_j}w^e z dx-\int_{I_j}(v^e-z^e)v_x dx+\int_{I_j}w^e w_x dx+\int_{I_j}v^e z_x dx, \tag{2.28}$$

$$\mathcal{III}=-\left(\left(v^e_{j-\frac{1}{2}}\right)^-\!-\left(z^e_{j-\frac{1}{2}}\right)^+\right)[v]_{j-\frac{1}{2}}+\left(w^e_{j-\frac{1}{2}}\right)^+[w]_{j-\frac{1}{2}}+\left(v^e_{j-\frac{1}{2}}\right)^-[z]_{j-\frac{1}{2}}, \tag{2.29}$$

and

$$\mathcal{IV}=\hat{h}_{j+\frac{1}{2}}-\hat{h}_{j-\frac{1}{2}} \tag{2.30}$$

for some flux function $\hat{h}$. Notice that v,w,z are given by (2.21) and v^e,w^e,x^e are given by (2.23), respectively.

Now, by using the simple inequality $ab\le\frac{1}{2}(a^2+b^2)$, and the standard approximation theory on $v_t^e=(\mathcal{S}U-U)_t$ (see, e.g., [7]), we have

$$\mathcal{I}\le C\Delta x_j^{2k+3}+\int_{I_j}\left(\frac{v^2}{2}\right)dx.$$

Because $\mathcal{P}$ is a local L^2 projection, and $\mathcal{S}$, even though not a local L^2 projection, does have the property that $w-\mathcal{S}w$ is locally orthogonal to all polynomials of degree up to $k-1$, all the terms in $\mathcal{II}$ are actually zero. The last term in $\mathcal{III}$ is zero because of the special interpolating property of the projection $\mathcal{S}$. An application of the simple inequality $ab\le\frac{1}{2}(a^2+b^2)$ for the first two terms in $\mathcal{III}$ and standard approximation theory on the point values of $v^e-z^e=(\mathcal{S}U-U)+(\mathcal{P}P-P)$ and of $w^e=\mathcal{P}Q-Q$ (see, e.g., [7]) then gives

$$\mathcal{III}\le C(\Delta x_{j-1}^{2k+2}+\Delta x_j^{2k+2})+\frac{1}{4}\left([v]^2+[w]^2\right).$$

Finally, $\mathcal{IV}$ only contains flux difference terms which will vanish upon a summation in j.

Combining all these and summing over j we obtain the inequality

$$\frac{d}{dt}\int_0^1 \left(\frac{v^2}{2}\right) dx + \frac{1}{4}\left([v]^2 + [w]^2\right) \le C\Delta x^{2k+1} + \int_0^1 \left(\frac{v^2}{2}\right) dx.$$

An integration in t plus the standard approximation theory on $v^e = \mathcal{S}U - U$ then gives the desired error estimate (2.18). □

We remark that the actual numerical computations in section 4 demonstrate that the order of accuracy is $k+1$ in both L^2 and L^∞ norms. It is not clear if the error estimate (2.18) is sharp. The trick to getting the extra half-order in the error estimate is through the choice of projections in (2.23), similar to $\mathcal{S}$ there but satisfying the point condition on the left boundary. This would eliminate the boundary terms in $\mathcal{III}$ but would cause problems in the control of volume integrals in $\mathcal{II}$. Notice that for first order linear hyperbolic equations, the optimal order of accuracy is $k+1$ in one dimension, and also in tensor product multidimensional cases [22], while the optimal order is $k + 1/2$ for general multidimensional cases [23].

3. The local discontinuous Galerkin method for the multiple dimensional case. In this section, we generalize the scheme discussed in the previous section to multiple space dimensions $x = (x_1, \ldots, x_d)$. We solve the following nonlinear problem:

(3.1)
$$U_t + \sum_{i=1}^{d} f_i(U)_{x_i} + \sum_{i=1}^{d} \left(r_i'(U) \sum_{j=1}^{d} g_{ij}(r_i(U)_{x_i})_{x_j} \right)_{x_i} = 0, \quad 0 \le x_i \le 1, \quad i = 1, \ldots, d,$$

with an initial condition

$$U(x,0) = U^0(x), \quad 0 \le x_i \le 1, \quad i = 1, \ldots, d, \tag{3.2}$$

and periodic boundary conditions. Here $f_i(U)$, $r_i(U)$, and $g_{ij}(Q)$ are arbitrary (smooth) nonlinear functions. Notice that the assumption of a box geometry and periodic boundary conditions is for simplicity only and is not essential: the method can be easily designed for arbitrary domain and for nonperiodic boundary conditions.

Let's denote a triangulation of the unit box by $\mathcal{T}_{\Delta x}$, consisting of nonoverlapping polyhedra completely covering the unit box. Hanging nodes are allowed. Here Δx measures the longest edge of all polyhedra in $\mathcal{T}_{\Delta x}$. We again denote the finite element space by

$$\mathcal{V}_{\Delta x}^d = \{v : \ v \text{ is a polynomial of degree at most } k \text{ for } x \in K \ \forall K \in \mathcal{T}_{\Delta x}\}. \tag{3.3}$$

Similar to the one-dimensional case, to define the local discontinuous Galerkin method we first introduce the new variables

$$Q_i = r_i(U)_{x_i}, \quad P_i = \sum_{j=1}^{d} g_{ij}(Q_i)_{x_j}, \quad i = 1, \ldots, d, \tag{3.4}$$

and rewrite (3.1) as a first order system:

$$\begin{aligned} &U_t + \sum_{i=1}^{d} (f_i(U) + r_i'(U)P_i)_{x_i} = 0, \\ &P_i - \sum_{j=1}^{d} g_{ij}(Q_i)_{x_j} = 0, \quad Q_i - r_i(U)_{x_i} = 0, \quad i = 1, \ldots, d. \end{aligned} \tag{3.5}$$

The local discontinuous Galerkin method is obtained by discretizing the above system with the discontinuous Galerkin method. This is achieved by multiplying the equations in (3.5) by test functions v, w_i, z_i for $i = 1, \ldots, d$, respectively, integrating over an element $K \in \mathcal{T}_{\Delta x}$, and integrating by parts. We again need to pay special attention to the boundary terms resulting from the procedure of integration by parts, as in the one-dimensional case. Thus we seek piecewise polynomial solutions $u, p_i, q_i \in V_{\Delta x}^d$, where $V_{\Delta x}^d$ is defined in (3.3), such that for all test functions $v, w_i, z_i \in V_{\Delta x}^d$ we have

$$\int_K u_t v dx - \sum_{i=1}^d \int_K (f_i(u) + r_i'(u)p_i) v_{x_i} dx + \int_{\partial K} \widehat{h_{n_K}} v^{int_K} ds = 0,$$

$$\int_K p_i w_i dx + \sum_{j=1}^d \int_K g_{ij}(q_i)(w_i)_{x_j} dx - \int_{\partial K} \widehat{g_{i,n_K}} w^{int_K} ds = 0, \qquad i = 1, \ldots, d, \tag{3.6}$$

$$\int_K q_i z_i dx + \int_K r_i(u)(z_i)_{x_i} dx - \int_{\partial K} \widehat{r_{i,n_K}} z^{int_K} ds = 0, \qquad i = 1, \ldots, d,$$

where ∂K is the boundary of element K, and the numerical fluxes (the "hats") are defined similar to the one-dimensional cases, namely,

$$\widehat{h_{n_K}} = \widehat{f_{n_K,K}}(u^{int_K}, u^{ext_K}) + \frac{\sum_{i=1}^d \left(r_i(u^{ext_K}) - r_i(u^{int_K})\right) p_i^+ n_{i,K}}{u^{ext_K} - u^{int_K}},$$

$$\widehat{g_{i,n_K}} = \widehat{g_{i,n_K,K}}(q^{int_K}, q^{ext_K}), \quad \widehat{r_{i,n_K}} = r_i(u^-)\, n_{i,K}. \tag{3.7}$$

Here $n_K = (n_{1,K}, \ldots, n_{d,K})$ is the outward unit normal for element K along the element boundary ∂K, u^{int_K} denotes the value of u evaluated from inside the element K, and u^{ext_K} denotes the value of u evaluated from outside the element K (inside the neighboring element). On the other hand, p^+ denotes the value of p evaluated from a predesignated "plus" side along an edge e, which is always the boundaries of two neighboring elements. For example, we could choose a fixed vector β, which is not parallel with any normals of element boundaries, and then designate the "plus" side to be the side at the end of the arrow of the normal n with $n \cdot \beta > 0$; see Figure 3.1. $\widehat{f_{n_K,K}}(u^{int_K}, u^{ext_K})$ is a monotone flux for $f_{n_K}(u) = \sum_{i=1}^d f_i(u) n_{i,K}$, namely, $\widehat{f_{n_K,K}}(u^{int_K}, u^{ext_K})$ is a Lipschitz continuous function in both arguments u^{int_K} and u^{ext_K}, is consistent with $f_{n_K}(u)$ in the sense that $\widehat{f_{n_K}}(u, u) = f_{n_K}(u)$, and is a nondecreasing function in u^{int_K} and a nonincreasing function in u^{ext_K}. Moreover, it is conservative (that is, there is only one flux at each edge shared by two elements, added to the residue for one and subtracted from the residue for another), namely,

$$\widehat{f_{n_K,K}}(a, b) = -\widehat{f_{n_{K'},K'}}(b, a),$$

where K and K' share the same edge where the flux is computed and hence $n_{K'} = -n_K$. Likewise, $-\widehat{g_{i,n_K,K}}(q_i^{int_K}, q_i^{ext_K})$ is a monotone flux for $-g_{i,n_K}(q_i) = -\sum_{j=1}^d g_{ij}(q) n_{j,K}$. Notice that we can again use the one-dimensional monotone fluxes as in the previous section. For example, we can use the simple Lax–Friedrichs flux

$$\widehat{f_{n_K,K}}(u^{int_K}, u^{ext_K}) = \frac{1}{2}\left(\sum_{i=1}^d \left(f_i(u^{int_K}) + f_i(u^{ext_K})\right) n_{i,K} - \alpha(u^{ext_K} - u^{int_K})\right), \tag{3.8}$$

$$\alpha = \max_u |f_{n_K}'(u)|,$$

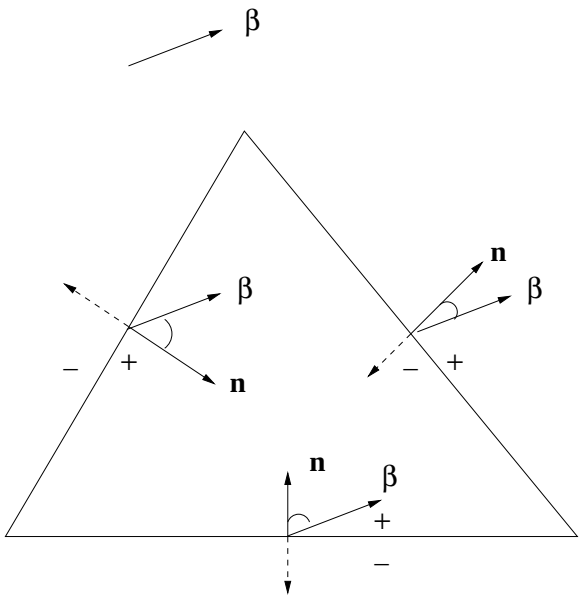

FIG. 3.1. *Illustration of the definition of "plus" and "minus" sides determined by a predetermined vector* β.

where the maximum is taken over a relevant range of u. The algorithm is now well defined.

Again, the algorithm (3.6)–(3.7) is very easy for numerical implementation. Given u, one first locally solves for the q_i, then locally solves for the p_i, and finally locally solves for the update of u. All the advantages listed for the method for the one-dimensional case are still valid in this multiple dimensional case.

We still have the following "cell entropy inequality" for the scheme (3.6)–(3.7). The proof follows along the same lines as that for the one-dimensional case, so we will omit it.

PROPOSITION 3.1 (cell entropy inequality). *There exist conservative numerical entropy fluxes* $\widehat{H_{n_K,K}}$ *such that the solution to the scheme* (3.6)–(3.7) *satisfies*

$$\frac{d}{dt}\int_K \left(\frac{u^2(x,t)}{2}\right) dx + \int_{\partial K} \widehat{H_{n_K,K}} ds \le 0. \tag{3.9}$$

The definition of the numerical entropy flux $\widehat{H_{n_K,K}}$ is similar to (2.11) for the one-dimensional case and is a bit longer in notation; thus we do not write it out. It is not important what the exact form of this numerical entropy flux is, as long as it is a "flux", i.e., shared by both sides of the edge and coming into the edge from one cell and out to the other, thus summing to zero when both cells are considered.

The L^2 stability of the method is then again a trivial corollary by summing up the cell entropy inequalities over K as follows.

COROLLARY 3.2 (L^2 stability). *The solution to the scheme* (3.6)–(3.7) *satisfies the* L^2 *stability*

$$\frac{d}{dt}\int_\Omega \left(\frac{u^2(x,t)}{2}\right) dx \le 0. \tag{3.10}$$

The same cell entropy inequality also holds for the implicit time discretizations as follows.

PROPOSITION 3.3 (implicit time discretization). *The cell entropy inequality and the L^2 stability also hold for the time discretization* (2.14) *with* $\frac{1}{2} \le \theta \le 1$ *for the scheme* (3.6)–(3.7). *That is,*

$$\int_K \left(\frac{(u^{n+1}(x))^2 - (u^n(x))^2}{2\Delta t} \right) dx + \int_{\partial K} \widehat{H^{n+\theta}_{n_K,K}} ds \le 0 \tag{3.11}$$

and

$$\int_\Omega (u^{n+1}(x))^2 dx \le \int_\Omega (u^n(x))^2 dx. \tag{3.12}$$

Unfortunately, we could not obtain an error estimate similar to the one-dimensional case because of the lack of a similar suitable projection $\mathcal{S}$. However, numerical examples in the next section verify that the accuracy holds as in the one-dimensional case. We remark that we could change the scheme to add an extra penalty term for the jumps of p (i.e., modifying the definition of the flux $\hat{r}$ in (2.6) by adding an additional term $-c[p]$, where c is a positive constant); then the error estimate proof would proceed in a straightforward way since there will be an additional $[p]^2$ term in the definition of Θ in (2.19). However, the resulting scheme would be much less attractive because it will lose the local solvability property for q and p. In order to get q and p one would then need to solve a global system, thus losing the main advantage of a local discontinuous Galerkin method. We do not give further details of this modified scheme here because it has little practical value, but interested readers can find similar issues addressed for the convection diffusion problems in [13].

4. Numerical examples. In this section we provide a few preliminary numerical examples to illustrate the accuracy and capability of the method. Attention has not been paid to efficiency in time discretizations, so an explicit third order Runge–Kutta method [26] is used, with small time steps so that spatial errors always dominate. We have also computed them with implicit time discretizations obtaining essentially the same results. Study of suitable implicit time discretizations which have efficient iterative solvers maintaining the local structure of the method is the subject of future work.

We would like to illustrate through these numerical examples the high order accuracy of the methods for both one-dimensional and two-dimensional linear and nonlinear problems. We would also like to illustrate the good behavior of the method for the so-called convection dominated cases, namely, the case where the coefficients of the third derivative terms are small.

Example 4.1. We compute the solution of the linear one-dimensional equation

$$U_t + U_{xxx} = 0 \tag{4.1}$$

with an initial condition $U(x,0) = \sin(x)$ and periodic boundary conditions (with 2π periodicity). The exact solution is given by $U(x,t) = \sin(x+t)$. Both uniform meshes and nonuniform meshes are used. The nonuniform meshes in this and later examples are a repeated pattern of $0.9\Delta x$ and $1.1\Delta x$ with an even number of elements. The L^2 and L^∞ errors, $||U-u||_{L^2}$ and $||U-u||_{L^\infty}$, and the numerical order of accuracy are contained in Table 4.1 for the uniform mesh case and in Table 4.2 for the nonuniform mesh case. We can clearly see that the method with P^k elements gives a uniform

$(k+1)$th order of accuracy in both norms for both the uniform and the nonuniform meshes.

Example 4.2. We compute the solution of the linear two-dimensional equation

$$U_t + U_{xxx} + U_{yyy} = 0 \tag{4.2}$$

with an initial condition $U(x,y,0) = \sin(x+y)$ and periodic boundary conditions (with 2π periodicity) in both directions. The exact solution is given by $U(x,y,t) = \sin(x+y+2t)$. Both uniform and nonuniform rectangular meshes are used. The nonuniform meshes are a repeated pattern of $0.9\Delta x$ and $1.1\Delta x$, in both directions, with an even number of edges in both directions. The L^2 and L^∞ errors and the numerical order of accuracy are contained in Table 4.3 for the uniform mesh case and in Table 4.4 for the nonuniform mesh case. We can clearly see again that the method with P^k elements gives a uniform $(k+1)$th order of accuracy for both the uniform and the nonuniform meshes.

Example 4.3. In order to see the accuracy of the method for nonlinear problems, we compute the classical soliton solution of the KdV equation

$$U_t - 3\left(U^2\right)_x + U_{xxx} = 0 \tag{4.3}$$

in $-10 \le x \le 12$. The initial condition is given by

$$U(x,0) = -2\,\mathrm{sech}^2(x).$$

TABLE 4.3

$U_t + U_{xxx} + U_{yyy} = 0$. $U(x, y, 0) = \sin(x + y)$. Periodic boundary conditions. L^2 and L^∞ errors. Uniform meshes with $N \times N$ cells. Local discontinuous Galerkin methods with $k = 0, 1, 2, 3$. $t = 1$.

	L^∞	6.0982E-03	4.0321E-04	3.92	2.5340E-05	3.99

The exact solution is

$$U(x, t) = -2\,\mathrm{sech}^2(x - 4t).$$

Table 4.5 (uniform mesh) and Table 4.6 (nonuniform mesh) give the errors of numerical solution at $t = 0.5$ using the boundary condition

$$U(-10, t) = g_1(t), \quad U_x(12, t) = g_2(t), \quad U_{xx}(12, t) = g_3(t), \tag{4.4}$$

where $g_i(t)$ corresponds to the data from the exact solution. Notice that the local discontinuous Galerkin method allows for an easy implementation of such boundary conditions. We can see from these tables that the orders of accuracy are comparable to that for the linear case.

Example 4.4. In order to see the accuracy of the method for nonlinear problems with small coefficient for the third derivative term, we compute the soliton solution of the generalized KdV equation [5]

$$U_t + U_x + \left(\frac{U^4}{4}\right)_x + \epsilon U_{xxx} = 0 \tag{4.5}$$

in $-2 \le x \le 3$, where we take $\epsilon = 0.2058 \times 10^{-4}$. The initial condition is given by

$$U(x, 0) = A\,\mathrm{sech}^{\frac{2}{3}}\left(K(x - x_0)\right) \tag{4.6}$$

with $A = 0.2275$, $x_0 = 0.5$, and $K = 3\left(\frac{A^3}{40\epsilon}\right)^{\frac{1}{2}}$. The exact solution is

$$U(x,t) = A\,\mathrm{sech}^{\frac{2}{3}}\left(K(x - x_0) - \omega t\right),$$

where $\omega = K\left(1 + \frac{A^3}{10}\right)$. We compute the solution using the boundary condition

$$U(-2,t) = g_1(t), \quad U_x(3,t) = g_2(t), \quad U_{xx}(3,t) = g_3(t) \tag{4.7}$$

with a nonuniform mesh. The result is contained in Table 4.7. The scheme clearly

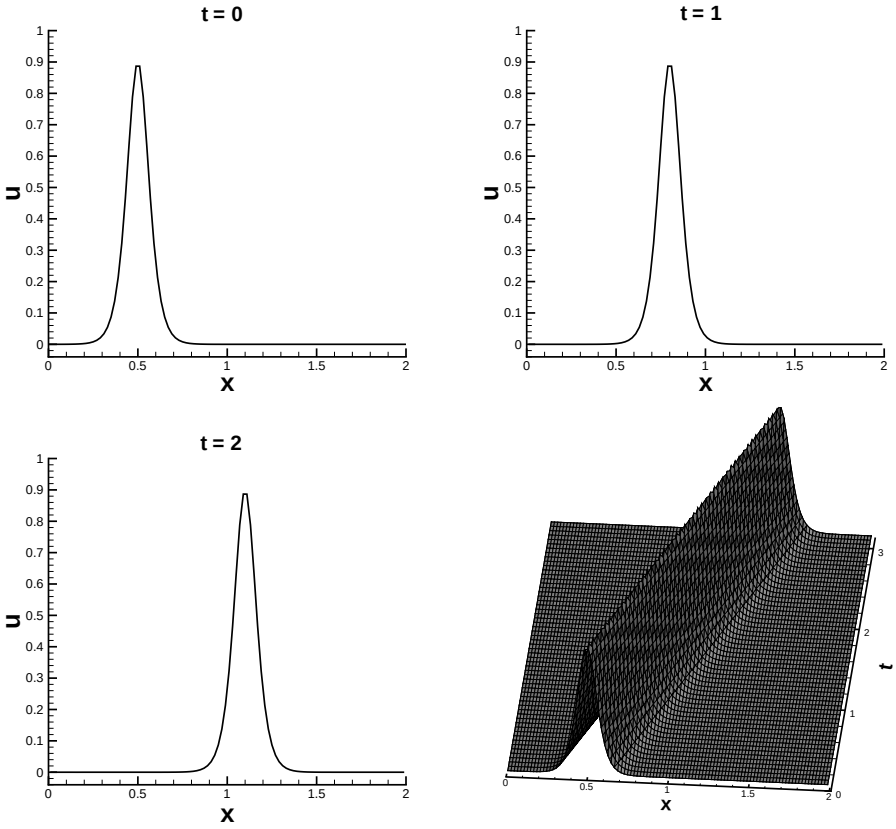

FIG. 4.1. *Single soliton profiles. Solutions of* (4.8) *with initial condition* (4.9) *and periodic boundary conditions in* $[0, 2]$ *using* P^2 *elements with* 100 *cells. Top left: solution at* $t = 0$; *top right:* $t = 1$; *bottom left:* $t = 2$; *bottom right: space time graph of the solution up to* $t = 3$.

demonstrates an order of accuracy of $k + 1$ for P^k elements in both the L^2 and L^∞ norms for this problem with strong nonlinearity in the first derivative term, small dispersive term, and nonperiodic boundary conditions.

Example 4.5. In this example we compute the classical soliton solutions of the KdV equation

$$U_t + \left(\frac{U^2}{2}\right)_x + \epsilon U_{xxx} = 0. \tag{4.8}$$

The examples are those used in [15].

The single soliton case has the initial condition

$$U_0(x) = 3c\,\mathrm{sech}^2\left(k(x - x_0)\right) \tag{4.9}$$

with $c = 0.3$, $x_0 = 0.5$, $k = (1/2)\sqrt{c/\epsilon}$, and $\epsilon = 5 \times 10^{-4}$. The solution is computed in $x \in [0, 2]$ with periodic boundary conditions, using P^2 elements with 100 cells, and is shown in Figure 4.1.

The double soliton collision case has the initial condition

$$U_0(x) = 3c_1\,\mathrm{sech}^2\left(k_1(x - x_1)\right) + 3c_2\,\mathrm{sech}^2\left(k_2(x - x_2)\right) \tag{4.10}$$

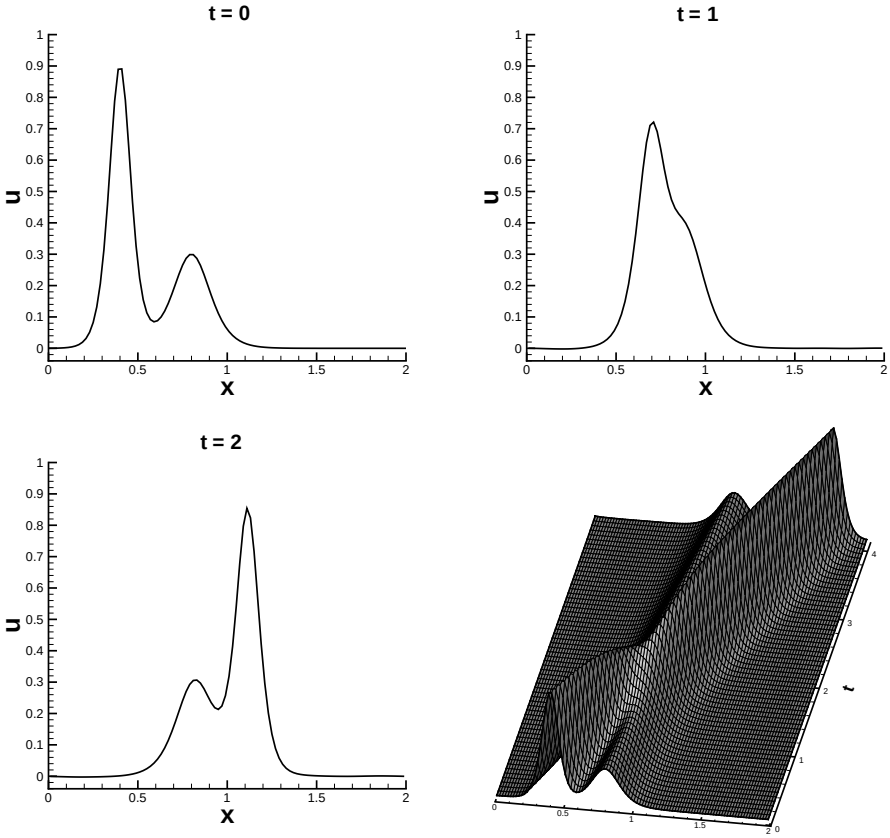

FIG. 4.2. *Double soliton collision profiles. Solutions of* (4.8) *with initial condition* (4.10) *and periodic boundary conditions in* $[0,2]$ *using* P^2 *elements with* 100 *cells. Top left: solution at* $t=0$; *top right:* $t=1$; *bottom left:* $t=2$; *bottom right: space time graph of the solution up to* $t=4$.

with $c_1 = 0.3$, $c_2 = 0.1$, $x_1 = 0.4$, $x_2 = 0.8$, $k_i = (1/2)\sqrt{c_i/\epsilon}$ for $i = 1, 2$, and $\epsilon = 4.84 \times 10^{-4}$. The solution is computed in $x \in [0, 2]$ with periodic boundary conditions, using P^2 elements with 100 cells, and is shown in Figure 4.2.

The triple soliton splitting case has the initial condition

$$U_0(x) = \frac{2}{3}\operatorname{sech}^2\left(\frac{x-1}{\sqrt{108\epsilon}}\right) \tag{4.11}$$

with $\epsilon = 10^{-4}$. The solution is computed in $x \in [0, 3]$ with periodic boundary conditions and is shown in Figure 4.3.

Example 4.6. We compute in this example the KdV zero dispersion limit of conservation laws. The equation is (4.8) with an initial condition

$$U(x, 0) = 2 + 0.5\sin(2\pi x) \tag{4.12}$$

for $x \in [0, 1]$ with periodic boundary conditions, and we are interested in the limit when $\epsilon \to 0^+$. Theoretical and numerical discussions about this limit can be found in [21] and [27]. Here we are concerned mainly with the capability of our numerical method in resolving the small scale solution structures in this limit when ϵ is small.

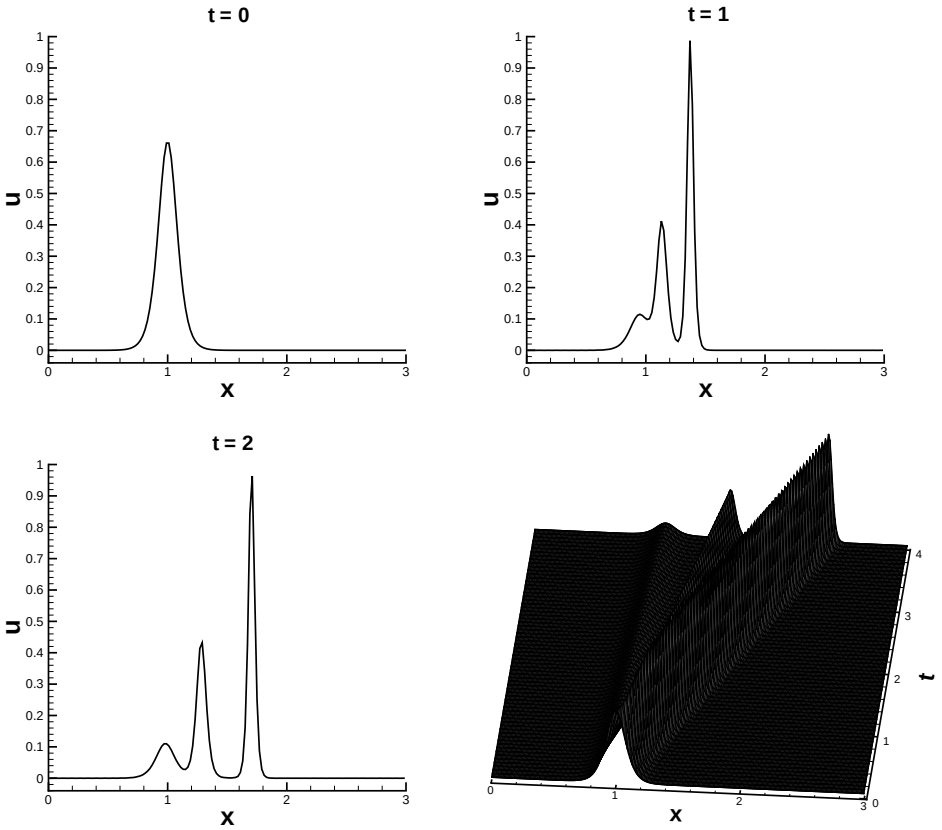

FIG. 4.3. *Triple soliton splitting profiles. Solutions of* (4.8) *with initial condition* (4.11) *and periodic boundary conditions in* $[0, 3]$ *using* P^2 *elements with* 150 *cells. Top left: solution at* $t = 0$; *top right:* $t = 1$; *bottom left:* $t = 2$; *bottom right: space time graph of the solution up to* $t = 4$.

For this purpose we compute the solution to $t = 0.5$ with $\epsilon = 10^{-4}, 10^{-5}, 10^{-6}$, and 10^{-7} using P^2 elements with 300 cells for the first two cases, 800 cells for the third case, and 1700 cells for the last case. We have verified that these are "converged" solutions in the sense that further increasing the number of cells does not change the solutions graphically. These solutions are shown in Figure 4.4. Notice the physical "oscillations" which are typical in such dispersive limits; see, e.g., [21]. Clearly our method is very suitable for computing such solutions.

5. Concluding remarks. We have designed a class of local discontinuous Galerkin methods for solving KdV type equations containing third derivatives and have proven their stability for any space dimensions for a general class of nonlinear equations. Numerical examples are shown to illustrate the accuracy and capability of the methods, especially for the convection dominated cases where the coefficients of the third derivative terms are small. Efficient implicit time discretizations which have efficient iterative solvers maintaining the local structure of the method, an accuracy enhancement study, and more numerical experiments with physically interesting problems constitute an ongoing project.

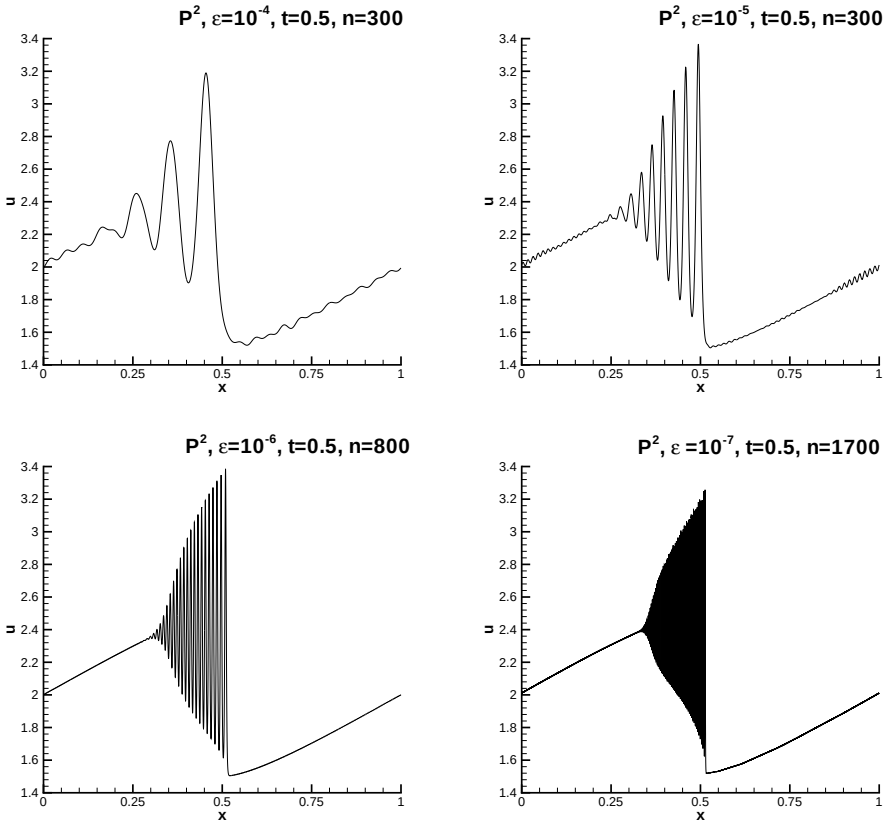

FIG. 4.4. *Zero dispersion limit of conservation laws. Solutions of* (4.8) *with initial condition* (4.12) *and periodic boundary conditions in* $[0,1]$ *using* P^2 *elements at* $t = 0.5$. *Top left:* $\epsilon = 10^{-4}$ *with* 300 *cells; top right:* $\epsilon = 10^{-5}$ *with* 300 *cells; bottom left:* $\epsilon = 10^{-6}$ *with* 800 *cells; bottom right:* $\epsilon = 10^{-7}$ *with* 1700 *cells.*

Acknowledgments. We would like to thank Bernardo Cockburn for his valuable help in the discussion about the projection $\mathcal{S}$ and thank Andrew Majda for pointing out reference [21] and test cases of zero dispersive limits of conservation laws in Example 4.6.

A CONVERGENCE ANALYSIS OF DYKSTRA'S ALGORITHM FOR POLYHEDRAL SETS*

CHRIS PERKINS†

Abstract. Let H be a nonempty closed convex set in a Hilbert space X determined by the intersection of a finite number of closed half spaces. It is well known that given an $x_0 \in X$, Dykstra's algorithm applied to this collection of closed half spaces generates a sequence of iterates that converge to $P_H(x_0)$, the orthogonal projection of x_0 onto H. The iterates, however, do not necessarily lie in H. We propose a combined Dykstra–conjugate-gradient method such that, given an $\varepsilon > 0$, the algorithm computes an $x \in H$ with $\|x - P_H(x_0)\| < \varepsilon$. Moreover, for each iterate x_m of Dykstra's algorithm we calculate a bound for $\|x_m - P_H(x_0)\|$ that approaches zero as m tends to infinity. Applications are made to computing bounds for $\|x_m - P_H(x_0)\|$ where H is a polyhedral cone. Numerical results are presented from a sample isotone regression problem.

Key words. Dykstra's algorithm, best approximation from polyhedra, Hildreth's algorithm, linear inequalities

1. Introduction.

Let X be a Hilbert space and $K_0, K_1, \ldots, K_{n-1}$ be n closed convex sets in X whose intersection, K, is nonempty. Given an $x_0 \in X$, the Boyle–Dykstra algorithm [3] generates a sequence of iterates $\{x_m\}$ whose limit is the orthogonal projection of x_0 onto K. Defining P_{K_i} to be the orthogonal projection onto K_i, letting $[m]$ denote m mod n, and setting

$$e_{-n} = e_{-(n-1)} = \cdots = e_{-1} = \vec{0},$$

Dykstra's algorithm can be written as

$$\begin{aligned} x_{m+1} &= P_{K_{[m]}}(x_m + e_{m-n}), \\ e_m &= (x_m + e_{m-n}) - x_{m+1} \end{aligned}$$

for $m = 0, 1, \ldots$. If the n closed convex sets are half spaces of the form $H_i = \{x \mid \langle x, z_i \rangle \leq f_i\}$, where $z_i \in X$ and $f_i \in \Re$, then the formula for the $(m+1)$st iterate of Dykstra's algorithm can be written as $x_{m+1} = x_m + \xi_m z_{[m]}$, where $\xi_m \in \Re$.

For this finite collection of intersecting closed half spaces, Iusem and De Pierro [11] showed that the Dykstra algorithm converged linearly. Subsequently Deutsch and Hundal [6] have sharpened the rate of convergence bound established in [11] and have shown that

$$\|x_m - P_H(x_0)\| \leq \rho c^m, \tag{1.1}$$

where $H = \cap_{i=0}^{n-1} H_i$, ρ is a constant, $0 \leq c < 1$, and $m = 0, 1, \ldots$. In general, the use of the Deutsch–Hundal result to explicitly bound $\|x_m - P_H(x_0)\|$ is problematic in that although c can be calculated a priori, ρ cannot be. This means that in practice when computing x_m, inequality (1.1) cannot be used to calculate a bound for $\|x_m - P_H(x_0)\|$

for $m = 0, 1, \ldots$. Xu comments in [15] that the applicability of Dykstra's algorithm for polyhedron approximation is restrictive unless it is possible to find an active bound for ρ. This lack of a computable error bound for the Dykstra iterates is the motivation for this manuscript. Here we develop a method to explicitly bound $\|x_m - P_H(x_0)\|$ by a ρ_m, where $\lim_{m\to\infty} \rho_m = 0$. This convergence analysis allows the algorithm to be terminated when x_m is within a prescribed distance of $P_H(x_0)$.

In section 2, we first review the equivalence between Dykstra's algorithm for polyhedral sets in the general Hilbert space setting and the finite dimensional Hildreth algorithm [10]. This equivalence is critical to our computation of the error bounds for the iterates. The finite dimensional version allows us to use a linear algebraic analysis to determine a ρ_m such that $\|x_m - P_H(x_0)\| \le \rho_m$ with $\lim_{m\to\infty} \rho_m = 0$. Given that it is possible to determine when an x_m is arbitrarily close to $P_H(x_0)$, we are then able to calculate an $x \in H$ such that $\|x - P_H(x_0)\| < \varepsilon$.

Section 3 shows how the previously established results can be modified if $\{z_i\}$ is linearly independent. Other implementation details are discussed and the N-convex regression problems are reviewed. Numerical results are presented from a sample isotone regression problem.

There are other methods available for computing $P_H(x_0)$. These include solving a related least distance quadratic programming problem [7]. More recently, Xu has published an algorithm with an error analysis that also computes the nearest point mapping for polyhedrons in a finite number of iterations [15]. Unfortunately, the use of Xu's algorithm requires a priori knowledge of a point in H. Such a point can first be calculated using the algorithm proposed by T. S. Motzkin [14] and discussed in Agmon [1].

2. Definitions, lemmas, and theory. In 1988 Han [9] rediscovered Hildreth's algorithm [10] and commented that the arguments used to show convergence in Euclidean space can be used in the general Hilbert space setting where the intersecting closed convex sets are half spaces. Deutsch and Hundal [6] later reported that in Euclidean space, where the intersection of closed convex sets in polyhedral, Dykstra's algorithm reduces to Hildreth's algorithm.

In fact, the Deutsch–Hundal statement can be strengthened, and Han's result is immediately applicable to the general Hilbert space setting. This is due to the fact that in Hilbert space, Dykstra's algorithm applied to a finite set of intersecting closed half spaces is equivalent to Hildreth's algorithm applied to a related set of linear inequalities. We next review this equivalence.

Let X be a Hilbert space and $H_0, H_1, \ldots, H_{n-1}$ be closed half spaces of the form $H_i = \{x \mid \langle x, z_i\rangle \le f_i\}$ for $0 \le i \le n-1$, where $z_i \in X$, $\|z_i\| = 1$, $f_i \in \Re$, and $H = \cap_{i=0}^{n-1} H_i$ is nonempty. The boundary of each closed half space H_i is the hyperplane B_i, where $B_i = \{x \mid \langle x, z_i\rangle = f_i\}$.

LEMMA 2.1. *Given $x \in X$,*

$$P_{H_i}(x) = \begin{cases} x & \text{if } x \in H_i, \\ x - (\langle x, z_i\rangle - f_i) z_i & \text{if } x \notin H_i, \end{cases}$$

$$P_{B_i}(x) = x - (\langle x, z_i\rangle - f_i) z_i,$$

$$\mathrm{d}(x, B_i) = |\langle x, z_i\rangle - f_i|$$

for $i = 0, 1, \ldots, n-1$. □

LEMMA 2.2. *Given an $x_0 \in X$, the iterates of Dykstra's algorithm lie in* $\operatorname{span}\{x_0, z_0, \ldots, z_{n-1}\}$.

Proof. This follows from Dykstra's algorithm, the fact that the closed convex sets are half spaces, Lemma 2.1, and a simple inductive argument. □

By Lemma 2.2, the Dykstra iterates $\{x_m\}$ are contained in a finite dimensional subspace of X. Thus we can use Gram–Schmidt to generate an orthonormal basis $\{w_j\}_{j=1}^{k}$ for $\text{span}\{x_0, z_0, \ldots, z_{n-1}\}$, and we can write

$$x_0 = \sum_{j=1}^{k} \gamma_j w_j \tag{2.1}$$

as well as

$$z_i = \sum_{j=1}^{k} \alpha_{ij} w_j \tag{2.2}$$

for $0 \leq i \leq n-1$.

Since any finite dimensional Hilbert space is isometric to $l_2(k)$, we reduce the convergence analysis of Dykstra's algorithm in X to an equivalent analysis in $\Re^k$.

Defining

$$y_0 = (\gamma_1, \ldots, \gamma_k)^{\mathrm{T}} \tag{2.3}$$

and

$$a_i = (\alpha_{i1}, \ldots, \alpha_{ik})^{\mathrm{T}} \tag{2.4}$$

for $0 \leq i \leq n-1$, it is possible to define the n closed half spaces in $\Re^k$ by

$$h_i = \{y \mid \langle y, a_i \rangle \leq f_i\} \tag{2.5}$$

and the corresponding boundaries by

$$b_i = \{y \mid \langle y, a_i \rangle = f_i\}. \tag{2.6}$$

We remark that Dykstra's algorithm applied to $h_0, h_1, \ldots, h_{n-1}$ is the same as Hildreth's algorithm applied to $Ay \leq f$, where $A^{\mathrm{T}} = [a_0, \ldots, a_{n-1}]$ and $f = (f_0, \ldots, f_{n-1})^{\mathrm{T}}$.

Throughout what follows, x_0 will be defined as in (2.1), $\{x_m\}$ will denote the sequence of Dykstra iterates generated by the closed half spaces $H_0, \ldots, H_{n-1}$ in X. Similarly, y_0 will be defined as in (2.3) and $\{y_m\}$ will denote the sequence of Dykstra iterates generated by the closed half spaces $h_0, \ldots, h_{n-1}$ in $\Re^k$ as specified in (2.5).

Let $S \subset \{0, 1, \ldots, n-1\}$. We define $\tilde{S} = \{i \mid 0 \leq i \leq n-1 \text{ and } i \notin S\}$ and $|S|$ to be the cardinality of set S. We introduce the notation H_S (resp., h_S) to denote $\cap_{i \in S} H_i$ (resp., $\cap_{i \in S} h_i$) and B_S (resp., b_S) to denote $\cap_{i \in S} B_i$ (resp., $\cap_{i \in S} b_i$). For notational simplicity, if $S = \{0, 1, \ldots, n-1\}$, the subscript S is omitted. A_S^{T} and f_S are defined to be

$$A_S^{\mathrm{T}} = [a_{s_1}, \ldots, a_{s_{|S|}}\}, \tag{2.7}$$

$$f_S = (f_{s_1}, \ldots, f_{s_{|S|}})^{\mathrm{T}}, \tag{2.8}$$

where $s_j \in S$, $1 \leq j \leq |S|$ with $s_j < s_{j+1}$. Let $C \subset \{0, 1, \ldots, n-1\}$ contain the indices of the critical boundaries. That is, $C = \{i \mid P_h(y_0) \in b_i\}$. If $C = \emptyset$, then $P_h(y_0) \in \text{int}(h)$ and $P_h(y_0) = y_0$. Henceforth we will assume that $C \neq \emptyset$.

Let $S \subset \{0, 1, \ldots, n-1\}$, $S \neq \emptyset$, and let A_S^{T} and f_S be as defined in (2.7) and (2.8). We denote the residual $r_{m,S} = f_S - A_S y_m$. If $f_S \in \mathrm{Range}(A_S)$ (equivalently $b_S \neq \emptyset$), then by (2.6),

$$\begin{aligned} r_{m,S} &= A_S P_{b_S}(y_m) - A_S y_m, \\ &= A_S(P_{b_S}(y_m) - y_m). \end{aligned}$$

A_S^+ is the Moore–Penrose generalized inverse of A_S, and $A_S^+ A_S$ is the projection onto the orthogonal complement of the null space of A_S (denoted $\mathrm{N}(A_S)^\perp$) [8]. If $b_S \neq \emptyset$, then $P_{b_S}(y_m) - y_m$ is an element of $\mathrm{N}(A_S)^\perp$,

$$A_S^+ A_S(P_{b_S}(y_m) - y_m) = P_{b_S}(y_m) - y_m,$$

and $A_S^\perp r_{m,S} = P_{b_S}(y_m) - y_m$. Therefore,

$$\|y_m - P_{b_S}(y_m)\| = \|A_S^+ r_{m,S}\| \leq \|A_S^+\| \, \|r_{m,S}\| \tag{2.9}$$

with $\|A_S^+\|$ being the inverse of the smallest nonzero singular value of A_S [8].

For each iterate y_m of Dykstra's algorithm we determine the existence of a set C_m with the properties

$$f_{C_m} \in \mathrm{Range}(A_{C_m}), \tag{2.10a}$$

$$\text{for all } j \in \tilde{C}_m, \quad 2\|A_{C_m}^+\| \, \|r_{m,C_m}\| < f_j - \langle y_m, a_j \rangle, \tag{2.10b}$$

$$\text{for all } j \in \tilde{C}_m, \quad e_{\pi_{m,j}} = \vec{0},$$

$$\text{where } \pi_{m,j} \in \{i \mid m - n \leq i \leq m-1 \text{ and } [i] = j\}. \tag{2.10c}$$

If no such C_m exists, we define the bound, ρ_m, on $\|y_m - P_h(y_0)\|$ to be ∞. In Theorem 2.16 we prove that for sufficiently large m, the set C satisfies properties (2.10a)–(2.10c).

For notational simplicity throughout what follows, we will use the notation r_m in place of r_{m,C_m} or $r_{m,C}$ where appropriate. We next assume that $C_m \neq \emptyset$ and develop the theory to bound $\|y_m - P_h(y_0)\|$ by ρ_m, where

$$\rho_m = 2\|A_{C_m}^+\| \, \|r_m\|. \tag{2.11}$$

Thereafter, in Theorem 2.17 we will show sufficient conditions on the selection of $\{C_m\}$ to guarantee the bound $\rho_m = 2\|A_{C_m}^+\| \, \|r_m\|$ tends to zero.

By the construction of C_m and inequality (2.9),

$$2\|y_m - P_{b_{C_m}}(y_m)\| \leq 2\|A_{C_m}^+\| \, \|r_m\| \tag{2.12}$$

$$< f_j - \langle y_m, a_j \rangle \tag{2.13}$$

$$= \mathrm{d}(y_m, b_j)$$

for all $j \in \tilde{C}_m$.

The following lemma shows that if $C_m \neq \{0, 1, \ldots, n-1\}$, then the closed ball centered at $P_{b_{C_m}}(y_m)$ with radius $\mathrm{d}(y_m, P_{b_{C_m}}(y_m))$ is contained in the $\mathrm{int}(h_{\tilde{C}_m})$. To facilitate subsequent discussion, we define

$$\mathcal{B}_m = \mathcal{B}[P_{b_{C_m}}(y_m), \mathrm{d}(y_m, P_{B_{C_m}}(y_m))]. \tag{2.14}$$

LEMMA 2.3. *If $C_m \neq \{0, 1, \ldots, n-1\}$, then the closed ball $\mathcal{B}_m \subset \text{int}(h_{\tilde{C}_m})$.*

Proof. We will show that, given any element y contained in the closed ball $\mathcal{B}_m$, $\langle y, a_j \rangle < f_j$ for every $j \in \tilde{C}_m$. This will imply that $y \in \text{int}(h_{\tilde{C}_m})$. Let $y \in \mathcal{B}_m$ and define $\varepsilon_1 = \text{d}(y_m, P_{b_{C_m}}(y_m))$. Then $P_{b_{C_m}}(y_m) = y_m + \varepsilon_1 v_1$ for some unit vector v_1. Since $y \in \mathcal{B}_m$, $y = P_{b_{C_m}}(y_m) + \varepsilon_2 v_2$ for $0 \leq \varepsilon_2 \leq \text{d}(y_m, P_{b_{C_m}}(y_m)) = \varepsilon_1$ and some unit vector v_2. Let $j \in \tilde{C}_m$. Then

$$\begin{aligned}
\langle y, a_j \rangle &= \langle P_{b_{C_m}}(y_m) + \varepsilon_2 v_2, a_j \rangle \\
&= \langle y_m + \varepsilon_1 v_1 + \varepsilon_2 v_2, a_j \rangle \\
&= \langle y_m, a_j \rangle + \varepsilon_1 \langle v_1, a_j \rangle + \varepsilon_2 \langle v_2, a_j \rangle \\
&\leq \langle y_m, a_j \rangle + \varepsilon_1 \|v_1\| \, \|a_j\| + \varepsilon_2 \|v_2\| \, \|a_j\| \\
&= \langle y_m, a_j \rangle + \varepsilon_1 + \varepsilon_2 \\
&\leq \langle y_m, a_j \rangle + 2\varepsilon_1 \\
&= \langle y_m, a_j \rangle + 2\text{d}(y_m, P_{b_{C_m}}(y_m)) \\
&= \langle y_m, a_j \rangle + 2\|y_m - P_{b_{C_m}}(y_m)\| \\
&< \langle y_m, a_j \rangle + f_j - \langle y_m, a_j \rangle \quad \text{by (2.13)} \\
&= f_j.
\end{aligned}$$

Thus $y \in \text{int}(h_j)$. Since j was arbitrary in $\tilde{C}_m$, $y \in \text{int}(h_{\tilde{C}_m})$, and $\mathcal{B}_m \subset \text{int}(h_{\tilde{C}_m})$. ∎

In order to show the bound stated in (2.11), we will prove that all subsequent Dykstra iterates are elements of the closed ball $\mathcal{B}_m$. We will then have $\{y_{m+k}\}_{k=0}^{\infty} \subset \mathcal{B}_m$. $\mathcal{B}_m$, by construction, is closed and must contain its limit points. Since $\{y_{m+k}\}_{k=0}^{\infty}$ converges to $P_h(y_0)$, $P_h(y_0)$ would then be contained in $\mathcal{B}_m$. This will allow us to compute a bound on $\|y_m - P_h(y_0)\|$.

The following result is proved in [6]. As in section 1, $[m]$ denotes m mod n.

RESULT 2.4. *If y_m is the mth iterate of Dykstra's algorithm, then $y_{m+1} = (1 - \lambda)y_m + \lambda P_{b_{[m]}}(y_m)$ for some λ, $0 \leq \lambda \leq 1$.*

The following proposition can be proved in part by using the characterization of best approximation from subspaces in Hilbert space [5].

PROPOSITION 2.5. *Let $y \in \Re^k$, $S \subset \{0, 1, \ldots, n-1\}$, $S \neq \emptyset$, $b_S \neq \emptyset$, $m \geq 0$ with $[m] \in S$; then for $0 \leq \lambda \leq 1$*

$$\|(1 - \lambda)y + \lambda P_{b_{[m]}}(y) - P_{b_S}(y)\| \leq \|y - P_{b_S}(y)\|.$$

Let $S \neq \emptyset$ and define the subspace

$$\hat{b}_S = \bigcap_{i \in S} \{y \mid \langle y, a_i \rangle = 0\}.$$

If $b_S \neq \emptyset$, then $P_{b_S}(y) = P_{\hat{b}_S}(y) + P_{b_S}(\vec{0})$. Since $P_{\hat{b}_S}$ is continuous, Proposition 2.6 follows.

PROPOSITION 2.6. *Let $S \neq \emptyset$ and $b_S \neq \emptyset$; then P_{b_S} is continuous.*

PROPOSITION 2.7. *Let $y \in \Re^k$, $S \neq \emptyset$, and $b_S \neq \emptyset$; then*

$$P_{b_S}\left(y + \sum_{i \in S} \xi_i a_i\right) = P_{b_S}(y).$$

Proposition 2.7 can be shown using the fact that $P_{b_S}(y) = P_{\hat{b}_S}(y) + P_{b_S}(\vec{0})$, $P_{\hat{b}_S}$ is a linear operator, and $\hat{b}_S$ is the orthogonal complement of $\text{span}_{i \in S}\{a_i\}$.

Lemma 2.8 next shows that y_m and all subsequent Dykstra iterates are elements of the closed ball $\mathcal{B}_m$. As previously defined, $\mathcal{B}_m = \mathcal{B}[P_{b_{C_m}}(y_m),\ \mathrm{d}(y_m, P_{b_{C_m}}(y_m))]$. The lemma is actually proven by showing a stronger result as stated in the induction hypothesis.

LEMMA 2.8. *The iterates of Dykstra's algorithm y_{m+k}, $k = 0, 1, \ldots$, are contained in the closed ball $\mathcal{B}_m$.*

Proof. The proof is by induction.

It is evident that $y_m \in \mathcal{B}_m$. Moreover, by the definition of C_m (2.10c), for all $y \in \tilde{C}_m$, $e_{\pi_{m,j}} = \vec{0}$, where $\pi_{m,j} \in \{i \mid m - n \leq i \leq m - 1 \text{ and } [i] = j\}$.

We will assume that for each l, $1 \leq l \leq k$, $y_{m+l} \in \mathcal{B}_m$ and for all $j \in \tilde{C}_m$, $e_{\pi_{m+l,j}} = \vec{0}$, where $\pi_{m+l,j} \in \{i \mid m + l - n \leq i \leq m + l - 1 \text{ and } [i] = j\}$.

Next we will show that $y_{m+k+1} \in \mathcal{B}_m$.

If $[m+k] \in \tilde{C}_m$, then, by Lemma 2.3 and the induction hypothesis, $y_{m+k} \in h_{[m+k]}$. Therefore

$$y_{m+k+1} = P_{h_{[m+k]}}(y_{m+k} + \vec{0}) = P_{h_{[m+k]}}(y_{m+k}) = y_{m+k}.$$

Since $y_{m+k} \in \mathcal{B}_m$, $y_{m+k+1} \in \mathcal{B}_m$.

If $[m + k] \in C_m$, then by applying Result 2.4 to the $m + k + 1$ iterate,

$$y_{m+k+1} = (1 - \lambda)y_{m+k} + \lambda P_{b_{[m+k]}}(y_{m+k})$$

for some λ, $0 \leq \lambda \leq 1$. By Proposition 2.5,

$$\|(1 - \lambda)y_{m+k} + \lambda P_{b_{[m+k]}}(y_{m+k}) - P_{b_{C_m}}(y_{m+k})\| \leq \|y_{m+k} - P_{b_{C_m}}(y_{m+k})\|$$

for $0 \leq \lambda \leq 1$. Thus,

$$\|y_{m+k+1} - P_{b_{C_m}}(y_{m+k})\| \leq \|y_{m+k} - P_{b_{C_m}}(y_{m+k})\|.$$

Using the induction hypothesis, we have $y_{m+l} = y_{m+l-1}$ whenever $[m + l - 1] \in \tilde{C}_m$. Therefore, it can be shown that $y_{m+k} = y_m + \sum_{j \in C_m} \xi_j a_j$ and, by Proposition 2.7, $P_{b_{C_m}}(y_{m+k}) = P_{b_{C_m}}(y_m)$.

Therefore

$$\|y_{m+k+1} - P_{b_{C_m}}(y_m)\| \leq \|y_{m+k} - P_{b_{C_m}}(y_m)\|.$$

Since $y_{m+k} \in \mathcal{B}_m$, it follows that $y_{m+k+1} \in \mathcal{B}_m$.

Moreover, regardless of whether $[m + k] \in C_m$ or $[m + k] \in \tilde{C}_m$ for all $j \in \tilde{C}_m$, $e_{\pi_{m+k+1,j}} = \vec{0}$, where $\pi_{m+k+1,j} \in \{i \mid m + k + 1 - n \leq i \leq m + k \text{ and } [i] = j\}$.

Therefore, for $k = 0, 1, \ldots, y_{m+k} \in \mathcal{B}_m$. ∎

We next bound $\|y_m - P_h(y_0)\|$.

LEMMA 2.9. $\|y_m - P_h(y_0)\| \leq 2\|y_m - P_{b_{C_m}}(y_m)\|$.

Proof. By Lemma 2.8, $\{y_{m+k}\}_{k=0}^{\infty} \subset \mathcal{B}_m$. Since $\mathcal{B}_m$ is closed and $\lim_{k\to\infty} y_{m+k} = P_h(y_0)$, we have that $P_h(y_0) \in \mathcal{B}_m$. By the triangle inequality,

$$\begin{aligned}\|y_m - P_h(y_0)\| &\le \|y_m - P_{b_{C_m}}(y_m)\| + \|P_{b_{C_m}}(y_m) - P_h(y_0)\| \\ &\le 2\|y_m - P_{b_{C_m}}(y_m)\|. \qquad \square\end{aligned}$$

The first major result of this section follows.

THEOREM 2.10. $\|y_m - P_h(y_0)\| \le 2\|A_{C_m}^+\|\,\|r_m\|$.

Proof. By inequality (2.12), $2\|y_m - P_{b_{C_m}}(y_m)\| \le 2\|A_{C_m}^+\|\,\|r_m\|$. By Lemma 2.9, $\|y_m - P_h(y_0)\| \le 2\|y_m - P_{b_{C_m}}(y_m)\|$ and thus $\|y_m - P_h(y_0)\| \le 2\|A_{C_m}^+\|\,\|r_m\|$. $\square$

We now show the prerequisites for proving Theorems 2.16 and 2.17. Lemma 2.11 shows that $C = \{i \mid P_h(y_0) \in b_i\}$ satisfies property (2.10a).

LEMMA 2.11. $f_C \in \text{Range}(A_C)$.

Proof. By definition of C, $P_h(y_0) \in b_C$. Therefore $A_C P_h(y_0) = f_C$ and $f_C \in \text{Range}(A_C)$. $\square$

If $C = \{0, 1, \ldots, n-1\}$, then since y_m converges to $P_h(y_0)$, there exists a smallest integer M such that, for all $m > M - n$, $\|y_m - P_h(y_0)\| < \frac{1}{3\kappa}$, where $\kappa = \|A^+\|\,\|A\|$. Otherwise $C \neq \{0, 1, \ldots, n-1\}$, and again by the convergence of y_m to $P_h(y_0)$, there exists a smallest integer M such that, for all $m > M - n$, $\|y_m - P_h(y_0)\| < \frac{\varepsilon_C}{3\kappa_C}$, where $\kappa_C = \|A_C^+\|\,\|A_C\|$ and $\varepsilon_C > 0$ such that $\mathcal{B}[P_h(y_0), \varepsilon_C] \subset \text{int}(h_{\tilde{C}})$.

LEMMA 2.12. *For all $m > M$ and $j \in \tilde{C}$, $e_{\pi_{m,j}} = \vec{0}$, where $\pi_{m,j} \in \{i \mid m - n \le i \le m - 1$ and $[i] = j\}$.*

Proof. If $C = \{0, 1, \ldots, n-1\}$, then the lemma is vacuously true. Next assume that $C \neq \{0, 1, \ldots, n-1\}$ and let $m > M$. Suppose there exists an $j \in \tilde{C}$ such that $e_{\pi_{m,j}} \neq \vec{0}$, where $\pi_{m,j} \in \{i \mid m - n \le i \le m - 1$ and $[i] = j\}$. Since $e_{\pi_{m,j}} \neq \vec{0}$, this implies that $y_{\pi_{m,j}+1} = P_{b_j}(y_{\pi_{m,j}})$ and $y_{\pi_{m,j}+1} \in b_j$. This is impossible since $\pi_{m,j} + 1 > M - n$ and $y_{\pi_{m,j}+1} \in \mathcal{B}[P_h(y_0), \varepsilon_C] \subset \text{int}(h_j)$. Clearly $\langle y_{\pi_{m,j}+1}, a_j\rangle < f_j$ and $\langle y_{\pi_{m,j}+1}, a_j\rangle = f_j$ cannot both be true. Therefore $e_{\pi_{m,j}} = \vec{0}$.

Thus for all $m > M$ and $j \in \tilde{C}$, $e_{\pi_{m,j}} = \vec{0}$, where $\pi_{m,j} \in \{i \mid m - n \le i \le m - 1$ and $[i] = j\}$. $\square$

Lemma 2.12 implies the following result.

RESULT 2.13. *For all $m > M$, $y_{m+1} = y_m$ whenever $[m] \in \tilde{C}$.*

We now prove that for sufficiently large m, $2\|A_C^+\|\,\|r_m\| < f_j - \langle y_m, a_j\rangle$ for all $j \in \tilde{C}$.

LEMMA 2.14. *If $\{y_m\}$ is the sequence of Dykstra iterates, then for all $m > M$, $P_{b_C}(y_m) = P_h(y_0)$.*

Proof. As a consequence of Result 2.13 and the definition of Dykstra's algorithm, for all $m > M$,

$$y_m = y_{M+1} + \sum_{i\in C} \xi_i a_i.$$

Using Proposition 2.7,

$$\begin{aligned}P_{b_C}(y_m) &= P_{b_C}\left(y_{M+1} + \sum_{i\in C} \xi_i a_i\right) \\ &= P_{b_C}(y_{M+1}).\end{aligned}$$

By Proposition 2.6, P_{b_C} is continuous, and thus for all $m > M$

$$\begin{aligned} P_{b_C}(y_m) &= P_{b_C}(y_{M+1}) \\ &= \lim_{m\to\infty} P_{b_C}(y_m) \\ &= P_{b_C}\left(\lim_{m\to\infty} y_m\right) \\ &= P_{b_C}(P_h(y_0)) \\ &= P_h(y_0). \end{aligned}$$

The last equality holds since $P_h(y_0) \in b_C$. ∎

As specified above, $\kappa_C = \|A_C^+\|\,\|A_C\|$, $\varepsilon_C > 0$ such that $\mathcal{B}[P_h(y_0), \varepsilon_C] \subset \operatorname{int}(h_{\tilde{C}})$, and M is selected such that for all $m > M - n$ we have $\|y_m - P_h(y_0)\| < \frac{\varepsilon_C}{3\kappa_C}$. Moreover, it can be shown that $\kappa_C \geq 1$ [12].

LEMMA 2.15. *If $m > M$, then $2\|A_C^+\|\,\|r_m\| < f_j - \langle y_m, a_j\rangle$ for all $j \in \tilde{C}$.*

Proof. If $C = \{0, 1, \ldots, n-1\}$, then the lemma is vacuously true. Next assume that $C \neq \{0, 1, \ldots, n-1\}$ and let $m > M$.

$$\begin{aligned} 2\|A_C^+\|\,\|r_m\| &= 2\|A_C^+\|\,\|f_C - A_C y_m\| \\ &= 2\|A_C^+\|\,\|A_C(P_{b_C}(y_m) - y_m)\| \\ &\leq 2\|A_C^+\|\,\|A_C\|\,\|y_m - P_{b_C}(y_m)\| \\ &\leq 2\kappa_C\|y_m - P_{b_C}(y_m)\| \\ &= 2\kappa_C\|y_m - P_h(y_0)\| \\ &< 2\kappa_C\frac{\varepsilon_C}{3\kappa_C} \\ &= \frac{2\varepsilon_C}{3}. \end{aligned}$$

It remains to be shown that $\frac{2\varepsilon_C}{3} < f_j - \langle y_m, a_j\rangle$ for all $j \in \tilde{C}$.

Suppose there exists a $j \in \tilde{C}$ such that $f_j - \langle y_m, a_j\rangle \leq \frac{2\varepsilon_C}{3}$. Then

$$\begin{aligned} \mathrm{d}(P_h(y_0), b_j) &\leq \mathrm{d}(P_h(y_0), P_{b_j}(y_m)) \\ &\leq \mathrm{d}(P_h(y_0), y_m) + \mathrm{d}(y_m, P_{b_j}(y_m)) \\ &= \|y_m - P_h(y_0)\| + \mathrm{d}(y_m, b_j) \\ &< \frac{\varepsilon_C}{3\kappa_C} + \mathrm{d}(y_m, b_j) \\ &\leq \frac{\varepsilon_C}{3} + \mathrm{d}(y_m, b_j) \\ &= \frac{\varepsilon_C}{3} + |\langle y_m, a_j\rangle - f_j| \\ &\leq \frac{\varepsilon_C}{3} + \frac{2\varepsilon_C}{3} \\ &= \varepsilon_C. \end{aligned}$$

Thus there exists an element of b_j that is within ε_C of $P_h(y_0)$. This is a contradiction since $\mathcal{B}[P_h(y_0), \varepsilon_C] \subset \text{int}(h_j)$. Therefore, for all $m > M$ and $j \in \tilde{C}$ we have that $2\|A_C^+\| \, \|r_m\| < f_j - \langle y_m, a_j \rangle$. ∎

THEOREM 2.16. *For all $m > M$, C satisfies properties* (2.10a)–(2.10c).

Proof. This is a consequence of Lemmas 2.11, 2.12, and 2.15. ∎

For the remainder of the section, we will assume that $C_m = C$ whenever $m > M$.

THEOREM 2.17. $\lim_{m\to\infty} \rho_m = 0$.

Proof. Let $m > M$. By assumption we have that $C_m = C$ and $\rho_m \leq 2\kappa_C \|y_m - P_{b_C}(y_m)\|$. By Lemma 2.14, for all $m > M$, $P_{b_C}(y_m) = P_h(y_0)$, and thus $\rho_m \leq 2\kappa_C \|y_m - P_h(y_0)\|$. Therefore

$$\lim_{m\to\infty} \rho_m \leq \lim_{m\to\infty} 2\kappa_C \|y_m - P_h(y_0)\| = 0,$$

and $\lim_{m\to\infty} \rho_m = 0$. ∎

We have now established that it is possible to construct a sequence $\{\rho_m\}$ such that $\|y_m - P_h(y_0)\| \leq \rho_m$ with $\lim_{m\to\infty} \rho_m = 0$. Next we exhibit a $y \in h$ such that $\|y - P_h(y_0)\| < \varepsilon$ for any $\varepsilon > 0$.

Given $\varepsilon > 0$, it is possible to determine an m such that C_m is nonempty and $\|y_m - P_h(y_0)\| < 2\varepsilon$. Bramley and Sameh have shown that using the conjugate-gradient method to solve $A_{C_m}^{\mathrm{T}} A_{C_m} y = A_{C_m}^{\mathrm{T}} b_{C_m}$ with an initial approximation of y_m results in a solution of $P_{b_{C_m}}(y_m)$ [2]. Using arguments in Lemma 2.9 and Theorem 2.10,

$$\|P_{b_{C_m}}(y_m) - P_h(y_0)\| < \varepsilon.$$

The following lemma shows that $P_{b_{C_m}}(y_m) \in h$.

LEMMA 2.18. *If $C_m \neq \emptyset$, then $P_{b_{C_m}}(y_m) \in h$.*

Proof. If $C_m = \{0, 1, \ldots, n-1\}$ (equivalently if $\tilde{C}_m = \emptyset$), then $P_b(y_m) \in b \subset h$. Next suppose that $\tilde{C}_m \neq \emptyset$. By Lemma 2.3, $P_{b_{C_m}}(y_m) \in \text{int}(h_{\tilde{C}_m}) \subset h_{\tilde{C}_m}$. In addition $P_{b_{C_m}}(y_m) \in b_{C_m} \subset h_{C_m}$. Therefore $P_{b_{C_m}}(y_m) \in (h_{C_m} \cap h_{\tilde{C}_m}) = h$. ∎

Thus setting $y = P_{b_{C_m}}(y_m)$ specifies a point in h with the property that $\|y - P_h(y_0)\| < \varepsilon$. Moreover, if $m > M$, then by Lemma 2.14, $y = P_{b_{C_m}}(y_m)$ is in fact $P_h(y_0)$.

3. Implementation, applications, and numerical results. The two main results of section 2 were Theorem 2.10 and Theorem 2.17. In Theorem 2.10 we showed that if $C_m \neq \emptyset$, then $\|y_m - P_h(y_0)\| \leq 2\|A_{C_m}^+\| \, \|r_m\|$, and we subsequently defined $\rho_m = 2\|A_{C_m}^+\| \, \|r_m\|$. Theorem 2.17 implied that for sufficiently large m, if $C_m = C$, then $\lim_{m\to\infty} \rho_m = 0$. We remark that for m sufficiently large and $C_m = C$, we have, using Lemma 2.14, $\|y_m - P_h(y_0)\| \leq \frac{1}{2}\rho_m$.

Next we show how to construct a sequence $\{C_m\}$ so that for large enough m, $C_m = C$. Lemma 3.1 shows that if $C_m \neq \emptyset$, then $C \subset C_m$. As previously specified, $\mathcal{B}_m = \mathcal{B}[P_{b_{C_m}}(y_m), \, \mathrm{d}(y_m, P_{b_{C_m}}(y_m))]$, $C = \{i \mid P_h(y_0) \in b_i\}$, and C_m is selected to satisfy properties (2.10a)–(2.10c).

LEMMA 3.1. *If $C_m \neq \emptyset$, then $C \subset C_m$.*

Proof. The proof is by contradiction.

Suppose there exists an m such that $C - C_m \neq \emptyset$. Let $j \in C - C_m$ and hence $j \in \tilde{C}_m$. By Lemma 2.3 the closed ball $\mathcal{B}_m \subset \text{int}(h_j)$. By Lemma 2.8, $\{y_{m+k}\}_{k=0}^{\infty} \subset \mathcal{B}_m$. Since $\mathcal{B}_m$ is closed and $\lim_{k\to\infty} y_{m+k} = P_h(y_0)$, $P_h(y_0) \in \mathcal{B}_m$. By definition of C, $P_h(y_0) \in b_j$. In addition we have shown above that $P_h(y_0) \in \mathcal{B}_m \subset \text{int}(h_j)$. It

is impossible for $P_h(y_0)$ to be both in the interior of h_j and on the boundary of h_j. Therefore, if $C_m \neq \emptyset$, we have that $C \subset C_m$. □

By Theorem 2.16, $C_m = C$ satisfies properties (2.10a)–(2.10c) for sufficiently large m. By Lemma 3.1, if $C_m \neq \emptyset$, then $C \subset C_m$. Therefore, if C_m is chosen to have the smallest cardinality of any set satisfying properties (2.10a)–(2.10c), then for sufficiently large m, C_m must be the set C.

As previously stated, we compute

$$\rho_m = 2\|A^+_{C_m}\| \, \|r_m\|,$$

where

$$\|A^+_{C_m}\| = (\sigma_{\min}(A_{C_m}))^{-1},$$

$\sigma_{\min}(A_{C_m}) \neq 0$.

If the columns of A^{T} are linearly independent, we will subsequently show how to reduce the computational effort required to bound $\|y_m - P_h(y_0)\|$.

Proposition 3.2 may be directly inferred by the repeated application of the interlacing property for singular values [12].

PROPOSITION 3.2. *Let A^{T} have linearly independent columns and $S \subset \{0, 1, \ldots, n-1\}$, $S \neq \emptyset$; then $\|A^+_S\| \leq \|A^+\|$.*

We next determine a set C_m with the properties

$$f_{C_m} \in \mathrm{Range}(A_{C_m}), \tag{3.1a}$$

$$\text{for all } j \in \tilde{C}_m, \quad 2\|A^+\| \, \|r_m\| < f_j - \langle y_m, a_j \rangle, \tag{3.1b}$$

$$\text{for all } j \in \tilde{C}_m, \quad e_{\pi_{m,j}} = \vec{0},$$

$$\text{where } \pi_{m,j} \in \{i \mid m - n \leq i \leq m-1 \ \text{ and } \ [i] = j\}. \tag{3.1c}$$

C_m is well defined as $C_m = \{0, 1, \ldots, n-1\}$ vacuously satisfies properties (3.1a)–(3.1c). Using arguments similar to those presented in section 2, it can be shown that $\|y_m - P_h(y_0)\| \leq 2\|A^+\| \, \|r_m\|$. Thus, in order to bound the error of each Dykstra iterate we need only determine $\sigma_{\min}(A)$ and $\|r_m\|$.

PROPOSITION 3.3. *Let $S \subset \{0, 1, \ldots, n-1\}$, $S \neq \emptyset$, then $\|A_S\| \leq \|A\|$.*

Assuming that the columns of A^{T} are linearly independent, using Propositions 3.2 and 3.3 and selecting C_m to satisfy properties (3.1a)–(3.1c),

$$\begin{aligned}
\|y_m - P_h(y_0)\| &\leq 2\|A^+\| \, \|r_m\| \\
&= 2\|A^+\| \, \|A_{C_m}(y_m - P_{h_{C_m}}(y_m))\| \\
&\leq 2\|A^+\| \, \|A_{C_m}\| \, \|y_m - P_{h_{C_m}}(y_m)\| \\
&\leq 2\|A^+\| \, \|A\| \, \|y_m - P_{h_{C_m}}(y_m)\| \\
&= 2\kappa\|y_m - P_{h_{C_m}}(y_m)\|,
\end{aligned}$$

where $\kappa = \|A^+\| \, \|A\|$.

In order for the bound $2\|A^+\| \, \|r_m\|$ to be useful, $\{C_m\}$ must be selected such that $\lim_{m\to\infty} \|A^+\| \, \|r_m\| = 0$. To guarantee that

$$\lim_{m\to\infty} 2\kappa\|y_m - P_{h_{C_m}}(y_m)\| = 0,$$

it suffices that for sufficiently large m, $C_m = C$. As in section 2, with such a selection of $\{C_m\}$, $\lim_{m\to\infty} 2\|A^+\|\,\|r_m\| = 0$.

An important class of problems in statistical inference is to find the N-convex regression for a real valued function g_0 defined on a finite subset of $\Re$. Let $t_1 < t_2 < \cdots < t_q$, $q \geq N+1$. For a given $y_0 = (g_0(t_1), \ldots, g_0(t_q))^{\mathrm{T}}$ in $\Re^q$ we want to determine the best approximation to y_0 from the set of N-convex functions in $\Re^q$.

The real valued function g defined on $t_1, \ldots, t_q$ is N-convex if for any set of $N+1$ points $t_{i_1} < t_{i_2} < \cdots < t_{i_{N+1}}$, the Nth order divided difference, $g[t_{i_1}, \ldots, t_{i_{N+1}}] \geq 0$. This type of approximation problem generates a rectangular system of linear inequalities $Ay \leq f$ such that $\{y \mid Ay \leq f\}$ is a closed convex cone.

For N-convex regression problems it is possible to show that if $h = \{y \in \Re^q \mid y \text{ is } N\text{-convex}\}$, then $h = \cap_{i=0}^{q-N-1} h_i$, where $h_i = \{y \in \Re^q \mid \langle y, z_i\rangle \leq 0\}$, $b_i = \{y \in \Re^q \mid \langle y, z_i\rangle = 0\}$, and

$$\hat{z}_i(j) = \begin{cases} (-1)^{j-i+N}\binom{N}{j-i-1} & \text{whenever } \ 0 \leq j-i-1 \leq N, \\ 0 & \text{otherwise} \end{cases}$$

with

$$z_i = \frac{\hat{z}_i}{\|\hat{z}_i\|}. \tag{3.2}$$

The following proposition is easily proved.

PROPOSITION 3.4. *The* $\{z_i\}_{i=0}^{q-N-1}$ *as defined in* (3.2) *is linearly independent.*

Thus it is possible, given $y_0 = (g_0(t_1), \ldots, g_0(t_q))^{\mathrm{T}}$, to use Dykstra's algorithm to approximate $P_h(y_0)$ and to bound the norm of the error for each Dykstra iterate, $\|y_k - P_h(y_0)\|$, using the previously developed theory.

The set h of monotonically increasing functions can be expressed using a system of linear inequalities $h = \{y \in \Re^q \mid Ay \leq \vec{0}\}$, where $A^{\mathrm{T}} \in \Re^{q\times q-1}$. Let $\hat{e} \in \Re^q$ and for $i = 1, \ldots, q$, $j = 1, \ldots, q$, define

$$\hat{e}_i(j) = \begin{cases} 0 & \text{whenever } \ i = j, \\ 1 & \text{otherwise.} \end{cases}$$

Then $A^{\mathrm{T}} = [a_0, \ldots, a_{q-2}]$, where $a_i = \frac{1}{\sqrt{2}}(\hat{e}_{i+2} - \hat{e}_{i+1})$ for $i = 0, \ldots, q-2$.

By Proposition 3.4, the columns of A^{T} are linearly independent. In order to bound the norm of the error of the Dykstra iterates when approximating $P_h(y_0)$, we need only to calculate $\|A^+\|$ and $\|r_m\|$. As previously stated, $\|A^+\| = (\sigma_{\min}(A))^{-1}$ and since $(\sigma_{\min}(A))^{-1} = \lambda_{\min}(AA^{\mathrm{T}})^{-\frac{1}{2}}$, we need to estimate the smallest eigenvalue of AA^{T}. The matrix AA^{T} is tridiag$(-0.5, 1, -0.5)$, and thus $\lambda_{\min}(AA^{\mathrm{T}})$ can be approximated by using the QR algorithm with Givens rotations.

We present an example of monotonic regression and exhibit error bounds on $\|y_m - P_h(y_0)\|$. Here $y_0 = (g_0(t_1), \ldots, g_0(t_q))^{\mathrm{T}}$, where $g_0(t_i) \geq g_0(t_j)$ whenever $1 \leq i < j \leq q$. It can be shown that $P_h(y_0) = (g(t_1), \ldots, (g(t_1))^{\mathrm{T}}$, where $g(t_i) = \frac{1}{q}\sum_{j=1}^{q} g_0(t_j)$ for $1 \leq i \leq q$. Thus it is possible to compare $\|y_m - P_h(y_0)\|$ to the error bounds calculated using the previously derived theory. In the example $q = 31$, $g_0(t_i) = 16 - i$ for $1 \leq i \leq 31$ and $C = \{0, 1, \ldots, 30\}$. Table 3.1 shows $\|y_m - P_h(y_0)\|$ and $\rho_m = 2\|A^+\|\,\|r_m\|$ for selected values of m.

In order to compute the error bounds for this illustration, we need to determine for each iterate a set C_m that satisfies properties (3.1a)–(3.1c). For $m = 1, \ldots,$ it

TABLE 3.1.

m	$\|y_m - P_h(y_0)\|$	$\rho_m = 2\|A^+\| \, \|r_m\|$

5.4 E +4	4.5096 E −7	9.0740 E −7
6.0 E +e	5.7617 E −8	1.1593 E −7

can be shown that $C_m = \{0, 1, \ldots, 30\}$ satisfies properties (3.1a)–(3.1c). In addition, it is impossible to construct a proper subset of C_m which also satisfies these same properties. Thus, to compute a bound on $\|y_m - P_h(y_0)\|$ which tends to zero, we need only to calculate $\|r_m\| = \|Ay_m\|$ and multiply by the constant $2\|A^+\|$. In general, in order to guarantee that $\lim_{m\to\infty} \rho_m = 0$, the sequence of sets C_m must be selected judiciously. As previously discussed in this section, selecting C_m to have the smallest cardinality of any set satisfying properties (2.10a)–(2.10c) guarantees that $\lim_{m\to\infty} \rho_m = 0$.

The previous discussion shows that it is possible to compute a bound in the general Hilbert space setting on $\|x_m - P_H(x_0)\|$ that tends to zero where x_n is the nth iterate of Dykstra's algorithm and H is the intersection of a finite number of closed half spaces. The convergence is studied via an equivalent problem in $\Re^k$. This approach is well suited for those occasions where H is a closed convex cone uniquely determined by intersecting half spaces. The analysis is of particular interest to the author when using Dykstra's algorithm to estimate attribute utility values in nonmetric trade-off experiments.

POSTPROCESSING THE LINEAR FINITE ELEMENT METHOD*

JAVIER DE FRUTOS† AND JULIA NOVO†

Abstract. We extend the idea of the postprocessing Galerkin methods for dissipative evolution equations to the case of the linear finite element method. The postprocessing technique has been developed earlier for spectral methods and for higher order finite element methods.

The analysis shows that this procedure improves the order of convergence of the piecewise linear Galerkin finite element approximation in the H^1 norm. We show by means of numerical experiments that there is no improvement in the order of convergence in the L^2 norm.

Key words. dissipative equations, postprocessing linear finite element methods

1. Introduction.

Let $\Omega \subset \mathbb{R}^d$, $d = 2, 3$, be a bounded domain with a smooth boundary. We consider dissipative partial differential equations which can be written in the abstract form

$$u_t + \nu Au + F(u) = f, \tag{1.1}$$

in a suitable Hilbert space H. In (1.1) $\nu > 0$ is a scalar, $-A$ is usually the Laplace operator with appropriate boundary conditions, although other elliptic operators can also be considered, F is a nonlinear term (typically a reaction or a convection term), and f is a function that can be time-dependent. Throughout the paper we suppose that for each initial condition $u(\cdot, 0) = u_0$, smooth enough, (1.1) has a unique solution defined in some interval $[0, T]$.

Recently, a postprocessing technique has been introduced to increase the efficiency of Galerkin methods of spectral type [4], including the p-version of the finite element method (spectral element method); see [10], [7], [8], [9]. Postprocessed methods yield greater accuracy than standard Galerkin schemes at nearly the same computational cost so that the postprocessed Galerkin method really improves the efficiency of the method to which it is applied.

In [11] the postprocessing technique has been extended to the h-version of the finite element method for dissipative partial differential equations. There, the authors prove that the postprocessed method has a higher rate of convergence than the standard finite element method when other than piecewise linear (say, quadratic, cubic, ...) finite elements are used. The main reason for this limitation is that in [11] the emphasis is on error analysis in the $L^2(\Omega)$ norm, whereas, in the case of piecewise linear finite elements, the improvement in the rate of convergence is observed only in the $H^1(\Omega)$ norm (the energy norm).

In the present paper we prove that the postprocessing technique applied to the linear finite element method improves the rate of convergence of this method when the error is measured in the $H^1(\Omega)$ norm. Furthermore, we present some numerical

experiments showing that the lack of gain in the $L^2(\Omega)$ norm is really observed in practice and thus is not merely a consequence of the technique employed in the proofs. We wish to note that this fact has not been previously reported. We point out that our technique of proof is related to but different from the one employed in [11].

For the sake of simplicity, in this paper we shall concentrate on equations of convection-diffusion type as, for example,

$$u_t - \nu\Delta u + (u \cdot \nabla)u = f, \tag{1.2}$$

or reaction-diffusion type, such as

$$u_t - \nu\Delta u + g(u) = f, \tag{1.3}$$

on a bounded domain $\Omega \subset \mathbb{R}^d$, $d = 2, 3$, subject to homogeneous Dirichlet boundary conditions. We confine ourselves to reaction terms of polynomial type

$$g(u) = \sum_{j=0}^{2p-1} b_j u^j, \qquad b_{2p-1} > 0,$$

although, in both cases, more general types of nonlinearities can also be treated along very similar lines. The Hilbert space in the abstract formulation (1.1) is $L^2(\Omega)^n$, with $n = 1$ for (1.3) or $n = d$ for (1.2). In what follows we will denote by $F(u)$ either $F(u) = (u \cdot \nabla)u$ or $F(u) = g(u)$.

In this paper we show that the gain in the convergence rate that is obtained through postprocessing the linear finite element method is the same for reaction-diffusion and convection-diffusion equations. This fact is confirmed by the numerical experiments we present. In [11] the improvement obtained by postprocessing reaction-diffusion type equations was superior to the one obtained by postprocessing convection-diffusion equations, but only when the postprocessing was applied after using the finite element method with polynomials of degree greater than or equal to 3, and boundary data approximations were performed with a sufficiently high order of accuracy by means of superparametric finite elements.

The rest of the paper is as follows. Section 2 contains some standard preliminary material; in section 3 the postprocessed method is introduced. Section 4 is devoted to the proof of the main results of the paper. Finally, some numerical experiments are presented in section 5.

2. Preliminaries and notation. Let $W^{s,p}(\Omega)$, $H^s(\Omega)$, $p \geq 1$, $s \geq 0$ be the standard Sobolev spaces. For simplicity of notation, when we consider (1.2), we shall write $W^{s,p}(\Omega)$, $H^s(\Omega)$, or $L^p(\Omega)$ instead of $W^{s,p}(\Omega)^d$, $H^s(\Omega)^d$, or $L^p(\Omega)^d$. For reasons of convenience we denote by $\|\cdot\|_0$, $\|\cdot\|_\infty$, and $\|\cdot\|_1$ the norms of the spaces $L^2(\Omega)$, $L^\infty(\Omega)$, and $H^1(\Omega)$, respectively. Let $H_0^1(\Omega)$ be the space of functions in $H^1(\Omega)$ with null trace at the boundary of Ω. The norm of its dual space will be denoted by $\|\cdot\|_{-1}$.

We will frequently make use of the following Sobolev inequalities:

$$\|u\|_\infty \leq C\|u\|_{H^{d/2+\epsilon}(\Omega)}, \qquad u \in H^{d/2+\epsilon}(\Omega) \quad \epsilon > 0, \tag{2.1}$$

$$\|u\|_{W^{j,q}(\Omega)} \leq C\|u\|_{W^{j+s,p}(\Omega)}, \quad \frac{1}{p} \geq \frac{1}{q} \geq \frac{1}{p} - \frac{s}{d}, \quad u \in W^{j+s,p}(\Omega). \tag{2.2}$$

We refer to [1, Lemma 5.15] for (2.1) and to [1, Theorem 5.4], [2, Theorem 6.5.1] for (2.2).

In $H_0^1(\Omega)$ we consider the bilinear form induced by $A = -\triangle$, that is,

$$a(u,v) = (A^{1/2}u, A^{1/2}v) = (\nabla u, \nabla v), \qquad u, v \in H_0^1(\Omega).$$

It is well known that $a(\cdot,\cdot)$ is continuous and coercive in $H_0^1(\Omega)$.

Let us fix a positive time T. The error estimates in section 4 and the constant in (2.8) below depend on the constant

$$K(u) = \max(K_1(u), K_2(u)), \tag{2.3}$$

where

$$K_1(u) = \max_{0\le t\le T} \|u(\cdot,t)\|_{H^2(\Omega)}, \qquad K_2(u) = \max_{0\le t\le T} \|u_t(\cdot,t)\|_{H^2(\Omega)}.$$

Notice that we implicitly assume that the solution is sufficiently regular. Equation (1.1) has sufficiently smooth solutions; in fact, the solution is analytic in time if we assume that the nonlinear terms and the data of the problem are smooth and satisfy certain compatibility conditions. We refer to [12] for results concerning the regularity properties of solutions of dissipative partial differential equations.

In order to simplify the description of the postprocessed method, in the following we shall suppose that Ω is a convex polygonal or polyhedral domain, although the results we present are applicable to the general case in which Ω is a bounded domain with a smooth boundary.

Let $\mathcal{T}_h = (\tau_i^h, \phi_i^h)$, $h > 0$, be a family of partitions of Ω; the parameter h is the maximum diameter of the elements τ_i^h in $\mathcal{T}_h$ and ϕ_i^h are affine mappings of the reference simplex τ_0 onto τ_i^h. For $r \ge 2$ we consider the finite element spaces

$$S_{h,r} = \left\{ \chi_h \in C(\overline{\Omega}) \ \mid \chi_{h|\tau_i^h} \circ \phi_i^h \in \mathbb{P}^{r-1}(\tau_0),\ \chi_h(x) = 0\ \forall x \in \partial\Omega \right\},$$

where $\mathbb{P}^{r-1}(\tau_0)$ denotes the space of polynomials of degree $r-1$ or less on τ_0.

We shall restrict ourselves to quasi-uniform meshes $\mathcal{T}_h$ so that the following inverse estimate holds for any element $\tau \in \mathcal{T}_h$ and $v_h \in S_{h,2}$ (see, e.g., [13]):

$$\|v_h\|_{W^{m,p}(\tau)} \le C h^{l-m-d(\frac{1}{q}-\frac{1}{p})} \|v_h\|_{W^{l,q}(\tau)}, \quad 0 \le l \le m \le 1, \quad 1 \le q \le p \le \infty. \tag{2.4}$$

There exists a piecewise linear (quasi) interpolant such that, for $1 \le p \le \infty$, $0 \le m \le s \le 2$ and any $u \in L^1(\Omega) \cap W^{s,p}(\Omega)$ [3],

$$\|u - I_h(u)\|_{W^{m,p}(\Omega)} \le C h^{s-m} \|u\|_{W^{s,p}(\Omega)}. \tag{2.5}$$

Let $a_h(\cdot,\cdot)$ be the bilinear form on $S_{h,r}$ defined by

$$a_h(\chi_h, \psi_h) = (\nabla\chi_h, \nabla\psi_h) \quad \forall \chi_h, \psi_h \in S_{h,r}.$$

We shall denote by A_h the associated positive, self-adjoint operator, that is,

$$a_h(\chi_h, \psi_h) = (A_h\chi_h, \psi_h) \quad \forall \chi_h, \psi_h \in S_{h,r}.$$

The standard $L^2(\Omega)$ orthogonal projection and the elliptic projection onto $S_{h,r}$ are denoted by $P_{h,r}$ and $R_{h,r}$, respectively. Recall that, for $u \in H_0^1(\Omega)$,

$$a_h(R_{h,r}(u), \chi_h) = a(u, \chi_h) \quad \forall \chi_h \in S_{h,r}.$$

We shall use the bound [14], [5]

$$\|u - R_{h,2}(u)\|_0 + h\|u - R_{h,2}(u)\|_1 \leq Ch^2\|u\|_{H^2(\Omega)}, \qquad u \in D(A). \tag{2.6}$$

Let u be the solution of (1.2) or (1.3) with initial condition $u(\cdot,0) = u_0$. Then the Galerkin linear finite element approximation to u is $u_h : [0,T] \to S_{h,2}$, $u_h(0) = R_{h,2}(u_0)$ such that, for all $t \in [0,T]$ and $\varphi_h \in S_{h,2}$,

$$((u_h)_t, \varphi_h) + \nu(\nabla u_h, \nabla\varphi_h) + (F(u_h), \varphi_h) = (f, \varphi_h). \tag{2.7}$$

The next error estimate for the approximation u_h is well known:

$$\|u(t) - u_h(t)\|_0 + h\|u(t) - u_h(t)\|_1 \leq C(K(u))h^2, \qquad 0 \leq t \leq T. \tag{2.8}$$

Finally, set $B(u,v) = (u \cdot \nabla)v$. We shall make use of the following inequality [6, Remark 6.2]. For each $u \in L^\infty(\Omega)$, $v \in H^1(\Omega)$, and $w \in L^2(\Omega)$,

$$|(B(u,v),w)| \leq C\|u\|_\infty\|v\|_1\|w\|_0. \tag{2.9}$$

3. The postprocessed method. Fix $T > 0$ and let us suppose that the Galerkin approximation $u_h(T) \in S_{h,2}$ has been computed solving (2.7). We consider an improved finite element space $\widetilde{S}_h$. Two choices are possible for the new space:

(1) $\widetilde{S}_h = S_{h',2}$, $h' < h$, the linear finite element space that is obtained from $S_{h,2}$ by refining the partition. That is, every element τ_i^h is divided into a finite number of elements $\tau_j^{h'}$.

(2) If the solution u of (1.2) or (1.3) with initial condition u_0 belongs to $H^3(\Omega) \cap H_0^1(\Omega)$ we can take $\widetilde{S}_h = S_{h,3}$, the space of piecewise quadratic polynomials over the same grid.

The postprocessed approximation $\tilde{u}_h(T) \in \widetilde{S}_h$ is the solution of the discrete elliptic problem

$$\nu(\nabla\tilde{u}_h(T), \nabla\varphi_h) = -(F(u_h(T)), \varphi_h) - ((u_h(T))_t, \varphi_h) + (f, \varphi_h) \tag{3.1}$$

for all $\varphi_h \in \widetilde{S}_h$.

Remark 3.1. Let W_h be the orthogonal complement of $S_{h,2}$ in $\widetilde{S}_h$ with respect to the inner product in $H_0^1(\Omega)$ (i.e., $(\nabla\cdot, \nabla\cdot)$). Then the postprocessed approximation $\tilde{u}_h(T)$ at time $T > 0$ can also be obtained adding to the Galerkin approximation $u_h(T)$, the *approximate inertial manifold* $\Phi_h(u_h(T)) \in W_h$ defined by

$$\nu(\nabla\Phi_h(u_h(T)), \nabla\psi_h) = -(F(u_h(T)), \psi_h) - ((u_h(T))_t, \psi_h) + (f, \psi_h) \tag{3.2}$$

for all $\psi_h \in W_h$.

4. Analysis of the postprocessed method. In this section we establish the rate of convergence of the postprocessed linear finite element method in the $H^1(\Omega)$ norm. We shall prove that the postprocessed approximation improves, up to one unit in terms of h (up to a logarithmic term), the rate of convergence of the Galerkin linear finite element method for both choices of the refined finite element space $\widetilde{S}_h$.

The proof of the two main theorems will require several preparatory lemmas which we now state.

LEMMA 4.1. *Let $g \in L^\infty([0,T], S_{h,2})$. For all $t \in [0,T]$ we have*

$$\left\| \int_0^t e^{-(t-s)\nu A_h} A_h g(s)\, \mathrm{d}s \right\|_0 \leq C\nu^{-1}\log(1/h) \max_{0\leq t\leq T} \|g(t)\|_0,$$

where the constant C does not depend on h.

Proof. We refer to [8, Lemma 4.7] since the proof can be obtained by the same steps. The only requirement needed in that proof is the bound

$$(A_h v_h, v_h) \le Ch^{-2}\|v_h\|_0^2, \qquad v_h \in S_{h,2},$$

which is a direct consequence of the inverse inequality (2.4). ∎

LEMMA 4.2. *Let u be the solution of* (1.2) *with initial condition u_0 and let u_h be the Galerkin linear finite element approximation to u. Then, if $d = 2$, the following bound holds with $l = -1, 0$:*

$$\|B(u_h, u_h) - B(u, u)\|_l \le C\|u - u_h\|_{l+1}\|u\|_{H^{3/2}(\Omega)}. \tag{4.1}$$

If $d = 3$, for $l = -1, 0$, and $\epsilon \in (0, 1/2]$,

$$\|B(u_h, u_h) - B(u, u)\|_l \le C\|u - u_h\|_{l+1}\|u\|_{H^{3/2+\epsilon}(\Omega)}. \tag{4.2}$$

Proof. We first notice that

$$\|B(u_h, u_h) - B(u, u)\|_l \le \|B(u_h - u, u_h)\|_l + \|B(u, u_h - u)\|_l. \tag{4.3}$$

Let us prove (4.1). Taking into account that in this case $d = 2$, we first observe that

$$\|\nabla u_h\|_{L^4(\Omega)} \le C\|u\|_{H^{3/2}(\Omega)}. \tag{4.4}$$

To obtain this bound we use (2.8), (2.4), (2.5), and (2.2) to get

$$\begin{aligned}
\|\nabla u_h\|_{L^4(\Omega)} &\le \|\nabla(u_h - I_h u)\|_{L^4(\Omega)} + \|\nabla(I_h u - u)\|_{L^4(\Omega)} + \|\nabla u\|_{L^4(\Omega)} \\
&\le Ch^{-1/2}\|\nabla(u_h - I_h u)\|_{L^2(\Omega)} + C\|u\|_{W^{1,4}(\Omega)} + \|\nabla u\|_{L^4(\Omega)} \\
&\le Ch^{-1/2}\left(\|\nabla(u_h - u)\|_{L^2(\Omega)} + \|\nabla(u - I_h u)\|_{L^2(\Omega)}\right) + C\|u\|_{W^{1,4}(\Omega)} \\
&\le Ch^{-1/2}h^{1/2}\|u\|_{H^{3/2}(\Omega)} + C\|u\|_{W^{1,4}(\Omega)} \\
&\le C\|u\|_{H^{3/2}(\Omega)}.
\end{aligned}$$

Then we have

$$\begin{aligned}
|(B(u_h - u, u_h), \varphi)| &\le \|u - u_h\|_0\|\nabla u_h\|_{L^4(\Omega)}\|\varphi\|_{L^4(\Omega)} \\
&\le C\|u - u_h\|_0\|u\|_{H^{3/2}(\Omega)}\|\varphi\|_{H^{1/2}(\Omega)} \\
&\le C\|u - u_h\|_0\|u\|_{H^{3/2}(\Omega)}\|\varphi\|_1,
\end{aligned}$$

where we have used (4.4) and (2.2). Consequently, the first term in (4.3) is bounded by

$$\|B(u_h - u, u_h)\|_{-1} \le C\|u - u_h\|_0\|u\|_{H^{3/2}(\Omega)}.$$

The proof for the case $l = -1$ is completed by using (2.9), (2.1), and (2.2) to estimate the second term in (4.3). Thus we get

$$\begin{aligned}
|(B(u, u_h - u), \varphi)| &\le \|(B(u, \varphi), u_h - u)| + |(\mathrm{div}(u)(u_h - u), \varphi)| \\
&\le \|u - u_h\|_0\left(\|\varphi\|_1\|u\|_\infty + \|\nabla u\|_{L^4(\Omega)}\|\varphi\|_{L^4(\Omega)}\right) \\
&\le C\|u - u_h\|_0\|u\|_{H^{3/2}(\Omega)}\|\varphi\|_1.
\end{aligned}$$

The case $l = 0$ is treated in a similar way. We have

$$|(B(u_h - u, u_h), \varphi)| \leq \|u_h - u\|_{L^4(\Omega)} \|\nabla u_h\|_{L^4(\Omega)} \|\varphi\|_0.$$

This gives

$$\begin{aligned} \|B(u_h - u, u_h)\|_0 &\leq C\|u_h - u\|_{H^{1/2}(\Omega)} \|u\|_{H^{3/2}(\Omega)} \\ &\leq C\|u_h - u\|_1 \|u\|_{H^{3/2}(\Omega)} \end{aligned}$$

after using (4.4) and (2.2). Finally, using (2.9),

$$|(B(u, u_h - u), \varphi)| \leq C\|u\|_\infty \|u - u_h\|_1 \|\varphi\|_0, \tag{4.5}$$

and then, using (2.1), we get

$$\|B(u, u_h - u)\|_0 \leq C\|u\|_{H^{1+\epsilon}(\Omega)} \|u - u_h\|_1, \qquad \epsilon > 0.$$

This completes the proof of (4.1).

The proof of (4.2) follows along the same lines as before. We begin with the case $l = -1$. Using (2.2) we get

$$\begin{aligned} |(B(u_h - u, u_h), \varphi)| &\leq \|u - u_h\|_0 \|\nabla u_h\|_{L^3(\Omega)} \|\varphi\|_{L^6(\Omega)} \\ &\leq C\|u - u_h\|_0 \|u\|_{H^{3/2}(\Omega)} \|\varphi\|_1, \end{aligned}$$

where we have used the estimate

$$\|\nabla u_h\|_{L^3(\Omega)} \leq C\|u\|_{H^{3/2}(\Omega)}. \tag{4.6}$$

This bound is obtained using again (2.8), (2.4), (2.5), and (2.2) in the following way:

$$\begin{aligned} \|\nabla u_h\|_{L^3(\Omega)} &\leq \|\nabla(u_h - I_h u)\|_{L^3(\Omega)} + \|\nabla(I_h u - u)\|_{L^3(\Omega)} + \|\nabla u\|_{L^3(\Omega)} \\ &\leq Ch^{-1/2} \|\nabla(u_h - I_h u)\|_{L^2(\Omega)} + C\|u\|_{W^{1,3}(\Omega)} + \|\nabla u\|_{L^3(\Omega)} \\ &\leq Ch^{-1/2} \left(\|\nabla(u_h - u)\|_{L^2(\Omega)} + \|\nabla(u - I_h u)\|_{L^2(\Omega)} \right) + C\|u\|_{W^{1,3}(\Omega)} \\ &\leq Ch^{-1/2} h^{1/2} \|u\|_{H^{3/2}(\Omega)} + C\|u\|_{W^{1,3}(\Omega)} \\ &\leq C\|u\|_{H^{3/2}(\Omega)}. \end{aligned}$$

For the second term in (4.3) we use first (2.9) and then (2.1) and (2.2):

$$\begin{aligned} |(B(u, u_h - u), \varphi)| &\leq |(B(u, \varphi), u_h - u)| + |(\mathrm{div}(u)(u_h - u), \varphi)| \\ &\leq \|u - u_h\|_0 \left(\|\varphi\|_1 \|u\|_\infty + \|\nabla u\|_{L^3(\Omega)} \|\varphi\|_{L^6(\Omega)} \right) \\ &\leq C\|u - u_h\|_0 \|u\|_{H^{3/2+\epsilon}(\Omega)} \|\varphi\|_1, \ \epsilon > 0. \end{aligned}$$

The case $l = 0$ can be treated in a similar way as in the proof of (4.1). The only difference is that now, after using (4.6) and (2.2), we have

$$\begin{aligned} |(B(u_h - u, u_h), \varphi)| &\leq \|u_h - u\|_{L^6(\Omega)} \|\nabla u_h\|_{L^3(\Omega)} \|\varphi\|_0 \\ &\leq C\|u_h - u\|_1 \|u\|_{H^{3/2}(\Omega)} \|\varphi\|_0 \end{aligned}$$

so that in this case also

$$\|B(u_h - u, u_h)\|_0 \leq C\|u_h - u\|_1 \|u\|_{H^{3/2}(\Omega)}.$$

Finally, using (4.5) and (2.1) we obtain

$$\|B(u,u_h-u)\|_0 \le C\|u_h-u\|_1\|u\|_{H^{3/2+\epsilon}(\Omega)}, \qquad \epsilon>0,$$

which completes the proof. ∎

LEMMA 4.3. *Let u be the solution of* (1.3) *with initial condition u_0 and let u_h be the Galerkin linear finite element approximation to u. Then, if $d=2$, the following bound holds with $l=-1,0$:*

$$\|g(u_h)-g(u)\|_l \le C(\|u\|_1)\|u-u_h\|_{l+1}. \tag{4.7}$$

If $d=3$, for $l=-1,0$,

$$\|g(u_h)-g(u)\|_l \le C(\|u\|_{H^{3/2}(\Omega)})\|u-u_h\|_{l+1}. \tag{4.8}$$

Proof. Let us first observe that

$$g(u_h)-g(u)=(u_h-u)\left(\sum_{j=1}^{2p-1} b_j\left(\sum_{k=1}^{j} u_h^{j-k}u^{k-1}\right)\right)=(u_h-u)G(u_h,u).$$

Since, for $d=2,3$, using (2.2),

$$\begin{aligned}|(g(u_h)-g(u),\varphi)| &= |((u_h-u)G(u_h,u),\varphi)|\\ &\le \|u_h-u\|_0\|G(u_h,u)\|_{L^4(\Omega)}\|\varphi\|_{L^4(\Omega)}\\ &\le \|u_h-u\|_0\|G(u_h,u)\|_{L^4(\Omega)}\|\varphi\|_1\end{aligned}$$

and

$$\begin{aligned}\|G(u_h,u)\|_{L^4(\Omega)} &\le \sum_{j=1}^{2p-1}|b_j|\sum_{k=1}^{j}\|u_h^{j-k}u^{k-1}\|_{L^4(\Omega)}\\ &\le \sum_{j=1}^{2p-1}|b_j|\sum_{k=1}^{j}\|u_h\|^{j-k}_{L^{8(j-k)}(\Omega)}\|u\|^{k-1}_{L^{8(k-1)}(\Omega)},\end{aligned}$$

the estimate (4.7) with $l=-1$ is readily obtained by taking into account that, after using (2.2), $\|u_h\|_{L^{8(j-k)}(\Omega)}$ and $\|u\|_{L^{8(k-1)}(\Omega)}$ are bounded in terms of $\|u_h\|_1$ and $\|u\|_1$, respectively, and then $\|G(u_h,u)\|_{L^4(\Omega)}\le C(\|u\|_1)$.

To obtain (4.8), we again use (2.2) to get

$$\|u\|_{L^{8(k-1)}(\Omega)} \le C\|u\|_{H^{3/2}(\Omega)}.$$

Now using (2.4), (2.5), (2.8), and (2.2), we have, for $q=8(j-k)$,

$$\begin{aligned}\|u_h\|_{L^q(\Omega)} &\le \|u_h-I_hu\|_{L^q(\Omega)}+\|I_hu-u\|_{L^q(\Omega)}+\|u\|_{L^q(\Omega)}\\ &\le Ch^{-3/2}\|u_h-I_hu\|_{L^2(\Omega)}+C\|u\|_{L^q(\Omega)}+\|u\|_{L^q(\Omega)}\\ &\le Ch^{-3/2}h^{3/2}\|u\|_{H^{3/2}(\Omega)}+C\|u\|_{H^{3/2}(\Omega)},\end{aligned}$$

which gives $\|G(u_h,u)\|_{L^4(\Omega)}\le C(\|u\|_{H^{3/2}(\Omega)})$. This completes the proof in the case $l=-1$. The corresponding results for $l=0$ are obtained in a similar way, taking into account that

$$|(g(u_h)-g(u),\varphi)| \le \|u_h-u\|_{L^4(\Omega)}\|G(u_h,u)\|_{L^4(\Omega)}\|\varphi\|_0$$

and again using (2.2). ∎

We now state the first main result of the paper which yields a superconvergence result. More precisely, we prove that the $H^1(\Omega)$ norm of the difference between the elliptic projection of the exact solution and the Galerkin approximation to this solution is $O(h^2)$, up to a logarithmic term.

THEOREM 4.4. *Fix $T > 0$, let u be the solution of* (1.2) *or* (1.3) *with initial condition u_0, let u_h be its Galerkin linear finite element approximation* (2.7)*, and let $r_h = R_{h,2}(u)$ be the elliptic projection of u onto $S_{h,2}$. Then*

$$\max_{0\le t\le T} \|u_h - r_h\|_1 \le C(K(u))\nu^{-1}\log(1/h)h^2,$$

where $K(u)$ is the constant in (2.3).

Proof. It is easy to see that the error $e_h = u_h - r_h$ satisfies, for all $\varphi_h \in S_{h,2}$,

$$((e_h)_t, \varphi_h) = -\nu(\nabla e_h, \nabla\varphi_h) + (F(u_h) - F(u), \varphi_h) + (\tau, \varphi_h), \tag{4.9}$$

where $\tau = (r_h)_t - u_t$. Hence,

$$\begin{aligned} e_h(t) = e^{-\nu A_h t}e_h(0) &+ \int_0^t e^{-\nu A_h(t-s)}P_{h,2}(F(u_h) - F(u))\,\mathrm{d}s \\ &+ \int_0^t e^{-\nu A_h(t-s)}P_{h,2}\tau\,\mathrm{d}s. \end{aligned} \tag{4.10}$$

Taking into account that $e_h(0) = 0$ and applying $A_h^{1/2}$ to both sides of (4.10), we obtain

$$\begin{aligned} A_h^{1/2}e_h(t) = &\int_0^t e^{-\nu A_h(t-s)}A_h^{1/2}P_{h,2}(F(u_h) - F(u))\,\mathrm{d}s \\ &+ \int_0^t e^{-\nu A_h(t-s)}A_h^{1/2}P_{h,2}((r_h)_t - u_t)\,\mathrm{d}s. \end{aligned} \tag{4.11}$$

On the other hand, it is clear that for every function $f \in L^2(\Omega)$ one has

$$\|A_h^{-1/2}P_{h,2}f\|_0 \le C\|f\|_{-1}.$$

Then, using Lemma 4.1, we have

$$\begin{aligned} \left\|\int_0^t e^{-\nu A_h(t-s)}A_h^{1/2}P_{h,2}f\,\mathrm{d}s\right\|_0 &= \left\|\int_0^t e^{-\nu A_h(t-s)}A_hA_h^{-1/2}P_{h,2}f\,\mathrm{d}s\right\|_0 \\ &\le C\nu^{-1}\log(1/h)\|A_h^{-1/2}P_{h,2}f\|_0 \\ &\le C\nu^{-1}\log(1/h)\|f\|_{-1}. \end{aligned}$$

Applying the above inequality to the terms on the right-hand side of (4.11) we obtain

$$\begin{aligned} \|A_h^{1/2}e_h\|_0 &\le C\nu^{-1}\log(1/h)\left(\|F(u_h) - F(u)\|_{-1} + \|(r_h)_t - u_t\|_{-1}\right) \\ &\le C\nu^{-1}\log(1/h)\left(C(K(u))\|u_h - u\|_0 + \|(r_h)_t - u_t\|_0\right), \end{aligned}$$

where in the last inequality we have used Lemma 4.2 or Lemma 4.3. Finally, by (2.8) and (2.6) we get

$$\|A_h^{1/2}e_h\|_0 \le C\nu^{-1}\log(1/h)C(K(u))h^2,$$

which proves the theorem, on taking into account that since $e_h \in H_0^1(\Omega)$ the norm $\|A_h^{1/2} e_h\|$ is equivalent to $\|e_h\|_1$. ∎

We next state and prove another technical lemma and then the main theorem of the paper that gives the rate of convergence of the postprocessed method.

LEMMA 4.5. *Let u be the solution of* (1.2) *or* (1.3) *with initial condition u_0 and u_h its Galerkin linear finite element approximation defined by* (2.7). *Then*

$$\max_{0\le t\le T} \|(u_h)_t - u_t\|_0 \le C(K(u)) \log(1/h) h.$$

Proof. Let us first observe that $\|(u_h)_t - u_t\|_0 \le \|(e_h)_t\|_0 + \|(r_h)_t - u_t\|_0$. The second term, using (2.6), is bounded by $CK(u)h^2$. We now consider the first term. From (4.9) and taking $\varphi_h = (e_h)_t$ we obtain

$$\begin{aligned}\|(e_h)_t\|_0^2 &\le C\nu \|e_h\|_1 \|(e_h)_t\|_1 + \|F(u_h) - F(u)\|_0 \|(e_h)_t\|_0 + \|(r_h)_t - u_t\|_0 \|(e_h)_t\|_0 \\ &\le C\|(e_h)_t\|_0 \left(\nu \|e_h\|_1 h^{-1} + \|F(u_h) - F(u)\|_0 + \|(r_h)_t - u_t\|_0\right),\end{aligned}$$

where we have used the inverse inequality (2.4). Then

$$\|(e_h)_t\|_0 \le Ch^{-1}\nu \|e_h\|_1 + \|F(u_h) - F(u)\|_0 + \|(r_h)_t - u_t\|_0.$$

Now, taking into account Theorem 4.4, Lemma 4.2 or Lemma 4.3, (2.8), and (2.6) we get

$$\|(e_h)_t\|_0 \le C(K(u)) \log(1/h) h + C(K(u))h + CK(u)h^2,$$

which is the desired conclusion. ∎

THEOREM 4.6. *Fix $T > 0$, let u be the solution of* (1.2) *or* (1.3) *with initial condition u_0, and let $\tilde{u}_h(T) = u_h(T) + \Phi_h(u_h(T)) \in \widetilde{S}_h$ be the postprocessed approximation to $u(T)$ defined in* (3.1). *If $\widetilde{S}_h = S_{h',2}$, then*

$$\|u(T) - \tilde{u}_h(T)\|_1 \le C(K(u))\nu^{-1} \log(1/h) h^2 + C\|u(\cdot, T)\|_{H^2(\Omega)} h'. \tag{4.12}$$

If $u(\cdot, T) \in H^3(\Omega) \cap H_0^1(\Omega)$ and $\widetilde{S}_h = S_{h,3}$, then

$$\|u(T) - \tilde{u}_h(T)\|_1 \le C(K(u))\nu^{-1} \log(1/h) h^2 + C\|u(\cdot, T)\|_{H^3(\Omega)} h^2. \tag{4.13}$$

Proof. From the decomposition $\widetilde{S}_h = S_{h,2} \oplus W_h$ (see Remark 3.1) we define Ψ_h such that $\tilde{r}_h = r_h + \Psi_h$, where $\tilde{r}_h$ stands for the elliptic projection of u over the space $\widetilde{S}_h$. Let us denote $\Phi_h(u_h(T))$ by Φ_h. Then the error of the postprocessed approximation can be decomposed in the following way:

$$\|u - (u_h + \Phi_h)\|_1 \le \|u - \tilde{r}_h\|_1 + \|r_h - u_h\|_1 + \|\Psi_h - \Phi_h\|_1. \tag{4.14}$$

The second term on the right-hand side above was estimated in Theorem 4.4.

To bound the third term we first observe that

$$\nu(\nabla \Psi_h, \nabla \psi_h) = -(F(u), \psi_h) - (u_t, \psi_h) + (f, \psi_h) \quad \forall \psi_h \in W_h. \tag{4.15}$$

Subtracting (4.15) from (3.2) we obtain

$$\nu(\nabla(\Phi_h - \Psi_h), \nabla \psi_h) = (F(u) - F(u_h), \psi_h) + ((u - u_h)_t, \psi_h)$$

for all $\psi_h \in W_h$. Using the coercivity of $a(\cdot,\cdot)$,

$$\nu\alpha\|\Phi_h - \Psi_h\|_1 \leq \|F(u) - F(u_h)\|_{-1} + Ch\|(u_h - u)_t\|_0. \tag{4.16}$$

In this last inequality we used that

$$\|w\|_0 \leq Ch\|w\|_1 \quad \forall w \in W_h. \tag{4.17}$$

To prove (4.17) we observe that if $w \in W_h$, then $w = w - R_{h,2}(w)$ so that (4.17) follows from (2.6). Now, using Lemma 4.2 or Lemma 4.3 and Lemma 4.5 in (4.16) we get

$$\begin{aligned}\nu\alpha\|\Phi_h - \Psi_h\|_1 &\leq C(K(u))\|u - u_h\|_0 + C(K(u))\log(1/h)h^2 \\ &\leq C(K(u))h^2 + C(K(u))\log(1/h)h^2\end{aligned}$$

after using (2.8) in the last inequality.

To complete the proof it remains only to bound the first term of (4.14). We distinguish two cases. If $\widetilde{S}_h = S_{h',2}$, then using (2.6) this term is bounded by $C\|u(\cdot,T)\|_{H^2(\Omega)}h'$ and (4.12) is obtained. In the case $\widetilde{S}_h = S_{h,3}$ we use the well-known bound [5]

$$\|u - R_{h,3}(u)\|_1 \leq Ch^2\|u\|_{H^3(\Omega)}, \tag{4.18}$$

instead of (2.6), to deduce that this term is bounded by $C\|u(\cdot,T)\|_{H^3(\Omega)}h^2$ so that the desired estimate (4.13) is obtained. □

Remark 4.1. We observe from Theorem 4.6 that the highest possible rate of convergence in the $H^1(\Omega)$ norm for the postprocessed method is $O(h^2)$ up to a logarithmic term. Then using the postprocessing technique we can obtain an improvement over the standard linear finite element error bound which is $O(h)$ in the $H^1(\Omega)$ norm (see (2.8)). However, to obtain this rate of convergence by postprocessing in the space $S_{h',2}$, that is, by means of some refinement of the mesh, we need $h' = O(h^2)$. This is a very demanding requirement especially in two or three dimensions. Fortunately, for practical computations, only a slightly refined mesh is usually sufficient in order to observe a considerable reduction of the error in the $H^1(\Omega)$ norm (see the next section). Since the refinement of the mesh is performed only at the final time T, the extra cost of the postprocessing is almost negligible when compared with the cost of integrating in time from $t = 0$ to $t = T$ on the coarser mesh.

When the solution u is smooth enough we can use quadratic polynomials over the same grid once the time integration is completed. In view of (4.13) this procedure always improves the rate of convergence of the standard Galerkin method by a single power of h (up to a logarithmic term).

For a general domain with smooth boundary, one can still benefit from using the postprocessed method. In this case, each $\mathcal{T}_h$ is a partition of a domain Ω_h that approximates Ω. For an affine family of finite elements

$$\delta(h) = \max_{x\in\Omega_h} \operatorname{dist}(x, \partial\Omega) \leq ch^2$$

so that (2.6) remains valid; see [14, p. 61]. Therefore, it is possible to obtain exactly the same bounds as in Theorem 4.6, postprocessing with $\widetilde{S}_h = S_{h',2}$. Postprocessing with piecewise quadratic polynomials requires that boundary data approximations are

performed to a sufficiently high order of accuracy since the bound (4.18) is no longer valid in a straight mesh.

Finally, we remark that the one-dimensional case can be treated in a much easier way. In this case one can either refine the partition or increase the degree of the polynomials used in the postprocessing step at the final time level.

5. Numerical experiments. In this section we present some numerical experiments to assess some features of the postprocessed linear finite element method. We begin with a simple one-dimensional example which will help us to illuminate the results we have presented in previous sections.

Let us consider the one-dimensional Burgers equation

$$u_t - \nu u_{xx} + u u_x = 0, \qquad 0 < x < 1,$$

subject to homogeneous Dirichlet boundary conditions $u(0,t) = u(1,t) = 0$, $t \geq 0$. We take as the initial condition $u(x,0) = \sin(2\pi x)$. The value of ν in these experiments is $\nu = 0.01$, but similar results have been obtained for other values of the diffusion parameter.

We use linear finite elements in space over a uniform partition of $[0,1]$ and integrate in time using the *backward differentiation formulae* implemented in the variable-step variable-order mode. The final time chosen is $T = 1$. The Galerkin approximation at the final time is postprocessed using linear finite elements but over a refined partition. If the Galerkin approximation has been calculated over a partition of size h, then $h' \approx h^2$ has been taken as the new diameter of the refined partition for the postprocessing step.

The "exact" solution u has been computed using the Galerkin method with a sufficiently small mesh size and a sufficiently small value of the tolerance in the time integrator in order to ensure that the errors in time and space are negligible. Then the computed solution may be taken as exact, for all intents and purposes, as it is sufficiently more accurate than those shown in the experiments.

In Figure 5.1 we show, in a logarithmic scale, the $L^2(0,1)$ and $H^1(0,1)$ norms of the relative errors for the linear finite element method (continuous line) and the postprocessed method (discontinuous line) against the number $N = 1/h$ of subintervals in the partition used in the calculations. We have used circles to represent the errors measured in the $L^2(0,1)$ norm and diamonds for the errors in the $H^1(0,1)$ norm. For each value of h the experiments were carried out with decreasing values of the time integration tolerance until further reduction of the tolerance did not reduce the error any further. This means that, at this point, the time discretization error is negligible when compared with the spatial error. In the figure it is observed that the postprocessed method *does not reduce the error in the* $L^2(0,1)$ *norm*, while *a considerable reduction of the error is obtained in the* $H^1(0,1)$ *norm*. In fact, the slopes of the lines in the convergence diagram in the $L^2(0,1)$ norm are -1.99 for the standard Galerkin scheme and -1.95 for the postprocessed Galerkin method. That is, the order of convergence in $L^2(0,1)$ is the same for both methods. The slopes in the $H^1(0,1)$ norm are -1.01 and -1.94 for the standard and postprocessed Galerkin method, respectively. This result is in agreement with the bound on the error of the postprocessed method obtained in Theorem 4.6 that predicts quadratic convergence in $H^1(0,1)$ in contrast to the linear convergence of the Galerkin method in the same norm. Notice that, as we mentioned before, the value of h' in this experiment is taken to be $O(h^2)$.

In Figure 5.2 we show the same errors as before (for the $H^1(0,1)$ norm only)

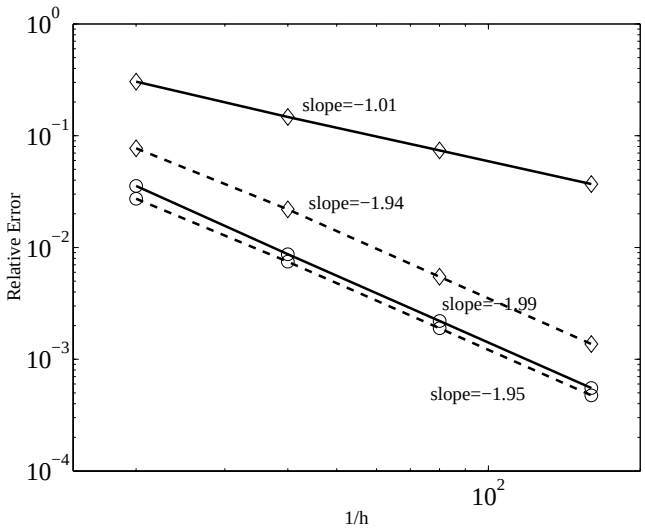

FIG. 5.1. *Burgers equation, $\nu = 0.01$; relative errors against $N = 1/h$; continuous line: Galerkin method, discontinuous line: postprocessed method; circle: $L^2(\Omega)$ norm; diamond: $H^1(\Omega)$ norm.*

but plotted against the CPU time that was required to compute the corresponding solutions. The CPU time shown was the smallest among those yielding a given error but using different values of the time integration tolerance. It can be seen that, for a given accuracy, the postprocessed method achieves a dramatic reduction in the CPU time required to compute the corresponding solution. Thus in this experiment the postprocessing procedure really improves the efficiency of the standard linear finite element method in the $H^1(0,1)$ norm. We remark that the semidiscrete Galerkin equations (2.7) are a stiff system of ordinary differential equations that must be integrated by means of some implicit time stepping procedure. Thus at each time step one has to solve a nonlinear system of equations by means of some Newton or quasi-Newton iteration. The cost of the postprocessing step is the same as an extra single (quasi-) Newton iteration on the refined mesh. Although in this experiment the mesh size we have used to postprocess is much smaller than the one used to obtain the Galerkin solution, the most expensive part of the algorithm is the time integration procedure which is carried out on the coarse mesh. Furthermore, as we show in the next experiment, usually only a slightly refined mesh is sufficient for ensuring a substantial reduction in the error. This fact greatly reduces in practice the cost of the postprocessing step.

Next we present a two-dimensional example. We now consider the following reaction-diffusion equation with a cubic nonlinearity:

$$u_t - \nu\Delta u - u + u^3 = f(t,\mathbf{x}), \qquad \mathbf{x} \in \Omega,$$

in the domain $\Omega = (-1,1) \times (-1,1)$. We impose a homogeneous Dirichlet boundary condition on u. The value of ν in the experiment is $\nu = 0.01$ and the final time is $T = 1$. We chose the forcing term so that the exact solution is $u(x,y,t) = \cos(2\pi t)\sin(\pi x)\sin(\pi y)$.

In the calculations we took a regular triangulation of Ω induced by the set of nodes $(-1+2j/N, -1+2k/N)$, $0 \le j,k \le N$, where $N = 2/h$ is an integer. The meshes were

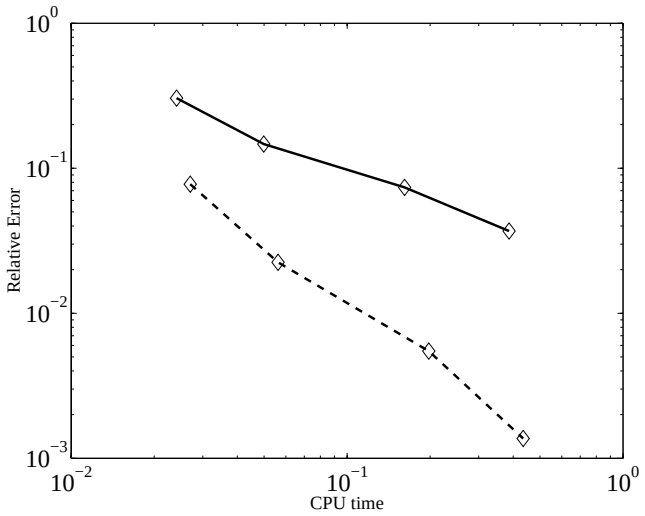

FIG. 5.2. *Burgers equation, $\nu = 0.01$; relative errors in the $H^1(\Omega)$ norm against CPU time; continuous line: Galerkin method, discontinuous line: postprocessed method.*

generated using the finite element package of MATLAB. We use the MATLAB time integrator ODE15s for the time integration of the semidiscrete Galerkin equations.

In Figure 5.3 we show the $L^2(\Omega)$ and $H^1(\Omega)$ norms of the relative errors for the Galerkin and postprocessed Galerkin methods using the same symbols as before: a continuous line for the Galerkin method and a discontinuous (dashed or dash-dotted) line for the postprocessed method, circles for the $L^2(\Omega)$ norm, and diamonds for the $H^1(\Omega)$ norm, respectively. In the postprocessing step we first construct a uniform refinement of the partition taking $h' = h/8$, that is, three regular refinements of the mesh used in the Galerkin equations. We observe in the figure that the postprocessing procedure does not improve the error in the $L^2(\Omega)$ norm. Indeed, for each value of h, the $L^2(\Omega)$ norm of the error of the postprocessed method (dashed line, circles) is significantly larger than the corresponding error of the Galerkin method (continuous line, circles), although both exhibit quadratic convergence. The slopes in the convergence diagram are -1.98 for the $L^2(\Omega)$ norm of the Galerkin error and -1.89 for the $L^2(\Omega)$ norm of the postprocessed error.

If we consider the errors achieved in the $H^1(\Omega)$ norm the situation is completely different. Now the postprocessed errors (dashed line, diamonds) are below the Galerkin errors (continuous line, diamonds) except for the first point that corresponds to $h = 2/8$. Furthermore, the difference between Galerkin and postprocessed Galerkin errors increases as the value of h decreases. The computed slope for the line representing the postprocessed errors in the $H^1(\Omega)$ norm is -1.83 showing that the convergence is almost quadratic. This result is again in agreement with the error bounds of Theorem 4.6. Indeed, we could have obtained exactly quadratic convergence with the postprocessed method had we postprocessed the last two points in the picture using a smaller value of h'. However, from a practical point of view, although the postprocessed step is carried out only at the final time T, the use of a mesh of size $h' \approx h^2$ for ensuring quadratic convergence is not very useful. Fortunately, one still benefits from using the postprocessed method in two dimensions even if $h' \gg h^2$. To show this fact we have depicted in Figure 5.3, using diamonds joined by a dashed-

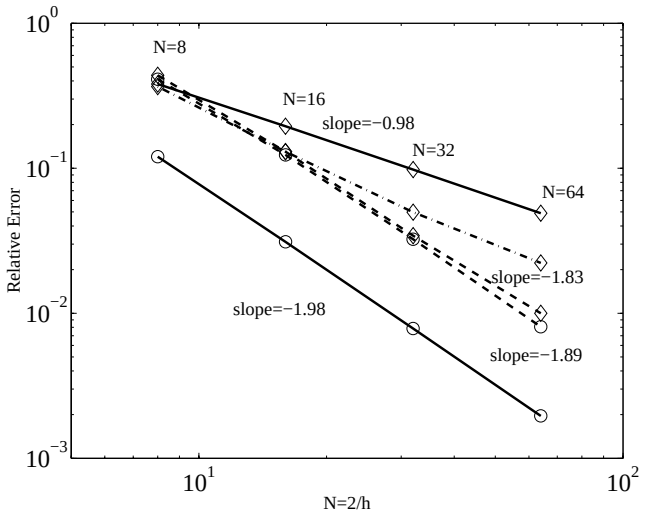

FIG. 5.3. *Reaction-diffusion equation, $\nu = 0.01$; relative errors against $N = 2/h$; continuous line: Galerkin method, discontinuous line: postprocessed method; circle: $L^2(\Omega)$ norm, diamond: $H^1(\Omega)$ norm.*

dotted line, the $H^1(\Omega)$ norm of the errors in the postprocessed solution based on linear elements over a refined mesh of size $h' = h/2$ (only one regular refinement). Notice then that by postprocessing at the final time $T = 1$ the Galerkin solution that has been computed using a mesh of size $h = 2/16$ we obtain the same error as if we had used a mesh of size $h = 2/32$ over the full time interval $[0, T]$ to calculate the Galerkin solution. The same result is true for other values of h; compare, for example, the results with $h = 2/32$ (postprocessed with $h' = 2/64$) and $h = 2/64$. *Postprocessing the Galerkin approximation with $h' = h/2$ one can achieve a smaller error than by computing the Galerkin solution on a mesh of half the spacing.* This version of applying the postprocessed method is clearly an efficient way to improve the accuracy of the Galerkin method in the $H^1(\Omega)$ norm. Notice that now the cost of the postprocessing step is only slightly larger than that of one (quasi-) Newton iteration in one step of the time integration procedure, and, furthermore, the postprocessed method is applied only once at time T where the numerical solution is required.

Acknowledgment. The authors thank Professor Endre Süli for his valuable suggestions, especially concerning the proof of Lemma 4.2, which is a significant improvement over a previous version.

STABILITY OF DISCRETE SHOCKS FOR DIFFERENCE APPROXIMATIONS TO SYSTEMS OF CONSERVATION LAWS*

DANIEL MICHELSON†

Abstract. The asymptotic stability of weak discrete stationary shocks for systems of conservation laws in one space dimension is proved. The difference approximation should be conservative, dissipative, and kth order accurate in space with odd k. The problem is considered in a finite interval $|x| \le \ell$ with appropriate boundary conditions, where ℓ is large compared with the width of the shock layer $\varepsilon^{-1} = |u_R - u_L|^{-1/k}$. The proof is based on the assumption that the corresponding continuous shocks for the scalar problem $u_t + uu_x = -(i\partial_x)^{k+1}u$ are stable. The latter is known to be true for $k = 1$ and $k = 3$.

Key words. discrete shocks, systems of conservation laws, asymptotic stability, viscous shock profiles, high order dissipation

1. Introduction.

Consider a system of conservation laws

$$u_t + f(u)_x = 0, \tag{1.1}$$

where $f\colon R^n \to R^n$ is a smooth vector function and the unknown function $u = u(x,t) \in R^n$ depends on $-\infty < x < \infty$ and $t > 0$. By planar stationary shock, one means the solutions

$$u = u_L, \quad x < x_0; \qquad u = u_R, \quad x > x_0, \tag{1.2}$$

where u_L, u_R satisfy the Rankine–Hugoniot condition

$$f(u_L) = f(u_R). \tag{1.3}$$

Suppose that (1.1) is approximated by a dissipative system

$$u_t + f(u)_x = -(i\partial_x)^{\frac{k+1}{2}}\Big[A(u)(i\partial_x)^{\frac{k+1}{2}}\Big]u, \qquad k \text{ odd}. \tag{1.4}$$

Stationary solutions u_{st} of (1.4) which attain the above limits u_L and u_R as $x \to -\infty$ and $x \to \infty$ correspondingly are called stationary viscous shocks. (The traveling shocks by a change of variables $x - c \cdot t \to x$ are reduced to the stationary ones.) If the difference $|u_R - u_L|$ is small, the shock is called weak. We assume that u_L, u_R lie in a small neighborhood of a point u_0 such that the differential $df[u_0]$ of f at u_0 has *distinct real* eigenvalues with a zero eigenvalue $\lambda_1(u_0) = 0$. Without loss of generality, we may assume that

$$df[u_0] = \operatorname{diag}\Big(\lambda_1(u_0), \lambda_2(u_0), \dots, \lambda_n(u_0)\Big). \tag{1.5}$$

*Received by the editors September 5, 2000; accepted for publication (in revised form) February 20, 2002; published electronically August 1, 2002.

†Department of Computer Science and Applied Mathematics, The Weizmann Institute of Science, Rehovot 76100, Israel (daniel_michel@wisdom.weizmann.ac.il).

The eigenvalue $\lambda_1(u)$ also should be *genuinely nonlinear*, i.e., the directional derivative

$$d\lambda_1[u_0] \cdot e_1 \neq 0, \qquad e_1 = (1, 0, \ldots, 0)^T. \tag{1.6}$$

We assume that the pair u_L, u_R is entropy-satisfying, i.e.,

$$\lambda_1(u_L) > 0 > \lambda_1(u_R), \tag{1.7}$$

and the right-hand side (r.h.s.) of (1.4) is dissipative in a proper sense (see the dissipativity assumption in section 2). Under the above assumptions, the existence of viscous shocks for $k = 1$ and $k = 3$ follows from [1]. Using the idea of Conley's index [2] and the reduction to the central manifold as in [1], one can actually prove the existence of viscous shocks for any odd k.

A natural question to ask is whether these shocks are asymptotically stable. Namely, given an initial condition $u(x, 0)$ which is a small perturbation of the stationary viscous shock $u_{st}(x)$, will $u(x, t)$ tend to $u_{st}(x)$ as $t \to \infty$? For $k = 1$ this problem was studied by Goodman in [3]. Under the assumption of zero mean perturbation, i.e., $\int_{-\infty}^{\infty}(u(x, 0) - u_{st}(x))dx = 0$, he proved that the shock is asymptotically stable. Liu in [4] removed the above restriction but assumed that u_L and u_R are connected by a nondegenerate sum of n shocks. Then he showed that $u(x, t)$ tends asymptotically to a sum of traveling viscous shocks. As far as we know, for $k = 3$ the stability problem was never considered.

Lately, while studying the stability of Bunsen flames [5] we became involved in the stability problem for the shock solution of the scalar equation

$$u_t + \left(\frac{u^2}{2}\right)_x = -u_{xxxx}. \tag{1.8}$$

The stationary shock u_{st} satisfies the equation

$$u_{xxx} = \frac{1}{2}(1 - u^2), \qquad u(\mp\infty) = \pm 1, \tag{1.9}$$

and is not monotone. As a result, the energy method in the L_2 space is not applicable to (1.8). Instead, we used a rigorous computer-assisted proof to show that the linear problem

$$su + (u_{st} \cdot u)_x + u_{xxxx} = 0, \qquad -\infty < x < \infty, \tag{1.10}$$

for complex s with $\operatorname{Re} s \geq 0$ does not have solutions which decrease exponentially as $|x| \to \infty$. (See Theorem 5.1 in [5].) Recently, Engelberg [6] proved analytically that the solution u_{st} of (1.8) is stable in a norm with a weight function $w(x)$ which grows exponentially as $|x| \to \infty$. It seems that our result could be deduced directly from [6] or by strengthening the result in [6]. Unfortunately, the weighted norm estimates are not applicable to systems as in (1.4). Instead, we study the existence and asymptotic stability of a stationary solution u_{st} on a finite interval $|x| \leq \ell$.

In the case $1 < n_1 < n$ (n_1 is defined at (1.14) below), in order to prove the existence of stationary solutions u_{st}, one needs the restriction

$$\delta_0^{-1}\varepsilon^{-1} \leq \ell \leq \delta_0\varepsilon^{-k} \tag{1.11}$$

and $k \geq 3$. (For stability of u_{st} one needs even more, i.e., $\ell \leq \delta_0\varepsilon^{-2}$.) In cases $n_1 = 1$ and $n_1 = n$, ℓ should satisfy

$$\delta_0^{-1}\varepsilon^{-1} \leq \ell \leq \delta_0\varepsilon^{-k-1} \tag{1.12}$$

and $k \geq 1$. Here ε^{-1} is proportional to the width of the boundary layer

$$\varepsilon^{-1} \sim \Big(\lambda_1(u_{_L})\Big)^{-1/k} \sim |u_{_R} - u_{_L}|^{-1/k}, \tag{1.13}$$

and δ_0 is a small constant. The boundary conditions should include

$$P\Big(f(u) + (i\partial_x)^{\frac{k-1}{2}}\Big[A(u)(i\partial_x)^{\frac{k+1}{2}}u\Big]\Big) = 0, \qquad x = \pm\ell, \tag{1.14}$$

where $P\colon R^n \to R^n$ is a projector on the first n_1 components of u. This implies that the integral $\int_{-\ell}^{\ell} Pudx$ is conserved in time. Note that u_{st} tends exponentially fast to $u_{_L}$, $u_{_R}$ with respect to the variable εx. Thus the boundaries $x = \pm\ell$ are practically at infinity.

In this paper we will prove asymptotic stability only in the cases $n_1 = 1$ and $n_1 = n$ since, in the case $1 < n_1 < n$, the result is much weaker and requires special treatment. However, the existence of a stationary solution u_{st} will be proved for a general n_1. The perturbation u of u_{st} should have the same mean value $\int_{-\ell}^{\ell} Pudx$ as u_{st}. But this is not a restriction on the perturbation since there is an n_1 parameter family of u_{st} depending on this mean value (see (2.89) in what follows).

The real motivation for the shock stability problem comes from computations. Hence, instead of the continuous model (1.4), we will consider a discrete approximation to (1.1). The continuous problem could be solved in a similar way. The discrete setting will follow the one in [7], where we proved the existence of weak discrete shocks for dissipative approximations with $k = 1$ and 3. Our numerical experiments for a 2×2 system of polytropic gas indicate that u_{st} also is stable for strong shocks if $k = 1$ or $k = 3$. We conjecture that the same holds for all odd k. Thus, we consider in this paper the case of a general odd k, under the assumption that the eigenvalue problem in (1.10) with $(i\partial_x)^{k+1}u$ derivative has no eigensolutions with $\operatorname{Re} s \geq 0$. The precise statement of our results will be given in the next section.

One should mention the most recent papers on the subject of stability of viscous shocks: Kreiss and Kreiss [10], Zumbrun and Howard [11], and Liu and Yu [12]. All three papers deal with the case of second order viscosity only. In [10] and [11] the continuous problem is studied. In [10] the Jacobian of the flux is assumed to be the same at $\pm\infty$, which does not hold in real physical applications. The existence and linear stability of the shock is also postulated. In [11, p. 760] the Evans function criterion (condition D) is postulated. It holds indeed in the case of weak shocks; however, it is not clear whether the estimates in [11] give an efficient bound on the size of the perturbation of the stationary shock as the strength of the shock tends to 0. The paper of Liu and Yu [12] is closest to our results. Their estimates, unlike ours, hold on the whole line. They also prove existence of moving shocks while we consider only stationary ones. However, their uniform dissipativity assumption is much stronger than our "characteristic-component" dissipativity assumption in (2.16) below. It would be a great challenge to extend the results of [12] to the case of fourth order dissipation and to the boundary value problems.

Let us conclude this section with a practical remark. The most popular numerical schemes for shock wave computations produce monotone shock profiles. As such, they exclude high order approximations unless the scheme is modified outside the shock layer. Our result indicates that the high order schemes, although producing one overshoot of about 20% in the shock layer, converge exponentially fast to the stationary solution. Since the special oscillations have a canonical form, they could be filtered out at the end of computation without sacrificing the overall high accuracy.

2. The difference approximation. The system of conservation laws (1.1) is approximated by a difference scheme

$$G\Big(\big\{E^j u(x,t)\big\}\Big) = 0, \qquad j = (j_1, j_2) \in J \subset \mathbb{Z}^2, \qquad j_2 \le 0. \tag{2.1}$$

Here J is a finite set; $G = G(\{u_j\})$ is a smooth (at least C^3) vector function of vector variables $u_j \in R^n$, $j \in J$; and $E^j = E_x^{j_1} E_t^{j_2}$ is a shift operator

$$E^j u(x,t) = u(x + j_1 h, t + j_2 h). \tag{2.2}$$

We consider $u(x,t)$ in (2.1) as a grid-function defined on a uniform grid with a mesh size h,

$$D_h = I_h \times (R_+)_h, \tag{2.3}$$

in the half-strip $[-\ell, \ell] \times [0, \infty)$. Since the step size h does not enter the problem explicitly, we will assume that $h = 1$ so that 2ℓ is equal to the number of grid points in I_h. The scheme G should be *conservative*, i.e.,

$$G\Big(\big\{E^j u(x,t)\big\}\Big) = (E_x - I) G_1\Big(\big\{E^j u(x,t)\big\}\Big) + (E_t - I) G_2\Big(\big\{E^j u(x,t)\big\}\Big) \tag{2.4}$$

with multi-index j in G_1, G_2 varying over corresponding subsets of J. We assume that G is *consistent* with (1.1), i.e.,

$$G_1\Big(\{u\}\Big) = f(u), \qquad G_2\Big(\{u\}\Big) = u, \tag{2.5}$$

where $\{u\}$ stands for the set $\{u_j\}$ of vectors $u_j = u$. Since G_2 approximates u, it is natural to assume that

$$G_2\Big(\{u_j\}\Big) \text{ is a linear function.} \tag{2.6}$$

(This assumption is not essential but somewhat simplifies the proof.)

Since the domain is bounded, there are boundary conditions

$$S_{_L}\Big(\big\{E^j u(-\ell, t)\big\}, u_{_L}\Big) = 0, \qquad S_{_R}\Big(\big\{E^j u(\ell, t)\big\}, u_{_R}\Big) = 0, \tag{2.7}$$

where $S_{_L}$ and $S_{_R}$ depend smoothly on its arguments and j belongs to a finite set. The range of $j = (j_1, j_2)$ in $S_{_L}$ is such that $j_1 \ge 0$, $j_2 \le 0$, while in $S_{_R}$, $j_1 \le 0$, $j_2 \le 0$. The boundary conditions should be *consistent* with a constant solution, i.e.,

$$S_{_L}\Big(\{u\}, u\Big) \equiv S_{_R}\Big(\{u\}, u\Big) \equiv 0. \tag{2.8}$$

There are also initial conditions

$$u(x,t) = u_{in}(x,t), \qquad x = j_1 \in [-\ell, \ell], \qquad t = j_2 \in [0, \Delta j_2 - 1], \tag{2.9}$$

where $-\Delta j_2$ is the minimal value of the index j_2 in the functions G, $S_{_L}$, and $S_{_R}$. Note that we can always add to G, $S_{_L}$, $S_{_R}$ dummy variables u_j so that they have a common minimal j_2.

We consider a family of initial boundary value problems (IBVPs) that depend on the parameter $\varepsilon \sim (\lambda_1(u_{_L}))^{1/k}$ with $u_{_L}$, $u_{_R}$ satisfying (1.3) and (1.7) so that

$u_{_L}(\varepsilon = 0) = u_{_R}(\varepsilon = 0) = u_0$ and ℓ lies in the bounds of (1.11) or (1.12). More precisely,

$$u_{_L} = u_0 + \mu e_1, \quad u_{_R} = u_0 - \mu e_1 + O(\mu^2), \quad \mu = b\varepsilon^k / \Big(d\lambda_1[u_0] \cdot e_1 \Big), \tag{2.10}$$

where b is the (positive) dissipation coefficient defined in (2.16) below and e_1 is the unit vector as in (1.6).

Equation (2.1) is defined for (x,t) in a subdomain $\mathring{D}_h \subset D_h$ such that $(x+j_1, t+j_2)$ lie in D_h for all $j \in J$. Denote by $x_{-\ell}$, $x_\ell - 1$ the left and right end points of $\mathring{D}_h$, and sum the equation in (2.1) for $x \in [x_{-\ell}, x_\ell - 1]$. We obtain the global conservation law

$$(E_t - I) \sum G_2\Big(\big\{ E^j u(x,t) \big\} \Big) = G_1\Big(\big\{ E^j u(x_{-\ell}, t) \big\} \Big) - G_1\Big(\big\{ E^j u(x_\ell, t) \big\} \Big). \tag{2.11}$$

It would be natural to assume that

$$G_1\Big(\big\{ E^j u(x_{\pm\ell}) \big\} \Big) - f(u_{_{R,L}}) = 0; \tag{2.12}$$

i.e., (2.12) is a part of the boundary conditions in (2.7). More generally, we will assume that

$$P\Big(G_1\Big(\big\{ E^j u(x_{\pm\ell}, t) \big\} \Big) - f(u_{_{R,L}}) \Big) = 0, \tag{2.13}$$

where $P = P(\mu)\colon R^n \to R^n$ is a projector which depends smoothly on μ such that $P(0)$ is the standard projection on the first n_1 components of u. As a result, the solution of IBVPs (2.1), (2.7), (2.9) satisfies

$$P \sum G_2\Big(\big\{ E^j u(x,t) \big\} \Big) = P \sum G_2\Big(\{ E^j u_{in} \} \Big). \tag{2.14}$$

Let us linearize the above IBVP at the constant state $u = u_0$ and $\mu = 0$ with arbitrary ℓ. The resulting constant coefficient difference operators will be denoted by $dG[u_0](E_x, E_t)$, $dS[u_0](E_x, E_t)$, or simply $dG[u_0]$, $dS[u_0]$. The Laplace–Fourier symbol of $dG[u_0]$ is defined as $dG[u_0](e^{i\xi}, e^s)$. As in [7], we impose the following assumptions.

Dissipativity assumption. The symbol $dG[u](e^{i\xi}, e^s)$ is nonsingular for all pairs (ξ, s) with $\operatorname{Re} s \geq 0$, but $s = 0$ and $\xi = 0 \bmod 2\pi$, where u is any vector in a neighborhood of u_0.

Remark 1. Actually, we need the above dissipativity only at $u = u_0$, and the usual stability at u close to u_0.

Accuracy assumption. The difference operator $dG[u_0]$, when restricted to the x variable, is exactly a kth order accurate approximation of $df[u_0]\frac{\partial}{\partial x}$ in the direction $e_1 = (1, 0, \dots, 0)^{^T}$. More precisely,

$$dG[u_0](e^{i\xi}, 1)e_1 = i\xi df[u_0]e_1 + O(\xi^{k+1}) = O(\xi^{k+1}), \tag{2.15}$$

where the first component $O_1(\xi^{k+1})$ of $O(\xi^{k+1})$ satisfies

$$O_1(\xi^{k+1}) = b\xi^{k+1} + O(\xi^{k+2}), \qquad b \neq 0. \tag{2.16}$$

It is easy to show (see Proposition 2.1 in [7]) that the dissipativity assumption then implies $b > 0$. Note that the scheme need not be kth order accurate in t.

Obviously, one should assume that the linear problem

$$dG[u_0]u = F, \qquad dS_{_L}[u_0]u = g_{_L}, \qquad dS_{_R}[u_0]u = g_{_R} \tag{2.17}$$

is solvable in time. Namely, let $dG^{(0)}$, $dS_{_L}^{(0)}$, $dS_{_R}^{(0)}$ be the upper parts of dG, $dS_{_L}$, $dS_{_R}$ in t. We should then consider only the half-line problems

$$dG^{(0)}[u_0]u = F, \quad x \geq -\ell; \qquad dS_{_L}^{(0)}[u_0]u(-\ell) = g \tag{2.18}$$

and

$$dG^{(0)}[u_0]u = F, \quad x \leq \ell; \qquad dS_{_R}^{(0)}[u_0]u(\ell) = g. \tag{2.19}$$

Solvability assumption. For any F and g, problems (2.18) and (2.19) have a unique solution u satisfying the estimate

$$\|u\|_2^2 \leq K\Big(\|F\|_2^2 + |g|^2\Big), \tag{2.20}$$

where $\|\cdot\|_2$ is the ℓ_2 norm and K is independent of F and g. Theorem 1.1 in [8] states an equivalent algebraic (Lopatinsky) condition on $dG^{(0)}$, $dS^{(0)}$. If ℓ is large enough, this implies the Lopatinsky condition for the combined (2.18), (2.19) problem in $[-\ell, \ell]$. The last, in turn, implies estimate (2.20) in norm $\|\cdot\|_p$, $p \geq 1$, for the combined problem. Then, by the inverse function theorem, the nonlinear IBVP (2.1), (2.7), (2.9) is solvable for u in a small neighborhood of u_0.

Finally, let us state the stability condition. Apply to (2.17) the Laplace–Fourier transform in t; i.e., consider

$$dG[u_0](E_x, e^s)u = F, \quad dS_{_L}[u_0](E_x, e^s) = g_{_L}, \quad dS_{_R}[u_0](E_x, e^s)u = g_{_R}. \tag{2.21}$$

The weak Lopatinsky condition. For $\operatorname{Re} s \geq 0$, $s \neq 0$, the corresponding half-line problems have no nontrivial solutions in ℓ_2.

As in the solvability case, for $\operatorname{Re} s \geq 0$ and $|s| > \delta$ we obtain for problem (2.21) a uniform estimate (2.20). (Actually, the norm $\|\cdot\|_2$ could be replaced by any norm $\|\cdot\|_p$, $p \geq 1$.) The crucial point, of course, is $s = 0$. Since $\lambda_1(u_0) = 0$, the boundaries $x = \pm\ell$ are characteristic. We will see in the next section that, for $s = s'\varepsilon^{k+1}$, the homogeneous solution of the linearized shock problem in proper coordinates consists of three parts: y_1, $\{y_i\}$, $2 \leq i \leq n$, and $y_{_{I,II}}$. The first part y_1 is a discrete approximation to a solution of the linearized scalar shock equation

$$s'y_1 + \partial_\tau(y_{sh}y_1) + (-1)^{\frac{k+1}{2}}\partial_\tau^{k+1}y_1 = 0, \tag{2.22}$$

where y_{sh} is the solution of the problem

$$(-1)^{\frac{k+1}{2}}\partial_\tau^k y_{sh} = \tfrac{1}{2}(1 - y_{sh}^2), \qquad y_{sh}(-\infty) = 1, \quad y_{sh}(\infty) = -1, \tag{2.23}$$

and $\tau = \varepsilon x$. The second, noncharacteristic part approximates the solution of the equation

$$sy_i + \lambda_i(u_0)\partial_x y_i = 0, \qquad 2 \leq i \leq n, \tag{2.24}$$

where $\lambda_i(u_0)$ are the nonzero eigenvalues of $df[u_0]$. The third, boundary layer part corresponds to the exponentially decreasing ($y_{_I}$) and increasing ($y_{_{II}}$) solutions of the equation

$$dG_1[u_0](E_x, 1)u = 0. \tag{2.25}$$

The variables y_i, $1 \le i \le n$, modulo $O(s)$ terms affect only u_i components of u, but $y_{I,II}$, due to a possible coupling in the dissipative term, may affect all components of u. The boundary condition is designed so that the problem for $y_- = (\{y_i\}, i \ge 2; y_{I,II})$ almost decouples from the one for y_1. Toward that end we assume that the boundary operators dS_L and dS_R split into three parts,

$$\begin{aligned} &\text{(a)} \quad P dG_1 u = 0, \\ &\text{(b)} \quad dS_1 u = 0, \\ &\text{(c)} \quad dS_2 u = 0. \end{aligned} \tag{2.26}$$

Represent the projector $P(\mu)$ as an orthogonal sum

$$P(\mu) = P_1(\mu) \oplus P_-(\mu) \tag{2.27}$$

such that $P_1(0)$ is the standard projection on the unit vector e_1. The equation $P_1 dG_1 u = 0$ in (2.26)(a) is used to integrate (2.22) with respect to τ. The remaining components of (2.26)(a) are used to specify the hyperbolic variables $y_2, \dots, y_n$ at the inflow boundaries, which are

$$x = -\ell \quad \text{if} \quad \lambda_i(u_0) > 0 \qquad \text{and} \qquad x = \ell \quad \text{if} \quad \lambda_i(u_0) < 0. \tag{2.28}$$

There are $n_1 - 1$ unused conditions in (2.26)(a) which are replaced by the conservation laws

$$P_- \sum_x dG_2[u_0](E_x, E_t) u = 0. \tag{2.29}$$

The operator $dS_1[u_0]$ has exactly $\frac{k-1}{2}$ components at each end $x = \pm\ell$ and supplies the boundary conditions for (2.22). Denote by $dS_{1j}^{(1)}[u_0]$ the entry in the first column and jth row of $dS_1[u_0]$. We assume that for $1 \le j \le \frac{k-1}{2}$,

$$dS_{1j}^{(1)}[u_0] = c_j (E_x - I)^{d_j} + \text{ higher powers of } (E_x - I), \tag{2.30}$$

where

$$\begin{aligned} &0 \le d_j \le k-1 \quad \text{for} \quad n_1 = 1 \quad \text{and} \\ &0 \le d_j \le k-2 \quad \text{for} \quad 1 < n_1 \le n \end{aligned} \tag{2.31}$$

are all distinct and $c_j \ne 0$. The boundary condition (2.26)(b) thus approximates for small ε the conditions $\partial_\tau^{d_j} y_1 = 0$ at $\tau = -\varepsilon\ell$ or $\tau = \varepsilon\ell$. The resulting boundary value problem for (2.22) should satisfy the one-sided Lopatinsky conditions, namely, the following.

The scalar shock stability condition. For complex s with $\operatorname{Re} s \ge 0$ and real $\delta \ge 0$ such that $|s| + \delta \ne 0$, let $\lambda_1, \lambda_2, \dots, \lambda_{\frac{k+1}{2}}$ be the roots of the equation

$$s \pm \delta\lambda + (-1)^{\frac{k+1}{2}} \lambda^{k+1} = 0 \tag{2.32}$$

with corresponding $\pm \operatorname{Re} \lambda \le 0$. Then for all such s, the determinant

$$\det(\lambda_i^{d_j+1}), \qquad 1 \le i \le \frac{k+1}{2}, \quad 0 \le j \le \frac{k-1}{2}, \quad d_0 \stackrel{df}{=} -1 \tag{2.33}$$

is nonzero. (In the case $s = 0$, $\lambda_1 = 0$ and $\lambda_1^{d_0+1} \stackrel{df}{=} 1$.)

This condition is obviously satisfied if $d_j = j - 1$. If λ_i is a multiple root, then besides $\lambda_i^{d_j+1}$ we have also the rows $(d/d\lambda)^m(\lambda^{d_j+1})|_{\lambda=\lambda_i}$, where $1 \le m < r_j$, and r_j is the multiplicity of the root λ_i. Note that the exponents d_j at $x = -\ell$ and $x = \ell$ need not be the same. Due to a scaling, the parameter δ, if nonzero, could be chosen to be $\delta = 1$. Note also that for $k = 1$ the set of boundary conditions (2.26)(b) is empty.

The boundary conditions (2.26)(c) and the conservation laws (2.29) are used to define the boundary layer $y_{I,II}$ and the remaining hyperbolic variables $y_{n_1+1}, \dots, y_n$. We wish the contribution of y_1 to y_- for $s = s'\varepsilon^{k+1}$ to be of order $O(\varepsilon^k)$. Therefore, we assume that the first column $dS_2^{(1)}$ of dS_2 satisfies

$$dS_2^{(1)}[u_0](E_x, 1) \text{ is divisible by } (E_x - 1)^k \tag{2.34}$$

and, similarly,

$$P_-(\mu = 0)dG_2^{(1)}[u_0](E_x, 1) \text{ is divisible by } (E_x - 1)^{k+1}\ . \tag{2.35}$$

The above two conditions (2.34), (2.35) will be called the *decoupling conditions* since they imply that the Lopatinsky condition for the whole solution y decouples into one for y_1 as in (2.22) and one for the y_- variables.

Now consider the homogeneous problem $dG[u_0](E_x, e^s)u = 0$ for small $|s|$ with $\operatorname{Re} s \ge 0$. Denote the solutions that correspond to the noncharacteristic hyperbolic components y_i, $2 \le i \le n$, by φ_i and the ones that correspond to $y_{I,II}$ by $\varphi_I(x)$, $\varphi_{II}(x)$. Thus, if we disregard the contribution of y_1, the general solution u is a linear combination

$$u(x) = \sum_{i=2}^{n} \varphi_i(x)c_i + \varphi_I(x)c_I + \varphi_{II}(x)c_{II}. \tag{2.36}$$

If $\lambda_i(u_0) > 0$, then

$$\begin{aligned} \varphi_i(x)c_i &= X_i(s)\exp\Big(\mu_i(s)(x+\ell)\Big)c_i = X_i(x)y_i(x), \\ X_i(s) &= e_i + O(s), \quad e_i - \text{unit vector}. \end{aligned} \tag{2.37}$$

Here $\mu_i(s) = \frac{-s}{\lambda_i(u_0)+O(s^2)}$ and, by the dissipativity assumption, $\operatorname{Re}\mu_i(s) < 0$. Since s could be arbitrarily small and ℓ arbitrarily large, the factor $\rho_i = \exp(2\ell\mu_i(s))$ could be any complex number with the only restriction $|\rho_i| < 1$. For $\varphi_I c_I$ we have

$$\varphi_I(x)c_I = X_I(s)\Big(M_I(s)\Big)^{x+\ell}c_I = X_I(s)y_I(x), \tag{2.38}$$

where $\|M_I\| < 1$. Similar relations hold for $\varphi_i c_i$ in the case $\lambda_i(u_0) < 0$ and for $\varphi_{II}c_{II}$. One can assume that $X_i(s)$, $X_{I,II}(s)$ depend analytically on s and that the columns φ_i, $\varphi_{I,II}$ are independent as functions of x. Note that $\varphi_I(\ell)$ and $\varphi_{II}(-\ell)$ are exponentially small so that their contribution to the boundary condition will be (formally) neglected. On the other hand, the solutions $\varphi_i(x)$ couple together the boundary conditions at $x = -\ell$ and $x = \ell$. Let us split the hyperbolic variables y_i, $2 \le i \le n$, into four groups $y^{(j_1,j_2)}$, $j_1 = 1, 2$, $j_2 = 1, 2$, where $j_1 = 1$ if $i \le n_1$, and 2 if $i > n_1$, while $j_2 = 1$ if $\lambda_i(u_0) > 0$, and 2 if $\lambda_i(u_0) < 0$. Substitute the solution u in

(2.36) into the boundary conditions $P_- dG_1[u_0]u = 0$ in (2.26)(a). In terms of the y variables, we obtain

$$\begin{aligned}
&\text{(a)} \quad \Big(\lambda^{(1,1)} + O(s)\Big) y^{(1,1)}(-\ell) = sB^{(1)}\Big(y(-\ell); s\Big),\\
&\text{(b)} \quad \Big(\lambda^{(1,2)} + O(s)\Big) y^{(1,2)}(\ell) = sB^{(2)}\Big(y(\ell); s\Big),\\
&\text{(c)} \quad B^{(1)}\Big(y(\ell); s\Big) - \rho^{(1,1)} B^{(1)}\Big(y(-\ell); s\Big) = 0,\\
&\text{(d)} \quad B^{(2)}\Big(y(-\ell); s\Big) - \rho^{(1,2)} B^{(2)}\Big(y(\ell); s\Big) = 0.
\end{aligned} \tag{2.39}$$

Here $\rho^{(1,1)} = \operatorname{diag}(\rho_i)$, $\lambda^{(1,1)} = \operatorname{diag}(\lambda_i(u_0))$, where ρ_i, λ_i correspond to the $(1,1)$ group and similarly for the group $(1,2)$. The functions $B^{(1)}$, $B^{(2)}$ depend linearly on $y_- = (y_j, 2 \le j \le n;\ y_I, y_{II})$ and analytically on s. As $s \to 0$, (2.39) becomes

$$\begin{aligned}
&\text{(a)} \quad y^{(1,1)}(-\ell) = 0,\\
&\text{(b)} \quad y^{(1,2)}(\ell) = 0,\\
&\text{(c)} \quad B^{(1)}\Big(y(\ell); 0\Big) - \rho^{(1,1)} B^{(1)}\Big(y(-\ell); 0\Big) = 0,\\
&\text{(d)} \quad B^{(2)}\Big(y(-\ell); 0\Big) - \rho^{(1,2)} B^{(2)}\Big(y(\ell); 0\Big) = 0.
\end{aligned} \tag{2.40}$$

In the vectors $y(-\ell)$, $y(\ell)$, we assume

$$\begin{aligned}
&y_{II}(-\ell) = y_I(\ell) = 0, \qquad && y^{(2,1)}(\ell) = \rho^{(2,1)} y^{(2,1)}(-\ell),\\
&&& y^{(2,2)}(-\ell) = \rho^{(2,2)} y^{(2,2)}(\ell).
\end{aligned} \tag{2.41}$$

To find the function B, one should observe that

$$\begin{aligned}
&s^{-1} dG_1[u_0](E_x, e^s)\varphi_I(x) c_I\\
&\quad = -s^{-1}(e^s - 1) dG_2[u_0](M_I, e^s)(M_I - 1)^{-1} X_I(s) y_I(x)\\
&\quad = -dG_2[u_0](M_I, 1)(M_I - 1)^{-1} X_I(s) y_I(x) + O(s) y_I(x),
\end{aligned} \tag{2.42}$$

where the matrix M_I has eigenvalues inside the unit circle.

A similar formula holds for $\varphi_{II}(x)$. For φ_i we have

$$\begin{aligned}
&s^{-1} dG_1[u_0](E_x, e^s)\varphi_i(x) c_i\\
&\quad = -\Big(1 + O(s)\Big) dG_2[u_0](e^{\mu_i(s)}, e^s)\mu_i^{-1}(s) X_i(s) y_i(x).
\end{aligned} \tag{2.43}$$

The matrices $B^{(1)}$ and $B^{(2)}$ are obtained by projecting the r.h.s.'s of (2.42), (2.43) onto the components of u corresponding to the groups $y^{(1,1)}$ and $y^{(1,2)}$. Notice that the r.h.s. of (2.42) is the summation formula for $\sum dG_2[u_0]\varphi_I(x)c_I$ and similarly for (2.43). Thus (2.39)(a)–(d) are equivalent to the equations obtained by substitution of u in (2.36) into $(n_1 - 1)$ equations $P_- dG_1(u) = 0$ and $(n_1 - 1)$ equations in (2.29). By consistency, $dG_2[u_0](E_x, e^s)X_i(s) = e_i + O(s)$. If $i > n_1$, then $Pe_i = 0$ so that indeed B depends analytically on s. In a particular case when the symbols $dG_j[u_0](\kappa, e^s)$, $j = 1, 2$, *are diagonal* modulo quadratic terms in $(\kappa - 1)$ and s, the contribution of φ_i to B is $O(s)$ so that y_i, $2 \le i \le n$, *do not enter* (2.40)(c),(d). For example, if the scheme G is at least second order accurate, one can rearrange G_1 and G_2 so that the

above holds. Another trivial case when y_i do not enter (2.40)(c),(d) is $n_1 = n$. The remaining boundary conditions (2.26)(c) at $s = 0$,

$$dS_2[u_0](E_x, 1)u = 0, \tag{2.44}$$

involve, generally speaking, all components of $y_-(\pm\ell)$.

The generalized stability condition. The system of equations (2.40), (2.41), (2.44) is nonsingular for all complex ρ_i, $n_1 < i \le n$, with $|\rho_i| \le 1$.

Usually the numerical boundary conditions consist of the physical ones and artificial ones. The artificial boundary conditions are extrapolatory and vanish on constant solutions. The physical ones represent some rules of reflection, i.e., express the ingoing characteristic components in terms of the outgoing ones. Thus, let us assume that the boundary conditions (2.44) split into

$$\begin{aligned} &\text{(a)} \quad dS^{(1)}_{2,\pm\ell}(E_x, 1)u = 0, \\ &\text{(b)} \quad dS^{(2)}_{2,\pm\ell}(E_x, 1)u = 0, \end{aligned} \tag{2.45}$$

such that

$$dS^{(2)}_{2,\pm\ell}(1, 1)(I - P) = 0, \tag{2.46}$$

while $dS^{(1)}_{2,\pm\ell}(1, 1)u = 0$ provide a full set of $n - n_1$ equations for $y^{(2,1)}(-\ell)$, $y^{(2,2)}(\ell)$ correspondingly. As above, we assume also that $y^{(2,1)}$, $y^{(2,2)}$ do not enter (2.40)(c),(d). Thus (2.40)(c),(d) and (2.45)(b) provide a full set of boundary conditions for $y_I(-\ell)$, $y_{II}(\ell)$. The generalized stability condition then implies that $y_I(-\ell), y_{II}(\ell) = 0$. In other words, we obtain the following condition.

The stationary boundary layer condition. The equation $dG_1[u_0](E_x, 1)u = 0$ has no boundary layer solutions u which satisfy (2.45)(b) and the conservation laws

$$P_- \sum_x dG_2[u_0](E_x, 1)u = 0.$$

By (2.45)(a), the vectors $y^{(2,1)}(-\ell)$, $y^{(2,2)}(\ell)$ could be expressed as

$$\begin{aligned} &\text{(a)} \quad y^{(2,1)}(-\ell) = R^{(1)} y^{(2,2)}(-\ell), \\ &\text{(b)} \quad y^{(2,2)}(\ell) = R^{(2)} y^{(2,1)}(\ell). \end{aligned} \tag{2.47}$$

The generalized stability condition now implies that

$$\det(R^{(1)}\rho^{(2,2)}R^{(2)}\rho^{(2,1)} - I) \ne 0. \tag{2.48}$$

The last clearly holds if

$$\|R^{(1)}\| \cdot \|R^{(2)}\| < 1; \tag{2.49}$$

i.e., the reflection boundary conditions in (2.47) are dissipative. It is well known that if the boundary conditions are nondissipative, a system of hyperbolic differential equations may have exponentially growing solutions. Clearly, (2.49) and the stationary boundary layer condition imply the generalized stability condition, provided

$$P_- dG_2[u_0](1, 1)(I - P) = 0 \tag{2.50}$$

and (2.46) hold. Thus, for a wide class of boundary conditions we obtain $\{\rho_i\}$ independent criteria of stability. In particular, if the scheme $dG[u_0]$ is diagonal and if the boundary conditions do not mix different components of u, then the stability criteria become very simple. Indeed, the problem becomes scalar. Condition (2.48) is absent. Since the conservation law $\sum dG_2[u_0]u = 0$ is scalar, either $dS^{(2)}_{2,-\ell}(E_x, 1)u = 0$ uniquely define $y_{I}(-\ell)$ or $dS^{(2)}_{2,\ell}(E_x, 1)u = 0$ uniquely define $y_{II}(\ell)$. In any case the boundary conditions for $y_{I}(-\ell)$, $y_{II}(\ell)$ are uncoupled. Then one can use for $S^{(2)}_2$ boundary conditions which satisfy scheme-independent stability criteria. For s away from zero the eigenvalues of $dG[u_0](E_x, e^s)$ are away from the unit circle. The Lopatinsky condition for the half-line problems in (2.21) again holds for these boundary conditions.

Remark 2. Notice that the global conservation laws (2.14), though formally following from (2.13), actually fail for large time due to the round-off errors. Therefore, at the outflow boundary, the ith component of (2.12) for $2 \le i \le n_1$ should be replaced by the ith component of (2.14). (The outflow boundary is the opposite of the inflow one in (2.28).) For $i = 1$ one can do the replacement at either boundary.

Examples. Let us approximate the derivative $f(u)_x$ in (1.1) by

$$F\Big(\{E^\alpha u\}\Big) = \frac{1}{\Delta x}\Big(D_x^{(k+1)} f(u) + (-1)^{k_1} K (E_x^{1/2} - E_x^{-1/2})^{k+1} u\Big), \qquad k_1 = \frac{k+1}{2}, \tag{2.51}$$

where $(\Delta x)^{-1} D_x^{(k+1)}$ is a $k+1$ order central difference approximation of the operator ∂_x and $K = O^*(1)$ is a positive constant. For example,

$$D_x^{(k+1)} = \sum_{j=1}^{k_1} c_j (E_x^j - E_x^{-j}), \qquad c_j = \frac{(-1)^{j-1}(k_1!)^2}{j(k_1 - j)!(k_1 + j)!}, \tag{2.52}$$

has a maximal accuracy for the $k+2$ point lattice. Since $k+1$ is even, the dissipative term $(-1)^{k_1}(E_x^{1/2} - E_x^{-1/2})^{k+1}$ contains only integer powers of E_x. Now we replace (1.1) by the equation

$$u_t + F(u) = 0 \qquad \Big(F(u) \text{ is shorthand for } F\big(\{E^\alpha u\}\big)\Big) \tag{2.53}$$

in the space of grid-function $u(x)$, $x \in I_h$, and approximate it by an mth order ODE solver with $m \ge k$. For example, one can use the mth order Adams–Bashforth multistep method

$$(I - E_t^{-1}) + \Delta t \sum_{i=1}^{m} d_i E_t^{-i} F(u) = 0. \tag{2.54}$$

Clearly, $F(u) = (E_x - I)F_1(u)$, and hence the scheme is in conservation form (2.4). Let $d\widehat{F}[u_0]$ be the Fourier symbol of the differential of F at $[u_0]$. The eigenvalues λ of $\Delta t d\widehat{F}[u_0]$ are

$$\lambda = \frac{\Delta t}{\Delta x}\left(\lambda_i(u_0)\sqrt{-1}\sum_{j=1}^{k_1} 2c_j \sin j\xi + K(2\sin\xi/2)^{k+1}\right). \tag{2.55}$$

For the stability of the Cauchy problem, one needs that the roots z of the characteristic equation

$$1 - z^{-1} + \sum d_i z^{-1} \lambda = 0 \tag{2.56}$$

satisfy $|z| \le 1$. In other words, $-\lambda$ should belong to the domain Ω of absolute stability of the multistep method. Since the method is of order m, a point $-\lambda$ near 0 with $\operatorname{Re}\lambda \ge K_1 |\operatorname{Im}\lambda|^{m+1}$ belongs to Ω. Thus, if $m > k+1$, then $-\lambda$ in (2.55) for small ξ always belongs to Ω. If $m = k+1$, then it might be necessary to increase K or to decrease $\frac{\Delta t}{\Delta x}$. For nonsmall values of ξ the condition $-\lambda \in \Omega$ restricts from above the values of $|\lambda_i(u_0)\frac{\Delta t}{\Delta x}|$ and $K\frac{\Delta t}{\Delta x}$. The scheme clearly satisfies the accuracy and dissipativity assumptions. The boundary conditions could be set as follows: The zero flux conditions (2.12),

$$P\Big(F_1\Big(u(x_{\pm\ell}, t)\Big) - f(u_{L,R})\Big) = 0, \qquad x_{-\ell} = -\ell + k_1, \qquad x_\ell = \ell - k_1, \tag{2.57}$$

are used to compute $Pu(\pm\ell, t)$. Hence K should be such that

$$K \ne |c_{k_1} \lambda_i(u_0)|, \qquad 1 \le i \le n_1. \tag{2.58}$$

For $1 \le i \le n_1$ we need $k_1 - 1$ more conditions to compute $u_i(x,t)$, $-\ell + 1 \le x < -\ell + k_1$. These conditions are

$$u_i(-\ell+1, t) = u_{L,i}, \quad (E_x - I)^j u_i(-\ell+1, t) = 0, \quad 1 \le j \le k_1 - 2. \tag{2.59}$$

If $i > n_1$ and $\lambda_i(u_0) > 0$, i.e., $x = -\ell$ is the inflow boundary, then the conditions are

$$u_i(-\ell, t) = u_{L,i}, \qquad (E_x - I)^j u_i(-\ell, t) = 0, \qquad 1 \le j \le k_1 - 1, \tag{2.60}$$

and in the outflow case,

$$(E_x - I)^j u_i(-\ell, t) = 0, \qquad 1 \le j \le k_1, \tag{2.61}$$

or, instead,

$$(E_x - 1)^d E_x^j u_i(-\ell, t) = 0, \qquad 0 \le j \le k_1 - 1, \quad d \ge 1 \text{ an integer}. \tag{2.62}$$

Similar conditions are imposed at the right boundary. Note that in (2.62) we used a fixed type of extrapolation translated along the boundary points. Such boundary conditions were suggested by [9]. Since the scheme is explicit, it is easy to see that the boundary conditions define all the boundary values of $u(x)$; i.e., the scheme is solvable. Let us now check the weak Lopatinsky condition. Since the scheme is diagonal it suffices to consider the case of scalar $f(u) = \lambda_i u$. Due to the stability of the Cauchy problem, the characteristic equation $dG[u_0](\kappa, e^s) = 0$ for $\operatorname{Re} s \ge 0$ has only solutions κ inside or outside the unit circle. Let κ_ν, $1 \le \nu \le N$, be the roots $|\kappa| < 1$ counted with their multiplicities. By solvability, $N = k_1$ is the number of boundary conditions. If all κ_ν are distinct, then the substitution of the general decreasing homogeneous solution $\varphi(x) = \sum c_\nu \kappa_\nu^{(x+\ell)}$ into (2.62) results in a matrix $D = \{(\kappa_\nu - 1)^d \kappa_\nu^j\}$, which is proportional to a Vandermonde matrix and hence is nonsingular. If some κ_ν is a multiple root, then the matrix D will contain the corresponding column and its

derivatives; hence again D is nonsingular. In view of (2.42), the boundary condition (2.57) implies

$$\sum_{\nu} \kappa_\nu^{k_1} (\kappa_\nu - 1)^{-1} c_\nu = 0. \tag{2.63}$$

The factor $\kappa_\nu^{k_1}$ is due to the negative power $E_x^{-k_1}$ in (2.51). The boundary conditions in (2.59) result in a system

$$\sum_{\nu} \kappa_\nu (\kappa_\nu - 1)^j c_\nu = 0, \qquad 0 \le j \le k_1 - 2. \tag{2.64}$$

Since $\kappa^{k_1}(\kappa-1)^{-1} = \kappa(\kappa-1)^{-1} + \sum_{j=0}^{k_1-2} \operatorname{coef} \cdot \kappa(\kappa-1)^j$, the matrix which corresponds to (2.63), (2.64) is equivalent to $D = \{\kappa_\nu(\kappa_\nu - 1)^j\}$, $-1 \le j \le k_1 - 2$, and is nonsingular, provided $\kappa_\nu \ne 0$. The last follows from (2.58). Notice that for our proof it is essential that the boundary conditions (2.59) are applied to $x = -\ell + 1$ and not to $x = -\ell$. Clearly, conditions (2.59) for $i = 1$ are of type (2.30). The scalar shock stability condition in (2.32) is satisfied since $d_j = j - 1$. The decoupling condition in (2.34), (2.35) is satisfied trivially since the corresponding columns are empty. The stationary boundary layer condition was already verified above. Since the scheme is diagonal and (2.46) holds trivially, the generalized stability condition follows. Thus our difference approximation satisfies all the requirements of asymptotic stability of the weak discrete shocks.

Another important method of solution of (2.53) is by an explicit r-stage Runge–Kutta method

$$k_q = \Delta t F\left(u + \sum_{j=1}^{q-1} \alpha_{qj} k_j\right), \quad E_t u = u + \sum_{q=1}^{r} \alpha_{r+1,q} k_q, \quad \alpha_{q,q-1} \ne 0. \tag{2.65}$$

Again, for stability of the Cauchy problem the eigenvalues λ in (2.55) should lie in the domain Ω of absolute stability of the Runge–Kutta method. For example, for a four stage fourth order Runge–Kutta method the domain Ω is

$$\left|\sum_{i=1}^{4} \frac{\lambda^i}{i!}\right| \le 1. \tag{2.66}$$

It is easy to check that Ω includes an imaginary interval around zero (precisely $(-\sqrt{8}i, \sqrt{8}i)$). Hence the Cauchy stability holds for any odd k and any K, provided Δt small enough. In case of a two step second order Runge–Kutta method, Ω is

$$\left|1 + \lambda + \frac{\lambda^2}{2}\right| \le 1. \tag{2.67}$$

The boundary of Ω for small λ satisfies

$$\operatorname{Re}\lambda = -\frac{(\operatorname{Im}\lambda)^4}{4} + O(\operatorname{Im}\lambda)^5; \tag{2.68}$$

hence for $k = 3$ and sufficiently small $\frac{\Delta t}{\Delta x}$ the Cauchy stability holds. For the sake of the global conservation law we impose the boundary conditions

$$PF_1\left(u + \sum_{j=1}^{q-1} \alpha_{q_j} k_j\right)\Bigg|_{x = x_{\pm\ell}} - Pf(u_{L,R}) = 0, \qquad 2 \le q \le r + 1. \tag{2.69}$$

These conditions are used to determine the values of $Pk_q(\pm\ell)$, $1 \le q \le r$. Notice that the equation in (2.69) for $q = r + 1$ implies

$$PF_1(E_t u)|_{x=x_{\pm\ell}} - Pf(u_{L,R}) = 0. \tag{2.70}$$

The boundary conditions (2.59)–(2.62) are replaced correspondingly by

$$P_i(E_x - I)^j k_q(-\ell + 1, t) = 0, \qquad 0 \le j \le k_1 - 2, \tag{2.71}$$

$$P_i(E_x - I)^j k_q(-\ell, t) = 0, \qquad 0 \le j \le k_1 - 1, \tag{2.72}$$

$$P_i(E_x - I)^j k_q(-\ell, t) = 0, \qquad 1 \le j \le k_1, \tag{2.73}$$

and

$$P_i(E_x - I)^d E_x^j k_q(-\ell, t) = 0, \qquad 1 \le j \le k_1 - 1, \tag{2.74}$$

where P_i are the standard projections and $1 \le q \le r$. We assume that $u(t = 0)$ satisfies (2.59)–(2.62). Hence $u(t)$ satisfies (2.57) and (2.59)–(2.62). Notice that for linear F_1 the equations in (2.69) become

$$PF_1(k_q)|_{x=x_{\pm\ell}} = 0, \qquad 1 \le q \le r. \tag{2.75}$$

Thus all k_q satisfy the same homogeneous boundary conditions. We can consider the operator F as acting in the space of grid-functions satisfying (2.71)–(2.75). Denote the extended operator by $\mathcal{F}$. Then

$$E_t u = p(\Delta t \mathcal{F})u, \tag{2.76}$$

where p is an rth degree polynomial and $p(0) = 1$. We can consider (2.76) also on half-lines $x \ge -\ell$ or $x \le \ell$. The weak Lopatinsky condition for (2.76) is satisfied if the operator $\Delta t\mathcal{F}$ restricted to the above half-lines does not have eigenvalues $\lambda \ne 0$, $\lambda \notin \mathrm{Int}(\Omega)$. The analysis now proceeds as in the multistep case. Due to the stability of the Cauchy problem, for λ as above the roots κ of the characteristic equation

$$\det \left| \lambda I - \Delta t dF[u_0](\kappa) \right| = 0 \tag{2.77}$$

do not lie on the unit circle. The substitution of the roots $|\kappa| < 1$ into the boundary conditions (2.71)–(2.75) leads to the Vandermonde-type matrices. In view of (2.58), the boundary conditions (2.69), (2.71)–(2.74) uniquely define the boundary values of k_q and hence the scheme is solvable. According to Remark 2, the boundary conditions (2.57) at the outflow boundaries should be replaced by the global conservation law

$$\sum_{x_{-\ell} \le x \le x_\ell - 1} Pu(x, t) = \text{ const.}, \tag{2.78}$$

and correspondingly, (2.69) should be replaced by

$$\sum_{-x_\ell \le x \le x_\ell - 1} Pk_q(x) = 0. \tag{2.79}$$

We again denote the operator $\mathcal{F}$ with modified boundary conditions by $\mathcal{F}$. Since the scheme is diagonal, the generalized stability condition decouples into corresponding conditions for the half-line problems. Namely, for $\lambda_i(u_0) > 0$ (i.e., the inflow boundary at $x = -\ell$) the problem for the ith component $P_i dG[u_0](E_x, 1)u = 0$, $x \geq -\ell$, with the boundary conditions (2.71)–(2.74) and (2.75) at $x = x_{-\ell}$ should have no bounded solutions u. Since the resulting problem could be written in a polynomial form

$$P_i\Big(p(\Delta t\mathcal{F}) - 1\Big)u = P_i \prod_{j=1}^{r} (\Delta t\mathcal{F} - \mu_j)u = 0, \tag{2.80}$$

it is enough to show that $P_i(\Delta t\mathcal{F} - \mu_j)u = 0$ does not have solutions $u \in \ell_\infty$ on the half-line. Here $\mu_1 = 0$ and the remaining $\mu_j \neq 0$ belong to the boundary of Ω. The case $\mu_j \neq 0$ was already considered above, and the case $\mu_j = 0$ was also considered when we studied the multistep scheme. For the problem on the half-line $x \leq \ell$ the boundary conditions $P_i F_1(k_q) = 0$ are replaced by

$$\sum_{-\infty \leq x \leq x_\ell - 1} P_i k_q(x) = 0. \tag{2.81}$$

Now the resulting problem should have no solutions in ℓ_1 on the half-line. Again we arrive at the equations $P_i(\Delta t\mathcal{F} - \mu_j)u = 0$ which were studied above in the multistep case.

Remark 3. The Runge–Kutta scheme employed here is not exactly of type (2.1) with boundary conditions (2.13). Indeed, if we eliminate the intermediate steps k_q, the resulting scheme could be rewritten as

$$(E_t - I)u + (E_x - I)G_1\Big(\big\{E^j u(x,t)\big\}, x\Big) = 0, \tag{2.82}$$

where the flux G_1 changes its form as a discrete function of x. For inner points $-\ell + k_1 r < x < \ell - k_1 r$ the flux G_1 depends on $E^j u$, $-k_1 r \leq j \leq k_1 r - 1$, while at $x \equiv x_{\pm\ell}$, $G_1 = \Delta t F_1$. One can consider the equations in (2.82) for boundary points (i.e., noninner points) as artificial boundary conditions which are included in (2.45)(b). The remaining boundary conditions (2.57), (2.59)–(2.62) are used to compute $E_t u$ for $-\ell \leq x \leq -\ell + k_1$ and $\ell - k_1 \leq x \leq \ell$. The first condition in (2.60) belongs to (2.45)(a), the conditions in (2.59) for $i = 1$ belong to (2.26)(b), (2.57) stands for (2.26)(a), and the remaining conditions in (2.59)–(2.62) belong to (2.45)(b). Now formula (2.42) does not hold. However, if $u = \varphi_{_I}(x)c_{_I}$ in (2.38) is a solution of the equation

$$\Big(sI + (E_x - I)dG_1[u_0, x]\Big)u = 0 \tag{2.83}$$

for all $-\ell \leq x$, then for $s = 0$, $dG_1[u_0, x]u \equiv 0$, and for small $|s|$, $dG_1[u_0, x]u = O(s)$. Hence the functions $B^{(1)}$, $B^{(2)}$ in (2.39) are well defined. With these remarks in mind, our general theory applies also to the Runge–Kutta scheme.

Finally, let us check the generalized stability condition for the first component $P_1 u$. Since the problem is scalar, it is enough to check the stationary boundary layer condition. The projector P_- vanishes on the first component; hence there is no global conservation law condition. Thus the boundary layers at $x = \pm\ell$ are uncoupled. Hence we can assume that the boundary layer u is defined for $x \geq -\ell$, decays exponentially as $x \to \infty$, and satisfies the equation $(E_x - I)dG_1[u_0, x]u = 0$ for all $x \geq -\ell$ (see (2.83)) but not conditions (2.59) and (2.57) for the first component. If we represent

the polynomial p in (2.76) as $p(z) = 1 + zp_1(z)$, then the solution u satisfies the functional equation

$$\mathcal{F}_0 p_1(\Delta t \mathcal{F}) u = 0, \tag{2.84}$$

where $\mathcal{F}_0$ is given by the difference operator $dF[u_0]$ on the half-line $x \geq -\ell$ without boundary conditions. Since $\lambda_1(u_0) = 0$, $\mathcal{F}_0 \approx (E_x - 1)^{k+1}$. Hence u satisfies the equation $p_1(\Delta t \mathcal{F})u = \prod_{j=2}^{r}(\Delta t \mathcal{F} - \mu_j)u = 0$. It was shown above that this equation has no bounded solutions. The decoupling condition in (2.35) is absent for diagonal schemes. The boundary operator in (2.34) is given by $P_1(E_x - I)dG_1[u_0, x]$, which is divisible by $(E_x - I)^{k+1}$. Thus the asymptotic stability theory applies also to the above Runge–Kutta approximation.

Our final assumption pertains to the continuous problem (2.22).

The continuous stability hypothesis. The problem (2.23) with odd k has a solution y_{sh} such that for $\operatorname{Re} s' \geq 0$, problem (2.22) has no solutions $y_1 \in H^{k+1}(R^1)$ with $\int_{-\infty}^{\infty} y_1 dx = 0$.

The above hypothesis holds trivially for $k = 1$ and has been proved in [5] for $k = 3$. In both cases the solution y_{sh} is unique (up to translation). Now we can state the main results.

THEOREM 2.1 (the existence of stationary shocks). *Let all the above assumptions hold for $s = 0$. Then there exist ε_0 and δ_0 such that for $\varepsilon < \varepsilon_0$ and $\ell > \delta_0^{-1}\varepsilon^{-1}$ problem* (2.1), (2.2) *has an $n_1 \geq 1$ parameter family of stationary solutions u_{st}, where $n_1 = \dim \operatorname{Im} P$. This solution has the form*

$$u_{st} = u_{sh} + \Delta u_{st}, \tag{2.85}$$

where

$$u_{sh} = \tfrac{1}{2}(u_{L} + u_{R}) + \tfrac{1}{2}(u_{L} - u_{R}) y_{sh}\Big(\varepsilon(x - x_0)\Big), \quad \varepsilon = \Big(\lambda_1(u_{L})\Big)^{1/k}, \tag{2.86}$$

$y_{sh}(\tau)$ is a solution of (2.23), *$u_{L,R} = u_0 + O(\varepsilon^k)$ are as in* (1.3), *and*

$$\varepsilon \|\Delta u_{st}\|_1 + \|\Delta u_{st}\|_\infty \leq \delta_0 \varepsilon^k \ . \tag{2.87}$$

For $n_1 = 1$, $k \geq 1$, and for $1 < n_1 < n$, $k \geq 3$, in addition we have

$$\|(E_x - I)\Delta u_{st}\|_1 \leq K\varepsilon^{2k-1} + \delta_0 \varepsilon^k. \tag{2.88}$$

Here $\|\cdot\|_p$ is the usual ℓ_p norm over the interval $[-\ell, \ell]$.

THEOREM 2.2. *Let all the above assumptions hold for all $\operatorname{Re} s \geq 0$. Then there exist ε_0 and δ_0 such that for all $\varepsilon < \varepsilon_0$ and all ℓ as in* (1.12) *for $n_1 = 1$ or $n_1 = n$, the solution of problems* (2.1), (2.7), (2.9) *with initial condition u_{in} in a small neighborhood of u_{st} tends to u_{st} as $t \to \infty$, provided*

$$P \sum G_2\Big(\{E^j u_{st}\}\Big) = P \sum G_2\Big(\{E^j u_{in}\}\Big). \tag{2.89}$$

The last condition uniquely selects the appropriate u_{st} out of the n_1 parameter family of stationary solutions. The precise size of the neighborhood of u_{st} and the rate of the exponential decay of $|u - u_{st}|$ is given in section 6, estimates (6.26), (6.27), (6.39), (6.40).

3. The linearized problem.

3.1. Preliminary transformations and the normal block form. Let u_{st} be a stationary solution as in (2.85)–(2.87), and consider the linearized problem

$$\begin{aligned} &\text{(a)} \quad dG[u_{st}](E_x, E_t)u = F, \\ &\text{(b)} \quad dS[u_{st}](E_x, E_t)u = g = (g_{_L}, g_{_R}, g_{\rm sum}). \end{aligned} \tag{3.1}$$

Here $dG[u_{st}](E_x, E_t)$ is the differential of $G(\{E^j u(x,t)\})$ at $u = u_{st}$ and similarly for dS. The boundary operator dS consists of the differential of $S_{_L}$ and $S_{_R}$ in (2.7) and of the left-hand side (l.h.s.) of (2.14) with respect to $u(x,t)$. The partition of g above corresponds to the above partition of dS. We will study the resolvent problem

$$\begin{aligned} &\text{(a)} \quad dG[u_{st}](E_x, e^s)u = F, \\ &\text{(b)} \quad dS[u_{st}](E_x, e^s)u = g, \end{aligned} \tag{3.2}$$

where s is a complex parameter with $\operatorname{Re} s \ge 0$. Recall that $dS_{_L}$ and $dS_{_R}$ consist of three parts as in (2.26) and, correspondingly, $g_{_L}$, $g_{_R}$ split as

$$g_{_L} = (g_{_{L,0}}, g_{_{L,1}}, g_{_{L,2}}), \qquad g_{_R} = (g_{_{R,0}}, g_{_{R,1}}, g_{_{R,2}}). \tag{3.3}$$

Clearly the system in (3.2) is overdetermined since

$$P \sum_{x=x_{-\ell}}^{x_\ell - 1} F(x) = (1 - e^{-s}) g_{\rm sum} + g_{_{R,0}} - g_{_{L,0}}. \tag{3.4}$$

To make it uniquely solvable one should proceed as in Remark 2.

For $\operatorname{Re} s \ge 0$ and $s \ne 0$ the roots κ of the characteristic equation $\det dG[u](\kappa, e^s) = 0$ (here u is a constant grid-function) are away from the unit circle $|\kappa| = 1$, and problem (3.2) is trivial. Hence we will consider the more difficult case of small $|s|$ (actually, the most difficult is the subcase of $|s| < K\varepsilon^{k+1}$). In order to eliminate the zero eigenvalue $s' = 0$ in (2.22) one should integrate at least the first component of (3.2)(a). We found it convenient to integrate all components of (3.2)(a). Namely, represent

$$dG_2(E_x, e^s) = dG_2(1, e^s) + (E_x - I)\Delta dG_2(E_x, e^s) \tag{3.5}$$

and define $U(x)$ by

$$(E_x - I)U = u, \qquad U(x_{-\ell}) = -\Big(dG_2(1, e^s)\Big)^{-1} \Delta dG_2(E_x, e^s) u(x_{-\ell}) \tag{3.6}$$

so that U satisfies the boundary condition

$$dG_2(E_x, e^s) U(x_{-\ell}) = 0. \tag{3.7}$$

The summation of (3.2)(a) from $x_{-\ell}$ until $x - 1 \le x_\ell - 1$ yields

$$\begin{aligned} &dG[u_{st}(x)](E_x, e^s)U(x) \\ &\quad \stackrel{df}{=} (e^s - 1) dG_2(E_x, e^s)U(x) + dG_1[u_{st}(x)](E_x, e^s)(E_x - I)U(x) \\ &\quad = \sum_{x_{-\ell}}^{x-1} F(\xi) + dG_1[u_{st}(x_{-\ell})](E_x, e^s) u(x_{-\ell}) = F^{(1)}(x). \end{aligned} \tag{3.8}$$

Recall that by (2.13),

$$PdG_1[u_{st}(x_{-\ell})](E_x, e^s)u(x_{-\ell}) = g_{L,0}. \tag{3.9}$$

It will turn out that Δu_{st} in (2.85) is a negligible term, and hence u_{st} in (3.8) and (3.2)(b) will be replaced by u_{sh}. The resulting difference operators dG_1 and dS still depend on u_{sh} at several grid points $x + j_1$. We replace $u_{sh}(x + j_1)$ in dG_1 and dS by $u_{sh}(x)$ so that the coefficients of dG_1 and dS depend only on a point value of $u_{sh}(x)$, and we consider the difference problem

$$\begin{aligned} &\text{(a)} \quad dG(\eta)(E_x, e^s)U(x) \\ &\qquad \stackrel{df}{=} \Big[(e^s - 1)dG_2(E_x, e^s) + dG_1(\eta)(E_x, e^s)(E_x - 1)\Big]U \\ &\qquad = F^{(1)}(x), \qquad x_{-\ell} + 1 \le x \le x_\ell, \\ &\text{(b)} \quad dS(\eta)u = g. \end{aligned} \tag{3.10}$$

Here

$$\eta = u_{sh}(x) - u_0 = \mu e_1 y_{sh}\Big(\varepsilon(x - x_0)\Big) + O(\mu^2) \tag{3.11}$$

(see (2.10)) is a small parameter. The new grid-functions $F^{(1)}$ and g relate to the old ones in (3.8) and (3.2)(b) by

$$F^{(1)}_{\text{new}} = F^{(1)}_{\text{old}} + \Big(O(\Delta u_{st}) + O(\eta')\Big)u, \tag{3.12}$$

$$g_{\text{new}} = g_{\text{old}} + \Big(O(\Delta u_{st}) + O(\eta')\Big)u. \tag{3.13}$$

Remark 4. We do not modify $dG_1\big[u_{st}(x_{-\ell})\big](E_x, e^s)$ in (3.8) and (3.9). Recall that, by (2.87),

$$\|\Delta u_{st}\|_1 \le \delta_0 \varepsilon^{k-1}, \tag{3.14}$$

where δ_0 is a small constant, while

$$\|\eta'\|_1 = |\mu| \, \|\varepsilon \partial_\tau y_{sh}(\tau)\|_1 \le K|\mu| = K\varepsilon^k. \tag{3.15}$$

Without loss of generality, we may assume that the powers of E_x in dG are nonnegative,

$$dG(\eta)(E_x, e^s) = L(\eta, s, E_x) = \sum_{i=0}^{\nu_0} L_i(\eta, s)E_x^i. \tag{3.16}$$

Introduce the grid vector functions

$$\widetilde{U}(x) = \Big(U(x), E_x U(x), \dots, E_x^{\nu_0 - 1}U(x)\Big)^T, \qquad \widetilde{F} = \Big(0, 0, \dots, F^{(1)}\Big)^T \tag{3.17}$$

and difference operators

$$B = \begin{bmatrix} 0 & -I & 0 & & 0 \\ 0 & 0 & -I & & \\ & & & \ddots & \\ & & & & -I \\ L_0 & L_1 & & \cdots & L_{\nu_0 - 1} \end{bmatrix}, \qquad A = \operatorname{diag}(I, I, \dots, L_{\nu_0}). \tag{3.18}$$

Then (3.10) could be rewritten as

$$\widetilde{L}(\eta, s, E_x)\widetilde{U} = \Big(A(\eta, s)E_x + B(\eta, s)\Big)\widetilde{U} = \widetilde{F}. \tag{3.19}$$

The operators $\widetilde{L}$ and dG are related by the equivalence

$$D_2(\eta, s, E_x)\widetilde{L}(\eta, s, E_x)D_1(E_x) = L(\eta, s, E_x) \oplus I_{n(\nu_0-1)}, \tag{3.20}$$

where D_1, D_2 and their inverses are polynomial matrices in E_x, and the first block column of D_1 is $(I, E_x, \dots, E_x^{\nu_0-1})^T$. Note that we do not assume that A or B are nonsingular. The eigenvalues of the pencil of matrices $\widetilde{L}(\eta, s, \kappa) = A\kappa + B$ satisfy

$$\det \widetilde{L}(\eta, s, \kappa) = \det L(\eta, s, \kappa) = 0. \tag{3.21}$$

The infinite eigenvalues or those which are close to infinity are defined by

$$\det \kappa\widetilde{L}(\eta, s, \kappa^{-1}) = \det \kappa^{\nu_0} L(\eta, s, \kappa^{-1}) = 0. \tag{3.22}$$

At $s = \eta = 0$ and κ close to 1, $L(\eta, s, \kappa)$ becomes

$$L(0, 0, \kappa) = (\kappa - 1)\Big(\operatorname{diag}(\lambda_1(u_0), \dots, \lambda_n(u_0)) + O(\kappa - 1)\Big), \qquad \lambda_1(u_0) = 0, \tag{3.23}$$

where by (2.15) the first column of $O(\kappa-1)$ is actually $O(\kappa-1)^k$. Hence the characteristic equation (3.21) at $s = \eta = 0$ has the eigenvalue $\kappa = 1$ of multiplicity $n+k$. By the dissipativity assumption, all other eigenvalues are not on the unit circle. We will split them into two groups: I, for $|\kappa| < 1$, and II, for $|\kappa| > 1$. There are, correspondingly, two projectors

$$Q_{I}(\eta, s) = (2\pi i)^{-1} \oint_{|\kappa|=1-\delta} \Big(\kappa A(\eta, s) + B(\eta, s)\Big)^{-1} A(\eta, s) d\kappa, \tag{3.24}$$

$$Q_{II}(\eta, s) = (2\pi i)^{-1} \oint_{|\kappa|=1-\delta} \Big(A(\eta, s) + \kappa B(\eta, s)\Big)^{-1} B(\eta, s) d\kappa \tag{3.25}$$

on the invariant spaces of the pencil $A\kappa+B$ corresponding to the eigenvalues of groups I and II. Here δ is such that the eigenvalues κ of the first group and the inverses κ^{-1} of the second group lie in the disc $|\kappa| < 1 - \delta$. One can choose basis $X_{I,II}$ in $\operatorname{Im} Q_{I,II}$ which depends analytically on s and η in a neighborhood of zero such that

$$AX_{I}M_{I} + BX_{I} = 0, \qquad AX_{II} + BX_{II}M_{II} = 0, \tag{3.26}$$

where M_{I}, M_{II} also depend analytically on s and

$$\|M_{I,II}\| < 1 - \delta \tag{3.27}$$

(e.g., see pp. 14–17 in [8]). The projector Q_0 associated with the eigenvalue $\kappa = 1$ is

$$Q_0(\eta, s) = (2\pi i)^{-1} \oint_{|\kappa-1|=\delta} \Big(\kappa A(\eta, s) + B(\eta, s)\Big)^{-1} A(\eta, s) d\kappa \tag{3.28}$$

and has an $n+k$ dimensional image. In order to split $\operatorname{Im} Q_0(\eta, s)$ into simple components, we rewrite

$$\begin{aligned} L(\eta, s, \kappa) &= dG_2(\kappa, e^s)\Big((e^s - I)I + (\kappa - 1)dG_2^{-1}(\kappa, e^s)dG_1(\eta)(\kappa, e^s)\Big) \\ &= dG_2(\kappa, e^s)\Big((e^s - 1)I + (\kappa - 1)L'(\eta, s, \kappa)\Big). \end{aligned} \tag{3.29}$$

Recall that, by consistency in (2.5), $dG_2(\kappa, e^s) = I + O(\kappa - 1) + O(s)$, and hence

$$L'(\eta, s, \kappa) = \operatorname{diag}\Big(\lambda_1(u_0), \dots, \lambda_n(u_0)\Big) + O(\kappa - 1) + O(s) + O(\eta). \tag{3.30}$$

Since the eigenvalues $\lambda_i(u_0)$ are distinct, L' could be brought to a diagonal form

$$C^{-1}(\eta, s, \kappa)L'(\eta, s, \kappa)C'(\eta, s, \kappa) = \operatorname{diag}\Big(p_1'(\eta, s, \kappa), \dots, p_n'(\eta, s, \kappa)\Big), \tag{3.31}$$

where C and p_i' depend analytically on the parameters $C(0, 0, 1) = I$ and $p_i'(0, 0, 1) = \lambda_i(u_0)$. Hence, for $i = 2, \dots, n$ the matrix $L(\eta, s, \kappa)$ has eigenvalues

$$\kappa_i = 1 - s\Big(\lambda_i^{-1}(u_0) + O(s) + O(\eta)\Big) \tag{3.32}$$

with the eigenvectors

$$C_i(\eta, s, \kappa_i) = e_i + O(s) + O(\eta), \tag{3.33}$$

where C_i is the ith column of C. The matrix $\widetilde{L}(\eta, s, \kappa)$ has the corresponding eigenvectors

$$X_i(\eta, s) = (C_i, \kappa_i C_i, \dots, \kappa_i^{\nu_0 - 1} C_i)^T = (e_i, \dots, e_i)^T + O(s) + O(\eta). \tag{3.34}$$

By the dissipativity assumption, for $\operatorname{Re} s \geq 0$ and small real η,

$$\begin{aligned} &|\kappa_i(\eta, s)| \leq 1 \quad \text{if} \quad \lambda_i(u_0) > 0, \\ &|\kappa_i(\eta, s)| \geq 1 \quad \text{if} \quad \lambda_i(u_0) < 0. \end{aligned} \tag{3.35}$$

The determinant of $L'(\eta, s, \kappa)$ as follows from (2.15), (2.16) is

$$\begin{aligned} &\det L'(\eta, s, \kappa) = \Big(1 + O(\kappa - 1) + O(s)\Big) \\ &\cdot \left(\prod_{i=2}^{n} \lambda_i(u_0) b_1 (\kappa - 1)^k + O(s) + O_1(\eta) + O\Big((\kappa - 1)^{k+1}\Big) + O(\eta)O(\kappa - 1)\right), \end{aligned} \tag{3.36}$$

where

$$\begin{aligned} O_1 &= \partial_{e_1} f_1(u_0 + \eta) \prod_{i=2}^{n} \lambda_i(u_0) + O(\eta^2) \\ &= d\partial_{e_1} f_1(u_0) \cdot \eta \prod_{i=2}^{n} \lambda_i(u_0) + O(\eta^2) \end{aligned} \tag{3.37}$$

and

$$b_1 = (-1)^{\frac{k+1}{2}} b \qquad \text{(see (2.16))}. \tag{3.38}$$

Here f_1 is the first component of the flux f in (1.1). On the other hand,

$$\begin{aligned} \det L'(\eta, s, \kappa) &= \prod_{i=1}^{n} p_i'(\eta, s, \kappa) \\ &= \left(\prod_{i=2}^{n} \lambda_i(u_0) + O(\kappa - 1) + O(s) + O(\eta) \right) p_1'(\eta, s, \kappa). \end{aligned} \tag{3.39}$$

Hence

$$\begin{aligned} p_1'(\eta, s, \kappa) &= b_1(\kappa - 1)^k + d\partial_{e_1} f_1(u_0) \cdot \eta \\ &\quad + O\Big((\kappa - 1)^{k+1}\Big) + O(s) + O(\eta^2) + O(\eta) \cdot O(\kappa - 1). \end{aligned} \tag{3.40}$$

Thus the remaining $k+1$ roots κ of (3.21) in a neighborhood of $\kappa = 1$, $s, \eta = 0$ satisfy

$$\begin{aligned} p_1(\eta, s, \kappa) &= (e^s - 1) + (\kappa - 1) p_1'(\kappa, s) \\ &= b_1(\kappa - 1)^{k+1} + \Big(d\partial_{e_1} f_1(u_0)\eta \Big)(\kappa - 1) + s \\ &\quad + (\kappa - 1)\Big(O(\kappa - 1)^{k+1} \\ &\qquad + O(\eta^2) + O(\eta) O(\kappa - 1) + O(s) \Big) + O(s^2)\ . \end{aligned} \tag{3.41}$$

By the Weierstrass preparation theorem, $p_1(\eta, s, \kappa)$ is equivalent to a $(k+1)$ degree polynomial in $(\kappa - 1)$,

$$p_1(\eta, s, \kappa) = \widetilde{p}_1(\eta, s, \kappa) q_1(\eta, s, \kappa) = \left(\sum_{i=0}^{k+1} \alpha_i(\eta, s)(\kappa - 1)^i \right) q_1(\eta, s, \kappa), \tag{3.42}$$

where

$$\begin{aligned} \alpha_0(\eta, s) &= s\Big(b_1^{-1} + O(s) + O(\eta) \Big), \\ \alpha_1(\eta, s) &= \partial_{e_1} df_1(u_0) \eta b_1^{-1} + O(s) + O(\eta^2), \\ \alpha_i(\eta, s) &= O(s) + O(\eta), \qquad 2 \le i \le k, \qquad \alpha_{k+1}(\eta, s) = 1, \end{aligned} \tag{3.43}$$

and q_1 is an analytic function of η, s, $(\kappa - 1)$ which does not vanish at $\eta, s = 0$, $\kappa = 1$. We remark that in view of the accuracy assumption (2.15),

$$C_1(\eta, s, \kappa) = e_1 + C_{10}(s)(\kappa - 1)^k + O(\kappa - 1)^{k+1} + O(\eta) + O(s). \tag{3.44}$$

Without loss of generality, we may assume that the first component $C_1^{(1)}(\eta, s, \kappa) \equiv 1$.

Now we can construct the basis $X_1 = (X_{1,1}, \dots, X_{1,k+1})$ for the invariant space corresponding to the $k+1$ roots of $\widetilde{p}_1(\eta, s, \kappa - 1)$. Note that the image of the projector Q_0 is not changed if we replace the integrand $A d\kappa$ in (3.28) by $\varphi(\kappa) d\kappa$, where $\varphi(\kappa)$ is any holomorphic vector function (e.g., see [8, p. 14]). By (3.20),

$$\begin{aligned} &\oint \Big(\kappa A(\eta, s) + B(\eta, s) \Big)^{-1} \varphi(\kappa) d\kappa \\ &\qquad = \oint D_1(\kappa) \Big(L^{-1}(\eta, s, \kappa) \oplus I \Big) D_2(\eta, s, \kappa) \varphi(\kappa) d\kappa \in \operatorname{Im} Q_0. \end{aligned} \tag{3.45}$$

If we replace $D_2\varphi$ by $\binom{\varphi}{0}$, where $\dim\varphi = n$, and again replace $C^{-1}\varphi$ by $\binom{q_1\varphi}{0}$, where φ is a scalar function and q_1 is as in (3.42), we obtain the vector

$$(3.46)\qquad (2\pi i)^{-1}\oint_{|\kappa-1|=\delta} D_1(\kappa)C_1(\eta,s,\kappa)\Big(\widetilde{p}_1(\eta,s,\kappa)\Big)^{-1}\varphi(\kappa)d\kappa \in \operatorname{Im} Q_0.$$

The vectors $X_{1,i}$, $1\le i\le k+1$, are obtained by substituting, correspondingly,

$$(3.47)\qquad \varphi = \varphi_i = \sum_{j=i}^{k+1}\alpha_j(\eta,s)(\kappa-1)^{j-i}.$$

At $s=\eta=0$, by direct integration we obtain

$$(3.48)\qquad \begin{aligned} X_{1,i}(0) = \left(\frac{d}{d\kappa}\right)^{i-1}\Big(e_1,\kappa e_1,\dots,\kappa^{(\nu_0-1)}e_1\Big)^{T}\Big|_{\kappa=1} \\ +\delta_{i,k+1}\Big(C_{10}(0),C_{10}(0),\dots,C_{10}(0)\Big)^{T}. \end{aligned}$$

Application of B to $X_{1,i}(\eta,s)$ yields

$$(3.49)\qquad \begin{aligned} BX_{1,i} &= (2\pi i)^{-1}\oint_{|\kappa-1|=\delta}(\widetilde{L}-A\kappa)D_1\widetilde{p}_1^{-1}\varphi_i d\kappa \\ &= -A(2\pi i)^{-1}\oint_{|\kappa-1|=\delta} D_1C_1\widetilde{p}_1^{-1}(\varphi_i+\varphi_{i-1}-\alpha_{i-1}\varphi_{k+1})d\kappa \\ &= -A(X_{1,i}+X_{1,i-1}-\alpha_{i-1}X_{1,k+1}). \end{aligned}$$

For $i=1$ the term φ_{i-1} becomes $\widetilde{p}_1$, and hence $X_{1,i-1}$ disappears. Then the basis $X_1(\eta,s)$ satisfies

$$(3.50)\qquad AX_1M_1+BX_1=0,\qquad M_1 = I+\begin{bmatrix} 0 & 1 & & & & \\ & 0 & 1 & & & \\ \vdots & & & \ddots & & \\ 0 & & & & 0 & 1 \\ -\alpha_0 & & & & & -\alpha_k \end{bmatrix},$$

where both X_1 and M_1 depend analytically on η and s. If we combine all vectors X_j, $1\le j\le n$, into one basis of $\operatorname{Im} Q_0$,

$$(3.51)\quad X_0=(X_1,X_2,\dots,X_n),\qquad M_0=\oplus_{j=1}^{n}M_j,\qquad M_j=\kappa_j,\qquad j>1,$$

then

$$(3.52)\qquad AX_0M_0+BX_0=0.$$

In view of (3.34), (3.48), the columns of X_0 are linearly independent for small $|\eta|$ and $|s|$. Thus the matrix

$$(3.53)\qquad X=(X_{_0},X_{_I},X_{_{II}})$$

is nonsingular for small $|\eta|$ and $|s|$ and

$$(3.54)\qquad (A\kappa+B)X = T\begin{pmatrix} \kappa I-M_{_0} & 0 & 0 \\ 0 & \kappa I-M_{_I} & 0 \\ 0 & 0 & -\kappa M_{_{II}}+I \end{pmatrix},$$

where

$$T = (AX_0, AX_I, BX_{II}). \tag{3.55}$$

Since $A\kappa + B$ is nonsingular for κ which are not the roots of (3.21), $T = T(\eta, s)$ is nonsingular for small $|\eta|$ and $|s|$.

3.2. The a priori estimate. We now consider (3.19) with boundary conditions (3.10)(b) and (3.7), where u and U are related by (3.6). With X as in (3.53), we define the new variables $Y(x)$ and $y(x)$ by

$$\widetilde{U}(x) = X\Big(\eta(x), s\Big)Y(x), \qquad (E_x - I)Y(x) = y(x) \tag{3.56}$$

so that

$$\begin{aligned}\widetilde{u}(x) &= \Big(u(x), \dots, E_x^{\nu_0 - 1}u(x)\Big)^{T} = (E_x - I)\widetilde{U}(x)\\ &= \Big((E_x - I)X\Big(\eta(x), s\Big)\Big)E_xY(x) + X\Big(\eta(x), s\Big)(E_x - I)Y(x)\\ &= X\Big(\eta(x), s\Big)y(x) + O(\eta')E_xY(x).\end{aligned} \tag{3.57}$$

It is also possible to express Y in terms of y. Indeed, by (3.6) one can express the vector $\widetilde{U}(x_{-\ell})$ in terms of $\widetilde{u}(x_{-\ell})$. Then by (3.56), (3.57),

$$X \cdot Y(x_{-\ell}) = O^*(1)y(x_{-\ell}) + O(\eta')\Big(Y(x_{-\ell}) + y(x_{-\ell})\Big). \tag{3.58}$$

Since X is nonsingular and $O(\eta')$ is small, we obtain

$$Y(x_{-\ell}) = O^*(1)y(x_{-\ell}), \qquad Y(x) = O^*(1)y(x_{-\ell}) + \sum_{\xi = x_{-\ell}}^{x-1} y(\xi). \tag{3.59}$$

In view of (3.54), (3.19) in the Y variables becomes

$$\begin{aligned}&\begin{pmatrix} E_x - M_0 & 0 & 0\\ 0 & E_x - M_I & 0\\ 0 & 0 & -M_{II}E_x + I\end{pmatrix} Y\\ &\qquad = T^{-1}\Big(\widetilde{F} - A\Big((E_x - I)X\Big)E_xY\Big) = H.\end{aligned} \tag{3.60}$$

The vector Y is partitioned into groups Y_0, Y_I, Y_{II} and $Y_0 = (Y_1, \dots, Y_n)$, $Y_1 = (Y_{1,1}, \dots, Y_{1,k+1})$ according to X, and the same applies for vectors y and H. In the case $n_1 = n$ we will treat only system (3.60). In the case $n_1 = 1$ we will consider the equations

$$\begin{aligned}&\text{(a)} \quad (E_x - M_1)Y_1 = H_1,\\ &\text{(b)} \quad (E_x - M_j)y_j = (E_x - I)H_j + O(\eta' s)Y_j = h_j, \qquad 2 \le j \le n,\\ &\text{(c)} \quad (E_x - M_I)y_I = (E_x - I)H_I + O(\eta')Y_I = h_I,\\ &\text{(d)} \quad (-M_{II}E_x + I)y_{II} = (E_x - I)H_{II} + O(\eta')Y_{II} = h_{II}.\end{aligned} \tag{3.61}$$

(The term $O(\eta' s)$ in (3.61)(b) comes from κ_i in (3.32).) Here and elsewhere, $\eta' = \partial_x \eta(x)$, and by (3.15) and (2.86),

$$\varepsilon \|O(\eta')\|_1 + \|O(\eta')\|_\infty \le K\varepsilon^{k+1}. \tag{3.62}$$

The general solution of equation $(E_x - M_j)Y_j = H_j$, $\lambda_j > 0$, could be written as

$$\begin{aligned} &Y_j = C_j \varphi_{\eta,j} + \mathring{Y}_j, \qquad \varphi_{\eta,j} = \prod_{-\ell \le x' \le x-1} M_j\Big(\eta(x'), s\Big), \quad \varphi_{\eta,j}(-\ell) = 1, \\ &\mathring{Y}_j(x+1) = \sum_{x'=-\ell}^{x-1} \prod_{\xi=x'+1}^{x} M_j\Big(\eta(\xi), s\Big) H_j(x') + H_j(x), \end{aligned} \tag{3.63}$$

and we have similar formulas for (3.61)(b),(c):

$$y_j = c_j \varphi_{\eta,j} + \mathring{y}_j, \qquad y_{I} = c_{I} \varphi_{\eta,I} + \mathring{y}_{I}. \tag{3.64}$$

In the case $\lambda_j < 0$, we instead have $\varphi_{\eta,j}(\ell) = 1$ and similar formulas for Y_j, y_j, and y_{II}. In view of (3.27),

$$\|\mathring{y}_{I}\|_1 + \|\mathring{y}_{II}\|_1 \le K\Big(\|h_{I}\|_1 + \|h_{II}\|_1\Big) \tag{3.65}$$

and

$$\|\mathring{y}_{I}\|_\infty + \|\mathring{y}_{II}\|_\infty \le K\Big(\|h_{I}\|_\infty + \|h_{II}\|_\infty\Big). \tag{3.66}$$

Since, by (3.35) for $j > 1$ and $\lambda_j > 0$, $|M_j(\eta, s)| \le 1$, we have

$$\|\mathring{Y}_j\|_\infty \le K\|H_j\|_1 \qquad \text{and} \qquad \|\mathring{y}_j\|_\infty \le K\|h_j\|_1. \tag{3.67}$$

The coefficients C and c in (3.63), (3.64) are determined by the following boundary conditions from (3.10)(b) and (3.7):

$$\begin{aligned} &\text{(a)} \quad P_- dG_2(E_x, e^s)U(x_{-\ell}) = 0, \\ &\text{(b)} \quad P_- \sum_x dG_2(E_x, e^s)u(x) = P_- g_{\text{sum}}, \\ &\text{(c)} \quad dS_2(u_{sh})u = g_2. \end{aligned} \tag{3.68}$$

Note that in view of (3.7) we have

$$\begin{aligned} \sum_x dG_2(E_x, e^s)(E_x - I)U &= dG_2(E_x, e^s)U(x_\ell) - dG_2(E_x, e^s)U(x_{-\ell}) \\ &= dG_2(E_x, e^s)U(x_\ell), \end{aligned} \tag{3.69}$$

and hence (3.68)(b) could be rewritten as

$$P_- dG_2(E_x, e^s)U(x_\ell) = P_- g_{\text{sum}}. \tag{3.70}$$

We start with the case $n_1 = n$. The components $Y_{I,II}$ are written in the form

$$Y_{I} = C_{I} \varphi_{\eta,I} + \mathring{Y}_{I}, \qquad Y_{II} = C_{II} \varphi_{\eta,II} + \mathring{Y}_{II} \tag{3.71}$$

as Y_j in (3.63) and satisfy

$$\|\mathring{Y}_{I}\|_p + \|\mathring{Y}_{II}\|_p \le K\Big(\|H_{I}\|_p + \|H_{II}\|_p\Big), \qquad p = 1, \infty. \tag{3.72}$$

In view of (2.34), (2.35), and (3.48), the contribution of Y_1 to the l.h.s. of (3.68)(a),(c) and (3.70) is bounded by

$$\Big|(E_x - I)^{k+1} Y_1\Big| + \Big|(E_x - I) Y_{1,k+1}\Big| + |\eta'|\,|Y_1| + \Big(|s| + |\eta|\Big)\Big|(E_x - I) Y_1\Big|. \tag{3.73}$$

Note that by the generalized stability condition, the system of equations for $C_{I,II}$ and C_j, $j \ge 1$, is solvable and

$$\begin{aligned} |C_{I,II}| + \sum_{j>1} |C_j| \le K \left(|P_- g_{\rm sum}| + |g_2| + \|H_{I,II}\|_\infty + \sum_{j>1} \|H_j\|_1 \right) \\ + \text{the terms in (3.73).} \end{aligned} \tag{3.74}$$

Hence

$$\|Y_{I,II}\|_1 + \sum_{j>1} \|Y_j\|_\infty \le K\Big(|P_- g_{\rm sum}| + |g_2| + \|H\|_1\Big) + \text{the terms in (3.73).} \tag{3.75}$$

In order to estimate the Y_1 components, it is convenient to introduce the scale

$$\sigma = \varepsilon + |s|^{\frac{1}{k+1}}, \qquad \varepsilon' = \frac{\varepsilon}{\sigma}, \qquad s' = \frac{b_1^{-1} s}{\sigma^{k+1}}, \qquad \tau = x\sigma, \qquad \ell' = \sigma \ell \tag{3.76}$$

and rescale the vectors Y_1, H_1, α,

$$Y'_{1,i} = \sigma^{-i+1} Y_{1,i}, \qquad H'_{1,i} = \sigma^{-i} H_{1,i}, \qquad \alpha'_i = \sigma^{i-k-1} \alpha_i. \tag{3.77}$$

The difference equation for Y'_1 could be written as

$$D_\tau Y'_1 - J Y'_1 + \left(0, \dots, 0, \sum_{i=1}^{k+1} \alpha'_{i-1} Y'_{1,i}\right)^T = D_\tau Y'_1 - M'_1 Y'_1 = H'_1, \tag{3.78}$$

where J is a Jordan cell with zero diagonal and

$$D_\tau = \frac{(E_x - I)}{\sigma} \tag{3.79}$$

approximates the derivative $\frac{d}{d\tau}$. The equations

$$\begin{aligned} &\text{(a)} \quad P_1 dG_2(E_x, e^s) U(x_{-\ell}) = 0, \\ &\text{(b)} \quad P_1 dG_2(E_x, e^s) U(x_\ell) = P_1 g_{\rm sum}, \\ &\text{(c)} \quad dS_1 u(x) = dS_1 (E_x - I) U(x) = g_1, \qquad x = x_{-\ell} \quad \text{or} \quad x = x_\ell, \end{aligned} \tag{3.80}$$

provide $k+1$ boundary conditions for Y'_1. In view of the consistency assumption in (2.5), (3.80)(a),(b) could be written in the form

$$\begin{aligned} Y'_{1,1}(x) + O(\sigma) Y'_1(x) = O(1) Y_{I,II}(x) + \textstyle\sum_{j=2}^n \Big(O(\eta) + O(s)\Big) Y_j(x) \\ + (0, P_1 g_{\rm sum}) = g'_{1,0}, \qquad x = x_{\pm\ell}. \end{aligned} \tag{3.81}$$

In view of (2.30), (3.34), and (3.48), boundary condition (3.80)(c) could be normalized as

$$\begin{aligned} Y'_{1,d_i+2} + O(\sigma)Y'_1 &= \sigma^{-d_i-1}\left(O(1)Y_{I,II} + \sum_{j=2}^{n} \Big(O(\eta) + O(s)\Big) Y_j + O(1) g_{1,i} \right) \\ &= g'_{1,i}, \quad 1 \le i \le \frac{k-1}{2}, \quad x = x_{\pm\ell}. \end{aligned} \tag{3.82}$$

Consider the boundary value problem (3.78), (3.81), (3.82). By (3.43), (3.11), (3.38), and (2.10),

$$\begin{aligned} \sum_{i=1}^{k+1} \alpha'_{i-1} Y'_{1,i} &= s' Y'_{1,1} + \partial_{e_1} df_1(u_0) e_1 \mu b_1^{-1} \sigma^{-k} y_{sh}\Big(\varepsilon(x - x_0)\Big) Y'_{1,2} + O(\sigma) Y'_1 \\ &= s' Y'_{1,1} + (\varepsilon')^k (-1)^{\frac{k+1}{2}} y_{sh}\Big(\varepsilon(x - x_0)\Big) Y'_{1,2} + O(\sigma) Y'_1. \end{aligned} \tag{3.83}$$

Now it is clear that (3.78) approximates the differential equation

$$\partial_\tau^{k+1} Y'_{1,1} + (\varepsilon')^k (-1)^{\frac{k+1}{2}} y_{sh}\Big(\varepsilon'(\tau - \tau_0)\Big) \partial_\tau Y'_{1,1} + s' Y'_{1,1} = \sum_{i=0}^{k} \partial_\tau^i H'_{1,k+1-i}. \tag{3.84}$$

The l.h.s. of (3.84) is the integral of (2.22) with $\partial_\tau Y_{1,1} = y_1$ modulo a change of scale $\varepsilon'\tau \to \tau$ and $s'/[(\varepsilon')^{k+1}(-1)^{\frac{k+1}{2}}] \to s'$. We will show in section 4 that, under the scalar shock stability condition in (2.32) and the continuous stability hypothesis for (2.22), the problem (3.78), (3.81), (3.82) satisfies the estimate

$$\sum_{i+j \le k+2} \|D_\tau^i Y'_{1,j}\|_\infty \le K \left(\sum_{i+j \le k+1} \|D_\tau^i H'_{1,j}\|_{1,\sigma} + |g'_1| \right), \tag{3.85}$$

where $\|H\|_{1,\sigma} = \sum_\tau |H(\tau)| \cdot \sigma$ is the usual ℓ_1 norm on the grid-interval $[-\ell', \ell']$ with step size σ. It is assumed that $\ell\varepsilon \ge \delta_0^{-1}$ is sufficiently large. The constant K is independent of ℓ and σ. For $|s| \gg \varepsilon^{k+1}$ one can replace the norm $\|\cdot\|_{1,\sigma}$ in the r.h.s. of (3.85) by the norm $\|\cdot\|_\infty$ so that (3.85) will become the usual estimate in $\|\cdot\|_\infty$ for elliptic boundary value problems.

By means of (3.85) we can estimate the terms in (3.73). Indeed,

$$\begin{aligned} &\Big|(E_x - I)^{k+1} Y_1\Big| + \Big|(E_x - I) Y_{1,k+1}\Big| + |\eta'|\,|Y_1| + \Big(|s| + |\eta|\Big)\Big|(E_x - I) Y_1\Big| \\ &\le \sum_{j=1}^{k+1} \Big(\|(E_x - I)^{k+2-j} Y_{1,j}\|_\infty + \varepsilon^{k+1} \|Y_{1,j}\|_\infty + \sigma^k \|(E_x - I) Y_{1,j}\|_\infty \Big) \\ &\le \sigma^{k+1} \sum_{i+j \le k+2} \|D_\tau^i Y'_{1,j}\|_\infty \le K\sigma^{k+1} \left(\sum_{i+j \le k+1} \|D_\tau^i H'_{1,j}\|_{1,\sigma} + |g'_1| \right) \\ &\le K\Big(\sigma \|H_1\|_1 + \sigma^{k+1} |g'_1| \Big). \end{aligned} \tag{3.86}$$

Thus, from (3.75) and (3.85) we obtain a combined estimate

$$\|Y_{I,II}\|_1 + \sum_{j>1} \|Y_j\|_\infty \le K\Big(\|H\|_1 + \sigma^{k+1} |g'_1| + |P_- g_{\text{sum}}| + |g_2| \Big). \tag{3.87}$$

The grid-function H in (3.60) is $O(1)\widetilde{F} + O(\eta')Y$; hence

$$\|H\|_1 \le K\Big(\|\widetilde{F}\|_1 + \|\eta'\|_1 \cdot \|Y\|_\infty\Big) \le K\Big(\|\widetilde{F}\|_1 + \varepsilon^k\|Y\|_\infty\Big). \tag{3.88}$$

The term $\varepsilon^k\|Y\|_\infty$ is absorbed in the l.h.s. of (3.87) with the exception of the component $\varepsilon^k\|Y_1\|_\infty$. Now we should estimate more carefully the contribution of $O(\eta')Y$ to the r.h.s. of (3.85). We have

$$\|D_\tau^i\sigma^{-j}O(\eta')Y\|_{1,\sigma} \le K\sigma^{-i-j}\varepsilon^k \cdot \sigma\|Y\|_\infty \le K\|Y\|_\infty. \tag{3.89}$$

This is a sufficiently nice estimate for the components $Y_{I,II}$, Y_j, $j \ge 2$, and $Y_{1,j} = \sigma^{j-1}Y'_{1,j}$, $j > 1$. The latter are dominated by the l.h.s. of (3.85). For $Y_{1,1}$,

$$\|D_\tau^i\sigma^{-j}O(\eta')Y_{1,1}\|_{1,\sigma} \le K\sigma^{-j}\varepsilon^k \cdot \sigma\sum_{i_1\le i}\|D_\tau^{i_1}Y_{1,1}\|_\infty. \tag{3.90}$$

The worst case is $i = 0$, $j = k+1$. This comes from the contribution of $T^{-1}A(E_x - I)X_{1,1}E_xY_{1,1}$ in (3.60) to the component $H_{1,k+1}$. Note, however, that this contribution is not $O(\eta')$ but $O(\eta's)$. Indeed, for $s = 0$ the vectors $X_j(\eta)$, $j \ge 2$, and $X_{1,1}(\eta)$ are eigenvectors of the pencil $A\kappa + B$ with eigenvalues $\kappa = 1$ and form a basis in the space V_0 of repeated ν_0+1 tuples $(u, u, \dots, u)$, $u \in \mathbb{C}^n$. Since $(E_x - I)X_{1,1}(\eta) \in V_0$, it is a linear combination of the above $X_j(\eta)$, $X_{1,1}(\eta)$. Hence the above $O(\eta')Y_{1,1}$ term for $s = 0$ contributes only to H_j, $j \ge 2$, and $H_{1,1}$. Thus estimate (3.85) implies

$$\sum_{ij\le k+2}\|D_\tau^iY'_{1,j}\|_\infty \le K\left(\sigma^{-k}\|\widetilde{F}\|_1 + |g'_1| + \|Y_{I,II}\|_\infty + \sum_{j\ge2}\|Y_j\|_\infty\right) \tag{3.91}$$

and

$$\begin{aligned}\|Y_{I,II}\|_1 + \sum_{j>1}\|Y_j\|_\infty + \sigma^k\sum_{i+j\le k+2}\|D_\tau^iY'_{1,j}\|_\infty \\ \le K\Big(\|\widetilde{F}\|_1 + \sigma^k|g'_1| + |P_-g_{\mathrm{sum}}| + |g_2|\Big).\end{aligned} \tag{3.92}$$

Recall that $\widetilde{F}$ is related to the original F by formulas (3.17), (3.12), and (3.8). Hence

$$\begin{aligned}\|\widetilde{F}\|_1 \le \left\|\sum_{x_{-\ell}}^{x-1}F(\xi)\right\|_1 + \Big|dG_1[u_{st}(x_{-\ell})](E_x, e^s)u(x_{-\ell})\Big| \cdot \ell \\ +\|O(\Delta u_{st})u\|_1 + \|O(\eta')u\|_1.\end{aligned} \tag{3.93}$$

Since $n_1 = n$, PdG_1u in (2.26)(a) is dG_1u, and in the notation of (3.2), (3.3) we have

$$dG_1\Big[u_{st}(x_{-\ell})\Big](E_x, e^s)u(x_{-\ell}) = g_{L,0}. \tag{3.94}$$

Next, by (3.14), (3.15),

$$\|O(\Delta u_{st})u\|_1 + \|O(\eta')u\|_1 \le \delta_0\varepsilon^{k-1}\|u\|_\infty + K\varepsilon^k\|u\|_\infty. \tag{3.95}$$

The grid-function u could be expressed in terms of Y (see (3.57)). These terms are negligible with respect to the l.h.s. of (3.92). The only problematic term comes from the contribution of $(E_x - I)Y_1$ to u (see (3.57)). However,

$$\delta_0\varepsilon^{k-1}\|(E_x - I)Y_{1,j}\|_\infty \le \delta_0\varepsilon^{k-1}\sigma^j\|D_\tau Y'_{1,j}\|_\infty \ll \sigma^k\|D_\tau Y'_{1,j}\|_\infty. \tag{3.96}$$

From (3.82) we obtain

$$|\sigma^k g'_{1,i}| \le \sigma^{k-d_i-1}\left(\|Y_{I,II}\|_\infty + \sigma^k \sum_{j=2}^{n} \|Y_j\|_\infty + |g_{1,i}|\right). \tag{3.97}$$

Because of the $Y_{I,II}$ term, we have to assume that

$$0 \le d_i \le k-2, \qquad 1 \le i \le \frac{k-1}{2}. \tag{3.98}$$

Note that for $k = 1$ the set of $\{d_i\}$ is empty. For odd $k \ge 3$ the restriction in (3.98) does not exclude the set of boundary conditions suggested in (2.59). Hence, the terms with $Y_{I,II}$, Y_j in $\sigma^k g'_{1,i}$ are negligible. Altogether, from (3.98) we arrive at the estimate

$$\begin{aligned}&\|Y_{I,II}\|_1 + \sum_{j>1}\|Y_j\|_\infty + \sigma^k \sum_{i+j\le k+2} \|D_\tau^i Y'_{1,j}\|_\infty \\ &\le K\left(\left\|\sum_{x-\ell}^{x-1} F(\xi)\right\|_1 + \sigma^k \sum |\sigma^{-d_i-1} g_{1,i}| + |P_- g_{\mathrm{sum}}| + \sigma^k |P_1 g_{\mathrm{sum}}| + |g_2| + |g_{L,0}|\cdot \ell\right).\end{aligned} \tag{3.99}$$

From here we can obtain estimates for the variable U. By (3.48), the contribution of Y_1 to the components U_j, $j > 1$, is bounded by $(O(s) + O(\eta))Y_1 + O(1)Y_{1,k+1}$. Hence

$$\sum_{j>1}\|U_j\|_\infty + \sum_{i\le k}\|\sigma^{k-i}(E_x - I)^i U_1\|_\infty \le \text{r.h.s. of (3.99)}. \tag{3.100}$$

Now we consider the most important case, $n_1 = 1$. The single global conservation law prevents the shock wave from "shifting." Let us return to (3.61)(b)–(d) with the solutions (3.64). Since the projector P_- is zero, the coefficients c_j, $j > 1$, and $c_{I,II}$ are determined by the boundary conditions (3.68)(c). In order to express these boundary conditions in terms of y_j, $y_{I,II}$, we use the relations (3.57) and (3.59). Hence

$$\begin{aligned}&dS_2(u_{sh})\left(\sum_{j>1} X_j y_j + X_I y_I + X_{II} y_{II}\right) \\ &\qquad = g_2 + O(\eta')Y - dS_2(u_{sh}) X_1 y_1.\end{aligned} \tag{3.101}$$

Recall that the contribution of $y_1 = (E_x - I)Y_1$ to the r.h.s. of (3.101) is bounded by the terms in (3.73). Hence

$$\begin{aligned}&\sum_{j>1}|c_j| + |c_I| + |c_{II}| \\ &\le K\cdot\left(|g_2| + \sum_{j>1}\|\mathring{y}_j\|_\infty + \|\mathring{y}_{I,II}\|_\infty + \varepsilon^{k+1}\|Y\|_\infty + \text{the terms in (3.73)}\right),\end{aligned} \tag{3.102}$$

and by (3.65), (3.67),

$$\begin{aligned}&\sum_{j>1}\|y_j\|_\infty + \|y_{I,II}\|_1 \\ &\le K\cdot\left(\|h_{I,II}\|_1 + \sum_{j>1}\|h_j\|_1 + |g_2| + \varepsilon^{k+1}\|Y\|_\infty + \text{terms in (3.73)}\right).\end{aligned} \tag{3.103}$$

The variable Y_1 was already estimated in (3.85). Unfortunately, the contribution of the constant term $dG_1 \cdot u(x_{-\ell})$ in (3.8) to the norm $\|H'_{1,j}\|_{1,\sigma}$ in (3.85) for $j = k$ results in terms like $\|y_i\|_\infty \ell \sigma^{-k+1}$, $i > 1$. This term contributes to $\varepsilon^{k+1}\|Y_1\|_\infty$ a value $\ell\varepsilon^2|y_j|_\infty$, which is not negligible if $\ell = o(1)\varepsilon^{-k-1}$, $k > 1$. Therefore we will improve estimate (3.85) in the following manner. Define the variables

$$\widetilde{Y}'_{1,i} = Y'_{1,i} + H'_{1,i-1}, \qquad i \geq 2; \qquad \widetilde{Y}'_{1,1} = Y'_{1,1}. \tag{3.104}$$

Then $\widetilde{Y}'_1$ satisfies system (3.78) with H'_1 replaced by

$$\begin{aligned} &\widetilde{H}'_{1,1} = 0; \qquad \widetilde{H}'_{1,i} = D_\tau H'_{1,i-1}, \qquad 2 \leq i \leq k; \\ &\widetilde{H}'_{1,k+1} = H'_{1,k+1} + D_\tau H'_{1,k} + \textstyle\sum_{i=1}^k \alpha'_i H'_{1,i}. \end{aligned} \tag{3.105}$$

By (3.43) and (3.77),

$$\sum_{i=1}^k \alpha'_i H'_{1,i} = \sum_{i=1}^k \sigma^{i-k-1}\Big(O(\eta) + O(s)\Big)\sigma^{-i} H_{1,i} = O(\sigma^{-1})H_1. \tag{3.106}$$

In boundary conditions (3.81), (3.82), one should replace $g'_{1,i}$ by

$$\widetilde{g}'_{1,i} = g'_{1,i} + H'_{1,d_i+1} + O(\sigma)H'_1. \tag{3.107}$$

Now, from the basic estimate (3.85) for $\widetilde{Y}'_1$, we obtain

$$\begin{aligned} \sum_{i+j\leq k+2} \|D_\tau^i Y'_{1,j}\|_\infty \leq K\Bigg(&\sum_{i+j\leq k} \|D_\tau^i D_\tau H'_{1,j}\|_{1,\sigma} + \|H'_{1,k+1}\|_{1,\sigma} \\ &+ \|\sigma^{-1}H_1\|_{1,\sigma} + \sum_{\substack{i+j\leq k+1 \\ j\leq k}} \|D_\tau^i H'_{1,j}\|_\infty + |g'_1| \Bigg). \end{aligned} \tag{3.108}$$

In order to estimate the component $H_{1,k+1}$, we will need the following elementary lemma.

LEMMA 3.1. *The $H_{1,k+1}$ component of the vector H in* (3.60) *depends on $F^{(1)}$ in* (3.10)(a) *as*

$$H_{1,k+1} = O(1)P_1 F^{(1)} + \Big(O(\eta) + O(s)\Big)(I - P_1)F^{(1)}. \tag{3.109}$$

(Here P_1 is the projection on the first component.)

Proof. Let $\eta, s = 0$. Take $F^{(1)}$ to be a constant grid-function with $P_1 F^{(1)} = 0$. Then (3.10)(a) has a solution $P_j U = x \cdot P_j F^{(1)}/\lambda_j$, $j \geq 2$, $P_1 U = 0$. Here P_j is the projection on the jth component. The corresponding vector functions Y and H defined by (3.17), (3.56), and (3.60) satisfy system (3.60). In particular, Y_1 satisfies $(E_x - I)Y_1 - JY_1 = H_1$. Notice, however, that $\widetilde{U}$ in (3.17) is a first order polynomial in x and so is Y. On the other hand, $F^{(1)}$, $\widetilde{F}$, and H are constants. Hence, $JY_1 = H_1 - (E_x - I)Y_1$ is constant. In particular, $Y_{1,k+1}$ is constant and $H_{1,k+1} = (E_x - I)Y_{1,k+1} = 0$. Since $H(x)$ depends only on $F^{(1)}(x)$, we obtain that $H_{1,k+1}$ for $s, \eta = 0$ is independent of $(I - P_1)F^{(1)}$. Hence for small s, η, $H_{1,k+1}$ satisfies (3.109).

Now we can express the r.h.s. of (3.108) in terms of $F^{(1)}$ in (3.10)(a) as

$$\begin{aligned}\sum_{i+j\le k+2}\|D_\tau^i Y'_{1,j}\|_\infty \le K\Big(&\|\sigma^{-k}(E_x-I)F^{(1)}\|_1+\|\sigma^{-k}P_1F^{(1)}\|_1\\ &+\|F^{(1)}\|_1+\|\sigma^{-k-1}(E_x-I)F^{(1)}\|_\infty+\|\sigma^{-k}F^{(1)}\|_\infty+|g'_1|+\|Y\|_\infty\Big).\end{aligned}\tag{3.110}$$

We already have shown in (3.90) that the actual contribution of $Y_{1,1}$ to $\|Y\|_\infty$ is negligible. Thus $\|Y\|_\infty$ above could be replaced by $\|Y_{I,II}\|_\infty+\sum_{j\ge2}\|Y_j\|_\infty$. The contribution of $dG_1u(x_{-\ell})$ in (3.8) to the r.h.s. of (3.110) is bounded by

$$\Big|\sigma^{-k}P_1dG_1u(x_{-\ell})\Big|\ell+\Big|(I-P_1)dG_1u(x_{-\ell})\Big|\cdot(\ell+\sigma^{-k}).\tag{3.111}$$

By the accuracy assumption in (2.15) and formulas (3.48), (3.57),

$$\begin{aligned}\Big|(I-P_1)dG_1[u_0]u(x_{-\ell})\Big|&\le K\Big(|(I-P_1)u|_\infty+|(E_x-I)^{k+1}P_1u|_\infty\Big)\\ &\le K\left(\|y_{I,II}\|_\infty+\sum_{j\ge2}\|y_j\|_\infty+\|y_{1,k+1}\|_\infty+\sigma^k\|y\|_\infty+\varepsilon^{k+1}\|Y\|_\infty\right).\end{aligned}\tag{3.112}$$

Since $dG_1u(x_{-\ell})$ is actually $dG_1[u_{st}(x_{-\ell})](E_x,e^s)u(x_{-e})$, by (2.86)–(2.87) we should add to the above the term $K\varepsilon^k\|y\|_\infty$, which is absorbed in $\sigma^k\|y\|_\infty$. The component $P_1dG_1u(x_{-\ell})$ is nothing but $P_1g_{L,0}$ (see (3.3)). Next, the contribution of the term $(O(\Delta u_{st})+O(\eta'))u$ in (3.12) to the r.h.s. of (3.110) is bounded by

$$\begin{aligned}K\Big(&\Big\|\sigma^{-k}\Big(O(\Delta u_{st})+O(\eta')\Big)u\Big\|_1\\ &+\Big\|\sigma^{-k-1}\Big(O(\Delta u_{st})+O(\eta')\Big)u\Big\|_\infty\Big)\le K\delta_0\sigma^{-1}\|u\|_\infty.\end{aligned}\tag{3.113}$$

What is left from $F^{(1)}$ in (3.8) is the sum $\sum_{x_{-\ell}}^{x-1}F(\xi)$. Its contribution to the r.h.s. of (3.110) is bounded by

$$\begin{aligned}K\Big(&\|\sigma^{-k}F\|_1+\|\sigma^{-k-1}F\|_\infty\\ &+\Big\|\sigma^{-k}P_1\sum F(\xi)\Big\|_1+\Big\|\sum F(\xi)\Big\|_1+\Big\|\sigma^{-k}\sum F(\xi)\Big\|_\infty\Big).\end{aligned}\tag{3.114}$$

Finally, consider the term g'_1. Instead of (3.82), we rewrite boundary conditions (3.80)(c) as

$$\begin{aligned}Y'_{1,d_i+2}+O(\sigma)Y'_1&=\sigma^{-d_i-1}\left(O(1)y_{I,II}+\sum_{j\ge2}O(1)y_j+O(\eta')Y+O(1)g_{1,i}\right)\\ &=g'_{1,i},\qquad i\ge1.\end{aligned}\tag{3.115}$$

Hence

$$|g'_{1,i}|\le K\sigma^{-d_i-1}\left(\|y_{I,II}\|_\infty+\sum_{j\ge2}\|y_j\|_\infty+\varepsilon^{i+1}\|Y\|_\infty+|g_{1,i}|\right),\quad i\ge1.\tag{3.116}$$

By (3.81),

$$|g'_{1,0}| \le K\left(\|Y_{I,II}\|_\infty + \sigma^k \sum_{j\ge 2}\|Y_j\|_\infty + |P_1 g_{\rm sum}|\right). \tag{3.117}$$

Altogether,

$$\begin{aligned}\sum_{i+j\le k+2}\|D_\tau^i Y'_{1,j}\|_\infty \le K\Big(&\|\sigma^{-k}F\|_1 + \|\sigma^{-k-1}F\|_\infty + \Big\|\sigma^{-k}P_1\sum F(\xi)\Big\|_1\\ &+\Big\|\sum F(\xi)\Big\|_1 + \Big\|\sigma^{-k}\sum F(\xi)\Big\|_\infty + \sigma^{-k}|g_{L,0}|\cdot\ell + |P_1 g_{\rm sum}|\\ &+\sum_{i\ge 1}\sigma^{-d_i-1}|g_{1,i}| + (\ell+\sigma^{-k})\Big(\|y_{I,II}\|_\infty + \sum_{j\ge 2}\|y_j\|_\infty + \|y_{1,k+1}\|_\infty\\ &+\sigma^k\|y_1\|_\infty + \varepsilon^{k+1}\|Y\|_\infty\Big) + \delta_0\sigma^{-1}\|u\|_\infty + \|Y_{I,II}\|_\infty + \sum_{j\ge 2}\|Y_j\|_\infty\Big).\end{aligned} \tag{3.118}$$

Unlike in (3.98), we can relax the restriction on d_i to be

$$0 \le d_i \le k-1, \qquad 1 \le i \le \frac{k-1}{2}. \tag{3.119}$$

The contribution of the y_1 and Y_1 components to the r.h.s. of (3.118) is bounded by

$$\begin{aligned}K\Big((\ell+\sigma^{-k})\Big(&\|\sigma^{k+1}D_\tau Y'_{1,k+1}\|_\infty + \sigma^k\|\sigma D_\tau Y_1\|_\infty + \varepsilon^{k+1}\|Y_1\|_\infty\Big)\\ &+\delta_0\sigma^{-1}\|\sigma D_\tau Y_1\|_\infty\Big).\end{aligned} \tag{3.120}$$

Recall that we consider $|s| \le K\varepsilon^{k+1}$. Since $\ell\varepsilon^{k+1} \le \delta_0$, for sufficiently small δ_0, $K\ell\sigma^{k+1}$ is small. Hence the terms in (3.120) are dominated by the l.h.s. of (3.118). By (3.59),

$$\|Y_{I,II}\|_\infty + \sum_{j\ge 2}\|Y_j\|_\infty \le K\|y\|_\infty + \ell\left(\|y_{I,II}\|_\infty + \sum_{j\ge 2}\|y_j\|_\infty\right). \tag{3.121}$$

Hence all y, u, and Y terms in the r.h.s. of (3.118) could be replaced by

$$K(\ell+\sigma^{-k})\left(\|y_{I,II}\|_\infty + \sum_{j\ge 2}\|y_j\|_\infty\right). \tag{3.122}$$

We now return to estimate (3.103). In view of (3.121), the term $\varepsilon^{k+1}(\|Y_{I,II}\|_\infty + \sum_{j\ge 2}\|Y_j\|_\infty)$ is dominated by the l.h.s. of (3.103) (modulo the negligible term $K\varepsilon^{k+1}\|y_1\|_\infty$). By (3.86), the terms in (3.73) are bounded by σ^{k+1} times the l.h.s. of

(3.118). The same holds for $\varepsilon^{k+1}\|Y_1\|_\infty$. The term $\|h\|_1$ is estimated as

$$\begin{aligned}
&\|h_{I,II}\|_1+\sum_{j\ge 2}\|h_j\|_1\le\|(E_x-I)H_{I,II}\|_1+\sum_{j\ge 2}\|(E_x-I)H_j\|_1\\
&\quad+\|O(\eta')\|_1\Big(\|Y_{I,II}\|_\infty+|s|\sum_{j\ge 2}\|Y_j\|_\infty\Big)\\
&\quad\le K\Big(\|(E_x-I)\widetilde F\|_1+\|O(\eta')\|_1\|\widetilde F\|_\infty+\|O(\eta')\|_1\\
&\qquad\cdot\Big(\|y\|_\infty+\varepsilon\|Y\|_\infty\Big)+\varepsilon^k\Big(\|y_{I,II}\|_1+\sigma^{k+1}\ell\sum_{j\ge 2}\|y_j\|_\infty+\sigma^{k+1}\|y\|_\infty\Big)\Big).
\end{aligned}\tag{3.123}$$

Clearly, the $y_{I,II}$ and y_j, $j\ge 2$, terms are negligible, and the y_1, Y_1 terms are bounded by σ^{k+1} times the l.h.s. of (3.118). Now consider the $\widetilde F\approx F^{(1)}$ terms in the r.h.s. of (3.123). The contribution of $dG_1u(x_{-\ell})$ in (3.8) to $\|O(\eta')\|_1\|\widetilde F\|_\infty$ is

$$\begin{aligned}
\varepsilon^k\Big|dG_1[u_{st}](x_{-\ell})(E_x,e^s)u(x_{-\ell})\Big|&\le\varepsilon^k\Big(\|y\|_\infty+\varepsilon^{k+1}\|Y\|_\infty\Big)\\
&\le\varepsilon^k\Big(\|y\|_\infty+\varepsilon^{k+1}\|Y\|_\infty\Big)\le\varepsilon^k(1+\varepsilon^{k+1}\ell)\|y\|_\infty
\end{aligned}\tag{3.124}$$

and is already included in the $\varepsilon^k\|y\|_\infty$ term of the r.h.s. of (3.123). The contribution of $(O(\Delta u_{st})+O(\eta'))u$ in (3.12) is bounded by

$$\begin{aligned}
&\Big\|\Big((E_x-I)\Big(O(\Delta u_{st})+O(\eta')\Big)\Big)\Big\|_1\cdot\|u\|_\infty\\
&\qquad+\Big(\|\Delta u_{st}\|_1+\|\eta'\|_1\Big)\|(E_x-I)u\|_\infty\\
&\qquad\le K\varepsilon^k\|u\|_\infty+\delta_0\varepsilon^{k-1}\|(E_x-I)u\|_\infty
\end{aligned}\tag{3.125}$$

(see (2.87), (2.88)). The norms of u and $(E_x-I)u$ could be expressed in terms of y and Y using (3.57). Namely,

$$\|u\|_\infty\le\|y\|_\infty+\varepsilon^{k+1}\|Y\|_\infty\tag{3.126}$$

and

$$\|(E_x-I)u\|_\infty\le K\Big(\varepsilon^{k+1}\|y\|_\infty+\|(E_x-I)y\|_\infty+\varepsilon^{k+2}\|Y\|_\infty\Big).\tag{3.127}$$

The contribution of y_j, $j\ge 2$, and $y_{I,II}$ components to the r.h.s. of (3.125) is negligible compared with the l.h.s. of (3.103). For the Y_1 component, the worst term is

$$K\varepsilon^k\|y_1\|_\infty+\delta_0\varepsilon^{k-1}\|(E_x-I)y_1\|_\infty\le K\sigma^{k+1}\Big(\|D_\tau Y_1\|_\infty+\|D_\tau^2Y_1\|_\infty\Big)\tag{3.128}$$

and is bounded by $K\sigma^{k+1}$ times the l.h.s. of (3.118). Finally, in the $|g_2|$ term at the r.h.s. of (3.103) we have the contribution of $(O(\Delta u_{st})+O(\eta'))u$ in (3.13). This is bounded by $\delta_0\varepsilon^k\|u\|_\infty$.

We are ready to derive the combined estimate. Multiply (3.118) by $K_1\sigma^{k+1}$, where K_1 is a large constant, and add the result to (3.103). We obtain

$$\begin{aligned}
&K_1\sigma^{k+1}\sum_{i+j\le k+2}\|D_\tau^i Y'_{1,j}\|_\infty+\sum_{j>1}\|y_j\|_\infty+\|y_{I,II}\|_1\\
&\quad\le K_1K\sigma^{k+1}\bigg(\|\sigma^{-k}F\|_1+\|\sigma^{-k-1}F\|_\infty+\Big\|\sigma^{-k}P_1\sum F(\xi)\Big\|_1\\
&\qquad+\Big\|\sum F(\xi)\Big\|_1+\Big\|\sigma^{-k}\sum F(\xi)\Big\|_\infty\\
&\qquad+\sigma^{-k}|g_{L,0}|\cdot\ell+|P_1g_{\rm sum}|+\sum_{i\ge1}\sigma^{-d_i-1}|g_{1,i}|\bigg)\\
&\quad+K\Big(\|F\|_1+\varepsilon^k\Big\|\sum F(\xi)\|_\infty+|g_2|\Big).
\end{aligned}\tag{3.129}$$

Indeed, $K_1\sigma^{k+1}$ times the terms in (3.122) results in $K_1K(\ell\sigma^{k+1}+\sigma)(\|y_{I,II}\|_\infty+\sum_{j>1}\|y_j\|_\infty)$. Since $\sigma\approx\varepsilon$, these terms are bounded by the l.h.s. of (3.129), provided $K_1K\delta_0\ll1$. In order to neutralize the contribution of Y_1 to the r.h.s. of (3.103), it is enough that $K_1>K$. Since $\sigma^{k+1}\ell\approx\varepsilon^{k+1}\ell\ll1$, estimate (3.129) could be rewritten in an equivalent form

$$\begin{aligned}
&\sigma^{k+1}\sum_{i+j\le k+2}\|D_\tau^i Y'_{1,j}\|_\infty+\sum_{j>1}\|y_j\|_\infty+\|y_{I,II}\|_1\\
&\quad\le K\bigg(\|F\|_1+\sigma\Big\|P_1\sum F(\xi)\Big\|_1+\sigma\ell|g_{L,0}|\\
&\qquad+\sigma^{k+1}|P_1g_{\rm sum}|+\sum_{i\ge1}\sigma^{k-d_i}|g_{1,i}|+|g_2|\bigg).
\end{aligned}\tag{3.130}$$

Since $\sigma D_\tau Y_1=(E_x-I)Y_1=y_1$,

$$\sigma^k\sum_{i+j\le k+1}\|D_\tau^i\sigma^{-j+1}y_{1,j}\|_\infty+\|y_{I,II}\|_1+\sum_{j>1}\|y_j\|_\infty\le\text{r.h.s. of (3.130)}.\tag{3.131}$$

In the original u variables, we obtain

$$\sum_{j>1}\|u_j\|_\infty+\sum_{i=-1}^{k}\|\sigma^{k-i}(E_x-I)^iu_1\|_\infty\le\text{r.h.s. of (3.130)},\tag{3.132}$$

where $(E_x-I)^{-1}u_1\stackrel{df}{=}\sum_\xi u_1(\xi)$.

In case $K\varepsilon^{k+1}<|s|<\delta$, the norm $\|\cdot\|_1$ in (3.110) is replaced by the $\sigma^{-1}\|\cdot\|_\infty$ norm. As a result, the terms $\|\sigma^{-k}P_1\sum F(\xi)\|_1+\|\sum F(\xi)\|_1$ in (3.129) are replaced by $\sigma^{-k-1}\|P_1\sum F(\xi)\|_\infty+\sigma^{-1}\|\sum F(\xi)\|_\infty\le\sigma^{-k-1}\|F\|_1$. Therefore we obtain estimate (3.130) without the term $\sigma\|P_1\sum F(\xi)\|_1$. Finally, instead of (3.132) we obtain

$$\begin{aligned}
&\sum_{j>1}\|u_j\|_\infty+\sum_{i=-1}^{k}\|\sigma^{k-i}(E_x-I)^iu_1\|_\infty\\
&\quad\le K\left(\|F\|_1+|g_{L,0}|+\sigma^{k+1}|P_1g_{\rm sum}|+\sum_{i\ge1}\sigma^{k-d_i}|g_{1,i}|+|g_2|\right).
\end{aligned}\tag{3.133}$$

In order to prove exponential decay of the solution u, we need to extend estimates (3.100), (3.132), and (3.133) into the domain

$$0 \geq \operatorname{Re} s \geq -\frac{\delta\varepsilon^k}{\ell}. \tag{3.134}$$

Indeed, the bound $\delta\varepsilon^k/\ell$ cannot be increased, since the differential equation in (3.84) (with r.h.s. $= 0$) has for small $|s'|$ and large $|\tau|$ the exponential solutions with exponents $\approx s'\tau/(\varepsilon')^k$. If $\operatorname{Re} s' < 0$, then these exponents reach on the interval $[-\ell, \ell]$ the values of the order $\exp((\operatorname{Re} s)/\varepsilon^k \cdot \ell)$. Since these values have to be bounded, we must impose the bound in (3.134). In order to extend the estimates, we write $s = \operatorname{Im} s + \operatorname{Re} s$ and move the $O(\operatorname{Re} s)u$ terms in (3.2)(a),(b) to the r.h.s. of the equations. Note that the $O(s)u$ term in (3.2)(a) is

$$\begin{aligned} O(s)u &= (e^s - 1)dG_2(u) + O(s)(E_x - I)O(u) \\ &= (e^s - 1)u + (E_x - I)O(s)u + O(s^2)u, \end{aligned} \tag{3.135}$$

where $O(s^2)$ has constant coefficients. Hence, the contribution of the $O(\operatorname{Re} s)u$ term to the r.h.s. of (3.99) is bounded by

$$|\operatorname{Re} s| \left(\left\| \sum_\xi u(\xi) \right\|_1 + \|u\|_\infty \right) \leq \delta\varepsilon^k \|U\|_\infty \tag{3.136}$$

and is bounded by the l.h.s. of (3.100). In case $n_1 = 1$, $|s| \leq K\varepsilon^{k+1}$, the contribution of $O(\operatorname{Re} s)u$ to the r.h.s. of (3.130) is estimated as

$$\begin{aligned} &|\operatorname{Re} s| \left(\sigma \left\| \sum_\xi P_1 u(\xi) \right\|_1 + |s|\sigma \left\| \sum_\xi u(\xi) \right\|_1 + \|u\|_1 \right) \\ &\leq \left(\delta\sigma\varepsilon^k \left\| \sum_\xi P_1 u(\xi) \right\|_\infty + \delta\varepsilon^k \|u\|_\infty \right) \end{aligned} \tag{3.137}$$

and is bounded by the l.h.s. of (3.132). The contribution of $O(\operatorname{Re} s)u$ to the term $\|F\|_1$ in (3.133) is negligible. Clearly, for $\operatorname{Re} s$ as in (3.134) and $\ell \gg \varepsilon^{-1}$,

$$\varepsilon + |\operatorname{Im} s|^{1/(k+1)} \sim \varepsilon + |s|^{1/(k+1)}. \tag{3.138}$$

Thus, estimates (3.100), (3.132), (3.133) are valid also for s as in (3.134).

4. The basic stability estimate for the scalar problem. In this section we will prove the basic stability estimate (3.85) for problem (3.78), (3.81), (3.82). Let us first consider the analogous differential equation

$$\partial_\tau Y - MY = H, \tag{4.1}$$

where

$$M = \begin{pmatrix} 0 & 1 & & \\ & & \ddots & \\ & & & 1 \\ -\alpha_0' - \alpha_1' & & & -\alpha_k' \end{pmatrix}, \qquad M \approx \sigma^{-1} \log(I + \sigma M_1'), \quad M_1' \text{ in (3.78)}.$$

The coefficients $\alpha_i' \bmod O(\sigma)$ coincide with α_i' in (3.78). They depend analytically on $y_{sh}(\varepsilon'(\tau-\tau_0))$, s', ε', and σ and $\alpha_0' = (-1)^{\frac{k+1}{2}} s' + O(\sigma)$, $\alpha_1' = (-1)^{\frac{k+1}{2}} (\varepsilon')^k y_{sh} + O(\sigma)$, $\alpha_i' = O(\sigma)$, $i \geq 2$. Equation (4.1) is solved on interval $-\ell' \leq \tau \leq \ell'$ with boundary conditions at $\tau = \pm\ell'$,

$$Y_1 + O(\sigma)Y = g_0, \qquad Y_{d_i+2} + O(\sigma)Y = g_i, \qquad 1 \leq i \leq \frac{k-1}{2}. \tag{4.2}$$

The characteristic equation for (4.1) at $\tau = \pm\infty$ is correspondingly

$$(-1)^{\frac{k+1}{2}} \lambda^{k+1} \mp (\varepsilon')^k \lambda + s' + O(\sigma) = 0 \qquad \text{(see (3.84))} \tag{4.3}$$

(where $O(\sigma)$ depends also on λ, ε', s'). We consider the parameter vector $p = (\varepsilon', s', \sigma)$ in a neighborhood of a point $p_0 = (\varepsilon_0', s_0', 0)$, where

$$\varepsilon_0' + |b_1 s_0'|^{\frac{1}{k+1}} = 1, \qquad \varepsilon_0' > 0, \qquad \operatorname{Re} s_0' \geq 0 \qquad \text{(see (3.76))}. \tag{4.4}$$

If $s_0' \neq 0$, then the roots of (4.3) split into groups I and II with $\frac{k+1}{2}$ eigenvalues λ' correspondingly in the half-planes $\operatorname{Re}\lambda < 0$ or $\operatorname{Re}\lambda > 0$. If $s_0' = 0$, then there is a simple root λ_0 near 0. In order for $\operatorname{Re}\lambda_0 \neq 0$, we should assume that $\operatorname{Re} s \geq 0$ and $\sigma \geq 0$. In order to get an estimate for (4.1), (4.2), we split the interval $(-\ell', \ell')$ into three subintervals $(-\ell', -\ell_0')$, $(-\ell_0', \ell_0')$, (ℓ_0', ℓ'). We will assume that $\ell' \geq \delta_0^{-1}$ (as in (1.11), (1.12)) and could be arbitrarily large. The number ℓ_0' will be specified in what follows. On the interval $[\ell_0', \ell']$ we consider (4.1) as a perturbation of a constant coefficient problem

$$\partial_\tau Y - M(\infty)Y = \Delta M Y + H = F, \qquad \Delta M = M - M(\infty). \tag{4.5}$$

At $\tau = \ell'$ we impose the boundary conditions (4.2). At $\tau = \ell_0'$ the boundary condition is

$$P_{I}(\tau)Y = g^{(0)}, \qquad \tau = \ell_0', \tag{4.6}$$

where $P_{I}(\tau)$ is an orthogonal projection on the $\frac{k+1}{2}$ dimensional subspace $V_{I}(\tau)$ of exponentially decreasing solutions of (4.1). Note that the "near zero" root λ_0 belongs to group II. The interval $[-\ell', -\ell_0']$ is treated in a similar way. The solution of problem (4.5), (4.6), (4.2) on $[\ell_0', \ell']$ and $[-\ell', \ell_0']$ will be expressed as

$$Y = G_1\Big(H, g(\ell'), g^{(0)}(\ell_0')\Big), \qquad Y = G_{-1}\Big(H, g(-\ell'), g^{(0)}(-\ell_0')\Big). \tag{4.7}$$

On the interval $[-\ell_0', \ell_0']$, (4.1) is solved as an initial value problem. Thus we obtain

$$Y(\ell_0') = G_0\Big(H, Y(-\ell_0')\Big). \tag{4.8}$$

Finally, we substitute the values of $Y(-\ell_0')$, $Y(\ell_0')$ from (4.7) into (4.8) and obtain a system of $k+1$ equations for $k+1$ unknown components of $g^{(0)}(\ell_0') \in V_{I}(\ell_0')$ and $g^{(0)}(-\ell_0') \in V_{II}(-\ell_0')$. This is the idea. To carry it through we should get bounds on G_1, G_{-1} and prove solvability of (4.8).

LEMMA 4.1. *The solution $Y = G_1(F, g(\ell'), g^{(0)}(\ell_0'))$ satisfies the estimate*

$$\|Y\|_\infty \leq K\Big(\|H\|_1 + |g| + |g^{(0)}|\Big), \tag{4.9}$$

where K is independent of ℓ'. For $H = 0$, $g(\ell') = 0$ the boundary value $Y(\ell'_0)$ is

$$Y(\ell'_0) = g^{(0)}(\ell'_0)\Big(1 + O(e^{-\delta(\ell'-\ell'_0)})\Big), \qquad \delta > 0 \text{ a constant.} \tag{4.10}$$

Proof. Without loss of generality, one can assume that $M(\infty)$ is in the block form $M(\infty) = M_{I} \oplus M_{II}$, where $\operatorname{Re} M_{I} < -\delta I$ and $\operatorname{Re} M_{II} \geq 0$. Similarly, we partition $Y = (Y_{I}, Y_{II})$, H, and F. First find a particular solution of (4.5) with boundary condition $Y_{I}(\ell'_0) = 0$, $Y_{II}(\ell') = 0$. Then

$$\frac{1}{2}|Y_{II}(\tau)|^2 + \int_{\tau}^{\ell'} (\operatorname{Re} M_{II}\, Y_{II}, Y_{II})d\tau = -\int_{\tau}^{\ell'} (F_{II}, Y_{II})d\tau \tag{4.11}$$

and similarly for Y_{I}. Thus

$$\tfrac{1}{2}\|Y\|_{\infty} \leq \|F\|_1 \leq \|H\|_1 + \|\Delta M\|_1 \|Y\|_{\infty}. \tag{4.12}$$

Recall that $\Delta M = O(y_{sh}(\varepsilon'(\tau - \tau_0)) - 1) = O(e^{-\delta_1(\tau-\tau_0)})$. We should choose ℓ'_0 sufficiently large so that for $\tau > \ell'_0$, $\|\Delta M\|_1 \leq \frac{1}{4}$. Thus we find a particular solution $Y^{(1)}$ such that

$$\|Y^{(1)}\|_{\infty} \leq 4\|H\|_1. \tag{4.13}$$

Now we solve the homogeneous equation $\partial_\tau Y - MY = 0$ with original boundary conditions. For Y_{II}, instead of (4.11), we obtain

$$\tfrac{1}{2}\|Y_{II}\|_{\infty}^2 \leq \|\Delta M\|_1 \|Y\|_{\infty}^2 + \tfrac{1}{2}|Y_{II}(\ell')|^2. \tag{4.14}$$

The equation for Y_{I} is multiplied by $\exp(\delta_2(\tau - \ell'_0))$, $\delta_2 < \min(\delta, \delta_1)$, and integrated. Then, instead of (4.14) we obtain

$$\begin{aligned} &\tfrac{1}{2}\Big\|Y_{I} \exp\Big(\delta_2(\tau - \ell'_0)\Big)\Big\|_{\infty}^2 \\ &\quad \leq \Big\|\Delta M \exp\Big(\delta_2(\tau - \ell'_0)\Big)\Big\|_1 \|Y\|_{\infty} \Big\|Y_{I} \exp\Big(\delta_2(\tau - \ell'_0)\Big)\Big\|_{\infty} \\ &\qquad + \tfrac{1}{2}|Y_{I}(\ell'_0)|^2 \ . \end{aligned} \tag{4.15}$$

Since ΔM decays faster than $\exp(\delta_2(\tau - \ell'_0))$ grows, we may assume also that $\|\Delta M \exp \delta_2(\tau - \ell'_0)\|_1$ is small. Since the boundary condition in (4.2) is Lopatinsky well posed at $\tau = \infty$, we can express

$$Y_{II}(\ell') = O(g) + O\Big(Y_{I}(\ell') \exp \delta_2(\ell' - \ell'_0)\Big) \exp\big(-\delta_2(\ell' - \ell'_0)\big). \tag{4.16}$$

From (4.6) we obtain

$$Y_{I}(\ell'_0) = O(g^{(0)}) + O\Big(Y_{II}(\ell'_0)\Big). \tag{4.17}$$

Indeed, $P_{I}(\ell'_0) = P_{I}(\infty) + O(\exp(-\delta_2 \ell'_0))$, while $P_{I}(\infty)$ acts as an identity on the Y_{I} component. Substitute (4.16), (4.17) into (4.14), (4.15), multiply (4.14) by $c \gg 1$, and add the result to (4.15). For large $\delta_2(\ell' - \ell'_0)$ the contribution of Y_{I} in (4.16) is negligible relative to the l.h.s. of (4.15). Hence

$$\Big\|Y_{I} \exp\Big(\delta_2(\tau - \ell'_0)\Big)\Big\|_{\infty} + \|Y_{II}\|_{\infty} \leq K\Big(|g| + |g^{(0)}|\Big). \tag{4.18}$$

The above g, $g^{(0)}$ are also affected by the solution $Y^{(1)}$ estimated in (4.13). Altogether the sum of the two solutions solves the original problem and satisfies estimate (4.9). In order to prove (4.10), we take an approximate solution $Y^{(1)} \in V_{I}$ with $Y^{(1)}(\ell_0') = g^{(0)}$. Since it decays exponentially, its contribution to the boundary condition at ℓ' is $O(\exp(-\delta(\ell' - \ell_0')))$. By estimate (4.9) we bound the correction to $Y^{(1)}$.

Now, return to (4.8):

$$\begin{aligned} &G_1\Big(H, g(\ell'), 0\Big) + g^{(0)}(\ell_0')\Big(1 + O\Big(\exp(-\delta(\ell' - \ell_0'))\Big)\Big) \\ &\quad = G_0\Big(H, G_{-1}(H, g(-\ell'), 0)\Big) \\ &\qquad + G_0\Big(0, g^{(0)}(-\ell_0')\Big(1 + O\Big(\exp(-\delta(\ell' - \ell_0'))\Big)\Big)\Big). \end{aligned} \tag{4.19}$$

Since ℓ_0' is fixed, G_0 is a bounded map. The vectors $g^{(0)}(\ell_0') \in V_{I}(\ell_0')$, $g^{(0)}(-\ell_0') \in V_{II}(-\ell_0')$. By the continuous stability hypothesis, $G_0(0, V_{II}(-\ell_0'))$ is transversal to $V_{I}(-\ell_0')$ for the value of parameter $p = p_0$. Otherwise equation $\partial_\tau Y - MY = 0$ or, equivalently, (2.22), would have a nontrivial solution which decays asymptotically at infinity. Since $\exp(-\delta(\ell' - \ell_0'))$ is small, the problem in (4.19) is boundedly solvable with respect to $g^{(0)}(\ell_0')$, $g^{(0)}(-\ell_0')$. The corresponding function Y solves the boundary value problem (4.1), (4.2) and satisfies the estimate

$$\|Y\|_\infty \le K\Big(\|H\|_1 + |g|\Big). \tag{4.20}$$

Remark 5. If $s_0' \ne 0$, then we may assume also that $\operatorname{Re} M_{II} > \delta I$. Then instead of (4.12) we can obtain a stronger estimate $\|Y\|_p + \|Y\|_\infty \le K(\|H\|_p + \|H\|_\infty)$, $p = \infty, 1$, and therefore a final estimate will be

$$\|Y\|_p + \|Y\|_\infty \le K\Big(\|H\|_p + \|H\|_\infty + |g|\Big), \qquad p = \infty, 1. \tag{4.21}$$

Now return to the discrete problem (3.78), (3.81), (3.82). We solve it exactly as the continuous one. The space $V_{I}(\tau)$ is replaced by the corresponding space $V_{I}'(\tau)$ of decreasing solutions of (3.78), and the projection P_{I} by a projection P_{I}' on $V_{I}'(\tau)$. The difference equation (3.78) is rewritten as

$$\begin{aligned} &\text{(a)} \quad E_\tau Y_{I}' - (I + \sigma M_{I}')Y_{I}' = \sigma H_{I}' + \sigma O(\Delta M')Y' = \sigma F_{I}', \\ &\text{(b)} \quad E_\tau Y_{II}' - (I + \sigma M_{II}')Y_{I}' = \sigma H_{II}' + \sigma O(\Delta M')Y' = \sigma F_{II}'. \end{aligned} \tag{4.22}$$

(For brevity we dropped the subscript 1 in (3.78).) Here $(I + \sigma M_{I}')^*(I + \sigma M_{I}') \le (1 - 2\delta)I$, $(I + \sigma M_{II}')^*(I + \sigma M_{II}') \ge I$. Multiply both sides of (4.22)(a) by $E_\tau Y_{I}' + (I + \sigma M_{I}')Y_{I}'$ and sum from ℓ_0' until τ and similarly for (4.22)(b). Instead of (4.12), (4.13), we obtain the estimate $\|Y'\|_\infty \le K\|F'\|_{1,\sigma}$ and $\|Y'^{(1)}\|_\infty \le K\|H'\|_{1,\sigma}$. The rest of the proof of Lemma 4.1 is repeated word for word. Now we arrive at the functional equation (4.19). The operator G_0 is replaced by the solution operator G_0' of the difference equation. By the standard convergence theorem for the Euler method, it follows that G_0' approximates G_0 as $\sigma \to 0$. Similarly, the stable manifold $V_{I}'(\ell_0')$ approximates $V_{I}(\ell_0')$ as $\sigma \to 0$. This result is less standard; e.g., see Theorem 5.3 in [7]. Then by continuity, G_0' maps $V_{II}'(-\ell_0')$ transversally to the subspace $V_{I}'(\ell_0')$. Finally, we obtain the estimate

$$\|Y_1'\|_\infty \le K\Big(\|H_1'\|_{1,\sigma} + |g'|\Big), \tag{4.23}$$

and in case $|s_0'| \neq 0$,

$$\|Y_1'\|_{p,\sigma} + \|Y_1'\|_\infty \leq K\Big(\|H_1'\|_{p,\sigma} + \|H_1'\|_\infty + |g'|\Big), \qquad p = 1, \infty. \tag{4.24}$$

5. Existence of stationary shocks. In [7] we proved existence of stationary discrete shocks on the whole line. In this section we will prove Theorem 2.1 about existence of an n_1 parameter family of stationary shocks on the interval $[-\ell, \ell]$. Unlike the nonstationary case, we also will treat the case $1 < n_1 < n$. The n_1 parameters are the components of the vector

$$P\sum_x G_2\Big(\{E_x^j u_{st}(x)\}\Big) = g_{\text{sum}}. \tag{5.1}$$

The function u_{st} satisfies the equation

$$G_1\Big(\{E_x^j u_{st}(x)\}\Big) = \text{const}. \tag{5.2}$$

We will represent this constant as a value $f(u_{_L} + \Delta u_{_L})$ and look for the solution in the form

$$u_{st} = u_{sh}\Big(\varepsilon(x - x_0), u_{_L} + \Delta u_{_L}\Big) + \Delta u_{st}. \tag{5.3}$$

Here $u_{sh}(\varepsilon(x - x_0), u_{_L} + \Delta u_{_L})$ is defined as in (2.86), namely,

$$\begin{aligned} u_{sh}\Big(\varepsilon(x - x_0), u_{_L} + \Delta u_{_L}\Big) &= \tfrac{1}{2}(u_{_L} + \Delta u_{_L} + u_{_R} + \Delta u_{_R}) \\ &+ \tfrac{1}{2}(u_{_L} + \Delta u_{_L} - u_{_R} - \Delta u_{_R}) y_{sh}\Big(\varepsilon(x - x_0)\Big), \\ \varepsilon &= \Big(\lambda_1(u_{_L} + \Delta u_{_L})\Big)^{1/k}, \end{aligned} \tag{5.4}$$

$\Delta u_{_R}$ is defined uniquely by the equation

$$f(u_{_L} + \Delta u_{_L}) = f(u_{_R} + \Delta u_{_R}), \tag{5.5}$$

and y_{sh} is a solution of (2.23). Then, by boundary condition (2.13),

$$P\Big(f(u_{_L} + \Delta u_{_L}) - f(u_{_L})\Big) = 0. \tag{5.6}$$

The remaining boundary conditions are

$$S_{_{L,1}}\Big(\{E_x^j u_{st}(x_{-\ell})\}, u_{_L}\Big) = 0, \qquad S_{_{R,1}}\Big(\{E_x^j u_{st}(x_\ell), u_{_R}\Big) = 0 \tag{5.7}$$

and

$$S_{_{L,2}}\Big(\{E_x^j u_{st}(x_{-\ell})\}, u_{_L}\Big) = 0, \qquad S_{_{R,2}}\Big(\{E_x^j u_{st}(x_\ell), u_{_R}\Big) = 0 \tag{5.8}$$

(see (2.7), (2.26)(b),(c)). Equation (5.2) will be rewritten as

$$dG_1[u_{sh}]\Delta u_{st} = f(u_{_L} + \Delta u_{_L}) - G_1\Big(\{E_x^j u_{sh}(\cdot, u_{_L} + \Delta u_{_L})\}\Big) + O(\Delta u_{st})^2 = F. \tag{5.9}$$

It is easy to see that for u_L, u_R as in (2.10),

$$\begin{aligned} &P_1\Big(f(u_L) - G_1\Big(\{E_x^j u_{sh}(\varepsilon x, u_L)\}\Big)\Big) = O(\varepsilon\mu^2),\\ &(I-P_1)\Big(f(u_L) - G_1\Big(\{E_x^j u_{sh}(\varepsilon x, u_L)\}\Big)\Big) = O(\mu^2). \end{aligned} \tag{5.10}$$

Note that by consistency, the r.h.s. of (5.10) vanishes at $\varepsilon x = \pm\infty$ so that actually $O(\varepsilon\mu^2)$, $O(\mu^2)$ are multiplied by an exponent of the type $e^{-\varepsilon\delta|x|}$. The above result is obviously valid if we replace u_L by $u_L + \Delta u_L$ and μ by $\lambda_1(u_L + \Delta u_L)$. However, the projectors P_1 and $(I - P_1)$ depend on the point $u_0 = u_0(u_L)$. If we change u_L to $u_L + \Delta u_L$ and do not change P_1 and $I - P_1$, then the correct formula will be

$$\begin{aligned} &\text{(a) } P_1\Big(f(u_L+\Delta u_L) - G_1\Big(\{E_x^j u_{sh}(\varepsilon x, u_L+\Delta u_L)\}\Big)\Big),\\ &\qquad = O\Big(\varepsilon\lambda_1^2(u_L+\Delta u_L)\Big) + O\Big(\lambda_1^2(u_L+\Delta u_L)\Big)O(\Delta u_L),\\ &\text{(b) } (I-P_1)\Big(f(u_L+\Delta u_L) - G_1\Big(\{E_x^j u_{sh}(\varepsilon x, u_L+\Delta u_L)\}\Big)\Big)\\ &\qquad = O\Big(\lambda_1^2(u_L+\Delta u_L)\Big). \end{aligned} \tag{5.11}$$

The contribution of $\Delta u_{sh} = u_{sh}(\varepsilon(x-x_0), u_L + \Delta u_L) - u_{sh}(\varepsilon x, u_L)$ to (5.1) is

$$\begin{aligned} \sum_x G_2\Big(\{E_x^j \Delta u_{sh}\}\Big) &= (\Delta u_L + \Delta u_R)\Big(\ell + O(1)\Big)\\ &\quad + (u_L + \Delta u_L - u_R - \Delta u_R)x_0\left(1 + O\left(\frac{e^{-\varepsilon\delta\ell}(1 - e^{-x_0\delta\varepsilon})}{x_0\varepsilon}\right)\right)\\ &= (\Delta u_L + \Delta u_R)\Big(\ell + O(1)\Big)\\ &\quad + (u_L + \Delta u_L - u_R - \Delta u_R)x_0\Big(1 + O(e^{-\varepsilon\delta\ell})\Big). \end{aligned} \tag{5.12}$$

The correspondence $u_R = u_R(u_L)$ is given by an invariant formula

$$u_R = u_L - 2\lambda_1(u_L)e_1(u_L) + O\Big(\lambda_1(u_L)\Big)^2, \tag{5.13}$$

where $e_1(u_L)$ is the eigenvector of $df[u_L]$ corresponding to $\lambda_1(u_L)$ and normalized so that

$$\nabla\lambda_1(u_L)\cdot e_1(u_L) = 1. \tag{5.14}$$

Hence

$$\begin{aligned} (P-P_1)(\Delta u_L + \Delta u_R) &= (P-P_1)2\Delta u_L + O\Big(\lambda_1(u_L)\Big)\Delta u_L,\\ (P-P_1)(u_L + \Delta u_L - u_R - \Delta u_R) &= O\Big(\lambda_1(u_L)\Big)^2 + O\Big(\lambda_1(u_L)\Big)\Delta u_L, \end{aligned} \tag{5.15}$$

$$\begin{aligned} P_1(\Delta u_L + \Delta u_R) &= 2P_1\Delta u_L - 2\Big(\nabla\lambda_1(u_L), \Delta u_L\Big) + O\Big(\lambda_1(u_L)\Big)\Delta u_L,\\ P_1(u_L + \Delta u_L - u_R - \Delta u_R) &= 2\lambda_1(u_L) + 2\Big(\nabla\lambda_1(u_L), \Delta u_L\Big)\\ &\quad + O\Big(\lambda_1(u_L)\Big)^2 + O\Big(\lambda_1(u_L)\Big)\Delta u_L. \end{aligned} \tag{5.16}$$

By (5.6) one can express $P\Delta u_{_L}$ as a function of $(I-P)\Delta u_{_L}$. Namely,

$$P\Big(df[u_{_L}]\Delta u_{_L}+O(\Delta u_{_L})^2\Big)=0, \tag{5.17}$$

where $df[u_{_L}]=T\,\mathrm{diag}(\lambda_1(u_{_L}),\lambda_2(u_{_L}),\dots,\lambda_n(u_{_L}))T^{-1}$ and $T=I+O(\mu)$. Note that the entry $(df[u_{_L}])_{11}$ is $\lambda_1(u_{_L})+O(\mu^2)=O^*(\mu)$. If $\Delta u_{_L}/\mu$ is small, then one can write the solution of (5.17) as

$$\begin{aligned}(P-P_1)\Delta u_{_L}&=O(\mu)\Big(O(P_1\Delta u_{_L})+O\Big((I-P)\Delta u_{_L}\Big)\Big),\\ P_1\Delta u_{_L}&=O\Big((I-P)\Delta u_{_L}\Big).\end{aligned} \tag{5.18}$$

From (5.1), (5.12), (5.15), (5.16), and (5.18) we obtain for Δu_{st} the integral relations

$$\begin{aligned}&(P-P_1)\sum_x G_2\Big(\{E_x^j\Delta u_{st}(x)\}\Big)\\ &\quad=(P-P_1)\Big(g_{\rm sum}-\sum_x G_2\Big(\{E_x^j u_{sh}(\varepsilon x,u_{_L})\}\Big)\Big)\\ &\qquad+O(\mu)\Big(\ell+O(1)\Big)(I-P)\Delta u_{_L}\\ &\qquad+\Big(O(\mu^2)+O(\mu)(I-P)\Delta u_{_L}\Big)x_0\Big(1+O(1)\Big)=\tau_-;\end{aligned} \tag{5.19}$$

$$\begin{aligned}&P_1\sum_x G_2\Big(\{E_x^j\Delta u_{st}(x)\}\Big)\\ &\quad=P_1\Big(g_{\rm sum}-\sum_x G_2\Big(\{E_x^j u_{sh}(x)\}\Big)\Big)\\ &\qquad+\ell\Big(1+o(1)\Big)O\Big((I-P)\Delta u_{_L}\Big)+x_0\Big(1+o(1)\Big)\\ &\qquad\cdot\Big(2\lambda_1(u_{_L})+2\Big(\nabla\lambda_1(u_{_L}),\Delta u_{_L}\Big)+O(\mu^2)+O(\mu\Delta u_{_L})\Big).\end{aligned} \tag{5.20}$$

The remaining boundary conditions for Δu_{st} follow from (5.7), (5.8),

$$dS_{_{L,1}}\Big(\{E_x^j\Delta u_{st}(x_{-\ell})\}\Big)=-S_{_{L,1}}\Big(\{E_x^j u_{sh}(x_{-\ell})\},u_{_L}\Big)+O(\Delta u_{st})^2 \tag{5.21}$$

and similarly for $dS_{_{R,1}}$, $dS_{_{L,2}}$, $dS_{_{R,2}}$. By the consistency assumption in (2.8),

$$S_{_L}\Big(\{E_x^j u_{sh}(x_{-\ell})\},u_{_L}\Big)=dS_{_L}\Delta u_{_L}+O(\Delta u_{_L})^2+O(e^{-\delta\varepsilon\ell})\Big(O(\mu)+O(\Delta u_{_L})\Big) \tag{5.22}$$

and similarly for the right boundary. Note that by (5.4) and (5.13), $(I-P_1)(u_{sh}-u_{_L}-\Delta u_{_L})=(O(\mu^2)+O(\mu\Delta u_{_L}))(y_{sh}-1)$. Hence by (2.30),

$$\begin{aligned}&S_{1j}\Big(\{E_x^j u_{sh}(x_{-\ell})\}\Big)\\ &\quad=dS_{1j}(I-P_1)\Delta u_{_L}+O(\varepsilon^{d_j}e^{-\delta\varepsilon\ell})\Big(O(\mu)+O(\Delta u_{_L})\Big)+O(\Delta u_{_L})^2\ .\end{aligned} \tag{5.23}$$

Similarly, by (2.34),

$$
\begin{aligned}
&S_2\Big(\{E_x^j u_{sh}(x_{-\ell})\}\Big)\\
&\qquad = dS_2(I-P_1)\Delta u_{\scriptscriptstyle L} + O(\varepsilon^k e^{-\delta\varepsilon\ell})\Big(O(\mu)+O(\Delta u_{\scriptscriptstyle L})\Big) + O(\Delta u_{\scriptscriptstyle L})^2\ .
\end{aligned}
\tag{5.24}
$$

We will solve (5.9) with constraints (5.18), (5.19), (5.21). Instead of fixing $g_{\rm sum}$ we will assume that τ_- in (5.19) and x_0 are given. The solution Δu_{st}, $\Delta u_{\scriptscriptstyle L}$ will thus depend on τ_- and (implicitly) on x_0. Then $(P-P_1)g_{\rm sum}$ will be determined by (5.19) and $P_1 g_{\rm sum}$ by (5.20). This way we can overcome the restriction $\ell\varepsilon^k \ll 1$. However, we need this restriction in order to obtain one-to-one correspondence between $g_{\rm sum}$ and τ_-, x_0.

In order to solve (5.9) we proceed as in section 3. Namely, transform the variables

$$
\Delta\widetilde{u}_{st}(x) = \Big(\Delta u_{st}(x), \dots, E_x^{\nu_0-1}\Delta u_{st}(x)\Big)^{\scriptscriptstyle T} = X\Big(\eta(x)\Big)y(x),
\tag{5.25}
$$

where $\eta(x) = u_{sh}(\varepsilon(x-x_0), u_{\scriptscriptstyle L}+\Delta u_{\scriptscriptstyle L})$. Then (5.9) becomes

$$
\begin{aligned}
&\begin{pmatrix} E_x - M_1 & 0 & 0\\ 0 & E_x - M_{\scriptscriptstyle I} & 0\\ 0 & 0 & E_x - M_{\scriptscriptstyle II}\end{pmatrix} y\\
&\qquad = T^{-1}\Big(\widetilde{F} - A\Big((E_x - I)X\Big)E_x y\Big) = H.
\end{aligned}
\tag{5.26}
$$

Here we have $\widetilde{F} = (0,\dots,0,F)^{\scriptscriptstyle T}$ as in (3.17), A as in (3.18), and $M_{\scriptscriptstyle I}$, $M_{\scriptscriptstyle II}$ as in (3.26). Since the operator dG_1 is $dG(s=0)/(E_x - I)$, the matrix M_1 in (5.26) is nothing but the lower $k\times k$ block of the matrix M_1 in (3.50). Namely,

$$
M_1 = I + \begin{bmatrix} 0 & 1 & & & \\ & 0 & 1 & & \\ \vdots & & & \ddots & \\ 0 & & & & 1\\ -\alpha_1 & & & & -\alpha_k\end{bmatrix},
\tag{5.27}
$$

where $\alpha_i = \alpha_i(\eta, s=0)$ as in (3.43). The characteristic equation

$$
\det(M_1 - \kappa I) = (\kappa-1)^k + \sum_{i=1}^{k}\alpha_i(\eta)(\kappa-1)^{i-1} = 0
\tag{5.28}
$$

at $\varepsilon x = \pm\infty$ has roots

$$
\kappa = 1 + \varepsilon(\pm 1)^{1/k} + O(\varepsilon^2).
\tag{5.29}
$$

Unlike (4.3), now the values of $\lambda = \varepsilon^{-1}\log\kappa$ are away from the imaginary line $\operatorname{Re}\lambda = 0$. In such a situation, instead of (4.23) we have a stronger estimate (4.24). Let us first find $y_{\scriptscriptstyle I}$, $y_{\scriptscriptstyle II}$. As in (3.64), we represent $y_{\scriptscriptstyle I} = c_{\scriptscriptstyle I}\varphi_{\eta,{\scriptscriptstyle I}} + \mathring{y}_{\scriptscriptstyle I}$ and similarly for $y_{\scriptscriptstyle II}$. For $\mathring{y}_{{\scriptscriptstyle I},{\scriptscriptstyle II}}$ we have the estimate

$$
\|\mathring{y}_{\scriptscriptstyle I}\|_1 + \|\mathring{y}_{\scriptscriptstyle II}\|_1 \le K\Big(\|H_{\scriptscriptstyle I}\|_1 + \|H_{\scriptscriptstyle II}\|_1\Big).
\tag{5.30}
$$

As in (3.68), the coefficients $c_{I,II}$ are determined by the boundary conditions (5.19) (with given τ_-) and (5.21) (with $(dS_{L,2}, dS_{R,2}) = dS_2$ instead of $dS_{L,1}$). The vector $(I-P)\Delta u_L$ plays the role of c_j, $n_1 < j \le n$. By the generalized stability condition for the system (2.40), (2.41), (2.44) (with $\rho \equiv 1$), these boundary conditions are uniquely solvable in terms of $c_{I,II}$, $(I-P)\Delta u_L$. We should merely collect all terms which contribute to the r.h.s. of these equations. In view of (2.35), the contribution of y_1 to (5.19) is estimated

$$\left|(P-P_1)\Big(\sum_x e_1 y_{1,1}(x) + \sum O(\eta) y_1(x)\Big)\right| \le K\varepsilon^k \|y_1\|_1. \tag{5.31}$$

Notice that because of the reduction of order, the vectors $X_{1,i}(0)$ in (3.48), $1 \le i \le k$, are not affected by C_{10}. The contribution of y_1 to $dS_2 \cdot \Delta u_{st}$ is estimated as in (3.73) and is bounded by

$$K\Big(\|(E_x - I)^k y_1\|_\infty + \varepsilon^k \|y_1\|_\infty\Big). \tag{5.32}$$

The contribution of the particular solution $\mathring{y}_{I,II}$ to (5.19) is bounded by $K(\|H_I\|_1 + \|H_{II}\|_1)$. The nonhomogeneous terms in (5.19) and (5.24) are the ones which do not include Δu_L (since Δu_L depends on $(I-P)\Delta u_L$). Thus we obtain the estimate

$$\begin{aligned} &\|y_I\|_1 + \|y_{II}\|_1 + |\Delta u_L| + \mu^{-1}|(P-P_1)\Delta u_L| \\ &\quad \le K\Big(\|H_I\|_1 + \|H_{II}\|_1 + \varepsilon^k \|y_1\|_1 + \|(E_x - I)^k y_1\|_\infty \\ &\qquad + |\tau_-| + \varepsilon^{2k} e^{-\delta\varepsilon\ell} + |\Delta u_L|^2 + \|\Delta u_{st}\|_\infty^2\Big). \end{aligned} \tag{5.33}$$

For y_1 we have the estimate

$$\begin{aligned} &\sum_{i+j\le k+1} \Big(\|D_\tau^i y'_{1,j}\|_{1,\varepsilon} + \|D_\tau^i y'_{1,j}\|_\infty\Big) \\ &\quad \le K\Bigg(\sum_{i+j\le k} \|D_\tau^i H'_{1,j}\|_{1,\varepsilon} + \sum \varepsilon^{-d_j} |dS_{1j}(I-P_1)\Delta u_L| \\ &\qquad + O(e^{-\delta\varepsilon\ell}\mu) + O(e^{-\delta\varepsilon\ell}\Delta u_L) + \varepsilon^{-(k-1)}\Big(\|\Delta u_{st}\|_\infty^2 + |\Delta u_L|^2\Big)\Bigg), \end{aligned} \tag{5.34}$$

where $y'_{1,j} = \varepsilon^{-j+1} y_{1,j}$, $H'_{1,j} = \varepsilon^{-j} H_{1,j}$. Multiply (5.34) by $K_1 \varepsilon^{k-1}$, where $K_1 \gg K$, and add to (5.33). We obtain

$$\begin{aligned} &\|y_{I,II}\|_1 + \varepsilon^{k-1} \sum_{i+j\le k+1} \Big(\|D_\tau^i y'_{1,j}\|_{1,\varepsilon} + \|D_\tau^i y'_{1,j}\|_\infty\Big) \\ &\qquad + |\Delta u_L| + \mu^{-1}|(P-P_1)\Delta u_L| \\ &\quad \le K\Bigg(\|H_{I,II}\|_1 + \varepsilon^{k-1} \sum_{i+j\le k} \|D_\tau^i H'_{1,j}\|_{1,\varepsilon} + |\tau_-| \\ &\qquad + \varepsilon^{2k-1} e^{-\delta\varepsilon\ell} + \|\Delta u_{st}\|_\infty^2 + |\Delta u_L|^2\Bigg). \end{aligned} \tag{5.35}$$

The terms $K\varepsilon^k\|y_1\|_1 = K\varepsilon^{k-1}\|y_1\|_{1,\varepsilon}$ and $K\|(E_x - I)^k y_1\|_\infty = K\varepsilon^k\|D_\tau^k y_1\|_\infty$ are majorated by $K_1\varepsilon^{k-1}$ times the l.h.s. of (5.34). In the case $1 < n_1 < n$ we have assumed that $d_j \le k-2$; hence $\varepsilon^{k-1}\varepsilon^{-d_j}O(\Delta u_{_L})$ is negligible. The terms with H_1' are bounded by

$$\varepsilon^{k-1}\|D_\tau^i H'\|_{1,\varepsilon} = \varepsilon^k\|D_\tau^i H'_{1,j}\|_1 \le \|H_{1,j}\|_1. \tag{5.36}$$

The contribution of y to $\|H\|_1$ is bounded by

$$\|O(\eta')y\|_1 \le K\varepsilon^k\|y\|_\infty \tag{5.37}$$

and is negligible compared with the l.h.s. of (5.35). Thus in $\|H\|_1$ we are left with $\|F\|_1$, where F is defined in (5.9). Recall that the r.h.s. of (5.11) is actually multiplied by $e^{-\varepsilon\delta|x|}$. Hence

$$\begin{aligned}\|F\|_1 &\le K\Big(\varepsilon^{-1}|\lambda_1^2(u_{_L} + \Delta u_{_L})| + \|(\Delta u_{st})^2\|_1\Big)\\ &\le K\Big(\varepsilon^{2k-1} + \varepsilon^{-1}|\Delta u_{_L}|^2 + \|\Delta u_{st}\|_\infty\|\Delta u_{st}\|_1\Big).\end{aligned} \tag{5.38}$$

The biggest nonhomogeneous term on the r.h.s. of (5.35) is $K\varepsilon^{2k-1}$ in (5.38). Thus we will assume that

$$|\tau_-| \le K\varepsilon^{2k-1}. \tag{5.39}$$

From (5.35) we obtain the estimate for Δu_{st}:

$$\begin{aligned}&\|(I-P_1)\Delta u_{st}\|_1 + \varepsilon^{k-1}\|P_1\Delta u_{st}\|_\infty\\ &\quad+\varepsilon^k\|P_1\Delta u_{st}\|_1 + \varepsilon^{k-1}\|P_1(E_x - I)\Delta u_{st}\|_1\\ &\quad+|\Delta u_{_L}| + \mu^{-1}|(P-P_1)\Delta u_{_L}|\\ &\le K\Big(\varepsilon^{2k-1} + \varepsilon^{-1}|\Delta u_{_L}|^2 + \|\Delta u_{st}\|_\infty\|\Delta u_{st}\|_1\Big).\end{aligned} \tag{5.40}$$

Unfortunately, the last estimate is too weak since it gives the bounds $\|P_1\Delta u_{st}\|_\infty = O(\varepsilon^k)$, $\|P_1\Delta u_{st}\|_1 = O(\varepsilon^{k-1})$, and hence the $\|\Delta u_{st}\|_\infty \cdot \|\Delta u_{st}\|_1$ term is not negligible. Therefore, return to estimate (5.34). We remark that by Lemma 3.1 the components $(I-P_1)F$ in (5.9) affect $H_{1,k}$ in (5.34) as $O(\mu)(I-P_1)F$. By (5.11),

$$\|\varepsilon(I-P_1)F\|_1 + \|P_1F\|_1 \le K\Big(\varepsilon^{2k} + \varepsilon^{2k-1}|\Delta u_{_L}| + \|(\Delta u_{st})^2\|_1\Big). \tag{5.41}$$

Multiply estimate (5.34) by $\delta_1\varepsilon^{k-2}$, where δ_1 is a small constant, and add the result to (5.33). We obtain

$$\begin{aligned}&\|y_{_{I,II}}\|_1 + \delta_1\varepsilon^{k-2}\sum_{i+j\le k+1}\Big(\|D_\tau^i y'_{1,j}\|_{1,\varepsilon} + \|D_\tau^i y'_{1,j}\|_\infty\Big)\\ &\quad+|\Delta u_{_L}| + \mu^{-1}|(P-P_1)\Delta u_{_L}|\\ &\le K\Bigg(\|H_{_{I,II}}\|_1 + \delta_1\varepsilon^{k-2}\sum_{i+j\le k}\|D_\tau^i H'_{1,j}\|_{1,\varepsilon} + |\tau_-| + \varepsilon^{2k}e^{-\delta\varepsilon\ell}\\ &\quad+\delta_1|\Delta u_{_L}| + \delta_1 e^{-\delta\varepsilon\ell}\varepsilon^{2k-2} + \varepsilon^{-1}\delta_1\Big(\|\Delta u_{st}\|_\infty^2 + |\Delta u_{_L}|^2\Big)\Bigg)\\ &\le K\Big(\varepsilon^{2k-1} + \delta_1 e^{-\delta\varepsilon\ell}\varepsilon^{2k-2} + \delta_1|\Delta u_{_L}|\\ &\qquad+\varepsilon^{-1}|\Delta u_{_L}|^2 + \delta_1\varepsilon^{-1}\|\Delta u_{st}\|_1\|\Delta u_{st}\|_\infty + \delta_1\varepsilon^{k-1}\|y\|_\infty\Big).\end{aligned} \tag{5.42}$$

Now instead of (5.40) we obtain the estimate

$$\begin{aligned}&\|(I-P_1)\Delta u_{st}\|_1+\varepsilon^{k-1}\|P_1\Delta u_{st}\|_1+\varepsilon^{k-2}\|P_1\Delta u_{st}\|_\infty\\&\quad+\varepsilon^{k-2}\|P_1(E_x-I)\Delta u_{st}\|_1+|\Delta u_{_L}|+\mu^{-1}|(P-P_1)\Delta u_{_L}|\\&\quad\le K\Big(\varepsilon^{2k-1}+e^{-\delta\varepsilon\ell}\varepsilon^{2k-2}+\varepsilon^{-1}\|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty\\&\qquad+\varepsilon^{-1}|\Delta u_{_L}|^2+|\tau_-|\Big).\end{aligned}\tag{5.43}$$

If $\varepsilon\ell\gg 1$ then, modulo the quadratic terms,

$$\|\Delta u_{st}\|_1\ll\varepsilon^{k-1},\qquad\|\Delta u_{st}\|_\infty\ll\varepsilon^{k},\qquad|\Delta u_{_L}|\ll\varepsilon^{2k-2}.\tag{5.44}$$

Hence

$$\varepsilon^{-1}\|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty+\varepsilon^{-1}|\Delta u_{_L}|^2\ll\varepsilon^{2k-2}+\varepsilon^{4k-5}\ll\varepsilon^{2k-2},\tag{5.45}$$

provided $2k>3$. The last is true since, in the case $1<n_1<n$, we have assumed that $k>1$. Thus, in (5.43) we can disregard the quadratic terms. Now, at the r.h.s. of (5.40) we have the terms

$$\|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty+\varepsilon^{-1}|\Delta u_{_L}|^2\ll\varepsilon^{2k-1}+\varepsilon^{4k-5}\le 2\varepsilon^{2k-1}\tag{5.46}$$

since $2k-4\ge 0$. We obtain the final estimates

$$\begin{aligned}&\text{(a)}\quad\|(I-P_1)\Delta u_{st}\|_1+|\Delta u_{_L}|+\varepsilon^{-k}|(P-P_1)\Delta u_{_L}|\le K\varepsilon^{2k-1},\\&\text{(b)}\quad\varepsilon\|P_1\Delta u_{st}\|_1+\|\Delta u_{st}\|_\infty\\&\qquad+\|P_1(E_x-I)\Delta u_{st}\|_1\le K(\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k).\end{aligned}\tag{5.47}$$

Recall that the difference Δu_{st} in (2.85), in our present notation, is the sum $\Delta u_{st}+u_{sh}(\varepsilon(x-x_0),u_{_L}+\Delta u_{_L})-u_{sh}(\varepsilon x,u_{_L})$. Thus the norm $\varepsilon\|\Delta u_{st}\|_1+\|\Delta u_{st}\|_\infty+\|(E_x-I)\Delta u_{st}\|_1$ in (2.87) and (2.88) is bounded by

$$\begin{aligned}&\varepsilon\|\Delta u_{st}\|_1+\|\Delta u_{st}\|_\infty+\|(I-P_1)\Delta u_{st}\|_1\\&\quad+\|P_1(E_x-I)\Delta u_{st}\|_1+\varepsilon|\Delta u_{_L}|\cdot\ell+|\Delta u_{_L}|+K\varepsilon|x_0|\varepsilon^k\\&\qquad\le K\Big(\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k+(\varepsilon^k\ell)\varepsilon^k+\varepsilon|x_0|\varepsilon^k\Big).\end{aligned}\tag{5.48}$$

We will assume

$$\varepsilon|x_0|\ll 1.\tag{5.49}$$

Then, by (1.11), the r.h.s. of (5.48) is bounded by $\delta_0\varepsilon^k$ as in (2.87). Thus Theorem 2.1 has been proved in the case $1<n_1<n$. Equations (5.19), (5.20) define the correspondence between τ_-, x_0 and Pg_{sum}. Rescale the variables

$$\begin{aligned}&\tau_-'=\tau_-/\varepsilon^{2k-1},\qquad x_0'=\varepsilon x_0,\qquad\Delta u_{_L}'=\Delta u_{_L}/\varepsilon^{2k-1},\\&(P-P_1)g_{\text{sum}}'=(P-P_1)\Big(g_{\text{sum}}-\sum_x G_2\Big(\{E_x^j u_{sh}(\varepsilon x,u_{_L})\}\Big)\Big)/\varepsilon^{2k-1},\\&P_1g_{\text{sum}}'=P_1\Big(g_{\text{sum}}-\sum_x G_2\Big(\{E_x^j u_{sh}(\varepsilon x,u_{_L})\}\Big)\Big)/\varepsilon^{k-1}.\end{aligned}\tag{5.50}$$

Then

$$(P-P_1)g'_{\rm sum} = (\ell\varepsilon^k)O(\Delta u'_{_L}) + x'_0\Big(O(1)+O(\varepsilon^k\Delta u'_{_L})\Big) + \tau'_- \tag{5.51}$$

$$\begin{aligned} -P_1 g'_{\rm sum} = {} & (\ell\varepsilon^k)O(\Delta u'_{_L}) + x'_0\Big(2\lambda_1(u_{_L})/\varepsilon^k + o(1)\Big) \\ & -P_1\varepsilon^{-k+1}\sum_x G_2\Big(\{E_x^j\Delta u_{st}(x)\}\Big). \end{aligned} \tag{5.52}$$

By (5.47), $\Delta u'_{_L} = O(1)$, $P_1\varepsilon^{-k+1}\sum_x G_2(\{E_x^j\Delta u_{st}(x)\}) = O(\varepsilon) + O(e^{-\delta\varepsilon\ell})$. Since $\ell\varepsilon^k \ll 1$ and $\lambda_1(u_{_L})/\varepsilon^k = O^*(1)$, (5.51) and (5.52) are uniquely solvable with respect to x'_0 and τ'_-. In order to satisfy (5.39), (5.49) we should assume that

$$|P_1 g'_{\rm sum}| \ll 1, \qquad |(P-P_1)g'_{\rm sum}| \le K. \tag{5.53}$$

Thus we obtain an n_1 parameter family of stationary solutions which depend on the vector $Pg'_{\rm sum}$.

Now consider the special cases $n_1 = 1$ and $n_1 = n$ while $k \ge 1$ and $\ell\varepsilon^{k+1} \ll 1$. In the case $n_1 = 1$ the terms (5.31) which contribute to (5.19) are absent. Thus, instead of (5.33), we obtain

$$\begin{aligned} \|y_{_{I,II}}\|_1 + |\Delta u_{_L}| \le K\Big(& \|H_{_{I,II}}\|_1 + \varepsilon^k\|y_1\|_\infty + \|(E_x-I)^k y_1\|_\infty \\ & + \varepsilon^{2k}e^{-\delta\varepsilon\ell} + |\Delta u_{_L}|^2 + \|\Delta u_{st}\|_\infty^2\Big). \end{aligned} \tag{5.54}$$

Besides the norm $\|\cdot\|_1$, we can estimate the norm $\|y_{_{I,II}}\|_\infty$,

$$\begin{aligned} \|y_{_{I,II}}\|_\infty + |\Delta u_{_L}| \le K\Big(& \|H_{_{I,II}}\|_\infty + \varepsilon^k\|y_1\|_\infty + \|(E_x-I)^k y_1\|_\infty \\ & + \varepsilon^{2k}e^{-\delta\varepsilon\ell} + |\Delta u_{_L}|^2 + \|\Delta u_{st}\|_\infty^2\Big), \end{aligned} \tag{5.55}$$

$$\begin{aligned} & \|y_{_{I,II}}\|_\infty + K_1\varepsilon^k \sum_{i+j\le k+1}\Big(\|D_\tau^i y'_{1,j}\|_{1,\varepsilon} + \|D_\tau^i y'_{1,j}\|_\infty\Big) + |\Delta u_{_L}| \\ & \le K\Big(\|H_{_{I,II}}\|_\infty + \varepsilon^{2k}e^{-\delta\varepsilon\ell}\Big) + K_1K\Big(\varepsilon\|H_1\|_1 + \sum\varepsilon^{k-d_j}|\Delta u_{_L}| \\ & \qquad + \varepsilon^{2k}e^{-\delta\varepsilon\ell} + \varepsilon\Big(\|\Delta u_{st}\|_\infty^2 + |\Delta u_{_L}|^2\Big)\Big). \end{aligned} \tag{5.56}$$

The contribution of y to the norm of H at the r.h.s. of (5.55) is bounded by $K\varepsilon^{k+1}\|y\|_\infty$ $+K_1\varepsilon^{k+1}\|y\|_\infty$, which is negligible. Now, we have a relaxed condition $d_j \le k-1$. Thus $\Delta u_{_L}$ term at the r.h.s. of (5.56) could be dropped. Altogether,

$$\begin{aligned} & \|y_{_{I,II}}\|_\infty + \varepsilon^k\Big(\sum\|D_\tau^i y'_{1,j}\|_{1,\varepsilon} + \|D_\tau^i y'_{1,j}\|_\infty\Big) + |\Delta u_{_L}| \\ & \qquad \le K\Big(\|F\|_\infty + \varepsilon^{2k}e^{-\delta\varepsilon\ell} + \varepsilon\|\Delta u_{st}\|_\infty^2\Big) \\ & \qquad \le K\Big(\varepsilon^{2k} + \|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty\Big). \end{aligned} \tag{5.57}$$

Now return to (5.34). The term with H_1' in the r.h.s. of (5.34) is estimated as in (5.36), (5.37) with a correction as in (5.41). Thus we obtain

$$\begin{aligned}
&\sum_{i+j\le k+1}\Big(\|D_\tau^i y'_{1,j}\|_{1,\varepsilon}+\|D_\tau^i y'_{1,j}\|_\infty\Big)\\
&\qquad\le K\Big(\varepsilon^{-k+1}\Big(\varepsilon^{2k}+|\Delta u_{_L}|+\|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty+\varepsilon^k\|y\|_\infty\Big)\\
&\qquad\qquad+e^{-\delta\varepsilon\ell}\varepsilon^k+e^{-\delta\varepsilon\ell}|\Delta u_{_L}|+\varepsilon^{-k+1}\Big(\|\Delta u_{st}\|_\infty^2+|\Delta u_{_L}|^2\Big)\Big)\\
&\qquad\le K\Big(\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k+\varepsilon^{-k+1}\|\Delta u_{st}\|_1\cdot\|\Delta u_{st}\|_\infty\Big).
\end{aligned}\tag{5.58}$$

Then estimate (5.54) implies

$$\|y_{_{I,II}}\|_1\le K\Big(\varepsilon^{2k-1}+\|\Delta u_{st}\|_1\|\Delta u_{st}\|_\infty\Big).\tag{5.59}$$

By (5.57)–(5.59),

$$\|\Delta u_{st}\|_\infty\le K\Big(\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k+\varepsilon^{-k+1}\|\Delta u_{st}\|_1\|\Delta u_{st}\|_\infty\Big)\tag{5.60}$$

and

$$\|\Delta u_{st}\|_1\le K\Big(\varepsilon^k+e^{-\delta\varepsilon\ell}\varepsilon^{k-1}+\varepsilon^{-k}\|\Delta u_{st}\|_1\|\Delta u_{st}\|_\infty\Big).\tag{5.61}$$

Hence

$$\varepsilon^{-2k+1}\|\Delta u_{st}\|_\infty\|\Delta u_{st}\|_1=A\le K^2(\varepsilon+e^{-\delta\varepsilon\ell}+A)^2\tag{5.62}$$

or $A\le K(\varepsilon+e^{-\delta\varepsilon\ell})$. Now, by (5.57)–(5.59) we arrive at estimates (5.47). For $(I-P_1)\Delta u_{st}$, $\Delta u_{_L}$ we have a better estimate

$$\|(I-P_1)\Delta u_{st}\|_\infty+|\Delta u_{_L}|\le K(\varepsilon^{2k}+e^{-\delta\varepsilon\ell}\varepsilon^{2k-1}).\tag{5.63}$$

Then, as in (5.48),

$$\begin{aligned}
&\varepsilon\|\Delta u_{st}\|_1+\|\Delta u_{st}\|_\infty+\varepsilon|\Delta u_{_L}|\ell+K\varepsilon|x_0|\varepsilon^k\\
&\qquad\le K\Big(\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k+\varepsilon^{k+1}\ell\cdot\varepsilon^k+(\varepsilon\ell)e^{-\delta\varepsilon\ell}\varepsilon^{2k-1}+\varepsilon|x_0|\varepsilon^k\Big)\\
&\qquad\le\delta_0\varepsilon^k,
\end{aligned}\tag{5.64}$$

provided $\varepsilon^{k+1}\ell\ll 1$, $\varepsilon|x_0|\ll 1$, $\varepsilon\ell\gg 1$. The difference $(E_x-I)\Delta u_{st}$ is estimated with the aid of (5.58), (5.59), (5.62),

$$\|(E_x-I)\Delta u_{st}\|_1\le K\Big(\|y_{_{I,II}}\|_1+\varepsilon\|D_\tau y_1\|_1\Big)\le K(\varepsilon^{2k-1}+\varepsilon^{k+1}+e^{-\delta\varepsilon\ell}\varepsilon^k).\tag{5.65}$$

Thus, for $n_1=1$ we obtained the requested estimates (2.87), (2.88). The only free parameter in the definition of Δu_{st} is $x_0'=\varepsilon x_0$. It is related to $P_1 g'_{\rm sum}$ by (5.52). Note that $\Delta u'_{_L}=\Delta u_{_L}/\varepsilon^{2k-1}=O(\varepsilon)+O(e^{-\delta\varepsilon\ell})$. Hence

$$\ell\varepsilon^k O(\Delta u'_{_L})=O(\ell\varepsilon^{k+1})+O(\ell\varepsilon^k e^{-\delta\varepsilon\ell})\ll 1.\tag{5.66}$$

Thus x_0' in (5.52) is in one-to-one correspondence with $P_1 g'_{\rm sum}$, provided $|P_1 g'_{\rm sum}| \ll 1$.

It remains to consider the case $n_1 = n$, when $\Delta u_{_L} = 0$. Estimate (5.35) is valid with $\Delta u_{_L} = 0$. We can afford $d_j \le k-1$ since there are no terms $\varepsilon^{k-1}\varepsilon^{-d_j} O(\Delta u_{_L})$ at the r.h.s. of (5.35). We proceed as in (5.36)–(5.39) and arrive at (5.40) with $(\Delta u_{_L} = 0)$. All estimates (5.41)–(5.46) are valid; only the term ε^{4k-5} in (5.45), (5.46) is absent. Thus there is no restriction $k > 1$. Hence estimate (5.47) holds also for $k = 1$. Instead of (5.48) we have

$$\varepsilon\|\Delta u_{st}\|_1 + \|\Delta u_{st}\|_\infty + K\varepsilon|x_0|\varepsilon^k \le K\Big(\varepsilon^{k+1} + e^{-\delta\varepsilon\ell}\varepsilon^k + \varepsilon|x_0|\varepsilon^k\Big) \le \delta_0\varepsilon^k, \tag{5.67}$$

provided (5.49) holds. Equations (5.51), (5.52) (with $\Delta u_{_L} = 0$) define one-to-one correspondence between $g'_{\rm sum}$ and x_0' and τ'_- under the restriction (5.53).

6. Asymptotic stability of the nonlinear problem. In this section we will prove the main theorem, Theorem 2.2, about asymptotic stability of the IBVP (2.1), (2.7), (2.9). Let u be a solution of the IBVP and u_{st} a stationary solution of (2.1), (2.7) as described in section 5. Denote by Δu the difference $u - u_{st}$. Since G has the form (2.4) with linear operator G_2, Δu satisfies the equation

$$dG[u_{st}](E_x, E_t)\Delta u = (E_x - I)O(\Delta u)^2 = F. \tag{6.1}$$

In case $n_1 = n$, one should integrate the above equation. Thus we consider first the case $n_1 = 1$. Since both u and u_{st} satisfy the boundary conditions (2.7), the difference Δu satisfies

$$dS_{_{L,R}}[\Delta u_{st}]\Delta u = O(\Delta u)^2 = g_{_{L,R}}. \tag{6.2}$$

However, we remove from (6.2) the boundary condition (2.13) at $x = x_\ell$ and replace it by the integral condition (6.5) below. The initial values of Δu are

$$\Delta u_{in}(x,t) = u_{in}(x,t) - u_{st}(x), \qquad (x,t) \text{ as in (2.9)}. \tag{6.3}$$

We will assume that $g_{\rm sum}$ defined by the initial values u_{in},

$$P_1 \sum_x G_2\big(\{E^j u_{in}\}\big) = g_{\rm sum}, \tag{6.4}$$

satisfies conditions (5.53), where $g'_{\rm sum}$ is defined by (5.50). Then, as shown in section 5, one can choose u_{st} such that

$$P_1 \sum_x dG_2 \Delta u \equiv \Delta g_{\rm sum} = 0. \tag{6.5}$$

The estimates for the IBVP problem (6.1)–(6.3), (6.5) follow from estimates (3.100), (3.132), (3.133) for the resolvent problem. Although the procedure is standard, for completeness we present it here. First we rewrite the problem (6.1), (6.2), (6.5) in global operator form,

$$L(E_t)\Delta u = \sum_{i=0}^{\nu_0} L_i E_t^i \Delta u = F^{(1)} = (F, g_{_{L,R}}, \Delta g_{\rm sum}), \tag{6.6}$$

where $\nu_0 = \Delta j_2$ is defined in (2.9). Then problem (6.6) is transformed as in (3.19) into a two-level scheme

$$\widetilde{L}(E_t)\widetilde{u} = (A \cdot E_t + B)\Delta\widetilde{u} = \widetilde{F}, \tag{6.7}$$

where

$$\Delta\widetilde{u}(t) = \Big(\Delta u(t), E_t\Delta u(t), \dots, E_t^{\nu_0-1}\Delta u(t)\Big)^T, \qquad \widetilde{F} = (0, \dots, 0, F^{(1)})^T. \tag{6.8}$$

The operators $\widetilde{L}(E_t)$ and $L(E_t)$ are related by the identity (3.20). The explicit form of D_1 and D_2 is

$$D_1 = \begin{bmatrix} I & 0 & 0 & \cdots & 0 \\ E_t & I & 0 & & 0 \\ E_t^2 & E_t & I & & 0 \\ \vdots & & & \ddots & \\ E_t^{\nu_0-1} & \cdots & E_t^2 & E_t & I \end{bmatrix}, \qquad D_2 = \begin{bmatrix} C_{\nu_0-1} & C_{\nu_0-2} & \cdots & C_1 & I \\ -I & 0 & & 0 & 0 \\ & -I & & & \\ \vdots & & & & \vdots \\ 0 & \cdots & & -I & 0 \end{bmatrix}, \tag{6.9}$$

where

$$C_1 = L_{\nu_0}E_t + L_{\nu_0-1}, \quad C_{\nu+1} = C_\nu E_t + L_{\nu_0-1-\nu} \quad \text{for } \nu = 1, 2, \dots, \nu_0 - 2.$$

By the solvability assumption, the operator A is invertible. Thus the problem (6.7), (6.3) becomes

$$E_t\widetilde{u} = -A^{-1}B\widetilde{u} + A^{-1}\widetilde{F}, \qquad \Delta\widetilde{u}(0) = \Delta\widetilde{u}_{in}. \tag{6.10}$$

Recall that the estimates for the resolvent problem could be extended into the domain $\operatorname{Re} s \ge -\delta\varepsilon^k/\ell$. As a result, the difference $\Delta\widetilde{u}$ will decay in time as $\exp(-s_0 t)$, $s_0 \approx \delta\varepsilon^k/\ell$. Let us fix $s_0 = \delta\varepsilon^k/2\ell$ and change the variables

$$\Delta\widetilde{u} = e^{-s_0 t}v, \qquad e^{s_0(t+1)}A^{-1}\widetilde{F}(t) = H(t). \tag{6.11}$$

Then v satisfies

$$E_t v = \widetilde{A}v + H, \qquad \widetilde{A} = -e^{s_0}A^{-1}B. \tag{6.12}$$

The solution v is a convolution

$$v(t) = \sum_{\tau=0}^{t} \widetilde{A}^\tau H(t-\tau) + \widetilde{A}^t\Delta\widetilde{u}_{in}. \tag{6.13}$$

The power $\widetilde{A}$ is computed by the integral

$$\begin{aligned} \widetilde{A}^\tau \cdot H &= (2\pi i)^{-1}\oint_{|z|=e^{-s_0}} (z - \widetilde{A})^{-1} z^\tau H dz \\ &= (2\pi i)^{-1}\oint_{|z|=e^{-s_0}} (Ae^{-s_0}z + B)^{-1} z^\tau e^{-s_0} AH dz \\ &= (2\pi i)^{-1}\oint_{|z|=e^{-2s_0}} D_1(z)\Big(L(z) \oplus I\Big)^{-1} D_2(z)(ze^{s_0})^\tau AH dz \\ &= (2\pi i)^{-1}\oint_{|z|=e^{-2s_0}} D_1(z)\Big(L^{-1}(z) \oplus 0\Big) D_2(z)(ze^{s_0})^\tau AH dz. \end{aligned} \tag{6.14}$$

Note that

$$D_2(z)AH(t) = D_2(z)e^{s_0(t+1)}\widetilde{F}(t) = e^{s_0(t+1)}\Big(F^{(1)}(t),0,\dots,0\Big). \tag{6.15}$$

Since $D_1(z)$ is bounded,

$$\|\widetilde{A}^\tau H(t-\tau)\|_\infty \le Ke^{-s_0\tau}\oint_{|z|=e^{-2s_0}} \|L^{-1}(z)F^{(1)}(t-\tau)e^{s_0(t-\tau)}\|_\infty |dz|. \tag{6.16}$$

For $z=e^s$, $\operatorname{Re} s = -2s_0$, $|\operatorname{Im} s| \le K\varepsilon^{k+1}$, $u = L^{-1}(z)F^{(1)}$ satisfies estimate (3.132) and for $K\varepsilon^{k+1} \le |\operatorname{Im} s| \le \delta$ satisfies estimate (3.133). For s away from 0, by dissipativity, the operator dG is zero order elliptic. However, because of the global condition (2.14) we still have the norm $\|F\|_1$ at the r.h.s. of (3.133). Estimate (3.133) could be strengthened, but it would not improve the estimate for the power of $\widetilde{A}$. Now return to the integral in (6.16). In the domain $|\operatorname{Im} s| \le K\varepsilon^{k+1}$, this integral is bounded by

$$\begin{aligned} &K\int \sigma^{-k}\bigg(\|F\|_1 + \sigma\|P_1\sum F(\xi)\|_1 + \sigma\ell|g_{L,0}| \\ &\qquad + \sum_{i\ge 1}\sigma^{k-d_i}|g_{1,i}| + |g_2|\bigg)|dz| \\ &\le K\varepsilon^{k+1}\varepsilon^{-k}\bigg(\|F\|_1 + \varepsilon\|P_1\sum F(\xi)\|_1 + \varepsilon\ell|g_{L,0}| \\ &\qquad + \sum_{i\ge 1}\varepsilon^{k-d_i}|g_{1,i}| + |g_2|\bigg). \end{aligned} \tag{6.17}$$

In the domain $|\operatorname{Im} s| \ge K\varepsilon^{k+1}$ the integral is bounded by

$$K\left(\|F\|_1 + |g_{L,0}| + \sum_{i\ge 1}|g_{1,i}| + |g_2|\right). \tag{6.18}$$

Altogether,

$$\begin{aligned} &\|\widetilde{A}^\tau H(t-\tau)\|_\infty \\ &\quad \le Ke^{-s_0\tau}e^{s_0(t-\tau)}\Big(\|(E_x-I)O(\Delta u)^2\|_1 + \|O(\Delta u)^2\|_\infty \\ &\qquad\qquad + \varepsilon^2\Big(\|O(\Delta u)^2\|_1 + \ell\|O(\Delta u)^2\|_\infty\Big)\Big) \\ &\quad \le Ke^{-s_0 t}\ell\|v(t-\tau)\|_\infty^2 \end{aligned} \tag{6.19}$$

and

$$\left\|\sum_{\tau=0}^{t}\widetilde{A}^\tau H(t-\tau)\right\| \le Kte^{-s_0 t}\ell \sup_{0\le\tau\le t}\|v(\tau)\|_\infty^2. \tag{6.20}$$

In the initial term $\widetilde{A}^t\Delta\widetilde{u}_{in}$ we should apply the last integral in (6.14) to the function $A\Delta\widetilde{u}_{in}$. By (3.18) and (6.9) the first block row of $D_2A\Delta\widetilde{u}_{in}$ is

$$C_{\nu_0-1}\Delta u_{in}(\nu_0-1) + \cdots + C_1\Delta u_{in}(1) + L_{\nu_0}\Delta u_{in}(0). \tag{6.21}$$

The resulting vector could be partitioned as $(F, g_{L,R}, g_{\text{sum}})$. The F component is affected by the operator $dG[u_{st}]$ in (6.1), $g_{L,R}$ by $dS_{L,R}[u_{st}]$ in (6.2), and g_{sum} by $P_1 \sum dG_2$. Recall that the variable coefficient part of dG is $(E_x - I)dG_1$. Hence the term $\|P_1 \sum F(\xi)\|_1$ is bounded by

$$\ell \|\Delta \widetilde{u}_{in}\|_\infty + \left\| \sum_\xi \Delta \widetilde{u}_{in}(\xi) \right\|_1 . \tag{6.22}$$

One should add to (6.17), (6.18) the $|g_{\text{sum}}|$ term which is bounded by $|\sum_\xi \Delta \widetilde{u}_{in}(\xi)|$. Altogether,

$$\|\widetilde{A}^t \Delta \widetilde{u}_{in}\|_\infty \le K e^{-s_0 t} \left(\varepsilon^2 \left\| \sum_\xi \Delta \widetilde{u}_{in}(\xi) \right\|_1 + \|\Delta \widetilde{u}_{in}\|_1 + \varepsilon^2 \ell \|\Delta \widetilde{u}_{in}\|_\infty \right). \tag{6.23}$$

In order to estimate $\sup_{0 \le \tau \le t} \|v(\tau)\|_\infty$, we should assume that

$$K t e^{-s_0 t} \ell \sup_{0 \le \tau \le t} \|v(\tau)\|_\infty < \tfrac{1}{2}. \tag{6.24}$$

Then in turn,

$$\|v(t)\|_\infty \le 2 \|\widetilde{A}^t \Delta \widetilde{u}_{in}\|_\infty. \tag{6.25}$$

Thus a sufficient condition for estimate (6.25) to hold for all t is

$$\begin{aligned} &\varepsilon^2 \left\| \textstyle\sum_\xi \Delta \widetilde{u}_{in}(\xi) \right\|_1 + \|\Delta \widetilde{u}_{in}\|_1 + \varepsilon^2 \ell \|\Delta \widetilde{u}_{in}\|_\infty \\ &\qquad \le \frac{\delta \ell^{-1}}{\max(t e^{-s_0 t})} \le \delta s_0 \ell^{-1} \approx \delta \varepsilon^k \ell^{-2} . \end{aligned} \tag{6.26}$$

The difference Δu decays as

$$\|\Delta u(t)\|_\infty \le K \varepsilon^k \ell^{-2} e^{-\delta \varepsilon^k \ell^{-1} t}. \tag{6.27}$$

For minimal possible $\ell \approx K \varepsilon^{-1}$, the rate of decay is

$$\|\Delta u(t)\|_\infty \le K \varepsilon^{k+2} e^{-\delta \varepsilon^{k+1} t}. \tag{6.28}$$

Now consider the case $n_1 = n$. The original nonlinear problem (2.1) is integrated,

$$G_1\Big(\{E^j (E_x - I) U(x,t)\}\Big) + (E_t - I) G_2\Big(\{E^j U(x,t)\}\Big) = f(u_{_L}), \tag{6.29}$$

where $(E_x - I)U(x,t) = u(x,t)$ and $U(x,t)$ satisfies the boundary condition

$$\begin{aligned} &\text{(a)} \quad G_2\Big(\{E^j U(x_{-\ell}, t)\}\Big) = 0, \\ &\text{(b)} \quad G_2\Big(\{E^j U(x_\ell, t)\}\Big) = g_{\text{sum}} \stackrel{df}{=} \textstyle\sum_x G_2\Big(\{E^j u_{in}(x)\}\Big). \end{aligned} \tag{6.30}$$

The boundary conditions at $x = x_{-\ell}$ are used to define the value $U(x_{-\ell}, t)$, $t \ge \nu_0$, while for $t < \nu_0$ the values $U(x_{-\ell}, t)$ are arbitrary. The remaining boundary conditions are the one in (2.26)(b),(c) or, more precisely, in the nonlinear form

$$S_1\Big((E_x - I)U\Big) = 0, \qquad S_2\Big((E_x - I)U\Big) = 0. \tag{6.31}$$

Given stationary solution u_{st}, which satisfies the conservation law $\sum_x G_2(\{E^j u_{st}(x)\}) = g_{\rm sum}$, one can define U_{st}, $(E_x - I)U_{st} = u_{st}$, which satisfies (6.30)(a) and therefore also (6.30)(b). The difference $\Delta U = U - U_{st}$ satisfies the equations

$$dG_1[u_{st}](E_x, E_t)(E_x - I)\Delta U + (E_t - I)dG_2\Delta U = F = O\Big((E_x - I)\Delta U\Big)^2, \tag{6.32}$$

$$dG_2 \cdot \Delta U = 0, \qquad x = x_{\pm\ell}, \tag{6.33}$$

and

$$dS_{1,2}[u_{st}]\Delta U = g_{1,2} = O\Big((E_x - I)\Delta U\Big)^2, \tag{6.34}$$

with initial conditions

$$\Delta U(x,t) = \Delta U_{in}, \qquad 0 \le t \le \nu_0 - 1. \tag{6.35}$$

We proceed as in the case $n_1 = 1$. Now we use estimate (3.100). We remark that the function F in (6.32) stands for the sum $\sum F(\xi)$ in (3.99). The terms $g_{\rm sum}$ and $g_{L,0}$ are 0. Therefore instead of (6.19) we obtain

$$\|\widetilde{A}^\tau H(t-\tau)\|_\infty \le Ke^{-s_0\tau}e^{s_0(t-\tau)}\Big(\|F\|_1 + |g_{1,2}|\Big) \le Ke^{-s_0 t}\ell\|v(t-\tau)\|_\infty^2. \tag{6.36}$$

The initial term is estimated as

$$\|\widetilde{A}^t\Delta\widetilde{U}_{in}\|_\infty \le Ke^{-s_0 t}\|\Delta\widetilde{U}_{in}\|_1. \tag{6.37}$$

Estimate (6.25) is replaced by

$$\|V(t)\|_\infty \le 2\|\widetilde{A}^t\Delta\widetilde{U}_{in}\|_\infty, \tag{6.38}$$

and condition (6.26) by

$$\|\Delta\widetilde{U}_{in}\|_1 \le \delta\varepsilon^k\ell^{-2}. \tag{6.39}$$

Finally, instead of (6.27) we have

$$\|\Delta U\|_1 \le K\varepsilon^k\ell^{-2}e^{-\delta\varepsilon^k\ell^{-1}t}. \tag{6.40}$$

GEOMETRIC PROPERTIES OF RUNGE–KUTTA DISCRETIZATIONS FOR INDEX 2 DIFFERENTIAL ALGEBRAIC EQUATIONS*

JOHANNES SCHROPP†

Abstract. We analyze Runge–Kutta discretizations applied to index 2 differential algebraic equations (DAEs). The asymptotic features of the numerical and the exact solutions are compared. It is shown that Runge–Kutta methods satisfying the first order constraint condition of the DAE correctly reproduce the geometric properties of the continuous system. The proof combines embedding techniques of index 2 DAEs and ordinary differential equations (ODEs) with some invariant manifolds results of Nipp and Stoffer [*Attractive Invariant Manifolds for Maps*, SAM Research Report 92-11, ETH, Zurich, Switzerland, 1992]. The results support the favorable behavior of these Runge–Kutta methods applied to index 2 DAEs for $t \geq 0$.

Key words. differential algebraic systems, projected and half-explicit Runge–Kutta methods, invariant manifolds

1. Introduction.

Differential algebraic problems of index 2 frequently arise when modeling phenomena from scientific computations. (An important class of such problems is, e.g., multibody systems with constraints on the velocity level or in the Gear–Gupta–Leimkuhler formulation [8].) They also occur as auxiliary systems for minimization problems when searching for an evolution that approaches a local minimum of an objective function restricted by algebraic constraints (see, e.g., Schropp [16]).

Quite often, analytic treatment of the system is impossible and, hence, numerical simulations become important to gain a deeper understanding of the global behavior. In particular, the question arises of which qualitative properties of the continuous system are preserved by a numerical method.

In the present paper we analyze the behavior of some widely used Runge–Kutta type discretizations applied to index 2 differential algebraic equations (DAEs) in Hessenberg form. To be more precise, we focus our interest on two different aspects. It is well known that the solution flow of the DAE takes place in a submanifold of the state times control space. We characterize how that submanifold persists under discretization with projected and half-explicit Runge–Kutta methods. We show that the discretized dynamics possesses an invariant submanifold close to the original one. Moreover, we deal with the following subject. The index 0 formulation of the DAE is an ordinary differential equation (ODE) on the manifold defined by the first order constrained condition. Runge–Kutta schemes satisfying that condition can be regarded as discrete flows on the constrained manifold. Hence, questions about the behavior of numerical methods near invariant sets like stationary points or periodic orbits on manifolds are of interest.

Our main tools are embedding and invariant manifold techniques. We embed the original DAE into another DAE of the same index such that the corresponding index 0 ODE admits a representation as a dynamical system on an open subset of the Euclidian space. Then, using the discrete invariant manifold techniques of Nipp and Stoffer [14], we mimic that approach for the projected and half-explicit Runge–Kutta dynamics. An important feature of this method is that it makes general techniques of regular perturbation methods available for DAEs. Applying the results of Beyn [2] for one-step methods in $\mathbb{R}^N$, we can establish that hyperbolic periodic orbits persist under discretization in invariant closed curves. Moreover, in Schropp [17] it is shown that the phase portrait near hyperbolic equilibria is correctly reproduced. These results underpin the use of projected or half-explicit Runge–Kutta DAE methods when dealing with the behavior of index 2 DAEs in the long time run.

Our work was largely motivated by the discretization results of Beyn [2], [3], Garay, [7], and Kloeden and Lorenz [12] for one-step methods near compact, invariant sets. Later we learned the convergence theory for DAEs from the excellent book of Hairer, Lubich, and Roche [10]. After finishing our paper we were informed about a forthcoming paper of Nipp [13], in which a persistence result of the invariant manifold of an index 2 DAE under discretization is shown for the special class of stiffly accurate Runge–Kutta methods and for linear multistep methods of backward differentiation formulae (BDF) type. Nipp's result is obtained with a different method of proof which does not allow analyzing the discrete behavior near compact invariant sets.

2. The main results. We consider the DAE

$$\begin{aligned} \dot{u} &= f(u,\lambda), \quad u(0) = u_0, \\ 0 &= g(u), \qquad \lambda(0) = \lambda_0, \end{aligned} \tag{2.1}$$

with $u \in \mathbb{R}^N$ and $\lambda \in \mathbb{R}^l$ in Hessenberg form. Let C_b^ν denote the space of functions of class C^ν with bounded derivatives up to order ν. We make the following assumptions:

(A1) $f \in C_b^\nu(\mathbb{R}^{N+l}, \mathbb{R}^N)$, $g \in C_b^{\nu+1}(\mathbb{R}^N, \mathbb{R}^l)$ for ν sufficiently large.

(A2) There is a C_b^ν-function ψ_0 satisfying $Dg(u)f(u,\psi_0(u)) = 0$ for $u \in D_\tau := \{u \in \mathbb{R}^N |\ \|g(u)\|_2 < \tau\}$, $\tau > 0$.

(A3) $Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi_0(u))$ is invertible for $u \in D_\tau$ and the inverse has bounded norm.

In particular, problem (2.1) is of index 2, and consistent initial values for (2.1) must satisfy $g(u_0) = 0$ and $Dg(u_0)f(u_0,\psi_0(u_0)) = 0$. Additionally, condition (A3) says that $Dg(u)$ is of full rank so that the second equation of (2.1) defines the submanifold $S := \{u \in \mathbb{R}^N \mid g(u) = 0\}$ of $\mathbb{R}^N$, and the underlying index 0 ODE reads

$$\dot{u} = f(u,\psi_0(u)), \qquad u(0) = u_0 \in S \tag{2.2}$$

(for an illustration of S and the dynamics on it, see Hairer and Wanner [11, p. 458]). We denote the solution flow of (2.2) with $\bar{u}(t,u_0)$, $u_0 \in S$. Then, (A2) implies the solution flow $(\bar{u}(t,u_0), \bar{\lambda}(t,u_0))$, $\bar{\lambda}(t,u_0) = \psi_0(\bar{u}(t,u_0))$ for (2.1). This means that the manifold

$$M_0 = \{(u,\lambda) \in D_\tau \times \mathbb{R}^l \mid g(u) = 0,\ \lambda = \psi_0(u)\}$$

is the phase space of the solution flow of (2.1).

We are interested in the qualitative, geometric features of s-stage Runge–Kutta type methods with Butcher tableau

$$\begin{array}{c|c} c & A \\ \hline & b^T \end{array}, \quad A = (a_{ij})_{1\le i,j\le s} \in \mathbb{R}^{s,s}, \quad b, c \in \mathbb{R}^s, \tag{2.3}$$

and constant step size h when applied to (2.1). The Runge–Kutta method possesses stage order q if

$$\sum_{j=1}^{s} a_{ij} c_j^{k-1} = \frac{c_i^k}{k}, \quad k = 1, \dots, q, \quad i = 1, \dots, s.$$

To avoid drift problems in the discrete long time run, we must focus our interest on Runge–Kutta type methods which retain the first order constraint $g(u) = 0$. This leads us to the widely used projected Runge–Kutta methods introduced by Ascher and Petzold [1] or to the half-explicit Runge–Kutta methods due to Hairer, Lubich, and Roche [9]. For the Butcher tableau of the projected Runge–Kutta method, we impose the following conditions:

(B1) The Runge–Kutta matrix A is invertible.
(B2) $R(\infty) = 1 - b^T A^{-1} \mathbb{I}$, $\mathbb{I} = (1, \dots, 1)$, satisfies $|R(\infty)| < 1$.
(B3) The method is of classical order p and possesses stage order q with $p \geq q \geq 1$.

Applied to (2.1), the projected Runge–Kutta method has the form

$$\begin{aligned} \tilde{u}_{n+1} &= u_n + h(b^T \otimes I) \bar{f}(U^n, \Lambda^n), \\ \lambda_{n+1} &= (1 - b^T A^{-1} \mathbb{I}) \lambda_n + (b^T A^{-1} \otimes I) \Lambda^n, \end{aligned} \tag{2.4}$$

where $U^n = (U_1^n, \dots, U_s^n) \in \mathbb{R}^{Ns}$, $\Lambda^n = (\Lambda_1^n, \dots, \Lambda_s^n) \in \mathbb{R}^{ls}$ denote the solution of the algebraic system

$$\begin{aligned} U - (\mathbb{I} \otimes u_n) &= h(A \otimes I) \bar{f}(U, \Lambda), \\ 0 &= \bar{g}(U), \end{aligned} \tag{2.5}$$

and $\bar{f}, \bar{g}$ stand for $\bar{f}(U^n, \Lambda^n) = (f(U_1^n, \Lambda_1^n), \dots, f(U_s^n, \Lambda_s^n))$, $\bar{g}(U^n) = (g(U_1^n), \dots, g(U_s^n))$. Finally, the projection step

$$\begin{aligned} u_{n+1} &= \tilde{u}_{n+1} + \frac{\partial}{\partial \lambda} f(u_{n+1}, \lambda_{n+1}) \gamma, \\ 0 &= g(u_{n+1}) \end{aligned} \tag{2.6}$$

determines u_{n+1}. In (2.6) the variable γ is needed for the projection only.

A Runge–Kutta method satisfying $a_{sj} = b_j$, $j = 1, \dots, s$, is called stiffly accurate. Stiffly accurate Runge–Kutta solutions satisfy the first order constraint $g(u) = 0$ and, hence, the projection step (2.6) is superfluous.

For the half-explicit Runge–Kutta methods, that is, $a_{i,j} = 0$ for $i \leq j$ in the Butcher tableau, we assume the following:

(B1′) $a_{i+1,i} \neq 0$ for $i = 1, \dots, s-1$ and $b_s \neq 0$.
(B2′) The method is of DAE order p (see Hairer and Wanner [11, Chap. VII.6] for conditions on A, b, c).

The application of a half-explicit Runge–Kutta method to (2.1) reads as follows: Solve (2.5) in the case $a_{i,j} = 0$ for $j \geq i$ and obtain U^n and Λ_i^n, $i = 1, \dots, s-1$. Then Λ_s^n and u_{n+1} are computed by

$$\begin{aligned} u_{n+1} &= u_n + h(b^T \otimes I) \bar{f}(U^n, \Lambda^n), \\ 0 &= g(u_{n+1}). \end{aligned} \tag{2.7}$$

With the matrix

$$\tilde{A} = \begin{pmatrix} a_{21} & & & & \\ a_{31} & a_{32} & & & \\ \vdots & & \ddots & & \\ a_{s1} & \dots & \dots & a_{ss-1} & \\ b_1 & \dots & \dots & b_{s-1} & b_s \end{pmatrix} \in \mathbb{R}^{s,s} \tag{2.8}$$

and $\tilde{U}^n := (U_2^n, \dots, U_s^n, u_{n+1})$, the half-explicit Runge–Kutta scheme can be written in the compact form

$$\begin{aligned} \tilde{U}^n - \mathbb{I} \otimes u_n &= h(\tilde{A} \otimes I)\bar{f}((u_n, \tilde{U}_1^n, \dots, \tilde{U}_{s-1}^n), \Lambda^n), \\ 0 &= \bar{g}(\tilde{U}^n) \end{aligned} \tag{2.9}$$

(see, e.g., formula (4.59) in Hairer, Lubich, and Roche [10]).

To compute the λ-component one has several possibilities. The most accurate is the computation of λ from the index 2 condition, that is, $\lambda_{n+1} = \psi_0(u_{n+1})$. Here we follow the more efficient approach of Hairer, Lubich, and Roche [10]. They propose to require $c_s = 1$ and take

$$\lambda_{n+1} = \Lambda_s^n. \tag{2.10}$$

Moreover, we assume

(B3′) $\Lambda_s^n - \bar{\lambda}(h, u_n) = O(h^r)$, $r \le p$ (see, e.g., Brasey and Hairer [5] for sufficient conditions on A, b, c).

The qualitative properties of the discrete schemes are characterized in the following.

THEOREM 2.1. *Consider the DAE* (2.1) *and assume* (A1)–(A3). *Let* (u_n, λ_n) *denote the sequences generated with a projected* (*half-explicit*) *Runge–Kutta method satisfying* (B1)–(B3) (*respectively,* (B1′)–(B3′)), *when applied to* (2.1) *with consistent initial values* (u_0, λ_0).

Then there exists a positive constant h_0 *such that for* $h < h_0$ *the iterates* (u_n, λ_n) *exist for* $n \in \mathbb{N}$. *Moreover, for* $h \in]0, h_0]$ *there is a* C_b^ν*-function* $\psi_{0,h} : S \to \mathbb{R}^l$, $S = \{u \in \mathbb{R}^N \mid g(u) = 0\}$ *satisfying the following assertions:*

(i) *The set* $M_{0,h} = \{(u, \lambda) \in D_\tau \times \mathbb{R}^l \mid g(u) = 0,\ \lambda = \psi_{0,h}(u)\}$ *is invariant for the projected* (*half-explicit*) *Runge–Kutta map* (2.4)–(2.6) (*respectively,* (2.9)–(2.10)).

(ii) *The manifold* $M_{0,h}$ *is uniformly attractive with the constant* $\chi_h = |R(\infty)| + O(h^{q+1})$ $(\chi_h = 0)$, *that is,* $\|\lambda_{n+1} - \psi_{0,h}(u_{n+1})\| \le \chi_h \|\lambda_n - \psi_{0,h}(u_n)\|$ *for every discrete evolution* (u_n, λ_n) *starting sufficiently close to* M_0.

(iii) *For every initial value* (u_0, λ_0) *with* $\|\lambda_0 - \psi_0(u_0)\|$ *sufficiently small, there is* $(\tilde{u}_0, \tilde{\lambda}_0) \in M_{0,h}$ *and* $c, \hat{c} > 0$ *such that the corresponding evolutions* (u_n, λ_n) *and* $(\tilde{u}_n, \tilde{\lambda}_n)$ *satisfy*

$$\begin{aligned} \|u_i - \tilde{u}_i\| &\le c\chi_h^i \|\lambda_0 - \psi_0(u_0)\|, \quad i \in \mathbb{N}, \\ \|\lambda_i - \tilde{\lambda}_i\| &\le \hat{c}\chi_h^i \|\lambda_0 - \psi_0(u_0)\|, \quad i \in \mathbb{N}. \end{aligned}$$

(iv) $\|\psi_0(u) - \psi_{0,h}(u)\| \le Ch^q$ $[Ch^r]$ *for* $u \in S$.

Remark. The invariant manifold $M_{0,h}$ in the projected Runge–Kutta case is highly attractive if $R(\infty) = 0$. The manifold is infinitely attractive, that is, $(u_1, \lambda_1) \in M_{0,h}$ for every (u_0, λ_0) with $\|\lambda_0 - \psi_0(u_0)\|$ sufficiently small, if $\chi_h = 0$. This is valid for half-explicit and stiffly accurate Runge–Kutta methods.

Next we characterize the behavior of the projected and half-explicit Runge–Kutta methods for index 2 DAEs (2.1) in a neighborhood of hyperbolic periodic orbits. Here, we call $(\bar{u}(t,u_0),\bar{\lambda}(t,u_0))$, $\bar{\lambda}(t,u_0)=\psi_0(\bar{u}(t,u_0))$, $\bar{u}(t,u_0)=\bar{u}(t+T,u_0)$ a hyperbolic T-periodic orbit of (2.1) if $\bar{u}(t,u_0)$ is a hyperbolic T-periodic solution of (2.2). This means that the linearized T-flow mapping $T_{u_0}(S)=N(Dg(u_0))$ into itself has the simple eigenvalue 1, and all other eigenvalues are off the unit circle. Here $N(Dg(u_0))$ stands for the null space of $Dg(u_0)$, and $T_{u_0}(S)$ denotes the tangential space of the manifold S at u_0.

THEOREM 2.2. *Let the assumptions of Theorem* 2.1 *hold and let* $(\bar{u}(t,u_0),\bar{\lambda}(t,u_0))$, $\bar{\lambda}(t,u_0)=\psi_0(\bar{u}(t,u_0))$ *be a hyperbolic* T*-periodic orbit of the DAE* (2.1). *Additionally, let* (u_n,λ_n) *be generated by applying the projected Runge–Kutta scheme* (2.4)–(2.6) (*half-explicit Runge–Kutta method* (2.9)–(2.10)) *to the DAE* (2.1).

Then for sufficiently small step size h *the* u*-component of the discrete dynamics possesses an invariant curve* $\gamma^h=u^h(\mathbb{R})$, $u^h(t)=u^h(t+T)$, *satisfying*

$$\max\{\|\bar{u}(t,u_0)-u^h(t)\| \mid t\in\mathbb{R}\}\le Ch^q\ [Ch^r].$$

As a direct consequence of Theorems 2.1 and 2.2, we obtain the following.

COROLLARY 2.3. *Under the hypotheses of Theorems* 2.1 *and* 2.2, *there is an invariant curve* $S^h(\mathbb{R})=(u^h(\mathbb{R}),\psi_{0,h}(u^h(\mathbb{R})))$, $S^h(t)=S^h(t+T)$ *for the projected* (*half-explicit*) *Runge–Kutta map such that*

$$\max\{\|(\bar{u}(t,u_0),\bar{\lambda}(t,u_0))-S^h(t)\| \mid t\in\mathbb{R}\}\le Ch^q\ [Ch^r]$$

is valid.

Theorem 2.2 and Corollary 2.3 show that half-explicit or projected Runge–Kutta methods correctly reproduce the phase portrait in a neighborhood of a periodic orbit. Moreover, this result can be regarded as the analogue of Theorem 2.1 of Beyn [2] for ODEs on manifolds of the form $g(u)=0$. Using the results of Garay [7] it is shown in Schropp [17] that the continuous time-h flow of (2.1) and its corresponding projected or half-explicit Runge–Kutta time-h map are locally topologically conjugate near a hyperbolic equilibrium.

The rest of the paper is organized as follows. In section 3 we present existence results for the projected and half-explicit Runge–Kutta schemes, in section 4 Theorem 2.1 is proved, and in section 5 we give a proof of Theorem 2.2.

3. Embedding techniques for index 2 DAEs. We have seen in the previous section that the corresponding index 0 version (2.2) to an index 2 DAE (2.1) is a dynamical system on a manifold. For technical reasons it is useful to embed (2.1) into another DAE of the same index such that their corresponding index 0 ODE provides an embedding of (2.2) in an open neighborhood of S in $\mathbb{R}^N$. This allows us to attack DAE problems with well-developed ODE methods on $\mathbb{R}^N$. Results for the original DAE (2.1) are then obtained by pulling back the results for the state variable u derived on an open subset of $\mathbb{R}^N$ to the manifold S.

Assuming (A1)–(A3), an embedding of (2.2) into D_{τ_0}, $\tau_0\in\,]0,\tau]$, sufficiently small can be established as follows. Consider the DAE

$$\begin{aligned}\dot{u}&=f(u,\lambda), & u(0)&=u_0,\\ \dot{v}&=-B(u)v, & v(0)&=v_0,\\ 0&=g(u)-v, & \lambda(0)&=\lambda_0\end{aligned}\tag{3.1}$$

and suppose $\mu_2(-B(u)) \le -\eta$, $\eta > 0$ for $u \in D_\tau$ with a C_b^ν-function $B(\cdot)$ on $\mathbb{R}^N$ (e.g., choose $B \equiv I$). Here $\mu_2(C)$ stands for the logarithmic norm of a matrix $C \in \mathbb{R}^{l,l}$ (see, e.g., Dekker and Verwer [6, p. 27] for a definition). Our first aim here is to show that (A1)–(A3) imply the following assertions for the DAE (3.1):

(A1′) $f \in C_b^\nu(\mathbb{R}^{N+l}, \mathbb{R}^N)$, $g \in C_b^{\nu+1}(\mathbb{R}^N, \mathbb{R}^l)$, and $B \in C_b^\nu(\mathbb{R}^N, \mathbb{R}^{l,l})$ for ν sufficiently large.

(A2′) There is $\tau_0 \in \,]0, \tau]$ and a C_b^ν-function ψ satisfying $Dg(u)f(u, \psi(u, v)) + B(u)v = 0$ for $u \in D_{\tau_0}$ and $\|v\|_2 < \tau_0$.

(A3′) $Dg(u)\frac{\partial f}{\partial \lambda}(u, \psi(u, v))$ is invertible for $u \in D_{\tau_0}$, $\|v\|_2 < \tau_0$ and the inverse has bounded norm.

(A1′) holds trivially for (3.1). To prove (A2′) and (A3′) we need the following version of the Banach fixed point theorem in a ball which is, for later purposes, formulated in the more general concept of vector norms.

A functional $|\cdot| : W \to \mathbb{R}^k$ on a vector space W is called a generalized norm if

$$\begin{aligned} |v| \ge 0, \quad |v| = 0 \Longleftrightarrow v = 0, \\ |v_1 + v_2| \le |v_1| + |v_2|, \\ |\alpha v| = |\alpha|_{\mathbb{R}} |v| \end{aligned} \tag{3.2}$$

holds with the natural ordering "$\le$" on $\mathbb{R}^k$. Here $|\cdot|_{\mathbb{R}}$ denotes the absolute value in $\mathbb{R}$. Every norm $\|\cdot\|_*$ in $\mathbb{R}^k$ defines a norm $\|\cdot\|$ in W via $\|v\| = \| \, |v| \, \|_*$.

LEMMA 3.1. *Let $(W, |\cdot|)$ be a Banach space with generalized norm $|\cdot|$ and let $B_r(v_0) := \{v \in W \mid |v - v_0| \le r\}$ for $r > 0$. Let the map $F : B_r(v_0) \mapsto W$ be continuously differentiable with invertible $DF(v_0)$. Moreover, for some nonnegative matrices $P, K \in \mathbb{R}^{k,k}$, we assume*

$$\begin{aligned} |DF(v_0)^{-1} z| \le P|z|, \quad z \in W, \\ |(DF(v_0) - DF(v))z| \le K|z|, \quad z \in W, \quad v \in B_r(v_0), \\ P|F(v_0)| < (I - PK)r. \end{aligned}$$

Then $F(v) = 0$ has a unique solution in $B_r(v_0)$. In addition, the matrix $I - PK$ is nonsingular and we have the stability inequality

$$|v - w| \le (I - PK)^{-1} P |F(v) - F(w)| \quad \forall v, w \in B_r(v_0).$$

A proof of Lemma 3.1 can be found in Beyn and Schropp [4].

We construct ψ by applying Lemma 3.1 to the equation

$$F_{u,v}(\zeta) := Dg(u)f(u, \psi_0(u) + \zeta) + B(u)v = 0. \tag{3.3}$$

For $\zeta_0 = 0$ we can compute with $\rho := \sup\{\|B(u)\|_2 \mid u \in D_\tau\} < \infty$ the inequalities

$$\begin{aligned} \|F_{u,v}(0)\|_2 \le \rho \|v\|_2, \\ \|DF_{u,v}(0)^{-1}\|_2 \le C \end{aligned}$$

as well as $DF_{u,v}(0) - DF_{u,v}(\zeta) = Dg(u)(\frac{\partial f}{\partial \lambda}(u, \psi_0(u)) - \frac{\partial f}{\partial \lambda}(u, \psi_0(u) + \zeta))$. Hence, we obtain

$$\|DF_{u,v}(0) - DF_{u,v}(\zeta)\|_2 \le \hat{C} r_0 \quad \text{for } \|\zeta\|_2 \le r_0.$$

Obviously, the inequality

$$C\|F_{u,v}(0)\|_2 \le C\rho\|v\|_2 < (1 - C\hat{C}r_0)r_0$$

holds for $\|v\|_2, r_0 > 0$ sufficiently small. Then Lemma 3.1 guarantees that (3.3) possesses exactly one solution $\hat{\zeta}_{u,v}$ in $B_{r_0}(0)$; that is, $\psi(u,v) := \psi_0(u) + \hat{\zeta}_{u,v}$ satisfies $Dg(u)f(u,\psi(u,v)) + B(u)v = 0$ for $u \in D_{\tau_0}$, $\|v\|_2 \le \tau_0$, and an implicit function argument ensures the smoothness of ψ. The reader may notice that we have $\psi_0(u) = \psi(u,0)$ by uniqueness.

Moreover, an application of the Banach lemma with $Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi_0(u))$ and the perturbation $Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi(u,v))$ shows that $Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi(u,v))$, $\|v\|_2 < \tau_0$ is invertible, the inverse possesses a bounded norm and (A1′)–(A3′) is verified.

(A1′)–(A3′) imply that (3.1) is of index 2. Consistent initial values must satisfy $g(u_0) - v_0 = 0$ and $Dg(u_0)f(u_0,\lambda_0) + B(u_0)v_0 = 0$. The solution flow of (3.1) has the form $(\tilde{u}(t,u_0), \tilde{v}(t,u_0), \tilde{\lambda}(t,u_0))$, $u_0 \in D_{\tau_0}$, with $\tilde{v}(t,u_0) = g(\tilde{u}(t,u_0))$ and $\tilde{\lambda}(t,u_0) = \psi(\tilde{u}(t,u_0), \tilde{v}(t,u_0))$. Moreover,

$$M_e := \{(u,v,\lambda) \in D_{\tau_0} \times \mathbb{R}^{2l} \mid g(u) - v = 0,\ \lambda = \psi(u,v)\}$$

is the phase space of (3.1). Using the theory of logarithmic norms (see, e.g., Dekker and Verwer [6, Thm. 1.5.2]), we obtain that

$$\|\tilde{v}(t,v_0)\|_2 \le \|v_0\|_2 \exp(-\eta t) \tag{3.4}$$

is valid for the v-component of every solution of (3.1). In particular, with $v(0) = v_0 = 0$ problem (3.1) reduces to (2.1). After eliminating the v-variables by $g(u) = v$, the u-component of the underlying index 0 ODE of (3.1) reads

$$\dot{u} = f(u,\psi(u,g(u))), \qquad u(0) = u_0 \in D_{\tau_0} \subset \mathbb{R}^N \text{ open.} \tag{3.5}$$

Next we summarize the qualitative properties of the solutions of (3.1).

LEMMA 3.2. *Consider* (3.1) *on the phase space* M_e*, and let* (A1)–(A3) *hold.*

Then every solution of (3.1) *with initial values* $u_0 \in D_{\tau_0}$, $v_0 = g(u_0)$, *and* $\lambda_0 = \psi(u_0,v_0)$ *exists for all* $t \ge 0$. *Moreover,* $M_{0,e} = \{(u,v,\lambda) \in D_{\tau_0} \times \mathbb{R}^{2l} \mid g(u) = v = 0, \lambda = \psi(u,0)\}$ *is an invariant and globally attractive subset of the phase space* M_e.

Proof. The proof of Lemma 3.2 is a direct consequence of (3.4) and the fact that f, g, B are C_b^ν-functions. ∎

We are interested in the behavior of s-stage projected and half-explicit Runge–Kutta type methods of order p with Butcher tableau (2.3) and constant step size h when applied to (3.1). The projected Runge–Kutta method has the form

$$\begin{aligned} \tilde{u}_{n+1} &= u_n + h(b^T \otimes I)\bar{f}(U^n,\Lambda^n), \\ v_{n+1} &= v_n - h(b^T \otimes I)\bar{B}(U^n)V^n, \\ \lambda_{n+1} &= (1 - b^T A^{-1}\mathbb{I})\lambda_n + (b^T A^{-1} \otimes I)\Lambda^n, \end{aligned} \tag{3.6}$$

where $U^n = (U_1^n, \dots, U_s^n) \in \mathbb{R}^{Ns}$, $V^n = (V_1^n, \dots, V_s^n) \in \mathbb{R}^{ls}$, $\Lambda^n = (\Lambda_1^n, \dots, \Lambda_s^n) \in \mathbb{R}^{ls}$ denote the solution of the algebraic system

$$\begin{aligned} U - (\mathbb{I} \otimes u_n) &= h(A \otimes I)\bar{f}(U,\Lambda), \\ V - (\mathbb{I} \otimes v_n) &= -h(A \otimes I)\bar{B}(U)V, \\ 0 &= \bar{g}(U) - V, \end{aligned} \tag{3.7}$$

and $\bar{B}$ stands for $\bar{B}(U^n) = \operatorname{diag}(B(U_1^n), \dots, B(U_s^n))$. Finally, the projection step

$$\begin{aligned} u_{n+1} &= \tilde{u}_{n+1} + \frac{\partial}{\partial \lambda} f(u_{n+1},\lambda_{n+1})\gamma, \\ 0 &= g(u_{n+1}) - v_{n+1} \end{aligned} \tag{3.8}$$

is used to compute u_{n+1}.

With $\tilde{A}$ from (2.8), $\tilde{U}^n := (U_2^n, \dots, U_s^n, u_{n+1})$, and $\tilde{V}^n = (V_2^n, \dots, V_s^n, v_{n+1})$, the application of half-explicit Runge–Kutta methods to (3.1) reads as follows:

$$\begin{aligned} \tilde{U}^n - \mathbb{I} \otimes u_n &= h(\tilde{A} \otimes I)\bar{f}((u_n, \tilde{U}_1^n, \dots, \tilde{U}_{s-1}^n), \Lambda^n), \\ \tilde{V}^n - \mathbb{I} \otimes g(u_n) &= -h(\tilde{A} \otimes I)\bar{B}((u_n, \tilde{U}_1^n, \dots, \tilde{U}_{s-1}^n))(g(u_n), \tilde{V}_1^n, \dots, \tilde{V}_{s-1}^n), \\ 0 &= \bar{g}(\tilde{U}^n) - \tilde{V}^n. \end{aligned} \tag{3.9}$$

This has to be completed by $\lambda_{n+1} = \psi(u_{n+1}, v_{n+1})$ or, more efficiently, by $\lambda_{n+1} = \Lambda_s^n$, provided $c_s = 1$ holds.

The reader may notice that (3.6)–(3.8) and (3.9) reduce to (2.4)–(2.6) and (2.9), respectively, when initialized with $g(u_0) = v_0 = 0$.

In this section we will guarantee the existence and uniqueness of the discrete iterates generated by a projected or a half-explicit Runge–Kutta method for all $n \in \mathbb{N}$. If one identifies the two state variables (u, v), then the solvability of the discrete systems (3.6)–(3.9) for $n \in \mathbb{N}$ with $0 \le nh \le t_{end}$ is guaranteed by the standard theory; see, e.g., Hairer and Wanner [11, Chaps. VII.4 and VII.6]. But in the process of proving Theorem 2.1 a refined stability inequality which distinguishes the two variables u and v is needed. To establish inequalities of that type we work with the concept of vector norms (see (3.2)).

LEMMA 3.3. *Let the assumptions of Theorem* 2.1 *hold and let* $u_0 \in D_{\tau_0}$, $v_0 = g(u_0)$, $\lambda_0 = \psi(u_0, v_0)$ *be a consistent initial value for the DAE* (3.1).

Then for $0 < h \le h_0$, $h_0 > 0$ *sufficiently small the projected and half-explicit Runge–Kutta iterates* (u_n, v_n, λ_n) *exist for* $n \in \mathbb{N}$. *For the stages* (U, V, Λ) *of the projected* (*respectively*, $(\tilde{U}, \tilde{V}, \Lambda)$ *of the half-explicit*) *Runge–Kutta dynamics, we have with* $v_0(u) := (\mathbb{I} \otimes u, \mathbb{I} \otimes g(u), \mathbb{I} \otimes \psi(u, g(u)))$, $u \in D_{\tau_0}$, *and* $k(u) := f(u, \psi(u, g(u)))$ *the inequality*

$$\begin{aligned} |(U, V, \Lambda) - v_0(u)| &\le O(h)(\|k(u)\| + \|g(u)\|)\ (1, 1, 1), \\ (|(\tilde{U}, \tilde{V}, \Lambda) - v_0(u)| &\le O(h)(\|k(u)\| + \|g(u)\|)\ (1, 1, 1)). \end{aligned} \tag{3.10}$$

Moreover, the coefficient $\gamma = \gamma(h, u, \lambda)$ *from the projection step* (3.8) *satisfies*

$$\|\gamma\| = O(h^{q+1}) \quad \text{for } u \in D_{\tau_0}, \quad \|\lambda - \psi(u, g(u))\| \text{ sufficiently small.}$$

Remark. The existence result for the half-explicit and projected Runge–Kutta methods applied to DAE (2.1) follows from Lemma 3.3 by restriction to initial values satisfying $g(u_0) = v_0 = 0$.

Now we give a proof of Lemma 3.3.

Proof. The first step of a projected Runge–Kutta method is a classical Runge–Kutta step. Following Hairer and Wanner [11, p. 493], we replace (3.7) for $h > 0$ by the equivalent system

$$\begin{aligned} U - (\mathbb{I} \otimes u_n) &= h(A \otimes I)\bar{f}(U, \Lambda), \\ V - (\mathbb{I} \otimes v_n) &= -h(A \otimes I)\bar{B}(U)V, \\ 0 &= \int_0^1 \operatorname{diag}(Dg(u_n + \tau(U_i^n - u_n)),\ i = 1, \dots, s)d\tau\ (A \otimes I)\bar{f}(U^n, \Lambda^n) \\ &\quad + (A \otimes I)\bar{B}(U)V + \frac{1}{h}(\bar{g}(\mathbb{I} \otimes u_n) - \mathbb{I} \otimes v_n). \end{aligned} \tag{3.11}$$

We use $v_n = g(u_n)$ and prove Lemma 3.3 by applying Lemma 3.1 to the equation

$$T_1(h,u,U,V,\Lambda) := \begin{pmatrix} U - (\mathbb{I}\otimes u) - h(A\otimes I)\bar{f}(U,\Lambda) \\ V - (\mathbb{I}\otimes g(u)) + h(A\otimes I)\bar{B}(U)V \\ \int_0^1 \operatorname{diag}(Dg(u+\tau(U_i-u)), i=1,\dots,s)d\tau\ (A\otimes I)\bar{f}(U,\Lambda) \\ +(A\otimes I)\bar{B}(U)V \end{pmatrix}$$

$$= 0, \quad u \in D_{\tau_0}. \tag{3.12}$$

Introducing the generalized norm $|(U,V,\Lambda)| = (\|U\|,\|V\|,\|\Lambda\|) \in \mathbb{R}^3$ and the central point $v_0(u) := (\mathbb{I}\otimes u, \mathbb{I}\otimes g(u), \mathbb{I}\otimes\psi(u,g(u)))$, we calculate

$$T_1(h,u,v_0(u)) = (O(h),O(h),0). \tag{3.13}$$

For the derivative of T_1 with respect to (U,V,Λ), we find with $\hat{\gamma}(u) := (u,\psi(u,g(u)))$ the representation

$$\frac{\partial}{\partial(U,V,\Lambda)}T_1(h,u,v_0(u)) = \begin{pmatrix} I+O(h) & 0 & O(h) \\ O(h) & I+O(h) & 0 \\ O(1) & O(1) & A\otimes Dg(u)\frac{\partial f}{\partial\lambda}(\hat{\gamma}(u)) \end{pmatrix}.$$

Now (A3′) and (B1) imply that $(A\otimes Dg(u)\frac{\partial f}{\partial\lambda}(\hat{\gamma}(u)))$ is nonsingular. Hence, the matrix $\frac{\partial}{\partial(U,V,\Lambda)}T_1(h,u,v_0(u))$ is invertible for $0 < h \le h_0$, $h_0 > 0$, sufficiently small and the inverse is of the form

$$\frac{\partial}{\partial(U,V,\Lambda)}T_1(h,u,v_0(u))^{-1} = \begin{pmatrix} I & 0 & 0 \\ 0 & I & 0 \\ O(1) & O(1) & (A\otimes(Dg(u)\frac{\partial f}{\partial\lambda}(\hat{\gamma}(u))))^{-1} \end{pmatrix} + O(h).$$

In terms of vector norms this leads to $|\frac{\partial}{\partial(U,V,\Lambda)}T_1(h,u,v_0(u))^{-1}| \le P_h$ with

$$P_h := \begin{pmatrix} 1+O(h) & O(h) & O(h) \\ O(h) & 1+O(h) & O(h) \\ O(1) & O(1) & O(1) \end{pmatrix} \in \mathbb{R}^{3,3}.$$

Then, following along the lines of the proof of Lemma 4.1 in Beyn and Schropp [4], we obtain the unique solvability of (3.12) in $B_r(v_0) := \{(U,V,\Lambda) \in \mathbb{R}^{(N+l+l)s} \mid |(U,V,\Lambda) - (\mathbb{I}\otimes u, \mathbb{I}\otimes g(u), \mathbb{I}\otimes\psi(u,g(u)))| \le r\}$, $r = (r_1,r_2,r_3) > 0$ for $0 < h \le h_0$, $h_0 > 0$, sufficiently small. We remark that an application of the implicit function theorem ensures the smooth dependency of the solution (U,V,Λ) from (h,u). In addition, the claimed stability inequality (3.10) holds.

The second step is the projection of the classical Runge–Kutta iterates onto the constrained manifold $g(u) - v = 0$. We define the function $\lambda_p = \lambda_p(h,u,\lambda) := R(\infty)\lambda + (b^TA^{-1}\otimes I)\Lambda(h,u)$ and consider the equation

$$T_2(h,u,\lambda,u_p,v_p,\gamma) = \begin{pmatrix} u_p - u - h(b^T\otimes I)\bar{f}(U(h,u),\Lambda(h,u)) - \frac{\partial}{\partial\lambda}f(u_p,\lambda_p)\gamma \\ v_p - g(u) + h(b^T\otimes I)\bar{B}(U(h,u))V(h,u) \\ g(u_p) - v_p \end{pmatrix}$$

$$= 0 \quad \text{for } 0 < h < h_0, \quad u \in D_{\tau_0}. \tag{3.14}$$

With the central point $v_0(u) = (v_0(u)_1, v_0(u)_2, v_0(u)_3)$,

$$\begin{aligned} v_0(u)_1 &= u + h(b^T\otimes I)\bar{f}(U(h,u),\Lambda(h,u)), \\ v_0(u)_2 &= g(u) - h(b^T\otimes I)\bar{B}(U(h,u))V(h,u), \\ v_0(u)_3 &= 0, \end{aligned}$$

we can compute

$$T_2(h,u,\lambda,v_0(u)) = (0,0,g(v_0(u)_1) - v_0(u)_2) =: (0,0,r(h,u)).$$

Obviously, $r(h,u) = O(h^{q+1})$ holds from the local error analysis of the underlying classical Runge–Kutta map (see, e.g., Hairer and Wanner [11, Chap. VII, Lem. 4.4]).

Next, using $\lambda_p(h,u,\lambda) = R(\infty)\lambda + (b^T A^{-1} \otimes I)\Lambda(h,u) = \psi(u,g(u)) + O(h) + O(\epsilon)$ with $\epsilon = \|\lambda - \psi(u,g(u))\|$ and $v_0(u)_1 = u + O(h)$, we obtain

$$\frac{\partial}{\partial(u_p,v_p,\gamma)} T_2(h,u,\lambda,v_0(u)) = \begin{pmatrix} I & 0 & -\frac{\partial}{\partial\lambda} f(\hat\gamma(u)) \\ 0 & I & 0 \\ Dg(u) & -I & 0 \end{pmatrix} + O(h) + O(\epsilon). \tag{3.15}$$

Thus, $\frac{\partial}{\partial(u_p,v_p,\gamma)} T_2(h,u,\lambda,v_0(u))$ is invertible for h and ϵ sufficiently small.

Moreover, $T_2(h,u,\lambda,.,.,.) = 0$ possesses a unique solution in $B_r(v_0)$ for $r > 0$ appropriate and h, ϵ sufficiently small. Finally, the stability inequality of Lemma 3.1 in the γ-component reads

$$\|\gamma\| = O(h^{q+1}) \quad \text{for } u \in D_{\tau_0}, \qquad \|\lambda - \psi(u,g(u))\| < \epsilon.$$

It remains to show that the sequence (u_n, v_n, λ_n) generated by a projected Runge–Kutta method with consistent initial value u_0, $v_0 = g(u_0)$, $\lambda_0 = \psi(u_0, g(u_0))$ satisfies

$$\|\lambda_n - \psi(u_n,g(u_n))\| < \epsilon, \quad n \in \mathbb{N}, \quad 0 < h \le h_0, \quad h_0 > 0 \text{ sufficiently small.} \tag{3.16}$$

To that purpose we define $\eta_n := \lambda_n - \psi(u_n, g(u_n))$. The iteration scheme of this sequence reads

$$\begin{aligned} \eta_{n+1} &= R(\infty)\eta_n + \psi(u_n,g(u_n)) - \psi(u_{n+1},g(u_{n+1})) \\ &\quad + (b^T A^{-1} \otimes I)(\Lambda(h,u_n) - \mathbb{I} \otimes \psi(u_n,g(u_n))) \\ &=: R(\infty)\eta_n + \beta_n, \quad \eta_0 = 0, \end{aligned} \tag{3.17}$$

with $\beta_n := \beta(h,u_n,\eta_n) = O(h)$. Here, due to the construction of the method, we have u_{n+1} as a function of (h,u_n,η_n). Using $|R(\infty)| < 1$, the theory of difference equations yields

$$\|\eta_n\| \le \|\eta_0\| + \frac{1}{1 - R(\infty)} \sup\{\|\beta_n\| \mid n \in \mathbb{N}\} = O(h) \quad \forall n \in \mathbb{N}, \tag{3.18}$$

and (3.16) is verified.

Finally, we prove the existence of the iterates (u_n, v_n, λ_n) for half-explicit Runge–Kutta methods. We define $\tilde U = (U_2, \dots, U_s, u_p)$, $\tilde V = (V_2, \dots, V_s, v_p)$, $\Lambda = (\Lambda_1, \dots, \Lambda_s)$ as well as $U_1 = u$, $V_1 = g(u)$. Then, we rewrite (3.9) in the form

$$\begin{aligned} T(h,u,\tilde U,\tilde V,\Lambda) &= \begin{pmatrix} \tilde U - \mathbb{I} \otimes u - h(\tilde A \otimes I)\bar f((u,\tilde U_1,\dots,\tilde U_{s-1}),\Lambda) \\ \tilde V - \mathbb{I} \otimes g(u) + h(\tilde A \otimes I)\bar B((u,\tilde U_1,\dots,\tilde U_{s-1}))(g(u),\tilde V_1,\dots,\tilde V_{s-1}) \\ \bar g(\tilde U) - \tilde V \end{pmatrix} \\ &= 0 \end{aligned} \tag{3.19}$$

and apply Lemma 3.1. Except for the shift of (U,V) to $(\tilde U, \tilde V)$, this is equivalent to a classical Runge–Kutta step with invertible matrix $\tilde A$. Thus, we can adapt the first step of the projected Runge–Kutta proof with the central point $v_0(u) = (\mathbb{I} \otimes u, \mathbb{I} \otimes$

$g(u), \mathbb{I} \otimes \psi(u, g(u)))$ to work for half-explicit methods too. Moreover, for the stages $(\tilde{U}, \tilde{V}, \Lambda)$, the stability inequality

$$|(\tilde{U}, \tilde{V}, \Lambda) - v_0(u)| \leq Ch \left(\|k(u)\| + \|g(u)\|\right) (1, 1, 1) \tag{3.20}$$

is valid. This finishes the proof of Lemma 3.3. ∎

Next we complete the existence results of the projected and half-explicit Runge–Kutta methods with some qualitative properties. This is done in the following.

LEMMA 3.4. *Let the conditions of Lemma* 3.2 *hold for* (3.1). *By* (u_n, v_n, λ_n) *we denote the sequences generated with a projected Runge–Kutta method satisfying* (B1)–(B3) *or a half-explicit Runge–Kutta method fulfilling* (B1′)–(B3′) *when applied to* (3.1) *with initial values* $u_0 \in D_{\tau_0}$, $v_0 = g(u_0)$, *and* $\lambda_0 = \psi(u_0, v_0)$.

Then h_0, $\epsilon > 0$ *exist such that for* $0 < h < h_0$, $n \in \mathbb{N}$, *the projected or half-explicit Runge–Kutta scheme correctly reproduces the phase portrait of* (3.1) *in the state variables* (u, v); *that is,* $M_{0,e,\epsilon} := \{(u, v, \lambda) \in D_{\tau_0} \times \mathbb{R}^{2l} \mid g(u) = v = 0, \|\lambda - \psi(u, v)\| < \epsilon\}$ *is a positive invariant and globally attractive subset for the discrete dynamics.*

Proof. We consider the v-component of the discrete scheme (3.6)–(3.8) in more detail. We extract V from the second line in (3.7) explicitly, insert this representation into (3.6), and obtain

$$v_{n+1} = v_n - h(b^T \otimes I)\bar{B}(U(h, u_n))[I + h(A \otimes I)\bar{B}(U(h, u_n))]^{-1}(\mathbb{I} \otimes v_n). \tag{3.21}$$

Moreover, we know

$$\bar{B}(U(h, u_n)) = \bar{B}(\mathbb{I} \otimes u_n) + O(h) = (I \otimes B(u_n)) + O(h) \tag{3.22}$$

from Lemma 3.3. Combining (3.21) and (3.22) yields

$$\begin{aligned} v_{n+1} &= v_n - h(b^T \otimes I)(I \otimes B(u_n))(\mathbb{I} \otimes v_n) + O(h^2)v_n \\ &= (I - hB(u_n) + O(h^2))v_n. \end{aligned} \tag{3.23}$$

Next, with $\mu_2(-B(u)) \leq -\eta$, $u \in D_{\tau_0}$, we can compute

$$\begin{aligned} \|I - hB(u) + O(h^2)\|_2 &= \max\{\lambda \in \sigma(I - (h/2)\,(B(u) + B(u)^T) + O(h^2))\} \\ &\leq 1 - h\eta/4, \quad 0 < h \leq h_0, \quad u \in D_{\tau_0} \text{ uniformly.} \end{aligned} \tag{3.24}$$

Then, with $u_n \in D_{\tau_0}$ for $n \in \mathbb{N}$ and formula (3.24), the inequality

$$\|g(u_n)\|_2 \leq \prod_{j=0}^{n-1} \|I - hB(u_j) + O(h^2)\|_2 \cdot \|g(u_0)\|_2 \quad \to \quad 0 \quad \text{as } n \to \infty$$

follows. This shows our result for the projected Runge–Kutta scheme.

The proof also works for half-explicit Runge–Kutta methods, since (3.21) holds for these methods too. ∎

4. Embedded index 2 systems under discretization. In this section we give a proof of Theorem 2.1. We show the assertions (i)–(iv) of Theorem 2.1 simultaneously by applying Theorem 5 of Nipp and Stoffer [14] on the discrete Runge–Kutta dynamics of the DAE (3.1). First, let us analyze the projected Runge–Kutta methods. Using

the structure of the operator T_2 (see (3.14)) and the scheme (3.6), the projected Runge–Kutta iteration can be written in the explicit form

$$\begin{aligned} u_{n+1} &= \left[I - \frac{\partial}{\partial\lambda} f(\cdot, \lambda_p(h,u_n,\lambda_n))\gamma(h,u_n,\lambda_n)\right]^{-1} \\ &\quad \cdot (u_n + h(b^T \otimes I)\bar{f}(U(h,u_n), \Lambda(h,u_n))), \\ v_{n+1} &= g(u_n) - h(b^T \otimes I)\bar{B}(U(h,u_n))V(h,u_n), \\ \lambda_{n+1} &= R(\infty)\lambda_n + (b^T A^{-1} \otimes I)\Lambda(h,u_n). \end{aligned} \tag{4.1}$$

Moreover, the stability inequality of Lemma 3.3 implies $\gamma(h,u,\lambda) = O(h^{q+1})$. Then, using $(I - O(h^{q+1}))^{-1} = I + O(h^{q+1})$ (see, e.g., Söderlind [18, Cor. 2.3]) and neglecting the v-component, iteration (4.1) can be written in the form

$$\begin{aligned} u_{n+1} &= u_n + h[(b^T \otimes I)\bar{f}(U(h,u_n), \Lambda(h,u_n)) + h^q \hat{f}(h,u_n,\lambda_n)], \\ \lambda_{n+1} &= R(\infty)\lambda_n + (b^T A^{-1} \otimes I)\Lambda(h,u_n) \end{aligned} \tag{4.2}$$

with a smooth and bounded function $\hat{f}$.

Introducing $\eta_n := \lambda_n - \psi(u_n, g(u_n))$ and rewriting (4.2) yields

$$\begin{aligned} u_{n+1} &= u_n + h[(b^T \otimes I)\bar{f}(U(h,u_n), \Lambda(h,u_n)) + h^q \hat{f}(h,u_n,\eta_n + \psi(u_n, g(u_n)))] \\ &=: u_n + G_1(h,u_n,\eta_n), \\ \eta_{n+1} &= R(\infty)\eta_n + (b^T A^{-1} \otimes I)(\Lambda(h,u_n) - \mathbb{I} \otimes \psi(u_n, g(u_n))) \\ &\quad + \psi(u_n, g(u_n)) - \psi(u_n + G_1(h,u_n,\eta_n), g(u_n + G_1(h,u_n,\eta_n))) \\ &=: G_2(h,u_n,\eta_n). \end{aligned} \tag{4.3}$$

The functions G_1, G_2 are Lipschitzian with the constants

$$\begin{aligned} L_{G_1,u} &= O(h), \qquad L_{G_1,\eta} = O(h^{q+1}), \\ L_{G_2,u} &= O(1), \qquad L_{G_2,\eta} = |R(\infty)| + O(h^{q+1}) < 1. \end{aligned} \tag{4.4}$$

Obviously, for a fixed number $r \in \mathbb{N}$, the conditions

$$\begin{aligned} 2\sqrt{L_{G_1,\eta} L_{G_2,u}} &< 1 - L_{G_1,u} - L_{G_2,\eta}, \\ L_{G_2,\eta} + L_{G_1,\eta}\alpha &< (1 - L_{G_1,u} - L_{G_1,\eta}\alpha)^r, \end{aligned}$$

with

$$\alpha := \frac{2L_{G_2,u}}{1 - L_{G_1,u} - L_{G_2,\eta} + \sqrt{(1 - L_{G_1,u} - L_{G_2,\eta})^2 - 4L_{G_1,\eta}L_{G_2,u}}},$$

are satisfied for $h > 0$ sufficiently small. Now, Theorem 5 of Nipp and Stoffer [14] guarantees the existence of a C_b^ν-function η_h which defines the discrete invariant manifold by $\eta = \eta_h(u)$. In the (u,λ)-coordinates we obtain the following result with $\psi_h(u) := \psi(u, g(u)) + \eta_h(u)$, $u \in D_{\tau_0}$, for $0 < h \le h_0$, $h_0 > 0$, sufficiently small:

(i) The set $M_h = \{(u,\lambda) \in D_{\tau_0} \times \mathbb{R}^l \mid \lambda = \psi_h(u)\}$ is invariant for the projected Runge–Kutta map (4.2).

(ii) The manifold M_h is uniformly attractive with attractivity constant $\chi_h = |R(\infty)| + O(h^{q+1})$.

(iii) For every initial value (u_0, λ_0) with $\|\lambda_0 - \psi(u_0, g(u_0))\|$ sufficiently small, there is $(\tilde{u}_0, \tilde{\lambda}_0) \in M_h$ and $c, \hat{c} > 0$ such that the corresponding evolutions (u_n, λ_n) and $(\tilde{u}_n, \tilde{\lambda}_n)$ satisfy

$$\begin{aligned} \|u_i - \tilde{u}_i\| &\le c\chi_h^i \|\lambda_0 - \psi(u_0, g(u_0))\|, \quad i \in \mathbb{N}, \\ \|\lambda_i - \tilde{\lambda}_i\| &\le \hat{c}\chi_h^i \|\lambda_0 - \psi(u_0, g(u_0))\|, \quad i \in \mathbb{N}. \end{aligned}$$

(iv) $\|\psi(u, g(u)) - \psi_h(u)\| \le C \sup\{\|\beta(h, u, \lambda - \psi(u, g(u)))\| \mid (h, u, \lambda) \in \Gamma_{h_0,\epsilon,\tau_0}\}$ with $\Gamma_{h_0,\epsilon,\tau_0} := \{(h, u, \lambda) \in]0, h_0] \times D_{\tau_0} \times \mathbb{R}^l \mid \|\lambda - \psi(u, g(u))\| < \epsilon\}$.

Here the reader may notice that to apply Theorem 5 of Nipp and Stoffer [14] formally, we have to enlarge the domain of G_1, G_2 for $u \in \mathbb{R}^N$ as C_b^ν-maps which satisfy the Lipschitz conditions (4.4).

Reduced to the invariant manifold M_h, the u-component of a projected Runge–Kutta method reads

$$u_{n+1} = u_n + h[(b^T \otimes I)\bar{f}(U(h, u_n), \Lambda(h, u_n)) + h^q \hat{f}(h, u_n, \psi_h(u_n))]. \tag{4.5}$$

Obviously, the iteration scheme (4.5) can be regarded as a qth order one-step method applied to the initial value problem

$$\dot{u} = f(u, \psi(u, g(u))), \quad u(0) = u_0. \tag{4.6}$$

Next we estimate the distance between M_h and

$$M = \{(u, \lambda) \in D_{\tau_0} \times \mathbb{R}^l \mid \lambda = \psi(u, g(u))\}.$$

Since $\beta_n = O(h)$ holds with β from (3.17) we directly obtain $M_h - M = O(h)$.

The next step in the proof of Theorem 2.1 for the projected Runge–Kutta methods is to show $\beta_n := \beta(h, u_n, \eta_n) = O(h^q)$. Due to formula (3.17), the representation

$$\begin{aligned} \beta_n = {} & (b^T A^{-1} \otimes I)(\Lambda(h, u_n) - \bar{\psi}(U(h, u_n), \bar{g}(U(h, u_n)))) \\ & + (b^T A^{-1} \otimes I)(\bar{\psi}(U(h, u_n), \bar{g}(U(h, u_n))) - \mathbb{I} \otimes \psi(u_n, g(u_n))) \\ & + \psi(u_n, g(u_n)) - \psi(u_{n+1}, g(u_{n+1})) \end{aligned} \tag{4.7}$$

is valid. Now, we analyze the first term on the right-hand side of (4.7). With the solution flow $(\tilde{u}(t, u_0), \tilde{v}(t, u_0), \tilde{\lambda}(t, u_0))$, $u_0 \in D_{\tau_0}$, $\tilde{v}(t, u_0) = g(\tilde{u}(t, u_0))$, $\tilde{\lambda}(t, u_0) = \psi(\tilde{u}(t, u_0), \tilde{v}(t, u_0))$ of the underlying DAE (3.1), this gives

$$\begin{aligned} & (b^T A^{-1} \otimes I)(\Lambda(h, u_n) - \bar{\psi}(U(h, u_n), \bar{g}(U(h, u_n)))) \\ & \quad = O(1)[\Lambda_i(h, u_n) + \psi(\tilde{u}(c_i h, u_n), g(\tilde{u}(c_i h, u_n))) - \tilde{\lambda}(c_i h, u_n) \\ & \qquad - \psi(U_i(h, u_n), g(U_i(h, u_n))),\ i = 1, \dots, s] \\ & \quad = O(h^q), \end{aligned} \tag{4.8}$$

since

$$\begin{aligned} U_i(h, u_n) - \tilde{u}(c_i h, u_n) &= O(h^{q+1}), \quad i = 1, \dots, s, \\ \Lambda_i(h, u_n) - \tilde{\lambda}(c_i h, u_n) &= O(h^q), \qquad i = 1, \dots, s, \end{aligned} \tag{4.9}$$

hold (see, e.g., Hairer and Wanner [11, Chap. VII, Lem. 4.4]).

To examine the second term on the right-hand side of (4.7) appropriately we have to do some preparation. Let

$$\begin{aligned} \hat{u}_{n+1} &= \hat{u}_n + h(b^T \otimes I)\bar{f}(\hat{U}(h,\hat{u}_n), \hat{\Lambda}(h,\hat{u}_n)), \\ \hat{\lambda}_{n+1} &= R(\infty)\hat{\lambda}_n + (b^T A^{-1} \otimes I)\hat{\Lambda}(h,\hat{u}_n), \end{aligned} \tag{4.10}$$

with $(\hat{U}(h,\hat{u}_n), \hat{\Lambda}(h,\hat{u}_n))$ being a solution of

$$S(h,\hat{u}_n,\hat{U},\hat{\Lambda}) = \begin{pmatrix} \hat{U} - \mathbb{I}\otimes\hat{u}_n - h(A\otimes I)\bar{f}(\hat{U},\hat{\Lambda}) \\ D\bar{g}(\hat{U})\bar{f}(\hat{U},\hat{\Lambda}) + \bar{B}(\hat{U})\bar{g}(\hat{U}) \end{pmatrix} = 0, \tag{4.11}$$

stand for the Runge–Kutta method with tableau (2.3) applied to the DAE

$$\begin{aligned} \dot{u} &= f(u,\lambda), \\ 0 &= Dg(u)f(u,\lambda) + B(u)g(u). \end{aligned} \tag{4.12}$$

Equation (4.12) is the index 1 problem with eliminated v-variables corresponding to (3.1). From (4.11) and the fact that the continuous solution $(\tilde{u}(t,u), \tilde{\lambda}(t,u))$, $u \in D_{\tau_0}$, satisfies (4.12), we can conclude with (4.9) that

$$\begin{aligned} S(h,\hat{u}_n,U(h,\hat{u}_n),\Lambda(h,\hat{u}_n)) &= (0, D\bar{g}(U(h,\hat{u}_n))\bar{f}(U(h,\hat{u}_n),\Lambda(h,\hat{u}_n)) \\ &\quad - \bar{B}(U(h,\hat{u}_n))\bar{g}(U(h,\hat{u}_n))) \\ &= (0, O(1)[(U_i(h,\hat{u}_n) - \tilde{u}(c_i h,\hat{u}_n),\ i=1,\dots,s), \\ &\quad (\Lambda_i(h,\hat{u}_n) - \tilde{\lambda}(c_i h,\hat{u}_n),\ i=1,\dots,s)]) = (0, O(h^q)). \end{aligned}$$

Here, $(U,\Lambda) = (U(h,\hat{u}_n),\Lambda(h,\hat{u}_n))$ denotes the solution of (3.12). Moreover, we have

$$\frac{\partial}{\partial(\hat{U},\hat{\Lambda})} S(h,\hat{u}_n,\hat{U}(h,\hat{u}_n),\hat{\Lambda}(h,\hat{u}_n)) = \begin{pmatrix} I & 0 \\ O(1) & I\otimes Dg(\hat{u}_n)\frac{\partial f}{\partial\lambda}(\hat{\gamma}(\hat{u}_n)) \end{pmatrix} + O(h).$$

Thus, for $h>0$ sufficiently small, $\frac{\partial}{\partial(\hat{U},\hat{\Lambda})} S(h,\hat{u}_n,\hat{U}(h,\hat{u}_n),\hat{\Lambda}(h,\hat{u}_n))$ is invertible and the stability inequality of Lemma 3.1 shows

$$(U-\hat{U},\Lambda-\hat{\Lambda})(h,\hat{u}_n) = O(h^q). \tag{4.13}$$

We insert (4.13) into formula (4.10) and obtain with $u_n = \hat{u}_n$ and (4.2) the relation

$$\hat{u}_{n+1} = u_{n+1} + O(h^{q+1}). \tag{4.14}$$

With the formulae (4.13) and (4.14) we manipulate the second term on the right-hand side of (4.7) as follows:

(4.15)

$$\begin{aligned} &(b^T A^{-1}\otimes I)(\bar{\psi}(U(h,u_n),\bar{g}(U(h,u_n))) - \mathbb{I}\otimes\psi(u_n,g(u_n))) \\ &\qquad + \psi(u_n,g(u_n)) - \psi(u_{n+1},g(u_{n+1})) \\ &= (b^T A^{-1}\otimes I)(\bar{\psi}(\hat{U}(h,\hat{u}_n),\bar{g}(\hat{U}(h,\hat{u}_n))) - \mathbb{I}\otimes\psi(\hat{u}_n,g(\hat{u}_n))) \\ &\qquad + \psi(\hat{u}_n,g(\hat{u}_n)) - \psi(\hat{u}_{n+1},g(\hat{u}_{n+1})) + O(h^q). \end{aligned}$$

Next, we embed the index 1 problem (4.12) into the singular perturbed problem

$$\begin{aligned} \dot{u} &= f(u,\lambda), \\ \epsilon\dot{\lambda} &= Dg(u)f(u,\lambda) + B(u)g(u). \end{aligned} \tag{4.16}$$

We define $H(u,\lambda) := Dg(u)f(u,\lambda) + B(u)g(u)$ and consider the discrete scheme corresponding to (4.16). This reads

$$\hat{u}^\epsilon_{n+1} = \hat{u}^\epsilon_n + h(b^T \otimes I)\bar{f}(\hat{U}^\epsilon(h,\hat{u}_n), \hat{\Lambda}^\epsilon(h,\hat{u}_n)),$$
$$\hat{\lambda}^\epsilon_{n+1} = \hat{\lambda}^\epsilon_n + \frac{h}{\epsilon}(b^T \otimes I)\bar{H}(\hat{U}^\epsilon(h,\hat{u}_n), \hat{\Lambda}^\epsilon(h,\hat{u}_n)),$$

with $(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \hat{\Lambda}^\epsilon(h,\hat{u}^\epsilon_n))$ being the solution of

$$\hat{U}^\epsilon - \mathbb{I} \otimes \hat{u}^\epsilon_n = h(A \otimes I)\bar{f}(\hat{U}^\epsilon, \hat{\Lambda}^\epsilon),$$
$$\epsilon(\hat{\Lambda}^\epsilon - \mathbb{I} \otimes \hat{\lambda}^\epsilon_n) = h(A \otimes I)\bar{H}(\hat{U}^\epsilon, \hat{\Lambda}^\epsilon.$$

Following Nipp and Stoffer [15, formulae (6) and (7)], we define the functions

$$\begin{aligned} E(\hat{u}^\epsilon_n, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) &:= \bar{\psi}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{g}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n))) - \mathbb{I} \otimes \psi(\hat{u}^\epsilon_n, g(\hat{u}^\epsilon_n)) \\ &\quad - \frac{h}{\epsilon}(A \otimes I)\bar{H}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{\psi}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{g}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n)))), \\ e(\hat{u}^\epsilon_n, \hat{u}^\epsilon_{n+1}, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) &:= \psi(\hat{u}^\epsilon_n, g(\hat{u}^\epsilon_n)) - \psi(\hat{u}^\epsilon_{n+1}, g(\hat{u}^\epsilon_{n+1})) \\ &\quad - \frac{h}{\epsilon}(b^T \otimes I)\bar{H}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{\psi}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{g}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n)))). \end{aligned}$$

Then with $E(\hat{u}^\epsilon_n, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) = O(h^{q+1}) + O(\epsilon)$, $e(\hat{u}^\epsilon_n, \hat{u}^\epsilon_{n+1}, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) = O(h^{q+1}) + O(\epsilon)$ (see formula (18) in Nipp and Stoffer [15]), the relation

$$\begin{aligned} &(b^T A^{-1} \otimes I)E(\hat{u}^\epsilon_n, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) - e(\hat{u}^\epsilon_n, \hat{u}^\epsilon_{n+1}, \hat{U}^\epsilon(h,\hat{u}^\epsilon_n)) \\ &\quad = (b^T A^{-1} \otimes I) \cdot (\bar{\psi}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n), \bar{g}(\hat{U}^\epsilon(h,\hat{u}^\epsilon_n))) - \mathbb{I} \otimes \psi(\hat{u}^\epsilon_n, g(\hat{u}^\epsilon_n))) \\ &\qquad + \psi(\hat{u}^\epsilon_n, g(\hat{u}^\epsilon_n)) - \psi(\hat{u}^\epsilon_{n+1}, g(\hat{u}^\epsilon_{n+1})) = O(h^{q+1}) + O(\epsilon) \end{aligned} \tag{4.17}$$

follows. Letting $\epsilon \to 0$ in (4.17), noticing $\hat{U}^0 = \hat{U}$, $\hat{\Lambda}^0 = \hat{\Lambda}$, $\hat{u}^0_n = \hat{u}_n$, $\hat{\lambda}^0_n = \hat{\lambda}$, and inserting (4.17) with $\epsilon = 0$ into (4.15) and finally in (4.7) gives $\beta_n = O(h^q)$. This shows $\|\psi(u,g(u)) - \psi_h(u)\| \le Ch^q$, $u \in D_{\tau_0}$.

Now, we complete the proof of Theorem 2.1. Since the projected Runge–Kutta methods applied to the original DAE (2.1) can be regarded as the same method applied to the embedded DAE (3.1) with $v(0) = v_0 = 0$, we can draw back the results derived for (3.1) to (2.1). We restrict (4.5) to the invariant set S and define $\psi_{0,h} := \psi_h|_S$ by $\psi_{0,h}(u) = \psi_h(u)$, $u \in S$, as well as $M_{0,h} = \{(u,\lambda) \in D_{\tau_0} \times \mathbb{R}^l \mid g(u) = 0,\ \lambda = \psi_{0,h}(u)\}$.

In the case of half-explicit Runge–Kutta methods, we obtain the iteration scheme

$$\begin{aligned} u_{n+1} &= u_n + h(b^T \otimes I)\bar{f}((u_n, \tilde{U}_1(h,u_n), \dots, \tilde{U}_{s-1}(h,u_n)), \Lambda(h,u_n)), \\ \lambda_{n+1} &= \Lambda_s(h,u_n) \end{aligned} \tag{4.18}$$

from (3.19) and (2.10). Again, introducing $\eta_n = \lambda_n - \psi(u_n, g(u_n))$ yields

$$\begin{aligned} u_{n+1} &= u_n + h(b^T \otimes I)\bar{f}((u_n, \tilde{U}_1(h,u_n), \dots, \tilde{U}_{s-1}(h,u_n)), \Lambda(h,u_n)) \\ &= u_n + \tilde{G}_1(h,u_n,\eta_n), \\ \eta_{n+1} &= \Lambda_s(h,u_n) - \psi(u_n + \tilde{G}_1(h,u_n,\eta_n), g(u_n + \tilde{G}_1(h,u_n,\eta_n))) = \tilde{G}_2(h,u_n,\eta_n). \end{aligned}$$

Then we can adapt the proof of the projected Runge–Kutta method to the half-explicit Runge–Kutta scheme. With (B3′) and $c_s = 1$ we can estimate

$$\begin{aligned} \beta_n &= \Lambda_s(h,u_n) - \psi(u_{n+1}, g(u_{n+1})) \\ &= \Lambda_s(h,u_n) - \tilde{\lambda}(h,u_n) + \psi(\tilde{u}(h,u_n), g(\tilde{u}(h,u_n))) - \psi(u_{n+1}, g(u_{n+1})) = O(h^r). \end{aligned}$$

Finally, the attraction constant $\chi_h = 0$ follows from the fact that $L_{\tilde{G}_{1,\eta}} = L_{\tilde{G}_{2,\eta}} = 0$. This finishes the proof of Theorem 2.1.

5. Discretization near periodic orbits. In this section we prove Theorem 2.2. Let $(\bar{u}(t,u_0),\psi_0(\bar{u}(t,u_0)))$ be a hyperbolic T-periodic orbit of the DAE (2.1). By definition this means that $\bar{u}(t,u_0)$ is a hyperbolic T-periodic orbit of the corresponding index 0 equation (2.2) with phase space $S=\{u\in D_{\tau_0}\mid g(u)=0\}$. For fixed t we have the linearized flow

$$\frac{\partial}{\partial u}\bar{u}(t,u_0):N(Dg(u_0))\to N(Dg(\bar{u}(t,u_0)))$$

of (2.1), and $\frac{\partial}{\partial u}\bar{u}(t,u_0)v$, $v\in N(Dg(u_0))$, can be computed via solving

$$\begin{aligned}\dot{z}&=\left[\frac{\partial f}{\partial u}(\Gamma(t,u_0))+\frac{\partial f}{\partial\lambda}(\Gamma(t,u_0))D\psi_0(\bar{u}(t,u_0))\right]z,\\ z(0)&=v\in N(Dg(u_0)).\end{aligned}$$

Here $\Gamma(t,u_0)$ stands for $(\bar{u}(t,u_0),\psi_0(\bar{u}(t,u_0)))$. The reader may recall that the image space of $\frac{\partial}{\partial u}\bar{u}(t,u_0)$ is $N(Dg(\bar{u}(t,u_0)))$ since $g(\bar{u}(t,u_0))=0$, $t\in\mathbb{R}$.

For $t=T$ we obtain $\frac{\partial}{\partial u}\bar{u}(T,u_0):N(Dg(u_0))\to N(Dg(u_0))$. The hyperbolicity says that the linearized T-flow has the simple eigenvalue 1 and all other eigenvalues have absolute value different from 1.

Now, let $V\in\mathbb{R}^{N,N-l}$ denote a basis of $N(Dg(u_0))$. Then, with the monodromy matrix $X(T)=(X^1(T),\dots,X^{N-l}(T))\in\mathbb{R}^{N-l,N-l}$ in the basis $V=(v_1,\dots,v_{N-l})$, we obtain

$$\frac{\partial}{\partial u}\bar{u}(T,u_0)v_i=VX^i(T),\quad i=1,\dots,N-l. \tag{5.1}$$

Here, $X^i(T)$, v_i, $i=1,\dots,N-l$, denote the ith column of $X(T)$, V, respectively. Our first goal in this section is to show that $\bar{u}(t,u_0)$ is a hyperbolic periodic orbit of (3.5). This is the content of the following lemma.

LEMMA 5.1. *Let* (A1)–(A3) *hold and let* $(\bar{u}(t,u_0),\psi_0(\bar{u}(t,u_0)))$, $\bar{u}(t,u_0)=\bar{u}(t+T,u_0)$ *denote a hyperbolic* T*-periodic orbit of the DAE* (2.1). *Then* $\bar{u}(t,u_0)$ *is a hyperbolic* T*-periodic orbit of the ODE* (3.5).

Proof. Let $\tilde{u}(t,u)$ denote the solution flow of (3.5) and let $\bar{u}(t,u)$ stand for the solution flow of (2.2). We know $\tilde{u}(t,u)=\bar{u}(t,u)$ for $u\in S$. Obviously, $\bar{u}(t,u_0)$ is a T-periodic orbit for (3.5). It remains to show the hyperbolicity.

Linearizing (3.5) at the T-periodic orbit $\bar{u}(t,u_0)$ we obtain that $\frac{\partial}{\partial u}\tilde{u}(t,u_0)$ solves the variational equation

$$\dot{Y}(t)=Dk(\bar{u}(t,u_0))Y(t),\quad Y(0)=I.$$

We split the whole space according to $\mathbb{R}^N=N(Dg(u_0))\oplus R(\frac{\partial f}{\partial\lambda}(u_0,\psi_0(u_0)))=:R(V)\oplus R(W)$. Here the reader may recall that the split of $\mathbb{R}^N$ is possible due to the index 2 condition (A3). We analyze the behavior of $Y(T)$ for initial values in V and W separately. We claim

$$\frac{\partial}{\partial u}\tilde{u}(T,u_0)V\alpha=\frac{\partial}{\partial u}\bar{u}(T,u_0)V\alpha,\quad \alpha\in\mathbb{R}^{N-l}, \tag{5.2}$$

for initial values in $R(V)$. In what follows, we first assume (5.2) and finish the proof. Combining the formulae (5.1), (5.2) yields $Y(T)V=VX(T)$ with the monodromy matrices $X(T)$, $Y(T)$ of the periodic orbits $\bar{u}(t,u_0)$ and $\tilde{u}(t,u_0)$.

Now, let $Z(t) := Dg(\bar{u}(t,u_0))Y(t)\frac{\partial f}{\partial \lambda}(\Gamma(0,u_0))S(u_0)^{-1}$, $S(u) := Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi_0(u))$. A straightforward computation shows that Z is the fundamental matrix of

$$\dot{w} = -B(\bar{u}(t,u_0))w. \tag{5.3}$$

To analyze the behavior of $Y(T)$ for initial values in $R(W)$ we make the ansatz

$$Y(T)W = V\Lambda_{12}(T) + W\Lambda_{22}(T)$$

with matrices $\Lambda_{12}(T) \in \mathbb{R}^{N-l,l}$ and $\Lambda_{22}(T) \in \mathbb{R}^{l,l}$. Using $Dg(u_0)V \equiv 0$ we can calculate

$$Y(T)(V,W) = (V,W)\cdot\begin{pmatrix} X(T) & \Lambda_{12}(T) \\ 0 & S(u_0)^{-1}Z(T)S(u_0)\end{pmatrix}. \tag{5.4}$$

Finally, with $\mu_2(-B(u)) \le -\eta$, $\eta > 0$, we obtain

$$\|w(t)\|_2 = \|Z(t)w(0)\|_2 \le \exp(-\eta t)\|w(0)\|_2$$

for the solution of (5.3) (see Dekker and Verwer [6, Thm. 1.5.2]). Hence, $\|Z(t)\|_2 \le \exp(-\eta t)$ and $\rho(S(u_0)^{-1}Z(T)S(u_0)) = \rho(Z(T)) \le \exp(-\eta T)$ follows. Together with formula (5.4) this shows the eigenvalue condition for the monodromy matrix $Y(T)$ of the periodic orbit $\bar{u}(t,u_0)$ of (3.5).

It remains to show formula (5.2). To this purpose we need some additional relations, which we now provide. First, a straightforward calculation with $\hat{\gamma}(u) = (u,\psi(u,g(u)))$ shows

$$Dk(u) = \frac{\partial f}{\partial u}(\hat{\gamma}(u)) + \frac{\partial f}{\partial \lambda}(\hat{\gamma}(u))\left(\frac{\partial \psi}{\partial u}(u,g(u)) + \frac{\partial \psi}{\partial v}(u,g(u))Dg(u)\right). \tag{5.5}$$

Moreover, implicit differentiation of relation $Dg(u)f(u,\psi(u,v)) + B(u)v = 0$ with respect to u and v yields

$$\begin{aligned}\frac{\partial \psi}{\partial u}(u,v) = &-\left(Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi(u,v))\right)^{-1}\left[Dg(u)\frac{\partial f}{\partial u}(u,\psi(u,v)) + DB(u)v\right.\\ &\left.+ D^2g(u)f(u,\psi(u,v))\right],\\ \frac{\partial \psi}{\partial v}(u,v) = &-\left(Dg(u)\frac{\partial f}{\partial \lambda}(u,\psi(u,v))\right)^{-1}B(u).\end{aligned} \tag{5.6}$$

Thus, with $v = g(u)$ and the projector $Q(u) := \frac{\partial f}{\partial \lambda}(\hat{\gamma}(u))(Dg(u)\frac{\partial f}{\partial \lambda}(\hat{\gamma}(u)))^{-1}Dg(u)$ onto $R(\frac{\partial f}{\partial \lambda}(\hat{\gamma}(u)))$ we insert (5.6) into (5.5) and obtain

$$\begin{aligned}Dk(u) = (I - Q(u))\frac{\partial f}{\partial u}(\hat{\gamma}(u)) - \frac{\partial f}{\partial \lambda}(\hat{\gamma}(u))\left(Dg(u)\frac{\partial f}{\partial \lambda}(\hat{\gamma}(u))\right)^{-1}\\ \cdot [B(u)Dg(u) + DB(u)g(u) + D^2g(u)k(u)].\end{aligned}$$

Using $(I - Q(u))\frac{\partial f}{\partial \lambda}(\hat{\gamma}(u)) = 0$, we can compute

$$(I - Q(u))Dk(u) = (I - Q(u))\frac{\partial f}{\partial u}(\hat{\gamma}(u)). \tag{5.7}$$

To link the vectorfields $k(u) = f(u, \psi(u, g(u)))$ and $f(u, \psi_0(u))$, we differentiate the relation $Dg(u)f(u, \psi_0(u)) = 0$ (compare with (A2)) and obtain

$$D\psi_0(u) = -\left(Dg(u)\frac{\partial f}{\partial \lambda}(\hat{\gamma}(u))\right)^{-1}\left[Dg(u)\frac{\partial f}{\partial u}(\hat{\gamma}(u)) + D^2g(u)f(u, \psi_0(u))\right]. \tag{5.8}$$

Finally, we need

$$Dg(\tilde{u}(t, u_0))\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha = 0. \tag{5.9}$$

Relation (5.9) follows from the fact that $\tilde{w}(t) := Dg(\tilde{u}(t, u_0))\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha$ solves (5.3) with initial condition $\tilde{w}(0) = 0$.

Then, with (5.7)–(5.9) and $S(u) = Dg(u)\frac{\partial f}{\partial \lambda}(u, \psi_0(u))$, we can compute

$$\begin{aligned}
\frac{\partial^2}{\partial t \partial u}\tilde{u}(t, u_0)V\alpha &= Dk(\tilde{u}(t, u_0))\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha \\
&= \Bigg[(I - Q(\tilde{u}(t, u_0)))\frac{\partial f}{\partial u}(\Gamma(t, u_0)) \\
&\quad + Q(\tilde{u}(t, u_0))Dk(\tilde{u}(t, u_0))\Bigg]\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha \\
&= \Bigg[\frac{\partial f}{\partial u}(\Gamma(t, u_0)) - \frac{\partial f}{\partial \lambda}(\Gamma(t, u_0))S(\tilde{u}(t, u_0))^{-1}\Bigg[Dg(\tilde{u}(t, u_0)) \\
&\quad \cdot \frac{\partial f}{\partial u}(\Gamma(t, u_0)) + D^2g(\tilde{u}(t, u_0))k(\tilde{u}(t, u_0))\Bigg]\Bigg]\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha \\
&= \left[\frac{\partial f}{\partial u}(\Gamma(t, u_0)) + \frac{\partial f}{\partial \lambda}(\Gamma(t, u_0))D\psi_0(\bar{u}(t, u_0))\right]\frac{\partial}{\partial u}\tilde{u}(t, u_0)V\alpha,
\end{aligned} \tag{5.10}$$

and (5.2) is shown. This finishes the proof. □

In the remainder of this section we give a proof of Theorem 2.2. By virtue of Lemma 5.1, $\bar{u}(t, u_0)$ is a hyperbolic T-periodic orbit of (4.6) and, in section 4, we have seen that (4.5) is a smooth qth order one-step method applied to (4.6). Thus, Beyn [2, Thm. 1] is applicable and ensures for sufficiently small step size h the existence of an invariant curve $\bar{u}^h(\mathbb{R})$, $\bar{u}^h(t) = \bar{u}^h(t + T)$, for the one-step method

$$\begin{aligned}
u_{n+1} &= u_n + h(b^T \otimes I)\bar{f}(U(h, u_n), \Lambda(h, u_n)) + h^{q+1}\hat{f}(h, u_n, \psi_h(u_n)) \\
&=: G_h(u_n), \quad u_0 \in D_{\tau_0}
\end{aligned} \tag{5.11}$$

(compare with (4.5)) having properties

$$\begin{aligned}
\bar{u}^h(t + h + O(h^{q+1})) &= G_h(\bar{u}^h(t)), \\
\max\{\|\bar{u}(t, u_0) - \bar{u}^h(t)\| \mid t \in \mathbb{R}\} &\le Ch^q.
\end{aligned} \tag{5.12}$$

The last step in our proof is to draw back the results (5.12) to S. Obviously, we have $g(\bar{u}^h(\mathbb{R})) = 0$. This is a consequence of the fact that $\bar{u}^h(\mathbb{R})$ is an invariant set and every invariant set is located in the maximal invariant set S.

On the phase space S the iteration scheme (5.11) coincides with the u-component of the projected Runge–Kutta method (2.4)–(2.6) applied to $\dot{u} = f(u, \lambda)$, $g(u) = 0$. Thus, the discrete iteration scheme (2.4)–(2.6) possesses an invariant curve which is $O(h^q)$ close to the periodic orbit.

An analogous argument works for the half-explicit Runge–Kutta methods too and ensures the existence of an $O(h^r)$ invariant curve close to the periodic orbit.

UNIFORM STABILITY OF A FINITE DIFFERENCE SCHEME FOR TRANSPORT EQUATIONS IN DIFFUSIVE REGIMES*

A. KLAR† AND A. UNTERREITER‡

Abstract. An asymptotic preserving numerical scheme (with respect to diffusion scalings) for a linear transport equation is investigated. The scheme is adopted from a class of schemes developed in [S. Jin, L. Pareschi, and G. Toscani, *SIAM J. Numer. Anal.*, 38 (2000), pp. 913–936] and [A. Klar, *SIAM J. Numer. Anal.*, 35 (1998), pp. 1073–1094]. Stability is proven uniformly in the mean free path under a CFL-type condition turning into a parabolic CFL condition in the diffusion limit.

Key words. transport equations, relaxation methods, stability analysis

1. Introduction.

Transport equations and kinetic equations are used for a variety of applications, for example, to simulate radiative heat transfer processes or rarefied gas flows. Near to the continuum regimes the equations are approximated by macroscopic equations like diffusion equations or fluid dynamic equations. In recent years, asymptotic preserving schemes for kinetic equations and transport equations have gained considerable attention in the literature. These schemes are used to treat singularly perturbed transport equations in situations with small mean free paths, i.e., in the above-mentioned macroscopic limits. Schemes for in-stationary transport equations in the diffusion limit can be found, for example, in [6, 7, 8, 12] and references therein. Schemes for other types of transport equations with diffusive macroscopic limits have been developed in [5, 4, 1, 9, 11, 10].

Concerning the numerical analysis of these schemes, proofs of uniform consistency with respect to a small mean free path ϵ can be found in [7, 1, 8]. Furthermore, using the homogenization theory for transport equations, a proof of uniform convergence (as $\epsilon \to 0$) for time-continuous equations discretized spatially and in velocity is given in [3, 2].

The aim of our paper is to prove a uniform stability result for semidiscrete (time- and space-discrete) numerical schemes for transport equations as developed in [7, 8]. (Numerical investigations of these schemes and proofs of uniform consistency can be found in [7, 8].)

A time-and-space discretization is performed and linear stability is proved uniformly in ϵ using a careful direct analysis of the iterative scheme. First, the problem is tackled by a von Neumann analysis of the system in a continuous function space setting. This gives explicit and accurate estimates.

Under an ϵ-dependent CFL-type restriction, the iterations are proved to be uniformly bounded. As ϵ tends to 0, the CFL-type condition turns into a parabolic CFL condition which can be satisfied by ϵ-independent grids.

For a large mean free path, the CFL condition is adapted to the transport equation.

In a further step, it is shown that the stability analysis carries over to discrete function spaces with piecewise linear finite element method (FEM) for the spatial discretization.

The paper is organized as follows. In section 2 equations and the semidiscrete scheme are introduced. Section 3 contains some definitions and the statement of the main result. In section 4 several preliminary results are established, and section 5 contains the proof of the main result. Section 6 is concerned with the recursion on a discrete function space.

2. Equations and numerical scheme. Our model problem is the one-dimensional linear transport equation with isotropic scattering,

$$\epsilon^2\,\partial_t F + \epsilon\, v\,\partial_x F = \frac{1}{2}\int_{-1}^{1} F dv - F, \tag{2.1}$$

with density $F = F(x, v, t)$, $x \in \mathbb{R}$, $v \in [-1, 1]$, and $t \in [0, \infty)$. We pass to the even-odd parity formulation by introducing, for $v > 0$, the even and odd functions

$$f(v) = \frac{1}{2}(F(v) + F(-v)),$$
$$g(v) = \frac{1}{2\epsilon}(F(v) - F(-v)).$$

This defines

$$F(v) = f(v) + \epsilon g(v), \qquad v > 0,$$
$$F(v) = f(-v) - \epsilon g(-v), \qquad v < 0,$$

such that (2.1) becomes, for $v > 0$,

$$\partial_t f + v\,\partial_x g = \frac{1}{\epsilon^2}\left([f] - f\right), \qquad [f] := \int_0^1 f dv, \tag{2.2}$$

$$\partial_t g + \frac{v}{\epsilon^2}\,\partial_x f = -\frac{1}{\epsilon^2} g. \tag{2.3}$$

Remark. Concerning the limit $\epsilon \to 0$ in (2.2), (2.3) we obtain, from a formal asymptotic expansion,

$$f = \rho = [f], \qquad g = -v\,\partial_x f,$$

where $\rho = \rho(x, t)$ fulfills the diffusion equation

$$\partial_t \rho = \frac{1}{3}\partial_{xx}\rho. \tag{2.4}$$

We describe a semidiscrete scheme which is taken from a general class of schemes developed in [8, 6]. For the time discretization we use the time step $\Delta t \in \mathbb{R}^+$. The spatial step size is Δx. The time iterations approximating $f(x, v, n\Delta t)$ and $g(x, v, n\Delta t)$ are $f^n(x, v)$ and $g^n(x, v)$ (for $n \in \mathbb{N}$ or $n = 0$), respectively.

Given f^n, g^n we calculate f^{n+1}, g^{n+1} by a fractional step scheme, where the spatial discretization is a first order discretization.

Remark. The reader is invited to consult [6] for more sophisticated approaches.

Notation. In what follows, $\mathbb{N}_0 = \mathbb{N} \cup \{0\}$.

ALGORITHM.

Step 1. *Approximate the solution of the system*

$$\begin{aligned} \partial_t f + v\partial_x g &= 0, \\ \partial_t g &= 0 \end{aligned}$$

by an explicit discretization; i.e., determine $f^{n+\frac{1}{2}}, g^{n+\frac{1}{2}}$ *via*

$$\left.\begin{aligned} f^{n+\frac{1}{2}} &= f^n - \Delta t\, v\, D_+ g^n \\ g^{n+\frac{1}{2}} &= g^n \end{aligned}\right\} \quad n \in \mathbb{N}_0,$$

where D_+ *is the forward difference with step size* Δx,

$$D_+ f(x) = \frac{f(x+\Delta x) - f(x)}{\Delta x}.$$

Step 2. *Approximate the solution of the system*

$$\left.\begin{aligned} \partial_t f &= \frac{1}{\epsilon^2}([f] - f) \\ \partial_t g &= \frac{1}{\epsilon^2}(-v\,\partial_x f - g) \end{aligned}\right\} \quad n \in \mathbb{N}_0$$

by a semi-implicit discretization to treat the stiffness of the equations correctly; i.e., determine f^{n+1}, g^{n+1} *from* $f^{n+\frac{1}{2}}, g^{n+\frac{1}{2}}$ *via*

$$\left.\begin{aligned} f^{n+1} &= f^{n+\frac{1}{2}} + \frac{\Delta t}{\epsilon^2}\left(\left[f^{n+\frac{1}{2}}\right] - f^{n+1}\right) \\ g^{n+1} &= g^{n+\frac{1}{2}} + \frac{\Delta t}{\epsilon^2}\left[-v\, D_- f^{n+1} - g^{n+1}\right] \end{aligned}\right\} \quad n \in \mathbb{N}_0,$$

where D_- *denotes the backward difference with step size* Δx.

We rewrite the recursion formula of Step 2 as

$$\left.\begin{aligned} f^{n+1} &= A f^{n+\frac{1}{2}} + B\left[f^{n+\frac{1}{2}}\right] \\ g^{n+1} &= A g^{n+\frac{1}{2}} - B\, v\, D_- f^{n+1} \end{aligned}\right\} \quad n \in \mathbb{N}_0, \tag{2.5}$$

with

$$\begin{aligned} A &:= \left(1 + \frac{\Delta t}{\epsilon^2}\right)^{-1}, \\ B &:= \frac{\Delta t}{\epsilon^2} A = 1 - A = \left(\frac{\epsilon^2}{\Delta t} + 1\right)^{-1}. \end{aligned}$$

For the numerical analysis, it is convenient to combine both steps into a single step,

$$\left.\begin{aligned} f^{n+1} &= A(f^n - \Delta t\, v\, D_+ g^n) + B\left[f^n - \Delta t\, v\, D_+ g^n\right] \\ g^{n+1} &= A g^n - v\, A\, B\, D_- f^{n+1} - v\, B^2\, D_-\left[f^{n+1}\right] \end{aligned}\right\} \quad n \in \mathbb{N}_0, \tag{2.6}$$

or

$$g^{n+1} = A g^n - v\, A\, B\, D_-(f^n - \Delta t\, v\, D_+ g^n) - v\, B^2\, D_-\left[f^n - \Delta t\, v\, D_+ g^n\right], \quad n \in \mathbb{N}_0.$$

We are concerned mainly with investigations of scheme (2.6). Uniform consistency of similar schemes has been considered in [8] and [7]. We will prove a *uniform (in ϵ)* stability result.

Remark. Keeping Δt fixed and considering the limit $\epsilon \to 0$ of (2.6), we have $A \to 0, B \to 1$ as $\epsilon \to 0$, and we obtain the scheme

$$f^{n+1} = \left[f^{n+1}\right] = \left[f^n - \Delta t\, v\, D_+ g^n\right],$$
$$g^{n+1} = -v\, D_- \left[f^{n+1}\right];$$

i.e., in terms of $\rho^n = [f^n]$,

$$\rho^{n+1} = \rho^n + \frac{1}{3}\Delta t\, D_+ D_- \rho^n,$$

which is a straightforward explicit discretization of the diffusion equation (2.4).

3. The main result. In this section we state a theorem on uniform stability for (2.6). The proof is settled on a von Neumann stability analysis.

The recursion scheme (2.6) involves two positive discretization parameters Δt, Δx (which enter via $D_\pm$) and the scaled mean free path $\epsilon \in (0, \infty)$. We assume that $\Delta t, \Delta x, \epsilon$ satisfy the following condition.

DEFINITION. *$\Delta t, \Delta x$, and ϵ fulfill the transport CFL condition iff*

$$\frac{\Delta t}{(\Delta x)^2}\frac{\Delta t}{\epsilon^2 + \Delta t} < \frac{1}{2}. \tag{3.1}$$

Remark. Condition (3.1) is equivalent to

$$\frac{\Delta t}{(\Delta x)^2} < \frac{\epsilon^2 + \Delta t}{2\Delta t} \tag{3.2}$$

or

$$\frac{\Delta t}{\Delta x} < \sqrt{\frac{\epsilon^2 + \Delta t}{2}}. \tag{3.3}$$

For $\epsilon^2 \ll \Delta t$, condition (3.2) reduces to a *parabolic CFL condition*,

$$\frac{\Delta t}{(\Delta x)^2} < \frac{1}{2}, \tag{3.4}$$

related to the diffusion equation and, in case $\epsilon^2 \gg \Delta t$, condition (3.3) reduces to

$$\frac{\Delta t}{\Delta x} < \frac{\epsilon}{\sqrt{2}} \tag{3.5}$$

which is, for fixed ϵ, a *hyperbolic CFL condition* related to the transport equation.

Remark. Introducing

$$\rho := \frac{\Delta t}{\epsilon^2}, \quad \text{i.e., } \Delta t = \rho\epsilon^2,$$

the transport CFL condition (3.1) holds iff

$$\exists \delta \in \mathbb{R}^+ : \quad (\Delta x)^2 = 2\rho^2 \frac{1+\delta}{1+\rho} \cdot \epsilon^2.$$

Here, $\rho \ll 1$ corresponds to the well-resolved case $\Delta t \ll \epsilon^2$, and $1 \ll \rho$ corresponds to the underresolved case $\epsilon^2 \ll \Delta t$.

In the following, a von Neumann stability analysis of the semidiscrete scheme (2.6) will be performed.

First, we shall give the recursion (2.6) a well-defined meaning by introducing sets of functions on which the recursion operator of (2.6) acts. The recursion scheme will be viewed as an operator acting on a continuous function space. Remarks on the action of the recursion on discrete functions given by the values at the grid points are included in section 6.

We introduce the spaces

$$M := \{\phi : \mathbb{R} \times [0,1] \to \mathbb{C} : \ \phi \text{ is measurable}\},$$

$$\mathcal{L}^2(dx) := \left\{\varphi : \mathbb{R} \to \mathbb{C} : \ \varphi \text{ is measurable and } \int_{\mathbb{R}} |\varphi|^2 \, dx < \infty\right\},$$

$$\mathcal{L}^1(dv) := \left\{\varphi : [0,1] \to \mathbb{C} : \ \varphi \text{ is measurable and } \int_{[0,1]} |\varphi| \, dv < \infty\right\},$$

$$\mathcal{L}^2(d(x,v)) := \left\{\varphi \in M : \int_{\mathbb{R}\times[0,1]} |\varphi|^2 \, d(x,v) < \infty\right\}$$

equipped with the standard seminorms

$$\forall \varphi \in \mathcal{L}^2(dx): \quad \|\varphi\|_{\mathcal{L}^2(dx)} = \sqrt{\int_{\mathbb{R}} |\varphi|^2 \, dx},$$

$$\forall \varphi \in \mathcal{L}^1(dv): \quad \|\varphi\|_{\mathcal{L}^1(dv)} = \int_{[0,1]} |\varphi| \, dv,$$

$$\forall \varphi \in \mathcal{L}^2(d(x,v)): \quad \|\varphi\|_{\mathcal{L}^2(d(x,v))} = \sqrt{\int_{\mathbb{R}\times[0,1]} |\varphi|^2 \, d(x,v)}.$$

We choose the anisotropic Lebesgue space

$$\mathcal{L}^2(dx, \mathcal{L}^1(dv)) = \left\{\phi \in M : \ \left(\forall x \in \mathbb{R} : \ \phi(x,.) \in \mathcal{L}^1(dv)\right) \wedge \left(\|\phi\|_{\mathcal{L}^1(dv)} \in \mathcal{L}^2(dx)\right)\right\}$$

equipped with the canonical seminorm

$$\|\phi\|_{\mathcal{L}^2(dx,\mathcal{L}^1(dv))} = \sqrt{\int_{\mathbb{R}} \|\phi(x,.)\|^2_{\mathcal{L}^1(dv)} \, dx}, \qquad \phi \in \mathcal{L}^2(dx, \mathcal{L}^1(dv)),$$

as the domain of the integration operator [.].

Remark. Obviously, $\mathcal{L}^2(d(x,v)) \subseteq \mathcal{L}^2(dx, \mathcal{L}^1(dv))$ and

$$\|\varphi\|_{\mathcal{L}^2(dx,\mathcal{L}^1(dv))} \le \|\varphi\|_{\mathcal{L}^2(d(x,v))}, \qquad \phi \in \mathcal{L}^2(d(x,v)).$$

Then we have, in operator notation,

$$[.] : \mathcal{L}^2(dx, \mathcal{L}^1(dv)) \to \mathcal{L}^2(dx), \quad [\phi](x) = \int_{[0,1]} \phi(x,.)\, dv, \quad x \in \mathbb{R}.$$

Obviously, [.] is linear and

$$|[\phi]|(x) \le \|\phi(x,.)\|_{\mathcal{L}^1(dv)}, \qquad (\phi, x) \in \mathcal{L}^2(dx, \mathcal{L}^1(dv)) \times \mathbb{R}.$$

The Fourier transform of $\phi \in \mathcal{L}^2(dx, \mathcal{L}^1(dv))$ with respect to x is

$$\hat{\phi}(\xi, v) := \frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} \phi(x,v)\, \exp(-ix\xi)\, dx, \qquad (\xi, v) \in \mathbb{R} \times [0,1].$$

Certainly,

$$\hat{\phi} \in \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)), \qquad \phi \in \mathcal{L}^2(dx, \mathcal{L}^1(dv)).$$

For later reference we introduce the Bessel potential space

$$\mathcal{H}^1\left(dx, \mathcal{L}^1(dv)\right) = \left\{ \phi \in \mathcal{L}^2(d(x,v)) : \int_{\mathbb{R}} |\xi|^2 \left\| \hat{\phi}(\xi,.) \right\|^2_{\mathcal{L}^1(dv)} d\xi < \infty \right\}$$

with canonical seminorm

$$\|\phi\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} = \sqrt{\|\phi\|^2_{\mathcal{L}^2(d(x,v))} + \int_{\mathbb{R}} |\xi|^2 \left\| \hat{\phi}(\xi,.) \right\|^2_{\mathcal{L}^1(dv)} d\xi}.$$

Remark. Obviously, $\mathcal{H}^1\left(dx, \mathcal{L}^1(dv)\right) \subset \mathcal{L}^2(d(x,v)) \subset \mathcal{L}^2(d\xi, \mathcal{L}^1(dv))$.

Remark. If $\phi \in \mathcal{L}^2(d(x,v))$ and if $\phi(.,v) \in H^1(\mathbb{R})$ for almost all $v \in [0,1]$, with square integrable (with respect to v) seminorm $\|\phi(.,v)\|_{H^1(\mathbb{R})}$, then by the theory of Sobolev spaces, $\phi \in \mathcal{H}^1\left(dx, \mathcal{L}^1(dv)\right)$.

Furthermore, let

$$\mathcal{L}^\infty(dv, \mathcal{L}^2(dx)) = \left\{ \varphi \in M : \sup_{v \in [0,1]} \|\varphi(.,v)\|_{\mathcal{L}^2(dx)} < \infty \right\}$$

equipped with the canonical seminorm

$$\|\varphi\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} = \sup_{v \in [0,1]} \|\varphi(.,v)\|_{\mathcal{L}^2(dx)}, \qquad \varphi \in \mathcal{L}^\infty(dv, \mathcal{L}^2(dx)).$$

Applying the Fourier transform (with respect to x) on (2.6) gives

$$\left.\begin{aligned} \hat{f}^{n+1} &= A\left(\hat{f}^n + v\,\alpha\,\hat{g}^n\right) + B\left[\hat{f}^n + \alpha\, v\, \hat{g}^n\right] \\ \hat{g}^{n+1} &= A\left(\hat{g}^n + v\,\beta\,\hat{f}^n - \Theta\, v^2\, \hat{g}^n\right) + B\, v\, \beta\left[\hat{f}^n + \alpha\, v\, \hat{g}^n\right] \end{aligned}\right\} \quad n \in \mathbb{N}_0, \tag{3.6}$$

where

$$\alpha = \alpha(\xi, \Delta t, \Delta x) = \frac{\Delta t}{\Delta x}\left(1 - \mathrm{e}^{i\xi\Delta x}\right) = \xi \Delta t H(\xi \Delta x), \tag{3.7}$$

$$\beta = \beta(\xi, \Delta t, \Delta x, \epsilon) = \frac{B}{\Delta x}\left(\mathrm{e}^{-i\xi\Delta x} - 1\right) = -\frac{\xi \Delta t}{\epsilon^2 + \Delta t} \overline{H}(\xi \Delta x), \tag{3.8}$$

$$\Theta = \Theta(\xi, \Delta t, \Delta x, \epsilon) = -\alpha\,\beta = \frac{\Delta t}{(\Delta x)^2}\frac{\Delta t}{\epsilon^2 + \Delta t}\,(2 - 2\cos(\xi \Delta x)), \tag{3.9}$$

and the holomorphic function H,

$$H : \mathbb{C} \to \mathbb{C}, \quad H(z) = \begin{cases} \dfrac{1 - \exp(iz)}{z}, & z \neq 0, \\ -i, & z = 0, \end{cases}$$

is bounded on $\mathbb{R}$ with $|H|(\sigma) < 1$ for all $\sigma \in \mathbb{R}$ with $\sigma \neq 0$, and $|H|(0) = 1$. Furthermore, $|\sigma H(\sigma)| \leq 2$ for all $\sigma \in \mathbb{R}$.

Remark. We have

$$0 = \inf_{\xi \in \mathbb{R}} \Theta(\xi, \Delta t, \Delta x, \epsilon) < \sup_{\xi \in \mathbb{R}} \Theta(\xi, \Delta t, \Delta x, \epsilon) = \frac{4\Delta t}{(\Delta x)^2}\frac{\Delta t}{\epsilon^2 + \Delta t}$$

for all positive $\Delta t, \Delta x, \epsilon$, which highlights the importance of the value of Θ.

Remark. The transport CFL condition is equivalent to

$$\sup_{\xi \in \mathbb{R}} \Theta(\xi, \Delta t, \Delta x, \epsilon) < 2.$$

Remark. Concerning α, β we have, on the one hand, estimates which are independent of ξ and of ϵ but depend on the grid sizes Δt and Δx,

$$|\alpha|(\xi, \Delta t, \Delta x) \leq \frac{2\Delta t}{\Delta x}, \qquad |\beta|(\xi, \Delta t, \Delta x) \leq \frac{2}{\Delta x}; \tag{3.10}$$

on the other hand, there are estimates which are "almost linear" in ξ, which depend in an acceptable way on Δt, and which are independent of ϵ,

$$|\alpha|(\xi, \Delta t, \Delta x) \leq \Delta t\,|\xi|, \qquad |\beta|(\xi, \Delta t, \Delta x) \leq |\xi|. \tag{3.11}$$

Remark. Obviously, (3.11) is suitable for uniform stability analysis, however, due to the "linear" dependence of the estimates on $|\xi|$ for the price of obtaining estimates involving different kinds of seminorms.

It is convenient to introduce for $(f, g) \in \mathcal{L}^2(dx, \mathcal{L}^1(dv)) \times \mathcal{L}^2(dx, \mathcal{L}^1(dv))$ the notation

$$\mathfrak{f} = (f, g), \qquad \hat{\mathfrak{f}} = (\hat{f}, \hat{g}).$$

We rewrite recursion (2.6) as

$$\mathfrak{f}^{n+1} = S\mathfrak{f}^n \tag{3.12}$$

and the Fourier transformed recursion (3.6) as

$$\hat{\mathfrak{f}}^{n+1} = (AT + BT_0)\,\hat{\mathfrak{f}}^n \tag{3.13}$$

with $A, B \in (0, 1), A + B = 1$ as above and $n \in \mathbb{N}_0$. The linear operators T and T_0 depend on the parameters α, β. Due to (3.10) we have

$$\begin{aligned} &T : \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \times \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \to \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \times \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)), \\ &T(\hat{\mathfrak{f}})(\xi, v) = \Big(\hat{f}(\xi, v) + \alpha\, v\, \hat{g}(\xi, v), \beta\, v\, \hat{f}(\xi, v) + (1 - \Theta\, v^2)\, \hat{g}(\xi, v)\Big), \\ &\qquad\qquad (\xi, v) \in \mathbb{R} \times [0, 1], \end{aligned} \tag{3.14}$$

and

$$T_0 : \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \times \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \to \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \times \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)), \tag{3.15}$$
$$T_0(\hat{\mathfrak{f}})(\xi, v) = \left(\left[\hat{f} + \alpha\, v\, \hat{g} \right](\xi), \beta\, v \left[\hat{f} + \alpha\, v\, \hat{g} \right](\xi) \right), \quad (\xi, v) \in \mathbb{R} \times [0,1].$$

Remark. Due to (3.10) it is seemingly impossible to obtain uniform estimates (with respect to ϵ and the grid sizes) on the operator seminorms of T_0, T_1.

Our aim is to prove uniform bounds in *suitable* seminorms of the iterations $\mathfrak{f}^n = (f^n, g^n)$ for all $n \in \mathbb{N}_0$ and for all $\epsilon \geq 0$.

The results will depend on *pointwise* estimates of $\hat{\mathfrak{f}}^n$. Let us consider the formal limiting problem when ϵ is set to zero. In this situation, recursion (3.12) reduces to $\hat{\mathfrak{f}}^{n+1} = (\hat{f}^{n+1}, \hat{g}^{n+1}) = T_0 \hat{\mathfrak{f}}^n$. This means

$$\left.\begin{aligned} \hat{f}^{n+1} &= \left[\hat{f}^n + \alpha\, v\, \hat{g}^n \right] \\ \hat{g}^{n+1} &= v\, \beta \left[\hat{f}^n + \alpha\, v\, \hat{g}^n \right] = v\, \beta \left[\hat{f}^{n+1} \right] \end{aligned}\right\} \quad n \in \mathbb{N}_0,$$

with

$$\beta = \beta(\xi, \Delta t, \Delta x, \epsilon = 0) = -\xi\, \overline{H}(\xi \Delta x),$$

and therefore,

$$\hat{f}^{n+1} = \left(1 - \Theta \left[v^2\right]\right) \left[\hat{f}^n\right] = \left(1 - \frac{\Theta}{3}\right) \left[\hat{f}^n\right], \qquad n \in \mathbb{N}_0,$$

where

$$\Theta = \Theta(\xi, \Delta t, \Delta x, \epsilon = 0) = \frac{\Delta t}{(\Delta x)^2}(2 - 2\cos(\xi \Delta x)).$$

Thus, we have *pointwise* estimates

$$\left.\begin{aligned} \left|\hat{f}^n\right|(\xi, v) &= \left|1 - \frac{\Theta}{3}\right|^n \left|\left[\hat{f}^0\right]\right|(\xi) \\ \left|\hat{g}^{n+1}\right|(\xi, v) &\leq |v|\, |\xi| \left|1 - \frac{\Theta}{3}\right|^n \left|\left[\hat{f}^0\right]\right|(\xi) \end{aligned}\right\} \quad n \in \mathbb{N}_0. \tag{3.16}$$

In particular, whenever

$$\sup_{\xi \in \mathbb{R}} \Theta(\xi, \Delta t, \Delta x, \epsilon = 0) \leq 6,$$

which is the case iff the usual parabolic CFL condition for the diffusion equation (2.4),

$$\frac{\Delta t}{(\Delta x)^2} \leq \frac{3}{2}, \tag{3.17}$$

holds, then we obtain from (3.16)

$$\left|\hat{f}^n\right|(\xi, v) \leq \left\|\hat{f}^0(\xi, .)\right\|_{\mathcal{L}^1(dv)}, \qquad (n, \xi, v) \in \mathbb{N}_0 \times \mathbb{R} \times [0,1], \tag{3.18}$$

$$\left|\hat{g}^{n+1}\right|(\xi, v) \leq |\xi| \left\|\hat{f}^0(\xi, .)\right\|_{\mathcal{L}^1(dv)}, \qquad (n, \xi, v) \in \mathbb{N}_0 \times \mathbb{R} \times [0,1], \tag{3.19}$$

and therefore, since the Fourier transform is an isometry between $\mathcal{L}^2(dx)$ and $\mathcal{L}^2(d\xi)$,

$$\|f^n\|_{\mathcal{L}^2(d(x,v))} \le \left\|f^0\right\|_{\mathcal{L}^2(d(x,v))}, \quad \|f^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le \left\|f^0\right\|_{\mathcal{L}^2(d(x,v))}, \qquad n \in \mathbb{N}_0,$$

and, furthermore,

$$\left\|g^{n+1}\right\|_{\mathcal{L}^2(d(x,v))} \le \left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^2(dv))},$$

$$\left\|g^{n+1}\right\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le \left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^2(dv))}, \qquad n \in \mathbb{N}_0,$$

which indicates that the introduced spaces are canonical.

Our main result is the following theorem.

THEOREM 3.1. *Assume* $\Delta x, \Delta t, \epsilon \in \mathbb{R}^+$ *satisfy* (3.1). *With initial values* $\mathfrak{f}^0 \in \mathcal{L}^2(d(x,v)) \times \mathcal{L}^2(d(x,v))$, *define the sequence* $(\mathfrak{f}^n)_{n\in\mathbb{N}} = ((f^n, g^n))_{n\in\mathbb{N}}$ *by* (2.6).

Then, for all $n \in \mathbb{N}_0$,

(a) $\|f^n\|_{\mathcal{L}^2(d(x,v))} \le 21. \left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + 33.\sqrt{\epsilon^2+\Delta t}. \left\|g^0\right\|_{\mathcal{L}^2(d(x,v))}$

and

$$\|g^n\|_{\mathcal{L}^2(d(x,v))} \le \left(30 + \frac{3\epsilon^2}{(\epsilon^2+\Delta t)^{3/2}}\right) \cdot \left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left(3 + 48.\sqrt{\epsilon^2+\Delta t}\right) \cdot \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))},$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^2(d(x,v))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$;

(b) *if* $\mathfrak{f}^0 \in \mathcal{L}^\infty(dv,\mathcal{L}^2(dx))$, *then*

$$\|f^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le 24 \left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + 35\sqrt{\epsilon^2+\Delta t} \left\|g^0\right\|_{\mathcal{L}^2(d(x,v))}$$

and

$$\|g^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le \left(30 + \frac{9\epsilon^2}{(\epsilon^2+\Delta t)^{3/2}}\right) \left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left(4 + 48.\sqrt{\epsilon^2+\Delta t}\right) \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))},$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^2(d(x,v))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$.

Theorem 3.1 allows for the derivation of several stability results for (2.6) independently of ϵ. As examples, we deduce the following.

COROLLARY 3.2. *Let* M, ϵ_0 *be positive constants. Then there is a positive constant* $C_0 = C_0(M,\epsilon_0)$ *such that, for all* $\Delta x, \Delta t, \epsilon \in \mathbb{R}^+$, *if* $\Delta t, \Delta x, \epsilon$ *satisfy* (3.1), $\Delta t + \epsilon \le M$, *and* $\epsilon \le \epsilon_0 \Delta t$, *then the following estimates hold for any sequence* $(\mathfrak{f}^n)_{n\in\mathbb{N}_0} = ((f^n, g^n))_{n\in\mathbb{N}}$ *defined by* (2.6) *with initial value* $\mathfrak{f}^0 \in \mathcal{L}^2(d(x,v)) \times \mathcal{L}^2(d(x,v))$:

$$\|f^n\|_{\mathcal{L}^2(d(x,v))} \le C_0. \left(\left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + \left\|g^0\right\|_{\mathcal{L}^2(d(x,v))}\right)$$

and

$$\|g^n\|_{\mathcal{L}^2(d(x,v))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} \right),$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^2(d(x,v))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$.

COROLLARY 3.3. *Let* M, ϵ_1 *be positive constants. Then there is a positive constant* $C_1 = C_1(M,\epsilon_1)$ *such that, for all* $\Delta x, \Delta t, \epsilon \in \mathbb{R}^+$, *if* $\Delta t, \Delta x, \epsilon$ *satisfy* (3.1), $\Delta t + \epsilon \le M$, *and* $\epsilon_1 \le \epsilon$, *then the following estimates hold for any sequence* $(\mathfrak{f}^n)_{n\in\mathbb{N}} = ((f^n, g^n))_{n\in\mathbb{N}}$ *defined by* (2.6) *with initial value* $\mathfrak{f}^0 \in \mathcal{L}^\infty(dv, \mathcal{L}^2(dx))$:

$$\|f^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + \left\|g^0\right\|_{\mathcal{L}^2(d(x,v))} \right)$$

and

$$\|g^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} \right),$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$.

Remark. We notice that although the scheme is developed based on consideration of the diffusive limit ϵ tending to 0, the transport CFL condition (3.1) is sufficient to guarantee stability also for large ϵ. In particular, for large mean free paths, the time step is no longer restricted by a parabolic CFL condition related to the limiting diffusion equation (2.4), but it is restricted by the hyperbolic CFL condition (3.5) related to the transport equation (2.1).

Remark. The transport CFL condition (3.1) is seemingly not optimal. For example, for ϵ tending to 0 we have

$$\frac{\Delta t}{(\Delta x)^2} < \frac{1}{2}.$$

However, as the direct analysis for $\epsilon = 0$ shows, actually, the correct restriction is the parabolic CFL (3.17)

$$\frac{\Delta t}{(\Delta x)^2} < \frac{3}{2}.$$

Remark. The conditions $\epsilon_0 \le \epsilon \le M$ and $\epsilon \le \epsilon_1 \Delta t$ cover the well-resolved and underresolved cases, respectively.

4. Preliminaries. The main ingredients of the proof of Theorem 3.1 are investigations of recursion formulae. These investigations require several preliminary estimates.

LEMMA 4.1. *We define*

$$\psi : [0,2] \times [0,1] \to [0,1], \qquad \psi(\sigma, v) = \arccos\left(1 - \frac{\sigma v^2}{2}\right).$$

Then for all $(\sigma, n) \in [0,2] \times \mathbb{N}_0$,

$$\left| \int_0^1 \left(\cos(n\psi(\sigma,v)) - \sin(n\psi(\sigma,v)) \frac{1-\cos(\psi(\sigma,v))}{\sin(\psi(\sigma,v))} \right) dv \right| \le 1.$$

Proof. Introducing for fixed $\sigma \in (0,2)$ the new variable $t := \psi(\sigma, v)$, we obtain

$$\begin{aligned}
&\int_0^1 \left(\cos(n\psi(\sigma,v)) - \sin(n\psi(\sigma,v)) \frac{1-\cos(\psi(\sigma,v))}{\sin(\psi(\sigma,v))} \right) \, dv \\
&= \frac{1}{\sqrt{2\sigma}} \int_0^{\psi(\sigma,1)} \left(\sqrt{1+\cos(t)}.\cos(nt) - \sqrt{1-\cos(t)}.\sin(nt) \right) \, dt \\
&= \frac{1}{\sqrt{\sigma}} \int_0^{\psi(\sigma,1)} \left(\cos(t/2).\cos(nt) - \sin(t/2).\sin(nt) \right) \, dt \\
&= \frac{1}{\sqrt{\sigma}} \frac{\sin((n+(1/2)).\psi(\sigma,1))}{n+(1/2)} = \frac{\sin((n+(1/2)).\psi(\sigma,1))}{(n+(1/2))\sqrt{2(1-\cos(\psi(\sigma,1)))}} \\
&= \frac{\sin((n+(1/2)).\psi(\sigma,1))}{(n+(1/2)).\psi(\sigma,1)} \cdot \frac{\psi(\sigma,1)/2}{\sin(\psi(\sigma,1)/2)} \in [-1,+1]. \qquad \square
\end{aligned}$$

LEMMA 4.2. *Let $(c_n)_{n\in\mathbb{N}_0}$ and $(\gamma_n)_{n\in\mathbb{N}_0}$ be complex sequences. Define a complex sequence $(\kappa_n)_{n\in\mathbb{N}_0}$ by recursion via*

$$\kappa_0 = c \in \mathbb{C} \quad \forall n \in \mathbb{N}_0 : \quad \kappa_{n+1} = c_n + \left(\kappa_0.\gamma_{n-1} + \kappa_1.\gamma_{n-2} + \cdots + \kappa_{n-1}.\gamma_0 \right).$$

Assume

$$\sum_{k=0}^{\infty} |c_k| < \infty, \qquad \sum_{k=0}^{\infty} |\gamma_k| \le 1.$$

Then the sequence $(\kappa_n)_{n\in\mathbb{N}_0}$ is bounded; more precisely,

$$\forall n \in \mathbb{N}_0 : \quad |\kappa_n| \le |\kappa_0| + \left(|c_0| + \cdots + |c_{n-1}| \right). \tag{4.1}$$

Proof. We prove (4.1) by induction. There is nothing to do in case $n = 0$. To pass from n to $n+1$, we calculate

$$\begin{aligned}
|\kappa_{n+1}| &= \left| c_n + \sum_{j=0}^{n-1} \kappa_j.\gamma_{n-1-j} \right| \le |c_n| + \sum_{j=0}^{n-1} |\kappa_j|.|\gamma_{n-1-j}| \\
&\le |c_n| + \max\{|\kappa_0|, \ldots, |\kappa_{n-1}|\} \sum_{j=0}^{n-1} |\gamma_j| \le |c_n| + |\kappa_0| + |c_0| + \cdots + |c_{n-1}|. \qquad \square
\end{aligned}$$

Furthermore, we require the following result about the recursion scheme (2.6) when A is set to 1 (or equivalently, when B is set to 0).

LEMMA 4.3. *Let $\xi \in \mathbb{R}$ and let $\Delta t, \Delta x, \epsilon$ be positive real numbers. Let α, β, Θ be as in* (3.7), (3.8), (3.9), *respectively. For $(\hat{f}_0, \hat{g_0}) \in \mathcal{L}^2(d\xi, \mathcal{L}^1(dv)) \times \mathcal{L}^2(d\xi, \mathcal{L}^1(dv))$ and $(\xi, v) \in \mathbb{R} \times [0,1]$, we write T from* (3.14) *in vector notation:*

$$T \begin{pmatrix} \hat{f}_0 \\ \hat{g_0} \end{pmatrix} (\xi, v) = \begin{pmatrix} 1 & \alpha\, v \\ \beta\, v & 1 - \Theta\, v^2 \end{pmatrix} \begin{pmatrix} \hat{f}_0(\xi, v) \\ \hat{g_0}(\xi, v) \end{pmatrix}.$$

For $n \in \mathbb{N}$ let

$$\begin{pmatrix} \hat{f_n} \\ \hat{g_n} \end{pmatrix} = T^n \begin{pmatrix} \hat{f}_0 \\ \hat{g}_0 \end{pmatrix}.$$

Assume $\Delta t, \Delta x, \epsilon$ satisfy the transport CFL condition (3.1). *Then for all $n \in \mathbb{N}_0$ and for all $(\xi, v) \in \mathbb{R} \times (0,1)$,*

(a) $|\hat{f}_n|(\xi,v) \le \left(2|\hat{f}_0| + \sqrt{2(\epsilon^2+\Delta t)}\,|\hat{g}_0|\right)(\xi,v)$.

(b) $|\hat{g_n}|(\xi,v) \le \left(\frac{\sqrt{2}}{\sqrt{\epsilon^2+\Delta t}}\,|\hat{f}_0| + 2|\hat{g}_0|\right)(\xi,v)$.

(c) $|\alpha\, v\, \hat{g_n}|(\xi,v) \le \left(2|\hat{f}_0| + 4\sqrt{\epsilon^2+\Delta t}\,|\hat{g}_0|\right)(\xi,v)$.

(d) *If* $\hat{f}_0 = 1$ *and* $\hat{g}_0(\xi,v) = \beta\, v$, *then*

$$|\hat{f_n}|(\xi,v) \le 2, \quad |\hat{g_n}|(\xi,v) \le 3\,|\xi|, \quad \left|\int_0^1 (\hat{f_n}(\xi,s) + \alpha\, s\ \hat{g_n}(\xi,s))\, ds\right| \le 1.$$

Proof. First, we prove statements (a) and (b). We recall that if $\Delta t, \Delta x, \epsilon$ satisfy (3.1), then $\sup_{\xi\in\mathbb{R}} \Theta(\xi,\Delta t,\Delta x,\epsilon) < 2$. We shall use this estimate frequently.

We keep $(\xi, v) \in \mathbb{R}\times[0,1]$ fixed and introduce the 2×2 matrix

$$R := R(\alpha,\beta,\Theta,v) := \begin{pmatrix} 1 & \alpha\, v \\ \beta\, v & 1-\Theta\, v^2 \end{pmatrix}.$$

Then we have for all $n \in \mathbb{N}_0$,

$$T^n \begin{pmatrix} \hat{f}_0 \\ \hat{g}_0 \end{pmatrix}(\xi,v) = R^n \cdot \begin{pmatrix} \hat{f}_0(\xi,v) \\ \hat{g}_0(\xi,v) \end{pmatrix}.$$

If $\Theta = 0$, then $\xi = 0$ and therefore $\alpha = \beta = 0$ as well. In this case, R is the identity matrix and the proof of the lemma is straightforward.

Let us assume $\Theta > 0$ henceforth. The eigenvalues of R are

$$\lambda_{1,2}(v) = \left(1 - \frac{\Theta\, v^2}{2}\right) \pm \sqrt{\left(\frac{\Theta\, v^2}{2}\right)^2 - \Theta\, v^2}.$$

Since $a := \Theta\, v^2/2 < 1$, we have $2\,a - a^2 > 0$ such that

$$\lambda_{1,2} = (1-a) \pm i\,\sqrt{2\,a - a^2};$$

i.e., R has two distinct, nonreal, complex conjugate eigenvalues

$$\lambda_1 = \lambda := (1-a) + i\,\sqrt{2\,a-a^2}, \qquad \lambda_2 = \overline{\lambda}.$$

Hence there is a regular 2×2 matrix $B = B(\alpha,\beta,\Theta,v)$ with

$$R^n = B \begin{pmatrix} \lambda^n & 0 \\ 0 & \overline{\lambda}^n \end{pmatrix} B^{-1}, \qquad n \in \mathbb{N}_0.$$

Since $|\lambda| = 1$, we have $\lambda := e^{i\,\theta}$ for some $\theta \in (0, 2\pi)$. Since $\cos(\theta) = 1 - a > 0$ and $\sin(\theta) = \sqrt{2\,a - a^2} > 0$, we have $\theta \in (0, \pi/2)$. Furthermore,

$$v = \sqrt{\frac{2a}{\Theta}} = \sqrt{\frac{2}{\Theta}\cdot(1-\cos(\theta))} = \frac{2}{\sqrt{\Theta}}\sin(\theta/2) \tag{4.2}$$

and

$$B = \begin{pmatrix} -\alpha\, v & -\alpha\, v \\ 1-e^{i\theta} & 1-e^{-i\theta} \end{pmatrix}$$

such that for all $n \in \mathbb{N}_0$

$$
\begin{aligned}
R^n &= \frac{i}{2\alpha v \sin(\theta)} \begin{pmatrix} -\alpha\, v & -\alpha\, v \\ 1-e^{i\theta} & 1-e^{-i\theta} \end{pmatrix} \begin{pmatrix} e^{ni\theta} & 0 \\ 0 & e^{-ni\theta} \end{pmatrix} \begin{pmatrix} 1-e^{-i\theta} & \alpha\, v \\ -1+e^{i\theta} & -\alpha\, v \end{pmatrix} \\
&= \frac{i}{2\alpha v \sin(\theta)} \begin{pmatrix} -\alpha\, v & -\alpha\, v \\ 1-e^{i\theta} & 1-e^{-i\theta} \end{pmatrix} \begin{pmatrix} e^{ni\theta}-e^{(n-1)i\theta} & \alpha\, v\, e^{ni\theta} \\ -e^{-ni\theta}+e^{-(n-1)i\theta} & -\alpha\, v e^{-ni\theta} \end{pmatrix} \\
&= \begin{pmatrix} \frac{\sin(n\theta)-\sin((n-1)\theta)}{\sin(\theta)} & \alpha v \frac{\sin(n\theta)}{\sin(\theta)} \\ -\frac{2\sin(n\theta)-\sin((n-1)\theta)-\sin((n+1)\theta)}{\alpha v \sin(\theta)} & -\frac{\sin(n\theta)-\sin((n+1)\theta)}{\sin(\theta)} \end{pmatrix} \\
&= \begin{pmatrix} \frac{\sin(n\theta)-\sin((n-1)\theta)}{\sin(\theta)} & \frac{2\alpha}{\sqrt{\Theta}} \frac{\sin(\theta/2)\sin(n\theta)}{\sin(\theta)} \\ -\frac{\sqrt{\Theta}}{2\alpha} \frac{2\sin(n\theta)-\sin((n-1)\theta)-\sin((n+1)\theta)}{\sin(\theta/2)\sin(\theta)} & \frac{\sin(n\theta)-\sin((n+1)\theta)}{\sin(\theta)} \end{pmatrix} \\
&= \begin{pmatrix} \cos(n\theta)+\sin(n\theta)\frac{1-\cos(\theta)}{\sin(\theta)} & \frac{2\alpha}{\sqrt{\Theta}}\, \sin(n\theta)\, \frac{\sin(\theta/2)}{\sin(\theta)} \\ -\frac{\sqrt{\Theta}}{\alpha}\, \sin(n\theta)\, \frac{1-\cos(\theta)}{\sin(\theta/2)\, \sin(\theta)} & \cos(n\theta)-\sin(n\theta)\frac{1-\cos(\theta)}{\sin(\theta)} \end{pmatrix} \\
&=: \begin{pmatrix} R_{n;11} & R_{n;12} \\ R_{n;21} & R_{n;22} \end{pmatrix}.
\end{aligned}
$$

Since $\theta \in (0, \pi/2)$, we have

$$
|R_{n;11}|, |R_{n;22}| \le 2, \qquad n \in \mathbb{N}_0. \tag{4.3}
$$

Furthermore, we have for all $n \in \mathbb{N}_0$,

$$
\begin{aligned}
R_{n;12} &= \frac{2\alpha}{\sqrt{\Theta}}\, \sin(n\theta)\, \frac{\sin(\theta/2)}{\sin(\theta)} = \alpha v \frac{\sin(n\theta)}{\sin(\theta)} = \alpha v \frac{\sin(n\theta)}{\sqrt{\Theta} v \sqrt{1-\frac{\Theta v^2}{4}}} \\
&= \frac{\alpha}{\sqrt{\Theta}} \frac{\sin(n\theta)}{\sqrt{1-\frac{\Theta v^2}{4}}} = \frac{(\xi \Delta t H(\xi \Delta x))(\Delta x \sqrt{\epsilon^2+\Delta t})}{\Delta t \sqrt{2(1-\cos(\xi \Delta x))}} \frac{\sin(n\theta)}{\sqrt{1-\frac{\Theta v^2}{4}}} \\
&= \sqrt{\epsilon^2+\Delta t} \frac{\xi \Delta x H(\xi \Delta x)}{\sqrt{2(1-\cos(\xi \Delta x))}} \frac{\sin(n\theta)}{\sqrt{1-\frac{\Theta v^2}{4}}} \\
&= \sqrt{\epsilon^2+\Delta t} \frac{H(\xi \Delta x)}{|H(\xi \Delta x)|} \frac{\sin(n\theta)}{\sqrt{1-\frac{\Theta v^2}{4}}},
\end{aligned} \tag{4.4}
$$

and analogously,

$$
R_{n;21} = -\frac{1}{\sqrt{\epsilon^2+\Delta t}} \frac{|H(\xi \Delta x)|}{H(\xi \Delta x)} \frac{\sin(n\theta)}{\sqrt{1-\frac{\Theta v^2}{4}}}; \tag{4.5}
$$

hence

$$
\begin{aligned}
|R_{n;12}| &\le \sqrt{2(\epsilon^2+\Delta t)}, \\
|R_{n;21}| &\le \tfrac{\sqrt{2}}{\sqrt{\epsilon^2+\Delta t}}.
\end{aligned} \tag{4.6}
$$

Since for all $n \in \mathbb{N}_0$,

$$\begin{aligned} \hat{f}_n(\xi, v) &= R_{n;11}\, \hat{f}_0(\xi, v) + R_{n;12}\, \hat{g}_0(\xi, v), \\ \hat{g_n}(\xi, v) &= R_{n;21}\, \hat{f}_0(\xi, v) + R_{n;22}\, \hat{g}_0(\xi, v), \end{aligned} \tag{4.7}$$

statements (a) and (b) of the lemma follow from (4.3), (4.6), and (4.7).

Now we prove statement (c). We calculate for all $n \in \mathbb{N}_0$,

$$\alpha v R_{n;21} = -v\sqrt{\Theta}\, \sin(n\theta)\, \frac{1-\cos(\theta)}{\sin(\theta/2)\, \sin(\theta)} = -2 \sin(n\theta) \cdot \frac{1-\cos(\theta)}{\sin(\theta)}$$

and

$$\alpha v R_{n;22} = 2 \sin(\theta/2) \frac{\alpha}{\sqrt{\Theta}} R_{n;22}.$$

Hence for all $n \in \mathbb{N}_0$,

$$|\alpha v R_{n;21}| \leq 2 \tag{4.8}$$

and

$$|\alpha v R_{n;22}| \leq 4\, \sqrt{\epsilon^2 + \Delta t}. \tag{4.9}$$

Statement (c) of the lemma follows from (4.7), (4.8), and (4.9).

For the proof of statement (d), we finally turn our attention to $\hat{f}_0 = 1$ and $\hat{g}_0(\xi, v) = \beta\, v$. We set

$$P_0 = 1, \qquad Q_0 = 1$$

and easily verify

$$\hat{f}_n = P_n, \quad \hat{g_n} = \beta\, v\, Q_n, \quad n \in \mathbb{N}_0,$$

where, for $n \in \mathbb{N}_0$,

$$\begin{pmatrix} P_{n+1} \\ \\ Q_{n+1} \end{pmatrix} = \begin{pmatrix} 1 & -\Theta\, v^2 \\ \\ 1 & 1 - \Theta\, v^2 \end{pmatrix} \begin{pmatrix} P_n \\ \\ Q_n \end{pmatrix},$$

from which we obtain, after some elementary manipulations for all $n \in \mathbb{N}_0$ (we recall $\Theta < 2$),

$$\begin{aligned} P_n &= \mathrm{Re}\left(\left((1-a) - i.\sqrt{2a - a^2} \right)^n . \left(1 - \frac{i.(2a - a^2)}{\sqrt{2a - a^2}} \right) \right), \\ Q_n &= \mathrm{Re}\left(\left((1-a) - i.\sqrt{2a - a^2} \right)^n . \left(1 + \frac{i.(2 - 2a)}{\sqrt{2a - a^2}} \right) \right), \end{aligned}$$

where we recall $a = \frac{\Theta v^2}{2}$. Then we have for all $n \in \mathbb{N}_0$,

$$\left[(1, \alpha v) \cdot \begin{pmatrix} \hat{f}_n \\ \hat{g_n} \end{pmatrix} \right] = \left[(1, \alpha v) \cdot \begin{pmatrix} P_n \\ \beta\, v\, Q_n \end{pmatrix} \right] = \left[P_n - \Theta\, v^2\, Q_n \right] = [P_{n+1}]. \tag{4.10}$$

Writing as above,

$$(1-a)+i\sqrt{2a-a^2}=e^{i\theta},$$

we have $\theta\in(0,\pi/2)$, $\cos(\theta)=(1-a)$, $\sin(\theta)=\sqrt{2a-a^2}$. Hence for all $n\in\mathbb{N}_0$,

$$P_n=\cos(n\theta)-\sin(n\theta)\frac{1-\cos(\theta)}{\sin(\theta)},$$

$$Q_n=\cos(n\theta)+2\sin(n\theta)\frac{1-\cos(\theta)}{\sin(\theta)}$$

such that for all $n\in\mathbb{N}_0$,

$$|\hat{f_n}|(\xi,v)=|P_n|(\xi,v)\le 2,\ |\hat{g_n}|(\xi,v)=|\beta|\,|v|\,|Q_n|(\xi,v)\le 3\,|\beta|\le 3\,|\xi|,$$

and due to Lemma 4.1 and (4.10) for all $n\in\mathbb{N}_0$,

$$\begin{aligned}(4.11)\quad &\int_0^1 (1,\alpha\,s)\cdot\begin{pmatrix}\hat{f_n}(\xi,s)\\ \hat{g_n}(\xi,s)\end{pmatrix}\,ds=[P_{n+1}](\xi)\\ &=\int_0^1\left(\cos((n+1)\theta(s))-\sin((n+1)\theta(s))\frac{1-\cos(\theta(s))}{\sin(\theta(s))}\right)\,ds\in[-1,+1],\end{aligned}$$

where $\cos(\theta(s))=1-\frac{\Theta\,s^2}{2}$, $s\in(0,1)$. ∎

5. Proof of Theorem 3.1. For $n\in\mathbb{N}$ let $\hat{f}^n,\hat{g}^n$ be as in (3.6) and let $(\xi,v)\in\mathbb{R}\times(0,1)$ be fixed. We now introduce for $n\in\mathbb{N}$ or $n=0$ the complex number

$$\kappa_n:=B\left[\hat{f}^n+\alpha\,v\,\hat{g}^n\right](\xi). \tag{5.1}$$

Then it is easy to see that for all $n\in\mathbb{N}$,

$$\begin{pmatrix}\hat{f}^n\\ \hat{g}^n\end{pmatrix}=A^n\,T^n\begin{pmatrix}\hat{f}^0\\ \hat{g}^0\end{pmatrix}+\sum_{j=0}^{n-1}\kappa_j\,A^{n-1-j}\,T^{n-1-j}\begin{pmatrix}1\\ \beta v\end{pmatrix}. \tag{5.2}$$

We derive from (5.2) a recursion formula for $(\kappa_n)_{n\in\mathbb{N}}$,

$$\begin{aligned}\kappa_0&=B.\left[\hat{f}^0+\alpha\,v\,\hat{g}^0\right](\xi),\\ \kappa_n&=B.\left[(1,\alpha\,v)\cdot\begin{pmatrix}\hat{f}^n\\ \hat{g}^n\end{pmatrix}\right]\\ &=A^nB.\left[(1,\alpha v)\cdot\left(T^n\begin{pmatrix}\hat{f}^0\\ \hat{g}^0\end{pmatrix}\right)\right]\\ &\quad+\sum_{j=0}^{n-1}\kappa_jBA^{n-1-j}\left[(1,\alpha v)\cdot\left(T^{n-1-j}\begin{pmatrix}1\\ \beta v\end{pmatrix}\right)\right]\\ &=c_n+(\kappa_0\gamma_{n-1}+\cdots+\kappa_{n-1}\gamma_0),\end{aligned}$$

where for $n\in\mathbb{N}$,

$$c_n:=A^nB\left[(1,\alpha v)\cdot\left(T^n\begin{pmatrix}\hat{f}^0\\ \hat{g}^0\end{pmatrix}\right)\right](\xi),$$

$$\gamma_n = BA^n \left[(1, \alpha v) \cdot \left(T^n \begin{pmatrix} 1 \\ \beta v \end{pmatrix} \right) \right] (\xi).$$

By part (d) of Lemma 4.3 we have for all $n \in \mathbb{N}$,

$$|\gamma_n| \leq BA^n;$$

hence,

$$\sum_{n=0}^{\infty} |\gamma_n| \leq 1. \tag{5.3}$$

Furthermore, due to parts (a) and (c) of Lemma 4.3, we have for all $n \in \mathbb{N}$,

$$\begin{aligned} &\left| \left[(1, \alpha v) \cdot \left(T^n \begin{pmatrix} \hat{f}^0 \\ \hat{g}^0 \end{pmatrix} \right) \right] \right| (\xi) \\ &\qquad \leq \left[2 \left| \hat{f}^0 \right| + \sqrt{2(\epsilon^2 + \Delta t)} \, \left| \hat{g}^0 \right| \right] (\xi) + \left[2 \left| \hat{f}^0 \right| + 4\sqrt{\epsilon^2 + \Delta t} \, \left| \hat{g}^0 \right| \right] (\xi) \\ &\qquad\qquad \leq 4 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 6\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)}; \end{aligned}$$

hence for all $n \in \mathbb{N}$,

$$|c_n| \leq A^n B \left(4 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 6\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} \right); \tag{5.4}$$

in particular, $(c_n)_{n \in \mathbb{N}}$ is in $\ell^1(\mathbb{C})$.

We can therefore apply Lemma 4.2 to deduce for all $n \in \mathbb{N}$ the estimate

$$\begin{aligned} &|\kappa_n| \leq |\kappa_0| + (|c_0| + \cdots + |c_{n-1}|) \qquad (5.5) \\ &\leq \left| B \left[\hat{f}^0 + \alpha \, v \, \hat{g}^0 \right] \right| + \left(4 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 6\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} \right) \sum_{j=0}^{n-1} A^n B \\ &\leq [|\hat{f}^0|](\xi) + 2\sqrt{\epsilon^2 + \Delta t} \, [|\hat{g}^0|](\xi) + 4 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 6\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} \\ &\qquad = 5 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 8\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)}, \end{aligned}$$

where we made use of $|\alpha \, v| \leq 2\sqrt{\epsilon^2 + \Delta t}$; see (4.2).

From (5.2), (5.5), and parts (a) and (d) of Lemma 4.3, we deduce the estimate

$$\begin{aligned} |\hat{f}^n|(\xi, v) &\leq \left(2 \, |\hat{f}^0| + \sqrt{2 \, (\epsilon^2 + \Delta t)} \, |\hat{g}^0| \right) (\xi, v) \qquad (5.6) \\ &\quad + 10 \left\| \hat{f}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)} + 16\sqrt{\epsilon^2 + \Delta t} \, \left\| \hat{g}^0(\xi, .) \right\|_{\mathcal{L}^1(dv)}, \\ &\qquad\qquad (n, \xi, v) \in \mathbb{N}_0 \times \mathbb{R} \times [0, 1], \end{aligned}$$

and therefore due to

$$\forall (\delta_1, \delta_2, \delta_3, \delta_4) \in \mathbb{R}^4 : \quad (|\delta_1| + |\delta_2| + |\delta_3| + \delta_4|)^2 \leq 4. \left(|\delta_1|^2 + |\delta_2|^2 + |\delta_3|^2 + \delta_4|^2 \right),$$

we obtain the estimate

$$\left\|\hat{f}^n\right\|^2_{\mathcal{L}^2(d(\xi,v))} \leq 416.\left\|\hat{f}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))} + 1032.\left(\epsilon^2+\Delta t\right).\left\|\hat{g}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))}, \qquad n\in\mathbb{N}_0.$$

Hence, via

$$\forall(\delta_1,\delta_2)\in\mathbb{R}^2: \quad \sqrt{|\delta_1|^2+|\delta_2|^2}\leq|\delta_1|+|\delta_2|,$$

we deduce

$$\begin{aligned}\|f^n\|_{\mathcal{L}^2(d(x,v))} = \left\|\hat{f}^n\right\|_{\mathcal{L}^2(d(\xi,v))} &\leq 21.\left\|\hat{f}^0\right\|_{\mathcal{L}^2(d(\xi,v))} + 33.\sqrt{\epsilon^2+\Delta t}.\left\|\hat{g}^0\right\|_{\mathcal{L}^2(d(\xi,v))}\\ &= 21.\left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + 33.\sqrt{\epsilon^2+\Delta t}.\left\|g^0\right\|_{\mathcal{L}^2(d(x,v))}, \qquad n\in\mathbb{N}_0.\end{aligned}$$

In a similar way we deduce from (5.2), (5.5), and parts (b) and (d) of Lemma 4.3 the estimate

$$\begin{aligned}(5.7)\quad |\hat{g}^n|(\xi,v) &\leq A\left(\frac{\sqrt{2}}{\sqrt{\epsilon^2+\Delta t}}\,|\hat{f}^0|+2\,|\hat{g}^0|\right)(\xi,v)\\ &\quad+|\xi|\left(15\left\|\hat{f}^0(\xi,.)\right\|_{\mathcal{L}^1(dv)}+24\sqrt{\epsilon^2+\Delta t}\,\left\|\hat{f}^0(\xi,.)\right\|_{\mathcal{L}^1(dv)}\right)\\ &\leq\left(\frac{\sqrt{2}\,\epsilon^2}{(\epsilon^2+\Delta t)^{3/2}}\,|\hat{f}^0|+2\,|\hat{g}^0|\right)(\xi,v)\\ &\quad+|\xi|\left(15\left\|\hat{f}^0(\xi,.)\right\|_{\mathcal{L}^1(dv)}+24\sqrt{\epsilon^2+\Delta t}\,\left\|\hat{g}^0(\xi,.)\right\|_{\mathcal{L}^1(dv)}\right),\\ &\qquad\qquad (n,\xi,v)\in\mathbb{N}_0\times\mathbb{R}\times[0,1],\end{aligned}$$

and therefore

$$\begin{aligned}|\hat{g}^n|^2(\xi,v) &\leq \frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}\cdot|\hat{f}^0|^2(\xi,v)+900.|\xi|^2.\left\|\hat{f}^0(\xi,.)\right\|^2_{\mathcal{L}^1(dv)}\\ &\quad+8|\hat{g}^0|^2(\xi,v)+2304.|\xi|^2.\left(\epsilon^2+\Delta t\right).\left\|\hat{g}^0(\xi,.)\right\|^2_{\mathcal{L}^1(dv)},\\ &\leq\left(\frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}+900\right).\left(|\hat{f}^0|^2(\xi,v)+|\xi|^2.\left\|\hat{f}^0(\xi,.)\right\|^2_{\mathcal{L}^1(dv)}\right)\\ &\quad+\left(8+2304.\left(\epsilon^2+\Delta t\right)\right).\left(|\hat{g}^0|^2(\xi,v)+|\xi|^2.\left\|\hat{g}^0(\xi,.)\right\|^2_{\mathcal{L}^1(dv)}\right),\\ &\qquad\qquad (n,\xi,v)\in\mathbb{N}_0\times\mathbb{R}\times[0,1],\end{aligned}$$

which implies

$$\begin{aligned}&\|g^n\|_{\mathcal{L}^2(d(x,v))}\\ &\leq\sqrt{\frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}+900.}\,\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(v))}\sqrt{8+2304.(\epsilon^2+\Delta t)}.\left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(v))}\\ &\leq\left(30+\frac{3\epsilon^2}{(\epsilon^2+\Delta t)^{3/2}}\right).\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))}+\left(3+48.\sqrt{\epsilon^2+\Delta t}\right).\left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))},\\ &\qquad\qquad n\in\mathbb{N}_0.\end{aligned}$$

This establishes part (a) of Theorem 3.1. On the other hand, we deduce from (5.6) that due to the fact that the Fourier transform is an isometry between $\mathcal{L}^2(dx)$ and $\mathcal{L}^2(d\xi)$,

$$\begin{aligned}\left\|f^n(.,w)\right\|^2_{\mathcal{L}^2(dx)} &\leq 16\left\|f^0(.,w)\right\|^2_{\mathcal{L}^2(dx)} + 8\left(\epsilon^2+\Delta t\right)\left\|g^0(.,w)\right\|^2_{\mathcal{L}^2(dx)} \\ &\quad + 400\left\|f^0\right\|^2_{\mathcal{L}^2(d(x,v))} + 1024.\left(\epsilon^2+\Delta t\right).\left\|g^0\right\|^2_{\mathcal{L}^2(d(x,v))}, \\ &\qquad\qquad (n,w)\in\mathbb{N}_0\times[0,1],\end{aligned}$$

and therefore

$$\begin{aligned}\left\|f^n\right\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} &\leq 4\left\|f^0\right\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} + 3\sqrt{\epsilon^2+\Delta t}\left\|g^0\right\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \\ &\quad + 20\left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + 32.\sqrt{\epsilon^2+\Delta t}.\left\|g^0\right\|_{\mathcal{L}^2(d(x,v))}, \qquad n\in\mathbb{N}_0,\end{aligned}$$

which yields, via

$$\left\|\varphi\right\|_{\mathcal{L}^2(d(x,v))} \leq \left\|\varphi\right\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))}, \qquad \varphi\in\mathcal{L}^\infty(dv,\mathcal{L}^2(dx)),$$

the first estimate of (b).

Finally, we deduce from (5.7),

$$\begin{aligned}\left\|g^n(.,w)\right\|^2_{\mathcal{L}^2(dx)} &\leq \frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}\cdot\left\|f^0\right\|^2_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} + 16\left\|g^0\right\|^2_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \\ &\quad + 900\left\|\xi.\hat{f}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))} + 2304.\left(\epsilon^2+\Delta t\right).\left\|\xi.\hat{g}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))}, \\ &\leq \frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}\cdot\left\|f^0\right\|^2_{\mathcal{L}^2(d(x,v))} + 16\left\|g^0\right\|^2_{\mathcal{L}^2(d(x,v))} \\ &\quad + 900\left\|\xi.\hat{f}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))} + 2304.\left(\epsilon^2+\Delta t\right).\left\|\xi.\hat{g}^0\right\|^2_{\mathcal{L}^2(d(\xi,v))}, \\ &\leq \left(\frac{8\epsilon^4}{(\epsilon^2+\Delta t)^3}+900\right)\left\|f^0\right\|^2_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left(16+2304.\left(\epsilon^2+\Delta t\right)\right)\left\|g^0\right\|^2_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))}, \\ &\qquad\qquad (n,w)\in\mathbb{N}_0\times[0,1].\end{aligned}$$

The second estimate of (b) follows by elementary manipulations. ∎

6. Discrete function spaces. In this section we investigate the action of the recursion (3.12), (2.6) on a discrete space. The discretization considered here is a piecewise affine FEM on a uniform grid $(j.\Delta x)_{j\in\mathbb{Z}}$; i.e., the values at the spatial gridpoints given by the recursion define a continuous function on the whole space via linear interpolation.

We introduce some notation. The identity function on $\mathbb{R}$ is $\mathrm{id}:\mathbb{R}\to\mathbb{R}$, $\mathrm{id}(x)=x$ and if $A\subseteq\mathbb{R}$, then the indicator function of A is $\mathrm{ind}_A:\mathbb{R}\to\{0,1\}$, $\mathrm{ind}_A(x)=1$ iff $x\in A$. If $\varphi:\mathbb{R}\to\mathbb{R}$ and if $A\subseteq\mathbb{R}$, then the restriction of φ to A is

$$\varphi\restriction A : A\to\mathbb{R}, \qquad (\varphi\restriction A)(x)=\varphi(x).$$

We introduce the sequence space

$$\ell^2(\Delta x,dv)=\left\{(\gamma_j)_{j\in\mathbb{Z}}:\ \left(\forall j\in\mathbb{Z}:\ \gamma_j\in\mathcal{L}^2(dv)\right)\right\}$$

equipped with the Δx-dependent norm

$$\|(\gamma_j)_{j\in\mathbb{Z}}\|_{\ell^2(\Delta x,dv)} = \Delta x \cdot \sqrt{\sum_{j\in\mathbb{Z}} \|\gamma_j\|^2_{\mathcal{L}^2(dv)}}.$$

Given $\Delta x \in \mathbb{R}^+$, a function $\varphi : \mathbb{R}\times[0,1] \to \mathbb{C}$ is a square integrable affine Δx finite element function iff $\varphi \in \mathcal{L}^2(d(x,v))$ and if there is $(\gamma_j)_{j\in\mathbb{Z}} \in \ell^2(\Delta x, dv)$ such that

$$\varphi = \sum_{j\in\mathbb{Z}} \left(\gamma_{j+1} \cdot \frac{\mathrm{id} - j.\Delta x}{\Delta x} + \gamma_j \cdot \frac{(j+1).\Delta x - \mathrm{id}}{\Delta x} \right) \cdot \mathrm{ind}_{[j.\Delta x,(j+1).\Delta x)};$$

i.e., $\varphi \in \mathcal{L}^2(d(x,v))$ is an affine Δx finite element function iff for all $v \in [0,1]$, $\varphi(.,v)$ is continuous and for all $(j,v) \in \mathbb{Z}\times[0,1]$, $\varphi(.,v) \restriction [j.\Delta x,(j+1).\Delta x)$ is affine.

The set of all square integrable affine Δx finite element functions is $\mathcal{L}^2(\Delta x, dv)$.

We observe that the mapping

$$\iota_{\Delta x} : \mathcal{L}^2(\Delta x, dv) \to \ell^2(\Delta x, dv), \qquad \iota_{\Delta x}(\phi) = (\phi(j\Delta x, .))_{j\in\mathbb{Z}}$$

is a linear isometry.

Next we shall prove the following lemma.

LEMMA 6.1. *For all $(\Delta x, \Delta t, \epsilon) \in \mathbb{R}^+\times\mathbb{R}^+\times\mathbb{R}^+$, the operator S of algorithm (2.6) maps $\mathcal{L}^2(\Delta x, v)\times\mathcal{L}^2(\Delta x, v)$ into itself. Furthermore, if $(f,g) \in \mathcal{L}^2(\Delta x, dv)\times\mathcal{L}^2(\Delta x, dv)$, and if we set*

$$(f^*, g^*) = S(f,g),$$

then for all $(j,v) \in \mathbb{Z}\times[0,1]$,

(6.1)
$$f^*(j\Delta x, v) = A(f(j\Delta x, v) - \Delta t\, v\, D_+ g(j\Delta x, v)) + B\left[f(j\Delta x, .) - \Delta t\, v\, D_+ g(j\Delta x, .)\right],$$

(6.2)
$$g^*(j\Delta x, v) = Ag(j\Delta x, v) - v\, A\, B\, D_-(f(j\Delta x, v) - \Delta t\, v\, D_+ g(j\Delta x, v)) - v\, B^2\, D_-\left[f(j\Delta x, .) - \Delta t\, v\, D_+ g(j\Delta x, .)\right].$$

Proof. We recall that if $(f,g) \in \mathcal{L}^2(\Delta x, dv)\times\mathcal{L}^2(\Delta x, dv)$, and if $(f^*, g^*) = S(f,g)$, then

$$f^* = A(f - \Delta t\, v\, D_+ g) + B\left[f - \Delta t\, v\, D_+ g\right], \tag{6.3}$$

$$g^* = Ag - v\, A\, B\, D_-(f - \Delta t\, v\, D_+ g) - v\, B^2\, D_-\left[f - \Delta t\, v\, D_+ g\right]. \tag{6.4}$$

Furthermore, for all $\varphi \in \mathcal{L}^2(\Delta x, dv)$—in particular for f and for g—we have

$$\varphi = \sum_{j\in\mathbb{Z}} \left(\varphi((j+1)\Delta x, .)\frac{\mathrm{id} - j.\Delta x}{\Delta x} + \varphi(j\Delta x, .)\frac{(j+1).\Delta x - \mathrm{id}}{\Delta x} \right) \mathrm{ind}_{[j.\Delta x,(j+1).\Delta x)}.$$

We proceed stepwise.

Step 1. Since $(f,g) \in \mathcal{L}^2(\Delta x, dv) \times \mathcal{L}^2(\Delta x, dv)$, and since $\mathcal{L}^2(\Delta x, dv) \subset \mathcal{L}^2(d(x,v))$, we have $(f,g) \in \mathcal{L}^2(d(x,v)) \times \mathcal{L}^2(d(x,v))$, and thus $(f^*, g^*) = S(f,g) \in \mathcal{L}^2(d(x,v)) \times \mathcal{L}^2(d(x,v))$.

Step 2. The function $\varphi(. + \Delta x, .) : \mathbb{R} \times [0,1] \to \mathbb{C}$, $(x,v) \mapsto \varphi(x + \Delta x, v)$ is in $\mathcal{L}^2(\Delta x, dv)$. Indeed, we have $\varphi(. + \Delta x, .) \in \mathcal{L}^2(d(x,v))$ and, for all $(x,v) \in \mathbb{R} \times [0,1]$,

$$
\begin{aligned}
&\varphi\left(x + \Delta x, v\right) \\
&= \sum_{j \in \mathbb{Z}} \left(\varphi((j+1).\Delta x, v) \cdot \frac{x + \Delta x - j.\Delta x}{\Delta x} + \varphi(j.\Delta x, v) \cdot \frac{(j+1).\Delta x - (x + \Delta x)}{\Delta x} \right) \\
&\qquad \cdot \operatorname{ind}_{[j.\Delta x, (j+1).\Delta x)}(x + \Delta x) \\
&= \sum_{j \in \mathbb{Z}} \left(\varphi((j+2).\Delta x, v) \cdot \frac{x + \Delta x - (j+1).\Delta x}{\Delta x} \right. \\
&\qquad \left. + \varphi((j+1).\Delta x, v) \cdot \frac{(j+2).\Delta x - (x + \Delta x)}{\Delta x} \right) \cdot \operatorname{ind}_{[j.\Delta x, (j+1).\Delta x)}(x) \\
&= \sum_{j \in \mathbb{Z}} \left(\varphi((j+2).\Delta x, v) \cdot \frac{x - j.\Delta x}{\Delta x} + \varphi((j+1).\Delta x, v) \cdot \frac{(j+1).\Delta x - x}{\Delta x} \right) \\
&\qquad \cdot \operatorname{ind}_{[j.\Delta x, (j+1).\Delta x)}(x);
\end{aligned}
$$

i.e., for all $(j,v) \in \mathbb{Z} \times [0,1]$, $\varphi(. + \Delta x, v) \restriction [j.\Delta x, (j+1).\Delta x)$ is affine, and $\varphi(. + \Delta x, v)$ is continuous.

Step 3. The proof of Step 2 can be easily modified to prove that the function $\varphi(. - \Delta x, .) : \mathbb{R} \times [0,1] \to \mathbb{C}$, $(x,v) \mapsto \varphi(x - \Delta x, v)$ is in $\mathcal{L}^2(\Delta x, dv)$.

Step 4. $[\varphi] \in \mathcal{L}^2(\Delta x, dv)$. Certainly, $[\varphi] \in \mathcal{L}^2(d(x,v))$. Furthermore, for all $(x,v) \in \mathbb{R} \times [0,1]$,

$$
\begin{aligned}
[\varphi]\left(x\right) = \sum_{j \in \mathbb{Z}} \left([\varphi((j+1).\Delta x, .)] \cdot \frac{x - j.\Delta x}{\Delta x} + [\varphi(j.\Delta x, .)] \cdot \frac{(j+1).\Delta x - x}{\Delta x} \right) \\
\cdot \operatorname{ind}_{[j.\Delta x, (j+1).\Delta x)}(x);
\end{aligned}
$$

i.e., for all $(j,v) \in \mathbb{Z} \times [0,1]$, $[\varphi] \restriction [j.\Delta x, (j+1).\Delta x)$ is affine, and $[\varphi]$ is continuous.

Step 5. By Steps 1 and 2, $D_+ g \in \mathcal{L}^2(\Delta x, dv)$. Hence $\Delta t\, v\, D_+ g \in \mathcal{L}^2(\Delta x, dv)$, and therefore $f - \Delta t\, v\, D_+ g \in \mathcal{L}^2(\Delta x, dv)$, which implies, via Step 4, $[f - \Delta t\, v\, D_+ g] \in \mathcal{L}^2(\Delta x, dv)$, such that $f^* = A.\,(f - \Delta t\, v\, D_+ g) + B.[f - \Delta t\, v\, D_+ g] \in \mathcal{L}^2(\Delta x, dv)$. In a similiar way we prove $g^* \in \mathcal{L}^2(\Delta x, dv)$.

Step 6. Formulae (6.1) and (6.2) follow from evaluations (6.3) and (6.4) at $(j\Delta x, v)$, $(j,v) \in \mathbb{Z} \times [0,1]$.

This finishes the proof of Lemma 6.1. ∎

Since a function $\varphi \in \mathcal{L}^2(\Delta x, dv)$ is entirely determined by $\varphi(j\Delta, v)$, $(j,v) \in \mathbb{Z} \times [0,1]$, we deduce the following corollary from Lemma 6.1.

COROLLARY 6.2. *Let* $(f_j^0)_{j \in \mathbb{Z}} \in \ell^2(\Delta x, dv)$, $(g_j^0)_{j \in \mathbb{Z}} \in \ell^2(\Delta x, dv)$. *For* $n \in \mathbb{N}_0$ *let*

$(f_j^{n+1})_{j\in\mathbb{Z}}$, $(g_j^{n+1})_{j\in\mathbb{Z}}$ be pointwise defined via the following version of (2.6):

$$f_j^{n+1}(v) = A.\left(f_j^{n+1}(v) - \Delta t\, v\,\frac{g_{j+1}^n(v) - g_j^n(v)}{\Delta x}\right) + B.\left[f_j^{n+1}(.) - \Delta t\, v\,\frac{g_{j+1}^n(.) - g_j^n(.)}{\Delta x}\right], \tag{6.5}$$

$$\begin{aligned} g_j^{n+1}(v) &= A\, g_j^n \\ &\quad - v\, A\, B\,\left(\frac{f_{j-1}^n(v) - f_j^n(v)}{\Delta x}\right) + \Delta t\, v^2\,\left(\frac{g_{j+1}^n(v) - 2g_j^n(v) + g_{j-1}^n(v)}{(\Delta x)^2}\right) \\ &\quad - v\, B^2\,\left[\frac{f_{j-1}^n(.) - f_j^n(.)}{\Delta x}\right] + \Delta t\, v\, B^2\,\left[v\cdot\frac{g_{j+1}^n(.) - 2g_j^n(.) + g_{j-1}^n(.)}{(\Delta x)^2}\right]. \end{aligned} \tag{6.6}$$

Then

$$(f_j^n)_{j\in\mathbb{Z}} \in \ell^2(\Delta x, dv), \quad (g_j^n)_{j\in\mathbb{Z}} \in \ell^2(\Delta x, dv), \qquad n \in \mathbb{N}_0,$$

and if we set

$$f^n = \sum_{j\in\mathbb{Z}}\left(f_{j+1}^n\cdot\frac{\mathrm{id} - j.\Delta x}{\Delta x} + f_j^n\cdot\frac{(j+1).\Delta x - \mathrm{id}}{\Delta x}\right)\cdot \mathrm{ind}_{[j.\Delta x,(j+1).\Delta x)}, \quad n\in\mathbb{N}_0, \tag{6.7}$$

and

$$g^n = \sum_{j\in\mathbb{Z}}\left(g_{j+1}^n\cdot\frac{\mathrm{id} - j.\Delta x}{\Delta x} + g_j^n\cdot\frac{(j+1).\Delta x - \mathrm{id}}{\Delta x}\right)\cdot \mathrm{ind}_{[j.\Delta x,(j+1).\Delta x)}, \quad n\in\mathbb{N}_0, \tag{6.8}$$

then

$$\forall n\in\mathbb{N}_0: \quad (f^{n+1}, g^{n+1}) = S(f^n, g^n);$$

i.e., the sequence $((f^n, g^n))_{n\in\mathbb{N}_0}$ is obtained via recursion (2.6) *from the initial pair (f^0, g^0).*

Now we are in the position to finally derive two results which show that for the affine Δx FEM recursion (6.5), (6.6) the same error estimates hold as in the continuous case.

COROLLARY 6.3. *Given $(f^0, g^0) \in \mathcal{L}^2(\Delta x, dv)\times\mathcal{L}^2(\Delta x, dv)$, let*

$$f_j^0 : [0,1]\to\mathbb{C}, \quad f_j^0(v) = f^0(j\Delta x, v), \qquad j\in\mathbb{Z},$$

$$g_j^0 : [0,1]\to\mathbb{C}, \quad g_j^0(v) = g^0(j\Delta x, v), \qquad j\in\mathbb{Z}.$$

Furthermore, let M, ϵ_0 be positive constants. Then there is a positive constant $C_0 = C_0(M,\epsilon_0)$ such that, for all $\Delta x, \Delta t, \epsilon\in\mathbb{R}^+$, if $\Delta t, \Delta x, \epsilon$ satisfy (3.1), *$\Delta t+\epsilon\le M$, and $\epsilon\le\epsilon_0\Delta t$, then the following estimates hold for the sequence $(\mathfrak{f}^n)_{n\in\mathbb{N}_0} = ((f^n, g^n))_{n\in\mathbb{N}}$ defined by* (6.5), (6.6), (6.7), *and* (6.8):

$$\|f^n\|_{\mathcal{L}^2(d(x,v))} \le C_0.\left(\|f^0\|_{\mathcal{L}^2(d(x,v))} + \|g^0\|_{\mathcal{L}^2(d(x,v))}\right)$$

and

$$\|g^n\|_{\mathcal{L}^2(d(x,v))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} \right),$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^2(d(x,v))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$.

COROLLARY 6.4. *Given* $(f^0, g^0) \in \mathcal{L}^2(\Delta x, dv) \times \mathcal{L}^2(\Delta x, dv)$, *let*

$$f_j^0 : [0,1] \to \mathbb{C}, \quad f_j^0(v) = f^0(j\Delta x, v), \qquad j \in \mathbb{Z},$$

$$g_j^0 : [0,1] \to \mathbb{C}, \quad g_j^0(v) = g^0(j\Delta x, v), \qquad j \in \mathbb{Z}.$$

Furthermore, let M, ϵ_1 *be positive constants. Then there is a positive constant* $C_1 = C_1(M, \epsilon_1)$ *such that, for all* $\Delta x, \Delta t, \epsilon \in \mathbb{R}^+$, *if* $\Delta t, \Delta x, \epsilon$ *satisfy* (3.1), $\Delta t + \epsilon \le M$, *and* $\epsilon_1 \le \epsilon$, *then the following estimates hold for the sequence* $(\mathfrak{f}^n)_{n\in\mathbb{N}_0} = ((f^n, g^n))_{n\in\mathbb{N}}$ *defined by* (6.5), (6.6), (6.7), *and* (6.8):

$$\|f^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{L}^2(d(x,v))} + \left\|g^0\right\|_{\mathcal{L}^2(d(x,v))} \right)$$

and

$$\|g^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))} \le C_0 \cdot \left(\left\|f^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} + \left\|g^0\right\|_{\mathcal{H}^1(dx,\mathcal{L}^1(dv))} \right),$$

where the right-hand side of the estimate on $\|g^n\|_{\mathcal{L}^\infty(dv,\mathcal{L}^2(dx))}$ *is set to* ∞ *whenever* $\mathfrak{f}^0 \notin \mathcal{H}^1(dx,\mathcal{L}^1(dv)) \times \mathcal{H}^1(dx,\mathcal{L}^1(dv))$.

7. Conclusions. We have proved uniform stability of the iterative scheme under the following two restrictions:

- Uniform bounds of the iterative scheme could be proven for underresolved numerical computations $\epsilon \le \epsilon_0 \Delta t$ or a bounded mean free path $\epsilon_1 \le \epsilon \le M$.
- The necessary CFL restriction is, in the diffusive limit, a parabolic CFL condition, as was expected. However, for finite values of ϵ the parabolic restriction can be relaxed. One obtains a CFL condition adapted to the hyperbolic part of the original kinetic equation.

Acknowledgment. We are grateful to Ed Larsen for interesting discussions and suggestions.

SYMMETRIC ERROR ESTIMATES FOR MOVING MESH GALERKIN METHODS FOR ADVECTION-DIFFUSION EQUATIONS*

TODD F. DUPONT† AND YINGJIE LIU‡

Abstract. This work tries to increase our understanding of why moving mesh methods often work very well. It combines techniques from the symmetric error estimates (SEEs) of Dupont [*Math. Comp.,* 39 (1982), pp. 85–107] and Bank and Santos [*SIAM J. Numer. Anal.,* 30 (1993), pp. 1–18] with ideas that motivated the analysis of a modified method of characteristics by Douglas and Russell [*SIAM J. Numer. Anal.,* 19 (1982), pp. 871–885]. By changing the usual time derivative to a time derivative along approximate characteristics in the SEE norm, the symmetric error estimate of Bank and Santos can be improved. In addition, by introducing yet another SEE norm which is more strongly mesh dependent, we provide another SEE which provides different insights into the convergence of these methods; one symmetric error estimate that is presented can be used to derive optimal order L^2 convergence in certain settings.

Key words. Galerkin methods, parabolic equations, finite element, moving mesh

1. Introduction.

Moving mesh finite element methods have been known for quite a while [6, 5] and they are increasingly used in practice, but the analytical understanding of these methods is far from complete.

A symmetric error estimate (SEE) is, roughly speaking, a statement of the following form: If the error *can be* small in a certain norm, then it *is* small in that same norm. Somewhat more precisely, there is a norm, $\|\!| \cdot |\!\|$, and a constant, C, such that

$$\|\!|error|\!\| \leq C \|\!|\text{best approximation error}|\!\|,$$

where the left-hand side measures the error in the method at hand and the right-hand side reflects the distance between the true solution and the function spaces used in the method. Of course, we need control on C if such an estimate is to be informative.

The results in section 2 of [4], section 3 of [1], and section 3 of this work give bounds of this type. There are two things that distinguish the bounds given here from earlier work. The first is that here the constant, C, does not increase as the advective term increases in size, provided the mesh movement approximates the advective term well in a sense that is made precise. Hence, these results make it more clear that the mesh movement is actually modeling the advection. The second is that the norm in section 3 involves the convective derivative instead of the partial with respect to time and, as Douglas and Russell pointed out in [3], for advection dominated problems the convective derivative will be much smoother, and therefore easier to approximate well. To give credit where it is due, Bank and Santos noted in [1] that in part of their analysis the constants could be made independent of the size of the advective term,

and they also noted the similarity between the difference equations and the modified method of characteristics [3].

While symmetric error estimates for parabolic equations have a certain attractiveness in the simplicity of the statement that they make, it is sometimes hard to see the precise meaning of the result. In the case of Galerkin methods for elliptic equations, one has a symmetric error estimate in the H^1-norm, a statement that is relatively easy to understand. In the case of parabolic equations, symmetric error estimates [2, 4, 1] involve combining several norms and seminorms; in the case of [4], for example, the $\|\!| \cdot |\!\|$ is constructed from two norms and a seminorm: the maximum in time of the L^2-norm in space, the L^2 in time norm of the H^1-norm in space, and the L^2 in time norm of the discrete H^{-1} seminorm in space of the time derivative. In one of the analogous results here, the H^1-norm is replaced by the "discrete H^1"-norm, i.e., the H^1-norm of the H^1-projection into the space. It might appear at first that weakening the norms is not an advantage, but it actually highlights the importance of the only remaining norm to such a degree that one can get optimal order L^2 convergence in some contexts. In a sense, the SEE that results from this norm provides a way to combine the techniques of [4] with those of Wheeler [7]. We view this as one of the most interesting results of this work.

In section 2 we give the advection-diffusion problem whose approximate solution we are studying here, and we define a continuous-time moving mesh method in terms of a "convected time derivative." In section 3 we give three symmetric error bounds for the continuous-time case. Then we present a symmetric error estimate for a discrete time case. In sections 4 and 5 we give two optimal order L^2 error bounds that follow from the results of section 3.

2. Model problem and a moving mesh Galerkin method. Consider the following advection-diffusion model problems on $Q = \Omega \times (0, T)$:

$$\begin{cases} \partial_t u - \bigtriangledown \cdot (a \bigtriangledown u) + v \cdot \bigtriangledown u + cu = f & \text{on } Q, \\ \dfrac{\partial u}{\partial \nu} = g & \text{on } \Gamma_N \times (0,T), \\ u = 0 & \text{on } \Gamma_D \times (0,T), \\ u = u_0 & \text{for } t = 0, \end{cases} \tag{2.1}$$

where $a(x,t), v(x,t), c(x,t), f(x,t)$, and $g(x,t)$ are smooth and bounded and $0 < a_0 \le a \le a_1$ for some constants $a_0, a_1 > 0$. Ω is a bounded domain in R^d. For simplicity, we assume that Ω is a fixed polyhedron. Γ_D, Γ_N are parts of the boundary $\partial\Omega$ such that $\Gamma_D \cap \Gamma_N = \emptyset$, $\Gamma_D \cup \Gamma_N = \partial\Omega$, and Γ_D is closed. Suppose that $\bar{D} = \cup D_i$ is a fixed polyhedron, where the D_i's are closed sets with nonvoid interior such that the interiors of the D_i's are disjoint. We need few restrictions on the D_i's for much of the argument, but to keep the discussion simple we suppose that each D_i is a simplex and that together they form a tessellation of D. We suppose that there is a continuous mapping $\mathcal{G}$ from $\bar{D} \times [0,T]$ onto $\bar{\Omega}$ such that (1) for each t, $\mathcal{G}(\cdot, t)$ is a one-to-one piecewise linear mapping (with respect to $\{D_j\}$) of $\bar{D}$ onto $\bar{\Omega}$; and (2) $\mathcal{G}$ is continuously differentiable on each $D_i \times [0,T]$. We also suppose that $\partial D = \gamma_D \cup \gamma_N$ and that $\Gamma_D = \mathcal{G}(\gamma_D, t)$ and $\Gamma_N = \mathcal{G}(\gamma_N, t)$. We denote by $\Omega_i = \Omega_i(t)$ the image of D_i under $\mathcal{G}(\cdot, t)$. Let $\mathcal{M}_D$ be a finite dimensional subspace of $H^1(D)$ so that each function in $\mathcal{M}_D$ vanishes on γ_D; then the finite element space on Ω is defined by $\mathcal{M}(t) = \{\phi(x,t) : \phi(\mathcal{G}(\cdot,t),t) \in \mathcal{M}_D\}$. It is sometimes convenient to think of this moving mesh as being generated by a mapping of Ω onto itself. (See Figure 2.1.)

Let $\mathcal{G}^{-1} = \mathcal{G}^{-1}(\cdot, t)$ denote the inverse of $\mathcal{G}$ as a map of $\bar{D}$ onto $\bar{\Omega}$ with t fixed;

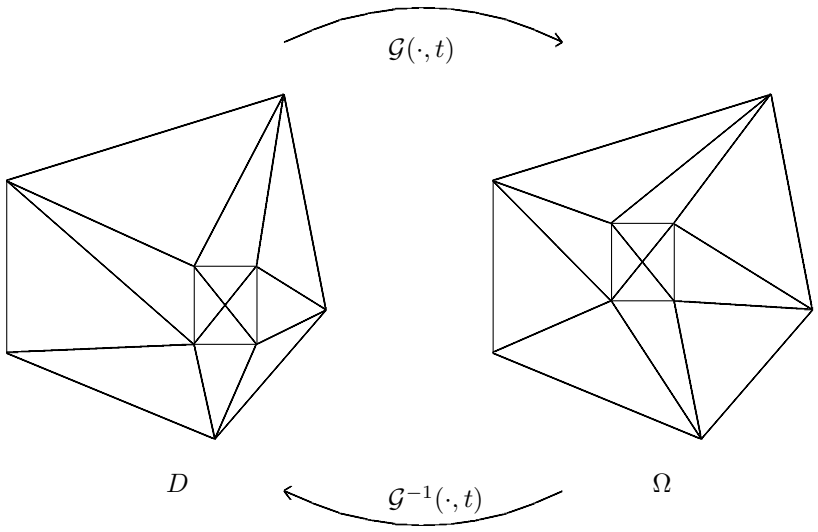

FIG. 2.1. *Moving mesh as a time dependent mapping* $\mathcal{G}$.

this function can be thought of as being defined on $\bar{Q}$. Let $\mathcal{G}_t$ be the partial derivative of $\mathcal{G}$ with respect to t. The finite element mesh is advected with a flow that is given by

$$\dot{x}(t) = \mathcal{G}_t(\mathcal{G}^{-1}(x,t),t).$$

Denote a particular directional derivative as follows:

$$\frac{D}{Dt}F(x,t) = \frac{\partial}{\partial t}F(x,t) + w \cdot \bigtriangledown_x F(x,t),$$

where $w(x,t)$ is a differentiable vector function such that $w \cdot \nu = 0$ on Γ_N for $t \geq 0$ and ν is the unit outer normal of $\partial\Omega$.

We will use $\|\cdot\|_k$ as the norm on the Sobolev space $H^k(\Omega)$; for domains R other than Ω we will use the more explicit notation $\|\cdot\|_{H^k(R)}$. The norm and inner product on $L^2(\Omega)$ will be denoted as $\|\cdot\|$ and $(\cdot,\cdot)$, respectively.

The exact solution of (2.1) will satisfy

$$\left(\frac{Du}{Dt},\psi\right) + (a \bigtriangledown u, \bigtriangledown\psi) + ((v-w)\cdot\bigtriangledown u,\psi) + (cu,\psi) = (f,\psi) + \int_{\Gamma_N} g\psi ds \tag{2.2}$$

for any $\psi \in H^1(\Omega)$. We are looking for $U \in \mathcal{M}(t)$ such that

$$\left(\frac{DU}{Dt},\phi\right) + (a \bigtriangledown U, \bigtriangledown\phi) + ((v-w)\cdot\bigtriangledown U,\phi) + (cU,\phi) = (f,\phi) + \int_{\Gamma_N} g\phi ds \tag{2.3}$$

for any $\phi \in \mathcal{M}(t)$. The inclusion of the convective derivative here is not really a change from the method discussed in [4]—we have just added and subtracted a term. However, it reflects a change in the way that we think about and analyze the method. We will take the initial value for U to be the L^2-projection of u_0 into $\mathcal{M}(0)$.

3. Symmetric error bounds. First, we get a basic relation that will be used in bounding the error. Taking $\Psi \in \mathcal{M}(t)$ and setting $\Phi = U - \Psi \in \mathcal{M}(t)$ and $\eta = u - \Psi$ give, for $\phi \in \mathcal{M}(t)$,

$$\begin{aligned}\left(\frac{D\Phi}{Dt}, \phi\right) + (a \bigtriangledown \Phi, \bigtriangledown\phi) + ((v-w)\cdot\bigtriangledown\Phi, \phi) + (c\Phi, \phi)\\ = \left(\frac{D\eta}{Dt}, \phi\right) + (a \bigtriangledown \eta, \bigtriangledown\phi) + ((v-w)\cdot\bigtriangledown\eta, \phi) + (c\eta, \phi).\end{aligned} \tag{3.1}$$

From the definition of the directional derivative we have the following equality which we use in the energy-type arguments used later.

LEMMA 1. *Suppose that $\phi(t) \in \mathcal{M}(t)$ and that ϕ is differentiable with respect to t as a map into $L^2(\Omega)$. Then*

$$\left(\frac{D\phi}{Dt}, \phi\right) = \frac{1}{2}\left\{\frac{d}{dt}\|\phi\|^2 - \int_\Omega \phi^2 \bigtriangledown_x \cdot w dx\right\}.$$

Proof.

$$\begin{aligned}\frac{d}{dt}\|\phi\|^2 &= 2\int_\Omega \phi_t\phi dx\\ &= 2\int_\Omega \frac{D\phi}{Dt}\phi dx - 2\int_\Omega (w\cdot\bigtriangledown\phi)\phi dx\\ &= 2\int_\Omega \frac{D\phi}{Dt}\phi dx + \int_\Omega \phi^2(\bigtriangledown\cdot w)dx - \int_{\Gamma_N}\phi^2 w\cdot\nu ds\\ &= 2\int_\Omega \frac{D\phi}{Dt}\phi dx + \int_\Omega \phi^2(\bigtriangledown\cdot w)dx. \qquad \square\end{aligned} \tag{3.2}$$

Define the mesh-dependent seminorm $\|\cdot\|_{(-1,\mathcal{M}(t))}$ by

$$\|u\|_{(-1,\mathcal{M}(t))} = \sup_{\phi\in\mathcal{M}(t),\phi\neq 0}\frac{|(u,\phi)|}{\|\phi\|_1}.$$

For X a normed space and v a function that maps $(0,T)$ into X, let

$$\|v\|_{L^p(0,T;X)}$$

denote the L^p-norm on the interval $(0,T)$ of the X-norm of v. The first SEE will be given in the norm $|||\cdot|||$ defined by

$$|||v|||^2 = \|v\|^2_{L^\infty(0,T;L^2(\Omega))} + \|v\|^2_{L^2(0,T;H^1(\Omega))} + \int_0^T \left\|\frac{Dv}{Dt}\right\|^2_{(-1,\mathcal{M}(t))} dt.$$

THEOREM 1. *Suppose that there exist constants c_1 and c_2 such that for all $(x,t) \in Q$,*

$$\bigtriangledown_x \cdot w(x,t) \le c_1, \qquad |w-v|(x,t) \le c_2. \tag{3.3}$$

Then there is a constant C depending only on c_1, c_2, T, and bounds on the coefficients a and c such that, for any smooth function Ψ from $[0,T]$ into $L^2(\Omega)$ with $\Psi(t) \in \mathcal{M}(t)$,

$$|||u - U||| \le C|||u - \Psi|||.$$

Proof. By using $\phi = \Phi$ in (3.1) we see then that

$$\frac{d}{dt}\|\Phi\|^2 + a_0\|\Phi\|_1^2 \le C\left\{\|\Phi\|^2 + \left\|\frac{D\eta}{Dt}\right\|^2_{(-1,\mathcal{M}(t))} + \|\eta\|_1^2\right\}. \tag{3.4}$$

This estimate and Gronwall's inequality give that

$$\|\Phi\|^2_{L^\infty(0,T;L^2(\Omega))} + a_0\|\Phi\|^2_{L^2(0,T;H^1(\Omega))} \le C\left(\|\Phi(0)\|^2_{L^2(\Omega)} + |||\eta|||^2\right). \tag{3.5}$$

Also, for any $\phi \in \mathcal{M}(t)$, (3.1) gives that

$$\left(\frac{D\Phi}{Dt}, \phi\right) \le C\left\{\|\Phi\|_1 + \left\|\frac{D\eta}{Dt}\right\|_{(-1,\mathcal{M}(t))} + \|\eta\|_1\right\}\|\phi\|_1. \tag{3.6}$$

Therefore

$$\int_0^T \left\|\frac{D\Phi}{Dt}\right\|^2_{(-1,\mathcal{M}(t))} dt \le C|||\eta|||^2. \tag{3.7}$$

Since $U(0)$ is the L^2-projection into $\mathcal{M}(0)$ of u_0, we see that $\|\Phi(0)\| \le \|\eta(0)\|$. Hence $|||\Phi||| \le C|||\eta|||$. The triangle inequality then gives that $|||u - U||| \le C|||u - \Psi|||$. ∎

In the application of Gronwall's inequality one gets exponential growth in time of the estimate of the error unless there is sufficient dissipation in the equation to counter it. If we let c_0 be a bound for the absolute value of $c(x,t)$ on Q, then the arithmetic of the proof gives that the constant C of (3.5) contains a factor $\exp(KT)$, where K can be of the form

$$K = 3c_0 + c_1 + c_2 + a_0/3 + 3c_2^2/a_0.$$

Hence, if c_2 is large and a_0 is small, this constant is very big. An interesting aspect of the above calculation is that most of it is local so that the important quantity for most parts of the estimate is the maximum of $|v - w|^2/a$. This would lead one to conjecture that in parts of the problem where diffusion is small, the directional derivatives that we bring into the estimation should be very close to the ones that point in characteristic directions.

The function w in the definition of the directional derivative should be chosen so that $|||u - \Psi|||$ in the above theorem is small. To illustrate how this might be done, we consider the case in which $\mathcal{M}(t)$ is the space of continuous piecewise linear functions over a triangular mesh given by the Ω_i's. If we take $w = \dot{x}$, then nodal interpolation commutes with the convective differentiation; i.e., $\frac{DIu}{Dt} = I\frac{Du}{Dt}$, where Iu is the nodal interpolant of u. Therefore,

$$\left\|\frac{D(u - Iu)}{Dt}\right\|_{(-1,\mathcal{M}(t))} \le \left\|\frac{D(u - Iu)}{Dt}\right\| \le C\left(\sum_i h_i^4 \left\|\frac{Du}{Dt}\right\|^2_{H^2(\Omega_i)}\right)^{\frac{1}{2}},$$

where h_i is the diameter of Ω_i. Here we emphasize that the norm involved is applied to the convective derivative, which can be a much smoother function than the usual partial time derivative.

Next we weaken the norm used in the previous theorem in two different ways to get somewhat different results.

Let $c_3 = (a_0 + c_2^2/a_0)/2$. Set

$$\mathcal{B}(\varphi, \psi) = (a \bigtriangledown (\varphi), \bigtriangledown \psi) + ((v - w) \cdot \bigtriangledown \varphi, \psi) + c_3(\varphi, \psi).$$

It is easy to check that for any $\varphi \in H^1(\Omega)$,

$$\mathcal{B}(\varphi, \varphi) \geq \frac{a_0}{2} \|\varphi\|_1^2. \tag{3.8}$$

We define a linear projection $P_1 : H^1(\Omega) \to \mathcal{M}(t)$ by

$$\mathcal{B}(v - P_1 v, \phi) = 0 \tag{3.9}$$

for all $\phi \in \mathcal{M}(t)$. Now we can define a new norm $\|\!| \cdot |\!\|_0$ in which the H^1 part of the previous norm has been weakened to be a seminorm:

$$\|\!| v |\!\|_0^2 = \|v\|^2_{L^\infty(0,T;L^2(\Omega))} + \|P_1 v\|^2_{L^2(0,T;H^1(\Omega))} + \int_0^T \left\| \frac{Dv}{Dt} \right\|^2_{(-1,\mathcal{M}(t))} dt. \tag{3.10}$$

The mnemonic for the use of the subscript 0 is that this norm emphasizes the H^0 or L^2 part of the norm.

Another norm also can be defined to put more weight on the $L^2(H^1)$ part of $\|\!| \cdot |\!\|$ by weakening the $L^\infty(L^2)$ part. Let P_0 be the L^2-projection onto $\mathcal{M}(t)$. Set

$$\|\!| v |\!\|_1^2 = \|P_0 v\|^2_{L^\infty(0,T;L^2(\Omega))} + \|v\|^2_{L^2(0,T;H^1(\Omega))} + \int_0^T \left\| \frac{Dv}{Dt} \right\|^2_{(-1,\mathcal{M}(t))} dt. \tag{3.11}$$

THEOREM 2. *If the conditions of Theorem* 1 *hold, then there is a constant* $C \geq 0$ *depending only on* c_1, c_2, T, *and bounds on the coefficients* a, c *such that for any smooth function* Ψ *from* $[0, T]$ *into* $L^2(\Omega)$ *with* $\Psi(t) \in \mathcal{M}(t)$,

$$\|\!| u - U |\!\|_0 \leq C \|\!| u - \Psi |\!\|_0,$$
$$\|\!| u - U |\!\|_1 \leq C \|\!| u - \Psi |\!\|_1.$$

Proof. Because the test function ϕ in (3.1) is in the space $\mathcal{M}(t)$, we can rewrite that relation as

$$\begin{aligned} &\left(\frac{D\Phi}{Dt}, \phi \right) + (a \bigtriangledown \Phi, \bigtriangledown \phi) + ((v - w) \cdot \bigtriangledown \Phi, \phi) + (c\Phi, \phi) \\ &= \left(\frac{D\eta}{Dt}, \phi \right) + \mathcal{B}(P_1 \eta, \phi) + ((c - c_3)\eta, \phi). \end{aligned} \tag{3.12}$$

This gives the following analogue of (3.4):

$$\frac{d}{dt} \|\Phi\|^2 + a_0 \|\Phi\|_1^2 \leq C \left\{ \|\Phi\|^2 + \left\| \frac{D\eta}{Dt} \right\|^2_{(-1,\mathcal{M}(t))} + \|P_1 \eta\|_1^2 + \|\eta\|^2 \right\}. \tag{3.13}$$

Since $P_1\Phi = \Phi$, this becomes

$$\frac{d}{dt}\|\Phi\|^2 + a_0\|P_1\Phi\|_1^2 \le C\left\{\|\Phi\|^2 + \left\|\frac{D\eta}{Dt}\right\|^2_{(-1,\mathcal{M}(t))} + \|P_1\eta\|_1^2 + \|\eta\|^2\right\}. \tag{3.14}$$

The estimate (3.6) becomes

$$\left(\frac{D\Phi}{Dt}, \phi\right) \le C\left\{\|P_1\Phi\|_1 + \left\|\frac{D\eta}{Dt}\right\|_{(-1,\mathcal{M}(t))} + \|P_1\eta\|_1 + \|\eta\|\right\}\|\phi\|_1. \tag{3.15}$$

The relations (3.14) and (3.15) give the bound for the $\|\!|\cdot|\!\|_0$ norm, just as in the proof of Theorem 1.

Examination of (3.4) shows that the η term in (3.5) can be replaced by $\|\!|\eta|\!\|_1$. The fact $P_0\Phi = \Phi$ gives

$$\|P_0\Phi\|^2_{L^\infty(0,T;L^2(\Omega))} + a_0\|\Phi\|^2_{L^2(0,T;H^1(\Omega))} \le C\left(\|P_0\Phi(0)\|^2_{L^2(\Omega)} + \|\!|\eta|\!\|_1^2\right).$$

Next, from (3.6) and the above relation we see that the analogue of (3.7) holds with $\|\!|\eta|\!\|$ replaced by $\|\!|\eta|\!\|_1$. Also, the use of $U(0) = P_0u(0)$ gives that $\|\Psi(0)\| = \|\eta(0)\|$. Combining these observations completes the proof of the second inequality in the theorem. □

Next we examine a fully discrete scheme. In this case we restrict ourselves to the case $w(x,t) = \dot{x}$. Following [1], for a given partition $P = \{t_0 = 0, t_1, \dots, t_{n-1}, t_n = T\}$ of $[0,T]$, consider $\mathcal{G}(s,t)$ to be linear in t for $t \in [t_{i-1}, t_i)$, for any i, and continuous in t on the whole of $[0,T]$. Let M be the collection of functions $\phi(x,t)$ on Q such that $\phi(\cdot,t) \in \mathcal{M}(t)$ for any $t \in [0,T]$, and such that ϕ is continuous in t and piecewise linear along the trajectory of mesh movement, i.e.,

$$\phi(\mathcal{G}(s,t),t) = \phi(\mathcal{G}(s,t_{j-1}),t_{j-1}) + \theta[\phi(\mathcal{G}(s,t_j),t_j) - \phi(\mathcal{G}(s,t_{j-1}),t_{j-1})],$$

where $t = t_{j-1} + \theta(t_j - t_{j-1})$ for any $\theta \in [0,1]$. The following relation holds for any $t \in (t_{i-1}, t_i)$, $s \in D_j$, for all i, j:

$$\frac{\phi(\mathcal{G}(s,t_i),t_i) - \phi(\mathcal{G}(s,t_{i-1}),t_{i-1})}{t_i - t_{i-1}} = \frac{D\phi}{Dt}(\mathcal{G}(s,t),t).$$

Note that $\frac{D\phi}{Dt}$ is just the same as in the continuous-time case on each (t_{i-1}, t_i) with the restriction that $w = \dot{x}$, but it also has a discrete form in this special case. It is clear that functions in M are defined by their values at the t_j's, so to define the approximate solution we need only say how it is computed at the times t_j.

The time discrete approximate solution $U \in M$ is such that $U(0)$ is the L^2-projection of $u(0)$ onto $\mathcal{M}(0)$ and, for $t = t_j-$,

$$\left(\frac{DU}{Dt}, \phi\right) + (a \bigtriangledown U, \bigtriangledown\phi) + ((v-w)\cdot\bigtriangledown U, \phi) + (cU, \phi) = (f,\phi) + \int_{\Gamma_N} g\phi ds \tag{3.16}$$

for any $\phi \in \mathcal{M}(t_j)$, $j = 1, 2, \dots, n$. Let

$$\|\!|v|\!\|^2_{0,d} = \max_{0\le j\le n}\|v(t_j)\|^2 + \sum_{j=1}^{n}(t_j - t_{j-1})\left\{\|P_1v(t_j)\|_1^2 + \left\|\frac{D}{Dt}v(t_j-)\right\|^2_{(-1,\mathcal{M}(t_j))}\right\};$$

we have the following theorem parallel to Theorem 3.1 in [1].

THEOREM 3. *Let $\mathcal{D}(t_j)$ denote the piecewise constant function $|\det(\bigtriangledown_s \mathcal{G})|$ on D. If there are constants $c_1, c_2 > 0$ independent of the mesh so that*

$$\frac{\mathcal{D}(t_j) - \mathcal{D}(t_{j-1})}{t_j - t_{j-1}} \leq c_1 \mathcal{D}(t_{j-1})$$

for $1 \leq j \leq n$, and $|w - v|(x,t) \leq c_2$ for all $(x,t) \in Q$, then there is a constant $C \geq 0$ depending only on c_1, c_2, T, and bounds of coefficients a, c such that $\|\!|u - U|\!\|_{0,d} \leq C\|\!|u - \Psi|\!\|_{0,d}$ for any $\Psi \in M$.

Proof. The fully discretized scheme yields an error similar to (3.12), with $t = t_j-$. Let $\phi = \Phi(t_j)$ in the analogue of (3.12), and use an argument like that in [1] to get

$$\begin{aligned}\left(\frac{D\Phi(t_j-)}{Dt}, \Phi(t_j)\right) \geq \quad & \frac{1}{2\Delta t_j}(\|\Phi(t_j)\|^2 - \|\Phi(t_{j-1})\|^2) \\ & -\frac{c_1}{2}\|\Phi(t_{j-1})\|^2,\end{aligned} \tag{3.17}$$

where $\Delta t_j = t_j - t_{j-1}$. We then have

$$\begin{aligned}&\frac{1}{\Delta t_j}(\|\Phi(t_j)\|^2 - \|\Phi(t_{j-1})\|^2) + \frac{1}{2}a_0\| \bigtriangledown \Phi(t_j)\|^2 \\ &\quad \leq C\left\{\left\|\frac{D\eta(t_j-)}{Dt}\right\|^2_{(-1,\mathcal{M}(t_j))} + \|P_1\eta(t_j)\|_1^2 + \|\Phi(t_j)\|^2 + \|\eta(t_j)\|^2\right\}.\end{aligned} \tag{3.18}$$

From the discrete Gronwall's inequality one obtains the following:

$$\|\Phi(t_j)\|^2 + \frac{1}{2}a_0 \sum_{i=1}^{j} \Delta t_i \| \bigtriangledown \Phi(t_i)\|^2 \leq C\|\!|\eta|\!\|^2_{0,d}. \tag{3.19}$$

Also, from the analogue to (3.12) at $t = t_j-$, for any $\phi \in \mathcal{M}(t_j)$,

$$\begin{aligned}\left(\frac{D\Phi(t_j-)}{Dt}, \phi(t_j)\right) \quad \leq \quad & C\Bigg\{\| \bigtriangledown \Phi(t_j)\| + \|\Phi(t_j)\| + \left\|\frac{D\eta(t_j-)}{Dt}\right\|_{(-1,\mathcal{M}(t_j))} \\ & + \|P_1\eta(t_j)\|_1 + \|\eta(t_j)\|\Bigg\}\|\phi(t_j)\|_1.\end{aligned} \tag{3.20}$$

With the help of (3.19), (3.20) becomes

$$\sum_{i=1}^{j} \Delta t_i \left\|\frac{D\Phi(t_i-)}{Dt}\right\|_{(-1,\mathcal{M}(t_i))} \leq C\|\!|\eta|\!\|_{0,d}. \tag{3.21}$$

Finally, combine (3.19), (3.21), and a triangle inequality to complete the proof. ∎

4. An optimal order L^2 error estimate. In this section, we prove the following optimal order error estimate for the one-space dimensional, continuous-time case: We will take $\mathcal{M}_D$ to be the space of continuous piecewise linear functions over a mesh $0 = s_0 < s_1 < \cdots < s_m = 1$ on the reference domain $D = [0,1]$, so $\mathcal{M}(t)$ is just the space of continuous functions which are polynomials of degree at most 1 on each interval $\Omega_i = [x_{i-1}, x_i]$, with $x_i(t) = \mathcal{G}(s_i, t)$. Take $w = \dot{x}$. Let h_i denote the length of Ω_i, and note that $\dot{x}$ is a continuous piecewise linear function over the mesh.

The following theorem gives an optimal order error estimate in which the error bound depends on the bounds of the difference between the growth rate of the length of each element with respect to time and the rate of "compression" of the exact solution (i.e., c_1), the difference between the convection velocity and the velocity of mesh movement (i.e., c_2), and other bounds of the coefficients of (2.1). Most importantly, the error bound does not depend on the convection velocity v, which shows an advantage of mesh movement.

THEOREM 4. *If there are constants $c_1, c_2, c_3 > 0$ so that $\|\partial_x(v - \dot{x})\|_\infty \le c_1$, $\|v - \dot{x}\|_\infty \le c_2$, and $\max_i \|\partial_x a\|_{L^\infty(\Omega_i)} \le c_3$ for all $t \in [0, T]$, then there is a constant $C(c_1, c_2, c_3, a_0, a_1, c, T; \Omega)$ such that*

$$\begin{aligned} \|u - U\|(t) \le \quad & C \left\{ \left\| \left(\sum_i h_i^4 \|u\|^2_{H^2(\Omega_i)} \right)^{1/2} \right\|_{L^\infty[0,T]} \right. \\ & \left. + \left\| \left(\sum_i h_i^4 \left\| \frac{Du}{Dt} \right\|^2_{H^2(\Omega_i)} \right)^{1/2} \right\|_{L^2[0,T]} \right\} \end{aligned} \tag{4.1}$$

for any $0 \le t \le T$.

Proof. The proof is an application of Theorem 2 using $\|\!| \cdot |\!\|_0$. Since $\|\!| u - U |\!\|_0$ dominates the term we want to bound, it suffices to show that $\|\!| u - \Psi |\!\|_0$ can be bounded by terms on the right-hand side of (4.1). We choose Ψ to be the nodal interpolant Iu of u. The estimate of $\|u - \Psi\|_{L^\infty(0,T;L^2(\Omega))}$ is straightforward. The observation that $\frac{D}{Dt}$ commutes with interpolation means that $\|\frac{D}{Dt}(u - \Psi)\|_{L^2(0,T;L^2(\Omega))}$ can be bounded by the terms on the right-hand side of (4.1); hence, the weaker semi-norm on $\frac{D}{Dt}(u - \Psi)$ is also bounded.

The $H^1(\Omega)$-norm of $P_1(u - \Psi)$ can be bounded as follows: For any $\phi \in \mathcal{M}(t)$,

$$\begin{aligned} & \mathcal{B}(P_1(u - \Psi), \phi) = \mathcal{B}(u - \Psi, \phi) \\ = \quad & \sum_i \int_{\Omega_i} a \partial_x (u - \Psi)\, \partial_x \phi dx + \sum_i \int_{\Omega_i} (v - \dot{x}) \partial_x (u - \Psi)\, \phi dx \\ & + c_3(u - \Psi, \phi) \\ = \quad & -\sum_i \int_{\Omega_i} (u - \Psi) \partial_x a\, \partial_x \phi dx - \sum_i \int_{\Omega_i} (u - \Psi) \{ \phi \partial_x (v - \dot{x}) \\ & + (v - \dot{x}) \partial_x \phi \} dx + c_3(u - \Psi, \phi) \\ \le \quad & \|\partial_x a\|_{L^\infty(\Omega)} \|u - \Psi\| \|\phi\|_1 + \|\partial_x (v - \dot{x})\|_{L^\infty(\Omega)} \|u - \Psi\| \|\phi\| \\ & + \|v - \dot{x}\|_{L^\infty(\Omega)} \|u - \Psi\| \|\phi\|_1. \end{aligned} \tag{4.2}$$

Using the coercivity of $\mathcal{B}(\cdot, \cdot)$ (see (3.8)) and taking $\phi = P_1(u - \Psi)$, we get that

$$\|P_1(u - \Psi)\|_1 \le C \|u - \Psi\|. \qquad \square$$

Note that the integration by parts was done subinterval by subinterval so a need only be locally smooth. The approximation results in this section are more local than we can prove in the general case studied in the next section.

5. Optimal order $L^2(\Omega)$ error estimate for general space dimension. In this section we return to the d-dimensional case. There will be several situations in which we need to use surface integrals on the elements Ω_i; we will use 2-dimensional terminology and refer to these as integrals over the edges. Thus an edge is the intersection of $\bar{\Omega}_i$'s with positive $(d-1)$-dimensional measure. Consider the Dirichlet problem, $\Gamma_N = \emptyset$, and take $w = \dot{x}$. Denote by e_j the edge between two adjacent elements and by n_{e_j} a normal to e_j, and define the jump operator $[\cdot]$ across the edge e_j by

$$[\mathcal{F}](x) = \lim_{\epsilon \to 0+} \{\mathcal{F}(x + \epsilon n_{e_j}) - \mathcal{F}(x - \epsilon n_{e_j})\} \quad \forall x \in e_j.$$

Assume that Ω and a are such that the Dirichlet problem has uniform H^2 regularity; i.e., there is a constant C such that for any $t \in [0,T]$, $q \in L^2(\Omega)$, there exists a $\xi \in H_0^1(\Omega) \cap H^2(\Omega)$ satisfying

$$\int_\Omega a \bigtriangledown \xi \cdot \bigtriangledown \eta dx = \int_\Omega q\eta dx \quad \forall \eta \in H_0^1(\Omega), \tag{5.1}$$

and $\|\xi\|_2 \leq C\|q\|$.

Suppose that $\mathcal{M}_D$ consists of a space of continuous piecewise polynomials of degree at most r. We assume that there is a constant $\tilde{C}$ such that for any $t \in [0,T]$ and for any $\xi \in H_0^1(\Omega) \cap \{\Pi_i H^s(\Omega_i)\}$, $s \geq 2$,

$$\inf_{\phi \in \mathcal{M}(t)} \|\xi - \phi\|_l^2 \leq \tilde{C} \sum_i h_i^{2(\min\{r+1,s\}-l)} \|\xi\|^2_{H^s(\Omega_i)}, \qquad l = 0, 1,$$

where h_i is the diameter of the element Ω_i. Let h denote $\max_i h_i$.

In this section we need bounds on $\bigtriangledown \dot{x}$, the Jacobian of the function $\dot{x}$ with respect to x. We will use the norm on matrices that is induced by the Euclidean norm on vectors. In particular, $\| \bigtriangledown \dot{x}\|_\infty$ is the $L^\infty(\Omega)$-norm of the norm of the matrix $\bigtriangledown \dot{x}$.

We have the following optimal order estimate for the $L^2(\Omega)$-norm of the error. While it looks like a generalization of Theorem 4 to higher dimensional spaces, there are differences. The hypotheses are stronger here, and the result is not quite so local.

THEOREM 5. *Suppose that there are constants $c_1, c_2, c_3, c_4, c_5 > 0$ so that, for all $t \in [0.T]$, we have $\| \bigtriangledown \dot{x}\|_\infty \leq c_1$; $\| \bigtriangledown \cdot v\|_\infty \leq c_2$; $\|v - \dot{x}\|_\infty \leq c_3$; and $\|\frac{Da}{Dt}\|_\infty, \| \bigtriangledown a\|_\infty, \| \bigtriangledown \frac{Da}{Dt}\|_\infty \leq c_4$; and the norm of the jump in $\bigtriangledown \dot{x}$ across an edge $e = \bar{\Omega}_k \cap \bar{\Omega}_m$ is bounded by $c_5 \min\{h_k, h_m\}$. Then there is a constant $C(c_1, c_2, c_3, c_4, c_5, a_0, a_1, c, T, \Omega)$ such that*

$$\begin{aligned} \|u - U\|(t) \quad \leq \quad & C \left\{ \left\| h \left(\sum_i h_i^{2(\min\{r+1,s\}-1)} \|u\|^2_{H^s(\Omega_i)} \right)^{1/2} \right\|_{L^\infty[0,T]} \right. \\ & \left. + \left\| h \left(\sum_i h_i^{2(\min\{r+1,s\}-1)} \left\| \frac{Du}{Dt} \right\|^2_{H^s(\Omega_i)} \right)^{1/2} \right\|_{L^2[0,T]} \right\} \end{aligned} \tag{5.2}$$

for any $t \in [0,T]$.

Proof. Again we will use Theorem 2 to establish this $L^2(\Omega)$ estimate. We will use an elliptic projection to give the Ψ that is in Theorem 2. The most tedious part of

the proof is bounding the time derivative part of $\|\!|\ |\!\|_0$; we do that here by estimating the $L^2(\Omega)$-norm of that term.

Set $\mathcal{B}_1(\xi,\eta) = (a \bigtriangledown \xi, \bigtriangledown\eta)$, and define a linear projection $P : H_0^1(\Omega) \to \mathcal{M}(t)$ by

$$\mathcal{B}_1(\xi - P\xi, \phi) = 0 \quad \forall \phi \in \mathcal{M}(t).$$

Denote $\eta = u - Pu$. For any given $t \in [0,T]$, let $\phi(x)$ be any function in $\mathcal{M}(t)$. Let $\psi(x,\tilde{t}) = \phi(\mathcal{G}(\mathcal{G}^{-1}(x,\tilde{t}),t))$ for any $\tilde{t} \in [0,T]$. It is easy to see that $\psi(x,t) = \phi(x)$ and $\frac{D\psi}{D\tilde{t}} = 0$ for any $\tilde{t} \in [0,T]$.

We have, at time t,

$$\begin{aligned} 0 &= \frac{d}{dt}\{\mathcal{B}_1(\eta(.,t),\psi(.,t))\} = \sum_i \left\{ \frac{d}{dt}\int_{\Omega_i} a \bigtriangledown \eta \cdot \bigtriangledown \psi dx \right\} \\ &= \sum_i \left\{ \int_{\Omega_i} a_t \bigtriangledown \eta \cdot \bigtriangledown \phi dx + \int_{\Omega_i} a \bigtriangledown \eta_t \cdot \bigtriangledown \phi dx \right. \\ &\quad \left. + \int_{\Omega_i} a \bigtriangledown \eta \cdot \bigtriangledown \psi_t dx + \int_{\partial\Omega_i} a \bigtriangledown \eta \cdot \bigtriangledown \phi (\dot{x}\cdot n) ds \right\}, \end{aligned} \tag{5.3}$$

where n is the outer norm of $\partial\Omega_i$. Note that

$$\int_{\Omega_i} a \bigtriangledown \eta_t \cdot \bigtriangledown \phi dx = \int_{\Omega_i} a \bigtriangledown \frac{D\eta}{Dt} \cdot \bigtriangledown \phi dx - \int_{\Omega_i} a \bigtriangledown (\dot{x}\cdot\bigtriangledown\eta)\cdot\bigtriangledown\phi dx$$

and

$$\begin{aligned} \dot{x}\cdot\bigtriangledown(\bigtriangledown\eta\cdot\bigtriangledown\phi) &= \sum_k \dot{x_k}\partial_{x_k}\left(\sum_j \partial_{x_j}\eta\partial_{x_j}\phi\right) \\ &= \sum_k\sum_j (\dot{x_k}\partial_{x_j}\partial_{x_k}\eta\partial_{x_j}\phi + \dot{x_k}\partial_{x_j}\partial_{x_k}\phi\partial_{x_j}\eta) \\ &= \bigtriangledown(\dot{x}\cdot\bigtriangledown\eta)\cdot\bigtriangledown\phi - (\bigtriangledown\eta)^T(\bigtriangledown\dot{x})(\bigtriangledown\phi) \\ &\quad + \bigtriangledown(\dot{x}\cdot\bigtriangledown\phi)\cdot\bigtriangledown\eta - (\bigtriangledown\phi)^T(\bigtriangledown\dot{x})(\bigtriangledown\eta). \end{aligned} \tag{5.4}$$

Using the fact that $0 = \frac{D\psi(x,t)}{Dt} = \psi_t(x,t) + \dot{x}\cdot\bigtriangledown\phi(x)$, we have

$$\begin{aligned} &\frac{d}{dt}\int_{\Omega_i} a \bigtriangledown \eta \cdot \bigtriangledown \psi dx \\ &= \int_{\Omega_i} \frac{Da}{Dt} \bigtriangledown \eta \cdot \bigtriangledown \phi dx + \int_{\Omega_i} a \bigtriangledown \left(\frac{D\eta}{Dt}\right)\cdot\bigtriangledown\phi dx + \int_{\Omega_i} a \bigtriangledown \eta\cdot\bigtriangledown\phi(\bigtriangledown\cdot\dot{x})dx \\ &\quad - \int_{\Omega_i} a(\bigtriangledown\eta)^T(\bigtriangledown\dot{x})(\bigtriangledown\phi)dx - \int_{\Omega_i} a(\bigtriangledown\phi)^T(\bigtriangledown\dot{x})(\bigtriangledown\eta)dx. \end{aligned} \tag{5.5}$$

Therefore we can write

$$\frac{d}{dt}\mathcal{B}_1(\eta,\psi) = \mathcal{B}_1\left(\frac{D\eta}{Dt},\phi\right) + E(\eta,\phi) = 0,$$

where

$$
\begin{aligned}
E(\eta,\phi) &= \int_\Omega \frac{Da}{Dt} \bigtriangledown \eta \cdot \bigtriangledown \phi dx + \int_\Omega a \bigtriangledown \eta \cdot \bigtriangledown \phi (\bigtriangledown \cdot \dot{x}) dx \\
&\quad - \int_\Omega a (\bigtriangledown \eta)^T \{ \bigtriangledown \dot{x} + (\bigtriangledown \dot{x})^T \} (\bigtriangledown \phi) dx.
\end{aligned} \tag{5.6}
$$

It is easy to see that $E(u,v) \le C\|u\|_1 \|v\|_1$, so

$$
\begin{aligned}
\left\| \frac{D\eta}{Dt} \right\|_1^2 &\le C\mathcal{B}_1 \left(\frac{D\eta}{Dt}, \frac{D\eta}{Dt} \right) \\
&= C \left\{ \mathcal{B}_1 \left(\frac{D\eta}{Dt}, \frac{D\eta}{Dt} - \phi \right) + E\left(\eta, \frac{D\eta}{Dt} - \phi \right) - E\left(\eta, \frac{D\eta}{Dt} \right) \right\} \\
&\le C \left\{ \left\| \frac{D\eta}{Dt} \right\|_1 \left\| \frac{D\eta}{Dt} - \phi \right\|_1 + \|\eta\|_1 \left\| \frac{D\eta}{Dt} - \phi \right\|_1 + \|\eta\|_1 \left\| \frac{D\eta}{Dt} \right\|_1 \right\}.
\end{aligned} \tag{5.7}
$$

It follows that

$$
\left\| \frac{D\eta}{Dt} \right\|_1 \le C \left\{ \|\eta\|_1 + \inf_{\phi \in \mathcal{M}(t)} \left\| \frac{Du}{Dt} - \phi \right\|_1 \right\}. \tag{5.8}
$$

Next we use a duality argument to get an estimate of $\|\frac{D\eta}{Dt}\|$. Let $\xi \in H_0^1(\Omega) \cap H^2(\Omega)$ satisfy

$$
\int_\Omega a \bigtriangledown \xi \cdot \bigtriangledown \zeta dx = \int_\Omega \frac{D\eta}{Dt} \zeta dx \quad \forall \zeta \in H_0^1(\Omega).
$$

For any $\phi \in \mathcal{M}(t)$,

$$
\begin{aligned}
\left(\frac{D\eta}{Dt}, \frac{D\eta}{Dt} \right) &= \mathcal{B}_1 \left(\frac{D\eta}{Dt}, \xi \right) \\
&= \mathcal{B}_1 \left(\frac{D\eta}{Dt}, \xi - \phi \right) + E(\eta, \xi - \phi) - E(\eta, \xi),
\end{aligned} \tag{5.9}
$$

and by integration by parts,

$$
\begin{aligned}
E(\eta,\xi) &= -\int_\Omega \eta \left(\bigtriangledown \frac{Da}{Dt} \cdot \bigtriangledown \xi + \frac{Da}{Dt} \bigtriangleup \xi \right) dx - \sum_i \int_{\Omega_i} \eta \bigtriangleup \xi (\bigtriangledown \cdot \dot{x}) dx \\
&\quad - \sum_j \int_{e_j} \eta \frac{\partial \xi}{\partial n_{e_j}} [\bigtriangledown \cdot \dot{x}] ds \\
&\quad + \sum_i \int_{\Omega_i} \eta \{ (\bigtriangledown a)^T (\bigtriangledown \dot{x}) (\bigtriangledown \xi) + a \bigtriangledown \cdot ((\bigtriangledown \dot{x})(\bigtriangledown \xi)) \} dx \\
&\quad + \sum_j \int_{e_j} a\, \eta ([\bigtriangledown \dot{x}](\bigtriangledown \xi)) \cdot n_{e_j} ds \\
&\quad + \sum_i \int_{\Omega_i} \eta \{ (\bigtriangledown a)^T (\bigtriangledown \dot{x})^T (\bigtriangledown \xi) + a \bigtriangledown \cdot ((\bigtriangledown \dot{x})^T (\bigtriangledown \xi)) \} dx \\
&\quad + \sum_j \int_{e_j} a\, \eta ([\bigtriangledown \dot{x}]^T (\bigtriangledown \xi)) \cdot n_{e_j} ds.
\end{aligned} \tag{5.10}
$$

We need to take a close look at the integrals over the edges. Suppose that an edge $e = \bar{\Omega}_k \cap \bar{\Omega}_m$. Let $h(e) = \min\{h_k, h_m\}$. The first boundary integral in (5.10) can be bounded as follows:

$$\begin{aligned}
\sum_j \int_{e_j} \eta \frac{\partial \xi}{\partial n_{e_j}} [\bigtriangledown \cdot \dot{x}] ds &\le C \sum_j \|h^{1/2}(e_j)\eta\|_{L^2(e_j)} \left\| h^{1/2}(e_j) \frac{\partial \xi}{\partial n_{e_j}} \right\|_{L^2(e_j)} \\
&\le C(\epsilon) \sum_j \|h^{1/2}(e_j)\eta\|^2_{L^2(e_j)} + \epsilon \sum_j \left\| h^{1/2}(e_j) \frac{\partial \xi}{\partial n_{e_j}} \right\|^2_{L^2(e_j)} \\
&\le C(\epsilon) \sum_i (\|\eta\|^2_{L^2(\Omega_i)} + h_i^2 |\eta|^2_{H^1(\Omega_i)}) + C\epsilon \sum_i (|\xi|^2_{H^1(\Omega_i)} + h_i^2 |\xi|^2_{H^2(\Omega_i)}) \\
&\le C(\epsilon) \left\{ \|\eta\|^2 + \sum_i h_i^2 |\eta|^2_{H^1(\Omega_i)} \right\} + C\epsilon \|\tfrac{D\eta}{Dt}\|^2 \quad \forall \epsilon > 0.
\end{aligned} \tag{5.11}$$

Similar results can be achieved for the other integrals over the edges e_j, so that by choosing ϵ small enough, we can conclude that

$$|E(\eta, \xi)| \le C \left\{ \|\eta\|^2 + \sum_i h_i^2 |\eta|^2_{H^1(\Omega_i)} \right\} + \frac{1}{4} \left\| \frac{D\eta}{Dt} \right\|^2.$$

Also choose $\phi \in \mathcal{M}(t)$ so that

$$\mathcal{B}_1 \left(\frac{D\eta}{Dt}, \xi - \phi \right) \le C \left\| \frac{D\eta}{Dt} \right\|_1 \|\xi - \phi\|_1 \le Ch \left\| \frac{D\eta}{Dt} \right\|_1 \left\| \frac{D\eta}{Dt} \right\|$$

and

$$E(\eta, \xi - \phi) \le Ch \|\eta\|_1 \left\| \frac{D\eta}{Dt} \right\|.$$

Therefore we have from (5.9),

$$\begin{aligned}
\left\| \frac{D\eta}{Dt} \right\|^2 &\le C \left\{ h^2 \left\| \frac{D\eta}{Dt} \right\|^2_1 + h^2 \|\eta\|^2_1 + \|\eta\|^2 + \sum_i h_i^2 |\eta|^2_{H^1(\Omega_i)} \right\} \\
&\le Ch^2 \sum_i h_i^{2(\min\{r+1,s\}-1)} \left\{ \left\| \frac{Du}{Dt} \right\|^2_{H^s(\Omega_i)} + \|u\|^2_{H^s(\Omega_i)} \right\}.
\end{aligned} \tag{5.12}$$

The rest of the proof is an application of Theorem 2 using $\|\!| \cdot |\!\|_0$. Since $\|\!| u - U |\!\|_0$ dominates the term we want to bound, it suffices to show that $\|\!| u - \Psi |\!\|_0$ can be bounded by terms on the right-hand side of (4.1).

We choose $\Psi = Pu$. The estimate of $\|u - \Psi\|_{L^\infty(0,T;L^2(\Omega))}$ is straightforward. The weaker seminorm on $\frac{D}{Dt}(u - \Psi)$ is also bounded from (5.12). The $H^1(\Omega)$-norm of $P_1(u - \Psi)$ can be bounded as follows: For any $\phi \in \mathcal{M}(t)$,

$$\begin{aligned}
& \mathcal{B}(P_1(u - \Psi), \phi) = \mathcal{B}(u - \Psi, \phi) \\
= \;& \mathcal{B}_1(u - \Psi, \phi) + ((v - \dot{x}) \cdot \bigtriangledown (u - \Psi), \phi) + c_3(u - \Psi, \phi) \\
= \;& -((u - \Psi), \phi \bigtriangledown \cdot (v - \dot{x}) + (v - \dot{x}) \cdot \bigtriangledown \phi) + c_3(u - \Psi, \phi) \\
\le \;& (\| \bigtriangledown \cdot (v - \dot{x}) \|_{L^\infty(\Omega)} + c_3) \|u - \Psi\| \|\phi\| \\
& + \|v - \dot{x}\|_{L^\infty(\Omega)} \|u - \Psi\| \|\phi\|_1.
\end{aligned} \tag{5.13}$$

Using the coercivity of $\mathcal{B}(\cdot,\cdot)$ (see (3.8)) and taking $\phi = P_1(u-\Psi)$, we get that

$$\|P_1(u-\Psi)\|_1 \le C\|u-\Psi\|. \qquad \square$$

The $\frac{D\eta}{Dt}$ term was estimated in $L^2(\Omega)$ instead of the discrete H^{-1} seminorm, so one might think that, if (5.1) satisfies an H^3-regularity bound and $\dot{x}$ was smooth enough, one might be able to weaken the norm on $\frac{D\eta}{Dt}$. We were not able to do this, except in trivial special cases.

6. Remarks. If we replace the boundary condition $w\cdot\nu = 0$ on Γ_N by $(w-\dot{x})\cdot\nu = 0$ on Γ_N, Lemma 1 holds even if the domain Ω is time dependent. Therefore it seems possible to get analogous results in this situation. However, a more interesting situation is one in which mesh elements flow into and out of the domain instead of just moving around in the domain; this will be the topic of future work.

MULTIGRID SOLVER FOR THE INNER PROBLEM IN DOMAIN DECOMPOSITION METHODS FOR *P*-FEM*

SVEN BEUCHLER†

Abstract. From the literature it is known that the conjugate gradient method with domain decomposition preconditioners is one of the most efficient methods for solving systems of linear algebraic equations resulting from p-version finite element discretizations of elliptic boundary value problems. The ingredients of such a preconditioner are a preconditioner for the Schur complement, a preconditioner related to the Dirichlet problems in the subdomains, and an extension operator from the boundaries of the subdomains into their interior. In the case of Poisson's equation, we propose a preconditioner for the problems in the subdomains which can be interpreted as the stiffness matrix resulting from an h-version finite element discretization of a degenerate operator. For solving the corresponding systems of finite element equations a multigrid algorithm with a special line smoother is used. We prove that the convergence rate of the multigrid method is independent of the discretization parameter. The proof is based on the strengthened Cauchy inequality. The theoretical result is confirmed by numerical examples.

1. Introduction.

1.1. Origin of the problem from the *p*-version.

We consider the boundary value problem

$$\begin{array}{rcccc} -\triangle u & = & f & \text{in} & \Omega, \\ u & = & 0 & \text{on} & \partial\Omega, \end{array} \tag{1.1}$$

where $\Omega \subset \mathbb{R}^2$ is a domain which can be decomposed into (straight-line) quadrilaterals. Problem (1.1) will be discretized by means of the p-version of the finite element method using quadrilaterals R_s. Let $\mathcal{R} = (-1,1)^2$ be the reference element and $\Phi_s : \mathcal{R} \to R_s$ be the bilinear mapping to the element R_s. We define the finite element space

$$\mathbb{M} := \{u \in H_0^1(\Omega), u\mid_{R_s} = u(\Phi_s(\xi,\eta)) = \tilde{u}(\xi,\eta), \tilde{u} \in Q_p\},$$

where Q_p is the space of all polynomials $p(\xi,\eta) = p_1(\xi)p_2(\eta)$ of maximal degree p in each variable. Now we can formulate the following discretized problem: Find $u_p \in \mathbb{M}$ such that

$$a_\triangle(u_p, v_p) := \int_\Omega \nabla u_p \cdot \nabla v_p = \int_\Omega f v_p \quad \forall v_p \in \mathbb{M} \tag{1.2}$$

holds. Let $(\psi_1, \ldots, \psi_{n_p})$ be a basis of $\mathbb{M}$. Then problem (1.2) is equivalent to solving the system of algebraic finite element equations

$$A_p \underline{u}_p = \underline{f}_p, \quad \text{where} \quad A_p = [a_\triangle(\psi_j, \psi_i)]_{i,j=1}^{n_p}, \quad \underline{f}_p = \left[\int_\Omega f\psi_i\right]_{i=1}^{n_p}.$$

Now we specify the choice of the basis and divide the shape functions into three distinct groups:

- the vertex functions, which are the usual piecewise bilinear functions;
- the edge bubble functions;
- the interior bubbles, which are nonzero only on one element.

An edge bubble function corresponds to an edge e of the mesh. Its support is formed by those two elements which have this edge e in common. Corresponding to the division of the shape functions, we split the matrix A_p as follows:

$$A_p = \begin{pmatrix} A_{vert} & A_{vert,edg} & A_{vert,int} \\ A_{edg,vert} & A_{edg} & A_{edg,int} \\ A_{int,vert} & A_{int,edg} & A_{int} \end{pmatrix}. \tag{1.3}$$

The indices *vert*, *edg*, and *int* denote the blocks corresponding to the vertex, edge bubble, and interior bubble function, respectively. Jensen and Korneev [16] and Ivanov and Korneev [14], [15] developed preconditioners for the p-version of the finite element method in a two-dimensional domain using domain decomposition techniques [4]. They considered the preconditioning matrix

$$C_p = \begin{pmatrix} A_{vert} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & A_{edg} & A_{edg,int} \\ \mathbf{0} & A_{int,edg} & A_{int} \end{pmatrix} \tag{1.4}$$

and proved that the condition number $\kappa(C_p^{-1}A_p)$ grows as $1+\log p$; cf. Lemma 2.3 in [14]. Therefore, the vertex unknowns can be determined separately. Computing the other unknowns, we factorize the remaining 2×2 block as follows:

$$\begin{pmatrix} A_{edg} & A_{edg,int} \\ A_{int,edg} & A_{int} \end{pmatrix} = \begin{pmatrix} I & A_{edg,int}A_{int}^{-1} \\ \mathbf{0} & I \end{pmatrix} \begin{pmatrix} S & \mathbf{0} \\ \mathbf{0} & A_{int} \end{pmatrix} \begin{pmatrix} I & \mathbf{0} \\ A_{int}^{-1}A_{int,edg} & I \end{pmatrix}$$

with the Schur complement $S := A_{edg} - A_{edg,int}A_{int}^{-1}A_{int,edg}$. The matrix A_{int} is a block diagonal matrix; one block corresponds to one element. Therefore, for computing the interior unknowns, we have to solve a Dirichlet problem on each quadrilateral. The edge unknowns are computed via the Schur complement S.

Hence, in addition to a solver for A_{vert}, we require three tools to define a preconditioner for the matrix of (1.4), namely a preconditioner for the interior problem, a preconditioner for the Schur complement, and an extension operator from the edges of a quadrilateral into its interior. Ivanov and Korneev [14], [15] derived some preconditioners C_S for the Schur complement. The condition number of $C_S^{-1}S$ is $\mathcal{O}(1+\log^2 p)$ in the worst case, where p is the polynomial degree. The solution of $C_S\underline{x} = \underline{y}$ can be done fast by solving triangular systems and fast Fourier transforms.

Jensen and Korneev [16] considered a scaled version of the integrated Legendre polynomials as the basis of the space $\mathbb{M}$. They found a spectral equivalent preconditioner C_{int} for the interior problem, which has $\mathcal{O}(p^2)$ nonzero entries. In the case of parallelogram elements, the element stiffness matrix has $\mathcal{O}(p^2)$ nonzero entries; otherwise it is a dense matrix. However, the suggested methods compute the solution of the system of equations with this preconditioning matrix in $\mathcal{O}(p^3)$ arithmetical operations. Finding a fast solver, i.e., a solver which requires $\mathcal{O}(p^2)$ arithmetical operations, was an open question. This paper is concerned with the construction of such an efficient preconditioner for the interior problem. The matrix C_{int} is a block diagonal

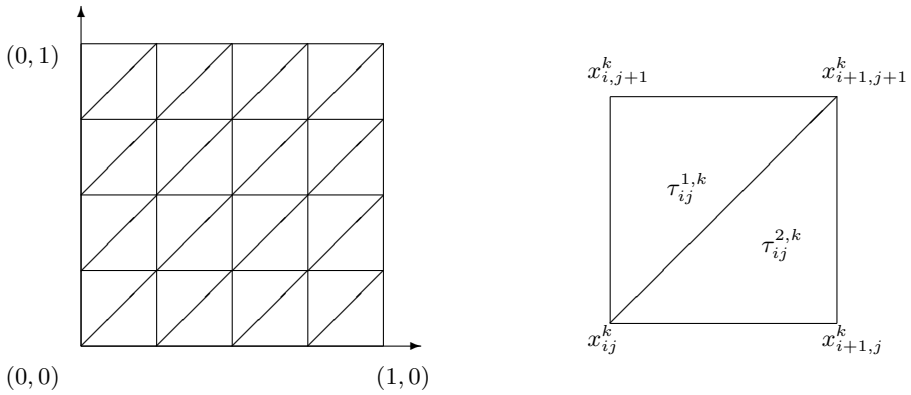

FIG. 1.1. *Mesh for h-version (left); notation within a macroelement $\mathcal{E}^k_{ij}$ (right).*

matrix of four blocks $C_{int,m}$, $m = 1, 2, 3, 4$. In [5], we derived a new preconditioner C_4 for each block of C_{int}. This matrix is defined via the matrices D_4 and T_3,

$$D_4 := \operatorname{diag}\left(4\left(i^2 + \frac{1}{6}\right)\right)_{i=1}^{n-1}, \quad T_3 := \frac{1}{2}\operatorname{tridiag}(-1, 2, -1),$$

$$C_4 := D_4 \otimes T_3 + T_3 \otimes D_4, \tag{1.5}$$

where $\otimes$ denotes the Kronecker product. We have proved in [5] that the condition number of the matrix $C_4^{-1}C_{int,m}$ grows as $(1 + \log p)$. We can interpret the matrix C_4 as the stiffness matrix arising from an h-version finite element method for an elliptic boundary value problem with a degenerate operator. This will be discussed in the following.

1.2. Formulation of the elliptic problem. We consider the following problem: Find $u \in H^1_0(\Omega_1) = \{u \in H^1(\Omega_1) : \ u = 0 \text{ on } \partial\Omega_1\}$ such that

$$a(u, v) := \int_{\Omega_1} y^2 u_x v_x + x^2 u_y v_y = \int_{\Omega_1} gv =: \langle g, v\rangle \quad \forall v \in H^1_0(\Omega_1) \tag{1.6}$$

holds. The domain $\Omega_1 = (0, 1)^2$ is the unit square. The differential operator in (1.6) is not uniformly elliptic in the Sobelev space $H^1(\Omega_1)$; an estimate of the type

$$a(u, u) \geq \gamma \parallel u \parallel^2_{H^1(\Omega_1)}$$

with a constant $\gamma > 0$ is not satisfied. We refer to the book of Kufner and Sändig [17] for such problems.

We want to find an approximate solution of (1.6) using finite elements. For this purpose, we introduce some notation. Let k be the level of approximation and $n = 2^k$. Let us denote by x^k_{ij} the nodes $x^k_{ij} = (\frac{i}{n}, \frac{j}{n})$, $i, j = 0, \ldots, n$. We triangulate Ω_1 into congruent, isosceles, right-angled triangles $\tau^{s,k}_{ij}$, where $0 \leq i, \ j < n$, and $s = 1, 2$; see Figure 1.1. The triangle $\tau^{1,k}_{ij}$ has the three vertices x^k_{ij}, $x^k_{i+1,j+1}$, and $x^k_{i,j+1}$, whereas $\tau^{2,k}_{ij}$ has the three vertices x^k_{ij}, $x^k_{i+1,j+1}$, and $x^k_{i+1,j}$; see Figure 1.1.

Furthermore, let $\mathcal{E}_{ij}^k = \overline{\tau_{ij}^{1,k} \cup \tau_{ij}^{2,k}}$ be the square (macroelement)

$$\left[\frac{i}{n}, \frac{i+1}{n}\right] \times \left[\frac{j}{n}, \frac{j+1}{n}\right].$$

Let $\mathbb{V}_k := \operatorname{span}\{\phi_{ij}^k,\ 0 < i, j < n\} \subset H_0^1(\Omega_1)$ be the subspace of piecewise linear functions. The basis functions ϕ_{ij}^k are continuous, linear on each triangle $\tau_{lm}^{s,k} \subset \Omega_1$, and fulfill the condition $\phi_{ij}^k(x_{lm}^k) = \delta_{il}\delta_{jm}$. ($\delta_{il}$ denotes the Kronecker delta.)

Now we can formulate the discrete problem. Find $u^k \in \mathbb{V}_k$ such that

$$a(u^k, v^k) = \langle g, v^k \rangle \quad \forall v^k \in \mathbb{V}_k \tag{1.7}$$

holds. Problem (1.7) is equivalent to solving the system of algebraic finite element equations $K_k \underline{u}_k = \underline{g}_k$ with

$$K_k = a(\phi_{lm}^k, \phi_{ij}^k)_{i,j;l,m=1}^{n-1}, \quad \underline{g}_k = \langle g, \phi_{lm}^k \rangle_{l,m=1}^{n-1}, \quad \underline{u}_k = (u_{ij})_{i,j=1}^{n-1}.$$

Then $u^k = \sum_{i,j=1}^{n-1} u_{ij}\phi_{ij}^k$ is the solution of (1.7). By a simple calculation one obtains

$$a(\phi_{ij}^k, \phi_{i+1,j}^k) = -\frac{1}{n^2}\left(\frac{1}{6} + j^2\right),$$

where $n > i, j$ and $j > 0$, but $i \geq 0$. By symmetry, we have ($i > 0$, $j \geq 0$)

$$a(\phi_{ij}^k, \phi_{i,j+1}^k) = -\frac{1}{n^2}\left(\frac{1}{6} + i^2\right)$$

and

$$a(\phi_{ij}^k, \phi_{ij}^k) = -\left(a(\phi_{ij}^k, \phi_{i+1,j}^k) + a(\phi_{ij}^k, \phi_{i,j+1}^k) + a(\phi_{ij}^k, \phi_{i,j-1}^k) + a(\phi_{ij}^k, \phi_{i-1,j}^k)\right).$$

All other matrix entries are zero. Inserting the boundary condition and using the definition of C_4 (1.5), we get the relation

$$K_k = \frac{1}{2n^2} C_4$$

after a proper permutation of the unknowns. In this paper, we will derive a fast solver for the degenerate problem (1.6).

For systems of finite element equations arising from the discretization of boundary value problems as, e.g., $-u_{xx} - u_{yy} = f$, efficient solution techniques are known. Examples for such solvers are the preconditioned conjugate gradient (PCG) method, with BPX preconditioners [9] or hierarchical basis preconditioners [23], and multigrid methods [12], [13]. However, we have to solve problems with variable coefficients. These coefficients tend to 0 if $x \to 0$ or $y \to 0$. Bramble and Zhang [10] consider multigrid methods in a more general case as for Laplace. They proved multigrid convergence for differential operators of the type $-(f(x,y)u_x)_x - (g(x,y)u_y)_y$, where $0 < g(x,y) \leq g_{\max}$ and $0 < f_{\min} < f(x,y) < f_{\max}$; i.e., one of the coefficients can be arbitrarily small. However, in (1.6) both coefficients can be arbitrarily small.

This paper deals with the solution of (1.7) by a multigrid method with special line smoothers. We get another efficient solver when these special line smoothers are applied within an AMLI preconditioner (see [2], [3] for the definition of the AMLI

preconditioner). In [6], we give a convergence proof for the PCG method with such an AMLI preconditioner. The analysis of both methods is based on the strengthened Cauchy inequality.

This paper is organized as follows. In section 2, we present the multigrid convergence proof for problem (1.7). In section 3 we describe and analyze the smoother used in the multigrid method and explain implementational details. Finally, in section 4 we give some numerical experiments confirming the theory.

2. Multigrid method for solving $-y^2u_{xx} - x^2u_{yy}$. For solving (1.7) approximately, we will employ the following multigrid algorithm.

2.1. Multigrid algorithm. We represent the space $\mathbb{V}_k$ as the direct sum

$$\mathbb{V}_k = \mathbb{V}_{k-1} \oplus \mathbb{W}_k, \quad \text{where} \quad \mathbb{W}_k := \operatorname{span}\{\phi_{ij}^k\}_{(i,j)\in N_k}. \tag{2.1}$$

The subset N_k contains the indices of the new nodes on level k and is given by

$$N_k := \{(i,j) \in \mathbb{N}^2, 1 \le i,j \le n-1, i = 2m+1 \text{ or } j = 2m+1, m \in \mathbb{N}\}. \tag{2.2}$$

Let u_0 be the initial guess. One step of the multigrid algorithm $u_1 = MULT(k, u_0, g)$ is defined recursively as follows.

- Set $l = k$. If $l > 1$, then do
  1. Presmoothing on $\mathbb{W}_l$: Solve
  $$a(w,v) = \langle g, v\rangle - a(u_0, v) \quad \forall v \in \mathbb{W}_l$$
  approximately by using ν steps of a simple iterative method S; the approximate solution is $\tilde{w}$. Set $u_0^1 = u_0 + \tilde{w}$.
  2. Coarse grid correction on $\mathbb{V}_{l-1}$: Find $w \in \mathbb{V}_{l-1}$ such that
  $$a(w,v) = \langle g, v\rangle - a(u_0^1, v) = \langle r, v\rangle \quad \forall v \in \mathbb{V}_{l-1}$$
  holds. Compute an approximate solution $\tilde{w}$ by using μ_{l-1} steps of the algorithm $MULT(l-1, 0, r)$. Set $u_0^2 = u_0^1 + \tilde{w}$.
  3. Postsmoothing on $\mathbb{W}_l$: Solve
  $$a(w,v) = \langle g, v\rangle - a(u_0^2, v) \quad \forall v \in \mathbb{W}_l$$
  approximately by using ν steps of a simple iterative method S; the approximate solution is $\tilde{w}$. Set $u_1 = u_0^2 + \tilde{w}$.
- else
  - Solve $a(w,v) = \langle g, v\rangle - a(u_0, v)\ \forall v \in \mathbb{V}_l$ exactly.
- endif.

Remark 2.1. In a standard multigrid algorithm the space $\mathbb{W}_l$ in steps 1 and 3 is replaced by $\mathbb{V}_l$; e.g., the smoother operates on the complete approximation space.

2.2. Algebraic multigrid proof. We prove the convergence of the multigrid algorithm for solving (1.7) using $\mu = \mu_l = 3$ and a special line smoother, which will be defined in (2.21). From [19], [20] the following convergence theorem for multigrid algorithms of the type of the algorithm $MULT$ is known.

THEOREM 2.1. *Let us assume that the following assumptions are fulfilled.*

- *Let $a(\cdot,\cdot)$ be a symmetric and positive definite bilinear form on $\mathbb{V}_k$, and let $\|\cdot\|_a^2 := a(\cdot,\cdot)$ be the energy norm.*

- *Let S be a smoother satisfying*

$$\| S^\nu w \|_a^2 \leq \rho^{2\nu} \| w \|_a^2 \quad \forall w \in \mathbb{W}_k, \tag{2.3}$$

where $0 \leq \rho < 1$ is independent of k.
- *There is a constant $0 \leq \gamma < 1$ independent of k such that the strengthened Cauchy inequality*

$$(a(v,w))^2 \leq \gamma^2 a(v,v)a(w,w) \quad \forall w \in \mathbb{W}_k, \forall v \in \mathbb{V}_{k-1} \tag{2.4}$$

holds.
- *Let $u_{j+1,k} = MULT(k, u_{j,k}, g)$, let u^* be the exact solution of (1.7), and let*

$$\sigma_k := \sup_{u_{j,k} - u^* \in \mathbb{V}_k} \frac{\| u_{j+1,k} - u^* \|_a}{\| u_{j,k} - u^* \|_a}$$

be the convergence rate of $MULT$ with ν smoothing operations.

Then, the following recursion formula holds:

$$\sigma_k \leq \sigma_{k-1}^{\mu_{k-1}} + (1 - \sigma_{k-1}^{\mu_{k-1}})(\rho^\nu + (1-\rho^\nu)\gamma)^2. \tag{2.5}$$

Proof. The proof is given by Theorem 2.2 of [20] with $\rho = \rho_1 = \rho_3$; see also Theorem 4 of [19]. ∎

The following lemma of the standard multigrid theory is helpful for the analysis of the recursion formula (2.5).

LEMMA 2.1. *Let $\mu_k = \mu \in \mathbb{N}$, $\mu > 1$, and*

$$\kappa := (\rho^\nu + (1-\rho^\nu)\gamma)^2 < \frac{\mu - 1}{\mu}. \tag{2.6}$$

Then the elements σ_k of the recursion

$$\sigma_0 := 0, \qquad \sigma_k := \sigma_{k-1}^\mu + (1 - \sigma_{k-1}^\mu)\kappa$$

are contained in the interval $[0, \sigma)$. The equation $\sigma = \kappa + \sigma^\mu(1-\kappa)$ has a solution $\sigma \in (0,1)$. More precisely, the sequence $\{\sigma_k\}_{k=0}^\infty$ is monotonically increasing and bounded from above by $\sigma < 1$ for $0 < \kappa < \frac{\mu-1}{\mu}$.

Proof. The proof can be found in several papers; see, e.g., Lemma 3 of [19] or Lemma 3.2 of [20]. ∎

Using Theorem 2.1 and Lemma 2.1, we can prove a mesh-size independent convergence rate in the case $\mu = 2$, i.e., the W-cycle, if $\kappa < \frac{1}{2}$.

If $\mu = 3$ and $\kappa < \frac{2}{3}$, from (2.6) it can be concluded that $\nu > \frac{\ln(\sqrt{\frac{2}{3}} - \gamma) - \ln(1-\gamma)}{\ln \rho}$ smoothing steps are needed if $\gamma^2 < \frac{2}{3}$. We want to prove multigrid convergence for system (1.7) via Theorem 2.1. For this aim, we have to determine bounds for ρ in (2.3) and γ^2 in (2.4). In the next subsection we summarize some lemmas which are helpful for our aim. Most of them are standard or trivial, and we refer to [1], [8], [11], [18], [21] or the preprint [7] for the proofs.

2.2.1. Basic definitions and helpful lemmas of the linear algebra. For proving the strengthened Cauchy inequality

$$(a(v,w))^2 \leq \gamma^2 a(v,v)a(w,w) \quad \forall v \in \mathbb{V}_{k-1}, w \in \mathbb{W}_k$$

with $\gamma^2 < 1$, we split $a(v,w)$ into

$$a(v,w) = \int_\Omega y^2 v_x w_x + x^2 v_y w_y = \sum_{i,j} \int_{\mathcal{E}^k_{i,j}} y^2 v_x w_x + x^2 v_y w_y =: \sum_{i,j} a^{\mathcal{E}^k_{i,j}}(v,w).$$

The angle between the spaces $\mathbb{V}_{k-1}$ and $\mathbb{W}_k$ can be estimated using the local angles.

LEMMA 2.2. *Let $a(\cdot,\cdot)$ be a symmetric, positive definite bilinear form. Under the assumption that*

$$\left(a^{\mathcal{E}^k_{ij}}(v,w)\right)^2 \leq \gamma^2 a^{\mathcal{E}^k_{ij}}(v,v) a^{\mathcal{E}^k_{ij}}(w,w)$$

for all $v \in \mathbb{V}_{k-1}\,|_{\mathcal{E}^k_{ij}}$ and $w \in \mathbb{W}_k\,|_{\mathcal{E}^k_{ij}}$ holds, we have

$$\left(a(v,w)\right)^2 \leq \gamma^2 a(v,v) a(w,w) \quad \forall v \in \mathbb{V}_{k-1}, w \in \mathbb{W}_k,$$

where $\mathbb{V}\,|_{\mathcal{E}^k_{ij}}$ denotes the restriction of $\mathbb{V}$ on $\mathcal{E}^k_{ij}$.

Proof. The proof is standard [8], [18]. ∎

The following lemma (see [11], [21]) relates the constant of the strengthened Cauchy inequality to the largest eigenvalue of a generalized eigenvalue problem. In order to formulate it, we need the following definition. Let $\mathbb{X}$ be a linear (finite-dimensional) space, and let $\mathbb{Y}$ be a subspace of $\mathbb{X}$. We define the difference $\mathbb{X} - \mathbb{Y}$ as any linear subspace satisfying

$$\mathbb{X} = \mathbb{Y} \oplus (\mathbb{X} - \mathbb{Y}).$$

Note that the choice of $\mathbb{X} - \mathbb{Y}$ is not unique.

LEMMA 2.3. *Consider the splitting $\mathbb{V} \oplus \mathbb{W}$. Let*

$$\mathbb{V} = \operatorname{span}\{\phi_i\}_{i=1}^n, \qquad \mathbb{W} = \operatorname{span}\{\psi_i\}_{i=1}^m,$$

$$G = [a(\phi_j,\phi_i)]_{i,j=1}^n, \quad H^t = [a(\phi_j,\psi_i)]_{i,j=1}^{n,m}, \quad K = [a(\psi_j,\psi_i)]_{i,j=1}^m.$$

Furthermore, let $\mathbb{V} \cap \mathbb{W} = \{\mathbf{0}\}$ and $\ker a \subset \mathbb{V}$, where $\ker a = \{v \in \mathbb{V} : a(v,w) = 0 \quad \forall w \in \mathbb{V}\}$ is the kernel of the bilinear form a. The bilinear form $a(\cdot,\cdot)$ is symmetric and positive semidefinite. Then the minimal constant γ^2 with

$$a(v,w)^2 \leq \gamma^2 a(v,v) a(w,w) \quad \forall v \in \mathbb{V}, w \in \mathbb{W}$$

is equal to the largest eigenvalue λ of

$$V^t H^t K^{-1} H V \underline{w} = \lambda V^t G V \underline{w},$$

where $V \in \mathbb{R}^{n,n-q}$ is chosen such that $\operatorname{im} V = \mathbb{R}^n - \ker G$ and $\ker V^t = \mathbf{0}$. The parameter q denotes the dimension of $\ker G$.

Proof. See [11], [21].

For the proof of the strengthened Cauchy inequality we need in our case an estimate for the eigenvalues of a 2×2 matrix. A useful tool is the next lemma.

LEMMA 2.4. *Let $M \in \mathbb{R}^{2,2}$ be a matrix with real eigenvalues and ϑ a real number with*

$$p = 2\vartheta - \operatorname{trace}(M) \geq 0 \quad \text{and} \quad q = \det M + \vartheta^2 - \vartheta \operatorname{trace}(M) \geq 0.$$

Then we have $\lambda_{max}(M) \leq \vartheta$.

Proof. The proof is trivial; cf. [7]. ∎

The following lemma (see [1], [22]) of the finite element analysis is helpful for the proof of the smoothing property (2.3). It analyzes the eigenvalue bounds of an assembled matrix by the eigenvalue bounds of the element matrices.

LEMMA 2.5. *Let* $\{A_i \in \mathbb{R}^{m_i,m_i}\}_{i=1}^s$ *be a finite set of symmetric positive definite matrices. Let* $A = \sum_{i=1}^s L_i^t A_i L_i$, *where* $L_i \in \mathbb{R}^{m_i,m}$ *and* $A \in \mathbb{R}^{m,m}$. *Furthermore, let* C_i *be a preconditioner for the matrix* A_i; *i.e., for all* $\underline{w} \in \mathbb{R}^{m_i}$ *the relations*

$$\underline{\lambda}_i(C_i\underline{w},\underline{w}) \leq (A_i\underline{w},\underline{w}) \leq \overline{\lambda}^i(C_i\underline{w},\underline{w})$$

with $0 < \overline{\lambda^i}$ *and* $0 \leq \underline{\lambda_i}$ *hold. Let* $C = \sum_{i=1}^s L_i^t C_i L_i$. *Then, for all* $\underline{v} \in \mathbb{R}^m$

$$\underline{\lambda}(C\underline{v},\underline{v}) \leq (A\underline{v},\underline{v}) \leq \overline{\lambda}(C\underline{v},\underline{v})$$

is valid with

$$\underline{\lambda} = \min_i \underline{\lambda}_i, \quad \overline{\lambda} = \max_i \overline{\lambda}^i.$$

2.2.2. Discussion of the strengthened Cauchy inequality on the macroelements $\mathcal{E}_{ij}^k$. We prove the strengthened Cauchy inequality (2.4) with the bilinear form $a(\cdot,\cdot)$ restricted on $\tau_{ij}^{1,k}$ and $\tau_{ij}^{2,k}$ if $i,j > 0$, and on the macroelements $\mathcal{E}_{ij}^k$ if $i = 0$ or $j = 0$.

We want to obtain the stiffness matrix on the macroelements $\mathcal{E}_{ij}^k$ with respect to the two level basis built by the basis functions of $\mathbb{V}_k \mid_{\mathcal{E}_{ij}^k}$ and $\mathbb{W}_{k+1} \mid_{\mathcal{E}_{ij}^k}$. We start with the introduction of the basis functions on $\mathcal{E}_{ij}^k$. Note that the triangle $\tau_{ij}^{2,k}$ is the union of the triangles $\tau_{2i,2j}^{2,k+1}$, $\tau_{2i+1,2j}^{1,k+1}$, $\tau_{2i+1,2j}^{2,k+1}$, and $\tau_{2i+1,2j+1}^{2,k+1}$, and the triangle $\tau_{ij}^{1,k}$ is the union of the triangles $\tau_{2i,2j}^{1,k+1}$, $\tau_{2i,2j+1}^{1,k+1}$, $\tau_{2i,2j+1}^{2,k+1}$, and $\tau_{2i+1,2j+1}^{1,k+1}$. The nodes x_{ij}^k, $x_{i,j+1}^k$, $x_{i+1,j}^k$, and $x_{i+1,j+1}^k$ are the coarse grid nodes, and the nodes $x_{2i+1,2j}^{k+1}$, $x_{2i,2j+1}^{k+1}$, $x_{2i+2,2j+1}^{k+1}$, $x_{2i+1,2j+2}^{k+1}$, and $x_{2i+1,2j+1}^{k+1}$ are new in the level $k+1$; compare Figure 2.1.

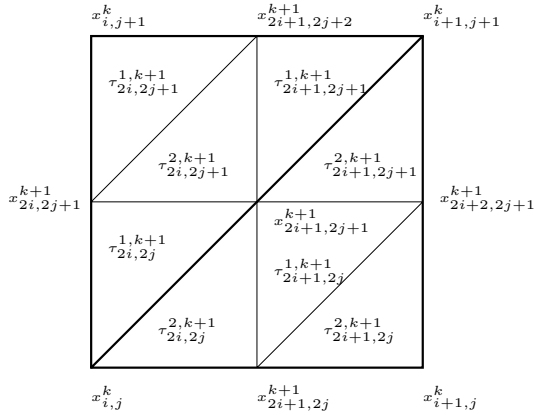

FIG. 2.1. *Local numbering of the nodes and subtriangles of* $\mathcal{E}_{ij}^k$.

Using this notation, we have

$$\mathbb{V}_k \mid_{\mathcal{E}_{ij}^k} = \operatorname{span}\{\phi_{lm}^k\}_{(l,m)\in N_{ij}^{\mathbb{V}_k}} \quad \text{and} \quad \mathbb{W}_{k+1} \mid_{\mathcal{E}_{ij}^k} = \operatorname{span}\{\phi_{lm}^{k+1}\}_{(l,m)\in N_{ij}^{\mathbb{W}_{k+1}}},$$

where

$$N_{ij}^{\mathbb{V}_k} := \{(l,m) \in \mathbb{N}^2, i \le l \le i+1, j \le m \le j+1\}$$

and with the help of N_{k+1} defined in (2.2),

$$N_{ij}^{\mathbb{W}_{k+1}} := N_{k+1} \cap \{(l,m) \in \mathbb{N}^2, 2i \le l \le 2i+2, 2j \le m \le 2j+2\}.$$

Note that for boundary macroelements $\mathcal{E}_{ij}^k$, i.e., with $i = 0, j = 0, i = n-1, j = n-1$, some modifications are necessary because of $\mathbb{V}_k \subset H_0^1(\Omega)$.

We define the matrices

$$\begin{aligned} G &:= \left[a^{\tau_{ij}^{2,k}}(\phi_{lm}^k, \phi_{rs}^k)\right]_{(r,s),(l,m)\in N_{ij}^{2,\mathbb{V}_k}}, \\ H^t &:= \left[a^{\tau_{ij}^{2,k}}(\phi_{lm}^k, \phi_{rs}^{k+1})\right]_{(r,s)\in N_{ij}^{2,\mathbb{V}_k},(l,m)\in N_{ij}^{2,\mathbb{W}_{k+1}}}, \\ K &:= \left[a^{\tau_{ij}^{2,k}}(\phi_{lm}^{k+1}, \phi_{rs}^{k+1})\right]_{(r,s),(l,m)\in N_{ij}^{2,\mathbb{W}_{k+1}}}, \end{aligned}$$

with $N_{ij}^{2,\mathbb{V}_k} := T_{ij}^2 \cap N_{ij}^{\mathbb{V}_k}$ and $N_{ij}^{2,\mathbb{W}_{k+1}} := T_{ij}^2 \cap N_{ij}^{\mathbb{W}_{k+1}}$, where $T_{ij}^2 := \{(l,m) \in \mathbb{N}^2, l-m \ge i-j\}$. The ordering of the rows and columns in the matrices G, H, and K corresponds to the ordering of the coarse grid nodes and of the new nodes introduced above. The matrices G, H, and K can be determined by a straightforward calculation. We start with the case $0 < i, j < n-1$. With

$$\begin{aligned} &a := \frac{48i^2+48i+14}{192n^2}, \quad b := \frac{48i^2+16i+2}{192n^2}, \quad c := \frac{48i^2+80i+34}{192n^2}, \\ &d := \frac{48j^2+48j+14}{192n^2}, \quad e := \frac{48j^2+16j+2}{192n^2}, \quad f := \frac{48j^2+80j+34}{192n^2} \end{aligned} \tag{2.7}$$

one obtains

$$\begin{aligned} H^t &= 2\begin{pmatrix} 0 & -d & d \\ a & d & -a-d \\ -a & 0 & a \end{pmatrix}, \qquad K = 4\begin{pmatrix} a+e & 0 & -a \\ 0 & c+d & -d \\ -a & -d & a+d \end{pmatrix}, \\ G &= \begin{pmatrix} d+e & -d-e & 0 \\ -d-e & a+c+d+e & -a-c \\ 0 & -a-c & a+c \end{pmatrix}. \end{aligned} \tag{2.8}$$

We note that in the case of elements laying on the boundary of the domain Ω_1, the matrices G, H, and K (2.8) are similarly defined, but we have only to cancel all rows and columns in G, H, and K which correspond to boundary nodes.

For choosing the matrix V of Lemma 2.3 we need $\ker G$. From the last relations it follows $\ker G = \operatorname{span}\{(1,1,1)^t\}$ and $\ker H = \operatorname{span}\{(1,1,1)^t\}$.

COROLLARY 2.1. *We have* $\ker G \subset \ker H$.

Now we determine the constant $\gamma_{\tau_{ij}^{2,k}}$, the constant of the strengthened Cauchy inequality on the triangle $\tau_{ij}^{2,k}$, by solving a generalized eigenvalue problem of the type (2.3).

LEMMA 2.6. *For* $1 \le i, j \le n-2$ *one obtains*

$$\left(a^{\tau_{ij}^{2,k}}(v,w)\right)^2 \le \gamma_{\tau_{ij}^{2,k}}^2 a^{\tau_{ij}^{2,k}}(v,v) a^{\tau_{ij}^{2,k}}(w,w) \quad \forall v \in \mathbb{V}_k\,|_{\tau_{ij}^{2,k}}, w \in \mathbb{W}_{k+1}\,|_{\tau_{ij}^{2,k}} \tag{2.9}$$

with $\gamma^2_{\tau^{2,k}_{ij}} = \frac{95}{176}$.

Proof. Corollary 2.1 states that $\ker G \subset \ker H$, and relation (2.8) states that $\ker K$ is trivial. Hence, we can apply Lemma 2.3. We know $\ker G = \operatorname{span}\{(1,1,1)^t\}$. Thus, we can choose

$$V = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}. \tag{2.10}$$

The matrix V^tGV is symmetric and positive definite; the matrix $V^tH^tK^{-1}HV$ is symmetric. Therefore, the generalized 2×2 eigenvalue problem has real eigenvalues and is equivalent to the eigenvalue problem

$$(V^tGV)^{-1}V^tH^tK^{-1}HV\underline{x} = \lambda\underline{x}.$$

This is a 2×2 eigenvalue problem for which we can apply Lemma 2.4. With the help of a computer algebra system we computed the matrix

$$M := (V^tGV)^{-1}V^tH^tK^{-1}HV.$$

The choice $\gamma^2_{\tau^{2,k}_{ij}} = \frac{95}{176}$ yields

$$p = 2\gamma^2_{\tau^{2,k}_{ij}} - \operatorname{trace}(M) \geq 0 \text{ and } q = \det M + \gamma^4_{\tau^{2,k}_{ij}} - \gamma^2_{\tau^{2,k}_{ij}}\operatorname{trace}(M) \geq 0. \tag{2.11}$$

Using Lemmas 2.3 and 2.4 we infer (2.9). ∎

Note that the detailed proof of the lemma is very technical. The terms p and q of (2.11) are rational functions in i and j of the type

$$\frac{\sum_{s,r=0}^{6} b_{rs}(i-1)^r(j-1)^s}{\sum_{s,r=0}^{6} c_{rs}(i-1)^r(j-1)^s}$$

with $b_{rs} \geq 0$ and $c_{rs} > 0$ for all $r, s = 0, \ldots, 6$ and $i, j > 0$. Our aim was finding a constant $\gamma^2_{\tau^{2,k}_{ij}}$ as small as possible. The direct computation of the eigenvalues for the element $\tau^{2,k}_{1,1}$ leads to the value $\gamma^2_{\tau^{2,k}_{1,1}} = \frac{95}{176}$. Therefore, this constant cannot be improved.

The estimates presented above are valid for all $i, j > 0$. Therefore, the theory of Lemma 2.6 can be extended to the boundary elements at $x = 1$ or $y = 1$.

COROLLARY 2.2. *Let $i > 0$ and $j > 0$. The inequality*

$$\left(a^{\tau^{2,k}_{ij}}(v,w)\right)^2 \leq \gamma^2_{\tau^{2,k}_{ij}} a^{\tau^{2,k}_{ij}}(v,v)a^{\tau^{2,k}_{ij}}(w,w) \quad \forall v \in \mathbb{V}_k\,|_{\tau^{2,k}_{ij}}, w \in \mathbb{W}_{k+1}\,|_{\tau^{2,k}_{ij}} \tag{2.12}$$

is valid for $i = n-1$ or $j = n-1$ with $\gamma^2_{\tau^{2,k}_{ij}} \leq \frac{95}{176}$.

Proof. We start with $j = n-1$ and $0 < i < n-1$. We omit the unknown corresponding to $\phi^k_{i+1,j+1}$. Thus, we have to cancel the last row and column in the matrix G (2.8), which is the same as choosing the matrix V^tGV (2.10). In the case $i = n-1$ and $0 < j < n-1$, the unknowns corresponding to the second and last row and column in G and the third in K are omitted. ∎

By symmetry of the differential operator, the relation (2.12) is valid for $\tau_{ij}^{1,k}$, $0 < i, j \leq n-1$. Hence, the constant in the strengthened Cauchy inequality for the macroelements $\mathcal{E}_{ij}^k$, $0 < i, j \leq n-1$, fulfills (cf. Lemma 2.2)

$$\left(a^{\mathcal{E}_{ij}^k}(v,w)\right)^2 \leq \gamma_{\mathcal{E}_{ij}^k}^2 a^{\mathcal{E}_{ij}^k}(v,v) a^{\mathcal{E}_{ij}^k}(w,w) \quad \forall v \in \mathbb{V}_k \mid_{\mathcal{E}_{ij}^k}, w \in \mathbb{W}_k \mid_{\mathcal{E}_{ij}^k} \tag{2.13}$$

with $\gamma_{\mathcal{E}_{ij}^k}^2 = \frac{95}{176}$.

It remains to consider the case $i = 0$ or $j = 0$. The proof is similar and uses explicitly the Dirichlet boundary conditions at $x = 0$ and $y = 0$. We compute the constant of the strengthened Cauchy inequality directly on the macroelements $\mathcal{E}_{ij}^k$. We obtain

$$\gamma_{\mathcal{E}_{ij}^k}^2 < \frac{95}{176} \tag{2.14}$$

for $i = 0$ or $j = 0$. For details, see [7, Lemma 5.20 and Lemma 5.22].

Now we are able to formulate the main result of this subsection.

THEOREM 2.2. *The inequality*

$$(a(v,w))^2 \leq \gamma^2 a(v,v) a(w,w) \quad \forall v \in \mathbb{V}_k, w \in \mathbb{W}_{k+1}$$

is valid with $\gamma^2 = \frac{95}{176}$.

Proof. We apply Lemma 2.2. By inequalities (2.13) and (2.14) the assertion follows. ∎

2.2.3. Construction of the smoother. We need a good smoother for applying a multigrid solver to the linear system (1.7). This smoother will be constructed according to the local behavior of the differential operator. An idea presented in [1] for the construction of smoothers in the case of anisotropic problems is extended to the problem (1.6). This smoother operates only on the space $\mathbb{W}_{k+1}$. Consider the triangle $\tau_{ij}^{2,k}$. For our discussion only the submatrix K is needed, which corresponds to the nodal basis functions of $\mathbb{W}_{k+1}$. We discuss the two cases $i < j$ and $i \geq j$. Recall from (2.8) that

$$K_{2,ij} = 4 \begin{pmatrix} a+e & 0 & -a \\ 0 & c+d & -d \\ -a & -d & a+d \end{pmatrix}.$$

The indices i, j and 2 induce that this is the stiffness matrix with respect to $\mathbb{W}_k$ on the triangle $\tau_{ij}^{2,k}$; the index k is omitted. We now define a local preconditioner $C_{2,ij}$ for this matrix by omitting all those off-diagonal entries whose absolute values are small with respect to the main diagonals. We start with the case $i < j$. By (2.7), $a < d$ holds. Hence, we set

$$C_{2,ij} := 4 \begin{pmatrix} a+e & 0 & 0 \\ 0 & c+d & -d \\ 0 & -d & a+d \end{pmatrix}. \tag{2.15}$$

This matrix is a good preconditioner for $K_{2,ij}$ as the following lemma shows.

LEMMA 2.7. *For* $0 \leq i < j < n$ *one has*

$$\lambda_{min}(C_{2,ij}^{-1} K_{2,ij}) \geq 1 - \sqrt{\frac{1}{3}} \quad \textit{and} \quad \lambda_{max}(C_{2,ij}^{-1} K_{2,ij}) \leq 1 + \sqrt{\frac{1}{3}}.$$

Proof. The roots of the characteristical polynomial of $C_{2,ij}^{-1}K_{2,ij}$ are

$$\lambda_1 = 1, \quad \lambda_{2,3} = 1 \pm \sqrt{\rho}, \quad \text{where} \quad \rho = \frac{a}{a+e}\frac{ac+ad}{ac+ad+cd}.$$

We have for $i \le j-1$ that $\frac{c}{d} \le 1$ and $\frac{e}{a} \ge 1$. Therefore, using $a < c$, we obtain

$$\frac{ac+ad}{ac+ad+cd} \le \frac{2}{3} \quad \text{and} \quad \frac{a}{a+e} \le \frac{1}{2}. \tag{2.16}$$

Inserting the estimates (2.16), we obtain $1 - \sqrt{\frac{1}{3}} \le \lambda_3 \le \lambda_2 \le 1 + \sqrt{\frac{1}{3}}$. Hence, the assertion follows immediately. ∎

We now consider $i \ge j$. Then, $a > d$ holds, and we define

$$C_{2,ij} := 4 \begin{pmatrix} a+e & 0 & -a \\ 0 & c+d & 0 \\ -a & 0 & a+d \end{pmatrix}. \tag{2.17}$$

LEMMA 2.8. *It holds that*

$$\lambda_{min}(C_{2,ij}^{-1}K_{2,ij}) \ge 1 - \frac{1}{10}\sqrt{35} \quad \textit{and} \quad \lambda_{max}(C_{2,ij}^{-1}K_{2,ij}) \le 1 + \frac{1}{10}\sqrt{35}$$

for $n > i \ge j \ge 0$.

Proof. The proof is similar to the proof of Lemma 2.7. However, we have to distinguish the cases

- $i < n-1$ and $j > 0$, the same case as in Lemma 2.7;
- $i = n-1$ and $j > 0$, where $C_{2,ij}^{-1}K_{2,ij} = I$;
- $j = 0$, where we have to solve an eigenvalue problem with 2×2 matrices.

For details, see [7]. ∎

We define matrices $C_{1,ij}$ corresponding to the triangle $\tau_{ij}^{1,k}$ in the same way:

$$\begin{aligned} C_{1,ij} &:= 4 \begin{pmatrix} b+d & 0 & -d \\ 0 & a+f & 0 \\ -d & 0 & a+d \end{pmatrix} \quad \text{for} \quad i \le j, \\ C_{1,ij} &:= 4 \begin{pmatrix} b+d & 0 & 0 \\ 0 & a+f & -a \\ 0 & -a & a+d \end{pmatrix} \quad \text{for} \quad i > j. \end{aligned} \tag{2.18}$$

By the symmetry of the differential operator, we obtain the same results as in Lemmas 2.7 and 2.8.

Now we define a global preconditioner $C_{\mathbb{W}_{k+1}}$ using the local matrices $C_{s,ij}$. We know that

$$K_{\mathbb{W}_{k+1}} = a(\phi_{ij}^{k+1}, \phi_{lm}^{k+1})_{(i,j),(l,m)\in N_{k+1}}$$

is the stiffness matrix K_k restricted to the space $\mathbb{W}_{k+1}$ (compare (2.1), (2.2)). The matrix $K_{\mathbb{W}_{k+1}}$ is the result of assembling the local stiffness matrices $K_{s,ij}$ (2.8), $s = 1, 2$ and $i, j = 0, \ldots, n-1$, i.e.,

$$K_{\mathbb{W}_{k+1}} = \sum_{s=1}^{2} \sum_{i,j=0}^{n-1} L_{s,ij}^t K_{s,ij} L_{s,ij}. \tag{2.19}$$

The matrices $L_{s,ij} \in \mathbb{R}^{3\cdot 4^{k-1}-2^k,3}$ are the usual finite element assembling matrices. We define the matrix $C_{\mathbb{W}_{k+1}}$ by

$$C_{\mathbb{W}_{k+1}} = \sum_{s=1}^{2} \sum_{i,j=0}^{n-1} L_{s,ij}^t C_{s,ij} L_{s,ij}. \tag{2.20}$$

Because of the properties of the local preconditioners $C_{s,ij}$, the matrix $C_{\mathbb{W}_{k+1}}$ is a good preconditioner for $K_{\mathbb{W}_{k+1}}$. This result is stated as the main theorem of this subsection.

THEOREM 2.3. *It holds that*

$$\lambda_{min}(C_{\mathbb{W}_{k+1}}^{-1} K_{\mathbb{W}_{k+1}}) \geq 1 - \frac{1}{10}\sqrt{35}, \qquad \lambda_{max}(C_{\mathbb{W}_{k+1}}^{-1} K_{\mathbb{W}_{k+1}}) \leq 1 + \frac{1}{10}\sqrt{35}.$$

Proof. Use Lemmas 2.5, 2.7, and 2.8, and relations (2.19) and (2.20). ∎

Applying Theorem 2.3 an efficient smoother in the multigrid algorithm $MULT$ can be built as a preconditioned simple iteration method. The iteration operator of this method is defined by

$$S := I - \omega C_{\mathbb{W}_{k+1}}^{-1} K_{\mathbb{W}_{k+1}}. \tag{2.21}$$

COROLLARY 2.3. *Then, for all* $w \in \mathbb{W}_{k+1}$, $\nu \geq 1$, *and* $\omega = \omega_{opt} = 1$

$$\| S^\nu w \|_a \leq \rho^\nu \| w \|_a$$

holds with $\rho = \frac{1}{10}\sqrt{35}$.

Proof. The assertion follows by the theory of Jacobi smoothers; for details, see [7]. ∎

2.3. Application of the multigrid theory to $-x^2u_{yy} - y^2u_{xx} = g$. We now apply the theory of subsection 2.1 to problem (1.7). We state the main theorem of this paper.

THEOREM 2.4. *Consider* (1.7) *with the exact solution* u^*. *This linear system is solved by the multigrid algorithm* $MULT(k, u_{j,k}, g)$ *with* $\mu = 3$ *and* $\nu \geq 3$ *smoothing steps. Then the rate of convergence* σ_k *on level* k *can be bounded by*

$$\sigma_k \leq \sigma < 1.$$

Proof. We check the assumptions of Theorem 2.1. From Theorem 2.2 we have the estimate $\gamma^2 \leq \frac{95}{176}$ for the constant in the strengthened Cauchy inequality (2.4). The second assumption (2.3) is fulfilled for the smoother S defined in (2.21); cf. Corollary 2.3. Hence, we can prove a convergence rate $0 \leq \sigma < 1$ of the multigrid algorithm for $\mu \geq 3$.

Using Lemma 2.1, we can analyze the number of smoothing steps ν which is necessary for a convergence rate $\sigma < 1$. We have to show

$$\kappa = \rho^\nu + (1 - \rho^\nu)\gamma^2 < \frac{2}{3}$$

with $\gamma^2 = \frac{95}{176}$ and $\rho = \frac{1}{10}\sqrt{35}$ (Corollary 2.3). Therefore, we have for $\nu \geq 3$ a mesh-size independent convergence rate $\sigma < 1$. ∎

3. Implementational details. For applying the smoother S (2.21), the linear system

$$C_{\mathbb{W}_{k+1}} \underline{w} = \underline{r} \tag{3.1}$$

has to be solved. In this section, we explain an algorithm for solving (3.1). We want to show that this matrix is a block diagonal matrix of tridiagonal blocks. Furthermore, we show that the smoother S is a line smoother operating on lines L_{2m-1} which will be defined below. According to (2.20), (2.15), (2.17), and (2.18), the matrix $C_{\mathbb{W}_{k+1}}$ has the structure

$$C_{\mathbb{W}_{k+1}} = \operatorname{diag}(K_{\mathbb{W}_{k+1}}) + R,$$

where $\operatorname{diag}(K_{\mathbb{W}_{k+1}})$ is the diagonal part of the matrix $K_{\mathbb{W}_{k+1}}$ defined in (2.19). The matrix R will be defined below. Let $b : \mathbb{W}_k \times \mathbb{W}_k \to \mathbb{R}$ be the following bilinear form uniquely determined by the values of the basis functions $\{\phi_{ij}^k\}_{(i,j)\in N_k} \in \mathbb{W}_k$:

$$b(\phi_{ij}^k, \phi_{lm}^k) := \begin{cases} a(\phi_{ij}^k, \phi_{lm}^k) & \text{if} \quad \begin{array}{llll} i = l = 2r-1, & j = 2, \dots, i, & m = j-1, \\ j = m = 2r-1, & i = 2, \dots, j, & l = i-1, \end{array} \\ 0 & \text{otherwise} \end{cases}$$

for $r = 1, \dots, \frac{n}{2}$. Note that $a(\phi_{ij}^k, \phi_{lm}^k)$ is equal to the element $(i,j),(l,m)$ of the matrix K_k. The matrix R is defined via the bilinear form b. More precisely

$$R := \left[b(\phi_{ij}^k, \phi_{lm}^k) + b(\phi_{lm}^k, \phi_{ij}^k) \right]_{(i,j),(l,m)\in N_k};$$

i.e., the entries of the matrix R are those entries of the matrix $C_{\mathbb{W}_{k+1}}$ which correspond to edges marked by a bold line in Figure 3.1.

After a proper permutation the matrix $C_{\mathbb{W}_{k+1}}$ is a block diagonal matrix with diagonal and tridiagonal blocks. Therefore, we can solve the system (3.1) using Cholesky decomposition in $\mathcal{O}(n^2)$ flops. Hence, the operation $S\underline{w}$ is arithmetically optimal. We can choose $\nu = 3$ on each level. The number of unknowns of the system (1.7) increase per level to the factor 4. Therefore, using Theorem 2.4 the multigrid algorithm $MULT$ for $\mu = 3$ is an arithmetically optimal method [13].

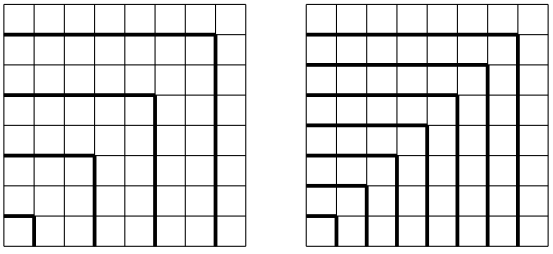

FIG. 3.1. *Nonzero entries of the matrices R (left) and $\tilde{R}$ (right).*

Additionally, a smoother S_1 is built, which uses the ideas of (2.21). This smoother operates on the space $\mathbb{V}_k$. Let $\tilde{C}_k := \operatorname{diag}(K_k) + \tilde{R}$, where

$$\tilde{R} := \left[\tilde{b}(\phi_{ij}^k, \phi_{lm}^k) + \tilde{b}(\phi_{lm}^k, \phi_{ij}^k) \right]_{i,j;l,m=1}^{n-1},$$

with the bilinear form $\tilde{b} : \mathbb{V}_k \times \mathbb{V}_k \to \mathbb{R}$, where

$$\tilde{b}(\phi_{ij}^k, \phi_{lm}^k) := \begin{cases} a(\phi_{ij}^k, \phi_{lm}^k) & \text{if} \quad \begin{array}{rlll} & i = l = r, & j = 2, \dots, i, & m = j - 1, \\ \text{or} & j = m = r, & i = 2, \dots, j, & l = i - 1, \end{array} \\ 0 & \text{otherwise} \end{cases}$$

for $r = 1, \dots, n-1$. We now define the smoother

$$S_1 = I - \omega \tilde{C}_k^{-1} K_k. \tag{3.2}$$

In contrast to the smoother S (2.21) this smoother is a line smoother on each bold line of Figure 3.1. Therefore, we expect better convergence rates of a standard multigrid algorithm (cf. Remark 2.1) in contrast to S. The matrix $\tilde{C}_k$ is block tridiagonal. Therefore, $S_1 \underline{w} = \underline{r}$ can be solved arithmetically optimal using Cholesky decompostion in $\mathcal{O}(n^2)$ flops.

4.1. Convergence rate of multigrid. Table 4.1 shows the convergence rates of the multigrid algorithm $MULT$ for solving (1.7) with $g(x, y) \equiv 1$. We use several kinds of cycles. We stop the algorithm when the relative error measured in the $K_k^T K_k$ norm is less than 10^{-7}.

The V-cycle has clearly growing numbers of iterations, but for $\mu \geq 3$ we have mesh-independent convergence rates. It is not clear if the convergence rates for the W-cycle are bounded from above by $\sigma < 1$. The reason for the bad convergence of the V-cycle is the smoother S which operates only on the nodes on $\mathbb{W}_k$.

Additionally, we perform numerical experiments with multigrid algorithms using the smoother S_1, which we have defined in (3.2). Table 4.2 displays the convergence rates for this algorithm using the smoother S_1. We solve (1.7) with $g(x, y) \equiv 1$ and stop the algorithm when the error in the energy norm is less than 10^{-7}. We choose $\omega = 0.8$, which shows the best convergence rates. We obtain for the V- and W-cycle mesh-independent convergence rates.

4.2. Number of iterations for multigrid as preconditioner in the PCG method. We expect to obtain better convergence properties by using a PCG method with one multigrid cycle as preconditioner. Table 4.3 shows the number of iterations to reduce the error in the preconditioned energy norm by a factor 10^{-9}. We choose $g(x, y) \equiv 1$. We see constant numbers of iterations in two cases, V-cycle with smoother

S_1 and for $\mu = 3$ with smoother S, but with a growing number of iterations for the V-cycle and smoother S. The results for the W-cycle ($\mu = 2$) give no precise answer as to whether the number of iterations are bounded or not.

5. Concluding remarks. Finally, we restate the two main results of this paper. A degenerate boundary value problem in the unit square was discretized by piecewise linear finite elements on a simple mesh. We constructed an arithmetically optimal multigrid method for the solution of the system of algebraic finite element equations arising from this discretization.

The second result concerns the application of this problem to the p-version of the finite element method. Consider (1.1) in $\Omega = (-1, 1)^2$. Discretize this problem by the p-version of the finite element method and use only one element. Then the blocks corresponding to the vertex functions and edge bubbles do not exist, i.e., $A_p = A_{int}$ in (1.3). We choose as preconditioner

$$\hat{C}_p := \text{blockdiag}\left[C_4[I - M]^{-1}\right]_{i=1}^{4},$$

where M denotes the iteration operator of our multigrid method. Then it follows from Theorem 3.4 in [7] and Theorem 2.4 (see also Theorem 7.1 in [7]) that the condition number of $\hat{C}_p^{-1}K_p$ grows as $1 + \log p$. Numerical experiments confirm the theory in this case [7]. Hence, we have found a preconditioner $\hat{C}_p$ for the interior problem of the p-version of the finite element method which is nearly optimal. Furthermore, the operation $\underline{r} = \hat{C}_p^{-1}\underline{w}$ can be done in $\mathcal{O}(p^2)$ arithmetical operations.

Acknowledgment. I thank Michael Jung for helpful comments.

A FINITE DIFFERENCE SCHEME FOR SOME NONLINEAR DIFFUSION EQUATIONS IN AN ABSORBING MEDIUM: SUPPORT SPLITTING PHENOMENA*

TATSUYUKI NAKAKI† AND KENJI TOMOEDA‡

Abstract. In the porous media equation $v_t = (v^m)_{xx}$ $(m > 1)$, it is well known that there appears a finite propagation of the initial support and that, if the initial support is connected, so is $\operatorname{supp} v(t,\cdot)$ for $t > 0$. When the effect of the absorption is considered as the additional lower order term $-cv^p$ $(c > 0,\ p > 0)$, the possibility that the support will split is expected. Rosenau and Kamin [*Phys. D*, 8 (1983), pp. 273–283] tried the numerical computations and suggested the support splitting phenomena. But the theoretical justification is not discussed. In this paper, such phenomena are investigated by use of finite difference schemes, and the sufficient conditions under which the support begins to split are obtained in the specific case where $m + p = 2$ and $0 < p < 1$.

1. Introduction.

We are concerned with the propagation of thermal waves in an absorbing medium occupying all of $\boldsymbol{R}^1$ in which there is an interaction between diffusion and absorption. The equation which describes this process is written in the form of the following initial value problem for the nonlinear diffusion equation with absorption which is used to describe the flow of liquids through porous media:

$$v_t = (v^m)_{xx} - cv^p, \qquad x \in \boldsymbol{R}^1, \quad t > 0, \tag{1.1}$$

$$v(0,x) = v^0(x), \qquad x \in \boldsymbol{R}^1, \tag{1.2}$$

where $m(> 1)$, $p(> 0)$, and $c(\geq 0)$ are constants, and $v^0(x) \in C^0(\boldsymbol{R}^1)$ is nonnegative and has compact support. In a heated plasma, v denotes the temperature and $-cv^p$ describes the losses caused by radiation. We may take $p = 0.5$ for bremsstrahlung radiation and $0.5 \leq p \leq 2$ for synchrotron radiation [24].

The existence and uniqueness of the nonnegative weak solution v of (1.1)–(1.2) was established by Oleinik, Kalashnikov, and Chzou [23], Kalashnikov [13], [14], Kersner [16], and Herrero and Vázquez [11]. The smoothness of v in the open set $\{(x,t); v(t,x) > 0 \text{ and } t > 0\}$ is also proved. Moreover, Kalashnikov proved that the solution becomes extinct in a finite time for $c > 0$ and $0 < p < 1$.

Since the diffusion rate mv^{m-1} vanishes at points where $v = 0$, the initial support propagates at finite speed; that is, there appear interface curves between the region where $v > 0$ and the region where $v = 0$. It is shown in the following papers that $\operatorname{supp} v(t,\cdot)$ exhibits three properties:

(i) **Positivity.** $\operatorname{supp} v(t,\cdot)$ expands as t increases and $\lim_{t\to\infty} \operatorname{supp} v(t,\cdot) = \boldsymbol{R}^1$, when $c = 0$, or $c > 0$ and $m \leq p$ [1], [3], [11], [13], [14], [18];

‡Osaka Institute of Technology, Asahi-ku, Osaka 535–8585, Japan (tomoeda@ge.oit.ac.jp).

(ii) **Localization.** $\operatorname{supp} v(t,\cdot)$ expands as t increases and is uniformly bounded with respect to t, when $c > 0$ and $1 \le p < m$ [3], [10], [13], [14], [17], [18]. There exist constants M_j $(j = 1, 2)$ such that $\operatorname{supp} v(t,\cdot) \subset [M_1, M_2]$ for all $t \ge 0$;

(iii) **Total extinction.** $\operatorname{supp} v$ is compact in $[0,\infty) \times \boldsymbol{R}^1$, when $c > 0$, $m > 1$, and $0 < p < 1$. Thus $\operatorname{supp} v(t,\cdot)$ expands and/or shrinks and $v(t,x)$ becomes extinct in a finite time: $v(t,\cdot) \equiv 0$ for $t \ge T^*$, and $v(t,\cdot) \not\equiv 0$ for $t < T^*$, where $T^* > 0$ is some constant and is called the extinction time of v [13], [14], [15], [17].

When the solution v possesses the *positivity property* or the *localization property*, $\operatorname{supp} v(t,\cdot)$ never becomes disconnected, even if the initial function $v^0(x)$ has zeros in the interval (α_1, α_2), where $[\alpha_1, \alpha_2] = \operatorname{supp} v^0(x)$ ((A),(B)→(a) in Figure 1.1). When the solution v has the *total extinction property*, that is, absorption can cool the medium faster than diffusion supplies heat from hot area, the support shrinks and becomes disconnected ((A)→(b)). Moreover, there is the possibility of the support splitting into several disjoint sets, even if $v^0(x)$ is positive on (α_1, α_2) ((B)→(b)).

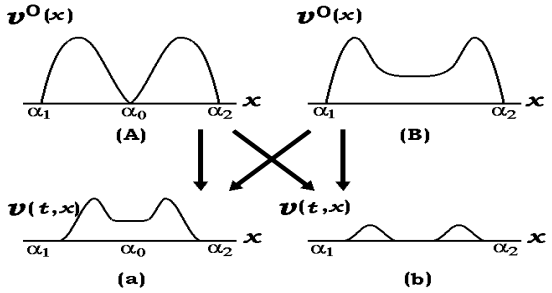

FIG. 1.1. *Support splitting and connecting.*

This motivates us to investigate the problem "How does the support vary when t varies?" To answer this problem we consider the behavior of $\operatorname{supp} v(t,\cdot)$ for the following two cases.

Case 1. $v^0(x) \in C^0(\boldsymbol{R}^1)$ is a nonnegative function with compact support $[\alpha_1, \alpha_2]$ and has only one zero $\alpha_0 \in (\alpha_1, \alpha_2)$; that is,

$$v^0(\alpha_0) = 0 \quad \text{and} \quad v^0(x) > 0 \quad \text{on} \quad (\alpha_1, \alpha_0) \cup (\alpha_0, \alpha_2). \tag{1.3}$$

Case 2. $v^0(x) \in C^0(\boldsymbol{R}^1)$ has compact support $[\alpha_1, \alpha_2]$ and satisfies

$$v^0(x) > 0 \quad \text{on } (\alpha_1, \alpha_2). \tag{1.4}$$

Rosenau and Kamin [24] tried numerical computations in Case 2, and obtained the numerical profile of v beginning to split into several subpulses, which means the splitting of the support. But they did not theoretically prove the appearance of such phenomena. From analytical points of view, Chen, Matano, and Mimura [4] constructed the solution $v(t,x)$ such that $\operatorname{supp} v(t,\cdot)$, while initially connected, splits into multiple connected components in a finite time. For Case 1 there are Kersner's results [15] which are useful to determine whether or not $\operatorname{supp} v(t,\cdot)$ becomes disconnected (see Remarks 5.1 and 5.2). In this paper, we treat such a problem from numerical points of view under the following assumption.

Assumption A. The constants m and p satisfy

$$m + p = 2 \quad \text{and} \quad 0 < p < 1. \tag{1.5}$$

To analyze the behavior of the support we have to construct the finite difference scheme of which both numerical solutions and numerical interfaces converge to the exact ones. Putting $u = v^{m-1}$, we rewrite (1.1)–(1.2) as

$$u_t = muu_{xx} + a(u_x)^2 - c', \quad a = \frac{m}{m-1}, \quad c' = (m-1)c, \tag{1.6}$$

$$u(0,x) = u^0(x) \equiv (v^0(x))^{m-1}. \tag{1.7}$$

We note that the effect of absorption is expressed as the constant $-c'$ under Assumption A.

Our difference scheme is constructed along the two important ideas which are proposed by Graveleau and Jamet [9] and DiBenedetto and Hoff [5]. Their difference schemes give the approximation to (1.6)–(1.7) with $c = 0$; that is, the porous media equation. Graveleau and Jamet's scheme is based on splitting the operator $Au = muu_{xx} + a(u_x)^2$ into two parts $u_t = Pu \equiv muu_{xx}$ and $u_t = Hu \equiv a(u_x)^2$. These two equations are discretized separately by the suitable difference schemes and solved alternately to approximate the solution of (1.6)–(1.7). They proved the convergence of numerical solutions and the finite propagation of support. However, since their difference scheme includes an artificial viscosity in approximating the nonlinear hyperbolic equation $u_t = Hu$, it does not give good approximations in realizing the interfaces. DiBenedetto and Hoff's scheme approximates (1.6)–(1.7) with the interface equation $\dot{\zeta}(t) = -\frac{m}{m-1}u_x(t,\zeta(t))$. They succeeded in proving the convergence of numerical solutions and numerical interfaces, and obtained error bounds. We note that their idea is applied to the approximation of the interfaces for a doubly degenerate parabolic equation [12].

Along the idea of Graveleau and Jamet, we construct the difference scheme consisting of three approximations to $u_t = Pu$, $u_t = Hu$, and $u_t = Du \equiv -c'$ in section 2. By solving Riemann problems included in $u_t = Hu$ and using the Rankine–Hugoniot jump equation, we propose the improved scheme so that an artificial viscosity is excluded. In sections 3 and 4 we succeed in proving the convergence of numerical solutions and numerical interfaces by using DiBenedetto and Hoff's argument. However, we are unable to obtain error bounds. In section 5, we partially improve Kersner's results in Case 1. Moreover, we obtain the sufficient condition under which the support begins to split into at least two disjoint sets in Case 2. Unfortunately, when $m + p \neq 2$, $m > 1$, and $0 < p < 1$, we are unable to construct the difference scheme satisfying the basic inequalities (Theorem 2.1) in approximating $u_t = Du$. However, our numerical computations show support splitting phenomena, which seems true. We need the improvement of our mathematical proofs to justify such phenomena. Numerical examples will be submitted for publication elsewhere.

On the other hand, Galaktionov [6], Galaktionov and Samarskii [7], [8], Kurdyumov, Kurkina, Malinetskii, and Samarskii [19], Kurdyumov, Gurevich, and Tel'kovskaya [20], and Samarskii, Galaktionov, Kurdyumov, and Mikhailov [25] established the existence of an unbounded solution for the equation with the effect of heat sources:

$$v_t = \nabla \cdot (v^m \nabla v) + v^p, \quad t > 0, \quad x \in \boldsymbol{R}^n.$$

They constructed self-similar solutions and difference solutions, and obtained the interesting properties of the behavior of the solution.

2. Difference schemes.

2.1. Difference operators. Our difference scheme approximates the problem (1.6)–(1.7) instead of (1.1)–(1.2), and is described as follows: Find the sequence $\{u_h^n\}_{n=1,2,\dots} \subset V_h$ for each $u_h^0 \in V_h$ such that

$$u_h^{n+1} = S_{h,k}u_h^n \equiv (P_{h,\kappa})^\mu \cdot \prod_{j=1}^{\nu} H_{h,\tau_j} \cdot D_{h,k}u_h^n \quad \text{for } n = 0, 1, 2, \dots. \tag{2.1}$$

Here $k \equiv k_{n+1} \equiv t_{n+1} - t_n$ ($t_0 = 0$), $\tau_j \equiv \tau_{n+1,j}$, and $\kappa \equiv \kappa_{n+1}$ are variable time steps, h is a space mesh width, $\mu \equiv \mu_{n+1}$ and $\nu \equiv \nu_{n+1}$ are positive integers satisfying

$$\sum_{j=1}^{\nu_{n+1}} \tau_{n+1,j} = \mu_{n+1}\kappa_{n+1} = k_{n+1}, \tag{2.2}$$

$D_{h,k}$, H_{h,τ_j}, and $P_{h,\kappa}$ are difference operators approximating $u_t = -c'$, $u_t = Hu$, and $u_t = Pu$, respectively, which are stated later, and V_h is the set of the nonnegative continuous functions $u_h = u_h(x)$ with the following properties:

(i) u_h has compact support with the left and right interfaces $\ell(u_h)$ and $r(u_h)$, respectively, which are defined by

$$\ell(u_h) = \sup\{\xi;\ u_h(x) = 0 \quad \text{on} \quad (-\infty, \xi]\}, \tag{2.3}$$

$$r(u_h) = \inf\ \{\xi;\ u_h(x) = 0 \quad \text{on} \quad [\xi, \infty)\}; \tag{2.4}$$

(ii) u_h is linear on each interval $[x_i, x_{i+1}]$ ($i \in \boldsymbol{Z}$), where $x_i = x_i(\ell, r)$ ($i \in \boldsymbol{Z}$),

$$x_i(\ell, r) = \begin{cases} ih & \text{for } i \in \boldsymbol{Z} \setminus \{L-1, R+1\}, \\ \ell & \text{for } i = L-1, \\ r & \text{for } i = R+1, \end{cases} \tag{2.5}$$

$$L \equiv L(\ell), \quad L(\ell) = \min\{i \in \boldsymbol{Z};\ ih > \ell\}, \quad \ell = \ell(u_h), \tag{2.6}$$

$$R \equiv R(r), \quad R(r) = \max\{i \in \boldsymbol{Z};\ ih < r\}, \quad r = r(u_h). \tag{2.7}$$

The determination of the variable time steps k, τ_j, and κ are stated in the description of $D_{h,k}$, H_{h,τ_j}, and $P_{h,\kappa}$, respectively. When $D_{h,k}u_h^{n^*} \equiv 0$ holds for some integer $n^* > 0$, we denote the numerical extinction time by $T_h^* = t_{n^*+1} \equiv t_{n^*} + k_{n^*+1}$ and stop the numerical computation by putting

$$t_n = T_h^* + (n - n^* - 1)k_{n^*+1} \ \text{ and } \ u_h^n(x) = 0 \quad \text{for all} \ \ n \geq n^* + 1. \tag{2.8}$$

We put $X(\ell, r) = \{x_i(\ell,\ r)\ ;\ i \in \boldsymbol{Z}\}$ and

$$\ell_n = \ell(u_h^n), \quad r_n = r(u_h^n), \quad L_n = L(\ell_n), \quad R_n = R(r_n) \quad (n = 0, 1, \dots, n^*). \tag{2.9}$$

For simplicity, we introduce the following notations, which will be used in the proof of Theorem 3.1 and the descriptions of Theorem 4.1 and Lemma 4.2:

$$\begin{cases} u_h^{n+1,s} = \left(\prod_{j=1}^{s} H_{h,\tau_{n+1,j}}\right) u_h^{n+1,0} \quad (s = 1, 2, \dots, \nu_{n+1}), \\ u_h^{n+1,0} = D_{h,k_{n+1}}u_h^n, \end{cases} \tag{2.10}$$

$$L_{n+1,s} = L(\ell_{n+1,s}), \quad \ell_{n+1,s} = \ell(u_h^{n+1,s}) \quad (s = 0, 1, \dots, \nu_{n+1}), \tag{2.11}$$

$$\begin{cases} u_h^{n+1,\cdot,q} = (P_{h,\kappa_{n+1}})^q u_h^{n+1,\cdot,0}\ (q = 1, 2, \dots, \mu_{n+1}), \\ u_h^{n+1,\cdot,0} = u_h^{n+1,\nu_{n+1}}, \end{cases} \tag{2.12}$$

$$L_{n+1,\cdot,q} = L(\ell_{n+1,\cdot,q}), \quad \ell_{n+1,\cdot,q} = \ell(u_h^{n+1,\cdot,q})\ (q = 0, 1, \dots, \mu_{n+1}). \tag{2.13}$$

Now we describe the difference operators $D_{h,k}$, $H_{h,\tau}$, and $P_{h,\kappa}$ by putting

$$\begin{array}{ll} h_i = x_{i+1} - x_i, & u_i = u_h(x_i), \\ \delta u_i = (u_{i+1} - u_i)/h_i, & \delta^2 u_i = 2(\delta u_i - \delta u_{i-1})/(h_i + h_{i-1}). \end{array}$$

2.1.1. Difference operator $D_{h,k}$. For $u_h \in V_h$ we define $D_{h,k}u_h$ by

$$D_{h,k}u_h(x_i') = \max\{u_h(x_i') - c'k, 0\} \text{ for all } x_i' \in X(\ell(D_{h,k}u_h), r(D_{h,k}u_h)), \tag{2.14}$$

$$\ell(D_{h,k}u_h) = \max\{\ell(u_h),\ (L'-1)h\}, \quad r(D_{h,k}u_h) = \min\{r(u_h),\ (R'+1)h\}, \tag{2.15}$$

where

$$L' = L(\ell(u(k,\cdot))), \quad R' = R(r(u(k,\cdot))). \tag{2.16}$$

We determine the time step k by either (2.17) with $i = L$ or (2.17) with $i = R-1$:

$$k = \frac{1}{c'}\max(u_i,\ u_{i+1}) \quad (i = L \text{ or } R-1). \tag{2.17}$$

2.1.2. Difference operator $H_{h,\tau}$. For $u_h \in V_h$ let $u(\tau, x)$ be the exact solution of $u_t = Hu$ with the initial value $u(0,x) = u_h(x)$. We define $H_{h,\kappa}u_h$ by

$$H_{h,\tau}u_h(x_i') = u(\tau, x_i') \quad \text{for all} \quad x_i' \in X(\ell(H_{h,\tau}u_h),\ r(H_{h,\tau}u_h)), \tag{2.18}$$

$$\ell(H_{h,\tau}u_h) = \ell(u(\tau,\cdot)), \qquad r(H_{h,\tau}u_h) = r(u(\tau,\cdot)). \tag{2.19}$$

The time step τ is the number satisfying

$$a\|(u_h)_x\|_\infty \tau \le \min\left\{\frac{h}{4},\ Lh - \ell(u_h),\ r(u_h) - Rh\right\}, \tag{2.20}$$

where $\|\cdot\|_\infty$ denotes $\|\cdot\|_{L^\infty(\boldsymbol{R}^1)}$. We put $\ell' = \ell(H_{h,\tau}u_h)$, $r' = r(H_{h,\tau}u_h)$, $L' = L(\ell')$, and $R' = R(r')$. Then, for $x_i' \in X(\ell',\ r')$, (2.18) and (2.19) are rewritten as

$$H_{h,\tau}u_h(x_i') = \begin{cases} u_i + a(\delta u_i)^2\tau & \text{if} \quad i \in S^+ = S_S^+ \cup S_R^+, \\ u_i + a(\delta u_{i-1})^2\tau & \text{if} \quad i \in S^- = S_S^- \cup S_R^-, \\ u_i & \text{if} \quad i \in S^0, \\ (L'h - \ell')\delta u_{L-1} & \text{if} \quad i = L' = L-1, \\ (R'h - r')\delta u_R & \text{if} \quad i = R' = R+1, \\ 0 & \text{if} \quad i \in \boldsymbol{Z} \setminus \{L', \dots, R'\}, \end{cases} \tag{2.21}$$

$$\ell' = \ell(u_h) - a\delta u_{L-1}\tau, \quad r' = r(u_h) - a\delta u_R\tau, \tag{2.22}$$

where

$$\begin{aligned} S_S^+ &= \Big\{i \in \{L, \dots, R\};\ \delta u_{i-1} < \delta u_i \quad \text{and} \quad \delta u_{i-1} > -\delta u_i\Big\}, \\ S_S^- &= \Big\{i \in \{L, \dots, R\};\ \delta u_{i-1} < \delta u_i \quad \text{and} \quad \delta u_{i-1} \le -\delta u_i\Big\}, \\ S_R^+ &= \Big\{i \in \{L, \dots, R\};\ \delta u_{i-1} \ge \delta u_i > 0\Big\}, \\ S_R^- &= \Big\{i \in \{L, \dots, R\};\ 0 > \delta u_{i-1} \ge \delta u_i\Big\}, \\ S^0 &= \Big\{i \in \{L, \dots, R\};\ \delta u_{i-1} \ge 0 \ge \delta u_i\Big\}. \end{aligned}$$

We apply the expression (2.21) to numerical computations, which we can show by integrating the solution $w(t,x)$ of the following Riemann initial value problem:

$$w_t = a(w^2)_x \quad \text{with the initial value} \quad w(0,x) = (u_h(x))_x. \tag{2.23}$$

Here (2.23) is derived from $u_t = Hu$ by putting $w = u_x$. The numerical interface equations (2.22) are well known as the Rankine–Hugoniot jump equation determining the line on which the solution w has a shock.

2.1.3. Difference operator $P_{h,\kappa}$. For $u_h \in V_h$ we define $P_{h,\kappa}u_h$ by the usual explicit difference operator

$$P_{h,\kappa}u_h(x_i') = u_i + \kappa m u_i \delta^2 u_i \quad \text{for all } x_i' \in X(\ell(P_{h,\kappa}u_h),\ r(P_{h,\kappa}u_h)), \tag{2.24}$$

$$\ell(P_{h,\kappa}u_h) = \ell(u_h), \quad r(P_{h,\kappa}u_h) = r(u_h). \tag{2.25}$$

The time step κ is the largest number satisfying

$$m\|u_h\|_\infty \kappa \Big\{ \frac{1}{h^2} + \frac{2}{h(h+h_j)} \Big\} \le 1 \quad \text{and} \quad \frac{4m\|(u_h)_x\|_\infty \kappa}{h+h_j} \le 1 \tag{2.26}$$

for $j = L-1$ and R.

2.2. Basic inequalities.

THEOREM 2.1 (basic inequalities). *Let $\{u_h^n\}_{n=1,2,\dots}$ be given by the scheme (2.1) for $u_h^0 \in V_h$. Then u_h^n either becomes extinct or belongs to V_h for each $n \ge 0$, and the following estimates hold for all $n \ge 0$:*

$$\ell_0 - a\|(u_h^0)_x\|_\infty t_n \le \ell_n \le r_n \le r_0 + a\|(u_h^0)_x\|_\infty t_n \text{ if } u_h^n \not\equiv 0, \tag{2.27}$$

$$0 \le u_h^n(x) \le \max(\|u_h^0\|_\infty - c' t_n,\ 0) \quad \text{on } \boldsymbol{R}^1, \tag{2.28}$$

$$\|(u_h^n)_x\|_\infty \le \|(u_h^0)_x\|_\infty, \tag{2.29}$$

$$TV((u_h^n)_x) \le TV((u_h^0)_x), \tag{2.30}$$

$$\|(u_h^{n+1} - u_h^n)/k_{n+1}\|_{L^1(\boldsymbol{R}^1)} \le (m+a)\|u_h^0\|_\infty TV((u_h^0)_x) + c' \left\{ r_0 - \ell_0 + 2a\|(u_h^0)_x\|_\infty t_n \right\}, \tag{2.31}$$

$$\inf_{i\in\boldsymbol{Z}} \delta^2 u_i^0 \le \inf_{i\in\boldsymbol{Z}} \delta^2 u_i^n, \tag{2.32}$$

where $TV(f)$ denotes the total variation of f on $\boldsymbol{R}^1$.

Proof. The inequalities (2.27)–(2.32) with $c = 0$ immediately follow from Lemmas 3.1, 3.2, and 5.1 in [21]. Put $u_h' = D_{h,k}u_h$ ($u_h \in V_h$). By simple calculations, it can be shown that

$$\|u_h'\|_\infty \le \max(\|u_h\|_\infty - c'k, 0),\ \|((u_h'))_x\|_\infty \le \|(u_h)_x\|_\infty,\ TV((u_h')_x) \le TV((u_h)_x),$$
$$\|(u_h' - u_h)/k\|_{L^1(\boldsymbol{R}^1)} \le c' \{r(u_h) - \ell(u_h)\},\ \inf_{i\in\boldsymbol{Z}} \delta^2 u_i \le \inf_{i\in\boldsymbol{Z}} \delta^2 u_i'.$$

Hence (2.27)–(2.32) hold for $c > 0$ by these inequalities and (2.15). ∎

2.3. Numerical extinction time. We show the existence of the numerical extinction time.

THEOREM 2.2 (existence of numerical extinction time). *Let $\{u_h^n\}_{n=1,2,\dots}$ be given by the scheme (2.1) for $u_h^0 \in V_h$. Then there exists an integer $N(h)$ such that $t_{N(h)}$ attains the numerical extinction time T_h^*, and the following estimate holds:*

$$T_h^* \le t_n + \frac{\|u_h^n\|_\infty}{c'} \quad \text{for all } n \ge 0. \tag{2.33}$$

Proof. We prove the existence of $N(h)$ such that $t_{N(h)} = T_h^*$. Assume the contrary; that is, suppose $u_h^n > 0$ for all $n \geq 0$. Then, it follows from (2.28) that

$$t_n < \frac{\|u_h^0\|_\infty}{c'} \quad \text{for all } n \geq 0. \tag{2.34}$$

Let Q_ℓ and Q_r be the sets of nonnegative integers defined by

$$Q_\ell = \{n; k = k_{n+1} \text{ satisfies (2.17) with } i = L\} \text{ and}$$
$$Q_r = \{n; k = k_{n+1} \text{ satisfies (2.17) with } i = R-1\},$$

respectively. From the determination of the numerical interfaces (see (2.15)) it follows that

$$\ell'_n - \ell_n \geq h \quad \text{for } n \in Q_\ell \quad \text{and} \quad r_n - r'_n \geq h \quad \text{for } n \in Q_r, \tag{2.35}$$

where $\ell'_n = \ell(D_{h,k_{n+1}} u_h^n)$ and $r'_n = r(D_{h,k_{n+1}} u_h^n)$. By using (2.22), (2.29), and (2.35), we have

$$\ell_{n+1} - \ell_n = \ell_{n+1} - \ell'_n + \ell'_n - \ell_n \geq \begin{cases} -a\|(u_h^0)_x\|_\infty k_{n+1} + h & \text{for } n \in Q_\ell, \\ -a\|(u_h^0)_x\|_\infty k_{n+1} & \text{for } n \notin Q_\ell, \end{cases} \tag{2.36}$$

$$r_{n+1} - r_n = r_{n+1} - r'_n + r'_n - r_n \leq \begin{cases} a\|(u_h^0)_x\|_\infty k_{n+1} - h & \text{for } n \in Q_r, \\ a\|(u_h^0)_x\|_\infty k_{n+1} & \text{for } n \notin Q_r. \end{cases} \tag{2.37}$$

Since $\{\ell_n\}$ and $\{r_n\}$ are bounded sequences by (2.27) and (2.34), we can extract convergent subsequences $\{\ell_{n_s}\}$ and $\{r_{n_s}\}$. We find from (2.36) and (2.37) that

$$\ell_{n_{s+1}} - \ell_{n_s} = \sum_{j=n_s}^{n_{s+1}-1} (\ell_{j+1} - \ell_j) \geq -a\|(u_h^0)_x\|_\infty \sum_{j=n_s}^{n_{s+1}-1} k_{j+1} + h \quad \text{for } n_s \in Q_\ell,$$
$$r_{n_{s+1}} - r_{n_s} = \sum_{j=n_s}^{n_{s+1}-1} (r_{j+1} - r_j) \leq \quad a\|(u_h^0)_x\|_\infty \sum_{j=n_s}^{n_{s+1}-1} k_{j+1} - h \quad \text{for } n_s \in Q_r,$$

which yield

$$a\|(u_h^0)_x\|_\infty \sum_{j=n_s}^{n_{s+1}-1} k_{j+1} \geq \begin{cases} \ell_{n_s} - \ell_{n_{s+1}} + h & \text{for } n_s \in Q_\ell, \\ r_{n_{s+1}} - r_{n_s} + h & \text{for } n_s \in Q_r. \end{cases}$$

Then there exists an integer s_0 such that

$$a\|(u_h^0)_x\|_\infty \sum_{j=n_s}^{n_{s+1}-1} k_{j+1} \geq \frac{h}{2} \qquad \text{for } s \geq s_0,$$

which implies

$$t_{n_q} - t_{n_{s_0}} = \sum_{s=s_0}^{q-1} \sum_{j=n_s}^{n_{s+1}-1} k_{j+1} \geq \frac{(q-s_0)h}{2a\|(u_h^0)_x\|_\infty} \qquad \text{for } q \geq s_0 + 1. \tag{2.38}$$

Hence $\lim_{q\to+\infty} t_{n_q} = +\infty$, which contradicts (2.34). Thus we have $t_{N(h)} = T_h^*$ for some integer $N(h)$.

Finally we show (2.33). From (2.28) we obtain

$$\|u_h^m\|_\infty \le \max\{\|u_h^n\|_\infty - c'(t_m - t_n),\ 0\} \quad \text{for all } m > n,$$

which immediately yields

$$\|u_h^m\|_\infty = 0 \quad \text{for} \quad t_m \ge t_n + \frac{\|u_h^n\|_\infty}{c'}.$$

Hence (2.33) holds, and the proof is complete. □

3. Convergence of numerical solutions. In this section we state the convergence of the numerical solutions. For this end, we start the scheme (2.1) with $u_h^0 \in V_h$ given by

$$\begin{cases} \ell(u_h^0) = \ell(u^0), \quad r(u_h^0) = r(u^0), \\ u_h^0(x_i) = u^0(x_i) \qquad \text{for all } i \in \boldsymbol{Z}. \end{cases} \tag{3.1}$$

We define the function $u_h(t,x)$ by

$$u_h(t,x) = u_h^n(x) \quad \text{on} \quad [t_n, t_{n+1}) \times \boldsymbol{R}^1 \qquad \text{for all } \ t_n \text{ and } h \tag{3.2}$$

and impose Condition B on v^0.

Condition B. $u^0 \equiv (v^0)^{m-1} \in C^0(\boldsymbol{R}^1)$ is a nonnegative function with compact support and $u_x^0 \in L^\infty(\boldsymbol{R}^1) \cap BV(\boldsymbol{R}^1)$.

From Theorem 2.1 we have the following convergence theorem.

THEOREM 3.1 (convergence of numerical solutions u_h). *Assume Condition* B. *Let $\{h\}$ be an arbitrary sequence which tends to zero. Then there exist a subsequence $\{h'\}$ of $\{h\}$ and a function u with the following properties:*

(i) $u \in C^0(\mathcal{H}) \cap L^\infty(\mathcal{H}), \quad u_x \in L^\infty(\mathcal{H})$;

(ii) $u(0,x) = u^0(x) \qquad$ *for all* $\quad x \in \boldsymbol{R}^1$;

(iii) *as* $h' \to 0$,

$$\|u_{h'} - u\|_{L^\infty(\mathcal{H})} \to 0, \tag{3.3}$$

$$\|(u_{h'})_x - u_x\|_{L^p(\mathcal{H})} \to 0 \quad (1 \le p < +\infty); \tag{3.4}$$

(iv) *u is a weak solution; that is, the following integral relation holds for any function $\phi(t,x) \in C^{1,1}(\mathcal{H})$ with compact support*

$$\iint_{\text{supp } u} (u\phi_t - muu_x\phi_x - (m-a)(u_x)^2\phi - c'\phi)dxdt + \int_{\boldsymbol{R}^1} u(0,x)\phi(0,x)dx = 0; \tag{3.5}$$

(v) *$u_{xx} \in \mathcal{E}'$ and $u_t \in \mathcal{E}'$, where $\mathcal{E}'$ is the dual of the space $\mathcal{E}$ consisting of all continuous functions with compact support in $(0,\infty) \times \boldsymbol{R}^1$.*

As a direct corollary of Theorem 3.1 we have the following theorem.

THEOREM 3.2 (convergence of numerical solutions v_h). *Let the same assumptions as stated in Theorem* 3.1 *be satisfied. Then $v_h \equiv (u_h)^{\frac{1}{m-1}}$ converges uniformly on $\mathcal{H}$ to the unique weak solution v of* (1.1)–(1.2) *as h tends to zero.*

Proof of Theorem 3.1. By following Graveleau and Jamet (Theorem 6.1 and Lemma 7.1 in [9]), the properties (i), (ii), (iii), and (v) are proved.

We now show the property (iv). We note that u has a compact support from (2.27), (2.33), and (3.3). Let $\{h\}$ take the value belonging to the extracted subsequence $\{h'\}$. From (2.1) we have

$$u_i^{n+1} - u_i^n = \sum_{q=0}^{\mu_{n+1}-1} \left(u_i^{n+1,\cdot,q+1} - u_i^{n+1,\cdot,q} \right) + \sum_{s=0}^{\nu_{n+1}-1} \left(u_i^{n+1,s+1} - u_i^{n+1,s} \right) + \left(u_i^{n+1,0} - u_i^n \right),$$

where $u_i^{n+1,s}$ $(s = 0, 1, \ldots, \nu_{n+1})$ and $u_i^{n+1,\cdot,q}$ $(q = 0, 1, \ldots, \mu_{n+1})$ are defined by (2.10) and (2.12), respectively. Let $\phi(t,x) \in C^{1,1}(\mathcal{H})$ have compact support and T^* be the extinction time of v. Then we have

$$\begin{aligned} &\sum_{(t_n, ih) \in \text{supp } u} h\phi_i^n \left(u_i^{n+1} - u_i^n \right) \\ &\quad = - \sum_{ih \in \text{supp } u^0} h u_i^0 \phi_i^0 - \sum_{(t_n, ih) \in \text{supp } u} h u_i^{n+1} (\phi_i^{n+1} - \phi_i^n) + \sum_{ih \in \text{supp } u(t_{n^*}, \cdot)} h u_i^{n^*+1} \phi_i^{n^*+1} \\ &\quad = A_h + B_h + C_h, \end{aligned}$$

where $\phi_i^n = \phi(t_n, ih)$, the integer n^* satisfies $t_{n^*} < T^*$ and $t_{n^*+1} \geq T^*$, and

$$\begin{aligned} A_h &= \sum_{(t_n, ih) \in \text{supp } u} h\phi_i^n \left\{ \sum_{q=0}^{\mu_{n+1}-1} (u_i^{n+1,\cdot,q+1} - u_i^{n+1,\cdot,q}) \right\}, \\ B_h &= \sum_{(t_n, ih) \in \text{supp } u} h\phi_i^n \left\{ \sum_{s=0}^{\nu_{n+1}-1} (u_i^{n+1,s+1} - u_i^{n+1,s}) \right\}, \\ C_h &= \sum_{(t_n, ih) \in \text{supp } u} h\phi_i^n (u_i^{n+1,0} - u_i^n). \end{aligned}$$

The following convergence is obvious:

$$\sum_{ih \in \text{supp } u^0} h u_i^0 \phi_i^0 \longrightarrow \int_{\boldsymbol{R}^1} u(0,x)\phi(0,x)\, dxdt \qquad \text{as} \quad h \to 0, \tag{3.6}$$

$$\sum_{ih \in \text{supp } u(t_{n^*}, \cdot)} h u_i^{n^*+1} \phi_i^{n^*+1} \longrightarrow 0 \qquad \text{as} \quad h \to 0. \tag{3.7}$$

By Lemma 4.1 in [21] we obtain

$$\sum_{(t_n, ih) \in \text{supp } u} h u_i^{n+1} (\phi_i^{n+1} - \phi_i^n) \longrightarrow \iint_{\text{supp } u} u\phi_t \, dxdt \qquad \text{as} \quad h \to 0, \tag{3.8}$$

$$A_h \longrightarrow - \iint_{\text{supp } u} \{muu_x\phi_x + m(u_x)^2\phi\} dxdt \qquad \text{as} \quad h \to 0, \tag{3.9}$$

$$B_h \longrightarrow \iint_{\text{supp } u} \{a(u_x)^2\phi\} dxdt \qquad \text{as} \quad h \to 0. \tag{3.10}$$

We prove the following convergence:

$$C_h \longrightarrow \iint_{\text{supp } u} (-c'\phi)\, dxdt \qquad \text{as} \quad h \to 0. \tag{3.11}$$

Let ε be an arbitrary positive number. Then we can choose the compact sets $G_j(\varepsilon)$ $(j = 1, 2, 3)$ such that

$$G_1(\varepsilon) \subset \overset{\circ}{G}_2(\varepsilon), \quad G_2(\varepsilon) \subset \overset{\circ}{\operatorname{supp}}\ u, \quad \operatorname{supp} u \subset \overset{\circ}{G}_3(\varepsilon), \tag{3.12}$$

$$\operatorname{meas}(G_2 \setminus G_1) < \varepsilon, \quad \operatorname{meas}(\operatorname{supp} u \setminus G_2) < \varepsilon, \quad \operatorname{meas}(G_3 \setminus \operatorname{supp} u) < \varepsilon, \tag{3.13}$$

where $\overset{\circ}{G}$ denotes the set of interior points of the set G, and $\operatorname{meas}(A)$ is the measure of the set A. Since u_h converges uniformly on $\mathcal{H}$, there exist positive numbers $\tilde{h}_1(\varepsilon)$ and $\tilde{h}_2(\eta_\varepsilon)$ for ε and the positive constant $\eta_\varepsilon \equiv \frac{1}{2}\min_{G_2(\varepsilon)} u(t, x)$, respectively, such that

$$\begin{aligned}(t + k_{n+1}, x + h) &\in G_3(\varepsilon) \setminus G_1(\varepsilon) \\ &\text{for} \quad (t, x) \in \operatorname{supp} u \setminus G_2(\varepsilon), \quad n \geq 0, \quad \text{and} \quad h < \tilde{h}_1(\varepsilon),\end{aligned} \tag{3.14}$$

$$\begin{aligned}u_h^n(x) - c' k_{n+1} &\geq u_h(t_n, x) - 2\|u_x^0\|_\infty h > \eta_\varepsilon \\ &\text{for} \quad (t_{n+1}, x) \in G_2(\varepsilon) \quad \text{and} \quad h < \tilde{h}_2(\eta_\varepsilon).\end{aligned} \tag{3.15}$$

Here we use the inequality $c' k_{n+1} \leq 2\|u_x^0\|_\infty h$ which follows from (2.17). From the definition of the difference operator $D_{h,k}$ it follows that

$$-c' \leq \frac{u_i^{n+1,0} - u_i^n}{k_{n+1}} \leq 0 \quad \text{for} \quad n \geq 0 \text{ and } i \in \boldsymbol{Z}, \tag{3.16}$$

$$\frac{u_i^{n+1,0} - u_i^n}{k_{n+1}} = -c' \quad \text{for} \quad (t_n, ih) \in G_2(\varepsilon) \text{ and } h < \min\{\tilde{h}_1(\varepsilon), \tilde{h}_2(\eta_\varepsilon)\}. \tag{3.17}$$

Since there exists a positive number $\tilde{h}_3(\varepsilon)$ such that

$$\left| \sum_{(t_n, ih) \in G_2(\varepsilon)} h k_{n+1} (-c' \phi_i^n) - \iint_{G_2(\varepsilon)} (-c' \phi)\, dxdt \right| < \varepsilon \quad \text{for} \quad h < \tilde{h}_3(\varepsilon),$$

we obtain from (3.12)–(3.17)

$$\begin{aligned}&\left| C_h - \iint_{\operatorname{supp} u} (-c' \phi)\, dxdt \right| \\ &\quad \leq \Big| \sum_{(t_n, ih) \in \operatorname{supp} u \setminus G_2(\varepsilon)} h k_{n+1} \phi_i^n \frac{u_i^{n+1,0} - u_i^n}{k_{n+1}} \Big| + \left| \iint_{\operatorname{supp} u \setminus G_2(\varepsilon)} c' \phi\, dxdt \right| \\ &\qquad + \Big| \sum_{(t_n, ih) \in G_2(\varepsilon)} h k_{n+1} \phi_i^n \frac{u_i^{n+1,0} - u_i^n}{k_{n+1}} - \iint_{G_2(\varepsilon)} (-c' \phi)\, dxdt \Big| \\ &\quad \leq (4c' \|\phi\|_\infty + 1)\varepsilon \quad \text{for} \quad h < \min\{\tilde{h}_1(\varepsilon), \tilde{h}_2(\eta_\varepsilon), \tilde{h}_3(\varepsilon)\},\end{aligned} \tag{3.18}$$

which yields (3.11). Hence, the property (iv) follows from (3.6)–(3.11), which completes the proof. □

THEOREM 3.3 (convergence of numerical extinction time). *Let the same assumptions as stated in Theorem* 3.1 *be satisfied. Then*

$$|T_h^* - T^*| \longrightarrow 0 \quad \textit{as} \quad h \to 0, \tag{3.19}$$

where T^* is the extinction time of the unique weak solution v of (1.1)–(1.2).

Proof. From Theorem 3.2 there exist $\tilde{x} \in \boldsymbol{R}^1$ and $h' > 0$ for an arbitrary fixed $t < T^*$ such that $v_h(t, \tilde{x}) \geq \frac{1}{2} v(t, \tilde{x}) > 0$ holds for $h < h'$. Then

$$\liminf_{h \to 0} T_h^* \geq T^*. \tag{3.20}$$

By (2.33) the inequality $T_h^* \leq T^* + \frac{1}{c'} \|u_h(T^*, \cdot)\|_\infty$ holds. Since $\|u(T^*, \cdot)\|_\infty = 0$ and

$$\|u_h(T^*, \cdot) - u(T^*, \cdot)\|_\infty \longrightarrow 0 \qquad \text{as } h \longrightarrow 0,$$

we have

$$\limsup_{h \to 0} T_h^* \leq T^*. \tag{3.21}$$

Hence (3.19) follows. □

4. Convergence of numerical interfaces. Let $\{u_h^n\}_{n=0,1,2,\ldots}$ be the numerical solutions given by (2.1) with (3.1). We introduce the set $\boldsymbol{W}$ consisting of all functions $\varphi(x)$ which satisfy Condition B and the following conditions:

(i) $(\varphi^{m-1})_x(x)$ is absolutely continuous on $\boldsymbol{I} \equiv \operatorname{supp} \varphi$;

(ii) $\operatorname{ess.inf}_{x \in \boldsymbol{I}} (\varphi^{m-1})_{xx}(x)$ is finite.

Since $\varphi(x) \in \boldsymbol{W}$ has compact support, it is clear that $\operatorname{ess.inf}_{x \in \boldsymbol{I}} (\varphi^{m-1})_{xx}(x)$ is negative.

For $v^0(x) \in \boldsymbol{W}$ we put

$$C_0 = \|u^0\|_\infty, \quad C_1 = \|u_x^0\|_\infty, \quad C_2 = -\operatorname*{ess.inf}_{x \in \boldsymbol{I}} u_{xx}^0(x), \tag{4.1}$$

where $u^0(x) = (v^0(x))^{m-1}$ and $\boldsymbol{I} = \operatorname{supp} v^0$, and define the left (resp., right) numerical interface $\ell_h(t)$ (resp., $r_h(t)$) by piecewise linearly interpolating (t_n, ℓ_n) (resp., (t_n, r_n)) $(0 \leq n \leq n^*)$. Then we obtain the following theorem, which plays an important role in proving the convergence of numerical interfaces and in finding the behavior of the support.

THEOREM 4.1. *For $v^0(x) \in \boldsymbol{W}$, assume that M and ε are positive constants satisfying*

$$u_x^0(x) > M \qquad \text{for } x \in [\ell(u^0), \ell(u^0) + \varepsilon). \tag{4.2}$$

Let the time step k_{n+1} $(n \geq 0)$ satisfy (2.17) *with $i = L$. Then the following estimates hold for each positive constant $M' < M$:*

$$\delta u_{L_0 - 1}^0, \quad \delta u_{L_0}^0, \quad \delta u_{L_0 + 1}^0 > M' \qquad \text{for} \quad h < \tilde{h}, \tag{4.3}$$

$$\delta u_{L_{n+1,s} - 1}^{n+1,s}, \quad \delta u_{L_{n+1,s}}^{n+1,s}, \quad \delta u_{L_{n+1,s} + 1}^{n+1,s} > M' (s = 0, 1, \ldots, \nu_{n+1}) \tag{4.4}$$

$$\text{for} \quad t_{n+1} \leq \tilde{T} \quad \text{and} \quad h < \tilde{h},$$

$$\delta u_{L_{n+1} - 1}^{n+1}, \quad \delta u_{L_{n+1}}^{n+1}, \quad \delta u_{L_{n+1} + 1}^{n+1} > M' \qquad \text{for} \quad t_{n+1} \leq \tilde{T} \quad \text{and} \quad h < \tilde{h}, \tag{4.5}$$

where $u_i^{n+1,s}$ $(s = 0, 1, \ldots, \nu_{n+1})$ are defined by (2.10), *and*

$$\tilde{T} = \frac{(M - M')M'}{2(2a + m)C_1 C_2 M' + 6c' C_2}, \qquad \tilde{h} = \min\left(\varepsilon, \frac{M - M'}{4C_2}\right). \tag{4.6}$$

Proof. In order to prove the theorem, we need Lemma 4.2, the proof of which is stated after the proof of this theorem.

LEMMA 4.2. *Let $v^0(x) \in \boldsymbol{W}$ and (2.17) with $i = L$ be satisfied. Then,*

$$\delta u^{n+1,0}_{L_{n+1,0}-1} \geq \delta u^{n}_{L_n-1} - 2C_2h, \tag{4.7}$$

$$\delta u^{n+1,s}_{L_{n+1,s}-1} \geq \delta u^{n+1,0}_{L_{n+1,0}-1} - C_2h - 2aC_1C_2\sum_{j=1}^{s}\tau_{n+1,j} \quad (s = 1, 2, \ldots, \nu_{n+1}), \tag{4.8}$$

$$\delta u^{n+1,\cdot,q}_{L_{n+1,\cdot,q}-1} \geq \delta u^{n+1,\cdot,0}_{L_{n+1,\cdot,0}-1} - mC_1C_2\,q\kappa_{n+1} \quad (q = 1, 2, \ldots, \mu_{n+1}) \tag{4.9}$$

for all $n \geq 0$, where $u_i^{n+1,\cdot,q}$ $(q = 0, 1, \ldots, \mu_{n+1})$ are given by (2.12).

Now we prove the theorem. It follows from (4.1), (4.2), and (4.6) that

$$\delta u^0_{L_0-1} > M > M' \qquad \text{for } h < \tilde{h}, \tag{4.10}$$

$$\delta u^0_{L_0} = \delta u^0_{L_0-1} + \frac{h + L_0h - \ell_0}{2}\delta^2 u^0_{L_0} > M - C_2h > M' \qquad \text{for } h < \tilde{h}, \tag{4.11}$$

$$\delta u^0_{L_0+1} = \delta u^0_{L_0} + h\delta^2 u^0_{L_0+1} > M - 2C_2h > M' \qquad \text{for } h < \tilde{h}, \tag{4.12}$$

which implies (4.3).

We note that (4.4) is shown in the proof of (4.5) and that the following estimates hold by Lemma 5.1 in [21] and the inequality $\inf_{i\in\boldsymbol{Z}}\delta^2 u_i \leq \inf_{i\in\boldsymbol{Z}}\delta^2 u'_i$ $(u'_h = D_{h,k}u_h)$ in the proof of Theorem 2.1:

$$\delta^2 u_i^n, \delta^2 u_i^{n+1,s}\ (s = 0, 1, \ldots, \nu_{n+1}), \delta^2 u_i^{n+1,\cdot,q}\ (q = 1, 2, \ldots, \mu_{n+1}) \geq -C_2 \quad \text{for all } i \in \boldsymbol{Z} \quad \text{and} \quad n \geq 0. \tag{4.13}$$

By Lemma 4.2 and (4.13) we have

$$\begin{aligned}
\delta u^{n+1,0}_{L_{n+1,0}+i} &\geq \delta u^{n}_{L_n-1} - 2C_2h - (i+1)C_2h \\
&\geq \delta u^{n,\cdot,0}_{L_{n,\cdot,0}-1} - mC_1C_2k_n - 2C_2h - (i+1)C_2h \\
&\geq \delta u^{n,0}_{L_{n,0}-1} - (2a+m)C_1C_2k_n - 3C_2h - (i+1)C_2h \\
&\geq \delta u^{1,0}_{L_{1,0}-1} - (2a+m)C_1C_2t_n - 3C_2nh - (i+1)C_2h \\
&\geq \delta u^{0}_{L_0-1} - (2a+m)C_1C_2t_n - 3C_2nh - 2C_2h - (i+1)C_2h \quad \text{for } n \geq 0,
\end{aligned} \tag{4.14}$$

$$\begin{aligned}
\delta u^{n+1,s}_{L_{n+1,s}+i} &\geq \delta u^{n+1,0}_{L_{n+1,0}-1} - C_2h - 2aC_1C_2k_{n+1} - (i+1)C_2h \\
&\geq \delta u^{0}_{L_0-1} - (2a+m)C_1C_2t_n - 2aC_1C_2k_{n+1} \\
&\quad - 3C_2(n+1)h - (i+1)C_2h \quad (s = 1, 2, \ldots, \nu_{n+1}) \quad \text{for } n \geq 0,
\end{aligned} \tag{4.15}$$

$$\begin{aligned}
\delta u^{n+1}_{L_{n+1}+i} &\geq \delta u^{n+1,\cdot,\mu_{n+1}}_{L_{n+1,\cdot,\mu_{n+1}}-1} - (i+1)C_2h \\
&\geq \delta u^{n+1,\cdot,0}_{L_{n+1,\cdot,0}-1} - mC_1C_2k_{n+1} - (i+1)C_2h \\
&\geq \delta u^{0}_{L_0-1} - (2a+m)C_1C_2t_{n+1} - 3C_2(n+1)h - (i+1)C_2h \quad \text{for } n \geq 0,
\end{aligned} \tag{4.16}$$

where $i = -1, 0, 1$.

Let us prove (4.5) by induction on n $(n \geq 0)$. Let $n = 0$. Since (4.3) and (2.17) with $i = L$ yield

$$hM' < c'k_1 = u^0_{L_0+1}, \tag{4.17}$$

we have from (4.2), (4.6), and (4.14)–(4.16)

$$\begin{aligned}
&\min(\delta u^{1,0}_{L_{1,0}+i}, \delta u^{1,1}_{L_{1,1}+i}, \ldots, \delta u^{1,\nu_1}_{L_{1,\nu_1}+i},\ \delta u^{1}_{L_1+i}) \\
&\quad > M - (2a+m)C_1C_2t_1 - \frac{3c'C_2k_1}{M'} - \frac{M-M'}{2} \geq M' \quad (i = -1, 0, 1),
\end{aligned} \tag{4.18}$$

which implies (4.4) and (4.5) with $n = 0$.

Suppose that (4.5) holds for all $n-1$ ($n \geq 1$). Then we have from (2.17) with $i = L$

$$hM' < c'k_{j+1} = u^j_{L_j+1} \quad (j = 0, 1, \ldots, n). \tag{4.19}$$

Hence, by (4.2), (4.6), and (4.14)–(4.16)

$$\begin{aligned} &\min(\delta u^{n+1,0}_{L_{n+1,0}+i}, \delta u^{n+1,1}_{L_{n+1,1}+i}, \ldots, \delta u^{n+1,\nu_{n+1}}_{L_{n+1,\nu_{n+1}}+i}, \delta u^{n+1}_{L_{n+1}+i}) \\ &\quad > M - (2a+m)C_1C_2t_{n+1} - 3C_2\sum_{j=0}^{n}\frac{c'k_{j+1}}{M'} - \frac{M-M'}{2} \\ &\quad = M - \Big\{(2a+m)C_1C_2 + \frac{3c'C_2}{M'}\Big\}t_{n+1} - \frac{M-M'}{2} \geq M' \quad (i = -1, 0, 1), \end{aligned} \tag{4.20}$$

which shows that (4.4) and (4.5) hold for n. Thus the induction on n is complete, and the theorem is proved. □

Proof of Lemma 4.2. For simplicity we put

$$\begin{aligned} &u^{\cdot,s}_h = u^{n+1,s}_h, \quad u^{\cdot,\cdot,q}_h = u^{n+1,\cdot,q}_h, \ \kappa = \kappa_{n+1}, \quad \tau_j = \tau_{n+1,j}, \\ &L_{\cdot,s} = L_{n+1,s}, \quad L_{\cdot,\cdot,q} = L_{n+1,\cdot,q}, \ell_{\cdot,s} = \ell_{n+1,s}, \quad \ell_{\cdot,\cdot,q} = \ell_{n+1,\cdot,q}. \end{aligned}$$

We first show (4.7) and (4.9). From (2.17) and (4.13) it follows that

$$\delta u^{\cdot,0}_{L_{\cdot,0}-1} \geq \begin{cases} \delta u^n_{L_n+1} \geq \delta u^n_{L_n-1} - 2C_2h & \text{if} \quad \delta u^n_{L_n} \geq 0, \\ 0 \geq \delta u^n_{L_n} \geq \delta u^n_{L_n-1} - C_2h & \text{if} \quad \delta u^n_{L_n} < 0, \end{cases}$$

which yields (4.7). From (2.24) we have

$$u^{\cdot,\cdot,q}_{L_{\cdot,\cdot,q}} = u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}} + \kappa m u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}}\delta^2 u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}}.$$

Since

$$\begin{aligned} &u^{\cdot,\cdot,q}_{L_{\cdot,\cdot,q}} = (L_{\cdot,\cdot,q}h - \ell_{\cdot,\cdot,q})\delta u^{\cdot,\cdot,q}_{L_{\cdot,\cdot,q}-1}, \quad u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}} = (L_{\cdot,\cdot,q-1}h - \ell_{\cdot,\cdot,q-1})\delta u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}-1}, \\ &\ell_{\cdot,\cdot,q} = \ell_{\cdot,\cdot,q-1} = \ell_{\cdot,\cdot,0}, \qquad\qquad L_{\cdot,\cdot,q} = L_{\cdot,\cdot,q-1} = L_{\cdot,\cdot,0}, \end{aligned}$$

we obtain

$$\delta u^{\cdot,\cdot,q}_{L_{\cdot,\cdot,q}-1} \geq \delta u^{\cdot,\cdot,q-1}_{L_{\cdot,\cdot,q-1}-1} - mC_1C_2\,\kappa \geq \delta u^{\cdot,\cdot,0}_{L_{\cdot,\cdot,0}-1} - mC_1C_2\,q\kappa, \tag{4.21}$$

which shows (4.9).

Next we show (4.8). By using the expression (2.21) we obtain

$$\delta u^{\cdot,s}_{L_{\cdot,s}-1} \geq \min(\delta u^{\cdot,s-1}_{L_{\cdot,s-1}-1},\ \delta u^{\cdot,s-1}_{L_{\cdot,s-1}}) \ (s = 1, 2, \ldots, \nu_{n+1}), \tag{4.22}$$

$$\delta u^{\cdot,s}_{L_{\cdot,s}} \geq \min(\delta u^{\cdot,s-1}_{L_{\cdot,s-1}-1},\ \delta u^{\cdot,s-1}_{L_{\cdot,s-1}} - 2aC_1C_2\tau_s) \ (s = 1, 2, \ldots, \nu_{n+1}). \tag{4.23}$$

For $s = 1$ we have from (4.22) and (4.13)

$$\delta u^{\cdot,1}_{L_{\cdot,1}-1} \geq \delta u^{\cdot,0}_{L_{\cdot,0}-1} - C_2h. \tag{4.24}$$

For $2 \le s \le \nu_{n+1}$ it follows from (4.22), (4.23), and (4.13) that

$$
\begin{aligned}
(4.25)\qquad \delta u^{\cdot,s}_{L_\cdot,s-1} &\ge \min(\delta u^{\cdot,s-1}_{L_\cdot,s-1-1},\ \delta u^{\cdot,s-2}_{L_\cdot,s-2-1},\ \delta u^{\cdot,s-2}_{L_\cdot,s-2} - 2aC_1C_2\tau_{s-1}) \\
&\ge \min\big(\delta u^{\cdot,s-1}_{L_\cdot,s-1-1},\ \delta u^{\cdot,s-2}_{L_\cdot,s-2-1},\ \delta u^{\cdot,s-3}_{L_\cdot,s-3-1} - 2aC_1C_2\tau_{s-1}, \\
&\qquad \delta u^{\cdot,s-4}_{L_\cdot,s-4-1} - 2aC_1C_2(\tau_{s-1}+\tau_{s-2}),\dots, \\
&\qquad \delta u^{\cdot,0}_{L_\cdot,0-1} - 2aC_1C_2(\tau_{s-1}+\tau_{s-2}+\cdots+\tau_2), \\
&\qquad \delta u^{\cdot,0}_{L_\cdot,0} - 2aC_1C_2(\tau_{s-1}+\tau_{s-2}+\cdots+\tau_1)\big) \\
&\ge \min(\delta u^{\cdot,0}_{L_\cdot,0-1},\ \delta u^{\cdot,0}_{L_\cdot,0}) - 2aC_1C_2(\tau_{s-1}+\tau_{s-2}+\cdots+\tau_1) \\
&\ge \delta u^{\cdot,0}_{L_\cdot,0-1} - C_2h - 2aC_1C_2(\tau_1+\tau_2+\cdots+\tau_s).
\end{aligned}
$$

Hence the desired inequality (4.8) holds by (4.24) and (4.25), which completes the proof. □

From Theorem 4.1 we have the following theorem.

THEOREM 4.3 (convergence of the left numerical interface). *Let the assumptions of Theorem* 4.1 *be satisfied. Then the left numerical interface $\ell_h(t)$ converges uniformly to the exact one on $[0,\tilde{T}]$ for each positive constant $M' < M$, where $\tilde{T}$ is given by* (4.6).

Proof. Since by Theorem 4.1

$$0 < u^n_{L_n} < u^n_{L_n+1} < u^n_{L_n+2} \qquad \text{for all } t_n \le \tilde{T},$$

it follows from Theorem 2.1 and (2.17) with $i = L$ that

$$
\begin{aligned}
\ell_{n+1} - \ell_n &= \frac{u^n_{L_n}}{\delta u^n_{L_n-1}} + \frac{c'k_{n+1} - u^n_{L_n}}{\delta u^n_{L_n}} - \sum_{s=1}^{\nu_{n+1}} a\delta u^{n+1,s-1}_{L_{n+1,s-1}-1}\tau_{n+1,s} \\
&\begin{cases} > -a\|u^0_x\|_\infty k_{n+1} & \text{for } t_{n+1} \in [0,\tilde{T}], \\ < \dfrac{c'k_{n+1}}{M'} & \text{for } t_{n+1} \in [0,\tilde{T}], \end{cases}
\end{aligned}
$$

which gives

$$|\dot{\ell}_h(t)| \le \max\Big(a\|u^0_x\|_\infty,\ \frac{c'}{M'}\Big) \qquad \text{for } t \in [0,\tilde{T}]. \tag{4.26}$$

From (2.27) we have

$$\ell_0 - a\|u^0_x\|_\infty\tilde{T} \le \ell_h(t) \le r_0 + a\|u^0_x\|_\infty\tilde{T} \qquad \text{for } t \in [0,\tilde{T}]. \tag{4.27}$$

By (4.26) and (4.27) we can apply Ascoli–Arzelà's theorem to the sequence $\{\ell_h\}$. Thus there exist a Lipschitz continuous function $\tilde{\ell}(t)$ and a subsequence $\{\ell_{h'}\}$ satisfying

$$\|\ell_{h'} - \tilde{\ell}\|_{L^\infty([0,\tilde{T}])} \longrightarrow 0 \quad \text{as} \quad h' \to 0. \tag{4.28}$$

Now we show that $\tilde{\ell}(t)$ is the left interface of the weak solution v of (1.1)–(1.2). For simplicity we use h instead of h'.

Let $t^* \in [0,\tilde{T}]$. Then there exist integers n and L_n such that $t_n \le t^* < t_{n+1}$ and $(L_n-1)h \le \ell_h(t_n) < L_nh$, which imply

$$u_h(t^*, (L_n-1)h - \xi) = 0 \qquad \text{for any positive number } \xi. \tag{4.29}$$

For each fixed $\eta \in (0, \frac{M'}{C_2})$ let p be the positive integer satisfying $(p-1)h \le \eta < ph$. Then we have

$$
\begin{aligned}
(4.30)\ u_h(t^*, (L_n+p)h) &> h \sum_{i=L_n}^{L_n+p-1} \delta u_i^n = h \sum_{j=0}^{p-1} \left\{ \delta u_{L_n-1}^n + \sum_{i=L_n}^{L_n+j} (\delta u_i^n - \delta u_{i-1}^n) \right\} \\
&\ge ph\delta u_{L_n-1}^n - h \sum_{j=0}^{p-1} (j+1) C_2 h = ph\Big\{ \delta u_{L_n-1}^n - \frac{(p-1)C_2 h}{2} - C_2 h \Big\} \\
&> \eta\Big(M' - \frac{C_2\eta}{2} - C_2 h \Big) > \frac{\eta(M' - 2C_2 h)}{2} > \frac{\eta M'}{4} \quad \text{for} \ \ h < \frac{M'}{4C_2}.
\end{aligned}
$$

Since u_h converges uniformly to $u = v^{m-1}$ on $\mathcal{H}$ by Theorems 3.1 and 3.2, we have from (4.29) and (4.30)

$$
u(t^*, \tilde{\ell}(t^*) - \xi) = 0 \quad \text{for any positive number } \xi, \tag{4.31}
$$

$$
u(t^*, \tilde{\ell}(t^*) + \eta) \ge \frac{\eta M'}{4} \quad \text{for each } \eta \in \Big(0, \frac{M'}{C_2}\Big). \tag{4.32}
$$

Hence, $\tilde{\ell}(t)$ becomes the left interface on $[0, \tilde{T}]$. Since the left interface is uniquely determined, $\ell_h(t)$ converges to it on $[0, \tilde{T}]$ as the whole sequence $\{h\}$ tends to zero. Thus the proof is complete. □

Remark 4.1. Taking the statement of Theorems 4.1 and 4.3 into consideration, we can easily obtain the convergence of the right numerical interface.

Remark 4.2. When $\operatorname{supp} u^0$ is concave downward on its support, the convergence of v_h, ℓ_h, r_h, and T_h^* is shown by Nakaki (see Theorems 4.2, 4.3, and 5.2 in [22]).

5. Behavior of the support. In this section we consider the possibility that the support will split in Cases 1 and 2 stated in section 1. We obtain the following theorem in Case 1, which improves Kersner's result [15]. To state it we put

$$
w_1^0(x) = \begin{cases} v^0(x) & \text{if } x \le \alpha_0, \\ 0 & \text{if } x > \alpha_0, \end{cases} \qquad w_2^0(x) = \begin{cases} 0 & \text{if } x \le \alpha_0, \\ v^0(x) & \text{if } x > \alpha_0. \end{cases} \tag{5.1}
$$

THEOREM 5.1. *In Case* 1, *assume* $w_j^0(x) \in \boldsymbol{W}$ $(j = 1, 2)$. *Put* $W_j(x) = (w_j^0)^{m-1}(x)$ $(j = 1, 2)$. *Suppose*

$$
a\left((W_1)_x(\alpha_0 - 0)\right)^2 \quad \text{and} \quad a\left((W_2)_x(\alpha_0 + 0)\right)^2 > c'. \tag{5.2}
$$

Then there exist a constant $\tilde{T} > 0$ *such that* $\operatorname{supp} v(t, \cdot)$ *is connected for each* $t \in [0, \tilde{T}]$.

Suppose

$$
a\|(W_j)_x\|_\infty^2 < c' \quad (j = 1, 2). \tag{5.3}
$$

Then $\operatorname{supp} v(t, \cdot)$ *is disconnected for each* $t \in (0,\ T_*)$, *where* $T_* = \min(T_1^*, T_2^*)$ *and* T_1^* *and* T_2^* *are the extinction times of the solutions of* (1.1)–(1.2) *with* $v^0(x) = w_1^0(x)$ *and* $v^0(x) = w_2^0(x)$, *respectively.*

Proof. Let $\tilde{\ell}(t)$ and $\{u_h^n\}_{n=0,1,2,\dots}$ be the left interface of the solution v of (1.1)–(1.2) with $v^0(x) = w_2^0(x)$ and the numerical solutions given by (2.1) with (3.1), respectively, where (2.17) with $i = L$ is satisfied and $\tilde{\ell}(0) = \alpha_0$.

We show the first assertion of the theorem. We take arbitrary positive constants K_1 and K_1' such that

$$
\Big(\frac{c'}{a}\Big)^{\frac{1}{2}} < K_1' < K_1 < (W_2)_x(\alpha_0 + 0). \tag{5.4}
$$

By applying Theorem 4.1 to the initial function $v^0(x) = w_2^0(x)$ with the positive constants $M = K_1$ and $M' = K_1'$, we have

$$\delta u_{L_n-1}^n, \quad \delta u_{L_n}^n, \quad \delta u_{L_n+1}^n > K_1' \quad \text{for } t_n \le \tilde{T}_1 \text{ and } h < \tilde{h}, \tag{5.5}$$

$$\delta u_{L_{n+1,s}-1}^{n+1,s}, \quad \delta u_{L_{n+1,s}}^{n+1,s}, \quad \delta u_{L_{n+1,s}+1}^{n+1,s} > K_1' \quad (s = 0, 1, \dots, \nu_{n+1}) \quad \text{for } t_{n+1} \le \tilde{T}_1 \text{ and } h < \tilde{h}, \tag{5.6}$$

where $\tilde{T}_1$ and $\tilde{h}$ are some positive constants. Hence, it follows from (2.15), (2.17) with $i = L$, and (2.22) that

$$\begin{aligned} \ell_{n+1} &= \ell_n + \frac{u_{L_n}^n}{\delta u_{L_n-1}^n} + \frac{c' k_{n+1} - u_{L_n}^n}{\delta u_{L_n}^n} - \sum_{s=1}^{\nu_{n+1}} a \delta u_{L_{n+1,s-1}-1}^{n+1,s-1} \tau_{n+1,s} \\ &< \ell_n + \frac{c' k_{n+1}}{K_1'} - a K_1' k_{n+1} \\ &< \ell_0 - \frac{1}{K_1'}(a K_1'^2 - c') t_{n+1} < \ell_0 = \alpha_0 \qquad \text{for } t_{n+1} \in (0, \tilde{T}_1], \end{aligned} \tag{5.7}$$

which gives

$$\ell_h(t) < \alpha_0 - \frac{1}{K_1'}(a K_1'^2 - c') t < \alpha_0 \qquad \text{for } t \in (0, \tilde{T}_1].$$

From the convergence of $\ell_h(t)$ we have

$$\tilde{\ell}(t) \le \alpha_0 - \frac{1}{K_1'}(a K_1'^2 - c') t < \alpha_0 \qquad \text{for } t \in (0, \tilde{T}_1]. \tag{5.8}$$

Taking arbitrary positive constants K_2 and K_2' such that

$$\left(\frac{c'}{a}\right)^{\frac{1}{2}} < K_2' < K_2 < -(W_1)_x(\alpha_0 - 0), \tag{5.9}$$

we can similarly obtain

$$\tilde{r}(t) \ge \alpha_0 + \frac{1}{K_2'}(a K_2'^2 - c') t > \alpha_0 \qquad \text{for } t \in (0, \tilde{T}_2], \tag{5.10}$$

where $\tilde{r}(t)$ is the right interface of the solution v of (1.1)–(1.2) with $v^0(x) = w_1^0(x)$, $\tilde{r}(0) = \alpha_0$, and $\tilde{T}_2$ is some positive constant. Put $T' = \min(\tilde{T}_1, \tilde{T}_2)$. Then we have from (5.8), (5.10), and the comparison theorem on the initial data (see [2])

$$v(t, \alpha_0) > 0 \quad \text{for } t \in (0, T']. \tag{5.11}$$

Hence, the continuity of $v(t, x)$ yields the existence of a positive constant $\tilde{T} (< T')$ such that $\operatorname{supp} v(t, \cdot)$ is connected for each $t \in [0, \tilde{T}]$.

We prove the second assertion of the theorem. Let K_3 be an arbitrary positive constant satisfying

$$\|(W_j)_x\|_\infty < K_3 < \left(\frac{c'}{a}\right)^{\frac{1}{2}} \quad (j = 1, 2). \tag{5.12}$$

By Lemma 3.1 in [21] and Theorem 2.1 we have

$$\|\delta u_i^n\|_\infty, \|\delta u_i^{n+1,s}\|_\infty < K_3 \ (i \in \boldsymbol{Z}, s = 0, 1, \dots, \nu_{n+1}) \text{ for } t_{n+1} \in (0, T_2^*]. \tag{5.13}$$

Then, it follows from (2.15), (2.17) with $i = L$, and (2.22) that

$$\begin{aligned}(5.14)\qquad \ell_{n+1} &\geq \ell_n + \frac{c'k_{n+1}}{\max(\delta u^n_{L_n}, \delta u^n_{L_n-1})} - \sum_{s=1}^{\nu_{n+1}} a\delta u^{n+1,s-1}_{L_{n+1,s-1}-1}\tau_{n+1,s} \\ &> \ell_n + \frac{c'k_{n+1}}{K_3} - aK_3k_{n+1} \\ &> \ell_0 + \frac{1}{K_3}(c' - aK_3^2)t_{n+1} > \ell_0 = \alpha_0 \qquad \text{for } t_{n+1} \in (0, T_2^*],\end{aligned}$$

which immediately yields

$$(5.15)\qquad \tilde{\ell}(t) \geq \alpha_0 + \frac{1}{K_3}(c' - aK_3^2)t > \alpha_0 \qquad \text{for } t \in (0, T_2^*].$$

Similarly, we have

$$(5.16)\qquad \tilde{r}(t) \leq \alpha_0 - \frac{1}{K_3}(c' - aK_3^2)t < \alpha_0 \qquad \text{for } t \in (0, T_1^*].$$

Hence $\operatorname{supp} v(t,\cdot)$ becomes disconnected for $t \in (0, T_*)$, which completes the proof. □

Remark 5.1. The first assertion of Theorem 5.1 holds, when the orders of vanishing of $(w_j^0(x))^{m-1}$ $(j = 1, 2)$ at $x = \alpha_0$ are less than 1. This result also coincides with the one given by Kersner (see Theorem 2 in [15]).

Remark 5.2. Let us consider the sufficient condition under which $v(t, \alpha_0) = 0$ holds for all $t \geq 0$. Put

$$(5.17)\qquad v^0(x) = \begin{cases} A_1\{(\alpha_1 - x)(x - \alpha_0)\}^{\frac{s}{m-1}} & \text{if } \alpha_1 \leq x \leq \alpha_0, \\ A_2\{(\alpha_0 - x)(x - \alpha_2)\}^{\frac{s}{m-1}} & \text{if } \alpha_0 \leq x \leq \alpha_2, \\ 0 & \text{otherwise,} \end{cases}$$

where $s = 1 + \varepsilon$ $(\varepsilon \geq 0)$ and A_j $(j = 1, 2)$ are positive constants. According to Theorem 1 in [15], Kersner's sufficient condition is

$$(5.18)\quad 4A_j^{2(m-1)}\left(\frac{|\alpha_0 - \alpha_j|}{2}\right)^{2+4\varepsilon}(1+\varepsilon)(1+m\varepsilon) < \frac{c(m-1)^2}{m} \quad (j = 1, 2).$$

Our sufficient condition (5.3) yields

$$(5.19)\quad 4A_j^{2(m-1)}\left(\frac{|\alpha_0 - \alpha_j|}{2}\right)^{2+4\varepsilon}\left(\frac{2\varepsilon}{1+2\varepsilon}\right)^{2\epsilon}\frac{(1+\varepsilon)^2}{1+2\varepsilon} < \frac{c(m-1)^2}{m} \quad (j = 1, 2).$$

For $\varepsilon = 0$ his sufficient condition coincides with ours. For $\varepsilon > 0$ we find that the condition imposed on A_j $(j = 1, 2)$ by (5.19) is weaker than that imposed by (5.18).

We show a sufficient condition under which the support begins to split into at least two disjoint sets.

THEOREM 5.2. *In Case* 2, *let* $v^0(x) \in \boldsymbol{W}$ *and* $\alpha_1 < \beta_1 < \gamma_1 < \gamma_2 < \beta_2 < \alpha_2$. *Assume*

$$(5.20)\qquad \frac{u^0(\beta_j)}{c' + mC_0C_2} > \frac{\|u^0\|_{L^1[\gamma_1,\gamma_2]}}{c'(\gamma_2 - \gamma_1) - (m+a)C_0TV(u_x^0)} > 0 \quad (j = 1, 2),$$

where $u^0(x) = (v^0(x))^{m-1}$ *and* C_j $(j = 0, 2)$ *are constants given by* (4.1). *Then there exist* $\tilde{t} > 0$ *and* $\tilde{x} \in [\gamma_1, \gamma_2]$ *such that*

$$v(\tilde{t}, \tilde{x}) = 0 \quad \textit{and} \quad v(\tilde{t}, \beta_j) > 0 \quad (j = 1, 2). \tag{5.21}$$

Also, if $u^0(x)$ *satisfies*

$$a\|u_x^0\|_\infty^2 < c', \tag{5.22}$$

then there exists a positive constant t^* *such that supp* $v(t, \cdot)$ *is disconnected for each* $t \in (\tilde{t}, \tilde{t} + t^*)$.

Proof. Let $\{u_h^n\}_{n=0,1,2,\dots}$ and u_h be the numerical solutions given by (2.1) with (3.1) and by (3.2), respectively. Put

$$T_j = \frac{u^0(\beta_j)}{c' + mC_0C_2} \quad (j = 1, 2), \quad \tilde{T} = \frac{\|u^0\|_{L^1[\gamma_1,\gamma_2]}}{c'(\gamma_2 - \gamma_1) - (m + a)C_0TV(u_x^0)}, \tag{5.23}$$

$$T' = \tilde{T} + \frac{1}{4}\{\min(T_1, T_2) - \tilde{T}\}, \quad T'' = \tilde{T} + \frac{1}{2}\{\min(T_1, T_2) - \tilde{T}\}, \tag{5.24}$$

$$\boldsymbol{S} = [0, T''] \times [\gamma_1, \gamma_2]. \tag{5.25}$$

We first show that $\boldsymbol{S}$ contains at least one point $(\tilde{t}, \tilde{x})$ such that $v(\tilde{t}, \tilde{x}) = 0$. For this end we assume the contrary; that is, suppose the solution $v(t, x)$ is positive on $\boldsymbol{S}$. Since $(u_h)^{1/(m-1)}$ converges uniformly to the solution v on $\boldsymbol{S}$ by Theorem 3.2, there exists a positive number $h'(\eta)$ for the constant $\eta \equiv \frac{1}{2}\min_{(t,x)\in\boldsymbol{S}} u(t, x) > 0$ such that

$$u_h^n(x) - c'k_{n+1} \ge u_h(t_n, x) - 2\|u_x^0\|_\infty h > \eta \quad \text{for} \quad (t_{n+1}, x) \in \boldsymbol{S} \quad \text{and} \quad h < h'(\eta). \tag{5.26}$$

Here we use the inequality $c'k_{n+1} \le 2\|u_x^0\|_\infty h$ which follows from (2.17). Then we have from Lemmas 3.1 and 3.2 in [21] and Theorem 2.1 that

$$\begin{aligned}
\|u_h^{n+1}\|_{L^1[\gamma_1,\gamma_2]} &\le \left\| u_h^{n+1} - \left(\prod_{j=1}^{\nu} H_{h,\tau_j} \right) D_{h,k_{n+1}} u_h^n \right\|_{L^1[\gamma_1,\gamma_2]} \\
&\quad + \left\| \left(\prod_{j=1}^{\nu} H_{h,\tau_j} \right) D_{h,k_{n+1}} u_h^n - D_{h,k_{n+1}} u_h^n \right\|_{L^1[\gamma_1,\gamma_2]} + \|D_{h,k_{n+1}} u_h^n\|_{L^1[\gamma_1,\gamma_2]} \\
&\le mC_0TV(u_x^0)k_{n+1} + aC_0TV(u_x^0)k_{n+1} + \|u_h^n\|_{L^1[\gamma_1,\gamma_2]} - c'(\gamma_2 - \gamma_1)k_{n+1} \\
&\le \|u_h^0\|_{L^1[\gamma_1,\gamma_2]} - \{c'(\gamma_2 - \gamma_1) - (m + a)C_0TV(u_x^0)\}t_{n+1} \\
&= \|u_h^0\|_{L^1[\gamma_1,\gamma_2]} - \|u^0\|_{L^1[\gamma_1,\gamma_2]} + \left(1 - \frac{t_{n+1}}{\tilde{T}}\right)\|u^0\|_{L^1[\gamma_1,\gamma_2]} \\
&\qquad \text{for} \quad t_{n+1} \in (0, T''] \quad \text{and} \quad h < h'(\eta).
\end{aligned} \tag{5.27}$$

Since $T' > \tilde{T}$, we have

$$\|u_h^{n+1}\|_{L^1[\gamma_1,\gamma_2]} < 0 \qquad \text{for } t_{n+1} \in (T', T''] \text{ and for sufficiently small } h, \tag{5.28}$$

which is a contradiction. Hence we obtain

$$u(\tilde{t},\ \tilde{x}) = 0 \quad \text{for some} \quad (\tilde{t}, \tilde{x}) \in \boldsymbol{S}. \tag{5.29}$$

Next, we have

$$
\begin{aligned}
(5.30)\quad u_h^{n+1}(\beta_j) &= \left(u_h^{n+1} - \left(\prod_{j=1}^{\nu} H_{h,\tau_j}\right) D_{h,k_{n+1}} u_h^n\right)(\beta_j) \\
&\quad + \left(\left(\prod_{j=1}^{\nu} H_{h,\tau_j}\right) D_{h,k_{n+1}} u_h^n - D_{h,k_{n+1}} u_h^n\right)(\beta_j) + (D_{h,k_{n+1}} u_h^n)(\beta_j) \\
&\geq -mC_0C_2k_{n+1} + u_h^n(\beta_j) - c'k_{n+1} \geq u_h^0(\beta_j) - (c' + mC_0C_2)t_{n+1} \\
&\geq u_h^0(\beta_j) - u^0(\beta_j) + (c' + mC_0C_2)(T_j - T'') \quad \text{for } t_{n+1} \in [0, T''] \ (j = 1, 2).
\end{aligned}
$$

Letting $h \to 0$, we obtain

$$
(5.31)\qquad u(t, \beta_j) \geq (c' + mC_0C_2)(T_j - T'') > 0 \quad \text{for} \quad t \in [0, T''] \quad (j = 1, 2),
$$

which implies

$$
(5.32)\qquad u(\tilde{t},\ \beta_j) > 0 \quad (j = 1, 2).
$$

Thus (5.21) follows from (5.29) and (5.32).

Finally, we show the last assertion of the theorem. Let $w_j(t, x)$ $(j = 1, 2)$ be the solutions of (1.1)–(1.2) with $v^0(x) = w_j^0(x)$ $(j = 1, 2)$, where

$$
(5.33)\qquad w_1^0(x) = \begin{cases} v(\tilde{t}, x) & \text{if } x \leq \tilde{x}, \\ 0 & \text{if } x > \tilde{x}, \end{cases} \qquad w_2^0(x) = \begin{cases} 0 & \text{if } x \leq \tilde{x}, \\ v(\tilde{t}, x) & \text{if } x > \tilde{x}. \end{cases}
$$

Since the solution v is smooth in the open set $\{(t, x);\ v(t, x) > 0\}$, it follows from Theorems 2.1 and 3.2 that $w_j^0(x)$ $(j = 1, 2)$ belong to $\boldsymbol{W}$. Applying the second assertion of Theorem 5.1 to $w_j^0(x)$ $(j = 1, 2)$, we have

$$
(5.34)\qquad r(w_1(t, x)) < \tilde{x} < \ell(w_2(t, x)) \quad \text{for } t \in (0, t^*),
$$

where $t^* = \min(T_1^*, T_2^*)$ and T_1^* and T_2^* are the extinction times of $w_1(t, x)$ and $w_2(t, x)$, respectively. Thus $\operatorname{supp} v(t, \cdot)$ is disconnected for each $t \in (\tilde{t}, \tilde{t} + t^*)$, and the proof is complete. □

Remark 5.3. We briefly explain the construction of the initial function for which (5.20) is satisfied. In Theorem 5.2 we assume

$$
(5.35)\qquad \frac{u^0(\beta_j)}{c' + mC_0C_2} > \frac{\varepsilon}{c'} \quad (j = 1, 2) \quad \text{and} \quad u^0(x) = \varepsilon \text{ on } [\gamma_1, \gamma_2]
$$

instead of (5.20), where ε is a positive constant. For an arbitrary positive number d let

$$
(5.36)\qquad u_d^0(x) = \begin{cases} u^0(x + d) & \text{if} \quad x < \gamma_1 - d, \\ \varepsilon & \text{if} \quad \gamma_1 - d \leq x \leq \gamma_2 + d, \\ u^0(x - d) & \text{if} \quad x > \gamma_2 + d, \end{cases}
$$

and put $C_0(d) = \|u_d^0\|_\infty$ and $C_2(d) = -\operatorname{ess.inf}_{x \in \boldsymbol{I}} (u_d^0)_{xx}(x)$. Since $C_j(d) = C_j$ $(j = 0, 2)$ and $TV((u_d^0)_x) = TV(u_x^0)$, we can choose d sufficiently large so that

$$
(5.37)\qquad \frac{u_d^0(\beta_j + (-1)^j d)}{c' + mC_0(d)C_2(d)} > \frac{\varepsilon}{c' - \frac{(m+a)C_0(d)TV((u_d^0)_x)}{\gamma_2 - \gamma_1 + 2d}} > \frac{\varepsilon}{c'} \quad (j = 1, 2).
$$

Then, by using $\|u_d^0\|_{L^1[\gamma_1-d,\gamma_2+d]} = (\gamma_2-\gamma_1+2d)\varepsilon$, we find that $u_d^0(x)$ satisfies (5.20), where β_j and γ_j $(j=1,2)$ are replaced by $\beta_j+(-1)^j d$ and $\gamma_j+(-1)^j d$ $(j=1,2)$, respectively.

MINIMIZERS OF COST-FUNCTIONS INVOLVING NONSMOOTH DATA-FIDELITY TERMS. APPLICATION TO THE PROCESSING OF OUTLIERS*

MILA NIKOLOVA†

Abstract. We present a theoretical study of the recovery of an unknown vector $x \in \mathbb{R}^p$ (such as a signal or an image) from noisy data $y \in \mathbb{R}^q$ by minimizing with respect to x a regularized cost-function $\mathcal{F}(x, y) = \Psi(x, y) + \alpha\Phi(x)$, where Ψ is a data-fidelity term, Φ is a smooth regularization term, and $\alpha > 0$ is a parameter. Typically, $\Psi(x, y) = \|Ax - y\|^2$, where A is a linear operator. The data-fidelity terms Ψ involved in regularized cost-functions are generally smooth functions; only a few papers make an exception to this and they consider restricted situations. Nonsmooth data-fidelity terms are avoided in image processing. In spite of this, we consider both smooth and nonsmooth data-fidelity terms. Our goal is to capture essential features exhibited by the local minimizers of regularized cost-functions in relation to the smoothness of the data-fidelity term.

In order to fix the context of our study, we consider $\Psi(x, y) = \sum_i \psi(a_i^T x - y_i)$, where a_i^T are the rows of A and ψ is $\mathcal{C}^m$ on $\mathbb{R} \setminus \{0\}$. We show that if $\psi'(0^-) < \psi'(0^+)$, then typical data y give rise to local minimizers $\hat{x}$ of $\mathcal{F}(., y)$ which fit exactly a certain number of the data entries: there is a possibly large set $\hat{h}$ of indexes such that $a_i^T \hat{x} = y_i$ for every $i \in \hat{h}$. In contrast, if ψ is smooth on $\mathbb{R}$, for almost every y, the local minimizers of $\mathcal{F}(., y)$ do not fit any entry of y. Thus, the possibility that a local minimizer fits some data entries is due to the nonsmoothness of the data-fidelity term. This is a strong mathematical property which is useful in practice. By way of application, we construct a cost-function allowing aberrant data (outliers) to be detected and to be selectively smoothed. Our numerical experiments advocate the use of nonsmooth data-fidelity terms in regularized cost-functions for special purposes in image and signal processing.

1. Introduction.

We consider the general problem where a sought vector (e.g., an image or a signal) $\hat{x} \in \mathbb{R}^p$ is obtained from noisy data $y \in \mathbb{R}^q$ by minimizing a regularized cost-function $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ of the form

$$\mathcal{F}(x, y) = \Psi(x, y) + \alpha\Phi(x), \tag{1}$$

where typically $\Psi : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ is a data-fidelity term and $\Phi : \mathbb{R}^p \to \mathbb{R}$ is a regularization term, with $\alpha > 0$ a parameter. In many applications, the relation between x and y is modeled by $y_i = a_i^T x + n_i$ for $i = 1, \ldots, q$, where $a_i^T : \mathbb{R}^p \to \mathbb{R}$ are linear operators and n_i accounts for perturbations. We focus on such situations and assume that a_i^T, $i = 1, \ldots, q$, are known and non-null. The relevant data-fidelity term assumes the form

$$\Psi(x, y) = \sum_{i=1}^{q} \psi_i(a_i^T x - y_i), \tag{2}$$

†CNRS URA820–ENST Dpt. TSI, ENST, 46 rue Barrault, 75013 Paris, France (nikolova@tsi.enst.fr).

where $\psi_i : \mathbb{R} \to \mathbb{R}$, $i = 1, \ldots, q$, are continuous functions which decrease on $(-\infty, 0]$ and increase on $[0, +\infty)$. Usually, $\psi_i = \psi$ for all i. One usual choice is $\psi(t) = |t|^\rho$, for $\rho > 0$, which yields [31, 4]

$$\Psi(x, y) = \sum_{i=1}^{q} |a_i^T x - y_i|^\rho. \tag{3}$$

Let $A \in \mathbb{R}^{q \times p}$ be the matrix whose rows are a_i^T for $i = 1, \ldots, q$. This matrix can be ill-posed, or singular, or invertible. Most often, $\Psi(x, y) = \|Ax - y\|^2$, that is, $\psi(t) = t^2$. Such data-fidelity terms are currently used in denoising, in deblurring, and in numerous inverse problems [37, 35, 13, 33, 1, 14, 38]. In a statistical framework, Ψ accounts for both the distortion and the noise intervening between the original x and the device recording the data y. The above quadratic form of Ψ corresponds to white Gaussian noise $\{n_i\}$. Recall that many papers are dedicated to the minimization of $\Psi(., y)$ *alone* and of the form (3), i.e., $\mathcal{F} = \Psi$, mainly for $\psi(t) = t^2$ [22], in some cases for $\psi(t) = |t|$ [8], but functions $\psi(t) = |t|^\rho$ for different values for ρ in the range $(0, \infty]$ also have been considered [31, 30]. Specific data-fidelity terms arise in applications such as emission and transmission computed tomography, X-ray radiography, eddy-currents evaluation, and many others [23, 20, 34, 10]. In general, for every y, the data-fidelity term $\Psi(., y)$ is a function which is smooth and usually convex. The introduction of nonsmooth data-fidelity terms in regularized cost-functions (1) remains very unusual. Only a few papers make an exception to this; we cite [2, 3], where Ψ corresponds to $\psi(t) = |t|$ and $a_i^T x = x_i$ for all i. Nonsmooth data-fidelity terms Ψ are avoided in image processing, for instance. In spite of this, we analyze the effects produced by both smooth and nonsmooth data-fidelity terms Ψ. In the latter case we suppose that $\{\psi_i\}$ *are any functions which are* $\mathcal{C}^m$*-smooth on* $\mathbb{R} \setminus \{0\}$*,* $m \geq 2$*, whereas at zero they admit finite side derivatives which satisfy* $\psi_i'(0^-) < \psi_i'(0^+)$.

The regularization term Φ usually takes the form

$$\Phi(x) = \sum_{i=1}^{r} \varphi(\|G_i^T x\|), \tag{4}$$

where $G_i^T : \mathbb{R}^p \to \mathbb{R}^s$ for $s \in \mathbb{N}^*$ are linear operators, e.g., operators yielding the differences between neighboring samples; $\|.\|$ stands for a norm on $\mathbb{R}^s$; and $\varphi : \mathbb{R} \to \mathbb{R}$ is a potential function. In a Bayesian estimation framework, Φ is the prior energy of the unknown x modeled using a Markov random field [6, 17, 24]. Several customarily used potential functions φ are [20, 29, 21, 33, 9, 7, 39, 36]

$$\begin{array}{ll}
\mathrm{L}^\nu & \varphi(t) = |t|^\nu,\ 1 \leq \nu \leq 2, \\
\text{Lorentzian} & \varphi(t) = \nu t^2/(1 + \nu t^2), \\
\text{Concave} & \varphi(t) = \nu|t|/(1 + \nu|t|), \\
\text{Gaussian} & \varphi(t) = 1 - \exp(-\nu t^2), \\
\text{Huber} & \varphi(t) = t^2 \text{ if } |t| \leq \nu, \quad \varphi(t) = \nu(\nu + 2|t - \nu|) \text{ if } |t| > \nu, \\
\text{Mean-field} & \varphi(t) = -\log\big(\exp(-\nu t^2) + 1\big),
\end{array} \tag{5}$$

where $\nu > 0$ is a parameter. Being convex and differentiable, the function L^ν for $1 < \nu \leq 2$ is preferred in many applications requiring intensive computation [9, 10]. In our paper, Φ *in* (1) *is any* $\mathcal{C}^m$*-smooth function*, with $m \geq 2$.

The visual aspect of a minimizer of a cost-function is determined on the one hand by the data and on the other hand by the shape of the cost-function. Our goal is to

capture essential features expressed by the local minimizers of cost-functions of the form (1)–(2) in relation to the smoothness of the data-fidelity term Ψ. Note that all our results hold for local minimizers, and hence for global minimizers as well, so we systematically speak of local minimizers. There is a striking distinction in the behavior of the local minimizers relevant to smooth and nonsmooth data-fidelity terms. It concerns the possibility of fitting *exactly* a certain number of the data entries, i.e., that for y given, a local minimizer $\hat{x}$ of $\mathcal{F}(.,y)$ satisfies $a_i^T\hat{x} = y_i$ for some, or even for many, indexes i (see section 2). Intuitively, one is unlikely to obtain such minimizers, especially when data are noisy. *Our main result states that for $\mathcal{F}$ of the form* (1)–(2)*, with Ψ nonsmooth as specified, typical data y give rise to local minimizers $\hat{x}$ which fit a certain number of the data entries; i.e., there is a nonempty set $\hat{h}$ of indexes such that $a_i^T\hat{x} = y_i$ for every $i \in \hat{h}$* (see sections 3 and 4). This effect is due to the nondifferentiability of Ψ since it cannot occur when $\mathcal{F}$ is differentiable (see section 5). The obtained result is a strong mathematical property which can be used in different ways. Based on it, we construct a cost-function allowing aberrant data (outliers) to be detected and to be selectively smoothed from signals, or from images, or from noisy data, while preserving efficiently all the nonaberrant entries (see section 7). This is illustrated using numerical experiments.

Readers may associate cost-functions where Ψ is nonsmooth (e.g., $\psi(t) = |t|$) with cost-functions where Ψ is smooth and Φ is nonsmooth, e.g., $\Psi(x,y) = \|Ax - y\|^2$ and $\varphi(t) = |t|$ in (4), as in total-variation methods [33, 1, 14, 12]. Since the latter methods arouse an increasing interest in the area of image and signal restoration, we compare in section 6 nonsmooth regularization to the cost-functions considered in this paper. To this end, we use some previous results [26, 27] and illustrate the strikingly different visual effects they produce (see section 7).

2. The problem of an exact fit for some data entries. We shall use the symbol $\|.\|$ to denote the ℓ_2-norm of vectors. Next, we denote by $\mathbb{N}^*$ the positive integers and $\mathbb{R}_+ = \{t \in \mathbb{R} : t \geq 0\}$. The letter S will systematically denote the centered, unit sphere in $\mathbb{R}^n$, say $S := \{x \in \mathbb{R}^n : \|x\| = 1\}$, for whatever dimension n is appropriate in the context. For $x \in \mathbb{R}^n$ and $\rho > 0$, we put $B(x,\rho) := \{x' \in \mathbb{R}^n : \|x' - x\| < \rho\}$. For any $i = 1, \ldots, n$ the letter e_i represents the ith vector of the canonical basis of $\mathbb{R}^n$ (i.e., $e_i = e_i[i] = 1$ and $e_i[j] = 0$ for all $j \neq i$). The closure of a set N will be denoted $\overline{N}$. For a subspace T; its orthogonal complement is denoted $T^\perp$. If a function $f : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ depends on two variables, its kth differential with respect to the jth variable is denoted $D_j^k f$. The notation $f \in \mathcal{C}^m(N)$ means that the function f is $\mathcal{C}^m$-smooth on the set N. For a discrete, finite set $h \subset \{1, \ldots, n\}$, with $n \in \mathbb{N}^*$, the symbol $\#h$ is the cardinality of h and h^c is the complementary of h. Next we introduce a set-valued function which is constantly evoked in what follows.

DEFINITION 1. *Let $\mathcal{H}$ be the function which for every $x \in \mathbb{R}^p$ and $y \in \mathbb{R}^q$ yields the following set:*

$$(x,y) \quad \to \quad \mathcal{H}(x,y) = \left\{ i \in \{1, \ldots, q\} : a_i^T x = y_i \right\}. \tag{6}$$

Given y and a local minimizer $\hat{x}$ of $\mathcal{F}(.,y)$, the set of all data entries which are fitted exactly by $\hat{x}$ reads $\hat{h} := \mathcal{H}(\hat{x},y)$. Furthermore, with every $h \subseteq \{1, \ldots, q\}$ we associate the following sets:

$$(h,y) \to \Theta_h(y) := \{x \in \mathbb{R}^p : \ a_i^T x = y_i \ \forall i \in h \text{ and } a_i^T x \neq y_i \ \forall i \in h^c\}, \tag{7}$$

$$h \quad \to \quad T_h := \{u \in \mathbb{R}^p : \ a_i^T u = 0 \ \ \forall\, i \in h\}, \tag{8}$$

$$h \quad \to \quad M_h := \{(x,y) \in \mathbb{R}^p \times \mathbb{R}^q : \ a_i^T x = y_i \ \forall i \in h \text{ and } a_i^T x \neq y_i \ \forall i \in h^c\}. \tag{9}$$

Note that for every y and $h \neq \emptyset$, the sets $\Theta_h(y)$ and M_h are composed of a finite number of connected components, whereas their closures $\overline{\Theta_h(y)}$ and $\overline{M_h}$, respectively, are affine subspaces. The family of all Θ_h, when h ranges over all the subsets of $\{1,\ldots,q\}$, forms a partition of $\mathbb{R}^p$. Observe that for $y \in \mathbb{R}^q$ fixed, $\{x \in \mathbb{R}^p : (x,y) \in M_h\} = \Theta_h(y)$. Notice also the equivalences

$$\mathcal{H}(x',y') = h \;\Leftrightarrow\; x' \in \Theta_h(y') \;\Leftrightarrow\; (x',y') \in M_h. \tag{10}$$

The theory in this paper is developed by analyzing how the local minimizers of every $\mathcal{F}(.,y)$ behave under small variations of the data y. We thus consider local minimizer functions.

Definition 2. *Let $f : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ and $N \subseteq \mathbb{R}^q$. The family $f(.,N) := \{f(.,y) : y \in N\}$ is said to admit a local minimizer function $\mathcal{X} : N \to \mathbb{R}^p$ if for any $y \in N$ the function $f(.,y)$ has a strict local minimum at $\mathcal{X}(y)$.*

The next lemma addresses local minimizer functions relevant to smooth cost-functions.

Lemma 1. *Let $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q$ be a $\mathcal{C}^m$-function with $m \geq 2$. For $y \in \mathbb{R}^q$, assume that $\hat{x} \in \mathbb{R}^p$ is such that $D_1\mathcal{F}(\hat{x},y) = 0$, and $D_1^2\mathcal{F}(\hat{x},y)$ is positive definite.*

Then there exists a neighborhood $N \subset \mathbb{R}^q$ containing y and a $\mathcal{C}^{m-1}$-function $\mathcal{X} : N \to \mathbb{R}^p$ such that for every $y' \in N$ we have $D_1\mathcal{F}(\mathcal{X}(y'),y') = 0$, and $D_1^2\mathcal{F}(\mathcal{X}(y'),y')$ is positive definite. In particular, $\hat{x} = \mathcal{X}(y)$.

Equivalently, $\mathcal{X} : N \to \mathbb{R}^p$ is a local minimizer function relevant to $\mathcal{F}(.,N)$ such that $D_1^2\mathcal{F}(\mathcal{X}(y'),y')$ is positive definite for every $y' \in N$.

Proof. Being a local minimizer of $\mathcal{F}(.,y)$, $\hat{x}$ satisfies $D_1\mathcal{F}(\hat{x},y) = 0$. We focus on the equation $D_1\mathcal{F}(x',y') = 0$ in the vicinity of $(\hat{x},y)$ and notice that $D_1^2\mathcal{F}(\hat{x},y)$ determines an isomorphism from $\mathbb{R}^p$ to itself. From the implicit functions theorem [5], there exist $\rho_1 > 0$ and a unique $\mathcal{C}^{m-1}$-function $\mathcal{X} : B(y,\rho_1) \to \mathbb{R}^p$ such that $D_1\mathcal{F}\left(\mathcal{X}(y'),y'\right) = 0$ for all $y' \in B(y,\rho_1)$. Furthermore, since $y' \to \det D_1^2\mathcal{F}(\mathcal{X}(y'),y')$ is continuous and $\det D_1^2\mathcal{F}(\hat{x},y) > 0$, there is $\rho_2 \in (0,\rho_1]$ such that $\det D_1^2\mathcal{F}(\mathcal{X}(y'),y') > 0$ for all $y' \in B(y,\rho_2)$. □

Remark 1 (on the conditions required in Lemma 1). The minimizers of $\mathcal{C}^m$-functions of the form

$$\mathcal{F}(x,y) = \|Ax - y\|^2 + \alpha\Phi(x)$$

are extensively studied in [16]. It is shown there that if $\mathrm{rank}A = p$, and under some assumptions ensuring that $\mathcal{F}(.,y)$ admits local minimizers for every $y \in \mathbb{R}^q$, the data domain $\mathbb{R}^q$ contains a subset N whose interior is dense in $\mathbb{R}^q$ such that for every $y \in N$, then every local minimizer $\hat{x}$ of the corresponding $\mathcal{F}(.,y)$ is strict and $D_1^2\mathcal{F}(\hat{x},y)$ is positive definite. Reciprocally, all data leading to minimizers at which the conditions of Lemma 1 fail belong to a closed negligible subset of $\mathbb{R}^q$: the chance of acquiring data placed in such subsets is null.

The central question of this paper is how the shape of a cost-function $\mathcal{F}$ favors, or inhibits, the possibility that a local minimizer $\hat{x}$ of $\mathcal{F}(.,y)$, for $y \in \mathbb{R}^q$, fits a certain number of the entries of this same y, i.e., that the set $\hat{h} := \mathcal{H}(\hat{x},y)$ is nonempty. It will appear that this possibility is closely related to the smoothness of Ψ. We recall some facts about nonsmooth functions [32].

Definition 3. *Let $E_0 \subseteq \mathbb{R}^p$ be an affine subspace and E be the relevant vector space. Consider a function $f : E_0 \to \mathbb{R}$, and let $x \in E_0$ and $u \in E$. The function f admits a one-sided derivative at x in the direction of $u \neq 0$, denoted by $\delta g(x)(u)$, if*

the following (possibly infinite) limit exists:

$$\delta f(x)(u) := \lim_{t \downarrow 0} \frac{f(x+tu) - f(x)}{t}.$$

If $u = 0$, *put* $\delta f(x)(0) = 0$.

The downward pointing arrow above means that $t \in \mathbb{R}_+$ converges to zero by positive values. If f is differentiable at x, then $\delta f(x)(u) = Df(x).u$. If $f : \mathbb{R} \to \mathbb{R}$, we have $\delta f(x)(1) = f'(x^+)$. The left derivative of f at x for u is $-\delta f(x)(-u)$. In the following, $\delta_1 \mathcal{F}$ will address one-sided derivatives of $\mathcal{F}$ with respect to its first argument.

3. Cost-functions with nonsmooth data-fidelity terms. Here and in section 4 we focus on cost-functions which read

$$\mathcal{F}(x, y) = \Psi(x, y) + \alpha \Phi(x, y), \tag{11}$$

$$\Psi(x, y) = \sum_{i=1}^{q} \psi(a_i^T x - y_i), \tag{12}$$

where $\psi : \mathbb{R} \to \mathbb{R}$ is $\mathcal{C}^m$ on $\mathbb{R} \setminus \{0\}$, with $m \geq 2$, whereas at zero it admits finite side derivatives satisfying $\psi'(0^-) < \psi'(0^+)$. The term $\Phi : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$ is any $\mathcal{C}^m$-function. This formulation allows us to address data-fidelity terms composed of a nonsmooth function Ψ and of a smooth function $\tilde{\Psi}$, since we can write $\Phi(x, y) = \tilde{\Psi}(x, y) + \tilde{\Phi}(x)$ with $\tilde{\Phi}$ a regularization term. For example, we can have $\Phi(x, y) = \sum_i \big(\phi_i(B_i^T x - y_{q_i}) + \varphi_i(G_i^T x)\big)$, where $\phi_i : \mathbb{R}^{q_i} \to \mathbb{R}$ and $\varphi_i : \mathbb{R}^{p_i} \to \mathbb{R}$ are $\mathcal{C}^m$-functions, $y_{q_i} \in \mathbb{R}^{q_i}$ are data, and $B_i^T \in \mathbb{R}^{q_i \times p}$ and $G_i^T \in \mathbb{R}^{p_i \times p}$, with $p_i \in \mathbb{N}^*$ and $q_i \in \mathbb{N}^*$.

Remark 2. The results presented in sections 3 and 4 are developed for Ψ of the form (12), that is, $\psi_i = \psi$ for all i, but we should emphasize that they remain true for Ψ of the form (2) provided that all ψ_i, for $i = 1, \ldots, q$, have finite side derivatives at zero satisfying $\psi_i'(0^-) < \psi_i'(0^+)$. The proofs are straightforward to extend to this situation but at the expense of complicated notation which may cloud the presentation.

We start by providing a sufficient condition for a strict local minimum.

PROPOSITION 1. *For* $y \in \mathbb{R}^q$, *let* $\mathcal{F}(., y) : \mathbb{R}^p \to \mathbb{R}$ *be of the form* (11)–(12), *where* $\Phi \in \mathcal{C}^m(\mathbb{R}^p \times \mathbb{R}^q)$ *for* $m \geq 1$ *and* $\psi \in \mathcal{C}^m(\mathbb{R} \setminus \{0\})$ *satisfies* $-\infty < \psi'(0^-) < \psi'(0^+) < +\infty$. *Let* $\hat{x} \in \mathbb{R}^p$ *be such that*

1. *the restricted function* $\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y)}}(., y) : \overline{\Theta_{\hat{h}}(y)} \to \mathbb{R}$ *reaches a strict local minimum at* $\hat{x}$,
2. $\delta_1 \mathcal{F}(\hat{x}, y)(u) > 0$ *for all* $u \in T_{\hat{h}}^{\perp} \cap S$,

where $\hat{h} := \mathcal{H}(\hat{x}, y)$, $\Theta_{\hat{h}}(y)$, *and* $T_{\hat{h}}$ *are determined according to* (6), (7), *and* (8), *respectively.*

Then $\mathcal{F}(., y)$ *reaches a strict local minimum at* $\hat{x}$.

Proof. The result is a tautology if $\hat{h} = \emptyset$ since then $\Theta_{\hat{h}}(y) = \mathbb{R}^p$. So consider that $\hat{h}$ is nonempty. First of all, we put $\mathcal{F}$ into a more convenient form. Define

$$\tilde{\psi}(t) := \psi(t) - \frac{t}{2}\big(\psi'(0^-) + \psi'(0^+)\big) - \psi(0). \tag{13}$$

Now we have

$$\tilde{\psi}'(0^+) = -\tilde{\psi}'(0^-) > 0 \quad \text{and} \quad \tilde{\psi}(0) = 0, \tag{14}$$

which will allow important simplifications. By means of $\tilde{\psi}$, the cost-function $\mathcal{F}$ assumes the form

$$\mathcal{F}(x,y) = \tilde{\Psi}(x,y) + \tilde{\Phi}(x,y), \tag{15}$$

$$\text{where } \tilde{\Psi}(x,y) = \sum_{i=1}^{q} \tilde{\psi}(a_i^T x - y_i)$$

$$\text{and } \tilde{\Phi}(x,y) = \sum_{i=1}^{q} \frac{\psi'(0^-) + \psi'(0^+)}{2}(a_i^T x - y_i) + q\psi(0) + \alpha\Phi(x,y).$$

Both $\tilde{\Psi}$ and $\tilde{\Phi}$ satisfy the assumptions about Ψ and Φ, respectively. Henceforth, we deal with the formulation of $\mathcal{F}$ given in (15). For notational convenience, we systematically write ψ for $\tilde{\psi}$, Ψ for $\tilde{\Psi}$, and Φ for $\tilde{\Phi}$.

Let us consider the altitude increment of $\mathcal{F}(.,y)$ at $\hat{x}$ in the direction of an arbitrary $u \in S$,

$$\mathcal{F}(\hat{x} + tu, y) - \mathcal{F}(\hat{x}, y) \quad \text{for } t \in \mathbb{R}_+.$$

In order to avoid misunderstandings, u_0 will denote a vector of $T_{\hat{h}}$ and $u_{\perp}$ a vector of $T_{\hat{h}}^{\perp}$. Using the fact that every $u \in S$ has a unique decomposition into

$$u = u_0 + u_{\perp} \text{ with } u_0 \in T_{\hat{h}} \cap \overline{B(0,1)} \text{ and } u_{\perp} \in T_{\hat{h}}^{\perp} \cap \overline{B(0,1)}, \tag{16}$$

we decompose the altitude increment of $\mathcal{F}(.,y)$ accordingly:

$$\mathcal{F}(\hat{x} + tu, y) - \mathcal{F}(\hat{x}, y) = \mathcal{F}(\hat{x} + tu_0 + tu_{\perp}, y) - \mathcal{F}(\hat{x} + tu_0, y) \tag{17}$$

$$+ \mathcal{F}(\hat{x} + tu_0, y) - \mathcal{F}(\hat{x}, y). \tag{18}$$

The term on the right-hand side of (17) is analyzed with the aid of assumption 2. In order to calculate the side derivative $\delta_1\mathcal{F}(\hat{x},y)$, we decompose $\mathcal{F}$ into

$$\mathcal{F}(x',y') = \Psi_{\hat{h}}(x',y') + \mathcal{F}_{\hat{h}}(x',y'), \tag{19}$$

$$\text{where } \Psi_{\hat{h}}(x',y') := \sum_{i \in \hat{h}} \psi(a_i^T x' - y_i')$$

$$\text{and } \mathcal{F}_{\hat{h}}(x',y') = \sum_{i \in \hat{h}^c} \psi(a_i^T x - y_i') + \alpha\Phi(x',y').$$

This decomposition is used recurrently in the following.

Remark 3. The function $\mathcal{F}_{\hat{h}}$ is $\mathcal{C}^m$ on a neighborhood of $(\hat{x},y)$ which contains $B(\hat{x},\sigma) \times B(y,\sigma)$ for

$$\sigma := \frac{1}{2(\|a\|_\infty + 1)} \min_{i \in \hat{h}^c} |a_i^T \hat{x} - y_i|, \tag{20}$$

$$\|a\|_\infty := \max_{i=1}^{q} \|a_i\|. \tag{21}$$

Indeed, for every $(x',y') \in B(\hat{x},\sigma) \times B(y,\sigma)$ we have

$$i \in \hat{h}^c \quad \Rightarrow \quad |a_i^T x' - y_i'| = \left|(a_i^T \hat{x} - y_i) + a_i^T(x' - \hat{x}) + (y_i - y_i')\right| \tag{22}$$

$$\geq \left|a_i^T \hat{x} - y_i\right| - \left|a_i^T(x' - \hat{x})\right| - |y_i - y_i'|$$

$$\geq \min_{i \in \hat{h}^c} |a_i^T \hat{x} - y_i| - \|a\|_\infty \sigma - \sigma = (\|a\|_\infty + 1)\sigma > 0,$$

since clearly $\|a\|_\infty > 0$ and $\sigma > 0$.

In contrast, $\Psi_{\hat{h}}$ is nonsmooth at $(\hat{x}, y)$. Using Definition 3 we calculate that for every $u \in \mathbb{R}^p$,

$$\delta_1 \mathcal{F}(x,y)(u) = \delta_1 \Psi_{\hat{h}}(\hat{x},y)(u) + D\mathcal{F}_{\hat{h}}(\hat{x},y).u, \tag{23}$$

$$\text{where } \ \delta_1 \Psi_{\hat{h}}(\hat{x},y)(u) = \psi'(0^+) \sum_{i \in \hat{h}} |a_i^T u|, \tag{24}$$

since $\delta\psi(a_i^T\hat{x} - y_i)(u) = \lim_{t\downarrow 0} \psi(ta_i^T u)/t = \psi'(0^+)|a_i^T u|$, for every $i \in \hat{h}$, which accounts for (14). Notice that $\delta_1\Psi_{\hat{h}}(\hat{x},y)(u) = \delta_1\Psi_{\hat{h}}(\hat{x},y)(-u) \geq 0$ for every $u \in \mathbb{R}^p$. Applying assumption 2 to both $u_\perp \in T_{\hat{h}}^\perp$ and $-u_\perp$ yields

$$|D\mathcal{F}_{\hat{h}}(\hat{x},y).u_\perp| < \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_\perp| \ \ \forall u_\perp \in T_{\hat{h}}^\perp. \tag{25}$$

Now consider the function

$$f : T_{\hat{h}}^\perp \cap S \to \mathbb{R},$$
$$u_\perp \to f(u_\perp) := \frac{|D\mathcal{F}_{\hat{h}}(\hat{x},y).u_\perp|}{\psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u_\perp|}.$$

Since for every $u_\perp \in T_{\hat{h}}^\perp \cap S$ there is at least one index $i \in \hat{h}$ such that $a_i^T u_\perp \neq 0$, this function is well defined and continuous. If $u_\perp \to D\mathcal{F}_{\hat{h}}(\hat{x},y).u_\perp$ is not identically null on $T_{\hat{h}}^\perp$, put

$$c_0 := \sup_{u_\perp \in T_{\hat{h}}^\perp \cap S} f(u_\perp). \tag{26}$$

Since $T_{\hat{h}}^\perp \cap S$ is compact, f reaches the maximum value c_0. By (25) we see that $0 < c_0 < 1$. If $D\mathcal{F}_{\hat{h}}(\hat{x},y).u_\perp = 0$ for all $u_\perp \in T_{\hat{h}}^\perp$, we put $c_0 := 1/2$. In both cases,

$$|D\mathcal{F}_{\hat{h}}(\hat{x},y).u_\perp| \leq c_0\, \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_\perp| \ \ \forall u_\perp \in T_{\hat{h}}^\perp. \tag{27}$$

Using (19), the right-hand side of (17) takes the form

$$\mathcal{F}(\hat{x}+tu_0+tu_\perp, y) - \mathcal{F}(\hat{x}+tu_0, y) = \Psi_{\hat{h}}(\hat{x}+tu_0+tu_\perp, y) - \Psi_{\hat{h}}(\hat{x}+tu_0, y) \tag{28}$$
$$+ \mathcal{F}_{\hat{h}}(\hat{x}+tu_0+tu_\perp, y) - \mathcal{F}_{\hat{h}}(\hat{x}+tu_0, y). \tag{29}$$

First, we focus on the right-hand side of (28). From the definition of $\hat{h}$ and (16),

$$\Psi_{\hat{h}}(\hat{x}+tu_0, y) = 0,$$
$$\Psi_{\hat{h}}(\hat{x}+tu_0+tu_\perp, y) = \sum_{i\in\hat{h}} \psi\left(a_i^T(\hat{x}+tu_\perp+tu_0) - y_i\right) = \sum_{i\in\hat{h}} \psi(ta_i^T u_\perp).$$

Applying Definition 3 to $\psi'(0^+)$ shows that there is $\eta_0 \in (0, \sigma]$ such that

$$\frac{\psi(t)}{t} \geq \psi'(0^+) - \frac{1-c_0}{2}\psi'(0^+) \ \ \forall t \in (0, \|a\|_\infty \eta_0)\,,$$

since $(1-c_0)/2 \in (0,1)$. On the other hand, $|a_i^T u| \leq \|a_i\|\|u\| \leq \|a\|_\infty$ for all $u \in \overline{B(0,1)}$ and for all $i \in \{1,\ldots,q\}$. Then

$$t \in (0,\eta_0) \;\Rightarrow\; \psi(ta_i^T u_{\perp\!\!\!\perp}) \geq \frac{c_0+1}{2}\psi'(0^+)\, t\, |a_i^T u_{\perp\!\!\!\perp}| \;\; \forall u_{\perp\!\!\!\perp} \in T_{\hat{h}}^{\perp} \cap \overline{B(0,1)}.$$

Hence, taking $t \in (0,\eta_0)$ ensures that for all $u \in S$, decomposed into $u = u_0 + u_{\perp\!\!\!\perp}$ as in (16), we have

$$\Psi_{\hat{h}}(\hat{x} + tu_0 + tu_{\perp\!\!\!\perp}, y) \geq \frac{c_0+1}{2}\, t\, \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}|. \tag{30}$$

Second, we consider (29). Define the constants

$$c_1 := \min_{u_{\perp\!\!\!\perp} \in T_{\hat{h}}^{\perp} \cap S} \sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}|, \tag{31}$$

$$c_2 := c_1 \psi'(0^+) \frac{1-c_0}{4}, \tag{32}$$

and notice that $c_1 > 0$ and $c_2 > 0$, and that (31) implies

$$\sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}| \geq c_1 \|u_{\perp\!\!\!\perp}\| \quad \forall u_{\perp\!\!\!\perp} \in T_{\hat{h}}^{\perp}. \tag{33}$$

Since $\mathcal{F}_{\hat{h}}(.,y) \in \mathcal{C}^1\left(B(\hat{x},\sigma)\right)$ (see Remark 3), the mean-value theorem [5] shows that for every $u \in S$ and for every $t \in [0,\sigma)$ there exists $\theta \in (0,1)$ such that

$$\mathcal{F}_{\hat{h}}(\hat{x} + tu_0 + tu_{\perp\!\!\!\perp}, y) - \mathcal{F}_{\hat{h}}(\hat{x} + tu_0, y) = tD_1\mathcal{F}_{\hat{h}}(\hat{x} + tu_0 + \theta t u_{\perp\!\!\!\perp}, y).u_{\perp\!\!\!\perp}, \tag{34}$$

where $u = u_0 + u_{\perp\!\!\!\perp}$ is decomposed as in (16). Moreover, there is $\eta_1 \in (0,\eta_0)$ such that for every $t \in (0,\eta_1)$,

$$\left|D_1\mathcal{F}_{\hat{h}}(\hat{x} + tu_0 + \theta t u_{\perp\!\!\!\perp}, y).u_{\perp\!\!\!\perp} - D_1\mathcal{F}_{\hat{h}}(\hat{x},y).u_{\perp\!\!\!\perp}\right| \leq c_2\|u_{\perp\!\!\!\perp}\| \quad \forall u \in S, \;\; \forall \theta \in (0,1),$$

and hence

$$\left|D_1\mathcal{F}_{\hat{h}}(\hat{x} + tu_0 + \theta t u_{\perp\!\!\!\perp}, y).u_{\perp\!\!\!\perp}\right| \leq \left|D_1\mathcal{F}_{\hat{h}}(\hat{x},y).u_{\perp\!\!\!\perp}\right| + c_2\|u_{\perp\!\!\!\perp}\| \;\; \forall u \in S, \;\; \forall \theta \in (0,1). \tag{35}$$

Starting with (28)–(29), we derive

$$\begin{aligned}
&\mathcal{F}(\hat{x} + tu_0 + tu_{\perp\!\!\!\perp}, y) - \mathcal{F}(\hat{x} + tu_0, y) \qquad (36)\\
&\geq \frac{c_0+1}{2} t\, \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}| - t\left|D_1\mathcal{F}_{\hat{h}}(\hat{x} + tu_0 + \theta t u_{\perp\!\!\!\perp}, y).u_{\perp\!\!\!\perp}\right| \quad \text{[by (30) and (34)]}\\
&\geq \frac{c_0+1}{2} t\, \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}| - t\left|D_1\mathcal{F}_{\hat{h}}(\hat{x},y).u_{\perp\!\!\!\perp}\right| - tc_2\|u_{\perp\!\!\!\perp}\| \quad \text{[by (35)]}\\
&\geq \frac{1-c_0}{2} t\, \psi'(0^+) \sum_{i\in\hat{h}} |a_i^T u_{\perp\!\!\!\perp}| - tc_2\|u_{\perp\!\!\!\perp}\| \quad \text{[by (27)]}\\
&\geq \frac{1-c_0}{2} \psi'(0^+) tc_1\|u_{\perp\!\!\!\perp}\| - tc_2\|u_{\perp\!\!\!\perp}\| \quad \text{[by (33)]}\\
&= \frac{1-c_0}{4} \psi'(0^+) tc_1\|u_{\perp\!\!\!\perp}\|. \quad \text{[by (32)]} \qquad (37)
\end{aligned}$$

Consequently,

$$(38)\ t \in (0,\eta_1) \quad \Rightarrow \quad \mathcal{F}(\hat{x}+tu_0+tu_\perp,y)-\mathcal{F}(\hat{x}+tu_0,y)>0 \quad \forall u\in S \text{ with } u_\perp \neq 0.$$

From assumption 1, there exists $\eta_2 \in (0,\eta_1]$ such that

$$(39)\quad t\in(0,\eta_2) \quad \Rightarrow \quad \mathcal{F}(\hat{x}+tu_0,y)-\mathcal{F}(\hat{x},y)>0 \quad \forall u_0 \in T_{\hat{h}} \cap \overline{B(0,1)} \setminus \{0\}.$$

If $u_0=0$, then (38) holds since $\|u_\perp\|=1$, whereas if $u_\perp=0$, then (39) is true since $\|u_0\|=1$. Introducing (38) and (39) into (17)–(18) shows that if $t\in(0,\eta_2)$, then $\mathcal{F}(\hat{x}+tu,y)-\mathcal{F}(\hat{x},y)>0$ for every $u\in S$. ∎

Remark 4. The conditions required in Proposition 1 are pretty weak. Indeed, if an arbitrary function $\mathcal{F}(.,y):\mathbb{R}^p\to\mathbb{R}$ has a strict minimum at $\hat{x}$, then assumption 1 is trivially true and necessarily $\delta_1\mathcal{F}(\hat{x},y)(u)\geq 0$ for all $u\in T_{\hat{h}}^{\perp}\cap S$ [32]. In comparison, assumption 2 requires only that the latter inequality be strict.

Observe that the above sufficient condition for strict minimum concerns the behavior of $\mathcal{F}(.,y)$ on two orthogonal subspaces *separately*. This occurs because of the nonsmoothness of ψ.

4. Minimizers that fit exactly some data entries. The theorem below states the main contribution of this work.

THEOREM 1. *Consider $\mathcal{F}$ as given in* (11)–(12)*, where $\Phi\in\mathcal{C}^m(\mathbb{R}^p\times\mathbb{R}^q)$ for $m\geq 2$, and $\psi\in\mathcal{C}^m(\mathbb{R}\setminus\{0\})$ has finite side derivatives at zero such that $\psi'(0^-)<\psi'(0^+)$. Given $y\in\mathbb{R}^q$ and $\hat{x}\in\mathbb{R}^p$, let $\hat{h}:=\mathcal{H}(\hat{x},y)$, $\Theta_{\hat{h}}(y)$, and $T_{\hat{h}}$ be obtained by* (6)*,* (7)*, and* (8)*, respectively. Suppose the following:*

1. *The set $\{a_i : i\in\hat{h}\}$ is linearly independent;*
2. *for every $u\in T_{\hat{h}}\cap S$ we have $D_1(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y)}})(\hat{x},y).u=0$ and $D_1^2(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y)}})(\hat{x},y)(u,u)>0$;*
3. *for every $u\in T_{\hat{h}}^{\perp}\cap S$ we have $\delta_1\mathcal{F}(\hat{x},y)(u)>0$.*

Then there is a neighborhood $N\subset\mathbb{R}^q$ containing y and a $\mathcal{C}^{m-1}$ local minimizer function $\mathcal{X}:N\to\mathbb{R}^p$ relevant to $\mathcal{F}(.,N)$ (see Definition 2) yielding, in particular, $\hat{x}=\mathcal{X}(y)$, whereas for every $y'\in N$,

$$(40)\qquad \begin{aligned} a_i^T\mathcal{X}(y') &= y'_i \quad \text{if} \quad i\in\hat{h},\\ a_i^T\mathcal{X}(y') &\neq y'_i \quad \text{if} \quad i\in\hat{h}^c. \end{aligned}$$

The latter means that $\mathcal{H}(\mathcal{X}(y'),y')=\hat{h}$ is constant on N.

Proof. If $\hat{h}=\emptyset$, then $\Theta_{\hat{h}}(y')=\mathbb{R}^p$ for all y'. Applying Lemma 1 shows the existence of $\tilde{N}\subset\mathbb{R}^q$ and of a $\mathcal{C}^{m-1}$ local minimizer function $\mathcal{X}$ relevant to $\mathcal{F}(.,\tilde{N})$. By the continuity of $\mathcal{X}$, there is $N\subset\tilde{N}$ where (40) holds, in which case (40) is reduced to $a_i^T\mathcal{X}(y')\neq y'_i$ for all $i\in\{1,\dots,q\}$.

In the following we consider that $\hat{h}$ is nonempty. As in the proof of Proposition 1, we use the formulation of $\mathcal{F}$ given in (13)–(15) and write ψ for $\tilde{\psi}$ and Φ for $\tilde{\Phi}$. This proof is based on two lemmas given next.

LEMMA 2. *Let assumptions* 1 *and* 2 *of Theorem* 1 *be satisfied. Then there exist $\nu>0$ and a $\mathcal{C}^{m-1}$-function $\mathcal{X}:B(y,\nu)\to\mathbb{R}^p$ so that for every $y'\in B(y,\nu)$ the point $\hat{x}':=\mathcal{X}(y')$ belongs to $\Theta_{\hat{h}}(y')$ and satisfies*

$$(41)\qquad D_1\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}\right)(\hat{x}',y').u=0 \ \text{ and } \ D_1^2\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}\right)(\hat{x}',y')(u,u)>0 \quad \forall u\in T_{\hat{h}}\setminus\{0\}.$$

In particular, $\hat{x} = \mathcal{X}(y)$.

Proof of Lemma 2. We start by commenting on the restricted functions in (41).

Remark 5. For σ as in (20), the inequality reached in (22) shows that for all $(x', y') \in B(\hat{x}, \sigma) \times B(y, \sigma)$ we have $\mathcal{H}(x', y') \subseteq \hat{h}$. On the other hand, if $x' \in \overline{\Theta_{\hat{h}}(y')}$, then $\mathcal{H}(x', y') \supseteq \hat{h}$. If we put

$$B_{\hat{h}}\left((\hat{x}, y), \sigma\right) := \left(B(\hat{x}, \sigma) \times B(y, \sigma)\right) \cap \overline{M_{\hat{h}}}, \tag{42}$$

where $M_{\hat{h}}$ is given in (9), we have

$$(x', y') \in B_{\hat{h}}\left((\hat{x}, y), \sigma\right) \quad \Rightarrow \quad \mathcal{H}(x', y') = \hat{h},$$

and $B_{\hat{h}}\left((\hat{x}, y), \sigma\right) \subset M_{\hat{h}}$. By (7) and (10), for every $(x', y') \in M_{\hat{h}}$ we find $\Psi_{\hat{h}}(x', y') = 0$ and hence $\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}(x', y') = \mathcal{F}_{\hat{h}}|_{\overline{\Theta_{\hat{h}}(y')}}(x', y')$. Since $\mathcal{F}_{\hat{h}} \in \mathcal{C}^m\left(B(\hat{x}, \sigma) \times B(y, \sigma)\right)$ (see Remark 3), we get

$$\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}} \in \mathcal{C}^m\left(B_{\hat{h}}\left((\hat{x}, y), \sigma\right)\right) \text{ and } \mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}(x', y') = \mathcal{F}_{\hat{h}}(x', y') \ \forall\ (x', y') \in B_{\hat{h}}\left((\hat{x}, y), \sigma\right).$$

We now pursue the proof of the lemma. Let the indexes contained in $\hat{h}$ read $\hat{h} = \{j_1, \ldots, j_{\#\hat{h}}\}$. Let $I_{\hat{h}}$ be the $\#\hat{h} \times q$ matrix with entries $I_{\hat{h}}[i, j_i] = 1$ for $i = 1, \ldots, \#\hat{h}$, the remaining entries being null. Thus $y_{\hat{h}} := I_{\hat{h}} y \in \mathbb{R}^{\#\hat{h}}$ is composed of only those entries of y whose indexes are in $\hat{h}$. Similarly, put $A_{\hat{h}} := I_{\hat{h}} A$; then $A_{\hat{h}} \in \mathbb{R}^{\#\hat{h} \times p}$ and $A_{\hat{h}} \hat{x} = y_{\hat{h}}$. With this notation, $\overline{M_{\hat{h}}} = \left\{(x', y') \in \mathbb{R}^p \times \mathbb{R}^q : A_{\hat{h}} x' - I_{\hat{h}} y' = 0\right\}$. By assumption 1, $\mathrm{rank} A_{\hat{h}} = \#\hat{h}$. Then for every y' we have the following dimensions: $\dim \overline{\Theta_{\hat{h}}(y')} = \dim T_{\hat{h}} = p - \#\hat{h}$ while $\dim \overline{M_{\hat{h}}} = p - \#\hat{h} + q$. Recalling that $A_{\hat{h}} A_{\hat{h}}^T$ is invertible, put

$$P_{\hat{h}} := A_{\hat{h}}^T \left(A_{\hat{h}} A_{\hat{h}}^T\right)^{-1} I_{\hat{h}}. \tag{43}$$

Let $C_{\hat{h}} : T_{\hat{h}} \to \mathbb{R}^{p - \#\hat{h}}$ be an isomorphism. The affine mapping

$$\begin{aligned} \Gamma : \quad & \overline{M_{\hat{h}}} \to \mathbb{R}^{p - \#\hat{h}}, \\ & (x', y') \to \Gamma(x', y') = C_{\hat{h}}\left(x' - \hat{x} - P_{\hat{h}}(y' - y)\right) \end{aligned} \tag{44}$$

is well defined for every $y' \in \mathbb{R}^q$ since on the one hand $\hat{x} + P_{\hat{h}}\left(y' - y\right)$ is the orthogonal projection[1] of $\hat{x}$ onto $\overline{\Theta_{\hat{h}}(y')}$, whereas on the other hand $x' \in \overline{\Theta_{\hat{h}}(y')}$ by (10). Consider also the conjugate mapping

$$\begin{aligned} \Gamma^\dagger : \quad & \mathbb{R}^{p - \#\hat{h}} \times \mathbb{R}^q \to \overline{\Theta_{\hat{h}}(y')}, \\ & (z, y') \to \Gamma^\dagger(z, y') = C_{\hat{h}}^{-1} z + \hat{x} + P_{\hat{h}}(y' - y), \end{aligned} \tag{45}$$

[1] The orthogonal projection of $\hat{x}$ onto $\overline{\Theta_{\hat{h}}(y')}$, denoted by $\hat{x}_{y'}$, is unique and is determined by solving the problem

$$\text{minimize } \ \|\hat{x}_{y'} - \hat{x}\| \quad \text{subject to } \ \hat{x}_{y'} \in \overline{\Theta_{\hat{h}}(y')}.$$

The latter constraint also reads $A_{\hat{h}} \hat{x}_{y'} = y'_{\hat{h}}$ if we denote $y'_{\hat{h}} = I_{\hat{h}} y'$. It is easily calculated that the solution to this problem reads

$$\hat{x}_{y'} = \hat{x} - A_{\hat{h}}^T \left(A_{\hat{h}} A_{\hat{h}}^T\right)^{-1} \left(A_{\hat{h}} \hat{x} - y'_{\hat{h}}\right).$$

Recalling that $A_{\hat{h}} \hat{x} = I_{\hat{h}} y$ from the definition of $\hat{h}$, we obtain that $\hat{x}_{y'} = \hat{x} + P_{\hat{h}}\left(y' - y\right)$.

which is also well defined. Let

$$\nu_0 := \frac{\sigma}{2}\,\min\left\{1,\,\left(\sup_{z\in S}\|C_{\hat{h}}^{-1}z\| + \sup_{y'\in S}\|P_{\hat{h}}y'\|\right)^{-1}\right\}. \tag{46}$$

Clearly, $0 < \nu_0 < \sigma$. It is worth noticing that

$$\Gamma^\dagger(z,y') \in \overline{\Theta_{\hat{h}}(y')} \cap B(\hat{x},\sigma) \subset \Theta_{\hat{h}}(y') \quad \forall (z,y') \in B(0,\nu_0)\times B(y,\nu_0), \tag{47}$$

since on the one hand (45) shows that $\Gamma^\dagger(z,y') \in \overline{\Theta_{\hat{h}}(y')}$ whereas, on the other hand,

$$\|\Gamma^\dagger(z,y') - \hat{x}\| \le \|C_{\hat{h}}^{-1}\|\,\|z\| + \|P_{\hat{h}}\|\,\|y'-y\| \le (\|C_{\hat{h}}^{-1}\| + \|P_{\hat{h}}\|)\,\nu_0 < \sigma.$$

Now we introduce the function

$$\begin{aligned} &\mathcal{G} : \mathbb{R}^{p-\#\hat{h}} \times \mathbb{R}^q \to \mathbb{R}, \\ &\qquad (z,y') \to \mathcal{G}(z,y') := \mathcal{F}_{\hat{h}}\left(\Gamma^\dagger(z,y'),\ y'\right). \end{aligned} \tag{48}$$

Since for every $y' \in \mathbb{R}^q$ we have

$$z = \Gamma(x',y') \quad \Leftrightarrow \quad x' = \Gamma^\dagger(z,y'),$$

then

$$\mathcal{G}\left(\Gamma(x',y'),y'\right) = \mathcal{F}_{\hat{h}}(x',y') = \mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}(x',y') \quad \forall (x',y') \in B_{\hat{h}}\left((\hat{x},y),\sigma\right),$$

where the last equality comes from Remark 5. Now for every $(x',y') \in B_{\hat{h}}\left((\hat{x},y),\sigma\right)$, the derivatives of $\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}$, mentioned in (41), can be calculated in terms of $\mathcal{G}$ and Γ as follows:

$$D_1\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}\right)(x',y').u_0 = D_1\mathcal{G}\left(\Gamma(x',y'),y'\right).C_{\hat{h}}u_0 \qquad \forall u_0 \in T_{\hat{h}}, \tag{49}$$

$$D_1^2\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y)}}\right)(x',y')(u_0,u_0) = D_1^2\mathcal{G}\left(\Gamma(x',y'),y'\right).\left(C_{\hat{h}}u_0, C_{\hat{h}}u_0\right) \qquad \forall u_0 \in T_{\hat{h}}. \tag{50}$$

Since $C_{\hat{h}}$ is an isomorphism, $D_1\Gamma(x',y').u_0 = C_{\hat{h}}.u_0 \neq 0$ for every $u_0 \in T_{\hat{h}} \setminus \{0\}$, whereas $C_{\hat{h}}.T_{\hat{h}} = \mathbb{R}^{p-\#\hat{h}}$. Then assumption 2, combined with the fact that $\Gamma(\hat{x},y) = 0$ by construction, yields

$$\begin{aligned} D_1\mathcal{G}(0,y) &= 0, \\ D_1^2\mathcal{G}(0,y)(u,u) &> 0 \quad \forall u \in \mathbb{R}^{p-\#\hat{h}} \setminus \{0\}. \end{aligned}$$

By Lemma 1, there exist $\nu \in (0,\nu_0]$ and a unique $\mathcal{C}^{m-1}$-function $\mathcal{Z} : B(y,\nu) \to B(0,\nu_0)$ such that

$$D_1\mathcal{G}\left(\mathcal{Z}(y'),\ y'\right) = 0 \ \text{ and } \ D_1^2\mathcal{G}\left(\mathcal{Z}(y'),\ y'\right) \text{ is positive definite } \quad \forall y' \in B(y,\nu), \tag{51}$$

with, in particular, $\mathcal{Z}(y) = 0$. Next we express the derivatives in (51) in terms of $\mathcal{F}_{\hat{h}}$ and $\Gamma^\dagger$. From (47) and Remark 5 it follows that $\mathcal{F}_{\hat{h}}$ is $\mathcal{C}^m$ at every $\left(\Gamma^\dagger(z,y'),y'\right)$ relevant to $(z,y') \in B(0,\nu_0)\times B(y,\nu)$, in which case (48) gives rise to

$$D_1\mathcal{G}(z,y').u = D_1\mathcal{F}_{\hat{h}}(\Gamma^\dagger(z,y'),y').C_{\hat{h}}^{-1}u, \tag{52}$$

$$D_1^2\mathcal{G}(z,y')(u,u) = D_1^2\mathcal{F}_{\hat{h}}(\Gamma^\dagger(z,y'),y')\left(C_{\hat{h}}^{-1}u, C_{\hat{h}}^{-1}u\right). \tag{53}$$

Put

$$\mathcal{X}(y') := \Gamma^{\dagger}\left(\mathcal{Z}(y'), y'\right) \quad \forall y' \in B(y,\nu), \tag{54}$$

and notice that $\mathcal{X}(y') \in \Theta_{\hat{h}}(y')$. Then (51) implies that for every $y' \in B(y,\nu)$,

$$D_1\mathcal{F}_{\hat{h}}(\mathcal{X}(y'), y').C_{\hat{h}}^{-1}u = 0 \quad \forall u \in \mathbb{R}^{p-\#\hat{h}},$$
$$D_1^2\mathcal{F}_{\hat{h}}(\mathcal{X}(y'), y')\left(C_{\hat{h}}^{-1}u, C_{\hat{h}}^{-1}u\right) > 0 \quad \forall u \in \mathbb{R}^{p-\#\hat{h}} \setminus \{0\}.$$

Since $C_{\hat{h}}^{-1}u \neq 0$ for all $u \in \mathbb{R}^{p-\#\hat{h}} \setminus \{0\}$ and $C_{\hat{h}}^{-1}.\mathbb{R}^{p-\#\hat{h}} = T_{\hat{h}}$, it follows that for every $y' \in B(y,\nu)$,

$$D_1\mathcal{F}_{\hat{h}}\left(\mathcal{X}(y'),\ y'\right).u_0 = 0 \ \text{ and } \ D_1^2\mathcal{F}_{\hat{h}}(\mathcal{X}(y'), y').(u_0,u_0) > 0 \ \ \forall u_0 \in T_{\hat{h}} \setminus \{0\}.$$

Again applying Remark 5 allows us to write that if $y' \in B(y,\nu)$, then

$$D_1\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}\right)\left(\mathcal{X}(y'),\ y'\right).u_0 = 0 \ \text{ and } \ D_1^2\left(\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}\right)(\mathcal{X}(y'), y')(u_0,u_0) > 0$$
$$\forall u_0 \in T_{\hat{h}} \setminus \{0\}.$$

The proof of Lemma 2 is complete. □

The next lemma addresses assumption 3 of the theorem.

LEMMA 3. *Given $\hat{x} \in \mathbb{R}^p$ and $y \in \mathbb{R}^q$, let $\hat{h} = \mathcal{H}(\hat{x}, y) \neq \emptyset$. Let assumption 3 of Theorem 1 hold.*

Then there exists $\mu > 0$ such that

$$y' \in B(\hat{x},\mu) \ \text{ and } \ x' \in \Theta_{\hat{h}}(y') \cap B(\hat{x},\mu) \ \Rightarrow \ \delta_1\mathcal{F}(x',y')(u_{\perp}) > 0 \ \ \forall u_{\perp} \in T_{\hat{h}}^{\perp} \cap S. \tag{55}$$

Proof of Lemma 3. We decompose $\mathcal{F}$ according to (19). Let σ and $B_{\hat{h}}\left((\hat{x},y),\sigma\right)$ be defined according to (20) and (42), respectively. Remark 5 applies to $B_{\hat{h}}\left((\hat{x},y),\sigma\right)$. Similarly to (23)–(24), for every $(x',y') \in B_{\hat{h}}\left((\hat{x},y),\sigma\right)$ we have

$$\delta_1\mathcal{F}(x',y')(u) = \psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u| + D_1\mathcal{F}_{\hat{h}}(x',y').u \quad \forall u \in \mathbb{R}^p. \tag{56}$$

By the continuity of $D_1\mathcal{F}_{\hat{h}}$, there is $\mu \in (0,\sigma]$ such that for every $(x',y') \in B_{\hat{h}}\left((\hat{x},y),\mu\right)$,

$$\left|D_1\mathcal{F}_{\hat{h}}(x',y').u_{\perp} - D_1\mathcal{F}_{\hat{h}}(\hat{x},y).u_{\perp}\right| \leq \frac{1-c_0}{2}\psi'(0^+)c_1\|u_{\perp}\| \quad \forall u_{\perp} \in T_{\hat{h}}^{\perp}, \tag{57}$$

where $c_0 \in (0,1)$ and $c_1 > 0$ are the constants given in (26) and (31), respectively. We derive the following inequality chain which holds for all $(x',y') \in B_{\hat{h}}\left((\hat{x},y),\mu\right)$ and for all $u_{\perp} \in T_{\hat{h}}^{\perp}$:

$$\begin{aligned}
&\left|D_1\mathcal{F}_{\hat{h}}(x',y').u_{\perp}\right| \\
&\leq \left|D_1\mathcal{F}_{\hat{h}}(\hat{x},y).u_{\perp}\right| + \frac{1-c_0}{2}\psi'(0^+)c_1\|u_{\perp}\| && \text{[by (57)]} \\
&\leq c_0\,\psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u_{\perp}| + \frac{1-c_0}{2}\psi'(0^+)c_1\|u_{\perp}\| && \text{[by (27)]} \qquad (58)\\
&\leq c_0\,\psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u_{\perp}| + \frac{1-c_0}{2}\psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u_{\perp}| && \text{[by (33)]} \\
&= \frac{c_0+1}{2}\,\psi'(0^+)\sum_{i\in\hat{h}}|a_i^T u_{\perp}|. && (59)
\end{aligned}$$

On the other hand, (56) shows that for every $(x', y') \in B_{\hat{h}}((\hat{x}, y), \mu)$ and for all $u_{\perp} \in T_{\hat{h}}^{\perp} \cap S$, we have

$$\begin{aligned}\delta_1 \mathcal{F}(x', y')(u_{\perp}) &\geq \psi'(0^+) \sum_{i \in \hat{h}} |a_i^T u_{\perp}| - |D_1 \mathcal{F}_{\hat{h}}(x', y').u_{\perp}| \\ &\geq \left(1 - \frac{c_0 + 1}{2}\right) \psi'(0^+) \sum_{i \in \hat{h}} |a_i^T u_{\perp}| > 0. \qquad \text{[by (59)]}\end{aligned}$$

The last inequality is strict since for every $u_{\perp} \in T_{\hat{h}}^{\perp} \cap S$, there is at least one index $i \in \hat{h}$ for which $a_i^T u_{\perp} \neq 0$. □

We now complete the proof of Theorem 1. Consider $\nu > 0$ and $\mu > 0$ the radii found in Lemmas 2 and 3 and $\mathcal{X}$ the function exhibited in Lemma 2. By the continuity of $\mathcal{X}$, there exists $\xi \in (0, \min\{\mu, \nu\}]$ such that $\mathcal{X}(y') \in B(\hat{x}, \mu)$ for every $y' \in B(y, \xi)$. For any $y' \in B(y, \xi)$, consider the point $\hat{x}' := \mathcal{X}(y')$. From Lemma 2, $\hat{x}' \in \Theta_{\hat{h}}(y')$ and $\hat{x}'$ is a strict local minimizer of $\mathcal{F}|_{\overline{\Theta_{\hat{h}}(y')}}(., y')$. From Lemma 3, $\delta_1 \mathcal{F}(\hat{x}', y')(u_{\perp}) > 0$ for all $u_{\perp} \in T_{\hat{h}}^{\perp} \cap S$. All the conditions of Proposition 1 being satisfied, $\mathcal{F}(., y')$ reaches a strict local minimum at $\hat{x}'$. It follows that $\mathcal{X} : B(y, \xi) \to \mathbb{R}^p$ is the sought-after $\mathcal{C}^{m-1}$ minimizer function. □

We now focus on the assumptions involved in this theorem. Assumption 2 is nothing else but the very classical sufficient condition for a strict local minimum of a smooth function over an affine subspace. Assumption 3 was used in Proposition 1 and was discussed therein.

Remark 6 (on assumption 1). The subset $\{a_i : i \in \hat{h}\}$ in assumption 1 is determined by (6). With the notation introduced in the beginning of Lemma 2, $y_{\hat{h}} := I_{\hat{h}} y \in \mathbb{R}^{\#\hat{h}}$ belongs to the range of $A_{\hat{h}}$, denoted by $\mathcal{R}(A_{\hat{h}})$. Since $\dim \mathcal{R}(A_{\hat{h}}) = \text{rank} A_{\hat{h}}$, it follows that if $\text{rank} A_{\hat{h}} < \#\hat{h}$, then all $y'_{\hat{h}}$ belonging to $\mathcal{R}(A_{\hat{h}})$ belong to a subspace of dimension strictly smaller than $\#\hat{h}$. Thus, assumption 1 fails to hold only if y is included in a subspace of dimension smaller than q. But the chance that noisy data y belong to such a subspace is null. Hence, assumption 1 is satisfied for almost all $y \in \mathbb{R}^q$.

It is worth emphasizing that the independence of the whole set $\{a_i : i \in \{1, \ldots, q\}\}$ is not required. Thus, Theorem 1 addresses any matrix A whether it be ill conditioned, or singular, or invertible.

Theorem 1 entails some important consequences which are discussed next.

Remark 7 (stability of minimizers). The fact that there is a $\mathcal{C}^{m-1}$ local minimizer function shows that, in spite of the nonsmoothness of $\mathcal{F}$, for any y, all the strict local minimizers of $\mathcal{F}(., y)$ which satisfy the conditions of the theorem are *stable under weak perturbations of data* y. This result extends Lemma 1 to nonsmooth functions of the form (11)–(12). Moreover, if for every $y \in \mathbb{R}^q$ the function $\mathcal{F}(., y)$ is strictly convex, then the unique minimizer function $\mathcal{X} : \mathbb{R}^q \to \mathbb{R}^p$, relevant to $\mathcal{F}(., \mathbb{R}^q)$, is $\mathcal{C}^{m-1}$ on $\mathbb{R}^q$.

Remark 8 (stability of $\hat{h}$). The result formulated in (40) means that *the set-valued function* $y' \to \mathcal{H}(\mathcal{X}(y'), y')$ *is constant on* N, *i.e., that* $\mathcal{H}$ *is constant under small perturbations of* y. Equivalently, *all residuals* $(a_i^T \mathcal{X}(y') - y'_i)$ *for* $i \in \hat{h}$ *are null on* N.

Remark 9 (data domain). Theorem 1 reveals that the data domain $\mathbb{R}^q$ contains *volumes of positive measure* composed of data that lead to local minimizers which

fit exactly the data entries belonging to the same set (e.g., for A invertible, $\alpha = 0$ yields $\hat{h} = \{1, \ldots, q\}$ and the data volume relevant to this $\hat{h}$ is $\mathbb{R}^q$). For a meaningful choice of ψ, Φ, and α, there are volumes corresponding to various $\hat{h}$, and they are large enough so that noisy data come across them. That is why in practice, nonsmooth data-fidelity terms yield minimizers fitting exactly a certain number of the data entries. The resultant numerical effect is observed in section 7.

Next we present a simple example which illustrates Theorem 1.

Example 1 (nonsmooth data-fidelity term). Consider the function

$$\mathcal{F}(x, y) = \sum_{i=1}^{q} |x_i - y_i| + \alpha \sum_{i=1}^{q} \frac{x_i^2}{2},$$

where $\alpha > 0$. For every $y \in \mathbb{R}^q$, the function $\mathcal{F}(., y)$ is strictly convex, so it has a unique minimizer and the latter is strict. Moreover,

$$\min_x \mathcal{F}(x, y) = \sum_{i=1}^{q} \min_{x_i} f(x_i, y_i),$$
$$\text{where} \quad f(x_i, y_i) = |x_i - y_i| + \frac{\alpha x_i^2}{2} \quad \text{for} \quad i = 1, \ldots, q.$$

For $y \in \mathbb{R}^q$, let $\hat{x}$ be the minimizer of $\mathcal{F}(., y)$. Now $\hat{h} = \{i : \hat{x}_i = y_i\}$. For every i, the fact that $f(., y_i)$ has a minimum at $\hat{x}_i$ means that $\delta_1 f(\hat{x}_i, y_i)(u) \geq 0$ for every $u \in \mathbb{R}$. Then for every $u \in \mathbb{R}$ we have

$$\text{if} \ \ (i \in \hat{h}^c \ \Leftrightarrow \ \hat{x}_i \neq y_i), \ \text{then} \ \delta_1 f(x_i, y_i)(u) = Df(x_i, y_i).u = (\operatorname{sign}(x_i - y_i) + \alpha x_i) .u \geq 0;$$
$$\text{if} \ \ (i \in \hat{h} \ \Leftrightarrow \ \hat{x}_i = y_i), \ \text{then} \ \delta_1 f(\hat{x}_i, y_i)(u) = |u| + (\alpha y_i) .u \geq 0.$$

From Proposition 1, the entries of the minimizer function $\mathcal{X}$ are

$$\text{if} \ \ |y_i| > \frac{1}{\alpha}, \quad \text{then} \quad \mathcal{X}_i(y) = \frac{1}{\alpha} \operatorname{sign}(y_i);$$
$$\text{if} \ \ |y_i| \leq \frac{1}{\alpha}, \quad \text{then} \quad \mathcal{X}_i(y) = y_i.$$

Theorem 1 applies, provided that $|y_i| \neq 1/\alpha$ for every $i \in \hat{h}$, which corresponds to assumption 3. In such a case, we can take for the neighborhood exhibited in Theorem 1

$$N = B(y, \xi) \ \text{ with } \ \xi = \min_{i=1}^{q} \left| \ |y_i| - \frac{1}{\alpha} \right|.$$

We see that $y' \to \mathcal{H}(\mathcal{X}(y'), y')$ reads

$$\mathcal{H}(\mathcal{X}(y'), y') = \left\{ i \in \{1, \ldots, q\} : |y'_i| \leq \frac{1}{\alpha} \right\}$$

and is constant on N. The above expression shows also that the cardinality of $\hat{h}$ increases when α decreases.

We now illustrate Remark 9. For $h \subset \{1, \ldots, q\}$, put

$$V_h := \left\{ y \in \mathbb{R}^q : \ |y_i| \leq \frac{1}{\alpha} \ \forall i \in h \ \text{ and } \ |y_i| > \frac{1}{\alpha} \ \forall i \in h^c \right\}.$$

Obviously, every $y' \in V_h$ gives rise to a minimizer $\hat{x}'$ of $\mathcal{F}(.,y')$ satisfying $\mathcal{H}(\hat{x}',y') = h$. That is, the function $y' \to \mathcal{H}(\mathcal{X}(y'),y')$ is constant on V_h. Note that $V_\emptyset = \{y \in \mathbb{R}^q : |y_i| > 1/\alpha \text{ for all } i\}$ and that $V_\emptyset = \emptyset$ if $\alpha = 0$. Moreover, *for every* $h \subset \{1,\dots,q\}$, *the set* V_h *has a positive volume in* $\mathbb{R}^q$, whereas the family of all V_h, when h ranges over the family of all the subsets of $\{1,\dots,q\}$ (including the empty set), is a *partition* of $\mathbb{R}^q$.

5. Smooth data-fidelity terms. In this section we focus on smooth cost-functions with the goal of checking whether we can get minimizers which fit exactly a certain number of data entries. We start with an illuminating example.

Example 2 (smooth cost-function). For $A \in \mathbb{R}^{q\times p}$ and $G \in \mathbb{R}^{r\times p}$ with $r \in \mathbb{N}^*$, consider the cost-function $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$,

$$\mathcal{F}(x,y) = \|Ax - y\|^2 + \alpha\|Gx\|^2. \tag{60}$$

Recall that since the publication of [37], cost-functions of this form are among the most widely used tools in signal and image estimations [25, 22, 35, 13]. Under the classical assumption $\ker A^TA \cap \ker G^TG = \emptyset$, it is seen that for every $y \in \mathbb{R}^q$, $\mathcal{F}(.,y)$ is strictly convex and its unique minimizer $\hat{x}$ is determined by solving the equation

$$D_1\mathcal{F}(\hat{x},y) = 0 \quad \text{where} \quad D_1\mathcal{F}(\hat{x},y) = 2(A\hat{x} - y)^TA + 2\alpha\hat{x}^TG^TG.$$

The relevant minimizer function $\mathcal{X} : \mathbb{R}^q \to \mathbb{R}^p$ reads

$$\mathcal{X}(y) = (A^TA + \alpha\, G^TG)^{-1}A^T.\, y. \tag{61}$$

We now determine the set of *all* data points $y \in \mathbb{R}^q$ for which $\hat{x} := \mathcal{X}(y)$ fits exactly the ith data entry y_i. To this end, we have to solve with respect to y the equation

$$a_i^T\,\mathcal{X}(y) = y_i. \tag{62}$$

Using (61), this is equivalent to solving the equation

$$\begin{aligned} &p_i(\alpha).y = 0, \\ \text{where} \quad &p_i(\alpha) \quad = a_i^T(A^TA + \alpha\, G^TG)^{-1}A^T - e_i^T. \end{aligned} \tag{63}$$

We can have $p_i(\alpha) = 0$ only if α belongs to the discrete set of several values which satisfy a data-independent system of q polynomials of degree p. However, α will almost never belong to such a set so, in general, $p_i(\alpha) \neq 0$. Then (63) implies $y \in \{p_i(\alpha)\}^\perp$. More generally, we have the implication

$$\exists i \in \{1,\dots,q\} \ \text{ such that } \ \mathcal{X}_i(y) = y_i \quad \Rightarrow \quad y \in \bigcup_{j=1}^{q} \{p_j(\alpha)\}^\perp.$$

Since every $\{p_i(\alpha)\}^\perp$ is a subspace of $\mathbb{R}^q$ of dimension $q-1$, the union on the right-hand side above is a *closed, negligible subset of* $\mathbb{R}^q$. The chance that noisy data come across this union is null. Hence, the chance that noisy data y yield a minimizer $\mathcal{X}(y)$ which fits even one data entry, i.e., that there is at least one index i such that (62) holds, is null.

The theorem stated below generalizes this example.

THEOREM 2. *Consider a* $\mathcal{C}^m$*-function* $\mathcal{F} : \mathbb{R}^p \times \mathbb{R}^q \to \mathbb{R}$, *with* $m \geq 2$, *of the form* (1)–(2), *and let* $h \subset \{1\dots,q\}$ *be nonempty. Assume the following:*

1. *For all* $i = 1, \dots, q$, *the functions* $\psi_i : \mathbb{R} \to \mathbb{R}$ *satisfy* $\psi_i''(t) > 0$ *for all* $t \in \mathbb{R}$;
2. A *is invertible* (*recall that for every* $i = 1, \dots, q$, *the* i*th row of* A *is* a_i^T);
3. *there is an open domain* $N_0 \subset \mathbb{R}^q$ *so that* $\mathcal{F}(., N_0)$ *admits a* $\mathcal{C}^{m-1}$ *local minimizer function* $\mathcal{X} : N_0 \to \mathbb{R}^p$, *such that* $D_1^2\mathcal{F}(\mathcal{X}(y), y)$ *is positive definite, for all* $y \in N_0$;
4. *for every* $x \in \mathcal{X}(N_0) \subset \mathbb{R}^p$ *and for every* $i \in h$ *we have* $D^2\Phi(x).[A^{-1}]_i \neq 0$, *where* $[A^{-1}]_i$ *denotes the* i*th column of* A^{-1}, *for* $i = 1, \dots, q$.

For a given set of constants $\{\theta_i, i \in h\}$, *and for any* $N \subset N_0$ *a closed subset of* $\mathbb{R}^q$, *put*

$$\Upsilon_h := \left\{ y \in N : a_i^T \mathcal{X}(y) = y_i + \theta_i \ \forall i \in h \right\}. \tag{64}$$

Then Υ_h *is a closed subset of* $\mathbb{R}^q$ *whose interior is empty.*

Proof. For every h nonempty we have

$$\Upsilon_h = \bigcap_{i \in h} \Upsilon_{\{i\}}.$$

It is hence sufficient to consider $\Upsilon_{\{i\}}$ for some $i \in h$. For simplicity, in the following we write Υ_i for $\Upsilon_{\{i\}}$. Since $\mathcal{X}$ is continuous on N, every Υ_i is closed in N and hence in $\mathbb{R}^q$. Our reasoning below is developed *ad absurdum*. So suppose that Υ_i contains an open, connected subset of $\mathbb{R}^q$, say $\tilde{N} \subset \Upsilon_i \subset N$. We can hence write

$$a_i^T \mathcal{X}(y) = y_i + \theta_i \quad \forall y \in \tilde{N}. \tag{65}$$

Differentiating both sides of this identity with respect to y yields

$$a_i^T D\mathcal{X}(y) = e_i^T \quad \forall y \in \tilde{N}. \tag{66}$$

We next determine the form of $D\mathcal{X}$. Since for every $y \in \tilde{N}$ the point $\mathcal{X}(y)$ is a local minimizer of $\mathcal{F}(., y)$, it satisfies $D_1\mathcal{F}(\mathcal{X}(y), y) = 0$. Differentiating both sides of the latter identity leads to

$$D_1^2\mathcal{F}\left(\mathcal{X}(y), y\right) D\mathcal{X}(y) + D_{1,2}\mathcal{F}\left(\mathcal{X}(y), y\right) = 0 \quad \forall y \in \tilde{N}. \tag{67}$$

The Hessian of $x \to \mathcal{F}(x, y)$, denoted $H(x, y) := D_1^2\mathcal{F}(x, y)$, reads

$$\begin{aligned} H(x, y) &= D_1^2\Psi(x, y) + \alpha D^2\Phi(x) \\ &= A^T \operatorname{Diag}\left(\ddot{\psi}(x, y)\right) A + \alpha D^2\Phi(x), \end{aligned} \tag{68}$$

where for every x and y, $\ddot{\psi}(x, y) \in \mathbb{R}^q$ is the vector whose entries read

$$[\ddot{\psi}(x, y)]_i = \psi_i''(a_i^T x - y_i) \ \text{ for } \ i = 1, \dots, q.$$

By assumption 3, $H\left(\mathcal{X}(y), y\right)$ is an invertible matrix for every $y \in \tilde{N}$. Furthermore,

$$D_{1,2}\mathcal{F}(x, y) = -A^T \operatorname{Diag}\left(\ddot{\psi}(x, y)\right).$$

Inserting the last expression and (68) into (67) shows that

$$D\mathcal{X}(y) = \left(H(\mathcal{X}(y), y)\right)^{-1} A^T \operatorname{Diag}\left(\ddot{\psi}(\mathcal{X}(y), y)\right) \quad \forall y \in \tilde{N}. \tag{69}$$

Now introducing (69) into (66) yields

$$a_i^T \left(H(\mathcal{X}(y),y)\right)^{-1} A^T \operatorname{Diag}\left(\ddot{\psi}(\mathcal{X}(y),y)\right) = e_i^T \quad \forall y \in \tilde{N}. \tag{70}$$

By assumption 1, $\operatorname{Diag}\big(\ddot{\psi}(\mathcal{X}(y),y)\big)$ is invertible for every $y \in \tilde{N}$. Its inverse is a diagonal matrix whose diagonal terms are $\left(\psi_i''(a_i^T\mathcal{X}(y)-y_i)\right)^{-1}$ for $i=1\ldots,q$. Noticing that

$$e_i^T \left(\operatorname{Diag}\left(\ddot{\psi}(\mathcal{X}(y),y)\right)\right)^{-1} = \frac{e_i^T}{\psi_i''\left(a_i^T\mathcal{X}(y)-y_i\right)},$$

we find that (70) equivalently reads

$$\psi_i''(a_i^T\mathcal{X}(y)-y_i)\,.a_i^T \left(H(\mathcal{X}(y),y)\right)^{-1} = e_i^T A^{-T} \quad \forall y \in \tilde{N},$$

where $A^{-T} := \left(A^T\right)^{-1}$. Then, taking into account (68),

$$\psi_i''(a_i^T\mathcal{X}(y)-y_i)\,.a_i^T = e_i^T A^{-T}\left(A^T \operatorname{Diag}\left(\ddot{\psi}(\mathcal{X}(y),y)\right) A + \alpha D^2\Phi(\mathcal{X}(y))\right) \quad \forall y \in \tilde{N}.$$

By the invertibility of A (assumption 2), and noticing that $e_i^T A = a_i^T$, the latter expression is simplified to

$$\psi_i''\left(a_i^T\mathcal{X}(y)-y_i\right)\,.a_i^T = \psi_i''\left(a_i^T\mathcal{X}(y)-y_i\right)\,.a_i^T + \alpha e_i^T A^{-T} D^2\Phi(\mathcal{X}(y)) \quad \forall y \in \tilde{N},$$

and finally to

$$D^2\Phi(\mathcal{X}(y)).A^{-1}e_i = 0 \quad \forall y \in \tilde{N}.$$

However, the obtained identity contradicts assumption 4. Hence the conclusion. □

Let us comment on the assumptions taken in this theorem. Recall first that assumption 3 was discussed in Lemma 1 and Remark 1. In the typical case when Ψ is a data-fidelity measure, every ψ_i is a strictly convex function satisfying $\psi_i(0)=0$ and $\psi_i(t)=\psi_i(-t)$.

Remark 10 (on assumption 2). This proposition also addresses the case when

$$\mathcal{F}(x,y) = \|Ax-y\|^2 + \alpha\Phi(x) \;\text{ with }\; \operatorname{rank}A = p \le q.$$

Indeed, for $p<q$, $\mathcal{F}$ can equivalently be expressed in terms of an invertible $p\times p$ matrix $\tilde{A}$ with $\tilde{A}^T\tilde{A} = A^TA$ in place of A.

Remark 11 (on assumption 4). By the invertibility of A (assumption 2), we see that $[A^{-1}]_i = A^{-1}e_i \neq 0$ for every $i=1,\ldots,q$. It would be a "pathological" situation to have some of the columns of A^{-1} in $\ker D^2\Phi(x)$ for some x. For instance, focus on the classical case given in (4) with $G_i^T : \mathbb{R}^p \to \mathbb{R}$. Let G denote the $r\times p$ matrix whose rows are G_i^T for $i=1,\ldots,r$. Then $D^2\Phi(x) = G^T\operatorname{Diag}\left(\ddot{\varphi}(Gx)\right)G$, where $\ddot{\varphi}(Gx)\in\mathbb{R}^r$ is the vector with entries $[\ddot{\varphi}(Gx)]_i = \varphi''(G_i^Tx)$ for $i=1,\ldots,r$. Focus on the case when $\varphi''(t)>0$ for all $t\in\mathbb{R}$ (e.g., φ is strictly convex) and G yields first-order differences between neighboring samples. Then $\operatorname{Ker}D^2\Phi(x)$ is composed of the constant vectors $\kappa[1,\ldots,1]^T$, $\kappa\in\mathbb{R}$. Then assumption 4 is satisfied provided that A^{-1} does not involve constant columns.

Remark 12 (meaning of the theorem). If for some $y\in\mathbb{R}^q$ a minimizer $\hat{x}$ of $\mathcal{F}(.,y)$ satisfies an affine equation of the form $a_i^T\hat{x} = y_i + \theta_i$, then Theorem 2 asserts that

y belongs to a closed subset of $\mathbb{R}^q$ whose interior is empty. There is no chance that noisy data y yield local minimizers of a smooth cost-function $\mathcal{F}(.,y)$ satisfying such an equation.

The next proposition states the same conclusions but under different assumptions.

PROPOSITION 2. *Consider a $\mathcal{C}^m$-function $\mathcal{F}:\mathbb{R}^p\times\mathbb{R}^q\to\mathbb{R}$, with $m\geq 2$, of the form (1)–(2) and let $h\subset\{1\ldots,q\}$ be nonempty. Assume the following:*

1. *There is a domain $N_0\subset\mathbb{R}^q$ so that $\mathcal{F}(.,N_0)$ admits a $\mathcal{C}^{m-1}$ local minimizer function $\mathcal{X}:N_0\to\mathbb{R}^p$ such that $D_1^2\mathcal{F}(\mathcal{X}(y),y)$ is positive definite for all $y\in N_0$;*
2. *for every $y\in N_0$ and for every $i\in h$ there exists $j\in\{1,\ldots,q\}$ such that the function $\mathcal{K}_{i,j}$,*

$$\mathcal{K}_{i,j}(y'):=\psi_i''\left(a_j^T\mathcal{X}(y')-e_j^Ty'\right).a_i^T\left(H(\mathcal{X}(y'),y')\right)^{-1}.a_j,$$

where H was given in (68), is nonconstant on any neighborhood of y.

For $\{\theta_i\in\mathbb{R}:i\in h\}$ given, and for every $N\subset N_0$ a closed subset of $\mathbb{R}^q$, put

$$\Upsilon_h:=\left\{y\in N:a_i^T\mathcal{X}(y)=y_i+\theta_i\ \forall i\in h\right\}. \tag{71}$$

Then Υ_h is a closed subset of $\mathbb{R}^q$ whose interior is empty.

Proof. As in the proof of Theorem 2, we focus on Υ_i for $i\in h$ and develop our reasoning by contradiction. So suppose that Υ_i contains an open ball $\tilde{N}$. Then (65) and (66) are true. In particular, comparing (66) for $y'\neq y$ with the same equality for y yields

$$a_i^TD\mathcal{X}(y')=a_i^TD\mathcal{X}(y)\quad\forall y'\in\tilde{N}. \tag{72}$$

Notice that $A^T\operatorname{Diag}\big(\ddot{\psi}(x,y')\big)$ is a matrix whose jth column reads $\psi''(a_j^Tx-y_j').a_j$. Introducing (69) into (72) shows that the latter is equivalent to the system

$$\mathcal{K}_{i,j}(y')=\mathcal{K}_{i,j}(y)\ \ \forall j\in\{1,\ldots,q\},\ \ \forall y'\in\tilde{N}.$$

The obtained result contradicts assumption 2. ∎

Remark 13 (on assumption 2). Although a general proof of the validity of this assumption appears to be more intricate than important, we conjecture that it is usually satisfied. The intuitive arguments are the following. Let us focus on the classical case when Φ is as in (4). The entries of $H(x',y')$ read

$$[H(x',y')]_{m,n}=\sum_{j=1}^q\eta_{j,m}^2\psi''(a_jx'-y_j')+\sum_{j=1}^r\kappa_{j,n}^2\varphi''(G_jx')\ \text{ for }\ (m,n)\in\{1,\ldots,p\}^2, \tag{73}$$

where $\eta_{j,m}$, $j=1,\ldots,q$, and $\kappa_{j,n}$, $j=1,\ldots,r$, are constants that are calculated from G and A. From Cramer's rule for matrix inversion, for every j, the term $a_i^T\left(H(x',y')\right)^{-1}a_j$ is the fraction of two polynomials. The entries of the numerator read $\beta_{s,m,n}([H(x',y')]_{m,n})^s$ for all $(m,n)\in\{1,\ldots,p\}^2$ with $\beta_{s,m,n}\in\mathbb{R}$ for $s=0,\ldots,p-1$. In the denominator we have $\gamma_{s,m,n}([H(x',y')]_{m,n})^s$ for all $(m,n)\in\{1,\ldots,p\}^2$ with $\gamma_{s,m,n}\in\mathbb{R}$ for $s=0,\ldots,p$. For $\mathcal{X}$ a minimizer function and j and i given, $\mathcal{K}_{i,j}$ has the form

$$\mathcal{K}_{i,j}(y')=\psi''\left(a_j^T\mathcal{X}(y')-y_j'\right).\frac{\sum_{s=1}^{p-1}\sum_{(m,n)}\beta_{s,m,n}([H(\mathcal{X}(y'),y')]_{m,n})^s}{\sum_{s=1}^{p}\sum_{(m,n)}\gamma_{s,m,n}([H(\mathcal{X}(y'),y')]_{m,n})^s}. \tag{74}$$

Assumption 2 requires that for $i\in h$, there is at least one index $j\in\{1,\ldots,q\}$ for which the relevant function $\mathcal{K}_{i,j}$ does not remain constant on any neighborhood of y.

6. Nonsmooth regularization versus nonsmooth data-fidelity. In this section we compare cost-functions involving nonsmooth data-fidelity terms to cost-functions involving nonsmooth regularization terms. The visual effects produced by these classes of cost-functions can be seen in section 7.

Cost-functions with *nonsmooth regularization* typically have the form (1), where Ψ is a $\mathcal{C}^m$-function, $m \geq 2$, whereas Φ is as in (4) with φ nonsmooth at zero. Most often, $\Psi(x, y) = \|Ax - y\|^2$. Nonsmooth functions φ are, for instance, the L^1- and concave functions in (5). Since the publication of [33, 18], such cost-functions are customarily used in signal and image restoration [18, 1, 14, 11, 12, 38]. Visually, the obtained minimizers exhibit a *staircasing effect* since they typically involve many constant regions—see, for instance, Figures 6 and 10 in section 8. This effect is discussed by many authors [18, 15, 14, 12]. In particular, the ability of the L^1-function to recover noncorrelated "nearly black" images in the simplest case when $G_i = e_i$ for all i was interpreted in [15] using mini-max decision theory. Total-variation methods, corresponding to $\varphi(t) = |t|$ also, were observed to yield "blocky images" [14, 12]. The concave function was shown to transform ramp-shaped data into a step-shaped minimizer [19].

A theoretical explanation of staircasing was given in [26, 27, 28]. It was shown there that regularization of the form (4) with φ nonsmooth at zero yields local minimizers $\hat{x}$ which satisfy $G_i^T \hat{x} = 0$ *exactly* for many indexes i. For instance, if G_i^T, $i = 1, \ldots, r$, yield first-order differences between neighboring samples (if x is a signal of $\mathbb{R}^p$, $G_i^T x = x_i - x_{i+1}$ for $i = 1, \ldots, p-1$), the relevant minimizers $\hat{x}$ are constant over many zones. If G_i^T, $i = 1, \ldots, r$, yield second-order differences, then $\hat{x}$ involves many zones over which it is affine, etc. More generally, the sets of indexes i for which $G_i^T \hat{x} = 0$ determine zones which can be said to be *strongly homogeneous* [27]. Staircasing is due to a special form of stability property which is explained next. Let a data point y give rise to a local minimizer $\hat{x}$ which satisfies $G_i^T \hat{x} = 0$ for all $i \in \hat{h}$, where $\hat{h} \neq \emptyset$. It is shown in [26, 27, 28] that y is in fact contained in a neighborhood $N \in \mathbb{R}^q$ whose elements $y' \in N$ (noisy data) give rise to local minimizers $\hat{x}'$ of $\mathcal{F}(., y')$, placed near $\hat{x}$, which satisfy $G_i^T \hat{x}' = 0$ for all $i \in \hat{h}$. Since every such N is a volume of positive measure, noisy data come across these volumes and yield minimizers satisfying $G_i^T \hat{x}' = 0$ for many indexes i. Notice that this behavior is due to the nonsmoothness of φ at zero since it cannot occur with differentiable cost-functions [27, 28].

The behavior of the minimizers of cost-functions with *nonsmooth data-fidelity*, as considered in Theorem 1, is opposite. If y leads to a minimizer $\hat{x}$ which fits exactly a set $\hat{h}$ of entries of y, Theorem 1 shows that y is contained in a neighborhood N such that the relevant minimizer function $\mathcal{X}$ follows closely every small variation of all data entries y'_i for $i \in \hat{h}$ when y' ranges over N. Thus $a_i^T \mathcal{X}(y')$ is never constant in the vicinity of y for $i \in \hat{h}$.

7. Nonsmooth data-fidelity to detect and smooth outliers. Our objective now is to process data in order to detect, and possibly to smooth, outliers and impulsive noise. To this end, take $a_i = e_i$ for every $i \in \{1, \ldots, q\}$ in (2). Focus on

$$\mathcal{F}(x, y) = \sum_{i=1}^{q} \psi(x_i - y_i) + \alpha \sum_{i=1}^{r} \varphi(G_i^T x), \tag{75}$$

where $G_i^T : \mathbb{R}^p \to \mathbb{R}$ for $i = 1, \ldots, r$ yield differences between neighboring samples (e.g., $G_i^T x = x_i - x_{i+1}$ if x is a signal); ψ and φ are even and strictly increasing on $[0, \infty)$, with $\psi'(0^+) > 0$ and φ smooth on $\mathbb{R}$. Suppose that $\hat{x}$ is a strict minimizer

of $\mathcal{F}(.,y)$ and put $\hat{h}=\mathcal{H}(\hat{x},y)$. Based on the results in section 4, we naturally come to the following method for the detection of outliers. Since every y_i corresponding to $i\in\hat{h}$ is kept intact in the minimizer $\hat{x}$, that is, $\hat{x}_i=y_i$, every such y_i can be considered as a *faithful data entry*. In contrast, every y_i with $i\in\hat{h}^c$ corresponds to $\hat{x}_i\neq y_i$ which can indicate that this y_i is aberrant. In other words, *given $y\in\mathbb{R}^q$, we posit that $\hat{h}^c$, the complementary of $\hat{h}=\mathcal{H}(\mathcal{X}(y),y)$, provides an estimate of the locations of the outliers in y*. The possibility of keeping intact all faithful data entries is both spectacular and valuable from a practical point of view, e.g., to preprocess data.

Remark 14 (stability of the detection of outliers). If a minimizer $\hat{x}$ of $\mathcal{F}(.,y)$ for $y\in\mathbb{R}^q$ gives rise to $\hat{h}=\mathcal{H}(\hat{x},y)$, then Theorem 1 ensures that all data y' placed near y yield minimizers $\hat{x}'$ which recover exactly the same set of outlier positions $\hat{h}^c$. Hence, the suggested method for detection of outliers is stable under small data variations.

We also can envisage *smoothing* outliers since the value of every $\hat{x}_i$ for $i\in\hat{h}^c$ is obtained from the values of neighboring data samples through the terms $\alpha\varphi(G_j^T\hat{x})$ for all j neighbor of i. Small values of α make the weight of Ψ more important, so the relevant minimizers $\hat{x}$ fit larger sets of data entries, i.e., $\hat{h}$ is larger. At the same time, all samples $\hat{x}_i$ for $i\in\hat{h}^c$ incur an only-weak smoothing and may remain close to y_i. In contrast, large values of α improve smoothing since they increase the weight of Φ. To resume, small values of α are better adapted for the detection of outliers while large values of α are better suited for smoothing of outliers. We are hence faced with a compromise between efficiency of detection and quality of smoothing. The next example, as well as the experiments presented below, corroborate this conjecture.

Example 3. Consider the following cost-function:

$$\mathcal{F}(x,y)=\sum_{i=1}^{q}|x_i-y_i|+\alpha\sum_{i=1}^{p-1}(x_i-x_{i+1})^2.$$

Let $\hat{x}$ be a minimizer of $\mathcal{F}(.,y)$ for which $\hat{h}:=\mathcal{H}(\hat{x},y)$ is nonempty. Focus on $i\in\hat{h}^c$. Since $\hat{x}_i\neq y_i$, then

$$0=\frac{\partial\mathcal{F}(\hat{x},y)}{\partial\hat{x}_i}=\operatorname{sign}(\hat{x}_i-y_i)+2\alpha\left((\hat{x}_i-\hat{x}_{i+1})-(\hat{x}_{i-1}-\hat{x}_i)\right),$$

which yields

$$\hat{x}_i=\frac{\hat{x}_{i-1}+\hat{x}_{i+1}}{2}-\frac{\operatorname{sign}(\hat{x}_i-y_i)}{4\alpha}. \tag{76}$$

Hence, $\hat{x}_i$ takes the form (76) only if we have

$$\text{either}\quad y_i>\frac{\hat{x}_{i-1}+\hat{x}_{i+1}}{2}+\frac{1}{4\alpha}\quad\text{or}\quad y_i<\frac{\hat{x}_{i-1}+\hat{x}_{i+1}}{2}-\frac{1}{4\alpha}.$$

We remark that (76) does not involve y_i but only the sign of $(\hat{x}_i-y_i)$. Thus, if y_i is an outlier, the value of $\hat{x}_i$ relies only on faithful data entries y_j for $j\in\hat{h}$ by means of $\hat{x}_{i-1}$ and $\hat{x}_{i+1}$. Moreover, the smoothing incurred by $\hat{x}_i$ is stronger for large values of α, since then $\hat{x}_i$ is closer to the mean of $\hat{x}_{i-1}$ and $\hat{x}_{i+1}$. Otherwise, if $i\in\hat{h}$, we have $\delta_1\mathcal{F}(\hat{x},y)(e_i)\geq 0$, which yields

$$\hat{x}_i=y_i\quad\Leftrightarrow\quad\frac{\hat{x}_{i-1}+\hat{x}_{i+1}}{2}-\frac{1}{4\alpha}\leq y_i\leq\frac{\hat{x}_{i-1}+\hat{x}_{i+1}}{2}+\frac{1}{4\alpha}.$$

This inequality is easier to satisfy if α is small, in which case numerous data samples are fitted exactly, whereas only a few samples are detected as outliers.

Concrete results depend on the shape of ψ, φ, $\{G_i^T\}$, and α. We leave this crucial question for future work. In order to recover and smooth outliers, we take the following cost-function:

$$\mathcal{F}(x,y) = \sum_{i=1}^{q} |x_i - y_i| + \alpha \sum_{i=1}^{p} \sum_{j \in \mathcal{N}(i)} |x_i - x_j|^\nu \quad \text{for} \quad \nu \in (1,2], \tag{77}$$

where for every $i = 1, \ldots, p$ the set $\mathcal{N}(i)$ contains the indexes of all samples j which are neighbors to i. In all the restorations presented below, $\mathcal{N}(i)$ is composed of the eight nearest neighbors. Since the publication of [9], we can expect that $\nu > 1$ but close to 1 allow edges to be better preserved when outliers are smoothed. Based on this, all the experiments with (77) in the following correspond to $\nu = 1.1$.

The minimizer $\hat{x}$ of $\mathcal{F}(.,y)$ for $y \in \mathbb{R}^q$ is calculated by continuation. Using that the Huber function (5),

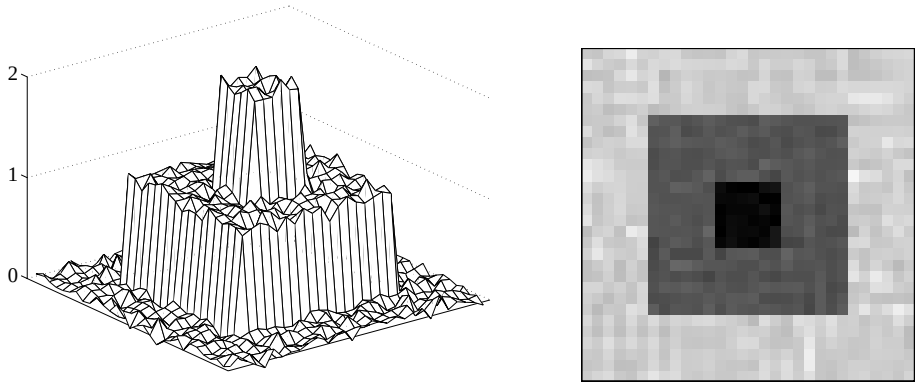
$$\psi_\nu(t) = \begin{cases} t^2 & \text{if} \quad |t| \leq \nu, \\ \nu(\nu + 2|t - \nu|) & \text{if} \quad |t| > \nu, \end{cases} \quad \text{where} \quad \nu > 0,$$

satisfies $\psi_\nu(t) \to |t|$ when $\nu \downarrow 0$, we construct a family of functions $\mathcal{F}_\nu(.,y)$ indexed by $\nu > 0$:

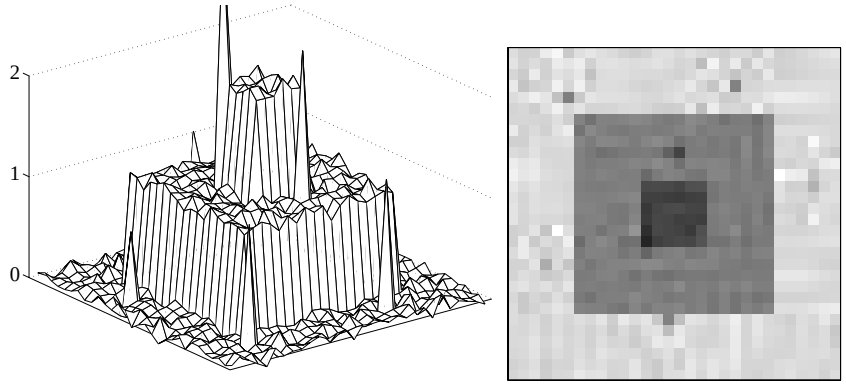
$$\mathcal{F}_\nu(x,y) := \sum_{i=1}^{q} \psi_\nu(a^T x - y_i) + \Phi(x).$$

Being strictly convex and differentiable, every $\mathcal{F}_\nu(.,y)$ has a unique minimizer, denoted by $\hat{x}_\nu$, which is calculated by a gradient descent. Since by construction having $\nu > \nu'$ entails $\mathcal{F}_\nu(x,y) \geq \mathcal{F}_{\nu'}(x,y)$ for all $x \in \mathbb{R}^p$, we see that $\mathcal{F}_\nu(\hat{x}_\nu, y)$ decreases monotonically when ν decreases to 0. It is easy to check that, moreover, as $\nu \downarrow 0$, we have $\mathcal{F}_\nu(\hat{x}_\nu, y) \to \mathcal{F}(\hat{x}, y)$, and hence $\hat{x}_\nu \to \hat{x}$, since every $\mathcal{F}_\nu(.,y)$ has a unique minimizer and the latter is strict. Total-variation methods are similar from a numerical point of view since they involve $\varphi(t) = |t|$. Many authors used smooth approximations [33, 38], e.g., $\varphi_\nu = \sqrt{t^2 + \nu}$. However, approximation using the Huber function has the numerical advantage of involving only quadratic and affine segments. At the same time, the fact that ψ'_ν is discontinuous at $\pm\nu$ is of no practical importance since the chance of obtaining a minimizer $\hat{x}_\nu$ involving a difference whose modulus is exactly ν is null [27].

First experiment. The original image x in Figure 1(a) can be assumed to be a noisy version of an ideal piecewise constant image. Data y in Figure 1(b) are obtained by adding aberrant impulsions to x whose locations are seen in Figure 4, left. Recall that our goal is to detect, and possibly smooth, the outliers in y, while preserving all the remaining entries of y.



(a) Original x.

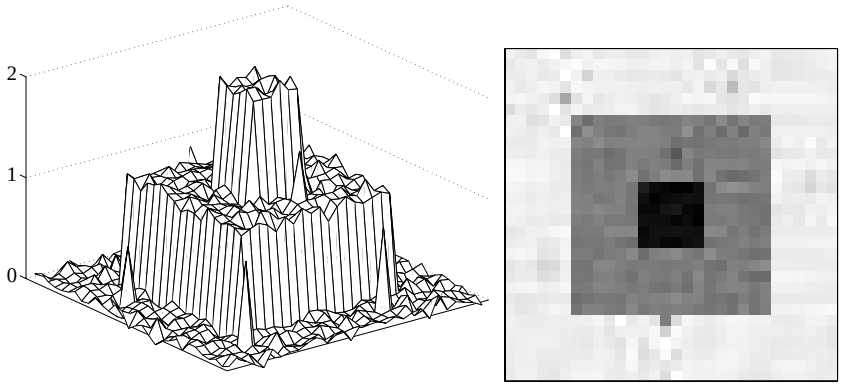


(b) Data $y = x +$ outliers.

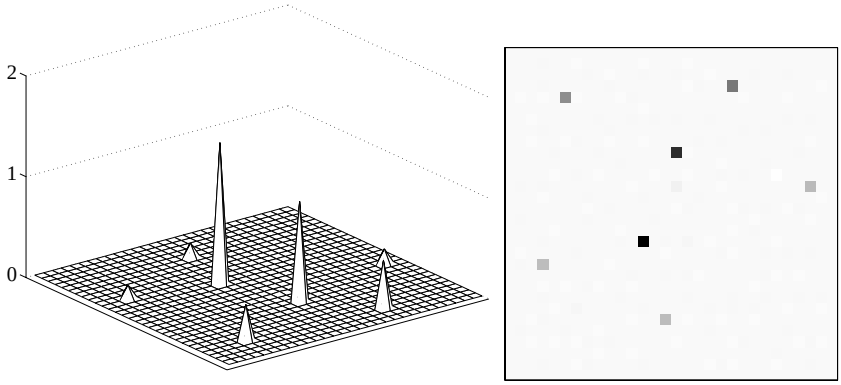
FIG. 1. *Original x and data y degraded by outliers.*

The image in Figure 2(a) is the minimizer $\hat{x}$ of the cost-function $\mathcal{F}(., y)$ proposed in (77), with $\nu = 1.1$ and $\alpha = 0.14$. The outliers are clearly visible although their amplitudes are considerably reduced. The image of the residuals $y - \hat{x}$, shown in Figure 2(b), is null everywhere except at the positions of the outliers in y. Reciprocally, the pixels corresponding to nonzero residuals (i.e., the elements of $\hat{h}^c$) provide a faithful estimate of the locations of the outliers in y, as seen in Figure 4, middle. Next, in Figure 3(a) we show a minimizer $\hat{x}$ of the same $\mathcal{F}(., y)$ obtained for $\alpha = 0.25$. This minimizer does not contain visible outliers and is very close to the original image x. The image of the residuals $y - \hat{x}$ in Figure 3(b) is null only on restricted areas but has a very small magnitude everywhere beyond the positions of the outliers. However, applying the above detection rule now leads to numerous false detections, as seen in Figure 4, right. These experiments confirm our conjecture about the role of α.

The issue of the minimization of a smooth cost-function, namely, $\mathcal{F}$ in (75) with $\psi(t) = \varphi(t) = t^2$ and $\alpha = 0.2$, is shown in Figure 5(a). As expected, edges are blurred, whereas outliers are clearly seen. The residuals in Figure 5(b) are large everywhere, which shows that $\hat{x}$ does not fit any data entry. The minimizer in Figure 6(a) is obtained using nonsmooth regularization, where $\mathcal{F}$ is of the form (75) with $\psi(t) = t^2$, $\varphi(t) = |t|$, and $\alpha = 0.2$. In accordance with our discussion in section 6, $\hat{x}$ exhibits



(a) Restoration $\hat{x}$ for $\alpha = 0.14$.



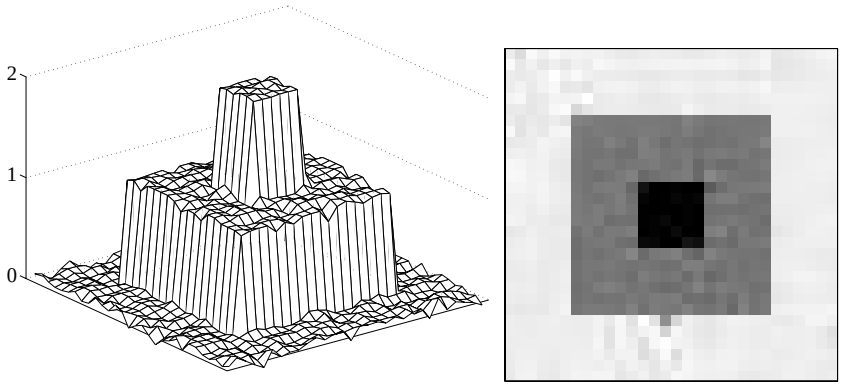
(b) Residuals $y - \hat{x}$.

FIG. 2. *Restoration using the proposed cost-function $\mathcal{F}$ with nonsmooth data-fidelity in* (77) *for $\nu = 1.1$ and $\alpha = 0.14$. The residuals provide a faithful estimator for the locations of outliers.*

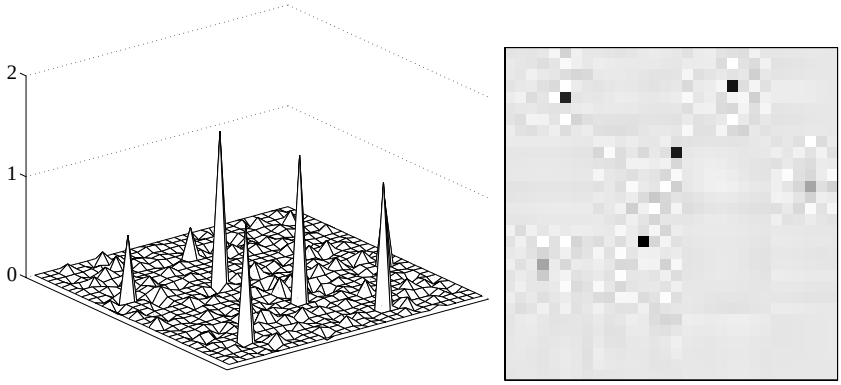
staircasing since it is constant on very large regions.

Second experiment. The original, clean image x is shown in Figure 7(a). The data y, shown in Figure 7(b), are obtained by adding to x 770 impulsions with random locations and random amplitudes in the interval $(0, 1.2)$.

In Figure 8(a) we show a zoom of the histograms of x (up) and of y (down). Figure 8(b) shows the result from applying to y two iterations of median filtering. The obtained image contains only a few outliers with weak amplitude but the entire image is degraded and, in particular, the edges are blurred. The ℓ_1-norm of the error $\|\hat{x} - x\|_1 = \sum_i |\hat{x}_i - x_i|$ is 523. The next two restorations in Figure 9 are obtained by minimizing the cost-function $\mathcal{F}$ with nonsmooth data-fidelity proposed in (77), where $\nu = 1.1$. The minimizer in Figure 9(a) corresponds to $\alpha = 0.2$ and it fits exactly the data everywhere except for several hundred pixels, where it detects outliers. This detection gives rise to 50 erroneous nondetections and to 15 false alarms, the remaining detections being correct. Figure 9(b) is obtained for $\alpha = 0.55$. The minimizer $\hat{x}$ does not contain outliers any longer but it fits exactly only a restricted number of the data entries. Nevertheless, it remains very close to all data entries which are not outliers, since the ℓ_1-norm of the error is 126. This minimizer provides a very clean restoration,



(a) Restoration $\hat{x}$ for $\alpha = 0.25$.



(b) Residuals $y - \hat{x}$.

FIG. 3. *Restoration using the proposed cost-function $\mathcal{F}$ in* (77) *for $\nu = 1.1$ and $\alpha = 0.25$. The outliers are well smoothed in $\hat{x}$, whereas the residuals remain small everywhere beyond the outlier locations.*

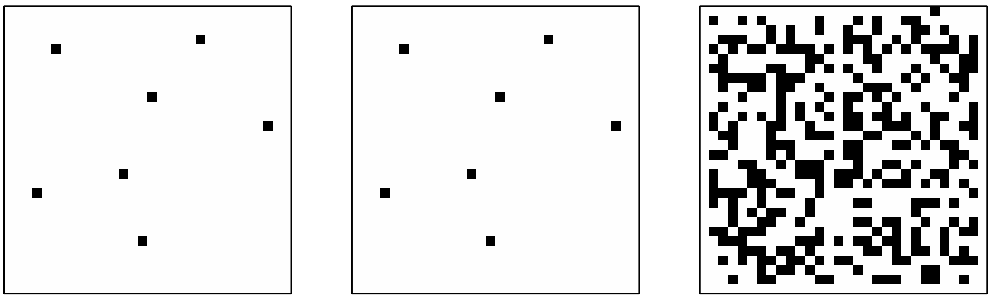


FIG. 4. *Left: The locations of the outliers in y. Middle: The locations of the pixels i of $\hat{x}$ at which $\hat{x}_i \neq y_i$, where $\hat{x}$ is the minimizer obtained for $\alpha = 0.14$ given in Figure* 2. *Right: The same locations for $\hat{x}$ the minimizer relevant to $\alpha = 0.25$, shown in Figure* 3.

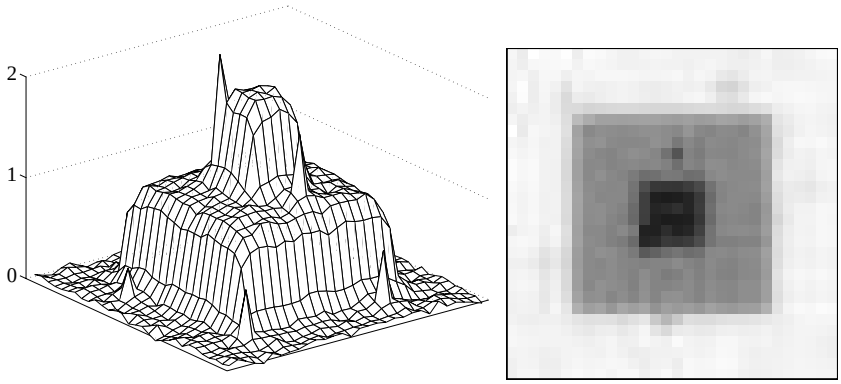
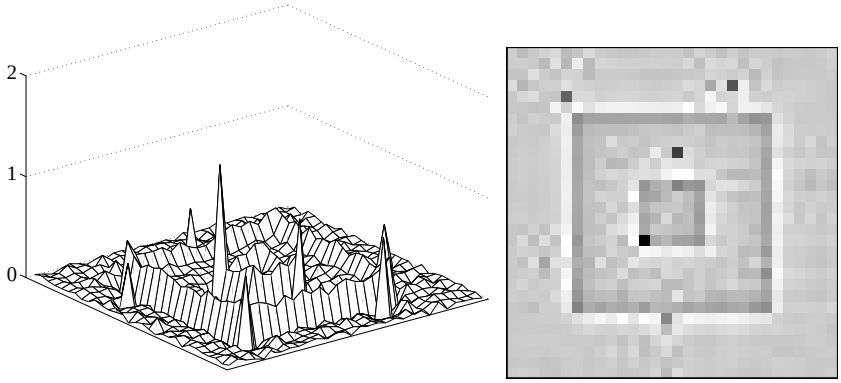
where both edges and smoothly varying areas are nicely preserved. The restoration in Figure 10(a) results from a smooth cost-function $\mathcal{F}$, as in (75) with $\psi(t) = \varphi(t) = t^2$



(a) Restoration from $yo\ \hat{x}$ for $\alpha = 0.2$.



(b) Residuals $y - \hat{x}$.

FIG. 5. *Restoration using a smooth cost-function, namely,* $\mathcal{F}$ *in* (75) *with* $\psi(t) = \varphi(t) = t^2$ *and* $\alpha = 0.2$.

and $\alpha = 0.2$. This image fits no data entry while edges are smooth. Figure 10(b) illustrates the staircasing effect induced by nonsmooth regularization. This minimizer corresponds to $\mathcal{F}$, of the form (75) with $\psi(t) = t^2$ and $\varphi(t) = |t|$, for $\alpha = 0.4$ and it still contains several outliers.

8. Conclusion. We showed that taking nonsmooth data-fidelity terms in a regularized cost-function yields minimizers which fit exactly a certain number of the data entries. In contrast, this cannot occur for a smooth cost-function. These are strong properties which can be used in different ways. We proposed a cost-function with a nonsmooth data-fidelity term in order to process outliers. The obtained results advocate the use of nonsmooth data-fidelity terms in image processing.

ANALYSIS OF NUMERICAL ERRORS IN LARGE EDDY SIMULATION*

V. JOHN† AND W. J. LAYTON‡

Abstract. We consider the question of "numerical errors" in large eddy simulation. It is often claimed that straightforward discretization and solution using centered methods of models for large eddy motion can simulate the motion of turbulent flows with complexity independent of the Reynolds number and dependence only on the resolution "δ" of the eddies sought. This report considers this question analytically: Is it possible to prove error estimates for discretizations of *actually used* large eddy models whose error constants depend only on δ but not Re? We consider the most common, simplest, and most mathematically tractable model and the most mathematically clear discretization. In two cases, we prove such an error estimate and try to explain why our technique of proof fails in the most general case. Our analysis aims to assume as little time regularity on the true solution as possible.

Key words. large eddy simulation, Navier–Stokes equations, turbulence, finite element methods

1. Introduction.

The laminar or turbulent flow of an incompressible fluid is modeled by solutions (u, p) of the incompressible Navier–Stokes equations:

$$\begin{aligned} u_t + u \cdot \nabla u + \nabla p - Re^{-1}\Delta u &= f && \text{in } \Omega \times (0,T], \\ \nabla \cdot u &= 0 && \text{in } \Omega \times [0,T], \\ u(x,0) &= u_0(x) && \text{in } \Omega, \\ u &= 0 && \text{on } \Gamma \times [0,T], \\ \int_\Omega p\, dx &= 0 && \text{in } (0,T]. \end{aligned} \tag{1.1}$$

Here $\Omega \subset \mathbb{R}^d (d = 2, 3)$ is a bounded, simply connected domain with polygonal boundary Γ, $u : \Omega \times [0,T] \to \mathbb{R}^d$ is the fluid velocity, $p : \Omega \times (0,T] \to \mathbb{R}$ is the fluid pressure, $f(x,t)$ is the (known) body force, $u_0(x)$ is the initial flow field, and Re is the Reynolds number. Unfortunately, when Re is large the resulting turbulent flow is typically so complex that so-called direct numerical simulation of (u, p) is not practically feasible.

One conjecture of Leray is that "turbulence" in nature is associated with a breakdown of uniqueness of weak solutions to (1.1). It is known that, for example, weak solutions to (1.1) are unique for $d = 3$ and for very small time intervals, e.g., $0 \le t \le O(Re^{-3})$, and, more importantly, over $O(1)$ time intervals $0 \le t \le T$ if

$$\int_0^T \|\nabla u\|^4_{L^2(\Omega)} dt < \infty.$$

There are numerous generalizations of this basic result [13, 28]. With this in mind, solutions u to (1.1) with $\|\nabla u\|_{L^2(\Omega)} \in L^4(0,T)$ are frequently described as "laminar." Thus, the L^p-regularity in time which can be reasonably assumed is of critical importance.

There are numerous approaches to the simulation of turbulent flows in practical settings. One of the most promising current approaches is large eddy simulation (LES) in which approximations to local spatial averages of u are calculated. A spatial length scale δ is selected. The large eddies are considered to be those of size greater than or equal to $O(\delta)$ and the small eddies are considered to be those of size less than $O(\delta)$. The large eddies are approximated directly while the effects of the small eddies on the large eddies are modeled. In computational turbulence studies using LES it is often reported that *the resulting computational complexity is independent of the Reynolds number* (but dependent on the resolution sought, δ). There has been little or no analytical support for this observation, however. The goal of this report is to begin numerical analysis in support of this claim.

To be more specific, a smooth, nonnegative function $g(x)$ with $g(0) = 1$ and $\int_{\mathbb{R}^d} g\, dx = 1$ is selected and the mollifer $g_\delta(x)$ is defined in the usual way:

$$g_\delta(x) = \delta^{-d} g(x/\delta).$$

One common example is a Gaussian, $g(x) = (6/\pi)^{d/2} \exp(-6x_j x_j)$, where the summation convention is used. The spatial averaging/filtering operation is now defined by convolution:

$$\overline{u}(x,t) = g_\delta * u(x,t), \quad \overline{p} = g_\delta * p, \quad \overline{f} = g_\delta * f, \text{ etc.}$$

In LES, approximations to $(\overline{u}, \overline{p})$ are sought rather than to (u,p). The usual procedure is to first filter the Navier–Stokes equations:

$$\begin{aligned} \overline{u}_t + \nabla \cdot (\overline{u}\ \overline{u}) + \nabla \overline{p} - Re^{-1} \Delta \overline{u} &= \overline{f} + \nabla \cdot \mathbb{T} && \text{in } \Omega, \\ \nabla \cdot \overline{u} &= 0 && \text{in } \Omega, \end{aligned}$$

where the "Reynolds stress tensor" $\mathbb{T}$ is

$$\mathbb{T} = \mathbb{T}(\overline{u}, u) = \overline{u}\ \overline{u} - \overline{u\ u}.$$

Closure is addressed by a modeling step in which $\mathbb{T}$ is written in terms of $\overline{u}$. The resulting (closed) space filtered Navier–Stokes equations are solved numerically. In this procedure, there are three essential issues:

1. The "modeling error" committed in approximating $\mathbb{T}$.
2. The "numerical error" in solving the resulting system.
3. Correct boundary conditions for the flow averages.

In this report, we study the numerical error analytically. Since there are many models in LES (see, e.g., [25, 14, 23, 9, 2, 31, 35, 34]) and few analytical studies, we take herein the simplest model commonly in use, presented, for example, in Ferziger and Peric [9, section 9.3].

To describe the model, let $\mathbb{D}(u)$ be the deformation tensor associated with the indicated velocity field by

$$\mathbb{D}(u) = \frac{1}{2}(\nabla u + \nabla u^t) = \frac{1}{2}(u_{i,x_j} + u_{j,x_i}).$$

The Reynolds stresses are thought of as a turbulent diffusion process based upon the Boussinesq assumption or eddy viscosity hypothesis that "turbulent fluctuations are dissipative in the mean," [25, 11, 32, 34]. We will accordingly consider a model of the form

$$\nabla \cdot \mathbb{T} \sim \nabla \cdot (\nu_{\text{turb}}(\overline{u}, \delta) \;\; \mathbb{D}(\overline{u})),$$

where $\nu_{\text{turb}} \doteq \nu_{\text{turb}}(\overline{u}, \delta)$ is the so-called turbulent viscosity or eddy viscosity. This turbulent viscosity's determination can be very complex, involving even solutions of accompanying systems of nonlinear partial differential equations. In the simplest case, the turbulent viscosity depends on the mean flow $\overline{u}$ through the magnitude of the deformation of $\overline{u}, \nu_{\text{turb}} = \nu_{\text{turb}}(\mathbb{D}(\overline{u}))$, with a functional dependence. Under the Boussinesq assumption, $\nabla \cdot \mathbb{T}$ should act like a physical viscosity. Following the reasoning of Ladyzhenskaya [29], thermodynamic considerations imply that the Taylor series of $\nu_{\text{turb}}(\mathbb{D})$ should be dominated by odd degree terms. The simplest case is of linear dependence upon $|\mathbb{D}|$:

$$\nu_{\text{turb}} = \nu_{\text{turb}}(|\mathbb{D}(\overline{u})|) = a_0(\delta) + a_1(\delta)|\mathbb{D}(\overline{u})|, \tag{1.2}$$

where $|\mathbb{D}(\overline{u})|$ denotes the Frobenius norm of $\mathbb{D}(\overline{u})$. For specificity and for accord with the most commonly used Smagorinsky [37] model, we take the bulk turbulent viscosity $a_0(\delta) \geq 0$ and $a_1(\delta) = C_s\delta^2$. Other scalings are possible [30] though less tested, as are many other subgridscale models [25, 35]. Here C_s is typically either chosen to be around 0.1 or taken to be a function $C_s = C_s(x, t)$ and extrapolated as in the "dynamic subgridscale model" of Germano et al. [15].

With the model (1.2), the resulting system of equations for the approximations (w, q) to $(\overline{u}, \overline{p})$ is

$$\begin{aligned} w_t + \nabla \cdot (w\ w) + \nabla q - Re^{-1}\Delta w - \nabla \cdot (\nu_{\text{turb}}\mathbb{D}(w)) &= \overline{f} && \text{in } \Omega \times (0, T], \\ \nabla \cdot w &= 0 && \text{in } \Omega \times [0, T], \\ w(x, 0) &= w_0(x) && \text{in } \Omega, \\ \int_\Omega q\ dx &= 0 && \text{in } [0, T]. \end{aligned} \tag{1.3}$$

Boundary conditions must be supplied for the large eddies. It is physically clear that large eddies do not adhere to solid walls. (For example, tornadoes and hurricanes move while touching the earth and lose energy as they move.) Therefore, in [14, 26] (see also [34] for the use of similar boundary conditions in a conventional turbulence model), it was proposed that the large eddies should satisfy a no-penetration condition and a slip with friction condition on $\partial\Omega$:

$$\begin{aligned} w \cdot \hat{n} &= 0 && \text{on } \Gamma, \\ w \cdot \hat{\tau} &= 0 && \text{on } \Gamma_0,\ \text{meas}\ (\Gamma_0) > 0, \\ \beta w \cdot \hat{\tau} + \vec{t} \cdot \hat{\tau} &= 0 && \text{on } \ \Gamma \setminus \Gamma_0, \end{aligned} \tag{1.4}$$

where $\vec{t}$ is the Cauchy stress vector on Γ (for background information, see Serrin [36]), $\beta = \beta(\delta, Re)$ is the friction coefficient (calculated explicitly in [26]), $\hat{n}$ is the outward unit normal, and $\hat{\tau}$ is an orthonormal system of tangent vectors on each face of Γ. The friction coefficient β can be calculated once a specific filter is chosen [26]. It has the property [26] that no slip conditions are recovered as $\delta \to 0$:

$$\beta(Re,\ \delta) \to \infty \quad \text{as } \delta \to 0.$$

A Dirichlet boundary condition $w = w_{\text{inflow}}$ on Γ_0 is appropriate if Γ_0 is an inflow boundary upon which $\overline{u}$ can be calculated by extending the known, inflow velocity field upstream. We take $w_{\text{inflow}} = 0$ for simplicity.

The Cauchy stress vector $\vec{t}$ includes the action of both the viscous stresses and Reynolds stresses and is given by

$$\vec{t}(w) := \hat{n} \cdot [-q\mathbb{I} + 2Re^{-1}\mathbb{D}(w) + a_0(\delta)\mathbb{D}(w) + C_s\delta^2|\mathbb{D}(w)|\mathbb{D}(w)].$$

Standard properties of convolution operators imply that the flow averages $(\overline{u}, \overline{p})$ are $C^\infty(\Omega)$ in space, have bounded kinetic energy

$$\int_\Omega |\overline{u}|^2 dx \le \int_\Omega |u|^2 dx \le C(\Omega, f, u_0),$$

have no solution scales smaller than $O(\delta)$, and converge to u as $\delta \to 0$ [24]. On the other hand, it is *not* obvious, nor has it been proven yet, that solutions (w, q) to the large eddy model approximating $(\overline{u}, \overline{p})$ share *any* of these properties! Nevertheless, the spatial regularity of solutions (w, q) we shall consider to be a *modeling* issue (beyond the scope of this report studying *numerical errors* in LES). The *time regularity* of solutions (w, q) is still an important consideration. For example, we shall show that solutions of this model satisfy

$$\int_0^T \|\nabla w\|_{L^3}^3 dt < \infty$$

uniformly in Re. One goal is thus to assume no greater time regularity than this. The fundamental error analysis of Heywood and Rannacher [22] for the Navier–Stokes equations is based, in part, on a laminar-type assumption $\nabla u \in L^\infty(0, T; L^2(\Omega))$. Weakening this to an assumption of the form $\nabla u \in L^3(0, T; L^3(\Omega))$ (as we seek to do herein) is nontrivial.

2. Preliminaries. This section sets the notation used in the report, describes the function spaces employed, and collects several useful inequalities. The notation used is standard for the most part. The $L^p(\Omega)$ norms, for $p \neq 2$, are explicitly denoted as $\|f\|_{L^p}$. Sobolev spaces $W^{k,p}(\Omega)$ are defined in the usual way [1]. The associated norm is denoted by $\|\cdot\|_{k,p}$. If the domain in question is *not* Ω (e.g., $\Omega \times (0, T)$), then it will be explicitly indicated. If $p = 2$, these norms will be written $\|\cdot\|_k$ for the $W^{k,2}(\Omega)$ norm and $\|\cdot\|_{k,\Gamma}$ for the $W^{k,2}(\Gamma)$ norm and $\|\cdot\|$ and $\|\cdot\|_\Gamma$, respectively, for the $L^2(\Omega)$ and $L^2(\Gamma)$ norms. We suppose the polygonal boundary Γ is composed of faces $\Gamma_0, \Gamma_1, \ldots, \Gamma_J$, where (with some abuse of notation) Γ_0 consists of the face(s) upon which $v = 0$ is strongly imposed.

The spaces associated with the boundary conditions (1.4) are

$$X := \{v : v \in \left(W^{1,3}(\Omega)\right)^d, v = 0 \text{ on } \Gamma_0 \text{ and } v \cdot \hat{n} = 0 \text{ on } \Gamma_j, j = 1, \ldots, J\},$$
$$Q := L_0^2(\Omega) := \left\{q \in L^2(\Omega) : \int_\Omega q \, dx = 0\right\}.$$

The boundary condition in X is defined to hold in the sense of the trace theorem on each Γ_j, and $\hat{n}$ is the outward unit normal to Γ. The $L^2(\Omega)$ and $L^2(\Gamma)$ inner products are denoted by $(\cdot, \cdot)$ and $(\cdot, \cdot)_\Gamma$, respectively.

If $v \in X$, $\mathbb{D}(v)$ denotes the usual deformation tensor, defined in the introduction. The unit vector $\hat{\tau}$ denotes an orthonormal system of tangent vectors on Γ. Whenever

$\hat{\tau}$ occurs, it will be understood that the term is to be summed over the two tangent vectors if $d = 3$; for example,

$$\|v \cdot \hat{\tau}\|^2_{\Gamma_j} \text{ if } d = 3 \text{ means } (\|v \cdot \hat{\tau}_1\|^2_{\Gamma_j} + \|v \cdot \hat{\tau}_2\|^2_{\Gamma_j}).$$

LEMMA 2.1 (inf-sup condition). *Let* $\tilde{X} := \{v : v \in \left(W^{1,2}(\Omega)\right)^d$, $v = 0$ *on* Γ_0 *and* $v \cdot \hat{n} = 0$ *on* $\Gamma_j, j = 1, \ldots, J\}$. *The velocity-pressure spaces* $(\tilde{X}, Q)$ *satisfy the inf-sup condition*

$$\inf_{\lambda \in Q} \sup_{v \in \tilde{X}} \frac{(\lambda, \nabla \cdot v)}{\|\lambda\| \left[\|\mathbb{D}(v)\|^2 + \sum_{j=1}^J \|v \cdot \hat{\tau}\|^2_{1/2,\Gamma_j}\right]^{1/2}} \geq C > 0. \tag{2.1}$$

Proof. Since $\|\nabla v\| \geq \|\mathbb{D}(v)\|$, the trace theorem [20] shows that (2.1) is implied by the usual inf-sup condition

$$\inf_{\lambda \in Q} \sup_{v \in \tilde{X} \cap H^1_0(\Omega)^d} \frac{(\lambda, \nabla \cdot v)}{\|\lambda\| \, \|\nabla v\|} \geq C > 0. \qquad \square$$

Lemma 2.1 implies that the space of weakly divergence free functions V,

$$V := \{v \in \tilde{X} : (\lambda, \nabla \cdot v) = 0 \text{ for all } \lambda \in Q\},$$

is a well defined, nontrivial, closed subspace of $\tilde{X}$.

Remark 2.1. Since Γ is *not* C^1, discontinuities in $\hat{\tau}$ and $\hat{n}_j$ have forced modifications in the norms to piecewise definition. For example, $v \cdot \hat{\tau} \notin H^{1/2}(\Gamma)$ for $v \in H^1(\Omega)$ but $v \cdot \hat{\tau} \in H^{1/2}(\Gamma_j), j = 0, \ldots, J$.

The conforming finite element method for this problem begins by selecting finite element spaces $X^h \subset X$ and $Q^h \subset Q$, where h denotes as usual a representative mesh width for (X^h, Q^h), satisfying the usual approximation theoretic conditions required of finite element spaces. The condition that $X^h \subset X$ imposes the restriction that $v^h \cdot \hat{n}_{|\Gamma_j} = 0$ for all $v^h \in X^h$. For intricate boundaries, this could possibly be onerous so it is interesting to consider imposing $v^h \cdot \hat{n}_{|\Gamma} = 0$ with penalty or Lagrange multiplier methods, following, e.g., the work in [31]. Nevertheless, there is already considerable computational experience with imposing this condition in finite element methods (see, e.g., [19, 8]), so we shall not focus on the interesting detail of the treatment of corners. Without these additional regularizations in the numerical method, it is useful in the analysis to assume that (X^h, Q^h) satisfies the discrete analogue of (2.1),

$$\inf_{\lambda^h \in Q^h} \sup_{v^h \in X^h} \frac{(\lambda^h, \nabla \cdot v^h)}{\|\lambda^h\| \left[\|\mathbb{D}(v^h)\|^2 + \sum_{j=1}^J \|v^h \cdot \hat{\tau}\|^2_{1/2,\Gamma_j}\right]^{1/2}} \geq C > 0, \tag{2.2}$$

where $C > 0$ is independent of h. The next lemma shows, in essence, that if the computational mesh follows the boundary and if the velocity space, restricted to no slip boundary conditions, and the pressure space satisfy the usual inf-sup condition, then (2.2) holds.

LEMMA 2.2 (discrete inf-sup condition). *If* (X^h, Q^h) *satisfies*

$$\inf_{\lambda_h \in Q^h} \sup_{v_h \in X^h \cap H^1_0(\Omega)^d} \frac{(\lambda^h, \nabla \cdot v^h)}{\|\lambda^h\| \, \|\nabla v^h\|} \geq C_1 > 0,$$

then (2.2) *holds.*

Proof. By trace theorem [20] and the Poincaré–Friedrichs inequality, for any $\lambda_h \neq 0$, $v^h (\neq 0) \in X^h$,

$$\frac{(\lambda^h, \nabla \cdot v^h)}{\|\lambda^h\| \left[\|\mathbb{D}(v^h)\|^2 + \sum_{j=1}^J \|v^h \cdot \hat{\tau}\|^2_{1/2,\Gamma_j} \right]^{1/2}} \geq C \frac{(\lambda^h, \nabla \cdot v^h)}{\|\lambda^h\| \, \|v^h\|_1} \geq C \frac{(\lambda^h, \nabla \cdot v^h)}{\|\lambda^h\| \, \|\nabla v^h\|}. \qquad \square$$

Thus, (2.2) will be assumed throughout this report. Under (2.2), the space of discretely divergence free functions

$$V^h := \{v^h \in X^h : (\lambda^h, \nabla \cdot v^h) = 0 \text{ for all } \lambda^h \in Q^h\}$$

is a nontrivial closed subspace of X^h [16, 21].

We shall frequently use Young's inequality in the form

$$ab \leq \frac{\epsilon}{q} a^q + \frac{\epsilon^{-q'/q}}{q'} b^{q'}, \quad 1 < q, q' < \infty, \quad \frac{1}{q} + \frac{1}{q'} = 1.$$

The generalization of Hölder's inequality

$$\int_\Omega |u| \, |v| \, |w| dx \leq \|u\|_{L^p} \|v\|_{L^q} \|w\|_{L^r}, \quad \frac{1}{p} + \frac{1}{q} + \frac{1}{r} = 1, \quad 1 \leq p, q, r \leq \infty,$$

is also useful. We shall frequently use the Sobolev embedding theorem, often, but not always, in the form that in three dimensions $W^{1,3}(\Omega) \hookrightarrow L^p(\Omega)$ for $1 \leq p < \infty$.

The nonlinear form in the subgridscale term, for $v, w \in (W^{1,3}(\Omega))^d$

$$(|\mathbb{D}(w)|\mathbb{D}(w), \mathbb{D}(v)),$$

is of p-Laplacian type (with $p = 3$). Thus, it is strongly monotone and locally Lipschitz continuous in the sense made precise in the following well-known lemma; see, e.g., [30, 7].

LEMMA 2.3 (strong monotonicity and local Lipschitz-continuity). *There are constants* $\underline{C}$ *and* $\overline{C}$ *such that for all* $u_1, u_2, v \in (W^{1,3}(\Omega))^d$ *and* $d = 2$ *or* 3, *with* $r = \max\{\|\mathbb{D}(u_1)\|_{L^3}, \|\mathbb{D}(u_2)\|_{L^3}\}$,

$$(|\mathbb{D}(u_1)|\mathbb{D}(u_1) - |\mathbb{D}(u_2)|\mathbb{D}(u_2), \mathbb{D}(u_1 - u_2)) \geq \underline{C} \|\mathbb{D}(u_1 - u_2)\|^3_{L^3},$$
$$(|\mathbb{D}(u_1)|\mathbb{D}(u_1) - |\mathbb{D}(u_2)|\mathbb{D}(u_2), \mathbb{D}(v)) \leq \overline{C} r \|\mathbb{D}(u_1 - u_2)\|_{L^3} \|\mathbb{D}(v)\|_{L^3}.$$

Korn's inequalities relate L^p norms of the deformation tensor $\mathbb{D}(v)$ to those same norms of the gradient for $1 < p < \infty$ (see Galdi, Heywood, and Rannacher [13], Gobert [17, 18], Temam [39], or Fichera [10]) and fail if $p = 1$.

THEOREM 2.4 (Korn's inequalities). *There is a* $C > 0$ *such that for* $1 < p < \infty$

$$\|v\|^p_{W^{1,p}} \leq C(\Omega)[\|v\|^p_{L^p} + \|\mathbb{D}(v)\|^p_{L^p}]$$

for all $v \in (W^{1,p}(\Omega))^d$.

Further, if $\gamma(v)$ *is a seminorm on* $L^p(\Omega)$ *which is a norm on the constants, then*

$$\|\nabla v\|_{L^p} \leq C(\Omega)[\gamma(v) + \|\mathbb{D}(v)\|_{L^p}]$$

holds for $1 < p < \infty$ *and for all* $v \in (W^{1,p}(\Omega))^d$.

As a consequence of Korn's inequality it follows that, taking $\gamma(v) = \|v\|_{L^p(\Gamma_0)}$, if $\text{meas}(\Gamma_0) > 0$, then

$$\|\nabla v\|_{L^p}^p \le \|v\|_{1,p}^p \le C_K \|\mathbb{D}(v)\|_{L^p}^p$$

for all $v \in \{v \in W^{1,p}(\Omega)^d : v_{|\Gamma_0} = 0\}$.

We will often use Poincaré's inequality, which holds since $v \cdot \hat{n} = 0$ on Γ (Galdi [12, p. 56]),

$$\|v\| \le C(\Omega)\|\nabla v\| \text{ for all } v \in X.$$

We shall use the Gagliardo–Nirenberg inequality in $W^{1,p}(\Omega) \cap X$. This inequality [1, 33, 13, 6] states that, provided Γ satisfies a weak regularity condition (holding in particular for polygonal domains) and $\text{meas}(\Gamma_0) > 0$ for all $v \in W^{1,p}(\Omega) \cap X, 1 \le q, s \le \infty$,

$$\|v\|_{L^q} \le C\|\nabla v\|_{L^p}^a \|v\|_{L^s}^{1-a} \text{ for all } v \in \left(W^{1,p}(\Omega)\right)^d \cap X,$$

where, for $\Omega \subset \mathbb{R}^3$ (improvable if $\Omega \subset \mathbb{R}^2$), $p \ge 3$, $q \ge s$, $0 \le a < 1$, and

$$a = \left(\frac{1}{s} - \frac{1}{q}\right)\left(\frac{1}{3} - \frac{1}{p} + \frac{1}{s}\right)^{-1}.$$

In particular, note that taking $q = 6$, $p = 3$, and $s = 2$ gives

$$\|v\|_{L^6(\Omega)} \le C\|\nabla v\|_{L^3(\Omega)}^{2/3} \|v\|^{1/3}. \tag{2.3}$$

The following combination of this and Korn's inequality will be useful in section 4.

LEMMA 2.5. *Let* $\text{meas}(\Gamma_0) > 0$ *and* $\Omega \subset \mathbb{R}^d$, $d = 2, 3$. *Then,*

$$\|v\|_{L^6} \le C\|v\|^{1/3}\|\mathbb{D}(v)\|_{L^3}^{2/3}, \; C = C(\Omega).$$

Proof. This follows immediately from (2.3) and Korn's inequality. ∎

The following dual norms are defined in an equivalent but slightly nonstandard way: for $\frac{1}{q} + \frac{1}{q'} = 1, 1 < q, q' < \infty$,

$$\|f\|_* := \sup_{v \in X} \frac{(f, v)}{\|\mathbb{D}(v)\|},$$

$$\|f\|_{W^{-1,3/2}} := \sup_{v \in X} \frac{(f, v)}{\|\mathbb{D}(v)\|_{L^3}},$$

$$\|f\|_{W^{-1,q'}(\Omega \times (0,t))} := \sup_{v \in L^q(0,T;X)} \frac{\int_0^t (f, v)dt'}{(\int_0^t \|\mathbb{D}(v)\|_{L^q}^q dt')^{1/q}}.$$

Note that $\|\mathbb{D}(\cdot)\|_{L^3}$ defines a norm in X as a consequence of Poincaré's and Korn's inequality.

3. The finite element formulation. This section develops the finite element method for the LES model. The stability of the model is also studied. In particular, we show w and $w^h \in L^\infty(0, T; L^2(\Omega)) \cap L^3(0, T; H^1(\Omega))$ uniformly in Re. Lastly, the error in an equilibrium projection is considered.

The variational formulation is derived in the usual way by multiplication of (1.3) by $(v, q) \in (X, Q)$ and applying the divergence theorem. The boundary integral terms

require careful treatment (following, e.g., [31]) on account of the slip with friction condition on Γ. Let $\alpha \geq 0$ be a constant. The formulation which results is to find $w : [0,T] \to X, q : (0,T] \to Q$ satisfying

$$\begin{aligned}(w_t, v) + \beta(\delta, Re) \sum_{j=1}^{J} (w \cdot \hat{\tau}, v \cdot \hat{\tau})_{\Gamma_j} + \left((2Re^{-1} + a_0(\delta) + C_s \delta^2 |\mathbb{D}(w)|)\mathbb{D}(w), \mathbb{D}(v)\right) \\ + (w \cdot \nabla w, v) - (q, \nabla \cdot v) + \alpha(\nabla \cdot w, \nabla \cdot v) = (\overline{f}, v) \quad \text{for all } v \in X, \\ (\lambda, \nabla \cdot w) = 0 \quad \text{for all } \lambda \in Q,\end{aligned} \tag{3.1}$$

and $w(x,0) = \overline{u}_0(x) \in X$. For compactness, define the nonlinear and trilinear form:

$$\begin{aligned}a(u,w,v) &:= \alpha(\nabla \cdot w, \nabla \cdot v) + \sum_{j=1}^{J} \beta(w \cdot \hat{\tau}, v \cdot \hat{\tau})_{\Gamma_j} \\ &\quad + ((2Re^{-1} + a_0(\delta) + C_s \delta^2 |\mathbb{D}(u)|)\mathbb{D}(w), \mathbb{D}(v)), \\ b(u,w,v) &:= \frac{1}{2}(u \cdot \nabla w, v) - \frac{1}{2}(u \cdot \nabla v, w).\end{aligned}$$

It is a simple index calculation to check that for $v \in X, w \in V$ (since such functions have zero normal components on Γ) $(w \cdot \nabla w, v) = b(w,w,v)$. Thus, the variational formulation can be rewritten as follows: find $(w,q) : [0,T] \to (X,Q)$ satisfying $w(x,0) = \overline{u}_0(x)$ and

$$(w_t, v) + a(w,w,v) + b(w,w,v) + (\lambda, \nabla \cdot w) - (q, \nabla \cdot v) = (\overline{f}, v) \tag{3.2}$$

for all $(v, \lambda) \in (X, Q)$.

Using Lemma 2.3, it is easy to prove that the LES model (1.3), (1.4) satisfies the analogue of Leray's inequality for the Navier–Stokes equations.

LEMMA 3.1 (Leray's inequality for the LES model). *A solution of* (3.2) *satisfies*

$$\begin{aligned}\frac{1}{2}\|w(t)\|^2 + \int_0^t \left[\sum_{j=1}^{J} \beta \|w \cdot \hat{\tau}\|_{\Gamma_j}^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w)\|^2 + \underline{C} C_s \delta^2 \|\mathbb{D}(w)\|_{L^3}^3 \right] dt' \\ \leq \frac{1}{2}\|w(0)\|^2 + \int_0^t (\overline{f}, w) dt'.\end{aligned}$$

Proof. Set $v = w, \lambda = q$ in (3.2) and use Lemma 2.3. ∎

Remark 3.1.

1. Because of the slip with friction boundary conditions (1.4), it is important to choose the formulation of the viscous terms, as in (3.1), (3.2), involving the deformation tensor.

2. Leray's inequality immediately implies stability in various norms (which we will develop) and is the key, first step in proving existence of weak solutions to (1.3), (1.4). This last question is fully investigated (under different boundary conditions) in remarkable papers by Ladyzhenskaya [27], Parés [34], and Du and Gunzburger [7].

LEMMA 3.2. *Let (w,q) be the solution of* (1.3). *Then, there is a constant C independent of Re such that for almost all $t \in (0,T)$ with $0 < T < \infty$*

$$\begin{aligned}\|w_t\|_{W^{-1,3/2}} \leq C \left(\|w\|_{L^3}^2 + \|q\|_{L^{3/2}} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w)\|_{L^{3/2}} \right. \\ \left. + C_s \delta^2 \|\mathbb{D}(w)\|_{L^3}^2 + \|\overline{f}\|_{W^{-1,3/2}} \right),\end{aligned}$$

$$\|w_t\|^{3/2}_{L^{3/2}(0,T;W^{-1,3/2})} \le C\Big(\|w\|^3_{L^3(0,T;L^3)} + \|q\|^{3/2}_{L^{3/2}(0,T;L^{3/2})} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w)\|^{3/2}_{L^{3/2}(0,T;L^{3/2})} + C_s\delta^2\|\mathbb{D}(w)\|^3_{L^3(0,T;L^3)} + \|\overline{f}\|^{3/2}_{L^{3/2}(0,T;W^{-1,3/2})}\Big).$$

Proof. From the momentum equation in (1.3) it follows that for almost all $t \in (0,T)$ (alternately, dividing (3.1) by $\|v\|_{W^{1,3}}$ and taking the supremum over v)

$$\|w_t\|_{W^{-1,3/2}} \le \|\nabla\cdot(ww)\|_{W^{-1,3/2}} + \|\nabla q\|_{W^{-1,3/2}} + C_s\delta^2\|\nabla\cdot(|\mathbb{D}(w)|\mathbb{D}(w))\|_{W^{-1,3/2}} + (2Re^{-1} + a_0(\delta))\|\nabla\cdot\mathbb{D}(w)\|_{W^{-1,3/2}} + \|\overline{f}\|_{W^{-1,3/2}}.$$

The definition of the norm, integration by parts, using $v\cdot n = 0$ on Γ for $v \in X$, Hölder's inequality, and Korn's inequality give, e.g.,

$$\|\nabla q\|_{W^{-1,3/2}} = \sup_{v\in X}\frac{\int_\Omega -q(\nabla\cdot v)dx}{\|\mathbb{D}(v)\|_{L^3}} \le \sup_{v\in X}\frac{\|q\|_{L^{3/2}}\|\nabla\cdot v\|_{L^3}}{\|\mathbb{D}(v)\|_{L^3}} \le C\|q\|_{L^{3/2}}.$$

The other terms are estimated in the same way also using $\|ww\|_{L^{3/2}} = \|w\|^2_{L^3}$ and $\||\mathbb{D}(w)|\mathbb{D}(w)\|_{L^{3/2}} = \|\mathbb{D}(w)\|^2_{L^3}$.

The second inequality follows raising both sides to the power 3/2 and integrating in time. ∎

The continuous-in-time finite element method for (1.3) uses the variational formulation (3.2) as follows. First, velocity-pressure finite element spaces $X^h \subset X \cap (W^{1,3}(\Omega))^d$, $Q^h \subset Q$ satisfying (2.2), and the parameter $\alpha \ge 0$ are selected.

The finite element approximations to (w,q) are maps $(w^h, q^h) : [0,T] \to (X^h, Q^h)$ satisfying

$$(w^h_t, v^h) + a(w^h, w^h, v^h) + b(w^h, w^h, v^h) + (\lambda^h, \nabla\cdot w^h) - (q^h, \nabla\cdot v^h) = (\overline{f}, v^h) \tag{3.3}$$

for all $(v^h, \lambda^h) \in (X^h, Q^h)$ where $w^h(x,0) \in X^h$ is an approximation to $w(x,0) = \overline{u}_0$.

It is straightforward to verify that Leray's inequality holds for w^h as well as w.

LEMMA 3.3 (Leray's inequality for w^h). *For $\alpha \ge 0$, any solution of* (3.3) *satisfies*

$$\frac{1}{2}\|w^h(t)\|^2 + \int_0^t\Big[\beta\sum_{j=1}^J\|w^h\cdot\hat{\tau}\|^2_{\Gamma_j} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w^h)\|^2 + \alpha\|\nabla\cdot w^h\|^2 + \underline{C}\ C_s\delta^2\|\mathbb{D}(w^h)\|^3_{L^3}\Big]dt' \le \frac{1}{2}\|w^h(0)\|^2 + \int_0^t(\overline{f}, w^h)dt'.$$

Using various inequalities in the right-hand side, stability bounds for w^h follow from Lemma 3.3.

PROPOSITION 3.4 (stability of w^h). *The solution w^h of* (3.3) *satisfies*

$$\frac{1}{2}\|w^h(t)\|^2 + \int_0^t\Big[\sum_{j=1}^J\beta\|w^h\cdot\hat{\tau}\|^2_{\Gamma_j} + (Re^{-1} + a_0(\delta))\|\mathbb{D}(w^h)\|^2 + \alpha\|\nabla\cdot w^h\|^2 + \underline{C}C_s\delta^2\|\mathbb{D}(w^h)\|^3_{L^3}\Big]dt' \le \frac{1}{2}\|w^h(0)\|^2 + \frac{Re}{4}\int_0^t\|\overline{f}\|^2_*dt', \tag{3.4}$$

$$\frac{1}{2}\|w^h(t)\|^2 + \int_0^t \left[\sum_{j=1}^{J} \beta \|w^h \cdot \hat{\tau}\|^2_{\Gamma_j} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w^h)\|^2 + \alpha \|\nabla \cdot w^h\|^2 \right.$$
$$\left. + \frac{2}{3}\underline{C}C_s\delta^2 \|\mathbb{D}(w^h)\|^3_{L^3} \right] dt' \leq \frac{1}{2}\|w^h(0)\|^2$$
$$+ \frac{2}{3}(\underline{C}C_s)^{-1/2}\delta^{-1}\|\overline{f}\|^{3/2}_{W^{-1,3/2}(\Omega\times(0,t))}, \tag{3.5}$$

$$\|w^h(t)\|^2 + 2\int_0^t e^{t-t'} \left[\sum_{j=1}^{J} \beta \|w^h \cdot \hat{\tau}\|^2_{\Gamma_j} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w^h)\|^2 + \alpha \|\nabla \cdot w^h\|^2 \right.$$
$$\left. + \underline{C}C_s\delta^2 \|\mathbb{D}(w^h)\|^3_{L^3} \right] dt' \leq e^t\|w^h(0)\|^2 + \int_0^t e^{t-t'}\|\overline{f}\|^2 dt'. \tag{3.6}$$

Proof. Inequality (3.4) follows by applying Young's inequality to Lemma 3.3. The bound (3.5) follows from the definition of the dual norm and $ab \leq \frac{\epsilon}{3}a^3 + \frac{2}{3}\epsilon^{-1/2}b^{3/2}$ applied in the same manner.

For (3.6), set $v^h = w^h$ and $\lambda^h = q^h$ in (3.3), use Lemma 2.3, and apply Young's inequality on the right-hand side. This gives

$$\frac{d}{dt}\|w^h\|^2 - \|w^h\|^2 + 2\left[\sum_{j=1}^{J} \beta \|w^h \cdot \hat{\tau}\|^2_{\Gamma_j} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w^h)\|^2 + \alpha \|\nabla \cdot w^h\|^2 \right.$$
$$\left. + \underline{C}C_s\delta^2 \|\mathbb{D}(w^h)\|^3_{L^3} \right] \leq \|\overline{f}\|^2.$$

Inequality (3.6) now follows by using an integrating factor. ∎

In the analysis of the error in the approximation of the time dependent problem, it is useful to have a clear description of the error in the Stokes projection under slip with friction boundary conditions [31]. It is also necessary that any dependence on Re, δ, and β be made explicit.

Under the discrete inf-sup condition, the Stokes projection $\Pi : (X, Q) \to (X^h, Q^h)$ is defined as follows. Let $\Pi(w, q) = (\tilde{w}, \tilde{q})$, where $(\tilde{w}, \tilde{q})$ satisfies

$$\alpha(\nabla \cdot (w - \tilde{w}), \nabla \cdot v^h) + (2Re^{-1} + a_0(\delta))(\mathbb{D}(w - \tilde{w}), \mathbb{D}(v^h))$$
$$+ \sum_{j=1}^{J} \beta((w - \tilde{w}) \cdot \hat{\tau}, v^h \cdot \hat{\tau})_{\Gamma_j} - (q - \tilde{q}, \nabla \cdot v^h) = 0 \quad \text{for all } v^h \in X^h,$$
$$(\nabla \cdot (w - \tilde{w}), \lambda^h) = 0 \quad \text{for all } \lambda^h \in Q^h.$$

This is equivalent to the following formulation provided $w \in V$ and $v^h \in V^h$. Given (w, q), find $\tilde{w} \in V^h$ satisfying

$$\alpha(\nabla \cdot (w - \tilde{w}), \nabla \cdot v^h) + (2Re^{-1} + a_0(\delta))(\mathbb{D}(w - \tilde{w}), \mathbb{D}(v^h))$$
$$+ \sum_{j=1}^{J} \beta((w - \tilde{w}) \cdot \hat{\tau}, v^h \cdot \hat{\tau})_{\Gamma_j} - (q - \lambda^h, \nabla \cdot v^h) = 0$$

for all $v^h \in V^h$ and $\lambda^h \in Q^h$. Under the discrete inf-sup condition, it is well known that $(\tilde{w}, \tilde{q})$ is a quasi-optimal approximation of (w, q). The dependence of the stability

and error constants upon Re and $\beta = \beta(Re, \delta)$ is important to the error analysis. That dependence is described in the next lemma and proposition.

LEMMA 3.5 (stability of the projection $\tilde{w}$). *Let $w \in V$ be given. Then if $\alpha > 0$, $\tilde{w}$ satisfies*

$$\alpha\|\nabla\cdot\tilde{w}\|^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(\tilde{w})\|^2 + \sum_{j=1}^{J}\beta\|\tilde{w}\cdot\hat{\tau}\|_{\Gamma_j}^2$$
$$\leq \alpha^{-1}\|q\|^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w)\|^2 + \sum_{j=1}^{J}\beta\|w\cdot\hat{\tau}\|_{\Gamma_j}^2.$$

If $\alpha = 0$, then

$$\frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\tilde{w})\|^2 + \sum_{j=1}^{J}\beta\|\tilde{w}\cdot\hat{\tau}\|_{\Gamma_j}^2$$
$$\leq 2(2Re^{-1} + a_0(\delta))^{-1}\|q\|^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w)\|^2 + \sum_{j=1}^{J}\beta\|w\cdot\hat{\tau}\|_{\Gamma_j}^2.$$

Proof. Set $v^h = \tilde{w} \in V^h$ in the second formulation of the Stokes projection. This immediately gives

$$\alpha\|\nabla\cdot\tilde{w}\|^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(\tilde{w})\|^2 + \sum_{j=1}^{J}\beta\|\tilde{w}\cdot\hat{\tau}\|_{\Gamma_j}^2$$
$$= (2Re^{-1} + a_0(\delta))(\mathbb{D}(w), \mathbb{D}(\tilde{w})) + \sum_{j=1}^{J}\beta(w\cdot\hat{\tau}, \tilde{w}\cdot\hat{\tau})_{\Gamma_j} + (q - \lambda^h, \nabla\cdot\tilde{w})$$
$$\leq \frac{1}{2}(2Re^{-1} + a_0(\delta))[\|\mathbb{D}(w)\|^2 + \|\mathbb{D}(\tilde{w})\|^2] + \sum_{j=1}^{J}\frac{\beta}{2}[\|w\cdot\hat{\tau}\|_{\Gamma_j}^2 + \|\tilde{w}\cdot\hat{\tau}\|_{\Gamma_j}^2]$$
$$+ \frac{\alpha}{2}\|\nabla\cdot\tilde{w}\|^2 + \frac{1}{2\alpha}\|q\|^2,$$

from which the first result follows. If $\alpha = 0$, the term $(q, \nabla\cdot\tilde{w})$ is bounded by noting that $\nabla\cdot\tilde{w} = \text{trace}\,(\mathbb{D}(\tilde{w}))$ so that

$$(q, \nabla\cdot\tilde{w}) \leq \|q\|\,\|\mathbb{D}(\tilde{w})\| \leq \frac{1}{4}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\tilde{w})\|^2 + (2Re^{-1} + a_0(\delta))^{-1}\|q\|^2. \qquad \square$$

PROPOSITION 3.6. *Suppose the discrete inf-sup condition (2.2) holds. Then, $(\tilde{w}, \tilde{q})$ exists uniquely in (X^h, Q^h) and satisfies*

$$\alpha\|\nabla\cdot(w - \tilde{w})\|^2 + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w - \tilde{w})\|^2 + \sum_{j=1}^{J}\beta\|(w - \tilde{w})\cdot\hat{\tau}\|_{\Gamma_j}^2$$
$$\leq C \inf_{v^h\in X^h, \lambda^h\in Q^h}\Bigg\{(2Re^{-1} + a_0(\delta))\|\mathbb{D}(w - v^h)\|^2$$
$$+ \sum_{j=1}^{J}\beta\|(w - v^h)\cdot\hat{\tau}\|_{\Gamma_j}^2 + \min\{\alpha^{-1}, (2Re^{-1} + a_0(\delta))^{-1}\}\|q - \lambda^h\|^2\Bigg\}.$$

Proof. The proof follows standard arguments, carefully tracking the dependence of the constants upon Re and β. ∎

Note that the use of least squares penalization of incompressibility allows an error estimate for the Stokes projection whose constants are essentially independent of the Reynolds number in a suitably weighted norm.

4. The convergence theorem. Let us first note that for standard piecewise polynomial finite element spaces it is known that the L^2-projection of a function in $L^p, p \geq 2$, is in L^p itself and the L^2-projection operator is stable in $L^p, p \geq 2$ [5].

Let $e = w - w^h$ and let $\tilde{w}$ denote a stable approximation of w in $V^h \cap (W^{1,3}(\Omega))^d$, for example, the L^2-projection under the conditions of [5]. This stability in $W^{1,p}$ follows for many piecewise polynomial finite element spaces using [5].

The error is decomposed as $e = (w - \tilde{w}) - (w^h - \tilde{w}) = \eta - \phi^h$, where $\eta = w - \tilde{w}$ and $\phi^h = w^h - \tilde{w} \in V^h$. An error equation is obtained by subtracting (3.2) from (3.3) and using the fact that $w \in V$. This gives, for any $v^h \in V^h \cap (W^{1,3}(\Omega))^d$ and $\lambda^h \in Q^h$,

$$\begin{aligned}(e_t, v^h) + a(w, w, v^h) - a(w^h, w^h, v^h) \\ + b(w, w, v^h) - b(w^h, w^h, v^h) - (q - \lambda^h, \nabla \cdot v^h) = 0.\end{aligned} \tag{4.1}$$

This is rewritten, adding and subtracting terms and setting $v^h = \phi^h$, as follows:

$$\begin{aligned}(\phi_t^h, \phi^h) + a(w^h, w^h, \phi^h) - a(\tilde{w}, \tilde{w}, \phi^h) = (\eta_t, \phi^h) \\ + a(w, w, \phi^h) - a(\tilde{w}, \tilde{w}, \phi^h) + b(w, w, \phi^h) - b(w^h, w^h, \phi^h) - (q - \lambda^h, \nabla \cdot \phi^h).\end{aligned} \tag{4.2}$$

The monotonicity lemma (Lemma 2.3) implies that

$$\begin{aligned}&a(w^h, w^h, \phi^h) - a(\tilde{w}, \tilde{w}, \phi^h) \\ &\geq \underline{C} C_s \delta^2 \|\mathbb{D}(\phi^h)\|_{L^3}^3 + \alpha \|\nabla \cdot \phi^h\|^2 + (2Re^{-1} + a_0(\delta)) \|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J} \beta \|\phi^h \cdot \hat{\tau}\|_{\Gamma_j}^2,\end{aligned}$$

and with $r := \max\{\|\mathbb{D}(w)\|_{L^3}, \|\mathbb{D}(\tilde{w})\|_{L^3}\}$

$$\begin{aligned}&a(w, w, \phi^h) - a(\tilde{w}, \tilde{w}, \phi^h) \\ &\leq (2Re^{-1} + a_0(\delta)) \|\mathbb{D}(\phi^h)\| \, \|\mathbb{D}(\eta)\| + \sum_{j=1}^{J} \beta \|\phi^h \cdot \hat{\tau}\|_{\Gamma_j} \, \|\eta \cdot \hat{\tau}\|_{\Gamma_j} \\ &\quad + C_s \overline{C} \delta^2 r \|\mathbb{D}(\eta)\|_{L^3} \|\mathbb{D}(\phi^h)\|_{L^3} + \alpha \|\nabla \cdot \eta\| \, \|\nabla \cdot \phi^h\|.\end{aligned}$$

Remark 4.1. If $\tilde{w}$ is taken to be the Stokes projection of (w, q) into V^h, then, e.g., the term "$Re^{-1} \|\mathbb{D}(\phi^h)\| \, \|\mathbb{D}(\eta)\|$" on this last right-hand side does not occur.

Inserting these two bounds in (4.2) and using the Cauchy–Schwarz and Young's inequalities gives

$$\begin{aligned}&\frac{1}{2} \frac{d}{dt} \|\phi^h\|^2 + \underline{C} C_s \delta^2 \|\mathbb{D}(\phi^h)\|_{L^3}^3 + \alpha \|\nabla \cdot \phi^h\|^2 \\ &\quad + (2Re^{-1} + a_0(\delta)) \|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J} \beta \|\phi^h \cdot \hat{\tau}\|_{\Gamma_j}^2 \\ &\leq |b(w, w, \phi^h) - b(w^h, w^h, \phi^h)| + \frac{\epsilon_1}{3} \delta^2 \|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{2}{3} \epsilon_1^{-1/2} \delta^{-1} \|\eta_t\|_{W^{-1,3/2}}^{3/2}\end{aligned}$$

$$
\begin{aligned}
&+\frac{1}{2}(2Re^{-1}+a_0(\delta))\|\mathbb{D}(\phi^h)\|^2\frac{1}{2}(2Re^{-1}+a_0(\delta))\|\mathbb{D}(\eta)\|^2\\
&+\sum_{j=1}^{J}\left(\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|^2_{\Gamma_j}+\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|^2_{\Gamma_j}\right)+\frac{\epsilon_1}{3}\delta^2\|\mathbb{D}(\phi^h)\|^3_{L^3}\\
&+\frac{2}{3}\epsilon_1^{-1/2}\delta^2\overline{C}^{3/2}C_s^{3/2}r^{3/2}\|\mathbb{D}(\eta)\|^{3/2}_{L^3}+\frac{\alpha}{2}\|\nabla\cdot\phi^h\|^2+\frac{1}{\alpha}\|q-\lambda^h\|^2+\alpha\|\nabla\cdot\eta\|^2.
\end{aligned}
$$

Picking $\epsilon_1=\underline{C}C_s$ and collecting terms gives

$$
\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2+\frac{1}{3}\underline{C}C_s\delta^2\|\mathbb{D}(\phi^h)\|^3_{L^3}+\frac{\alpha}{2}\|\nabla\cdot\phi^h\|^2\\
&\quad+\frac{1}{2}(2Re^{-1}+a_0(\delta))\|\mathbb{D}(\phi^h)\|^2+\sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|^2_{\Gamma_j}\\
&\le|b(w,w,\phi^h)-b(w^h,w^h,\phi^h)|+\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|^{3/2}_{W^{-1,3/2}}\\
&\quad+\frac{1}{2}(2Re^{-1}+a_0(\delta))\|\mathbb{D}(\eta)\|^2+\sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|^2_{\Gamma_j}\\
&\quad+\frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|^{3/2}_{L^3}+\alpha^{-1}\|q-\lambda^h\|^2+\alpha\|\nabla\cdot\eta\|^2.
\end{aligned}
\tag{4.3}
$$

This is the basic differential inequality for the error. Three cases will be considered, revolving around the treatment of the first term on the right-hand side of (4.3).

Remark 4.2. If $\alpha=0$, an estimate which is uniform in Re can still be obtained by using Korn's inequality and Young's inequality on the term $(q-\lambda^h,\nabla\cdot\phi^h)$ as follows:

$$
\begin{aligned}
(q-\lambda^h,\nabla\cdot\phi^h)&\le\|q-\lambda^h\|_{L^{3/2}}\|\nabla\cdot\phi\|_{L^3}\le C\|\mathbb{D}(\phi^h)\|_{L^3}\|q-\lambda^h\|_{L^{3/2}}\\
&\le\frac{1}{3}\underline{C}C_s\delta^2\|\mathbb{D}(\phi^h)\|^3_{L^3}+C\delta^{-1}\|q-\lambda^h\|^{3/2}_{L^{3/2}}.
\end{aligned}
$$

However, an estimate of the nonlinear convective term which is uniform in Re fails in the case $\alpha=0$; see Remark 4.7.

Consider the convection terms

$$
b(w,w,\phi^h)-b(w^h,w^h,\phi^h)=b(w,\eta-\phi^h,\phi^h)+b(\eta-\phi^h,w^h,\phi^h).
\tag{4.4}
$$

The terms containing η shall be bounded first. Consider $b(w,\eta,\phi^h)$ and $b(\eta,w^h,\phi^h)$. Using the inequalities in section 2 appropriately gives

$$
\begin{aligned}
|b(w,\eta,\phi^h)|&=\left|\frac{1}{2}[(w\cdot\nabla\eta,\phi^h)-(w\cdot\nabla\phi^h,\eta)]\right|\\
&\le\frac{1}{2}\left[\|\phi^h\|\,\|\nabla\eta\|_{L^{s'}}\|w\|_{L^s}+\|\nabla\phi^h\|_{L^3}\|w\|_{L^q}\|\eta\|_{L^{q'}}\right],
\end{aligned}
$$

where $\frac{1}{2}+\frac{1}{s'}+\frac{1}{s}=1$ and $\frac{1}{3}+\frac{1}{q}+\frac{1}{q'}=1$. Picking $s'=3$, $s=6$, $q=2$, and $q'=6$ gives

$$
\begin{aligned}
|b(w,\eta,\phi^h)|&\le\frac{1}{2}\left[\|\phi^h\|\,\|\nabla\eta\|_{L^3}\|w\|_{L^6}+\|\nabla\phi^h\|_{L^3}\|w\|\,\|\eta\|_{L^6}\right]\\
&\le\frac{1}{4}\|\phi^h\|^2\|w\|^2_{L^6}+\frac{1}{4}\|\nabla\eta\|^2_{L^3}+\frac{\epsilon_3}{6}\|\mathbb{D}(\phi^h)\|^3_{L^3}+\frac{C}{3}\epsilon_3^{-1/2}\|w\|^{3/2}\|\eta\|^{3/2}_{L^6}.
\end{aligned}
\tag{4.5}
$$

The term $b(\eta, w^h, \phi^h)$ is similarly bounded as follows:

$$
\begin{aligned}
|b(\eta, w^h, \phi^h)| &= \left| \frac{1}{2}[(\eta \cdot \nabla w^h, \phi^h) - (\eta \cdot \nabla \phi^h, w^h)] \right| \\
&\leq \frac{1}{2} \|\nabla w^h\|_{L^3} \|\eta\|_{L^6} \|\phi^h\| + \frac{1}{2} \|\nabla \phi^h\|_{L^3} \|\eta\|_{L^6} \|w^h\| \\
&\leq \frac{1}{4} \|\nabla w^h\|_{L^3}^2 \|\phi^h\|^2 + \frac{1}{4} \|\eta\|_{L^6}^2 + \frac{\epsilon_3}{6} \|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{C}{3} \epsilon_3^{-1/2} \|\eta\|_{L^6}^{3/2} \|w^h\|^{3/2}. \qquad (4.6)
\end{aligned}
$$

Korn's inequality and the stability bounds (3.5) and (3.6) immediately imply that $\mathbb{D}(w^h) \in L^3(0,T;L^3)$ uniformly in Re so that $\|\nabla w^h\|_{L^3}^2 \in L^1(0,T)$, uniformly in Re. The Sobolev imbedding theorem and Korn's inequality also imply $\|w\|_{L^6}^2 \in L^1(0,T)$ uniformly in Re. Thus, these bounds suffice for a later application of Gronwall's inequality.

The first term containing only $\phi^h, b(w, \phi^h, \phi^h)$, is zero due to skew symmetry. Thus, there only remains the term $b(\phi^h, w^h, \phi^h)$. Estimating the term $b(\phi^h, w^h, \phi^h)$ is the essential, core difficulty in obtaining an error bound which is uniform in Re. There are only a few natural ways to bound this using Hölder's inequality and the Sobolev embedding theorem. There are two cases in which the analysis is successful:

(i) $a_0(\delta) \neq 0$ and $\nabla w \in L^3(0,T;L^3(\Omega))$,

(ii) $a_0(\delta) = 0$ and ∇w very regular, $\nabla w \in L^2(0,T;L^\infty(\Omega))$.

There is one important case in which the analysis fails:

(iii) $a_0(\delta) = 0$ and $\nabla w \in L^3(0,T;L^3(\Omega))$.

To highlight subsequent analysis and, hopefully, spur further study, we shall first present the case (iii) and explain the failure of the analysis.

Remark 4.3. On the condition $a_0(\delta) > 0$ in part (i), if $a_1(\delta) > 0$ and $a_0(\delta) \geq 0$, then it is known that the difference between two weak solutions of (1.3) can be bounded (nonuniformly in Re) by the change in the problem data [7, 29, 34]. These bounds imply uniqueness over $O(1)$ time intervals. On the other hand, if $a_1(\delta) \equiv 0$ and $a_0(\delta) > 0$, weak solutions are then only known to be unique over very small time intervals $0 \leq t \leq T^*(\delta)$, where (loosely speaking) $T^*(\delta) \sim (a_0(\delta) + Re^{-1})^3$.

4.1. The case $\nabla w \in L^3(0,T;L^3(\Omega))$ and $a_0(\delta) = 0$. If we assume only that $\nabla w \in L^3(0,T;L^3(\Omega))$, there is no need to add and subtract terms since a priori bounds on $\|\nabla w^h\|_{L^3(0,T;L^3)}$ have been proven which are uniform in Re. Thus, we can use Hölder's inequality to write

$$
\begin{aligned}
|b(\phi^h, w^h, \phi^h)| &= \left| \frac{1}{2}(\phi^h \cdot \nabla w^h, \phi^h) - \frac{1}{2}(\phi^h \cdot \nabla \phi^h, w^h) \right| \\
&\leq \frac{1}{2} \|\nabla w^h\|_{L^3} \|\phi^h\|_{L^s} \|\phi^h\|_{L^{s'}} + \frac{1}{2} \|\nabla \phi^h\|_{L^3} \|\phi^h\| \, \|w^h\|_{L^6},
\end{aligned}
$$

where $\frac{1}{3} + \frac{1}{s'} + \frac{1}{s} = 1$ and $1 \leq s', s \leq \infty$. Thus, picking $s' = 2$, $s = 6$, using the embedding $W^{1,3}(\Omega) \to L^6(\Omega)$ and Poincaré's inequality gives

$$
\begin{aligned}
|b(\phi^h, w^h, \phi^h)| &\leq \frac{C(\Omega)}{2} \|\nabla w^h\|_{L^3} \|\phi^h\| \, \|\phi^h\|_{1,3} + \frac{C(\Omega)}{2} \|\nabla \phi^h\|_{L^3} \|\phi^h\| \, \|w^h\|_{1,3} \\
&\leq \frac{\epsilon}{6} \|\phi^h\|_{1,3}^3 + C\epsilon^{-1/2} \|\nabla w^h\|_{L^3}^{3/2} \|\phi^h\|^{3/2} + \frac{\epsilon}{6} \|\mathbb{D}(\phi^h)\|_{L^3}^3. \qquad (4.7)
\end{aligned}
$$

Remark 4.4. Using Lemma 2.5 instead of the embedding of $W^{1,3} \to L^6$ changes the critical exponent on $\|\phi^h\|$ "3/2" to 12/7 in the first term of (4.7) but not the final conclusion.

Combining (4.5), (4.6), (4.7) with $\epsilon_3 = \epsilon$ gives an initial bound on the convection term's difference:

$$
\begin{aligned}
&|b(w,w,\phi^h) - b(w^h,w^h,\phi^h)| \\
&\le \left[\frac{1}{4}\|\nabla\eta\|_{L^3}^2 + \frac{1}{4}\|\eta\|_{L^6}^2 + C\epsilon^{-1/2}\left(\|w\|^{3/2} + \|w^h\|^{3/2}\right)\|\eta\|_{L^6}^{3/2}\right] \\
&\quad + \frac{2\epsilon}{3}\|\nabla\phi^h\|_{L^3}^3 + C\epsilon^{-1/2}\|\nabla w^h\|_{L^3}^{3/2}\|\phi^h\|^{3/2} + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2\right]\|\phi^h\|^2. \qquad (4.8)
\end{aligned}
$$

Inserting (4.8) into (4.3), applying Korn's inequality, and collecting terms gives

$$
\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2 + \left(\frac{1}{3}\underline{C}C_s\delta^2 - \frac{2\epsilon}{3}\right)\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{\alpha}{2}\|\nabla\cdot\phi^h\|^2 \\
&\quad + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|_{\Gamma_j}^2 \\
&\le \left[\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|_{W^{-1,3/2}}^{3/2} + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\eta)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|_{\Gamma_j}^2\right. \\
&\quad + \frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|_{L^3}^{3/2} + \alpha^{-1}\|q-\lambda^h\|^2 + \alpha\|\nabla\cdot\eta\|^2 + \frac{1}{4}\|\nabla\eta\|_{L^3}^2 \\
&\quad \left. + C\epsilon^{-1/2}\|w\|^{3/2}\|\eta\|_{L^6}^{3/2} + \frac{1}{4}\|\eta\|_{L^6}^2 + C\epsilon^{-1/2}\|\eta\|_{L^6}^{3/2}\|w^h\|^{3/2}\right] \\
&\quad + C\epsilon^{-1/2}\|\nabla w^h\|_{L^3}^{3/2}\|\phi^h\|^{3/2} + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2\right]\|\phi^h\|^2.
\end{aligned}
$$

Thus, pick ϵ such that

$$\frac{2\epsilon}{3} = \frac{1}{6}\underline{C}C_s\delta^2,$$

i.e., $\epsilon = O(\delta^2)$. This gives

$$
\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2 + \frac{1}{6}\underline{C}C_s\delta^2\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{\alpha}{2}\|\nabla\cdot\phi^h\|^2 + Re^{-1}\|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|_{\Gamma_j}^2 \\
&\le \left[\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|_{W^{-1,3/2}}^{3/2} + Re^{-1}\|\mathbb{D}(\eta)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|_{\Gamma_j}^2\right. \\
&\quad + \frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|_{L^3}^{3/2} + \alpha^{-1}\|q-\lambda^h\|^2 + \alpha\|\nabla\cdot\eta\|^2 + \frac{1}{4}\|\nabla\eta\|_{L^3}^2 \\
&\quad \left. + \frac{C}{\delta}\left(\|w\|^{3/2} + \|w^h\|^{3/2}\right)\|\eta\|_{L^6}^{3/2} + \frac{1}{4}\|\eta\|_{L^6}^2\right] \\
&\quad + \left[C\delta^{-1}\|\nabla w^h\|_{L^3}^{3/2}\right]\|\phi^h\|^{3/2} + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2\right]\|\phi^h\|^2.
\end{aligned}
$$

Consider the bracketed terms on this right-hand side. The first is approximation theoretic; the second is an L^1 function multiplying $\|\phi^h(t)\|^{3/2}$; the third is an L^1

function multiplying $\|\phi^h(t)\|^2$. Let $y(t) := \|\phi^h(t)\|^2$. This inequality may then be written as

$$\frac{d}{dt}y(t) + (\text{nonnegative terms}) \leq C(t)h^\gamma + a(t)y(t) + b(t)\delta^{-1}y^{3/4}(t),$$

where $a(t), b(t) \in L^1(0,T)$.

The final step would normally be to apply Gronwall's inequality to deduce $y(t) = \frac{1}{2}\|\phi^h(t)\|^2$ to be bounded by its initial values and approximation theoretic terms. Unfortunately, the term $y^{3/4}$ is not Lipschitz, so the argument fails at this last step.

Tracing the inequalities backward, the problem term arises from the steps used to bound $b(\phi^h, w^h, \phi^h)$ to obtain Re independence. The error analysis in the successful cases (i) and (ii) centers therefore on alternate bounds for this term. We shall first consider case (i).

Remark 4.5. If the estimate in (4.7) is improved as noted in Remark 4.3, the term $y(t)^{3/4}$ is changed to $y(t)^{6/7}$ but the final conclusion still holds.

4.2. The case $\nabla w \in L^3(0,T;L^3(\Omega))$ and $a_0(\delta) > 0$. The main result of this section is the following theorem.

THEOREM 4.1. *Assume $\alpha > 0$ and $a_0(\delta) > 0$. Let*

$$a(t) = \frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2 + \frac{C}{a_0(\delta)}\|\nabla w^h\|_{L^3}^2 + Ca_0(\delta)^{-1/2}\alpha^{-3/2}\|\mathbb{D}(w^h)\|_{L^3}^3.$$

Then, there is a $C_1 = C_1(\delta)$, independent of Re and h, such that

$$\|a(t)\|_{L^1(0,T)} \leq C_1(\delta).$$

Further, there is a $C_2 = C_2(\delta)$, independent of Re and h, such that

$$\frac{C}{\delta}\left(\|w\|^{3/2} + \|w^h\|^{3/2}\right) \leq C_2(\delta).$$

Then, the error $w - w^h$ satisfies for $T > 0$

$$\begin{aligned}
&\|w - w^h\|_{L^\infty(0,T;L^2)}^2 + \delta^2\|\mathbb{D}(w - w^h)\|_{L^3(0,T;L^3)}^3 + \alpha\|\nabla\cdot(w - w^h)\|_{L^2(0,T;L^2)}^2 \\
&\quad + \left(Re^{-1} + Ca_0(\delta)\right)\|\mathbb{D}(w - w^h)\|_{L^2(0,T;L^2)}^2 + \sum_{j=1}^{J}\beta\|(w - w^h)\cdot\hat{\tau}\|_{L^2(0,T;L^2(\Gamma_j))}^2 \\
&\leq C\exp(C_1(\delta))\|(w - w^h)(x,0)\|^2 + C\inf_{\tilde{w}\in V^h\cap(W^{1,3}(\Omega))^d, \lambda^h\in Q^h}\mathcal{F}(w - \tilde{w}, q - \lambda^h, \delta)
\end{aligned}$$

with

$$\begin{aligned}
&\mathcal{F}(w - \tilde{w}, r - q^h, \delta) \\
&= \|w - \tilde{w}\|_{L^\infty(0,T;L^2)}^2 + \delta^2\|\mathbb{D}(w - \tilde{w})\|_{L^3(0,T;L^3)}^3 \\
&\quad + \exp(C_1(\delta))\Bigg[\|(w - \tilde{w})(x,0)\|^2 + \delta^{-1}\|(w - \tilde{w})_t\|_{L^{3/2}(0,T;W^{-1,3/2})}^{3/2} \\
&\quad + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w - \tilde{w})\|_{L^2(0,T;L^2)}^2 + \sum_{j=1}^{J}\beta\|(w - \tilde{w})\cdot\hat{\tau}\|_{L^2(0,T;L^2(\Gamma_j))}^2 \\
&\quad + C(\delta)\|\mathbb{D}(w - \tilde{w})\|_{L^3(0,T;L^3)}^{3/2} + \alpha^{-1}\|q - \lambda^h\|_{L^2(0,T;L^2)}^2 + \alpha\|\nabla\cdot(w - \tilde{w})\|_{L^2(0,T;L^2)}^2 \\
&\quad + \|\nabla(w - \tilde{w})\|_{L^2(0,T;L^3)}^2 + \|w - \tilde{w}\|_{L^2(0,T;L^6)}^2 + C_2(\delta)\|w - \tilde{w}\|_{L^{3/2}(0,T;L^6)}^{3/2}\Bigg].
\end{aligned}$$

Proof. This analysis follows the previous discussion closely except for the treatment of the $b(\phi^h, w^h, \phi^h)$ term and the final application of Gronwall's inequality.

Consider, therefore, $b(\phi^h, w^h, \phi^h)$. Integration by parts and using the fact that $\phi^h \cdot \hat{n} = 0$ on Γ give

$$\begin{aligned} b(\phi^h, w^h, \phi^h) &= \frac{1}{2}(\phi^h \cdot \nabla w^h, \phi^h) - \frac{1}{2}(\phi^h \cdot \nabla \phi^h, w^h) \\ &= (\phi^h \cdot \nabla w^h, \phi^h) + \frac{1}{2}(\nabla \cdot \phi^h, \phi^h \cdot w^h) \\ &\le \|\nabla w^h\|_{L^3} \|\phi^h\|_{L^3}^2 + \frac{1}{2}|(\nabla \cdot \phi^h, \phi^h \cdot w^h)|. \end{aligned} \tag{4.9}$$

Using the embedding $H^{1/2} \hookrightarrow L^3$ in $d = 2, 3$ and Young's inequality give

$$\left|b(\phi^h, w^h, \phi^h)\right| \le \frac{\epsilon_1}{2}\|\mathbb{D}(\phi^h)\|^2 + \frac{C}{2\epsilon_1}\|\nabla w^h\|_{L^3}^2 \|\phi^h\|^2 + \frac{1}{2}|(\nabla \cdot \phi^h, \phi^h \cdot w^h)|. \tag{4.10}$$

Consider now the last term on the above right-hand side. By Hölder's inequality, we obtain

$$|(\nabla \cdot \phi^h, \phi^h \cdot w^h)| \le \|\nabla \cdot \phi^h\| \, \|\phi^h\|_{L^{r'}} \|w^h\|_{L^s},$$

where $\frac{1}{r'} + \frac{1}{s} = \frac{1}{2}$. Thus,

$$|(\nabla \cdot \phi^h, w^h \cdot \phi^h)| \le \frac{\alpha}{4}\|\nabla \cdot \phi^h\|^2 + \alpha^{-1}\|\phi^h\|_{L^{r'}}^2 \|w^h\|_{L^s}^2. \tag{4.11}$$

The Sobolev embedding theorem implies that for any $s, 1 \le s < \infty$ in two or three dimensions, $W^{1,3}(\Omega) \hookrightarrow L^s(\Omega)$. Thus,

$$\|w^h\|_{L^s}^2 \le C(s, \Omega) \, \|w^h\|_{W^{1,3}(\Omega)}^2 \le C(s, \Omega)\|\mathbb{D}(w^h)\|_{L^3}^2.$$

This implies that for any $r' > 2$

$$|(\nabla \cdot \phi^h, w^h \cdot \phi^h)| \le \frac{\alpha}{4}\|\nabla \cdot \phi^h\|^2 + C(r', \Omega)\alpha^{-1}\|\phi^h\|_{L^{r'}}^2 \|\mathbb{D}(w^h)\|_{L^3}^2.$$

Consider the last term on the above right-hand side. The Sobolev embedding theorem also implies

$$\|\phi^h\|_{L^{r'}} \le C(r', \Omega)\|\phi^h\|_{W^{t,2}(\Omega)} \text{ for } t \ge \frac{3}{2} - \frac{3}{r'}.$$

(The final result is not improved by applying here instead the Gagliardo–Nirenberg inequality.) As $r' \to 2, t \to 0$ in this inequality. Thus, picking $r' = r'(t) > 2$ close enough to 2 implies that, using an embedding inequality and Korn's inequality,

$$\|\phi^h\|_{L^{r'}}^2 \le C(t, \Omega)\|\phi^h\|_t^2 \le C(t, \Omega)\|\phi^h\|^{2(1-t)} \, \|\mathbb{D}(\phi^h)\|^{2t}$$

for any $t > 0$. Thus, for these values of r' and s

$$\frac{1}{\alpha}\|\phi^h\|_{L^{r'}}^2 \|w^h\|_{L^s}^2 \le \frac{C}{\alpha}\|\mathbb{D}(\phi^h)\|^{2t}\|\phi^h\|^{2(1-t)}\|\mathbb{D}(w^h)\|_{L^3}^2$$

for any $t > 0$. For conjugate exponents $q = 3$ and $q' = \frac{3}{2}$ in Young's inequality, we then have

$$\frac{1}{\alpha}\|\phi^h\|_{L^{r'}}^2 \|w^h\|_{L^s}^2 \le \frac{\epsilon}{3}\|\mathbb{D}(\phi^h)\|^{6t} + \epsilon^{-1/2}\alpha^{-3/2}C\|\phi^h\|^{3(1-t)}\|\mathbb{D}(w^h)\|_{L^3}^3.$$

Picking $t = \frac{1}{3} > 0$ gives for these values of r' and s

$$\frac{1}{\alpha}\|\phi^h\|_{L^{r'}}^2\|w^h\|_{L^s}^2 \leq \frac{\epsilon}{3}\|\mathbb{D}(\phi^h)\|^2 + C(r',s,t,\Omega)\epsilon^{-1/2}\alpha^{-3/2}\|\phi^h\|^2\|\mathbb{D}(w^h)\|_{L^3}^3.$$

Using this bound, (4.10) and (4.11) finally give

$$\begin{aligned}|b(\phi^h, w^h, \phi^h)| \leq{}& \frac{\epsilon_1}{2}\|\mathbb{D}(\phi^h)\|^2 + \frac{C}{2\epsilon_1}\|\nabla w^h\|_{L^3}^2\|\phi^h\|^2 \\ &+ \frac{\alpha}{8}\|\nabla\cdot\phi^h\|^2 + \frac{\epsilon_2}{6}\|\mathbb{D}(\phi^h)\|^2 + C\epsilon_2^{-1/2}\alpha^{-3/2}\|\mathbb{D}(w^h)\|_{L^3}^3\|\phi^h\|^2.\end{aligned}$$

Remark 4.6. It appears on first consideration that this last term $(\nabla\cdot\phi^h, w^h\cdot\phi^h)$ can be agreeably bounded more directly and easily by

$$\begin{aligned}|(\nabla\cdot\phi^h, w^h\cdot\phi^h)| &\leq C\|\nabla\cdot\phi^h\|\ \|\nabla w^h\|\ \|\phi^h\|^{1/2}\ \|\nabla\phi^h\|^{1/2} \\ &\leq C\|\nabla\phi^h\|^{3/2}\|\phi^h\|^{1/2}\|\nabla w^h\| \leq \epsilon\|\nabla\phi^h\|^2 + C(\epsilon)\|\nabla w^h\|^4\|\phi^h\|^2.\end{aligned}$$

This bound, while certainly true, is not sufficient because of the condition that inevitably arises from using it that w^h or $w \in L^4(0,T;H^1(\Omega))$. The extra work in the bound we use reduces the time regularity requirements arising from this term to $w^h \in L^3(0,T;W^{1,3}(\Omega))$ (which is bounded uniformly in Re by problem data in section 3).

Substituting this bound for $b(\phi^h, w^h, \phi^h)$ in the derivation of the upper estimate (4.8) for the difference of the convection terms gives

$$\begin{aligned}&|b(w,w,\phi^h) - b(w^h,w^h,\phi^h)| \\ &\leq \left[\frac{1}{4}\|\nabla\eta\|_{L^3}^2 + \frac{C}{3}\epsilon_3^{-1/2}\|w\|^{3/2}\|\eta\|_{L^6}^{3/2} + \frac{1}{4}\|\eta\|_{L^6}^2 + \frac{C}{3}\epsilon_3^{-1/2}\|\eta\|_{L^6}^{3/2}\|w^h\|^{3/2}\right] \\ &\quad + \left[\frac{\epsilon_3}{3}\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{\epsilon_1}{2}\|\mathbb{D}(\phi^h)\|^2 + \frac{\alpha}{8}\|\nabla\cdot\phi^h\|^2 + \frac{\epsilon_2}{6}\|\mathbb{D}(\phi^h)\|^2\right] \\ &\quad + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2 + \frac{C}{2\epsilon_1}\|\nabla w^h\|_{L^3}^2 + C\epsilon_2^{-1/2}\alpha^{-3/2}\|\mathbb{D}(w^h)\|_{L^3}^3\right]\|\phi^h\|^2.\end{aligned} \tag{4.12}$$

To proceed further, (4.12) is inserted in the right-hand side of (4.3). This yields the differential inequality

$$\begin{aligned}&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2 + \left(\frac{1}{3}\underline{C}C_s\delta^2 - \frac{\epsilon_3}{3}\right)\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{3}{8}\alpha\|\nabla\cdot\phi^h\|^2 \\ &\quad + \left(\frac{1}{2}(2Re^{-1} + a_0(\delta)) - \frac{\epsilon_1}{2} - \frac{\epsilon_2}{6}\right)\|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|_{\Gamma_j}^2 \\ &\leq \left[\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|_{W^{-1,3/2}}^{3/2} + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\eta)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|_{\Gamma_j}^2\right. \\ &\quad + \frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|_{L^3}^{3/2} + \alpha^{-1}\|q-\lambda^h\|^2 + \alpha\|\nabla\cdot\eta\|^2 + \frac{1}{4}\|\nabla\eta\|_{L^3}^2 \\ &\quad \left. + \frac{C}{3}\epsilon_3^{-1/2}\left(\|w\|^{3/2} + \|w^h\|^{3/2}\right)\|\eta\|_{L^6}^{3/2} + \frac{1}{4}\|\eta\|_{L^6}^2\right] \\ &\quad + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2 + \frac{C}{\epsilon_1}\|\nabla w^h\|_{L^3}^2 + C\epsilon_2^{-1/2}\alpha^{-3/2}\|\mathbb{D}(w^h)\|_{L^3}^3\right]\|\phi^h\|^2.\end{aligned} \tag{4.13}$$

Pick $\epsilon_3 = C\underline{C}C_s\delta^2, C < 1/3$, $\epsilon_1 = a_0(\delta)/3$, and $\epsilon_2 = a_0(\delta)$. These choices simplify (4.13) to

$$\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2 + C\underline{C}C_s\delta^2\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{3}{8}\alpha\|\nabla\cdot\phi^h\|^2 \\
&\quad + \left(Re^{-1} + \frac{a_0(\delta)}{6}\right)|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|_{\Gamma_j}^2 \\
&\le \left[\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|_{W^{-1,3/2}}^{3/2} + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\eta)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|_{\Gamma_j}^2\right. \\
&(4.14)\quad + \frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|_{L^3}^{3/2} + \alpha^{-1}\|q-\lambda^h\|^2 + \alpha\|\nabla\cdot\eta\|^2 \\
&\qquad \left. + \frac{1}{4}\|\nabla\eta\|_{L^3}^2 + \frac{C}{\delta}(\|w\|^{3/2} + \|w^h\|^{3/2})\|\eta\|_{L^6}^{3/2} + \frac{1}{4}\|\eta\|_{L^6}^2\right] \\
&\qquad + \left[\frac{1}{4}\|w\|_{L^6}^2 + \frac{1}{4}\|\nabla w^h\|_{L^3}^2 + \frac{C}{a_0(\delta)}\|\nabla w^h\|_{L^3}^2 + \frac{C}{a_0(\delta)^{1/2}\alpha^{3/2}}\|\mathbb{D}(w^h)\|_{L^3}^3\right]\|\phi^h\|^2.
\end{aligned}$$

Before applying Gronwall's inequality, let us first verify that it will indeed give us an error bound that is uniform in the Reynolds number by considering the coefficients on the right-hand side of (4.14).

First, note that $r \le C\|D(w)\|_{L^3}$. By the stability estimates $\|w\| \in L^\infty(0,T)$ and $\|w^h\| \in L^\infty(0,T)$ uniformly in Re. Thus,

$$\frac{C}{\delta}\|w\|^{3/2}\|\eta\|_{L^6}^{3/2} + \frac{C}{\delta}\|\eta\|_{L^6}^{3/2}\|w^h\|^{3/2} \le \frac{C}{\delta}(\|w\|^{3/2} + \|w^h\|^{3/2})\|\eta\|_{L^6}^{3/2} \le C_2(\delta)\|\eta\|_{L^6}^{3/2}.$$

Consider the (critical) bracketed coefficient of the last term on the right-hand side. We must show this coefficient is in $L^1(0,T)$ uniformly in Re. Indeed, by the stability estimates and the Sobolev imbedding $\|w\|_{L^6}$, $\|\mathbb{D}(w^h)\|_{L^3}$, $\|\mathbb{D}(w)\|_{L^3} \in L^3(0,T)$ uniformly in Re. Since $T < \infty$, $L^3(0,T) \subset L^2(0,T)$, and thus the first factor of the last term is in $L^1(0,T)$ uniformly in Re.

Hiding all constants in generic C's, Gronwall's lemma now implies for almost all $t \in [0,T]$ that

$$\begin{aligned}
&\|\phi^h(x,t)\|^2 + \delta^2\|\mathbb{D}(\phi^h)\|_{L^3(0,t;L^3)}^3 + \alpha\|\nabla\cdot\phi^h\|_{L^2(0,t;L^2)}^2 \\
&\quad + \left(Re^{-1} + Ca_0(\delta)\right)\|\mathbb{D}(\phi^h)\|_{L^2(0,t;L^2)}^2 + \sum_{j=1}^{J}\beta\|\phi^h\cdot\hat{\tau}\|_{L^2(0,t;L^2(\Gamma_j))}^2 \\
&\le C\exp\left(\|a(t)\|_{L^1(0,t)}\right)\|\phi^h(x,0)\|^2 \\
&\quad + C\exp\left(\|a(t)\|_{L^1(0,t)}\right)\Bigg[\delta^{-1}\|\eta_t\|_{L^{3/2}(0,T;W^{-1,3/2})}^{3/2} + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(\eta)\|_{L^2(0,t;L^2)}^2 \\
&\quad + \sum_{j=1}^{J}\beta\|\eta\cdot\hat{\tau}\|_{L^2(0,t;L^2(\Gamma_j))}^2 + \delta^2\int_0^t\|\mathbb{D}(w)\|_{L^3}^{3/2}\|\mathbb{D}(\eta)\|_{L^3}^{3/2}dt' \\
&\quad + \alpha^{-1}\|q-\lambda^h\|_{L^2(0,t;L^2)}^2 + \alpha\|\nabla\cdot\eta\|_{L^2(0,t;L^2)}^2 + \|\nabla\eta\|_{L^2(0,t;L^3)}^2 + \|\eta\|_{L^2(0,t;L^6)}^2 \\
&\quad + \int_0^t\frac{1}{\delta}(\|w\|^{3/2} + \|w^h\|^{3/2})\|\eta\|_{L^6}^{3/2}dt'\Bigg].
\end{aligned}$$

Note that by the Cauchy–Schwarz inequality in $L^2(0,t)$, $t \in [0,T]$, and the stability estimates

$$\int_0^t \|\mathbb{D}(w)\|_{L^3}^{3/2} \|\mathbb{D}(\eta)\|_{L^3}^{3/2} dt' \leq \|\mathbb{D}(w)\|_{L^3(0,t;L^3)}^{3/2} \|\mathbb{D}(\eta)\|_{L^3(0,t;L^3)}^{3/2} \leq C(\delta) \|\mathbb{D}(\eta)\|_{L^3(0,t;L^3)}^{3/2}.$$

Now, the essential supremum of $t \in [0,T]$ is applied on both sides of the inequality. As $w - w^h = \eta - \phi^h$, the triangle inequality completes the proof of Theorem 4.1. ∎

Remark 4.7. On the condition $\alpha > 0$, the least squares control of $\nabla \cdot u$ seems to be essential to get an estimate uniform in Re. Consider (4.9) in the proof of Theorem 4.1. There are two important nonlinear terms in the error equation corresponding loosely to convection and reaction. The reaction term is controlled by the subgrid model. The convection term can be converted into a reaction-like term. It is controllable provided that $\nabla \cdot \phi^h$ is controllable, which $\alpha > 0$ accomplishes.

Another promising approach is to use a variational formulation, such as SUPG developed by Brooks and Hughes [3], which will control the convection term directly. We note that both SUPG and least squares control of $\nabla \cdot u$ are consistent: they work on the error and do not change the solution.

4.3. The case $\nabla w \in L^2(0,T;L^\infty(\Omega))$ and $a_0(\delta) \geq 0$. We now consider the case of smoother w, i.e.,

$$w \in L^2(0,T;W^{1,\infty}(\Omega)) \text{ uniformly in } Re,$$

allowing for the case $a_0(\delta) \equiv 0$. This case is primarily of interest because many tests involve "academic" flow fields given in closed form (as in section 5). These are typically smooth and bounded. In this case Theorem 4.2 gives an error estimate with constants independent of Re (but depending on δ and α). It is noteworthy in this estimate that *multiplicative constants* depend on δ but the *rate constant* in the (inevitable) exponential term takes the form

$$\exp(C_3(w)), \quad C_3 = C_3(\|w\|_{L^2(0,T;W^{1,\infty}(\Omega))}),$$

with no *explicit* dependence on δ.

THEOREM 4.2. *Suppose $a_0(\delta) \geq 0$, $\alpha > 0$, and $w \in L^2(0,T;W^{1,\infty}(\Omega))$ uniformly in Re. Let*

$$a(t) := \frac{3}{4} + \|\nabla w\|_{L^\infty} + \left(\frac{1}{4} + \frac{1}{4\alpha}\right) \|w\|_{L^\infty}^2 + \frac{1}{2} \|\nabla w\|_{L^\infty}^2;$$

then there is a $C_3 = C_3(w)$ such that

$$\|a(t)\|_{L^1(0,T)} \leq C_3(w).$$

Let $C_4 = C_4(\delta)$ be such that

$$\|\mathbb{D}(w^h)\|_{L^3(0,T;L^3)} \leq C_4(\delta).$$

Then, the error $w - w^h$ satisfies

$$\begin{aligned}
&\|w - w^h\|_{L^\infty(0,T;L^2)}^2 + \delta^2 \|\mathbb{D}(w - w^h)\|_{L^3(0,T;L^3)}^3 + \alpha \|\nabla \cdot (w - w^h)\|_{L^2(0,T;L^2)}^2 \\
&\quad + \left(Re^{-1} + C a_0(\delta)\right) \|\mathbb{D}(w - w^h)\|_{L^2(0,T;L^2)}^2 + \sum_{j=1}^{J} \beta \|(w - w^h) \cdot \hat{\tau}\|_{L^2(0,T;L^2(\Gamma_j))}^2 \\
&\leq C \exp(C_3(w)) \|(w - w^h)(x,0)\|^2 + C \inf_{\tilde{w} \in V^h \cap (W^{1,3}(\Omega))^d, \lambda^h \in Q^h} \mathcal{F}(w - \tilde{w}, q - \lambda^h, \delta)
\end{aligned}$$

with

$$
\begin{aligned}
&\mathcal{F}(w-\tilde{w}, r-q^h, \delta)\\
&= \|w-\tilde{w}\|^2_{L^\infty(0,T;L^2)} + \delta^2\|\mathbb{D}(w-\tilde{w})\|^3_{L^3(0,T;L^3)}\\
&\quad + \exp(C_3(w))\Bigg[\|(w-\tilde{w})(x,0)\|^2 + \delta^{-1}\|(w-\tilde{w})_t\|^{3/2}_{L^{3/2}(0,T;W^{-1,3/2})}\\
&\quad + (2Re^{-1} + a_0(\delta))\|\mathbb{D}(w-\tilde{w})\|^2_{L^2(0,T;L^2)} + \sum_{j=1}^{J}\beta\|(w-\tilde{w})\cdot\hat{\tau}\|^2_{L^2(0,T;L^2(\Gamma_j))}\\
&\quad + C(\delta)\|\mathbb{D}(w-\tilde{w})\|^{3/2}_{L^3(0,T;L^3)} + \alpha^{-1}\|q-\lambda^h\|^2_{L^2(0,T;L^2)}\\
&\quad + \left(\frac{1}{4}+\alpha\right)\|\nabla\cdot(w-\tilde{w})\|^2_{L^2(0,T;L^2)} + \|w-\tilde{w}\|^2_{L^2(0,T;L^2)}\\
&\quad + C_4(\delta)\left(\|\mathbb{D}(w-\tilde{w})\|^2_{L^{18/5}(0,T;L^3)} + \|w-\tilde{w}\|^2_{L^6(0,T;L^6)}\right)\Bigg].
\end{aligned}
$$

Proof. In this case, the difference in the nonlinear terms is decomposed a bit differently as

$$
\begin{aligned}
|b(w,w,\phi^h) - b(w^h,w^h,\phi^h)| &= |b(\eta-\phi^h,w,\phi^h) + b(w^h,\eta-\phi^h,\phi^h)|\\
&= |b(\eta,w,\phi^h) - b(\phi^h,w,\phi^h) + b(w^h,\eta,\phi^h)|.
\end{aligned}
\tag{4.15}
$$

Consider the individual terms on the right-hand side of (4.15):

$$
\begin{aligned}
|b(\eta,w,\phi^h)| &= \left|\frac{1}{2}(\eta\cdot\nabla w,\phi^h) - \frac{1}{2}(\eta\cdot\nabla\phi^h,w)\right|\\
&= \left|(\eta\cdot\nabla w,\phi^h) + \frac{1}{2}(\nabla\cdot\eta,\phi^h\cdot w)\right|\\
&\le \frac{1}{2}\|\eta\|^2 + \frac{1}{2}\|\nabla w\|^2_{L^\infty}\|\phi^h\|^2 + \frac{1}{4}\|\nabla\cdot\eta\|^2 + \frac{1}{4}\|w\|^2_{L^\infty}\|\phi^h\|^2,\\
|b(\phi^h,w,\phi^h)| &= \left|(\phi^h\cdot\nabla w,\phi^h) + \frac{1}{2}(\nabla\cdot\phi^h,w\cdot\phi^h)\right|\\
&\le \|\nabla w\|_{L^\infty}\|\phi^h\|^2 + \frac{\alpha}{4}\|\nabla\cdot\phi^h\|^2 + \frac{1}{4\alpha}\|w\|^2_{L^\infty}\|\phi^h\|^2,\\
|b(w^h,\eta,\phi^h)| &= \left|(w^h\cdot\nabla\eta,\phi^h) + \frac{1}{2}(\nabla\cdot w^h,\eta\cdot\phi^h)\right|\\
&\le \|w^h\|_{L^6}\|\nabla\eta\|_{L^3}\|\phi^h\| + \frac{1}{2}\|\nabla\cdot w^h\|_{L^3}\|\eta\|_{L^6}\|\phi^h\|\\
&\le C\left(\|w^h\|^2_{L^6}\|\nabla\eta\|^2_{L^3} + \|\mathbb{D}(w^h)\|^2_{L^3}\|\eta\|^2_{L^6}\right) + \frac{3}{4}\|\phi^h\|^2.
\end{aligned}
$$

Combining these three estimates gives

$$
\begin{aligned}
&|b(w,w,\phi^h) - b(w^h,w^h,\phi^h)|\\
&\le \frac{1}{2}\|\eta\|^2 + \frac{1}{4}\|\nabla\cdot\eta\|^2 + C\|w^h\|^2_{L^6}\|\nabla\eta\|^2_{L^3} + C\|\mathbb{D}(w^h)\|^2_{L^3}\|\eta\|^2_{L^6} + \frac{\alpha}{4}\|\nabla\cdot\phi^h\|^2\\
&\quad + \left(\frac{3}{4} + \frac{1}{2}\|\nabla w\|^2_{L^\infty} + \frac{1}{4}\|w\|^2_{L^\infty} + \|\nabla w\|_{L^\infty} + \frac{1}{4\alpha}\|w\|^2_{L^\infty}\right)\|\phi^h\|^2.
\end{aligned}
\tag{4.16}
$$

The term $\|w^h\|_{L^6}$ is bounded using the Gagliardo–Nirenberg inequality (Lemma 2.5)

$$\|w^h\|_{L^6}^2 \leq C\|w^h\|^{2/3}\|\mathbb{D}(w^h)\|_{L^3}^{4/3}.$$

Since $\|w^h\|$ is bounded uniformly in ν and h by (3.5) or (3.6), it follows that

$$\|w^h\|_{L^6}^2 \leq C\|\mathbb{D}(w^h)\|_{L^3}^{4/3}.$$

This bound, together with (4.16), is now inserted in the right-hand side of (4.3) giving

$$\begin{aligned}
&\frac{1}{2}\frac{d}{dt}\|\phi^h\|^2 + \frac{1}{3}\underline{C}C_s\delta^2\|\mathbb{D}(\phi^h)\|_{L^3}^3 + \frac{\alpha}{2}\|\nabla\cdot\phi^h\|^2 \\
&\quad + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\phi^h)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\phi^h\cdot\hat{\tau}\|_{\Gamma_j}^2 \\
&\leq \left[\frac{2}{3}(CC_s)^{-1/2}\delta^{-1}\|\eta_t\|_{W^{-1,3/2}}^{3/2} + \frac{1}{2}(2Re^{-1} + a_0(\delta))\|\mathbb{D}(\eta)\|^2 + \sum_{j=1}^{J}\frac{\beta}{2}\|\eta\cdot\hat{\tau}\|_{\Gamma_j}^2\right. \\
&\quad + \frac{2}{3}\underline{C}^{-1/2}C_s\overline{C}^{3/2}r^{3/2}\delta^2\|\mathbb{D}(\eta)\|_{L^3}^{3/2} + \alpha^{-1}\|q-\lambda^h\|^2 + \alpha\|\nabla\cdot\eta\|^2 + \frac{1}{2}\|\eta\|^2 \\
&\quad \left. + \frac{1}{4}\|\nabla\cdot\eta\|^2 + C\|\mathbb{D}(w^h)\|_{L^3}^{4/3}\|\nabla\eta\|_{L^3}^2 + C\|\mathbb{D}(w^h)\|_{L^3}^2\|\eta\|_{L^6}^2\right] + \left[\frac{\alpha}{4}\|\nabla\cdot\phi^h\|^2\right] \\
&\quad + \left(\frac{3}{4} + \|\nabla w\|_{L^\infty} + \left(\frac{1}{4}+\frac{1}{4\alpha}\right)\|w\|_{L^\infty}^2 + \frac{1}{2}\|\nabla w\|_{L^\infty}^2\right)\|\phi^h\|^2.
\end{aligned}$$

To apply Gronwall's inequality we need

$$\frac{3}{4} + \|\nabla w\|_{L^\infty} + \left(\frac{1}{4}+\frac{1}{4\alpha}\right)\|w\|_{L^\infty}^2 + \frac{1}{2}\|\nabla w\|_{L^\infty}^2 \in L^1(0,T),$$

in other words $w \in L^2(0,T;W^{1,\infty}(\Omega))$. The term on the right-hand side of this inequality containing $r^{3/2}$ is treated as in the proof of Theorem 4.1. In the final result of Gronwall's lemma, we must also verify that the resulting terms containing $\|\mathbb{D}(w^h)\|_{L^3}$ are bounded uniformly in Re. To this end, apply Hölder's inequality

$$\int_0^T \|\mathbb{D}(w^h)\|_{L^3}^{4/3}\|\mathbb{D}(\eta)\|_{L^3}^2 dt \leq \|\mathbb{D}(w^h)\|_{L^{4q/3}(0,T;L^3)}^{4/3}\|\mathbb{D}(\eta)\|_{L^{2q'}(0,T;L^3)}^2,$$

where $\frac{1}{q} + \frac{1}{q'} = 1$. From the stability estimates, we clearly must take q such that $4q/3 \leq 3$. Accordingly, take $q = \frac{9}{4}, q' = \frac{9}{5}$. This gives

$$\begin{aligned}
\int_0^T \|\mathbb{D}(w^h)\|_{L^3}^{4/3}\|\mathbb{D}(\eta)\|_{L^3}^2 dt &\leq C\|\mathbb{D}(w^h)\|_{L^3(0,T;L^3)}^{4/3}\|\mathbb{D}(\eta)\|_{L^{18/5}(0,T;L^3)}^2 \\
&\leq CC_4(\delta)\|\mathbb{D}(\eta)\|_{L^{18/5}(0,T;L^3)}^2.
\end{aligned}$$

Similarly, for q and q' conjugate exponents take $q = \frac{3}{2}$, $q' = 3$,

$$\begin{aligned}
\int_0^T \|\mathbb{D}(w^h)\|_{L^3}^2\|\eta\|_{L^6}^2 dt &\leq \|\mathbb{D}(w^h)\|_{L^{2q}(0,T;L^3)}^2\|\eta\|_{L^{2q'}(0,T;L^6)}^2 \\
&\leq \|\mathbb{D}(w^h)\|_{L^3(0,T;L^3)}^2\|\eta\|_{L^6(0,T;L^6)}^2 \leq C_4(\delta)\|\eta\|_{L^6(0,T;L^6)}^2.
\end{aligned}$$

The stated error estimate now follows from Gronwall's inequality and the triangle inequality as in the proof of Theorem 4.1. ∎

5. A numerical example. To give a numerical illustration several decisions must be made, mainly whether to work on an "academic" flow problem with a known exact solution or to work on a more realistic flow problem containing the accompanying uncertainties. Since our aim is to illustrate a convergence theorem, we have chosen the former. (To assess a model or study the limitations of an algorithm, we would naturally have chosen the latter.) Accordingly, we have selected the vortex decay problem of Chorin [4], used also by others, e.g., Tafti [38]. The domain is $\Omega = (0,1)^2$ and we choose

$$\begin{aligned} w_1 &= -\cos(n\pi x)\sin(n\pi y)\exp(-2n^2\pi^2 t/\tau), \\ w_2 &= \sin(n\pi x)\cos(n\pi y)\exp(-2n^2\pi^2 t/\tau), \\ q &= -\tfrac{1}{4}(\cos(2n\pi x)+\cos(2n\pi y))\exp(-4n^2\pi^2 t/\tau). \end{aligned} \tag{5.1}$$

For the relaxation time $\tau = Re$ this is a solution of the Navier–Stokes equation consisting of an array of opposite signed vortices which decay as $t \to \infty$. The right-hand side f, initial condition, and nonhomogeneous Dirichlet boundary conditions are chosen so that (w_1, w_2, q) is the closed form solution of (1.3).

Since we are studying convergence as $h \to 0$ for δ fixed and Re varying we have accordingly chosen a 4×4 array of the vortices (so $n = 4$) and

$$\begin{aligned} \tau &= 1000, \\ \text{final time } T &= 8, \\ \text{eddy scale } \delta &= 0.1, \\ \text{Smagorinski constant } C_s &= 0.05, \\ a_0(\delta) &= 0. \end{aligned}$$

It is significant that $\delta = 0.1 \le \frac{1}{4} = \frac{1}{n}$ so that the vortices are larger than $O(\delta)$ and hence should be "visible" to the model.

The fractional—step θ—scheme with an equal distant time step $\Delta t_n = 0.001$ is used as discretization in time. The time discretization error should be kept small by using this very small time step. In space, the Q_2/P_1^{disc} and the Q_3/P_2^{disc} finite element discretizations are applied; see Table 1 for the number of degrees of freedom for different mesh sizes. The unit square was divided into an $h \times h$ mesh with $h = 1/2$ on level 0. Both the Smagorinsky subgridscale model and the convection term are treated implicitly. The viscous term is treated not as $(\nabla w^h, \nabla v^h)$ but as using the deformation tensor formulation, $(\mathbb{D}(w^h), \mathbb{D}(v^h))$, as analyzed herein. The least squares constant α is chosen to be zero and we used the convective form of the nonlinear convection term. The nonlinear system in each time step is solved up to a Euclidean norm of the residual vector less than 10^{-10}.

The numbers of degrees of freedom in space are certainly not extremely large. However, their importance is only relative to the Reynolds number, ranging from 10^2

to 10^{10}, and the resolution sought, $\delta = 0.1$. Again, LES is focused on situations in which the number of degrees of freedom is small relative to Re. Thus, the chosen values of h and Re seem appropriate.

Tables 2 and 3 present the $L^\infty(0,T;L^2)$ norm of the error for both discretizations in space. Note that the behavior is exactly as anticipated by the theory: the error in this norm is clearly independent of Re.

Tables 4 and 5 present the errors in $L^2(0,T;H^1)$. These errors are not predicted to be in general uniform in Re. But in the particular example which we have chosen, one can observe uniformity in Re.

6. Conclusions. Reynolds number dependence in finite element error analysis arises in three basic places: multiplicative error constants (Re), time scale constants ($\exp(C(Re)T)$), and time regularity assumptions on the true solution (needed even to prove continuous dependence on the initial data) which might fail for turbulent flows. In the error analysis of a large eddy model all three sources must be addressed. The idea of our error analysis herein for the Smagorinsky model has been that the greater spatial regularity of the large eddies must be used to compensate for the reduced time regularity of the underlying turbulent flow. The execution of this idea is necessarily technical since it entails using, in so far as possible, L^3 bounds (the natural norm arising from the model) for the nonlinear error terms. For different models, this same idea can be possibly applied; its execution will vary with the particular features of the model.

The error equation contains nonlinear terms resembling both convection and reaction. Our analysis suggests that uniformity in Re can be accomplished by the control of both effects. The second is controlled by the subgrid model while the first seems to need a correctly adapted numerical method; see Remark 4.7.

10^9	5.11166	2.31908e-1	2.31825e-2	2.72698e-3
10^{10}	5.11166	2.31908e-1	2.31825e-2	2.72759e-3

We note that replacing multipliers like $\exp(C(Re)T)$ in the error estimate by $\exp(C(\delta)T)$ establishes that a LES will be valid over a much longer time interval than a DNS, although still not over $0 < t \leq \infty$. It would certainly be interesting to know which flow statistics could be accurately approximated over $0 < t \leq \infty$, but this requires a different analysis.

A SINGULAR FIELD METHOD FOR MAXWELL'S EQUATIONS: NUMERICAL ASPECTS FOR 2D MAGNETOSTATICS*

CHRISTOPHE HAZARD† AND STEPHANIE LOHRENGEL‡

Abstract. The present paper deals with the solution of Maxwell-type problems by means of nodal H^1-conforming finite elements. In a nonconvex piecewise regular domain surrounded by a perfect conductor, such a discretization cannot in general approximate the singular behavior of the electromagnetic field near "reentrant" corners or edges. The *singular field method* consists of adding to the finite element discretization space some particular fields which take into account the singular behavior. The latter are deduced from the singular functions associated with the scalar Laplace operator.

The theoretical justification of this approach as well as the analysis of the convergence of the approximation are presented for a very simple model problem arising from magnetostatics in a translation invariant setting, but the study can be easily extended to numerous Maxwell-type problems. The numerical implementation of both variants is studied for a domain containing a single reentrant corner.

Key words. Maxwell's equations, singularities of solutions, finite element method, singular function methods, error analysis

1. Introduction.

In a previous paper [8], we described the theoretical aspects of a method for solving Maxwell's equations in a polyhedron of $\mathbb{R}^3$ by means of nodal finite elements. This approach is based on the fact that a H^1-conforming discretization cannot in general approximate the singular behavior of the electromagnetic field near nonconvex edges or corners of a perfect conductor (which explains the imperfection of the attempts in engineering to make nodal elements work; see, e.g., [6] and the remarks in [9]). However, this behavior can be expressed explicitly in terms of the so-called *singularities* of the scalar Laplace operator. The idea of the *singular field method* consists of using this explicit knowledge by splitting the electromagnetic field into two parts: a *regular* part which can be approximated by a H^1-conforming finite element method and a *singular* part which is taken into account explicitly.

The initial motivation of this work was to find a cure for the failure of classical Lagrange elements for solving Maxwell-type problems in nonconvex piecewise regular domains. To a certain extent the *singular field method* proposes a way to adapt usual codes for those who cling to H^1-conforming elements! The question is to know whether this approach represents a good alternative to the popular edge elements. The answer depends on the problem to be solved. Of course, edge elements take into account the singular behavior of the field near reentrant corners, provided the mesh is properly refined. However, in the case of the time-dependent Maxwell equations, refinement in space induces refinement in time and thus heavy computations. Nodal

elements are also advantageous when coupled with other codes requiring continuous fields, for instance in the resolution of the Vlasov–Maxwell system.

The aim of the present paper is not to compare both methods (which would require a precise investigation of convergence rates) but rather to describe some practical aspects of the *singular field method* in the two-dimensional case.

For the sake of simplicity, we consider a simple model problem which describes magnetostatics in a translation invariant setting and holds for transversal components of the field. Such a particular problem is hardly of practical interest. However, as mentioned in [8], there are numerous straightforward extensions of the method for Maxwell-type problems: time-harmonic full Maxwell's equations, eddy current models, inhomogeneous media, exterior scattering by obstacles or screens, etc. A more interesting but more complex application is presented in [25]: it deals with the determination of guided modes in an inhomogeneous cylindrical optical waveguide. More generally, the method applies for two-dimensional elliptic variational problems (or compact perturbations of such problems) in some piecewise $\mathcal{H}(\mathrm{curl}, \mathrm{div})$ space (i.e., for fields $\boldsymbol{E} \in L^2$ such that $\mathrm{curl}\, \boldsymbol{E} \in L^2$ and $\mathrm{div}\, \boldsymbol{E} \in L^2$) containing proper boundary or transmission conditions along piecewise regular curves. To extend the *singular field method* to such a problem, the main difficulty consists of identifying the singular fields related to the variational space, which amounts to the determination of scalar singular functions (by means of the techniques described for instance in Grisvard [21, 22] or Dauge [18]).

The paper is organized as follows. In section 2, we define our model problem and exhibit an equivalent *regularized* formulation, as well as a "spurious" regularized problem: the latter consists in the same variational equation as the former, set in a smaller functional space (which contains only regular fields). The key to the method lies in the fact that the latter space can be completed by a finite dimensional space of *singular fields* in order to solve the proper regularized problem: two such decompositions are given in section 3. They lead to the *singular field method* (SFM) and its orthogonal variant, the orthogonal singular field method (OSFM) which are described in section 4. The analysis of the convergence of these methods is the object of section 5. Both numerical schemes seem to have the same rate of convergence, but the numerical applications presented in section 6 clearly show that the OSFM yields far better results: we shall try to explain why.

Let us mention a similar approach developed by Assous, Ciarlet, and Segré [3] and Assous, Ciarlet, and Garcia [2] in the context of time-dependent Maxwell's equations (see also [23] for a unified presentation of both approaches): their method is based on an alternative decomposition of the electromagnetic field into regular and singular components. This approach has been extended to three dimensions in the case of axisymmetric geometries [1, 11]. Also worth mentioning is the procedure proposed by Costabel, Dauge, and Martin [17]. Contrary to our approach, the idea is to penalize the homogeneous boundary condition near the perfect conductor by an impedance condition simulating an imperfect conductor with high conductivity. From a theoretical point of view, the addition of singular fields is no longer necessary. Indeed, this is due to the density of regular fields in the functional space associated with the penalized problem (see [12, 16]). In practice, however, the choice of the penalization parameter is not obvious. Notice that for the unpenalized problem the density result fails: this is precisely the underlying cause of the failure of a direct use of nodal elements.

2. Classical and regularized formulations. Let $\Omega \subset \mathbb{R}^2$ be a bounded, simply connected, nonconvex polygonal domain with boundary Γ. We denote by $\boldsymbol{n} = (n_1, n_2)$ the unit normal vector to Γ. We are looking for a numerical approximation of the solution $\boldsymbol{E} = (E_1, E_2) \in \mathbb{R}^2$ to

$$\mathbf{curl}\,\mathrm{curl}\,\boldsymbol{E} = \boldsymbol{J} \ \text{ in } \Omega, \tag{1}$$

$$\mathrm{div}\,\boldsymbol{E} = 0 \ \text{ in } \Omega, \tag{2}$$

$$\boldsymbol{E} \times \boldsymbol{n} = E_1 n_2 - E_2 n_1 = 0 \ \text{ on } \Gamma, \tag{3}$$

where the datum $\boldsymbol{J}$ is assumed divergence-free:

$$\mathrm{div}\,\boldsymbol{J} = 0 \ \text{ in } \Omega. \tag{4}$$

The notations curl and **curl** distinguish between the scalar and vector curl operators:

$$\mathrm{curl}\,\boldsymbol{E} = \frac{\partial E_2}{\partial x_1} - \frac{\partial E_1}{\partial x_2} \quad \text{and} \quad \mathbf{curl}\,\varphi = \left(\frac{\partial \varphi}{\partial x_2}, -\frac{\partial \varphi}{\partial x_1}\right).$$

Let us mention that (1)–(3) does not define a "real vector problem" since it is known to reduce to a scalar problem. Indeed, the assumption (4) amounts to saying that $\boldsymbol{J} = \mathbf{curl}\, f$ for some scalar potential f (which can be chosen such that $\int_\Omega f = 0$; see, e.g., [20]). Hence the solution to (1)–(3) is nothing but $\boldsymbol{E} = \mathbf{curl}\,\psi$, where ψ satisfies

$$\begin{aligned} -\Delta\psi &= f \ \text{ in } \Omega, \\ \frac{\partial \psi}{\partial \boldsymbol{n}} &= 0 \ \text{ on } \Gamma \end{aligned}$$

since $\mathrm{curl}\,\mathbf{curl} = -\Delta$. Nevertheless, the vector formulation (1)–(3) here plays the role of a model problem whose interest lies in its simplicity rather than in its physical significance. The reader interested in the full Maxwell equations may replace operator $\mathbf{curl}\,\mathrm{curl}$ by $\mathbf{curl}\,\mathrm{curl} - k^2$ in (1) (with k^2 real or complex). Except for well-posedness results, the same method applies. From a numerical point of view, the only difference induced by this perturbation is the coupling between the regular and singular parts of the field which appears in the OSFM variant (see section 4).

The SFM is based on the fact that the solution to (1)–(3) can be found by solving an equivalent *regularized* problem involving the vector Laplace operator $\boldsymbol{\Delta}$ instead of $\mathbf{curl}\,\mathrm{curl}$ and a divergence-free boundary condition instead of the volume condition (2). For the time being, we write the regularized problem in an imprecise form:

$$-\boldsymbol{\Delta}\boldsymbol{E} = \boldsymbol{J} \ \text{ in } \Omega, \tag{5}$$

$$\mathrm{div}\,\boldsymbol{E} = 0 \ \text{ on } \Gamma, \tag{6}$$

$$\boldsymbol{E} \times \boldsymbol{n} = 0 \ \text{ on } \Gamma. \tag{7}$$

Formally, a solution to (1)–(3) satisfies (5)–(7) (since $-\boldsymbol{\Delta} = \mathbf{curl}\,\mathrm{curl} - \mathbf{grad}\,\mathrm{div}$), and, conversely, a solution to (5)–(7) is divergence-free (which shows that it satisfies (1)–(3)). Indeed, by denoting $\varphi = \mathrm{div}\,\boldsymbol{E}$, we deduce from (5) and (6) that

$$\begin{aligned} -\Delta\varphi &= 0 \ \text{ in } \Omega, \\ \varphi &= 0 \ \text{ on } \Gamma, \end{aligned}$$

which yields $\varphi \equiv 0$ provided φ is regular enough.

In order to clarify the real meaning of the equivalence between the initial and regularized problems, we have to make precise the functional framework which leads to their variational interpretations. Following the notations used in [8], we introduce the spaces

$$\begin{aligned}
\mathcal{H}_N(\mathrm{curl}) &= \left\{ \boldsymbol{E} \in L^2(\Omega)^2 \;\middle|\; \mathrm{curl}\, \boldsymbol{E} \in L^2(\Omega) \text{ and } (\boldsymbol{E} \times \boldsymbol{n})_{|\Gamma} = 0 \right\}, \\
\mathcal{H}_N(\mathrm{curl}, \mathrm{div}) &= \left\{ \boldsymbol{E} \in \mathcal{H}_N(\mathrm{curl}) \;\middle|\; \mathrm{div}\, \boldsymbol{E} \in L^2(\Omega) \right\}, \\
\mathcal{H}_N(\mathrm{curl}, \mathrm{div}\, 0) &= \left\{ \boldsymbol{E} \in \mathcal{H}_N(\mathrm{curl}) \;\middle|\; \mathrm{div}\, \boldsymbol{E} = 0 \text{ in } \Omega \right\}, \\
\mathcal{H}_N(\mathrm{grad}) &= \left\{ \boldsymbol{E} \in H^1(\Omega)^2 \;\middle|\; (\boldsymbol{E} \times \boldsymbol{n})_{|\Gamma} = 0 \right\}
\end{aligned}$$

(where the index N indicates that the fields are normal to Γ). We denote by $(\cdot\,,\cdot)$ the usual scalar product in $L^2(\Omega)^2$. Notice that the sesquilinear form

$$a(\boldsymbol{E}, \boldsymbol{E}') = (\mathrm{curl}\, \boldsymbol{E}, \mathrm{curl}\, \boldsymbol{E}') + (\mathrm{div}\, \boldsymbol{E}, \mathrm{div}\, \boldsymbol{E}')$$

is continuous and coercive in the last three spaces: for each of them, it defines actually a scalar product whose associated norm is equivalent to the graph norm. For $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$, this derives from the compactness of the embedding of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$ in $L^2(\Omega)^2$ (see, e.g., [28]). The case of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div}\, 0)$ follows since it is a closed subspace of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$. (Note that $a(\cdot\,,\cdot) = (\mathrm{curl}\,\cdot\,, \mathrm{curl}\,\cdot)$ in this case.) Finally, for $\mathcal{H}_N(\mathrm{grad})$, the result is not obvious (see Costabel [13]): $\mathcal{H}_N(\mathrm{grad})$ appears as a closed subspace of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$ with finite codimension (see section 3).

In what follows, we denote by $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$, $\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$, and $\mathcal{P}_N(\mathrm{grad})$ the following problems:

$$(\mathcal{P}_N(\cdots)) \qquad \begin{array}{l} \text{Find } \boldsymbol{E} \in \mathcal{H}_N(\cdots) \text{ such that} \\ a(\boldsymbol{E}, \boldsymbol{E}') = (\boldsymbol{J}, \boldsymbol{E}') \quad \forall \boldsymbol{E}' \in \mathcal{H}_N(\cdots) \end{array}$$

for a given $\boldsymbol{J} \in L^2(\Omega)^2$. The coerciveness of $a(\cdot\,,\cdot)$ shows that these problems are well posed. (The assumption (4) is necessary only for $\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$.) The question is to understand the role of each of them.

$\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$ is the variational interpretation of our initial problem (1)–(3): it is easy to see that a field $\boldsymbol{E} \in \mathcal{H}_N(\mathrm{curl}, \mathrm{div}\, 0)$ satisfies (1) in the sense of distributions (in $\mathcal{D}'(\Omega)^2$) if and only if it is a solution to $\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$ (see [24]).

$\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$ is actually the "good" interpretation which makes the *regularized* problem (5)–(7) equivalent to (1)–(2): its solution coincide with that to $\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$, provided $\mathrm{div}\, \boldsymbol{J} = 0$. Indeed, if $\boldsymbol{E} \in \mathcal{H}_N(\mathrm{curl}, \mathrm{div}\, 0)$ satisfies (1), then $(\mathrm{curl}\, \boldsymbol{E}, \mathrm{curl}\, \boldsymbol{E}') = (\boldsymbol{J}, \boldsymbol{E}')$ for every $\boldsymbol{E}' \in \mathcal{H}_N(\mathrm{curl})$; hence it is also a solution to $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$.

$\mathcal{P}_N(\mathrm{grad})$ is a sort of "spurious" interpretation of the regularized problem, where the boundary condition (6) has to be understood in a "weak" sense (see [8]). In general, its solution differs from that to $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$, for $\mathcal{H}_N(\mathrm{grad})$ is strictly contained in $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$.

3. Decomposition of $\boldsymbol{\mathcal{H}_N(\mathrm{curl}, \mathrm{div})}$. With regard to the numerical approximation of $\mathcal{P}_N(\mathrm{curl}, \mathrm{div}\, 0)$, the idea of solving its regularized formulation $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$ seems attractive since it involves the elliptic operator $-\boldsymbol{\Delta}$ and avoids taking into account the divergence-free condition in Ω. However, one has to be careful: a H^1-conforming finite element discretization can provide only an approximation of the "spurious" solution to $\mathcal{P}_N(\mathrm{grad})$ but not of the "physical" solution. The SFM consists of adding to $\mathcal{H}_N(\mathrm{grad})$ a complementary subspace $\mathcal{H}_{\mathrm{sing}}$ such that

$$\mathcal{H}_N(\mathrm{curl}, \mathrm{div}) = \mathcal{H}_N(\mathrm{grad}) \oplus \mathcal{H}_{\mathrm{sing}}. \tag{8}$$

In order to understand how to construct such a *singular subspace*, let us first recall some classical results about the *singularities* of the (scalar) Laplace operator in a nonconvex polygon (see Grisvard [22]). We denote by $\boldsymbol{x}_\ell$, for $\ell = 1$ to L, the vertices of the polygon Ω, numbered according to the positive orientation. At each vertex, we define local polar coordinates (r_ℓ, θ_ℓ), where $r_\ell(\boldsymbol{x}) = \|\boldsymbol{x} - \boldsymbol{x}_\ell\|$, $\theta_\ell(\boldsymbol{x}_{\ell+1}) = 0$, and $\theta_\ell(\boldsymbol{x}_{\ell-1}) = \omega_\ell > 0$. (Here we denote $\boldsymbol{x}_{L+1} = \boldsymbol{x}_1$ and $\boldsymbol{x}_0 = \boldsymbol{x}_L$.) For every ℓ, consider a regular cut-off function $\eta_\ell = \eta_\ell(r_\ell)$ such that $\eta_\ell \equiv 1$ near $\boldsymbol{x}_\ell$ and η_ℓ vanishes if $r_\ell > c_\ell$ with $0 < c_\ell < \min_{\ell' \neq \ell} \|\boldsymbol{x}_{\ell'} - \boldsymbol{x}_\ell\|$. For the reentrant corners, i.e., for ℓ such that $\omega_\ell > \pi$, let us finally introduce the *singular functions*

$$s_\ell(r_\ell, \theta_\ell) = r_\ell^{\pi/\omega_\ell} \sin\left(\frac{\pi}{\omega_\ell}\,\theta_\ell\right). \tag{9}$$

Function s_ℓ satisfies $\Delta s_\ell = 0$ in the sector $\{(r, \theta_\ell) \mid r > 0, \theta_\ell \in]0, \omega_\ell[\}$, vanishes on its boundary, and belongs to $H^1(\Omega) \setminus H^2(\Omega)$. Hence, the truncated singular function $\eta_\ell s_\ell$ belongs to $H_0^1(\Omega) \setminus H^2(\Omega)$ and satisfies $\Delta(\eta_\ell s_\ell) = 0$ in a neighborhood of the reentrant corner.

Then consider the subspace $\mathcal{S}$ of $H_0^1(\Omega)$ defined by

$$\mathcal{S} = \operatorname{span}\{\eta_\ell s_\ell \mid \omega_\ell > \pi\}. \tag{10}$$

This space, whose dimension is exactly the number of "reentrant corners,"gives us the first level of singularity of the solution $\varphi \in H_0^1(\Omega)$ of the variational equation

$$(\mathbf{grad}\,\varphi, \mathbf{grad}\,\psi) = (f, \psi) \quad \forall \psi \in H_0^1(\Omega)$$

for a given $f \in L^2(\Omega)$. Indeed, φ can be uniquely decomposed as

$$\varphi = \varphi_{\text{reg}} + \varphi_{\text{sing}}, \quad \text{where} \quad \varphi_{\text{reg}} \in H_0^1(\Omega) \cap H^2(\Omega) \text{ and } \varphi_{\text{sing}} \in \mathcal{S}.$$

The space $\mathcal{S}$ offers a first possible choice for the singular subspace $\mathcal{H}_{\text{sing}}$ in (8). Indeed, notice that $\mathbf{grad}\,\mathcal{S} \subset \mathcal{H}_N(\text{curl}, \text{div})$ since $\text{curl}\,\mathbf{grad}\,\varphi = 0$, $(\mathbf{grad}\,\varphi \times \boldsymbol{n})_{|\Gamma} = 0$ for all $\varphi \in H_0^1(\Omega)$ and $\text{div}(\mathbf{grad}(\eta_\ell s_\ell)) = \Delta(\eta_\ell s_\ell)$ is a regular function in Ω. As a consequence, we infer that

$$\mathbf{grad}\,\mathcal{S} \subset \mathcal{H}_N(\text{curl}, \text{div}) \setminus \mathcal{H}_N(\text{grad}).$$

The point is that $\mathbf{grad}\,\mathcal{S}$ describes all the possible singularities of fields in the space $\mathcal{H}_N(\text{curl}, \text{div})$, which is expressed by the following direct decomposition of type (8) (see [5] or [8] for the proof):

$$\mathcal{H}_N(\text{curl}, \text{div}) = \mathcal{H}_N(\text{grad}) \oplus \mathbf{grad}\,\mathcal{S}. \tag{11}$$

This sum is not orthogonal, but it can be used to construct an orthogonal complementary subspace of $\mathcal{H}_N(\text{grad})$. Indeed, for each ℓ such that $\omega_\ell > \pi$, the field

$$\boldsymbol{E}_\ell = \mathbf{grad}(\eta_\ell s_\ell) + \boldsymbol{G}_\ell \quad \text{with} \quad \boldsymbol{G}_\ell \in \mathcal{H}_N(\text{grad}) \tag{12}$$

is orthogonal to $\mathcal{H}_N(\text{grad})$ (for the scalar product $a(\cdot\,,\cdot)$) if and only if

$$a(\boldsymbol{G}_\ell, \boldsymbol{E}') = -(\Delta(\eta_\ell s_\ell), \text{div}\,\boldsymbol{E}') \quad \forall \boldsymbol{E}' \in \mathcal{H}_N(\text{grad}),$$

which amounts to solving $\mathcal{P}_N(\mathrm{grad})$ for $\boldsymbol{J} = \mathbf{grad}(\Delta(\eta_\ell s_\ell))$. Following the idea proposed by Moussaoui [27] for the scalar Laplace operator, another way of writing the decomposition (12) is

$$\boldsymbol{E}_\ell = \mathbf{grad}(s_\ell) + \boldsymbol{F}_\ell, \tag{13}$$

where $\boldsymbol{F}_\ell = \boldsymbol{G}_\ell + \mathbf{grad}((\eta_\ell - 1)s_\ell)$. Noticing that $\Delta s_\ell = 0$, we see that $\boldsymbol{F}_\ell$ is the solution to the following inhomogeneous variational problem (similar to $\mathcal{P}_N(\mathrm{grad})$) :

$$\begin{array}{l} \text{Find } \boldsymbol{F}_\ell \in H^1(\Omega)^2 \text{ such that} \\ a(\boldsymbol{F}_\ell, \boldsymbol{E}') = 0 \quad \forall \boldsymbol{E}' \in \mathcal{H}_N(\mathrm{grad}), \quad \text{and} \\ \boldsymbol{F}_\ell \times \boldsymbol{n} = -\,\mathbf{grad}\, s_\ell \times \boldsymbol{n} \ \text{ on } \Gamma. \end{array} \tag{14}$$

Hence the decomposition (8) becomes orthogonal if we choose

$$\mathcal{H}_{\mathrm{sing}} = \mathrm{span}\,\{\boldsymbol{E}_\ell \mid \omega_\ell > \pi\}\,. \tag{15}$$

4. Numerical implementation. We shall illustrate the numerical implementation of the SFM in the case of a simple model domain. To this end, let us consider a domain Ω which has only one reentrant corner situated at the origin $\mathbf{0}$. We thus can omit the subscript ℓ in the notation of the angle ω, the local polar coordinates (r, θ), the singular function s, and the cut-off function η introduced in the previous section. We shall indicate the complications that arise from the numerical implementation for more than one reentrant corner.

Let $\mathcal{T}_h, 0 < h \leq h_0$ be a family of regular triangulations of the domain Ω; that means that there exist two constants $c_0, c_1 > 0$ such that every triangle $T_h \in \mathcal{T}_h$ contains a circular disc with radius $c_0 h$ and is contained within another disc with radius $c_1 h$. The associated discretization space of finite elements of type P1 is given by

$$Y_h = \left\{ \boldsymbol{E}_h \in H^1(\Omega)^2 \;\middle|\; \boldsymbol{E}_{h|T_h} \text{ is affine } \forall\, T_h \in \mathcal{T}_h \right\}. \tag{16}$$

Let $\{M_I\}_{I=1,\ldots,\dim Y_h}$ be the set of nodal points of the triangulation. Then

$$V_h = \{\boldsymbol{E}_h \in Y_h \mid \text{“}(\boldsymbol{E}_h \times \boldsymbol{n})(M_I) = 0\text{”} \ \forall M_I \in \Gamma\} \tag{17}$$

is a finite dimensional subspace of $\mathcal{H}_N(\mathrm{grad})$, and we denote $(\boldsymbol{w}_I)_{I=1,\ldots,N_h}$ its basis. Note that the discrete boundary condition “$(\boldsymbol{E}_h \times \boldsymbol{n})(M_I) = 0$” is ambiguous at a vertex of the polygon: the use of the quotes means that here $\boldsymbol{E}_h(M_I) = 0$.

As mentioned in [8], the idea of the SFM consists of discretizing the regular part of the solution by means of nodal finite elements, whereas the singular part is taken into account explicitly. The question is now, Which choice of the complementary space $\mathcal{H}_{\mathrm{sing}}$ is the best? In what follows, we shall illustrate the approach for the two spaces introduced in section 3.

4.1. The SFM. The nonorthogonal decomposition (11) of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$ naturally leads to the following discretization space:

$$X_h = V_h \oplus \mathbf{grad}\,\mathcal{S}, \tag{18}$$

where $\mathcal{S} = \mathrm{span}\{\eta s\}$ with the notations introduced at the beginning of this section. The corresponding discrete problem then reads as follows:

$$\begin{array}{l} \text{Find } \boldsymbol{E}_h \in X_h \ \text{ such that} \\ a(\boldsymbol{E}_h, \boldsymbol{E}'_h) = (\boldsymbol{J}, \boldsymbol{E}'_h) \quad \forall \boldsymbol{E}'_h \in X_h. \end{array} \tag{19}$$

It is clear that X_h is of dimension N_h+1, and (19) may be written in an equivalent manner in matrix form:

$$\begin{pmatrix} A_{\mathrm{FE}} & C \\ C^T & a_s \end{pmatrix} \begin{pmatrix} E_R \\ \alpha_h \end{pmatrix} = \begin{pmatrix} J_{\mathrm{FE}} \\ j_s \end{pmatrix}, \tag{20}$$

where

- A_{FE} and J_{FE}, respectively, denote the stiffness matrix and the right-hand side corresponding to the space of finite elements, V_h,

$$A_{\mathrm{FE}} = (a(\boldsymbol{w}_J, \boldsymbol{w}_I))_{I,J=1,\dots,N_h}, \text{ and } J_{\mathrm{FE}} = ((\boldsymbol{J}, \boldsymbol{w}_I))^T_{I=1,\dots,N_h}; \tag{21}$$

- a_s and j_s denote the matrix and the right-hand side of order 1 corresponding to the singular field,

$$a_s = a(\mathbf{grad}(\eta s), \mathbf{grad}(\eta s)) \text{ and } j_s = (\boldsymbol{J}, \mathbf{grad}(\eta s)); \tag{22}$$

- C is finally a matrix of order $N_h \times 1$ coupling the basis functions of FE-type and the singular field,

$$C = (a(\mathbf{grad}(\eta s), \boldsymbol{w}_I))^T_{I=1,\dots,N_h}. \tag{23}$$

The decomposition (18) appears in the block structure of the stiffness matrix, and we may rewrite (20) in order to solve two subproblems involving only the standard FE-matrix A_{FE}. The algorithm of the SFM then consists of the following three steps:

1. Solve two linear systems

$$\begin{cases} A_{\mathrm{FE}} E_{\mathrm{FE}} = J_{\mathrm{FE}}, \\ A_{\mathrm{FE}} S = C. \end{cases} \tag{24}$$

2. Calculate the approximate singular coefficient α_h through the identity

$$\alpha_h = \frac{j_s - C^T E_{\mathrm{FE}}}{a_s - C^T S}. \tag{25}$$

3. Finally, set

$$\boldsymbol{E}_h = \sum_{I=1}^{N_h} (E_{\mathrm{FE},I} - \alpha_h S_I) \boldsymbol{w}_I + \alpha_h \, \mathbf{grad}(\eta s) \tag{26}$$

in order to obtain the approximate solution.

Remark 4.1. In the case of more than one reentrant corner, say N_s, the coefficient a_s becomes a $N_s \times N_s$ matrix A_s whose generic term is simply given by

$$(A_s)_{\ell,\ell'} = a(\mathbf{grad}(\eta_\ell s_\ell), \mathbf{grad}(\eta_{\ell'} s_{\ell'})).$$

Notice that this is a diagonal matrix since the supports of the different cut-off functions η_ℓ do not intersect. Similarly, j_s becomes a $N_s \times 1$ matrix, denoted J_s, and the coupling matrix $C = (C_1 \dots C_{N_s})$ is of order $N_h \times N_s$. The adaptation of the algorithm described above then reads as follows: in step 1, we have to solve $N_s + 1$ linear systems of order N_h involving the same *sparse* matrix A_{FE},

$$\begin{cases} A_{\mathrm{FE}} E_{\mathrm{FE}} = J_{\mathrm{FE}}, \\ A_{\mathrm{FE}} S_l = C_l, \ l \in \{1, \dots, N_s\}. \end{cases} \tag{27}$$

In step 2, the computation of the N_s singular coefficients $\alpha_{h,l}$, may be achieved by solving the linear system of order N_s,

$$(A_s - C^T S)\alpha_h = J_s - C^T E_{\mathrm{FE}}, \tag{28}$$

where $\alpha_h = (\alpha_{h,1} \dots \alpha_{h,N_s})^T$ and $S = (S_1 \dots S_{N_s}) \in \mathbb{R}^{N_h \times N_s}$. The formula corresponding to (26) is straightforward.

4.2. The OSFM. Let us notice that the SFM presented in the previous section depends on the choice of the cut-off function η. It is well known from the implementation of *singular function methods* that the use of a cut-off function may cause numerical difficulties since its derivatives take very high values. Therefore we consider here a singular subspace, $\mathcal{H}_{\mathrm{sing}}$, that does not use any cut-off function. Indeed, it has been shown in section 3 that this may be done by choosing the following orthogonal decomposition of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$:

$$\mathcal{H}_N(\mathrm{curl}, \mathrm{div}) = \mathcal{H}_N(\mathrm{grad}) \oplus \mathrm{span}\{\mathbf{grad}(s) + \boldsymbol{F}\}, \tag{29}$$

where $\boldsymbol{F}$ is the solution to the inhomogeneous problem (14).

In order to use (29) for an approximation of the solution to $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$, we thus have to discretize separately $\mathcal{H}_N(\mathrm{grad})$ and $\mathrm{span}\{\mathbf{grad}(s) + \boldsymbol{F}\}$. With regard to $\mathcal{H}_N(\mathrm{grad})$, this will be done as before by means of nodal finite elements. However, contrary to the SFM, the singular field $\mathbf{grad}(s) + \boldsymbol{F}$ is not known exactly because of the contribution of $\boldsymbol{F}$. We are thus led to introduce an approximate singular field

$$\mathbf{grad}(s) + \boldsymbol{F}_h, \tag{30}$$

where $\boldsymbol{F}_h$ is the FE-approximation of $\boldsymbol{F}$, that is, the solution to the following problem:

$$\begin{array}{l} \text{Find } \boldsymbol{F}_h \in Y_h \ \text{ such that} \\ a(\boldsymbol{F}_h, \boldsymbol{E}'_h) = 0 \quad \forall \boldsymbol{E}'_h \in V_h, \ \text{and} \\ \text{“}(\boldsymbol{F}_h \times \boldsymbol{n})(M_J) = -(\mathbf{grad}(s) \times \boldsymbol{n})(M_J)\text{”} \quad \forall M_J \in \Gamma. \end{array} \tag{31}$$

If $\widetilde{X_h}$ denotes the finite dimensional subspace of $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$ given by

$$\widetilde{X_h} = V_h \oplus \mathrm{span}\{\mathbf{grad}(s) + \boldsymbol{F}_h\}, \tag{32}$$

the discrete formulation of $\mathcal{P}_N(\mathrm{curl}, \mathrm{div})$ reads as follows:

$$\begin{array}{l} \text{Find } \widetilde{\boldsymbol{E}_h} \in \widetilde{X_h} \ \text{ such that} \\ a(\widetilde{\boldsymbol{E}_h}, \boldsymbol{E}'_h) = (\boldsymbol{J}, \boldsymbol{E}'_h) \quad \forall \boldsymbol{E}'_h \in \widetilde{X_h}, \end{array} \tag{33}$$

or, equivalently, in matrix form

$$\begin{pmatrix} A_{\mathrm{FE}} & 0 \\ 0 & \tilde{a}_s \end{pmatrix} \begin{pmatrix} E_{\mathrm{FE}} \\ \tilde{\alpha}_h \end{pmatrix} = \begin{pmatrix} J_{\mathrm{FE}} \\ \tilde{\jmath}_s \end{pmatrix}. \tag{34}$$

As before, A_{FE} and J_{FE} denote the stiffness matrix and the right-hand side of the FE-discretization, and $\tilde{a}_s$ and $\tilde{\jmath}_s$ are, respectively, given by

$$\tilde{a}_s = a(\boldsymbol{F}_h, \boldsymbol{F}_h) \ \text{ and } \tilde{\jmath}_s = (\boldsymbol{J}, \mathbf{grad}(s) + \boldsymbol{F}_h) \tag{35}$$

since $\mathbf{grad}(s)$ is curl- and divergence-free. Note as well that no coupling terms occur in (34) because of the discrete orthogonality relation

$$a(\mathbf{grad}(s) + \boldsymbol{F}_h, \boldsymbol{E}'_h) = 0 \quad \forall \boldsymbol{E}'_h \in V_h. \tag{36}$$

The algorithm of the OSFM then reads as follows:

1. Solve (31) and the linear system
$$A_{\mathrm{FE}} E_{\mathrm{FE}} = J_{\mathrm{FE}}.$$
2. Calculate the approximate singular coefficient $\tilde{\alpha}_h$ through the identity
$$\tilde{\alpha}_h = \frac{\tilde{j}_s}{\tilde{a}_s}.$$
3. Set
$$\widetilde{\boldsymbol{E}_h} = \sum_{I=1}^{N_h} E_{\mathrm{FE},I}\, \boldsymbol{w}_I + \tilde{\alpha}_h \left(\mathbf{grad}(s) + \boldsymbol{F}_h\right).$$

Remark 4.2. As for the SFM, the algorithm can be easily adapted for $N_s > 1$ reentrant corners. Step 1 will consist of solving $N_s + 1$ linear systems (one for E_{FE} and one for each problem of type (31) corresponding to each singular function s_ℓ). The determination of the N_s singular coefficients in step 2 will be achieved by solving a linear system of order N_s which involves a full matrix $\widetilde{A_s}$ describing the coupling between the N_s discrete singular fields. Finally, note that for more involved situations (such as the full Maxwell equations), the inhomogeneous problem of type (31) has to be replaced by the following problem:

$$\begin{array}{l} \text{Find } \boldsymbol{F}_{h,\ell} \in Y_h \ \text{ such that} \\ a(\boldsymbol{F}_h, \boldsymbol{E}'_h) = -a(\mathbf{grad}(s_\ell), \boldsymbol{E}'_h) \quad \forall \boldsymbol{E}'_h \in V_h, \text{ and} \\ \text{“}(\boldsymbol{F}_{h,\ell} \times \boldsymbol{n})(M_J) = -(\mathbf{grad}(s_\ell) \times \boldsymbol{n})(M_J)\text{”} \quad \forall M_J \in \Gamma, \end{array} \tag{37}$$

introducing a coupling of singular fields and basis functions of FE-type.

4.3. Computational cost. In this section we will compare the computational cost of both SFM and OSFM in the general case of the full Maxwell equations and multiple corners.

Notice that in both methods we have to solve $N_s + 1$ linear systems of order N_h involving the standard (sparse) FE-matrix and *one* linear system of order $N_s \ll N_h$ involving a full symmetric matrix. From this point of view, SFM and OSFM thus have the same complexity.

What about the computational cost and the implementation of the respective matrices and right-hand sides? Besides the standard FE-matrix A_{FE} and the right-hand side J_{FE}, which may be calculated using a standard finite element code, there are three kinds of terms:

- pure FE-terms obtained by matrix-vector or vector-vector products of order N_h (such as $C^T S$ in the SFM and $a(\boldsymbol{F}_{h,\ell}, \boldsymbol{F}_{h,\ell'}) = F_\ell^T A_{\mathrm{FE}} F_{\ell'}$ in the OSFM),
- coupling terms of order N_h which need high order quadrature rules at least near the corners, and
- singular terms which may be calculated analytically or again by means of high order quadrature rules.

Notice that coupling and singular terms in OSFM occur only for the full Maxwell equations and are reduced to L^2-scalar products (i.e., containing no derivatives of the singular fields) since the function s_ℓ is harmonic for all ℓ, and $\mathbf{grad}(s_\ell)$ is thus curl- and divergence-free in Ω.

Summing up, the number of FE-terms, singular and coupling terms is of order $\mathcal{O}(N_s)$ in SFM and of order $\mathcal{O}(N_s^2)$ for OSFM. However, the number of reentrant corners is not significant compared to the complexity of the mesh, and thus there is no real difference between the computational complexity of the two methods.

5. Error analysis. In this section, we shall investigate error estimates for the respective solutions obtained by the SFM and the OSFM based on finite elements of type P1. The generalization of the results to higher order elements is straightforward. We study the global error in the energy norm and in the L^2-norm as well as the error on the singularity coefficient. It turns out that the SFM and the OSFM are of the same order.

PROPOSITION 5.1 (energy norm estimates for the SFM). *Let $\boldsymbol{E}$ and $\boldsymbol{E}_h$ be the respective solutions of $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ and* (19)*. There exists a constant $C > 0$ such that*

$$||\boldsymbol{E}-\boldsymbol{E}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq C \inf_{\boldsymbol{E'}_h \in V_h} ||\boldsymbol{E}_{\mathrm{reg}}-\boldsymbol{E'}_h||_{1,\Omega}\,, \tag{38}$$

where $\boldsymbol{E}_{\mathrm{reg}}$ denotes the regular part of $\boldsymbol{E}$ corresponding to the decomposition (11)*. If in addition $\boldsymbol{E}_{\mathrm{reg}}$ belongs to $H^{s+1}(\Omega)^2$ with $s > 0$, there is a constant $C' > 0$ such that*

$$||\boldsymbol{E}-\boldsymbol{E}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq C'\, h^{\min(s,1)}\, ||\boldsymbol{E}_{\mathrm{reg}}||_{s+1,\Omega}\,. \tag{39}$$

Remark 5.2. Estimate (38) implies that the SFM will converge but does not give any convergence order. Nevertheless, the regular part $\boldsymbol{E}_{\mathrm{reg}}$ of the solution to $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ always belongs to $H^{s+1}(\Omega)^2$ for all $s < \frac{2\pi}{\omega} - 1$ (see [15] and Lemma 5.5). Hence, (39) implies that the SFM is at least of order $\frac{2\pi}{\omega} - 1 - \varepsilon$ (with $\varepsilon > 0$ arbitrarily small).

Proof of Proposition 5.1. Since the bilinear form $a(\cdot,\cdot)$ is continuous and coercive on $\mathcal{H}_N(\mathrm{curl},\mathrm{div})$, Cea's lemma implies

$$||\boldsymbol{E}-\boldsymbol{E}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq C \inf_{\boldsymbol{E}'_h \in X_h} ||\boldsymbol{E}-\boldsymbol{E}'_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}\,, \tag{40}$$

where $C > 0$ depends only on the continuity and coercivity constants of $a(\cdot,\cdot)$. Decomposition (11) implies that there is $\boldsymbol{E}_{\mathrm{reg}} \in \mathcal{H}_N(\mathrm{grad})$ and $\alpha \in \mathbb{R}$ such that

$$\boldsymbol{E} = \boldsymbol{E}_{\mathrm{reg}} + \alpha\, \mathbf{grad}(\eta s).$$

Now note that for any field $\boldsymbol{G}_h$ belonging to the FE-space V_h the field

$$\boldsymbol{E'}_h = \boldsymbol{G}_h + \alpha\, \mathbf{grad}(\eta s)$$

belongs to X_h, and hence

$$\inf_{\boldsymbol{E}'_h \in X_h} ||\boldsymbol{E}-\boldsymbol{E}'_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq \inf_{\boldsymbol{G}_h \in V_h} ||\boldsymbol{E}_{\mathrm{reg}}-\boldsymbol{G}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}\,,$$

and we obtain (38) since, on $\mathcal{H}_N(\mathrm{grad})$, the norms $||\cdot||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}$ and $||\cdot||_{1,\Omega}$ are equivalent.

If, in addition, the regular part $\boldsymbol{E}_{\mathrm{reg}}$ of the solution belongs to $H^{s+1}(\Omega)^2$ with $s > 0$, the standard error analysis of the FE-method yields (39) (see [10, 21]). ∎

Remark 5.3. Note that the error on the singular coefficient of the SFM is governed by the same term as the global error, that is, the interpolation error of the finite element method. Indeed, the decomposition of $\mathcal{H}_N(\mathrm{curl},\mathrm{div})$ into the *direct* sum of $\mathcal{H}_N(\mathrm{grad})$ and $\mathcal{H}_{\mathrm{sing}}$ yields

$$|\alpha - \alpha_h| \leq C\, ||\boldsymbol{E}-\boldsymbol{E}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}$$

and thus estimates similar to (38) and (39) for the error on the singular coefficient. Hence, there is a fundamental difference compared to *singular function methods* known to *improve* the convergence order of a nodal finite element method: these methods are of order 1 (for finite elements of type P1) with regard to the global error in the energy norm but of order less than 1 (depending on the angle of the reentrant corner) with regard to the convergence of the singular coefficient (see, e.g., [7]). In our context the fact that $\mathcal{H}_N(\mathrm{grad})$ is a *closed* subspace of $\mathcal{H}_N(\mathrm{curl},\mathrm{div})$ forbids any nodal discretization to approach the singular fields. In other words, the "angle" between $\mathbf{grad}\,\mathcal{S}$ and V_h (see (18)) cannot shrink to zero.

The next proposition gives error estimates in the L^2-norm.

PROPOSITION 5.4 (L^2-estimates for the SFM). *Let $\boldsymbol{E}$ and $\boldsymbol{E}_h$ be the respective solutions of $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ and (19), and let $\boldsymbol{E}_{\mathrm{reg}}$ denote the regular part of $\boldsymbol{E}$ corresponding to the decomposition (11). Assume that $\boldsymbol{E}_{\mathrm{reg}}$ belongs to $H^{s+1}(\Omega)^2$, where $s>0$. There is a constant $C>0$ such that*

$$||\boldsymbol{E}-\boldsymbol{E}_h||_{0,\Omega} \le C\,h^{\lambda}\,||\boldsymbol{E}_{\mathrm{reg}}||_{s+1,\Omega} \quad \forall \lambda < \min(s,1)+\frac{2\pi}{\omega}-1. \tag{41}$$

Proof. In order to get the L^2-error estimates for the SFM, we apply the Aubin–Nitsche trick which yields

$$\begin{aligned}&||\boldsymbol{E}-\boldsymbol{E}_h||_{0,\Omega}\\ &\le C\,||\boldsymbol{E}-\boldsymbol{E}_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}\left(\sup_{\boldsymbol{K}\in L^2(\Omega)^2}\left\{\frac{1}{||\boldsymbol{K}||_{0,\Omega}}\inf_{\boldsymbol{E}'_h\in X_h}||\boldsymbol{E}_K-\boldsymbol{E}'_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})}\right\}\right),\end{aligned}$$

where $\boldsymbol{E}_K\in\mathcal{H}_N(\mathrm{curl},\mathrm{div})$ denotes the unique solution to $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ corresponding to a datum $\boldsymbol{K}$ in $L^2(\Omega)^2$. According to Proposition 5.1, the first factor in the preceding inequality can be bounded by

$$C\,h^{\min(s,1)}\,||\boldsymbol{E}_{\mathrm{reg}}||_{s+1,\Omega}.$$

In order to get an estimate for the second factor, we consider the regular part of $\boldsymbol{E}_K$ which belongs to $H^{t+1}(\Omega)^2$ for all $t<\frac{2\pi}{\omega}-1$ (see [15] and Lemma 5.5 below). We thus infer once more from Proposition 5.1 that

$$\inf_{\boldsymbol{E}'_h\in X_h}||\boldsymbol{E}_K-\boldsymbol{E}'_h||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \le C\,h^t\,||\boldsymbol{E}_{K,\mathrm{reg}}||_{t+1,\Omega} \quad \forall t<\frac{2\pi}{\omega}-1.$$

Now notice that $||\boldsymbol{E}_{K,\mathrm{reg}}||_{t+1,\Omega}\le C\,||\boldsymbol{K}||_{0,\Omega}$ according to the a priori inequality (42) of Lemma 5.5. This completes the proof. ∎

For the sake of completeness, we now prove the a priori estimate that was used in the proof of Proposition 5.4.

LEMMA 5.5. *Let $\boldsymbol{E}$ be the solution to $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ with a right-hand side $\boldsymbol{J}$ in $L^2(\Omega)^2$. Let $\boldsymbol{E}_{\mathrm{reg}}$ denote the regular part of $\boldsymbol{E}$ according to decomposition (11). Then $\boldsymbol{E}_{\mathrm{reg}}\in H^{t+1}(\Omega)^2$ for all $t<\frac{2\pi}{\omega}-1$, and there exists a constant $C>0$ such that the following a priori estimate holds:*

$$||\boldsymbol{E}_{\mathrm{reg}}||_{t+1,\Omega}\le C\,||\boldsymbol{J}||_{0,\Omega}. \tag{42}$$

Proof. According to (11) we get the following decomposition of $\boldsymbol{E}$:

$$\boldsymbol{E}=\boldsymbol{E}_{\mathrm{reg}}+\alpha\,\mathbf{grad}(\eta s).$$

The regularity result has been proven in [15]. The definition of $\mathcal{P}_N(\mathrm{curl},\mathrm{div})$ implies

$$a(\boldsymbol{E}_{\mathrm{reg}},\boldsymbol{E}') = (\boldsymbol{J},\boldsymbol{E}') - \alpha(\Delta(\eta s),\mathrm{div}\,\boldsymbol{E}') \quad \forall \boldsymbol{E}' \in \mathcal{H}_N(\mathrm{grad}). \tag{43}$$

$\boldsymbol{E}_{\mathrm{reg}}$ thus coincides with the solution to $\mathcal{P}_N(\mathrm{grad})$ corresponding to the datum $\widetilde{\boldsymbol{J}} = \boldsymbol{J} + \alpha\,\mathbf{grad}(\Delta(\eta s))$. (Note that no boundary terms occur in the integration by parts of the right-hand side of (43) since $\Delta(\eta s) \in H_0^1(\Omega)$.) We infer that

$$||\boldsymbol{E}_{\mathrm{reg}}||_{t+1,\Omega} \leq C_1(||\boldsymbol{J}||_{0,\Omega} + |\alpha|\,||\Delta(\eta s)||_{1,\Omega}) \tag{44}$$

from the *closed graph theorem*. Indeed, consider the linear operator $\mathbb{T} : L^2(\Omega)^2 \to H^s(\Omega)^2$ defined by $\mathbb{T}\boldsymbol{J} = \boldsymbol{E}$, where $\boldsymbol{E} \in \mathcal{H}_N(\mathrm{grad})$ is the unique solution to $\mathcal{P}_N(\mathrm{grad})$ with right-hand side $\boldsymbol{J}$. Inequality (44) is nothing but the continuity of $\mathbb{T}$ whose graph is a closed subset of $L^2(\Omega)^2 \times H^s(\Omega)^2$.

As in Remark 5.3, we have

$$|\alpha| \leq C_2\,||\boldsymbol{E}||_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq C_3\,||\boldsymbol{J}||_{0,\Omega}$$

and (42) follows with $C = C_1(1 + C_3\,||\Delta(\eta s)||_{1,\Omega})$. ∎

Remark 5.6. The weak point of the SFM is hidden among the above estimates. It is actually related to the cut-off function η involved in the definition of the singular field $\mathbf{grad}(\eta s)$. Such a function introduces artificially high variations of the regular part $\boldsymbol{E}_{\mathrm{reg}}$ in the region where η varies from 0 to 1. Inequality (44) yields a quantified representation of this effect: the right-hand side depends on the H^1-norm of $\Delta(\eta s)$ which involves the third derivatives of the cut-off function η. Hence the constant in the estimate (42) may have a very high value. We shall come back to this problem in the next section.

The error analysis for the OSFM is very similar to the one for the SFM, the main difference lying in an appropriate definition of the interpolation error.

For a given real parameter α let us introduce the space $Y_{h,\alpha}$ of those fields $\boldsymbol{G}_h$ of Y_h which satisfy the inhomogeneous boundary condition "$(\boldsymbol{G}_h \times \boldsymbol{n})(M_I) = -\alpha(\mathbf{grad}(s) \times \boldsymbol{n})(M_I)$" for all $M_I \in \Gamma$. Note that $Y_{h,\alpha}$ is an affine subspace of Y_h of the form $\alpha\boldsymbol{R} + V_h$, where $\boldsymbol{R}$ is some fixed FE-element lifting of the tangential trace of $-\mathbf{grad}(s)$.

One gets the analogous error estimates when substituting $\boldsymbol{E}_{\mathrm{reg}}$ by $\widetilde{\boldsymbol{E}_{\mathrm{reg}}} + \alpha\boldsymbol{F}$, where $\widetilde{\boldsymbol{E}_{\mathrm{reg}}}$ and α denote, respectively, the regular part and the singular coefficient of $\boldsymbol{E}$ corresponding to the decomposition (29) and $\boldsymbol{F}$ is the solution in $H^1(\Omega)^2$ to (14).

PROPOSITION 5.7 (energy norm estimates for the OSFM). *Let $\widetilde{\boldsymbol{E}_h}$ denote the solution of* (31). *There exists a constant $C > 0$ such that*

$$\left|\left|\boldsymbol{E} - \widetilde{\boldsymbol{E}_h}\right|\right|_{\mathcal{H}_N(\mathrm{curl},\mathrm{div})} \leq C \inf_{\boldsymbol{E}'_h \in Y_{h,\alpha}} \left|\left|(\widetilde{\boldsymbol{E}_{\mathrm{reg}}} + \alpha\boldsymbol{F}) - \boldsymbol{E}'_h\right|\right|_{1,\Omega} \tag{45}$$

with the notations introduced just before.

Proof. We use the following characterization of $\widetilde{X_h}$:

$$\begin{aligned} &\boldsymbol{E}_h \in \widetilde{X_h} \text{ if and only if } \exists \boldsymbol{G}_h \in Y_h \text{ and } \alpha \in \mathbb{R} \text{ such that} \\ &\boldsymbol{E}_h = \boldsymbol{G}_h + \alpha\,\mathbf{grad}(s), \text{ and} \\ &\text{“}(\boldsymbol{G}_h \times \boldsymbol{n})(M_I) = -\alpha(\mathbf{grad}(s) \times \boldsymbol{n})(M_I)\text{”} \quad \forall M_I \in \Gamma. \end{aligned} \tag{46}$$

It may be easily seen that (32) and (46) indeed define the same space.

As for the SFM, Cea's lemma leads us to look for an estimation of the interpolation error on $\widetilde{X_h}$. With a given field $\boldsymbol{G}_h$ belonging to $Y_{h,\alpha}$ we associate the field $\boldsymbol{E}'_h =$

$\boldsymbol{G}_h + \alpha\,\mathbf{grad}(s)$, where α is the singular coefficient of $\boldsymbol{E}$. $\boldsymbol{E}'_h$ clearly belongs to $\widetilde{X_h}$ and (45) follows as before. ∎

The estimates corresponding to (39) and (41) follow in the same way.

Remark 5.8. It may easily be seen that the fields $\boldsymbol{E}_{\rm reg}$ and $\widetilde{\boldsymbol{E}_{\rm reg}} + \alpha\boldsymbol{F}$ (corresponding to decompositions (11) and (29), respectively) have the same regularity: they differ by the field $\alpha\,\mathbf{grad}((1-\eta)s)$ which is of class $\mathcal{C}^\infty$. The convergence order of both methods is thus apparently the same.

Remark 5.9. The generalization of the previous error analysis to the case of multiple corners is straightforward. Indeed, the energy norm estimates (38) and (39) keep unchanged. Notice that the minimal regularity of the regular part is now H^{s+1} with

$$s < \min_{1\le\ell\le N_s} \frac{2\pi}{\omega_\ell}.$$

Consequently, the convergence rate of the error in the L^2-norm is $\mathcal{O}(h^\lambda)$ with $\lambda < \min(s,1) + \min_l \frac{2\pi}{\omega_\ell} - 1$.

6. Numerical results. In this section, we present numerical tests of the SFM and the OSFM for several examples where the exact solutions are known. The model domain is formed by the three quarters of a disc with center $\mathbf{0}$ and radius 2; the only reentrant corner is thus of measure $3\pi/2$. Such a "camembert-like"domain is polygonal near the reentrant corner and convex in the neighborhood of any other irregular point of the boundary. The results obtained in the previous sections thus carry over to this curvilinear polygon.

Notice that both methods have been implemented in the case of one reentrant corner only, but the generalization to several corners is straightforward and has been described in section 4 (Remarks 4.1 and 4.2). The additional complexity has been investigated in section 4.3.

We consider two classes of exact solution fields which are defined with the help of the respective eigenfunctions of the Laplace–Beltrami operator on $]0,\omega[$ with Dirichlet and Neumann boundary conditions:

$$\boldsymbol{G}_n(r,\theta) = \mathbf{grad}(\eta(r) r^{na} \sin(na\theta)) \tag{47}$$

and

$$\boldsymbol{H}_n(r,\theta) = \mathbf{curl}(\eta(r) r^{na} \cos(na\theta)), \quad \text{where } a = \pi/\omega = 2/3 \text{ and } n \in \mathbb{N}. \tag{48}$$

Note that

$$\boldsymbol{H}_n = -\boldsymbol{G}_n + \text{regular field},$$

where the regular field vanishes near the corners. The regularity of the fields $\boldsymbol{H}_n$ and $\boldsymbol{G}_n$ depends on n:

$$\boldsymbol{G}_n, \boldsymbol{H}_n \in H^s(\Omega)^2 \quad \forall s < na.$$

In particular, $\boldsymbol{G}_n$ and $\boldsymbol{H}_n$ belong to $\mathcal{H}_N(\mathrm{grad})$ for $n > 1$, whereas $\boldsymbol{G}_1$ and $\boldsymbol{H}_1$ are singular fields in the sense that they have a nonzero component in $\mathcal{H}_{\rm sing}$. ($\boldsymbol{G}_1$ does indeed coincide with the singular field that spans $\mathcal{H}_{\rm sing}$ in the case of the SFM.)

The "numerical proof" that the FE-method fails for singular fields appears clearly in Figure 6.1. We represent the x-component of the FE-element approximation of $\boldsymbol{G}_1$

on a mesh with $h = 2^{-4}$ and compare it to the analogous approximation obtained by the SFM (Figure 6.2). It turns out that nodal finite elements are not at all able to reproduce the singular behavior at the reentrant corner. Indeed, the condition $(\boldsymbol{E}_h \times \boldsymbol{n}) = 0$ on the boundary nodes forces the FE-approximation to vanish at $\mathbf{0}$, whereas the exact solution tends to ∞ at the corner. Thus, we do not have to deal with an accuracy problem but, as it has been mentioned in section 3, with the choice of the appropriate functional frame: the FE-approximation converges to the solution to $\mathcal{P}_N(\mathrm{grad})$.

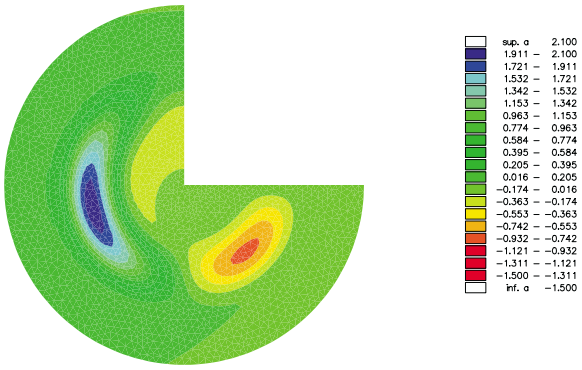

FIG. 6.1. *FE-approximation of* $\boldsymbol{G}_1$.

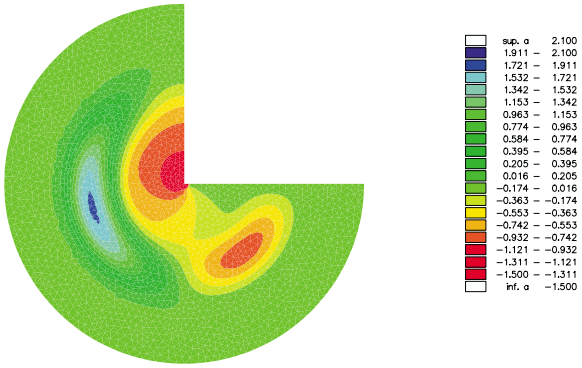

FIG. 6.2. *SFM-approximation of* $\boldsymbol{G}_1$.

Both the SFM and the OSFM have been tested on unstructured triangulations $\mathcal{T}_h$ *without mesh refinement* near the corner. (See Figure 6.3 for an example.) We use Lagrange finite elements of type P1. Notice that in this case the error induced by the approximation of the curvilinear domain Ω by a polygon does not affect the convergence rate of the method.

The mesh parameter $h = \sup_{T_l \in \mathcal{T}_h} \operatorname{diam} T_l$ varies from $h = 2^{-2}$ to $h = 2^{-6}$, the latter corresponding to roughly 2×31900 degrees of freedom.

The cut-off function η is a piecewise polynomial function of class $\mathcal{C}^3$: $\eta \equiv 1$ for $0 \le r < 0.5$, $\eta = p_\eta$ for $0.5 \le r < 1.5$ with a polynomial p_η of degree 7, and $\eta \equiv 0$ for

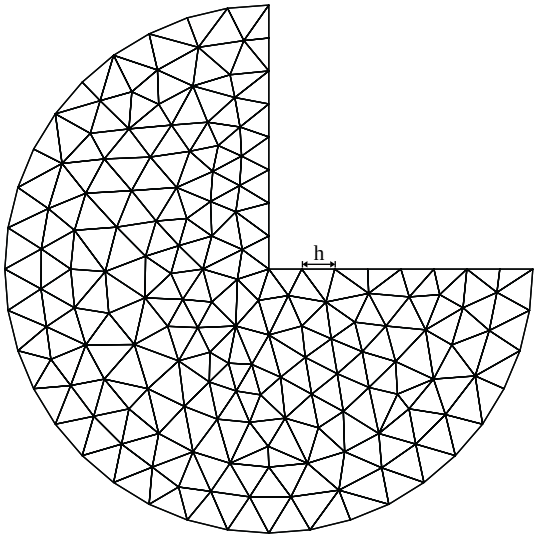

FIG. 6.3. *The coarse mesh* ($h = 1/4$).

$1.5 \leq r \leq 2$. The coefficients of the coupling term C are computed using a 7-point-quadrature formula which is exact for polynomials up to order 5. The coefficients a_s and j_s are calculated analytically.

The implementation of the boundary condition is realized via a rotation which maps the canonical basis on a local basis of the normal and tangential vectors; in the latter basis the vector boundary condition becomes decoupled and standard techniques apply. In order to implement the inhomogeneous boundary condition in the algorithm of the OSFM (see (31)), we use a FE-lifting $\boldsymbol{R}$ of the tangential trace of $-\mathbf{grad}(s)$ on Γ. Again, the only difficulty comes from the coupling of the two degrees of freedom at each boundary node and we proceed in the same way as in the homogeneous case.

The linear systems occurring in the algorithms are solved by a direct method based on Cholesky factorization. All tests have been realized with the FE-code MELINA.[1]

We represent the error on the exact solution in logarithmic scale for a discrete L^2-norm which is given by

$$||\boldsymbol{E} - \boldsymbol{E}_h||_h = \left(\frac{1}{N_h} \sum_{I \in \overset{\circ}{\Omega}} |\boldsymbol{E}(M_I) - \boldsymbol{E}_h(M_I)|^2 \right)^{1/2} . \tag{49}$$

We could have chosen instead a discrete energy norm, which may appear more relevant from a physical point of view. Our aim, however, is simply to compare the numerical results with the theoretical predictions, in spite of their poor practical interest.

Figures 6.4–6.7 show the convergence rates of the SFM and the OSFM for the fields $\boldsymbol{G}_n$ and $\boldsymbol{H}_n$ with $n = 2$ and $n = 5$. This illustrates the L^2-error estimate of Proposition 5.4. For $n = 2$, the numerical values are in good concordance with the theory which yields an order of 2/3. The influence of the reentrant corner may be seen even if the exact solution belongs to H^2 (cf. the tests for $\boldsymbol{G}_5$ and $\boldsymbol{H}_5$): the observed

[1] Developed by D. Martin (IRMAR, University of Rennes 1, and ENSTA/SMP, Paris, France) [26].

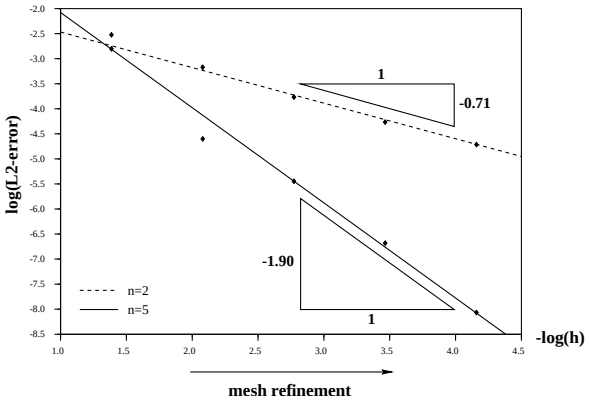

FIG. 6.4. *The SFM for* $\boldsymbol{G}_n$, $n = 2, n = 5$.

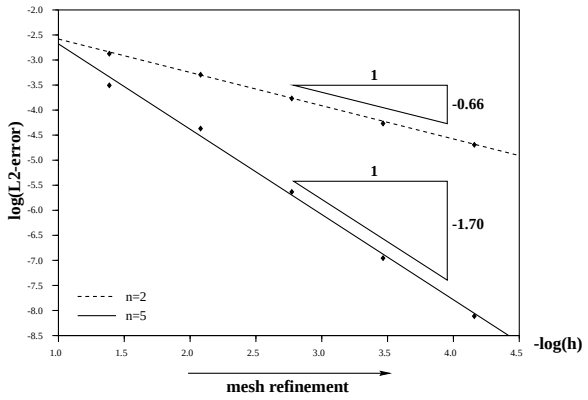

FIG. 6.5. *The SFM for* $\boldsymbol{H}_n$, $n = 2, n = 5$.

convergence rates still keep below the "optimal" rate $\mathcal{O}(h^2)$ for finite elements of type P1 in regular domains. It turns out, however, that the numerical values for $n = 5$ are higher than the order given by Proposition 5.4, $\mathcal{O}(h^{4/3})$.

Next, we represent the approximation of the singular fields $\boldsymbol{G}_1$ and $\boldsymbol{H}_1$. Figure 6.8 shows once again that a nodal finite element method does fail: the relative error on the approximation of $\boldsymbol{G}_1$ is of 52% for the finest mesh (and there is no reason to believe in a convergence as poor as it may be ...), compared to 0.1% for the OSFM. The points representing the error of the finite element method seem to have a horizontal asymptote (corresponding to the "gap" between $\mathcal{H}_N(\mathrm{grad})$ and $\mathcal{H}_N(\mathrm{curl}, \mathrm{div})$).

At last, Figure 6.9 compares the SFM- and the OSFM-approximation of $\boldsymbol{H}_1$, and it is obvious that the OSFM yields much better results. As mentioned in Remark 5.6, this is due to the cut-off function η. Indeed, the performance of the SFM depends on the implementation of the singular field involving the cut-off function and its derivatives. The strong variations of the latter lead to high values of the constant in the error estimations and hence to poor accuracy: in the case of the two coarsest grids we cannot even speak of an approximation since the relative errors are too high (about 70% for $h = 1/8$ compared to 1% for the OSFM) and even the finest mesh still yields an error of 7%. This means that much more mesh refinement has to be done when using the SFM in order to get results comparable with those of the OSFM.

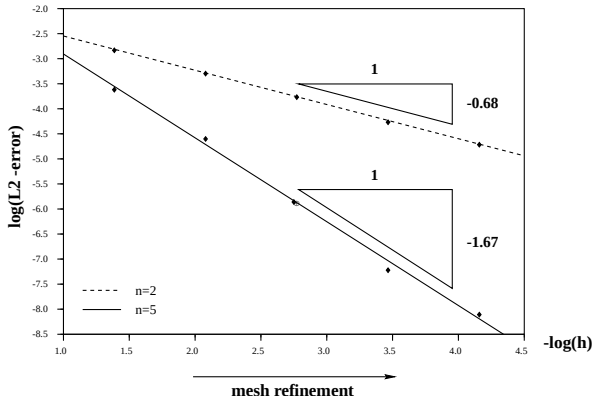

FIG. 6.6. *The OSFM for* $\boldsymbol{G}_n$, $n = 2, n = 5$.

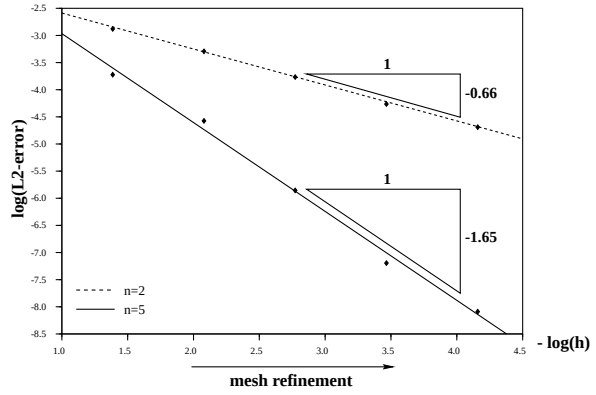

FIG. 6.7. *The OSFM for* $\boldsymbol{H}_n$, $n = 2, n = 5$.

Nevertheless, the numerical results confirm the theoretical order of convergence for the SFM: taking into account the finest three meshes only, the observed convergence rate is $\mathcal{O}(h^{1.24})$ compared to $\mathcal{O}(h^{4/3})$. For the OSFM, a "superconvergence" is observed. We were not able to find a theoretical justification of this phenomena. Maybe it is due to some particular symmetry of the exact solution. Notice as well that we omitted the error of the OSFM for $h = 1/64$ since it is slightly higher than the one for $h = 1/32$. This is probably due to the influence of rounding errors since the FE-solver is implemented with simple precision only.

One question may arise in comparing the SFM and the OSFM: why do accuracy problems occur only for the field $\boldsymbol{H}_1$? To understand this, consider the fields $\boldsymbol{G}_n$ and $\boldsymbol{H}_n$ for $n > 1$. The FE-method will converge since the fields belong to $\mathcal{H}_N(\mathrm{grad})$. It seems plausible that the convergence in the variable θ is much better than in r due to the influence of the cut-off function which does not depend on θ. If we further assume that the FE-method keeps approximately the separation in variables of the exact solution, that is,

$$\boldsymbol{G}_{n,\mathrm{FE}} \approx \mathbf{grad}(u_n(r)\sin(na\theta)) \quad \forall n > 1,$$
$$\boldsymbol{H}_{n,\mathrm{FE}} \approx \mathbf{curl}(v_n(r)\cos(na\theta)) \quad \forall n > 1,$$

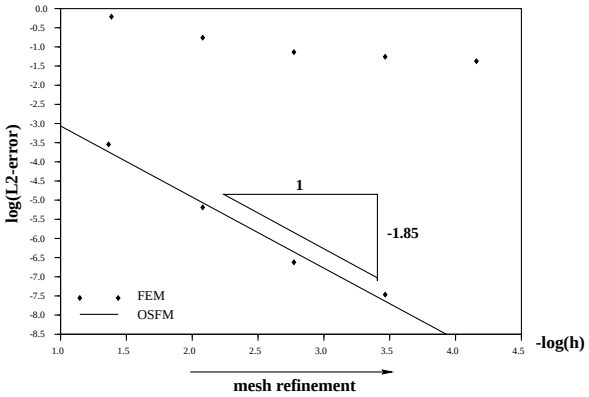

FIG. 6.8. *FEM/OSFM for* $\boldsymbol{G}_1$.

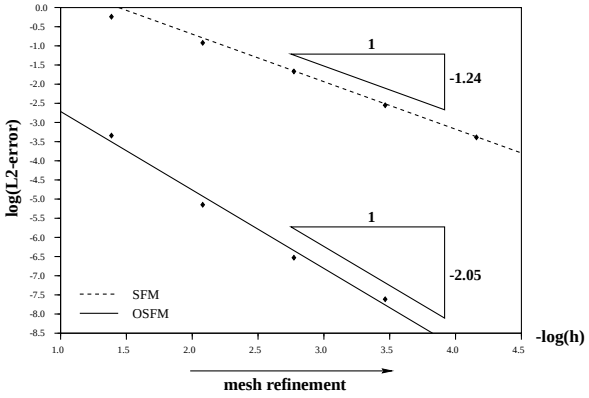

FIG. 6.9. *SFM/OSFM for* $\boldsymbol{H}_1$.

we get

$$(\boldsymbol{G}_{n,\mathrm{FE}}, \mathbf{grad}(\eta s)) \approx \int_\Omega u_n(r)\sin(na\theta)w(r)\sin(a\theta)\, r\, dr d\theta = 0 \tag{50}$$

and

$$a(\boldsymbol{G}_{n,\mathrm{FE}}, \mathbf{grad}(\eta s)) \approx 0, \tag{51}$$

since $\sin(na\theta)$ and $\sin(a\theta)$ are orthogonal on $(0,\omega)$, and the corresponding terms for $\boldsymbol{H}_{n,\mathrm{FE}}$ vanish as well. Now, if we introduce these identities into (25) (note that $C^T E_{\mathrm{FE}}$ is nothing but the left-hand side of (51)) and take into account that $j_s = 0$, we get a good approximation of the singular coefficient $\alpha = 0$, in spite of an eventual pollution effect due to the cut-off function.

On the other hand, consider the field $\boldsymbol{H}_1$. The corresponding FE-solution $\boldsymbol{H}_{1,\mathrm{FE}}$ yields an approximation of the solution to the "spurious" problem $\mathcal{P}_N(\mathrm{grad})$ which is different from $\boldsymbol{H}_1$. In particular, there is no reason to get the "quasi orthogonality"of (50) and (51). The computation of the singular coefficient α_h thus involves the coupling terms $C^T E_{\mathrm{FE}}$ and $C^T S$, and the above-mentioned difficulties due to the cut-off function appear. Unfortunately, this is the general situation, the "superconvergence"observed for $\boldsymbol{G}_n$ and $\boldsymbol{H}_n (n > 1)$ being a lucky exception.

7. Conclusion. We proposed two variants, SFM and OSFM, of a *singular field method* in order to solve Maxwell equations in two-dimensional regions with corners. Both methods were implemented for a simple model problem on a curvilinear polygon with one reentrant corner. The SFM is based on singular fields *localized* to a neighborhood of the corners, whereas its orthogonal variant, OSFM, makes use of approximate singular fields which are *orthogonal* (for an appropriate scalar product) to the discretization space of standard finite elements. With regard to computational complexity, the methods are equivalent, and the error analysis suggests that they are of the same order. In practice, however, the OSFM yields better results, the principal difficulty of the SFM being the implementation of the cut-off function.

Notice that for more involved situations as the one of the model problem studied in this paper, coupling and singular terms occur in the OSFM which have to be calculated on the whole domain. This increases slightly the computational cost of the method. However, the singular fields are regular away from the corners. Hence, special attention has to be paid only near the geometric singularities. If the domain does contain large regions where the boundary is regular, a hybrid method, similar to domain decomposition techniques, may apply which uses the OSFM only near the corners and a standard FE-method (without singular fields) anywhere else.

To finish, let us have a glance at the three-dimensional situation. Whereas the theory is now well understood (see, for example, [8, 14, 15]), the implementation of the method is less simple. This is essentially due to the infinite dimension of the singular subspace. Roughly speaking, the singular coefficient corresponding to the reentrant edge of a polyhedron is now a function belonging to some weighted Sobolev space, and its discretization is far from being obvious. However, some results have been obtained recently in the particular case of an axisymmetric conical point [19]: in this case the space of singular fields is still of finite dimension.

Acknowledgment. The authors would like to thank the anonymous referees for many valuable comments and suggestions.

STRONG CONVERGENCE OF EULER-TYPE METHODS FOR NONLINEAR STOCHASTIC DIFFERENTIAL EQUATIONS*

DESMOND J. HIGHAM†, XUERONG MAO‡, AND ANDREW M. STUART§

Abstract. Traditional finite-time convergence theory for numerical methods applied to stochastic differential equations (SDEs) requires a global Lipschitz assumption on the drift and diffusion coefficients. In practice, many important SDE models satisfy only a local Lipschitz property and, since Brownian paths can make arbitrarily large excursions, the global Lipschitz-based theory is not directly relevant. In this work we prove strong convergence results under less restrictive conditions. First, we give a convergence result for Euler–Maruyama requiring only that the SDE is locally Lipschitz and that the pth moments of the exact and numerical solution are bounded for some $p > 2$. As an application of this general theory we show that an implicit variant of Euler–Maruyama converges if the diffusion coefficient is globally Lipschitz, but the drift coefficient satisfies only a one-sided Lipschitz condition; this is achieved by showing that the implicit method has bounded moments and may be viewed as an Euler–Maruyama approximation to a perturbed SDE of the same form. Second, we show that the optimal *rate* of convergence can be recovered if the drift coefficient is also assumed to behave like a polynomial.

Key words. backward Euler, Euler–Maruyama, finite-time convergence, implicit, moment bounds, nonlinearity, one-sided Lipschitz condition, split-step

1. Introduction.

In this paper we study the numerical solution of the stochastic differential equation (SDE)

$$dy(t) = f(y(t))dt + g(y(t))dW(t), \quad 0 \le t \le T, \quad y(0) = y_0. \tag{1.1}$$

Here $y(t) \in \mathbb{R}^m$ for each t, and $W(t)$ is a d-dimensional Brownian motion. Thus $f : \mathbb{R}^m \to \mathbb{R}^m$ and $g : \mathbb{R}^m \to \mathbb{R}^{m\times d}$. We assume that the initial condition is chosen independently of the Wiener measure driving the equation and that all pth moments of y_0, $p > 0$, are finite. Our primary objective is to study strong convergence questions for numerical approximations in the case where f and g are not necessarily globally Lipschitz functions. Most of the existing convergence theory for numerical methods requires f and g to be globally Lipschitz; see [12, 14], for example. Recent work has studied convergence in probability [6, 8] and almost sure convergence [7], under more relaxed conditions on f and g. We focus here on strong mean square convergence, in the sense of [12, Theorem 10.6.3], which implies convergence in probability. The main result of [11] is directly related to our work; we summarize the connections at the end of this section. We also note that the work of Schurz [16] contains a number

of a priori bounds on the numerical solutions of SDEs from a nonlinear stability perspective, under structural assumptions similar to those we employ here.

In section 2, we prove that the Euler–Maruyama method converges strongly if f and g are locally Lipschitz (e.g., for $f, g \in C^1$) and the exact and numerical solution have a bounded pth moment for some $p > 2$ (Theorem 2.2). The bounded moment assumption will not, of course, hold, in general, as solutions to the SDE may explode in a finite time. In section 3 we therefore impose further assumptions on f and g to ensure that $y(t)$ has bounded moments: we assume that g is globally Lipschitz and that f satisfies a one-sided Lipschitz condition. The one-sided Lipschitz condition has proved effective in the analysis of numerical methods for deterministic problems and occurs naturally in a variety of applications [1, 3, 4, 5, 17]. For a suitably constructed "split-step" implicit variant of Euler–Maruyama we establish strong convergence (Theorem 3.3) by (a) showing that the method corresponds to Euler–Maruyama on a perturbed SDE and (b) showing that all moments of the numerical solution are bounded. We are unable to establish moment bounds for the forward Euler method and, indeed, it may not be possible to do so; the work of [7] is of importance for nonimplicit methods since, being an almost sure convergence study, it does not require moment bounds.

In section 4 we turn our attention to establishing an optimal *rate* of convergence for the split-step implicit method. We show that if f satisfies a one-sided Lipschitz condition and behaves polynomially, then Euler–Maruyama converges strongly at the optimal rate (Theorem 4.4), provided moment bounds hold. We use this to study the split-step implicit method, for which moment bounds can be found (Theorem 4.7), again by showing that the method corresponds to Euler–Maruyama on a perturbed SDE. In section 5 this result is extended to a more widely used implicit variant of Euler–Maruyama by relating the two implicit methods (Theorem 5.3). A summary is given in section 6.

It is worth mentioning at this point how our work compares with that of Hu [11]. Theorem 2.4 of [11] is a very important contribution to numerical SDE theory, being, to our knowledge, the first strong convergence result without global Lipschitz assumptions. Hu considered only the backward Euler method and derived a result with the optimal rate of convergence, and hence his work may be compared with Theorem 5.3 below. Both results assume C^1 coefficients in the SDE, a one-sided Lipschitz condition for the drift, and a global Lipschitz condition for the diffusion. Theorem 5.3 below imposes polynomial-type growth on the drift (Assumption 4.1), whereas Hu allows for a more general exponential growth. On the other hand, Theorem 5.3 and all the other results in our work deal with a very strong error measure, $\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Z}(t)-y(t)|^2\right]$, whereas [11] uses the less stringent measure $\int_0^T \mathbb{E}|\overline{Z}(t)-y(t)|^2\,dt$. We also note that [11] uses a different continuous-time extension. Overall, Hu's result for backward Euler applies to a wider class of SDEs but controls a weaker measure of the error. The techniques of analysis are significantly different, although both hinge on establishing moment bounds for the exact and numerical solutions.

2. General result for Euler–Maruyama. Given a stepsize $\Delta t > 0$, the Euler–Maruyama (EM) method applied to (1.1) computes approximations $X_k \approx y(t_k)$, where $t_k = k\Delta t$, by setting $X_0 = y_0$ and forming

$$X_{k+1} = X_k + \Delta t f(X_k) + g(X_k)\Delta W_k, \tag{2.1}$$

where $\Delta W_k = W(t_{k+1}) - W(t_k)$. We find it convenient to use continuous-time approximations, and hence we define $\overline{X}(t)$ by

$$\overline{X}(t) := X_k + (t - t_k)f(X_k) + g(X_k)(W(t) - W(t_k)) \quad \text{for } t \in [t_k, t_{k+1}).$$

In our analysis it will be more natural to work with the equivalent definition

$$\overline{X}(t) := X_0 + \int_0^t f(X(s))ds + \int_0^t g(X(s))dW(s), \tag{2.2}$$

where $X(t)$ is defined by

$$X(t) := X_k \quad \text{for } t \in [t_k, t_{k+1}). \tag{2.3}$$

Note that $\overline{X}(t_k) = X(t_k) = X_k$; that is, $\overline{X}(t)$ and $X(t)$ coincide with the discrete solution at the gridpoints. We refer to $X(t)$ and $\overline{X}(t)$ as *continuous-time extensions* of the discrete approximation $\{X_k\}$. We will study the error in $\overline{X}(t)$ in the supremum norm; this will, of course, give an immediate bound for the error in the discrete approximation.

Our first result makes the following assumption on the SDE (1.1) and the exact and numerical solutions. Here, and throughout the paper, $|\cdot|$ is used to denote both the Euclidean vector norm and the Frobenius (or trace) matrix norm.

ASSUMPTION 2.1. *For each $R > 0$ there exists a constant C_R, depending only on R, such that*

$$|f(a) - f(b)|^2 \vee |g(a) - g(b)|^2 \leq C_R|a - b|^2 \ \forall a, b \in \mathbb{R}^m \text{ with } |a| \vee |b| \leq R. \tag{2.4}$$

For some $p > 2$ there is a constant A such that

$$\mathbb{E}\left[\sup_{0\leq t\leq T} |\overline{X}(t)|^p\right] \vee \mathbb{E}\left[\sup_{0\leq t\leq T} |y(t)|^p\right] \leq A. \tag{2.5}$$

Inequality (2.4) is a local Lipschitz assumption. From the mean value theorem, any f and g in C^1 will satisfy (2.4). The inequality (2.5) states that the pth moments of the exact and numerical solution are bounded for some $p > 2$. We now prove that Assumption 2.1 is sufficient to ensure strong convergence of EM.

THEOREM 2.2. *Under Assumption* 2.1, *the EM solution* (2.1) *with continuous-time extension* (2.2) *satisfies*

$$\lim_{\Delta t\to 0} \mathbb{E}\left[\sup_{0\leq t\leq T} |\overline{X}(t) - y(t)|^2\right] = 0. \tag{2.6}$$

Proof. First, we define

$$\tau_R := \inf\{t \geq 0 : |\overline{X}(t)| \geq R\}, \quad \rho_R := \inf\{t \geq 0 : |y(t)| \geq R\}, \quad \theta_R := \tau_R \wedge \rho_R$$

and

$$e(t) := \overline{X}(t) - y(t).$$

Recall the Young inequality: for $r^{-1} + q^{-1} = 1$

$$ab \leq \frac{\delta}{r}a^r + \frac{1}{q\delta^{q/r}}b^q \quad \forall a, b, \delta > 0.$$

We thus have for any $\delta > 0$

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\right] &= \mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\mathbf{1}_{\{\tau_R>T,\rho_R>T\}}\right] + \mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\mathbf{1}_{\{\tau_R\le T \text{ or } \rho_R\le T\}}\right]\\ &\le \mathbb{E}\left[\sup_{0\le t\le T}|e(t\wedge\theta_R)|^2\mathbf{1}_{\{\theta_R>T\}}\right] + \frac{2\delta}{p}\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^p\right]\\ &\quad + \frac{1-\frac{2}{p}}{\delta^{2/(p-2)}}\mathbb{P}\big(\tau_R\le T \text{ or } \rho_R\le T\big). \qquad (2.7)\end{aligned}$$

Now

$$\mathbb{P}\left(\tau_R\le T\right) = \mathbb{E}\left[\mathbf{1}_{\{\tau_R\le T\}}\frac{|\overline{X}(\tau_R)|^p}{R^p}\right] \le \frac{1}{R^p}\mathbb{E}\left[\sup_{0\le t\le T}|\overline{X}(t)|^p\right] \le \frac{A}{R^p},$$

using (2.5). A similar result can be derived for ρ_R so that

$$\mathbb{P}\big(\tau_R\le T \text{ or } \rho_R\le T\big) \le \mathbb{P}\big(\tau_R\le T\big) + \mathbb{P}\big(\rho_R\le T\big) \le \frac{2A}{R^p}.$$

Using these bounds along with

$$\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^p\right] \le 2^{p-1}\mathbb{E}\left[\sup_{0\le t\le T}\big(|\overline{X}(t)|^p + |y(t)|^p\big)\right] \le 2^pA$$

in (2.7) gives

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\right] &\le \mathbb{E}\left[\sup_{0\le t\le T}|\overline{X}(t\wedge\theta_R) - y(t\wedge\theta_R)|^2\right]\\ &\quad + \frac{2^{p+1}\delta A}{p} + \frac{(p-2)2A}{p\delta^{2/(p-2)}R^p}. \qquad (2.8)\end{aligned}$$

Now we bound the first term on the right-hand side of (2.8) using an approach similar to a finite-time convergence proof for the globally Lipschitz case. Using

$$y(t\wedge\theta_R) := y_0 + \int_0^{t\wedge\theta_R} f(y(s))ds + \int_0^{t\wedge\theta_R} g(y(s))dW(s),$$

(2.2), and Cauchy–Schwarz, we have

$$\begin{aligned}|\overline{X}(t\wedge\theta_R) - y(t\wedge\theta_R)|^2 &= \left|\int_0^{t\wedge\theta_R} f(X(s)) - f(y(s))ds\right.\\ &\qquad \left. + \int_0^{t\wedge\theta_R} g(X(s)) - g(y(s))dW(s)\right|^2\\ &\le 2\left[T\int_0^{t\wedge\theta_R}|f(X(s)) - f(y(s))|^2ds\right.\\ &\qquad \left. + \left|\int_0^{t\wedge\theta_R} g(X(s)) - g(y(s))dW(s)\right|^2\right].\end{aligned}$$

So, from the local Lipschitz condition (2.4) and Doob's martingale inequality [14] we have for any $\tau \le T$

$$\begin{aligned}
&\mathbb{E}\left[\sup_{0\le t\le\tau}|\overline{X}(t\wedge\theta_R)-y(t\wedge\theta_R)|^2\right]\\
&\le 2C_R(T+4)\mathbb{E}\int_0^{\tau\wedge\theta_R}|X(s)-y(s)|^2ds\\
&\le 4C_R(T+4)\mathbb{E}\int_0^{\tau\wedge\theta_R}\left[|X(s)-\overline{X}(s)|^2+|\overline{X}(s)-y(s)|^2\right]ds\\
&\le 4C_R(T+4)\left[\mathbb{E}\int_0^{\tau\wedge\theta_R}|X(s)-\overline{X}(s)|^2ds+\mathbb{E}\int_0^{\tau}|\overline{X}(s\wedge\theta_R)-y(s\wedge\theta_R)|^2ds\right]\\
&\le 4C_R(T+4)\left[\mathbb{E}\int_0^{\tau\wedge\theta_R}|X(s)-\overline{X}(s)|^2ds+\int_0^{\tau}\mathbb{E}\sup_{0\le r\le s}|\overline{X}(r\wedge\theta_R)-y(r\wedge\theta_R)|^2ds\right].
\end{aligned}\tag{2.9}$$

To bound the first term in the parentheses on the right-hand side of (2.9), given $s\in[0,T\wedge\theta_R)$, let k_s be the integer for which $s\in[t_{k_s},t_{k_s+1})$. Then

$$\begin{aligned}
X(s)-\overline{X}(s)&=X_{k_s}-\left(X_{k_s}+\int_{t_{k_s}}^{s}f(X(s))ds+\int_{t_{k_s}}^{s}g(X(s))dW(s)\right)\\
&=-f(X_{k_s})(s-t_{k_s})-g(X_{k_s})\left(W(s)-W(t_{k_s})\right).
\end{aligned}$$

Hence,

$$|X(s)-\overline{X}(s)|^2\le 2\left[|f(X_{k_s})|^2\Delta t^2+|g(X_{k_s})|^2|W(s)-W(t_{k_s})|^2\right].\tag{2.10}$$

Now, from the local Lipschitz condition (2.4), for $|y|\le R$ we have

$$|f(y)|^2\le 2\left(|f(y)-f(0)|^2+|f(0)|^2\right)\le 2\left(C_R|y|^2+|f(0)|^2\right),$$

and, similarly,

$$|g(y)|^2\le 2\left(C_R|y|^2+|g(0)|^2\right).$$

Hence, in (2.10),

$$|X(s)-\overline{X}(s)|^2\le 4(C_R|X_{k_s}|^2+|f(0)|^2\vee|g(0)|^2)(\Delta t^2+|W(s)-W(t_{k_s})|^2).$$

Thus, using (2.5) and the Lyapunov inequality [12]

$$\begin{aligned}
&\mathbb{E}\int_0^{\tau\wedge\theta_R}|X(s)-\overline{X}(s)|^2ds\\
&\le\mathbb{E}\int_0^{\tau\wedge\theta_R}4(C_R|X_{k_s}|^2+|f(0)|^2\vee|g(0)|^2)(\Delta t^2+|W(s)-W(t_{k_s})|^2)ds\\
&\le\int_0^{\tau}4\mathbb{E}\left[C_R|X_{k_s}|^2+|f(0)|^2\vee|g(0)|^2)(\Delta t^2+|W(s)-W(t_{k_s})|^2\right]ds\\
&\le\int_0^{T}4(C_R\mathbb{E}[|X_{k_s}|^2]+|f(0)|^2\vee|g(0)|^2)(\Delta t^2+m\Delta t)ds\\
&\le 4T(C_RA^{2/p}+|f(0)|^2\vee|g(0)|^2)\Delta t(\Delta t+m).
\end{aligned}$$

In (2.9) we then have

$$\begin{aligned}&\mathbb{E}\left[\sup_{0\le t\le\tau}\left|\overline{X}(t\wedge\theta_R)-y(t\wedge\theta_R)\right|^2\right]\\&\le 16C_R(T+4)T\Delta t(\Delta t+m)(C_RA^{2/p}+|f(0)|^2\vee|g(0)|^2)\\&\quad+4C_R(T+4)\int_0^\tau\mathbb{E}\sup_{0\le r\le s}\left[\left|\overline{X}(r\wedge\theta_R)-y(r\wedge\theta_R)\right|^2\right]ds.\end{aligned}$$

Applying the Gronwall inequality [14] we obtain

$$\mathbb{E}\left[\sup_{0\le t\le T}\left|\overline{X}(t\wedge\theta_R)-y(t\wedge\theta_R)\right|^2\right]\le C\Delta t(C_R^2+1)e^{4C_R(T+4)},$$

where here, and in the following, C is a universal constant independent of Δt, R, and δ. Inserting this into (2.8) gives

$$\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\right]\le C\Delta t(C_R^2+1)e^{4C_R(T+4)}+\frac{2^{p+1}\delta A}{p}+\frac{(1-\frac{2}{p})2A}{\delta^{2/(p-2)}R^p}. \tag{2.11}$$

Given any $\epsilon>0$, we can choose δ so that $(2^{p+1}\delta A)/p<\epsilon/3$, then choose R so that

$$\frac{(1-\frac{2}{p})2A}{\delta^{2/(p-2)}R^p}<\frac{\epsilon}{3},$$

and then choose Δt sufficiently small for

$$C\Delta t(C_R^2+1)e^{4C_R(T+4)}<\frac{\epsilon}{3}$$

so that, in (2.11), $\mathbb{E}[\sup_{0\le t\le T}|e(t)|^2]<\epsilon$, as required. □

We remark that the proof of Theorem 2.2 is optimal in the sense that in the globally Lipschitz case ($C_R\le C$ for all R) we may take $\delta=\Delta t$ and $R=\Delta t^{-1/(p-2)}$ in (2.11) to recover the classical finite-time convergence result

$$\mathbb{E}\left[\sup_{0\le t\le T}|e(t)|^2\right]=O(\Delta t),$$

found, for example, in [12, 14].

3. Convergence with a one-sided Lipschitz condition.

3.1. The one-sided Lipschitz condition. In this section we impose further assumptions on the SDE. In section 3.2 we show that these assumptions guarantee moment bounds for $y(t)$. Theorem 2.2 requires bounds on the pth moment of the exact *and* numerical solution—a condition that is difficult to verify in practice for the method (2.1) and indeed may fail to hold. In section 3.3 we introduce an implicit version of the EM method for which moment bounds, and hence a convergence result, can be obtained.

We make the following assumptions on the SDE.

ASSUMPTION 3.1. *The functions f and g in* (1.1) *are C^1, and there exist constants $\mu, c>0$ such that*

$$\langle a-b,f(a)-f(b)\rangle\le\mu|a-b|^2\quad\forall a,b\in\mathbb{R}^m, \tag{3.1}$$

$$|g(a)-g(b)|^2\le c|a-b|^2\quad\forall a,b\in\mathbb{R}^m. \tag{3.2}$$

Note that we work with the case $\mu > 0$. In the deterministic setting there is a lot of attention paid to the contractive case $\mu < 0$. This case is of less interest here because, for most diffusion coefficients g, contractivity is destroyed. Hence $\mu > 0$ is a natural assumption.

It follows from Assumption 3.1 that

$$\langle f(a), a\rangle = \langle f(a) - f(0), a\rangle + \langle f(0), a\rangle \le \mu|a|^2 + |f(0)||a| \le \tfrac{1}{2}|f(0)|^2 + (\mu + \tfrac{1}{2})|a|^2$$

and

$$|g(a)|^2 \le 2|g(0)|^2 + 2|g(a) - g(0)|^2 \le 2|g(0)|^2 + 2c|a|^2.$$

This gives

$$\langle f(a), a\rangle \vee |g(a)|^2 \le \alpha + \beta|a|^2 \quad \forall a \in \mathbb{R}^m, \tag{3.3}$$

where

$$\alpha := \tfrac{1}{2}|f(0)|^2 \vee 2|g(0)|^2 \quad \text{and} \quad \beta := (\mu + \tfrac{1}{2}) \vee 2c. \tag{3.4}$$

The inequality (3.3) will prove very useful in what follows. We note that from [14, Theorem 2.3.5] $f, g \in C^1$ and (3.3) ensure the existence of a unique solution to the SDE (1.1).

The inequality (3.1) in Assumption 3.1, which is known as a *one-sided Lipschitz condition*, has been exploited successfully in the deterministic numerical analysis literature [1, 3, 4, 5, 17] and in the case of SDEs has been used in [11, 15, 16]. The condition (3.3) is closely related to the *monotone* condition in [14, section 2.4]. Any f of the form $f(y) = -y^p + y$, where the integer $p \ge 3$ is odd, satisfies (3.1), and further examples can be found in [17].

3.2. Moment bounds for the SDE. We now show that under Assumption 3.1 the SDE solution has a bounded pth moment for each $p > 2$.

LEMMA 3.2. *Under Assumption* 3.1*, for each* $p > 2$ *there is* $C = C(p, T) > 0$ *such that*

$$\mathbb{E}\left[\sup_{0\le t\le T} |y(t)|^p\right] \le C(1 + \mathbb{E}|y_0|^p). \tag{3.5}$$

Proof. Theorem 2.4.1 of [14] shows that, for $p \ge 2$, there is $C = C(p, T)$ such that

$$\mathbb{E}|y(t)|^p \le C[1 + \mathbb{E}|y_0|^p] \quad \forall t \in [0, T]. \tag{3.6}$$

By the Itô formula

$$|y(t)|^2 = |y_0|^2 + 2\int_0^t \langle f(y(s)), y(s)\rangle ds + \int_0^t |g(y(s))|^2 ds + 2\int_0^t \langle y(s), g(y(s))dB(s)\rangle.$$

By (3.3) we have that, for some $K = K(p)$ and $t_1 \in [0, T]$,

$$\sup_{0\le t\le t_1} |y(t)|^p \le K\left(|y_0|^p + \left\{\int_0^{t_1} [\alpha + \beta|y(s)|^2]ds\right\}^{p/2} + \sup_{0\le t\le t_1}\left|\int_0^t \langle y(s), g(y(s))dB(s)\rangle\right|^{p/2}\right).$$

By property (3.6) we can take expectations to give, for a possibly different $K = K(p,T)$,

$$\mathbb{E}\left[\sup_{0\le t\le t_1}|y(t)|^p\right] \le K\left(1+\mathbb{E}|y_0|^p + \int_0^{t_1}\mathbb{E}|y(s)|^p ds \right. \\ \left. + \mathbb{E}\left[\sup_{0\le t\le t_1}\left|\int_0^t \langle y(s), g(y(s))dB(s)\rangle\right|^{p/2}\right]\right).$$

By the Burkholder–Davis–Gundy inequality [14], we compute that, again for redefined $K = K(p,T)$,

$$\mathbb{E}\left[\sup_{0\le t\le t_1}|y(t)|^p\right] \le K\left(1+E|y_0|^p + \int_0^{t_1}\mathbb{E}|y(s)|^p ds \right. \\ \left. + \mathbb{E}\left[\int_0^{t_1}|y(s)|^2|g(y(s))|^2 ds\right]^{p/4}\right). \tag{3.7}$$

Next, note that, by Cauchy–Schwarz,

$$\begin{aligned}\mathbb{E}\left[\int_0^{t_1}|y(s)|^2|g(y(s))|^2 ds\right]^{p/4} &\le \mathbb{E}\left[\sup_{0\le s\le t_1}|y(s)|^{p/2}\left(\int_0^{t_1}|g(y(s))|^2 ds\right)^{p/4}\right] \\ &\le \frac{1}{2K}\mathbb{E}\left[\sup_{0\le s\le t_1}|y(s)|^p\right] + \frac{K}{2}\mathbb{E}\left[\int_0^{t_1}|g(y(s))|^2 ds\right]^{p/2} \\ &\le \frac{1}{2K}\mathbb{E}\left[\sup_{0\le s\le t_1}|y(s)|^p\right] \\ &\quad + \frac{K}{2}T^{(p-2)/2}\mathbb{E}\int_0^{t_1}(\alpha+\beta|y(s)|^2)^{p/2}ds.\end{aligned}$$

Substituting this into (3.7) yields, again for a possibly different $K = K(p,T)$,

$$\mathbb{E}\left[\sup_{0\le t\le t_1}|y(t)|^p\right] \le K\left(1+\mathbb{E}|y_0|^p + \int_0^{t_1}\mathbb{E}|y(s)|^p ds\right).$$

The required assertion now follows from property (3.6). ∎

3.3. Split-step backward Euler. We now consider the split-step backward Euler (SSBE) method, which is defined by taking $Y_0 = y_0$ and, generally,

$$Y_k^\star = Y_k + \Delta t f(Y_k^\star), \tag{3.8}$$

$$Y_{k+1} = Y_k^\star + g(Y_k^\star)\Delta W_k. \tag{3.9}$$

We state our convergence theorem here and then give a sequence of results that lead to a proof.

THEOREM 3.3. *Consider the SSBE* (3.8)–(3.9) *applied to the SDE* (1.1) *under Assumption* 3.1. *There exists a continuous-time extension* $\overline{Y}(t)$ *of the numerical solution (so that* $\overline{Y}(t_k) = Y_k$*) for which*

$$\lim_{\Delta t\to 0}\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Y}(t)-y(t)|^2\right] = 0.$$

Proof. See the end of this subsection. ∎

Note that (3.8) is an implicit equation that must be solved in order to obtain the intermediate approximation $Y_k^\star$. Having obtained $Y_k^\star$, adding the appropriate stochastic increment $g(Y_k^\star)\Delta W_k$ produces the next approximation Y_{k+1} in (3.9). The SSBE method reduces to the deterministic backward Euler method [5, 9] when $g \equiv 0$ and y_0 is nonrandom. The method is also studied in [15], where it is effective for inheriting ergodicity; for related reasons it is effective here in enabling the derivation of moment bounds. Another stochastic extension of the deterministic backward Euler method is considered in section 5.

Our proof of Theorem 3.3 relies on showing that SSBE has two key properties under Assumption 3.1: (a) it may be regarded as EM applied to a modified SDE of a similar form, and (b) it produces solutions with all moments bounded. The first property is established in the next lemma and corollary.

LEMMA 3.4. *Let Assumption* 3.1 *hold and suppose* $\Delta t \in (0, \Delta t_c), \Delta t_c < 1/(2\beta)$, *where* β *is defined in* (3.4). *Given* $d \in \mathbb{R}^m$ *the implicit equation*

$$c = d + \Delta t f(c) \tag{3.10}$$

has a unique solution c. *If we define the functions* $F_{\Delta t}(\cdot)$, $f_{\Delta t}(\cdot)$ *and* $g_{\Delta t}(\cdot)$ *by*

$$F_{\Delta t}(d) = c, \quad f_{\Delta t}(d) = f(F_{\Delta t}(d)), \quad \text{and} \quad g_{\Delta t}(d) = g(F_{\Delta t}(d)), \tag{3.11}$$

then $F_{\Delta t}, f_{\Delta t}, g_{\Delta t} \in C^1$, $g_{\Delta t}(\cdot) \to g(\cdot)$ *and* $f_{\Delta t}(\cdot) \to f(\cdot)$ *as* $\Delta t \to 0$ *in* C^1 *uniformly on compact sets and, for any* $a, b \in \mathbb{R}^m$,

$$|f_{\Delta t}(a)| \le \frac{|f(a)|}{1 - \Delta t\mu}, \tag{3.12}$$

$$|F_{\Delta t}(d) - F_{\Delta t}(e)|^2 \le \frac{1}{1 - 2\Delta t\mu}|d - e|^2, \tag{3.13}$$

$$\langle a - b, f_{\Delta t}(a) - f_{\Delta t}(b)\rangle \le \frac{\mu}{1 - 2\mu\Delta t}|a - b|^2. \tag{3.14}$$

Further, $g_{\Delta t}$ *is globally Lipschitz, and there exist* $\alpha', \beta' > 0$ *such that*

$$\langle f_{\Delta t}(a), a\rangle \vee |g_{\Delta t}(a)|^2 \le \alpha' + \beta'|a|^2 \quad \forall a \in \mathbb{R}^m. \tag{3.15}$$

Proof. See Appendix A. ∎

COROLLARY 3.5. *Let Assumption* 3.1 *hold and suppose* $\Delta t \in (0, \Delta t_c), \Delta t_c < 1/(2\beta)$, *where* β *is defined in* (3.4). *Then SSBE applied to* (1.1) *is equivalent to EM applied to the modified SDE*

$$dy_{\Delta t}(t) = f_{\Delta t}(y_{\Delta t}(t))dt + g_{\Delta t}(y_{\Delta t}(t))dW(t), \qquad 0 \le t \le T,\ y_{\Delta t}(0) = y_0, \tag{3.16}$$

where $f_{\Delta t}, g_{\Delta t}$ *are defined in Lemma* 3.4.

Proof. Lemma 3.4 allows us to express the SSBE method (3.8)–(3.9) in the form

$$Y_{k+1} = Y_k + \Delta t f_{\Delta t}(Y_k) + g_{\Delta t}(Y_k)\Delta W_k, \tag{3.17}$$

and the result is then immediate. ∎

Next, we show that the solution of the modified SDE (3.16) has bounded moments and converges strongly to $y(t)$.

LEMMA 3.6. *Under Assumption* 3.1, *for each* $p > 2$, *there is* $C = C(p,T) > 0$ *such that*

$$\mathbb{E}\left[\sup_{0\le t\le T}|y_{\Delta t}(t)|^p\right] \le C(1+\mathbb{E}|y_0|^p), \tag{3.18}$$

provided Δt *is sufficiently small. In addition,*

$$\lim_{\Delta t\to 0}\mathbb{E}\left[\sup_{0\le t\le T}|y(t)-y_{\Delta t}(t)|^2\right] = 0. \tag{3.19}$$

Proof. It follows from Lemma 3.4 that for sufficiently small Δt the functions $f_{\Delta t}$ and $g_{\Delta t}$ satisfy (3.3) with α and β replaced by 2α and 2β. Following through the proof of Lemma 3.2, which is based entirely on (3.3), we obtain (3.18).

Now to prove (3.19) we note from Lemma 3.4 that given $R > 0$ there is a function $K_R : (0,\infty) \to (0,\infty)$ such that $K_R(\Delta t) \to 0$ as $\Delta t \to 0$ and

$$|f_{\Delta t}(u) - f(u)|^2 \vee |g_{\Delta t}(u) - g(u)|^2 \le K_R(\Delta t) \quad \forall u \in \mathbb{R}^m, |u| \le R, \tag{3.20}$$

provided Δt is sufficiently small. Also, since $f, g \in C^1$, there is a constant H_R such that

$$|f(u) - f(v)|^2 \vee |g(u) - g(v)|^2 \le H_R|u-v|^2 \quad \forall u, v \in \mathbb{R}^m, |u| \vee |v| \le R. \tag{3.21}$$

From Lemma 3.2 and (3.18) we have

$$\mathbb{E}\left[\sup_{0\le t\le T}|y(t)|^p\right] \vee \mathbb{E}\left[\sup_{0\le t\le T}|y_{\Delta t}(t)|^p\right] \le K := C(1+\mathbb{E}|y_0|^p). \tag{3.22}$$

The remainder of the proof follows in a similar manner to that of Theorem 2.2. Define

$$\tau_R = \inf\{t \ge 0 : |y(t)| \ge R\}, \quad \rho_R = \inf\{t \ge 0 : |y_{\Delta t}(t)| \ge R\}, \quad \theta_R = \tau_R \wedge \rho_R.$$

For any $\delta > 0$, in the same way that (2.8) was obtained, we have

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le t\le T}|y(t)-y_{\Delta t}(t)|^2\right] &\le \mathbb{E}\left[\sup_{0\le t\le T}|y(t\wedge\theta_R)-y_{\Delta t}(t\wedge\theta_R)|^2\right] \\ &\quad + \frac{2^{p+1}\delta K}{p} + \frac{(p-2)2K}{p\delta^{2/(p-2)}R^p}.\end{aligned} \tag{3.23}$$

To bound the first term on the right-hand side of (3.23), we observe that

$$\begin{aligned}&y(t\wedge\theta_R) - y_{\Delta t}(t\wedge\theta_R) \\ &= \int_0^{t\wedge\theta_R}[f(y(s)) - f(y_{\Delta t}(s)) + f(y_{\Delta t}(s)) - f_{\Delta t}(y_{\Delta t}(s))]ds \\ &\quad + \int_0^{t\wedge\theta_R}[g(y(s)) - g(y_{\Delta t}(s)) + g(y_{\Delta t}(s)) - g_{\Delta t}(y_{\Delta t}(s))]dW(s).\end{aligned}$$

Using (3.20), (3.21), Cauchy–Schwarz, and the Doob martingale inequality, we have that, for any $\tau \le T$,

$$\begin{aligned}&\mathbb{E}\left[\sup_{0\le t\le\tau}|y(t\wedge\theta_R)-y_{\Delta t}(t\wedge\theta_R)|^2\right] \\ &\le 4H_R(T+4)\int_0^\tau \mathbb{E}\left[\sup_{0\le t\le s}|y(t\wedge\theta_R)-y_{\Delta t}(t\wedge\theta_R)|^2\right]ds \\ &\quad + 4T(T+4)K_R(\Delta t).\end{aligned}$$

So the Gronwall inequality yields

$$\mathbb{E}\left[\sup_{0\le t\le T}|y(t\wedge\theta_R)-y_{\Delta t}(t\wedge\theta_R)|^2\right]\le 4T(T+4)K_R(\Delta t)e^{4H_R(T+4)T}.$$

Inserting this into (3.23) gives

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le t\le T}|y(t)-y_{\Delta t}(t)|^2\right]&\le 4T(T+4)K_R(\Delta t)e^{4H_R(T+4)T}\\&\quad+\frac{2^{p+1}\delta K}{p}+\frac{(p-2)2K}{p\delta^{2/(p-2)}R^p}.\end{aligned}\tag{3.24}$$

The final step of the proof follows that of Theorem 2.2. □

Now we show that the special structure of SSBE makes it possible for us to bound all moments of the numerical solution, under Assumption 3.1. We deal first with the discrete approximation and then with a continuous-time extension.

LEMMA 3.7. *Suppose Assumption* 3.1 *holds and let* $\Delta t\le\Delta t_c<1/(2\beta)$*, where* β *is defined in* (3.4)*. Then for each* $p\ge 2$ *there exists a* $C=C(p,T)>0$ *(independent of* Δt*) such that for the SSBE method* (3.8)–(3.9)

$$\mathbb{E}\sup_{n\Delta t\in[0,T]}|Y_n|^{2p}\le C.$$

Proof. In the following we assume that N and M are positive integers such that $N\Delta t\le M\Delta t\le T$. From (3.3) and (3.8) we have

$$\begin{aligned}|Y_n^\star|^2&=\langle Y_n,Y_n^\star\rangle+\Delta t\langle f(Y_n^\star),Y_n^\star\rangle\\&\le\tfrac12|Y_n|^2+\tfrac12|Y_n^\star|^2+\Delta t(\alpha+\beta|Y_n^\star|^2).\end{aligned}$$

Thus

$$|Y_n^\star|^2\le\frac{|Y_n|^2+2\alpha\Delta t}{1-2\beta\Delta t}.\tag{3.25}$$

From (3.9) and (3.25) we have

$$\begin{aligned}|Y_{n+1}|^2&\le|Y_n|^2+\frac{2\beta\Delta t}{1-2\beta\Delta t}|Y_n|^2+\frac{2\alpha\Delta t}{1-2\beta\Delta t}\\&\quad+2\langle Y_n^\star,g(Y_n^\star)\Delta W_n\rangle+|g(Y_n^\star)\Delta W_n|^2.\end{aligned}$$

Summing, and using the notation $K=(1-2\beta\Delta t)^{-1}$, we obtain

$$\begin{aligned}|Y_N|^2&\le|Y_0|^2+2\beta\Delta tK\sum_{j=0}^{N-1}|Y_j|^2+2\alpha\Delta tNK\\&\quad+2\sum_{j=0}^{N-1}\langle Y_j^\star,g(Y_j^\star)\Delta W_j\rangle+\sum_{j=0}^{N-1}|g(Y_j^\star)\Delta W_j|^2.\end{aligned}$$

Raising both sides to the power p we have

$$\frac{1}{5^{p-1}}|Y_N|^{2p} \le |Y_0|^{2p} + (2\beta\Delta t K)^p \left(\sum_{j=0}^{N-1} |Y_j|^2\right)^p + (2\alpha T K)^p + 2^p \left|\sum_{j=0}^{N-1} \langle Y_j^\star, g(Y_j^\star)\Delta W_j\rangle\right|^p + \left(\sum_{j=0}^{N-1} |g(Y_j^\star)\Delta W_j|^2\right)^p$$

$$\le |Y_0|^{2p} + (2\beta K)^p T^{p-1}\Delta t \sum_{j=0}^{N-1} |Y_j|^{2p} + (2\alpha T K)^p + 2^p \left|\sum_{j=0}^{N-1} \langle Y_j^\star, g(Y_j^\star)\Delta W_j\rangle\right|^p + N^{p-1}\sum_{j=0}^{N-1} |g(Y_j^\star)\Delta W_j|^{2p}. \tag{3.26}$$

Now

$$\mathbb{E}\left[\sup_{0\le N\le M} \sum_{j=0}^{N-1} |Y_j|^{2p}\right] = \sum_{j=0}^{M-1} \mathbb{E}|Y_j|^{2p}. \tag{3.27}$$

Also, letting $C = C(p,T)$ be a constant that may change line by line,

$$\begin{aligned}
\mathbb{E}\left[\sup_{0\le N\le M} \sum_{j=0}^{N-1} |g(Y_j^\star)\Delta W_j|^{2p}\right] &= \mathbb{E}\sum_{j=0}^{M-1} |g(Y_j^\star)\Delta W_j|^{2p} \\
&\le \sum_{j=0}^{M-1} \mathbb{E}|g(Y_j^\star)|^{2p}\mathbb{E}|\Delta W_j|^{2p} \\
&\le C\Delta t^p \sum_{j=0}^{M-1} \mathbb{E}[\alpha + \beta|Y_j^\star|^2]^p \\
&\le C\Delta t^p \sum_{j=0}^{M-1} \mathbb{E}[\alpha^p + \beta^p|Y_j^\star|^{2p}] \\
&\le C\Delta t^{p-1} + C\Delta t^p \sum_{j=0}^{M-1} \mathbb{E}[|Y_j|^2 + 2\alpha\Delta t|]^p \\
&\le C\Delta t^{p-1} + C\Delta t^p \sum_{j=0}^{M-1} \mathbb{E}|Y_j|^{2p}, \qquad (3.28)
\end{aligned}$$

where we have used (3.3) and (3.25). Finally, using the Burkholder–Davis–Gundy inequality [14],

$$\begin{aligned}
\mathbb{E}\left[\sup_{0\le N\le M} \left|\sum_{j=0}^{N-1} \langle Y_j^\star, g(Y_j^\star)\Delta W_j\rangle\right|^p\right] &\le C\mathbb{E}\left[\sum_{j=0}^{M-1} |Y_j^\star|^2|g(Y_j^\star)|^2\Delta t\right]^{p/2} \\
&\le C(\Delta t)^{p/2} M^{p/2-1}\mathbb{E}\sum_{j=0}^{M-1} |Y_j^\star|^p(\alpha + \beta|Y_j^\star|^2)^{p/2} \\
&\le C\Delta t \sum_{j=0}^{M-1} [1 + \mathbb{E}|Y_j^\star|^{2p}]
\end{aligned}$$

$$\leq C\Delta t \sum_{j=0}^{M-1} [1 + \mathbb{E}(2\alpha\Delta t + |Y_j|^2)^p]$$

$$\leq C + C\Delta t \sum_{j=0}^{M-1} \mathbb{E}|Y_j|^{2p}. \tag{3.29}$$

Combining (3.26)–(3.29) we obtain

$$\mathbb{E}\left[\sup_{0\leq N\leq M} |Y_N|^{2p}\right] \leq C + C\Delta t \sum_{j=0}^{M-1} \mathbb{E}|Y_j|^{2p} \leq C + C\Delta t \sum_{j=0}^{M-1} \mathbb{E}\left[\sup_{0\leq N\leq j} \mathbb{E}|Y_N|^{2p}\right].$$

Using the discrete-type Gronwall inequality (see, for example, [13]) and noting that $M\Delta t \leq T$, we obtain

$$\mathbb{E}\left[\sup_{0\leq N\leq M} |Y_N|^{2p}\right] \leq Ce^{C\Delta tM} \leq Ce^{CT},$$

and the desired result follows. ∎

COROLLARY 3.8. *Suppose Assumption* 3.1 *holds and let* $\Delta t \in (0, \Delta t_c), \Delta t_c < 1/(2\beta)$*, where* β *is defined in* (3.4)*. Let* $p \geq 2$*. Then there exists a continuous-time extension* $\overline{Y}(t)$ *of the SSBE solution* $\{Y_k\}$ *and a constant* $C = C(p, T) > 0$ *(independent of* Δt*) such that*

$$\mathbb{E} \sup_{0\leq t\leq T} |\overline{Y}(t)|^{2p} \leq C.$$

Proof. We know that SSBE can be regarded as EM applied to the modified SDE (3.16). Hence, we may define $\overline{Y}(t)$ using (2.2)–(2.3) with f, g replaced by $f_{\Delta t}$, $g_{\Delta t}$ and X, $\overline{X}, X_k$ replaced by Y, $\overline{Y}, Y_k$. By definition we have, for $t_n = n\Delta t$,

$$\overline{Y}(t_n + s) = Y_n + sf_{\Delta t}(Y_n) + g_{\Delta t}(Y_n)\Delta W_n(s), \quad s \in [0, \Delta t),$$

where

$$\Delta W_n(s) := W(t_n + s) - W(t_n).$$

However, $Y_n^\star = Y_n + \Delta t f_{\Delta t}(Y_n)$ and so, for $a = s/\Delta t$, we have

$$\overline{Y}(t_n + s) = aY_n^\star + (1 - a)Y_n + g_{\Delta t}(Y_n)\Delta W_n(s), \qquad s \in [0, \Delta t).$$

Since $\Delta t \leq \Delta t_c < 1/(2\beta)$, it follows from (3.25) that

$$|\overline{Y}(t_n + s)|^2 \leq C[1 + |Y_n|^2 + |g_{\Delta t}(Y_n)\Delta W_n(s)|^2].$$

Thus

$$\sup_{0\leq t\leq T} |\overline{Y}(t)|^{2p} \leq \sup_{0\leq n\Delta t\leq T} \sup_{0\leq s\leq \Delta t} |\overline{Y}(t_n + s)|^{2p}$$

$$\leq \sup_{0\leq n\Delta t\leq T} \sup_{0\leq s\leq \Delta t} C[1 + |Y_n|^{2p} + |g_{\Delta t}(Y_n)\Delta W_n(s)|^{2p}]$$

$$\leq C[1 + \sup_{0\leq n\Delta t\leq T} |Y_n|^{2p} + \sup_{0\leq s\leq \Delta t} \sum_{j=0}^{N} |g_{\Delta t}(Y_j)\Delta W_j(s)|^{2p}], \tag{3.30}$$

where $0 \le N\Delta t \le T$. Now, using Doob's martingale inequality [14] and (3.15)

$$\begin{aligned}\mathbb{E}\sup_{0\le s\le \Delta t}|g_{\Delta t}(Y_j)\Delta W_j(s)|^{2p} &\le C\mathbb{E}|g_{\Delta t}(Y_j)\Delta W_j(\Delta t)|^{2p}\\ &\le C\mathbb{E}|g_{\Delta t}(Y_j)|^{2p}\mathbb{E}|\Delta W_j(\Delta t)|^{2p}\\ &\le C\Delta t^p[1+\mathbb{E}|Y_j|^{2p}]\\ &\le C\Delta t, \qquad (3.31)\end{aligned}$$

where C is a universal constant, independent of Δt. Since $N\Delta t \le T$, combining Lemma 3.7, (3.30), and (3.31) gives the desired result. □

Proof of Theorem 3.3. The proof now follows from an application of the triangle inequality: the SSBE method has a solution close to the solution of an SDE with modified vector fields, and the solution of this SDE in turn is close to that of the original SDE. More precisely, we may use Corollary 3.8 to define $\overline{Y}(t)$ and bound $\mathbb{E}\sup_{0\le t\le T}|\overline{Y}(t)|^p$ and Lemma 3.6 to bound $\mathbb{E}\sup_{0\le t\le T}|y_{\Delta t}(t)|^p$. We also know from Lemma 3.4 that $f_{\Delta t}$ and $g_{\Delta t}$ are uniformly locally Lipschitz for small Δt. Hence, we may follow the proof of Theorem 2.2 to give

$$\lim_{\Delta t\to 0}\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Y}(t)-y_{\Delta t}(t)|^2\right]=0.$$

Combining this with (3.19) in Lemma 3.6 via the triangle inequality gives the result. □

4. Convergence rates. In this section we show that by augmenting Assumption 3.1 with the condition that f behaves polynomially, it is possible to establish a rate of convergence. The rate is optimal, agreeing with the standard theory for the explicit EM scheme in the globally Lipschitz case. The work of [7] also yields optimal rates of almost sure convergence for the EM scheme, under conditions on the vector fields similar to ours.

ASSUMPTION 4.1. *There exist constants $D \in \mathbb{R}^+$ and $q \in \mathbb{Z}^+$ such that for all $a, b \in \mathbb{R}^m$,*

$$|f(a)-f(b)|^2 \le D\,(1+|a|^q+|b|^q)\,|a-b|^2. \qquad (4.1)$$

To obtain a convergence rate for EM we require the following moment bound assumption.

ASSUMPTION 4.2. *The SDE and EM solutions satisfy*

$$\mathbb{E}\sup_{0\le t\le T}|y(t)|^p, \quad \mathbb{E}\sup_{0\le t\le T}|X(t)|^p, \quad \mathbb{E}\sup_{0\le t\le T}|\overline{X}(t)|^p<\infty \qquad \forall p\ge 1.$$

Throughout the following analysis, K and u denote generic positive real and integer constants whose values may change between occurrences. Before obtaining a convergence rate for EM, we give the following lemma.

LEMMA 4.3. *Under Assumptions* 3.1, 4.1, and 4.2, *for any even integer $r \ge 2$, there exists a constant $E = E(r)$ such that*

$$\sup_{0\le t\le T}\mathbb{E}|X(t)-\overline{X}(t)|^r \le E\Delta t^{r/2}.$$

Proof. Let $t \in [k\Delta t, (k+1)\Delta t)$. Then

$$\begin{aligned}|X(t) - \overline{X}(t)|^r &= |(t-t_k)f(X_k) + g(X_k)(W(t) - W(t_k))|^r \\ &\le 2^r \left(\Delta t^r |f(X_k)|^r + |g(X_k)|^r |W(t) - W(t_k)|^r\right).\end{aligned}$$

Hence, for some $E = E(r)$,

$$\mathbb{E}|X(t) - \overline{X}(t)|^r \le E\left(\Delta t^r \left[1 + \mathbb{E}\sup_{0\le t\le T}|X(t)|^u\right] + \left[1 + \mathbb{E}\sup_{0\le t\le T}|X(t)|^u\right](t-t_k)^{r/2}\right).$$

Since $t - t_k \le \Delta t$, the result follows by redefinition of E. ∎

THEOREM 4.4. *Under Assumptions* 3.1, 4.1, *and* 4.2 *the EM solution* (2.1) *with continuous-time extension* (2.2) *satisfies*

$$\mathbb{E}\left[\sup_{0\le t\le T}|\overline{X}(t) - y(t)|^2\right] = O(\Delta t).$$

Proof. Using (2.2) and

$$y(t) = y_0 + \int_0^t f(y(s))ds + \int_0^t g(y(s))dW(s), \tag{4.2}$$

and letting $e(t) := y(t) - \overline{X}(t)$, the Itô formula gives

$$\begin{aligned}|e(t)|^2 &= \int_0^t 2\langle f(y(s)) - f(X(s)), e(s)\rangle ds + \int_0^t |g(y(s)) - g(X(s))|^2 ds \\ &\quad + M(t) \\ &\le \int_0^t \left(2\langle f(y(s)) - f(\overline{X}(s)), e(s)\rangle + c|y(s) - X(s)|^2\right) ds \\ &\quad + \int_0^t 2\langle f(\overline{X}(s)) - f(X(s)), e(s)\rangle ds \\ &\quad + M(t) \\ &\le \int_0^t 2\mu|e(s)|^2 + 2c|e(s)|^2 + 2c|X(s) - \overline{X}(s)|^2 ds \\ &\quad + \int_0^t |f(\overline{X}(s)) - f(X(s))|^2 + |e(s)|^2 ds \\ &\quad + M(t) \\ &\le (1 + 2(\mu + c))\int_0^t |e(s)|^2 ds + \int_0^t K\left(1 + |\overline{X}(s)|^q + |X(s)|^q\right)|X(s) - \overline{X}(s)|^2 ds \\ &\quad + M(t),\end{aligned}$$

where

$$M(t) = \int_0^t 2\langle e(s), (g(y(s)) - g(X(s)))dW(s)\rangle.$$

Using Cauchy–Schwarz and Lemma 4.3 with $r = 4$

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] &\le (1+2(\mu+c))\int_0^t \mathbb{E}|e(s)|^2 ds \\ &\quad + \int_0^t K\left(\mathbb{E}\left(1+|\overline{X}(s)|^q+|X(s)|^q\right)^2\mathbb{E}|X(s)-\overline{X}(s)|^4\right)^{1/2} ds + m(t) \\ &\le (1+2(\mu+c))\int_0^t \mathbb{E}|e(s)|^2 ds + K\Delta t\int_0^t \mathbb{E}\left(1+|\overline{X}(s)|^{2q}+|X(s)|^{2q}\right) ds \\ &\quad + m(t) \\ &\le (1+2(\mu+c))\int_0^t \mathbb{E}|e(s)|^2 ds + K\Delta t + m(t), \qquad (4.3)\end{aligned}$$

where

$$m(t) = \mathbb{E}\left[\sup_{0\le s\le t}|M(s)|\right].$$

From the Burkholder–Davis–Gundy inequality,

$$\begin{aligned} m(t) &\le 16\mathbb{E}\left[\int_0^t |e(s)|^2|g(y(s))-g(X(s))|^2 ds\right]^{1/2} \\ &\le 16\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\int_0^t c|y(s)-X(s)|^2 ds\right]^{1/2} \\ &\le \tfrac{1}{2}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] + 128c\mathbb{E}\int_0^t |y(s)-X(s)|^2 ds \\ &\le \tfrac{1}{2}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] + 256c\int_0^t [\mathbb{E}|e(s)|^2 + \mathbb{E}|\overline{X}(s)-X(s)|^2] ds \\ &\le \tfrac{1}{2}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] + 256c\int_0^t \mathbb{E}|e(s)|^2 ds + K\Delta t. \end{aligned}$$

Hence, in (4.3),

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] &\le 2(1+2(\mu+c)+256c)\int_0^t \mathbb{E}|e(s)|^2 ds + K\Delta t \\ &\le 2(1+2(\mu+c)+256c)\int_0^t \mathbb{E}\left[\sup_{0\le r\le s}|e(r)|^2\right] ds + K\Delta t.\end{aligned}$$

The result follows from the Gronwall inequality. ∎

Note that Theorem 4.4 requires moment bounds on the numerical solution (Assumption 4.2). We know that SSBE has bounded moments under Assumption 3.1, and hence we would expect to get an analogous convergence result for this method without requiring Assumption 4.2. To obtain such a result we first establish further properties of $f_{\Delta t}$ and $g_{\Delta t}$ under Assumptions 3.1 and 4.1.

LEMMA 4.5. *Under Assumptions* 3.1 *and* 4.1, *for* $\Delta t \le \Delta t_c < 1/(2\beta)$, *where* β *is defined in* (3.4), *there exist constants* $c', D' \in \mathbb{R}^+$ *and* $q' \in \mathbb{Z}^+$ *such that for all* $a, b \in \mathbb{R}^m$

$$|f_{\Delta t}(a) - f_{\Delta t}(b)|^2 \le D'\left(1+|a|^q+|b|^q\right)|a-b|^2, \qquad (4.4)$$

$$|f(a) - f_{\Delta t}(a)|^2 \le c'\left(1+|a|^{q'}\right)\Delta t^2, \qquad (4.5)$$

$$|g(a) - g_{\Delta t}(a)|^2 \le c'\left(1+|a|^{q'}\right)\Delta t^2. \qquad (4.6)$$

Proof. See Appendix A. ∎

LEMMA 4.6. *Under Assumptions* 3.1 *and* 4.1 *the solution* $y_{\Delta t}(t)$ *of the modified SDE* (3.16) *satisfies*

$$\mathbb{E}\left[\sup_{0\le t\le T}|y_{\Delta t}(t)-y(t)|^2\right]=O(\Delta t^2).$$

Proof. Using

$$y_{\Delta t}(t)=y_0+\int_0^t f_{\Delta t}(y_{\Delta t}(s))ds+\int_0^t g_{\Delta t}(y_{\Delta t}(s))dW(s),$$

and (4.2), and letting $e(t):=y(t)-y_{\Delta t}(t)$, the Itô formula gives

$$\begin{aligned}
|e(t)|^2 &= \int_0^t 2\langle f(y(s))-f_{\Delta t}(y_{\Delta t}(s)),e(s)\rangle ds+\int_0^t |g(y(s))-g_{\Delta t}(y_{\Delta t}(s))|^2 ds\\
&\quad + M(t)\\
&= \int_0^t 2\langle f(y(s))-f(y_{\Delta t}(s))+f(y_{\Delta t}(s))-f_{\Delta t}(y_{\Delta t}(s)),e(s)\rangle ds\\
&\quad + \int_0^t |g(y(s))-g_{\Delta t}(y_{\Delta t}(s))|^2 ds\\
&\quad + M(t)\\
&\le \int_0^t [2\mu|e(s)|^2+|f(y_{\Delta t}(s))-f_{\Delta t}(y_{\Delta t}(s))|^2+|e(s)|^2]ds\\
&\quad + 2\int_0^t |g(y(s))-g(y_{\Delta t}(s))|^2+|g(y_{\Delta t}(s))-g_{\Delta t}(y_{\Delta t}(s))|^2 ds\\
&\quad + M(t)\\
&\le K\int_0^t |e(s)|^2\,ds+K\Delta t^2\int_0^t\left(1+|y_{\Delta t}(s)|^{q'}\right)ds\\
&\quad + M(t),
\end{aligned}$$

where we used Lemma 4.5 and

$$M(t)=\int_0^t 2\langle e(s),(g(y(s))-g_{\Delta t}(y_{\Delta t}(s)))dW(s)\rangle.$$

Hence,

$$\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right]\le K\int_0^t \mathbb{E}|e(s)|^2\,ds+K\Delta t^2\int_0^t \mathbb{E}\left[1+|y_{\Delta t}(s)|^{q'}\right]ds+m(t),$$

where

$$m(t)=\mathbb{E}\left[\sup_{0\le s\le t}|M(s)|\right].$$

Since $y_{\Delta t}(s)$ has bounded moments, we have

$$\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right]\le K\int_0^t \mathbb{E}|e(s)|^2\,ds+K\Delta t^2+m(t). \tag{4.7}$$

However, in the same way as in the proof of Theorem 4.4, we can show

$$m(t) \le \tfrac{1}{2}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] + 128\mathbb{E}\int_0^t |g(y(s)) - g_{\Delta t}(y_{\Delta t}(s))|^2 ds,$$

while

$$\begin{aligned}\mathbb{E}\int_0^t |g(y(s)) - g_{\Delta t}(y_{\Delta t}(s))|^2 ds &\le 2\mathbb{E}\int_0^t |g(y(s)) - g(y_{\Delta t}(s))|^2 \\ &\quad + |g(y_{\Delta t}(s)) - g_{\Delta t}(y_{\Delta t}(s))|^2 ds \\ &\le K\int_0^t \mathbb{E}|e(s)|^2\, ds + K\Delta t^2.\end{aligned}$$

In (4.7) we therefore have

$$\begin{aligned}\mathbb{E}\left[\sup_{0\le s\le t}|e(s)|^2\right] &\le K\int_0^t \mathbb{E}|e(s)|^2\, ds + K\Delta t^2 \\ &\le K\int_0^t \mathbb{E}\left[\sup_{0\le r\le s}|e(r)|^2\right] ds + K\Delta t^2.\end{aligned}$$

The result follows from the Gronwall inequality. □

We may now prove a convergence result for SSBE.

THEOREM 4.7. *Consider the SSBE method* (3.8)–(3.9) *applied to the SDE* (1.1) *under Assumptions* 3.1 *and* 4.1. *There exists a continuous-time extension* $\overline{Y}(t)$ *of the numerical solution (so that* $\overline{Y}(t_k) = Y_k$*) for which*

$$\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Y}(t) - y(t)|^2\right] = O(\Delta t).$$

Proof. We know that SSBE can be regarded as EM applied to the modified SDE (3.16). Lemmas 3.6 and 3.7 and Corollary 3.8 show that $y_{\Delta t}(t)$, $Y(t)$, and $\overline{Y}(t)$ have bounded moments. Hence, copying the proof of Theorem 4.4 we may conclude that

$$\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Y}(t) - y_{\Delta t}(t)|^2\right] = O(\Delta t).$$

Combining this with Lemma 4.6 via the triangle inequality gives the required result. □

5. Backward Euler. The SSBE method (3.8)–(3.9) is a stochastic extension of the deterministic backward Euler method. Another, perhaps more natural, extension of backward Euler is given by $Z_0 = y_0$ and

$$Z_{k+1} = Z_k + \Delta t f(Z_{k+1}) + g(Z_k)\Delta W_k. \tag{5.1}$$

Indeed, this implicit method has appeared frequently in the literature—it is a member of the *family of implicit Euler schemes* [12, section 12.2] or the stochastic theta method class [10] and is sometimes called the semi-implicit Euler method [2]. We will refer to the method (5.1) as simply the backward Euler (BE) method for (1.1). As mentioned at the end of section 1, our convergence result, Theorem 5.3 below, is closely related to that of [11, Theorem 2.4].

The BE method (5.1) requires an implicit equation to be solved. Under Assumption 3.1, the homotopy argument in the proof of Lemma 3.4 shows that for $2\mu\Delta t < 1$ a unique solution exists with probability one. The next lemma points out a useful connection between BE and SSBE.

LEMMA 5.1. *Let $\{Y_k\}$ and $\{Z_k\}$ denote the SSBE and BE solutions, given by* (3.8)–(3.9) *and* (5.1), *respectively. Under Assumption* 3.1, *if $Y_0 = Z_0 - \Delta t f(Z_0)$, then*

$$Z_k = Y_k + \Delta t f_{\Delta t}(Y_k) \qquad \forall k \geq 0. \tag{5.2}$$

Proof. Let $Q_k^\star = Z_k$ and $Q_k = Z_k - \Delta t f(Z_k)$, where $\{Z_k\}$ is the BE solution (5.1). Then

$$Q_k^\star = Q_k + \Delta t f(Q_k^\star)$$

and, using (5.1),

$$Q_{k+1} = Z_{k+1} - \Delta t f(Z_{k+1}) = Q_k^\star + g(Q_k^\star)\Delta W_k.$$

Hence, $\{Q_k\}$ is precisely the SSBE solution. This gives $Y_k = Z_k - \Delta t f(Z_k)$. The relation (5.2) then follows immediately from Lemma 3.4. ∎

Lemma 5.1 shows that the BE solution can be regarded as an $O(\Delta t)$ perturbation of the SSBE solution. We may use this relation between BE and SSBE in order to obtain a convergence result for BE via Theorem 3.3. We first deal with the perturbation to the initial data.

LEMMA 5.2. *Under Assumptions* 3.1 *and* 4.1, *if $y(t)$ and $z(t)$ are solutions of the SDE* (1.1) *with initial conditions such that*

$$\mathbb{E}|y(0)|^p,\ \mathbb{E}|z(0)|^p \leq \infty \qquad \forall p \geq 1,$$

then, for some constant M,

$$\mathbb{E}\left[\sup_{0\leq t\leq T} |y(t) - z(t)|^2\right] \leq M\mathbb{E}|y(0) - z(0)|^2.$$

Proof. Letting $e(t) := y(t) - z(t)$ and applying the Itô formula to $|e(t)|^2$, the inequality can be obtained by following the process used in the proofs of Theorem 4.4 and Lemma 4.6. ∎

THEOREM 5.3. *Consider the BE method* (5.1) *applied to the SDE* (1.1) *under Assumptions* 3.1 *and* 4.1. *There exists a continuous-time extension $\overline{Z}(t)$ of the numerical solution (so that $\overline{Z}(t_k) = Z_k$) for which*

$$\mathbb{E}\left[\sup_{0\leq t\leq T} |\overline{Z}(t) - y(t)|^2\right] = O(\Delta t).$$

Proof. Let $\overline{Y}(t)$ denote the continuous-time extension to SSBE defined in Theorem 3.3, with initial data $\overline{Y}(0) = y_0 - \Delta t f(y_0)$. Also, let $\overline{Z}(t) = \overline{Y}(t) + \Delta t f_{\Delta t}(\overline{Y}(t))$, so that, from Lemma 5.1, $\overline{Z}(t)$ is a continuous-time extension to the BE solution with $\overline{Z}(0) = y_0$. We let $\widehat{y}_{\Delta t}(t)$ denote the solution to (1.1), with initial data $y_{\Delta t}(0) = y_0 - \Delta t f(y_0)$.

From Lemma 5.2 we have

$$\mathbb{E}\left[\sup_{0\leq t\leq T} |y(t) - \widehat{y}_{\Delta t}(t)|^2\right] \leq M\Delta t^2\mathbb{E}|f(y_0)|^2 = O(\Delta t^2). \tag{5.3}$$

Also, the SSBE convergence result in Theorem 4.7 shows that

$$\mathbb{E}\left[\sup_{0\le t\le T}|\widehat{y}_{\Delta t}(t)-\overline{Y}(t)|^2\right]=O(\Delta t). \tag{5.4}$$

Further,

$$\mathbb{E}\left[\sup_{0\le t\le T}|\overline{Y}(t)-\overline{Z}(t)|^2\right]\le \Delta t^2\mathbb{E}\left[\sup_{0\le t\le T}|f_{\Delta t}(\overline{Y}(t))|^2\right]=O(\Delta t^2), \tag{5.5}$$

because, by Lemma 4.5, $f_{\Delta t}$ is polynomially bounded. Combining (5.3)–(5.5) completes the proof. □

6. Summary. Our aim in this work was to extend strong mean square convergence theory for numerical SDE simulations beyond the realm of globally Lipschitz problems. The only previous published work in this area that we are aware of is [11]. We gave a strong convergence theorem for EM in the case where the vector fields are locally Lipschitz (e.g., C^1) and moment bounds are available. This style of analysis is useful whenever moment bounds can be established, both for the EM method and for other methods that can be shown to be "close" to EM. In general, it is not clear when such moment bounds can be expected to hold for explicit methods with $f, g \in C^1$. However, for an implicit variant of EM, we obtained bounds on all moments in the case where the diffusion coefficient is globally Lipschitz but the drift coefficient satisfies only a one-sided Lipschitz condition. Then, by interpreting the implicit method as EM applied to a modified SDE we were able to get a strong convergence result. We then considered the case where it is further assumed that f behaves like a polynomial. If all moments are bounded, then EM can be shown to converge strongly at the optimal rate, again assuming moment bounds. Moment bounds can be established for two different implicit variants of EM, allowing us to show that these implicit methods converge at the optimal rate. One of these convergence results is comparable to the main result in [11]—we use a stronger error measure but require a more restrictive assumption on the growth of the drift coefficient.

The methods of analysis could be extended to other implicit methods, such as the stochastic theta method with $\theta \in [1/2, 1]$. Such schemes, especially their split-step variants, may be of practical interest for Hamiltonian problems perturbed by damping and/or noise in the case $\theta = 1/2$.

Appendix A. Proofs of Lemmas 3.4 and 4.5.

Proof of Lemma 3.4. Existence and uniqueness for (3.10) can be proved via a contraction mapping theorem, which also establishes the C^1 smoothness of $f_{\Delta t}$ and $F_{\Delta t}$ and the convergence property of $f_{\Delta t}$; see [5, 17]. The smoothness and convergence properties of $g_{\Delta t}$ follow from $g_{\Delta t}(\cdot) = g(F_{\Delta t}(\cdot))$.

An alternative proof of uniqueness for (3.10) via a homotopy argument is given in [9, Theorem 14.2]. We repeat the homotopy construction here, as it will be used to obtain the bound (3.12).

Suppose $h = h(\tau)$ satisfies

$$h = d + \Delta t f(h) + (\tau - 1)\Delta t f(d), \tag{A.1}$$

where τ is our homotopy parameter. For $\tau = 1$, h solves (3.10). For $\tau = 0$ we have

$$h - d = \Delta t\,(f(h) - f(d))$$

and so, using Assumption 3.1,

$$|h-d|^2 = \Delta t\langle h-d, f(h)-f(d)\rangle \le \Delta t\mu |h-d|^2.$$

Note that $\beta > \mu$ so that $2\Delta t\mu < 1$. It follows that $h = d$ is the unique solution to (A.1) when $\tau = 0$. Differentiating (A.1) with respect to τ gives

$$\dot{h} = \Delta t \frac{\partial f}{\partial y}(h)\dot{h} + \Delta t f(d).$$

So

$$|\dot{h}|^2 - \Delta t \left\langle \dot{h}, \frac{\partial f}{\partial y}(h)\dot{h} \right\rangle = \Delta t\langle \dot{h}, f(d)\rangle. \tag{A.2}$$

Setting $a - b = \epsilon u$ in (3.1) and letting $\epsilon \to 0$, we see that

$$\left\langle u, \frac{\partial f}{\partial y}(b)u \right\rangle \le \mu |u|^2 \quad \text{for any } u, b \in \mathbb{R}^m.$$

Hence, in (A.2),

$$|\dot{h}|^2 - \Delta t\mu |\dot{h}|^2 \le \Delta t|\dot{h}|\,|f(d)|.$$

So

$$|\dot{h}| \le \Delta t \frac{|f(d)|}{1-\Delta t\mu}.$$

It follows that $h(\tau)$ exists uniquely for all $\tau > 0$ and

$$|h(1)-d| = \left| \int_0^1 \dot{h}(s)\,ds \right| \le \Delta t \frac{|f(d)|}{1-\Delta t\mu},$$

which establishes (3.12).

To obtain (3.13) we note that if $c^{(1)} = d^{(1)} + \Delta t f(c^{(1)})$ and $c^{(2)} = d^{(2)} + \Delta t f(c^{(2)})$, then

$$|c^{(1)}-c^{(2)}|^2 - \Delta t\langle f(c^{(1)}) - f(c^{(2)}), c^{(1)} - c^{(2)}\rangle = \langle d^{(1)} - d^{(2)}, c^{(2)} - c^{(2)}\rangle$$

and so, using Assumption 3.1,

$$(1-\Delta t\mu)|c^{(1)}-c^{(2)}|^2 \le \frac{1}{2}|d^{(1)}-d^{(2)}|^2 + \frac{1}{2}|c^{(1)}-c^{(2)}|^2,$$

which gives (3.13).

Next, note from the implicit definition (3.11) that $f_{\Delta t}(a)$ is equivalent to $f(a + \Delta t f_{\Delta t}(a))$. Using (3.1) we thus have

$$\langle f_{\Delta t}(a) - f_{\Delta t}(b), a + \Delta t f_{\Delta t}(a) - b - \Delta t f_{\Delta t}(b)\rangle \le \mu |a + \Delta t f_{\Delta t}(a) - b - \Delta t f_{\Delta t}(b)|^2.$$

Hence,

$$\langle f_{\Delta t}(a) - f_{\Delta t}(b), a-b\rangle + \Delta t|f_{\Delta t}(a) - f_{\Delta t}(b)|^2 \le \mu|a-b|^2 + 2\mu\langle a-b, f_{\Delta t}(a) - f_{\Delta t}(b)\rangle\Delta t + \mu\Delta t^2|f_{\Delta t}(a) - f_{\Delta t}(b)|^2,$$

and (3.14) follows.

The global Lipschitz property of $g_{\Delta t}$ follows from (3.13).

Finally, we use $f_{\Delta t}(a) = f(a + \Delta t f_{\Delta t}(a))$ and (3.3) to give

$$\langle f_{\Delta t}(a), a + \Delta t f_{\Delta t}(a)\rangle \le \alpha + \beta|a + \Delta t f_{\Delta t}(a)|^2.$$

Hence

$$(1 - 2\beta\Delta t)\langle f_{\Delta t}(a), a\rangle \le \alpha + \beta|a|^2 + [\beta\Delta t^2 - \Delta t]|f_{\Delta t}(a)|^2 \le \alpha + \beta|a|^2.$$

Since $g_{\Delta t}$ is globally Lipschitz, the inequality (3.15) follows. □

Proof of Lemma 4.5. Recall from Lemma 3.4 that $f_{\Delta t}(a) := f(F_{\Delta t}(a))$, where $F_{\Delta t}$ is globally Lipschitz. Hence,

$$\begin{aligned}|f_{\Delta t}(a) - f_{\Delta t}(b)|^2 &= |f(F_{\Delta t}(a)) - f(F_{\Delta t}(b))|^2 \\ &\le D\,(1 + |F_{\Delta t}(a)|^q + |F_{\Delta t}(b)|^q)\,|F_{\Delta t}(a) - F_{\Delta t}(b)|^2 \\ &\le D'\,(1 + |a|^q + |b|^q)\,|a-b|^2.\end{aligned}$$

Next, it follows from the equivalence of $f_{\Delta t}(a)$ in (3.11) and $f(a + \Delta t f_{\Delta t}(a))$ that

$$|f(a) - f_{\Delta t}(a)|^2 \le D\,(1 + |a|^q + |a + \Delta t f_{\Delta t}(a)|^q)\,\Delta t^2|f_{\Delta t}(a)|^2.$$

From (3.12), $|f_{\Delta t}(a)| \le 2|f(a)|$, and hence we obtain (4.5). A similar argument gives (4.6). □

GALERKIN METHODS IN AGE AND SPACE FOR A POPULATION MODEL WITH NONLINEAR DIFFUSION*

BRUCE P. AYATI† AND TODD F. DUPONT‡

Abstract. We present Galerkin methods in both the age and space variables for an age-dependent population undergoing nonlinear diffusion. The methods presented are a generalization of methods, where the approximation space in age is the space of piecewise constant functions. In this paper, we allow the use of discontinuous piecewise polynomial subspaces of L^2 as the approximation space in age. As in the piecewise constant case, we move the discretization along characteristic lines. The time variable has been left continuous. The methods are shown to be superconvergent in the age variable.

1. Introduction.

We present Galerkin methods in both the age and space variables for a model of an age-dependent population undergoing nonlinear diffusion. The methods presented are a generalization of methods presented in [2], where the approximation space in age was taken to be the space of piecewise constant functions. The use, analysis, and numerical solution of models with dependence on age and time, and of models that also include space, is discussed in [2] and references therein.

In this paper, we allow the use of discontinuous piecewise polynomial subspaces of L^2 as the approximation space in age. As in the piecewise constant case, we move the discretization along characteristic lines. This preserves the important fact that age and time advance together and that the resulting discretization will be dispersion-free.

Some previous numerical methods [8, 9, 12] for age-structured models with spatial diffusion also discretized along characteristics, but they did so simultaneously in age and time and thus imposed the often crippling constraint that the time and age steps be both constant and equal. The difficulty with this approach is twofold. First, the use of constant age and time steps prevents adaptivity of the discretization in age or, especially, time. Second, and more importantly, the coupling of the age and time meshes can cause great losses of efficiency since only rarely will the dynamics in time be on the same scale as the dynamics in age. This is particularly the case when space is involved since sharp moving fronts can require small time steps, whereas the behavior in the age variable can remain relatively smooth. A computational example illustrating the advantages of decoupling age and time is presented in [2] and for the context of *Proteus mirabilis* swarm colony development [6, 14] in Chapter 4 of [1].

The age discretization presented in [8, 9, 12] can be viewed as special cases of the methods presented here and in [2] by setting the time and age meshes to be constant

and equal and using a backward Euler discretization in time and a piecewise constant finite element space in age.

The importance of allowing different age and time discretizations is perhaps illustrated by the application of the methods of de Roos [3]. These methods have found use in the study of ecological systems such as *Daphnia* (see [4] and the references therein) as well as in theoretical population biology [10, 13]. The methods of de Roos are formulated for the case of time and a variable representing some sort of physiological structure, most simply age, and involve moving the age nodes along characteristics. However, the representation of the approximate solution is probabilistic and not functional, and birth and death are handled differently than in this paper. Even so, it would be interesting to know if an energy analysis could provide a framework for the convergence analysis sought in [5]. The main effect of de Roos's methods is to separate the age and time discretizations, while yielding an approximation that is dispersion-free in age, in order to provide a method that works in practice.

The main purpose of this paper is to provide a description and analysis of the use of higher order finite element spaces in the age variable. The time variable has been left continuous. The use of continuous time simplifies the presentation and analysis of the method as well as emphasizes the independence of the age discretization from any suitable time discretization. The methods are shown to be superconvergent in the age variable. We provide an example system that illustrates some of the benefits of using a higher order approximation space in age as well as highlights some of the interactions between the age and time discretizations in these methods.

2. A continuous model. We consider the age-dependent population model with nonlinear diffusion,

$$\partial_t u + \partial_a u = \nabla \cdot \big(k(x,p)\nabla u\big) - \mu(x,a,p)u, \qquad x \in \Omega,\ a > 0,\ t > 0, \tag{2.1}$$

where ∇ and $\nabla\cdot$ denote the gradient and the divergence, respectively, in x. The function $u(x,a,t)$ represents the distribution of individuals, $\Omega \subset \mathbb{R}^n$ represents the spatial domain, a represents age, and t represents time. The function $\mu > 0$ is the death rate. The total population density, p, is given by

$$p(x,t) = \int_0^\infty u(x,a,t)\,da, \qquad x \in \Omega,\ t > 0. \tag{2.2}$$

We have a birth condition

$$u(x,0,t) = b(x,u(x,\cdot,t)), \qquad x \in \Omega,\ t > 0, \tag{2.3}$$

that is dependent on the entire population distribution. We note that b is an operator whose second argument is a function defined on $\mathbb{R}^+$, where $\mathbb{R}^+$ denotes the nonnegative real numbers. The diffusion arises from the symmetric random motion of each individual (Fickian diffusion). We have a Neumann boundary condition, with ν denoting the outward normal to $\partial\Omega$,

$$k(x,p)\nabla u \cdot \nu = 0, \qquad x \in \partial\Omega,\ a > 0,\ t > 0, \tag{2.4}$$

that represents an isolated habitat. The initial condition is

$$u(x,a,0) = u_0(x,a), \qquad x \in \Omega,\ a > 0. \tag{2.5}$$

Langlais [11] proved the existence of unique nonnegative solutions for the case when k, μ, and β in (2.6) are independent of x, and Ω is bounded. A corresponding treatment for the system (2.1)–(2.5) is beyond the scope of this paper; we will concentrate on the numerical aspects of the problem. Thus we assume existence and uniqueness of smooth, nonnegative solutions.

We make several assumptions.

CONDITION 2.1. *There exists constants C_0 and C_1 such that, for $(x,p) \in \Omega \times \mathbb{R}$, k satisfies $0 < C_0 \le k(x,p) \le C_1$ and μ satisfies $0 < C_0 \le \mu(x,a,p) \le C_1$ for all a.*

CONDITION 2.2. *The functions $k(x,p)$ and $\mu(x,a,p)$ are uniformly Lipschitz continuous with respect to p with Lipschitz constants K_k and K_μ, respectively. The derivative $\partial_p k(x,p)$ exists. The derivative $\partial_a \mu(x,a,p)$ exists, is uniformly bounded by C_1 as a function of all its arguments, and $\|\partial_a \mu(x,\cdot,p)\|_{L^2(\mathbb{R}^+)} \le C_1$ uniformly as a function of x and p.*

CONDITION 2.3. *The birth operator, $b : \Omega \times \left(L^1(\mathbb{R}^+) \cap L^2(\mathbb{R}^+)\right) \to \mathbb{R}^+$, is of the form*

$$b(x,\varphi(x,\cdot,t)) = \int_0^\infty \beta(x,a,\Phi)\varphi(x,a,t)\ da, \tag{2.6}$$

where $\beta \ge 0$ is the birth rate and Φ is the total population density, i.e., the integral of φ with respect to age. The function β is assumed to be uniformly Lipschitz continuous as a function of Φ. As a function of a, $\beta(x,a,\Phi)$ is in $H^1(\mathbb{R}^+)$, with its H^1-norm bounded independently of x and Φ; and it is also assumed that there is a positive a_{small} and a natural number k_0 such that $\beta(x,\cdot,\Phi)$ is a polynomial of degree at most k_0 on $(0, a_{small})$ with the coefficients bounded independently of x and Φ.

CONDITION 2.4. *The initial condition, $u_0(x,a)$, is bounded and nonnegative, and there exists $\tilde{a}_{max}$ such that $u_0(x,a) = 0$ for $a > \tilde{a}_{max}$.*

We note that the birth operator, b, is uniformly bounded and satisfies the Lipschitz condition

$$\begin{aligned}|b(x,\varphi(x,\cdot,t)) - b(x,\psi(x,\cdot,t))| \\ \le K_b \left(\left(1 + \|\varphi\|_{L^1(\mathbb{R}^+)}\right) \left| \int_0^\infty (\varphi - \psi)\ da \right| + \|\varphi - \psi\|_{H^{-1}(\mathbb{R}^+)} \right),\end{aligned}$$

where $H^{-1}(\mathbb{R}^+)$ is the dual to $H^1(\mathbb{R}^+)$. The condition that β be polynomial in a for small a allows us to avoid some issues associated with the introduction of a new age interval.

Condition 2.4 is technically convenient and seems mild in light of the exponential decay of u in age [2]. A consequence of this condition is that $u(x,a,t)$ is zero if $a > \tilde{a}_{\max} + t$. Since we are dealing with time in a bounded interval in this work, the fact that the age is bounded above means that the behavior of β for very large a is unimportant.

3. An age and space discrete method. Let $D = \partial_t + \partial_a$. We reuse the symbol k to denote the form

$$k(\Phi;\varphi,v) = \int_\Omega k(x,\Phi)\nabla\varphi \cdot \nabla v\ dx;$$

the distinction between the form and $k(x,\Phi)$ should be clear from context. In variational form, for every $t \in \mathbb{R}^+$ and every $v \in H^1(\Omega) \otimes L^2(\mathbb{R}^+)$, we have

$$\int_0^\infty (Du, v) + k(p; u, v) + (\mu u, v)\ da = (b(x, u(x,\cdot,t)) - u(x,0,t), v(x,0)), \tag{3.1}$$

where $(\cdot,\cdot)$ denotes the L^2-inner product over Ω. Note that no regularity in a is required on v because both sides are zero independent of the choice of v, but we find it useful to think of $v(x,0)$ being the trace of v at $a = 0$ when v is smooth.

Let $\mathcal{M}$ denote a finite dimensional subspace of $H^1(\Omega)$. Let $\{a_i\}_{i=0}^{-\infty}$ be a sequence such that $a_0 = \tilde{a}_{\max}$, $0 < a_{i+1} - a_i < \Delta a$, and $a_i \to -\infty$ as $i \to -\infty$. Let $\mathcal{J}$ be the set of a_i's and let $\check{\mathcal{J}}$ denote the set of $-a_i$'s. For a fixed nonnegative integer q, let $\mathcal{C}$ denote the space of all piecewise continuous functions over the partition of $\mathbb{R}$ defined by $\mathcal{J}$ such that $\varphi \in \mathcal{C}$ has the property that φ restricted to (a_i, a_{i+1}) is a polynomial of degree at most q for $i < 0$ and φ is zero on (a_0, ∞). We define a finite dimensional space in age that moves along the characteristic curves, $da/dt = 1$:

$$\mathcal{A}(t) = \left\{\varphi \in L^2(\mathbb{R}^+) : \varphi(\cdot) = \psi(\cdot - t)\big|_{\mathbb{R}^+},\ \psi \in \mathcal{C}\right\}.$$

Note that the dimension of $\mathcal{A}$ increases by $q+1$ as t goes from $-a_i - 0$ to $-a_i + 0$. This discretization will allow the numerical method to be free of numerical dispersion in age. We take $U(\cdot,\cdot,t) \in \mathcal{M} \otimes \mathcal{A}(t)$. For $t \notin \check{\mathcal{J}}$,

$$\begin{aligned}\int_0^\infty (DU, v) + k(P; U, v) + (\mu(x,a,P)U, v)\ da \\ = (b(x, U(x,\cdot,t)) - U(x,0,t), v(x,0,t))\end{aligned} \tag{3.2}$$

for every $v(\cdot,\cdot,t) \in \mathcal{M} \otimes \mathcal{A}(t)$. So that U is defined across points in $\mathcal{J}$, we require U to be a continuous mapping of time into $L^2(\Omega) \otimes L^2(\mathbb{R}^+)$. The total population density is approximated by

$$P(x,t) = \int_0^\infty U(x,a,t)\ da.$$

We want to emphasize that the function U is differentiable in the characteristic direction so that DU makes sense. Functions in $\mathcal{A}(t)$ are discontinuous, but those discontinuities move along characteristic directions.

The system defined by (3.2) is just a set of ordinary differential equations when $t \notin \check{\mathcal{J}}$. Consider $t \in \check{\mathcal{J}}$. Since the part that is nonstandard is related to the age variables, we will suppress the x variables. Let $\{\varphi_i\}$ denote a basis for $\mathcal{C}$, where each φ_i has support in one interval $[a_k, a_{k+1}]$. Then a natural basis for $\mathcal{A}(t)$ is of the form $\{\varphi_i(\cdot - t)\}$; the functions in the basis for $\mathcal{A}$ are restricted to $\mathbb{R}^+$, and there are only a finite number of these that are nontrivial. The function U is expressed as

$$U(a,t) = \sum_i c_i(t)\varphi_i(a-t) \text{ so that } DU = \sum_i c_i'(t)\varphi_i(a-t).$$

While it is natural to look at a set of relations of the form

$$\int_0^\infty DU(a,t)\varphi_j(a-t)da = F(t,U,\varphi_j) + (b(U) - U(0,t))\varphi_j(0-t) \tag{3.3}$$

as a set of ordinary differential equations for the c_i's, there is a difficulty because the coefficient of the vector of c_i''s is singular at a transition. Note that

$$\int_0^\infty DU\varphi_j(a-t)da + U(0,t)\varphi_j(0-t) = \frac{d}{dt}\int_0^\infty U\varphi_j(a-t)da.$$

Thus (3.3) can be written as $m_j' = F(t,U,\varphi_j) + b(U)\varphi_j(0-t)$, where

$$m_j(t) = \int_0^\infty U(a,t)\varphi_j(a-t)da;$$

these are the natural variables. The initial values for the new m_j's added to the system when t crosses a point of $\tilde{\mathcal{J}}$ are clearly zero because of the assumed continuity of U (as a map into $L^2(\mathbb{R}^+)$) at such points. The m_j's already present are continuous at these transitions. We must check whether the birth operator is Lipschitz with respect to these natural variables. This is easy to confirm in the case in which the function β is polynomial of degree at most k_0 near $a=0$, and that is why we chose to address birth operators of that form. What is needed is that we can choose a basis such that the coefficients of the L^2-projection of $\beta(a)$ into $\mathcal{A}$ are bounded. This is trivial away from $a=0$ because of the equivalence of norms on finite dimensional spaces.

4. Error analysis. Wheeler, in her analysis for parabolic equations [15], showed the value of choosing the right projection in constructing an argument; in her case it was the elliptic projection. In this paper we use a tensor product projection based on an elliptic projection in space and an L^2-projection in age.

It is convenient to use $H^{-1}(\Omega)$ as the dual to $H^1(\Omega)$. Let $\|\cdot\|$, $\|\cdot\|_{L^\infty}$, $\|\cdot\|_{H^1}$, and $\|\cdot\|_{H^{-1}}$ denote the L^2, L^∞, H^1, and H^{-1} norms over Ω, respectively. Suppose that Υ is a normed space with norm $\|\cdot\|_\Upsilon$. Then, for any sufficiently nice function $\varphi : \mathbb{R}^+ \to \Upsilon$, let

$$|\!|\!|\varphi|\!|\!|_\Upsilon^2 = \int_0^\infty \|\varphi(a)\|_\Upsilon^2 \, da.$$

A lack of a subscript indicates $\Upsilon = L^2(\Omega)$. For $\varphi : \Omega \to \Upsilon$, define

$$\|\varphi\|_{L^p(\Omega,\Upsilon)} = \Big\| \, \|\varphi(x)\|_\Upsilon \, \Big\|_{L^p(\Omega)}.$$

We show that the approximate solution U is close to a function X, which is the elliptic projection in space and the L^2-projection in age of the true solution u. Let $\mathsf{A}(t) : L^2(\mathbb{R}^+) \to \mathcal{A}(t)$ denote the L^2-projection. To construct X we first project into space. For each (a,t), we take $\tilde{X}(a,t) \in \mathcal{M}$ such that $k(p; u-\tilde{X}, v) = 0$ for all $v \in \mathcal{M}$ and such that

$$\int_\Omega |u - \tilde{X}| \, dx = 0.$$

Similarly, for each t, we take $Y(t) \in \mathcal{M}$ to satisfy $k(p; p-Y, v) = 0$ for all $v \in \mathcal{M}$ and

$$\int_\Omega |p - Y| \, dx = 0.$$

To project into age, we choose $X(t) \in \mathcal{M} \otimes \mathcal{A}(t)$ such that $X(t) = \mathsf{A}(\tilde{X}(a,t))$. We set

$$\vartheta = U - X, \quad \eta = u - \tilde{X}, \quad \tilde{\eta} = \tilde{X} - X, \quad \varpi = P - Y, \text{ and } \sigma = p - Y.$$

In the following estimate we will suppose that ∇Y and the L^2-norm in age of ∇X are uniformly bounded. We could instead add conditions on $\mathcal{M}$, Ω, and u that would imply these bounds, but this would add complexity with no benefit in understanding why the numerics work. We add the following condition.

CONDITION 4.1. *We suppose the quantities*

$$\|\!|u|\!\|_{L^\infty}, \quad \|u\|_{L^\infty(\Omega\times\mathbb{R}^+)}, \quad \|u\|_{L^\infty(\Omega,L^1(\mathbb{R}^+))}, \quad K_k\|\!|\nabla X|\!\|_{L^\infty}, \|p\|_{L^\infty}, \text{ and } K_k\|\!|\nabla Y|\!\|_{L^\infty}$$

are bounded uniformly in time.

THEOREM 4.1. *Let*

$$\theta_1(t) = \int_0^t C_0(\|\!|\vartheta|\!\|_{H^1}^2 + \|\varpi\|_{H^1}^2)(\tau)\, d\tau,$$

$$\epsilon(t) = \int_0^t (\|\!|\eta|\!\|^2 + \|\sigma\|^2 + \|\!|D\eta|\!\|_{H^{-1}}^2 + \|\partial_t\sigma\|_{H^{-1}}^2 + (\Delta a)^2\|\!|\tilde\eta|\!\|^2 + \|\eta(x,0)\|^2)(\tau)\, d\tau.$$

Assume Conditions 2.1, 2.2, 2.3, 2.4, and 4.1 *hold. There exists* $C^*(t) > 0$ *(dependent only on* K_b, K_μ, C_0, C_1, *and the bounds in Condition* 4.1*) such that*

$$(\|\!|\vartheta|\!\|^2 + \|\varpi\|^2 + \theta_1)(t) \le C^*(t)\big((\|\!|\vartheta|\!\|^2 + \|\varpi\|^2)(0) + \epsilon(t)\big).$$

Remark. This result shows superconvergence of one additional power of Δa in the age variable since only $\tilde\eta$ involves approximation in age. Hence, as a function of age, U is closer to the L^2-projection in age of u than it is to u itself, at least for Δa sufficiently small.

Proof. For this proof C will denote an arbitrary constant with dependencies not greater than those of C^*. When only a single argument is given to U, u, η, $\tilde\eta$, or ϑ, that argument denotes age.

Subtract (3.1) from (3.2) and let $v = \vartheta$ to get

$$\int_0^\infty (D(\vartheta - \eta - \tilde\eta), \vartheta) + k(P;U,\vartheta) - k(p;u,\vartheta) + (\mu(P)U,\vartheta) - (\mu(p)u,\vartheta)\, da + (U(0) - u(0), \vartheta(0)) = (b(U) - b(u), \vartheta(0)). \tag{4.1}$$

By orthogonality, for $v(\cdot,\cdot,t) \in \mathcal{M}\otimes\mathcal{A}(t)$,

$$\int_0^\infty (\tilde\eta, v)\, da = 0. \tag{4.2}$$

For $t \notin \check{\mathcal{J}}$, let $\delta > 0$ be such that $(t-\delta, t+\delta)\cap\check{\mathcal{J}} = \emptyset$. For a given $v(\cdot,\cdot,t) \in \mathcal{M}\otimes\mathcal{A}(t)$ and $-s \in (t-\delta, t+\delta)$, take $v(\cdot,\cdot,s) \in \mathcal{M}\otimes\mathcal{A}(s)$ such that v is constant along characteristics. By (4.2) we have, for $0 < \Delta t < \delta$,

$$\begin{aligned}
0 &= \frac{1}{\Delta t}\int_0^\infty \big(\tilde\eta(\cdot,a,t+\Delta t), v(\cdot,a,t+\Delta t)\big) - \big(\tilde\eta(\cdot,a,t), v(\cdot,a,t)\big)\, da \\
&= \frac{1}{\Delta t}\int_0^\infty \big(\tilde\eta(\cdot,a+\Delta t,t+\Delta t) - \tilde\eta(\cdot,a,t), v(\cdot,a+\Delta t,t+\Delta t)\big)\, da \\
&\quad + \frac{1}{\Delta t}\int_0^{\Delta t} \big(\tilde\eta(\cdot,a,t+\Delta t), v(\cdot,a,t+\Delta t)\big)\, da \\
&\quad + \frac{1}{\Delta t}\int_0^\infty \big(\tilde\eta(\cdot,a,t), v(\cdot,a+\Delta t,t+\Delta t) - v(\cdot,a,t)\big)\, da.
\end{aligned}$$

In this expression the last term is zero because v is constant along characteristics. Taking limits we see that for $v(\cdot,\cdot,t) \in \mathcal{M} \otimes \mathcal{A}(t)$,

$$\int_0^\infty \big(D\tilde{\eta}(\cdot,a,t), v(\cdot,a,t)\big)\ da + \big(\tilde{\eta}(\cdot,0,t), v(\cdot,0,t)\big) = 0.$$

Hence, with $v = \vartheta$, we note that

$$\begin{aligned}(4.3)\qquad \big(U-u,\vartheta\big)(0) - \int_0^\infty \big(D\tilde{\eta},\vartheta\big)\ da &= \big(\vartheta-\eta-\tilde{\eta},\vartheta\big)(0) - \int_0^\infty \big(D\tilde{\eta},\vartheta\big)\ da \\ &= \|\vartheta(0)\|^2 - \big(\eta,\vartheta\big)(0) \\ &\geq \frac{3}{4}\|\vartheta(0)\|^2 - \|\eta(0)\|^2.\end{aligned}$$

Rearranging terms in (4.1) and applying (4.2) and (4.3) gives

$$\begin{aligned}\int_0^\infty (D\vartheta,\vartheta) + k(P;\vartheta,\vartheta) + (\mu(P)\vartheta,\vartheta)\ da + \frac{3}{4}\|\vartheta(0)\|^2 \\ \leq \int_0^\infty (k(x,Y)-k(x,P), \nabla X\cdot\nabla\vartheta) + (k(x,p)-k(x,Y), \nabla X\cdot\nabla\vartheta)\ da \\ + \int_0^\infty ((\mu(p)-\mu(P))u,\vartheta) + (D\eta,\vartheta) + (\mu(P)(\eta+\tilde{\eta}),\vartheta)\ da \\ + \ (b(U)-b(u),\vartheta(0)) + \|\eta(0)\|^2.\end{aligned}$$

We have the equality

$$\int_0^\infty (D\vartheta,\vartheta)\ da = \frac{1}{2}\int_0^\infty D\|\vartheta\|^2\ da = \frac{1}{2}\partial_t|\!|\!|\vartheta|\!|\!|^2 - \frac{1}{2}\|\vartheta(0)\|^2.$$

Using Conditions 2.1–2.2, Hölder's inequality, and the arithmetic-geometric inequality, $yz \leq \frac{1}{2}(\varepsilon y^2 + (1/\varepsilon)z^2)$, we get the following bounds:

$$\begin{aligned}\int_0^\infty k(P;\vartheta,\vartheta) + (\mu(P)\vartheta,\vartheta)\ da &\geq C_0|\!|\!|\vartheta|\!|\!|^2_{H^1}, \\ \int_0^\infty (k(x,Y)-k(x,P),\nabla X\cdot\nabla\vartheta)\ da &\leq \int_0^\infty (K_k|\varpi|, |\nabla X\cdot\nabla\vartheta|)\ da \\ &\leq \frac{2K_k^2}{C_0}|\!|\!|\nabla X|\!|\!|^2_{L^\infty}\|\varpi\|^2 + \frac{C_0}{8}|\!|\!|\vartheta|\!|\!|^2_{H^1}, \\ \int_0^\infty (k(x,Y)-k(x,P),\nabla X\cdot\nabla\vartheta)\ da &\leq \frac{2K_k^2}{C_0}|\!|\!|\nabla X|\!|\!|^2_{L^\infty}\|\sigma\|^2 + \frac{C_0}{8}|\!|\!|\vartheta|\!|\!|^2_{H^1}, \\ \int_0^\infty ((\mu(p)-\mu(P))u,\vartheta)\ da &\leq \int_0^\infty (K_\mu|P-p|, |u\vartheta|)\ da \\ &\leq \frac{K_\mu}{2}|\!|\!|u|\!|\!|_{L^\infty}\left(2(\|\varpi\|^2+\|\sigma\|^2) + |\!|\!|\vartheta|\!|\!|^2\right), \\ \int_0^\infty (D\eta,\vartheta)\ da &\leq \frac{1}{C_0}|\!|\!|D\eta|\!|\!|^2_{H^{-1}} + \frac{C_0}{4}|\!|\!|\vartheta|\!|\!|^2_{H^1}, \\ \int_0^\infty (\mu(P)\eta,\vartheta)\ da &\leq \frac{C_1}{2}(|\!|\!|\eta|\!|\!|^2 + |\!|\!|\vartheta|\!|\!|^2).\end{aligned}$$

Let $\bar{\mu}$ denote the average of μ in age over each interval of the age discretization. Then

$$\begin{aligned}\int_0^\infty (\mu(P)\tilde{\eta},\vartheta)\ da &= \int_0^\infty \big((\mu(P)-\bar{\mu}(P))\tilde{\eta},\vartheta\big)\ da\\ &\le \frac{1}{2}\big(\|\mu(P)-\bar{\mu}(P)\|^2_{L^\infty(\Omega\times\mathbb{R}^+)}|\!|\!|\tilde{\eta}|\!|\!|^2+|\!|\!|\vartheta|\!|\!|^2\big)\\ &\le \frac{(\Delta a)^2}{8}C_1^2|\!|\!|\tilde{\eta}|\!|\!|^2+\frac{1}{2}|\!|\!|\vartheta|\!|\!|^2.\end{aligned}$$

For the birth term we make the bound

$$\begin{aligned}(b(U)-b(u),\vartheta(0)) &\le \|b(U)-b(u)\|^2+\frac{1}{4}\|\vartheta(0)\|^2\\ &\le 3K_b^2\Big((1+\|u\|^2_{L^\infty(\Omega,L^1(\mathbb{R}^+))})\|P-p\|^2\\ &\qquad +\|U-u\|^2_{L^2(\Omega,H^{-1}(\mathbb{R}^+))}\Big)+\frac{1}{4}\|\vartheta(0)\|^2.\end{aligned}$$

We combine the above inequalities and use the fact that $\|\tilde{\eta}\|_{L^2(\Omega,H^{-1}(\mathbb{R}^+))}\le\frac{\Delta a}{\pi}|\!|\!|\tilde{\eta}|\!|\!|$ (see Appendix A of [2]) to get

$$\begin{aligned}\partial_t|\!|\!|\vartheta|\!|\!|^2+C_0|\!|\!|\vartheta|\!|\!|^2_{H^1} &\le C\Big(\|\varpi\|^2+|\!|\!|\vartheta|\!|\!|^2+\|\sigma\|^2+|\!|\!|\eta|\!|\!|^2+|\!|\!|D\eta|\!|\!|^2_{H^{-1}}\\ &\qquad +(\Delta a)^2|\!|\!|\tilde{\eta}|\!|\!|^2+\|\eta(0)\|^2\Big).\end{aligned}\tag{4.4}$$

Before we can use the above evolution inequality to get bounds on the error, we need corresponding relationships for the total population density. We integrate (2.1) over a and take the inner product with a test function $v\in\mathcal{M}$ to obtain

$$(\partial_t p,v)+k(p;p,v)+\left(\int_0^\infty \mu(p)u\ da\,,v\right)=(b(u),v).\tag{4.5}$$

For the approximate total population density we have

$$(\partial_t P,v)+k(P;P,v)+\left(\int_0^\infty \mu(P)U\ da\,,v\right)=(b(U),v).\tag{4.6}$$

We subtract (4.5) from (4.6) and let $v=\varpi$ to get

$$\begin{aligned}\frac{1}{2}\partial_t\|\varpi\|^2+k(P;P,\varpi)-k(p;p,\varpi)+\left(\int_0^\infty \mu(P)U-\mu(p)u\ da,\varpi\right)\\ =(b(U)-b(u),\varpi)+(\partial_t\sigma,\varpi).\end{aligned}$$

This has a form similar to (4.1). We have the bound

$$\begin{aligned}\left(\int_0^\infty \mu(P)\tilde{\eta}\ da,\varpi\right) &= \left(\int_0^\infty (\mu(P)-\bar{\mu}(P))\tilde{\eta}\ da,\varpi\right)\\ &\le \Big(\|\mu(x,\cdot,P)-\bar{\mu}(x,\cdot,P)\|^2_{L^2(\mathbb{R}^+)}\|\tilde{\eta}(x,\cdot,t)\|^2_{L^2(\mathbb{R}^+)},\varpi\Big)\\ &\le \frac{(\Delta a)^2C_1^2}{2\pi^2}|\!|\!|\tilde{\eta}|\!|\!|^2+\frac{1}{2}\|\varpi\|^2.\end{aligned}$$

Using bounds similar to those for (4.1) for the other terms gives

$$\partial_t\|\varpi\|^2 + C_0\|\varpi\|^2_{H^1} \le C\Big(\|\varpi\|^2 + |\!|\!|\vartheta|\!|\!|^2 + \|\sigma\|^2 + |\!|\!|\eta|\!|\!|^2 + \|\partial_t\sigma\|^2_{H^{-1}} + (\Delta a)^2|\!|\!|\tilde{\eta}|\!|\!|^2\Big). \tag{4.7}$$

By adding (4.4) and (4.7) and applying a Gronwall's lemma,[1] we obtain the stated result. □

5. Computational example. In this section we provide a computational example that shows some of the benefits of using a higher order approximation space in the age variable. In particular, we are able to use a coarser age discretization for the same or better error.

The example system in [2] illustrates the importance of being able to decouple the age and time discretizations so that the age and time steps are neither uniform nor equal. The spatial dynamics of the problem require small time steps for accurate resolution. The small time steps taken in the simulation, particularly the initial step, are caused by roughness in space. The behavior in age is relatively smooth, which in turn calls for a much coarser discretization in age than in time.

The example presented in [2] was meant to illustrate the need for a method that discretizes age and time separately because of the influence of space. It does not clearly illustrate two aspects of the interaction of age and time. First, it is not clear what is needed to align the introduction of an age interval with the start of a time step. Second, it does not illustrate the level to which the age dynamics of a system will determine the size of the time step.

We present an example system that illustrates the benefits of using higher order approximation spaces in age, as well as some aspects of the interaction of age and time in these methods. In order to achieve the latter goal, we assume uniformity in space. Because the dynamics in age can be, and often are, independent of space, the benefits of using higher order polynomial spaces in age will generalize to systems that include spatial dynamics.

We consider the system (2.1)–(2.5) with $k = 0$. We use the birth term,

$$b(x, u(x,\cdot,t)) = \int_0^\infty 5a\,u\;da,$$

so that fecundity increases linearly with age. For the death modulus, we use

$$\mu(x,a,p) = \mu(a) = \frac{10e^{10(a-0.8)}}{e^{10(a-0.8)} + e^{-10(a-0.8)}} + \frac{1}{2}.$$

This represents a situation where mortality remains low until around a certain age, at which point it increases dramatically. This is the case in *Proteus mirabilis* swarm colony development [6].

For the initial condition, we use a population of older organisms,

$$u_0(x,a) = 128|a-0.5|^3 - 48(a-0.5)^2 + 1,$$

if $|a-0.5| < 0.25$, and $u_0(x,a) = 0$, otherwise.

[1] Assume $u, b, c \ge 0$ are continuous and $g \ge 0$ is differentiable. Then $g'(t) + b(t) \le c(t) + u(t)g(t)$ implies $g(t) + \int_0^t b(\tau)\;d\tau \le \exp(\int_0^t u(\tau)\;d\tau)(g(0) + \int_0^t c(\tau)\;d\tau)$.

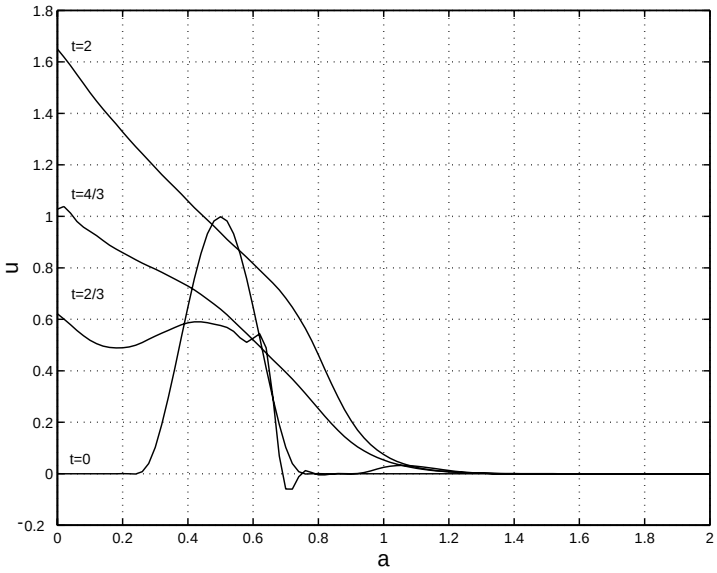

FIG. 5.1. *Profiles of the population density, u. The profiles are $t = 2/3$ apart.*

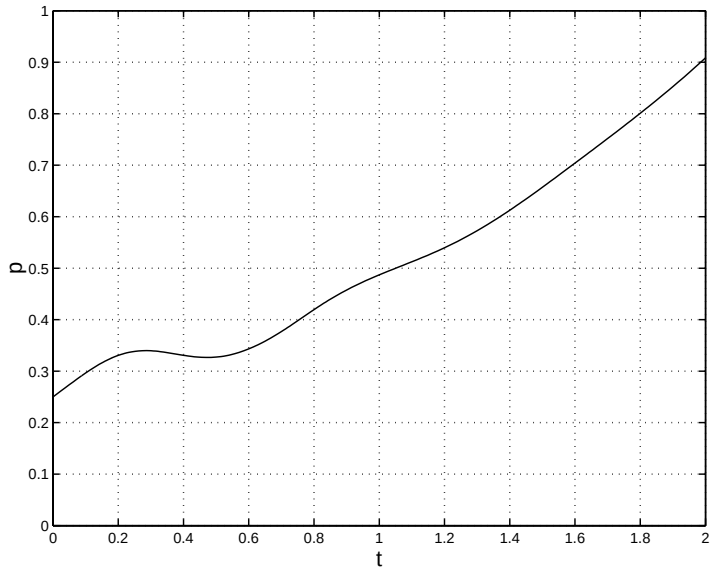

FIG. 5.2. *The total population density, p.*

We take the temporal domain to be $[0, 2]$. We find that truncating the age domain to $[0, 2]$ is sufficient. We assume uniformity of the solution over the spatial domain Ω.

We implement step-size control in time via step-doubling (without extrapolation) [1, 7]. This means that for each time step we take a step of size Δt and compare it to the solution obtained by taking two steps of size $\Delta t/2$. We adjust a parameter that limits local truncation error so that the simulation is well resolved in time.

For the age discretization, we assume $\mathcal{J}$ is uniform with age intervals of size Δa.

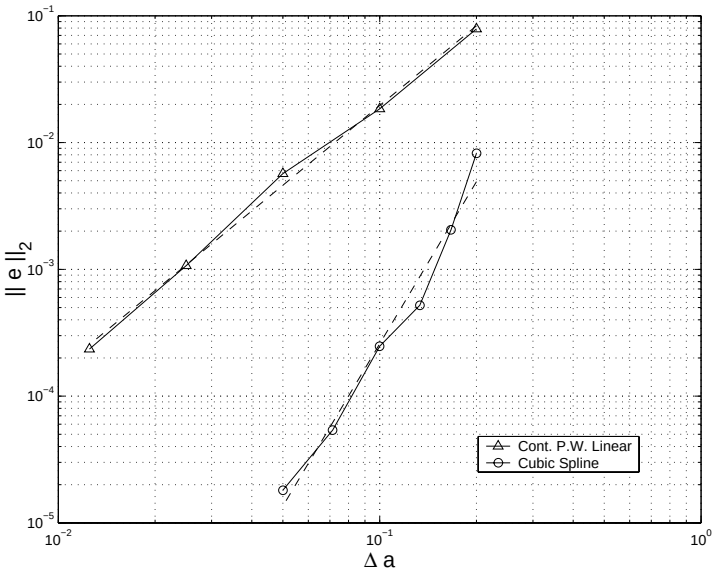

FIG. 5.3. *Convergence study for $q = 0$ and $q = 1$ showing second order and fourth order convergence of the method, respectively. The comparison is of the computed solution, u, at time $t = 2$. The slope of the least squares fit for the piecewise constant case postprocessed to continuous piecewise linear functions is approximately* 2.09. *The slope of the least squares fit for the discontinuous piecewise linear case postprocessed to cubic splines is approximately* 4.25.

In other words, all age intervals that are not the birth interval are of length Δa. We study the convergence of the method with piecewise constants postprocessed to continuous piecewise linear functions ($q = 0$) and with discontinuous piecewise linear functions postprocessed to cubic splines ($q = 1$). The postprocessing for piecewise constants was discussed in [2]; it involves using knot values that are obtained from a line connecting the midpoints of adjacent intervals. The cubic splines can be produced from the discontinuous linear functions in several ways; here we used the two Gauss points in each of two adjacent intervals to define a cubic that is used to give knot values and slopes. This is a natural choice since the L^2-projection into discontinuous piecewise linear functions is superconvergent at the two Gauss points.

Figure 5.1 shows solution profiles $t = 2/3$ apart for the simulation using $q = 1$ and $\Delta a = 0.1$. The solution at $t = 2/3$ has a discontinuity because the initial condition does not contain any newborns. However, this discontinuity dies out over time. Figure 5.2 shows the growth of the total population density. There is a period of population decline, due to the die-off of the initial population, before the population enters a stage of exponential growth.

Figure 5.3 shows the results of a convergence study using $q = 0$ and $q = 1$ with postprocessing. The error is determined by comparison with the numerical solution solved with $\Delta a = 6.25 \times 10^{-3}$ for the case of $q = 0$ and $\Delta a = 2.5 \times 10^{-2}$ for $q = 1$. We get the expected result that the use of discontinuous piecewise linear functions gives fourth order convergence with much better initial error than the second order convergence given by the use of piecewise constants.

Figure 5.4 shows the time steps taken for the simulation using $q = 1$ and $\Delta a = 0.1$. We find that the time step needed to resolve this simulation is roughly 10^{-2}, with the exception of a trough at $t \approx 1.8$ that corresponds to the die-off of the relatively

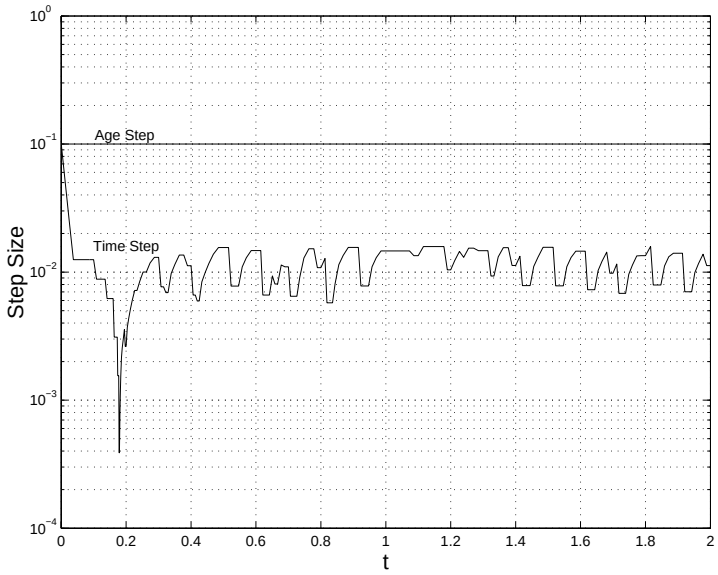

FIG. 5.4. *Step sizes for the age and time discretizations. There were* 204 *accepted steps and* 22 *rejected steps during the simulation. The smallest step size was approximately* 3.88×10^{-4} *taken at* $t \approx 1.8$. *This trough corresponds to the die-off of the relatively large initial population of older individuals.*

large initial population of older individuals. The need for this small time step is due to the increased complexity of the underlying problem at this point, not the moving age grid.

The restrictions on the time steps imposed by the age discretization are due to the need to introduce a new age interval at the start of a time step. This requires that $\Delta t \leq \Delta a$. Moreover, this restriction may require a slightly smaller time step before the introduction of a new age interval at the birth boundary. Smaller time steps may also be needed during the initial birthing into a new age interval. These cause the minor time step fluctuations we see throughout the latter part of the simulation.

SQUEEZABLE ORTHOGONAL BASES: ACCURACY AND SMOOTHNESS*

GEORGE C. DONOVAN†, JEFFREY S. GERONIMO‡, AND DOUGLAS P. HARDIN§

Abstract. We present a method for generating local orthogonal bases on arbitrary partitions of $\mathbf{R}$ from a given local orthogonal shift-invariant basis via what we call a *squeeze map*. We give necessary and sufficient conditions for a squeeze map to generate a nonuniform basis that preserves any smoothness and/or accuracy (polynomial reproduction) of the shift-invariant basis. When the shift-invariant basis has sufficient smoothness or accuracy, there is a unique squeeze map associated with a given partition that preserves this property and, in this case, the squeeze map may be calculated locally in terms of the ratios of adjacent intervals. If both the smoothness and accuracy are large enough, then the resulting nonuniform space contains the nonuniform spline space characterized by that smoothness and accuracy.

Our examples include a multiresolution on nonuniform partitions such that each space has a local orthogonal basis consisting of continuous piecewise quadratic functions. We also construct a family of smooth, local, orthogonal, piecewise polynomial generators with arbitrary approximation order.

Key words. orthogonal bases, nonuniform grids, polynomial reproduction, piecewise polynomial, multiresolution

1. Introduction.

Finitely generated shift-invariant (FSI) spaces naturally arise in several areas of numerical analysis and approximation theory, including the theory of splines and wavelets. A major advantage of an FSI space is the existence of a convenient basis generated by a (usually) small number of functions. When the basis is local and orthogonal the process of finding the orthogonal projection Pf of $f \in L^2(\mathbf{R})$ onto the space is local so that changing f on a compact interval affects only Pf on a slightly larger interval.

In this paper we introduce and investigate a method for adapting local shift-invariant bases to nonuniform partitions via what we call a *squeeze map*. When the shift-invariant basis is orthogonal, the squeeze map may be chosen so that the nonuniform basis is also orthogonal.

The notion of squeeze maps generalizes ideas introduced in [4], where we gave examples of local orthogonal piecewise polynomial shift-invariant bases that are easily adaptable to arbitrary grids in $\mathbf{R}$. The focus of this paper is on characterizing when a squeeze map generates a nonuniform basis preserving any smoothness and/or accuracy (polynomial reproduction) of the shift-invariant basis. When the shift-invariant basis has sufficient smoothness or accuracy, there is a unique squeeze map associated with a given partition of $\mathbf{R}$ that preserves this property and, in this case, the squeeze map may be calculated locally in terms of the ratios of adjacent intervals. When both the smoothness and accuracy are large enough, we find that the resulting nonuniform

space contains the nonuniform spline space characterized by that smoothness and accuracy.

Two applications that provide motivation for our work are adaptive least squares and the construction of orthogonal wavelets on semiregular and irregular families of grids:

(1) Since the bases constructed here are local and orthogonal and depend locally on the given grid, it is relatively easy to calculate changes in the orthogonal projection of a given function (onto the span of this basis) resulting from changes in the grid, making them well suited for adaptive least square problems.

(2) While we do not focus on refinable spaces in this paper, it is the refinable case that provides the main motivation for our study. We remark that our methods provide a means to adapt a multiresolution on uniform grids to one on a semiuniform family of grids (that is, an arbitrary coarse grid that is uniformly subdivided). In the example in section 6.3, we start with Daubechies's famous orthogonal scaling function ${}_2\phi$. We find that, given a nonuniform grid, there is a unique squeeze map that preserves the accuracy of the space. In the example in section 6.4, we use ideas from [5] to construct a multiresolution on an arbitrary nonuniform subdivision. (The only requirement is that each interval is subdivided into two subintervals.) Each space has a local orthogonal basis consisting of continuous piecewise quadratic functions.

Finally, in section 7 we construct a family of smooth, local, orthogonal, piecewise polynomial generators with arbitrary approximation order using techniques developed in [6]. These generators have fewer components than the corresponding refinable generators constructed in [6], and so we prefer them when refinability is not required. We mention that a possible application of this family is to code division multiple access (CDMA) technology, where several users share a single channel using orthogonal decompositions.

1.1. Shift-invariant spaces. We call a compactly supported, finite-length (column) vector

$$\Phi = \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_n \end{pmatrix} \in L^2(\mathbf{R})^n$$

a *generator*. Note that when it is clear from the context, we also consider a generator Φ to be the set of its components; that is, we also consider $\Phi \subset L^2(\mathbf{R})$. When we refer to the span of Φ we mean the subspace of $L^2(\mathbf{R})$ spanned by the components of Φ.

For a generator Φ, let

$$B(\Phi) := \{\phi_i(\cdot - j) \mid j \in \mathbf{Z}, i = 1, \ldots, n\}.$$

If $B(\Phi)$ is an orthogonal set, we say Φ is an *orthogonal generator*. For a generator Φ, let

$$S(\Phi) := \left\{ \sum_{j \in \mathbf{Z}} c(j)^\top \Phi(\cdot - j) \mid c(j) \in \mathbf{R}^n, j \in \mathbf{Z} \right\}.$$

If $V = S(\Phi)$ for some generator Φ, then V is called a *finitely generated shift-invariant* (FSI) space.

1.2. Minimally supported generators. Our procedure for constructing local bases on nonuniform partitions starts with generators supported on $[-1,1]$ satisfying a local linear independence condition on $[0,1]$. In particular, for $k \le n$, we say that a generator

$$\Phi = \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_k \\ \phi_{k+1} \\ \vdots \\ \phi_n \end{pmatrix} = \begin{pmatrix} \bar{\Phi} \\ \breve{\Phi} \end{pmatrix}$$

(where $\bar{\Phi}$ consists of the first k elements of Φ and $\breve{\Phi}$ consists of the last $n-k$) is a *minimally supported k-generator* (or just *minimally supported*) if

(1) supp $\Phi \subset [-1,1]$;
(2) supp $\breve{\Phi} \subset [0,1]$;
(3) the collection $\breve{\Phi} \cup \bar{\Phi}\chi_{[0,1]} \cup (\bar{\Phi}(\cdot - 1))\chi_{[0,1]}$ is linearly independent.

We denote the collection of all minimally supported k-generators with n components by $\mathcal{G}_k^n$. See section 5 for several illustrative examples of orthogonal minimally supported generators. The notion of generators minimally supported on $[-1,1]$ played a central role in the construction of orthogonal, smooth, piecewise polynomial wavelets given in [5].

For $\Phi \in \mathcal{G}_k^n$, we denote the "left" and "right" pieces of $\bar{\Phi}$ by

$$\Phi_R := \bar{\Phi}\chi_{[0,1]} \text{ and } \Phi_L := \bar{\Phi}\chi_{[-1,0)}.$$

Obviously, condition (3) can be rewritten as $\breve{\Phi} \cup \Phi_R \cup \Phi_L(\cdot - 1)$ is linearly independent. If Φ is minimally supported, then it follows from the local linear independence condition (3) above that $B(\Phi)$ is linearly independent; that is, any $f \in S(\Phi)$ has a unique representation of the form $f = \sum c_j \Phi(\cdot - j)$. In the remainder of this paper, when there is clearly some underlying minimally supported generator with k and n as above, then, for any (row or column) vector v of length n, we let $\bar{v}$ denote the subvector of the first k components of v and $\breve{v}$ the subvector of the last $n-k$ components of v.

Also, for $f, g \in L^2(\mathbf{R})^n$ we define $\langle f, g \rangle := \int_{\mathbf{R}} f(x)g(x)^\top dx \in \mathbf{R}^{n\times n}$, where $v^\top$ denotes the transpose of a (column) vector v.

2. Squeeze maps. Let $a = (a_j)_{j\in\mathbf{Z}}$ be a strictly increasing real-valued sequence with no accumulation point in $\mathbf{R}$, in which case we call a a *knot sequence*. Let $L_j := a_{j+1} - a_j$ denote the length of the jth interval $[a_j, a_{j+1}]$ and let $\tau_j = \tau_j^a$ be given by

$$\tau_j(x) = \begin{cases} (x - a_j)/L_{j-1} & \text{for } x \le a_j, \\ (x - a_j)/L_j & \text{for } x \ge a_j. \end{cases} \tag{2.1}$$

Then τ_j maps the points a_{j-1}, a_j, and a_{j+1} to -1, 0, and 1, respectively.

Suppose Φ is an orthogonal minimally supported generator. Consider

$$B_0 = \bigcup_{j\in\mathbf{Z}} \Phi \circ \tau_j.$$

If Φ is continuous and $k = 1$ (for example, see the example in section 6.1), then (because τ_j is affine on each "overlap" interval $[a_j, a_{j+1}]$ and continuous on $\mathbf{R}$) it follows that B_0 is a continuous orthogonal basis for its span.

On the other hand, if $\Phi \in C^1(\mathbf{R})$ and $\Phi'(0) \neq 0$ (for example, consider the continuously differentiable Φ with $k = 2$ in the example in section 6.2), then the components of B_0 are not in $C^1(\mathbf{R})$ for nonuniform a. In particular, $\bar{\Phi} \circ \tau_j$ is not differentiable at a_j unless $L_{j-1} = L_j$. This leads us to consider a more general construction in which linear combinations of $\bar{\Phi}_L \circ \tau_j$ are pieced together with linear combinations of $\bar{\Phi}_R \circ \tau_j$ via what we call a *squeeze map*.

More specifically, let $A_{\mathrm{L}}^{(j)}$ and $A_{\mathrm{R}}^{(j)}$ be invertible $k \times k$ matrices for $j \in Z$ and let $A_j : \mathbf{R} \to \mathbf{R}^{k\times k}$ denote the matrix-valued function on $\mathbf{R}$ defined by

$$A_j = \chi_{[-1,0)} A_{\mathrm{L}}^{(j)} + \chi_{[0,1]} A_{\mathrm{R}}^{(j)}.$$

Given A and a knot sequence a, we call the sequence of mappings $\sigma = (\sigma_j)_{j\in\mathbf{Z}}$, where $\sigma_j : \mathcal{G}_k^n \to L^2(\mathbf{R})^n$ is given by

$$\sigma_j(\Phi) = \begin{pmatrix} A_j \bar{\Phi} \circ \tau_j \\ \breve{\Phi} \circ \tau_j \end{pmatrix},$$

a *squeeze map (on $\mathcal{G}_k^n$)*.

As before, we let $\bar{\sigma}_j(\Phi)$ denote the vector of the first k components of $\sigma_j(\Phi)$ and $\breve{\sigma}_j(\Phi)$ the remaining $n - k$ components. Observe that

$$\bar{\sigma}_j(\Phi) = \left(\chi_{[-1,0)} A_{\mathrm{L}}^{(j)} \bar{\Phi} + \chi_{[0,1]} A_{\mathrm{R}}^{(j)} \bar{\Phi}\right) \circ \tau_j = \left(A_{\mathrm{L}}^{(j)} \Phi_L + A_{\mathrm{R}}^{(j)} \Phi_R\right) \circ \tau_j$$

and $\mathrm{supp}\bar{\sigma}_j(\Phi) \subset [a_{j-1}, a_{j+1}]$, while $\mathrm{supp}\breve{\sigma}_j(\Phi) \subset [a_j, a_{j+1}]$.

If σ is a squeeze map on $\mathcal{G}_k^n$ and $\Phi \in \mathcal{G}_k^n$, then we define

$$B_\sigma(\Phi) := \bigcup_{j\in\mathbf{Z}} \sigma_j(\Phi)$$

and

$$S_\sigma(\Phi) := \left\{ \sum_{j\in\mathbf{Z}} c(j)^\top \sigma_j(\Phi) \mid c(j) \in \mathbf{R}^n, j \in \mathbf{Z} \right\}.$$

The minimal support of Φ and the invertibility of $A_{\mathrm{L}}^{(j)}$ and $A_{\mathrm{R}}^{(j)}$ imply that $B_\sigma(\Phi)$ is linearly independent.

If σ is a squeeze map with matrix sequences $(A_{\mathrm{L}}^{(j)})$ and $(A_{\mathrm{R}}^{(j)})$, we define

$$R_j = R_j(\sigma) := (A_{\mathrm{L}}^{(j)})^{-1} A_{\mathrm{R}}^{(j)} \qquad (j \in \mathbf{Z}).$$

We say that two squeeze maps σ and ν on $\mathcal{G}_k^n$ are *equivalent* whenever $S_\sigma(\Phi) = S_\nu(\Phi)$ for any $\Phi \in \mathcal{G}_k^n$.

LEMMA 2.1. *Suppose σ and ν are squeeze maps on $\mathcal{G}_k^n$. Then σ and ν are equivalent if and only if*

$$R_j(\sigma) = R_j(\nu) \qquad (j \in \mathbf{Z}). \tag{2.2}$$

Proof. Suppose (2.2) holds. Then

$$\left(A_{\mathrm{L}}^{(j)}\right)^{-1}\bar{\sigma}_j(\Phi) = \left(\tilde{A_{\mathrm{L}}}^{(j)}\right)^{-1}\bar{\nu}_j(\Phi) \qquad (j \in \mathbf{Z}),$$

where σ has matrix sequences $(A_{\mathrm{L}}^{(j)})$ and $(A_{\mathrm{R}}^{(j)})$ and ν has matrix sequences $(\tilde{A_{\mathrm{L}}}^{(j)})$ and $(\tilde{A_{\mathrm{R}}}^{(j)})$. Since $A_{\mathrm{L}}^{(j)}$ and $\tilde{A_{\mathrm{L}}}^{(j)}$ are nonsingular the above shows that $\bar{\sigma}_j(\Phi)$ and $\bar{\nu}_j(\Phi)$ (considered as sets) have the same span. By definition $\breve{\sigma}_j(\Phi)$ and $\breve{\nu}_j(\Phi)$ have the same span showing that $\sigma_j(\Phi)$ and $\nu_j(\Phi)$ have the same span, and hence $S_\sigma(\Phi) = S_\nu(\Phi)$.

On the other hand, if $S_\sigma(\Phi) = S_\nu(\Phi)$, then the local linear independence of $B_\sigma(\Phi)$ and $B_\nu(\Phi)$ shows that $\bar{\sigma}_j(\Phi)$ and $\bar{\nu}_j(\Phi)$ have the same span for each $j \in \mathbf{Z}$. Thus, there must be some nonsingular matrix W_j such that

$$\bar{\nu}_j(\Phi) = W_j\bar{\sigma}_j(\Phi) \qquad (j \in \mathbf{Z}),$$

which implies that (2.2) holds. ∎

Our motivation for considering squeeze maps is that if Φ is a minimally supported orthogonal generator, then we can always find a local orthogonal basis for $S_\sigma(\Phi) \cap L^2(\mathbf{R})$. To see this, note that the elements of $\bar{\sigma}_j(\Phi)$ are orthogonal to the elements of $\bar{\sigma}_{j+1}(\Phi)$:

$$\langle\bar{\sigma}_j(\Phi), \bar{\sigma}_{j+1}(\Phi)\rangle = L_j A_{\mathrm{R}}^{(j)}\langle\Phi_R, \Phi_L(\cdot - 1)\rangle\left(A_{\mathrm{L}}^{(j+1)}\right)^{\top} = 0 \qquad (j \in \mathbf{Z}).$$

It then follows that $\sigma_j(\Phi)$ is orthogonal to $\sigma_{j'}(\Phi)$ for any $j \neq j' \in \mathbf{Z}$. Finally, for each $j \in \mathbf{Z}$, we choose some orthogonal basis for the span of $\bar{\sigma}_j(\Phi)$ (for instance, by applying the Gram–Schmidt process to $\bar{\sigma}_j(\Phi)$). This change of basis corresponds to constructing a squeeze map ν equivalent to σ such that $B_\nu(\Phi)$ is an orthogonal set and is equivalent to performing the following matrix factorization: Let $B_jB_j^{\top}$ be a Cholesky factorization of $\langle\bar{\sigma}_j, \bar{\sigma}_j\rangle$, that is,

(2.3)
$$B_jB_j^{\top} = \langle\bar{\sigma}_j(\Phi), \bar{\sigma}_j(\Phi)\rangle = L_{j-1}A_{\mathrm{L}}^{(j)}\langle\Phi_L, \Phi_L\rangle\left(A_{\mathrm{L}}^{(j)}\right)^{\top} + L_jA_{\mathrm{R}}^{(j)}\langle\Phi_R, \Phi_R\rangle\left(A_{\mathrm{R}}^{(j)}\right)^{\top}.$$

Then ν with matrix sequences $(B_j^{-1}A_{\mathrm{L}}^{(j)})$ and $(B_j^{-1}A_{\mathrm{R}}^{(j)})$ is equivalent to σ, and $B_\nu(\Phi)$ is an orthogonal basis for $S_\sigma(\Phi) \cap L^2(\mathbf{R})$. Thus we have the following lemma.

LEMMA 2.2. *Suppose Φ is a minimally supported orthogonal generator and σ is a squeeze map for Φ. Then there is some squeeze map ν equivalent to σ such that $B_\nu(\Phi)$ is an orthogonal basis for $S_\sigma(\Phi) \cap L^2(\mathbf{R})$.*

3. Polynomial reproduction and smoothness. In this section we give necessary and sufficient conditions for a squeeze map σ to preserve the accuracy (polynomial reproduction) and regularity of $S(\Phi)$. Throughout this section Φ is a generator in $\mathcal{G}_k^n$ and σ is a squeeze map on $\mathcal{G}_k^n$ with matrix sequences $(A_{\mathrm{L}}^{(j)})$ and $(A_{\mathrm{R}}^{(j)})$. Recall that $R_j = (A_{\mathrm{L}}^{(j)})^{-1}A_{\mathrm{R}}^{(j)}$ for $j \in \mathbf{Z}$.

First we address the smoothness of $S_\sigma(\Phi)$. Since $S_\sigma(\Phi)$ restricted to bounded intervals has finite dimension it follows that $S_\sigma(\Phi) \subset C^m(\mathbf{R})$ if and only if $\sigma_j(\Phi) \subset C^m(\mathbf{R})$ for all $j \in \mathbf{Z}$.

THEOREM 3.1. *Suppose $\Phi \subset C^m(\mathbf{R})$. Then, for $j \in \mathbf{Z}$, $\sigma_j(\Phi) \subset C^m(\mathbf{R})$ if and only if $\bar{\Phi}^{(q)}(0)$ is either 0 or a right eigenvector of R_j with eigenvalue $(L_j/L_{j-1})^q$ for $0 \le q \le m$, that is, if and only if*

$$R_j \bar{\Phi}^{(q)}(0) = (L_j/L_{j-1})^q \bar{\Phi}^{(q)}(0). \tag{3.1}$$

(Here $\bar{\Phi}^{(q)}$ denotes the qth derivative of $\bar{\Phi}$.)

Hence, $S_\sigma(\Phi) \subset C^m(\mathbf{R})$ if and only if (3.1) holds for all $j \in \mathbf{Z}$.

Proof. The theorem follows from

$$\sigma_j(\Phi)^{(q)}(j^-) = \begin{pmatrix} (L_{j-1})^{-q} A_{\mathrm{L}}^{(j)} \bar{\Phi}^{(q)}(0^-) \\ 0 \end{pmatrix}$$

and

$$\sigma_j(\Phi)^{(q)}(j^+) = \begin{pmatrix} (L_j)^{-q} A_{\mathrm{R}}^{(j)} \bar{\Phi}^{(q)}(0^+) \\ 0 \end{pmatrix}$$

for $0 \le q \le m$ and $j \in \mathbf{Z}$. □

Let Π_p, $p \ge 0$, denote the collection of univariate polynomials of degree at most p. A generator Φ is said to have *accuracy* $p+1$ if $\Pi_p \subset S(\Phi)$. If Φ has accuracy $p+1$, then (since $B(\Phi)$ is a linearly independent set), for each $l = 0, \dots, p$, there is a unique sequence of $1 \times n$ vectors $(\alpha_l(j))_{j \in \mathbf{Z}}$ such that

$$x^l = \sum_{j \in \mathbf{Z}} \alpha_l(j) \Phi(x-j) = \sum_j \bar{\alpha}_l(j) \bar{\Phi}(x-j) + \breve{\alpha}_l(j) \breve{\Phi}(x-j). \tag{3.2}$$

We say $S_\sigma(\Phi)$ has *accuracy* $p+1$ if $\Pi_p \subset S_\sigma(\Phi)$, in which case there exists, for each $l = 0, \dots, p$, a unique sequence $(\alpha'_l(j))_{j \in \mathbf{Z}}$, such that

$$x^l = \sum_j \alpha'_l(j) \sigma_j(\Phi)(x). \tag{3.3}$$

THEOREM 3.2. *Suppose Φ has accuracy $p+1$ and σ is a squeeze map for Φ. Then $S_\sigma(\Phi)$ has accuracy $p+1$ if and only if $\bar{\alpha}_l(0)$ is either 0 or a left eigenvector of R_j with eigenvalue $(L_j/L_{j-1})^l$ for $l = 0, \dots, p$ and all $j \in \mathbf{Z}$.*

Proof. Using (3.3) and the definition of $\sigma_j(\Phi)$, observe that $S_\sigma(\Phi)$ having accuracy $p+1$ is equivalent to the existence of sequences $(\alpha'_l(j))_{j \in \mathbf{Z}}$, $l = 0, \dots, p$, such that

$$x^l = \bar{\alpha}'_l(j) A_{\mathrm{R}}^{(j)} \bar{\Phi} \circ \tau_j(x) + \bar{\alpha}'_l(j+1) A_{\mathrm{L}}^{(j+1)} \bar{\Phi} \circ \tau_{j+1}(x) + \breve{\alpha}'_l(j) \breve{\Phi} \circ \tau_j(x),$$

for $j \in \mathbf{Z}$, and $x \in \tau_j^{-1}([0,1]) = [a_j, a_{j+1}]$. By substituting $\tau_j^{-1}(x)$ for x in the above, we obtain

$$\sum_{i=0}^{l} \binom{l}{i} L_j^i x^i a_j^{l-i} = \bar{\alpha}'_l(j) A_{\mathrm{R}}^{(j)} \bar{\Phi}(x) + \bar{\alpha}'_l(j+1) A_{\mathrm{L}}^{(j+1)} \bar{\Phi}(x-1) + \breve{\alpha}'_l(j) \breve{\Phi}(x),$$

where l and j are as above, but here $x \in [0,1]$. Now, since Φ has accuracy $p+1$, we can use (3.2) to replace x^i in the above. In particular,

$$x^i = \bar{\alpha}_i(0) \bar{\Phi}(x) + \bar{\alpha}_i(1) \bar{\Phi}(x-1) + \breve{\alpha}(0) \breve{\Phi}(x)$$

for $x \in [0,1]$. With this substitution and the minimal support properties of Φ, we find an equivalent system of equations,

$$\begin{aligned} \breve{\alpha}_l'(j) &= \sum_{i=0}^{l} \binom{l}{i} L_j^i a_j^{l-i} \breve{\alpha}_i(0), \\ \bar{\alpha}_l'(j) A_{\mathrm{R}}^{(j)} &= \sum_{i=0}^{l} \binom{l}{i} L_j^i a_j^{l-i} \bar{\alpha}_i(0), \\ \bar{\alpha}_l'(j+1) A_{\mathrm{L}}^{(j+1)} &= \sum_{i=0}^{l} \binom{l}{i} L_j^i a_j^{l-i} \bar{\alpha}_i(1). \end{aligned} \tag{3.4}$$

Now, since $A_{\mathrm{L}}^{(j)}$ and $A_{\mathrm{R}}^{(j)}$ are invertible for all j, the last two of these lead to

$$\sum_{i=0}^{l} \binom{l}{i} L_j^i a_j^{l-i} \bar{\alpha}_i(0) (A_{\mathrm{R}}^{(j)})^{-1} = \sum_{i=0}^{l} \binom{l}{i} L_{j-1}^i a_{j-1}^{l-i} \bar{\alpha}_i(1) (A_{\mathrm{L}}^{(j)})^{-1}. \tag{3.5}$$

Here, we may apply Lemma 3.6 proved at the end of this section, observing that $\alpha_i(0)$ and $\alpha_i(1)$ satisfy (3.11), as, therefore, do $\bar{\alpha}_i(0)$ and $\bar{\alpha}_i(1)$. The "only if" part of the result follows.

All steps in the above argument are reversible except the one from (3.4) to (3.5). The "if" part of the result is achieved by choosing $\breve{\alpha}'$ and $\bar{\alpha}'$ as in (3.4). The choice is consistent with (3.5) and leads to the desired accuracy of $S_\sigma(\Phi)$. □

If $\Phi \subset C^m(\mathbf{R})$ and has accuracy $p+1$, then $\breve{\Phi}^{(q)}(0) = 0$ for $0 \le q \le m$ and so

$$\bar{\alpha}_l(0) \bar{\Phi}^{(q)}(0) = \left. \frac{d^q}{dx^q} x^l \right|_{x=0} = (q!) \delta_{l,q} \tag{3.6}$$

for $0 \le q \le m$ and $0 \le l \le p$, where $\delta_{l,q}$ denotes the Kronecker delta. For $0 \le q \le m$ and $0 \le l \le p$, we define the following matrices:

$$V_l = \begin{pmatrix} \bar{\alpha}_0(0) \\ \vdots \\ \bar{\alpha}_l(0) \end{pmatrix} \text{ and } W_q = \left(\bar{\Phi}(0) \cdots \bar{\Phi}^{(q)}(0) \right). \tag{3.7}$$

Then (3.6) is equivalent to the matrix equation

$$V_p W_m = D, \tag{3.8}$$

where D is the $(p+1) \times (m+1)$ diagonal matrix whose (l,l)th component is $(l-1)!$. The rank of the right side of (3.8) is $\min(m+1, p+1)$. Also, V_p and W_m have rank at most k which gives the following bound for k.

LEMMA 3.3. *Suppose $\Phi \subset C^m(\mathbf{R})$ and has accuracy $p+1$; then*

$$k \ge \min(m+1, p+1).$$

Next we consider when accuracy or smoothness uniquely determines the squeeze map (up to equivalency) and when accuracy forces smoothness or smoothness forces accuracy.

THEOREM 3.4. *Suppose $\Phi \subset C^m(\mathbf{R})$ and has accuracy $p+1$. Let a be a given knot sequence.*

(i) *If $k \le p+1$ and the square matrix V_{k-1} is nonsingular, then there exists a unique (up to equivalence) squeeze map σ with knot sequence a such that $S_\sigma(\Phi)$ has accuracy k. In addition, $S_\sigma(\Phi) \subset C^m(\mathbf{R})$.*

(ii) *If $k \le m+1$ and the square matrix W_{k-1} is nonsingular, then there exists a unique (up to equivalence) squeeze map σ with knot sequence a such that $S_\sigma(\Phi) \subset C^{k-1}(\mathbf{R})$. Furthermore, $S_\sigma(\Phi)$ has accuracy $p+1$.*

Proof. Case (i). Suppose $k \le p+1$, $V := V_{k-1}$ is nonsingular, and σ is a squeeze map for Φ. Then $\bar\alpha_l(0) \ne 0$ for $0 \le l \le k-1$, and so Theorem 3.2 asserts that $S_\sigma(\Phi)$ has accuracy k if and only if $\bar\alpha_l(0)$ is a left eigenvector of R_j with eigenvalue $(\frac{L_j}{L_{j-1}})^l$ for $0 \le l \le k-1$ and $j \in \mathbf{Z}$. The latter condition is equivalent to

$$V\,R_j = \Lambda(L_j/L_{j-1})\,V \qquad (j \in \mathbf{Z}),$$

where $\Lambda(\lambda)$ is a $k \times k$ diagonal matrix whose (l,l)th component is λ^{l-1} for $\lambda \in \mathbf{R}_+$. Thus, $S_\sigma(\Phi)$ has accuracy k if and only if

$$R_j = V^{-1}\,\Lambda(L_j/L_{j-1})\,V \qquad (j \in \mathbf{Z}). \tag{3.9}$$

Equation (3.8) shows that $\Phi^{(q)}(0)$ is the qth column of $V^{-1}D$. Multiplying both sides of (3.9) on the right by $\Phi^{(q)}(0)$ then shows that $\bar\Phi^{(q)}(0)$ is a right eigenvector of R_j with eigenvalue $(\frac{L_j}{L_{j-1}})^q$ for $0 \le q \le m$. Hence, Theorem 3.1 shows that $S_\sigma(\Phi) \subset C^m(\mathbf{R})$.

Case (ii). Now suppose $k \le m+1$ and $W := W_{k-1}$ is nonsingular. As in case (i) we find that $S_\sigma(\Phi)$ has accuracy k if and only if

$$R_j = W\,\Lambda(L_j/L_{j-1})\,W^{-1} \tag{3.10}$$

and that $\bar\alpha_l(0)$ is a left eigenvector of R_j with eigenvalue $(\frac{L_j}{L_{j-1}})^l$ for $0 \le l \le p$. Hence Theorem 3.2 shows that $S_\sigma(\Phi)$ has accuracy $p+1$. □

If $k = \min(m+1, p+1)$, then it follows from (3.8) that V_{k-1} and W_{k-1} are both nonsingular, and so both cases in Theorem 3.4 hold. The next theorem shows that $S_\sigma(\Phi)$ contains the spline space

$$S_p^m(a) := \{f \in C^m(\mathbf{R}) \mid f|_{(a_j, a_{j+1})} \in \Pi_p,\ j \in \mathbf{Z}\}$$

when $k = \min(m+1, p+1)$. In this case, it is known from classical spline theory that the accuracy determines the approximation order of $S_\sigma(\Phi)$. Note that $S_p^m(a) = \Pi_p$ if $m \ge p$.

THEOREM 3.5. *Suppose $\Phi \subset C^m(\mathbf{R})$, Φ has accuracy $p+1$ and $k = \min(m+1, p+1)$. Let a be a given knot sequence.*

(i) *There exists a squeeze map σ with knot sequence a such that $S_\sigma(\Phi) \subset C^m(\mathbf{R})$ and has accuracy $p+1$.*

(ii) *If ν is any other squeeze map with knot sequence a such that either $S_\nu(\Phi) \subset C^{k-1}(\mathbf{R})$ or (ν, Φ) has accuracy k, then ν is equivalent to σ.*

(iii) *$S_p^m(a) \subset S_\sigma(\Phi)$. (This is nontrivial only when $m < p$, in which case $k = m+1$.)*

Proof. If $k = \min(m+1, p+1)$, then it follows from (3.8) that V_{k-1} and W_{k-1} are both nonsingular and parts (i) and (ii) follow from Theorem 3.4.

From part (i) we have $\Pi_p \subset S_\sigma(\Phi)$, and so we need only consider the case $m < p$. Since W_{k-1} is nonsingular, it follows from (3.8) that $\bar{\alpha}_l(0) = 0$ for $l = m+1, \ldots, p$.

For simplicity, first suppose that one of the knots, say a_i, is 0. Then (3.4) implies

$$\bar{\alpha}_l'(i) A_{\mathrm{R}}^{(j)} = L_i^l \bar{\alpha}_l(i) = 0 \qquad (l = m+1, \ldots, p).$$

Thus (3.3) becomes

$$x^l = \breve{\alpha}_l'(i)\breve{\sigma}_i(\Phi) + \sum_{j \neq i} \alpha_l'(j)\sigma_j(\Phi).$$

Thus the truncated powers $(x_+)^l$, $l = m+1, \ldots, p$, can be written as

$$(x_+)^l = \breve{\alpha}_l'(i)\breve{\sigma}_i(\Phi) + \sum_{j > i} \alpha_l'(j)\sigma_j(\Phi),$$

and so they are in $S_\sigma(\Phi)$ for $l = m+1, \ldots, p$. Observe that shifting the knots by a constant shift translates the basis $B_\sigma(\Phi)$ by the same amount. Hence $S_\sigma(\Phi)$ contains the truncated powers $((x - a_j)_+)^l$ for $l = m+1, \ldots, p$ and $j \in \mathbf{Z}$. The truncated powers form a basis for $S_p^m(a)$ showing that (iii) holds. □

Finally, we prove the following lemma that was used in the proof of Theorem 3.2.

LEMMA 3.6. *Suppose $a_0, a_1, L_1 \in \mathbf{R}$ and $L_0 = a_1 - a_0$. Further, suppose $\alpha(0)$ and $\alpha(1)$ are sequences of $1 \times k$ vectors such that*

$$\alpha_l(1) = \sum_{i=0}^{l} \binom{l}{i} \alpha_i(0) \tag{3.11}$$

for $l = 0, \ldots, p$. Then the $k \times k$ matrices C and D satisfy the conditions

$$\sum_{i=0}^{l} \binom{l}{i} L_1^i a_1^{l-i} \alpha_i(0) C = \sum_{i=0}^{l} \binom{l}{i} L_0^i a_0^{l-i} \alpha_i(1) D \tag{3.12}$$

for $l = 0, \ldots, p$ if and only if

$$\alpha_l(0)(L_1^l C - L_0^l D) = 0 \tag{3.13}$$

for $l = 0, \ldots, p$.

Proof. For a given l, we may use (3.11) to substitute for $\alpha_i(1)$ in (3.12). Then using routine combinatorial manipulations we find

$$\sum_{i=0}^{l} \binom{l}{i} L_1^i a_1^{l-i} \alpha_i(0) C = \sum_{j=0}^{l} \binom{l}{j} \alpha_j(0) D \sum_{i=j}^{l} \binom{l-j}{i-j} L_0^i a_0^{l-i}. \tag{3.14}$$

By shifting the index on the inner sum by j, the left-hand side becomes

$$\begin{aligned} &\sum_{j=0}^{l} \binom{l}{j} \alpha_j(0) D \sum_{i=0}^{l-j} \binom{l-j}{i} L_0^{i+j} a_0^{l-i-j} \\ &= \sum_{j=0}^{l} \binom{l}{j} \alpha_j(0) L_0^j a_1^{l-j} D, \end{aligned}$$

where the final equality follows from $a_1 = a_0 + L_0$ and the binomial theorem. Thus (3.12) is equivalent to

$$\sum_{i=0}^{l} \binom{l}{i} a_1^{l-i} \alpha_i(0)(L_1^i C - L_0^i D) = 0.$$

From here it is easy to show the equivalence with (3.13) by induction on $l = 0, \ldots, p$. □

4. Constructing the squeeze map. Suppose $\Phi \subset C^m(\mathbf{R})$, Φ has accuracy $p+1$ and $k \le \max(m+1, p+1)$. Then either case (i) or (ii) of Theorem 3.4 holds and the squeeze map preserving accuracy in case (i) or smoothness in case (ii) is unique up to equivalence. In both cases there is a full set of k eigenvectors for R_j for $j \in \mathbf{Z}$ with specified eigenvalues. These eigenvectors then uniquely determine R_j through either (3.9) or (3.10). In case (i), let $U = V_{k-1}$ and in case (ii) let $U = W_{k-1}^{-1}$, where V_{k-1} and W_{k-1} are given by (3.7). Let

$$R(\lambda) := U^{-1}\,\Lambda(\lambda)\,U \qquad (\lambda > 0). \tag{4.1}$$

Then $R_j = R(\lambda_j)$, where $\lambda_j := L_j/L_{j-1}$ for $j \in \mathbf{Z}$. Thus, the squeeze map is determined (up to equivalence) for an arbitrary knot sequence. Furthermore, each R_j is determined only by the ratio L_j/L_{j-1}.

Now suppose Φ is an orthogonal generator. Let σ be the squeeze map with matrix sequences (I, R_j). Following the proof of Lemma 2.2, an equivalent squeeze map ν so that $B_\nu(\Phi)$ is orthogonal may be found as follows. First, find a Cholesky factorization (see (2.3)):

$$B(\lambda)B(\lambda)^\top = \langle \Phi_L, \Phi_L \rangle + \lambda R(\lambda) \langle \Phi_R, \Phi_R \rangle R(\lambda)^\top. \tag{4.2}$$

Let $B_j = \sqrt{L_{j-1}} B(\lambda_j)$ for $j \in \mathbf{Z}$. Then ν with matrix sequences $A_{\mathrm{L}}^{(j)} = (B_j^{-1})$ and $A_{\mathrm{R}}^{(j)} = (B_j^{-1} R_j)$ gives an orthogonal basis. Again note that for fixed Φ, B_j depends only on L_{j-1} and L_j, and (since a Cholesky factorization is equivalent to an LU factorization using Gaussian elimination) we can find a closed form expression for ν_j in terms of the ratio $\lambda_j = L_j/L_{j-1}$. This makes it simple and quick to construct the squeeze map for an arbitrary knot sequence.

In our examples we consider only $k = 1$ or $k = 2$. When $k = 1$ it is trivial to obtain B_j. Suppose

$$A = \begin{pmatrix} a & b \\ b & c \end{pmatrix}$$

is a symmetric positive definite matrix. (That is, $v^\top A v > 0$ for any nonzero 2-vector v.) Then A is positive definite if and only if both a and $\det A$ are positive. One choice for B such that $BB^\top = A$ is given by

$$B = \frac{1}{\sqrt{a}} \begin{pmatrix} a & 0 \\ b & \sqrt{\det A} \end{pmatrix}. \tag{4.3}$$

5. Orthogonal minimally supported generators.

5.1. Rescaling orthogonal generators. Any orthogonal compactly supported generator may be used to construct an orthogonal generator supported on $[-1,1]$ as we next describe. If the support of $\Phi = (\phi_1, \dots, \phi_n)^\top$ is contained in $[-1, M]$, then let Φ_M denote the generator consisting of the concatenation of the M generators $\Phi(M \cdot + k)$, $(k = 0, \dots, M-1)$. Then Φ_M is an orthogonal generator supported in $[-1,1]$ and $S(\Phi_M)$ equals $S(\Phi)(M\cdot)$ (that is, the dilation by $1/M$ of the space $S(\Phi)$). The local linear independence conditions for minimal support must then be checked separately. However, when Φ is an orthogonal scalar ($n = 1$) refinable generator it is known that Φ is locally linearly independent (that is, the nonzero restrictions of the shifts of Φ to any open interval are linearly independent), which implies the weaker type of local linear independence we require in the definition of minimal support. The example in section 6.3 is constructed in this way.

5.2. General construction. In [5] the authors developed a method for constructing orthogonal generators. For $W \subset L^2(\mathbf{R})$, let P_W denote the orthogonal projection onto W.

LEMMA 5.1 (see [5]). *Suppose Φ is a minimally supported k-generator. There exists an orthogonal minimally supported k-generator Ψ such that $S(\Psi) = S(\Phi)$ if and only if*

$$(I - P_{S(\check{\Phi})})\bar{\Phi} \perp (I - P_{S(\check{\Phi})})\bar{\Phi}(\cdot - 1). \tag{5.1}$$

(That is, $(I - P_{S(\check{\Phi})})\phi_i \perp (I - P_{S(\check{\Phi})})\phi_j(\cdot - 1)$ for $1 \le i, j \le k$.)

Proof (sketch of proof). Let $\check{\Psi}$ be an orthogonal basis for the span of $\check{\Phi}$ and choose $\bar{\Psi}$ to be an orthogonal basis for the span of $(I - P_{S(\check{\Phi})})\bar{\Phi}$. Then Ψ is an orthogonal, minimally supported k-generator for $S(\Phi)$ if Ψ and $\Psi(\cdot - 1)$ are orthogonal (or, equivalently, if (5.1) holds). The other direction relies on the observation that if Φ and Ψ are minimally supported k-generators such that $S(\Psi) = S(\Phi)$, then

$$\operatorname{span}\check{\Phi} = \operatorname{span}\check{\Psi}$$

and

$$\operatorname{span}\Phi \cup \check{\Phi}(\cdot + 1) = \operatorname{span}\check{\Psi} \cup \check{\Psi}(\cdot + 1) \qquad \square$$

The idea of the construction is to choose $\check{\Phi}$ so that (5.1) holds. The orthogonal generators in the examples in sections 6.1 and 6.2 and section 7 are constructed in this way.

6. Examples. In this section we present several examples to illustrate our methods. The examples in sections 6.1 and 6.2 first appeared in [4]. In both examples it is the smoothness condition that determines the squeeze map. Also, in these two examples, $k = \min(m+1, p+1)$, and so the resulting $S_\sigma(\Phi)$ contains $S_p^m(a)$ by Theorem 3.5.

In the example in section 6.3, we rescale Daubechies's orthogonal scaling function ${}_2\phi$ as described in section 5.1 to construct a continuous orthogonal refinable generator minimally supported on [-1,1] with $k = n = 2$. The accuracy in this case is $p + 1 = 2$ and, by Theorem 3.4 (i), the squeeze map is uniquely determined by the accuracy condition once a knot sequence is specified. In fact, it is this example that motivated our study of the accuracy of squeezed spaces $S_\sigma(\Phi)$. In the example in section 6.3 we have $m + 1 = 1 < 2 = k$, and so Theorem 3.5 does not apply in this case.

We are also interested in this example because the generator Φ is *refinable*; that is,

$$\Phi(\cdot/2) = \sum_{j\in\mathbf{Z}} c(j)\Phi(\cdot - j) \tag{6.1}$$

for some finitely supported sequence $c : \mathbf{Z} \mapsto \mathbf{R}^{n\times n}$. (In this case the support of c is $\{-2,-1,0,1\}$.)

We next remark that such a refinable minimally supported generator Φ generates a *semiregular multiresolution analysis* (that is, a multiresolution consisting of a nonuniform coarse space that is uniformly refined; see [3]) as follows: Let a^0 be an arbitrary knot sequence and let $a^1 \supset a^0$ be given by

$$a^1_{2j} = a^0_j \text{ and } a^1_{2j+1} = (a^0_j + a^0_j)/2 \qquad (j \in \mathbf{Z}).$$

Let σ^0 and σ^1 be the squeeze maps determined (up to equivalence) by the knot sequences a^0 and a^1, respectively. Then one may verify that $S_{\sigma^0}(\Phi) \subset S_{\sigma^1}(\Phi)$. *Thus we provide a way to construct orthogonal semiregular multiresolutions from orthogonal scaling functions in a way that preserves the accuracy and smoothness of the shift-invariant multiresolution.*

In the example in section 4, we construct an *irregular multiresolution analysis* (that is, a fully nonuniform multiresolution; see [3]) such that each space in the multiresolution has a compactly supported orthogonal basis consisting of continuous piecewise quadratic functions. The spaces in this irregular multiresolution are not, strictly speaking, squeezed spaces of the form $S_\sigma(\Phi)$ but instead result from a slight generalization of our notion of the squeeze map.

6.1. $k = 1$, $m = 0$, $p = 1$, $n = 2$. Let h denote the hat function defined by $h(x) = (1 - |x|)^+$ and suppose $w \in L^2(\mathbf{R})$ is nontrivial and supported in the interval $[0,1]$. Let $\Phi = (h, w)$. Then (5.1) reduces to

$$\langle h, h(\cdot - 1)\rangle = \frac{\langle h, w\rangle\langle w, h(\cdot - 1)\rangle}{\langle w, w\rangle}. \tag{6.2}$$

Thus, any $w \in L^2(\mathbf{R})$ supported in $[0,1]$ and satisfying (6.2) gives an orthogonal generator Ψ by the process described in Lemma 5.1. For example, let q be the piecewise quadratic function given by $q(x) = x(1-x)\chi_{[0,1]}(x)$. Choose $w \in \operatorname{span}\{q, q^2\}$ so that $w = c_1 q + c_2 q^2$ for some constants c_1, c_2. Substituting into (6.2) yields a quadratic equation in the variable $\alpha := c_2/c_1$:

$$\alpha^2 + 30\alpha + 105 = 0$$

or $\alpha = -15 \pm 2\sqrt{30}$. The graphs of ϕ_1 and ϕ_2 are shown in Figure 6.1 for $\alpha = -15 - 2\sqrt{30}$. (This example was first given in [4].)

For $0 \le x \le 1$, we have

$$\phi_1(x) = \sqrt{3}\,(1-x)\,\left(1 - 2\,x + \left(-3 + \sqrt{30}\right)\,x\,(1 - 5\,(1-x)\,x)\right)$$

and

$$\phi_2(x) = \sqrt{330 - 60\,\sqrt{30}}\,(1-x)\,x\,\left(-1 + \left(15 + 2\,\sqrt{30}\right)\,(1-x)\,x\right).$$

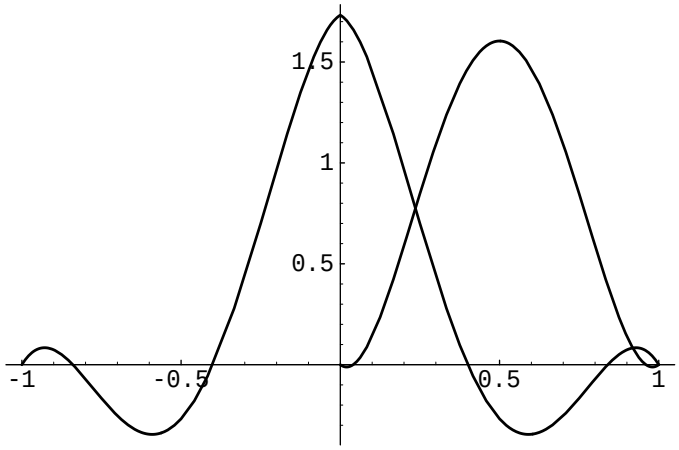

FIG. 6.1. *Continuous orthogonal generator of the example in section* 6.1.

Note that ϕ_1 is even and supported on $[-1,1]$ and that ϕ_2 has support $[0,1]$.

In the case $k=1$ and $m=0$, the squeeze maps preserving continuity are given by $R_j = 1$ for all $j \in \mathbf{Z}$. By Theorem 3.4, this squeeze map will also preserve the approximation of Φ. By the symmetry of Φ we have

$$\langle \Phi_L, \Phi_L \rangle = \langle \Phi_R, \Phi_R \rangle = 1/2.$$

Using (2.3) we get that σ given by

$$A_L^j = A_R^j = \sqrt{\frac{2}{L_{j-1} + L_j}}$$

generates an orthogonal basis $B_\sigma(\Phi)$.

6.2. $k=2$, $m=1$, $p=3$, $n=4$. We next construct a continuously differentiable orthogonal generator. We start with the C^1 cubic Hermite spline functions

$$h_1(x) = \begin{cases} (1+x)^2(1-2x), & x \in [-1,0], \\ (1-x)^2(1+2x), & x \in [0,1], \\ 0 & \text{otherwise}, \end{cases}$$

$$h_2(x) = \begin{cases} (1+x)^2 x, & x \in [-1,0], \\ (1-x)^2 x, & x \in [0,1], \\ 0 & \text{otherwise} \end{cases}$$

and add two continuously differentiable functions w_1 and w_2 supported on $[0,1]$. (In [5], it is shown that at least two w's are required in this case.) The condition (6.2) is equivalent to the following:

$$\langle h_i, h_j(\cdot - 1) \rangle = \frac{\langle h_i, w_1 \rangle \langle w_1, h_j(\cdot - 1) \rangle}{\langle w_1, w_1 \rangle} + \frac{\langle h_i, w_2 \rangle \langle w_2, h_j(\cdot - 1) \rangle}{\langle w_2, w_2 \rangle}. \tag{6.3}$$

Again let q be the piecewise quadratic function given by $q(x) = x(1-x)\chi_{[0,1]}(x)$. We choose w_1 to be of the form $(c_1 + c_2 q + c_3 q^2)q^2$ and w_2 of the form $(\cdot - 1/2)(c_4 + c_5 q)q^2$

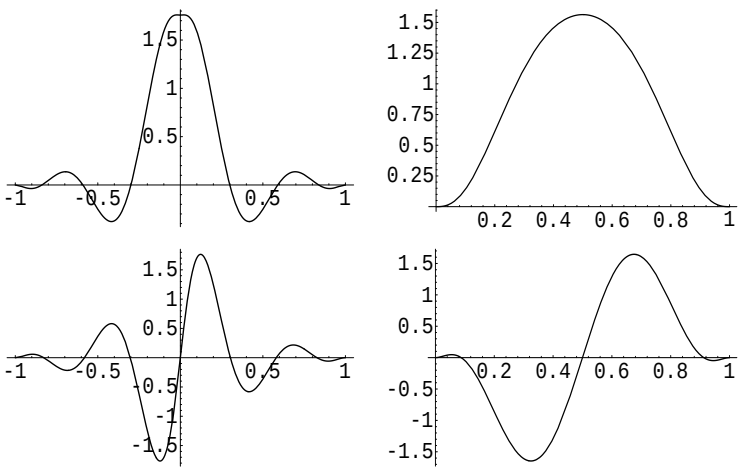

FIG. 6.2. *The C^1 orthonormal generator of the example in section* 6.2. *From upper left, going clockwise: ϕ_1, ϕ_3, ϕ_4, ϕ_2.*

so that w_1 is symmetric about $x = 1/2$ and w_2 is antisymmetric about $x = 1/2$. Substituting into (6.3) yields three quadratic equations in the three variables c_2/c_1, c_3/c_1, and c_5/c_4. Solving these equations numerically and choosing c_1 and c_4 so that $\|w_1\| = \|w_2\| = 1$ yields several solutions. One solution with good properties is given by

c_1	+2.102558692333885
c_2	+214.7707569159831
c_3	-492.4339092336308
c_4	-112.0742772596177
c_5	+1401.893433767276

The graphs of the components of the resulting orthogonal generator $(\phi_1, \phi_2, \phi_3, \phi_4)$ are shown in Figure 6.2.

From the construction of Φ we see that $W = \left(\bar{\Phi}(0)\, \bar{\Phi}'(0)\right)$ is diagonal, and so, using (4.1), we get that $S_\sigma(\Phi) \subset C^1(\mathbf{R})$ if

$$R_j = R(\lambda_j) = \begin{pmatrix} 1 & 0 \\ 0 & \lambda_j \end{pmatrix},$$

where $\lambda_j := L_j / L_{j-1}$.

Since Φ is piecewise polynomial, the inner products $\langle \Phi_L, \Phi_L \rangle$ and $\langle \Phi_R, \Phi_R \rangle$ are easily calculated. Using *Mathematica* to perform these calculations, we arrive at the squeeze maps defined by

$$A_L^{(j)} = \frac{1}{\sqrt{L_{j-1}}} \times \begin{pmatrix} \frac{1.414213}{\sqrt{1+\lambda_j}} & 0 \\ \frac{2.829115 - 2.829115\,\lambda_j^2}{(1+\lambda_j)\sqrt{(0.381634+\lambda_j)\,(1+\lambda_j)\,(2.62031+\lambda_j)}} & \frac{3.162893}{\sqrt{(0.381634+\lambda_j)\,(1+\lambda_j)\,(2.62031+\lambda_j)}} \end{pmatrix}$$

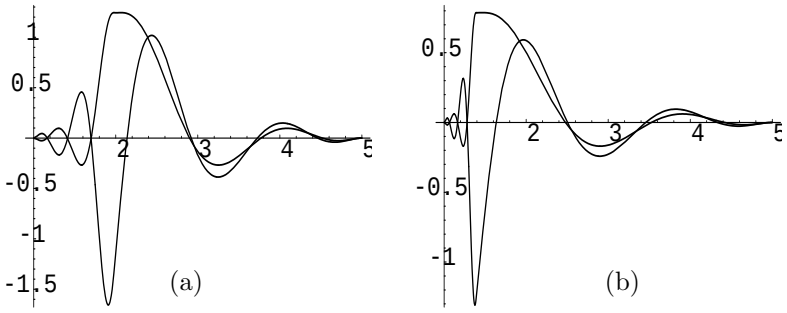

FIG. 6.3. *C^1 basis functions $\bar{\sigma}_j(\Phi)$ from the example in section* 6.2 *for* (a) $\lambda_j = 3$ *(knots at* 1, 2, *and* 5*) and* (b) $\lambda_j = 7$ *(knots at* 1, 3/2, *and* 5*).*

and

$$A_R^{(j)} = \frac{1}{\sqrt{L_{j-1}}} \times \begin{pmatrix} \frac{1.414213}{\sqrt{1+\lambda_j}} & 0 \\ \frac{2.829115-2.829115\,\lambda_j^2}{(1+\lambda_j)\sqrt{(0.381634+\lambda_j)\,(1+\lambda_j)\,(2.62031+\lambda_j)}} & \frac{3.162893\,\lambda_j}{\sqrt{(0.381634+\lambda_j)\,(1+\lambda_j)\,(2.62031+\lambda_j)}} \end{pmatrix}.$$

We show in Figure 6.3 the resulting $\bar{\sigma}_j(\Phi)$ for several values of λ_j.

6.3. Semiregular multiresolution analysis: $k = 2$, $m = 0$, $p = 1$, $n = 2$. Let ${}_2\phi$ denote the continuous orthogonal scaling function of Daubechies supported on $[0, 3]$ (see [2]) and let

$$\Phi = \sqrt{2} \begin{pmatrix} {}_2\phi(2 \cdot +2) \\ {}_2\phi(2 \cdot +1) \end{pmatrix}.$$

Then, as discussed in section 5.1, Φ is an orthogonal generator supported on $[-1, 1]$. The local linear independence condition for minimal support may be verified from the support properties of Φ and the fact that the components of Φ_R are orthogonal to the components of Φ_L, thus showing that Φ is a minimally supported generator with $k = 2$. Also, note that Φ is continuous and has accuracy 2. In this example, it is the accuracy that determines the squeeze map.

Recall that ${}_2\phi$ satisfies a refinement equation

$$ {}_2\phi = \sum_{j=0}^{3} c_j \, {}_2\phi(2 \cdot -j), \tag{6.4}$$

where

$$c_0 = \frac{1+\sqrt{3}}{4}, \quad c_1 = \frac{3+\sqrt{3}}{4}, \quad c_2 = \frac{3-\sqrt{3}}{4}, \quad c_3 = \frac{1-\sqrt{3}}{4}.$$

Using the refinement equation it is possible to calculate the following coefficients

from the zeroth and first moments of ${}_2\phi$ (see [1]):

$$\alpha_0(0) = \left(\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right), \qquad \alpha_1(0) = \left(\frac{-1-\sqrt{3}}{4\sqrt{2}}, \frac{1-\sqrt{3}}{4\sqrt{2}}\right)$$

and

$$\langle \Phi_R, \Phi_R \rangle = \begin{pmatrix} \frac{7}{12} + \frac{5}{7\sqrt{3}} & \frac{1}{28\sqrt{3}} \\ \frac{1}{28\sqrt{3}} & \frac{5}{12} + \frac{5}{7\sqrt{3}} \end{pmatrix}, \qquad \langle \Phi_L, \Phi_L \rangle = \begin{pmatrix} \frac{5}{12} - \frac{5}{7\sqrt{3}} & \frac{-1}{28\sqrt{3}} \\ \frac{-1}{28\sqrt{3}} & \frac{7}{12} - \frac{5}{7\sqrt{3}} \end{pmatrix}.$$

Then

$$R(\lambda) = \frac{1}{2}\begin{pmatrix} 1-\sqrt{3}+\left(1+\sqrt{3}\right)\lambda & \left(1+\sqrt{3}\right)(1-\lambda) \\ \left(1-\sqrt{3}\right)(1-\lambda) & 1+\sqrt{3}+\left(1-\sqrt{3}\right)\lambda \end{pmatrix}$$

and

$$\left(\langle \Phi_L, \Phi_L \rangle + \lambda R(\lambda) \langle \Phi_R, \Phi_R \rangle R(\lambda)^\top\right) = \frac{1}{84}\begin{pmatrix} a(\lambda) & b(\lambda) \\ b(\lambda) & c(\lambda) \end{pmatrix},$$

where

$$a(\lambda) = 35 - 20\sqrt{3} + 4\left(21+8\sqrt{3}\right)\lambda - 4\left(44+23\sqrt{3}\right)\lambda^2 + \left(141+80\sqrt{3}\right)\lambda^3,$$

$$b(\lambda) = (-1+\lambda)\left(\sqrt{3} - 84\lambda - 31\sqrt{3}\lambda + 42\lambda^2 + 19\sqrt{3}\lambda^2\right),$$

$$c(\lambda) = 49 - 20\sqrt{3} + 4\left(21+8\sqrt{3}\right)\lambda - 4\left(19+2\sqrt{3}\right)\lambda^2 + \left(27-4\sqrt{3}\right)\lambda^3.$$

The factors B_j may then be calculated from (4.3).

6.4. Irregular multiresolution analysis: $k = 1$, $m = 0$, $p = 2$, $n = 3$. Let $\left(a^\ell\right)_{\ell \in \mathbf{Z}}$ be a sequence of nested knot sequences such that $a^{\ell+1}_{2j} = a^\ell_j$ for ℓ, $j \in \mathbf{Z}$ and such that $\{a^\ell_j \mid \ell, j \in \mathbf{Z}\}$ is dense in $\mathbf{R}$. Let $V_\ell = S_{0,2}(a^\ell)$ denote the space of continuous piecewise quadratic splines with break points given by a^ℓ. From the theory of splines it follows that (V_ℓ) is a multiresolution analysis. Here we construct a multiresolution (V'_ℓ) such that

$$V_\ell \subset V'_\ell \subset V_{\ell+1}$$

and each V'_ℓ has a local orthogonal basis. The local orthogonal basis for V'_ℓ is generated with a generalization of the squeeze map idea. Our construction here extends the idea of intertwining multiresolution analyses developed in [5] to the nonuniform case.

Let $\Phi = (h, q)$, where h and q are as in the example in section 6.1. Then $V_\ell = S_{\sigma^\ell}(\Phi)$, where σ^ℓ is the squeeze map with knot sequence a^ℓ given by $R_j = 1$.

Let $I^\ell_j = [a^\ell_j, a^\ell_{j+1}]$. The idea of the construction is to add basis functions $w^\ell_j \in V_\ell$ supported on I^ℓ_j for each $j \in \mathbf{Z}$ to the basis $B_{\sigma^\ell}(\Phi)$ in such a way that the resulting space V'_ℓ has a local orthogonal basis. We first describe the construction when $I = I^\ell_j = [0,1]$; the general case will follow by rescaling. Then $a := a^{\ell+1}_{2j+1}$ is in $(0,1)$. Define $q_{1,0}$, $q_{1,1}$, and h_1 by

$$q_{1,0}(x) = q(x/a), \qquad q_{1,1} = q\left(\frac{x-a}{a}\right)$$

and

$$h_1(x) = \begin{cases} x/a & \text{for } x \in [0,a], \\ (1-x)/(1-a) & \text{for } x \in [a,1], \\ 0 & \text{otherwise.} \end{cases}$$

Observe that the space $\mathcal{A}$ of functions in $V^{\ell+1}$ whose support is contained in [0,1] is spanned by $q_{1,0}$, $q_{1,1}$, and h_1. Note that q is in this 3-dimensional space. We choose $w = w_j^\ell$ in the 2-dimensional orthogonal complement of q in $\mathcal{A}$. A basis for this space is given by (with help from *Mathematica*)

$$\begin{aligned} u_0 &= a^2(3a-5)q_{1,0} + (1-a)^2(2+3a)q_{1,1} \\ u_1 &= \left(-2+3\,(-1+a)\,a^3\right)q_{1,0} + \left(-2+3\,(-1+a)^3\,a\right)q_{1,1} \\ &\quad + \left(\frac{16}{5} - 12\,(-1+a)^2\,a^2\right)h_1. \end{aligned}$$

We choose w in $\mathcal{A}$ and orthogonal to q so that it is of the form

$$w = c_1 u_1 + c_2 u_2.$$

Define

$$\theta_R = (I - P_{\mathrm{span}(w,q)})h_R$$

and

$$\theta_L = (I - P_{\mathrm{span}(w(\cdot+1),q(\cdot+1))})h_L,$$

where $h_R = h\chi_{[0,1)}$ and $h_L = h\chi_{[-1,0)}$. In order to construct a local orthogonal basis we require

$$\langle \theta_R, \theta_L(\cdot - 1)\rangle = 0,$$

which is equivalent to the following quadratic equation in the variable $c = c_1/c_2$:

$$\begin{aligned} 0 =& 5\left(4 - 5\,(1-a)^2\,a^2\,(15 + (1-a)\,a)\right) \\ &- 20\,(2 + a\,(9 + 13\,a\,(-3 + 2\,a)))\,c + 4\,(1 + 45\,(1-a)\,a)\,c^2. \end{aligned} \tag{6.5}$$

The discriminant of this equation is

$$80\left(4 - 15\,(1-a)^2\,a^2\right)^2,$$

giving the two solutions

$$c = \frac{20(2 + a(9 + 13a(2a-3))) \pm 4\sqrt{5}(4 - 15(1-a)^2a^2)}{8(1 + 45(1-a)a)}.$$

Hence, there are two choices for w for any $a \in (0,1)$. For each $a \in (0,1)$ choose one such w and denote it by W_λ, where $\lambda = (1-a)/a$ is the ratio of the lengths of the two subintervals $[0,a]$ and $[a,1]$. Let $\theta_{R,\lambda} = \theta_R$ and $\theta_{L,\lambda} = \theta_L$ with $w = W_\lambda$. Define

$$\Phi^{\lambda_L,\lambda_R} = \begin{pmatrix} \theta_{L,\lambda_L} + \theta_{R,\lambda_R} \\ q \\ W_{\lambda_R} \end{pmatrix}$$

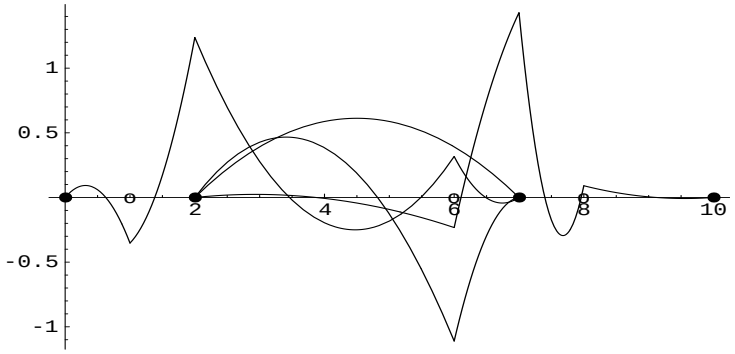

FIG. 6.4. *Continuous, orthogonal piecewise quadratic basis functions from the example in section* 6.4 *with knots* $a_{\ell+1} = \dots, 0, 1, 3, 6, 7, 8, 10, \dots$.

and note that $\Phi^{\lambda_L,\lambda_R}$ is continuous and supported on $[-1, 1]$. Given $a^{\ell+1}$ we construct basis functions supported on $[a^\ell_{j-1}, a^\ell_{j+1}] = [a^{\ell+1}_{2j-2}, a^{\ell+1}_{2j+2}]$ as follows. Let τ^ℓ_j be as in (2.1) with knot sequence a^ℓ, let $L^\ell_j = a^\ell_{j+1} - a^\ell_j$, and let

$$\lambda^\ell_j = L^{\ell+1}_{2j+1}/L^{\ell+1}_{2j}.$$

Note that the collection of functions

$$B^\ell = \bigcup_{j\in\mathbf{Z}} \Phi^{\lambda^\ell_{j-1},\lambda^\ell_j} \circ \tau^\ell_j$$

is an orthogonal system of functions. Let

$$V'_\ell = \operatorname{span}_{L^2} B^\ell$$

for $\ell \in \mathbf{Z}$. Then

$$V_\ell \subset V'_\ell \subset V_{\ell+1} \subset V'_{\ell+1},$$

from which it follows that $(V'_\ell)_{\ell\in\mathbf{Z}}$ is a multiresolution with local orthogonal basis B^ℓ.

Figure 6.4 shows several of the basis functions (we chose the minus branch of the square root) for $a_\ell = \dots, 0, 3, 7, 10, \dots$ and $a_{\ell+1} = \dots, 0, 1, 3, 6, 7, 8, 10, \dots$.

7. Higher order accuracy and smoothness. Let S^n_m be the space of polynomial splines of degree n with C^m knots at the integers. If we denote $A^{n,m} = \{g \in S^n_m : \operatorname{supp} g = [0, 1]\}$, then it is easy to see [6] that an orthogonal basis for $A^{n,m}$ is provided by $\phi^m_i(t) = t^m(1-t)^m p^{2m+5/2}_{i-2m-2}(2t-1)$, $2m+2 \le i \le n$, where $p^{2m+5/2}_j(t)$ is the monic ultraspherical polynomial of degree j with $\lambda = 2m + 5/2$. If we set $\Phi = (\phi^m_0 \cdots \phi^m_n)^T$, where ϕ^m_i, $i = 0, \dots, m$, $\operatorname{supp} \phi^m_i = [-1, 1]$ are appropriately chosen (i.e., judicious linear combinations of r^i_m and l^i_m, $i = 0, \dots, m$, with $r^i_m(t) = t^i(1+t)^{m+1} - 1 \le t \le 0$ and $l^i_m(t) = t^i(1-t)^{m+1} 0 < t \le 1$), then Φ and all its integer translates form a basis for S^n_m. This basis is not orthogonal, so Φ does not generate a local orthogonal basis. We will modify Φ in order to construct an orthogonal set of generators. We do this by adding to Φ, $m+1$ functions w_i chosen so that $W \perp A^{n,m}$ and $\langle (I - P_W)\hat\phi^m_i, (I - P_W)\hat\phi^m_j(\cdot - 1)\rangle = 0$ $i, j = 1, \dots, m+1$. Here $W = \operatorname{span}\{w_i : i = 1, \dots, m+1\}$, P_W is the orthogonal projection onto

W, and $\hat{\phi}_i^m = (I - P_{\{A^{n,m}, A^{n,m}(+1)\}})\phi_i^m$. In the examples given below we will choose w_i to be linear combinations of $\{\phi_j^m\}_{j>n}$. In this way $w_i \perp A^{n,m}$ since the $\{t^m(1-t)^m p_l^{2m+5/2}(2\cdot -1)\}_{l=0}^{\infty}$ is a set of orthogonal polynomials. Notice that the above w_i will have their knots located at the integers. This is in contrast to the construction carried out in [6] where in order to build a MRA it was necessary to use w_i with half integer knots.

7.1. C^0 example. As a first example we consider the case $m = 0$. Then $r_0(t) = (1+t)$ and $l_0(t) = (1-t)$, and we will choose $w_1^n = \phi_{n+1}^0 + \alpha_n \phi_{n+3}^0$. Since ϕ_i^0 is symmetric or antisymmetric about $1/2$ depending on whether i is even or odd, respectively, we see that w_1^n chosen above will be either symmetric or antisymmetric. With $\hat{r}_0^n(\cdot) = (I - P_{A^{n,0}})r_0(\cdot - 1)$ and $\hat{l}_0^n(t) = (I - P_{A^{n_0}})l_0$ we choose α_n so that $\langle (I - P_{w_1^n})\hat{r}_0, (I - P_{w_1^n})\hat{l}_0(t)\rangle = 0$. This gives the following quadratic equation for α_n:

$$\langle \hat{r}_0^n, \hat{l}_0^n\rangle \langle w_1^n, w_1^n\rangle = \langle w_1^n, r_0(\cdot - 1)\rangle \langle w_1^n, l_0\rangle \tag{7.1}$$

or

$$\begin{aligned} &\langle \hat{r}_0^n, \hat{l}_0^n\rangle (\langle \phi_{n+1}^0, \phi_{n+1}^0\rangle + \alpha_n^2 \langle \phi_{n+3}^0, \phi_{n+3}^0\rangle) \\ &= (\langle \phi_{n+1}^0, r_0(\cdot - 1)\rangle + \alpha_n \langle \phi_{n+3}^0, r_0(\cdot - 1)\rangle)(\langle \phi_{n+1}^0, l_0\rangle + \alpha_n \langle \phi_{n+3}^0, l_0\rangle). \end{aligned} \tag{7.2}$$

From [6] we find $\langle \hat{r}_0^n, \hat{l}_0^n\rangle = \frac{(-1)^{n+1} n!}{(n+3)!}$, $\langle \hat{r}_0^n, \hat{r}_0^n\rangle = \frac{1}{n(n+2)}$, and $\langle r_0, \phi_n^0\rangle = 2^{n-2}\frac{n!(n-2)}{2n!}$. Furthermore, since $\langle \phi_n^0, \phi_n^0\rangle = \frac{1}{32}\frac{(n+2)!(n-2)!}{(2n-1)!(2n+1)!!}$, the above equation may be solved for α_n to obtain

$$\alpha_n = -\frac{((2n+7)(2n+3)(n+1) \pm \sqrt{3(2n+7)(2n+3)(n+1)(n+3)}(n+3))(2n+5)}{(n+2)(n+1)(n^2-5n-30)},$$

and $\phi_0^{n,0}$ is given by

$$\phi_0^{n,0}(t) = (I - P_{(w_1^n, w_1^n(\cdot+1))})h(t),$$

where $h(t) = (1-|t|)^+$.

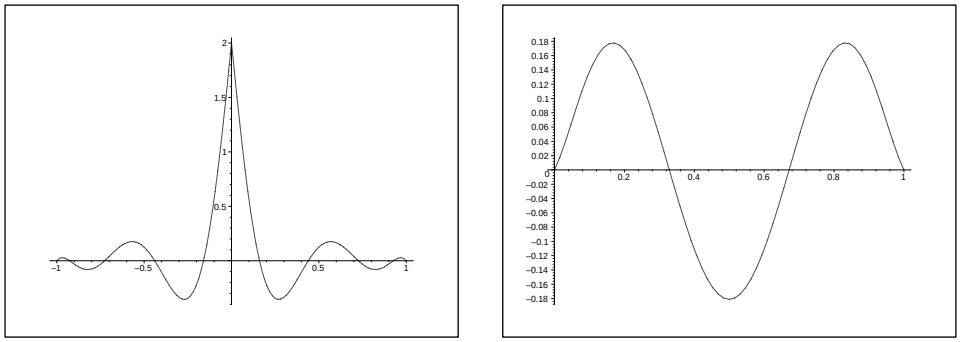
With $\phi_1^{n,0} = w_1^n$ we have the following theorem,

THEOREM 7.1. *For $n \geq 3$, $\Phi_n = (\phi_0^{n,0}, \phi_1^{n,0}, \phi_2^0 \dots, \phi_n^0)^T$ constructed as above is a continuous orthogonal generator for $B(\Phi)$. Furthermore, Φ_n has accuracy $n+1$.*

Figure 7.1 shows $\phi_0^{n,0}$ and $\phi_1^{n,0}$ for $n = 3$.

7.2. C^1 example. We now construct a family of C^1 orthogonal compactly supported generators which have varying degrees of accuracy. In this case four ramp functions, $r_1^i = t^i(1+t)^2$, $i = 0, 1$ and $l_1^i = t^i(1-t)^2$, $i = 0, 1$, are needed in the construction of the orthogonal generators with support equal to $[-1, 1]$. We set $\hat{r}_1^{n,i}(\cdot) = (I - P_{A^{n,1}})r_1^i(\cdot - 1)$ and $\hat{l}_1^{n,i}(t) = (I - P_{A^{n,1}})l_1^i$. The necessary integrals to compute the above projections can be found in [6]. In order to make the computations somewhat more tractable we biorthogonalize the above ramp functions. Utilizing the integrals [6]

$$\langle \hat{r}_0^{n,1}, \hat{l}_0^{n,1}\rangle = \frac{4(-1)^{n+1}(n^2+2n-9)(n-2)!}{(n+3)!}, \tag{7.3}$$



$\phi_0^{3,0}$ $\phi_1^{3,0}$

FIG. 7.1. *The functions* ϕ_0 *and* ϕ_3 *from section* 7.1 *for* $n = 3$.

$$\langle \hat{r}_0^{n,1}, \hat{l}_1^{n,1} \rangle = \frac{12(-1)^{n+1}(n-2)!}{(n+3)!}, \tag{7.4}$$

and

$$\langle \hat{r}_1^{n,1}, \hat{l}_1^{n,1} \rangle = \frac{36(-1)^{n+1}(n-3)!}{(n+4)!}, \tag{7.5}$$

we set $r_{n,0} = \hat{r}_0^{n,1}$, $l_{n,0} = \hat{l}_0^{n,1}$, $r_{n,1} = \hat{r}_1^{n,1} - \frac{\langle \hat{r}_1^{n,1}, l_{n,0} \rangle}{\langle r_{n,0}, l_{n,0} \rangle} r_{n,0}$, and $l_{n,1} = \hat{l}_1^{n,1} - \frac{\langle \hat{l}_1^{n,1}, r_{n,0} \rangle}{\langle r_{n,01}, l_{n,1} \rangle} l_{n,1}$. With the help of the inner products given above, we find

$$\langle r_{n,1}, l_{n,1} \rangle = \frac{(-1)^n 36(n-3)!}{(n+4)!(n^2+2n-9)} \tag{7.6}$$

and

$$\langle r_{n,1}, \phi_i^1 \rangle = -\frac{3}{8} \frac{2^{n+i}(n+i)!(n+i-4)!(i^2+i+2ni-n-3)}{(2n+2i)!(n^2+2n-9)}. \tag{7.7}$$

Two functions w_i, $i = 1, 2$ will be needed to construct orthogonal generators from the above ramp functions, and these will be symmetric and antisymmetric with respect to $1/2$ in order to construct symmetric or antisymmetric generators. To this end let $w_1 = v_0(n) + \alpha_1(n) v_2(n)$, where $v_i(n)$ linear combinations of ϕ_{n+1+i}^1 and ϕ_{n+3+i}^1 and chosen so that $\langle v_i(n), r_{n,1} \rangle = 0$. Thus $v_0(n) = -\frac{(5n+9)(n-2)}{2(2n+5)(2n+3)} \phi_{n+1}^1 + \phi_{n+3}^1$ and $v_2(n) = -9 \frac{(n+3)(n+1)n}{2(2n+9)(2n+7)(5n+9)} \phi_{n+3}^1 + \phi_{n+5}^1$. Likewise, $w_2 = v_1(n) + \alpha_2(n) v_3(n)$, where $v_i(n)$ $i = 1, 3$ are orthogonal to $r_{n,0}$. In this case $v_1(n) = -\frac{(n+8)(n+1)n}{2(2n+7)(2n+5)(n+8)} \phi_{n+2}^1 + \phi_{n+4}^1$ and $v_3(n) = v_1(n+2)$. The biorthogonality of the ramps and the construction of v_i, $i = 0, 1, 2, 3$ imply that each $\alpha_i(n)$ must be chosen as a solution to the equation

$$\langle r_{n,i}, l_{n,i} \rangle \langle w_{i+1}, w_{i+1} \rangle = \langle w_{i+1}, r_i^1(\cdot - 1) \rangle \langle w_{i+1}, l_i^1 \rangle.$$

Utilizing (7.6), (7.7), and $\langle \phi_n^1, \phi_n^1 \rangle = \frac{n!(n+8)!}{256(2n+9)!!(2n+7)!!}$ to compute the inner products needed in the above equation we find using *Maple* that

$$\alpha_1(n) = \frac{(5n+9)(2n+7)}{(n+3)} \times \frac{(2n+11)q_1(n) \pm (n+4)(n+5)(5n+9)(2n+7)\left\{\frac{5(2n+11)(n+4)}{n(n+1)(2n+3)} q_2(n)\right\}^{\frac{1}{2}}}{2q_3(n)},$$

where

$$q_1(n) = 41n^5 + 625n^4 + 3733n^3 + 11099n^2 + 17010n + 11340,$$

$$q_2(n) = 17n^5 + 131n^4 - 105n^3 - 2979n^2 - 7884n - 6804,$$

and

$$q_3(n) = 37n^7 + 1376n^6 + 18862n^5 + 139394n^4 + 502291n^3 + 1099160n^2 + 1287090n + 635040.$$

Likewise,

$$\alpha_2(n) = \frac{(2n+9)(n+8)}{(n+3)(n+6)} \times \frac{\left(-(2n+13)q_4(n) \pm (n+5)(n+6)(n+8)(2n+9)\left\{\frac{7(2n+13)(n+4)(n+1)}{(2n+5)(n+2)} q_5(n)\right\}^{\frac{1}{2}}\right)}{2q_6(n)},$$

where

$$q_4(n) = 11n^6 + 115n^5 + 323n^4 + 893n^3 + 8642n^2 + 28968n + 25200,$$

$$q_2(n) = 3n^5 + 27n^4 + 7n^3 - 503n^2 - 1486n - 1400,$$

and

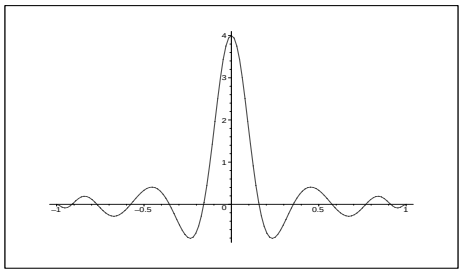
$$q_6(n) = 5n^7 + 39n^6 - 335n^5 - 5129n^4 - 29484n^3 - 112048n^2 - 242304n - 159600.$$

Knowing w_1 and w_2, we are now able to construct the orthogonal C^1 generator. Let $h_0(t) = 2|t|^3 - 3|t|^2 + 1$, if $t \in [-1, 1)$, and 0 elsewhere; $h_1(t) = (1-|t|)^2 t$, if $t \in [-1, 1)$, and 0 elsewhere; and $\phi_{i+1}^{n,1} = w_i$, $i = 1, 2$. Figure 7.2 shows $\phi_0^{n,1}$, $\phi_1^{n,1}$, $\phi_2^{n,1}$, and $\phi_1^{3,1}$ for $n = 6$. Then with

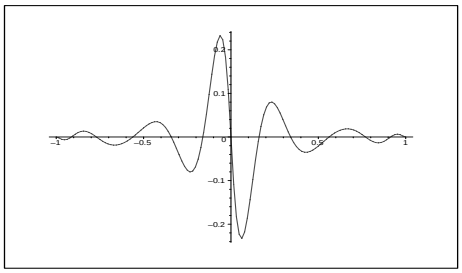
$$\phi_i^{n,1} = \left(I - P_{(\phi_2^1, \ldots, \phi_n^1, \phi_2^1(\cdot+1), \ldots, \phi_n^1(\cdot+1))}\right) h_i \qquad (i = 0, 1),$$

the above computations give the following theorem.

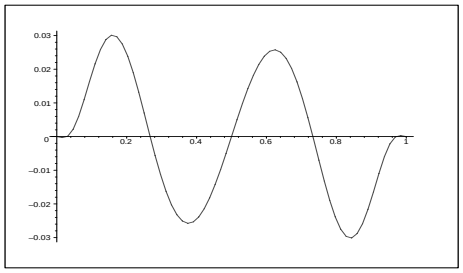
THEOREM 7.2. *For $n \geq 5$, and $\alpha_i(n)$ given above, $\Phi^1(n) = (\phi_0^{n,1}, \ldots, \phi_n^1)^T$ is a continuously differentiable orthogonal generator for $B(\Phi^1(n))$. Furthermore, the last $n-1$ functions are symmetric or antisymmetric about $1/2$. The first function $\phi_0^{n,1}$ is symmetric about 0, while $\phi_1^{n,1}$ is antisymmetric about 0.*



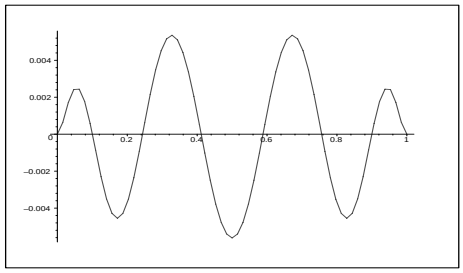
$\phi_0^{6,1}$



$\phi_1^{6,1}$



$\phi_2^{6,1}$



$\phi_3^{6,1}$

FIG. 7.2. *The functions* $\phi_i^{n,1}$ *for* $n = 6$ *and* $i = 0, \ldots, 3$.

We now construct the squeeze map associated with $\Phi^1(n)$. Since the last $n-2$ generators are supported on $[0,1]$ we need only concentrate on $\phi_0^{n,1}$ and $\phi_1^{n,1}$. Because of the definition of h_0 and h_1 and the symmetry of $\phi_0^{n,1}$ and $\phi_1^{n,1}$ it is easy to see that $W(n)$ is a diagonal matrix for all n. Therefore $R(n)$ is as in the previous C^1 example, and with $A_L^{(j)}$ a diagonal matrix $R(n)$ is equal to $A_R^{(j)}$. In order to complete the construction of the squeeze map we need to compute the inner products $\langle \Phi_L, \Phi_L \rangle$ and $\langle \Phi_R, \Phi_R \rangle$. From (3.9) in [6] (we would like to point out some errors in that equation; namely, $r_{i+1}^{n,k}$ in the first term on the right-hand side should be $r_i^{n,k}$, the factor multiplying the third term on the right-hand side should be $(n-k-1-i)$, and the factor multiplying the last term should be $(n+k+i+3)$) we find that

$$\langle r_0^{n,1}, r_0^{n,1} \rangle = 4 \frac{(n^2+2n-6)(n-2)!}{(n+3)!}, \tag{7.8}$$

$$\langle r_1^{n,1}, r_0^{n,1} \rangle = 6 \frac{(n-2)!}{(n+3)!}, \tag{7.9}$$

and

$$\langle r_1^{n,1}, r_1^{n,1} \rangle = 12 \frac{(n-3)!}{(n+4)!}. \tag{7.10}$$

To continue on we choose the minus sign in $\alpha_1(n)$ and the plus sign in $\alpha_2(n)$ to compute $\phi_i^{n,1}$ $i = 2, 3$. Then (7.7) and the norm squared of ϕ_n^1 can be employed to compute (using *Maple*) the norms of $\phi_i^{n,1}$, $i = 2, 3$ and the inner products of these functions with $\hat{r}_i^{n,1}, i = 0, 1$. With these in hand, (7.8), (7.9), and (7.10) can be used to compute $\langle \Phi_R, \Phi_R \rangle$, which is

$$\langle \Phi_R, \Phi_R \rangle = \begin{pmatrix} 4\frac{n^5+3n^4-10n^3-21n^2+27n+18}{(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} & -6\frac{n^3-9n+6}{(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} \\ -6\frac{n^3-9n+6}{(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} & 12\frac{n-3}{(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} \end{pmatrix}.$$

Since these functions are either symmetric or antisymmetric $\langle \Phi_L, \Phi_L \rangle$ is the same as the above matrix, except that the off diagonal elements take the opposite sign. Thus (2.3) becomes

$$BB^T = (L_j + L_{j-1}) \times \begin{pmatrix} 4\frac{(n^5+3n^4-10n^3-21n^2+27n+18)}{(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} & 6\frac{(L_j-L_{j-1})(n^3-9n+6)}{L_{j-1}(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} \\ 6\frac{(L_j-L_{j-1})(n^3-9n+6)}{L_{j-1}(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} & 12\frac{(L_j^2-L_jL_{j-1}+L_{j-1}^2)(n-3)}{L_{j-1}^2(n-2)(n^2+2n+9)(n+1)(n+2)(n+3)} \end{pmatrix}.$$

The determinant of the above matrix may be written as

$$\det(BB^T) = (L_j + L_{j-1})^2 \times \frac{12(n^3 - 9n - 18)(L_j^2 + L_{j-1}^2) + 6(5n^5 - 92n^3 + 54n^2 + 423n - 450)L_jL_{j-1}}{(L_{j-1}(n-2)(n^2+2n+9)(n+1)(n+2)(n+3))^2}$$

so that (4.3) may be used to compute B.

Acknowledgment. We thank the anonymous referees for their careful reading and suggestions.

A PRECONDITIONER FOR THE ELECTRIC FIELD INTEGRAL EQUATION BASED ON CALDERON FORMULAS*

SNORRE H. CHRISTIANSEN† AND JEAN-CLAUDE NÉDÉLEC†

Abstract. We describe a preconditioning technique for the Galerkin approximation of the electric field integral equation (EFIE), which arises in the scattering theory for harmonic electromagnetic waves. It is based on a discretization of the Calderon formulas and the Helmholtz decomposition. We prove several properties of the method, in particular that it produces a variational solution on a subspace of the Galerkin space for which we have an LBB inf-sup condition. When the Krylov spaces associated with the continuous operators are nondegenerate we prove that the discrete Krylov spaces converge as the mesh refinement goes to zero; when, moreover, the EFIE is nondegenerate on the continuous Krylov spaces, the discrete Krylov iterates converge towards the continuous ones. We also argue that one might expect the continuous Krylov iterates to exhibit superlinear convergence of the form $n \mapsto C^n(n!)^{-\alpha}$ for some $C > 0$ and $\alpha > 0$. Finally, we illustrate the theory with numerical experiments.

Key words. electric field integral equation, Calderon formula, preconditioning, Krylov subspace

Introduction. In [51] Steinbach and Wendland described several strategies for the preconditioning of some boundary integral equations of the first kind, based on the knowledge of an operator of the opposite order. On several examples of symmetric positive definite (SPD) integral operators, they provided a discretization of the operators to construct a preconditioner such that the extreme eigenvalues of the preconditioned matrix remain bounded away from 0 and $+\infty$ independently of the mesh refinement. When iterative algorithms are used to solve the matrix equations, this in turn is well known to yield convergence estimates that are also independent of the mesh refinement, of the form $\|U^n - U^\star\| \leq C\alpha^n\|U^\star\|$ for some $C > 0$, $0 < \alpha < 1$ (so-called linear convergence).

In [17] we adapted the theory to some non-SPD problems. We showed that in these cases one can still prove that the spectral condition number of the preconditioned matrix remains bounded independently of the mesh refinement, as long as all the bilinear forms involved satisfy uniform inf-sup estimates on the Galerkin spaces. This was applied to some problems of three-dimensional acoustic scattering. Complementary results, in particular close to resonant frequencies, were exposed in [18].

We restricted our attention to preconditioners deduced from Calderon formulas—for some scalar operators—and remarked that they provide an inverse up to a compact endomorphism. One would expect this to produce a matrix with a spectrum clustered around 1. This would imply very fast, perhaps in some sense superlinear, convergence of Krylov subspace methods. However, we presented no formal proof of this intuition.

In this paper we use the Calderon formulas—for some operators on tangential vector fields—to construct a preconditioner for the electric field integral equation (EFIE). Compared with the scalar case there is a major pitfall: the involved bilinear forms do not all satisfy uniform inf-sup conditions on the standard Galerkin spaces

(Proposition 3.1). We nevertheless construct a numerically efficient preconditioner for which we can identify and prove satisfactory properties. In effect the Galerkin problem is solved on a subspace of the standard space, and we show that this subspace has all the properties required to ensure the well-posedness of the EFIE on it (Theorem 3.15). We also prove that the discretized preconditioner is stable and approximating in the sense of Proposition 4.6. The discrete Krylov spaces converge as the mesh refinement h decreases to 0 (Theorem 4.7) and from this we deduce that, under some natural hypotheses, the approximate solution at iteration n converges as $h \to 0$, towards a vector u^n (Corollary 4.10). We also explain why we expect (u^n) to converge superlinearly, perhaps even at the rate $C^n(n!)^{-\alpha}$, for some $C > 0$, $\alpha > 0$ (section 4.3).

We first officially detailed this discretization technique in [16] and announced the theorems justifying it in [19]. Proofs of one of them (Theorem 1.2) can be found in [15]. (This paper also contains complementary results on the behavior of the equation at resonant frequencies.) In the present paper we explicitate and prove—and sometimes improve—the remaining announced results, as well as a few others that sustain the construction.

At about the same time, in [21], another research team announced progress on what also amounts to the use of the Calderon formulas for the construction of a stable method. However, discretizations were proposed only for Nyström schemes, and it seems that for these they did not encounter a difficulty comparable to Proposition 3.1. Since this was the main problem we had to solve in the Galerkin setting, in extending the method from acoustics to electromagnetics, we believe there to be no overlap for the techniques involved.

Outline. The paper is organized as follows:

Section 1. We describe the continuous problem we are dealing with and state sufficient conditions for the discretization to satisfy uniform inf-sup estimates. We also prove the Calderon formulas.

Section 2. We define the Galerkin spaces we will use and give some useful properties: negative norm estimates, approximation properties for harmonic tangent fields, and properties of the discrete Helmholtz decomposition.

Section 3. We introduce the preconditioner we propose, after having described the main difficulty. Then we give a first interpretation of the system we solve and the projections we use. We give several characterizations of the range of the discrete rotation operator and deduce from these that the EFIE is well posed on this subspace. We also devise an intrinsic stopping criterion for the algorithm.

Section 4. We show the convergence of the Krylov subspaces and explain why this should lead to superlinear convergence of the iterates.

Section 5. We illustrate the theory with numerical results for diffraction by a sphere, a cavity, and a singular geometry.

1. The EFIE. We briefly recall the setting for exterior boundary value problems for the harmonic Maxwell equations, the integral representation of exterior electromagnetic fields, and the related integral equation known as the EFIE, as presented, for instance, in Cessenat [14] or Nédélec [43]. Then we turn to the discretization of this equation by the Galerkin method and state some new sufficient conditions (obtained in Christiansen [15]) for its well-posedness, in the sense of satisfying a uniform inf-sup condition. This in turn is well known to guarantee *quasi-optimal* convergence of the approximate solutions. Finally, we include a proof of the Calderon formulas and explain why they should lead to an efficient preconditioning technique.

1.1. The continuous problem. Let Ω_- be a smooth, bounded, and open subset of $\mathbb{R}^3$, denote by Γ its surface, and denote by Ω_+ the complement of $\Omega_- \cup \Gamma$. We refer to Ω_- as the interior domain and to Ω_+ as the exterior domain. The unit-length orthogonal vector field on Γ, pointing into Ω_+, is denoted n. We suppose throughout that Ω_+ is connected. The free-space harmonic Maxwell equations for vector fields E and H in Ω_+ are

$$\operatorname{curl} E = +i\omega\mu H, \tag{1.1}$$

$$\operatorname{curl} H = -i\omega\epsilon E, \tag{1.2}$$

where μ is the magnetic permeability, ϵ is the electric permittivity, and ω is the pulsation. Define the wavenumber k and the impedance Z by

$$k = \omega(\mu\epsilon)^{1/2}, \tag{1.3}$$

$$Z = (\mu/\epsilon)^{1/2}. \tag{1.4}$$

Then we have $+i\omega\mu = +ikZ$ and $-i\omega\epsilon = -ik/Z$.

Spaces of functions. On any smooth Riemannian manifold M which is either an open subset of an Euclidean space or is compact without boundary, the usual Sobolev spaces of scalar and tangential fields of regularity order $s \in \mathbb{R}$ are denoted $\mathrm{H}^s(M)$ and $\mathrm{H}^s_{\mathrm{T}}(M)$, respectively (see, e.g., Taylor [52, Chap. 4]), and the corresponding norms are both written

$$u \mapsto |u|_s. \tag{1.5}$$

On any open subset Ω of $\mathbb{R}^3$, define the Sobolev spaces $\mathrm{H}^s_{\mathrm{curl}}(\Omega)$ of vector fields by

$$\mathrm{H}^s_{\mathrm{curl}}(\Omega) = \{v \in \mathrm{H}^s_{\mathrm{T}}(\Omega) \ : \ \operatorname{curl} v \in \mathrm{H}^s_{\mathrm{T}}(\Omega)\}. \tag{1.6}$$

We will use also the Hilbert spaces $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$ of tangent fields on Γ defined by

$$\mathrm{H}^s_{\mathrm{div}}(\Gamma) = \{u \in \mathrm{H}^s_{\mathrm{T}}(\Gamma) \ : \ \operatorname{div} u \in \mathrm{H}^s(\Gamma)\}. \tag{1.7}$$

The spaces $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$ are equipped with the norms

$$u \mapsto \|u\|_s \ : \ \|u\|_s^2 = |u|_s^2 + |\operatorname{div} u|_s^2. \tag{1.8}$$

We define $\mathrm{H}^s_{\mathrm{rot}}(\Gamma)$ in a similar way, but we do not introduce any notation for the corresponding norm. Notice that $u \mapsto u \times n$ induces isomorphisms $\mathrm{H}^s_{\mathrm{rot}}(\Gamma) \to \mathrm{H}^s_{\mathrm{div}}(\Gamma)$ and $\mathrm{H}^s_{\mathrm{div}}(\Gamma) \to \mathrm{H}^s_{\mathrm{rot}}(\Gamma)$.

For any space of (scalar) distributions X on Γ, we denote by $X^\bullet$ the subspace of elements u such that for all v that are constant on each connected component of Γ (i.e., satisfying $\Delta v = 0$) $\langle u, v\rangle = 0$. Δ has a meaning even for vector distributions (currents). As usual, the Hilbert spaces we consider are vector spaces over $\mathbb{C}$ obtained as complexifications of real Hilbert spaces of scalar and tangent fields. In particular, they are equipped with conjugations $u \mapsto \overline{u}$, induced by the standard conjugation in $\mathbb{C}$.

Recall the result of Paquet [45] (see [43, Thm. 5.4.2, p. 209]) that we have well-defined continuous and surjective tangential trace operators for arbitrary large enough $R > 0$ (with $B_R = \{x \in \mathbb{R}^3 \ : \ |x| < R\}$):

$$\gamma_{\mathrm{T}} : \left\{ \begin{array}{rcl} \mathrm{H}^0_{\mathrm{curl}}(\Omega_+ \cap B_R) & \to & \mathrm{H}^{-1/2}_{\mathrm{rot}}(\Gamma), \\ v & \mapsto & v_{\mathrm{T}} = v - (v \cdot n)n. \end{array} \right. \tag{1.9}$$

For simplicity we denote by $\mathrm{H}^0_{\mathrm{curl}}(\Omega_+)_{loc}$ the Fréchet space of vector fields in Ω_+ whose restrictions are in $\mathrm{H}^0_{\mathrm{curl}}(\Omega_+ \cap B_R)$ for all $R > 0$. We caution the reader that this notation is sometimes (but not in this article) used for a different space consisting of the fields whose restrictions are in $\mathrm{H}^0_{\mathrm{curl}}(\Omega_+ \cap U)$ for all open U such that $\overline{U}$ is a compact subset of Ω_+. This space is larger, since it allows rather wild behavior close to Γ. In particular, there is no trace operator on this space.

A technique we shall use many times is to write tangential vector fields u in the form of their Helmholtz decomposition:

$$u = \operatorname{grad} p + \operatorname{rot} q + \alpha, \tag{1.10}$$

with $\Delta\alpha = 0$, and to use regularity theorems of the Laplacian to characterize p and q. We shall refer to this technique as the *HDRL*. It was used to study electromagnetic scattering by DeLaBourdonnaye [24].

Integral representation for exterior scattering problems. The basic property for exterior boundary value problems for the harmonic Maxwell equations is (see [43, Thm. 5.4.6, p. 220]) that for any $k > 0$, and any $v \in \mathrm{H}^{-1/2}_{\mathrm{rot}}(\Gamma)$, there is a unique $(E, H) \in \mathrm{H}^0_{\mathrm{curl}}(\Omega_+)^2_{loc}$ such that

- (E, H) solves the harmonic Maxwell equations in Ω_+,
- (E, H) satisfies the Silver–Müller radiation conditions,
- and $\gamma_{\mathrm{T}} E = v$.

Let G_k be the fundamental solution of the Helmholtz operator $-\Delta - k^2$ satisfying the Sommerfeld radiation condition

$$G_k(x, y) = \frac{e^{ik|x-y|}}{4\pi|x-y|}, \tag{1.11}$$

and let Φ_k be the potential, mapping any sufficiently smooth tangent field u on Γ to the field in $\mathbb{R}^3$ defined away from Γ by

$$(\Phi_k u)(y) = \int_\Gamma G_k(x, y) u(x) \mathrm{d}x. \tag{1.12}$$

Returning to the above boundary value problem, if k is not a resonance of the *interior* Maxwell equations there is a unique $u \in \mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$ such that for all $y \in \Omega_+$

$$E = (1 + (1/k^2) \operatorname{grad} \operatorname{div}) \Phi_k u, \tag{1.13}$$

$$H = 1/(ikZ) \operatorname{curl} \Phi_k u. \tag{1.14}$$

This formula is a special case of the Stratton–Chu integral representation (see [43, Thm. 5.5.1, p. 234]). For any $k \neq 0$ we define the electric field integral operator A_k by

$$A_k u = \gamma_{\mathrm{T}} (1 + (1/k^2) \operatorname{grad} \operatorname{div}) \Phi_k u. \tag{1.15}$$

One shows that the EFIO is continuous $A_k : \mathrm{H}^s_{\mathrm{div}} \to \mathrm{H}^s_{\mathrm{rot}}$ and that if k is not a resonance of the interior problem it is an isomorphism (see [43, Thm. 5.6.2, p. 247]).

Thus if k is not a resonant frequency the exterior problem for a given $v \in \mathrm{H}^{-1/2}_{\mathrm{rot}}(\Gamma)$ is reduced to the problem of solving the integral equation $A_k u = v$, called EFIE.

Variational formulation. From the HDRL it follows that the bilinear form on smooth tangent fields,

$$(u,v) \mapsto \langle u, v\rangle = \int_\Gamma u \cdot v, \tag{1.16}$$

extends continuously to a duality between $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$ and $\mathrm{H}^{-1-s}_{\mathrm{rot}}(\Gamma)$ (see also [43, Lem. 4.5.1, p. 208]). Thus one obtains the variational formulation of the EFIE. For a given $v \in \mathrm{H}^s_{\mathrm{rot}}(\Gamma)$, solve

$$u \in \mathrm{H}^s_{\mathrm{div}}(\Gamma) \quad \text{and} \quad \forall u' \in \mathrm{H}^{-1-s}_{\mathrm{div}}(\Gamma) \quad \langle A_k u, u'\rangle = \langle v, u'\rangle. \tag{1.17}$$

Remark that the case $s = -1/2$ is symmetric. From a practical point of view it is important that we have the following expression, with only weakly singular integrals (all integrals are on Γ):

$$\begin{aligned}\langle A_k u, u'\rangle = &\iint G_k(x,y) u(x)\cdot u'(y)\mathrm{d}x\mathrm{d}y \\ &-(1/k^2)\iint G_k(x,y)\,\mathrm{div}\, u(x)\,\mathrm{div}\, u'(y)\mathrm{d}x\mathrm{d}y.\end{aligned} \tag{1.18}$$

1.2. Discretization. Put $X = \mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$. Given some sequence (X_h) of closed (finite-dimensional) subspaces of X, the Galerkin method to solve (1.17) is to consider the problems

$$u \in X_h \quad \text{and} \quad \forall u' \in X_h \quad \langle A_k u, u'\rangle = \langle v, u'\rangle. \tag{1.19}$$

When it is uniquely solvable for each h one obtains a sequence (u_h), and it is of fundamental importance to know to which extent it converges towards $A_k^{-1}v$.

In this context we have the following fundamental theorem due to Babuska [2].

THEOREM 1.1. *Let X be a reflexive Banach space and $\mathcal{A} : X \to X^\star$ be linear and continuous. Suppose we have a closed subspace X_h of X and that for some $\alpha > 0$ we have*

$$\inf_{u\in X_h}\sup_{u'\in X_h}\frac{|(\mathcal{A}u)(u')|}{\|u\|\,\|u'\|} \geq \alpha \tag{1.20}$$

$$\forall u' \in X_h \quad \big(\forall u \in X_h\ (\mathcal{A}u)(u') = 0\big) \Rightarrow \big(u' = 0\big). \tag{1.21}$$

Then the induced map $\mathcal{A}_h : X_h \to X_h^\star$ is invertible (with an inverse of norm less than α^{-1}). Moreover, for all $l \in X^\star$, if we have a solution $u \in X$ to $\mathcal{A}u = l$, then

$$\|\mathcal{A}_h^{-1}(l|_{X_h}) - u\| \leq \big(1 + \alpha^{-1}\|\mathcal{A}\|\big)\inf\{\|u' - u\| \ :\ u' \in X_h\}. \tag{1.22}$$

Notice that finite-dimensional subspaces are closed and that for these condition (1.21) is implied by (1.20).

Now suppose we have a family (X_h) of closed subspaces of X. When there is an α that holds for all h in estimate (1.20), and (1.21) holds for all h, we say that we have a *uniform discrete inf-sup condition*. Then the only remaining point is whether the spaces X_h are *approximating*, in the sense that

$$\forall u \in X \quad \lim_h \inf\{\|u - u'\| \ :\ u' \in X_h\} = 0. \tag{1.23}$$

In general this question is well studied in the literature (with improved convergence estimates on some dense subspaces of X). However, in order to justify the preconditioning technique we shall describe in this paper, we will need to study this question for some nonstandard spaces.

Inf-sup conditions for the EFIE. The Galerkin discretization of the EFIE by Raviart–Thomas-type vector fields was studied by Bendali [4, 5]. More generally, we consider the following hypotheses for the Galerkin spaces (X_h).

(H0) The spaces X_h are finite-dimensional subspaces of $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$, which are stable under the conjugation $u \mapsto \overline{u}$ (*conj.-stable* for short).

(H1) There is $C > 0$ such that for all $u \in \mathrm{H}^1_{\mathrm{div}}(\Gamma)$

$$\inf_{u' \in X_h} \|u - u'\|_0 \leq Ch\|u\|_1. \tag{1.24}$$

(H2) There is $C > 0$ such that, for all $u \in X_h$, $\|u\|_0 \leq Ch^{-1}\|u\|_{-1}$.

(H3) Putting $W_h = \{u \in X_h \ : \ \operatorname{div} u = 0\}$, there is $C > 0$ such that for all $u \in X_h$, if

$$\forall w \in W_h \quad \langle u, w\rangle = 0, \tag{1.25}$$

then the solution ϕ of

$$\phi \in \mathrm{H}^1(\Gamma)^\bullet \quad \text{and} \quad \Delta\phi = \operatorname{div} u \tag{1.26}$$

satisfies

$$|u - \operatorname{grad}\phi|_0 \leq Ch|\operatorname{div} u|_0. \tag{1.27}$$

Notice that (H3) implies the usual inf-sup estimate: There is $C > 0$ such that

$$\inf_{q \in \operatorname{div} X_h} \sup_{u \in X_h} \frac{|\langle q, \operatorname{div} u\rangle|}{|q|_0\|u\|_0} \geq \frac{1}{C}. \tag{1.28}$$

The following theorem was proved in Christiansen [15].

THEOREM 1.2. *If k is not a resonance of the interior problem and a family (X_h) of Galerkin spaces satisfies the four conditions* (H0),...,(H3)*, then the bilinear form induced by A_k on X satisfies a uniform inf-sup condition on X_h.*

Of course these hypotheses also guarantee that in addition the (X_h) are approximating, so the approximate solution converges to the exact one (see section 2.2 for some details on this question).

The fact that the fields obtained by suitable transportation of Raviart–Thomas fields onto Γ satisfy these hypotheses is also checked in Christiansen [15], relying mostly on classical results that can be found, for instance, in Brezzi and Fortin [12]. Variants of the estimate on discrete Helmholtz decompositions appearing in (H3) have been used to study eigenvalue problems in mixed form and related discrete compactness results (see Kikuchi [37], Boffi [7], Boffi, Brezzi, and Gastaldi [8], and Demkowicz et al. [27]). Here, as already indicated, we will need to prove the hypothesis for some new spaces, in order to justify our preconditioning technique.

Solving the matrix equation. To solve the Galerkin problem one chooses a basis $e_h = (e_h(i))$ of X_h and defines the matrix $A_h(k)$ and the tuple V_h by

$$A_h(k)_{ij} = \langle A(k)e_h(j), e_h(i)\rangle, \qquad (V_h)_i = \langle v, e_h(i)\rangle. \tag{1.29}$$

In other words $A_h(k)$ is the matrix, from e_h to its dual basis, of the induced map

$$\mathcal{A}_h(k) : \left\{ \begin{array}{rcl} X_h & \to & X_h^\star, \\ u & \mapsto & \langle A(k)u, \cdot\rangle, \end{array} \right. \tag{1.30}$$

whereas V_h is the coordinate vector, in the dual basis of e_h, of the linear form $\langle v, \cdot \rangle$ restricted to X_h.

Then the discrete Galerkin problem (1.19) is stated in matrix terms as

$$A_h(k)U = V_h. \tag{1.31}$$

When this equation is solved iteratively one usually observes very slow convergence, if one observes it at all. Loosely speaking this is due to the fact that the operator A_k, via the Helmholtz decomposition, is seen to have one term of order 1 and another of order -1 acting on supplementary infinite-dimensional subspaces and with different signs. Thus, at least if the basis e_h is such that the canonical scalar product on $\mathbb{C}^{\dim X_h}$ corresponds to the $\mathrm{H}^0_{\mathrm{T}}(\Gamma)$ scalar product, the spectrum of $A_h(k)$ accumulates both at 0 and ∞. The presence of resonant frequencies further deteriorates the conditioning of the matrix.

This motivates our search for a preconditioner, that is, a matrix Z_h, such that, when Z_h is incorporated in an iterative solver, the reduction in the number of iterations required to obtain a satisfactory approximate solution outweighs the overhead of multiplying by Z_h. It is well known that this is achieved whenever Z_h is some easily computable approximate inverse of $A_h(k)$.

For ease of interpretation we will drop the matrix point of view and look instead for some easily computable $\mathcal{Z}_h : X_h^\star \to X_h$ which approximately inverts $\mathcal{A}_h(k)$. However, it should be kept in mind that the method is effective only in as far as it can be translated into a matrix manipulating algorithm.

1.3. Calderon formulas. The preconditioning technique we study in this paper is based on the Calderon formulas which we start by recalling. They are detailed in the electromagnetic setting in both Cessenat [14] and Nédélec [43]. We include a derivation of them mainly because the notations adopted here are not quite the same. Of course many of the arguments developed in this section were implicitly assumed while we introduced the EFIE and should be placed earlier in a strictly logical development.

Denote by B the operator on tangent fields on Γ defined by

$$Bu = u \times n. \tag{1.32}$$

Let $\wp$ be the orthogonal projection onto Γ, which is defined and smooth on a tubular neighborhood of Γ. Extending n to this neighborhood by $\wp$, we can define at any point x of this neighborhood, the tangential component of any vector v, by $\mathrm{T}_x v = v - (v \cdot n(x))n(x)$. Define an operator C_k on tangent fields on Γ, by taking the principal value of the tangential component in the exterior and interior domains (with respect to shrinking balls centered on Γ), of the following potential:

$$C_k u = \mathrm{PV}\,\mathrm{T}\,\mathrm{curl}\,\Phi_k u. \tag{1.33}$$

In fact, for smooth u the field $\mathrm{curl}\,\Phi_k u$ has different interior and exterior tangential traces which are both finite. More precisely, denoting γ_{T}^+ and γ_{T}^- the exterior and interior trace operators one has

$$\gamma_{\mathrm{T}}^+ \,\mathrm{curl}\,\Phi_k u = +(1/2)Bu + C_k u, \tag{1.34}$$

$$\gamma_{\mathrm{T}}^- \,\mathrm{curl}\,\Phi_k u = -(1/2)Bu + C_k u. \tag{1.35}$$

In particular, one has the familiar *jump formula*

$$u = [(\mathrm{curl}\,\Phi_k u) \times n] = B(\gamma^- \,\mathrm{curl}\,\Phi_k u - \gamma^+ \,\mathrm{curl}\,\Phi_k u). \tag{1.36}$$

We also remind the reader that for potentials of the form

$$(1+(1/k^2)\operatorname{grad}\operatorname{div})\Phi_k u, \tag{1.37}$$

the exterior and interior tangential traces are equal (and given by the EFIO), thus there is no tangential "jump" for these.

To derive the Calderon formulas the last ingredient we need is the *representation theorem*.

THEOREM 1.3. *Suppose (E,H) is a field whose restrictions to Ω_- and Ω_+ are in $\mathrm{H}^0_{\mathrm{curl}}(\Omega_-)^2$ and $\mathrm{H}^0_{\mathrm{curl}}(\Omega_+)^2_{loc}$ and solve Maxwell's equations for a given wavenumber k. Suppose also that it verifies the Silver–Müller radiation conditions. Define the electric and magnetic currents j and m on Γ by the jump formulas*

$$j=[H\times n]=(\gamma_{\mathrm{T}}^- H-\gamma_{\mathrm{T}}^+ H)\times n, \tag{1.38}$$

$$m=[E\times n]\ =(\gamma_{\mathrm{T}}^- E-\gamma_{\mathrm{T}}^+ E)\times n. \tag{1.39}$$

Then in Ω_- and Ω_+ we have

$$E=\ (+ikZ)(1+(1/k^2)\operatorname{grad}\operatorname{div})\Phi_k j\ +\operatorname{curl}\Phi_k m, \tag{1.40}$$

$$H=(-ik/Z)(1+(1/k^2)\operatorname{grad}\operatorname{div})\Phi_k m+\operatorname{curl}\Phi_k j. \tag{1.41}$$

Now the theorem we are interested in is the following.

THEOREM 1.4. *The following operator is a projector:*

$$\begin{bmatrix} 1/2-BC_k & -(-ik/Z)BA_k \\ -(+ikZ)BA_k & 1/2-BC_k \end{bmatrix}. \tag{1.42}$$

More explicitly, we have

$$BC_kBC_k+k^2BA_kBA_k=1/4, \tag{1.43}$$

$$BC_kBA_k+BA_kBC_k=0. \tag{1.44}$$

Proof. Choose two (smooth enough) tangent fields u and v on Γ. Define fields E and H by putting, *in the exterior domain*,

$$E=\ (+ikZ)(1+(1/k^2)\operatorname{grad}\operatorname{div})\Phi_k u\ +\operatorname{curl}\Phi_k v, \tag{1.45}$$

$$H=(-ik/Z)(1+(1/k^2)\operatorname{grad}\operatorname{div})\Phi_k v+\operatorname{curl}\Phi_k u. \tag{1.46}$$

Then we have

$$-\gamma_{\mathrm{T}}^+ H\times n=-(-ik/Z)BA_k v+(1/2-BC_k)u, \tag{1.47}$$

$$-\gamma_{\mathrm{T}}^+ E\times n=-(+ikZ)BA_k u+(1/2-BC_k)v. \tag{1.48}$$

In the interior domain put $E=0$ and $H=0$. Now we have

$$[H\times n]=-\gamma_{\mathrm{T}}^+ H\times n, \tag{1.49}$$

$$[\,E\times n]=-\gamma_{\mathrm{T}}^+ E\times n. \tag{1.50}$$

Using the representation theorem, these tangent fields give rise to new integral representations for E and H. Now to say that the announced operator is a projector just expresses that taking the jumps (or the appropriate exterior traces) of these new

integral representations for the same fields (E, H) should yield the same jumps (or exterior traces). □

The operator appearing in (1.42) is called the *exterior Calderon projector*.

The crucial remark is now that the operator BC_kBC_k is a compact endomorphism of $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$, thus $4k^2BA_kB$ inverts A_k up to a compact operator. The scalar coefficient $4k^2$ is unimportant for preconditioning purposes, so our aim will be to discretize the operator BA_kB. Since we deal with variational formulations we express our goal in terms of bilinear forms, for which it is preferable to have symmetric formulations, so, remarking that $B = -B^\star = B^{\star-1}$, we set out to discretize the map

$$\mathcal{Z}_k = \mathcal{B}^{\star-1}\mathcal{A}_k\mathcal{B}^{-1}, \tag{1.51}$$

where $\mathcal{B}$ is the isomorphism

$$\left\{ \begin{array}{rcl} \mathrm{H}^s_{\mathrm{div}}(\Gamma) & \to & \mathrm{H}^{-1-s}_{\mathrm{div}}(\Gamma)^\star, \\ u & \mapsto & \langle Bu, \cdot \rangle. \end{array} \right. \tag{1.52}$$

2. Some properties of some Galerkin spaces. We recall the definition and basic properties of the Galerkin spaces on Γ that we will use in this article, including the null sequences relating spaces of scalar and tangent finite elements, as well as some negative norm estimates. Of particular importance will be the approximation of harmonic tangent fields and the structure of the discrete Helmholtz decomposition that largely follows from it.

2.1. Surface finite element spaces. Recall that we denote by $\wp$ the orthogonal projection onto Γ, which is defined and smooth on a tubular neighborhood of Γ. Let $(\mathcal{T}_h)$ be a family of triangulations of Γ, where for all h the largest diameter of a triangle of $\mathcal{T}_h$ is h. We will always suppose that $(\mathcal{T}_h)$ is regular and most often that it is (globally) quasi-uniform. Let Γ_h be the affine polyhedron determined by $\mathcal{T}_h$, considered as a Lipschitz manifold. For small enough h, $\wp$ induces Lipschitz isomorphisms $\Gamma_h \to \Gamma$, and we denote by Ξ_h the inverse mappings.

Fix a nonzero $m \in \mathbb{N}$. On Γ_h we consider the space $\mathsf{S}^0(\mathcal{T}_h)$ of continuous scalar functions whose restriction to any triangle is P^m (a polynomial of degree m), the space $\mathsf{S}^1(\mathcal{T}_h)$ of Raviart–Thomas $\mathrm{H}^0_{\mathrm{div}}$-conforming vector fields of degree m, and the space $\mathsf{S}^2(\mathcal{T}_h)$ of scalar functions whose restriction to any triangle is P^{m-1}.

From these finite element spaces on Γ_h we deduce finite element spaces on Γ by the transport formulas

$$\begin{array}{rcll} \mathsf{S}^0_h & = & \{x \mapsto & u(\Xi_h(x)) : u \in \mathsf{S}^0(\mathcal{T}_h)\}, \\ \mathsf{S}^1_h & = & \{x \mapsto & \mathrm{Jac}\,\Xi_h(x)\mathrm{D}\Xi_h(x)^{-1}u(\Xi_h(x)) : u \in \mathsf{S}^1(\mathcal{T}_h)\}, \\ \mathsf{S}^2_h & = & \{x \mapsto & \mathrm{Jac}\,\Xi_h(x)u(\Xi_h(x)) : u \in \mathsf{S}^2(\mathcal{T}_h)\}. \end{array} \tag{2.1}$$

These transport formulas were chosen to make the following diagram commute. The horizontal arrows are the differential operators rot and div, whereas the vertical ones are the above transport formulas.

$$\begin{array}{ccccccccc} 0 & \to & \mathsf{S}^0(\mathcal{T}_h) & \to & \mathsf{S}^1(\mathcal{T}_h) & \to & \mathsf{S}^2(\mathcal{T}_h) & \to & 0 \\ \downarrow & 0 & \downarrow & \mathrm{rot} & \downarrow & \mathrm{div} & \downarrow & 0 & \downarrow \\ 0 & \to & \mathsf{S}^0_h & \to & \mathsf{S}^1_h & \to & \mathsf{S}^2_h & \to & 0 \end{array} \tag{2.2}$$

Of course this diagram is a realization of a corresponding diagram on differential forms, on which the exterior derivative act, transported by the standard pull-back

of differential forms determined by Ξ_h. The connection between finite elements and differential forms, especially Whitney forms, was stressed by Bossavit [9] and further explicitated in the affine case in Hiptmair [32]. While this is useful to keep in mind we stick to tangent vector fields and scalar fields on Γ, since in accordance with widespread conventions we have chosen to represent the exterior electromagnetic fields as fields of vectors, not alternate forms. The relevance of commuting diagrams to the study of finite elements is noted in Boffi [7].

Remark also that when studying the approximation of the boundary Γ by piecewise polynomial triangulations as in Nédélec [40], one is led to consider Galerkin spaces defined by pull-backs by maps that are slightly different from Ξ_h.

2.2. Basic negative norm estimates. Since negative (and noninteger) Sobolev norms and corresponding approximation results pervade this article, we now recall rather informally the results needed. Of course we do not claim any originality for these results, and we have included them mainly for the convenience of the exposition.

Let (X_h) be a family of Galerkin spaces satisfying (H0) and (H1). Let $\mathcal{Q}_h$ be the $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$-orthogonal projection onto X_h.

It is well known that

$$\|\mathcal{Q}_h u\|_0 \leq C\|u\|_0 \quad \text{and} \quad \|u - \mathcal{Q}_h u\|_0 \leq Ch\|u\|_1. \tag{2.3}$$

From the HDRL (section 1.1) it follows that the spaces $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$ for $0 \leq s \leq 1$ can be obtained by interpolation. Hence interpolation on the operator $\mathcal{I} - \mathcal{Q}_h$, for $0 \leq s \leq 1$, gives

$$\|u - \mathcal{Q}_h u\|_0 \leq Ch^s\|u\|_s. \tag{2.4}$$

Then one uses the regularity of the $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$-inner product (written $(\cdot|\cdot)_0$) on various Sobolev spaces. This technique is the familiar Aubin–Nitsche trick. That $\mathrm{H}^s_{\mathrm{div}}(\Gamma)$ and $\mathrm{H}^{-s}_{\mathrm{div}}(\Gamma)$ are dual with respect to the $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$-inner product can be deduced from the fact that the operator $I - \operatorname{grad}\operatorname{div}$ is an isomorphism $\mathrm{H}^s_{\mathrm{div}}(\Gamma) \to \mathrm{H}^{s-1}_{\mathrm{rot}}(\Gamma)$ and that this space, as already remarked, is the $\mathrm{L}^2_{\mathrm{T}}$-dual of $\mathrm{H}^{-s}_{\mathrm{div}}(\Gamma)$. Both of these facts can be proved using the HDRL. For $0 \leq s \leq 1$ we have

$$\|u - \mathcal{Q}_h u\|_{-s} \leq C \sup_{v \in \mathrm{H}^s_{\mathrm{div}}} \frac{|(u - \mathcal{Q}_h u|v)_0|}{\|v\|_s} \tag{2.5}$$

$$\leq C \sup_{v \in \mathrm{H}^s_{\mathrm{div}}} \frac{|(u - \mathcal{Q}_h u|v - \mathcal{Q}_h v)_0|}{\|v\|_s} \tag{2.6}$$

$$\leq C\|u - \mathcal{Q}_h u\|_0 \, \|\mathcal{I} - \mathcal{Q}_h\|_{0,s}. \tag{2.7}$$

Here $\|\mathcal{I} - \mathcal{Q}_h\|_{0,s}$ is of course the norm of the induced map

$$\mathcal{I} - \mathcal{Q}_h : \mathrm{H}^s_{\mathrm{div}}(\Gamma) \to \mathrm{H}^0_{\mathrm{div}}(\Gamma). \tag{2.8}$$

This gives for $0 \leq s, s' \leq 1$

$$\|u - \mathcal{Q}_h u\|_{-s} \leq Ch^{s+s'}\|u\|_{s'}. \tag{2.9}$$

If in addition we have the inverse inequality (H2) we obtain

$$\|\mathcal{Q}_h u\|_{-1} \leq \|u\|_{-1} + \|u - \mathcal{Q}_h u\|_{-1} \leq \|u\|_{-1} + Ch\|u\|_0 \leq C\|u\|_{-1}. \tag{2.10}$$

This is proved first for $u \in \mathrm{H}^0_{\mathrm{div}}(\Gamma)$ and then extended to $u \in \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)$ by a density argument. By interpolation on $\mathcal{Q}_h$ one then extends this stability result to all $-1 \leq s \leq 0$:

$$\|\mathcal{Q}_h u\|_s \leq C\|u\|_s. \tag{2.11}$$

2.3. Approximation of harmonic fields. Since we deal with surfaces which we do not require to be simply connected, a useful construct is that of the associated cohomology groups of which we give the realizations in terms of vector and scalar fields, the so-called harmonic fields. (This notion of harmonicity is only remotely related to the harmonicity of the electromagnetic waves we consider.) We denote these spaces by $\mathbb{G}^i$ for $i = 0, 1, 2$. For instance $\mathbb{G}^1$ can be characterized as the L_2-orthogonal of the range of the rot operator on smooth scalar fields (or $\mathrm{H}^1(\Gamma)$), in the kernel of the div operator on smooth tangent fields (resp., $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$).

Noticing that the two rows in the diagram (2.2) are null sequences, we consider, for each horizontal pair of consecutive arrows, the L_2-orthogonal of the range of the left arrow, in the kernel of the right arrow. For the second row we denote these vector spaces by G^0_h, G^1_h, and G^2_h.

It is a remarkable fact that these "discrete" cohomology groups have the "right" dimension, i.e., the dimension of their continuous analogues $\mathbb{G}^i$. This is either elementary or can be deduced from the *Euler–Poincaré formula*. The use of this formula should not come as a surprise, since it is one of the main reasons for the effectiveness of *simplical* triangulations in algebraic topology. It has been used in finite element theory for quite some time, even at the textbook level; see, for instance, Nédélec [42].

For each h, let N^0_h be the number of vertices, N^1_h the number of edges (segments), and N^2_h the number of faces (triangles) in $\mathcal{T}_h$. Let N^C be the number of connected components of Γ.

We leave it as an exercise to check that for G^0_h and G^2_h the dimension is the number N^C of connected components of Γ. Remark also that $\mathsf{G}^0_h = \mathbb{G}^0$, whereas $\mathsf{G}^2_h \neq \mathbb{G}^2$. However, the elements of $\mathbb{G}^2$, which are the functions that are constant on each connected component of Γ, are of course well approximated by the elements of G^2_h.

We now turn to the more interesting case of G^1_h. We have

$$\dim \mathsf{G}^1_h = \big(\dim \mathsf{S}^1_h - (\dim \mathsf{S}^2_h - N^C)\big) - \big(\dim \mathsf{S}^0_h - N^C\big) \tag{2.12}$$

$$= -\dim \mathsf{S}^0_h + \dim \mathsf{S}^1_h - \dim \mathsf{S}^2_h + 2N^C \tag{2.13}$$

$$= -\big(N^0_h + (m-1)N^1_h + (m-2)(m-1)/2N^2_h\big) \tag{2.14}$$

$$+\big(mN^1_h + m(m-1)N^2_h\big) - \big(m(m+1)/2N^2_h\big) + 2N^C \tag{2.15}$$

$$= -N^0_h + N^1_h - N^2_h + 2N^C \tag{2.16}$$

$$= \dim \mathbb{G}^1. \tag{2.17}$$

To see that G^1_h converges in some sense to $\mathbb{G}^1$, consider the map Ω_h, called a Fortin operator in Boffi [6], which to any $u_0 \in \mathrm{H}^0_{\mathrm{div}}(\Gamma)$ associates the first component u of the solution (u, q) of

$$\left\{ \begin{array}{l} u \in \mathsf{S}^1_h \\ q \in \mathsf{S}^{2\bullet}_h \end{array} \right. \quad \left\{ \begin{array}{lll} \forall u' \in \mathsf{S}^1_h & \langle u, u'\rangle + \langle q, \operatorname{div} u'\rangle & = \langle u_0, u'\rangle; \\ \forall q' \in \mathsf{S}^{2\bullet}_h & \langle q', \operatorname{div} u\rangle & = \langle q', \operatorname{div} u_0\rangle. \end{array} \right. \tag{2.18}$$

This saddle-point problem satisfies the LBB inf-sup conditions; therefore there is a $C > 0$ such that for all h and all $u \in \mathrm{H}^0_{\mathrm{div}}(\Gamma)$ we have

$$\|u - \Omega_h u\|_0 \leq C \inf\{\|u - u'\|_0 \ : \ u' \in \mathsf{S}^1_h\}. \tag{2.19}$$

Notice also that Ω_h maps divergence-free fields to divergence-free fields and that if $u \in \mathrm{H}^0_{\mathrm{div}}(\Gamma)$ is such that $\mathrm{rot}\, u = 0$ (as elements of $\mathrm{H}^{-1}(\Gamma)$), then $\Omega_h u$ is L_2-orthogonal to $\mathrm{rot}\, \mathsf{S}^0_h$. In particular, Ω_h maps $\mathbb{G}^1$ into G^1_h. Since all norms on $\mathbb{G}^1$ are equivalent, we therefore have an estimate of the form

$$\forall u \in \mathbb{G}^1 \quad \|u - \Omega_h u\|_0 \leq C h^m \|u\|_0 \tag{2.20}$$

($m = 1 > 0$ for lowest order elements[1]) so that, for sufficiently small h, Ω_h determines injections $\mathbb{G}^1 \to \mathsf{G}^1_h$ which are arbitrarily close in norm to the identity mapping on $\mathbb{G}^1$. Since the spaces have the same dimension these induced maps are in fact isomorphisms, and the inverse mappings are Ch^m-close to the identity mapping on G^1_h.

Remark. For reasons of dimension, for the above system (2.18) to satisfy the LBB inf-sup conditions it is necessary that, *among all spaces that contain* $\mathrm{div}\, \mathsf{S}^1_h$, $\mathsf{S}^{2\bullet}_h$ be minimal. (Of course the LBB condition can be verified for some smaller spaces that do not contain $\mathrm{div}\, \mathsf{S}^1_h$.) On the other hand, for the above constructed injection $\mathbb{G}^1 \to \mathsf{G}^1_h$ to be *onto* it is necessary that $\mathsf{S}^{0\bullet}_h$ be maximal *among all spaces that* rot *maps into* S^1_h. It is remarkable that these algebraic optimality conditions (which were our guide for the choice of spaces) are also sufficient for convergence purposes.

Given a tangent field u one may now ask how the field a_0 defined by

$$a_0 \in \mathbb{G}^1 \quad \text{and} \quad \forall a' \in \mathbb{G}^1 \quad \langle a_0, a' \rangle = \langle u, a' \rangle \tag{2.21}$$

relates to its discrete analogue a_h defined by

$$a_h \in \mathsf{G}^1_h \quad \text{and} \quad \forall a' \in \mathsf{G}^1_h \quad \langle a_h, a' \rangle = \langle u, a' \rangle. \tag{2.22}$$

Since G^1_h is not a subspace of $\mathbb{G}^1$ one can view this as a nonconforming Galerkin problem. We have already proved that G^1_h converges in a sense to $\mathbb{G}^1$. Later, in Proposition 4.8 we provide the necessary variant of Theorem 1.1 to deduce from this the existence of a_h and its convergence to a_0.

PROPOSITION 2.1. *For the exact and approximate harmonic tangent fields a_0 and a_h obtained as solutions of* (2.21) *and* (2.22)*, for a given tangent field u, we have the estimates*

$$\|a_h - a_0\|_0 \leq C h^m \|u\|_{\mathrm{H}^{-1}_{\mathrm{rot}}(\Gamma)}. \tag{2.23}$$

Another useful observation is that, parallel to the fact that all norms on the finite-dimensional space $\mathbb{G}^1$ are equivalent, we have easily obtained the following.

LEMMA 2.2. *There is $C > 0$ such that for all $-1 \leq s \leq 0$ and all h*

$$\forall u \in \mathsf{G}^1_h \quad \|u\|_0 \leq C \|u\|_s. \tag{2.24}$$

2.4. Discrete Helmholtz decomposition. We will frequently use the fact that each $u \in \mathsf{S}^1_h$ can be written in a unique way:

$$u = \mathrm{rot}\, p + a + g, \tag{2.25}$$

with $p \in \mathsf{S}^{0\bullet}_h$, $a \in \mathsf{G}^1_h$, and g in the L_2-orthogonal of the kernel of the divergence operator in S^1_h. Notice that this decomposition expresses that S^1_h is split into a direct

[1] In fact, to derive the inf-sup estimates and related stability results we need, it will not be necessary to know that higher order elements yield higher order estimates.

sum of three subspaces which are orthogonal both for the $\mathrm{H}^0_{\mathrm{T}}$ and the $\mathrm{H}^0_{\mathrm{div}}$ scalar products.

What makes this decomposition useful is that it has the following continuity and approximation properties, compared with the "exact" Helmholtz decomposition, which we write

$$u = \operatorname{rot} p_0 + a_0 + g_0, \tag{2.26}$$

with $p_0 \in \mathrm{H}^{1/2}(\Gamma)^\bullet$, $a_0 \in \mathbb{G}^1$, and $g_0 \in \operatorname{grad} \mathrm{H}^{3/2}(\Gamma)$.

PROPOSITION 2.3. *There is $C > 0$ such that for all h, all $u \in \mathsf{S}^1_h$, the above decompositions* (2.25) *and* (2.26) *are related by*

$$\|g - g_0\|_0 \le Ch\|u\|_0, \qquad \|g\|_{-1} \le C\|u\|_{-1}, \tag{2.27}$$

$$\|a - a_0\|_0 \le Ch\|u\|_0, \qquad \|a\|_{-1} \le C\|u\|_{-1}, \tag{2.28}$$

$$\|\operatorname{rot} p - \operatorname{rot} p_0\|_0 \le Ch\|u\|_0, \qquad \|\operatorname{rot} p\|_{-1} \le C\|u\|_{-1}. \tag{2.29}$$

Proof. (i) As already remarked, by hypothesis (H3), we have

$$|g - g_0|_0 \le Ch|\operatorname{div} u|_0. \tag{2.30}$$

This immediately gives $\|g - g_0\|_0 \le Ch\|u\|_0$. Then we remark that

$$\|g\|_{-1} \le \|g - g_0\|_{-1} + \|g_0\|_{-1} \le Ch\|u\|_0 + \|u\|_{-1} \le C\|u\|_{-1}. \tag{2.31}$$

(ii) The fact that $\|a - a_0\|_0 \le Ch\|u\|_0$ was proved in the preceding section and gives $\|a\|_{-1} \le C\|u\|_{-1}$ just as above.

(iii) The last part of the proposition is deduced from the two preceding ones writing

$$\operatorname{rot} p - \operatorname{rot} p_0 = -(g + a) + (g_0 + a_0) = (g_0 - g) + (a_0 - a). \tag{2.32}$$

□

3. Stable discretizations of the Calderon formulas. First we explain why the most natural idea (at least to us, for quite some time) is actually flawed. Then we define the discretization which we propose to use for preconditioning. It is associated with a subspace of the usual Galerkin space for which we prove an LBB inf-sup condition and some basic approximation properties.

3.1. A flawed idea. Given a family of Galerkin spaces X_h in X the most straightforward idea is to introduce the maps

$$\mathcal{B}_h : \left\{ \begin{array}{rcl} X_h & \to & X_h^\star, \\ u & \mapsto & \langle Bu, \cdot \rangle \end{array} \right. \tag{3.1}$$

and then to put

$$\mathcal{Z}_h(k) = \mathcal{B}_h^{\star -1} \mathcal{A}_h(k) \mathcal{B}_h^{-1}. \tag{3.2}$$

As remarked in Christiansen and Nédélec [17], if not only $\mathcal{A}_h(k)$ but also $\mathcal{B}_h$ satisfies a uniform discrete inf-sup condition on X_h, then the spectral condition number of $\mathcal{Z}_h(k)\mathcal{A}_h(k)$ is bounded independently of h. Of course, since the operators we deal with are not SPD, this is not enough to guarantee convergence of Krylov subspace algorithms, but it is nevertheless a significant progress compared with the lack of a

preconditioner. Unfortunately, for the standard Galerkin spaces, this last inf-sup condition does not hold. Indeed, throughout this paragraph let X_h denote the Raviart–Thomas spaces of degree m (with our conventions the minimal degree is $m = 1$) on Γ. We will use the fact that X_h satisfies the hypotheses (H0),...,(H3).

PROPOSITION 3.1. *Let $X_h = \mathsf{S}_h^1$. Let K_h be the space*

$$\{u \in \mathsf{S}_h^1 \ : \ \forall v \in \mathsf{S}_h^1 \quad \operatorname{div} v = 0 \Rightarrow \langle u, v\rangle = 0 \quad \textit{and} \\ \forall v \in \mathsf{S}_h^0 \quad \langle u, \operatorname{grad} v\rangle = 0\}. \tag{3.3}$$

Then we have

$$\liminf_h \frac{\dim K_h}{\dim X_h} \geq \frac{1}{2m+1} \tag{3.4}$$

and

$$\limsup_h \sup_{u\in K_h} \sup_{u'\in X_h} \frac{b(u,u')}{\|u\|_{-1/2}\|u'\|_{-1/2}} h^{-1/2} < +\infty. \tag{3.5}$$

Proof. (i). We have

$$\dim K_h \geq (\dim \mathsf{S}_h^2 - N^C) - (\dim \mathsf{S}_h^0 - N^C) \tag{3.6}$$

$$\geq (m(m+1)/2)N_h^2 \\ -N_h^0 + (m-1)N_h^1 + ((m-2)(m-1)/2)N_h^2 \tag{3.7}$$

$$\geq -N_h^0 - (m-1)N_h^1 + (2m-1)N_h^2. \tag{3.8}$$

Recall that since each segment is shared by exactly two triangles, $2N_h^1 = 3N_h^2$, which together with the Euler–Poincaré formula gives

$$N_h^1 \sim 3N_h^0 \quad \text{and} \quad N_h^2 \sim 2N_h^0. \tag{3.9}$$

This gives

$$-N_h^0 - (m-1)N_h^1 + (2m-1)N_h^2 \sim mN_h^0. \tag{3.10}$$

One also checks that

$$\dim X_h \sim m(2m+1)N_h^0. \tag{3.11}$$

This gives the first inequality.

(ii). To prove the second part of the theorem we use the fact that X_h satisfies (H3). For any $u \in X_h$ we denote by ϕ_u the unique $\phi \in \mathrm{H}^1(\Gamma)^\bullet$ such that $\Delta\phi = \operatorname{div} u$. Then (H3) asserts that if $u \in X_h$ is L_2-orthogonal to the kernel of the divergence operator on X_h, then we have an estimate of the form $|u - \operatorname{grad}\phi_u|_0 \leq Ch|\operatorname{div} u|_0$. From Proposition 2.3, using an inverse inequality, one can deduce that

$$\|u - \operatorname{grad}\phi_u\|_{-1/2} \leq Ch^{1/2}\|u\|_{-1/2} \tag{3.12}$$

and

$$\|\operatorname{grad}\phi_u\|_{-1/2} \leq C\|u\|_{-1/2}. \tag{3.13}$$

Choose $u \in K_h$ and $u' \in X_h$. Put $u' = \operatorname{rot} p' + a' + g'$ as in (2.25). Remark first that

$$\langle u \times n, \operatorname{rot} p' \rangle = -\langle \operatorname{div} u, p' \rangle = 0. \tag{3.14}$$

Then write

$$\langle u \times n, g' \rangle = \langle (u - \operatorname{grad} \phi_u + \operatorname{grad} \phi_u) \times n, (g' - \operatorname{grad} \phi_{g'} + \operatorname{grad} \phi_{g'}) \rangle. \tag{3.15}$$

Developing and using the continuity of b as well as the fact that

$$\langle \operatorname{grad} \phi_u \times n, \operatorname{grad} \phi_{g'} \rangle = 0, \tag{3.16}$$

we obtain

$$|\langle u \times n, g' \rangle| \le C \|u - \operatorname{grad} \phi_u\|_{-1/2} \|g' - \operatorname{grad} \phi_{g'}\|_{-1/2} \tag{3.17}$$

$$+ C \|u - \operatorname{grad} \phi_u\|_{-1/2} \|\operatorname{grad} \phi_{g'}\|_{-1/2} \tag{3.18}$$

$$+ C \|\operatorname{grad} \phi_u\|_{-1/2} \|g' - \operatorname{grad} \phi_{g'}\|_{-1/2}. \tag{3.19}$$

By the above estimates (3.12) and (3.13) it follows that

$$|\langle u \times n, g' \rangle| \le C h^{1/2} \|u\|_{-1/2} \|g'\|_{-1/2}. \tag{3.20}$$

Therefore

$$|\langle u \times n, g' \rangle| \le C h^{1/2} \|u\|_{-1/2} \|u'\|_{-1/2}. \tag{3.21}$$

Finally, for the last part, for any $\tilde{a}'$, $\langle u \times n, a' \rangle$ equals

$$\langle (u - \operatorname{grad} \phi_u) \times n, \tilde{a}' \rangle + \langle \operatorname{grad} \phi_u \times n, \tilde{a}' \rangle + \langle u \times n, (a' - \tilde{a}') \rangle. \tag{3.22}$$

Choosing $\tilde{a}' \in \mathbb{G}^1$ to be an approximation of a', one immediately obtains the proposition. □

Thus one sees that the reason for the degeneracy is that the subspace of X_h of elements which are in a sense discrete gradients does not have the same dimension as the subspace of rotationals.

3.2. Auxiliary spaces. Let $(\mathsf{S}_h^0, \mathsf{S}_h^1, \mathsf{S}_h^2)$, and $(\mathsf{S}_h'^0, \mathsf{S}_h'^1, \mathsf{S}_h'^2)$ be two triples of spaces of the type we discussed; more precisely, they should satisfy the null sequence condition, the discrete cohomology groups should have the "right" dimension, and S_h^1 and $\mathsf{S}_h'^1$ should satisfy the hypotheses (H0),...,(H3).

Two examples to keep in mind (the first one detailed and the second one mentioned in Christiansen and Nédélec [19]) are

- the case where S_h^1 and $\mathsf{S}_h'^1$ are equal and consist of lowest order Raviart–Thomas fields (then S_h^0 consists of continuous P^1 FE and S_h^2 of P^0 FE);
- the case where $(\mathsf{S}_h^0, \mathsf{S}_h^1, \mathsf{S}_h^2)$ corresponds to lowest order Raviart–Thomas fields, whereas $(\mathsf{S}_h'^0, \mathsf{S}_h'^1, \mathsf{S}_h'^2)$ corresponds to lowest order Brezzi–Douglas–Marini fields on the same mesh (then $\mathsf{S}_h'^0$ consists of continuous P^2 FE and $\mathsf{S}_h'^2$ of P^0 FE).

More generally (though it is not necessary) one might want to choose spaces such that the L_2-projections $\mathsf{S}_h^{2\bullet} \to \mathsf{S}_h'^{0\bullet}$, and $(\ker_{\operatorname{div}} \mathsf{S}_h^1) \times n \to \mathsf{S}_h'^1$ have kernels which are small in some sense (for instance have dimensions bounded by some small integer independently of h). Anticipating what follows, this would guarantee that the subspace $(\mathsf{S}_h^1)^\wedge$ of S_h^1, to be defined later, is almost all of S_h^1. If the first triple of

spaces is based on Raviart–Thomas fields of any order, one can take for this purpose Brezzi–Douglas–Marini fields *of the same order* on the same mesh in the second triple.

In fact, in addition to the hypothesis H0, ... ,H3 we will use some L^2 estimates for the spaces S_h^0 and S_h^2 (in the proofs of Lemmas 3.11 and 3.12) and an additional L^2 estimate for S_h^1 (proof of Proposition 4.2). Therefore we require in what follows that the spaces $(\mathsf{S}_h^0, \mathsf{S}_h^1, \mathsf{S}_h^2)$ and $(\mathsf{S}_h'^0, \mathsf{S}_h'^1, \mathsf{S}_h'^2)$ are the standard finite element spaces based on Raviart–Thomas or Brezzi–Douglas–Marini finite elements. The two triples can, however, have different orders m and m'. They can even be constructed on different meshes (with associated parameters h and h') as long as $(1/C)h \leq h' \leq Ch$. The most useful cases are $m' \geq m$ and $h' \leq h$.

Other Galerkin spaces are commonly used to solve boundary integral equations, and the method might work in the present state for such Galerkin spaces also. For instance, finite elements based on meshes with both triangular and quadrilateral elements pose no additional problem, once one has identified the appropriate null sequences called microlocal discretizations which are currently being developed.

3.3. Definition. Our starting point is to try to construct a preconditioner for the variational formulation of the EFIE on S_h^1. For this purpose we will use the auxiliary spaces $(\mathsf{S}_h'^0, \mathsf{S}_h'^1, \mathsf{S}_h'^2)$. As it turns out, with this preconditioner the EFIE is actually solved variationally on a subspace of S_h^1. However, we shall prove that this subspace (it will be denoted $(\mathsf{S}_h^1)^\wedge$) satisfies the hypotheses (H0),...,(H3), which ensures the well-posedness of the discrete problem.

Starting with a linear form $l \in \mathsf{S}_h^{1\star}$, determine the solution (u, q) of

$$\left\{ \begin{array}{l} u \in \mathsf{S}_h^1 \\ q \in \mathsf{S}_h^{2\bullet} \end{array} \right. \quad \left\{ \begin{array}{ll} \forall u' \in \mathsf{S}_h^1 & \langle u, u' \rangle + \langle q, \operatorname{div} u' \rangle = l(u'); \\ \forall q' \in \mathsf{S}_h^{2\bullet} & \langle q', \operatorname{div} u \rangle = 0. \end{array} \right. \tag{3.23}$$

Then to (u, q) associate the following element of $\mathsf{S}_h'^1$:

$$v = \mathcal{P}_{\mathsf{S}_h'^1}(u \times n) - \operatorname{rot} \mathcal{P}_{\mathsf{S}_h'^{0\bullet}}(q), \tag{3.24}$$

where for any space X_h, $\mathcal{P}_{\mathsf{X}_h}$ denotes the L_2-orthogonal projections onto X_h.

Let $\Theta_h : \mathsf{S}_h^{1\star} \to \mathsf{S}_h'^1, l \mapsto v$ be the composition of these two maps (defined by (3.23) and (3.24)), and let $\Theta_h^\star : \mathsf{S}_h'^{1\star} \to \mathsf{S}_h^{1\star\star} \approx \mathsf{S}_h^1$ be its adjoint. Then we put

$$\mathcal{Z}_h = \Theta_h^\star \mathcal{A}_h'(k) \Theta_h, \tag{3.25}$$

where $\mathcal{A}_h'(k) : \mathsf{S}_h'^1 \to \mathsf{S}_h'^{1\star}$ is the map induced by $\mathcal{A}(k)$.

Remark. In some cases it might be of interest to replace $\mathcal{A}_h'(k)$ by $\mathcal{A}_h'(k')$ for some different, possibly complex, wavenumber k'. In particular, a small perturbation $k' = k + i\epsilon$ guarantees invertibility even at resonant frequencies and is related to the limiting absorption principle. However, we will not discuss this possibility here.

3.4. Interpretation of the system. The invertibility in the sense of Babuska–Brezzi of the system (3.23) can be reinterpreted as the fact that the bilinear form b satisfies a uniform LBB inf-sup estimate on the spaces $\mathsf{S}_h^{1\#} \times \mathsf{S}_h^1$, where we have used the notation

$$\mathsf{S}_h^{1\#} = \{u \times n : u \in \mathsf{S}_h^1 \quad \text{and} \quad \operatorname{div} u = 0\} + \{\operatorname{rot} q : q \in \mathsf{S}_h^{0\bullet}\}. \tag{3.26}$$

To give a precise meaning to and prove this statement, notice that $\mathsf{S}_h^{1\#}$ is a subspace of $\mathrm{H}_{\mathrm{div}}^{-1}(\Gamma)$ (but contains vector-valued measures concentrated on the curved lines $\Xi_h^{-1}([S])$, where S is a segment in $\mathcal{T}_h$). We will also need the following lemma.

LEMMA 3.2. *Any $v \in \mathrm{H}^{-1+s}_{\mathrm{div}}(\Gamma)$, can be written in a unique way:*

$$v = u \times n - \mathrm{rot}\, q, \tag{3.27}$$

with $u \in \mathrm{H}^{s}_{\mathrm{div}}(\Gamma)$, $\mathrm{div}\, u = 0$, and $q \in \mathrm{H}^{s}(\Gamma)^{\bullet}$, and we have the equivalence of norms[2]

$$\|v\|^2_{-1+s} \approx |u|^2_s + |q|^2_s. \tag{3.28}$$

Proof. This can be proved using the HDRL (section 1.1). □

The lemma expresses that we have exhibited isomorphisms (for each s):

$$\{u \in \mathrm{H}^{s}_{\mathrm{div}}(\Gamma) \ : \ \mathrm{div}\, u = 0\} \times \mathrm{H}^{s}(\Gamma)^{\bullet} \to \mathrm{H}^{s-1}_{\mathrm{div}}(\Gamma). \tag{3.29}$$

In particular, the sum appearing in the definition of $\mathsf{S}^{1\#}_h$ is direct. Furthermore, we notice that

$$b(u \times n - \mathrm{rot}\, q, v') = \langle B(u \times n - \mathrm{rot}\, q), v' \rangle = -\langle u, v' \rangle - \langle q, \mathrm{div}\, v' \rangle, \tag{3.30}$$

where we have used the notation $\langle \cdot, \cdot \rangle$ for the three different standard dualities on

$$\mathrm{H}^{-1}_{\mathrm{rot}} \times \mathrm{H}^{0}_{\mathrm{div}} \ , \ \mathrm{H}^{0}_{\mathrm{T}} \times \mathrm{H}^{0}_{\mathrm{T}}, \quad \text{and} \quad \mathrm{H}^{0} \times \mathrm{H}^{0}. \tag{3.31}$$

Therefore, given $l \in \mathsf{S}^{1\star}_h$, if (u, q) solves system (3.23), then $v = u \times n - \mathrm{rot}\, q$ solves

$$v \in \mathsf{S}^{1\#}_h \quad \forall v' \in \mathsf{S}^{1}_h \quad -b(v, v') = l(v'), \tag{3.32}$$

and if v solves this equation, then, writing $v = u \times n - \mathrm{rot}\, q$ as in (3.26), (u, q) is also given by the *continuous* inverse of the map (3.29) and solves system (3.23).

Using the well-known properties of this system, one immediately obtains the following.

PROPOSITION 3.3. *There is $C > 0$ such that for all h*

$$\inf_{v \in \mathsf{S}^{1\#}_h} \sup_{v' \in \mathsf{S}^{1}_h} \frac{|b(v, v')|}{\|v\|_{-1} \|v'\|_0} \geq 1/C. \tag{3.33}$$

One also checks directly that these spaces have the same dimension.

3.5. Interpretation of the projections. According to Lemma 3.2 the projections defined by (3.24) correspond to a projection in the $\mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)$-norm. Lemma 3.16 and Proposition 3.18 further justify this interpretation.

3.6. A characterization of the kernel of $\boldsymbol{\Theta_h}$. In this paragraph, for any space X_h, $\mathcal{P}_{\mathsf{X}_h}$ is the orthogonal projection onto X_h for the usual L_2-inner product (on scalar or vector fields). The symbol $\perp$ is also relative to these inner products.

We introduce the following auxiliary spaces:

$$\mathsf{s}^0_h = \{ \ p \in \mathsf{S}^{0\bullet}_h \ : \ p \perp \mathsf{S}'^{2\bullet}_h \} \quad \text{and} \quad \mathsf{s}^2_h = \{ \ q \in \mathsf{S}^{2\bullet}_h \ : \ q \perp \mathsf{S}'^{0\bullet}_h \}. \tag{3.34}$$

Define also

$$(\mathsf{S}^1_h)^{\wedge} = \{v \in \mathsf{S}^1_h \ : \ v \perp \mathrm{rot}\, \mathsf{s}^0_h \quad \text{and} \quad \mathrm{div}\, v \perp \mathsf{s}^2_h\}. \tag{3.35}$$

[2]There is an obvious misprint in [19].

The introduction of s_h^0 and s_h^2 is justified by the two following lemmas, whereas that of $(\mathsf{S}_h^1)^\wedge$ is justified by Proposition 3.7. It shows that (for h small enough—we will not always repeat this condition—) $(\mathsf{S}_h^1)^\wedge$ is the range of $\Theta_h^\star$.

LEMMA 3.4. *There is h_0 such that for all $h < h_0$ and all divergence-free $u \in \mathsf{S}_h^1$*

$$\mathcal{P}_{\mathsf{S}_h'^1}(u \times n) = 0 \iff u \in \operatorname{rot} \mathsf{s}_h^0. \tag{3.36}$$

Proof. We use the fact that for all $\epsilon > 0$ there is $h_0 > 0$ such that for $h < h_0$

$$\forall a \in \mathsf{G}_h^1 \quad |a \times n - \mathcal{P}_{\mathsf{G}_h'^1}(a \times n)|_0 \leq \epsilon |a|_0. \tag{3.37}$$

Choosing a h_0 relative to a $\epsilon < 1$ we suppose from now on that $h < h_0$.

Pick $u \in \ker_{\mathsf{S}_h^1} \operatorname{div}$. Put $u = \operatorname{rot} p + a$, with $p \in \mathsf{S}_h^{0\bullet}$ and $a \in \mathsf{G}_h^1$.

(i). Suppose that the projection of $u \times n$ is zero. For all divergence-free $a' \in \mathsf{S}_h'^1$, we have

$$0 = \langle \mathcal{P}_{\mathsf{S}_h'^1}(-\operatorname{grad} p + a \times n), \overline{a'} \rangle = \langle (-\operatorname{grad} p + a \times n), \overline{a'} \rangle = \langle a \times n, \overline{a'} \rangle. \tag{3.38}$$

Put $a' = \mathcal{P}_{\mathsf{G}_h'^1}(a \times n)$. Then

$$|a|_0^2 = |\langle a \times n, \overline{a \times n} \rangle| = |\langle a \times n, (\overline{a \times n - a'}) \rangle| \leq \epsilon |a|_0^2. \tag{3.39}$$

Hence $a = 0$. Moreover, for all $v \in \mathsf{S}_h'^1$,

$$\langle \operatorname{rot} p \times n, v \rangle = \langle p, \operatorname{div} v \rangle. \tag{3.40}$$

It follows that $p \perp \mathsf{S}_h'^{2\bullet}$ and $u \in \operatorname{rot} \mathsf{s}_h^0$.

(ii). Conversely, if $u \in \operatorname{rot} \mathsf{s}_h^0$, then the above equality (3.40) shows that $u \times n \perp \mathsf{S}_h'^1$, and hence its projection is zero. ∎

LEMMA 3.5. *For all $q \in \mathsf{S}_h^{2\bullet}$ we have*

$$\operatorname{rot} \mathcal{P}_{\mathsf{S}_h'^{0\bullet}}(q) = 0 \iff \mathcal{P}_{\mathsf{S}_h'^{0\bullet}}(q) = 0 \iff q \in \mathsf{s}_h^2. \tag{3.41}$$

Proof. The proof is trivial. ∎

LEMMA 3.6. *The spaces $\mathcal{P}_{\mathsf{S}_h'^1}((\ker_{\mathrm{H}^0_{\operatorname{div}}(\Gamma)} \operatorname{div}) \times n)$ and $\operatorname{rot} \mathsf{S}_h'^0$ are L_2-orthogonal.*

Proof. Indeed, if $u \in \mathrm{H}^0_{\operatorname{div}}(\Gamma)$ is divergence-free and $p \in \mathsf{S}_h'^0$, then (since $\operatorname{rot} p \in \mathsf{S}_h'^1$)

$$\langle \mathcal{P}_{\mathsf{S}_h'^1}(u \times n), \operatorname{rot} p \rangle = \langle u \times n, \operatorname{rot} p \rangle = -\langle \operatorname{div} u, p \rangle = 0. \tag{3.42}$$ ∎

We now prove the following.

PROPOSITION 3.7. *For all $l \in \mathsf{S}_h^{1\star}$ we have*

$$\Theta_h(l) = 0 \iff \forall u' \in (\mathsf{S}_h^1)^\wedge \quad l(u') = 0. \tag{3.43}$$

Proof. Pick $l \in \mathsf{S}_h^{1\star}$. Let (u, q) be the solution of

$$\left\{ \begin{array}{l} u \in \mathsf{S}_h^1 \\ q \in \mathsf{S}_h^{2\bullet} \end{array} \right. \quad \left\{ \begin{array}{lll} \forall u' \in \mathsf{S}_h^1 & \langle u, u' \rangle + \langle q, \operatorname{div} u' \rangle & = \quad l(u'); \\ \forall q' \in \mathsf{S}_h^{2\bullet} & \langle q', \operatorname{div} u \rangle & = \quad 0. \end{array} \right. \tag{3.44}$$

With these definitions we have $\Theta_h(l) = 0$ if and only if

$$\mathcal{P}_{\mathsf{S}_h'^1}(u \times n) - \operatorname{rot} \mathcal{P}_{\mathsf{S}_h'^{0\bullet}}(q) = 0. \tag{3.45}$$

According to Lemma 3.6, this is in turn equivalent to

$$\mathcal{P}_{\mathsf{S}'^1_h}(u \times n) = 0 \quad \text{and} \quad \operatorname{rot} \mathcal{P}_{\mathsf{S}'^0_h \bullet}(q) = 0. \tag{3.46}$$

In Lemmas 3.4 and 3.5 we gave equivalent statements for these two conditions.

(i). If $\Theta_h(l) = 0$, then $u \in \operatorname{rot} \mathsf{s}^0_h$ and $q \in \mathsf{s}^2_h$; hence, for all $u' \in (\mathsf{S}^1_h)^\wedge$,

$$l(u') = \langle u, u' \rangle + \langle q, \operatorname{div} u' \rangle = 0. \tag{3.47}$$

That is to say, l vanishes on $(\mathsf{S}^1_h)^\wedge$.

(ii). If l vanishes on $(\mathsf{S}^1_h)^\wedge$, then

- for all $u' \in \ker_{\mathsf{S}^1_h} \operatorname{div}$ such that $u' \perp \operatorname{rot} \mathsf{s}^0_h$ we have (since $u' \in (\mathsf{S}^1_h)^\wedge$)

$$\langle u, u' \rangle = l(u') = 0, \tag{3.48}$$

  so $u \in \operatorname{rot} \mathsf{s}^0_h$;
- for all $q' \in \mathsf{S}^{2\bullet}_h$ such that $q' \perp \mathsf{s}^2_h$, picking $u' \in \mathsf{S}^1_h$ such that $\operatorname{div} u' = q'$ and $u' \perp \ker_{\mathsf{S}^1_h} \operatorname{div}$, we have (since $u' \in (\mathsf{S}^1_h)^\wedge$)

$$\langle q, q' \rangle = \langle q, \operatorname{div} u' \rangle = l(u') = 0, \tag{3.49}$$

  and hence $q \in \mathsf{s}^2_h$.

The proof is complete. ∎

3.7. Approximation properties of the range of $\Theta^\star_h$. We give yet another characterization of $(\mathsf{S}^1_h)^\wedge$, which will enable us to deduce its approximation properties.

LEMMA 3.8. *Pick $u \in \mathsf{S}^1_h$. Put $u = \operatorname{rot} p + a + g$ with $p \in \mathsf{S}^{0\bullet}_h$, $a \in \mathsf{G}^1_h$, and $g \in \mathsf{S}^1_h$ such that $g \perp \ker_{\mathsf{S}^1_h} \operatorname{div}$. Then we have*

$$u \in (\mathsf{S}^1_h)^\wedge \iff \operatorname{rot} p \perp \operatorname{rot} \mathsf{s}^0_h \quad \textit{and} \quad \operatorname{div} g \perp \mathsf{s}^2_h. \tag{3.50}$$

Proof. The proof is trivial. ∎

Now we give equivalent expressions for the above two conditions.

LEMMA 3.9. *Choose $q \in \mathsf{S}^{2\bullet}_h$. We have*

$$q \perp \mathsf{s}^2_h \iff \exists p \in \mathsf{S}'^{0\bullet}_h, \qquad q = \mathcal{P}_{\mathsf{S}^{2\bullet}_h}(p). \tag{3.51}$$

Proof. More generally, we have the following result: Let X be a Hilbert space. The orthogonal projection onto a closed subspace Y of X is written P_Y, and orthogonality is denoted by $\perp$. If Y and Z are two closed subspaces of X, we put

$$Y_{\perp Z} = \{x \in Y \ : \ x \perp Z\}. \tag{3.52}$$

Let A and B be two closed subspaces of X. Then

$$A_{\perp(A_{\perp B})} = P_A(B). \tag{3.53}$$

∎

LEMMA 3.10. *Choose $p \in \mathsf{S}^{0\bullet}_h$. We have*

$$\operatorname{rot} p \perp \operatorname{rot} \mathsf{s}^0_h \iff \exists q \in \mathsf{S}'^{2\bullet}_h, \qquad \operatorname{rot} p = \mathcal{P}_{\operatorname{rot} \mathsf{S}^{0\bullet}_h}(\operatorname{rot} \Delta^{-1} q). \tag{3.54}$$

Proof. We apply the same technique once again. For all $p \in \mathsf{S}^{0\bullet}_h$ and all $q \in \mathsf{S}'^{2\bullet}_h$ we have

$$\langle p, q \rangle = -\langle \operatorname{rot} p, \operatorname{rot} \Delta^{-1} q \rangle. \tag{3.55}$$

Hence

$$\operatorname{rot} p \in \operatorname{rot} \mathsf{s}_h^0 \iff p \in \mathsf{s}_h^0 \tag{3.56}$$

$$\iff p \perp \mathsf{S}_h'^{2\bullet} \tag{3.57}$$

$$\iff \operatorname{rot} p \perp \operatorname{rot} \Delta^{-1} \mathsf{S}_h'^{2\bullet} \tag{3.58}$$

$$\iff \operatorname{rot} p \perp \mathcal{P}_{\operatorname{rot} \mathsf{S}_h^{0\bullet}} (\operatorname{rot} \Delta^{-1} \mathsf{S}_h'^{2\bullet}). \tag{3.59}$$

So

$$\operatorname{rot} p \perp \operatorname{rot} \mathsf{s}_h^0 \iff \operatorname{rot} p \in \mathcal{P}_{\operatorname{rot} \mathsf{S}_h^{0\bullet}} (\operatorname{rot} \Delta^{-1} \mathsf{S}_h'^{2\bullet}). \tag{3.60}$$ ∎

We will also need the following two approximation results.

LEMMA 3.11. *There is $C > 0$ such that for all h and all $\phi \in \mathrm{H}^1(\Gamma)^\bullet$*

$$\inf\{|\phi - q|_0 \ : \ q \in \mathcal{P}_{\mathsf{S}_h^{2\bullet}} (\mathsf{S}_h'^{0\bullet})\} \leq Ch|\phi|_1. \tag{3.61}$$

Proof. Notice that

$$|\phi - \mathcal{P}_{\mathsf{S}_h^{2\bullet}} \mathcal{P}_{\mathsf{S}_h^{0\bullet}} \phi| \leq |\phi - \mathcal{P}_{\mathsf{S}_h^{0\bullet}} \phi| + |\mathcal{P}_{\mathsf{S}_h^{0\bullet}} \phi - \mathcal{P}_{\mathsf{S}_h^{2\bullet}} \mathcal{P}_{\mathsf{S}_h^{0\bullet}} \phi| \tag{3.62}$$

$$\leq Ch|\phi|_1 + Ch|\mathcal{P}_{\mathsf{S}_h^{0\bullet}} \phi|_1 \tag{3.63}$$

$$\leq Ch|\phi|_1. \tag{3.64}$$ ∎

LEMMA 3.12. *There is $C > 0$ such that for all h and all $\phi \in \mathrm{H}^2(\Gamma)^\bullet$*

$$\inf\{|\operatorname{rot} \phi - u|_0 \ : \ u \in \mathcal{P}_{\operatorname{rot} \mathsf{S}_h^{0\bullet}} (\operatorname{rot} \Delta^{-1} \mathsf{S}_h'^{2\bullet})\} \leq Ch|\operatorname{rot} \phi|_1. \tag{3.65}$$

Proof. We have

$$|\Delta^{-1} \mathcal{P}_{\mathsf{S}_h'^{2\bullet}} \Delta\phi - \phi|_1 \leq C|\mathcal{P}_{\mathsf{S}_h'^{2\bullet}} \Delta\phi - \Delta\phi|_{-1} \leq Ch|\Delta\phi|_0. \tag{3.66}$$

So, with $\psi = \Delta^{-1} \mathcal{P}_{\mathsf{S}_h^{2\bullet}} \Delta\phi$, we have

$$|\operatorname{rot} \psi - \operatorname{rot} \phi|_0 \leq Ch|\operatorname{rot} \phi|_1 \tag{3.67}$$

and

$$|\mathcal{P}_{\operatorname{rot} \mathsf{S}_h^{0\bullet}} \operatorname{rot} \psi - \operatorname{rot} \psi|_0 \leq Ch|\operatorname{rot} \psi|_1. \tag{3.68}$$

However,

$$|\operatorname{rot} \psi|_1 \leq C|\Delta^{-1} \mathcal{P}_{\mathsf{S}_h'^{2\bullet}} \Delta\phi|_2 \leq C|\mathcal{P}_{\mathsf{S}_h'^{2\bullet}} \Delta\phi|_0 \leq C|\Delta\phi|_0 \leq C|\operatorname{rot} \phi|_1. \tag{3.69}$$

Now combine inequalities (3.68) and (3.69) and conclude using (3.67). ∎

From the above results we deduce the following fundamental theorem.

THEOREM 3.13. *The spaces $X_h = (\mathsf{S}_h^1)^\wedge$ satisfy hypothesis* (H1).

Proof. Pick $u \in \mathrm{H}^1_{\mathrm{div}}(\Gamma)$. Consider its Helmholtz decomposition

$$u = \operatorname{rot} \phi + \alpha + \operatorname{grad} \psi. \tag{3.70}$$

(i) The field $\operatorname{rot} \phi$ is approximated using Lemma 3.12, which gives an element of X_h according to Lemmas 3.8 and 3.10.

(ii) The field α is approximated by $a = \Omega_h \alpha$, where Ω_h is defined by system (2.18).

(iii) The field $\Delta\psi$ is approximated by a $q \in \mathcal{P}_{\mathsf{S}_h^{2\bullet}} (\mathsf{S}_h'^{0\bullet})$ following Lemma 3.11. Then we consider $\Omega_h \operatorname{grad} \Delta^{-1} q$ which is in X_h according to Lemmas 3.8 and 3.9. ∎

3.8. Well-posedness.

PROPOSITION 3.14. *The spaces* $X_h = (\mathsf{S}^1_h)^\wedge$ *satisfy hypothesis* (H3).

Proof. Choose $u \in X_h$ such that

$$u \perp \ker_{X_h} \operatorname{div}. \tag{3.71}$$

Trivially we have $u \in \mathsf{S}^1_h$. Moreover, if u' is a divergence-free element of S^1_h it can be written $\operatorname{rot} p + u''$ with $p \in \mathsf{s}^0_h$ and a divergence-free $u'' \in X_h$. (To see this just remark that the L_2-orthogonal of $\operatorname{rot} \mathsf{s}^0_h$ in $\ker_{\mathsf{S}^1_h} \operatorname{div}$ is a subspace of X_h.) And since $u \perp \operatorname{rot} \mathsf{s}^0_h$ and $u \perp u''$ we therefore have

$$u \perp \ker_{\mathsf{S}^1_h} \operatorname{div}. \tag{3.72}$$

Then the proposition follows from the result known to hold for S^1_h. ∎

We have therefore reached the main goal of this section.

THEOREM 3.15. *The spaces* $(\mathsf{S}^1_h)^\wedge$ *satisfy the four hypothesis* (H0),...,(H3).

If $\mathcal{A}(k)$ were symmetric positive definite, then $\mathcal{Z}_h\mathcal{A}_h$ would determine an isomorphism $(\mathsf{S}^1_h)^\wedge \to (\mathsf{S}^1_h)^\wedge$, and, for a given h, the preconditioned conjugate gradients (PCG) algorithm would converge towards the variational solution on $(\mathsf{S}^1_h)^\wedge$, which by the above theorem is a good one.

In our indefinite case it might be that $\mathcal{Z}_h\mathcal{A}_h$ does not determine an isomorphism $(\mathsf{S}^1_h)^\wedge \to (\mathsf{S}^1_h)^\wedge$; this would be the case if the bilinear form induced by $\mathcal{A}$ on the range of Θ_h (as opposed to $\Theta^\star_h$) were degenerate, a question we have not settled. However, we are sure that the PCG algorithm constructs iterates that are in $(\mathsf{S}^1_h)^\wedge$, and later—in section 3.9—we will show how to construct stopping criteria that guarantee that the residual is small as a linear form on $(\mathsf{S}^1_h)^\wedge$. Thus one can *check* that the approximate solution given by the PCG algorithm is close to the variational solution on $(\mathsf{S}^1_h)^\wedge$. Theorem 3.15 ensures that this variational solution (exists, is unique, and) is close to the *best* (for any chosen norm) approximation on $(\mathsf{S}^1_h)^\wedge$ of the exact solution and that for small h this best approximation is a *good* approximation.

3.9. Stopping criterion. Proposition 3.7 shows that, for all $u \in (\mathsf{S}^1_h)^\wedge$, u solves the variational problem

$$u \in (\mathsf{S}^1_h)^\wedge \quad \text{and} \quad \forall v \in (\mathsf{S}^1_h)^\wedge \quad a(u,v) = l(v) \tag{3.73}$$

if and only if

$$\Theta_h(\mathcal{A}_h u - l_h) = 0, \tag{3.74}$$

which is in turn equivalent to

$$\|\Theta_h(\mathcal{A}_h u - l_h)\| = 0, \tag{3.75}$$

for any norm $\|\cdot\|$ on S'^1_h. We now set out to define norms on S'^1_h that are uniformly equivalent to the $\mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)$-norm but more readily computable.

The following lemma should be seen in relation to Lemma 3.2.

LEMMA 3.16. *There is* $C > 0$ *such that for all* $u \in \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)$*, if* $u = \operatorname{rot} p + v$ *with* $v \in \mathrm{H}^0_{\mathrm{T}}(\Gamma)$ *and* $p \in \mathrm{H}^0(\Gamma)$*, we have*

$$\|u\|^2_{-1} \le C\big(|p|^2_0 + |v|^2_0\big). \tag{3.76}$$

Proof. It holds

$$\|\operatorname{rot} p + v\|_{-1}^2 = |\operatorname{rot} p + v|_{-1}^2 + |\operatorname{div} v|_{-1}^2. \tag{3.77}$$

However,

$$|\operatorname{rot} p + v|_{-1}^2 \le 2\big(|\operatorname{rot} p|_{-1}^2 + |v|_{-1}^2\big) \le C\big(|p|_0^2 + |v|_{-1}^2\big). \tag{3.78}$$

Then one immediately concludes using $|\operatorname{div} v|_{-1} \le C|v|_0$. ∎

For convenience we state as a separate lemma the following fact which follows from (H3).

LEMMA 3.17. *There is $C > 0$ such that for all $u \in X_h$, if*

$$\forall u' \in X_h \quad \operatorname{div} u' = 0 \;\Rightarrow\; \langle u, u' \rangle = 0, \tag{3.79}$$

then

$$|u|_0 \le C|\operatorname{div} u|_{-1}. \tag{3.80}$$

Proof. Let ϕ be the solution of

$$\phi \in \mathrm{H}^1(\Gamma)^\bullet \quad \text{and} \quad \Delta\phi = \operatorname{div} u. \tag{3.81}$$

We have

$$|u|_0 \le |u - \operatorname{grad}\phi|_0 + |\operatorname{grad}\phi|_0 \le Ch|\operatorname{div} u|_0 + C|\operatorname{div} u|_{-1}. \tag{3.82}$$

The lemma then follows from an inverse inequality. ∎

It is a particular case of Lemma 3.2 that the converse inequality of Lemma 3.16 holds whenever v is such that $\operatorname{rot} v = 0$. This fact has the following discrete analogue.

PROPOSITION 3.18. *There is $C > 0$, such that for all h and all $u \in \mathsf{S}_h^1$, if $u = \operatorname{rot} p + v$ with $p \in \mathsf{S}_h^{0\bullet}$ and $v \perp \operatorname{rot} \mathsf{S}_h^{0\bullet}$, then*

$$|p|_0^2 + |v|_0^2 \le C\|u\|_{-1}^2. \tag{3.83}$$

Proof. Put $v = a + w$ with $a \in \mathsf{G}_h^1$ and $w \perp \ker_{\mathsf{S}_h^1} \operatorname{div}$. We have

$$|v|_0^2 = |a|_0^2 + |w|_0^2. \tag{3.84}$$

However, by Lemma 2.2 and Proposition 2.3 we have

$$|a|_0 \le C|a|_{-1} \le C\|u\|_{-1}, \tag{3.85}$$

and by Lemma 3.17 we have

$$|w|_0 \le C|\operatorname{div} w|_{-1} = |\operatorname{div} u|_{-1} \le \|u\|_{-1}. \tag{3.86}$$

So

$$|v|_0^2 \le C\|u\|_{-1}^2. \tag{3.87}$$

Moreover,

$$|p|_0^2 \le C|\operatorname{rot} p|_{-1}^2 \le C\big(|\operatorname{rot} p + v|_{-1}^2 + |v|_{-1}^2\big). \tag{3.88}$$

The proposition follows. ∎

Of course the same holds true for the spaces with a prime, which is in fact what will be of interest to us.

Let l be a linear form on S_h^1, and, as in the definition of the preconditioner, let (u, q) be the solution of system (3.23) so that

$$\Theta_h l = \mathcal{P}_{\mathsf{S}_h'^1}(u \times n) - \operatorname{rot} \mathcal{P}_{\mathsf{S}_h'^0 \bullet}(q). \tag{3.89}$$

Lemma 3.16 together with Proposition 3.18 now prove that we have the uniform (i.e., independent of h) equivalence of norms

$$\|\Theta_h l\|_{-1}^2 \approx |\mathcal{P}_{\mathsf{S}_h'^1}(u \times n)|_0^2 + |\mathcal{P}_{\mathsf{S}_h'^0 \bullet}(q)|_0^2. \tag{3.90}$$

A stopping criterion can therefore be a sufficient reduction of this norm. It is important to notice that to effectively compute these norms in the course of a conjugate gradients algorithm is a negligible task compared with the other ones, requiring only two sparse matrix products (at each iteration).

Another norm which is both natural and easily computable is $\|\Theta_h l\|_0$. Also, the quantity $(\|\Theta_h l\|_0 \|\Theta_h l\|_{-1})^{1/2}$, though not a norm, satisfies the interpolation inequality

$$\|\Theta_h l\|_{1/2} \leq C\big(\|\Theta_h l\|_0 \|\Theta_h l\|_{-1}\big)^{1/2} \tag{3.91}$$

and is therefore another good candidate for the construction of a stopping criterion. We have not determined to which extent the choice between these candidates really produces any significant differences on industrial problems.

4. Behavior of the iterates. We denote by Θ the continuous analogue of Θ_h, that is, the map $(\mathrm{H}^0_{\mathrm{div}}(\Gamma))^\star \to \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)$ which to l associates $u \times n - \operatorname{rot} q$, where u and q are the solutions of the continuous saddle-point problem. We also have $\mathcal{Z} = \Theta^\star \mathcal{A} \Theta$.

The Krylov subspaces are defined to be

$$\mathfrak{K}_h^n = \{P(\mathcal{Z}_h \mathcal{A}_h)\mathcal{Z}_h l|_{\mathsf{S}_h^1} \ : \ P \in \mathbb{C}[X], \ \deg P \leq n\}. \tag{4.1}$$

Their importance stems from the fact that—for fixed h—the PCG algorithm attempts to determine (by short recurrences) the sequence of solutions (u_h^n) of the problems

$$u \in \mathfrak{K}_h^n \quad \text{and} \quad \forall v \in \mathfrak{K}_h^n \quad a(u, v) = l(v). \tag{4.2}$$

For generalities about the PCG and related algorithms we refer to Barrett et al. [3] or Kelley [36]. Since we deal with complex-symmetric matrices, see also Freund [29]. In this section we investigate the convergence of the spaces $\mathfrak{K}_h^n$ towards their continuous analogues $\mathfrak{K}^n$, for fixed n as $h \to 0$, where naturally we have put

$$\mathfrak{K}^n = \{P(\mathcal{Z}\mathcal{A})\mathcal{Z} l \ : \ P \in \mathbb{C}[X], \ \deg P \leq n\}. \tag{4.3}$$

We will deduce from this results on the convergence as $h \to 0$ of the iterate u_h^n towards the solution u^n of

$$u \in \mathfrak{K}^n \quad \text{and} \quad \forall v \in \mathfrak{K}^n \quad a(u, v) = l(v). \tag{4.4}$$

We emphasize that for non-SPD problems the convergence or breakdown of the Lanczos process is as of today not completely understood. Here our point of view is to suppose that the continuous Lanczos process is well-defined up to iteration n, and then show that for small enough h, the discrete one is also well-defined, and yields

arbitrarily close iterates. If the ideal Lanczos process breaks down one should not expect the discrete one to behave well. We have not observed this pathology yet but should it occur one can consider in addition to various restart and look-ahead techniques perturbating the preconditioning operator.

Finally, we argue that the sequence (u^n) might converge superlinearly, as we show it to be the case for SPD operators, when the preconditioner is an inverse modulo a compact endomorphism.

4.1. Stability and convergence of Krylov subspaces.

PROPOSITION 4.1. *There is $C > 0$ such that for all h and all $l \in (\mathsf{S}_h^1)^\star$*

$$\|\Theta_h(l)\|_{-1} \leq C \sup_{v \in \mathsf{S}_h^1} \frac{|l(v)|}{\|v\|_0}. \tag{4.5}$$

Proof. Lemma 3.16 gives

$$\|\Theta_h(l)\|_{-1}^2 \leq C\big(|\mathcal{P}_{\mathsf{S}_h^{\prime 1}}(u \times n)|_0^2 + |\mathcal{P}_{\mathsf{S}_h^{\prime 0}\bullet}(q)|_0^2\big) \leq C\big(|u|_0^2 + |q|_0^2\big). \tag{4.6}$$

This gives the announced estimate. ∎

PROPOSITION 4.2. *There is $C > 0$ such that for all $l \in (\mathrm{H}_{\mathrm{div}}^{-1}(\Gamma))^\star$ and all h*

$$\|\Theta_h l|_{\mathsf{S}_h^1} - \Theta l\|_{-1} \leq Ch\|l\|_{-1\star}. \tag{4.7}$$

Proof. Let (u_h, q_h) be the solutions of the discrete saddle-point problem, and let (u_0, q_0) be the solutions of the continuous one. The well-known properties of this problem (in particular, Propositions 2.13 (p. 64) and 3.9 (p. 132) in Brezzi and Fortin [12]) yield

$$|u_h - u_0|_0^2 + |q_h - q_0|_0^2 \leq Ch^2(|u_0|_1^2 + |q_0|_1^2) \leq Ch^2\|l\|_{-1\star}^2. \tag{4.8}$$

Denoting for simplicity the L_2-orthogonal projections onto the appropriate spaces by $\mathcal{P}_h$, we have

$$|\mathcal{P}_h(u_h \times n) - (u_0 \times n)|_0 \tag{4.9}$$

$$\leq |\mathcal{P}_h(u_h \times n) - \mathcal{P}_h(u_0 \times n)|_0 + |\mathcal{P}_h(u_0 \times n) - u_0 \times n|_0 \tag{4.10}$$

$$\leq |(u_h \times n) - (u_0 \times n)|_0 + Ch|u_0 \times n|_1 \tag{4.11}$$

$$\leq Ch|u_0|_1. \tag{4.12}$$

Using the same technique, we also obtain

$$|\mathcal{P}_h(q_h) - q_0|_0 \leq Ch|q_0|_1. \tag{4.13}$$

This completes the proof, using Lemma 3.16. ∎

From these two propositions we deduce stability and convergence estimates for Θ_h in half-integer Sobolev norms.

COROLLARY 4.3. *There is $C > 0$ such that for all h and all $l \in \mathrm{H}_{\mathrm{div}}^{-1}(\Gamma)^\star$*

$$\|\Theta_h l|_{\mathsf{S}_h^1} - \Theta l\|_{-1/2} \leq Ch^{1/2}\|l\|_{-1\star}, \tag{4.14}$$

and there is $C > 0$ such that for all h and all $l \in (\mathsf{S}_h^1)^\star$

$$\|\Theta_h l\|_{-1/2} \leq C \sup_{v \in \mathsf{S}_h^1} \frac{|l(v)|}{\|v\|_{-1/2}}. \tag{4.15}$$

Proof. Let $\mathcal{Q}_h$ be the $\mathrm{H}^0_{\mathrm{div}}(\Gamma)$-orthogonal projection onto S'^1_h. The required properties of this projection were summarized in section 2.2. We have for all $l \in \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)^\star$

$$\|\Theta_h l|_{\mathsf{S}^1_h} - \Theta l\|_{-1/2} \le \|\Theta_h l|_{\mathsf{S}^1_h} - \mathcal{Q}_h\Theta l\|_{-1/2} + \|\mathcal{Q}_h\Theta l - \Theta l\|_{-1/2} \tag{4.16}$$

$$\le Ch^{-1/2}\|\Theta_h l|_{\mathsf{S}^1_h} - \mathcal{Q}_h\Theta l\|_{-1} + Ch^{1/2}\|\Theta l\|_0 \tag{4.17}$$

$$\le Ch^{-1/2}\big(\|\Theta_h l|_{\mathsf{S}^1_h} - \Theta l\|_{-1} + \|\Theta l - \mathcal{Q}_h\Theta l\|_{-1}\big) + \cdots \tag{4.18}$$

$$\le Ch^{1/2}\|l\|_{-1\star}, \tag{4.19}$$

and repeating the same sort of arguments, still supposing that $l \in \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)^\star$,

$$\|\Theta_h l|_{\mathsf{S}^1_h}\|_0 \le \|\Theta_h l - \mathcal{Q}_h\Theta l\|_0 + \|\mathcal{Q}_h\Theta l\|_0 \tag{4.20}$$

$$\le Ch^{-1}\|\Theta_h l - \mathcal{Q}_h\Theta l\|_{-1} + \|\Theta l\|_0 \tag{4.21}$$

$$\le Ch^{-1}\big(\|\Theta_h l - \Theta l\|_{-1} + \|\Theta l - \mathcal{Q}_h\Theta l\|_{-1}\big) + \cdots \tag{4.22}$$

$$\le C\|l\|_{-1\star}. \tag{4.23}$$

Combining this estimate with Proposition 4.1 by interpolation, we obtain, for $l \in \mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)^\star$,

$$\|\Theta_h l|_{\mathsf{S}^1_h}\|_{-1/2} \le C\|l\|_{-1/2\star}. \tag{4.24}$$

The apparently more refined version announced can then be deduced from the existence of an extension operator with norm one (the adjoint of the $\mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$-orthogonal projection onto S^1_h) or a Hahn–Banach theorem. ∎

We have similar estimates for $\Theta^\star_h$.

Corollary 4.4. *There is $C > 0$ such that for all h and all $l \in \mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)^\star$*

$$\|\Theta^\star_h l|_{\mathsf{S}'^1_h} - \Theta^\star l\|_{-1/2} \le Ch^{1/2}\|l\|_{-1\star}, \tag{4.25}$$

and there is $C > 0$ such that for all h and all $l \in (\mathsf{S}'^1_h)^\star$

$$\|\Theta^\star_h l\|_{-1/2} \le C \sup_{v\in\mathsf{S}'^1_h} \frac{|l(v)|}{\|v\|_{-1/2}}. \tag{4.26}$$

Proof. Using the fact that a (bounded) operator has the same norm as its adjoint we first obtain from Proposition 4.2 that

$$\|\Theta^\star_h l|_{\mathsf{S}'^1_h} - \Theta^\star l\|_{-1} \le Ch\|l\|_{-1\star}. \tag{4.27}$$

As in the proof of Corollary 4.3 this yields the first equation. The second one follows trivially from the second estimate of the same corollary. ∎

From this one deduces the following.

Corollary 4.5. *Let (l_h) be a sequence of linear forms on $\mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$ which converges to l (in the norm sense in the dual of $\mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$). Then $\Theta_h l_h|_{\mathsf{S}^1_h}$ converges to Θl in $\mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)$. Similarly, $\Theta^\star_h l_h|_{\mathsf{S}'^1_h}$ converges to $\Theta^\star l$.*

Proof. The technique of proof is very classical (see, for instance, Folland [28, Prop. 5.17, p. 169] for the just as easy case of constant l_h) and relies on Corollary 4.3 (and Corollary 4.4 for the second part) using the density of $\mathrm{H}^{-1}_{\mathrm{div}}(\Gamma)^\star$ in $\mathrm{H}^{-1/2}_{\mathrm{div}}(\Gamma)^\star$. ∎

Then we immediately obtain stability and approximation properties for the preconditioner $\mathcal{Z}_h$.

PROPOSITION 4.6. *There is $C > 0$ such that for all h and all $l \in \mathrm{H}_{\mathrm{div}}^{-1/2}(\Gamma)^\star$*

$$\|\mathcal{Z}_h l|_{\mathsf{S}_h^1}\|_{-1/2} \leq C\|l\|_{-1/2\star}. \tag{4.28}$$

If a sequence of linear forms $l_h \in \mathrm{H}_{\mathrm{div}}^{-1/2}(\Gamma)^\star$ converges to l in $\mathrm{H}_{\mathrm{div}}^{-1/2}(\Gamma)^\star$, then $\mathcal{Z}_h l_h|_{\mathsf{S}_h^1}$ converges to $\mathcal{Z}l$.

We are now ready to prove the announced theorem.

THEOREM 4.7. *For all $l \in (\mathrm{H}_{\mathrm{div}}^{-1/2})^\star$ and all $n \in \mathbb{N}$, $(\mathcal{Z}_h\mathcal{A}_h)^n\mathcal{Z}_h l|_{\mathsf{S}_h^1}$ converges to $(\mathcal{Z}\mathcal{A})^n\mathcal{Z}l$ in $\mathrm{H}_{\mathrm{div}}^{-1/2}(\Gamma)$.*

Proof. This follows from the above results using a simple recursion argument. ∎

Remark. We have not derived any optimal orders of convergence, for smoother than necessary data and perhaps higher order finite elements, though we do not expect this to yield any serious difficulties or require methods of proof different from the above ones. Nor have we tried to determine the minimum hypotheses on the regularity of the triangulations under which our conclusions hold; in particular, we have not determined to which extent the quasi-uniformity hypothesis (which is used for the inverse inequalities) can be relaxed. Of course also working on nonsmooth surfaces would put severe limitations on the range of Sobolev spaces we could use.

4.2. Convergence of the iterates. Let X be a Banach space and X_1, X_0 two closed subspaces. When these are nonzero, the *gap* from X_1 to X_0, denoted $\delta(X_1, X_0)$, is defined to be

$$\delta(X_1, X_0) = \sup_{u_1 \in X_1} \inf_{u_0 \in X_0} \|u_1 - u_0\|/\|u_1\|. \tag{4.29}$$

This definition is extended straightforwardly to the case when X_1 or X_0 is zero. For a thorough discussion of the gap we refer to Kato [35] but for us the definition is enough.

Suppose that X_0 *splits*, i.e., has a closed supplementary (for instance finite-dimensional spaces automatically split, as do closed subspaces of Hilbert spaces), so that we have a continuous projector $P : X \to X$ with range X_0. For all $u \in X$, one has

$$\forall u' \in X_0 \quad \|u - Pu\| = \|(u - u') - (Pu - u')\| = \|(u - u') - P(u - u')\|. \tag{4.30}$$

Hence

$$\|u - Pu\| \leq \|I - P\| \left(\inf_{u' \in X_0} \|u - u'\|/\|u\| \right) \|u\|. \tag{4.31}$$

In particular,

$$\forall u \in X_1 \quad \|u - Pu\| \leq \|I - P\|\delta(X_1, X_0)\|u\|. \tag{4.32}$$

Thus if (X_h) is a family of closed subspaces such that $\lim_h \delta(X_h, X_0) = 0$, then for sufficiently small h the spaces PX_h are closed in X_0 and P induces isomorphisms $X_h \to PX_h$ which are arbitrarily close in norm to the identity mapping on X_h.

PROPOSITION 4.8. *Let X be a reflexive Banach space and $\mathcal{A} : X \to X^\star$ a continuous linear map. Suppose X_0 is a closed subspace that splits yielding a projector*

P. Suppose X_h is another closed subspace, and that the induced maps $\mathcal{A}_0 : X_0 \to X_0^\star$, $\mathcal{A}_h : X_h \to X_h^\star$ satisfy the inf-sup conditions (1.20), (1.21), *with constants α_0 and α_h. Also put $\delta_h = \delta(X_h, X_0)$.*

Then $\mathcal{A}_0$ and $\mathcal{A}_h$ are invertible ; moreover, for any $l \in X^\star$, if we put $u_h = \mathcal{A}_h^{-1} l|_{X_h}$ and $u_0 = \mathcal{A}_0^{-1} l|_{X_0}$, we have for all $u' \in X_h$

$$\|u_h - u_0\| \leq \alpha_h^{-1}(1 + \alpha_0^{-1}\|\mathcal{A}\|)\|I - P\|\delta_h\|l\| + (1 + \alpha_h^{-1}\|\mathcal{A}\|)\|u_0 - u'\|. \tag{4.33}$$

Proof. That $\mathcal{A}_0$ and $\mathcal{A}_h$ are invertible is part of Theorem 1.1. Concerning the approximation property, we have (as usual we denote by a the bilinear form corresponding to $\mathcal{A}$)

$$\|u_h - u_0\| \leq \|u_h - u'\| + \|u' - u_0\| \leq \alpha_h^{-1} \sup_{v \in X_h} \frac{|a(u_h - u', v)|}{\|v\|} + \|u' - u_0\|. \tag{4.34}$$

Now (for $v \in X_h$) write

$$a(u_h - u', v) = a(u_h, v) + a(u_0 - u', v) - a(u_0, Pv) - a(u_0, v - Pv) \tag{4.35}$$

$$= l(v - Pv) + a(u_0 - u', v) - a(u_0, v - Pv). \tag{4.36}$$

Therefore,

$$|a(u_h - u', v)|/\|v\| \leq (1 + \alpha_0^{-1}\|a\|)(\|I - P\|)\delta_h\|l\| + \|a\|\,\|u_0 - u'\|. \tag{4.37}$$

This proves the proposition. □

Remark. Just as Theorem 1.1 this proposition can easily be extended to the more general setting of a continuous map $\mathcal{A} : X \to Y^\star$ and subspaces $X_0 \subset X$ and $Y_0 \subset Y$.

Suppose now (and this is the case for both the approximation of harmonic fields and the approximation of Krylov subspaces we were discussing) that we have a family (X_h) of subspaces of X and *surjective* linear maps $\Lambda_h : X_0 \to X_h$ such that $\lim_h \|\Lambda_h - I\| = 0$. When $\|\Lambda_h - I\| < 1$, Λ_h is invertible (so X_h is closed), and $\|\Lambda_h^{-1}\| \leq (1 - \|\Lambda_h - I\|)^{-1}$, and $\Lambda_h^{-1} - I$ considered as a map $X_h \to X$ has norm $\|\Lambda_h^{-1} - I\| \leq (1 - \|\Lambda_h - I\|)^{-1}\|\Lambda_h - I\|$. In particular,

$$\delta(X_h, X_0) \leq (1 - \|\Lambda_h - I\|)^{-1}\|\Lambda_h - I\|. \tag{4.38}$$

We also trivially have

$$\delta(X_0, X_h) \leq \|\Lambda_h - I\|. \tag{4.39}$$

Given some continuous bilinear form a on X, we define is_h and is_0 by

$$\mathrm{is}_h = \inf_{u \in X_h} \sup_{v \in X_h} \frac{|a(u,v)|}{\|u\|\,\|v\|} \quad \text{and} \quad \mathrm{is}_0 = \inf_{u \in X_0} \sup_{v \in X_0} \frac{|a(u,v)|}{\|u\|\,\|v\|}. \tag{4.40}$$

Some tedious elementary manipulations yield (independently of the existence of the map Λ_h) the inequality

$$\mathrm{is}_h \geq \mathrm{is}_0 \frac{\big(1 - \delta(X_h, X_0)\big)}{\big(1 + \delta(X_0, X_h)\big)} - \|a\| \left(\frac{\big(1 + \delta(X_h, X_0)\big)}{\big(1 - \delta(X_0, X_h)\big)} \delta(X_0, X_h) + \delta(X_h, X_0) \right). \tag{4.41}$$

Now if we plug estimates (4.38) and (4.39) into (4.41) we can conclude that as $h \to 0$, is_h becomes greater than $\mathrm{is}_0 - \epsilon$ for any $\epsilon > 0$. Combining this fact with Proposition 4.8, we obtain the following.

PROPOSITION 4.9. *Let X be a reflexive Banach space and $\mathcal{A} : X \to X^\star$ be a continuous linear map. Suppose that X_0 is a closed linear subspace that splits yielding a projector P and that $\mathcal{A}$ induces an isomorphism $X_0 \to X_0^\star$, with an inf-sup estimate α_0. Suppose we have a family (X_h) of subspaces of X, equipped with surjective linear continuous maps $\Lambda_h : X_0 \to X_h$, such that $\lim_h \|I - \Lambda_h\| = 0$.*

Then for any $0 < \alpha < \alpha_0$ there is $h_0 > 0$ such that, for all $h < h_0$, $\mathcal{A}$ induces isomorphisms $X_h \to X_h^\star$, and, for all $l \in X^\star$, with the notations of Proposition 4.8, *we have*

$$\|u_h - u_0\| \leq \alpha^{-1}(1 + \alpha^{-1}\|\mathcal{A}\|)(1 + \|I - P\|)\,\|\Lambda_h - I\|\,\|l\|. \tag{4.42}$$

Applying this proposition to the discrete and continuous Krylov spaces yields the following.

COROLLARY 4.10. *Fix an $n \in \mathbb{N}$. Suppose that $\dim \mathfrak{K}^n = n+1$ and that the map $\mathfrak{K}^n \to \mathfrak{K}^{n\star}$ induced by $\mathcal{A}$ is invertible. Then there is $h_n > 0$ such that for all $h < h_n$ the map $\mathfrak{K}_h^n \to \mathfrak{K}_h^{n\star}$ induced by $\mathcal{A}$ is invertible; moreover, given $l \in \mathrm{H}_{\mathrm{div}}^{-1/2}(\Gamma)^\star$, the solutions u_h^n and u^n of* (4.2) *and* (4.4) *satisfy an estimate of the form*

$$\|u_h^n - u^n\|_{-1/2} \leq C\|\Lambda_h^n - I\|, \tag{4.43}$$

where $\Lambda_h^n : \mathfrak{K}^n \to \mathfrak{K}_h^n$ is the unique linear map that satisfies, for $0 \leq i \leq n$,

$$\Lambda_h^n : (\mathcal{Z}\mathcal{A})^i \mathcal{Z} l \mapsto (\mathcal{Z}_h \mathcal{A}_h)^i \mathcal{Z}_h l|_{\mathsf{S}_h^1}. \tag{4.44}$$

Of course Theorem 4.7 shows that (for fixed n) $\|\Lambda_h^n - I\| \to 0$, and the above mentioned question of regularity is whether for smooth l we have estimates of the form $\|\Lambda_h^n - I\| \leq Ch^s$ for $s > 0$.

It is also possible to give a slightly different and more algorithmic variant of this corollary. Namely, define an "abstract" conjugate gradients algorithm by skipping all the h indices in some implementation in terms of $\mathcal{Z}_h$ and $\mathcal{A}_h$ of the conjugate gradient algorithm on S_h^1. (It should be checked that this is actually possible.) Then if the abstract algorithm is well defined up to iteration n there is $h_n > 0$ such that for all $h < h_n$ the discrete algorithm is well defined up to iteration n. Convergence of the iterates is described by the above corollary. Notice that it covers the case of algorithms that can skip full rank Krylov subspaces on which $\mathcal{A}$ is degenerate, as long as the next Krylov subspace is also full rank and $\mathcal{A}$ is nondegenerate on it, so-called Look-ahead algorithms described in Parlett, Taylor, and Liu [46]. Abstract conjugate gradient algorithms are common folklore even for non-Hermitian operators and described for instance in Gutknecht [30].

Remark. We have not proved that the spectral condition number of the restriction of $\mathcal{Z}_h\mathcal{A}_h$ to $(\mathsf{S}_h^1)^\wedge$ is uniformly bounded, and we even suspect that this may not be true. More precisely, the spectral radius of the endomorphism induced by $\mathcal{Z}_h\mathcal{A}_h$ on $(\mathsf{S}_h^1)^\wedge$ is uniformly bounded but perhaps not that of its inverse. The lack of this property (which was the guide and main focus of Steinbach and Wendland [51] and Christiansen and Nédélec [17]) was our principal motivation for proving the convergence of the Krylov spaces and the corresponding approximate solutions.

4.3. Evidence of superlinear convergence. The above discussion (in particular Corollary 4.10) suggests that the behavior of the approximate solutions (u_h^n) is similar to the behavior of (u^n), at least for moderate n (compared with $\dim \mathsf{S}_h^1 \approx h^{-2}$). Concerning the behavior of (u^n), the convergence theory is more satisfactory in the SPD case than in the non-SPD case we are dealing with.

Here we remind the reader how, in the infinite-dimensional SPD case, the property of inversion up to a compact operator leads to *superlinear* convergence. In other words, with the proposed preconditioner for the first kind integral equation EFIE, one recovers the kind of convergence usually associated with second kind integral equations. Though preconditioning was not a focus at the time, such estimates seem to date back to Hayes [31]. The theory does not directly apply to the studied case, but (for smooth surfaces) it does give complementary convergence estimates on some related preconditioning techniques, in particular those described in Steinbach and Wendland [51], which were the starting point of the method we have described here. We also believe these developments to give good *indication* on the behavior we can expect for our present problem.

Suppose X is a real Hilbert space, $\mathcal{A} : X \to X^\star$ is linear continuous, and induces a symmetric positive definite bilinear form. Suppose $\mathcal{Z} : X^\star \to X$ is linear continuous and symmetric. Given $l = \mathcal{A}u^\star \in X^\star$ define the Krylov spaces as above with real polynomials only. We suppose that we do not provide an approximate solution—other than 0—to start the algorithm, though this can easily be accounted for.

Remark first that $\mathcal{A}$ induces a scalar product on X with associated norm $\|\cdot\|_{\mathcal{A}}$ and that u^n solves (4.4) if and only if $u \mapsto \|u - u^\star\|_{\mathcal{A}}$ is minimal on $\mathfrak{K}^n$ at u^n. Thus for all real polynomials P such that $\deg P \leq n$,

$$\|u^n - u^\star\|_{\mathcal{A}} \leq \|P(\mathcal{Z}\mathcal{A})\mathcal{Z}\mathcal{A}u^\star - u^\star\|_{\mathcal{A}}. \tag{4.45}$$

Hence for all P such that $\deg P \leq n+1$, and $P(0) = 1$,

$$\|u^n - u^\star\|_{\mathcal{A}} \leq \|P(\mathcal{Z}\mathcal{A})u^\star\|_{\mathcal{A}}. \tag{4.46}$$

Then remark that $\mathcal{Z}\mathcal{A}$ is continuous, and symmetric with respect to the bilinear form induced by $\mathcal{A}$, and therefore has a resolution of the identity E on the spectrum $\sigma = \sigma(\mathcal{Z}\mathcal{A}) \subset \mathbb{R}$ such that we can write (we refer to Rudin [50, Chap. 12] for definitions and notations)

$$\|P(\mathcal{Z}\mathcal{A})u^\star\|_{\mathcal{A}}^2 \leq \int_\sigma |P(\lambda)|^2 \mathrm{d}E_{u^\star,u^\star} \tag{4.47}$$

$$\leq \sup\{|P(\lambda)|^2 \ : \ \lambda \in \sigma \cap \operatorname{supp} \mathrm{d}E_{u^\star,u^\star}\} \, \|u^\star\|_{\mathcal{A}}^2. \tag{4.48}$$

Finally in the case were $\mathcal{Z}\mathcal{A} - I$ is compact we can put $\sigma = \{1\} \cup \{\lambda_i : i \in \mathbb{N}\}$, where $(|\lambda_i - 1|)$ is a decreasing sequence converging to 0. To be sure that the algorithm is well-defined for all n we suppose that $\mathcal{Z}$ is positive definite. Then $\lambda_i \neq 0$, and we can define polynomials P_n by

$$P_n \ : \ P_n(\lambda) = \Pi_{i=0}^n (1 - \lambda/\lambda_i). \tag{4.49}$$

Remark that for any i and any λ such that $|1 - \lambda| \leq |1 - \lambda_i|$

$$|1 - \lambda/\lambda_i| = |(\lambda_i - 1 + 1 - \lambda)/\lambda_i| \leq 2|1 - 1/\lambda_i|, \tag{4.50}$$

which gives

$$\sup_{\lambda \in \sigma} |P_n(\lambda)| \leq 2^{n+1} \Pi_{i=0}^n |1 - 1/\lambda_i|. \tag{4.51}$$

Since $|1 - 1/\lambda_i| \to 0$, this immediately implies superlinear convergence. More generally, if (λ_i) is a sequence of nonzero *complex* numbers, such that $(|\lambda_i - 1|)$ decreases

to 0, the estimates (4.50) (for complex λ) and (4.51) (with the same definition of P_n, and still with $\sigma = \{1\} \cup \{\lambda_i \ : \ i \in \mathbb{N}\}$) remain true, which might be of interest to other Krylov-subspace algorithms applied to non-SPD operators. Moreover, if the asymptotic behavior of the eigenvalues of the residual $\mathcal{Z}\mathcal{A} - I$ is known and we have an estimate of the form $|1-\lambda_i| \leq Ci^{-\alpha}$ for some $C > 0$, $\alpha > 0$, we get the convergence estimate (for a larger C and the same α)

$$\|u^n - u^\star\|_{\mathcal{A}} \leq C^n (n!)^{-\alpha} \|u^\star\|_{\mathcal{A}}. \tag{4.52}$$

More explicitly, returning to the case of operators on a smooth compact Riemannian manifold Γ, if the dimension of the manifold is N and the residual is an operator of order $-s$ for some $s > 0$ (i.e., in terms of Sobolev spaces, continuous $\mathrm{H}^{s'}(\Gamma) \to \mathrm{H}^{s'+s}(\Gamma)$ for all s') which commutes with the Laplacian on Γ, this holds with $\alpha = s/N$. This can be deduced from the eigenvalue asymptotics of the Laplacian, for which we refer to Taylor [52, Vol. II, Chap. 8]. An alternative and more general approach based on trace-class theory is exposed in Winther [56] and also gives a factor of the form $C^n(n!)^{-\alpha}$. When Γ has symmetries an even larger α might hold in the estimate (4.52) due to the degeneracy of eigenvalues. For the determination of the orders of different integral operators we refer to Nédélec [43]; in particular, the order of the residual in our preconditioning strategy for the EFIE is -2 (though we do not even claim to have proved that the PCG does not break down in this case).

5. Numerical results. In order to evaluate the performance of the preconditioner it is customary to show the convergence graphs. We use the notations of (1.29), and we denote by U_h^n the tuple of coordinates of the approximate solution u_h^n at iteration n in the chosen basis. The convergence graphs are then of the form

$$n \mapsto \log_{10}(\|A_h(k)U_h^n - V_h\|/\|V_h\|) \tag{5.1}$$

for a given choice of norms on the tuples. The standard norm is the ℓ_2 norm on tuples. From a functional point of view this is not very natural, but on the other hand functional norms are not readily computable—with a notable exception for those we defined in section 3.9.

5.1. Sphere. We start by showing convergence graphs for the canonical example of diffraction of a plane wave by the unit sphere for the wave lengths $\lambda = 8,\ 4,\ 2,\ 1$ ($k = 2\pi/\lambda$); see Figure 5.1. The discretization of the sphere has 2252 vertices and 4500 triangles, leading to 6750 degrees of freedom for lowest order Raviart–Thomas finite elements.

We consider here the case of the preconditioner using the same Galerkin space as the original and use a complex symmetric conjugate gradients algorithm.

Each graphic displays three curves. The thin line (upper graph) is obtained without preconditioning for the ℓ_2 norm on tuples; the dotted line (which stagnates) is obtained with the proposed preconditioner for the ℓ_2 norm on tuples; the third line (the bottom graph) is obtained with the proposed preconditioner for the natural norm defined in section 3.9.

We make the following comments:

- With the preconditioner, each iteration is a little more than twice as slow as without any preconditioner: we apply the Galerkin matrix once more, and do a considerable amount of sparse matrix manipulations.

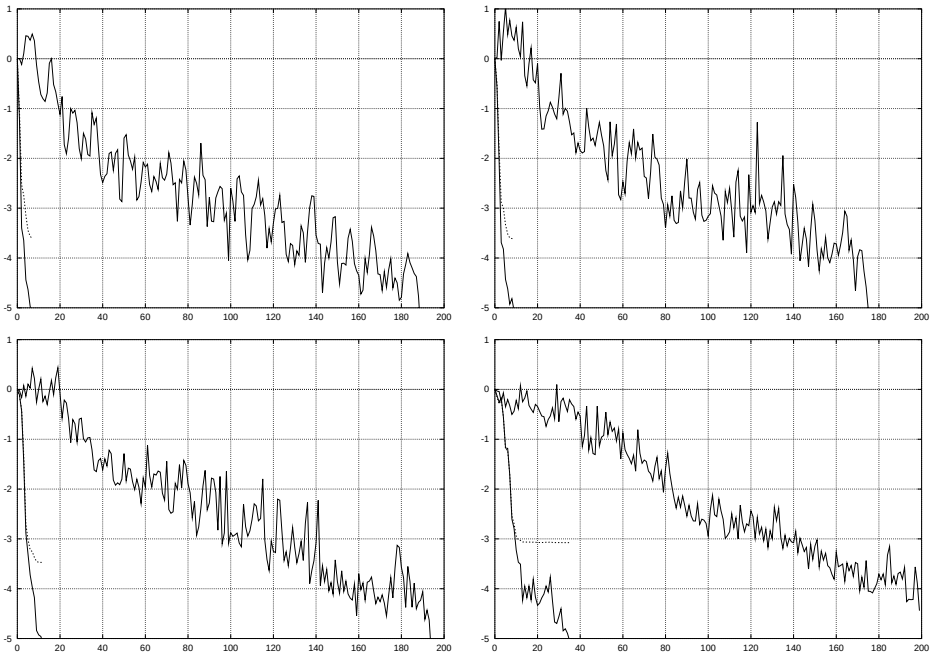

FIG. 5.1. *Convergence graphs for the unit sphere at* $\lambda = 8,\ 4,\ 2,\ 1$ *(top left to bottom right).*

- In the preconditioned case and in particular at $\lambda = 1$, the ℓ_2 norm (dotted line) of the residual stagnates, whereas the natural norm continues to decrease, confirming that the variational problem is indeed solved on a strict subspace.
- The preconditioner is particularly efficient at low frequencies—which is the only really ill-conditioned case on spheres.
- Usual stopping criteria vary from 10^{-2} to 10^{-5}, depending on the accuracy of the result required; for all these the preconditioned algorithm is several times faster than the algorithm without preconditioning.
- The auxiliary problems in the preconditioner were solved iteratively with a tolerance of 10^{-7} (saddle-point problem) and 10^{-8} (L^2 projections); accumulation of such errors and other round-off errors could also partly explain the instabilities observed at the last iterations at $\lambda = 1$.
- The far-field patterns deduced from the electric currents computed iteratively with and without preconditioner were not graphically distinguishable from those computed by standard factorization.
- Using the Brezzi–Douglas–Marini finite elements in the preconditioner (while still using Raviart–Thomas for the original problem) yields slightly better accuracy and requires slightly fewer iterations. Also the dotted line does not stagnate, confirming that the equation is then solved variationally on a much larger subspace. However, each iteration is much slower, since there are twice as many degrees of freedom in the preconditioner (at the lowest level).

5.2. Cavity. We consider now diffraction by a cavity. In cavities trapped rays create long range nontrivial interactions. This is a considerably more challenging problem than scattering by convex objects, since, without preconditioning, it happens that the iterates do not converge.

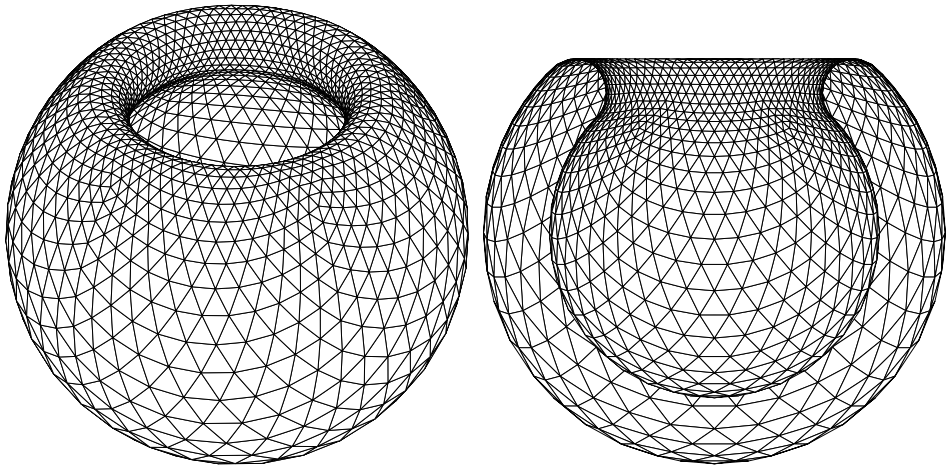

FIG. 5.2. *Cavity seen from outside and vertical section.*

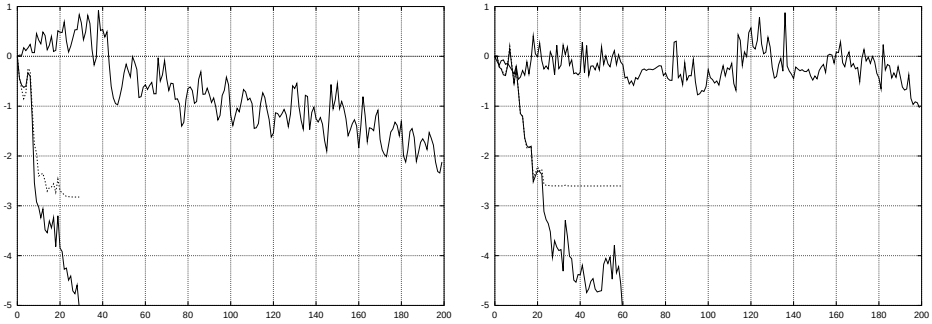

FIG. 5.3. *Convergence graphs for the cavity at* $\lambda = 8,\ 2$ *(left and right).*

The particular geometry we consider can be described as follows: take two concentric spheres, one with radius 5/6 and one with radius 7/6; excavate a cone with top at the origin and half-angle $\pi/4$ and join the interior surface with the exterior one with half a torus. See Figure 5.2. The mesh of the cavity was constructed from a mesh of the unit sphere (in fact the same one as in the preceding example) by successive deformations.

The cavity is lit by a horizontally polarized plane wave entering the cavity tangentially to its walls. (The wave vector makes an angle of $3\pi/4$ with the vertical direction.) The convergence graphs obtained for the cavity are displayed in Figure 5.3.

Notice that at $\lambda = 2$, the preconditioner not only speeds up convergence, it actually enables it.

In the preconditioned case, we observe a slow-down in the convergence, which we interpret as stemming from the fact that the Calderon formulas are less well represented on a discrete level. (The discrete iterates depart from the continuous ones.) It seems also that the slow-down always occurs slightly after the ℓ_2 norm of the residual stagnates. This stagnation could be indication that the current iterate is as close to the exact continuous solution as the exact Galerkin solution. Thus the

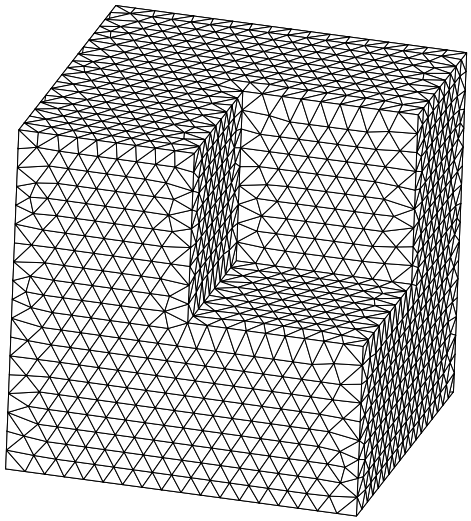

FIG. 5.4. *Indented cube seen from outside.*

stagnation in the ℓ_2 norm of the residual would be a good stopping criterion and then the slow-down would never be observed.

5.3. Indented cube. The Galerkin discretization of the EFIE is well known to perform well not only on smooth surfaces but also for the polyhedral ones that often occur in applications. Though we have justified the preconditioning technique only for smooth surfaces, it appears to perform well also on such nonsmooth ones. However, when the preconditioning operator $Z : X' \to X$ does not invert the operator $A : X \to X'$ up to a compact residual, but rather is such that ZA is an automorphism of X, one expects the ideal conjugate gradients algorithm to converge not superlinearly, but rather linearly, as is easily proven for SPD operators.

We show numerical results for the following geometry. The scattering object is the indented cube $[-1,1]^3 \backslash]0,1]^3$. The interior domain contains several types of singularities, both convex and nonconvex. Also when a plane wave with wave-vector $\sigma = (\sigma_1, \sigma_2, \sigma_3)$, with $\sigma_i < 0$, hits the reentrant corner, geometrical optics predicts that it should be scattered mainly in the direction $-\sigma$, after three reflections. The mesh used for the numerical experiments is shown in Figure 5.4. It has 2164 vertices and 4324 triangles, leading to 6486 edges (and degrees of freedom for Raviart–Thomas finite elements).

In Figure 5.5 we show the convergence graphs obtained for an incident plane wave with wave-vector positively proportional to $(-1,-1,-1)$, with wavelength $\lambda = 8$ and $\lambda = 4$, and with horizontal polarization. Contrary to the case of smooth surfaces there might be significant loss of accuracy when solving the Galerkin problem on $(\mathsf{S}_h^1)^\wedge$ rather than S_h^1 when lowest degree Raviart–Thomas fields are used both in the problem formulation and the preconditioner. This problem would be remedied using Brezzi–Douglas–Marini fields in the preconditioner, since then $(\mathsf{S}_h^1)^\wedge$ has very low codimension in S_h^1. However, for the wavelengths used here the far-field patterns were not graphically distinguishable.

Perspectives. The study of the method on nonsmooth surfaces is still ongoing. In particular, the evaluation of the impact of singularities in the surface and corre-

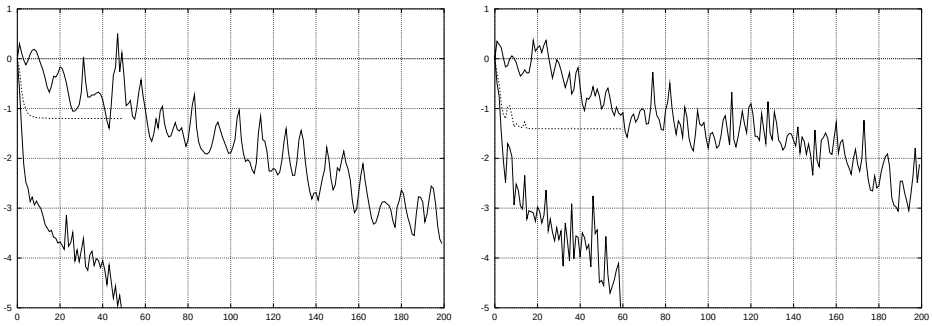

FIG. 5.5. *Convergence graphs for the indented cube at* $\lambda = 8,\ 4$ *(left and right).*

sponding mesh refinement strategies is important for many applications and could perhaps be achieved using recent results from Buffa, Costabel, and Schwab [13] and Hiptmair and Schwab [33].

As remarked on the numerical experiments, the preconditioning technique displays good stability at low frequencies. This stability can be enhanced by making the discrete Helmholtz decompositions still more explicit. For instance, focusing on the preconditioner, one applies separately the two terms of the operator in (1.18) to the two terms of the vector in (3.24). We shall come back elsewhere to this point, which is important for simulating semiconductor devices.

The method can also be extended to treat scattering by perfectly conducting simplical complexes (including open surfaces as well as branched ones, where more than two surfaces meet at an edge). In these cases one can no longer keep the same type of Galerkin spaces in the preconditioner as in the variational formulation of the EFIE, and the Calderon formulas, which require the surface to be orientable, need to be adapted. For some generalizations of the method described here we have obtained speed-ups comparable to the above ones, though the justifications are as of today at best intuitive.

Acknowledgments. We thank F. Béreux for his precious help with this project. We also thank both referees for many constructive remarks.

SECOND ORDER NUMERICAL METHODS FOR FIRST ORDER HAMILTON–JACOBI EQUATIONS*

ADAM SZPIRO† AND PAUL DUPUIS‡

Abstract. We present practical numerical methods which produce provably second order approximations for a class of stationary first order Hamilton–Jacobi partial differential equations. Using probabilistic methods, we derive high order asymptotic expansions for a first order method and then use those results to design second order methods. We prove second order convergence for the solution and for its gradient on a subset of the domain where the solution is smooth. Although we limit our attention to second order schemes, in principle the techniques in this paper can be extended to arbitrarily high order methods. Examples illustrate the rate of convergence as well as global sharp resolution of discontinuities. The Hamilton–Jacobi equations we consider correspond to deterministic optimal control problems, and our rate of convergence results are valid for the value functions and for the optimal feedback controls.

Key words. Hamilton–Jacobi equations, numerical approximation, second order convergence, asymptotic expansion, Markov chain approximation, finite difference approximation

1. Introduction.

This paper is concerned with the numerical solution of a class of first order stationary Hamilton–Jacobi partial differential equations (PDEs). We begin by specifying the PDEs of interest and giving a practical description of our proposed second order numerical methods. The PDEs that we study arise in connection with a variety of applications in computer vision, large deviations, and robust control [3], and they can be interpreted as dynamic programming equations for a class of deterministic optimal control problems on a finite domain. Under our assumptions, the value function $V^0(x)$ for a given control problem is the unique viscosity solution to the corresponding Hamilton–Jacobi PDE, and the optimal feedback control function $u^0(x)$ is obtained by taking the argument in the optimization part of the Hamilton–Jacobi equation on those parts of the domain where it is uniquely defined. We exploit this connection to develop the theoretical underpinnings of the proposed second order numerical methods. We give a detailed asymptotic analysis of a first order Markov chain-based numerical method and use that analysis to motivate our second order methods. Finally, we demonstrate under some assumptions that the proposed second order methods in fact yield second order convergent results and give several illustrative examples.

Much of the difficulty in solving equations of this type derives from the fact that the solutions need not be smooth on the entire domain. Under our assumptions, $V^0(x)$ is globally Lipschitz, but it need not be differentiable at all points. The control function $u^0(x)$ is closely related to the gradient of $V^0(x)$. It need not be uniquely

defined at all points, and it is often discontinuous across those points where it is not uniquely defined. Typically, however, there are regions of strong regularity (RSRs) which are open and dense in the domain, and in those regions both $V^0(x)$ and $u^0(x)$ are as smooth as the problem data. Our asymptotic results hold on certain subsets of the RSRs, and we propose numerical methods which provide provably second order estimates for $V^0(x)$ and $u^0(x)$ on those regions, without sacrificing global convergence properties.

To our knowledge, there are no similar results which rigorously establish second order convergence of any fully implementable numerical method for nonlinear Hamilton–Jacobi PDEs in multiple dimensions (or for the closely related nonlinear conservation laws). Computational examples illustrate that the proposed methods also lead to well-behaved approximations which are second order convergent in the regions of interest. Given the difficulty of the problem, strong assumptions are to be expected for the theoretical analysis, and a major drawback to the current methodology is that one cannot determine the boundaries of the RSRs directly from the data. In addition, a key limiting assumption is contained in Assumption 5.1. That assumption requires that the optimal feedback controls be of fixed sign on the regions of interest, a condition which is typically only satisfied on a small subset of the domain. Nonetheless, the numerical methods appear to work well even where this assumption is violated. Perhaps more importantly, the analysis clarifies what sort of additional smoothness in the numerical methods would be required to obtain rigorous convergence results without such a restrictive assumption.

The numerical methods we consider are of finite difference type. We follow Kushner [24] and Kushner and Dupuis [25] and work in a probabilistic framework, beginning with the classical first order methods and proceeding to our proposed second order methods. The first order numerical methods can also be analyzed in a purely PDE framework using viscosity solution techniques [1, 6]. Several approaches to obtaining higher order approximations have been suggested in the literature, especially for the finite time case [12, 13, 27, 28, 23, 26, 22]. Many of these are based on numerical methods for conservation laws and have produced convincing numerical results. However, complete convergence proofs are not available, and adaptation to stationary problems has proven challenging [20]. We also note that the numerical method for conservation laws given in [21] is similar in philosophy to the first of our proposed second order methods.

We specify some notation. Let $\mathbb{R}^n$ be the n-dimensional Euclidian space, and let $\mathbb{Z}^n$ be the subset of $\mathbb{R}^n$ consisting of n-tuples of integers. For vectors $x, y \in \mathbb{R}^n$, $\langle x, y\rangle$ is the scalar product, $\|x\| = \sqrt{\langle x, x\rangle}$ is the Euclidean norm, $\|x\|_1 = \Sigma_{i=0}^n |x_i|$ is the l^1-vector norm, and $|x| = (|x_1|, \ldots, |x_n|)$ is the componentwise absolute value. For a process $X(\cdot)$ taking values in $\mathbb{R}^n$ and for $S < +\infty$, $\| X(\cdot) \|_S = \sup_{0\le t\le S} \|X(t)\|$ is the uniform L^2 norm. For any two subsets A and A' of $\mathbb{R}^n$, $d(A, A')$ denotes the minimum Euclidean distance between $\bar{A}$ and $\bar{A}'$. The positive part of a scalar is $a^+ = \max(a, 0)$, and its negative part is $a^- = -\min(a, 0)$. For a vector, the positive and negative parts are taken componentwise so that $x^\pm = (x_1^\pm, \ldots, x_n^\pm)$. In general, we use subscripts to denote the components of a vector, while superscripts index possibly vector valued quantities. Thus, x_i is always a scalar quantity, while x^i may denote a vector.

For a smooth function f mapping $\mathbb{R}^n$ to $\mathbb{R}$ and for a positive integer r, put $D_i^r f(x) = \frac{\partial^r}{\partial^r x_i} f(x)$. The diagonal of the array of rth order partial derivatives is denoted by

$$D_\setminus^r f(x) = (D_1^r f(x), \ldots, D_n^r f(x)).$$

In the case $r = 1$, we use the standard notation $Df(x) = D^1_{\setminus} f(x)$ for the gradient of f. For $h > 0$, the operators $D^{h,\pm}$ are one-sided finite difference approximations to the gradient operator. The ith component of $D^{h,+}f(x)$ is given by

$$D_i^{h,+} f(x) = \frac{f(x + he_i) - f(x)}{h},$$

while the ith component of $D^{h,-}f(x)$ is given by

$$D_i^{h,-} f(x) = \frac{f(x) - f(x - he_i)}{h}.$$

In addition, $D^{h,c}f(x)$ is the centered difference approximation to the gradient vector $Df(x)$, while $D^{2,h}_{\setminus} f(x)$ is the centered difference approximation to the diagonal second derivative vector $D^2_{\setminus} f(x)$.

2. PDE and numerical methods. In this section, we describe the problem of interest and give a practical description of the proposed numerical methods. The remainder of the paper is concerned with a rigorous analysis of what is discussed here. Let $G \subset \mathbb{R}^n$ be open with compact closure, and assume that G satisfies uniform interior and exterior cone conditions (see [3] for definitions). Let b and c be C^∞ functions from $\mathbb{R}^n$ to $\mathbb{R}$, and let a be a C^∞ function from $\mathbb{R}^n$ to the space of symmetric positive definite $n \times n$ matrices. Notice that a is uniformly positive definite on G. Assume that $c(x) \geq c_0 > 0$ on G. Define

$$L(x,u) = \frac{1}{2}\langle (u - b(x)), a^{-1}(x)(u - b(x))\rangle + c(x), \tag{2.1}$$

and consider the PDE

$$\inf_u \left[\langle u, DV^0(x)\rangle + L(x,u)\right] = 0, \tag{2.2}$$

with the continuous boundary condition $V^0(x) = 0$ on ∂G. This class of PDEs is of Hamilton–Jacobi type with Hamiltonians convex in the gradient $DV^0(x)$ and includes several PDEs of general interest. For example, the Eikonal equation $\|DV^0(x)\|^2 = 2c(x)$ is obtained by letting $a(x)$ be the identity matrix and taking $b(x) = 0$. Equation (2.2) may not have a classical solution, but it is proved in [2, Theorem 6.1] to have a unique nonnegative viscosity solution $V^0(x)$. (See the discussion around Lemma 3.1.) The corresponding optimal control $u^0(x)$ is not uniquely defined everywhere, but it is given by $u^0(x) = -a(x)DV^0(x) + b(x)$ where $V^0(x)$ is smooth.

In general, there is no analytical way to identify the solution $V^0(x)$, so we are interested in numerical approximation methods. The starting place for our discussion is the first order method described in detail in section 3 and in a slightly more general setting in [3] . Those discussions are in terms of a Markov chain interpretation that is convenient for theoretical analysis. Here we restrict ourselves to a formal description of the numerical method. For $h > 0$ and for $u \in \mathbb{R}^n$ we define

$$\overline{\Delta t}^h(u) = \begin{cases} \frac{h}{\|u\|_1} & u \neq 0, \\ h & u = 0 \end{cases} \tag{2.3}$$

and

$$p^h(x, y|u) = \begin{cases} \frac{u_i^{\pm}}{\|u\|_1} & \text{if } y = x \pm he_i, \\ 0 & \text{otherwise.} \end{cases} \tag{2.4}$$

Then we take as a first order numerical approximation the unique solution $V^h(x)$ to

$$V^h(x) = \inf_u \left[\sum_{y \in \mathbb{R}^n} p^h(x, y|u) V^h(y) + \overline{\Delta t}^h(u) L(x, u) \right] \tag{2.5}$$

on $G^h = h\mathbb{Z}^n \cap G$ with zero boundary condition on the complement of G^h. Additionally, we define the approximate optimal control $u^h(x)$ to be the minimizing argument in (2.5). It is easy to see that (2.5) is equivalent to an upwind first order finite difference approximation to (2.2). As discussed in [3], this discrete equation can be solved efficiently by a Gauss–Seidel iteration, with the optimal value at each step computed analytically; the reader interested in implementation should consult [3] for further details. See also [30] for an interesting discussion of an alternative to Gauss–Seidel iteration for a subclass of problems. It can be shown that $V^h(x) \to V^0(x)$ on G. Additionally, it can be shown on the RSRs that $u^h(x) \to u^0(x)$ and that the convergence $V^h(x) \to V^0(x)$ is first order. See sections 3 and 4 and the reference cited there [3, 11].

Our primary interest in this paper is in second order numerical methods. Our second order methods are motivated by the formal asymptotic expansion

$$V^h(x) = V^0(x) + he^1(x) + O(h^2), \tag{2.6}$$

where formally $e^1(x)$ satisfies

$$\langle u^0(x), De^1(x) \rangle + \frac{1}{2} \langle |u^0(x)|, D^2_{\backslash} V^0(x) \rangle = 0 \tag{2.7}$$

with zero boundary condition. A rigorous analysis of this asymptotic expansion is given in sections 4 and 5. In this analysis, we draw liberally from ideas developed in [15, 10]. Note also that related results are obtained using viscosity solution methods in [17]. We observe that the asymptotic expansion motivates two distinct approaches to obtaining a second order approximation to $V^0(x)$.

Approximation Method I. The idea is to directly construct an approximation $e^{1,h}(x)$ to $e^1(x)$. Evidently, the unknowns $V^0(x)$ and $u^0(x)$ appear in relation (2.7), but it is possible to use the first order approximations $V^h(x)$ and $u^h(x)$ to construct the approximation by way of the linear equation

$$\langle u^{h,+}, D^{h,+} e^{1,h} \rangle - \langle u^{h,-}, D^{h,-} e^{1,h} \rangle + \frac{1}{2} \langle |u^h|, D^{2,h}_{\backslash} V^h \rangle = 0 \tag{2.8}$$

with zero boundary condition. This equation can be solved iteratively using an efficient Gauss–Seidel method. The second order approximations are defined to be

$$V^{h,*}(x) = V^h(x) - he^{1,h}(x)$$

and

$$u^{h,*}(x) = -a(x) D^{h,c} V^{h,*}(x) + b(x)$$

for all x in G^h.

Approximation Method II. Alternatively, (2.6) suggests Richardson extrapolation as a method to obtain a second order approximation. As such, we may define new approximations by

$$V^{h,*}(x) = 2V^h(x) - V^{2h}(x)$$

and

$$u^{h,*}(x) = 2u^h(x) - u^{2h}(x).$$

The form of $u^{h,*}(x)$ is motivated by an asymptotic expansion for $u^0(x)$ similar in form to (2.6). It should be noted that the $V^{h,*}(x)$ obtained here is not the same as in Method I. Both involve removing an approximation to the error term $e^1(x)$, but the approximations used in the two methods are in general not the same.

A detailed discussion of the derivation and convergence properties of these second order approximation methods is found in section 6, and computational examples are given in section 7. Both methods produce consistent numerical second order approximations to $V^0(x)$ and $u^0(x)$ on the RSRs when convergence is measured in the L^1 norm. Results are less consistent when measured in the L^∞ norm. No spurious oscillations are observed in the approximations to $V^0(x)$. Some oscillations are evident near discontinuities in the approximations to $u^0(x)$ (which is related to the gradient of $V^0(x)$), but the oscillations appear to be bounded as the grid is refined, indicating that the second order methods are numerically stable for both $V^0(x)$ and $u^0(x)$.

3. Connection with dynamic programming and first order numerical approximation. We describe a deterministic optimal control problem and its connection to the PDE discussed in the previous section. Then we describe in a Markov chain framework the first order numerical method used to approximate the solution, and we recall results which guarantee convergence of the numerical value function and of the numerical feedback control to their respective counterparts in the problem being approximated.

Let $G \subset \mathbb{R}^n$, $a(x)$, $b(x)$, $c(x)$, and $c_0 > 0$ be as in the previous section. For a control $\underline{u}^0(t)$ which is in $L^2([0,S];\mathbb{R}^n)$ for all $S < +\infty$ and for an initial condition $x \in G$, we define $\underline{X}^0(t)$ by the dynamics

$$\underline{X}^0(t) = x + \int_0^t \underline{u}^0(s)ds, \tag{3.1}$$

up to the time when it exits from the domain G. The corresponding generator $\mathcal{L}_u^0$ is given by

$$\mathcal{L}_u^0 f = \langle u, Df \rangle \tag{3.2}$$

for any smooth function f mapping $\mathbb{R}^n$ to $\mathbb{R}$. We define the exit time $\underline{\tau}^0 = \inf[t : \underline{X}^0(t) \notin G]$. For the running cost

$$L(x,u) = \frac{1}{2}\langle (u - b(x)), a^{-1}(x)(u - b(x))\rangle + c(x),$$

we define the payoff functional

$$J^0(x,\underline{u}^0) = \int_0^{\underline{\tau}^0} L(\underline{X}^0(t), \underline{u}^0(t))dt.$$

The problem is to minimize the payoff by choosing a suitable control. Define the value function,

$$V^0(x) = \inf_{\underline{u}^0} J^0(x,\underline{u}^0),$$

where the infimum is over controls $\underline{u}^0$ which are in $L^2([0,S];\mathbb{R}^n)$ for all $S < +\infty$. We employ the underscore notation here to indicate trajectories which are obtained from an arbitrary control. The same notations, without the underscores, will be used later to refer to trajectories which are obtained through the application of an optimal control.

The dynamics in (3.1) involve an open loop control $\underline{u}^0(t)$ which is defined for all $t > 0$. It is generally desirable, from the point of view of robustness and for convenience of implementation, to consider controls which can be represented in the feedback form

$$\underline{X}^0(t) = x + \int_0^t \underline{u}^0(\underline{X}^0(s))ds. \tag{3.3}$$

A key feature of the RSRs is that the optimal open loop controls for all initial conditions in a region of strong regularity correspond to a unique smooth feedback function $u^0(x)$. The following lemma is proved by elementary arguments in [11, Lemma 2.1]. We will use the $T < +\infty$ from this lemma frequently in our analysis.

LEMMA 3.1. *$V^0(x)$ is bounded and uniformly Lipschitz on G, and there exists $T < +\infty$ such that every optimal trajectory exits from G by time $T-1$. Furthermore, there exists a compact set $U \subset \mathbb{R}^n$ such that every optimal open loop control is contained in the interior of U for each $0 \le t \le T-1$.*

The value function V^0 need not be differentiable on the entire domain G, but, given Lemma 3.1, it follows from [2, Theorem 6.1] that it is the unique nonnegative viscosity solution on G to the Hamilton–Jacobi dynamic programming equation (DPE)

$$\inf_u \left[\mathcal{L}_u^0 V^0(x) + L(x,u)\right] = 0, \tag{3.4}$$

with the continuous boundary condition $V^0(x) = 0$ on ∂G, where the generator $\mathcal{L}_u^0$ is defined in (3.2). See references [1] and [16] for a thorough account of the relationship between viscosity solutions of Hamilton–Jacobi PDEs and the value functions for various types of optimal control problems.

It turns out that V^0 is smooth on most of the domain G. Let Q be a subset of $\bar{G}$ which is open relative to G. We call Q an RSR if the following hold:

1. For each initial condition $x \in Q$, there is a unique optimal open loop control, and the corresponding trajectory $X_x^0(t)$ is contained in Q up to its exit time τ_x^0. The optimal trajectory meets ∂G nontangentially at a point z_x^0.
2. $V^0 \in C^\infty(Q)$.
3. There is a unique $u^0 \in C^\infty(Q)$ such that the optimal control can be represented in feedback form and is given by $u^0(x)$ for each $x \in Q$.
4. For $\xi \in Q \cap \partial G$, let T_ξ be the supremum of the exit times for optimal trajectories beginning in Q and exiting at ξ. The bijective map $\Xi(s,\xi)$ from

$$\{(s,\xi) : \xi \in Q \cap \partial G, 0 \le s < T_\xi\}$$

to Q given by $\Xi(\tau_x^0 - t, z_x^0) = X_x^0(t)$ is nonsingular in the sense that the quantities

$$\frac{\partial \Xi}{\partial s}(s,\xi), \frac{\partial \Xi}{\partial \nu_1}(s,\xi), \ldots, \frac{\partial \Xi}{\partial \nu_{n-1}}(s,\xi)$$

are linearly independent, where the ν_i are linearly independent tangent vectors to ∂G at the boundary point ξ.

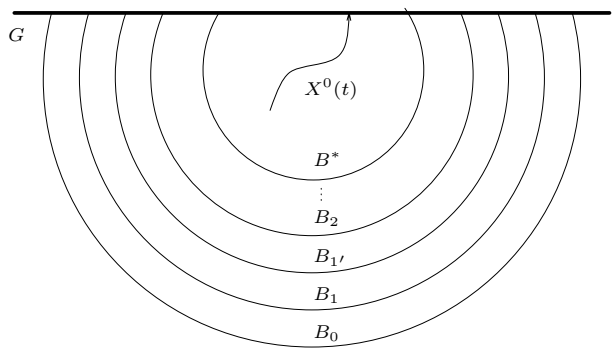

FIG. 1. *RSRs.*

The rather technical fourth condition in the above definition is the requirement that points in the RSRs not be conjugate. The uniqueness of optimal trajectories in the first condition is equivalent to the statement that the map $\Xi(s,\xi)$ is one-to-one. The nondegeneracy required in the fourth condition is a slightly stronger statement which precludes "almost" nonuniqueness in an infinitesimal sense. The classical method of characteristics and its application to proving the existence of RSRs for the present problem is discussed in the appendices of references [15, 17]. Detailed information on the structure of the regions of strong regularity for closely related problems can be found in references [4, 5, 14]. In general, the union of the RSRs is open and dense in the domain. We note that the C^∞ smoothness is a consequence of the assumed C^∞ smoothness of the data. Similar smoothness for finitely many derivatives would follow if the assumptions on the data were commensurately relaxed, and the asymptotic results in this paper would then be restricted to a finite order. For simplicity, we restrict ourselves to the case of C^∞ data.

Let B^* be a subset of $\bar{G}$ such that $\bar{B}^* \subset Q$. Our asymptotic results will hold on sets which include $\bar{B}^*$. Let $M \geq 1$ be a fixed integer. While our choice of M here is arbitrary, it corresponds to the order of the asymptotic expansion that we will obtain in section 5. Consider a region of strong regularity B_0, and, for $i = 1, \ldots, M$, regions of strong regularity B_i and $B_{i'}$ such that

$$\bar{B}^* \subset B_{M'} \subset \cdots \subset B_1 \subset \bar{B}_1 \subset B_0 \subset \bar{B}_0 \subset Q, \tag{3.5}$$

and such that

$$\bar{B}_{i+1} \subset B_{i'} \subset \bar{B}_{i'} \subset B_i \tag{3.6}$$

for each $i = 1, \ldots, M$, where B_{M+1} is taken to be B^* in (3.6). The existence of such nested RSRs follows from Theorem 2.4 in reference [17]. These relationships are illustrated in Figure 1.

Since V^0 is a classical solution to the DPE (3.4) on the RSR Q, the optimal feedback control can be explicitly evaluated there:

$$u^0(x) = -a(x)DV^0(x) + b(x). \tag{3.7}$$

We assume the following.

ASSUMPTION 3.2. *The boundary section $Q \cap \partial G$ is parallel to one of the coordinate hyperplanes. Furthermore, the minimum distance in the outward normal direction from $Q \cap \partial G$ to $\partial G/Q$ is equal to $\tilde{\delta} > 0$.*

We now present a first order Markov chain-based numerical approximation to the deterministic optimal control problem discussed above, along with known convergence results. The method of approximation by Markov chains was first described by Kushner [24], and an up-to-date treatment can be found in the book of Kushner and Dupuis [25]. Our approximation is essentially the one used in [3] and in [11]. In the sections which follow, we will present more detailed asymptotic results for this approximation and then describe a new numerical method which yields a qualitatively better rate of convergence.

Let $h > 0$ be a discretization parameter and define the discrete domain $G^h = h\mathbb{Z}^n \cap G$. For any $A \subset \mathbb{R}^n$, we define $A^h = h\mathbb{Z}^n \cap A^o$, where A^o is the interior of A. We consider limits as $h \to 0$, with the h chosen such that the hyperplane in which the boundary section $Q \cap \partial G$ lies lines up with the lattice $h\mathbb{Z}^n$. (See Assumption 3.2 and Figure 2.) We will construct a continuous time controlled jump Markov process on G^h which approximates the deterministic dynamics in (3.3).

Let $\underline{u}^h$ be any feedback control on G^h. Let $\underline{X}^h$ be the Markov process with controlled generator $\mathcal{L}_u^h$ given by

$$\mathcal{L}_u^h f = \langle u^+, D^{h,+} f \rangle - \langle u^-, D^{h,-} f \rangle$$

for any smooth function f mapping $\mathbb{R}^n$ to $\mathbb{R}$. See section 1 for the notation in this definition. The corresponding stochastic dynamics will be called the h-dynamics. As in the description of the limit problem, we employ the underscore notation to indicate objects which are obtained from the application of an arbitrary possibly suboptimal feedback control.

Since we consider only feedback controls, it is straightforward to construct $\underline{X}^h$, as in section 4.3 of [25] and in [7]. We define a sequence of independently and identically distributed exponential random fields parameterized by u, with mean values specified as follows:

$$\overline{\Delta t}^h(u) = \begin{cases} \frac{h}{\|u\|_1} & u \neq 0, \\ h & u = 0. \end{cases} \tag{3.8}$$

Suppose that after $m-1$ jumps, $\underline{X}^h(s)$ is defined for $0 \leq s \leq t$ and that $\underline{X}^h(t) = x$. Then we take $\underline{X}^h(s) = x$ for all $t \leq s < t + \eta$, where the waiting time η is the exponential random variable obtained by evaluating the mth random field with the parameter value $u = \underline{u}^h(\underline{X}^h(s))$. If $u = 0$, then $\underline{X}^h(t + \eta) = x$, but otherwise it is conditionally distributed according to the jump probabilities

$$p^h(x, y|u) = \begin{cases} \frac{u_i^{\pm}}{\|u\|_1} & \text{if } y = x \pm he_i, \\ 0 & \text{otherwise.} \end{cases} \tag{3.9}$$

It is easy to verify that the mean velocity of $\underline{X}^h$ at time t conditioned on $\underline{X}^h(t) = x$ is equal to $\underline{u}^h(x)$, so this is a consistent approximation to the limit dynamics in (3.3) if $\underline{u}^0(x)$ is replaced by $\underline{u}^h(x)$ there.

We now formulate the discrete approximation to the optimal control problem discussed above. Define the value function

$$V^h(x) = \inf_{\underline{u}^h} E_x \int_0^{\tau^h} L(\underline{X}^h(t), \underline{u}^h(\underline{X}^h(t)))dt,$$

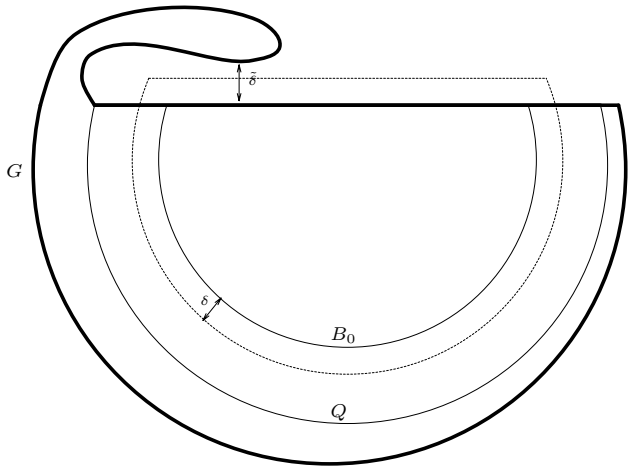

FIG. 2. *Region for smooth extension of* u^0.

where the exit time is $\underline{\tau}^h = \inf[t : \underline{X}^h(t) \notin G^h]$, and the infimum is over feedback controls $\underline{u}^h$. Using standard methods [25, section 4.3] it can be shown that V^h is the unique solution on G^h to the DPE

$$\inf_u \left[\mathcal{L}_u^h V^h(x) + L(x,u)\right] = 0, \tag{3.10}$$

with zero boundary condition on $h\mathbb{Z}^n/G^h$. It is straightforward to verify that (3.10) is equivalent to

$$V^h(x) = \inf_u \left[\sum_{y\in\mathbb{R}^n} p^h(x,y|u)V^h(y) + \overline{\Delta t}^h(u)L(x,u)\right] \tag{3.11}$$

and that the minimizing values of u are the same for these two equations. As suggested by the form of (3.11), the fixed point and an optimal feedback control can be found numerically using either Jacobi or Gauss–Seidel iteration schemes. We note that (3.11) is the DPE for a different approximating control problem, where, instead of the continuous time Markov chain described above, a discrete time Markov chain is used to approximate the deterministic dynamics. That is the approach taken in [3], where the time step $\overline{\Delta t}^h(u)$ is used to interpolate the Markov chain into continuous time. As discussed in [3], the choice of one-sided transition probabilities and of a control-dependent time step facilitates rapid convergence of the iterative schemes used to solve (3.11), and the required infima at each step can be evaluated analytically.

The DPE (3.10) gives rise to an approximate value function $V^h(x)$ on G^h as well as an approximate optimal feedback control $u^h(x)$ on G^h. Typical convergence results for numerical methods dealing with optimal control problems concern the convergence of the value functions $V^h(x)$ to the limit value $V^0(x)$. The following theorem is proved for the present problem in [3, Theorem 5.4].

THEOREM 3.3. *For any* $\varepsilon > 0$*, there exists* $h_0 > 0$ *such that*

$$|V^h(x) - V^0(x)| < \varepsilon$$

for all $0 < h \le h_0$ *and all* $x \in G^h$.

For applications it is often important to have a good numerical approximation to the optimal feedback control $u^0(x)$. Typically, this quantity is not uniquely defined on the entire domain, and until recently no general approximation theorems were available. The following theorem [11, Corollary 5.6] establishes convergence of the approximate optimal controls $u^h(x)$ to $u^0(x)$ on the RSRs for the present problem. Aside from its intrinsic value, this result plays a pivotal role in the detailed asymptotic analysis that we carry out in the this paper.

THEOREM 3.4. *For any $\varepsilon > 0$, there exists $h_0 > 0$ such that*

$$\|u^h(x) - u^0(x)\| < \varepsilon$$

for all $0 < h \le h_0$ and for all $x \in B_0^h$.

It is convenient to have $u^0(x)$ defined and Lipschitz on all of $\mathbb{R}^n$ and to have $u^h(x)$ defined on all of $h\mathbb{Z}^n$. We abuse notation by extending $u^0(x)$ to $\mathbb{R}^n$ and changing its values on the complement of $\bar{B}_0$. Let $\delta > 0$ be such that $\delta < d(B_0, \partial Q \cap G)$ and such that $\delta \le \bar{\delta}$, where $\bar{\delta}$ is as in Assumption 3.2; see Figure 2. We define a Lipschitz function $\tilde{u}^0(x)$ on $B_\delta(\bar{B}_0)$ by setting $\tilde{u}^0(x) = u^0(x)$ on $B_\delta(\bar{B}_0) \cap G$ and by extending it to $B_\delta(\bar{B}_0) \cap G^c$ as follows. For $x \in B_\delta(\bar{B}_0) \cap \partial G$ and for $0 \le \gamma \le \delta$, let $\tilde{u}^0(x + \gamma n) = u^0(x)$, where n is the outward normal vector at x; see Figure 2. Now let $\phi(x)$ be a C^∞ function on $\mathbb{R}^n$ taking values in $[0,1]$ such that $\phi(x) = 1$ on $B_{\delta/2}(\bar{B}_0)$ and $\phi(x) = 0$ outside of $B_\delta(\bar{B}_0)$. Such a function can be constructed by standard methods using a smooth convolution kernel [18, Theorem 0.17]. We can now redefine $u^0(x)$ to be equal to $\phi(x)\tilde{u}^0(x)$ on $B_\delta(\bar{B}_0)$ and zero everywhere else. This new $u^0(x)$ is Lipschitz on $\mathbb{R}^n$ and satisfies (3.7) on the region B_0. Finally, we put $u^h(x) = u^0(x)$ for all $x \in h\mathbb{Z}^n / B_0$. Notice that, by Lemma 3.1 and by Theorem 3.4, we have $u^0(x)$ and $u^h(x)$ contained in the compact set U for all x at which they are defined for $h > 0$ sufficiently small.

For most of what follows, we will be concerned only with initial conditions x in the RSR B_0. For $x \in B_0$, we define the optimal trajectory $X_x^0(t)$ for all $t \ge 0$ by applying the extended feedback control $u^0(x)$. Since B_0 is an RSR, $X_x^0(t)$ is optimally controlled until time τ_x^0, which is its first exit time from G and from the interior of B_0. We also define the exit location $z_x^0 = X_x^0(\tau_x^0)$. For $x \in B_0^h$, there is a unique process $X_x^h(t)$ defined for all $t \ge 0$ which is optimally controlled by $u^h(x)$ until it exits from B_0^h. We define the exit time $\tau_{x,B_0}^h = \inf[t : X_x^h(t) \notin B_0^h]$ and the exit location $z_{x,B_0}^h = X_x^h(\tau_{x,B_0}^h)$. We will often suppress the initial conditions in the subscripts of all of these notations.

The following lemma is proved just like [11, Lemma 2.3]. We use it to parlay information about convergence of trajectories into information about convergence of the corresponding exit times and locations.

LEMMA 3.5. *Let M_2,M_1 be RSRs such that $\bar{M}_1 \subset M_2 \subset B_0$. For each sufficiently small $\varepsilon > 0$, there exists $\eta > 0$ such that the following holds. Let X be a function of t that is continuous on the right with limits on the left and that has initial condition in M_2, and let τ_{M_2} and z_{M_2} be its exit time and location from the interior of M_2. If $x \in M_2$ is such that $\|\!| X - X_x^0 |\!\|_T \le \eta$ holds, then $\tau_{M_2} \le \tau_x^0 + \varepsilon$. If, in addition, $x \in M_1$, then it also follows that $|\tau_{M_2} - \tau_x^0| \le \varepsilon$ and $\|z_{M_2} - z_x^0\| \le \varepsilon$.*

Our proofs of the detailed asymptotic results in this paper depend upon having sharp estimates for the rate of convergence of the prelimit processes to the corresponding limit trajectories. We derive exponential rates of convergence in probability from the large deviations upper bound in Theorem B.1. For an RSR $M_2 \subset B_0$, consider a sequence of feedback control functions $\hat{u}^h(x)$ defined on $h\mathbb{Z}^n$ which satisfy

$\hat{u}^h(x) = u^0(x)$ for $x \notin M_2^h$. Suppose that, for each $\varepsilon > 0$, there exists $h_0 > 0$ such that

$$\|\hat{u}^h(x) - u^0(x)\| < \varepsilon$$

for all $0 < h \le h_0$ and for all $x \in M_2^h$. In particular, given Theorem 3.4, we can take for $\hat{u}^h(x)$ either $u^h(x)$ or $u^0(x)$. For $x \in M_2^h$, let $\hat{X}_x^h(t)$ be the process defined for $t \ge 0$ by applying the control $\hat{u}^h$ in the h-dynamics. Define $\hat{\tau}_{x,M_2}^h$ to be the exit time of $\hat{X}_x^h$ from M_2^h, and let $\hat{z}_{x,M_2}^h$ be its exit location.

LEMMA 3.6. *Let M_2, M_1 be RSRs such that $\bar{M}_1 \subset M_2 \subset B_0$, and let $\hat{u}^h(x)$ and its corresponding trajectories be as above. For any $\varepsilon > 0$, there exists $K > 0$ such that*

$$\text{(i)} \qquad P_x\left[\|\!| \hat{X}^h - X_x^0 |\!\|_T \ge \varepsilon\right] < \frac{1}{K} e^{-K/h},$$

$$\text{(ii)} \qquad P_x\left[\hat{\tau}_{M_2}^h > \tau_x^0 + \varepsilon\right] < \frac{1}{K} e^{-K/h}$$

holds for all $x \in M_2^h$ and for all sufficiently small $h > 0$. In addition,

$$\text{(iii)} \qquad P_x\left[|\hat{\tau}_{M_2}^h - \tau_x^0| \ge \varepsilon\right] < \frac{1}{K} e^{-K/h},$$

$$\text{(iv)} \qquad P_x\left[\|\hat{z}_{M_2}^h - z_x^0\| \ge \varepsilon\right] < \frac{1}{K} e^{-K/h}$$

holds for all $x \in M_1^h$ and for all sufficiently small $h > 0$.

Proof. Part (i) is obtained by applying the large deviations upper bound in Theorem B.1 with $n_1 = n, n_2 = 0$. In the lemma, we set $\bar{a}^h(x) = 0$, $\bar{a}(x) = 0$, $\bar{b}^h(x) = \hat{u}^h(x)$, and $\bar{b}(x) = u^0(x)$. We define the measure $\bar{\mu}^h(x)$ by

$$\bar{\mu}^h(x)(y) = \begin{cases} \hat{u}_i^{h,\pm}(x) & \text{if } y = \pm h e_i, \\ 0 & \text{otherwise,} \end{cases} \tag{3.12}$$

and we define the limit measure $\bar{\mu}(x)$ to put mass $\|u^0(x)\|_1$ at the origin. Finally, we take $F = \{\phi : \|\!| \phi - X_x^0 |\!\|_T \ge \varepsilon\}$, and we note that $I_x(\phi)$ is uniformly bounded away from zero for all $\phi \in F$. To get parts (ii)–(iv), pick $0 < \eta < \varepsilon$ to satisfy the conclusion of Lemma 3.5. Then pick $K > 0$ such that (i) holds with ε replaced by η, and parts (ii)–(iv) follow from Lemma 3.5. □

4. First term in the asymptotic expansion. In this section, we derive a first order asymptotic expansion for $V^h(x)$ around $V^0(x)$ in the RSR B_1. Our methodology is essentially that employed in [10], and Theorem 3.4 plays a key role in the proof. The first order expansion is of independent interest, as it establishes a rate of convergence for $V^h(x)$ as an approximation to $V^0(x)$ in the RSRs. Our primary interest in this paper, however, is in the fact that the first order expansion suggests that it is possible to obtain higher order convergence through a modification of the Markov chain approximation. In the sections which follow, we prove, under some additional assumptions, that such schemes can be implemented to yield second order convergence.

For each $x \in B_0$ and for each $u \in U$, we define the difference between the prelimit and the limit generators applied to $V^0(x)$ by

$$\begin{aligned} r^h(x,u) &= \mathcal{L}_u^h V^0(x) - \mathcal{L}_u^0 V^0(x), \\ &= \frac{1}{2}\, h\, \langle |u|, D_{\setminus}^2 V^0(x) \rangle + O(h^2), \end{aligned} \tag{4.1}$$

where the $O(h^2)$ term is uniform on $B_0 \times U$. We can now write the DPE (3.4) for $V^0(x)$ in the alternative form

$$\inf_u \left[\mathcal{L}_u^h V^0(x) + L(x,u) - r^h(x,u) \right] = 0. \tag{4.2}$$

Equation (4.2) is the DPE for an optimal control problem with Markov chain dynamics and with running cost equal to $L - r^h$. A comparison with the DPE for $V^h(x)$ in (3.10) suggests that the difference between $V^h(x)$ and $V^0(x)$ should be approximately equal to an integral of r^h along the optimal trajectory with initial condition x. The theorem below verifies that this intuition is correct, at least to a first order approximation. It is useful in what follows to define a compact notation for the running cost under a feedback control $u(x)$ by

$$L_u(x) = L(x, u(x)).$$

Similarly, we define

$$r_u^h(x) = r^h(x, u(x))$$

for all $x \in B_0$ and for all $h > 0$.

For $x \in B_0$, we define the error function

$$e^1(x) = \frac{1}{2} \int_0^{\tau_x^0} \langle \left| u^0(X_x^0(t)) \right|,\ D_{\setminus}^2 V^0(X_x^0(t)) \rangle dt, \tag{4.3}$$

and we note that the integrand is a scaled version of the first order approximation to r^h given in (4.1) above. Recall the region of strong regularity B_1 and the relationships specified in (3.5) and illustrated in Figure 1.

THEOREM 4.1. *The asymptotic expansion*

$$V^h(x) = V^0(x) + h e^1(x) + o(h) \tag{4.4}$$

holds as $h \to 0$, uniformly for $x \in B_1^h$.

Proof. We prove this theorem in two steps, first considering the upper bound on $V^h(x)$ and then the lower bound.

Upper bound. It is useful here to identify the suboptimal trajectories obtained by applying the limit optimal feedback control $u^0(x)$ in the h-dynamics. For an initial condition x in B_1^h, let $X^{h,0}$ be the process obtained by taking $\underline{u}^h = u^0$ in the Markov chain dynamics of section 3 with parameter h. Define the exit time $\tau_{B_0}^{h,0} = \inf[t : X^{h,0}(t) \notin B_0^h]$ and the exit location $z_{B_0}^{h,0} = X^{h,0}(\tau_{B_0}^{h,0})$. Since the infimum in (4.2) is achieved at $u^0(x)$, we can use a standard verification argument to establish for all $x \in B_1^h$ the representation

$$V^0(x) = E_x \left[\int_0^{\tau_{B_0}^{h,0}} L_{u^0}(X^{h,0}) - r_{u^0}^h(X^{h,0}) dt + V^0(z_{B_0}^{h,0}) \right]. \tag{4.5}$$

We use part (ii) of Lemma 3.6 and the strong Markov property to obtain the uniform integrability of the $\tau_{B_0}^{h,0}$ needed for the right-hand side of (4.5) to be finite. We obtain the following series of relations holding for x in B_1^h:

$$
\begin{aligned}
V^h(x) &\leq E_x\left[\int_0^{\tau_{B_0}^{h,0}} L_{u^0}(X^{h,0})dt + V^h(z_{B_0}^{h,0})\right] \\
&= V^0(x) + E_x\left[\int_0^{\tau_{B_0}^{h,0}} r_{u^0}^h(X^{h,0})dt\right] \\
&\quad + E_x\big[V^h(z_{B_0}^{h,0}) - V^0(z_{B_0}^{h,0})\big] \\
&= V^0(x) + \frac{1}{2}hE_x\left[\int_0^{\tau_{B_0}^{h,0}} \Big\langle |u^0(X^{h,0})|, D_{\setminus}^2 V^0(X^{h,0})\Big\rangle dt\right] \\
&\quad + E_x\big[V^h(z_{B_0}^{h,0}) - V^0(z_{B_0}^{h,0})\big] + O(h^2).
\end{aligned}
\tag{4.6}
$$

The first line follows from the definition of $V^h(x)$ and from the strong Markov property; the second line is a consequence of the representation in (4.5); and the third line is obtained from the estimate in (4.1), where the $O(h^2)$ term is uniform on B_1^h.

Using parts (i) and (iii) of Lemma 3.6, it is straightforward to see that the integral term in the last line of (4.6) is equal to $he^1(x) + o(h)$, uniformly for x in B_1^h. It remains to estimate the boundary term in the last line of (4.6). Let $\varepsilon > 0$ be equal to $d(B_1, \partial B_0 \cap G)$; see Figure 3 in the next section. Since $z_x^0 \in B_{q+1} \cap \partial G$, it follows from the fact that $h > 0$ is chosen so that the lattice $h\mathbb{Z}^n$ lines up with $Q \cap \partial G$ that if $\|z_{B_0}^{h,0} - z_x^0\| < \varepsilon$, then $z_{B_0}^{h,0} \in \partial G$, and in that case

$$V^h(z_{B_0}^{h,0}) = V^0(z_{B_0}^{h,0}) = 0.$$

Since $V^0(x)$ and $V^h(x)$ are uniformly bounded, part (iv) of Lemma 3.6 implies that the boundary term in the last line of (4.6) is equal to $O(e^{-K/h})$, uniformly for x in B_1^h. Combining these estimates, we have

$$V^h(x) \leq V^0(x) + he^1(x) + o(h),$$

holding uniformly for x in B_1^h.

Lower bound. Similarly to (4.6) in the proof of the upper bound, we obtain the

following series of relations holding for x in B_1^h:

$$
\begin{aligned}
V^0(x) &\leq E_x\left[\int_0^{\tau_{B_0}^h} L_{u^h}(X^h) - r_{u^h}^h(X^h)dt + V^0(z_{B_0}^h)\right] \\
&= V^h(x) - E_x\left[\int_0^{\tau_{B_0}^h} r_{u^h}^h(X^h)dt\right] \\
&\quad + E_x\left[V^0(z_{B_0}^h) - V^h(z_{B_0}^h)\right] \\
&= V^h(x) - \frac{1}{2}hE_x\left[\int_0^{\tau_{B_0}^h} \left\langle |u^h(X^h)|, D_{\setminus}^2 V^0(X^h)\right\rangle dt\right] \\
&\quad + E_x\left[V^0(z_{B_0}^h) - V^h(z_{B_0}^h)\right] + O(h^2).
\end{aligned} \tag{4.7}
$$

The first line is a consequence of the fact that $u^h(x)$ is suboptimal in the control problem corresponding to (4.2) and of the strong Markov property; the second line follows from the definition of $V^h(x)$; and the third line is obtained from the estimate in (4.1), where the $O(h^2)$ term is uniform on B_1^h.

As in the proof of the upper bound, we estimate the terms in the last line of (4.7) to obtain

$$V^0(x) \leq V^h(x) - he^1(x) + o(h),$$

holding uniformly for x in B_1^h. This time we need to use the convergence of u^h to u^0 from Theorem 3.4 in the application of Lemma 3.6 and then again to show that the integrand in the last line of (4.7) converges to the integrand in the definition of $e^1(x)$. □

Theorem 4.1 establishes the rate of convergence of $V^h(x)$ to $V^0(x)$ in the RSRs. It is not surprising that the convergence is first order, since the Markov chain approximation we consider gives rise to a discrete DPE (3.10) which could be obtained by replacing the derivatives in (3.4) with first order finite difference approximations. In fact, all numerical methods for problems of this type which have been proved to converge are intrinsically first order accurate.

What is promising about Theorem 4.1 is that (4.4) suggests that we can modify the present first order Markov chain method in order to obtain second order convergence in the RSRs. One approach is to approximate $e^1(x)$ and to subtract this approximation from $V^h(x)$. For this approach to be successful, two issues need to be addressed. First, we need to verify that the $o(h)$ error estimate in (4.4) can be sharpened to $O(h^2)$. Second, we need a first order approximation to $e^1(x)$. To get this we require first order estimates to the unknown quantities $u^0(x)$ and $D_{\setminus}^2 V^0(x)$. Both of these issues would be addressed if we could establish a higher order asymptotic expansion of the form

$$V^h(x) = V^0(x) + he^1(x) + h^2e^2(x) + O(h^3), \tag{4.8}$$

where both $e^1(x)$ and $e^2(x)$ are smooth functions of x. If (4.8) holds, then we can obtain first order approximations to the first and second derivatives of $V^0(x)$ by applying standard finite difference operators to $V^h(x)$. Since $u^0(x)$ is closely related

to $DV^0(x)$, this information can be used to obtain a first order approximation to $u^0(x)$. Another approach to obtaining second convergence is to apply Richardson extrapolation directly to the approximate value functions. If (4.8) is verified, then it is trivial that

$$2V^{h/2}(x) - V^h(x)$$

differs from $V^0(x)$ by an error which is $O(h^2)$, uniformly on the relevant RSR. In the sections which follow, we will specify conditions under which (4.8) can be verified, and then we will describe in detail how this information can be used to construct global numerical methods which provide second order approximation for both $V^0(x)$ and $u^0(x)$ in the RSRs.

5. Full asymptotic expansion. In this section, we establish an asymptotic expansion of $V^h(x)$ around $V^0(x)$ to order M, where M is an arbitrary positive integer. The results which follow require that we impose the following additional restriction on the region B_0.

ASSUMPTION 5.1. *There exists $\kappa > 0$ such that*

$$|u_i^0(x)| > \kappa$$

holds for each $i = 1, \ldots, n$ and for all $x \in B_0$. Since $u^0(x)$ is continuous on B_0, Assumption 5.1 implies that each component of the optimal control $u^0(x)$ has a fixed sign in the region B_0. Thus, without loss of generality, we can assume that there exists $\kappa > 0$ such that

$$u_i^0(x) > \kappa$$

for each $i = 1, \ldots, n$ and for all $x \in B_0$. Theorem 3.4 guarantees that, for $h > 0$ sufficiently small, we also have $u_i^h(x) > 0$ holding for each $i = 1, \ldots, n$ and for all $x \in B_0^h$. Thus, as long as we restrict the analysis which follows to sufficiently small $h > 0$, we can deal exclusively with forward differences in the numerical approximation. As such, we redefine the generator for the h-dynamics to be such that

$$\mathcal{L}_u^h f = \langle u, D^h f \rangle$$

for any smooth function f mapping $\mathbb{R}^n$ to $\mathbb{R}$. The operator D^h is taken to be $D^{h,+}$, the forward finite difference approximation to the gradient defined in section 1.

For convenience, we record here the DPEs for the limit problem and for the prelimit problem, with the generators fully written out. The limit DPE (3.4) takes the form

$$\begin{aligned} 0 &= \inf_u \left[\langle u, DV^0 \rangle + L \right] \\ &= -\frac{1}{2} \langle DV^0, aDV^0 \rangle + \langle b, DV^0 \rangle + c, \end{aligned} \tag{5.1}$$

and it holds for all $x \in B_0$, with the minimizer $u^0(x)$ given by (3.7). Similarly, the DPE (3.10) for the problem with h-dynamics can now be written in the form

$$\begin{aligned} 0 &= \inf_u \left[\langle u, D^h V^h \rangle + L \right] \\ &= -\frac{1}{2} \langle D^h V^h, aD^h V^h \rangle + \langle b, D^h V^h \rangle + c, \end{aligned} \tag{5.2}$$

where the minimizer $u^h(x)$ can be explicitly evaluated

$$u^h(x) = -a(x)D^hV^h(x) + b(x) \tag{5.3}$$

for all $x \in B_0^h$ and for all $h > 0$ sufficiently small.

In light of the discussion at the end of section 4, the condition in Assumption 5.1 is quite natural. In order for our approach to analyzing a second order numerical approximation to be successful, we require that both $e^1(x)$ and $e^2(x)$ in the asymptotic expansion (4.8) be smooth functions of x. In general, this fails to be true even for $e^1(x)$, owing to the $|u^0|$ term in the integrand of (4.3). Under the present assumptions, however, we can write $e^1(x)$ in the form

$$e^1(x) = \frac{1}{2}\int_0^{\tau_x^0} \langle u^0(X_x^0(t)),\ D_{\backslash}^2 V^0(X_x^0(t))\rangle dt, \tag{5.4}$$

which implies that $e^1(x)$ is a smooth function of x, and it satisfies the equation

$$\langle u^0, De^1\rangle + \frac{1}{2}\langle u^0, D_{\backslash}^2 V^0\rangle = 0, \tag{5.5}$$

for all x in B_0, with zero boundary condition on $\partial G \cap B_0$. The increased regularity can be accounted for by the fact that the Hamiltonian in the DPE (5.2) is smooth, whereas the Hamiltonian in the DPE (3.10) fails to be a continuously differentiable function of $D^{h,\pm}V^h(x)$. We remark that even in those regions where Assumption 5.1 fails to hold, our methods seem to work quite well; see the examples in section 7.

Before stating the main theorem of this section, we recall our standing assumptions. The domain $G \subset \mathbb{R}^n$ is open with compact closure and satisfies uniform interior and exterior cone conditions. We assume that b and c are C^∞ functions from $\mathbb{R}^n$ to $\mathbb{R}$ with $c(x) \geq c_0 > 0$ on G and that a is a C^∞ function from $\mathbb{R}^n$ to the space of symmetric positive definite $n \times n$ matrices. Additionally, we assume that we have RSRs as specified by (3.5)–(3.6) such that the flat boundary condition of Assumption 3.2 and the condition on the optimal controls given in Assumption 5.1 both hold.

It is useful for what follows to introduce some notation. For $h > 0$, we define a new approximate feedback control

$$\bar{u}^h(x) = \frac{1}{2}(u^0(x) + u^h(x)). \tag{5.6}$$

Combining (5.1) and (5.2), and noting that

$$\bar{u}^h(x) = -\frac{1}{2}a(x)D^hV^h(x) - \frac{1}{2}DV^0(x) + b(x) \tag{5.7}$$

holds for all x in B_0^h, we conclude that

$$\langle \bar{u}^h, D^h(V^h - V^0)\rangle + \langle \bar{u}^h, D^hV^0 - DV^0\rangle = 0 \tag{5.8}$$

holds on the region B_0^h.

THEOREM 5.2. *Recall the region B^* from* (3.5). *With $M \geq 1$ the arbitrary constant chosen in section* 3 *and with the $e^m(x)$ as given below, the asymptotic expansion*

$$V^h(x) = V^0(x) + \sum_{m=1}^{M} h^m e^m(x) + o(h^M) \tag{5.9}$$

holds as $h \to 0$, *uniformly for* $x \in (B^*)^h$.

The following corollary establishes an analogous asymptotic expansion for the optimal feedback control. It is a direct consequence of Theorem 5.2 and of the expressions for $u^0(x)$ and $u^h(x)$ given in (3.7) and (5.3).

COROLLARY 5.3. *With* $M \geq 1$ *the arbitrary constant chosen in section* 3 *and with the* $e^m(x)$ *as given below, the asymptotic expansion*

$$\begin{aligned} u^h(x) &= u^0(x) - a(x) \sum_{m=1}^{M-1} h^m D^h e^m(x) \\ &\quad - a(x) \sum_{m=1}^{M-1} h^m \frac{1}{(m+1)!} D_{\backslash}^{m+1} V^0(x) + o(h^{M-1}) \end{aligned} \tag{5.10}$$

holds as $h \to 0$, *uniformly for* $x \in (B^*)^h$.

In section 4, we were able to determine the value of $e^1(x)$ by considering the formal difference between the generators $\mathcal{L}_u^0$ and $\mathcal{L}_u^h$, and then through the new dynamic programming equation (4.2), considering $V^0(x)$ as the value function for a modified optimal control problem with the h-dynamics. We cannot use this approach to determine the form of $e^m(x)$ for $m \geq 2$ because, in addition to the higher order terms in the expansion of $r^h(x)$, there are approximation effects which result from the difference between the controls $u^h(x)$ and $u^0(x)$. Instead, we use a formal recursive procedure, illustrated below for the case $m = 2$.

Assume that the expansion in (5.10) holds to first order, so it follows that

$$\bar{u}^h(x) = u^0(x) - \frac{1}{2} h a(x) D e^1(x) - \frac{1}{4} h a(x) D_{\backslash}^2 V^0(x) + o(h). \tag{5.11}$$

We now combine (5.5) and (5.8) to obtain

$$\begin{aligned} &\langle \bar{u}^h, h^{-2} D^h [V^h - V^0 - h e^1] \rangle \\ &\quad + h^{-2} \langle \bar{u}^h, D^h V^0 - D V^0 \rangle - \frac{1}{2} h^{-1} \langle u^0, D_{\backslash}^2 V^0 \rangle \\ &\quad + h^{-1} \langle \bar{u}^h - u^0, D^h e^1 \rangle + h^{-1} \langle u^0, D^h e^1 - D e^1 \rangle = 0. \end{aligned}$$

Using the expression in (5.11), along with the fact that Taylor's theorem implies

$$D^h f(x) = \sum_{m=1}^{M} \frac{1}{m!} h^{m-1} D_{\backslash}^m f(x) + o(h^M) \tag{5.12}$$

for all smooth functions $f(x)$, we conclude that

$$\langle \bar{u}^h, h^{-2} D^h [V^h - V^0 - h e^1] \rangle + r^2 + o(1) = 0, \tag{5.13}$$

where we define $r^2(x)$ by

$$r^2(x) = \frac{1}{2}\langle u^0(x), D_\backslash^2 e^1(x)\rangle + \frac{1}{6}\langle u^0(x), D_\backslash^3 e^0(x)\rangle$$
$$- \frac{1}{2}\langle De^1(x), a(x)D_\backslash^2 e^0(x)\rangle - \frac{1}{2}\langle De^1(x), a(x)De^1(x)\rangle$$
$$- \frac{1}{8}\langle D_\backslash^2 e^0(x), a(x)D_\backslash^2 e^0(x)\rangle.$$

Heuristically, (5.13) suggests that we should set

$$e^2(x) = \frac{1}{2}\int_0^{\tau_x^0} r^2(X_x^0(t))dt.$$

The formal argument outlined above will be made rigorous when we prove Theorem 5.2 later in this section.

In order to record the general form of $e^m(x)$ for $m = 1, \ldots, M$, we adopt the convention $e^0(x) = V^0(x)$ and define

$$r^m(x) = \sum_{k=2}^{m+1} \frac{1}{k!}\langle u^0(x)\ ,\ D_\backslash^k e^{m+1-k}(x)\rangle$$
$$- \frac{1}{2}\sum_{l=2}^{m}\sum_{k=1}^{m+2-l} \frac{1}{k!l!}\langle D_\backslash^l e^0(x)\ ,\ a(x)D_\backslash^k e^{m+2-l-k}(x)\rangle$$
$$- \frac{1}{2}\sum_{j=1}^{m-1}\sum_{l=1}^{m-j}\sum_{k=1}^{m+2-j-l} \frac{1}{k!l!}\langle D_\backslash^l e^j(x)\ ,\ a(x)D_\backslash^k e^{m+2-j-l-k}(x)\rangle$$

for all x in B_0. Then recursively applying the heuristic outlined above suggests that we should define $e^m(x)$ by

$$e^m(x) = \frac{1}{2}\int_0^{\tau_x^0} r^m(X_x^0(t))dt \tag{5.14}$$

for each $m = 1, \ldots, M$ and for all x in B_0. By the method of characteristics, we then have that

$$\langle u^0, De^m\rangle + r^m = 0 \tag{5.15}$$

holds for each $m = 1, \ldots, M$ and for all x in B_0, with zero boundary conditions on $\partial G \cap B_0$. Since each $r^m(x)$ depends upon the $e^i(x)$ with $i < m$, we define the $e^m(x)$ recursively beginning with $m = 1$. We note that the conclusion of Lemma 5.7 serves to verify that we have properly defined the $e^m(x)$ for the problem at hand.

An alternative heuristic method to derive (5.15) is to assume that (5.9) holds and that the error term $o(h^M)$ is a smooth function of x. We apply the operator D^h to both sides of (5.9) and then use (5.12) to express $D^h V^h(x)$ in terms of derivatives of smooth functions. We substitute this expression into the DPE (5.2), formally differentiate the resulting equation m times with respect to the parameter h, and then set $h = 0$ to obtain the equation for $e^m(x)$.

The proof of Theorem 5.2 can be broken down into three lemmas to be applied recursively. To make the notation consistent, we define a new region $B_{0'}$ to be equal to B_0. See equations (3.5) and (3.6) along with Figure 1 for the relationships between the RSRs in the following lemmas. Given an asymptotic expansion for $D^h V^h(x)$ to q terms, the first lemma establishes the expansion for $V^h(x)$ to $q+1$ terms. The needed expansion for $D^h V^h(x)$ with $q = 0$ has been established in Theorem 3.4. Although it is not needed for the development, we also note that in section 4 we have already proved Lemma 5.4 for the case $q = 0$.

LEMMA 5.4. *Let $0 \le q \le M-1$ be an integer, and suppose that*

$$D^h V^h(x) = D^h V^0(x) + \sum_{m=1}^{q} h^m D^h e^m(x) + o(h^q) \tag{5.16}$$

holds as $h \to 0$, uniformly for x in $B^h_{q'}$. Then

$$V^h(x) = V^0(x) + \sum_{m=1}^{q+1} h^m e^m(x) + o(h^{q+1}) \tag{5.17}$$

holds as $h \to 0$, uniformly for x in B^h_{q+1}.

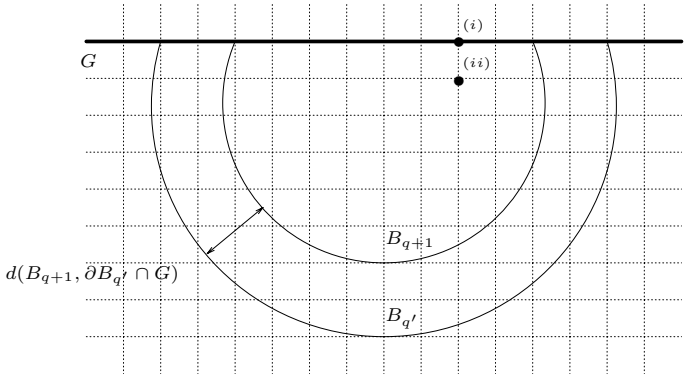

FIG. 3. *Boundary points.*

The next lemma establishes the expansion for $D^h V^h(x)$ to $q+1$ terms but only in a neighborhood of the boundary. The two cases in the lemma are illustrated in Figure 3.

LEMMA 5.5. *Let $0 \le q \le M-1$ be an integer, and suppose that* (5.16) *holds. Then, for each $p = 1, \ldots, n$,*

$$D^h_p V^h(x) = D^h_p V^0(x) + \sum_{m=1}^{q+1} h^m D^h_p e^m(x) + o(h^{q+1}) \tag{5.18}$$

holds as $h \to 0$, uniformly for $x \in \mathbb{R}^n$ such that either (i) *$x \in \partial G$ and $x + he_p \in B^h_{q+1}$ or* (ii) *$x \in B^h_{q+1}$ and $x + he_p \in \partial G$.*

Finally, given the conclusion of Lemma 5.5, the third lemma carries the asymptotic expansion for $D^h V^h(x)$ to $q+1$ terms on a smaller RSR.

LEMMA 5.6. *Let $0 \le q \le M-1$ be an integer, and suppose that* (5.16) *and* (5.18) *hold. Then*

$$D^h V^h(x) = D^h V^0(x) + \sum_{m=1}^{q+1} h^m D^h e^m(x) + o(h^{q+1}) \tag{5.19}$$

holds as $h \to 0$, uniformly for x in $B^h_{(q+1)'}$.

Given the nesting of the RSRs, these three lemmas complete one step of a recursive process. We can apply Lemma 5.4 with q replaced by $q+1$ and iterate until we have established the full asymptotic series to order M. In preparation for the proofs of these lemmas, we introduce some more notation. For $q = 1, \dots, M$ and for $x \in B_0$, we define

$$\Phi^{h,q}(x) = \frac{1}{h^q}\left[V^h(x) - V^0(x) - \sum_{m=1}^{q} h^m e^m(x)\right],$$

and, for each $p = 1, \dots, n$,

$$\begin{aligned}\Psi^{h,q}_p(x) &= D^h_p \Phi^{h,q}(x) \\ &= \frac{1}{h^q}\left[D^h_p V^h(x) - D^h_p V^0(x) - \sum_{m=1}^{q} h^m D^h_p e^m(x)\right],\end{aligned}$$

and then we put $\Psi^{h,q}(x) = (\Psi^{h,q}_1(x), \dots, \Psi^{h,q}_n(x))$. The conclusions in the above lemmas can now be formulated in terms of the convergence as $h \to 0$ of the $\Phi^{h,q+1}(x)$ and the $\Psi^{h,q+1}(x)$ to zero.

The proofs of Lemmas 5.4–5.6 involve some elementary but rather lengthy algebraic calculations. We summarize the results of these calculations in the following lemma, the proof of which is deferred to Appendix A. It should be emphasized that, while the proof of Lemma 5.7 is elementary, it is in fact the key step which confirms that we have properly defined the $e^m(x)$ for the particular numerical approximation that we are studying. We recall our convention that subscripts refer to the components of a vector, while superscripts act as indices for possibly vector valued quantities.

LEMMA 5.7. *Let $0 \le q \le M-1$ be an integer, and suppose that* (5.16) *holds. Then*

$$\langle \bar{u}^h, D^h \Phi^{h,q+1} \rangle + \phi^{h,q+1} = 0, \tag{5.20}$$

where $\phi^{h,q+1} = o(1)$ as $h \to 0$, uniformly for x in $B^h_{q'}$. Furthermore, for each $p = 1, \dots, n$

$$\langle \hat{u}^{h,q+1,p}, D^h \Psi^{h,q+1}_p \rangle + \langle \lambda^{h,q+1,p}, \Psi^{h,q+1} \rangle + \psi^{h,q+1}_p = 0, \tag{5.21}$$

where $\hat{u}^{h,q+1,p} = u^0 + o(1)$, $\lambda^{h,q+1,p} = D_p u^0 + o(1)$, and $\psi^{h,q+1}_p = o(1)$ as $h \to 0$, uniformly for x in $B^h_{q'}$.

Proof of Lemma 5.4. The conclusion in (5.17) is equivalent to the statement that $\Phi^{h,q+1}(x)$ converges to zero as $h \to 0$, uniformly for x in B^h_{q+1}. For such x, let $\bar{X}^h_x(t)$ be the process defined for $t \ge 0$ by applying the control $\bar{u}^h$ in the h-dynamics. Define $\bar{\tau}^h_{x,B_{q'}}$ to be the exit time of $\bar{X}^h_x$ from $B_{q'}$, and let $\bar{z}^h_{x,B_{q'}}$ be its exit location. In light of (5.20), a standard verification argument shows that $\Phi^{h,q+1}(x)$ satisfies

$$\Phi^{h,q+1}(x) = E_x\left[\int_0^{\bar{\tau}^h_{B_{q'}}} \phi^{h,q+1}(\bar{X}^h)dt + \Phi^{h,q+1}(\bar{z}^h_{B_{q'}})\right] \tag{5.22}$$

for each x in B^h_{q+1}. Part (ii) of Lemma 3.6 and the strong Markov property imply that the $\bar{\tau}^h_{B_{q'}}$ are uniformly integrable, which guarantees that the right-hand side in the above expression is finite. We use that $\phi^{h,q+1}(x)$ converges to zero uniformly on $B_{q'}$ and that the $E_x[\bar{\tau}^h_{B_{q'}}]$ are uniformly bounded, along with the fact that $\Phi^{h,q+1}(x)$ is equal to zero on ∂G, to conclude that

$$\Phi^{h,q+1}(x) = o(1) + P_x\big[\bar{z}^h_{B_{q'}} \notin \partial G\big] O(h^{-(q+1)})$$

holds uniformly for x in B^h_{q+1}. Let $\varepsilon > 0$ be equal to $d(B_{q+1}, \partial B_{q'} \cap G)$; see Figure 3. Since $z^0_x \in B_{q+1} \cap \partial G$, it follows from the fact that $h > 0$ is chosen so that the lattice $h\mathbb{Z}^n$ lines up with $Q \cap \partial G$ that if $\|\bar{z}^h_{x,B_{q'}} - z^0_x\| < \varepsilon$, then $\bar{z}^h_{x,B_{q'}} \in \partial G$. Thus, we can apply the exponential bound from part (iv) of Lemma 3.6 to conclude that $\Phi^{h,q+1}(x)$ converges to zero as $h \to 0$, uniformly for x in B^h_{q+1}. That completes the proof of the lemma. □

Proof of Lemma 5.5. For simplicity, we fix p and treat only case (ii), where $x \in B^h_{(q+1)'}$ and $x + he_p \in \partial G$. The proof for case (i) differs only in notation. Since V^h, V^0, and all of the e^m satisfy a zero boundary condition on ∂G, we have for each x satisfying condition (ii)

$$\begin{aligned}
&\frac{1}{h^{q+1}} \left| D^h_p V^h(x) - D^h_p V^0(x) - \sum_{m=1}^{q+1} h^m D^h_p e^m(x) \right| \\
&\qquad = \frac{1}{h^{q+1}} \left[\frac{1}{h} |V^h(x) - V^0(x) - \sum_{m=1}^{q+1} h^m e^m(x)| \right] \\
&\qquad = \frac{1}{h} |\Phi^{h,q+1}(x)|.
\end{aligned}$$

Thus, it suffices to prove that $\frac{1}{h}|\Phi^{h,q+1}(x)|$ converges to zero, uniformly for x satisfying condition (ii). Equation (5.22) implies that the relation

$$\frac{1}{h}|\Phi^{h,q+1}(x)| = \frac{1}{h} E_x\big[\bar{\tau}^h_{B_{q'}}\big] o(1) + P_x\big[\bar{z}^h_{B_{q'}} \notin \partial G\big] O(h^{-(q+2)}) \tag{5.23}$$

holds uniformly for x satisfying condition (ii). As in the proof of Lemma 5.4, the exponential bound from part (iv) of Lemma 3.6 implies that the second term in the right-hand side of (5.23) converges to zero as $h \to 0$, uniformly for x satisfying condition (ii). Thus, it remains to show that $\frac{1}{h} E_x[\bar{\tau}^h_{B_{q'}}]$ is uniformly bounded so that the first term in the right-hand side of (5.23) also converges to zero. We observe that

$$E_x\big[\bar{\tau}^h_{B_{q'}}\big] \le E_x\big[\bar{\tau}^h_{B_{q'}}; A_1\big] + E_x\big[\bar{\tau}^h_{B_{q'}}; A_2\big] + E_x\big[\bar{\tau}^h_{B_{q'}}; A_3\big],$$

where we define the events

$$A_1 = \big[\bar{X}^h(t) + he_p \in \partial G \ , \ 0 \le t \le \bar{\tau}^h_{B_{q'}}\big],$$

$$A_2 = \big[\bar{\tau}^h_{B_{q'}} > T\big],$$

$$A_3 = \big[\bar{\tau}^h_{B_{q'}} \le T \ , \ \exists\, t \in [0, \bar{\tau}^h_{B_{q'}}) \text{ such that } \bar{X}^h(t) + he_p \notin \partial G\big].$$

Given the nontangential exit property for the limit optimal trajectories and the convergence of $\bar{u}^h$ to u^0, there exists $\eta > 0$ such that the following holds. For sufficiently small $h > 0$, if $x \in B^h_{q+1}$ and if $x + he_p \in \partial G$, the probability of exiting from G in one jump is at least equal to η; see Figure 3. Furthermore, since $\|\bar{u}^h\|_1$ is bounded away from zero, the conditional expected value of each interjump waiting time is bounded by δh for some fixed $\delta > 0$. Thus,

$$E_x\left[\bar{\tau}^h_{B_{q'}}; A_1\right] \leq \delta h \eta \left(\sum_{i=0}^{\infty} i(1-\eta)^{i-1}\right) P_x\left[A_1\right] = O(h),$$

so $\frac{1}{h} E_x[\bar{\tau}^h_{B_{q'}}; A_1]$ is uniformly bounded for all x satisfying condition (ii). It follows from part (ii) of Lemma 3.6 and from the strong Markov property that $E_x[\bar{\tau}^h_{B_{q'}} | A_2]$ is uniformly bounded. Again applying part (ii) of Lemma 3.6, we obtain the uniform bound

$$P_x[A_2] = O(e^{-K/h}) \tag{5.24}$$

so that $\frac{1}{h} E_x[\bar{\tau}^h_{B_{q'}}; A_2]$ converges to zero uniformly for all x satisfying condition (ii). Since $E_x[\bar{\tau}^h_{B_{q'}} | A_3]$ is clearly bounded by T, we can complete the proof by obtaining a bound similar to the last display for the probability of the event A_3. On account of the fact that we use one-sided transition probabilities and given the nontangential exit property for the limit optimal trajectories, it follows from the fact that the boundary segment $B_{q'} \cap \partial G$ is parallel to one of the coordinate hyperplanes that $\bar{X}^h$ with initial condition x satisfying condition (ii) must move parallel to the boundary segment $B_{q'} \cap \partial G$ up to the time when it exits from $B_{q'}$; see Assumption 3.2 and Figure 3. Consequently, event A_2 can occur only if the exit location $\bar{z}^h_{B_{q'}}$ is not in ∂G. Thus, since $z^0_x \in B_{q+1} \cap G$, the fact that $d(B_{q+1}, \partial B_{q'} \cap G) > 0$ implies that we can obtain a bound for $P_x[A_3]$ analogous to (5.24) by applying part (iv) of Lemma 3.6. □

Proof of Lemma 5.6. The conclusion in (5.19) is equivalent to the statement that $\Psi^{h,q+1}(x)$ converges to zero as $h \to 0$, uniformly for x in $B^h_{(q+1)'}$. Our plan is to proceed as in the proof of Lemma 5.4, first obtaining a representation for $\Psi^{h,q+1}(x)$ analogous to the representation for $\Phi^{h,q+1}(x)$ given in (5.22) and then using that representation to show that $\Psi^{h,q+1}(x)$ converges to zero. In this case, however, we cannot use an entirely standard representation because $\Psi^{h,q+1}(x)$ is a vector quantity, and the equations for its components are coupled. We develop the representation fairly carefully in order to highlight what we believe to be a novel aspect of our approach that may prove useful in developing high order numerical methods based directly upon the use of higher order finite difference approximations; see the discussion in section 1. First, along the lines suggested in [19, section 5.4], we expand the state space so that $(x, p) \in \mathbb{R}^n \times \{1, \ldots, n\}$ is the state variable, rather than just x. To that end, we recall the quantities defined in Lemma 5.7 and abuse notation by defining

$$\Psi^{h,q+1}(x,p) = \Psi^{h,q+1}_p(x), \qquad \psi^{h,q+1}(x,p) = \psi^{h,q+1,p}(x),$$

$$\hat{u}^{h,q+1}(x,p) = \hat{u}^{h,q+1,p}(x), \qquad \lambda^{h,q+1}(x,p) = \lambda^{h,q+1,p}(x),$$

for each (x, p), and we note that $\Psi^{h,q+1}$ and $\psi^{h,q+1}$ are scalar valued, while $\hat{u}^{h,q+1}$ and $\lambda^{h,q+1}$ are vector valued. We can now regard p as an argument rather as an index

in (5.21) and obtain the scalar equation

$$\begin{aligned}
&\langle \hat{u}^{h,q+1}(x,p), D^h \Psi^{h,q+1}(x,p) \rangle \\
&+ \sum_{i=1}^{n} \lambda_i^{h,q+1}(x,p) \left[\Psi^{h,q+1}(x,i) - \Psi^{h,q+1}(x,p) \right] \\
&+ \sum_{i=1}^{n} \lambda_i^{h,q+1}(x,p) \Psi^{h,q+1}(x,p) + \psi^{h,q+1}(x,p) = 0,
\end{aligned} \tag{5.25}$$

holding for all $x \in B_{q+1}^h$ and for all $p = 1, \ldots, n$. If the $\lambda_i^{h,q+1}(x,p)$ were known to be nonnegative, it would be possible to regard them as probabilities of jumping from (x,p) to (x,i) and then to deduce a representation for $\Psi^{h,q+1}(x,p)$ in terms of a Markov chain directly from (5.25). Since the signs of the $\lambda_i^{h,q+1}(x,p)$ are indefinite, however, we must further expand the state space in a novel way to eliminate the possibility of negative transition probabilities. We consider state variable $(x,p,\sigma) \in \mathbb{R}^n \times \{1,\ldots,n\} \times \{-1,1\}$ and again abuse notation by defining

$$\Psi^{h,q+1}(x,p,\sigma) = \sigma \Psi^{h,q+1}(x,p), \qquad \psi^{h,q+1}(x,p,\sigma) = \sigma \psi^{h,q+1}(x,p),$$

$$\lambda^{h,q+1}(x,p,\sigma) = \lambda^{h,q+1}(x,p)$$

for each (x,p,σ). Notice that $\lambda^{h,q+1}(x,p,\sigma)$ is actually independent of σ; we introduce the dependence only for convenience. In light of this notation, the linear structure of (5.25) implies that we can write

$$\begin{aligned}
&\langle \hat{u}^{h,q+1}(x,p), D^h \Psi^{h,q+1}(x,p,\sigma) \rangle \\
&+ \sum_{i=1}^{n} \left(\lambda_i^{h,q+1}(x,p,\sigma) \right)^+ \left[\Psi^{h,q+1}(x,i,\sigma) - \Psi^{h,q+1}(x,p,\sigma) \right] \\
&+ \sum_{i=1}^{n} \left(\lambda_i^{h,q+1}(x,p,\sigma) \right)^- \left[\Psi^{h,q+1}(x,i,-\sigma) - \Psi^{h,q+1}(x,p,\sigma) \right] \\
&+ \| \lambda^{h,q+1}(x,p,\sigma) \|_1 \Psi^{h,q+1}(x,p,\sigma) + \psi^{h,q+1}(x,p,\sigma) = 0
\end{aligned} \tag{5.26}$$

for all $x \in B_{q+1}^h$, $p = 1, \ldots, n$, and $\sigma \in \{-1,1\}$. The left-hand side of (5.26) indicates the action on $\Psi^{h,q+1}(x)$ of a legitimate generator with positive transition probabilities, so we can use it to derive a representation for $\Psi^{h,q+1}(x)$ in terms of a Markov chain $\Xi^{h,q+1}(t)$ taking values in $\mathbb{R}^n \times \{1,\ldots,n\} \times \{-1,1\}$. We construct the Markov chain $\Xi^{h,q+1}$ with exponentially distributed waiting times with mean

$$\overline{\Delta t}^{h,q+1}(x,p,\sigma) = \frac{h}{\Gamma^{h,q+1}(x,p,\sigma)},$$

where

$$\Gamma^{h,q+1}(x,p,\sigma) = \| \hat{u}^{h,q+1}(x,p) \|_1 + h \| \lambda^{h,q+1}(x,p,\sigma) \|_1,$$

and with transition probabilities given by

$$p^{h,q+1}(x,p,\sigma;\xi) = \begin{cases} \frac{\hat{u}_i^{h,q+1}(x,p)}{\Gamma^{h,q+1}(x,p,\sigma)}, & \xi = (x+he_i,p,\sigma), \\ h\frac{\left(\lambda_i^{h,q+1}(x,p,\sigma)\right)^+}{\Gamma^{h,q+1}(x,p,\sigma)}, & \xi = (x,i,\sigma), \\ h\frac{\left(\lambda_i^{h,q+1}(x,p,\sigma)\right)^-}{\Gamma^{h,q+1}(x,p,\sigma)}, & \xi = (x,i,-\sigma), \\ 0 & \text{otherwise.} \end{cases}$$

For details on the construction of such a process, see the discussion in section 3. Let $X^{h,q+1}$ be the first component of $\Xi^{h,q+1}$. For initial conditions (x,p,σ) such that x is in $B_{(q+1)'}$, let $\tau^{h,q+1}_{B_{q+1}}$ be the first exit time of $X^{h,q+1}$ from B^h_{q+1}, and let $z^{h,q+1}_{B_{q+1}}$ be equal to its exit location. Although the full Markov chain $\Xi^{h,q+1}$ does not converge to a deterministic limit, Theorem B.1 implies that a large deviations upper bound holds for the component process $X^{h,q+1}$. Combined with Lemma 3.5, the large deviations upper bound implies the following analogue of Lemma 3.6. For any $\varepsilon > 0$, there exists $K > 0$ such that

$$\text{(i)} \qquad P_{x,p,\sigma}\left[\|\!| X^{h,q+1} - X^0_x |\!\|_T \geq \varepsilon\right] < \frac{1}{K}e^{-K/h},$$

$$\text{(ii)} \qquad P_{x,p,\sigma}\left[\tau^{h,q+1}_{B_{q+1}} > \tau^0_x + \varepsilon\right] < \frac{1}{K}e^{-K/h}$$

holds for all initial conditions such that x is in B_{q+1}, while

$$\text{(iii)} \qquad P_{x,p,\sigma}\left[|\tau^{h,q+1}_{B_{q+1}} - \tau^0_x| \geq \varepsilon\right] < \frac{1}{K}e^{-K/h},$$

$$\text{(iv)} \qquad P_{x,p,\sigma}\left[\|z^{h,q+1}_{B_{q+1}} - z^0_x\| \geq \varepsilon\right] < \frac{1}{K}e^{-K/h}$$

holds for all initial conditions such that x is in $B_{(q+1)'}$. The representation for $\Psi^{h,q+1}(x)$ now takes the form

$$\begin{aligned} &\Psi^{h,q+1}(x,p,\sigma) \\ &\quad = \left[E_{x,p,\sigma}\int_0^{\tau^{h,q+1}_{B_{q+1}}} e^{\int_0^t \|\lambda^{h,q+1}(\Xi^{h,q+1}(s))\|_1 ds}\psi^{h,q+1}(\Xi^{h,q+1}(t))dt\right. \\ &\qquad \left. + \ \Psi^{h,q+1}(\Xi^{h,q+1}(\tau^{h,q+1}_{B_{q+1}}))\right] \end{aligned} \tag{5.27}$$

for all (x,p,σ) such that x is in $B^h_{(q+1)'}$. Property (ii) above and the strong Markov property guarantee that

$$P_{x,p,\sigma}\left[\tau^{h,q+1}_{B_{q+1}} \geq kT\right] \leq \left(\frac{1}{K}\right)^k e^{-kK/h}$$

holds for all initial conditions such that x is in $B^h_{(q+1)'}$ where $h > 0$ is sufficiently small and for all integers $k \geq 1$. Since the $\lambda^{h,q+1}$ are uniformly bounded, this is sufficient to guarantee that the right-hand side of (5.27) is finite for sufficiently small $h > 0$ so that a standard verification argument can be used to establish that the indicated representation holds. In fact, since by Lemma 5.7 the $\psi^{h,q+1}(x,p,\sigma)$ converge uniformly to zero, this reasoning also implies that the first term on the right-hand side converges to zero as $h \to 0$. Thus, we can complete the proof of the lemma by showing that the second term also converges to zero. Since $\Psi^{h,q+1}(x,p,\sigma)$ is equal to zero whenever $x \in \partial G$, the second term in (5.27) is bounded by

$$P_{x,p,\sigma}\big[z^{h,q+1}_{B_{q+1}} \notin \partial G\big] O(h^{-(q+2)}).$$

Let $\varepsilon > 0$ be equal to $d(B_{(q+1)'}, \partial B_{q+1} \cap G)$. As in the proof of Lemma 5.4, Assumption 3.2 implies that if $\|z^{h,q+1}_{B_{q+1}} - z^0_x\| < \varepsilon$, then $z^{h,q+1}_{B_{q+1}} \in \partial G$. Thus, we can apply the exponential bound from property (iv) above to conclude that the last display converges to zero as $h \to 0$, uniformly for all (x,p,σ) such that x is in B_{q+1}. This completes the proof that $\Psi(x,p,\sigma)$ converges uniformly to zero and so establishes the lemma. □

6. Second order numerical approximations. The numerical method described in section 3 yields approximations to the value function and to the optimal control which are first order accurate as $h \to 0$ on the RSRs. This notion is made precise in Theorem 4.1 and in the stronger results in Theorem 5.2 and Corollary 5.3 which hold under Assumption 5.1. In this section, we exploit the detailed asymptotic information from section 5 to propose two different second order numerical methods. We prove in Theorem 6.1 that each of the modified numerical methods produces approximations to $V^0(x)$ and to $u^0(x)$ on the region B^* which are second order convergent as $h \to 0$. While these theoretical results apply only on RSRs where each component of the limit optimal control is bounded away from zero, in practice we do not know the locations of such regions. As such, our methods are of necessity applied on the entire domain. As the numerical examples in the next section illustrate, we obtain second order convergence even in large parts of the domain where the theoretical results do not apply.

Approximation Method I. For the purpose of defining a practical algorithm on the entire domain, we abuse notation by reverting to the optimal feedback control function $u^h(x)$ which is obtained on all of G^h by taking the maximizing argument in the DPE (3.10) before it is redefined on $h\mathbb{Z}^n/B_0$ in section 3. Additionally, we consider versions of X^h, τ^h, and z^h which are defined using that control up to the exit time from G^h. When we prove the convergence properties on B^*, we will again employ the modified control and trajectories which were defined at the end of section 3 and which were used in the analysis up to now.

The first step in the present algorithm is to obtain $V^h(x)$ and $u^h(x)$ by applying the first order method from section 3. By Theorem 5.2, we have the asymptotic result

$$V^h(x) = V^0(x) + he^1(x) + h^2e^2(x) + O(h^3), \tag{6.1}$$

holding for all $x \in (B^*)^h$, where the $e^m(x)$ are as defined in (5.14). For each x in G^h, we define an approximation to $e^1(x)$ by

$$e^{1,h}(x) = \frac{1}{2}E_x\left[\int_0^{\tau^h} \langle |u^h(X^h)|, D^{2,h}_{\setminus} V^h(X^h)\rangle dt\right],$$

and we note that $e^{1,h}(x)$ can be obtained by applying an iterative method to solve the linear equation

$$\langle u^{h,+}, D^{h,+}e^{1,h}\rangle - \langle u^{h,-}, D^{h,-}e^{1,h}\rangle + \frac{1}{2}\langle |u^h|, D^{2,h}_{\backslash} V^h\rangle = 0, \tag{6.2}$$

with zero boundary condition on the complement of G^h. To implement an iterative solver, we express (6.2) in the form

$$e^{1,h}(x) = \sum_{y\in\mathbb{R}^n} p^h(x,y|u^h(x))e^{1,h}(y) + \overline{\Delta t}^h(u^h(x))\frac{1}{2}\langle |u^h(x)|, D^{2,h}_{\backslash} V^h(x)\rangle, \tag{6.3}$$

which is analogous to the expression for the discrete DPE given in (3.11). Since the value function $V^h(x)$ is finite and since the running cost is bounded away from zero, every state in the optimally controlled Markov chain corresponding to (3.11) and (6.3) must communicate with the boundary. Thus, the right-hand side is a contraction, and the equation is guaranteed to have a unique fixed point. We now define a new approximation to $V^0(x)$ by subtracting a correction term from $V^h(x)$,

$$V^{h,*}(x) = V^h(x) - he^{1,h}(x), \tag{6.4}$$

and a new approximation to the optimal control by

$$u^{h,*}(x) = -a(x)D^{h,c}V^{h,*}(x) + b(x), \tag{6.5}$$

for all x in G^h, where $D^{h,c}$ is the centered difference approximation to the gradient operator. We will prove that $e^{1,h}(x)$ is a first order approximation to $e^1(x)$ on B^*, so it will follow directly from (6.1) that $V^{h,*}(x)$ is a second order approximation to $V^0(x)$. Additionally, a more detailed analysis of the asymptotic properties of $e^{1,h}(x)$ will be used to establish that $u^{h,*}(x)$ is a second order approximation to $u^0(x)$ on the region B^*.

We recall that the rate of convergence results that we will prove in Theorem 6.1 apply only on RSRs where each component of the limit optimal feedback control is bounded away from zero. A potential drawback of the method just described is that it may degrade the convergence properties of $V^h(x)$ and of $u^h(x)$ on those parts of the domain where second order convergence is not guaranteed. Our numerical experiments suggest that this is largely a theoretical concern, but nonetheless we mention here a possible approach to avoiding the problem. If we knew that the $e^{1,h}(x)$ were uniformly bounded, then it would follow from the definition of $V^{h,*}(x)$ that it has convergence properties at least as good as those proved for $V^h(x)$. That is, in addition to second order convergence on the RSRs which satisfy Assumption 5.1, the $V^{h,*}(x)$ would exhibit uniform convergence to $V^0(x)$ on the entire domain and first order convergence on the RSRs. In general, the $e^{1,h}(x)$ need not be uniformly bounded, but a sensible approach to guaranteeing this type of robustness would be to limit the norm of $D^{2,h}_{\backslash} V^h(x)$ in the definition of the $e^{1,h}(x)$. Similarly, if we could uniformly bound the $D^{h,c}e^{1,h}(x)$, then it would also follow that the $u^{h,*}(x)$ converge uniformly to the optimal feedback control on those parts of the RSRs where second order convergence is not assured. In any case, our numerical experiments have been done without any type of limiter, and we have not observed significant difficulties of this type.

Approximation Method II. Another approach to obtaining second order convergence on the RSRs is to apply Richardson extrapolation to the approximations

$V^h(x)$ and $u^h(x)$ obtained from the first order method in section 3. As in the description of Method I, we abuse notation by considering the optimal feedback control function $u^h(x)$ which is obtained on all of G^h by taking the maximizing argument in the DPE (3.10). For x in the grid $2h\mathbb{Z}^n$, we define a new approximation to the value function by

$$V^{h,*}(x) = 2V^h(x) - V^{2h}(x)$$

and a new approximate optimal feedback control by

$$u^{h,*}(x) = 2u^h(x) - u^{2h}(x).$$

It is a trivial consequence of Theorem 5.2 and of Corollary 5.3 that these are second order approximations to $V^0(x)$ and $u^0(x)$ on the region B^*.

An advantage of Richardson extrapolation over Method I is that there is no concern that the $V^{h,*}(x)$ or the $u^{h,*}(x)$ will exhibit qualitatively poorer convergence than their first order counterparts on those parts of the domain where Theorem 6.1 does not apply. This is a consequence of the fact that the new approximations are obtained by taking linear combinations of the first order approximations $V^h(x)$ and $u^h(x)$. This does not seem to be a practical problem even for Method I, and Method I has the advantages of producing somewhat smaller errors in our experiments and of being more straightforward to code because it involves only a single grid. Still, in circumstances where it is vital to maintain first order convergence outside of the regions where second order convergence is guaranteed, the present approach may be preferred.

THEOREM 6.1. *Let $V^{h,*}(x)$ and $u^{h,*}(x)$ be obtained by either Method* I *or* II *above. Then the estimates*

$$V^{h,*}(x) = V^0(x) + O(h^2)$$

and

$$u^{h,*}(x) = u^0(x) + O(h^2)$$

hold uniformly for all $x \in (B^*)^h$.

For the purposes of proving this theorem, we return to using the feedback control $u^h(x)$ and the corresponding trajectories which were defined at the end of section 3 and which were used for the analysis in the previous sections. Recall that $u^h(x)$ is defined for all x in $h\mathbb{Z}^n$ but is optimal only on the region B_0^h. Furthermore, Assumption 5.1 implies that each component of $u^h(x)$ is positive on the region B_0^h.

Proof of Theorem 6.1. As noted above, the conclusion of the theorem for the case of Method II is a trivial consequence of Theorem 5.2 and of Corollary 5.3. Thus, we proceed to prove the result for the case where $V^{h,*}(x)$ and $u^{h,*}(x)$ are obtained by Method I. We define the function

$$\Theta^h(x) = \frac{1}{h}\left[e^1(x) - e^{1,h}(x)\right]$$

for all x in $(B_0)^h$. Then it follows from (6.1) that

$$V^{h,*}(x) = V^0(x) + h^2\Theta^h(x) + h^2 e^2(x) + O(h^3), \tag{6.6}$$

so the estimate for $V^{h,*}(x)$ will be verified if we show that the $\Theta^h(x)$ are bounded uniformly on $(B^*)^h$. Define the function $\theta^h(x)$ by

$$\begin{aligned}\theta^h &= \left\langle \frac{1}{h}(u^0 - u^h), D^h e^1 \right\rangle + \left\langle u^0, \frac{1}{h}(De^1 - D^h e^1) \right\rangle \\ &\quad + \frac{1}{2}\left\langle \frac{1}{h}(u^0 - u^h), D^{2,h} V^h \right\rangle + \frac{1}{2}\left\langle u^0, \frac{1}{h}(D^2 V^0 - D^{2,h} V^h) \right\rangle.\end{aligned}$$

Given the fact that all of the components of $u^h(x)$ are assumed to be positive, (5.5) and (6.2) imply that $\Theta^h(x)$ satisfies

$$\langle u^h, D^h \Theta^h \rangle + \theta^h = 0, \tag{6.7}$$

for all x in $(B^*)^h$, with a zero boundary condition on $\partial G \cap (B^*)^h$. Thus, we have the representation

$$\Theta^h(x) = E_x \left[\int_0^{\tau^h_{B^*}} \theta^h(X^h) dt + \Theta^h(z^h_{B^*}) \right]. \tag{6.8}$$

The asymptotic expansions in Theorem 5.2 and in Corollary 5.3 imply that the $\theta^h(x)$ are uniformly bounded on $(B^*)^h$, so part (ii) of Lemma 3.6 implies that the integral term in (6.8) is bounded. Since the $\Theta^h(x)$ are uniformly bounded by $O(h^{-2})$ on B_0^h, we can apply the exponential estimate from part (iv) of Lemma 3.6 to bound the last term in (6.8). See the proof of Lemma 5.4, where details are given for a similar argument. We have shown that the $\Theta^h(x)$ are uniformly bounded on $(B^*)^h$, and this completes the proof of the first part of the theorem.

In light of the formula for $u^0(x)$ in (3.7) and the definition of $u^{h,*}(x)$, it is sufficient for the second part of the theorem to show that $D^{h,c} V^{h,*}(x)$ is a second order approximation to $D^{h,c} V^0(x)$, which is in turn a second order approximation to $DV^0(x)$. Since we do not know that $\Theta^h(x)$ satisfies a Lipschitz-type bound, we cannot derive such an estimate directly from (6.6). Instead, we will derive a first order asymptotic expansion of the form

$$\Theta^h(x) = \Theta(x) + O(h), \tag{6.9}$$

where $\Theta(x)$ is a smooth function. We can then substitute this expression into (6.6) and apply the second order centered difference operator $D^{h,c}$ to both sides of that equation in order to verify that $D^{h,c} V^{h,*}(x)$ is a second order approximation to $D^{h,c} V^0(x)$.

We define the function

$$\Theta(x) = \int_0^{\tau^0_x} \theta(X^0_x) dt,$$

for all x in B_0, where $\theta(x)$ is given by

$$\begin{aligned}\theta &= \left\langle \frac{1}{2} a D^2_{\backslash} V^0 + aDe^1, De^1 \right\rangle + \left\langle u^0, -\frac{1}{2} D^2_{\backslash} e^1 \right\rangle \\ &\quad + \frac{1}{2}\left\langle \frac{1}{2} a D^2_{\backslash} V^0 + aDe^1, D^2 V^0 \right\rangle + \frac{1}{2}\left\langle u^0, -\frac{1}{2} D^2 e^1 \right\rangle.\end{aligned}$$

Thus, $\Theta(x)$ satisfies the equation

$$\langle u^0, D\Theta \rangle + \theta = 0, \tag{6.10}$$

for all x in B^*, with a zero boundary condition on $\partial G \cap B^*$. In light of Theorem 5.2 and Corollary 5.3, a term by term comparison of the definitions of $\theta^h(x)$ and $\theta(x)$ reveals that

$$\theta^h(x) = \theta(x) + O(h),$$

uniformly for x in $(B^*)^h$. We can now combine (6.7) and (6.10) to obtain the relation

$$\langle u^h, D^h[\Theta^h - \Theta]\rangle + O(h) = 0,$$

holding for all x in $(B^*)^h$, with a zero boundary condition on $\partial G \cap (B^*)^h$. Just as in the proof of the first part of the theorem, we can derive a representation for the quantity $[\Theta^h(x) - \Theta(x)]$ and use the exponential estimates from Lemma 3.6 to establish that it is equal to $O(h)$. This implies that (6.9) holds uniformly on $(B^*)^h$ and completes the proof of the theorem. □

7. Examples. In this section, we present the results of experiments which illustrate the rates of convergence for the numerical methods described in this paper. For each example, we compute solutions using the first order method of section 3 and then using the two second order methods described in section 6. We solve the DPE (3.10), and for the second order Method I a linear version of that equation, by Gauss–Seidel iteration with a tolerance of 10^{-8}. Error values are indicated in the L^1 and L^∞ norms on the entire domain and on regions where the solution is known to be smooth. Approximate rates of convergence are determined by taking $\log_2(E_{m/2+1}/E_{m+1})$, where E_k is the error obtained using k gridpoints. In the case of the results obtained by Method II using Richardson extrapolation, the indicated number of gridpoints corresponds to the more refined of the two grids used in the calculation. In general, we observe second order or near second order convergence of the value functions in the L^1 norm on the entire domain and in the L^1 and L^∞ norms on the RSRs. In the case of the optimal controls, we generally observe second order convergence only in the L^1 norm on the RSRs. Results of this type are to be expected, since Assumption 5.1 is typically violated on some parts of the RSRs, so the theoretical rate of convergence results in Theorem 6.1 which would guarantee second order convergence in the L^∞ norm do not apply everywhere. In addition to the error values, we indicate the total number of iterative steps required to obtain each solution. As expected with Gauss–Seidel iteration, the number of iterations is essentially independent of the number of gridpoints. This last observation is very important in terms of the efficiency of practical calculations.

Example 1. One-dimensional problem. We begin with a one-dimensional example on the domain $[-1, 1]$. The running cost is taken to be

$$L(x, u) = (2 + 3x^2)^2 + \frac{1}{4}u^2,$$

and we can analytically evaluate the solution

$$V(x) = \begin{cases} 2x + x^3 + 3, & x \le 0, \\ -2x - x^3 + 3, & x > 0. \end{cases}$$

Approximations to the value function and to the optimal control are shown in Figure 4. The value function is approximated quite well by the first order method and by both second order methods, with only a slight overshoot appearing at the singularity when

we use Method I. This is an apparent manifestation of our observation in section 6 that it is possible for this method to result in the loss of convergence at points of discontinuity. The discontinuity in the optimal control is resolved quite sharply, although sizable overshoots occur with both second order methods. We note, however, that these overshoots appear to remain bounded as the grid is refined, so they do not indicate a lack of numerical stability.

In Table 1, we indicate the errors in computing the value function using the three numerical schemes considered in this paper. We discuss the results for the optimal feedback control in the following paragraph. Errors are given for the entire domain and for those points which are at least a distance of 0.1 away from the singularity. Using the first order scheme, we obtain clear first order convergence of the value function in both the L^1 and the L^∞ norms on the entire domain and on the RSRs. Both second order schemes result in second order convergence of the value function in the L^1 norm on the entire domain as well as in the L^1 and L^∞ norms on the RSRs. Results of this quality are expected for a one-dimensional problem, since the optimal control cannot change sign within an RSR, and Theorem 6.1 is valid on every such region. Somewhat surprisingly, Method II also yields second order convergence of the value function in the L^∞ norm on the entire domain.

The situation with the optimal feedback control is unusual due to the fact that the problem is one-dimensional. Using the first order scheme, the approximate feedback controls on the RSRs are exactly (to machine accuracy) equal to the optimal feedback control for the limit problem. The following simple observation clarifies why this behavior is to be expected. Equations (5.1) and (5.2) imply for each x in the RSRs that

$$\frac{1}{2}\langle DV^0(x), a(x)DV^0(x)\rangle + \langle b(x), DV^0(x)\rangle + c(x) = 0$$

and

$$\frac{1}{2}\langle D^hV^h(x), a(x)DV^h(x)\rangle + \langle b(x), DV^h(x)\rangle + c(x) = 0.$$

In one dimension, these quadratic equations imply that there are only two possible values for $DV^0(x)$ and $D^hV^h(x)$. Since Theorem 3.4 guarantees that the $D^hV^h(x)$ converge to $DV^0(x)$, it must be that they are equal for sufficiently small $h > 0$. Given the relationships between the optimal feedback controls and $DV^0(x)$ and $D^hV^h(x)$, it follows that the approximate optimal feedback controls should be exactly correct. This observation applies only in one dimension, and our two-dimensional examples exhibit more typical convergence of the optimal feedback controls. For the present problem, Method II inherits the exact convergence of the optimal feedback controls, since it involves taking linear combinations of results obtained using the first order method, while Method I produces second order convergence in the L^1 and L^∞ norms in the RSRs.

Example 2. Perturbed escape time. Our next example is a two-dimensional problem which is obtained by perturbing the escape time problem on the unit square. The escape time problem has the simple running cost $\tilde{L}(x,u) = \frac{1}{2}\|u\|^2 + 1/2$, and its value function is known analytically to be given by the shortest distance to any of the four edges of the square. Thus, the complement of the diagonals $x_1 = x_2$ and $x_1 = -x_2$ is a maximal RSR, and the value function is linear in each connected component of that region. As in [11], we modify the data for this problem to obtain

one with smooth data and a more interesting solution that can still be determined analytically. To that end, we introduce the C^∞ double bump function defined by

$$\chi(\xi) = \begin{cases} e^{-\lambda((\xi-m)^2-\sigma^2)^{-2}}, & \xi \in [m-\sigma, m+\sigma], \\ e^{-\lambda((-\xi-m)^2-\sigma^2)^{-2}}, & \xi \in [-m-\sigma, -m+\sigma], \\ 0 & \text{otherwise}, \end{cases}$$

where we use the parameter values $m = 0.7$, $\sigma = 0.5$, and $\lambda = 0.07$. Now we define a mollifier by

$$\Phi(x) = \chi(x_1 + x_2)\chi(x_1 - x_2)$$

for all $x = (x_1, x_2)$ in the unit square and then define the value function $V^0(x)$ by multiplying the value function for the escape time problem by $1+\Phi(x)$. The resulting function has the same RSRs as the escape time problem, and it maintains the simple structure in a neighborhood of the singularities. In a similar spirit, we define

$$a(x) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} + 3\sin(2\pi x_1)^2 \begin{bmatrix} 2 & 5 \\ 5 & 18 \end{bmatrix} \Phi(x)$$

and

$$b(x) = \begin{bmatrix} 0 \\ 0 \end{bmatrix} + 5 \begin{bmatrix} x_1 \\ x_2 \sin((x_1^2 + x_2^2)^{1/2} - 1/2) \end{bmatrix} \Phi(x)$$

so that $a(x)$ is the identity and $b(x)$ is the zero vector in a neighborhood of the singularities. Now we define $c(x)$ on the RSRs by

$$c(x) = (1/2)\langle DV^0(x), a(x)DV^0(x)\rangle - \langle b(x), DV^0(x)\rangle.$$

Our use of a mollifier in defining all of the relevant functions ensures that the cost function $c(x)$ extends smoothly to $c(x) = 1/2$ at the singularities, and it turns out that $V^0(x)$ solves the limit control problem for the indicated cost structure.

In Table 2, we indicate the errors in computing the value function and the optimal controls using the three numerical schemes considered in this paper. Errors are given for the entire domain and for those regular points which are at least a distance of 0.1 away from the singularities. The first order method consistently produces first order convergence of the value function and of the optimal controls, except when the control errors are measured in the L^∞ norm on the entire domain. This is expected, since the convergence results for the optimal controls do not apply at the singular points. The qualitative behaviors of the two second order methods are essentially the same, although the absolute error values for the feedback control are somewhat smaller using Method I. We obtain second order convergence of the value functions in the L^1 norm on the entire domain, while first order convergence is maintained in the L^∞ norm. In the RSRs, convergence in the L^1 norm is second order, and convergence in the L^∞ norm is significantly better than first order but perhaps not second order. We note that the lack of clear second order convergence in the L^∞ norm is to be expected, since Assumption 5.1 does not hold everywhere in the RSRs for this problem.

In the case of the optimal controls, first order convergence is maintained in the L^1 norm on the entire domain, and we observe second order convergence in the L^1 norm in the RSRs. The errors on the RSRs measured in the L^∞ norm appear to decay only

at a first order rate. This can be accounted for by the fact that the present problem does not satisfy Assumption 5.1 on the maximal RSR, as the optimal controls for the limit problem are not of fixed sign. By considering subsets of the RSRs where the controls do not change signs, we can obtain more convincing second order convergence in the L^∞ norm for both the value function and the optimal control. The results in Table 3 are obtained by restricting our attention to those parts of the domain where $x > 0.5$ and $y > 0$ and where $x < -0.5$ and $y < 0$. This is a somewhat arbitrary choice, but it singles out a set of points where the sign changes do not seem to interfere with second order convergence.

In Figure 5, we display the exact values of $V^0(x)$ and of the first component of $u^0(x)$, as well as approximations obtained by using 41 points in the two second order numerical methods. The graphs of the feedback controls illustrate that our methods resolve discontinuities quite sharply. It is also worth noting the slight overshoot in the center of the value function obtained by Method I. We observed in section 6 that it is theoretically possible for convergence of the value function at singular points to be compromised when this second order method is employed. The overshoot is the only apparent manifestation of that possibility, and as predicted by the theory it does not appear when we compute the approximations using Method II.

Example 3. Quadratic running cost. Our final example is a two-dimensional problem on the unit square where the boundaries of the maximal RSR are curved. The running cost is defined to be $L(x,u) = \frac{1}{2}\|u\|^2 + 6x_1^2 + 1$. We do not have an analytic expression for the solution, but, by looking at approximate solutions, it is easy to visually identify the boundaries of the RSRs. In Figure 6(a), we indicate those boundaries, as well as the subset of the domain which we utilize for the purpose of calculating rates of convergence on the RSRs, and in Figure 6(b) we show approximations to the characteristics.

In Table 4, we give relative errors for the first order scheme and for the two second order schemes, both on the entire domain and on a subset of the RSRs. The relative errors are computed by comparing the solution computed using $m+1$ gridpoints to the solution computed using $m/2+1$ gridpoints. These values are not as reliable as absolute errors for determining rates of convergence, but they do give a reasonable indication, and the results are consistent with our expectations. As in the previous example, both second order methods produce second order convergence of the value functions when measured in the L^1 norm on the entire domain and on the RSRs. When these errors are measured in the L^∞ norm on the RSRs, Method I produces second order convergence, while the convergence with Method II is somewhat better than first order. In the case of the optimal controls, both methods apparently give rise to second order convergence in the L^1 norm on the RSRs, while preserving first order convergence in the L^1 norm on the entire domain and in the L^∞ norm on the RSRs. Again, since Assumption 5.1 does not appear to hold everywhere on the RSRs, results of this type are not surprising.

Figures 6(c)–6(f) show approximations with 41 points to the value function and to the first component of the optimal feedback control. There are no apparent qualitative differences in the two approximations to the value function. With Method I, the discontinuities in the control are resolved quite sharply. Method II seems to produce large overshoots, but we note that these are bounded as the grid is refined and do not indicate lack of numerical stability.

8. Conclusion. We have exhibited two global second order numerical methods for the solution of a class of Hamilton–Jacobi PDE which are related to deterministic

optimal control problems. Our analysis establishes that these methods produce provably second order approximations to the value function and to the optimal feedback control on certain subsets of the RSRs. The rate of convergence results apply only on those regions where each component of the limit optimal feedback control is bounded away from zero so that the sign remains constant. In practice, we observe second order convergence in the L^1 norm on the RSRs even where this assumption is violated, but the results are less favorable when the L^∞ norm is used to measure the errors.

The reason that our theory cannot accommodate changes in the signs of the optimal controls is that the transition probabilities given in (3.9) are singular as functions of the control u wherever any of the components of u are equal to zero. It is likely that we could eliminate the theoretical restrictions on the present method by applying our techniques to a first order method with smooth transition probabilities. In order for such an approach to be practical, however, it would be necessary that the new transition probabilities preserve the highly desirable qualitative properties of those considered here. The one-sided nature of the present transition probabilities is important in terms of achieving sharp resolution of the discontinuities, and their simple form allows us to evaluate the minima analytically at each step in the iterative process used to solve the discrete DPE. Additionally, the control-dependent mean jump times in (3.8) ensure that the number of Gauss–Seidel iterations needed to solve the DPE is small and essentially bounded as the grid is refined. We do not know of smooth transition probabilities which have these qualities, so it is not presently possible for us to improve upon the methods in this paper.

We conclude by suggesting other possible extensions to our work. In principle, the high order asymptotic analysis carried out in section 5 can be used to formulate numerical methods of arbitrarily high order, either by using a more refined correction term in Method I or by taking the linear combination of several approximate solutions in Method II. As a practical matter, since even the second order convergence is not as consistent as we might have hoped in the typical situation where Assumption 5.1 is violated, we do not pursue this avenue. Our analysis considers only homogeneous boundary conditions, but this should not be an essential restriction. Homogeneity at the boundary is used quite strongly in our proof of Lemma 5.5 and in an analogous step in the proof of Theorem 3.4 [11], so it would be necessary to find an alternative approach to estimating the gradient at points near the boundary. Next, the quadratic structure of the running cost as a function of u is probably not needed for the type of asymptotic analysis that we carry out. In practice, this structure is essential for the efficient solution of the discrete DPE as it enables us to evaluate the minima analytically, but it would also be interesting to construct higher order numerical methods for problems where the running cost does not have this form. Finally, we remark that it is worth considering the possibility of applying methods like ours to construct higher order numerical methods for the solution of the second order Hamilton–Jacobi PDEs which arise from stochastic control problems with dynamics given by controlled diffusions.

Appendix A. Proof of Lemma 5.7. The purpose of this appendix is to indicate the calculations which are used to prove Lemma 5.7. The argument essentially consists of elementary algebraic manipulations, but they are rather involved, so it is worthwhile to set out some of the key steps. We combine (5.8) and (5.15) with $m = 1, \dots, q+1$ to obtain the following relation holding on the region B_0^h:

$$
\begin{aligned}
&\langle \bar{u}^h, D^h \Phi^{h,q+1} \rangle \\
&\quad + \sum_{i=0}^{q+1} h^{-(q+1-i)} \, \langle u^0, D^h e^i - D e^i \rangle \\
&\quad - \sum_{m=1}^{q+1} \sum_{k=2}^{m+1} \frac{1}{k!} h^{-(q+1-m)} \langle u^0, D_\backslash^k e^{m+1-k} \rangle \qquad \Big\} \text{(a)} \\
&\quad + h^{-(q+1)} \langle \bar{u}^h - u^0, D^h e^0 - D e^0 \rangle \\
&\quad + \frac{1}{2} \sum_{m=1}^{q+1} \sum_{l=2}^{m} \sum_{k=1}^{m+2-l} \frac{1}{l!k!} h^{-(q+1-m)} \langle D_\backslash^l e^0, a D_\backslash^k e^{m+2-l-k} \rangle \qquad \Big\} \text{(b)} \\
&\quad + \sum_{j=1}^{q+1} h^{-(q+1-j)} \, \langle \bar{u}^h - u^0, D^h e^j \rangle \\
&\quad + \frac{1}{2} \sum_{m=1}^{q+1} \sum_{j=1}^{m-1} \sum_{l=1}^{m-j} \sum_{k=1}^{m+2-j-l} \frac{1}{l!k!} h^{-(q+1-m)} \langle D_\backslash^l e^j, a D_\backslash^k e^{m+2-j-l-k} \rangle \qquad \Big\} \text{(c)} \\
&= 0.
\end{aligned} \tag{A.1}
$$

The first part of Lemma 5.7 will be established if we show that each of the expressions (a)–(c) converges to zero, uniformly for x in $B_{q'}^h$. A key observation is that we can use (5.16) along with (3.7) and (5.7) to obtain the relation

$$
\bar{u}^h - u^0 = -\frac{1}{2} a \sum_{k=2}^{q+1} \frac{1}{k!} h^{k-1} D_\backslash^k e^0 - \frac{1}{2} a \sum_{i=1}^{q} \sum_{k=1}^{q+1} \frac{1}{k!} h^{i+k-1} D_\backslash^k e^i + o(h^q), \tag{A.2}
$$

holding uniformly on $B_{q'}^h$. We indicate the details of the manipulations for (b) and note that the calculations are similar for (a) and (c). Consider the following series of relations which is easily seen to imply that (b) converges to zero, uniformly on $B_{q'}$. Each line is explained after the display.

$$
\begin{aligned}
&h^{-(q+1)} \langle \bar{u}^h - u^0, D^h e^0 - D e^0 \rangle \\
&= -\frac{1}{2} \sum_{l=2}^{q+1} \sum_{k=2}^{q+3-l} \frac{1}{l!k!} h^{-(q+3-k-l)} \langle a D_\backslash^k e^0, D_\backslash^l e^0 \rangle \\
&\quad - \frac{1}{2} \sum_{i=1}^{q} \sum_{l=2}^{q+2-i} \sum_{k=1}^{q+3-l-i} \frac{1}{l!k!} h^{-(q+3-k-l-i)} \langle a D_\backslash^k e^i, D_\backslash^l e^0 \rangle + o(1)
\end{aligned}
$$

$$
\begin{aligned}
&= -\frac{1}{2}\sum_{l=2}^{q+1}\sum_{k=2}^{q+3-l}\frac{1}{l!k!}h^{-(q+3-k-l)}\langle D_{\backslash}^{l}e^{0}, aD_{\backslash}^{k}e^{0}\rangle \\
&\quad -\frac{1}{2}\sum_{l=2}^{q+1}\sum_{k=1}^{q+2-l}\sum_{m=l+k-1}^{q+1}\frac{1}{l!k!}h^{-(q+1-m)}\langle D_{\backslash}^{l}e^{0}, aD_{\backslash}^{k}e^{m+2-l-k}\rangle + o(1) \\
&= -\frac{1}{2}\sum_{l=2}^{q+1}\sum_{k=2}^{q+3-l}\sum_{m=l+k-2}^{m=l+k-2}\frac{1}{l!k!}h^{-(q+1-m)}\langle D_{\backslash}^{l}e^{0}, aD_{\backslash}^{k}e^{m+2-l-k}\rangle \\
&\quad -\frac{1}{2}\sum_{l=2}^{q+1}\sum_{k=1}^{q+2-l}\sum_{m=l+k-1}^{q+1}\frac{1}{l!k!}h^{-(q+1-m)}\langle D_{\backslash}^{l}e^{0}, aD_{\backslash}^{k}e^{m+2-l-k}\rangle + o(1) \\
&= -\frac{1}{2}\sum_{m=2}^{q+1}\sum_{l=2}^{m}\sum_{k=1}^{m+2-l}\frac{1}{l!k!}h^{-(q+1-m)}\langle D_{\backslash}^{l}e^{0}, aD_{\backslash}^{k}e^{m+2-l-k}\rangle + o(1).
\end{aligned}
$$

The first equality is obtained by applying expression (A.2) and by using the Taylor expansion for $e^0(x)$, as in (5.12); to get the second equality, we rearrange the orders of summation and make the change of variables $m = i + l + k - 2$; we get the third equality by introducing m as a dummy variable in the first summation; the final equality is obtained by rearranging the orders of summation in each of the two terms in the previous line and then combining them into a single summation.

We now turn to verifying the second part of Lemma 5.7. It is easy to see that the following discrete product rule is valid for $p = 1, \ldots, n$:

$$
\begin{aligned}
D_p^h\langle f(x), g(x)h(x)\rangle &= \langle D_p^h f(x), g(x+he_p)h(x+he_p)\rangle \\
&\quad + \langle f(x), g(x+he_p)D_p^h h(x)\rangle \\
&\quad + \langle f(x), D_p^h g(x)h(x)\rangle.
\end{aligned}
$$

Our first application of this product rule to prove the second part of Lemma 5.7 actually involves the simpler case where $g(x)$ is the identity matrix. We state the rule for general $g(x)$ because it will be used later in dealing with the special case of proving the second part of Lemma 5.7 for $q = 0$. For each $p = 1, \ldots, n$, we apply the operator D_p^h to (A.1) and obtain

$$
\langle \bar{u}^h(x+he_p), D^h\Psi_p^{h,q+1}(x)\rangle + \langle D_p^h\bar{u}^h(x), \Psi^{h,q+1}(x)\rangle + \cdots = 0,
$$

where the unspecified quantities are those obtained by applying the product rule with $g(x)$ the identity matrix to the terms (a)–(c) in (A.1). This yields six new terms, and, as in the treatment of (b) above, each of these can be expanded and rearranged to obtain coefficients converging to zero. In the case $q \geq 1$, the condition in (5.16) implies that $D_p^h\bar{u}^h$ converges to $D_p u^0$, so these manipulations suffice to establish the lemma.

Unfortunately, this general calculation is not sufficiently detailed to prove the second part of Lemma 5.7 when $q = 0$, so we treat that as a special case. We do not generalize the manipulations which work for $q = 0$, as they are considerably more involved than the ones indicated above. By using the product rule to apply the

operator D_p^h directly to (5.1), (5.2), and (5.5) and then taking a linear combination of the resulting expressions, we obtain after some manipulations

$$\begin{aligned}
&\Big\langle -a(x+he_p)\left(\frac{1}{2}D^hV^h(x+he_p)+\frac{1}{2}D^hV^h(x)\right)\\
&\quad + b(x+he_p)-\frac{1}{2}ha(x+he_p)D_p^hDV^0(x)\ ,\ D^h\Psi_p^{h,1}(x)\Big\rangle\\
&+\Big\langle -a(x+he_p)D_p^hDV^0(x)-D_p^ha(x)\left(\frac{1}{2}D^hV^h(x)+\frac{1}{2}DV^0(x)\right)\\
&\quad + D_p^hb(x)\ ,\ \Psi^{h,1}(x)\Big\rangle\\
&+o(1)=0,
\end{aligned}$$

holding uniformly for x in B_1^h. Given the assumed convergence of the D^hV^h to DV^0 and the representation for u^0 in (3.7), it is easy to see that the above expression is consistent with (5.21), so it completes the proof of the lemma.

Appendix B. Large deviations upper bound. In this appendix, we state a general large deviations upper bound for a broad class of Markov processes with possibly discontinuous statistics. Our result is essentially an extension of [9, Theorem 1.1], and the reader interested in a proof should consult [9], as well as [29] for comments on the extension. We carefully define the needed notation and end this appendix with a statement of the theorem. Note that the notation in this appendix is independent of the notation in the preceding sections.

Let $\mathbb{R}^n = R^{n_1+n_2}$, and consider a sequence of Markov processes $X^h = (X_1^h, X_2^h)$ with trajectories in $\mathcal{D}([0,\infty):\mathbb{R}^n)$ and generators $\mathcal{L}^h$ such that, for any smooth function $f(x)$ mapping $\mathbb{R}^n$ to $\mathbb{R}$,

$$\begin{aligned}
\mathcal{L}^hf(x) &= \langle \bar{b}^h(x), Df(x)\rangle + \frac{h}{2}\mathrm{tr}[\bar{a}^h(x)D^2f(x)]\\
&\quad + \frac{1}{h}\int_{\mathbb{R}^n}[f(x+h\nu)-f(x)-h\langle \nu, Df(x)\rangle]\bar{\mu}^h(x)(d\nu).
\end{aligned}$$

For each $h>0$, $\bar{a}^h(x)$ and $\bar{b}^h(x)$ are uniformly bounded functions from $\mathbb{R}^n$ to the spaces of $n\times n$ matrices and n-vectors, respectively, and $\bar{\mu}^h(x)$ is a function from $\mathbb{R}^n$ to the space of nonnegative measures on $\mathbb{R}^n$ such that $\bar{\mu}^h(x)$ is uniformly bounded and has uniformly compact support for $x\in\mathbb{R}^n$. We consider block decompositions

$$\bar{a}^h(x)=\begin{bmatrix}\bar{a}_{11}^h(x) & \bar{a}_{12}^h(x)\\ \bar{a}_{21}^h(x) & \bar{a}_{22}^h(x)\end{bmatrix},\qquad \bar{b}^h(x)=\begin{bmatrix}\bar{b}_1^h(x)\\ \bar{b}_2^h(x)\end{bmatrix},$$

where $\bar{a}_{11}^h(x)$ is an $n_1\times n_1$ matrix valued function, $\bar{b}_1^h(x)$ is an n_1-vector valued function, and the other blocks are of appropriate sizes to complete the decompositions. Also, we let $\bar{\mu}_1^h(x)$ be the marginal measure of $\bar{\mu}^h(x)$ on $\mathbb{R}^{n_1}$. In general, we will employ without comment the notation $x=(x_1,x_2)$, where $x_i\in\mathbb{R}^{n_i}$ for $i=1,2$.

For the space of finite measures on $\mathbb{R}^{n_1}$, we define a metric $d(\cdot,\cdot)$ as follows. For two such measures η_1 and η_2, the distance $d(\eta_1,\eta_2)$ is defined to be the supremum of

$$\left|\int_{\mathbb{R}^{n_1}} f(\xi)\eta_1(d\xi)-\int_{\mathbb{R}^{n_1}} f(\xi)\eta_2(d\xi)\right|$$

over all functions $f(\xi)$ for which $\|f\|_\infty \leq 1$ and which satisfy a Lipschitz condition with constant no greater than 1. We note that $d(\cdot,\cdot)$ metrizes weak convergence of probability measures [8, Proposition 11.3.2]. Assume the following:

1. The $\bar{a}_{11}^h(x)$ and $\bar{b}_1^h(x)$ are uniformly bounded for all $x \in \mathbb{R}^n$ and for all $h > 0$.
2. There exists a compact set $K \subset \mathbb{R}^{n_1}$ and a constant $M < +\infty$ such that $\bar{\mu}_1^h(x)(K^c) = 0$ and $\bar{\mu}_1^h(x)(K) \leq M$ for all $x \in \mathbb{R}^n$ and for all $h > 0$.
3. There exist functions $\bar{a}_{11}(x)$ and $\bar{b}_1(x)$ such that

$$\bar{a}_{11}^h(x) \to \bar{a}_{11}(x), \qquad \bar{b}_1^h(x) \to \bar{b}_1(x)$$

   hold as $h \to 0$, uniformly for x in $\mathbb{R}^n$ with x_1 in compact subsets of $\mathbb{R}^{n_1}$.
4. There exists a measure valued function $\bar{\mu}_1(x)$ such that

$$d\Big(\bar{\mu}_1^h(x), \bar{\mu}_1(x)\Big) \to 0$$

   holds as $h \to 0$, uniformly for x in $\mathbb{R}^n$ with x_1 in compact subsets of $\mathbb{R}^{n_1}$.

Notice that conditions 1 and 2 are uniform for all $h > 0$, and hence are more restrictive than what is assumed earlier in the definition of $\mathcal{L}^h$. We now proceed to define the rate function for our large deviations upper bound. For each $x \in \mathbb{R}^n$ and for each vector $\alpha \in \mathbb{R}^{n_1}$, define the convex function

$$H(x,\alpha) = \langle \bar{b}_1(x), \alpha\rangle + \frac{1}{2}\mathrm{tr}[\bar{a}_{11}(x)\alpha\alpha^t] + \int_{\mathbb{R}^{n_1}} [e^{\langle \nu,\alpha\rangle} - 1 - \langle \nu,\alpha\rangle]\mu_1(x)(d\nu),$$

and then for each $x_1 \in \mathbb{R}^{n_1}$

$$H_1(x_1,\alpha) = \sup_{x_2 \in \mathbb{R}^{n_2}} H((x_1,x_2),\alpha).$$

We further define the upper semicontinuous regularization,

$$h_1(x_1,\alpha) = \lim_{\delta \to 0} h_{1,\delta}(x_1,\alpha),$$

where

$$h_{1,\delta}(x_1,\alpha) = \sup_{\|y_1 - x_1\| \leq \delta} H(y_1,\alpha).$$

Consider the Legendre–Fenchel transform given by

$$l(x_1,\beta) = \sup_{\alpha \in \mathbb{R}^{n_1}} [\langle \beta,\alpha\rangle - h_1(x_1,\alpha)]$$

for each $\beta \in \mathbb{R}^{n_1}$. Given $T < +\infty$ and for each $x \in \mathbb{R}^n$, we define the rate function $I_{x_1}(\phi_1)$ by

$$I_{x_1}(\phi_1) = \int_0^T l(\phi_1(s), \dot{\phi}_1(s))ds$$

for absolutely continuous functions ϕ_1 taking values in $\mathbb{R}^{n_1}$ which satisfy $\phi_1(0) = x_1$, and we set $I_{x_1}(\phi_1)$ to be $+\infty$ otherwise.

We can now state the main large deviations theorem.

THEOREM B.1. *Assume conditions* 1–4 *above. Given a compact set* $C \subset \mathbb{R}^{n_1}$, *the following hold:*

(i) *Given $L < +\infty$ and for each $x_1 \in \mathbb{R}^{n_1}$, define*

$$\Phi_{x_1}(L) = \{\phi_1 \in \mathcal{D}([0,T] : \mathbb{R}^{n_1}) : I_{x_1}(\phi_1) \leq L\}.$$

Then the set $\bigcup_{x_1 \in C} \Phi_{x_1}(L)$ is compact.

(ii) *For each closed set $F \subset \mathcal{D}([0,T] : \mathbb{R}^{n_1})$,*

$$\limsup_{h \to 0} h \log P_x\{X_1^h \in F\} \leq - \inf_{\phi_1 \in F} I_{x_1}(\phi_1)$$

holds uniformly for $x \in \mathbb{R}^n$ such that $x_1 \in C$.

A STABLE TIME DISCRETIZATION OF THE STEFAN PROBLEM WITH SURFACE TENSION*

BEN SCHWEIZER†

Abstract. We present a time discretization for the single phase Stefan problem with Gibbs–Thomson law. The method resembles an operator splitting scheme with an evolution step for the temperature distribution and a transport step for the dynamics of the free boundary. The evolution step involves only the solution of a linear equation that is posed on the old domain. We prove that the proposed scheme is stable in function spaces of high regularity. In the limit $\Delta t \to 0$ we find strong solutions of the continuous problem. This proves consistency of the scheme, and additionally it yields a new short-time existence result for the continuous problem.

Key words. free boundary problem, time discretization, operator splitting

1. Introduction.

The Stefan problem is a set of equations that describe the melting of ice or the growth of ice cristals. At time t the ice (or the water) occupies a region Ω_t, and the second phase occupies the complement of Ω_t. The position of the interface $\partial\Omega_t$ is not known a priori but must be determined together with the temperature distribution $\Theta(t)$. Several sets of evolution equations can be found in the extensive literature (see [11] for equations and further references). Commonly used is the heat equation (2.1) in the domain Ω_t (in the two phase problem another heat equation is posed in the complement of Ω_t). The latent heat relates the normal heat flux on the free boundary (or its jump across the boundary) with the speed of the free boundary as in (2.2). In order to determine the evolution we need one more boundary condition. Various possibilities are studied for that: (a) fixed temperature $\Theta = 0$, (b) the Gibbs–Thomson relation $\Theta \sim \kappa$ with κ being the mean curvature of the boundary, and (c) kinetic undercooling: temperature plus a multiple of the speed is proportional to the mean curvature. In the paper at hand we are interested in case (b), the Gibbs–Thomson relation (2.3).

The aim of this paper is to introduce a stable time discretization of the two-dimensional free boundary value problem. We consider the single phase problem for simplicity; the two phase problem can be treated with the same method. Since the domain changes with time, it is not clear what equations we should pose at every time step, how to define a new domain, and how to define a temperature distribution on the new domain. Thinking of the numerical use of the scheme it is desirable that at each time step only a linear equation must be solved. This linear equation should be posed on the old domain. Our scheme will provide exactly this. As a by-product of our stability result in Theorem 2.2 we find a short-time existence result for (2.1)–(2.3) in Corollary 2.3. Such a result (in different function spaces) was proved earlier by Radkevich in [8]. Our approach is more elementary in the sense that it involves less functional-analytic machinery.

Another time discretization for the Gibbs–Thomson law was introduced by Luckhaus in [6]. His approach assumes only very low regularity such that solutions can be defined past geometric singularities. For that it is necessary to use explicitly the new domain in the definition of the time step. In this context we wish to mention the work of Bänsch [3] dealing with a time discretization for the Navier–Stokes equations with a free boundary. Also in these more complicated equations the new geometry is needed in the definition of the new iterate.

Let us compare the Gibbs-Thomson law (b) with kinetic undercooling (c). The term introduced in case (c) is regularizing; mathematically it has the effect that one can regard the equations as a coupled system of a heat equation and an equation for the motion of the free boundary. The regularity properties of the two evolution equations allow us to iterate the two solution operators. The fixed point is a solution of the original problem. Such an iteration is used by Chen and Reitich in [4] and by Abergel et al. in [1] in order to derive an existence result in case (c). A spatial semidiscretization was studied by Veeser in [10]. In contrast to case (c), it seems impossible to decouple the equations in case (b).

This paper is organized as follows. In section 2 we present the operator splitting scheme (OS) for a time discretization. Each time step consists of (1) defining an auxiliary velocity field v, (2) solving a linear equation with transport term $v \cdot \nabla$, and (3) defining the new domain and a temperature field on the new domain by advection. In Theorem 2.2 and Corollary 2.3 we state our main result: the proposed scheme (OS) is stable and consistent.

Within this paper we introduce three different schemes. Scheme (OS) is the numerically applicable scheme in physical variables. The analysis of (OS) is the goal of this paper, and the results are collected in section 2. In order to prove our results we introduce a linear Crank–Nicolson-type scheme (CN) for unknowns (u, h). (CN) is defined on a fixed domain and considers a given right-hand side f; detailed a priori estimates are derived in section 3. The next step is to consider scheme (CN) with a right-hand side of the form $f = f(u, h)$. Note that this is in general not a practical numerical scheme, since f may depend on the values of the solution at later times. The special choice of $f(u, h)$ in section 4 is motivated by the original equations and their transformation to a fixed domain. We prove the existence of solutions and a priori estimates. In section 5 we conclude that the original scheme (OS) inherits these properties.

As already mentioned, our analysis is based on the study of a linear problem. This linear problem is obtained by transforming the equations onto a rectangle and linearizing them. This defines an operator in the unknown quantities temperature distribution u and height function of the free boundary h. This linear operator has a compact inverse with regularizing properties. It allows us to solve instationary problems with a time discretization (CN). The discretization can be proven to be stable by a testing procedure. Since the nonlinearity requires regular solutions, we apply the results also to discrete time derivatives and to second spatial derivatives of the time-discrete solutions. This yields estimates in function spaces of high regularity. In section 3 we collect estimates for (CN), the semidiscrete equations on a fixed domain. Some care must be taken of compatibility conditions of the initial values.

Note that similar facts of the corresponding linearized problem were used in [9] in order to treat the Navier–Stokes equations with a free boundary. Let us again compare cases (b) and (c): in case (c) the properties of the linear operator can be shown with an iteration that solves successively for u and h. In the case at hand one actually has to study the coupled system.

In section 4 we consider a time discretization of transformed equations and apply the results of section 3. It turns out to be of importance in which point we linearize the equations. Concerning the mean curvature operator of the Gibbs–Thomson law it is sufficient to linearize it about the initial values. This is different for the nonlinearity introduced by the domain transformation: it has a different structure and cannot be treated by introducing error terms on the right-hand side (see Lemma 3.2 and remarks thereafter). We have to use in every time step the linearization of the equations on the current "old" domain. This introduces time-dependent coefficient matrices in the equations, but this way the transformation respects the variational character of the problem. As it turns out, the scheme (OS) mimics this strategy of linearization.

We encounter the fact that the solution of the discrete equations does not satisfy maximal regularity estimates. Therefore we have to be careful in the discretization of the nonlinearity.

In section 5 we prove Theorem 2.2 for scheme (OS). The idea is to transform the operator splitting scheme onto a reference domain and to apply the results of section 3. It will turn out that the transformation of scheme (OS) is actually identical to the scheme of section 4. The results of section 4 imply the stability of the transformed scheme and therefore the stability of the original scheme. Since (OS) is consistent with the continuous equations we can conclude that weak limits of the discrete solutions define strong solutions of the original problem.

2. The free boundary problem and the time discretization. We denote the domain that is covered with ice (or water) at time t by Ω_t. For notational convenience we assume that the free boundary is given as the graph of a single function. We study the two-dimensional case and write $S := [0,1]_{per}$ for the unit interval with identified endpoints. A function defined on S is automatically periodic; in particular, all derivatives (if defined) coincide in the endpoints. We write the domain as

$$\Omega_t = \{(x,y) | x \in S, 0 < y < h(t,x)\}.$$

The height function h will be close to 1, and we can always parametrize Ω_t over the standard rectangle $S \times (0,1)$. Again, all functions on the rectangle are automatically periodic on the lateral boundaries. We introduce the time-dependent function $H(t,x) = (x, h(t,x))$ to parametrize the upper boundary of Ω_t. In the following we will often omit the argument t. By a rescaling argument we can assume that the physical constants latent heat, surface tension, and thermal diffusion are all equal to 1. The physical equations then read

$$\partial_t \Theta = \Delta \Theta \qquad \text{in } \bigcup_{t>0} \{t\} \times \Omega_t, \tag{2.1}$$

$$\partial_t h = -(n \cdot \nabla \Theta) \circ H \sqrt{1 + |\partial_x h|^2} \qquad \text{on } \{(t,x) | t > 0, x \in S\}, \tag{2.2}$$

$$\Theta \circ H = \kappa \qquad \text{on } \{(t,x) | t > 0, x \in S\}. \tag{2.3}$$

Here

$$\kappa := -\partial_x \left(\frac{\partial_x h}{\sqrt{1 + |\partial_x h|^2}} \right)$$

is the mean curvature of the free boundary, n is the exterior normal of Ω, and $n_2 = (1 + |\partial_x h|^2)^{-1/2}$ the second component of n. The above equations are complemented with a boundary condition for Θ on the lower boundary, say,

$$\Theta(t,x,0) = \psi(t,x).$$

For notational convenience we will use $\psi \equiv 0$ in the following. All results remain valid for smooth ψ. Additionally, initial values $\Theta(t=0) = \Theta_0$ and $h(t=0) = h_0 > 0$ are imposed.

Later on we will use the linearization of the mean curvature operator about $h = h_0$,

$$\underline{\Delta} h := \; -D\kappa(h_0) \cdot h = \partial_x \left(\frac{\partial_x h}{\sqrt{1 + |\partial_x h_0|^2}^3} \right).$$

For smooth and small h_0 the properties of $\underline{\Delta}$ are similar to those of $\Delta_x = \partial_x^2$, therefore the notation.

We now introduce a uniform discretization of the time interval $(0, T)$ by $t_k := k \cdot \Delta t$. Note that nonuniform time partitions can also be treated with our method. The pair (Θ^k, h^k) is meant to approximate $(\Theta(t_k), h(t_k))$. We set $(\Theta^0, h^0) := (\Theta_0, h_0)$. The function h^k defines the domain $\Omega^k := \{(x, y) | x \in S, 0 < y < h^k(x)\}$ and the normal vector n^k. We use $H^k(x) := (x, h^k(x)) \in \mathbb{R}^2$. In the following definition we need functions $\Theta^{(-1)} := \tilde{\Theta}^{(-1)} := \Theta^0$ for the first execution of Step 1. We define $H^{(-1)}$ and $n^{(-1)}$ via $h^{(-1)} := h^0$.

Let us motivate in advance (2.5): let Θ solve $\partial_t \Theta = \Delta \Theta$ on the time-dependent domain Ω_t. We consider $\tilde{\Theta}(t, .) := \Theta(t, \Phi(t, .))$, where $\Phi(t, .)$ parametrizes Ω_t over the fixed domain Ω_{t_0}: $\Phi(t, .) : \Omega_{t_0} \to \Omega_t$. Then $\tilde{\Theta}$ satisfies

$$\partial_t \tilde{\Theta} = (\partial_t \Theta) \circ \Phi + (\nabla \Theta) \circ \Phi \cdot \partial_t \Phi = \Delta \Theta|_\Phi + \partial_t \Phi \cdot \nabla \Theta|_\Phi.$$

If we want to calculate on a given domain (the "old" domain Ω_{t_0}), then we have to include a convective term in the heat equation. In the numerical scheme it remains to choose a guess for the corresponding velocity field.

DEFINITION 2.1. We assume that an initial domain Ω^0 is given by h^0 and an initial temperature by $\Theta^0 : \Omega^0 \to \mathbb{R}$. Let $X^0 : R \to \Omega^0$ be a parametrization of Ω^0.

The operator splitting scheme (OS) for a time discretization of (2.1)–(2.3) is defined by the following three steps; they are executed beginning with $k = 0$.

Step 1. We use the temperature data of the last time step in order to define a vertical velocity field $v^k = (v_1, v_2) = (0, v_2) : \Omega^k \to \mathbb{R}^2$ with boundary values

$$n^{k-1} \circ H^{k-1} \cdot v^k \circ H^k = \left(n^{k-1} \cdot \nabla \frac{\Theta^{k-1} + \tilde{\Theta}^{k-1}}{2} \right) \circ H^{k-1}$$

by the linear interpolation

$$v^k(x, y) = \frac{y}{h^k(x)} v^k(x, h^k(x)). \tag{2.4}$$

Step 2. Find $\tilde{\Theta}^k : \Omega^k \to \mathbb{R}$ and $h^{k+1} : [0, 1] \to \mathbb{R}$ with

$$\frac{\tilde{\Theta}^k - \Theta^k}{\Delta t} = \Delta \left(\frac{\Theta^k + \tilde{\Theta}^k}{2} \right) + v^k \cdot \nabla \frac{\Theta^k + \tilde{\Theta}^k}{2} \text{ in } \Omega^k, \tag{2.5}$$

$$\frac{h^{k+1} - h^k}{\Delta t} = -\sqrt{1 + |\partial_x h^k|^2} \left(n^k \cdot \nabla \frac{\Theta^k + \tilde{\Theta}^k}{2} \right) \circ H^k \quad \text{in } [0, 1], \tag{2.6}$$

$$\tilde{\Theta}^k \circ H^k + \underline{\Delta}(h^{k+1} - h^k) = \kappa(h^k) \quad \text{in } [0, 1]. \tag{2.7}$$

On the lower boundary we impose $\tilde{\Theta}^k(x,0) = \psi(x,t_k)$. We slightly change the definition in the first time step $k=0$. There we use Θ_0 instead of $\frac{1}{2}(\Theta^0 + \tilde{\Theta}^0)$ in the convective term of (2.5).

Step 3. The function h^{k+1} defines the new domain Ω^{k+1}. We now want to define a temperature field Θ^{k+1} on the new domain. We set

$$X^{k+1}(x,y) := X^k(x,y) + \left(0, \frac{X_2^k(x,y)}{h^k(x)}\right) \cdot (h^{k+1} - h^k)(x), \tag{2.8}$$

$$\Theta^{k+1} \circ X^{k+1} := \tilde{\Theta}^k \circ X^k \qquad \text{in } R. \tag{2.9}$$

We will show that the above scheme can be used to define uniquely $(\Theta^k, X^k)_{k=0,\dots,K}$. The functions Θ^k are defined on domains that depend on time (on k). The domains are always parametrized by $X^k = (X_1^k, X_2^k)$. In order to formulate estimates we introduce the pairs $(u^k, h^k) := (\Theta^k \circ X^k, h^k)$. The functions u^k are then defined on the time-independent domain R.

The main result of this paper is the following theorem. It is proved together with its corollary in section 5.

THEOREM 2.2. *Let the initial values (u_0, h_0) satisfy the regularity and compatibility assumption, Assumption* 5.1, *and let $h_0 - 1$ be small in $C^{0,1}(S)$. Let the initial domain be parametrized over the rectangle $R = S \times (0,1)$ with a diffeomorphism $X^0 \in H^{4+1/2}(R)$ with $X^0 - id$ small in $C^{0,1}(R)$, $X_1^0(x,y) = x$ and $\partial_2 X_2^0(.,1) = 1$.*

Then, on a small time interval $I = (0,T)$ the scheme (OS) has a unique solution for $k = 1, \dots, K$ with $t_K < T$. The scheme is stable: the linear interpolant (u,h) of $(u^k, h^k)_k$ satisfies the estimate

$$\begin{aligned} &\|h\|_{L^\infty(I;H^{4+1/2}(S))} + \|h\|_{W^{1,\infty}(I;H^{2+1/2}(S))} \\ &\quad + \|u\|_{L^\infty(I;H^3(R))} + \|u\|_{W^{1,\infty}(I;H^1(R))} \le C. \end{aligned}$$

The number C and the time interval I depend only on the initial values (Θ_0, h_0). They are independent of the time-step size Δt.

COROLLARY 2.3. *Consider solutions $(u,X)_{\Delta t}$ as in Theorem* 2.2. *For a subsequence $\Delta t \to 0$ there holds*

$$(u,X)_{\Delta t} \longrightarrow (\tilde{u}, \tilde{X}) \qquad \text{for} \quad \Delta t \to 0 \tag{2.10}$$

in the norms of $L^2(I;H^2(R)) \cap H^1(I;L^2(R))$ and of $H^1(I;H^3(R))$. The limit function $(\Theta, X) := (\tilde{u} \circ \tilde{X}^{-1}, \tilde{X})$ is a strong solution of the physical problem (2.1)–(2.3).

Note that in the above results no smallness assumption is made on Θ_0; the velocity of the boundary can be large, and convective effects must be included in the scheme. On the other hand, we assume smallness of X^0. This is not a severe restriction, since one could parametrize all domains Ω^k over a reference domain that is close to Ω^0. Then smallness of X^0 is guaranteed.

A remark on implementations of the scheme. In the stability result we use the assumption that initially the height function is almost constant. This is done in order to simplify the proofs. It would be sufficient to have the initial domain close to a smooth reference domain (which is no restriction if the initial values are smooth).

Running the scheme is possible only for small times. This is because one of the following may happen: (1) The domain transformation onto the reference domain introduces large errors. (2) Using the linearization of the mean curvature operator about the initial values is no longer appropriate. (3) A geometric singularity makes a

smooth parametrization impossible. Note that this is possible also for the continuous equations.

The best we can expect of the discretization is to work well as long as there exist continuous solutions of the system, that is, until problem (3) appears. In general, our method will fail to work before that time, due to problem (1) or (2). In this case one may continue with a restart: choose a new smooth reference domain, calculate the new linearized mean curvature operator, and restart the scheme.

3. A Crank–Nicolson scheme on the reference domain. After a transformation of (2.1)–(2.3) onto the reference domain $R = S \times (0,1)$ the equations have a linearization of the form (3.1)–(3.3). This section is devoted to the study of these linear equations on the rectangle.

$$\partial_t u = \nabla \cdot A(t) \nabla u + f_0 \qquad \text{in } R, \tag{3.1}$$

$$\partial_t h = -a(t) \cdot \nabla u(.,1) + f_1 \qquad \text{on } S, \tag{3.2}$$

$$u(.,1) = -\underline{\Delta} h + f_2 \qquad \text{on } S. \tag{3.3}$$

We assume $a(t) = e_2 \cdot A(t)$ and $A(t) : R \to \mathbb{R}^{2\times 2}$. In the following we always impose without further mentioning the condition $u = \psi = 0$ (and $u^k = 0$) on the lower boundary $\{(x,y)|y = 0\}$. This also enables us to make use of the Poincaré inequality in what follows. A natural time discretization of (3.1)–(3.3) is the following Crank–Nicolson scheme.

DEFINITION 3.1. *We denote the following scheme by (CN). In every time step we define* $u^{k+1} : R \to \mathbb{R}$, $h^{k+1} : S \to \mathbb{R}$ *as the solution of*

$$\frac{u^{k+1} - u^k}{\Delta t} = \nabla \cdot A^k \nabla \frac{u^k + u^{k+1}}{2} + f_0^k \qquad \textit{in } R, \tag{3.4}$$

$$\frac{h^{k+1} - h^k}{\Delta t} = -a^k \cdot \nabla \left(\frac{u^k + u^{k+1}}{2} \right)(.,1) + f_1^k \qquad \textit{on } S, \tag{3.5}$$

$$u^{k+1}(.,1) = -\underline{\Delta} h^{k+1} + f_2^{k+1} \qquad \textit{on } S. \tag{3.6}$$

Notation. In the following we will denote the averages of solutions at intermediate points as $u^{k+1/2} := \frac{u^k + u^{k+1}}{2}$. The linear interpolant of the values (u^k, h^k) will always be denoted by (u,h), and linear interpolants of $f^k = (f_0^k, f_1^k, f_2^k)$ are denoted by $f = (f_0, f_1, f_2)$. We will once also use the linear interpolant of the values $u^{k+1/2}$; it will be denoted by $\bar{u}$.

In the scheme (CN) the matrices A^k will be uniformly close to the identity $I_2 \in \mathbb{R}^{2\times 2}$. Nevertheless, it will be of importance to use the coefficient matrices in (3.4) and the corresponding oblique derivatives in (3.5). Loosely speaking, we must avoid any error term f_1^k in (3.5). This statement is made precise in the subsequent lemma. The lemma gives a result on the resolvent problem corresponding to (3.1)–(3.3). It introduces function spaces that are natural for the problem.

LEMMA 3.2 (the resolvent problem in energy spaces). *Let* $A : R \to \mathbb{R}^{2\times 2}$ *be a field of uniformly elliptic and symmetric matrices. Then for* $\lambda > 0$ *the equations*

$$\lambda u - \nabla \cdot A \nabla u = g_0 \qquad \textit{in } R, \tag{3.7}$$

$$\lambda h + e_2 \cdot A \cdot \nabla u(.,1) = g_1 \qquad \textit{on } S, \tag{3.8}$$

$$u(.,1) + \Delta_x h = g_2 \qquad \textit{on } S, \tag{3.9}$$

together with $u(.,0) = 0$, have a unique solution (u,h). It satisfies the resolvent estimate

$$\begin{aligned}\lambda^2\|u\|_0^2 + \|\nabla\cdot A\nabla u\|_0^2 + \lambda^2\int_S |\partial_x h|^2 + \lambda\|h\|_{2+1/2}^2 \\ \leq C\,(\|g_0\|_0^2 + \|g_1\|_1^2 + \lambda^2\|g_2\|_{-1}^2 + \lambda\|g_2\|_{1/2}^2),\end{aligned} \tag{3.10}$$

with C independent of λ. Here $\|.\|_s$ denotes the norm of H^s.

Proof. To prove existence we assume $g_2 = 0$; this can be achieved by defining the new unknown to be $h - \Delta_x^{-1} g_2$. We find u as the minimizer of

$$\begin{aligned}E(u) := \lambda\int_R u^2 + \int_R A\nabla u\cdot\nabla u - \lambda\int_S \Delta_x^{-1}u(.,1)\cdot u(.,1) \\ - 2\int_R g_0\cdot u + 2\int_S g_1\cdot u(.,1)\end{aligned}$$

in $\{u \in H^1(R) | u(.,0) = 0, \int_S u(.,1) = 0\}$. Here the operator Δ_x^{-1} is defined by prescribing vanishing averages. With the function $\tilde{h} := \Delta_x^{-1}u(.,1)$ the pair $(u,\tilde{h})$ solves (3.7), (3.9) exactly and (3.8) up to a constant function. Defining $h(x) := \bar{h} + \tilde{h}(x)$ with an appropriate constant $\bar{h}$ we obtain a solution to (3.7)–(3.9).

To find the a priori estimate we multiply (3.7) with $\lambda u - \nabla\cdot A\nabla u$ and integrate over R. This yields

$$\lambda^2\int_R |u|^2 + \int_R |\nabla\cdot A\nabla u|^2 - 2\lambda\int_R u\,\nabla\cdot A\nabla u = \int_R (\lambda u - \nabla\cdot A\nabla u)g_0.$$

With another integration by parts we find

$$\begin{aligned}\lambda^2\int_R |u|^2 + \int_R |\nabla\cdot A\nabla u|^2 + 2\lambda\int_R \nabla u\cdot A\nabla u \\ + 2\lambda\int_S (g_2 - \Delta_x h)(\lambda h - g_1) = \int_R (\lambda u - \nabla\cdot A\nabla u)g_0.\end{aligned}$$

The third term is positive, and in the fourth term we perform an integration by parts over S. We find an estimate for the first three terms on the left-hand side of (3.10). The estimate for $\sqrt{\lambda}h \in H^{2+1/2}(S)$ then follows from regularity for (3.9). ∎

We read the above lemma as follows: the linearized problem has a good resolvent operator, and we can expect high regularity of solutions of the coupled problem. There are two restrictive points. In (3.10) an estimate of λg_2 is needed on the right-hand side. This means that in the time-dependent problem the time derivative of f_2 must be controlled. The second difficulty is the regularity property that is assumed for g_1. In particular, we cannot insert an error of the form "trace of a first derivative of u." This is the reason why we use the oblique derivatives in (3.5).

DEFINITION 3.3. *For a solution (u,h) we define the Banach space $Y := Y_u \times Y_h$ with*

$$\begin{aligned}Y_u &:= L^\infty(0,T;H^1(R)) \cap H^1(0,T;L^2(R)),\\ Y_h &:= L^\infty(0,T;H^{2+1/2}(S)) \cap H^1(0,T;H^1(S)).\end{aligned}$$

To control the right-hand side we define the Banach spaces

$$\begin{aligned}X_0 &:= L^2(0,T;L^2(R)),\\ X_1 &:= L^2(0,T;H^1(S)),\\ X_2 &:= L^\infty(0,T;H^{1/2}(S)) \cap H^1(0,T;H^{-1}(S)).\end{aligned}$$

Observe that the above are not the maximal regularity spaces of the continuous equations. For that we would expect additional estimates for $u \in L^2(I;H^2)$ and $h \in L^2(I;H^{3+1/2})$. However, the above Crank–Nicolson scheme will not provide such an estimate. It can provide it at best for the interpolant of the midpoints $\frac{1}{2}(u^k+u^{k+1})$.

LEMMA 3.4 (the scheme (CN) in energy spaces). *Assume that the coefficient matrices A^k in Definition* 3.1 *are symmetric and satisfy*

$$\sup_k \|A^k - I_2\|_{L^\infty(R)} + \sum_k \left\| \frac{A^{k+1}-A^k}{\Delta t} \right\|_{L^\infty(R)} \Delta t < \delta. \tag{3.11}$$

We consider initial values $u_0 \in H^1(R)$, $h_0 \in H^{2+1/2}(S)$. Let (3.6) *be satisfied for the initial values $(u^0,h^0) := (u_0,h_0)$; that is,* (3.6) *holds for $k=-1$. Given a right-hand side $(f^k)_k$ we will write estimates in terms of the linear interpolant $f : I \to L^2(R)^2 \times L^2(S) \times L^2(S)$. Let the time interval $I=(0,T)$ and $\delta > 0$ be small enough.*

Then for every $K \in \mathbb{N}$ with $K \cdot \Delta t \le T$ the linear scheme (CN) of Definition 3.1 *has a unique solution $(u^k,h^k)_{k=0,\dots,K}$. The linear interpolant (u,h) of $(u^k,h^k)_k$ satisfies the estimate*

$$\|(u,h)\|_Y \le C_1 \|u_0\|_{H^1(R)} + C_2 \ (\|f_0\|_{X_0} + \|f_1\|_{X_1} + \|f_2\|_{X_2}) \tag{3.12}$$

with C_1 and C_2 independent of Δt.

The estimate (3.12) *can be improved: on the right-hand side we can replace $\|f_2\|_{X_2}$ by $\|f_2\|_{H^1(0,T;H^{-1}(S))} + C_\star$, where $C_\star$ has the property that for some $C > 0$ every solution of* (3.6) *satisfies*

$$\|h^{k+1}\|_{H^{2+1/2}(S)} \le C_\star + C\|u^{k+1}\|_{H^1(R)}.$$

Proof. The proof of this lemma relies on a testing procedure; it is analogous to the proof of the resolvent estimate of Lemma 3.2. We multiply (3.4) with $-\nabla \cdot A^k \nabla(\frac{u^k+u^{k+1}}{2})$. An integration over R yields

$$\begin{aligned} &\int_R \nabla \frac{u^{k+1}-u^k}{\Delta t} \cdot A^k \nabla \frac{u^k+u^{k+1}}{2} + \left\| \nabla \cdot A^k \nabla \frac{u^k+u^{k+1}}{2} \right\|_{L^2(R)}^2 \\ &- \int_S a^k \cdot \nabla \left(\frac{u^k+u^{k+1}}{2} \right) \frac{u^{k+1}-u^k}{\Delta t} = - \int_R f_0^k \cdot \nabla \cdot A^k \nabla \frac{u^k+u^{k+1}}{2}. \end{aligned} \tag{3.13}$$

We use the symmetry of A^k to calculate for the first term

$$\begin{aligned} &\int_R \nabla \frac{u^{k+1}-u^k}{\Delta t} \cdot A^k \nabla \frac{u^k+u^{k+1}}{2} \\ &\quad = \frac{1}{2\Delta t} \int_R A^k \nabla u^{k+1} \cdot \nabla u^{k+1} - \frac{1}{2\Delta t} \int_R A^k \nabla u^k \cdot \nabla u^k. \end{aligned}$$

To evaluate the boundary integral we use (3.5) with index k and (3.6) with the indices k and $k+1$:

$$\begin{aligned} &\int_S a^k \cdot \nabla \left(\frac{u^k+u^{k+1}}{2} \right) \left(\frac{u^{k+1}-u^k}{\Delta t} \right) \\ &\quad = \int_S \left(\frac{h^{k+1}-h^k}{\Delta t} - f_1^k \right) \cdot \left(\underline{\Delta} \frac{h^{k+1}-h^k}{\Delta t} - \frac{f_2^{k+1}-f_2^k}{\Delta t} \right). \end{aligned}$$

Inserting this into (3.13) we find

$$\begin{aligned}
&\frac{1}{2\Delta t}\int_R A^{k+1}\nabla u^{k+1}\cdot\nabla u^{k+1} - \frac{1}{2\Delta t}\int_R A^k\nabla u^k\cdot\nabla u^k \\
&+ \left\|\nabla\cdot A^k\nabla\frac{u^k+u^{k+1}}{2}\right\|^2_{L^2(R)} - \int_S \frac{h^{k+1}-h^k}{\Delta t}\cdot\underline{\Delta}\frac{h^{k+1}-h^k}{\Delta t} \\
&= -\int_R f_0^k\cdot\nabla\cdot A^k\nabla\frac{u^k+u^{k+1}}{2} + \int_R \frac{A^{k+1}-A^k}{2\Delta t}\nabla u^{k+1}\cdot\nabla u^{k+1} \\
&- \int_S\left(\frac{h^{k+1}-h^k}{\Delta t} - f_1^k\right)\cdot\frac{f_2^{k+1}-f_2^k}{\Delta t} - \int_S f_1^k\cdot\underline{\Delta}\frac{h^{k+1}-h^k}{\Delta t}.
\end{aligned}$$

Multiplication with Δt and summing up over $k = 0,\dots,K-1$ we find

$$\begin{aligned}
&\int_R A^K\nabla u^K\cdot\nabla u^K + \sum_k\left\|\nabla\cdot A^k\nabla\frac{u^k+u^{k+1}}{2}\right\|^2_{L^2(R)}\Delta t \\
&+\sum_k\int_S\left|\partial_x\left(\frac{h^{k+1}-h^k}{\Delta t}\right)\right|^2\Delta t \;\le\; 2\|\nabla u^0\|^2_{L^2(R)} \\
&+2\sum_k\left\|\frac{A^{k+1}-A^k}{\Delta t}\right\|_{L^\infty(R)}\cdot\left\|\nabla u^{k+1}\right\|^2_{L^2(R)}\;\Delta t \\
&+C\sum_k\left\{\|f_0^k\|_0^2 + \int_S[|\partial_x f_1^k|^2 + |f_1^k|^2] + \left\|\frac{f_2^{k+1}-f_2^k}{\Delta t}\right\|^2_{-1}\right\}\Delta t.
\end{aligned} \tag{3.14}$$

For the linear interpolant (u,h) of the sequence (u^k,h^k) we find with (3.4) the estimate

$$\|u\|_{L^\infty(I;H^1(R))} + \|\partial_t u\|_{L^2(I;L^2(R))} + \|\partial_x\partial_t h\|_{L^2(I;L^2(S))} \le C. \tag{3.15}$$

It remains to prove spatial regularity properties of h. Since traces of u^k are bounded in the space $l^\infty(\{0,\dots,K\};H^{1/2}(S))$, (3.6) implies the regularity of h. The improved version of the estimate mimics this argument. □

The nonlinearity of the original problem requires the control of the domain in regular norms. Estimates of higher order can be derived by considering derivatives of solutions. They satisfy again equations of the type (3.4)–(3.6), and we can apply Lemma 3.4.

We introduce a notation. As before we write g for the linear interpolant of a set of functions $(g^k)_k$. We will write $\bar\partial_t g$ for the linear interpolant of the discrete time derivatives $\frac{g^k-g^{k-1}}{\Delta t}$. In this way we can use also time derivatives of $\bar\partial_t g$; they are piecewise constant functions with values $\frac{g^{k+1}-2g^k+g^{k-1}}{(\Delta t)^2}$. The function $\bar\partial_t g$ is defined on the time interval $(\Delta t, T)$, and all norms are calculated on that interval.

PROPOSITION 3.5 (the scheme (CN) with higher regularity). *Let the compatibility assumption, Assumption* 3.6, *on the initial values be satisfied. Assume that the coefficient matrices are symmetric and satisfy*

$$\begin{aligned} \sup_k \|A^k - I_2\|_{C^0(\bar{R})} &< \delta, \\ \sum_k \left\{ \|\nabla A^k\|^2_{H^2(R)} + \|\nabla A^k(.,1)\|^2_{H^2(S)} \right\} \Delta t &< \delta^2, \\ \sum_k \left\{ \left\| \frac{A^{k+1} - A^k}{\Delta t} \right\|^2_{H^1(R)\cap L^\infty(R)} + \left\| \frac{A^{k+1} - A^k}{\Delta t}(.,1) \right\|^2_{H^1(S)} \right\} \Delta t &< \delta^2. \end{aligned} \tag{3.16}$$

On the initial values we assume $\|h_0 - 1\|_{C^{0,1}(S)} < \delta$. *Let* $T > 0$ *and* $\delta > 0$ *be small enough and* $(u^k, h^k)_k$ *be a solution of scheme (CN). Then the linear interpolant* (u, h) *satisfies*

$$\begin{aligned} &\|\bar{\partial}_t(u,h)\|_Y + \|\partial_x^2(u,h)\|_Y \\ &\quad \le C_1 \left[\|\nabla \cdot A(0)\nabla u_0 + f_0(0)\|_{H^1(R)} + \|\partial_x^2 u_0\|_{H^1(R)} \right] \\ &\quad\quad + C_2 \left[\|\bar{\partial}_t f_0\|_{X_0} + \|\bar{\partial}_t f_1\|_{X_1} + \|\bar{\partial}_t f_2\|_{X_2} \right] \\ &\quad\quad + C_3 \left[\|\partial_x^2 f_0\|_{X_0} + \|\partial_x^2 f_1\|_{X_1} + \|\partial_x^2 f_2\|_{X_2} \right] \\ &\quad\quad + C_4\delta \left[\|f_0\|_{L^\infty(I;H^1(R))} + \|A\|_{L^\infty(I;H^2(R))} \right]. \end{aligned} \tag{3.17}$$

The linear interpolant $\bar{u}$ *of the midpoint values* $u^{k+1/2}$ *satisfies additionally the regularity estimate*

$$\|\bar{u}\|_{L^\infty(I;H^3(R))} \le C_5(c_0 + \|f_0\|_{L^\infty(I;H^1(R))} + \sup_k \|A^k\|_{H^2(R)}), \tag{3.18}$$

where c_0 *denotes the right-hand side of* (3.17).

Proof. The assumptions on A are stronger than those in Lemma 3.4. In particular, we know that a unique discrete solution exists on a small time interval and that it satisfies the estimate (3.12).

Part I. Time derivatives. We introduce discrete derivatives

$$\tilde{u}^k := \frac{u^k - u^{k-1}}{\Delta t}, \qquad \tilde{h}^k := \frac{h^k - h^{k-1}}{\Delta t} \tag{3.19}$$

for all $k = 1, \dots, K$. We now use the definition of (u^k, h^k) in (3.4)–(3.6). Taking the equations with index k and subtracting the equations with index $k-1$ yields for the new functions the following set of equations:

$$\begin{aligned} \frac{\tilde{u}^{k+1} - \tilde{u}^k}{\Delta t} &= \nabla \cdot A^k \nabla \frac{\tilde{u}^k + \tilde{u}^{k+1}}{2} + \frac{f_0^k - f_0^{k-1}}{\Delta t} \\ &\quad + \nabla \cdot \left(\frac{A^k - A^{k-1}}{\Delta t} \nabla \frac{u^{k-1} + u^k}{2} \right), \end{aligned} \tag{3.20}$$

$$\begin{aligned} \frac{\tilde{h}^{k+1} - \tilde{h}^k}{\Delta t} &= -a^k \cdot \nabla \left(\frac{\tilde{u}^k + \tilde{u}^{k+1}}{2} \right)(.,1) + \frac{f_1^k - f_1^{k-1}}{\Delta t} \\ &\quad - \frac{a^k - a^{k-1}}{\Delta t} \cdot \nabla \left(\frac{u^{k-1} + u^k}{2} \right)(.,1), \end{aligned} \tag{3.21}$$

$$\tilde{u}^{k+1}(.,1) = -\underline{\Delta}\tilde{h}^{k+1} + \frac{f_2^{k+1} - f_2^k}{\Delta t}. \tag{3.22}$$

We read these equations as follows: $(\tilde u^k, \tilde h^k)_{k=1,\dots,K}$ is a solution of the scheme (CN) of Definition 3.1 with initial values $(\tilde u^1, \tilde h^1)$. The right-hand side is

$$\begin{aligned}
\tilde f_0^k &:= \frac{f_0^k - f_0^{k-1}}{\Delta t} + \nabla \cdot \left(\frac{A^k - A^{k-1}}{\Delta t} \nabla \frac{u^k + u^{k-1}}{2} \right), \\
\tilde f_1^k &:= \frac{f_1^k - f_1^{k-1}}{\Delta t} - \frac{a^k - a^{k-1}}{\Delta t} \cdot \nabla \left(\frac{u^k + u^{k-1}}{2} \right) (.,1), \\
\tilde f_2^k &:= \frac{f_2^k - f_2^{k-1}}{\Delta t}
\end{aligned}$$

for $k = 1, \dots, K$. We next apply Lemma 3.4 on the sequence $(\tilde u^k, \tilde h^k)_k$. We recall the notation $(\tilde u, \tilde h)$ for the linear interpolant of $(\tilde u^k, \tilde h^k)_k$ and introduce $\tilde f_i$ for the linear interpolant of $(\tilde f_i^k)_k$. Note that the domain of definition is $(\Delta t, T)$; on this time interval we have by Lemma 3.4

$$\|(\tilde u, \tilde h)\|_Y \le c_0 \|\tilde u^1\|_{H^1(R)} + c_1 \left[\|\tilde f_0\|_{X_0} + \|\tilde f_1\|_{X_1} + \|\tilde f_2\|_{X_2} \right]. \tag{3.23}$$

The discrete time derivatives $\bar\partial_t f_i$ of f_i enter the bound (3.17) explicitly. It remains to estimate the contributions

$$\begin{aligned}
&\nabla \cdot \left(\frac{A^k - A^{k-1}}{\Delta t} \nabla \frac{u^k + u^{k-1}}{2} \right) \in X_0, \\
&\frac{a^k - a^{k-1}}{\Delta t} \cdot \nabla \left(\frac{u^k + u^{k-1}}{2} \right) (.,1) \in X_1.
\end{aligned}$$

We find $c > 0$ such that

$$\begin{aligned}
&\sum_k \left\| \nabla \cdot \left(\frac{A^k - A^{k-1}}{\Delta t} \nabla \frac{u^k + u^{k-1}}{2} \right) \right\|_{L^2(R)}^2 \Delta t \\
&\quad \le c \sum_k \left\| \frac{A^k - A^{k-1}}{\Delta t} \right\|_{H^1(R)}^2 \Delta t \cdot \sup_k \left\| \nabla \frac{u^k + u^{k-1}}{2} \right\|_{H^2(R)}^2, \\
&\sum_k \left\| \frac{a^k - a^{k-1}}{\Delta t} \cdot \nabla \left(\frac{u^k + u^{k-1}}{2} \right) (.,1) \right\|_{H^1(S)}^2 \Delta t \\
&\quad \le c \sum_k \left\| \frac{a^k - a^{k-1}}{\Delta t} (.,1) \right\|_{H^1(S)}^2 \Delta t \cdot \sup_k \left\| \nabla \frac{u^k + u^{k-1}}{2} (.,1) \right\|_{H^1(S)}^2.
\end{aligned}$$

With the assumptions on A and f_i Lemma 3.4 yields for $\bar\partial_t (u,h) = (\tilde u, \tilde h)$ the estimate

$$\|\bar\partial_t (u,h)\|_Y \le c_0 \, \|\tilde u^1\|_{H^1(R)} + c_1 \delta \, \sup_k \left\| \frac{u^k + u^{k-1}}{2} \right\|_{H^3(R)} + c_2, \tag{3.24}$$

where c_2 depends only on the norms of $\bar\partial_t f_i$.

In order to treat the second term on the right-hand side we now show estimate (3.18). This is done with the help of the original equation (3.4). The elliptic equation with the boundary condition (3.5) yields the estimate

$$\begin{aligned}
\left\| u^{k+1/2} \right\|_{H^3(R)} \le C \big(&\|f_0^k\|_{H^1(R)} + \|f_1^k\|_{H^{3/2}(S)} \\
&+ \|\bar\partial_t (u,h)\|_Y + \|A^k\|_{H^2(R)} \big).
\end{aligned}$$

Here the norm of f_1 is controlled by the right-hand side of (3.17). We have $\bar\partial_t f_1$ bounded in $L^2(0,T;H^1(S))$ and f_1 bounded in $L^2(0,T;H^3(S))$. An interpolation yields an estimate in $L^\infty(0,T;H^{3/2}(S))$ for f_1,

$$\sup_k \|f_1^k\|_{H^{3/2}(S)} \le C\left\{\|\partial_t f_1\|_{X_1} + \|\partial_x^2 f_1\|_{X_1}\right\}.$$

Equation (3.18) is shown.

We now insert (3.18) into estimate (3.24) and find with new constants c_0, c_1, and c_2,

$$\begin{aligned}\|\bar\partial_t(u,h)\|_Y \le c_0\ &\|\tilde u^1\|_{H^1(R)}\\ &+ c_1\delta\left(\|f_0\|_{L^\infty(I;H^1(R))} + \|A\|_{L^\infty(I;H^2(R))}\right) + c_2,\end{aligned} \tag{3.25}$$

where c_2 depends only on the norms of $\bar\partial_t f_i$.

Part II. Spatial derivatives. Estimate (3.25) does not suffice for the analysis of the nonlinear problem. Note that the best spatial estimate for the boundary so far is $h \in C^\alpha(I;H^{2+1/2})$. We next want to derive an estimate for $h \in L^\infty(I;H^{4+1/2}(S))$ to have good control of the regularity of the boundary. This estimate could be derived from an estimate for $u \in L^\infty(I;H^3(R))$. A similar estimate does appear in (3.18) but only for interpolants of $\frac12(u^k+u^{k+1})$ and not for interpolants of u^k. In order to derive the regularity estimate on h we perform an analysis of second spatial derivatives of the semidiscrete solution. While we used discrete derivatives in Part I we can now use classical derivatives. We introduce

$$\hat u^k := \partial_x^2 u^k, \qquad \hat h^k := \partial_x^2 h^k. \tag{3.26}$$

As in Part I we will use the fact that $(\hat u^k, \hat h^k)_k$ is a solution of scheme (CN) for an appropriate right-hand side. To be precise, $(\hat u^k, \hat h^k)_k$ satisfies (3.4)–(3.6) with $(f_0^k, f_1^k, f_2^k)_k$ replaced by $(\hat f_0^k, \hat f_1^k, \hat f_2^k)_k$, defined by

$$\begin{aligned}\hat f_0^k &:= \partial_x^2 f_0^k + \nabla\cdot\left(\left[\partial_x^2, A^k\right]\nabla\frac{u^k+u^{k+1}}{2}\right),\\ &\left[\partial_x^2, A^k\right]w = (\partial_x^2 A^k)w + 2(\partial_x A^k)\partial_x w \quad \forall w,\end{aligned} \tag{3.27}$$

$$\begin{aligned}\hat f_1^k &:= \partial_x^2 f_1^k - \left[\partial_x^2, a^k\right]\cdot\nabla\frac{u^k+u^{k+1}}{2},\\ &\left[\partial_x^2, a^k\right]\cdot w = (\partial_x^2 a^k)w + 2(\partial_x a^k)\partial_x w \quad \forall w,\end{aligned} \tag{3.28}$$

$$\begin{aligned}\hat f_2^k &:= \partial_x^2 f_2^k - \partial_x\left(\left[\partial_x^2, \gamma_0\right]\partial_x h^k\right),\\ &\left[\partial_x^2, \gamma_0\right]w = \left(\partial_x^2\gamma_0\right)w + 2\partial_x\gamma_0\partial_x w \quad \forall w,\end{aligned} \tag{3.29}$$

where we introduced the abbreviation

$$\gamma_0 = \frac{1}{\sqrt{1+|h_0'|^2}^3}.$$

We now use Lemma 3.4. With the notation $I_K = \{0,\dots,K\}$ and $\bar u^k := \frac{u^k+u^{k+1}}{2}$ we have to show estimates for

$$\begin{aligned}&\nabla\partial_x^2 A^k\cdot\nabla\bar u^k,\ \nabla\partial_x A^k\cdot\nabla\partial_x\bar u^k,\\ &\qquad\partial_x^2 A^k\cdot\Delta\bar u^k,\ \partial_x A^k\cdot\Delta\partial_x\bar u^k \in l^2(I_K;L^2(R)),\\ &\partial_x^2 a^k\cdot\nabla\bar u^k(.,1),\ \partial_x a^k\cdot\nabla\partial_x\bar u^k(.,1) \in l^2(I_K;H^1(S)),\end{aligned}$$

and additionally estimates in $l^2(I_K; H^{-1/2}(S))$ for the discrete time derivatives of the functions

$$\partial_x^4 h_0 \cdot \partial_x h^k,\ \partial_x^3 h_0 \cdot \partial_x^2 h^k,\ \partial_x^2 h_0 \cdot \partial_x^3 h^k.$$

On the functions of the last line we additionally have to give an estimate in $l^\infty(I_K; H^{1/2}(S))$ or we use the improved version of estimate (3.12). We use the latter and see from the original equation (3.6) for h^{k+1} that we can use $C_\star = C\|f_2^k\|_{H^{2+1/2}(S)} \leq C(\|\partial_x^2 f_2\|_{X_2} + \|\partial_t f_2\|_{X_2})$, where C depends only on $\|h_0\|_{H^{4+1/2}(S)}$. All the above error terms can be estimated by a small multiple of the solution norm in (3.17). While the other terms can be estimated directly, the most intricate term is the one containing second derivatives of the trace of derivatives of $\bar{u}^k$. It suffices to estimate for the interpolation

$$\partial_x^2 \nabla \bar{u}(.,1) \in L^2(I; L^2(S))$$

by the norms of u and f in (3.17). This estimate can be derived from (3.4) if we differentiate that equation twice with respect to x. We use $\partial_t \partial_x^2 u, \partial_x^2 f_0 \in L^2(I; L^2(R))$, and, for the boundary condition, $\partial_t \partial_x^2 h \in L^2(I; H^1(S))$. Elliptic theory yields $\partial_x^2 \bar{u} \in L^2(I; H^2(R))$ and therefore the result.

We can now apply Lemma 3.4 which yields the Y-estimates for $\partial_x^2(u,h)$. The compatibility condition ((3.6) is satisfied for $k=-1$) holds, since we took only second derivatives on both sides. Note that without the estimates of the time derivative we could not have derived the spatial estimates on $\bar{u}$ but only estimates on higher x-derivatives of u.

Part III. The first time step. It remains to control the first discrete time derivative $\tilde{u}^1 \in H^1(R)$ of (3.25) by the first term on the right-hand side of (3.17). This is done in the subsequent lemma which concludes the proof of the proposition. ∎

ASSUMPTION 3.6. *We assume that $A = A(0)$ is a Sym$(\mathbb{R}^2)$-valued function of class $H^3(R)$, sufficiently close to the identity in $L^\infty(R)$.*

The compatibility conditions for the discrete scheme read

$$u_0(.,1) = -\underline{\Delta} h_0 + f_2^0, \tag{3.30}$$

$$(\nabla \cdot A\nabla u_0 + f_0^0)(.,1) = \underline{\Delta}(a \cdot \nabla u_0(.,1) - f_1^0) + \frac{f_2^1 - f_2^0}{\Delta t}. \tag{3.31}$$

LEMMA 3.7. *Let Assumption 3.6 be satisfied. Then the solution (u^1, h^1) for the first time step in scheme (CN) satisfies*

$$\left\| \frac{u^1 - u^0}{\Delta t} \right\|_{H^1(R)} \leq C\ \|\nabla \cdot A\nabla u_0 + f_0\|_{H^1(R)} \tag{3.32}$$

with C independent of Δt.

Proof. We write $\underline{\Delta} = \partial_x(\gamma_0 \partial_x)$ with γ_0 close to 1 in $L^\infty(S)$. We use $a = e_2 \cdot A$ and study the operator

$$B : \begin{pmatrix} u \\ h \end{pmatrix} \mapsto \begin{pmatrix} \nabla \cdot A\nabla u \\ -a \cdot \nabla u(.,1) \end{pmatrix}$$

defined on

$$D(B) := \left\{ (u,h) \in X_0 | u \in H^2(R), u(.,1) = -\underline{\Delta} h, u(.,0) = 0 \right\},$$

a subset of the space

$$X_0 := \left\{ (u,h) | \int_0^1 h = 0 \right\} \subset X := L^2(R) \times H^1(S).$$

On X_0 we use the scalar product

$$\left\langle \begin{pmatrix} u \\ h \end{pmatrix}, \begin{pmatrix} \hat{u} \\ \hat{h} \end{pmatrix} \right\rangle := \int_R u \cdot \hat{u} + \int_S \gamma_0 \, \partial_x h \cdot \partial_x \hat{h}.$$

Then the operator B is densely defined in X_0, it has a compact inverse by Lemma 3.2, and it is symmetric. By the spectral theorem we find a complete set of eigenfunctions (σ^j, η^j) of B; that is,

$$\lambda_j \sigma^j - \nabla \cdot A \nabla \sigma^j = 0, \tag{3.33}$$

$$\lambda_j \eta^j + a \cdot \nabla \sigma^j(.,1) = 0, \tag{3.34}$$

$$\sigma^j(.,1) + \underline{\Delta} \eta^j = 0. \tag{3.35}$$

In order to have a basis (σ^j, η^j) of X (and not only on X_0) we extend the basis by eigenfunctions of the form $\sigma(x,y) = U(y)$, $h(x) = 1$.

The functions (σ^j, η^j) can be normalized such that

$$\int_R \sigma^j \cdot \sigma^l + \int_S \gamma_0 \, \partial_x \eta^j \partial_x \eta^l = \delta_{jl}. \tag{3.36}$$

Furthermore, one verifies that all eigenvalues are negative, and orthogonality also holds with the scalar product

$$\int_R A \nabla \sigma^j \cdot \nabla \sigma^l = -\lambda_j \delta_{jl}. \tag{3.37}$$

This scalar product defines a norm equivalent to the H^1-norm by the Poincaré inequality. We denote the Hilbert space corresponding to the product $(v,w) \mapsto \int_R Av \cdot w$ in the following by L^2_A. We next consider pairs $(u,h) = \sum_{j=1}^{\infty} c_j (\sigma^j, \eta^j)$. For $(u,h) \in D(B)$ we can conclude with $u_N := \sum_{j=1}^{N} c_j \sigma^j$ that $\|\nabla u_N\|_{L^2_A} \le \|\nabla u\|_{L^2_A}$ and

$$\left\| \nabla \sum_j^{\infty} c_j \sigma^j \right\|^2_{L^2_A(R)} = \sum_j^{\infty} |c_j|^2 \, |\lambda_j|. \tag{3.38}$$

In particular, if one side in this equality is finite, then the other is also finite.

We now expand the initial values and the right-hand side in terms of eigenfunctions and write

$$(u^0, h^0 - \underline{\Delta}^{-1} f_2^0) = \sum_j a_j (\sigma^j, \eta^j), \quad (u^1, h^1 - \underline{\Delta}^{-1} f_2^1) = \sum_j b_j (\sigma^j, \eta^j),$$

$$\left(f_0^0, f_1^0 - \underline{\Delta}^{-1} \frac{f_2^1 - f_2^0}{\Delta t} \right) = \sum_j d_j (\sigma^j, \eta^j).$$

Here $\underline{\Delta}^{-1}$ denotes any right inverse of $\underline{\Delta}$. Equations (3.4), (3.5) for the first time step translate into

$$\frac{b_j - a_j}{\Delta t} = \lambda_j \frac{b_j + a_j}{2} + d_j \qquad \forall j \in \mathbb{N}. \tag{3.39}$$

We find

$$b_j = \frac{1}{\frac{1}{\Delta t} - \frac{1}{2}\lambda_j} \left(a_j \left[\frac{1}{\Delta t} + \frac{1}{2}\lambda_j \right] + d_j \right).$$

Therefore

$$\frac{b_j - a_j}{\Delta t} = \frac{\lambda_j a_j + d_j}{1 - \frac{1}{2}\lambda_j \Delta t}. \tag{3.40}$$

We have to estimate the H^1-norm of the function $\sum_j \frac{b_j - a_j}{\Delta t}\sigma_j$ by the H^1-norm of the function $\sum_j (\lambda_j a_j + d_j)\sigma^j$. We use (3.38) for the following two pairs that are both in $D(B)$ by the compatibility assumption:

$$\left(u^1 - u^0, h^1 - h^0 - \underline{\Delta}^{-1}(f_2^1 - f_2^0)\right),$$

$$\left(\nabla \cdot A\nabla u_0 + f_0^0, -a \cdot \nabla u_0(., 1) + f_1^0 - \underline{\Delta}^{-1}\frac{f_2^1 - f_2^0}{\Delta t}\right).$$

We can calculate

$$\begin{aligned}
\left\| \nabla \sum_j \frac{b_j - a_j}{\Delta t}\sigma_j \right\|^2_{L^2_A(R)} &= \sum_j |\lambda_j| \left| \frac{b_j - a_j}{\Delta t} \right|^2 \\
&\leq \sum_j |\lambda_j| \, |\lambda_j a_j + d_j|^2 = \left\| \nabla \sum_j (\lambda_j a_j + d_j)\sigma_j \right\|^2_{L^2_A(R)} \\
&\leq C \|\nabla \cdot A\nabla u_0 + f_0^0\|^2_{H^1}.
\end{aligned}$$

This concludes the proof. ∎

4. A discretization of the transformed equations. We perform some elementary calculations for the transformation of (2.1)–(2.3) onto a reference domain. Our aim is to replace the temperature $\Theta(t) : \Omega_t \to \mathbb{R}$ by the new unknown $u(t) : R \to \mathbb{R}$. We denote the upper boundary of Ω by Γ and the upper boundary of R by $\Gamma_R = \{(x, 1) : x \in S\}$. Given a domain transformation $\Psi : \Omega \to R$ we use $u \circ \Psi = \Theta$ and, in the calculation below, also $v \circ \Psi = \varphi$. We define

$$B_{ij} := \nabla_j \Psi_i, \quad J := \det(B)^{-1}, \quad A := J \cdot B \cdot B^t. \tag{4.1}$$

We see that the equation

$$\int_\Omega \nabla\Theta \cdot \nabla\varphi + \int_\Omega f \circ \Psi\varphi - \int_\Gamma g \circ \Psi\varphi = 0 \qquad \forall \varphi \in C^1(\Omega)$$

transforms into

$$\begin{aligned}
&\int_R (B^t \cdot \nabla u) \cdot (B^t \cdot \nabla v) \; J + \int_R fv \; J \\
&\qquad - \int_{\Gamma_R} gv\sqrt{1 + |\partial_x h|^2} = 0 \qquad \forall v \in C^1(R).
\end{aligned}$$

We conclude that the equation

$$\Delta\Theta = f \circ \Psi \quad \text{in } \Omega, \quad n \cdot \nabla\Theta = g \circ \Psi \quad \text{on } \Gamma$$

transforms into

$$\nabla \cdot A\nabla u = J\ f \quad \text{in } R, \quad e_2 \cdot A\nabla u = g\sqrt{1+|h'|^2} \quad \text{on } \Gamma_R.$$

Therefore the physical equations (2.1)–(2.3) transform into

$$J\partial_t u + J\partial_t \Psi \cdot \nabla u = \nabla \cdot A\nabla u, \tag{4.2}$$

$$\partial_t h = -e_2 \cdot A\nabla u, \tag{4.3}$$

$$u|_h + \underline{\Delta} h = \underline{\Delta} h + \kappa(h). \tag{4.4}$$

The equations formally coincide with (3.1)–(3.3) if we set

$$f_0 := (1-J)\partial_t u - J\ (\partial_t \Psi) \cdot \nabla u, \tag{4.5}$$

$$f_1 := 0, \qquad f_2 := \underline{\Delta} h + \kappa(h). \tag{4.6}$$

We now want to choose a discretization of (4.2)–(4.4). The idea is to define matrices A^k as in (4.1) and to define f_i^k as in (4.5), (4.6). In order to proceed we have to define domain transformations $\Psi^k : \Omega^k \to R$ that we can insert in (4.1). We define Ψ^k as the inverse of functions $X^k : R \to \Omega^k$ with

$$X^{k+1}(x,y) - X^k(x,y) = \frac{X_2^k(x,y)}{h^k(x)}(h^{k+1}(x) - h^k(x))e_2.$$

We choose an initial parametrization X^0 as in Theorem 2.2.

To discretize formula (4.5) we have to discretize $\partial_t \Psi$. Since the definition of X is consistent with the continuous equation

$$\partial_t \Psi^{-1}(t,x,y) = \frac{(\Psi^{-1})_2(x,y)}{h(x)}\ \partial_t h(t,x)\ e_2,$$

we find from $\partial_t(\Psi \circ \Psi^{-1}) = 0$ the continuous equation

$$\partial_t \Psi(t,\xi,\zeta) = -\partial_\zeta \Psi \cdot \frac{\zeta}{h}\partial_t h(t,\xi).$$

Because of $J = (\partial_\zeta \Psi_2)^{-1}$ the right-hand side of the discrete scheme can be defined consistently by

$$\begin{aligned} f_0^k &:= (1-J^k)\frac{u^{k+1}-u^k}{\Delta t} + \frac{X_2^k}{h^k}\ \frac{h^k - h^{k-1}}{\Delta t}\partial_y \frac{u^k + u^{k+1}}{2}, \\ f_1^k &:= 0, \qquad f_2^{k+1} := \underline{\Delta} h^k + \kappa(h^k). \end{aligned} \tag{4.7}$$

In the definition of f_0^0, the first time step, we insert the formal time derivative of h instead of $\frac{h^0 - h^{-1}}{\Delta t}$, and we use u_0 instead of $\frac{u^0+u^1}{2}$. To have f_2 defined on the whole time interval we set $f_2^0 = \underline{\Delta} h_0 + \kappa(h_0) \equiv f_2^1$. This defines a discrete scheme that is consistent with (4.2)–(4.4). Note that in the above definition f_0^k depends on u^{k+1}.

An assumption concerning the compatibility of the initial values will be needed. This is not an artifact of the discretization—the same is true for the continuous

equations. Let (u,h) be a classical solution such that $\partial_t(u,h)$ is continuous in $t=0$. We conclude that the formal time derivative $\tilde{\partial}_t(u,h)$ defined by (4.2) and (4.3) must satisfy on the boundary the time derivative of (4.4). We will therefore use later on the following assumption.

ASSUMPTION 4.1. *We say that the compatibility conditions for the continuous equations are satisfied if for $u_0 \in H^3(R)$ the formal time derivative $\tilde{\partial}_t u_0$ is in $H^1(R)$ and*

$$u_0(.,1) - \kappa(h_0) = 0, \tag{4.8}$$

$$\tilde{\partial}_t u_0(.,1) + \underline{\Delta}\tilde{\partial}_t h_0 = 0. \tag{4.9}$$

THEOREM 4.2. *Let the initial values (u_0,h_0) satisfy the compatibility condition of Assumption 4.1 and let $h_0 - 1$ be small in $C^{0,1}(S)$. We consider scheme (CN) with f_i^k as in (4.7) and A^k defined by (4.1).*

Then there exists $T > 0$ such that the scheme (CN) has a unique solution $(u^k,h^k)_k$. The linear interpolants (u,h) of $(u^k,h^k)_k$ and $\bar{u}$ of $\frac{1}{2}(u^k+u^{k+1})$ satisfy the estimate

$$\|\bar{\partial}_t(u,h)\|_Y + \|\partial_x^2(u,h)\|_Y + \|\bar{u}\|_{L^\infty(I;H^3(R))} \le C, \tag{4.10}$$

where C and T depend only on the norm of the initial values and are independent of Δt.

Proof. The proof is given in three parts (A)–(C). Part (A) is concerned with the initial values and their compatibility. In part (B) the crucial estimates on solutions are derived with the help of Proposition 3.5 on the scheme (CN) with a fixed right-hand side. In part (C) we show the existence of a bounded solution.

(A) Compatibility of initial values. We want to use Proposition 3.5. In order to do so, we have to guarantee that the compatibility assumption, Assumption 3.6, is satisfied. By definition of f_2^0, (3.30) holds. Concerning (3.31) we observe that $f_2^1 - f_2^0 = 0$. In the above scheme the time derivative $\frac{u^1-u^0}{\Delta t}$ appears in f_0^0. This in general changes the compatibility condition for the scheme. However, our construction imposed $J^0 = 1$ on the upper boundary and therefore

$$f_0^0(.,1) = -\tilde{\partial}_t h(0)\ \partial_y u^0(.,1).$$

Then the discrete compatibility assumption (3.31) coincides with the continuous version (4.9).

(B) Improvement of a priori bounds. This part of the proof is based on estimate (3.17). We use the constant C_1 and the first term of the right-hand side of that estimate and define

$$C_0 := 2C_1\left[\|\nabla\cdot A(0)\nabla u_0 + f_0(0)\|_{H^1(R)} + \|\partial_x^2 u_0\|_{H^1(R)}\right].$$

We will show that given $\delta > 0$ we can choose a small $T > 0$ and a small a priori bound for $\|h_0 - 1\|_{C^{0,1}(S)}$ such that for every solution (u,h)

$$\begin{aligned} &\|\bar{\partial}_t(u,h)\|_Y + \|\partial_x^2(u,h)\|_Y \le 2C_0 \\ \Rightarrow &\|\bar{\partial}_t(u,h)\|_Y + \|\partial_x^2(u,h)\|_Y \le C_0. \end{aligned} \tag{4.11}$$

This is shown in four steps. With a constant C independent of δ and T there holds the following:

1. $\bar{u} \in L^\infty(I;H^2(R))$ is bounded by C.
2. The coefficients A^k defined by (4.1) satisfy $(3.16)_\delta$.

3. The norms of $\bar{\partial}_t f$ and of $\partial_x^2 f$ on the right-hand side of (3.17) are bounded by $C\delta$.
4. The norms of $f_0 \in L^\infty(I; H^1(R))$ and of $A \in L^\infty(I; H^2(R))$ are bounded by C.

Once we have shown 1–4, we can choose a new $\delta > 0$ and $T > 0$ and use Proposition 3.5 to obtain the implication (4.11).

Now consider a solution (u, h) with the bound $2C_0$ as in (4.11).

1. Regularity of $\bar{u}$. The function f_0 is bounded in $L^\infty(I; L^2(R))$ (see below). We use the elliptic equation (3.4) for $u^{k+1/2}$:

$$\nabla \cdot A^k \nabla u^{k+1/2} = \frac{u^{k+1} - u^k}{\Delta t} - f_0^k \in L^2(R).$$

The boundary condition (3.5) is smooth enough to imply the desired estimate for $\sup_k \|u^{k+1/2}\|_{H^2(R)}$.

2. Estimates for A. By an interpolation we see that for some $\alpha > 0$ the function h is also bounded as

$$h \in C^\alpha(I; H^4(S)).$$

Then the matrix $B = \nabla\Psi$ satisfies

$$B \in C^\alpha(I; H^3(R)), \qquad B(.,1) \in C^\alpha(I; H^3(S)).$$

Since $H^3(R)$ is an algebra (see, e.g., [2]), the matrix A satisfies estimates in the same spaces. Choosing T small we immediately infer the first two lines in (3.16).

In order to verify the third line we again use an interpolation: with $p > 2$ we find an estimate for

$$\partial_t h \in L^p(I; H^3(S)).$$

This implies an estimate for

$$\partial_t B \in L^p(I; H^2(R)).$$

Again, $\partial_t A$ satisfies estimates in the same space. If necessary we choose a smaller T in order to infer the third line in (3.16).

We turn to the estimates for f_i. The function f_1 vanishes identically, and all estimates are trivial.

3. and 4. Estimates for f_0. We first consider the term $(1 - J)\partial_t u$. The factor $(1 - J)$ is small in $L^\infty(I; L^\infty(R))$ by smallness of h_0 in $C^{0,1}(S)$. We use

$$\begin{aligned}
&\partial_t u \in Y_u \Rightarrow \partial_t^2 u \in L^2L^2 \Rightarrow \partial_t[(1 - J)\partial_t u] \in L^2L^2,\\
&\partial_x^2 u \in Y_u \Rightarrow \partial_t\partial_x^2 u \in L^2L^2 \Rightarrow \partial_x^2[(1 - J)\partial_t u] \in L^2L^2,\\
&\partial_t u \in Y_u \Rightarrow \partial_t u \in L^\infty H^1 \Rightarrow [(1 - J)\partial_t u] \in L^\infty H^1.
\end{aligned}$$

These implications together with their corresponding estimates give the desired estimate for the first term in f_0. Note that the smallness of, e.g., $\partial_t[(1 - J)\partial_t u] = (1 - J)\partial_t^2 u - \partial_t J\partial_t u$ follows for the first term by smallness of $1 - J$, for the second term by a compactness argument: $\partial_t J \in L^\infty H^{3/2}$ and $\partial_t u \in L^\infty H^1$ imply (for small T) smallness of the second term in L^2L^2. The estimate of $(1 - J)\partial_t^2 u$ is the only place where we use the smallness of h_0.

The other term of f_0 has the regularity properties of $\tilde\partial_t\Psi\cdot\nabla\bar u$. We use step 1 with the estimate for $\bar u\in L^\infty H^2$. It yields

$$\tilde\partial_t\Psi\in L^\infty(I;H^{2+1/2}(R)),\quad \nabla\bar u\in L^\infty(I;H^1(R)),$$

and we find the estimate for $f_0\in L^\infty(I;H^1(R))$. The estimates for $\partial_t f_0$ and $\partial_x^2 f_0$ are direct. Smallness of the $L^2(I)$-norms follows by the compactness argument.

Estimates for f_2. Concerning f_2 we have to take special care of the first time step. However, let us first consider f_2 as defined by $f_2^1,\dots,f_2^K$: the functions f_2^k are composed from first and second derivatives of h. Remember that the operator $-\underline\Delta h$ is the linearization of the mean curvature $\kappa(h)$ in $h=h_0$. By the $2C_0$-bound of (4.11) we can estimate the differences $\partial_x h-\partial_x h_0$ pointwise by a small number (depending on T). Then f_2 has the form $f_2=-\kappa(h)-\underline\Delta h=G(\partial_x h,\partial_x h_0)\cdot(1,\partial_x^2 h)$ with $G(0,0)=0$ and G differentiable. We find the estimate

$$\|f_2\|\le C\,\varepsilon\,\|h\|,$$

where the norms are those of (3.17) and of (4.11), and ε is arbitrarily small for T small.

Let us now consider the first time step. $f_2^0\in H^{2+1/2}(S)$ by Assumption 4.1. There holds $f_2^1-f_2^0=0$, and we find the estimate for the first discrete time derivative of f_2. The second discrete time derivative is

$$\bar\partial_t^2 f_2(0):=\frac{f_2^2-2f_2^1+f_2^0}{(\Delta t)^2}=\frac{f_2^2-f_2^1}{(\Delta t)^2}=\frac{\kappa(h^1)+\underline\Delta h^1-\kappa(h^0)-\underline\Delta h^0}{(\Delta t)^2}.$$

We introduce $T[\partial_x h]:=\frac{\partial_x h}{\sqrt{1+|\partial_x h|^2}}$ to write

$$\bar\partial_t^2 f_2(0)=-\frac{1}{(\Delta t)^2}\partial_x\left(T[\partial_x h^1]-T[\partial_x h^0]-T'[\partial_x h^0]\cdot\partial_x(h^1-h^0)\right).$$

We find

$$\|\bar\partial_t^2 f_2(0)\|_{H^{-1}(S)}\le C\left\|\frac{\partial_x(h^1-h^0)}{\Delta t}\right\|^2_{L^\infty(S)}\le C\left\|\frac{u^1-u^0}{\Delta t}\right\|^2_{H^1(R)}.$$

(C) Existence of a solution—the continuity argument. Note that a time step of scheme (CN) with f as in (4.7) is still a linear equation for (u^{k+1},h^{k+1}). We see that the single time step can always be solved as long as $1-J^k$ and $\frac{X_2^k}{h^k}$ $\frac{h^k-h^{k-1}}{\Delta t}$ are small in L^∞. Still, it could happen that on the time interval $(0,t^k)$ the solution has norm less than C_0 and on the time interval $(0,t^{k+1})$ the solution has a norm larger than $2C_0$. We will show that this cannot happen.

We connect the initial values (u_0,h_0) with a continuous path $(u_\lambda,h_\lambda)_{\lambda\in[0,1]}$ with the trivial initial values $(u_1,h_1)=0$. This can be done in such a way that (u_λ,h_λ) satisfies the compatibility condition for all $\lambda\in[0,1]$. If scheme (CN) with f as in (4.7) and with initial values (u_λ,h_λ) has a solution on $I=(0,T)$ we denote this solution by (u^λ,h^λ). This family of solutions has the following two properties.

1. Every weak limit $\lim_{\lambda\to\lambda_0}(u^\lambda,h^\lambda)$ in the topology of (4.11) of bounded solutions is again a bounded solution. This follows immediately, since we can take the limit in all equations.

2. If $(u^{\lambda_0}, h^{\lambda_0})$ is a solution, bounded by C_0, then also in a neighborhood $(\lambda_0 - \varepsilon, \lambda_0 + \varepsilon)$ of λ_0 there exist solutions that are bounded by C_0. This follows because we deal with a fixed (finite) number of time steps. The norm of the solution depends continuously on λ. In general the norm might exceed the value C_0, but we can achieve that it does not exceed $2C_0$. Now property (4.11) ensures that the norm remains bounded by C_0.

We combine the above facts 1 and 2 to conclude. The set

$$\{\lambda \in [0,1] | \text{ a solution } (u,h)_\lambda \text{ exists and } \|(u,h)_\lambda\| \le C_0\}$$

is a nonempty ($\lambda = 1$ is in the set), closed (by property 1), and open (by property 2) subset of $[0,1]$. Therefore $\lambda = 0$ is in the above set, and therefore a solution (u^0, h^0) to initial values (u_0, h_0) exists and satisfies the estimate. This concludes the proof of the theorem. ∎

COROLLARY 4.3. *Let h_0, u_0, and $T > 0$ as in the last theorem. Then, for a subsequence $\Delta t \to 0$, the solutions (u^k, h^k) converge to solutions of (4.2)–(4.4). In particular, (2.1)–(2.3) with compatible initial conditions possess a solution on a short-time interval.*

Proof. By the above theorem the solutions $(u,h)_{\Delta t}$ of the discrete problems are uniformly bounded. Therefore there exists a subsequence with a weak limit (u,h). The convergence is strong for $u \in L^2(I; H^2(R)) \cap H^1(I; L^2(R))$ and for $h \in L^2(I; H^5(R)) \cap H^1(I; H^3(R))$. Because of consistency in the definition of A and f we can conclude that (u,h) is a strong solution to the transformed equations (4.2)–(4.4). The transformed solution (Θ, h) is a solution of the original problem. ∎

5. Proof of Theorem 2.2. Theorem 4.2 yields a stable discretization of the original equations. The drawback for a use as a numerical scheme is the need to transform all equations onto a fixed domain. It is more natural to use the operator splitting scheme (OS). We will prove in this section the stability of scheme (OS) as it was stated in Theorem 2.2. The proof uses a transformation of the discrete scheme onto a fixed domain. It will turn out that scheme (OS) is in fact identical to the scheme (CN) of section 4.

ASSUMPTION 5.1. *Let n be the normal vector of the initial domain given by h_0. We introduce the formal time derivatives in $t = 0$ by*

$$\begin{aligned} \tilde{\partial}_t \Theta|_{t=0} &:= \Delta \Theta_0, \\ \tilde{\partial}_t h|_{t=0} &:= -n_2^{-1} \, (n \cdot \nabla \Theta_0) \circ H_0. \end{aligned}$$

We impose on the initial values the regularity $\tilde{\partial}_t \Theta|_{t=0} \in H^1(\Omega_0)$ and the compatibility conditions

$$\begin{aligned} \Theta \circ H_0 &= \kappa(h_0), \\ \tilde{\partial}_t \Theta|_{t=0}(x, h_0(x)) + \partial_2 \Theta_0(x, h_0(x)) \cdot \tilde{\partial}_t h|_{t=0}(x) &= D\kappa(h_0) \tilde{\partial}_t h|_{t=0}(x). \end{aligned}$$

Proof of Theorem 2.2. We introduce the following functions:

$$\begin{aligned} u^k &:= \Theta^k \circ X^k : R \to \mathbb{R}, \\ \bar{v}^k &:= v^k \circ X^k : R \to \{0\} \times \mathbb{R} \subset \mathbb{R}^2, \\ \tilde{u}^k &:= \tilde{\Theta}^k \circ X^k. \end{aligned}$$

We now interpret scheme (OS) as a scheme for (u^k, h^k). Step 3 of (OS) reads in the new notation

$$\tilde{u}^k = u^{k+1}.$$

We use this identity to write the equations of Step 2 in terms of u^{k+1}. We use the transformation of section 4 with corresponding B^k, A^k, J^k.

$$J^k \ \frac{u^{k+1}-u^k}{\Delta t} = \nabla \cdot \left(A^k \nabla \frac{u^k+u^{k+1}}{2} \right) + J^k \ \bar{v}^k \cdot (B^k)^t \cdot \nabla \frac{u^k+u^{k+1}}{2} \qquad \text{in } R, \tag{5.1}$$

$$\frac{h^{k+1}-h^k}{\Delta t} = -e_2 \cdot A^k \cdot \nabla \frac{u^k+u^{k+1}}{2}(.,1) \qquad \text{in } [0,1], \tag{5.2}$$

$$u^{k+1}(.,1) + \underline{\Delta} h^{k+1} = \kappa(h^k) + \underline{\Delta} h^k \qquad \text{in } [0,1]. \tag{5.3}$$

This is nothing but scheme (CN) with the right-hand side

$$f_0^k := (1-J^k) \ \frac{u^{k+1}-u^k}{\Delta t} - J^k \ \bar{v}^k \cdot (B^k)^t \cdot \nabla \frac{u^k+u^{k+1}}{2},$$
$$f_1^k := 0, \qquad f_2^{k+1} := \kappa(h^k) + \underline{\Delta} h^k,$$

where in the definition of f_0^0 the convective term is calculated explicitly. The scheme is identical to that of section 4, since

$$J^k \ e_2 \cdot (B^k)^t = e_2 \quad \text{and} \quad \bar{v}^k(x,y) = \frac{X_2^k(x,y)}{h^k(x)} \ \frac{h^k(x)-h^{k-1}(x)}{\Delta t} e_2.$$

Theorem 2.2 is a consequence of Theorem 4.2. □

Corollary 2.3 follows from the theorem just as Corollary 4.3 followed from Theorem 4.2. Let us demonstrate without referring to section 4 that the scheme is consistent. From (2.9) and (2.5) we conclude

$$\Theta^{k+1} \circ X^{k+1} - \Theta^k \circ X^k = \left(\Delta \frac{\Theta^k + \tilde{\Theta}^k}{2} \right) \circ X^k + \left(v \cdot \nabla \frac{\Theta^k + \tilde{\Theta}^k}{2} \right) \circ X^k.$$

In the limit $\Delta t \to 0$ we infer

$$\partial_t (\Theta \circ X) = (\Delta \Theta) \circ X + (v \cdot \nabla \Theta) \circ X.$$

This yields the original equation (2.1), since by definition of v in (2.4)

$$\nabla \Theta \cdot \partial_t X(x,y) = \nabla \Theta \cdot \left(\frac{X_2(x,y)}{h(x)} \partial_t h \right) \ e_2 = v \cdot \nabla \Theta.$$

AN ADAPTIVE UZAWA FEM FOR THE STOKES PROBLEM: CONVERGENCE WITHOUT THE INF-SUP CONDITION*

EBERHARD BÄNSCH†, PEDRO MORIN‡, AND RICARDO H. NOCHETTO§

Abstract. We introduce and study an adaptive finite element method (FEM) for the Stokes system based on an Uzawa outer iteration to update the pressure and an elliptic adaptive inner iteration for velocity. We show linear convergence in terms of the outer iteration counter for the pairs of spaces consisting of continuous finite elements of degree k for velocity, whereas for pressure the elements can be either discontinuous of degree $k-1$ or continuous of degree $k-1$ and k. The popular Taylor–Hood family is the sole example of stable elements included in the theory, which in turn relies on the stability of the continuous problem and thus makes no use of the discrete inf-sup condition. We discuss the realization and complexity of the elliptic adaptive inner solver and provide consistent computational evidence that the resulting meshes are quasi-optimal.

Key words. a posteriori error estimators, adaptive mesh refinement, convergence, data oscillation, performance, quasi-optimal meshes

1. Introduction.

Adaptive finite element methods (FEM) have become essential tools in science and engineering for the numerical solution of multiscale phenomena governed by partial differential equations (PDE). We refer to [1, 20] for references on adaptivity and restrict the list of papers to those strictly related to our work.

Computational experience strongly suggests that, starting from a coarse mesh, adaptive algorithms converge within any prescribed tolerance in a finite number of steps, but their convergence for general—even linear—problems is largely an open question. This issue has been recently tackled for *elliptic* problems, in the multidimensional setting, by Morin, Nochetto, and Siebert [15, 16], exploiting an idea of Dörfler [11]. In [11, 15, 16], the fact that the elliptic operator is *positive definite* (or *coercive*) plays a fundamental role.

In this article we devise an adaptive finite element algorithm for the Stokes problem and prove its convergence. The essential difference with elliptic problems is that the Stokes operator is *not* positive definite but rather leads to a saddle-point problem. The role of coercivity is thus played by the weaker condition of sole invertibility given by the inf-sup condition (1.2) below.

To be more specific, let Ω be a polygonal (polyhedral) domain in $\mathbb{R}^d$ for $d \geq 2$, and let $\mathbb{V} = \left(\mathring{H}^1(\Omega)\right)^d$ be the usual Sobolev space of vector-valued square integrable functions, having also square integrable first derivatives whose trace vanishes on $\partial\Omega$. Let $\mathbb{P} := \mathring{L}^2(\Omega)$ be the space of square integrable functions with mean value zero. Then, the weak form of the Stokes problem in its primitive variables reads as follows: Find a pair $(\mathbf{u}, p) \in \mathbb{V} \times \mathbb{P}$ such that for all $(\mathbf{v}, q) \in \mathbb{V} \times \mathbb{P}$,

$$\int_\Omega \nabla \mathbf{u} : \nabla \mathbf{v} - \int_\Omega p \, \operatorname{div} \mathbf{v} = \int_\Omega \mathbf{f} \cdot \mathbf{v} \quad \text{and} \quad \int_\Omega q \, \operatorname{div} \mathbf{u} = 0, \tag{1.1}$$

where throughout this paper we assume $\mathbf{f} \in \left(L^2(\Omega)\right)^d$. To avoid confusion, vector-valued functions will always be denoted with boldface characters.

The existence and uniqueness of solutions to (1.1) are equivalent to the so-called inf-sup condition,

$$\inf_{q \in \mathbb{P}} \sup_{\mathbf{v} \in \mathbb{V}} \frac{\int_\Omega q \, \operatorname{div} \mathbf{v}}{\|q\| \, \|\nabla \mathbf{v}\|} > 0, \tag{1.2}$$

which holds for the pair $(\mathbb{V}, \mathbb{P})$ as defined above [3]. Hereafter, $\|\cdot\| = \|\cdot\|_\Omega$, and for any domain G, $\|w\|_G = (\int_G |w|^2)^{1/2}$ denotes the usual $L^2(G)$-norm for scalar- as well as vector- and matrix-valued functions on G.

The classical approach to solving the Stokes equations with finite elements is the following. Let $\mathcal{T}_h$ be a triangulation of Ω, and let $\mathbb{V}_h \subset \mathbb{V}$, $\mathbb{P}_h \subset \mathbb{P}$ be finite element spaces defined on $\mathcal{T}_h$. Find a pair $(\mathbf{U}_h, P_h) \in \mathbb{V}_h \times \mathbb{P}_h$ such that

$$\int_\Omega \nabla \mathbf{U}_h : \nabla \mathbf{V}_h - \int_\Omega P_h \, \operatorname{div} \mathbf{V}_h = \int_\Omega \mathbf{f} \cdot \mathbf{V}_h \quad \forall \, \mathbf{V}_h \in \mathbb{V}_h, \tag{1.3}$$

$$\int_\Omega Q_h \, \operatorname{div} \mathbf{U}_h = 0 \quad \forall \, Q_h \in \mathbb{P}_h; \tag{1.4}$$

discrete functions will always be written in capitals. Again, this discrete problem admits a unique solution if and only if the discrete inf-sup condition

$$\inf_{Q_h \in \mathbb{P}_h} \sup_{\mathbf{V}_h \in \mathbb{V}_h} \frac{\int_\Omega Q_h \, \operatorname{div} \mathbf{V}_h}{\|Q_h\| \, \|\nabla \mathbf{V}_h\|} \geq \kappa > 0 \tag{1.5}$$

holds. Moreover, the following *optimal a priori bound* holds:

$$\|\nabla(\mathbf{u} - \mathbf{U}_h)\| + \|p - P_h\| \leq C_\kappa \left(\inf_{\mathbf{V}_h \in \mathbb{V}_h} \|\nabla(\mathbf{u} - \mathbf{V}_h)\| + \inf_{Q_h \in \mathbb{P}_h} \|p - Q_h\| \right), \tag{1.6}$$

where C_κ is a positive constant depending only on κ [3]. When a pair of finite element spaces $(\mathbb{V}_h, \mathbb{P}_h)$ satisfies (1.5), with κ independent of h, the method is called *stable*.

In this article, exploiting an idea introduced in [8] in the context of wavelet approximations to the Stokes problem, we propose and analyze an adaptive FEM for the solution of the Stokes problem. This algorithm consists of an inexact Uzawa iteration at an infinite-dimensional level, and the inner solve is based upon a convergent adaptive FEM for elliptic problems. Amazingly, the *convergence of our adaptive Uzawa algorithm (AUA) does not need the discrete* inf-sup *condition* (1.5) *but rather the continuous* inf-sup *condition* (1.2). This allows for unstable pairs $(\mathbb{V}_h, \mathbb{P}_h)$.

In section 2 we will precisely state the algorithm and prove its convergence for the pairs of spaces consisting of continuous finite elements of degree k for velocity,

whereas for pressure the elements can be either discontinuous of degree $k-1$ or continuous of degree $k-1$ and k. These elements are all *unstable*, except for the Taylor–Hood elements, which consist of continuous elements of degree k for velocity and degree $k-1$ for pressure. We stress that adaptivity is an inherently *nonlinear* process, which appears to detect and exploit the stability of the underlying PDE, namely (1.2), regardless of the finite element spaces. This is perhaps the most salient consequence of our work, which reproduces in the finite element setting the crucial observation made in [7, 8] for wavelets.

This may seem to contradict the celebrated theory of mixed methods [3]. However, it is important to realize that the jth iterate $(\mathbf{U}_j, P_j)$ of our algorithm is not necessarily a solution of the discrete Stokes problem (1.3)–(1.4); it is just an *approximate* solution. Therefore our notion of convergence is fundamentally different from the customary one arising from a priori error analysis in which (1.5) plays a central role and asymptotics is understood in the sense that the meshsize h_j of partition $\mathcal{T}_j$ satisfies $h_j \to 0$: we think of $j \to \infty$ rather than $h_j \to 0$. Depending on the flatness of $\mathbf{u}$ and p, our algorithm may yield convergence even for h_j not tending to zero globally.

Although our theory covers only the class of elements mentioned above and described more specifically in (2.5) and (2.6), extensive computations show convergence for other combinations of elements. Moreover, the computational rate of convergence in terms of degrees of freedom is always optimal. This will be discussed in detail in section 3.

The rest of the article is organized as follows. In section 2 we introduce the AUA and prove its convergence. In section 3 we present numerical evidence showing that the meshes obtained through the AUA are quasi-optimal for any pair of finite element spaces. In section 4 we discuss a posteriori error estimates specially designed for the inexact Uzawa iteration, which are used to stop the outer iterations. Finally, we investigate the properties and complexity of the elliptic inner solver ELLIPTIC in section 5.

In what follows, unless specified otherwise, C will represent a positive constant, possibly depending on mesh-regularity, and the refinements will be done using bisection [2, 19], thus ensuring mesh-regularity.

2. The AUA. We start this section by describing the *exact* Uzawa algorithm in infinite dimensions as an iteration to solve (1.1). Given $p_0 \in \mathbb{P}$, we seek, for $j \geq 1$,

$$
\begin{aligned}
&\mathbf{u}_j \in \mathbb{V}: \qquad \int_\Omega \nabla \mathbf{u}_j : \nabla \mathbf{v} = \int_\Omega \mathbf{f}\cdot\mathbf{v} + \int_\Omega p_{j-1}\ \mathrm{div}\,\mathbf{v} \quad \forall \mathbf{v} \in \mathbb{V},\\
&p_j \in \mathbb{P}: \qquad \int_\Omega p_j q = \int_\Omega p_{j-1} q - \alpha \int_\Omega q\ \mathrm{div}\,\mathbf{u}_j \quad \forall q \in \mathbb{P}.
\end{aligned}
\tag{2.1}
$$

Recall that $\mathbb{V} = \big(\mathring{H}^1(\Omega)\big)^d$, $\mathbb{V}^* = \big(H^{-1}(\Omega)\big)^d$, and $\mathbb{P} = \mathring{L}^2(\Omega)$ and let us denote with $\langle\cdot,\cdot\rangle$ the pairing between $\mathbb{V}$ and $\mathbb{V}^*$ as well as the inner product in $\mathbb{P}$. Let us define the operators $-\Delta$, ∇, and div as follows:

$$
\begin{aligned}
-\Delta : \mathbb{V} \to \mathbb{V}^* \quad \langle -\Delta \mathbf{v},\, \mathbf{w}\rangle &:= \int_\Omega \nabla\mathbf{v} : \nabla\mathbf{w} \quad \forall \mathbf{w} \in \mathbb{V},\\
\nabla : \mathbb{P} \to \mathbb{V}^* \quad \langle \nabla q,\, \mathbf{w}\rangle &:= -\int_\Omega q\ \mathrm{div}\,\mathbf{w} \quad \forall \mathbf{w} \in \mathbb{V},\\
\mathrm{div} : \mathbb{V} \to \mathbb{P} = \mathbb{P}^* \quad \langle \mathrm{div}\,\mathbf{v},\, q\rangle &:= \int_\Omega q\,\mathrm{div}\,\mathbf{v} \quad \forall q \in \mathbb{P}.
\end{aligned}
$$

The *Schur complement operator* $\mathcal{S} : \mathbb{P} \to \mathbb{P}$ is defined by

$$\mathcal{S} := -\operatorname{div}(-\Delta)^{-1}\nabla \tag{2.2}$$

and turns out to be positive definite, self-adjoint, and bounded [6]. Moreover, the Uzawa iteration (2.1) can be written in terms of $\mathcal{S}$ as

$$p_j = (I - \alpha\mathcal{S})p_{j-1} + \alpha F, \tag{2.3}$$

where $F := -\operatorname{div}(-\Delta)^{-1}\mathbf{f}$. Therefore, if $0 < \alpha < 2/\|\mathcal{S}\|_{\mathcal{L}(\mathbb{P},\mathbb{P})}$, then

$$\beta := \big\|I - \alpha\mathcal{S}\big\|_{\mathcal{L}(\mathbb{P},\mathbb{P})} < 1, \tag{2.4}$$

where $\|\cdot\|_{\mathcal{L}(\mathbb{P},\mathbb{P})}$ denotes the norm in the space of bounded linear operators from the Hilbert space $\mathbb{P}$ into itself. Since $\|\mathcal{S}\|_{\mathcal{L}(\mathbb{P},\mathbb{P})} \le 1$ (see [17]), we could take $0 < \alpha < 2$; we chose $\alpha = 1$ in the numerical experiments of section 3.

From now on, $j \ge 0$ will always denote the Uzawa iteration counter, and $\mathcal{T}_j$ will be the jth shape-regular partition of Ω. If k is the polynomial degree for velocity, and l is that for pressure, then we study the pairs of *continuous* finite element spaces

$$\mathbb{V}_j = \mathcal{P}^k(\mathcal{T}_j) \cap \mathbb{V}, \quad \mathbb{P}_j = \mathcal{P}^l(\mathcal{T}_j) \cap \mathbb{P}, \quad l = k, k-1 \ge 1, \tag{2.5}$$

as well as the *discontinuous* finite element spaces

$$\mathbb{V}_j = \mathcal{P}^k(\mathcal{T}_j) \cap \mathbb{V}, \quad \mathbb{P}_j = \mathcal{P}_d^{k-1}(\mathcal{T}_j) \cap \mathbb{P}, \quad k \ge 1. \tag{2.6}$$

Hereafter, $\mathcal{P}_d^k(\mathcal{T}_j)$ denotes the space of—scalar-valued as well as vector-valued—(possibly *discontinuous*) functions that, restricted to an element T, are polynomials of degree $\le k$ for all $T \in \mathcal{T}_j$, and $\mathcal{P}^k(\mathcal{T}_j)$ denotes the subspace of *continuous* functions of $\mathcal{P}_d^k(\mathcal{T}_j)$. We observe that $l = k-1$ in (2.5) corresponds to the popular Taylor–Hood family of finite elements. Any other choice in either (2.5) or (2.6) yields an *unstable* pair of spaces.

Our AUA builds upon a convergent adaptive algorithm for elliptic problems, the procedure ELLIPTIC of section 5, which replaces the first equation in (2.1) by an *approximation*. To introduce such a procedure, we first consider the following auxiliary elliptic problem: Given $\mathbf{f} \in (L^2(\Omega))^d$ and a pressure function $P_{j-1} \in \mathbb{P}_{j-1}$ for $j \ge 1$, solve

$$\mathbf{u}_j \in \mathbb{V} : \int_\Omega \nabla\mathbf{u}_j : \nabla\mathbf{v} = \int_\Omega \mathbf{f}\cdot\mathbf{v} + \int_\Omega P_{j-1}\operatorname{div}\mathbf{v} \quad \forall\mathbf{v} \in \mathbb{V}. \tag{2.7}$$

In contrast with (2.1), we observe that P_{j-1} is discrete in (2.7). If ε_j stands for an adjustable error tolerance, then the procedure ELLIPTIC,

$$(\mathcal{T}_j, \mathbf{U}_j) \leftarrow \text{ELLIPTIC}(\mathcal{T}_{j-1}, P_{j-1}, \varepsilon_j, \mathbf{f}),$$

finds adaptively a refined mesh $\mathcal{T}_j$ of $\mathcal{T}_{j-1}$ and solves the discrete *elliptic* problem

$$\mathbf{U}_j \in \mathbb{V}_j : \quad \int_\Omega \nabla\mathbf{U}_j : \nabla\mathbf{V} = \int_\Omega \mathbf{f}\cdot\mathbf{V} + \int_\Omega P_{j-1}\operatorname{div}\mathbf{V} \quad \forall\ \mathbf{V} \in \mathbb{V}_j, \tag{2.8}$$

within the prescribed error bound

$$\big\|\nabla(\mathbf{u}_j - \mathbf{U}_j)\big\| \le C\varepsilon_j, \tag{2.9}$$

with $C > 0$ independent of j. We point out that this estimate is not standard in that the right-hand side $\mathbf{f} - \nabla P_{j-1}$ of (2.7) may not be in $L^2(\Omega)$ when dealing with discontinuous pressures. This issue is assessed in section 5.

In addition, let $\Pi_j : L^2(\Omega) \to \mathbb{P}_j$ denote the orthogonal L^2-projection into $\mathbb{P}_j$. In section 5, we will show the existence of a constant C independent of j such that the output function $\mathbf{U}_j$ of ELLIPTIC satisfies

$$\| \operatorname{div} \mathbf{U}_j - \Pi_j \operatorname{div} \mathbf{U}_j \| \leq C\varepsilon_j. \tag{2.10}$$

The pressure update is performed by the procedure

$$P_j \leftarrow \text{UPDATE}(\mathcal{T}_j, P_{j-1}, \mathbf{U}_j, \alpha)$$

which computes, according to (2.1) with $\mathbb{P}$ replaced by $\mathbb{P}_j$,

$$P_j \in \mathbb{P}_j : \quad \int_\Omega P_j Q = \int_\Omega P_{j-1} Q - \alpha \int_\Omega Q \operatorname{div} \mathbf{U}_j \quad \forall Q \in \mathbb{P}_j,$$

or equivalently,

$$P_j = P_{j-1} - \alpha\, \Pi_j \operatorname{div} \mathbf{U}_j. \tag{2.11}$$

We are now in a position to introduce the AUA. This algorithm consists of an inexact inner solve using ELLIPTIC in place of (2.1), followed by an update of pressure given by UPDATE. A similar algorithm was first considered by Dahlke, Hochmuth, and Urban [8, 9] in the context of adaptive wavelet methods, which builds upon Elman and Golub [12].

Adaptive Uzawa Algorithm (AUA)

Choose parameters $0 < \alpha < 2$, $0 < \gamma < 1$, $\varepsilon_0 > 0$; set $j = 1$.
1. Select any initial mesh $\mathcal{T}_0$ and any function $P_0 \in \mathbb{P}_0$.
2. Update $\varepsilon_j \leftarrow \gamma \varepsilon_{j-1}$.
3. Compute $(\mathcal{T}_j, \mathbf{U}_j) \leftarrow \text{ELLIPTIC}(\mathcal{T}_{j-1}, \mathbf{f}, P_{j-1}, \varepsilon_j)$.
4. Compute $P_j \leftarrow \text{UPDATE}(\mathcal{T}_j, P_{j-1}, \mathbf{U}_j, \alpha)$.
5. Update $j \leftarrow j + 1$.
6. Go to step 2.

We observe that the AUA makes sense for any pair of spaces $(\mathbb{V}_h, \mathbb{P}_h)$, even *unstable* pairs; this freedom is further investigated in section 3.

THEOREM 2.1. *Let $\alpha > 0$ satisfy* (2.4)*, and let* ELLIPTIC *fulfill* (2.9) *and* (2.10)*. Then, there exist positive constants C_1 and $\delta < 1$ such that the iterates $(\mathbf{U}_j, P_j)$ produced by the* AUA *satisfy*

$$\big\|\nabla(\mathbf{u} - \mathbf{U}_j)\big\| + \big\|p - P_j\big\| \leq C_1 \delta^j.$$

Proof. Let us first observe that (2.7) implies $\mathbf{u}_j = (-\Delta)^{-1}(\mathbf{f} - \nabla P_{j-1})$ for any $j \geq 1$. Hence

$$\begin{aligned} P_j &= P_{j-1} - \alpha\, \Pi_j \operatorname{div} \mathbf{U}_j \\ &= P_{j-1} - \alpha \operatorname{div} \mathbf{u}_j + \alpha \operatorname{div}(\mathbf{u}_j - \mathbf{U}_j) + \alpha(I - \Pi_j) \operatorname{div} \mathbf{U}_j \\ &= (I - \alpha \mathcal{S}) P_{j-1} - \alpha \operatorname{div}(-\Delta)^{-1} \mathbf{f} + \alpha \operatorname{div}(\mathbf{u}_j - \mathbf{U}_j) + \alpha(I - \Pi_j) \operatorname{div} \mathbf{U}_j, \end{aligned}$$

where $\mathcal{S}$ stands for the Schur operator (2.2). Analogously, the exact p satisfies

$$p = (I - \alpha\mathcal{S})p - \alpha \operatorname{div}(-\Delta)^{-1}\mathbf{f},$$

which implies

$$p - P_j = (I - \alpha\mathcal{S})(p - P_{j-1}) - \alpha \operatorname{div}(\mathbf{u}_j - \mathbf{U}_j) - \alpha(I - \Pi_j)\operatorname{div}\mathbf{U}_j.$$

Therefore, in view of (2.4), (2.9), and (2.10), together with property $\|\operatorname{div}\mathbf{v}\| \le \|\nabla\mathbf{v}\|$ [17], we get

$$\begin{aligned}\|p - P_j\| &\le \beta\|p - P_{j-1}\| + \alpha\|\nabla(\mathbf{u}_j - \mathbf{U}_j)\| + \alpha\|(I - \Pi_j)\operatorname{div}\mathbf{U}_j\| \\ &\le \beta\|p - P_{j-1}\| + C\alpha\varepsilon_j = \beta\|p - P_{j-1}\| + C\alpha\varepsilon_0\gamma^j,\end{aligned}$$

where γ is the reduction factor used in step 2 of the AUA. By induction we obtain

$$\|p - P_j\| \le \beta^j\|p - P_0\| + C\alpha\varepsilon_0 \sum_{\ell=0}^{j-1} \beta^\ell\gamma^{j-\ell}, \tag{2.12}$$

and setting $\eta := \max\{\beta, \gamma\}$, we thus have

$$\|p - P_j\| \le \|p - P_0\|\eta^j + \alpha\varepsilon_0 j\eta^j \le C\delta^j \tag{2.13}$$

for some positive constants C and $\eta < \delta < 1$.

To obtain a similar bound for $\|\nabla(\mathbf{u} - \mathbf{U}_j)\|$, we first observe that

$$\int_\Omega \nabla(\mathbf{u} - \mathbf{u}_j) : \nabla\mathbf{v} = \int_\Omega (p - P_{j-1})\operatorname{div}\mathbf{v} \le \|p - P_{j-1}\|\,\|\nabla\mathbf{v}\| \quad \forall\mathbf{v} \in \mathbb{V},$$

whence $\|\nabla(\mathbf{u} - \mathbf{u}_j)\| \le \|p - P_{j-1}\|$. Since

$$\|\nabla(\mathbf{u} - \mathbf{U}_j)\| \le \|\nabla(\mathbf{u} - \mathbf{u}_j)\| + \|\nabla(\mathbf{u}_j - \mathbf{U}_j)\| \le \|p - P_{j-1}\| + \varepsilon_j,$$

(2.13) yields the desired assertion. ∎

Several comments about the AUA and its convergence properties are now in order.

Remark 2.1. For discontinuous pressure spaces $\mathcal{P}_d^l(\mathcal{T}_j)$, $l \ge k-1$, the procedure UPDATE of the AUA hinges upon a pressure correction within the subspace $\operatorname{div}\mathbb{V}_j \subset \mathcal{P}_d^{k-1}(\mathcal{T}_j)$. Consequently, for $l \ge k-1$, the output of the AUA is insensitive to l because the *effective* pressure space is

$$\mathbb{P}_j = \operatorname{div}\mathbb{V}_j;$$

this justifies the restriction $l = k-1$ in (2.6). In contrast, if we enforce continuity of pressure, as in (2.5), then UPDATE works within the subspace $\Pi_j \operatorname{div}\mathbb{V}_j$ of $\mathbb{P}_j = \mathcal{P}^l(\mathcal{T}_j)$ for any $l \ge k-1$, and the output of UPDATE does depend on l.

Remark 2.2. It is remarkable that the discrete inf-sup condition (1.5) plays no role in our analysis. In fact, the above proof hinges solely on the continuous inf-sup condition (1.2) or, equivalently, on the stability of the infinite-dimensional problem (property $\beta < 1$ of $\mathcal{S}$). This observation was first made by Dahlke, Hochmuth, and Urban [8, 9], and very recently exploited by Dahlke, Dahmen, and Urban [7] and Cohen, Dahmen, and DeVore [5], in the context of wavelet approximations of the Stokes system.

Remark 2.3. Unstable elements such as (2.6) are known to yield checkerboard patterns in pressure [3]. One may thus wonder whether any adaptive procedure, which extracts discrete regularity via a posteriori error estimation, may be misled by pressure oscillations and thus fail to produce *selective local* mesh refinement. A possible cure for pressure oscillations within the classical mixed finite element context consists of having a uniformly refined mesh for velocity [3]. In view of (2.8), it turns out that $(\mathbf{U}_j, P_{j-1})$ is a solution to (1.3) with P_{j-1} defined on a grid $\mathcal{T}_{j-1}$ coarser than $\mathcal{T}_j$. This may be regarded as a built-in *stabilization*, but different from the usual one because $\mathcal{T}_j$ is never a global refinement of $\mathcal{T}_{j-1}$ and (1.4) is never fulfilled. This is confirmed by the numerical experiments of section 3, which show optimal meshes for these elements. It thus seems that the nonlinear process associated with adaptivity selects the least amount of refinement necessary to stabilize the method.

Remark 2.4. The procedure ELLIPTIC of the AUA entails an inner loop of the form SOLVE → ESTIMATE → REFINE for the symmetric and coercive elliptic problem (2.7). To achieve the error reduction of (2.9), two ingredients are necessary. First, we need upper and local lower a posteriori error bounds for (2.8). Second, we need a marking strategy and associated error reduction result (2.9). These issues are discussed in section 5.

Remark 2.5. Parameters α, γ, and ε_0 control the behavior of the AUA. The convergence of the AUA, but not its rate, is independent of γ and ε_0 but *not* of α because it dictates the size of the reduction factor β in (2.4). Even though the AUA converges for any choice of γ and ε_0, provided $0 < \gamma < 1$ and $\varepsilon_0 > 0$, its *performance* is greatly influenced by them, especially for unstable elements. In particular, if $\beta < \gamma < 1$, then the *complexity* of ELLIPTIC is independent of j, as will be shown in section 5.2.

Remark 2.6. To stop the AUA it is necessary to have a posteriori error estimators especially designed for the pair $(\mathbf{U}_j, P_{j-1})$, which is *not* a solution of the discrete Stokes problem over $\mathcal{T}_j$. This issue is further investigated in section 4.

3. Experiments and mesh optimality. In this section we focus on the computational performance of the algorithm. We analyze it not only for the elements of Theorem 2.1 but also for cases beyond this. All numerical experiments were carried out using the finite element toolbox ALBERT [18, 19], which provides a flexible programming environment for adaptive finite element computations. Some pictures (Figures 3.2, 3.3, 3.5, 3.7) were produced with the graphics package GRAPE [13].

In order to have an appropriate test bed for the algorithm, we consider two examples in two dimensions and one in three dimensions and run simulations with the AUA for several pairs of elements. They can be divided into three groups, all containing unstable elements: elements of type (2.6), elements of type (2.5)—which include the Taylor–Hood elements—and the continuous unstable pair $\mathcal{P}^1$-$\mathcal{P}^2$ which is not covered by our theory. We always use the following parameters and initial guess:

$$\alpha = 1.0, \quad \gamma = 0.95, \quad \varepsilon_0 = 2.0, \quad P_0 = 0. \tag{3.1}$$

In order to compare our method with the classical adaptive approach to solving the Stokes equations, we also run experiments with a conventional adaptive strategy of the form SOLVE → ESTIMATE → REFINE. For these experiments we use the Taylor–Hood elements $\mathcal{P}^2$-$\mathcal{P}^1$ and $\mathcal{P}^3$-$\mathcal{P}^2$ and the usual residual-type error estimators. An important difference with the AUA is that in SOLVE we solve the saddle-point problem (1.3), (1.4).

The comparative results for the three groups of elements as well as for the conventional approach are reported below in Tables 3.1, 3.2, and 3.3. To describe the information they contain, let us assume that we expect a relation of the form

$$\mathrm{ERR}_j := \|\nabla(u - U_j)\| + \|p - P_j\| \approx C\, N_j^{-r/d},$$

where N_j denotes the number of degrees of freedom (DOFs) at the step j of the outer loop in the AUA, $r = \min\{k, l+1\}$ is the order of the FEM, and d is the dimension. We then define the experimental orders of convergence EOC_j to be

$$\mathrm{EOC}_j := -d\,\frac{\log(\mathrm{ERR}_j/\mathrm{ERR}_{j-1})}{\log(N_j/N_{j-1})},$$

and EOC to be the asymptotic value of EOC_j for large values of j. We also introduce the average error decay (AED) in the energy norm for consecutive outer iterations of the AUA, and the number of DOFs for which the relative energy error

$$\frac{\|\nabla(u - U_j)\| + \|p - P_j\|}{\|\nabla u\| + \|p\|}$$

is less than or equal to prescribed tolerances of 10%, 5%, 1%, and 0.1%, respectively. To compute the errors, we integrated elementwise using a quadrature rule exact for polynomials up to degree 17 in two dimensions and 7 in three dimensions.

We show pictures of pressure (Figures 3.2, 3.3, 3.5), the variable most sensitive to instabilities, and corresponding meshes for several elements at 5% relative accuracy. The velocity never exhibits oscillations, is always well approximated, and is thus not depicted.

We also report curves depicting the relative energy error decay in terms of DOFs and compare them with the optimal slope $-r/d$.

Finally, we draw some conclusions common to all the experiments.

3.1. Example: Smooth solution in two dimensions. Let $\Omega := (-1,1) \times (-1,1)$ and let the velocity $\mathbf{u}$ and pressure p be given by

$$\mathbf{u}(x,y) := \begin{bmatrix} 2y\cos(x^2+y^2) \\ -2x\cos(x^2+y^2) \end{bmatrix}, \qquad p = e^{-10(x^2+y^2)} - p_m,$$

where p_m is such that $\int_\Omega p = 0$ and the forcing $\mathbf{f}$ is computed as $\mathbf{f} = -\Delta u + \nabla p$.

We report the computational results in Table 3.1 and the error decays in Figure 3.1. The behavior of the pressure is illustrated for several pairs of elements in Figures 3.2 and 3.3.

3.2. Example: Singular solution in two dimensions. We consider the L-shaped domain

$$\Omega := \big((-1,1) \times (-1,1)\big) \setminus \big([0,1] \times [-1,0]\big)$$

with reentrant angle $\omega = 3\pi/2$ at the origin. Let $\alpha \approx 0.544$ be an approximation of the smallest root of the nonlinear equation [10]:

$$\frac{\sin^2(\alpha\omega) - \alpha^2 \sin^2\omega}{\alpha^2} = 0.$$

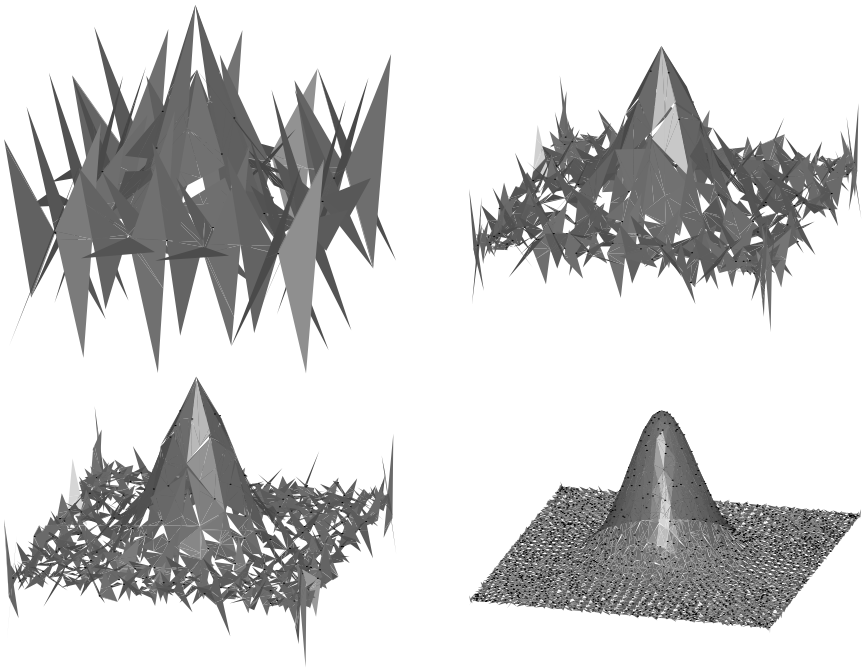

FIG. 3.3. *Example* 3.1: *Sequence of pressures for the unstable pair* $\mathcal{P}^2$-$\mathcal{P}^1_d$ *and outer iterations (respectively, DOFs) j* = 20 (*DOFs* = 482), 60 (2802), 70 (4066), 120 (40986). *Oscillations are present in the early stages of adaptivity but are cured later by selective refinement.*

The exact velocity $\mathbf{u}$ and pressure p are given in polar coordinates by [10, 21]

$$\mathbf{u}(r,\varphi) = r^\alpha \begin{bmatrix} \cos(\varphi)\psi'(\varphi) + (1+\alpha)\sin(\varphi)\psi(\varphi) \\ \sin(\varphi)\psi'(\varphi) - (1+\alpha)\cos(\varphi)\psi(\varphi) \end{bmatrix} = r^\alpha \big(\psi'(\varphi)\mathbf{e}_r - (1+\alpha)\psi(\varphi)\mathbf{e}_\varphi\big)$$

and

$$p(r,\varphi) = -r^{\alpha-1}\frac{(1+\alpha)^2\psi'(\varphi) + \psi'''(\varphi)}{1-\alpha},$$

where $\psi(\varphi)$ is the function

$$\psi(\varphi) = \frac{\sin\left((1+\alpha)\varphi\right)\cos(\alpha\omega)}{1+\alpha} - \cos\left((1+\alpha)\varphi\right) + \frac{\sin\left((\alpha-1)\varphi\right)\cos(\alpha\omega)}{1-\alpha} + \cos((\alpha-1)\varphi).$$

The forcing term is $\mathbf{f} = \mathbf{0}$.

We report the computational results in Table 3.2 and the error decays in Figure 3.4. The behavior of the pressure is illustrated for several pairs of elements in Figure 3.5. In contrast to Example 3.1, the singular nature of p makes selective refinement apparently more effective in this example, which is less prone to oscillations.

3.3. Example: Smooth solution in three dimensions. We consider the cube $\Omega = (-1,1)^3$, and the exact velocity $\mathbf{u}$ and pressure p,

$$\mathbf{u}(x,y,z) = \begin{bmatrix} 2y\cos(x^2+y^2) \\ -2x\cos(x^2+y^2) \\ 0 \end{bmatrix}, \qquad p = \mu e^{-\lambda(x^2+y^2+z^2)} - p_m,$$

where p_m is such that $\int_\Omega p = 0$. The forcing term $\mathbf{f}$ is computed as $\mathbf{f} = -\Delta u + \nabla p$.

We report the computational results in Table 3.3 and the error decays in Figure 3.6, both for $\mu = 1, \lambda = 10$. Meshes for two finite element pairs are shown in Figure 3.7 for $\mu = 10, \lambda = 300$.

3.4. Conclusions. We now collect and comment on the consistent information about the AUA extracted from the experiments of sections 3.1–3.3.

- Tables 3.1, 3.2, and 3.3 show that error decay in each outer iteration of the AUA is about 0.95, regardless of example and pair of elements. This is a consequence of the choice of $\gamma = 0.95$ of (3.1) and is further discussed in Remark 5.6. Tables 3.1 and 3.2 also reveal convergence for the unstable pair $\mathcal{P}^1$-$\mathcal{P}^2$ in two dimensions, which is not covered by our theory.
- Tables 3.1, 3.2, and 3.3 show that the EOC is optimal for all element pairs and examples and obeys the formula $r = \min\{k, l+1\}$.
- Figures 3.1, 3.4, and 3.6 demonstrate that the relation between error and number of DOFs is optimal for all element pairs and examples: the slopes of the curves match those of the triangles, namely, $-r/d$. The resulting meshes are thus *quasi-optimal* in all cases.

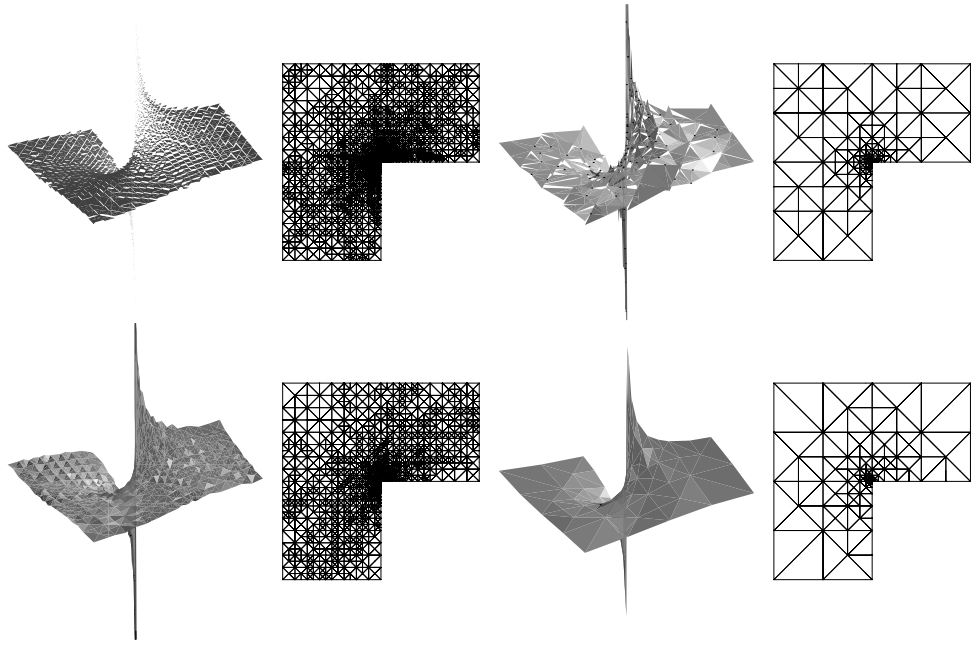

FIG. 3.5. *Example* 3.2: *Pressures and meshes for tolerance of* 5% *and finite element pairs (respectively, outer iteration number/DOFs);* $\mathcal{P}^1$-$\mathcal{P}^0_d$ (50/9680), $\mathcal{P}^2$-$\mathcal{P}^1_d$ (35/1940), $\mathcal{P}^1$-$\mathcal{P}^1$ (50/4971), $\mathcal{P}^2$-$\mathcal{P}^1$ (50/1200). *The oscillations for unstable elements do not persist under further selective refinement.*

- Tables 3.1, 3.2, and 3.3 corroborate the fact that higher order elements are superior to lower order elements for piecewise analytic solutions such as those in Examples 3.1–3.3. For a given tolerance, they need many fewer DOFs than lower order elements.
- Tables 3.1, 3.2, and 3.3 display very similar performance between the AUA, with the element pairs of (2.5) and $l = k - 1$, and the saddle-point approach with the Taylor–Hood families $\mathcal{P}^2$-$\mathcal{P}^1$ and $\mathcal{P}^3$-$\mathcal{P}^2$ (last 2 rows of these tables).
- The stable element pairs (2.5) with $l = k - 1$ exhibit a slightly better performance than the corresponding unstable pairs (2.6). This is documented in Tables 3.1,

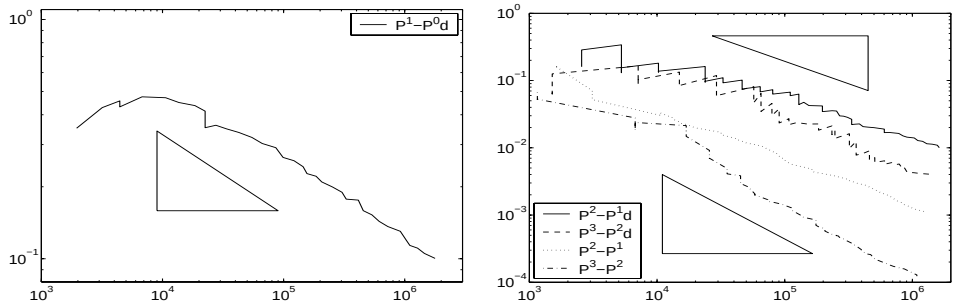

FIG. 3.6. *Example* 3.3 ($\mu = 1, \lambda = 10$): *Relative energy error versus DOFs. Triangles have slopes* $-1/d = -1/3$ *(left) and* $-2/d = -2/3$, $-3/d = -1$ *(right), respectively. Quasi-optimality of the resulting meshes is thus evident.*

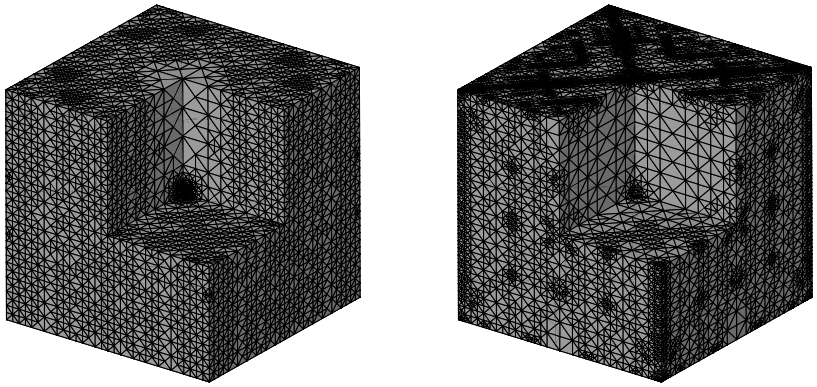

FIG. 3.7. *Example* 3.3 ($\mu = 10, \lambda = 300$): *Mesh for finite element pair* $\mathcal{P}^2$-$\mathcal{P}^1$ *at outer iteration number* $j = 105$, *DOFs* $= 1063176$ *(left), and mesh for finite element pair* $\mathcal{P}^2$-$\mathcal{P}^1_d$ *at* $j = 70$, *DOFs* $= 2007799$ *(right). The first octant has been removed for visualization purposes.*

3.2, and 3.3 in terms of DOFs for a given tolerance, and in Figures 3.2, 3.3, and 3.5 in terms of oscillations.

- It is important to note that oscillations tend to zero in L^2, thereby giving rise to convergence of pressure in L^2. However, as suggested by Figures 3.2 and 3.3, this might be a rather weak concept of convergence in practice, which is in contrast to common belief.

4. A posteriori error estimators. In this section we derive a posteriori error estimators for the pair $(\mathbf{U}_j, P_{j-1})$, which are instrumental to stopping the outer loop in the AUA. We start by defining the bilinear form $\mathcal{L} : (\mathbb{V} \times \mathbb{P}) \times (\mathbb{V} \times \mathbb{P}) \to \mathbb{R}$,

$$\mathcal{L}\left[(\mathbf{v}, q), (\mathbf{w}, r)\right] := \int_\Omega \nabla \mathbf{v} : \nabla \mathbf{w} - \int_\Omega q \ \mathrm{div}\, \mathbf{w} + \int_\Omega r \ \mathrm{div}\, \mathbf{v},$$

and noting that (1.1) is equivalent to finding a pair $(\mathbf{u}, p) \in \mathbb{V} \times \mathbb{P}$ such that

$$\mathcal{L}\left[(\mathbf{u}, p), (\mathbf{v}, q)\right] = \int_\Omega \mathbf{f} \cdot \mathbf{v} \quad \forall (\mathbf{v}, q) \in \mathbb{V} \times \mathbb{P}.$$

Moreover, the *continuous* inf-sup condition (1.2) is equivalent to the existence of a constant $\Lambda > 0$ such that

$$\|\nabla \mathbf{v}\| + \|q\| \leq \Lambda \sup_{(\mathbf{w},r)\in \mathbb{V}\times\mathbb{P}} \frac{\mathcal{L}\,[(\mathbf{v},q),(\mathbf{w},r)]}{\|\nabla \mathbf{w}\| + \|r\|}. \tag{4.1}$$

This property alone, or equivalently, the *stability* of the continuous problem, is responsible for a posteriori error estimates for the Stokes system, even for unstable elements. Therefore, the mere derivation of a posteriori error estimators is no guarantee of convergence of any adaptive algorithm based on them.

In what follows we derive both global upper and local lower a posteriori error bounds for the pair $(\mathbf{U}_j, P_{j-1})$. This pair is a solution of (2.8), but not of the discrete Stokes problem (1.3)–(1.4) for the following two reasons:

- pressure P_{j-1} is piecewise polynomial in the mesh $\mathcal{T}_{j-1}$, which is coarser than $\mathcal{T}_j$;
- equation (1.4) is not fulfilled.

Altogether, this makes our error analysis a bit unusual. However, since the same techniques reported in [1, 20] apply in our context, we only sketch the proofs for completeness. We first set $\mathbf{e}_u := \mathbf{u} - \mathbf{U}_j$ and $e_p := p - P_{j-1}$ and observe that, from (1.1) and (2.8), we have

$$\mathcal{L}\,[(\mathbf{e}_u, e_p),(\mathbf{w},r)] = \sum_{T\in\mathcal{T}_j} \left(\int_T \mathbf{f}\cdot\mathbf{w} - (\nabla \mathbf{U}_j - P_{j-1}\mathbf{I}) : \nabla \mathbf{w} - r\ \mathrm{div}\,\mathbf{U}_j \right)$$

for any $\mathbf{w} \in \mathbb{V}$, $r \in \mathbb{P}$; here $\mathbf{I} \in \mathbb{R}^{d\times d}$ stands for the identity matrix. Since the matrix $\mathbf{T}_j := \nabla \mathbf{U}_j - P_{j-1}\mathbf{I}$ plays a crucial role, we introduce the *jump residual*,

$$\mathbf{J}_j := [\![\mathbf{T}_j \cdot \mathbf{n}]\!] = [\![\nabla \mathbf{U}_j \cdot \mathbf{n} - P_{j-1}\mathbf{n}]\!], \tag{4.2}$$

which indicates the jump of the vector-valued function $\mathbf{T}_j \cdot \mathbf{n}$ across interelement sides S. Such a jump is independent of the choice of the normal $\mathbf{n}$ to S and is defined as zero for boundary sides. We also introduce the *interior residual*,

$$\mathbf{R}_j := \mathbf{f} + \Delta \mathbf{U}_j - \nabla P_{j-1}, \tag{4.3}$$

which is computed elementwise.

LEMMA 4.1 (upper bound). *Let $\{(\mathbf{U}_j, P_j)\}_{j=1}^{\infty}$ be the sequence of solutions produced by the* AUA. *Then there exists a constant C^* depending only on mesh shape-regularity such that the following a posteriori upper bound for the error of the pair $(\mathbf{U}_j, P_{j-1})$ holds:*

$$\|\nabla(\mathbf{u} - \mathbf{U}_j)\| + \|p - P_{j-1}\| \leq C^* \left(\sum_{T\in\mathcal{T}_j} \zeta_j(T)^2 \right)^{1/2},$$

where the local error indicators $\zeta_j(T)$ are given by

$$\zeta_j(T)^2 = h_T^2 \|\mathbf{R}_j\|_T^2 + h_T \|\mathbf{J}_j\|_{\partial T}^2 + \|\,\mathrm{div}\,\mathbf{U}_j\|_T^2 \quad \forall\ T \in \mathcal{T}_j,$$

and the quantity h_T represents the diameter of the element $T \in \mathcal{T}_j$.

Proof. Exploiting (2.8), we deduce Galerkin orthogonality $\mathcal{L}[(\mathbf{e}_u, e_p), (\mathbf{W}, 0)] = 0$ for all $\mathbf{W} \in \mathbb{V}_j$. We then have

$$\mathcal{L}\left[(\mathbf{e}_u, e_p), (\mathbf{w}, r)\right] = \mathcal{L}\left[(\mathbf{e}_u, e_p), (\mathbf{w} - \mathbf{W}, r)\right] \quad \forall\ \mathbf{W} \in \mathbb{V}_j,$$

and integrating by parts, with $\mathbf{z} = \mathbf{w} - \mathbf{W}$ we obtain

$$\mathcal{L}\left[(\mathbf{e}_u, e_p), (\mathbf{w}, r)\right] = \sum_{T \in \mathcal{T}_j} \left(\int_T \mathbf{R}_j \mathbf{z} + \frac{1}{2} \int_{\partial T} \mathbf{J}_j \mathbf{z} - \int_T r \ \mathrm{div}\, \mathbf{U}_j \right).$$

Finally, taking $\mathbf{W} \in \mathbb{V}_j$ as the Clément interpolant of $\mathbf{w}$, we arrive at

$$\|\mathbf{z}\|_T \leq C h_T \left\|\nabla \mathbf{w}\right\|_{\mathcal{N}_j(T)}, \qquad \|\mathbf{z}\|_{\partial T} \leq C h_T^{1/2} \left\|\nabla \mathbf{w}\right\|_{\mathcal{N}_j(T)},$$

where $\mathcal{N}_j(T)$ is the union of all elements of $\mathcal{T}_j$ sharing at least a vertex with $T \in \mathcal{T}_j$. This, together with (4.1), leads to the assertion. ∎

Remark 4.1. The a posteriori error analysis for the Stokes system is based exclusively on satisfaction of the momentum equation (1.3), or (2.8), but not of the incompressibility equation (1.4). In fact, (1.4) is not valid in either our setting or when stabilizing terms are added [14].

Before stating the local lower error bound, we need to introduce the concept of *data oscillation*, which accounts for information missing due to the averaging process associated with the FEM. Given a subset of elements $\mathcal{F}$ of $\mathcal{T}_j$, we set

$$\mathrm{osc}(\mathbf{f}, \mathcal{F}) := \left(\sum_{T \in \mathcal{F}} h_T^2 \|\mathbf{f} - \mathbf{f}_T\|_T^2 \right)^{1/2}, \tag{4.4}$$

where $\mathbf{f}_T$ is the (local) L^2-projection of $\mathbf{f}$ into the polynomial space $\mathcal{P}^{k-1}(T)$, and k is the polynomial degree of the velocity space $\mathbb{V}_j$. Given an element $T \in \mathcal{T}_j$ we designate with $\mathcal{F}_j(T)$ either the set of elements of $\mathcal{T}_j$ sharing a face with T or their union. This abuse of notation will not lead to confusion.

LEMMA 4.2 (lower bound). *Let $\{(\mathbf{U}_j, P_j)\}_{j=1}^{\infty}$ be the sequence of solutions produced by the* AUA. *Then there exists a constant C_*, depending only on mesh shape-regularity, such that the following local a posteriori lower bound for the error of the pair $(\mathbf{U}_j, P_{j-1})$ holds:*

$$\zeta_j(T) \leq C_* \Big(\left\|\nabla(\mathbf{u} - \mathbf{U}_j)\right\|_{\mathcal{F}_j(T)} + \left\|p - P_{j-1}\right\|_{\mathcal{F}_j(T)} + \mathrm{osc}(\mathbf{f}, \mathcal{F}_j(T)) \Big).$$

We omit the proof because it is the same as that in [1, 21, 20]. This result shows that the upper bound is sharp (global efficiency), and implies that *local efficiency* refining where the local indicators $\zeta_j(T)$ are large is always necessary to reduce the error. This property seems to be distinctive of finite elements and in fact is not valid for wavelets.

5. ELLIPTIC: Realization and complexity. In this section we first define the procedure ELLIPTIC and prove the key properties (2.9) and (2.10) for the finite element families (2.5) and (2.6). Second, we analyze the complexity of ELLIPTIC in terms of the number of iterations necessary to achieve (2.9).

5.1. Realization. The study of convergence of adaptive FEM for elliptic problems in the multidimensional setting started with the seminal work by Dörfler [11] and was further developed by Morin, Nochetto, and Siebert in [15, 16]. In this section we will follow the approach in [15, 16] to state the algorithm and prove its convergence for a special class of H^{-1} right-hand sides. This is the class of L^2 vector-valued functions plus gradients of functions in the pressure space $\mathbb{P}_h$ which might have discontinuities across interelement boundaries.

In this section we drop the outer counter j and relabel the input arguments $\mathcal{T}_{j-1}$, P_{j-1}, ε_j of ELLIPTIC as $\mathcal{T}^0$, P, ε and relabel the output $\mathcal{T}_j, \mathbf{U}_j$ as $\mathcal{T}, \mathbf{U}$. Hence

$$(\mathcal{T}, \mathbf{U}) \leftarrow \text{ELLIPTIC}(\mathcal{T}^0, P, \varepsilon, \mathbf{f}). \tag{5.1}$$

To avoid confusion we always use *superscripts*, instead of subscripts, whenever inner iterates of ELLIPTIC are involved. Consequently, for $i \geq 1$ we denote by $\mathcal{T}^i$ a refinement of $\mathcal{T}^{i-1}$, by $\mathbb{V}^i$ the corresponding finite element space for velocities, and by $\mathbf{U}^i$ the solution to the following discrete elliptic problem:

$$\mathbf{U}^i \in \mathbb{V}^i : \quad \int_\Omega \nabla \mathbf{U}^i : \nabla \mathbf{V} = \int_\Omega \mathbf{f} \cdot \mathbf{V} + \int_\Omega P \operatorname{div} \mathbf{V} \quad \forall\, \mathbf{V} \in \mathbb{V}^i. \tag{5.2}$$

This is the discretization of (2.7) or, equivalently, of the elliptic PDE $-\Delta \mathbf{u} = \mathbf{f} - \nabla P$ with $\mathbf{u} = \mathbf{u}_j$; since $\mathbf{f} - \nabla P \in \mathbb{V}^*$, there exists a unique solution to (2.7). We notice that P does *not* change with i and that, when ELLIPTIC stops, (5.2) becomes (2.8). According to (4.2) and (4.3), the residuals of (5.2) are

$$\mathbf{J} := [\![\nabla \mathbf{U}^i \cdot \mathbf{n} - P\mathbf{n}]\!], \qquad \mathbf{R} := \mathbf{f} + \Delta \mathbf{U}^i - \nabla P. \tag{5.3}$$

LEMMA 5.1. *Let $\mathbf{u}$ be the solution of (2.7). For $i \geq 1$, let $\mathcal{T}^i$ be a refinement of $\mathcal{T}^{i-1}$ and let $\mathbf{U}^i$ be the solution to (5.2). Let the local error indicators $\eta^i(T)$ be*

$$\eta^i(T)^2 := h_T^2 \, \|\mathbf{R}\|_T^2 + h_T \, \|\mathbf{J}\|_{\partial T}^2 \quad \forall\, T \in \mathcal{T}^i.$$

Then there exist two constants K^*, K_* depending only on mesh shape-regularity, but otherwise independent of $\mathbf{u}$, $\mathbf{f}$, P, and $\mathcal{T}^i$, such that

$$\left\| \nabla(\mathbf{u} - \mathbf{U}^i) \right\|^2 \leq K^* \sum_{T \in \mathcal{T}^i} \eta^i(T)^2, \tag{5.4}$$

$$\eta^i(T)^2 \leq K_* \big(\left\| \nabla(\mathbf{u} - \mathbf{U}^i) \right\|^2_{\mathcal{F}^i(T)} + \operatorname{osc}(\mathbf{f}, \mathcal{F}^i(T))^2 \big) \quad \forall\, T \in \mathcal{T}^i. \tag{5.5}$$

Proof. We note that the error equation can be written equivalently as

$$\int_\Omega \nabla(\mathbf{u} - \mathbf{U}^i) : \nabla \mathbf{v} = \int_\Omega \mathbf{f} \cdot \mathbf{v} - \int_\Omega (\nabla \mathbf{U}^i - P\mathbf{I}) : \nabla \mathbf{v} \quad \forall\, \mathbf{v} \in \mathbb{V}.$$

The argument now proceeds as in Lemma 4.1 with $r = 0$; see also [20]. ∎

Remark 5.1. Regardless of the adaptive algorithm used to reduce the error, the estimate (5.4) allows us to measure the error $\mathbf{u} - \mathbf{U}^i$ up to a factor K^*. Stopping the inner iterations of ELLIPTIC when $\sum_{T \in \mathcal{T}^i} \eta^i(T)^2 < \varepsilon^2$ thus guarantees (2.9).

To motivate the subsequent discussion about the convergence of adaptive FEM for elliptic problems, we observe that consecutive spaces are nested $\mathbb{V}^i \subset \mathbb{V}^{i+1}$, whence $\mathbf{U}^i - \mathbf{U}^{i+1} \in \mathbb{V}^{i+1}$. Consequently, using the orthogonal decomposition $\mathbf{u} - \mathbf{U}^i = (\mathbf{u} - \mathbf{U}^{i+1}) + (\mathbf{U}^{i+1} - \mathbf{U}^i)$, the Pythagoras theorem yields

$$\left\| \nabla(\mathbf{u} - \mathbf{U}^{i+1}) \right\|^2 = \left\| \nabla(\mathbf{u} - \mathbf{U}^i) \right\|^2 - \left\| \nabla(\mathbf{U}^i - \mathbf{U}^{i+1}) \right\|^2. \tag{5.6}$$

The error reduction is thus exactly $\|\nabla(\mathbf{U}^i - \mathbf{U}^{i+1})\|^2$. In order to guarantee that the error decreases a fixed proportion of the current error $\|\nabla(\mathbf{u}-\mathbf{U}^i)\|$, we have to bound $\|\nabla(\mathbf{U}^i - \mathbf{U}^{i+1})\|$ from below by $\|\nabla(\mathbf{u} - \mathbf{U}^i)\|$; this is the key idea from [11]. In view of Lemma 5.1, this reduces to showing a local lower bound for $\|\nabla(\mathbf{U}^i - \mathbf{U}^{i+1})\|_{\mathcal{F}^i(T)}$ in terms of $\eta^i(T)$.

The following lemma states such a lower bound and is crucial for the error reduction property that leads to convergence. Its proof is different from that in [16] due to the presence of the singular term ∇P in (5.2) and is postponed until the end of this section. We say that an element $T \in \mathcal{T}^i$ satisfies the *interior node* property if

(5.7) *the element $T \in \mathcal{T}^i$, as well as each of its faces, contains a node of the finer mesh $\mathcal{T}^{i+1}$ in its interior.*

LEMMA 5.2. *Let $\mathcal{T}^{i+1}$ be a refinement of $\mathcal{T}^i$, and let $T \in \mathcal{T}^i$ be an element for which every $T' \in \mathcal{F}^i(T)$ satisfies* (5.7)*. Then, there exists a constant K_*, depending only on mesh shape-regularity, such that*

$$\eta^i(T)^2 \le K_*\big(\|\nabla(\mathbf{U}^{i+1} - \mathbf{U}^i)\|^2_{\mathcal{F}^i(T)} + \operatorname{osc}(\mathbf{f}, \mathcal{F}^i(T))^2\big).$$

Remark 5.2. We refer to [15] for a thorough discussion about the requirement (5.7) and its importance for convergence.

We now present the following algorithm, which was first proposed in [15], based on a marking strategy due to Dörfler [11].

ELLIPTIC$(\mathcal{T}^0, P, \varepsilon, \mathbf{f})$

Choose parameters $0 < \theta,\ \theta_f < 1$, and set $i = 0$.
1. Compute the discrete solution $\mathbf{U}^i \in \mathbb{V}^i$ of (5.2) over $\mathcal{T}^i$.
2. Compute the local indicators $\eta^i(T)$.
3. If $\big(\sum_{T\in\mathcal{T}^i} \eta^i(T)^2\big)^{1/2} \le \varepsilon$, return the pair $(\mathcal{T}^i, \mathbf{U}^i)$ to AUA.
4. Mark a subset $\hat{\mathcal{T}}^i \subset \mathcal{T}^i$ such that

$$\textstyle\sum_{T\in\hat{\mathcal{T}}^i} \eta^i(T)^2 \ge \theta \sum_{T\in\mathcal{T}^i} \eta^i(T)^2.$$

5. Define $\tilde{\mathcal{T}}^i$ to be the set of all elements $T' \in \mathcal{F}^i(T)$ for $T \in \hat{\mathcal{T}}^i$.
6. Enlarge (if necessary) $\tilde{\mathcal{T}}^i$ to satisfy

$$\textstyle\sum_{T\in\tilde{\mathcal{T}}^i} h_T^2 \|f - f_T\|_T^2 \ge \theta_f \sum_{T\in\mathcal{T}^i} h_T^2 \|f - f_T\|_T^2.$$

7. Refine $\mathcal{T}^i$ so that every element $T' \in \tilde{\mathcal{T}}^i$ satisfies (5.7).
8. Update $i \leftarrow i + 1$ and go to step 1.

Remark 5.3. Let us note that step 6 implies the existence of a constant $\rho_f \in (0, 1)$, depending only on θ_f and mesh shape-regularity, such that

$$\operatorname{osc}(f, \mathcal{T}^{i+1}) \le \rho_f \operatorname{osc}(f, \mathcal{T}^i) \quad \forall\ i \ge 0. \tag{5.8}$$

This assertion has been proved in [15] for linear finite elements, but that proof remains valid for any polynomial degree and is thus omitted.

Remark 5.4. Since (5.2) is not the ultimate goal of the AUA, but rather an intermediate problem, we used $\theta = \theta_f = 0.1$ in the experiments of section 3 for the refinement decisions of ELLIPTIC to be rather conservative. This yields a suitable

work balance between ELLIPTIC and UPDATE. Moreover, step 6 of ELLIPTIC plays no significant role in practice for smooth $\mathbf{f}$ [15].

For ELLIPTIC we have the following result, which guarantees that (2.9) can be achieved with finite iterations. We show in Proposition 5.6 that this number of iterations is indeed independent of the outer counter j.

PROPOSITION 5.3. *Let $\mathbf{U}^i$ be a sequence of finite element solutions produced by* ELLIPTIC. *Then, there exist two constants C_0 and $\rho < 1$, depending only on the parameters θ, θ_f of* ELLIPTIC*, such that*

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\| \le \rho^i \max\left\{ \left\|\nabla(\mathbf{u}-\mathbf{U}^0)\right\|, C_0\,\mathrm{osc}(f,\mathcal{T}^0)\right\}. \tag{5.9}$$

Proof. By virtue of Lemmas 5.1, 5.2, and step 4 of ELLIPTIC, we have that

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\|^2 \le \frac{K^*}{\theta}\sum_{T\in\hat{\mathcal{T}}^i}\eta^i(T)^2 \le \frac{1}{\lambda}\left(\left\|\nabla(\mathbf{U}^i-\mathbf{U}^{i+1})\right\|^2 + \mathrm{osc}(f,\mathcal{T}^i)^2\right),$$

with $\lambda = \frac{\theta}{(d+2)\,K^*\,K_*}$. Combining this with (5.6) we arrive at

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^{i+1})\right\|^2 \le (1-\lambda)\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\|^2 + \mathrm{osc}(f,\mathcal{T}^i)^2.$$

If $\mu > 0$ is sufficiently small so that $\rho_e^2 := 1-\lambda+\mu^2 < 1$, as well as

$$\mathrm{osc}(f,\mathcal{T}^i) \le \mu\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\|, \tag{5.10}$$

we then get the error reduction formula

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^{i+1})\right\| \le \rho_e\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\|. \tag{5.11}$$

To prove (5.9) we set $\rho := \max\{\rho_e,\rho_f\}$, $C_0 := (\mu\,\rho)^{-1}$, with ρ_f as in Remark 5.3, and argue by induction. Since the claim holds trivially for $i=0$, we assume that it holds for $i \ge 0$. Then, we have the two alternatives

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\| > \rho^{i+1}C_0\,\mathrm{osc}(f,\mathcal{T}^0), \tag{5.12}$$

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\| \le \rho^{i+1}C_0\,\mathrm{osc}(f,\mathcal{T}^0). \tag{5.13}$$

In case (5.12), we see from Remark 5.3 that $\mathrm{osc}(f,\mathcal{T}^i) \le \rho_f^i\,\mathrm{osc}(f,\mathcal{T}^0)$, whence

$$\mathrm{osc}(f,\mathcal{T}^i) \le \mu\rho^{i+1}\frac{\mathrm{osc}(f,\mathcal{T}^0)}{\rho\mu} = \mu\rho^{i+1}C_0\,\mathrm{osc}(f,\mathcal{T}^0) < \mu\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\|.$$

Consequently, (5.10) holds and, by (5.11) and the induction assumption, we deduce

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^{i+1})\right\| \le \rho\left\|\nabla(\mathbf{u}-\mathbf{U}^i)\right\| \le \rho^{i+1}\max\left\{\left\|\nabla(\mathbf{u}_j-\mathbf{U}^0)\right\|, C_0\,\mathrm{osc}(f,\mathcal{T}^0)\right\}.$$

On the other hand, exploiting that $\mathcal{T}^{i+1}$ is a refinement of $\mathcal{T}^i$, and thus that the error cannot increase $\|\nabla(\mathbf{u}-\mathbf{U}^{i+1})\| \le \|\nabla(\mathbf{u}-\mathbf{U}^i)\|$, we handle (5.13) as follows:

$$\left\|\nabla(\mathbf{u}-\mathbf{U}^{i+1})\right\| \le \rho^{i+1}C_0\,\mathrm{osc}(f,\mathcal{T}_0) \le \rho^{i+1}\max\left\{\left\|\nabla(\mathbf{u}-\mathbf{U}^0)\right\|, C_0\,\mathrm{osc}(f,\mathcal{T}^0)\right\}.$$

The proof is thus complete. ∎

We now verify property (2.10) for the families (2.5) and (2.6). We note that $\mathrm{div}\,\mathcal{P}^k(\mathcal{T}_j) \subset \mathcal{P}_d^{k-1}(\mathcal{T}_j)$, whence Π_j reduces to the identity for (2.6) and thus (2.10) is trivially satisfied. The case (2.5) is more delicate and is the subject of our next result.

PROPOSITION 5.4. *The following interpolation estimate is valid:*

$$\|g - \Pi_j g\| \le C \left(\sum_{T \in \mathcal{T}_j} h_T \, \|[\![g]\!]\|^2_{\partial T} \right)^{1/2} \qquad \forall\ g \in \mathcal{P}_d^{k-1}(\mathcal{T}_j). \tag{5.14}$$

Proof. We recall that $\Pi_j g \in \mathbb{P}_j$ is the best L^2-approximation in $\mathbb{P}_j = \mathcal{P}^l(\mathcal{T}_j)$ of g and $l \ge k-1$. To prove the assertion we could simply replace $\Pi_j g$ by any interpolant of g into $\mathbb{P}_j$. We now construct an interpolation operator I_j closely related to the Clément operator [4]. Let ω_i be the star of $\mathcal{T}_j$ corresponding to the node x_i, and let $g_i \in P^l(\omega_i)$ be the L^2-projection of g into the space of continuous *piecewise* polynomials $P^l(\omega_i)$:

$$g_i \in P^l(\omega_i): \quad \int_{\omega_i} (g - g_i) q = 0 \quad \forall q \in P^l(\omega_i).$$

We then set $I_j g(x_i) := g_i(x_i)$ and recall that to estimate the error $g - I_j g$ it suffices to bound $g - g_i$ over ω_i for all i [4]. To this end, we first scale ω_i to a reference situation of unit size and then realize that, since $g - g_i$ is piecewise polynomial, all its norms are equivalent. In particular, we claim that the seminorm

$$|g - g_i|_{\omega_i} := \left(\sum_{S \subset \omega_i} \|[\![g]\!]\|^2_S \right)^{1/2}$$

is a norm. In fact, if $|g - g_i|_{\omega_i} = 0$ then $g - g_i$ is continuous in ω_i, $g - g_i \in \mathcal{P}^l(\omega_i)$, and thus $g - g_i$ is orthogonal to itself, whence $g - g_i = 0$. A scaling back to ω_i yields the power of meshsize asserted in (5.14) and concludes the proof. ∎

We point out that Proposition 5.4 remains true if Π_j is an L^2-projection into any space of continuous piecewise polynomials containing $\mathcal{P}^{k-1}(\mathcal{T}_j)$.

COROLLARY 5.5. *There exists a constant $C > 0$, depending only on mesh shape-regularity and k, such that*

$$\|\nabla \mathbf{V} - \Pi_j \nabla \mathbf{V}\| \le C \left(\sum_{T \in \mathcal{T}_j} h_T \, \|[\![\nabla \mathbf{V} \cdot \mathbf{n}]\!]\|^2_{\partial T} \right)^{1/2} \qquad \forall\ \mathbf{V} \in \mathcal{P}^k(\mathcal{T}_j).$$

Proof. We take $g \in \mathcal{P}_d^{k-1}(\mathcal{T}_j)$ to be any partial derivative of $\mathbf{V} \in \mathcal{P}^k(\mathcal{T}_j)$ and observe that $|[\![g]\!]| \le |[\![\nabla \mathbf{V} \cdot \mathbf{n}]\!]|$ because V being continuous makes the jump $[\![\nabla \mathbf{V}]\!]$ vanish in any tangential direction. We now apply Proposition 5.4. ∎

To derive (2.10) from Corollary 5.5 in case (2.5), we further note that if $\mathbb{P}_{j-1}$ is a space of continuous finite elements, then the jump residual of (5.3) reduces to the jumps of $\nabla \mathbf{U}_j$, which are bounded by ε_j when ELLIPTIC stops.

Proof of Lemma 5.2. We first prove the following estimate for the interior residual $\mathbf{R}$ of (5.3), provided $T \in \mathcal{T}^i$ has a node of the finer mesh $\mathcal{T}^{i+1}$ in its interior:

$$h_T^2 \, \|\mathbf{R}\|_T^2 \le C \big(\big\|\nabla(\mathbf{U}^{i+1} - \mathbf{U}^i)\big\|_T^2 + \operatorname{osc}(\mathbf{f}, T)^2 \big). \tag{5.15}$$

We recall that $\mathbf{f}_T$ denotes the orthogonal L^2-projection of any vector-valued function $\mathbf{f}$ into $\mathcal{P}^{k-1}(T)$. Then, since the degree of the pressure space is $\ell \le k$, $(\Delta \mathbf{U}^i - \nabla P)_T = \Delta \mathbf{U}^i - \nabla P$, whence $\mathbf{R} - \mathbf{R}_T = \mathbf{f} - \mathbf{f}_T$.

Now let φ_T be the canonical continuous piecewise linear basis function of the triangulation $\mathcal{T}^{i+1}$ corresponding to the node inside T; thus $\operatorname{supp}\varphi_T \subset T$. Since $\mathbf{R}_T$ is a polynomial, both $\|\mathbf{R}_T\|_T^2$ and $\int_T |R_T|^2\varphi_T$ are equivalent up to a constant depending on mesh-regularity. Therefore, integrating by parts and using the fact that $\mathbf{R}_T\varphi_T \in \mathbb{V}^{i+1}$, we get

$$\begin{aligned}\|\mathbf{R}_T\|_T^2 &\le C\int_T |\mathbf{R}_T|^2\varphi_T = \int_T \mathbf{R}\cdot(\mathbf{R}_T\varphi_T) + \int_T (\mathbf{R}_T-\mathbf{R})\cdot(\mathbf{R}_T\varphi_T)\\ &= \int_T \nabla(\mathbf{U}^{i+1}-\mathbf{U}^i):\nabla(\mathbf{R}_T\varphi_T) + \int_T (\mathbf{f}_T-\mathbf{f})\cdot(\mathbf{R}_T\varphi_T)\\ &\le C\big(\big\|\nabla(\mathbf{U}^{i+1}-\mathbf{U}^i)\big\|_T \|\nabla(\mathbf{R}_T\varphi_T)\|_T + \|\mathbf{f}_T-\mathbf{f}\|_T\,\|\mathbf{R}_T\varphi_T\|_T\big).\end{aligned}$$

Since $\mathbf{R}_T\varphi_T \in \mathbb{V}^{i+1}$, applying the inverse inequality $\|\nabla(\mathbf{R}_T\varphi_T)\|_T \le Ch_T^{-1}\|\mathbf{R}_T\varphi_T\|_T$, together with the triangle inequality $\|\mathbf{R}\|_T \le \|\mathbf{R}_T\|_T + \|\mathbf{f}-\mathbf{f}_T\|$, results in (5.15).

We next consider a side S of $\mathcal{T}^i$ having a node of $\mathcal{T}^{i+1}$ in its interior and prove the following estimate for the residual $\mathbf{J}$ in (5.3):

$$h_T\|\mathbf{J}\|_S^2 \le C\big(h_T\|\mathbf{R}\|_{\mathcal{F}^i(S)}^2 + \big\|\nabla(\mathbf{U}^{i+1}-\mathbf{U}^i)\big\|_{\mathcal{F}^i(S)}^2\big). \tag{5.16}$$

Let us first observe that $\mathbf{J}$ is a polynomial of degree at most $k-1$ on S. In fact, if $P \in \mathbb{P} = \mathcal{P}_d^{k-1}(\mathcal{T}_j)$, then this is obvious (case (2.6)), and if $P \in \mathbb{P} = \mathcal{P}^l(\mathcal{T}_j)$, then P does not jump and $\mathbf{J} = [\![\nabla\mathbf{U}_j\cdot\mathbf{n}]\!]$ (case (2.5)). Therefore, $\mathbf{J}$ admits a piecewise polynomial extension to $\mathcal{F}^i(S)$ of degree at most $k-1$, which is still denoted by $\mathbf{J}$ (simply scale to the master element and extend $\mathbf{J}$ as a constant in the direction normal to S).

Now let φ_S be the continuous piecewise linear basis function of the triangulation $\mathcal{T}^{i+1}$ corresponding to the node inside S; thus $\operatorname{supp}\varphi_S \subset \mathcal{F}^i(S)$. Hence $\mathbf{J}\varphi_S \in \mathbb{V}^{i+1}$ and $\operatorname{supp}(\mathbf{J}\varphi_S) \subset \mathcal{F}^i(S)$. Since $\|\mathbf{J}\|_S^2$ is equivalent to $\int_S |\mathbf{J}|^2\varphi_S$, integrating by parts and using the fact that $\mathbf{J}\varphi_S \in \mathbb{V}^{i+1}$, we obtain

$$\begin{aligned}\|\mathbf{J}\|_S^2 &\le C\int_S |\mathbf{J}|^2\varphi_S = \int_S [\![\nabla\mathbf{U}^i\cdot\mathbf{n} - P\mathbf{n}]\!]\cdot\mathbf{J}\varphi_S\\ &= -\int_{\mathcal{F}^i(S)} \mathbf{R}\cdot\mathbf{J}\varphi_S + \int_{\mathcal{F}^i(S)} \nabla(\mathbf{U}^{i+1}-\mathbf{U}^i):\nabla(\mathbf{J}\varphi_S)\\ &\le \|\mathbf{R}\|_{\mathcal{F}^i(S)}\|\mathbf{J}\varphi_S\|_{\mathcal{F}^i(S)} + \big\|\nabla(\mathbf{U}^{i+1}-\mathbf{U}^i)\big\|_{\mathcal{F}^i(S)}\|\nabla(\mathbf{J}\varphi_S)\|_{\mathcal{F}^i(S)}\\ &\le \left(\|\mathbf{R}\|_{\mathcal{F}^i(S)} + \frac{1}{h_S}\big\|\nabla(\mathbf{U}^{i+1}-\mathbf{U}^i)\big\|_{\mathcal{F}^i(S)}\right)\|\mathbf{J}\varphi_S\|_{\mathcal{F}^i(S)}.\end{aligned}$$

Multiplying by h_S and using the equivalence of $\|\mathbf{J}\|_S$ and $\frac{1}{h_T}\|\mathbf{J}\|_{\mathcal{F}^i(S)}^2$, we arrive at the desired estimate (5.16).

To complete the proof, we let $T \in \mathcal{T}^i$ satisfy the assumption that all elements $T' \in \mathcal{F}^i(T)$ possess the interior node property (5.7). We realize that for all those T' we can apply (5.15) and next insert the bound for $\|\mathbf{R}_{T'}\|_{T'}$ into (5.16). ∎

Remark 5.5. The above proof uncovers the need for the relation $k \ge l$ between the polynomial degrees k for velocity and l for pressure. If this were not true, then ∇P would differ from $(\nabla P)_T$ and we should then account for the oscillation $\nabla P - (\nabla P)_T$, which is not given data. Since procedure UPDATE reveals no accuracy gain for $l \ge k$, our assumption $l \le k$ in (2.5) and (2.6) is not a serious restriction.

5.2. Complexity. We now turn to the analysis of the complexity of ELLIPTIC. We first observe that the lower bound (5.5), together with the rates of convergence (5.9) and of oscillation reduction (5.8), implies

$$\begin{aligned}\sum_{T\in\mathcal{T}^i}\eta^i(T)^2 &\le K_*(d+2)\big(\left\|\nabla(\mathbf{u}_j-\mathbf{U}^i)\right\|^2+\operatorname{osc}(\mathbf{f},\mathcal{T}^i)^2\big)\\ &\le K_1\rho^{2i}\left\|\nabla(\mathbf{u}_j-\mathbf{U}^0)\right\|^2+K_2\rho^{2i}\operatorname{osc}(\mathbf{f},\mathcal{T}^0)^2,\end{aligned}\tag{5.17}$$

where the constants K_1, K_2 depend only on mesh-regularity and the parameters θ, θ_f of ELLIPTIC. Therefore, the stopping criterion in step 3 of ELLIPTIC can be fulfilled in a finite number of iterations.

A fundamental question that remains open is whether this number can be *bounded uniformly* with respect to the outer iteration counter j. The answer is affirmative and is the subject of the following statement.

PROPOSITION 5.6. *Let the tolerance reduction factor γ of the AUA satisfy $\gamma>\beta$, where $\beta=\left\|I-\alpha\mathcal{S}\right\|_{\mathcal{L}(\mathbb{P},\mathbb{P})}<1$ is defined in* (2.4)*. Then, the number of iterations in the inner loop of* ELLIPTIC *is bounded by a constant which depends only on* $\mathbf{f}$*, the initial pressure guess P_0, the initial triangulation $\mathcal{T}_0$ of the AUA, the ratio β/γ, and the parameters θ and θ_f of* ELLIPTIC*, but not on the outer index j.*

Proof. By the preceding comment, the number of iterations of ELLIPTIC is bounded for all outer counters j. It is thus sufficient to consider the case $j>1$.

We need to prove the existence of a constant C such that for some $i<C$,

$$\sum_{T\in\mathcal{T}^i}\eta^i(T)^2\le\varepsilon^2.$$

We recall that the initial mesh $\mathcal{T}^0$ of the inner loop is always taken to be the mesh $\mathcal{T}_{j-1}$ of the previous outer loop. Since the term $\Delta\mathbf{U}_j-\nabla P_{j-1}$ of the interior residual $\mathbf{R}_{j-1}$ does not oscillate, using definition (4.4), we get

$$\begin{aligned}\operatorname{osc}(\mathbf{f},\mathcal{T}^0)=\operatorname{osc}(\mathbf{R}_{j-1},\mathcal{T}_{j-1}) &\le\left(\sum_{T\in\mathcal{T}_{j-1}}h_T^2\|\mathbf{R}_{j-1}\|_T^2\right)^{1/2}\\ &\le\left(\sum_{T\in\mathcal{T}_{j-1}}h_T^2\|\mathbf{R}_{j-1}\|_T^2+h_T\|\mathbf{J}_{j-1}\|_{\partial T}^2\right)^{1/2}\\ &=\left(\sum_{T\in\mathcal{T}_{j-1}}\eta_{j-1}(T)^2\right)^{1/2}\le\varepsilon_{j-1}=\varepsilon_0\gamma^{j-1},\end{aligned}$$

where the last inequality is guaranteed by the stopping criterion (step 3) of ELLIPTIC. This accounts for the second term in (5.17).

To estimate $\left\|\nabla(\mathbf{u}_j-\mathbf{U}^0)\right\|$ in (5.17), we first split it into three parts:

$$\left\|\nabla(\mathbf{u}_j-\mathbf{U}^0)\right\|\le\|\nabla(\mathbf{u}_j-\mathbf{u}_{j-1})\|+\|\nabla(\mathbf{u}_{j-1}-\mathbf{U}_{j-1})\|+\left\|\nabla(\mathbf{U}_{j-1}-\mathbf{U}^0)\right\|.$$

By virtue of (2.9), we have

$$\|\nabla(\mathbf{u}_{j-1}-\mathbf{U}_{j-1})\|\le C\varepsilon_{j-1}=C\varepsilon_0\gamma^{j-1}.$$

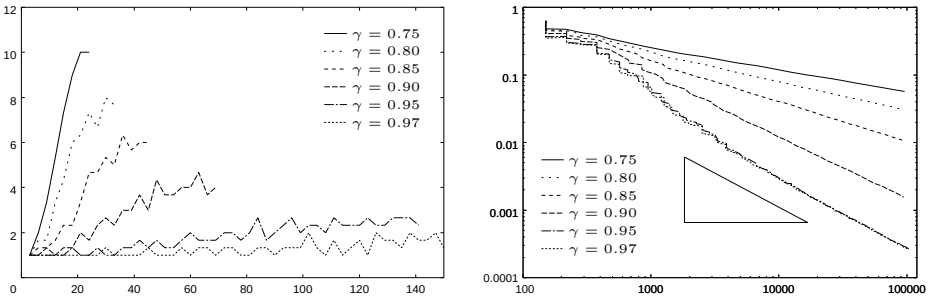

FIG. 5.1. *Example* 3.2: *Number of inner iterations versus outer interations (left) and error decay versus DOFs (right) for different values of* γ. *A triangle shows the optimal decay.*

Since $\mathbb{V}^0 = \mathbb{V}_{j-1}$, both $\mathbf{U}^0$ and $\mathbf{U}_{j-1}$ belong to $\mathbb{V}_{j-1}$ and, by (2.8), they satisfy

$$\int_\Omega \nabla(\mathbf{U}^0 - \mathbf{U}_{j-1}) : \nabla \mathbf{V} = \int (P_{j-1} - P_{j-2}) \operatorname{div} \mathbf{V} \quad \forall\, \mathbf{V} \in \mathbb{V}_{j-1}.$$

Hence, taking $\mathbf{V} = \mathbf{U}^0 - \mathbf{U}_{j-1}$ implies

$$\left\|\nabla(\mathbf{U}_{j-1} - \mathbf{U}^0)\right\| \le \|P_{j-1} - P_{j-2}\| \le \|P_{j-1} - p\| + \|p - P_{j-2}\|.$$

A similar energy argument, based on the fact that $\mathbf{u}_j$ is the solution to (2.7), yields the same estimate for $\|\nabla(\mathbf{u}_j - \mathbf{u}_{j-1})\|$. To derive a suitable estimate for $\|p - P_j\|$, we now improve (2.12) as follows:

$$\|p - P_j\| \le \beta^j \|p - P_0\| + C\alpha\varepsilon_0 \sum_{\ell=0}^{j-1} \beta^\ell \gamma^{j-\ell} \le \beta^j \|p - P_0\| + C\alpha\varepsilon_0 \gamma^j \frac{1 - (\beta/\gamma)^j}{1 - (\beta/\gamma)}.$$

Inserting the previous estimates back into (5.17), we find a constant K, depending on f, the initial pressure guess P_0, the initial triangulation $\mathcal{T}_0$ of the AUA, the parameters θ, θ_f of ELLIPTIC, and the ratio $\beta/\gamma < 1$, such that

$$\left(\sum_{T \in \mathcal{T}^i} \eta^i(T)^2 \right)^{1/2} \le K \rho^i \gamma^j. \tag{5.18}$$

Therefore, $K\rho^i\gamma^j \le \varepsilon_j = \varepsilon_0\gamma^j$ whenever $\rho^i \le \varepsilon_0/K$, and the assertion is proved. ∎

Remark 5.6. It might seem at first sight that $\gamma > \beta$ is an artificial requirement of the proof and thus that the result should still hold for any $\gamma < 1$. If $\gamma < \beta$, then the above proof would also give (5.18) with β instead of γ, whence

$$i \le C_1 j + C_2$$

for appropriate constants $C_1, C_2 > 0$. This linear growth is corroborated by the simulations leading to Figure 5.1, which depicts the number of inner loops i versus the outer loop counter j for Example 3.2 with the Taylor–Hood element $\mathcal{P}^2$-$\mathcal{P}^1$.

Remark 5.7. Since β is not known in general, the requirement $\beta < \gamma < 1$ may seem restrictive in practice. On the other hand, a value of γ too close to 1 results in a large number of outer iterations. We found a practical compromise $\gamma = 0.95$ for all simulations of section 3 that leads to a number of inner iterations between 3 and 5.

Acknowledgment. The authors would like to thank Kunibert G. Siebert for his assistance with the implementation of discontinuous finite elements within ALBERT and for many valuable suggestions and discussions about this work.

ADAPTIVE WAVELET METHODS FOR SADDLE POINT PROBLEMS—OPTIMAL CONVERGENCE RATES*

STEPHAN DAHLKE†, WOLFGANG DAHMEN‡, AND KARSTEN URBAN§

Abstract. In this paper an adaptive wavelet scheme for saddle point problems is developed and analyzed. Under the assumption that the underlying continuous problem satisfies the inf-sup condition, it is shown in the first part under which circumstances the scheme exhibits asymptotically optimal complexity. This means that within a certain range the convergence rate which relates the achieved accuracy to the number of involved degrees of freedom is asymptotically the same as the error of the best wavelet N-term approximation of the solution with respect to the relevant norms. Moreover, the computational work needed to compute the approximate solution stays proportional to the number of degrees of freedom. It is remarkable that compatibility constraints on the trial spaces such as the Ladyzhenskaya–Babuška–Brezzi (LBB) condition do not arise. In the second part the general results are applied to the Stokes problem. Aside from the verification of those requirements on the algorithmic ingredients the theoretical analysis had been based upon, the regularity of the solutions in certain Besov scales is analyzed. These results reveal under which circumstances the work/accuracy balance of the adaptive scheme is even asymptotically better than that resulting from preassigned uniform refinements. This in turn is used to select and interpret some first numerical experiments that are to quantitatively complement the theoretical results for the Stokes problem.

Key words. saddle point problems, wavelet bases, norm equivalences, adaptive refinements, fast approximate operator application, Uzawa iteration

1. Introduction.

This paper draws on two major sources of motivation. First, it has recently been shown in [8] that certain adaptive wavelet schemes are asymptotically optimal for a wide class of self-adjoint elliptic operator equations. This means that the achieved accuracy in the energy norm expressed in terms of the numbers of involved degrees of freedom is asymptotically the same as the rate of the *best N-term approximation*, i.e., the minimal number of basis functions needed to approximate the solution within the given accuracy tolerance. Moreover, (up to additional log-factors in sorting operations; see also Remark 4.10 below) it was shown that the computational work needed to compute the approximate solution stays proportional to the number of degrees of freedom. While the class of operator equations covers boundary value problems for partial differential equations as well as singular integral equations, symmetry did play a crucial role in the analysis and design of the scheme. These techniques have meanwhile been extended to noncoercive problems through *wavelet least squares formulations* [9].

Second, in [14] the results of a predecessor [13] of [8] also for the symmetric elliptic case have been extended to saddle point problems. The key idea there was

to use an outer Uzawa iteration and to solve the interior symmetric positive definite problems by a scheme of the type considered in [13]. However, no statements about the efficiency of such schemes in terms of convergence rates and work count was made in [14].

In this paper we also consider saddle point problems actually under slightly weaker assumptions than in [14] and propose an adaptive wavelet scheme for their numerical solution. In order to avoid (among other things) the squaring of condition numbers, it is based as in [14] on an outer Uzawa iteration although it differs from the scheme in [14] in several essential ways. It draws on detailed algorithmic ingredients from [8] which allow one to quantify concrete computational steps and estimate their complexity, which results in a somewhat different balance of accuracies. It also applies when the symmetric bilinear form is only elliptic on the kernel of the constraint operator.

On a more fundamental level, in the same spirit as in [8, 9], there are two essential features that distinguish the present approach from [13, 14] and more so from classical discretization. The first one is that through appropriate wavelet bases the original continuous problem is transformed right from the beginning into an *equivalent* problem which is *well-posed in the Euclidean metric*. All essential computational steps refer then to approximation in ℓ_2 and therefore bear a great potential of being portable to other problem classes. In fact, many of the basic routines developed in [2, 8] in the context of elliptic problems can be used here as well. The second important point is that the wavelet representation allows us to think of performing, up to a controlled perturbation, an iteration on the full infinite dimensional problem realized through the *adaptive approximate application* of the full infinite dimensional operators. The tolerances have to be chosen so that the convergence speed of the perturbed realizable iteration is indeed governed by the properties of the ideal infinite dimensional iteration.

This offers, in particular, a first intuitive explanation for the following fact which at first glance strikes one as a paradox; namely, compatibility constraints on the choice of trial functions such as the *Ladyzhenskaya–Babuška–Brezzi (LBB) condition* do *not* arise. In fact, recall that even when the infinite dimensional saddle point problem is well-posed and hence satisfies an inf-sup condition, inappropriate choices of finite dimensional trial spaces could lead to discrete problems with poor stability properties; that is, the inverses of the corresponding system matrices may have arbitrarily large norms. This fact is relevant whenever linear systems are to be solved for any such given pair of trial spaces. In the present context this situation will never arise. Instead an iterative process is conceptually applied to the *full infinite dimensional problem*, where each iteration involves an adaptive application of the underlying infinite dimensional operators within a certain stage dependent dynamic accuracy tolerance. This process is inherently nonlinear. Roughly speaking, proper adaptation in the above sense inherits the stability of the infinite dimensional problem. In this sense adaptation not only reduces complexity but also *stabilizes* the computation *automatically*.

The paper is organized as follows. After formulating the problem in section 2 we describe and analyze an adaptive method in section 3. It will be shown in section 4 under which conditions on the algorithmic ingredients it exhibits an *asymptotically optimal accuracy/work balance* in the following sense. Whenever the exact solution has, within a certain range of exponents s, an error of *best N-term approximation* with respect to an underlying wavelet basis decaying like N^{-s}, then the error achieved by the adaptive scheme also decays like N^{-s}, where N is the number of used degrees of freedom. Moreover, the computational work stays proportional to N. A key role

in this context is played by the *compressibility range* of the involved operators in wavelet coordinates. Given this property, one can employ a certain adaptive scheme for applying the operator to any finitely supported vector with optimal accuracy/work balance [8].

In section 5 the general results are applied to the *Stokes problem*. Specifically, we investigate in section 5.3 the compressibility range of the wavelet representation of the Stokes operator for a certain family of wavelet bases and derive sharp estimates for this range. This identifies the range of decay rates for which the general results from the preceding sections apply.

It should be stressed that the scheme works without *any* a priori assumptions on the solution, while its complexity is analyzed under the assumption that the solution has a certain order of best N-term approximations and the involved operators in wavelet coordinates have a certain compressibility range (see section 4). Certain rates of the decay of best N-term approximation, in turn, are (almost) equivalent to a certain regularity of the solution in a *Besov scale*. Roughly speaking, when the Sobolev regularity of the solution is lower than its Besov regularity, the adaptive scheme is expected to offer even an *asymptotically better* accuracy/work balance than linear schemes. To see whether or under which circumstances the adaptive scheme can be rigorously proven to offer even an asymptotically better accuracy/work balance than schemes based on uniform preassigned mesh refinements, we investigate in section 5.4 the Besov regularity of singularity solutions for the Stokes problem. The results show that in two spatial dimensions sufficiently high order wavelet bases would give rise to adaptive schemes with *arbitrarily* high convergence rates.

Finally, in section 6 we present some numerical experiments essentially guided by the above-mentioned theoretical considerations. Here we make use of the software developed in [2] as well as in [25]. The results confirm that the adaptive scheme performs essentially independently of the pairing of trial functions for velocities and pressure. For instance, the rate of decay of the best N-term approximation is met within a factor two when both velocities and pressure are approximated by piecewise linear trial functions.

After completion of this work we became aware of related investigations in [4] pursuing similar ideas in a finite element context. There, convergence in the sense of [14] is proven for a similar Uzawa technique without establishing, however, rigorous estimates for the corresponding work/accuracy balance.

2. Saddle point problems.

2.1. The setting. Let X, M denote Hilbert spaces with norms $\|\cdot\|_X, \|\cdot\|_M$, respectively. Dual pairings on $X \times X'$ and $M \times M'$ (X', M' denoting the duals of X, M, respectively) will always be denoted by $\langle\cdot,\cdot\rangle$. It will be clear from the context which spaces are referred to. Suppose that $a(\cdot,\cdot)$ is a continuous symmetric bilinear form on $X \times X$ and that $b(\cdot,\cdot)$ is a continuous bilinear form on $X \times M$; i.e.,

$$|a(v,w)| \lesssim \|v\|_X \|w\|_X, \quad |b(q,v)| \lesssim \|v\|_X \|q\|_M.$$

We shall often write $A \lesssim B$ to indicate the existence of an absolute constant $c > 0$ such that $A \le cB$. In addition, $A \sim B$ means $A \lesssim B \lesssim A$.

Moreover, denoting by $B : X \to M'$ the operator induced by $b(p,v) = \langle p, Bv\rangle$ and setting $V := \ker B$, assume that $a(\cdot,\cdot)$ is elliptic on V and $b(\cdot,\cdot)$ satisfies the *inf-sup*

condition

$$a(v,v) \geq \alpha \|v\|_X^2, \quad v \in V, \qquad \inf_{q \in M} \sup_{v \in X} \frac{b(q,v)}{\|v\|_X \|q\|_M} > \beta, \qquad \alpha, \beta > 0. \tag{2.1.1}$$

It is well known that then the variational problem

$$\begin{array}{rcl} a(u,v) + b(p,v) & = & \langle f, v\rangle, \quad v \in X, \\ b(q,u) & = & \langle q, g\rangle, \quad q \in M, \end{array} \tag{2.1.2}$$

has a unique solution $U = (u,p) \in X \times M$ for any $f \in X'$, $g \in M'$; see, e.g., [5]. Defining $A : X \to X'$ by $a(v,w) = \langle v, Aw\rangle$, $v \in X$, (2.1.2) is equivalent to the 2×2 block operator equation

$$\mathcal{L}U := \begin{pmatrix} A & B' \\ B & 0 \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix} =: F, \tag{2.1.3}$$

where $\mathcal{L}$ is an isomorphism from $X \times M$ into its dual $X' \times M'$; i.e., there exist positive constants $c_{\mathcal{L}}, C_{\mathcal{L}}$ such that

$$c_{\mathcal{L}} \left(\|v\|_X^2 + \|q\|_M^2 \right)^{1/2} \leq \left\| \mathcal{L} \begin{pmatrix} v \\ q \end{pmatrix} \right\|_{X' \times M'} \leq C_{\mathcal{L}} \left(\|v\|_X^2 + \|q\|_M^2 \right)^{1/2}. \tag{2.1.4}$$

Classical examples are mixed formulations of second order elliptic boundary value problems, the Stokes problem, or the system obtained when appending essential boundary conditions by Lagrange multipliers.

2.2. Wavelet coordinates. Now suppose that we have wavelet bases $\Psi_X = \{\psi_{X,\lambda} : \lambda \in \mathcal{J}_X\}$, $\Psi_M = \{\psi_{M,\lambda} : \lambda \in \mathcal{J}_M\}$ for X and M at our disposal ($\mathcal{J}_X$ and $\mathcal{J}_M$ being the corresponding index sets) such that for suitable diagonal matrices $\mathbf{D}_X$, $\mathbf{D}_M$ and constants c_X, C_X, c_M, C_M one has

$$c_X \|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \leq \|\mathbf{v}^T \mathbf{D}_X^{-1} \Psi_X\|_X \leq C_X \|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)}, \tag{2.2.1}$$

and likewise

$$c_M \|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)} \leq \|\mathbf{q}^T \mathbf{D}_M^{-1} \Psi_M\|_M \leq C_M \|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)}, \tag{2.2.2}$$

where $\mathbf{v}^T \mathbf{D}_X^{-1} \Psi_X := \sum_{\lambda \in \mathcal{J}_X} d_{X,\lambda}^{-1} v_\lambda \psi_{X,\lambda}$. The validity of such norm equivalences will be crucial in what follows. Note that often M is a closed subspace of finite codimension in a larger Hilbert space $\hat{M}$ for which (2.2.2) holds. For instance, in the case of the Stokes problem, M is the space of all L_2 functions with zero mean. Thus the arrays of wavelet coefficients of elements in M will, in general, form a closed subspace $\ell_{2,0}(\mathcal{J}_M)$ of finite codimension in $\ell_2(\mathcal{J}_M)$.

At this point we dispense with any additional technical details about the precise nature of the basis functions but refer to [7, 15] for surveys and further references; see also the comments in connection with numerical realizations below. A further important property is the *cancellation property* which entails near sparseness of wavelet representations for many operators. This also will be detailed when necessity arises.

Defining now for any two countable arrays Θ, Φ and some inner product $c(\cdot,\cdot)$ the matrix $c(\Theta,\Phi) := (c(\theta,\phi))_{\theta \in \Theta, \phi \in \Phi}$, consider as usual the scaled wavelet representations

$$\mathbf{A} := a(\mathbf{D}_X^{-1} \Psi_X, \mathbf{D}_X^{-1} \Psi_X), \quad \mathbf{B} := b(\mathbf{D}_M^{-1} \Psi_M, \mathbf{D}_X^{-1} \Psi_X), \tag{2.2.3}$$

as well as the arrays $\mathbf{f} := \mathbf{D}_X^{-1}\langle \Psi_X, f\rangle$, $\mathbf{g} := \mathbf{D}_M^{-1}\langle \Psi_M, g\rangle$, and $\mathbf{F} := (\mathbf{f}^T, \mathbf{g}^T)^T$. Then (2.1.2) or (2.1.3) is equivalent to the following two by two block matrix system:

$$\begin{pmatrix} \mathbf{A} & \mathbf{B}^T \\ \mathbf{B} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \mathbf{u} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} \mathbf{f} \\ \mathbf{g} \end{pmatrix}. \tag{2.2.4}$$

It will make things much more transparent when working from now on exclusively in the ℓ_2 setting.

2.3. Well-posedness in ℓ_2. It follows from (2.2.1) and (2.2.2) together with (2.1.4) that the operator

$$\mathbf{L} := \begin{pmatrix} \mathbf{A} & \mathbf{B}^T \\ \mathbf{B} & \mathbf{0} \end{pmatrix} : \ell_2(\mathcal{J}) := \ell_2(\mathcal{J}_X) \times \ell_{2,0}(\mathcal{J}_M) \to \ell_2(\mathcal{J}), \quad \mathcal{J} := \mathcal{J}_X \times \mathcal{J}_M,$$

is an isomorphism; i.e., there exist positive constants c_L, C_L such that for $\mathbf{V} := (\mathbf{v}^T, \mathbf{q}^T)^T \in \ell_2(\mathcal{J})$, $\|\mathbf{V}\|^2_{\ell_2(\mathcal{J})} = \|\mathbf{v}\|^2_{\ell_2(\mathcal{J}_X)} + \|\mathbf{q}\|^2_{\ell_2(\mathcal{J}_M)}$

$$c_L\|\mathbf{V}\|_{\ell_2(\mathcal{J})} \le \|\mathbf{L}\mathbf{V}\|_{\ell_2(\mathcal{J})} \le C_L\|\mathbf{V}\|_{\ell_2(\mathcal{J})}, \quad \mathbf{V} \in \ell_2(\mathcal{J}); \tag{2.3.1}$$

see, e.g., [15, 21] for further details. Clearly, c_L, C_L can be expressed in terms of the constants $c_{\mathcal{L}}, C_{\mathcal{L}}$, c_Y, C_Y for $Y \in \{X, M\}$. Furthermore, there exist constants C_B, C'_A such that

$$\|\mathbf{B}\mathbf{v}\|_{\ell_2(\mathcal{J}_M)} \le C_B\|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)}, \quad \|\mathbf{B}^T\mathbf{q}\|_{\ell_2(\mathcal{J}_X)} \le C_B\|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)}, \tag{2.3.2}$$

and

$$\|\mathbf{A}\mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \le C'_A\|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)}. \tag{2.3.3}$$

2.4. The Schur complement. In many cases a somewhat stronger property than the first relation in (2.1.1) is valid; namely, that

$$a(v, v) \sim \|v\|^2_X, \qquad v \in X, \tag{2.4.1}$$

which, of course means that $\mathbf{A}$ is invertible on all of $\ell_2(\mathcal{J}_X)$. In this case, block elimination reduces (2.2.4) to the so-called reduced system

$$\mathbf{S}\mathbf{p} = \mathbf{B}\mathbf{A}^{-1}\mathbf{f} - \mathbf{g}, \tag{2.4.2}$$

involving the (infinite dimensional) *Schur complement*

$$\mathbf{S} := \mathbf{B}\mathbf{A}^{-1}\mathbf{B}^T : \ell_{2,0}(\mathcal{J}_M) \to \ell_{2,0}(\mathcal{J}_M), \tag{2.4.3}$$

which is symmetric positive definite and, under the above assumptions, in fact an automorphism on $\ell_{2,0}(\mathcal{J}_M)$; i.e., there exist positive constants c_S, C_S such that

$$c_S\|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)} \le \|\mathbf{S}\mathbf{q}\|_{\ell_2(\mathcal{J}_M)} \le C_S\|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)}, \quad \mathbf{q} \in \ell_{2,0}(\mathcal{J}_M). \tag{2.4.4}$$

Once $\mathbf{p}$ has been determined from (2.4.2) it remains to solve the positive definite problem

$$\mathbf{A}\mathbf{u} = \mathbf{f} - \mathbf{B}^T\mathbf{p}. \tag{2.4.5}$$

However, under the weaker assumption (2.1.1) on the bilinear form $a(\cdot,\cdot)$ one first has to take a precaution whose variational counterpart is sometimes referred to as *augmented Lagrangian method*. In the present setting it boils down to considering the matrix

$$\hat{\mathbf{A}} := \mathbf{A} + c\mathbf{B}^T\mathbf{B}, \tag{2.4.6}$$

where c is some sufficiently large but fixed positive constant.

REMARK 2.1. *Assume that* (2.1.1) *hold. Let* c *in* (2.4.6) *be any fixed positive constant, when the operator* A *in* (2.1.3) *is positive semidefinite on* X*, and otherwise satisfy* $c > C_B^2 C'_A/c_L^4$*, where* c_L, C_B, C'_A *are the constants from* (2.4.3), (2.3.2), *and* (2.3.3)*, respectively. Then the matrix* $\hat{\mathbf{A}}$ *is an automorphism on* $\ell_2(\mathcal{J}_X)$*; i.e., there exist positive constants* c_A, C_A *such that*

$$c_A\|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \le \|\hat{\mathbf{A}}\mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \le C_A\|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)}, \quad \mathbf{v} \in \ell_2(\mathcal{J}_X). \tag{2.4.7}$$

Proof. In order to identify concrete conditions on c for later purposes, we include the proof although it is in principle standard. It follows from (2.3.2) and (2.3.3) that $\hat{\mathbf{A}}$ is bounded on $\ell_2(\mathcal{J}_X)$. Moreover, by (2.3.1) the matrix $\mathbf{L}^T\mathbf{L} = \mathbf{L}^2$ is positive definite on $\ell_2(\mathcal{J})$. Since $\mathbf{B}\mathbf{B}^T$ is a principal block of $\mathbf{L}^2$, it is positive definite on $\ell_{2,0}(\mathcal{J}_M)$. This entails that $\hat{\mathbf{A}}$ is also injective on $\ell_2(\mathcal{J}_X)$. To see this, note that by the first relation in (2.1.1), $\mathbf{v}^T\hat{\mathbf{A}} \neq \mathbf{0}$ for $\mathbf{v} \in \ker\mathbf{B}$. On the other hand, when $\mathbf{v}$ is in the range of $\mathbf{B}^T$, i.e., $\mathbf{v} = \mathbf{B}^T\mathbf{q}$ for some $\mathbf{q} \in \ell_{2,0}(\mathcal{J}_M)$, then one has

$$\mathbf{v}^T\hat{\mathbf{A}}\mathbf{v} = \mathbf{q}^T\mathbf{B}\mathbf{A}\mathbf{B}^T\mathbf{q} + c\|\mathbf{B}\mathbf{B}^T\mathbf{q}\|^2_{\ell_2(\mathcal{J}_M)}. \tag{2.4.8}$$

Noting that, by (2.3.1), $\|\mathbf{B}\mathbf{B}^T\mathbf{q}\|^2_{\ell_2(\mathcal{J}_M)} \ge c_L^4\|\mathbf{q}\|^2_{\ell_2(\mathcal{J}_M)}$, (2.4.8) is readily seen to be strictly positive under the above assumptions on c whenever $\mathbf{q} \neq \mathbf{0}$. This confirms the injectivity of $\hat{\mathbf{A}}$ on $\ell_2(\mathcal{J}_X)$. By symmetry, (2.4.8) also implies surjectivity. Due to the boundedness of $\hat{\mathbf{A}}$, the claim follows now from the inverse mapping theorem. ∎

One easily verifies that (2.2.4) is equivalent to the system

$$\begin{pmatrix} \hat{\mathbf{A}} & \mathbf{B}^T \\ \mathbf{B} & \mathbf{0} \end{pmatrix}\begin{pmatrix} \mathbf{u} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} \hat{\mathbf{f}} \\ \mathbf{g} \end{pmatrix}, \qquad \hat{\mathbf{f}} := \mathbf{f} + c\mathbf{B}^T\mathbf{g}, \tag{2.4.9}$$

where $\hat{\mathbf{A}}$ is given by (2.4.6). By Remark 2.1, for suitable $c > 0$, block elimination can be applied to this new system (2.4.9), which then reduces to the coupled systems (2.4.2), (2.4.5) with $\mathbf{A}$ and $\mathbf{f}$ replaced by $\hat{\mathbf{A}}$ and $\hat{\mathbf{f}}$, respectively.

To simplify notation we will use the following convention throughout the remainder of the paper. We will always set

$$\mathbf{A} := \mathbf{D}_X^{-1}a(\Psi_X,\Psi_X)\mathbf{D}_X^{-1} + c\mathbf{B}^T\mathbf{B}, \quad \mathbf{f} := \mathbf{D}_X^{-1}\langle\Psi_X, f\rangle + c\mathbf{B}^T\mathbf{g}, \tag{2.4.10}$$

with $\mathbf{B} := \mathbf{D}_M^{-1}b(\Psi_M,\Psi_X)\mathbf{D}_X^{-1}$ as in (2.2.3) and $\mathbf{g} := \mathbf{D}_M^{-1}\langle\Psi_M, g\rangle$. When the bilinear form $a(\cdot,\cdot)$ satisfies the stronger assumption (2.4.1), the constant c in (2.4.10) can be chosen to be zero. Otherwise, c will always be assumed in the following to be a fixed positive constant as specified in Remark 2.1. Thus, without loss of generality, we can always make use of the reduced systems (2.4.3), (2.4.5) with a proper interpretation of the matrix $\mathbf{A}$ according to the above convention. Consequently, $\mathbf{A}$ satisfies in this sense (2.4.7).

A standard way of formulating finite dimensional problems is to take Galerkin discretizations for (2.1.2). As soon as one *fixes* a pair of finite dimensional trial spaces in X and M, for instance, spanned by collections of wavelets, the corresponding Galerkin discretization gives rise to a finite dimensional linear system, e.g., in terms of a principal finite submatrix of (2.2.4). However, it is well known that stability of the infinite dimensional problem does not guarantee the finite dimensional problems to be uniformly stable as well. Compatibility constraints in terms of the LBB condition come into play. It will be seen that this will *not* be the case in the following adaptive framework.

3. An adaptive Uzawa strategy.

3.1. Infinite dimensional Uzawa iteration. The idea is to use a stationary iterative scheme for the solution of the reduced system (2.4.2), which is essentially the Uzawa strategy proposed in [14]. In contrast, we formulate it here directly for the discrete infinite dimensional ℓ_2-problem (2.2.4). To this end, we first have to address an issue which is somewhat hidden in the ℓ_2-setting. The spaces X, M are always function spaces on some domain Ω. As will be explained in more detail later, the wavelet bases Ψ_X and Ψ_M are then typically constructed as *Riesz bases* for the corresponding spaces $L_2(\Omega)$; i.e., in addition to the norm equivalences (2.2.1), (2.2.2), one also has

$$\|\mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \sim \|\mathbf{v}^T\Psi_X\|_{L_2(\Omega)}, \quad \|\mathbf{q}\|_{\ell_2(\mathcal{J}_M)} \sim \|\mathbf{q}^T\Psi_M\|_{L_2(\Omega)}. \tag{3.1.1}$$

This means that there exist *dual* bases $\tilde\Psi_X$, $\tilde\Psi_M$ in $L_2(\Omega)$ which are also Riesz bases and satisfy

$$(\Psi_X, \tilde\Psi_X) = \mathbf{id}, \quad (\Psi_M, \tilde\Psi_M) = \mathbf{id}, \tag{3.1.2}$$

where $(\cdot,\cdot)$ denotes the standard inner product in $L_2(\Omega)$. In full agreement with the fact that the operator B maps X onto M', one observes that for $v = \mathbf{v}^T\mathbf{D}_X^{-1}\Psi_X$ the array $\mathbf{Bv}$ represents expansion coefficients of Bv with respect to the *dual basis* $\tilde\Psi_M$. In fact,

$$\begin{aligned}(\mathbf{Bv})^T\mathbf{D}_M\tilde\Psi_M &= \mathbf{v}^T\langle B\mathbf{D}_X^{-1}\Psi_X, \Psi_M\rangle\mathbf{D}_M^{-1}\mathbf{D}_M\tilde\Psi_M = \mathbf{v}^T\langle B\mathbf{D}_X^{-1}\Psi_X, \Psi_M\rangle\tilde\Psi_M \\ &= B(\mathbf{v}^T\mathbf{D}_X^{-1}\Psi_X) = \langle Bv, \Psi_M\rangle\tilde\Psi_M = Bv.\end{aligned}$$

Likewise, the array $\mathbf{g}$ consists by definition of the wavelet coefficients with respect to the dual basis $\tilde\Psi_M$. On the other hand, the unknown array $\mathbf{p}$ in the reduced system (2.4.2) contains coefficients with respect to the primal basis Ψ_M. Now, as mentioned before, in some cases the space M is actually a closed subspace of a somewhat larger Hilbert space characterized by Ψ_M. Therefore the wavelet coefficients of elements of M with respect to Ψ_M (or $\mathbf{D}_M^{-1}\Psi_M$) satisfy certain constraints which generally depend on the particular wavelet basis. To change representations if necessary, observe that, in view of (3.1.2), $\tilde\Psi_M = (\tilde\Psi_M, \tilde\Psi_M)\Psi_M$, so that such a change of bases is realized by the matrix

$$\mathbf{R} := (\tilde\Psi_M, \tilde\Psi_M) \tag{3.1.3}$$

because $\tilde{\mathbf{p}}^T\tilde\Psi_M = \tilde{\mathbf{p}}^T\mathbf{R}\Psi_M = (\mathbf{R}\tilde{\mathbf{p}})^T\Psi_M$. It immediately follows from (3.1.1) that both $\mathbf{R}$ and $\mathbf{R}^{-1} = (\Psi_M, \Psi_M)$ are bounded on $\ell_2(\mathcal{J}_M)$:

$$\|\mathbf{R}\|_{\ell_2(\mathcal{J}_M)\to\ell_2(\mathcal{J}_M)} \le C_R. \tag{3.1.4}$$

Since $\mathbf{S}$ is positive definite and satisfies (2.4.4), there exists therefore some positive ω (e.g., $\omega < 2/(C_S C_R)$) such that

$$\rho := \|\mathbf{id} - \omega \mathbf{RS}\|_{\ell_2(\mathcal{J}_M)\to\ell_2(\mathcal{J}_M)} < 1. \tag{3.1.5}$$

Then the infinite dimensional version of the Uzawa scheme reads as follows.

UZAWA: *Given any* $\mathbf{p}_0 \in \ell_{2,0}(\mathcal{J}_M)$*, compute for* $i = 1, 2, \ldots$

$$\mathbf{A}\mathbf{u}_i = \mathbf{f} - \mathbf{B}^T \mathbf{p}_{i-1}, \tag{3.1.6}$$

$$\mathbf{p}_i = \mathbf{p}_{i-1} + \omega \mathbf{R}(\mathbf{B}\mathbf{u}_i - \mathbf{g}). \tag{3.1.7}$$

This is known to converge when $\rho < 1$. In fact, since $\mathbf{u} = \mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\mathbf{p})$, it is easy to see that

$$\mathbf{p} - \mathbf{p}_i = (\mathbf{id} - \omega \mathbf{RS})(\mathbf{p} - \mathbf{p}_{i-1}),$$

so that

$$\|\mathbf{p} - \mathbf{p}_i\|_{\ell_2(\mathcal{J}_M)} \le \rho^i \|\mathbf{p} - \mathbf{p}_0\|_{\ell_2(\mathcal{J}_M)}. \tag{3.1.8}$$

Moreover, it has been shown in [14] that for $\mathbf{p}_0 = \mathbf{0}$ one has

$$\|\mathbf{p} - \mathbf{p}_i\|_{\ell_2(\mathcal{J}_M)} \le \|\mathbf{A}^{-1}\mathbf{f}\|_{\ell_2(\mathcal{J}_X)} \|\omega \mathbf{RSB}\|_{\ell_2(\mathcal{J}_X)\to\ell_2(\mathcal{J}_M)} \frac{\rho^i}{1-\rho}. \tag{3.1.9}$$

3.2. The adaptive scheme. As in [9] the key idea is to apply the above Uzawa iteration to the infinite dimensional problem. In view of (3.1.6) and (3.1.7), this involves three tasks, namely, adding sequences with generally infinite support such as the data $\mathbf{f}$ and $\mathbf{g}$, the application of *infinite* matrices like $\mathbf{B}$ or $\mathbf{B}^T$ to *finitely supported* vectors, as well as the solution of elliptic problems involving the infinite matrix $\mathbf{A}$. Of course, in practice neither one of these tasks can be performed *exactly*. Therefore one has to employ suitable approximations whose accuracy will depend on the current stage of the algorithm and which will be described next.

To this end, we shall not distinguish formally between finitely supported vectors and infinite sequences in $\ell_2(\mathcal{J}')$, where in what follows $\mathcal{J}' \in \{\mathcal{J}_X, \mathcal{J}_M\}$, but rather we will view both quantities as sequences (expanded by zero entries if necessary).

The first basic ingredient is the routine **NCOARSE** from [8] which solves the following task.

NCOARSE $[\eta, \mathbf{v}] \to (\bar{\mathbf{v}}, \Lambda)$ determines for a given *finitely supported* vector $\mathbf{v}$ a vector $\bar{\mathbf{v}}$ with smallest possible support Λ such that

$$\|\mathbf{v} - \bar{\mathbf{v}}\|_{\ell_2(\mathcal{J})} \le \eta. \tag{3.2.1}$$

For a detailed description of this routine and the analysis of its computational complexity, see [8, Properties 6.1, 6.3]. In particular, **NCOARSE** will be used to approximate the arrays $\mathbf{f}^\circ := \mathbf{D}_X^{-1}\langle \Psi_X, f\rangle_X$ and $\mathbf{g}$ of given data by finitely supported vectors. The way to think about **NCOARSE** in this context can be formulated as follows.

ASSUMPTION 3.1. *In a preprocessing step for a given target accuracy, sufficiently many (wavelet) coefficients in the arrays* $\mathbf{f}^\circ := \mathbf{D}_X^{-1}\langle \Psi_X, f\rangle$ *and* $\mathbf{g}$ *are made available and ordered by size.*

In many applications f and g are simple and, as model data given by the user, are considered here as completely accessible. Coarser approximations of the data are then obtained by applying **NCOARSE** to these preprocessed finite arrays (see [8, section 6.1] for a more detailed discussion).

The second basic ingredient taken from [8] is an approximate application of an infinite matrix to a finitely supported vector. Given an infinite matrix $\mathbf{C}$ (as a mapping from $\ell_2(\mathcal{J}'')$ to $\ell_2(\mathcal{J}')$ for any pair $(\mathcal{J}', \mathcal{J}'') \in \{\mathcal{J}_X, \mathcal{J}_M\}^2$), we use the scheme **APPLY** from [8] for serving the following purpose.

APPLY $[\eta, \mathbf{C}, \mathbf{v}] \to (\mathbf{w}, \Lambda)$ produces for any finitely supported input vector $\mathbf{v}$ a vector $\mathbf{w}$ with finite support $\Lambda \subset \mathcal{J}'$ such that

$$\|\mathbf{C}\mathbf{v} - \mathbf{w}\|_{\ell_2(\mathcal{J}')} \le \eta. \tag{3.2.2}$$

A scheme with this property has been developed in [8, section 6.4]; see [2] for implementation issues and numerical experiments. We postpone a quick description of the relevant features along with estimates for its computational cost to a later section.

Note that, in particular, the routines **APPLY** and **NCOARSE** allow us to approximately evaluate the right-hand sides of (3.1.6) and (3.1.7).

So the remaining task in an approximate Uzawa iteration of the form (3.1.6), (3.1.7) is to solve the operator equation (3.1.6) with system matrix $\mathbf{A}$. This is an elliptic problem in the sense of [8], and we will make heavy use of the results obtained there; also see [2] for implementations and numerical tests. The scheme from [8] is also built solely on the above routines **NCOARSE** and **APPLY**. There are, however, two minor points that need to be briefly addressed.

First, in [8] the matrix $\mathbf{A}$ is just the wavelet representation of the underlying elliptic operator, while in the present situation, $\mathbf{A}$ has the form (2.4.10) for some positive constant c, when $a(\cdot,\cdot)$ is not elliptic on all of X. Nevertheless, once a scheme **APPLY** for wavelet representations is available, a scheme for applying matrices of the form (2.4.10) with $c \neq 0$ is easily obtained from such a building block as follows. To simplify notation we set $\mathbf{A}^\circ := \mathbf{D}_X^{-1} a(\Psi_X, \Psi_X) \mathbf{D}_X^{-1}$.

APPLY$^*[\eta, \mathbf{A}, \mathbf{v}] \to (\mathbf{w}, \Lambda)$:

(i) **APPLY** $[\eta/2, \mathbf{A}^\circ, \mathbf{v}] \to (\mathbf{w}_1, \Lambda_1)$;

(ii) **APPLY** $[\eta/4cC_B, \mathbf{B}, \mathbf{v}] \to (\mathbf{w}_2, \Lambda_2)$;

(iii) **APPLY** $[\eta/4, c\mathbf{B}^T, \mathbf{w}_2] \to (\mathbf{w}_3, \Lambda_3)$ and set $\mathbf{w} := \mathbf{w}_1 + \mathbf{w}_3, \quad \Lambda := \Lambda_1 \cup \Lambda_3$.

REMARK 3.2. *One easily derives from* (3.2.2) *that the output* $\mathbf{w}$ *produced by* **APPLY**$^*[\eta, \mathbf{A}, \mathbf{v}]$ *satisfies for* $\mathbf{A}$ *given by* (2.4.10)

$$\|\mathbf{A}\mathbf{v} - \mathbf{w}\|_{\ell_2(\mathcal{J}_X)} \le \eta. \tag{3.2.3}$$

Moreover, it is also clear that up to a uniform constant, the work/accuracy balance for **APPLY*** *is the same as that for* **APPLY**. *Note that the matrix* $\mathbf{B}^T\mathbf{B}$ *is, of course, never computed.*

According to (3.1.6), **UZAWA** requires the solution of elliptic problems. For this purpose we shall employ here an adaptive scheme referred to as **ELLSOLVE**, developed and analyzed in [8]; also see [9] for the identification of those requirements on the routine **APPLY** in this context that ensure asymptotically optimal complexity. This will allow us, in particular, to employ the variant **APPLY*** in place of the original scheme without changing the asymptotical work/accuracy rate.

To explain the features of the scheme **ELLSOLVE** from [8], consider for $\mathbf{A}$ as above the elliptic problem

$$\mathbf{A}\mathbf{u} = \mathbf{h} \tag{3.2.4}$$

for some $\mathbf{h} \in \ell_2(\mathcal{J}_X)$, and denote its exact solution by $\hat{\mathbf{u}}$. The scheme **ELLSOLVE** solves the following task (see Algorithm III in [8, Theorem 7.6]).

ELLSOLVE $[\varepsilon, \mathbf{A}, \mathbf{v}, \mathbf{h}] \to (\bar{\mathbf{u}}, \Lambda)$: Given $\varepsilon > 0$ and an approximate solution $\mathbf{v}$ to (3.2.4), then the output $\bar{\mathbf{u}}$ with finite support Λ satisfies

$$\|\hat{\mathbf{u}} - \bar{\mathbf{u}}\|_{\ell_2(\mathcal{J}_X)} \le \varepsilon. \tag{3.2.5}$$

The second point is that in [8] the right-hand side data are assumed to be a given array of wavelet coefficients as explained above that can be preprocessed. In the present situation the right-hand side data are composed of such preprocessable data like $\mathbf{f}$ and an additional matrix/vector product involving dynamically updated entities. We therefore have to approximate these data by finitely supported vectors that can then be processed as in [8, sections 7.2, 7.3]. The corresponding perturbations can be estimated as follows.

REMARK 3.3. *Again consider* (3.2.4) *and suppose that approximate finitely supported right-hand side data* $\mathbf{h}_\eta \in \ell_2(\mathcal{J}_X)$ *are given such that*

$$\|\mathbf{h} - \mathbf{h}_\eta\|_{\ell_2(\mathcal{J}_X)} \le \eta. \tag{3.2.6}$$

Then the output $\bar{\mathbf{u}}$ *of* **ELLSOLVE** $[\eta, \mathbf{A}, \mathbf{v}, \mathbf{h}_\eta]$ *satisfies*

$$\|\hat{\mathbf{u}} - \bar{\mathbf{u}}\|_{\ell_2(\mathcal{J}_X)} \le \varepsilon + c_A^{-1}\eta. \tag{3.2.7}$$

Proof The claim follows from (3.2.5) combined with (2.4.7) to estimate the perturbation effect. □

Next, we will describe the computation of a finitely supported $\mathbf{h}_\eta$ when $\mathbf{h} = \mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}$; see (3.1.6). Recall from (2.4.10) that

$$\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1} = \mathbf{f}^\circ - \mathbf{B}^T(\bar{\mathbf{p}}_{i-1} - c\mathbf{g}), \qquad \mathbf{f}^\circ = \mathbf{D}_X^{-1}\langle \Psi_X, f\rangle,$$

which thus involves coarsening the given (preprocessed) data $\mathbf{f}^\circ, \mathbf{g}$ and a multiplication by $\mathbf{B}^T$. The respective concrete accuracy tolerances are given in the following routine.

RHS $[\bar{\mathbf{p}}, \eta] \to (\mathbf{h}_\eta, \Lambda^h)$:
Given a finitely supported $\bar{\mathbf{p}}$, the routine **RHS** computes a vector $\mathbf{h}_\eta$ with finite support Λ^h satisfying

$$\|\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}} - \mathbf{h}_\eta\|_{\ell_2(\mathcal{J}_X)} \le \eta \tag{3.2.8}$$

as follows:

(i) **NCOARSE** $[\eta/3, \mathbf{f}^\circ] \to (\bar{\mathbf{f}}, \Lambda^f)$,
NCOARSE $[\eta/3cC_B, \mathbf{g}] \to (\bar{\mathbf{g}}, \Lambda^g)$, and set $\mathbf{r} := \bar{\mathbf{p}} - c\bar{\mathbf{g}}$.
(ii) **APPLY** $[\eta/3, \mathbf{B}^T, \mathbf{r}] \to (\mathbf{w}, \Lambda^w)$ and set $\mathbf{h}_\eta := \bar{\mathbf{f}} - \mathbf{w}$, $\Lambda^h := \Lambda^f \cup \Lambda^w$.

Since by (3.2.1), $\|(\bar{\mathbf{p}} - c\mathbf{g}) - \mathbf{r}\|_{\ell_2(\mathcal{J}_X)} \le \eta/3C_B$, the estimate (3.2.8) indeed readily follows from (3.2.2).

Our numerical realization of the *ideal* (infinite dimensional) Uzawa scheme (3.1.6), (3.1.7) has the following structure. A fixed uniformly bounded number K, depending only on the constants associated with the wavelet bases and the mapping properties

of the involved operators, of approximate applications of (3.1.6), (3.1.7) are applied, which is then followed by a coarsening step before the iteration is further resumed. Such an *iteration block* will be arranged to *advance* the current approximate solutions so as to reduce the current error bounds by a fixed factor. Before giving a precise description, we would like to stress that the Uzawa scheme as a gradient method for the reduced system (2.4.2) treats in some sense $\mathbf{p} \in \ell_{2,0}(\mathcal{J}_M)$ as the "preferred" variable. In fact, the accuracy of the approximate solution to the elliptic problem (3.1.6) need not be too high relative to the current accuracy of the approximation of $\mathbf{p}$. In order to formulate now the basic iteration block as a concrete routine, we will use the following choice for the number K of perturbed iterations before the next coarsening step. Let γ_i denote any positive summable numbers, e.g., $\gamma_i = (1+i)^{-2}$. It will be convenient to assume always that, as in this example, $\gamma_i \le 1$, $i \in \mathbb{N}$. Moreover, we need some control parameters. Set

$$C_1 := \omega(C_R C_B + 2)\gamma + 1, \tag{3.2.9}$$

where $\gamma := \sum_{i=0}^{\infty} \gamma_i$, and let K denote the smallest integer such that

$$\rho^K \max\left\{C_1, (\rho c_A)^{-1} C_B C_1 + 1\right\} \le 1/10. \tag{3.2.10}$$

Note that, since c_A, C_B appear in lower, respectively, upper, bounds, $(\rho c_A)^{-1} C_B$ will typically be larger than one, so that the maximum will usually be attained by the second term in the curly brackets in the left-hand side of (3.2.10).

Now we have collected all the ingredients for composing the core of a computational version of **UZAWA**.

ADV $[\bar{\mathbf{u}}, \bar{\mathbf{p}}, \delta] \to (\tilde{\mathbf{u}}, \tilde{\mathbf{p}}, \Lambda_u, \Lambda_q)$:
Given current approximations $\bar{\mathbf{u}}, \bar{\mathbf{p}}$ of the solution to (2.2.4) such that

$$\|\bar{\mathbf{u}} - \mathbf{u}\|_{\ell_2(\mathcal{J}_X)} \le \delta, \quad \|\bar{\mathbf{p}} - \mathbf{p}\|_{\ell_2(\mathcal{J}_M)} \le \delta, \tag{3.2.11}$$

ADV $[\bar{\mathbf{u}}, \bar{\mathbf{p}}, \delta]$ produces new approximations $\tilde{\mathbf{u}}, \tilde{\mathbf{p}}$ as follows:
(i) Set $i = 1$, $\bar{\mathbf{p}}_0 := \bar{\mathbf{p}}$, $\bar{\mathbf{u}}_0 := \bar{\mathbf{u}}$.
(ii) If $i \le K$, go to (iii); else
  NCOARSE $[2\delta/5, \bar{\mathbf{p}}_{i-1}] \to (\tilde{\mathbf{p}}, \Lambda_p)$;
  NCOARSE $[2\delta/5, \bar{\mathbf{u}}_{i-1}] \to (\tilde{\mathbf{u}}, \Lambda_u)$; STOP;
(iii) **RHS** $[\bar{\mathbf{p}}_{i-1}, c_A \gamma_i \rho^i \delta/2] \to (\mathbf{h}_i, \Lambda_i^h)$;
(iv) **ELLSOLVE** $[\gamma_i \rho^i \delta/2, \mathbf{A}, \bar{\mathbf{u}}_{i-1}, \mathbf{h}_i] \to (\bar{\mathbf{u}}_i, \Lambda_i^X)$.
(v) **NCOARSE** $[\gamma_i \rho^i \delta/2C_R, \mathbf{g}] \to (\hat{\mathbf{g}}_i, \hat{\Lambda}_i)$;
  APPLY $[\gamma_i \rho^i \delta/2, \mathbf{R}, \hat{\mathbf{g}}_i] \to (\mathbf{g}_i, \Lambda_i^q)$;
  APPLY $[\gamma_i \rho^i \delta/2C_R, \mathbf{B}, \bar{\mathbf{u}}_i] \to (\hat{\mathbf{p}}_i, \hat{\Lambda}_i)$;
  APPLY $[\gamma_i \rho^i \delta/2, \mathbf{R}, \hat{\mathbf{p}}_i] \to (\mathbf{p}_i', \Lambda_i^p)$;
  set $\bar{\mathbf{p}}_i = \bar{\mathbf{p}}_{i-1} + \omega(\mathbf{p}_i' - \mathbf{g}_i)$; and $i + 1 \to i$ and go to (ii).

The routine **ADV** *advances* given finitely supported approximate solutions $(\bar{\mathbf{u}}, \bar{\mathbf{p}})$ to a new pair $(\tilde{\mathbf{u}}, \tilde{\mathbf{p}})$ by a finite number of perturbed Uzawa steps, followed by a coarsening step. It will be shown later that the tolerances in **ADV** are chosen so as to reduce the error bounds of the new approximations by at least a factor of two. The final application of **NCOARSE** in step (ii) of **ADV**, following the iteration block, will be seen later to play an important role with regard to asymptotically optimal complexity. Roughly speaking, it ensures that only sufficiently significant coefficients are propagated.

Of course, when the characterization of the space M does not entail any constraints on the wavelet coefficients, $\mathbf{R}$ can be replaced by the identity in (3.1.7), in which case step (v) of **ADV** simplifies in an obvious manner.

To formulate the main algorithm, recall that by (2.3.1)

$$\|\mathbf{u}\|^2_{\ell_2(\mathcal{J}_X)} + \|\mathbf{p}\|^2_{\ell_2(\mathcal{J}_M)} \le c_L^{-1}\left(\|\mathbf{f}^\circ\|^2_{\ell_2(\mathcal{J}_X)} + \|\mathbf{g}\|^2_{\ell_2(\mathcal{J}_M)}\right).$$

Therefore the right-hand side gives a bound for the initial error when using $\mathbf{0}$ as the initial guess for $\mathbf{u}, \mathbf{p}$, respectively. The complete adaptive Uzawa iteration can be described now as follows.

UZAWA^c $[\mathbf{A}, \mathbf{B}, \mathbf{f}, \mathbf{g}, \varepsilon] \to (\mathbf{u}(\varepsilon), \mathbf{p}(\varepsilon))$:
Set $\mathbf{\Lambda}_0 := (\Lambda_0^X, \Lambda_0^M) \subset \mathcal{J} =: \mathcal{J}_X \times \mathcal{J}_M$ to be empty, $\Lambda_0^M = \Lambda_0^X = \emptyset$, $\mathbf{p}_0 = \bar{\mathbf{p}}_0 = \mathbf{0}$, $\bar{\mathbf{u}} = \mathbf{0}$, $\delta_0 := c_L^{-1/2}(\|\mathbf{f}^\circ\|^2_{\ell_2(\mathcal{J}_X)} + \|\mathbf{g}\|^2_{\ell_2(\mathcal{J}_M)})^{1/2}$, $J = 0$, choose a target accuracy ε.
(i) **ADV** $[\bar{\mathbf{u}}, \bar{\mathbf{p}}, \delta_J] \to (\tilde{\mathbf{u}}, \tilde{\mathbf{p}}, \Lambda_u, \Lambda_q)$;
(ii) Set $\delta_{J+1} := \delta_J/2$;
If $\delta_{J+1} \le \varepsilon$, set $\mathbf{u}(\varepsilon) := \tilde{\mathbf{u}}, \mathbf{p}(\varepsilon) := \tilde{\mathbf{p}}$; STOP;
Else, set $\bar{\mathbf{u}} = \tilde{\mathbf{u}}$, $\bar{\mathbf{p}} = \tilde{\mathbf{p}}$, $J + 1 \to J$ and go to (i).

3.3. Convergence. The convergence of **UZAWA**^{c} relies on the error reduction caused by **ADV**.

PROPOSITION 3.4. *Given a scheme* **APPLY** *such that* (3.2.2) *holds, under the above Assumption* 3.1 *concerning* **NCOARSE** *on the data* $\mathbf{f}^\circ, \mathbf{g}$, *the vectors* $\tilde{\mathbf{u}}, \tilde{\mathbf{p}}$ *produced by* **ADV** $[\bar{\mathbf{u}}, \bar{\mathbf{p}}, \delta]$ *above satisfy*

$$\|\tilde{\mathbf{u}} - \mathbf{u}\|_{\ell_2(\mathcal{J}_X)} \le \delta/2, \quad \|\tilde{\mathbf{p}} - \mathbf{p}\|_{\ell_2(\mathcal{J}_M)} \le \delta/2. \tag{3.3.1}$$

Hence, after finitely many steps the scheme **UZAWA**^{c} *produces finitely supported solutions* $(\mathbf{u}(\varepsilon), \mathbf{p}(\varepsilon))$ *satisfying*

$$\|\mathbf{u} - \mathbf{u}(\varepsilon)\|_{\ell_2(\mathcal{J}_X)} \le \varepsilon, \quad \|\mathbf{p} - \mathbf{p}(\varepsilon)\|_{\ell_2(\mathcal{J}_M)} \le \varepsilon. \tag{3.3.2}$$

Proof. Set $\mathbf{p}_0 := \bar{\mathbf{p}}_0 = \bar{\mathbf{p}}$, $\bar{\mathbf{u}}_0 := \bar{\mathbf{u}}$ and observe that

$$\begin{aligned}
\mathbf{p}_i - \bar{\mathbf{p}}_i &= \mathbf{p}_{i-1} + \omega\mathbf{R}(\mathbf{B}\mathbf{u}_i - \mathbf{g}) - \bar{\mathbf{p}}_{i-1} - \omega(\mathbf{p}_i' - \mathbf{g}_i) \\
&= \mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1} + \omega(\mathbf{R}\mathbf{B}\mathbf{u}_i - \mathbf{p}_i' - \mathbf{R}\mathbf{g} + \mathbf{g}_i) \\
&= (\mathbf{id} - \omega\mathbf{R}\mathbf{S})(\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}) + \omega(\mathbf{R}(\mathbf{B}\mathbf{A}^{-1}\mathbf{B}^T)(\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}) \\
&\qquad + \mathbf{R}\mathbf{B}\mathbf{u}_i - \mathbf{p}_i' + \mathbf{g}_i - \mathbf{R}\mathbf{g}).
\end{aligned} \tag{3.3.3}$$

Since $\mathbf{A}\mathbf{u}_i = \mathbf{f} - \mathbf{B}^T\mathbf{p}_{i-1}$, we can replace $\mathbf{B}^T\mathbf{p}_{i-1}$ by $\mathbf{f} - \mathbf{A}\mathbf{u}_i$ to obtain

$$\begin{aligned}
&\omega\left(\mathbf{R}(\mathbf{B}\mathbf{A}^{-1}\mathbf{B}^T)(\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}) + \mathbf{R}\mathbf{B}\mathbf{u}_i - \mathbf{p}_i' + \mathbf{g}_i - \mathbf{R}\mathbf{g}\right) \\
&= \omega\left(\mathbf{R}(\mathbf{B}\mathbf{A}^{-1}\mathbf{f} - \mathbf{B}\mathbf{u}_i + \mathbf{B}\mathbf{u}_i - \mathbf{B}\mathbf{A}^{-1}\mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \mathbf{p}_i' + \mathbf{g}_i - \mathbf{R}\mathbf{g}\right) \\
&= \omega\left(\mathbf{R}\mathbf{B}\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \mathbf{p}_i' + (\mathbf{g}_i - \mathbf{R}\mathbf{g})\right).
\end{aligned} \tag{3.3.4}$$

Thus

$$\mathbf{R}\mathbf{B}\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \mathbf{p}_i' = \mathbf{R}\mathbf{B}\left(\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \bar{\mathbf{u}}_i\right) + (\mathbf{R}\mathbf{B}\bar{\mathbf{u}}_i - \mathbf{p}_i'). \tag{3.3.5}$$

Hence combining (3.3.3), (3.3.4), and (3.3.5) and recalling (3.1.5) yields

$$\begin{aligned}
\|\mathbf{p}_i - \bar{\mathbf{p}}_i\|_{\ell_2(\mathcal{J}_M)} &\le \rho\|\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}\|_{\ell_2(\mathcal{J}_M)} + \omega\left(\|\mathbf{R}\mathbf{B}\left(\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \bar{\mathbf{u}}_i\right)\|_{\ell_2(\mathcal{J}_M)}\right. \\
&\quad \left. + \|\mathbf{R}\mathbf{B}\bar{\mathbf{u}}_i - \mathbf{p}_i'\|_{\ell_2(\mathcal{J}_M)} + \|\mathbf{g}_i - \mathbf{R}\mathbf{g}\|_{\ell_2(\mathcal{J}_M)}\right) \\
&\le \rho\|\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}\|_{\ell_2(\mathcal{J}_M)} + \omega C_R C_B\|\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \bar{\mathbf{u}}_i\|_{\ell_2(\mathcal{J}_X)} \\
&\quad + 2\omega\gamma_i\rho^i\delta,
\end{aligned} \tag{3.3.6}$$

where we have used the tolerances in step (v) of **ADV**. By (3.2.8) we have for the output $\mathbf{h}_i$ of step (iii) in **ADV** that $\|\mathbf{h}_i - (\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1})\|_{\ell_2(\mathcal{J}_X)} \le c_A\gamma_i\rho^i\delta/2$, which, in view of the tolerances in step (iv) of **ADV** and (3.2.7), implies that

$$\|\mathbf{A}^{-1}(\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}) - \bar{\mathbf{u}}_i\|_{\ell_2(\mathcal{J}_X)} \le \gamma_i\rho^i\delta. \tag{3.3.7}$$

Therefore, we deduce from (3.3.6) that

$$\|\mathbf{p}_i - \bar{\mathbf{p}}_i\|_{\ell_2(\mathcal{J}_M)} \le \rho\|\mathbf{p}_{i-1} - \bar{\mathbf{p}}_{i-1}\|_{\ell_2(\mathcal{J}_M)} + \omega(C_RC_B + 2)\gamma_i\rho^i\delta. \tag{3.3.8}$$

Iterating this estimate, and bearing in mind that $\mathbf{p}_0 = \bar{\mathbf{p}}_0$, provides

$$\|\mathbf{p}_i - \bar{\mathbf{p}}_i\|_{\ell_2(\mathcal{J}_M)} \le \omega(C_RC_B + 2)\rho^i\delta\sum_{l=1}^{i}\gamma_l. \tag{3.3.9}$$

Since by (3.1.8) and the assumption $\|\mathbf{p} - \mathbf{p}_i\|_{\ell_2(\mathcal{J}_M)} \le \rho^i\|\mathbf{p} - \mathbf{p}_0\|_{\ell_2(\mathcal{J}_M)} = \rho^i\|\mathbf{p} - \bar{\mathbf{p}}\|_{\ell_2(\mathcal{J}_M)} \le \rho^i\delta$, we conclude that

$$\|\mathbf{p} - \bar{\mathbf{p}}_i\|_{\ell_2(\mathcal{J}_M)} \le \left(\omega(C_RC_B + 2)\sum_{l=1}^{i}\gamma_l + 1\right)\rho^i\delta \le C_1\rho^i\delta, \tag{3.3.10}$$

where C_1 is the constant from (3.2.9). In view of (3.2.10), this gives

$$\|\mathbf{p} - \bar{\mathbf{p}}_K\|_{\ell_2(\mathcal{J}_M)} \le \delta/10. \tag{3.3.11}$$

Now recall that by step (ii) of **ADV**, the final approximation $\tilde{\mathbf{p}}$ is obtained by coarsening $\bar{\mathbf{p}}_K$. Thus

$$\|\mathbf{p} - \tilde{\mathbf{p}}\|_{\ell_2(\mathcal{J}_M)} \le \|\mathbf{p} - \bar{\mathbf{p}}_K\|_{\ell_2(\mathcal{J}_M)} + \|\bar{\mathbf{p}}_K - \tilde{\mathbf{p}}\|_{\ell_2(\mathcal{J}_M)} \le \left(\frac{2}{5} + \frac{1}{10}\right)\delta = \frac{\delta}{2}, \tag{3.3.12}$$

as claimed.

It remains to estimate the accuracy of $\bar{\mathbf{u}}_K$. Denoting by $\hat{\mathbf{u}}_i$ the exact solution of $\mathbf{A}\hat{\mathbf{u}}_i = \mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1}$, (3.3.7) says that $\|\hat{\mathbf{u}}_i - \bar{\mathbf{u}}_i\|_{\ell_2(\mathcal{J}_X)} \le \gamma_i\rho^i\delta$. Writing

$$\mathbf{u} - \bar{\mathbf{u}}_i = \mathbf{u} - \hat{\mathbf{u}}_i + \hat{\mathbf{u}}_i - \bar{\mathbf{u}}_i = \mathbf{A}^{-1}\mathbf{B}^T(\bar{\mathbf{p}}_{i-1} - \mathbf{p}) + \hat{\mathbf{u}}_i - \bar{\mathbf{u}}_i, \tag{3.3.13}$$

one infers from (3.3.10) that

$$\|\mathbf{u} - \bar{\mathbf{u}}_i\|_{\ell_2(\mathcal{J}_X)} \le (c_A\rho)^{-1}C_BC_1\rho^i\delta + \gamma_i\rho^i\delta = \left((c_A\rho)^{-1}C_BC_1 + \gamma_i\right)\rho^i\delta.$$

Again, since $\gamma_i \le 1$, we conclude from (3.2.10) that

$$\|\mathbf{u} - \bar{\mathbf{u}}_K\|_{\ell_2(\mathcal{J}_X)} \le \delta/10, \tag{3.3.14}$$

so that by the same reasoning as in (3.3.12), $\tilde{\mathbf{u}}$ produced by $\mathbf{NCOARSE}\,[2\delta/5, \bar{\mathbf{u}}_K]$ satisfies $\|\mathbf{u} - \tilde{\mathbf{u}}\|_{\ell_2(\mathcal{J}_X)} \le \delta/2$. This completes the proof. □

As an immediate consequence of the norm equivalences (2.2.1), (2.2.2) one has the following fact.

COROLLARY 3.5. *Let $u = \mathbf{u}^T\mathbf{D}_X^{-1}\Psi_X$, $p = \mathbf{p}^T\mathbf{D}_M^{-1}\Psi_M$ be the exact solution of (2.1.2). Then the finite expansions $u(\varepsilon) := \mathbf{u}^T(\varepsilon)\mathbf{D}_X^{-1}\Psi_X$, $p(\varepsilon) = \mathbf{p}^T(\varepsilon)\mathbf{D}_M^{-1}\Psi_M$ with terms from the finite index sets $\Lambda_{u(\varepsilon)} \subset \mathcal{J}_X$, $\Lambda_{q(\varepsilon)} \subset \mathcal{J}_M$ satisfy*

$$\|u - u(\varepsilon)\|_X \le C_X\varepsilon, \quad \|p - p(\varepsilon)\|_M \le C_M\varepsilon \tag{3.3.15}$$

uniformly in ε, where C_X, C_M are the constants in (2.2.1)*, respectively,* (2.2.2)*.*

To keep things transparent we have based the above considerations on the simplest version (3.1.6), (3.1.7) of an Uzawa iteration. It will be seen below that already this version gives rise to asymptotically optimal convergence properties. Of course, similar results would be obtained for different accuracy tolerances as long as they differ by constants leading possibly to different values of K. Nevertheless, several more important possibilities suggest themselves for realizing quantitative improvements, e.g., replacing the Richardson iteration by a gradient or conjugate gradient iteration. This avoids the need for estimating step size parameters and should speed error reduction. Note that these variants still involve only the same algorithmic tasks, namely, approximate application of operators in the above sense. Furthermore, the number K of subiterations is likely to be too pessimistic. Therefore it would be preferable to monitor the error decay as follows. Note that $\mathbf{p}_i - \mathbf{g}_i$ in step (v) of **ADV** approximates $\mathbf{R}(\mathbf{B}\mathbf{u}_i - \mathbf{p}_i)$ and, in view of (3.1.6), (3.1.7), the residual $\mathbf{R}(\mathbf{B}\mathbf{A}^{-1}\mathbf{f} - \mathbf{g} - \mathbf{S}\mathbf{p}_{i-1})$. By (2.4.4) and the bounded invertibility of $\mathbf{R}$, this residual can be bounded from below and above by fixed constant multiples of the current error of the approximate solution of the reduced system (2.4.2). Thus monitoring $\|\mathbf{p}_i' - \mathbf{g}_i\|_{\ell_2(\mathcal{J}_M)}$ can be used as a stopping criterion. This is expected to result in frequent early termination of step (ii) in **ADV**. These points will be taken up in more detail elsewhere.

4. Complexity analysis. Of course, the central questions now are how do we come up with an **APPLY** scheme with the desired properties and what is the computational cost of $\mathbf{UZAWA}^c$ for a given target accuracy ε. In the present generality, cost will be measured by storage requirements and the number of flops required by the scheme (being well aware of the fact that this is not the full story).

4.1. Best *N*-term approximation. As in [8] we will relate the performance of the adaptive scheme to what could be achieved at best, namely, the approximation of the solution in terms of *possibly few degrees of freedom* within the given discretization context—here determined by the underlying wavelet bases. Note that, in view of (3.3.15), it suffices to deal with the conceptually much simpler approximation in $\ell_2(\mathcal{J})$. To explain this, it is useful to recall first the following notion of *best N-term approximation* in ℓ_2:

$$\sigma_{N,\ell_2(\mathcal{J}')}(\mathbf{v}) := \inf_{\mathbf{w},\#\operatorname{supp}\mathbf{w}\le N} \|\mathbf{v}-\mathbf{w}\|_{\ell_2(\mathcal{J}')}, \tag{4.1.1}$$

where $\ell_2(\mathcal{J}')$ stands again for $\ell_2(\mathcal{J}_X)$ or $\ell_2(\mathcal{J}_M)$. Thus $\sigma_{N,\ell_2(\mathcal{J}')}(\mathbf{v})$ describes the error as a function of the number of degrees of freedom when the (possibly infinitely supported) vector is approximated by a vector with at most N nonzero entries whose value and position can be freely chosen. Thus the approximant is not taken from any fixed linear space but from the nonlinear manifold of all vectors with at most N nonzero entries. This notion is well understood for ℓ_2; see, e.g., [19]. Obviously, $\sigma_{N,\ell_2(\mathcal{J}')}(\mathbf{v})$ is realized by retaining the N *largest* coefficients in $\mathbf{v}$ which are, of course, unknown when $\mathbf{v}$ is a solution of a system of equations. To understand how this error behaves, denote for any $\mathbf{v} \in \ell_2(\mathcal{J}')$ by $\mathbf{v}^* = \{v_{\lambda_l}\}_{l\in\mathbb{N}} =: \{v_l^*\}_{l\in\mathbb{N}}$ its *decreasing rearrangement* in the sense that $|v_{\lambda_l}| \ge |v_{\lambda_{l+1}}|$ and let

$$\Lambda(\mathbf{v},N) := \{\lambda_l : l = 1,\dots,N\}, \quad \mathbf{v}_N := \mathbf{v}|_{\Lambda(\mathbf{v},N)}. \tag{4.1.2}$$

It is clear that $\mathbf{v}_N$ is a best N-term approximation of $\mathbf{v}$.

In particular, it will be important to characterize the sequences in $\ell_2(\mathcal{J}')$ whose best N-term approximation behaves like N^{-s} for some $s > 0$. The following facts are well known [8, 19]. Let for $0 < \tau < 2$

$$|\mathbf{v}|_{\ell_\tau^w(\mathcal{J}')} := \sup_{n\in\mathbb{N}} n^{1/\tau}|v_n^*|, \quad \|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')} := \|\mathbf{v}\|_{\ell_2(\mathcal{J}')} + |\mathbf{v}|_{\ell_\tau^w(\mathcal{J}')}. \tag{4.1.3}$$

It is easy to see that for any $\tau < \tau' \le 2$

$$\|\mathbf{v}\|_{\ell_{\tau'}(\mathcal{J}')} \lesssim \|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')} \le 2\|\mathbf{v}\|_{\ell_\tau(\mathcal{J}')}, \tag{4.1.4}$$

so that by Jensen's inequality, in particular, $\ell_\tau^w(\mathcal{J}') \subset \ell_2(\mathcal{J}')$.

We shall use the following characterization of decay rates of best N-term approximation in $\ell_2(\mathcal{J}')$; see [8, Proposition 3.2].

PROPOSITION 4.1. *Let*

$$\frac{1}{\tau} = s + \frac{1}{2}. \tag{4.1.5}$$

Then $\mathbf{v}$ *belongs to* $\ell_\tau^w(\mathcal{J}')$ *if and only if* $\sigma_{N,\ell_2(\mathcal{J}')}(\mathbf{v}) \lesssim N^{-s}$, *and one has the error estimate*

$$\|\mathbf{v} - \mathbf{v}_N\|_{\ell_2(\mathcal{J}')} \lesssim N^{-s}\|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')}. \tag{4.1.6}$$

In complete analogy one can define $\|\cdot\|_{\ell_\tau^w(\mathcal{J})}$ for $\ell_\tau^w(\mathcal{J}) := \ell_\tau^w(\mathcal{J}_X \times \mathcal{J}_M)$ by forming the rearrangements from both component vectors $\mathbf{v} \in \ell_2(\mathcal{J}_X)$, $\mathbf{p} \in \ell_{2,0}(\mathcal{J}_M)$ and regrouping the entries to both component vectors.

We will make use of the following result from [8] which interrelates best N-term approximation in ℓ_2 with the routine **NCOARSE**; see [8, Property 6.3].

PROPOSITION 4.2. *Suppose that* $\mathbf{v} \in \ell_2(\mathcal{J}')$ *and a finitely supported* $\mathbf{w}$ *satisfies for some tolerance* $\eta > 0$

$$\|\mathbf{v} - \mathbf{w}\|_{\ell_2(\mathcal{J}')} \le \eta/5.$$

Then (as has been used before), the output $\bar{\mathbf{w}}$ *of* $\mathbf{NCOARSE}\,[\mathbf{w}, 4\eta/5]$ *satisfies* $\|\mathbf{v} - \bar{\mathbf{w}}\|_{\ell_2(\mathcal{J}')} \le \eta$. *Moreover, when* $\mathbf{v} \in \ell_\tau^w(\mathcal{J}')$ *and* $\frac{1}{\tau} = s + \frac{1}{2}$ *for some* $s > 0$, *then there exists a constant* C, *depending only on* s *when* s *tends to infinity, such that*

$$\|\mathbf{v} - \bar{\mathbf{w}}\|_{\ell_2(\mathcal{J}')} \le C\|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')}(\#\operatorname{supp}\bar{\mathbf{w}})^{-s}, \tag{4.1.7}$$

and

$$\|\bar{\mathbf{w}}\|_{\ell_\tau^w(\mathcal{J}')} \le C\|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')}, \quad \#\operatorname{supp}\bar{\mathbf{w}} \le C\|\mathbf{v}\|^{1/s}_{\ell_\tau^w(\mathcal{J}')}\eta^{-1/s}. \tag{4.1.8}$$

Best N-term approximation will be one important ingredient in the realization of the approximate application of infinite matrices represented by **APPLY**. The other one is the (a priori known) quasi sparseness of wavelet representations which can be formalized as follows; see [8].

DEFINITION 4.3. *A matrix* $\mathbf{C}$ *belongs to the class* $\mathcal{C}_{s^*}$ *if for every* $s < s^*$ *there exists a positive summable sequence* $(\alpha_j)_{j\ge0}$ *and for every* $j \ge 0$ *there exists a matrix* $\mathbf{C}_j$ *with at most* $2^j\alpha_j$ *nonzero entries per row and column such that*

$$\|\mathbf{C}_j - \mathbf{C}\| \lesssim \alpha_j 2^{-sj}. \tag{4.1.9}$$

A matrix in $\mathcal{C}_{s^*}$ is called compressible *or sometimes s^*-compressible.*

Compressibility of a wavelet representation of certain operators follows from the above-mentioned cancellation properties of the wavelets; see [8] as well as section 5.3 for concretizations.

Now suppose that the (possibly infinite) matrix $\mathbf{C}$ (defined on $\ell_2(\mathcal{J}')$, say) is known to be compressible in the sense of (4.1.9) for some range of $s > 0$. For any given finitely supported $\mathbf{v} \in \ell_2(\mathcal{J}')$, let $\mathbf{v}_{[j]} := \mathbf{v}_{2^j}$ denote its best 2^j-term approximation in $\ell_2(\mathcal{J}')$. We shall numerically approximate $\mathbf{Cv}$ by using the vector

$$\mathbf{w}_k := \mathbf{C}_k\mathbf{v}_{[0]} + \mathbf{C}_{k-1}(\mathbf{v}_{[1]} - \mathbf{v}_{[0]}) + \cdots + \mathbf{C}_0(\mathbf{v}_{[k]} - \mathbf{v}_{[k-1]}) \tag{4.1.10}$$

for a certain value of k determined by the desired numerical accuracy. This leads to a practical scheme $\mathbf{APPLY}\ [\eta, \mathbf{C}, \mathbf{v}] \to (\mathbf{w}, \Lambda)$, whose detailed description is given in [8], section 6.4; see also [2]. For later use we recall its properties; see Property 6.4 in [8].

PROPOSITION 4.4. *Assume that $\mathbf{C} \in \mathcal{C}_{s^*}$. Given a tolerance $\eta > 0$ and a vector $\mathbf{v}$ with finite support, the algorithm* **APPLY** *produces a vector $\mathbf{w} = \mathbf{w}(\mathbf{v}, \eta)$ which satisfies* (3.2.2).

Moreover, if $\mathbf{v} \in \ell_\tau^w(\mathcal{J}')$, with $\tau = (s + 1/2)^{-1}$ and $0 < s < s^*$, then the following properties hold:

(i) *The size of the output Λ is bounded by*

$$\#(\Lambda) \le C\|\mathbf{v}\|^{1/s}_{\ell_\tau^w(\mathcal{J}')}\eta^{-1/s}, \tag{4.1.11}$$

and the number of entries of $\mathbf{C}$ that need to be computed is $\le C\|\mathbf{v}\|^{1/s}_{\ell_\tau^w(\mathcal{J}')}\eta^{-1/s}$.

(ii) *The number of* arithmetic operations *needed to compute $\mathbf{w}(\mathbf{v}, \eta)$ does not exceed $C\eta^{-1/s}\|\mathbf{v}\|^{1/s}_{\ell_\tau^w(\mathcal{J}')} + 2N$ with $N := \#\operatorname{supp}\mathbf{v}$.*

(iii) *The number of operations for* sorting *needed to assemble the slices $\mathbf{v}_{[j]}$ of $\mathbf{w}(\mathbf{v}, \eta)$, $j = 0, 1, \ldots, \lfloor \log N \rfloor$, does not exceed $CN \log N$.*

(iv) *The output vector $\mathbf{w}$ satisfies*

$$\|\mathbf{w}\|_{\ell_\tau^w(\mathcal{J}')} \le C\|\mathbf{v}\|_{\ell_\tau^w(\mathcal{J}')}. \tag{4.1.12}$$

As for the log terms for sorting, see Remark 4.10 at the end of this section. We shall make use of the following fact; see [8].

REMARK 4.5. *It follows from Proposition* 4.1 *and Proposition* 4.4(i) *that any matrix $\mathbf{C} \in \mathcal{C}_{s^*}$ is bounded on ℓ_τ^w when τ is related to $s < s^*$ by* (4.1.5).

As mentioned above, wavelet representations of differential operators are compressible. Therefore the following observation is useful.

REMARK 4.6. *When $\mathbf{A}^\circ = \mathbf{D}_X^{-1}a(\Psi_X, \Psi_X)\mathbf{D}_X^{-1}$ and $\mathbf{B}$ belong to $\mathcal{C}_{s^*}$ for some $s^* > 0$, then one easily shows that the scheme* $\mathbf{APPLY}^*$ *inherits all the properties described in Proposition* 4.4 *above; see* [8, Property 6.4].

The complexity estimates in (ii) and (iii) of Proposition 4.4 hold under the assumption that the entries of $\mathbf{C}$ are accessible during the calculation. In fact, the subsequent developments will always be based on the following assumption.

ASSUMPTION 4.7. *The entries of the matrices $\mathbf{A}^\circ$ and $\mathbf{B}$ are accessible at unit cost.*

Using piecewise polynomial wavelets, this assumption can be realized for constant coefficient operators in a relatively straightforward manner. This task becomes much more delicate under more general circumstances, e.g., when isoparametric mappings

are involved in the construction of the wavelets; see section 5.2 below. In [3] a fast evaluation scheme is developed that computes sufficiently accurate approximations to the summands on the right-hand side of (4.1.10) at a computational cost that still satisfies the bounds in (ii), (iii) of Proposition 4.4 above. Thus Assumption 4.7 is justified for a wide range of practically relevant situations.

With Remark 4.6 at hand, we are now in the position for estimating the complexity analysis of **ELLSOLVE** based on the results in [8, 9] with the **APPLY** scheme for compressible matrices replaced, if necessary, by the extended version **APPLY*** introduced above. The fact that in the present context **ELLSOLVE** applies to varying auxiliary problems with little a priori information on the corresponding intermediate solutions prevents us from applying the results from [8] directly. Nevertheless, we can extract from the analysis in [8, 9] some facts that will apply in the present situation as well. This is most transparent when considering the simplified scheme in [9] which (in the very spirit of the current approach) for the special case of an elliptic (coercive) problem is based on a simple iteration for (3.2.4) of the form

$$\hat{\mathbf{u}}^{n+1} = \hat{\mathbf{u}}^n + \bar{\omega}(\mathbf{h} - \mathbf{A}\hat{\mathbf{u}}^n). \tag{4.1.13}$$

In particular, when the right-hand sides are already finitely supported as in the present situation, the scheme consists of at most $\bar{K}$ perturbed iterations of the form (4.1.13), employing **APPLY*** and **NCOARSE** with judiciously chosen accuracy tolerances, followed by a coarsening step so as to reduce a current error bound by a factor of two, say (see the algorithm **SOLVE** in section 4.2 of [9]). This implies the following fact.

PROPOSITION 4.8. *Consider the problem* (3.2.4) *and suppose that the initial approximation* $\mathbf{v}$ *used as input for* **ELLSOLVE** *satisfies*

$$\|\hat{\mathbf{u}} - \mathbf{v}\|_{\ell_2(\mathcal{J}_X)} \le \bar{\varepsilon} \tag{4.1.14}$$

for some $\bar{\varepsilon} > \varepsilon$. *Moreover, assume that* s *and* τ *are related by* (4.1.5) *and that*

$$\varepsilon \le \bar{C}\bar{\varepsilon} \tag{4.1.15}$$

for some positive constant $\bar{C}$. *Then the output* $\bar{\mathbf{u}}$ *and* $\Lambda := \operatorname{supp} \bar{\mathbf{u}}$ *of* **ELLSOLVE** $[\varepsilon, \mathbf{A}, \mathbf{v}, \mathbf{h}]$ *satisfies*

$$\#(\Lambda) \le \hat{C}\left(\#(\operatorname{supp}\mathbf{v}) + \left(\|\mathbf{v}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)} + \|\mathbf{h}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)}\right)\varepsilon^{-1/s}\right),$$

$$\|\bar{\mathbf{u}}\|_{\ell^w_\tau(\mathcal{J}_X)} \le \hat{C}\left(\|\mathbf{v}\|_{\ell^w_\tau(\mathcal{J}_X)} + \|\mathbf{h}\|_{\ell^w_\tau(\mathcal{J}_X)}\right). \tag{4.1.16}$$

Moreover, the number of arithmetic operations required for the computation of $\bar{\mathbf{u}}$ *remains bounded by*

$$\hat{C}\left\{\#\operatorname{supp}\mathbf{v} + \varepsilon^{-1/s}\left(\|\mathbf{v}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)} + \|\mathbf{h}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)}\right)\right\}. \tag{4.1.17}$$

An additional factor $\hat{C}\log\varepsilon^{-1}$ *is allowed for operations spent on sorting arrays (see Remark* 4.10*). The constant* $\hat{C}$ *depends in all cases only on the constants in* (2.4.7), (2.2.1), *on* s *when* s *tends to infinity, and on the constant* $\bar{C}$ *in* (4.1.15).

Proof. In view of (4.1.15), only a uniformly bounded number of blocks of perturbed iterations (4.1.13) separated by coarsening steps is needed to reduce the current error bound from $\bar{\varepsilon}$ to ε; see Proposition 4.2 in [9]. This number depends clearly on the bound $\bar{C}$ for the ratio $\bar{\varepsilon}/\varepsilon$. Each block, in turn, involves a uniformly bounded

number $\bar{K}$ of perturbed applications of (4.1.13), where $\bar{K}$ depends only on the constants in (2.4.7) and (2.2.1). The claim follows now immediately from Propositions 4.2 and 4.4 (see also the proof of Theorem 5.7 in [9]). ∎

The main result can now be formulated as follows.

THEOREM 4.9. *Assume that the scaled wavelet representations* $\mathbf{A}^\circ$, $\mathbf{B}$ *in* (2.2.4), *and* $\mathbf{R}$ *from* (3.1.3) *belong to* $\mathcal{C}_{s^*}$ *for some* $s^* > 0$, *where the underlying wavelet bases* Ψ_X, Ψ_M *satisfy* (2.2.1), (2.2.2). *Moreover, assume that* (2.1.2) *is well-posed in the sense of* (2.1.4). *If the exact solution* (u, p) *of* (2.1.2) *satisfies for some* $s < s^*$

$$\inf_{\#\mathrm{supp}\mathbf{v}\le N} \|u-\mathbf{v}^T\mathbf{D}_X^{-1}\Psi_X\|_X \lesssim N^{-s}, \quad \inf_{\#\mathrm{supp}\mathbf{q}\le N} \|p-\mathbf{q}^T\mathbf{D}_M^{-1}\Psi_M\|_M \lesssim N^{-s}, \ \ N\to\infty, \tag{4.1.18}$$

then the approximations $(\mathbf{u}(\varepsilon), \mathbf{p}(\varepsilon))$ *produced by* **UZAWA**^{c} *satisfy*

$$\|u-\mathbf{u}(\varepsilon)^T\mathbf{D}_X^{-1}\Psi_X\|_X \lesssim (\#\mathrm{supp}\,\mathbf{u}(\varepsilon))^{-s}, \quad \|p-\mathbf{p}(\varepsilon)^T\mathbf{D}_M^{-1}\Psi_M\|_M \lesssim (\#\mathrm{supp}\,\mathbf{p}(\varepsilon))^{-s}. \tag{4.1.19}$$

Moreover, under the Assumptions 3.1 *and* 4.7, *the computational work needed to compute* $\mathbf{u}(\varepsilon), \mathbf{p}(\varepsilon)$ *is also of the order* $\varepsilon^{-1/s}$ *(except for additional* log *terms for sorting).*

Proof. First note that, by (2.2.1) and (2.2.2), $\sigma_{N,\ell_2(\mathcal{J}_X)}(\mathbf{u}) \lesssim N^{-s}$ and $\sigma_{N,\ell_2(\mathcal{J}_M)}(\mathbf{p}) \lesssim N^{-s}$. Proposition 4.1 says that then $\mathbf{u} \in \ell_\tau^w(\mathcal{J}_X)$ and $\mathbf{p} \in \ell_\tau^w(\mathcal{J}_M)$. It follows now from (2.2.4) and Remark 4.5 that $\mathbf{g} \in \ell_\tau^w(\mathcal{J}_M)$. Since by the same argument $\mathbf{B}^T\mathbf{p}, \mathbf{A}\mathbf{u} \in \ell_\tau^w(\mathcal{J}_X)$, (2.4.5) says that also $\mathbf{f} \in \ell_\tau^w(\mathcal{J}_X)$, i.e.,

$$\|\mathbf{g}\|_{\ell_\tau^w(\mathcal{J}_M)} \lesssim \|\mathbf{u}\|_{\ell_\tau^w(\mathcal{J}_X)}, \quad \|\mathbf{f}\|_{\ell_\tau^w(\mathcal{J}_X)} \lesssim \|\mathbf{u}\|_{\ell_\tau^w(\mathcal{J}_X)} + \|\mathbf{p}\|_{\ell_\tau^w(\mathcal{J}_M)}. \tag{4.1.20}$$

We proceed now estimating the computational cost of one call of **ADV** adhering to the notation used in this context before. We will make frequent use of the fact that all accuracy tolerances appearing in **ADV** remain, in view of the uniform boundedness of K, proportional to the current accuracy $\delta = \delta_J$ in the Jth call of **ADV** in **UZAWA**^{c}. We begin with step (ii) of **ADV**, since the effect of **NCOARSE** determines also the properties of the input of **ADV**. To this end, recall that the perturbed iterate $\bar{\mathbf{p}}_K$, which forms one of the inputs of the coarsening step, is a finitely supported approximation of $\mathbf{p}$, satisfying the error estimate (3.3.11). It is important to note that, regardless of the sizes of its support, Proposition 4.2 implies that then

$$\#(\mathrm{supp}\,\tilde{\mathbf{p}}) \le C\delta^{-1/s}\|\mathbf{p}\|^{1/s}_{\ell_{\tau'}^w(\mathcal{J}_M)}, \qquad \|\tilde{\mathbf{p}}\|_{\ell_{\tau'}^w(\mathcal{J}_M)} \le C\|\mathbf{p}\|_{\ell_{\tau'}^w(\mathcal{J}_M)}, \tag{4.1.21}$$

where C depends only on s when s tends to infinity. Likewise, in view of the error bound (3.3.14) for $\bar{\mathbf{u}}_K$, Proposition 4.2 ensures that

$$\|\tilde{\mathbf{u}}\|_{\ell_\tau^w(\mathcal{J}_X)} \le C\|\mathbf{u}\|_{\ell_\tau^w(\mathcal{J}_X)}, \quad \#\mathrm{supp}\,\tilde{\mathbf{u}} \le C\delta^{-1/s}\|\mathbf{u}\|^{1/s}_{\ell_\tau^w(\mathcal{J}_X)}, \tag{4.1.22}$$

where, as before, $\delta = \delta_J$ is the current accuracy level in the Jth call of **ADV** in **UZAWA**^{c}. As before in (4.1.21), the constant C is independent of $\bar{\mathbf{u}}_K$.

We still have to control the computational cost of the intermediate steps (iii)–(iv) of **ADV**, leading to the final perturbed iterates $\bar{\mathbf{p}}_K, \bar{\mathbf{u}}_K$, which are then subjected to the coarsening step that led to the above estimates. To this end, we infer from Remark 4.5, Propositions 4.2 and 4.4 that

$$\#(\mathrm{supp}\,\bar{\mathbf{p}}_i) \le C\delta^{-1/s}\left(\|\bar{\mathbf{u}}_i\|^{1/s}_{\ell_\tau^w(\mathcal{J}_X)} + \|\mathbf{g}\|^{1/s}_{\ell_\tau^w(\mathcal{J}_M)}\right) + \#(\mathrm{supp}\,\bar{\mathbf{p}}_{i-1}), \quad i = 1,\dots,K, \tag{4.1.23}$$

and

$$\|\bar{\mathbf{p}}_i\|_{\ell^w_{\tau'}(\mathcal{J}_M)} \leq C\left(\|\bar{\mathbf{p}}_{i-1}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\bar{\mathbf{u}}_i\|_{\ell^w_\tau(\mathcal{J}_X)}\right), \quad 1,\dots,K. \tag{4.1.24}$$

Thus we have to estimate next the quantities $\|\bar{\mathbf{u}}_i\|_{\ell^w_\tau(\mathcal{J}_X)}$, $\#\operatorname{supp}\bar{\mathbf{u}}_i$, $i = 1,\dots,K$. To this end, we first have to determine the accuracy of $\bar{\mathbf{u}}_{i-1}$ as an initial guess for $\mathbf{ELLSOLVE}\,[\gamma_i\rho^i\delta/2, \mathbf{A}, \bar{\mathbf{u}}_{i-1}, \mathbf{h}_i]$. In fact, a little care is needed because the right-hand sides $\mathbf{h}_i$ change. To this end, let $\check{\mathbf{u}}_i$ denote the exact solution of $\mathbf{A}\check{\mathbf{u}}_i = \mathbf{h}_i$; see (iii) in **ADV**. Then, by (3.3.13), for $\delta = \delta_J$ in the Jth call of **ADV** in $\mathbf{UZAWA}^c$ one obtains for some constant C

$$\begin{aligned}
\|\check{\mathbf{u}}_i - \bar{\mathbf{u}}_{i-1}\|_{\ell_2(\mathcal{J}_X)} &\leq \|\check{\mathbf{u}}_i - \mathbf{u}\|_{\ell_2(\mathcal{J}_X)} + \|\mathbf{u} - \bar{\mathbf{u}}_{i-1}\|_{\ell_2(\mathcal{J}_X)} \\
&\leq c_A^{-1}\|\mathbf{f} - \mathbf{B}^T\mathbf{p} - \mathbf{h}_i\|_{\ell_2(\mathcal{J}_X)} + C\delta \\
&\leq c_A^{-1}\left(\|\mathbf{f} - \mathbf{B}^T\mathbf{p} - (\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1})\|_{\ell_2(\mathcal{J}_X)}\right. \\
&\qquad \left. + \|\mathbf{f} - \mathbf{B}^T\bar{\mathbf{p}}_{i-1} - \mathbf{h}_i\|_{\ell_2(\mathcal{J}_X)}\right) + C\delta \\
&\leq c_A^{-1}C_B\|\mathbf{p} - \bar{\mathbf{p}}_{i-1}\|_{\ell_2(\mathcal{J}_M)} + \gamma_i\rho^i\delta/2 + C\delta \\
&\leq C'\delta_J,
\end{aligned}$$

where we have used (3.3.10) and (3.2.8). Thus, the ratio of initial and target accuracies in each call of **ELLSOLVE** remains uniformly bounded by a constant $\bar{C}$ depending on the number K in **ADV**, so that Proposition 4.8 applies. To this end, consider first $i = 1$ in step (iv) of **ADV**. By the above bound (4.1.21) on $\bar{\mathbf{p}}_0 = \tilde{\mathbf{p}}^{J-1}$, Remark 4.5, Propositions 4.2, 4.4, and steps (i), (ii) in **RHS**, we conclude that

$$\|\mathbf{h}_1\|_{\ell^w_\tau(\mathcal{J}_X)} \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{f}\|_{\ell^w_\tau(\mathcal{J}_X)}) \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|_{\ell^w_\tau(\mathcal{J}_X)}), \tag{4.1.25}$$

where we have used (4.1.20) in the last step. Here and in what follows, unless stated otherwise, C will be a constant (that may vary from place to place) which is independent of $\mathbf{u}, \mathbf{p}$ and at most dependent on the problem constants as before. Proposition 4.8 combined with (4.1.22) now implies

$$\begin{aligned}
&\|\bar{\mathbf{u}}_1\|_{\ell^w_\tau(\mathcal{J}_X)} \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|_{\ell^w_\tau(\mathcal{J}_X)}), \\
&\#(\operatorname{supp}\bar{\mathbf{u}}_1) \leq C\left(\#(\operatorname{supp}\bar{\mathbf{u}}_0) + \delta^{-1/s}(\|\mathbf{p}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)})\right).
\end{aligned} \tag{4.1.26}$$

Again keeping (4.1.21) in mind and substituting (4.1.26) in (4.1.24) for $i = 1$, we obtain

$$\|\bar{\mathbf{p}}_1\|_{\ell^w_\tau(\mathcal{J}_M)} \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|_{\ell^w_\tau(\mathcal{J}_X)}). \tag{4.1.27}$$

We can now repeat this argument K times and obtain that for all $i \leq K$,

$$\begin{aligned}
&\|\bar{\mathbf{u}}_i\|_{\ell^w_\tau(\mathcal{J}_X)} \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|_{\ell^w_\tau(\mathcal{J}_X)}), \\
&\#(\operatorname{supp}\bar{\mathbf{u}}_i) \leq C\left(\#(\operatorname{supp}\bar{\mathbf{u}}_0) + \delta^{-1/s}(\|\mathbf{p}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)})\right), \\
&\|\bar{\mathbf{p}}_i\|_{\ell^w_\tau(\mathcal{J}_M)} \leq C(\|\mathbf{p}\|_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|_{\ell^w_\tau(\mathcal{J}_X)}), \\
&\#(\operatorname{supp}\bar{\mathbf{p}}_i) \leq C\left(\#(\operatorname{supp}\bar{\mathbf{p}}_{i-1}) + \delta^{-1/s}(\|\mathbf{p}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_M)} + \|\mathbf{u}\|^{1/s}_{\ell^w_\tau(\mathcal{J}_X)})\right).
\end{aligned} \tag{4.1.28}$$

In view of the operations count given in Propositions 4.4, 4.8, estimate (4.1.28) says that the computational cost in steps (iii)–(v) remains proportional to $\delta^{-1/s}$. Of course,

the constant C of proportionality depends on the number of steps K and may build up if the perturbed iterations were simply continued. However, the thresholding in step (ii) of **ADV** produces a new constant that no longer depends on K and in this sense sets the proportionality constant back. Thus, we conclude that, under the given assumptions on the exact solutions $\mathbf{u}, \mathbf{p}$, the convergence rate N^{-s} is indeed preserved by $\mathbf{UZAWA}^c$ within the claimed bounds for the corresponding computational work. The assertion follows now directly from Corollary 3.5, (3.3.15). □

REMARK 4.10. *One should note that a strict ordering of the wavelet coefficients by size is actually not essential. What matters is to group the coefficients in binary bins, i.e., to collect all those coefficients whose modulus falls into* $[a2^{-j}, a2^{-j+1})$*, say. In this way one can avoid the logarithmic terms appearing in the work counts for sorting; see* [1].

5. Applications to the Stokes problem. In this section the above developments will be applied to a classical example, namely the *Stokes problem*. In particular, we shall identify suitable wavelet bases and determine the compressibility range s^* for which Theorem 4.9 ensures asymptotically optimal performance.

5.1. The continuous problem. We consider a Lipschitz domain $\Omega \subset \mathbb{R}^d$ and assume for simplicity homogeneous boundary conditions; i.e.,

$$-\Delta u + \nabla p = f, \quad \nabla \cdot u = 0 \quad \text{in } \Omega \subset \mathbb{R}^d, \qquad u|_{\partial\Omega} = 0. \tag{5.1.1}$$

The standard L_2 inner product on a domain G will be denoted by $\langle v, w\rangle_G := \int_G v(x)\, w(x)\, dx$, where we will drop the subscript whenever the inner product refers to Ω. The mixed formulation takes the form (2.1.2) with

$$X = H_0^1(\Omega)^d, \quad M = L_{2,0}(\Omega) := \left\{ v \in L_2(\Omega) : \int_\Omega v(x)\, dx = 0 \right\}, \tag{5.1.2}$$

and

$$a(u, v) := (\nabla u, \nabla v), \qquad b(q, v) := -\langle \nabla \cdot v, q\rangle. \tag{5.1.3}$$

It is well known that (2.1.1) holds in this case even with the stronger relation (2.4.1), so that (2.1.4) is true for (5.1.2). In view of the preceding discussion we have to address the following issues. First, we identify a class of suitable wavelet bases which will be employed later in numerical experiments. Then we determine the compressibility range of the corresponding wavelet representations. Next, we discuss the regularity of the solution to (5.1.1) in a certain scale of Besov spaces. Although this information has no effect on the algorithmic realization, it will allow us to determine under which principal circumstances the adaptive scheme offers even an asymptotically better work/accuracy balance than discretizations based on uniform mesh refinements. These results will guide the selection of our test examples.

5.2. Wavelet representation. When Ω can be partitioned into regular parametric images $\Omega_l = \kappa_l(\square)$ of the unit d-cube $\square := (0, 1)^d$, one can use the constructions from [6, 17] yielding conforming trial spaces for the velocities and pressure. We proceed now collecting the relevant properties of these bases in the present context.

We will reserve the notation Ψ_X for the wavelet basis for $X = H_0^1(\Omega)^d$; i.e., each wavelet $\psi_{X,\lambda}$ is a vector valued function with components $\psi_{\lambda,i}, \lambda \in \mathcal{J}_X$, $i = 1, \ldots, d$. A wavelet $\psi_{\lambda,i}$ which is supported in a single patch Ω_l is then constructed as a linear combination of tensor product B-splines of (coordinatewise) order m_X (which is for

simplicity taken to be the same for each component i) composed with κ_l^{-1}. Wavelets whose support intersects several domains are obtained by suitably patching together such functions across interfaces; see [6, 17] for details. At this point a word on the nature of the indices λ is in order. Without going into details, λ encodes the spatial location of the wavelet $\psi_{X,\lambda}$ as well as its scale denoted by $|\lambda|$. We will employ only compactly supported wavelets whose supports then scale like $\operatorname{diam}(\operatorname{supp}\psi_\lambda) \sim 2^{-|\lambda|}$. The coarsest scale $|\lambda| = 0$ corresponds to finitely many functions, which roughly speaking span the polynomial part in an expansion. Thus for each component i the corresponding *multiresolution spaces* $S_{i,J} := \operatorname{span}\{\psi_{\lambda,i} : |\lambda| < J\}$ can be viewed as trial spaces on meshes of size 2^{-J}. To have a conforming discretization the $S_{i,J}$ are arranged to be contained in $H_0^1(\Omega)$. Being generated by m_Xth order B-splines, they realize approximation order m_X in $H^{m_X}(\Omega) \cap H_0^1(\Omega)$. Such a basis can be realized for any order $m_X \in \mathbb{N}$. We will later vary this order, keeping in mind that the restrictions to a patch Ω_l satisfy

$$\Psi_X|_{\Omega_l} \subset H^{m_X - 1/2}(\Omega_l)^d; \tag{5.2.1}$$

see [24]. Moreover, recall that a wavelet basis consists of two disjoint collections of functions Ψ_X^+ and Ψ_X^- (and analogously for Ψ_M). As indicated above, Ψ_X^+ is comprised of finitely many *scaling functions* of level $|\lambda| = 0$ whose preimages under the parametric mappings span all polynomials of order m_X on $\square$ (up to boundary conditions). The infinite collection Ψ_X^- contains the "true wavelets" in the following sense. In fact, the construction of Ψ_X involves a second important parameter $\tilde{m}_X$. Given any m_X, one can take any $\tilde{m}_X \in \mathbb{N}$, $\tilde{m}_X \geq m_X$ such that $m_X + \tilde{m}_X$ is even and arrange Ψ_X so that for any $\psi_{\lambda,i}$ supported in Ω_l the following m_Xth order *moment conditions* hold:

$$(P, \psi_{\lambda,i})_{\Omega_l} = 0 \qquad \text{for all } P \in \Pi_{\tilde{m}_X,\kappa_l},\quad \psi_{\lambda,i} \in \Psi_i^-, \tag{5.2.2}$$

where $(\cdot,\cdot)_{\Omega_l}$ denotes the standard inner product on the subdomain Ω_l. Here $\Pi_{\tilde{m},\kappa_l} := \{P : P = g_l Q \circ \kappa_l^{-1}, Q \in \Pi_{\tilde{m}}\}$, where $g_l := |\det \partial\kappa_l^{-1}|$ and $\Pi_{\tilde{m}}$ denotes the space of all polynomials of degree less than $\tilde{m}$. With a slight abuse of terminology we will refer to the elements of Π_{m,κ_l} simply as *polynomials*. In fact, since by assumption the g_l are smooth and bounded away from zero, the local approximation properties of $\Pi_{\tilde{m},\kappa_l}$ are the same as those of $\Pi_{\tilde{m}}$, which is what matters for the compression properties.

The pressure functions will be expanded in a basis $\Psi_M = \{\psi_{M,\lambda} : \lambda \in \mathcal{J}_M\}$, which is also generated by B-splines of order m_M in the above sense. Likewise the order of moment conditions will be denoted by $\tilde{m}_M$, i.e.,

$$(P, \psi_{M,\lambda})_{\Omega_l} = 0 \quad \text{for all } P \in \Pi_{\tilde{m}_M,\kappa_l},\ \psi_{M,\lambda} \in \Psi_M^-. \tag{5.2.3}$$

REMARK 5.1. *There are some important distinctions between Ψ_X and Ψ_M though (aside from the fact that Ψ_X is vector and Ψ_M is scalar valued). First, $\psi_{M,\lambda}$ do not satisfy any boundary conditions. Moreover, the moment conditions hold everywhere in Ω since all wavelets are always fully supported in a single patch Ω_l; i.e., the wavelets need not be continuous across patch interfaces.*

Since by (5.2.3) the wavelets in Ψ_M^- have zero mean, an ab initio wavelet basis for $L_2(\Omega)$ can easily be transformed into one for the constrained space $L_{2,0}(\Omega)$ by modifying only the finitely many elements in Ψ_M^+, a fact that will be important later in the numerical realization.

It has been shown in [6, 17] that bases Ψ_X and Ψ_M satisfy the norm equivalences (2.2.1) and (2.2.2) with scaling weights

$$(D_X)_\lambda := 2^{|\lambda|}, \quad (D_M)_\lambda := 1. \tag{5.2.4}$$

In fact, the alternative choice $(D_X)_\lambda := a(\psi_{X,\lambda}, \psi_{X,\lambda})^{1/2}$ typically gives rise to quantitatively better results, but we will stick with (5.2.4) for simplicity.

Hence, the resulting wavelet representations $\mathbf{A}$ and $\mathbf{B}^T$ are of the following form:

$$\mathbf{A} = (a_{\lambda,\lambda'})_{\lambda,\lambda'\in\mathcal{J}_X}, \quad a_{\lambda,\lambda'} = \sum_{i,l=1}^{d} 2^{-(|\lambda|+|\lambda'|)} \int_\Omega \frac{\partial\psi_{\lambda,i}}{\partial x_l}\frac{\partial\psi_{\lambda',i}}{\partial x_l}dx, \tag{5.2.5}$$

$$\mathbf{B}^T = (b_{\lambda,\lambda'})_{\lambda\in\mathcal{J}_X,\lambda'\in\mathcal{J}_M}, \quad b_{\lambda,\lambda'} = -\sum_{i=1}^{d} 2^{-|\lambda|} \int_\Omega \psi_{M,\lambda'}(x)\frac{\partial\psi_{\lambda,i}}{\partial x_i}(x)dx. \tag{5.2.6}$$

5.3. Compression properties. The matrices $\mathbf{A}$, $\mathbf{B}$, defined by (5.2.5) and (5.2.6), are known to be compressible in a range that depends on the regularity of the wavelets; see [8]. However, the special piecewise polynomial nature of the above bases allows us to establish a somewhat larger range of compressibility compared with the general estimates in [8]. In this subsection, we briefly discuss the compression properties of the matrices $\mathbf{A}$ and $\mathbf{B}$, $\mathbf{B}^T$. The analysis is based on the following version of the *Schur lemma* which follows from interpolation between ℓ_∞ and ℓ_1.

LEMMA 5.2. *Let $\mathbf{T} = (T_{l,l'})_{l\in\mathcal{I},l'\in\mathcal{I}'}$ be a matrix and let $\mathcal{I},\mathcal{I}'$ be countable index sets. Suppose that there exist sequences $(\varpi_l)_{l\in\mathcal{I}}$ and $(\tilde{\varpi}_{l'})_{l'\in\mathcal{I}'}$ such that*

$$\sum_{l'\in\mathcal{I}'} |T_{l,l'}|\tilde{\varpi}_{l'} \le c\varpi_l \qquad \text{and} \qquad \sum_{l\in\mathcal{I}} |T_{l,l'}|\varpi_l \le c\tilde{\varpi}_{l'}, \qquad l\in\mathcal{I},\ l'\in\mathcal{I}'; \tag{5.3.1}$$

then $\|\mathbf{T}\| \le c$.

Our numerical examples refer to the L-shaped domain $\Omega = (-1,1)^2 \setminus (-1,0]^2$. Thus Ω can be decomposed, e.g., into three subpatches Ω_l, $l = 1,2,3$, each being a simple translate of the unit square $(0,1)^2$. The spaces Π_{m,κ_l} consist then of polynomials in the classical sense. The moment conditions (5.2.2) hold then on all of Ω also for those wavelets whose support overlaps more than one subdomain. In this case the truncation rule that produces the compressed matrices $\mathbf{A}_j$ from (4.1.9) reads as follows; see [8, 2]. In order to indicate the role of the spatial dimension we keep the general notation although the example refers to $d = 2$. Given j, set

$$\tilde{a}_{\lambda,\nu} := \begin{cases} a_{\lambda,\nu}, & \big||\lambda| - |\nu|\big| \le j/d, \\ 0, & \text{else.} \end{cases} \tag{5.3.2}$$

Unless otherwise stated, we shall henceforth use the abbreviation $m = m_X$, $\tilde{m} = \tilde{m}_X$.

THEOREM 5.3. *For the matrix $\mathbf{A}$ defined by* (5.2.5) *and any $\epsilon > 0$, the following compression estimate holds:*

$$\|\mathbf{A} - \mathbf{A}_J\| \lesssim 2^{-J(m-3/2-\epsilon)/d}, \quad \textit{i.e.,} \quad \mathbf{A}\in\mathcal{C}_{s^*}, \quad s^* = (m-3/2)/d. \tag{5.3.3}$$

Proof. The estimate (5.3.3) can be established by using Lemma 5.2 with $\mathcal{I} = \mathcal{I}' = \mathcal{J}_X$ and $\varpi_\lambda = \tilde{\varpi}_\lambda = 2^{|\lambda|(1-d)}$ for all $\lambda\in\mathcal{J}_X$. To this end, let $\Omega_{\lambda,i}$, $\mathbb{P}_m$ denote the support of the i-component of ψ_λ and the space of polynomials of degree at most m. We recall that derivatives of wavelets are again wavelets with the order of vanishing

moments increased by one [22]. Exploiting this fact, and recalling that $\tilde{m} \geq m$ and $|\lambda'| \geq |\lambda|$, we obtain

$$|(\nabla\psi_{X,\lambda}, \nabla\psi_{X,\lambda'})| \leq \sum_{i,l=1}^{d} \inf_{P\in\mathbb{P}_m} \left| \left(\frac{\partial\psi_{\lambda,i}}{\partial x_l} - P, \frac{\partial\psi_{\lambda',i}}{\partial x_l} \right) \right|$$
$$\lesssim 2^{|\lambda'|} \sum_{i,l=1}^{d} \inf_{P\in\mathbb{P}_m} \left\| \frac{\partial\psi_{\lambda,i}}{\partial x_l} - P \right\|_{L_2(\Omega_{\lambda',i})},$$

where we have applied (2.2.1) with the weights from (5.2.4) to estimate the term $\|\frac{\partial\psi_{\lambda',i}}{\partial x_l}\|_{L_2}$ by $2^{|\lambda'|}$. Setting $j := |\lambda|$, $j' := |\lambda'|$, since $\frac{\partial\psi_{\lambda,i}}{\partial x_l} \in H^s$, $s < m - 3/2$, a classical Whitney-type estimate therefore yields

$$|\,(\nabla\psi_\lambda, \nabla\psi_{\lambda'})\,| \lesssim \sum_{i,l=1}^{d} 2^{j'} 2^{-j'(m-3/2-\epsilon)} \left| \frac{\partial\psi_{\lambda,i}}{\partial x_l} \right|_{H^{m-3/2-\epsilon}}$$
$$\lesssim \sum_{i=1}^{d} 2^{j'} 2^{-j'(m-3/2-\epsilon)} |\psi_{\lambda,i}|_{H^{m-1/2-\epsilon}}$$
$$\lesssim 2^{j'} 2^{-j'(m-3/2-\epsilon)} 2^{j(m-1/2-\epsilon)} \lesssim 2^{(j-j')(m-3/2-\epsilon)} 2^{j+j'}.$$

Thus, taking the scaling matrix $\mathbf{D}_X$ into account and treating the case $j' \leq j$ in an analogous fashion, we derive

$$|a_{\lambda,\lambda'}| \lesssim 2^{-||\lambda|-|\lambda'||(m-3/2-\epsilon)}. \tag{5.3.4}$$

In view of (5.3.3) and (5.3.1), we have to estimate $\sum_{|j-j'|>J/d} \sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| 2^{j'(1-d)}$. Again consider the case $j' > j$ first and observe that (5.3.4) can be refined for certain entries because in the present case the wavelets are piecewise polynomial. In fact, the nonvanishing entries correspond only to the wavelets $\psi_{\lambda'}$ for which the support of one component $\psi_{\lambda',i}$ intersects the corresponding singular support $\mathcal{S}_{\lambda',i}$ of $\psi_{\lambda,i}$. The set $\mathcal{S}_{\lambda',i}$ can be viewed as a submanifold of dimension $d-1$ with measure of the order $2^{-j(d-1)}$. Consequently, for $j' > j$, there are at most a fixed constant multiple of $2^{(j'-j)(d-1)}$ many wavelets possessing a nontrivial intersection with $\mathcal{S}_{\lambda',i}$. Therefore we obtain

$$\sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| \lesssim 2^{(j-j')(m-3/2-\epsilon)} 2^{(j'-j)(d-1)} \lesssim 2^{(j-j')(m-3/2-\epsilon+1-d)} \tag{5.3.5}$$

and hence finally

$$\sum_{j'-j>J/d} \sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| 2^{j'(1-d)} \lesssim \sum_{j'=j+J/d}^{\infty} 2^{(j-j')(m-3/2-\epsilon+1-d)} 2^{j'(1-d)} \tag{5.3.6}$$
$$\lesssim 2^{j(1-d)} 2^{-J(m-3/2-\epsilon)/d}.$$

The case $j' \leq j$ can be treated analogously, and the second condition in (5.3.1) follows in this case by symmetry, which confirms (5.3.3). ∎

REMARK 5.4. *By combining the results in* [8] *with the analysis in* [13]*, one derives the following bound for the range of compressibility of the wavelet representation of an elliptic differential operator of order* $2t$*:*

$$s^* := \max\left\{0, \min\left\{\frac{\sigma}{d} - \frac{1}{2}, \frac{2t+2\tilde{m}}{d}\right\}\right\}.$$

Here the parameter σ *must satisfy* $t + \sigma < \gamma$*, where* γ *bounds the Sobolev regularity of the wavelets. In the present case one has* $t = 1,\ \gamma = m - 1/2$*, i.e.,* $\sigma = m - 3/2$*, and hence* $s^* = (m-3/2)/d - 1/2$*. Therefore* (5.3.3) *ensures in any spatial dimension a gain in the compression range by* $1/2$ *when compared with the usual estimate in* [8, Proposition 3.4].

For more general domains, when the κ_l are no longer affine, some constructions of wavelet bases guarantee the full order of vanishing moments (5.2.2) only for those wavelets that are supported in a single patch Ω_l. Those wavelets overlapping several subdomains still have at least first order moments, and hence their gradients have second order moments. Of course, this occurs only along a $(d-1)$ dimensional manifold and can be compensated by modifying the compression rule (5.3.2). Moreover, those entries $a(\psi_\lambda, \psi_{\lambda'})$, for which the supports overlap each other but their singular supports (cut regions of tensor product B-splines) do not intersect, are no longer zero. However, since one of the wavelets is arbitrarily smooth throughout the integration domain, the order of vanishing moments increases to $\tilde{m}_X + 1$ so that these entries are much smaller than the remaining ones, which suffices as well. Alternatively, one can employ the construction from [18], where vanishing moments are not constrained through patch interfaces.

A similar result can also be established for the matrix $\mathbf{B}^T$ defined in (5.2.6).

THEOREM 5.5. *Suppose that the order* m_X *of the multiresolution spaces for the velocity space* X *and the order* $\tilde{m}_M$ *of the vanishing moments of the pressure wavelets defined in* (5.2.3) *satisfy* $\tilde{m}_M \geq m_X - 1$*. Then for the matrix* $\mathbf{B}^T$ *defined in* (5.2.6) *and any* $\epsilon > 0$*, the following compression estimate holds:*

$$\|\mathbf{B}^T - \mathbf{B}_J^T\| \lesssim 2^{-J(m-3/2-\epsilon)/d}, \quad \textit{i.e.,} \quad \mathbf{B}^T \in \mathcal{C}_s,\ s < s^* = (m-3/2)/d. \tag{5.3.7}$$

The proof of Theorem 5.5 follows the lines of the proof of Theorem 5.3 with $\mathcal{I} = \mathcal{J}_X,\ \mathcal{I}' = \mathcal{J}_M,\ \varpi_\lambda = 2^{|\lambda|(1-d)},\ \lambda \in \mathcal{J}_X$, and $\tilde{\varpi}_{\lambda'} = 2^{|\lambda'|(1-d)}, \lambda' \in \mathcal{J}_M$.

To determine finally the compressibility of the matrix $\mathbf{R}$ from (3.1.3), we can apply the same reasoning for $\partial\psi_{\lambda,i}/\partial x_l$ and $\psi_{M,\lambda'}$ replaced by $\tilde{\psi}_{M,\lambda}$. Since in this case no derivatives are involved and $\tilde{\Psi}_M$ is patchwise defined just as Ψ_M is, the compressibility range is again determined by the order m_M of the primal basis Ψ_M (which limits the order of the polynomials that can be subtracted in the inner products) and the Sobolev regularity $\tilde{\gamma}_M$ of the dual basis $\tilde{\Psi}$ inside each patch Ω_l. Combining tensor products of the wavelet bases on $[0,1]$ from [16] with parametric mappings allows one to realize therefore any desired order s_R^* of compressibility for $\mathbf{R}$, provided that m_M and $\tilde{\gamma}_M$ are chosen accordingly.

Theorems 5.3 and 5.5 tell us now in which range for a given choice of wavelet bases the general results Theorem 4.9 and Corollary 3.5 assert asymptotically optimal accuracy/work balance for the adaptive solution of the Stokes problem.

5.4. Regularity theory for the Stokes problem. So far we have presented some numerical tools to serve as input for an adaptive scheme that realizes asymptotically optimal convergence rates in (essentially) linear time within a certain range

of error decay orders determined by the compressibility of the involved wavelet representations. A natural question is whether at all or under which circumstances the corresponding accuracy/work balance is better than for technically much simpler schemes based, e.g., on uniformly refined meshes—in brief, when does adaptivity pay? It turns out that this question is inherently related to the *regularity* of the approximated solution. More precisely, while a given order of best approximation from trial spaces for preassigned uniform meshes (referred to as *linear schemes*) is characterized by the *Sobolev* regularity of the approximant, the order of *nonlinear* or *best N-term approximation* is (almost) characterized by the regularity in a certain *Besov scale* to be specified in a moment; see also [19]. To explain this let H^t denote a (closed subspace of a) Sobolev space such as $H_0^1(\Omega)$, respectively, $H_0^1(\Omega)^d$ or $L_{2,0}(\Omega)$ for $t = 0$ and let Υ denote a wavelet basis in H^t satisfying a norm equivalence of the form (2.2.1) with suitable scaling matrix $\mathbf{D}^t$. In analogy to (4.1.1), let

$$\sigma_{N,H^t}(v) := \inf_{\mathbf{w},\#\mathbf{w}\le N} \|v - \mathbf{w}^T(\mathbf{D}^t)^{-1}\Upsilon\|_{H^t} \tag{5.4.1}$$

denote the error of best wavelet N-term approximation in H^t. The following fact has been shown in [12].

PROPOSITION 5.6. *Whenever $t \le r$ for some $r \in \mathbb{R}_+$ depending on the regularity of the wavelet basis, let*

$$\frac{1}{\alpha} = \frac{r-t}{d} + \frac{1}{2} \tag{5.4.2}$$

for some $r \in \mathbb{R}$. Then (for a sufficiently regular basis Υ) one has

$$\sum_{N=1}^{\infty} \Big(N^{(r-t)/d}\sigma_{N,H^t}(v)\Big)^{\alpha} < \infty \quad \text{if and only if} \quad v \in B_\alpha^r(L_\alpha(\Omega)). \tag{5.4.3}$$

Note that $B_\alpha^r(L_\alpha(\Omega))$ is the largest space of smoothness r in L_α which is still embedded in H^t, since (5.4.2) marks the Sobolev embedding line; see the "DeVore diagram" in [19]. Clearly, (2.2.1) says that for $v = \mathbf{v}^T(\mathbf{D}^t)^{-1}\Upsilon$ one has

$$\sigma_{N,H^t}(v) \sim \sigma_{N,\ell_2}(\mathbf{v}). \tag{5.4.4}$$

Moreover, (5.4.3), (5.4.4) mean that when $v \in B_\alpha^r(L_\alpha(\Omega))$ the error of the best N-term approximation of its wavelet coefficients $\mathbf{v}$ decays at least like $\sigma_{N,\ell_2}(\mathbf{v}) \lesssim N^{-(r-t)/d}$. This is sharp in the sense that the exponent $s = (r-t)/d$ is best possible. This subtle gap in the characterization of the Besov spaces is due to the small difference between the classical spaces ℓ_τ (characterizing wavelet coefficients for elements in the Besov space) and the weak-type space ℓ_τ^w characterizing best N-term approximation of the wavelet coefficient sequences in ℓ_2 [19].

These facts suggest asking for the regularity of the solution (u, p) of the Stokes problem (5.1.1) in the relevant Besov scales.

We shall briefly review now some results from [10, 20, 23] concerning the regularity of the solution to the Stokes problem (5.1.1) for the L-shaped domain, which are relevant for the subsequent selection of numerical examples. In our case, one can identify the singular part u_S of the velocity which is independent of smooth right-hand sides f and describes the influence of the domain.

In fact, by specializing the results in [10, 11], one can identify solutions u_S of the Stokes problem (referred to as *singular solution*) exhibiting the strongest singularity

induced by the reentrant corner for smooth right-hand sides. The following result can then be established.

THEOREM 5.7. *Any singular solution u_S of the Stokes problem* (5.1.1) *on the L-shaped domain satisfies*

$$u_S \in B^r_\tau(L_\tau(\Omega))^2 \qquad \text{for all} \quad r > 0, \quad \frac{1}{\tau} = \frac{r-1}{2} + \frac{1}{2}. \tag{5.4.5}$$

Noting that $\nabla p = f + \Delta u$, one concludes (by the shift properties of the gradient and the Laplacian in Besov spaces) that also the pressure has arbitrarily high Besov regularity along the critical embedding line through L_2; see [10]. Furthermore, one can likewise determine (for smooth right-hand sides f) the singular parts p_S of the pressure; see also [20, 23]. The relevant conclusions for the present context can be formulated as follows.

REMARK 5.8. *One can verify that*

$$\begin{aligned} &u \in H^r(\Omega)^2, \quad r < r^*_X \approx 1.54448373678246 \qquad \text{and} \\ &p \in H^r(\Omega), \quad r < r^*_M \approx 0.54448373678246 \end{aligned}$$

(i.e., $u \notin H^{r^*_X}(\Omega)^2$, $p \notin H^{r^*_M}(\Omega)$), which limits the convergence rate of uniform refinements. On the other hand, u and p both have arbitrary *high Besov regularity. Hence, in principle, wavelet bases with high order regularity would give rise to correspondingly high order adaptive approximation rates.*

6. Numerical results. In this section, we present some numerical experiments for the Stokes problem on the planar L-shaped domain $\Omega = (-1,1)^2 \setminus (-1,0]^2$. We employ different versions from the family of wavelet bases Ψ_X and Ψ_M from section 5.2 for velocities and pressure, respectively.

Our objective is not to present a fully matured code but to gain additional quantitative insight that complements the preceding theoretical results of primarily asymptotic nature. This concerns the quantitative effect of "violating" the LBB condition and the tradeoff between larger supports and better compressibility when using higher order wavelets as well as suggestions for further algorithmic variants and developments. For instance, the theoretical estimates, e.g., on the number K of iterations in **ADV**, are presumably overly conservative. So it would be interesting to see experimentally whether typically smaller numbers suffice or whether monitoring residuals pays to realize significantly earlier terminations. Furthermore, we wish to see how the scheme copes with highly singular cases suggested by the discussion in section 5.4 compared with more regular solutions. More extensive tests of variants derived from first experiences will be presented elsewhere.

6.1. Discretization of the pressure. Recall from (5.1.2) that $L_{2,0}(\Omega)$ is the appropriate pressure space. Hence the zero mean constraint requires special care. Here we exploit the fact that all wavelets in Ψ^-_M have, according to (5.2.3), vanishing moments of order $\tilde{m}_M \geq m_M \geq 1$, so that

$$\int_\Omega \psi_{M,\lambda}(x)\,dx = 0, \qquad \lambda \in \mathcal{J}_M, |\lambda| > j_0.$$

Hence for any $q = \mathbf{q}^T \Psi_M$ one has

$$\int_\Omega q(x)\,dx = \sum_{|\lambda|=j_0} q_\lambda \int_\Omega \psi_{M,\lambda}(x)\,dx =: \sum_{|\lambda|=j_0} q_\lambda \alpha_\lambda =: I_\Omega(q).$$

On the other hand, the scaling functions form a partition of unity, i.e.,

$$1 \equiv \sum_{|\lambda|=j_0} \tilde{\alpha}_\lambda \, \psi_{M,\lambda}(x), \qquad x \in \Omega, \qquad \tilde{\alpha}_\lambda := \int_\Omega \tilde{\psi}_{M,\lambda}(x)\, dx = (1, \tilde{\psi}_{M,\lambda}),$$

where $\{\tilde{\psi}_{M,\lambda} : |\lambda| = j_0\}$ is the (explicitly known) *dual basis* for the scaling functions in Ψ_M, i.e., $(\psi_{M,\lambda}, \tilde{\psi}_{M,\lambda'}) = \delta_{\lambda,\lambda'}$; see [6, 17]. Thus, denoting by $\mu(\Omega)$ the Lebesgue measure of Ω, we obtain a projection $P_0 : L_2(\Omega) \to L_{2,0}(\Omega)$ by

$$P_0(q) := \sum_{|\lambda|=j_0} \Big(q_\lambda - \frac{I_\Omega(q)}{\mu(\Omega)} \tilde{\alpha}_\lambda \Big) \psi_{M,\lambda} + \sum_{|\lambda|>j_0} q_\lambda \psi_{M,\lambda}$$

that factors out constants. Hence, realizing the zero mean constraint requires modifications only on the *coarsest* level, whereas the wavelet coefficients remain unchanged. Since operators are applied only approximately, corresponding corrections are needed after applying $\mathbf{B}$ and also after coarsening. Since the projection P_0 depends on the particular primal wavelet basis for $L_2(\Omega)$, all arrays have to refer to the same basis so that the Riesz map $\mathbf{R} = (\tilde{\Psi}_M, \tilde{\Psi}_M)$ is needed in the second step (3.1.7) of the Uzawa iteration.

Note that the present way of factoring out constants is only a first convenient option. A drawback reflected by the experiments below is that due to the nature of P_0 always *all* coarse scale functions will be involved in the pressure approximations. In particular, for higher order trial functions this number grows, so that at least for the first few refinement steps the work/accuracy balance of the scheme is less favorable for the pressure component. Local coarse scale basis functions would remedy this effect.

A detailed description of the routines **APPLY** and **NCOARSE** can be found in [2, 8] combined with the above provisions with respect to the matrix $\mathbf{B}$. As mentioned before, the routine **ELLSOLVE** is essentially the adaptive Poisson solver from [2]. This indicates the principal potential of recycling these basic routines for the treatment of problems with increasing complexity.

6.2. Description of the test cases. We wish to report below on two different test cases. Example (I) corresponds to *the most singular* solution described in section 5.4. As can be seen in Figure 6.1, the pressure exhibits a strong singularity at the reentrant corner. In order to keep the effort for computing an exact reference solution as moderate as possible, we have computed an approximation of the exact solution by truncating p. Of course, this limits the number of iterations of the adaptive algorithm for which meaningful comparisons can be made.

Example (II) involves a pressure which is *localized* around the reentrant corner, has strong gradients, but is smooth. More precisely, we have chosen an exact solution for the velocity which is very similar to the one above and a pressure solution which is constant around the reentrant corner and multiplied by a smooth cutoff function. These functions are displayed in Figure 6.2.

6.3. Choice of the parameters. We expect that some of the constants resulting from the analysis are actually too pessimistic. For instance, deriving estimates for the constants in the norm equivalences, we have estimated K to be in the range of 15, which turned out to entail unnecessarily high accuracy in the treatment of the inner Poisson problems while the pressure approximation and hence the right-hand side for the Laplace problem are still poor. Several numerical experiments with different trial functions and for different test cases indicate that $K = 3$ already seems to suffice

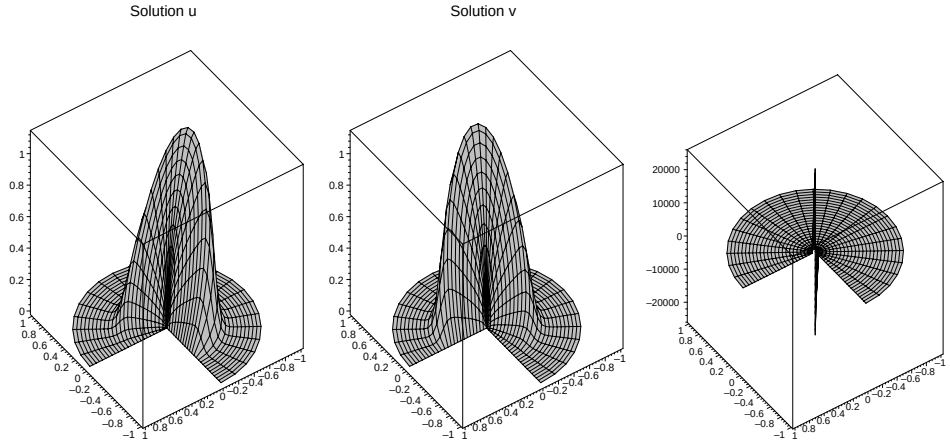

FIGURE 6.1. *Exact solution for the first example. Velocity components (left and middle) and pressure (right). The pressure function exhibits a strong singularity and is only shown up to* $r = 0.001$ *in polar coordinates.*

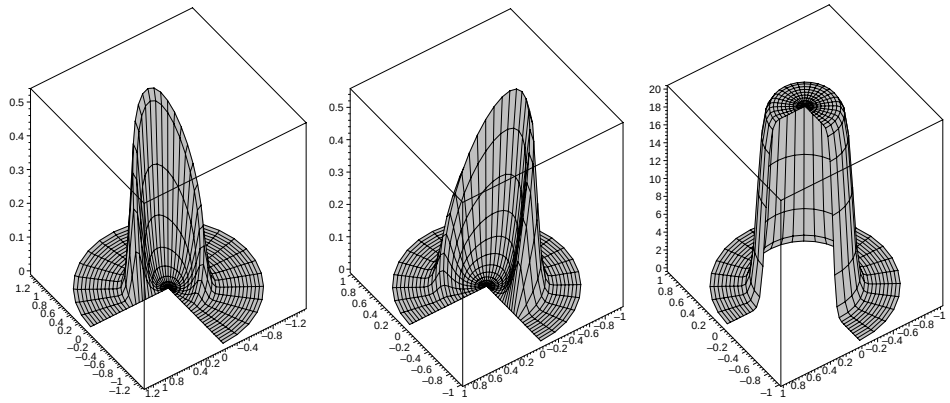

FIGURE 6.2. *Exact solution for the second example. Velocity components (left and middle) and pressure (right).*

and that the alternatives discussed in section 3 are in these cases not necessary. All subsequent results are therefore based on this choice. Moreover, we have used $\rho = 0.6$ and $\omega = 1.3$ in all experiments.

6.4. Rate of convergence. Table 6.1 displays the results for Example (I), employing piecewise linear trial functions for the velocity and piecewise constant functions for the pressure. We are interested in the relation between the error produced for a given number of degrees of freedom by the adaptive scheme and the error of best N-term approximation with respect to the underlying wavelet basis. To describe the results we denote by $\mathbf{u}^1, \mathbf{u}^2$ the wavelet coefficient arrays of the first and second velocity component and for $\mathbf{x} \in \{\mathbf{u}^1, \mathbf{u}^2, \mathbf{p}\}$ by

$$\rho_{\mathbf{x}} := \frac{\|\mathbf{x} - \mathbf{x}_{\mathbf{\Lambda}}\|_{\ell_2}}{\|\mathbf{x} - \mathbf{x}_{\#\mathbf{\Lambda}}\|_{\ell_2}}, \qquad r_{\mathbf{x}} := \frac{\|\mathbf{x} - \mathbf{x}_{\mathbf{\Lambda}}\|_{\ell_2}}{\|\mathbf{x}\|_{\ell_2}},$$

the ratio of the error of the adaptive approximation and the corresponding best N-term approximation and the relative errors of the solution components x_Λ, respec-

tively. Recall from Corollary 3.5 that these quantities also reflect the error in the energy norms. We see that the velocity approximation is from the beginning very close to its best N-term approximation. For the reasons indicated above this is different for the pressure. The application of P_0 fills up the coarsest level, which in this example has 768 degrees of freedom. To explain this in more detail assume that the adaptive method picks exactly one scaling function, so that the degree of freedom for the pressure would be 1. Since the integral of a scaling function is not zero, the pressure projection P_0 produces a nonzero constant whose expansion involves *all* scaling function coefficients. This is the reason why at the early stage of the refinement process the work accuracy balance for the pressure is less favorable. However, the last two iterates shown in the table indicate that the scheme catches up with the optimal rate. Local coarse scale bases would of course yield better results already from the beginning of the adaptive refinements.

The results for Example (II) are shown in Table 6.2, and plots of the approximations are displayed in Figure 6.3. We see that the computed approximations differ only by a very moderate factor from the best N-term approximation. The results suggest the following directions for more systematic implementations. The simple Richardson iteration should be replaced (possibly after a few initial steps) by gradient or conjugate gradient steps. This should speed up convergence and avoid a necessarily pessimistic estimation of step size parameters. Since all algorithmic ingredients still require the same type of (approximate) matrix/vector multiplications, one can employ the same routines. One should then include, however, monitoring residuals which, due to (2.3.1), should detect rapid convergence for a possible early termination of the iterations in **ADV** (ii). Moreover, higher order wavelets should be tested to exploit larger compressibility ranges.

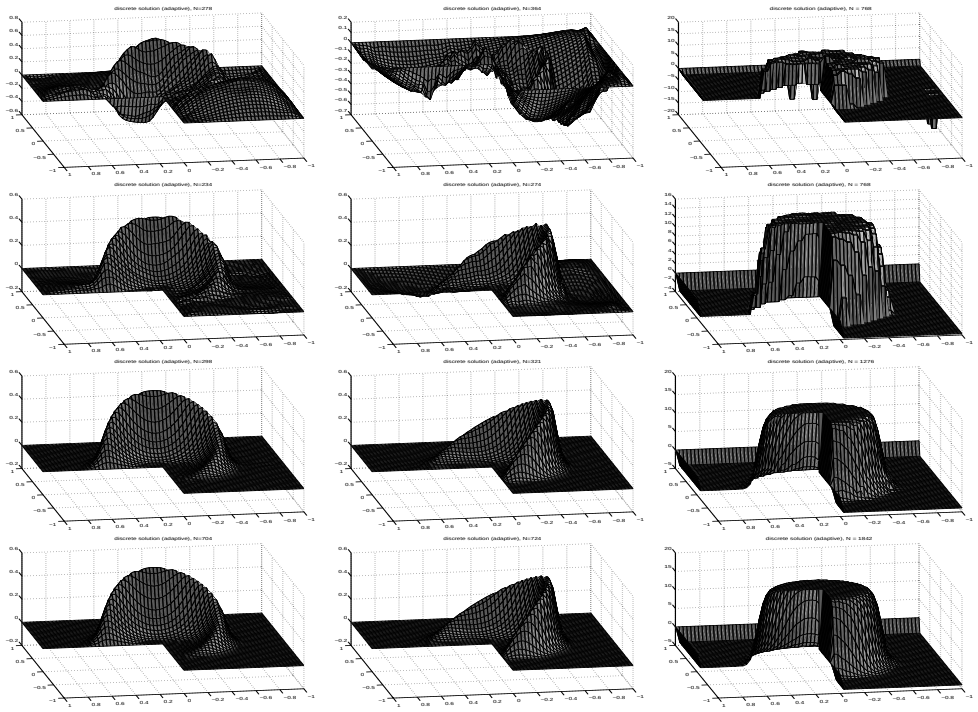

FIGURE 6.3. *First, third, sixth, and eighth approximations for Example* (II). *First and second velocity component (left and middle columns) and pressure (right column).*

6.5. High order discretizations. Recall from section 5.3 that the compressibility range of the wavelet representations grows with increasing regularity and hence order of the wavelet bases; see Theorems 5.3, 5.5. Moreover, the regularity results from Theorem 5.7 and Remark 5.8 indicate that the larger the compressibility range of the wavelet representations, the more an adaptive scheme would gain at least asymptotically over uniform refinements. This suggests investigating the quantitative effect of employing higher order spline wavelets.

We now compare discretizations of various orders for the pressure in the second example. In Figure 6.4, we have shown the relative error versus the number of unknowns in a logarithmic scale. Comparing the slopes of the best N-term approximation, we obtain the expected asymptotic gain for increasing orders, again at the end with moderate values for the ratios $\rho_{\mathbf{x}}$. However, we also see that the fast decay of the rate of the best N-term approximation is delayed more and more for an increasing order of trial functions. For instance, for piecewise cubic wavelets, we obtain an almost horizontal line until $N \approx 2000$. This is, on one hand, due to some technical restrictions of the particular patchwise tensor product wavelet bases used here that require a certain coarsest level j_0 on each patch. The values for j_0 are shown in Table 6.3 for different orders. We see that j_0 increases with m (the case $m = 2$ is somewhat special due to the very local character of primal and dual functions). We display also the number of unknowns for the coarsest level, i.e., the number of scaling functions on level $j = j_0$. On the other hand, as pointed out before, the nature of P_0 keeps all coarse scale basis functions active. This explains why the slope of the best N-term approximation is almost horizontal until all scaling functions are used up. There are

several ways to alleviate this problem also for higher order discretizations. Aside from using local coarse scale basis functions with zero mean, one can take a fictitious domain approach and append the boundary conditions by Lagrange multipliers. This allows one to use periodic wavelet bases on the fictitious domain where the minimal level can be always chosen as $j_0 = 0$ for all values of m and $\tilde{m}$. This issue will be addressed elsewhere.

6.6. The LBB condition. At first glance it is somewhat puzzling that in the analysis of the adaptive Uzawa method the LBB condition did not play any role. Roughly speaking, this is due to the fact that conceptually at every stage of the algorithm the full infinite dimensional operator is applied within a certain tolerance that has to be chosen tight enough to inherit the stability properties of the original infinite dimensional problem. This effect of adaptive schemes in connection with saddle point problems and also with more complex variational problems has been observed first in [9]; see also [14] for saddle point problems. Hence it is interesting to study the quantitative influence of the choice of bases. Therefore, we have included a combination of bases for which pairs of fixed finite dimensional subspaces would violate the LBB condition, namely, piecewise linear trial functions for both velocity and pressure. The results are displayed in Table 6.4. We see that the rate of the best

N-term approximation is still matched fairly well with ratios that are only slightly larger than in Table 6.2 for the piecewise linear/piecewise constant discretization. Note that the oscillations in the pressure approximation for unstable elements shown by the experiments in [4] are not observed in the present context; see Figure 6.3. This seems to result from the different pressure update.

SUPERCONVERGENCE FOR THE GRADIENT OF FINITE ELEMENT APPROXIMATIONS BY L^2 PROJECTIONS*

BJØRN-OVE HEIMSUND†, XUE-CHENG TAI†, AND JUNPING WANG‡

Abstract. A gradient recovery technique is proposed and analyzed for finite element solutions which provides new gradient approximations with high order of accuracy. The recovery technique is based on the method of least-squares surface fitting in a finite-dimensional space corresponding to a coarse mesh. It is proved that the recovered gradient has a high order of superconvergence for appropriately chosen surface fitting spaces. The recovery technique is robust, efficient, and applicable to a wide class of problems such as the Stokes and elasticity equations.

Key words. finite element methods, superconvergence, error estimates, adaptive refinement

1. Introduction.

It has been known for a long time that finite element solutions of partial differential equations can have superconvergence in some subregions of the domain [26, 23, 8, 1]. *Superconvergence* is a phenomenon that the numerical solution converges to the exact solution at a rate higher than the optimal order error estimate. To exploit superconvergence in the finite element method, several methods have been proposed in the literature in the last 30 years. The method of local averaging has turned out to be a common and useful technique in the study of superconvergence in most of the existing results; see, for example, [23, 8, 1, 7, 35, 19, 18, 20, 17, 21, 25, 26, 10, 13] and the references therein. In theory, all the existing results require the underlying finite element mesh to have some special properties such as uniformity [23, 7, 21], local point symmetry [25, 26], local translation invariance [1, 26], or orthogonality (e.g., rectangular partition) [8, 10, 13, 19, 18, 20, 28, 34].

The Zienkiewicz and Zhu (ZZ) method [32, 33] is a procedure which postprocesses the gradient of the finite element solution by using a discrete least-squares fitting on a local patch with high order polynomials. Due to its high efficiency and robustness, the ZZ postprocessing has been widely used for mesh adaptivity and error control in finite element methods [32, 33, 5, 6]. For appropriately chosen discrete norms, this procedure has been computationally justified to yield some superconvergence for the gradient. If the underlying finite element partition is uniform or rectangular, one can provide a theoretical proof for the ZZ method [31, 34, 30] by using some existing superconvergent estimates [8, 23, 17, 35, 18].

Our objective of this paper is twofold. First, we modify the ZZ method by applying a global least-squares fitting to the gradient of the finite element approximation. The surface fitting space consists of continuous or discontinuous piecewise polynomials of high order on a coarse partition. Second, we provide a theoretical analysis for

the modified ZZ (MZZ) method by establishing a superconvergence estimate for the recovered gradient/flux on general quasi-uniform meshes. To the authors' knowledge, our result is the first that gives a theoretical proof for the superconvergence of the ZZ method with some modifications under general assumptions for the finite element partition. The essential idea behind the approach is the use of a coarser mesh and a higher order of polynomials which can be translated to the method of "long" and "accurate" finite difference quotients. The same idea has been applied in [15] to yield asymptotically exact a posteriori estimators for the pointwise gradient error.

Our presentation follows a framework established in Wang [27] (see also [29]), where the least-squares surface fitting (the projection method) was applied to the finite element solution u_h in order to produce a new and better approximation for the original unknown function $u = u(x)$ and its gradient ∇u. The approach of this paper is different in that the projection will be applied directly to the numerical gradient ∇u_h in order to provide a superconvergent numerical solution for ∇u. Like all the existing results in superconvergence, our results are based on a certain regularity assumption for the exact solution of the underlying model problem.

For simplicity of discussion, our superconvergence result will be presented only for Dirichlet boundary value problems. The results can be extended to Neumann and Robin boundary conditions without any difficulty.

The paper is organized as follows. In section 2, we introduce a model problem for which the required regularity condition is satisfied. In section 3, we present an extension of the ZZ method by using a global least-squares fitting in a high order finite element space corresponding to a coarse mesh. Some error estimates for the new gradient approximation will be derived in section 4. In sections 5 and 6 we apply the error estimate to show that the projected gradient is superconvergent if the fitting space is properly chosen. Section 7 applies the gradient recovery scheme to mesh adaption, and section 8 gives numerical results and comparison for various adaptive schemes.

2. A model problem. To illustrate the idea, we consider boundary value problems for the second order elliptic equation. Let Ω be an open bounded domain in $\mathbb{R}^d, d = 2, 3$. Denote by $x = (x_1, \ldots, x_d)$ the points in Ω. Let $\partial_i = \frac{\partial}{\partial x_i}$ be the partial derivative operator in the direction of $x_i, i = 1, \ldots, d$. The Dirichlet boundary value problem seeks a function $u = u(x)$ such that $u(x) = g(x)$ for any $x \in \partial\Omega$ and

$$\sum_{i,j=1}^{d} \partial_j(a_{ij}\partial_i u) + \sum_{i=1}^{d} b_i \partial_i u + cu = f \qquad \text{in } \Omega, \tag{1}$$

where $\boldsymbol{a} = (a_{ij})_{i,j=1}^d$ is the coefficient tensor which is symmetric, bounded, and uniformly positive definite in the domain Ω with measurable entries $a_{ij} = a_{ij}(x)$. The other coefficients $\boldsymbol{b} = (b_i(x))_{i=1}^d$ and $c = c(x)$ are assumed to ensure a uniqueness of solutions for (1).

Standard notations for Sobolev spaces and norms are adopted in this paper. For an $s \geq 0$, which may not be an integer, and a given domain Ω, $H^s(\Omega)$ denotes the Sobolev space with norm $\|\cdot\|_s$ as defined in [14]. The space $H_0^s(\Omega)$ is a closed subspace of $H^s(\Omega)$ that is the closure of $C_0^s(\Omega)$ (the set of compact-supported C^s functions) in the norm of $H^s(\Omega)$. For $s < 0$, $H^s(\Omega)$ is defined to be the dual space of $H^{-s}(\Omega)$; see [14] for details. The Sobolev space $H^0(\Omega)$ coincides with $L^2(\Omega)$, in which case the norm and inner product are denoted by $\|\cdot\|$ and $(\cdot, \cdot)$, respectively.

Let

$$a(u,v) = \sum_{i,j=1}^{d} \int_\Omega a_{ij}\partial_i u \partial_j v dx + \sum_{i=1}^{d} \int_\Omega b_i \partial_i uv dx + \int_\Omega cuv dx$$

be a bilinear form defined in $H^1(\Omega) \times H^1(\Omega)$. A weak form for the problem (1) seeks a function $u \in H^1(\Omega)$ such that $u = g$ on $\partial\Omega$ and

$$a(u,v) = (f,v) \quad \forall v \in H_0^1(\Omega). \tag{2}$$

Here we have assumed that the boundary data $g \in H^{1/2}(\partial\Omega)$.

Let $s \geq 1$ be a positive real number. Assume that the dual problem of (2) has H^s regularity in the sense that, for any given $f \in H^{s-2}(\Omega)$, the problem

$$a(v,w) = (f,v) \quad \forall v \in H_0^1(\Omega)$$

has a unique solution $w \in H_0^1(\Omega) \cap H^s(\Omega)$ such that

$$\|w\|_s + \left\| \frac{\partial w}{\partial \boldsymbol{n_a}} \right\|_{s-\frac{3}{2},\partial\Omega} \leq C\|f\|_{s-2}, \tag{3}$$

where $\boldsymbol{n}$ is the unit outward normal vector of $\partial\Omega$ and $\frac{\partial w}{\partial \boldsymbol{n_a}} = (\boldsymbol{a}\nabla w)\cdot \boldsymbol{n}$ denotes the normal component of the flux variable on the boundary $\partial\Omega$ for the dual solution w. It is well known that the bilinear form $a(\cdot,\cdot)$ is bounded in $H^1(\Omega)$. In other words, there exists a constant C such that

$$|a(u,v)| \leq C\|u\|_1\|v\|_1 \quad \forall\ u,v \in H^1(\Omega).$$

The finite element solution of (2) is a function $u_h = u_h(x)$ from a finite element space $S_h \subset H^1(\Omega)$ associated with a prescribed finite element partition Ω_h such that $u_h(x) = g_h(x)$ for all $x \in \partial\Omega$ and

$$a(u_h,v) = (f,v) \quad \forall v \in S_h^0. \tag{4}$$

Here $S_h^0 = H_0^1(\Omega) \cap S_h$ and g_h is a certain approximation of the Dirichlet boundary data g. Let Λ_h be the restriction of the finite element space S_h on the boundary of Ω. For simplicity, we shall deal with polygonal or polyhedral domain Ω so that the boundary $\partial\Omega$ is exactly represented by the finite element partition Ω_h. Among many possibilities, we are particularly interested in two cases for the approximate boundary data:

- *g_h is the standard nodal interpolation of g in Λ_h for sufficiently smooth g.*
- *g_h is the L^2 projection of g in Λ_h.*

We recall that the L^2 projection of g in Λ_h is given by solving the following system of linear equations:

$$\langle g_h, v\rangle = \langle g, v\rangle \quad \forall v \in \Lambda_h, \tag{5}$$

where $\langle\cdot,\cdot\rangle$ is the standard L^2-inner product on $\partial\Omega$.

Assume that S_h consists of continuous piecewise polynomials of order $k \geq 1$. Let h be the mesh parameter for the finite element partition Ω_h. The finite element space S_h is assumed to have the following approximation property:

$$\inf_{v\in S_h} (\|w-v\| + h\|w-v\|_1) \leq Ch^m\|w\|_m \quad \forall w \in H^m(\Omega)$$

for any $0 \leq m \leq k+1$.

3. Gradient recovery by projections. To obtain an approximate gradient and flux with superconvergence, we consider a new finite-dimensional space $\mathcal{L}_\tau$ with parameter $\tau \gg h$ and a higher order approximation property than S_h [15]. The functions in $\mathcal{L}_\tau$ are vector valued and will be employed to approximate the exact gradient/flux variable $\boldsymbol{q} = \boldsymbol{a}\nabla u$. In practice, the mesh parameter τ is proportional to h^α for some $\alpha \in (0,1)$ in order to obtain a superconvergent approximation from the projection space $\mathcal{L}_\tau$. Details can be found from Wang [27].

For simplicity, assume that $\mathcal{L}_\tau$ is a finite element space associated with another finite element partition Ω_τ and consists of piecewise polynomials of order $r \geq 0$. The finite element space $\mathcal{L}_\tau$ is required to satisfy the following properties:

- Inverse property.

$$\|\boldsymbol{v}_\tau\|_{[H^m(K)]^d} \leq C\tau^{-m}\|\boldsymbol{v}_\tau\|_{[L^2(K)]^d} \quad \forall \boldsymbol{v}_\tau \in \mathcal{L}_\tau, \quad \forall K \in \Omega_\tau \tag{6}$$

  for all nonnegative integer $m \geq 0$.

- Approximation property.

$$\inf_{\boldsymbol{v}_\tau \in \mathcal{L}_\tau} \|\boldsymbol{v} - \boldsymbol{v}_\tau\|_0 \leq C\tau^m \|\boldsymbol{v}\|_m \quad \forall \boldsymbol{v} \in [H^m(\Omega)]^d, \quad 0 \leq m \leq r+1. \tag{7}$$

- Smoothness property.

$$\mathcal{L}_\tau \subset [H^{s-1}(\Omega)]^d. \tag{8}$$

  Here $s \geq 1$ is associated with the regularity of the dual problem as indicated in (3).

We emphasize that the space $\mathcal{L}_\tau$ can be replaced by other finite-dimensional spaces as trigonometric functions, B-splines, and any special functions if the domain is of special type. In such cases the approximation property and the inverse inequality will be different, and the forthcoming analysis must be modified accordingly.

3.1. Recovery based on a mixed formulation. Our objective here is to provide a very accurate approximation for the flux variable $\boldsymbol{q}$ by using the finite element solution u_h. The relation between the flux $\boldsymbol{q} = \boldsymbol{q}(x)$ and the original function $u = u(x)$ can be rewritten as follows:

$$\boldsymbol{a}^{-1}\boldsymbol{q} = \nabla u. \tag{9}$$

Let

$$H(\mathrm{div};\Omega) = \{\boldsymbol{v} : \ \boldsymbol{v} \in [L^2(\Omega)]^d, \ \nabla \cdot \boldsymbol{v} \in L^2(\Omega)\}$$

be equipped with the norm

$$\|\boldsymbol{v}\|_H = \left(\|\boldsymbol{v}\|^2 + \|\nabla \cdot \boldsymbol{v}\|^2\right)^{1/2}.$$

By testing (9) against any $\boldsymbol{v} \in H(\mathrm{div};\Omega)$ we arrive at

$$(\boldsymbol{a}^{-1}\boldsymbol{q}, \boldsymbol{v}) = -(u, \nabla \cdot \boldsymbol{v}) + \langle g, \boldsymbol{v} \cdot \boldsymbol{n}\rangle, \tag{10}$$

where we have employed the integration by parts to the term on the right-hand side.

Equation (10) can be employed to provide a new flux/gradient recovery $\tilde{\boldsymbol{q}}_\tau$ defined as follows:

$$(\boldsymbol{a}^{-1}\tilde{\boldsymbol{q}}_\tau, \boldsymbol{v}) = -(u_h, \nabla \cdot \boldsymbol{v}) + \langle g, \boldsymbol{v} \cdot \boldsymbol{n}\rangle \quad \forall \boldsymbol{v} \in \mathcal{L}_\tau. \tag{11}$$

The new flux approximation $\tilde{\boldsymbol{q}}_\tau$ will be denoted by

$$\tilde{\boldsymbol{q}}_\tau = \tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h.$$

It is clear that $\tilde{\boldsymbol{Q}}_\tau$ can be regarded as a linear operator onto the fitting space $\mathcal{L}_\tau$.

Since (11) was obtained by using test functions in the space $H(\mathrm{div};\Omega)$, the fitting space $\mathcal{L}_\tau$ has to be constructed as a finite element subspace of $H(\mathrm{div};\Omega)$. In practical computation, the standard mixed finite element spaces of Raviart and Thomas [24], Brezzi et al. [2, 3], Brezzi, Douglas, and Marini [4], and Douglas and Wang [11] can be employed to accomplish the goal. Of course, one can also use continuous finite element spaces in the place of $\mathcal{L}_\tau$. The well-known *inf-sup* condition is no longer an issue in this procedure because the flux computed is based on a Galerkin approximation of the scalar variable.

3.2. Recovery based on L^2 projections. Let $\boldsymbol{Q}_\tau$ be the weighted L^2 projection onto the fitting space $\mathcal{L}_\tau$ with respect to the weighted inner product $(\boldsymbol{a}^{-1}\cdot,\cdot)$. More precisely, for any $\boldsymbol{v} \in \left[L^2(\Omega)\right]^d$, the projection $\boldsymbol{Q}_\tau \boldsymbol{v}$ is a function in $\mathcal{L}_\tau$ such that

$$(\boldsymbol{a}^{-1}\boldsymbol{Q}_\tau \boldsymbol{v}, \boldsymbol{\phi}) = (\boldsymbol{a}^{-1}\boldsymbol{v}, \boldsymbol{\phi}) \quad \forall \boldsymbol{\phi} \in \mathcal{L}_\tau. \tag{12}$$

It follows from the definition of the Galerkin approximation u_h that $\boldsymbol{q}_h = \boldsymbol{a}\nabla u_h$ is an approximate solution of the exact flux variable $\boldsymbol{q}$. In addition, it is not hard to derive the following error estimate:

$$\|\boldsymbol{q} - \boldsymbol{q}_h\| \le C\|u - u_h\|_1$$

for some constant C.

With the L^2-projection operator $\boldsymbol{Q}_\tau$, we can provide a new flux approximation given as follows:

$$\boldsymbol{q} = \boldsymbol{a}\nabla u \approx \boldsymbol{Q}_\tau \boldsymbol{q}_h. \tag{13}$$

From the definition of $\boldsymbol{Q}_\tau$, we see that the new flux approximation $\boldsymbol{Q}_\tau \boldsymbol{q}_h$ satisfies the following system of equations:

$$(\boldsymbol{a}^{-1}\boldsymbol{Q}_\tau \boldsymbol{q}_h, \boldsymbol{\phi}) = (\nabla u_h, \boldsymbol{\phi}) \quad \forall \boldsymbol{\phi} \in \mathcal{L}_\tau. \tag{14}$$

When the fitting space $\mathcal{L}_\tau$ consists of discontinuous piecewise polynomials of order k on each element of Ω_τ, our flux recovery method is closely related to the ZZ [32, 33] patch recovery technique. The difference lies on the selection of the fitting space $\mathcal{L}_\tau$ and the way that the projection was defined. The ZZ method uses a discrete version of the L^2-inner product, and the fitting space is based on a patch of elements from the original finite element partition Ω_h.

In practical computation, the recovery space contains polynomials of higher order than the original finite element space. In other words, the value of the parameter r is normally larger than k.

4. Error estimates. The objective of this section is to analyze the approximation formulas (13) and (11). The accuracy of the approximations is given in Theorem 4.1 for the case when the boundary data g is approximated by its L^2 projection in Λ_h. In case that g_h is the nodal point interpolation or other approximations satisfying (29), the corresponding superconvergence estimate is given in Theorem 4.2.

For simplicity of notation, we use the following element-wise Sobolev norms:

$$|||v|||_{m,h} = \left(\sum_{K \in \Omega_h} |v|^2_{H^m(K)} \right)^{1/2}, \qquad |||v|||_{m,\tau} = \left(\sum_{K \in \Omega_\tau} |v|^2_{H^m(K)} \right)^{1/2},$$

where

$$|v|_{H^m(K)} = \left(\sum_{K \in \Omega_h} \sum_{|\alpha|=m} \int_K |D^\alpha v|^2 dx \right)^{1/2}$$

is the seminorm of $v \in H^m(K)$. Here $\alpha = (\alpha_1, \ldots, \alpha_d), \alpha_i \geq 0$ is a multi-index and $D^\alpha v = \partial_1^{\alpha_1} \cdots \partial_d^{\alpha_d} v$. Thus, our function v above needs only to be in the Sobolev space $H^m(K)$ over each element K from Ω_h or Ω_τ in order to guarantee that the norms exist. If (6) and (7) are satisfied, then it is not hard to prove the following estimate:

$$\|\boldsymbol{v} - \boldsymbol{Q}_\tau \boldsymbol{v}\|_0 \leq C\tau^m |||\boldsymbol{v}|||_{m,\tau}, \quad 0 \leq m \leq r+1. \tag{15}$$

4.1. Projection space $\mathcal{L}_\tau$ of class $H(\mathrm{div};\Omega)$. Let us analyze the approximation schemes (11) and (13) by assuming that the projection space $\mathcal{L}_\tau$ is of class $H(\mathrm{div};\Omega)$. The following theorem is concerned with the case when the Dirichlet boundary data is approximated by L^2 projections.

THEOREM 4.1. *Let u be the exact solution of* (2) *and u_h be its finite element approximation given by* (4). *Let $\boldsymbol{q} = \boldsymbol{a}\nabla u$ be the flux/gradient with the obvious approximation $\boldsymbol{q}_h = \boldsymbol{a}\nabla u_h$ and let $\mathcal{G}_\tau$ be a postprocessing operator given by either $\boldsymbol{Q}_\tau$ or $\tilde{\boldsymbol{Q}}_\tau$ as in the previous section. Assume that the approximate boundary value g_h is taken to be the $L^2(\partial\Omega)$ projection of g and* (3) *and* (8) *are valid for an $s \in [1, k+1]$. Assume that the fitting (projection) space $\mathcal{L}_\tau$ is constructed so that $\mathcal{L}_\tau \subset H(\mathrm{div};\Omega)$. Then*

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C\tau^{r+1} |||\boldsymbol{q}|||_{r+1,\tau} + C(h\tau^{-1})^{s-1} \|u - u_h\|_1. \tag{16}$$

Proof. First, we provide a proof for $\mathcal{G}_\tau = \tilde{\boldsymbol{Q}}_\tau$. To this end, we observe that

$$\|\tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h - \boldsymbol{Q}_\tau \boldsymbol{q}\|_0 \leq C \sup_{\boldsymbol{\phi} \in \mathcal{L}_\tau, \|\boldsymbol{\phi}\|_{L^2}=1} (\boldsymbol{a}^{-1}\tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h - \boldsymbol{a}^{-1}\boldsymbol{Q}_\tau \boldsymbol{q}, \boldsymbol{\phi}). \tag{17}$$

For a given $\boldsymbol{\phi} \in \mathcal{L}_\tau$, it is true that

$$\begin{aligned}(\boldsymbol{a}^{-1}\tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h - \boldsymbol{a}^{-1}\boldsymbol{Q}_\tau \boldsymbol{q}, \boldsymbol{\phi}) &= (\boldsymbol{a}^{-1}\tilde{\boldsymbol{Q}}_\tau(\boldsymbol{a}\nabla u_h) - \boldsymbol{a}^{-1}\boldsymbol{Q}_\tau(\boldsymbol{a}\nabla u), \boldsymbol{\phi}) \\ &= -(u_h, \nabla \cdot \boldsymbol{\phi}) + \langle g, \boldsymbol{\phi} \cdot \boldsymbol{n} \rangle - (\nabla u, \boldsymbol{\phi}) = (u - u_h, \nabla \cdot \boldsymbol{\phi}).\end{aligned}$$

Define $w \in H_0^1(\Omega)$ to be the solution of

$$a(v, w) = (v, \nabla \cdot \boldsymbol{\phi}) \quad \forall v \in H_0^1(\Omega). \tag{18}$$

Applying the theory of distributions, it can be proved that

$$a(v, w) - \left\langle \frac{\partial w}{\partial \boldsymbol{n}_{\boldsymbol{a}}}, v \right\rangle = (\nabla \cdot \boldsymbol{\phi}, v) \quad \forall v \in H^1(\Omega).$$

Using (2), (4), (5), and the above equation, it is easy to see that, for any $v \in S_h^0$ and $\xi \in \Lambda_h$,

$$(u-u_h, \nabla\cdot\phi) = a(u-u_h, w) - \left\langle \frac{\partial w}{\partial \boldsymbol{n_a}}, u-u_h \right\rangle$$
$$= a(u-u_h, w-v) - \left\langle \frac{\partial w}{\partial \boldsymbol{n_a}} - \xi, g-g_h \right\rangle.$$

It follows that

$$|(u-u_h, \nabla\cdot\phi)| \le C\|u-u_h\|_1\|w-v\|_1 + \|\frac{\partial w}{\partial \boldsymbol{n_a}} - \xi\|_{-\frac{1}{2},\partial\Omega}\|u-u_h\|_{\frac{1}{2},\partial\Omega}.$$

Using the trace inequality

$$\|v\|_{\frac{1}{2},\partial\Omega} \le C\|v\|_1 \quad \forall v \in H^1(\Omega)$$

and the interpolation estimates

$$\inf_{v\in S_h} \|w-v\|_1 \le Ch^{s-1}\|w\|_s, \tag{19}$$

$$\inf_{\xi\in\Lambda_h} \left\| \frac{\partial w}{\partial \boldsymbol{n_a}} - \xi \right\|_{-\frac{1}{2},\partial\Omega} \le Ch^{s-1}\|w\|_s, \tag{20}$$

we obtain

$$|(u-u_h, \nabla\cdot\boldsymbol{\phi})| \le Ch^{s-1}\|u-u_h\|_1\|w\|_s \tag{21}$$

for an $s \in [1, k+1]$. Next, we use the H^s regularity assumption (3) to obtain

$$|(u-u_h, \nabla\cdot\boldsymbol{\phi})| \le Ch^{s-1}\|u-u_h\|_1\|\nabla\cdot\boldsymbol{\phi}\|_{s-2} \le Ch^{s-1}\tau^{1-s}\|u_h-u\|_1\|\boldsymbol{\phi}\|_0,$$

where we have also used the inverse property (6) in the last inequality. Collecting all the estimates we obtain

$$\|\tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h - \boldsymbol{Q}_\tau \boldsymbol{q}\|_0 \le Ch^{s-1}\tau^{1-s}\|u_h-u\|_1, \tag{22}$$

which, together with (15), gives the desired error estimate for $\mathcal{G}_\tau = \tilde{\boldsymbol{Q}}_\tau$.

To analyze the case $\mathcal{G}_\tau = \boldsymbol{Q}_\tau$, it suffices to estimate $\|\boldsymbol{Q}_\tau(\boldsymbol{q}-\boldsymbol{q}_h)\|_0$. Since

$$\|\boldsymbol{Q}_\tau(\boldsymbol{q}-\boldsymbol{q}_h)\|_0 \le C \sup_{\boldsymbol{\phi}\in\mathcal{L}_\tau, \|\boldsymbol{\phi}\|_0=1} (\boldsymbol{a}^{-1}\boldsymbol{Q}_\tau(\boldsymbol{q}-\boldsymbol{q}_h), \boldsymbol{\phi}) \tag{23}$$

and

$$(\boldsymbol{a}^{-1}\boldsymbol{Q}_\tau(\boldsymbol{q}-\boldsymbol{q}_h), \boldsymbol{\phi}) = (\nabla(u-u_h), \boldsymbol{\phi}), \tag{24}$$

then it is sufficient to estimate $|(\nabla(u-u_h), \boldsymbol{\phi})|$. Recall that, by assumption, we have $\mathcal{L}_\tau \subset H(\mathrm{div};\Omega)$. Thus, it follows from the integration by parts that

$$(\nabla(u_h-u), \boldsymbol{\phi}) = (u-u_h, \nabla\cdot\boldsymbol{\phi}) + \langle u_h-u, \boldsymbol{\phi}\cdot\boldsymbol{n}\rangle. \tag{25}$$

Let $w \in H_0^1(\Omega)$ be defined as the solution of the following problem:

$$a(v,w) = -(\nabla\cdot\boldsymbol{\phi}, v) \qquad \forall v \in H_0^1(\Omega). \tag{26}$$

It follows from (2), (4), and (5) that, for any $v \in S_h^0$ and $\xi \in \Lambda_h$,

$$
\begin{aligned}
&(\nabla(u_h - u), \boldsymbol{\phi}) = (u - u_h, \nabla \cdot \boldsymbol{\phi}) + \langle u_h - u, \boldsymbol{\phi} \cdot \boldsymbol{n} \rangle \\
&= a(u - u_h, w) + \left\langle \tfrac{\partial w}{\partial \boldsymbol{n_a}}, u_h - u \right\rangle + \langle \boldsymbol{\phi} \cdot \boldsymbol{n}, u_h - u \rangle \\
&= a(u - u_h, w - v) + \left\langle \tfrac{\partial w}{\partial \boldsymbol{n_a}} + \boldsymbol{\phi} \cdot \boldsymbol{n} - \xi, u_h - u \right\rangle .
\end{aligned} \tag{27}
$$

Using the standard approximation property of Λ_h and the trace inequality in Sobolev spaces as in (20)–(21), we obtain

$$
\inf_{\xi \in S_h} \left\| \frac{\partial w}{\partial \boldsymbol{n_a}} + \boldsymbol{\phi} \cdot \boldsymbol{n} - \xi \right\|_{-\frac{1}{2}, \partial\Omega} \leq C h^{s-1} \tau^{1-s} \|\boldsymbol{\phi}\|_0 .
$$

It is also not hard to see that

$$
\inf_{v \in S_h^0} |a(u - u_h, w - v)| \leq C h^{s-1} \tau^{1-s} \|u - u_h\|_1 \|\boldsymbol{\phi}\|_0 .
$$

Substituting the above two estimates into (27), we obtain

$$
|(\nabla(u_h - u), \boldsymbol{\phi})| \leq C h^{s-1} \tau^{1-s} \|u - u_h\|_1 \|\boldsymbol{\phi}\|_0 ,
$$

which implies that

$$
\|\boldsymbol{Q}_\tau(\boldsymbol{q} - \boldsymbol{q}_h)\|_0 \leq C h^{s-1} \tau^{1-s} \|u - u_h\|_1 . \tag{28}
$$

This completes the proof of the theorem. □

If the exact solution is sufficiently smooth, then we have from the estimate (16) that

$$
\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C(u, \boldsymbol{q}) \left(\tau^{r+1} + \tau^{1-s} h^{k+s-1} \right) .
$$

Assume that the model problem has the H^{k+1} regularity (i.e., $s = k + 1$). Thus,

$$
\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C(u, \boldsymbol{q}) \left(\tau^{r+1} + \tau^{-k} h^{2k} \right) .
$$

By choosing $\tau = h^\alpha$, the above estimate becomes

$$
\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C(u, \boldsymbol{q}) \left(h^{\alpha(r+1)} + h^{(2-\alpha)k} \right) ,
$$

which is optimized when

$$
\alpha(r+1) = (2 - \alpha)k \Longleftrightarrow \alpha = \frac{2k}{r + k + 1} .
$$

The corresponding error estimate is given by

$$
\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C(u, \boldsymbol{q}) h^{\frac{2k(r+1)}{r+k+1}} .
$$

With $k = 3$ and $r = 3$, the above estimate implies an accuracy of order $h^{\frac{8}{3}}$ which is much better than the optimal order h^2.

In practical computation, the Dirichlet boundary data is often approximated by a scheme different from the L^2 projection. Thus, the estimate in Theorem 4.1 is

no longer valid for such problems. Our next goal of this section is to derive some superconvergence for general approximation schemes of the Dirichlet boundary data.

THEOREM 4.2. *Assume that* (3) *and* (8) *are valid for an* $s \in [3/2, k+1]$ *and that* g_h *is an approximation of the Dirichlet data* g *on the boundary such that*

$$\|g - g_h\|_{0,\partial\Omega} \le Ch^{k+1}\|g\|_{k+1,\partial\Omega}. \tag{29}$$

Assume that the projection space $\mathcal{L}_\tau \subset H(\mathrm{div};\Omega)$. *Then there exists a constant* C *such that*

$$\|\boldsymbol{q} - \tilde{\boldsymbol{Q}}_\tau \boldsymbol{q}_h\|_0 \le C\tau^{r+1}|\!|\!|\boldsymbol{q}|\!|\!|_{r+1,\tau} + Ch^{s-1}\tau^{1-s}\|u - u_h\|_1 + Ch^{k+1}\tau^{-\frac{1}{2}}\|g\|_{k+1,\partial\Omega}.$$

Proof. The proof is similar to that of Theorem 4.1. The only modification is on the treatment of $(u - u_h, \nabla\cdot\boldsymbol{\phi})$. To this end, we observe that

$$(u - u_h, \nabla\cdot\boldsymbol{\phi}) = a(u - u_h, w - v) - \left\langle \frac{\partial w}{\partial \boldsymbol{n_a}}, g - g_h \right\rangle.$$

Thus,

$$\begin{aligned}
|(u - u_h, \nabla\cdot\boldsymbol{\phi})| &\le Ch^{s-1}\|u - u_h\|_1\|w\|_s + \left\|\frac{\partial w}{\partial \boldsymbol{n_a}}\right\|_{0,\partial\Omega}\|g - g_h\|_{0,\partial\Omega} \\
&\le Ch^{s-1}\|u - u_h\|_1\|\nabla\cdot\boldsymbol{\phi}\|_{s-2} + Ch^{k+1}\|w\|_{\frac{3}{2}}\|g\|_{k+1,\partial\Omega} \\
&\le Ch^{s-1}\tau^{1-s}\|u_h - u\|_1\|\boldsymbol{\phi}\|_0 + Ch^{k+1}\tau^{-1/2}\|g\|_{k+1,\partial\Omega}\|\boldsymbol{\phi}\|_0.
\end{aligned}$$

The rest of the proof is similar to that of Theorem 4.1 and is omitted. ∎

Theorem 4.2 shows that if the Dirichlet boundary data is not approximated by the L^2 projection, then the superconvergence estimate for the recovered flux/gradient approximation will suffer. In fact, our estimate of Theorem 4.2 ensures only a superconvergence of order $O(h^{k+1})$ for sufficiently smooth solution u and the projection space $\mathcal{L}_\tau$.

4.2. Discontinuous projection space $\mathcal{L}_\tau$. The flux approximation scheme (13) or (14) is well defined for discontinuous projection space $\mathcal{L}_\tau$. When discontinuous finite elements are employed in the projection method, the computation of the recovered flux/gradient can be implemented locally on each element $K \in \Omega_\tau$, which results in a great saving of computer time and efficiency. However, due to the use of integration by parts in (25), the superconvergence established in Theorems 4.1 and 4.2 is no longer applicable to discontinuous projection space. Our objective of this section is to provide a superconvergent theory for the approximation scheme (13) when $\mathcal{L}_\tau$ contains discontinuous finite element functions.

Let K be any element from the partition Ω_τ. It is not hard to show that there exists a constant C independent of K and v such that

$$\int_{\partial K} v^2 ds \le C\left((\tau^{-1} + \epsilon^{-1})\int_K v^2 dx + \epsilon\int_K |\nabla v|^2 dx\right), \tag{30}$$

where $\epsilon > 0$ is any real number.

THEOREM 4.3. *Let* u *be the exact solution of* (2) *and let* u_h *be its finite element approximation given by* (4). *Let* $\boldsymbol{q} = \boldsymbol{a}\nabla u$ *be the flux/gradient with the obvious approximation* $\boldsymbol{q}_h = \boldsymbol{a}\nabla u_h$ *and let* $\mathcal{G}_\tau$ *be a postprocessing operator given by* $\boldsymbol{Q}_\tau$. *Then,*

for any projection space $\mathcal{L}_\tau$ which is a piecewise polynomial of order r, we have for any $\epsilon > 0$

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \le C\tau^{r+1} |\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau} + C\tau^{-\frac{1}{2}}((\tau^{-\frac{1}{2}} + \epsilon^{-\frac{1}{2}})\|u - u_h\|_0 + \epsilon^{\frac{1}{2}}\|u - u_h\|_1). \tag{31}$$

Proof. Since $\mathcal{G}_\tau = \boldsymbol{Q}_\tau$, then

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \le \|\boldsymbol{q} - \boldsymbol{Q}_\tau \boldsymbol{q}\|_0 + \|\boldsymbol{Q}_\tau \boldsymbol{q} - \boldsymbol{Q}_\tau \boldsymbol{q}_h\|_0.$$

The error $\|\boldsymbol{q} - \boldsymbol{Q}_\tau \boldsymbol{q}\|_0$ can be estimated by using (15). To estimate $\|\boldsymbol{Q}_\tau(\boldsymbol{q} - \boldsymbol{q}_h)\|_0$, we see from (23) and (24) that it suffices to deal with $(\nabla(u - u_h), \boldsymbol{\phi})$ for any $\boldsymbol{\phi} \in \mathcal{L}_\tau$ such that $\|\boldsymbol{\phi}\| = 1$. To this end, using the integration by parts we obtain

$$(\nabla(u - u_h), \boldsymbol{\phi}) = \sum_{K \in \Omega_\tau} \int_K (u_h - u) \nabla \cdot \boldsymbol{\phi} dx + \sum_{K \in \Omega_\tau} \int_{\partial K} (u - u_h) \boldsymbol{\phi} \cdot \boldsymbol{n}_K ds. \tag{32}$$

The first term on the right-hand side of (32) can be bounded as follows:

$$\left| \sum_{K \in \Omega_\tau} \int_K (u_h - u) \nabla \cdot \boldsymbol{\phi} dx \right| \le \|u - u_h\|_0 \, \|\nabla \cdot \boldsymbol{\phi}\|_0 \le C\tau^{-1} \|u - u_h\|_0, \tag{33}$$

where we have used the standard inverse estimate for $\|\nabla \cdot \boldsymbol{\phi}\|$. To estimate the second term on the right-hand side of (32), we use the Schwarz inequality to obtain

$$\begin{aligned} \left| \sum_{K \in \Omega_\tau} \int_{\partial K} (u - u_h) \boldsymbol{\phi} \cdot \boldsymbol{n}_K ds \right| &\le \sum_{K \in \Omega_\tau} \int_{\partial K} |u - u_h| |\boldsymbol{\phi} \cdot \boldsymbol{n}_K| ds \\ &\le \sum_{K \in \Omega_\tau} \|u - u_h\|_{0,\partial K} \|\boldsymbol{\phi}\|_{0,\partial K} \\ &\le \left(\sum_{K \in \Omega_\tau} \|u - u_h\|^2_{0,\partial K} \right)^{\frac{1}{2}} \left(\sum_{K \in \Omega_\tau} \|\boldsymbol{\phi}\|^2_{0,\partial K} \right)^{\frac{1}{2}}. \end{aligned} \tag{34}$$

It follows from (30) that

$$\|u - u_h\|^2_{0,\partial K} \le C \left((\tau^{-1} + \epsilon^{-1}) \|u - u_h\|^2_{0,K} + \epsilon \|\nabla(u - u_h)\|^2_{0,K} \right).$$

Similarly, from (30) with $\epsilon = \tau$ we have

$$\|\boldsymbol{\phi}\|^2_{0,\partial K} \le C(\tau^{-1} \|\boldsymbol{\phi}\|^2_{0,K} + \tau \|\nabla \boldsymbol{\phi}\|^2_{0,K}).$$

Substituting the above two estimates into (34) yields

$$\begin{aligned} &\left| \sum_{K \in \Omega_\tau} \int_{\partial K} (u - u_h) \boldsymbol{\phi} \cdot \boldsymbol{n}_K ds \right| \\ &\le C \left((\tau^{-1} + \epsilon^{-1}) \|u - u_h\|^2_0 + \epsilon \|\nabla(u - u_h)\|^2_0 \right)^{\frac{1}{2}} \left(\tau^{-1} \|\boldsymbol{\phi}\|^2_0 + \tau \|\nabla \boldsymbol{\phi}\|^2_0 \right)^{\frac{1}{2}}. \end{aligned}$$

Now using the standard inverse inequality and the fact that $\|\boldsymbol{\phi}\|_0 = 1$, we obtain

$$\tau^{-1} \|\boldsymbol{\phi}\|^2_0 + \tau \|\nabla \boldsymbol{\phi}\|^2_0 \le C\tau^{-1}.$$

Thus,

$$\left|\sum_{K\in\Omega_\tau}\int_{\partial K}(u-u_h)\boldsymbol{\phi}\cdot\boldsymbol{n}_K ds\right| \tag{35}$$
$$\le C\tau^{-\frac{1}{2}}((\tau^{-\frac{1}{2}}+\epsilon^{-\frac{1}{2}})\|u-u_h\|_0+\epsilon^{\frac{1}{2}}\|\nabla(u-u_h)\|_0).$$

The combination of (32) with (33) and (35) gives

$$|(\nabla(u-u_h),\boldsymbol{\phi})|\le C\tau^{-\frac{1}{2}}((\tau^{-\frac{1}{2}}+\epsilon^{-\frac{1}{2}})\|u-u_h\|_0+\epsilon^{\frac{1}{2}}\|\nabla(u-u_h)\|_0),$$

which completes the proof. ∎

The discontinuous projection space $\mathcal{L}_\tau$ has many distinguished features in theory and application. In practical implementation, it allows a local and parallel computation of the projected flux $\boldsymbol{Q}_\tau\boldsymbol{q}_h$. In addition, one does not need to worry about any special treatment of the boundary condition $u=g$. From the analysis of Theorem 4.3, we see that the estimate (31) does not require the regularity/smoothness assumptions (3) and (8). However, in order to get a superconvergence from the estimate (31), the L^2 norm of the error must have a higher order of convergence than the H^1 norm. This is often accomplished via a duality argument which requires a certain regularity for the dual problem.

For illustration, we consider a model problem where the flux $\boldsymbol{q}$ and the solution u satisfy

$$C(u)=|\!|\!|u|\!|\!|_{k+1,h}<\infty,\quad C(\boldsymbol{q})=|\!|\!|\boldsymbol{q}|\!|\!|_{r+1,\tau}<\infty. \tag{36}$$

Assume that the H^2 regularity is satisfied for the dual problem. Then the following error estimate is well known:

$$\|u-u_h\|_0+h\|\nabla(u-u_h)\|_0\le C(u)h^{k+1}.$$

Substituting the above with $\tau=h^\alpha$ and $\epsilon=h$ into (31) yields

$$\|\boldsymbol{q}-\mathcal{G}_\tau\boldsymbol{q}_h\|_0\le C(u,\boldsymbol{q})(h^{\alpha(r+1)}+h^{k+0.5-0.5\alpha}).$$

The above estimate is optimized when

$$\alpha(r+1)=k+0.5-0.5\alpha\Longleftrightarrow\alpha=\frac{k+0.5}{r+1.5},$$

which gives the following error estimate:

$$\|\boldsymbol{q}-\mathcal{G}_\tau\boldsymbol{q}_h\|_0\le C(u,\boldsymbol{q})h^{\frac{(k+0.5)(r+1)}{r+1.5}}. \tag{37}$$

With $k=2$ and $r=3$ we obtain

$$\|\boldsymbol{q}-\mathcal{G}_\tau\boldsymbol{q}_h\|_0\le C(u,\boldsymbol{q})h^{\frac{20}{9}},$$

which is much better than the optimal order error estimate $\mathcal{O}(h^2)$ for the straightforward gradient approximation $\boldsymbol{q}_h=\boldsymbol{a}\nabla u_h$.

For problems with reentrant corners in the domain or discontinuous data in the coefficient tensor $\{a_{ij}\}$, the H^2 regularity for the dual problem is not satisfied. The dual problem, however, has the $H^{1+\sigma}(\Omega)$ regularity for some $\sigma\in(0,1)$. For sufficiently smooth solution u and the flux $\boldsymbol{q}$, it is possible to show that

$$\|u-u_h\|_0+h^\sigma\|\nabla(u-u_h)\|_0\le C(u)h^{k+\sigma}.$$

By choosing ϵ properly in Theorem 4.3, one is able to determine a value of α in $\tau=h^\alpha$ which gives a superconvergence for the gradient. Details of this analysis are omitted.

5. A relation with ZZ patch recovery. For a given element K of S_h, the ZZ method projects ∇u_h to a covering patch $\tilde{K}$ consisting of K and several neighboring elements [32, 33]. The projection space in the ZZ method is the restriction of S_h on each patch $\tilde{K}$. The superconvergence of the original ZZ patch recovery has been observed only through numerical experiments with specially defined discrete L^2-inner products.

We shall modify the ZZ patch recovery method as follows. First, we replace the ZZ projection space by the space of polynomials of order $r \geq 0$ on each patch. Second, we assume that each patch is of size τ which is larger than the original mesh size h. By adjusting the size τ and the fitting polynomial order r, we are able to obtain a superconvergence for the MZZ patch recovery method.

We now present a detailed discussion on the MZZ method. Based on the finite element partition for S_h, we shall first divide the mesh domain Ω into many nonoverlapping and simply connected subdomains Ω_i. Each subdomain is a union of finite elements of Ω_h. Assume that the partition $\{\Omega_i\}$ is regular in the sense that each Ω_i is of diameter proportional to τ and contains a ball of diameter also proportional to τ. The finite element space $\mathcal{L}_\tau$ is defined as

$$\mathcal{L}_\tau = \{\boldsymbol{v} = (v_1, \ldots, v_d) : \quad v_i|_{\Omega_i} \in P_r \ \forall i\}.$$

In other words, for $\boldsymbol{v} \in \mathcal{L}_\tau$, each component of $\boldsymbol{v}$ in Ω_i is the restriction of a polynomial of order r. Notice that $\boldsymbol{v}$ can be discontinuous on the interface between the subdomains. Here are some points of why discontinuous fitting functions are preferable:

- Each subdomain (element) Ω_i is constructed from the elements of Ω_h by regrouping. Thus, the implementation of the projection operator $\boldsymbol{Q}_\tau$ is computationally feasible, since the corresponding numerical integration for the matrix problem of $\boldsymbol{Q}_\tau$ is easy to compute.
- As the functions $\boldsymbol{v}$ can be totally discontinuous on the interfaces, the boundary of the element Ω_i does not need to be straight lines.
- The projection operator $\boldsymbol{Q}_\tau$ can be computed on each subdomain in parallel, and the projections over the subdomains do not interact with each other.

An error estimate can be established for the MZZ scheme by using Theorem 4.3. In fact, from the estimate (31) with $\epsilon = h$ we have

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C\tau^{r+1} |\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau} + \tau^{-\frac{1}{2}} (h^{-\frac{1}{2}} \|u - u_h\|_0 + h^{\frac{1}{2}} \|u - u_h\|_1),$$

where $\mathcal{G}_\tau$ is given by $\boldsymbol{Q}_\tau$. If the exact solution u is sufficiently smooth, then

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C(\tau^{r+1} |\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau} + \tau^{-\frac{1}{2}} h^{k+0.5} |\!|\!| u |\!|\!|_{k+1,h}). \tag{38}$$

For a given τ, we can choose the order of polynomials of $\mathcal{L}_\tau$ properly such that $\tau^{r+1} \leq \sqrt{\frac{h}{\tau}}\, h^k$. Hence, the gain on the convergence for the flux/gradient is of a factor $\sqrt{\frac{h}{\tau}}$.

In case that u has only a limited regularity, we need to choose the mesh size τ properly to obtain the best possible superconvergence. For example, if $\boldsymbol{q} \in [H^2(\Omega)]^d$ and $u \in H^2(\Omega)$ and S_h contains continuous piecewise linear functions, we take the projection space $\mathcal{L}_\tau$ to be the restriction of linear functions on each subdomain (or patch) Ω_i. For any $\boldsymbol{v} \in \mathcal{L}_\tau$, we have

$$\boldsymbol{v}|_{\Omega_i} = a_0^i + \sum_{j=1}^{d} a_j^i x_j.$$

In computing the projection of the flux over each Ω_i, we need only to compute the coefficients $a_0^i, a_1^i, \ldots, a_d^i$ on each Ω_i by using the standard least-squares method. As $k = r = 1$, we have that

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C\tau^2 \|\!|\boldsymbol{q}|\!\|_{2,\tau} + C(h/\tau)^{0.5} h \|\!|u|\!\|_{2,h}.$$

By choosing $\tau = h^{\frac{3}{5}}$, we arrive at the following superconvergence:

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq Ch^{\frac{6}{5}} (\|\!|\boldsymbol{q}|\!\|_{2,\tau} + \|\!|u|\!\|_{2,h}).$$

The gain for the convergence order for the flux or gradient is then 1/5. If we use quadratic functions for $\mathcal{L}_\tau$, then we need to take $\tau = h^{\frac{3}{7}}$, and the gain for the convergence order is 2/7. In case that $r = 3$, the gain of the convergence order can be 1/3.

For the original ZZ method, it is typical that $r = k$ and $\tau = Lh$ for some fixed value $L \geq 1$. Correspondingly, our estimate implies that

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq CL^{k+1} h^{k+1} \|\!|\boldsymbol{q}|\!\|_{k+1,\tau} + C\sqrt{L^{-1}}\, h^k \|\!|u|\!\|_{k+1,h},$$

which does not claim any superconvergence for the recovered flux or gradient approximation.

6. A remark on continuous least-squares surface fitting. Locality and parallelization are the main features in using discontinuous finite elements to fit the approximate flux. However, as indicated by (38), the maximum gain on the order of convergence with discontinuous projection space is $h^{\frac{1}{2}}$ over the optimal order error estimate. In fact, our convergence analysis in previous sections suggests that continuous finite element fitting spaces should be used in order to achieve a high order of superconvergence for the recovered flux/gradient approximation.

Let $\mathcal{L}_\tau$ be a finite element space of class C^0 consisting of continuous piecewise polynomials of order r over each element. Recall that the finite element partition for Ω_h does not need to be a refinement of the elements of Ω_τ. It is well known that, for any $\epsilon \in (0, \frac{1}{2})$, $\mathcal{L}_\tau \subset H^{\frac{3}{2}-\epsilon}(\Omega)$. In other words, assumption (8) is satisfied with $s = 2.5 - \epsilon$. Assume that (3) is also valid with $s = 2.5 - \epsilon$. An application of Theorem 4.1 shows that the convergence for the recovered flux approximations is given by

$$\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \leq C\tau^{r+1} \|\!|\boldsymbol{q}|\!\|_{r+1,\tau} + C(h/\tau)^{1.5-\epsilon} \|u - u_h\|_1,$$

where $\mathcal{G}_\tau$ is either $\tilde{\boldsymbol{Q}}_\tau$ or $\boldsymbol{Q}_\tau$. If u is sufficiently smooth, we can choose the order of polynomials of $\mathcal{L}_\tau$ properly such that $\tau^{r+1} \leq C(h/\tau)^{1.5-\epsilon}$. In such a case, the gain of the convergence for the flux and gradient is of a factor $(h/\tau)^{1.5-\epsilon}$. For simplicity of discussion, we shall assume $\epsilon = 0$ in the rest of this section. In case that u has only a limited regularity, we need to choose r according to the regularity of u and choose τ such that $O(\tau^{r+1}) = (h/\tau)^{1.5}\, h^k$. In Table 1, we show some theoretical gain of the convergence order for the flux/gradient with different values of r and k. In theory, the computational result can only be better than this.

In a similar manner, the improvement on the convergence of the flux/gradient would be of a factor $O(h/\tau)^{(\ell+1.5)}$ if $\mathcal{L}_\tau$ is a finite element space of class C^ℓ for $0 \leq \ell \leq k - 1.5$. In case that u has only a limited regularity, we need to choose the mesh size τ properly to get the best possible superconvergence.

TABLE 1
The value of β in $\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}_h\|_0 \le Ch^{k+\beta}$.

	$r=1$	$r=2$	$r=3$	$r=4$	$r=5$
$k=1$	0.4286	0.6667	0.8182	0.9231	1.0000
$k=2$		0.3333	0.5455	0.6923	0.8000
$k=3$			0.2727	0.4615	0.6000
$k=4$				0.2308	0.4000

7. An application to mesh adaptivity. The superconvergence estimates can be used to refine the finite element mesh adaptively. Let us note that

$$\|\boldsymbol{q} - \boldsymbol{q}_h\|_0 \le \|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}\|_0 + \|\mathcal{G}_\tau(\boldsymbol{q} - \boldsymbol{q}_h)\|_0 + \|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_0.$$

Assume that the finite element solution u_h is nontrivial in the sense that

$$\|\boldsymbol{q} - \boldsymbol{q}_h\|_0 \cong h^k |\!|\!| \boldsymbol{q} |\!|\!|_{k,h}. \tag{39}$$

From (15), (22), and (28), and assuming that $\boldsymbol{q}$ has the needed regularity, we obtain

$$\begin{aligned}
&\|\boldsymbol{q} - \mathcal{G}_\tau \boldsymbol{q}\|_0 + \|\mathcal{G}_\tau(\boldsymbol{q} - \boldsymbol{q}_h)\|_0 \\
&\le C\tau^{r+1} |\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau} + \|\mathcal{G}_\tau(\boldsymbol{q} - \boldsymbol{q}_h)\|_0 \\
&\le C\frac{\tau^{r+1}}{h^k} \frac{|\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau}}{|\!|\!| \boldsymbol{q} |\!|\!|_{k,h}} \|\boldsymbol{q} - \boldsymbol{q}_h\|_0 + C\left(\frac{h}{\tau}\right)^{s-1} \|\boldsymbol{q} - \boldsymbol{q}_h\|_0 \\
&= \alpha \|\boldsymbol{q} - \boldsymbol{q}_h\|_0,
\end{aligned}$$

where

$$\alpha = C\frac{\tau^{r+1}}{h^k} \frac{|\!|\!| \boldsymbol{q} |\!|\!|_{r+1,\tau}}{|\!|\!| \boldsymbol{q} |\!|\!|_{k,h}} + C\left(\frac{h}{\tau}\right)^{s-1}.$$

The mesh parameters τ and r can be chosen properly to ensure that $\alpha \to 0$ when $\tau \to 0, h \to 0$. For simplicity, let us take $\tau = \kappa h$. Thus,

$$\alpha = C(\boldsymbol{q})\kappa^{r+1} h^{r+1-k} + C\kappa^{-(s-1)}.$$

By letting $\kappa \to \infty$ and $\kappa \le o(h^{k/(r+1)-1})$, we have $\alpha \to 0$. In fact, the choices we have discussed for k, r, h, τ in sections 5 and 6 will all guarantee that $\alpha \to 0$. Thus,

$$(1 - \alpha)\|\boldsymbol{q} - \boldsymbol{q}_h\|_0 \le \|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_0.$$

We emphasize that the right-hand side of the above estimate is computable. In practical computations, the value of α is small but not known exactly. We can produce a mesh to guarantee that

$$\|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_0 \le \varepsilon, \tag{40}$$

where ε stands for a prescribed tolerance. To this end, for a given coarse mesh $\mathcal{L}_\tau$, we compute the maximum value of the error indicator over all the coarse mesh elements:

$$\eta_\tau = \max_{K \in \Omega_\tau} \|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_{0,K}.$$

We choose a parameter $\theta \in (0,1)$. For a given coarse mesh element $K \in \Omega_\tau$, we refine K if

$$\|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_{0,K} \geq \theta \eta_\tau.$$

The refinement process is stopped if either (40) is satisfied or the memory limit has been reached, or the change of the computed solution in the energy norm is less than a given tolerance.

Under assumption (39), the error indicator $\|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_0$ is in fact equivalent to the true error due to the fact that

$$\begin{aligned}\|\mathcal{G}_\tau \boldsymbol{q}_h - \boldsymbol{q}_h\|_0 &\leq \|\mathcal{G}_\tau(\boldsymbol{q}_h - \boldsymbol{q})\|_0 + \|\mathcal{G}_\tau \boldsymbol{q} - \boldsymbol{q}\|_0 + \|\boldsymbol{q} - \boldsymbol{q}_h\|_0 \\ &\leq (1+\alpha)\|\boldsymbol{q} - \boldsymbol{q}_h\|_0.\end{aligned}$$

Note that we refine the coarse mesh Ω_τ instead of the fine mesh Ω_h. The fine mesh Ω_h is always produced from Ω_τ by refining each coarse mesh element into several smaller elements. See [5] for some results about using averaging-type error estimators and the ZZ method for mesh refinement for general unstructured meshes.

8. Numerical experiments. Two meshes Ω_τ and Ω_h are needed in the computation. The coarse mesh Ω_τ is produced by the adaptive strategy of section 7. The fine mesh Ω_h is always produced from Ω_τ. To produce Ω_h, each coarse mesh element is refined into 4 elements by connecting the edge middle points or refined uniformly twice to produce 16 elements for two-dimensional problems. Continuous piecewise linear finite element functions over Ω_τ and Ω_h are used for the projection $\mathcal{G}_\tau$ and for the solution of the finite element approximation u_h, respectively.

The proposed algorithms are tested for

$$-\nabla \cdot (a \nabla u) = f \quad \text{on} \quad \Omega, \qquad u = g \quad \text{on} \quad \partial\Omega \tag{41}$$

with $\Omega = (0,1) \times (0,1), f = 2\pi^2 \sin(\pi x)\sin(\pi y), g = 0, a = 1$. The exact solution is easily seen to be $u = \sin(\pi x)\sin(\pi y)$.

The global coarse mesh recovery is as described earlier, and the element-wise coarse mesh recovery works by projecting the gradient in S_h to the fitting space $\mathcal{L}_\tau$ consisting of piecewise linear functions over Ω_τ. Equation (14) is thus solved for each element in Ω_τ independently, and these local solutions are combined to a global solution by an averaging procedure. As we shall see, this gives a worse convergence rate than the global projection, but it is still superconvergent.

We use Figures 1 and 2 to show the computational results. In the plot, the x-axis represents the degree of freedom of the mesh. The y-axis represents the L^2 error of the gradient. Note that both axes are scaled using $\log_{10}$. Figure 2 compares the mesh quality produced by the superconvergence error estimator and the error estimator of Johnson [16] and Eriksson and Johnson [12]. The error for the finite element solution over S_h, i.e., the mesh produced by the superconvergence error estimator, is slightly better than the error for the finite element solution for the mesh produced by the error estimator of [16, 12]. To reach the same accuracy, we need a much smaller degree of freedom in our new method; see also Figure 1. The projected gradient over Ω_τ has a better convergence order, as can be seen from Figure 1. The convergence rate for the different errors are plotted in Figure 1. The convergence rate and the accuracy of the MZZ and the ZZ methods are nearly the same.

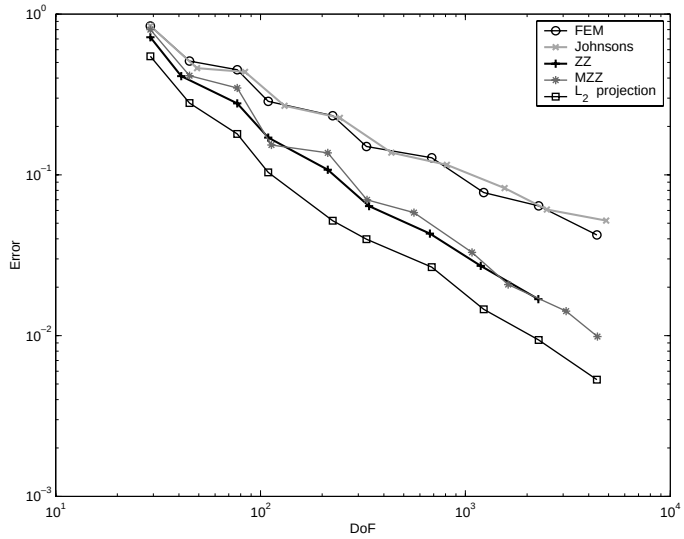

FIG. 1. *Comparison of the mesh quality produced by different recovery methods compared to the error estimator of Johnson* [16] *and Eriksson and Johnson* [12]. *All the errors are measured in* L^2 *for the gradients. FEM refers to the error* $\|\nabla u_h - \nabla u\|_0$, *where* u_h *is the finite element solution over* S_h.

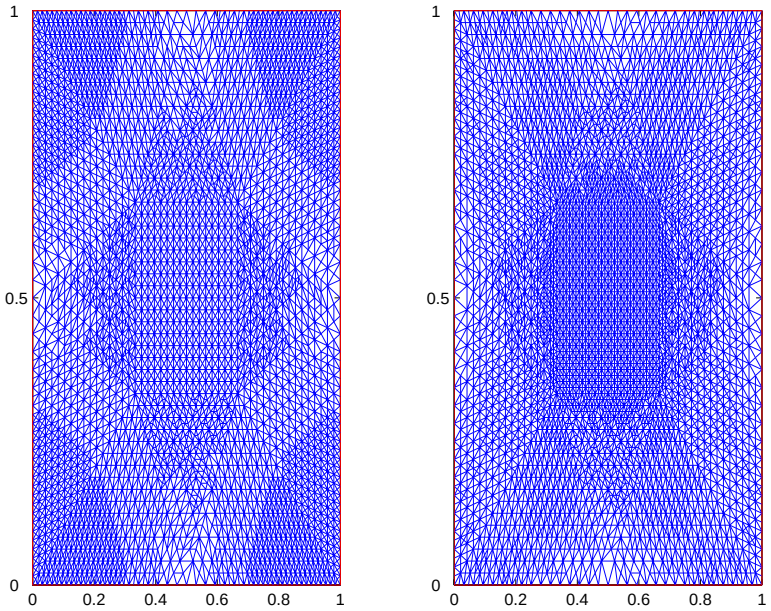

FIG. 2. *The left is the mesh produced by the superconvergence estimator of this paper, and the right is the mesh of the residual error estimator of Johnson* [16] *and Eriksson and Johnson* [12]. *The* L^2 *error for the left mesh is* 0.0094 *with* 2279 *nodes, and the right mesh has an* L^2 *error of* 0.061 *with* 2497 *nodes.*

Our computational experiment reveals that the convergence rate of standard Galerkin finite element solution over S_h is 1.2. For ZZ recovery the order of convergence is 1.72. The MZZ method proposed earlier has a convergence order of 1.74.

Johnson's method gives a rate of 1.08. Finally, the L^2 projection has a convergence of order 1.84. We clearly see that the L^2 projection has superior performance. The convergence order is evaluated by using the formula $\log_{10} \|\nabla u_h - \nabla u\|_0 / \log_{10}(\sqrt{DoF})$ as in [6, 22], where DoF stands for the total number of nodal points in the finite element partition. The continuous least-squares surface fitting is easy to implement and has the best accuracy.

A WIGNER-MEASURE ANALYSIS OF THE DUFORT–FRANKEL SCHEME FOR THE SCHRÖDINGER EQUATION*

PETER A. MARKOWICH†, PAOLA PIETRA‡, CARSTEN POHL§, AND HANS PETER STIMMING†

Abstract. We apply Wigner transform techniques to the analysis of the Dufort–Frankel difference scheme for the Schrödinger equation and to the continuous analogue of the scheme in the case of a small (scaled) Planck constant (semiclassical regime). In this way we are able to obtain sharp conditions on the spatial-temporal grid which guarantee convergence for average values of observables as the Planck constant tends to zero. The theory developed in this paper is *not* based on local and global error estimates and does *not* depend on whether or not caustics develop. Numerical test examples are presented to help interpret the theory and to compare the Dufort–Frankel scheme to other difference schemes for the Schrödinger equation.

Key words. Schrödinger equation, finite difference scheme, semiclassical limit, Wigner measure

1. Introduction.

We shall analyze the Dufort–Frankel discretization scheme for the linear Schrödinger equation

$$\varepsilon u_t^\varepsilon = i\frac{\varepsilon^2}{2}\Delta u^\varepsilon - iV(x)u^\varepsilon, \quad x \in \mathbb{R}^d, \quad t \in \mathbb{R} \tag{1.1}$$

$$u^\varepsilon(x, t=0) = u_I^\varepsilon(x), \qquad x \in \mathbb{R}^d. \tag{1.2}$$

Here $0 < \varepsilon \leq \varepsilon_0 < 0$ is the (scaled) Planck constant (generally assumed to be small in what follows), $V = V(x)$ is a given electrostatic potential, and $u^\varepsilon = u^\varepsilon(x,t)$ is the (complex valued) wave function. In classical quantum physics, this function is used to compute observables (including the primary physical quantities), which are quadratic functions (or functionals) of $u^\varepsilon(t)$ [LL]. In this paper, we want to study the behavior of the discretization scheme in the limit case $\varepsilon \to 0$, the so-called semiclassical limit. As the Schrödinger equation propagates oscillations of wavelength ε, the wave function u^ε does not converge strongly, for example, in $L_t^\infty(L_x^2)$, and weak convergence is not sufficient for passing to the limit in the observables. By introducing the Wigner measure (see [G2], [LP], [MMP], [GMMP], [Wi] or other tools of microlocal analysis [G1], [T]) this passage to the limit in the macroscopic densities becomes possible.

The highly oscillatory nature of the solutions of (1.1) poses a problem if this equation is solved numerically in the case of a small scaled Planck constant ε. The

oscillations may disturb the numerical solution in such a way that the physical observables come out completely wrong. If the microlocal techniques used to analyze the semiclassical limit for the IVP (1.1)–(1.2) are adapted to the analysis of finite difference discretizations, sharp conditions can be found which guarantee the convergence of observables. This has been done in [MPP] for other numerical schemes, in particular for the Crank–Nicolson and Leap-Frog schemes.

For the sake of transparency we shall now set up the Dufort–Frankel scheme for the case of one space dimension ($d = 1$). Also, the subsequent analysis will mainly focus on the case $d = 1$. Generalizations to $d > 1$ are immediate for tensor product grids, and the results remain valid without modifications.

We choose a spatial mesh size $\Delta x > 0$ and a temporal mesh size $\Delta t > 0$ and denote the grid points

$$x_j := j\,\Delta x, \quad t_n := n\,\Delta t, \quad n, j \in \mathbb{Z}.$$

The Dufort–Frankel scheme for (the one-dimensional version of) (1.1) reads

$$\varepsilon \frac{u_j^{n+1} - u_j^{n-1}}{2\Delta t} = i\frac{\varepsilon^2}{2} \frac{u_{j+1}^n - (u_j^{n+1} + u_j^{n-1}) + u_{j-1}^n}{(\Delta x)^2} - iV(x_j)\frac{u_j^{n+1} + u_j^{n-1}}{2}, \quad n \in \mathbb{Z}, \quad j \in \mathbb{Z} \tag{1.3}$$

$$u_j^0 = u_I^\varepsilon(x_j), \qquad j \in \mathbb{Z}, \tag{1.4}$$

$$u_j^1 = \tilde{u}_{I,j}^\varepsilon, \qquad j \in \mathbb{Z}. \tag{1.5}$$

Obviously, the solution u_j^n is considered an approximation of $u^\varepsilon(x_j, t_n)$. Observe that if in (1.3) the time average $(u_j^{n+1} + u_j^{n-1})/2$ is replaced by u_j^n, we obtain the Leap-Frog scheme.

Since the Dufort–Frankel scheme is a two-step scheme (in time), additional initial data at $t = \Delta t$ (or $t = -\Delta t$) have to be prescribed. Later on we shall discuss the choice of the values $\tilde{u}_{I,j}^\varepsilon$ in detail.

Although, formally, the scheme (1.3) is implicit, the $(n+1)$st time level contributions on the right-hand side of (1.3) occur only on the diagonal, thus the computational effort involved in solving (1.3) is exactly the same as for an explicit scheme (e.g., the Leap-Frog scheme). The scheme also is time reversible and has some favorable stability properties, which make it suitable for the numerical solution of the Schrödinger equation. This was done in [IR] and [W] for both linear and nonlinear Schrödinger equations for the case of $\varepsilon > 0$ fixed, i.e., *not* close to the semiclassical regime. There the authors use the classical stability-consistency method described below but do not address the question of the behavior of the discretization in the case of the limit $\varepsilon \to 0$.

The classical analysis of finite difference schemes relies on the stability-consistency concept. The local discretization error of a difference scheme is calculated by inserting the "exact" solution of the differential equation into the difference scheme and calculating the residual by, say, Taylor expansion. Replacing u_j^n in (1.3) by $u^\varepsilon(x_j, t_n)$ gives

$$\begin{aligned} \varepsilon u_t^\varepsilon = i\frac{\varepsilon^2}{2} u_{xx}^\varepsilon - iVu^\varepsilon - i\frac{\varepsilon^2}{2}\left(\frac{\Delta t}{\Delta x}\right)^2 u_{tt}^\varepsilon \\ + O\left(\varepsilon^2(\Delta x)^2 u_{xxxx}^\varepsilon\right) + O\left(\varepsilon(\Delta t)^2 u_{ttt}^\varepsilon\right) \\ + O\left((\Delta t)^2 u_{tt}^\varepsilon\right) + O\left(\varepsilon^2\left(\frac{\Delta t}{\Delta x}\right)^2 (\Delta t)^2 u_{tttt}^\varepsilon\right). \end{aligned} \tag{1.6}$$

It is then clear that the scheme, for fixed ε, is consistent only if $\frac{\Delta t}{\Delta x}$ goes to zero with $\Delta t \to 0$ and $\Delta x \to 0$. Actually, since typically

$$\left\| \frac{\partial^{k_1+k_2}}{\partial x^{k_1} \partial t^{k_2}} u^\varepsilon(t) \right\|_{L^2(\mathbb{R})} = O\left(\frac{1}{\varepsilon^{k_1+k_2}} \right), \qquad k_1, k_2 \in \mathbb{N} \cup \{0\}, \tag{1.7}$$

the local discretization error is

$$l^\varepsilon = O\left(\left(\frac{\Delta t}{\Delta x} \right)^2 \left(1 + \left(\frac{\Delta t}{\varepsilon} \right)^2 \right) + \left(\frac{\Delta t}{\varepsilon} \right)^2 + \left(\frac{\Delta x}{\varepsilon} \right)^2 \right). \tag{1.8}$$

Even when $\frac{\Delta t}{\Delta x}$ is $o(1)$, l^ε tends to zero as ε, Δt, and Δx tend to zero only when temporal and spatial $O(\varepsilon)$-wavelength oscillations are accurately resolved by the temporal-spatial grid.

Note that the above computation of the local discretization error is highlighted by rewriting (1.3) as

$$\begin{aligned} \varepsilon \frac{u_j^{n+1} - u_j^{n-1}}{2\Delta t} &= i \frac{\varepsilon^2}{2} \frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{(\Delta x)^2} - iV(x_j) u_j^n \\ &\quad - i \frac{\varepsilon^2}{2} \frac{u_j^{n+1} - 2u_j^n + u_j^{n-1}}{(\Delta t)^2} \left(\left(\frac{\Delta t}{\Delta x} \right)^2 + \left(\frac{\Delta t}{\varepsilon} \right)^2 V(x_j) \right). \end{aligned} \tag{1.9}$$

Stability then implies that the local discretization error is not amplified (enough to ruin convergence).

We shall obtain convergence results by both the classical method and by the Wigner measure, finding that the classical method result requires much more restrictions on the choice of discretization steps than the Wigner measure method. We identify the semiclassical Wigner measure (on the scale ε) for combinations of ε and the space and time mesh sizes and conclude convergence of all (smooth) observables in exactly those cases for which the Wigner measure of the numerical scheme is identical to the Wigner measure of the Schrödinger equation itself.

We remark that the analysis of the Dufort–Frankel scheme (which is frequently used in applications) is technically much more challenging than the analysis for the other schemes presented in [MPP]. This is mainly due to the mixing of spatial and temporal grids in this two-step scheme.

The paper is organized as follows. In section 2, we shall give a brief presentation of the analytical tools and calculate the Wigner measure of the modified equation related to the form (1.9) of the scheme (in order to get a "feeling" for the analysis). In section 3, we shall derive a conservation property of the Dufort–Frankel scheme and from this the stability, as well as the convergence by the classical method, keeping track explicitly of the parameter ε in the convergence estimate. In section 4, we shall calculate the Wigner measure of the scheme, and in section 5 we present a sample of numerical computations illustrating the theory.

2. The modified Schrödinger equation. Let μ be a positive parameter (not necessarily small) and consider

$$\varepsilon v_t^{\varepsilon,\mu} = i \frac{\varepsilon^2}{2} \Delta v^{\varepsilon,\mu} - iV(x) v^{\varepsilon,\mu} - i \frac{\varepsilon^2}{2} \mu^2 v_{tt}^{\varepsilon,\mu}, \quad x \in \mathbb{R}^d, \quad t \in \mathbb{R}, \tag{2.1}$$

$$v^{\varepsilon,\mu}(x, t=0) = v_I^{\varepsilon,\mu}(x), \tag{2.2}$$

$$v_t^{\varepsilon,\mu}(x, t=0) = p_I^{\varepsilon,\mu}(x), \qquad x \in \mathbb{R}^d. \tag{2.3}$$

Notice that (2.1) is a "continuous" version of (1.9). We expect to get important asymptotic information on (1.9) by first analyzing (2.1). The superscript ε for the solution $u = u^\varepsilon$ of the Schrödinger equation (1.1) and ε, μ for the solution $v = v^{\varepsilon,\mu}$ of the modified Schrödinger equation (2.1) were introduced to emphasize the dependence of the solution on the parameters. Where convenient, these superscripts will be skipped in what follows to simplify the notation.

At first we remark that the transformation $z^{\varepsilon,\mu} := \exp(-i\frac{t}{\varepsilon\mu^2})v^{\varepsilon,\mu}$ gives the Klein–Gordon equation with potential $V(x) + \frac{1}{2\mu^2}$:

$$\frac{\varepsilon^2\mu^2}{2} z_{tt}^{\varepsilon,\mu} = \frac{\varepsilon^2}{2}\Delta z^{\varepsilon,\mu} - \left(V(x) + \frac{1}{2\mu^2}\right) z^{\varepsilon,\mu}, \quad x \in \mathbb{R}^d, \quad t \in \mathbb{R} \tag{2.4}$$

$$z^{\varepsilon,\mu}(x, t = 0) = v_I^{\varepsilon,\mu}(x), \tag{2.5}$$

$$z_t^{\varepsilon,\mu}(x, t = 0) = p_I^{\varepsilon,\mu}(x) - \frac{i}{\varepsilon\mu^2} v_I^{\varepsilon,\mu}(x), \qquad x \in \mathbb{R}^d. \tag{2.6}$$

The IVP (2.4) does not conserve total charge (as opposed to the Schrödinger equation).

However, energy conservation is easily proven by multiplying (2.1) by $\overline{v}_t = \overline{v}_t^{\varepsilon,\mu}$ ("–" stands for complex conjugation) and integrating over $\mathbb{R}^d$. We obtain

$$\begin{aligned} E^{\varepsilon,\mu}(t) &:= \int_{\mathbb{R}^d} \left(\frac{\varepsilon^2}{2} |\nabla v^{\varepsilon,\mu}|^2 + \frac{\varepsilon^2}{2}\mu^2 |v_t^{\varepsilon,\mu}|^2 + V(x)|v^{\varepsilon,\mu}|^2 \right) dx \\ &= \int_{\mathbb{R}^d} \left(\frac{\varepsilon^2}{2} |\nabla v_I^{\varepsilon,\mu}|^2 + \frac{\varepsilon^2}{2}\mu^2 |p_I^{\varepsilon,\mu}|^2 + V(x)|v_I^{\varepsilon,\mu}|^2 \right) dx \\ &=: E_I^{\varepsilon,\mu} \quad \forall t \in \mathbb{R}. \end{aligned} \tag{2.7}$$

For the sake of simplicity we shall assume from now on that

$$\begin{aligned} &V \in C^\infty(\mathbb{R}^d) \quad \forall l_1, \ldots, l_d \in \mathbb{N} : \quad \frac{\partial^{l_1+\cdots+l_d}}{\partial x_1^{l_1} \cdots \partial x_d^{l_d}} V \in L^\infty(\mathbb{R}^d), \\ &V(x) \geq 0 \text{ on } \mathbb{R}^d. \end{aligned} \tag{2.8}$$

We conclude L^2-stability in the following lemma.

LEMMA 2.1. *The estimate*

$$\|v^{\varepsilon,\mu}(t)\|_{L^2(\mathbb{R}^d)} \leq \mu\sqrt{2E_I^{\varepsilon,\mu}} + \|v_I^{\varepsilon,\mu}\|_{L^2(\mathbb{R}^d)} \tag{2.9}$$

holds for all $t \in \mathbb{R}$.

Proof. Multiplication of (2.1) by the conjugate $\overline{v}$, integration over $\mathbb{R}^d \times (0, T)$, and taking real parts gives

$$\int_{\mathbb{R}^d} |v(T)|^2 dx = \int_{\mathbb{R}^d} |v(0)|^2 dx + \varepsilon\mu^2 \int_{\mathbb{R}^d} \mathrm{Im}\,(v_t(0)\overline{v}(0) - v_t(T)\overline{v}(T)) dx$$

and, using (2.7),

$$\int_{\mathbb{R}^d} |v(T)|^2 dx \leq \int_{\mathbb{R}^d} |v(0)|^2 dx + \mu\sqrt{2E_I^{\varepsilon,\mu}} \left(\|v(T)\|_{L^2(\mathbb{R}^d)} + \|v(0)\|_{L^2(\mathbb{R}^d)} \right).$$

Then (2.9) is immediate. ∎

The L^2-stability is uniform in ε and μ if the initial energy and the initial local charge are bounded uniformly in ε and μ and if $\mu \leq \mu_0 < \infty$.

The following theory will be largely based on Wigner transforms. For functions $v, u \in L^2(\mathbb{R}^d)$ we define their Wigner transform on the scale $\varepsilon > 0$ as the phase space function

$$w^\varepsilon(u,v)(x,\xi) := \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} u\left(x - \frac{\varepsilon}{2}\eta\right) \overline{v}\left(x + \frac{\varepsilon}{2}\eta\right)\ e^{i\xi\cdot\eta}\ d\eta. \tag{2.10}$$

Obviously, $w^\varepsilon(u,v)$ is bilinear and $w^\varepsilon(u,u) =: w^\varepsilon[u]$ is a real-valued function.

The mathematical (and physical) literature on Wigner transforms is substantial, and we are not able to give a detailed review here. As basic references we recommend [G1], [LP], [GMMP], [MPP].

Here we remark only that for $a \in S(\mathbb{R}^{2d}_{x,\xi})$ we have

$$E^\varepsilon_a[u] := \int_{\mathbb{R}^d} (a(x,\varepsilon D)^W u)\ \overline{u}\ dx = \int_{\mathbb{R}^d_x \times \mathbb{R}^d_\xi} a(x,\xi)\ w^\varepsilon[u](x,\xi)\ dxd\xi, \tag{2.11}$$

where $a(\,.\,,\varepsilon D)^W$ denotes the Weyl operator associated with the symbol $a(x,\xi)$, defined as

$$a(\,.\,,\varepsilon D)^W\varphi(x) := \frac{1}{(2\pi)^m} \int_{\mathbb{R}^d_y} \int_{\mathbb{R}^d_\xi} a\left(\frac{x+y}{2}, \varepsilon\xi\right) \varphi(y) e^{i(x-y)\cdot\xi} d\xi dy \tag{2.12}$$

(see [HM3], [GMMP]). Physically, the left-hand side of (2.11) denotes the average value of the observable a in the state u (cf. [LL]), which by (2.11) can be obtained by testing the symbol $a(x,\xi)$ against the Wigner transform of the function u.

Note that the average values of observables (2.11) are the physically important quantities which can be obtained as a "postprocessing" from the wave function $u = u^\varepsilon$ after having solved the Schrödinger equation.

Also, we remark that a can be chosen independent of x in (2.11) such that

$$\rho(x) := |u(x)|^2 = \int_{\mathbb{R}^d_\xi} w^\varepsilon[u](x,\xi)\ d\xi. \tag{2.13}$$

Similarly,

$$J(x) := \varepsilon \mathrm{Im}\ (\overline{u}(x)\nabla u(x)) = \int_{\mathbb{R}^d_\xi} \xi\ w^\varepsilon[u](x,\xi)\ d\xi \tag{2.14}$$

and, formally,

$$e(x) := \frac{\varepsilon^2}{2}|\nabla u(x)|^2 - \frac{\varepsilon^2}{2}\mathrm{Re}\ (\overline{u}(x)\Delta u(x)) = \int_{\mathbb{R}^d_\xi} |\xi|^2 w^\varepsilon[u](x,\xi)\ d\xi. \tag{2.15}$$

Here ρ, J, e denote the position density, current density, and energy density of the state u, respectively.

Also, let $u^\varepsilon = u^\varepsilon(x)$ be a sequence, uniformly bounded in $L^2(\mathbb{R}^d)$ as $\varepsilon \to 0$. Then there exists a subsequence $(\varepsilon_k) \rightharpoonup 0$ such that

$$w^{\varepsilon_k}[u^{\varepsilon_k}] \overset{\varepsilon_k \rightharpoonup 0}{\rightharpoonup} w^0 = w^0[u^{\varepsilon_k}] \quad \text{in } S'(\mathbb{R}^{2d}_{x,\xi}), \tag{2.16}$$

where w^0 is a positive phase space measure, called the Wigner measure of u^ε on the scale ε_k.

It is now our goal to compute the Wigner measure(s) of the solution $v = v^{\varepsilon,\mu}$ of (2.1) on the ε-scale with, say, $\mu = \mu(\varepsilon) > 0$. We set

$$w^{\varepsilon,\mu} := w^{\varepsilon}[v^{\varepsilon,\mu}] = w^{\varepsilon}(v^{\varepsilon,\mu}, v^{\varepsilon,\mu}).$$

Differentiation of the bilinear Wigner transform with respect to t gives

$$\frac{\partial}{\partial t} w^{\varepsilon,\mu} = \frac{2}{\varepsilon}\, \mathrm{Im}\, w^{\varepsilon}\left(\frac{\varepsilon^2}{2}\Delta v - Vv,\ v\right) - \varepsilon\, \mathrm{Im}\, w^{\varepsilon}\left(\mu^2 v_{tt},\ v\right), \tag{2.17}$$

using $w^{\varepsilon}(f,g) = \overline{w^{\varepsilon}(g,f)}$, $\partial_t w^{\varepsilon}(v,v) = 2\ \mathrm{Re}\, w(v_t, v)$, and (2.1).

To proceed we shall use the following lemma.

LEMMA 2.2. *Let $P \in C^{\infty}(\mathbb{R}^m_x \times \mathbb{R}^m_{\xi})$ satisfy for some $M \geq 0, C_{\alpha} \geq 0$*

$$|\partial^{\alpha}_{x,\xi} P(x,\xi)| \leq C_{\alpha}(1 + |\xi|)^M \quad \forall \alpha \in \mathbb{N}^m_0 \times \mathbb{N}^m_0. \tag{2.18}$$

Then, if f, g lie in a bounded subset of $L^2(\mathbb{R}^m)$, the expansion

$$w^{\varepsilon}\left(P(\,.\,, \varepsilon D)^W f, g\right) = P w^{\varepsilon}(f,g) + \frac{\varepsilon}{2i}\{P, w^{\varepsilon}(f,g)\} + O(\varepsilon^2)$$

holds in $S'(\mathbb{R}^m \times \mathbb{R}^m)$ uniformly for all symbols $P = P(x,\xi)$ satisfying (2.18).

Here $\{\ .\ ,\ .\ \}$ denotes the Poisson bracket

$$\{f,g\} = \nabla_{\xi} f \nabla_x g - \nabla_x f \nabla_{\xi} g. \tag{2.19}$$

A proof of Lemma 2.2 can be found in [GMMP]. We can now pass to the limit in the first term of the right-hand side setting $P(x,\xi) = \frac{1}{2}|\xi|^2 + V(x)$:

$$\frac{2}{\varepsilon}\, \mathrm{Im}\, w^{\varepsilon}\left(\frac{\varepsilon^2}{2}\Delta v - Vv,\ v\right) \rightharpoonup \left\{\ \frac{1}{2}|\xi|^2 + V(x),\ w^0\right\},$$

where

$$w^0 := \ \mathrm{w}\text{-}\lim_{\varepsilon \to 0}\ w^{\varepsilon}(v^{\varepsilon,\mu}, v^{\varepsilon,\mu})$$

(after extraction of a subsequence). To pass to the limit in the second term we multiply by a real-valued smooth test function φ with sufficient decay at $|x| = \infty$, $|\xi| = \infty$ and integrate by parts:

$$\begin{aligned} &\varepsilon\ \mathrm{Im} \int_{\mathbb{R}^{2d}_{x,\xi}} \int_{\mathbb{R}_t} \varphi w^{\varepsilon}(\mu^2 v_{tt}, v)\ dtdxd\xi \\ &= -\ \varepsilon \int_{\mathbb{R}^{2d}_{x,\xi}} \int_{\mathbb{R}_t} \varphi\ \mathrm{Im}\, w^{\varepsilon}(\mu v_t, \mu v_t)\ dtdxd\xi \\ &\quad -\ \mu \int_{\mathbb{R}^{2d}_{x,\xi}} \int_{\mathbb{R}_t} \varphi_t\ \mathrm{Im}\, w^{\varepsilon}(\varepsilon\mu v_t, v)\ dtdxd\xi. \end{aligned} \tag{2.20}$$

The first term is zero, since $w^{\varepsilon}(f,f)$ is real-valued, and the second term can be estimated using

$$\|w^{\varepsilon}(f,g)\|_{\mathcal{A}^*} \leq \|f\|_{L^2(\mathbb{R}^d)} \|g\|_{L^2(\mathbb{R}^d)}, \tag{2.21}$$

where $\mathcal{A}$ is a suitable Banach space of test functions (cf. [LP]) containing $\mathcal{D}(\mathbb{R}^{2d}_{x,v})$. Choosing $\varphi \in C_0^\infty(\mathbb{R}_t; \mathcal{A})$ we obtain

$$\begin{aligned}&\varepsilon \left| \operatorname{Im} \int_{\mathbb{R}^{2d}_{x,v}} \varphi w^\varepsilon(\mu^2 v_{tt}, v)\, dtdxdv \right| \\ &\le \mu K(\varphi) \sup_{t\in\mathbb{R}} \left\| \varepsilon\mu v_t(t) \right\|_{L^2(\mathbb{R}^d)} \left\| v(t) \right\|_{L^2(\mathbb{R}^d)}.\end{aligned}$$

We have thus proven the following lemma.

LEMMA 2.3. *Let $E_I^{\varepsilon,\mu} \le L$ for $\varepsilon \to 0$ and let $\mu \to 0$. Then the Wigner measures satisfy*

$$w_t^0 + \left\{ \frac{1}{2}|\xi|^2 + V(x),\ w^0 \right\} = 0, \tag{2.22}$$

$$w^0(t=0) = w^0[v_I^{\varepsilon,\mu}]. \tag{2.23}$$

Note that the possible nonuniqueness of the Wigner measures stem from the possible nonuniqueness of the initial Wigner measures $w^0[v_I^{\varepsilon,\mu}]$. (Different subsequences might give different limits.)

If μ does not tend to zero we have to proceed differently. Therefore we use (2.1) to compute the second term on the right-hand side of (2.20). (The first term is zero!) For $\mu = \text{const}$ we obtain

$$\begin{aligned}w^\varepsilon(\mu^2 v_t, v) &= -\frac{i}{\varepsilon} w^\varepsilon \left(\mu^2 \left(\frac{\varepsilon^2}{2}\Delta v - Vv \right), v \right) + i\frac{\varepsilon}{2} w^\varepsilon(\mu^4 v_{tt}, v) \\ &= -\frac{i}{\varepsilon}\mu^2 \left(\frac{|\xi|^2}{2} + V(x) \right) w^\varepsilon \\ &\quad + \frac{1}{2}\mu^2 \left\{ \frac{|\xi|^2}{2} + V(x), w^\varepsilon \right\} + O(\varepsilon\mu^2) \\ &\quad + i\frac{\varepsilon}{2}\mu^4 w^\varepsilon(v_{tt}, v)\end{aligned}$$

such that

$$\begin{aligned}\varepsilon \operatorname{Im} w^\varepsilon(\mu^2 v_t, v) = &-\mu^2 \left(\frac{|\xi|^2}{2} + V(x) \right) w^\varepsilon + O(\varepsilon^2\mu^2) \\ &+ \frac{\varepsilon^2\mu^4}{2} \operatorname{Re} w^\varepsilon(v_{tt}, v).\end{aligned}$$

Since, for $r, s \in \mathbb{R}^d$,

$$\big(\overline{v}(r,t)v(s,t)\big)_{tt} = \overline{v}(r,t)_{tt} v(s,t) + 2\overline{v}_t(r,t)v_t(s,t) + \overline{v}(r,t)v_{tt}(s,t)$$

we conclude that

$$\operatorname{Re} w^\varepsilon(v_{tt}, v) = \frac{1}{2} w^\varepsilon(v,v)_{tt} - w^\varepsilon(v_t, v_t),$$

and thus

$$\begin{aligned}\frac{\varepsilon^2\mu^4}{2} \operatorname{Re} w^\varepsilon(v_{tt}, v) = &\frac{\varepsilon^2\mu^4}{4} w^\varepsilon(v,v)_{tt} \\ &- \mu^2 w^\varepsilon \left(\frac{\varepsilon\mu}{\sqrt{2}} v_t, \frac{\varepsilon\mu}{\sqrt{2}} v_t \right).\end{aligned}$$

We obtain as $\varepsilon \to 0$

$$\varepsilon \mathrm{Im}\, w^\varepsilon(\mu^2 v_t, v) \overset{\varepsilon\to 0}{\to} -\mu^2 \left(\frac{|\xi|^2}{2} + V(x)\right) w^0 - \mu^2 w^{(1)},$$

where

$$w^{(1)} := \text{w–}\lim_{\varepsilon\to 0} w^\varepsilon \left(\frac{\varepsilon\mu}{\sqrt{2}} v_t^{\varepsilon,\mu}, \frac{\varepsilon\mu}{\sqrt{2}} v_t^{\varepsilon,\mu}\right). \tag{2.24}$$

Clearly, $w^{(1)}$ exists as a positive measure if the initial energy $E_I^{\varepsilon,\mu}$ is uniformly bounded as $\varepsilon \to 0$.

LEMMA 2.4. *Let $E_I^{\varepsilon,\mu} \le L$ for $\varepsilon \to 0$ and let $\mu > 0$ be constant. Then*

$$\left(1 + \mu^2 \left(\frac{|\xi|^2}{2} + V(x)\right)\right) w_t^0 + \left\{\frac{1}{2}|\xi|^2 + V(x),\ w^0\right\} + \mu^2 w_t^{(1)} = 0,$$

$$w^0(t=0) = w^0[v_I^{\varepsilon,\mu}].$$

We are thus left with calculating $w^{(1)}$.

Therefore we shall apply the homogenization theory for systems developed in [GMMP]. We start by defining the new variables

$$q := i\sqrt{V(x)}v, \quad r := \frac{\varepsilon}{\sqrt{2}}\mu v_t, \quad s := \frac{\varepsilon}{\sqrt{2}}\nabla v \tag{2.25}$$

and rewrite (2.1) as the system

$$\varepsilon \begin{pmatrix} q \\ r \\ s \end{pmatrix}_t + i \begin{pmatrix} 0 & -\frac{\sqrt{2}}{\mu}\sqrt{V} & 0 \\ -\frac{\sqrt{2}}{\mu}\sqrt{V} & -\frac{2}{\mu^2} & i\frac{\varepsilon}{\mu}\,\mathrm{div}_x \\ 0 & i\frac{\varepsilon}{\mu}\nabla_x & 0 \end{pmatrix} \begin{pmatrix} q \\ r \\ s \end{pmatrix} = 0, \tag{2.26}$$

$$q(t=0) = i\sqrt{V(x)}v_I^{\varepsilon,\mu}, \quad r(t=0) = \frac{\varepsilon}{\sqrt{2}}\mu p_I^{\varepsilon,\mu}, \quad s(t=0) = \frac{\varepsilon}{\sqrt{2}}\nabla v_I^{\varepsilon,\mu}, \tag{2.27}$$

with the symbol matrix

$$P^\mu(x,\xi) := \begin{pmatrix} 0 & -\frac{\sqrt{2V(x)}}{\mu} & 0 \\ -\frac{\sqrt{2V(x)}}{\mu} & -\frac{2}{\mu^2} & -\frac{1}{\mu}\xi^T \\ 0 & -\frac{1}{\mu}\xi & 0 \end{pmatrix}. \tag{2.28}$$

Then (2.26) reads

$$\varepsilon\psi_t + iP^\mu(x, \varepsilon D)^W \psi = 0, \qquad \psi(t=0) = \psi_I^{\varepsilon,\mu}, \tag{2.29}$$

where we set $\psi = (q,\ r,\ s)$ with $\psi_I^{\varepsilon,\mu}$ defined by (2.27), $D = -i\nabla_x$, and the superscript "W" denotes the Weyl operator which in (2.29) agrees with the operator generated by P^μ as left symbol matrix. Here we wrote (2.29) with the Weyl operator in accordance with [GMMP].

Since $P^\mu(x,\xi)$ is pointwise symmetric, $P^\mu(x,\varepsilon D)^W$ is formally self-adjoint (self-adjointness is easily concluded from the assumed regularity of $V(x)$) and, then, $e^{\varepsilon,\mu} := |\psi|^2$ is an $L^1(\mathbb{R}^d)$-conserved quantity; in fact,

$$E^{\varepsilon,\mu} = \int_{\mathbb{R}^d} e^{\varepsilon,\mu}(x,t)dx, \tag{2.30}$$

where $E^{\varepsilon,\mu}$ is the total energy defined in (2.7).

We can now define the Wigner matrix

$$W^\varepsilon(t) := \begin{pmatrix} w^\varepsilon(q,q) & w^\varepsilon(q,r) & w^\varepsilon(q,s_1) & \cdots & w^\varepsilon(q,s_d) \\ w^\varepsilon(r,q) & w^\varepsilon(r,r) & w^\varepsilon(r,s_1) & \cdots & w^\varepsilon(r,s_d) \\ w^\varepsilon(s_1,q) & w^\varepsilon(s_1,r) & w^\varepsilon(s_1,s_1) & \cdots & w^\varepsilon(s_1,s_d) \\ \vdots & \vdots & \vdots & & \vdots \\ w^\varepsilon(s_d,q) & w^\varepsilon(s_d,r) & w^\varepsilon(s_d,s_1) & \cdots & w^\varepsilon(s_d,s_d) \end{pmatrix} \tag{2.31}$$

and conclude, as for the scalar case,

$$W^\varepsilon \rightharpoonup W^0 \quad \text{in } L^\infty\left(\mathbb{R}_t;\ S'(\mathbb{R}^d_x \times \mathbb{R}^d_\xi)^{d+2}\right), \tag{2.32}$$

where the hermitian matrix W^0 is positive definite in the sense of measures; i.e.,

$$\xi^T W^0 \xi \in L^\infty\left(\mathbb{R}_t;\ \mathcal{M}^+(\mathbb{R}^d_x \times \mathbb{R}^d_\xi)\ \right) \quad \forall \xi \in \mathbb{R}^d.$$

($\mathcal{M}^+$ denotes the space of positive measures.)

The result from the theory in [GMMP], which we shall restate here, requires the following assumptions on the matrix symbol $P^\mu(x,\xi)$:

(A1) (i) There exists a closed subset E of $\mathbb{R}^d_x \times \mathbb{R}^d_\xi$ such that, for every $(x,\xi) \notin E$, the eigenvalues of $P^\mu(x,\xi)$ can be ordered as follows:

$$\lambda_1(x,\xi) < \cdots < \lambda_l(x,\xi),$$

where, for $1 \le k \le l$, the multiplicity of λ_k does not depend on $(x,\xi) \notin E$.

(ii) For $1 \le k \le l$, the Hamiltonian flow of λ_k leaves invariant the set

$$\Omega = (\mathbb{R}^d_x \times \mathbb{R}^d_\xi) \setminus E.$$

(iii) E is a null set of the measure $w^0_I = \operatorname{tr}(W^0_I)$.

For $1 \le k \le l$, we denote by $\Pi_q(x,\xi)$ the orthogonal projection of $\mathbb{C}^d$ on the eigenspace associated with $\lambda_k(x,\xi)$.

(A2) $\exists \sigma \in \mathbb{R}$: $P^\mu \in S^\sigma(\mathbb{R}^d)^{d+2\times d+2}$ uniformly in ε, which means that for all $\alpha,\beta \in \mathbb{N}_0$ there exists $C_{\alpha,\beta}$ such that for all $l,k \in \{1,\dots,d\}$ and for all $\varepsilon \in (0,\varepsilon_0]$ we have

$$\left| \frac{\partial^{\alpha+\beta}}{\partial x_k^\alpha \partial \xi_l^\beta} P^\mu(x,\xi) \right| \le C_{\alpha,\beta}(1+|\xi|)^{\sigma-\beta}$$

for all $(x,\xi) \in \mathbb{R}^d_x \times \mathbb{R}^d_\xi$.

For the convergence of the energy density $e^{\varepsilon,\mu}$, we also need more assumptions on the initial data $\psi_I^{\varepsilon,\mu}$:

(A3) $\psi_I^{\varepsilon,\mu}$ is bounded in $L^2(\mathbb{R}^d_x)^{d+2}$, ε-oscillatory, and compact at infinity, which means that, for every continuous compactly supported function φ on $\mathbb{R}^d$,

$$\overline{\lim_{\varepsilon\to 0}} \int_{|\xi|\geq R/\varepsilon} \left|\widehat{\varphi\psi}_I^{\varepsilon,\mu}(\xi)\right|^2 \to 0 \quad \text{as } R\to+\infty, \tag{2.33}$$

respectively,

$$\overline{\lim_{\varepsilon\to 0}} \int_{|x|\geq R} |\psi_I^{\varepsilon,\mu}(x)|^2 dx \to 0 \quad \text{as } R\to+\infty. \tag{2.34}$$

We state the main result of [GMMP].

LEMMA 2.5. *Let $P^\mu(x,\xi)$ be essentially self-adjoint on $L^2(\mathbb{R}^d)^{d+2}$ and satisfy* (A1), (A2), *and let $\psi_I^{\varepsilon,\mu}$ satisfy* (A3). *Let $\{.,.\}$ denote the Poisson bracket* (2.19).

(i) *For $1\leq k\leq l$, we denote by $w_k^0(t)$ the continuously t-dependent positive scalar measure on $\mathbb{R}^d_x\times\mathbb{R}^d_\xi$ defined by*

$$\begin{aligned} \frac{\partial}{\partial t} w_k^0 + \{\lambda_k, w_k^0\} &= 0 \quad \text{on } \mathbb{R}_t\times\Omega,\\ w_k^0(t=0) &= tr\,(\Pi_k W_I^0) \quad \text{on } \Omega,\\ w_k^0(t,E) &= 0, \qquad t\in\mathbb{R}. \end{aligned} \tag{2.35}$$

Then the scalar Wigner transform of $\psi^\varepsilon(t)$, defined by $w^\varepsilon(x,\xi,t) := tr\, W^\varepsilon(t)$ (which is defined in (2.31)), *converges locally uniformly in t to*

$$w^0(x,\xi,t) = \sum_{k=1}^{l} w_k^0(x,\xi,t), \tag{2.36}$$

and $n^\varepsilon(t,x) := |\psi^{\varepsilon,\mu}|^2$ converges locally uniform in t to

$$n^0(t,x) = \int_{\mathbb{R}^d_\xi} w^0(t,x,d\xi). \tag{2.37}$$

(ii) *For $1\leq k\leq l$, we set $F_k = [\Pi_k,\{\lambda_k,\Pi_k\}] + \frac{1}{2}\sum_{j=1}^l(\lambda_k-\lambda_j)\Pi_k\{\Pi_j,\Pi_j\}\Pi_k$; denote by W_k^0 the continuously t-dependent positive matrix-valued measure on $\mathbb{R}^d_x\times\mathbb{R}^d_\xi$ defined by*

$$\begin{aligned} \frac{\partial}{\partial t} W_k^0 + \{\lambda_k, W_k^0\} &= [W_k^0, F_k] \quad \text{on } \mathbb{R}_t\times\Omega,\\ W_k^0(t=0) &= \Pi_k W_I^0 \Pi_k \quad \text{on } \Omega,\\ W_k^0(t,E) &= 0, \qquad t\in\mathbb{R}. \end{aligned} \tag{2.38}$$

Then the Wigner matrix (2.31) *converges in $L^\infty(\mathbb{R}_t, S')$ weak - $*$ to*

$$W^0 = \sum_{k=1}^{l} W_k^0. \tag{2.39}$$

Denoting $W^0 = (W^0_{ij})_{i,j=1}^{d+2}$, we obtain $w^{(1)}$ of Lemma 2.4 as $W^0_{2,2} = w^0(r,r) = w^{(1)}$, according to the definition in (2.31).

As already mentioned (cf. (2.30)), the energy density $n^\varepsilon = |\psi^\varepsilon|^2$ is equal to the total energy of (2.1). Consequently, by (2.37) we also have convergence of the energy of (2.1), provided that $\psi_I^{\varepsilon,\mu}$ fulfills (A3).

It remains to check the above assumptions on P^μ. The eigenvalues of $P^\mu(x,\xi)$ are

$$\begin{aligned}
\lambda_1 &= -\frac{1}{\mu^2}\left(1+\sqrt{1+\mu^2(|\xi|^2+2V(x))}\right),\\
\lambda_2 &= 0,\\
\lambda_3 &= -\frac{1}{\mu^2}\left(1-\sqrt{1+\mu^2(|\xi|^2+2V(x))}\right),
\end{aligned}$$

where λ_2 is of multiplicity d. If we now set $E = \{(x,\xi)|\xi = 0, V(x) = 0\}$, we have

$$\lambda_1(x,\xi) < \lambda_2(x,\xi) < \lambda_3(x,\xi) \quad \forall (x,\xi) \in \mathbb{R}^d_x \times \mathbb{R}^d_\xi \setminus E.$$

We now assume $w^0_I(\{(x,\xi)|\xi = 0, V(x) = 0\}) = 0$. Then (A1) is satisfied, since the Hamiltonian flows of λ_1, λ_2, and λ_3 map E into E bijectively. The corresponding projector matrices are

$$\Pi_1(x,\xi) = \frac{\mu^2}{2(\theta^2+\theta)}\begin{pmatrix} 2V & \frac{\sqrt{2V}}{\mu}(1+\theta) & \sqrt{2V}\xi^T \\ \frac{\sqrt{2V}}{\mu}(1+\theta) & \frac{1}{\mu^2}(1+\theta)^2 & \frac{1}{\mu}(1+\theta)\xi^T \\ \sqrt{2V}\xi & \frac{1}{\mu}(1+\theta)\xi & \xi\otimes\xi \end{pmatrix},$$

$$\Pi_2(x,\xi) = \begin{pmatrix} \sum_{k=1}^d \frac{\xi_k^2}{\xi_k^2+2V} & 0 & -\frac{\sqrt{2V}\xi_1}{\xi_1^2+2V} & \cdots & -\frac{\sqrt{2V}\xi_d}{\xi_d^2+2V} \\ 0 & 0 & 0 & \cdots & 0 \\ -\frac{\sqrt{2V}\xi_1}{\xi_1^2+2V} & 0 & \frac{2V}{\xi_1^2+2V} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \\ -\frac{\sqrt{2V}\xi_d}{\xi_d^2+2V} & 0 & 0 & & \frac{2V}{\xi_d^2+2V} \end{pmatrix},$$

$$\Pi_3(x,\xi) = \frac{\mu^2}{2(\theta^2-\theta)}\begin{pmatrix} 2V & \frac{\sqrt{2V}}{\mu}(1-\theta) & \sqrt{2V}\xi^T \\ \frac{\sqrt{2V}}{\mu}(1-\theta) & \frac{1}{\mu^2}(1-\theta)^2 & \frac{1}{\mu}(1-\theta)\xi^T \\ \sqrt{2V}\xi & \frac{1}{\mu}(1-\theta)\xi & \xi\otimes\xi \end{pmatrix}.$$

Here we denoted $\theta = \theta^\mu(x,\xi) := \sqrt{1+\mu^2(|\xi|^2+2V(x))}$. (A2) holds by the smoothness assumption on $V(x)$. We leave the (very tedious) explicit calculation of the right-hand sides of the transport equations (2.38) to the interested reader.

In the case $\mu \to \infty$, the transport equation (2.35) reads, for $1 \le k \le 3$,

$$\frac{\partial}{\partial t} w_k^0 = 0, \qquad w_k^0(t=0) = \operatorname{tr}\,(\Pi_k W_I^0),$$

since for the derivatives of the eigenvalues of $P^\mu(x,\xi)$

$$\begin{aligned}
\nabla_x \lambda_{1,3} &= \frac{\mp \nabla_x V}{\sqrt{1+\mu^2(|\xi|^2+2V)}},\\
\nabla_\xi \lambda_{1,3} &= \frac{\pm \xi}{\sqrt{1+\mu^2(|\xi|^2+2V)}},
\end{aligned}$$

$$\nabla_x \lambda_2 = \nabla_\xi \lambda_2 = 0$$

we have as $\mu \to \infty$

$$\lim_{\mu\to\infty} \nabla_x \lambda_k(x,\xi) = \lim_{\mu\to\infty} \nabla_\xi \lambda_k(x,\xi) = 0, \qquad k = 1,2,3.$$

Since also $\lim_{\mu\to\infty} \lambda_k(x,\xi) = 0$ holds for $k = 1,2,3$, (2.38) in this case is

$$\frac{\partial}{\partial t} W_k^0 = 0, \qquad W_k^0(t=0) = \Pi_k W_I^0 \Pi_k,$$

and the Wigner measure matrix remains constant in time.

3. Energy estimates and the consistency-stability method. We now consider the inhomogeneous version of the scheme (1.3):

$$\varepsilon \frac{u^{n+1}(x) - u^{n-1}(x)}{2\Delta t} = i\frac{\varepsilon^2}{2} \frac{u^n(x+\Delta x) - (u^{n+1}(x) + u^{n-1}(x)) + u^n(x-\Delta x)}{(\Delta x)^2} \tag{3.1}$$

$$- iV(x)\frac{u^{n+1}(x) + u^{n-1}(x)}{2} + if^n(x), \quad x \in \mathbb{R}, \quad n \in \mathbb{Z}$$

$$u^0(x) = u_I^\varepsilon(x), \qquad x \in \mathbb{R} \tag{3.2}$$

$$u^1(x) = \tilde{u}_I^\varepsilon(x), \qquad x \in \mathbb{R}. \tag{3.3}$$

For the sake of convenience in the subsequent computation we extended (1.3) from the grid $\{j\Delta x | j \in \mathbb{Z}\}$ to $\mathbb{R}$; i.e., $u^n(j\Delta x) = u_j^n$. $f^n(x)$ denotes an inhomogeneity on the time level $t = n\Delta t$.

We set for the following

$$\delta = \frac{\Delta t}{\Delta x}, \qquad \gamma = \frac{\varepsilon \Delta t}{(\Delta x)^2} \tag{3.4}$$

and define the functional

$$\begin{aligned} E(f,g) := {} & (1+\gamma^2)\left(\|f\|_{L^2}^2 + \|g\|_{L^2}^2\right) \\ & + \delta^2 \int_{\mathbb{R}} V(x)\left(|f|^2 + |g|^2\right) dx \\ & - \operatorname{Re}\left(i\gamma(1-i\gamma)\int_{\mathbb{R}} (f(x-\Delta x) + f(x+\Delta x))\overline{g(x+\Delta x)}dx\right) \end{aligned} \tag{3.5}$$

for $f, g \in L^2(\mathbb{R};\mathbb{C})$. At first we prove the following lemma.

LEMMA 3.1.

$$\frac{1}{2}\left(\|f\|_{L^2}^2 + \|g\|_{L^2}^2\right) \le E(f,g).$$

Proof. The third term in $E(f,g)$ is clearly bounded above by $\gamma\sqrt{1+\gamma^2}(\|f\|_{L^2}^2 + \|g\|_{L^2}^2)$. Therefore

$$E(f,g) \ge \left(1 + \gamma^2 - \gamma\sqrt{1+\gamma^2}\right)\left(\|f\|_{L^2}^2 + \|g\|_{L^2}^2\right),$$

and the assertion follows since

$$1+\gamma^2-\gamma\sqrt{1+\gamma^2}=\frac{\sqrt{1+\gamma^2}}{\gamma+\sqrt{1+\gamma^2}}\geq\frac{1}{2}. \qquad \square$$

We now show that $E(u^n,u^{n+1})$ is a "kind of energy" for (3.1).

LEMMA 3.2. *Let $u^n, n=1,2,\ldots$ satisfy* (3.1). *Then*

$$\begin{aligned}E(u^n,u^{n+1})=E(u^{n-1},u^n)&+\frac{\Delta t}{\varepsilon}\mathrm{Re}\left(\int_{\mathbb{R}}f^n(x)(\overline{u^{n+1}(x)}+\overline{u^{n-1}(x)})\,dx\right)\\&+\gamma\frac{\Delta t}{\varepsilon}\mathrm{Im}\left(\int_{\mathbb{R}}f^n(x)(\overline{u^{n+1}(x)}-\overline{u^{n-1}(x)})\,dx\right).\end{aligned}\tag{3.6}$$

Proof. The assertion of the lemma follows immediately by multiplying (3.1) by the complex conjugate of $(1+i\gamma)u^{n+1}+(1-i\gamma)u^{n-1}$ and integration over $\mathbb{R}$. $\square$

In particular, for the homogeneous problem (3.1) with $f^n=0$ for all $n\in\mathbb{N}$, we conclude "energy" conservation

$$E(u^n,u^{n+1})=E(u^{n-1},u^n),\qquad n=1,2,\ldots \tag{3.7}$$

(cf. [W]) and an $L^2(\mathbb{R})$-estimate from Lemma 3.1:

$$\|u^n\|_{L^2}^2+\|u^{n+1}\|_{L^2}^2\leq E(u_I^\varepsilon,\tilde{u}_I^\varepsilon),\qquad n\in\mathbb{N}. \tag{3.8}$$

We shall now use (3.8) to derive an appropriate choice for the function $\tilde{u}_I^\varepsilon$. Therefore we use the following lemma.

LEMMA 3.3. *$E(f,g)$ can be rewritten as*

$$\begin{aligned}E(f,g)=\|f\|_{L^2}^2&+\|g\|_{L^2}^2\\&+\gamma^2\int_{\mathbb{R}}\left|g(x)-\frac{f(x-\Delta x)+f(x+\Delta x)}{2}\right|^2dx\\&+\frac{\gamma^2}{4}\int_{\mathbb{R}}|f(x+\Delta x)-f(x-\Delta x)|^2\,dx\\&-\gamma\mathrm{Im}\left(\int_{\mathbb{R}}\overline{(f(x-\Delta x)+f(x+\Delta x))}g(x)\,dx\right).\end{aligned}\tag{3.9}$$

The form (3.9) of $E(f,g)$ is easily verified by a direct computation.

We now choose

$$\tilde{u}_I^\varepsilon(x):=\frac{u_I^\varepsilon(x+\Delta x)+u_I^\varepsilon(x-\Delta x)}{2}. \tag{3.10}$$

Then (3.9) simplifies to

$$\begin{aligned}E(u_I^\varepsilon,\tilde{u}_I^\varepsilon)=\|u_I^\varepsilon\|_{L^2}^2&+\left\|\frac{u_I^\varepsilon(\,.\,+\Delta x)+u_I^\varepsilon(\,.\,-\Delta x)}{2}\right\|_{L^2}^2\\&+\gamma^2\Delta x^2\int_{\mathbb{R}}\left|\frac{u_I^\varepsilon(x+\Delta x)-u_I^\varepsilon(x-\Delta x)}{2\Delta x}\right|^2dx.\end{aligned}$$

Assuming that

$$\left\|\frac{d^l}{dx^l}u_I^\varepsilon\right\|_{L^2}=O\left(\frac{1}{\varepsilon^l}\right),\qquad l=0,1,\ldots, \tag{3.11}$$

we conclude that

$$E(u_I^\varepsilon(x), \tilde{u}_I^\varepsilon(x)) = O\left(1 + \left(\frac{\Delta t}{\Delta x}\right)^2\right) \tag{3.12}$$

and L^2-stability follows for the homogeneous problem (3.1) with (3.10) by (3.8) if $\frac{\Delta t}{\Delta x}$ is bounded, which is also required by consistency of the Dufort–Frankel scheme. We summarize in the following proposition.

PROPOSITION 3.1. *Let* (3.11) *hold (for* $l = 0$ *and* $l = 1$*). Then the solution* $u^n = u^n(x)$ *of the homogeneous version (i.e.,* $f^n(x) = 0$*,* $n = 1, 2, \ldots$*) of* (3.1) *with* $\tilde{u}_I^\varepsilon$ *given by* (3.10) *satisfies*

$$\|u^n\|_{L^2} = O\left(1 + \frac{\Delta t}{\Delta x}\right) \tag{3.13}$$

uniformly as $\varepsilon \to 0^+$*. In particular, the scheme is* L^2*-stable if* $\frac{\Delta t}{\Delta x}$ *is bounded as* $\Delta t \to 0$*,* $\Delta x \to 0$*.*

Now we expand the recursion (3.6) in the form

$$E(u^n, u^{n+1}) = E(u^0, u^1) + \frac{\Delta t}{\varepsilon} \sum_{k=1}^{n} A_k,$$

collecting the two last terms on the right-hand side of (3.6) as A_n. Rewriting the terms corresponding to the last term in (3.6) as

$$\begin{aligned}
&\sum_{k=1}^{n} f^k(\overline{u^{k+1}} - \overline{u^{k-1}}) \\
&= \sum_{k=2}^{n-1} (f^{k-1} - f^{k+1})\overline{u^k} + f^{n-1}\overline{u^n} + f^n\overline{u^{n+1}} - f^1\overline{u^0} - f^2\overline{u^1}
\end{aligned}$$

we estimate $E(u^n, u^{n+1})$ as

$$\begin{aligned}
E(u^n, u^{n+1}) \le E(u^0, u^1) &+ \Delta t \sum_{k=1}^{n} \left(\frac{1}{2}\|u^{k+1}\|_{L^2}^2 + \frac{1}{2}\|u^{k-1}\|_{L^2}^2 + \left\| \frac{f^k}{\varepsilon} \right\|_{L^2}^2 \right) \\
&+ \gamma \frac{\Delta t}{2} \left(\|u^n\|_{L^2}^2 + \|u^{n+1}\|_{L^2}^2 + \left\| \frac{f^{n-1}}{\varepsilon} \right\|_{L^2}^2 + \left\| \frac{f^n}{\varepsilon} \right\|_{L^2}^2 \right. \\
&\qquad \left. + \|u^0\|_{L^2}^2 + \|u^1\|_{L^2}^2 + \left\| \frac{f^1}{\varepsilon} \right\|_{L^2}^2 + \left\| \frac{f^2}{\varepsilon} \right\|_{L^2}^2 \right) \\
&+ \gamma \frac{2\Delta t}{\varepsilon} \Delta t \sum_{k=1}^{n-2} \frac{1}{2} \left(\left\| \frac{f^k - f^{k+2}}{2\Delta t} \right\|_{L^2}^2 + \|u^k\|_{L^2}^2 \right).
\end{aligned}$$

By Lemma 3.1, and as $\gamma \Delta t = \varepsilon \delta^2$, we obtain for $n\Delta t \le T$

$$\begin{aligned}
E(u^n, u^{n+1}) \le \left(1 + \frac{\varepsilon\delta^2}{2}\right) E(u^0, u^1) &+ \frac{\varepsilon\delta^2}{2} E(u^n, u^{n+1}) + \Delta t \sum_{k=1}^{n} E(u^{k-1}, u^k) \\
&+ \left(T + \frac{\varepsilon\delta^2}{2}\right) \max_{k=1,\ldots,n} \left\| \frac{f^k}{\varepsilon} \right\|_{L^2}^2 + T\,\delta^2 \max_{k=1,\ldots,n-2} \left\| \frac{f^k - f^{k+2}}{2\Delta t} \right\|_{L^2}^2.
\end{aligned}$$

Assuming that Δt is small enough so $\delta = \Delta t/\Delta x$ remains bounded, we have by the discrete Gronwall lemma

$$E(u^n, u^{n+1}) \le CE(u^0, u^1) + C \max_{k=1,\dots,n-1} \left\| \frac{f^k}{\varepsilon} \right\|_{L^2}^2 + C \max_{k=1,\dots,n-3} \left\| \frac{f^k - f^{k+2}}{2\Delta t} \right\|_{L^2}^2, \tag{3.14}$$

with $C = C(T)$.

THEOREM 3.1. *Let the exact solution u^ε of* (1.1) *satisfy* (1.7) *and let $\tilde{u}_I^\varepsilon$ be chosen as in* (3.10). *Then*

$$\|u^n - u^\varepsilon(n\Delta t)\|_{L^2(\mathbb{R})}^2 = O\left(\frac{\Delta t^2}{\varepsilon^3}\right) + O\left(\frac{\Delta x^2}{\varepsilon^3}\right) + O\left(\frac{\delta^2}{\varepsilon}\right). \tag{3.15}$$

Proof. Inserting the local discretization error obtained in (1.8) as inhomogeneity into (3.6), we obtain from (3.14):

$$\begin{aligned} &E(u^n - u^\varepsilon(n\Delta t), u^{n+1} - u^\varepsilon((n+1)\Delta t)) \\ &\le\ C\ E(u^0 - u_I^\varepsilon, u^1 - u^\varepsilon(\Delta t)) \\ &+ C\left(\frac{\Delta t^2}{\varepsilon^3} + \frac{\Delta x^2}{\varepsilon^3} + \frac{1}{\varepsilon}\left(\frac{\Delta t}{\Delta x}\right)^2 + \frac{\Delta t^2}{\varepsilon^3}\left(\frac{\Delta t}{\Delta x}\right)^2\right), \end{aligned} \tag{3.16}$$

and the statement then follows from Lemma 3.1 and (3.12). ∎

The estimate (3.15) implies the same bound for the errors of all observables $|E_a^\varepsilon[u^\varepsilon(n\Delta t)] - E_a^\varepsilon[u^n]|$, $a \in S$. We see that in order to obtain $L^2(\mathbb{R})$-convergence of the ("discrete") solution of the Dufort–Frankel scheme to the ("continuous") solution of the Schrödinger equation by Theorem 3.1 we need

$$\frac{\Delta t^2}{\varepsilon^3} \to 0, \quad \frac{\Delta x^2}{\varepsilon^3} \to 0, \quad \frac{\delta^2}{\varepsilon} \to 0. \tag{3.17}$$

4. Calculation of the Wigner measure of the Dufort–Frankel scheme. In this section we take a different approach to analyzing the convergence behavior of the Dufort–Frankel scheme and of the associated observables. We shall calculate its Wigner measure, as we already did with the modified equation (2.1) in section 2, and determine conditions on the mesh such that the Wigner measure of the Dufort–Frankel scheme is identical to the Wigner measure of the Schrödinger equation. By this method we will see that weaker conditions on the grid than those determined in section 3 suffice to obtain accurate observables.

To apply the Wigner measure approach to the solution of the scheme, we need uniform (in ε) L^2-stability of the scheme. We assume from now on that $\frac{\Delta t}{\Delta x} \to \delta_0 < \infty$ as $\Delta t \to 0$ and $\Delta x \to 0$ and choose (3.10) as second initial layer $\tilde{u}_I^\varepsilon$. Under these conditions the (uniform) L^2-stability of the scheme is provided by Proposition 3.1.

We consider the scheme in the form (1.9). To be able to apply Lemma 2.2, we need to rewrite the scheme in a pseudodifferential way. We formulate the x-direction part of the finite difference operator as a discrete Weyl operator, which is, according to (2.12), generated by the symbol

$$Q_{\Delta x,\varepsilon}(x,\xi) := -\frac{1}{2}\left(\frac{\varepsilon}{\Delta x}\right)^2 \left(e^{i\frac{\Delta x}{\varepsilon}\xi} - 2 + e^{-i\frac{\Delta x}{\varepsilon}\xi}\right) + V(x).$$

With this definition (and extending u_j^n to $\mathbb{R}$ as in the previous chapter), the scheme (1.9) reads

$$\begin{aligned}\varepsilon\frac{u_\sigma^{n+1}(x)-u_\sigma^{n-1}(x)}{2\Delta t} =& -iQ_{\Delta x,\varepsilon}\left(x,\varepsilon D\right)^W u_\sigma^n(x)\\ &-\frac{i}{2}\left(\varepsilon^2\delta^2+V\Delta t^2\right)\frac{u_\sigma^{n+1}(x)-2u_\sigma^n(x)+u_\sigma^{n-1}(x)}{\Delta t^2},\end{aligned}$$

$$x\in\mathbb{R},\qquad n\in\mathbb{Z}, \tag{4.1}$$

$$u_\sigma^0(x)=u_\sigma^I(x),\qquad x\in\mathbb{R}, \tag{4.2}$$

$$u_\sigma^1(x)=\tilde{u}_\sigma^I(x),\qquad x\in\mathbb{R}. \tag{4.3}$$

Here (and in what follows) we denote by σ the vector of the small parameters on which the solution depends: $\sigma:=(\varepsilon,\Delta x,\Delta t)$. The Weyl operator associated with the symbol $Q_{\Delta x,\varepsilon}(x,\xi)$ is

$$Q_{\Delta x,\varepsilon}(x,\varepsilon D)^W\varphi=-\frac{\varepsilon^2}{2}\frac{\varphi(x+\Delta x)-2\varphi(x)+\varphi(x-\Delta x)}{\Delta x^2}+V(x)\varphi(x).$$

It was shown in [MPP] that

$$Q_{\Delta x,\varepsilon}\psi\overset{\varepsilon,\Delta x\to 0}{\longrightarrow}Q\psi\quad\forall\,\psi\in S(\mathbb{R}_x^d\times\mathbb{R}_\xi^d) \tag{4.4}$$

holds if and only if $\Delta x/\varepsilon\to 0$, where $Q(x,\xi)=\frac{1}{2}|\xi|^2+V$ is the generating symbol of the Weyl operator of the continuous equation (1.1). If $\Delta x/\varepsilon\to 1/\rho$, for some $\rho>0$, then

$$Q_{\Delta x,\varepsilon}\to Q_\rho:=-\frac{1}{2}\rho^2(e^{-i\xi/\rho}-2+e^{i\xi/\rho})+V(x),$$

in the sense of (4.4), independently of ε and Δx. In the case $\Delta x/\varepsilon\to\infty$, the limit of $Q_{\Delta x,\varepsilon}$ does not approximate Q in any way and therefore no reasonable numerical results can be expected in this case, which will not be investigated further. For a detailed review on discrete pseudodifferential operators we refer to [MP], [M1], [M2], [M3].

We use the Wigner transform (2.10) and define, for $n,m\in\mathbb{Z}$, $w^{n,m}:=w^\varepsilon(u_\sigma^n,u_\sigma^m)$ and $w^n:=w^\varepsilon(u_\sigma^n,u_\sigma^n)$. In order to obtain the evolution equation for the Wigner transform, we observe that

$$\begin{aligned}&\varepsilon\frac{w^{n+1}-w^{n-1}}{2\Delta t}\\ &=w^\varepsilon\left(\varepsilon\frac{u_\sigma^{n+1}-u_\sigma^{n-1}}{2\Delta t},u_\sigma^{n+1}\right)+w^\varepsilon\left(u_\sigma^{n-1},\varepsilon\frac{u_\sigma^{n+1}-u_\sigma^{n-1}}{2\Delta t}\right).\end{aligned} \tag{4.5}$$

Using the identity (4.1), and applying Lemma 2.2, we obtain

$$\begin{aligned}&\frac{w^{n+1}-w^{n-1}}{2\Delta t}\\ &=-i\left(\frac{\Delta t}{\varepsilon}Q_{\Delta x,\varepsilon}-\eta\right)\frac{w^{n,n+1}-w^{n-1,n}}{\Delta t}-\frac{1}{2}\{Q_{\Delta x,\varepsilon},w^{n,n+1}+w^{n-1,n}\}\\ &\quad-i\eta\frac{w^{n+1}-w^{n-1}}{2\Delta t}\end{aligned}$$

$$
\begin{aligned}
&- \frac{1}{4}\{V, w^{n+1} + w^{n-1} - 2(w^{n,n+1} + w^{n-1,n})\} + O(\varepsilon) \\
&- \frac{1}{2}\Bigg\{V, \frac{1-\eta^2+2i\eta}{1+\eta^2} w^{n-1} \\
&\quad + \frac{2i-2\eta}{1+\eta^2}\Big(\Big(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\Big) w^{n-1,n} - i\frac{\Delta t}{2}\{Q_{\Delta x,\varepsilon} - V, w^{n-1,n}\}\Big) \\
&\quad - \Delta t \frac{1-\eta^2+2i\eta}{(1+\eta^2)^2}\Bigg(\{V, w^{n-1}\} \\
&\quad + i\left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) \partial_x V \left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) \partial_\xi w^{n-1,n}\Bigg)\Bigg\},
\end{aligned}
$$

where we denoted

$$
\eta = \eta(x) := \gamma + \frac{\Delta t}{\varepsilon} V(x) = \frac{\varepsilon}{\Delta t}\delta^2 + \frac{\Delta t}{\varepsilon} V(x)
$$

and used (4.1) to express $w^{n-1,n+1}$. Now we set $a^n := \operatorname{Im} w^{n,n+1}$ and $b^n := \operatorname{Re} w^{n,n+1}$, and obtain as the real part of the above equation

$$
\begin{aligned}
\frac{w^{n+1} - w^{n-1}}{2\Delta t} &= \left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) \frac{a^n - a^{n-1}}{\Delta t} \\
&\quad - \frac{1}{2}\{Q_{\Delta x,\varepsilon} - V, b^n + b^{n-1}\} - \frac{1}{4}\left\{V, w^{n+1} + w^{n-1}\right\} \\
&\quad - \frac{1}{2}\Bigg\{V, \frac{2}{1+\eta^2}\Bigg(\frac{1-\eta^2}{2} w^{n-1} \\
&\qquad - \eta\left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) b^{n-1} - \left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) a^{n-1} \\
&\qquad - \frac{\Delta t}{2}\left(\eta\{Q_{\Delta x,\varepsilon} - V, a^{n-1}\} + \{Q_{\Delta x,\varepsilon} - V, b^{n-1}\}\right)\Bigg) \\
&\qquad - \frac{\Delta t}{(1+\eta^2)^2}\Bigg((1-\eta^2)\{V, w^{n-1}\} \\
&\qquad - (1-\eta^2)\partial_x V \left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) \partial_\xi a^{n-1} \\
&\qquad - 2\eta\, \partial_x V \left(\frac{\Delta t}{\varepsilon} Q_{\Delta x,\varepsilon} - \eta\right) \partial_\xi b^{n-1}\Bigg)\Bigg\} + O(\varepsilon).
\end{aligned} \tag{4.6}
$$

We denote

$$
W^0(t) := \text{w–}\lim_{\sigma\to 0}\ w^\varepsilon(u^n_\sigma, u^n_\sigma)
$$

for $t = t_n$ fixed (where the limit is understood to hold for appropriate subsequences) and denote by $w^0(t)$ the Wigner measure of the Schrödinger equation (1.1), (1.2) (in one dimension):

$$
w^0(t) := \text{w–}\lim_{\sigma\to 0}\ w^\varepsilon(u^\varepsilon(t), u^\varepsilon(t)).
$$

THEOREM 4.1. *For the scheme* (4.1) *let* $\sigma \to 0$, $\frac{\Delta x}{\varepsilon} \to 1/\rho_0 < \infty$, *and* $\frac{\Delta t}{\Delta x} \to \delta_0 < \infty$. *Furthermore, let* $\gamma = \frac{\varepsilon \Delta t}{\Delta x^2} \to \gamma_0 < \infty$ *and set* $\tilde{u}^I_\sigma = \tilde{u}^\varepsilon_I$ *with definition* (3.10).

Case 1. $\Delta t/\varepsilon \to 0$.

Also let $\Delta x/\varepsilon \to 0$. *Then any Wigner measure* W^0 *of scheme* (4.1)–(4.3) *satisfies*

$$W^0_t + \{Q, W^0\} = 0, \qquad t \in \mathbb{R}, \tag{4.7}$$

$$W^0(t=0) = w^0[u^\varepsilon_I].$$

So the Wigner measure W^0 *of scheme* (4.1) *is the same as the Wigner measure* w^0 *of the Schrödinger equation* (1.1), (1.2).

If, on the other hand, $\Delta x/\varepsilon \to 1/\rho_0$ *for some* $0 < \rho_0 < \infty$, *then* W^0 *satisfies the above equation with* Q *replaced by* Q_{ρ_0}. *Thus the Wigner measure of the scheme is different from the Wigner measure of the continuous equation.*

Case 2. $\Delta t/\varepsilon \to \omega_0 \in (0, \infty)$.

Then there are initial data $u^\varepsilon_I \in L^2(\mathbb{R})$, *uniformly as* $\varepsilon \to 0$, *such that the Wigner measure* W^0 *of the scheme is different from the Wigner measure* w^0 *of* (1.1), (1.2).

For the proof of Theorem 4.1 we shall use the following lemma.

LEMMA 4.1. *If* $\gamma \to \gamma_0 \in [0, \infty)$ *and* $\frac{\Delta t}{\varepsilon} \to 0$, *then* $\varepsilon \frac{u^{n+1}_\sigma - u^n_\sigma}{\Delta t}$ *is bounded in* $L^2(\mathbb{R})$, *uniformly in* n, *as* $\sigma \to 0$.

Proof of Lemma 4.1. Define $v^n := \varepsilon \frac{u^{n+1}_\sigma - u^n_\sigma}{\Delta t}$. Since v^n satisfies (1.3), according to Lemma 3.1, (3.7), and (3.8)

$$\|v^n\|_{L^2} \le E(v^n, v^{n+1}) = E(v^0, v^1) \le K(\gamma)(\|v^0\|_{L^2} + \|v^1\|_{L^2}),$$

where K is bounded on compact subsets of $[0, \infty)$. We have

$$v^0 = \varepsilon \frac{u^1_\sigma - u^0_\sigma}{\Delta t} = \varepsilon \frac{\frac{u^\varepsilon_I(x+\Delta x) + u^\varepsilon_I(x-\Delta x)}{2} - u^\varepsilon_I(x)}{\Delta t}$$

by (3.10), so $\|v^0\|^2_{L^2} \le C \frac{1}{2} \frac{\varepsilon}{\Delta t} \frac{(\Delta x)^2}{\varepsilon^2} = C/\gamma$ by assumption (3.11) on u^ε_I. For v^1 we find

$$v^1 = \varepsilon \frac{u^2_\sigma - u^1_\sigma}{\Delta t} = 2\varepsilon \frac{u^2_\sigma - u^0_\sigma}{2\Delta t} + 2\varepsilon \frac{u^0_\sigma - u^1_\sigma}{2\Delta t}. \tag{4.8}$$

The second term on the right-hand side is bounded (in L^2) by C/γ, by the argument above. For the first term, using the scheme gives

$$\begin{aligned} \varepsilon \frac{u^2_\sigma - u^0_\sigma}{2\Delta t} &= i \frac{\varepsilon^2}{2} \frac{u^1_\sigma(x+\Delta x) - (u^2_\sigma(x) + u^0_\sigma(x)) + u^1_\sigma(x-\Delta x)}{(\Delta x)^2} \\ &\quad - iV(x) \frac{u^2_\sigma(x) + u^0_\sigma(x)}{2} \\ &= A(x) - i \frac{\varepsilon^2}{2} \frac{u^2_\sigma - u^0_\sigma}{\Delta x^2} - iV(x) \frac{u^2_\sigma - u^0_\sigma}{2}, \end{aligned}$$

with $A(x) := i \frac{\varepsilon^2}{4} \frac{u^0_\sigma(x+2\Delta x) - 2u^0_\sigma(x) + u^0_\sigma(x-2\Delta x)}{(\Delta x)^2} - iV(x) u^0_\sigma(x)$ bounded in L^2. The above equation is equivalent to

$$\varepsilon \frac{u^2_\sigma - u^0_\sigma}{2\Delta t} \left(1 + i\varepsilon \frac{\Delta t}{\Delta x^2} + i \frac{\Delta t}{\varepsilon} V(x)\right) = A(x).$$

So, by (4.8), $\|v^1\|_{L^2}$ is bounded uniformly and the result follows. ∎

Proof of Theorem 4.1. Since the scheme is uniformly (in ε) L^2-stable under the given conditions, the measures

$$\begin{aligned} W^0(t) &:= \text{w–}\lim_{\sigma\to 0}\ w^\varepsilon(u_\sigma^n, u_\sigma^n),\\ A^0(t) &:= \text{w–}\lim_{\sigma\to 0}\ \operatorname{Im}\{w^\varepsilon(u_\sigma^n, u_\sigma^{n+1})\},\\ B^0(t) &:= \text{w–}\lim_{\sigma\to 0}\ \operatorname{Re}\{w^\varepsilon(u_\sigma^n, u_\sigma^{n+1})\} \end{aligned}$$

(for $t = t_n$ fixed) exist, after selection of a subsequence. Assume $\Delta x/\varepsilon \to 0$. By (4.4), we then have $Q_{\Delta x,\varepsilon}(x,\xi) \to Q(x,\xi)$.

Case 1. Letting $\sigma \to 0$ in (4.6) we obtain

$$W_t^0 = -\gamma_0 A_t^0 - \{Q, B^0\} + \frac{1}{1+\gamma_0^2}\{V, B^0 - W^0 - \gamma_0 A^0\} \tag{4.9}$$

for some $\gamma_0 \in [0,\infty)$. Now observe that

$$w^\varepsilon(u_\sigma^n, u_\sigma^{n+1}) = w^\varepsilon(u_\sigma^n, u_\sigma^n) + \frac{\Delta t}{\varepsilon} w^\varepsilon\left(u_\sigma^n, \varepsilon\frac{u_\sigma^{n+1} - u_\sigma^n}{\Delta t}\right). \tag{4.10}$$

By Lemma 4.1 and (2.21), we conclude that

$$w^\varepsilon(u_\sigma^n, u_\sigma^{n+1}) - w^\varepsilon(u_\sigma^n, u_\sigma^n) \rightharpoonup 0 \tag{4.11}$$

in the case $\frac{\Delta t}{\varepsilon} \to 0$, and thus

$$B^0 \equiv W^0, \qquad A^0 \equiv 0.$$

Then from (4.9) we conclude (4.7). Also, by the choice (3.10) for $\tilde u_\sigma^I$, we have $\lim_{\sigma\to 0} w^0(u_I^\varepsilon, \tilde u_\sigma^I) = w^0[u_I^\varepsilon]$, which is real-valued, and so $B_I^0 = w^0[u_I^\varepsilon]$ and $A_I^0 = 0$.

In the case $\Delta x/\varepsilon \to 1/\rho_0$, we have $Q_{\Delta x,\varepsilon}(x,\xi) \to Q_{\rho_0}(x,\xi)$, and the same arguments hold true if Q is replaced by Q_{ρ_0} in (4.9).

Case 2. Since $\gamma = \frac{\Delta t}{\varepsilon}(\frac{\varepsilon}{\Delta x})^2$, the conditions on γ and on $\Delta x/\varepsilon$ imply that $\Delta x/\varepsilon \to 1/\rho_0$ for some $\rho_0 < \infty$ such that $Q_{\Delta x,\varepsilon}(x,\xi) \to Q_{\rho_0}(x,\xi)$. Assume now that the Wigner measure W^0 of the scheme would be the same as the one of (1.1). Then it has to satisfy $B^0 \equiv W^0 \equiv w^0$, $A^0 \equiv 0$, as we saw in the previous case. Inserting this into (4.6), after letting $\sigma \to 0$ we find

$$W_t^0 + \{Q_{\rho_0}, W^0\} = \left\{V, \omega_0 \frac{\eta_0}{1+\eta_0^2} Q_{\rho_0} W^0\right\}, \qquad t \in \mathbb{R}, \tag{4.12}$$

with $\eta_0 = \gamma_0 + \omega_0 V(x)$ for $\gamma \to \gamma_0 < \infty$, which is not the correct equation. Obviously, there are data w_I^0 such that W^0 is different from w^0, which is a contradiction. ∎

Note that the case $\Delta t/\varepsilon \to \infty$ is excluded by the assumptions, since both $\Delta t/\Delta x$ and $\Delta x/\varepsilon$ have to be bounded.

W^0 is the unique Wigner measure of scheme (4.1) if the initial data u_I^ε is chosen such that the Wigner measure $w^0[u_I^\varepsilon]$ is unique.

In Case 1, for $\Delta x/\varepsilon \to 0$, the transport equation for the Wigner measure of the scheme is identical to the one for the Wigner measure of the continuous equation, which was derived in Lemma 2.3, and the initial conditions coincide. Therefore, the Wigner measure of the scheme coincides with the Wigner measure of the original

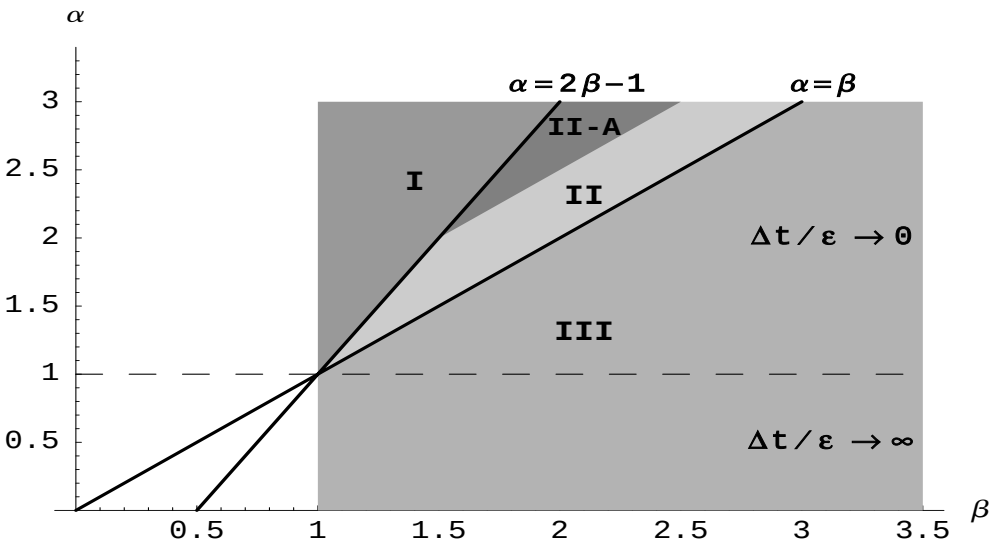

FIG. 1. *γ and δ for different exponents.*

equation. So, as a consequence of Theorem 4.1, we have convergence of the scheme under the condition that $\Delta t/\varepsilon \to 0$, $\Delta x/\varepsilon \to 0$, and $\gamma = \frac{\Delta t}{\Delta x^2}\varepsilon \to \gamma_0 < \infty$ (which also imply the stability condition $\delta < \infty$). We also have convergence of all smooth observables, since the limit of average values of observables with symbol in S can be obtained from the Wigner measure by using (2.11). These convergence conditions are much weaker than the requirements (3.17) of the "classical" consistency-stability method; however, no error estimate for the observables is provided. In all other cases, the Wigner measure is, for general initial data, different from the Wigner measure of the Schrödinger equation, and observables of the scheme are not guaranteed to converge to the exact observables.

The case $\gamma \to \infty$ is not covered by Theorem 4.1. Numerical evidence indicates that there are observables which do not converge correctly (see section 5, Figures 13–15).

To clarify the meaning of the conditions of Theorem 4.1 in terms of restrictions on the discretization steps, we consider a choice of Δt and Δx as powers of ε. So let $\Delta t = \omega_0 \varepsilon^\alpha$ and $\Delta x = \frac{1}{\rho_0}\varepsilon^\beta$, which means

$$\delta = \frac{\Delta t}{\Delta x} = \omega_0 \rho_0 \ \varepsilon^{\alpha-\beta},$$

$$\gamma = \frac{\varepsilon \Delta t}{\Delta x^2} = \omega_0 \rho_0^2 \ \varepsilon^{1+\alpha-2\beta}.$$

Figure 1 shows α versus β. We consider only the cases $\beta \geq 1$, where the "spatial convergence" (4.4) is given. The corresponding cases of Theorem 4.1 are the following:

- Region I. $\delta \to 0$ and $\gamma \to \gamma_0 < \infty$. Case 1.
- Region II. $\delta \to 0$ and $\gamma \to \infty$. No assertion in Theorem 4.1.
- Region II-A. $\delta \to 0$, $\gamma \to \infty$, and $\alpha, \beta > 1.5$, $\alpha > \beta + 0.5$. No assertion in Theorem 4.1 but convergence according to (3.17).
- Region III. $\delta \to \infty$ and $\gamma \to \infty$. No uniform L^2-stability.

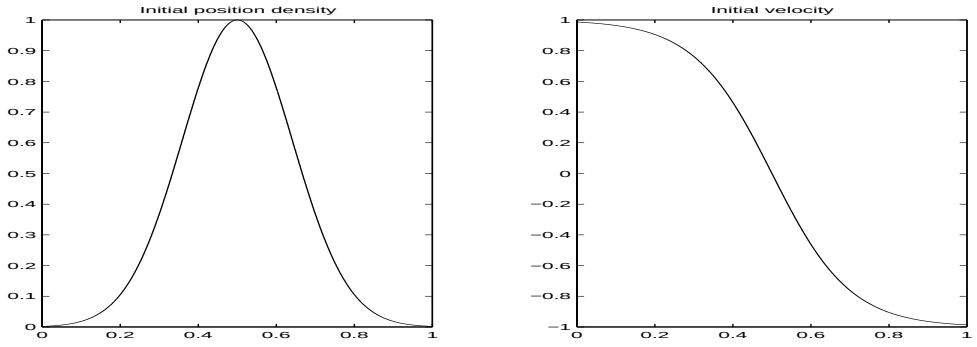

FIG. 2. *Initial condition* (5.2).

Case 2 corresponds to the point $\alpha = \beta = 1$. As already pointed out, there are choices of the spatial-temporal mesh (corresponding to Region II) which are not included in Theorem 4.1. However, among them there are cases for which the result (3.17) shows convergence (corresponding to Region II-A) and, consequently, the observables do converge correctly. Note that the mesh restrictions of (3.17) require $\alpha > 2$; that is, Δt is $O(\varepsilon^{2+r})$ for some positive r, which is computationally unaffordable.

5. Examples and numerical results. In [MPP] different numerical schemes for the linear Schrödinger equation were analyzed by the same approach as in this paper. Those are the forward and backward Euler, Crank–Nicolson, and Leap-Frog schemes. In order to be able to put our results in line with the results obtained there, we shall use the same numerical examples here as in [MPP]. We consider WKB-type initial data in one space dimension:

$$u_I^\varepsilon(x) = \sqrt{n_I(x)}\exp\Big(\frac{i}{\varepsilon}S_I(x)\Big), \qquad x \in \mathbb{R}^m, \tag{5.1}$$

with n_I and S_I real-valued and independent of ε.

We choose the following data, shown in Figure 2,

$$n_I = \big(\exp(-25(x-0.5)^2)\big)^2, \tag{5.2}$$

$$\frac{d}{dx}S_I(x) = -\tanh\left(5(x-0.5)\right) \tag{5.3}$$

on the interval $[0,1]$ (imposing periodic boundary conditions). Equation (3.10) is chosen for u_σ^1. Here the characteristics of the free Burgers equation (which is the classical limit of the velocity equation before singularities occur; cf. [GM]), given by $x(t) = v_I(s)t + s$ (where $x(0) = s \in \mathbb{R}$), intersect in finite time because the initial velocity $v_I(x) = \frac{d}{dx}S_I(x)$ is compressive. The curves which separate the areas without intersection of characteristics from the area where intersection occurs are called caustics and are given as follows (obtained from a simple calculation):

$$x_{1,2}(t) = 0.5 \pm \ln\left(\frac{\sqrt{t}+\sqrt{t-0.2}}{\sqrt{0.2}} \mp \frac{t-0.2+\sqrt{t(t-0.2)}}{t+\sqrt{t(t-0.2)}}\right),$$

emanating from the focus $t = 0.2,\ x = 0.5$.

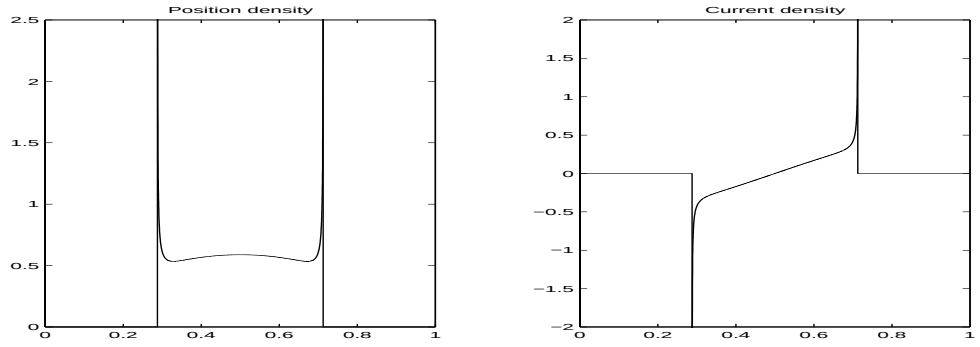

FIG. 3. n^0 *and* J^0 *at* $t = 0.54$.

Once the solution u_j^n of (1.3) has been computed, we compute its discrete position and current densities $n_\sigma,\ J_\sigma$, which are (in the one-dimensional case)

$$n_\sigma(x_j, t_n) = |u_j^n|^2, \qquad n, j \in \mathbb{Z},$$

$$J_\sigma(x_j, t_n) = \varepsilon\ \mathrm{Im}\left(\overline{u_j^n}\frac{u_{j+1}^n - u_j^n}{\Delta x}\right), \qquad n, j \in \mathbb{Z}.$$

In the continuous case, the limits of the position density (2.13) and the current density (2.14) are recovered as moments of the Wigner measure if u^ε is ε-oscillatory. (They cannot be obtained by means of (2.11), since the symbols are not in S.) Under this condition (which is defined in (2.33)), we have

$$n^\varepsilon \to n^0 := \int_{\mathbb{R}^d_\xi} w^0(x, d\xi, t)$$

and

$$J^\varepsilon \to J^0 := \int_{\mathbb{R}^d_\xi} \xi\ w^0(x, d\xi, t).$$

Again we refer to [GMMP] for more details. The ε-oscillatory condition is satisfied by the initial data (5.2)–(5.3). Although in general this property is not preserved by the Dufort–Frankel scheme, it is preserved in the constant coefficient case (which is the case in the examples presented). Thus, in this case we have $n_\sigma \overset{\sigma\to 0}{\longrightarrow} n^0$ and $J_\sigma \overset{\sigma\to 0}{\longrightarrow} J^0$, provided that the Wigner measures are identical.

n^0 and J^0 are L^1_{loc} functions, assuming infinite value on the caustics. They are shown in Figure 3. For $\varepsilon > 0$, the continuous observables n^ε and J^ε are oscillating with wavelength $\mathrm{O}(\varepsilon)$ in those areas where two or more characteristics intersect.

The following pictures show the computed densities n_σ and J_σ at time $t = 0.54$, i.e., after the caustics develop. For reference purposes the weak limits n^0 and J^0 are also depicted, using dashed lines.

Figures 4–6 refer to Case 1, $\Delta t/\varepsilon \to 0$, with $\Delta x/\varepsilon \to 0$ and $\gamma \to 0$, for $\varepsilon = 2\cdot 10^{-3}$, $1\cdot 10^{-3}$, and $0.5\cdot 10^{-3}$, respectively. The discretization parameters are $\Delta x = \varepsilon^{1.2}, \Delta t = \varepsilon^{1.5}$. We set $V = 0$. In this case the transport equations for the Wigner measure of the difference scheme and of the continuous problem coincide. The obtained solutions

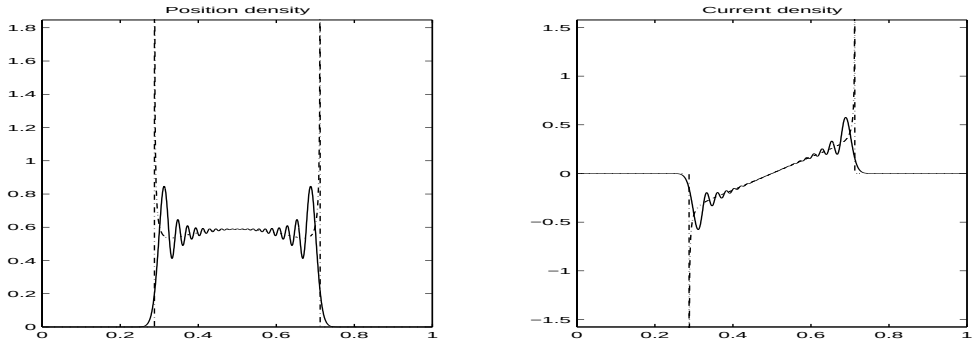

FIG. 4. $\varepsilon = 2 \cdot 10^{-3}$, $\Delta t = \varepsilon^{1.5}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.155$, $\gamma = 0.54$, $V = 0$.

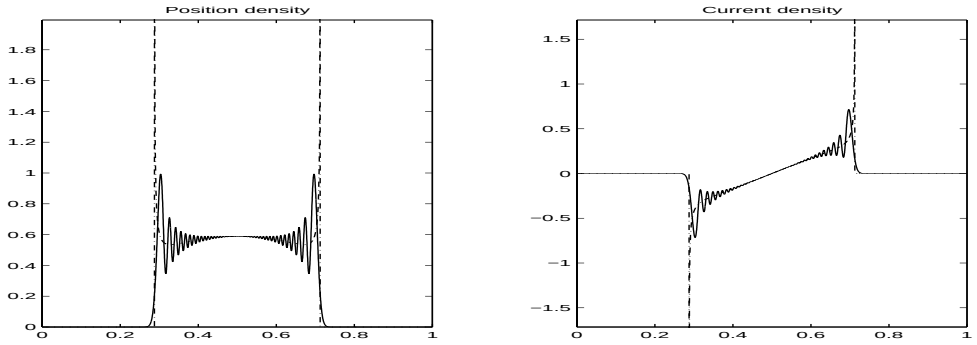

FIG. 5. $\varepsilon = 10^{-3}$, $\Delta t = \varepsilon^{1.5}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.126$, $\gamma = 0.50$, $V = 0$.

oscillate around n^0 and J^0 with wavelength ε. It can be observed that the number of oscillations doubles when ε is halved. The amplitude of the oscillations does not grow (except for the first one). There is evidence that the sequences $\{n_\sigma\}_\sigma$ and $\{J_\sigma\}_\sigma$ weakly converge to n^0 and J^0. One can say that these solutions are good approximations of n^ε and J^ε for the selected ε. We remark that the constraints of the consistency-stability analysis are not satisfied, and this choice of parameters would be discarded, according to (3.17).

Figures 7–9 correspond to Case 1 with a constant γ. The parameters are $\varepsilon = 4 \cdot 10^{-4}$, $2 \cdot 10^{-4}$, and 10^{-4}, with $\Delta x = \varepsilon^{1.2}$, $\Delta t = \varepsilon^{1.4}$, and $V = 0$. So we have $\gamma = \gamma_0 = 1$, and the Wigner measure of the scheme is still correct. The figures indicate that, as in the previous example, the sequences $\{n_\sigma\}_\sigma$ and $\{J_\sigma\}_\sigma$ weakly converge to n^0 and J^0.

Figures 10–12 show Case 1 in the situation $\Delta x/\varepsilon \to 1/\rho_0 > 0$. Here the Wigner measure of the scheme is different from the continuous one. n_σ and J_σ converge to functions with smaller support than n^0 and J^0. At fixed ε the amplitude of oscillations is larger than in the example of Figures 4–6. In this case, there is no convergence to n^0 and J^0, and n_σ, J_σ are poor approximations of n^ε and J^ε for the corresponding fixed ε.

Figures 13–15 explore the case not covered in Theorem 4.1. The consistency condition $\delta \to 0$ is satisfied, but the condition $\gamma \to \gamma_0 < \infty$ is violated. The parameters are $\varepsilon = 8 \cdot 10^{-4}$, $4 \cdot 10^{-4}$, and $2 \cdot 10^{-4}$ respectively, and $\Delta x = \varepsilon^{1.35}$, $\Delta t = \varepsilon^{1.4}$ ($\gamma = \varepsilon^{-0.3}$). The results show a smaller support than the continuous limits, similarly

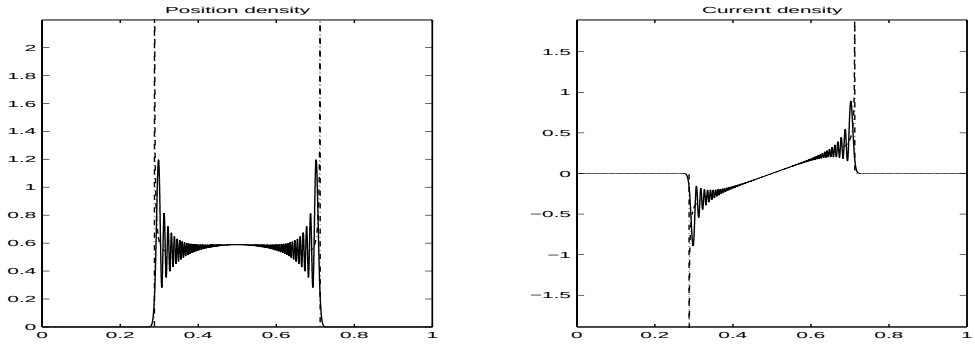

FIG. 6. $\varepsilon = 0.5 \cdot 10^{-3}$, $\Delta t = \varepsilon^{1.5}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.102$, $\gamma = 0.47$, $V = 0$.

to the previous example, and there is no convergence of n_σ and J_σ to n^0 and J^0.

The results of Theorem 4.1, being asymptotic statements, are valid only for "sufficiently small" ε. Statements like "$\Delta t/\varepsilon \to 0$" must be interpreted as "$\Delta t/\varepsilon$ small" when applied to a fixed ε. Since, in contrast to (1.1), the numerical scheme is not gauge invariant, the choice of those Δx and Δt which guarantee a good approximation depends on V.

Figures 16 and 17 show a situation of Case 1 with a positive constant potential V. We show the results for $\varepsilon = 10^{-3}$ and $\varepsilon = 5 \cdot 10^{-4}$ with the discretization parameters $\Delta t = \varepsilon^{1.3}$ and $\Delta x = \varepsilon^{1.1}$, and $V = 3$. According to the relations of the discretization parameters, the conditions for the correct Wigner measure $\Delta t/\varepsilon,\ \Delta x/\varepsilon \to 0$, $\gamma < \infty$ as $\varepsilon \to 0$ are satisfied. The computed densities are clearly poor approximations of n^ε, respectively, J^ε. Moreover, they also exhibit fast oscillations in time as well as in space, even before caustics develop, as shown in Figure 18, where the first time layers of n^σ for $0 < t < 4.78 \cdot 10^{-3}$ are plotted for $\varepsilon = 10^{-3}$. The oscillations are of almost the same wavelength as the discretization steps.

Figures 19–21 show results for increasing values of V. The obtained results deviate more and more with growing V from n^0 and J^0.

Compared to the Crank–Nicolson scheme, in Case 1 the results are of the same quality as in the case of convergence there. The choice of discretization parameters is less restrictive for the Crank–Nicolson scheme, since the conditions $\Delta t/\Delta x \to 0$ and $\gamma < \infty$ are not needed. That scheme also has the advantage of better conservation properties; it conserves total charge as well as a discrete version of the energy. However, these advantages have to be traded in for an implicit computation complexity, which is a serious disadvantage in performance critical problems.

In comparison to the Leap-Frog scheme, we also have the same quality of results in the convergent case. The Leap-Frog scheme has similar conservation properties, as it conserves some discrete analogon of the energy. The choice of the discretization steps is slightly more restrictive there, since there is the stability condition

$$\frac{\Delta t}{\Delta x^2}\varepsilon + \frac{\Delta t}{2\varepsilon} V_{\max} < \frac{1}{2}$$

to be satisfied, in comparison with the convergence condition $\gamma = \frac{\Delta t}{\Delta x^2}\varepsilon \to \gamma_0 < \infty$ of the Dufort–Frankel scheme.

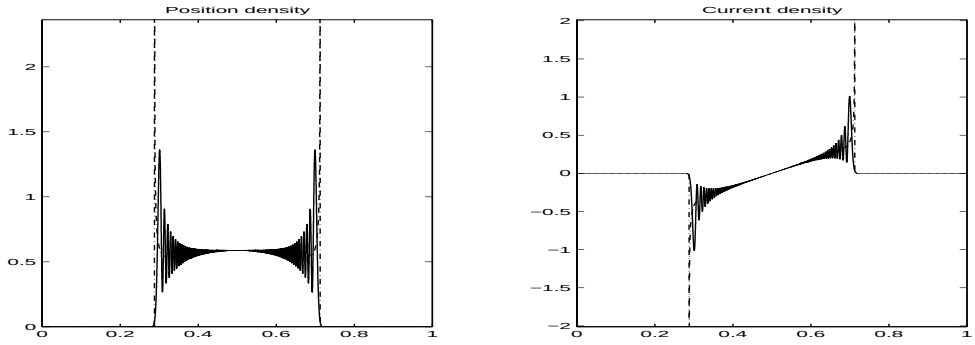

FIG. 7. $\varepsilon = 4 \cdot 10^{-4}$, $\Delta t = \varepsilon^{1.4}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.209$, $\gamma = 1$, $V = 0$.

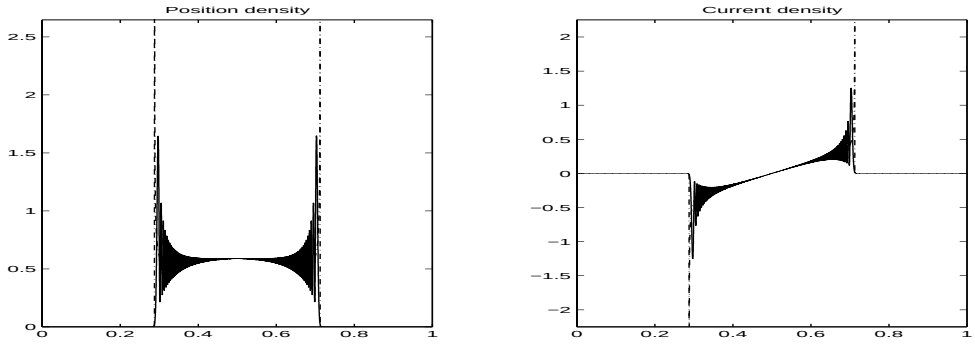

FIG. 8. $\varepsilon = 2 \cdot 10^{-4}$, $\Delta t = \varepsilon^{1.4}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.182$, $\gamma = 1$, $V = 0$.

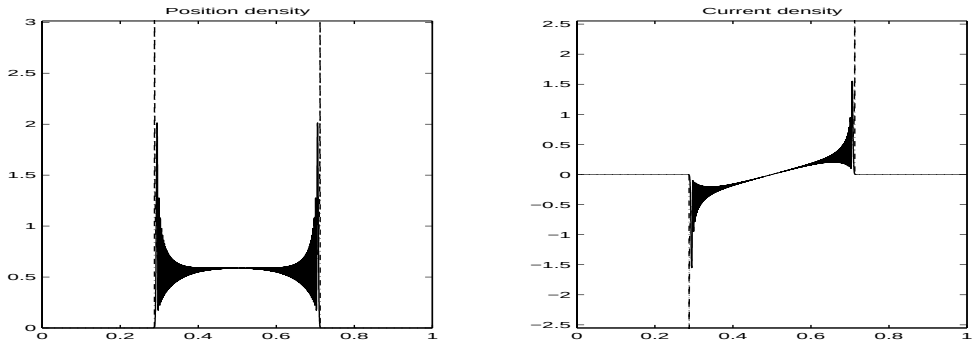

FIG. 9. $\varepsilon = 10^{-4}$, $\Delta t = \varepsilon^{1.4}$, $\Delta x = \varepsilon^{1.2}$, $\delta = 0.159$, $\gamma = 1$, $V = 0$.

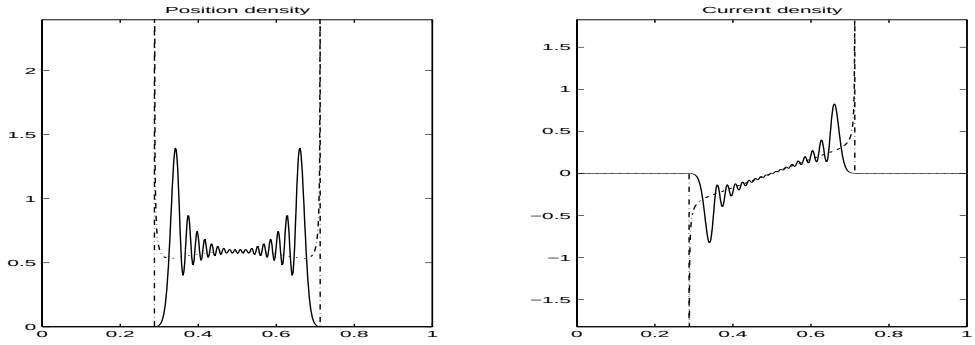

FIG. 10. $\varepsilon = 2 \cdot 10^{-3}$, $\Delta t = \varepsilon^{1.5}$, $\Delta x = \varepsilon$, $\delta = \gamma = 0.045$, $V = 0$.

TOPOLOGICAL AND ε-ENTROPY FOR LARGE VOLUME LIMITS OF DISCRETIZED PARABOLIC EQUATIONS*

GABRIEL J. LORD† AND JACQUES ROUGEMONT†

Abstract. We consider semidiscrete and fully discrete approximations of nonlinear parabolic equations in the limit of unbounded domains, which by a scaling argument is equivalent to the limit of vanishing viscosity. We define the spatial density of ε-entropy, topological entropy, and dimension for the attractors and show that these quantities are bounded. We also provide practical means of computing lower bounds on them. The proof uses the property that solutions lie in Gevrey classes of analyticity, which we define in a way that does not depend on the size of the spatial domain. As a specific example we discuss the complex Ginzburg–Landau equation.

Key words. parabolic partial differential equations, large volume, entropy, dimension

1. Introduction.

We consider the following general parabolic equation:

$$\partial_t u = \nu \Delta u + \gamma u + F(u) , \qquad x \in [-L\pi, L\pi]^d , \qquad t \geq 0 , \tag{1.1}$$

for a complex valued function $u = u(x,t)$ and bounded continuous initial condition $u(x,0) = u_0(x)$. We restrict ourselves to $L \in \mathbb{N}$ for convenience. The coefficients of (1.1) satisfy

$$\nu \in \mathbb{C} , \qquad \mathrm{Re}(\nu) > 0 , \quad \gamma \in \mathbb{R} ,$$

and we assume that $\mathrm{Re}(F)$ and $\mathrm{Im}(F)$ are real analytic functions of $\mathrm{Re}(u)$ and $\mathrm{Im}(u)$.

We are interested in the large volume limit ($L \to \infty$) of the long time dynamics (in particular the attractor) of (1.1) and its approximation by numerical schemes. In the latter case we are interested in the limit when the mesh size of our discretization is kept constant while taking the limit $L \to \infty$, thereby obtaining an infinite-dimensional but still discrete system. (See section 6 for results of upper semicontinuity of the attractors in terms of the different parameters of the problem.)

We remark that, by a scaling transformation, the large volume limit can be interpreted as a small viscosity limit. The rescaled function $v(y,t) = u(Ly,t)$ with $y \in [-\pi,\pi]^d$ satisfies the following equation:

$$\partial_t v = \frac{\nu}{L^2} \Delta v + \gamma v + F(v) ,$$

with periodic boundary conditions on $[-\pi,\pi]^d$. It is, however, easier to work with (1.1) (with periodic boundary conditions) and take $L \to \infty$. Indeed, since the problem on the full space $\mathbb{R}^d$ is well posed, we have a priori bounds for all $L < \infty$. In fact, we view the periodic boundary conditions on $[-L\pi, L\pi]^d$ for large L as an approximation of the infinite volume.

†Department of Mathematics, Heriot–Watt University, Edinburgh EH14 4AS, United Kingdom (G.J.Lord@ma.hw.ac.uk, J.Rougemont@ma.hw.ac.uk). The work of the second author was supported by the Fonds National Suisse de la Recherche Scientifique and the EPSRC GR/R29949/01.

For each fixed $L < \infty$, (1.1) generates a semiflow Φ_L^t. We discretize this time evolution spatially by truncating to a finite number of (Fourier) modes. We make this truncation by multiplying by a smooth function in Fourier space (rather than a sharp indicator function) to have better control as $L \to \infty$ (when the spectrum becomes dense). We then discretize in time using an explicit scheme inspired by [26]. This scheme is amenable to analysis and also proves to be an efficient numerical scheme for smooth initial conditions.

It is not the purpose of this paper to prove the existence of global attractors for (1.1) or for the discretizations; this has been considered in different setups in a large number of publications (see, for example, [27, 24, 3, 1, 29]). Instead, we assume the existence of a semiflow and of a family of global attractors, $\widehat{\mathcal{A}}(L)$, for the continuous and discrete problems (see Definition 3.2).

We compute bounds on statistical quantities that are valid for both the discrete and continuous systems. The first of these statistical quantities is the (Kolmogorov) ε-entropy

$$H_\varepsilon := \limsup_{L\to\infty} \frac{\log \mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L))}{(2L\pi)^d} ,$$

where $\mathcal{N}$ is the minimum number of balls of radius ε in the topology of L^∞ that are needed to cover the attractor $\widehat{\mathcal{A}}(L)$ (see Definition 3.3). We prove that H_ε is a finite number in Theorem 4.3. We thereby get a bound on the upper density of dimension

$$d_{\text{up}} = \limsup_{\varepsilon\to 0} \frac{H_\varepsilon}{\log \varepsilon^{-1}} .$$

This is to be compared with the results of Kolmogorov and Tikhomirov [15], where they obtain a bound of the same type for the set of all entire analytic functions of exponential type. This result follows from a sampling result for such functions (Proposition D.3); namely, any of these analytic functions can be reconstructed by interpolation of a discrete set of values. Although the functions on $\widehat{\mathcal{A}}$ are not entire functions, they are still determined by a discrete sampling.

Remark that it is appropriate to take the L^∞ topology, since the diameter of $\widehat{\mathcal{A}}(L)$ does not depend on L in this topology, unlike the topology of Sobolev spaces of nonzero order. We remark that the L^∞ topology is stronger than the L^2 topology, and hence our results do not follow from [9, 8, 29].

We also wish to emphasize here that the order of the limits in our definition of d_{up} is important. A more "naive" definition would be

$$\widehat{d}_{\text{up}} = \limsup_{L\to\infty} \limsup_{\varepsilon\to 0} \frac{\log \mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L))}{(2L\pi)^d \log \varepsilon^{-1}} .$$

The two limits do not commute in general; see [5]. We believe our approach is more natural from an experimental/numerical point of view, in the sense that L is a parameter that can be varied in a series of measurements/simulations made at a fixed accuracy ε.

We also consider the density of topological entropy in section 5. We show that the spatial densities satisfy the analogue of the following well-known inequalities [14, 22]:

$$\mathcal{V} \le h_{\text{top}} \le \lambda d_{\text{up}} ,$$

where $\mathcal{V}$ is the volume expansion rate, λ is the largest Lyapunov exponent, h_{top} is the topological entropy, and d_{up} is the upper Hausdorff dimension.

The paper is organized as follows. In the remainder of this section we introduce the notation for the paper. In section 2 the semidiscrete and fully discrete approximations to (1.1) are presented. In section 3, we define the density of ε-entropy, topological entropy, of upper dimension and the volume growth rate and state our assumptions on the equation and its approximations. A key result of the paper is Lemma 4.2 (proved in Appendix A), which states that the evolution has a fast local smoothing effect, a property which allows us to establish upper bounds on the ε-entropy (section 4). This is then applied in section 5 to show that the topological entropy is finite. We also show that it is bounded below by the volume expansion rate (section 5.2). We discuss the upper semicontinuity of the attractors in section 6. Technical proofs are given at the end of the paper: Appendix B contains a proof of analyticity for the fully discrete scheme, Appendix C contains a lemma on analytic functions, and Appendix D recalls some results on Gevrey and Bernstein classes.

1.1. Notation. We use the following conventions: $\overline{z}$ is the complex conjugate of z and $|z| = \sqrt{z\overline{z}}$, its modulus. A function $f = f_1 + if_2$ with both f_1 and f_2 real analytic is identified with the vector-valued function $f = (f_1, f_2)$. Its analytic extension to the complex plane has the form $(f_1 + ig_1, f_2 + ig_2)$, and we write $|f| = (|f_1|^2 + |f_2|^2 + |g_1|^2 + |g_2|^2)^{1/2}$ which, on the real axis, is equal to the modulus of the complex function f. The convolution of two functions f, g is denoted $f \star g(x) := \int f(x-y)g(y)dy$.

If u is a function of t (time) and x (space), then we consider it either as a function of two variables with values in $\mathbb{C}$, written $u(x,t) \in \mathbb{C}$, or as a function of time with values in the functions of x, written $u(t) \in \mathcal{C}_{\mathrm{b}}(\mathbb{R}^d)$ (the set of bounded continuous functions). A function in the set $\mathcal{C}_{\mathrm{per}}([-L\pi, L\pi]^d)$ of $2L\pi$-periodic continuous functions will often be identified with its lift (by periodic extension) to $\mathcal{C}_{\mathrm{b}}(\mathbb{R}^d)$.

The spaces $\mathcal{C}_{\mathrm{b}}(\mathbb{R}^d)$ and $\mathcal{C}_{\mathrm{per}}([-L\pi, L\pi]^d)$ are Banach spaces with the sup norm $\|\cdot\|_\infty$ and may be viewed as subspaces of $\big(L^\infty(\mathbb{R}^d), \|\cdot\|_\infty\big)$ and $\big(L^\infty([-L\pi, L\pi]^d), \|\cdot\|_\infty\big)$, respectively. We also make extensive use of the Gevrey class $\mathcal{G}_\alpha(C)$ and the Bernstein class $\mathcal{B}_\sigma(C)$. These are both discussed in Appendix D. If $\mathrm{Re}\big(f\big)$ and $\mathrm{Im}\big(f\big)$ belong to the Gevrey class $\mathcal{G}_\alpha(C)$, we use the notation $f \in [\mathcal{G}_\alpha(R)]^2$ (similarly for $\mathcal{B}_\sigma(C)$).

We denote by $\mathcal{T}$ the standard Fourier transform operator

$$\big(\mathcal{T} f\big)(k) \;:=\; \frac{1}{(2\pi)^d} \int e^{ik\cdot x} f(x)\, dx \;, \qquad \big(\mathcal{T}^{-1} f\big)(x) \;:=\; \int e^{-ik\cdot x} f(x)\, dk \;.$$

The Fourier series operator for $2L\pi$-periodic functions is denoted with the same symbol:

$$\big(\mathcal{T} f\big)_n \;:=\; \frac{1}{(2L\pi)^d} \int_{|x|\le L\pi} e^{in\cdot x/L} f(x)\, dx \;, \qquad \big(\mathcal{T}^{-1} f\big)(x) \;:=\; \sum_{n\in\mathbb{Z}^d} e^{-in\cdot x/L} f_n \;. \tag{1.2}$$

We introduce two different smooth cutoff functions (see Figure 1). The first of these, φ, acts in real space and serves as a weight in L^p norms in order to get bounds that do not depend on L.

DEFINITION 1.1. *Let φ be a real-space cutoff function satisfying*

$$\varphi(x) > 0 \quad \forall x \in \mathbb{R}^d, \quad \varphi(-x) \,=\, \varphi(x) \;, \quad \int \varphi(x)\, dx \,=\, 1 \;, \quad \left\| \frac{\nabla\varphi}{\varphi} \right\|_\infty \,<\, \infty \;,$$

and, moreover, φ^{-1} is a tempered distribution, i.e., $\int \varphi^{-1} f < \infty$ for any Schwartz function f.

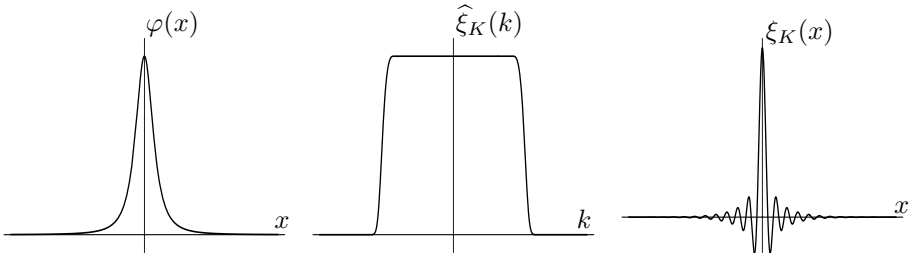

FIG. 1. *The cutoff functions of Definitions* 1.1–1.2.

Examples. The function

$$\varphi(x) \;=\; \frac{1}{(1+|C_\varphi x|^2)^{d/2+1}}$$

satisfies all of our requirements. (Here, C_φ is a normalization constant determined by the equation $\int \varphi = 1$, similarly for C_ψ below.) However, the function

$$\psi(x) \;=\; \frac{1}{\cosh(C_\psi x_1)\cdots\cosh(C_\psi x_d)}\;,$$

which has a sharper decay at infinity, cannot be used because it fails the last property; namely, $\cosh(x)$ is not a tempered distribution. The importance of this may be seen in Lemma 4.2.

Note that for (1.1) the function ψ could be used and would provide sharper bounds in our proofs. This does not work, however, with the truncation to a finite number of modes (such as given by the semidiscrete system (2.3) or fully discrete system (2.5)).

Our second cutoff function, ξ_K, is defined in terms of its Fourier transform. It smoothly truncates to a finite set of Fourier modes and hence produces a finite-dimensional problem.

DEFINITION 1.2. *Let $K > 1$ and let $\widehat{\xi}_K$ be a $\mathcal{C}^\infty$ function taking the following values:*

$$\widehat{\xi}_K(k) \;=\; \begin{cases} 1 & \text{if } |k| \le K-1\;, \\ 0 & \text{if } |k| \ge K\;. \end{cases}$$

Its inverse Fourier transform $\xi_K = \mathcal{T}^{-1}(\widehat{\xi}_K)$ is an (entire) Schwartz function.

Note that if f is a Schwartz function, then $\xi_K \star f$ is a Schwartz function whose Fourier transform has support in $[-K,K]^d$, and hence it belongs to $\mathcal{B}_K(C)$ for some C; see [23].

2. Semidiscrete and fully discrete approximations. In this section, we propose a spatial discretization of (1.1) and a fully discrete scheme.

2.1. Galerkin scheme. The semidiscretization we describe here is a spectral method. Let $N \in \mathbb{N}$; then we use the Fourier cutoff ξ_K of Definition 1.2 with $K = N$ to define the operators P^N and $\mathrm{Q}^N f := f - \mathrm{P}^N f$, where

$$\mathrm{P}^N f \;:=\; \xi_N \star f \;=\; \mathcal{T}^{-1}\left(\widehat{\xi}_N \mathcal{T}(f)\right)\;, \tag{2.1}$$

i.e.,

$$\mathrm{P}^N \sum_{n\in\mathbb{Z}^d} f_n e^{-in\cdot x/L} \;:=\; \sum_{|n|\le NL} \widehat{\xi}_N(n/L) f_n e^{-in\cdot x/L}\;.$$

Notice that P^N truncates to $(2NL)^d$ modes, not $(2N)^d$. In this way, $\mathcal{T}\big(\mathrm{P}^N f\big)$ has support contained in $[-N,N]^d$ for all L. The operator P^N is not a projector, since $\mathrm{P}^N\mathrm{P}^N \neq \mathrm{P}^N$.

The Galerkin approximation is defined as follows: the solution $u(x,t)$ to (1.1) is replaced by a finite Fourier series

$$u^N(x,t) := \sum_{|n|\leq NL} u_n(t) e^{-in\cdot x/L} \ . \tag{2.2}$$

The evolution equation is obtained by applying P^N to the nonlinear term of (1.1) and to the initial condition u_0:

$$\partial_t u^N = \big(\gamma + \nu\Delta\big)u^N + \mathrm{P}^N F(u^N) \ , \qquad u^N(x,0) = \big(\mathrm{P}^N u_0\big)(x) \ . \tag{2.3}$$

2.2. Fully discrete scheme. The time discretization is an exact exponential integrator for the linear part and a simple (order 1) quadrature for the nonlinear term appearing in the variation of constants formula. It is similar to that considered in [26], although they need a different definition of discrete Gevrey space, which depends on the time step. The full discretization is obtained by applying this time discretization to the Galerkin scheme (2.3). We use this particular scheme because it makes it straightforward to prove that solutions are (Gevrey) analytic functions (uniformly in the parameters of the scheme; see Appendix B), a fact that we rely on heavily in the next sections.

Let $\mathcal{L} = \gamma + \nu\Delta$ and $\mathcal{K}(x,t)$ be the convolution kernel associated with the operator $\exp(t\mathcal{L})$:

$$\mathcal{K}(x,t) = \frac{1}{(2\pi)^d}\int e^{-ik\cdot x + (\gamma - \nu|k|^2)t}\, dk \ . \tag{2.4}$$

Note that the operator P^N commutes with $\mathcal{K}\star\cdot$, since both are convolution operators. Let $h > 0$ denote the time step. Then the fully discrete approximation to $u(x,t)$ is defined iteratively by

$$u^N\big((n+1)h\big) = \mathcal{K}(h) \star \big(u^N(nh) + h\mathrm{P}^N F\big(u^N(nh)\big)\big) \ . \tag{2.5}$$

In terms of the Fourier coefficients, (2.2), we get

$$\begin{aligned} u^N_m\big((n+1)h\big) &= e^{h\lambda_m}\left(u^N_m(nh) + h\mathrm{P}^N\mathcal{T}F\big(\mathcal{T}^{-1}u^N(nh)\big)_m\right) \\ &= e^{h\lambda_m}(u^N_m(nh) + h\widehat{\xi}_N(m/L)\mathcal{T}F\big(\mathcal{T}^{-1}u^N(nh)\big)_m) \ , \end{aligned}$$

where $\{\lambda_m\}_{m\in\mathbb{Z}^d}$ are the eigenvalues of $\mathcal{L}$; namely, $\lambda_m = \gamma - \nu|m|^2/L^2$, n is the time index, m is the Fourier index, and $\mathcal{T}$ is the Fourier transform (1.2).

For the purposes of analysis, it is useful to consider this scheme in terms of piecewise solutions of a linear differential equation. Indeed, $u^N(x,(n+1)h)$ is the solution at time $t = h$ of

$$\partial_t u(x,t) = \nu\Delta u(x,t) + \gamma u(x,t) \tag{2.6}$$

with initial condition $u^N(x,nh) + h\mathrm{P}^N F\big(u^N(x,nh)\big)$ at $t = 0$.

Remark. We could apply our techniques to other numerical schemes. We require only the numerical approximation to belong to the Gevrey class $\mathcal{G}_\alpha(C)$ of bounded real analytic functions for some $\alpha > 0$, $C > 0$ (see Appendix D). There exists many wavelet and finite element schemes satisfying this requirement; see [7, 18]. In particular, Propositions D.2 and D.3 provide a natural example of a different basis of analytic functions on which our problem can be decomposed and then a truncation applied: this basis consists of the functions

$$\Psi_{j,k}(x) \;=\; \frac{3e^{ik\cdot x}\sin\bigl(2x-\frac{1}{3}j\pi\bigr)\sin\bigl(6x-j\pi\bigr)}{(6x-j\pi)^2}$$

for $j,k\in\mathbb{Z}^d$. These functions have the advantage of being localized both in real space, and in Fourier space, although the numerical implementation is more involved.

3. Definitions and assumptions. Since we are interested in the large volume limit we specify this dependence in the definitions below.

ASSUMPTION 3.1. *For initial data $u_0\in\mathcal{C}_{\rm per}([-L\pi,L\pi]^d)$, we assume that*

- (1.1) *is the generator of a semiflow $\Phi_L^t : u_0\mapsto u(t)$;*
- *for all $N>N_0$ the semidiscrete* (2.3) *is the generator of a semiflow $\Phi_{L,N}^t : u_0\mapsto u(t)$;*
- *for all $N>N_0$ and $h<h_0$ the fully discrete equation* (2.5) *is the generator of a semiflow $\Phi_{L,N,h}^t : u_0\mapsto u(t)$ with $t=nh$, $n\in\mathbb{N}$.*

Furthermore, we assume for each of the semiflows above that there exists constants $\alpha>0$ and $R>0$, independent of L and t, such that $\mathrm{Re}\bigl(u(t)\bigr)$ and $\mathrm{Im}\bigl(u(t)\bigr)$ belong to the Gevrey class $\mathcal{G}_\alpha(R)$ for all $t>T(u)$, and so $u(t)\in[\mathcal{G}_\alpha(R)]^2$. In other words, the following sets are absorbing balls for their corresponding semiflows:

$$\begin{aligned}
B(L) &:= \mathcal{C}_{\rm per}([-L\pi,L\pi]^d)\bigcap[\mathcal{G}_\alpha(R)]^2\ ,\\
B_N(L) &:= \mathrm{P}^N\mathcal{C}_{\rm per}([-L\pi,L\pi]^d)\bigcap[\mathcal{G}_\alpha(R)]^2\ ,\\
B_{N,h}(L) &:= \mathrm{P}^N\mathcal{C}_{\rm per}([-L\pi,L\pi]^d)\bigcap[\mathcal{G}_\alpha(R)]^2\ .
\end{aligned}$$

Throughout the paper we use $\widehat{\Phi}^t$ to denote any of the semiflows (with t taken appropriately) defined above and $\widehat{B}(L)$ to denote the corresponding absorbing balls.

We next define the attractors of the different evolutions introduced above.

DEFINITION 3.2. *We define the following invariant attracting sets for the flows defined in Assumption* 3.1:

$$\begin{aligned}
\mathcal{A}(L) &:= \bigcap_{t>0}\Phi_L^t\bigl(B(L)\bigr)\ ,\\
\mathcal{A}_N(L) &:= \bigcap_{t>0}\Phi_{L,N}^t\bigl(B_N(L)\bigr)\ ,\\
\mathcal{A}_{N,h}(L) &:= \bigcap_{n\in\mathbb{N}}\Phi_{L,N,h}^{nh}\bigl(B_{N,h}(L)\bigr)\ .
\end{aligned}$$

Throughout the paper we use $\widehat{\mathcal{A}}(L)$ to denote any of the above attracting sets.

Clearly, finite trigonometric sums like (2.2) are entire functions. However, the assumption that there exists a strip around the real axis where u^N is bounded by the same constant for all N is not trivial. Results of this type are known for a number of parabolic partial differential equations of the form (1.1), under the assumption that

F is dissipative in an appropriate sense (see, for example, [1, 25]). For numerical approximations, existence of semiflows and global attractors is a well-considered problem (see, for example, [24]). Gevrey regularity of solutions for numerical schemes has not been so widely considered; two different approaches are in [17, 26]. Appendix B contains a sketch of how to obtain this result for the fully discrete scheme given by (2.5). The proof relies only on an a priori L^∞ bound on the solutions and the assumption that the nonlinearity F is analytic.

We next introduce the notion of ε-entropy. The proof that this is a finite quantity will be given in section 4. From this we define the upper density of dimension.

DEFINITION 3.3. *Let Y be a subset of a metric space X. A set $\mathcal{U} = \{U_1, \dots, U_N\}$ of open sets in X is called a cover of Y if $\bigcup_{n=1}^N U_n \supset Y$. It is called an ε-cover if* $\max_{n=1,\dots,N} \operatorname{diam}(U_n) \le \varepsilon$.

Let $\widehat{\mathcal{A}}(L)$ be endowed with the metric defined by the norm $\|\cdot\|_\infty$. Let

$$\mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L)) := \inf\bigl\{\operatorname{card}(\mathcal{U}) : \mathcal{U} \text{ is an } \varepsilon\text{-cover of } \widehat{\mathcal{A}}(L)\bigr\} .$$

We define the ε-entropy H_ε as the limit

$$H_\varepsilon := \limsup_{L\to\infty} \frac{\log \mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L))}{(2L\pi)^d} .$$

The upper density of dimension d_{up} is defined by

$$d_{\mathrm{up}} := \limsup_{\varepsilon\to 0} \frac{H_\varepsilon}{\log \varepsilon^{-1}} .$$

Remark. In [4, 5, 6], H_ε was defined with a limit instead of a limit superior. The existence of the limit followed from a subadditivity argument which cannot be used here because of the boundary conditions. That is, the set $\widehat{\mathcal{A}}(L)$ we are considering here changes with L, whereas, in the papers [4, 5, 6], only the topology on $\mathcal{A}$ depended on L, not the set itself. See also [31, 32] for similar results.

Another more classical notion of entropy is the topological entropy. It serves to measure to complexity of a dynamical system. Similarly to the previous definition, we consider here the spatial density of topological entropy. See section 5 for results on the topological entropy.

DEFINITION 3.4. *For $\tau > 0$, we define a pseudometric $d_{m,\tau}$ on $\mathcal{C}_{\mathrm{per}}([-L\pi, L\pi]^d)$ by*

$$d_{m,\tau}(u, v) := \max_{k=0,\dots,m-1} \|\widehat{\Phi}^{k\tau}(u) - \widehat{\Phi}^{k\tau}(v)\|_\infty .$$

An (m, ε)-cover of $\widehat{\mathcal{A}}(L)$ is a collection of open sets whose diameter in the metric $d_{m,\tau}$ is at most ε and whose union contains $\widehat{\mathcal{A}}(L)$. Let $\mathcal{M}_{m,\tau}(\varepsilon, \widehat{\mathcal{A}}(L))$ be the cardinality of such a minimal (m, ε)-cover.

The (spatial density of) topological entropy is defined as follows:

$$h_{\mathrm{top}} := \limsup_{\varepsilon\to 0} \limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \lim_{m\to\infty} \frac{1}{m\tau} \log \mathcal{M}_{m,\tau}(\varepsilon, \widehat{\mathcal{A}}(L)) . \tag{3.1}$$

The existence of the first limit in (3.1) can be proved by a subadditivity argument; see [4, 6, 14]. A useful way of computing a lower bound on the topological entropy is by measuring the volume expansion rate (see section 5.2).

DEFINITION 3.5. *Let $L \mapsto \mathcal{D}(L)$ be a family of ℓ-dimensional $\mathcal{C}^\infty$ submanifolds of the absorbing ball $\widehat{B}$. We define $\mathcal{V}$, the volume expansion rate, by*

$$\mathcal{V} := \limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \limsup_{m\to\infty} \frac{1}{m\tau} \log \mathrm{Vol}_\ell\big(\widehat{\Phi}^{m\tau}(\mathcal{D}(L))\big) \ ,$$

where Vol_ℓ *is the ℓ-dimensional (Euclidean) volume.*

4. Upper bound on the ε-entropy. We now work towards proving our main result which is a bound on the ε-entropy. First we discuss a preliminary result on the smoothing property of the semiflow which is proved in Appendix A.

4.1. Smoothing property of the semiflow. We consider here differences $w = u - v$ of two orbits u and v of the semiflow $\widehat{\Phi}^t$ of Assumption 3.1. We define functions G_1 and G_2 in such a way that w satisfies

$$\partial_t w \ = \ \big(\gamma + \nu\Delta\big)w + \mathrm{P}^N\big(G_1(u,v)w + G_2(u,v)\overline{w}\big) \tag{4.1}$$

for continuous time and

$$w\big((n+1)h\big) \ = \ \mathcal{K}(h) \star \big(w(nh) + h\mathrm{P}^N\big(G_1(nh)w(nh) + G_2(nh)\overline{w}(nh)\big)\big) \tag{4.2}$$

for discrete time. From now on we view G_1 and G_2 as functions of x and t (rather than of u and v), and we use the following consequence of Assumption 3.1.

LEMMA 4.1. *There exists $\alpha > 0$ and $R > 0$, both independent of N, L, and t, such that $w(t)$, $G_1(t)$, and $G_2(t)$ all belong to $[\mathcal{G}_\alpha(R)]^2$ for all $t > 0$ (and $t/h \in \mathbb{N}$ for (4.2)).*

Remark. We may assume without loss of generality that the R and the α of Assumption 3.1 and Lemma 4.1 are equal and that they are also equal for the fully continuous, semidiscrete, and fully discrete equations.

We compute bounds on the weighted L^2 norm of w shifted in the complex plane over a finite time interval. Instead of taking the usual (flat) L^2 norm over $[-L\pi, L\pi]^d$, which would not behave well in the limit $L \to \infty$, we take a norm over the whole of $\mathbb{R}^d$ weighted with the function φ from Definition 1.1. Therefore, L disappears completely from our estimates. However, in Definition 3.3, we chose to work with the L^∞ topology. We therefore use the following bootstrap argument. From a bound in L^∞ at time $t = 0$, we get a bound in weighted L^2 at time $t = 0$. Using the next lemma we deduce a bound at $t = 1$ in a weighted L^2 space on a strip of the complex plane. This is in turn combined with Lemma C.1 and provides an L^∞ bound at $t = 1$.

LEMMA 4.2. *There is a constant $b > 0$ such that, for any $\beta \in (-\alpha, \alpha)$, any N, and any L, the following bound holds on w a solution of (4.1) (or (4.2)) as long as $t \le 1$ (and $t/h \in \mathbb{N}$ in the case of a fully discrete scheme):*

$$\sup_{|y|\le L\pi} \int \varphi(x-y)|w(x+i\beta t,t)|^2\,dx \ \le \ e^{2bt} \sup_{|y|\le L\pi} \int \varphi(x-y)|w(x,0)|^2\,dx \ . \tag{4.3}$$

The proof of Lemma 4.2 is given in Appendix A.

These L^2 norms shifted in the complex plane can be understood in terms of the classical Gevrey norms. First consider $\varphi \equiv 1$. Then, using Fourier series and taking $\beta > 0$, we see that

$$\int \big(|f(x+2i\beta)|^2 + |f(x-2i\beta)|^2\big)\,dx \ = \ \Big\|\Gamma e^{\beta(-\Delta)^{1/2}} f\Big\|_2^2 \ , \tag{4.4}$$

where Γ is the bounded invertible operator defined by

$$\big(\mathcal{T}(\Gamma f)\big)_n \;=\; (1+e^{-2\beta|n|/L})(\mathcal{T}f)_n \;.$$

This means that the left-hand side of (4.4) is equivalent to a Gevrey norm. (Similar norms have been used in [11, 12].) We apply a nonconstant weight function φ to this norm in order to get estimates which are independent of L and take the sup over $|\beta| \le \alpha$ to be able to use Lemma C.1. Similar issues have been raised in the paper [21], but our approach is different in that we never explicitly work in Fourier space. We note also that the norms used in [21] grow with the domain size (due to the embedding constant), a problem we avoid here by using the cutoff φ.

4.2. Proof of the upper bound. We next show that the ε-entropy H_ε (Definition 3.3) is of order $\log \varepsilon^{-1}$ at most.

THEOREM 4.3. *There exists a constant $C < \infty$, independent of ε, such that*

$$H_\varepsilon \;\le\; C \log\left(\frac{R}{\varepsilon}\right) \;,$$

where R is the radius of the absorbing ball $\widehat{B}(L)$ in Assumption 3.1.

The proof is based on the following lemma.

LEMMA 4.4. *There is a constant $C > 0$ such that, for all $\varepsilon > 0$, the following holds:*

$$H_\varepsilon \;\le\; H_{2\varepsilon} + C \;.$$

Proof. The proof is a consequence of the smoothness result of the previous section. We give the proof for the time continuous cases (1.1), (2.3). The time discrete case (2.5) is similar; it requires only restricting t to multiples of h.

Suppose we are given a 2ε-cover $\{U_1, \dots, U_{\mathcal{N}}\}$ of $\widehat{\mathcal{A}}(L)$. Then by invariance of $\widehat{\mathcal{A}}$ the set

$$\{\widehat{\Phi}^t(U_1), \dots, \widehat{\Phi}^t(U_{\mathcal{N}})\}$$

is a cover of $\widehat{\mathcal{A}}(L)$ for all $t > 0$. Moreover, if $u, v \in U_1$, by Lemma C.1 combined with Lemma 4.2, we have

$$\sup_{|x|\le L\pi\,,\,2|y|\le\alpha} |\big(\widehat{\Phi}^1(u) - \widehat{\Phi}^1(v)\big)(x+iy)| \;\le\; C\varepsilon \;.$$

That is, if we let $w = \widehat{\Phi}^1(u) - \widehat{\Phi}^1(v)$, then $w \in [\mathcal{G}_{\alpha/2}(C\varepsilon)]^2$ with C independent of L and ε.

We now use an argument due to Tikhomirov [28], discussed in [15, section 8, Theorem XXII]. By Proposition D.2 w can be written as

$$w(z) \;=\; \sum_{n\in\mathbb{Z}^d} e^{-\alpha|n|/2} e^{in\cdot z} w_n(z) \;, \tag{4.5}$$

with w_n in the Bernstein class $[\mathcal{B}_2(C'\varepsilon)]^2$. (See Appendix D for the definition of $\mathcal{B}_2$.) Thus, splitting the sum in (4.5) in two, we can find a K independent of ε and L, and a $\widetilde{w} \in [\mathcal{B}_K(C'\varepsilon)]^2$, such that

$$\|w - \widetilde{w}\|_\infty \;\le\; \frac{\varepsilon}{2} \;.$$

If $\widetilde{w} \in [\mathcal{B}_K(C\varepsilon)]^2$, then, by Proposition D.3,

$$\widetilde{w}(x) \;=\; \sum_{n\in\mathbb{Z}^d} \widetilde{w}\big(x_K(n)\big)\mathcal{F}_K\big(x - x_K(n)\big)\;,$$

and hence there is a $\delta > 0$ depending only on K such that $\|\widetilde{w}\|_\infty \le \varepsilon/2$ if $|\widetilde{w}(x_K(n))| \le \delta\varepsilon$ for all $n \in \mathbb{Z}^d$ for which $x_K(n) = (n\pi)/(3K) \in [-L\pi, L\pi]^d$. There are $c(K)(2L\pi)^d$ such points, and hence at most

$$\left(\frac{C\varepsilon}{\delta\varepsilon}\right)^{c(K)(2L\pi)^d} \;=:\; C_*^{(2L\pi)^d}$$

balls of radius $\varepsilon/2$ will be needed to cover $[\mathcal{B}_K(C\varepsilon)]^2$. This covers all the functions $\widetilde{w}$ obtained from the set $\widehat{\Phi}^1(U_1)$ by the above construction. Consequently, $\widehat{\Phi}^1(U_1)$ can be covered with the same number of balls of diameter ε.

Repeating the operation with each one of the $\mathcal{N}(2\varepsilon, \widehat{\mathcal{A}}(L))$ sets of diameter 2ε of the original cover $\{U_1, \dots, U_{\mathcal{N}}\}$, we obtain a cover with at most

$$\mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L)) \;\le\; \mathcal{N}(2\varepsilon, \widehat{\mathcal{A}}(L)) C_*^{(2L\pi)^d}$$

elements. Taking the logarithm, dividing by $(2L\pi)^d$, and passing to the limit $L \to \infty$, we obtain Lemma 4.4. □

Proof of Theorem 4.3. It trivially holds that $H_R = 0$, because $\mathcal{N}(R, \widehat{\mathcal{A}}(L)) = 1$ by Assumption 3.1. Let k be the smallest integer larger than $\log(R/\varepsilon)/\log 2$; then by Lemma 4.4 we have

$$H_\varepsilon \;\le\; H_{2\varepsilon} + C \;\le\; \cdots \;\le\; H_{2^k\varepsilon} + Ck \;\le\; C' \log R/\varepsilon\;.$$

This proves Theorem 4.3. □

5. The topological entropy.

5.1. Upper bound by the dimension. In this section, we prove that the topological entropy of the attractors $\widehat{\mathcal{A}}$ is bounded by a multiple of the upper density of dimension, a quantity related to the ε-entropy. The corresponding inequality for finite-dimensional dynamical systems is well known; see [14].

THEOREM 5.1. *There is a $b < \infty$ such that*

$$h_{\text{top}} \;\le\; b d_{\text{up}} \;<\; \infty\;. \tag{5.1}$$

Proof. The right-hand inequality is a direct consequence of Theorem 4.3. The left-hand inequality follows from the arguments in [4, 14] that we summarize here. Let $\rho > 0$ be such that $H_\varepsilon \le \big(d_{\text{up}} + \rho\big)\log 1/\varepsilon$ for all $\varepsilon < \varepsilon_0$ and then let $L_0 = L_0(\varepsilon, \rho)$ be such that, for all $L > L_0$,

$$\frac{\log \mathcal{N}(\varepsilon, \widehat{\mathcal{A}}(L))}{(2L\pi)^d} \;\le\; H_\varepsilon + \rho \;\le\; \big(d_{\text{up}} + \rho\big)\log\frac{1}{\varepsilon} + \rho\;.$$

By iterating Lemma C.1 and Lemma 4.2, there is a $b > 0$ such that, for all L and all (sufficiently small) $\varepsilon > 0$, if $\|u - v\|_\infty \le \varepsilon$, then, for $t > 0$,

$$\|\widehat{\Phi}^t(u) - \widehat{\Phi}^t(v)\|_\infty \;\le\; e^{bt}\varepsilon\;.$$

Let $\varepsilon' = \exp(-bT)\varepsilon$. Let an ε'-cover of $\widehat{\mathcal{A}}(L)$ (in the sense of Definition 3.3) be given. Then it is also a $(T/\tau, \varepsilon)$-cover (in the sense of Definition 3.4), and hence

$$\mathcal{M}_{T/\tau,\tau}(\varepsilon, \widehat{\mathcal{A}}(L)) \le \mathcal{N}(\varepsilon', \widehat{\mathcal{A}}(L)) .$$

It follows that

$$\begin{aligned} h_{\text{top}} &= \limsup_{\varepsilon\to 0} \limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \lim_{T\to\infty} \frac{1}{T} \log \mathcal{M}_{T/\tau,\tau}(\varepsilon, \widehat{\mathcal{A}}(L)) \\ &= \limsup_{\varepsilon\to 0} \limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \inf_{T} \frac{1}{T} \log \mathcal{M}_{T/\tau,\tau}(\varepsilon, \widehat{\mathcal{A}}(L)) \\ &\le \limsup_{\varepsilon\to 0} \limsup_{L\to\infty} \frac{1}{T} \frac{\log \mathcal{N}(\varepsilon', \widehat{\mathcal{A}}(L))}{(2L\pi)^d} \\ &\le \limsup_{\varepsilon\to 0} \limsup_{L\to\infty} \frac{1}{T} \left((d_{\text{up}} + \rho) \log \frac{1}{\varepsilon'} + \rho \right) . \end{aligned}$$

Since $\log 1/\varepsilon' = bT + \log 1/\varepsilon$, the limit $T \to \infty$ and $\rho \to 0$ leaves only bd_{up} on the right-hand side above. ∎

5.2. Lower bound by the expansion rate. We provide here a way of computing a lower bound on the topological entropy (hence on the upper dimension d_{up} by Theorem 5.1), based on Yomdin's theorem [30], an account of which may be found in [22].

THEOREM 5.2. *Let h_{top} be as in Definition* 3.4. *Then for all choices of $\mathcal{D}(L)$ in Definition* 3.5,

$$\mathcal{V} \le h_{\text{top}} .$$

Remark. The lower bound in [5] is in the same spirit. An adequate sequence of submanifolds is chosen (small balls around the trivial solution). The volume expansion rate of that sequence can be controlled, yielding a lower bound on the (ε-)entropy.

Proof. The proof follows from the argument by Yomdin [30] and Gromov [10]. By a lemma of Gromov [10], there exists a $C > 0$ such that if $\widehat{\Phi}^\tau$ is $\mathcal{C}^r$, then

$$\text{Vol}_\ell\big(\widehat{\Phi}^{m\tau}(\mathcal{D}(L))\big) \le \mathcal{M}_{m,\tau}(\varepsilon, \widehat{\mathcal{A}}(L))(C\|D\widehat{\Phi}^\tau\|_\infty)^{m\ell/r} , \text{ and}$$

hence

$$\begin{aligned} &\limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \limsup_{m\to\infty} \frac{1}{m\tau} \log \text{Vol}_\ell\big(\widehat{\Phi}^{m\tau}(\mathcal{D}(L))\big) \\ &\le \limsup_{L\to\infty} \frac{1}{(2L\pi)^d} \limsup_{m\to\infty} \frac{1}{m\tau} \log \mathcal{M}_{m,\tau}(\varepsilon, \widehat{\mathcal{A}}(L)) \\ &\quad + \limsup_{L\to\infty} \frac{\ell/r}{(2L\pi)^d} \log\big(C^{1/\tau}\|D\widehat{\Phi}^\tau\|_\infty^{1/\tau}\big) . \end{aligned}$$

Since τ can be arbitrarily large, the constant C drops out, and, since $\widehat{\Phi}^\tau$ is $\mathcal{C}^\infty$, the second term is arbitrarily small by letting $r \to \infty$. The first term tends to h_{top} upon letting $\varepsilon \to 0$. ∎

6. Upper semicontinuity of the infinite volume attractors. In this section we discuss four different invariant sets and their mutual relationship. The first two invariant sets are $\mathcal{A}_{N,h}(L)$ and $\mathcal{A}(L)$ from Definition 3.2. Then we also introduce two large volume limits:

$$\mathcal{A}_{N,h}(\infty) := \overline{\bigcup_{L\in\mathbb{N}} \mathcal{A}_{N,h}(L)}\ , \qquad \mathcal{A}(\infty) := \overline{\bigcup_{L\in\mathbb{N}} \mathcal{A}(L)}\ , \tag{6.1}$$

where the closure is taken in the uniformly local topology of [19]. We define the distance between a point and a set and between two sets in the standard way:

$$\begin{aligned} \operatorname{dist}\big(U,\mathcal{V}\big) &:= \inf_{V\in\mathcal{V}} \|U-V\|_{L^\infty([-L\pi,L\pi]^d)}\ , \\ \operatorname{dist}\big(\mathcal{U},\mathcal{V}\big) &:= \sup_{U\in\mathcal{U}} \operatorname{dist}\big(U,\mathcal{V}\big)\ . \end{aligned}$$

We claim that

$$\lim_{N\to\infty,h\to 0} \operatorname{dist}\big(\mathcal{A}_{N,h}(L),\mathcal{A}(L)\big) \,=\, 0\ , \qquad \lim_{N\to\infty,h\to 0} \operatorname{dist}\big(\mathcal{A}_{N,h}(\infty),\mathcal{A}(\infty)\big) \,=\, 0\ , \tag{6.2}$$

and the following relations are straightforward from (6.1):

$$\begin{aligned} \lim_{L\to\infty} \operatorname{dist}\big(\mathcal{A}_{N,h}(L),\mathcal{A}_{N,h}(\infty)\big) &= 0\ , \\ \lim_{L\to\infty} \operatorname{dist}\big(\mathcal{A}(L),\mathcal{A}(\infty)\big) &= 0\ . \end{aligned}$$

Hence we obtain the following diagram, in which each arrow represents a relation of upper semicontinuity:

$$\begin{array}{ccc} \mathcal{A}_{N,h}(L) & \xrightarrow[h\to 0]{N\to\infty} & \mathcal{A}(L) \\ {\scriptstyle L\to\infty}\big\downarrow & & \big\downarrow{\scriptstyle L\to\infty} \\ \mathcal{A}_{N,h}(\infty) & \xrightarrow[h\to 0]{N\to\infty} & \mathcal{A}(\infty)\ . \end{array}$$

The relation (6.3) is a consequence of the following (see, e.g., [13, 17, 19, 20]).

THEOREM 6.1. *For all $\varepsilon > 0$, there is a T_1, an h_1, and an N_1 such that if $h < h_1$ and $N > N_1$, then, for all $L \in \mathbb{N}$,*

$$\Phi^T_{L,N,h}\left(B_{N,h}(L)\right) \subset \mathcal{U}_\varepsilon(\mathcal{A}(L)) \qquad \forall T > T_1\ ,$$

where $\mathcal{U}_\varepsilon(\mathcal{A}(L))$ is the ε-neighborhood of $\mathcal{A}(L)$ in L^∞.

Proof. The proof is by induction using the attracting property of the attractor and a finite time error estimate.

By the attraction property of $\mathcal{A}(L)$, there exists a T such that, for all $T > T_1$,

$$\Phi^T_L\left(B(L)\cup B_{N,h}(L)\right) \subset \mathcal{U}_{\varepsilon/2}(\mathcal{A}(L))$$

for all $L \in \mathbb{N}$. Hence for any $u_0 \in B_{N,h}(L)$ we have

$$\begin{aligned} \operatorname{dist}\big(\Phi^{nh}_{L,N,h}(u_0),\mathcal{A}(L)\big) &= \inf_{u\in\mathcal{A}(L)} \|\Phi^{nh}_{L,N,h}(u_0)-u\|_\infty \\ &\le \inf_{u\in\mathcal{A}(L)} \|\Phi^{nh}_{L}(u_0)-u\|_\infty + \|\Phi^{nh}_{L,N,h}(u_0)-\Phi^{nh}_{L}(u_0)\|_\infty \\ &\le \frac{\varepsilon}{2} + \|\Phi^{nh}_{L,N,h}(u_0)-\Phi^{nh}_{L}(u_0)\|_\infty\ , \end{aligned} \tag{6.3}$$

provided $nh > T$.

We next show that N, h can be chosen in such a way that the second term above is smaller than $\varepsilon/2$ for all $T \in (0, 2T_1]$.

Let $v(t) = \Phi_L^t(u_0)$ and $w(nh+s) = \Phi_{\mathrm{Lin}}^s \Phi_{L,N,h}^{nh}(u_0)$, where Φ_{Lin}^s is the solution semiflow of (2.6). We thus have for $s < h$

$$\begin{aligned}\partial_t\big(v(nh+s) - w(nh+s)\big) &= \big(\gamma + \nu\Delta\big)\big(v(nh+s) - w(nh+s)\big) + F\big(v(nh+s)\big) \\ &= \big(\gamma + \nu\Delta\big)\big(v(nh+s) - w(nh+s)\big) + \mathrm{P}^N\left(F\big(v(nh+s)\big) - F\big(w(nh+s)\big)\right) \\ &\quad -\mathrm{P}^N F\big(w(nh+s)\big) + \mathrm{Q}^N F\big(v(nh+s)\big) \ .\end{aligned}$$

Using Proposition D.2 we see that

$$\sup_{s<h} \|\mathrm{Q}^N F\big(v(nh+s)\big)\|_\infty \ \le\ C(R) e^{-\alpha N} \ .$$

It is also quite easy (using Fourier transforms) to see that

$$\left\| \int_0^h \left(\mathrm{P}^N F\big(w((n+1)h)\big) - \mathcal{K}(s) \star \mathrm{P}^N F\big(w((n+1)h - s)\big)\right) ds \right\|_\infty \ \le\ C(R) h \ .$$

Hence, using the same analysis as in the proof of Lemma 4.2, we obtain

$$\|v((n+1)h) - w((n+1)h)\|_\infty \ \le\ e^{ch} \|v(nh) - w(nh)\|_\infty + C(R)h\big(1 + e^{-\alpha N}\big) \ .$$

By iteration, we obtain

$$\|v(nh) - w(nh)\|_\infty \ \le\ e^{cnh} \|v(0) - w(0)\|_\infty + C(R) e^{cnh} h (1 + e^{-\alpha N}) \ . \tag{6.4}$$

Taking h small enough, we can make the second term of (6.3) smaller than $\varepsilon/2$ for all $T \in (0, 2T_1]$.

To complete the induction we note that the absorbing ball is forward invariant, and so we can repeat the argument for $T > 2T_1$. □

7. Discussion: The complex Ginzburg–Landau equation. An interesting example to which our results apply is the (cubic) complex Ginzburg–Landau (CGL) equation in $d = 1$ space dimension

$$\partial_t u(x,t) \ =\ (1+ia)\partial_x^2 u(x,t) + u(x,t) - (1+ib)|u(x,t)|^2 u(x,t) \ . \tag{7.1}$$

In terms of the notations of (1.1), we have

$$d \ =\ 1 \ , \quad \nu \ =\ 1 + ia \ , \quad \gamma \ =\ 1 \ , \quad F(u) \ =\ -(1+ib)|u|^2 u \ .$$

Remark that the equation for the difference $w = u - v$ of two solutions u and v that we use in section 4.1 admits a simple expression:

$$\begin{aligned}\partial_t w(x,t) = (1+ia)\partial_x^2 w(x,t) + w(x,t) \\ + \int \xi_N(x-y)\big(G_1(y,t) w(y,t) + G_2(y,t)\overline{w}(y,t)\big) dy \ ,\end{aligned}$$

where

$$G_1(x,t) \ =\ -(1+ib)\big(|u(x,t)|^2 + |v(x,t)|^2\big) \ , \qquad G_2(x,t) \ =\ -(1+ib) u(x,t) v(x,t) \ .$$

The CGL equation (7.1) arises as a "normal form" in certain types of bifurcation with continuous spectrum; see [1, 3]. Assumption 3.1 for the continuous case follows from the works [2, 1, 25]. In particular, the following results have been proved.

THEOREM 7.1. *Equation* (7.1) *defines a semiflow* Φ^t *on* $L^\infty(\mathbb{R})$ *which has an absorbing ball* B *in* $\mathcal{G}_\alpha(C)$ *for some* $C > 0$ *and* $\alpha > 0$ *(see Appendix D). The attractor* $\mathcal{A} = \cap_{t>0}\Phi^t(B)$ *exists and is compact in* $L^\infty([-L, L])$ *for any* $L > 0$.

Remark that these results hold on the whole space without boundary conditions, but they obviously remain true on the set of spatially periodic solutions, which is invariant under the time evolution.

The following rigorous upper and lower bounds on the ε-entropy in unbounded volumes were obtained in [5].

THEOREM 7.2. *Let* $\mathcal{A}$ *be the attractor of* (7.1) *for general initial conditions in* $L^\infty(\mathbb{R})$ *and let* $\mathcal{N}(\varepsilon, \mathcal{A})$ *be the minimum the number of balls in an* ε*-cover of* $\mathcal{A}$ *in the topology of* $L^\infty([-L, L])$. *There is a* $C > 0$ *for which*

$$C^{-1}\log(1/\varepsilon) \,\le\, H_\varepsilon(\mathcal{A}) \,=\, \lim_{L\to\infty} \frac{\log \mathcal{N}(\varepsilon, \mathcal{A})}{2L} \,\le\, C\log(1/\varepsilon)\ .$$

In particular, the limit exists.

The discretization (2.5) in the particular case of the CGL equation is

$$u_m^N\big((n+1)h\big) \,=\, e^{(1-(1+ia)m^2)nh}\Big(1 - h(1+ib)\widehat{\xi}_N(m/L)|u_m^N(nh)|^2\Big)u_m^N(nh)\ , \tag{7.2}$$

where $n = 0, 1, \ldots$ is the time index and $m = -N, \ldots, N$ is the Fourier index.

A closely related time discretization was considered in [26]. Although there is no formal proof of existence of a semiflow and global attractor for the modified Galerkin scheme considered here, this can be seen to be true by considering the error bound (6.4) and the results of Theorem 7.1 over a finite time interval $[0, T]$. This suffices to prove that the discretized evolution is well defined and solutions stay bounded on that time interval. Iterating over $[qT, (q+1)T]$ for all $q > 0$ we obtain the existence of a global semiflow. The proof of existence of the absorbing balls of Assumption 3.1 is sketched in Appendix B. This implies that the following theorem holds as a special case of Theorem 4.3.

THEOREM 7.3. *Consider the CGL equation* (7.2). *There exists a constant* $C < \infty$, *independent of* ε, *such that*

$$H_\varepsilon \,\le\, C\log\left(\frac{R}{\varepsilon}\right)\ ,$$

where R *is the radius of the absorbing ball* B *in Gevrey space for* (7.2), *and* H_ε *is defined in Definition* 3.3.

Appendix A. Proof of Lemma 4.2. We first consider the time continuous case (4.1). We write the analytic extension of w as a vector-valued function with components $w_{\rm r}$ and $w_{\rm i}$ (each of which is complex-valued), and its complex argument $x + iy$ is also written as a vector of reals. Namely,

$$w(x + iy, t) \,=\, \big(w_{\rm r}(x, y; t), w_{\rm i}(x, y; t)\big)\ .$$

As a preparation for the proof, we estimate the following expression:

$$\begin{aligned}&\operatorname{Re}\nu \int \varphi(x)(\overline{w}_{\rm r}(x, y; t)\Delta_x w_{\rm r}(x, y; t) + \overline{w}_{\rm i}(x, y; t)\Delta_x w_{\rm i}(x, y; t))\,dx\\ &+ \operatorname{Re} i\beta \int \varphi(x)(\overline{w}_{\rm r}(x, y; t)\nabla_y w_{\rm r}(x, y; t) + \overline{w}_{\rm i}(x, y; t)\nabla_y w_{\rm i}(x, y; t))\,dx.\end{aligned} \tag{A.1}$$

By using the Cauchy–Riemann equations ($|\nabla_y u_{\mathrm{r,i}}| = |\nabla_x u_{\mathrm{r,i}}|$), we obtain

$$\begin{aligned}
&\operatorname{Re}\nu \int \varphi\Big(\overline{w}_{\mathrm{r}}\Delta_x w_{\mathrm{r}} + \overline{w}_{\mathrm{i}}\Delta_x w_{\mathrm{i}}\Big)\,dx + \operatorname{Re} i\beta \int \varphi(\overline{w}_{\mathrm{r}}\nabla_y w_{\mathrm{r}} + \overline{w}_{\mathrm{i}}\nabla_y w_{\mathrm{i}})\,dx \\
&= \ -\operatorname{Re}\nu \int \varphi\big(|\nabla_x w_{\mathrm{r}}|^2 + |\nabla_x w_{\mathrm{i}}|^2\big)\,dx - \operatorname{Re}\nu \int \nabla_x\varphi(\overline{w}_{\mathrm{r}}\nabla_x w_{\mathrm{r}} + \overline{w}_{\mathrm{i}}\nabla_x w_{\mathrm{i}})\,dx \\
&\quad + \operatorname{Re} i\beta \int \varphi(\overline{w}_{\mathrm{r}}\nabla_y w_{\mathrm{r}} + \overline{w}_{\mathrm{i}}\nabla_y w_{\mathrm{i}})\,dx \\
&\le -\operatorname{Re}\nu \int \varphi\big(|\nabla_x w_{\mathrm{r}}|^2 + |\nabla_x w_{\mathrm{i}}|^2\big)\,dx \\
&\quad + |\nu| \left\| \frac{\nabla\varphi}{\varphi} \right\|_\infty \int \varphi(|w_{\mathrm{r}}||\nabla_x w_{\mathrm{r}}| + |w_{\mathrm{i}}||\nabla_x w_{\mathrm{i}}|)\,dx \\
&\quad + |\beta| \int \varphi(|w_{\mathrm{r}}||\nabla_x w_{\mathrm{r}}| + |w_{\mathrm{i}}||\nabla_x w_{\mathrm{i}}|)\,dx \\
&\le \frac{|\beta|^2 + |\nu|^2\|\nabla\varphi/\varphi\|_\infty^2}{2\mathrm{Re}\nu} \int \varphi\big(|w_{\mathrm{r}}|^2 + |w_{\mathrm{i}}|^2\big)\,dx \\
&=: b_0 \int \varphi\big(|w_{\mathrm{r}}|^2 + |w_{\mathrm{i}}|^2\big)\,dx\ . \qquad \text{(A.2)}
\end{aligned}$$

Define

$$\varphi_y(x) := \varphi(x-y)\ , \qquad \xi_y^*(x) := \xi_N(x-y)\ ,$$

where φ and ξ_N are as in Definitions 1.1–1.2. We next compute the time derivative of the left-hand side of (4.3). The expression (A.1) is the linear part of the time derivative, and hence we simply insert the bound (A.2) and compute the nonlinear part:

$$\begin{aligned}
&\frac{1}{2}\partial_t \sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \ \le\ \frac{1}{2}\sup_y \partial_t \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \\
&\le \big(\gamma + b_0\big)\sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \\
&\quad + \operatorname{Re}\sup_y \Big| \int \varphi_y(x)\overline{w}(x+i\beta t,t) \\
&\quad \times \left(\int \xi_x^*(z)(G_1(z+i\beta t,t)\overline{w}(z+i\beta t,t) + G_2(z+i\beta t,t)w(z+i\beta t,t))dz \right) dx \Big| \\
&\le \big(\gamma + b_0\big)\sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \\
&\quad + \sup_y \int \varphi_y(x)|w(x+i\beta t,t)| \\
&\quad \times \left(\int \frac{|\xi_x^*(z)|}{\sqrt{\varphi_x(z)}}\sqrt{\varphi_x(z)}(|G_1(z+i\beta t,t)| + |G_2(z+i\beta t,t)|)|w(z+i\beta t,t)|dz \right) dx\ .
\end{aligned}$$

At this point, we apply the Cauchy–Schwarz inequality to each of the two integrals on the right-hand side. Using Lemma 4.1 we know that

$$\sup_{|\beta|\le\alpha}\ \sup_{t\le 1}\ \sup_{x\in\mathbb{R}^d} \big(|G_1(x+i\beta,t)| + |G_2(x+i\beta,t)|\big) \ \le\ 2R\ .$$

This gives

$$\begin{aligned}
\frac{1}{2}\partial_t \sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \;&\le\; \big(\gamma+b_0\big)\sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \\
&+\sup_y \left(\int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx\right)^{1/2}\left(\int \varphi(x)\,dx\int \frac{\xi_N^2(z)}{\varphi(z)}\,dz\right)^{1/2} \\
&\times 2R\left(\sup_x \int \varphi_x(z)|w(z+i\beta t,t)|^2\,dz\right)^{1/2} \\
\le\; &\left(\gamma+b_0+2R\left(\int \frac{\xi_N^2}{\varphi}\right)^{1/2}\right)\sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx \\
=:\; & b\sup_y \int \varphi_y(x)|w(x+i\beta t,t)|^2\,dx\ ,
\end{aligned}$$

where we used that, by Definition 1.1, $\int \xi_N^2/\varphi<\infty$ because ξ_N^2 is a Schwartz function and $1/\varphi$ is a Schwartz distribution. Equation (4.3) now follows from Gronwall's lemma.

In the discrete case, we solve the linear differential equation (see (2.6))

$$\partial_t w(nh+t) \;=\; \big(\gamma+\nu\Delta\big)w(nh+t)$$

for $t\in[0,h)$ with initial condition $w(nh)+h\xi_N\star\big(G_1(nh)w(nh)+G_2(nh)\overline{w}(nh)\big)$, and then we iterate for $n=0$ to $n=[1/h]+1$. Over one time step, the same calculations as in the continuous case give

$$\begin{aligned}
&\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x+i\beta(n+1)h,(n+1)h)|^2\,dx \\
&\le e^{2bh}\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x+i\beta nh,nh)|^2\,dx\ ,
\end{aligned}$$

and, similarly,

$$\begin{aligned}
&\sup_{|y|\le L\pi}\int \varphi(x-y)|h\xi_N\star\big(G_1((n+1)h)w((n+1)h)+G_2((n+1)h)\overline{w}((n+1)h)\big)|^2\,dx \\
&\le (2Rh)^2\left(\int\frac{\xi_N^2}{\varphi}\right)\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x+i\beta(n+1)h,(n+1)h)|^2 \\
&\le e^{Ch}\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x+i\beta(n+1)h,(n+1)h)|^2\ ,
\end{aligned}$$

and hence we can iterate

$$\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x+i\beta nh,nh)|^2\,dx \;\le\; e^{2bnh}\sup_{|y|\le L\pi}\int \varphi(x-y)|w(x,0)|^2\,dx\ .$$

This completes the proof of Lemma 4.2.

Appendix B. Analyticity for the fully discrete scheme. The full discretization discussed in section 2.2 is similar to that introduced in [26], where Gevrey regularity is proved. We give here another simple and direct proof that the semigroup generated by (2.5) maps into $\mathcal{G}_\alpha(C)$ (see Appendix D) for some α and C independent

of N and L. Our proof is in the spirit of Collet [1] or Takáč et al. [25]. We assume that the solution $u(x, nh)$ of (2.5) has reached an absorbing ball in L^∞, and hence there is an $R > 0$ such that $\|u(nh)\|_\infty \le R$ irrespective of u_0 and n. We then use a contraction argument to show that, for small T, for $nh \in [0, T]$, there is a unique solution to (2.5) in the metric space of functions satisfying $|||u||| \le R$, where

$$|||f||| \;=\; \max_{nh\in[0,T]} \sup_{|x|\le L\pi} |f(x + i\sqrt{nh}, nh)| \;.$$

Remark that, if $T < h$, there is nothing to prove. (The solutions are entire functions anyway.) The purpose of this section is to provide bounds on the radius of analyticity which are independent of h and N, and hence we may assume h to be small.

We seek a solution to the equation $u(nh) = \mathcal{Y}\big(u, u_0\big)(nh)$ with $\mathcal{Y}$ defined by

$$\mathcal{Y}\big(f, f_0\big)(nh) \;=\; \mathcal{K}(nh) \star f_0 + \sum_{j=0}^{n-1} h\mathcal{K}\big(h(n-j)\big) \star \mathrm{P}^N F(f(jh)) \;,$$

where $\mathcal{K}$ is given by (2.4).

It is easy to see that, for small $T > 0$, $\mathcal{Y}(\cdot, f_0)$ is a contraction:

$$\begin{aligned}
&\big|\mathcal{Y}\big(f, f_0\big)(x + i\sqrt{nh}, nh) - \mathcal{Y}\big(g, f_0\big)(x + i\sqrt{nh}, nh)\big| \\
&\le \sum_{j=0}^{n-1} \int h|\mathrm{P}^N \mathcal{K}\big(y - z + i(\sqrt{nh} - \sqrt{jh}), h(n-j)\big)| \\
&\quad \times \Big|F\big(f(z + i\sqrt{jh}, jh)\big) - F\big(g(z + i\sqrt{jh}, jh)\big)\Big| dz \\
&\le \mathrm{Lip}(F, R)\, |||f - g||| \sum_{j=0}^{[T/h]} \int h|\mathrm{P}^N \mathcal{K}\big(x + i(\sqrt{nh} - \sqrt{jh}), h(n-j)\big)|\, dx.
\end{aligned}$$

Here $\mathrm{Lip}(F, R)$ is the Lipschitz constant of F in the ball of radius R, and hence by taking T small enough (depending on $\mathrm{Lip}(F, R)$ only) the solution to the fixed point problem exists and is unique. Since u belongs to an absorbing ball of L^∞, the argument can be iterated indefinitely, and hence u is analytic for all times thereafter.

Appendix C. Uniform bounds on complex analytic functions. In this section we show that an L^p bound in a strip of the complex plane provides an L^∞ bound in a smaller strip.

LEMMA C.1. *Let $p \ge 1$. There is a constant $C = C(\varphi, \delta)$ such that any function f analytic in $|\mathrm{Im}(x)| \le \delta$ satisfies*

$$|f(y + iz)|^p \;\le\; C \sup_{|\gamma|\le\delta} \int \varphi(x - y)|f(x + i\gamma)|^p \, dx$$

for all $y \in \mathbb{R}^d$ and $|z| \le \delta/2$.

Proof. We take $y = 0$ and $\delta = 1$ for simplicity. The general case is obtained by translation and scaling. Since analytic functions are harmonic the following mean value property holds (see [16]). Let $\mathcal{D}$ be the unit ball centered at 0 in the n-dimensional complex space; then

$$f(0) \;=\; \frac{1}{\mathrm{Vol}(\mathcal{D})} \int_{\mathcal{D}} f(x + i\gamma)\, dx\, d\gamma \;.$$

We apply Jensen's inequality and use that there is a C for which

$$\inf_{|x|\le 1} C\varphi(x) \;\ge\; 1$$

(see Definition 1.1) to obtain

$$\begin{aligned}|f(0)|^p &\le \frac{1}{\mathrm{Vol}(\mathcal{D})}\int_{\mathcal{D}} |f(x+i\gamma)|^p\,dx\,d\gamma \\ &\le \frac{1}{\mathrm{Vol}(\mathcal{D})}\sup_{|\gamma|\le 1}\int_{|x|\le 1} |f(x+i\gamma)|^p\,dx \\ &\le \frac{C}{\mathrm{Vol}(\mathcal{D})}\sup_{|\gamma|\le 1}\int \varphi(x)|f(x+i\gamma)|^p\,dx\ . \qquad \square\end{aligned}$$

Appendix D. Gevrey and Bernstein classes of analytic functions. We introduce here the metric spaces $\mathcal{B}_\sigma(C)$ (the Bernstein class) and $\mathcal{G}_\alpha(C)$ (the Gevrey class) and recall two properties of functions belonging to these spaces (see [7, 15, 18] for details).

DEFINITION D.1. *The Bernstein class $\mathcal{B}_\sigma(C)$ is the set of all functions f having an analytic extension to the whole of $\mathbb{C}^d$ with exponential growth along the imaginary directions:*

$$|f(x+iy)| \le Ce^{\sigma|y|}\ \forall (x,y)\in\mathbb{R}^d\times\mathbb{R}^d\ .$$

The Gevrey class $\mathcal{G}_\alpha(C)$ is the set of all functions f admitting an analytic extension to a strip of width 2α around the real axes and which are uniformly bounded in this strip:

$$|f(x+iy)| \le C\ \forall (x,y)\in\mathbb{R}^d\times[-\alpha,\alpha]^d\ .$$

The first result states that any function in $\mathcal{G}_\alpha(C)$ can be written as a sum of entire functions.

PROPOSITION D.2. *Let $f\in\mathcal{G}_\alpha(C)$. Then there exists a C' depending on C only such that*

$$f(z) = \sum_{n\in\mathbb{Z}^d} e^{-\alpha|n|}e^{in\cdot z}f_n(z)\ ,$$

with $f_n\in\mathcal{B}_2(C')$.

The second result is a classical sampling formula (see [7] or [15] where it is called the Cartwright formula).

PROPOSITION D.3. *For all $f\in\mathcal{B}_\sigma(C)$, the following identity holds:*

$$f(z) = \sum_{n\in\mathbb{Z}^d} f\big(x_\sigma(n)\big)\mathcal{F}_\sigma\big(z-x_\sigma(n)\big)\ ,$$

where

$$x_\sigma(n) = \frac{n\pi}{3\sigma}\ , \qquad \mathcal{F}_\sigma(x) = \frac{\sin(3\sigma x)\sin(\sigma x)}{3\sigma^2x^2}\ .$$

COMPUTING THE EFFECTIVE HAMILTONIAN IN THE MAJDA–SOUGANIDIS MODEL OF TURBULENT PREMIXED FLAMES*

BOUALEM KHOUIDER† AND ANNE BOURLIOUX†

Abstract. Turbulence enhances the speed of propagation of a premixed flame front. According to the Majda–Souganidis model, the procedure to predict this enhancement involves computing the effective Hamiltonian in a small-scale nonlinear cell-problem. We first discuss how to transform this problem into computing the steady-state solution of a system of conservation laws whose vector solution represents the gradient of the eigenfunction associated with the effective Hamiltonian. Theoretical arguments as well as numerical evidence are presented to emphasize the importance of enforcing the constraint that the vector solution must effectively be the gradient of a scalar function. We introduce a scheme that satisfies this constraint exactly by relying on staggered grids for the gradient components. Also discussed is the issue of selecting a time integrator to achieve fast convergence to a steady state. Validation is performed by examining convergence under grid refinement and by comparison with analytical results when available.

Key words. gradient-preserving scheme, essentially nonoscillatory, staggered grid, Hamilton–Jacobi equation, conservation laws, steady state

1. Introduction.

The flamelet regime in premixed combustion is characterized by a very thin reaction zone that separates burnt and fresh gas so that, for all practical matters, it can be viewed as an infinitely thin flame front, propagating normal to itself due to burning and advection. The speed of propagation of that interface can be easily predicted in the laminar case, where advection plays a trivial role. It is, however, much more difficult to predict its enhancement due to turbulence, when the front is wrinkled by a multiple scale advecting flow field. A rigorous asymptotic strategy to predict this enhancement has been developed by Majda and Souganidis [17] for a flow field with separate scales. According to the theory, the procedure to compute the enhanced burning speed involves minimizing a function of the effective Hamiltonian for the flame; the effective Hamiltonian must be computed as the eigenvalue of a nonlinear cell-problem. In [5], this procedure was implemented for the simple case of a one-dimensional shear layer; for that case, the solution can be expressed mostly through explicit formulas. The method presented in this paper extends the procedure for more general small-scale turbulent-like flows such as steady arrays of eddies or combinations of eddies and shears; for such cases, explicit formulas are no longer available and the problem must be solved numerically. Solving the cell-problem

is the hardest part: it requires computing the eigenvalue of a Hamilton–Jacobi equation. Numerical methods for Hamilton–Jacobi equations (without eigenvalues) are well known [4, 18], and so are iterative methods to compute the eigenvalues for large linear systems. The present case combines both problems and the challenge from a numerical point of view is to provide a scheme capable of a robust handling of the nonlinearity of Hamilton–Jacobi equations and of an efficient search for the eigenvalue of the resulting discretized equations (hence, a large nonlinear system). The method presented in this paper tackles this challenge by reformulating the problem so that the eigenvalue is effectively eliminated from the preliminary phase of the computation by differentiation of the eigenvalue problem. This strategy leads to a very robust and practical scheme for two main reasons: the entire eigenvalue search is replaced by a simple algebraic postprocessing of the results instead of the typical iterative process; the system obtained by differentiation leads to a system of conservation laws which is a class of problems for which a well-established numerical machinery is available.

The paper is organized as follows. In section 2, the Majda–Souganidis asymptotic model equations are stated as well as the reformulation of the eigenvalue problem as one of finding a pseudotime steady-state solution for the eigenfunction gradient. In sections 3 and 4, some key theoretical properties of the equations are discussed to motivate the strategy to design the scheme. In section 3, the lack of strong hyperbolicity of the gradient equation is established. Yet, in section 4, convergence results for the equivalent time marching problem for the eigenfunction itself are exploited to formulate the principal constraint to guarantee that a discrete solution of the gradient problem will also converge to a steady state. This constraint is that the discrete vector solution be in some sense the discrete gradient of a scalar function. In section 5, we describe a novel *gradient-preserving* scheme, i.e., a scheme that explicitly preserves the gradient structure of the initial data throughout the computation, in some appropriate discrete sense. The fact that the gradient-preserving property is essential for convergence is further demonstrated by numerical experiments in section 6, where the performance of the gradient-preserving scheme is contrasted with that of other schemes which do not quite satisfy that constraint. A second order spatially accurate version of the scheme is presented in section 7, along with a discussion on how to select the time integrator to accelerate convergence to a steady state. In section 8, the performance of the method is validated systematically by comparison with the reference solutions for the case of a simple shear layer [5, 6].

2. Homogenization theory formulation.

2.1. The Majda–Souganidis asymptotic model. Here we simply state the model equations to be solved numerically; details regarding the derivation of the model can be found in [5, 17]. Assuming that the heat release due to combustion is weak and that temperature and all the relevant chemical species diffuse at the same rate (Lewis number unity), the flame propagation can be described using a single advection-diffusion-reaction equation for temperature. The homogenization theory that leads to the model equations (2.1) and (2.2) below applies under the following additional assumptions:

- The reaction zone is thin, as a result of the balance between very weak diffusion and very fast reaction.
- The incompressible advecting velocity field includes two separate scales: one large scale and a scale intermediate between the large scale and the flame thickness.
- The reaction rate is of the Kolmogorov–Petrovskii–Piskunov type. A typical

example of such reaction rate is given by $f(T) = \overline{K}\,T(1-T)$, where the temperature T has been normalized between $T = 0$ on the cold (unburnt) side and $T = 1$ on the hot (burnt) side and $\overline{K} > 0$ is the reaction rate constant.

The intermediate scale velocity field causes the flame front to wrinkle: qualitatively, the increase in flame area due to this wrinkling leads to an overall burning speed enhancement. The objective of the homogenization theory is to predict this enhanced speed of propagation of the flame. The equations in the form stated below describe how to do this assuming that, at large scales, the advecting velocity field is constant and the flame front is planar.

Given the flame front unit normal $\mathbf{n} = (\cos\theta, \sin\theta)$, the flame speed $F(\mathbf{n})$ in that direction must be computed as

$$F(\mathbf{n}) = \min_{r>0} \frac{H(r\mathbf{n}) + \bar{K}}{r}, \tag{2.1}$$

where $\overline{K} = f'(0)$ is the positive constant used to define the reaction rate above and H is the effective Hamiltonian of the flame, computed as the unique eigenvalue of the following so-called *cell-problem*:

$$-|\mathbf{p} + \mathbf{D}w|^2 + \mathbf{V}(\mathbf{y}) \cdot (\mathbf{p} + \mathbf{D}w) = -H(\mathbf{p}). \tag{2.2}$$

(At least for steady flows, it is trivial from a numerical point of view to deal with the unsteady terms—they are linear—so we will not discuss this issue in this paper; see [14] for examples with unsteady flows.) The eigenfunction $w(\mathbf{y})$ must be of zero mean and biperiodic with respect to the spatial variables $\mathbf{y} = (x, y)$. (One can always assume that the biperiodic domain has been rescaled to a unit square.) $\mathbf{D}w$ represents the spatial gradient of the eigenfunction. The velocity field $\mathbf{V}(\mathbf{y})$ is assumed to combine a large-scale constant flow and the smaller scale "turbulent" flow:

$$\mathbf{V} = \bar{\mathbf{v}} + \lambda\mathbf{v} = \bar{\lambda}(\cos\bar{\theta}, \sin\bar{\theta}) + \lambda\mathbf{v}(\mathbf{y}).$$

Here, $\bar{\lambda}$ and λ represent the magnitude of the velocity field, respectively, at large and intermediate scales, while $\mathbf{v}(\mathbf{y})$ is the intermediate scale velocity field defined over the unit periodic box. It is also assumed to have a zero mean and to be biperiodic as well as to be incompressible. For example, in section 8 below and elsewhere [2, 15], we use our procedure on velocity fields obtained from the Childress–Soward stream function $\psi(\mathbf{y})$:

$$\psi(\mathbf{y}) = \psi(x, y) = \sin(2\pi x)\sin(2\pi y) + \delta\cos(2\pi x)\cos(2\pi y), \qquad 0 \le \delta \le 1. \tag{2.3}$$

Streamlines for $\delta = 0, 0.5, 1$ are shown in Figure 2.1.

In summary, the input data are

- the front angle θ;
- δ, λ: the parameters that define the "turbulent" velocity field responsible for the burning speed enhancement;
- $\overline{\lambda}$, $\overline{\theta}$: the parameters that define the large-scale (constant) velocity field.

Results are typically presented in terms of the flame speed enhancement F_e defined as

$$F_e = F + \overline{\mathbf{v}} \cdot \mathbf{n} - S_L \tag{2.4}$$

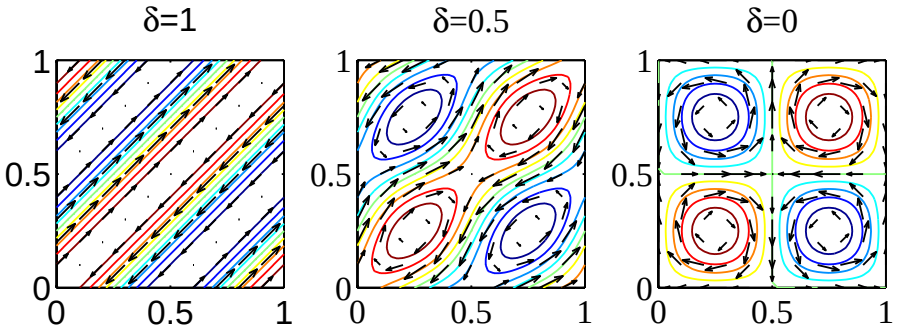

FIG. 2.1. *Streamlines for the Childress–Soward flow.* $\delta = 1$*: simple shear tilted at* 45 *degrees,* $\delta = 0.5$*: combination of eddies and shear layers, and* $\delta = 0$*: periodic array of eddies.*

with $S_L = 2/\sqrt{\overline{\overline{K}}}$ the laminar burning speed of the flame. In the rest of the paper, the problem is rescaled so that $S_L = 1$; F_e represents the increase in burning speed of the flame compared to the laminar case. A qualitative understanding of the wrinkling of the front can be achieved by looking at the isolevels of the eigenfunction w: they can be related to successive realizations of the wrinkled flame front as it moves across the periodic cell due to burning and advection.

The main challenge in performing the optimization over the variable r in (2.1) is to provide the effective Hamiltonian $H(r\mathbf{n})$, which must be computed as the eigenvalue in (2.2.) The ultimate objective here is to design a method sufficiently efficient to allow for the extensive tabulation of F_e as a function of all the input data. Each entry in such a table requires iterating numerically over many values of r to perform the minimization in (2.1), hence requiring multiple evaluations of H; the main issue is therefore to design an efficient, robust, fully automated algorithm to compute this effective Hamiltonian for a wide range of parameters.

Equation (2.2) is both nonlinear and contains an eigenvalue (the effective Hamiltonian H): it is very challenging numerically to deal simultaneously with both difficulties, and it is therefore very tempting to try to avoid dealing directly with at least one of them. One possible strategy along that line would be to linearize the problem, hence eliminating the nonlinearity aspect and retaining the eigenvalue; this could be done by adding a small viscous term of order ϵ and doing the following transformation: $T^\epsilon(x, y) = \exp(Z(x, y)/\epsilon)$ with $Z(x, y) = \mathbf{p} \cdot (x, y) + w(x, y)$; formulating the problem in terms of T^ϵ instead of w basically undoes one of the steps in the homogenization procedure in [17]. The main difficulty with this approach is that the amount of viscosity ϵ needed to lead to a system of equations that can be safely discretized by a centered scheme is not known a priori but is solution-dependent. Another difficulty is that the discretized equations would lead to a very large linear eigenvalue problem, requiring a costly iterative procedure for its numerical solution along with the need of generating an adequate initial guess for the eigenvalue.

In that sense, the strategy to be discussed in the rest of the paper is much more robust. It is the eigenvalue aspect that is eliminated from the formulation by differentiating the cell-problem, resulting in a system of equations for the eigenfunction gradient that is still nonlinear but that no longer contains the eigenvalue explicitly. This strategy is described next.

2.2. Reformulation as a gradient problem. By differentiating (2.2) with respect to $\mathbf{y}$, we eliminate the eigenvalue and obtain the following nonlinear equation for the eigenfunction gradient $\mathbf{D}w$:

$$\mathbf{D}\{-|\mathbf{D}w|^2 - 2\mathbf{p}\cdot\mathbf{D}w + (\overline{\mathbf{v}} + \lambda\mathbf{v}(\mathbf{y}))\cdot\mathbf{D}w + \lambda\mathbf{v}(\mathbf{y})\cdot\mathbf{p}\} = 0. \tag{2.5}$$

Integrating (2.2) over one periodic cell and using the divergence theorem, one obtains a formula that relates algebraically H and $\mathbf{D}w$:

$$H(\mathbf{p}) = |\mathbf{p}|^2 + \langle|\mathbf{D}w|^2\rangle - \overline{\mathbf{v}}\cdot\mathbf{p}, \tag{2.6}$$

where $\langle\cdot\rangle$ represents the average over the periodic cell. Therefore, assuming that indeed one is able to solve (2.2), the effective Hamiltonian H can be computed very economically a posteriori by simple postprocessing of the solution for $\mathbf{D}w$, hence avoiding entirely any eigenvalue iterative procedure.

A practical approach to compute the solution of (2.5) is to view it as the steady state of the following system:

$$\begin{cases} \partial_s u + \partial_x K(u,v,x,y) = 0, \\ \partial_s v + \partial_y K(u,v,x,y) = 0, \end{cases} \tag{2.7}$$

where K is given by

$$K(\mathbf{u},x,y) = -|\mathbf{u}|^2 - 2\mathbf{p}\cdot\mathbf{u} + (\overline{\mathbf{v}} + \lambda\mathbf{v}(x,y))\cdot\mathbf{u} + \lambda\mathbf{v}(x,y)\cdot\mathbf{p} \tag{2.8}$$

and $\mathbf{u} = (u,v) = \mathbf{D}w$ is the eigenfunction gradient.

The pseudotime marching method to solve (2.7) to a steady state is described in detail in section 5 below. Before describing the numerical method, however, some results regarding the equation before discretization are reported in section 3 (lack of strong hyperbolicity) and section 4 (effective convergence to a steady state); those results provide essential insight on the type of constraints to be taken into account in order to design a successful numerical method, with a particular concern for the convergence property of the algorithm toward a steady-state solution.

3. Lack of strong hyperbolicity. Here we prove that (2.7) is not strongly hyperbolic. Set $F = (F_1, F_2)$ with

$$F_1(\mathbf{u},x,y) = \begin{pmatrix} K(\mathbf{u},x,y) \\ 0 \end{pmatrix} \text{ and } \quad F_2(\mathbf{u},x,y) = \begin{pmatrix} 0 \\ K(\mathbf{u},x,y) \end{pmatrix}.$$

The associated system is strongly hyperbolic if for all reals α and β the matrix

$$A = \alpha\frac{\partial F_1}{\partial \mathbf{u}} + \beta\frac{\partial F_2}{\partial \mathbf{u}},$$

where

$$\frac{\partial F_1}{\partial \mathbf{u}} = \begin{bmatrix} \frac{\partial K}{\partial u} & \frac{\partial K}{\partial v} \\ 0 & 0 \end{bmatrix}$$

and

$$\frac{\partial F_2}{\partial \mathbf{u}} = \begin{bmatrix} 0 & 0 \\ \frac{\partial K}{\partial u} & \frac{\partial K}{\partial v} \end{bmatrix},$$

has two real eigenvalues and two linearly independent eigenvectors [10].

The eigenvalues of the matrix A are $\nu = \alpha\frac{\partial K}{\partial u} + \beta\frac{\partial K}{\partial v}$ and 0. Clearly, if $\frac{\partial K}{\partial v} \neq 0$ or $\frac{\partial K}{\partial v} \neq 0$ one can choose the constants α and β such that ν is zero and the matrix A is not identically zero. This is equivalent to setting

$$\begin{cases} \dfrac{\partial K}{\partial u} \neq 0 \text{ or } \dfrac{\partial K}{\partial v} \neq 0, \\ \alpha\dfrac{\partial K}{\partial u} + \beta\dfrac{\partial K}{\partial v} = 0. \end{cases} \tag{3.1}$$

In this case, the matrix A has only one free eigenvector associated with the double eigenvalue 0; i.e., A is equivalent to a Jordan block. Thus, (2.7) is not strongly hyperbolic. The lack of strong hyperbolicity for the pseudotime marching equation has important consequences regarding the possibility of reaching numerically a steady state by long time marching:

1. Without taking into account other specific properties of the system studied here (as will be done in section 4 below), the lack of strong hyperbolicity means that there is no guarantee that the solution will converge to a steady state [8].
2. Standard numerical methods for conservation laws might not work, as most rely on the strong hyperbolic nature of the equations.

Remark 1. The vector solution to be computed here is actually a gradient, a property which was not taken into account in the discussion above. It is interesting to notice that imposing this additional constraint on the solution is not, per se, sufficient to recover strong hyperbolicity.

Take $\mathbf{u} = \mathbf{D}\phi$ and $\mathbf{V} = \overline{\mathbf{v}} + (\psi_y, -\psi_x)$ for some periodic functions ϕ and ψ with zero mean, a mean flow $\overline{\mathbf{v}} = (\overline{v}_1, \overline{v}_2)$, and a mean flame gradient $\mathbf{p} = (p_1, p_2)$. The conditions of nonhyperbolicity (3.1) are equivalent to

$$\begin{cases} 2\phi_x + 2p_1 - \overline{v}_1 - \psi_y \neq 0 \text{ or } 2\phi_y + 2p_2 - \overline{v}_2 + \psi_x \neq 0, \\ \alpha(2\phi_x + 2p_1 - \overline{v}_1 - \psi_y) + \beta(2\phi_y + 2p_2 - \overline{v}_2 + \psi_x) = 0. \end{cases}$$

It is easy to construct examples that would satisfy those nonhyperbolicity conditions. For example, set $\phi(x, y) = \psi(-y, x)/2$ so that the conditions

$$2\phi_x = \psi_y \text{ and } 2\phi_y = -\psi_x$$

are satisfied on the curve $y = -x$ and choose the constant parameters such that

$$2p_1 - \overline{v}_1 \neq 0 \text{ or } 2p_2 - \overline{v}_2 \neq 0$$

and

$$\alpha(2p_1 - \overline{v}_1) + \beta(2p_2 - \overline{v}_2) = 0.$$

4. Convergence to a steady state. The main conclusion from section 3 is that if one views the system of equations in (2.7) as a system of conservation laws for a vector solution, there is no guaranty that, starting from general initial data, convergence to a steady state can be achieved by pseudotime marching because of the lack of strong hyperbolicity of the system of equations (2.7).

Such a convergence result, however, can be recovered by first considering the convergence of the following pseudotime marching equation for the eigenfunction itself:

$$w_s - |\mathbf{p} + \mathbf{D}w|^2 + \mathbf{V}(\mathbf{y}) \cdot (\mathbf{p} + \mathbf{D}w) = -H(\mathbf{p}), \tag{4.1}$$

with H the eigenvalue of the cell-problem in (2.2). Convergence of $w + Hs$ to a steady solution was proved by Barles and Souganidis [1] for general initial data. This long-time convergence property automatically implies convergence, in the weak sense, of the gradient $\mathbf{D}w$, therefore establishing that the pseudotime iterations on (2.7) should converge, at least theoretically (i.e., before numerical discretization). The key implication of this remark relevant to the design of a scheme to solve those equations numerically is that one way to recover convergence for the gradient system is to ensure that the vector solution of (2.7) is effectively the gradient, in some appropriate discrete sense, of a scalar function.

For smooth functions, a vector function is a gradient if it is curl-free. We state next an equivalent definition to the curl-free condition which does not involve derivatives and hence constitutes a useful generalization to weak derivatives. This equivalent definition will also turn out to be very useful in dealing with discrete data, as is done in the next section. Let (u, v) be an integrable vector function:

- (u, v) is the gradient of a function w if and only if, given a reference point (a, b), we have the double equality

$$w(x, y) = \int_a^x u(\xi, y)\, d\xi + w(a, y) = \int_b^y v(x, \xi)\, d\xi + w(x, b)$$

for a.e. each point (x, y). However, similarly,

$$w(a, y) = \int_b^y v(a, \xi)\, d\xi + w(a, b)$$

and

$$w(x, b) = \int_a^x u(\xi, b)\, d\xi + w(a, b);$$

hence, without referring to any primitive, we can state that $(u(x, y), v(x, y))$ is a gradient in the weak sense if and only if for a.e. (x, y) we have

$$\int_b^y v(a, \xi)\, d\xi + \int_a^x u(\xi, y)\, d\xi = \int_a^x u(\xi, b)\, d\xi + \int_b^y v(x, \xi)\, d\xi. \tag{4.2}$$

- In addition, the primitive function is biperiodic of period T if and only if for a.e. (x, y)

$$\int_a^{a+T} u(\xi, y)\, d\xi = 0, \tag{4.3}$$

$$\int_b^{b+T} v(x, \xi)\, d\xi = 0. \tag{4.4}$$

5. Gradient-preserving scheme. Brute force attempts at numerically solving (2.5) to a steady state with standard numerical schemes for conservation laws failed to converge, and this comes as no surprise given the considerations in sections 3 and 4 above. Instead, the results in section 4 suggest that convergence could be guaranteed only if the discrete vector solution is actually a gradient. The method we propose here has precisely this property: the scheme is *gradient-preserving* in the discrete sense of formula (4.2) inasmuch as, given initial vector data which are a discrete gradient, the solution will remain a discrete gradient at all later discrete times. (In practice, the simplest such initial data are identically zero.) The scheme is actually based on a fairly standard conservative formulation except for the staggered discretization grids to be described first.

5.1. Staggered grids. Let $h = 1/n$ define the mesh discretization of the interval $[0,1]$ with $x_i = ih$, $x_{i+1/2} = x_i + h/2$, $y_j = jh$, and $y_{j+1/2} = y_j + h/2$ for any integers $0 \le i, j \le n$. We consider the staggered grid obtained by the superposition of the two grids (x_i, y_j) and $(x_{i+1/2}, y_{j+1/2})$ (see Figure 5.1).

The first component, u, of the gradient solution is defined at the nodes (x_i, y_j), while the second component, v, is defined at the nodes $(x_{i+1/2}, y_{j+1/2})$. The scalar primitive (the eigenfunction) w itself is defined at the hybrid nodes $(x_{i+1/2}, y_j)$.

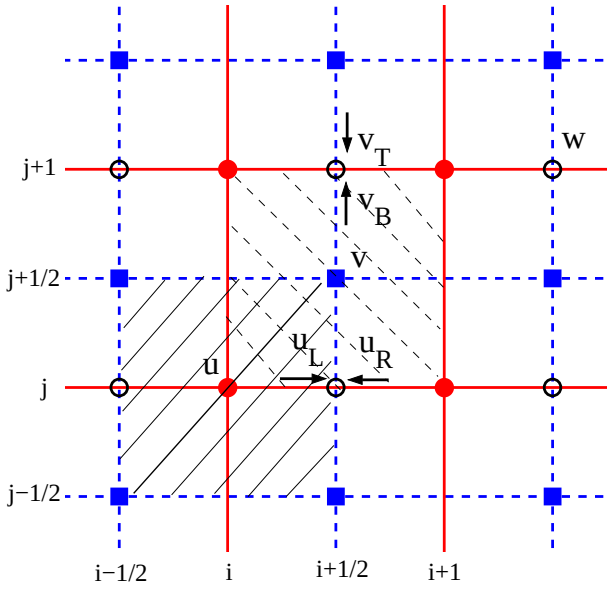

FIG. 5.1. *Staggered grid for a gradient-preserving scheme: u is defined on the vertices (i,j) by its cell averages on $[i-1/2, i+1/2]\times[j-1/2, j+1/2]$ (filled circles), v on the vertices $(i+1/2, j+1/2)$ by its cell averages on $[i, i+1]\times[j, j+1]$ (filled squares), and the primitive w is obtained on $(i+1/2, j)$ (empty circles). The shaded squares show the control volumes for u and v, respectively, and the arrows point out the associated Riemann problems.*

5.2. Conservative formulation. Using the notation $\mathbf{V} = (V_1, V_2)$ and $\mathbf{p} = (p_1, p_2)$, the starting point of the strategy is to notice the symmetry in the flux function K in (2.8), which can be split into two independent parts, $K(u, v, x, y) = f(u, x, y) + g(v, x, y)$, with

$$f = f(u, x, y) = -u^2 - 2p_1 u + V_1(x, y)u + V_1(x, y)p_1$$

and

$$g = g(v, x, y) = -v^2 - 2p_2 v + V_2(x, y)v + V_2(x, y)p_2.$$

The conservative formulation is obtained by integrating the conservation laws over each u- and v-control volume. Taking the integral of

$$\partial_s u + \partial_x f(u, x, y) + \partial_x g(v, x, y) = 0$$

over the cell $[x_{i-1/2}, x_{i+1/2}] \times [y_{j-1/2}, y_{j+1/2}] \times [s_n, s_{n+1}]$ and the integral of

$$\partial_s v + \partial_y f(u, x, y) + \partial_y g(v, x, y) = 0,$$

over $[x_{i-1}, x_i] \times [y_{j-1}, y_j] \times [s_n, s_{n+1}]$ and then dividing by the control volume area h^2, one obtains the following equations in conservative form:

$$\begin{aligned} \overline{u}_{i,j}^{n+1} = \overline{u}_{i,j}^{n} &- \frac{1}{h^2} \int_{s_n}^{s_{n+1}} \int_{y_{j-1/2}}^{y_{j+1/2}} \left\{ f(u, x_{i+1/2}, y) + g(v, x_{i+1/2}, y) \right\} dy\, ds \\ &+ \frac{1}{h^2} \int_{s_n}^{s_{n+1}} \int_{y_{j-1/2}}^{y_{j+1/2}} \left\{ f(u, x_{i-1/2}, y) + g(v, x_{i-1/2}, y) \right\} dy\, ds \end{aligned} \tag{5.1}$$

and

$$\begin{aligned} \overline{v}_{i-1/2,j-1/2}^{n+1} = \overline{v}_{i-1/2,j-1/2}^{n} &- \frac{1}{h^2} \int_{s_n}^{s_{n+1}} \int_{x_{i-1}}^{x_i} \left\{ f(u, x, y_j) + g(v, x, y_j) \right\} dx\, ds \\ &+ \frac{1}{h^2} \int_{s_n}^{s_{n+1}} \int_{x_{i-1}}^{x_i} \left\{ f(u, x, y_{j-1}) + g(v, x, y_{j-1}) \right\} dx\, ds, \end{aligned} \tag{5.2}$$

where

$$\overline{u}_{i,j}^{k} = \frac{1}{h^2} \int_{x_{i-1}}^{x_i} \int_{y_{j-1/2}}^{y_{j+1/2}} u(x, y, s_k) dx dy$$

is the cell average of u with the obvious corresponding considerations for v. This can be expressed simply as

$$\overline{u}_{i,j}^{n+1} = \overline{u}_{i,j}^{n} - \frac{\Delta s}{h} \left(F_{i+1/2,j}^{n,1} - F_{i-1/2,j}^{n,1} \right) \tag{5.3}$$

and

$$\overline{v}_{i-1/2,j-1/2}^{n+1} = \overline{v}_{i-1/2,j-1/2}^{n} - \frac{\Delta s}{h} \left(F_{i-1/2,j+1}^{n,2} - F_{i-1/2,j}^{n,2} \right), \tag{5.4}$$

where the flux $F_{i-1/2,j}^{n,1}$ corresponds to the double space-time integral in (5.1) over one time-step and over the vertical edge (of a u-cell) with the edge center located at $(x_{i-1/2}, y_j)$:

$$F_{i-1/2,j}^{n,1} = \frac{1}{h\,\Delta s} \int_{s_n}^{s_{n+1}} \int_{y_{j-1/2}}^{y_{j+1/2}} \left\{ f(u, x_{i+1/2}, y) + g(v, x_{i+1/2}, y) \right\} dy\, ds, \tag{5.5}$$

while the flux $F^{n,2}_{i-1/2,j}$ corresponds to the double space-time integral in (5.2) over one time-step and over the horizontal edge (of a v-cell) with the edge center also located at $(x_{i-1/2}, y_j)$:

$$F^{n,2}_{i-1/2,j} = \frac{1}{h\,\Delta s}\int_{s_n}^{s_{n+1}}\int_{x_{i-1}}^{x_i}\{f(u,x,y_{j-1}) + g(v,x,y_{j-1})\}\,dx\,ds. \tag{5.6}$$

As will be shown in Proposition 5.1 below, the key in designing a gradient-preserving scheme is to use the same numerical value for $F^{n,1}_{i-1/2,j}$ and $F^{n,2}_{i-1/2,j}$. This can be justified as follows. In evaluating $F^{n,1}_{i-1/2,j}$, for instance, it is clear that the f-component of the flux (corresponding to the integration of $f(u,x,y)$) should be estimated using a standard Riemann solver, with left and right states corresponding to $\bar{u}^n_{i-1,j}$ and $\bar{u}^n_{i,j}$, respectively (for a first order method at least). The g-component of the flux, however, can be specified somewhat more arbitrarily because it depends only on v and is independent of u. A second order accurate choice is to estimate that portion of the integral by its value at the midpoint of the edge $(x_{i-1/2}, y_j)$, in which case this contribution can be shown to be equal to second order to the g-component of the $F^{n,2}_{i-1/2,j}$ flux, to be estimated by resorting again to a Riemann solver, this time with top and bottom states given by $\bar{v}^n_{i-1/2,j}$ and $\bar{v}^n_{i-1/2,j-1}$, respectively. Specifically,

$$F^{n,1}_{i-1/2,j} = F^{n,2}_{i-1/2,j} = F^n_{i-1/2,j} = f(\Re^1_{i-1/2,j}, x_{i-1/2}, y_j) + g(\Re^2_{i-1/2,j}, x_{i-1/2}, y_j), \tag{5.7}$$

where $\Re^1_{i-1/2,j}$ is the solution of the Riemann problem for the flux f associated with the vertical edge $(i-1/2, j)$ and the left and right states u_L and u_R ($\overline{u}_{i-1,j}$ and $\overline{u}_{i,j}$ for the first order scheme) and $\Re^2_{i-1/2,j}$ is the solution for the Riemann problem for the flux g at the horizontal edge $(i-1/2, j)$ for the bottom and top states v_B and v_T ($\overline{v}_{i-1/2,j-1/2}$ and $\overline{v}_{i-1/2,j+1/2}$ for the first order scheme); see Figure 5.1. The scheme can be rewritten as

$$\begin{aligned}\overline{u}^{n+1}_{i,j} &= \overline{u}^n_{i,j} - \frac{\Delta s}{h}\left\{F^n_{i+1/2,j} - F^n_{i-1/2,j}\right\},\\ \overline{v}^{n+1}_{i-1/2,j-1/2} &= \overline{v}^n_{i-1/2,j-1/2} - \frac{\Delta s}{h}\left\{F^n_{i-1/2,j} - F^n_{i-1/2,j-1}\right\}.\end{aligned} \tag{5.8}$$

PROPOSITION 5.1. *The scheme in* (5.8) *is gradient preserving in the sense that if the numerical vector solution satisfies the condition* (4.2) *at some given initial time, s_0, then this condition will be satisfied at any latter time, $s_n > s_0$. Furthermore, if the primitive function is periodic at the initial time, then it remains periodic; i.e.,* (4.3) *and* (4.4) *are also satisfied at time s_n if they were satisfied at time s_0.*

Proof. It is straightforward to verify the second part of the proposition by exploiting the conservative formulation. To prove the first claim, recall that the discrete values representing the numerical solution for (u, v) are cell averages, so, given these values at any time, s_n, we can get the solution primitive at the hybrid vertices $((i-1/2), j)$, without any further approximation. Taking $(a, b) = (x_{1/2}, y_0)$ and $(x, y) = (x_{i-1/2}, y_j)$ in (4.2) leads to

$$\sum_{k=1}^{i-1}\overline{u}_{k,0} + \sum_{k=1}^{j}\overline{v}_{i-1/2,k-1/2} = \sum_{k=1}^{j}\overline{v}_{1/2,k-1/2} + \sum_{k=1}^{i-1}\overline{u}_{k,j}. \tag{5.9}$$

To show that the scheme is gradient preserving, we must show that if the discrete solution at time s_n verifies (5.9), then so does the solution at time $s_{n+1} = s_n + \Delta s$, which is equivalent to showing that the same condition is satisfied by the difference of the two vector solutions in (5.8), i.e.,

$$\sum_{k=1}^{i-1} F^n_{k+1/2,0} - F^n_{k-1/2,0} + \sum_{k=1}^{j} {F^n}_{i-1/2,k} - {F^n}_{i-1/2,k-1}$$
$$= \sum_{k=1}^{j} {F^n}_{1/2,k} - {F^n}_{1/2,k-1} + \sum_{k=1}^{i-1} {F^n}_{k+1/2,j} - {F^n}_{k-1/2,j},$$

and the two sides of the equality collapse to their common value

$${F^n}_{i-1/2,j} - {F^n}_{1/2,0};$$

thus, (5.8) is gradient preserving. □

Remark 2. A standard von Neumann stability analysis [11, 12] applied to the model problem

$$\begin{cases} u_s + a u_x + b v_y = 0, \\ v_s + a u_x + b v_y = 0 \end{cases} \tag{5.10}$$

(with $a, b > 0$) shows that the gradient-preserving scheme in (5.8) is linearly stable under the CFL condition

$$\lambda_1 + \lambda_2 \leq 1,$$

where $\lambda_1 = a\Delta s/h$ and $\lambda_2 = b\Delta s/h$ [13].

6. Failure of non-gradient-preserving schemes. The constraint of formulating a gradient-preserving scheme was motivated theoretically in sections 3 and 4. Here, we provide more practical motivations by reporting the results from failed numerical experiments with three schemes that do not quite satisfy that constraint.

6.1. Roe's scheme (GNPS1). The first scheme is the standard Roe's Riemann solver approximation scheme for hyperbolic systems [16]. The scheme relies heavily on hyperbolic features, so it obviously may not work for our system because of the lack of strong hyperbolicity.

6.2. Direction-splitting on a single uniform grid (GNPS2). The second scheme is obtained by giving up the staggered grid, instead using the same uniform grid for the two components (u, v). The direction-splitting leads to the following expressions for the edge fluxes:

$$F^{n,1}_{i-1/2,j} = f(\Re^1_{i-1/2,j}, x_{i-1/2}, y_j) + g(v^n_{i-1/2,j}, x_{i-1/2}, y_j),$$
$$F^{n,2}_{i,j-1/2} = f(u^n_{i,j-1/2}, x_i, y_{j-1/2}) + g(\Re^2_{i,j-1/2}, x_i, y_{j-1/2}),$$

where one can simply estimate

$$v^n_{i-1/2,j} = (v^n_{i-1,j} + v^n_{i,j})/2$$

and a similar expression for $u^n_{i,j-1/2}$. Those centered approximations are adequate here because of the directional-splitting.

6.3. Staggered grid without flux approximation (GNPS3). For the third scheme, we retain the staggered grid in Figure 5.1 and the conservative formulation in (5.1) and (5.2) but give up the centered quadrature approximation for the integrals, using instead the exact integration in space-time of the corresponding Riemann problem. For instance,

$$F^{n,1}_{i-1/2,j} = f(\Re^1_{i-1/2,j}, x_{i-1/2}, y_j) + \frac{1}{h\,\Delta s}\int_{s_n}^{s_{n+1}}\int_{y_{j-1/2}}^{y_{j+1/2}} g(v_{\Re^2}(y,s), x_{i-1/2}, y)dy\,ds,$$

where $v_{\Re^2}(y,s)$ represents the detailed solution in space-time of the Riemann problem with initial states (v_B, v_T). The gradient-preserving scheme simply replaces the detailed expression for $v(y,s)$ in the integral by the constant value $v(y = y_j, s) = \Re^2_{i-1/2,j}$.

Except for the fact that they do not automatically preserve gradients, the last two test schemes are actually very similar to the gradient-preserving scheme (5.8), and one could expect them to perform similarly. In Figure 6.1, however, the difference in performance is striking. The eigenvalue is seen to grow indefinitely with time for each one of the three alternative test schemes and converges to a steady state only in the case of the gradient-preserving scheme. This confirms the theoretical intuition that, to achieve convergence, the gradient-preserving property is essential to compensate for the lack of strong hyperbolicity in the system of conservation laws for the gradient.

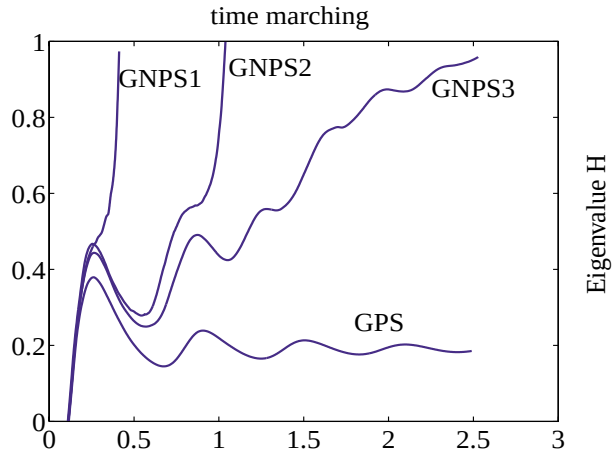

FIG. 6.1. *Effective Hamiltonian H(r) as a function of pseudotime; comparison of the performance of the gradient-preserving scheme (GPS) with the three non-gradient-preserving schemes (GNPS) described in section* 6. *Spatial resolution* 40×40, 800 *pseudotime iterations with CFL*=0.45*;* $\lambda = 1$, $\overline{\lambda} = 2$, $\theta = \overline{\theta} = \delta = 0$.

7. Efficient second order scheme. A second order version of the scheme is designed by resorting to the essentially nonoscillatory (ENO) interpolation strategy in space, coupled with a Runge–Kutta time integrator [12, 16].

Increasing the spatial order of accuracy to second order will be shown in section 8 to improve significantly the efficiency of the method, as much less resolution is required to achieve a given accuracy with the higher order method than with the first order scheme. However, pseudotime accuracy is not needed here: the main consideration for an efficient scheme is that a converged state be reached in as few pseudotime steps as possible, so as to minimize the overall cost of the calculation.

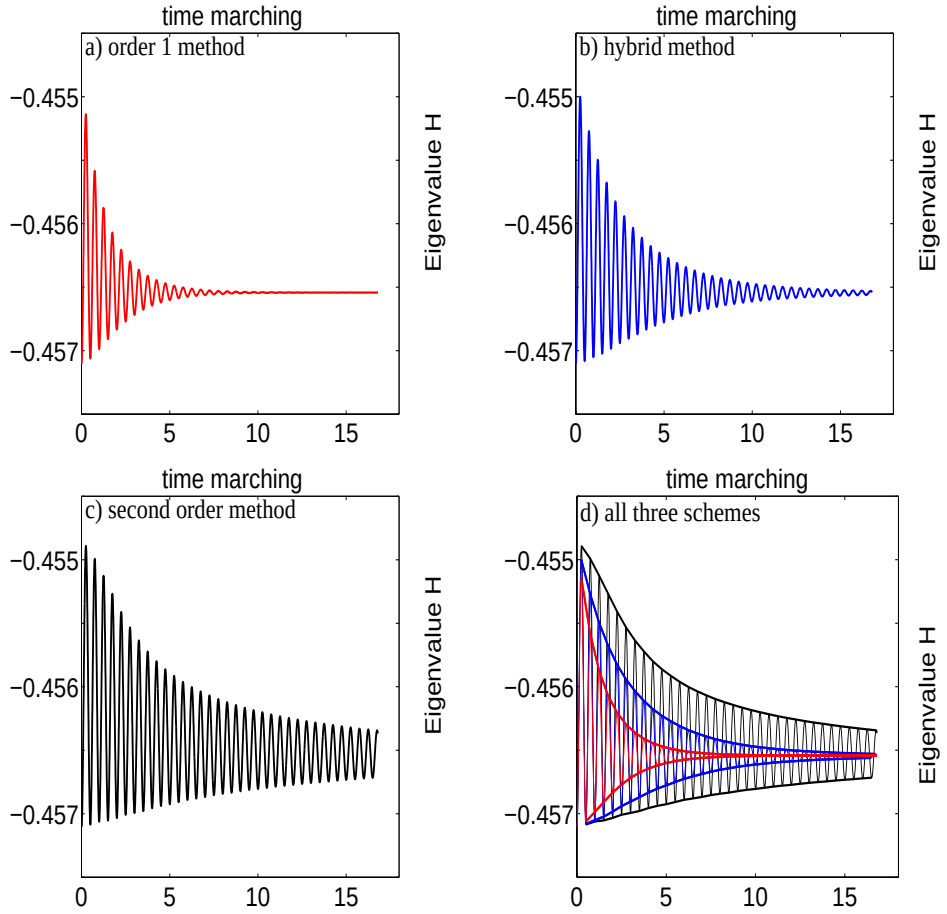

FIG. 7.1. *Effective Hamiltonian H as a function of pseudotime, comparing the performance of the hybrid scheme (second order in space, first order in time) compared with the overall second order scheme and with the first order scheme. Spatial resolution* 40×40*, 3200 time iterations with* $CFL = 0.45$*;* $\overline{\lambda} = 2$*,* $\theta = \pi/4$*,* $\delta = 0.5$ *and* $\lambda = 0.1$*.*

Numerical experiments such as the one reported in Figure 7.1 (a) and (c) reveal that the ENO second order scheme coupled with a standard Runge–Kutta method of the same order does not converge to a steady state as rapidly as the first order scheme previously discussed. This is a serious drawback if the scheme is to be used repeatedly for tabulation. In the rest of this section, we gain some insight on the time-convergence properties of various two-step Runge–Kutta time integrators by studying their linear stability for two limit versions of the ENO scheme: the two limit schemes are obtained by artificially freezing the discretization stencils and correspond, respectively, to the best (upwind) and worst (downwind) case scenario. We use this insight to identify constraints on the coefficients of the Runge–Kutta integrator likely to lead to good damping properties and fast convergence to a steady state.

7.1. Order of accuracy. To analyze the stability and accuracy properties of a generic explicit two-step Runge–Kutta scheme for our set of equations, we introduce first the difference operator $\mathcal{A}$ associated with the original first order scheme (5.8);

i.e.,

$$\mathcal{A}\begin{pmatrix} \overline{u}_{i,j} \\ \overline{v}_{i-1/2,j-1/2} \end{pmatrix} = \frac{1}{h}\begin{pmatrix} F_{i+1/2,j} - F_{i-1/2,j} \\ F_{i-1/2,j} - F_{i-1/2,j-1} \end{pmatrix}$$

for which the left and right states in the Riemann problems are reconstructed by the primitive functions according to the ENO second order interpolation. Set

$$U^n = \begin{pmatrix} \overline{u}^n_{i,j} \\ \overline{v}^n_{i-1/2,j-1/2} \end{pmatrix}$$

so that the Euler version of our scheme can be written

$$U^{n+1} = U^n - \Delta s \mathcal{A}(U^n).$$

We consider the Runge–Kutta two-step method

$$\begin{aligned} U^{n+1/2} &= U^n - \beta_0 \Delta s \mathcal{A}(U^n), \\ U^{n+1} &= \alpha_1 U^n + \alpha_2 U^{n+1/2} - \Delta s \beta_1 \mathcal{A}(U^n) - \Delta s \beta_2 \mathcal{A}(U^{n+1/2}) \end{aligned}$$

or

$$U^{n+1} = (\alpha_1 + \alpha_2)U^n - (\alpha_2\beta_0 + \beta_1)\Delta s \mathcal{A}(U^n) - \beta_2 \Delta s \mathcal{A}(U^n - \beta_0 \Delta s \mathcal{A}(U^n)).$$

A standard accuracy analysis by matching terms in the Taylor expansion of the exact solution leads to the usual *conditions for first order accuracy*

$$\alpha_1 + \alpha_2 = 1, \tag{7.1}$$

$$\alpha_2\beta_0 + \beta_1 + \beta_2 = 1 \tag{7.2}$$

and the usual *additional condition for second order accuracy*

$$\beta_2\beta_0 = \frac{1}{2}. \tag{7.3}$$

If the coefficients of the time integrator satisfy those constraints, the complete scheme coupling this integrator with the second order ENO scheme in space will lead to an overall convergent scheme with second order accuracy in smooth regions, as long as the time-step is subjected to the appropriate CFL condition [16].

7.2. Linear stability of frozen-stencil schemes. Taking into account the constraint for a first order accuracy in (7.1), the scheme can be written as

$$U^{n+1} = U^n - (1 - \beta_2)\Delta s \mathcal{A}(U^n) - \Delta s \beta_2 \mathcal{A}(U^n - \Delta s \beta_0 \mathcal{A}(U^n)). \tag{7.4}$$

We apply the discretization in (7.4) to the linear system in (5.10) where we take the gradient-preserving scheme in (5.8) as the spatial discretization operator $\mathcal{A}$, with a second order ENO interpolation strategy at the interfaces of the associated Riemann problems:
