For the more general problem (1.1), similar results hold. Let S be a vertex of Ω, and denote the corresponding interior angle of Ω by $\omega(S)$. Let $\mathcal{A}$ and $\mathcal{T}$ be matrices such that $\mathcal{A} = (a_{ij}(S))_{i,j=1}^2$ and $-\mathcal{T}\mathcal{A}\mathcal{T}^T = I$, and let $\omega_A(S)$ be the angle at the vertex $\mathcal{T}\mathcal{S}$ of the transformed domain $\mathcal{T}\Omega = \{\mathcal{T}x : x \in \Omega\}$. Define

$$\omega = \max_S \omega_A(S) \quad \text{and} \quad p_\omega = \frac{2}{2 - \pi/\omega}.$$

3. The finite volume element method. In order to analyze the finite volume element method (1.4) we shall need to rewrite it in a variational form resembling the one for the finite element problem (1.5) (cf., e.g., [13]). For this purpose we introduce the space

$$Y_h = \{\eta \in L_2(\Omega) : \ \eta|_{b_z} \text{ is constant}, \quad z \in Z_h^0, \ \eta|_{b_z} = 0 \text{ if } z \in \partial\Omega\}.$$

For an arbitrary $\eta \in Y_h$ we multiply the integral relation (1.4) by $\eta(z)$ and sum over all $z \in Z_h^0$. Thus we obtain the following Petrov–Galerkin formulation of the finite volume element method: Find $u_h \in X_h$ such that

$$a_h(u_h, \eta) = (f, \eta), \quad \forall \eta \in Y_h, \tag{3.1}$$

where the bilinear form $a_h(\cdot,\cdot) : X_h \times Y_h \to \mathbb{R}$ is defined by

$$a_h(v, \eta) = -\sum_{z \in Z_h^0} \eta(z) \int_{\partial b_z} (A\nabla v) \cdot n \, ds, \quad v \in X_h, \ \eta \in Y_h. \tag{3.2}$$

Further, we consider the interpolation operator $I_h : C(\Omega) \to Y_h$, defined by

$$I_h v = \sum_{z \in Z_h^0} v(z)\varphi_z, \tag{3.3}$$

where φ_z is the characteristic function of b_z. Then, we can rewrite (1.4) as

$$a_h(u_h, I_h\chi) = \sum_{z \in Z_h^0} \chi(z) \int_{b_z} f \, dx, \quad \forall \chi \in X_h. \tag{3.4}$$

Note that for every $f \in L_p$ and $\chi \in X_h$,

$$(f, I_h\chi) = \sum_{z \in Z_h} \chi(z) \int_\Omega f\varphi_z \, dx = \sum_{z \in Z_h^0} \chi(z) \int_{b_z} f \, dx. \tag{3.5}$$

Thus (3.4) can be written equivalently in the form

$$a_h(u_h, I_h\chi) = (f, I_h\chi), \quad \forall \chi \in X_h. \tag{3.6}$$

Existence of u_h follows from the fact that a_h is coercive, for h sufficiently small (cf., e.g., [13] or [28, Theorem 3.2.1]),

$$\exists\, c_0 > 0 : \quad c_0|\chi|_{H^1}^2 \le a_h(\chi, I_h\chi), \quad \forall \chi \in X_h.$$

Then this, the local stability of I_h,

$$\|I_h\chi\|_{L_p(K)} \le C\|\chi\|_{L_p(K)}, \quad \forall\chi \in X_h,\ K \in T_h,\ p > 1,$$

and the Sobolev imbedding

$$\|\chi\|_{L_p} \le C\|\chi\|_{H^1}, \quad \forall\chi \in X_h,\ p > 1,$$

give the stability of the finite volume scheme (3.6),

$$\|u_h\|_{H^1} \le C\|f\|_{L_p}, \quad p > 1. \tag{3.7}$$

Also, note that if $A(x)$ is a constant matrix over each finite element $K \in T_h$, then $a_h(\chi, I_h\psi) = a(\chi,\psi),\ \forall\chi,\psi \in X_h$ (cf., e.g., [27]). In particular, if $A = I$, we have

$$a_h(\chi, I_h\psi) = a(\chi,\psi) = \int_\Omega \nabla\chi\cdot\nabla\psi\,dx, \quad \forall\chi,\psi \in X_h \tag{3.8}$$

(cf., e.g., [6]). Thus, (3.6) takes the form

$$a(u_h,\chi) = (f, I_h\chi), \quad \forall\chi \in X_h. \tag{3.9}$$

In the case of general matrix $A(x)$, the identity (3.8) is not valid. However, following [13], we are able to rewrite a_h in a form similar to a. Indeed, we transform the left-hand side of (1.4) using integration by parts to get, for $z \in Z_h^0$ and $K \in T_h$,

$$\int_{K_z} L\chi\,dx + \int_{\partial K_z\cap\partial K} A\nabla\chi\cdot n\,ds = -\int_{\partial K_z\cap\partial b_z} A\nabla\chi\cdot n\,ds, \quad \forall\chi \in X_h.$$

Thus, multiplying by $\psi(z)$, $\psi \in X_h$, and summing over the triangles having z as a vertex and then over the vertices $z \in Z_h^0$, we obtain

$$a_h(\chi, I_h\psi) = \sum_K\{(L\chi, I_h\psi)_K + (A\nabla\chi\cdot n, I_h\psi)_{\partial K}\}, \quad \forall\chi,\psi \in X_h. \tag{3.10}$$

This is similar to

$$a(\chi,\psi) \equiv (A\nabla\chi,\nabla\psi) = \sum_K\{(L\chi,\psi)_K + (A\nabla\chi\cdot n,\psi)_{\partial K}\}, \quad \forall\chi,\psi \in X_h.$$

Due to this similarity and for convenience, in what follows we shall use (3.10) as a definition of the bilinear form a_h.

4. Nonsmooth data: L_p case. In this section we shall derive H^1-, L_2-, and L_∞-norm estimates of the error $u - u_h$ for $f \in L_p$, $p > 1$. First, we shall demonstrate that the finite element method (1.5) and finite volume element method (3.6) have the same convergence rate in the H^1-norm. The L_2-norm error estimate is quite different, and we derive two separate results. First, we will show suboptimal order L_2-norm error estimates for $f \in L_p$, $p > 1$, where the order is less than in the corresponding order for the finite element scheme (1.5). Next, assuming higher regularity for f, namely $f \in W_\alpha^t$, $t \in (0, 1]$, $\alpha \in (1, 2]$, we will show again suboptimal order L_2-norm error estimates, but now depending on α and t, these could be of the same order as the corresponding estimates of the finite element scheme. Finally, we show almost optimal L_∞-norm estimates of the error $u - u_h$.

For the analysis of the finite volume element method (3.6) we shall need to estimate the errors ε_h and ε_a defined by

$$\varepsilon_h(f,\chi) = (f,\chi) - (f, I_h\chi), \qquad \forall f \in L_p,\ \chi \in X_h,$$
$$\varepsilon_a(\chi,\psi) = a(\chi,\psi) - a_h(\chi, I_h\psi), \quad \forall \chi,\psi \in X_h.$$

In section 6 we will give the proof of the following two lemmas.

LEMMA 4.1. *There exists a constant C such that for every $\chi \in X_h$,*

$$|\varepsilon_h(f,\chi)| \le Ch\|f\|_{L_p}\,|\chi|_{W^1_{p'}}, \qquad \forall f \in L_p,\ \frac{1}{p}+\frac{1}{p'}=1, \tag{4.1}$$

$$|\varepsilon_h(f,\chi)| \le Ch^{1+t}\|f\|_{W^t_p}\,|\chi|_{W^1_{p'}}, \quad \forall f \in W^t_p,\ 0<t\le 1. \tag{4.2}$$

LEMMA 4.2. *Assume that $A \in W^2_\infty$. Then there exists a positive constant $C = C(A)$ such that*

$$|\varepsilon_a(\psi,\chi)| \le Ch|\psi|_{W^1_{\bar p}}\,|\chi|_{W^1_{\bar p'}}, \qquad \forall \chi,\psi \in X_h, \tag{4.3}$$

$$|\varepsilon_a(u_h,\chi)| \le Ch\big(\|\nabla(u-u_h)\|_{L_2} + h\|u\|_{W^2_{\bar p}}\big)|\chi|_{W^1_{\bar p'}}, \quad \forall \chi \in X_h. \tag{4.4}$$

Next, we derive H^1- and L_2-norm error estimates for the finite volume element method (1.4).

THEOREM 4.3. *Let u and u_h be the solutions of* (1.1) *and* (1.4)*, respectively, with $f \in L_p$, $p>1$. Then, there exists a constant C, independent of h, such that*

$$\|u-u_h\|_{H^1} \le C\big(h^s\|u\|_{W^2_{\bar p}} + h^{\min(1,2-2/p)}\|f\|_{L_p}\big) \le Ch^s\|f\|_{L_p}, \tag{4.5}$$

$$\|u-u_h\| \le C\big(h^{s+\delta}\|u\|_{W^2_{\bar p}} + h^{\min(1,s+\delta)}\|f\|_{L_p}\big), \quad \textit{for any } \delta < \pi/\omega, \tag{4.6}$$

with $\bar p$ and s given by (2.3) *and* (2.4)*, respectively.*

Remark 4.4. The H^1-norm error estimation (4.5) is of optimal order (cf. (1.7)). However, the L_2-norm error estimation is not of the same order as the finite element approximation (cf. (1.6)) for every p. For example, for p sufficiently close to 1, $s+\delta<1$, thus, $\|u-u_h\| = O(h^{s+\delta})$. However, for $p \ge 2$, $s = 2-2/\bar p \approx \pi/\omega$. Therefore, since $s+\delta \approx 2\pi/\omega > 1$, $\|u-u_h\| = O(h)$. The most interesting outcome of this theorem is that the convergence rate for the L_2-norm is suboptimal and lower than the rate of the finite element method (1.5). This estimate is sharp, as first demonstrated by a counterexample in [27], for convex domains. Later in section 7 we give a similar example to the one in [27], which shows the sharpness of the L_2-error estimate (4.6).

Proof. In view of (2.2), $u \in W^2_{\bar p}$, with $\bar p$ defined by (2.3). Using the triangle inequality,

$$\|u-u_h\|_{H^1} \le \|u-\chi\|_{H^1} + \|u_h-\chi\|_{H^1}, \quad \forall \chi \in X_h, \tag{4.7}$$

and the approximation properties (1.7) of X_h, it suffices to consider the last term of (4.7). The positive definiteness of A, (1.2), gives

$$\alpha_0\|u_h-\chi\|^2_{H^1} \le a(u_h-\chi, u_h-\chi), \quad \forall \chi \in X_h. \tag{4.8}$$

Thus, in view of

$$a(u_h-\chi,u_h-\chi)=a(u-u_h,u_h-\chi)+a(u-\chi,u_h-\chi)\\ \le a(u-u_h,u_h-\chi)+C\|u-\chi\|_{H^1}\|u_h-\chi\|_{H^1},\quad \forall\chi\in X_h,$$

and (4.8), we get for every $\chi\in X_h$,

$$\|u_h-\chi\|_{H^1}^2\le C|a(u-u_h,u_h-\chi)|+C\|u-\chi\|_{H^1}^2. \tag{4.9}$$

In addition, using the definitions of ε_h and ε_a, we have

$$a(u-u_h,u_h-\chi)=a(u,u_h-\chi)-a_h(u_h,I_h(u_h-\chi))-\varepsilon_a(u_h,u_h-\chi)\\ =\varepsilon_h(f,u_h-\chi)-\varepsilon_a(u_h,u_h-\chi),\quad \forall\chi\in X_h. \tag{4.10}$$

Applying then, to this relation, (4.1), (4.3), and the inverse inequality

$$|\chi|_{W^1_{p'}}\le Ch^{2/p'-1}|\chi|_{H^1},\quad p'>2,\ \forall\chi\in X_h,$$

we obtain

$$|a(u-u_h,u_h-\chi)|\le C(h^{\min(1,2-2/p)}\|f\|_{L_p}+h\|u_h\|_{H^1})\|u_h-\chi\|_{H^1}. \tag{4.11}$$

Thus, for h sufficiently small, this estimate, (3.7) and (4.9) yield

$$\|u_h-\chi\|_{H^1}\le C\|u-\chi\|_{H^1}+Ch^{\min(1,2-2/p)}\|f\|_{L_p},\quad \forall\chi\in X_h, \tag{4.12}$$

which combined with (1.7) and (4.7) gives

$$\|u-u_h\|_{H^1}\le C\big(h^s\|u\|_{W^2_{\bar p}}+h^{\min(1,2-2/p)}\|f\|_{L_p}\big).$$

Using now the fact that for $p<p_\omega$, $s=2-2/p$ and for $p\ge p_\omega$, $s<\min(1,2-2/p)$, we get

$$\|u-u_h\|_{H^1}\le Ch^s\big(\|u\|_{W^2_{\bar p}}+\|f\|_{L_p}\big). \tag{4.13}$$

Finally, employing the a priori regularity estimation of u, (2.2), we obtain the desired estimate (4.5).

We now prove (4.6) by using a duality argument. We consider the following auxiliary problem: Seek $\varphi\in H^1_0$ such that

$$L\varphi=u-u_h\quad\text{in }\Omega\quad\text{and}\quad\varphi=0\quad\text{on }\partial\Omega. \tag{4.14}$$

In view of (2.2) and the fact that $u-u_h\in L_2$, we have $\varphi\in W^2_\gamma$, where $\gamma<p_\omega$, i.e. $2/\gamma=2-\pi/\omega+\varepsilon$, with arbitrary small $\varepsilon>0$, and satisfies the a priori estimate

$$\|\varphi\|_{W^2_\gamma}\le C\|u-u_h\|,\quad \gamma<p_\omega. \tag{4.15}$$

Now let $\Pi_h: W^2_\gamma\cap H^1_0\to X_h$ denote the standard nodal interpolation operator. It is well known that Π_h has the following approximation property (cf., e.g., [17, Theorem 3.1.6] and [2, Theorem 5.4]),

$$\|\Pi_h v-v\|_{H^1}\le Ch^{\pi/\omega-\varepsilon}\|v\|_{W^2_\gamma},\quad \forall v\in W^2_\gamma\cap H^1_0, \tag{4.16}$$

and Π_h is bounded in $\|\cdot\|_{W_q^1}$ (cf., e.g., [17, Theorem 3.1.6] and [2, Theorem 5.4]),

$$\|\Pi_h v\|_{W_q^1} \le C\|v\|_{W_\gamma^2}, \quad \forall v \in W_\gamma^2 \cap H_0^1, \quad q \le p'_\gamma = 2\gamma/(2-\gamma), \tag{4.17}$$

where $p_\gamma = 2\gamma/(3\gamma-2)$.

Using (4.14) and Green's formula, we easily obtain

$$\begin{aligned} \|u-u_h\|^2 &= -(u-u_h, L\varphi) = a(u-u_h,\varphi) \\ &= a(u-u_h, \varphi-\Pi_h\varphi) + a(u-u_h,\Pi_h\varphi) := I + II. \end{aligned} \tag{4.18}$$

The first term, I, can obviously be bounded in the following way by using (4.13) and (4.16):

$$|I| \le C\|u-u_h\|_{H^1}\,\|\varphi-\Pi_h\varphi\|_{H^1} \le Ch^{s+\pi/\omega-\varepsilon}\big(\|u\|_{W_{\bar p}^2} + \|f\|_{L_p}\big)\,\|\varphi\|_{W_\gamma^2}. \tag{4.19}$$

Also, in view of (4.10), the second term, II, can be written in the form

$$II = a(u-u_h,\Pi_h\varphi) = \varepsilon_h(f,\Pi_h\varphi) - \varepsilon_a(u_h,\Pi_h\varphi). \tag{4.20}$$

Then using (4.1) and (4.4), II can be estimated by

$$|II| \le Ch\|f\|_{L_p}|\Pi_h\varphi|_{W_{p'}^1} + h\big(\|\nabla(u-u_h)\|_{L_2} + h\|u\|_{W_{\bar p}^2}\big)\,|\Pi_h\varphi|_{W_{\bar p'}^1}. \tag{4.21}$$

In order to bound $|\Pi_h\varphi|_{W_{p'}^1}$ and $|\Pi_h\varphi|_{W_{\bar p'}^1}$ in (4.21) we consider two different cases for p: (1) $p \ge p_\gamma = 2\gamma/(3\gamma-2)$, and (2) $1 < p < p_\gamma$. We can easily see that $p_\gamma < p_\omega$. Thus, in view of the definition of $\bar p$ (cf. (2.3)), for $p \ge p_\gamma$ we also have $\bar p \ge p_\gamma$ and for $1 < p < p_\gamma$, $\bar p < p_\gamma$.

Let us first consider the case $p \ge p_\gamma$. Then we have $p' \le p'_\gamma$ and $\bar p' \le p'_\gamma$ so for the respective norms of $\Pi_h\varphi$ in (4.21) we can apply the estimate (4.17). Using also (4.13) we get

$$\begin{aligned} |II| &\le C(h\|f\|_{L_p} + h^{1+s}(\|u\|_{W_{\bar p}^2} + \|f\|_{L_p}))\|\varphi\|_{W_\gamma^2} \\ &\le C(h\|f\|_{L_p} + h^{1+s}\|u\|_{W_{\bar p}^2})\|\varphi\|_{W_\gamma^2}. \end{aligned} \tag{4.22}$$

Combining now this estimation with (4.19), (4.15), and (4.18), we obtain the desired estimate (4.6), for $p \ge p_\gamma$.

In the remaining case $1 < p < p_\gamma$ we cannot directly employ (4.17) for the estimation of II. However, the inverse inequality

$$|\chi|_{W_q^1} \le Ch^{2/q-2/p'_\gamma}|\chi|_{W_{p'_\gamma}^1}, \quad q > p'_\gamma, \quad \forall \chi \in X_h,$$

and (4.17), give

$$|\Pi_h v|_{W_q^1} \le Ch^{2/q-1+\pi/\omega-\varepsilon}\|v\|_{W_\gamma^2}, \quad \forall v \in W_\gamma^2 \cap H_0^1,\ q > p'_\gamma. \tag{4.23}$$

Using now this estimation in (4.21) and the fact that for $1 < p < p_\gamma$, $2/p' = 2-2/p = s$, we get

$$\begin{aligned} |II| &\le Ch^{2/p'+\pi/\omega-\varepsilon}\big(\|f\|_{L_p} + h\|u\|_{W_{\bar p}^2}\big)\,\|\varphi\|_{W_\gamma^2} \\ &\le Ch^{s+\pi/\omega-\varepsilon}\big(\|f\|_{L_p} + h^s\|u\|_{W_{\bar p}^2}\big)\,\|\varphi\|_{W_\gamma^2}. \end{aligned} \tag{4.24}$$

Then, combining this estimation with (4.19), (4.15), and (4.18), we obtain

$$\|u-u_h\| \le Ch^{s+\delta}(\|u\|_{W^2_{\bar p}} + \|f\|_{L_p}).$$

Finally, (4.6) follows from the fact that for $1 < p < p_\gamma$, $s = 2 - \frac{2}{p} < 2 - \frac{2}{p_\gamma} = \frac{2}{\gamma} - 1 = 1 - \frac{\pi}{\omega} + \varepsilon$. ∎

Remark 4.5. For the proof of Theorems 4.3 and 4.6 it is not necessary to assume a quasi-uniform mesh T_h. This is done in order to simplify the proof, and it is only required for the validity of the inverse inequalities that are used. This assumption can be avoided by applying local inverse inequalities which hold in more general triangulations.

Next, we shall demonstrate that under some additional assumptions on the smoothness of the data the convergence rate in the L_2-norm can be improved and be equal to the rate of the corresponding finite element method.

THEOREM 4.6. *Let u and u_h be the solutions of* (1.1) *and* (1.4)*, respectively. Assume that $f \in W^t_\alpha$, $1 < \alpha \le 2$, $0 < t \le 1$, and $A \in W^2_\infty$. Then there exists a constant C, independent of h, such that*

$$\|u-u_h\| \le C(h^{s+\delta}\|f\|_{L_p} + h^{1+t+\min(0,1-2/\alpha+\delta)}\|f\|_{W^t_a}), \text{ for any } \delta < \pi/\omega, \tag{4.25}$$

with $p = 2\alpha/(2-t\alpha)$ and $\bar p$ and s given by (2.3) *and* (2.4)*, respectively.*

Remark 4.7. For $\alpha < \tilde p_\omega = \frac{2p_\omega}{3p_\omega - 2}$, we have $2/\alpha > 1 + \pi/\omega$. Thus $1+t+\min(0, 1-2/\alpha+\delta) = 2+t-2/\alpha+\delta = 2-2/p+\delta \ge s+\delta$. Therefore, $\|u-u_h\| = O(h^{s+\delta})$, i.e., in this case the L_2-norm error estimate of the finite volume element method has the same convergence rate as the corresponding finite element method. If $\alpha \ge \tilde p_\omega$, i.e., $2/\alpha \le 1+\delta$, then the order of $\|u-u_h\|$ is $\min(s+\delta, 1+t)$.

Proof. The proof will be similar to the one for (4.6). First, let us note that since $f \in W^t_\alpha$, we have by imbedding (cf. [2, Theorem 7.57]) that $f \in L_p$, with $p = 2\alpha/(2-t\alpha)$. Thus, in view of (2.2), $u \in W^2_{\bar p}$ with $\bar p$ given by (2.3).

Let again $\gamma < p_\omega$, such that $2/\gamma = 2 - \pi/\omega + \varepsilon$, with arbitrary small $\varepsilon > 0$, and let $\varphi \in W^2_\gamma \cap H^1_0$ be the solution of the auxiliary problem (4.14). Obviously, in order to show a higher order L_2-norm error estimation of $u - u_h$, we need to derive "better" bounds for I and II of (4.18). It is obvious that the estimation of I, (4.19), derived in Theorem 4.3 is of the desired order. Thus, it suffices to show a better estimate for II than the ones derived in Theorem 4.3 (cf. (4.22) and (4.24)).

Using (4.2) and (4.4) in (4.20), we get

$$|II| \le C(h^{1+t}\|f\|_{W^t_\alpha}|\Pi_h\varphi|_{W^1_{\alpha'}} + h^{1+s}\|f\|_{L_p}|\Pi_h\varphi|_{W^1_{\bar p'}}). \tag{4.26}$$

Similarly, as in Theorem 4.3 we need to derive bounds for

$$|\Pi_h\varphi|_{W^1_{\alpha'}} \quad \text{and} \quad |\Pi_h\varphi|_{W^1_{\bar p'}},$$

and we will need to consider various cases for α and p with respect to $p_\gamma = 2\gamma/(3\gamma-2)$.

Since $p = 2\alpha/(2-t\alpha)$, we can easily see that $p > \alpha$; thus we have the following three cases: (1) $p > \alpha \ge p_\gamma$, (2) $p \ge p_\gamma > \alpha$, and (3) $p_\gamma > p > \alpha$.

First, we consider the case $p > \alpha \ge p_\gamma$. For such p, according to (2.3), we have $\bar p > p_\gamma$. Thus, using (4.17) in (4.26), and the fact that $1/2 < \pi/\omega < 1$, we get

$$|II| \le C(h^{1+t}\|f\|_{W^t_\alpha} + h^{s+\pi/\omega-\varepsilon}\|f\|_{L_p})\|\varphi\|_{W^2_\gamma}. \tag{4.27}$$

Therefore, combining this estimation, (4.19), (4.15), (4.18), and the fact that if $\alpha > p_\gamma$, then $2/\alpha < 2/p_\gamma = 1 + \pi/\omega - \varepsilon$, we obtain the desired result, (4.25), in the case $p > \alpha \geq p_\gamma$.

Now let $p \geq p_\gamma > \alpha$. Again we can easily see that $\bar{p} \geq p_\gamma$. Therefore, applying (4.23) and (4.17) in (4.26) and using the fact that $1/2 < \pi/\omega < 1$, we obtain

$$\begin{aligned} |II| &\leq C(h^{t+2/\alpha'+\pi/\omega-\varepsilon}\|f\|_{W^t_\alpha} + h^{1+s}\|f\|_{L_p})\|\varphi\|_{W^2_\gamma} \\ &\leq C(h^{1+t+1-2/\alpha+\pi/\omega-\varepsilon}\|f\|_{W^t_\alpha} + h^{s+\pi/\omega-\varepsilon}\|f\|_{L_p})\|\varphi\|_{W^2_\gamma}. \end{aligned} \tag{4.28}$$

Therefore, combining this estimation, (4.19), (4.15), (4.18), and the fact that if $\alpha \leq p_\gamma$, then $2/\alpha > 1 + \pi/\omega - \varepsilon$, we obtain the desired result, (4.25), if $p > p_\gamma \geq \alpha$.

In the remaining case $p_\gamma > p > \alpha$, we have $\bar{p} = p < p_\gamma$. Thus, applying (4.23) in (4.26) and using the fact that $1/2 < \pi/\omega < 1$, we have

$$\begin{aligned} |II| &\leq C(h^{t+2/\alpha'+\pi/\omega-\varepsilon}\|f\|_{W^t_\alpha} + h^{2/p'+\pi/\omega-\varepsilon+s}\|f\|_{L_p})\|\varphi\|_{W^2_\gamma} \\ &\leq C(h^{1+t+1-2/\alpha+\pi/\omega-\varepsilon}\|f\|_{W^t_\alpha} + h^{s+\pi/\omega-\varepsilon}\|f\|_{L_p})\|\varphi\|_{W^2_\gamma}. \end{aligned} \tag{4.29}$$

Therefore, combining this estimation, (4.19), (4.15), and (4.18) we obtain the desired result, (4.25), for the remaining case $p_\gamma \geq p > \alpha$. ∎

Finally, we will show an almost optimal L_∞-norm error estimate.

THEOREM 4.8. *Let u and u_h be the solutions of* (1.1) *and* (1.4)*, respectively, with $f \in L_p$, $p > 1$, and $A \in W^2_\infty$. Then there exists a constant C, independent of h, such that*

$$\|u - u_h\|_{L_\infty} \leq Ch^s \log \frac{1}{h}\|f\|_{L_p}. \tag{4.30}$$

Proof. We split the error $u - u_h$ by adding and subtracting the Galerkin finite element approximation $\underline{u}_h$ (cf. (1.5)); thus $u - u_h = (u - \underline{u}_h) + (\underline{u}_h - u_h)$. The estimation of $\|u - \underline{u}_h\|_{L_\infty}$ is well known (cf., e.g., [32]). However, we shall briefly demonstrate it.

In view of [32, equation (0.8)] and the standard imbedding $W^2_{\bar{p}} \subset C^{0,2-2/\bar{p}}$ (cf., e.g., [24, Theorem 1.4.5.2]), we have

$$\|u - \underline{u}_h\|_{L_\infty} \leq Ch^s \log \frac{1}{h}\|u\|_{C^{0,s}} \leq Ch^s \log \frac{1}{h}\|u\|_{W^2_{\bar{p}}},$$

where $s = 2 - 2/\bar{p}$ and $C^{m,\ell}$ is the space of m times continuously differentiable functions whose mth order derivative fulfills a uniform Hölder condition of order ℓ.

Then, combining this with the elliptic regularity estimate,

$$\|u\|_{W^2_{\bar{p}}} \leq C_{\bar{p}}\|f\|_{L_p} \tag{4.31}$$

(cf. [24, Theorem 5.2.7]), we obtain

$$\|u - \underline{u}_h\|_{L_\infty} \leq C_{\bar{p}}h^s \log \frac{1}{h}\|f\|_{L_p}, \quad p > 1. \tag{4.32}$$

We turn now to the estimation of $\|\underline{u}_h - u_h\|_{L_\infty}$. Let $x_0 \in K_0 \in \mathcal{T}_h$ such that $\|\underline{u}_h - u_h\|_{L_\infty} = |(\underline{u}_h - u_h)(x_0)|$ and $\delta_{x_0} = \delta \in C_0^\infty(\bar{\Omega})$ a regularized Dirac δ-function satisfying

$$(\delta, \chi) = \chi(x_0), \quad \forall \chi \in X_h.$$

For such a function δ (cf., e.g., [9]) we have

$$\operatorname{supp}\delta \subset B = \{x \in \Omega : |x - x_0| \le h/2\}, \quad \int_\Omega \delta = 1, \quad 0 \le \delta \le Ch^{-2},$$
$$\|\delta\|_{L_p} \le Ch^{2(1-p)/p}, \quad 1 < p < \infty.$$

Also let us consider the corresponding regularized Green's function $G \in H_0^1$, defined by

$$a(G, v) = (\delta, v), \quad \forall v \in H_0^1. \tag{4.33}$$

Then, we have

$$\begin{aligned} \|\underline{u}_h - u_h\|_{L_\infty} &= (\delta, \underline{u}_h - u_h) = a(G, \underline{u}_h - u_h) = a(G_h, \underline{u}_h - u_h) \\ &= a(u - u_h, G_h) = \varepsilon_h(f, G_h) - \varepsilon_a(u_h, G_h), \end{aligned} \tag{4.34}$$

where $G_h \in X_h$ is the finite element approximation of G, i.e.,

$$a(G, \chi) = a(G_h, \chi), \quad \forall \chi \in X_h.$$

Further, using (4.1), (4.3), and the inverse inequality

$$|\chi|_{W_q^1} \le Ch^{2/q-1}|\chi|_{H^1}, \quad \forall \chi \in X_h,\ q > 2,$$

in (4.34) we obtain

$$\begin{aligned} \|\underline{u}_h - u_h\|_{L_\infty} &\le C\big\{h\big(\|\nabla(u - u_h)\|_{L_2} + h\|u\|_{W_{\bar p}^2}\big)|G_h|_{W_{\bar p'}^1} + h\|f\|_{L_p}|G_h|_{W_{p'}^1}\big\} \\ &\le C\big\{h^{2-2/\bar p}\big(\|\nabla(u - u_h)\|_{L_2} + h\|u\|_{W_{\bar p}^2}\big) \\ &\qquad + h^{\min(1,2-2/p)}\|f\|_{L_p}\big\}\|G_h\|_{H^1}, \end{aligned} \tag{4.35}$$

with $p > 1$. In addition, in view of [31, Lemma 3.1] we get

$$\|G_h\|_{H^1} \le C\|\nabla G\|_{L_2} \le C\frac{1}{(q-1)^{1/2}}\,\|\delta\|_{L_q} \tag{4.36}$$

with $q \downarrow 1$. Choosing now $q = 1 + (\log \frac{1}{h})^{-1}$ we have

$$\|G_h\|_{H^1} \le C\left(\log\frac{1}{h}\right)^{1/2}. \tag{4.37}$$

Combining now (4.34)–(4.37) and Theorem 4.3, we obtain

$$\|\underline{u}_h - u_h\|_{L_\infty} \le Ch^{2s}\left(\log\frac{1}{h}\right)^{1/2}\|u\|_{W_{\bar p}^2} + Ch^{\min(1,2-2/p)}\left(\log\frac{1}{h}\right)^{1/2}\|f\|_{L_p}. \tag{4.38}$$

From this, (4.31), and (4.32) we get the desired estimation (4.30). ∎

Remark 4.9. Assuming $f \in L_\infty$ will not improve the convergence rate in (4.30), we can easily see that in this case (4.38) does not contribute terms of order higher than 1. However, (4.32) gives terms of order almost $2-2/\bar p$, which is less than 1. Also, if we assume $f \in W_\alpha^t$, then similarly as in Theorem 4.6 we can show $\|\underline{u}_h - u_h\|_{L_\infty} = O(h^{1+t})$, but again the error $\|u - \underline{u}_h\|_{L_\infty}$ will be at most of order $2 - 2/\bar p$.

5. Nonsmooth data: $H^{-\ell}$ case. In this section we will consider problem (2.1), i.e., $A = I$, and we shall derive H^1-, L_2- and L_∞-norm estimates of the error $u - u_h$ for $f \in H^{-\ell}$, $\ell \in (0, 1/2)$. We will show optimal H^1-, suboptimal L_2-, and almost optimal L_∞-norm error estimates. The H^1- and L_∞-norm estimations are of the same order with the corresponding estimations for the finite element scheme, whereas the L_2-norm estimates are smaller.

This time for the analysis of the finite volume element method (3.6) we shall need in addition the following lemma, which we prove in section 6.

LEMMA 5.1. *There exists a constant C such that for every $\chi \in X_h$,*

$$|\varepsilon_h(f,\chi)| \le Ch^{1-\ell}\|f\|_{H^{-\ell}}\,|\chi|_{H^1}, \quad \forall f \in H^{-\ell},\ 0 < \ell < 1/2. \tag{5.1}$$

THEOREM 5.2. *Let u and u_h be the solutions of (2.1) and (1.4), respectively, with $f \in H^{-\ell}$, $0 \le \ell < 1/2$. Then there exists a constant C, independent of h, such that*

$$\|u - u_h\|_{H^1} \le C\big(h^s\|u\|_{H^{1+s}} + h^{1-\ell}\|f\|_{H^{-\ell}}\big) \le Ch^s\|f\|_{H^{-\ell}}, \tag{5.2}$$

$$\|u - u_h\| \le C\big(h^{s+\delta}\|u\|_{H^{1+s}} + h^{1-\ell}\|f\|_{H^{-\ell}}\big), \quad \textit{any } \delta < \pi/\omega. \tag{5.3}$$

Remark 5.3. The convergence rate of the H^1-norm is of optimal order (cf. (1.7)). However, since $s + \delta > 1 \ge 1 - \ell$, for δ arbitrarily close to π/ω and $\delta < \pi/\omega$, the convergence rate in the L_2-norm is suboptimal and lower than the rate of the corresponding finite element method (cf. (1.5)). Later in section 7 we give an example similar to the one in [27], which shows the sharpness of the L_2-error estimate (5.3).

Proof. The proof is similar as in Theorem 4.3, thus it suffices to estimate the first term of the right-hand side of (4.9). If $f \in H^{-\ell}$, with $0 < \ell < 1/2$, then in view of (2.5), $u \in H^{1+s}$, with s defined by (2.6). Since $A = I$, $\varepsilon_a \equiv 0$. Therefore, using (5.1) in (4.10) we obtain

$$|a(u - u_h, u_h - \chi)| \le Ch^{1-\ell}\|f\|_{H^{-\ell}}|u_h - \chi|_{H^1}, \quad \forall \chi \in X_h. \tag{5.4}$$

Then, in view of the approximation property (1.7) of X_h we get

$$\|u - u_h\|_{H^1} \le C\big(h^s\|u\|_{H^{1+s}} + h^{1-\ell}\|f\|_{H^{-\ell}}\big).$$

Using now the fact that for $s_0 < \ell < 1/2$, $s = 1 - \ell$ (cf. (2.6)), and for $0 \le \ell \le s_0$, $s < 1 - \ell$, and the a priori regularity estimate (2.5), we obtain the desired estimate (5.2).

We now turn to (5.3). Using again the same arguments as in Theorem 4.3 it suffices to estimate term II of (4.18). Let again $\gamma < p_\omega$, such that $2/\gamma = 2 - \pi/\omega + \varepsilon$, with arbitrarily small $\varepsilon > 0$, and let $\varphi \in W^2_\gamma \cap H^1_0$ be the solution of the auxiliary problem (4.14). Combining (4.10) and (5.1), we have

$$|II| \le Ch^{1-\ell}\|f\|_{H^{-\ell}}|\Pi_h\varphi|_{H^1}. \tag{5.5}$$

Finally, since, $p_\gamma < 2$, we can employ (4.17) in the estimation above, and then combining (4.18), (4.16), (5.2), and (4.15), we obtain the desired estimate (5.3). ∎

In Theorem 5.2 we demonstrated that $\|u - u_h\|_{H^1} \approx Ch^s$, for $u \in H^{1+s}$, $s < \pi/\omega$. In general, we know that $u \notin H^{1+\pi/\omega}$, even if f is smooth. In Theorem 5.4, we will show that for $f \in H^{-\ell}$, with $\ell \in (0, s_0)$, $\|u - u_h\|_{H^1} \approx C_\ell h^{\pi/\omega}$, where the constant C_ℓ blows up when $\ell \to s_0$. This is a slight improvement of the result of Theorem 5.2, which in this case gives $\|u - u_h\|_{H^1} \approx Ch^{\pi/\omega-\varepsilon}$ with $\varepsilon > 0$ arbitrarily small. Here we use the technique developed in [5].

THEOREM 5.4. *Let u and u_h be the solutions of (2.1) and (1.4), respectively, with $f \in H^{-\ell}$, $0 \le \ell < s_0$. Then there exists a constant C, independent of h, such that*

$$\|u - u_h\|_{H^1} \le C \frac{1}{s_0 - \ell} h^{\pi/\omega} \|f\|_{H^{-\ell}}. \tag{5.6}$$

Proof. Obviously, if $f \in H^{-\ell}$, with $0 \le \ell < s_0$, then $f \in H^{-\tilde{\ell}}$, $\tilde{\ell} \in (s_0, 1/2)$. Then according to Theorem 5.2, we have that

$$\|u - u_h\|_{H^1} \le C h^{1-\tilde{\ell}} \big(\|u\|_{H^{2-\tilde{\ell}}} + \|f\|_{H^{-\tilde{\ell}}} \big). \tag{5.7}$$

Also, since $u \in H^{2-\tilde{\ell}}$, we have

$$(f, v) = a(u, v) \le \|u\|_{H^{2-\tilde{\ell}}} \|v\|_{H^{\tilde{\ell}}}, \quad \forall v \in H^1_0; \tag{5.8}$$

thus, $\|f\|_{H^{-\tilde{\ell}}} \le \|u\|_{H^{2-\tilde{\ell}}}$, which in view of (5.7) gives

$$\|u - u_h\|_{H^1} \le C h^{1-\tilde{\ell}} \|u\|_{H^{2-\tilde{\ell}}}. \tag{5.9}$$

In addition, we can easily see that if $u \in H^2 \cap H^1_0$,

$$\|u - u_h\|_{H^1} \le C h \|u\|_{H^2}. \tag{5.10}$$

Then, by interpolation between (5.9) and (5.10), we get

$$\|u - u_h\|_{H^1} \le C h^{1-s_0} \|u\|_X, \tag{5.11}$$

where $X = [H^2 \cap H^1_0, H^{2-\tilde{\ell}} \cap H^1_0]_{s_0/\tilde{\ell}, \infty}$. Here $[V, W]_{\theta, q}$, $0 \le \theta \le 1$, $1 \le q \le \infty$, denote the Banach spaces intermediate between V and W defined by the K-functional, which are used in interpolation theory (cf., e.g., [7, Chapter 5]). Denote now with $L_{2,\psi}$ the orthogonal space with respect to the L_2-inner–product to the space spanned by the function $\psi = \varphi + u_R$, where $\varphi = r^{-\pi/\omega} \sin(\vartheta\pi/\omega)\eta$, and $u_R \in H^1_0$ the variational solution of $-\Delta u_R = \Delta\varphi$. Then, in view of [5, Theorem 4.1], we have

$$\|u\|_X \le C \|f\|_Y \tag{5.12}$$

with $Y = [L_{2,\psi}, H^{-\tilde{\ell}}]_{s_0/\tilde{\ell}, \infty}$; thus

$$\|u - u_h\|_{H^1} \le C h^{1-s_0} \|f\|_Y. \tag{5.13}$$

Further, since $\tilde{\ell} > s_0$, $[L_{2,\psi}, H^{-1}]_{\tilde{\ell}, 2} = [L_2, H^{-1}]_{\tilde{\ell}, 2} = H^{-\tilde{\ell}}$ (cf., e.g., [5, equation (3.16)]). Therefore, in view of the reiteration theorem for the interpolation of spaces (cf., e.g., [7, Chapter 5]), we get

$$Y = [L_{2,\psi}, H^{-1}]_{s_0, \infty}. \tag{5.14}$$

In addition, in view of [5, Theorem 3.1 and Remark 3.1], we have

$$\|f\|_{[L_{2,\psi}, H^{-1}]_{s_0,\infty}} \le C \frac{1}{s_0 - \ell} \|f\|_{H^{-\ell}}, \quad \forall f \in H^{-\ell}. \tag{5.15}$$

Thus, combining (5.13)–(5.15) we get the desired estimate. ∎

Finally, we will show an almost optimal L_∞-norm error estimate.

THEOREM 5.5. *Let u and u_h be the solutions of (2.1) and (1.4), respectively, with $f \in H^{-\ell}$, $0 < \ell < 1/2$. Then there exists a constant C, independent of h, such that*

$$\|u - u_h\|_{L_\infty} \le Ch^s \log \frac{1}{h} \|f\|_{H^{-\ell}}. \tag{5.16}$$

Proof. The proof is similar to the one for Theorem 4.8. Hence, we will derive bounds for $\|u - \underline{u}_h\|_{L_\infty}$ and $\|\underline{u}_h - u_h\|_{L_\infty}$.

This time using [32, equation (0.8)] and the standard imbedding $H^{1+s} \subset C^{0,s}$ (cf., e.g., [24, Theorem 1.4.5.2]), we have

$$\|u - \underline{u}_h\|_{L_\infty} \le Ch^s \log \frac{1}{h} \|u\|_{C^{0,s}} \le Ch^s \log \frac{1}{h} \|u\|_{H^{1+s}}.$$

Then, combining this with the elliptic regularity estimate,

$$\|u\|_{H^{1+s}} \le C_\ell \|f\|_{H^{-\ell}}$$

(cf. [4]), we obtain

$$\|u - \underline{u}_h\|_{L_\infty} \le C_\ell h^s \log \frac{1}{h} \|f\|_{H^{-\ell}}, \quad 0 \le \ell < 1/2. \tag{5.17}$$

We turn now to the estimation of $\|\underline{u}_h - u_h\|_{L_\infty}$. Since $A = I$, (4.34) gives

$$\|\underline{u}_h - u_h\|_{L_\infty} = \varepsilon_h(f, G_h), \tag{5.18}$$

where $G_h \in X_h$ is the finite element approximation of the regularized Green function G (cf. (4.33)). Then, using Lemma 5.1 and (4.37), we obtain

$$\|\underline{u}_h - u_h\|_{L_\infty} \le Ch^{1-\ell} \left(\log \frac{1}{h} \right)^{1/2} \|f\|_{H^{-\ell}}.$$

From this and (5.17) we get the desired estimation (5.16). ∎

6. Auxiliary results. In this section we shall prove Lemmas 4.1, 4.2, and 5.1 of the previous sections.

Proof of Lemma 4.1. We can easily see that the interpolation operator I_h satisfies the property

$$\begin{aligned} \|\chi - I_h\chi\|^q_{L_q(K)} &= \sum_{z \in Z_h(K} \int_{K_z} (\chi - \chi(z))^q \, dx \\ &\le h_K^q |\chi|^q_{W^1_q(K)}, \quad \forall \chi \in X_h, \ q > 1, \end{aligned} \tag{6.1}$$

with $Z_h(K)$ the set of the vertices of K. Also, since in the construction of the control volumes we choose z_K to be the barycenter of K, we have

$$\int_K \chi \, dx = \int_K I_h\chi \, dx, \quad \forall K \in T_h, \ \forall \chi \in X_h. \tag{6.2}$$

In view of (6.1), (4.1) follows easily. Let now $\bar{f}_K$ be the mean value of f in K. Thus,

$$\|f - \bar{f}_K\|_{L_p(K)} \le Ch_K |f|_{W^1_p(K)}, \quad \forall f \in W^1_p(K), \ p > 1. \tag{6.3}$$

Then, by interpolation of this estimate and $\|f-\bar f_K\|_{L_p(K)} \le C\|f\|_{L_p(K)}$, we get, for $f \in W_p^t(K)$, $p>1$, and $0<t\le 1$

$$\|f-\bar f_K\|_{L_p(K)} \le Ch_K^t |f|_{W_p^t(K)}. \tag{6.4}$$

Since $\bar f_K$ is constant over K, due to (6.2), we have

$$(f, \chi - I_h\chi)_K = (f-\bar f_K, \chi - I_h\chi)_K, \quad \forall \chi \in X_h.$$

Thus, due to this, (6.4), and (6.1), we get for every $\chi \in X_h$,

$$|(f, \chi - I_h\chi)_K| = |(f-\bar f_K, \chi - I_h\chi)_K| \le Ch_K^{1+t}|f|_{W_p^t(K)}\,|\chi|_{W_{p'}^1(K)},$$

which concludes the proof of (4.2). ∎

We now turn to the proof of Lemma 4.2. For this we shall need the following auxiliary result.

LEMMA 6.1. *Let K be a triangle and e a side of K. Then for $\varphi \in W_p^1(K)$, $p>1$, there exists a constant C independent of K such that*

$$\left|\int_e \varphi(\chi - I_h\chi)\,ds\right| \le Ch|\varphi|_{W_p^1(K)}|\chi|_{W_{p'}^1(K)}, \quad \forall \chi \in \mathbb{P}_1(K).$$

Proof of Lemma 6.1. It is obvious that, for c constant, $I_h c = c$ and

$$\int_e I_h\chi\,ds = \int_e \chi\,ds, \quad \forall \chi \in X_h,\ \forall e \in E_h. \tag{6.5}$$

Thus, we have for every $\chi \in \mathbb{P}_1(K)$ and $\varphi \in L_2(e)$,

$$\int_e \varphi(\chi - I_h\chi)\,ds = \int_e (\varphi - c_1)(\chi - c_2 - I_h(\chi - c_2))\,ds,$$

for all constants $c_1, c_2 \in \mathbb{R}$, $K \in T_h$, and $e \in E_h(K)$. Using now in the relation above the fact that $\|I_h\chi\|_{L_\infty(e)} \le \|\chi\|_{L_\infty(e)}$ and a local inverse inequality, we get for all constants $c_1, c_2 \in \mathbb{R}$, $\chi \in \mathbb{P}_1(K)$, and $\varphi \in W_p^1(K)$,

$$\begin{aligned}\left|\int_e \varphi(\chi - I_h\chi)\,ds\right| &\le \|\varphi - c_1\|_{L_p(e)}\|\chi - c_2 - I_h(\chi - c_2)\|_{L_{p'}(e)}\\ &\le h_e^{1/p'}\|\varphi - c_1\|_{L_p(e)}\,\|\chi - c_2 - I_h(\chi - c_2)\|_{L_\infty(e)}\\ &\le Ch_e^{1/p'}\|\varphi - c_1\|_{L_p(e)}\|\chi - c_2\|_{L_\infty(e)}\\ &\le C\|\varphi - c_1\|_{L_p(e)}\,\|\chi - c_2\|_{L_{p'}(e)}\end{aligned} \tag{6.6}$$

with $h_e = |e|$. In view of the Bramble–Hilbert lemma and a standard homogeneity argument, we can easily show

$$\inf_{c\in\mathbb{R}} \|\varphi - c\|_{L_p(e)} \le Ch_e^{1-1/p}|\varphi|_{W_p^1(K)}, \quad \forall \varphi \in W_p^1(K),\ p>1.$$

Finally, combining this with (6.6) we obtain the desired estimate. ∎

We now turn to the proof of Lemma 4.2.

Proof of Lemma 4.2. First we will show (4.3). In view of Green's formula, we have

$$\varepsilon_a(\psi,\chi)=\sum_K (L\psi,\chi-I_h\chi)_K+\sum_K (A\nabla\psi\cdot n,\chi-I_h\chi)_{\partial K}=I+II. \tag{6.7}$$

For the first term we have from (6.1),

$$|I|\le C\sum_K \|L\psi\|_{L_p(K)}\,\|\chi-I_h\chi\|_{L_{p'}(K)}\le C\sum_K h_K|\psi|_{W^1_{\bar p}(K)}\,|\chi|_{W^1_{\bar p'}(K)}.$$

The bound for II follows at once from Lemma 6.1 since $|A\nabla\psi\cdot n|_{W^1_{\bar p}(K)}\le C|\psi|_{W^1_{\bar p}(K)}$.

We now turn to (4.4). Let $\psi=u_h$ in (6.7) and $(\nabla A)_K$ be the average over K. Then in view of (6.1)–(6.3) we have for every $\chi\in X_h$,

$$(Lu_h,\chi-I_h\chi)_K=([\nabla A-(\nabla A)_K]\nabla u_h,\chi-I_h\chi))_K\le Ch_K^2|u_h|_{W^1_{\bar p}(K)}\,|\chi|_{W^1_{\bar p'}(K)}$$

with $\bar p$ given by (2.3). From the estimation above we easily obtain the desired bound for I. Let now $E_h(K)$ be the set of edges of $K\in T_h$ and $\bar A_e=A(m_e)$, where m_e is the midpoint of the edge e. We will show that for every $\chi\in X_h$,

$$II=\sum_K\sum_{e\in E_h(K)}((A-\bar A_e)\nabla(u_h-u)\cdot n,\chi-I_h\chi)_e. \tag{6.8}$$

Provided that this holds, we may apply Lemma 6.1 and the estimate

$$|(A-\bar A_e)\nabla(u_h-u)|_{W^1_{\bar p}(K)}\le C\big(\|\nabla(u-u_h)\|_{L_2(K)}+h\|u\|_{W^2_{\bar p}(K)}\big) \tag{6.9}$$

to obtain

$$|II|\le Ch\big(\|\nabla(u-u_h)\|_{L_2}+h\|u\|_{W^2_{\bar p}}\big)\,|\chi|_{W^1_{\bar p'}},\quad \forall\chi\in X_h,$$

which gives the desired estimate for II. Therefore, it remains to prove (6.8). We will show, for every $\psi\in X_h$,

$$\sum_K(A\nabla u\cdot n,\psi-I_h\psi)_{\partial K}=\sum_K\sum_{e\in E_h(K)}(\bar A_e\nabla u\cdot n,\psi-I_h\psi)_e=0. \tag{6.10}$$

In the first sum we have by Green's formula for every $\psi\in X_h$,

$$\sum_K(A\nabla u\cdot n,\psi)_{\partial K}=\sum_K(A\nabla u,\nabla\psi)_K-(Lu,\psi)_K=(A\nabla u,\nabla\psi)-(Lu,\psi)=0.$$

In addition, $\sum_K(A\nabla u\cdot n,I_h\psi)_{\partial K}=0$ because $I_h\psi$ is piecewise constant on each interior edge e and $A\nabla u\cdot n$ is continuous across e (in the trace sense), and $I_h\psi=0$ on $\partial\Omega$. Since the first sum in (6.10) vanishes for each smooth A and is continuous in A on $L_1(\cup\partial K)$, the second sum is the limit of sums with a smooth A and, therefore, also vanishes. Finally, since $\bar A_e\nabla u_h\cdot n$ is constant on each e, in view of (6.5) we have

$$\sum_K\sum_{e\in E_h(K)}(\bar A_e\nabla u_h\cdot n,\chi-I_h\chi)_e=0,\quad\forall\chi\in X_h.\qquad\square$$

It remains now to prove Lemma 5.1.

Proof of Lemma 5.1. In view of the definition of ε_h, it suffices to show

$$|\chi - I_h\chi|_{H^\ell} \le Ch^{1-\ell}\|\nabla\chi\|_{L_2}, \quad 0 < \ell < 1/2.$$

The fractional order seminorm $|\cdot|_{H^\ell}$ is given by

$$|w|^2_{H^\ell} = \int_\Omega\int_\Omega \frac{|w(x)-w(y)|^2}{|x-y|^{2(1+\ell)}}\,dy\,dx; \tag{6.11}$$

therefore,

$$\begin{aligned}|\chi - I_h\chi|^2_{H^\ell} &= \sum_{z,w\in Z_h}\int_{b_z}\int_{b_w}\frac{|(\chi-I_h\chi)(x)-(\chi-I_h\chi)(y)|^2}{|x-y|^{2(1+\ell)}}\,dy\,dx\\ &\le 4\sum_{\substack{z,w\in Z_h\\ z\neq w}}\int_{b_z}\int_{b_w}|\nabla\chi(z)|^2\frac{|x-z|^2}{|x-y|^{2(1+\ell)}}\,dy\,dx\\ &\quad+\sum_{z\in Z_h}\int_{b_z}\int_{b_z}|\nabla\chi(z)|^2|x-y|^{-2+2(1-\ell)}\,dy\,dx = 4I + II.\end{aligned}$$

For the estimation of II we rewrite the integral with respect to the y variable in polar coordinates (r,θ) having as center x; thus $|x-y| = r$ and

$$\int_{b_z}|x-y|^{-2+2(1-\ell)}\,dy \le C\int_0^h r^{(1-\ell)p-2+1}\,dr = Ch^{2(1-\ell)}.$$

Therefore,

$$\int_{b_z}\int_{b_z}|\nabla\chi|^2|x-y|^{-2+2(1-\ell)}\,dy\,dx \le Ch^{2(1-\ell)}\|\nabla\chi\|^2_{L_2(b_z)}, \tag{6.12}$$

which gives the desired estimate for II. Let us consider now $z \neq w$ and fix temporarily an $x \in K_z$. Using again polar coordinates with center x we estimate the integral with respect to y,

$$\int_{b_w}|x-y|^{-2(1+\ell)}\,dy \le C\int_{r_0(x)}^\infty r^{1-2(1+\ell)}\,dr \le Cr_0^{-2\ell}(x) = III,$$

where $r_0(x) = \operatorname{dist}(x, b_w)$. Let us assume that vertices z and w are in a different triangle and $|r_0(x)| > kh$; therefore, $|III| \le C|r_0(x)|^{-2\ell} \le Ch^{-2\ell}$. Thus,

$$\int_{b_z}\int_{b_w}|\nabla\chi(z)|^2|x-z|^2|x-y|^{-2(1+\ell)}\,dy\,dx \le Ch^{2(1-\ell)}\|\nabla\chi\|^2_{L_2(b_z)}. \tag{6.13}$$

Finally, let us consider the case that $z \neq w$ and are vertices of the same triangle K. Then $r_0(x)$ could be arbitrarily small and in order for

$$\int_{b_z} r_0(x)^{-2\ell}(x)\,dx < +\infty,$$

we need to assume that $\ell < 1/2$. In a such case, we have

$$\int_{b_z}\int_{b_w}|\nabla\chi(z)|^2|x-z|^2|x-y|^{-2(1+\ell)}\,dy\,dx \le Ch^2\int_{b_z}|\nabla\chi(z)|^2r_0^{2\ell}(x)\,dx. \tag{6.14}$$

Next we will estimate the right-hand side of the relation above. For this, it suffices to bound $\int_{K_z} |\nabla\chi(z)|^2 r_0^{2\ell}$. Let us denote with x_1 and x_2 the two coefficients of a point x in K_z and introduce a rotation and translation of the (x_1, x_2)-coordinate system to $(\tilde{x}_1, \tilde{x}_2)$, where $\tilde{x}_1$-axis is the common edge $K_z \cap K_w$. We can easily see that for any point in $x \in K_z$,

$$r_0(x) = \operatorname{dist}(x, b_w) \geq \operatorname{dist}((\tilde{x}_1, 0), b_w) = \tilde{x}_1.$$

Therefore, $r_0^{-2\ell}(x) \leq \tilde{x}_1^{-2\ell}$, $\forall x \in K_z$. Then

$$\begin{aligned} h^2 \int_{K_z} |\nabla\chi(z)|^2 r_0^{-2\ell}(x)\, dx &\leq Ch^2 |\nabla\chi(z)|^2 \int_0^h \int_0^h \tilde{x}_1^{-2\ell}\, d\tilde{x}_1\, d\tilde{x}_2 \\ &\leq Ch^{2(1-\ell)} \|\nabla\chi\|^2_{L_2(K_z)}, \end{aligned}$$

assuming $\ell < 1/2$. Hence, the relation above and (6.14) give

$$\int_{b_z} \int_{b_w} |\nabla\chi(z)|^2 |x - z|^2 |x - y|^{-2(1+\ell)}\, dy\, dx \leq Ch^{2(1-\ell)} \|\nabla\chi\|^2_{L_2(b_z)}.$$

Combining this with (6.12) and (6.13), we obtain the desired estimate. ∎

7. Numerical results. In this section we will illustrate on several numerical examples the theoretical results of section 4. Our examples are similar to the ones considered in [8, 27].

First, we will show that the theoretical L_2-norm convergence rate of Theorem 4.6 is satisfied for the model Dirichlet boundary value problem for the Poisson equations in a Γ-shaped domain (cf. Figure 7.1), with vertices $(0,0)$, $(1,0)$, $(1,1)$, $(-1,1)$, $(-1,-1)$, and $(0,-1)$. As in [8], we consider the following two singular functions for this Γ-shaped domain:

$$S_1(r,\theta) = \phi(r) r^{2/3} \sin\left(\frac{2}{3}\theta\right), \qquad S_2(r,\theta) = \phi(r) r^{\beta} \sin\left(\frac{2}{3}\theta\right),$$

where $\beta \in (0,1)$ and ϕ is a cutoff function defined by

$$\phi(r) = \begin{cases} 1 & 0 \leq r \leq 1/4, \\ -192r^5 + 480r^4 - 440r^3 + 180r^2 - \frac{135}{4}r + \frac{27}{8}, & 1/4 \leq r \leq 3/4, \\ 0 & 3/4 \leq r. \end{cases}$$

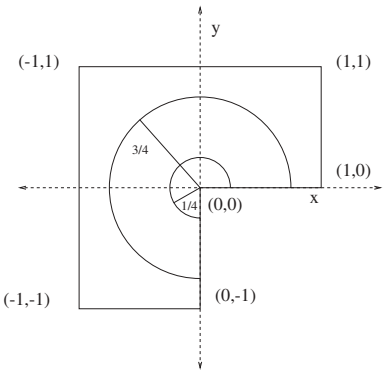

FIG. 7.1. *A Γ-shaped domain.*

TABLE 7.1
Approximate theoretical convergence rate for exact solution $u = S_1 + S_2 + (x - x^3)(y^2 - y^4)$.

$p_\omega = 3/2, \quad \tilde{p}_\omega = 6/5$		β			
		1/3	1/2	2/3	3/4

rate in H^1-norm $= s$		1/3	1/2	2/3	2/3
rate in L_2–norm $\approx$	$s + 2/3, \ (\alpha < \tilde{p}_\omega)$	$s + \frac{2}{3} = 1$			
	$\min(s + 2/3, 1 + t), (\alpha \geq \tilde{p}_\omega)$		$s + \frac{2}{3} = \frac{7}{6}$	$s + \frac{2}{3} = \frac{4}{3}$	$s + \frac{2}{3} = \frac{4}{3}$
rate in L_∞-norm $\approx s$		1/3	1/2	2/3	2/3

For $f = -\Delta(S_1 + S_2) + 6x(y^2 - y^4) + (x - x^3)(12y^2 - 2)$ the exact solution is $u = S_1 + S_2 + (x - x^3)(y^2 - y^4)$. We can easily see that

$$\Delta(S_1 + S_2) = \phi(r)(\beta^2 - (2/3)^2)r^{\beta-2}\sin\left(\frac{2}{3}\theta\right) + (2\beta + 1)\phi'(r)r^{\beta-1}\sin\left(\frac{2}{3}\theta\right) + \phi''(r)r^{\beta}\sin\left(\frac{2}{3}\theta\right) + \frac{7}{3}\phi'(r)r^{-1/3}\sin\left(\frac{2}{3}\theta\right) + \phi''(r)r^{2/3}\sin\left(\frac{2}{3}\theta\right).$$

Since ϕ is a smooth cutoff function and $6x(y^2-y^4)+(x-x^3)(12y^2-2)$ is a polynomial, the nonsmoothness of f results from $-\Delta(S_1 + S_2)$ and for $\beta \in (0, 1)$ this is dictated from the term $r^{\beta-2}$, except in the case $\beta = 2/3$, where the leading term is $r^{-1/3}$.

According to [24, Theorem 1.4.5.3], if a function g can be written as $g = r^\gamma \varphi(\vartheta)$, in polar coordinates, where φ is smooth function, then $g \in W^t_\alpha$, with $t > 0$ and $\alpha > 1$, for $\gamma > t - 2/\alpha$. Thus, applying this to f, we have that f is almost in $W^{\beta-2+2/\alpha}_\alpha$, with $\alpha \in (1, 2/(2-\beta))$, for $\beta \neq 2/3$, and $f \in W^{-1/3+2/\alpha}_\alpha$, with $\alpha \in (1, 6)$, for $\beta = 2/3$. In addition, in view of the imbedding $L_p \subset W^t_a$, with $p = 2\alpha/(2 - t\alpha)$, for $\beta \neq 2/3$, then $f \in L_p$, with $p = 2/(2 - \beta)$, and for $\beta = 2/3$, $f \in L_6$.

Since we have considered a Γ-shaped domain, the largest interior angle is $3\pi/2$; therefore, $p_\omega = 2/(2 - (\pi/\frac{3\pi}{2})) = 3/2$. Thus, in view of (2.2), the solution u of the Poisson problem is almost in $W^2_{\bar{p}}$, with $\bar{p} = \min(2/(2 - \beta), 3/2)$, or else u is almost in H^{1+s} with $s = \min(\beta, 2/3)$.

For example, we consider $\beta = 1/3$, $1/2$, $2/3$, and $3/4$. Then f is almost in the Sobolev spaces $W^{10/66}_{11/10}$, $W^{1/6}_{6/5}$, $W^{4/3}_{6/5}$, and $W^{5/12}_{6/5}$ for $\beta = 1/3$, $1/2$, $2/3$, and $3/4$, respectively. In Table 7.1 we present the theoretical and in Tables 7.2 and 7.3 the computed rates of convergence of the finite volume element method which illustrate the results of Theorem 4.6. The computation is done in the following way: For a given triangulation with number of nodes N and stepsize $2h$, we compute the finite volume solution and the norms of the errors $\|u - u_{2h}\|_T$, where $T = H^1, L_2, L_\infty$. Then we split each triangle into four similar triangles and compute the solution u_h and the corresponding norms of the errors, $\|u - u_h\|_T$. Then the computed rates are given by $\log_2 \frac{\|u-u_{2h}\|_T}{\|u-u_h\|_T}$. This procedure is repeated up to seven levels of refinement. The integrals in the finite volume formulation were approximated with a 13-point Gaussian quadrature. For the solution of the corresponding linear system we used a multigrid preconditioner.

One may argue that the suboptimal order of the L_2-norm error estimates in Theorems 4.3 and 5.4 of the finite volume element method might be an artifact of the proof and expect the same rate as in the finite element method. However, this is not correct. In what follows, we consider a counterexample which is based on a

similar argument given in [27]. The following arguments can easily be modified and apply to a model problem in a convex domain. This can then be used to illustrate the theoretical convergence rates derived in [14, 23].

First we will show that the L_2-norm estimate in Theorem 4.3 is sharp. We consider the model problem

$$-\Delta u = f \quad \text{in } \Omega, \quad \text{and} \quad u = 0 \quad \text{on } \partial\Omega, \tag{7.1}$$

where $f \in L_2$ and Ω is the Γ-shaped domain with vertices $(0,0)$, $(2,0)$, $(2,2)$, $(-2,2)$, $(-2,-2)$, and $(0,-2)$. Since $\pi/\omega = 2/3$, according to Theorem 4.3 we know that

$$\|u - u_h\|_{H^1} \le Ch^s \|f\|_{L_2}$$

with $s = 2/3 - \varepsilon$, $\varepsilon > 0$ arbitrarily small. Let us assume then that (4.6) is not true and the finite volume and finite element methods converge in the L_2-norm with the same rate, i.e.,

$$\|u - u_h\|_{L_2} \le Ch^{2s} \|f\|_{L_2}.$$

Obviously,

$$\|u - u_h\|_{L_2} = \sup_{\phi \in L_2 \setminus \{0\}} \frac{(u - u_h, \phi)}{\|\phi\|_{L_2}}.$$

Hence, our assumption leads to

$$|(u - u_h, \phi)| \le Ch^{2s} \|\phi\|_{L_2} \|f\|_{L_2}. \tag{7.2}$$

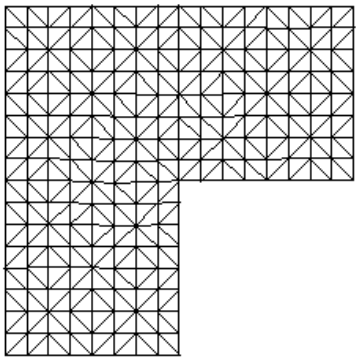

FIG. 7.2. *An example of a triangulation. The successive uniform refinement occurs by splitting the triangles into four.*

Next, let us denote $\psi \in H^{1+s} \cap H_0^1$ the solution of the auxiliary problem

$$-\Delta\psi = \phi \quad \text{in } \Omega, \quad \text{and} \quad \psi = 0 \quad \text{on } \partial\Omega. \tag{7.3}$$

Thus,

$$(u - u_h, \phi) = a(u - u_h, \psi) = a(u - u_h, \psi - \Pi_h\psi) + a(u - u_h, \Pi_h\psi), \tag{7.4}$$

where $\Pi_h\psi$ is the interpolant of ψ in X_h. Obviously, then

$$a(u - u_h, \Pi_h\psi) = (f, \Pi_h\psi - I_h\Pi_h\psi). \tag{7.5}$$

We can easily see that

$$a(u - u_h, \psi - \Pi_h\psi) \le Ch^{2s}\|\phi\|_{L_2}\|f\|_{L_2}.$$

Thus combining (7.2)–(7.5), we get

$$(f, \Pi_h\psi - I_h\Pi_h\psi) \le Ch^{2s}\|\phi\|_{L_2}\|f\|_{L_2}.$$

Since f is an arbitrary function of L_2, this leads to

$$\|\Pi_h\psi - I_h\Pi_h\psi\|_{L_2} \le Ch^{2s}\|\phi\|_{L_2}.$$

Hence,

$$\|\psi - I_h\Pi_h\psi\|_{L_2} \le Ch^{2s}\|\phi\|_{L_2}.$$

Then, since ϕ is also an arbitrary function, this should be true for any function $\psi \in H^{1+s} \cap H_0^1$. Therefore, let us consider a function $\psi \in H^{1+s} \cap H_0^1$ such that

$$\psi(x_1, x_2) = x_1(1 - x_1), \quad (x_1, x_2) \in \Omega_1 = [1/2, 3/2] \times [1/2, 3/2]. \tag{7.6}$$

For this ψ we should get

$$\|\psi - I_h\Pi_h\psi\|_{L_2(\Omega_1)} \le Ch^{2s}. \tag{7.7}$$

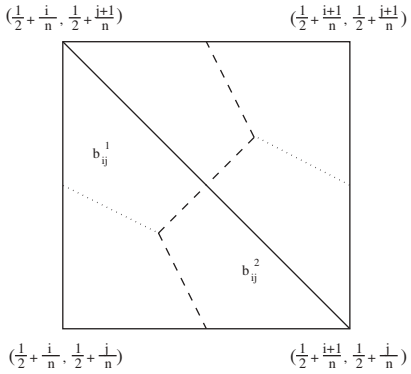

FIG. 7.3. *A sample square K_{ij}. The two regions b_{ij}^1 and b_{ij}^2 are separated with the dashed line.*

We discretize Ω_1 into n^2 equal size squares with length $h = 1/n$, and each square is divided further into two right triangles in the same direction. Next, we construct the relative control volumes by connecting the barycenter of its triangle with the middle of the edges. Let us denote z_{ij} the vertices $(1/2 + i/n, 1/2 + j/n)$, $i, j = 0, \ldots, n-1$. Also, let K_{ij} be the square $[1/2 + i/n, 1/2 + (i+1)/n] \times [1/2 + j/n, 1/2 + (j+1)/n]$, $i, j = 1, \ldots, n$, and $b_{ij}^1 = K_{ij} \cap (b_{ij} \cup b_{i(j+1)})$ and $b_{ij}^2 = K_{ij} \cap (b_{(i+1)j} \cup b_{(i+1)(j+1)})$ (cf. Figure 7.3). Then, since ψ depends only on x, $I_h\psi_I$ has the same value on the control volumes b_{ij}, $j = 0, \ldots, n-1$, for every $i = 0, \ldots, n-1$. For this reason, on the square K_{ij}, $I_h\psi = \psi(z_{ij})$ on b_{ij}^1 and $I_h\psi = \psi(z_{(i+1)j})$ on b_{ij}^2. Then we have

$$\begin{aligned}
\|\psi - I_h\Pi_h\psi\|_{L_2(\Omega_1)}^2 &= \int_{\Omega_1} \psi^2 \, dx_1 \, dx_2 + \int_{\Omega_1} (I_h\Pi_h\psi)^2 \, dx_1 \, dx_2 \\
&\quad - 2\int_{\Omega_1} \psi I_h\Pi_h\psi \, dx_1 \, dx_2 \\
&= \int_{1/2}^{3/2} x_1^2(1-x_1)^2 \, dx_1 + \sum_{i,j=0}^{n-1} (\psi^2(z_{ij})|b_{ij}^1| + \psi^2(z_{(i+1)j})|b_{ij}^2|) \\
&\quad - 2\sum_{i,j=0}^{n-1} \left(\psi(z_{ij}) \int_{b_{ij}^1} x_1(1-x_1) \, dx_1 \, dx_2 \right. \\
&\qquad \left. + \psi(z_{(i+1)j}) \int_{b_{ij}^2} x_1(1-x_1) \, dx_1 \, dx_2 \right) \\
&= \frac{10}{81n^2} + \frac{1}{405n^4}.
\end{aligned}$$

Finally, we have

$$\|\psi - I_h\Pi_h\psi\|_{L_2(\Omega_1)} = \frac{\sqrt{10}}{9}\frac{1}{n} + o\left(\frac{1}{n}\right) = O(h).$$

Combining this with (7.7) we get a contradiction, since $2s \approx 4/3$.

Similar arguments can be used in order to show now the sharpness of the L_2-norm error estimate in Theorem 5.2. Thus, let us consider this time the model problem (7.1), with $f \in H^{-1/3}$.

According to Theorem 5.2 we have that

$$\|u-u_h\|_{H^1} \le Ch^s \|f\|_{H^{-1/3}},$$

with $s = 2/3-\varepsilon$, $\varepsilon > 0$, arbitrarily small. Let us assume that the L_2-norm error estimate in Theorem 5.4 does not hold and the finite volume and finite element methods converge in L_2-norm with the same rate, i.e.,

$$\|u-u_h\|_{L_2} \le Ch^{2s} \|f\|_{H^{-1/3}}.$$

Repeating similar arguments as in the previous counterexample, the function $\psi \in H^{1+s} \cap H_0^1$ that satisfies (7.6) and (7.3) should also satisfy

$$\|\Pi_h\psi - I_h\Pi_h\psi\|_{H^{1/3}} \le Ch^{2s}\|\phi\|_{L_2}. \tag{7.8}$$

We discretize again Ω_1 in the same way as before, into n^2 equal size squares with length $h = 1/n$, and each square is divided further into two right triangles in the same direction. We construct the control volumes b_{ij} in the same manner as before and denote z_{ij} the vertices $(1/2+i/n, 1/2+j/n)$, $i,j = 0,\dots,n-1$. Then, using the definition of $|\cdot|_{H^\ell}$ (6.11), we can estimate $\|\Pi_h\psi - I_h\Pi_h\psi\|_{H^{1/3}(\Omega_1)}$ from below by

$$\|\Pi_h\psi - I_h\Pi_h\psi\|^2_{H^{1/3}(\Omega_1)} \ge \sum_{i,j=1}^{n-1} \int_{b_{z_{ij}}}\int_{b_{z_{ij}}} \frac{|\nabla\Pi_h\psi(z_{ij})\cdot(x-y)|^2}{|x-y|^{2(1+1/3)}}\,dy\,dx. \tag{7.9}$$

Also, let $x=(x_1,x_2)$, $y=(y_1,y_2)$, and $\tilde{K}_{ij} = [1/2+i/n, 1/2+i/n+1/3n]\times[1/2+j/n, 1/2+j/n+1/3n]$, and since ψ is invariant in the x_2-direction and $|x-y| \le \sqrt{2}/3n$, (7.9) gives

$$\begin{aligned}
&\|\Pi_h\psi - I_h\Pi_h\psi\|^2_{H^{1/3}(\Omega_1)} \\
&\quad\ge \sum_{i,j=1}^{n-1} \int_{\tilde{K}_{ij}}\int_{\tilde{K}_{ij}} \frac{|\nabla\Pi_h\psi(z_{ij})\cdot(x-y)|^2}{|x-y|^{2(1+1/3)}}\,dy\,dx \\
&\quad\ge \left(\frac{3n}{\sqrt{2}}\right)^{2(1+1/3)} (n-1)\sum_{i=1}^{n-1} \int_{\tilde{K}_{i1}}\int_{\tilde{K}_{i1}} \left|\frac{\partial\Pi_h\psi(z_{i1})}{\partial x_1}\right|^2 (x_1-y_1)^2\,dy\,dx.
\end{aligned} \tag{7.10}$$

Next, we can easily see that $|\frac{\partial\Pi_h\psi(z_{i1})}{\partial x_1}| = (2i+1)/n$ and

$$\int_{\tilde{K}_{i1}}\int_{\tilde{K}_{i1}} (x_1-y_1)^2\,dy\,dx = \frac{1}{2\cdot 3^7 n^6}.$$

Thus,

$$\sum_{i=1}^{n-1} \int_{\tilde{K}_{i1}}\int_{\tilde{K}_{i1}} \left|\frac{\partial\Pi_h\psi(z_{i1})}{\partial x_1}\right|^2 (x_1-y_1)^2\,dy\,dx \ge \frac{1}{2\cdot 3^7 n^8}\sum_{i=1}^{n-1} i^2 = \frac{n(n-1)(2n-1)}{4\cdot 3^8 n^8}.$$

Finally, employing this in (7.10) we get

$$\|\Pi_h\psi - I_h\Pi_h\psi\|_{H^{-1/3}(\Omega_1)} \ge \frac{C}{n^{2/3}} + o\left(\frac{1}{n^{2/3}}\right) = O(h^{2/3}).$$

Combining this with (7.8) we get a contradiction, since $2s \approx 4/3$.

Acknowledgment. The authors thank Dr. S. Tomov for performing and discussing some of the numerical experiments presented in this paper.

LOCALLY CONSERVATIVE COUPLING OF STOKES AND DARCY FLOWS*

BÉATRICE RIVIÈRE† AND IVAN YOTOV†

Abstract. A locally conservative numerical method for solving the coupled Stokes and Darcy flows problem is formulated and analyzed. The approach employs the mixed finite element method for the Darcy region and the discontinuous Galerkin method for the Stokes region. A discrete inf-sup condition and optimal error estimates are derived.

Key words. multiphysics, porous media flow, incompressible fluid flow, discontinuous Galerkin, mixed finite element, error estimates, inf-sup condition

1. Introduction.

The numerical modeling of reactive transport necessitates the use of numerical schemes that do not create artificial mass [14]. Mixed finite element (MFE) and discontinuous Galerkin (DG) methods are two examples of locally mass conservative methods that are used in the geosciences. MFE methods are quite popular for porous media problems [16, 34, 17, 4] and DG methods are attractive for modeling flow on unstructured meshes [33, 31, 30, 32].

Many applications involve different physical processes in different parts of the simulation domain. In this paper we propose a numerical method for approximating the solution to the coupled Darcy–Stokes problem. Such systems arise, for example, in modeling the interaction between surface water (river) and groundwater (aquifer). There are few works in the literature that address the numerical analysis of the coupled Darcy–Stokes problem. In [25], Layton, Schieweck, and Yotov consider a formulation based on the Beavers–Joseph–Saffman interface conditions [5, 35, 24], prove the existence and uniqueness of a weak solution, and analyze a continuous finite element scheme coupled with MFE. A similar formulation is studied by Discacciati, Miglio, and Quarteroni [15], where continuous finite elements are used in both regions. An application of this formulation to vugular porous media is studied in [3]. A singularly perturbed Stokes problem, which models Darcy flow as a limiting case, is considered by Mardal, Tai, and Winther [27]. There, a new finite element is proposed which behaves uniformly in the perturbation parameter. Ewing, Iliev, and Lazarov [18] employ finite difference methods for a similar model involving the Navier–Stokes equations with an added Darcy term.

The model we consider, which is similar to the one in [25], is based on imposing the correct local equations in each region, coupled with appropriate interface conditions. In particular, the fluid region is modeled by the Stokes equations and the porous media region is modeled by the Darcy's law. Continuity of flux, balance of forces, and the Beavers–Joseph–Saffman slip with friction condition (see (2.10) below) are imposed on the interface. In this work we emphasize locally mass conservative discretizations. Conserving mass locally is especially important when the flow equations are coupled

with the reactive transport of chemical species. In the porous media region, the fluid velocity and pressure are obtained by MFE, and in the incompressible flow region, the fluid velocity and pressure are approximated by DG. An advantage of our approach is the possibility of coupling existing highly optimized MFE-based porous media simulators with the flexibility and easy implementation of DG methods for incompressible flows. The meshes at the interface between the two regions may be nonmatching. The estimates are derived for two-dimensional problems. The results are also valid in higher dimension, and depend on the existence of approximation operators (see Remark 4.4 below).

The outline of the paper is as follows. In section 2, the model problem, notation, and scheme are presented. Section 3 contains the derivation of the discrete inf-sup condition. In section 4, approximation results and optimal a priori error estimates are proved. Some concluding remarks follow.

2. Model problem, notation, and scheme. Let Ω be a domain in $\mathbb{R}^d$, $d = 2$, subdivided into two subdomains Ω_1, Ω_2. Let Γ_{12} be the interface $\partial\Omega_1 \cap \partial\Omega_2$. Define $\Gamma_i = \partial\Omega_i \backslash \Gamma_{12}$, $i = 1, 2$. Denote by $\boldsymbol{n}$ the outward normal vector to $\partial\Omega$. Let $\boldsymbol{n}_{12}$ (resp., $\boldsymbol{\tau}_{12}$) be the unit normal (resp., tangential) vector to Γ_{12} outward of Ω_1. Denote by $\boldsymbol{u} = (\boldsymbol{u}_1, \boldsymbol{u}_2)$ the fluid velocity and by $p = (p_1, p_2)$ the fluid pressure, where $\boldsymbol{u}_i = \boldsymbol{u}|_{\Omega_i}$ and $p_i = p|_{\Omega_i}$. The flow in the domain Ω_1 is assumed to be of Stokes type, and therefore the following equations are satisfied:

$$-\nabla \cdot \boldsymbol{T}(\boldsymbol{u}_1, p_1) = \boldsymbol{f}_1 \quad \text{in } \Omega_1, \tag{2.1}$$

$$\nabla \cdot \boldsymbol{u}_1 = 0 \quad \text{in } \Omega_1, \tag{2.2}$$

$$\boldsymbol{u}_1 = 0 \quad \text{on } \Gamma_1. \tag{2.3}$$

Here $\boldsymbol{T}$ is the stress tensor

$$\boldsymbol{T}(\boldsymbol{u}_1, p_1) = -p_1 \boldsymbol{I} + 2\mu \boldsymbol{D}(\boldsymbol{u}_1)$$

which depends on the viscosity $\mu > 0$ and the strain tensor

$$\boldsymbol{D}(\boldsymbol{u}_1) = \frac{1}{2}(\nabla \boldsymbol{u}_1 + \nabla \boldsymbol{u}_1^T).$$

In the region Ω_2, the fluid pressure and velocity satisfy the single phase Darcy flow equations

$$\nabla \cdot \boldsymbol{u}_2 = f_2 \quad \text{in } \Omega_2, \tag{2.4}$$

$$\boldsymbol{u}_2 = -\boldsymbol{K} \nabla p_2 \quad \text{in } \Omega_2, \tag{2.5}$$

$$\boldsymbol{u}_2 \cdot \boldsymbol{n} = 0 \quad \text{on } \Gamma_2, \tag{2.6}$$

where $\boldsymbol{K}$ is a symmetric and positive definite tensor representing the permeability divided by the viscosity and satisfying, for some $0 < \kappa_0 \le \kappa_1 < \infty$,

$$\kappa_0 \xi^T \xi \le \xi^T \boldsymbol{K}(x) \xi \le \kappa_1 \xi^T \xi \quad \forall x \in \Omega_2,\ \forall \xi \in \mathbb{R}^d. \tag{2.7}$$

The physical quantities are coupled through appropriate interface conditions

$$\boldsymbol{u}_1 \cdot \boldsymbol{n}_{12} = \boldsymbol{u}_2 \cdot \boldsymbol{n}_{12}, \tag{2.8}$$

$$p_1 - 2\mu((\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12}) \cdot \boldsymbol{n}_{12}) = p_2, \tag{2.9}$$

$$\boldsymbol{u}_1 \cdot \boldsymbol{\tau}_{12} = -2G(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12}) \cdot \boldsymbol{\tau}_{12}. \tag{2.10}$$

Note that condition (2.8) represents the mass conservation across the interface, condition (2.9) imposes balance of forces across the interface, and condition (2.10) is the Beavers–Joseph–Saffman law, where $G > 0$ is a friction constant that can be determined experimentally. The reader should refer to [5, 35, 24, 25] for a detailed description and motivation for the choice of these interface conditions.

For $i = 1, 2$, let $\mathcal{E}_h^i$ be a nondegenerate quasi-uniform subdivision of Ω_i [11] such that the partition $\mathcal{E}_h^1$ consists of triangles and $\mathcal{E}_h^2$ consists of either triangles or rectangles. Let Γ_h^i be the set of interior edges and let h_i denote the maximum diameter of elements in $\mathcal{E}_h^i$. The meshes at the interface between the two domains Ω_i may not match. For $s \geq 0$, $p > 1$, and a domain $E \subset \mathbb{R}^d$, let $W^{s,p}(E)$ be the usual Sobolev spaces [1], let $H^s(E) = W^{s,2}(E)$ be equipped with the usual norm $\|\cdot\|_{s,E}$, and let $L_0^2(E)$ denote the space of L^2 functions with zero average. In the formulation for the Stokes region, we need that both the gradient of $\boldsymbol{u}_1$ and the pressure p_1 have a trace on line segments. For this, it suffices to define the following velocity-pressure spaces for the Stokes region:

$$\boldsymbol{X}^1 = \{\boldsymbol{v}_1 \in (L^2(\Omega_1))^d : \ \forall E \in \mathcal{E}_h^1, \ \boldsymbol{v}_1|_E \in (W^{2,4/3}(E))^d\},$$
$$M^1 = \{q_1 \in L^2(\Omega_1) : \ \forall E \in \mathcal{E}_h^1, \ q_1|_E \in W^{1,4/3}(E)\},$$

with norms

$$|||\boldsymbol{v}_1|||_{s,\Omega_1}^2 = \sum_{E \in \mathcal{E}_h^1} \|\boldsymbol{v}_1\|_{s,E}^2,$$
$$\|\boldsymbol{v}_1\|_{X^1}^2 = |||\nabla \boldsymbol{v}_1|||_{0,\Omega_1}^2 + \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \frac{\sigma_e}{|e|} \|[\boldsymbol{v}_1]\|_{0,e}^2 + \frac{\mu}{G} \sum_{e \in \Gamma_{12}} \|\boldsymbol{v}_1 \cdot \boldsymbol{\tau}_{12}\|_{0,e}^2,$$
$$\|q_1\|_{M^1} = \|q_1\|_{0,\Omega_1}.$$

Here, the parameter $\sigma_e \geq 0$ takes a constant value over each edge e, and $|e|$ denotes the measure (or length) of e. Given a fixed normal vector $\boldsymbol{n}_e$ on each edge $e = \partial E_e^1 \cap \partial E_e^1$, directed from E_e^1 to E_e^2, the average and jump of functions in $\boldsymbol{X}^1$ and M^1 can be defined as

$$\{w\} = \frac{1}{2}(w|_{E_e^1}) + \frac{1}{2}(w|_{E_e^2}), \quad [w] = (w|_{E_e^1}) - (w|_{E_e^2}) \quad \forall e = \partial E_e^1 \cap \partial E_e^2,$$
$$\{w\} = w|_{E_e^1}, \quad [w] = w|_{E_e^1} \quad \forall e = \partial E_e^1 \cap \partial \Omega_1.$$

The velocity-pressure spaces for the Darcy region are

$$\boldsymbol{X}^2 = \left\{\boldsymbol{v} \in H(\mathrm{div}; \Omega_2) : \int_{\partial \Omega_2} \boldsymbol{v} \cdot \boldsymbol{n} w = 0 \ \forall w \in H_{0,\Gamma_{12}}^1(\Omega_2)\right\},$$
$$M^2 = L^2(\Omega_2),$$

where $H(\mathrm{div}; \Omega_2)$ is the space of vectors in $(L^2(\Omega_2))^d$ whose divergence lies in $L^2(\Omega_2)$ and

$$H_{0,\Gamma_{12}}^1(\Omega_2) = \{w \in H^1(\Omega_2) : w = 0 \text{ on } \Gamma_{12}\}.$$

The norms associated with $(\boldsymbol{X}^2, M^2)$ are

$$\|\boldsymbol{v}_2\|_{X^2}^2 = \|\boldsymbol{v}_2\|_{0,\Omega_2}^2 + \|\nabla \cdot \boldsymbol{v}_2\|_{0,\Omega_2}^2, \qquad \|q_2\|_{M^2} = \|q_2\|_{0,\Omega_2}. \tag{2.11}$$

We can now define $\boldsymbol{X} = \boldsymbol{X}^1 \times \boldsymbol{X}^2$ and $M = (M^1 \times M^2) \cap L_0^2(\Omega)$, the spaces for the coupled formulation with the usual norms

$$\|\boldsymbol{v}\|_X^2 = \|\boldsymbol{v}_1\|_{X^1}^2 + \|\boldsymbol{v}_2\|_{X^2}^2, \qquad \|q\|_M^2 = \|q_1\|_{M^1}^2 + \|q_2\|_{M^2}^2. \tag{2.12}$$

In [25], it was shown that there exists a unique weak solution $(\boldsymbol{u}, p)$ of the coupled problem (2.1)–(2.10), with $\boldsymbol{u}_1 \in (H^1(\Omega_1))^d$, $\boldsymbol{u}_2 \in \boldsymbol{X}^2$, and $p \in M$. We will assume that the solution $(\boldsymbol{u}, p)$ is regular enough, so that it is a strong solution of (2.1)–(2.10). Next, we introduce the bilinear forms $a_1 : \boldsymbol{X}^1 \times \boldsymbol{X}^1 \to \mathbb{R}$ and $b_1 : \boldsymbol{X}^1 \times M^1 \to \mathbb{R}$,

$$\begin{aligned} a_1(\boldsymbol{u}_1, \boldsymbol{v}_1) = {} & 2\mu \sum_{E \in \mathcal{E}_h^1} \int_E \boldsymbol{D}(\boldsymbol{u}_1) : \boldsymbol{D}(\boldsymbol{v}_1) + \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \frac{\sigma_e}{|e|} \int_e [\boldsymbol{u}_1] \cdot [\boldsymbol{v}_1] \\ & - 2\mu \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \int_e \{\boldsymbol{D}(\boldsymbol{u}_1)\} \boldsymbol{n}_e \cdot [\boldsymbol{v}_1] + 2\mu\epsilon \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \int_e \{\boldsymbol{D}(\boldsymbol{v}_1)\} \boldsymbol{n}_e \cdot [\boldsymbol{u}_1] \\ & + \frac{\mu}{G} \sum_{e \in \Gamma_{12}} \int_e \boldsymbol{u}_1 \cdot \boldsymbol{\tau}_{12} \boldsymbol{v}_1 \cdot \boldsymbol{\tau}_{12}, \end{aligned} \tag{2.13}$$

$$b_1(\boldsymbol{v}_1, p_1) = - \sum_{E \in \mathcal{E}_h} \int_E p_1 \nabla \cdot \boldsymbol{v}_1 + \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \int_e \{p_1\} [\boldsymbol{v}_1] \cdot \boldsymbol{n}_e. \tag{2.14}$$

Here, ϵ is a constant that takes the value -1 or $+1$, which makes the bilinear form a_1 symmetric or nonsymmetric. The bilinear forms corresponding to the Darcy region are $a_2 : \boldsymbol{X}^2 \times \boldsymbol{X}^2 \to \mathbb{R}$ and $b_2 : \boldsymbol{X}^2 \times M^2 \to \mathbb{R}$:

$$a_2(\boldsymbol{u}_2, \boldsymbol{v}_2) = \int_{\Omega_2} \boldsymbol{K}^{-1} \boldsymbol{u}_2 \cdot \boldsymbol{v}_2, \tag{2.15}$$

$$b_2(\boldsymbol{v}_2, q_2) = - \int_{\Omega_2} q_2 \nabla \cdot \boldsymbol{v}_2. \tag{2.16}$$

Let k_1, k_2, and l_2 be positive integers. Let $\boldsymbol{X}_h$ and M_h be finite-dimensional subspaces of $\boldsymbol{X}$ and M, respectively, such that

$$\boldsymbol{X}_h = \boldsymbol{X}_h^1 \times \boldsymbol{X}_h^2, \qquad M_h = M_h^1 \times M_h^2,$$

where $(\boldsymbol{X}_h^1, M_h^1)$ is the pair of discontinuous finite element spaces

$$\begin{aligned} \boldsymbol{X}_h^1 &= \{\boldsymbol{v}_1 \in \boldsymbol{X}^1 : \ \forall E \in \mathcal{E}_h^1, \ \boldsymbol{v}_1 \in (\mathbb{P}_{k_1}(E))^d\}, \\ M_h^1 &= \{q_1 \in M^1 : \ \forall E \in \mathcal{E}_h^1, \ q_1 \in \mathbb{P}_{k_1 - 1}(E)\}. \end{aligned}$$

The discrete spaces corresponding to the Darcy region consist of the standard mixed finite element spaces (such as RT spaces [29], BDM spaces [9], BDFM spaces [8], and BDDF spaces [7]). The mixed spaces $\boldsymbol{X}_h^2$ and M_h^2 contain all polynomials of degree at least k_2 and l_2, respectively. Note that for the Raviart–Thomas (RT) spaces, the condition $l_2 = k_2$ holds. We also assume that

$$\forall \boldsymbol{v}_2 \in \boldsymbol{X}_h^2, \quad \boldsymbol{v}_2 \cdot \boldsymbol{n} = 0 \quad \text{on } \Gamma_2.$$

Let E be a mesh element with diameter h_E. Given $p \in L_0^2(\Omega)$, we denote by $\tilde{p}$ the L^2 projection of p in M_h satisfying

$$\forall q \in \mathbb{P}_{k_1 - 1}(E), \quad \int_E q(\tilde{p} - p) = 0 \quad \forall E \in \mathcal{E}_h^1, \tag{2.17}$$

$$\forall q \in \mathbb{P}_{l_2}(E), \quad \int_E q(\tilde{p} - p) = 0 \quad \forall E \in \mathcal{E}_h^2, \tag{2.18}$$

and, if $p|_{\Omega_1} \in H^{k_1}(\Omega_1)$ and $p|_{\Omega_2} \in H^{l_2+1}(\Omega_2)$, then

$$\|p-\tilde{p}\|_{m,E} \le Ch_E^{k_1-m}|p|_{k_1,E}, \quad E \subset \Omega_1,\ m=0,1, \tag{2.19}$$

$$\|p-\tilde{p}\|_{m,E} \le Ch_E^{l_2+1-m}|p|_{l_2+1,E}, \quad E \subset \Omega_2,\ m=0,1. \tag{2.20}$$

Remark 2.1. One advantage of the DG method is that one can vary the polynomial degrees from element to element. Here we assume that k_1 is the minimum of the polynomial degrees used in the Stokes region.

Here and throughout the paper, C denotes a varying constant that is independent of the diameter of the mesh elements. We also make use of the quasi-local interpolant $\boldsymbol{\Pi}_h^1 : (H^1(\Omega_1))^d \to \boldsymbol{X}_h^1$ [13, 19, 12, 22] satisfying, for all $\boldsymbol{v}_1 \in (H^1(\Omega_1))^d$,

$$b_1(\boldsymbol{\Pi}_h^1\boldsymbol{v}_1 - \boldsymbol{v}_1, q_1) = 0 \quad \forall q_1 \in M_h^1, \tag{2.21}$$

$$\forall e \in \Gamma_h^1 \cup \Gamma_1,\ \int_e [\boldsymbol{\Pi}_h^1\boldsymbol{v}_1]\cdot q_1 = 0 \quad \forall \boldsymbol{v}_1 \in (H^1(\Omega_1))^d : \boldsymbol{v}_1 = 0 \text{ on } \Gamma_1,\ \forall q_1 \in M_h^1, \tag{2.22}$$

$$|||\boldsymbol{\Pi}_h^1\boldsymbol{v}_1|||_{1,\Omega_1} \le C\|\boldsymbol{v}_1\|_{1,\Omega_1}. \tag{2.23}$$

The operator $\boldsymbol{\Pi}_h^1$ has the optimal approximation properties

$$|\boldsymbol{\Pi}_h^1\boldsymbol{v}_1 - \boldsymbol{v}_1|_{m,E} \le Ch_E^{s-m}|\boldsymbol{v}_1|_{s,\delta(E)} \quad \forall 1 \le s \le k_1+1,\ \forall \boldsymbol{v}_1 \in H^s(\Omega_1),\ m=0,1, \tag{2.24}$$

where $\delta(E)$ is a suitable macro-element containing E. Moreover, it holds that for at least one edge e of every element $E \in \mathcal{E}_h^1$,

$$\int_e (\boldsymbol{\Pi}_h^1\boldsymbol{v}_1 - \boldsymbol{v}_1) = 0 \quad \forall \boldsymbol{v}_1 \in (H^1(\Omega_1))^d. \tag{2.25}$$

We note that (2.25) holds true for all edges in the cases $k=1$ and $k=2$. For $k=3$, we can assume, without loss of generality, that (2.25) is satisfied for all edges in Γ_{12}. We will make use of the following bounds on $\boldsymbol{\Pi}_h^1$.

LEMMA 2.2. *Let* $1 \le s \le k_1+1$. *For all* $\boldsymbol{v}_1 \in (H^s(\Omega_1))^d$,

$$\|\boldsymbol{\Pi}_h^1\boldsymbol{v}_1 - \boldsymbol{v}_1\|_{X^1} \le Ch_1^{s-1}|\boldsymbol{v}_1|_{s,\Omega_1}, \tag{2.26}$$

$$\|\boldsymbol{\Pi}_h^1\boldsymbol{v}_1\|_{X^1} \le C\|\boldsymbol{v}_1\|_{1,\Omega_1}. \tag{2.27}$$

Proof. From Lemma 3.10 of [22] and from (2.24), we have

$$\|\boldsymbol{v}_1 - \boldsymbol{\Pi}_h^1\boldsymbol{v}_1\|_{X^1} \le C|||\nabla(\boldsymbol{v}_1 - \boldsymbol{\Pi}_h^1\boldsymbol{v}_1)|||_{0,\Omega_1} \le Ch_1^{s-1}|\boldsymbol{v}_1|_{s,\Omega_1}. \tag{2.28}$$

The bound (2.27) follows easily from the triangle inequality and (2.26) with $s=1$, using that $\|\boldsymbol{v}_1\|_{X^1} \le C\|\boldsymbol{v}_1\|_{1,\Omega_1}$ for $\boldsymbol{v}_1 \in (H^1(\Omega_1))^d$. ∎

We also recall the MFE interpolant $\boldsymbol{\Pi}_h^2 : \boldsymbol{X}^2 \cap (H^\theta(\Omega_2))^d \to \boldsymbol{X}_h^2$ for any $\theta > 0$, satisfying [10], for any $\boldsymbol{v}_2 \in \boldsymbol{X}^2 \cap (H^\theta(\Omega_2))^d$,

$$b_2(\boldsymbol{\Pi}_h^2\boldsymbol{v}_2 - \boldsymbol{v}_2, q_2) = 0 \quad \forall q_2 \in M_h^2, \tag{2.29}$$

$$\int_e ((\boldsymbol{\Pi}_h^2\boldsymbol{v}_2 - \boldsymbol{v}_2)\cdot\boldsymbol{n}_e)\boldsymbol{w}_2\cdot\boldsymbol{n}_e = 0 \quad \forall e \in \Gamma_h^2,\ \forall \boldsymbol{w}_2 \in \boldsymbol{X}_h^2. \tag{2.30}$$

Moreover, $\boldsymbol{\Pi}_h^2$ satisfies the approximation properties

$$\|\boldsymbol{v}_2 - \boldsymbol{\Pi}_h^2\boldsymbol{v}_2\|_{0,E} \le Ch_E^s|\boldsymbol{v}_2|_{s,E}, \quad 1 \le s \le k_2+1, \tag{2.31}$$

$$\|\nabla\cdot(\boldsymbol{v}_2 - \boldsymbol{\Pi}_h^2\boldsymbol{v}_2)\|_{0,E} \le Ch_E^s|\nabla\cdot\boldsymbol{v}_2|_{s,E}, \quad 0 \le s \le l_2+1. \tag{2.32}$$

It has been shown by Mathew in [28] for the Raviart–Thomas elements [29] that

$$\|\boldsymbol{\Pi}_h^2 \boldsymbol{v}_2\|_{H(\mathrm{div};\Omega_2)} \leq C(\|\boldsymbol{v}_2\|_{\theta,\Omega_2} + \|\nabla \cdot \boldsymbol{v}_2\|_{0,\Omega_2}), \tag{2.33}$$

a result that can be trivially extended to the other families of MFE spaces. Recall the basic trace inequalities on any mesh element E with diameter h_E

$$\forall \phi \in H^1(E),\ \forall e \subset \partial E, \quad \|\phi\|_{0,e}^2 \leq C(h_E^{-1}\|\phi\|_{0,E}^2 + h_E|\phi|_{1,E}^2), \tag{2.34}$$

$$\forall \phi \in H^2(E),\ \forall e \subset \partial E, \quad \|\nabla\phi \cdot \boldsymbol{n}\|_{0,e}^2 \leq C(h_E^{-1}\|\phi\|_{1,E}^2 + h_E|\phi|_{2,E}^2), \tag{2.35}$$

$$\forall \phi \in \mathbb{P}_k(E),\ \forall e \subset \partial E, \quad \|\nabla\phi \cdot \boldsymbol{n}\|_{0,e} \leq C h_E^{-1/2}|\phi|_{1,E}, \tag{2.36}$$

Recall also the Korn's inequality proved in [6]

$$\forall \boldsymbol{v} \in \boldsymbol{X}_h^1, \quad C|||\nabla \boldsymbol{v}|||_{0,\Omega_1}^2 \leq |||\boldsymbol{D}(\boldsymbol{v})|||_{0,\Omega_1}^2 + \sum_{e \in \Gamma_h^1 \cup \Gamma_1} \frac{1}{|e|}\|[\boldsymbol{v}]\|_{0,e}^2. \tag{2.37}$$

Define the finite-dimensional space of functions on the interface $\Lambda_h = X_h^2 \cdot \boldsymbol{n}_{12}$ and let

$$\boldsymbol{V}_h = \left\{ \boldsymbol{v} = (\boldsymbol{v}_1, \boldsymbol{v}_2) \in \boldsymbol{X}_h : \sum_{e \in \Gamma_{12}} \int_e \eta(\boldsymbol{v}_1 - \boldsymbol{v}_2) \cdot \boldsymbol{n}_{12} = 0\ \forall \eta \in \Lambda_h \right\}.$$

Defining $a = a_1 + a_2$ and $b = b_1 + b_2$, the numerical scheme is, Find $(\boldsymbol{U}, P) \in \boldsymbol{V}_h \times M_h$ such that

$$a(\boldsymbol{U}, \boldsymbol{v}) + b(\boldsymbol{v}, P) = \int_{\Omega_1} \boldsymbol{f}_1 \cdot \boldsymbol{v} \quad \forall \boldsymbol{v} \in \boldsymbol{V}_h, \tag{2.38}$$

$$b(\boldsymbol{U}, q) = \int_{\Omega_2} f_2 q \quad \forall q \in M_h. \tag{2.39}$$

Remark 2.3. This scheme is locally mass conservative. Indeed, if one chooses the test function in (2.39) such that $q = 1$ on E and $q = 0$ on the rest of the domain, we have

$$\int_{\partial E} \{\boldsymbol{U}\} \cdot \boldsymbol{n}_E = 0 \quad \forall E \subset \mathcal{E}_h^1,$$
$$\int_{\partial E} \boldsymbol{U} \cdot \boldsymbol{n}_E = \int_E f_2 \quad \forall E \subset \mathcal{E}_h^2.$$

Remark 2.4. The space of weakly-continuous-normal velocities $\boldsymbol{V}_h$ is introduced to facilitate the analysis of the numerical method. A direct construction of this space may, however, be difficult. An equivalent formulation to (2.38)–(2.39) is given in section 5. It is only based on the space $\boldsymbol{X}_h$ and is more suitable for implementation. The space Λ_h plays the role of a Lagrange multiplier or mortar space for imposing continuity of the normal velocities on Γ_{12}. The choice $\Lambda_h = X_h^2 \cdot \boldsymbol{n}_{12}$ is critical for the stability and accuracy of the numerical scheme, even in the case of nonmatching grids across Γ_{12}. This choice differs from the mortar space used in [2] in the case of MFE discretizations on nonmatching grids.

In the rest of the section, we show that the solution of the coupled problem satisfies the scheme up to an interface consistency error. We also prove uniqueness and existence of the discrete solution.

LEMMA 2.5. *If $(\boldsymbol{u},p)\in \boldsymbol{X}\times M$ solves the coupled Stokes–Darcy flow problem (2.1)–(2.10), such that $\boldsymbol{u}_i=\boldsymbol{u}|_{\Omega_i}$ and $p_i=p|_{\Omega_i}$, then $(\boldsymbol{u},p)$ satisfies the variational problem*

$$a(\boldsymbol{u},\boldsymbol{v})+b(\boldsymbol{v},p)=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1-\sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{v}_1-\boldsymbol{v}_2)\cdot\boldsymbol{n}_{12}\quad\forall\boldsymbol{v}\in\boldsymbol{V}_h, \tag{2.40}$$

$$b(\boldsymbol{u},q)=\int_{\Omega_2}f_2q\quad\forall q\in M_h. \tag{2.41}$$

Proof. Multiplying the Stokes equation (2.1) by $\boldsymbol{v}_1\in\boldsymbol{X}_h^1$ and integrating by parts over one element E,

$$\int_E T(\boldsymbol{u}_1,p_1):\nabla\boldsymbol{v}_1-\int_{\partial E}T(\boldsymbol{u}_1,p_1)\boldsymbol{n}_E\cdot\boldsymbol{v}_1=\int_E\boldsymbol{f}_1\cdot\boldsymbol{v}_1.$$

Summing over all elements E,

$$\begin{aligned}&\sum_E\int_E(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1)):\nabla\boldsymbol{v}_1-\sum_{e\in\Gamma_h^1}\int_e[(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))]\boldsymbol{n}_e\cdot\boldsymbol{v}_1\\&\quad-\int_{\Gamma_{12}}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1-\int_{\Gamma_1}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}\cdot\boldsymbol{v}_1=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1.\end{aligned}$$

It is easy to show that $\boldsymbol{D}(\boldsymbol{u}_1):\nabla\boldsymbol{v}_1=\boldsymbol{D}(\boldsymbol{u}_1):\boldsymbol{D}(\boldsymbol{v}_1)$ and that $\boldsymbol{I}:\nabla\boldsymbol{v}_1=\nabla\cdot\boldsymbol{v}_1$. Thus, the equation becomes

$$\begin{aligned}&\sum_E\int_E(2\mu\boldsymbol{D}(\boldsymbol{u}_1):\boldsymbol{D}(\boldsymbol{v}_1)-p_1\nabla\cdot\boldsymbol{v}_1)\\&\quad-\sum_{e\in\Gamma_h^1}\int_e\{-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{v}_1]-\sum_{e\in\Gamma_h^1}\int_e[-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1)]\boldsymbol{n}_e\cdot\{\boldsymbol{v}_1\}\\&\quad-\int_{\Gamma12}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1-\int_{\Gamma_1}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}\cdot\boldsymbol{v}_1=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1.\end{aligned}$$

By regularity of the true solution, we have

$$\begin{aligned}&\sum_E\int_E(2\mu\boldsymbol{D}(\boldsymbol{u}_1):\boldsymbol{D}(\boldsymbol{v}_1)-p_1\nabla\cdot\boldsymbol{v}_1)-\int_{\Gamma_{12}}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1\\&\quad-\sum_{e\in\Gamma_h^1}\int_e\{-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{v}_1]+\epsilon\sum_{e\in\Gamma_h^1}\int_e\{2\mu\boldsymbol{D}(\boldsymbol{v}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{u}_1]\\&\quad-\int_{\Gamma_1}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}\cdot\boldsymbol{v}_1+\epsilon\int_{\Gamma_1}2\mu\boldsymbol{D}(\boldsymbol{v}_1)\boldsymbol{n}\cdot\boldsymbol{u}_1=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1.\end{aligned}$$

Let us now consider the interface term

$$(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}=-p_1\boldsymbol{n}_{12}+(2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{\tau}_{12})\boldsymbol{\tau}_{12}+(2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{n}_{12})\boldsymbol{n}_{12},$$

which, combined with $\boldsymbol{v}_1=(\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12})\boldsymbol{\tau}_{12}+(\boldsymbol{v}_1\cdot\boldsymbol{n}_{12})\boldsymbol{n}_{12}$, gives

$$\begin{aligned}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1=&-p_1(\boldsymbol{v}_1\cdot\boldsymbol{n}_{12})+2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{\tau}_{12}(\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12})\\&+2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{n}_{12}(\boldsymbol{v}_1\cdot\boldsymbol{n}_{12}).\end{aligned}$$

Thus,

$$-\int_{\Gamma_{12}}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1=-\int_{\Gamma_{12}}(-p_1+2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{n}_{12})(\boldsymbol{v}_1\cdot\boldsymbol{n}_{12})$$
$$-\int_{\Gamma_{12}}2\mu(\boldsymbol{D}(\boldsymbol{u}_1)\boldsymbol{n}_{12})\cdot\boldsymbol{\tau}_{12}(\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12}).$$

With the interface conditions (2.9) and (2.10), we obtain

$$-\int_{\Gamma_{12}}(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_{12}\cdot\boldsymbol{v}_1=\int_{\Gamma_{12}}p_2(\boldsymbol{v}_1\cdot\boldsymbol{n}_{12})+\frac{\mu}{G}\int_{\Gamma_{12}}(\boldsymbol{u}_1\cdot\boldsymbol{\tau}_{12})(\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12}).$$

Thus,

$$\sum_E\int_E(2\mu\boldsymbol{D}(\boldsymbol{u}_1):\boldsymbol{D}(\boldsymbol{v}_1)-p_1\nabla\cdot\boldsymbol{v}_1)$$
$$-\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{(-p_1\boldsymbol{I}+2\mu\boldsymbol{D}(\boldsymbol{u}_1))\boldsymbol{n}_e\}\cdot[\boldsymbol{v}_1]+\epsilon\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{2\mu\boldsymbol{D}(\boldsymbol{v}_1)\boldsymbol{n}_e\}\cdot[\boldsymbol{u}_1]$$
$$+\int_{\Gamma_{12}}p_2\boldsymbol{v}_1\cdot\boldsymbol{n}_{12}+\frac{\mu}{G}\int_{\Gamma_{12}}\boldsymbol{u}_1\cdot\boldsymbol{\tau}_{12}\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12}=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1$$

which is equivalent to

$$a_1(\boldsymbol{u}_1,\boldsymbol{v}_1)+b_1(\boldsymbol{v}_1,p_1)+\int_{\Gamma_{12}}p_2\boldsymbol{v}_1\cdot\boldsymbol{n}_{12}=\int_{\Omega_1}\boldsymbol{f}_1\cdot\boldsymbol{v}_1\quad\forall\boldsymbol{v}_1\in\boldsymbol{X}_h^1. \tag{2.42}$$

The Darcy's law (2.5) can be rewritten as $\boldsymbol{K}^{-1}\boldsymbol{u}_2=-\nabla p_2$. As usual, multiplication by $\boldsymbol{v}_2\in\boldsymbol{X}_h^2$ and integration by parts on the Darcy region yields

$$\int_{\Omega_2}\boldsymbol{K}^{-1}\boldsymbol{u}_2\cdot\boldsymbol{v}_2=-\int_{\Omega_2}\nabla p_2\cdot\boldsymbol{v}_2=\int_{\Omega_2}p_2\nabla\cdot\boldsymbol{v}_2-\int_{\partial\Omega_2}p_2\boldsymbol{v}_2\cdot\boldsymbol{n}$$
$$=\int_{\Omega_2}p_2\nabla\cdot\boldsymbol{v}_2-\int_{\Gamma_2}p_2\boldsymbol{v}_2\cdot\boldsymbol{n}+\int_{\Gamma_{12}}p_2\boldsymbol{v}_2\cdot\boldsymbol{n}_{12},$$

or equivalently,

$$a_2(\boldsymbol{u}_2,\boldsymbol{v}_2)+b_2(\boldsymbol{v}_2,p_2)-\int_{\Gamma_{12}}p_2\boldsymbol{v}_2\cdot\boldsymbol{n}_{12}=0\quad\forall\boldsymbol{v}_2\in\boldsymbol{X}_h^2. \tag{2.43}$$

Adding (2.42) and (2.43) yields (2.40). Clearly, (2.2) and the regularity of the solution gives

$$b_1(\boldsymbol{u}_1,q)=0\quad\forall q\in M_h^1.$$

Finally, a simple integration in (2.4) yields

$$b_2(\boldsymbol{u}_2,q)=\int_{\Omega_2}f_2q\quad\forall q\in M_h^2,$$

and adding to the previous equation gives the result. ∎

Next, we prove a coercivity lemma that holds true under the following condition.

Hypothesis A. In the definition of the bilinear form $a_1(\cdot,\cdot)$, let us assume that either the condition (a) or (b) holds true.

(a) $\epsilon = 1$ and $\sigma_e > 1$ for all edges in $\Gamma_h^1 \cup \Gamma_1$. For instance, one may choose $\sigma_e = 2$.
(b) $\epsilon = -1$ and $\sigma_e \geq \sigma_0 > 0$ for σ_0 large enough.

LEMMA 2.6. *Assuming Hypothesis A, there exists a positive constant C_0 such that*

$$C_0\|\boldsymbol{v}\|_X^2 \leq a(\boldsymbol{v},\boldsymbol{v}) \quad \forall \boldsymbol{v} \in \boldsymbol{X}_h : \nabla\cdot\boldsymbol{v} = 0 \text{ a.e. in } \Omega_2.$$

Proof. Let $\boldsymbol{v} \in \boldsymbol{X}_h$. Then $\boldsymbol{v} = (\boldsymbol{v}_1, \boldsymbol{v}_2)$ with $\boldsymbol{v}_i \in \boldsymbol{X}_h^i$, $i = 1, 2$. Using (2.13) and (2.15),

$$\begin{aligned} a(\boldsymbol{v},\boldsymbol{v}) = {} & 2\mu \sum_{E\in\mathcal{E}_h^1} \int_E \boldsymbol{D}(\boldsymbol{v}_1) : \boldsymbol{D}(\boldsymbol{v}_1) + \sum_{e\in\Gamma_h^1\cup\Gamma_1} \frac{\sigma_e}{|e|}\int_e [\boldsymbol{v}_1]^2 \\ & - 2(1-\epsilon)\mu \sum_{e\in\Gamma_h^1\cup\Gamma_1} \int_e \{\boldsymbol{D}(\boldsymbol{v}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{v}_1] + \frac{\mu}{G}\sum_{e\in\Gamma_{12}}\int_e (\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12})^2 + \int_{\Omega_2} \boldsymbol{K}^{-1}\boldsymbol{v}_2\cdot\boldsymbol{v}_2. \end{aligned}$$

Using Korn's inequality (2.37) and the bound on $\boldsymbol{K}$ (2.7) gives

$$\begin{aligned} a(\boldsymbol{v},\boldsymbol{v}) \geq {} & C\mu|||\nabla\boldsymbol{v}|||_{0,\Omega_1}^2 + C\sum_{e\in\Gamma_h^1\cup\Gamma_1} \frac{\sigma_e - 1}{|e|}\int_e [\boldsymbol{v}_1]^2 \\ & - 2(1-\epsilon)\mu \sum_{e\in\Gamma_h^1\cup\Gamma_1} \int_e \{\boldsymbol{D}(\boldsymbol{v}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{v}_1] + \frac{\mu}{G}\sum_{e\in\Gamma_{12}}\int_e (\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12})^2 + \frac{1}{\kappa_1}\|\boldsymbol{v}_2\|_{0,\Omega_2}^2. \end{aligned}$$

If $\epsilon = 1$, then the result is straightforward. If $\epsilon = -1$, we have from trace inequality (2.36)

$$\begin{aligned} 2(1-\epsilon)\mu \sum_{e\in\Gamma_h^1\cup\Gamma_1} \int_e \{\boldsymbol{D}(\boldsymbol{v}_1)\}\boldsymbol{n}_e\cdot[\boldsymbol{v}_1] &\leq 4\mu \sum_{e\in\Gamma_h^1\cup\Gamma_1} h_1^{-1/2}\|\nabla\boldsymbol{v}_1\|_{0,E_e}\left(\frac{|e|}{|e|}\right)^{1/2}\|[\boldsymbol{v}_1]\|_{0,e} \\ &\leq \frac{C}{2}\mu|||\nabla\boldsymbol{v}_1|||_{0,\Omega_1}^2 + \tilde{C}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{1}{|e|}\int_e [\boldsymbol{v}_1]^2. \end{aligned}$$

Thus, we obtain if $\epsilon = -1$,

$$\begin{aligned} a(\boldsymbol{v}_1,\boldsymbol{v}_1) \geq {} & \frac{3}{4}\mu|||\nabla\boldsymbol{v}_1|||_{0,\Omega_1}^2 + \sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{C(\sigma_e-1)-\tilde{C}}{|e|}\int_e [\boldsymbol{v}_1]^2 \\ & + \frac{\mu}{G}\sum_{e\in\Gamma_{12}}\int_e (\boldsymbol{v}_1\cdot\boldsymbol{\tau}_{12})^2 + \frac{1}{\kappa_1}\|\boldsymbol{v}_2\|_{0,\Omega_2}^2 \geq C_0(\|\boldsymbol{v}_1\|_{X^1}^2 + \|\boldsymbol{v}_2\|_{0,\Omega_2}^2) \end{aligned}$$

with C_0 positive constant, assuming that σ_e is large enough:

$$(C(\sigma_e - 1) - \tilde{C} \geq C_0 > 0). \qquad \square$$

We are now ready to prove that the discrete scheme (2.38)–(2.39) is solvable.

LEMMA 2.7. *If Hypothesis A holds, then there exists a unique solution to the problem* (2.38)–(2.39).

Proof. Since the problem (2.38)–(2.39) is finite dimensional, it suffices to show that the solution is unique. Set $f_i = 0$ and choose $\boldsymbol{v} = \boldsymbol{U}$ and $q = P$. Then

$$a(\boldsymbol{U},\boldsymbol{U}) = 0.$$

In addition,

$$b(\boldsymbol{U}, q) = 0 \quad \forall q \in M_h,$$

which implies that $\nabla \cdot \boldsymbol{U} = 0$ in Ω_2, since $\nabla \cdot \boldsymbol{X}_h^2 = M_h^2$. Therefore Lemma 2.6 directly implies that $\boldsymbol{U} = 0$. Thus, the pressure satisfies

$$b(\boldsymbol{v}, P) = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{V}_h.$$

The inf-sup condition (3.1) proved below implies that $P = 0$. ∎

3. A discrete inf-sup condition. In this section, a discrete inf-sup condition is proved.

THEOREM 3.1. *There exists a positive constant β such that*

$$\inf_{q_h \in M_h} \sup_{\boldsymbol{v}_h \in \boldsymbol{V}_h} \frac{b(\boldsymbol{v}_h, q_h)}{\|\boldsymbol{v}_h\|_X \|q_h\|_M} \geq \beta. \tag{3.1}$$

Proof. Let $q_h \in M_h$ be given. Then there exists [20, 21] $\boldsymbol{v} \in (H^1(\Omega))^d$ such that

$$\nabla \cdot \boldsymbol{v} = -q_h \quad \text{in } \Omega, \qquad \boldsymbol{v} = 0 \quad \text{on } \partial\Omega,$$

satisfying

$$\|\boldsymbol{v}\|_{1,\Omega} \leq C \|q_h\|_{0,\Omega}.$$

Note that

$$b(v, q_h) = -\int_\Omega (\nabla \cdot \boldsymbol{v}) q_h = \|q_h\|_M^2,$$

which, together with the above a priori bound, implies

$$b(\boldsymbol{v}, q_h) \geq \frac{1}{C} \|\boldsymbol{v}\|_{1,\Omega} \|q_h\|_M.$$

Next, we need to construct an operator $\pi_h : \boldsymbol{X}^1 \times (\boldsymbol{X}^2 \cap (H^1(\Omega_2))^d) \to \boldsymbol{V}_h$ satisfying

$$b(\pi_h \boldsymbol{v} - \boldsymbol{v}, q_h) = 0 \quad \forall q_h \in M_h, \qquad \text{and} \qquad \|\pi_h \boldsymbol{v}\|_X \leq C \|\boldsymbol{v}\|_{1,\Omega}. \tag{3.2}$$

Let $\pi_h \boldsymbol{v} = (\pi_h^1 \boldsymbol{v}, \pi_h^2 \boldsymbol{v}) \in \boldsymbol{X}_h^1 \times \boldsymbol{X}_h^2$. We take $\pi_h^1 \boldsymbol{v} = \boldsymbol{\Pi}_h^1 \boldsymbol{v}_1$ where $\boldsymbol{\Pi}_h^1 : \boldsymbol{X}^1 \to \boldsymbol{X}_h^1$ is the quasi-local interpolant defined in (2.21). Clearly, due to (2.27),

$$\|\pi_h^1 \boldsymbol{v}\|_{X^1} \leq C \|\boldsymbol{v}\|_{1,\Omega_1}. \tag{3.3}$$

To define $\pi_h^2 \boldsymbol{v}$, consider the auxiliary problem

$$\nabla \cdot \nabla \varphi = 0 \quad \text{in } \Omega_2, \tag{3.4}$$

$$\nabla \varphi \cdot \boldsymbol{n} = 0 \quad \text{on } \Gamma_2, \tag{3.5}$$

$$\nabla \varphi \cdot \boldsymbol{n}_{12} = (\pi_h^1 \boldsymbol{v} - \boldsymbol{v}) \cdot \boldsymbol{n}_{12} \quad \text{on } \Gamma_{12}. \tag{3.6}$$

The problem is well posed, since

$$\int_{\Gamma_{12}} (\pi_h^1 \boldsymbol{v} - \boldsymbol{v}) \cdot \boldsymbol{n}_{12} = 0,$$

due to (2.25). Let $\boldsymbol{z} = \nabla\varphi$. We note that the piecewise smooth function $\pi_h^1\boldsymbol{v}\cdot\boldsymbol{n}_{12} \in H^\theta(\Gamma_{12})$ for any $0 < \theta < 1/2$. By elliptic regularity [26],

$$\|\boldsymbol{z}\|_{\theta,\Omega_2} \le C\|(\pi_h^1\boldsymbol{v}-\boldsymbol{v})\cdot\boldsymbol{n}_{12}\|_{\theta-1/2,\Gamma_{12}}, \quad 0\le\theta\le 1/2. \tag{3.7}$$

Let $\boldsymbol{w} = \boldsymbol{v}+\boldsymbol{z}$. Clearly $\nabla\cdot\boldsymbol{w} = \nabla\cdot\boldsymbol{v}$ in Ω_2 and $\boldsymbol{w}\cdot\boldsymbol{n}_{12} = \pi_h^1\boldsymbol{v}\cdot\boldsymbol{n}_{12}$ on Γ_{12}. We now define $\pi_h^2\boldsymbol{v} := \boldsymbol{\Pi}_h^2\boldsymbol{w}$, where $\boldsymbol{\Pi}_h^2 : \boldsymbol{X}^2 \cap (H^\theta(\Omega_2))^d \to \boldsymbol{X}_h^2$ is the MFE interpolant defined in (2.29). Note that, using (2.29),

$$\begin{aligned} b_2(\pi_h^2\boldsymbol{v}, q_h) &= b_2(\boldsymbol{\Pi}_h^2\boldsymbol{w}, q_h) = b_2(\boldsymbol{w}, q_h) \\ &= -\int_{\Omega_2}(\nabla\cdot\boldsymbol{w})q_h = -\int_{\Omega_2}(\nabla\cdot\boldsymbol{v})q_h = b_2(\boldsymbol{v}, q_h) \quad \forall q_h\in M_h^2, \end{aligned}$$

thus the so-constructed $\pi_h\boldsymbol{v} = (\pi_h^1\boldsymbol{v}, \pi_h^2\boldsymbol{v})$ satisfies

$$b(\pi_h\boldsymbol{v}-\boldsymbol{v}, q_h) = 0 \quad \forall q_h\in M_h.$$

It is easy to see that $\pi_h\boldsymbol{v}\in\boldsymbol{V}_h$. Indeed, for every $e\in\Gamma_h^{12}$ and $\eta\in\Lambda_h$, using (2.30) and the fact that $\Lambda_h = X_h^2\cdot\boldsymbol{n}_{12}$,

$$\int_e \pi_h^2\boldsymbol{v}\cdot\boldsymbol{n}_{12}\eta = \int_e \boldsymbol{\Pi}_h^2\boldsymbol{w}\cdot\boldsymbol{n}_{12}\eta = \int_e \boldsymbol{w}\cdot\boldsymbol{n}_{12}\eta = \int_e \pi_h^1\boldsymbol{v}\cdot\boldsymbol{n}_{12}\eta.$$

It remains to show the bound in (3.2). Using (2.31), (2.32), and (3.7),

$$\begin{aligned} \|\pi_h^2\boldsymbol{v}\|_{X^2} &= \|\boldsymbol{\Pi}_h^2\boldsymbol{w}\|_{X^2} \\ &\le \|\boldsymbol{\Pi}_h^2\boldsymbol{v}\|_{X^2} + \|\boldsymbol{\Pi}_h^2\boldsymbol{z}\|_{X^2} \\ &\le C(\|\boldsymbol{v}\|_{1,\Omega_2} + \|\boldsymbol{z}\|_{\theta,\Omega_2}) \\ &\le C(\|\boldsymbol{v}\|_{1,\Omega_1} + \|(\pi_h^1\boldsymbol{v}-\boldsymbol{v})\cdot\boldsymbol{n}\|_{\Gamma_{12}}) \end{aligned}$$

The last term can be bounded as follows. For every $e\in\Gamma_{12}$, and edge (face) of $E\in\mathcal{E}_h^1$, using (2.34) and (2.24),

$$\|(\pi_h^1\boldsymbol{v}-\boldsymbol{v})\cdot\boldsymbol{n}_{12}\|_e \le C(h_E^{-1/2}\|\pi_h^1\boldsymbol{v}-\boldsymbol{v}\|_{0,E} + h_E^{1/2}|\pi_h^1\boldsymbol{v}-\boldsymbol{v}|_{1,E}) \le Ch_E^{1/2}|\boldsymbol{v}|_{1,\delta(E)}. \tag{3.8}$$

Therefore

$$\|\pi_h^2\boldsymbol{v}\|_{X^2} \le C\|\boldsymbol{v}\|_{1,\Omega},$$

which, combined with (3.3), implies the bound in (3.2). Now using (3.2),

$$\frac{1}{C}\|q_h\|_M \le \frac{b(\boldsymbol{v}, q_h)}{\|\boldsymbol{v}\|_{1,\Omega}} = \frac{b(\pi_h\boldsymbol{v}, q_h)}{\|\boldsymbol{v}\|_{1,\Omega}} \le \frac{b(\pi_h\boldsymbol{v}, q_h)}{\frac{1}{C}\|\pi_h\boldsymbol{v}\|_X} \quad \forall q_h\in M_h,$$

which proves (3.1). ∎

4. A priori error estimates. In this section, optimal error estimates in the energy norm are obtained for the velocity field. Also, optimal error estimates in the L^2 norm of the error for the pressure are obtained. We start with an approximation result for the weakly normal-continuous velocity space $\boldsymbol{V}_h$.

LEMMA 4.1. *For $\boldsymbol{v} \in (H^1(\Omega))^d$ such that $\boldsymbol{v}|_{\Omega_1} \in (H^{k_1+1}(\Omega_1))^d$, $\boldsymbol{v}|_{\Omega_2} \in (H^{k_2+1}(\Omega_2))^d$, and $\nabla \cdot \boldsymbol{v}|_{\Omega_2} \in (H^{l_2+1}(\Omega_2))^d$, there exists $\tilde{\boldsymbol{v}} \in \boldsymbol{V}_h$ such that*

$$b(\boldsymbol{v} - \tilde{\boldsymbol{v}}, q) = 0 \quad \forall q \in M_h, \tag{4.1}$$

$$\forall e \in \Gamma_h^1 \cup \Gamma_1, \ \int_e [\tilde{\boldsymbol{v}}] \cdot \boldsymbol{q} = 0 \quad \forall \boldsymbol{q} \in (\mathbb{P}_{k_1-1}(e))^d, \tag{4.2}$$

$$\|\boldsymbol{v} - \tilde{\boldsymbol{v}}\|_X \le C\{h_1^{k_1}|\boldsymbol{v}|_{k_1+1,\Omega_1} + h_2^{k_2+1}|\boldsymbol{v}|_{k_2+1,\Omega_2} + h_2^{l_2+1}|\nabla \cdot \boldsymbol{v}|_{l_2+1,\Omega_2}\}. \tag{4.3}$$

Proof. We will show that the interpolant $\pi_h \boldsymbol{v}$ constructed in Theorem 3.1 satisfies the above conditions. Indeed, (4.1) and (4.2) follow directly from the construction of $\pi_h \boldsymbol{v}$. To show (4.3), we first note that (2.26) implies that

$$\|\boldsymbol{v} - \pi_h \boldsymbol{v}\|_{X^1} \le C h_1^{k_1} |\boldsymbol{v}|_{k_1+1,\Omega_1}. \tag{4.4}$$

Next,

$$\|\boldsymbol{v} - \pi_h \boldsymbol{v}\|_{X^2} = \|\boldsymbol{v} - \boldsymbol{\Pi}_h^2 \boldsymbol{w}\|_{X^2} \le \|\boldsymbol{v} - \boldsymbol{\Pi}_h^2 \boldsymbol{v}\|_{X^2} + \|\boldsymbol{\Pi}_h^2(\boldsymbol{w} - \boldsymbol{v})\|_{X^2}. \tag{4.5}$$

For the first term on the right in (4.5), using (2.31) and (2.32),

$$\|\boldsymbol{v} - \boldsymbol{\Pi}_h^2 \boldsymbol{v}\|_{X^2} \le C h_2^{k_2+1} |\boldsymbol{v}|_{k_2+1,\Omega_2} + h_2^{l_2+1} |\nabla \cdot \boldsymbol{v}|_{l_2+1,\Omega_2}. \tag{4.6}$$

The last term in (4.5) can be bounded as follows, using (2.33), (3.7), (3.8), and (2.24):

$$\begin{aligned} \|\boldsymbol{\Pi}_h^2(\boldsymbol{w} - \boldsymbol{v})\|_{X^2} &= \|\boldsymbol{\Pi}_h^2 \boldsymbol{z}\|_{X^2} \le \|\boldsymbol{z}\|_{\theta,\Omega_2} \\ &\le C\|(\pi_h^1 \boldsymbol{v} - \boldsymbol{v}) \cdot \boldsymbol{n}_{12}\|_{0,\Gamma_{12}} \le C h_1^{k_1+1/2} |\boldsymbol{v}|_{k_1+1,\Omega_1}. \end{aligned} \tag{4.7}$$

A combination of (4.4)–(4.7) completes the proof. ∎

THEOREM 4.2. *Let $(\boldsymbol{u}, p) \in \boldsymbol{X} \times M$ be the solution of the coupled problem (2.1)–(2.10). Assume that $\boldsymbol{u}|_{\Omega_i} \in H^{k_i+1}(\Omega_i)$ for $i = 1, 2$. Assume that $p|_{\Omega_1} \in H^{k_1}(\Omega_1)$ and that $p|_{\Omega_2} \in H^{l_2+1}(\Omega_2)$. Assume that Hypothesis A holds. Let $(\boldsymbol{U}, P)$ be the discrete solution of (2.38)–(2.39) Then, the following estimate holds:*

$$\begin{aligned} \|\boldsymbol{u} - \boldsymbol{U}\|_X \le{}& C h_1^{k_1}(|\boldsymbol{u}|_{k_1+1,\Omega_1} + |p|_{k_1,\Omega_1}) + C h_2^{k_2+1} |\boldsymbol{u}|_{k_2+1,\Omega_2} \\ &+ C(h_2^{l_2+1} + h_2^{l_2+1/2} h_1^{1/2}) |p|_{l_2+1,\Omega_2}. \end{aligned}$$

Proof. Let $\tilde{\boldsymbol{u}}$ be the interpolant of $\boldsymbol{u}$ defined in Lemma 4.1 and let $\tilde{p}$ be the interpolant of p, satisfying (2.17)–(2.20). From (2.40), (2.41), and (2.38)–(2.39), the error equation is

$$\begin{aligned} a(\boldsymbol{U} - \tilde{\boldsymbol{u}}, \boldsymbol{v}) + b(\boldsymbol{v}, P - \tilde{p}) &= a(\boldsymbol{u} - \tilde{\boldsymbol{u}}, \boldsymbol{v}) + b(\boldsymbol{v}, p - \tilde{p}) \\ &\quad - \sum_{e \in \Gamma_{12}} \int_e p_2(\boldsymbol{v}_1 - \boldsymbol{v}_2) \cdot \boldsymbol{n}_{12} \quad \forall \boldsymbol{v} \in \boldsymbol{V}_h, \end{aligned} \tag{4.8}$$

$$b(\boldsymbol{U} - \tilde{\boldsymbol{u}}, q) = b(\boldsymbol{u} - \tilde{\boldsymbol{u}}, q) \quad \forall q \in M_h. \tag{4.9}$$

Note that (4.1) implies that $b(\boldsymbol{U}-\tilde{\boldsymbol{u}},q)=0$ for all $q\in M_h$, which implies that

$$\nabla\cdot(\boldsymbol{U}-\tilde{\boldsymbol{u}})=0 \quad \text{in } \Omega_2,$$

since $\nabla\cdot\boldsymbol{X}_h^2=M_h^2$. Define $\boldsymbol{\chi}=\boldsymbol{U}-\tilde{\boldsymbol{u}}$ and $\xi=P-\tilde{p}$. Choose $\boldsymbol{v}=\boldsymbol{\chi}$ and $q=\xi$. Then,

$$a(\boldsymbol{\chi},\boldsymbol{\chi})+b(\boldsymbol{\chi},\xi)=a(\boldsymbol{u}-\tilde{\boldsymbol{u}},\boldsymbol{\chi})+b(\boldsymbol{\chi},p-\tilde{p})-\sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{\chi}_1-\boldsymbol{\chi}_2)\cdot\boldsymbol{n}_{12},$$
$$b(\boldsymbol{\chi},\xi)=0.$$

Equivalently,

$$a(\boldsymbol{\chi},\boldsymbol{\chi})=a(\boldsymbol{u}-\tilde{\boldsymbol{u}},\boldsymbol{\chi})+b(\boldsymbol{\chi},p-\tilde{p})-\sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{\chi}_1-\boldsymbol{\chi}_2)\cdot\boldsymbol{n}_{12}. \tag{4.10}$$

The first term on the right can be estimated as follows:

$$\begin{aligned}a_1(\boldsymbol{u}-\tilde{\boldsymbol{u}},\boldsymbol{\chi})&=2\mu\sum_{E\in\mathcal{E}_h^1}\int_E\boldsymbol{D}(\boldsymbol{u}-\tilde{\boldsymbol{u}}):\boldsymbol{D}(\boldsymbol{\chi})\\&\quad-2\mu\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(\boldsymbol{u}-\tilde{\boldsymbol{u}})\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}]+2\mu\epsilon\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(\boldsymbol{\chi})\}\boldsymbol{n}_e\cdot[\boldsymbol{u}-\tilde{\boldsymbol{u}}]\\&\quad+\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\int_e[\boldsymbol{u}-\tilde{\boldsymbol{u}}]\cdot[\boldsymbol{\chi}]+\frac{\mu}{G}\sum_{e\in\Gamma_{12}}\int_e(\boldsymbol{u}-\tilde{\boldsymbol{u}})\cdot\boldsymbol{\tau}_{12}\boldsymbol{\chi}\cdot\boldsymbol{\tau}_{12}\\&=T_1+\cdots+T_5.\end{aligned}$$

Using Cauchy–Schwarz inequality, and the approximation result (4.3), we have

$$\begin{aligned}T_1&\le 2\mu\sum_{E\in\mathcal{E}_h^1}\|\nabla(\boldsymbol{u}-\tilde{\boldsymbol{u}})\|_{0,E}\|\nabla\boldsymbol{\chi}\|_{0,E}\le\frac{1}{8}|||\nabla\boldsymbol{\chi}|||_{0,\Omega_1}^2+C|||\nabla(\boldsymbol{u}-\tilde{\boldsymbol{u}})|||_{0,\Omega_1}^2\\&\le\frac{1}{8}|||\nabla\boldsymbol{\chi}|||_{0,\Omega_1}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2.\end{aligned}$$

Let $L_h(\boldsymbol{u})$ denote the standard Lagrange interpolant of degree k_1 defined in Ω_1 and let us insert it in the second integral term. Note that $L_h(\boldsymbol{u})$ satisfies the optimal error estimates

$$|L_h(\boldsymbol{u})-\boldsymbol{u}|_{m,E}\le Ch_E^{s-m}|\boldsymbol{u}|_{s,E}\quad\forall 2\le s\le k_1+1,\ m=0,1,2. \tag{4.11}$$

For e a segment of $\Gamma_h^1\cup\Gamma_1$, we have

$$\int_e\{\boldsymbol{D}(\boldsymbol{u}-\tilde{\boldsymbol{u}})\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}]=\int_e\{\boldsymbol{D}(\boldsymbol{u}-L_h(\boldsymbol{u}))\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}]+\int_e\{\boldsymbol{D}(L_h(\boldsymbol{u})-\tilde{\boldsymbol{u}})\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}].$$

Expanding the first integral, we obtain from the trace inequality (2.35) and from the

fact that the Lagrange interpolant satisfies (4.11)

$$\begin{aligned}
&\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(\boldsymbol{u}-L_h(\boldsymbol{u}))\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}]\\
&\quad\le\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e^{1/2}}{|e|^{1/2}}\|[\boldsymbol{\chi}]\|_{0,e}\frac{|e|^{1/2}}{\sigma_e^{1/2}}\|\{\boldsymbol{D}(\boldsymbol{u}-L_h(\boldsymbol{u}))\}\boldsymbol{n}_e\|_{0.e}\\
&\quad\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+C\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{|e|}{\sigma_e}(h_e^{-1}|\boldsymbol{u}-L_h(\boldsymbol{u})|_{1,E_e^{12}}^2+h_e|\boldsymbol{u}-L_h(\boldsymbol{u})|_{2,E_e^{12}}^2)\\
&\quad\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2.
\end{aligned}$$

Similarly, using the trace inequality (2.36), triangle inequality, and (4.3)

$$\begin{aligned}
\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(L_h(\boldsymbol{u})-\tilde{\boldsymbol{u}})\}\boldsymbol{n}_e\cdot[\boldsymbol{\chi}]&\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2\\
&\quad+C\sum_{e\in\Gamma_h^1\cup\Gamma_1}|\tilde{\boldsymbol{u}}-L_h(\boldsymbol{u})|_{1,E_e^{12}}^2\\
&\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2.
\end{aligned}$$

Therefore,

$$T_2\le\frac{1}{4}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2.$$

The third term vanishes because of the continuity of $\boldsymbol{u}$ and property (4.2) of $\tilde{\boldsymbol{u}}$:

$$T_3=0. \tag{4.12}$$

Using Cauchy–Schwarz inequality, the jump term is bounded by virtue of (2.24) and (2.34):

$$\begin{aligned}
T_4&\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+C\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{u}-\tilde{\boldsymbol{u}}]\|_{0,e}^2\\
&\le\frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|_{0,e}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k+1,\Omega_1}^2.
\end{aligned}$$

The last term is bounded as follows, from the trace inequality (2.34):

$$\begin{aligned}
T_5&\le\frac{\mu}{G}\sum_{e\in\Gamma_{12}}\|\boldsymbol{u}-\tilde{\boldsymbol{u}}\|_{0,e}\|\boldsymbol{\chi}\cdot\boldsymbol{\tau}_{12}\|_{0,e}\\
&\le\frac{\mu}{2G}\sum_{e\in\Gamma_{12}}\|\boldsymbol{\chi}\cdot\boldsymbol{\tau}_{12}\|_{0,e}^2+C\sum_{e\in\Gamma_1}(h_e^{-1}\|\boldsymbol{u}-\tilde{\boldsymbol{u}}\|_{0,E}^2+h_e|\boldsymbol{u}-\tilde{\boldsymbol{u}}|_{1,E}^2)\\
&\le\frac{\mu}{2G}\sum_{e\in\Gamma_{12}}\|\boldsymbol{\chi}\cdot\boldsymbol{\tau}_{12}\|_{0,e}^2+Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2.
\end{aligned}$$

Let us now estimate $a_2(\boldsymbol{u}-\tilde{\boldsymbol{u}},\boldsymbol{\chi})$, using the result (4.3),

$$a_2(\boldsymbol{u}-\tilde{\boldsymbol{u}},\boldsymbol{\chi}) = \int_{\Omega_2} \boldsymbol{K}^{-1}(\boldsymbol{u}-\tilde{\boldsymbol{u}})\cdot\boldsymbol{\chi} \le \frac{1}{8}\|\boldsymbol{K}^{-1/2}\boldsymbol{\chi}\|^2_{0,\Omega_2} + h_2^{2k_2+2}|\boldsymbol{u}|^2_{k_2+1,\Omega_2}.$$

Let us now estimate $b_1(\boldsymbol{\chi}, p-\tilde{p})$. By property (2.17), (2.19), and the trace estimate (2.34),

$$\begin{aligned} b_1(\boldsymbol{\chi}, p-\tilde{p}) &= -\sum_{E\in\mathcal{E}_h}\int_E (p-\tilde{p})\nabla\cdot\boldsymbol{\chi} + \sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e \{p-\tilde{p}\}[\boldsymbol{\chi}]\cdot\boldsymbol{n}_e \\ &= \sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e \{p-\tilde{p}\}[\boldsymbol{\chi}]\cdot\boldsymbol{n}_e \\ &\le \frac{1}{8}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\int_e [\boldsymbol{\chi}]^2 + Ch_1^{2k_1}|p|^2_{k_1,\Omega_1}. \end{aligned}$$

Now estimate $b_2(\boldsymbol{\chi}, p-\tilde{p})$ using Cauchy–Schwarz inequality and approximation result (2.20)

$$b_2(\boldsymbol{\chi}, p-\tilde{p}) = -\int_{\Omega_2}(p-\tilde{p})\nabla\cdot\boldsymbol{\chi} \le \frac{1}{8}|||\nabla\boldsymbol{\chi}|||^2_{0,\Omega_2} + Ch_2^{2l_2+2}|p|^2_{l_2+1,\Omega_2}$$

It remains to bound the last term in (4.10). Since $\boldsymbol{\chi}$ belongs to $\boldsymbol{V}_h$, we have

$$\sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{\chi}_1-\boldsymbol{\chi}_2)\cdot\boldsymbol{n}_{12} = \sum_{e\in\Gamma_{12}}\int_e (p_2-\tilde{p}_2^e)(\boldsymbol{\chi}_1-\boldsymbol{\chi}_2)\cdot\boldsymbol{n}_{12},$$

where $\tilde{p}_2^e\in\Lambda_h$ is the L^2 projection of p_2 with respect to the L^2 inner product on the edge e. Therefore, by definition of the projection and since $\Lambda_h = \boldsymbol{X}_h^2\cdot\boldsymbol{n}_{12}$, we have

$$\sum_{e\in\Gamma_{12}}\int_e (p_2-\tilde{p}_2^e)\boldsymbol{\chi}_2\cdot\boldsymbol{n}_{12} = 0.$$

We also note that for any edge e and any constant vector $\boldsymbol{c}_e$, we have

$$\begin{aligned} \sum_{e\in\Gamma_{12}}\int_e (p_2-\tilde{p}_2^e)\boldsymbol{\chi}_1\cdot\boldsymbol{n}_{12} &= \sum_{e\in\Gamma_{12}}\int_e (p_2-\tilde{p}_2^e)(\boldsymbol{\chi}_1-\boldsymbol{c}_e)\cdot\boldsymbol{n}_{12} \\ &\le \sum_{e\in\Gamma_{12}}\|p_2-\tilde{p}_2^e\|_{0,e}\|\boldsymbol{\chi}_1-\boldsymbol{c}_e\|_{0,e}. \end{aligned}$$

Assume that each edge e of Γ_{12} is shared by the element $E_e^2\in\mathcal{E}_h^2$ and parts of the elements $E_{e,i}^1\in\mathcal{E}_h^1$, $i=1,n_e$. Then, from the approximation properties and the trace inequality (2.34), we obtain

$$\int_e (p_2-\tilde{p}_2^e)\boldsymbol{\chi}_1\cdot\boldsymbol{n}_{12} \le Ch_2^{l_2+1/2}\|p_2\|_{l_2+1,E_e^2}\sum_{i=1}^{n_e}(h_1^{-1/2}\|\boldsymbol{\chi}_1-\boldsymbol{c}_e\|_{0,E_{e,i}^1} + h_1^{1/2}\|\nabla\boldsymbol{\chi}_1\|_{0,E_{e,i}^1}),$$

thus

$$\begin{aligned} \sum_{e\in\Gamma_{12}}\int_e (p_2-\tilde{p}_2^e)\boldsymbol{\chi}_1\cdot\boldsymbol{n}_{12} &\le C\sum_{e\in\Gamma_{12}} h_2^{l_2+1/2}|p_2|_{l_2+1,E_e^2}\sum_{i=1}^{n_e} h_1^{1/2}\|\nabla\boldsymbol{\chi}_1\|_{0,E_{e,i}^1} \\ &\le \frac{1}{8}|||\nabla\boldsymbol{\chi}|||^2_{0,\Omega_1} + Ch_2^{2l_2+1}h_1|p_2|^2_{l_2+1,\Omega_2}. \end{aligned}$$

Combining all bounds above yields

$$a(\boldsymbol{\chi},\boldsymbol{\chi}) \le \frac{1}{4}|||\nabla\boldsymbol{\chi}|||^2_{0,\Omega_1} + \frac{3}{4}\sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\|[\boldsymbol{\chi}]\|^2_{0,e} + \frac{\mu}{2G}\sum_{e\in\Gamma_{12}}\|\boldsymbol{\chi}\cdot\boldsymbol{\tau}_{12}\|^2_{0,e}$$
$$+\frac{1}{4}\|\boldsymbol{K}^{-1/2}\boldsymbol{\chi}\|^2_{0,\Omega_2} + Ch_2^{2k_2+2}|\boldsymbol{u}|_{k_2+1,\Omega_2} + C(h_2^{2l_2+2}+h_2^{2l_2+1}h_1)|p|^2_{l_2+1,\Omega_2}$$
$$+Ch_2^{2k_1}|\boldsymbol{u}|^2_{k_1+1,\Omega_1} + Ch_1^{2k_1}|p|^2_{k_1,\Omega_1}.$$

Equivalently,

$$a(\boldsymbol{\chi},\boldsymbol{\chi}) \le Ch_2^{2k_2+2}|\boldsymbol{u}|^2_{k_2+1,\Omega_2} + C(h_2^{2l_2+2}+h_2^{2l_2+1}h_1)|p|^2_{l_2+1,\Omega_2}$$
$$+Ch_1^{2k_1}(|\boldsymbol{u}|^2_{k_1+1,\Omega_1} + |p|^2_{k_1,\Omega_1}).$$

Now, since $\nabla\cdot\boldsymbol{\chi}=0$ in Ω_2, the coercivity Lemma 2.6 implies

$$\|\boldsymbol{u}-\boldsymbol{U}\|_X \le \|\boldsymbol{u}-\tilde{\boldsymbol{u}}\|_X + \|\boldsymbol{U}-\tilde{\boldsymbol{u}}\|_X$$
$$\le \|\boldsymbol{u}-\tilde{\boldsymbol{u}}\|_X + \frac{1}{\sqrt{C_0}}a(\boldsymbol{\chi},\boldsymbol{\chi})^{1/2}$$

which concludes the proof, using (4.3). ∎

THEOREM 4.3. *Under the assumptions and notation of Theorem* 4.2*, we have*

$$\|p-P\|_{0,\Omega} \le Ch_1^{k_1}(|\boldsymbol{u}|_{k_1+1,\Omega_1} + |p|_{k_1,\Omega_1}) + Ch_2^{k_2+1}|\boldsymbol{u}|_{k_2+1,\Omega_2}$$
$$+C(h_2^{l_2+1} + h_2^{l_2+1/2}h_1^{1/2})|p|_{l_2+1,\Omega_2},$$

where C is a constant independent of h_1, h_2.

Proof. The error equation (4.8) can be written as

$$\forall\boldsymbol{v}\in\boldsymbol{V}_h,\ \ a(\boldsymbol{U}-\boldsymbol{u},\boldsymbol{v}) + b(\boldsymbol{v},P-\tilde{p}) = b(\boldsymbol{v},p-\tilde{p}) - \sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{v}_1-\boldsymbol{v}_2)\cdot\boldsymbol{n}_{12}. \tag{4.13}$$

From the discrete inf-sup condition (3.1),

$$\|P-\tilde{p}\|_{0,\Omega} \le \frac{1}{\beta}\sup_{\boldsymbol{v}_h\in\boldsymbol{V}_h}\frac{b(\boldsymbol{v}_h,P-\tilde{p})}{\|\boldsymbol{v}_h\|_X}. \tag{4.14}$$

Using (4.13), for any $\boldsymbol{v}_h\in\boldsymbol{V}_h$,

$$b(\boldsymbol{v}_h,P-\tilde{p}) = -a(\boldsymbol{U}-\boldsymbol{u},\boldsymbol{v}_h) + b(\boldsymbol{v}_h,p-\tilde{p}) - \sum_{e\in\Gamma_{12}}\int_e p_2(\boldsymbol{v}_{h1}-\boldsymbol{v}_{h2})\cdot\boldsymbol{n}_{12}.$$

For the first term on the right,

$$a(\boldsymbol{U}-\boldsymbol{u},\boldsymbol{v}_h) = 2\mu\sum_{E\in\mathcal{E}_h^1}\int_E \boldsymbol{D}(\boldsymbol{U}-\boldsymbol{u}):\boldsymbol{D}(\boldsymbol{v}_h) + \sum_{e\in\Gamma_h^1\cup\Gamma_1}\frac{\sigma_e}{|e|}\int_e[\boldsymbol{U}-\boldsymbol{u}]\cdot[\boldsymbol{v}_h]$$
$$-2\mu\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(\boldsymbol{U}-\boldsymbol{u})\boldsymbol{n}_e\}\cdot[\boldsymbol{v}_h] + 2\mu\epsilon\sum_{e\in\Gamma_h^1\cup\Gamma_1}\int_e\{\boldsymbol{D}(\boldsymbol{v}_h)\boldsymbol{n}_e\}\cdot[\boldsymbol{U}-\boldsymbol{u}]$$
$$+\frac{\mu}{G}\sum_{e\in\Gamma_{12}}\int_e(\boldsymbol{U}-\boldsymbol{u})\cdot\boldsymbol{\tau}_{12}\boldsymbol{v}_h\cdot\boldsymbol{\tau}_{12} + \int_{\Omega_2}\boldsymbol{K}^{-1}(\boldsymbol{U}-\boldsymbol{u})\cdot\boldsymbol{v}_h$$
$$= Q_1+\cdots+Q_6.$$

We now bound each Q_i term. From Cauchy–Schwarz inequality, the terms Q_1, Q_2, Q_5, and Q_6 are easily bounded

$$Q_1 + Q_2 + Q_5 + Q_6 \leq C\|\boldsymbol{v}_h\|_X \|\boldsymbol{U} - \boldsymbol{u}\|_X.$$

We now bound Q_3,

$$\begin{aligned} Q_3 &\leq C \sum_{e\in\Gamma_h^1\cup\Gamma_1} \left(\frac{|e|}{\sigma_e}\right)^{1/2} \|\nabla(\boldsymbol{U}-\boldsymbol{u})\|_{0,e} \left(\frac{\sigma_e}{|e|}\right)^{1/2} \|[\boldsymbol{v}_h]\|_{0,e} \\ &\leq C\|\boldsymbol{v}_h\|_X \left(\sum_{e\in\Gamma_h^1\cup\Gamma_1} (h_1\|\nabla(\boldsymbol{U}-\tilde{\boldsymbol{u}})\|_{0,e}^2 + h_1\|\nabla(\boldsymbol{u}-\tilde{\boldsymbol{u}})\|_{0,e}^2) \right)^{1/2} \\ &\leq C\|\boldsymbol{v}_h\|_X (\|U-\tilde{\boldsymbol{u}}\|_X^2 + Ch_1^{2k_1}|\boldsymbol{u}|_{k_1+1,\Omega_1}^2)^{1/2}. \end{aligned}$$

Now, Q_4 is bounded similarly, from trace inequality (2.36),

$$\begin{aligned} Q_4 &\leq C \sum_{e\in\Gamma_h^1\cup\Gamma_1} \|\{\boldsymbol{D}(\boldsymbol{v}_h)\boldsymbol{n}_e\}\|_{0,e} \|[\boldsymbol{U}-\boldsymbol{u}]\|_{0,e} \\ &\leq C \sum_{e\in\Gamma_h^1\cup\Gamma_1} h^{-1/2}\|\nabla\boldsymbol{v}_h\|_{0,E_e^{12}} \left(\frac{\sigma_e}{|e|}\right)^{1/2-1/2} \|[\boldsymbol{U}-\boldsymbol{u}]\|_{0,e} \\ &\leq C\|\boldsymbol{v}_h\|_X \|\boldsymbol{U}-\boldsymbol{u}\|_X. \end{aligned}$$

Let us now estimate $b(\boldsymbol{v}_h, p-\tilde{p})$. From the property (2.17), it is reduced to

$$\begin{aligned} b(\boldsymbol{v}_h, p-\tilde{p}) &= \sum_{e\in\Gamma_h^1\cup\Gamma_1} \int_e \{p-\tilde{p}\}[\boldsymbol{v}_h]\cdot\boldsymbol{n}_e \\ &\leq \sum_{e\in\Gamma_h^1\cup\Gamma_1} \left(\frac{\sigma_e}{|e|}\right)^{1/2} \|[\boldsymbol{v}_h]\|_{0,e} \left(\frac{|e|}{\sigma_e}\right)^{1/2} \|\{p-\tilde{p}\}\|_{0,e} \\ &\leq \|\boldsymbol{v}_h\|_X Ch_1^{k_1}|p|_{k_1,\Omega_1}. \end{aligned}$$

Finally, following the same approach as in the proof of Theorem 4.2, we bound the interface integral

$$\begin{aligned} \sum_{e\in\Gamma_{12}} \int_e p_2(\boldsymbol{v}_{h1}-\boldsymbol{v}_{h2})\cdot\boldsymbol{n}_{12} &= \sum_{e\in\Gamma_{12}} \int_e (p_2-\tilde{p}_2^e)\boldsymbol{v}_{h1}\cdot\boldsymbol{n}_{12} \\ &\leq C\|\boldsymbol{v}_h\|_X h_2^{l_2+1/2} h_1^{1/2} |p_2|_{l_2+1,\Omega_2}. \end{aligned}$$

Combining all the bounds with (4.14) yields

$$\|P-\tilde{p}\|_{0,\Omega} \leq C\left(\|\boldsymbol{U}-\boldsymbol{u}\|_X + h_1^{k_1}(|\boldsymbol{u}|_{k_1+1,\Omega_1} + |p|_{k_1,\Omega_1}) + h_2^{l_2+1/2}h_1^{1/2}\|p\|_{l_2+1,\Omega_2}\right).$$

Using Theorem 4.2 concludes the proof. ∎

Remark 4.4. The results proven in this section are valid and unchanged in three-dimensional domains, assuming there exist interpolants $\boldsymbol{\Pi}_h^1$ and $\boldsymbol{\Pi}_h^2$ defined in (2.21) and (2.29). The existence of $\boldsymbol{\Pi}_h^1$ for $k=1$ in three dimensions is given in [13]. The existence of $\boldsymbol{\Pi}_h^2$ in any dimension is a well-known fact [10].

5. Implementation issues and conclusions. In this paper, the convergence of a numerical scheme for solving the coupled Darcy–Stokes problem is proved. In order to parallelize the implementation of the scheme, a Lagrange multiplier $\lambda \in \Lambda_h$ approximating p_2 on Γ_{12} can be introduced. We recall the definition of $\Lambda_h = \boldsymbol{X}_h^2 \cdot \boldsymbol{n}_{12}$ given in section 2. Defining the bilinear form on the interface,

$$\Lambda(\eta, \boldsymbol{v}) = \sum_{e \in \Gamma_{12}} \int_e \eta(\boldsymbol{v}_1 - \boldsymbol{v}_2) \cdot \boldsymbol{n}_{12} \quad \forall \eta \in \Lambda_h, \ \forall \boldsymbol{v} \in \boldsymbol{X}_h,$$

the scheme can be rewritten as: Find $(\boldsymbol{U}, P, \lambda) \in \boldsymbol{X}_h \times M_h \times \Lambda_h$ such that $\boldsymbol{U}_i = \boldsymbol{U}|_{\Omega_i}$ and $P_i = P|_{\Omega_i}$ satisfy

$$a_1(\boldsymbol{U}_1, \boldsymbol{v}_1) + b_1(\boldsymbol{v}_1, P_1) + \Lambda(\lambda, \boldsymbol{v}_1) = \int_{\Omega_1} \boldsymbol{f}_1 \cdot \boldsymbol{v}_1 \quad \forall \boldsymbol{v}_1 \in \boldsymbol{X}_h^1, \tag{5.1}$$

$$b_1(\boldsymbol{U}_1, q_1) = 0 \quad \forall q_1 \in M_h^1, \tag{5.2}$$

$$a_2(\boldsymbol{U}_2, \boldsymbol{v}_2) + b_2(\boldsymbol{v}_2, P_2) - \Lambda(\lambda, \boldsymbol{v}_2) = 0 \quad \forall \boldsymbol{v}_2 \in \boldsymbol{X}_h^2, \tag{5.3}$$

$$b_2(\boldsymbol{U}_2, q_2) = \int_{\Omega_2} f_2 q_2 \quad \forall q_2 \in M_h^2, \tag{5.4}$$

$$\Lambda(\eta, \boldsymbol{U}) = 0 \quad \forall \eta \in \Lambda_h. \tag{5.5}$$

It can easily be shown that the two discrete formulations are equivalent. Formulation (5.1)–(5.5) is suitable for a parallel implementation. In particular, using an approach from [23], a nonoverlapping domain decomposition algorithm can be formulated that reduces the coupled system to a symmetric and positive definite interface problem for λ. In addition to its parallel efficiency, this approach allows for existing codes solving the Stokes or the Darcy equations to be utilized.

ON CONVERGENCE OF MINMOD-TYPE SCHEMES*

SERGEI KONYAGIN†, BOJAN POPOV‡, AND OGNIAN TRIFONOV§

Abstract. A class of nonoscillatory numerical methods for solving nonlinear scalar conservation laws in one space dimension is considered. This class of methods contains the classical Lax–Friedrichs and the second-order Nessyahu–Tadmor schemes. In the case of linear flux, new l_2 stability results and error estimates for the methods are proved. Numerical experiments confirm that these methods are one-sided l_2 stable for convex flux instead of the usual Lip+ stability.

Key words. conservation laws, minmod-type schemes, convergence

1. Introduction.

We are interested in the scalar hyperbolic conservation law

$$\begin{cases} u_t + f(u)_x = 0, & (x,t) \in \mathbb{R} \times (0,\infty), \\ u(x,0) = u^0(x), & x \in \mathbb{R}, \end{cases} \tag{1.1}$$

where f is a given flux function. In recent years, there has been enormous activity in the development of the mathematical theory and in the construction of numerical methods for (1.1). Even though the existence-uniqueness theory of weak solutions is complete [12], there are many numerically efficient methods for which the questions of convergence and error estimates are still open. For example, there are many nonoscillatory schemes based on the minmod limiter which are numerically robust, at least in many numerical tests, but theoretical results about convergence and error estimates are still missing [3, 6, 7, 18].

In this paper, we consider a class of the so-called Godunov-type schemes for solving (1.1). There are two main steps in such schemes: evolution and projection. In the original Godunov scheme, the projection is onto piecewise constant functions—the cell averages. In the general Godunov-type method, the projection is onto piecewise polynomials. To determine the properties of these schemes it is necessary to study the properties of the projection operator. We limit our attention to the case of piecewise linear projection based on cell averages using minmod limiters for the slope reconstruction, and we call such a scheme *minmod-type*. For example, the Nessyahu–Tadmor scheme [15] is of minmod-type and is based on staggered evolution; other examples include the second-order nonoscillatory central schemes with nonstaggered grids given in [8, 9], and the UNO and TVD2 schemes in [6]. Theoretical results about convergence of such schemes to the entropy solution, or error estimates, are still missing. In most cases the authors give a variation bound for such a scheme, which is enough to conclude that the method converges to a weak solution; see [10]. The only paper which has a convergence result is the paper of Nessyahu and Tadmor [15] in

which the authors prove a single cell entropy inequality for a minor modification of the original minmod scheme. A single entropy inequality is enough to conclude that the scheme is convergent to the unique entropy solution but does not give any rate of convergence. In order to get a rate, one has to have a family of entropy inequalities (see [1, 2, 11, 14]). Alternatively, for a convex flux, one can impose Lip+ stability on the projection and then prove convergence via Tadmor's Lip$'$ theory [16, 19]. Unfortunately, it is well known that minmod-type schemes are incompatible with the Lip+ condition—the Lip+ seminorm is not preserved by a minmod-type projection. It is easy to think about minmod-type schemes in terms of new/old cell averages. That is, we start with a sequence of cell averages $\{w_j\}$, and after one time step (projection and evolution) we get a new sequence $\{w'_j\}$. A scheme is *total variation diminishing* (TVD) if the variation of the new sequence $\sum_j |w'_j - w'_{j-1}|$ is not bigger than the variation of the old one $\sum_j |w_j - w_{j-1}|$, i.e., the l_1 norm of the jumps does not increase in time. In the Lip+ case (for convex flux) the condition on the jumps is that the biggest nonnegative jump does not increase in time:

$$\sup_j (w'_j - w'_{j-1})_+ \le \sup_j (w_j - w_{j-1})_+.$$

In section 3 of this paper, we prove that for linear flux the l_2 norm of the jumps for some minmod-type schemes does not increase in time. This class of schemes include the NT scheme and the TVD2 scheme considered in [6]. Based on that, we use the dual approach (see [16, 19]) to derive a new error estimate in L^2 in section 4. The rate of convergence that we prove is $1/2$ in L^2, which improves the known result of $1/4$ (see [19]). In section 5, we present numerical examples in the case of linear and convex flux and discuss the nonconvex case. Our numerical tests show that for convex flux the minmod schemes preserve the one-sided analogue

$$\sum_j (w'_j - w'_{j-1})_+^2 \le \sum_j (w_j - w_{j-1})_+^2,$$

which suggests a different approach to proving convergence and error estimates for such schemes in the convex case. The l_2 norm of the jumps is a natural candidate norm for the analysis of high-order schemes, such as central or ENO [7] type, due to its numerical viscosity. We view the results of this paper as a step toward obtaining convergence results and estimates for the rate of convergence of minmod-type schemes for solving (1.1) in the case of convex nonlinear flux.

2. Nonoscillatory central schemes. In this section, we are concerned with nonoscillatory central differencing approximations to the scalar conservation law

$$u_t + f(u)_x = 0. \tag{2.1}$$

The prototypes of all central schemes are the staggered form of the Lax–Friedrichs (LxF) scheme and its second-order extension, the Nessyahu–Tadmor (NT) scheme [15]. For an introduction to central schemes, see [8, 9, 13, 15]. For simplicity, we limit our attention to the staggered NT scheme described below. Let $v(x,t)$ be an approximate solution to (2.1), and assume that the space mesh Δx and the time mesh Δt are uniform. Let $x_j := j\Delta x$, $j \in \mathbb{Z}$, $\lambda := \frac{\Delta t}{\Delta x}$, and

$$v_j(t) := \frac{1}{\Delta x} \int_{x_{j-1/2}}^{x_{j+1/2}} v(x,t)\, dx \tag{2.2}$$

be the average of v at time t over $(x_{j-1/2}, x_{j+1/2})$. Let us assume that $v(\cdot,t)$ is a piecewise linear function, and that it is linear on the intervals $(x_{j-1/2}, x_{j+1/2})$, $j \in \mathbb{Z}$, of the form

$$v(x,t) = L_j(x,t) := v_j(t) + (x - x_j)\frac{1}{\Delta x}v'_j, \quad x_{j-1/2} < x < x_{j+1/2}, \tag{2.3}$$

where $\frac{1}{\Delta x}v'_j$ is the numerical derivative of v, which is yet to be determined. Integration of (2.1) over the staggered space-time cell $(x_j, x_{j+1}) \times (t, t+\Delta t)$ yields

$$\begin{aligned} v_{j+1/2}(t+\Delta t) = {} & \frac{1}{\Delta x}\left(\int_{x_j}^{x_{j+1/2}} L_j(x,t)\,dx + \int_{x_{j+1/2}}^{x_{j+1}} L_{j+1}(x,t)\,dx\right) \\ & - \frac{1}{\Delta x}\left(\int_t^{t+\Delta t} f(v(x_{j+1},\tau))\,d\tau - \int_t^{t+\Delta t} f(v(x_j,\tau))\,d\tau\right). \end{aligned} \tag{2.4}$$

The first two integrals on the right-hand side of (2.4) can be evaluated exactly. Moreover, if the CFL condition

$$\lambda \max_{x_j \le x \le x_{j+1}} |f'(v(x,t))| \le \frac{1}{2}, \quad j \in \mathbb{Z}, \tag{2.5}$$

is met, then the last two integrants on the right of (2.4) are smooth functions of τ. Hence, they can be integrated approximately by the midpoint rule with third-order local truncation error. Note that, in the case of zero slopes $\frac{1}{\Delta x}v'_j$ and $\frac{1}{\Delta x}v'_{j+1}$, the time integration is exact for any flux f, and even for nonzero slopes the time integration can be exact for a low degree polynomial flux. Thus, following [15], we arrive at

$$\begin{aligned} v_{j+1/2}(t+\Delta t) = {} & \frac{1}{2}(v_j(t) + v_{j+1}(t)) + \frac{1}{8}(v'_j - v'_{j+1}) \\ & - \lambda\left(f\left(v\left(x_{j+1}, t+\frac{\Delta t}{2}\right)\right) - f\left(v\left(x_j, t+\frac{\Delta t}{2}\right)\right)\right). \end{aligned} \tag{2.6}$$

By Taylor expansion and the conservation law (2.1), we obtain

$$v\left(x_j, t+\frac{\Delta t}{2}\right) = v_j(t) - \frac{1}{2}\lambda f'_j, \tag{2.7}$$

where $\frac{1}{\Delta x}f'_j$ stand for an approximate numerical derivative of the flux $f(v(x=x_j,t))$. The following choices are widely used as approximations of the numerical derivatives (we drop t to simplify the notation):

$$\begin{aligned} v'_j &= \mathrm{m}(v_{j+1} - v_j, v_j - v_{j-1}), \\ f'_j &= \mathrm{m}(f(v_{j+1}) - f(v_j), f(v_j) - f(v_{j-1})), \end{aligned} \tag{2.8}$$

where $\mathrm{m}(a,b)$ stands for the minmod limiter

$$\mathrm{m}(a,b) \equiv \mathrm{MinMod}(a,b) := \frac{1}{2}(\mathrm{sgn}(a) + \mathrm{sgn}(b)) \cdot \min(|a|, |b|) \tag{2.9}$$

with the usual generalization

$$\mathrm{m}(E) := \begin{cases} \inf(E) & \text{if} \quad E \subset \mathbb{R}_+, \\ \sup(E) & \text{if} \quad E \subset \mathbb{R}_-, \\ 0 & \text{otherwise.} \end{cases} \tag{2.10}$$

A generalization of this numerical approximation is based the so-called minmod-θ limiters

$$v'_j = \mathrm{m}\left(\theta(v_{j+1}-v_j), \frac{1}{2}(v_{j+1}-v_{j-1}), \theta(v_j - v_{j-1})\right), \tag{2.11}$$
$$f'_j = \mathrm{m}\left(\theta(f(v_{j+1})-f(v_j)), \frac{1}{2}(f(v_{j+1})-f(v_{j-1})), \theta(f(v_j)-f(v_{j-1}))\right).$$

Given the approximate slopes and flux derivatives (2.11), we have a family of central schemes in the predictor-corrector form

$$v\left(x_j, t+\frac{\Delta t}{2}\right) = v_j(t) - \frac{1}{2}\lambda f'_j,$$
$$v_{j+1/2}(t+\Delta t) = \frac{1}{2}(v_j(t)+v_{j+1}(t)) + \frac{1}{8}(v'_j - v'_{j+1}) \tag{2.12}$$
$$- \lambda\left(f\left(v\left(x_{j+1}, t+\frac{\Delta t}{2}\right)\right) - f\left(v\left(x_j, t+\frac{\Delta t}{2}\right)\right)\right),$$

where we start with $v_j(0) := \frac{1}{\Delta x}\int_{x_{j-1/2}}^{x_{j+1/2}} u_0(x)\,dx$. Note that we alternate between two uniform partitions of the real line: all intervals with integer end points for $t = 2k\Delta t$, $k \in \mathbb{Z}$, and half integers for $t = (2k+1)\Delta t$, $k \in \mathbb{Z}$. As a special case, we recover the staggered LxF scheme for $\theta = 0$ and the basic minmod scheme for $\theta = 1$ (the middle slope in the minmod limiter (2.11) drops if $\theta \le 1$).

3. l_2 stability for linear flux. In this section we will prove that the central scheme given in (2.12) is l_2 stable for any θ in the interval $[0,1]$. Based on this stability we will also derive a new error estimate in L^2 instead of the usual L^1 estimates in the conservation laws. Note that even for linear flux f, the minmod-type schemes are not linear and the only global property known is that the total variation does not increase in time under an appropriate CFL condition; see [15]. The class of minmod-type schemes is also not Lip+ stable except for the obvious choice $\theta = 0$. Let us consider a linear flux $f(u) = au$, uniform time steps $t_n = n\Delta t$, and restrict the minmod limiter to $\theta \le 1$. We denote $v_j^n := v_j(t_n)$, $\delta_j^n := v_j^n - v_{j-1}^n$. The minmod scheme (2.12) reduces to

$$v_{j+1/2}^{n+1} = \frac{1}{2}(v_j^n + v_{j+1}^n) + \frac{\theta}{8}\left(\mathrm{m}(\delta_j^n, \delta_{j+1}^n) - \mathrm{m}(\delta_{j+1}^n, \delta_{j+2}^n)\right) \tag{3.1}$$
$$- \frac{a\Delta t}{\Delta x}\left(v_{j+1}^n - \frac{a\Delta t}{2\Delta x}\theta\mathrm{m}(\delta_{j+1}^n, \delta_{j+2}^n) - v_j^n + \frac{a\Delta t}{2\Delta x}\theta\mathrm{m}(\delta_j^n, \delta_{j+1}^n)\right).$$

Hence, we have an explicit formula for the new cell averages (at time t_{n+1}) on a staggered grid in terms of the old ones (at time t_n) on a regular grid. In order to simplify the notation, we drop the time dependence and denote $w_j := v_j^n$, $w'_{j+1} := v_{j+1/2}^{n+1}$, $\delta'_j := w'_j - w'_{j-1}$, $\alpha := \frac{1}{2} + \frac{a\Delta t}{\Delta x}$, and $\beta := \frac{1}{2}\alpha(1-\alpha)$. With this notation, we have the following relation between the sequence of the new averages $\{w'_j\}$ and the old ones $\{w_j\}$:

$$w'_j = \alpha w_{j-1} + (1-\alpha)w_j + \theta\beta\left(\mathrm{m}(\delta_{j-1}, \delta_j) - \mathrm{m}(\delta_j, \delta_{j+1})\right). \tag{3.2}$$

Using that $\delta_j = w_j - w_{j-1}$, we derive the formula for the sequence of new jumps in terms of the old ones:

$$\delta'_j = \alpha\delta_{j-1} + (1-\alpha)\delta_j - \theta\beta\mathrm{m}(\delta_{j-2}, \delta_{j-1}) + 2\theta\beta\mathrm{m}(\delta_{j-1}, \delta_j) - \theta\beta\mathrm{m}(\delta_j, \delta_{j+1}). \tag{3.3}$$

The CFL condition (2.5) reduces to $0 \le \alpha \le 1$ because $\alpha = \frac{1}{2} + \frac{a\Delta t}{\Delta x}$ and $|\frac{a\Delta t}{\Delta x}| \le \frac{1}{2}$. The main result in this section is the following stability result.

THEOREM 3.1. *If the initial condition $u_0 \in L^1_{loc}(\mathbb{R})$, then the l_2 norm of the jumps of the approximate solution $v(\cdot, t)$ is nonincreasing in time. That is,*

$$\|\{\delta'_j\}\|_{l_2} \equiv \|\{v^{n+1}_j - v^{n+1}_{j-1}\}\|_{l_2} \le \|\{\delta_j\}\|_{l_2} \equiv \|\{v^n_j - v^n_{j-1}\}\|_{l_2} \tag{3.4}$$

for all $n \ge 1$.

Proof. It is clear that we have to prove the result for one step, assuming that $\|\{\delta_j\}\|_{l_2} < \infty$. We split the proof into two parts. First, we prove the stability for a monotone sequence $\{w_j\}$. By symmetry, it is sufficient to consider the case $\delta_j \ge 0$ for all $j \in \mathbb{Z}$. Then we apply that result locally to derive the l_2 stability for a general sequence.

THEOREM 3.2. *Let us assume that $\delta_j \ge 0$, $j \in \mathbb{Z}$, and δ'_j are given by* (3.3). *Then*

$$\|\{\delta'_j\}\|_{l_2} \le \|\{\delta_j\}\|_{l_2}. \tag{3.5}$$

Proof. Let us recall that $\{\delta_j\}_{-\infty}^{\infty} \in l_2$ and $\delta_j \ge 0$ for all j. It is enough to prove Theorem 3.2 only for $0 < \alpha < 1$. Let $\beta_1 := \theta\beta$; then $0 < \beta_1 \le \beta$. We construct the new sequence $\{\delta'_j\}$ by using the rule

$$\delta'_j = (1-\alpha)\delta_j + \alpha\delta_{j-1} - \beta_1 \min(\delta_{j-2}, \delta_{j-1}) + 2\beta_1 \min(\delta_{j-1}, \delta_j) - \beta_1 \min(\delta_j, \delta_{j+1}) \tag{3.6}$$

for each j. First we assume that $\{\delta_j\}$ has finite support. It is easy to see how to modify the proof in case the support is not finite. Therefore we assume $\delta_j = 0$ for $j \le 3$ and for $j \ge N-3$ for some integer N. Then $\delta'_j = 0$ for $j \le 3$ and $j \ge N-2$. Thus it suffices to prove

$$\sum_{j=1}^{N} \delta_j^2 \ge \sum_{j=1}^{N} (\delta'_j)^2. \tag{3.7}$$

Let us introduce some notation. Let $y_j = \min(\delta_j, \delta_{j+1})$, $\Delta\delta_j = \delta_j - \delta_{j-1}$, $\Delta y_j = y_j - y_{j-1}$, $\Delta^2\delta_j = \delta_j - 2\delta_{j-1} + \delta_{j-2}$, and $\Delta^2 y_j = y_j - 2y_{j-1} + y_{j-2}$. Then (3.6) becomes

$$\delta'_j = ((1-\alpha)\delta_j + \alpha\delta_{j-1}) - \beta_1 \Delta^2 y_j \quad \text{and}$$

$$\sum_{j=1}^{N} (\delta'_j)^2 = \sum_{j=1}^{N} \left(((1-\alpha)\delta_j + \alpha\delta_{j-1})^2 - 2\beta_1((1-\alpha)\delta_j + \alpha\delta_{j-1})\Delta^2 y_j + \beta_1^2 (\Delta^2 y_j)^2 \right).$$

Note that since $\delta_0 = \delta_1 = 0$ and $\delta_{N-1} = \delta_N = 0$, we have

$$\begin{aligned} \sum_{j=1}^{N} \delta_j^2 - ((1-\alpha)\delta_j + \alpha\delta_{j-1})^2 &= \sum_{j=1}^{N} (1 - (1-\alpha)^2 - \alpha^2)\delta_j^2 - 2\alpha(1-\alpha)\delta_j\delta_{j-1} \\ &= 2\beta \sum_{j=1}^{N} (2\delta_j^2 - 2\delta_j\delta_{j-1}) = 2\beta \sum_{j=1}^{N} (\delta_j - \delta_{j-1})^2 = 2\beta \sum_{j=1}^{N} (\Delta\delta_j)^2. \end{aligned}$$

Thus we get

(3.8)
$$\sum_{j=1}^{N}\delta_j^2-\sum_{j=1}^{N}(\delta_j')^2=\sum_{j=1}^{N}\left(2\beta(\Delta\delta_j)^2+2\beta_1((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta_1^2(\Delta^2y_j)^2\right).$$

To prove Theorem 3.2, we need to prove

$$\sum_{j=1}^{N}\left(2\beta(\Delta\delta_j)^2+2\beta_1((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta_1^2(\Delta^2y_j)^2\right)\ge 0.$$

Note that

$$\begin{aligned}
&\sum_{j=1}^{N}\left(2\beta(\Delta\delta_j)^2+2\beta_1((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta_1^2(\Delta^2y_j)^2\right)\\
&\quad=\beta_1\left(\sum_{j=1}^{N}\left(2\left(\frac{\beta}{\beta_1}\right)(\Delta\delta_j)^2+2((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta_1(\Delta^2y_j)^2\right)\right)\\
&\quad\ge\beta_1\left(\sum_{j=1}^{N}\left(2(\Delta\delta_j)^2+2((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta(\Delta^2y_j)^2\right)\right)\\
&\quad=\left(\frac{\beta_1}{\beta}\right)\sum_{j=1}^{N}\left(2\beta(\Delta\delta_j)^2+2\beta((1-\alpha)\delta_j+\alpha\delta_{j-1})\Delta^2y_j-\beta^2(\Delta^2y_j)^2\right).
\end{aligned}$$

Therefore it is sufficient to prove the theorem in the case $\beta_1=\beta$, which is the worst case in a certain sense. Now we use $\Delta^2y_j=\Delta y_j-\Delta y_{j-1}$, $\Delta y_j=0$, $\delta_j=0$ for $j\le 1$, $j\ge N-1$, and Abel's transform to obtain

$$\sum_{j=1}^{N}\delta_j\Delta^2y_j=\sum_{j=1}^{N}(\delta_j-\delta_{j+1})\Delta y_j\quad\text{and}\quad\sum_{j=1}^{N}\delta_{j-1}\Delta^2y_j=\sum_{j=1}^{N}(\delta_{j-1}-\delta_j)\Delta y_j.$$

Thus, (3.8) becomes

$$\begin{aligned}
\sum_{j=1}^{N}\delta_j^2-\sum_{j=1}^{N}(\delta_j')^2=2\beta\Bigg(&\sum_{j=1}^{N}(\Delta\delta_j)^2-(1-\alpha)\sum_{j=1}^{N}\Delta\delta_{j+1}\Delta y_j\\
&-\alpha\sum_{j=1}^{N}\Delta\delta_j\Delta y_j-\frac{\beta}{2}\sum_{j=1}^{N}(\Delta^2y_j)^2\Bigg).
\end{aligned}$$

Recall that $y_j=\min(\delta_j,\delta_{j+1})$, $\Delta\delta_j=\delta_j-\delta_{j-1}$, $\Delta y_j=y_j-y_{j-1}$, $\Delta^2\delta_j=\delta_j-2\delta_{j-1}+\delta_{j-2}$, and $\Delta^2y_j=y_j-2y_{j-1}+y_{j-2}$. To finish the proof of Theorem 3.2, it is sufficient to prove the following two lemmas.

LEMMA 3.3.

$$\sum_{j=1}^{N}(\Delta\delta_j)^2-(1-\alpha)\sum_{j=1}^{N}\Delta\delta_{j+1}\Delta y_j-\alpha\sum_{j=1}^{N}\Delta\delta_j\Delta y_j-\beta\sum_{j=1}^{N}(\Delta^2\delta_j)^2\ge 0.$$

LEMMA 3.4.

$$2\sum_{j=1}^{N}(\Delta^2\delta_j)^2 \geq \sum_{j=1}^{N}(\Delta^2 y_j)^2.$$

Proof of Lemma 3.3. We consider that $\sum_j$ denotes $\sum_{j=1}^{N}$. Define

$$A = \sum_j \Delta\delta_{j+1}\Delta y_j \quad \text{and} \quad B = \sum_j \Delta\delta_j \Delta y_j.$$

Our aim is to prove that

$$\sum_j (\Delta\delta_j)^2 - (1-\alpha)A - \alpha B - \beta\sum_j (\Delta^2\delta_j)^2 \geq 0. \tag{3.9}$$

Let $u_+ = \max(u,0)$, $u_- = \min(u,0)$. It is easy to check that

$$\Delta y_j = (\Delta\delta_j)_+ + (\Delta\delta_{j+1})_-. \tag{3.10}$$

We can transform A as follows:

$$\begin{aligned} A &= \sum_j \Delta\delta_{j+1}((\Delta\delta_j)_+ + (\Delta\delta_{j+1})_-) \\ &= \sum_j \Delta\delta_{j+1}(\Delta\delta_j)_+ + \sum_j \Delta\delta_j(\Delta\delta_j)_- = \sum_{\Delta\delta_j\leq 0}(\Delta\delta_j)^2 + \sum_{\Delta\delta_j\geq 0}\Delta\delta_j\Delta\delta_{j+1} \\ &= \sum_{\Delta\delta_j\leq 0}(\Delta\delta_j)^2 + \sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\leq 0}\Delta\delta_j\Delta\delta_{j+1} + D, \end{aligned} \tag{3.11}$$

where $D = \sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\geq 0}\Delta\delta_j\Delta\delta_{j+1}$. Further,

$$\begin{aligned} D &= \frac{1}{2}\sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\geq 0}\left((\Delta\delta_j)^2 + (\Delta\delta_{j+1})^2 - (\Delta^2\delta_{j+1})^2\right) \\ &= \frac{1}{2}\sum_{\Delta\delta_{j-1}\geq 0,\ \Delta\delta_j\geq 0}\left((\Delta\delta_{j-1})^2 + (\Delta\delta_j)^2 - (\Delta^2\delta_j)^2\right) \\ &= \frac{1}{2}\sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\geq 0}(\Delta\delta_j)^2 + \frac{1}{2}\sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j-1}\geq 0}(\Delta\delta_j)^2 - \frac{1}{2}\sum_{\Delta\delta_{j-1}\geq 0,\ \Delta\delta_j\geq 0}(\Delta^2\delta_j)^2. \end{aligned}$$

By (3.11),

$$\begin{aligned} A = \sum_j(\Delta\delta_j)^2 &- \frac{1}{2}\sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}<0}(\Delta\delta_j)^2 - \frac{1}{2}\sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j-1}<0}(\Delta\delta_j)^2 \\ &- \frac{1}{2}\sum_{\Delta\delta_{j-1}\geq 0,\ \Delta\delta_j\geq 0}(\Delta^2\delta_j)^2 + \sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\leq 0}\Delta\delta_j\Delta\delta_{j+1}. \end{aligned} \tag{3.12}$$

Transform B in the same way as A:

$$B = \sum_{\Delta\delta_j\geq 0}(\Delta\delta_j)^2 + \sum_{\Delta\delta_j\geq 0,\ \Delta\delta_{j+1}\leq 0}\Delta\delta_j\Delta\delta_{j+1} + E, \tag{3.13}$$

where $E = \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j+1} \le 0} \Delta\delta_j \Delta\delta_{j+1}$. The quantity E can also be rewritten in the same way as D:

$$E = \frac{1}{2} \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j+1} \le 0} (\Delta\delta_j)^2 + \frac{1}{2} \sum_{\Delta\delta_{j-1} \le 0,\, \Delta\delta_j \le 0} (\Delta\delta_j)^2 - \frac{1}{2} \sum_{\Delta\delta_{j-1} \le 0,\, \Delta\delta_j \le 0} (\Delta^2\delta_j)^2.$$

Combining this equality with (3.13), we get

$$\begin{aligned} B = {} & \sum_j (\Delta\delta_j)^2 - \frac{1}{2} \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j+1} > 0} (\Delta\delta_j)^2 - \frac{1}{2} \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j-1} > 0} (\Delta\delta_j)^2 \\ & - \frac{1}{2} \sum_{\Delta\delta_{j-1} \le 0,\, \Delta\delta_j \le 0} (\Delta^2\delta_j)^2 + \sum_{\Delta\delta_{j+1} \le 0,\, \Delta\delta_j \ge 0} \Delta\delta_j \Delta\delta_{j+1}. \end{aligned} \tag{3.14}$$

By (3.12) and (3.14),

$$\sum_j (\Delta\delta_j)^2 - (1-\alpha)A - \alpha B - \beta \sum_j (\Delta^2\delta_j)^2 = F + G + H + I + J + K + L, \tag{3.15}$$

where

$$F = \frac{1-\alpha}{2} \sum_{\Delta\delta_j \ge 0,\, \Delta\delta_{j+1} < 0} (\Delta\delta_j)^2, \quad G = \frac{1-\alpha}{2} \sum_{\Delta\delta_j \ge 0,\, \Delta\delta_{j-1} < 0} (\Delta\delta_j)^2,$$

$$H = \frac{\alpha}{2} \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j+1} > 0} (\Delta\delta_j)^2, \quad I = \frac{\alpha}{2} \sum_{\Delta\delta_j \le 0,\, \Delta\delta_{j-1} > 0} (\Delta\delta_j)^2,$$

$$\begin{aligned} J = {} & - \sum_{\Delta\delta_{j+1} \le 0,\, \Delta\delta_j \ge 0} \Delta\delta_j \Delta\delta_{j+1} + \left(\frac{1-\alpha}{2} - \beta \right) \sum_{\Delta\delta_{j-1} \ge 0,\, \Delta\delta_j \ge 0} (\Delta^2\delta_j)^2 \\ & + \left(\frac{\alpha}{2} - \beta \right) \sum_{\Delta\delta_{j-1} \le 0,\, \Delta\delta_j \le 0} (\Delta^2\delta_j)^2, \end{aligned}$$

$$K = -\beta \sum_{\Delta\delta_{j-1} > 0,\, \Delta\delta_j < 0} (\Delta^2\delta_j)^2, \qquad \text{and} \quad L = -\beta \sum_{\Delta\delta_{j-1} < 0,\, \Delta\delta_j > 0} (\Delta^2\delta_j)^2.$$

We have to prove that $F + G + H + I + J + K + L \ge 0$. Among the sums F, G, H, I, J, K, L, only the two last sums might be negative; we will show that and

$$F + I + K \ge 0, \tag{3.16}$$

$$G + H + L \ge 0. \tag{3.17}$$

Indeed,

$$\begin{aligned} & \frac{1-\alpha}{2} (\Delta\delta_{j-1})^2 + \frac{\alpha}{2} (\Delta\delta_j)^2 - \beta (\Delta^2\delta_j)^2 = \frac{1-\alpha}{2} (\Delta\delta_{j-1})^2 + \frac{\alpha}{2} (\Delta\delta_j)^2 \\ & \quad - \frac{(1-\alpha)\alpha}{2} (\Delta\delta_j - \Delta\delta_{j-1})^2 = \frac{1}{2} ((1-\alpha)\Delta\delta_{j-1} + \alpha\Delta\delta_j))^2 \ge 0. \end{aligned}$$

Summing the last inequality over all j with $\Delta\delta_{j-1} > 0$, $\Delta\delta_j < 0$, we get (3.16). The inequality (3.17) can be proved similarly.

Additionally, we have

$$J \geq 0. \tag{3.18}$$

Finally, plugging (3.16), (3.17), and (3.18) into (3.15), we obtain the required (3.9). This completes the proof of Lemma 3.3.

Proof of Lemma 3.4. First, recall that $\Delta^2 y_j = 0$ for $j \leq 1$ and $j \geq N$. Also, from the proof of Lemma 3.3 we have

$$\Delta y_j = \begin{cases} \Delta\delta_{j+1} & \text{if} \quad \Delta\delta_{j+1} \leq 0, \quad \Delta\delta_j \leq 0, \\ \Delta\delta_{j+1} + \Delta\delta_j & \text{if} \quad \Delta\delta_{j+1} \leq 0, \quad \Delta\delta_j \geq 0, \\ \Delta\delta_j & \text{if} \quad \Delta\delta_{j+1} \geq 0, \quad \Delta\delta_j \geq 0, \\ 0 & \text{if} \quad \Delta\delta_{j+1} \geq 0, \quad \Delta\delta_j \leq 0. \end{cases}$$

Similarly,

$$\Delta y_{j-1} = \begin{cases} \Delta\delta_j & \text{if} \quad \Delta\delta_j \leq 0, \quad \Delta\delta_{j-1} \leq 0, \\ \Delta\delta_j + \Delta\delta_{j-1} & \text{if} \quad \Delta\delta_j \leq 0, \quad \Delta\delta_{j-1} \geq 0, \\ \Delta\delta_{j-1} & \text{if} \quad \Delta\delta_j \geq 0, \quad \Delta\delta_{j-1} \geq 0, \\ 0 & \text{if} \quad \Delta\delta_j \geq 0, \quad \Delta\delta_{j-1} \leq 0. \end{cases}$$

Therefore $\Delta\delta_{j-1}$, $\Delta\delta_j$, $\Delta\delta_{j+1}$ and their signs uniquely determine $\Delta^2 y_j$. We have eight cases depending on what the signs of $\Delta\delta_{j-1}$, $\Delta\delta_j$, $\Delta\delta_{j+1}$ are.

- *Case* I. $(+,+,+)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} \geq 0$. Then, $\Delta y_j = \Delta\delta_j$, $\Delta y_{j-1} = \Delta\delta_{j-1}$, and so $\Delta^2 y_j = \Delta^2\delta_j$; thus, $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_j)^2$ in this case.
- *Case* II. $(+,+,-)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} < 0$. Then, $\Delta y_j = \Delta\delta_{j+1} + \Delta\delta_j$, $\Delta y_{j-1} = \Delta\delta_{j-1}$, and so $\Delta^2 y_j = \Delta\delta_{j+1} + \Delta\delta_j - \Delta\delta_{j-1}$.
- *Case* III. $(+,-,+)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j < 0$, $\Delta\delta_{j+1} \geq 0$. Then, $\Delta y_j = 0$, $\Delta y_{j-1} = \Delta\delta_j + \Delta\delta_{j-1}$, and so $\Delta^2 y_j = -\Delta\delta_j - \Delta\delta_{j-1}$. In this case $(\Delta^2 y_j)^2 - (\Delta^2\delta_j)^2 = 4\Delta\delta_j\Delta\delta_{j-1} \leq 0$ and $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_j)^2$.
- *Case* IV. $(+,-,-)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j < 0$, $\Delta\delta_{j+1} < 0$. Then, $\Delta y_j = \Delta\delta_{j+1}$, $\Delta y_{j-1} = \Delta\delta_j + \Delta\delta_{j-1}$, and so $\Delta^2 y_j = \Delta\delta_{j+1} - \Delta\delta_j - \Delta\delta_{j-1}$.
- *Case* V. $(-,+,+)$, that is, $\Delta\delta_{j-1} < 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} \geq 0$. Then, $\Delta y_j = \Delta\delta_j$, $\Delta y_{j-1} = 0$, and so $\Delta^2 y_j = \Delta\delta_j$. In this case $0 \leq \Delta\delta_j < \Delta\delta_j - \Delta\delta_{j-1}$ and $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_j)^2$.
- *Case* VI. $(-,+,-)$, that is, $\Delta\delta_{j-1} < 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} < 0$. Then, $\Delta y_j = \Delta\delta_{j+1} + \Delta\delta_j$, $\Delta y_{j-1} = 0$, and so $\Delta^2 y_j = \Delta\delta_{j+1} + \Delta\delta_j$. In this case $(\Delta^2 y_j)^2 - (\Delta^2\delta_{j+1})^2 = 4\Delta\delta_{j+1}\Delta\delta_j \leq 0$ and $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_{j+1})^2$.
- *Case* VII. $(-,-,+)$, that is, $\Delta\delta_{j-1} < 0$, $\Delta\delta_j < 0$, $\Delta\delta_{j+1} \geq 0$. Then, $\Delta y_j = 0$, $\Delta y_{j-1} = \Delta\delta_j$, and so $\Delta^2 y_j = -\Delta\delta_j$. In this case $0 < -\Delta\delta_j \leq \Delta\delta_{j+1} - \Delta\delta_j$ and $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_{j+1})^2$.
- *Case* VIII. $(-,-,-)$, that is, $\Delta\delta_{j-1} < 0$, $\Delta\delta_j < 0$, $\Delta\delta_{j+1} < 0$. Then, $\Delta y_j = \Delta\delta_{j+1}$, $\Delta y_{j-1} = \Delta\delta_j$, and so $\Delta^2 y_j = \Delta^2\delta_{j+1}$. In this case $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_{j+1})^2$.

Therefore in Cases I $(+,+,+)$, III $(+,-,+)$, and V $(-,+,+)$, $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_j)^2$, and in Cases VI $(-,+,-)$, VII $(-,-,+)$, and VIII $(-,-,-)$, $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_{j+1})^2$. There are only two "bad" cases: II $(+,+,-)$ and IV $(+,-,-)$, which need a special treatment.

Next, we define a sequence of $+$ and $-$ signs $\{s_j\}$, where $s_j = +$ if $\Delta\delta_j \geq 0$ and $s_j = -$ if $\Delta\delta_j < 0$. Note that $s_j = +$ for $j \leq 3$ and $j \geq N-2$. There are three types of "bad" quadruples:

- Type A quadruple: $(+,+,-,-)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} < 0$, $\Delta\delta_{j+2} < 0$ for some j. We claim that in this case the following inequality holds:

$$(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 \leq 2(\Delta^2\delta_j)^2 + 2(\Delta^2\delta_{j+1})^2 + 2(\Delta^2\delta_{j+2})^2. \tag{3.19}$$

  In this case $\Delta^2 y_j = \Delta\delta_{j+1} + \Delta\delta_j - \Delta\delta_{j-1}$ and $\Delta^2 y_{j+1} = \Delta\delta_{j+2} - \Delta\delta_{j+1} - \Delta\delta_j$. If we denote $\Delta\delta_{j-1}$ by a, $\Delta\delta_j$ by b, $\Delta\delta_{j+1}$ by c, and $\Delta\delta_{j+2}$ by d, the above inequality becomes

$$\begin{aligned}&(c+b-a)^2 + (d-c-b)^2 \leq 2(b-a)^2 + 2(c-b)^2 + 2(d-c)^2\\ &\text{for } a \geq 0,\ b \geq 0,\ c < 0,\ d < 0,\end{aligned}$$

  which is equivalent to $a^2 + 2b^2 + 2c^2 + d^2 - 2ab + 2ac - 8bc + 2bd - 2cd \geq 0$, or

$$(a - b + c)^2 + (b - c + d)^2 - 4bc \geq 0,$$

  which holds since $b \geq 0$, $c < 0$.
- Type B quadruple: $(+,+,-,+)$, that is, $\Delta\delta_{j-1} \geq 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} < 0$, $\Delta\delta_{j+2} \geq 0$ for some j. We claim that in this case the following inequality holds:

$$(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 \leq 2(\Delta^2\delta_j)^2 + 2(\Delta^2\delta_{j+1})^2 + (\Delta^2\delta_{j+2})^2. \tag{3.20}$$

  In this case $\Delta^2 y_j = \Delta\delta_{j+1} + \Delta\delta_j - \Delta\delta_{j-1}$ and $\Delta^2 y_{j+1} = -\Delta\delta_{j+1} - \Delta\delta_j$. Using the notation we just introduced, the inequality becomes

$$\begin{aligned}&(c+b-a)^2 + (c+b)^2 \leq 2(b-a)^2 + 2(c-b)^2 + (d-c)^2\\ &\text{for } a \geq 0,\ b \geq 0,\ c < 0,\ d \geq 0.\end{aligned}$$

  Since $(d-c)^2 \geq c^2$, it is sufficient to prove

$$(c+b-a)^2 + (c+b)^2 \leq 2(b-a)^2 + 2(c-b)^2 + c^2, \text{ or}$$

$$a^2 + 2b^2 + c^2 - 2ab + 2ac - 8bc \geq 0, \text{ or } (a - b + c)^2 + b^2 - 6bc \geq 0,$$

  which holds for $b \geq 0$, $c < 0$.
- Type C quadruple: $(-,+,-,-)$, that is, $\Delta\delta_{j-1} < 0$, $\Delta\delta_j \geq 0$, $\Delta\delta_{j+1} < 0$, $\Delta\delta_{j+2} < 0$ for some j. We claim that in this case the following inequality holds:

$$(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 \leq (\Delta^2\delta_j)^2 + 2(\Delta^2\delta_{j+1})^2 + 2(\Delta^2\delta_{j+2})^2. \tag{3.21}$$

  In this case $\Delta^2 y_j = \Delta\delta_{j+1} + \Delta\delta_j$ and $\Delta^2 y_{j+1} = \Delta\delta_{j+2} - \Delta\delta_{j+1} - \Delta\delta_j$. Using the notation we just introduced, the inequality becomes

$$\begin{aligned}&(c+b)^2 + (d-c-b)^2 \leq (b-a)^2 + 2(c-b)^2 + 2(d-c)^2\\ &\text{for } a < 0,\ b \geq 0,\ c < 0,\ d < 0.\end{aligned}$$

  Since $(b-a)^2 \geq b^2$, it is sufficient to prove

$$(c+b)^2 + (d+c-b)^2 \leq b^2 + 2(c-b)^2 + 2(d-c)^2, \text{ or}$$

$$b^2 + 2c^2 + d^2 - 8bc + 2bd - 2cd \geq 0, \text{ or } (b - c + d)^2 + c^2 - 6bc \geq 0,$$

  which holds for $b \geq 0$, $c < 0$.

We will call the Type A (3.19), Type B (3.20), and Type C (3.21) inequalities "long" inequalities; we call the inequalities of type $(\Delta^2 y_j)^2 \le (\Delta^2 \delta_j)^2$ and $(\Delta^2 y_j)^2 \le (\Delta^2 \delta_{j+1})^2$ "short" inequalities.

Now, we construct a set of inequalities. We identify all "bad" quadruples and include the corresponding inequality (Type A, B, or C) in the set. Next, for all $j \in [1, N]$ such that s_j is not a middle element of a "bad" quadruple, and such that j does not belong to the "bad" Cases II and IV, we include the corresponding "short" inequality in the set. Finally, we add all inequalities in the set. Taking into account that $\Delta^2 \delta_j = 0$ and $\Delta^2 y_j = 0$ for $j > N$, the resulting inequality is

$$\sum_{j=1}^{N} a_j (\Delta^2 y_j)^2 \le \sum_{j=1}^{N} b_j (\Delta^2 \delta_j)^2, \tag{3.22}$$

where the a_j's and b_j's are nonnegative integers. To finish the proof of the lemma we need to show $a_j \ge 1$ and $b_j \le 2$ for all $j \in [1, N]$.

Note that all "long" inequalities have the form $(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 \le \cdots$, where s_j and s_{j+1} are the middle elements of a "bad" quadruple. Then $a_j \ge 1$ if s_j is a middle element of a "bad" quadruple. (By middle element of a quadruple we mean second or third element of the quadruple.)

Now, suppose that s_j is not a middle element of a "bad" quadruple. Then j does not belong to the "bad" Cases II and IV. Indeed if j is in Case II: $(s_{j-1}, s_j, s_{j+1}) = (+, +, -)$, then s_j is a middle element of Type B quadruple if $s_{j+2} = +$ and a middle element of Type A quadruple if $s_{j+2} = -$. Similarly, if j is in Case IV: $(s_{j-1}, s_j, s_{j+1}) = (+, -, -)$, then s_j is a middle element of Type A quadruple if $s_{j-1} = +$ and a middle element of Type C quadruple if $s_{j-1} = -$. Therefore a "short" inequality for $(\Delta^2 y_j)^2$ has been included in the set of inequalities. Thus $a_j \ge 1$ in this case as well. We have proved $a_j \ge 1$ for all $j \in [1, N]$.

Now, we prove $b_j \le 2$ for all $j \in [1, N]$. Note that $(\Delta^2 \delta_j)^2$ can appear in only two "short" inequalities: $(\Delta^2 y_j)^2 \le (\Delta^2 \delta_j)^2$ and $(\Delta^2 y_{j-1})^2 \le (\Delta^2 \delta_j)^2$. Therefore $b_j \le 2$ if $(\Delta^2 \delta_j)^2$ does not appear in any "long" inequalities, that is, if s_j is not a second, third, or fourth element of a "bad" quadruple.

The case when s_j is a second, third, or fourth element of a "bad" quadruple requires more work. First, note that two distinct "bad" quadruples have at most two common elements. Indeed all "bad" quadruples are of the form $(*, +, -, *)$, where $*$ denotes $+$ or $-$, and no "bad" quadruple has $(+, -)$ as its first two or last two elements. Next, the only case when two "bad" quadruples have two common elements is the following configuration:

$$(s_{j-1}, s_j, s_{j+1}, s_{j+2}, s_{j+3}, s_{j+4}) = (+, +, -, +, -, -). \tag{3.23}$$

Indeed, a Type A quadruple cannot share exactly two elements with another "bad" quadruple because no "bad" quadruple has $(-, -)$ as its first two elements, or $(+, +)$ as its last two elements. Similar analysis shows that the only way a Type B or Type C quadruple can share exactly two elements with another Type B or Type C quadruple is when the configuration (3.23) occurs.

Let us analyze the configuration (3.23). The "long" inequalities which correspond to the two "bad" quadruples in this configuration are

$$(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 \le 2(\Delta^2 \delta_j)^2 + 2(\Delta^2 \delta_{j+1})^2 + (\Delta^2 \delta_{j+2})^2, \tag{3.24}$$

$$(\Delta^2 y_{j+2})^2 + (\Delta^2 y_{j+3})^2 \le (\Delta^2 \delta_{j+2})^2 + 2(\Delta^2 \delta_{j+3})^2 + 2(\Delta^2 \delta_{j+4})^2. \tag{3.25}$$

Their sum is

$$(\Delta^2 y_j)^2 + (\Delta^2 y_{j+1})^2 + (\Delta^2 y_{j+2})^2 + (\Delta^2 y_{j+3})^2 \\ \leq 2(\Delta^2 \delta_j)^2 + 2(\Delta^2 \delta_{j+1})^2 + 2(\Delta^2 \delta_{j+2})^2 + 2(\Delta^2 \delta_{j+3})^2 + 2(\Delta^2 \delta_{j+4})^2.$$

In this case s_j, s_{j+1}, s_{j+2}, s_{j+3}, and s_{j+4} appear as second, third, or fourth elements of a "bad" quadruple. Since the configuration (3.23) starts with $(+,+)$ and ends with $(-,-)$, it cannot share two elements with a "bad" quadruple outside the configuration. This means that none of s_j, s_{j+1}, s_{j+2}, s_{j+3}, and s_{j+4} can be a second, third, or fourth element of a "bad" quadruple outside the configuration. In other words, none of $(\Delta^2\delta_j)^2$, $(\Delta^2\delta_{j+1})^2$, $(\Delta^2\delta_{j+2})^2$, $(\Delta^2\delta_{j+3})^2$, and $(\Delta^2\delta_{j+4})^2$ can appear in a "long" inequality other than (3.24) and (3.25). Since, s_j, s_{j+1}, s_{j+2}, and s_{j+3} are middle elements of "bad" quadruples, $(\Delta^2\delta_{j+1})^2$, $(\Delta^2\delta_{j+2})^2$, and $(\Delta^2\delta_{j+3})^2$ cannot appear in "short" inequalities either. Thus $b_{j+1} = b_{j+2} = b_{j+3} = 2$. Also, $(\Delta^2\delta_j)^2$ cannot appear in a "short" inequality. The only way this could happen is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_j)^2$, which is impossible since $j-1$ is either in Case I $(+,+,+)$ or Case V $(-,+,+)$, depending on what s_{j-2} is, and in both cases the short inequality is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_{j-1})^2$. Thus $b_j = 2$. Similarly, $(\Delta^2\delta_{j+4})^2$ cannot appear in a "short" inequality. The only way this could happen is $(\Delta^2 y_{j+4})^2 \leq (\Delta^2\delta_{j+4})^2$, which is impossible since $j+4$ is either in Case VII $(-,-,+)$ or Case VIII $(-,-,-)$, depending on what s_{j+5} is, and in both cases the short inequality is $(\Delta^2 y_{j+4})^2 \leq (\Delta^2\delta_{j+5})^2$. Thus $b_{j+4} = 2$. This concludes the analysis of the configuration (3.23).

Now, let s_j be a second, third, or fourth element of a "bad" quadruple but not an element of a configuration (3.23). This means that $(\Delta^2\delta_j)^2$ appears in exactly one "long" inequality (it cannot be a second, third, or fourth element of two distinct "bad" quadruples). If s_j is a third element of a "bad" quadruple, then s_{j-1} and s_j are the middle elements of the quadruple and $(\Delta^2\delta_j)^2$ does not appear in a short inequality. Thus, $b_j \leq 2$ in this case. The cases when s_j is a second or fourth element of a "bad" quadruple need separate consideration.

1. s_j is a second element of a Type A quadruple $(+,+,-,-)$. The only way $(\Delta^2\delta_j)^2$ could appear in a "short" inequality is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_j)^2$, which is impossible since $j-1$ is either in Case I $(+,+,+)$ or Case V $(-,+,+)$, depending on what s_{j-2} is, and in both cases the short inequality is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_{j-1})^2$. Thus $b_j = 2$.
2. s_j is a fourth element of a Type A quadruple $(+,+,-,-)$. The only way $(\Delta^2\delta_j)^2$ could appear in a "short" inequality is $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_j)^2$, which is impossible since j is either in Case VII $(-,-,+)$ or Case VIII $(-,-,-)$, depending on what s_{j+1} is, and in both cases the short inequality is $(\Delta^2 y_j)^2 \leq (\Delta^2\delta_{j+1})^2$. Thus $b_j = 2$.
3. s_j is a second element of a Type B quadruple $(+,+,-,+)$. Here the argument is word-by-word like in part 1. The only way $(\Delta^2\delta_j)^2$ could appear in a "short" inequality is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_j)^2$, which is impossible since $j-1$ is either in Case I $(+,+,+)$ or Case V $(-,+,+)$, depending on what s_{j-2} is, and in both cases the short inequality is $(\Delta^2 y_{j-1})^2 \leq (\Delta^2\delta_{j-1})^2$. Thus $b_j = 2$.
4. s_j is a fourth element of a Type B quadruple $(+,+,-,+)$. Since the coefficient of $(\Delta^2\delta_j)^2$ in the corresponding "long" inequality (3.20) is 1 and $(\Delta^2\delta_j)^2$ could appear in at most one "short" inequality, we conclude $b_j \leq 2$.
5. s_j is a second element of a Type C quadruple $(-,+,-,-)$. Since the coefficient of $(\Delta^2\delta_j)^2$ in the corresponding "long" inequality (3.21) is 1 and $(\Delta^2\delta_j)^2$ could appear in at most one "short" inequality, we conclude $b_j \leq 2$.

6. s_j is a fourth element of a Type C quadruple $(-,+,-,-)$. Here the argument is word-by-word like in Case 2. The only way $(\Delta^2\delta_j)^2$ could appear in a "short" inequality is $(\Delta^2 y_j)^2 \le (\Delta^2\delta_j)^2$, which is impossible since j is either in Case VII $(-,-,+)$ or Case VIII $(-,-,-)$, depending on what s_{j+1} is, and in both cases the short inequality is $(\Delta^2 y_j)^2 \le (\Delta^2\delta_{j+1})^2$. Thus $b_j = 2$.

We have shown that in all six cases $b_j \le 2$ for $j \in [1, N]$, which completes the proof of Lemma 3.4 and Theorem 3.2. □

Now, we continue with the general case, the proof of Theorem 3.1. That is, we want to show that the l_2 norms inequality

$$\|\{\delta'_j\}\|_{l_2} \le \|\{\delta_j\}\|_{l_2} \tag{3.26}$$

holds for *any* initial sequence $\{\delta_j\}$ with finite l_2 norm. We consider the sequence $\{w_j\}$ and restrict the index j to a maximal subset Λ_m on which the piecewise constant function w is monotone, recalling that $\delta_j = w_j - w_{j-1}$. Given a sequence $\{w_j\}$, we can decompose it into monotone subsequences. This decomposition also gives a decomposition of the sequence $\{\delta_j\}$ into subsequences such that in each subsequence all jumps have the same sign (nonnegative or nonpositive). Without any limitations, we assume that the jumps $\{\delta_j\}$ are nonnegative for all $l \le j \le r$, $\delta_{l-1} < 0$, and $\delta_{r+1} < 0$. That is, w_{l-1} is a local minimum and w_r is a local maximum of the piecewise constant function w. Let w^m be the following piecewise constant correction of w:

$$w^m_j := \begin{cases} w_j & \text{if} \quad l \le j \le r, \\ w_{l-1} & \text{if} \quad j < l, \\ w_r & \text{if} \quad j > r. \end{cases} \tag{3.27}$$

Note that $\Lambda_m = \{j : l \le j \le r+1\}$, and the jump sequence $\delta^m := \{\delta^m_j\}$ of w^m is given by

$$\delta^m_j := \begin{cases} w_j - w_{j-1} & \text{if} \quad l \le j \le r, \\ 0 & \text{otherwise.} \end{cases} \tag{3.28}$$

Hence, we have a sequence of monotone functions $\{w^m\}$ and the corresponding jump sequences $\{\delta^m_j\}_j$ such that

$$\sum_m \sum_{j\in\Lambda_m} \|\{\delta^m_j\}\|^2_{l_2} = \sum_{m,j\in\mathbb{Z}} \|\{\delta^m_j\}\|^2_{l_2} = \|\{\delta_j\}\|^2_{l_2},$$

because the sequence of the jumps of $\{\delta_j\}$ is decomposed into disjoint jump subsequences $\{\delta^m_j\}$. There are two types of jumps δ'_j. A jump δ'_j is of *type* 1 if it is equal to the jump $\delta'_j(\delta^m)$, that is, the jump generates with the starting sequence $\{\delta^m_j\}$, where the index m such that $j \in \Lambda_m$. A jump is of *type* 2 if it is not of *type* 1. Note that a *type* 2 jump δ'_{j^*} occurs only inside an interval which contains a strict local extremum. Near a local extremum we have two nonzero jumps, say $\delta^l_{j^*}$ and $\delta^r_{j^*}$, generated by the two monotone w^m's with index sets finishing/starting with j^*. It is easy to verify that

$$|\delta'_{j^*}| = \big||\delta^l_{j^*}| - |\delta^r_{j^*}|\big|.$$

Hence, we have that

$$(\delta'_{j^*})^2 < (\delta^l_{j^*})^2 + (\delta^r_{j^*})^2,$$

and we conclude that

$$\sum_j (\delta'_j)^2 \le \sum_m \sum_{j\in\Lambda_m} (\delta'_j(\delta^m))^2 \le \sum_m \sum_{j\in\Lambda_m} (\delta^m_j)^2 = \sum_n (\delta_j)^2,$$

where we use the notation $\delta'_j(\delta^m)$ for the new jumps generated by δ^m. It is also easy to prove a local inequality but with index set for δ'_j starting from an interval right after an extremum and finishing right before one. □

4. Error estimates for linear flux. Recall that u is the entropy solution to the conservation law $u_t + f(u)_x = 0$ with initial condition u^0, and v is the numerical solution described in (2.12). In the case of linear flux and $0 \le \theta \le 1$, the formula for the new averages of the minmod scheme is given in (3.1), and the conservation law (2.1) reduces to

$$u_t + a u_x = 0. \tag{4.1}$$

Let S_τ be the shift operator defined by $S_\tau g(\cdot) := g(\cdot - \tau)$. Then the exact solution of (4.1) at time t for any initial data u^0 is $u(\cdot, t) = S_{at}u^0$. Let A_h be the averaging operator defined on a uniform partition by $A_h g|_I := \frac{1}{h}\int_I g(s)ds$, where $|I| = h$. It will be useful to define a global approximate solution v. We first define the approximate solution at discrete times by $v^n := v(\cdot, n\Delta t)$, $n = 0, 1, \ldots, N$, in the following way: (i) $v^0 := u^0$; (ii) $v^n := S_{a\Delta t}P_h v^{n-1}$, where for odd n, $1 \le n \le N$, $P_h v$ is the linear function on $I_j := (x_{j-1/2}, x_{j+1/2})$ defined in (2.3) with the minmod slopes (2.8), and for even n we have the analogous definition of P_h on the shifted partition $\{I_{j+1/2} | \, j \in \mathbb{Z}\}$. Note that $P_h v^n = P_h A_h v^n$ because the piecewise linear projection P_h, defined in (2.3) and (2.8), is based only on the averages of v^n on the corresponding partition. The formula (3.1) for the new cell averages can be written as

$$v^n_{j+1/2} = A_h(v^n)|_{I_{j+1/2}} = A_h(S_{a\Delta t}P_h v^{n-1})|_{I_{j+1/2}}$$

for odd n, with A_h based on the staggered partition $\{I_{j+1/2} | \, j \in \mathbb{Z}\}$ and P_h based on regular partition $\{I_j | \, j \in \mathbb{Z}\}$. For even n, we have the same sequence of operators but on the reversed partitions. The global approximate solution v is defined by $v(\cdot, n\Delta t) = v^n$ and $v(\cdot, t) = S_{a(t-n\Delta t)}(P_h v^n)$ for $n\Delta t < t \le (n+1)\Delta t$ and $n = 0, 1, \ldots, N-1$. That is, v solves (4.1) exactly for $n\Delta t < t \le (n+1)\Delta t$ with initial data $P_h v^n$, $n = 0, 1, \ldots, N-1$.

In order to describe the next result, we need to introduce some notation. A function g is of bounded variation, i.e., $g \in \mathrm{BV}(\mathbb{R})$, if

$$|g|_{\mathrm{BV}(\mathbb{R})} := \sup \sum_{i=1}^{n} |g(x_{i+1}) - g(x_i)| < \infty,$$

where the supremum is taken over all finite sequences $x_1 < \cdots < x_n$ in $\mathbb{R}$. Functions of bounded variation have at most countably many discontinuities, and their left and right limits $g(x^-)$ and $g(x^+)$ exist at each point $x \in \mathbb{R}$. Since the values of the initial condition u^0 on a set of measure zero have no influence on the numerical solution v and the entropy solution u, it is desirable to replace the seminorm $|\cdot|_{\mathrm{BV}(\mathbb{R})}$ by a similar quantity independent of the function values on sets of measure zero. The standard approach in conservation laws is to consider the space $\mathrm{Lip}(1, \mathrm{L}^1(\mathbb{R}))$ of all functions $g \in L^1(\mathbb{R})$ such that the seminorm

$$|g|_{\mathrm{Lip}(1,\mathrm{L}^1(\mathbb{R}))} := \limsup_{s>0} \frac{1}{s}\int_{\mathbb{R}} |g(x+s) - g(x)| \, dx \tag{4.2}$$

is finite. It is clear that $|g|_{\mathrm{Lip}(1,\mathrm{L}^1(\mathbb{R}))}$ will not change if g is modified on a set of measure zero. At the same time the above two seminorms are equal for functions $g \in \mathrm{BV}(\mathbb{R})$ such that the value of g at a point of discontinuity lies between $g(x^-)$ and $g(x^+)$ (see Theorem 9.3 in [5]). Similarly, we define the space $\mathrm{Lip}(1, \mathrm{L}^p(\mathbb{R}))$, $1 \le p \le \infty$, which is the set of all functions $g \in L^p(\mathbb{R})$ for which

$$\|g(\cdot - s) - g(\cdot)\|_{L^p(\mathbb{R})} \le Ms, \quad s > 0. \tag{4.3}$$

The smallest $M \ge 0$ for which (4.3) holds is $|g|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}$. It is easy to see that in the case $p = 1$ the seminorm given in (4.3) is the same as the one in (4.2). In the case $p > 1$, the space $\mathrm{Lip}(1, \mathrm{L}^p(\mathbb{R}))$ is essentially the same as $W^1(L^p(\mathbb{R}))$; see [5] for details. With this notation, we have the following result.

THEOREM 4.1. *Let $u(x,t) = u(x - at, 0)$ be the solution to (2.1) with linear flux $f(z) = az$, and let v be the numerical solution described in (3.1) with $0 \le \theta \le 1$. If the CFL condition (2.5) is satisfied, $t_n = n\Delta t$, $0 \le n \le N$, and $T = N\Delta t$, we have*

$$\|u(\cdot, T) - v(\cdot, T)\|_{L^p(\mathbb{R})} \le C(Nh)^{1/2} h^{1/2} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))} \tag{4.4}$$

for $p = 1, 2$, where C is an absolute constant.

Proof. The L_1 estimate is based on the TVD property of the numerical solution v, and the L_2 estimate is based on the l_2 stability of the jumps proved in Theorem 3.1. Both estimates use a dual argument similar to the one in [19], and in the proof we use an index p, where $p \in \{1, 2\}$. Note that we consider the case of linear flux, and the usual Lip+ stability requirement is not needed in the dual approach because the negative norm stability (4.6) holds for any initial data (not just Lip+). In the proof, C will be an absolute constant that can be different at different places.

Let $e(x,t) := u(x,t) - v(x,t)$ and $E(x,t) := \int_{-\infty}^{x} e(s,t)ds$, where we assume that $u^0 \in L^1(\mathbb{R})$ to guarantee that E is well defined for all $(x,t) \in \mathbb{R} \times (0,T)$. We have that E also satisfies (4.1) for $n\Delta t < t \le (n+1)\Delta t$ with initial data $\int_{-\infty}^{x} u(s, n\Delta t) - P_h v^n(s)ds$, $n = 0, 1, \ldots, N-1$. For a function $g \in L^1(\mathbb{R})$ and $1 \le p \le \infty$, we define a *minus one* norm in the following way:

$$\|g\|_{-1,p} := \left\| \int_{-\infty}^{\cdot} g(s)\, ds \right\|_{L^p(\mathbb{R})}. \tag{4.5}$$

It is easy to verify that for any $\tau \in \mathbb{R}$

$$\|S_\tau g\|_{-1,p} = \|g\|_{-1,p}. \tag{4.6}$$

Recall that $T = N\Delta t$. Then we have the representations $u(\cdot, T) = (S_{a\Delta t})^N u^0$ and $v(\cdot, T) = (S_{a\Delta t} P_h)^N u^0$. Using (4.6), we have

$$\begin{aligned} \|e(\cdot, T)\|_{-1,p} &= \|(S_{a\Delta t})^N u^0 - (S_{a\Delta t} P_h)^N u^0\|_{-1,p} \\ &= \|(S_{a\Delta t})^{N-1} u^0 - P_h (S_{a\Delta t} P_h)^{N-1} u^0\|_{-1,p}, \end{aligned}$$

and by the triangle inequality we obtain

$$\begin{aligned} \|e(\cdot, T)\|_{-1,p} \le{}& \|(S_{a\Delta t})^{N-1} u^0 - (S_{a\Delta t} P_h)^{N-1} u^0\|_{-1,p} \\ &+ \|P_h (S_{a\Delta t} P_h)^{N-1} u^0 - (S_{a\Delta t} P_h)^{N-1} u^0\|_{-1,p}. \end{aligned} \tag{4.7}$$

Let $e^n = \left((S_{a\Delta t})^n - (S_{a\Delta t} P_h)^n\right) u^0$, $n = 0, 1, \ldots, N$. Then (4.7) is equivalent to

$$\|e^N\|_{-1,p} \le \|e^{N-1}\|_{-1,p} + \|P_h v^{N-1} - v^{N-1}\|_{-1,p}, \tag{4.8}$$

and applying (4.8) for $n = N, N-1, \dots, 1$, we get

$$\|e^N\|_{-1,p} \le \sum_{n=1}^{N-1} \|P_h v^n - v^n\|_{-1,p} \tag{4.9}$$

because $e^0 \equiv 0$. To prove the error estimates, we need the following technical lemma.

LEMMA 4.2. *For any $p \in \{1,2\}$ and any $n = 0, 1, \dots, N$, we have*

$$\text{(i)} \quad \|\{\delta_j^n\}\|_{l_p} \le h^{1-\frac{1}{p}} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))},$$

$$\text{(ii)} \quad \|P_h v^n - A_h v^n\|_{-1,p} \le \left(\frac{2}{p+1}\right)^{\frac{1}{p}} h^{1+\frac{1}{p}} \|\{\delta_j\}\|_{l_p},$$

$$\text{(iii)} \quad \|A_h v^n - v^n\|_{-1,p} \le \left(\frac{4}{p+1}\right)^{\frac{1}{p}} h^2 |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}.$$

Proof. The inequalities (i) and (ii) follow by standard arguments; therefore, we only prove (i) in the case $p = 2$ and omit the rest because their proofs are similar. Recall that $\delta_j^n = v_j^n - v_{j-1}^n$, and by Theorem 3.1 we have

$$\left(\sum_j (\delta_j^n)^2\right)^{1/2} \le \left(\sum_j (\delta_j^0)^2\right)^{1/2},$$

where $\delta_j^0 = u_j^0 - u_{j-1}^0$, $u_j^0 := \frac{1}{h}\int_{I_j} u^0(s)ds$. Hence, to prove (i) for $p = 2$, we need to prove

$$\sum_j (\delta_j^0)^2 \le h |u^0|^2_{\mathrm{Lip}(1,\mathrm{L}^2(\mathbb{R}))}.$$

Since

$$\sum_j (\delta_j^0)^2 = \sum_j \left(\frac{1}{h}\int_{I_j} (u^0(s+h) - u^0(s))ds\right)^2 \le h^{-2} \sum_j \left(\int_{I_j} |u^0(s+h) - u^0(s)|ds\right)^2,$$

and since by the Cauchy–Schwarz inequality $\left(\int_{I_j} |u^0(s+h) - u^0(s)|ds\right)^2 \le h \int_{I_j} |u^0(s+h) - u^0(s)|^2 ds$, we obtain

$$\sum_j (\delta_j^0)^2 \le h^{-1} \int_{\mathbb{R}} |u^0(s+h) - u^0(s)|^2 ds. \tag{4.10}$$

From (4.3), we have $\int_{\mathbb{R}} |u^0(s+h) - u^0(s)|^2 ds \le h^2 |u^0|^2_{\mathrm{Lip}(1,\mathrm{L}^2(\mathbb{R}))}$, and using that in (4.10), we conclude

$$\sum_j (\delta_j^0)^2 \le h |u^0|^2_{\mathrm{Lip}(1,\mathrm{L}^2(\mathbb{R}))},$$

which proves (i) for $p = 2$. To prove (iii), we note that

$$|A_h v^n - v^n|_{I_j} \le \max_{x \in I_j} v^n(x) - \min_{x \in I_j} v^n(x), \tag{4.11}$$

and because $v^n = S_{a\Delta t} v^{n-1}$, we have that

$$\max_{x \in I_j} v^n(x) - \min_{x \in I_j} v^n(x) \le 2 \max(|\delta_{j-1}^{n-1}|, |\delta_j^{n-1}|).$$

The rest of the proof of (iii) is analogous to the proof of (i). ∎

Combining (i)–(iii), we have $\|P_h v^n - v^n\|_{-1,p} \le Ch^2 |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}$, and after applying the above inequality in (4.9), we derive the following estimate:

$$\|e^N\|_{-1,p} \le CNh^2 |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}. \tag{4.12}$$

Because $v^N \notin \mathrm{Lip}(1, \mathrm{L}^2(\mathbb{R}))$, we approximate v^N by

$$\tilde{v} := \frac{1}{h} \int_{x-h/2}^{x+h/2} A_h v^N(s)\, ds.$$

Similar to Lemma 4.2, it is easy to verify that for $p \in \{1, 2\}$ we have

$$\|\tilde{v} - v^N\|_{-1,p} \le Ch^2 |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}, \tag{4.13}$$

$$\|\tilde{v} - v^N\|_{L^p(\mathbb{R})} \le Ch |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}, \tag{4.14}$$

and

$$|\tilde{v}|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))} \le |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}. \tag{4.15}$$

Let $\tilde{e} := u(\cdot, T) - \tilde{v}$. Then $\|\tilde{e}\|_{-1,p} \le \|e^N\|_{-1,p} + \|\tilde{v} - v^N\|_{-1,p}$, and combining the estimates (4.12) and (4.13), we have

$$\|\tilde{e}\|_{-1,p} \le CNh^2 |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}. \tag{4.16}$$

Kolmogorov–Landau inequalities in $L^p(\mathbb{R})$ (p. 156 in [5]) for the functions $\tilde{E}(x) := \int_\infty^x \tilde{e}(s)\, ds$, $\tilde{E}'$, and $\tilde{E}''$ give

$$\|\tilde{e}\|_{L^p} = \|\tilde{E}'\|_{L^p} \le \sqrt{2} \|\tilde{E}\|_{L^p}^{1/2} \|\tilde{E}''\|_{L^p}^{1/2} = \sqrt{2} \|\tilde{e}\|_{-1,p}^{1/2} |\tilde{e}|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}^{1/2}.$$

Using (4.16) and (4.15), we arrive at

$$\|\tilde{e}\|_{L^p} \le C(Nh)^{1/2} h^{1/2} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}. \tag{4.17}$$

Finally, by the triangle inequality,

$$\|e\|_{L^p} \le \|\tilde{e}\|_{L^p} + \|\tilde{v} - v^N\|_{L^p(\mathbb{R})} \le C(Nh)^{1/2} h^{1/2} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))},$$

and we combine (4.14) and (4.17) to conclude

$$\|u(\cdot, T) - v(\cdot, T)\|_{L^p(\mathbb{R})} = \|e\|_{L^p} \le C(Nh)^{1/2} h^{1/2} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}.$$

Note that C can be computed explicitly and is not very big ($C < 20$). In the case $p = 2$ and $u^0 \notin L^1(\mathbb{R})$, we get the same error estimate via an approximation procedure because the estimate is independent of the L^1 norm. ∎

COROLLARY 4.3. *In the case of $Nh \le C$, we get the convergence rate*

$$\|u(\cdot, T) - v(\cdot, T)\|_{L^p(\mathbb{R})} \le Ch^{1/2} |u^0|_{\mathrm{Lip}(1,\mathrm{L}^p(\mathbb{R}))}$$

for $p = 1$ and $p = 2$.

The L^1 estimate is not new—it follows from the arguments in [19]—but the $1/2$ rate in L^2 is new. Note that, using the L^1 estimate, by interpolation arguments we get only a $1/4$ rate in L^2. The rate $1/2$ is optimal for the case $\theta = 0$ because the numerical method in that case reduces to the LxF scheme, a special case of a monotone scheme. In the case $p = 1$, the sharpness of the $1/2$ bound is given in [20], with an extension to the nonlinear case in [17]. The sharpness in the case $p = 2$ follows from the more general result for formal first-order linear schemes; see [4]. The case $\theta > 0$ is more complicated because the schemes are nonlinear, and it will be addressed elsewhere.

5. Numerical examples. In this section, we present numerical evidence for the new l_2 stability result we proved in section 3. Our numerical tests suggest that in the case of linear flux the NT schemes do not increase the l_2 norm of the jumps for either $\theta \leq 1$ (as proved in Theorem 3.1) or for $1 < \theta \leq 2$. In the case of convex flux, we numerically observe the one-sided analogue of this property. We now give generic examples for this l_2 stability in the linear and convex case.

Example 1. Linear equation. We take a piecewise linear initial condition u^0 (see top left of Figure 5.1) and compare three different approximate solutions. It is easy to see that for a bigger value of θ we get smaller numerical diffusion (see top right panel of Figure 5.1). The other two plots on Figure 5.1 give the behaviors of the l_2 and the l_∞ norms of the jumps in time where the time is rescaled from $[0, 0.15]$ to $[0, 1]$ and the l_2 norm is also rescaled. Note the oscillatory behavior of the l_∞ norm

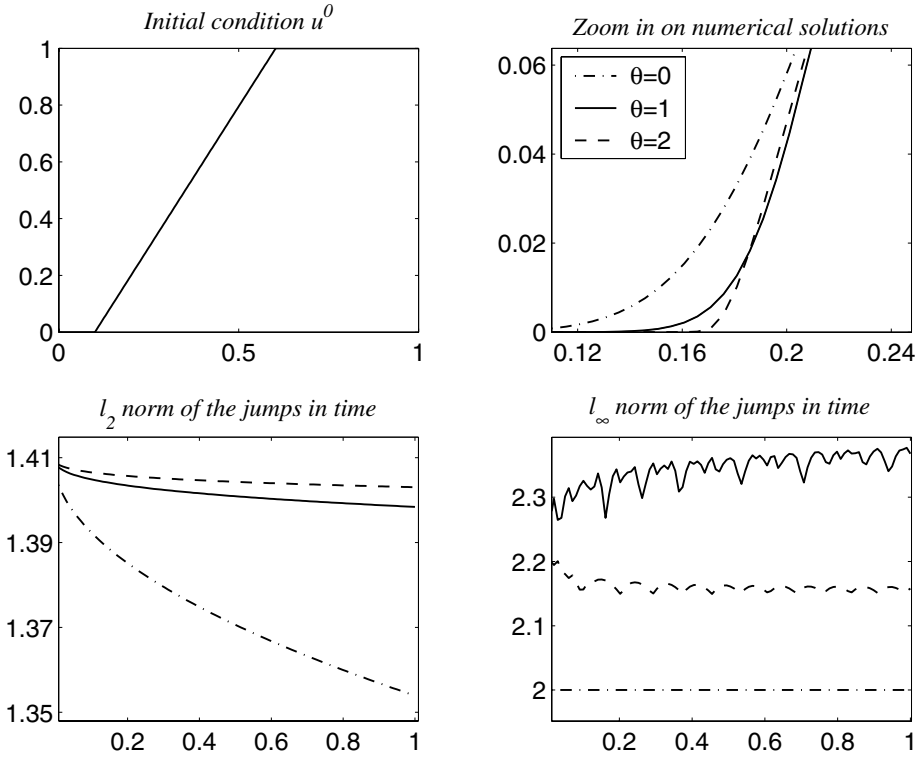

FIG. 5.1. $u_t + 0.5\, u_x = 0$. *The solid line represents* $\theta = 1$, *the dashed line represents* $\theta = 2$, *and the dash-dotted line stands for* $\theta = 0$, *the staggered LxF scheme. The values we used are* $\Delta x = 0.005$, $\lambda = 0.15$, *final time* $T = 0.15$, *and the flux is* $f(u) = 0.5u$.

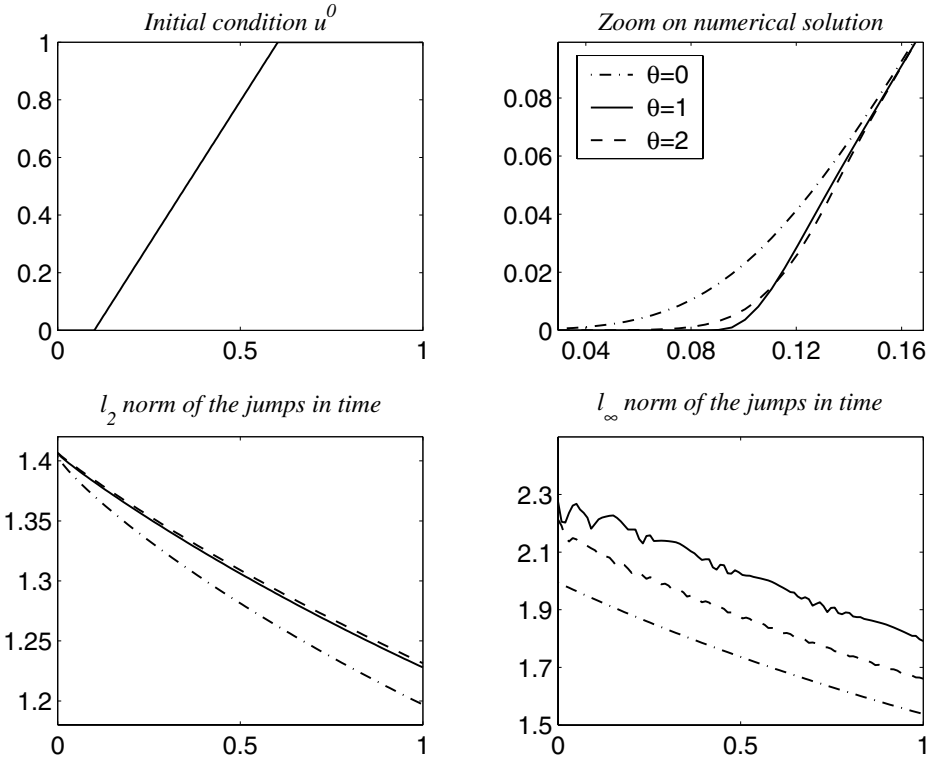

FIG. 5.2. $u_t + (0.5\,u^2)_x = 0$.

and the monotonicity of the l_2 norm for $\theta = 1, 2$.

The presence of shocks or local extrema in the initial data will only make the decrease of the l_2 norm of the jumps faster in the beginning, and then for large time the l_2 norm will decrease very slowly again. In some sense, the total amount of numerical diffusion is given in the decrease of the l_2 norm. In the so-called second-order methods (like $\theta = 1, 2$), the amount of diffusion is much smaller than in first-order methods represented here by the LxF scheme ($\theta = 0$). We will address this issue in a different paper and use it to improve the error estimate for $\theta = 1$.

Example 2. Burgers' equation (see Figure 5.2). We consider the same initial data, numerical schemes, Δx, λ, and T, as in the first example. Note again the oscillatory behavior of the l_∞ norm and the monotonicity of the l_2 norm for $\theta = 1, 2$. This is a generic case of nondecreasing initial data which corresponds to a region of spreading of the characteristics.

The nonlinearity of the flux in such regions helps to decrease overall any norm of the jumps. In the case of a general initial condition, the l_2 norm of the jumps decreases in every region of rarefaction. That is, for convex flux numerical schemes decrease the *one-sided* l_2 norm of the jumps,

$$\sum_j (v_j^{n+1} - v_{j-1}^{n+1})_+^2 \le \sum_j (v_j^n - v_{j-1}^n)_+^2.$$

It is important to note that in the case of convex/concave flux extreme values separate the regions of rarefactions from the regions of shocks, and we observe numerically that

the l_2 norm of the jumps decreases in every interval where the numerical solution is nondecreasing/nonincreasing.

In the nonconvex case (at least one inflection point), the situation is quite different. In one interval of monotonicity we can have both shocks and rarefaction waves. In that case, the NT scheme with $\theta = 2$ converges to a wrong weak solution even for the Buckley–Leverett problem; see Example 3 in [8]. Our numerical tests show that the NT scheme gives a wrong solution to that problem for any value of $\theta \geq 1.2$ and in general it looks like the biggest reliable value of θ for a nonconvex flux is $\theta = 1$.

Acknowledgments. The authors are grateful to Ronald DeVore for his inspiring discussions and constant support. We also thank the anonymous referees. Their comments and suggestions helped improve the paper.

A MORTAR FINITE ELEMENT METHOD FOR FOURTH ORDER PROBLEMS IN TWO DIMENSIONS WITH LAGRANGE MULTIPLIERS*

LESZEK MARCINKOWSKI†

Abstract. A mortar finite element method with a new Lagrange multipliers space for clamped plate problems is discussed. In the subdomains a conforming Hsieh–Clough–Tocher (HCT) macro element defined on nonmatching triangulations is utilized. The main result of the paper is the proof of an inf-sup condition with new test spaces. Finally, an error bound for Lagrange multipliers is proved.

Key words. plate problem, mortar finite element method, Lagrange multipliers, inf-sup condition, mesh-dependent norm, domain decomposition

1. Introduction. The numerical approximation of partial differential equations is often a very difficult and challenging task. This problem can be solved by using supercomputers; however, their efficiency strongly depends on the utilization of specially adapted numerical algorithms. Domain decomposition methods form a group of such tools, which have been analyzed and successfully used in solving practical problems. One domain decomposition method is the mortar method which allows us to use discretizations of different types with independent discretization parameters in nonoverlapping subdomains. A general presentation of the mortar method in two and three dimensions for elliptic boundary value problems of second order can be found, e.g., in [8], [4], or [5]. In [4], [9], and [29], the mortar methods for second order elliptic problems with saddle point approach were discussed. The mortar approach for discretizations of fourth order elliptic problems was studied in [3], where locally spectral discretizations were utilized, in [21], [22] for discrete Kirchhoff triangle local discretizations, and in [28], [27] for local Hsieh–Clough–Tocher (HCT), reduced HCT, and Adini and Morley finite element discretizations, and some parallel algorithms for solving a discrete problem were considered in [26]. There are also many algorithms for solving problems obtained by the mortar method; cf. [18], [1], [2], [14], [17], and many others.

In this paper, we consider a certain mortar method for local HCT discretizations of plate problems. We introduce a new type of test mortar spaces that contain functions of lower regularity (discontinuous) and prove that they are as good as the ones considered in [28]. The new choice of the test mortar spaces is also due to the more feasible implementation; the mass matrices in the two mortar conditions have a simpler structure. Next we reformulate the mortar discrete problem into a saddle point problem and prove an inf-sup condition in two different norms. Similar types of spaces in the mortar condition have been used for second order elliptic problems in two dimensions in [29] and in three dimensions in [20].

In [4] an inf-sup condition in some trace norms defined on interface was proved for second order differential equations, and a few years later in [29] and [9] an inf-sup condition in mesh-dependent norms for second order elliptic problems was stated. We generalized their results to plate problems.

We restrict ourselves to the geometrically conforming version of the mortar method; i.e., the polygonal domain Ω is divided into polygonal subdomains Ω_i which form a coarse triangulation. Locally, in the subdomains the conforming finite element method, i.e., the HCT macro element (cf. [16]), is utilized.

We first introduce independent local discretizations in each subdomain. The two-dimensional triangulations of two neighboring subregions do not necessarily match on their common interface. Then a mortar technique for plate problems which is presented here requires the continuity of the solution at the vertices of subdomains and that the solution on the two neighboring subdomains satisfies two mortar conditions of the L^2 type. We propose two new Lagrange multiplier spaces. We give error bounds analogous to the results of [28]; see also [27].

We also reformulate the mortar discrete problem into a saddle point problem. Then a proper representation of multipliers is given, and error bounds for multipliers are proved in two types of norm, mesh-dependent and dual to proper trace spaces defined on interfaces. We generalize the results of [29], [9], [4], which were obtained for the mortar method for second order elliptic problems, to fourth order problems.

The outline of the paper is as follows. In section 2 we present a differential problem and discuss local discretization of HCT type and the mortar method. Section 3 is devoted to presenting new spaces and proving an error estimate of the mortar method with these new test spaces. Finally, in section 4 inf-sup conditions are proved in both types of norms, and an estimate of an error of Lagrange multipliers is shown.

In the paper the following notation is used: $u \asymp v$, $x \succeq y$, and $w \preceq z$ mean that there exist positive constants c and C independent of the parameter of the fine triangulation of any substructure, and the number of subdomains is such that

$$c\,u \le v \le C\,u, \quad x \ge c\,y, \quad \text{and} \quad w \le C\,z, \ \text{respectively.}$$

2. Discrete problem. Let Ω be a polygonal domain in $\mathbf{R}^2$. The differential problem is to find $u^* \in H_0^2(\Omega)$ such that

$$a(u^*, v) = \int_\Omega f v \, dx \quad \forall v \in H_0^2(\Omega), \tag{2.1}$$

where u^* is the displacement, $f \in L^2(\Omega)$ is the body force, and

$$a(u,v) = \int_\Omega \left[\triangle u \triangle v + (1-\nu)\left(2u_{x_1x_2}v_{x_1x_2} - u_{x_1x_1}v_{x_2x_2} - u_{x_2x_2}v_{x_1x_1}\right)\right] dx.$$

Here

$$H_0^2(\Omega) = \{v \in H^2(\Omega) : \ v = \partial_n v = 0 \ \text{ on } \ \partial\Omega\},$$

∂_n is the normal unit derivative outward to $\partial\Omega$, and $u_{x_ix_j} := \frac{\partial^2 u}{\partial x_i \partial x_j}$ for $i,j = 1,2$. The Poisson ratio ν satisfies $0 < \nu < 1/2$. The Lax–Milgram theorem, utilizing the continuity and ellipticity of the bilinear form $a(\cdot,\cdot)$, yields the existence and the uniqueness of the solution; see, e.g., [11] or [16].

Let Ω be a union of nonoverlapping polygonal subdomains that are arbitrary, i.e.,

$$\overline{\Omega} = \bigcup_{k=1}^{N} \overline{\Omega}_k \ \text{ with } \ \Omega_k \cap \Omega_l = \emptyset, \ \ k \neq l.$$

We assume that the intersection of boundaries of two different subdomains $\partial\Omega_k \cap \partial\Omega_l, k \neq l$, is either the empty set, a vertex, or a common edge. Thus $\{\Omega_k\}$ forms a decomposition of Ω that we call the coarse triangulation with a parameter $H = \max_k H_k$, where $H_k = \operatorname{diam} \Omega_k$. We assume the shape regularity of that decomposition; e.g., cf. section 2, p. 5 in [10]. In the mortar method the interface $\overline{\Gamma} = \bigcup_{k=1}^{N} \overline{\partial\Omega_k \setminus \partial\Omega}$ plays an important role.

We triangulate each subdomain Ω_k into nonoverlapping triangles. We denote an element of this triangulation by τ. We assume that the arising fine triangulation $T_h(\Omega_k)$ is quasi-uniform with parameter $h_k = \max(\operatorname{diam} \tau)$ for $\tau \in T_h(\Omega_k)$; cf. [11].

We now introduce the mortar method that locally uses the HCT macro element; cf. Chapter 7, section 46, p. 279 in [16]. The local finite element space $X_h(\Omega_k)$ is defined by

$$\begin{aligned} X_h(\Omega_k) = \{ v \in C^1(\Omega_k) : \ \ & v_{|\tau} \in P_3(\tau_i) \ \text{ for triangles } \ \tau_i, \ \ i = 1,2,3, \\ & \text{formed by connecting the vertices of } \ \tau \in T_h(\Omega_k) \\ & \text{to its centroid, and } \ v = \partial_n v = 0 \ \text{ on } \ \partial\Omega_k \cap \partial\Omega \}; \end{aligned}$$

cf. [16] and Figure 2.1.

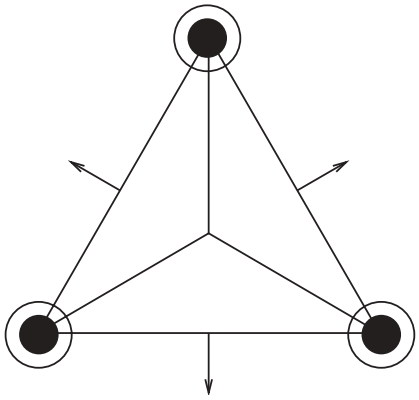

FIG. 2.1. *HCT macro element.*

The degrees of freedom of the HCT element are the following ones: $\{v(p), v_{x_1}(p), v_{x_2}(p), \partial_n v(m)\}$, where p is a vertex of an element and m is a midpoint of an edge of an element (cf. Figure 2.1).

The space $X_h(\Omega_k)$ is equipped with a local bilinear form defined by

$$a_k(u,v) = \int_{\Omega_k} \left[\triangle u \triangle v + (1-\nu) \left(2 u_{x_1 x_2} v_{x_1 x_2} - u_{x_1 x_1} v_{x_2 x_2} - u_{x_2 x_2} v_{x_1 x_1} \right) \right] dx.$$

We next define two global spaces $\tilde{X}_h(\Omega) = \prod_{k=1}^{N} X_h(\Omega_k)$ and its subspace $X_h(\Omega)$ of functions continuous at crosspoints, i.e., at common vertices of subdomains. We

also introduce a bilinear form $a_H(u,v) = \sum_{k=1}^N a_k(u,v)$, a so-called broken norm $\|u\|^2_{H^2_H(\Omega_k)} = \sum_{k=1}^N \|u\|^2_{H^2(\Omega_k)}$, and a broken seminorm $|u|^2_{H^2_H(\Omega_k)} = \sum_{k=1}^N |u|^2_{H^2(\Omega_k)}$.

For each interface $\overline{\Gamma}_{kl} = \partial\Omega_k \cap \partial\Omega_l$, we choose one side as a master (mortar) denoted by $\gamma_{kl} \subset \partial\Omega_k$ and the second one as a slave $\delta_{lk} \subset \partial\Omega_l$. Here the choice of the master side is arbitrary. Thus each interface $\overline{\Gamma}_{kl} = \partial\Omega_k \cap \partial\Omega_l$ has two independent one-dimensional triangulations, the first h_l one: $T^l_h(\delta_{lk})$ inherited from the two-dimensional triangulation of Ω_l and the second h_k one: $T^k_h(\gamma_{kl})$ inherited from the two-dimensional one of Ω_k.

We also introduce an additional notation: Let the set of all vertices of elements of the triangulation of Ω_k, $\overline{\Omega}_k$ $\partial\Omega_k$ and γ_{kl}, δ_{lk} be denoted by $\Omega_{k,h}$, $\overline{\Omega}_{k,h}$, $\partial\Omega_{k,h}$, $\gamma_{kl,h}$, and $\delta_{lk,h}$, respectively.

To properly define a mortar method we have to introduce two test spaces defined on a slave $\delta_{lk} \subset \Gamma$: $M^{1,h_l}(\delta_{lk})$ associated with tangential traces of functions from $X_h(\Omega_l)$ and $M^{2,h_l}(\delta_{lk})$ corresponding to normal traces. We will consider a new type of spaces; cf. [29] for the case of mortar method for second order elliptic equations. The test spaces will be defined below; see section 3.

We say that $u_k \in X_h(\Omega_k)$ and $u_l \in X_h(\Omega_l)$ for $\partial\Omega_l \cap \partial\Omega_k = \overline{\Gamma}_{kl}$ satisfy the mortar conditions if

$$\int_{\delta_{lk}} (u_k - u_l)\psi \, ds = 0 \quad \forall \psi \in M^{1,h_l}(\delta_{lk}) \tag{2.2}$$

and

$$\int_{\delta_{lk}} (\partial_n u_k - \partial_n u_l)\psi \, ds = 0 \quad \forall \psi \in M^{2,h_l}(\delta_{lk}). \tag{2.3}$$

We now define a space V^h as the subspace of $X_h(\Omega)$ formed by functions which satisfy the mortar conditions (2.2) and (2.3) on each interface $\Gamma_{kl} = \delta_{lk} = \gamma_{kl}$. Note that V^h contains functions which are continuous at the crosspoints. This is a technical requirement used in the proof of Lemma 3.14; cf. (3.6).

The discretization of (2.1) in V^h is of the form:
Find $u^*_h \in V^h$ such that

$$a_H(u^*_h, v) = \int_\Omega fv \, dx \quad \forall v \in V^h. \tag{2.4}$$

We now formulate our problem as a saddle point problem. We introduce a new discrete Hilbert space $M_h(\Gamma) = M_1(\Gamma) \times M_2(\Gamma)$ and a bilinear form $b(\cdot,\cdot) : X_h(\Omega) \times M_h(\Gamma) \to \mathbf{R}$, where

$$M_1(\Gamma) = \prod_{\delta_{ji} \subset \Gamma} M^{1,h_j}(\Gamma_{ij}) \ \text{ and } \ M_2(\Gamma) = \prod_{\delta_{ji} \subset \Gamma} M^{2,h_j}(\Gamma_{ij})$$

and

$$b(\psi, u) = \sum_{\delta_{ji} \subset \Gamma} \left(\int_{\Gamma_{ij}} [u]\psi_1 \, ds + \int_{\Gamma_{ij}} [\partial_n u]\psi_2 \, ds \right) \quad \forall u \in X_h(\Omega), \ \ \forall \psi \in M_h(\Gamma).$$

Here $[\cdot]$ is a jump across $\Gamma_{ij} = \delta_{ji} = \gamma_{ij}$, $u = (u_1, \ldots, u_N)$ and $\psi = (\psi_1, \psi_2)$. Then the new problem is to find a pair $(u^*_h, \lambda^*_h) \in X_h(\Omega) \times M_h(\Gamma)$ such that

$$\begin{aligned} a_H(u^*_h, v) + b(\lambda^*_h, v) &= (f, v) \quad \forall v \in X_h(\Omega), \\ b(\psi, u^*_h) &= 0 \qquad \forall \psi \in M_h(\Gamma). \end{aligned} \tag{2.5}$$

We prove below that this problem has a unique solution.

The second equation in (2.5) is equivalent to the mortar conditions (2.2) and (2.3). Thus we have

$$V^h = \{u \in X_h(\Omega) : b(\psi, u) = 0 \ \ \forall \psi \in M_h(\Gamma)\},$$

and the first term of a solution of (2.5) is also a solution of (2.4) and vice versa.

3. New Lagrange multiplier spaces. In this section we introduce a new type of mortar test space for the mortar methods for fourth order problem.

3.1. A new tangential test space. Let $W^{1,h_j}(\Gamma_{ij})$ be the space of traces (tangential) of $X_h(\Omega_j)$ onto δ_{ji} and $W_0^{1,h_j}(\Gamma_{ij}) = H_0^2(\Gamma_{ij}) \cap W^{1,h_j}(\Gamma_{ij})$. We introduce natural nodal bases of them. Basis functions of $W^{1,h_j}(\Gamma_{ij})$ and $W_0^{1,h_j}(\Gamma_{ij})$ are defined by

$$\phi^0_{1,p}(q) = \begin{cases} 1 & p = q, \\ 0 & p \neq q, \end{cases} \quad \partial_s \phi^0_{1,p}(q) = 0,$$

$$\partial_s \phi^1_{1,p}(q) = \begin{cases} 1 & p = q, \\ 0 & p \neq q, \end{cases} \quad \phi^1_{1,p}(q) = 0$$

for $p, q \in \overline{\delta}_{ij,h}$, and $\delta_{ji,h}$, respectively. Here ∂_s is the tangential derivative. We now introduce a mortar test space $M^{1,h}(\delta_{ji}) = \mathrm{Span}\{\theta^0_{1,p}, \theta^1_{1,p} : p \in \delta_{ji,h}\}$ for each interface $\Gamma_{ij} = \gamma_{ij} = \delta_{ji}$. It should be contained in the dual space of $H^{3/2}(\Gamma_{ij})$. The definition of our tangential space is quite simple, namely, let $M^{1,h}(\delta_{ji}) = \mathrm{Span}\{\theta^0_{1,p}, \theta^1_{1,p} : p \in \delta_{ji,h}\}$, where

$$\theta^0_{1,p}(s) = \begin{cases} 1 & \text{for} \quad s \in [m_l, m_r] \\ 0 & \text{for} \quad s \in \overline{\delta}_{ij} \setminus [m_l, m_r] \end{cases},$$

and (cf. Figures 3.1 and 3.2)

$$\theta^1_{1,p}(s) = \begin{cases} (s-p) & \text{for} \quad s \in [m_l, m_r] \\ 0 & \text{for} \quad s \in \overline{\delta}_{ij} \setminus [m_l, m_r] \end{cases}.$$

Here m_l and m_r are the right and left neighboring midpoints of a nodal point p. In the case of a nodal point p next to an end of this slave, we take the respective end instead of m_l in the case of the left end and m_r in the case of the right one. We have $\dim M^{1,h}(\delta_{ji}) = \dim W_0^{1,h_j}(\delta_{ji})$. This property is a very important one.

Note that the space $M^{1,h}(\delta_{ji})$ is much simpler than the one introduced in [28].

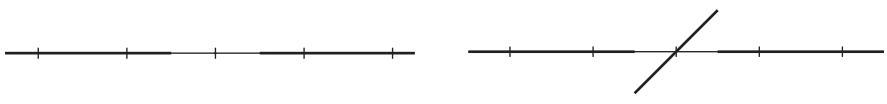

FIG. 3.1. *Tangential basis—interior nodal functions.*

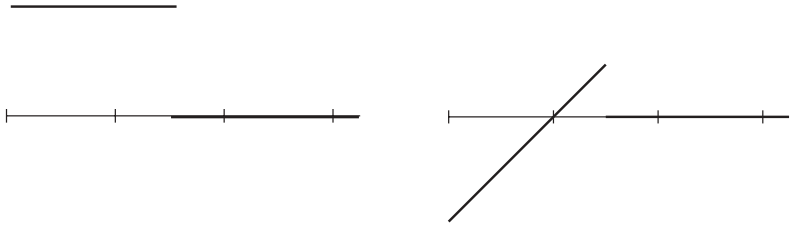

FIG. 3.2. *Tangential basis—near left endpoint of* δ_{ji}.

Let us consider a segment $[0,2]$, the standard cubic Hermitian interpolation basis on this segment, i.e., four functions $\phi_0(x) = 0.25 * (1+x) * (x-2)^2$, $\phi_1(x) = 0.25 * x * (x-2)^2$, $\phi_2(x) = 0.25 * x^2 * (3-x)$, and $\phi_3(x) = 0.25 * x^2 * (x-2)$, and four functions

$$\theta_0(s) = \begin{cases} 1 & \text{for} \quad s \in [0,1] \\ 0 & \text{for} \quad s \in (1,2] \end{cases}, \quad \theta_1(s) = \begin{cases} s & \text{for} \quad s \in [0,1] \\ 0 & \text{for} \quad s \in (1,2] \end{cases},$$

$$\theta_2(s) = \begin{cases} 0 & \text{for} \quad s \in [0,1] \\ 1 & \text{for} \quad s \in (1,2] \end{cases}, \quad \theta_3(s) = \begin{cases} 0 & \text{for} \quad s \in [0,1] \\ s-2 & \text{for} \quad s \in (1,2] \end{cases}.$$

Now we consider a 4×4 matrix $\mathbf{A} = \{\int_0^2 \phi_i \theta_j \, ds\}_{ij}$. We obtain

$$\mathbf{A} = 0.25 * \begin{pmatrix} 13/4 & 29/20 & 3/4 & -11/20 \\ 11/12 & 8/15 & 5/12 & -3/10 \\ 3/4 & 11/20 & 13/4 & -29/20 \\ -5/12 & -3/10 & -11/12 & 8/15 \end{pmatrix}.$$

Simple computation shows that the matrix $(\mathbf{A^T} + \mathbf{A})/2$ is symmetric and positive definite, which is equivalent to

$$(\mathbf{A}\mathbf{u}, \mathbf{u})_{\mathbf{R}^4} > 0 \ \ \forall \mathbf{u} \in \mathbf{R}^4, \ \mathbf{u} \neq 0. \tag{3.1}$$

From this follows a proposition.

PROPOSITION 3.1. *For any* $\tilde{w} = \sum_{p \in \delta_{ji,h}} (w(p)\theta^0_{1,p} + w'(p)\theta^1_{1,p}) \in M^{1,h_j}(\delta_{ji})$ *corresponding to* $w = \sum_{p \in \delta_{ji,h}} (w(p)\phi^0_{1,p} + w'(p)\phi^1_{1,p}) \in W_0^{1,h_j}(\delta_{ji})$ *it holds that*

$$\|w\|^2_{L^2(\delta_{ji})} \asymp \|\tilde{w}\|^2_{L^2(\delta_{ji})} \asymp \int_{\delta_{ji}} w\tilde{w} \, ds.$$

Proof. We show a spectral equivalence of the mass matrices that also proves our proposition: For any vector $\mathbf{w} = (\mathbf{w_0}, \mathbf{w_1})^\mathbf{T}$ corresponding to a function $w = \sum_{p \in \delta_{ji,h}} (w(p)\phi^0_{1,p} + w'(p)\phi^1_{1,p}) \in W_0^{1,h_j}(\delta_{ji})$ it holds that

$$(\mathbf{D}_1\mathbf{w}, \mathbf{w}) \preceq (\mathbf{W}_{1,0}\mathbf{w}, \mathbf{w}) \preceq (\mathbf{M}_1\mathbf{w}, \mathbf{w}) \preceq (\mathbf{D}_1\mathbf{w}, \mathbf{w}),$$

where

$$\mathbf{D}_1 = \begin{pmatrix} \mathbf{D}_{00} & 0 \\ 0 & \mathbf{D}_{11} \end{pmatrix}, \qquad \mathbf{W}_{1,0} = \begin{pmatrix} \mathbf{W}_{00} & 0 \\ 0 & \mathbf{W}_{11} \end{pmatrix}, \qquad \mathbf{M}_1 = \begin{pmatrix} \mathbf{M}_{00} & \mathbf{M}_{01} \\ \mathbf{M}_{10} & \mathbf{M}_{11} \end{pmatrix}$$

for the block diagonal matrices $\mathbf{D}_{kk} = \mathrm{diag}\{\int_{\Gamma_{ij}} (\theta^k_{1,p})^2\, ds\}_{p\in\delta_{ji,h}}$, $\theta^k_{1,p} \in M^{1,h_j}(\delta_{ji})$, and $\mathbf{W}_{kk} = \mathrm{diag}\{\int_{\Gamma_{ij}} (\phi^k_{1,p})^2\, ds\}_{p\in\delta_{ji,h}}$, $\phi^k_{1,p} \in W_0^{1,h_j}(\delta_{ji})$, and for matrices $\mathbf{M}_{kl} = \{\int_{\Gamma_{ij}} \phi^l_{1,p}\theta^k_{1,q}\, ds\}_{p,q\in\delta_{ji,h}}$ for $k, l = 0, 1$.

We first introduce local matrices associated with an element $e \in T^j_h(\delta_{ji})$ and obtained by integrating over this element. Let us define $\mathbf{W}_{kk|e} = \mathrm{diag}\{\int_e (\phi^k_{1,p})^2 ds\}_{p\in\delta_{ji,h}}$, $\mathbf{D}_{kk|e} = \mathrm{diag}\{\int_e (\theta^k_{1,p})^2\, ds\}_{p\in\delta_{ji,h}}$, and $\mathbf{M}_{kl|e} = \{\int_e \phi^l_{1,p}\theta^k_{t,q}\, ds\}_{p,q\in\delta_{ji,h}}$ for $k, l = 0, 1$. We have

$$\mathbf{D}_1 = \sum_{e\in T^j_h(\delta_{ji})} \mathbf{D}_e, \quad \mathbf{W}_{1,0} = \sum_{e\in T^j_h(\delta_{ji})} \mathbf{W}_e, \quad \mathbf{M}_1 = \sum_{e\in T^j_h(\delta_{ji})} \mathbf{M}_e.$$

Then note that

$$(\mathbf{D}_1\mathbf{u}, \mathbf{u}) = \sum_{e\in T^j_h(\delta_{ji})} (\mathbf{D}_e\mathbf{u}, \mathbf{u}), \quad (\mathbf{W}_{1,0}\mathbf{u}, \mathbf{u}) = \sum_{e\in T^j_h(\delta_{ji})} (\mathbf{W}_e\mathbf{u}, \mathbf{u}),$$

$$(\mathbf{M}_1\mathbf{u}, \mathbf{u}) = \sum_{e\in T^j_h(\delta_{ji})} (\mathbf{M}_e\mathbf{u}, \mathbf{u}).$$

The equivalence of $\mathbf{W_e}$ and $\mathbf{D}_e$ is obvious. We have to prove a spectral equivalence of $\mathbf{M}_e$ and $\mathbf{D}_e$. Moving to reference element $[0, 2]$ and utilizing (3.1) (in the case of element e not touching endpoints of δ_{ji}) and Lemma 5, section 4.1, p. 375 in [28] (in the case of end-elements), together with a scaling argument, yields the following bound $(\mathbf{D}_e\mathbf{u}, \mathbf{u}) \preceq (\mathbf{M}_e\mathbf{u}, \mathbf{u})$. The upper bound is obvious. ∎

Additionally we get an approximation property of this space in a standard way.

PROPOSITION 3.2. *The tangential space $M^{1,h}(\delta_{ji})$ has the following approximation property:*

$$\inf_{\psi\in M^{1,h_j}(\Gamma_{ij})} \|u - \psi\|_{L^2(\Gamma_{ij})} \preceq h_j^s |u|_{H^s(\Gamma_{ij})} \quad \forall u \in H^s(\Gamma_{ij}),$$

for $s = 0, \frac{1}{2}, 1, \frac{3}{2}, 2$.

Proof. The proof is standard for $s = 0, 1, 2$ (i.e., for $s = 1, 2$ the square of the L^2 norm over Γ_{ij} is represented as a sum of integrals over disjoint segments $[m_l, m_r]$ (notation as in the definition of $M^{1,h_j}(\delta_{ji})$)), and then using a scaling argument and a quotient space argument (cf., e.g., [16]) ends the proof of the case $s = 1, 2$. Next a Hilbertian interpolation argument yields the proper estimate for remaining cases. ∎

Remark 1. From the proof it can be seen that the statement of Proposition 3.2 can be extended to all $s \in [0.2]$, but in our paper we need only the result of that proposition.

3.2. A normal test space. As in the previous subsection, let $W^{2,h_j}(\Gamma_{ij})$ be the space of traces of normal derivatives of $X_h(\Omega_j)$ onto δ_{ji}, and let $W_0^{2,h_j}(\Gamma_{ij}) = H_0^1(\Gamma_{ij}) \cap W^{2,h_j}(\Gamma_{ij})$. That is, $W^{2,h_j}(\Gamma_{ij})$ is a space of all continuous piecewise quadratic functions on the h_j triangulation of δ_{ji}.

Let $\overline{\delta}_{ji,h/2}$ be the union of $\overline{\delta}_{ji,h}$ and of all midpoints of elements of the h_j triangulation of δ_{ji}, and let $\delta_{ji,h/2} = \overline{\delta}_{ji,h/2} \setminus \partial\delta_{ji}$; i.e., $\delta_{ji,h/2}$ is equal to $\overline{\delta}_{ji,h/2}$ minus the

ends of δ_{ji}. Then, we introduce a standard nodal basis of $W^{2,h_j}(\Gamma_{ij})$ and $W_0^{2,h_j}(\Gamma_{ij})$ as follows: Let

$$\phi_{2,p}(q) = \begin{cases} 1 & p = q, \\ 0 & p \neq q \end{cases} \tag{3.2}$$

for $p, q \in \overline{\delta}_{ji,h/2}$ and $\delta_{ji,h/2}$, respectively.

We now introduce a mortar test space $M^{2,h}(\delta_{ji}) = \mathrm{Span}\{\theta_{2,p},: p \in \delta_{ji,h/2}\}$ for each interface $\Gamma_{ij} = \gamma_{ij} = \delta_{ji}$ which should be contained in $(H^{1/2}(\Gamma_{ij}))'$. We take the one which already has been introduced in [30] where a mortar method for second order elliptic problems was considered. We define basis function of $M^{2,h_j}(\delta_{ji})$ as follows.

Let us first consider a nodal point $p \in \delta_{ji,h/2}$ which is in the closure of a left- or right-end element of δ_{ji}, respectively, denoted by $\overline{e}_l, \overline{e}_r$. Basis functions associated with such points (we have four such points) are defined in a special way: Let m_1 be a midpoint of the left-end element e_l and p_0, p_1, p_2, the three consecutive nodal points of $\delta_{ji,h}$, i.e., p_0, p_1 are the left and right neighbors of m_1, and p_0 is the left end of δ_{ji}; then

$$\theta_{2,m_1}(s) = \begin{cases} 2|p_0 - p_1|^{-1}|s - p_1| & \text{for} \quad s \in [p_0, p_1], \\ 0 & \text{for} \quad s \in \delta_{ji} \setminus [p_0, p_1], \end{cases}$$

and

$$\theta_{2,p_1}(s) = \begin{cases} |p_0 - p_1|^{-1}(2s - p_0 - p_1) & \text{for} \quad s \in [p_0, p_1], \\ \frac{1}{4}(2 + 4\phi_{2,p_1}(s) - 3\phi_{2,p_2}(s)) & \text{for} \quad s \in [p_1, p_2], \\ 0 & \text{for} \quad s \in \delta_{ji} \setminus [p_0, p_2], \end{cases}$$

respectively; cf. Figure 3.3. Here $\phi_{2,p}$ is a nodal basis function defined by (3.2). The two functions associated with two nodal points of $\delta_{ji,h/2}$ nearest to the right end of this slave are given analogously.

For the rest of the nodal points such that $p \in \delta_{ji,h}$ we set

$$\theta_{2,p}(s) = \begin{cases} \frac{1}{2}(5\phi_{2,p}(s) - 2) & \text{for} \quad s \in [p_l, p_r], \\ 0 & \text{for} \quad s \in \delta_{ji} \setminus [p_l, p_r], \end{cases}$$

and for $p \in \delta_{ji,h/2} \setminus \delta_{ji,h}$ (p is a midpoint) the function $\theta_{2,p}$ is defined by

$$\theta_{2,p}(s) = \begin{cases} \frac{1}{4}(2 - 3\phi_{2,p_l}(s) + 4\phi_{2,p_l}(s) - 3\phi_{2,p_l}(s)) & \text{for} \quad s \in [p_l, p_r], \\ 0 & \text{for} \quad s \in \delta_{ji} \setminus [p_l, p_r]. \end{cases}$$

Here $p_l, p_r \in \delta_{ji,h/2}$ are the left and right neighboring nodal points of $p \in \delta_{ji,h/2}$, respectively.

We have $\dim M^{2,h}(\delta_{ji}) = \dim W_0^{2,h_j}(\delta_{ji})$.

The two following propositions can be straightforwardly obtained from the results stated in section 1.2.4.3 in [30]; cf. also Properties (Sb), (Sd), and (Se) in section 1.2 in [30].

PROPOSITION 3.3. *The normal space $M^{2,h_j}(\Gamma_{ij})$ has the following approximation property:*

$$\inf_{\psi \in M^{2,h_j}(\Gamma_{ij})} \|u - \psi\|_{L^2(\Gamma_{ij})} \preceq h^s |u|_{H^s(\Gamma_{ij})} \ \ \forall u \in H^s(\Gamma_{ij}), \ \ s = 0, \frac{1}{2}, \frac{3}{2}.$$

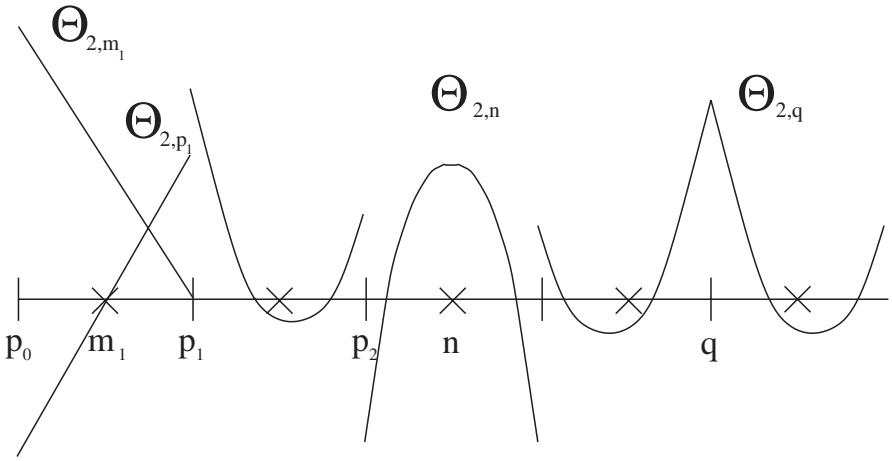

FIG. 3.3. *Normal basis functions.*

PROPOSITION 3.4. *For any* $u = \sum_{p\in\delta_{ji,h}} u(p)\phi_{2,p} \in W_0^{2,h_j}(\delta_{ji})$ *and the corresponding function* $\tilde{u} = \sum_{p\in\delta_{ji,h}} u(p)\theta_{2,p} \in M^{2,h_j}(\delta_{ji})$ *it holds that*

$$\|u\|^2_{L^2(\delta_{ji})} \asymp \|\tilde{u}\|^2_{L^2(\delta_{ji})} \asymp \int_{\delta_{ji}} u\tilde{u}\, ds.$$

3.3. Ellipticity of $a_H(\cdot,\cdot)$ in V^h. In this subsection we state an ellipticity property of $a_H(\cdot,\cdot)$ in V^h in the following proposition.

PROPOSITION 3.5. *For any* $u \in V^h$ *it holds that*

$$c\,\|u\|_{H^2_H(\Omega)} \le |u|_{H^2_H(\Omega)} \le C\,\|u\|_{H^2_H(\Omega)},$$

where c, C *are positive constants independent of* h_i *and the number of subdomains.*

Proof. Because Ω is bounded in $\mathbf{R^2}$ there exists a square $[a,b]\times[c,d]$ of the same diameter as Ω such that $\overline{\Omega} \subset [a,b]\times[c,d]$. Below we denote the extension of u to $[a,b]\times[c,d]$ by zero also by u. For any $(x_1,x_2) \in [a,b]\times[c,d]$

$$u_{x_1}(x_1,x_2) = \int_a^{x_1} u_{x_1x_1}(t,x_2)\,dt + \sum_{a_{kl}\in[a,x_1]\cap\Gamma_{kl}} [u_{x_1}](a_{kl},x_2),$$

where $[\cdot]$ denotes a jump over Γ_{kl} at point a_{kl}. Here a_{kl} is the common point of a segment $[a,x_1]$ and an interface $\Gamma_{kl} \subset \partial\Omega_k \cap \partial\Omega_l$.

By the Schwarz inequality we have

$$\int_a^{x_1} |u_{x_1x_1}(t,x_2)|\,dt \le \sqrt{\operatorname{diam}(\Omega)} \left(\int_a^b |u_{x_1x_1}(t,x_2)|^2\,dt\right)^{1/2}$$

and

$$\sum_{a_{kl}\in[a,x_1]\cap\Gamma_{kl}} |[u_{x_1}](a_{kl},x_2)| \le \left(\sum_{a_{kl}} |\Gamma_{kl}|\right)^{1/2} \left(\sum_{a_{kl}} |\Gamma_{kl}|^{-1} |[u_{x_1}](a_{kl},x_2)|^2\right)^{1/2}.$$

By the shape regularity of the division of Ω into substructures we obtain the estimate $\sum_{a_{kl}\in[a,b]\cap\Gamma_{kl}} |\Gamma_{kl}| \leq C_s\,|b-a|$, where the positive constant C_s depends only on the constant in the shape regularity condition, i.e., is independent of the number of subdomains; see Lemma 2.2 in [7].

Hence integrating over Ω, we get

$$|u|^2_{H^1_H(\Omega)} \preceq |u|^2_{H^2_H(\Omega)} + \sum_{\Gamma_{kl}\subset\Gamma} \frac{1}{|\Gamma_{kl}|} \int_{\Gamma_{kl}} [\partial_n u]^2 + [\partial_s u]^2\, ds.$$

We now have to estimate the second sum. By (2.3) the average values of $\partial_n u_k$ and $\partial_n u_l$ over interface Γ_{kl} are equal to each other. Thus the standard trace theorem and the Poincaré inequality yield that

$$\int_{\Gamma_{kl}} |\partial_n u_k - \partial_n u_l|^2\, ds \preceq \operatorname{diam}(\Omega_k)|u_k|^2_{H^2(\Omega_k)} + \operatorname{diam}(\Omega_l)|u_l|^2_{H^2(\Omega_l)}.$$

Note that $M^{1,h_l}(\delta_{lk})$ contains the space of linear polynomials. Thus by (2.2), a quotient space argument (see, e.g., Theorem 3.1.1, p. 115 in [15]), a scaling argument, and a trace theorem, we get

$$\int_{\Gamma_{kl}} |\partial_s u_k - \partial_s u_l|^2\, ds \preceq \operatorname{diam}(\Omega_k)|u_k|^2_{H^2(\Omega_k)} + \operatorname{diam}(\Omega_l)|u_l|^2_{H^2(\Omega_l)}.$$

Summing over all interfaces concludes the proof of the estimate of the H^1 seminorm. Here we used the fact that from the shape regularity assumption follows $\operatorname{diam}(\Omega_s) \preceq |\Gamma_{kl}|,\ s = k, l$.

The estimate of the L^2 norm can be proved in a similar way. ∎

As a direct consequence we have the following corollary.

COROLLARY 3.6. *The discrete problem* (2.4) *has a unique solution.*

3.4. Approximation property of V^h. In order to prove an approximation property of V^h we have to introduce two types of operators: the first one corresponds to normal parts of traces and was proposed in [30] (in more general form), and the other is associated with tangential traces.

DEFINITION 3.7. *Let* $\Pi^{(2)}_{ij} : L^2(\Gamma_{ij}) \to W_0^{2,h_j}(\delta_{ji})$ *be defined by*

$$\int_{\Gamma_{ij}} \Pi^{(2)}_{ij} uv\, ds = \int_{\Gamma_{ij}} uv\, ds \quad \forall v \in M^{2,h_j}(\delta_{ji}).$$

DEFINITION 3.8. *Let* $\Pi^{(1)}_{ij} : L^2(\Gamma_{ij}) \to W_0^{1,h_j}(\delta_{ji})$ *be defined by*

$$\int_{\Gamma_{ij}} \Pi^{(1)}_{ij} uv\, ds = \int_{\Gamma_{ij}} uv\, ds \quad \forall v \in M^{1,h_j}(\delta_{ji}).$$

We introduce $H^s_{00}(\Gamma_{ij}) = [L^2(\Gamma_{ij}), H^2_0(\Gamma_{ij})]_s$, a scale of Hilbertian interpolation spaces for $s \in [0,2]$. We note that $H^s_{00}(\Gamma_{ij}) = H^s(\Gamma_{ij})$ for $0 \leq s < 1/2$, specifically $H^0_{00}(\Gamma_{ij}) = L^2(\Gamma_{ij})$, and $H^1_{00}(\Gamma_{ij}) = H^1_0(\Gamma_{ij})$; cf. [24], [25]. The double zero in the subscript plays an important role only in the case of $s = 1/2$ and $3/2$.

We now state the most important properties of $\Pi^{(2)}_{ij}$ and $\Pi^{(1)}_{ij}$, namely, stability properties.

LEMMA 3.9. *An operator* $\Pi_{ij}^{(2)}$ *introduced in Definition* 3.7 *is well defined and satisfies*

$$\left\|\Pi_{ij}^{(2)}u\right\|_{H_{00}^s(\Gamma_{ij})} \preceq \|u\|_{H_{00}^s(\Gamma_{ij})} \quad \forall u \in H_{00}^s(\Gamma_{ij})$$

for $s \in [0,1]$.

The proof follows directly from Lemma 1.3 in [30]; cf. also section 1.2.4.1 in [30].

LEMMA 3.10. *An operator* $\Pi_{ij}^{(1)}$ *introduced in Definition* 3.8 *is well defined and, moreover, it holds that*

$$\left\|\Pi_{ij}^{(1)}u\right\|_{H_{00}^s(\Gamma_{ij})} \preceq \|u\|_{H_{00}^s(\Gamma_{ij})} \quad \forall u \in H_{00}^s(\Gamma_{ij})$$

for $s \in [0,2]$.

Proof. From Proposition 3.1 it follows that $\Pi_{ij}^{(1)}u$ is well defined for any $u \in L^2(\Gamma_{ij})$. Let $w = \Pi_{ij}^{(1)}u \in W_0^{1,h_j}(\Gamma_{ij})$ and $w = \sum_{l=0,1}\sum_{p\in\delta_{ji}} w^{(l)}\phi_{1,p}^l$ and define $\tilde{w} = \sum_{l=0,1}\sum_{p\in\delta_{ji}} w^{(l)}\theta_{1,p}^l \in M^{1,h_j}(\Gamma_{ij})$. Using Proposition 3.1 and Definition 3.8 we have

$$\begin{aligned}\|w\|_{L^2(\Gamma_{ij})}^2 &\asymp \int_{\Gamma_{ij}} w\tilde{w}\,ds = \int_{\Gamma_{ij}} u\tilde{w}\,ds \\ &\le \|u\|_{L^2(\Gamma_{ij})}\|\tilde{w}\|_{L^2(\Gamma_{ij})} \asymp \|u\|_{L^2(\Gamma_{ij})}\|w\|_{L^2(\Gamma_{ij})}.\end{aligned}$$

From this it follows that $\Pi_{ij}^{(1)}$ is well defined and stable in the L^2 norm.

We now prove the H_0^2 case. We have

$$\left|\Pi_{ij}^{(1)}u\right|_{H^2(\Gamma_{ij})} \le \left|\Pi_{ij}^{(1)}u - Q_{W_0^1}u\right|_{H^2(\Gamma_{ij})} + |Q_{W_0^1}u|_{H^2(\Gamma_{ij})},$$

where $Q_{W_0^1}$ is the standard $L^2(\Gamma_{ij})$ orthogonal projection onto $W_0^{1,h_j}(\Gamma_{ij})$ and it is a known fact that $Q_{W_0^1}$ is stable in the H^2 seminorm. Thus it suffices to estimate the first term. Utilizing an inverse inequality and the L^2 stability of $\Pi_{ij}^{(1)}$, we get

$$\begin{aligned}\left|\Pi_{ij}^{(1)}u - Q_{W_0^1}u\right|_{H^2(\Gamma_{ij})} &\preceq h_j^{-2}\left\|\Pi_{ij}^{(1)}u - Q_{W_0^1}u\right\|_{L^2(\Gamma_{ij})} \\ &= h_j^{-2}\left\|\Pi_{ij}^{(1)}(u - Q_{W_0^1}u)\right\|_{L^2(\Gamma_{ij})} \\ &\preceq h_j^{-2}\|u - Q_{W_0^1}u\|_{L^2(\Gamma_{ij})} \preceq |u|_{H^2(\Gamma_{ij})}.\end{aligned}$$

The last estimate follows from an approximation property of $Q_{W_0^1}$. We also used the the fact that $\Pi_{ij}^{(1)}$ is a projection (not orthogonal) onto $W_0^{1,h_j}(\Gamma_{ij})$. Using a Hilbertian interpolation argument ends the proof. ∎

LEMMA 3.11. *For any* $u \in H^4(\Omega) \cap H_0^2(\Omega)$, *it holds that*

$$\inf_{v\in V^h} |u - v|_{H_H^2(\Omega)}^2 \preceq \sum_{k=1}^N h_k^4 |u|_{H^4(\Omega_k)}^2.$$

The proof is similar to that of Lemma 4, section 4.1, p. 375 in [28]; therefore we omit some details.

Proof. Let $\tilde{u}$ be a function in $X_h(\Omega)$ (cf., e.g., Theorem 48.1, p. 296 in [16]), such that

$$|u-\tilde{u}_k|_{H^s(\Omega_k)} \preceq h_k^{4-s}|u|_{H^4(\Omega_k)}, \quad s=0,1,2. \tag{3.3}$$

We next define for each interface Γ_{ij} with the master γ_{ij} and respective slave δ_{ji} two functions: $w_{ji} = \Pi_{ij}^{(1)}(\tilde{u}_i - \tilde{u}_j)$ and $\partial_n w_{ji} = \Pi_{ij}^{(2)}(\partial_n \tilde{u}_i - \partial_n \tilde{u}_j)$. Here $\tilde{u}_i, \tilde{u}_j, \partial_n \tilde{u}_i, \partial_n \tilde{u}_j$ are respective traces onto the master γ_{ij} and the slave δ_{ji}. Then we define a global function $w \in X_h(\Omega)$ as follows: on a slave δ_{ji} we set $Tr\, w_{j|\delta_{ji}} = (w_{ji}, \partial_s w_{ji}, \partial_n w_{ji})$. Let Trw_j be equal to zero on all masters contained in $\partial\Omega_j$. We then define $w_j \in X_h(\Omega_j)$ as a discrete extension of Trw_j in $H^2(\Omega_j)$ such that

$$|w_j|_{H^2(\Omega_j)} \preceq |\nabla Trw_{|\partial\Omega_j}|_{H_{00}^{1/2}(\partial\Omega_j)};$$

cf. [12]. Then $v = \tilde{u} + w$ is in V^h, which follows from (2.2), (2.3), and Definitions 3.7 and 3.8. We have

$$|u-v|_{H_H^2(\Omega)} \le |u-\tilde{u}|_{H_H^2(\Omega)} + |w|_{H_H^2(\Omega)}.$$

Note that the first term was estimated by (3.3).

We now estimate the seminorm of w. We have

$$|w|^2_{H_H^2(\Omega)} \preceq \sum_{\Gamma_{ij}\subset\Gamma} \|\nabla w_j\|^2_{H_{00}^{1/2}(\delta_{ji})} \preceq \sum_{\Gamma_{ij}} \{\|\partial_s w_{ji}\|^2_{H_{00}^{1/2}(\delta_{ji})} + \|\partial_n w_{ji}\|^2_{H_{00}^{1/2}(\delta_{ji})}\}.$$

Thus by Lemmas 3.9 and 3.10 we have

$$|w|^2_{H_H^2(\Omega)} \preceq \sum_{\Gamma_{ij}\subset\Gamma} \|\nabla(\tilde{u}_i - \tilde{u}_j)\|^2_{H_{00}^{1/2}(\Gamma_{ij})} \preceq \sum_{\Gamma_{ij}\subset\Gamma} \sum_{k=i,j} \|\nabla(\tilde{u}_k - u)\|^2_{H_{00}^{1/2}(\Gamma_{ij})}.$$

Utilizing (3.3) and afterwards summing the resulting inequalities over all interfaces yields

$$|w|^2_{H_H^2(\Omega)} \preceq \sum_{\Gamma_{ij}\subset\Gamma} \left[h_i^4|u|^2_{H^4(\Omega_i)} + h_j^4|u|^2_{H^4(\Omega_j)}\right] \preceq \sum_{k=1}^{N} h_k^4|u|^2_{H^4(\Omega_k)}.$$

This concludes the proof. ∎

3.5. Consistency error. We first state two technical results.

LEMMA 3.12. *Let $Q_{1,ij}$ be the L^2 orthogonal projection onto the test space $M^{1,h_j}(\delta_{ji})$ defined on a slave $\delta_{ji} \subset \Gamma_{ij}$. Then, for $u \in H^r(\Gamma_{ij})$, it holds that*

$$h_j^s\|u - Q_{1,ij}u\|_{L^2(\Gamma_{ij})} + \|u - Q_{1,ij}u\|_{H^{-s}(\Gamma_{ij})} \preceq h_j^{s+r}|u|_{H^r(\Gamma_{ij})}, \quad s,r = \frac{1}{2}, \frac{3}{2}. \tag{3.4}$$

Proof. A proof of the estimate of the L^2 norm follows directly from Proposition 3.2. The estimates of the dual norms are proved using Proposition 3.2 and a duality trick:

$$\begin{aligned}
\|u - Q_{1,ij}u\|_{H^{-s}(\Gamma_{ij})} &= \sup_{\|\psi\|_{H^s(\Gamma_{ij})}\le 1} |(u - Q_{1,ij}u, \psi)| \\
&= \sup_{\|\psi\|_{H^s(\Gamma_{ij})}\le 1} |(u - Q_{1,ij}u, \psi - Q_{1,ij}\psi)| \\
&\le \sup_{\|\psi\|_{H^s(\Gamma_{ij})}\le 1} \|u - Q_{1,ij}u\|_{L^2(\Gamma_{ij})}\|\psi - Q_{1,ij}\psi\|_{L^2(\Gamma_{ij})} \\
&\preceq h_j^{s+r}|u|_{H^r(\Gamma_{ij})}.
\end{aligned}$$

The proof is complete. ∎

The next lemma states an analogous property of $Q_{2,ij}$, the L^2 orthogonal projection onto the normal space $M^{2,h_j}(\delta_{ji})$.

LEMMA 3.13. *Let $Q_{2,ij}$ be the L^2 orthogonal projection onto the test space $M^{2,h_j}(\delta_{ji})$ defined on a slave $\delta_{ji} \subset \Gamma_{ij}$. It holds that*

$$h_j^s \|u - Q_{2,ij}u\|_{L^2(\Gamma_{ij})} + \|u - Q_{2,ij}u\|_{H^{-s}(\Gamma_{ij})} \preceq h_j^{s+r} |u|_{H^r(\Gamma_{ij})}, \quad s, r = \frac{1}{2}, \frac{3}{2}. \tag{3.5}$$

The proof is very similar to the one of the previous lemma and follows from Proposition 3.3.

In the following lemma bounds for the consistency errors are given.

LEMMA 3.14. *Let u^*, a solution of (2.1), be in $H^4(\Omega) \cap H_0^2(\Omega)$. Then for $w \in V^h$ it holds that*

$$|a_H(u^* - u_h^*, w)| \preceq |w|_{H_H^2(\Omega)} \left(\sum_{k=1}^{N} h_k^4 |u^*|_{H^4(\Omega_k)}^2 \right)^{1/2},$$

where u_h^* is a solution of (2.4).

Proof. Using the Green's formulas (e.g., see (1.2.5) and (1.2.9), pp. 14–15 in [15]) and (2.4), we have

$$a_H(u^* - u_h^*, w) = a_H(u^*, w) - f(w) = \sum_{k=1}^{3} E_k(u^*, w),$$

where

$$E_1(u^*, w) = \int_\Gamma -\partial_n(\triangle u^*)[w]\, ds, \qquad E_2(u^*, w) = \int_\Gamma (1-\nu)\partial_n \partial_s u^* [\partial_s w]\, ds,$$

and

$$E_3(u^*, w) = \int_\Gamma (\triangle u^* - (1-\nu)\partial_s^2 u^*)[\partial_n w]\, ds.$$

We note that ∂_n, ∂_s are normal and tangential derivatives, while $[\cdot]$ is the jump across the interface Γ.

Utilizing the fact that $[w]$ is equal to zero at the ends of any interface Γ_{kl}, we obtain

$$E_2(u^*, w) = -\sum_{\Gamma_{ij}} (1-\nu) \int_{\Gamma_{ij}} \partial_s \partial_n \partial_s u^* [w]\, ds. \tag{3.6}$$

Let $E_0(u^*, w) = E_1(u^*, w) + E_2(u^*, w)$ and $E_0(u^*, w) = \int_\Gamma G_3 u^* [w]\, ds$, where $G_3 u^* = -\partial_n \triangle u^* - (1-\nu)\partial_s \partial_n \partial_s u^*$.

We now consider one interface Γ_{ij} which is equal geometrically to the mortar γ_{ij} and slave δ_{ji}. The mortar condition (2.2) yields that $Q_{1,ij} w_i = Q_{1,ij} w_j$ and

$$\begin{aligned} \int_{\Gamma_{ij}} G_3 u^* [w]\, ds &= \int_{\Gamma_{ij}} \left((I - Q_{1,ij}) G_3 u^* \right) [w]\, ds \\ &\preceq \|(I - Q_{1,ij}) G_3 u^*\|_{H^{-3/2}(\Gamma_{ij})} \left(\sum_{k=i,j} |w_k|_{H^{3/2}(\Gamma_{ij})} \right). \end{aligned}$$

Using the Schwarz inequality, Lemma 3.12, and the standard trace theorem (e.g., cf. Theorem 1.5.2.1, p. 42 in [19]), we have

$$\int_{\Gamma_{ij}} G_3 u^*[w]\, ds \preceq h_j^2 |u^*|_{H^4(\Omega_j)} (|w_i|_{H^2(\Omega_i)} + |w_j|_{H^2(\Omega_j)}).$$

Summing over all interfaces yields the estimate of $E_0(u^*, w)$.

Let $G_2 u^* = \triangle u^* - (1-\nu)(\partial_s^2 u^*)$; then proceeding similarly to above and using (2.3) instead of (2.2) and Lemma 3.13 we obtain

$$\begin{aligned}\int_{\Gamma_{ij}} G_2 u^*[\partial_n w]\, ds &\le \|(I - Q_{2,ij}) G_2 u^*\|_{H^{-1/2}(\delta_{ji})} \left(\sum_{k=i,j} |\partial_n w_k|_{H^{1/2}(\delta_{ji})} \right) \\ &\preceq h_j^2 |G_2 u^*|_{H^{3/2}(\delta_{ji})} (|\partial_n w_i|_{H^{1/2}(\delta_{ji})} + |\partial_n w_j|_{H^{1/2}(\delta_{ji})}) \\ &\preceq h_j^2 |u^*|_{H^4(\Omega_j)} (|w_i|_{H^2(\Omega_i)} + |w_j|_{H^2(\Omega_j)}).\end{aligned}$$

Summing over all interfaces yields the estimate of $E_3(u^*, w)$.

The proof is complete. ∎

As a simple consequence of the second Strang lemma (see, e.g., Lemma 8.1.9, p. 198 in [11] or [6]), Lemmas 3.11 and 3.14, and Proposition 3.5 we get an optimal error estimate that is stated in the following theorem.

THEOREM 3.15. *Let u^* and u_h^*, the solutions of* (2.1) *and of* (2.4)*, respectively, be in $H_0^2(\Omega) \cap H^4(\Omega)$. Then it holds that*

$$\|u^* - u_h^*\|_{H_H^2(\Omega)} \preceq \left(\sum_{k=1}^N h_k^4 |u^*|_{H^4(\Omega_k)}^2 \right)^{1/2}. \tag{3.7}$$

4. Inf-sup condition. In this section we prove that under our assumptions an inf-sup condition holds for (2.5). An interpretation of Lagrange multipliers is given. We follow [4] and [9] where second order elliptic problems were considered.

We first introduce a space $X_{00}(\Omega) \subset \prod_{k=1}^N H_C^2(\Omega_k)$ as follows:

$$\begin{aligned}X_{00}(\Omega) = \Bigg\{ & v \in \prod_{k=1}^N H_C^2(\Omega_k) : v \text{ continuous at crosspoints}, \\ & [v] \in H_{00}^{3/2}(\Gamma_{ij}), \text{ and } [\partial_n v] \in H_{00}^{1/2}(\Gamma_{ij}) \ \forall \Gamma_{ij} \subset \Gamma \Bigg\},\end{aligned} \tag{4.1}$$

where

$$H_C^2(\Omega_k) = \{ v \in H^2(\Omega_k) : v = \partial_n v = 0 \text{ on } \partial\Omega \cap \partial\Omega_k \}.$$

Remark 2. The space $X_{00}(\Omega)$ is not closed in the norm $\|\cdot\|_{H_H^2(\Omega)}$. The proof is very similar to that of Remark 2.1 in [9].

Therefore the space $X_{00}(\Omega)$ is endowed with the following norm:

$$\|v\|_X^2 = \|v\|_{H_H^2(\Omega)}^2 + \sum_{\Gamma_{ij} \subset \Gamma} \left\{ \|[v]\|_{H_{00}^{3/2}(\Gamma_{ij})}^2 + \|[\partial_n v]\|_{H_{00}^{1/2}(\Gamma_{ij})}^2 \right\}. \tag{4.2}$$

We have the following proposition.

PROPOSITION 4.1. *The space $X_{00}(\Omega)$ endowed with the norm $\|\cdot\|_X$ is complete; moreover, the following continuous embedding holds:*

$$H_0^2(\Omega) \subset X_{00}(\Omega) \subset \prod_{k=1}^{N} H_C^2(\Omega).$$

This proposition is analogous to Remark 2.2 in [9], where the case of H^1 space is considered. The proof is also quite similar to that in [9]; therefore it is skipped.

The space $H_0^2(\Omega)$ can be described as a subspace of $X_{00}(\Omega)$ formed by all functions for which

$$\begin{aligned} {}_{H_{00}^{-3/2}(\Gamma_{ij})}\langle \mu_1, [v] \rangle_{H_{00}^{3/2}(\Gamma_{ij})} &= 0 \quad \forall \mu_1 \in H_{00}^{-3/2}(\Gamma_{ij}), \\ {}_{H_{00}^{-1/2}(\Gamma_{ij})}\langle \mu_2, [\partial_n v] \rangle_{H_{00}^{1/2}(\Gamma_{ij})} &= 0 \quad \forall \mu_2 \in H_{00}^{-1/2}(\Gamma_{ij}). \end{aligned} \tag{4.3}$$

Here $H_{00}^{-3/2}(\Gamma_{ij})$ and $H_{00}^{-1/2}(\Gamma_{ij})$ denote the dual spaces of $H_{00}^{3/2}(\Gamma_{ij})$ and $H_{00}^{1/2}(\Gamma_{ij})$, respectively.

We introduce a space of Lagrange multipliers $M(\Gamma) = \prod_{\Gamma_{ij}\subset\Gamma} H_{00}^{-3/2}(\Gamma_{ij}) \times H_{00}^{-1/2}(\Gamma_{ij})$ endowed with the norm

$$\begin{aligned} \|\psi\|_M^2 &= \sum_{\Gamma_{ij}\subset\Gamma} \|\psi_{|\delta_{ji}}\|^2_{H_{00}^{-3/2}(\Gamma_{ij})\times H_{00}^{-1/2}(\Gamma_{ij})} \\ &= \sum_{\Gamma_{ij}\subset\Gamma} \left\{ \|\psi_1\|^2_{H_{00}^{-3/2}(\Gamma_{ij})} + \|\psi_2\|^2_{H_{00}^{-1/2}(\Gamma_{ij})} \right\}. \end{aligned} \tag{4.4}$$

Let us consider a saddle point problem: Find a pair $(u^*, \lambda^*) \in X_{00}(\Omega) \times M(\Gamma)$ such that

$$\begin{aligned} a_H(u^*, v) + b(\lambda^*, v) &= (f, v) \ \ \forall v \in X_{00}(\Gamma), \\ b(\mu, u^*) &= 0 \ \ \forall \mu \in M(\Gamma), \end{aligned} \tag{4.5}$$

where

$$b(\mu, v) = \sum_{\Gamma_{ij}\subset\Gamma} {}_{H_{00}^{-3/2}(\Gamma_{ij})}\langle \mu_1, [v] \rangle_{H_{00}^{3/2}(\Gamma_{ij})} + {}_{H_{00}^{-1/2}(\Gamma_{ij})}\langle \mu_2, [\partial_n v] \rangle_{H_{00}^{1/2}(\Gamma_{ij})}$$

Then we have the following theorem.

THEOREM 4.2. *The problem* (4.5) *has a unique solution since the following inf-sup condition holds:*

$$\inf_{\psi\in M(\Gamma)\setminus\{0\}} \sup_{u\in X_{00}(\Omega)\setminus\{0\}} \frac{b(\psi, u)}{\|\psi\|_M \|u\|_X} \geq C. \tag{4.6}$$

Moreover, the first term of the solution of (4.5) *is also a solution of* (2.1) *and if we assume that the solution of* (2.1) u^* *is in* $H_0^2 \cap H^4(\Omega)$*, then*

$$\lambda^* = (\lambda_1^*, \lambda_2^*) = (-\partial_n \triangle u^* - (1-\nu)\partial_s \partial_n \partial_s u^*, \triangle u^* - (1-\nu)\partial_s^2 u^*) \ \text{ on } \ \Gamma_{ij} \subset \Gamma.$$

Proof. The last statement of the theorem follows from the Green's integral formulas; cf., e.g., [16].

We obviously have that $b(\cdot,\cdot)$ is continuous over $X_{00}(\Omega)\times M(\Gamma)$ and that $a_H(\cdot,\cdot)$ is continuous over $X_{00}(\Omega)$ and from (4.3) we see that $a_H(\cdot,\cdot)$ is elliptic over

$$H_0^2(\Omega)=\{v\in X_{00}(\Omega): b(\mu,v)=0\ \ \forall \mu\in M(\Gamma)\}.$$

Thus there is a unique $u^*\in H_0^2(\Omega)$ which is the first part of a solution of (4.5). In order to get the existence of the second part of this solution, the Babuška–Brezzi–Ladyzhenskaya condition has to be proved.

Let $\mu\in M(\Gamma)$, $\mu=\{\mu_{ij}\}_{\Gamma_{ij}\subset\Gamma}$ for $\mu_{ij}=(\mu_1,\mu_2)\in H_{00}^{3/2}(\delta_{ji})\times H_{00}^{1/2}(\delta_{ji})$. For each interface $\Gamma_{ij}\subset\Gamma$, with jth the slave side of Γ_{ij}, we introduce a function $w_{ij}\in H^2_{0,\Gamma_{ij}}(\Omega_j)$ as a unique solution of

$$a_j(w_{ij},v)=\int_{\Gamma_{ij}}\mu_1 v\,ds+\int_{\Gamma_{ij}}\mu_2\partial_n v\,ds\quad\forall v\in H^2_{0,\delta_{ji}}(\Omega_j). \tag{4.7}$$

Here $a_j(\cdot,\cdot)=a_{|\Omega_j}(\cdot,\cdot)$ is the restriction of bilinear form $a(\cdot,\cdot)$ to the subregion Ω_j,

$$H^2_{0,\delta_{ji}}(\Omega_j)=\{u\in H^2(\Omega_j): u=\partial_n u=0 \text{ on } \partial\Omega_j\setminus\delta_{ji}\}, \tag{4.8}$$

and $\int_{\Gamma_{ij}}\mu_1 v\,ds$ and $\int_{\Gamma_{ij}}\mu_2\partial_n v\,ds$ denote the dual pairs for $H_{00}^{3/2}(\Gamma_{ij})$ and $H_{00}^{1/2}(\Gamma_{ij})$, respectively. The standard trace and extension theorems yield that

$$\|\mu_{|\Gamma_{ij}}\|_{H_{00}^{-3/2}(\delta_{ji})\times H_{00}^{-1/2}(\delta_{ji})}\asymp\sup_{|u|_{H^2(\Omega)}=1}\left(\int_{\delta_{ji}}\mu_1 u\,ds+\int_{\delta_{ji}}\mu_2\partial_n u\,ds\right),$$

where sup is taken over $H^2_{0,\delta_{ji}}(\Omega_j)$. Thus

$$\begin{aligned}\|\mu_{|\Gamma_{ij}}\|^2_{H_{00}^{-3/2}(\Gamma_{ij})\times H_{00}^{-1/2}(\Gamma_{ij})}&\asymp |w_{ij}|^2_{H^2(\Omega_j)}\\&=\int_{\Gamma_{ij}}\mu_1 w_{ij}\,ds+\int_{\Gamma_{ij}}\mu_2\partial_n w_{ij}\,ds.\end{aligned} \tag{4.9}$$

Then, we define a function $w=\{\sum_{\delta_{ji}\subset\partial\Omega_j}w_{ij}\}_{j=1}^N$. We have $w\in X_{00}(\Omega)$ as $[w]=w_{ij}$ and $[\partial_n w]=\partial_n w_{ij}$ on Γ_{ij}. By this, the Friedrich's theorem, and trace theorems we have

$$\|w\|_X^2\preceq\sum_{\Gamma_{ij}\subset\Gamma}|w_{ij}|^2_{H^2(\Omega_j)}\preceq\sum_{\Gamma_{ij}\subset\Gamma}\|\mu_{|\Gamma_{ij}}\|^2_{H_{00}^{-3/2}(\Gamma_{ij})\times H_{00}^{-1/2}(\Gamma_{ij})}=\|\mu\|_M^2.$$

Then

$$\|\mu\|_M^2=\sum_{\Gamma_{ij}\subset\Gamma}\|\mu_{|\Gamma_{ij}}\|^2_{H_{00}^{-3/2}(\Gamma_{ij})\times H_{00}^{-1/2}(\Gamma_{ij})}\preceq b(\mu,w)\preceq b(\mu,w)\frac{\|\mu\|_M}{\|w\|_X}.$$

Thus the inf-sup condition is proved. We can conclude that there is a unique solution of (4.5); see [13]. ∎

We next prove the following theorem which gives us a discrete inf-sup condition.

THEOREM 4.3. *For problem* (2.5) *the following inf-sup condition holds:*

$$\inf_{\psi\in M_h(\Gamma)\setminus\{0\}}\sup_{u\in X_h(\Omega)\setminus\{0\}}\frac{b(\psi,u)}{\|\psi\|_M\|u\|_X}\geq C, \tag{4.10}$$

where C is a constant independent of any h_k and the number of subdomains.

Proof. Let us consider a function $\psi \in M_h(\Gamma)$ and $\psi_{ij} = (\psi_1, \psi_2) \in M_h(\delta_{ji})$, its restriction to an interface $\Gamma_{ij} = \delta_{ji} = \gamma_{ij}$. Here $H^2_{0,\delta_{ji}}(\Omega_j)$ was defined in (4.8). Next, as in the proof of the previous theorem, we introduce an auxiliary function $w = \{\sum_{\delta_{ji}\subset\partial\Omega_j} w_{ij}\}_{j=1}^N$, where w_{ij} is a function defined locally on Ω_j ($\delta_{ji} \subset \partial\Omega_j$), as a unique solution of (4.7) with μ_k replaced by ψ_k for $k = 1, 2$. Again we have

$$\|\psi_{ij}\|^2_{H_{00}^{-3/2}(\delta_{ji})\times H_{00}^{-1/2}(\delta_{ji})} \asymp |w_{ij}|^2_{H^2(\Omega_j)} = \int_{\delta_{ji}} w_{ij}\psi_1\, ds + \int_{\delta_{ji}} \partial_n w_{ij}\psi_2\, ds. \tag{4.11}$$

We now construct a discrete function $w_h = \{\sum_{\delta_{ji}\subset\partial\Omega_j} w_{h,ij}\}_{j=1}^N \in X_h(\Omega)$ associated with w.

We define $w_{h,ij}$ for $\delta_{ji} \subset \partial\Omega_j$ locally over Ω_j as follows:

$$\begin{cases} a_j(w_{h,ij}, v) = 0 & \forall v \in X_{0,h}(\Omega_j), \\ Tr\, w_{h,ij} = \left(\Pi^{(1)}_{ij} w_{ij}, \partial_s\left(\Pi^{(1)}_{ij} w_{ij}\right), \Pi^{(2)}_{ij}\partial_n w_{ij}\right) & \text{on } \delta_{ji}, \\ Tr\, w_{h,ij} = 0 & \text{on } \partial\Omega_j \setminus \delta_{ji}, \end{cases} \tag{4.12}$$

where $Tr\, v = (v_{|\partial\Omega_j}, \nabla v_{|\partial\Omega_j})$ for $v, \nabla v$—the H^2 traces of $v \in H^2(\Omega_j)$, and $X_{0,h}(\Omega_j) = X_h(\Omega_j) \cap H^2_0(\Omega_j)$.

Now from the Friedrich's inequality, the discrete extension theorem (see, e.g., [23]), Lemmas 3.10 and 3.9, and the standard trace theorem we obtain

$$\begin{aligned} \|w_{h,ij}\|^2_{H^2(\Omega_j)} &\preceq \left\|\partial_s\left(\Pi^{(1)}_{ij} w_{ij}\right)\right\|^2_{H_{00}^{1/2}(\delta_{ji})} + \left\|\Pi^{(2)}_{ij}\partial_n w_{ij}\right\|^2_{H_{00}^{1/2}(\delta_{ji})} \\ &\preceq \|\partial_s w_{ij}\|^2_{H_{00}^{1/2}(\delta_{ji})} + \|\partial_n w_{ij}\|^2_{H_{00}^{1/2}(\delta_{ji})} \preceq |w_{ij}|^2_{H^2(\Omega_j)}. \end{aligned} \tag{4.13}$$

Note that

$$[w_h] = w_{h,ij} \text{ and } [\partial_n w_h] = \partial_n w_{h,ij} \text{ on } \delta_{ji} \subset \Gamma.$$

Thus

$$\begin{aligned} \|[\partial_s w_h]\|^2_{H_{00}^{1/2}(\delta_{ji})} + \|[\partial_n w_h]\|^2_{H_{00}^{1/2}(\delta_{ji})} &= \|\partial_s w_{h,ij}\|^2_{H_{00}^{1/2}(\delta_{ji})} + \|\partial_n w_{h|\delta_{ji}}\|^2_{H_{00}^{1/2}(\delta_{ji})} \\ &\preceq |w_{ij}|^2_{H^2(\Omega_j)}. \end{aligned}$$

Then summing over all interfaces we have

$$\|w_h\|^2_X \preceq \sum_{\delta_{ji}\subset\Gamma} |w_{ij}|^2_{H^2(\Omega_j)} \preceq \|\psi\|^2_M. \tag{4.14}$$

We next see that by Definitions 3.7 and 3.8

$$\begin{aligned} \|\psi\|^2_M &\asymp \sum_{\delta_{ji}\subset\Gamma} \left\{ \int_{\delta_{ji}} w_{ij}\psi_1\, ds + \int_{\delta_{ji}} \partial_n w_{ij}\psi_2\, ds \right\} \\ &= \sum_{\delta_{ji}\subset\Gamma} \left\{ \int_{\delta_{ji}} \Pi^{(1)}_{ij} w_{ij}\psi_1\, ds + \int_{\delta_{ji}} \Pi^{(2)}_{ij}\partial_n w_{ij}\psi_2 \right\} ds \end{aligned}$$

$$= \sum_{\delta_{ji}\subset\Gamma} \left\{ \int_{\delta_{ji}} w_{h,ij}\psi_1 \, ds + \int_{\delta_{ji}} \partial_n w_{h,ij}\psi_2 \right\} ds = b(\psi, w_h)$$

$$\preceq b(\psi, w_h) \frac{\|\psi\|_M}{\|w_h\|_X}.$$

The proof is completed. □

We also consider the mesh-dependent norms and introduce a series of mesh-dependent norms defined on a single slave $\delta_{ji} \subset \partial\Omega_j$ for any $\psi \in L^2(\delta_{ji})$:

$$\|\psi\|^2_{s,h,\delta_{ji}} = h_j^{-2s} \|\psi\|^2_{L^2(\delta_{ji})}, \quad s \in \mathbf{R}. \tag{4.15}$$

Certainly, we have

$$(u, v)_{L^2(\delta_{ji})} \leq \|u\|_{-s,h,\delta_{ji}} \|v\|_{s,h,\delta_{ji}}.$$

Let the mesh-dependent norm on $M_h(\Gamma)$ be defined by

$$\begin{aligned} \|\psi\|^2_{M,h} &= \sum_{\delta_{ji}\subset(\Gamma)} \{\|\psi_{t|\delta_{ji}}\|^2_{-3/2,h,\delta_{ji}} + \|\psi_{n|\delta_{ji}}\|^2_{-1/2,h,\delta_{ji}}\} \\ &= \sum_{\delta_{ji}\subset(\Gamma)} \left\{ h_j^3 \|\psi_1\|^2_{L^2(\delta_{ji})} + h_j \|\psi_2\|^2_{L^2(\delta_{ji})} \right\}, \end{aligned} \tag{4.16}$$

while on $X_h(\Omega)$ by

$$\|u\|^2_{X,h} = \|u\|^2_{H^2_H(\Omega)} + \sum_{\delta_{ji}\subset\Gamma} \{\|[u_{|\delta_{ji}}]\|^2_{3/2,h,\delta_{ji}} + \|[\partial_n u_{|\delta_{ji}}]\|^2_{1/2,h,\delta_{ji}}\}. \tag{4.17}$$

The next theorem gives us a discrete inf-sup condition in the mesh-dependent norm $\|\cdot\|_{M,h}$.

THEOREM 4.4. *For problem* (2.5) *the following inf-sup condition holds:*

$$\inf_{\psi\in M_h(\Gamma)\setminus\{0\}} \sup_{u\in X_h(\Omega)\setminus\{0\}} \frac{b(\psi, u)}{\|\psi\|_{M,h}\|u\|_{X,h}} \geq C, \tag{4.18}$$

where C is a constant independent of any h_k and the number of subdomains.

Proof. For a slave δ_{ji} and a restriction of $\mu = (\mu_1, \mu_2) \in M_h(\Gamma)$ to δ_{ji} we introduce two functions $\tilde{\mu}_1 \in W_0^{1,h_j}(\delta_{ji})$ and $\tilde{\mu}_2 \in W_0^{2,h_j}(\delta_{ji})$.

With a function $\mu_1 = \sum_{l=0,1} \sum_{p\in\delta_{ji,h}} \mu_1^{(l)}(p)\theta^l_{1,p} \in M^{1,h_j}(\Gamma_{ij})$ we associate $\tilde{\mu}_1 = \sum_{l=0,1} \sum_{p\in\delta_{ji,h}} \mu_1^{(l)}(p)\phi^l_{1,p}$ and for $\mu_2 = \sum_{p\in\delta_{ji,h/2}} \mu_2(p)\theta_{2,p} \in M^{2,h_j}(\Gamma_{ij})$ we define $\tilde{\mu}_2 = \sum_{p\in\delta_{ji,h/2}} \mu_2(p)\phi_{2,p}$. By Propositions 3.1 and 3.4 we have

$$\|\mu_k\|^2_{L^2(\delta_{ji})} \asymp \|\tilde{\mu}_k\|^2_{L^2(\delta_{ji})} \asymp \int_{\delta_{ji}} \mu_k\tilde{\mu}_k \, ds, \quad k = 1, 2. \tag{4.19}$$

We next see that

$$\|\mu_1\|_{-3/2,h,\delta_{ji}} \preceq \frac{h_j^{3/2} \int_{\delta_{ji}} \mu_1\tilde{\mu}_1 \, ds}{\|\tilde{\mu}_1\|_{0,h,\delta_{ji}}} = \frac{\int_{\delta_{ji}} \mu_1\tilde{\mu}_1 \, ds}{\|\tilde{\mu}_1\|_{3/2,h,\delta_{ji}}} = \int_{\delta_{ji}} \mu_1\hat{\mu}_1 \, ds, \tag{4.20}$$

where $\hat{\mu}_1 = \tilde{\mu}_1/\|\tilde{\mu}_1\|_{3/2,h,\delta_{ji}}$. Analogously, we get

$$\|\mu_2\|_{-1/2,h,\delta_{ji}} \preceq \int_{\delta_{ji}} \mu_2\hat{\mu}_2 \, ds, \tag{4.21}$$

where $\hat{\mu}_2 = \tilde{\mu}_2/\|\tilde{\mu}_1\|_{1/2,h,\delta_{ji}}$. Then we introduce two functions $w_{1,ij}, w_{2,ij} \in X_h(\Omega_j)$ as follows:

$$\begin{cases} a_j(w_{1,ij}, v) = 0 & \forall v \in X_{0,h}(\Omega_j), \\ Tr\, w_{1,ij} = (\hat{\mu}_1, \partial_s\hat{\mu}_1, 0) & \text{on} \quad \delta_{ji}, \\ Tr\, w_{1,ij} = 0 & \text{on} \quad \partial\Omega_j \setminus \delta_{ji}, \end{cases} \tag{4.22}$$

$$\begin{cases} a_j(w_{2,ij}, v) = 0 & \forall v \in X_{0,h}(\Omega_j), \\ Tr\, w_{2,ij} = (0, 0, \hat{\mu}_2) & \text{on} \quad \delta_{ji}, \\ Tr\, w_{2,ij} = 0 & \text{on} \quad \partial\Omega_j \setminus \delta_{ji}, \end{cases} \tag{4.23}$$

where $Tr\, v = (v_{|\partial\Omega_j}, \nabla v_{|\partial\Omega_j})$ for $v, \nabla v$—the H^2 traces of $v \in H^2(\Omega_j)$, and $X_{0,h}(\Omega_j) = X_h(\Omega_j) \cap H_0^2(\Omega_j)$. The extension of $w_{k,ij}, k = 1, 2$, by zero to Ω is denoted by the same symbols. By the Friedrich's inequality, the extension theorem of [23], and inverse inequalities we have

$$\|w_{1,ij}\|^2_{H^2(\Omega_j)} \preceq \|\partial_s\hat{\mu}_1\|^2_{H^{1/2}_{00}(\delta_{ji})} \preceq \|\hat{\mu}_1\|^2_{3/2,h,\delta_{ji}} = 1,$$
$$\|w_{2,ij}\|^2_{H^2(\Omega_j)} \preceq \|\hat{\mu}_2\|^2_{H^{1/2}_{00}(\delta_{ji})} \preceq \|\hat{\mu}_2\|^2_{1/2,h,\delta_{ji}} = 1.$$

We then define a function $w \in X_h(\Omega)$ as follows:

$$w = \sum_{k=1,2} \sum_{\delta_{ji} \subset \Gamma} b(\mu_k, w_{k,ij}) w_{k,ij} = \sum_{k=1,2} \sum_{\delta_{ji} \subset \Gamma} \int_{\delta_{ji}} \mu_k\hat{\mu}_k \, ds \, w_{k,ij}.$$

From the definition and a coloring argument we find that

$$\begin{aligned} \|w\|^2_{H^2_H(\Omega)} &\preceq \sum_{j=1}^{N} \sum_{\delta_{ji} \subset \partial\Omega_j} \sum_{k=1,2} b(\mu_k, w_{k,ij})^2 \|w_{k,ij}\|^2_{H^2(\Omega_j)} \\ &\preceq \sum_{\delta_{ji} \subset \Gamma} \{\|\mu_1\|^2_{-3/2,h,\delta_{ji}} \|w_{1,ij}\|^2_{3/2,h,\delta_{ji}} + \|\mu_1\|^2_{-1/2,h,\delta_{ji}} \|w_{2,ij}\|^2_{1/2,h,\delta_{ji}}\} \\ &= \sum_{\delta_{ji} \subset \Gamma} \{\|\mu_1\|^2_{-3/2,h,\delta_{ji}} + \|\mu_2\|^2_{-1/2,h,\delta_{ji}}\} = \|\mu\|^2_{M,h} \end{aligned} \tag{4.24}$$

and, analogously,

$$\|[w]\|_{3/2,h,\delta_{ji}} = |b(\mu_1, w_{1,ij})| \, \|w_{1,ij}\|_{3/2,h,\delta_{ji}} \preceq \|\mu_1\|_{-3/2,h,\delta_{ji}}$$

and

$$\|[\partial_n w]\|_{1/2,h,\delta_{ji}} = |b(\mu_2, w_{2,ij})| \, \|w_{2,ij}\|_{1/2,h,\delta_{ji}} \preceq \|\mu_2\|_{-1/2,h,\delta_{ji}}.$$

Summing over all $\delta_{ji} \subset \Gamma$ and utilizing (4.24) we get

$$\|w\|_{X,h} \preceq \|\mu\|_{M,h}.$$

Finally, this, (4.20), and (4.21) yield

$$\|\mu\|_{M,h}^2 \preceq \sum_{\delta_{ji}\subset\Gamma}\sum_{k=1,2} b(\mu_k, w_{k,ij}) = b(\mu, w) \preceq b(\mu, w)\frac{\|\mu\|_{M,h}}{\|w\|_{X,h}}.$$

Dividing by $\|\mu\|_{M,h}$ completes the proof. ∎

We then have a theorem which gives us estimates of the error for Lagrange multipliers in the norms $\|\cdot\|_M$ and $\|\cdot\|_{M,h}$.

THEOREM 4.5. *If we assume that u^*, a solution of* (2.1)*, belongs to $H_0^2 \cap H^4(\Omega)$, then*

$$\|\lambda^* - \lambda_h^*\|_M^2 + \|\lambda^* - \lambda_h^*\|_{M,h}^2 \preceq \sum_{k=1}^N h_k^2 |u^*|_{H^4(\Omega_k)}^2.$$

Proof. We first have for any $\mu \in M_h(\Gamma)$ (cf., e.g., [13])

$$\|\lambda^* - \lambda_h^*\|_M \le \|\lambda^* - \mu\|_M + \|\mu - \lambda_h^*\|_M \quad \forall \mu \in M_h(\Gamma).$$

Next, by Theorem 4.3 we get

$$\|\mu - \lambda_h^*\|_M \preceq \sup_{v\in X_h(\Omega)} \frac{b(\lambda_h^* - \mu, v)}{\|v\|_X},$$

and by (4.5) and (2.5)

$$b(\lambda_h^* - \mu, v) = b(\lambda_h^* - \lambda^*, v) + b(\lambda^* - \mu, v) = a_H(u^* - u_h^*, v) + b(\lambda^* - \mu, v).$$

Thus

$$\frac{b(\lambda_h^* - \mu, v)}{\|v\|_X} \preceq |u^* - u_h^*|_{H_H^2(\Omega)} + \|\lambda^* - \mu\|_M.$$

Finally, we get

$$\|\lambda^* - \lambda_h^*\|_M \preceq \inf_{\mu\in M_h(\Gamma)} \|\lambda^* - \mu\|_M + |u^* - u_h^*|_{H_H^2(\Omega)}.$$

The second term is bounded by Lemma 3.11. This estimate is also valid for the mesh-dependent norm. By continuous embeddings $H_{00}^{3/2}(\delta_{ji}) \subset H^{3/2}(\delta_{ji})$ and $H_{00}^{1/2}(\delta_{ji}) \subset H^{1/2}(\delta_{ji})$ we have

$$\|\cdot\|_{H_{00}^{-3/2}(\delta_{ji})} \preceq \|\cdot\|_{H^{-3/2}(\delta_{ji})} \text{ and } \|\cdot\|_{H_{00}^{-1/2}(\delta_{ji})} \preceq \|\cdot\|_{H^{-1/2}(\delta_{ji})}.$$

Thus Lemmas 3.12 and 3.13 and the trace theorems yield

$$\begin{aligned}\|\lambda_1^* - Q_{1,ij}\lambda_1^*\|_{H_{00}^{-3/2}(\delta_{ji})} &\le \|\lambda_1^* - Q_{1,ij}\lambda_1^*\|_{H^{-3/2}(\delta_{ji})} \preceq h_j^2 |\lambda_1^*|_{H^{1/2}(\delta_{ji})} \\ &\preceq h_j^2 |u^*|_{H^4(\Omega_j)}\end{aligned}$$

and

$$\begin{aligned}\|\lambda_2^* - Q_{2,ij}\lambda_2^*\|_{H_{00}^{-1/2}(\delta_{ji})} &\le \|\lambda_2^* - Q_{2,ij}\lambda_2^*\|_{H^{-1/2}(\delta_{ji})} \preceq h_j^2 |\lambda_2^*|_{H^{3/2}(\delta_{ji})} \\ &\preceq h_j^2 |u^*|_{H^4(\Omega_j)}.\end{aligned}$$

Summing over all $\delta_{ji} \subset \Gamma$ completes the proof.

The last part of the proof for the mesh-dependent norms $\|\cdot\|_{M,h}$ and $\|\cdot\|_{X,h}$ can be done in a very similar way, utilizing the L^2 estimates of Lemmas 3.12 and 3.13. □

Remark 3. Throughout this section the Poincaré inequalities and the trace and extension theorems are utilized frequently for the subdomains and then the respective constants depend on the diameter of the subdomain. This is taken into account implicitly in all proofs; however, it is not written explicitly. We also would like to note that the other equivalent approach is to use local norms scaled appropriately by the diameters of respective subdomains.

Acknowledgment. The author would like to thank Prof. Maksymilian Dryja for his encouragement and many helpful discussions.

DISCRETIZED STABILITY AND ERROR GROWTH OF THE NONAUTONOMOUS PANTOGRAPH EQUATION*

CHENGMING HUANG† AND STEFAN VANDEWALLE‡

Abstract. This paper is concerned with the stability properties of Runge–Kutta methods for the pantograph equation, a functional differential equation with a proportional delay. The focus is on nonautonomous equations. Both linear and nonlinear cases are considered. Sufficient and necessary conditions for the asymptotic stability of the numerical solution of general neutral pantograph equations are given. An upper bound for the error growth is investigated for algebraically stable methods applied to nonneutral equations. Finally, some stability results are extended to the case of a more general class of equations.

Key words. pantograph equation, asymptotic stability, error growth, Runge–Kutta methods

1. Introduction.

Many real-world phenomena can be modelled by initial value problems for functional differential equations of the form

$$y'(t) = f(t, y(t), y(t-\tau(t)), y'(t-\tau(t))). \tag{1.1}$$

In recent years, the study of numerical solvers for this problem has attracted the attention of many authors. The classical case where the term $\tau(t)$ is a constant can be regarded as a representative of finite time delay and has been widely studied in the literature (see, for example, Baker [1], Bellen and Zennaro [5] and the extensive bibliography therein). Another interesting case, which can be viewed as a representative of infinite time delay, is that of the pantograph equation, where

$$\tau(t) = (1-q)t, \quad q \in (0,1).$$

For applications of this type of equation, we refer to Iserles [16].

In order to get insight into the stability of numerical methods for the pantograph equation, the scalar linear autonomous equation

$$y'(t) = ay(t) + by(qt) + cy'(qt), \quad t > 0, \tag{1.2}$$

has been used as a test problem and many interesting results have been found (cf. [2, 6, 7, 8, 9, 17, 18, 22, 24, 25]). In the early work, a constant stepsize was considered. As pointed out in Liu [22, 24], however, this kind of stepsize precludes long time integration due to computer memory restrictions. In order to overcome this difficulty, Liu [22] transformed (1.2) into a differential equation with a constant delay by a change of variable, suggested by Jackiewicz [20]. Later, Liu [24] and Bellen,

Guglielmi, and Torelli [2] proposed nonconstant stepsize strategies where the stepsizes are geometrically increasing and they investigated the stability of θ-methods. Recently, Koto [21] further studied the stability of general Runge–Kutta methods for the multidimensional system

$$u'(t) = e^t Lu(t) + e^t Mu(t + \log q) + Nu'(t + \log q), \quad t > 0, \tag{1.3}$$

which is obtained from the equation

$$y'(t) = Ly(t) + My(qt) + qNy'(qt), \quad t > 0, \tag{1.4}$$

by a change of the independent variable $u(t) = y(e^t)$, where L, M, and N are constant complex $d \times d$ matrices. In an abstract sense the geometrically increasing mesh approach and the exponential transform method may be considered to be essentially the same (cf. [21]). Relevant to the nonautonomous pantograph equation, however, only few results on numerical stability have been published. Bellen, Guglielmi, and Torelli [2], and Guglielmi and Zennaro [13] discussed the asymptotic stability of θ-methods for scalar equations with variable coefficients. Bellen, Maset, and Torelli [4] studied the "first step" integration of linear systems of neutral type and investigated the contractivity of continuous Runge–Kutta methods. Zhang and Sun [28, 29] recently obtained some stability results of Runge–Kutta methods for a class of nonlinear equations of nonneutral type (see Theorem 6.1 of this paper).

In this paper, a new approach for proving numerical stability is introduced. Sufficient and necessary conditions for asymptotic stability are derived for both linear and nonlinear problems of neutral type. Also, upper bounds for the error growth are studied for nonneutral systems and some sharper results than those published in the literature are obtained.

This paper is organized as follows. In section 2, the discrete schemes based on Runge–Kutta methods are introduced. In section 3, we focus on the asymptotic stability of the schemes for linear systems of neutral type with variable coefficients. In section 4, an upper bound for the error growth is given for a class of linear problems. In section 5, we turn our attention to nonlinear equations and an asymptotic stability result is derived. In section 6, we further investigate the error growth bound for a class of nonlinear problems. In section 7, we generalize our stability analysis to the case of a more general class of equations. Finally, in section 8, some conclusions are drawn.

2. Adaptation of Runge–Kutta methods to functional-differential equations of pantograph type. In this section, we consider the adaptation of Runge–Kutta methods to the pantograph equation

$$\begin{cases} y'(t) = f(t, y(t), y(qt), y'(qt)), \quad t > 0, \\ y(0) = y_0, \end{cases} \tag{2.1}$$

where $f : [0, +\infty) \times \mathbb{C}^d \times \mathbb{C}^d \times \mathbb{C}^d \to \mathbb{C}^d$, is a given mapping and q is a constant satisfying $q \in (0, 1)$.

Let (A, b, c) denote a given Runge–Kutta method characterized by the $s \times s$ matrix $A = (a_{ij})$ and vectors $b = (b_1, \dots, b_s)^T$, $c = (c_1, \dots, c_s)^T$. In this paper we always assume that $\sum_{j=1}^{s} b_j = 1$. Let t_n, $n = 0, 1, \dots$, be grid points satisfying

$$0 = t_0 < t_1 < t_2 < \cdots < \infty, \quad \lim_{n\to\infty} t_n = \infty,$$

and $h_n = t_{n+1} - t_n$, the corresponding stepsizes. Approximations y_{n+1} to $y(t_{n+1})$ are defined by the following equations:

$$Y_i^{(n)} = y_n + h_n \sum_{j=1}^{s} a_{ij} f(t_n + c_j h_n, Y_j^{(n)}, \bar{Y}_j^{(n-m)}, \hat{Y}_j^{(n-m)}), \quad i = 1, \dots, s, \tag{2.2}$$

$$y_{n+1} = y_n + h_n \sum_{j=1}^{s} b_j f(t_n + c_j h_n, Y_j^{(n)}, \bar{Y}_j^{(n-m)}, \hat{Y}_j^{(n-m)}), \tag{2.3}$$

where each $Y_j^{(n)}$ is an approximation to $y(t_n + c_j h_n)$, the arguments $\bar{Y}_j^{(n-m)}$ and $\hat{Y}_j^{(n-m)}$ denote approximations to $y(q(t_n + c_j h_n))$ and $y'(q(t_n + c_j h_n))$, respectively, obtained by specific interpolation procedures at the point $t = q(t_n + c_j h_n)$, and m is a positive integer that will be defined later.

In this paper, we consider a nonconstant stepsize strategy where the stepsizes are geometrically increasing. This kind of grid was proposed by Liu [24], and by Bellen, Guglielmi, and Torelli [2]. As pointed out in the above references, it has two advantages. First, it can avoid the computer memory problems in the case of long-time integration. Second, an interpolation procedure is not necessary if we choose the grid such that every delayed point maps exactly onto a past grid point.

To formulate the grid, we partition the half-line $[0, +\infty)$ into a union of bounded intervals as follows:

$$[0, +\infty) = [0, h] \bigcup_{k=0}^{\infty} (q^{-k}h, q^{-k-1}h],$$

where h is an arbitrary but fixed positive number. Second, we further divide every interval $(q^{-k}h, q^{-k-1}h]$ into a fixed number m of subintervals whose length is proportionally increasing with the factor $p = q^{\frac{-1}{m}}$, i.e.,

$$(q^{-k}h, q^{-k-1}h] = \bigcup_{i=1}^{m} (q^{-k}p^{i-1}h, q^{-k}p^{i}h].$$

The first interval $[0, h]$ is divided as follows:

$$[0, h] = [0, qh] \bigcup_{i=1}^{m} (qp^{i-1}h, qp^{i}h].$$

Therefore, we obtain the global grid defined by

$$t_n = p^{n-m-1}h, \quad n = 1, 2, \dots,$$

which gives

$$h_n = t_{n+1} - t_n = p^{n-m-1}(p-1)h, \quad n = 1, 2, \dots,$$

and $h_0 = qh$. Hence, for $n = m+1, m+2, \dots,$

$$qt_n = t_{n-m} \quad \text{and} \quad qh_n = h_{n-m},$$

which shows the delayed point is just on the past grid point and

$$q(t_n + c_j h_n) = t_{n-m} + c_j h_{n-m}.$$

Therefore, we can set

$$\bar{Y}_j^{(n-m)} = Y_j^{(n-m)},$$
$$\hat{Y}_j^{(n-m)} = f(t_{n-m} + c_j h_{n-m}, Y_j^{(n-m)}, Y_j^{(n-2m)}, \hat{Y}_j^{(n-2m)}),$$

which on substitution into (2.2)–(2.3) gives

$$Y_i^{(n)} = y_n + h_n \sum_{j=1}^{s} a_{ij} \hat{Y}_j^{(n)}, \quad i = 1, \dots, s, \tag{2.4}$$

$$\hat{Y}_j^{(n)} = f(t_n + c_j h_n, Y_j^{(n)}, Y_j^{(n-m)}, \hat{Y}_j^{(n-m)}), \quad j = 1, \dots, s, \tag{2.5}$$

$$y_{n+1} = y_n + h_n \sum_{j=1}^{s} b_j \hat{Y}_j^{(n)}. \tag{2.6}$$

Remark 2.1. In Liu [24], this kind of stepsize was used in the numerical examples although a slightly more general assumption on the grid was considered in the theoretical analysis. In Bellen, Guglielmi, and Torelli [2], the stepsize strategy in the theoretical analysis is that every interval $(q^{-k}h, q^{-k-1}h]$ is divided into m intervals of the same size. The strategy of proportionally increasing stepsizes was also suggested in Remark 5.1 of their paper where it is pointed out that this choice can simplify the implementation of the method considerably and leads to a more regular behavior of the error.

Remark 2.2. Because we are interested in the stability of the numerical solution, we assume that the initial values $Y_j^{(n-1)}$, $\hat{Y}_j^{(n-1)}$, and y_n are available for $n = 1, 2, \dots, m$. For the integration of the first steps, i.e., the initializing methods, we refer to the paper by Bellen, Maset, and Torelli [4].

Now we introduce some concepts which will be used later.

DEFINITION 2.3 (see [14]). *The stability function of a Runge–Kutta method* (A, b, c) *is defined by*

$$R(z) = 1 + zb^T(I_s - zA)^{-1}e,$$

where $e = [1, \dots, 1]^T$ *and* I_s *stands for the* $s \times s$ *identity matrix.*

DEFINITION 2.4. *When* A *is nonsingular, the method is called strictly stable at infinity if*

$$|R(\infty)| = |1 - b^T A^{-1} e| < 1.$$

DEFINITION 2.5 (see [10]). *A Runge–Kutta method* (A, b, c) *is called algebraically stable if the following matrix* $\mathcal{M} = [\mathcal{M}_{ij}]$ *is nonnegative definite:*

$$\mathcal{M} = BA + A^T B - bb^T,$$

where $B = \operatorname{diag}(b_1, b_2, \dots, b_s)$.

3. Linear stability. In this section, we discuss the stability of Runge–Kutta methods for linear systems of the form

$$y'(t) = L(t)y(t) + M(t)y(qt) + N(t)y'(qt), \quad t > 0, \tag{3.1}$$

where $L(t)$, $M(t)$, and $N(t)$ are complex $d \times d$ matrices whose entries are continuous functions. First, we recall some results on the stability of the analytical solution. For

the autonomous case (1.4) of (3.1), a result obtained by Liu [23] (see also [16]) implies the following proposition.

PROPOSITION 3.1. *The zero solution of* (1.4) *is asymptotically stable if* L, M *satisfy*

$$\sigma[L] \subset \mathbb{C}^-, \qquad \rho[L^{-1}M] < 1, \tag{3.2}$$

where $\mathbb{C}^- = \{z \in \mathbb{C} : \operatorname{Re} z < 0\}$, *and* $\sigma[\cdot]$ *and* $\rho[\cdot]$ *denote the spectrum and spectral radius of a matrix, respectively.*

For the asymptotic stability of the nonautonomous neutral system (3.1), a result obtained by Iserles and Terjeki [19] implies the following proposition.

PROPOSITION 3.2. *The zero solution of* (3.1) *is asymptotically stable if there exists a vector norm* $\|\cdot\|_*$ *on* $\mathbb{C}^d$, *with induced matrix norm and the corresponding logarithmic norm* $\mu[\cdot]$ *such that for all* $t \geq 0$ *the following statements hold:*

$$\mu[L(t)] \leq 0, \qquad \|N(t)\|_* \leq \xi_0 < 1, \qquad \int_0^\infty \mu[L(t)]dt = -\infty, \tag{3.3}$$

$$\max_{x\in[0,t]} \|M(x) + N(x)L(qx)\|_* + k_0\mu[L(t)](1-\xi_0) \leq 0 \text{ for some } k_0 \in (0,1). \tag{3.4}$$

Now we analyze the conditions of Proposition 3.2 in order to motivate our assumptions for the numerical stability analysis. We consider the nonneutral case, i.e., $N(t) = 0$. If $\limsup_{t\to\infty} \mu[L(t)] = 0$, from (3.4) it follows that $M(t) = 0$, $t \in [0,\infty)$, which leads to a trivial case. Therefore, we assume that for sufficiently large t, $\mu[L(t)] \leq L_0 < 0$, which implies that the matrix $L(t)$ is nonsingular. Hence, from the properties of the logarithmic norm (cf. [12]), it follows that

$$\|L^{-1}(t)\|_* \leq \frac{1}{-\mu(L(t))} \leq \frac{1}{-L_0}.$$

In addition, for every $u \in \mathbb{C}^d$,

$$-\mu[L(t)]\|u\|_* \leq \|L(t)u\|_*,$$

which guarantees that, for every $v \in \mathbb{C}^d$,

$$-\mu[L(t)]\|L^{-1}(t)M(t)v\|_* \leq \|M(t)v\|_*.$$

Therefore, we have

$$-\mu[L(t)]\|L^{-1}(t)M(t)\|_* \leq \|M(t)\|_*,$$

which, combined with (3.4), implies

$$\|L^{-1}(t)M(t)\|_* \leq k_0 < 1.$$

In our analysis of the asymptotic stability of numerical methods, we will make use of the following assumption, which is a natural extension of the conditions for scalar equations given by Guglielmi and Zennaro [13], and which can also cover condition (3.2) in the autonomous case.

Assumption $\mathcal{A}$*:* There exist a vector norm $\|\cdot\|_*$ on $\mathbb{C}^d$ and induced matrix norm such that the matrices $L(t)$, $M(t)$, and $N(t)$ satisfy for all $t > 0$

$$\|L^{-1}(t)\|_* \leq C_0, \qquad \|L^{-1}(t)N(t)\|_* \leq \hat{C}_0, \qquad \|L^{-1}(t)M(t)\|_* \leq k_0 < 1,$$

where C_0, $\hat{C}_0$ and k_0 are constants.

The application of method (2.4–2.6) to (3.1) leads to the following difference equation:

$$Y_i^{(n)} = y_n + h_n \sum_{j=1}^{s} a_{ij} \hat{Y}_j^{(n)}, \quad i = 1, \dots, s, \tag{3.5}$$

$$\begin{aligned} \hat{Y}_j^{(n)} = {} & L(t_n + c_j h_n) Y_j^{(n)} + M(t_n + c_j h_n) Y_j^{(n-m)} \\ & + N(t_n + c_j h_n) \hat{Y}_j^{(n-m)}, \quad j = 1, \dots, s, \end{aligned} \tag{3.6}$$

$$y_{n+1} = y_n + h_n \sum_{j=1}^{s} b_j \hat{Y}_j^{(n)}. \tag{3.7}$$

Now we present a preliminary result that will be used further on. For the difference equation

$$u_n = \lambda_1 u_{n-m} + \lambda_2 v_n + \lambda_3 v_{n-m}, \tag{3.8}$$

$$v_{n+1} = \lambda_4 v_n + \lambda_5 u_n, \tag{3.9}$$

with $\lambda_i \in \mathbb{C}$, we have the asymptotic stability result stated in the following lemma.

LEMMA 3.3. *The difference equation* (3.8)–(3.9) *is asymptotically stable if*

$$|\lambda_1| < 1, \quad |\lambda_4| < 1, \quad (|\lambda_2| + |\lambda_3|)|\lambda_5| < (1 - |\lambda_1|)(1 - |\lambda_4|). \tag{3.10}$$

Proof. It is easy to see that the characteristic equation of (3.8)–(3.9) is given by

$$\det \begin{bmatrix} 1 - \lambda_1 z^{-m} & -\lambda_2 - \lambda_3 z^{-m} \\ -\lambda_5 & z - \lambda_4 \end{bmatrix} = 0,$$

which gives

$$\lambda_5(\lambda_2 + \lambda_3 z^{-m}) = z(1 - \lambda_4 z^{-1})(1 - \lambda_1 z^{-m}). \tag{3.11}$$

Suppose $|\lambda_1| < 1$, $|\lambda_4| < 1$, and there exists $z \in \mathbb{C}$ satisfying (3.11) with $|z| \geq 1$. Then

$$|\lambda_5|(|\lambda_2| + |\lambda_3|) \geq (1 - |\lambda_4|)(1 - |\lambda_1|),$$

which contradicts the third inequality of (3.10). This completes the proof. ∎

Now we state and prove the main result of this section.

THEOREM 3.4. *Let Assumption* $\mathcal{A}$ *hold and the matrix* A *be nonsingular. Then the difference equation* (3.5–3.7) *is asymptotically stable if the underlying Runge–Kutta method is strictly stable at infinity.*

Proof. It follows from (3.6) that

$$\begin{aligned} L^{-1}(t_n + c_i h_n) \hat{Y}_i^{(n)} = {} & Y_i^{(n)} + L^{-1}(t_n + c_i h_n) M(t_n + c_i h_n) Y_i^{(n-m)} \\ & + L^{-1}(t_n + c_i h_n) N(t_n + c_i h_n) \hat{Y}_i^{(n-m)}, \quad i = 1, \dots, s, \end{aligned}$$

which in combination with Assumption $\mathcal{A}$ gives

$$\|Y_i^{(n)}\|_* \leq k_0 \|Y_i^{(n-m)}\|_* + C_0 \|\hat{Y}_i^{(n)}\|_* + \hat{C}_0 \|\hat{Y}_i^{(n-m)}\|_*. \tag{3.12}$$

On the other hand, (3.5) plus the nonsingularity of A implies

$$\hat{Y}_i^{(n)} = h_n^{-1} \sum_{j=1}^{s} D_{ij}(Y_j^{(n)} - y_n), \tag{3.13}$$

where $D = [D_{ij}] = A^{-1}$. Substituting (3.13) into (3.7) yields

$$y_{n+1} = R(\infty) y_n + \sum_{i=1}^{s}\sum_{j=1}^{s} b_i D_{ij} Y_j^{(n)}. \tag{3.14}$$

Hence, there exists a constant $C_1 > 0$ such that

$$\|y_{n+1}\|_* \le |R(\infty)| \|y_n\|_* + C_1 \sum_{i=1}^{s} \|Y_i^{(n)}\|_*. \tag{3.15}$$

A combination of (3.12) and (3.13) leads to

(3.16)

$$\begin{aligned}\sum_{i=1}^{s} \|Y_i^{(n)}\|_* \le\ & k_0 \sum_{i=1}^{s} \|Y_i^{(n-m)}\|_* \\ & + \sum_{i=1}^{s}\sum_{j=1}^{s} |D_{ij}| (h_n^{-1} C_0 \|Y_j^{(n)} - y_n\|_* + h_{n-m}^{-1} \hat{C}_0 \|Y_j^{(n-m)} - y_{n-m}\|_*),\end{aligned}$$

which shows that there exists a constant $\hat{C}_1 > 0$ such that

$$\begin{aligned}\sum_{i=1}^{s} \|Y_i^{(n)}\|_* \le\ & k_0 \sum_{i=1}^{s} \|Y_i^{(n-m)}\|_* \\ & + \hat{C}_1 \left[h_n^{-1} \left(\sum_{j=1}^{s} \|Y_j^{(n)}\|_* + \|y_n\|_* \right) + h_{n-m}^{-1} \left(\sum_{j=1}^{s} \|Y_j^{(n-m)}\|_* + \|y_{n-m}\|_* \right) \right].\end{aligned}$$

Considering $h_n \to \infty$, there exist positive numbers $\mathcal{N}_0, k_1 < 1$, and $C_2 < (1-k_1)(1 - |R(\infty)|)/(2C_1)$ such that for every $n > \mathcal{N}_0$,

$$\sum_{i=1}^{s} \|Y_i^{(n)}\|_* \le k_1 \sum_{i=1}^{s} \|Y_i^{(n-m)}\|_* + C_2(\|y_n\|_* + \|y_{n-m}\|_*). \tag{3.17}$$

An application of Lemma 3.3 to (3.15) and (3.17) gives

$$\lim_{n\to\infty} \|y_n\|_* = 0 \quad \text{and} \quad \lim_{n\to\infty} \sum_{i=1}^{s} \|Y_i^{(n)}\|_* = 0.$$

Considering (3.13), we have

$$\lim_{n\to\infty} \sum_{i=1}^{s} h_n \|\hat{Y}_i^{(n)}\|_* = 0.$$

Therefore, the difference equation (3.5–3.7) is asymptotically stable. This completes the proof. ∎

Remark 3.5. In the case of constant coefficients, it is well known that the condition $\rho[L^{-1}M] < 1$ is equivalent to the condition that there exists a norm $\|\cdot\|_*$ such that $\|L^{-1}M\|_* < 1$. Therefore, specializing Theorem 3.4 to the case of autonomous equations, the obtained result is in accordance with that by Koto [21]. Here we have given a new approach to the proof which allowed us to study the variable coefficient case.

Remark 3.6. In the proof we only use the fact that $h_n \to \infty$. Hence, our result is also valid for the other grid types proposed in [2, 24]. In addition, it is easily seen from the proof that, if the condition $\|L^{-1}(t)M(t)\|_* \le k_0 < 1$ in Assumption $\mathcal{A}$ is replaced by $\lim_{t\to\infty} \|L^{-1}(t)M(t)\|_* \le k_0 < 1$, Theorem 3.4 still holds. In the one-dimensional case, the latter has been assumed for the stability analysis of θ-methods in [2]. Finally, specializing Theorem 3.4 to the nonneutral case, the induced result is also new.

Next, we show that the assumption of strict stability at infinity is also necessary for the asymptotic stability of the difference equation.

LEMMA 3.7. *Suppose the matrix A is nonsingular. Then there exists a constant $\mathcal{N}_1 > 0$ such that*

$$|R(z)| \ge |R(\infty)| - 2|z^{-1}||b^T A^{-2} e|, \quad |z| \ge \mathcal{N}_1,\ z \in \mathbb{C}. \tag{3.18}$$

Proof. Considering the nonsingularity of A and the fact

$$(A - z^{-1} I_s)^{-1} = A^{-1} + z^{-1} A^{-1} (A - z^{-1} I_s)^{-1},$$

we have

$$R(z) = R(\infty) - z^{-1} b^T A^{-1} (A - z^{-1} I_s)^{-1} e,$$

which gives

$$|R(z)| \ge |R(\infty)| - |z^{-1}||b^T A^{-1} (A - z^{-1} I_s)^{-1} e|. \tag{3.19}$$

Considering

$$\lim_{z\to\infty} |b^T A^{-1} (A - z^{-1} I_s)^{-1} e| = |b^T A^{-2} e|,$$

there exists a constant $\mathcal{N}_1$ such that for every $z \in \mathbb{C}$ with $|z| \ge \mathcal{N}_1$,

$$|b^T A^{-1} (A - z^{-1} I_s)^{-1} e| \le 2|b^T A^{-2} e|,$$

which, together with (3.19), implies the conclusion. ∎

The application of method (2.4–2.6) to the scalar equation

$$y'(t) = \lambda y(t), \quad \lambda \in \mathbb{R}, \tag{3.20}$$

leads to the difference equation

$$y_{n+1} = R(h_n \lambda) y_n. \tag{3.21}$$

THEOREM 3.8. *Suppose the matrix A is nonsingular and there exists a constant λ_0 such that the difference equation* (3.21) *is asymptotically stable for every λ satisfying $\lambda\lambda_0 > \lambda_0^2$. Then the underlying Runge–Kutta method is strictly stable at infinity.*

Proof. Suppose $|R(\infty)| \geq 1$. By the assumptions of the theorem we can choose λ such that

$$\lambda\lambda_0 > \lambda_0^2, \quad |h_i\lambda| \geq \mathcal{N}_1, \quad \text{and} \quad |h_i\lambda| > 4|b^T A^{-2} e|, \quad i = 0, 1,$$

which gives

$$|h_n\lambda| \geq \mathcal{N}_1 \quad \text{and} \quad |h_n\lambda| > 4|b^T A^{-2} e|, \quad n = 0, 1, 2, \ldots .$$

Considering Lemma 3.7, we have

$$\begin{aligned} |R(h_n\lambda)| &\geq |R(\infty)| - 2|h_n\lambda|^{-1}|b^T A^{-2} e| \\ &\geq |R(\infty)| \exp(-4|h_n\lambda|^{-1}|b^T A^{-2} e|/|R(\infty)|) \\ &= |R(\infty)| \exp(-4p^{-n+1}|h_1\lambda|^{-1}|b^T A^{-2} e|/|R(\infty)|), \end{aligned}$$

where we have used the fact that the function $1 - x - \exp(-2x)$ is positive for $x \in (0, 1/2)$. Therefore,

$$\begin{aligned} \prod_{i=1}^{n} |R(h_i\lambda)| &\geq \prod_{i=1}^{n} |R(\infty)| \exp(-4p^{-i+1}|h_1\lambda|^{-1}|b^T A^{-2} e|/|R(\infty)|) \\ &= |R(\infty)|^n \exp\left(-\frac{1 - p^{-n}}{1 - p^{-1}} 4|h_1\lambda|^{-1}|b^T A^{-2} e|/|R(\infty)|\right), \end{aligned}$$

which shows that the difference equation (3.21) is not asymptotically stable. This completes the proof. ∎

COROLLARY 3.9. *Suppose the matrix A is nonsingular and there exists a constant $\lambda_0 < 0$ such that* (3.21) *is asymptotically stable for every $\lambda \in (-\infty, \lambda_0]$. Then the underlying Runge–Kutta method is strictly stable at infinity.*

4. An upper bound of error growth for linear problems. Asymptotic stability implies that the initial error will eventually vanish for sufficiently large time points. From the viewpoint of a practical computation, it is also important to give an upper bound of error growth. This subject was studied in Koto [21], where the nonneutral pantograph equation

$$\begin{cases} y'(t) = Ly(t) + My(qt), & t > 0, \\ y(0) = y_0, \end{cases} \tag{4.1}$$

was used as a test problem and algebraically stable methods were considered. In this section we follow Koto's practice and pursue a sharper result for (4.1), which can be regarded as an error equation of a linear problem.

The application of method (2.4–2.6) to (4.1) yields

$$Y^{(n)} = (e \otimes I_d) y_n + h_n (A \otimes I_d) \hat{Y}^{(n)}, \tag{4.2}$$

$$\hat{Y}^{(n)} = (I_s \otimes L) Y^{(n)} + (I_s \otimes M) Y^{(n-m)}, \tag{4.3}$$

$$y_{n+1} = y_n + h_n (b^T \otimes I_d) \hat{Y}^{(n)}, \tag{4.4}$$

where $\otimes$ denotes the Kronecker product and

$$Y^{(n)} = \left(Y_1^{(n)^T}, Y_2^{(n)^T}, \ldots, Y_s^{(n)^T}\right)^T, \qquad \hat{Y}^{(n)} = \left(\hat{Y}_1^{(n)^T}, \hat{Y}_2^{(n)^T}, \ldots, \hat{Y}_s^{(n)^T}\right)^T.$$

The following notation is a generalization of that in [21]:

$$\mathcal{H}(\sigma) = -\begin{bmatrix} L^*G + GL + E & GM \\ M^*G & -\sigma E \end{bmatrix}, \tag{4.5}$$

where G and E are Hermitian positive definite matrices and the superscript $*$ stands for the Hermitian adjoint. It is also seen that $\mathcal{H}(\sigma_2)$ is necessarily nonnegative definite if $\mathcal{H}(\sigma_1)$ is nonnegative definite and $\sigma_2 > \sigma_1$. In the scalar case, if the complex numbers L, M satisfy

$$\sqrt{\sigma}(\mathrm{Re}\, L) + |M| < 0,$$

then $\mathcal{H}(\sigma)$ is nonnegative definite.

Throughout this section, we assume that the notations are the same as those in section 3.

LEMMA 4.1. *Suppose that the method (A, b, c) is algebraically stable and there exist a constant σ and matrices G and E such that $\mathcal{H}(\sigma)$ is nonnegative definite. Then the following inequality holds true:*

$$y_{n+1}^* G y_{n+1} \le y_n^* G y_n - h_n Y^{(n)^*}(B \otimes E) Y^{(n)} + \sigma h_n Y^{(n-m)^*}(B \otimes E) Y^{(n-m)}. \tag{4.6}$$

Proof. As in Burrage and Butcher [10], where it is proved that algebraic stability implies B-stability, we can obtain

$$\begin{aligned} &y_{n+1}^* G y_{n+1} - y_n^* G y_n - h_n Y^{(n)^*}(B \otimes G)\hat{Y}^{(n)} - h_n \hat{Y}^{(n)^*}(B \otimes G) Y^{(n)} \\ &\quad = -h_n^2 \hat{Y}^{(n)^*}(\mathcal{M} \otimes G)\hat{Y}^{(n)}. \end{aligned}$$

By using the algebraic stability of the method, we have

$$\begin{aligned} y_{n+1}^* G y_{n+1} &\le y_n^* G y_n + h_n Y^{(n)^*}(B \otimes G)\hat{Y}^{(n)} + h_n \hat{Y}^{(n)^*}(B \otimes G) Y^{(n)} \\ &= y_n^* G y_n - h_n Y^{(n)^*}(B \otimes E) Y^{(n)} + \sigma h_n Y^{(n-m)^*}(B \otimes E) Y^{(n-m)} \\ &\quad - h_n \sum_{i=1}^{s} b_i (Y_i^{(n)^*}, Y_i^{(n-m)^*}) \mathcal{H}(\sigma) (Y_i^{(n)^T}, Y_i^{(n-m)^T})^T \end{aligned}$$

which by the nonnegative definiteness of $\mathcal{H}(\sigma)$ gives (4.6). ∎

THEOREM 4.2. *Suppose that the method (A, b, c) is algebraically stable and there exist matrices G and E such that $\mathcal{H}(q)$ is nonnegative definite. Then we have that for every $n \ge m$,*

$$y_{n+1}^* G y_{n+1} + \sum_{i=n-m+1}^{n} h_i Y^{(i)^*}(B \otimes E) Y^{(i)} \le y_n^* G y_n + \sum_{i=n-m}^{n-1} h_i Y^{(i)^*}(B \otimes E) Y^{(i)}. \tag{4.7}$$

Proof. Inequality (4.7) immediately follows from Lemma 4.1 and the fact $q h_n = h_{n-m}$. ∎

Remark 4.3. By the same argument as in section 5 of Koto [21], it is seen that the functional

$$V(y(t)) = y(t)^* G y(t) + \int_{qt}^{t} y(x)^* E y(x) dx$$

is a Liapunov functional for equation (4.1) if $\mathcal{H}(q)$ is nonnegative definite. Inequality (4.7) can be regarded as a discrete analogue.

Remark 4.4. The proof of Lemma 4.1 is closely related to its counterpart in [21]. There, (4.1) was studied through an investigation of the corresponding constant delay system transformed by a change of independent variable.

In the following, we derive a result which can be applied to the more general case where $\mathcal{H}(\sigma)$ is nonnegative definite for some $\sigma \in [q, 1)$. Except for certain special statements, the following results remain valid for $\sigma \geq 1$ although they may not result in stability when $\sigma \geq 1$.

LEMMA 4.5. *Suppose that the method (A, b, c) is algebraically stable and there exist a constant $\sigma \geq q$ and matrices G and E such that $\mathcal{H}(\sigma)$ is nonnegative definite. Then we have that for every $k \geq 0$,*

$$\sum_{i=1}^{m} p^{-i} Y^{((k+2)m-i)^*} (B \otimes E) Y^{((k+2)m-i)} \leq q^2 \sigma^k \delta, \tag{4.8}$$

where

$$\delta = p h_1^{-1} y_m^* G y_m + q^{-1} \sigma \sum_{i=0}^{m-1} p^i Y^{(i)^*} (B \otimes E) Y^{(i)}. \tag{4.9}$$

Proof. It follows from Lemma 4.1 that

$$\begin{aligned} y_{n+1}^* G y_{n+1} \leq y_n^* G y_n - h_1 p^{n-1} Y^{(n)^*} (B \otimes E) Y^{(n)} \\ + \sigma q^{-1} h_1 p^{n-m-1} Y^{(n-m)^*} (B \otimes E) Y^{(n-m)}. \end{aligned}$$

By induction, one arrives at

$$\begin{aligned} y_{n+1}^* G y_{n+1} \leq y_m^* G y_m - h_1 \sum_{i=n-m+1}^{n} p^{i-1} Y^{(i)^*} (B \otimes E) Y^{(i)} \\ + (-1 + \sigma q^{-1}) h_1 \sum_{i=m}^{n-m} p^{i-1} Y^{(i)^*} (B \otimes E) Y^{(i)} \\ + \sigma q^{-1} h_1 \sum_{i=0}^{m-1} p^{i-1} Y^{(i)^*} (B \otimes E) Y^{(i)}. \end{aligned}$$

Therefore,

$$\sum_{i=n-m+1}^{n} p^i Y^{(i)^*} (B \otimes E) Y^{(i)} \leq \delta + (-1 + \sigma q^{-1}) \sum_{i=m}^{n-m} p^i Y^{(i)^*} (B \otimes E) Y^{(i)}.$$

Let $n = (k+2)m - 1$ for $k \geq 0$. We have

$$\begin{aligned} p^{(k+2)m} \sum_{i=1}^{m} p^{-i} Y^{((k+2)m-i)^*} (B \otimes E) Y^{((k+2)m-i)} \\ \leq \delta + (-1 + \sigma q^{-1}) \sum_{l=0}^{k-1} p^{(l+2)m} \sum_{i=1}^{m} p^{-i} Y^{((l+2)m-i)^*} (B \otimes E) Y^{((l+2)m-i)}, \end{aligned}$$

which gives

$$\sum_{i=1}^{m} p^{-i} Y^{((k+2)m-i)^*}(B\otimes E)Y^{((k+2)m-i)} \le q^{k+2}\delta + (-1+\sigma q^{-1})\sum_{l=1}^{k} q^l \sum_{i=1}^{m} p^{-i} Y^{((k+2-l)m-i)^*}(B\otimes E)Y^{((k+2-l)m-i)}.$$

We prove (4.8) by induction. When $k = 0$, (4.8) follows directly from the above inequality. Now we assume that (4.8) holds for every $k < j$ and show that it then also holds for $k = j$. It follows from the above inequality that

$$\begin{aligned}
&\sum_{i=1}^{m} p^{-i} Y^{((j+2)m-i)^*}(B\otimes E)Y^{((j+2)m-i)} \\
&\quad \le q^{j+2}\delta + (-1+\sigma q^{-1})\sum_{l=1}^{j} q^l \sum_{i=1}^{m} p^{-i} Y^{((j+2-l)m-i)^*}(B\otimes E)Y^{((j+2-l)m-i)} \\
&\quad \le q^{j+2}\delta + (-1+\sigma q^{-1})\sum_{l=1}^{j} q^{l+2}\sigma^{j-l}\delta \\
&\quad = q^2\sigma^j\delta.
\end{aligned}$$

Therefore, (4.8) holds for every $k \ge 0$. This completes the proof. ∎

COROLLARY 4.6. *Under the assumptions of Lemma* 4.5, (4.8) *implies that,*

$$Y^{(n)^*}(B\otimes E)Y^{(n)} \le \sigma^{n/m}\delta, \quad \textit{for every } n \ge m. \tag{4.10}$$

Proof. It follows from (4.8) that for every $k \ge 0$, $i \in \{1, \dots, m\}$,

$$Y^{((k+2)m-i)^*}(B\otimes E)Y^{((k+2)m-i)} \le p^i q^2 \sigma^k \delta = q^{2-i/m}\sigma^k\delta \le \sigma^{k+2-i/m}\delta, \tag{4.11}$$

which gives (4.10). ∎

THEOREM 4.7. *Suppose that the method (A, b, c) with a nonsingular matrix A is algebraically stable, $b_i > 0$ for all i and there exist a constant $\sigma \ge q$ and matrices G and E such that $\mathcal{H}(\sigma)$ is nonnegative definite. Then there exists a constant $\bar{C}$ such that for every $n \ge m$,*

$$\|y_{n+1}\|_* \le |R(\infty)|^{n+1-m}\|y_m\|_* + \bar{C}\sigma^{1/2}\delta^{1/2}\psi_{n+1-m}(|R(\infty)|, \sigma^{1/2m}), \tag{4.12}$$

where $\|\cdot\|_*$ denotes a norm on $\mathbb{C}^d$, and

$$\psi_n(x,y) = \begin{cases} \dfrac{x^n - y^n}{x-y}, & x \ne y, \\ nx^{n-1}, & x = y. \end{cases} \tag{4.13}$$

Proof. Since $b_i > 0$ for all i, it follows from Corollary 4.6 that there exists a constant $\bar{C}_1$ such that for every $n \ge m$

$$\sum_{j=1}^{s} \|Y_j^{(n)}\|_* \le \bar{C}_1 \sigma^{n/2m}\delta^{1/2}.$$

Considering (3.14) and the assumptions from the statement of the theorem, there exists a constant $\bar{C}_2$ such that

$$\|y_{n+1}\|_* \le |R(\infty)|\|y_n\|_* + \bar{C}_2 \sum_{j=1}^{s} \|Y_j^{(n)}\|_*.$$

By induction, we have

$$\begin{aligned}\|y_{n+1}\|_* &\le |R(\infty)|\|y_n\|_* + \bar{C}_1\bar{C}_2\sigma^{n/2m}\delta^{1/2} \\ &\le |R(\infty)|^{n+1-m}\|y_m\|_* + \bar{C}_1\bar{C}_2\sigma^{1/2}\delta^{1/2}\sum_{i=0}^{n-m}|R(\infty)|^i\sigma^{(n-m-i)/2m}.\end{aligned}$$

This implies inequality (4.12). ∎

Using the fact that $R(\infty) = 0$ for the Radau IA, Radau IIA, and Lobatto IIIC methods, and the fact that $|R(\infty)| = 1$ for the Gauss methods, we can state the following corollaries.

COROLLARY 4.8. *Suppose that there exist a constant $\sigma \ge q$ and matrices G and E such that $\mathcal{H}(\sigma)$ is nonnegative definite. Then for any Radau IA, Radau IIA, or Lobatto IIIC method, there exists a constant $\bar{C}$ such that for every $n \ge m$,*

$$\|y_{n+1}\|_* \le \bar{C}\sigma^{n/2m}\delta^{1/2}. \tag{4.14}$$

COROLLARY 4.9. *Suppose that there exist a constant $\sigma \in [q, 1)$ and matrices G and E such that $\mathcal{H}(\sigma)$ is nonnegative definite. Then for any Gauss method, there exists a constant $\bar{C}$ such that for every $n \ge m$,*

$$\|y_{n+1}\|_* \le \|y_m\|_* + \frac{\bar{C}\sigma^{1/2}\delta^{1/2}}{1-\sigma^{1/2m}}. \tag{4.15}$$

Remark 4.10. The Assumption (L) in Koto [21] is equivalent to the condition that there exist matrices G and E such that $\mathcal{H}(q)$ is nonnegative definite. Our result can be applied to the more general case $\sigma \ge q$.

5. Nonlinear stability. In this section, we derive conditions which guarantee the asymptotic stability of the numerical solution of nonlinear equations. First, we recall a result on the asymptotic stability of the analytical solution. Consider a system defined by the same function f as in (2.1) but with a different initial value,

$$\begin{cases} z'(t) = f(t, z(t), z(qt), z'(qt)), & t > 0, \\ z(0) = z_0. \end{cases} \tag{5.1}$$

Let $\langle\cdot,\cdot\rangle$ be an inner product on $\mathbb{C}^d$, let $\|\cdot\|$ be the corresponding norm, and let the function f satisfy the conditions

$$\begin{aligned}\mathrm{Re}\langle u_1 - u_2, f(t,u_1,v,\nu) - f(t,u_2,v,\nu)\rangle &\le \alpha(t)\|u_1-u_2\|^2, \\ &\text{for } t>0, u_1, u_2, v, \nu \in \mathbb{C}^d,\end{aligned} \tag{5.2}$$

$$\begin{aligned}\|f(t,u,v_1,\nu_1) - f(t,u,v_2,\nu_2)\| &\le \beta(t)\|v_1-v_2\| + \gamma(t)\|\nu_1-\nu_2\|, \\ &\text{for } t>0, u, v_1, v_2, \nu_1, \nu_2 \in \mathbb{C}^d,\end{aligned} \tag{5.3}$$

where $\alpha(t)$, $\beta(t)$, and $\gamma(t)$ are continuous functions. An application of Theorem 2.1 in Zennaro [27] (see also [5]) gives the following proposition.

PROPOSITION 5.1. *Suppose* $\gamma(t) = 0$ *and the functions* $\alpha(t)$ *and* $\beta(t)$ *satisfy*

$$\alpha(t) \le \alpha_0 < 0, \quad t > 0, \tag{5.4}$$

and, for some nonnegative real number $k_0 < 1$,

$$k_0\alpha(t) + \beta(t) \le 0, \quad t > 0. \tag{5.5}$$

Then, for the solutions $y(t)$ *and* $z(t)$ *of* (2.1) *and* (5.1), *it holds that*

$$\lim_{t\to\infty} \|y(t) - z(t)\| = 0. \tag{5.6}$$

Remark 5.2. In the literature, we have not found any stability results on general nonlinear neutral equations. Some results on equations of special form, such as separable systems and equations of Hale's form, can be found in [3, 19, 26]. We do not give the details of those results because they cannot directly be applied to equations of the form (2.1). Here, we will only use conditions (5.4) and (5.5) plus the boundedness of $\gamma(t)$ to analyze the asymptotic stability of numerical methods for nonlinear neutral equations of the form (2.1). Stability results for nonneutral equations are given in [5] (Theorem 9.7.1).

The Runge–Kutta method (A, b, c) applied to problem (5.1) leads to the following process:

$$Z_i^{(n)} = z_n + h_n \sum_{j=1}^{s} a_{ij} \hat{Z}_j^{(n)}, \quad i = 1, \dots, s, \tag{5.7}$$

$$\hat{Z}_j^{(n)} = f(t_n + c_j h_n, Z_j^{(n)}, Z_j^{(n-m)}, \hat{Z}_j^{(n-m)}), \quad j = 1, \dots, s, \tag{5.8}$$

$$z_{n+1} = z_n + h_n \sum_{j=1}^{s} b_j \hat{Z}_j^{(n)}. \tag{5.9}$$

Let

$$w_n = y_n - z_n, \quad W_j^{(n)} = Y_j^{(n)} - Z_j^{(n)}, \quad j = 1, \dots, s.$$

It follows from (2.4–2.6) and (5.7–5.9) that

$$W_i^{(n)} = w_n + h_n \sum_{j=1}^{s} a_{ij} (\hat{Y}_j^{(n)} - \hat{Z}_j^{(n)}), \quad i = 1, \dots, s, \tag{5.10}$$

$$w_{n+1} = w_n + h_n \sum_{j=1}^{s} b_j (\hat{Y}_j^{(n)} - \hat{Z}_j^{(n)}). \tag{5.11}$$

Now we are in the position to state and prove the main result of this section.

THEOREM 5.3. *Suppose that the method* (A, b, c) *with a nonsingular matrix* A *is strictly stable at infinity and that there exist positive constants* C_3, C_4, *and* k_2 *such that*

$$0 < -\alpha^{-1}(t) \le C_3, \quad |\alpha^{-1}(t)\gamma(t)| \le C_4, \quad |\alpha^{-1}(t)\beta(t)| \le k_2 < 1. \tag{5.12}$$

Then, the following results hold:

$$\lim_{n\to\infty} \|w_n\| = 0, \qquad \lim_{n\to\infty} \sum_{j=1}^{s} \|W_j^{(n)}\| = 0, \tag{5.13}$$

$$\lim_{n\to\infty} h_n \sum_{j=1}^{s} \|\hat{Y}_j^{(n)} - \hat{Z}_j^{(n)}\| = 0. \tag{5.14}$$

Proof. From (5.10) and the nonsingularity of A it follows that

$$\hat{Y}_i^{(n)} - \hat{Z}_i^{(n)} = h_n^{-1} \sum_{j=1}^{s} D_{ij}(W_j^{(n)} - w_n), \quad i = 1, \dots, s, \tag{5.15}$$

where $D = [D_{ij}] = A^{-1}$. Substituting (5.15) into (5.11) yields

$$w_{n+1} = R(\infty) w_n + \sum_{i=1}^{s} \sum_{j=1}^{s} b_i D_{ij} W_j^{(n)}. \tag{5.16}$$

Hence, there exists a constant $C_5 > 0$ such that

$$\|w_{n+1}\| \le |R(\infty)| \|w_n\| + C_5 \sum_{i=1}^{s} \|W_i^{(n)}\|. \tag{5.17}$$

On the other hand, conditions (5.2) and (5.3) imply that $\mathrm{Re}\langle W_j^{(n)}, \hat{Y}_j^{(n)} - \hat{Z}_j^{(n)} \rangle$ can be rewritten and bounded as follows:

$$\begin{aligned}
&\mathrm{Re}\langle W_j^{(n)}, f(t_n + c_j h_n, Y_j^{(n)}, Y_j^{(n-m)}, \hat{Y}_j^{(n-m)}) - f(t_n + c_j h_n, Z_j^{(n)}, Y_j^{(n-m)}, \hat{Y}_j^{(n-m)}) \rangle \\
&\quad + \mathrm{Re}\langle W_j^{(n)}, f(t_n + c_j h_n, Z_j^{(n)}, Y_j^{(n-m)}, \hat{Y}_j^{(n-m)}) - f(t_n + c_j h_n, Z_j^{(n)}, Z_j^{(n-m)}, \hat{Z}_j^{(n-m)}) \rangle \\
&\le \alpha(t_n + c_j h_n) \|W_j^{(n)}\|^2 + \beta(t_n + c_j h_n) \|W_j^{(n)}\| \|W_j^{(n-m)}\| \\
&\quad + \gamma(t_n + c_j h_n) \|W_j^{(n)}\| \|\hat{Y}_j^{(n-m)} - \hat{Z}_j^{(n-m)}\|.
\end{aligned}$$

Considering the inequality

$$\mathrm{Re}\langle W_j^{(n)}, \hat{Y}_j^{(n)} - \hat{Z}_j^{(n)} \rangle \ge -\|W_j^{(n)}\| \|\hat{Y}_j^{(n)} - \hat{Z}_j^{(n)}\|,$$

we have that

$$\|W_j^{(n)}\| \le k_2 \|W_j^{(n-m)}\| + C_4 \|\hat{Y}_j^{(n-m)} - \hat{Z}_j^{(n-m)}\| + C_3 \|\hat{Y}_j^{(n)} - \hat{Z}_j^{(n)}\|, \tag{5.18}$$

where we have used Assumption (5.12). Using (5.15), we further obtain

$$\begin{aligned}
\sum_{i=1}^{s} \|W_i^{(n)}\| \le k_2 \sum_{i=1}^{s} \|W_i^{(n-m)}\| &+ h_{n-m}^{-1} C_4 \sum_{i=1}^{s} \sum_{j=1}^{s} |D_{ij}| \|W_j^{(n-m)} - w_{n-m}\| \\
&+ h_n^{-1} C_3 \sum_{i=1}^{s} \sum_{j=1}^{s} |D_{ij}| \|W_j^{(n)} - w_n\|.
\end{aligned} \tag{5.19}$$

Considering $h_n \to \infty$, there exist positive numbers $\mathcal{N}_2, k_3 < 1$ and $C_6 < (1 - k_3)(1 - |R(\infty)|)/(2C_5)$ such that for every $n > \mathcal{N}_2$,

$$\sum_{i=1}^{s} \|W_i^{(n)}\| \le k_3 \sum_{i=1}^{s} \|W_i^{(n-m)}\| + C_6(\|w_n\| + \|w_{n-m}\|). \tag{5.20}$$

An application of Lemma 3.3 to (5.17) and (5.20) gives (5.13). Then (5.14) follows from (5.15). This completes the proof. ∎

Remark 5.4. In the proof, we only use $h_n \to \infty$. Hence, the result is also valid for the other grid types proposed in [2, 24]. From Corollary 3.9 we can see that the assumption of strict stability at infinity is also necessary to the result.

Remark 5.5. Theorem 5.3 is different from the asymptotic stability result obtained by Zhang and Sun [28] (see Theorem 6.1 of this paper). Therefore, specializing Theorem 5.3 to the case of nonneutral equations, our result is also new. In addition, our proof is completely different from that in [28].

Remark 5.6. It should be pointed out that Theorem 5.3 cannot cover the asymptotic stability results of section 3. In fact, specializing the Assumption (5.12) in Theorem 5.3 to the case of (3.1), the induced assumptions are stronger than Assumption $\mathcal{A}$.

6. An upper bound of error growth for nonlinear problems. In this section, we investigate error growth bounds of numerical methods for nonneutral, nonlinear problems of the form

$$\begin{cases} y'(t) = f(t, y(t), y(qt)), & t > 0, \\ y(0) = y_0, \end{cases} \tag{6.1}$$

where the function f satisfies the conditions

$$\mathrm{Re}\langle u_1 - u_2, f(t, u_1, v) - f(t, u_2, v)\rangle \le \alpha \|u_1 - u_2\|^2, \quad t > 0,\ u_1, u_2, v \in \mathbb{C}^d, \tag{6.2}$$

$$\|f(t, u, v_1) - f(t, u, v_2)\| \le \beta \|v_1 - v_2\|, \quad t > 0,\ u, v_1, v_2 \in \mathbb{C}^d, \tag{6.3}$$

where α and β are constants. Throughout this section, we assume that the other notations are the same as those in section 5.

For problems (6.1–6.3), Zhang and Sun (cf. [28]) have considered a stepsize strategy where every interval $(q^{-i}h, q^{-i-1}h]$ is divided into m subintervals of the same size, and obtained the following global and asymptotic stability results for $(k, l)-$ algebraically stable Runge–Kutta methods. Here, a method (A, b, c) is said to be (k, l)-algebraically stable if there exists a nonnegative diagonal matrix D such that the matrix

$$\begin{bmatrix} k - 1 - 2le^T De & e^T D - b^T - 2le^T DA \\ De - b - 2lA^T De & DA + A^T D - bb^T - 2lA^T DA \end{bmatrix}$$

is nonnegative definite (cf. [11]).

THEOREM 6.1 (see [28]). *Suppose that the method (A, b, c) is (k, l)-algebraically stable for a nonnegative diagonal matrix $D = \mathrm{diag}(d_1, d_2, \ldots, d_s)$, where $0 < k \le 1$ and the following condition holds:*

$$q\alpha + \beta \le 0, \quad (1 - q)(q\alpha + \beta)h \le mq^2 l, \tag{6.4}$$

then

$$\|w_{n+1}\| \le \left[1 + \sqrt{(q^{-1} - 1)\beta h}\right] \max\left\{\|w_m\|, \sum_{j=1}^{s} \left(\sqrt{b_j} \max_{-m \le i \le -1} \|W_j^{(m+i)}\|\right)\right\}. \tag{6.5}$$

If it is further assumed that $k < 1$, then

$$\lim_{n \to \infty} \|y_n - z_n\| = 0.$$

Here we obtain the following results.

THEOREM 6.2. *Suppose that the method (A, b, c) is algebraically stable and that the following condition holds:*

$$\alpha + q^{-1/2}\beta \le 0. \tag{6.6}$$

Then we have that for every $n \ge 2m-1$,

$$\begin{aligned} &\|w_{n+1}\|^2 - h_1(2\alpha + q^{-1/2}\beta) \sum_{i=n-m+1}^{n} \sum_{j=1}^{s} b_j p^{i-1} \|W_j^{(i)}\|^2 \\ &\qquad \le \|w_m\|^2 + h_1 q^{-1/2}\beta \sum_{i=0}^{m-1} \sum_{j=1}^{s} b_j p^{i-1} \|W_j^{(i)}\|^2. \end{aligned} \tag{6.7}$$

Proof. It is known (see [10]) that

$$\begin{aligned} &\|w_{n+1}\|^2 - \|w_n\|^2 - 2h_n \sum_{j=1}^{s} b_j \operatorname{Re}\langle W_j^{(n)}, \hat{Y}_j^{(n)} - \hat{Z}_j^{(n)} \rangle \\ &\qquad = -h_n^2 \sum_{i=1}^{s} \sum_{j=1}^{s} \mathcal{M}_{ij} \langle \hat{Y}_i^{(n)} - \hat{Z}_i^{(n)}, \hat{Y}_j^{(n)} - \hat{Z}_j^{(n)} \rangle. \end{aligned}$$

By means of the algebraic stability of the method and by (6.2) and (6.3), we have

$$\begin{aligned} \|w_{n+1}\|^2 &\le \|w_n\|^2 + 2h_n \sum_{j=1}^{s} b_j \operatorname{Re}\langle W_j^{(n)}, \hat{Y}_j^{(n)} - \hat{Z}_j^{(n)} \rangle \\ &= \|w_n\|^2 + 2h_n \sum_{j=1}^{s} b_j \operatorname{Re}\langle W_j^{(n)}, f(t_n + c_j h_n, Y_j^{(n)}, Y_j^{(n-m)}) \\ &\qquad - f(t_n + c_j h_n, Z_j^{(n)}, Y_j^{(n-m)}) \rangle \\ &\quad + 2h_n \sum_{j=1}^{s} b_j \operatorname{Re}\langle W_j^{(n)}, f(t_n + c_j h_n, Z_j^{(n)}, Y_j^{(n-m)}) \\ &\qquad - f(t_n + c_j h_n, Z_j^{(n)}, Z_j^{(n-m)}) \rangle \\ &\le \|w_n\|^2 + h_n \sum_{j=1}^{s} b_j [(2\alpha + q^{-1/2}\beta)\|W_j^{(n)}\|^2 + q^{1/2}\beta \|W_j^{(n-m)}\|^2], \end{aligned}$$

where we have used

$$2\|W_j^{(n)}\| \|W_j^{(n-m)}\| \le q^{-1/2}\|W_j^{(n)}\|^2 + q^{1/2}\|W_j^{(n-m)}\|^2. \tag{6.8}$$

By induction, one arrives at

$$\begin{aligned} \|w_{n+1}\|^2 \le \|w_m\|^2 + h_1 \sum_{j=1}^{s} b_j \Bigg[&\sum_{i=n-m+1}^{n} p^{i-1}(2\alpha + q^{-1/2}\beta)\|W_j^{(i)}\|^2 \\ &+ 2 \sum_{i=m}^{n-m} p^{i-1}(\alpha + q^{-1/2}\beta)\|W_j^{(i)}\|^2 \\ &+ \sum_{i=0}^{m-1} p^{i-1} q^{-1/2}\beta \|W_j^{(i)}\|^2 \Bigg], \end{aligned} \tag{6.9}$$

which, combined with (6.6), gives (6.7). This completes the proof. ∎

COROLLARY 6.3. *Under the assumptions of Theorem* 6.2*, we have that for every* $n \geq 2m-1$*,*

$$\|w_{n+1}\|^2 \leq \|w_m\|^2 + hp^{-1}q^{-1/2}(1-q)\beta \max_{\substack{0\leq i\leq m-1\\ 1\leq j\leq s}} \|W_j^{(i)}\|^2. \tag{6.10}$$

Proof. The conclusion follows from the fact that

$$\sum_{i=0}^{m-1} p^i \|W_j^i\|^2 \leq \frac{p^m-1}{p-1} \max_{0\leq i\leq m-1} \|W_j^{(i)}\|^2. \qquad \blacksquare$$

Remark 6.4. The above proof procedure is closely related to its counterpart in the case of a constant delay (cf. [15]) and in the case of a proportional delay (cf. [28]). Compared to Theorem 6.1 in the case of algebraically stable methods, our result is slightly sharper because Assumption (6.4) is stronger than (6.6).

Remark 6.5. In the case of time-dependent Lipschitz constants, if (6.6) is replaced by

$$2\alpha(t) + q^{-1/2}(\beta(t) + \beta(t/q)) \leq 0, \tag{6.11}$$

we can similarly obtain that for every $n \geq 2m-1$,

$$\begin{aligned} &\|w_{n+1}\|^2 - h_1 \sum_{i=n-m+1}^{n} \sum_{j=1}^{s} b_j p^{i-1}(2\alpha(t_i + c_j h_i) + q^{-1/2}\beta(t_i + c_j h_i))\|W_j^{(i)}\|^2 \\ &\leq \|w_m\|^2 + hp^{-1}q^{-1/2}(1-q) \max_{\substack{0\leq i\leq m-1\\ 1\leq j\leq s}} \beta(t_{i+m} + c_j h_{i+m})\|W_j^{(i)}\|^2. \end{aligned} \tag{6.12}$$

Next, we derive some results which can be applied to the more general case $\alpha + \beta < 0$. We define the following two constants

$$r = \begin{cases} 0, & \text{when } 2\alpha + (1+q^{-1})\beta \leq 0, \\ \dfrac{2\alpha + (1+q^{-1})\beta}{-(2\alpha+\beta)}, & \text{when } 2\alpha + (1+q^{-1})\beta > 0, \end{cases} \tag{6.13}$$

$$\Delta = \frac{\|w_m\|^2 p/h_1 + q^{-1}\beta \sum_{j=1}^{s} b_j \sum_{i=0}^{m-1} p^i \|W_j^{(i)}\|^2}{-(2\alpha+\beta)}. \tag{6.14}$$

THEOREM 6.6. *Suppose that the method* (A, b, c) *is algebraically stable and that the following condition holds:*

$$\alpha + \beta < 0. \tag{6.15}$$

Then we have that for every $k \geq 0$*,*

$$\sum_{j=1}^{s} b_j \sum_{i=1}^{m} p^{-i} \|W_j^{((k+2)m-i)}\|^2 \leq q^2(q+qr)^k \Delta. \tag{6.16}$$

Proof. If we replace (6.8) by the inequality

$$2\|W_j^{(n)}\|\|W_j^{(n-m)}\| \leq \|W_j^{(n)}\|^2 + \|W_j^{(n-m)}\|^2,$$

we obtain

$$\|w_{n+1}\|^2 \le \|w_n\|^2 + h_n \sum_{j=1}^{s} b_j[(2\alpha+\beta)\|W_j^{(n)}\|^2 + \beta\|W_j^{(n-m)}\|^2].$$

By induction, one arrives at

$$\|w_{n+1}\|^2 \le \|w_m\|^2 + h_1 p^{-1} \sum_{j=1}^{s} b_j \left[\sum_{i=n-m+1}^{n} p^i(2\alpha+\beta)\|W_j^{(i)}\|^2 + \sum_{i=m}^{n-m} p^i(2\alpha+(1+q^{-1})\beta)\|W_j^{(i)}\|^2 + \sum_{i=0}^{m-1} p^i q^{-1}\beta\|W_j^{(i)}\|^2 \right].$$

Therefore,

$$\sum_{j=1}^{s} b_j \sum_{i=n-m+1}^{n} p^i \|W_j^{(i)}\|^2 \le r \sum_{j=1}^{s} b_j \sum_{i=m}^{n-m} p^i \|W_j^{(i)}\|^2 + \Delta.$$

Let $n = (k+2)m - 1$ for $k \ge 0$. We then have

$$\sum_{j=1}^{s} b_j \sum_{i=1}^{m} p^{-i} \|W_j^{((k+2)m-i)}\|^2 \le r \sum_{l=1}^{k} q^l \sum_{j=1}^{s} b_j \sum_{i=1}^{m} p^{-i} \|W_j^{((k-l+2)m-i)}\|^2 + q^{k+2}\Delta.$$

By induction we can prove from the above inequality that (6.16) holds for every $k \ge 0$. This completes the proof. ∎

Remark 6.7. It is easy to verify the following inequality,

$$0 < q + qr \le \max\left(q, \frac{\beta}{-(2\alpha+\beta)}\right).$$

Hence, $q + qr < 1$ if $\alpha + \beta < 0$ and the right-hand side of (6.16) goes to zero for increasing k.

Remark 6.8. If condition (6.15) is replaced by the weaker condition

$$2\alpha + \beta < 0, \tag{6.17}$$

then Theorem 6.6 is still valid. Then, however, it is not guaranteed that $q + qr < 1$.

COROLLARY 6.9. *Under the assumptions of Theorem* 6.6*, inequality* (6.16) *implies that for every* $n \ge m$

$$\sum_{j=1}^{s} b_j \|W_j^{(n)}\|^2 \le (q+qr)^{n/m}\Delta. \tag{6.18}$$

Proof. It follows from (6.16) that for every $k \ge 0, i \in \{1, \dots, m\}$,

$$\sum_{j=1}^{s} b_j \|W_j^{((k+2)m-i)}\|^2 \le p^i q^2 (q+qr)^k \Delta = q^{2-i/m}(q+qr)^k\Delta \le (q+qr)^{k+2-i/m}\Delta,$$

which gives (6.18). ∎

THEOREM 6.10. *Suppose that the method (A, b, c) with a nonsingular matrix A is algebraically stable, $b_i > 0$ for all i and* (6.15) *holds. Then there exists a constant C_7, depending only on the coefficients of the method, such that for every $n \geq m$,*

$$\|w_{n+1}\| \leq |R(\infty)|^{n+1-m}\|w_m\| + C_7(q+qr)^{1/2}\Delta^{1/2}\psi_{n+1-m}(|R(\infty)|, (q+qr)^{1/2m}),$$

where the function $\psi_n(x, y)$ is defined by (4.13).

Proof. Considering (5.16) and the assumptions of the theorem, there exists a constant C_7, depending only on the coefficients, such that

$$\|w_{n+1}\| \leq |R(\infty)|\|w_n\| + C_7\left(\sum_{j=1}^{s} b_j\|W_j^{(n)}\|^2\right)^{1/2},$$

which in combination with (6.18) gives

$$\begin{aligned}\|w_{n+1}\| &\leq |R(\infty)|\|w_n\| + C_7(q+qr)^{n/2m}\Delta^{1/2}\\ &\leq |R(\infty)|^{n+1-m}\|w_m\|\\ &\quad + C_7(q+qr)^{1/2}\Delta^{1/2}\sum_{i=0}^{n-m}|R(\infty)|^i(q+qr)^{(n-m-i)/2m}.\end{aligned}$$

This implies the result of the theorem. ∎

COROLLARY 6.11. *Suppose* (6.15) *holds. Then for any Radau IA, Radau IIA, or Lobatto IIIC method, there exists a constant C_7 depending only on the coefficients of the method, such that for every $n \geq m$,*

$$\|w_{n+1}\| \leq C_7(q+qr)^{n/2m}\Delta^{1/2}.$$

COROLLARY 6.12. *Suppose* (6.15) *holds. Then for any Gauss method there exists a constant C_7, depending only on the coefficients of the method, such that for every $n \geq m$,*

$$\|w_{n+1}\| \leq \|w_m\| + \frac{C_7(q+qr)^{1/2}\Delta^{1/2}}{1-(q+qr)^{1/2m}}.$$

Remark 6.13. It is easy to extend the results of this section to the case of (k, l)-algebraically stable methods if we impose some restrictions on stepsize similar to those in [15].

7. Extension to a more general class of equations. In this section, we generalize some stability results to the more general equations

$$\text{(7.1)}\qquad \begin{cases} y'(t) = L(t)y(t) + M(t)y(t-\tau(t)) + N(t)y'(t-\tau(t)), & t \geq t_0,\\ y(t) = g(t), & t \leq t_0, \end{cases}$$

and

$$\text{(7.2)}\qquad \begin{cases} y'(t) = f(t, y(t), y(t-\tau(t)), y'(t-\tau(t))), & t \geq t_0,\\ y(t) = g(t), & t \leq t_0. \end{cases}$$

The ideas are related to those in [13]. We assume that there exists a constrained mesh in the interval $[t_0, +\infty)$ such that

$$\text{(7.3)}\qquad t_n - \tau(t_n) = t_{n-m}, \quad n \geq m,$$

for some integer m. The corresponding discretized schemes for (7.1) and (7.2) are (3.5–3.7) and (2.4–2.6), respectively. Then, a similar analysis leads to the following general results.

THEOREM 7.1. *Suppose that the method (A, b, c) with a nonsingular matrix A is strictly stable at infinity and that the coefficient matrices of* (7.1) *satisfy*

(7.4)
$$\lim_{n\to\infty} h_n^{-1}\|L^{-1}(t_n + c_i h_n)\| = 0, \quad \lim_{n\to\infty} h_{n-m}^{-1}\|L^{-1}(t_n + c_i h_n)N(t_n + c_i h_n)\| = 0,$$

and

$$\limsup_{n\to\infty} \|L^{-1}(t_n + c_i h_n)M(t_n + c_i h_n)\| = k_0 < 1, \tag{7.5}$$

for $i = 1, 2, \ldots, s$. Then, the scheme (3.5–3.7) *is asymptotically stable for* (7.1).

THEOREM 7.2. *Suppose that the method (A, b, c) with a nonsingular matrix A is strictly stable at infinity and that the function f of* (7.2) *satisfies conditions* (5.2) *and* (5.3) *with*

$$\lim_{n\to\infty} h_n\alpha(t_n + c_i h_n) = -\infty, \qquad \lim_{n\to\infty} \frac{\gamma(t_n + c_i h_n)}{h_{n-m}\alpha(t_n + c_i h_n)} = 0, \tag{7.6}$$

and

$$\limsup_{n\to\infty} \frac{\beta(t_n + c_i h_n)}{|\alpha(t_n + c_i h_n)|} = k_2 < 1, \tag{7.7}$$

for $i = 1, 2, \ldots, s$. Then, the scheme (2.4–2.6) *is asymptotically stable for* (7.2)*, i.e.,* (5.13) *and* (5.14) *hold.*

Remark 7.3. For the constant delay system (1.3), we can consider a constant stepsize strategy, i.e., $h_n = -\log q/m$, such that (7.3), (7.4), and (7.5) hold if $\rho[L^{-1}M] < 1$.

Remark 7.4. If the delay $\tau(t)$ satisfies the conditions

$$0 < \tau_0 \le \tau(t) < t, \quad t \ge t_0, \tag{7.8}$$

$$0 < q_* \le 1 - \tau'(t) \le q^* < 1, \quad t \ge t_0, \tag{7.9}$$

then $t - \tau(t)$ is strictly increasing and $\lim_{t\to\infty} t - \tau(t) = +\infty$, which guarantees the existence of a constrained mesh (cf. [5, 13]) and

$$h_{n-m} = h_n - (\tau(t_{n+1}) - \tau(t_n)) \le q^* h_n.$$

Hence,

$$\lim_{n\to\infty} h_n = +\infty,$$

which implies (7.4) if $L^{-1}(t)$ and $N(t)$ are bounded. In the case of vanishing delays, i.e., $\tau(0) = 0$, we can choose an appropriate point $t_0 > 0$ and assume we know an approximate solution in $[0, t_0]$ such that (7.8) hold.

Remark 7.5. If $c_i \in \{0, 1\}$ or $\tau(t)$ is of the form $qt + d$, we can appropriately choose stepsize such that (7.3) implies

$$t_n + c_i h_n - \tau(t_n + c_i h_n) = t_{n-m} + c_i h_{n-m},$$

see [5, section 6.3]. In the other case, however, the above equality may no longer hold, an interpolation for the delay argument is possibly necessary and a rigorous theoretical analysis is missing (and outside the scope of the present paper).

8. Concluding remarks. In this work the stability of Runge–Kutta methods for both linear and nonlinear nonautonomous pantograph equations has been analyzed. A new approach has been introduced to derive the asymptotic stability of numerical methods and some sufficient and necessary conditions have been found. By further exploiting the special structure of the stepsize, we have also obtained some upper bounds for the error growth.

The techniques of this paper can be applied to investigate the stability of numerical methods for the constant delay system derived from the pantograph equation. They could also possess a potential applicability to integro-differential equations with proportional delays.

Acknowledgments. The authors are grateful to the anonymous referee for his valuable comments and remarks. They are also indebted to Professor Hermann Brunner for suggesting the extension of the study to a more general class of equations.

ADAPTIVE OPTIMIZATION OF CONVEX FUNCTIONALS IN BANACH SPACES*

CLAUDIO CANUTO† AND KARSTEN URBAN‡

Abstract. This paper is concerned with optimization or minimization problems that are governed by operator equations, such as partial differential or integral equations, and thus are naturally formulated in an infinite dimensional function space V. We first construct a prototype algorithm of steepest descent type in V and prove its convergence. By using a Riesz basis in V we can transform the minimization problem into an equivalent one posed in a sequence space of type ℓ_p. We convert the prototype algorithm into an adaptive method in ℓ_p. This algorithm is shown to be convergent under mild conditions on the parameters that appear in the algorithm. Under more restrictive assumptions we are also able to establish the rate of convergence of our algorithm and prove that the work/accuracy balance is asymptotically optimal. Finally, we give two particular examples.

1. Introduction.

Optimization or minimization problems arise in many areas of modern science and technology. As examples let us mention control theory, image processing and segmentation, drag reduction, and shape optimization. Constrained and nonsmooth optimization, such as in modelling American options, and elastoplastic hardening and softening, pose additional challenges and require special care. Here we are particularly interested in problems that are governed by operator equations, such as partial differential or integral equations, and thus are naturally formulated in infinite-dimensional function spaces (see, e.g., [1, 7, 24, 28]).

The numerical solution of minimization problems in function spaces is traditionally based upon the choice of a suitable discretization of the spaces, leading to similar problems in finite dimension; these are then solved by some of the available optimization algorithms in Euclidean spaces. Such an approach may incorporate an adaptive strategy, which is highly appropriate for those problems whose minimizers contain well-localized structures. With the aid of a posteriori error analysis, a refinement or derefinement (coarsening) of the current discretization can be constructed yielding to an adaptively generated sequence of finite-dimensional discretizations. Even though these kinds of adaptive methods have been successfully used in many different applications, the literature on the numerical analysis of adaptive methods for minimization problems seems fairly limited. Not much is known on the convergence of the adaptive iterations and even less on the convergence speed.

Starting from recent investigations concerning adaptive wavelet methods [10, 11, 12], it is by now clear that using as much information from the original infinite-dimensional variational problem as possible gives in particular a strong mathematical

tool to prove convergence and convergence rate results. The new philosophy consists of combining an infinite-dimensional iteration with an approximate finite application of the underlying exact operators. By using an analogous approach, similar results for adaptive finite element methods have been obtained [3, 23, 27]. An important ingredient in the design and analysis of such algorithms has been provided by recent results in nonlinear approximation theory [22]. They give guidelines for the definition of refinement and coarsening strategies based upon a rigorous control of the resulting errors as well as the number of degrees of freedom. They set the appropriate notion of optimality by indicating the best possible relation between accuracy and number of degrees of freedom in approximating the solution to the particular problem at hand. It turns out that the correct functional setting for this notion is provided by certain approximation spaces. In many cases, these approximation spaces are close to Besov spaces in certain scales, in which the summability index decreases as the regularity index increases (as opposed to traditional scales of Sobolev spaces for nonadaptive methods).

The purpose of the present paper is to take a first step towards the adaptive numerical treatment of infinite dimensional minimization problems following the new philosophy described above. To this end, we start with a fairly classical situation in which we want to minimize a strictly convex, Fréchet differentiable functional J defined on a reflexive Banach space V. The assumption of convexity guarantees the existence of a global minimizer and global convergence toward it, allowing us to concentrate on the central issues related to the infinite-dimensional setting. Since the ultimate goal of our investigations will be to handle a broad class of problems including constrained or nonsmooth optimization (see, e.g., [25]), the minimization strategy will be based upon a general method of steepest descent type, coupled with a line search. The advantage is that we do not require strong regularity assumptions such as existence or boundedness of the Hessian of the functional.

After making suitable assumptions on the well-posedness of the minimization problem, we construct a steepest descent algorithm in the Banach space V which is proven to be convergent. This algorithm will serve as a prototype for the adaptive algorithms constructed next. By introducing a Riesz basis in V and by considering the sequence of the expansion coefficients of a function with respect to the chosen basis, we transform the minimization problem into an equivalent one posed in a sequence space of type ℓ_p. This transformation is a crucial step toward the concrete realization of the algorithm and for the introduction of adaptive concepts.

Next, we convert the previous algorithm into a steepest descent method defined in the sequence space. While the exact minimizer is in general represented by a sequence with infinitely many nonvanishing entries, the new algorithm acts only on finite vectors (i.e., sequences having only a finite number of nonvanishing entries); hence, it is numerically feasible. Since the number of active coefficients may grow in the descent stages, we incorporate a coarsening procedure in order to remove unnecessary details from time to time. This adaptive algorithm is shown to be convergent under mild conditions on the parameters that appear in its definition.

Under more restrictive assumptions we are also able to investigate the rate of convergence of our algorithm. Precisely, we prove that the error between the exact and the approximate minimizer decays at least in a geometric manner as the number of iterations increases. The number of approximate evaluations of the gradient of the functional applied to a finite vector (which is usually the most expansive part of the algorithm) grows in an asymptotically optimal way, i.e., at most logarithmically in the accuracy. Finally, we can prove that the output of the algorithm is optimal in the sense

of nonlinear approximation theory (asymptotically optimal work/accuracy balance) under the condition that the gradient can be efficiently approximated in a sparse way and an optimal thresholding procedure is available to realize the coarsening.

The paper is organized as follows. We start from a fairly general framework of convex optimization in Banach spaces. Under these weak assumptions, we formulate the abstract algorithm in section 2 and prove its convergence. Section 3 is devoted to the transformation of the algorithm into an equivalent one set in an ℓ_p-space. This abstract setting yields a method in infinite dimension which is in general not computable. Hence, in section 4 we investigate the ingredients that are needed to define a computable adaptive version of our general algorithm and then we prove the convergence of the resulting method.

In the second part of the paper, starting with section 5, we specialize our setting to the ℓ_2-case and we assume Lipschitz continuity of the gradient. In this framework we indicate a precise choice of the parameters in our abstract algorithm and construct more efficient adaptive algorithmic ingredients in order to obtain also a rate of convergence. In section 6, we investigate the optimality of the algorithm. At last, two examples are provided in section 7.

We will frequently use the notation $A \lesssim B$, which means that there exists a constant $c >$ such that $A \leq c\,B$, uniformly in all parameters on which A and B may depend. The notation $A \sim B$ means $A \lesssim B$ and $B \lesssim A$.

2. Convex optimization in Banach spaces. Our setting is as follows. Let V be a reflexive Banach space normed by $\|\cdot\|_V$ and let us denote by $\langle\cdot,\cdot\rangle$ the duality pairing between V and V'. Let $J : V \to \mathbb{R}$ be a Fréchet differentiable functional. We consider the following minimization problem: Find $u \in V$ such that

$$J(u) = \min_{v\in V} J(v). \tag{2.1}$$

We start by collecting the general assumptions on the functional J that will hold throughout the paper. Then we will recall the concept of admissible descent directions and stepsizes adapted to the Banach space setting. Finally, we formulate our abstract algorithm and prove its convergence.

2.1. General assumptions.

ASSUMPTION 2.1. *The functional J satisfies the following conditions:*

(i) *The Fréchet derivative $J' : V \to V'$ is uniformly continuous on each bounded subset of V;*

(ii) *J is V-elliptic in the sense that there exist $c_J > 0$ and $p > 1$ such that*

$$\langle J'(w) - J'(v), w - v\rangle \geq c_J\|w - v\|_V^p$$

for all $w, v \in V$.

Let us collect some consequences of the latter assumption.

LEMMA 2.2. *Let Assumption 2.1 be satisfied. Then, the following statements hold.*

(a) *For all $w, v \in V$ we have*

$$J(v) - J(w) \geq \langle J'(w), v - w\rangle + \frac{c_J}{p}\|v - w\|_V^p. \tag{2.2}$$

(b) *J is strictly convex and bounded from below.*

(c) *Let $u^{(0)} \in V$ be arbitrary; then the set $\mathcal{R}(u^{(0)}) := \{v \in V : J(v) \leq J(u^{(0)})\}$ is bounded.*

The straightforward proof can be found in Appendix A (see also [8]). In particular, we see from (b) that our assumptions are slightly stronger than convexity.

Under Assumption 2.1, there exists a unique solution to the minimization problem (2.1) (see, e.g., [7] for a proof).

2.2. Descent directions and stepsizes. As already said, we aim at formulating an algorithm of steepest descent type that leads to the solution u of the optimization problem (2.1). Since we are working in abstract Banach spaces, we cannot expect to have orthogonal descent directions available, no matter what inner product is used. Hence, we have to specify what directions are admissible in order to yield a possible descent. We require that the direction is *not* orthogonal to the current gradient.

DEFINITION 2.3. *Given $v \in V$, we call $s \in V$ an* admissible descent direction *for v if $\|s\| = 1$ and $\langle J'(v), s\rangle < 0$.*

Once an admissible descent direction is determined, one has to find the minimum of the functional J along the search direction. Again, we cannot hope to be able to determine this minimum exactly, even though this is a one-dimensional (1D) minimization problem. In order to ensure that the line search in fact yields a smaller value of the functional then the starting one, we identify a possible range of stepsizes that guarantees this descent. We adapt the classical concept of admissible stepsizes as follows (see, e.g., [21, subsection 6.3]).

DEFINITION 2.4 (Wolfe's condition). *Let α, β be fixed constants satisfying $0 < \alpha < \beta < 1$. For any $v \in V$ and any admissible descent direction $s \in V$, define $\mathcal{A}(J; v, s)$ as the set of all those $\mu \in \mathbb{R}_+$ satisfying the following conditions:*

$$J(v + \mu s) \le J(v) + \alpha\, \mu\, \langle J'(v), s\rangle, \tag{2.3}$$

$$\langle J'(v + \mu s), s\rangle \ge \beta\, \langle J'(v), s\rangle. \tag{2.4}$$

We call $\mathcal{A}(J; v, s)$ the set of admissible stepsizes.

In order to understand the meaning of the previous conditions, it is convenient to introduce the auxiliary univariate function

$$\varphi(\mu) := J(v + \mu s), \qquad \mu \in \mathbb{R}, \tag{2.5}$$

which is a strictly convex function satisfying $\varphi(0) = J(v)$, $\varphi'(0) = \langle J'(v), s\rangle < 0$, and $\varphi(\mu) \to +\infty$ for $\mu \to +\infty$. Then, condition (2.3) reads

$$\varphi(\mu) \le \varphi(0) + \alpha\, \varphi'(0)\, \mu \tag{2.6}$$

and, due to the convexity of φ, it identifies an interval of the form $(0, \mu_{\max}]$. Conversely, condition (2.4) reads

$$\varphi'(\mu) \ge \beta \varphi'(0) \tag{2.7}$$

and identifies an interval of the form $[\mu_{\min}, +\infty)$. Then, $\mathcal{A}(J; v, s)$ is the intersection of these two intervals. It is not empty since $\alpha < \beta$; see also Figure 2.1.

2.3. A convergent steepest descent algorithm. We are now ready to introduce the steepest descent algorithm for solving the optimization problem (2.1). In this first version, we assume that all evaluations of both the functional J and its gradient J' are done exactly. Hence, we term this version the *Exact Algorithm*.

We need the following notation.

DEFINITION 2.5. *Let $R : V' \to V$ denote the* Riesz operator*; i.e., $R(f)$ is defined for $f \in V'$ as the unique element in V such that $\|R(f)\|_V = 1$ and $\|f\|_{V'} = \langle f, R(f)\rangle$.*

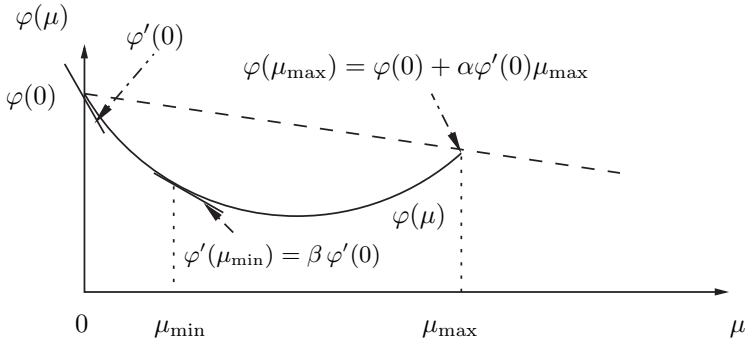

FIG. 2.1. *Conditions on the stepsize imposed by Definition* 2.4.

Obviously, $R(f)$ can also be characterized by

$$\langle f, R(f)\rangle = \sup_{v\in V} \frac{\langle f, v\rangle}{\|v\|}.$$

ALGORITHM 2.6 (Exact Algorithm). *Let $u^{(0)} \in V$ be given. Then, for $k = 0, 1, 2, \ldots$, while $J'(u^{(k)}) \neq 0$, do*

1. *choose the search direction as $s^{(k)} := -R(J'(u^{(k)}))$.*
2. *determine an admissible stepsize $\mu^{(k)} \in \mathcal{A}(J; u^{(k)}, s^{(k)})$.*
3. *update: $u^{(k+1)} := u^{(k)} + \mu^{(k)} s^{(k)}$.* □

PROPOSITION 2.7. *Under Assumption* 2.1, *the Exact Algorithm converges to u.*

Proof. Without loss of generality we assume that the algorithm produces an infinite sequence of vectors. We do the proof in several steps by adapting the convergence proof of the classical steepest descent method for a convex functional in *finite* dimension; see, e.g., [8].

(i) Using Lemma 2.2(a), we get

$$\frac{c_J}{p}\|u^{(k+1)} - u^{(k)}\|_V^p \leq [J(u^{(k+1)}) - J(u^{(k)})] - \langle J'(u^{(k)}), u^{(k+1)} - u^{(k)}\rangle.$$

Next, condition (2.3) can be equivalently written as

$$-\langle J'(u^{(k)}), u^{(k+1)} - u^{(k)}\rangle \leq \frac{1}{\alpha}[J(u^{(k)}) - J(u^{(k+1)})];$$

thus

$$\frac{c_J}{p}\|u^{(k+1)} - u^{(k)}\|_V^p \leq \left(\frac{1}{\alpha} - 1\right)[J(u^{(k)}) - J(u^{(k+1)})]. \tag{2.8}$$

(ii) By construction, we have that $\{J(u^{(k)})\}_{k\in\mathbb{N}_0}$ is monotonically decreasing and bounded from below by $J(u)$; hence

$$\lim_{k\to\infty}[J(u^{(k)}) - J(u^{(k+1)})] = 0.$$

Using (2.8), we obtain $\lim_{k\to\infty}\|u^{(k+1)} - u^{(k)}\|_V = 0$.

(iii) Now we have by condition (2.4)

$$\begin{aligned}\|J'(u^{(k)})\|_{V'} = \sup_{\|\varphi\|_V=1} \langle J'(u^{(k)}),\varphi\rangle &= -\langle J'(u^{(k)}), s^{(k)}\rangle \\ &= \langle J'(u^{(k+1)}) - J'(u^{(k)}), s^{(k)}\rangle - \langle J'(u^{(k+1)}), s^{(k)}\rangle \\ &\le \|J'(u^{(k+1)}) - J'(u^{(k)})\|_{V'}\,\|s^{(k)}\|_V - \beta\langle J'(u^{(k)}), s^{(k)}\rangle \\ &= \|J'(u^{(k+1)}) - J'(u^{(k)})\|_{V'} + \beta\,\|J'(u^{(k)})\|_{V'},\end{aligned}$$

and hence $\|J'(u^{(k)})\|_{V'} \le \frac{1}{1-\beta}\|J'(u^{(k+1)}) - J'(u^{(k)})\|_{V'}$.

(iv) The sequence $\{u^{(k)}\}_k$ lies in $\mathcal{R}(u^{(0)})$ since $J(u^{(k)}) \le J(u^{(k-1)}) \le \cdots \le J(u^{(0)})$. Hence by Assumption 2.1 and Lemma 2.2(c), we obtain

$$\|J'(u^{(k+1)}) - J'(u^{(k)})\|_{V'} \overset{k\to\infty}{\longrightarrow} 0,$$

which by (iii) implies

$$\lim_{k\to\infty} J'(u^{(k)}) = 0. \tag{2.9}$$

(v) Now using Assumption 2.1 and the fact that $J'(u) = 0$, we get

$$\begin{aligned}c_J\|u^{(k)} - u\|_V^p \le \langle J'(u^{(k)}) - J'(u), u^{(k)} - u\rangle &= \langle J'(u^{(k)}), u^{(k)} - u\rangle \\ &\le \|J'(u^{(k)})\|_{V'}\,\|u^{(k)} - u\|_V\end{aligned}$$

and finally by (2.9)

$$\|u^{(k)} - u\|_V \le \Big(\frac{1}{c_J}\|J'(u^{(k)})\|_{V'}\Big)^{1/(p-1)} \overset{k\to\infty}{\longrightarrow} 0.$$

This proves the assertion. ∎

3. Optimization in sequence spaces. So far, we considered a minimization problem in an *arbitrary* reflexive Banach space V. In many cases of interest, V is equipped with a Riesz basis Ψ; i.e., the norm in V of an expansion in Ψ is equivalent to a discrete norm of the expansion coefficients (see also (3.1) below). One may think of V being a function space and the basis being the Fourier basis. However, our considerations have been motivated by recent results in wavelet theory [9, 16]. In particular, we were driven by the results in [10, 11], where an adaptive wavelet method for solving certain operator equations was proven to be asymptotically optimally convergent. One main ingredient for defining the adaptive approximation and for analyzing it is the transformation of the operator equation into an equivalent discrete problem still on an infinite-dimensional space. We will mimic this approach for our minimization problem.

To this end, let us now consider a basis $\Psi := \{\psi_\lambda : \lambda \in \mathcal{J}\}$ in V and, for any $v = \sum_{\lambda\in\mathcal{J}} v_\lambda\psi_\lambda \in V$, let us denote by $\boldsymbol{v} = (v_\lambda)_{\lambda\in\mathcal{J}}$ the (possibly infinite) sequence of its coefficients; we will use the notation $v = \boldsymbol{v}^T\Psi$. We assume that Ψ is a Riesz basis in V, in the sense that there exists $1 < p < \infty$ and constants $0 < c_\Psi \le C_\Psi < \infty$ such that

$$c_\Psi\,\|\boldsymbol{v}\|_{\ell_p} \le \|v\|_V \le C_\Psi\,\|\boldsymbol{v}\|_{\ell_p} \quad \text{for all } v = \boldsymbol{v}^T\Psi = \sum_{\lambda\in\mathcal{J}} v_\lambda\,\psi_\lambda \in V. \tag{3.1}$$

Let us also denote by $\langle\cdot,\cdot\rangle$ the duality pairing between $\ell_p = \ell_p(\mathcal{J})$ and $\ell_{p'} = \ell_{p'}(\mathcal{J})$, where $\frac{1}{p} + \frac{1}{p'} = 1$. The isomorphism $v \mapsto \boldsymbol{v}$ induces an isomorphism $F \mapsto \boldsymbol{F}$ between V' and $\ell_{p'}$, by setting $\langle \boldsymbol{F}, \boldsymbol{v}\rangle = \langle F, v\rangle$ for all $\boldsymbol{v} \in \ell_{p'}$. The previous norm equivalences (3.1) yield

$$C_\Psi^{-1} \|\boldsymbol{F}\|_{\ell_{p'}} \le \|F\|_{V'} \le c_\Psi^{-1} \|\boldsymbol{F}\|_{\ell_{p'}} \quad \text{for all } F \in V'. \tag{3.2}$$

Thus, we can transfer the minimization in V to a minimization in the sequence space ℓ_p. To this end, let us introduce the functional $\mathbb{J} : \ell_p \to \mathbb{R}$ defined as

$$\mathbb{J}(\boldsymbol{v}) := J(\boldsymbol{v}^T\Psi). \tag{3.3}$$

We use $\mathbb{J}$ (and not $\boldsymbol{J}$) here to indicate that $\mathbb{J}(\boldsymbol{v}) \in \mathbb{R}$ is a number, whereas boldface characters always stand for sequences. Then, the minimization problem (2.1) can equivalently be formulated as follows: Find $\boldsymbol{u} \in \ell_p$ such that

$$\mathbb{J}(\boldsymbol{u}) = \min_{\boldsymbol{v}\in\ell_p} \mathbb{J}(\boldsymbol{v}). \tag{3.4}$$

Note that the solutions $u \in V$ of (2.1) and $\boldsymbol{u} \in \ell_p$ of (3.4) are related by $u = \boldsymbol{u}^T\Psi$.

The operator $\mathbb{J}$ inherits all the properties of the operator J. In particular, it satisfies the conditions in Assumption 2.1. Its derivative is given by

$$\boldsymbol{J}'(\boldsymbol{v}) = \langle J'(\boldsymbol{v}^T\Psi), \Psi\rangle,$$

where, for any $f \in V'$, we use the notation $\langle f, \Psi\rangle := (\langle f, \psi_\lambda\rangle)_{\lambda\in\mathcal{J}}$. In fact,

$$\begin{aligned}\langle \boldsymbol{J}'(\boldsymbol{v}), \boldsymbol{w}\rangle &= \lim_{t\to 0+} \frac{\mathbb{J}(\boldsymbol{v}+t\boldsymbol{w}) - \mathbb{J}(\boldsymbol{v})}{t} \;=\; \lim_{t\to 0+} \frac{J(\boldsymbol{v}^T\Psi + t\boldsymbol{w}^T\Psi) - J(\boldsymbol{v}^T\Psi)}{t} \\ &= \langle J'(\boldsymbol{v}^T\Psi), \boldsymbol{w}^T\Psi\rangle \;=\; \boldsymbol{w}^T \langle J'(\boldsymbol{v}^T\Psi), \Psi\rangle \;=\; \langle\langle J'(\boldsymbol{v}^T\Psi), \Psi\rangle, \boldsymbol{w}\rangle.\end{aligned}$$

Let us now define the operator $\boldsymbol{R} : \ell_{p'} \setminus \{0\} \to \ell_p$, $\frac{1}{p} + \frac{1}{p'} = 1$, by

$$(\boldsymbol{R}(\boldsymbol{f}))_\lambda := \frac{f_\lambda\, |f_\lambda|^{p'-2}}{\|\boldsymbol{f}\|_{\ell_{p'}}^{p'-1}}.$$

We have

$$\langle \boldsymbol{f}, \boldsymbol{R}(\boldsymbol{f})\rangle = \|\boldsymbol{f}\|_{\ell_{p'}}^{1-p'} \sum_\lambda f_\lambda^2\, |f_\lambda|^{p'-2} = \|\boldsymbol{f}\|_{\ell_{p'}};$$

since $p = \frac{p'}{p'-1}$, we also have

$$\|\boldsymbol{R}(\boldsymbol{f})\|_{\ell_p} = \|\boldsymbol{f}\|_{\ell_{p'}}^{1-p'} \Big(\sum_\lambda |f_\lambda|^{p(p'-1)}\Big)^{1/p} = \|\boldsymbol{f}\|_{\ell_{p'}}^{1-p'} \Big(\sum_\lambda |f_\lambda|^{p'}\Big)^{(p'-1)/p'} = 1.$$

Note that $\boldsymbol{R}$ coincides with the normalized Riesz operator in the Hilbert case $p = p' = 2$; otherwise the operator is nonlinear.

Now, we can formulate the discrete counterpart of Algorithm 2.6, which reads as follows.

ALGORITHM 3.1 (fully infinite-dimensional steepest descent method).
Let $\boldsymbol{u}^{(0)} \in V$ be given.
Then, for $k = 0, 1, 2, \ldots$, while $\boldsymbol{J}'(\boldsymbol{u}^{(k)}) \neq \boldsymbol{0}$, do

1. *determine the search direction $\boldsymbol{s}^{(k)}$ by $\boldsymbol{s}^{(k)} := -\boldsymbol{R}(\boldsymbol{J}'(\boldsymbol{u}^{(k)}))$;*
2. *determine an admissible stepsize $\mu^{(k)} \in \mathcal{A}(\mathbb{J}; \boldsymbol{u}^{(k)}, \boldsymbol{s}^{(k)})$;*
3. *update: $\boldsymbol{u}^{(k+1)} := \boldsymbol{u}^{(k)} + \mu^{(k)}\boldsymbol{s}^{(k)}$.*

The convergence of the latter algorithm to $\boldsymbol{u}$ follows by Proposition 2.7.

4. A general adaptive algorithm. The above fully infinite-dimensional algorithm is posed in general terms and is in general not computable. The next step is to replace all noncomputable operations by finite approximations. We start by identifying certain routines that are needed within the algorithm. To this end, for any sequence $\boldsymbol{v} \in \ell(\mathcal{J})$, we define supp $\boldsymbol{v}$ as the set of indices corresponding to the nonzero entries, i.e.,

$$\operatorname{supp} \boldsymbol{v} := \{\lambda \in \mathcal{J} : v_\lambda \neq 0\}, \tag{4.1}$$

and we call a vector *compactly (or finitely) supported* if $\#\operatorname{supp} \boldsymbol{v} < \infty$. We will often add the index Λ and use the notation $\boldsymbol{v}_\Lambda$ in order to indicate a compactly supported vector. Note that Λ sometimes (but not necessarily) coincides with supp $\boldsymbol{v}_\Lambda$. When this is the case, we will clearly state it.

There are several issues that we need to treat in order to define a computable version of the descent algorithm. First of all, even if $\boldsymbol{v}_\Lambda$ is a compactly supported vector, in general the gradient $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ has infinitely many components, so it cannot be computed exactly. Next, once an approximate descent direction has been found, an admissible stepsize has to be computed. This may require several evaluations of the functional $\mathbb{J}$. Finally, in order to achieve an algorithm of optimal complexity, the negligible components of the current approximation of the minimizer should be removed (possibly not at each iteration), by using a coarsening procedure.

We start by assuming the availability of three basic procedures for approximating the functional and its gradient as well as for thresholding a given vector.

ASSUMPTION 4.1. *A procedure* **EVAL-GRAD:** $[\boldsymbol{v}_\Lambda, \varepsilon] \mapsto \boldsymbol{w}_\Lambda$ *is available:*
Given a compactly supported vector $\boldsymbol{v}_\Lambda$ *and a tolerance* $\varepsilon > 0$*, a compactly supported vector* $\boldsymbol{w}_\Lambda$ *is computed, such that* $\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{w}_\Lambda\|_{\ell_{p'}} \leq \varepsilon$.

ASSUMPTION 4.2. *A procedure* **EVAL-J:** $[\boldsymbol{v}_\Lambda, \varepsilon] \mapsto g$ *is available:*
Given a compactly supported vector $\boldsymbol{v}_\Lambda$ *and a tolerance* $\varepsilon > 0$*, a real number* g *is computed, such that* $|\mathbb{J}(\boldsymbol{v}_\Lambda) - g| \leq \varepsilon$.

ASSUMPTION 4.3. *A procedure* **THRESH:** $[\boldsymbol{v}_\Lambda, \varepsilon] \mapsto \boldsymbol{z}_\Lambda$ *is available:*
Given a compactly supported vector $\boldsymbol{v}_\Lambda$ *and a tolerance* $\varepsilon > 0$*, a compactly supported vector* $\boldsymbol{z}_\Lambda$ *is computed, such that* $\|\boldsymbol{v}_\Lambda - \boldsymbol{z}_\Lambda\|_{\ell_p} \leq \varepsilon$ *and* supp $\boldsymbol{z}_\Lambda \subseteq$ supp $\boldsymbol{v}_\Lambda$ *has minimal cardinality, possibly subject to certain constraints on the distribution of its entries.*

Now we indicate how to use these routines in order to realize the main ingredients of the adaptive algorithm. We use **EVAL-GRAD** to create a procedure, called **APPROX-GRAD**, which yields an admissible descent direction. Next, we combine **EVAL-GRAD** and **EVAL-J** to construct a procedure, called **LINE-SEARCH**, which defines an admissible stepsize. In turn, the routines **APPROX-GRAD** and **LINE-SEARCH** are combined to form **DESCENT** which realizes one descent step of the algorithm. On the other hand, by **THRESH** and **APPROX-GRAD** we construct a procedure **COARSE** in order to coarsen the current iterate. Finally, **DESCENT** and **COARSE** are used to define our general adaptive algorithm **MINIMIZE**. For the sake of clarity, we show the hierarchy of these routines in Figure 4.1.

4.1. Approximation of the gradient. We first note that **EVAL-GRAD** may not yield an admissible descent direction. In fact, it may very well happen that the approximate evaluation of the gradient $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ gives $\boldsymbol{0}$ even though $\boldsymbol{v}_\Lambda$ is *not* the minimum of $\mathbb{J}$. Indeed, the approximation may discard many very small entries of $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ so that $\boldsymbol{v}_\Lambda$ may even be far away from the minimum. Hence, we have to ensure theoretically that $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ vanishes if and only if the exact gradient vanishes.

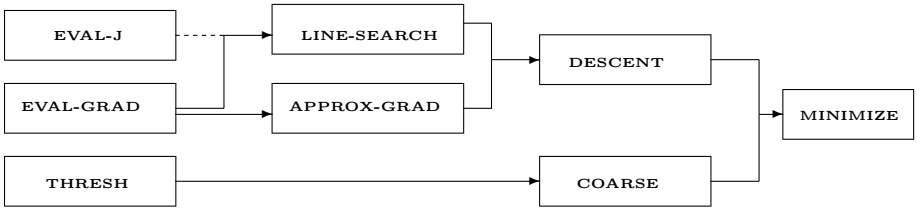

FIG. 4.1. *Hierarchy of procedures.*

This is accomplished by the procedure **APPROX-GRAD** shown below. Besides the input vector $\boldsymbol{v}_\Lambda$ and the accuracy $\varepsilon > 0$, **APPROX-GRAD** takes an extra input parameter, namely, $0 < \gamma < 1$, whose meaning will be discussed later on. Finally, $\nu \in (0,1)$ denotes any arbitrarily fixed constant.

APPROX-GRAD: $[\boldsymbol{v}_\Lambda, \varepsilon, \gamma] \mapsto [\boldsymbol{G}(\boldsymbol{v}_\Lambda), \eta]$
1. set $\eta^{(1)} := \varepsilon$;
2. for $n = 1, 2, \ldots$ do
   (a) $\boldsymbol{w}_\Lambda^{(n)} :=$ **EVAL-GRAD**$[\boldsymbol{v}_\Lambda, \eta^{(n)}]$;
   (b) if $\|\boldsymbol{w}_\Lambda^{(n)}\|_{\ell_2} \geq \frac{1+\gamma}{1-\gamma}\eta^{(n)}$, set $\boldsymbol{G}(\boldsymbol{v}_\Lambda) := \boldsymbol{w}^{(n)}$, $\eta := \eta^{(n)}$, RETURN;
   else set $\eta^{(n+1)} := \nu\,\eta^{(n)}$;
3. $\boldsymbol{G}(\boldsymbol{v}_\Lambda) := \boldsymbol{0}$, $\eta := 0$.

Note that statement 3 is reached only after an infinite loop in statement 2. Of course, in the computable version of the algorithm, we will insert a stopping criterion in statement 2; see section 5.6 below.

The following statement is an immediate consequence of the definition.

PROPOSITION 4.4. *The procedure* **APPROX-GRAD:** $[\boldsymbol{v}_\Lambda, \varepsilon, \gamma] \mapsto [\boldsymbol{G}(\boldsymbol{v}_\Lambda), \eta]$ *has the following property: Given* $0 < \gamma < 1$, $\varepsilon > 0$, *and a finitely supported vector* $\boldsymbol{v}_\Lambda$, *a vector* $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ *with finite support and a number* $\eta = \eta(\boldsymbol{v}_\Lambda) \in [0, \varepsilon]$ *are computed, such that*

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq \eta, \tag{4.2}$$

$$\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \geq \frac{1+\gamma}{1-\gamma}\,\eta. \tag{4.3}$$

□

Remark 4.5. Even though ε does not appear in (4.2) and (4.3), it serves as upper bound for the tolerance η determined inside the routine **APPROX-GRAD**.

The inequalities (4.2) and (4.3) show that the routine **APPROX-GRAD** defines an admissible descent direction whenever $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) \neq \boldsymbol{0}$. Precisely, the following results, which will play a crucial role in the subsequent analysis, hold.

PROPOSITION 4.6. $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ *satisfies the following properties:*

(a) *The inequality*

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} - \eta \leq \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} + \eta \tag{4.4}$$

holds.

(b) $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) = \boldsymbol{0}$ *if and only if* $\boldsymbol{G}(\boldsymbol{v}_\Lambda) = \boldsymbol{0}$.

(c) *If* $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) \neq \boldsymbol{0}$*, then for* $\boldsymbol{s}_\Lambda := -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$*, one has*

$$\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle \leq -\gamma \, \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}; \tag{4.5}$$

i.e., $\boldsymbol{s}_\Lambda$ *is an admissible descent direction.*

(d) *Finally, we have*

$$\gamma \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq |\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle| \leq \frac{2}{1+\gamma} \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}. \tag{4.6}$$

Proof. The first assertion is an immediate consequence of the triangle inequality. As for (b), if $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) = \boldsymbol{0}$, then

$$\frac{1+\gamma}{1-\gamma}\,\eta \leq \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq \eta,$$

which is possible only if $\eta = 0$ and consequently $\boldsymbol{G}(\boldsymbol{v}_\Lambda) = \boldsymbol{0}$. The converse is trivial.

If $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) \neq \boldsymbol{0}$, then

$$\begin{aligned}
\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle &= \langle \boldsymbol{G}(\boldsymbol{v}_\Lambda) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda)) \rangle - \langle \boldsymbol{G}(\boldsymbol{v}_\Lambda), \boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda)) \rangle \\
&\leq \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} - \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \\
&\leq \eta - (1+\gamma)\eta - \gamma \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \\
&= -\gamma \, (\eta + \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}) \;\leq\; -\gamma \, \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}
\end{aligned}$$

by (4.4) and Proposition 4.4, which proves (c). Note that with this choice the angle between the gradient and the descent direction is bounded away from 90°.

The first inequality in (d) follows directly from the proof of (c), taking into account that $\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle$ is negative. In fact, as above, we have

$$|\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle| \geq \gamma \, (\eta + \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}) \geq \gamma \, \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}.$$

As for the second inequality, we have

$$\begin{aligned}
|\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle| &\leq |\langle \boldsymbol{G}(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle| + |\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda \rangle| \\
&= \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} + \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}.
\end{aligned}$$

By (4.2) and (4.3), we get

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq \eta \leq \frac{1-\gamma}{1+\gamma} \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}},$$

from which (d) follows. ∎

Note that **APPROX-GRAD** gives the desired result after a finite number of steps if and only if $\boldsymbol{J}'(\boldsymbol{v}_\Lambda) \neq \boldsymbol{0}$.

Remark 4.7. Proposition 4.4 shows that **APPROX-GRAD** gives an approximation of the gradient up to a *relative* accuracy:

$$\frac{\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}}{\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}} \leq \frac{1-\gamma}{2\gamma}.$$

In fact, using (4.4) as well as (4.3) gives

$$\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \leq \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} + \eta \leq \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} + \frac{1-\gamma}{1+\gamma} \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}},$$

which implies

$$\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \le \frac{1+\gamma}{2\gamma}\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}. \tag{4.7}$$

Then, we conclude by (4.2) that

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \le \eta \le \frac{1-\gamma}{1+\gamma}\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}} \le \frac{1-\gamma}{2\gamma}\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}.$$

4.2. Approximate descent step. Let $\boldsymbol{v}_\Lambda$ be a given compactly supported vector, and let $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ be an approximation of the gradient $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ produced by **APPROX-GRAD**; let us set $\boldsymbol{s}_\Lambda = -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$. Hereafter, we describe how to select an admissible step size. The proposed algorithm is based on a bisection procedure, which yields the admissible step $\mu \in \mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$ after a finite number of bisections, and requires only the approximate evaluation of the functional $\mathbb{J}$.

Setting as in (2.5) $\varphi(\mu) := \mathbb{J}(\boldsymbol{v}_\Lambda + \mu \boldsymbol{s}_\Lambda)$, we look for μ satisfying (2.6) and the similar condition

$$\varphi(\mu) \ge \varphi(0) + \beta\,\varphi'(0)\,\mu;$$

indeed, the latter condition implies (2.7), thanks to Lagrange's theorem and the monotonicity of φ'. Thus, setting

$$Q(\mu) := \frac{\varphi(\mu) - \varphi(0)}{\mu\,\varphi'(0)} = \frac{\varphi(0) - \varphi(\mu)}{\mu\,|\varphi'(0)|},$$

we look for μ satisfying

$$\alpha \le Q(\mu) \le \beta. \tag{4.8}$$

This is possible, since $\lim_{\mu\to 0+} Q(\mu) = 1$ and Q is monotonically decreasing to $-\infty$ for $\mu \to +\infty$. On the other hand, only a computable approximation of $Q(\mu)$ can be used in the search. So, we approximate $Q(\mu)$ by

$$\tilde{Q}(\mu) := \frac{\tilde{\varphi}(0) - \tilde{\varphi}(\mu)}{\mu\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}},$$

where $\tilde{\varphi}(0) = \textbf{EVAL-J}[\boldsymbol{v}_\Lambda, \varepsilon]$, $\tilde{\varphi}(\mu) = \textbf{EVAL-J}[\boldsymbol{v}_\Lambda + \mu\boldsymbol{s}_\Lambda, \varepsilon]$, and $\varepsilon := \varrho\,\mu\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_{p'}}$, $\varrho > 0$ being a constant to be determined later on. It is easily seen that

$$\frac{2}{1+\gamma}\tilde{Q}(\mu) - \frac{4\varrho}{1+\gamma} \le Q(\mu) \le \frac{1}{\gamma}\tilde{Q}(\mu) + \frac{2\varrho}{\gamma}.$$

Thus, (4.8) holds if $\tilde{Q}(\mu)$ satisfies

$$\tilde{\alpha} \le \tilde{Q}(\mu) \le \tilde{\beta} \tag{4.9}$$

with

$$\tilde{\alpha} := \frac{1+\gamma}{2}\alpha + 2\varrho \qquad \text{and} \qquad \tilde{\beta} := \gamma\beta - 2\varrho.$$

Note that these bounds are meaningful provided that α, β, and γ are chosen such that

$$\beta > \frac{1+\gamma}{2\gamma}\alpha \tag{4.10}$$

holds. In fact, then we have $\gamma\beta - \frac{1+\gamma}{2}\alpha > 0$ and we can choose $\varrho > 0$ such that

$$\varrho < \frac{1}{4}\left(\gamma\beta - \frac{1+\gamma}{2}\alpha\right) \tag{4.11}$$

and thus $\tilde{\alpha} = \frac{1+\gamma}{2}\alpha + 2\varrho < \gamma\beta - 2\varrho = \tilde{\beta}$.

Starting from any tentative stepsize and possibly halving or doubling the current stepsize a finite number of times, either we satisfy (4.9), or we find two values $\mu_0^- < \mu_0^+$ such that $\tilde{Q}(\mu_0^-) > \tilde{\beta}$ and $\tilde{Q}(\mu_0^+) < \tilde{\alpha}$. In this case, we can start the classical bisection procedure applied to $\tilde{Q}$. Let us prove that this procedure guarantees that (4.9) is satisfied after a finite number of steps. We argue by contradiction, assuming that the procedure generates an infinite sequence of values $\mu_n^- < \mu_n^+$ such that $\tilde{Q}(\mu_n^+) < \tilde{\alpha}$, $\tilde{Q}(\mu_n^-) > \tilde{\beta}$, $\lim_{n\to\infty}(\mu_n^+ - \mu_n^-) = 0$. Then, there exists $\bar{\mu}$ such that $\lim_{n\to\infty}\mu_n^+ = \lim_{n\to\infty}\mu_n^- = \bar{\mu}$. By continuity, we have $\lim_{n\to\infty}(Q(\mu_n^-) - Q(\mu_n^+)) = 0$. On the other hand,

$$Q(\mu_n^-) \geq \frac{2}{1+\gamma}\,\tilde{Q}(\mu_n^-) - \frac{4\varrho}{1+\gamma} > \frac{2\tilde{\beta} - 4\varrho}{1+\gamma}$$

and

$$Q(\mu_n^+) \leq \frac{1}{\gamma}\,\tilde{Q}(\mu_n^+) + \frac{2\varrho}{\gamma} < \frac{2\varrho + \tilde{\alpha}}{\gamma}$$

so that

$$Q(\mu_n^-) - Q(\mu_n^+) > \omega - \nu\,\varrho$$

with

$$\omega = \omega(\alpha,\beta,\gamma) := \frac{2\gamma}{1+\gamma}\,\beta - \frac{1+\gamma}{2\gamma}\,\alpha, \qquad \text{and} \qquad \nu = \nu(\gamma) := \frac{\gamma}{1+\gamma} + \frac{4}{\gamma}.$$

Choosing α, β, and γ such that in addition to (4.10) we also have

$$\beta > \frac{(1+\gamma)^2\alpha + 4\varrho(1+3\gamma)}{4\gamma^2}, \tag{4.12}$$

we obtain $\omega - \varrho\nu > 0$, i.e., a contradiction. In fact, a straightforward calculation shows that (4.12) yields

$$\varrho < \frac{4\gamma^2\beta - (1+\gamma)^2\alpha}{4(1+3\gamma)} = \frac{\omega}{\nu}.$$

We summarize the result as follows.

PROPOSITION 4.8. *Given any compactly supported vector $\boldsymbol{v}_\Lambda$, let us set $\boldsymbol{s}_\Lambda = -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$, where $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ is an approximation of $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ satisfying conditions* (4.2) *and* (4.3)*. In addition, let Assumption* 4.2 *be satisfied. Then, choosing α, β, γ according to* (4.10) *and* (4.12)*, we can compute an admissible stepsize $\mu \in \mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$.* ∎

A different algorithm for choosing the stepsize will be described under more restrictive assumptions in section 5.1 below. Both algorithms are particular realizations of a general procedure **LINE-SEARCH** which we define as follows.

DEFINITION 4.9. *We call* **LINE-SEARCH:** $[\boldsymbol{v}_\Lambda, \boldsymbol{G}(\boldsymbol{v}_\Lambda), \alpha, \beta] \mapsto \eta$ *any procedure with the following property: Given* α, β *satisfying* $0 < \alpha < \beta < 1$*, a finitely supported vector* $\boldsymbol{v}_\Lambda$*, and an approximation* $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ *of its gradient produced by* **APPROX-GRAD***, and setting* $\boldsymbol{s}_\Lambda = -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$*, then an admissible stepsize* $\eta \in \mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$ *is computed.*

By the routines **APPROX-GRAD** and **LINE-SEARCH**, we perform one step of descent, which is detailed in the following routine.

DESCENT: $[\boldsymbol{v}_\Lambda, \varepsilon] \mapsto \boldsymbol{w}_\Lambda$
1. $[\boldsymbol{G}(\boldsymbol{v}_\Lambda), \eta] := \textbf{APPROX-GRAD}[\boldsymbol{v}_\Lambda, \varepsilon, \gamma]$
2. if $\eta = 0$, STOP ($\boldsymbol{v}_\Lambda = \boldsymbol{u}$); else
3. $\boldsymbol{s}_\Lambda := -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$;
4. $\mu := \textbf{LINE-SEARCH}[\boldsymbol{v}_\Lambda, \boldsymbol{G}(\boldsymbol{v}_\Lambda), \alpha, \beta]$;
5. $\boldsymbol{w}_\Lambda := \boldsymbol{v}_\Lambda + \mu \boldsymbol{s}_\Lambda$.

4.3. Coarsening. The problem of coarsening a vector is one of the central issues of nonlinear approximation theory (see [9, 22]). Several routines of this type are available in the literature; see, e.g., [10, 11, 12]. However, we are interested in a procedure which guarantees the possibility of significantly reducing the support of $\boldsymbol{v}_\Lambda$ while preserving the value of the functional $\mathbb{J}$ up to a small perturbation. The particular realization of the coarsening that we propose is based on the following result.

LEMMA 4.10. *Let* $\boldsymbol{v}_\Lambda$*,* $\boldsymbol{w}_\Lambda$ *be finitely supported vectors such that* $\operatorname{supp} \boldsymbol{w}_\Lambda \subseteq \operatorname{supp} \boldsymbol{v}_\Lambda =: \Lambda$*. Furthermore, let* $[\boldsymbol{G}(\boldsymbol{w}_\Lambda, \eta] = \textbf{APPROX-GRAD}[\boldsymbol{w}_\Lambda, \varepsilon, \gamma]$ *for some* $\varepsilon > 0$ *and* $0 < \gamma < 1$*. Then,*

$$\mathbb{J}(\boldsymbol{w}_\Lambda) - \mathbb{J}(\boldsymbol{v}_\Lambda) \le \Big(\|\boldsymbol{G}(\boldsymbol{w}_\Lambda)|_\Lambda\|_{\ell_{p'}} + \eta \Big) \|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_p}.$$

Proof. By the convexity of $\mathbb{J}$, we obtain

$$\mathbb{J}(\boldsymbol{w}_\Lambda) - \mathbb{J}(\boldsymbol{v}_\Lambda) \le \langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda), \boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda \rangle \le \|\boldsymbol{J}'(\boldsymbol{w})|_\Lambda\|_{\ell_{p'}} \, \|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_p}. \tag{4.13}$$

Next, by (4.2), we have

$$\|\boldsymbol{J}'(\boldsymbol{w})|_\Lambda - \boldsymbol{G}(\boldsymbol{w})|_\Lambda\|_{\ell_{p'}} \le \|\boldsymbol{J}'(\boldsymbol{w}) - \boldsymbol{G}(\boldsymbol{w})\|_{\ell_{p'}} \le \eta,$$

whence the result immediately follows. ∎

We are ready to introduce the routine **COARSE**. It depends on a parameter $\vartheta > 0$, which bounds from above the error in the functional, as clarified in Proposition 4.11 below.

COARSE: $[\boldsymbol{v}_\Lambda, \vartheta] \to \boldsymbol{w}_\Lambda$
1. $[\boldsymbol{G}(\boldsymbol{v}_\Lambda), \eta^{(0)}] = \textbf{APPROX-GRAD}[\boldsymbol{v}_\Lambda, \vartheta, \gamma]$;
2. $A^{(0)} = \|\boldsymbol{G}(\boldsymbol{v})|_\Lambda\|_{\ell_{p'}} + \eta^{(0)}$.
3. For $k = 0, \dots$ do
   (a) $\boldsymbol{w}_\Lambda^{(k)} = \textbf{THRESH}[\boldsymbol{v}_\Lambda, \frac{\vartheta}{A^{(k)}}]$;
   (b) $[\boldsymbol{G}(\boldsymbol{w}_\Lambda^{(k)}), \eta^{(k)}] = \textbf{APPROX-GRAD}[\boldsymbol{w}_\Lambda^{(k)}, \vartheta, \gamma]$;
   (c) $B^{(k)} = \|\boldsymbol{G}(\boldsymbol{w}_\Lambda^{(k)})|_\Lambda\|_{\ell_{p'}} + \eta^{(k)}$;
   (d) if $B^{(k)} \le A^{(k)}$, set $\boldsymbol{w}_\Lambda := \boldsymbol{w}_\Lambda^{(k)}$, RETURN;
   (e) else $A^{(k+1)} = \max(B^{(k)}, 2A^{(k)})$.

PROPOSITION 4.11. *Given a finitely supported vector* $\boldsymbol{v}_\Lambda$ *and a number* $\vartheta > 0$*, the procedure* **COARSE:** $[\boldsymbol{v}_\Lambda, \vartheta] \mapsto \boldsymbol{w}_\Lambda$ *produces a finitely supported vector* $\boldsymbol{w}_\Lambda$ *obtained by thresholding* $\boldsymbol{v}_\Lambda$ *such that* $\mathbb{J}(\boldsymbol{w}_\Lambda) < \mathbb{J}(\boldsymbol{v}_\Lambda) + \vartheta$*.*

Proof. Thanks to Lemma 4.10 and the fact that the sequence $A^{(k)}$ is geometrically increasing, one sees immediately that this procedure terminates in a finite number of iterations leading to the claimed inequality. □

An improved version of **COARSE** will be given in section 5.4 under more restrictive assumptions.

4.4. The general convergent adaptive algorithm. We are now ready to define a general adaptive algorithm. It depends on the choice of various parameters. A strategy for their selection will be detailed in the next section.

ALGORITHM 4.12. **MINIMIZE**
Let $\boldsymbol{u}^{(0)} = \boldsymbol{u}_\Lambda^{(0)} \in \ell_p$ *be given. Fix constants* α*,* β*,* γ *satisfying* $0 < \alpha < \beta < 1$ *and* $0 < \gamma < 1$*, which enter into the definition of* **DESCENT***.*

For $m = 0, 1, \ldots,$ *do*
  $\boldsymbol{v}_\Lambda^{(m,0)} := \boldsymbol{u}_\Lambda^{(m)}$
  choose an integer $K^{(m)} \geq 1$
  For $k = 0, 1, \ldots, K^{(m)} - 1$*, do*
    choose $\varepsilon^{(m,k)} > 0$
    $\boldsymbol{v}_\Lambda^{(m,k+1)} := \mathbf{DESCENT}[\boldsymbol{v}_\Lambda^{(m,k)}, \varepsilon^{(m,k)}]$
  End
  choose $\vartheta^{(m)} > 0$
  $\boldsymbol{u}_\Lambda^{(m+1)} := \mathbf{COARSE}[\boldsymbol{v}_\Lambda^{(m,K^{(m)})}, \vartheta^{(m)}]$
End

THEOREM 4.13. *Let the sequence* $(K^{(m)})_m$ *be arbitrary. Assume that the sequence* $(\varepsilon^{(m,k)})_{m,k}$ *satisfies*

$$\lim_{m\to\infty} \sup_k \varepsilon^{(m,k)} = 0, \tag{4.14}$$

whereas the sequence $(\vartheta^{(m)})_m$ *satisfies*

$$\vartheta^{(m)} \leq \frac{1}{2}[\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})})]. \tag{4.15}$$

Then, Algorithm 4.12 **MINIMIZE** *either yields* $\boldsymbol{u}$ *after a finite number of steps or produces an infinite sequence* $(\boldsymbol{u}_\Lambda^{(m)})_m$ *which converges to* $\boldsymbol{u}$*.*

Proof. If, for some m and k, the procedure **DESCENT** stops, then $\boldsymbol{v}_\Lambda^{(m,k)} = \boldsymbol{u}$. Otherwise, the algorithm produces an infinite sequence of vectors. Assuming the latter case, we first show that the sequence $(\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}))_m$ is strictly decreasing. Let m be fixed. By definition of **DESCENT**, we have

$$\mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k+1)}) < \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k)}), \qquad k = 0, 1, \ldots, K^{(m)} - 1, \tag{4.16}$$

whence

$$\mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) < \mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}). \tag{4.17}$$

Furthermore, by definition of **COARSE** and assumption (4.15), we get

$$\mathbb{J}(\boldsymbol{u}_\Lambda^{(m+1)}) \leq \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) + \vartheta^{(m)} \leq \frac{1}{2}[\mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) + \mathbb{J}(\boldsymbol{u}_\Lambda^{(m)})], \tag{4.18}$$

from which we obtain the desired result

$$\mathbb{J}(\boldsymbol{u}_\Lambda^{(m+1)}) - \mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) \le \frac{1}{2}[\mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) - \mathbb{J}(\boldsymbol{u}_\Lambda^{(m)})] < 0. \tag{4.19}$$

Next, since the functional $\mathbb{J}$ is bounded from below, we deduce that

$$\lim_{m\to\infty} [\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{u}_\Lambda^{(m+1)})] = 0. \tag{4.20}$$

Using (4.18) again, we easily get $\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) < 2[\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{u}_\Lambda^{(m+1)})]$. Hence, we also have that

$$\lim_{m\to\infty} \vartheta^{(m)} = \lim_{m\to\infty} \left[\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})})\right] = 0. \tag{4.21}$$

Thanks to (4.16), we obtain

$$\lim_{m\to\infty} \sup_k [\mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k+1)})] = 0.$$

Exactly as in the proof of Proposition 2.7(i), the latter result implies

$$\lim_{m\to\infty} \sup_k \|\boldsymbol{v}_\Lambda^{(m,k+1)} - \boldsymbol{v}_\Lambda^{(m,k)}\|_{\ell_p} = 0. \tag{4.22}$$

We now observe that, by (4.16) and (4.19), the sequence $(\boldsymbol{v}_\Lambda^{(m,k)})_{m,k}$ is contained in the bounded set $\mathcal{R}(u^{(0)})$. Using the uniform continuity of $\boldsymbol{J}'$ on bounded sets, we obtain from (4.22)

$$\lim_{m\to\infty} \sup_k \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k+1)}) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} = 0. \tag{4.23}$$

Next, setting $[\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}), \eta^{(m,k)}] := \textbf{APPROX-GRAD}[\boldsymbol{v}_\Lambda^{(m,k)}, \varepsilon^{(m,k)}, \gamma]$ and using (4.2) as well as step 3 of **DESCENT**, we have, for $0 \le k < K^{(m)}$,

$$\begin{aligned}
\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} - \eta^{(m,k)} \le \|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} &= -\langle \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle \\
&= \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}) - \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle \\
&\quad + \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k+1)}) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle \\
&\quad - \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k+1)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle.
\end{aligned}$$

Now, (2.4) and (4.2) yield

$$\begin{aligned}
&\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} - \eta^{(m,k)} \le \\
&\quad \le \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}) - \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(k)})\|_{\ell_{p'}} + \|\boldsymbol{J}'(\boldsymbol{v}^{(m,k+1)}) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} \\
&\qquad - \beta\, \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle \\
&\quad \le \eta^{(m,k)} + \|\boldsymbol{J}'(\boldsymbol{v}^{(m,k+1)}) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} + \beta\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}};
\end{aligned}$$

thus

$$(1-\beta)\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} \le \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k+1)})\|_{\ell_{p'}} + 2\eta^{(m,k)}.$$

By definition of **APPROX-GRAD** and assumption (4.14), we get $\eta^{(m,k)} \le \varepsilon^{(m,k)} \to 0$ as $m \to \infty$, uniformly in k. This and (4.23) imply

$$\lim_{m\to\infty} \sup_k \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} = 0.$$

Since $\|\boldsymbol{v}_\Lambda^{(m,k)} - \boldsymbol{u}\|_{\ell_p} \le \left(\frac{1}{c_{J,\Psi}}\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}}\right)^{1/(p-1)}$, we conclude that

$$\lim_{m\to\infty} \sup_k \|\boldsymbol{v}_\Lambda^{(m,k)} - \boldsymbol{u}\|_{\ell_p} = 0.$$

In particular, since $\boldsymbol{v}_\Lambda^{(m,0)} = \boldsymbol{u}_\Lambda^{(m)}$, this implies the claimed result. ∎

A few remarks are in order.

Remark 4.14. (i) Fulfilling assumption (4.15) may be accomplished as follows. By Wolfe's condition, the value of the functional is decreased when going from $\boldsymbol{v}_\Lambda^{(m,k)}$ to $\boldsymbol{v}_\Lambda^{(m,k+1)}$, provided the gradient is not yet zero causing the algorithm to stop. Precisely, setting $\boldsymbol{v}_\Lambda^{(m,k+1)} = \boldsymbol{v}_\Lambda^{(m,k)} + \mu^{(k)}\boldsymbol{s}^{(k)}$, we have by (2.3), (4.5), and (4.7)

$$\begin{aligned}\boldsymbol{J}(\boldsymbol{v}_\Lambda^{(m,k)}) - \boldsymbol{J}(\boldsymbol{v}_\Lambda^{(m,k+1)}) &\ge -\alpha\mu^{(k)}\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)}), \boldsymbol{s}_\Lambda^{(m,k)}\rangle \;\ge\; \alpha\gamma\,\mu^{(k)}\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}} \\ &\ge \alpha\frac{2\gamma^2}{1+\gamma}\mu^{(k)}\|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}}.\end{aligned}$$

Then, we obtain by using a telescopic sum

$$\begin{aligned}\mathbb{J}(\boldsymbol{u}_\Lambda^{(m)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) = \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,0)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) &= \sum_{k=0}^{K^{(m)}-1} \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,k+1)}) \\ &\ge \frac{2\alpha\gamma^2}{1+\gamma}\sum_{k=0}^{K^{(m)}-1}\mu^{(k)}\|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}};\end{aligned}$$

i.e., we can choose

$$\vartheta^{(m)} := \frac{\alpha\gamma^2}{1+\gamma}\sum_{k=0}^{K^{(m)}-1}\mu^{(k)}\|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_{p'}},$$

which is in fact computable.

(ii) In view of (4.21), a natural way to satisfy assumption (4.14) is to set

$$\varepsilon^{(m,k)} := \begin{cases} 1 & \text{if } m = 0, \\ \vartheta^{(m-1)} & \text{if } m \ge 1, \end{cases} \qquad k = 0, 1, \dots, K^{(m)} - 1.$$

5. An adaptive algorithm with convergence rate. From now on, we focus our analysis on the case $p = 2$. Furthermore, we assume that the Fréchet derivative J' is Lipschitz continuous on each bounded subset of V. Precisely, recalling that the set $\mathcal{R}(u^{(0)})$ (see Lemma 2.2) is bounded, we assume the existence of a constant $L_J > 0$, possibly depending on $u^{(0)}$, such that

$$\|J'(v) - J'(w)\|_{V'} \le L_J\,\|v - w\|_V, \quad v, w \in \mathcal{R}(u^{(0)}). \tag{5.1}$$

Recalling the norm equivalences (3.1) and (3.2) and setting $L_{J,\Psi} = L_J C_\Psi^2$, we obtain the discrete form of the previous inequality, namely,

$$\|\boldsymbol{J}'(\boldsymbol{v}) - \boldsymbol{J}'(\boldsymbol{w})\|_{\ell_2} \le L_{J,\Psi}\, \|\boldsymbol{v} - \boldsymbol{w}\|_{\ell_2}, \quad \boldsymbol{v}, \boldsymbol{w} \in \mathcal{R}(u^{(0)}). \tag{5.2}$$

Recalling Assumption 2.1(ii) and setting $c_{J,\Psi} = c_J c_\Psi^2$, we also get

$$c_{J,\Psi}\|\boldsymbol{v} - \boldsymbol{w}\|_{\ell_2}^2 \le \langle \boldsymbol{J}'(\boldsymbol{v}) - \boldsymbol{J}'(\boldsymbol{w}), \boldsymbol{v} - \boldsymbol{w}\rangle \le L_{J,\Psi}\|\boldsymbol{v} - \boldsymbol{w}\|_{\ell_2}^2, \quad \boldsymbol{v}, \boldsymbol{w} \in \mathcal{R}(u^{(0)}). \tag{5.3}$$

In this section, we present a particular realization of the abstract adaptive algorithm **MINIMIZE**, which exploits the extra properties of the functional $\mathbb{J}$ stated above. The convergence result of the algorithm will be supplemented by a precise estimate of the rate of decay of the error. This will allow us to determine the number of iterations needed to reach a target tolerance, as well as to relate the error of the algorithm to the best approximation error of the solution.

We start by describing a more efficient line-search algorithm than the one prescribed in section 4.2; it requires neither the evaluation of the functional, nor additional approximate evaluations of the gradient other than the already computed descent direction.

5.1. Line search. Given a compactly supported vector $\boldsymbol{v}_\Lambda \in \mathcal{R}(u^{(0)})$ and an approximation $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ of $\boldsymbol{J}'(\boldsymbol{v}_\Lambda)$ which satisfies conditions (4.2) and (4.3), we set $\boldsymbol{s}_\Lambda = -\boldsymbol{R}(\boldsymbol{G}(\boldsymbol{v}_\Lambda))$ and we define a closed interval with computable endpoints, contained in the interval $\mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$. To this end, let us set $\varphi(\mu) = \mathbb{J}(\boldsymbol{v}_\Lambda + \mu \boldsymbol{s}_\Lambda)$, so that $\varphi'(\mu) = \langle \mathbb{J}(\boldsymbol{v}_\Lambda + \mu \boldsymbol{s}_\Lambda), \boldsymbol{s}_\Lambda\rangle$, and let us recall that $\mu \in \mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$ if and only if conditions (2.6) and (2.7) are satisfied. In this subsection, we actually assume that (5.2) and, consequently, (5.3) hold indeed in a bounded set larger than $\mathcal{R}(u^{(0)})$, namely, in the neighborhood of $\mathcal{R}(u^{(0)})$ of radius $\bar{\mu} := \mathrm{diam}(\mathcal{R}(u^{(0)}))$ (in the ℓ_2-distance); obviously, this is not restrictive at all, since it amounts to properly (re-)defining the constant L_J. Thus, if we choose $\boldsymbol{v} = \boldsymbol{v}_\Lambda$ and $\boldsymbol{w} = \boldsymbol{v}_\Lambda + \mu \boldsymbol{s}_\Lambda$ in (5.3), we easily obtain

$$c_{J,\Psi}\, \mu \le \varphi'(\mu) - \varphi'(0) \le L_{J,\Psi}\, \mu, \qquad \mu \in [0, \bar{\mu}]. \tag{5.4}$$

Using the right-hand side of (5.4), we get for some $\theta \in (0,1)$

$$\varphi(\mu) = \varphi(0) + \varphi'(\theta\, \mu)\mu \le \varphi(0) + \varphi'(0)\, \mu + \theta\, L_{J,\Psi}\, \mu^2.$$

Hence, (2.6) is fulfilled if μ satisfies

$$\varphi'(0)\, \mu + L_{J,\Psi}\, \mu^2 \le \alpha\, \varphi'(0)\, \mu, \qquad \text{i.e., } L_{J,\Psi}\, \mu \le (1-\alpha)\, |\varphi'(0)|.$$

Taking into account the left-hand side of (4.6), we get the sufficient condition for the validity of (2.6)

$$\mu \le \mu^* := \gamma\, \frac{1-\alpha}{L_{J,\Psi}}\, \|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_2},$$

provided $\mu^* \le \bar{\mu}$. This is indeed the case, since by (4.7) and (5.2) we have

$$\mu^* \le \frac{1-\alpha}{L_{J,\Psi}}\, \frac{1+\gamma}{2}\, \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \le (1-\alpha)\, \frac{1+\gamma}{2}\, \|\boldsymbol{v}_\Lambda - \boldsymbol{u})\|_{\ell_2} < \bar{\mu}.$$

On the other hand, using the inequality on the left-hand side, condition (2.7) is fulfilled if μ satisfies

$$\varphi'(0) + c_{J,\Psi}\,\mu \geq \beta\,\varphi'(0), \qquad \text{i.e., } c_{J,\Psi}\,\mu \geq (1-\beta)\,|\varphi'(0)|.$$

By the right-hand side of (4.6), we get the sufficient condition for the validity of (2.7)

$$\mu \geq \mu_* := \frac{2}{1+\gamma}\,\frac{1-\beta}{c_{J,\Psi}}\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_2}.$$

Obviously, we have to require that $\mu_* \leq \mu^*$, i.e,

$$(1-\beta) \leq \frac{\gamma(\gamma+1)}{2}\,\frac{c_{J,\Psi}}{L_{J,\Psi}}(1-\alpha), \tag{5.5}$$

which can always be satisfied, e.g., by fixing α and choosing β as close to 1 as needed.

Thus, we have obtained the following result.

PROPOSITION 5.1. *For any $\alpha \in (0,1)$ and any $\gamma \in (0,1)$, there exists β^* satisfying $\alpha \leq \beta^* < 1$ such that for all $\beta \in [\beta^*, 1)$, the interval*

$$\left[\frac{2}{1+\gamma}\,\frac{1-\beta}{c_{J,\Psi}}\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_2}, \gamma\,\frac{1-\alpha}{L_{J,\Psi}}\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_2}\right] \tag{5.6}$$

is nonempty and contained in $\mathcal{A}(\mathbb{J}; \boldsymbol{v}_\Lambda, \boldsymbol{s}_\Lambda)$. □

Consequently, the output of the procedure **LINE-SEARCH**$[\boldsymbol{v}_\Lambda, \alpha, \beta]$ can be defined by picking any value in this interval.

5.2. Error reduction in one descent step. Let $\boldsymbol{v}_\Lambda \in \mathcal{R}(u^{(0)})$ be any compactly supported approximation of the exact minimizer $\boldsymbol{u}$. We apply the routine **DESCENT** to it and, assuming $\boldsymbol{v}_\Lambda \neq \boldsymbol{u}$, we get a new approximation $\boldsymbol{w}_\Lambda$. Hereafter, we are interested in studying the behavior of the approximation error in going from $\boldsymbol{v}_\Lambda$ to $\boldsymbol{w}_\Lambda$. In the analysis, the following definition will be useful.

DEFINITION 5.2. *For any compactly supported vector $\boldsymbol{v}_\Lambda$, we set*

$$\mathbb{E}(\boldsymbol{v}_\Lambda) := \mathbb{J}(\boldsymbol{v}_\Lambda) - \mathbb{J}(\boldsymbol{u}).$$

The quantity $\mathbb{E}(\boldsymbol{v}_\Lambda)$ is an a priori error bound; indeed, by (2.2) and (3.1), we get

$$\|\boldsymbol{v}_\Lambda - \boldsymbol{u}\|_{\ell_2}^2 \leq \frac{2}{c_{J,\Psi}}\mathbb{E}(\boldsymbol{v}_\Lambda). \tag{5.7}$$

In order to compare $\mathbb{E}(\boldsymbol{w}_\Lambda)$ to $\mathbb{E}(\boldsymbol{v}_\Lambda)$, we recall the definition of $\boldsymbol{w}_\Lambda = \boldsymbol{v}_\Lambda + \mu\,\boldsymbol{s}_\Lambda$ given at point 5 of **DESCENT**; from condition (2.3) and inequality (4.5), we immediately get

$$\mathbb{E}(\boldsymbol{w}_\Lambda) \leq \mathbb{E}(\boldsymbol{v}_\Lambda) - \alpha\gamma\mu\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}. \tag{5.8}$$

We now establish two technical results which will be used in what follows.

LEMMA 5.3. *Let $\mu =$ **LINE-SEARCH**$[\boldsymbol{v}_\Lambda, \alpha, \beta]$. Then the following inequality holds:*

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \leq \frac{L_{J,\Psi}}{\gamma(1-\beta)}\,\mu.$$

Proof. We start by the trivial identity

$$-\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda\rangle = \langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda\rangle - \langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda), \boldsymbol{s}_\Lambda\rangle.$$

Using (5.3) and condition (2.4), we obtain

$$-\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda\rangle \le L_{J,\Psi}\|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_2} - \beta\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{s}_\Lambda\rangle,$$

i.e.,

$$-\langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda), \boldsymbol{s}_\Lambda\rangle \le \frac{L_{J,\Psi}}{1-\beta}\,\|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_2}.$$

We conclude by (4.5). ∎

LEMMA 5.4. *The following inequality holds:*

$$\mathbb{E}(\boldsymbol{v}_\Lambda) \le \frac{1}{2c_{J,\Psi}}\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|^2_{\ell_2}.$$

Proof. We again apply (2.2) and (3.1) to get

$$\begin{aligned}\mathbb{J}(\boldsymbol{u}) - \mathbb{J}(\boldsymbol{v}_\Lambda) &\ge \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{u} - \boldsymbol{v}_\Lambda\rangle + \frac{c_{J,\Psi}}{2}\|\boldsymbol{u} - \boldsymbol{v}_\Lambda\|^2_{\ell_2}\\ &\ge \min_{\boldsymbol{z}\in\ell_2}\left\{\langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{z}\rangle + \frac{c_{J,\Psi}}{2}\|\boldsymbol{z}\|^2_{\ell_2}\right\}\\ &= \min_{\boldsymbol{z}\in\ell_2}\sum_{\lambda\in\mathcal{J}}\left\{\boldsymbol{J}'(\boldsymbol{v}_\Lambda)_\lambda\, z_\lambda + \frac{c_{J,\Psi}}{2}z_\lambda^2\right\}.\end{aligned}$$

We note that we can minimize along each component λ independently for each $\lambda \in \mathcal{J}$; the minimum is attained at $z_\lambda = -\frac{1}{c_{J,\Psi}}\,\boldsymbol{J}'(\boldsymbol{v}_\Lambda)_\lambda$. We conclude that

$$\mathbb{J}(\boldsymbol{u}) - \mathbb{J}(\boldsymbol{v}_\Lambda) \ge -\frac{1}{2c_{J,\Psi}}\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|^2_{\ell_2},$$

which is precisely the thesis. ∎

We are now ready to estimate the error reduction guaranteed by one application of **DESCENT**.

PROPOSITION 5.5. *Given a compactly supported vector $\boldsymbol{v}_\Lambda \in \mathcal{R}(u^{(0)})$ and any tolerance ε, define $\boldsymbol{w}_\Lambda := \mathbf{DESCENT}(\boldsymbol{v}_\Lambda, \varepsilon)$. Let α, β be any fixed constants satisfying Wolfe's condition in Definition* 2.4. *Then, setting*

$$\sigma := 1 - 2\frac{c_{J,\Psi}}{L_{J,\Psi}}\,\gamma^2\,(1-\beta)\,\alpha < 1, \tag{5.9}$$

we have

$$\mathbb{E}(\boldsymbol{w}_\Lambda) \le \sigma\,\mathbb{E}(\boldsymbol{v}_\Lambda).$$

Proof. By the two previous lemmas, we obtain

$$\mu\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \ge \frac{\gamma\,(1-\beta)}{L_{J,\Psi}}\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|^2_{\ell_2} \ge 2\frac{c_{J,\Psi}}{L_{J,\Psi}}\,\gamma\,(1-\beta)\,\mathbb{E}(\boldsymbol{v}_\Lambda).$$

The result follows from (5.8). ∎

Remark 5.6. The expression (5.9) for the error reduction factor σ suggests a simple strategy for selecting the two parameters α and β which appear in (2.3) and (2.4). Indeed, we observe that σ is monotonically decreasing as $1-\beta$ increases. Recalling condition (5.5), we are lead to choose

$$1-\beta = \frac{\gamma(\gamma+1)}{2}\,\frac{c_{J,\Psi}}{L_{J,\Psi}}\,(1-\alpha). \tag{5.10}$$

In this case, the interval (5.6) reduces to a point, which is the chosen stepsize; i.e., we set

$$\mu := \gamma\,\frac{1-\alpha}{L_{J,\Psi}}\,\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\ell_2}.$$

Substituting (5.10) into (5.9), we see that σ is minimized with respect to α by the choice $\alpha = \frac{1}{2}$. With this value for α, we finally obtain the error reduction rate

$$\sigma_{\mathrm{opt}} := 1 - \left(\frac{c_{J,\Psi}}{L_{J,\Psi}}\right)^2 \frac{\gamma^3\,(1+\gamma)}{4}. \tag{5.11}$$

As a by-product of the previous analysis, we obtain the next result, which describes the interplay between the available error control quantities.

PROPOSITION 5.7. *The following chain of inequalities holds:*

$$\|\boldsymbol{v}_\Lambda - \boldsymbol{u}\|_{\ell_2}^2 \le \frac{2}{c_{J,\Psi}}\,\mathbb{E}(\boldsymbol{v}_\Lambda) \le \frac{2}{c_{J,\Psi}^2}\,\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}^2 \le 2\left(\frac{L_{J,\Psi}}{c_{J,\Psi}}\right)^2 \|\boldsymbol{v}_\Lambda - \boldsymbol{u}\|_{\ell_2}^2,$$

for all $\boldsymbol{v}_\Lambda \in \mathcal{R}(u^{(0)})$.

Proof. It is enough to combine (5.7), Lemma 5.4, and (5.2) with $\boldsymbol{v} = \boldsymbol{v}_\Lambda$ and $\boldsymbol{w} = \boldsymbol{u}$. ∎

The result means that $(\mathbb{E}(\boldsymbol{v}_\Lambda))^{1/2}$ is an a priori error bound both from above and from below; similarly $\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}$ is an upper and lower a posteriori error estimator. Of course, in general, none of them is computable in practice. However, by using inequalities (4.4), we can easily obtain from the latter a computable a posteriori error estimator.

5.3. Improving the error estimate. In this section, we show that the application of **APPROX-GRAD** within the procedure **DESCENT** may lead to the improvement of the currently available estimate of the quantity $\mathbb{E}$. This feature will be crucial in the design of the adaptive algorithm considered in the next section.

Let $\boldsymbol{v}_\Lambda$ be any compactly supported vector and let $\mathbb{E}_\Lambda$ be any upper estimate of $\mathbb{E}(\boldsymbol{v}_\Lambda)$, i.e., $\mathbb{E}(\boldsymbol{v}_\Lambda) \le \mathbb{E}_\Lambda$. By Proposition 5.7, there exists a constant $\mathcal{C}_1$ (whose expression is easily computable) such that

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \le \mathcal{C}_1 \mathbb{E}(\boldsymbol{v}_\Lambda)^{1/2} \le \mathcal{C}_1 \mathbb{E}_\Lambda^{1/2}. \tag{5.12}$$

Let us enter **APPROX-GRAD**$[\boldsymbol{v}_\Lambda, \varepsilon, \gamma]$ with the choice $\varepsilon = \mathcal{C}_1 \mathbb{E}_\Lambda^{1/2}$. Observe that whenever the loop in **APPROX-GRAD** does not stop, i.e., whenever for some n we have $\|\boldsymbol{w}_\Lambda^{(n)}\|_{\ell_2} < \frac{1+\gamma}{1-\gamma}\eta^{(n)}$, then we get a new a priori information on the norm of the gradient, namely,

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \le \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda) - \boldsymbol{w}_\Lambda^{(n)}\|_{\ell_2} + \|\boldsymbol{w}_\Lambda^{(n)}\|_{\ell_2} < \eta^{(n)} + \frac{1+\gamma}{1-\gamma}\eta^{(n)} = \frac{2}{1-\gamma}\eta^{(n)}.$$

Thus, if $\bar{n}$ denotes the number of applications of **EVAL-GRAD** within **APPROX-GRAD**, then we know that

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \le \frac{2}{1-\gamma}\nu^{\bar{n}-1}\varepsilon = \mathcal{C}_1\frac{2}{1-\gamma}\nu^{\bar{n}-1}\mathbb{E}_\Lambda^{1/2}. \tag{5.13}$$

Again by Proposition 5.7 we have, for a suitable constant $\mathcal{C}_2$,

$$\mathbb{E}(\boldsymbol{v}_\Lambda) \le \mathcal{C}_2\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}^2 \le \mathcal{C}_2\mathcal{C}_1^2\frac{4}{(1-\gamma)^2}\nu^{2\bar{n}-2}\,\mathbb{E}_\Lambda. \tag{5.14}$$

If we define n_0 as the smallest integer ≥ 1 such that

$$\mathcal{C}_2\mathcal{C}_1^2\frac{4}{(1-\gamma)^2} \le \nu^{-2(n_0-1)}, \tag{5.15}$$

then we obtain

$$\mathbb{E}(\boldsymbol{v}_\Lambda) \le \nu^{2(\bar{n}-n_0)}\,\mathbb{E}_\Lambda.$$

Obviously, we have to take the most accurate estimate between this one and the initial one $\mathbb{E}(\boldsymbol{v}_\Lambda) \le \mathbb{E}_\Lambda$. Denoting by $(z)_+$ the positive part of a number z, we conclude that at the output of an application of **APPROX-GRAD**, in which $\bar{n}$ applications of **EVAL-GRAD** have been made, we know that

$$\mathbb{E}(\boldsymbol{v}_\Lambda) \le \nu^{2(\bar{n}-n_0)_+}\,\mathbb{E}_\Lambda. \tag{5.16}$$

5.4. Coarsening. The coarsening procedure **COARSE:** $[\boldsymbol{v}_\Lambda, \vartheta] \mapsto \boldsymbol{w}_\Lambda$ as described in section 4.3 can be simplified and optimized by exploiting the assumption (5.1). Under the sole condition that an estimate of $\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}$ is known, we can get $\boldsymbol{w}_\Lambda$ without any application of **APPROX-GRAD**, by calling once the procedure **THRESH** introduced therein. Indeed, by the convexity of $\mathbb{J}$ and by (5.1), we have for any $\boldsymbol{w}_\Lambda \in \mathcal{R}(u^{(0)})$

$$\begin{aligned}\mathbb{J}(\boldsymbol{w}_\Lambda) - \mathbb{J}(\boldsymbol{v}_\Lambda) &\le \langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda), \boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\rangle \\ &= \langle \boldsymbol{J}'(\boldsymbol{w}_\Lambda) - \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\rangle + \langle \boldsymbol{J}'(\boldsymbol{v}_\Lambda), \boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\rangle \\ &\le L_{J,\Psi}\|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_2}^2 + \|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2}\|\boldsymbol{w}_\Lambda - \boldsymbol{v}_\Lambda\|_{\ell_2}.\end{aligned}$$

Assume that $\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda)\|_{\ell_2} \le \xi$ for some $\xi > 0$. Then, setting

$$\varepsilon_\vartheta := \min\left(\left(\frac{\vartheta}{2L_{J,\Psi}}\right)^{1/2}, \frac{\vartheta}{2\xi}\right) \qquad \text{and} \qquad \boldsymbol{w}_\Lambda := \mathbf{THRESH}[\boldsymbol{v}_\Lambda, \varepsilon_\vartheta], \tag{5.17}$$

we obtain the desired coarsened vector $\boldsymbol{w}_\Lambda$.

5.5. The adaptive algorithm. Denote by $\mathbb{E}_0$ any computable estimate of the initial error $\mathbb{E}(\boldsymbol{u}_\Lambda^{(0)})$, i.e., choose $\mathbb{E}_0$ so that

$$\mathbb{E}(\boldsymbol{u}_\Lambda^{(0)}) := \mathbb{J}(\boldsymbol{u}_\Lambda^{(0)}) - \mathbb{J}(\boldsymbol{u}) \le \mathbb{E}_0. \tag{5.18}$$

Let $\nu \in (0,1)$ be a fixed constant. We now prove by recursion that the parameters appearing in Algorithm 4.12 **MINIMIZE** can be chosen in such a way that either

the exact solution $\boldsymbol{u}$ is obtained after a finite number of steps, or there exists a strictly increasing sequence of integers e_m with $e_0 = 0$ such that

$$\mathbb{E}(\boldsymbol{u}_\Lambda^{(m)}) \le \nu^{2e_m}\,\mathbb{E}_0; \tag{5.19}$$

furthermore, denoting by N_m the number of applications of **EVAL-GRAD** to get $\boldsymbol{u}_\Lambda^{(m)}$, we will relate N_m to e_m.

For $m = 0$, inequality (5.19) is precisely (5.18). By induction, we assume that (5.19) holds up to some $m \ge 0$. We set $e_{m,0} = 0$ and we prove by recursion that there exists a nondecreasing sequence of integers $e_{m,k}$ such that

$$\mathbb{E}(\boldsymbol{v}_\Lambda^{(m,k)}) \le \mathbb{E}_{m,k} \quad \text{with } \mathbb{E}_{m,k} := \sigma^k \nu^{2(e_m+e_{m,k})}\,\mathbb{E}_0, \qquad k = 0, 1, \dots. \tag{5.20}$$

By (5.19), this inequality holds for $k = 0$. By induction, assume that it holds up to some $k \ge 0$. Set

$$\varepsilon^{(m,k)} := \mathcal{C}_1 \mathbb{E}_{m,k}^{1/2} \tag{5.21}$$

and apply **DESCENT**$[\boldsymbol{v}_\Lambda^{(m,k)}, \varepsilon^{(m,k)}]$. If the output η of **APPROX-GRAD** within **DESCENT** is zero, we have found the exact solution and the algorithm stops. Otherwise, let $\bar{n}_{m,k}$ denote the number of applications of **EVAL-GRAD** inside the routine **DESCENT**$[\boldsymbol{v}_\Lambda^{(m,k)}, \varepsilon^{(m,k)}]$. Recalling (5.16) and Proposition 5.5, we obtain

$$\mathbb{E}(\boldsymbol{v}_\Lambda^{(m,k+1)}) \le \sigma \mathbb{E}(\boldsymbol{v}_\Lambda^{(m,k)}) \le \sigma \nu^{2(\bar{n}_{m,k}-n_0)_+}\,\mathbb{E}_{m,k}. \tag{5.22}$$

Setting $e_{m,k+1} := e_{m,k} + (\bar{n}_{m,k} - n_0)_+$, we obtain (5.20) with k replaced by $k+1$. This completes the inner recursion argument.

Let $K^{(m)}$ be an integer to be determined. The coarsening step **COARSE** yields

$$\mathbb{E}(\boldsymbol{u}_\Lambda^{(m+1)}) - \mathbb{E}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) = \mathbb{J}(\boldsymbol{u}_\Lambda^{(m+1)}) - \mathbb{J}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})}) \le \vartheta^{(m)}.$$

Choose

$$\vartheta^{(m)} := \bar{\mathcal{C}}\,\mathbb{E}_{m,K^{(m)}}, \tag{5.23}$$

where $\bar{\mathcal{C}} > 0$ is by now a constant which can be freely chosen, but in the next section will be chosen in order to guarantee the optimality of the thresholding procedure. Then, recalling the definition in (5.20), we obtain

$$\mathbb{E}(\boldsymbol{u}_\Lambda^{(m+1)}) \le (1+\bar{\mathcal{C}})\,\sigma^{K^{(m)}} \nu^{2(e_m+e_{m,K^{(m)}})}\,\mathbb{E}_0.$$

This suggests choosing $K^{(m)} \ge 1$ as the smallest integer for which we have

$$g_{m,K^{(m)}} \ge 1, \text{ where } g_{m,K^{(m)}} \text{ satisfies } \nu^{2g_{m,K^{(m)}}} := (1+\bar{\mathcal{C}})\,\sigma^{K^{(m)}} \nu^{2e_{m,K^{(m)}}}. \tag{5.24}$$

Note that $K^{(m)}$ is bounded by $\bar{K}$, where $\bar{K} \ge 1$ is the smallest integer satisfying $(1+\bar{\mathcal{C}})\,\sigma^{\bar{K}} \le \nu^2$. Setting

$$\bar{e}_m := [g_{m,K^{(m)}}] \ge 1 \qquad \text{and} \qquad e_{m+1} := e_m + \bar{e}_m, \tag{5.25}$$

we obtain (5.19) with m replaced by $m+1$. This completes the outer recursion argument.

We note that each coarsening step $\boldsymbol{u}_\Lambda^{(m+1)} := \mathbf{COARSE}[\boldsymbol{v}_\Lambda^{(m,K^{(m)})}, \vartheta^{(m)}]$ can be accomplished as described in section 5.4. Recalling (5.12), we have

$$\|\boldsymbol{J}'(\boldsymbol{v}_\Lambda^{(m,K^{(m)})})\|_{\ell_2} \le \mathcal{C}_1 \mathbb{E}(\boldsymbol{v}_\Lambda^{(m,K^{(m)})})^{1/2} \le \mathcal{C}_1 \mathbb{E}_{m,K^{(m)}}^{1/2} =: \xi^{(m)}.$$

Since we have chosen $\vartheta^{(m)} = \bar{\mathcal{C}}\,\mathbb{E}_{m,K^{(m)}}$, by (5.17) we obtain $\boldsymbol{u}_\Lambda^{(m+1)}$ as the output of $\mathbf{THRESH}[\boldsymbol{v}_\Lambda^{(m,K^{(m)})}, \varepsilon_\vartheta^{(m)}]$ with

$$\varepsilon_\vartheta^{(m)} := \min\left(\left(\frac{\bar{\mathcal{C}}}{2L_{J,\Psi}}\right)^{1/2}, \frac{\bar{\mathcal{C}}}{2\mathcal{C}_1}\right)\mathbb{E}_{m,K^{(m)}}^{1/2}. \tag{5.26}$$

Finally, let us count the number of applications of **EVAL-GRAD** in our algorithm. By the previous considerations, they occur only within **DESCENT**. Denote by $N_{m+1,m} = \bar{n}_{m,0} + \cdots + \bar{n}_{m,K^{(m)}-1}$ the number of applications of **EVAL-GRAD** needed to compute $\boldsymbol{u}_\Lambda^{(m+1)}$ from $\boldsymbol{u}_\Lambda^{(m)}$. We observe that surely $e_{m,K^{(m)}} \le \bar{e}_m + \delta\bar{K}$ for some $\delta \ge 1$. Thus,

$$\begin{aligned} N_{m+1,m} &= \sum_{k=0}^{K^{(m)}-1} (\bar{n}_{m,k} - n_0) + n_0 K^{(m)} \le \sum_{k=0}^{K^{(m)}-1} (\bar{n}_{m,k} - n_0)_+ + n_0\bar{K} \\ &= e_{m,K^{(m)}} + n_0\bar{K} \le \bar{e}_m + (n_0+\delta)\bar{K} \\ &\le (n_0+\delta+1)\bar{K}\bar{e}_m = q\bar{K}(e_{m+1} - e_m) \end{aligned}$$

with $q := n_0 + \delta + 1$ and n_0 defined in (5.15). We conclude that the number N_{m+1} of applications of **EVAL-GRAD** needed to compute $\boldsymbol{u}_\Lambda^{(m+1)}$ from $\boldsymbol{u}_\Lambda^{(0)}$ satisfies

$$N_{m+1} = \sum_{\mu=0}^{m} N_{\mu+1,\mu} \le q\bar{K}\sum_{\mu=0}^{m}(e_{\mu+1} - e_\mu) = q\bar{K}e_{m+1}.$$

Remark 5.8. In view of the subsequent optimality analysis, we observe that a version of the algorithm can be given in which each $\bar{n}_{m,k}$ (and hence $N_{m+1,m}$) is guaranteed to be uniformly bounded. In fact, (5.14) shows that the output $\boldsymbol{w}_\Lambda^{(n)}$ of the routine $\mathbf{EVAL-GRAD}[\boldsymbol{v}_\Lambda, \nu^{n-1}\varepsilon]$ satisfies

$$\mathbb{E}(\boldsymbol{w}_\Lambda^{(n)}) \le \mathcal{C}_2\mathcal{C}_1^2 \frac{4}{(1-\gamma)^2}\nu^{2n-2}\,\mathbb{E}_\Lambda,$$

where again $\mathbb{E}_\Lambda$ is an estimate for $\mathbb{E}(\boldsymbol{v}_\Lambda)$. Choosing $\bar{n}$ as the smallest integer satisfying

$$\mathcal{C}_2\mathcal{C}_1^2 \frac{4}{(1-\gamma)^2}\nu^{2n-2} \le \sigma,$$

we obtain $\mathbb{E}(\boldsymbol{w}_\Lambda^{(n)}) \le \sigma\,\mathbb{E}_\Lambda$. Hence, we can restrict the loop in **APPROX-GRAD** to $n = 1, 2, \ldots, \bar{n}$, with an absolute constant $\bar{n}$. If (4.3) is satisfied before the end of the loop, we leave **APPROX-GRAD** and proceed by **LINE-SEARCH** (resulting in some $\boldsymbol{v}_\Lambda$) and obtain the error reduction $\mathbb{E}(\boldsymbol{v}_\Lambda) \le \sigma\,\mathbb{E}_\Lambda$ by the above arguments. Otherwise, after at most $\bar{n}$ steps, we leave **APPROX-GRAD** and set $\boldsymbol{v}_\Lambda := \boldsymbol{w}_\Lambda^{(\bar{n})}$, avoiding the necessity of the line search in this case. This again results in the same error reduction.

Let us summarize our result in the following theorem.

THEOREM 5.9. *Let $p = 2$ and let* (5.1) *hold. We consider Algorithm* 4.12 **MINIMIZE**. *We fix a constant $\nu \in (0,1)$ and we choose a constant $\mathbb{E}_0$ satisfying* (5.18). *Then, for the choice* (5.24) *of the parameters $K^{(m)}$ (with $K^{(m)} \lesssim 1$), $\vartheta^{(m)}$ as in* (5.23) *and $\varepsilon^{(m,k)}$ as in* (5.21), *either the algorithm yields the exact solution $\boldsymbol{u}$ after a finite number of steps, or there exists a strictly increasing sequence $\{e_m\}$ of integers* (5.25), *with $e_0 = 0$, such that the sequence of approximations $\boldsymbol{u}_\Lambda^{(m)}$ produced by the algorithm satisfies*

$$\mathbb{E}(\boldsymbol{u}_\Lambda^{(m)}) \le \nu^{2e_m}\,\mathbb{E}_0, \qquad m = 0, 1, \dots.$$

Furthermore, the number N_m of applications of **EVAL-GRAD** *needed to compute $\boldsymbol{u}_\Lambda^{(m)}$ from $\boldsymbol{u}_\Lambda^{(0)}$ satisfies $N_m \lesssim e_m$; i.e., it grows at most as the logarithm of the obtained accuracy.* □

Recalling (3.1) and Proposition 5.7, we immediately obtain an error estimate in the V-norm.

COROLLARY 5.10. *Under the same conditions of the previous theorem, we have*

$$\|u_\Lambda^{(m)} - u\|_V \le \nu^{e_m}\, C_\Psi \left(\frac{2\mathbb{E}_0}{c_{J,\Psi}}\right)^{1/2}, \qquad m = 0, 1, \dots. \qquad \square$$

5.6. Stopping criteria. The previous algorithm produces arbitrarily close approximations to the exact solution u. In practice, one fixes a tolerance TOL and wishes to stop the algorithm as soon as the inequality $\|u_\Lambda^{(m)} - u\|_V < TOL$ is guaranteed to hold. According to the previous estimate, one can take as m the smallest integer for which

$$\nu^{e_m} < \frac{1}{C_\Psi}\left(\frac{c_{J,\Psi}}{2\mathbb{E}_0}\right)^{1/2} TOL.$$

On the other hand, the stopping test needs to be included also within **APPROX-GRAD**, in order to prevent an infinite loop, or simply to avoid unnecessary applications of **EVAL-GRAD** therein. Precisely, recalling (5.13), the loop in **APPROX-GRAD** is stopped if, for some n,

$$\frac{2}{1-\gamma}\nu^{n-1}\varepsilon < \omega\, TOL,$$

where $\omega \in (0,1)$ can be easily determined from Proposition 5.7 so that $\|\boldsymbol{v}_\Lambda - \boldsymbol{u}\|_{\ell_2} < TOL/(2C_\Psi)$. Setting $\boldsymbol{w}_\Lambda := \mathbf{THRESH}[\boldsymbol{v}_\Lambda, TOL/(2C_\Psi)]$, the triangle inequality yields $\|\boldsymbol{w}_\Lambda - \boldsymbol{u}\|_{\ell_2} < TOL/C_\Psi$, whence $\|w_\Lambda - u\|_V < TOL$ and the algorithm is stopped.

6. Optimality properties of the algorithm. We continue the discussion of the algorithm described in section 5. Here, we investigate how the number of active basis functions in $u_\Lambda^{(m)}$ (i.e., the cardinality of the support of $\boldsymbol{u}_\Lambda^{(m)}$) and the overall computational complexity needed to get $u_\Lambda^{(m)}$ (number of arithmetic operations and sortings) are related to the accuracy of the approximation.

The relationship between cardinality of the active degrees of freedom (i.e., the number of active basis functions) and accuracy is a central topic in nonlinear approx-

imation theory [22]. This involves the best N-term or the best η-accurate approximation to a given $\boldsymbol{v} \in \ell_2$ defined as follows. Let

$$\Sigma_N := \left\{ \boldsymbol{w} = \sum_{\lambda \in \Lambda} w_\lambda \, \psi_\lambda : \, |\Lambda| \leq N \right\}$$

(where $|\Lambda|$ denotes the cardinality of $\Lambda \subset \mathcal{J}$) be the nonlinear manifold of all linear combinations of basis functions containing at most N terms. Then a best N-term approximation $\boldsymbol{v}_N$ to $\boldsymbol{v}$ is defined by

$$\|\boldsymbol{v} - \boldsymbol{v}_N\|_{\ell_2} = \inf_{\boldsymbol{w}_N \in \Sigma_N^{\mathrm{con}}} \|\boldsymbol{v} - \boldsymbol{w}_N\|_{\ell_2} =: \varrho_N^{\mathrm{con}}(\boldsymbol{v}),$$

where $\Sigma_N^{\mathrm{con}} \subseteq \Sigma_N$ takes into account possible constraints in the choice of the active degrees of freedom (see (7.2) for an example).

Based on this, approximation spaces $\mathcal{A}^s$ are defined as the quasi-normed sequence space consisting of all those elements whose error $\varrho_N^{\mathrm{con}}(\boldsymbol{v})$ decays at least as N^{-s}. The quasi norm is defined by

$$\|\boldsymbol{v}\|_{\mathcal{A}^s} := \sup_{N>0} N^s \, \varrho_N^{\mathrm{con}}(\boldsymbol{v}).$$

On the other hand, a best η-accurate approximation $\boldsymbol{v}_\eta$ to $\boldsymbol{v}$ is a vector of smallest support compatible with the constraints, such that

$$\|\boldsymbol{v} - \boldsymbol{v}_\eta\|_{\ell_2} \leq \eta.$$

A typical result is as follows: any best η-accurate approximation $\boldsymbol{v}_\eta$ satisfies the inequality $|\operatorname{supp} \boldsymbol{v}_\eta| \lesssim \eta^{-1/s} \|\boldsymbol{v}\|_{\mathcal{A}^s}^{1/s}$ as $\eta \to 0$.

In this framework, the behavior of best N-term or best η-accurate approximations to $\boldsymbol{v}$ provides a benchmark to evaluate the quality of any compactly supported approximation of $\boldsymbol{v}$. Precisely, a family $\{\boldsymbol{v}_\Lambda\}$ of compactly supported vectors converging to $\boldsymbol{v}$ in the ℓ_2-norm is said to be *asymptotically optimal* if it satisfies $\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s} \lesssim \|\boldsymbol{v}\|_{\mathcal{A}^s}$ and

$$\|\boldsymbol{v} - \boldsymbol{v}_\Lambda\|_{\ell_2} \lesssim |\Lambda|^{-s} \|\boldsymbol{v}\|_{\mathcal{A}^s},$$

or, equivalently,

$$|\Lambda| \lesssim \|\boldsymbol{v} - \boldsymbol{v}_\Lambda\|_{\ell_2}^{-1/s} \|\boldsymbol{v}\|_{\mathcal{A}^s}^{1/s}.$$

The latter condition is surely satisfied if for any $\boldsymbol{v}_\Lambda$ there exists $\eta = \eta_\Lambda > 0$ such that

$$\|\boldsymbol{v} - \boldsymbol{v}_\Lambda\|_{\ell_2} \leq \eta \qquad \text{and} \qquad |\Lambda| \lesssim \eta^{-1/s} \|\boldsymbol{v}\|_{\mathcal{A}^s}^{1/s}.$$

Note that in this context the subscript Λ refers to the actual support of the vector. We remark that these results are known for L_p-spaces as well; see, e.g., [14, 22].

Before we proceed, let us give two concrete examples for the space $\mathcal{A}^s$. If no constraint is imposed on the choice of the active degrees of freedom, then $\mathcal{A}^s = \ell_\tau^{\mathrm{w}}$, where ℓ_τ^{w} (with $\frac{1}{\tau} = s + \frac{1}{2}$) is the Lorentz space of sequences $\boldsymbol{v} = \{v_\lambda\} \in \ell_2$ whose nonincreasing rearrangement $|v_{\lambda_1}| \geq |v_{\lambda_2}| \geq \cdots \geq |v_{\lambda_n}| \geq \cdots$ satisfies

$$|\boldsymbol{v}|_{\ell_\tau^{\mathrm{w}}} := \sup_n n^{1/\tau} |v_{\lambda_n}| < \infty.$$

This expression can be viewed as a quantitative measurement of the sparseness of the sequence $\boldsymbol{v}$. The space ℓ_τ^{w} is equipped with the (quasi) norm $\|\boldsymbol{v}\|_{\ell_\tau^{\mathrm{w}}} := \|\boldsymbol{v}\|_{\ell_2} + |\boldsymbol{v}|_{\ell_\tau^{\mathrm{w}}}$. If V is the Besov space $B^r_{p,p}(\Omega)$ of functions defined in a domain $\Omega \subset \mathbb{R}^d$, then $\boldsymbol{v} \in \mathcal{A}^s$ is implied by the regularity condition $v = \boldsymbol{v}^T\Psi \in B^{r+ds}_{\tau,\tau}(\Omega)$, provided the basis Ψ characterizes this space (see [5, 6, 15, 17, 18, 20] for more details, where the construction is detailed in $L_2(\Omega)$ but can easily be extended to the L_p-case).

As a second example, we consider a basis Ψ of compactly supported wavelets in Ω. Suppose that the set of active degrees of freedom is constrained to have a tree-structure (i.e., $\lambda \in \operatorname{supp} \boldsymbol{v}_N$ implies $\mu \in \operatorname{supp} \boldsymbol{v}_N$ for all wavelets ψ_μ whose support contains the support of ψ_λ). Then, $\mathcal{A}^s = \mathcal{A}^{s,\mathrm{tree}}$ is the space of sequences whose best tree N-term approximation converges at a rate N^{-s}, i.e., the space of all ℓ_2-sequences $\boldsymbol{v}$ such that

$$\varrho_N^{\mathrm{tree}}(\boldsymbol{v}) \;\lesssim\; N^{-s},$$

which is a quasi-normed space under the quasi norm

$$\|\boldsymbol{v}\|_{\mathcal{A}^{s,\mathrm{tree}}} := \sup_{n\in\mathbb{N}} N^s\, \varrho_N^{\mathrm{tree}}(\boldsymbol{v}).$$

Here $\boldsymbol{v} \in \mathcal{A}^s$ holds provided $v = \boldsymbol{v}^T\Psi \in B^{r+ds}_{\tau^*,\tau^*}(\Omega)$ holds for some $\tau^* > \tau$ with τ as above. We now suppose that the procedure **THRESH** defined in section 4.3 satisfies the following condition.

ASSUMPTION 6.1. *There exists a constant $C^* \geq 1$ such that if $\boldsymbol{v} \in \mathcal{A}^s$ and if $\boldsymbol{v}_\Lambda$ satisfies $\|\boldsymbol{v} - \boldsymbol{v}_\Lambda\|_{\ell_2} \leq \varepsilon$, then $\boldsymbol{z}_\Lambda := \mathbf{THRESH}[\boldsymbol{v}_\Lambda, C^*\varepsilon]$ satisfies*

$$\|\boldsymbol{v} - \boldsymbol{z}_\Lambda\|_{\ell_2} \leq (1 + C^*)\,\varepsilon, \quad |\operatorname{supp} \boldsymbol{z}_\Lambda| \;\lesssim\; \varepsilon^{-1/s}\|\boldsymbol{v}\|_{\mathcal{A}^s}, \quad \|\boldsymbol{z}_\Lambda\|_{\mathcal{A}^s} \;\lesssim\; \|\boldsymbol{v}\|_{\mathcal{A}^s}. \tag{6.1}$$

This condition holds both for the unconstrained thresholding (e.g., with $C^* = 4$; see [10, 11]) and for the tree-thresholding (with a possibly larger C^*; see [4, 12]). Obviously, with a larger constant C^*, the results are still valid.

From now on, let us suppose that $\boldsymbol{u} \in \mathcal{A}^s$ for some $s > 0$. We recall that, for any $m \geq 0$, the vector $\boldsymbol{v}_\Lambda^{(m,K^{(m)})}$ satisfies by Proposition 5.7 and by (5.20)

$$\|\boldsymbol{v}_\Lambda^{(m,K^{(m)})} - \boldsymbol{u}\|_{\ell_2} \leq \left(\frac{2}{c_{J,\Psi}}\right)^{1/2} \mathbb{E}^{1/2}_{m,K^{(m)}} =: \bar{\varepsilon}^{(m)}. \tag{6.2}$$

Furthermore, we recall that $\boldsymbol{u}_\Lambda^{(m+1)} = \mathbf{THRESH}[\boldsymbol{v}_\Lambda^{(m,K^{(m)})}, \varepsilon_\vartheta^{(m)}]$, where $\varepsilon_\vartheta^{(m)}$ is defined in (5.26). Now we choose the constant $\bar{\mathcal{C}}$ introduced in (5.23) in such a way that $\varepsilon_\vartheta^{(m)} = C^*\bar{\varepsilon}^{(m)}$, i.e.,

$$\min\left(\left(\frac{\bar{\mathcal{C}}}{2L_{J,\Psi}}\right)^{1/2}, \frac{\bar{\mathcal{C}}}{2\mathcal{C}_1}\right) = C^*\left(\frac{2}{c_{J,\Psi}}\right)^{1/2}. \tag{6.3}$$

In this way (6.1) applies to $\boldsymbol{v} = \boldsymbol{u}$, $\boldsymbol{v}_\Lambda = \boldsymbol{v}_\Lambda^{(m,K^{(m)})}$, and $\boldsymbol{z}_\Lambda = \boldsymbol{u}_\Lambda^{(m+1)}$. Finally, observing that $\mathbb{E}^{1/2}_{m,K^{(m)}} \sim \nu^{e_{m+1}}\mathbb{E}_0^{1/2}$ and shifting m into $m-1$, we get the following result.

PROPOSITION 6.2. *Let the assumptions of Theorem* 5.9 *and Assumption* 6.1 *hold. Then, the iterates $\boldsymbol{u}_\Lambda^{(m)}$ generated by Algorithm* 4.12 **MINIMIZE** *with the choice* (6.3) *satisfy*

$$|\operatorname{supp} \boldsymbol{u}_\Lambda^{(m)}| \;\lesssim\; (\nu^{e_m}\mathbb{E}_0^{1/2})^{-1/s}\|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} \qquad \textit{and} \qquad \|\boldsymbol{u}_\Lambda^{(m)}\|_{\mathcal{A}^s} \;\lesssim\; \|\boldsymbol{u}\|_{\mathcal{A}^s},$$

for $m = 0, 1, \ldots$. ∎

Since we have $\|\boldsymbol{u} - \boldsymbol{u}_\Lambda^{(m)}\|_{\ell_2} \lesssim \nu^{e_m}\mathbb{E}_0^{1/2}$ by Theorem 5.9, this proves the optimality of the approximation as far as the number of active degrees of freedom is concerned.

In order to control the possible growth of the supports of the vectors in the intermediate stages of the algorithm, as well as the computational complexity, we suppose that the procedure **EVAL-GRAD** defined in section 4.1 satisfies the following condition.

ASSUMPTION 6.3. *Given any tolerance $\varepsilon > 0$ and any compactly supported vector $\boldsymbol{v}_\Lambda$, then the output $\boldsymbol{w}_\Lambda := \mathbf{EVAL\text{-}GRAD}[\boldsymbol{v}_\Lambda, \varepsilon]$ satisfies*

$$\begin{aligned} |\operatorname{supp} \boldsymbol{w}_\Lambda| &\lesssim \varepsilon^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1), \\ \|\boldsymbol{w}_\Lambda\|_{\mathcal{A}^s} &\lesssim \|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s} + \|\boldsymbol{u}\|_{\mathcal{A}^s} + 1. \end{aligned}$$

The number $\operatorname{ops} \boldsymbol{w}_\Lambda$ of operations needed to compute $\boldsymbol{w}_\Lambda$ satisfies

$$\operatorname{ops} \boldsymbol{w}_\Lambda \lesssim \varepsilon^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1) + |\operatorname{supp} \boldsymbol{v}_\Lambda|. \tag{6.4}$$

This condition is fulfilled in a number of relevant cases, as described in [11, 12]. The second term on the right-hand side of (6.4) can be neglected in certain situations (e.g., in the linear and certain nonlinear cases). When it is needed, it accounts for computing a chain of near-best trees for the given input index set. It was shown in [13, Theorem 3.4] that the number $\log_2(\|\boldsymbol{v}_\Lambda\|/\varepsilon)$ of these trees depends on only $\|\boldsymbol{v}_\Lambda\|$ and the target accuracy. Moreover, it was shown there that the overall cost to compute these trees remains proportional to $\varepsilon^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + 1) + |\mathcal{T}(\boldsymbol{v}_\Lambda)|$, where $\mathcal{T}(\boldsymbol{v})$ denotes the smallest tree containing $\operatorname{supp} \boldsymbol{v}$. It is not restrictive to assume in the nonlinear case that the input as well as all intermediate vectors do already have tree structures. This shows that applying **EVAL-GRAD** to a sequence of decreasing tolerances for the *same* input vector simply may require computing additional near-best trees. This in turns means that $|\mathcal{T}(\boldsymbol{v}_\Lambda)| = |\operatorname{supp} \boldsymbol{v}_\Lambda|$ has to be counted only once in the operation count.

From the previous property, we deduce similar bounds for the output of the routine **APPROX-GRAD**. Precisely, recalling that **EVAL-GRAD** is recursively applied in **APPROX-GRAD** with the *same* input vector $\boldsymbol{v}_\Lambda$, we immediately deduce that

$$|\operatorname{supp} \boldsymbol{G}(\boldsymbol{v}_\Lambda)| \lesssim \eta^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1), \tag{6.5}$$

$$\|\boldsymbol{G}(\boldsymbol{v}_\Lambda)\|_{\mathcal{A}^s} \lesssim \|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s} + \|\boldsymbol{u}\|_{\mathcal{A}^s} + 1, \tag{6.6}$$

where the constants on the right-hand side do not depend on the number of applications of **EVAL-GRAD**.

Concerning the operation count, we have to take into account that the accuracy in the calls to **EVAL-GRAD** is reduced at a geometric rate; i.e., we have $\eta^{(k)} = \varepsilon\,\nu^{k-1}$ after k calls of **EVAL-GRAD**. Furthermore, we recall that the second term on the right-hand side of (6.4) can be counted only once. Hence, denoting again by $\bar{n}$ the number of calls to **EVAL-GRAD**, and observing that $\eta = \eta^{(\bar{n})}$, we have

$$\begin{aligned} \operatorname{ops} \boldsymbol{G}(\boldsymbol{v}_\Lambda) &\lesssim \sum_{k=1}^{\bar{n}} \operatorname{ops}\left(\mathbf{EVAL\text{-}GRAD}[\boldsymbol{v}_\Lambda, \eta^{(k)}]\right) \\ &\lesssim \sum_{k=1}^{\bar{n}} (\eta^{(k)})^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1) + |\operatorname{supp} \boldsymbol{v}_\Lambda| \\ &\lesssim \eta^{-1/s}(\|\boldsymbol{v}_\Lambda\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1) + |\operatorname{supp} \boldsymbol{v}_\Lambda|, \end{aligned} \tag{6.7}$$

where again the constants on the right-hand side do not depend on $\bar{n}$. Recalling Remark 5.8, we point out that the number of applications of **EVAL-GRAD** in each iteration can be uniformly bounded. We stress the fact that the crucial point is—as already pointed out earlier—that **EVAL-GRAD** is called within **APPROX-GRAD** with the *same* input vector $\boldsymbol{v}_\Lambda$ with a series of tolerances that are geometrically decreasing. This implies, as shown in (6.7), a uniform bound on the number of operations in terms of the error which is actually reachable for the input $\boldsymbol{v}_\Lambda$.

Consequently, we obtain similar estimates if, on the left-hand sides, we replace $\boldsymbol{G}(\boldsymbol{v}_\Lambda)$ by the output $\boldsymbol{w}_\Lambda := \mathbf{DESCENT}[\boldsymbol{v}_\Lambda, \varepsilon]$; in this case, η is the quantity determined within **APPROX-GRAD**.

We now apply these results within the Algorithm **MINIMIZE**, with the choice of parameters described in sections 5 and 6. For any $m \geq 0$ and $k = 0, \dots, K^{(m)} - 1$, set $[\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}), \eta^{(m,k)}] := \mathbf{APPROX\text{-}GRAD}[\boldsymbol{v}_\Lambda^{(m,k)}, \varepsilon^{(m,k)}]$. Recalling (5.20) and (5.21) as well as the definitions of $\bar{n}_{m,k}$ and $e_{m,k+1}$, it is straightforward to check that

$$\eta^{(m,k)} \geq \mathcal{C}_1 \sigma^{-1/2} \mathbb{E}_{m,k+1}^{1/2} \begin{cases} \nu^{n_0} & \text{if } \bar{n}_{m,k} \geq n_0, \\ 1 & \text{if } \bar{n}_{m,k} < n_0. \end{cases}$$

In both cases, $\eta^{(m,k)} \gtrsim \mathbb{E}_{m,k+1}^{1/2}$ uniformly in m and k. Thus, by (6.5)–(6.7) we obtain

$$|\operatorname{supp} \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})| \lesssim (\mathbb{E}_{m,k+1}^{1/2})^{-1/s} (\|\boldsymbol{v}_\Lambda^{(m,k)}\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1), \tag{6.8}$$

$$\|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\mathcal{A}^s} \lesssim \|\boldsymbol{v}_\Lambda^{(m,k)}\|_{\mathcal{A}^s} + \|\boldsymbol{u}\|_{\mathcal{A}^s} + 1, \tag{6.9}$$

$$\operatorname{ops} \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}) \lesssim (\mathbb{E}_{m,k+1}^{1/2})^{-1/s} (\|\boldsymbol{v}_\Lambda^{(m,k)}\|_{\mathcal{A}^s}^{1/s} + \|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1) + |\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,k)}|. \tag{6.10}$$

Next, from the definition of $\boldsymbol{v}_\Lambda^{(m,k+1)} = \boldsymbol{v}_\Lambda^{(m,k)} + \mu^{(m,k)} \boldsymbol{s}_\Lambda^{(m,k)}$, we deduce that

$$|\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,k+1)}| \leq |\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,k)}| + |\operatorname{supp} \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})|, \tag{6.11}$$

$$\operatorname{ops}(\boldsymbol{v}_\Lambda^{(m,k+1)}, \boldsymbol{v}_\Lambda^{(m,k)}) \lesssim \operatorname{ops} \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)}) + |\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,k+1)}|, \tag{6.12}$$

where $\operatorname{ops}(\boldsymbol{w}_\Lambda, \boldsymbol{v}_\Lambda)$ means the number of operations needed to compute $\boldsymbol{w}_\Lambda$, given $\boldsymbol{v}_\Lambda$. We observe that, by the particular realization of line search we have chosen, we have

$$\mu^{(m,k)} \boldsymbol{s}_\Lambda^{(m,k)} = \zeta^{(m,k)} \|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_2} \frac{\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})}{\|\boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})\|_{\ell_2}} = \zeta^{(m,k)} \boldsymbol{G}(\boldsymbol{v}_\Lambda^{(m,k)})$$

for some $\zeta^{(m,k)}$ uniformly bounded from above and below (see (5.6)). Thus, we have

$$\|\boldsymbol{v}_\Lambda^{(m,k+1)}\|_{\mathcal{A}^s} \lesssim \|\boldsymbol{v}_\Lambda^{(m,k)}\|_{\mathcal{A}^s} + \|\boldsymbol{u}\|_{\mathcal{A}^s} + 1. \tag{6.13}$$

Now, we apply a recursion argument; taking into account Proposition 6.2, using again the property of geometric series and the uniform boundedness of $K^{(m)}$, from (6.8)–(6.13), we deduce the estimates

$$\begin{aligned} |\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,k+1)}| + \operatorname{ops}(\boldsymbol{v}_\Lambda^{(m,k+1)}, \boldsymbol{u}^{(m)}) &\lesssim (\mathbb{E}_{m,k+1}^{1/2})^{-1/s} (\|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1) \\ &\lesssim (\nu^{e_{m+1}} \mathbb{E}_0^{1/2})^{-1/s} (\|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s} + 1), \\ \|\boldsymbol{v}_\Lambda^{(m,k+1)}\|_{\mathcal{A}^s} &\lesssim \|\boldsymbol{u}\|_{\mathcal{A}^s} + 1. \end{aligned} \tag{6.14}$$

Finally, recall that also the number of sortings needed in $\mathbf{THRESH}[\boldsymbol{v}_\Lambda^{(m,K^{(m)})}, \varepsilon_\vartheta^{(m)}]$ can be made proportional to $|\operatorname{supp} \boldsymbol{v}_\Lambda^{(m,K^{(m)})}|$ (see [2]). Shifting m into $m-1$, we get the following result.

PROPOSITION 6.4. *Under the assumptions of Proposition* 6.2 *and Assumption* 6.3, *the cardinality of the supports of all vectors involved in the computation of* $\boldsymbol{u}_\Lambda^{(m)}$ *starting from* $\boldsymbol{u}_\Lambda^{(0)}$, *as well as the complexity to compute* $\boldsymbol{u}_\Lambda^{(m)}$, *is bounded by the quantity* $C(\nu^{e_m}\mathbb{E}_0^{1/2})^{-1/s}(\|\boldsymbol{u}\|_{\mathcal{A}^s}^{1/s}+1)$. ∎

This completes the assessment of the optimality of the algorithm.

7. Examples. We conclude the paper with two concrete examples.

7.1. The nonlinear Laplacian. Let $\Omega \subset \mathbb{R}^n$ be a bounded domain with Lipschitz boundary $\partial\Omega$. Given some $p > 2$, let $\mathcal{V} = W_0^{1,p}(\Omega)$ be the closed subspace of the Sobolev space $W^{1,p}(\Omega)$ of the functions vanishing on $\partial\Omega$, equipped with the norm $\|v\|_{W_0^{1,p}(\Omega)} = \left(\sum_{i=1}^n \|\frac{\partial v}{\partial x_i}\|_{L^p(\Omega)}^p\right)^{1/p}$. Let f be an element in $\mathcal{V}' = W^{-1,p'}(\Omega)$, and let $\langle f, v\rangle_{\mathcal{V}'\times\mathcal{V}}$ denote the duality pairing between $\mathcal{V}'$ and $\mathcal{V}$.

We consider the functional $J : \mathcal{V} \to \mathbb{R}$ defined as

$$J(v) = \frac{1}{p}\|v\|_{\mathcal{V}}^p - \langle f, v\rangle_{\mathcal{V}'\times\mathcal{V}}.$$

Its Fréchet derivative is given by $J'(w) = A(w) - f$, where

$$A(w) = -\sum_{i=1}^n \frac{\partial}{\partial x_i}\left(\left|\frac{\partial w}{\partial x_i}\right|^{p-2}\frac{\partial w}{\partial x_i}\right)$$

is known as the p-Laplacian. The functional J satisfies Assumption 2.1. Indeed, condition (i) can be proven by a repeated application of Hölder's inequality in L^p-spaces, whereas condition (ii) easily follows from the existence of a constant $c_p > 0$ such that

$$(|s|^{p-2}s - |t|^{p-2}t)(s-t) \geq c_p|s-t|^p \qquad \text{for all } s,t \in \mathbb{R}. \tag{7.1}$$

Thus, there exists a unique minimizer of the functional J on $\mathcal{V}$, i.e., a unique solution of the Dirichlet problem $A(u) = f$ in Ω, $u = 0$ on $\partial\Omega$ (see, e.g., [26] for more details).

In view of the numerical discretization of such a problem, we introduce a wavelet basis $\Psi^* := \{\psi_\lambda^* : \lambda \in \mathcal{J}\}$ in $L^p(\Omega)$, such that $\|\psi_\lambda^*\|_{L^p(\Omega)} \sim 1$ for all λ. Here λ is a multi-index, containing all the relevant parameters of the wavelet, including the level index $j =: |\lambda|$. Furthermore, we denote by $B_{p,p,0}^r(\Omega)$ the closure of $\mathcal{C}_0^\infty(\Omega)$ in the Besov space $B_{p,p}^r(\Omega)$, and we assume that there exists $r^* > 1$ such that, for all r satisfying $0 < r < r^*$, Ψ^* is also a basis in $B_{p,p,0}^r(\Omega)$ and the norm equivalence

$$\|v\|_{B_{p,p,0}^r(\Omega)} \sim \left(\sum_{\lambda\in\mathcal{J}} 2^{pr|\lambda|}\,|v_\lambda^*|^p\right)^{1/p} \tag{7.2}$$

holds for all $v = \sum_{\lambda\in\mathcal{J}} v_\lambda^*\psi_\lambda^* \in B_{p,p,0}^r(\Omega)$. Examples of such bases can be found, e.g., in [5, 6, 15, 17, 18, 20].

It is well known (see, e.g., [29]) that $B^r_{p,p}(\Omega) = W^{r,p}(\Omega)$ algebraically and topologically for all $r \notin \mathbb{N}$, whereas, unfortunately, $B^k_{p,p}(\Omega) \neq W^{k,p}(\Omega)$ for $k \in \mathbb{N}$; one has only $B^{k+\varepsilon}_{p,p}(\Omega) \subset W^{k,p}(\Omega) \subset B^k_{p,p}(\Omega)$ for all $\varepsilon > 0$ with strict topological inclusions. Thus, we cannot apply the results of sections 3 and 4 taking $W^{1,p}_0(\Omega)$ as V therein.

We circumvent such a drawback by resorting to a perturbation argument. To this end, we assume that $u \in B^{1+\varepsilon_0}_{p,p,0}(\Omega)$ for some $\varepsilon_0 > 0$. Then, for any fixed $\varepsilon \in (0, \varepsilon_0]$, we set $V = V_\varepsilon = B^{1+\varepsilon}_{p,p,0}(\Omega)$ and we normalize the wavelets in the V_ε-norm; i.e., we set $\psi_\lambda = 2^{-(1+\varepsilon)|\lambda|}\,\psi^*_\lambda$ for all $\lambda \in \mathcal{J}$. Then, (7.2) yields precisely (3.1). Next, we introduce the perturbed functional $J_\varepsilon : V_\varepsilon \to \mathbb{R}$, defined as

$$J_\varepsilon(v) = \frac{\varepsilon}{p}\|\boldsymbol{v}\|^p_{\ell_p} + J(v) \qquad \text{for all } v = \boldsymbol{v}^T\Psi \in V_\varepsilon.$$

Its Fréchet derivative $J'_\varepsilon : V_\varepsilon \to V'_\varepsilon$ satisfies $\langle J'_\varepsilon(v), w\rangle_{V'_\varepsilon \times V_\varepsilon} = \varepsilon \sum_{\lambda\in\mathcal{J}} |v_\lambda|^{p-2} v_\lambda w_\lambda + \langle J'(v), w\rangle_{\mathcal{V}'\times\mathcal{V}}$ for all $v, w \in V_\varepsilon$. This functional, too, satisfies Assumption 2.1. Actually, condition (i) follows from the continuous inclusion $V_\varepsilon \subset W^{1,p}_0(\Omega)$, whereas condition (ii) is satisfied since (7.1) and the similar condition for J imply for all $w, v \in V_\varepsilon$

$$\langle J'_\varepsilon(w) - J'_\varepsilon(v), w - v\rangle_{V'_\varepsilon\times V_\varepsilon} \geq \varepsilon c_p \|\boldsymbol{w} - \boldsymbol{v}\|^p_{\ell_p} + c_J \|w - v\|^p_{W^{1,p}_0(\Omega)}. \tag{7.3}$$

Using (7.2), we obtain the existence of a constant c'_J (independent of ε) such that

$$\langle J'_\varepsilon(w) - J'_\varepsilon(v), w - v\rangle_{V'_\varepsilon\times V_\varepsilon} \geq c'_J(\varepsilon\|w - v\|^p_{B^{1+\varepsilon}_{p,p,0}(\Omega)} + \|w - v\|^p_{W^{1,p}_0(\Omega)}).$$

We can also express the ellipticity bound of the functional in terms of wavelet coefficients. Indeed, since $W^{1,p}_0(\Omega) \subset B^1_{p,p,0}(\Omega)$ with continuous inclusion, by (7.2) with $r = 1$ there exists a constant c''_J (again independent of ε) such that

$$\langle J'_\varepsilon(w) - J'_\varepsilon(v), w - v\rangle_{V'_\varepsilon\times V_\varepsilon} \geq c''_J \sum_{\lambda\in\mathcal{J}} (\varepsilon + 2^{-p\varepsilon|\lambda|})|w_\lambda - v_\lambda|^p.$$

Let $u_\varepsilon \in V_\varepsilon$ be the unique minimizer of J_ε in V_ε. Since all assumptions are fulfilled, we can apply Algorithm 4.12 **MINIMIZE** described in sections 3 and 4 to the functional J_ε.

The next result proves that u_ε can be made arbitrarily close to u by choosing ε small enough.

PROPOSITION 7.1. *The following estimate holds:*

$$\|u - u_\varepsilon\|_{W^{1,p}_0(\Omega)} \lesssim \varepsilon^{1/p}, \qquad 0 < \varepsilon \leq \varepsilon_0.$$

Proof. Set $N(v) := \frac{1}{p}\|\boldsymbol{v}\|^p_{\ell_p}$ and note that $J'_\varepsilon(u_\varepsilon) = 0$ and $J'_\varepsilon(u) = J'(u) + \varepsilon N'(u) = \varepsilon N'(u)$. Applying (7.3) with $w = u$ and $v = u_\varepsilon$, we obtain

$$\begin{aligned} c_J\|u - u_\varepsilon\|^p_{W^{1,p}_0(\Omega)} + \varepsilon c_p\|\boldsymbol{u} - \boldsymbol{u}_\varepsilon\|^p_{\ell_p} &\lesssim \langle J'_\varepsilon(u) - J'_\varepsilon(u_\varepsilon), u - u_\varepsilon\rangle_{V'_\varepsilon\times V_\varepsilon} \\ &\lesssim \varepsilon\,\langle N'(u), u - u_\varepsilon\rangle_{V'_\varepsilon\times V_\varepsilon} = \varepsilon\,\langle \boldsymbol{N}'(\boldsymbol{u}), \boldsymbol{u} - \boldsymbol{u}_\varepsilon\rangle_{\ell_{p'}\times\ell_p}. \end{aligned}$$

By Hölder's inequality,

$$\langle \boldsymbol{N}'(\boldsymbol{u}), \boldsymbol{u} - \boldsymbol{u}_\varepsilon\rangle_{\ell_{p'}\times\ell_p} \leq \|\boldsymbol{N}'(\boldsymbol{u})\|_{\ell_{p'}}\|\boldsymbol{u} - \boldsymbol{u}_\varepsilon\|_{\ell_p} \leq \frac{1}{p' c_p^{p'/p}}\|\boldsymbol{N}'(\boldsymbol{u})\|^{p'}_{\ell_{p'}} + \frac{c_p}{p}\|\boldsymbol{u} - \boldsymbol{u}_\varepsilon\|^p_{\ell_p},$$

whence the result easily follows from the assumption $u \in B^{1+\varepsilon_0}_{p,p,0}(\Omega)$. ∎

The proposition provides a guideline for selecting the perturbation parameter ε. Suppose that we wish to approximate u, in the $W_0^{1,p}(\Omega)$-norm, within an accuracy of order TOL. Then, it is enough to choose $\varepsilon = (TOL)^p$ and stop Algorithm **MINIMIZE** as soon as u_ε is itself approximated with an accuracy of order TOL.

7.2. The nonlinear reaction-diffusion problem. Let $G : \mathbb{R} \to \mathbb{R}^+$ be a smooth strictly convex function, such that $G(s) \lesssim |s|^p$ for all $s \in \mathbb{R}$, where $p \geq 2$ is chosen so that $H_0^1(\Omega) \hookrightarrow L^p(\Omega)$, $V = H_0^1(\Omega)$. We consider the functional

$$J(v) := \frac{1}{2}\int_\Omega |\nabla v|^2 + \int_\Omega G(v) - \langle f, v\rangle_{V'\times V},$$

which is strictly convex and unbounded. The Fréchet derivative is given by

$$J'(v) = -\Delta + g(v)I - f =: A(v) - f,$$

where $g(s) := G'(s)$ is strictly monotone in $\mathbb{R}$. It is readily seen that A is continuous and strictly monotone. Moreover, A is Lipschitz continuous and one can show that the following bounds hold:

$$\|v\|_V \lesssim \|A(v)\|_{V'} \lesssim \|v\|_V^{p-1}, \quad v \in V.$$

Thus, Assumption 2.1(i) is satisfied. Moreover, due to the monotonicity of g, for all $v, w \in V$, we have $(g(v) - g(w), v - w)_{0,\Omega} \geq 0$ and thus

$$\langle J'(v) - J'(w), v - w\rangle = \|\nabla(v - w)\|_{0,\Omega}^2 + (g(v) - g(w), v - w)_{0,\Omega} \gtrsim \|v - w\|_V^2,$$

so that (ii) holds for $p = 2$.

Let us take any wavelet basis Ψ of $H_0^1(\Omega)$ (see [5, 6, 15, 17, 18, 20]), so that the following norm equivalence holds:

$$\|v\|_V \sim \Big(\sum_{\lambda\in\mathcal{J}} 2^{2|\lambda|}|v_\lambda|^2\Big)^{1/2}, \qquad v = \sum_{\lambda\in\mathcal{J}} v_\lambda\,\psi_\lambda.$$

If the nonlinear function G is a global polynomial, then all required ingredients can be taken from the literature. Indeed, **EVAL-GRAD** and **EVAL-J** consist of a linear part which is described in [10, 11] and a nonlinearity of polynomial type. A corresponding evaluation scheme can be found in [13, 19]. In addition, a tree-coarsening routine is available in [12]. Finally, the gradient consists of the Laplacian and, again, a nonlinearity of polynomial type which can be realized using the methods described in [10, 11, 13, 19]. Moreover, note that if in addition the Fréchet derivative J'' of J' is well-posed in the sense that $\|J''(v)w\|_{V'} \sim \|w\|_V$ for all v in a neighborhood of the solution u of $J'(u) = 0$, then one can also use the adaptive wavelet method presented in [12] for the Euler–Lagrange equation in order to determine the minimizer u of J.

However, the function G may have a much more complicated structure, e.g., it may be defined piecewise. In this case, our general approach can also be used, provided corresponding routines for **EVAL-J**, **EVAL-GRAD**, and **THRESH** are available. Constructing and analyzing such schemes will be a subject of future research.

Appendix A. Proof of Lemma 2.2. As for Lemma 2.2(a), the proof is straightforward setting $w := u + t(v-u)$, i.e., $v - u = \frac{1}{t}(w-u)$, and using (ii) in Assumption 2.1 to obtain

$$\begin{aligned}
J(v) - J(u) &= \int_0^1 \frac{d}{dt} J(u + t(v-u))\, dt \\
&= \int_0^1 \langle J'(u + t(v-u)), v-u\rangle\, dt \\
&= \langle J'(u), v-u\rangle + \int_0^1 \langle J'(u + t(v-u)) - J'(u), v-u\rangle\, dt \\
&\geq \langle J'(u), v-u\rangle + c_J \int_0^1 \frac{1}{t} \|w-u\|_V^p\, dt \\
&= \langle J'(u), v-u\rangle + c_J \int_0^1 \frac{1}{t} \|t(u-v)\|_V^p\, dt \\
&= \langle J'(u), v-u\rangle + c_J \int_0^1 t^{p-1} \|u-v\|_V^p\, dt \\
&= \langle J'(u), v-u\rangle + \frac{c_J}{p} \|u-v\|_V^p.
\end{aligned}$$

Now we prove (b). Indeed,

$$J(v) \geq J(u) + \langle J'(u), v-u\rangle + \frac{c_J}{p}\|v-u\|^p;$$

hence, $J(v) > J(u) + \langle J'(u), v-u\rangle$ for all $u \neq v \in V$. For the boundedness, take again $u = 0$ in (a); then

$$J(v) \geq J(0) + \langle J'(0), v\rangle + \frac{c_J}{p}\|v\|_V^p \geq J(0) - \|J'(0)\|_{V'}\, \|v\|_V + \frac{c_J}{p}\|v\|_V^p,$$

which is bounded from below by the constant $J(0) - \|J'(0)\|_{V'}$.

As for (c), take $u = 0$ in (a). Then, for $v \in \mathcal{R}(u^{(0)})$, we have

$$\frac{c_J}{p}\|v\|_V^p \leq J(v) - J(0) - \langle J'(0), v\rangle \leq |J(u^{(0)})| + |J(0)| + \|J'(0)\|_{V'}\, \|v\|_V.$$

Since $p > 1$, we have $\|v\|_V \leq C(p, u^{(0)})$. ∎

EFFICIENT AND SAFE GLOBAL CONSTRAINTS FOR HANDLING NUMERICAL CONSTRAINT SYSTEMS*

YAHIA LEBBAH[†¶], CLAUDE MICHEL[‡¶], MICHEL RUEHER[‡¶], DAVID DANEY[§¶], AND JEAN-PIERRE MERLET[§¶]

Abstract. Numerical constraint systems are often handled by branch and prune algorithms that combine splitting techniques, local consistencies, and interval methods. This paper first recalls the principles of `Quad`, a global constraint that works on a tight and safe linear relaxation of quadratic subsystems of constraints. Then, it introduces a generalization of `Quad` to polynomial constraint systems. It also introduces a method to get safe linear relaxations and shows how to compute safe bounds of the variables of the linear constraint system. Different linearization techniques are investigated to limit the number of generated constraints. `QuadSolver`, a new branch and prune algorithm that combines `Quad`, local consistencies, and interval methods, is introduced. `QuadSolver` has been evaluated on a variety of benchmarks from kinematics, mechanics, and robotics. On these benchmarks, it outperforms classical interval methods as well as constraint satisfaction problem solvers and it compares well with state-of-the-art optimization solvers.

Key words. systems of equations and inequalities, constraint programming, reformulation linearization technique, global constraint, interval arithmetic, safe rounding

1. Introduction.

Many applications in engineering sciences require finding all isolated solutions to systems of constraints over real numbers. These systems may be nonpolynomial and are difficult to solve: the inherent computational complexity is NP-hard and numerical issues are critical in practice (e.g., it is far from being obvious to guarantee correctness and completeness as well as to ensure termination). These systems, called numerical CSP (constraint satisfaction problem) in the rest of this paper, have been approached in the past by different interesting methods:[1] interval methods [35, 24, 38, 20, 40], continuation methods [37, 2, 62], and constraint satisfaction methods [30, 6, 11, 61]. Of particular interest is the mathematical and programming simplicity of the latter approach: the general framework is a branch and prune algorithm that requires only specifying the constraints and the initial range of the variables.

The purpose of this paper is to introduce and study a new branch and bound algorithm called `QuadSolver`. The essential feature of this algorithm is a global constraint—called `Quad`—that works on a tight and safe linear relaxation of the polynomial relations of the constraint systems. More precisely, `QuadSolver` is a branch

[1]Alternative methods have been proposed for solving nonlinear systems. For instance, algebraic constraints can be handled with symbolic methods [13] (e.g., Groebner basis, resultant). However, these methods can neither handle nonpolynomial systems nor deal with inequalities.

and prune algorithm that combines `Quad`, local consistencies, and interval methods. That is to say, `QuadSolver` is an attempt to merge the best interval and constraint programming techniques. `QuadSolver` has been evaluated on a variety of benchmarks from kinematics, mechanics, and robotics. On these benchmarks, it outperforms classical interval methods as well as CSP solvers and it compares well with state-of-the-art optimization solvers.

The `Quad`-filtering algorithm [27] has first been defined for quadratic constraints. The relaxation of quadratic terms is adapted from a classical linearization method, the reformulation-linearization technique (RLT) [54, 53]. The simplex algorithm is used to narrow the domain of each variable with respect to the subset of the linear set of constraints generated by the relaxation process. The coefficients of these linear constraints are updated with the new values of the bounds of the domains and the process is restarted until no more significant reduction can be done. We have demonstrated [27] that the `Quad` algorithm yields a more effective pruning of the domains than local consistency filtering algorithms (e.g., 2b-consistency [30] or box-consistency [6]). Indeed, the drawback of classical local consistencies comes from the fact that the constraints are handled independently and in a blind way.[2] That is to say, classical local consistencies do not exploit the semantic of quadratic terms; in other words, these approaches do not take advantage of the very specific semantic of quadratic constraints to reduce the domains of the variables. Conversely, linear programming techniques [1, 54, 3] do capture most of the semantics of quadratic terms, e.g., convex and concave envelopes of these particular terms.[3]

The extension of `Quad` for handling any polynomial constraint system requires replacing nonquadratic terms by new variables and adding the corresponding identities to the initial constraint system. However, a complete quadrification [58] would generate a huge number of linear constraints. Thus, we introduce here an heuristic based on a good tradeoff between a tight approximation of the nonlinear terms and the size of the generated constraint system. This heuristic works well on classical benchmarks (see section 8).

A safe rounding process is a key issue for the `Quad` framework. Let us recall that the simplex algorithm is used to narrow the domain of each variable with respect to the subset of the linear set of constraints generated by the relaxation process. The point is that most implementations of the simplex algorithm are unsafe. Moreover, the coefficients of the generated linear constraints are computed with floating point numbers. So, two problems may occur in the `Quad`-filtering process.

1. The whole linearization may become incorrect due to rounding errors when computing the coefficients of the generated linear constraints.
2. Some solutions may be lost when computing the bounds of the domains of the variables with the simplex algorithm.

We propose in this paper a safe procedure for computing the coefficients of the generated linear constraints. Neumaier and Shcherbina [42] have addressed the second

[2] 3b-consistency and kb-consistency are partial consistencies that can achieve a better pruning since they are "less local" [11]. However, they require numerous splitting steps to find the solutions of a system of quadratic constraints; so, they may become rather slow.

[3] Sherali and Tuncbilek [55] have also proposed four different filtering techniques for solving quadratic problems. Roughly speaking, the first filtering strategy performs a feasibility check on inequality constraints to discard subintervals of the domains of the variables. This strategy is very close to box-consistency filtering (see [60]). The three other techniques are based on specific properties of optimization problems with a quadratic objective function: the eigenstructure of the quadratic objective function, fathoming node, and Lagrangian dual problem. Thus, these techniques can be considered as local consistencies for optimization problems (see also [59] and Neumaier's survey [41]).

problem.[4] They have proposed a simple and cheap procedure to get a rigorous upper bound of the objective function. The incorporation of these procedures in the Quad-filtering process allows us to call the simplex algorithm without worrying about safety. So, with these two procedures, linear programming techniques can be used to tackle continuous CSPs *without losing any solution*.

The rest of this paper is organized as follows. Section 2 gives an overview of the approach whereas section 3 contains the notation. Sections 4 and 5 recall the basics of interval programming and constraint programming. Section 6 details the principle of the Quad algorithm, the linearization process, and the extension to polynomial constraints. Section 7 introduces the rounding process we propose to ensure the safe relaxations. Section 8 describes the experimental results and discusses related work. Concluding remarks are given in section 9.

2. Overview of the approach. As mentioned, QuadSolver is a branch and prune algorithm that combines Quad and a box-consistency.

Box-consistency is the most successful adaptation of arc-consistency [31] to constraints over the real numbers. The box-consistency implementation of Van-Hentenryck, McAllester, and Kapur [60] is computed on three-interval extensions of the initial constraints: the natural interval extension, the distributed interval extension, and the Taylor interval extension with a conditioning step. The leftmost and the rightmost zeros are computed using a variation of the univariate interval Newton method.

The QuadSolver we propose here combines Quad-filtering and box-consistency filtering to prune the domain of the variables of numerical constraint systems. Operationally, QuadSolver performs the following filtering processes:

1. box-consistency filtering,
2. Quad-filtering.

The box-consistency is first used to detect some inconsistencies before starting the Quad-filtering algorithm which is more costly. These two steps are wrapped into a classical fixed point algorithm which stops when the domains of the variables cannot be further reduced.[5]

To isolate the different solutions, Quad uses classical branching techniques.

Before going into the details, let us outline the advantages of our approach on a couple of small examples.

2.1. Quad-filtering. Consider the constraint system $\mathcal{C} = \{2xy+y = 1, xy = 0.2\}$ which represents two intersecting curves (see Figure 2.1). Suppose that $\mathbf{x} = [-10, +10]$ and $\mathbf{y} = [-10, +10]$ are the domains of the variables x and y. An interval $\mathbf{x} = [\underline{x}, \overline{x}]$ denotes the set of reals $\{r | \underline{x} \leq r \leq \overline{x}\}$.

The RLT (see section 6.2) yields the following constraint system:

$$\text{(a)} \qquad \begin{cases} y + 2w = 1, \quad w = 0.2, \\ \underline{y}x + \underline{x}y - w \leq \underline{x}\underline{y}, \quad \overline{y}x + \underline{x}y - w \geq \underline{x}\overline{y}, \\ \underline{y}x + \overline{x}y - w \geq \overline{x}\underline{y}, \quad \overline{y}x + \overline{x}y - w \leq \overline{x}\overline{y}, \\ x \geq \underline{x}, \ x \leq \overline{x}, \quad y \geq \underline{y}, \ y \leq \overline{y}, \end{cases}$$

where w is a new variable that stands for the product xy. Note that constraint system (a) implies that $w \in [\underline{x}, \overline{x}] * [\underline{y}, \overline{y}]$.

[4] They have also suggested a solution to the first problem though their solution is dedicated to mixed integer programming problems.

[5] In practice, the loop stops when the domain reduction is lower than a given ϵ.

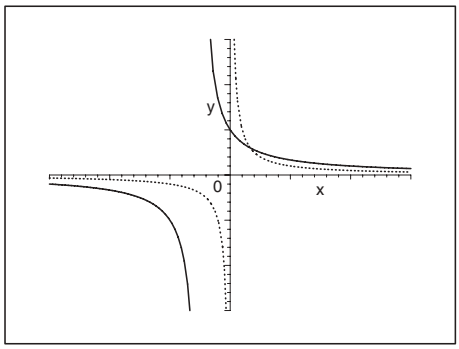

FIG. 2.1. *Geometrical representation of* $\{2xy + y = 1, xy = 0.2\}$.

Substituting $\underline{x}$, $\underline{y}$, $\overline{x}$, and $\overline{y}$ by their values and minimizing (resp., maximizing) x, y, and w with the simplex algorithm yield the following new bounds:

$$\mathbf{x} = [-9.38, 9.42], \quad \mathbf{y} = [0.6, 0.6], \quad \mathbf{w} = [0.2, 0.2].$$

By substituting the new bounds of x, y, and w in the constraint system (a), we obtain a new linear constraint system. One more minimizing (resp., maximizing) step is required to obtain tight bounds of $\mathbf{x}$. Note that numerous splitting operations are required to find the unique solution of the problem with a 3b-consistency filtering algorithm. The proposed algorithm solves the problem by generating 6 linear constraints and with 8 calls to the simplex algorithm. It finds the same solution as a solver based on 3b-consistency but without splitting and in less time.

2.2. A safe rounding procedure. Consider the constraint system

$$\mathcal{C} = \begin{cases} w_1 + w_2 = 1, \quad w_1 x_1 + w_2 x_2 = 0, \\ w_1 x_1 x_1 + w_2 x_2 x_2 = 1, \quad w_1 x_1 x_1 x_1 + w_2 x_2 x_2 x_2 = 0, \end{cases}$$

which represents a simple Gaussian quadrature formula to compute integrals [9]. Suppose that the domains of variables x_1, x_2, w_1, and w_2 are all equal to $[-1, +1]$. This system has two solutions:

- $x_1 = -1,\ x_2 = 1,\ w_1 = 0.5,\ w_2 = 0.5,$
- $x_1 = 1,\ x_2 = -1,\ w_1 = 0.5,\ w_2 = 0.5.$

A straightforward implementation of `Quad` would only find one unsafe solution with

$$x_2 \in [+0.9999\ldots944, +0.9999\ldots989].$$

Indeed, when we examine the `Quad`-filtering process, we can identify some linear programs where the simplex algorithm steps to the wrong side of the objective.

With the corrections we propose in section 7, we obtain a tight approximation of the two correct solutions (with $x_2 \in [-1.000000\ldots, -0.999999\ldots]$ and $x_2 \in [0.999999\ldots, 1.000000\ldots]$).

3. Notation and basic definitions. This paper focuses on CSPs where the domains are intervals and the constraints $C_j(x_1, \ldots, x_n)$ are n-ary relations over the reals. $\mathcal{C}$ stands for the set of constraints.

$\mathbf{x}$ or D_x denotes the domain of variable x, that is to say, the set of allowed values for x. $\mathcal{D}$ stands for the set of domains of all the variables of the considered constraint

system. $\mathbb{R}$ denotes the set of real numbers whereas $\mathbb{F}$ stands for the set of floating point numbers used in the implementation of nonlinear constraint solvers; if a is a constant in $\mathbb{F}$, a^+ (resp., a^-) corresponds to the smallest (resp., largest) number of $\mathbb{F}$ strictly greater (resp., lower) than a.

$\mathbf{x} = [\underline{x}, \overline{x}]$ is defined as the set of real numbers x verifying $\underline{x} \leq x \leq \overline{x}$. x, y denote real variables, X, Y denote vectors whereas $\mathbf{X}, \mathbf{Y}$ denote interval vectors. The *width* $w(\mathbf{x})$ of an interval $\mathbf{x}$ is the quantity $\overline{x} - \underline{x}$ while the *midpoint* $m(\mathbf{x})$ of the interval $\mathbf{x}$ is $(\overline{x} + \underline{x})/2$. A *point interval* $\mathbf{x}$ is obtained if $\underline{x} = \overline{x}$. A *box* is a set of intervals: its width is defined as the largest width of its interval members, while its center is defined as the point whose coordinates is the midpoint of the ranges. $\mathbb{IR}^n$ denotes the set of boxes and is ordered by set inclusion.

We use the RLT notation introduced in [54, 3] with slight modifications. More precisely, we will use the following notations: $[c]_L$ is the set of linear constraints generated by replacing the nonlinear terms by new variables in constraint c, and $[c]_{LI}$ denotes the set of equations that keep the link between the new variables and the nonlinear terms while $[c]_R$ contains linear inequalities that approximate the semantics of nonlinear terms of constraint c. These notations will be used indifferently whether c is a constraint or $\mathcal{C}$ is a set of constraints.

Rounding is necessary to close the operations over $\mathbb{F}$ (see [18]). A rounding function maps the result of the evaluation of an expression to available floating-point numbers. Rounding x towards $+\infty$ maps x to the least floating point number x_f such that $x \leq x_f$. $\bigtriangledown(x)$ (resp., $\bigtriangleup(x)$) denotes a rounding mode of x towards $-\infty$ (resp., $+\infty$).

4. Interval programming.

This section recalls the basic concepts of interval arithmetic that are required to understand the rest of the paper. Readers familiar with interval arithmetic may skip this section.

4.1. Interval arithmetic.

Interval arithmetic has been introduced by Moore [35]. It is based on the representation of variables as intervals.

Let f be a real-valued function of n unknowns $X = (x_1, \ldots, x_n)$. An *interval evaluation* of f for given ranges $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$ for the unknowns is an interval $\mathbf{y}$ such that

$$\underline{y} \leq f(\mathbf{X}) \leq \overline{y} \quad \text{for all} \quad X = (x_1, \ldots, x_n) \in \mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n). \tag{4.1}$$

In other words, $\underline{y}$ and $\overline{y}$ are lower and upper bounds for the values of f when the values of the unknowns are restricted to the box $\mathbf{X}$.

There are numerous ways to calculate an interval evaluation of a function [20, 46]. The simplest is the *natural evaluation* in which all the mathematical operators in f are substituted by their interval equivalents. Interval equivalents exist for all classical mathematical operators. Hence interval arithmetic allows us to calculate an interval evaluation for all nonlinear expressions, whether algebraic or not. For example, if $f(x) = x + \sin(x)$, then the interval evaluation of f for $x \in [1.1, 2]$ can be calculated as follows:

$$f([1.1, 2]) = [1.1, 2] + \sin([1.1, 2]) = [1.1, 2] + [0.8912, 1] = [1.9912, 3].$$

Interval arithmetic can be implemented with directed rounding to take into account round-off errors. There are numerous interval arithmetic packages implementing this property: one of the most famous library is BIAS/Profil,[6] but a promising new

[6] http://www.ti3.tu-harburg.de/Software/PROFILEnglisch.html.

package—based on the multiprecision software MPFR[7]—is MPFI [47].

The main limitation of interval arithmetic is *the overestimation of interval functions*. This is due to two well-known problems:

- the so-called *wrapping effect* [35, 39], which overestimates by a unique vector the image of an interval vector (which is in general not a vector). That is to say, $\{f(X)|X \in \mathbf{X}\}$ is contained in $f(\mathbf{X})$ but is usually not equal to $f(\mathbf{X})$;
- the so-called *dependency problem* [20], which is due to the independence of the different occurrences of some variables during the interval evaluation of an expression. In other words, during the interval evaluation process there is no correlation between the different occurrences of a same variable in an equation. For instance, consider $\mathbf{x} = [0, 10]$. $\mathbf{x} - \mathbf{x} = [\underline{x} - \overline{x}, \overline{x} - \underline{x}] = [-10, 10]$ instead of $[0, 0]$ as one could expect.

In general, it is not possible to compute the exact enclosure of the range for an arbitrary function over the real numbers [25]. Thus, Moore introduced the concept of *interval extension*: the interval extension of a function is an interval function that computes outer approximations on the range of the function over a domain [20, 36]. Two main extensions have been introduced: the natural extension and the Taylor extension [46, 20, 38].[8] Due to the properties of interval arithmetic, the evaluation of a function may yield different results according to the literal form of the equations. Thus, many literal forms may be used as, for example, factorized form (Horner for polynomial system) or distributed form [60].

Nevertheless, in general, neither the natural form nor the Taylor expansion allows us to compute the exact range of a function f. For instance, considering $f(x) = 1 - x + x^2$ and $\mathbf{x} = [0, 2]$, we have

$$\begin{aligned} f_{\text{tay}}([0,2]) &= f(x) + (2\mathbf{x} - 1)(\mathbf{x} - x) = f(1) + (2[0,2] - 1)([0,2] - 1) = [-2, 4], \\ f([0,2]) &= 1 - \mathbf{x} + \mathbf{x}^2 = 1 - [0,2] + [0,2]^2 = [-1, 5], \\ f_{\text{factor}}([0,2]) &= 1 + \mathbf{x}(\mathbf{x} - 1) = 1 + [0,2]([0,2] - 1) = [-1, 3], \end{aligned} \tag{4.2}$$

whereas the range of f over $X = [0, 2]$ is $[3/4, 3]$. In this case, this result could directly be obtained by a second form of factorization: $f_{\text{factor}_2}([0, 2]) = (\mathbf{x} - 1/2)^2 + 3/4 = ([0, 2] - 1/2)^2 + 3/4 = [3/4, 3]$.

4.2. Interval analysis methods. This section provides a short introduction to interval analysis methods (see [35, 20, 38, 40] for a more detailed introduction). We limit this overview to interval Newton-like methods for solving a multivariate system of nonlinear equations. Their use is complementary to methods provided by the constraint programming community.

The aim is to determine the zeros of a system of n equations $f_i(x_1, \ldots, x_n)$ in n unknowns x_i inside the interval vector $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_n)$ with $x_i \in \mathbf{x}_i$ for $i = 1, \ldots, n$.

First, consider solving an interval linear system of equations defined as follows:

$$AX = b, \quad A \in \mathbf{A}, b \in \mathbf{b}, \tag{4.3}$$

where $\mathbf{A}$ is an interval matrix and $\mathbf{b}$ is an interval vector. Solving this linear interval system requires us to determine an interval vector $\mathbf{X}$ containing all solutions of all scalar linear systems noted $AX = b$ such that $A \in \mathbf{A}$ and $b \in \mathbf{b}$. Finding the exact value of $\mathbf{X}$ is a difficult problem, but three basic interval methods exist: Gaussian

[7] http://www.mpfr.org.

[8] $f_{\text{tay}}(\mathbf{X}) = f(X) + \mathbf{A}(\mathbf{X} - X)$, where $\mathbf{A}$ is the Jacobian or the interval slope matrix.

elimination, Gauss–Seidel iterative method, or Krawczyk method (see [24, 38, 20, 40]). They may provide an overestimated interval vector $\mathbf{X}_1$ including $\mathbf{X}$. However, in general the computed intervals are too wide and a preconditioning is required, that is to say, a multiplication of both sides of (4.3) by the inverse of a midpoint of $\mathbf{A}$. The matrix $m(\mathbf{A})^{-1}\mathbf{A}$ is then "closer" to the identity matrix and the width of $\mathbf{X}_1$ is smaller [20].

To solve nonlinear systems, an interval Newton algorithm is often used—see [20] or [38]. The basic idea is to solve iteratively a linear approximation of the nonlinear system obtained by a Taylor expansion. Many improvements [24, 19], based on variations of the resolution of the linear subsystem or the preconditioning, have been proposed. Note that many interesting properties are provided by Newton-like methods: existence and/or uniqueness of a root, convergence area/rate, ...

5. Constraint programming. This section recalls the basics of constraint programming techniques which are required to understand the rest of this paper. A detailed discussion of these concepts and techniques can be found in [6, 26].

5.1. The general framework. The constraint programming framework is based on a branch and prune scheme which was inspired by the traditional branch and bound approach used in optimization problems. That is to say, it is best viewed as an iteration of two steps [60]:

1. pruning the search space;
2. making a choice to generate two (or more) subproblems.

The pruning step ensures that some local consistency holds. In other words, the pruning step reduces an interval when it can prove that the upper bound or the lower bound does not satisfy some constraint. Informally speaking, a constraint system $\mathcal{C}$ satisfies a partial consistency property if a relaxation of $\mathcal{C}$ is consistent. For instance consider $\mathbf{x} = [\underline{x}, \overline{x}]$ and $c(x, x_1, \ldots, x_n) \in \mathcal{C}$. Whenever $c(x, x_1, \ldots, x_n)$ does not hold for any values $a \in \mathbf{x} = [\underline{x}, x']$, then $\mathbf{x}$ may be shrunk to $\mathbf{x} = [x', \overline{x}]$. Local consistencies are detailed in the next subsection. Roughly speaking, they are relaxations of arc-consistency, a notion that is well known in artificial intelligence [31, 34].

The branching step usually splits the interval associated to some variable in two intervals with the same width. However, the splitting process may generate more than two subproblems and one may split an interval at a point different from its midpoint. The choice of the variable to split is a critical issue in difficult problems. Sophisticated splitting strategies have been developed for finite domains but few results [23] are available for continuous domains.

5.2. Local consistencies [11, 26]. Local consistencies are conditions that filtering algorithms must satisfy. A filtering algorithm can be seen as a fixed point algorithm defined by the sequence $\{\mathcal{D}_k\}$ of domains generated by the iterative application of an operator $Op : \mathbb{IR}^n \longrightarrow \mathbb{IR}^n$ (see Figure 5.1).

$$\mathcal{D}_k = \begin{cases} \mathcal{D} & \text{if } k = 0 \\ Op(\mathcal{D}_{k-1}) & \text{if } k > 0 \end{cases}$$

FIG. 5.1. *Filtering algorithms as fixed point algorithms.*

The operator Op of a filtering algorithm generally satisfies the following three properties:

- $Op(\mathcal{D}) \subseteq \mathcal{D}$ (contractance);
- Op is conservative; that is, it cannot remove any solution;

- $\mathcal{D}' \subseteq \mathcal{D} \Rightarrow Op(\mathcal{D}') \subseteq Op(\mathcal{D})$ (monotonicity).

Under those conditions, the limit of the sequence $\{\mathcal{D}_k\}$, which corresponds to the greatest fixed point of the operator Op, exists and is called a *closure*. A fixed point for Op may be characterized by an lc-consistency property, called a local consistency. The algorithm achieving filtering by lc-consistency is denoted lc-filtering. A CSP is said to be lc-satisfiable if lc-filtering of this CSP does not produce an empty domain.

Consistencies used in numerical CSP solvers can be categorized in two main classes: *arc-consistency*-like consistencies and strong consistencies. Strong consistencies will not be discussed in this paper (see [30, 26] for a detailed introduction).

Most of the numerical CSP systems (for example, BNR-prolog [43], Interlog [8], CLP(BNR) [7], PrologIV [12], UniCalc [4], Ilog Solver [22], Numerica [61], and RealPaver [5]) compute an approximation of arc-consistency [31] which will be named ac-like-consistency in this paper. An *ac*-like-consistency states a local property on a constraint and on the bounds of the domains of its variables. Roughly speaking, a constraint c_j is ac-like-consistent if for any variable x_i in $var(c_j)$, the bounds $\underline{x}_i$ and $\overline{x}_i$ have a support in the domains of all other variables of c_j.

The most famous ac-like consistencies are 2b-consistency and box-consistency.

2b-consistency (also known as hull consistency) [10, 7, 28, 30] requires only to check the arc-consistency property for each bound of the intervals. The key point is that this relaxation is more easily verifiable than arc-consistency itself. Informally speaking, variable x is 2b-consistent for constraint "$f(x, x_1, \ldots, x_n) = 0$" if the lower (resp., upper) bound of the domain of x is the smallest (resp., largest) solution of $f(x, x_1, \ldots, x_n)$. The box-consistency [6, 21] is a coarser relaxation (i.e., it allows less stringent pruning) of arc-consistency than 2b-consistency. Variable x is box-consistent for constraint "$f(x, x_1, \ldots, x_n) = 0$" if the bounds of the domain of x correspond to the leftmost and rightmost zeros of the optimal interval extension of $f(x, x_1, \ldots, x_n)$. 2b-consistency algorithms actually achieve a weaker filtering (i.e., a filtering that yields bigger intervals) than box-consistency, more precisely when a variable occurs more than once in some constraint (see Proposition 6 in [11]). This is due to the fact that 2b-consistency algorithms require a decomposition of the constraints with multiple occurrences of the same variable.

2b-consistency [30] states a local property on the bounds of the domains of a variable at a single constraint level. A constraint c is 2b-consistent if, for any variable x, there exist values in the domains of all other variables which satisfy c when x is fixed to $\underline{x}$ and $\overline{x}$.

The filtering by 2b-consistency of $P = (\mathcal{D}, \mathcal{C})$ is the CSP $P' = (\mathcal{D}', \mathcal{C})$ such that

- P and P' have the same solutions;
- P' is 2b-consistent;
- $\mathcal{D}' \subseteq \mathcal{D}$ and the domains in $\mathcal{D}'$ are the largest ones for which P' is 2b-consistent.

Filtering by 2b-consistency of P always exists and is unique [30], that is to say it is a closure.

The box-consistency [6, 21] is a coarser relaxation of arc-consistency than 2b-consistency. It mainly consists of replacing every existentially quantified variable but one with its interval in the definition of 2b-consistency. Thus, box-consistency generates a system of univariate interval functions which can be tackled by numerical methods such as interval Newton. In contrast to 2b-consistency, box-consistency does not require any constraint decomposition and thus does not amplify the locality problem. Moreover, box-consistency can tackle some dependency problems when each

constraint of a CSP contains only one variable which has multiple occurrences. More formally we have the following definition.

DEFINITION 5.1 (box-consistency). *Let $(\mathcal{D}, \mathcal{C})$ be a CSP and $c \in \mathcal{C}$ a k-ary constraint over the variables $(x_1, \ldots, x_k)$. c is box-consistent if, for all x_i, the following relations hold:*

1. $c(\mathbf{x}_1, \ldots, \mathbf{x}_{i-1}, [\underline{x}_i, \underline{x}_i^+), \mathbf{x}_{i+1}, \ldots, \mathbf{x}_k)$,
2. $c(\mathbf{x}_1, \ldots, \mathbf{x}_{i-1}, (\overline{x}_i^-, \overline{x}_i], \mathbf{x}_{i+1}, \ldots, \mathbf{x}_k)$.

Closure by box-consistency of P is defined similarly as closure by 2b-consistency of P.

Benhamou et al. have introduced HC4 [5], an ac-like-consistency that merges 2b-consistency and box-consistency and which optimizes the computation process.

6. `Quad` basics and extensions. This section first introduces `Quad`, a global constraint that works on a tight and safe linear relaxation of quadratic subsystems of constraints. Then, it generalizes `Quad` to the polynomial part of numerical constraint systems. Different linearization techniques are investigated to limit the number of generated constraints.

6.1. The `Quad` algorithm. The `Quad`-filtering algorithm (see Algorithm 1) consists of three main steps: reformulation, linearization, and pruning.

The reformulation step generates $[\mathcal{C}]_R$, the set of implied linear constraints. More precisely, $[\mathcal{C}]_R$ contains linear inequalities that approximate the semantics of nonlinear terms of $\mathcal{C}$.

The linearization process first decomposes each nonlinear term in sums and products of univariate terms; then it replaces nonlinear terms with their associated new variables. For example, considering constraint $c : x_2x_3x_4^2(x_6 + x_7) + \sin(x_1)(x_2x_6 - x_3) = 0$, a simple linearization transformation may yield the following sets:

- $[c]_L = \{y_1 + y_3 = 0, \quad y_2 = x_6 + x_7, \quad y_4 = y_5 - x_3\}$,
- $[c]_{LI} = \{y_1 = x_2x_3x_4^2y_2, \quad y_3 = \sin(x_1)y_4, \quad y_5 = x_2x_6\}$.

$[c]_L$ is the set of linear constraints generated by replacing the nonlinear terms by new variables and $[c]_{LI}$ denotes the set of equations that keep the link between the new variables and the nonlinear terms. Note that the nonlinear terms which are not directly handled by the `Quad` are taken into account by the box-filtering process.

Finally, the linearization step computes the set of final linear inequalities and equations $LR = [\mathcal{C}]_L \cup [\mathcal{C}]_R$, the linear relaxation of the original constraints $\mathcal{C}$.

The pruning step is just a fixed point algorithm that calls iteratively a linear programming solver to reduce the upper and lower bounds of every original variable. The algorithm converges and terminates if ϵ is greater than zero.

Now we are in the position to introduce the reformulation of nonlinear terms. Section 6.2 first introduces the handling of quadratic constraints while section 6.3 extends the previous results to polynomial constraints.

6.2. Handling quadratic constraints. Quadratic constraints are approximated by linear constraints in the following way. `Quad` creates a new variable for each quadratic term: y for x^2 and $y_{i,j}$ for x_ix_j. The produced system is denoted as

$$\left[\sum_{(i,j)\in M} a_{k,i,j}x_ix_j + \sum_{i\in N} b_{k,i}x_i^2 + \sum_{i\in N} d_{k,i}x_i = b_k \right]_L .$$

.

Function Quad_filtering(IN: $\mathcal{X}$, $\mathcal{D}$, $\mathcal{C}$, ϵ) **return** $\mathcal{D}'$
% $\mathcal{X}$: initial variables; $\mathcal{D}$: input domains; $\mathcal{C}$: constraints; ϵ: minimal reduction
% $\mathcal{D}'$: output domains

1. *Reformulation*: generation of linear inequalities $[\mathcal{C}]_R$ for the nonlinear terms in $\mathcal{C}$.
2. *Linearization*: linearization of the whole system $[\mathcal{C}]_L$.
   We obtain a linear system $LR = [\mathcal{C}]_L \cup [\mathcal{C}]_R$.
3. $\mathcal{D}' := \mathcal{D}$.
4. *Pruning*:
   While the amount of reduction of some bound is greater than ϵ **and** $\emptyset \notin \mathcal{D}'$ **Do**
   (a) $\mathcal{D} \leftarrow \mathcal{D}'$.
   (b) Update the coefficients of the linearizations $[\mathcal{C}]_R$ according to the domains $\mathcal{D}'$.
   (c) Reduce the lower and upper bounds $\underline{x}'_i$ and $\overline{x}'_i$ of each *initial* variable $x_i \in \mathcal{X}$ by computing min and max of x_i subject to LR with a linear programming solver.

ALGORITHM 1
The Quad*-algorithm.*

A tight linear (convex) relaxation, or outer-approximation to the convex and concave envelope of the quadratic terms over the constrained region, is built by generating new linear inequalities.

Quad uses two tight linear relaxation classes that preserve equations $y = x^2$ and $y_{i,j} = x_i x_j$ and that provide a better approximation than interval arithmetic [27].

6.2.1. Linearization of x^2. The term x^2 with $\underline{x} \leq x \leq \overline{x}$ is approximated by the following relations:

$$[x^2]_R \;=\; \begin{cases} L1(\alpha) \equiv [(x-\alpha)^2 \geq 0]_L, \quad \text{where } \alpha \in [\underline{x}, \overline{x}], \\ L2 \equiv [(\underline{x}+\overline{x})x - y - \underline{x}\overline{x} \geq 0]_L. \end{cases} \tag{6.1}$$

Note that $[(x-\alpha_i)^2 = 0]_L$ generates the tangent line to the curve $y = x^2$ at the point $x = \alpha_i$. Actually, Quad computes only $L1(\overline{x})$ and $L1(\underline{x})$. Consider for instance the quadratic term x^2 with $x \in [-4, 5]$. Figure 6.1 displays the initial curve (i.e., D_1) and the lines corresponding to the equations generated by the relaxations: D_2 for $L1(-4) \equiv y + 8x + 16 \geq 0$, D_3 for $L1(5) \equiv y - 10x + 25 \geq 0$, and D_4 for $L2 \equiv -y + x + 20 \geq 0$.

We may note that $L1(\overline{x})$ and $L1(\underline{x})$ are underestimations of x^2 whereas $L2$ is an overestimation. $L2$ is also the concave envelope, which means that it is the optimal concave overestimation.

6.2.2. Bilinear terms. In the case of bilinear terms xy, McCormick [32] proposed the following relaxations of xy over the box $[\underline{x}, \overline{x}] \times [\underline{y}, \overline{y}]$, stated in the equivalent RLT form [54]:

$$[xy]_R \;=\; \begin{cases} BIL1 \equiv [(x-\underline{x})(y-\underline{y}) \geq 0]_L, \\ BIL2 \equiv [(x-\underline{x})(\overline{y}-y) \geq 0]_L, \\ BIL3 \equiv [(\overline{x}-x)(y-\underline{y}) \geq 0]_L, \\ BIL4 \equiv [(\overline{x}-x)(\overline{y}-y) \geq 0]_L. \end{cases} \tag{6.2}$$

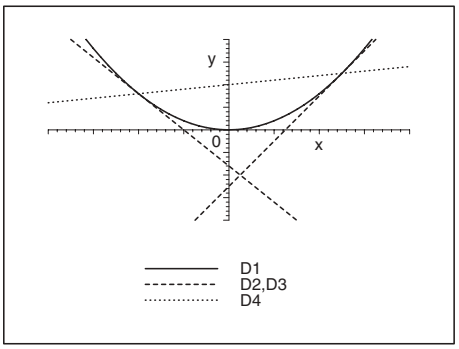

FIG. 6.1. *Approximation of* x^2.

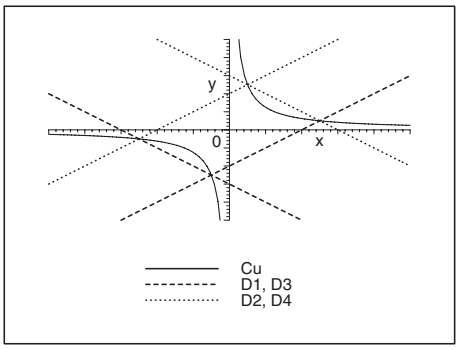

FIG. 6.2. *Illustration of xy relaxations.*

$BIL1$ and $BIL3$ define a convex envelope of xy whereas $BIL2$ and $BIL4$ define a concave envelope of xy over the box $[\underline{x}, \overline{x}] \times [\underline{y}, \overline{y}]$. Al-Khayyal and Falk [1] showed that these relaxations are the optimal convex/concave outer-estimations of xy.

Consider for instance the quadratic term xy with $x \in [-5, 5]$ and $y \in [-5, 5]$. The work done by the linear relaxations of the three-dimensional curve $z = xy$ is well illustrated in two dimensions by fixing z. Figure 6.2 displays the two-dimensional shape, for the level $z = 5$, of the initial curve (i.e., Cu) and the lines corresponding to the equations generated by the relaxations (where $z = 5$): D_1 for $BIL1 \equiv z+5x+5y+25 \geq 0$, D_2 for $BIL2 \equiv -z+5x-5y+25 \geq 0$, D_3 for $BIL3 \equiv -z-5x+5y+25 \geq 0$, and D_4 for $BIL4 \equiv z-5x-5y+25 \geq 0$.

6.3. Extension to polynomial constraints. In this section, we show how to extend the linearization process to polynomial constraints. We first discuss the quadrification process and compare it with RLT. Then, we present the linearizations of product and power terms.

6.3.1. Transformation of nonlinear constraints into quadratic constraints. In this section, we show how to transform a polynomial constraint system into an equivalent quadratic constraint system, a process called *quadrification* [58].

For example, considering the constraint $c : x_2x_3x_4^2 + 3x_6x_7 + \sin(x_1) = 0$, the proposed transformation yields

$$\{y_1y_2 + 3y_2 + s_1 = 0, \quad y_1 = x_2x_3, \quad y_2 = x_4x_4, \quad y_3 = x_6x_7\}$$

and the set $\{y_1 = x_2x_3, \quad y_2 = x_4^2, \quad y_3 = x_6x_7, \quad s_1 = \sin(x_1)\}$ of equations that keep the link between the new variables and the nonlinear terms that cannot be further quadrified. Such a transformation is one of the possible quadrifications. It is called a *single* quadrification.

We could generate all possible single quadrifications, or all quadrifying identities, and perform a so-called *complete* quadrification. For example, the complete quadrification of $E = \{x_2x_3x_4^2 + 3x_6x_7 + \sin(x_1) = 0\}$ is

$$\begin{cases} y_1 + 3y_2 + s_1 = 0, & y_2 = x_6x_7, \\ y_1 = y_3y_4, & y_3 = x_2x_3, & y_4 = x_4^2, \\ y_1 = y_5y_6, & y_5 = x_2x_4, & y_6 = x_3x_4, \\ y_1 = x_2y_7, & y_7 = x_3y_4, & y_7 = x_4y_6, \\ y_1 = x_3y_8, & y_8 = x_2y_4, & y_8 = x_4y_5, \\ y_1 = x_4y_9, & y_9 = x_2y_6, & y_9 = x_3y_5, & y_9 = x_4y_3, \end{cases}$$

where $s_1 = \sin(x_1)$.

A quadrification for polynomial problems was introduced by Shor [58]. Sherali and Tuncbilek [57] have proposed a direct reformulation/linearization (RLT) of the whole polynomial constraints without quadrifying the constraints. They did prove the dominance of their direct reformulation/linearization technique over Shor's quadrification [56].

A complete quadrification generates as many new variables as the direct RLT. Linearizations proposed in RLT are built on every nonordered combination of δ variables, where δ is the highest polynomial degree of the constraint system.

The complete quadrification generates linearizations on every couple of nonordered combined variables $[v_i, v_j]$ where v_i (resp., v_j) is the variable that has been introduced for linearizing the nonordered combination of variables.

Complete quadrification and direct RLT yield a tighter linearization than the single quadrification but the number of generated linearizations grows in an exponential way for nontrivial polynomial constraint systems. More precisely, the number of linearizations depends directly on the number of generated new variables.

To sum up, the linearization of polynomial systems offers two main possibilities: the transformation of the initial problem into an equivalent quadratic constraint system through a process called *quadrification*, or the direct linearization of polynomial terms by means of RLT. Theoretical considerations, as well as experimentations, have been conducted to exclude as practical a complete quadrification which produces a huge amount of linear inequalities for nontrivial polynomial systems. The next two subsections present our choices for the linearization of product and power terms.

6.3.2. Product terms. For the product term

$$x_1 x_2 \dots x_n \tag{6.3}$$

we use a two-step procedure: quadrification and bilinear relaxations.

Since many single quadrifications exist, an essential point is the choice of a good heuristic that captures most of the semantics of the polynomial constraints. We use a "middle" heuristic to obtain balanced degrees on the generated terms. For instance, considering $T \equiv x_1 x_2 \dots x_n$, a monomial of degree n, the middle heuristic will identify two monomials T_1 and T_2 of highest degree such that $T = T_1 T_2$. It follows that $T_1 = x_1 x_2 \dots x_{n \div 2}$ and $T_1 = x_{n \div 2+1} \dots x_n$.

The quadrification is performed by recursively decomposing each product $x_i \dots x_j$ into two products $x_i \dots x_d$ and $x_{d+1} \dots x_j$. Of course, there are many ways to choose the position of d. Ryoo and Sahinidis [49] and Sahinidis and Twarmalani [51] use what they call `rAI`, "recursive interval arithmetic," which is a recursive quadrification where $d = j - 1$. We use the middle heuristic `Qmid`, where $d = (i + j)/2$, to obtain balanced degrees on the generated terms. Let us denote by $[E]_{RI}$ the set of equations that transforms a product terms into a set of quadratic identities.

The second step consists of a *bilinear relaxation* $[[\mathcal{C}]_{RI}]_R$ of all the quadratic identities in $[\mathcal{C}]_{RI}$ with the bilinear relaxations introduced in section 6.2.2.

Sherali and Tuncbilek [57] have proposed a promising direct reformulation/ linearization technique (RLT) of the whole polynomial constraints without quadrifying the constraints. Applying RLT on the product term $x_1 x_2 \dots x_n$ generates the

following n-ary inequalities:[9]

$$\prod_{i\in J_1}(x_i-\underline{x}_i)\prod_{i\in J_2}(\overline{x}_i-x_i)\geq 0 \quad \text{for all } J_1,J_2\subseteq\{1,\dots,n\}\colon |J_1\cup J_2|=n, \tag{6.4}$$

where $\{1,\dots,n\}$ is to be understood as a multiset and where J_1 and J_2 are multisets.

We now introduce Proposition 6.1, which states the number of new variables and relaxations, respectively, generated by the quadrification and RLT process on the product term (6.3).

PROPOSITION 6.1. *Let $T\equiv x_1x_2\dots x_n$ be some product of degree $n\geq 1$ with n distinct variables. The RLT of T will generate up to (2^n-n-1) new variables and 2^n inequalities whereas the quadrification of T will generate only $(n-1)$ new variables and $4(n-1)$ inequalities.*

Proof. The number of terms of length i is clearly the number of combinations of i elements within n elements, that is to say C_n^i. In the RLT relaxations (6.4), we generate new variables for all these combinations. Thus, the number of variables is bounded by $\sum_{i=2,\dots,n}\mathrm{C}_n^i=\sum_{i=0,\dots,n}\mathrm{C}_n^i-n-1$, that is to say 2^n-n-1 since $\sum_{i=0,\dots,n}\mathrm{C}_n^i=2^n$. In (6.4), for each variable we consider alternatively the lower bound and the upper bound: thus there are 2^n new inequalities.

For the quadrification process, the proof can be done by induction. For $n=1$, the formula is true. Now suppose that for length i (with $1\leq i<n$), $(i-1)$ new variables are generated. For $i=n$, we can split the term at the position d with $1\leq d<n$. It results from the induction hypothesis that we have $d-1$ new variables for the first part, and $n-d-1$ new variables for the second part, plus one more new variable for the whole term. So, $n-1$ new variables are generated. Bilinear terms require four relaxations, thus we get $4(n-1)$ new inequalities. ∎

Proposition 6.2 states that quadrification with bilinear relaxations provides convex and concave envelopes with any d. This property results from the proof given in [49] for the `rAI` heuristic.

PROPOSITION 6.2. *$[[x_1x_2\dots x_n]_{RI}]_R$ provides convex and concave envelopes of the product term $x_1x_2\cdots x_n$.*

Generalization for sums of products, the so-called multilinear terms

$$\sum_{i=1,\dots,t} a_i\prod_{j\in J_i}x_j,$$

have been studied recently [14, 52, 48, 49]. It is well known that finding the convex or concave envelope of a multilinear term is an NP-hard problem [14]. The most common method of linear relaxation of multilinear terms is based on the simple product term. However, it is also well known that this approach leads to a poor approximation of the linear bounding of the multilinear terms. Sherali [52] has introduced formulae for computing convex envelopes of the multilinear terms. It is based on an enumeration of vertices of a pre-specified polyhedra which is of exponential nature. Rikun [48] has given necessary and sufficient conditions for the polyhedrality of convex envelopes. He has also provided formulae of some faces of the convex envelope of a multilinear function. To summarize, it is difficult to characterize convex and concave envelopes for general multilinear terms. Conversely, the approximation of "product of variables" is an effective approach; moreover, it is easy to implement [51, 50].

[9] Linearizations proposed in RLT on the whole polynomial problem are built on every nonordered combination of δ variables, where δ is the highest polynomial degree of the constraint system.

6.3.3. Power terms. A power term of the form x^n can be approximated by $n+1$ inequalities with a procedure proposed by Sherali and Tuncbilek [57], called "bound-factor product RLT constraints." It is defined by the following formula:

$$[x^n]_R \;=\; \{[(x-\underline{x})^i(\overline{x}-x)^{n-i} \geq 0]_L, i = 0, \ldots, n\}. \tag{6.5}$$

The essential observation is that this relaxation generates tight relations between variables on their upper and lower bounds. More precisely, suppose that some original variable takes a value equal to either of its bounds. Then all the corresponding new RLT linearization variables that involve this original variable take relative values that conform with actually fixing this original variable at its particular bound in the nonlinear expressions represented by these new RLT variables [57].

Note that relaxations (6.5) of the power term x^n are expressed with x^i for all $i \leq n$, and thus provide a fruitful relationship on problems containing many power terms involving some variable.

The univariate term x^n is convex when n is even, or when n is odd and the value of x is negative; it is concave when n is odd and the value of x is positive. Sahinidis and Twarmalani [50] have introduced the convex and concave envelopes when n is odd by taking the point where the power term x^n and its underestimator have the same slope. These convex/concave relaxations on x^n are expressed with only $[x^n]_L$ and x. In other words, they do not generate any relations with x^i for $1 < i < n$.

That is why we suggest implementing the approximations defined by formulae (6.5). Note that for the case $n = 2$, (6.5) provides the concave envelope.

7. A safe rounding procedure for the `Quad`-algorithm. This section details the rounding procedure we propose to ensure the completeness of the `Quad` algorithm [33]. First, we show how to compute safe coefficients for the generated linear constraints. In the second subsection we explain how a recent result from Neumaier and Shcherbina [42] allows us to use the simplex algorithm in a safe way.

7.1. Computing safe coefficients.

(a) *Approximation of* $L1$. The linear constraint $L1(y,\alpha) \equiv y - 2\alpha x + \alpha^2 \geq 0$ approximates a term x^2 with $\alpha \in [\underline{x}, \overline{x}]$. $L1(y,\alpha)$ corresponds to the tangent lines to the curve $y = x^2$ at the point (α, α^2).

Thus, the computation over the floats of the coefficients of $L1(y,\alpha)$ may change the slope of the tangent line as well as the intersection points with the curve $y = x^2$. Consider the case where α is negative: the solutions are above the tangent line; thus we have to decrease the slope to be sure to keep all of the solutions. It follows that we have to use a rounding mode towards $+\infty$. Likewise, when α is positive, we have to set the rounding mode towards $-\infty$. More formally, we have

$$L1_{\mathbb{F}}(y,\alpha) \;\equiv\; \begin{cases} y - \bigtriangledown(2\alpha)x + \bigtriangleup(\alpha^2) \geq 0 & \text{if } \alpha \geq 0, \\ y - \bigtriangleup(2\alpha)x + \bigtriangleup(\alpha^2) \geq 0 & \text{if } \alpha < 0, \end{cases}$$

where $\bigtriangledown(x)$ (resp., $\bigtriangleup(x)$) denotes a rounding mode of x towards $-\infty$ (resp., $+\infty$).

(b) *Approximation of* $L2$. The case of $L2$ is a bit more tricky since the "rotation axis" of the line defined by $L2$ is between the extremum values of x^2 ($L2(y)$ is an overestimation of y). Thus, to keep all the solutions we have to strengthen the slope

of this line at its smallest extremum. It follows that

$$L2_{\mathbb{F}} \equiv \begin{cases} \triangle(\underline{x}+\overline{x})x - y - \triangledown(\underline{x}\overline{x}) \geq 0 & \text{if } \underline{x} \geq 0, \\ \triangledown(\underline{x}+\overline{x})x - y - \triangledown(\underline{x}\overline{x}) \geq 0 & \text{if } \overline{x} < 0, \\ \triangle(\underline{x}+\overline{x})x - y & \\ \quad -\triangledown(\underline{x}\overline{x} + Ulp(\triangle(\underline{x}+\overline{x}))\underline{x}) \geq 0 & \text{if } \overline{x} > 0,\ \underline{x} < 0,\ |\underline{x}| \leq |\overline{x}|, \\ \triangledown(\underline{x}+\overline{x})x - y & \\ \quad -\triangledown(\underline{x}\overline{x} - \triangle(Ulp(\triangle(\underline{x}+\overline{x}))\overline{x})) \geq 0 & \text{if } \overline{x} > 0,\ \underline{x} < 0,\ |\underline{x}| > |\overline{x}|, \end{cases}$$

where $Ulp(x)$ computes the distance between x and the float following x.

(c) *Approximation of $BIL1, BIL2, BIL3$, and $BIL4$.* The general form of $BIL1$, $BIL2, BIL3$, and $BIL4$ is $x_ix_j + s_1b_1x_i + s_2b_2x_j + s_3b_1b_2 \geq 0$, where b_1 and b_2 are floating point numbers corresponding to bounds of x_i and x_j whereas $s_i \in \{-1, 1\}$.

The term $s_3b_1b_2$ is the only term which results from a computation: all the other terms use constants which are not subject to round-off errors. Thus, these linear constraints can be rewritten in the following form: $Y + s_3b_1b_2$.

A rounding of $s_3b_1b_2$ towards $+\infty$ enlarges the solution space, and thus ensures that all these linear constraints are safe approximations of x^2.

It follows that $BIL\{1, \ldots, 4\}_{\mathbb{F}} \equiv Y + \triangle(s_3b_1b_2) \geq 0$.

(d) *Approximation of multivariate linearizations.* We are now in the position to introduce the corrections of multivariate linearizations as introduced for the power of x. Such linearizations could be rewritten in the following form:

$$\sum_{i=1}^{n} a_ix_i + b \geq 0,$$

where a_i denotes the expression used to compute the coefficient of variable x_i, and b is the expression used to compute the constant value. Proposition 7.1 takes advantage of interval arithmetic to compute a safe linearization with coefficients over the floating point numbers.

PROPOSITION 7.1.

$$\sum_{i=1}^{n} \overline{a}_ix_i + \sup\left(\overline{b} + \sum_{i=1}^{n} \sup(\sup(\mathbf{a}_i\underline{x}_i) - \overline{a}_i\underline{x}_i)\right) \geq \sum_{i=1}^{n} a_ix_i + b \geq 0 \quad \text{for all } x_i \in \mathbf{x}_i.$$

Proof. For all $x_i \in \mathbf{x}_i$, we have

$$\sum_{i=1}^{n} \overline{a}_ix_i + \sup\left(\overline{b} + \sum_{i=1}^{n} \sup(\sup(\mathbf{a}_i\underline{x}_i) - \overline{a}_i\underline{x}_i)\right) \geq \sum_{i=1}^{n} \overline{a}_ix_i + b + \sum_{i=1}^{n} (\sup(\mathbf{a}_i\underline{x}_i) - \overline{a}_i\underline{x}_i)$$

and

$$\sum_{i=1}^{n} \overline{a}_ix_i + b + \sum_{i=1}^{n} (\sup(\mathbf{a}_i\underline{x}_i) - \overline{a}_i\underline{x}_i) = \sum_{i=1}^{n} (\overline{a}_i(x_i - \underline{x}_i) + \sup(\mathbf{a}_i\underline{x}_i)) + b.$$

As for all $i \in \{1, \ldots, n\}$, we have $\overline{a}_i \geq a_i$, $\sup(\mathbf{a}_i\underline{x}_i) \geq a_i\underline{x}_i$, and for all $x_i \in \mathbf{x}_i$, $x_i - \underline{x}_i \geq 0$. Therefore,

$$\sum_{i=1}^{n} (\overline{a}_i(x_i - \underline{x}_i) + \sup(\mathbf{a}_i\underline{x}_i)) + b \geq \sum_{i=1}^{n} (a_i(x_i - \underline{x}_i) + a_i\underline{x}_i) + b = \sum_{i=1}^{n} a_ix_i + b. \qquad \square$$

This proposition provides a safe approximation of a multivariate linearization which holds for any a_i, x_i, and b. This result could be refined by means of the previous approximations. For instance, whenever $\underline{x_i} \geq 0$, $\overline{a}_i x_i \geq a_i x_i$. In this case, there is no need for an additional correction.

(e) *Approximation of initial constant values.* Initial constant values are real numbers that may not have an exact representation within the set of floating point numbers. Thus, a safe approximation is required.

Constant values in inequalities have to be correctly rounded according to the orientation of the inequality. The result presented in the previous paragraph sets the rounding directions which have to be used.

Equations must be transformed into inequalities when their constant values have to be approximated.

7.2. Computation of safe bounds with linear programming algorithm. Linear programming methods can solve problems of the following form:

$$\begin{array}{rl} \min & C^T X \\ \text{such that} & \underline{B} \leq AX \leq \overline{B} \\ \text{and} & \underline{X} \leq X \leq \overline{X}. \end{array} \tag{7.1}$$

The solution of such a problem is a vector $X_r \in \mathbb{R}^n$. However, the solution computed by solvers like `CPLEX` or `SOPLEX` is a vector $X_f \in \mathbb{F}^n$ that may be different from X_r due to the rounding errors. More precisely, X_f is safe for the objective only if $C^T X_r \geq C^T X_f$.

Neumaier and Shcherbina [42] provide a cheap method to obtain a rigorous bound of the objective and certificates of infeasibility. The essential observation is that the dual of (7.1) is

$$\begin{array}{rl} \max & \underline{B}^T Z' + \overline{B}^T Z'' \\ \text{such that} & A^T(Z' - Z'') = C. \end{array} \tag{7.2}$$

Let $Y = Z' - Z''$, and let the residue $R = A^T Y - C \in \mathbf{R} = [\underline{R}, \overline{R}]$. It follows that

$$C^T X = (A^T Y - R)^T X = Y^T AX - R^T X \in Y^T [\underline{B}, \overline{B}] - \mathbf{R}^T [\underline{X}, \overline{X}]$$

and the value of μ, the lower bound of the value of the objective function, is

$$\mu = \inf(Y^T \mathbf{B} - \mathbf{R}^T \mathbf{X}) = \bigtriangledown(Y^T \mathbf{B} - \mathbf{R}^T \mathbf{X}). \tag{7.3}$$

Formula (7.3) is trivially correct by construction. Note that the precision of such a safe bound depends on the width of the intervals $[\underline{X}, \overline{X}]$.

So, we just have to apply this correction before updating the lower and the upper bounds of each variable.

However, the linear program (7.1) may be infeasible. In that case, Neumaier and Shcherbina show that whenever $d = \inf(\mathbf{R'}^T \mathbf{X} - Y^T \mathbf{B}) > 0$, where $R' = A^T Y \in \mathbf{R'}$, then it is certain that no feasible point exists. However, the precision of interval arithmetic does not always allow us to get a positive value for d while the linear program is actually infeasible. In the latter case, we consider it as feasible. Note that box-consistency may be able to reject most, if not all, of the domains of such variables.

8. Experimental results. This section reports experimental results of `Quad` on a variety of twenty standard benchmarks. Benchmarks `eco6`, `katsura5`, `katsura6`, `katsura7`, `tangets2`, `ipp`, `assur44`, `cyclic5`, `tangents0`, `chemequ`, `noon5`, `geneig`, `kinema`, `reimer5`, and `camera1s` were taken from Verschelde's web site,[10] `kin2` from [60], `didrit` from [15], `lee` from [29], and finally `yama194`, `yama195`, and `yama196` from [63]. The most challenging benchmark is `stewgou40` [16]. It describes the 40 possible positions of a Gough–Stewart platform as a function of the values of the actuators. The proposed modelling of this problem consists of 9 equations with 9 variables.

The experimental results are reported in Tables 8.1 and 8.2. Column n (resp., δ) shows the number of variables (resp., the maximum polynomial degree). `BP(Φ)` stands for a *Branch and Prune* solver based on the Φ filtering algorithm, that is to say, a search-tree exploration where a filtering technique Φ is applied at each node. `quad(H)` denotes the `Quad` algorithm where bilinear terms are relaxed with formulae (6.2), power terms with formulae (6.5), and product terms with the quadrification method; `H` stands for the heuristic used for decomposing terms in the quadrification process.

The performances of the following five solvers have been investigated.

1. `RealPaver`: a free *Branch and Prune* solver[11] that dynamically combines optimized implementations of box-consistency filtering and 2b-consistency filtering algorithms [5].
2. `BP(box)`: a *Branch and Prune* solver based on the ILOG[12] commercial implementation of box-consistency.
3. `BP(box+simplex)`: a *Branch and Prune* solver based on `box` and a simple linearization of the whole system without introducing linear relaxations of the nonlinear terms.
4. `BP(box+quad(Qmid))`: a *Branch and Prune* solver which combines `box` and the `Quad` algorithm where product terms are relaxed with the `Qmid` heuristic.
5. `BP(box+quad(rAI))`: a *Branch and Prune* solver which combines `box` and the `Quad` algorithm where product terms are relaxed with the `rAI` heuristic.

Note that the `BP(box+simplex)` solver implements a strategy that is slightly different from the approach of Yamamura, Kawata, and Tokue [63].

All the solvers have been parameterized to get solutions or boxes with precision of 10^{-8}. That is to say, the width of the computed intervals is smaller than 10^{-8}. A solution is said to be *safe* if we can prove its uniqueness within the considered box. This proof is based on the well-known Brouwer fixed point theorem (see [20]) and requires just a single test.

Sols, *Ksplit*, and $T(s)$ are, respectively, the number of solutions, the number of thousands of branchings (or splittings), and the execution time in seconds. The number of solutions is followed with a number of *safe* solutions between brackets. A "–" in the column $T(s)$ means that the solver was unable to find all the solutions within eight hours. All the computations have been performed on a PC with Pentium IV processor at 2.66 GHz running Linux. The compiler was GCC 2.9.6 used with the -O6 optimization flag.

The performances of `RealPaver`, `BP(box)`, and `BP(box+quad(Qmid))` are displayed in Table 8.1. The benchmarks have been grouped into three sets. The first

group contains problems where the `QuadSolver` does not behave very well. These problems are quite easy to solve and the overhead of the relaxation and the calls to a linear solver does not pay off. The second group contains a set of benchmarks for which the `QuadSolver` compares well with the two other constraint solvers: the `QuadSolver` requires always much less splitting and often less time than the other solvers. In the third group, which contains difficult problems, the `QuadSolver` outperforms the two other constraint solvers. The latter were unable to solve most of these problems within eight hours whereas the `QuadSolver` managed to find all the solutions for all but two of them in less than 8 minutes. For instance, `BP(box)` requires about 74 hours to find the four solutions of the `Lee` benchmark whereas the `QuadSolver` managed to do the job in a couple of minutes. Likewise, the `QuadSolver` did find the forty safe solutions of the `stewgou40` benchmark in about 15 minutes whereas `BP(box)` required about 400 hours. The essential observation is that the `QuadSolver` spends more time in the filtering step but it performs much less splitting than classical solvers. This strategy pays off for difficult problems.

All the problems, except `cyclic5` and `reimer5`, contain many quadratic terms and some product and power terms. `cyclic5` is a pure multilinear problem that contains only sums of products of variables. The `Quad` algorithm has not been very efficient for handling this problem. Of course, one could not expect an outstanding performance on this bench since product term relaxation is a poor approximation of multilinear terms. `reimer5` is a pure power problem of degree 6 that has been well solved by the `Quad` algorithm.

Table 8.2 displays the performances of solvers combining box-consistency and three different relaxation techniques. There is no significant difference between the solver based on the `Qmid` heuristics and the solver based on the `rAI` heuristics. Indeed, both heuristics provide convex and concave envelopes of the product terms. The `QuadSolver` with relaxations outperforms the `BP(box+simplex)` approach for all

benchmarks but `yama195`, which is a quasilinear problem. These performances on difficult problems illustrate well the capabilities of the relaxations.

Note that Verschelde's homotopy continuation system, `PHCpack` [62], required 115 s to solve `lee` and 1047 s to solve `stewgou40` on our computer. `PHCpack` is a state-of-the-art system in solving polynomial systems of equations. Unfortunately, it is limited to polynomial systems and does not handle inequalities. `PHCpack` searches for all the roots of the equations, whether real or complex, and it does not restrict its search to a given subspace. The homotopy continuation approach also suffers from an exponential growing computation time which depends on the number of nonlinear terms (`PHCpack` failed to solve `yama195` which contains 3600 nonlinear terms). In contrast to homotopy continuation methods, `QuadSolver` can easily be extended to nonpolynomial systems.

Thanks to Arnold Neumaier and Oleg Shcherbina, we had the opportunity to test BARON [50] with some of our benchmarks. `QuadSolver` compares well with this system. For example, BARON 6.0[13] and `QuadSolver` require more or less the same time to solve `camera1s`, `didrit`, `kinema`, and `lee`. BARON needs only 1.59 s to find all the solutions of `yama196` but it requires 859.6 s to solve `yama195`. Moreover, BARON loses some solutions on `reimer5` (22 solutions found) and `stewgou40` (14 solutions found) whereas it generates numerous wrong solutions for these two problems. We must also underline that BARON is a global optimization problem solver and that it has not been built to find all the solutions of a problem.

9. Conclusion. In this paper, we have exploited an RLT schema to take into account specific semantics of nonlinear terms. This relaxation process is incorporated in the *Branch and Prune* process [60] that exploits interval analysis and constraint satis-

[13]The tests were performed on an Athlon XP 1800 computer.

faction techniques to find rigorously all solutions in a given box. The reported experimental results show that this approach outperforms the classical constraint solvers.

Pesant and Boyer [44, 45] first introduced linear relaxations in a CLP language to handle geometrical constraints. However, the approximation of the constraints was rather weak. The approach introduced in this paper is also related to recent work that has been done in the interval analysis community as well as to some work achieved in the optimization community.

In the interval analysis community, Yamamura, Kawata, and Tokue [63] used a simple linear relaxation procedure where nonlinear terms are replaced by new variables to prove that some box does not contain solutions. No convex/concave outer-estimations are proposed to obtain a better approximation of the nonlinear terms. As pointed out by Yamamura, Kawata, and Tokue, this approach is well adapted to quasi-linear problems: *"This test is much more powerful than the conventional test if the system of nonlinear equations consists of many linear terms and a relatively small number of nonlinear terms"* [63].

The global optimization community also worked on solving nonlinear equation problems by transforming them into an optimization problem (see, for example, Chapter 23 in [17]). The optimization approach has the capability to take into account specific semantics of nonlinear terms by generating a tight outer-estimation of these terms. The pure optimization methods are usually not rigorous since they do not take into account rounding errors and do not prove the uniqueness of the solutions found.

Acknowledgments. We thank Arnold Neumaier for his fruitful comments on an early version of this paper. We are also grateful to Arnold Neumaier and Oleg Shcherbina for their help in testing BARON.

FAST MULTIPOLE METHOD FOR MULTIVARIABLE INTEGRALS*

OLIVIER BOKANOWSKI† AND MOHAMMED LEMOU‡

Abstract. We give a fast numerical algorithm to evaluate a class of multivariable integrals. A direct numerical evaluation of these integrals costs N^m, where m is the number of variables and N is the number of the quadrature points for each variable. For $m = 2$ and $m = 3$ and for only one-dimensional variables, we present an algorithm which is able to reduce this cost from N^m to a cost of the order of $O((-\log\epsilon)^{\mu_m} N)$, where ϵ is the desired accuracy and μ_m is a constant that depends only on m. Then, we make some comments about possible extensions of such algorithms to number of variables $m \geq 4$ and to higher dimensions. This recursive algorithm can be viewed as an extension of "fast multipole methods" to situations where the interactions between particles are more complex than the standard case of binary interactions. Numerical tests illustrating the efficiency and the limitation of this method are presented.

Key words. fast multipole method, multivariable integrals, multiparticle integrals, multidimensional integrals, multidimensional sums, correlated sums, $O(N)$ algorithm, molecular quantum physics

1. Introduction.

In this paper, we are concerned with numerical approximations of the following multivariable integrals:

$$\int_{\mathcal{C}\times\mathcal{C}\times\cdots\times\mathcal{C}} \phi_1(x_1)\phi_2(x_2)\cdots\phi_m(x_m)\left[\prod_{1\leq i<j\leq m} f_{ij}(x_i - x_j)\right] d\mu(x_1)\, d\mu(x_2)\cdots d\mu(x_m), \tag{1.1}$$

where $\mathcal{C}$ is a cube of $\mathbb{R}^d$, m is the number of variables, and μ is a positive measure. For instance, the measure μ can be the usual Lebesgue's measure or a discrete measure. The functions f_{ij} are assumed to be sufficiently regular on $\mathbb{R}^d\backslash\{0\}$. The functions ϕ_j and f_{ij} are such that the integrals (1.1) is absolutely convergent.

The basic example is the evaluation of the total interaction energy of a system of N charged particles:

$$E = \sum_{i,j=1;\ i\neq j}^{N} \frac{q_i r_j}{|x_i - x_j|}, \tag{1.2}$$

where x_i is the position of the ith particle and q_i its charge (here $r_i = q_i$), or the continuous version

$$E = \int_{\mathcal{C}\times\mathcal{C}} \frac{q(x)r(y)}{|x-y|} d\mu(x) d\mu(y). \tag{1.3}$$

The classical interactions described by (1.3) are binary in the sense that they correspond to the particular case $m = 2$ of (1.1). Fast computations of the integrals (1.3) for a large number of functions (q, r) must be performed in quantum chemistry, for "Hartree–Fock" models and "density functional" models involving many electrons, as explained and done in [8, 9], [18], or [19] (computation of the "J-matrix").

However, in more precise quantum models the particles are strongly correlated through a wave function $\Psi(x_1, \ldots, x_m)$, where $m \geq 3$ is the number of particles. In this case, the determination of the state of the particles leads to the problem of computing the following integrals ("Coulomb energy"):

$$\int_{\Omega^m} |\Psi(x_1, \ldots, x_m)|^2 \left(\sum_{1 \leq i < j \leq m} \frac{1}{|x_i - x_j|} \right) d\mu(x_1) \cdots d\mu(x_m), \tag{1.4}$$

with $\Omega \subset \mathbb{R}^d$, and where the function Ψ can take the following form:

$$\Psi(x_1, \ldots, x_m) := \phi_1(x_1)\phi_2(x_2) \cdots \phi_m(x_m) \prod_{1 \leq i < j \leq m} f_{ij}(x_i - x_j) \tag{1.5}$$

or

$$\Psi(x_1, \ldots, x_m) := \phi_1(x_1)\phi_2(x_2) \cdots \phi_m(x_m) \left(\sum_{1 \leq i < j \leq m} f_{ij}(x_i - x_j) \right). \tag{1.6}$$

When the variables x_i are not correlated ($f_{ij} = 1$), explicit computations for (1.4) and (1.5) can be done for some particular classes of ϕ_i's such as Gaussian functions [12, Chapters 1 and 2]. But this specific choice of Ψ is not always sufficient to describe the realistic behavior of the state of the particles [13]. On the other hand, if the particles are correlated ($f_{ij} \neq 1$), analytic computations are not possible in general, and Monte Carlo methods are usually used [10] (see also [11]). The main difficulties with these random methods, or pseudorandom methods, is to control the accuracy because of the presence of oscillations and convergence problems.

Hopefully there are some cases where partial analytic computations are possible. In the "Møller–Plesset perturbation theory of second order with linear r_{12} terms," or "MP2-R12 method" [14], the used typical functions are of the form (1.6) with $f_{ij}(x_i - x_j) = |x_i - x_j|$. In this case a simple algebraic calculation shows that the computation of the m-particle integral (1.4) reduces to the computation of $m = 2, 3$ or $m = 4$ particle integrals of the form (1.1), and of 1-particle integrals. This has been extensively used in order to compute very accurately the energy of small atoms and molecules as in Kutzelnigg and Klopper [15, 16] and Müller, Kutzelnigg, and Noga [17], or in [23]. Yet, a limitation of this approach is that a particular basis of functions ϕ_j is used in order to avoid or to approximate the computation of multiparticle integrals. It would be useful to be able to rapidly (and accurately) compute such integrals (for $m = 2, 3, 4$ only) without any particular constraint on the ϕ_j functions.

Note that for most real quantum applications, one should treat the case $d = 3$. However, quantum model problems on the line ($d = 1$) are also used [22].

In this paper we present an alternative approach. This approach is deterministic and is an extension of the well-known fast multiple method (FMM) to more complex systems of particles. The FMM method was introduced by Greengard and Rokhlin [1, 2] to compute the binary interaction (1.2) with a cost of the order of $O(N)$ instead

of the order of $O(N^2)$ (see also [5] and [6], and for instance [20] or [21] for recent developments of the FMM). Here we want to extend this technique to situations where the correlations between particles are stronger, as in multivariable integrals of the form (1.1). We give the details of the algorithm only in the case of two or three variables (i.e., $m = 2$ or $m = 3$) and for one-dimensional variables ($d = 1$). This work gives a first idea of how this algorithm could be used for more general situations ($d = 3$ for instance). However, a complete generalization is not obvious and is under investigation.

Our aim is to reduce the cost of the numerical evaluation of integrals (1.1). We use a regular mesh of $\mathcal{C}$ with N points and consider a discrete measure μ supported by the mesh. This also corresponds to a quadrature formula of the integrals (1.1), and leads to the problem of evaluating the following sums:

$$\sum_{i_1=1}^{N}\sum_{i_2=1}^{N}\cdots\sum_{i_m=1}^{N}\phi_1(x_{i_1})\phi_2(x_{i_2})\cdots\phi_m(x_{i_m})\left[\prod_{1\le k<\ell\le m} f_{k\ell}(x_{i_k}-x_{i_\ell})\right]. \tag{1.7}$$

A direct evaluation of the sums (1.7) requires a computational cost of the order of $O(N^m)$. The purpose of the paper is to present an algorithm reducing this cost to the order $O(\log_2(\frac{1}{\epsilon})^{\mu}\, N)$, where μ depends only on m and d and will be made precise in what follows (at least for the specific case $d = 1$ and $m \le 3$), and where ϵ is the relative error between the exact value of formula (1.7) and the result obtained by the present algorithm. The parameter ϵ is linked to the order of "multipole expansions" through the relation $p = \log_2(\frac{1}{\epsilon})$ (when $d = 1$) and does not depend on N. This result was already announced by the authors in [4] without proof.

In order to simplify the presentation of the algorithm, we shall assume that $d = 1$, $f_{ij}(r) = r^{\alpha_{ij}}$ (with $\alpha_{ij} > -1$), and $\mathcal{C} = [0, 1]$.

We also mention that the approach of [7] using wavelets, for $m = 3$ variables and with $d = 1$, can be used to compute some partially correlated sums or integrals. However, it cannot be applied here in general because the variables in the sum (1.7) are completely correlated.

We first present in section 2 the algorithm in the simple case of $m = 2$ variables. This corresponds to the case of binary interactions for which the multipole method has been widely developed by Greengard and Rokhlin [1, 2]. In sections 3 and 4, we focus on the case $m = 3$ and state our main results. We point out that this is not a straightforward generalization of the 2-variable case. In section 5, we give some numerical illustrations of the method in the case $m = 3$, and in section 6 we conclude with some remarks and extensions to the case $m \ge 4$.

2. The case of binary interactions ($m = 2$). In this section, we present a brief description of the approach in the case of binary interactions ($m = 2$). In this case, the used method is strongly related to the ideas of the classical FMM introduced by Greengard and Rokhlin [1, 2]. Even if the case of binary interactions is now classical, the presentation below is a first step in the understanding of the more complex approach for strongly correlated particles ($m = 3$ for instance). This last case is our main concern in this work and will be developed in the next section.

Consider first the case of binary interactions, i.e., the problem of approximating the following sum:

$$I_{dis} := \sum_{i,j=1}^{N}\phi_1(a_i)\phi_2(a_j)|a_i - a_j|^{\alpha}, \tag{2.1}$$

where $\alpha \geq 0$ and $a_i = \frac{1}{N}(i - \frac{1}{2})$, $i = 1, \ldots, N$, are the points of a regular mesh of $\mathcal{C}$. Note that when $-1 < \alpha < 0$ we can also consider the sum (2.1) for all pairs (i, j) with $i \neq j$. In order to simplify the presentation we restrict ourselves to the case $\alpha \geq 0$ (see Remark 3).

Note that I_{dis} is also equal to the following integral:

$$I_{dis} := \int_{\mathcal{C}\times\mathcal{C}} \phi_1(x_1)\phi_2(x_2)|x_1 - x_2|^\alpha \, d\mu(x_1)d\mu(x_2),$$

where $\mathcal{C} = [0, 1]$ and μ is the discrete measure defined on $\mathcal{C}$ by $\mu(\{x\}) = 1$ if $x = a_i$, and $\mu(\{x\}) = 0$ otherwise. To simplify, we set $d^2\mu = d\mu \otimes d\mu$ and $F(x_1, x_2) = \phi_1(x_1)\phi_2(x_2)|x_1 - x_2|^\alpha$.

To evaluate I_{dis} one needs $O(N^2)$ operations. Our purpose is to reduce this cost to the order $O(N)$. To achieve this we use a multigrid hierarchy and multipole expansions as follows.

Multigrid hierarchy. We split the interval $\mathcal{C} = \mathcal{C}_0^1$ in several parts according to the following hierarchy.

Level $k = 0$: $\mathcal{C}_0^1 = \mathcal{C}$.

Level $k = 1$: We split $\mathcal{C}$ into two equal parts (called its children) $\mathcal{C}_1^1 = [0, \frac{1}{2}]$, $\mathcal{C}_1^2 = [\frac{1}{2}, 1]$, and $\mathcal{C}_0^1$ is called their father.

Level $k = 2$: We split each $\mathcal{C}_1^i$ into two equal parts (its children). We obtain 2 intervals $\mathcal{C}_2^1, \mathcal{C}_2^2$ (when $i = 1$) or $\mathcal{C}_2^3, \mathcal{C}_2^4$ when $i = 2$.

Level k: We split each $\mathcal{C}_{k-1}^i$ into two equal parts, $\mathcal{C}_k^{2i-1}$ and $\mathcal{C}_k^{2i}$. We obtain 2^k intervals $(\mathcal{C}_k^i)_{i=1,\ldots,2^k}$.

The center of an interval $\mathcal{C}_k^i$ is $r_k^i = \frac{i-1/2}{2^k}$. We iterate this process until the finest mesh level n_g.

DEFINITION 2.1. (i) *Let $\mathcal{C}_k^i$ and $\mathcal{C}_k^j$ be two intervals of level k. We say that $\mathcal{C}_k^i$ and $\mathcal{C}_k^j$ are* well separated *if they are separated at least by one interval of the same level (i.e., $|i - j| \geq 2$).*

(ii) *We say that $\mathcal{C}_k^i$ and $\mathcal{C}_k^j$ are* neighbors *if $|i - j| \leq 1$ and then write $\mathcal{C}_k^i \in V(\mathcal{C}_k^j)$. $V(\mathcal{C}_k^i)$ denotes the set of neighbors of $\mathcal{C}_k^i$.*

(iii) *We define and denote by $Int(\mathcal{C}_k^i)$ the* interaction list *of a given interval $\mathcal{C}_k^i$ of level k, as the set of intervals $\mathcal{C}_k^j$ of the same level k, which are well separated, and whose fathers are neighbors.*

Graphic illustrations of neighboring intervals and well-separated intervals are given in Figure 2.1.

With this definition we have the following partition of $\mathcal{C} \times \mathcal{C}$:

$$\mathcal{C}\times\mathcal{C} = \left(\bigcup_{k=1,n_g} \bigcup_{\substack{i,j=1,\ldots,2^k \\ \mathcal{C}_k^j \in Int(\mathcal{C}_k^i)}} \mathcal{C}_k^i \times \mathcal{C}_k^j \right) \bigcup \left(\bigcup_{\substack{i,j=1,\ldots,2^{n_g} \\ \mathcal{C}_{n_g}^i, \mathcal{C}_{n_g}^j \text{ neighbors}}} \mathcal{C}_{n_g}^i \times \mathcal{C}_{n_g}^j \right). \tag{2.2}$$

From this remark we deduce that

$$I_{dis} = \left(\sum_{k=1,n_g} \sum_{\substack{i,j=1,\ldots,2^k \\ \mathcal{C}_k^j \in Int(\mathcal{C}_k^i)}} \int_{\mathcal{C}_k^i \times \mathcal{C}_k^j} F d^2\mu \right) + \left(\sum_{\substack{i,j=1,\ldots,2^{n_g} \\ \mathcal{C}_{n_g}^i, \mathcal{C}_{n_g}^j \text{ neighbors}}} \int_{\mathcal{C}_{n_g}^i \times \mathcal{C}_{n_g}^j} F d^2\mu \right). \tag{2.3}$$

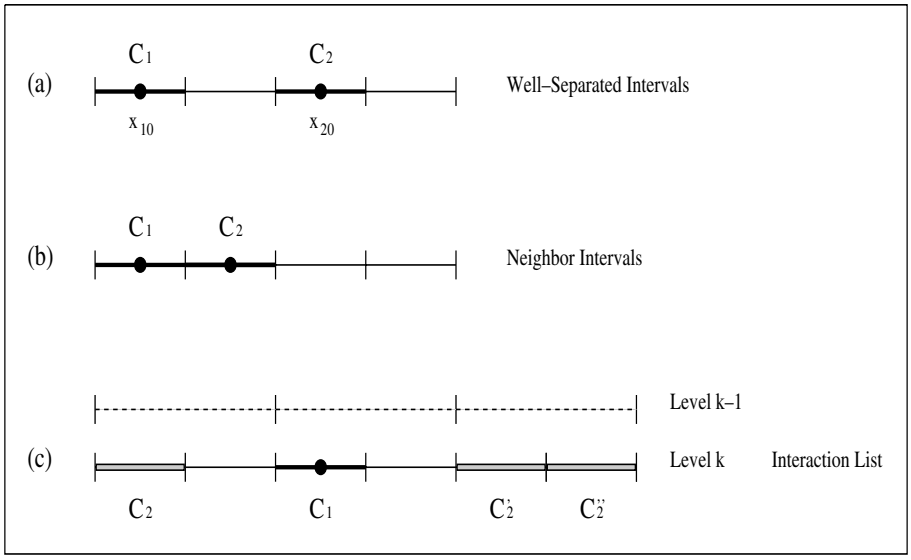

FIG. 2.1. *Example of well-separated intervals* (a) *and of neighboring intervals* (b) *at some level* k. (c) *Example of an interaction list* $Int(C_1) = (C_2, C_2', C_2'')$ *of an interval* C_1.

Thus, in order to evaluate I_{dis}, it suffices to evaluate the integrals $\int_{\mathcal{C}_k^i \times \mathcal{C}_k^j} F$ when $\mathcal{C}_k^i$ and $\mathcal{C}_k^j$ are well separated (at level k) but whose fathers are neighbors, and also the integrals $\int_{\mathcal{C}_{n_g}^i \times \mathcal{C}_{n_g}^j} F$ on neighboring intervals at the finest level n_g. Notice that in (2.2) or (2.3) we have only $O(N)$ contributions of products $\mathcal{C}_k^i \times \mathcal{C}_k^j$.

Notations. We define the moment of ϕ of order i on the interval $\mathcal{C}$ around y by

$$M_\phi(i, y, \mathcal{C}) := \int_{\mathcal{C}} \phi(x)(x-y)^i \, d\mu(x). \tag{2.4}$$

In the case where y is the center of the interval $\mathcal{C}$, we simply write

$$M_\phi(i, \mathcal{C}) := M_\phi(i, y, \mathcal{C}).$$

LEMMA 2.2 (multipole expansion). (i) *Let* $\alpha > -1$, *and let* $p \in \mathbb{N}$ *be such that* $p + 1 \geq \alpha$. *Let* $\mathcal{C}^1$ *and* $\mathcal{C}^2$ *be two intervals of the same level, which are well separated, and let* x_{10} *and* x_{20} *be their centers. Let* $u = \frac{x_{10} - x_{20}}{|x_{10} - x_{20}|}$ *(i.e.,* $u = \pm 1$*) and* $h_i = \frac{x_i - x_{i0}}{|x_{10} - x_{20}|}$. *There exist coefficients* $c_{ij}(\alpha, u)$ *such that for all* $x_1 \in \mathcal{C}^1$, *and for all* $x_2 \in \mathcal{C}^2$, *we have*

$$|x_1 - x_2|^\alpha = |x_{10} - x_{20}|^\alpha \left(\sum_{i+j \leq p} c_{ij}(\alpha, u) h_1^i h_2^j + \delta \right), \tag{2.5}$$

where $|\delta| \leq \dfrac{c_\alpha}{(p+1)^{\alpha+1} 2^p}$.

(ii) *We have the following expansion, called* multipole expansion [1]*:*

(2.6)

$$\int_{\mathcal{C}^1\times\mathcal{C}^2} F d^2\mu = |x_{10}-x_{20}|^\alpha \left(\sum_{i+j\le p} \frac{c_{ij}(\alpha,u)}{|x_{10}-x_{20}|^{i+j}} M_{\phi_1}(i,\mathcal{C}^1)\ M_{\phi_2}(j,\mathcal{C}^2) \right) + \eta,$$

where $F = F(x_1,x_2) = \phi_1(x_1)\phi_2(x_2)|x_1-x_2|^\alpha$, *and where* x_{10} *and* x_{20} *are the centers of* $\mathcal{C}^1$ *and* $\mathcal{C}^2$, *respectively. The error* η *satisfies*

$$|\eta| \le \frac{c'_\alpha}{(p+1)^{\alpha+1}2^p} \int_{\mathcal{C}^1\times\mathcal{C}^2} |F| d^2\mu,$$

where the constants c_α *and* c'_α *will be made precise in the proof.*

Note. By $\sum_{i+j\le p}$ we mean the sum for all pairs (i,j) such that $i\ge 0, j\ge 0$ and $i+j\le p$.

Proof of Lemma 2.2. We write

$$\begin{aligned} |x_1-x_2|^\alpha &= |(x_{10}-x_{20})+(x_1-x_{10})-(x_2-x_{20})|^\alpha \\ &= |x_{10}-x_{20}|^\alpha\ |u+h_1-h_2|^\alpha. \end{aligned}$$

Since C^1 and C^2 are well separated, $|h_i| \le \frac{1}{4}$. Consider the case $u=1$ (the case $u=-1$ is similar). We have $|u+h_1-h_2|^\alpha = (1+h)^\alpha$, where $h = h_1-h_2$ and $|h| \le |h_1|+|h_2| \le 2\frac{1}{4} \le \frac{1}{2}$. Then we expand $(1+h)^\alpha$ to the order p with respect to h:

$$(1+h)^\alpha = \sum_{n=0}^{p} \binom{\alpha}{n} h^n + R_{p+1}(\alpha,h),$$

where $\binom{a}{n} := \frac{a(a-1)\cdots(a-n+1)}{n!}$ and $R_p(\alpha,h) := \sum_{n=p}^\infty \binom{\alpha}{n} h^n$. Developing again $h^n = (h_1-h_2)^h = \sum_{j=1}^n \binom{j}{n} h_1^{n-j}(-h_2)^j$, we find formula (2.5) with

$$c_{ij}(u,\alpha) := (-1)^j u^{i+j} \binom{i}{i+j} \binom{\alpha}{i+j},$$

and with an error term δ that we want to bound. Let

$$q = q(\alpha) := \inf\{n\in\mathbb{N},\ n\ge\alpha\}.$$

We have $|\binom{\alpha}{n}| = A_\alpha B_\alpha(n)$ with

$$A_\alpha := \frac{1}{q!}\alpha(\alpha-1)(\alpha-2)\cdots(\alpha+1-q)$$

and

$$B_\alpha(n) := \left(1-\frac{\alpha+1}{q+1}\right)\left(1-\frac{\alpha+1}{q+2}\right)\cdots\left(1-\frac{\alpha+1}{n}\right).$$

From the definition of $q=q(\alpha)$, we have $\alpha \le q < \alpha+1$, and then $A_\alpha \le 1$. Now, using the inequality $1-x\le e^{-x}$, we obtain $0 \le B_\alpha(n) \le (\frac{q+1}{n+1})^{\alpha+1}$. Thus $|\binom{\alpha}{n}| \le (\frac{q+1}{n+1})^{\alpha+1}$. Hence, for $p\ge 1$, we have

$$
\begin{aligned}
R_p(\alpha,n) &\le (q+1)^{\alpha+1}\sum_{n\ge p}\frac{|h|^n}{(n+1)^{\alpha+1}}\\
&\le (q+1)^{\alpha+1}\frac{1}{|h|}\int_p^\infty \frac{|h|^t}{t^{\alpha+1}}dt\\
&\le (q+1)^{\alpha+1}\frac{1}{\log(1/|h|)}\frac{|h|^{p-1}}{p^{\alpha+1}}\\
&\le \frac{(q+1)^{\alpha+1}}{\log(2)}\frac{(\frac12)^{p-1}}{p^{\alpha+1}}.
\end{aligned}
$$

We then deduce that for $p\ge\alpha$, (i.e., $p\ge q$), $R_p(\alpha,n)\le c_\alpha\frac{1}{p^{\alpha+1}}(\frac12)^{p-1}$, where $c_\alpha=(\alpha+2)^{\alpha+1}/\log(2)$, and Lemma 2.2(i) follows.

(ii) Reporting this bound in the expression of I_i, and observing that $\frac23\le\frac{|x_{10}-x_{20}|}{|x_1-x_2|}\le 2$, we obtain the desired bound with $c'_\alpha:=c_\alpha\max(2^\alpha,(\frac23)^\alpha)$. □

Remark 1. We give also an estimate that will be useful in the next section. There exists a constant L_α such that, for $|h_1|\le\frac14$ and $|h_2|\le\frac14$, we have

$$\sum_{0\le i+j\le p}|c_{ij}(u,\alpha)||h_1|^i|h_2|^j\le L_\alpha,$$

where the coefficients $c_{ij}(u,\alpha)$ are defined in Lemma 2.2.

THEOREM 2.3. *Let $N=2^{n_g}s$, with s being a fixed integer. Let p be an integer such that $\bar p:=p+1\ge\alpha$. There exists an explicit algorithm that gives an approximation $I_{multipole}$ of the discretization I_{dis}, (2.1), using $O(\max\{1,\frac{\bar p}{s}\}\,\bar p\,N)$ operations with a relative error of the order of $O(1/\left(\bar p^{\alpha+1}\,2^p\right))$, i.e., $|I_{dis}-I_{multipole}|\le\frac{c_\alpha}{\bar p^{\alpha+1}\,2^p}\int_{\mathcal{C}_0\times\mathcal{C}_0}|F|$.*

Note that taking $s=\bar p$ we obtain a total cost of $O(\bar p\,N)$. Note also that s is the number of points inside each interval of the finest level n_g, and is naturally chosen to be small compared to N.

Remark 2 (elementary operations). For simplicity, we set to one all the costs of each of the following operations: one addition, one multiplication, one power (such as x^α or $|x|^\alpha$), and one evaluation of a known function. The cost of memory access will also be neglected.

Proof of Theorem 2.3. Assume that the moments $M_{\phi_j}(i,\mathcal{C})$ ($i=0,\dots,p$ and $j=1,2$) have been precalculated for all intervals $\mathcal{C}$ of each level of the multigrid hierarchy. Since an interaction list contains at most 3 intervals, it follows from Lemma 2.2 and (2.3) that the total cost of the evaluation of the integrals on well-separated intervals is of the order of $\sum_{k=1}^{n_g}3\;2^k\bar p^2\le 3\;2^{n_g+1}\bar p^2=O(p^2\frac{N}{s})$.

On the other hand, the integrals on neighboring intervals at level n_g are evaluated by direct quadrature formula (because here we cannot use a multipole expansion). The cost of this last evaluation is s^2 for each pair of intervals. There are at most 3 neighbors for each interval. Hence the total cost of these integrals is smaller than $3s^2 2^{n_g}=3sN$.

Now we present a recursive algorithm in order to precalculate the moments $M_{\phi_j}(i,\mathcal{C})$ at all levels $k=1,\dots,n_g$ and for $i=0,\dots,p$. First, we evaluate the moments at the finest mesh level n_g. This costs $s2^{n_g}(p+1)=O(\bar pN)$, since there are $\bar p=p+1$ moments for each interval, with s points per interval at the finest level. Suppose we have calculated the moments of level $k+1$. To evaluate a moment of order k, we use the decomposition of $\mathcal{C}_k^\ell$ into its two children: $\mathcal{C}_k^\ell=\mathcal{C}_{k+1}^{2\ell-1}\cup\mathcal{C}_{k+1}^{2\ell}$, and the formula

$$M_\phi(i,\mathcal{C}_k) = M_\phi(i,r_k,\mathcal{C}_k) = \sum_{j,\ \mathcal{C}_{k+1}^j \text{ child of } \mathcal{C}_k} M_\phi(i,r_k,\mathcal{C}_{k+1}^j). \tag{2.7}$$

Using the translation $x - r_k = x - r_{k+1}^j - (r_k - r_{k+1}^j)$, we obtain

$$M_\phi(i,r_k,\mathcal{C}_{k+1}^j) = \sum_{q=0}^{i} \begin{pmatrix} i \\ q \end{pmatrix} (r_k - r_{k+1}^j)^{i-q} M_\phi(q,\mathcal{C}_{k+1}^j). \tag{2.8}$$

Hence the computation of the moments $M_\phi(i,\mathcal{C}_k)$ for $i = 0,\dots,p$ requires $O(\bar{p}^2)$ operations. The total cost of the evaluation of all moments at all levels is $O(\bar{p}N) + O(\sum_{k=1}^{n_g-1} 2^k \bar{p}^2) = O(\bar{p}\,N + \frac{\bar{p}^2}{s}N)$, which concludes the proof of the first part of Theorem 2.3.

In order to obtain the error estimate of Theorem 2.3, we use the controlled multipole approximation of Lemma 2.2(ii). We obtain for any well-separated intervals $\mathcal{C}^1, \mathcal{C}^2$ of the same level

$$\left| \int_{\mathcal{C}^1 \times \mathcal{C}^2} F d^2\mu - I_{mult.}(\mathcal{C}^1 \times \mathcal{C}^2) \right| \le \frac{c'_\alpha}{\bar{p}^{\alpha+1} 2^p} \int_{\mathcal{C}^1 \times \mathcal{C}^2} |F| d^2\mu \tag{2.9}$$

with

$$I_{mult.}(\mathcal{C}^1 \times \mathcal{C}^2) := |x_{10} - x_{20}|^\alpha \left(\sum_{i+j \le p} \frac{c_{ij}(\alpha,u)}{|x_{10} - x_{20}|^{i+j}} M_{\phi_1}(i,\mathcal{C}^1)\ M_{\phi_2}(j,\mathcal{C}^2) \right).$$

Summing the above contributions (2.9) at all levels and over all products $\mathcal{C}^1 \times \mathcal{C}^2$ as in the partition (2.2), and adding the exact contributions at the finest level (for neighbor intervals), we obtain the desired error bound. This concludes the proof of Theorem 2.3. □

Remark 3. If we consider the sum (2.1) with $\alpha \in (-1,0)$ and for pairs (i,j) such that $i \ne j$, then the previous results and algorithm are unchanged except for the calculation of the sums at the finest mesh level (where we must sum only over (i,j) with $i \ne j$).

3. The case of multiple interactions ($m = 3$ variables). In this section, we consider the following three-variables integral:

$$I = \int_{\mathcal{C}_0 \times \mathcal{C}_0 \times \mathcal{C}_0} F(x_1,x_2,x_3) d^3\mu(x_1,x_2,x_3),$$

where

$$F(x_1,x_2,x_3) := \phi_1(x_1)\phi_2(x_2)\phi_3(x_3)|x_1 - x_2|^\alpha |x_2 - x_3|^\beta |x_3 - x_1|^\gamma,$$

$\mathcal{C}_0 = [0,1]$, and $\alpha,\beta,\gamma > -1$. We have also denoted $d^3\mu = d\mu \otimes d\mu \otimes d\mu$. As for the case $m = 2$, when μ is the discrete measure, this integral becomes

$$I_{dis} := \sum_{i_1,i_2,i_3=1}^{N} \phi_1(a_{i_1})\phi_2(a_{i_2})\phi_3(a_{i_3})|a_{i_1} - a_{i_2}|^\alpha |a_{i_2} - a_{i_3}|^\beta |a_{i_3} - a_{i_1}|^\gamma. \tag{3.1}$$

We shall also restrict ourselves to the case $\alpha,\beta,\gamma \ge 0$ as in the previous section in order to simplify the presentation of the result. However, as in Remark 3, it is not

difficult to extend our results to the case $\alpha, \beta, \gamma > -1$ (in which I_{dis} is defined as in (3.1) but where we sum only on $i_1 \neq i_2$, $i_2 \neq i_3$, and $i_3 \neq i_1$).

To evaluate I_{dis} one needs $O(N^3)$ operations. Our purpose is to reduce this cost to the order $O(N)$. We use the same hierarchy and the same definitions as in the previous section.

In the following theorem, we state our main result.

THEOREM 3.1. *Let $N = 2^{n_g} s$, with s being a fixed integer. Let p be an integer such that $p+1 \geq \max(\alpha, \beta, \gamma)$. Let $\bar{p} := p+1$. There exists an explicit algorithm that gives an approximation $I_{multipole}$ of the discretization I_{dis}, (3.1), using $O(\max\{\frac{\bar{p}}{s}, \frac{s^2}{\bar{p}^2}\}\bar{p}^2 N)$ operations with a relative error of the order of $O(p^{-\delta}2^{-p})$, where $\delta = \min(\alpha, \beta, \gamma)+1$, in the following sense:*

$$|I_{dis} - I_{multipole}| \leq C_{\alpha,\beta,\gamma} \frac{1}{\bar{p}^{\delta} 2^p} \int_{\mathcal{C}_0 \times \mathcal{C}_0 \times \mathcal{C}_0} |F| \, d^3\mu \ . \tag{3.2}$$

Note that taking $s = \bar{p}$ we obtain an $O(\bar{p}^2 N)$ algorithm, and taking $s = 1$ we obtain an $O(\bar{p}^3 N)$ algorithm. We recall that s is the number of particles in each interval at the finest mesh level n_g and that s is a small number compared to N.

Explicit theoretical cost bounds are given by (4.6), (4.7), and (4.8) in section 4.

Proof. To prove this theorem we follow the ideas of the previous section. We will first establish that the cost is proportional to N. We show that the proportionality factor depends only on s and $\bar{p}$, and we do not give the exact complexity in this section. In particular, we show that the cost is of the order of $O(\bar{p}^6 N)$ when $s \leq \bar{p}$. In section 4 we shall establish a more precise cost estimate using only summation techniques.

The proof of Theorem 3.1 is achieved in three steps.

3.1. Basic partition. Our first aim is to obtain a decomposition of I_{dis} in the same way as in (2.3). We then have to define a suitable notion of neighbors (for a set of three intervals), and select intervals which enter in interaction at each level.

Neighbors (or neighboring intervals). See Figure 3.1 for some examples. We say that a set of *three* intervals of a given level are *neighbors* (or *neighboring intervals*), if each of the three intervals is a neighbor of at least one of the two others. We recall that *two* intervals are neighbors if there is no interval between them. For instance,

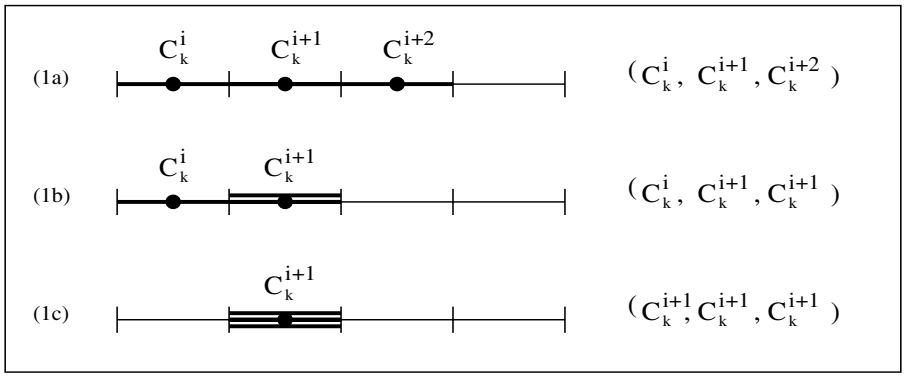

FIG. 3.1. *Example of neighbor intervals.*

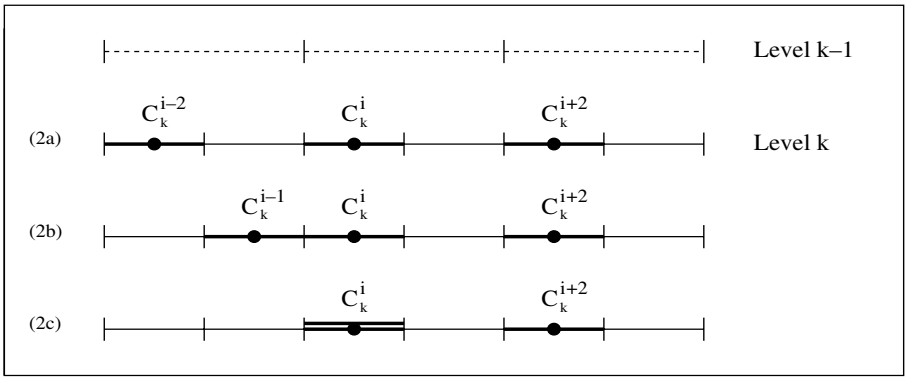

FIG. 3.2. *Example of intervals in interaction.* (a): *Case* (i); (b) *and* (c): *Case* (ii).

the *three* intervals

$$(\mathcal{C}_k^i, \mathcal{C}_k^{i+1}, \mathcal{C}_k^{i+2})$$

are neighboring intervals, even if the *two* intervals $(\mathcal{C}_k^i, \mathcal{C}_k^{i+2})$ are not neighbors.

Intervals in interaction (see Figure 3.2). We say also that *three* intervals of a given level are *in interaction* if they are *not* neighbors but their fathers are, in the sense defined above. For instance, the following intervals are always in interaction:

$$(\mathcal{C}_k^{i-2}, \mathcal{C}_k^i, \mathcal{C}_k^{i+2}), (\mathcal{C}_k^{i-1}, \mathcal{C}_k^i, \mathcal{C}_k^{i+2}). \tag{3.3}$$

Note that in this case there is at least one interval which is well separated from the two others.

Partition. Let Int_k be the product of intervals of level k which are in interaction:

$$Int_k := \bigcup_{(\mathcal{C}_k^{r_1},\ \mathcal{C}_k^{r_2},\ \mathcal{C}_k^{r_3}) \text{ in interaction}} \mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}.$$

Let also H_k be the product of intervals of level k which are neighbors:

$$H_k := \bigcup_{(\mathcal{C}_k^{r_1},\ \mathcal{C}_k^{r_2},\ \mathcal{C}_k^{r_3}) \text{ neighbors}} \mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}.$$

We note that $H_k = Int_{k+1} \cup H_{k+1}$ from the definitions, and that H_0 contains only one element: $H_0 = \mathcal{C} \times \mathcal{C} \times \mathcal{C}$ (recall that $\mathcal{C} = \mathcal{C}_0^1$). Hence we deduce the following partition of $\mathcal{C} \times \mathcal{C} \times \mathcal{C}$:

$$\mathcal{C} \times \mathcal{C} \times \mathcal{C} = \left(\bigcup_{k=2}^{n_g} Int_k \right) \bigcup H_{n_g}. \tag{3.4}$$

Note that $Int_k = \emptyset$ for $k = 1$, because intervals are neighbors.

Now, for later use, we decompose Int_k into two types of contributions. Let three intervals be in interaction. Since they are not neighbors, we have two cases.

Case (i). Each interval is well separated from the two others.

Case (ii). One interval is well separated from the two others, which are neighbors.

For instance, the first example in (3.3) corresponds to case (i), while the second corresponds to case (ii). We then have $Int_k = E_k \cup F_k$, where E_k and F_k are defined by

$$E_k := \bigcup_{(\mathcal{C}_k^{r_1},\ \mathcal{C}_k^{r_2},\ \mathcal{C}_k^{r_3}) \in Int_k,\ \text{case(i)}} \mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}$$

and

$$F_k := \bigcup_{(\mathcal{C}_k^{r_1},\ \mathcal{C}_k^{r_2},\ \mathcal{C}_k^{r_3}) \in Int_k,\ \text{case(ii)}} \mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}.$$

We finally obtain from (3.4) the following partition:

$$\mathcal{C} \times \mathcal{C} \times \mathcal{C} = \left(\bigcup_{k=2}^{n_g} E_k \cup F_k \right) \bigcup H_{n_g}. \tag{3.5}$$

Let $I_k^{r_1,r_2,r_3}$ be the integral on $\mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}$:

(3.6)
$$I_k^{r_1,r_2,r_3} = \int_{\mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3}} \phi_1(x_1)\phi_2(x_2)\phi_3(x_3)|x_1 - x_2|^\alpha |x_2 - x_3|^\beta |x_3 - x_1|^\gamma d^3\mu.$$

Then, as in (3.5), we obtain I_{dis} as the sum of all these previous contributions at all levels:

$$\begin{aligned} I_{dis} = &\sum_{k=2}^{n_g} \sum_{\mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3} \in E_k} I_k^{r_1,r_2,r_3} \\ &+ \sum_{k=2}^{n_g} \sum_{\mathcal{C}_k^{r_1} \times \mathcal{C}_k^{r_2} \times \mathcal{C}_k^{r_3} \in F_k} I_k^{r_1,r_2,r_3} \\ &+ \sum_{\mathcal{C}_k^{r_1}, \mathcal{C}_k^{r_2}, \mathcal{C}_k^{r_3}\ \text{neighbors}} I_{n_g}^{r_1,r_2,r_3}. \end{aligned} \tag{3.7}$$

3.2. Computation of moments and integrals: One-variable and two-variables moments. The first difference with the case of binary interactions ($m = 2$) is that we need to precalculate supplementary moments. In addition to the one-variable moments

$$M_\phi^1(i, \mathcal{C}) = \int_{\mathcal{C}} \phi(x)(x - x_0)^i d\mu(x) \tag{3.8}$$

(where x_0 is the center of $\mathcal{C}$), we define new moments (two-variables moments) as follows:

(3.9)
$$M^2_{\phi_1,\phi_2,\alpha}(i, j, \mathcal{C}^1, \mathcal{C}^2) := \int_{\mathcal{C}^1 \times \mathcal{C}^2} \phi_1(x_1)\phi_2(x_2)(x_1 - x_{10})^i (x_2 - x_{20})^j |x_1 - x_2|^\alpha d^2\mu(x_1, x_2),$$

where x_{10} and x_{20} are the centers of $\mathcal{C}^1$ and $\mathcal{C}^2$, respectively. The above integrals are sums (since μ is discrete), and for instance for M^2 we have the formula

$$M^2_{\phi_1,\phi_2,\alpha}(i,j,\mathcal{C}^1,\mathcal{C}^2) = \sum_{k,\ell=1,\dots,2^{n_g};\ a_k\in\mathcal{C}^1,\ a_\ell\in\mathcal{C}^2} \phi_1(a_k)\phi_2(a_\ell)(a_k-x_{10})^i(a_\ell-x_{20})^j|a_k-a_\ell|^\alpha$$

(we exclude the terms $k=\ell$ in the case $\alpha<0$). These moments will be used in the computation of the F_k integrals.

Developed formula with moments. We assume that all the one-variable moments have been calculated, and all the two-variables moments ($M^2_{\phi_1,\phi_2,\alpha}(i,j,\mathcal{C}^1,\mathcal{C}^2)$, $M^2_{\phi_2,\phi_3,\beta}(i,j,\mathcal{C}^1,\mathcal{C}^2)$, and $M^2_{\phi_3,\phi_1,\gamma}(i,j,\mathcal{C}^1,\mathcal{C}^2)$) have been calculated for $\mathcal{C}^1\in Int(\mathcal{C}^2)$, and at all levels. Starting from this hypothesis, we will determine the (asymptotic) cost of evaluating the total integral I_{dis}. According to the decompositions (3.5) or (3.7), we distinguish three kinds of integrals to compute.

We first consider the case of the E_k integrals. These are integrals of the form (3.6) in which the intervals $\mathcal{C}_k^{r_1}$, $\mathcal{C}_k^{r_2}$, and $\mathcal{C}_k^{r_3}$ are mutually well separated. The three variables can be mutually separated using Lemma 2.2, and we obtain an expression using only one-variable moments M^1:

$$\begin{aligned} I_k^{r_1,r_2,r_3} &= |x_{10}-x_{20}|^\alpha|x_{20}-x_{30}|^\beta|x_{30}-x_{10}|^\alpha \\ &\times\Bigg\{\sum_{i_1+j_1\le p}\ \sum_{i_2+j_2\le p}\ \sum_{i_3+j_3\le p} \frac{c_{i_1,j_1}(\alpha,u_1)\ c_{i_2,j_2}(\beta,u_2)\ c_{i_3,j_3}(\gamma,u_3)}{|x_{10}-x_{20}|^{i_1+j_1}\ |x_{20}-x_{30}|^{i_2+j_2}\ |x_{30}-x_{10}|^{i_3+j_3}} \\ &\times M^1_{\phi_1}(i_1+j_3,\mathcal{C}_k^{r_1})\ M^1_{\phi_2}(i_2+j_1,\mathcal{C}_k^{r_2})M^1_{\phi_3}(i_3+j_2,\mathcal{C}_k^{r_3})\Bigg\}+\eta_E, \end{aligned} \tag{3.10}$$

where η_E is the resulting error. Using Lemma 2.2 and Remark 1, and after easy calculations we get the following error estimate:

$$|\eta|\le C_{\alpha,\beta,\gamma}p^{-\min(\alpha,\beta,\gamma)-1}2^{-p}\int_{\mathcal{C}_k^{r_1}\times\mathcal{C}_k^{r_2}\times\mathcal{C}_k^{r_3}}|F|d^3\mu.$$

The evaluation of expression (3.10) costs $O(\bar{p}^6)$ operations. The computation of all E_k integrals then costs $O(\bar{p}^6\sum_{k=1}^{n_g}2^k)$, i.e., $O(\bar{p}^6 2^{n_g})$.

Now we consider the F_k integrals. If for instance $\mathcal{C}_k^{r_3}$ is well separated from $\mathcal{C}_k^{r_1}$ and $\mathcal{C}_k^{r_2}$, then using multipole expansions for $|x_2-x_3|^\beta$ and $|x_3-x_1|^\gamma$ (see Lemma 2.2) we obtain

$$\begin{aligned} I_k^{r_1,r_2,r_3} &= |x_{30}-x_{10}|^\gamma|x_{20}-x_{30}|^\beta\Bigg\{\sum_{i_1+j_1\le p}\ \sum_{i_2+j_2\le p}\frac{c^1_{i_1,j_1}(\gamma,u_3)\ c^2_{i_2,j_2}(\beta,u_2)}{|x_{30}-x_{10}|^{i_1+j_1}\ |x_{20}-x_{30}|^{i_2+j_2}} \\ &\times M^2_{\phi_1,\phi_2,\alpha}(i_1,i_2,\mathcal{C}_k^{r_1},\mathcal{C}_k^{r_2})\ M^1_{\phi_3}(j_1+j_2,\mathcal{C}_k^{r_3})\Bigg\}+\eta, \end{aligned} \tag{3.11}$$

where η is the error and satisfies $|\eta|\le C_{\beta,\gamma}p^{-\min(\beta,\gamma)-1}2^{-p}\int_{\mathcal{C}_k^{r_1}\times\mathcal{C}_k^{r_2}\times\mathcal{C}_k^{r_3}}|F|d^3\mu$. We point out that a fast computation of the two-variables moments again requires the use of multipole expansion (see below) and then involves an additional error. The error estimate η_F in the computation of the F_k integrals still follows the same expression

as for η_E, but the proof of such an estimate is much more technical than for the E_k integrals. Because of its limited interest, this proof is omitted.

Expression (3.11) can be calculated using the precalculated moments M^1 and M^2, and with a cost of the order of $O(\bar{p}^4)$. Then the total cost induced by the F_k integrals is of the order of $O(\bar{p}^4 \sum_{k=1}^{n_g} 2^k)$, i.e., $O(\bar{p}^4 2^{n_g})$.

Finally we consider the H_{n_g} integrals at the finest mesh level. For these, we use a direct computation of the sums of the terms of $I_{n_g}^{r_1,r_2,r_3}$. Because these integrals only concern neighboring intervals at the finest level n_g, this step costs $O(s^3 \cdot 2^{n_g})$.

Hence the total cost for the calculations of I_{dis}, using multipole expansions, is of the order of $O((s^3 + \bar{p}^6)\ 2^{n_g}) = O(\frac{s^3+\bar{p}^6}{s}\ N)$.

Computation of the moments. We first compute the moments $M^1_{\phi_j}(i, \mathcal{C})$ for the orders $i = 0, \ldots, 2p$. This costs $O(\bar{p}^2 \frac{N}{s}) + O(\bar{p}N)$ (see the previous section). We then compute the moments M^2 given by (3.9) in the only case where $\mathcal{C}^1$ and $\mathcal{C}^2$ are neighbors (other moments are not used). We proceed recursively as for the moments M^1.

First, we evaluate the moments M^2 at the finest mesh level n_g, for $i, j = 0, \ldots, p$. This costs $O(\bar{p}^2 \cdot s^2 \cdot 2^{n_g}) = O(\bar{p}^2 \cdot s \cdot N)$, where $N = 2^{n_g} \cdot s$ (since there are 2^{n_g} intervals and each interval contains s quadrature points). Now suppose we have calculated the moments M^2 at level $k+1$. To evaluate a moment M^2 at level k on neighbors $\mathcal{C}^1 \times \mathcal{C}^2$, we decompose $\mathcal{C}^1$ (resp., $\mathcal{C}^2$) into intervals of levels $k+1$: $\mathcal{C}^i_{k+1}$ (resp., $\mathcal{C}^j_{k+1}$). When $\mathcal{C}^i_{k+1}$ and $\mathcal{C}^j_{k+1}$ are well separated, we can use Lemma 2.2 in order to separate the variables and use only one-variable moments (we use also translations as in (2.8)). When $\mathcal{C}^i_{k+1}$ and $\mathcal{C}^j_{k+1}$ are neighbors, we can use the moments M^2 precalculated at level $k+1$ (we use also translations). The complexity of these last recursive operations will be determined in the next section. Roughly, the contribution corresponding to neighboring children $\mathcal{C}^i_{k+1}$ and $\mathcal{C}^j_{k+1}$ needs $O(\bar{p}^2)$ operations, because it only uses translations. The contributions of well-separated children requires both multipole expansions, and translations, and thus needs $O(\bar{p}^4)$ operations. Since we have $O(\bar{p}^2)$ moments $M^2_{\phi_1,\phi_2,\alpha}(i, j, \mathcal{C}^1, \mathcal{C}^2)$ $(i, j = 0, \ldots, p)$ to calculate, the total cost is of the order of $O(\bar{p}^6)$.

Since there are $O(2^{n_g}) = O(N/s)$ intervals, the total cost for computing the moments is of the order of $O(\bar{p}^2 sN) + O(\bar{p}^6 \frac{N}{s})$.

Total cost. Adding the previous bounds, we obtain a total cost of the order of $O(\bar{p}^2 sN) + O(\bar{p}^6 \frac{N}{s}) + O(\frac{s^3+\bar{p}^6}{s}\ N)$. This is bounded by $O(\frac{s^3+\bar{p}^6}{s}\ N)$. In particular, for $s \in [1, \bar{p}]$, we obtain a cost of the order of $O(\bar{p}^6\ N)$.

Up to now, we have shown that the total computational cost of the multipole algorithm is *asymptotically* proportional to N. In situations where N is not large enough, it is useful to know the value of the proportionality coefficient. In the next section, we give more precise expressions of the computational costs (or complexities) of the above-described algorithms. Since the proofs of such expressions are very technical and lengthy, we just present them without any proof. These reduction techniques are essentially based on reordering the terms of the various sums and/or writing them in terms of matrix-matrix products. We point out that these manipulations do not involve any additional error.

4. Exact cost. In this section, we give more precise expressions of the costs of the computations involved in the above-described multipole algorithm. These costs will be expressed as functions of the quantities p, s, and N.

Computing the one-variable moments. The computational cost of the one-variable moments, (3.8), $M_{\phi_q}(i, \mathcal{C}_k)$ for $i = 0, \ldots, 2p$, and for all levels $k = 2, 3, \ldots, n_g$, is

bounded by

$$\left(6\bar{p} + 44\frac{\bar{p}^2}{s}\right)\ N. \tag{4.1}$$

Computing the two-variables moments. As explained in the previous section, we need to compute all two-variables moments $M^2_{\phi_1,\phi_2,\alpha}(i,j,\mathcal{C}^1,\mathcal{C}^2)$ on *neighbor intervals*, at all levels, for $i,j = 0,\ldots,p$. These moments are expressed by (3.9), and their computation requires a more complicated algorithm than for the one-variable moments. The total cost for this algorithm is bounded by

$$\begin{aligned} &3 \cdot \left(18 \cdot (4\bar{p}^3 + 7\bar{p}^2) \cdot (2^{n_g} - 4) + (2s\bar{p}^2 + 12s^2\bar{p}) \cdot (3 \cdot 2^{n_g})\right) \\ &\quad \le 9 \cdot \left(6(4\bar{p}^3 + 7\bar{p}^2) + (2s\bar{p}^2 + 12s^2\bar{p})\right)\ 2^{n_g} \\ &\quad = 18\left(12\bar{p}^3 + 21\bar{p}^2 + s\bar{p}^2 + 6s^2\bar{p})\right)\ 2^{n_g} \\ &\quad = 18\left\{\frac{12\bar{p}}{s} + \frac{21}{s} + 1 + \frac{6s}{\bar{p}}\right\}\ \bar{p}^2 N, \end{aligned} \tag{4.2}$$

where the factor 3 takes the three types of two-variables moments into account, i.e., $M^2_{\phi_1,\phi_2,\alpha}$, $M^2_{\phi_2,\phi_3,\beta}$, and $M^2_{\phi_3,\phi_1,\gamma}$.

Note that for p large enough, choosing $s = \bar{p}$ (and $N = 2^{n_g}s$), this expression leads to the approximated cost bound $342\ \bar{p}^2 N$.

Computing the three-variable integrals. Using the basic partition (3.5), we know that the sum I_{dis} given by (3.1) can be split into three sets of contributions: E_k, F_k, and H_{n_g}. Here, we give the complexity of these contributions.

E_k integrals: These integrals are expressed by (3.10). The total cost of their evaluation is bounded by

$$c_E := 10\bar{p}^3 + 15\bar{p}^2 + \bar{p}. \tag{4.3}$$

Note that a direct computation of I_k would require $O(p^6)$ operations.

F_k integrals: These integrals are expressed by (3.11). The evaluation of an F_k integral needs a number of operations bounded by

$$c_F := 4\bar{p}^3 + 9\bar{p}^2.$$

H_{n_g} integrals: At level $k = n_g$, we make direct computations for neighboring intervals. The cost of the evaluation of an H_{n_g} integral is less than

$$(15s^3) \cdot 13 \cdot 2^{n_g} = 195\ s^2 N. \tag{4.4}$$

Recursion algorithm. We now proceed in the computation of the integrals corresponding to intervals which are in interaction at all levels, from level $k = n_g$ down to the level $k = 2$. The integrals of level k will be computed assuming that we have already computed the one- and two-variable moments at level k. Counting the number of occurrences of types E_k, F_k, and H_{n_g}, and using the previous costs, we get a total cost of the recursive algorithm (not including the cost induced by the computation of the moments) less than

$$456\ \left\{1 + \frac{2}{\bar{p}} + \frac{1}{19\bar{p}^2} + \frac{1}{6\bar{p}^3}\right\}\frac{\bar{p}^3}{s}\ N + 195\ s^2\ N. \tag{4.5}$$

Note that taking $s := \bar{p}$ large enough, this cost is equivalent to $651\ \bar{p}^2\ N$.

Total cost. The total cost for the evaluation of the integral I_{dis} is obtained by summing the previous costs (4.1), (4.2), and (4.5):

$$\begin{aligned} Total\ Cost \leq & \left\{ \frac{6}{\bar{p}} + \frac{44}{s} \right\}\ \bar{p}^2\ N \\ & + 18 \left\{ \frac{12\bar{p}}{s} + \frac{21}{s} + 1 + \frac{6s}{\bar{p}} \right\}\ \bar{p}^2\ N \\ & + 456\ \left\{ 1 + \frac{2}{\bar{p}} + \frac{1}{19\bar{p}^2} + \frac{1}{6\bar{p}^3} \right\} \frac{\bar{p}^3}{s}\ N + 195\ s^2\ N. \end{aligned} \tag{4.6}$$

Using the fact that $\max\{\frac{\bar{p}}{s}, 1, \frac{s}{\bar{p}}, \frac{s^2}{\bar{p}^2}\} = \max\{\frac{\bar{p}}{s}, \frac{s^2}{\bar{p}^2}\}$, and $s, \bar{p} \geq 1$, we obtain that the total cost is bounded by $O(\max\{\frac{\bar{p}}{s}, \frac{s^2}{\bar{p}^2}\} \cdot \bar{p}^2\, N)$. More precisely, we obtain the following bound:

$$Total\, Cost \leq 2800 \cdot \max \left\{ \frac{\bar{p}}{s}, \frac{s^2}{\bar{p}^2} \right\}\ \bar{p}^2\ N. \tag{4.7}$$

This concludes the proof of Theorem 3.1. □

Remark 4. For $s := \bar{p}$ we obtain from (4.6) the following asymptotic cost bound:

$$Total\, Cost \leq 993 \cdot \bar{p}^2\ N, \quad s = \bar{p} \to \infty. \tag{4.8}$$

Since a direct calculation of I_{dis} costs $15N^3$ (we count 14 elementary operations for the evaluation of the integrand term, plus 1 for the sum), in the case $s = \bar{p}$ we can predict that the FMM method is useful as soon as $993\bar{p}^2 N \leq 15N^3$, i.e., $N \geq 8.14\ \bar{p}$. For instance this gives $N \geq 82$ for $\bar{p} = 10$.

5. Numerical tests. We have chosen the functions $\phi_1(x) = \sqrt{x}$, $\phi_2(x) = \frac{x}{1+x}$, and $\phi_3(x) = \frac{x}{2+x}$, and the exponents $\alpha, \beta, \gamma = -0.2, -0.5, -0.9$. We have also taken a discretization mesh with n_g levels and $s_0 = 2$ points per interval at the finest level. Thus we have $N = 2^{n_g} s_0$ discretization points per variable. We shall also use the decomposition $N = 2^n s$ where $0 \leq n \leq n_g$ and $s = 2^{n_g - n} s_0$.

We have first tested the numerical behavior of the error with respect to the order p of the multipole expansion. In Table 5.1 and Figure 5.1 we give the absolute values of the errors $e(p) := |I_{dis} - I_{multipole}|$, versus p, in the case $n_g = 4$. The results are similar for other values of n_g. The relative error $|I_{dis} - I_{multipole}|/|I_{dis}|$ also decreases in the same way since here $I_{dis} \sim 0.86$ (with a $1/N^3$ normalization factor in the definition of I_{dis}). We note that best results are obtained for even values of p.

In particular, we observe that with $p = 10$ we have 7 correct digits, with $p = 20$ we have more than 11 correct digits, and with $p \geq 30$ we have more than 16 correct digits.

TABLE 5.1
Error versus the order p of multipole expansions (for p = 30 the error is smaller than 1E-16).

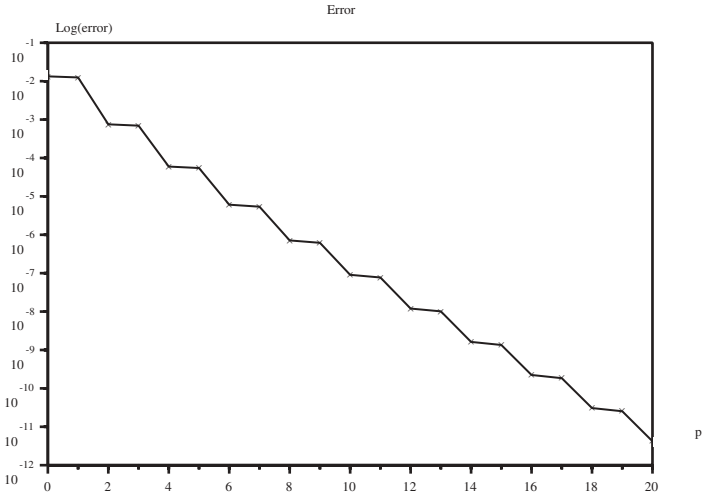

FIG. 5.1. *Error versus order p of multipole expansion.*

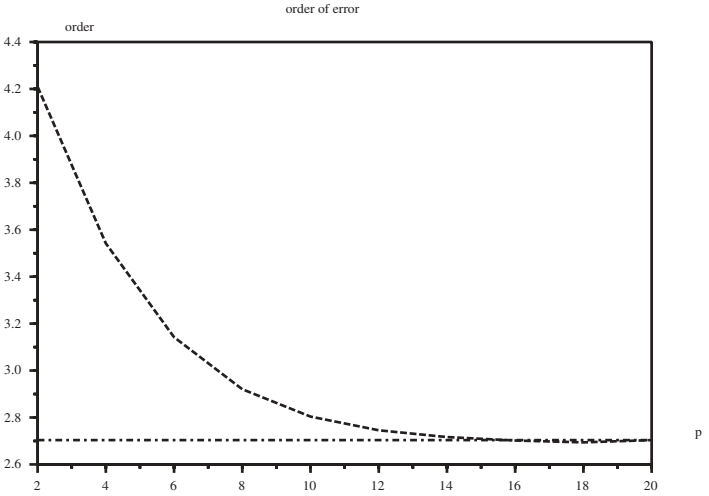

FIG. 5.2. $\sqrt{\frac{e(p-2)}{e(p)}}$ *(order of error) is plotted versus p (order of multipole expansions).*

In Figure 5.2, we have plotted $\sqrt{e(p-2)/e(p)}$, for even p, and observe that $\sqrt{e(p-2)/e(p)} \to 2.7$ for large p values. This means that the "observed" order of the method is approximately 2.7 (i.e., $e(p) \sim C/(2.7)^p$, for even p values). This is better than our theoretical bounds which predicts the order 2. The reason is that, in the theoretical analysis, the bounds for the multipole expansions are obtained in the worst case. This is a known fact in the usual FMM method [2] that can be used in order to improve the bounds.

We also mention that the CPU time increases very slowly with p (at least for small p values, $p \leq 40$). For instance with $p = 20$ it is roughly three times the CPU time of the case $p = 0$, and with $p = 10$ it is roughly 1.5 times the CPU time of $p = 0$. This is much faster than the predicted theoretical result: $O(\frac{p^3}{s}N)$ for fixed s

TABLE 5.2

CPU times. $t(n) := t_1 + t_2 + t_3$ *is the total time;* t_1, t_2 *are the computation times for the one- and two-variable moments, and* t_3 *for the three-variable integrals. Here* $p = 10$ *and* $n = n_g$*, excepted for the "optimized" multipole calculation where* $n = \max(n_g - 5, 0)$.

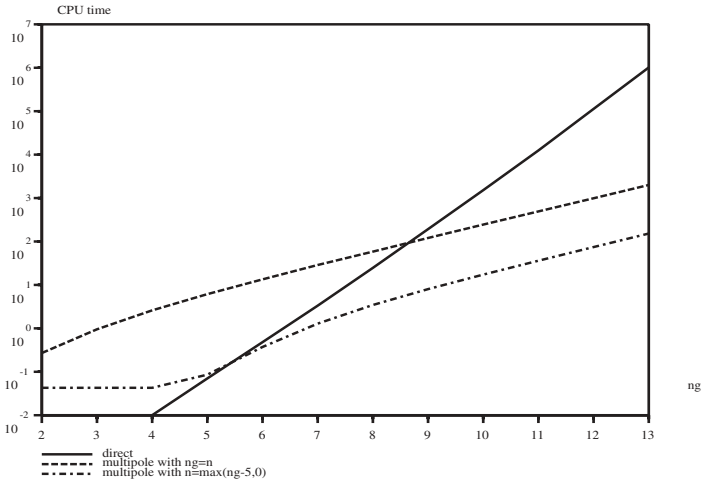

FIG. 5.3. *CPU time.*

and large p. In fact all moments have been computed using products of matrices and vectors, and thus are computed with a similar cost independently of p (for small p values, say $p \leq 30$).

In our second test we are interested in the numerical $O(N)$ behavior. In Table 5.2 and Figure 5.3, we have given the CPU time $t(n)$ versus the number of levels $n = \log_2(N/s)$, for different methods. The first method is with $n = n_g$ (and $s = s_0$); i.e., the number of levels n for the multipole method is the same as for the discretization mesh. We have fixed $p = 10$ for these calculations, since in practice the CPU time increases slowly with p as previously remarked. We see that we have $t(n)/[2t(n-1)] \sim 1$ for large n, which corresponds to an $O(N)$ behavior at this scale.

In Figure 5.3 the CPU time curves are in logarithmic scale for the time. The first curve concerns the CPU time obtained by *direct* calculations, simply doing a direct computation of the sum I_{dis} (using vectorized computations). For $n_g \geq 9$, this CPU time has been estimated (only by making a part of the calculation).

The second curve is the CPU time of our method, with $n = n_g$ and $p = 10$.

The third curve is obtained with $n = \max(n_g - 5, 0)$ and $s = 2^{n_g - n} s_0$. This means that we have used the first n levels for the multigrid hierarchy of the FMM method, and that, at level $k = n$, the moments and integrals are directly computed. At this level, there are $s = 2^{n_g - n} s_0$ points per interval (for $n_g \geq 5$, this leads to $s = 2^5 \cdot s_0 = 32 \cdot s_0$). This is like a multigrid method where a "rough" scale is used for the first levels $k \leq n$ (where we use the approximation of multipole expansions), and a refined scale is used at level $k = n$ (where exact computations are made).

We see that the multipole method (for $n = n_g$) becomes faster than the direct method for $n_g \geq 9$. The "optimized" multipole method, i.e., with $n = \max(n_g - 5, 0)$, is faster for $n_g \geq 5$. For instance, for $n_g = 10$ ($N^3 = 8 \cdot 2^{30} \sim 10^{10}$ points), the computation time is 17 s for the "optimized" FMM, which is roughly 90 times faster when compared to the direct computation, and 15 times faster than the FMM method ($n = n_g$). The fact that for small n_g values the time of the optimized multipole method is greater than the direct method is due to the initialization of one- and two-variable moments.

Note on computation and storage of moments. For each type of moments (one- and two-variable moments), and for the three-variable integrals, it is possible to use only one list of 2^{n_g} moments. Initially, the list contains the values of the moments at finest level n_g. Then, when we calculate recursively the moments of level $n_g - 1$, we can store them on the same list, using only the first $2^{n_g - 1}$ elements, and so on.

In order not to overwrite on the list of necessary moments, we proceed recursively as follows.

AT LEVEL $k = n_g$: Initialize the list of one- and second-order moments and the three-variable integrals.

FOR LEVELS $k = n_g - 1$ TO 0 STEP -1 DO:

• Computation of three-variable integrals at level k (requires at level $k + 1$ the one- and two-variable moments, and three-variable integrals). Storage in the list of three-variable integrals erases the three-variable integrals of level $k + 1$.

• Computation of two-variable moments at level k (requires one- and two-variable moments of level $k + 1$). Storage in the list of two-variable moments erases that of two-variable moments at level $k + 1$.

• Computation of one-variable moments at level k (requires one-variable moments of level $k + 1$). Storage erases the list of one-variable moments at level $k + 1$.

6. Concluding remarks. For $m \geq 2$, we have summarized in Table 6.1 some obtained results, with $N = 2^{n_g} \bar{p}$ and $\bar{p} = p + 1$. We recall that p is the order of the multipole expansions. The results between brackets are *conjectured*. (Here the dimension is $d = 1$ for each variable.) All the error bounds are of the form $O(\frac{1}{\bar{p}^\kappa 2^p})$, where $\kappa := \inf_{i<j}(\alpha_{ij}) + 1$.

TABLE 6.1
Costs and errors bounds for various numbers m of particles.

	$m = 2$	$m = 3$	$m = 4$	$m \geq 5$
Cost	$O(\bar{p}N)$	$O(\bar{p}^2 N)$	$O(\bar{p}^4 N)$	$\leq C_m \bar{p}^{\delta_m} N$
Error	$O\left(\frac{1}{\bar{p}^\kappa 2^p}\right)$	$O\left(\frac{1}{\bar{p}^\kappa 2^p}\right)$	$\left[O(\frac{1}{\bar{p}^\kappa 2^p})\right]$	$\left[O(\frac{1}{\bar{p}^\kappa 2^p})\right]$

For $m = 4$, we can prove that the cost of our FMM algorithm is $O(\bar{p}^4 N)$, using cost reduction techniques as in section 4, while the error is expected to be bounded

by $\frac{cste}{\bar{p}^\kappa 2^p}$.

For $m \geq 5$, there are $m(m-1)/2$ binary interactions in the integrand term. Again, we can prove a similar cost bound, of the form $C_m \bar{p}^{\delta_m} N$, where δ_m and C_m are some constants that depend only on m. However, we did not compute here an explicit estimate of δ_m when using cost reduction techniques.

For $d \geq 2$, i.e., for more than one dimension for the particle position, we expect a similar cost, i.e., $O(p^{\delta_{m,d}} N)$ (with $\delta_{m,d}$ being some constant). This task has not been addressed in this paper, but the simple case $d = 1$ should greatly help to treat the higher-dimensional case. In particular, one can see that the partition algorithm of the integration domain (developed in section 3.1) is independent of the variable dimension. This algorithm can be used for the three-dimensional case as it stands. However, the multipole expansions should be more technical for higher dimensions. This last point is under study and we think that this could be done using the techniques in [2] or in [3] where three-dimensional multipole expansions are developed. A complete three-dimensional algorithm is under investigation.

We also mention that it is possible to compute in $O(\bar{p}^{\mu_m} N)$ the following kind of one-particle operators:

$$v(x_1) = \int_{\mathcal{C}^{m-1}} \phi_2(x_2) \cdots \phi_m(x_m) \prod_{1 \leq i < j \leq m} |x_i - x_j|^{\alpha_{ij}} d\mu(x_2) \cdots d\mu(x_m)$$

(where x_1 takes values on a mesh with N points, and $d\mu$ is the discrete measure on the mesh). In this case, we have to use a "descending" algorithm as in the FMM of Greengard and Rokhlin [1].

Finally we mention that an alternative method based on the use of wavelet bases is the subject of a future work.

Acknowledgments. We thank P. Degond for showing us Greengard and Rokhlin's references. All tests have been done using the SCILAB programming language (http://scilab.inria.fr). We thank the SCILAB group, the *Saphir Control* team, and the *Medicis Lab* (http://www.medicis.polytechnique.fr) where part of the computations have been done.

FULLY LOCALIZED A POSTERIORI ERROR ESTIMATORS AND BARRIER SETS FOR CONTACT PROBLEMS*

RICARDO H. NOCHETTO†, KUNIBERT G. SIEBERT‡, AND ANDREAS VEESER§

Abstract. We derive novel pointwise a posteriori error estimators for elliptic obstacle problems which, except for obstacle resolution, completely vanish within the full-contact set (localization). We then construct a posteriori barrier sets for free boundaries under a natural stability (or nondegeneracy) condition. We illustrate localization properties as well as reliability and efficiency for both solutions and free boundaries via several simulations in 2 and 3 dimensions.

Key words. elliptic obstacle problem, stable free boundary, a posteriori error estimate, residual, maximum norm, maximum principle, barrier functions, barrier sets

1. Model problem, its discretization, and main results.

Free boundary problems are ubiquitous in applications, from nonlinear elasticity and plasticity to fluids and finance. The detection and accurate approximation of the free boundary is often a primary goal of the computation. There are, however, no results in the literature which provide a posteriori error estimates for interfaces. In case they are defined as level sets, then the mere control of the solution(s) does not yield, in general, control of the interfaces. In this paper we examine a model problem, namely the elliptic obstacle problem with Hölder obstacle, and derive novel *pointwise* a posteriori error estimates for both the solution and free boundary. The maximum norm is essential in this endeavor to convert error estimates for solutions into error estimates for interfaces. The estimators in turn exhibit complete localization (vanish within the *full-contact* set) and thus improve upon [15]. Their reliability and efficiency is assessed both theoretically and computationally herein.

We first introduce the *continuous* obstacle problem. Let Ω be a bounded, polyhedral, not necessarily convex domain in $\mathbb{R}^d$ with $d \in \{1, 2, 3\}$. Let $f \in L^\infty(\Omega)$ be a load function, $\chi \in H^1(\Omega) \cap C^{0,\alpha}(\bar{\Omega})$ be a lower obstacle, and $g \in H^1(\Omega) \cap C^{0,\alpha}(\bar{\Omega})$ be a Dirichlet boundary datum with $0 < \alpha \leq 1$. Both χ and g satisfy the compatibility condition

$$\chi \leq g \quad \text{on } \partial\Omega.$$

Let $\mathcal{K}$ be the following nonempty, closed, and convex subset of $H^1(\Omega)$:

$$\mathcal{K} := \{v \in H^1(\Omega) \mid v \geq \chi \text{ a.e. in } \Omega \text{ and } v = g \text{ on } \partial\Omega\}.$$

The variational formulation of the continuous obstacle problem reads as follows:

$$u \in \mathcal{K}: \qquad \langle \nabla u, \nabla(u-v)\rangle \le \langle f, u-v\rangle \qquad \text{for all } v \in \mathcal{K}. \tag{1.1}$$

Hereafter, $\langle \varphi, \psi\rangle$ denotes the scalar product in $L^2(\Omega)$ as well as the duality pairing between $\mathring{H}^1(\Omega)$ and $H^{-1}(\Omega)$. It is well known that (1.1) admits a unique solution u [11, Theorem 6.2], [9, 17], which is also Hölder continuous [8]. The latter implies that the *contact set*

$$\Lambda := \{u = \chi\} := \{x \in \Omega \mid u(x) = \chi(x)\}$$

and the *free boundary* or *interface*

$$\mathcal{F} := \partial\{u > \chi\} \cap \Omega$$

are closed in Ω. We are interested in the numerical study of these two sets. To this end, we first approximate u by means of finite elements and, later on, we construct appropriate a posteriori *barrier sets* depending on data and the finite element solution u_h.

Given a shape-regular partition $\mathcal{T}_h$ of Ω, the set of nodes of $\mathcal{T}_h$ is denoted by $\mathcal{N}_h$, and the subset of interior nodes by $\mathring{\mathcal{N}}_h$. Let $\mathbb{V}_h$ indicate the space of continuous piecewise affine finite element functions over $\mathcal{T}_h$ and $\mathring{\mathbb{V}}_h := \mathbb{V}_h \cap \mathring{H}^1(\Omega)$. The nodal basis functions of $\mathbb{V}_h$ are given by $(\phi_z)_{z\in\mathcal{N}_h}$, and they form a *partition of unity* of Ω, that is, $\sum_{z\in\mathcal{N}_h} \phi_z = 1$. Let I_h be the Lagrange interpolation operator onto $\mathbb{V}_h$.

Let $\chi_h := I_h\chi$ be the discrete obstacle and let $I_h g$ be the discrete Dirichlet boundary datum. The discrete counterpart $\mathcal{K}_h$ of $\mathcal{K}$ is then

$$\mathcal{K}_h := \{v_h \in \mathbb{V}_h \mid v_h \ge \chi_h \text{ in } \Omega \text{ and } v_h = I_h g \text{ on } \partial\Omega\}.$$

Note that it is sufficient to check the unilateral constraint of $\mathcal{K}_h$ only at the nodes. The set $\mathcal{K}_h$ is nonempty, convex, closed but in general not a subset of $\mathcal{K}$ (nonconforming approximation). The *discrete* obstacle problem reads as follows:

$$u_h \in \mathcal{K}_h: \quad \langle \nabla u_h, \nabla(u_h - v_h)\rangle \le \langle f, u_h - v_h\rangle \qquad \text{for all } v_h \in \mathcal{K}_h. \tag{1.2}$$

Problem (1.2) admits a unique solution (use [9, 11] in the Hilbert space $\mathbb{V}_h$).

In section 2 we introduce a computable, second order estimator $\mathcal{E}_h$, and prove in particular the a posteriori error bound

$$\|u - u_h\|_{0,\infty;\Omega} \le \mathcal{E}_h. \tag{1.3}$$

Later in section 4 we couple (1.3) with the *nondegeneracy* condition $f + \Delta\chi \le -\lambda < 0$, to show an a posteriori error bound for interfaces, which roughly reads as follows:

$$\begin{aligned} &\textit{The strip } \{x \in \Omega \mid 0 < \operatorname{dist}(x, \{u_h > \chi_h + \mathcal{E}_h\}) < r_h\} \\ &\textit{of width } r_h \approx \sqrt{\mathcal{E}_h/\lambda} \textit{ contains the exact interface } \mathcal{F}. \end{aligned} \tag{1.4}$$

The reasoning behind these results is rather different from other a posteriori error analyses, except for [15]. Indeed, in section 2 we construct continuous barrier functions for the exact solution u upon correcting the discrete solution u_h via the Riesz representation of the *Galerkin functional*, a nonlinear residual appropriate in this context; cf. [15, 20]. The derivation concludes with an application of the *continuous* maximum principle, which imposes no constraint on the triangulations $\mathcal{T}_h$, in contrast to a priori analyses.

The main theoretical results, (1.3) and (1.4), exhibit the following salient features:

- *Full localization* (see also [7]): The residual estimator inside $\mathcal{E}_h$ vanishes in the discrete full-contact set where $u_h = \chi_h$ (see section 2.1 for its definition). In particular, if $\chi = \chi_h$ and $u = \chi = u_h$ on a finite element star, then the residual indicator vanishes on the star as well. This gives rise to a rare local upper bound and is an important improvement over [15]. Its computational impact is discussed and illustrated in section 3.2.
- *Reliability and efficiency*: In addition to the upper bound (1.3) (reliability), we establish local lower bounds for all estimators (efficiency); this is discussed in section 2.5 and confirmed numerically in section 3.1.
- *Partition of unity and star-based estimators*: The error analysis is based on the partition of unity $(\phi_z)_{z\in\mathcal{N}_h}$, and consequently, the residual estimators entering $\mathcal{E}_h$ are star-based; see also [7, 12].
- *Element residual oscillation*: The customary element residual $\|h^2 f\|_{0,\infty;\Omega}$ is replaced here by data oscillation on stars, namely $\max_{z\in\mathring{\mathcal{N}}_h} \|(f-\hat{f}_z)\phi_z\|_{0,\infty;\Omega}$, which is generically of higher order asymptotically. This is achieved via an additional cancellation provided directly by the partition of unity, without dealing with the element residual as in [14]; see also [7].
- *Barrier sets and interface estimates*: Two important issues must be emphasized. First, the maximum norm is the most adequate one to link solutions and interfaces. Second, the approximation of level sets is not a direct consequence of precise estimates for solutions. The missing ingredient is the *nondegeneracy* condition $f + \Delta\chi \le -\lambda < 0$ due to Caffarelli [2], which is also used in the a priori error analysis of free boundaries [1, 5, 13]. Our second main result (1.4) is a dual counterpart of the latter, and the first computable error estimate for interfaces.

This paper is organized as follows. In section 2 we introduce the concept of full-contact set along with exact and discrete multipliers associated with the unilateral constraint. We then define and study the Galerkin functional for (1.1) and use it to construct barrier functions, which eventually yield the desired pointwise a posteriori error estimates for solutions. In section 3, we present two numerical examples which document reliability, efficiency, and full localization properties of $\mathcal{E}_h$. We introduce the concept of barrier sets and derive a posteriori error estimates for free boundaries in section 4. We conclude in section 5 with two revealing numerical examples which not only corroborate the theory of section 4, but also provide support of its optimality.

2. Pointwise a posteriori error estimates. Intuitively, one expects that a discrete counterpart of the exact contact set Λ enters into the a posteriori estimate of $\|u-u_h\|_{0,\infty;\Omega}$. Crucial facts, such as the location of Λ, are encoded in the nonpositive functional $\sigma \in H^{-1}(\Omega) = \mathring{H}^1(\Omega)^*$ defined by

$$\langle \sigma, \varphi\rangle = \langle f, \varphi\rangle - \langle \nabla u, \nabla\varphi\rangle \qquad \text{for all } \varphi \in \mathring{H}^1(\Omega), \tag{2.1}$$

which plays the role of a *multiplier* for the unilateral constraint. In fact, we have $\sigma = f + \Delta\chi$ in the interior of the contact set $\Lambda = \{u = \chi\}$, where σ is typically < 0, and $\sigma = 0$ in the open *noncontact* set $\Omega \setminus \Lambda = \{u > \chi\}$. It is then not surprising that the a posteriori error analysis needs a multiplier σ_h that is associated with u_h—the discrete counterpart of σ.

2.1. Discrete full-contact set and multiplier. We first introduce some notation. Let J_h be the jumps of the normal derivatives of u_h across interior sides (nodes/edges/faces in 1 dimension/2 dimensions/3 dimensions, respectively). More

precisely, given a common side S of two different simplices T^+ and T^-, we have on S

$$J_h = [\![\partial_n u_h]\!] = \left[\nabla u_{h|T^+} - \nabla u_{h|T^-}\right] \cdot n,$$

where n is the normal of S that points from T^- to T^+. We denote the union of all interior sides (interelement boundaries) by Γ. For a node $z \in \mathcal{N}_h$, let $\omega_z = \mathrm{supp}(\phi_z)$ be the finite element star and $\gamma_z = \Gamma \cap \mathrm{int}\ \omega_z$ be the union of all interior sides in ω_z. We define

$$\mathcal{C}_h = \{z \in \mathcal{N}_h \mid u_h = \chi_h \text{ and } f \le 0 \text{ in } \omega_z,\ J_h \le 0 \text{ on } \gamma_z\}$$

to be the set of *full-contact nodes* and denote by

$$\Omega_h^0 = \left\{ x \in \Omega \mid \sum_{z \in \mathcal{C}_h} \phi_z(x) = 1 \right\}, \qquad \Omega_h^+ = \Omega \backslash \Omega_h^0$$

the discrete *full-contact set* and its complement. Furthermore, we set $\Gamma_h^0 = \Gamma \cap \Omega_h^0$ and $\Gamma_h^+ = \Gamma \cap \Omega_h^+$. We clearly have

$$z \in \mathcal{N}_h \setminus \mathcal{C}_h \implies \omega_z \subset \overline{\Omega_h^+} \text{ and } \gamma_z \subset \overline{\Gamma_h^+}. \tag{2.2}$$

Finally, let $\Pi_h : L_1(\Omega) \to \mathring{\mathbb{V}}_h$ be the interpolation operator of [3]; see also [16]. Such a Π_h is both *positivity preserving*, which helps construct $\sigma_h \le 0$, and *second order* accurate, which is crucial in dealing with the second order maximum norm error.

With these notations at hand, we define the *discrete multiplier* $\sigma_h \in H^{-1}(\Omega)$ by using the partition of unity $\langle \sigma_h, \varphi \rangle = \sum_{z \in \mathcal{N}_h} \langle \sigma_h, \varphi\, \phi_z \rangle$ and setting

$$\begin{aligned} \langle \sigma_h, \varphi\, \phi_z \rangle = &\int_{\Omega_h^0} f\, \varphi\, \phi_z + \int_{\Gamma_h^0} J_h \varphi\, \phi_z \\ &+ \int_{\Omega_h^+} f\, (\Pi_h \varphi)(z)\, \phi_z + \int_{\Gamma_h^+} J_h\, (\Pi_h \varphi)(z)\, \phi_z \end{aligned} \tag{2.3}$$

for all $z \in \mathcal{N}_h$ and $\varphi \in \mathring{H}^1(\Omega)$. Note that $\Pi_h \varphi$ is evaluated at the node z and is thus a *constant* for each $z \in \mathcal{N}_h$. Therefore, (2.2) gives

$$z \in \mathcal{N}_h \setminus \mathcal{C}_h \implies \langle \sigma_h, \varphi\, \phi_z \rangle = (\Pi_h \varphi)(z)\, s_z, \tag{2.4}$$

where s_z is a *nodal* multiplier:

$$s_z := \int_\Omega f\, \phi_z + \int_\Gamma J_h \phi_z, \qquad z \in \mathcal{N}_h. \tag{2.5}$$

It satisfies $s_z \le 0$ whenever $z \in \mathring{\mathcal{N}}_h \cup \mathcal{C}_h$. This follows from the definition of $\mathcal{C}_h$, if $z \in \mathcal{C}_h$, and from utilizing $v_h = u_h + \phi_z \in \mathcal{K}_h$ in (1.2), if $z \in \mathring{\mathcal{N}}_h$.

We point out that the definition of the discrete multiplier σ_h via (2.3) is crucially distinct from those in [7, 15], which are in turn quite different from each other. In particular, the finite element star ω_z in (2.3) is divided into two parts and thus, in contrast to [7, 15], "broken" nodal multipliers are involved.

Let us finish this section with the observation that the discrete multiplier σ_h is, as the exact multiplier σ of (2.1), nonpositive.

LEMMA 2.1 (sign of σ_h). *The discrete multiplier σ_h satisfies $\sigma_h \le 0$.*

Proof. Let $\varphi \in \mathring{H}^1(\Omega)$ be nonnegative. Since $\Pi_h\varphi \geq 0$ in Ω and $\Pi_h\varphi = 0$ on $\partial\Omega$, (2.4) implies $\langle \sigma_h,\, \varphi\, \phi_z\rangle \leq 0$ for all $z \in \mathcal{N}_h \setminus \mathcal{C}_h$. On the other hand, if $z \in \mathcal{C}_h$, then $f \leq 0$ in ω_z as well as $J_h \leq 0$ on γ_z by definition, whence $\langle \sigma_h,\, \varphi\, \phi_z\rangle \leq 0$ follows from (2.3). ∎

The multiplier σ_h is *not* a discrete function and is thus noncomputable. In evaluating our error estimator, we will only make use of the nodal multipliers s_z for $z \in \mathring{\mathcal{N}}_h \cup \mathcal{C}_h$. The properties of these computable multipliers are closely related to properties of σ_h (see Proposition 2.5 below).

2.2. Galerkin functional: Definition and properties. We are now in the position to define the Galerkin functional $\mathcal{G}_h \in H^{-1}(\Omega)$, which plays the role of the residual for (unconstrained) equations; see [15, 20]:

$$\begin{aligned}\langle \mathcal{G}_h,\, \varphi\rangle &:= \langle \nabla(u - u_h),\, \nabla\varphi\rangle + \langle \sigma - \sigma_h,\, \varphi\rangle \\ &= -\langle \nabla u_h,\, \nabla\varphi\rangle + \langle f - \sigma_h,\, \varphi\rangle \qquad \text{for all } \varphi \in \mathring{H}^1(\Omega).\end{aligned} \tag{2.6}$$

Integrating by parts and employing the partition of unity $(\phi_z)_{z\in\mathcal{N}_h}$, we obtain

$$\begin{aligned}\langle \mathcal{G}_h,\, \varphi\rangle &= \int_\Omega f\,\varphi - \int_\Omega \nabla u_h \nabla\varphi - \langle \sigma_h,\, \varphi\rangle = \int_\Omega f\,\varphi + \int_\Gamma J_h\,\varphi - \langle \sigma_h,\, \varphi\rangle \\ &= \sum_{z\in\mathcal{N}_h} \Bigg\{ \int_\Omega f\,\varphi\,\phi_z + \int_\Gamma J_h\,\varphi\,\phi_z - \int_{\Omega_h^0} f\,\varphi\,\phi_z - \int_{\Gamma_h^0} J_h\,\varphi\,\phi_z \\ &\qquad\qquad - \int_{\Omega_h^+} f\,(\Pi_h\varphi)(z)\,\phi_z - \int_{\Gamma_h^+} J_h\,(\Pi_h\varphi)(z)\,\phi_z \Bigg\} \\ &= \sum_{z\in\mathcal{N}_h} \left\{ \int_{\Omega_h^+} f\,[\varphi - (\Pi_h\varphi)(z)]\,\phi_z + \int_{\Gamma_h^+} J_h\,[\varphi - (\Pi_h\varphi)(z)]\,\phi_z \right\} \\ &= \int_{\Omega_h^+} f\left[\varphi - \sum_{z\in\mathcal{N}_h} (\Pi_h\varphi)(z)\,\phi_z\right] + \int_{\Gamma_h^+} J_h\left[\varphi - \sum_{z\in\mathcal{N}_h} (\Pi_h\varphi)(z)\,\phi_z\right] \\ &= \int_{\Omega_h^+} f\,[\varphi - \Pi_h\varphi] + \int_{\Gamma_h^+} J_h\,[\varphi - \Pi_h\varphi].\end{aligned}$$

This expression shows the effect of *full localization* of the Galerkin functional to the set Ω_h^+. The construction of $\tilde\sigma_h$ in [15] leads merely to a *partial* localization. The full localization of σ_h defined by (2.3) is due to the notion of full-contact nodes, which was introduced in [7] so as to achieve full localization in the context of a first order estimator. In [7, Remark 4.5] one finds also an argument that the sign conditions on f and J_h in the definition of $\mathcal{C}_h$ are crucial.

To exploit further cancellation properties, we introduce the constant values

$$\bar\psi_z = \begin{cases} \left(\int_{\Omega_h^+} \phi_z\right)^{-1} \int_{\Omega_h^+} \psi\,\phi_z & \text{if } \rho_z = 0, \\ 0 & \text{else} \end{cases}$$

for all $z \in \mathcal{N}_h$ and $\psi \in L_1(\Omega)$, where

$$\rho_z := \int_{\Omega_h^+} f\,\phi_z + \int_{\Gamma_h^+} J_h\,\phi_z.$$

Note that, in view of (1.2) and (2.2), we certainly have $\rho_z = 0$ if $u_h(z) > \chi_h(z)$ and perhaps by chance otherwise. Setting $\psi := \varphi - \Pi_h\varphi$, employing again the partition of unity, and the fact that $\bar{\psi}_z\, \rho_z = 0$ we can rewrite $\langle \mathcal{G}_h,\, \varphi\rangle$ as follows:

$$\langle \mathcal{G}_h,\, \varphi\rangle = \sum_{z\in\mathcal{N}_h} \int_{\Omega_h^+} f\,[\psi - \bar{\psi}_z]\phi_z + \int_{\Gamma_h^+} J_h\,[\psi - \bar{\psi}_z]\,\phi_z.$$

For nodes $z \in \mathcal{N}_h$ with $\rho_z = 0$, the value $\bar{\psi}_z$ is the weighted L^2-projection of ψ to the constant functions on $\omega_z \cap \Omega_h^+$. Hence, we can subtract a constant from the element residual at these nodes without altering the expression. In particular, we can write

$$\langle \mathcal{G}_h,\, \varphi\rangle = \sum_{z\in\mathcal{N}_h} \int_{\omega_z^+} [f - \hat{f}_z]\,[\psi - \bar{\psi}_z]\phi_z + \int_{\gamma_z^+} J_h\,[\psi - \bar{\psi}_z]\,\phi_z, \tag{2.7}$$

where

$$\omega_z^+ = \omega_z \cap \Omega_h^+, \qquad \gamma_z^+ = \gamma_z \cap \Omega_h^+, \tag{2.8}$$

and

$$\hat{f}_z = \begin{cases} \frac{1}{2}\big(\min_{\omega_z^+} f + \max_{\omega_z^+} f\big) & \text{if } \rho_z = 0,\\ 0 & \text{else.}\end{cases} \tag{2.9}$$

This shows that only the *oscillation* $f - \hat{f}_z$ of the interior residual f enters in the estimators on all stars with $\rho_z = 0$ and not f itself.

2.3. Galerkin functional: Estimates. In order to bound the pointwise error $\|u - u_h\|_{0,\infty;\Omega}$, we shall need an estimate of $\mathcal{G}_h$ in the dual norm

$$\|\mathcal{G}_h\|_{-2,\infty;\Omega} := \sup\big\{\langle \mathcal{G}_h,\, \varphi\rangle \mid \varphi \in \mathring{H}^1(\Omega) \cap W_1^2(\Omega) \text{ with } \|D^2\varphi\|_{0,1;\Omega} \le 1\big\}. \tag{2.10}$$

In what follows, the symbol "$\preccurlyeq$" stands for "$\le C$," where the generic constant C may depend on the shape-regularity of the partition $\mathcal{T}_h$, the domain Ω, and its dimension d. The starting point for estimating (2.10) is (2.7). For $\varphi \in \mathring{H}^1(\Omega) \cap W_1^2(\Omega)$ and $\psi = \varphi - \Pi_h\varphi$, the Bramble–Hilbert lemma and *second order* interpolation estimates for Π_h provide

$$\|\psi - \bar{\psi}_z\|_{0,1;\omega_z} \preccurlyeq h_z\|\nabla\psi\|_{0,1;\omega_z} = h_z\|\nabla(\varphi - \Pi_h\varphi)\|_{0,1;\omega_z} \preccurlyeq h_z^2\|D^2\varphi\|_{0,1;\mathcal{U}_h(\omega_z)}$$

and, with the additional use of a scaled trace theorem,

$$\|\psi - \bar{\psi}_z\|_{0,1;\gamma_z} \preccurlyeq h_z^{-1}\|\psi - \bar{\psi}_z\|_{0,1;\omega_z} + \|\nabla\psi\|_{0,1;\omega_z} \preccurlyeq h_z\|D^2\varphi\|_{0,1;\mathcal{U}_h(\omega_z)},$$

where $\mathcal{U}_h(\omega_z)$ is the union of all simplices of $\mathcal{T}_h$ having nonempty intersection with the star ω_z. In view of (2.7), the last two estimates yield the following one:

$$|\langle \mathcal{G}_h,\, \varphi\rangle| \preccurlyeq \max_{z\in\mathcal{N}_h} \Big(h_z^2\|(f - \hat{f}_z)\,\phi_z\|_{0,\infty;\omega_z^+} + h_z\|J_h\,\phi_z\|_{0,\infty;\gamma_z^+}\Big)\,\|D^2\varphi\|_{0,1;\Omega}. \tag{2.11}$$

Analogously, one obtains

$$|\langle \mathcal{G}_h,\, \varphi\rangle| \preccurlyeq \left(\sum_{z\in\mathcal{N}_h} h_z^p\|(f - \hat{f}_z)\,\phi_z\|_{0,p;\omega_z^+}^p + h_z\|J_h\,\phi_z\|_{0,p;\gamma_z^+}^p\right)^{1/p} \|\nabla\varphi\|_{0,p';\Omega}, \tag{2.12}$$

where $p' = p/(p-1)$ is the dual exponent of $p \in [1,\infty)$. The proof of (2.11)–(2.12) is straightforward and thus omitted; we refer to [15] for similar bounds for a slightly different Galerkin functional $\mathcal{G}_h$. Let $w \in \mathring{H}^1(\Omega)$ be the Riesz representation of $\mathcal{G}_h$,

$$w \in \mathring{H}^1(\Omega): \qquad \int_\Omega \nabla w \cdot \nabla \varphi = \langle \mathcal{G}_h, \varphi \rangle \quad \text{for all } \varphi \in \mathring{H}^1(\Omega). \tag{2.13}$$

The following estimate will be instrumental in section 2.5 and, compared with [15], exhibits extra localization and cancellation of the element residual. Since the argument is similar to that in [15], which in turn is based on linear theory [4, 14], we only sketch it here for completeness.

LEMMA 2.2 (properties of w). *The function w is Hölder continuous and satisfies*

$$\|w\|_{0,\infty;\Omega} \le C^* |\log h_{\min}|^2 \max_{z\in\mathcal{N}_h} \eta_z, \tag{2.14}$$

where $C^* > 0$ is an interpolation constant solely depending on mesh regularity, $h_{\min} := \min_{z\in\mathcal{N}_h} h_z$, and η_z is the star-based residual indicator

$$\eta_z := h_z^2 \|(f - \hat{f}_z)\,\phi_z\|_{0,\infty;\omega_z^+} + h_z\,\|J_h\,\phi_z\|_{0,\infty;\gamma_z^+}, \tag{2.15}$$

with ω_z^+, γ_z^+, and $\hat{f}_z$ defined in (2.8) *and* (2.9).

Proof. We first apply the classical Hölder estimate of De Giorgi and Nash to deduce that $w \in C^{0,\alpha}(\Omega)$ for $\alpha = 1 - d/p > 0$ and $\|w\|_{C^{0,\alpha}(\Omega)} \preccurlyeq \|\mathcal{G}_h\|_{-1,p;\Omega}$. Consequently, (2.12) yields $\|w\|_{C^{0,\alpha}(\Omega)} \preccurlyeq \big(\sum_{z\in\mathcal{N}_h} \zeta_z^p\big)^{1/p}$ with

$$\zeta_z := h_z\,\|(f - \hat{f}_z)\,\phi_z\|_{0,p;\omega_z^+} + h_z^{1/p}\,\|J_h\,\phi_z\|_{0,p;\gamma_z^+}.$$

Hence

$$|w(x_0) - w(x_1)| \preccurlyeq |x_0 - x_1|^\alpha \|w\|_{C^{0,\alpha}(\Omega)} \preccurlyeq |x_0 - x_1|^\alpha \left(\sum_{z\in\mathcal{N}_h} \zeta_z^p\right)^{1/p}. \tag{2.16}$$

To prove a bound for $|w(x_0)| = \|w\|_{0,\infty;\Omega}$, we first invoke the uniform cone property of Ω and find a ball $B \subset \Omega$ of radius $\rho = h_{\min}^\beta$ ($\beta \ge 1$ to be determined) such that $\operatorname{dist}(x_0, B) \preccurlyeq \rho$. We then introduce a regularized delta function δ supported in B and corresponding regularized Green's function $G \in \mathring{H}^1(\Omega)$ satisfying $-\Delta G = \delta$. As in [4, 14], we get

$$\|D^2 G\|_{0,1;\Omega} \preccurlyeq |\log h_{\min}|^2,$$

whence, for some $x_1 \in B$ and with the help of (2.11),

$$w(x_1) = \langle w, \delta\rangle = \langle \nabla w, \nabla G\rangle = \langle \mathcal{G}_h, G\rangle \preccurlyeq |\log h_{\min}|^2 \max_{z\in\mathcal{N}_h} \eta_z. \tag{2.17}$$

Fixing $p > d$ and choosing $\beta = \alpha^{-1}$, we deduce that

$$h_{\min}^{\alpha\beta} \zeta_z \preccurlyeq h_z \zeta_z \preccurlyeq \eta_z |\omega_z^+|^{1/p} \qquad \text{for all } z \in \mathcal{N}_h. \tag{2.18}$$

Since $|x_0 - x_1|^\alpha \preccurlyeq \rho^\alpha = h_{\min}$, combining (2.16) and (2.17) leads to (2.14). ∎

Remark 2.3. We point out that (2.14) improves upon estimates in [4, 14] for linear elliptic PDEs (corresponding to the situation when $u > \chi$ and u_h/χ_h) in four respects.

First, there is no structural assumption $h_{\max} \preccurlyeq h_{\min}^{\gamma}$ ($\gamma \geq 1$) on the partition $\mathcal{T}_h$. Second, the assumption $\|w\|_{0,\infty;\Omega} \succcurlyeq h_{\max}^2$ is totally circumvented via (2.16) and (2.18). Third, the residual f need not be globally continuous—these three assumptions may not be valid in the present context (see section 3.2 below). Fourth, the usual interior residual $h_z\|f\phi_z\|_{0,\infty;\omega_z}$ is *directly* replaced by data oscillation $h_z\|(f-\hat{f}_z)\phi_z\|_{0,\infty;\omega_z}$, which is asymptotically smaller for $f \in C^0(\Omega)$; this is in the spirit of [14, Corollary 7.2].

Remark 2.4. The estimate (2.14) stems from *linear* theory and the constant C^* is the usual interpolation constant of residual-type estimators, which is not explicity known but can be estimated with the help of numerical experiments. It is conceivable that a sharp constant-free estimator in the maximum norm could be designed, but we are unaware of such an undertaking. Note also that w is an auxiliary function, never to be approximated and thus only accessible with additional work.

2.4. Barrier functions. We now introduce the continuous barriers u_* (lower) and u^* (upper), and derive a posteriori comparison estimates via the *continuous* maximum principle, thereby imposing no geometric constraints on the mesh. This is in striking contrast to existing a priori error analyses.

Given a function v, let $v^+ = \max(v, 0)$ denote its nonnegative part.

PROPOSITION 2.5 (lower barrier). *Let u_* be the function*

$$u_* := u_h + w - \|w\|_{0,\infty;\Omega} - \|g - I_h g\|_{0,\infty;\partial\Omega} - \|(u_h - \chi)^+\|_{0,\infty;\Lambda_h}, \tag{2.19}$$

where Λ_h is the contact set

$$\Lambda_h := \bigcup \{\omega_z : z \in \mathring{\mathcal{N}}_h \cup (\mathcal{C}_h \cap \partial\Omega) \text{ and } s_z < 0\} \tag{2.20}$$

with s_z defined in (2.5). *Then u_* satisfies*

$$u_* \leq u \qquad \text{in } \Omega.$$

Proof. We split the proof into four steps.

1. Since

$$(u_* - u)_{|\partial\Omega} \;\leq\; (u_h - u)_{|\partial\Omega} - \|g - I_h g\|_{0,\infty;\partial\Omega} \;\leq\; 0,$$

the function $v := (u_* - u)^+$ satisfies

$$v_{|\partial\Omega} = 0. \tag{2.21}$$

We want to show that $\|\nabla v\|_{0,2;\Omega} = 0$ and then use (2.21) to conclude that $v = 0$.

2. In view of (2.19), (2.13), (2.6), and $\sigma \leq 0$, we can write

$$\begin{aligned} \|\nabla v\|_{0,2;\Omega}^2 &= \int_\Omega \nabla(u_* - u)\cdot\nabla v = \int_\Omega \nabla(u_h - u)\cdot\nabla v + \int_\Omega \nabla w\cdot\nabla v \\ &= \langle \sigma - \sigma_h,\, v\rangle \leq -\langle \sigma_h,\, v\rangle . \end{aligned} \tag{2.22}$$

It thus remains to show $\langle \sigma_h, v\rangle = 0$, i.e., $\langle \sigma_h, v\,\phi_z\rangle = 0$ for all $z \in \mathcal{N}_h$.

3. We now show that

$$s_z = 0 \text{ or } z \in (\mathcal{N}_h \cap \partial\Omega) \setminus \mathcal{C}_h \implies \langle \sigma_h, v\,\phi_z\rangle = 0.$$

First, consider $z \in \mathcal{C}_h$ with $s_z = 0$. By definition of $\mathcal{C}_h$, we have $J_h \le 0$ on γ_z and $f \le 0$ in ω_z. Hence,

$$0 = s_z = \int_{\omega_z} f\,\phi_z + \int_{\gamma_z} J_h\,\phi_z$$

implies in fact $J_h = 0$ on γ_z and $f = 0$ in ω_z. This yields

$$\begin{aligned}\langle \sigma_h,\, v\,\phi_z\rangle = &\int_{\omega_z\cap\Omega_h^0} f\,v\,\phi_z + \int_{\gamma_z\cap\Omega_h^0} J_h\,v\,\phi_z \\ &+ (\Pi_h v)(z)\left[\int_{\omega_z\setminus\Omega_h^0} f\,\phi_z + \int_{\gamma_z\setminus\Omega_h^0} J_h\phi_z\right] = 0.\end{aligned}$$

Next, for $z \in \mathcal{N}_h\backslash\mathcal{C}_h$ with $s_z = 0$, we directly obtain $\langle \sigma_h,\, v\,\phi_z\rangle = 0$ by (2.4). Finally, if $z \in (\mathcal{N}_h \cap \partial\Omega) \setminus \mathcal{C}_h$ is a boundary node not being in full contact, then (2.4) and $(\Pi_h v)(z) = 0$ give $\langle \sigma_h,\, v\,\phi_z\rangle = 0$.

4. It remains to show that there is no node $z \in \mathring{\mathcal{N}}_h \cup \mathcal{C}_h$ with $\langle \sigma_h,\, v\,\phi_z\rangle < 0$ and $s_z < 0$. Suppose that z were such a node. Then there would exist an $x \in \omega_z$ with $v(x) > 0$, whence the definitions of u_* and Λ_h give

$$u_h(x) > u(x) + \|(u_h - \chi)^+\|_{0,\infty;\Lambda_h} \ge \chi(x) + \|(u_h - \chi)^+\|_{0,\infty;\omega_z} \ge u_h(x).$$

This contradiction concludes the proof. ∎

PROPOSITION 2.6 (upper barrier). *The function*

$$u^* := u_h + w + \|w\|_{0,\infty;\Omega} + \|g - I_h g\|_{0,\infty;\partial\Omega} + \|(\chi - u_h)^+\|_{0,\infty;\Omega} \tag{2.23}$$

satisfies

$$u \le u^* \qquad \text{in } \Omega.$$

Proof. We proceed as in Proposition 2.5, dealing with $v := (u - u^*)^+ \in \mathring{H}^1(\Omega)$ and using $\sigma_h \le 0$ from Lemma 2.1. The crucial property $\langle \sigma,\, (u - u^*)^+\rangle = 0$ follows easily as in [15, Proposition 4.1]. ∎

2.5. Upper and lower bounds. Combining the results of sections 2.3 and 2.4, we can now establish an upper a posteriori error estimate.

THEOREM 2.7 (reliability). *Let (u, σ) be the continuous solution satisfying* (1.1) *and* (2.1)*, and let (u_h, σ_h) be the discrete solution satisfying* (1.2) *and* (2.3)*, respectively. Then the following global a posteriori upper bound holds:*

$$\max\left\{\|u - u_h\|_{0,\infty;\Omega}, \|\sigma - \sigma_h\|_{-2,\infty;\Omega}\right\} \le \mathcal{E}_h, \tag{2.24}$$

where $\|\cdot\|_{-2,\infty;\Omega}$ is defined in (2.10)*, the error estimator $\mathcal{E}_h$ is given by*

$$\begin{aligned}\mathcal{E}_h := {} & C_*|\log h_{\min}|^2\ \max_{z\in\mathcal{N}_h}\eta_z && \textit{localized residual}\\ & + \|(\chi - u_h)^+\|_{0,\infty;\Omega} + \|(u_h - \chi)^+\|_{0,\infty;\Lambda_h} && \textit{localized obstacle approx.}\\ & + \|g - I_h g\|_{0,\infty;\partial\Omega} && \textit{boundary datum approx.}\end{aligned}$$

C_* is twice the geometric constant C^* in (2.14)*, solely depending on mesh regularity, η_z is the star-based indicator defined in* (2.15)*, and Λ_h is defined in* (2.20)*.*

Proof. Combining Propositions 2.5 and 2.6, we obtain $u_* \le u \le u^*$, whence

$$\begin{aligned}\|u-u_h\|_{0,\infty;\Omega} \le 2\|w\|_{0,\infty;\Omega} + \|(\chi-u_h)^+\|_{0,\infty;\Omega} \\ + \|(u_h-\chi)^+\|_{0,\infty;\Lambda_h} + \|g-I_hg\|_{0,\infty;\partial\Omega}.\end{aligned}$$

Lemma 2.2 then yields (2.24) for $u-u_h$. Finally, we resort to (2.6), namely,

$$\langle \sigma-\sigma_h,\,\varphi\rangle = \langle \mathcal{G}_h,\,\varphi\rangle + \langle u-u_h,\,\Delta\varphi\rangle \qquad \text{for all } \varphi\in \mathring{H}^1(\Omega)\cap W_1^2(\Omega),$$

and make use of (2.11) in conjunction with the bound above for $\|u-u_h\|_{0,\infty;\Omega}$ to derive the remaining estimate for $\sigma-\sigma_h$. ∎

The latter observation is important for the establishment of lower bounds and underlines the significance of the Galerkin functional. The global upper bound of Theorem 2.7 is of *optimal order* because the computable quantities therein are (locally) bounded by the combined error $\|u-u_h\|_{0,\infty;\Omega} + \|\sigma-\sigma_h\|_{-2,\infty;\Omega}$ and data approximation as follows.

Remark 2.8. The only constant in (2.24), C_* in $\mathcal{E}_h$, comes from linear theory (see Remark 2.4). The nonlinear theory of sections 2.4 and 2.5, which accounts for the highly nonlinear effects of the unilateral constraint, is thus constant-free.

THEOREM 2.9 (efficiency). *The following local lower bounds hold for any $z\in\mathcal{N}_h$ and $T\in\mathcal{T}_h$:*

$$\begin{aligned} h_z\|J_h\phi_z\|_{0,\infty;\gamma_z^+} &\preccurlyeq \|u-u_h\|_{0,\infty;\omega_z^+} + \|\sigma-\sigma_h\|_{-2,\infty;\omega_z^+} + h_z^2\|f-\hat f_z\|_{0,\infty;\omega_z^+}, \\ \|I_hg-g\|_{0,\infty;T\cap\partial\Omega} &\le \|u-u_h\|_{0,\infty;T}, \qquad \|(\chi-u_h)^+\|_{0,\infty;T} \le \|u-u_h\|_{0,\infty;T}, \end{aligned}$$

and, if $\omega_z\subset\Lambda_h$,

$$\begin{aligned}\|(u_h-\chi)^+\|_{0,\infty;\omega_z} \preccurlyeq \|u-u_h\|_{0,\infty;\omega_z} + \|\sigma-\sigma_h\|_{-2,\infty;\omega_z} + h_z^2\|f-\hat f_z\|_{0,\infty;\omega_z} \\ + \|(\chi_h-\chi)^+\|_{0,\infty;\omega_z} + \|\,[\![\partial_n\chi_h]\!]\,\|_{0,\infty;\gamma_z}.\end{aligned}$$

The proofs of these estimates are very similar to those of the corresponding lower bounds in [15, section 6] and are therefore omitted. The efficiency predicted by these estimates is corroborated computationally in section 3.

3. Numerical experiments I: Pointwise error. In this section we present a couple of insightful examples computed with the finite element toolbox ALBERT of Schmidt and Siebert [18, 19]. This code implements a bisection algorithm for refinement and thus guarantees mesh regularity. In each iteration of the adaptive algorithm, the solver for the resulting complementary problem is the projective nonlinear SOR analyzed in [6].

The factor $C_*|\log h_{\min}|$ of Theorem 2.7 is, in practice, replaced by $C^* = 0.02$. This choice is consistent with (2.24) for meshes with reasonable shape-regularity and moderate $h_{\min}$. For the computation of the maximum norm, functions are evaluated at the element Lagrange nodes corresponding to polynomials of degree 7. The marking strategy for refinement is based on the maximum norm criterion.

3.1. Madonna's obstacle: Reliability and efficiency. Let $\Omega := (-1,1)^2$ and the obstacle χ be the upward cone with tip at $x_0 = (\frac{3}{8},\frac{3}{8})$ and slope $m = 1.8$:

$$\chi(x) = 1 - m|x-x_0|.$$

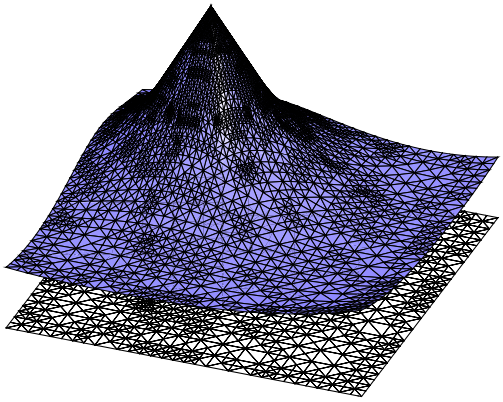

FIG. 3.1. *Madonna's obstacle: Graph and grid of the discrete solution for adaptive iteration* 14.

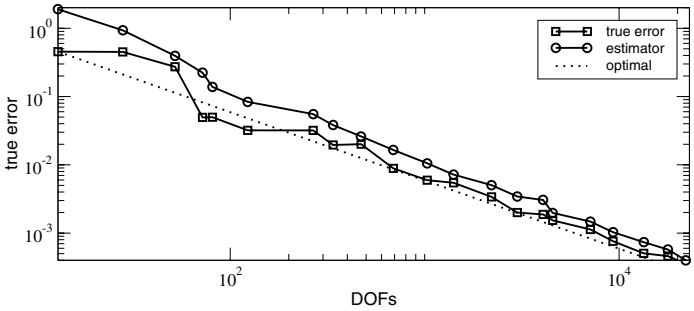

FIG. 3.2. *Madonna's obstacle: Equivalence of estimator* $\mathcal{E}_h$ *and true pointwise error* $\|u - u_h\|_{0,\infty;\Omega}$. *The optimal decay is indicated by the dotted line with slope* -1.

The exact solution is radially symmetric with respect to x_0, vanishes at $|x - x_0| = \frac{1}{m}$ and has a first order contact with the obstacle at $|x - x_0| = \frac{1}{2m}$; this corresponds to height $\frac{1}{2}$ (see Figure 3.1). The obstacle is thus singular within the contact set, due to the upward tip, which leads to local refinement. Several meshes are displayed in Figure 5.2 below.

Since we know the exact solution u, this example allows for a precise computational study of the estimator $\mathcal{E}_h$. Figure 3.2 displays both $\mathcal{E}_h$ and $\|u - u_h\|_{0,\infty;\Omega}$ versus the number of degrees of freedom (DOFs), and clearly demonstrates the equivalence between them. This result is consistent with Theorems 2.7 (reliability) and 2.9 (efficiency) and confirms their optimality.

3.2. Pyramid obstacle: Full localization. We now consider the same pyramid obstacle as in [15, section 7.4], namely

$$\chi(x) := \operatorname{dist}(x, \partial\Omega) - \tfrac{1}{5},$$

$f = -5$ and $g = 0$ on the square domain $\Omega := \{x \mid |x|_1 < 1\}$; see Figure 3.3. We show the dramatic effect of full localization of $\mathcal{E}_h$ in Figure 3.4, which exhibits coarse meshes within the full contact set (bottom row) in striking contrast to recent results

from [15] (top row). In addition, the new estimator is sharper with respect to the maximum norm than that in [15] and thus yields much fewer DOFs for about the same accuracy.

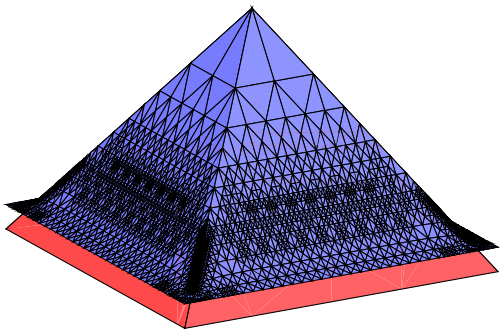

FIG. 3.3. *Pyramid obstacle: Graph with grid of the discrete solution over the obstacle for adaptive iteration* 10*, displaying lack of refinement along the diagonals inside the full-contact set (effect of full localization).*

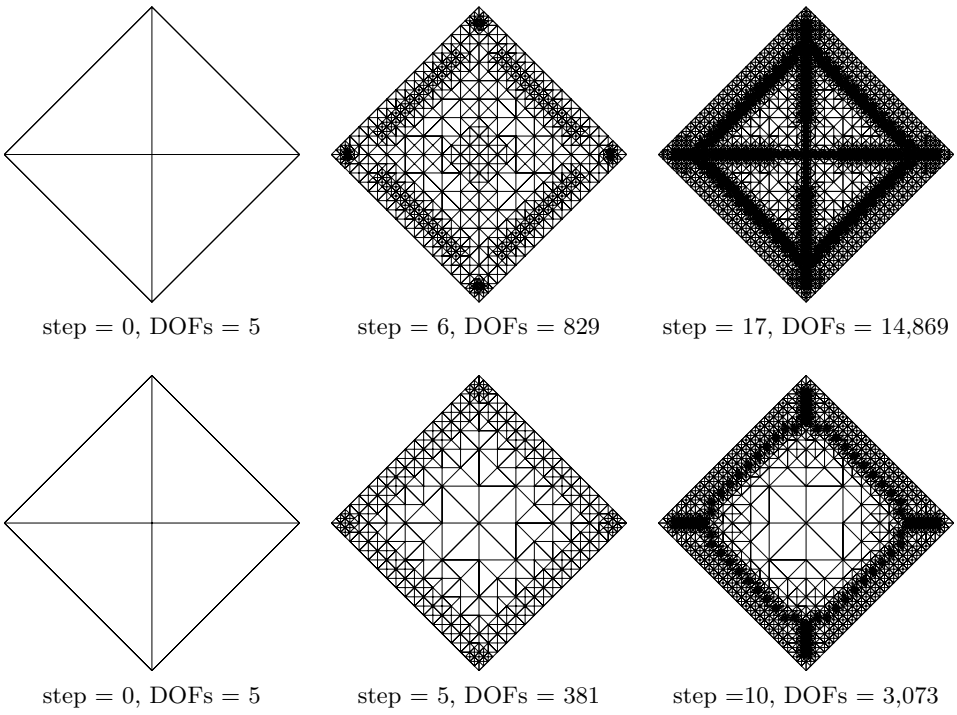

FIG. 3.4. *Pyramid obstacle: Comparison of grids obtained with the partially localized estimator of* [15] *(top) and the fully localized estimator (bottom). The meshes on the same column correspond to about the same value of the estimator, whereas the number of DOFs are much reduced with the new approach. The benefits of full localization are apparent since the refinement on the diagonals in contact is avoided.*

4. A posteriori barrier sets. The error in the approximation of σ is related to some "weak distance" of the exact contact set Λ and an appropriate approximation;

cf. [20, Remark 3.2]. However, the fact that the estimator $\mathcal{E}_h$ controls the pointwise error $\|u-u_h\|_{0,\infty;\Omega}$ allows, in certain situations, for more accurate a posteriori information on Λ and also on the exact free boundary (or interface) $\mathcal{F}$. This topic is the main concern of this section.

We consider the nondegenerate situation when one knows $\lambda > 0$ such that

$$\langle f,\, \varphi\rangle - \langle \nabla\chi,\, \nabla\varphi\rangle \;\le\; -\lambda \int_\Omega \varphi \tag{4.1}$$

for all $\varphi \in \mathring{H}^1(\Omega)$ with $\varphi \ge 0$. Condition (4.1) guarantees *stability* of the exact free boundary $\mathcal{F}$ and is due to Caffarelli [2]; see also [9, section 2.10]. Moreover, (4.1) implies

$$\sup_{B(x;r)} (u-\chi) \ge u(x) - \chi(x) + \frac{\lambda r^2}{2d} \tag{4.2}$$

for any $x \in \overline{\{u>\chi\}}$ and any $r>0$ such that $B(x;r) \subset \Omega$. Its proof proceeds along the same lines as that of Lemma 3.1 in [9, Chapter 2].

Let us define $K := \{\mathrm{dist}(\cdot, \partial\Omega) \ge r_h\}$ and the *barrier sets*

$$\Lambda^* := \{u_h \le \chi + \mathcal{E}_h\}, \qquad \Lambda_* := \Big\{\mathrm{dist}\big(\cdot, \{u_h \ge \chi_h + \mathcal{E}_h\}\big) \ge r_h\Big\}, \tag{4.3}$$

where

$$r_h^2 := \frac{2d}{\lambda}\big(2\mathcal{E}_h + \|(\chi_h - \chi)^+\|_{0,\infty;\{u_h \le \chi_h + \mathcal{E}_h\}}\big). \tag{4.4}$$

The following result, based on Theorem 2.7 and (4.2), locates the exact contact set Λ and the free boundary $\mathcal{F}$ a posteriori.

THEOREM 4.1 (a posteriori control of contact set and interface). *The set Λ^* is an upper barrier set for the exact contact set $\Lambda = \{u=\chi\}$, i.e., $\Lambda \subset \Lambda^*$.*

Moreover, if the stability condition (4.1) *holds, then the set Λ_* is a lower barrier set for Λ in the sense that $\Lambda_* \cap K \subset \Lambda \cap K$, whence*

$$\mathcal{F} \cap K \;\subset\; \big(\Lambda^* \cap K\big) \setminus \mathrm{int}\big(\Lambda_* \cap K\big).$$

Remark 4.2 (conditioning). In the light of (4.2), λ dictates the quadratic growth of $u-\chi$ in the noncontact set away from the free boundary $\mathcal{F}$, and so the larger λ, the more stable $\mathcal{F}$; that is, λ acts as a measure of conditioning of the free boundary. Correspondingly, the thicknesses of the strips $\Omega\setminus K$ and $\big(\Lambda^*\cap K\big)\setminus \mathrm{int}\big(\Lambda_*\cap K\big)$ depend inversely on λ.

Remark 4.3 (existence of exact interface). Suppose that condition (4.1) holds. Then $\Lambda_* \cap K \ne \emptyset$ implies $\Lambda \ne \emptyset$. Moreover, $\Lambda_* \cap K \ne \emptyset$ and $\Omega \setminus \Lambda^* \ne \emptyset$ imply $\mathcal{F} \ne \emptyset$.

Proof of Theorem 4.1. We first prove $\Lambda \subset \Lambda^*$. We use Theorem 2.7 with $x \in \Lambda$

$$u_h(x) = u(x) + \big[u_h(x) - u(x)\big] \le \chi(x) + \mathcal{E}_h$$

to deduce $x \in \Lambda^*$. We next prove $\Lambda_* \cap K \subset \Lambda \cap K$ provided that (4.1) holds. Let $x \in \Lambda_* \cap K$ and suppose that

$$u(x) > \chi(x). \tag{4.5}$$

Then, the definition of Λ_* in (4.3) implies that

$$u_h \le \chi_h + \mathcal{E}_h \qquad \text{in } \overline{B(x;r_h)} \tag{4.6}$$

holds and (4.2) yields

$$\sup_{B(x;r_h)} (u-\chi) > \frac{\lambda r_h^2}{2d}. \tag{4.7}$$

Consequently, Theorem 2.7, (4.4), and (4.7) give for some point $y \in \overline{B(x;r_h)}$:

$$\begin{aligned} u_h(y) &= u(y) + \big[u_h(y) - u(y)\big] > \chi(y) + \frac{\lambda r_h^2}{2d} - \mathcal{E}_h \\ &= \chi(y) + 2\mathcal{E}_h + \|(\chi_h - \chi)^+\|_{0,\infty;\{u_h \le \chi_h + \mathcal{E}_h\}} - \mathcal{E}_h \ \ge\ \chi_h(y) + \mathcal{E}_h. \end{aligned}$$

This contradicts (4.6) and so (4.5) is false. Consequently, $x \in \Lambda$ as asserted. ∎

Remark 4.4 (estimate in distance). We stress that Theorem 4.1 relies solely on (4.2) and not on estimating the measure of $\{0 < u - \chi < \epsilon\}$, the so-called *nondegeneracy property* of Caffarelli [2]. This leads, in the a priori error analysis for $\chi = \chi_h$, to estimates in measure for the discrete free boundary relative to $\mathcal{F}$ [1, 13]. Bounds in distance require regularity of $\mathcal{F}$ [1, 5, 13]. We locate here $\mathcal{F}$ relative to

$$\mathcal{F}_h = \partial\{u_h > \chi_h + \mathcal{E}_h\} \cap \Omega.$$

This dual approach yields estimates *in distance* without regularity assumptions on the exact free boundary $\mathcal{F}$.

Remark 4.5 (computation of effective condition number). Statement (4.6) reveals that (4.1) is needed in the proof of Theorem 4.1 only for positive test functions φ with $\operatorname{supp}\varphi \subset \{u_h \le \chi_h + \mathcal{E}_h\}$. Therefore, if $\chi \in H^2(\Omega)$, one can adaptively compute the condition number λ by

$$\lambda = - \sup_{\{u_h \le \chi_h + \mathcal{E}_h\}} (f + \Delta\chi).$$

Remark 4.6 (Computation of barrier sets). *The argument for Theorem* 4.1 itself is "constant-free." Therefore, the only not explicitly known quantity entering the definition of the barrier sets Λ^* and Λ_* is the constant C^* mentioned in Remark 2.4.

5. Numerical experiments II: Free boundaries. In this section we present several numerical experiments illustrating the impact of the a posteriori barrier sets in section 4 on the numerical study of exact free boundaries.

5.1. Madonna's obstacle: Reliability and efficiency. Let us reconsider the example from section 3.1, this time focusing on the approximation of the exact free boundary $\mathcal{F} = \{x \in \Omega \mid |x - x_0| = \frac{1}{2m}\}$. The condition number λ which enters the definition of r_h in (4.4), and thus the one of Λ_*, is computed according to Remark 4.5. Figure 5.1 depicts the true distance $\operatorname{dist}(\mathcal{F}, \mathcal{F}_h)$ between $\mathcal{F}$ and $\mathcal{F}_h = \partial\{u_h > \chi_h + \mathcal{E}_h\}$ together with r_h versus the number of DOFs; the number r_h essentially measures the gap between the two barrier sets. Both quantities decay with optimal order. Their behavior corroborates the reliability statement of Theorem 4.1 and, furthermore, reveals nice efficiency properties of r_h, which are not explained by the theory of section 4. Note also that, for the final computations the two barrier sets are quite close, i.e.,

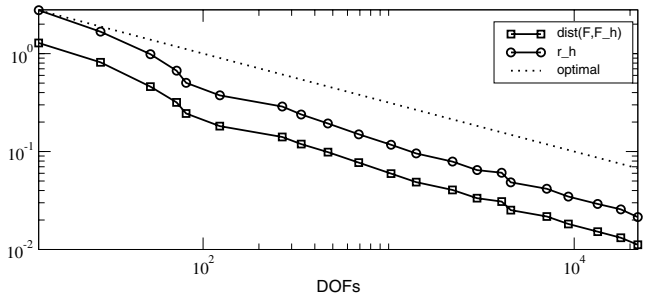

FIG. 5.1. *Madonna's obstacle: Equivalence of dist$(\mathcal{F}, \mathcal{F}_h)$ and the distance r_h of the barriers. The optimal decay is indicated by the dotted line with slope $-1/2$.*

$r_h \approx 0.02$. The grids and interface barriers in Figure 5.2 illustrate different stages in the information about the exact free boundary: the very coarse grid of the first column only indicates a possible exact free boundary; the still quite coarse grid of the second column assures the existence of the free boundary within the a posteriori annulus $\Lambda^* \backslash \Lambda_*$ (see Remark 4.3) and suggests that it might be a circle; the latter is further confirmed by the finer grid of the third column and corresponding better interface resolution.

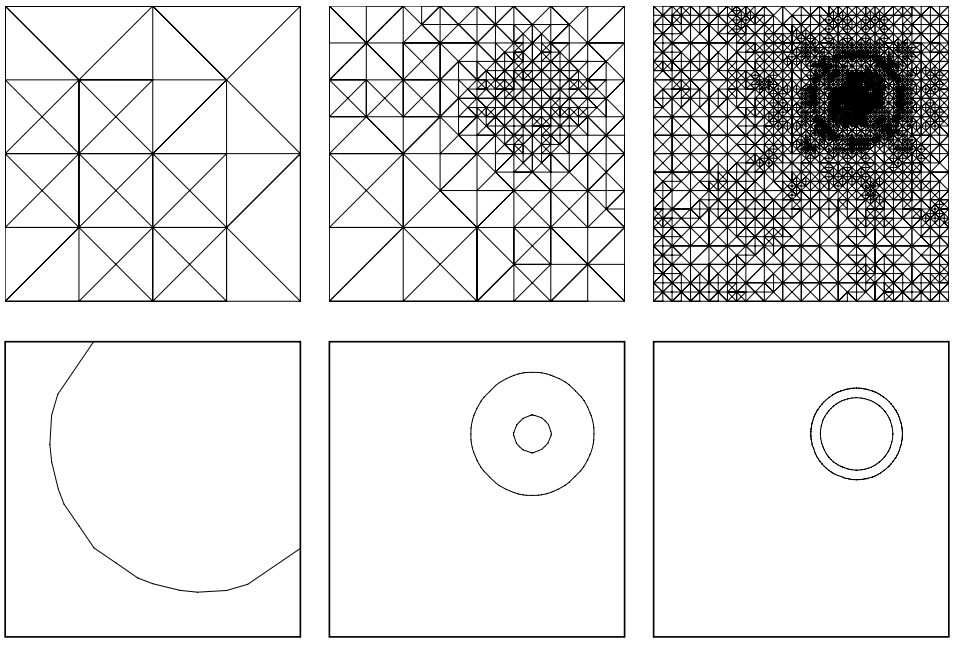

FIG. 5.2. *Madonna's obstacle: grids and interface barriers obtained by the adaptive algorithm in steps* 1, 6, *and* 13.

5.2. From balls to bones. We consider the domain $\Omega = (-2, 2) \times (-1, 1)^{d-1}$, boundary value $g = 0$, several constant loads f, and the smooth obstacle

$$\chi(x) = \alpha - \beta(x_1^2 - 1)^2 - \gamma(|x|^2 - x_1^2) \tag{5.1}$$

with α=10, β=6, γ=20 in 2 dimensions, and α=5, β=6, and γ=30 in 3 dimensions. In 2 dimensions the graph of the obstacle consists of two hills connected by a saddle.

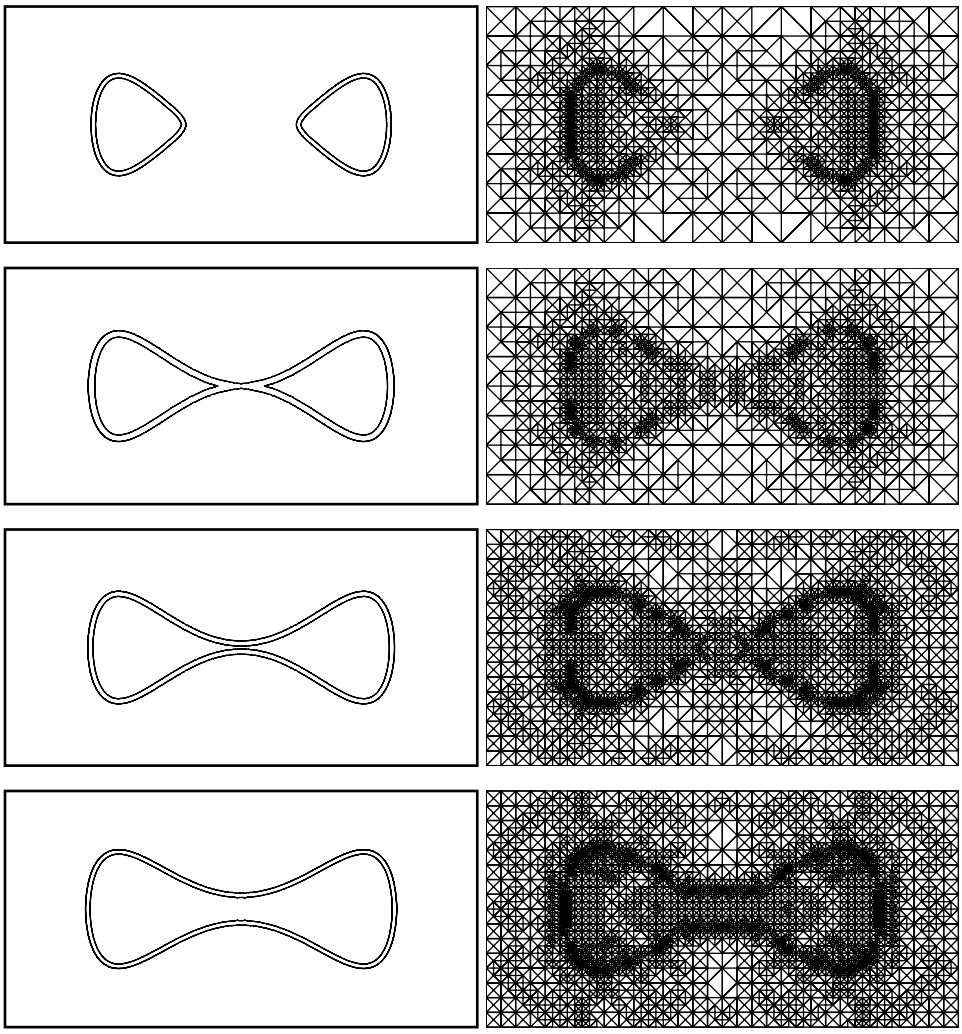

FIG. 5.3. *From balls to bones: Interface barriers for tolerance* ≈ 0.01 *(left) and adaptive grids for tolerance* ≈ 0.15 *(right) in* 2 *dimensions for forcing term* $f = 0, -5.9, -8.1, -15$ *(from top to bottom). The distance of the barriers is* ≈ 0.05 *for all four forces.*

In what follows, "barrier sets for tolerance $\approx \tau$" (> 0) denote those barrier sets which are constructed in the first adaptive iteration with $\mathcal{E}_h \leq \tau$. The left column in Figure 5.3 illustrates the interface barriers for four constant loads $f = 0$, $-5.9, -8.1, -15$ in 2 dimensions for about the same tolerance $\tau \approx 0.01$; the exterior curves correspond to $\partial\Lambda^*$ whereas the interior curves display $\partial\Lambda_*$. For $f = 0$, the contact set does not contain the saddle, whereas, for $f = -15$, it does. This happens because the solution, being pushed down by f, adheres longer to the obstacle. During the transition between these two extreme cases, the free boundary has a singular point, namely a "double-cusp" at the origin, for some critical value f_{crit}. The barrier sets constructed in section 4 from the discrete solution and the estimator give a reli-

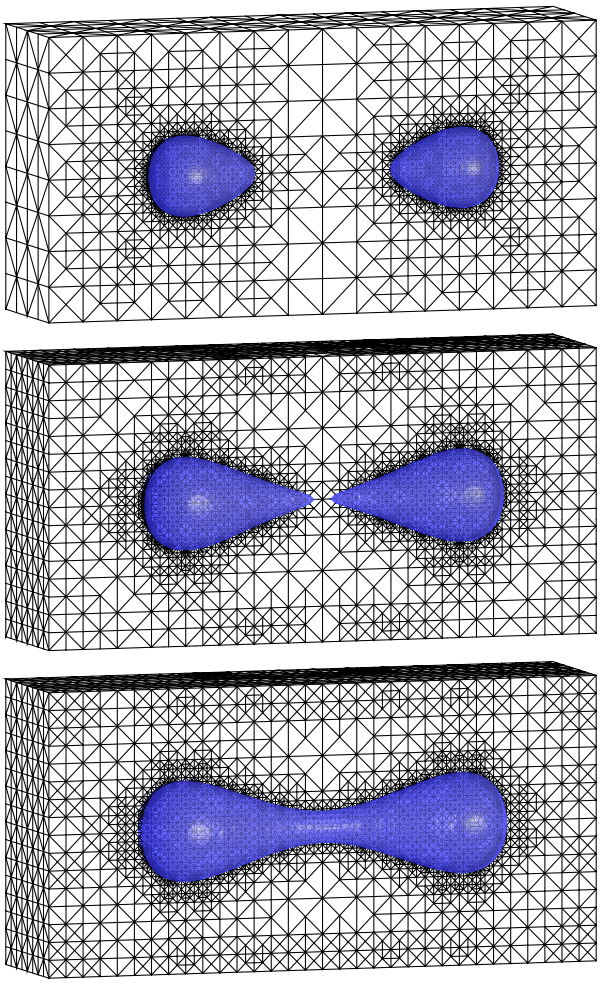

FIG. 5.4. *From balls to bones: Upper barrier* $\partial\Lambda^* \cap \Omega$ *and adaptive grids in* 3 *dimensions for tolerance* ≈ 0.25 *and* $f = 0, -8.5, -15.1$. *The distance of the barriers is* ≈ 0.1 *for all three forces.*

able range for f_{crit}: as long as Λ^* does not contain the saddle and $\Lambda_* \neq \emptyset$, the true contact set Λ exists and does not contain the saddle; this happens for $0 \geq f > -5.9$. For $f < -8.1$, the lower barrier Λ_* contains the saddle and exhibits a dumbbell shape, and so does Λ; hence, $f_{\text{crit}} \in (-5.9, -8.1)$. The size of this interval depends on the size of the estimator $\mathcal{E}_h$ and decreases for smaller values of $\mathcal{E}_h$, as documented in Table 5.1. Although the true interface develops a singularity, it is worth noticing that $u \in W^2_\infty(\Omega)$ and thus no special refinement is needed to approximate either u (or σ). Moreover, $f + \Delta\chi \leq -16$ in Ω for the 4 loads, which shows that the double-cusp is not due to lack of stability. The interface estimate of Theorem 4.1 thus applies and provides a posteriori error control of the entire free boundary including the double-cusp.

A similar situation occurs in 3 dimensions, as depicted in Figure 5.4, for tolerance ≈ 0.25 and values $f = 0, -8.5, -15.1$. These pictures, as well as Figure 3.1, were created using the graphics package GRAPE [10]. For tolerance ≈ 0.1, we can predict that a double-cusp forms for $f_{\text{crit}} \in (-9.3, -13.9)$. The interval for other tolerances is shown in Table 5.1.

TABLE 5.1

From balls to bones: A posteriori control of the interval containing f_{crit} for different tolerances in 2 dimensions (left) and 3 dimensions (right).

Tolerance	Interval for f_{crit}
$\tau \approx 0.5$	$(-3.3, -17.0)$
$\tau \approx 0.1$	$(-5.1, -9.5)$
$\tau \approx 0.05$	$(-5.5, -8.8)$
$\tau \approx 0.01$	$(-5.9, -8.1)$
$\tau \approx 0.005$	$(-6.0, -7.3)$
$\tau \approx 0.001$	$(-6.5, -6.9)$

Tolerance	Interval for f_{crit}
$\tau \approx 0.5$	$(-8.0, -21.0)$
$\tau \approx 0.25$	$(-8.5, -15.1)$
$\tau \approx 0.1$	$(-9.3, -13.9)$

ESTIMATION OF HIGHER SOBOLEV NORM FROM LOWER ORDER APPROXIMATION*

CARSTEN CARSTENSEN†

Abstract. Given an accurate piecewise constant flux approximation q of a smooth (but unknown) exact flux p, how can one compute a Sobolev norm of p over a small domain ω? This question arises in a duality argument of goal-oriented finite element a posteriori error analysis. Two equivalent practical estimators η_M and $\eta_{\mathcal{E}}$ are presented for an approximation $|||q|||$ of $|p|_{H^1(\omega)}$ and model situations are addressed where $|||q|||$ is asymptotically an upper and +lower bound of $|p|_{H^1(\Omega)}$.

Key words. a posteriori error estimates, approximation of higher order Sobolev norms, reliability, efficiency, finite element method

1. Introduction.

Given a known approximation $q \in L^2(\Omega)$ to some unknown $p \in H^2(\Omega)$ and a parameter $s > 0$, the expression

$$|||q||| := \sup_{r \in H^1_0(\Omega)^n \setminus \{0\}} \left(\int_\Omega q \ \mathrm{div}\, r \, dx \right) / (\|r\|_{L^2(\Omega)} + s|r|_{H^1(\Omega)}) \tag{1.1}$$

is discussed as a computable approximation to $|p|_{H^1(\Omega)}$. (L^2, H^m, H^m_0 follow standard notation for Lebesgue and Sobolev spaces with their respective norms $\|\cdot\|_{L^2}, \|\cdot\|_{H^m}$ and seminorm $|\cdot|_{H^m}$.) Indeed, for $p \in H^2_0(\Omega)$, i.e., if p and ∇p vanish on the boundary $\partial\Omega$ of the bounded Lipschitz domain $\Omega \Subset \mathbb{R}^n$, there holds

$$\begin{aligned} &(\max\{0, |||q||| - \sqrt{n}s^{-1}\|p-q\|_{L^2(\Omega)}\})^2 \le |p|^2_{H^1(\Omega)} \\ &\le |||q|||^2 + 2|p|_{H^2(\Omega)}(2\sqrt{n}\|p-q\|_{L^2(\Omega)} + s|p|_{H^1(\Omega)}). \end{aligned} \tag{1.2}$$

The point is that q exclusively belongs to $L^2(\Omega)$ and is assumed to be close to the smoother $p \in H^2_0(\Omega)$. Provided

$$\lim_{(s, \|p-q\|_{L^2(\Omega)}) \to 0} \|p-q\|_{L^2(\Omega)}/s = 0,$$

the established estimate guarantees (for fixed p)

$$\lim_{(s, \|p-q\|_{L^2(\Omega)}) \to 0} |||q||| = |p|_{H^1(\Omega)}.$$

In other words, under some conditions to be discussed below, $|||q|||$ appears to be a highly accurate approximation to $|p|_{H^1(\Omega)}$. (Notice carefully that the limit for $s \to 0$ and $q \to p$ is subject to the above side condition $\|p-q\|_{L^2(\Omega)} = o(s)$ and so neither $s = 0$ nor $s = 1$ is representative of the results of this paper.)

The simple proof of (1.2) utilizes the direct consequence

$$|||p-q||| \le \sqrt{n}s^{-1}\|p-q\|_{L^2(\Omega)} \quad \text{and} \quad |||p||| \le |p|_{H^1(\Omega)} \tag{1.3}$$

of the definition (1.1) to show the lower bound in (1.2) via

$$|||q||| \le |||p||| + |||p-q||| \le |p|_{H^1(\Omega)} + \sqrt{n}s^{-1}\|p-q\|_{L^2(\Omega)}. \tag{1.4}$$

An integration by parts and the Cauchy and Young inequality lead to

$$\begin{aligned}
|p|^2_{H^1(\Omega)} &= \int_\Omega \nabla p \cdot \nabla p \, dx = -\int_\Omega p\,\Delta p \, dx \\
&= \int_\Omega (q-p)\Delta p \, dx - \int_\Omega q \,\mathrm{div}\,\nabla p \, dx \\
&\le \sqrt{n}\|q-p\|_{L^2(\Omega)}|p|_{H^2(\Omega)} + |||q|||(|p|_{H^1(\Omega)} + s|p|_{H^2(\Omega)}) \\
&\le |p|_{H^2(\Omega)}(\sqrt{n}\|p-q\|_{L^2(\Omega)} + s|||q|||) + \frac{1}{2}|||q|||^2 + \frac{1}{2}|p|^2_{H^1(\Omega)}
\end{aligned}$$

and so to the upper bound in (1.2) after $s|||q|||$ is estimated with (1.4).

The indicated proof of (1.2) uses integration by parts at some stage and so $p = 0$ and $\nabla p = 0$ on $\partial\Omega$ to avoid any boundary contribution. This paper generalizes (1.2) for the case $p \in H^2(\omega)$ without any restriction of p on the boundary $\partial\omega$ of a Lipschitz domain ω. One additional argument for that is based on a deeper remark due to Tartar on some interpolation spaces [Ta].

The task to compute an approximation to $|p|_{H^1(\omega)}$ arises naturally in the a posteriori error analysis as reported in section 2 below and is (partly) justified in this paper. There, $p = \partial z/\partial x_j$ is one component of the gradient of an unknown dual solution z. A computed approximation z_h to z provides a (known) piecewise constant $q = \partial z_h/\partial x_j \in L^2(\omega)\backslash H^1(\omega)$. Up to a weight $C\,\mathrm{diam}(\omega)$, the interpolation error by nodal interpolation $z - Iz$ is then bounded by (the sum over all $j = 1, \ldots, n$ of) $|p|_{H^1(\omega)} = |\partial z/\partial x_j|_{H^1(\omega)}$ approximated by $|||q|||$. Two computable estimates $\eta_M \approx \eta_{\mathcal{E}}$ of $|||q|||$ will be studied in section 4 below. The localized version is discussed in section 5 for a model scenario where strict efficiency and reliability of $|||q|||$ imply that a mesh much finer than $h_\omega = \mathrm{diam}(\omega)$ is required to compute q as an accurate approximation to p on ω.

2. Motivation and main application. Given a Lipschitz domain Ω and a Sobolev space

$$H := H^1_0(\Omega)^m := \{v \in H^1(\Omega)^m : v = 0 \text{ on } \partial\Omega\}$$

we consider the exact solution $u \in H$ of

$$a(u,v) = b(v) \quad \text{for all } v \in H \tag{2.1}$$

and its Galerkin approximation $u_h \in H_h \subset H$ with

$$a(u_h, v_h) = b(v_h) \quad \text{for all } v_h \in H_h. \tag{2.2}$$

Here, $a : H \times H \to \mathbb{R}$ is a bounded bilinear form and $b : H \to \mathbb{R}$ is a bounded linear form of the weak form of an elliptic PDE. The error $e := u - u_h$ is monitored with

respect to a particular norm or goal functional. The latter is a linear and bounded functional $J : H \to \mathbb{R}$. To bound or approximate $J(e)$ one considers the dual problem

$$a(v, z) = J(v) \quad \text{for all } v \in H \tag{2.3}$$

with an exact solution $z \in H$. Based on the Galerkin orthogonality

$$a(e, v_h) = 0 \quad \text{for all } v_h \in H_h \tag{2.4}$$

(which is an immediate consequence of (2.1)–(2.2)), one infers

$$J(e) = a(e, z) = a(e, z - z_h) \tag{2.5}$$

for any $z_h \in H_h$. Typically, the residual $a(e, \cdot)$ assumes a representation

$$a(e, v) = \int_\Omega R_\Omega \cdot v \, dx + \int_{\cup\mathcal{E}} R_\mathcal{E} \cdot v \, ds = \mathrm{Res}(v) \tag{2.6}$$

with volume residuals $R_\Omega \in L^2(\Omega)^m$ and edge residuals $R_\mathcal{E} \in L^2(\cup\mathcal{E})^m$ on the skeleton $\cup\mathcal{E}$ of all inner-element edges with respect to a regular triangulation $\mathcal{T}$ of Ω [AO, BaS]. If a is coercive,

$$\|z\|_H \le C_{stab} \|J\|_{H^*} \tag{2.7}$$

for some stability constant $C_{stab} > 0$. Then, standard a posteriori estimates of the given linear functional Res (with $\mathrm{Res}(z_h) = 0$) prove

$$\begin{aligned} a(e, z - z_h) = \mathrm{Res}(z) &\le \| \mathrm{Res} \|_{H^*} \, \|z\|_H \\ &\le \|J\|_{H^*} \, C_{stab} \, \| \mathrm{Res} \|_{H^*} \end{aligned} \tag{2.8}$$

and so (combining (2.5) and (2.8))

$$|J(e)| \le \|J\|_{H^*} \, C_{stab} \| \mathrm{Res} \|_{H^*}. \tag{2.9}$$

The main disadvantage of this a posteriori estimate is that the local influence of J and z is not reflected in the global constant $\|J\|_{H^*} \, C_{stab}$, i.e., the error estimation is essentially that of the energy error $\|e\|_H \approx \| \mathrm{Res} \|_{H^*}$. Any local information needs a computation of z or of an approximation z_h. We refer to [AO, Chapter 8] and [BaS, section 6.2] for guaranteed lower and upper bounds of $J(e)$ in terms of a parallelogram identity and global errors $\|\alpha e \pm \alpha^{-1}(z - z_h)\|^2$ for some parameter $\alpha > 0$. Becker and Rannacher [BR] advertised a different and local approach where, given $z \in H^2(\Omega)$, one selects $z_h := Iz$ as the (nodal) interpolant of z and obtains, with some constant $C_I > 0$,

$$h_T^2 \|z - Iz\|_{L^2(T)} + h_T^{3/2} \|z - Iz\|_{L^2(\partial T)} \le C_I |z|_{H^2(T)} \tag{2.10}$$

for any element $T \in \mathcal{T}$. Then (2.5)–(2.6) and (2.10) yield

$$\begin{aligned} |J(e)| &\le \sum_{T \in \mathcal{T}} \left(\|R_\Omega\|_{L^2(T)} \, \|z - Iz\|_{L^2(T)} + \|R_\mathcal{E}\|_{L^2(\partial T)} \, \|z - Iz\|_{L^2(\partial T)} \right) \\ &\le \sum_{T \in \mathcal{T}} C_I \left(h_T^2 \|R_\Omega\|_{L^2(T)} + h_T^{3/2} \|R_\mathcal{E}\|_{L^2(\partial T)} \right) |z|_{H^2(T)}. \end{aligned} \tag{2.11}$$

The point is that the upper bound involves the unknown H^2 seminorm $|z|_{H^2(T)}$ which is to be replaced by some discrete analogue based on a computed approximation z_h.

The main result of this paper, Theorem 3.2, allows for $z \in H^3(\omega)$ an estimate

$$|z|_{H^2(\omega)} \le c_1\eta + c_2\|\nabla z - q\|^{1/2}_{L^2(\omega)}, \tag{2.12}$$

where the constant c_1 only depends on the shape of elements (aspect ratio, maximal angle, etc.) and c_2 on ω and $\|z\|_{H^3(\omega)}$. The quantity $q = \nabla z_h$ is a computed approximation of $p = \nabla z$ on which the calculation of η is based. We suppose that $\|\nabla z - q\|_{L^2(\omega)} \to 0$ as the maximal mesh-size h tends to zero. Notice that, here, ω is fixed and the mesh that covers ω becomes finer and finer. Then, the left-hand side of (2.12) stays bounded as well as the constants c_1 and c_2 while $\|\nabla z - q\|^{1/2}_{L^2(\omega)} \to 0$ (as a consequence of energy norm convergence of the Galerkin approximation z_h to the exact solution z as $h \to 0$).

As an application of (2.12) to the goal-oriented a posteriori error estimate (2.11), suppose that (2.12) holds for $\eta_\omega := \eta$ and any domain ω from a partition $\mathcal{P}$ of Ω subordinated to $\mathcal{T}$ (i.e., each domain $\omega \in \mathcal{P}$ is the interior of a union $\cup\mathcal{T}_\omega$ of elements in $\mathcal{T}_\omega \subset \mathcal{T}$ such that $\overline{\cup\mathcal{P}} = \overline{\Omega}$ and two distinct ω_1 and ω_2 in $\mathcal{P}$ are disjoint). Then, (2.11)–(2.12) yield

$$\begin{aligned} |J(e)| &\le \sum_{\omega\in\mathcal{P}} C_I\,(c_1\eta_\omega + \text{h.o.t.}) \\ &\quad\times \left(\sum_{T\in\mathcal{T}_\omega} \left(h_T^2\,\|R_\Omega\|_{L^2(T)} + h_T^{3/2}\,\|R_\mathcal{E}\|_{L^2(\partial T)}\right)^2\right)^{1/2} \end{aligned} \tag{2.13}$$

with higher order terms (h.o.t.) which tend to zero as $\|\nabla z - q\|_{L^2(\omega)}$ does with $h \to 0$. Notice that, up to h.o.t., the right-hand side of (2.13) is fully computable.

Two examples for the computable quantity $\eta = \eta_\omega$ are suggested in section 4, namely (with the $\mathcal{T}$-piecewise affine and globally continuous functions $\mathcal{S}^1(\mathcal{T})$, with the jumps $[q]$ across an inner element edge, and with the skeleton $\cup\mathcal{E}_\omega$ of such edges)

$$\eta = \min_{Q\in\mathcal{S}^1(\mathcal{T})} \|q - Q\|_{L^2(\omega)} \quad \text{or} \quad \eta = \|h_\mathcal{E}^{1/2}[q]\|_{L^2(\cup\mathcal{E}_\omega)}$$

for a piecewise constant $q = \nabla z_h$. Some remarks on the efficiency and on the situation with domains ω that shrink with $h \to 0$ follow in section 5.

With the above result (2.13), the approach from [BR] is justified for a fixed partition $\mathcal{P}$ and finer and finer triangulations $\mathcal{T}$.

3. Main result. The announced local version of (1.2) aims the estimation of $|p|_{H^1(\omega)}$ for a subdomain $\omega \subset \Omega$. Then, $p \not\equiv 0$ on $\partial\omega$ causes technical difficulties. To overcome them we work with Besov spaces that do not see boundary effects and employ the following known result.

THEOREM 3.1 (Tartar, Brezzi–Marini–Süli). *Given a Lipschitz domain $\omega \Subset \mathbb{R}^d$ of diameter h_ω there exists a constant $c(\omega) > 0$ such that*

$$\begin{aligned} &\forall t > 0\,\forall v \in H^1(\omega)\,\exists a \in L^2(\omega)\,\exists b \in H^1_0(\omega), v = a + b \text{ and} \\ &t^{-1/2}\|a\|_{L^2(\omega)} + t^{1/2}|b|_{H^1(\omega)} \\ &\quad\le c(\omega)\|v\|^{1/2}_{L^2(\omega)}\left(|v|^2_{H^1(\omega)} + \|v\|^2_{L^2(\omega)}/h_\omega^2\right)^{1/4}. \end{aligned}$$

The constant $c(\omega)$ depends only on the shape of ω and not on h_ω.

Sketch of the proof. The assertion follows from the analysis in [BMS, section 3] and hence we give solely an introduction to the arguments for a convenient reading. Two interpolation spaces,

$$X(\infty,\omega) = [L^2(\omega), H^1_0(\omega)]_{1/2,\infty} = \mathring{B}^{1/2}_{2,\infty}(\omega),$$
$$Y(1,\omega) = [L^2(\omega), H^1(\omega)]_{1/2,1} = B^{1/2}_{2,1}(\omega)$$

(identified with certain Besov spaces), are compared in a result due to Tartar [Ta], namely, for all $v \in H^1(\omega)$,

$$\|v\|_{X(\infty,\omega)} \le c_1(\omega)\|v\|_{Y(1,\omega)}.$$

The two norms are defined by real interpolation of Sobolev spaces with slightly different norms

$$\|v\|_{X(\infty,\omega)} = \operatorname{ess}\sup_{0<t<\infty} \inf\{t^{-1/2}\|a\|_{L^2(\omega)} + t^{1/2}|b|_{H^1(\omega)} : v = a+b, a \in L^2(\omega), b \in H^1_0(\omega)\},$$
$$\|v\|_{Y(1,\omega)} = \int_0^\infty \inf\{t^{-3/2}\|a\|_{L^2(\omega)} + t^{-1/2}(|b|^2_{H^1(\omega)} + \|b\|^2_{L^2(\omega)}/h^2_\omega)^{1/2} : v = a+b, a \in L^2(\omega), b \in H^1(\omega)\}\, dt.$$

The point is that the function b in $\|v\|_{X(\infty,\omega)}$ vanishes on $\partial\omega$ (and so only the H^1 seminorm arises) while there is no such restriction on b in $\|v\|_{Y(1,\omega)}$ (and hence the scaled L^2 norm arises). Given $v \in H^1(\omega)$ and $t > 0$, there exist $a \in L^2(\omega)$ and $b \in H^1_0(\omega)$ such that $v = a + b$ and

$$t^{-1/2}\|a\|_{L^2(\omega)} + t^{1/2}|b|_{H^1(\omega)} \le 2\|v\|_{X(\infty,\omega)}.$$

(This follows immediately from the definition of $\|v\|_{X(\infty,\omega)}$.) The norm $\|v\|_{Y(1,\omega)}$ is bounded from above by the interpolation estimate

$$\|v\|_{Y(1,\omega)} \le c_2(\omega)\|v\|^{1/2}_{L^2(\omega)}(|v|^2_{H^1(\omega)} + \|v\|^2_{L^2(\omega)}/h^2_\omega)^{1/4}$$

in Besov spaces [Tr]. A scaling argument justifies that $c_2(\omega)$ is h_ω independent [BMS]. The combination of the three estimates proves the theorem with $c(\omega) = 2c_1(\omega)c_2(\omega)$. □

The main result of this paper concerns a smooth function p and its approximation q with a seminorm $|||q|||$ such that

$$|p|_{H^1(\omega)} \le |||q||| + \text{h.o.t.},$$

where h.o.t. $\to 0$ as $\|p-q\|_{L^2(\omega)} + s|||q||| \to 0$ for fixed $p \in H^2(\omega)$. (Arguing as in (1.4), the latter follows merely from $s \to 0$ and $\|p-q\|_{L^2(\omega)} \to 0$ for fixed $p \in H^1(\omega)$.)

THEOREM 3.2. *Suppose $p \in H^2(\omega)$ and $q \in L^2(\omega)$ for a bounded Lipschitz domain ω in $\mathbb{R}^n$. Let $s > 0$ and let $|||q|||$ be given by*

$$|||q||| := \sup_{r \in H^1_0(\omega)^d \setminus \{0\}} \int_\omega q \operatorname{div} r\, dx / (\|r\|_{L^2(\omega)} + s|r|_{H^1(\omega)}). \tag{3.1}$$

Let $c(\omega)$ denote the h_ω-independent constant from Theorem 3.1. *Then there holds*

$$|p|_{H^1(\omega)} \le |||q||| + c(\omega)\sqrt{8}\left(|p|^2_{H^1(\omega)}/h^2_\omega + |p|^2_{H^2(\omega)}\right)^{1/4} \times \left(\sqrt{n}\|p-q\|_{L^2(\omega)} + s|||q|||\right)^{1/2}. \tag{3.2}$$

Proof. Set $t := (\sqrt{n}\|p-q\|_{L^2(\omega)} + s|||q|||)/|p|_{H^1(\omega)} > 0$ and choose $a_1, \dots, a_n \in L^2(\omega)$ and $b_1, \dots, b_n \in H^1_0(\omega)$ for each $j = 1, \dots, n$ from Theorem 3.1 with $a_j + b_j = \partial p/\partial x_j$ and

$$\begin{aligned} &t^{-1/2}\|a_j\|_{L^2(\omega)} + t^{1/2}|b_j|_{H^1(\omega)} \\ &\le c(\omega)\|\partial p/\partial x_j\|^{1/2}_{L^2(\omega)}\left(|\partial p/\partial x_j|^2_{H^1(\omega)} + \|\partial p/\partial x_j\|^2_{L^2(\omega)}/h^2_\omega\right)^{1/4}. \end{aligned}$$

Write $a = (a_1, \dots, a_n)$ and b as vectors. Cauchy inequalities verify

$$\begin{aligned} &1/2\left(t^{-1/2}\|a\|_{L^2(\omega)} + t^{1/2}|b|_{H^1(\omega)}\right)^2 \le t^{-1}\|a\|^2_{L^2(\omega)} + t|b|^2_{H^1(\omega)} \\ &\le c(\omega)^2 \sum_{j=1}^d \|\partial p/\partial x_j\|_{L^2(\omega)}\left(|\partial p/\partial x_j|^2_{H^1(\omega)} + \|\partial p/\partial x_j\|^2_{L^2(\omega)}/h^2_\omega\right)^{1/2} \\ &\le c(\omega)^2|p|_{H^1(\omega)}(|p|^2_{H^2(\omega)} + |p|^2_{H^1(\omega)}/h^2_\omega)^{1/2}. \end{aligned}$$

This and the definition of t yield

$$\begin{aligned} \|a\|_{L^2(\omega)} + t|b|_{H^1(\omega)} &\le \sqrt{2t}\, c(\omega)|p|^{1/2}_{H^1(\omega)}(|p|^2_{H^2(\omega)} + |p|^2_{H^1(\omega)}/h^2_\omega)^{1/4} \\ &\le \sqrt{2}\, c(\omega)\left(\sqrt{n}\|p-q\|_{L^2(\omega)} + s|||q|||\right)^{1/2} \\ &\quad \times \left(|p|^2_{H^2(\omega)} + |p|^2_{H^1(\omega)}/h^2_\omega\right)^{1/4}. \end{aligned} \tag{3.3}$$

On the other hand, $Dp = a + b$, a Cauchy inequality, and an integration by parts (notice $b = 0$ on $\partial\omega$) lead to

$$\begin{aligned} |p|^2_{H^1(\omega)} &= \int_\omega a \cdot Dp\, dx + \int_\omega b \cdot Dp\, dx \\ &\le \|a\|_{L^2(\omega)}\, |p|_{H^1(\omega)} - \int_\omega p \operatorname{div} b\, dx. \end{aligned} \tag{3.4}$$

The definition of $|||q|||$ in (3.1) shows

$$\begin{aligned} -\int_\omega p \operatorname{div} b\, dx &= -\int_\omega q \operatorname{div} b\, dx + \int_\omega (q-p)\operatorname{div} b\, dx \\ &\le |||q|||(\|b\|_{L^2(\omega)} + s|b|_{H^1(\omega)}) + \|p-q\|_{L^2(\omega)}\sqrt{n}\, |b|_{H^1(\omega)}. \end{aligned}$$

This, the definition of t, and $\|b\|_{L^2(\omega)} \le \|a\|_{L^2(\omega)} + |p|_{H^1(\omega)}$ result in

$$-\int_\omega p \operatorname{div} b\, dx \le |||q|||(\|a\|_{L^2(\omega)} + |p|_{H^1(\omega)}) + t|b|_{H^1(\omega)}|p|_{H^1(\omega)}. \tag{3.5}$$

The combination of (3.4)–(3.5) reads

$$|p|^2_{H^1(\omega)} \le |p|_{H^1(\omega)}(\|a\|_{L^2(\omega)} + t|b|_{H^1(\omega)} + |||q|||) + \|a\|_{L^2(\omega)}|||q|||,$$

and so with $\alpha := |p|_{H^1(\omega)}$, $\beta := |||q|||$, $\gamma := \|a\|_{L^2(\omega)} + t|b|_{H^1(\omega)}$,

$$\alpha^2 \leq \alpha(\beta+\gamma) + \beta\gamma = \alpha(\beta+2\gamma) + \beta\gamma - \alpha\gamma.$$

This is recast into

$$\alpha(\alpha+\gamma) \leq \alpha(\beta+2\gamma) + \beta\gamma \leq (\alpha+\gamma)(\beta+2\gamma)$$

and hence shows $\alpha \leq \beta + 2\gamma$, i.e.,

$$|p|_{H^1(\omega)} \leq |||q||| + 2(\|a\|_{L^2(\omega)} + t|b|_{H^1(\omega)}).$$

This and (3.3) conclude the proof. □

4. Computable bounds for $|||q|||$. This section concerns the estimation of $|||q|||$ by $\eta_{\mathcal{E}}$ and η_M for piecewise constant q. Throughout this section and subsequently, $A \lesssim B$ abbreviates an estimate $A \leq CB$ with a generic constant C (referred to as the multiplicative constant hidden in $A \lesssim B$) that depends on the dimension n and on the shape (not the size h_ω) of the domain ω through $c(\omega)$ of Theorem 3.1. The gradient of a scalar is written ∇ and the functional matrix of a vector valued function is written D.

DEFINITION 4.1. *Let ω be a bounded Lipschitz domain covered by the regular triangulation $\mathcal{T}_\omega$. Let $\mathcal{E}_\omega$ denote the set of edges inside $\cup\mathcal{T}_\omega \supset \overline{\omega}$, i.e., for any $E \in \mathcal{E}_\omega$ there exist $T_1, T_2 \in \mathcal{T}_\omega$ with $E = T_1 \cap T_2$. Given a triangulation $\mathcal{T}$ (resp., a set $\mathcal{E}$ of edges), let $\mathcal{L}^k(\mathcal{T})$ (resp., $\mathcal{L}^k(\mathcal{E})$) denote the $\mathcal{T}$-piecewise (resp., $\mathcal{E}$-piecewise) polynomials of degree $\leq k$ and set $\mathcal{S}^1(\mathcal{T}) := \mathcal{L}^1(\mathcal{T}) \cap C(\cup\mathcal{T})$.*

Given $q \in \mathcal{L}^0(\mathcal{T}_\omega)$, let $[q] \in \mathcal{L}^0(\mathcal{E}_\omega)$ denote its $\mathcal{E}_\omega$-piecewise constant jumps across the skeleton $\cup\mathcal{E}_\omega = \{x \in \overline{\Omega} : x \in E \in \mathcal{E}_\omega\}$, i.e., $[q]|_E := q|_{T_2} - q|_{T_1}$, where the normal ν_E along E points into T_2. Let $h_{\mathcal{E}} \in \mathcal{L}^0(\mathcal{E}_\omega)$ denote the $\mathcal{E}_\omega$-piecewise constant edge size, $h_{\mathcal{E}}|_E := h_E := \operatorname{diam}(E)$ for any $E \in \mathcal{E}_\omega$; recall that $h_{\mathcal{T}} \in \mathcal{L}^0(\mathcal{T}_\omega)$ denotes the $\mathcal{T}_\omega$-piecewise constant element size, $h_{\mathcal{T}}|_T := h_T := \operatorname{diam}(T)$ for any $T \in \mathcal{T}_\omega$. Then, let $\hat{\omega} := \operatorname{int}(\cup\mathcal{T}_\omega)$ and set

$$\eta_{\mathcal{E}} := \|h_{\mathcal{E}}^{-1/2}[q]\|_{L^2(\cup\mathcal{E}_\omega)} := \left(\sum_{E\in\mathcal{E}_\omega} h_E^{-1}\|[q]\|^2_{L^2(E)}\right)^{1/2}, \tag{4.1}$$

$$\eta_M := \min_{Q\in\mathcal{S}^1(\mathcal{T}_\omega)} \|(q-Q)/h_{\mathcal{T}}\|_{L^2(\hat{\omega})}. \tag{4.2}$$

The following theorem essentially asserts equivalence of $|||q||| \approx \eta_M \approx \eta_{\mathcal{E}}$ whenever the mesh-size $h_{\mathcal{T}} \approx s$ on ω is equivalent to the parameter $s > 0$.

THEOREM 4.2. *Given any $q \in \mathcal{L}^0(\mathcal{T}_\omega)$, define η_M and $\eta_{\mathcal{E}}$ by (4.1) and (4.2), respectively. Then there holds*

$$\sup_{r\in H^1_0(\omega)^n\setminus\{0\}} \int_\omega q \operatorname{div} r\, dx/(\|r\|_{L^2(\omega)} + \|h_{\mathcal{T}}Dr\|_{L^2(\omega)}) \lesssim \eta_M$$
$$\lesssim \eta_{\mathcal{E}} \lesssim \sup_{\hat{r}\in H^1_0(\hat{\omega})^n\setminus\{0\}} \int_{\hat{\omega}} q \operatorname{div} \hat{r}\, dx/(\|\hat{r}\|_{L^2(\hat{\omega})} + \|h_{\mathcal{T}}D\hat{r}\|_{L^2(\hat{\omega})}).$$

Proof. Given any $Q \in \mathcal{S}^1(\mathcal{T}_\omega)$ and $r \in H^1_0(\omega)^n$ (extended by zero outside ω) an

integration by parts and a Cauchy inequality show

$$\int_\omega q \operatorname{div} r\,dx = \int_\omega Q \operatorname{div} r\,dx + \int_\omega (q-Q)\operatorname{div} r\,dx \leq -\int_\omega r\cdot DQ\,dx + \sqrt{n}\|h_{\mathcal{T}} Dr\|_{L^2(\omega)}\|(q-Q)/h_{\mathcal{T}}\|_{L^2(\omega)}. \tag{4.3}$$

Let $D_{\mathcal{T}}$ denote the $\mathcal{T}_\omega$-piecewise action of the gradient operator D, e.g., $D_{\mathcal{T}} q = 0$ almost everywhere in ω. Then, a Cauchy inequality and an elementwise inverse estimate, i.e., $\|D(Q-q)\|_{L^2(T)} \lesssim \|q-Q\|_{L^2(T)}/h_T$, lead to

$$\begin{aligned} -\int_\omega r\cdot DQ\,dx &\leq \|r\|_{L^2(\omega)}\|D_{\mathcal{T}}(q-Q)\|_{L^2(\omega)} \\ &\lesssim \|r\|_{L^2(\omega)}\|(q-Q)/h_{\mathcal{T}}\|_{L^2(\cup\mathcal{T}_\omega)}. \end{aligned} \tag{4.4}$$

(Notice that $\cup\mathcal{T}_\omega$ may be larger than ω and, for simplicity, we employ the inverse estimate on complete elements.) The combination of (4.3)–(4.4) shows

$$\sup_{r\in H^1_0(\omega)^n\setminus\{0\}} \int_\omega q\operatorname{div} r\,dx/(\|r\|_{L^2(\omega)} + \|h_{\mathcal{T}} Dr\|_{L^2(\omega)}) \lesssim \eta_M.$$

The proof of $\eta_M \lesssim \eta_{\mathcal{E}}$ follows ideas from [C2, CB]. Let $(\varphi_z : z\in\mathcal{N})$ be a nodal basis of $\mathcal{S}^1(\mathcal{T}_\omega)$. Then $\sum_{z\in\mathcal{N}}\varphi_z = 1$ almost everywhere on $\hat\omega := \cup\mathcal{T}_\omega$ and so, for some $Q = \sum_{z\in\mathcal{N}} q_z\varphi_z$,

$$\begin{aligned} \eta_M^2 = \|(q-Q)/h_{\mathcal{T}}\|^2_{L^2(\hat\omega)} &= \Big\|\sum_{z\in\mathcal{N}}(q-q_z)\varphi_z/h_{\mathcal{T}}\Big\|^2_{L^2(\hat\omega)} \\ &= \sum_{T\in\mathcal{T}}\Big\|\sum_{z\in\mathcal{N}(T)}(q-q_z)\varphi_z\Big\|^2_{L^2(T)}/h_T^2. \end{aligned}$$

Since $\mathcal{N}(T) := \{z\in\mathcal{N} : z\in T\}$ has a bounded cardinality,

$$\Big\|\sum_{z\in\mathcal{N}(T)}(q-q_z)\varphi_z\Big\|^2_{L^2(T)} \lesssim \sum_{z\in\mathcal{T}}\|(q-q_z)\varphi_z\|^2_{L^2(T)}.$$

With $h_T \approx h_z$ for $z\in\mathcal{N}(T)$, $T\in\mathcal{T}$, we have shown

$$\begin{aligned} \eta_M^2 &\lesssim \min_{(q_z:\, z\in\mathcal{N})}\sum_{T\in\mathcal{T}}\sum_{z\in\mathcal{N}(T)}\|(q-q_z)\varphi_z\|^2_{L^2(T)}/h_z^2 \\ &= \min_{(q_z:\, z\in\mathcal{N})}\sum_{z\in\mathcal{N}}\|(q-q_z)\varphi_z\|^2_{L^2(\hat\omega)}/h_z^2 \\ &= \sum_{z\in\mathcal{N}}\min_{q_z\in\mathbb{R}}\|(q-q_z)\varphi_z\|^2_{L^2(\omega_z)}/h_z^2. \end{aligned} \tag{4.5}$$

For each node $z\in\mathcal{N}$ with patch $\omega_z := \operatorname{int}(\cup\{T\in\mathcal{T}_\omega : z\in T\})$, $q|_{\omega_z}$ belongs to a finite dimensional space $\mathcal{L}^0(\mathcal{T}_\omega|_{\omega_z}) := \{q|_{\omega_z} : q\in\mathcal{T}_\omega)\}$. Notice that

$$\begin{aligned} |\!|\!|q|\!|\!|_{z,1} &:= \min_{q_z\in\mathbb{R}}\|(q-q_z)\varphi_z\|_{L^2(\omega_z)}/h_z, \\ |\!|\!|q|\!|\!|_{z,2} &:= \|h_{\mathcal{E}}^{-1/2}[q]\|_{L^2(\cup\mathcal{E}_z)} \quad \text{with } \mathcal{E}_z := \{E\in\mathcal{E}_\omega : z\in E\}, \end{aligned}$$

define two seminorms on $\mathcal{L}^0(\mathcal{T}_\omega|_{\omega_z})$ with zero-set $\mathcal{P}_0(\omega_z)$ (i.e., $|||q|||_{z,j} = 0$ implies q is constant on ω_z). Hence $|||\cdot|||_{z,1}$ and $|||\cdot|||_{z,2}$ are norms on the quotient space $\mathcal{L}^0(\mathcal{T}_\omega|_{\omega_z})/\mathcal{P}_0(\omega_z)$ of a finite dimension $\leq \mathrm{card}(\mathcal{T}_\omega) \lesssim 1$. Since two norms on a finite dimensional space are equivalent we have

$$|||q|||_{z,1} \approx |||q|||_{z,2} \quad \text{for all } q \in \mathcal{L}^0(\mathcal{T}_\omega). \tag{4.6}$$

A scaling argument shows that the equivalence constants in (4.6) are h_z independent. Therefore, we deduce in (4.5) that

$$n_M^2 \lesssim \sum_{z\in\mathcal{N}} \|h_{\mathcal{E}}^{-1/2}[q]\|^2_{L^2(\cup\mathcal{E}_z)} \lesssim \eta_{\mathcal{E}}^2$$

(since the overlap of $(\cup\mathcal{E}_z : z \in \mathcal{N})$ is finite). It remains for us to prove the last asserted inequality with the inverse estimate technique from [V]. For $E = T_1 \cap T_2 \in \mathcal{E}_\omega$ let b_E denote the edge bubble defined through $b_E|_E \in \mathcal{P}_d(E)$, $b_E|_{T_j}$ is the product of all barycentric coordinates λ_ℓ on T_j with respect to a vertex of E. We regard $b_E \in H^1_0(\omega_E)$ as a function in $H^1(\mathbb{R}^d)$ which vanishes outside ω_E. Then,

$$0 \leq b_E \leq 1, \quad \|b_E\|_{L^2(E)} \approx |E|^{1/2},$$
$$\int_E b_E\,ds \approx |E|, \quad |b_E|_{H^1(\omega_E)} \approx |\omega_E|^{1/2}/h_E.$$

Set $J_E := [q]|_E \in \mathbb{R}$ and estimate

$$h_E^{-1}\|[q]\|^2_{L^2(E)} \approx J_E/h_E \int_E b_E[q]\,ds = J_E/h_E \int_E (b_E\nu_E)\cdot[q\,\nu_E]\,ds$$

for the unit normal vector ν_E along E. The elementwise application of the Gaussian divergence theorem to $q\,Db_E$ yields

$$h_E^{-1}\|[q]\|^2_{L^2(E)} \approx J_E/h_E \int_{\omega_E} (Db_E\cdot\nu_E)q\,dx.$$

The sum over all $E \in \mathcal{E}_\omega$ verifies

$$\eta_{\mathcal{E}}^2 \approx \int_{\hat\omega} fq\,dx \quad \text{for } f := \sum_{E\in\mathcal{E}_\omega} J_E(Db_E\cdot\nu_E)/h_E.$$

Since ν_E is constant, $Db_E\cdot\nu_E = \mathrm{div}(b_E\nu_E)$ and so

$$\eta_{\mathcal{E}}^2 \lesssim \int_{\hat\omega} q\,\mathrm{div}\,\hat r\,dx \quad \text{for } \hat r := \sum_{E\in\mathcal{E}_\omega} J_E(b_E/h_E)\,\nu_E \in H^1_0(\hat\omega)^n.$$

It therefore remains to verify

$$\|\hat r\|_{L^2(\hat\omega)} + \|h_{\mathcal{T}} D\hat r\|_{L^2(\hat\omega)} \lesssim \eta_{\mathcal{E}}. \tag{4.7}$$

For each $E \in \mathcal{E}_\omega$ we have

$$\begin{aligned}
&\|J_E b_E\,\nu_E/h_E\|^2_{L^2(\hat\omega)} + h_E^2\|J_E\,Db_E\otimes\nu_E/h_E\|^2_{L^2(\omega_E)}\\
&\approx |J_E|^2(\|b_E\|^2_{L^2(\omega_E)}/h_E^2 + |b_E|^2_{H^1(\omega_E)})\\
&\approx |J_E|^2|\omega_E|/h_E^2 \approx h_E\|[q]\|^2_{L^2(E)}.
\end{aligned}$$

Since $(\omega_E : E \in \mathcal{E}_\omega)$ has finite overlap, the sum of the last equivalences over all $E \in E_\omega$ verifies (4.7). This concludes the proof. ∎

Remark 4.1. With arguments of [C1, C2, V] it can be shown that η_M is equivalent to

$$\eta_A := \|(q - Aq)/h_{\mathcal{T}}\|_{L^2(\hat{\omega})}, \text{ where } Aq = \sum_{z \in \mathcal{N}} (Aq)(z)\, \varphi_z$$

with the local integral mean $(Aq)(z) := \int_{\omega_z} q\, dx/|\omega_z|$ of q over the patch ω_z of a node $z \in \mathcal{N}$.

5. Discussion. This section is devoted to a discussion about the implications and limitations of the usage of $|||q|||$ (or some computable approximation thereof) as an estimator for $|p|_{H^1(\omega)}$ for a fixed $p \in H^2(\Omega)$ and varying parameters h_ω (the diameter of $\omega \subset \Omega$) or mesh-size $h_{\min,\omega}$ and $h_{\max,\Omega}$ for the minimal and maximal mesh-size of the mesh $\mathcal{T}$ (used for the computation of q) on ω and Ω, respectively. Recall that $\|\!|q|\!\|$ defined in (3.1) involves a parameter $s > 0$ to be chosen properly.

5.1. The concepts of (strict) efficiency and reliability. The estimator $\|\!|q|\!\|$ is called *efficient* if

$$\text{(E)} \qquad \big(s^{-1}\|p - q\|_{L^2(\omega)} \lesssim |p|_{H^1(\omega)}\big)$$

(since then $\|\!|q|\!\| \lesssim |p|_{H^1(\omega)}$ by the arguments of (1.4)) and called *strict efficient* if

$$\text{(SE)} \qquad \big(s^{-1}\|p - q\|_{L^2(\omega)} \ll |p|_{H^1(\Omega)}\big)$$

(since then $\|\!|q|\!\| \le |p|_{H^1(\omega)} + o(1)$). The notation $A \ll B$ means that A/B is very small for small $h_{\max,\Omega}$ in the sense that $\lim_{h_{\max,\Omega} \to 0} A/\, B = 0$. The estimator $\|\!|q|\!\|$ is called *reliable* if

$$\text{(R)} \qquad \big(|p|_{H^1(\omega)}/h_\omega + |p|_{H^2(\omega)}\big)\, \big(\|p - q\|_{L^2(\omega)} + s\|\!|q|\!\|\big) \lesssim \|\!|q|\!\|^2$$

(since then $|p|_{H^1(\omega)} \lesssim \|\!|q|\!\|$ by Theorem 3.2) and called *strict reliable* if

$$\text{(SR)} \qquad \big(|p|_{H^1(\omega)}/h_\omega + |p|_{H^2(\omega)}\big)\, \big(\|p - q\|_{L^2(\omega)} + s\|\!|q|\!\|\big) \ll |p|^2_{H^1(\omega)}$$

(since then $|p|_{H^1(\omega)} \le \|\!|q|\!\| + o(1)|p|_{H^1(\omega)}$ and so $|p|_{H^1(\omega)} \le \|\!|q|\!\|(1 + o(1))$ for sufficiently small $h_{\max,\Omega}$).

Notice carefully that (each of) the concepts (E), (SE), (R), (SR) based on (1.4) and (3.2) are sufficient (but possibly not necessary) conditions for a justification of $\|\!|q|\!\| \approx |p|_{H^1(\omega)}$.

5.2. Implications of (E) and (R). This subsection is devoted to discussing necessary conditions for (E) and (R). If (E) holds, then

$$\|p - q\|_{L^2(\omega)} \lesssim s|p|_{H^1(\omega)}. \tag{5.1}$$

Assuming that $q = \nabla z_h$ is a first-order finite element approximation of $p = \nabla z$, the nodal interpolation error $|z - Iz|_{H^1(\omega)}$ is generically of size $\|hD^2 z\|_{L^2(\omega)}$ and a lower bound of $\|\nabla z - \nabla z_h\|_{L^2(\omega)}$. For the purpose of this discussion we will therefore suppose the estimate

$$h_{\min,\omega}|p|_{H^1(\omega)} \lesssim \|p - q\|_{L^2(\omega)}. \tag{5.2}$$

This hypothesis is untrue in very particular situations and we thereby exclude it from this discussion. Then, (5.1)–(5.2) imply

$$h_{\min,\omega} \lesssim s. \tag{5.3}$$

From (R) and $|||q||| \lesssim |p|_{H^1(\omega)}$ (a consequence of (E)) one deduces

$$\big(|p|_{H^1(\omega)}/h_\omega\big)\, s|||q||| \lesssim |||q|||\, |p|_{H^1(\omega)}$$

and so (assuming $0 < |p|_{H^1(\omega)}\, |||q|||$)

$$s \lesssim h_\omega. \tag{5.4}$$

In particular, $h_{\min,\omega} \lesssim s \lesssim h_\omega$. Thus, h_ω may *not* be much smaller than the mesh-size $h_{\min,\omega}$ on ω. Moreover, the aforementioned arguments suggest under the hypothesis (SE), (SR), and (5.2) that

$$h_{\min,\omega} \ll s \ll h_\omega. \tag{5.5}$$

This clearly enforces an approximation of q on a mesh much finer than $h_\omega = \operatorname{diam}(\omega)$. The analysis of this paper guarantees $|||q||| = |p|_{H^1(\omega)} + o(1)$ only if (5.5) holds.

5.3. Theoretical choice of s. The choice of $s := \|p-q\|_{L^2(\omega)}/|p|_{H^1(\omega)}$ immediately implies (E). Furthermore, this and

$$\|p-q\|_{L^2(\omega)} \big(|p|_{H^1(\omega)}/h_\omega + |p|_{H^2(\omega)}\big) \lesssim |||q|||^2 \tag{5.6}$$

imply (R). Hence, given a fixed $p \in H^2(\Omega)$ and a fixed domain ω, the condition

$$\|p-q\|_{L^2(\omega)} \to 0 \quad \text{as } h_{\max,\Omega} \to 0$$

and the above choice of s imply (E) and (R).

Proof. The left-hand side of (5.6) tends to zero and so either there holds (R) for sufficiently small $h_{\max,\Omega}$ or $|||q||| \to 0$ as $h_{\max,\Omega} \to 0$. The latter option is excluded for fixed $|p|_{H^1(\omega)} > 0$. ∎

The disadvantage of this choice of s is that it is unknown but required in the computation of $|||q|||$ in (3.1).

5.4. Asymptotic regime for $(h_\omega, h_{\max,\Omega}) \to 0$. To analyze sufficient conditions for (E) and (R) in the limit for $(h_\omega, h_{\max,\Omega}) \to 0$ we suppose that

$$H := h_{\max,\Omega}, \quad h_\omega = H^\alpha, \quad s = H^\beta, \quad \text{and } h_{\min,\omega} = H^\gamma$$

for some convergence rates $\alpha, \beta, \gamma > 0$. For instance, a uniform mesh leads to $\gamma = 1$ and $\alpha < 1$ indicates that the mesh is finer and finer than the size of the domain ω. From (5.2)–(5.4) we obtain $\alpha \le \beta \le \gamma$ as necessary conditions for (E) and (R) and $\alpha < \beta < \gamma$ as necessary conditions for (SE) and (SR). Sufficient conditions include the inverse assumption

$$|p|_{H^1(\omega)} + h_\omega\, |p|_{H^2(\omega)} \lesssim |p|_{H^1(\omega)} \tag{5.7}$$

(generically implied for a fixed $p \in H^2(\Omega)$ as ω varies) and the approximation estimate

$$\|p-q\|_{L^2(\omega)}/|p|_{H^1(\omega)} \lesssim H^\beta. \tag{5.8}$$

Then (5.7)–(5.8) and $\alpha < \beta$ imply (E) and (SR). (The proofs are immediate with the arguments already mentioned.)

It seems to be an open question to design weaker conditions sufficient for (weaker versions of) reliability. Theorem 3.2 suggests looking at the constants in (3.2) which, under the assumptions (5.7)–(5.8), leads to

$$|p|_{H^1(\omega)} \leq |||q||| + cH^{(\beta-\alpha)/2}\, |p|^{1/2}_{H^1(\omega)} \left(|p|_{H^1(\omega)} + |||q|||\right)^{1/2}. \tag{5.9}$$

In fact, that constant $c > 0$ depends on n, $c(\omega)$, and the constants involved in (5.7)–(5.8). For instance, if $\alpha < \beta$ and H is small or if $\alpha = \beta$ and $c < 1$ then (5.9) yields $|p|_{H^1(\omega)} \lesssim |||q|||$.

ORTHOGONAL HESSENBERG REDUCTION AND ORTHOGONAL KRYLOV SUBSPACE BASES*

JÖRG LIESEN† AND PAUL E. SAYLOR‡

Abstract. We study necessary and sufficient conditions that a nonsingular matrix A can be B-orthogonally reduced to upper Hessenberg form with small bandwidth. By this we mean the existence of a decomposition $AV = VH$, where H is upper Hessenberg with few nonzero bands, and the columns of V are orthogonal in an inner product generated by a hermitian positive definite matrix B. The classical example for such a decomposition is the matrix tridiagonalization performed by the hermitian Lanczos algorithm, also called the orthogonal reduction to tridiagonal form. Does there exist such a decomposition when A is nonhermitian? In this paper we completely answer this question. The related (but not equivalent) question of necessary and sufficient conditions on A for the existence of short-term recurrences for computing B-orthogonal Krylov subspace bases was completely answered by the fundamental theorem of Faber and Manteuffel [*SIAM J. Numer. Anal.*, 21 (1984), pp. 352–362]. We give a detailed analysis of B-normality, the central condition in both the Faber–Manteuffel theorem and our main theorem, and show how the two theorems are related. Our approach uses only elementary linear algebra tools. We thereby provide new insights into the principles behind Krylov subspace methods, that are not provided when more sophisticated tools are employed.

1. Introduction.

The decompositional approach to matrix computations, formalized by Householder in the 1950s, is counted among the "Top 10" algorithmic ideas of the 20th century [2]. One of the best known of these decompositions is the tridiagonalization of a nonsingular hermitian matrix A; see, e.g., [7, Chapter 9.1.2]. In a nutshell (and without specifying the respective matrix dimensions), for each nonzero vector v there exists a matrix V with first column v, and a square tridiagonal matrix H, such that $AV = VH$, and the columns of V are mutually orthogonal in the Euclidean inner product. This decomposition is computed by the hermitian Lanczos algorithm, and is sometimes called the *orthogonal reduction to tridiagonal form*. It is easy to see, by comparing columns in the matrix equation $AV = VH$, that the first j columns of V form a basis of $\mathcal{K}_j(A, v) \equiv \mathrm{span}\{v, \ldots, A^{j-1}v\}$, the jth Krylov subspace

generated by A and v. The importance of this reduction from a theoretical as well as from a practical point of view can hardly be underestimated.

When A is nonhermitian, we are naturally led to ask for generalizations of the orthogonal reduction to tridiagonal form. Specifically, we ask if there exists a hermitian positive definite (HPD) matrix B such that a nonsingular nonhermitian A can still be B-orthogonally reduced to an upper Hessenberg matrix *with small bandwidth*. B-orthogonally here means that the columns of V are orthogonal in the B-inner product.

This paper studies necessary and sufficient conditions on A that guarantee the existence of such a B-orthogonal reduction. Our subject seems to be elementary, and one might suspect that it is covered in many textbooks on numerical linear algebra. However, while it appears to be common knowledge that the orthogonal reduction to tridiagonal form does not exist in general, see, e.g., [7, p. 499], we are not aware of any publication where the potential for generalizations has been thoroughly studied.

On the other hand, the related question of necessary and sufficient conditions on A for the existence of a short-term recurrence for computing B-orthogonal Krylov subspace basis vectors was completely solved by the fundamental theorem of Faber and Manteuffel [4]. Denoting the columns of V by v_j, we say that these vectors can be computed by an $(s+2)$-term recurrence, when only the previous $s+1$ vectors, $v_{j-s}, \ldots, v_j$, are required to compute v_{j+1}. For example, if the matrix H in the decomposition $AV = VH$ is tridiagonal, then the vectors v_j are computed by a 3-term recurrence. This is a key recurrence in many algorithms, including the famous conjugate gradient method. One immediately expects that for a given matrix A the existence of an $(s+2)$-term recurrence for computing a B-orthogonal Krylov subspace basis is equivalent to B-reducibility of A to upper Hessenberg form with bandwidth $s+2$. However, due to intricate details that are easily overlooked, this expectation is in general false.

Our paper has the following goals. First, we give a thorough analysis of the B-reducibility of a nonsingular matrix A to upper Hessenberg form with small bandwidth. This is an interesting matrix property that apparently was not studied previously. Despite common belief, the necessary and sufficient conditions so that A has this property are not the same as the necessary and sufficient conditions in the Faber–Manteuffel theorem. This situation deserves to be clarified. Second, the proofs in this paper use standard tools of linear algebra only. We thereby hope to provide some additional insight into the necessity of the conditions in the Faber–Manteuffel theorem, for which no elementary (linear algebra based) proof is known. Third, we intend to improve the understanding of B-normality, the central necessary and sufficient condition in our context, by completely characterizing the set of HPD matrices B with respect to which a given matrix A is B-normal. Finally, our goal is to help in the general understanding of the foundations of and principles behind Krylov subspace methods.

The paper is organized as follows. In section 2 we discuss the basic algorithm for B-orthogonal Hessenberg reduction of a matrix and for computing B-orthogonal Krylov subspace bases. In section 3 we explain the sufficiency of B-normality in our context, and study this important concept in detail. In section 4 we discuss the necessity of B-normality. In section 5 we relate our results to the Faber–Manteuffel theorem and the existence of short-term recurrences for computing B-orthogonal Krylov subspace bases. Concluding remarks in section 6 close the paper.

Throughout the paper we assume exact arithmetic. In particular, the word

"computation" in this paper does not refer to a finite precision computation.

2. *B*-orthogonal reduction to upper Hessenberg form. Let A be any nonsingular N by N matrix, let v_1 be any nonzero N-vector (v_1 is assumed to be nonzero to exclude trivialities), and let

$$\mathcal{K}_j(A, v_1) \equiv \operatorname{span}\{v_1, Av_1, \ldots, A^{j-1}v_1\} \quad \text{for} \quad j = 1, 2, \ldots, \tag{2.1}$$

denote the jth Krylov subspace generated by A and v_1. It is well known that the $\mathcal{K}_j(A, v_1)$ form a nested sequence of subspaces of increasing dimension, and that there exists an index

$$d = d(A, v_1) \equiv \dim \mathcal{K}_N(A, v_1), \tag{2.2}$$

which is often called the grade of v_1 with respect to A, for which

$$\mathcal{K}_1(A, v_1) \subset \cdots \subset \mathcal{K}_{d-1}(A, v_1) \subset \mathcal{K}_d(A, v_1) = \mathcal{K}_{d+1}(A, v_1) = \cdots = \mathcal{K}_N(A, v_1).$$

Furthermore, for each v_1, $d \le d(A)$, where $d(A)$ denotes the degree of the minimal polynomial of A.

For any N by N HPD matrix B, the function $\langle \cdot, \cdot \rangle_B$, defined by $\langle x, y \rangle_B \equiv y^* B x$ for N-vectors x and y, is a positive definite inner product. Suppose that, for a given nonsingular matrix A, vector v_1, and HPD matrix B, we want to compute bases of the Krylov subspaces $\mathcal{K}_j(A, v_1)$, for $j = 1, 2, \ldots, d$, that are orthogonal with respect to the inner product $\langle \cdot, \cdot \rangle_B$ (B-orthogonal). In other words, we want to compute vectors $v_1, v_2, \ldots, v_d$ such that

$$\operatorname{span}\{v_1, \ldots, v_j\} = \mathcal{K}_j(A, v_1), \qquad j = 1, \ldots, d, \tag{2.3}$$

$$\langle v_j, v_k \rangle_B = 0, \qquad j \ne k, j = 1, \ldots, d, k = 1, \ldots, d. \tag{2.4}$$

Starting from v_1, this familiar and important task is performed by the following basic algorithm:

$$v_{k+1} = Av_k - \sum_{j=1}^{k} h_{jk} v_j, \qquad k = 1, \ldots, d, \tag{2.5}$$

where

$$h_{jk} = \frac{\langle Av_k, v_j \rangle_B}{\langle v_j, v_j \rangle_B}. \tag{2.6}$$

Apparently, this algorithm is nothing but the classical Gram–Schmidt implementation of Arnoldi's method; see, e.g., [7, Chapter 9.4.1].

Rewriting (2.5) in the form

$$Av_k = v_{k+1} + \sum_{j=1}^{k} h_{jk} v_j, \qquad k = 1, \ldots, d,$$

yields the matrix representation

$$A\,[v_1, \ldots, v_k] = [v_1, \ldots, v_{k+1}] \begin{bmatrix} h_{11} & \cdots & h_{1k} \\ 1 & \ddots & \vdots \\ & \ddots & h_{kk} \\ & & 1 \end{bmatrix}, \tag{2.7}$$

or

$$AV_k = V_{k+1}H_{k+1,k}\,, \qquad k = 1, \ldots, d-1\,, \tag{2.8}$$

where $H_{k+1,k}$ is a $(k+1)$ by k unreduced upper Hessenberg matrix. Since $v_{d+1} = 0$, the matrix representation for $k = d$ may be written as

$$AV_d \;=\; V_d \begin{bmatrix} h_{11} & \cdots & \cdots & h_{1d} \\ 1 & \ddots & & \vdots \\ & \ddots & \ddots & \\ & & 1 & h_{dd} \end{bmatrix} \;=\; V_d H_d\,, \tag{2.9}$$

where H_d is a d by d unreduced upper Hessenberg matrix. The B-orthogonality of the basis vectors, cf. (2.4), in this notation means that $V_d^* B V_d$ is a diagonal matrix.

For given A, v_1, and B, the decomposition (2.9) always exists and conditions (2.3) and (2.4) define it uniquely up to scaling of the columns of V_d. There are in fact several different algorithms that realize conditions (2.3) and (2.4). But in exact arithmetic all these algorithms lead to a decomposition of the form

$$A(V_d D) \;=\; (V_d D)\,(D^{-1} H_d D)\,,$$

where V_d and H_d are as in (2.9), and D is a nonsingular diagonal matrix. Clearly, the nonzero pattern of H_d is invariant under diagonal similarity transformation, and thus, for given A, v_1, and B, conditions (2.3) and (2.4) lead to a uniquely defined nonzero pattern of H_d.

In the following we will be mostly interested in this pattern, particularly in the upper bandwidth of H_d. We call an upper Hessenberg matrix $(s+2)$-*band Hessenberg*, if it has no nonzero entries above its sth superdiagonal. (Here the 0th superdiagonal is the diagonal.) This gives rise to the following definition.

DEFINITION 2.1. *The nonsingular matrix A is B-reducible to $(s+2)$-band Hessenberg form if there exists an HPD matrix B such that for each v_1, either H_d in the decomposition* (2.9) *is $(s+2)$-band Hessenberg, or $d \le s+1$.*

Note that for each nonsingular matrix A, $s \ge 0$ in Definition 2.1, since a 0- or 1-band Hessenberg matrix H_d is singular, which contradicts the nonsingularity of A. Hence B-reducibility to 2-band Hessenberg (lower bidiagonal) form is the one with smallest possible bandwidth that may occur. On the other hand, $s \le d(A) - 1$ always holds as well, since no matrix H_d in (2.9) can possibly have more than $d(A) - 1$ superdiagonals. The condition $d \le s+1$ in Definition 2.1 covers the trivial cases in which H_d has at most $s+2$ bands simply because it is of size at most $s+1$ by $s+1$.

The classical example is the one for $s = 1$, namely the reduction to tridiagonal form (tridiagonalization) with respect to the Euclidean inner product (i.e., $B = I$). For each nonsingular hermitian matrix A and each v_1 the decomposition (2.9) exists, where H_d is a tridiagonal (3-band Hessenberg) matrix and $V_d^* V_d$ is diagonal; see, e.g., [7, Chapter 9.1.2].

In the following sections we will study sufficient (section 3) and necessary (section 4) conditions that A is B-reducible to $(s+2)$-band Hessenberg form. We will then relate our result to the Faber–Manteuffel theorem, which gives necessary and sufficient conditions on A so that for each v_1, a B-orthogonal Krylov subspace basis can be computed by an $(s+2)$-term recurrence (section 5).

3. Sufficiency and characterization of B-normality. Let us consider the sufficient conditions that a given nonsingular matrix A is B-reducible to $(s+2)$-band Hessenberg form. A trivial sufficient condition is that the minimal polynomial of A has degree $d(A) \leq s+1$. Then, for each v_1 we obtain $d \leq d(A) \leq s+1$, and the second sufficient condition in Definition 2.1 is always satisfied. Thus, if $d(A) \leq s+1$, then A is B-reducible to $(s+2)$-band Hessenberg form for each HPD matrix B.

If $d(A) > s+1$, we require that there exists an HPD matrix B so that for each v_1 with $d > s+1$ the matrix H_d in (2.9) is $(s+2)$-band Hessenberg, i.e., that

$$h_{jk} \;=\; 0 \qquad \text{for} \quad j+s+1 \leq k \leq d\,. \tag{3.1}$$

From (2.6) it follows that $h_{jk} = 0$ if and only if

$$0 \;=\; \langle Av_k, v_j\rangle_B \;=\; \langle v_k, A^+ v_j\rangle_B\,,$$

where $A^+ \;\equiv\; B^{-1}A^*B$ is the B-adjoint of A.

Now suppose that $A^+ = p_s(A)$ for a polynomial p_s of degree s. Then, since each v_j is of the form $v_j = p_{j-1}(A)v_1$,

$$A^+ v_j \;=\; p_s(A)p_{j-1}(A)v_1 \;\in\; \mathcal{K}_{j+s}(A, v_1)\,.$$

But then B-orthogonality of v_k to $\operatorname{span}\{v_1, \ldots, v_{k-1}\} = \mathcal{K}_{k-1}(A, v_1)$ for all $k \geq 2$ shows that (3.1) indeed holds for $j+s+1 \leq k \leq d$. We formally state the nontrivial sufficient condition for B-reducibility of A to $(s+2)$-band Hessenberg form in the following definition.

DEFINITION 3.1. *If there exists an HPD matrix B such that*

$$A^+ \;\equiv\; B^{-1}A^*B \;=\; p_s(A)$$

for a polynomial p_s of degree s, then the matrix A is called normal of degree s with respect to B, or short B-normal(s).

Using this definition we can state our main theorem.

THEOREM 3.2. *The nonsingular matrix A is B-reducible to $(s+2)$-band Hessenberg form if and only if either A is B-normal(s), or $d(A) \leq s+1$.*

Above we have shown sufficiency. Before we continue with necessity we will study the important concept of B-normality in more detail. We start with a collection of equivalent characterizations.

THEOREM 3.3. *For any matrix A the following are equivalent:*

1. *There exists an HPD matrix B such that $A^+ = p(A)$ for a polynomial p.*
2. *There exists an HPD matrix B such that $AA^+ = A^+A$.*
3. *A is normalizable (similar to a normal matrix).*
4. *A is diagonalizable.*
5. *There exists an HPD matrix B such that A and A^+ (for this B) have the same complete set of B-orthogonal eigenvectors.*

Proof. (1) $\Rightarrow$ (2). Obviously, $p(A)A = Ap(A)$ for each polynomial p.

(2) $\Rightarrow$ (3). Assume (2) and define the matrix $\mathcal{A} \equiv B^{1/2}AB^{-1/2}$, to which A is similar. Then $\mathcal{A}\mathcal{A}^* = \mathcal{A}^*\mathcal{A}$, i.e., $\mathcal{A}$ is normal.

(3) $\Leftrightarrow$ (4). Suppose that A is normalizable, $A = S^{-1}MS$ with M normal. Since M is diagonalizable [8, Condition 11], A is diagonalizable as well. If A is diagonalizable, $A = WDW^{-1}$ with D diagonal, it is obviously similar to the normal matrix D.

(3) $\Rightarrow$ (1). Again assume that $A = S^{-1}MS$ with M normal. Define $B = S^*S$, which is HPD. By [8, Condition 17], $M^* = p(M)$ for some polynomial p, which implies $A^+ = (S^*S)^{-1}A^*(S^*S) = S^{-1}M^*S = S^{-1}p(M)S = p(A)$.

(3) $\Rightarrow$ (5). If $A = S^{-1}MS$ with M normal, define $B = S^*S$, which is HPD. By [8, Condition 11], there exist a unitary matrix U and a diagonal matrix D such that $M = U^*DU$. Hence, $A = (US)^{-1}D(US)$, where the columns of the matrix $(US)^{-1}$ form a complete set of eigenvectors of A. It is easy to see that these are B-orthogonal. In addition, A^+ for this B is of the form $A^+ = (US)^{-1}D^*(US)$, and hence has the same set of eigenvectors as A.

(5) $\Rightarrow$ (2). If there exists an HPD matrix B such that $A^+ = W\Lambda W^{-1}$ and $A = WDW^{-1}$, where Λ and D are diagonal, then $AA^+ = WD\Lambda W^{-1} = W\Lambda DW^{-1} = A^+A$. ∎

The implications in Theorem 3.3 have appeared in the literature before. In particular, the equivalence of (1), (2), (4), and (5) was proven in [5, Theorem 5 and Corollary 6], and later cited and used, for example, in [9, Theorem 4.4] and [1, p. 772]. However, the proofs in [5] are different from ours, as they do not directly make use of the fact that B-normality is equivalent to normalizability. Because we use this equivalence our proofs appear to be almost trivial, and the list of conditions in Theorem 3.3 can be easily extended by exploiting the lists of equivalent conditions of normality [3, 8], and rephrasing each such condition in terms of normalizability.

We will now characterize the HPD matrices B with respect to which a given (diagonalizable) matrix is normal. Clearly, the matrix B might not be uniquely defined. For example, if A itself is HPD, then it is normal with respect to $B = I$ and $B = A$.

As shown in Theorem 3.3, A is normal with respect to an HPD matrix B if and only if it has a complete set of B-orthogonal eigenvectors. Let these eigenvectors w_i be scaled to have B-norm one, i.e. $w_i^*Bw_i = 1$, and suppose the w_i are the columns of the matrix W. Then $W^*BW = \operatorname{diag}(w_i^*Bw_i) = I$. This is equivalent to $B = (WW^*)^{-1}$. On the other hand, let $B = (WW^*)^{-1}$, where the columns of W form any complete set of eigenvectors of A. Then an easy calculation shows that $AA^+ = A^+A$, i.e., that A is normal with respect to B. We thus have proven the following theorem.

THEOREM 3.4. *Suppose that the matrix A is diagonalizable. Then the set of all HPD matrices B with respect to which A is normal is given by*

$$\{\,(WW^*)^{-1} \;:\; W \text{ is an eigenvector matrix of } A\,\}. \tag{3.2}$$

The characterization (3.2) allows us to derive an expression for the unique B-adjoint of A in case A is normal with respect to B.

COROLLARY 3.5. *Suppose that the matrix A is diagonalizable, $A = W\Lambda W^{-1}$, and that it is normal with respect to an HPD matrix B. Then the B-adjoint of A corresponding to this B is given by*

$$A^+ = W\,\Lambda^*\,W^{-1}. \tag{3.3}$$

In particular, the B-adjoint of A is unique for all HPD matrices B with respect to which A is normal. Moreover, A is B-normal(s) if and only if A is diagonalizable and $p_s(\Lambda) = \Lambda^*$ for a polynomial of degree s.

Proof. Each HPD matrix B with respect to which A is normal is of the form (3.2). A direct computation shows that $A^+ = B^{-1}A^*B$ has the form (3.3), which is unique since it does not depend on the particular choice of W (similarly to A itself). For the second part of the corollary, suppose that A is B-normal(s), i.e., $A^+ = p_s(A)$

for a polynomial of degree s. Then A must be diagonalizable, $A = W\Lambda W^{-1}$, and (3.3) shows that $A^+ = W\Lambda^* W^{-1} = p_s(A) = W p_s(\Lambda) W^{-1}$, which yields $p_s(\Lambda) = \Lambda^*$.

The proof of the reverse implication is similar. ∎

Remark 3.6. The second part of this corollary was also derived in [9, Theorem B.1]. There the authors used a proof different from ours, and do not comment on the uniqueness of the B-adjoint in general.

As shown by Corollary 3.5, the B-normal degree of a diagonalizable matrix is determined by the location of its eigenvalues. It is well known that the B-normal(1) matrices are precisely the diagonalizable matrices that have all eigenvalues on a straight line in the complex plane [4, Lemma 3]. By sufficiency, each such matrix A is B-reducible to 3-band Hessenberg (tridiagonal) form. The standard examples are the hermitian and skew-hermitian matrices, that are all I-normal(1). Rare practical examples of B-normal(1) matrices that are normal with respect to an HPD matrix $B \neq I$ were derived in [6].

When the eigenvalues of the diagonalizable matrix A do not lie on a line, A must have B-normal degree $s > 1$. The question then arises about the lowest degree polynomial p_s for which $p_s(\Lambda) = \Lambda^*$. A recent result of Khavinson and Świątek [10] shows that each harmonic polynomial of the form $p_s(z) - \bar{z}$, where p_s is a polynomial of degree $s > 1$, has at most $3s-2$ complex zeros. Consequently, the class of B-normal(s) matrices with $s > 1$ contains diagonalizable matrices that may have at most $3s - 2$ distinct eigenvalues. This shows that the maximal size of the B-normal(s) matrices for small $s > 1$ is severely limited. We illustrate the results of this section by an example for $s = 3$.

Example 3.7. Consider the third degree harmonic polynomial

$$-\frac{1}{8}\, z(z^2 - 9) - \bar{z}\,, \quad \text{which has the 7 roots} \quad 0,\ \pm 1,\ \frac{\pm 5 \pm \sqrt{-7}}{2}\,.$$

We use the nonzero roots to define the diagonal nonsingular 6 by 6 matrix

$$A \;=\; \operatorname{diag}\left(\ \pm 1,\ \frac{1}{2}(\pm 5 \pm \sqrt{-7})\ \right)\,.$$

By the second part of Corollary 3.5, this matrix is B-normal(3), and by (3.3) its unique B-adjoint is given by $A^+ = A^* = A$. Theorem 3.4 shows that A is normal with respect to all diagonal HPD matrices B. If we use any such matrix B and any v_1 with $d = 6$ in the basic algorithm (2.5)–(2.6), then sufficiency in Theorem 3.2 shows that the resulting matrix H_6 in (2.9) is 5-band Hessenberg. In fact, A is B-reducible to 5-band Hessenberg form for any diagonal HPD matrix B.

4. Necessary conditions. In this section we will show that the conditions in Theorem 3.2 are necessary. To avoid confusion, we will in this section denote the grade of the vector v_1 with respect to A by $d(A, v_1)$, cf. (2.2). Furthermore, we assume that the given nonsingular N by N matrix A is nonderogatory, i.e., that $d(A) = N$. This assumption is made for notational convenience, and without loss of generality. In case A is derogatory, we may in our derivation restrict to starting vectors v_1 with $d(A, v_1) = d(A)$ and all results will then hold for N replaced by $d(A)$. We start our discussion with proving an essential technical lemma.

LEMMA 4.1. *For a nonsingular and nonderogatory N by N matrix A there exists an HPD matrix B such that*

$$A^+ v_1 \;\in\; \mathcal{K}_{s+1}(A, v_1) \qquad \textit{for all } v_1 \textit{ with} \quad d(A, v_1) \;=\; N\,, \tag{4.1}$$

if and only if either A is B-normal(s) for $0 \le s \le N-2$, or $s = N-1$.

Proof. We first prove sufficiency. Suppose that $s = N-1$. Then for all v_1 with $d(A, v_1) = N$, $\mathcal{K}_{s+1}(A, v_1) = \mathcal{K}_N(A, v_1)$ is equal to the whole (real or complex) N-dimensional space and thus $A^+ v_1 \in \mathcal{K}_N(A, v_1)$ holds for all HPD matrices B. Now consider that $0 \le s \le N-2$ and that A is B-normal(s). This means there exists an HPD matrix B for which $A^+ = p_s(A)$ for a polynomial p_s of degree s. Hence for each v_1, $A^+ v_1 = p_s(A) v_1 \in \mathcal{K}_{s+1}(A, v_1)$.

We next prove necessity, the harder part. Suppose that there exists an HPD matrix B such that (4.1) holds for some s with $0 \le s \le N-2$ (in case $s = N-1$ we are done). We need to show that A is B-normal(s).

Let $A = [X_1, \ldots, X_l] \operatorname{diag}(J_1, \ldots, J_l) [X_1, \ldots, X_l]^{-1}$ denote the Jordan canonical form of A, with the distinct eigenvalues $\lambda_1, \ldots, \lambda_l$. Since A is nonderogatory, only one Jordan block corresponds to each eigenvalue and, hence, each X_m, $m = 1, \ldots, l$, is a Jordan chain. Then it is easy to show that the vectors v that satisfy $d(A, v) = N$ are precisely the vectors that have a nonzero component corresponding to the last vector of *each* Jordan chain X_m. As a consequence, when we choose *any* v with $d(A, v) = N$, and *any* nonzero scalar γ with $\gamma \ne -\lambda_m$ for $m = 1, \ldots, l$, then the vector $w \equiv \gamma v + Av$ will satisfy $d(A, v) = d(A, Av) = d(A, w) = N$. In particular, we can find N linearly independent vectors v, such that v, Av, and $w \equiv \gamma v + Av$ for each nonzero $\gamma \ne -\lambda_m$, $m = 1, \ldots, l$, satisfy $d(A, v) = d(A, Av) = d(A, w) = N$.

Suppose that one such vector v is chosen, and let $w \equiv \gamma v + Av$ for some fixed nonzero $\gamma \ne -\lambda_m$, $m = 1, \ldots, l$. Then $d(A, w) = N$, so that by (4.1), $A^+ w \in \mathcal{K}_{s+1}(A, w)$. Hence there exist coefficients $\alpha_j^{(w)}$, $j = 0, \ldots, s$, such that

$$\begin{aligned} A^+ w &= \sum_{j=0}^{s} \alpha_j^{(w)} A^j w \\ &= \gamma \sum_{j=0}^{s} \alpha_j^{(w)} A^j v + \sum_{j=0}^{s} \alpha_j^{(w)} A^{j+1} v \\ &= \gamma \alpha_0^{(w)} v + \sum_{j=1}^{s} (\gamma \alpha_j^{(w)} + \alpha_{j-1}^{(w)}) A^j v + \alpha_s^{(w)} A^{s+1} v \,. \end{aligned} \tag{4.2}$$

Similarly, there exist coefficients $\alpha_j^{(v)}$ and $\alpha_j^{(Av)}$, $j = 0, \ldots, s$, such that

$$\begin{aligned} A^+ w &= \gamma A^+ v + A^+ (Av) \\ &= \gamma \sum_{j=0}^{s} \alpha_j^{(v)} A^j v + \sum_{j=0}^{s} \alpha_j^{(Av)} A^{j+1} v \\ &= \gamma \alpha_0^{(v)} v + \sum_{j=1}^{s} (\gamma \alpha_j^{(v)} + \alpha_{j-1}^{(Av)}) A^j v + \alpha_s^{(Av)} A^{s+1} v \,. \end{aligned} \tag{4.3}$$

Now note that since $d(A, v) = N$ and $0 \le s \le N-2$, the vectors $v, \ldots, A^{s+1} v$ are linearly independent. Thus, the equality of (4.2) and (4.3) implies that

$$\alpha_0^{(v)} = \alpha_0^{(w)} \,, \tag{4.4}$$

$$\gamma \alpha_j^{(v)} + \alpha_{j-1}^{(Av)} = \gamma \alpha_j^{(w)} + \alpha_{j-1}^{(w)} \,, \qquad j = 1, \ldots, s \,, \tag{4.5}$$

$$\alpha_s^{(Av)} = \alpha_s^{(w)} \,. \tag{4.6}$$

Let us define $\eta_j \equiv \alpha_j^{(Av)} - \alpha_j^{(v)}$ for $j = 0, \ldots, s$. By construction, the η_j do not depend on γ. Moreover, we claim that $\eta_j = 0$ for $j = 0, \ldots, s$.

If $s = 0$, then the set of conditions (4.5) is empty and our claim follows directly from comparing (4.4) and (4.6). To show our claim for $1 \leq s \leq N-2$, we rewrite (4.5) in the equivalent form

$$\alpha_j^{(w)} \;=\; \alpha_j^{(v)} \;+\; \frac{1}{\gamma}\,(\alpha_{j-1}^{(Av)} - \alpha_{j-1}^{(w)})\,, \qquad j = 1, \ldots, s\,. \tag{4.7}$$

Then (4.6) and (4.7) for $j = s$ yield

$$\eta_s \;=\; \frac{1}{\gamma}\,(\alpha_{s-1}^{(Av)} - \alpha_{s-1}^{(w)})\,.$$

In this formula we can replace $\alpha_{s-1}^{(w)}$ by the right-hand side of (4.7) for $j = s-1$,

$$\eta_s \;=\; \frac{1}{\gamma}\left(\alpha_{s-1}^{(Av)} - \alpha_{s-1}^{(v)} - \frac{1}{\gamma}\,(\alpha_{s-2}^{(Av)} - \alpha_{s-2}^{(w)})\right) \;=\; \frac{1}{\gamma}\left(\eta_{s-1} - \frac{1}{\gamma}\,(\alpha_{s-2}^{(Av)} - \alpha_{s-2}^{(w)})\right).$$

In the same way we now exploit (4.7) for $j = s-2, \ldots, 1$, and finally use (4.4) to replace $\alpha_0^{(w)}$ by $\alpha_0^{(v)}$. The result of this process is equivalent to the relation

$$\sum_{j=0}^{s} (-1)^{s-j}\,\eta_j\,\gamma^j \;=\; 0\,. \tag{4.8}$$

The coefficients η_j do not depend on γ, so that the left-hand side of (4.8) is a polynomial in γ of degree at most s. Since γ is allowed to vary almost freely without violating the assumption $d(A, v) = d(A, Av) = d(A, w) = N$ (see above), but on the other hand (4.8) must always hold, we conclude that $\eta_j = 0$ for $j = 0, \ldots, s$.

To summarize, since $d(A, v) = d(A, Av) = N$, (4.1) implies that $A^+ v = p_s(A)v$ and $A^+ Av = q_s(A)Av$ for two polynomials p_s and q_s of degree at most s, respectively. But since we have just shown that $p_s = q_s$, we receive

$$A^+ Av \;=\; q_s(A)Av \;=\; p_s(A)Av \;=\; Ap_s(A)v \;=\; AA^+ v\,.$$

Since we can find N linearly independent vectors v for which this is true, we conclude that $A^+ A = AA^+$, and indeed A must be B-normal(s). ∎

Remark 4.2. This lemma represents a strengthened version of a result of Faber and Manteuffel [4, Lemma 2]. In their result, (4.1) is replaced by "$A^+ v_1 \in \mathcal{K}_{s+1}(A, v_1)$ for all v_1," and their proof of necessity uses an eigenvector v_1 of A, i.e., a vector v_1 with $d(A, v_1) = 1$. Our proof is inspired by an idea of Voevodin and Tyrtyshnikov [12].

Necessity in Theorem 3.2. We now come to the main goal of this section, namely the proof of necessity in Theorem 3.2. Our supposedly necessary condition reads *either A is B-normal(s), or $N - 1 \leq s$*. We will prove this by assuming the opposite and then showing that A is *not* B-reducible to $(s+2)$-band Hessenberg form.

The opposite of our necessary condition is that *A is not B-normal(s) and* $0 \leq s \leq N-2$. But this is precisely the opposite of the nontrivial necessary condition in Lemma 4.1. Therefore, Lemma 4.1 implies that for each HPD matrix B there exists at least one vector v_1 with $d(A, v_1) = N$ such that $A^+ v_1 \notin \mathcal{K}_{s+1}(A, v_1)$. On the other hand, since $d(A, v_1) = N$, $A^+ v_1 \in \mathcal{K}_N(A, v_1)$. Hence $A^+ v_1$ is a linear combination of the basis vectors $v_1, \ldots, v_N$ computed by (2.5),

$$A^+ v_1 = \sum_{j=1}^{N} \beta_j v_j\,,$$

where (at least) one of the coefficients β_j, $s+2 \le j \le N$, is nonzero. Let this be the coefficient with index k. Then, according to (2.6) and the B-orthogonality conditions (2.4),

$$h_{1k} \;=\; \frac{\langle Av_k, v_1\rangle_B}{\langle v_1, v_1\rangle_B} \;=\; \frac{\langle v_k, A^+v_1\rangle_B}{\langle v_1, v_1\rangle_B} \;=\; \frac{\overline{\beta}_k \langle v_k, v_k\rangle_B}{\langle v_1, v_1\rangle_B} \;\neq\; 0\,, \tag{4.9}$$

for an index k with $s+2 \le k \le N$. Consequently, A is *not* B-reducible to $(s+2)$-band Hessenberg form, which completes the proof of necessity.

5. The existence of $(s+2)$-term recurrences. We next relate Theorem 3.2 to the existence of an $(s+2)$-term recurrence for computing B-orthogonal Krylov subspace bases.

Suppose that, for a given nonsingular matrix A, vector v_1, and HPD matrix B, only the previous $s+1$ vectors $v_k, v_{k-1}, \ldots, v_{k-s}$ are required to compute v_{k+1}, $k = 1, \ldots, d-1$, in (2.5). Then we say that the B-orthogonal basis $v_1, \ldots, v_d$ of $\mathcal{K}_d(A, v_1)$ is computed by an $(s+2)$-term recurrence.

Note that the basic algorithm (2.5)–(2.6) has computed all basis vectors $v_1, \ldots, v_d$ in step $k = d-1$. Therefore, in terms of the matrix representation (2.8), the B-orthogonal basis vectors are computed by an $(s+2)$-term recurrence, if $H_{d,d-1}$ is $(s+2)$-band Hessenberg. We stress that, unlike for the B-reducibility to $(s+2)$-band Hessenberg form, we here use $H_{d,d-1}$ and not H_d. It is a subtle and easily overlooked fact that the last column of H_d plays no role for the computation of the basis vectors $v_1, \ldots, v_d$. This column indeed may be full, and still the basis vectors are computed by an $(s+2)$-term recurrence.

DEFINITION 5.1. *The nonsingular matrix A admits an $(s+2)$-term recurrence, if there exists an HPD matrix B so that for each v_1, either $H_{d,d-1}$ in the decomposition* (2.8) *is $(s+2)$-band Hessenberg, or $d \le s+2$.*

The difference in the trivial conditions between this definition and Definition 2.1 ($d \le s+2$ versus $d \le s+1$) precisely corresponds to the different roles of the matrices $H_{d,d-1}$ and H_d. We immediately realize that if a nonsingular matrix A is B-reducible to $(s+2)$-band Hessenberg form, then it also admits an $(s+2)$-term recurrence. The reverse implication, however, does not hold. In other words, B-reducibility to $(s+2)$-band Hessenberg form and admissibility of an $(s+2)$-term recurrence are in general *not equivalent*. As an example, consider any nonsingular 3 by 3 matrix A with $d(A) = 3$. Then each v_1 with $d = 3$ leads to an H_3 of the form

$$H_3 \;=\; \begin{bmatrix} h_{11} & h_{12} & h_{13} \\ 1 & h_{22} & h_{23} \\ 0 & 1 & h_{33} \end{bmatrix}.$$

Trivially A admits a 3-term recurrence as each $H_{3,2}$ has only 3 nonzero bands (here $s = 1$). But B-reducibility to 3-band Hessenberg form requires that $h_{13} = 0$ for all v_1. Since $d(A) = 3 > s+1$, this holds by Theorem 3.2 only when A is B-normal(1).

Necessary and sufficient conditions for admissibility of an $(s+2)$-term recurrence were proven in the fundamental paper of Faber and Manteuffel [4].

THEOREM 5.2 (Faber–Manteuffel theorem). *The nonsingular matrix A admits an $(s+2)$-term recurrence if and only if either A is B-normal(s), or $d(A) \le s+2$.*

The proof of this result is based on a highly nontrivial and clever construction, which, unfortunately, provides little insight into the necessity of B-normality. A similar result was announced by Voevodin [11], but its proof by Voevodin and Tyrtyshnikov [12] is difficult to understand and appears to be unknown even to many

specialists in the field. Comparing Theorem 3.2 with the Faber–Manteuffel theorem yields the following important observation.

COROLLARY 5.3. *The nonsingular matrix A with $d(A) > s+2$ is B-reducible to $(s+2)$-band Hessenberg form if and only if it admits an $(s+2)$-term recurrence.*

In other words, in all cases of practical interest; i.e., when $d(A)$ is "large" and s is "small," the two matrix properties studied in this paper in fact are equivalent.

6. Concluding remarks. The reader may now ask if we successfully tried to prove necessity in the Faber–Manteuffel theorem using similar elementary (linear algebra) means as for our Theorem 3.2. The answer is yes, we tried, but no, we were unsuccessful. To explain the main difficulty, at least in our opinion, consider our proof of necessity in section 4. We assume the opposite of the necessary conditions and construct a certain nonzero entry h_{1k}, $s+2 \le k \le N$, in the first row of H_N, cf. (4.9). Hence H_N cannot be $(s+2)$-band Hessenberg, which leads to a contradiction showing that the conditions are indeed necessary. Except for the range $s+2 \le k \le N$, we have no information about the location of the nonzero entry h_{1k}. If we could show that indeed $h_{1k} \neq 0$ for a k in the range $s+2 \le k \le N-1$, then $H_{N,N-1}$ cannot be $(s+2)$-band Hessenberg either. This could subsequently be used to show necessity in the Faber–Manteuffel theorem. However, it is apparently quite difficult to "fix" k inside the range $s+2 \le k \le N-1$.

Acknowledgments. We thank Tom Manteuffel for sharing his insights in a thorough discussion of the subject that took place during the Copper Mountain Conference on Iterative Methods in March 2002. We also thank Zdeněk Strakoš, Petr Tichý, and an anonymous referee for many helpful and constructive comments.

A PRECONDITIONER FOR THE FETI-DP FORMULATION WITH MORTAR METHODS IN TWO DIMENSIONS*

HYEA HYUN KIM† AND CHANG-OCK LEE†

Abstract. In this paper, we consider a dual-primal FETI (FETI-DP) method for elliptic problems on nonmatching grids. The FETI-DP method is a domain decomposition method that uses Lagrange multipliers to match solutions continuously across subdomain boundaries in the sense of dual-primal variables. We use the mortar matching condition as the continuity constraints for the FETI-DP formulation. We construct a preconditioner for the FETI-DP operator and show that the condition number of the preconditioned FETI-DP operator is bounded by

$$C \max_{i=1,\dots,N}\{(1+\log(H_i/h_i))^2\},$$

where H_i and h_i are sizes of domain and mesh for each subdomain, respectively, and C is a constant independent of H_i's and h_i's. We allow jumps of coefficients of elliptic problems across subdomain boundaries. Numerical results are included.

1. Introduction.

This paper is concerned with preconditioners for an iterative method for the parallel solution of symmetric, positive definite systems of linear equations that arise from elliptic boundary value problems discretized by finite elements on nonconforming meshes. Nonconforming discretizations are important for multiphysics simulations, contact-impact problems, the generation of meshes and partitions aligned with jumps in diffusion coefficients, *hp*-adaptive methods, and special discretizations in the neighborhood of singularities (corners or joints).

Of the many methods for nonmatching meshes, including [3] and [13], we consider the mortar method [1, 2, 17, 18]. In mortar methods, orthogonality relations between the jumps in the traces across subdomain interfaces are satisfied using a discrete Lagrange multiplier space. The sparse linear systems that arise in mortar methods are similar to the systems solved by an iterative substructuring method with Lagrange multipliers developed for conforming discretizations (see [6, 8, 12, 14] for an introduction).

Recently the dual-primal FETI (FETI-DP) method introduced by Farhat, Lesoinne, and Pierson [7] has been applied to mortar finite elements methods [4, 5, 15]. The primary contribution of our work is using the framework of parallel subspace correction methods [19] to better formulate the FETI-DP preconditioner for the mortar matching condition.

The FETI-DP method enforces the continuity of the solution at cross points directly in the formulation of the dual problem: the degrees of freedom (d.o.f.) at a cross point remain common to all subdomains sharing the cross point and the continuity of the remaining d.o.f. on the interfaces are enforced by Lagrange multipliers [10]. The

†Division of Applied Mathematics, KAIST, Daejeon 305-701, Korea (mashy@amath.kaist.ac.kr, colee@amath.kaist.ac.kr).

d.o.f. are then eliminated and the resulting dual problem for the Lagrange multipliers is solved by preconditioned conjugate gradients (CGs).

For FETI-DP methods on nonmatching grids, Dryja and Widlund [4] proposed a preconditioner, the so-called Dirichlet preconditioner, which gives a condition number bound $C(1+\log(H/h))^2$ with the Neumann–Dirichlet ordering of substructures, where H and h denote the maximum diameter of subdomains and minimum size of meshes of all subdomains, respectively. In general cases, that is, without considering ordered substructures, they obtained $C(1+\log(H/h))^4$ for the condition number bound. Moreover, in [5], they proposed a different preconditioner, which is similar to the one in [9], and proved the condition number bound $C(1+\log(H/h))^2$. However, the constant C in the condition number bound depends on the ratio of meshes between neighboring subdomains. This restriction is impractical when the coefficients of elliptic problems are highly discontinuous between subdomains (see Wohlmuth [18]).

In this paper, we formulate an FETI-DP operator in a different way from that of Dryja and Widlund [4, 5] and propose a Neumann–Dirichlet preconditioner which gives the condition number bound $C(1+\log(H/h))^2$ with the constant C not depending on the ratio of meshes between neighboring subdomains. The proposed preconditioner is easy to implement and the operator from the nodal values on the interfaces of subdomains to the Lagrange multiplier space requires only the nodal values on the slave side. Hence, the cost for multiplying the operator to a vector is reduced by half compared with preconditioners developed elsewhere (see, e.g., [4, 5]). For the elliptic problems with heterogeneous coefficients, with careful choices of slave and master sides according to the magnitude of coefficients, the preconditioner gives the same condition number bound, which does not depend on the coefficients.

In the mortar matching condition, we consider a standard Lagrange multiplier space introduced by [2]. In the condition number analysis, we use the continuity of the mortar projection operator in an $H_{00}^{1/2}$-norm. Hence, our result can be extended to Lagrange multiplier spaces with this property. A few such Lagrange multiplier spaces are developed by Wohlmuth [17, 18].

This paper is organized as follows. In section 2, we introduce finite element spaces and norms and, in section 3, we derive the FETI-DP operator using the mortar matching condition as continuity constraints and propose a preconditioner. In section 4, we analyze the condition number bound of the preconditioned FETI-DP operator. Numerical results are provided in section 5. In the numerical tests, we compare the proposed preconditioner with that of Dryja and Widlund [5] for solving elliptic problems with highly discontinuous coefficients on noncomparable meshes.

2. Finite element spaces and norms.

2.1. A model problem and Sobolev spaces. Let Ω be a bounded polygonal domain in $\mathbb{R}^2$ and $L^2(\Omega)$ be the space of square integrable functions defined in Ω equipped with the norm $\|\cdot\|_{0,\Omega}$:

$$\|v\|_{0,\Omega}^2 := \int_\Omega v^2\,dx.$$

The space $H^1(\Omega)$ is the set of functions, which are square integrable up to the first weak derivatives, and the norm is given by

$$\|v\|_{1,\Omega} := \left(\int_\Omega \nabla v\cdot\nabla v\,dx + \frac{1}{d_\Omega^2}\int_\Omega v^2\,dx\right)^{1/2},$$

where d_Ω denotes the diameter of Ω.

We consider an FETI-DP method on nonmatching grids for the following elliptic problem: For $f \in L^2(\Omega)$, find $u \in H^1(\Omega)$ such that

$$\begin{aligned} -\nabla \cdot (A(x)\nabla u(x)) + \beta(x)u(x) &= f(x) \ \text{ in } \Omega, \\ u(x) &= 0 \ \text{ on } \Gamma_D, \\ \boldsymbol{n} \cdot (A(x)\nabla u(x)) &= 0 \ \text{ on } \Gamma_N. \end{aligned} \tag{2.1}$$

Here, $A(x) = (\alpha_{ij}(x))$ for $i, j = 1, 2$ and $\boldsymbol{n}$ is the outward unit vector normal to Γ_N. We assume that $\alpha_{ij}(x), \beta(x) \in L^\infty(\Omega)$, $A(x)$ is uniformly elliptic, $\beta(x) \geq 0$ for all $x \in \Omega$, and $|\Gamma_D| \neq 0$, where $|\Gamma_D|$ denotes the measure of Γ_D.

Let Ω be partitioned into nonoverlapping polygonal subdomains $\{\Omega_i\}_{i=1}^N$. We assume that the partition is geometrically conforming, which means that the subdomains intersect with neighboring subdomains on the whole of an edge or at a vertex. Ω_i^h denotes a quasi-uniform triangulation of the subdomain Ω_i. The quasi uniformity means that there exist constants γ and σ such that $\gamma h_i \leq d_\tau \leq \sigma \rho_\tau$ for all $\tau \in \Omega_i^h$, where ρ_τ is the diameter of the circle inscribed in τ, d_τ is the diameter of τ, and $h_i = \max_{\tau \in \Omega_i^h} d_\tau$. We note that the meshes need not match across the subdomain interfaces.

For each subdomain Ω_i, we introduce a finite element space

$$X_i := \{v \in H_D^1(\Omega_i) \ : \ v|_\tau \in P_1(\tau), \ \tau \in \Omega_i^h\},$$

where $H_D^1(\Omega_i) := \{v \in H^1(\Omega_i) \ : \ v = 0 \text{ on } \Gamma_D \cap \partial\Omega_i\}$ and $P_1(\tau)$ is a set of polynomials of degree ≤ 1 in τ. For $(u_i, v_i) \in X_i \times X_i$, define a bilinear form

$$a_i(u_i, v_i) := \int_{\Omega_i} A(x)\nabla u_i \cdot \nabla v_i \, dx + \int_{\Omega_i} \beta(x) u_i v_i dx.$$

To get the FETI-DP formulation, we need a finite element space in Ω as follows:

$$X := \left\{ v \in \prod_{i=1}^N X_i \ : \ v \text{ is continuous at subdomain vertices} \right\}.$$

By restricting the space X_i on the boundary of the subdomain Ω_i, we define

$$W_i := X_i|_{\partial\Omega_i} \ \forall i = 1, \ldots, N.$$

Then we let

$$W := \left\{ w \in \prod_{i=1}^N W_i \ : \ w \text{ is continuous at subdomain vertices} \right\}. \tag{2.2}$$

In this paper, we will use the same notation for finite element functions and the corresponding vectors of nodal values. For example, w_i is used to denote a finite element function or the vector of nodal values of that function. The same applies to the notation for function spaces such as W_i, X, W, etc.

We define S^i as the Schur complement matrix obtained from the bilinear form $a_i(\cdot, \cdot)$ over the finite elements X_i (see page 50 in [11]). Using this operator, a seminorm is defined for $w_i \in W_i$:

$$|w_i|_{S^i}^2 := \langle S^i w_i, w_i \rangle,$$

where $\langle\cdot,\cdot\rangle$ is the l^2-inner product of vectors. For $w \in W$, since w is continuous at subdomain vertices, by summing up these seminorms, we define a norm

$$\|w\|_W^2 := \sum_{i=1}^{N} |w_i|_{S^i}^2, \quad w_i = w|_{\partial\Omega_i}. \tag{2.3}$$

Moreover, we define a subspace of W

$$W_r := \{w \in W \ : \ w \text{ vanishes at subdomain vertices}\}. \tag{2.4}$$

Now, we introduce Sobolev spaces defined on the boundaries of subdomains. The space $H^{1/2}(\partial\Omega_i)$ is the trace space of $H^1(\Omega_i)$ equipped with the norm

$$\|w_i\|_{1/2,\partial\Omega_i}^2 := |w_i|_{1/2,\partial\Omega_i}^2 + \frac{1}{d_{\Omega_i}}\|w_i\|_{0,\partial\Omega_i}^2,$$

where

$$|w_i|_{1/2,\partial\Omega_i}^2 := \int_{\partial\Omega_i}\int_{\partial\Omega_i} \frac{|w_i(x) - w_i(y)|^2}{|x-y|^2}\, ds(x)\, ds(y).$$

For any $\Gamma_{ij} \in \partial\Omega_i$, $H_{00}^{1/2}(\Gamma_{ij})$ is the set of functions in $L^2(\Gamma_{ij})$ such that the zero extension of the function into $\partial\Omega_i$ is contained in $H^{1/2}(\partial\Omega_i)$. For $v \in H_{00}^{1/2}(\Gamma_{ij})$, let

$$|v|_{H_{00}^{1/2}(\Gamma_{ij})}^2 := |v|_{1/2,\Gamma_{ij}}^2 + \int_{\Gamma_{ij}} \frac{v^2(x)}{\operatorname{dist}(x,\partial\Gamma_{ij})}\, ds,$$

and the norm is given by

$$\|v\|_{H_{00}^{1/2}(\Gamma_{ij})} := \left(|v|_{H_{00}^{1/2}(\Gamma_{ij})}^2 + \frac{1}{d_{\Omega_i}}\|v\|_{0,\Gamma_{ij}}^2\right)^{1/2}.$$

From section 4.1 in [19], for $v \in H_{00}^{1/2}(\Gamma_{ij})$ we have the following relation:

$$C_1\|\widetilde{v}\|_{1/2,\partial\Omega_i} \le \|v\|_{H_{00}^{1/2}(\Gamma_{ij})} \le C_2\|\widetilde{v}\|_{1/2,\partial\Omega_i}, \tag{2.5}$$

where the constants C_1 and C_2 are independent of d_{Ω_i} and $\widetilde{v}$ denotes the zero extension of v into $\partial\Omega_i$.

2.2. Mortar matching conditions. We note that the space X is not contained in $H^1(\Omega)$. To approximate the solution of the problem (2.1) in X, we use the mortar matching condition. More precisely, we construct the Lagrange multiplier space as follows.

First, let $\Gamma_{ij} := \partial\Omega_i \cap \partial\Omega_j$. For Γ_{ij} such that $|\Gamma_{ij}| \neq 0$, we distinguish $\Omega_i^h|_{\Gamma_{ij}}$ and $\Omega_j^h|_{\Gamma_{ij}}$, as in Figure 1. We assume that both sides have more than three nodal points including end points. Then we choose one as a slave side and the other as a master side and define

$$m_i := \{j \ : \ |\Gamma_{ij}| \neq 0,\ \Omega_j^h|_{\Gamma_{ij}} \text{ is a master side of } \Gamma_{ij}\},$$
$$s_i := \{j \ : \ |\Gamma_{ij}| \neq 0,\ \Omega_j^h|_{\Gamma_{ij}} \text{ is a slave side of } \Gamma_{ij}\}.$$

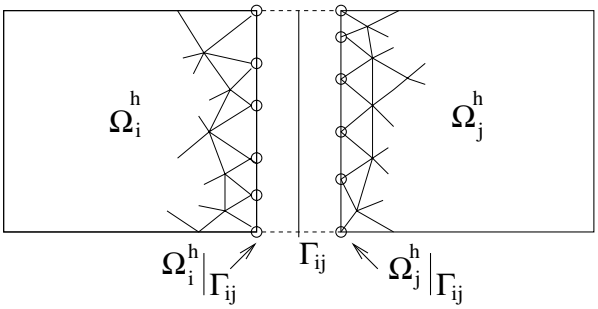

FIG. 1. *Master and slave sides of* Γ_{ij}.

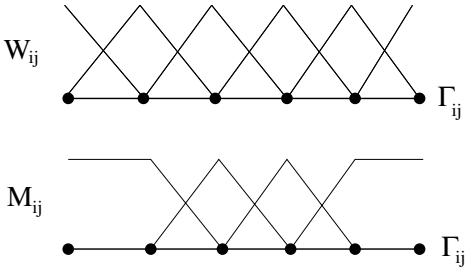

FIG. 2. *Basis functions for* W_{ij} *and* M_{ij}.

For $j \in m_i$, $\Omega_i^h|_{\Gamma_{ij}}$ is the slave side of Γ_{ij} and from the finite elements on the slave side, we get

$$W_{ij} := \{v|_{\Gamma_{ij}} \ : \ v \in X_i\} \ \ \forall\, j \in m_i.$$

Next, let

$$\{\phi_0^{ij},\ \phi_1^{ij}, \ldots, \phi_{N_{ij}}^{ij},\ \phi_{N_{ij}+1}^{ij}\}$$

be nodal basis functions for W_{ij}. Moreover, we assume that the basis functions are sequentially ordered according to the location of nodes on Γ_{ij}. Let (see Figure 2)

$$M_{ij} := \text{span}\{\phi_0^{ij} + \phi_1^{ij},\ \phi_2^{ij}, \ldots, \phi_{N_{ij}-1}^{ij}, \phi_{N_{ij}}^{ij} + \phi_{N_{ij}+1}^{ij}\}.$$

Then we take the Lagrange multiplier space

$$M := \prod_{i=1}^{N} \prod_{j \in m_i} M_{ij}.$$

Bernardi, Maday, and Patera [2] first introduced this type of Lagrange multiplier space. They imposed the following mortar matching condition on X, i.e., $v \in X$ satisfies

$$\int_{\Gamma_{ij}} (v_i - v_j)\lambda_{ij}\, ds = 0 \ \ \forall\ \lambda_{ij} \in M_{ij},\ i = 1, \ldots, N,\ j \in m_i. \tag{2.6}$$

In our FETI-DP formulation, we use (2.6) as continuity constraints and define a bilinear form $b(\cdot,\cdot) : W \times M \to \mathbb{R}$ as

$$b(w,\mu) := \sum_{i=1}^{N} \sum_{j\in m_i} \int_{\Gamma_{ij}} (w_i - w_j)\,\mu_{ij}\,ds \quad \forall (w,\mu) \in W \times M. \tag{2.7}$$

For $|\partial\Omega_i \cap \partial\Omega_j| \neq 0$, we denote $\partial\Omega_i \cap \partial\Omega_j$ as Γ_{ij} if $\Omega_i^h|_{\Gamma_{ij}}$ is a slave side and as Γ_{ji} otherwise. We assume that $\Omega_i^h|_{\Gamma_{ij}}$ is the slave side and $\Omega_j^h|_{\Gamma_{ij}}$ is the master side of Γ_{ij}. Denote the basis for M_{ij} by $\{\xi_k^{ij}\}_{k=1}^{N_{ij}}$ and let $\{\phi_k^{ji}\}_{k=0}^{N_{ji}+1}$ be the basis functions for $W_j|_{\Gamma_{ij}}$. Define matrices B_i^{ij} and B_j^{ij} with entries

$$\left(B_i^{ij}\right)_{lk} = \int_{\Gamma_{ij}} \xi_l^{ij}\phi_k^{ij}\,ds,\ l = 1,\dots,N_{ij},\ k = 0,\dots,N_{ij}+1,$$
$$\left(B_j^{ij}\right)_{lk} = -\int_{\Gamma_{ij}} \xi_l^{ij}\phi_k^{ji}\,ds,\ l = 1,\dots,N_{ij},\ k = 0,\dots,N_{ji}+1.$$

Then we rewrite (2.6) as

$$B_i^{ij} w_i^{ij} + B_j^{ij} w_j^{ij} = 0,$$

where $w_i^{ij} = v_i|_{\Gamma_{ij}}$ and $w_j^{ij} = v_j|_{\Gamma_{ij}}$.

Now define $E_{ij} : M_{ij} \to M$, an extension operator from M_{ij} to M by zero, and $R_{ij}^l : W_l \to W_l|_{\Gamma_{ij}}$ for $l = i, j$, a restriction operator. Let

$$B_i = \sum_{j\in m_i} E_{ij} B_i^{ij} R_{ij}^i + \sum_{j\in s_i} E_{ji} B_i^{ji} R_{ji}^i.$$

Then the mortar matching condition (2.6) becomes

$$\sum_{i=1}^{N} B_i w_i = 0,$$

where $w_i = v_i|_{\partial\Omega_i}$.

Define

$$W_{ij}^0 := \{v \in W_{ij} \ :\ v = 0 \text{ at the end points of } \Gamma_{ij}\}$$

and let

$$W^0 = \prod_{i=1}^{N} \prod_{j\in m_i} W_{ij}^0.$$

For $w_{ij} \in W_{ij}^0$, we define $\widetilde{w}_{ij} \in W_i$ by the zero extension of w_{ij} into $\partial\Omega_i$. Let $\widetilde{w}_i = \sum_{j\in m_i} \widetilde{w}_{ij}$ and $\widetilde{w} = (\widetilde{w}_1,\dots,\widetilde{w}_N)$. Since $\widetilde{w}$ is continuous at subdomain vertices, $\widetilde{w} \in W$. Hence for $w \in W^0$, we define a norm by

$$\|w\|_{W^0} := \|\widetilde{w}\|_W. \tag{2.8}$$

Let $\langle\cdot,\cdot\rangle_m$ be a duality pairing between M and W^0 such that

$$\langle\lambda, w\rangle_m := \sum_{i=1}^{N} \sum_{j\in m_i} \int_{\Gamma_{ij}} \lambda_{ij} w_{ij}\,ds \ \ \forall\,(\lambda, w) \in M \times W^0. \tag{2.9}$$

Using this, we define a dual norm on M by

$$\|\lambda\|_{(W^0)'} := \max_{w \in W^0 \setminus \{0\}} \frac{\langle \lambda, w \rangle_m}{\|w\|_{W^0}}. \tag{2.10}$$

3. FETI-DP formulation.

3.1. FETI-DP operator. In this section, we construct the FETI-DP operator for the problem (2.1) with the mortar matching condition as constraints. The derivation of the FETI-DP equation for the Lagrange multipliers follows [10]. However, the FETI-DP operator with mortar matching condition is new. Dryja and Widlund [4, 5] eliminate unknowns on both interior and vertex nodal points and impose a mortar matching condition over W_r in (2.4). Hence, the resulting solution u does not satisfy the mortar matching condition (2.6). We eliminate only interior nodal points and impose the mortar matching condition on the function over W in (2.2).

For $w_i \in W_i$ we write

$$w_i = \begin{pmatrix} w_r^i \\ w_c^i \end{pmatrix},$$

where r and c stand for the nodal values on the edges and vertices. From now on, we use the subscript symbol r and c to represent the d.o.f. corresponding to nodes on the edges and at the vertices, respectively.

Define W_c as the set of vectors which have d.o.f. corresponding to the union of subdomain vertices, that is, global corner points. For $w = (w_1, \dots, w_N) \in W$, since w is continuous at subdomain vertices, there exists $w_c \in W_c$ such that $L_c^i w_c = w_c^i$ for all $i = 1, \dots, N$, where the matrix L_c^i consists of 0 and 1 and restricts the value of w_c on the vertices of subdomain Ω_i. Hence, for $w = (w_1, \dots, w_N) \in W$, we write

$$w_i = \begin{pmatrix} w_r^i \\ L_c^i w_c \end{pmatrix} \ \forall i \ \text{ for some } w_c \in W_c.$$

Recall that S^i is the Schur complement matrix obtained from the bilinear form $a_i(\cdot,\cdot)$ and let g^i be the Schur complement forcing vector obtained from $\int_{\Omega_i} f v_i \, dx$. The matrix S^i and vector g^i are ordered in the following way:

$$S^i = \begin{pmatrix} S_{rr}^i & S_{rc}^i \\ S_{cr}^i & S_{cc}^i \end{pmatrix}, \quad g^i = \begin{pmatrix} g_r^i \\ g_c^i \end{pmatrix}.$$

Let $B_{i,r}$ and $B_{i,c}$ be matrices that consist of the columns of B_i corresponding to the nodal points on the edges and at the vertices, respectively.

Then the problem (2.1) becomes the following: Find $(w_r, w_c, \lambda) \in W_r \times W_c \times M$ such that

$$S_{rr} w_r + S_{rc} w_c + B_r^t \lambda = g_r, \tag{3.1}$$

$$S_{cr} w_r + S_{cc} w_c + B_c^t \lambda = g_c, \tag{3.2}$$

$$B_r w_r + B_c w_c = 0, \tag{3.3}$$

where

$$S_{rr} = \mathrm{diag}_{i=1,\dots,N} \left(S_{rr}^i \right),$$

$$S_{rc} = \begin{pmatrix} S_{rc}^1 L_c^1 \\ \vdots \\ S_{rc}^N L_c^N \end{pmatrix},$$

$$
\begin{aligned}
&S_{cr} = S_{rc}^t,\\
&S_{cc} = \sum_{i=1}^{N} (L_c^i)^t S_{cc}^i L_c^i,\\
&B_r = (B_{1,r}, \dots, B_{N,r}), \quad B_c = \sum_{i=1}^{N} B_{i,c} L_c^i,\\
&g_r = \begin{pmatrix} g_r^1 \\ \vdots \\ g_r^N \end{pmatrix}, \; g_c = \sum_{i=1}^{N} (L_c^i)^t \; g_c^i, \; w_r = \begin{pmatrix} w_r^1 \\ \vdots \\ w_r^N \end{pmatrix}.
\end{aligned}
$$

Since S_{rr} is invertible, we solve (3.1) for w_r to get

$$w_r = S_{rr}^{-1} \left(g_r - S_{rc} w_c - B_r^t \lambda \right).$$

After substituting w_r into (3.3) and (3.2), we obtain

$$
\begin{aligned}
B_r S_{rr}^{-1} B_r^t \lambda + \left(B_r S_{rr}^{-1} S_{rc} - B_c \right) w_c &= B_r S_{rr}^{-1} g_r,\\
\left(S_{cr} S_{rr}^{-1} B_r^t - B_c^t \right) \lambda - \left(S_{cc} - S_{cr} S_{rr}^{-1} S_{rc} \right) w_c &= - \left(g_c - S_{cr} S_{rr}^{-1} g_r \right).
\end{aligned}
$$

Let

$$
\begin{aligned}
&F_{I_{rr}} = B_r S_{rr}^{-1} B_r^t,\\
&F_{I_{rc}} = B_r S_{rr}^{-1} S_{rc} - B_c,\\
&F_{I_{cr}} = S_{cr} S_{rr}^{-1} B_r^t - B_c^t \left(= F_{I_{rc}}^t \right),\\
&F_{I_{cc}} = S_{cc} - S_{cr} S_{rr}^{-1} S_{rc},\\
&d_r = B_r S_{rr}^{-1} g_r,\\
&d_c = g_c - S_{cr} S_{rr}^{-1} g_r.
\end{aligned}
\tag{3.4}
$$

Then (λ, w_c) satisfies

$$\begin{pmatrix} F_{I_{rr}} & F_{I_{rc}} \\ F_{I_{cr}} & -F_{I_{cc}} \end{pmatrix} \begin{pmatrix} \lambda \\ w_c \end{pmatrix} = \begin{pmatrix} d_r \\ -d_c \end{pmatrix}.$$

Eliminating w_c in the above equation, we obtain

$$\left(F_{I_{rr}} + F_{I_{rc}} F_{I_{cc}}^{-1} F_{I_{cr}} \right) \lambda = d_r - F_{I_{rc}} F_{I_{cc}}^{-1} d_c.$$

Here, $F_{DP} = F_{I_{rr}} + F_{I_{rc}} F_{I_{cc}}^{-1} F_{I_{cr}}$ is called the FETI-DP operator for the problem (2.1).

3.2. Preconditioner. From now on, we will propose $\widehat{F}_{DP}^{-1}$, a preconditioner for F_{DP}, which is derived from the dual norm on the Lagrange multiplier space M in the following sense:

$$\langle \widehat{F}_{DP} \lambda, \lambda \rangle = \|\lambda\|_{(W^0)'}^2. \tag{3.5}$$

We will derive the matrix form of $\widehat{F}_{DP}$ from the above relation. Define $E_{ij}^i : W_{ij}^0 \to W_i$ as the extension operator by 0. Then we get

$$\widetilde{w}_{ij} = E_{ij}^i w_{ij} \quad \text{for} \quad w_{ij} \in W_{ij}^0.$$

Define $R_{ij} : W^0 \to W^0_{ij}$ to be a restriction operator. For $w \in W^0$, we let $w_{ij} = R_{ij}w$. Hence by (2.8) and (2.3), we get

$$\|w\|^2_{W^0} = \sum_{i=1}^{N} \left\langle S^i \left(\sum_{j\in m_i} E^i_{ij} R_{ij} w \right), \sum_{j\in m_i} E^i_{ij} R_{ij} w \right\rangle.$$

Let $E^i = \sum_{j\in m_i} E^i_{ij} R_{ij}$; then we have

$$\|w\|^2_{W^0} = \langle \widehat{S} w, w\rangle \quad \text{with} \quad \widehat{S} = \sum_{i=1}^{N} (E^i)^t S^i E^i. \tag{3.6}$$

Recall that

$$(B^{ij}_i)_{lk} = \int_{\Gamma_{ij}} \xi^{ij}_l \phi^{ij}_k \, ds, \ l = 1, \dots, N_{ij}, \ k = 0, 1, \dots, N_{ij} + 1,$$

and take $(B^{ij}_{i,r})_{lk} = (B^{ij}_i)_{lk}$ for $l, k = 1, \dots, N_{ij}$. Since $w_{ij} \in W^0_{ij}$, we have

$$\lambda^t_{ij} B^{ij}_{i,r} w_{ij} = \int_{\Gamma_{ij}} \lambda_{ij} w_{ij} \, ds.$$

Let

$$\widehat{B} = \mathrm{diag}_{i=1,\dots,N} \left(\mathrm{diag}_{j\in m_i} \left(B^{ij}_{i,r} \right) \right).$$

Then, for $(w, \lambda) \in W^0 \times M$, we get

$$\lambda^t \widehat{B} w = \sum_{i=1}^{N} \sum_{j\in m_i} \int_{\Gamma_{ij}} \lambda_{ij} w_{ij} \, ds, \tag{3.7}$$

where $\lambda_{ij} = \lambda|_{\Gamma_{ij}}$ and $w_{ij} = w|_{\Gamma_{ij}}$.

From the definition of the dual norm (2.10), (2.9), (3.7), and (3.6), we obtain

$$\|\lambda\|^2_{(W^0)'} = \max_{w\in W^0\setminus\{0\}} \frac{\langle \lambda, \widehat{B} w\rangle^2}{\langle \widehat{S} w, w\rangle}.$$

Since $\widehat{S}$ is symmetric and positive definite on W^0, in the above equation the maximum occurs when $\widehat{B}^t \lambda = \widehat{S} w$. Therefore, we have

$$\|\lambda\|^2_{(W^0)'} = \langle \widehat{B} \widehat{S}^{-1} \widehat{B}^t \lambda, \lambda\rangle$$

and let $\widehat{F}_{DP} = \widehat{B} \widehat{S}^{-1} \widehat{B}^t$. Then we take $\widehat{F}^{-1}_{DP} = (\widehat{B} \widehat{S}^{-1} \widehat{B}^t)^{-1}$ as a preconditioner for F_{DP} and call it a Neumann–Dirichlet preconditioner.

Note that $\widehat{F}^{-1}_{DP} = (\widehat{B}^t)^{-1} \widehat{S} \widehat{B}^{-1}$ is easy to implement due to the block diagonal structure of $\widehat{B}$ and $\widehat{B}^t = \widehat{B}$. Therefore, we have

$$\widehat{F}^{-1}_{DP} = \sum_{i=1}^{N} \left(\sum_{j\in m_i} R^t_{ij} (B^{ij}_{i,r})^{-1} (E^i_{ij})^t \right) S^i \left(\sum_{j\in m_i} E^i_{ij} (B^{ij}_{i,r})^{-1} R_{ij} \right) \tag{3.8}$$

so that the work can be done in parallel in each subdomain. Let

$$\widehat{B}_i = \sum_{j \in m_i} R_{ij}^t (B_{i,r}^{ij})^{-1} (E_{ij}^i)^t.$$

Moreover, from the operator $\widehat{B}_i$, we can see that the preconditioner $\widehat{F}_{DP}^{-1}$ is different from the preconditioners in [4, 5, 8, 9, 10]. Only on the slave sides of interfaces are the function values transferred between the spaces W_i and M. Hence, the cost needed to compute $\widehat{B}_i w_i$ and $\widehat{B}_i^t \lambda$ is reduced by half compared with other FETI (-DP) preconditioners.

4. Condition number estimation for the preconditioned FETI-DP operator. The following well-known result is given when $a_i(u,v) = \int_{\Omega_i} \nabla u \cdot \nabla v \, dx$ (see Theorem 4.1.3 in [11]). With slight modification, we can obtain a similar result for a general case.

LEMMA 4.1. *For $w_i \in W_i$, we have*

$$C_1 |w_i|^2_{1/2,\partial\Omega_i} \le \langle S^i w_i, w_i \rangle \le C_2 \|w_i\|^2_{1/2,\partial\Omega_i},$$

where C_1 and C_2 are constants depending on $A(x)$ and $\beta(x)$, but independent of H_i and h_i.

In the following, we obtain a formula that is useful for analyzing the condition number bound and the result is the same as Lemma 4.3 of Mandel and Tezaur [10]. However, in our formulation, the continuity constraints are imposed on $w \in W$, that is, the d.o.f. on edges and global corners (see (3.3)). The proof can be done similarly as in Lemma 37 of Tezaur [16].

LEMMA 4.2. *For $\lambda \in M$, we have*

$$\max_{w \in W \setminus \{0\}} \frac{b(w,\lambda)^2}{\|w\|_W^2} = \langle F_{DP} \lambda, \lambda \rangle.$$

Now, we estimate the lower bound of the condition number for the operator $\widehat{F}_{DP}^{-1} F_{DP}$.

LEMMA 4.3. *For any $\lambda \in M$, we have*

$$\max_{w \in W \setminus \{0\}} \frac{b(w,\lambda)^2}{\|w\|_W^2} \ge \|\lambda\|_{(W^0)'}.$$

Proof. For $w \in W^0$, let $\widetilde{w}_i = \sum_{j \in m_i} \widetilde{w}_{ij}$ and $\widetilde{w} = (\widetilde{w}_1, \dots, \widetilde{w}_N)$. Then we have $\widetilde{w} \in W$. Hence it follows that

$$\max_{w \in W \setminus \{0\}} \frac{b(w,\lambda)^2}{\|w\|_W^2} \ge \max_{w \in W^0 \setminus \{0\}} \frac{b(\widetilde{w},\lambda)^2}{\|\widetilde{w}\|_W^2}. \tag{4.1}$$

Since $\widetilde{w}_j = 0$ on Γ_{ij} for $j \in m_i$, we have

$$b(\widetilde{w},\lambda) = \sum_{i=1}^N \sum_{j \in m_i} \int_{\Gamma_{ij}} w_{ij} \lambda_{ij} \, ds = \langle \lambda, w \rangle_m. \tag{4.2}$$

Combining (4.2), (2.8), and (2.10), we obtain

$$\max_{w \in W^0 \setminus \{0\}} \frac{b(\widetilde{w},\lambda)^2}{\|\widetilde{w}\|_W^2} = \max_{w \in W^0 \setminus \{0\}} \frac{\langle \lambda, w \rangle_m^2}{\|w\|_{W^0}^2} = \|\lambda\|^2_{(W^0)'}. \tag{4.3}$$

From (4.1) and (4.3), we complete the proof. ∎

To estimate the upper bound for $\langle F_{DP}\lambda, \lambda\rangle$, we need the following estimate for $\|w_i - w_j\|^2_{H_{00}^{1/2}(\Gamma_{ij})}$.

LEMMA 4.4. *For $w \in W$, let $w_i = w|_{\partial\Omega_i}$ and $w_j = w|_{\partial\Omega_j}$. Then we have*

$$\|w_i - w_j\|^2_{H_{00}^{1/2}(\Gamma_{ij})} \le C \max_{l\in\{i,j\}} \left\{ \left(1 + \log \frac{H_l}{h_l}\right)^2 \right\} \left(|w_i|^2_{1/2,\partial\Omega_i} + |w_j|^2_{1/2,\partial\Omega_j} \right),$$

where C is a constant independent of h_i's and H_i's.

Proof. Let $I^H w$ be a linear function on Γ_{ij} that has the same value as w at the end points of Γ_{ij}. From Lemma 5.1 in [10], we have

$$|w_l - I^H w_l|_{H_{00}^{1/2}(\Gamma_{ij})} \le C \left(1 + \log \frac{H_l}{h_l}\right) |w_l|_{1/2,\partial\Omega_l} \text{ for } l = i, j.$$

Using the above bound and the equivalence of $|\cdot|_{H_{00}^{1/2}(\Gamma_{ij})}$ and $\|\cdot\|_{H_{00}^{1/2}(\Gamma_{ij})}$, the result follows. ∎

DEFINITION 4.5. *We define a projection $\pi_{ij} : H_{00}^{1/2}(\Gamma_{ij}) \to W_{ij}^0$ for $v \in H_{00}^{1/2}(\Gamma_{ij})$ by*

$$\int_{\Gamma_{ij}} (v - \pi_{ij} v)\lambda_{ij}\, ds \ = 0 \ \ \forall \lambda_{ij} \in M_{ij}.$$

From Lemma 2.2 in [1], π_{ij} is a continuous operator on $H_{00}^{1/2}(\Gamma_{ij})$, i.e., there exists a constant C such that

$$\|\pi_{ij} v\|_{H_{00}^{1/2}(\Gamma_{ij})} \le C \|v\|_{H_{00}^{1/2}(\Gamma_{ij})} \ \ \forall v \in H_{00}^{1/2}(\Gamma_{ij}). \tag{4.4}$$

We note that the constant C is independent of H_i's and h_i's.

Now, we estimate the upper bound for the operator $\widehat{F}_{DP}^{-1} F_{DP}$.

LEMMA 4.6. *For $\lambda \in M$, we have*

$$\max_{w\in W\setminus\{0\}} \frac{b(w,\lambda)^2}{\|w\|^2_W} \le C \max_{i=1,\dots,N} \left\{ \left(1 + \log \frac{H_i}{h_i}\right)^2 \right\} \|\lambda\|^2_{(W^0)'},$$

where C is a constant depending on $A(x)$ and $\beta(x)$, but independent of h_i's and H_i's.

Proof. From the definitions of $b(w,\lambda)$ in (2.7) and π_{ij}, we have

$$b(w,\lambda)^2 = \left(\sum_{i=1}^N \sum_{j\in m_i} \int_{\Gamma_{ij}} \pi_{ij}(w_i - w_j)\lambda_{ij}\, ds \right)^2.$$

We let $z \in W^0$ such that $z|_{\Gamma_{ij}} = \pi_{ij}(w_i - w_j)$. Then the above equation is the duality pairing between λ and z. Hence, using the definition of dual norm on λ, we get

$$b(w,\lambda)^2 \le \|\lambda\|^2_{(W^0)'} \|z\|^2_{W^0}. \tag{4.5}$$

Let $\widetilde{z} = (\widetilde{z}_1, \dots, \widetilde{z}_N) \in W$ be the zero extension of z. Then from (2.8), (2.3), Lemma 4.1, (2.5), (4.4), and Lemma 4.4,

$$
\begin{aligned}
\|z\|_{W^0}^2 &= \sum_{i=1}^{N} \langle S^i \widetilde{z}_i, \widetilde{z}_i \rangle \\
&\le C \sum_{i=1}^{N} \|\widetilde{z}_i\|_{1/2,\partial\Omega_i}^2 \\
&\le C \sum_{i=1}^{N} \sum_{j \in m_i} \|\pi_{ij}(w_i - w_j)\|_{H_{00}^{1/2}(\Gamma_{ij})}^2 \\
&\le C \sum_{i=1}^{N} \sum_{j \in m_i} \|w_i - w_j\|_{H_{00}^{1/2}(\Gamma_{ij})}^2 \\
&\le C \max_{i=1,\cdots,N} \left\{ \left(1 + \log \frac{H_i}{h_i} \right)^2 \right\} \sum_{i=1}^{N} |w_i|_{1/2,\partial\Omega_i}^2 \\
&\le C \max_{i=1,\cdots,N} \left\{ \left(1 + \log \frac{H_i}{h_i} \right)^2 \right\} \|w\|_W^2.
\end{aligned}
\tag{4.6}
$$

Here, C denotes a generic constant independent of h_i's and H_i's, which may vary from occurrence to occurrence. Combining (4.5) and (4.6), we complete the proof. □

Since the preconditioner $\widehat{F}_{DP}^{-1}$ follows from the dual norm of $\lambda \in M$ (see (3.5)), combining Lemmas 4.2, 4.3, and 4.6, we obtain the following estimate.

THEOREM 4.7. *For $\lambda \in M$, we have*

$$
\langle \widehat{F}_{DP}\lambda, \lambda \rangle \le \langle F_{DP}\lambda, \lambda \rangle \le C \max_{i=1,\dots,N} \left\{ \left(1 + \log \frac{H_i}{h_i} \right)^2 \right\} \langle \widehat{F}_{DP}\lambda, \lambda \rangle,
$$

where C is a constant depending on $A(x)$ and $\beta(x)$, but independent of H_i's and h_i's.

COROLLARY 4.8. *We have the following condition number estimate:*

$$
\kappa \left(\widehat{F}_{DP}^{-1} F_{DP} \right) \le C \max_{i=1,\dots,N} \left\{ \left(1 + \log \frac{H_i}{h_i} \right)^2 \right\},
$$

where C is a constant depending on $A(x)$ and $\beta(x)$, but independent of H_i's and h_i's.

Remark 4.1. On each Γ_{ij}, the choices of master and slave sides are arbitrary.

Remark 4.2. In Corollary 4.8, the condition number depends on $A(x)$ and $\beta(x)$. Now we consider the problem

$$
\begin{aligned}
-\nabla \cdot (\alpha(x) \nabla u(x)) &= f(x) \ \text{ in } \ \Omega, \\
u &= 0 \ \text{ on } \ \partial\Omega,
\end{aligned}
$$

where $\alpha(x)$ is a piecewise constant and has jumps across the subdomain boundaries, i.e., $\alpha(x) = \rho_i$ for all $x \in \Omega_i$ for some constant $\rho_i > 0$. On Γ_{ij}, we choose $\Omega_i^h|_{\Gamma_{ij}}$ as the slave side if $\rho_i \le \rho_j$. Otherwise, we choose $\Omega_i^h|_{\Gamma_{ij}}$ as the master side. Then we have

$$
C_1 \rho_i |w_i|_{1/2,\partial\Omega_i}^2 \le \langle S^i w_i, w_i \rangle \le C_2 \rho_i \|w_i\|_{1/2,\partial\Omega_i}^2,
$$

where C_1 and C_2 are constants independent of ρ_i's, h_i's, and H_i's. Following the proof of Lemma 4.6 and using the above inequalities instead of Lemma 4.1, we obtain

$$\begin{aligned}
\|z\|^2_{W^0} &\le C\sum_{i=1}^{N}\sum_{j\in m_i}\rho_i\|w_i-w_j\|^2_{H^{1/2}_{00}(\Gamma_{ij})}\\
&\le C\sum_{i=1}^{N}\sum_{j\in m_i}\left\{\max_{l\in\{i,j\}}\left\{\left(1+\log\frac{H_l}{h_l}\right)^2\right\}\right.\\
&\qquad\left.\times\left(\rho_i|w_i|^2_{1/2,\partial\Omega_i}+\rho_i|w_j|^2_{1/2,\partial\Omega_j}\right)\right\}\\
&\le C\sum_{i=1}^{N}\sum_{j\in m_i}\left\{\max_{l\in\{i,j\}}\left\{\left(1+\log\frac{H_l}{h_l}\right)^2\right\}\right.\\
&\qquad\left.\times\left(\langle S^i w_i,w_i\rangle+\frac{\rho_i}{\rho_j}\langle S^j w_j,w_j\rangle\right)\right\},
\end{aligned}$$

where C is a generic constant independent of ρ_i's, H_i's, and h_i's. Since $\rho_i \le \rho_j$, we can see that the constant C in Lemma 4.6 is bounded independently of the coefficients. Hence, the condition number bound is independent of ρ_i's.

5. Numerical results. In this section, we provide numerical tests for the FETI-DP formulation developed in this paper. Let $\Omega = [0,1]\times[0,1] \subset \mathbb{R}^2$ and consider the following model problem:

$$\begin{aligned}
-\nabla\cdot(\alpha(x,y)\nabla u) &= f \ \text{ in } \ \Omega,\\
u &= 0 \ \text{ on } \ \partial\Omega.
\end{aligned}\tag{5.1}$$

We compare the proposed preconditioner (3.8) with the preconditioner of Dryja and Widlund [5] for the cases when $\alpha(x,y)=1$ and mesh sizes are comparable between neighboring subdomains, and when $\alpha(x,y)$ are highly discontinuous across subdomain interfaces and mesh sizes are not comparable. In the following, we use the notation $\widehat{F}^{-1}_{KL}$ for the preconditioner (3.8) and use $\widehat{F}^{-1}_{DW}$ for Dryja and Widlund's. The preconditioner $\widehat{F}^{-1}_{DW}$ is

$$\widehat{F}^{-1}_{DW} = (B_r\widetilde{B}^t_r)^{-1}\widetilde{B}_r S_{rr}\widetilde{B}^t_r(\widetilde{B}_r B^t_r)^{-1},$$

where $\widetilde{B}_r$ is the scaled matrix of B_r divided by the mesh parameters of slave and master sides (see (3.13) in [5]).

First, we compare these two preconditioners for the same problem with nonmatching discretizations. We take $\alpha(x,y)=1$ and the exact solution $u(x,y) = y(1-y)\sin\pi x$. The CG iteration continues until the relative residual norm is less than 10^{-6}. We use n to denote the number of nodes on edges, including end points, and use N to denote the number of subdomains. In this problem, we use the same n for all subdomains, divide Ω into rectangular subdomains, as in Figure 3, and denote each subdomain by Ω_{ij}.

To make nonmatching grids across subdomain interfaces, we generate triangulations in each subdomain in the following way: For each subdomain, we have chosen n random quasi-uniform nodes on each horizontal and vertical edge. Using these

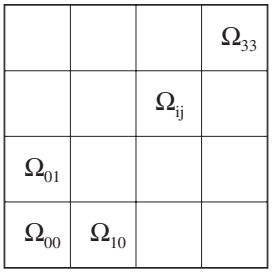

FIG. 3. *Partition of subdomains when* $N = 4 \times 4$.

TABLE 1

Comparison between the proposed preconditioner F_{KL}^{-1} *and the Dryja–Widlund preconditioner* F_{DW}^{-1} *on nonmatching grids when n increases with* $N = 4 \times 4$*: Iter (number of CG iteration), Cond (condition number of the preconditioned FETI-DP operator).*

$n-1$	L^2-error	H^1-error	$\widehat{F}_{KL}^{-1}$		$\widehat{F}_{DW}^{-1}$	
			Iter	Cond	Iter	Cond
4	5.0850e-4	6.0126e-2	10	3.07	7	1.94
8	1.2865e-4	3.0128e-2	13	5.67	8	2.68

32	8.0627e-6	7.5374e-3	16	9.99	10	4.80
64	2.0163e-6	3.7688e-3	17	12.6	11	6.14

nodes, we generate nonuniform structured grids in each subdomain. Since we use the same n for all subdomains, the sizes of meshes between neighboring subdomains are comparable.

In Table 1, we divide Ω into $N = 4 \times 4$ subdomains (see Figure 3), increase the number of nodes n, and compute L^2- and H^1-errors, the number of CG iterations and condition numbers for those preconditioners. For the H^1-error, we compute the broken H^1-norm of errors over all subdomains. Table 2 shows the numerical results when we fix $n - 1 = 4$ and increase the number of subdomains N. For the cases $N = 8 \times 8$, 16×16, and 32×32, we divide Ω into subdomains in the same manner as $N = 4 \times 4$. Here, we used the FETI-DP formulation developed in this paper. From Tables 1 and 2, we can see that our FETI-DP formulation gives $O(h^2)$ and $O(h)$ convergences for L^2- and H^1-errors, respectively. Furthermore, we can see that both preconditioners seem to give the $\log^2$-growth of the condition number bound and that the CG iteration of $\widehat{F}_{DW}^{-1}$ is smaller than $\widehat{F}_{KL}^{-1}$.

Now, we consider the problem (5.1) when $\alpha(x, y)$ is highly discontinuous across subdomain interfaces and the mesh sizes between subdomains are not comparable. In this situation, we will compare two preconditioners $\widehat{F}_{KL}^{-1}$ and $\widehat{F}_{DW}^{-1}$.

We consider the cases of $N = 2 \times 2$, 4×4, 8×8 subdomains. For each subdomain Ω_{ij}, we choose the coefficient $\alpha(x, y)$ in the following way:

$$\alpha(x,y) = \begin{cases} 1 & \text{if both } i \text{ and } j \text{ are even,} \\ 250 & \text{if } i \text{ is odd and } j \text{ is even,} \\ 5000 & \text{if } i \text{ is even and } j \text{ is odd,} \\ 10 & \text{if both } i \text{ and } j \text{ are odd,} \end{cases}$$

and denote them by ρ_{ij}. In addition, we consider the exact solution $u(x, y)$, which

TABLE 2

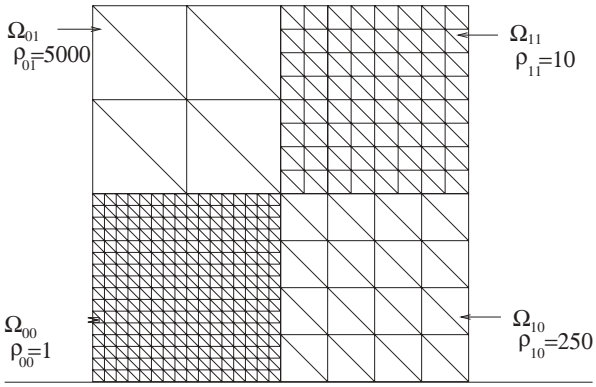

FIG. 4. *Triangulations for the case $N = 2 \times 2$ and $\max(H_{ij}/h_{ij}) = 16$.*

belongs to $H^1(\Omega)$, according to the partition of the domain:

$$u(x,y) = \begin{cases} p_1(x,y)\sin(\pi x)\sin(\pi y)/\alpha(x,y) & \text{when } N = 2 \times 2, \\ p_2(x,y)\sin(2\pi x)\sin(2\pi y)/\alpha(x,y) & \text{when } N = 4 \times 4, \\ \sin(8\pi x)\sin(8\pi y)/\alpha(x,y) & \text{when } N = 8 \times 8, \end{cases}$$

where

$$p_1(x,y) = (x-1/2)(y-1/2),$$
$$p_2(x,y) = (x-1/4)(x-3/4)(y-1/4)(y-3/4).$$

Following [18, section 1.5.3], we have chosen a different mesh size in each subdomain according to the ratio of coefficients between neighboring subdomains, that is,

$$\frac{h_{ij}}{h_{kl}} \simeq \sqrt[4]{\frac{\rho_{ij}}{\rho_{kl}}},$$

where h_{ij} is the mesh size of the subdomain Ω_{ij}, and we use H_{ij} to denote the size of the subdomain Ω_{ij}. Using the mesh sizes of these ratios, we divide each subdomain into uniform meshes. When $N = 2 \times 2$ and $\max(H_{ij}/h_{ij}) = 16$, we

TABLE 3
Comparison between the proposed preconditioner $\hat{F}_{KL}^{-1}$ and the Dryja–Widlund preconditioner $\hat{F}_{DW}^{-1}$ for the problem of highly discontinuous coefficients: Iter (number of GC iteration).

N	$\max(H_{ij}/h_{ij})$	L^2-error	H^1-error	$\hat{F}_{KL}^{-1}$	$\hat{F}_{DW}^{-1}$
				Iter	Iter
2×2	16	3.0571e-5	7.6362e-3	3	17
	32	7.8276e-6	3.8249e-3	3	26

	64	6.4579e-5	2.2240e-1	4	168

obtain triangulations as in Figure 4 and the triangulations are not comparable between neighboring subdomains.

In section 1.5.3 of [18], it was shown that a good approximation of the solution is obtained when the slave side is chosen to give a Lagrange multiplier space of higher dimension. Hence, choosing the subdomain with smaller h_{ij} (smaller ρ_{ij}) as the slave side, we can approximate the exact solution more accurately. This observation coincides with the choices of master and slave sides in Remark 4.2.

Table 3 shows L^2- and H^1-errors and CG iterations with $\widehat{F}_{KL}^{-1}$ and $\widehat{F}_{DW}^{-1}$ as preconditioners. In CG iteration, we use the same stopping criterion 10^{-6} as before. Increasing $\max(H_{ij}/h_{ij})$, we observe the $O(h^2)$ and $O(h)$ convergences of L^2- and H^1-errors, respectively, for all cases of N. Furthermore, we see that the CG iteration of $\widehat{F}_{KL}^{-1}$ is much smaller than $\widehat{F}_{DW}^{-1}$. Since, the condition number bound of the preconditioner $\widehat{F}_{DW}^{-1}$ depends on the ratio of meshes between neighboring subdomains, the preconditioner works inefficiently for these problems with noncomparable meshes.

From our numerical results, we conclude that our formulation gives the correct approximation of the model problem with nonmatching grids. For the case of continuous coefficients and comparable meshes between subdomain interfaces, the preconditioner $\widehat{F}_{DW}^{-1}$ by Dryja and Widlund gives a smaller number of iterations than our preconditioner $\widehat{F}_{KL}^{-1}$. However, our preconditioner $\widehat{F}_{KL}^{-1}$ turns out to be much more efficient than $\widehat{F}_{DW}^{-1}$ for the problem of highly discontinuous coefficients on noncomparable meshes.

THE ACCURACY OF THE CHEBYSHEV DIFFERENCING METHOD FOR ANALYTIC FUNCTIONS*

S. C. REDDY† AND J. A. C. WEIDEMAN‡

Abstract. The Chebyshev spectral collocation method is one of the most powerful tools for numerical differentiation, particularly when the function under consideration is smooth. An upper bound on the error, in the discrete maximum norm, is derived here when the function is analytic. Two model functions are analyzed in detail.

Key words. pseudospectral, spectral collocation, numerical differentiation, Chebyshev methods, interpolation

1. Introduction. Let $f(x)$ be a differentiable function defined on a bounded interval, say $[-1,1]$. In this interval, choose a discrete grid $\{x_j\}$ consisting of $N+1$ distinct points. How does one compute approximations to the derivative values $\{f'(x_j)\}$? One of the most powerful procedures for calculating this is also conceptually the simplest: Fit a polynomial of degree N, say $p_N(x)$, through the data values $\{(x_j, f(x_j))\}$. Then differentiate this polynomial (analytically) and evaluate the derivative at the gridpoints, i.e., $p'_N(x_j) \approx f'(x_j)$.

Approximation theory dictates that $\{x_j\}$ should not be just any set of points. Recall, e.g., the Runge phenomenon associated with an equidistant point distribution: those wild oscillations near the endpoints of the interval when a seemingly innocuous function such as $f(x) = 1/(1+25x^2)$ is interpolated on $[-1,1]$; see, for example, [16, p. 44]. Good sets of points are the roots or extrema of the Chebyshev polynomials. First, these points have precisely the right density distribution for avoiding the Runge phenomenon [16, p. 45]. Second, interpolants based on these sets of points are to within a relatively small factor of the best min-max polynomial approximation of $f(x)$ on $[-1,1]$ [11, p. 160]. Third, these interpolants may be evaluated quickly and efficiently with the aid of the fast Fourier transform (FFT) [11, p. 91].

The differentiation procedure described above is at the heart of what has become known as the Chebyshev pseudospectral method or, equivalently, the Chebyshev spectral collocation process. Since its introduction in the 1970s and early 1980s, this idea has been used in practice to solve a variety of differential equations; case studies are cited in the survey papers [7], [9], [17] and the monographs [3], [4], [6], [8], [10], [12], [16].

The Chebyshev differencing method works best when the function is smooth, and particularly when $f(x)$ can be continued into the complex plane as a function $f(z)$

which is analytic in an open neighborhood of $[-1,1]$. In this case, the error

$$E_N(f) = \max_{0\le j\le N} |f'(x_j) - p'_N(x_j)|$$

decays at least exponentially fast as $N \to \infty$, a fact mentioned (but not proved) in the monographs and survey papers listed above. To see a proof, we had to go to the research literature, and even then we could find only a single reference, namely that of Tadmor [15].

Tadmor gives very general results, including Sobolev estimates for the error when one assumes less regularity than analyticity. To get these estimates, Tadmor works in the space of Chebyshev coefficients. We present a fundamentally different approach here, which is based in the function space and, therefore, is more in the "spirit" of the pseudospectral (collocation) process. In the process, the error estimate in [15] is improved by a factor of $O(N^{3/2})$. On the negative side, our approach is strictly limited to functions that are analytic in some open neighborhood of $[-1,1]$.

2. General error bounds. Let $T_N(x)$ denote the Chebyshev polynomial of degree N. The differentiation process, described in the first paragraph of section 1, is typically implemented on the set of zeros $\{s_j\}$ of $T_{N+1}(x)$ or on the set of extrema $\{t_j\}$ of $T_N(x)$, including the endpoint extrema at $x = \pm 1$. That is, we define for $j = 0, 1, \ldots, N$,

$$\textit{Zeros:} \qquad s_j = \cos\left(\frac{(2j+1)\pi}{2N+2}\right), \tag{2.1}$$

$$\textit{Extrema:} \qquad t_j = \cos\left(\frac{j\pi}{N}\right). \tag{2.2}$$

Sometimes referred to as the Chebyshev points of the second kind, the second set of nodes is often preferable since it includes the endpoints $x = \pm 1$. In the solution of differential equations, this enables one to incorporate boundary conditions.

These two sets of points share the attractive feature that the derivative of the interpolant, $p'_N(x)$, can be evaluated at the $N+1$ nodes $\{s_j\}$ (resp., $\{t_j\}$) via the FFT in only $O(N \log N)$ operations. This stands in contrast to the direct implementation that requires $O(N^2)$ operations. For details, see [4], [6], [16], [17].

We record the following preliminary facts. Assuming $N+1$ distinct nodes $\{x_j\}$ in $[-1,1]$, the error in polynomial interpolation of the data $\{(x_j, f(x_j))\}$ is given by Hermite's contour integral [5, p. 68]

$$f(x) - p_N(x) = \frac{1}{2\pi i}\int_\Gamma \frac{\omega_{N+1}(x)}{\omega_{N+1}(z)}\,\frac{f(z)}{(z-x)}\,dz. \tag{2.3}$$

Here Γ is a simple closed positively oriented contour in the complex plane that (a) contains the point x and encloses $[-1,1]$, and (b) lies in some simply connected region in which $f(z)$ is analytic. The polynomial $\omega_{N+1}(x)$ is defined as

$$\omega_{N+1}(x) = c\prod_{j=0}^{N}(x - x_j),$$

where the normalization factor c is immaterial, as it cancels in the Hermite formula. For the two sets of interpolation nodes (2.1) and (2.2), we use, respectively,

$$\textit{Zeros:} \qquad \omega_{N+1}(x) = T_{N+1}(x), \tag{2.4}$$

$$\textit{Extrema:} \qquad \omega_{N+1}(x) = T_{N+1}(x) - T_{N-1}(x). \tag{2.5}$$

In the latter case the expression $\omega_{N+1}(x) = (1-x^2)T_N'(x)$ is commonly used in the literature but, owing to the identity [11, p. 35]

$$(1-x^2)T_N'(x) = \frac{1}{2}N(T_{N-1}(x) - T_{N+1}(x)),$$

we may use expression (2.5) instead, which is more useful for our purposes here.

By direct differentiation of the Hermite formula (2.3), one obtains an integral formula for the pointwise error

$$f'(x) - p_N'(x) = \frac{1}{2\pi i}\int_\Gamma \left(\frac{\omega_{N+1}'(x)}{(z-x)} + \frac{\omega_{N+1}(x)}{(z-x)^2}\right)\frac{f(z)}{\omega_{N+1}(z)}\,dz. \tag{2.6}$$

Evaluating this at $x = x_j$ and using the fact that $\omega_{N+1}(x_j) = 0$, one gets

$$f'(x_j) - p_N'(x_j) = \frac{1}{2\pi i}\int_\Gamma \frac{\omega_{N+1}'(x_j)}{\omega_{N+1}(z)}\frac{f(z)}{(z-x_j)}\,dz, \qquad j = 0,\ldots,N. \tag{2.7}$$

An appropriate contour Γ for estimating this integral is the ellipse E_ϱ, with foci at ± 1 and the sum of its semimajor and semiminor axes equal to $\varrho\,(>1)$, i.e.,

$$E_\varrho: \quad z = \frac{1}{2}(\varrho\, e^{i\theta} + \varrho^{-1}\, e^{-i\theta}), \qquad 0 \le \theta \le 2\pi. \tag{2.8}$$

The reason for choosing this particular contour is that the factor $\omega_{N+1}(z)$ appearing in the integrand of (2.3) and (2.7) is of nearly constant magnitude on the ellipse E_ϱ when N is large.

To show this, we follow the analysis of [11, p. 15]. The starting point is the following representation formula for the Chebyshev polynomials,

$$T_N(z) = \frac{1}{2}\left[\left(z+\sqrt{z^2-1}\right)^N + \left(z-\sqrt{z^2-1}\right)^N\right],$$

which implies that if $z \in E_\varrho$, then

$$\begin{aligned} T_N(z) &= \frac{1}{2}\left[(\varrho\, e^{i\theta})^N + (\varrho^{-1}\, e^{-i\theta})^N\right] \\ &= \frac{1}{2}\left[(\varrho^N + \varrho^{-N})\cos N\theta + i(\varrho^N - \varrho^{-N})\sin N\theta\right]. \end{aligned} \tag{2.9}$$

Hence

$$|T_N(z)| = \frac{1}{2}\sqrt{\varrho^{2N} + \varrho^{-2N} + 2\cos 2N\theta},$$

and therefore

$$\frac{1}{2}(\varrho^N - \varrho^{-N}) \le |T_N(z)| \le \frac{1}{2}(\varrho^N + \varrho^{-N}), \qquad z \in E_\varrho.$$

By introducing the positive number η through $\varrho = e^\eta$, we see that these inequalities become

$$\sinh(\eta N) \le |T_N(z)| \le \cosh(\eta N), \qquad z \in E_\varrho. \tag{2.10}$$

It is now possible to estimate the quantity $\omega_{N+1}(z)$ that appears in (2.7). In the case of Chebyshev zeros (cf. (2.4)), one simply replaces N by $N+1$ in (2.10) to get

$$\text{(2.11)} \qquad \textit{Zeros:} \qquad \sinh(\eta(N+1)) \;\le\; |\omega_{N+1}(z)| \;\le\; \cosh(\eta(N+1)).$$

In the case of Chebyshev extrema (cf. (2.5)), one proceeds as follows. From (2.9),

$$\omega_{N+1}(z) = T_{N+1}(z) - T_{N-1}(z) = \frac{1}{2}(\varrho\, e^{i\theta} - \varrho^{-1}\, e^{-i\theta})\,(\varrho^N\, e^{iN\theta} - \varrho^{-N}\, e^{-iN\theta})$$

when $z \in E_\varrho$, and therefore

$$|\omega_{N+1}(z)| = \frac{1}{2}\,\sqrt{\varrho^2 + \varrho^{-2} - 2\cos 2\theta}\,\sqrt{\varrho^{2N} + \varrho^{-2N} - 2\cos 2N\theta}.$$

The minimum value of this quantity occurs when $\theta = 0$, which gives the lower bound $\frac{1}{2}(\varrho - \varrho^{-1})(\varrho^N - \varrho^{-N})$. When N is odd, the maximum value occurs at $\theta = \pi/2$, which gives an upper bound $\frac{1}{2}(\varrho + \varrho^{-1})(\varrho^N + \varrho^{-N})$. When N is even, the same upper bound is obtained by maximizing the two terms on the right individually. We have therefore proved that if $z \in E_\varrho$, then

$$\text{(2.12)} \quad \textit{Extrema:} \quad 2\sinh(\eta)\sinh(\eta N) \;\le\; |\omega_{N+1}(z)| \;\le\; 2\cosh(\eta)\cosh(\eta N).$$

Since the upper and lower bounds in both (2.11) and (2.12) approach one another as $N \to \infty$, our assertion that $|\omega_{N+1}(z)|$ is nearly constant on E_ϱ for large N is affirmed.

Bounds on the quantities $\omega'_{N+1}(x_j)$ that appear in (2.7) are also required. By using elementary calculus and standard properties of the Chebyshev polynomials, it is possible to show that for each $N = 1, 2, \ldots$,

$$\text{(2.13)} \qquad \textit{Zeros:} \qquad \max_{0\le j\le N} |\omega'_{N+1}(s_j)| = (N+1)\csc\left(\frac{\pi}{2N+2}\right) \;\le\; (N+1)^2,$$

$$\text{(2.14)} \quad \textit{Extrema:} \qquad \max_{0\le j\le N} |\omega'_{N+1}(t_j)| = 4N.$$

In each case the maximum is achieved at the extreme two nodes s_0 and s_N (resp., t_0 and t_N). The bound on the right of (2.13) is the quantity $\max_{-1\le x\le 1} |\omega'_{N+1}(x)|$, which will be used in Remark 6 below (following Theorem 2.1). No such bound is provided for (2.14), as in fact $\max_{-1\le x\le 1} |\omega'_{N+1}(x)| = 4N$ in the case of extrema.

Finally, we record the following properties of the ellipse E_ϱ. Its length, say L_ϱ, can of course be expressed as an elliptic function, but as a more easily computable bound we use Euler's estimate

$$\text{(2.15)} \qquad L_\varrho \le \pi\sqrt{\varrho^2 + \varrho^{-2}},$$

which overestimates the perimeter by less than 12 percent. (Better bounds for the perimeter of an ellipse can be found in [2].) We shall also need the distance from E_ϱ to the interval $[-1, 1]$, say D_ϱ, which a quick calculation shows to be

$$\text{(2.16)} \qquad D_\varrho = \frac{1}{2}(\varrho + \varrho^{-1}) - 1.$$

The ratio between the perimeter and distance will feature in the error estimate below, and so we define, for $\varrho > 1$,

$$\text{(2.17)} \qquad \phi(\varrho) = \frac{\pi\sqrt{\varrho^2 + \varrho^{-2}}}{\frac{1}{2}(\varrho + \varrho^{-1}) - 1} = 2\pi\frac{\sqrt{\varrho^4 + 1}}{(\varrho - 1)^2}.$$

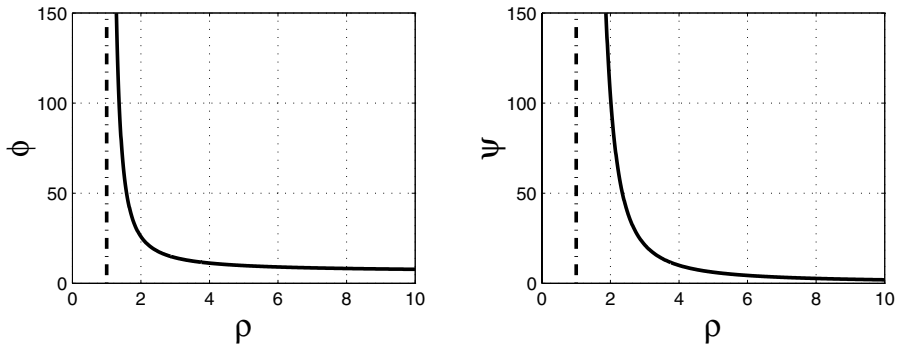

FIG. 1. *Graphs of the functions $\phi(\varrho)$ and $\psi(\varrho)$ defined, respectively, by* (2.17) *and* (4.4).

The graph of this function is shown in Figure 1. A strictly decreasing function on $(1,\infty)$, ϕ assumes values less than 100 for all $\varrho \geq 1.36$ and less than 10 for all $\varrho \geq 4.84$, with asymptotic value 2π as $\varrho \to \infty$.

We are now in a position to state the theorem.

THEOREM 2.1. *Let $p_N(x)$ be the polynomial interpolant of $f(z)$ at the set of Chebyshev zeros $\{s_j\}$ defined by* (2.1) *or extrema $\{t_j\}$ defined by* (2.2). *Suppose $f(z)$ is analytic in some ellipse E_ϱ, defined by* (2.8), *with $\varrho = e^\eta$, $\eta > 0$. Then, for each $N \geq 1$, we have*

$$\text{(2.18)} \qquad \textit{Zeros:} \quad \max_{0\leq j\leq N} |f'(s_j) - p_N'(s_j)| \leq \frac{1}{2\pi}\, C_\varrho\, \phi(\varrho)\, \frac{(N+1)}{\sin\left(\frac{\pi}{2N+2}\right)}\, \frac{1}{\sinh(\eta(N+1))},$$

$$\text{(2.19)} \qquad \textit{Extrema:} \quad \max_{0\leq j\leq N} |f'(t_j) - p_N'(t_j)| \leq \frac{1}{\pi}\, C_\varrho\, \phi(\varrho)\, N\, \frac{1}{\sinh(\eta)\sinh(\eta N)}.$$

In both cases, $\phi(\varrho)$ is defined by (2.17), *and*

$$\text{(2.20)} \qquad C_\varrho = \max_{z\in E_\varrho} |f(z)|.$$

Proof. Taking absolute values in the error integral (2.7), with $\Gamma = E_\varrho$, yields

$$\begin{aligned} |f'(x_j) - p_N'(x_j)| &\leq \frac{1}{2\pi}|\omega_{N+1}'(x_j)| \int_{E_\varrho} \frac{|f(z)|}{|\omega_{N+1}(z)||z-x_j|}|dz| \\ &\leq \frac{1}{2\pi}|\omega_{N+1}'(x_j)| \frac{\max_{z\in E_\varrho}|f(z)|}{\min_{z\in E_\varrho}|\omega_{N+1}(z)|} \int_{E_\varrho} \frac{|dz|}{|z-x_j|}. \end{aligned}$$

Taking the maximum over all nodes yields

$$\max_{0\leq j\leq N} |f'(x_j) - p_N'(x_j)| \leq \frac{1}{2\pi} \max_{0\leq j\leq N} |\omega_{N+1}'(x_j)| \frac{\max_{z\in E_\varrho}|f(z)|}{\min_{z\in E_\varrho}|\omega_{N+1}(z)|} \frac{L_\varrho}{D_\varrho}.$$

The error bounds (2.18)–(2.19) now follow from (2.11)–(2.17). ∎

Remark 1. The exponential convergence of the spectral method comes from the hyperbolic sine term in the denominators of (2.18)–(2.19). This can be made explicit by using the bound

$$\frac{1}{\sinh(\eta N)} \leq 2 \coth(\eta N)\, e^{-\eta N},$$

which is sharp to within a factor of 2, and an asymptotic equality in the limit $N \to \infty$, with η fixed. A large ellipse (i.e., a large region about $[-1, 1]$ in which the function is analytic) implies large values of ρ and hence η, which means quick convergence.

Remark 2. When the function is entire, i.e., free of singularities in the finite complex plane, the size of the ellipse E_ϱ is not limited by singularities but by the growth rate of the factor C_ϱ as ϱ increases. In this case convergence is typically faster than exponential, a situation referred to in [3, p. 26] as supergeometric convergence.

Remark 3. The equalities (2.13) and (2.14) give rise to algebraic factors of $O(N)$ and $O(N^2)$, respectively, in the error bounds (2.18) and (2.19). This shows that the Chebyshev extreme points are slightly better for differentiation than the Chebyshev zeros, as will also be observed empirically in the numerical experiment below.

Remark 4. Continuing the idea of Remark 3, the algebraic factor in the error estimate can be minimized by choosing the nodes x_j such that the maximum of $|\omega'_{N+1}(x)|$ on $[-1, 1]$ is minimized. Using the well-known min-max property of the Chebyshev polynomials, we therefore propose that

$$\omega'_{N+1}(x) = T_N(x).$$

Integration yields

$$\omega_{N+1}(x) = \frac{1}{2}\left(\frac{T_{N+1}(x)}{N+1} - \frac{T_{N-1}(x)}{N-1}\right) + c,$$

where the constant c may be chosen to make $\omega_{N+1}(1) = 0$ or $\omega_{N+1}(-1) = 0$ (depending on where a boundary condition needs to be enforced). If N is odd, both of these conditions can, owing to symmetry, be satisfied simultaneously. In addition, if N is odd, the roots of $\omega_{N+1}(x)$ lie in $[-1, 1]$, which is not the case for N even. With these roots as the nodes of the spectral collocation process, one should obtain an error estimate similar to (2.18)–(2.19), but with the leading algebraic term of size $O(1)$ instead of $O(N)$ or $O(N^2)$.

In practice this new set of points does indeed seem to give marginally better accuracy than the other two node sets analyzed here. With $N = 15$, for example, we computed the error in the numerical differentiation of the test function (2.21) below, using $a = 2$. The maximum error at the grid points were 2.3×10^{-7} and 9.1×10^{-8}, respectively, with Chebyshev zeros and Chebyshev extrema as nodes. The new set of nodes proposed here yielded an error 4.9×10^{-8}.

Remark 5. The algebraic factor in (2.19) is $O(N)$, which improves on the $O(N^{2.5})$ factor in [15, eq. (4.18)]. The exponential factors are identical.

Remark 6. It is possible to extend Theorem 2.1 with minimal effort to the continuous rather than the discrete maximum norm. First one applies the triangle inequality to the integral (2.6). Then one uses elementary bounds such as $\max_{-1\leq x\leq 1} |\omega_{N+1}(x)| \leq 1$ (zeros), $\max_{-1\leq x\leq 1} |\omega_{N+1}(x)| \leq 2$ (extrema), and the inequality (2.13) to obtain

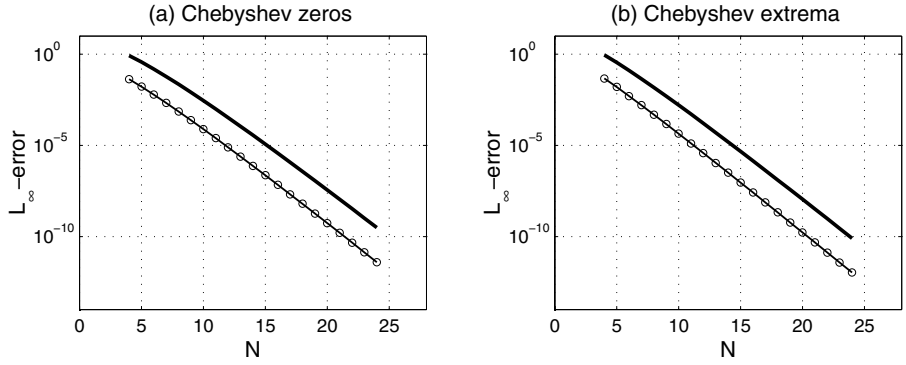

FIG. 2. *Actual error (dotted curve) and theoretical error bound (thicker curve) in the Chebyshev derivative of* $f(x) = 1/(x-a), a = 2$.

$$\textit{Zeros:} \quad \max_{-1\le x\le 1} |f'(x) - p_N'(x)| \le \frac{1}{2\pi}\, C_\varrho\, L_\varrho \left(\frac{(N+1)^2}{D_\varrho} + \frac{1}{D_\varrho^2}\right) \frac{1}{\sinh(\eta(N+1))},$$

$$\textit{Extrema:} \quad \max_{-1\le x\le 1} |f'(x) - p_N'(x)| \le \frac{1}{2\pi}\, C_\varrho\, L_\varrho \left(\frac{2N}{D_\varrho} + \frac{1}{D_\varrho^2}\right) \frac{1}{\sinh(\eta)\sinh(\eta N)}.$$

In each case, the asymptotic behavior of the error bound, as $N \to \infty$, is the same as in Theorem 2.1.

Numerical experiments. We checked the tightness of the bounds in Theorem 2.1 numerically, using

$$f(x) = \frac{1}{x-a}, \qquad a > 1, \tag{2.21}$$

as test function. In Figure 2 we show, as the thinner, dotted lines, the computed error $\max_{0\le j\le N} |f'(x_j) - p_N'(x_j)|$ as a function of N, for the case $a = 2$. Also shown, as the thicker curves, are the theoretical error bounds (2.18)–(2.19). In order to compute the bounds, one is free to choose the ellipse E_ϱ, the only constraint being that it intersects the real axis between $x = 1$ and the pole at $x = a$, i.e.,

$$1 < \frac{1}{2}\left(\varrho + \varrho^{-1}\right) < a \quad \Longrightarrow \quad 1 < \varrho < a + \sqrt{a^2 - 1}.$$

For each value of N we computed the right-hand sides of (2.18)–(2.19), for a thousand values of ϱ in the above interval, and picked the minimum value to determine the best upper bound.

We note from the figure that for $a = 2$ the theoretical bound overestimates the actual error by about one order of magnitude. If we decrease (resp., increase) the value of a, this overestimation factor increases (resp., decreases).

As a second example, we consider

$$f(x) = \sqrt{a - x}, \qquad a > 1, \tag{2.22}$$

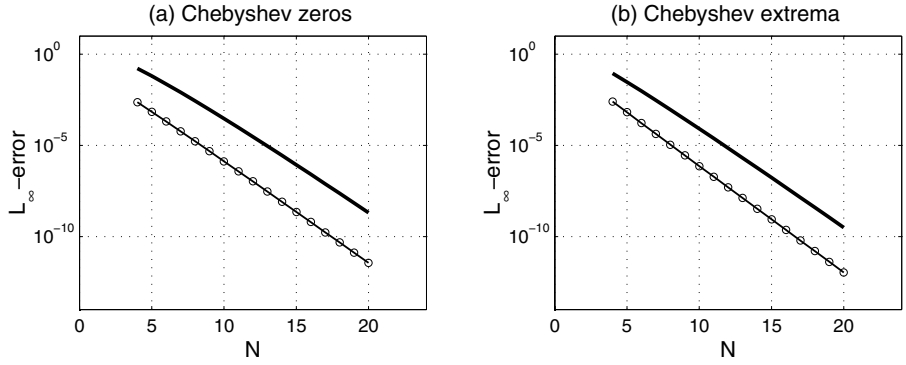

FIG. 3. *Same as Figure* 2, *but the function is* $f(x) = \sqrt{a-x}, a = 2$.

with corresponding error curves shown in Figure 3. Compared to the first example, one notices (a) that the actual errors in Figure 3 are smaller than in Figure 2 (note that the scale on the horizontal axis is different in the two figures), and (b) that the gap between the actual errors and the theoretical error bounds is slightly wider. Both of these observations will be explained in the next section.

The reason for the gap between the actual errors and the theoretical error bounds is the fact that the ellipse (2.8) is a general, all-purpose contour that has to cope with all possible singularities of the function. When specific assumptions regarding the singularities are made, different contours may yield more precise estimates. This will be done in the next section, where we investigate these numerical results more carefully. In fact, we shall obtain an explicit representation for the error in (2.21) and accurate estimates for the error in (2.22).

3. Analysis of two model functions. The test functions (2.21) and (2.22), representative of functions with poles and branch-point singularities, respectively, will be analyzed here with the aid of the contour shown in Figure 4. It consists of a large circle, centered at the origin and with radius R, and a small circle, centered at the singularity $z = a$ with radius ϵ. The larger circle is positively traversed, i.e., runs counterclockwise, and the small one runs clockwise. The two circles are connected by two line segments on the real interval $[a + \epsilon, R]$, as indicated by the arrows in the figure.

We start with the model function (2.21) and use Chebyshev zeros as collocation points. The error integral (2.7) thus becomes

$$f'(s_j) - p'_N(s_j) = \frac{T'_{N+1}(s_j)}{2\pi i} \int_\Gamma \frac{dz}{T_{N+1}(z)(z - s_j)(z - a)}.$$

Taking Γ to be the contour in Figure 4, the various contributions to the integral can be estimated using standard results from complex variable theory; see for example [14, Ch. 6]. The contribution on the large circle, $|z - a| = R$, vanishes in the limit $R \to \infty$, owing to the polynomial term in the denominator. The contribution along the connecting line segments cancels, and the contribution on the small circle, $|z - a| = \epsilon$, can be evaluated as a residue. The result is the explicit expression for the error that was announced at the end of section 2, namely

$$f'(s_j) - p'_N(s_j) = \frac{T'_{N+1}(s_j)}{T_{N+1}(a)} \frac{1}{s_j - a}, \qquad j = 0, 1, \ldots, N. \tag{3.1}$$

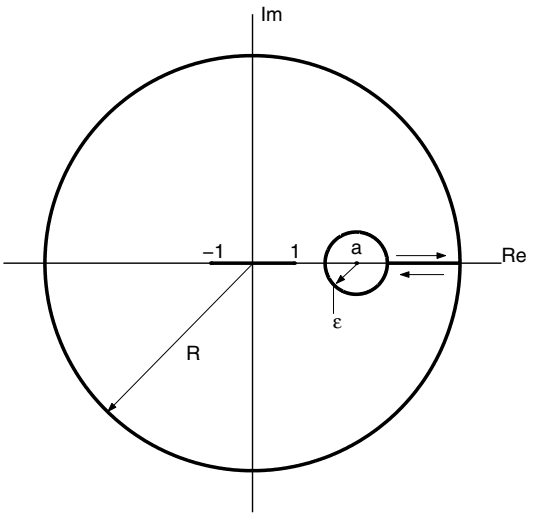

FIG. 4. *Contour used in the analysis of the model functions.*

A uniform bound on the right-hand side of (3.1) can be obtained by using (2.13) and the inequality

$$T_{N+1}(x) > \frac{1}{2}\Big(x + \sqrt{x^2-1}\Big)^{N+1}, \quad x > 1. \tag{3.2}$$

This yields

$$\max_{0\le j\le N} |f'(s_j) - p_N'(s_j)| \le \frac{2}{a-1}\frac{N+1}{\sin(\frac{\pi}{2N+2})}\Big(a + \sqrt{a^2-1}\Big)^{-(N+1)}, \tag{3.3}$$

a bound that is virtually indistinguishable from the actual error curve in Figure 2(a).

Comparing this tight bound with the general bound (2.18), one concludes that the latter formula captures the dependence on N perfectly. The gap between the actual error and the theoretical error bounds observed in Figure 2 is therefore entirely due to overestimating the constant factor.

Turning to the second model problem (2.21), we choose the branch-cut of $\sqrt{a-z}$ to be the real interval $[a,\infty)$. In this case, therefore, the contributions of the real line segments do not cancel, as one segment is "above" the branch-cut and the other "below" [14, Sect. 6.6]. In fact, these contributions represent the error completely, as the contribution on the small circle, $|z-a| = \epsilon$, vanishes in the limit $\epsilon \to 0$, and so does the contribution on the large circle, $|z| = R$, as $R \to \infty$.

Adding the contributions on $[a,\infty)$, one obtains in the case of Chebyshev zeros

$$f'(s_j) - p_N'(s_j) = \frac{T_{N+1}'(s_j)}{\pi}\int_a^\infty \frac{\sqrt{x-a}}{s_j - x}\frac{dx}{T_{N+1}(x)}, \quad j = 0,1,\dots,N. \tag{3.4}$$

We have not succeeded in finding a closed form expression for the integral on the right, but a relatively sharp bound can be obtained as follows.

Note that for $a > 1$ and $|s| \le 1$,

$$\int_a^\infty \frac{\sqrt{x-a}}{x-s}\frac{dx}{T_{N+1}(x)} \le \frac{1}{a-s}\int_a^\infty \frac{\sqrt{x-a}}{T_{N+1}(x)}\,dx \le \frac{2}{a-s}\int_a^\infty \frac{\sqrt{x-a}}{(x+\sqrt{x^2-1})^{N+1}}\,dx,$$

where (3.2) was used. The latter integral can be evaluated explicitly in terms of the beta function, B, and the hypergeometric function, ${}_2F_1$; see [13, entry 7, p. 314]. The result is

$$\int_a^\infty \frac{\sqrt{x-a}}{(x+\sqrt{x^2-1})^{N+1}}\,dx = \frac{\sqrt{a}}{2}(2a)^{-N}B\left(\frac{3}{2},N-\frac{1}{2}\right){}_2F_1\left(\frac{1}{2}N+\frac{1}{4},\frac{1}{2}N-\frac{1}{4};2+N;\frac{1}{a^2}\right).$$

In order to obtain a form of the ${}_2F_1$ function that can be expressed in terms of elementary functions, we replace the third parameter $2+N$ by $\frac{1}{2}+N$, which causes a relatively small overestimate when N is large. Using entry 15.1.13 from [1, p. 556], one consequently obtains

$$\int_a^\infty \frac{\sqrt{x-a}}{(x+\sqrt{x^2-1})^{N+1}}\,dx \le \frac{1}{2\sqrt{2}}B\left(\frac{3}{2},N-\frac{1}{2}\right)\left(a+\sqrt{a^2-1}\right)^{-N+1/2}.$$

Approximating the B function by Stirling's formula yields $B(\frac{3}{2},N-\frac{1}{2}) \sim (\sqrt{\pi}/2)N^{-(3/2)}$, $N \to \infty$. This approximation and the above inequalities are now inserted into (3.4) to obtain an error estimate similar to (3.3):

$$\max_{0\le j\le N}|f'(s_j)-p_N'(s_j)| \le \frac{1}{\sqrt{\pi}(a-1)(2N)^{3/2}}\frac{N+1}{\sin(\frac{\pi}{2N+2})}\left(a+\sqrt{a^2-1}\right)^{-N+1/2}. \tag{3.5}$$

Numerical verification confirms that this bound is tight. When compared to the data of Figure 3(a), the gap between this bound and the actual error curve is tiny. In fact, with $a = 2$ the right side of (3.5) overestimates the left side by less than a factor of 2 for all $N \ge 3$.

By first comparing (3.5) to the analogous expression for the first model function, equation (3.3), one sees that the errors in the second model function are smaller owing to the $N^{3/2}$ factor in the denominator. Next, by comparing (3.5) to the general error bound (2.18), one notices that the exponential dependence on N is the same. The leading algebraic factor in (2.18) is, however, overestimated by a factor of $O(N^{3/2})$, and this accounts for the widening gap between the actual error and the theoretical error bound in Figure 3(a).

The results in this section were presented for Chebyshev zeros only, but similar results can be derived for the extreme points. We omit the details.

4. Second derivatives. The results of section 2 can be generalized in a straightforward manner to second derivatives. Differentiating (2.3) twice with respect to x, and again using the fact that $\omega_{N+1}(x_j) = 0$ at the discretization points, we obtain for $j = 0,\dots,N$

$$f''(x_j)-p_N''(x_j) = \frac{1}{2\pi i}\int_\Gamma\left(\frac{2\omega_{N+1}'(x_j)}{(z-x_j)^2}+\frac{\omega_{N+1}''(x_j)}{(z-x_j)}\right)\frac{f(z)}{\omega_{N+1}(z)}\,dz. \tag{4.1}$$

The factor $|\omega''(x_j)|$ that appears in this formula can be estimated similarly to the estimation of (2.13)–(2.14), and one obtains for $N = 1, 2, \ldots,$

$$\textit{Zeros:} \quad \max_{0\le j\le N} |\omega''_{N+1}(s_j)| = (N+1)\cos\left(\frac{\pi}{2N+2}\right)\csc^3\left(\frac{\pi}{2N+2}\right), \\ \le \frac{1}{3}N(N+2)(N+1)^2,$$

$$\textit{Extrema:} \quad \max_{0\le j\le N} |\omega''_{N+1}(t_j)| = \frac{4}{3}N(2N^2+1).$$

The error bounds are as follows.

THEOREM 4.1. *Let $p_N(x)$ be the polynomial interpolant of $f(z)$ at the set of Chebyshev zeros $\{s_j\}$ defined by* (2.1) *or extrema $\{t_j\}$ defined by* (2.2). *Suppose $f(z)$ is analytic in some ellipse E_ϱ, defined by* (2.8), *with $\varrho = e^\eta$, $\eta > 0$. Then, for each $N \ge 2$,*

$$\textit{Zeros:} \quad \max_{0\le j\le N} |f''(s_j) - p''_N(s_j)| \\ \le \frac{1}{2\pi} C_\varrho \left(\alpha_N \psi(\varrho) + \beta_N \phi(\varrho)\right) \frac{1}{\sinh(\eta(N+1))}, \tag{4.2}$$

$$\textit{Extrema:} \quad \max_{0\le j\le N} |f''(t_j) - p''_N(t_j)| \\ \le \frac{1}{2\pi} C_\varrho \left(\gamma_N \psi(\varrho) + \delta_N \phi(\varrho)\right) \frac{1}{\sinh(\eta)\sinh(\eta N)}, \tag{4.3}$$

where C_ϱ and $\phi(\varrho)$ are defined by (2.20) *and* (2.17), *respectively, and*

$$\psi(\varrho) = 4\pi \frac{\varrho\sqrt{\varrho^4+1}}{(\varrho-1)^4}. \tag{4.4}$$

In addition,

$$\alpha_N = 2(N+1)\csc\left(\frac{\pi}{2N+2}\right), \quad \beta_N = (N+1)\cos\left(\frac{\pi}{2N+2}\right)\csc^3\left(\frac{\pi}{2N+2}\right), \\ \gamma_N = 4N, \qquad\qquad \delta_N = \frac{2}{3}N(2N^2+1).$$

Bounds on errors in higher derivatives can also be obtained. For the pth derivative, the leading algebraic factor scales like $O(N^{2p})$ for the Chebyshev zeros and like $O(N^{2p-1})$ for the Chebyshev extreme points.

Acknowledgments. The authors are indebted to Dave Sloan and two anonymous referees for a careful reading of the manuscript, and for many good suggestions. Milton Maritz provided help with the software package Mathematica.

AN OPTIMAL ADAPTIVE FINITE ELEMENT METHOD*

ROB STEVENSON†

Abstract. Although existing adaptive finite element methods for solving second order elliptic equations often perform better in practical computations than nonadaptive ones, usually they are not even proven to converge. Only recently in the work of Dörfler [*SIAM J. Numer. Anal.*, 33 (1996), pp. 1106–1124] and that of Morin, Nochetto, and Siebert [*SIAM J. Numer. Anal.*, 38 (2000), pp. 466–488], adaptive methods were constructed for which convergence could be demonstrated. However, convergence alone does not imply that the method is more efficient than its nonadaptive counterpart. In [*Numer. Math.*, 97 (2004), pp. 219–268], Binev, Dahmen, and DeVore added a coarsening step to the routine of Morin, Nochetto, and Siebert, and proved that the resulting method is quasi-optimal in the following sense: If the solution is such that for some $s > 0$, the error in energy norm of the best continuous piecewise linear approximations subordinate to any partition with n triangles is $\mathcal{O}(n^{-s})$, then given an $\varepsilon > 0$, the adaptive method produces an approximation with an error less than ε subordinate to a partition with $\mathcal{O}(\varepsilon^{-1/s})$ triangles, in only $\mathcal{O}(\varepsilon^{-1/s})$ operations.

In this paper, employing a different type of adaptive partition, we develop an adaptive method with properties similar to those of Binev, Dahmen, and DeVore's method, but unlike their method, our coarsening routine will be based on a transformation to a wavelet basis, and we expect it to have better quantitative properties. Furthermore, all our results are valid uniformly in the size of possible jumps of the diffusion coefficients. Since the algorithm uses solely approximations of the right-hand side, we can even allow right-hand sides in $H^{-1}(\Omega)$ that lie outside $L_2(\Omega)$, at least when they can be sufficiently well approximated by piecewise constants. In our final adaptive algorithm, all tolerances depend on an a posteriori estimate of the current error instead of an a priori one; this can be expected to provide quantitative advantages.

Key words. adaptive finite element method, optimal computational complexity, wavelet basis, a posteriori error estimator, discontinuous coefficients

1. Introduction.

For solving elliptic boundary value problems for which the solution has singularities, the use of adaptive finite element methods potentially has the advantage of a significant reduction of the computational cost, compared to nonadaptive methods. Although the adaptive methods that can be found in the literature often exhibit such a reduction, they are, usually, not even proven to converge, let alone shown to outperform nonadaptive methods. Only quite recently, in the work of Dörfler [11], which was later extended by Morin, Nochetto, and Siebert in [15], adaptive methods were constructed that were proven to converge. These methods are based on an adaptive refinement strategy that guarantees the so-called saturation property, namely that the difference between the solutions on two consecutive partitions is greater than some multiple of the error in the solution on the first partition. Exploiting Galerkin orthogonality, convergence then easily follows.

In [3], Binev, Dahmen, and DeVore added a coarsening step to the method from [15]. Basically the idea of such a step, which has to be applied after each fixed number of refinement steps, is to undo refinements that ultimately hardly contribute

†Department of Mathematics, Utrecht University, P.O. Box 80.010, NL-3508 TA Utrecht, The Netherlands (stevenson@math.uu.nl).

to a better approximation. Thanks to this coarsening, under some conditions on the right-hand side, the resulting adaptive method was proven to be quasi-optimal in the following sense: if the solution is such that, for some $s > 0$, the error in energy norm of the best continuous piecewise linear approximations subordinate to any partition with n triangles is $\mathcal{O}(n^{-s})$, then given an $\varepsilon > 0$, the adaptive method produces an approximation with an error less than ε subordinate to a partition with $\mathcal{O}(\varepsilon^{-1/s})$ triangles, in only $\mathcal{O}(\varepsilon^{-1/s})$ operations.

In this paper, we consider a method, as developed in [15] and extended with a coarsening in [3], in a slightly different context: instead of working with conforming partitions produced with the so-called newest vertex bisection method, we consider generally nonconforming partitions produced by only "red-refinement" steps, i.e., splittings of triangles into four congruent subtriangles. In this setting we extend the findings from [15] and [3] on some points.

- Following [15], we consider the model problem of Poisson's equation on a two-dimensional domain, generalized in the sense that a piecewise constant diffusion tensor is allowed. Assuming a so-called quasi-monotone distribution of possible jumps that this tensor may have, all results from this paper will be proven to hold uniformly in the size of such jumps.
- With an adaptive method, the right-hand side and the discrete Galerkin solution subordinate to the current partition together determine the next partition via an a posteriori error estimator. Aiming at proving optimal computational complexity, following [3] we consider inexact solutions of the discrete systems. In addition to that, we allow inexact right-hand sides to be used for both setting up the discrete systems and for the evaluation of the a posteriori error estimator. This generalization can be used to model the effect of the application of quadrature. Furthermore, it will allow us to prove quasi-optimality of the adaptive method even for right-hand sides in $H^{-1}(\Omega)$ outside $L_2(\Omega)$, at least when they can be sufficiently well approximated by piecewise constants.
- We introduce a new coarsening procedure that, unlike the procedure from [3], is based on a transformation to a wavelet basis for the space of continuous piecewise linears subordinate to the adaptively refined partition. We expect our procedure to have better quantitative properties, although admittedly a final answer can only be given after performing numerical tests. Both the coarsening from [3] and our coarsening rely on an adaptive tree approximation algorithm developed by Binev and DeVore in [5].
- The adaptive finite element method from [3] and our first routine **SOLVE1** require as input an a priori upper bound μ of the convergence rate of the algorithm without coarsening. When one supplies a μ that is too small, quasi-optimality as a consequence of the coarsening is not guaranteed. On the other hand, taking a μ that is unnecessarily close to 1 will result in a quantitatively less attractive algorithm, since, due to the coarsening, the convergence rate will be limited by this μ. In this paper, we develop a second routine **SOLVE2** in which the tolerances allowed in the inexact Galerkin solutions and in the approximations of the right-hand side, and those required in the coarsening, are all some fixed multiples of an a posteriori estimate of the current error. Apart from the fact that this releases the user from the task of supplying this most critical parameter, the new algorithm benefits from a better convergence rate than what might appear to be the case from an a priori worst case analysis.

Finally, let us comment on the necessity of applying a coarsening routine. In the numerical experiments reported in [15], the partitions, although produced without

coarsening, already seem to have a quasi-optimal cardinality. Of course, this does not exclude the possibility that there are other examples for which coarsening is necessary. On the other hand, it is also possible that coarsening is not a necessary ingredient of a quasi-optimal adaptive algorithm for solving these elliptic problems, but that a proof of such a fact is eluding us. In any case, we do not consider our construction of a coarsening routine as being relevant for theoretical purposes only. Instead, we expect that coarsening will be very useful inside adaptive routines for solving nonstationary problems.

This paper is organized as follows: In section 2 our model boundary value problem is described.

In section 3, we introduce the class of admissible partitions, which is the subclass of all partitions that can be generated by red-refinements for which the generations of neighboring triangles differ at most by one. We show that any partition can be refined to an admissible one by increasing the number of triangles by, at most, a constant factor.

In section 4, we introduce a wavelet basis for the space of continuous piecewise linears subordinate to any admissible partition. We show that both the basis transformation from wavelet to nodal basis and its inverse can be performed in optimal computational complexity.

Our coarsening routine is defined in section 5. It is based on a transformation to wavelet basis, an application of the adaptive tree approximation routine from [5], and, finally, a construction of a reduced partition subordinate to which the remaining terms in the wavelet expansion are continuous piecewise linear functions.

In section 6, an a posteriori error estimator is derived. A refinement strategy is developed that is shown to be convergent also for inexact, but sufficiently accurate, right-hand sides and discrete solutions.

In section 7, the coarsening routine and the convergent adaptive refinement strategy are combined into an optimal adaptive finite element method.

Finally, in section 8 we derive an optimal adaptive finite element method in which the tolerances for the errors in the right-hand side and in the discrete solution as well as for the coarsening routine are determined by an a posteriori estimate of the current error.

In order to avoid the repeated use of generic but unspecified constants, in this paper by $C \lesssim D$ we mean that C can be bounded by a multiple of D, independent of parameters which C and D may depend on. Obviously, $C \gtrsim D$ is defined as $D \lesssim C$, and $C \eqsim D$ as $C \lesssim D$ and $C \gtrsim D$.

2. Boundary value problem. Let Ω be a polygonal bounded domain in $\mathbb{R}^2$. We consider the following model boundary value problem in variational form: Given $f \in H^{-1}(\Omega)$, find $u \in H^1_0(\Omega)$ such that

$$a(u,w) := \int_\Omega \mathbf{A}\nabla u \cdot \nabla w = f(w), \quad (w \in H^1_0(\Omega)), \tag{2.1}$$

where $\mathbf{A} \in L_\infty(\Omega)$ is a symmetric 2×2 matrix with $\operatorname{ess\,inf}_{x\in\Omega}\lambda_{\min}(\mathbf{A}(x)) > 0$. Further assumptions on $\mathbf{A}$ are collected in the forthcoming Assumption 3.8. Defining $L : H^1_0(\Omega) \to H^{-1}(\Omega) = (H^1_0(\Omega))'$ by $(Lu)(w) = a(u,w)$, (2.1) can be rewritten as

$$Lu = f.$$

In some places we will assume that the right-hand side $f \in L_2(\Omega)$, in which case $f(w)$ should be interpreted as $\int_\Omega fw$.

Aiming at results that hold uniformly in the size of variations that the spectral radius $\rho := \rho(\mathbf{A})$ may have, we introduce a weighted $L_2(\Omega)$-scalar product

$$\langle u, w\rangle_0 = \int_\Omega \rho uw,$$

and define the weighted norms

$$\|w\|_0 = \langle w, w\rangle_0^{\frac{1}{2}}, \quad |w|_1 = a(w,w)^{\frac{1}{2}}, \quad \|g\|_{-1} = \sup_{0\neq w\in H_0^1(\Omega)} \frac{|g(w)|}{|w|_1}$$

on $L_2(\Omega)$, $H_0^1(\Omega)$ and $H^{-1}(\Omega)$, respectively. Equipped with these norms, L is an isomorphism between $H_0^1(\Omega)$ and $H^{-1}(\Omega)$.

For $\Sigma \subset \Omega$, we define $|w|_{1,\Sigma} := (\int_\Sigma \mathbf{A}|\nabla w|^2)^{\frac{1}{2}}$.

3. Partitions of Ω. We shall approximate the solution of (2.1) by continuous piecewise linear functions subordinate to a partition of Ω into triangles. In this subsection we precisely describe the type of partitions to be considered.

We will use P to denote a *partition* of Ω, defined as a collection of closed triangles $\triangle$ such that $\overline{\Omega} = \cup_{\triangle\in P}\triangle$ and $\text{meas}(\triangle \cap \tilde{\triangle}) = 0$ for any two different $\triangle, \tilde{\triangle} \in P$. When $\triangle \cap \tilde{\triangle} \neq \emptyset$, such triangles will be called *neighbors*. A partition $\tilde{P}$ is called a *refinement* of P, when $\tilde{P}$ can be constructed by, for zero or more $\triangle \in P$, replacing $\triangle$ by the four subtriangles created by connecting the midpoints of edges of $\triangle$ or by a recursive application of this elementary "red" refinement step. The above $\triangle$ will be referred to as being the *parent* of its four subtriangles, called *children* of $\triangle$. As expected, children of children of $\triangle$ are called *grandchildren* of $\triangle$.

Throughout this paper we consider only partitions P that are refinements of some *fixed initial partition* P_0 of Ω. Many of our statements will involve constants that actually depend on P_0. However, since P_0 is assumed to be fixed, for ease of presentation we ignore these dependencies. Clearly, any $\triangle \in P$ is *similar* to a triangle from P_0. For $\triangle \in P$, $\text{gen}(\triangle)$ will denote the number of elementary refinement steps needed to create $\triangle$ starting from some $\tilde{\triangle} \in P_0$, where $\text{gen}(\tilde{\triangle}) := 0$.

We call v a *vertex of* P, when there exists a $\triangle \in P$ such that v is a vertex of $\triangle$. A vertex v of P is called *nonhanging* when it is a vertex of all $\triangle \in P$ that contain v, otherwise it is called a *hanging* vertex of P. With $\bar{V}_P$ or V_P we will denote the set of all *nonhanging* vertices of P or all *nonhanging, interior* vertices of P, respectively. We assume that P_0 is *conforming*, i.e., all its vertices are nonhanging.

A vertex v of P is called *regular* when for all $\triangle \in P$ that contain v, $\text{gen}(\triangle)$ has the same value; see Figure 3.1. Note that a regular vertex is nonhanging.

For a vertex v of P, the number of $\triangle \in P$ that contain v is called the *valence* of v in P. The valence of any v of P is less than or equal to the maximum of 6 and the maximum valence of all vertices of P_0. If for a $\triangle \in P$, $\text{gen}(\triangle) = \max_{\tilde{\triangle}\in P} \text{gen}(\tilde{\triangle})$, then its edges cannot contain hanging nodes. As a consequence, for such $\triangle$, the number of its neighbors in P is given by the sum of the valences of its vertices minus the sum of 6 and the number of edges of $\triangle$ on $\partial\Omega$; this shows, in particular, that the number of neighbors is uniformly bounded.

PROPOSITION 3.1. *For any partition P of the type we consider, there exists a unique sequence of partitions*

$$P_0, P_1, \ldots, P_n$$

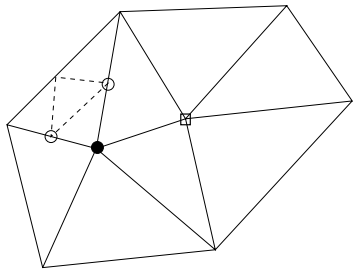

FIG. 3.1. *Regular (□), nonhanging but nonregular (•), and hanging vertices (○).*

with $\max_{\triangle\in P_i}\operatorname{gen}(\triangle)=i$, $P_n=P$, *and where* P_{i+1} *is created from* P_i *by refining some* $\triangle\in P_i$ *with* $\operatorname{gen}(\triangle)=i$. *For convenience, we set* $P_{-1}=\emptyset$ *and so* $V_{P_{-1}}=\emptyset$. *The following properties are valid:*

(i) $V_{P_{i-1}}\subset V_{P_i}$ *and so* $V_P=\cup_{i=0}^n V_{P_i}\backslash V_{P_{i-1}}$ *with empty mutual intersections;*

(ii) *a* $v\in V_{P_i}\backslash V_{P_{i-1}}$ *is not a vertex of* P_{i-1}, *and so it is a regular vertex of* P_i.

Proof. The existence and uniqueness of the sequence $(P_i)_i$ and also (i) are obvious.

Suppose that for some $1\le i\le n$, $v\in V_{P_i}\backslash V_{P_{i-1}}$ is a vertex of P_{i-1}; then it is a hanging vertex of P_{i-1}. So there is a $\triangle\in P_{i-1}$ with $\operatorname{gen}(\triangle)<i-1$ that contains v. However, by definition of the sequence $(P_i)_i$, such a $\triangle$ is not refined when going to P_i, meaning that v is also a hanging vertex of P_i, which gives a contradiction. □

NOTATION 3.2. *Throughout this paper, for any partition* P *(or* $\hat P$, $\tilde P$, *etc.), by* $(P_i)_i$ *(or* $(\hat P_i)_i$, $(\tilde P_i)_i$, *etc.) we will always mean the corresponding sequence, as in Proposition* 3.1. *When we write* $P=P_n$, *we mean that* P *is a partition with* $\max_{\triangle\in P}\operatorname{gen}(\triangle)=n$.

In view of the forthcoming discussion on adaptively refined partitions, we emphasize here that given any partition P, the definition of the corresponding sequence $(P_i)_i$ is independent of the way P has been constructed.

DEFINITION 3.3. *A partition* P^a *is called* admissible *when for all neighbors* $\triangle,\tilde\triangle\in P^a$, $|\operatorname{gen}(\triangle)-\operatorname{gen}(\tilde\triangle)|\le 1$.

As will turn out later, the reason to consider this restricted class of admissible partitions is given by the following proposition.

PROPOSITION 3.4. *Let* P^a *be admissible. For any* $\triangle\in P^a$ *with* $i:=\operatorname{gen}(\triangle)>0$ *the vertices of the parent* $\tilde\triangle\in P^a_{i-1}$ *of* $\triangle$ *are regular vertices of* P^a_{i-1}.

Proof. For $i=1$ the statement is true. Now let $i>1$. Suppose that some vertex v of $\tilde\triangle$ is not a regular vertex of P^a_{i-1}. Then there exists a $\hat\triangle\in P^a_{i-1}$ with $v\in\hat\triangle$ and $\operatorname{gen}(\hat\triangle)<i-1$. Since, by definition of the sequence $(P^a_i)_i$, this $\hat\triangle$ will never be refined, we get a contradiction with the fact that P^a is admissible. □

PROPOSITION 3.5. *If* $P^a=P^a_n$ *is admissible, then for any* $0\le i\le n$, P^a_i *is also admissible.*

Proof. Suppose P^a_i is not admissible; then it contains neighbors $\hat\triangle,\triangle$ with $\operatorname{gen}(\hat\triangle)<\operatorname{gen}(\triangle)-1$. Since $\operatorname{gen}(\hat\triangle)<i$, it will never be refined and so P^a cannot be admissible. □

Although not all partitions are admissible, any partition has an admissible refinement with a number of triangles which is at most a constant factor larger. Indeed, given a partition $P=P_n$, consider the following algorithm to compute the partition $P^a=P^a_n$.

ALGORITHM 3.6.
$P_0^a := P_0$
`for` $i = 0, \dots, n$ `do`
define P_{i+1}^a *as the union of* P_{i+1} *and, when* $i \leq n-2$*, the collection children of those* $\triangle \in P_i^a$ *that have a neighbor in* P_i *with grandchildren in* P_{i+2}
`od`

PROPOSITION 3.7. *The partition* P^a *produced by Algorithm* 3.6 *is an admissible refinement of* P *with* $\#P^a \lesssim \#P$.

Proof. The criterion to add children of a $\triangle \in P_i^a$ to P_{i+1} with the construction of P_{i+1}^a can only be fulfilled when $\triangle$ is a neighbor of a $\tilde{\triangle} \in P_i$, which was refined when going to P_{i+1}, and thus with $\mathrm{gen}(\tilde{\triangle}) = i$. As we have seen, since $\max_{\triangle \in P_i^a} \mathrm{gen}(\triangle) = i$, the number of neighbors in P_i^a of such a $\tilde{\triangle}$ is uniformly bounded. So defining λ_i or λ_i^a as the number of triangles that were refined when going from P_i to P_{i+1} or from P_i^a to P_{i+1}^a, respectively, we have $\lambda_i^a \lesssim \lambda_i$.

Note that $(P_i^a)_{0 \leq i \leq n}$ corresponds to P^a in the sense of Proposition 3.1. Since each time a triangle in a partition is refined the number of triangles is increased by 3, we conclude that

$$\#P^a = \#P_0 + 3\sum_{i=0}^{n-1} \lambda_i^a \lesssim \#P_0 + 3\sum_{i=0}^{n-1} \lambda_i = \#P.$$

What is left to show is that P^a is admissible. Obviously, the partitions P_0^a and P_1^a are admissible. Suppose that there exists an $1 \leq i \leq n-1$ such that P_i^a is admissible, whereas P_{i+1}^a is not. Then, there exist neighbors $\triangle, \tilde{\triangle} \in P_{i+1}^a$ with $\mathrm{gen}(\triangle) - \mathrm{gen}(\tilde{\triangle}) > 1$. Since P_i^a is admissible, necessarily $\mathrm{gen}(\triangle) = i+1$ and $\mathrm{gen}(\tilde{\triangle}) = i-1$.

If $\triangle \in P_{i+1}$, then $\tilde{\triangle} \in P_{i-1}^a$ has a neighbor in P_{i-1} with grandchildren in P_{i+1}. So, by construction, $\tilde{\triangle}$ would have been refined when going to P_i^a, which gives a contradiction with the assumption that $\tilde{\triangle} \in P_{i-1}^a$.

If $\triangle \in P_{i+1}^a \backslash P_{i+1}$, then by construction, its parent $\triangle_f \in P_i^a$ has a neighbor $\hat{\triangle} \in P_i$ with grandchildren in P_{i+2}, whereas obviously also $\triangle_f \in P_i^a$ and $\tilde{\triangle}$ are neighbors. Let $\triangle_{ff} \in P_{i-1}^a$ and $\hat{\triangle}_f \in P_{i-1}$ denote the parents of $\triangle_f$ and $\hat{\triangle}$, respectively. We are going to show that $\hat{\triangle}_f$ and $\tilde{\triangle}$ are neighbors in P_{i-1}^a, meaning, because $\hat{\triangle}_f$ has grandchildren in P_{i+1}, that $\tilde{\triangle}$ must have been refined when going to P_i^a, resulting in a contradiction with the assumption that $\tilde{\triangle} \in P_{i+1}^a$. We have to distinguish between two cases: If $\triangle_f$ is the central subtriangle of $\triangle_{ff}$, then both $\triangle_{ff}$ and $\hat{\triangle}_f$, and $\triangle_{ff}$ and $\tilde{\triangle}$ share an edge, and so $\hat{\triangle}_f$ and $\tilde{\triangle}$ are neighbors (cf. left picture in Figure 3.2). If $\triangle_f$ is a corner subtriangle of $\triangle_{ff}$, i.e, $\triangle_f$ and $\triangle_{ff}$ share a vertex v, then v is also a vertex of both $\hat{\triangle}_f$ and $\tilde{\triangle}$, again showing that they are neighbors (cf. right picture in Figure 3.2). ∎

With $P_0^* = P_0$, by induction on i we construct the partition P_i^* from P_{i-1}^* by applying a red refinement step to *all* $\triangle \in P_{i-1}^*$, i.e., P_i^* is the result of applying recursively i *uniform refinement steps* to P_0. Note that these definitions are in accordance with Notation 3.2. We define

$$V_* = \cup_{i \geq 0} V_{P_i^*} \backslash V_{P_{i-1}^*};$$

this set contains V_P for any partition $P = P_n$. Obviously, for $0 \leq i \leq n$, $V_{P_i} \subset V_{P_i^*}$, and Proposition 3.1(ii) shows that $V_{P_i} \backslash V_{P_{i-1}} \subset V_{P_i^*} \backslash V_{P_{i-1}^*}$.

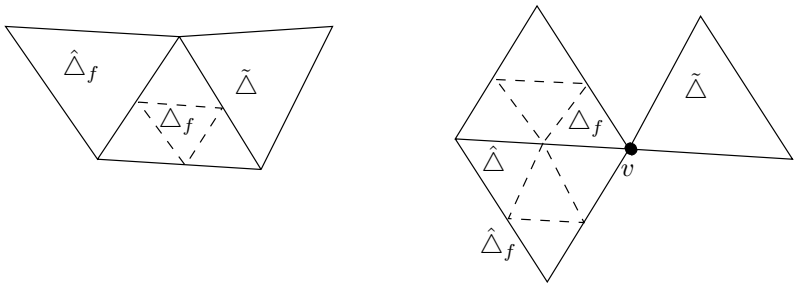

FIG. 3.2. *Illustration with the proof of Proposition* 3.7.

Finally, in this subsection, having defined the initial partition P_0, we are able to formulate all assumptions on the coefficient matrix $\mathbf{A}$ that we will need.

Assumption 3.8. In addition to assuming that $\mathbf{A} \in L_\infty(\Omega)$ is a symmetric 2×2 matrix with $\operatorname{ess\,inf}_{x\in\Omega}\lambda_{\min}(\mathbf{A}(x)) > 0$, we assume that $\mathbf{A} \eqsim \rho(\mathbf{A})\mathbf{id}$, uniformly over the domain (*isotropic diffusion*), and that $\mathbf{A}$ is *piecewise constant with respect to* P_0. Further, following [12], we assume that $\rho = \rho(\mathbf{A})$ is *quasi-monotone* with respect to P_0. That is, defining for $v \in \bar{V}_{P_0}$, $P_0(v) = \{\triangle \in P_0 : v \in \triangle\}$ and $\triangle(v) = \operatorname{argmax}\{\rho|_\triangle : \triangle \in P_0(v)\}$, we assume that for some absolute constant $c > 0$, for all $v \in \bar{V}_{P_0}$ and $\triangle \in P_0(v)$ there exist $\triangle = \triangle_1, \dots, \triangle_m = \triangle(v)$ such that $\triangle_i$ shares an edge with $\triangle_{i+1}$ and $\rho|_{\triangle_i} \le c\rho|_{\triangle_{i+1}}$. Moreover, if $v \in \bar{V}_{P_0}\backslash V_{P^0}$, then in addition we assume that there exists a $\triangle \in P_0(v)$ having an edge on $\partial\Omega$ such that $\rho|_{\triangle(v)} \le c\rho|_\triangle$. Under these assumptions, all of our results that depend on $\mathbf{A}$ should be interpreted as ones that hold *uniformly in* $(\rho|_\triangle)_{\triangle\in P_0}$.

4. Finite element spaces and bases, and Galerkin approximations. For a given partition P, let $\mathcal{S}_P \subset H^1_0(\Omega)$ denote the space of continuous, piecewise linear functions subordinate to P which vanish at $\partial\Omega$. The solution $u_P \in \mathcal{S}_P$ of

$$a(u_P, w_P) = f(w_P) \quad (w_P \in \mathcal{S}_P), \tag{4.1}$$

is called the *Galerkin approximation* of the solution u of (2.1). Defining $L_P : \mathcal{S}_P \to (\mathcal{S}_P)' \supset H^{-1}(\Omega)$ by $(L_P u_P)(w_P) = a(u_P, w_P)$, the solution of (4.1) is $L_P^{-1} f$.

On some places we will replace the right-hand side f by some approximation from $\mathcal{S}^0_P$, being defined as the space of functions that are piecewise constant with respect to P.

If $\tilde{P}$ is a refinement of P, then $\mathcal{S}_P \subset \mathcal{S}_{\tilde{P}}$ and $\mathcal{S}^0_P \subset \mathcal{S}^0_{\tilde{P}}$. Each $u \in \mathcal{S}_P$ is uniquely determined by its values on V_P, and so, in particular, $\#V_P = \dim\mathcal{S}_P$. Defining, for $v \in V_P$, $\phi^v_P \in \mathcal{S}_P$ by

$$\phi^v_P(\tilde{v}) = \begin{cases} 1, & v = \tilde{v}, \\ 0, & v \ne \tilde{v} \in V_P, \end{cases}$$

the set

$$\{\phi^v_P : v \in V_P\}$$

is a basis for $\mathcal{S}_P$, called the *nodal basis*.

One easily verifies the following result.

LEMMA 4.1. *Let v be a regular vertex of a partition P. Then, with $i := \mathrm{gen}(\triangle)$ for any (and thus all) $\triangle \in P$ that contain v, we have that $\phi^v_{P^*_i} \in \mathcal{S}_P$.*

PROPOSITION 4.2. *For any partition $P = P_n$, $\cup_{i=0}^n \{\phi^v_{P^*_i} : v \in V_{P_i} \backslash V_{P_{i-1}}\}$ is a basis for $\mathcal{S}_P$, called* hierarchical basis.

Proof. Proposition 3.1(ii) and Lemma 4.1 show that for $v \in V_{P_i} \backslash V_{P_{i-1}}$, $\phi^v_{P^*_i} \in \mathcal{S}_{P_i} \subset \mathcal{S}_P$. Since $\phi^v_{P^*_i}$ vanishes on $V_{P_{i-1}}$, by induction on i we conclude that for given scalars $(d_v)_{v \in V_P}$ the interpolation problem of finding scalars $(c_v)_{v \in V_P}$ with $\sum_{i=0}^n \sum_{v \in V_{P_i} \backslash V_{P_{i-1}}} c_v \phi^v_{P^*_i}(\tilde{v}) = d_{\tilde{v}}$ $(\tilde{v} \in V_P)$ has a unique solution. Since $\dim \mathcal{S}_P = \#V_P = \sum_{i=0}^n \#(V_{P_i} \backslash V_{P_{i-1}})$ by Proposition 3.1(i), the proof is completed. ∎

Besides the nodal and hierarchical bases, for admissible partitions P^a we introduce another basis for $\mathcal{S}_{P^a}$, which, as we shall see, is appropriately called a *wavelet basis*.

Let $v \in V_*$; then there exists a unique $i \in \mathbb{N}$ such that $v \in V_{P^*_i} \backslash V_{P^*_{i-1}}$. When $i > 0$, v is the midpoint of the common edge of two triangles $\triangle_1, \triangle_2 \in P^*_{i-1}$. Let us denote by $v_1(v), \ldots, v_4(v)$ the vertices of these $\triangle_1, \triangle_2$, with $v_2(v), v_3(v)$ being the vertices on the edge containing v; see Figure 4.1. For some scalars $\mu_{v,j}$ which will be specified later on, with $\mu_{v,j} := 0$ when $v_j(v) \in \partial\Omega$, we define

$$\psi^v := \phi^v_{P^*_i} - \sum_{j=1}^4 \mu_{v,j} \phi^{v_j(v)}_{P^*_{i-1}}, \tag{4.2}$$

and, for convenience, for $v \in V_{P^*_0}$ we set $\psi^v = \phi^v_{P^*_0}$.

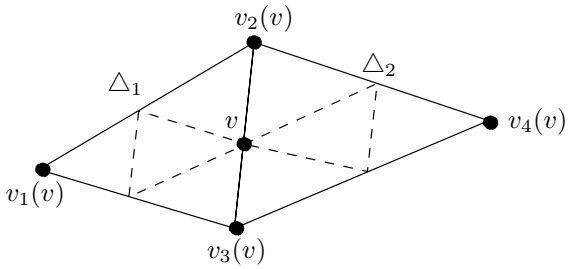

FIG. 4.1. *Definition of $v_j(v)$.*

PROPOSITION 4.3. *If P^a is* admissible, *then*

$$\{\psi^v : v \in V_{P^a}\} \tag{4.3}$$

is a basis for $\mathcal{S}_{P^a}$.

Proof. Obviously $\{\psi^v : v \in V_{P_0}\}$ is a basis for $\mathcal{S}_{P_0}$. Assuming that $\{\psi^v : v \in V_{P^a_{n-1}}\}$ is a basis for $\mathcal{S}_{P^a_{n-1}}$, the same argument as the one that was applied in the proof of Proposition 4.2 shows that $\{\psi^v : v \in V_{P^a_{n-1}}\} \cup \{\phi^v_{P^*_n} : v \in V_{P^a_n} \backslash V_{P^a_{n-1}}\}$ is a basis for $\mathcal{S}_{P^a_n}$. Proposition 3.1(ii) shows that each $v \in V_{P^a_n} \backslash V_{P^a_{n-1}}$ is the midpoint of $\triangle_1, \triangle_2 \in P^a_{n-1}$ with $\mathrm{gen}(\triangle_1) = \mathrm{gen}(\triangle_2) = n-1$, both of which are refined in the transition to P^a_n. Proposition 3.4 shows that each of $v_1(v), \ldots, v_4(v)$, which are the vertices of $\triangle_1$ and $\triangle_2$, is a regular vertex of P^a_{n-1}, obviously with $\mathrm{gen}(\hat{\triangle}) = n-1$ for any and thus all $\hat{\triangle} \in P^a_{n-1}$ which contain this vertex. From Lemma 4.1 we now conclude that $\sum_{j=1}^4 \mu_{v,j} \phi^{v_j(v)}_{P^*_{i-1}} \in \mathcal{S}_{P^a_{n-1}}$, from which it follows that also $\{\psi^v : v \in V_{P^a_n}\}$ is a basis for $\mathcal{S}_{P^a_n}$. ∎

For $P^a = P^a_n$ and $w_{P^a} \in \mathcal{S}_{P^a}$ given by its values $(w_{P^a}(v))_{v \in \bar{V}_{P^a}}$, i.e., the coefficients of its representation with respect to the nodal basis, where $w_{P^a}(v) := 0$ when

$v \in \bar{V}_{P^a} \backslash V_{P^a}$, an application of the following routine yields the coefficients $(c_v)_{v \in V_{P^a}}$ of its representation with respect to the wavelet basis (4.3).

ALGORITHM 4.4.

$c_v := w_{P^a}(v)$ *($v \in \bar{V}_{P^a}$)*
`for` $i = n, \dots, 1$ `do`
  $c_v := c_v - \frac{1}{2}(c_{v_2(v)} + c_{v_3(v)})$ *($v \in V_{P^a_i} \backslash V_{P^a_{i-1}}$)*
  $c_{v_j(v)} := c_{v_j(v)} + c_v \mu_{v,j}$ *($v \in V_{P^a_i} \backslash V_{P^a_{i-1}}$, $1 \le j \le 4$)*
`od`

Conversely, if $w_{P^a} \in \mathcal{S}_{P^a}$ is given by its coefficients $(c_v)_{v \in \bar{V}_{P^a}}$ with respect to the wavelet basis (4.3), where $c_v := 0$ when $v \in \bar{V}_{P^a} \backslash V_{P^a}$, then the values $(w_{P^a}(v))_{v \in V_{P^a}}$ are obtained from the following routine.

ALGORITHM 4.5.

`for` $i = 1, \dots, n$ `do`
  $c_{v_j(v)} := c_{v_j(v)} - c_v \mu_{v,j}$ *($v \in V_{P^a_i} \backslash V_{P^a_{i-1}}$, $1 \le j \le 4$)*
  $c_v := c_v + \frac{1}{2}(c_{v_2(v)} + c_{v_3(v)})$ *($v \in V_{P^a_i} \backslash V_{P^a_{i-1}}$)*
`od`
$w_{P^a}(v) := c_v$ *($v \in V_{P^a}$)*

One directly infers the following result.

PROPOSITION 4.6. *Both of the above algorithms for switching between the representation of a $w \in \mathcal{S}_{P^a}$ in terms of the nodal basis to its representation in terms of* (4.3)*, and vice versa, take $\mathcal{O}(\dim \mathcal{S}_{P^a})$ operations.*

Now we come to the specification of the coefficients $\mu_{v,j}$ from (4.2). We take

$$\mu_{v,j} = \frac{3(\rho|_{\triangle_1}\mathrm{meas}(\triangle_1) + \rho|_{\triangle_2}\mathrm{meas}(\triangle_2))}{8\sum_{\{\triangle \in P^*_{i-1}, v_j(v) \in \triangle\}} \rho|_{\triangle}\mathrm{meas}(\triangle)} \text{ when } j \in \{2,3\} \text{ and } v_j(v) \notin \partial\Omega, \tag{4.4}$$

and $\mu_{v,j} = 0$ otherwise. An alternative choice of the coefficients will be discussed later, in Remark 4.9. When both $v_2(v), v_3(v) \notin \partial\Omega$, a simple calculation reveals that, for $i \ge 1$ and $v \in V_{P^*_i} \backslash V_{P^*_{i-1}}$, $\int_\Omega \rho \psi^v = 0$, so that it is appropriate to call ψ^v a *wavelet*.

For coefficient matrices $\mathbf{A}$ that satisfy Assumption 3.8, a combination of results from [19, 18, 12] shows the following result.

THEOREM 4.7. *With $\bar{\psi}^v := \psi^v / |\psi^v|_1$,*

$$\{\bar{\psi}^v : v \in V_*\} \tag{4.5}$$

is a Riesz basis for $H^1_0(\Omega)$ equipped with $|\cdot|_1$. For the sake of completeness we emphasize that this result is valid uniformly in $(\rho|_{\triangle})_{\triangle \in P_0}$.

Defining $\|\!|w|\!\|_1 = (\sum_{v \in V_*} \bar{c}_v^2)^{\frac{1}{2}}$, where $w = \sum_{v \in V_*} \bar{c}_v \bar{\psi}^v$ is the unique expansion of $w \in H^1_0(\Omega)$, with $\lambda_{\bar{\Psi}}, \Lambda_{\bar{\Psi}} > 0$ we will denote the largest or smallest constant for which

$$\lambda_{\bar{\Psi}} \|\!| \cdot |\!\|_1^2 \le |\cdot|_1^2 \le \Lambda_{\bar{\Psi}} \|\!| \cdot |\!\|_1^2 \tag{4.6}$$

and $\kappa_{\bar{\Psi}} := \frac{\Lambda_{\bar{\Psi}}}{\lambda_{\bar{\Psi}}}$. We note that this equivalence between the $|\cdot|_1$-norm of a function in $H^1_0(\Omega)$ and the ℓ_2-norm of its, generally infinite, coefficient vector holds, in particular, for functions from $\mathcal{S}_{P^a}$ for admissible P^a, which by Proposition 4.3 have a finite wavelet expansion.

Remark 4.8. Since the proof of Theorem 4.7 can only be deduced by combining results from different papers, we briefly comment on its derivation. For any $\triangle \in \cup_{i \ge 0} P^*_i$, let $I_\triangle : C(\triangle) \to P_1(\triangle)$ be the nodal value interpolant, consider the bilinear

form $\langle\!\langle u, w\rangle\!\rangle_\triangle := \frac{1}{3}\mathrm{meas}(\triangle)\cdot\sum_{v \text{ vertex of } \triangle} u(v)w(v)$, and let

$$\langle u, w\rangle_\triangle := \langle\!\langle I_\triangle u, I_\triangle w\rangle\!\rangle_\triangle + \sum_{k=1}^{4}\left[\langle\!\langle u, w\rangle\!\rangle_{\triangle_k} - \langle\!\langle I_\triangle u, I_\triangle w\rangle\!\rangle_{\triangle_k}\right],$$

where $\triangle_1, \ldots, \triangle_4$ are the children of $\triangle$. Note that for $u, w \in P_1(\triangle)$, $\langle u, w\rangle_\triangle = \langle\!\langle u, w\rangle\!\rangle_\triangle$ which is a scalar product on $P_1(\triangle)$. Let $Y_\triangle : C(\triangle)\cap\prod_{k=1}^4 P_1(\triangle_k) \to P_1(\triangle)$ be the orthogonal projector with respect to $\langle\cdot,\cdot\rangle_\triangle$. Finally, for $i \geq 1$, on $\mathcal{S}_{P_i^*}\times\mathcal{S}_{P_i^*}$ let

$$\langle u, w\rangle_{\mathcal{S}_{P_i^*}} := \sum_{\triangle\in P_{i-1}^*} \rho|_\triangle \langle u, w\rangle_\triangle.$$

Using that $\{\phi^v_{P_{i-1}^*} : v \in V_{P_{i-1}^*}\}$ is an orthogonal set with respect to $\langle\cdot,\cdot\rangle_{\mathcal{S}_{P_i^*}}$, in [18, section 6] it was shown that for $i \geq 1$ the sets

$$\{\psi^v/\|\psi^v\|_0 : v \in V_{P_i^*}\backslash V_{P_{i-1}^*}\},$$

defined by (4.2), (4.4), are uniform Riesz bases for $\mathcal{S}_{P_i^*}\cap\mathcal{S}_{P_{i-1}^*}^{\perp_{\langle\,,\,\rangle_{\mathcal{S}_{P_i^*}}}}$ equipped with $\|\cdot\|_0$, where "uniform" refers both to the parameter i and to $(\rho|_\triangle)_{\triangle\in P_0}$.

With

$$t := \sup_{0\neq w\in C(\triangle)\cap\prod_{k=1}^4 P_1(\triangle_k)} \frac{\langle w, w\rangle_\triangle - \langle (I-Y_\triangle)w, (I-Y_\triangle)w\rangle_\triangle}{\sum_{k=1}^4 \langle\!\langle w, w\rangle\!\rangle_{\triangle_k}},$$

whose value is independent of the triangle $\triangle$, it follows from [19, Thm. 3.1 and (4.7)] that in case of *constant* $\mathbf{A} = \mathbf{id}$, for $\frac{3}{2} > s > \log_2\sqrt{t}$ the infinite collection

$$\cup_{i\geq 0}\{2^{(s-1)i}\psi^v : v \in V_{P_i^*}\backslash V_{P_{i-1}^*}\}$$

is a Riesz basis for $H_0^s(\Omega)$. Some calculations show that $t = \frac{181}{64}$, and so $\sqrt{t} \approx .7499$, meaning in particular that (4.5) is a Riesz basis for $H_0^1(\Omega)$.

With $Q_i : L_2(\Omega) \to \mathcal{S}_{P_i^*}$ being the $\langle\,,\,\rangle_0$-orthogonal projector onto $\mathcal{S}_{P_i^*}$, and $Q_{-1} := 0$, for coefficient matrices $\mathbf{A}$ that satisfy Assumption 3.8, it was shown in [12] that

$$\|w\|_1^2 \eqsim \sum_{i=0}^{\infty} 4^i\|(Q_i - Q_{i-1})w\|_0^2 \quad (w \in H_0^1(\Omega)),$$

uniformly in $(\rho|_\triangle)_{\triangle\in P_0}$. As was shown in [19], from this result and the fact that $t < 1$ it even follows that (4.5) is a Riesz basis for $H_0^1(\Omega)$ equipped with $|\cdot|_1$, uniformly in $(\rho|_\triangle)_{\triangle\in P_0}$.

Remark 4.9. For *constant* $\mathbf{A} = \mathbf{id}$, in [8] other values for the coefficients $\mu_{v,1}, \ldots, \mu_{v,4}$ from (4.2) were proposed; generally, all four of these coefficients are nonzero. Although uniform refinements of an arbitrary initial partition are considered, just as outlined above, for admissible $P^a = P_n^a$ a subset of the wavelet basis for $\mathcal{S}_{P_n^*}$ spans $\mathcal{S}_{P^a}$. For some $\tilde{s} > 0$ and $s \in (-\tilde{s}, \frac{3}{2})$, the infinite collection of properly scaled wavelets from [8] is shown to generate a Riesz basis for

$$\mathcal{H}^s(\Omega) = \begin{cases} H_0^s(\Omega) & \text{when } s \geq 0, \\ (H_0^{-s}(\Omega))' & \text{when } s < 0. \end{cases}$$

On regular "type-I triangulations" of the whole of $\mathbb{R}^2$, the wavelet proposals from [18, sect. 6] or [8] reduce to the so-called coarse-grid stabilized HB-systems from [13] with parameters $a = \frac{1}{8}$ or $a = -\frac{3}{16}$, respectively. There, it is shown that for these uniform triangulations the exact $H^s(\mathbb{R}^2)$ stability ranges are $s \in (0.022818, \frac{3}{2})$ and $s \in (-0.440765, \frac{3}{2})$, respectively (cf. also [9]).

Finally, numerical results [13, Table 1.2] show that both wavelet bases are also quantitatively well conditioned ($\kappa_{\tilde{\Psi}}$ is approximately 16 or 10, respectively, for $\mathbf{A} = \mathbf{id}$ and P_0 being the standard regular partition of the unit square into 8 triangles, so that $\#V_{P^0} = 1$).

5. A coarsening algorithm. In [6], a coarsening step was introduced into an adaptive algorithm in the framework of a wavelet method. The idea of such a step, which has to be applied after each fixed number of iterations that produce increasingly more accurate approximations, is to remove a possibly large number of small terms in the current approximation that hardly contribute to its quality but which, because of their number, spoil the complexity. With wavelet methods such "small terms" stand for terms in a wavelet expansion with small coefficients, and in our finite element setting they correspond to a representation of the approximation as a piecewise linear function subordinate to a locally fine partition, whereas it is close to being linear on the union of these triangles.

Given some current approximation defined on some partition, in order to find a more efficient representation without increasing the error too much, one cannot simply join arbitrary collections of triangles since, generally, their union will not be a triangle. Instead one can only join groups of all siblings of one parent, that is, one has to respect the underlying tree structure. In view of this, in [3], for each triangle in the tree associated to the partition, an error functional was defined. It was shown that, for any subtree, the ℓ_2-norm of these error functionals over the leaves is bounded by some multiple of the error of the best continuous piecewise linear approximation subordinate to the partition defined by this subtree. Giving a tolerance that one allows to be added to the current error, a tree-coarsening algorithm from [5] was run, which, modulo some constant factor, yields the smallest subtree for which the above ℓ_2-norm is less than this tolerance. The ℓ_2-norm could not be shown to be equivalent to the $|\cdot|_1$-norm of the error in the best approximation. Therefore, this procedure had to be completed by a number of uniform refinement steps.

In this paper, for the different type of partitions we consider, based on ideas from [3, 5] an alternative coarsening procedure is developed, which we hope is more attractive for practical computations. Given a current approximation from $\mathcal{S}_P$, in case P is not admissible, we will first embed it into $\mathcal{S}_{P^a}$, where P^a is constructed using Algorithm 3.6. Next, we determine its finite set of wavelet coefficients. Now using the norm equivalence (4.6), an obvious coarsening procedure would be just to order these coefficients by their modulus, and then to remove coefficients, starting with the smallest one, until the tolerance is met. Yet, the task is not to find an approximation with a minimum number of wavelet coefficients, but to find an approximation from a finite element space subordinate to a partition that has, modulo some constant factor, a minimum number of triangles, and the suggested procedure will generally fail to deliver this. Therefore we will equip the infinite index set V_* of all wavelets with a tree structure, and run the algorithm from [5] to find a subtree approximation at a distance less than or equal to the tolerance, which has, modulo some constant factor, a minimum number of terms. Since the tree structure will be designed so that for any subtree $\tilde{V}$ we can construct a partition P such that $\operatorname{span}\{\psi^v : v \in \tilde{V}\} \subset \mathcal{S}_P$, where

$\#P \lesssim \#\tilde{V}$, we will be able to conclude that we found an approximation subordinate to a partition that has, modulo some constant factor, a minimum number of triangles. An advantage of our coarsening procedure will be that it not only gives a (quasi-) optimal partition, but that, at the same time, it also yields a (quasi-) optimal continuous piecewise linear approximation subordinate to this partition.

The tree structure with which we equip V_* is defined as follows. The vertices from $V_{P_0^*}$ are the roots of the tree. For $i = 1$ and $v \in V_{P_i^*} \backslash V_{P_{i-1}^*}$, we assume that at least one of the vertices $v_1(v), \ldots, v_4(v)$ is not on $\partial\Omega$, and we just pick one of them to be the parent of v. Now let $i > 1$ and $v \in V_{P_i^*} \backslash V_{P_{i-1}^*}$. At least one of $v_1(v), \ldots, v_4(v)$ is in $V_{P_{i-1}^*} \backslash V_{P_{i-2}^*}$, and we may pick just one of them to be the parent of v. In the case of multiple choices, a deterministic rule to make the selection is given, for example, by the following: If one of $v_2(v)$ or $v_3(v)$ is in $\bar{V}_{P_{i-2}^*}$, then the other is in $V_{P_{i-1}^*} \backslash V_{P_{i-2}^*}$, and we define it to be the parent of v. Otherwise, if both $v_2(v), v_3(v) \in \bar{V}_{P_{i-1}^*} \backslash \bar{V}_{P_{i-2}^*}$, then one of the remaining $v_1(v), v_4(v)$ is in $\bar{V}_{P_{i-2}^*}$, and we call it $v_1(v)$, whereas the other, thus called $v_4(v)$, is in $\bar{V}_{P_{i-1}^*} \backslash \bar{V}_{P_{i-2}^*}$. After numbering $v_1(v), v_2(v), v_3(v)$ in a clockwise direction, we select the first of $v_2(v), v_3(v), v_4(v) \in V_{P_{i-1}^*} \backslash V_{P_{i-2}^*}$ to be the parent of v. The number of children of any parent in this tree is uniformly bounded and is only dependent on P_0.

For $w \in H_0^1(\Omega)$, let $w = \sum_{v \in V_*} \bar{c}_v \bar{\psi}^v$ be its expansion with respect to (4.5). Obviously, for any $\tilde{V} \subset V_*$, its best approximation with respect to $\|\!|\cdot|\!\|_1$ from $\operatorname{span}\{\bar{\psi}^v : v \in \tilde{V}\}$ is $\sum_{v \in \tilde{V}} \bar{c}_v \bar{\psi}^v$. The squared error $E(\tilde{V})$ of this approximation with respect to $\|\!|\cdot|\!\|_1$ is $E(\tilde{V}) = \sum_{v \in V_* \backslash \tilde{V}} |\bar{c}_v|^2$.

We will call $\tilde{V} \subset V_*$ a *subtree* when it contains all roots $V_{P_0^*}$, and when, for any $v \in \tilde{V}$, all its ancestors and all its siblings, i.e., those $w \in V_*$ that have the same parent as v, are also in $\tilde{V}$. The set of leaves $\mathcal{L}(\tilde{V})$ is defined as the set of those $v \in \tilde{V}$ which have no children in $\tilde{V}$. Defining for $v \in V_*$ the error functional $e(v) := \sum_{\bar{v} \text{ a descendant of } v} |\bar{c}_{\bar{v}}|^2$, we have $E(\tilde{V}) = \sum_{v \in \mathcal{L}(\tilde{V})} e(v)$.

Following [5], we define a modified error functional $\tilde{e}(v)$ for $v \in V_*$ as follows. For the roots $v \in V_{P_0^*}$, $\tilde{e}(v) := e(v)$. Assuming that $\tilde{e}(v)$ has been defined, then for all of its children $v_1, \ldots, v_m$,

$$\tilde{e}(v_j) := \frac{\sum_{i=1}^m e(v_i)}{e(v) + \tilde{e}(v)} \tilde{e}(v).$$

Now given a $w \in H_0^1(\Omega)$ and a tolerance $\varepsilon > 0$, the *thresholding second algorithm* from [5] for determining a quasi-optimal *subtree approximation* runs as follows.

ALGORITHM 5.1.

$\tilde{V} := V_{P_0^*}$
`while` $E(\tilde{V}) > \varepsilon^2$ `do`
    compute $\rho = \max_{v \in \mathcal{L}(\tilde{V})} \tilde{e}(v)$
    `forall` $v \in \mathcal{L}(\tilde{V})$ *with* $\tilde{e}(v) = \rho$ `do` *add all children of* v *to* $\tilde{V}$ `od`
`od`

Remark 5.2. During the evaluation of Algorithm 5.1, the values $\tilde{e}(v)$ for the current leaves should be stored as an ordered list. As a consequence, with $\tilde{V}$ being the subtree at termination, the operation count of Algorithm 5.1 will contain a term $\mathcal{O}(\#\tilde{V} \log((\#\tilde{V}))$ due to the insertions of $\tilde{e}(v)$ for newly created leaves in this list. Since the other costs of the algorithm are $\mathcal{O}(\#\tilde{V})$, asymptotically the cost of these insertions will dominate. Although it seems unlikely that this will happen with practical problem sizes, for mathematical completeness we sketch here a modification with

which the log-factor is avoided (see [1, 14, 20] for solutions of a similar problem in a wavelet context).

Noting that $\tilde{e}(v_j) \le \sum_{i=1}^m e(v_i) \le e(v) \le \|w\|_1^2$, we may store the current leaves v in binary bins $V_0, \dots, V_q$, where for $0 \le i \le q-1$, V_i contains those v with $\tilde{e}(v) \in (2^{-(i+1)}\|w\|_1^2, 2^{-i}\|w\|_1^2]$, and the remaining v, thus with $\tilde{e}(v) \le 2^{-q}\|w\|_1^2$, are put into V_q. Instead of replacing all $v \in \mathcal{L}(\tilde{V})$ with maximal $\tilde{e}(v)$ by their children, in each iteration of the while-loop we replace just one v taken from the first nonempty bin by its children. Again, from $\sum_{i=1}^m e(v_i) \le e(v)$ we have $\tilde{e}(v_j) \le \tilde{e}(v)$ meaning that for any i, once $V_0, \dots, V_i$ got empty they will remain empty.

If q is chosen so that during the iteration we only extract v from bins V_i with $i < q$, then the corresponding $\tilde{e}(v)$ will be at most a factor 2 smaller than the current maximal value of $\tilde{e}$. As a consequence, one may verify that, with the exception of the operation-counts, all results proven in [5] about Algorithm 5.1 are also valid for this modified version (making use of the property $\sum_{i=1}^m e(v_i) \le e(v)$, which is stronger than the assumption made in [5]; only (5.13) of [5] has to be adapted).

With $\tilde{V}$ being the subtree at termination, the number of operations required by this modified Algorithm 5.1 is $\lesssim \#\tilde{V} + q$, where q is the maximum number of bins that have to be generated or inspected for containing leaves. Thinking of the situation when in the course of the iteration the maximum value of $\tilde{e}$ over the leaves varies largely in size, note that, generally, q cannot be bounded in terms of $\#\tilde{V}$.

We will apply the modified Algorithm 5.1 only in the situation when there exists a finite subtree $\bar{V} \subset V_*$ such that

$$e(v) = 0 \qquad (v \in \mathcal{L}(\bar{V})), \tag{5.1}$$

which allows us to make a suitable choice for q. Note that the subtree $\tilde{V}$ at termination satisfies $\tilde{V} \subset \bar{V}$. The definition of $\tilde{e}(v)$ shows that $\sum_{j=1}^m \frac{e(v_j)}{\tilde{e}(v_j)} = 1 + \frac{e(v)}{\tilde{e}(v)}$. A recursive application of this formula gives $\sum_{v \in \mathcal{L}(\tilde{V})} \frac{e(v)}{\tilde{e}(v)} = \#(\tilde{V} \backslash \mathcal{L}(\tilde{V})) + \#V_{P_0^*} \le \#\tilde{V} \le \#\bar{V}$, and so $E(\tilde{V}) \le \#\bar{V} \max_{v \in \mathcal{L}(\tilde{V})} \tilde{e}(v)$. We conclude that the modified Algorithm 5.1 terminates before any leaf v with $\tilde{e}(v) \le \varepsilon^2/\#\bar{V}$ is replaced by its children. Solving for the smallest $q \in \mathbb{N}_0$ with $2^{-q}\|w\|_1^2 = \varepsilon^2/\#\bar{V}$ yields $q = \max\{0, \lceil \log_2(\varepsilon^{-2}\|w\|_1^2 \#\bar{V})\rceil\}$; such a q thus satisfies the assumption we made earlier.

The analysis of Algorithm 5.1 from [5], together with the additions from the above remark concerning our slight modification, yields the following result.

PROPOSITION 5.3 (see [5, Corollary 5.3]). *The subtree $\tilde{V}$ yielded by (the modified) Algorithm* 5.1 *satisfies $E(\tilde{V}) \le \varepsilon^2$. There exists absolute constants $t_1, T_2 > 0$, necessary with $t_1 \le 1 \le T_2$, such that if $\hat{V}$ is a subtree with $E(\hat{V}) \le t_1\varepsilon^2$, then $\#\tilde{V} \le T_2\#\hat{V}$. The number of evaluations of e and the number of additional arithmetic operations required by the modified Algorithm* 5.1 *are $\lesssim \#\tilde{V} + \max\{0, \log(\varepsilon^{-2}\|w\|_1^2\#\bar{V})\}$, with $\bar{V}$ being any subtree satisfying* (5.1).

We are now almost ready to define our coarsening routine. Inside this routine, for some admissible partition P^a we will apply the (modified) Algorithm 5.1 to a $w_{P^a} \in \mathcal{S}_{P^a}$. Such a w_{P^a} has an expansion $w_{P^a} = \sum_{v \in V_{P^a}} \bar{c}_v \bar{\psi}^v$, i.e., $\bar{c}_v = 0$ for $v \in V_* \backslash V_{P^a}$. Although V_{P^a} is nearly a subtree since it contains the roots V_{P_0} as well as all ancestors of any $v \in V_{P^a}$, it may contain $v \in V_{P^a}$ with siblings outside V_{P^a}. As a consequence, the (modified) Algorithm 5.1 may output a subtree $\tilde{V}$ containing such siblings. Yet, since the corresponding wavelet coefficients are zero, these siblings do not contribute to the approximation and can therefore be discarded. An efficient way of implementing this is to call the algorithm pretending that V_* is V_{P^a} so that

siblings outside V_{P^a} will never be created. The set $\bar{V}$ from (5.1) can be taken to be equal to V_{P^a}.

COARSE$[P, w_P, \varepsilon] \to [\tilde{P}^a, w_{\tilde{P}^a}]$:

% $P = P_n$ is some admissible partition, $w_P \in \mathcal{S}_P$ is given by its values $(w_P(v))_{v\in V_P}$
% and $\varepsilon > 0$. The output $\tilde{P}^a$ is an admissible partition, and $w_{\tilde{P}^a} \in \mathcal{S}_{\tilde{P}^a}$ is given by
% its values $(w_{\tilde{P}^a}(v))_{v\in V_{\tilde{P}^a}}$.

(i) *When P is admissible, let $P^a = P$; otherwise compute an admissible refinement P^a of P by applying Algorithm* 3.6. *Compute the values $(w_{P^a}(v))_{v\in V_{P^a}}$ of $w_{P^a} := w_P$.*

(ii) *Compute the wavelet coefficients $(\bar{c}_v)_{v\in V_{P^a}}$ of w_{P^a} using Algorithm* 4.4.

(iii) *Compute recursively $(e(v))_{v\in V_{P^a}}$ starting with each $v \in V_{P^0}$ as follows:*
`if` *v has no children in V_{P^a}* `then` $e(v) := 0$
`else` $e(v) := \sum_{\{\tilde{v}\in V_{P^a}:\tilde{v} \text{ is a child of } v\}} e(\tilde{v}) + \bar{c}_{\tilde{v}}^2$ `fi`

(iv) *Apply the modified Algorithm* 5.1, *with* $q := \max\{0, \lceil \log_2(\varepsilon^{-2}\|w_{P^a}\|_1^2 \# V_{P^a})\rceil\}$, *yielding a set $\tilde{V} \subset V_{P^a}$.*

(v) *Determine a partition $\tilde{P}$ as follows:*
$\tilde{P}_0 := P_0$, $i := 1$
`while` $\tilde{V} \cap (V_{P_i^*} \backslash V_{P_{i-1}^*}) \neq \emptyset$ `do`
construct $\tilde{P}_i$ from $\tilde{P}_{i-1}$ by refining those $\triangle \in \tilde{P}_{i-1}$ that contain a $v \in \tilde{V} \cap (V_{P_i^*} \backslash V_{P_{i-1}^*})$, $i{:=}i{+}1$
`od`

(vi) *Apply Algorithm* 3.6 *to determine an admissible refinement $\tilde{P}^a$ of $\tilde{P}$. Note that $\tilde{V} \subset V_{\tilde{P}} \subset V_{\tilde{P}^a}$, and thus that $w_{\tilde{P}^a} := \sum_{v\in\tilde{V}} \bar{c}_v \bar{\psi}^v \in \mathcal{S}_{\tilde{P}^a}$.*

(vii) *Apply Algorithm* 4.5 *to compute $(w_{\tilde{P}^a}(v))_{v\in V_{\tilde{P}^a}}$.*

THEOREM 5.4. (a) $[\tilde{P}^a, w_{\tilde{P}^a}] :=$ **COARSE**$[P, w_P, \varepsilon]$ *satisfies $\|w_P - w_{\tilde{P}^a}\|_1 \le \varepsilon$. There exists an absolute constant $D > 0$, such that for any partition $\hat{P}$ for which there exists a $w_{\hat{P}} \in \mathcal{S}_{\hat{P}}$ with $\|w_P - w_{\hat{P}}\|_1 \le t_1^{\frac{1}{2}}\varepsilon$, we have that $\#\tilde{P}^a \le D\#\hat{P}$.*

(b) *The call requires $\lesssim \#P + \max\{0, \log(\varepsilon^{-1}\|w_P\|_1)\}$ arithmetic operations.*

Proof. (a) The first statement follows by construction. Let $(\bar{c}_v)_{v\in V_*}$ be the wavelet coefficients in the expansion $w_P = \sum_{v\in V_*} \bar{c}_v\bar{\psi}_v$. Let $\hat{P}$, $w_{\hat{P}} \in \mathcal{S}_{\hat{P}}$ with $\|w_P - w_{\hat{P}}\|_1 \le t_1^{\frac{1}{2}}\varepsilon$. Let $\hat{P}^a$ be the admissible refinement of $\hat{P}$ constructed by applying Algorithm 3.6, and let $(\bar{c}_v)_{v\in V_{\hat{P}^a}}$ be the wavelet coefficients of $w_{\hat{P}} \in \mathcal{S}_{\hat{P}} \subset \mathcal{S}_{\hat{P}^a}$. Let $\hat{V}$ be the enlargement of $V_{\hat{P}^a}$ by adding all siblings of all $v \in V_{\hat{P}^a}$ to this set. Then $\hat{V}$ is a subtree with $\#\hat{V} \lesssim \#V_{\hat{P}^a} \lesssim \#\hat{P}^a \lesssim \#\hat{P}$. Because of

$$E(\hat{V}) = \sum_{v\in V_*\backslash\hat{V}} |\bar{c}_v|^2 \le \sum_{v\in V_*} |\bar{c}_v - \bar{c}_v|^2 = \|w_P - \hat{w}_P\|_1^2 \le t_1\varepsilon^2,$$

an application of Proposition 5.3 shows that $\tilde{V}$ constructed in (iv) satisfies $\#\tilde{V} \le T_2\#\hat{V}$. The proof is completed by noting that the partitions $\tilde{P}$ and $\tilde{P}^a$ constructed in (v) and (vi) satisfy $\#\tilde{P}^a \lesssim \#\tilde{P} \lesssim \#\tilde{V}$.

(b) The number of arithmetic operations required by (i)–(iii) is $\lesssim \#P^a \lesssim \#P$. Since $\#V_{P^a} \lesssim \#P^a \lesssim \#P$, Proposition 5.3 shows that (iv) requires $\lesssim \#\tilde{V} + \max\{0, \log(\varepsilon^{-2}\|w_P\|_1^2\#V_{P^a})\} \lesssim \#P + \max\{0, \log(\varepsilon^{-1}\|w_P\|_1)\}$ arithmetic operations. The number of arithmetic operations required by (v)–(vii) is $\lesssim \#\tilde{V} \lesssim \#P$. ∎

Had the unmodified Algorithm 5.1 been applied inside **COARSE**, the required number of arithmetic operations would have been $\lesssim \#P\log(\#P)$. In contrast with such a log-factor, for our application it will turn out that the log-*term* from

Theorem 5.4(b) is completely harmless. The next corollary shows that if for $u \in H^1_0(\Omega)$ and $s > 0$ the errors of the best approximations from any $\mathcal{S}_P$ with $\#P \leq n$ are $\mathcal{O}(n^{-s})$, then given any $\varepsilon > 0$, a partition P and a $w_P \in \mathcal{S}_P$ with $|u - w_P|_1 \leq \varepsilon$, by allowing the tolerance to increase by some suitable, sufficiently large constant factor, the coarsening procedure yields an (admissible) partition $\tilde{P}^a$ and a $w_{\tilde{P}^a} \in \mathcal{S}_{\tilde{P}^a}$ with $|u - w_{\tilde{P}^a}|_1 \lesssim \varepsilon$ and $\#\tilde{P}^a \lesssim \varepsilon^{-1/s}$, which, in view of the assumption, is the smallest size, modulo some constant factor, one can generally expect for an approximation with this accuracy. The short proof of this corollary is based on an argument taken from [3, proof of Theorem 4.9].

COROLLARY 5.5. *Let $\gamma > t_1^{-\frac{1}{2}}$. Then, for any $\varepsilon > 0$, $u \in H^1_0(\Omega)$, a partition P, $w_P \in \mathcal{S}_P$ with $\|\!|u - w_P|\!\|_1 \leq \varepsilon$, for $[\tilde{P}^a, w_{\tilde{P}^a}] := \mathbf{COARSE}[P, w_P, \gamma\varepsilon]$ we have that $\|\!|u - w_{\tilde{P}^a}|\!\|_1 \leq (1+\gamma)\varepsilon$, and*

$$\tilde{P}^a \leq D\#\hat{P}$$

for any partition $\hat{P}$ with $\inf_{w_{\hat{P}} \in \mathcal{S}_{\hat{P}}} \|\!|u - w_{\hat{P}}|\!\|_1 \leq (t_1^{\frac{1}{2}}\gamma - 1)\varepsilon$.

Proof. The first statement is an obvious consequence of Theorem 5.4. The second one also follows from this theorem using that

$$\inf_{w_{\hat{P}} \in \mathcal{S}_{\hat{P}}} \|\!|w_P - w_{\hat{P}}|\!\|_1 \leq \|\!|u - w_P|\!\|_1 + \inf_{w_{\hat{P}} \in \mathcal{S}_{\hat{P}}} \|\!|w_{\hat{P}} - u|\!\|_1 \leq \varepsilon + (t_1^{\frac{1}{2}}\gamma - 1)\varepsilon = t_1^{\frac{1}{2}}\gamma\varepsilon. \qquad \square$$

6. A convergent adaptive refinement strategy. We derive an a posteriori estimate of the error in the Galerkin approximation (4.1) of the solution of the boundary value problem (2.1) where we temporarily assume that the right-hand side $f \in L_2(\Omega)$. Second, under the assumption that f is piecewise constant with respect to the current partition, we derive a refinement strategy which guarantees that the difference between the Galerkin solutions on the new and old partition is greater than some fixed multiple of the error estimate for the solution on the old partition. Exploiting Galerkin orthogonality, we can therefore conclude that the error in the new solution is less than some absolute constant times the error in the old solution.

This section is largely based on ideas from [15] by Morin, Nochetto, and Siebert on the construction of an adaptive finite element method that can be proven to converge. The following are new aspects.

- We consider a different type of partitions (nonconforming ones generated by red-refinements vs. conforming ones generated by newest vertex bisection).
- Under Assumption 3.8 our results are valid uniformly in the size of jumps of $\rho = \rho(\mathbf{A})$.
- We use approximations of the right-hand side for setting up the discrete systems, with which the application of quadrature can be modeled, and, as in [3], we solve these systems inexactly. We evaluate the a posteriori error estimator using the inexact discrete solution and the approximate right-hand side. Because of the latter we can allow right-hand sides in $H^{-1}(\Omega)$ that lie outside $L_2(\Omega)$, at least when they can be sufficiently well approximated by piecewise constants.

We start by introducing some notation. We call e *an edge of a partition* P, when e is an edge of some $\triangle \in P$ and e connects two vertices from $\bar{V}_P$. Note that since we allow nonconforming partitions, not all edges of $\triangle \in P$ are edges of P. With $\bar{E}_P$ or E_P, respectively, we denote the set of all edges of P or all edges of P which are not part of $\partial\Omega$. Note that for an admissible partition P^a, any edge $e \in E_{P^a}$ is either the

common edge of $\triangle_1, \triangle_2 \in P^a$, or it is the common edge of $\triangle_1, \hat{\triangle}$, where $\triangle_1 \in P^a$ and $\hat{\triangle}$ is the parent of four triangles in P^a.

For $e \in E_P$ and $u \in \mathcal{S}_P$, we set

$$\eta_e(u) := \frac{\operatorname{diam}(e)}{\max\{\rho|_{e^-}, \rho|_{e^+}\}} \|[\mathbf{A}\nabla u]_e \cdot \mathbf{n}_e\|^2_{L_2(e)},$$

where $\mathbf{n}_e$ is a unit vector orthogonal to e, $[\mathbf{A}\nabla u]_e$ denotes the jump of $\mathbf{A}\nabla u$ in the direction of $\mathbf{n}_e$, and $\rho|_{e^\pm} = \rho(x \pm \delta \mathbf{n}_e)$ for arbitrary $x \in e$ and $\delta > 0$ small enough. For $\triangle \in P$ and $f \in L_2(\Omega)$, we set

$$\zeta_\triangle(f) := \frac{\operatorname{diam}(\triangle)^2}{\rho|_\triangle} \|f\|^2_{L_2(\triangle)},$$

and finally,

$$\mathcal{E}(P, f, u) := \left[\sum_{\triangle \in P} \zeta_\triangle(f) + \sum_{e \in E_P} \eta_e(u) \right]^{\frac{1}{2}}.$$

The a posteriori error estimate given in the following theorem extends results from [2, 17] for conforming partitions to admissible nonconforming partitions.

THEOREM 6.1. *There exists an absolute constant C_1, such that for any $f \in L_2(\Omega)$ and an admissible partition P^a, with $u := L^{-1}f$ and $u_{P^a} := L^{-1}_{P^a} f$, we have that*

$$|u - u_{P^a}|_1 \le C_1 \mathcal{E}(P^a, f, u_{P^a}).$$

Proof. For any $w \in H^1_0(\Omega)$, $w_{P^a} \in \mathcal{S}_{P^a}$, by the Galerkin orthogonality and because $\mathbf{A}$ is piecewise constant, integration by parts shows that

$$\begin{aligned} a(u - u_{P^a}, w) &= a(u - u_{P^a}, w - w_{P^a}) = \int_\Omega f(w - w_{P^a}) - a(u_{P^a}, w - w_{P^a}) \\ &= \sum_{\triangle \in P^a} \int_\triangle f(w - w_{P^a}) - \sum_{e \in E_{P^a}} \int_e ([\mathbf{A}\nabla u_{P^a}]_e \cdot \mathbf{n}_e)(w - w_{P^a}), \end{aligned} \tag{6.1}$$

where $\mathbf{n}_\triangle$ denotes the unit exterior normal to $\triangle$.

It was shown in [16, pp. 17–18] that for any triangle $\triangle$ and any of its vertices v, there exists a $\varphi(\triangle, v) \in L_\infty(\triangle)$ such that $\int_\triangle \varphi(\triangle, v)p = p(v)$ for all polynomials p of degree 1, and $\|\varphi(\triangle, v)\|_{L_\infty} \lesssim \operatorname{meas}(\triangle)^{-1}$ independently of $\triangle$. For each $v \in V_{P^a}$ we now select $\triangle_v = \operatorname{argmax}\{\rho|_\triangle : \triangle \in P^a, v \in \triangle\}$, and define $w_{P^a} \in \mathcal{S}_{P^a}$ by $w_{P^a}(v) = \int_{\triangle_v} \varphi(\triangle_v, v)w$. For $v \in \bar{V}_{P^a} \backslash V_{P^a}$, we set $\triangle_v = \emptyset$.

We start by estimating the first sum from (6.1). Let $\triangle \in P^a$, say $\triangle \in P^a_i$. The triangle $\triangle$ has between 0 and 3 hanging vertices. Since P^a is admissible, by Proposition 3.4 each of these hanging vertices is the midpoint of an edge connecting two vertices from $\bar{V}_{P^a_{i-1}}$. In the following we consider the case when $\triangle$ has one hanging vertex, and so in particular $i > 0$, but the other cases can be treated similarly.

Let $\tilde{\triangle} \in P^a_{i-1}$ be the parent of $\triangle$, v_1, v_2 the vertices of $\tilde{\triangle}$ such that the hanging vertex of $\triangle$ is the midpoint of the edge connecting v_1 and v_2, and let v_3 and v_4 be the nonhanging vertices of $\triangle$; see Figure 6.1. The linear function $w_{P^a}|_\triangle$ is the solution of the elementary interpolation problem with data $w_{P^a}(v_i)$ $(1 \le i \le 4)$, and

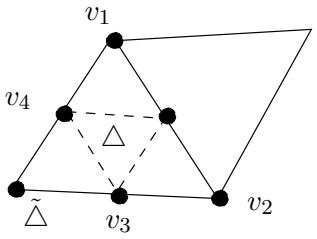

FIG. 6.1. *Illustration with the proof of Theorem* 6.1.

it is easily seen that $\|w_{P^a}\|_{L_2(\triangle)} \lesssim \operatorname{diam}(\triangle)\max_{1\le i\le 4}|w_{P^a}(v_i)|$. By construction, $|w_{P^a}(v_i)| \lesssim \operatorname{diam}(\triangle_{v_i})^{-1}\|w\|_{L_2(\triangle_{v_i})}$, or, when $v_i \in \partial\Omega$, $w_{P^a}(v_i) = 0$.

Since ρ is quasi-monotone (see Assumption 3.8), there exists a uniformly bounded collection $P^a_\triangle \subset P^a$ such that $\triangle, \triangle_{v_1}, \dots, \triangle_{v_4} \subset P^a_\triangle$, $\Omega_\triangle := \cup_{\tilde\triangle\subset P^a_\triangle}\tilde\triangle$ is a simply connected uniformly Lipschitz domain, $\rho|_\triangle \lesssim \inf_{\tilde\triangle\subset P^a_\triangle}\rho|_{\tilde\triangle}$, and, when one of $v_1,\dots,v_4$ is on $\partial\Omega$, $P^a_\triangle$ contains a $\tilde\triangle$ having an edge on $\partial\Omega$. From $\|w-w_{P^a}\|_{L_2(\triangle)} \lesssim \|w\|_{L_2(\Omega_\triangle)}$, a homogeneity argument, and either the fact that our interpolation operator reproduces any polynomial of first degree, and, in particular, any constant, together with the Bramble–Hilbert lemma, or, when one of $v_1,\dots,v_4$ is on $\partial\Omega$, the Poincaré–Friedrichs inequality, we infer that

$$\|w-w_{P^a}\|^2_{L_2(\triangle)} \lesssim \operatorname{diam}(\Omega_\triangle)^2|w|^2_{H^1(\Omega_\triangle)} \lesssim \frac{\operatorname{diam}(\triangle)^2}{\rho|_\triangle}\sum_{\tilde\triangle\in P^a_\triangle}\rho|_{\tilde\triangle}|w|^2_{H^1(\triangle)}.$$

By applying the Cauchy–Schwarz inequality, we deduce that

$$\left|\sum_{\triangle\in P^a}\int_\triangle f(w-w_{P^a})\right|^2 \lesssim \sum_{\triangle\in P^a}\frac{\operatorname{diam}(\triangle)^2}{\rho|_\triangle}\|f\|^2_{L_2(\triangle)}\sum_{\triangle\in P^a}\rho|_\triangle|w|^2_{H^1(\triangle)}. \tag{6.2}$$

Now we estimate the second sum from (6.1). Let $P^a = P^a_n$ and $e \in E_{P^a}$, then $e = \triangle_1\cap\triangle_2$ for some $\triangle_1,\triangle_2 \in \cup_{i=0}^n P^a_i$. Let us assume that $\rho|_{\triangle_1} \ge \rho|_{\triangle_2}$. Note that either $\triangle_1 \in P^a$ or it is the parent of four triangles from P^a. From the trace theorem we have $\|w\|_{L_2(e)} \lesssim \operatorname{diam}(e)^{-\frac12}\|w\|_{L_2(\triangle_1)} + \operatorname{diam}(e)^{\frac12}|w|_{H^1(\triangle_1)}$. With $v_1, v_2 \in \bar V_{P^a}$ being the endpoints of e, we have $\|w_{P^a}\|_{L_2(e)} \le \operatorname{diam}(e)^{\frac12}\max\{|w_{P^a}(v_1)|, |w_{P^a}(v_2)|\}$. From $|w_{P^a}(v_i)| \lesssim \operatorname{diam}(\triangle_{v_i})^{-1}\|w\|_{L_2(\triangle_{v_i})}$, or, when $v_i \in \partial\Omega$, $w_{P^a}(v_i) = 0$, we find that $\|w-w_{P^a}\|_{L_2(e)} \lesssim \operatorname{diam}(e)^{-\frac12}\|w\|_{L_2(\triangle_1\cup\triangle_{v_1}\cup\triangle_{v_2})} + \operatorname{diam}(e)^{\frac12}|w|_{H^1(\triangle\cup\triangle_1\cup\triangle_2)}$. As above, we can extend $\triangle_1, \triangle_{v_1}, \triangle_{v_2}$ to a uniformly bounded collection $P^a_e \subset P^a$, such that $\Omega_e := \cup_{\tilde\triangle\subset P^a_e}\tilde\triangle$ is a simply connected uniformly Lipschitz domain, $\rho|_{\triangle_1} \lesssim \inf_{\tilde\triangle\subset P^a_e}\rho|_{\tilde\triangle}$, and, when v_1 or v_2 is on $\partial\Omega$, P^a_e contains a $\tilde\triangle$ having an edge on $\partial\Omega$. Using the same arguments as above, we infer that

$$\|w-w_{P^a}\|^2_{L_2(e)} \lesssim \operatorname{diam}(e)|w|^2_{H^1(\Omega_e)} \lesssim \frac{\operatorname{diam}(e)}{\max\{\rho|_{e^-},\rho|_{e^+}\}}\sum_{\tilde\triangle\in P^a_e}\rho|_{\tilde\triangle}|w|^2_{H^1(\tilde\triangle)}.$$

By applying the Cauchy–Schwarz inequality, we deduce that

$$\left| \sum_{e\in E_{P^a}} \int_e ([\mathbf{A}\nabla u_{P^a}]_e \cdot \mathbf{n}_e)(w - w_{P^a}) \right|^2$$

$$\lesssim \sum_{e\in E_{P^a}} \frac{\operatorname{diam}(e)}{\max\{\rho|_{e^-}, \rho|_{e^+}\}} \|[\mathbf{A}\nabla u_{P^a}]_e \cdot \mathbf{n}_e\|^2_{L_2(e)} \sum_{\triangle\in P^a} \rho|_{\triangle} |w|^2_{H^1(\triangle)}. \tag{6.3}$$

On noting that $\sum_{\triangle\in P^a} \rho|_{\triangle} |w|^2_{H^1(\triangle)} \eqsim |w|^2_1$ and by substituting $w = u - u_{P^a}$, the proof follows from (6.1), (6.2), (6.3). ∎

The next lemma, which is based on [15, Lemma 4.2], gives local lower bounds on the difference between the Galerkin solution on some partition and a refinement of this partition. The differences with [15] are that we consider a different class of partitions, and that our results hold uniformly in the size of jumps of ρ. Furthermore, we simply assume that the right-hand side f is piecewise constant with respect to the first partition; for the moment we postpone the analysis in the case of more general f.

LEMMA 6.2. *Let P^a be an admissible partition and $\tilde{P}$ a refinement of P^a. Let $f_{P^a} \in L_2(\Omega)$ be* piecewise constant with respect to P^a, *i.e., $f_{P^a} \in \mathcal{S}^0_{P^a}$, and let $u_{P^a} = L^{-1}_{P^a} f_{P^a}, u_{\tilde{P}} = L^{-1}_{\tilde{P}} f_{P^a}$ be the corresponding Galerkin solutions.*

(a) *Let $\triangle_1, \triangle_2 \in P^a$ such that $e := \triangle_1 \cap \triangle_2 \in E_{P^a}$. Assume that $V_{\tilde{P}}$ contains points interior to $\triangle_1$, $\triangle_2$, and e; see Figure* 6.2. *Then*

$$|u_{\tilde{P}} - u_{P^a}|^2_{1,\triangle_1\cup\triangle_2} \gtrsim \eta_e(u_{P^a}) + \sum_{i=1}^{2} \zeta_{\triangle_i}(f_{P^a}).$$

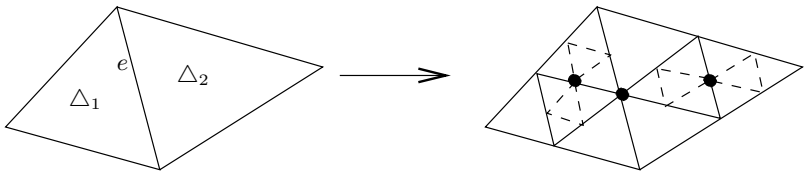

FIG. 6.2. *Illustration of Lemma* 6.2(a).

(b) *Let $\triangle_1, \hat{\triangle}$ such that $e := \triangle_1 \cap \hat{\triangle} \in E_{P^a}$, $\triangle_1 \in P^a$ and $\hat{\triangle}$ is the parent of four triangles $\triangle_2, \ldots, \triangle_5 \in P^a$, numbered such that $\triangle_2$, $\triangle_3$ have an edge e_2, e_3 on e. Assume that $V_{\tilde{P}}$ contains points interior to $\triangle_1$, $\triangle_2$, $\triangle_3$, e_2, and e_3; see Figure* 6.3. *Then*

$$|u_{\tilde{P}} - u_{P^a}|^2_{1,\triangle_1\cup\triangle_2\cup\triangle_3} \gtrsim \eta_e(u_{P^a}) + \sum_{i=1}^{3} \zeta_{\triangle_i}(f_{P^a}).$$

(c) *Assume that $V_{\tilde{P}}$ contains a point interior to $\triangle \in P^a$. Then*

$$|u_{\tilde{P}} - u_{P^a}|^2_{1,\triangle} \gtrsim \zeta_{\triangle}(f_{P^a}).$$

Proof. (a) By assumption, there exist $\varphi_1, \varphi_2, \varphi_3 \in H^1_0(\triangle_1 \cup \triangle_2) \cap \mathcal{S}_{\tilde{P}}$ with $|\varphi_i|_1 = 1$, and such that for $i \in \{1, 2\}$,

$$\operatorname{supp}(\varphi_i) \subset \triangle_i,\ \int_{\triangle_i} \varphi_i \eqsim \frac{\operatorname{meas}(\triangle_i)}{\rho|^{\frac{1}{2}}_{\triangle_i}},\ \int_{\triangle_i} \varphi_3 \eqsim \frac{\operatorname{meas}(\triangle_i)}{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}},\ \int_e \varphi_3 \eqsim \frac{\operatorname{meas}(e)}{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}}.$$

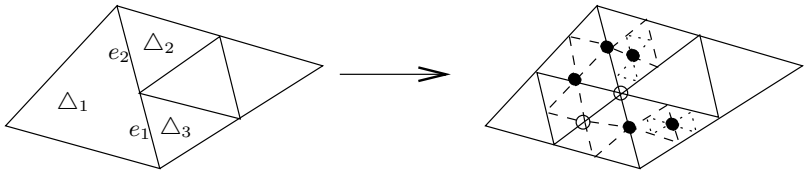

FIG. 6.3. *Illustration of Lemma* 6.2(b). *Open circles correspond to degrees of freedom that are not used.*

For any $\varphi = \sum_{i=1}^3 \mathbf{c}_i \varphi_i$, integration by parts shows that

$$\int_{\triangle_1 \cup \triangle_2} f_{P^a}\varphi - \int_e ([\mathbf{A}\nabla u_{P^a}]_e \cdot \mathbf{n}_e)\varphi = a(u_{\tilde{P}} - u_{P^a}, \varphi) \leq |u_{\tilde{P}} - u_{P^a}|_{1,\triangle_1\cup\triangle_2}|\varphi|_1 \lesssim |u_{\tilde{P}} - u_{P^a}|_{1,\triangle_1\cup\triangle_2}\|\mathbf{c}\|. \tag{6.4}$$

Let $g_j \in H^1_0(\triangle_1 \cup \triangle_2)'$ be defined by $g_j(\varphi) = \frac{\rho|^{\frac{1}{2}}_{\triangle_j}}{\mathrm{diam}(\triangle_j)\mathrm{meas}(\triangle_j)^{\frac{1}{2}}} \int_{\triangle_j} \varphi$ when $j = 1$ or 2, and $g_3(\varphi) = \frac{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}}{(\mathrm{diam}(e)\mathrm{meas}(e))^{\frac{1}{2}}} \int_e \varphi$, and let $\mathbf{B}_{ij} := g_j(\varphi_i)$. Then with $\mathbf{d}_j = \frac{\mathrm{diam}(\triangle_j)}{\rho|^{\frac{1}{2}}_{\triangle_j}} \|f_{P^a}\|_{L_2(\triangle_j)}$ when $j = 1$ or 2, and $\mathbf{d}_3 = \frac{\mathrm{diam}(e)^{\frac{1}{2}}}{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}} \|[\mathbf{A}\nabla u]_e \cdot \mathbf{n}_e\|_{L_2(e)}$, the left-hand side of (6.4) is $\sum_{i,j=1}^3 \mathbf{d}_j \mathbf{c}_i \mathbf{B}_{ij}$. Using (6.4), the statement of the lemma reduces to the question as to whether $\sup_{\mathbf{c}} \frac{\langle \mathbf{Bd}, \mathbf{c}\rangle}{\|\mathbf{c}\|} \gtrsim \|\mathbf{d}\|$ or $\|\mathbf{B}^{-1}\| \lesssim 1$. Since $\mathbf{B}_{ii} \eqsim 1$, and $\mathbf{B}_{31}, \mathbf{B}_{32} \lesssim 1$, whereas the other coefficients of $\mathbf{B}$ are zero, the proof of (a) is completed.

Part (b) can be proven similarly to (a). Note that, generally, $[\mathbf{A}\nabla u_{P^a}]_e$ has different values on e_2 and e_3. The proof of (c) poses no additional difficulties. ∎

As an immediate consequence we have the following result.

COROLLARY 6.3. *Let P^a be an admissible partition, $f_{P^a} \in \mathcal{S}^0_{P^a}$, and let $\tilde{P}$ be a refinement of P^a, such that for some $G \subset P^a$, $F \subset E_{P^a}$, for all $\triangle \in G$, $V_{\tilde{P}}$ satisfies the conditions from Lemma* 6.2(c), *and for all $e \in F$, $V_{\tilde{P}}$ satisfies the conditions from either Lemma* 6.2(a) *or Lemma* 6.2(b) *(it is sufficient that $\tilde{P}$ contains all grandchildren of all $\triangle \in P^a$ which either are in G or have an edge on an $e \in F$). Then, with $u_{P^a} = L^{-1}_{P^a} f_{P^a}, u_{\tilde{P}} = L^{-1}_{\tilde{P}} f_{P^a}$ denoting the corresponding Galerkin solutions, we have that*

$$|u_{\tilde{P}} - u_{P^a}|^2_1 \geq c_2^2 \left\{ \sum_{\triangle\in F} \zeta_\triangle(f_{P^a}) + \sum_{e\in G} \eta_e(u_{P^a}) \right\}$$

for some absolute constant $c_2 > 0$.

The way to obtain a convergent adaptive refinement strategy is to select the sets F and G such that $\sum_{\triangle\in F} \zeta_\triangle(f_{P^a}) + \sum_{e\in G} \eta_e(u_{P^a})$ is bounded from below by some multiple of $\sum_{\triangle\in P^a} \zeta_\triangle(f_{P^a}) + \sum_{e\in E_{P^a}} \eta_e(u_{P^a}) = \mathcal{E}(P^a, f_{P^a}, u_{P^a})^2$. Then, convergence follows by combining Theorem 6.1 and Corollary 6.3.

Since Lemma 6.2 also applies when $u_{\tilde{P}} = L^{-1}_{\tilde{P}} f_{P^a}$ is replaced by $u = L^{-1} f_{P^a}$, for later use we state the following result.

COROLLARY 6.4. *Let P^a be an admissible partition and let $f_{P^a} \in \mathcal{S}^0_{P^a}$. With $u := L^{-1} f_{P^a}$, $u_{P^a} := L^{-1}_{P^a} f_{P^a}$ and c_2 the constant from Corollary* 6.3, *we have that*

$$|u - u_{P^a}|_1 \geq c_2 \mathcal{E}(P^a, f_{P^a}, u_{P^a}).$$

In Corollary 6.3 it was assumed that the right-hand side f is piecewise constant with respect to the current partition P^a, and that the discrete system is solved exactly. In the remainder of this section we will relax both of these assumptions.

LEMMA 6.5. *There exists an absolute constant $C_3 > 0$ such that for any partition P, $f \in L_2(\Omega)$, $u_P, \tilde{u}_P \in \mathcal{S}_P$,*

$$|\mathcal{E}(P, f, u_P) - \mathcal{E}(P, f, \tilde{u}_P)| \leq C_3 |u_P - \tilde{u}_P|_1.$$

Proof. We have that

$$\begin{aligned} |\mathcal{E}(P, f, u_P) - \mathcal{E}(P, f, \tilde{u}_P)| &= \left[\sum_{\triangle \in P} \zeta_\triangle(f) + \sum_{e \in E_P} \eta_e(u_P) \right]^{\frac{1}{2}} \\ &\quad - \left[\sum_{\triangle \in P} \zeta_\triangle(f) + \sum_{e \in E_P} \eta_e(\tilde{u}_P) \right]^{\frac{1}{2}} \\ &\leq \left[\sum_{e \in E_P} (\eta_e(u_P)^{\frac{1}{2}} - \eta_e(\tilde{u})^{\frac{1}{2}})^2 \right]^{\frac{1}{2}}. \end{aligned}$$

For any $e \in E_P$,

$$\begin{aligned} |\eta_e(u_P)^{\frac{1}{2}} - \eta_e(\tilde{u}_P)^{\frac{1}{2}}| &= \frac{\operatorname{diam}(e)^{\frac{1}{2}}}{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}} \left| \|[\mathbf{A}\nabla u_P]_e \cdot \mathbf{n}_e\|_{L_2(e)} - \|[\mathbf{A}\nabla \tilde{u}_P]_e \cdot \mathbf{n}_e\|_{L_2(e)} \right| \\ &\leq \frac{\operatorname{diam}(e)^{\frac{1}{2}}}{\max\{\rho|_{e^-}, \rho|_{e^+}\}^{\frac{1}{2}}} \|[\mathbf{A}\nabla(u_P - \tilde{u}_P)]_e \cdot \mathbf{n}_e\|_{L_2(e)}. \end{aligned}$$

The proof is completed by the observation that, for any edge e_i of a $\triangle \in P$ and any $w \in P_1(\triangle)$ and unit vector $\mathbf{n}$, by a homogeneity argument we have that

$$\operatorname{diam}(e_i)^{\frac{1}{2}} \|\mathbf{A}\nabla w \cdot \mathbf{n}\|_{L_2(e_i)} \lesssim \rho|_\triangle |w|_{H^1(\triangle)} \eqsim \rho|_\triangle^{\frac{1}{2}} |w|_{1,\triangle}. \qquad \square$$

For some *fixed constant* $\theta \in (0, 1]$, we consider the following refinement procedure.
REFINE$[P^a, f_{P^a}, w_{P^a}] \to \tilde{P}$
% P^a is an admissible partition, $f_{P^a} \in \mathcal{S}^0_{P^a}$, and $w_{P^a} \in \mathcal{S}_{P^a}$.
Select $F \subset P^a$, $G \subset E_{P^a}$ such that

$$\sum_{\triangle \in F} \zeta_\triangle(f_{P^a}) + \sum_{e \in G} \eta_e(w_{P^a}) \geq \theta^2 \, \mathcal{E}(P^a, f_{P^a}, w_{P^a})^2.$$

Determine a refinement $\tilde{P}$ of P^a such that for all $\triangle \in F$, $V_{\tilde{P}}$ satisfies the conditions from Lemma 6.2(c), and for all $e \in G$, $V_{\tilde{P}}$ satisfies the conditions from either Lemma 6.2(a) or Lemma 6.2(b), where at the same time each $\tilde{\triangle} \in \tilde{P}$ is either in P^a or it is a child or a grandchild of a $\triangle \in P^a$.

As long as the selection of F and G is organized so that it does not involve the exact ordering of all $\zeta_\triangle(f_{P^a})$ and $\eta_e(w_{P^a})$ by their moduli (cf. discussion from Remark 5.2), we have the following result.

PROPOSITION 6.6. *The call* **REFINE**$[P^a, f_{P^a}, w_{P^a}]$ *requires a number of arithmetic operations $\lesssim \# P^a$.*

As stated before, we would like to consider $f \in H^{-1}(\Omega)$, possibly outside $L_2(\Omega)$, and we will use approximate right-hand sides both for setting up the discrete systems as well as for the evaluation of the a posteriori error estimator. In fact, since the terms $\zeta_\triangle(f)$ are only defined for $f \in L_2(\Omega)$, generally we will need approximate right-hand sides different from the exact one. The following theorem shows that if **REFINE** is called with a sufficiently accurate piecewise constant approximation for the right-hand side and a sufficiently accurate approximation of the discrete solution, then the solution on the new partition has an error that is less than the error in the solution on the previous partition. Together with the coarsening routine from section 5, in the next two subsections this theorem will be the basis for constructing adaptive finite element methods that converge with optimal rates.

THEOREM 6.7. *Let $f \in H^{-1}(\Omega)$, $u = L^{-1}f$, let P^a be an admissible partition, $f_{P^a} \in \mathcal{S}^0_{P^a}$, $u_{P^a} = L^{-1}_{P^a} f_{P^a}$, $\bar{u}_{P^a} \in \mathcal{S}_{P^a}$, $\tilde{P} = \mathbf{REFINE}[P^a, f_{P^a}, \bar{u}_{P^a}]$ or a refinement of it, $f_{\tilde{P}} \in H^{-1}(\Omega)$ and $u_{\tilde{P}} = L^{-1}_{\tilde{P}} f_{\tilde{P}}$. Then*

$$|u - u_{\tilde{P}}|_1 \le \left[1 - \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2\right]^{\frac{1}{2}} |u - u_{P^a}|_1 + 2c_2C_3|u_{P^a} - \bar{u}_{P^a}|_1 + 3\|f - f_{P^a}\|_{-1} + \|f - f_{\tilde{P}}\|_{-1}. \tag{6.5}$$

Proof. Let $\hat{u} = L^{-1}f_{P^a}$ and $\hat{u}_{\tilde{P}} = L^{-1}_{\tilde{P}} f_{P^a}$. With $F \subset P^a$, $G \subset E_{P^a}$ as determined in the call $\mathbf{REFINE}[P^a, f_{P^a}, \bar{u}_{P^a}]$, Corollary 6.3, two applications of Lemma 6.5, and Theorem 6.1 show that

$$\begin{aligned}
|\hat{u}_{\tilde{P}} - u_{P^a}|_1 &\ge c_2\left[\left\{\sum_{\triangle\in F}\zeta_\triangle(f_{P^a}) + \sum_{e\in G}\eta_e(u_{P^a})\right\}\right]^{\frac{1}{2}} \\
&\ge c_2\left[\left\{\sum_{\triangle\in F}\zeta_\triangle(f_{P^a}) + \sum_{e\in G}\eta_e(\bar{u}_{P^a})\right\}^{\frac{1}{2}} - C_3|u_{P^a} - \bar{u}_{P^a}|_1\right] \\
&\ge c_2[\theta\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) - C_3|u_{P^a} - \bar{u}_{P^a}|_1] \\
&\ge c_2[\theta\mathcal{E}(P^a, f_{P^a}, u_{P^a}) - 2C_3|u_{P^a} - \bar{u}_{P^a}|_1] \\
&\ge c_2\left[\frac{\theta}{C_1}|\hat{u} - u_{P^a}|_1 - 2C_3|u_{P^a} - \bar{u}_{P^a}|_1\right].
\end{aligned}$$

Since for any scalars a, b, $(a-b)^2 \ge \frac{1}{2}a^2 - b^2$, we infer that

$$|\hat{u}_{\tilde{P}} - u_{P^a}|_1^2 \ge \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2 |\hat{u} - u_{P^a}|_1^2 - 4c_2^2C_3^2|u_{P^a} - \bar{u}_{P^a}|_1^2.$$

Since $\hat{u}_{\tilde{P}} \in \mathcal{S}_{\tilde{P}}$ is the Galerkin approximation of $\hat{u}$ from $\mathcal{S}_{\tilde{P}}$ and $u_{P^a} - \hat{u}_{\tilde{P}} \in \mathcal{S}_{\tilde{P}}$, we have

$$\begin{aligned}
|\hat{u} - \hat{u}_{\tilde{P}}|_1^2 &= |\hat{u} - u_{P^a}|_1^2 - |u_{P^a} - \hat{u}_{\tilde{P}}|_1^2 \\
&\le \left[1 - \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2\right]|\hat{u} - u_{P^a}|_1^2 + 4c_2^2C_3^2|u_{P^a} - \bar{u}_{P^a}|_1^2 \\
&\le \left\{\left[1 - \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2\right]^{\frac{1}{2}}|\hat{u} - u_{P^a}|_1 + 2c_2C_3|u_{P^a} - \bar{u}_{P^a}|_1\right\}^2,
\end{aligned}$$

where we have used that $c_2 \le C_1$ and thus that $1 - \frac{1}{2}(\frac{c_2\theta}{C_1})^2 > 0$. The proof is completed by observing that $|u - \hat{u}|_1 = \|f - f_{P^a}\|_{-1}$ and $|u_{\tilde{P}} - \hat{u}_{\tilde{P}}|_1 \le \|f_{\tilde{P}} - f_{P^a}\|_{-1} \le \|f_{\tilde{P}} - f\|_{-1} + \|f - f_{P^a}\|_{-1}$. ∎

7. A first optimal adaptive finite element method. We start with a corollary that is an easy consequence of Theorem 6.7. It shows that the reduction of the error in the exact discrete solutions as a result of refinement extends to a similar reduction of the error in sufficiently accurate approximations of these discrete solutions.

COROLLARY 7.1. *For any* $\mu \in ([1-\frac{1}{2}(\frac{c_2\theta}{C_1})^2]^{\frac{1}{2}},1)$*, there exists a sufficiently small constant* $\delta>0$ *such that if for* $f\in H^{-1}(\Omega)$*, an admissible partition* P^a*,* $\bar{u}_{P^a}\in\mathcal{S}_{P^a}$*,* $f_{P^a}\in\mathcal{S}^0_{P^a}$*,* $\tilde{P}=\mathbf{REFINE}[P^a,f_{P^a},\bar{u}_{P^a}]$ *or a refinement of it,* $\bar{u}_{\tilde{P}}\in\mathcal{S}_{\tilde{P}}$*,* $f_{\tilde{P}}\in H^{-1}(\Omega)$ *and* $\varepsilon>0$*, with* $u=L^{-1}f$*,* $u_{P^a}=L^{-1}_{P^a}f_{P^a}$ *and* $u_{\tilde{P}}=L^{-1}_{\tilde{P}}f_{\tilde{P}}$*, we have that* $|u-\bar{u}_{P^a}|_1\le\varepsilon$ *and*

$$|u_{P^a}-\bar{u}_{P^a}|_1+\|f-f_{P^a}\|_{-1}+|u_{\tilde{P}}-\bar{u}_{\tilde{P}}|_1+\|f-f_{\tilde{P}}\|_{-1}\le 2(1+\mu)\delta\varepsilon$$

then $|u-\bar{u}_{\tilde{P}}|_1\le\mu\varepsilon$*.*

Proof. The proof is an easy consequence of Theorem 6.7, $|u-\bar{u}_{\tilde{P}}|_1\le|u-u_{\tilde{P}}|_1+|u_{\tilde{P}}-\bar{u}_{\tilde{P}}|_1$ and $|u-u_{P^a}|_1\le|u-\bar{u}_{P^a}|_1+|u_{P^a}-\bar{u}_{P^a}|_1$. ∎

We assume the availability of the following routine.

GALSOLVE$[P^a,f_{P^a},u^{(0)}_{P^a},\varepsilon]\to\bar{u}_{P^a}$

% P^a is an admissible partition, $f_{P^a}\in(\mathcal{S}_{P^a})'$, and $u^{(0)}_{P^a}\in\mathcal{S}_{P^a}$. With $u_{P^a}:=L^{-1}_{P^a}f_{P^a}$,
% the output $\bar{u}_{P^a}\in\mathcal{S}_{P^a}$ satisfies

$$|u_{P^a}-\bar{u}_{P^a}|_1\le\varepsilon.$$

% The call requires $\lesssim\max\{1,\log(\varepsilon^{-1}|u_{P^a}-u^{(0)}_{P^a}|_1|)\}\#P^a$ arithmetic operations.

Thus not only do we assume that we have an iterative solver at our disposal that converges with a rate independent of the problem size, but, in accordance with the idea of an adaptive solver, we additionally assume that we have an efficient and reliable control of the algebraic error. As a consequence the number of iterations to be performed does not depend on a possibly pessimistic a priori bound on the initial error. Two possible realizations of **GALSOLVE** are discussed in the next remark.

Remark 7.2. One can apply conjugate gradients, starting with $u^0_{P^a}$, to the representation of $L_{P^a}u_{P^a}=f_{P^a}$ with respect to $\{\bar{\psi}^v:v\in V_{P^a}\}$. In each iteration, that takes $\eqsim\#P^a$ operations, the $|\cdot|_1$-norm of the error is multiplied by a factor less than or equal to some constant $\tau<1$ only dependent on $\kappa_{\bar{\Psi}}$, meaning that after $\lceil\log_\tau(\varepsilon|u_{P^a}-u^{(0)}_{P^a}|_1^{-1})\rceil$ iterations the $|\cdot|_1$-norm of the error is $\le\varepsilon$. The $|\cdot|_1$-norm of the error in an approximation for u_{P^a} from $\mathcal{S}_{P^a}$ is less (respectively, greater) than or equal to $\lambda_{\bar{\Psi}}^{-\frac{1}{2}}$ (respectively, $\Lambda_{\bar{\Psi}}^{-\frac{1}{2}}$) times the Euclidean norm of the corresponding residual vector. So if one stops the iteration as soon as the latter norm is $\le\lambda_{\bar{\Psi}}^{\frac{1}{2}}\varepsilon$, then the $|\cdot|_1$-norm of the error is $\le\varepsilon$, whereas the number of iterations is bounded by

$$\lceil\log_\tau(\kappa_{\bar{\Psi}}^{-\frac{1}{2}}\varepsilon|u_{P^a}-u^{(0)}_{P^a}|_1^{-1})\rceil\lesssim\max\{1,\log(\varepsilon^{-1}|u_{P^a}-u^{(0)}_{P^a}|_1)\},$$

showing that this approach results in a valid routine **GALSOLVE**.

Alternatively, one may apply the conjugate gradient method to the representation of $L_{P^a}u_{P^a}=f_{P^a}$ with respect to the nodal basis $\{\phi^v_{P^a}:v\in V_{P^a}\}$ using a BPX preconditioner where, similarly as above, the Euclidean norm of the residual of the preconditioned system may serve to develop a stopping criterion. Indeed, when $P^a=P^a_n$, for $0\le i\le n$ one can select $\tilde{V}_{P^a_i}\subset V_{P^a_i}$ such that both $\operatorname{span}\{\bar{\psi}^v:v\in V_{P^a_i}\backslash V_{P^a_{i-1}}\}\subset\operatorname{span}\{\phi^v_{P^a_i}:v\in\tilde{V}_{P^a_i}\}$ and $\#\tilde{V}_{P^a_i}\lesssim\#(P^a_i\backslash P^a_{i-1})$. Using (4.6), it can then be proven that on $\mathcal{S}_{P^a}$, $\inf_{u=\sum_{i=0}^n\sum_{v\in\tilde{V}_{P^a_i}}c_i^v\phi^v_{P^a_i}}|c_i^v|^2|\phi^v_{P^a_i}|_1^2\eqsim|u|_1^2$,

showing that the resulting BPX preconditioner or, more precisely, in view of possible jumps of ρ the MDS preconditioner (cf. [16]) gives rise to uniformly well-conditioned systems, whereas it can be implemented in $\lesssim \#P^a$ operations.

Before continuing, let us first explain what we mean by an optimal method for solving the boundary value problem (2.1). Following [3], we say that a method is optimal if whenever the solution u is such that for some $s > 0$ the error of the best approximation from any $\mathcal{S}_P$ with $\#P \leq n$ is $\lesssim n^{-s}$, then for any $\varepsilon > 0$, the method yields a partition P and a $w_P \in \mathcal{S}_P$ with $|u - w_P|_1 \leq \varepsilon$ taking only $\lesssim \#P$ operations where $\#P \lesssim \varepsilon^{-1/s}$. Indeed, note that in view of the assumption on u, the smallest partition P for which there exists such a $w_P \in \mathcal{S}_P$ generally has cardinality $\eqsim \varepsilon^{-1/s}$. A definition of the class of functions $u \in H^1_0(\Omega)$ for which for some $s > 0$ the errors of the best approximations decay as indicated above is given by

$$\mathcal{A}^s = \left\{ u \in H^1_0(\Omega) : \sup_{n \geq 0} n^s \inf_{\#P \leq n} \inf_{u_P \in \mathcal{S}_P} |u - u_P|_1 < \infty \right\},$$

where P is any partition of the type we consider.

It is well known that for $s \leq \frac{1}{2}$, $H^1_0(\Omega) \cap H^{1+2s}(\Omega) \subset \mathcal{A}^s$. Indeed, for functions in $H^1_0(\Omega) \cap H^{1+2s}(\Omega)$, the sequence of errors of the best continuous piecewise linear approximations subordinate to the sequence of uniform refinements P_i^* of P_0 already exhibits a decay of $\lesssim (\#P_i^*)^{-s}$. Obviously, the class $\mathcal{A}^s$ contains many more functions than only those in $H^1_0(\Omega) \cap H^{1+2s}(\Omega)$, which is the reason to consider adaptive methods anyway. Although the class $\mathcal{A}^s$ is nontrivial for any $s > 0$, as it contains all $u \in \mathcal{S}_P$ for any partition P, since we are approximating with piecewise linears only for $s \leq \frac{1}{2}$ membership of $\mathcal{A}^s$ can be guaranteed by imposing suitable smoothness conditions. For partitions generated by the so-called newest vertex bisection, a characterization of $\mathcal{A}^s$ for $s \leq \frac{1}{2}$ in terms of Besov spaces can be found in [4]. We expect the same results to be valid for the type of partitions considered here. The characterization via Besov spaces, together with regularity results, as in [10], allows one to obtain a priori knowledge about the class $\mathcal{A}^s$ to which the solution u of the boundary value problem (2.1) belongs.

With the adaptive refinement strategy from Theorem 6.7 and Corollary 7.1, convergence can be guaranteed only when sufficiently accurate piecewise constant approximations to the right-hand side f are available. We assume the availability of the following routine **RHS** that, as the routine **REFINE**, may involve a refinement of the current partition.

RHS$[P, f, \varepsilon] \to [P^a, f_{P^a}]$
% P is a partition, $f \in H^{-1}(\Omega)$ and $\varepsilon > 0$. The output consists of an admissible
% refinement P^a of P, and an $f_{P^a} \in \mathcal{S}^0_{P^a}$ with $\|f - f_{P^a}\|_{-1} \leq \varepsilon$.

Assuming that the solution $u \in \mathcal{A}^s$ for some $s > 0$, the cost of approximating the right-hand side f using a routine **RHS** will generally not dominate the other costs of our adaptive method only if there is some constant c_f such that for any $\varepsilon > 0$ and any partition P, for $[P^a, f_{P^a}] := \mathbf{RHS}[P, f, \varepsilon]$ both $\#P^a$ and the number of arithmetic operations required by this call are $\lesssim \#P + c_f^{1/s} \varepsilon^{-1/s}$. We will call such a pair $(f, \mathbf{RHS})$ *s-optimal*. Obviously, given s, such a pair only exists when $f \in \bar{\mathcal{A}}^s$, defined by

$$\bar{\mathcal{A}}^s = \left\{ f \in H^{-1}(\Omega) : \sup_{n \geq 0} n^s \inf_{\#P \leq n} \inf_{f_P \in \mathcal{S}^0_P} \|f - f_P\|_{-1} < \infty \right\},$$

where P is any partition of the type we consider.

When $f \in L_2(\Omega)$ with $\|\rho^{-\frac{1}{2}} f\|_{L_2(\Omega)} \lesssim 1$, the routine **RHS** can be based on uniform refinements. Indeed, for some integer i to be determined below, let $\tilde{P}$ denote the smallest common refinement of the given P and P_i^*, let $\tilde{P}^a$ be its admissible refinement as a result of applying Algorithm 3.6, and with $Q^0_{\tilde{P}^a} : L_2(\Omega) \to \mathcal{S}^0_{\tilde{P}^a}$ denoting the $L_2(\Omega)$-orthogonal projector onto $\mathcal{S}^0_{\tilde{P}^a}$, let $f_{\tilde{P}^a} = Q^0_{\tilde{P}^a} f$. For any $w \in H^1_0(\Omega)$, we have

$$\left| \int_\Omega (f - f_{\tilde{P}^a}) w \right| = \left| \int_\Omega f(w - Q^0_{\tilde{P}^a} w) \right| \le C \sum_{\triangle \in \tilde{P}^a} \|f\|_{L_2(\triangle)} \mathrm{diam}(\triangle) \|\nabla w\|_{L_2(\triangle)}$$
$$\le C 2^{-i} \|\rho^{-\frac{1}{2}} f\|_{L_2(\Omega)} |w|_1,$$

where $C > 0$ is some absolute constant. By taking i to be the smallest integer such that $2^{-i} C \|\rho^{-\frac{1}{2}} f\|_{L_2(\Omega)} \le \varepsilon$, we have $\|f - f_{\tilde{P}^a}\|_{-1} \le \varepsilon$, and

$$\#\tilde{P}^a \lesssim \#P + \#P_i^* \lesssim \#P + (2^i)^2 \lesssim \#P + \varepsilon^{-2} \|\rho^{-\frac{1}{2}} f\|^2_{L_2(\Omega)}.$$

Thus, when for any $\triangle \in \cup_{j \ge 0} P_j^*$ the evaluation of $\int_\triangle f$ takes $\mathcal{O}(1)$ operations, we may conclude that for **RHS** based on this procedure $(f, \mathbf{RHS})$ is s-optimal with $s = \frac{1}{2}$, which, as we have seen, covers the range of main interest. Alternatively, instead of assuming the exact evaluation of $\int_\triangle f$, one easily infers that it also suffices to approximate the integral with an error $\lesssim \rho^{\frac{1}{2}} \mathrm{diam}(\triangle)$, which, in any case, is possible to accomplish in $\mathcal{O}(1)$ operations when $\rho^{-\frac{1}{2}} f$ has some piecewise smoothness with respect to P_0.

Obviously, the class $\bar{\mathcal{A}}^s$ is much larger than $L_2(\Omega)$. Yet, for $f \notin L_2(\Omega)$ the realization of a suitable routine **RHS** has to depend on the right-hand side at hand. We give one example.

Example 7.3. Let $\rho = 1$, and for a sufficiently smooth curve K in Ω, let $f \in H^{-1}(\Omega)$ be defined by $f(w) = \int_K w$. We define $\mathbf{RHS}[P, f, \varepsilon]$ by the following steps. Recursively refine all $\triangle \in P$ that have nonempty intersection with K, until all those $\triangle$ satisfy $\mathrm{diam}(\triangle) \le C\varepsilon^2$ for some constant $C > 0$. Let P^a be the admissible refinement of the obtained partition. Define $f_{P^a} \in \mathcal{S}^0_{P^a}$ by $f_{P^a}|_\triangle = \frac{\mathrm{length}(K \cap \triangle)}{\mathrm{vol}(\triangle)}$ $(\triangle \in P^a)$. Then one may verify that by choosing C suitably, we have that $\|f - f_{P^a}\|_{-1} \le \varepsilon$ and that both the number of arithmetic operations required by this call of **RHS** and $\#P^a$ are $\lesssim \#P + \varepsilon^{-2}$, showing that this $(f, \mathbf{RHS})$ pair is s-optimal with $s = \frac{1}{2}$. Note that although, depending on the curve, the exact evaluation of f applied to any $v_P \in \mathcal{S}_P$ might not pose any problems, nevertheless the piecewise constant approximations are required because of the evaluation of the a posteriori error estimator.

We are ready to give our first adaptive finite element method for solving (2.1). As expected, it is based on the repeated application of the triple **REFINE**, **RHS** and **GALSOLVE**, the latter two with suitable tolerances, which by Corollary 7.1 give rise to linearly convergent approximations. To obtain an optimal work-accuracy balance, **COARSE** is applied after every M iteration of the above triple, with M being some fixed constant.

SOLVE1$[f, \varepsilon, \bar{u}_{P_0}, \varepsilon_0] \to [P^a, \bar{u}_{P^a}]$:

The next theorem shows that **SOLVE1** is an optimal method whenever this is allowed by the $(f, \mathbf{RHS})$ pair.

THEOREM 7.4. *$[P^a, \bar{u}_{P^a}] := \mathbf{SOLVE1}[f, \varepsilon, \bar{u}_{P_0}, \varepsilon_0]$ satisfies $|u - \bar{u}_{P^a}|_1 \leq \varepsilon$. Assuming $\varepsilon_0 \lesssim |u|_1$, if for some $s > 0$, $u \in \mathcal{A}^s$ and $(f, \mathbf{RHS})$ is s-optimal, then both $\#P^a$ and the number of arithmetic operations required by this call are $\lesssim \max\{1, \varepsilon^{-1/s}(c_f^{1/s} + |u|_{\mathcal{A}^s}^{1/s})\}$.*

Proof. For $\varepsilon \geq \varepsilon_0$ there is nothing to prove, so let us assume that $\varepsilon < \varepsilon_0$. By induction on i we prove that at termination of the if-then-else-fi clause inside the loop over i,

$$|u - \bar{u}_{P^a}|_1 \leq (1 - 3\delta)\varepsilon_i. \tag{7.1}$$

For $i = 1$, this follows from the input condition on ε_0. Let us now assume (7.1) for some $i \geq 1$. Then, after the call $[P^a, f_{P^a}] := \mathbf{RHS}[P^a, f, \delta\varepsilon_i]$, by definition

$$\|f - f_{P^a}\|_{-1} \leq \delta\varepsilon_i. \tag{7.2}$$

So, for $u_{P^a} := L_{P^a}^{-1} f_{P^a}$ we have

$$\begin{aligned} |u - u_{P^a}|_1 &\leq |u - L^{-1}f_{P^a}|_1 + |L^{-1}f_{P^a} - u_{P^a}|_1 \leq |u - L^{-1}f_{P^a}|_1 + |L^{-1}f_{P^a} - \bar{u}_{P^a}|_1 \\ &\leq 2|u - L^{-1}f_{P^a}|_1 + |u - \bar{u}_{P^a}|_1 = 2\|f - f_{P^a}\|_{-1} + |u - \bar{u}_{P^a}|_1 \\ &\leq 2\delta\varepsilon_i + (1 - 3\delta)\varepsilon_i = (1 - \delta)\varepsilon_i, \end{aligned} \tag{7.3}$$

where for the second inequality we have used that $\bar{u}_{P^a} \in \mathcal{S}_{P^a}$ and that u_{P^a} is the best approximation with respect to $|\cdot|_1$ of $L^{-1}f_{P^a}$ from $\mathcal{S}_{P^a}$. We conclude that after the update of $\bar{u}_{P^a}$ by the call of **GALSOLVE**,

$$|u_{P^a} - \bar{u}_{P^a}|_1 \leq \delta\varepsilon_i \text{ and so } |u - \bar{u}_{P^a}|_1 \leq |u - u_{P^a}|_1 + |u_{P^a} - \bar{u}_{P^a}|_1 \leq \varepsilon_i. \tag{7.4}$$

After the first calls of **REFINE**, **RHS**, and **GALSOLVE** in the inner loop, i.e., when $j = 1$, for the new P^a, f_{P^a}, $\bar{u}_{P^a}$, $u_{P^a} := L_{P^a}^{-1}f_{P^a}$ we have $\|f - f_{P^a}\|_{-1} \leq \delta\mu\varepsilon_i$ and $|u_{P^a} - \bar{u}_{P^a}|_1 \leq \delta\mu\varepsilon_i$, and so by (7.2), (7.4), Corollary 7.1 shows that $|u - \bar{u}_{P^a}|_1 \leq \mu\varepsilon_i$. Repeating this argument for $j = 2, \ldots, M$ shows that at termination of the inner loop

over j, we have that $|u-\bar{u}_{P^a}|_1 \leq \mu^M \varepsilon_i$. In particular, when $i=N$, we have that $|u-\bar{u}_{P^a}|_1 \leq \mu^M \varepsilon_N = (\frac{\mu^M}{1-3\delta})^N((1+\gamma)\kappa_{\bar{\Psi}}^{\frac{1}{2}})^{N-1}\varepsilon_0 \leq \varepsilon$ by definition of N. Otherwise, if $i<N$, then in the next iteration, thus after increasing i by one, just before the call of **COARSE**, we have that $\|\!|u-\bar{u}_{P^a}|\!\|_1 \leq \lambda_{\bar{\Psi}}^{-\frac{1}{2}}|u-\bar{u}_{P^a}|_1 \leq \lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1}$. By Corollary 5.5, after this call we have

$$|u-\bar{u}_{P^a}|_1 \leq \Lambda_{\bar{\Psi}}^{\frac{1}{2}}\|\!|u-\bar{u}_{P^a}|\!\|_1 \leq \Lambda_{\bar{\Psi}}^{\frac{1}{2}}(1+\gamma)\lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1} = (1-3\delta)\varepsilon_i, \tag{7.5}$$

which completes the proof of (7.1), and thus that of $|u-\bar{u}_{P^a}|_1 \leq \varepsilon$ at termination of **SOLVE1**.

Now we will prove that for any $i=1,\ldots,N$, both $\#P^a$ at the end of the outer cycle for this i and the cost of this cycle excluding, for $i>1$, the cost of the **COARSE**, but including, for $i<N$, the cost of the **COARSE** in the next cycle, are $\lesssim \varepsilon_i^{-1/s}(c_f^{1/s}+|u|_{\mathcal{A}^s}^{1/s})$. Because of $\sum_{i=1}^N \varepsilon_i^{-1/s} \lesssim \varepsilon_N^{-1/s} \leq \varepsilon^{-1/s}$ this will prove the statement about the complexity.

At the start of the outer cycle for $i=1$, we have $\#P^a \lesssim \varepsilon_i^{-1/s}|u|_{\mathcal{A}^s}^{1/s}$, which follows from $\#P^a = \#P_0 \lesssim 1$ and the assumption that $\varepsilon_0 \lesssim |u|_1$. Since, as we have seen, for $i>1$ before the call of **COARSE**, we have that $\|\!|u-\bar{u}_{P^a}|\!\|_1 \leq \lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1}$, Corollary 5.5 shows that after this call, $\#P^a \leq D\#\hat{P}$ for any partition $\hat{P}$ with $\inf_{u_{\hat{P}}\in\mathcal{S}_{\hat{P}}}\|\!|u-u_{\hat{P}}|\!\|_1 \leq (t_1^{\frac{1}{2}}\gamma-1)\lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1}$. From $\|\!|\cdot|\!\|_1 \leq \lambda_{\bar{\Psi}}^{-\frac{1}{2}}|\cdot|_1$ and $u\in\mathcal{A}^s$, we find that

$$\#P^a \leq D(\#P_0 + [(t_1^{\frac{1}{2}}\gamma-1)\mu^M\varepsilon_{i-1}]^{-1/s}|u|_{\mathcal{A}^s}^{1/s}) \lesssim \varepsilon_i^{-1/s}|u|_{\mathcal{A}^s}^{1/s}.$$

Since $(f,\mathbf{RHS})$ is s-optimal and M is a fixed constant, from the properties of **RHS** and **REFINE** we conclude that for any i, at the end of the outer cycle

$$\#P^a \lesssim \varepsilon_i^{-1/s}(c_f^{1/s}+|u|_{\mathcal{A}^s}^{1/s}), \tag{7.6}$$

whereas the cost of all calls of **RHS** and **REFINE** inside this cycle are also $\lesssim \varepsilon_i^{-1/s}(c_f^{1/s}+|u|_{\mathcal{A}^s}^{1/s})$. Furthermore, for $i<N-1$, Theorem 5.4(b) shows that the cost of **COARSE** in the next iteration is $\lesssim \#P^a + \max\{0,\log(\varepsilon_i^{-1}\|\!|\bar{u}_{P^a}|\!\|_1)\}$. From $\log(\varepsilon_i^{-1}\|\!|\bar{u}_{P^a}|\!\|_1) \leq \varepsilon_i^{-1/s}\|\!|\bar{u}_{P^a}|\!\|_1^{1/s}$, $\|\!|\bar{u}_{P^a}|\!\|_1 \lesssim |\bar{u}_{P^a}|_1 \leq |u|_1+\varepsilon_0 \lesssim |u|_1 \leq |u|_{\mathcal{A}^s}$, and (7.6), we conclude also that these costs are $\lesssim \varepsilon_i^{-1/s}(c_f^{1/s}+|u|_{\mathcal{A}^s}^{1/s})$.

What is left is to bound the cost of the applications of **GALSOLVE**. As we have seen, just before the call **GALSOLVE**$[P^a, f_{P^a}, \bar{u}_{P^a}, \delta\varepsilon_i]$ outside the inner loop over j, we have that $|u-\bar{u}_{P^a}|_1 \leq (1-3\delta)\varepsilon_i$, and with $u_{P^a} := L_{P^a}^{-1}f_{P^a}$, $|u-u_{P^a}|_1 \leq (1-\delta)\varepsilon_i$, and so $|u_{P^a}-\bar{u}_{P^a}|_1 \leq 2(1-2\delta)\varepsilon_i$. Since $\frac{2(1-2\delta)\varepsilon_i}{\delta\varepsilon_i}$ is a constant, we conclude that the cost of this call is $\lesssim \#P^a$.

Let us now consider a call **GALSOLVE**$[P^a, f_{P^a}, \bar{u}_{P^a}, \delta\mu^j\varepsilon_i]$ inside the loop over j. Just before this call we have that $|u-\bar{u}_{P^a}|_1 \leq \mu^{j-1}\varepsilon_i$ and $\|f-f_{P^a}\|_{-1} \leq \delta\mu^j\varepsilon_i$. As in (7.3), for $u_{P^a} := L_{P^a}^{-1}f_{P^a}$ we have

$$|u-u_{P^a}|_1 \leq 2\|f-f_{P^a}\|_{-1} + |u-\bar{u}_{P^a}|_1 \leq (2\delta\mu^j+\mu^{j-1})\varepsilon_i,$$

and so $|u_{P^a}-\bar{u}_{P^a}|_1 \leq 2(\delta\mu^j+\mu^{j-1})\varepsilon_i$. Since $\frac{(2\delta\mu^j+\mu^{j-1})\varepsilon_i}{\delta\mu^j\varepsilon_i}$ is a constant, we conclude that the cost of this call is $\lesssim \#P^a$, which completes the proof. ∎

8. An optimal adaptive finite element method with a posteriori error control. It follows from the proof of Theorem 7.4 that the approximations $\bar{u}_{P^a}$ on the sequence of partitions produced by **SOLVE1** converge with an asymptotic rate $\leq (\frac{(1+\gamma)\kappa_{\bar{\Psi}}^{\frac{1}{2}}\mu^M}{1-3\delta})^{1/(M+1)}$, which is close to μ when M is not too small. Because of the application of a coarsening, the asymptotic rate is generally even equal to the above number. Indeed, after the evaluation of $[P^a, \bar{u}_{P^a}] := \mathbf{COARSE}[P^a, `\bar{u}_{P^a}^{old}', \gamma\lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1}]$, we have that

$$|u-\bar{u}_{P^a}|_1 \geq \lambda_{\bar{\Psi}}^{\frac{1}{2}}\|\!|u-\bar{u}_{P^a}|\!\|_1 \geq \lambda_{\bar{\Psi}}^{\frac{1}{2}}\left|\|\!|\bar{u}_{P^a}-\bar{u}_{P^a}^{old}|\!\|_1 - \|\!|u-\bar{u}_{P^a}^{old}|\!\|_1\right| \geq ((\gamma-\eta)-1)\mu^M\varepsilon_{i-1},$$

where η can be arbitrary small, so that this lower bound is only by a constant factor smaller than the upper bound for $|u-\bar{u}_{P^a}|_1$ from (7.5). The value μ has to be supplied by the user. It should be large enough to ensure that indeed $\lambda_{\bar{\Psi}}^{-\frac{1}{2}}\mu^M\varepsilon_{i-1}$ is an upper bound for $\|\!|u-\bar{u}_{P^a}^{old}|\!\|_1$, so that the quasi-optimality of the partition after **COARSE** is guaranteed by Corollary 5.5. A safe choice of μ will be the result of a worst-case analysis, and so likely it will be unnecessarily close to 1, resulting in a quantitatively less attractive algorithm. All adaptive finite element or wavelet methods based on coarsening introduced so far share this drawback that a judicious choice of such a parameter μ has to be made.

In this final subsection, we develop a modified routine **SOLVE2** in which the tolerances used in the routines **COARSE**, **RHS**, and **GALSOLVE** will depend on an a posteriori estimate of the error, instead of an a priori one. Moreover, as is also suggested in [7], instead of performing a fixed number of iterations of the **REFINE**, **RHS**, **GALSOLVE** triple between two applications of **COARSE**, in **SOLVE2** the iteration is stopped as soon as sufficient reduction of the error has taken place as indicated by the a posteriori error estimator. We will use our estimator $\mathcal{E}$, extended with some terms to incorporate the error in the right-hand side and that as a consequence of the inexact solution of the discrete system; cf. (8.1). One problem is that a monotone decrease of the a posteriori error estimates cannot be guaranteed. In Proposition 8.1, however, we show that the error estimates are equivalent to quantities that do decrease linearly; cf. (8.2) and (8.4).

PROPOSITION 8.1. *Let $C_4 := 1 + C_1C_3$, where $C_1, C_3 > 0$ are the constants from Theorem* 6.1 *and Lemma* 6.5. *For $f \in H^{-1}(\Omega)$, any admissible partition P^a, $\bar{u}_{P^a} \in \mathcal{S}_{P^a}$, and $f_{P^a} \in L_2(\Omega)$, with $u = L^{-1}f$, $u_{P^a} = L_{P^a}^{-1}f_{P^a}$ we have*

$$|u-\bar{u}_{P^a}|_1 \leq C_1\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \|f-f_{P^a}\|_{-1} + C_4|u_{P^a}-\bar{u}_{P^a}|_1. \tag{8.1}$$

With $f_{P^a} \in \mathcal{S}_{P^a}^0$, and ζ_{P^a} being an upper bound for $\|f-f_{P^a}\|_{-1}+C_4|u_{P^a}-\bar{u}_{P^a}|_1$, we have that

$$C_1\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \zeta_{P^a} \eqsim |u-\bar{u}_{P^a}|_1 + \zeta_{P^a}. \tag{8.2}$$

Finally, for any $\mu \in ([1-\frac{1}{2}(\frac{c_2\theta}{C_1})^2]^{\frac{1}{2}}, 1)$, there exists $\bar{\delta} > 0$ small enough and $C_5 > 0$ large enough, such that if $\tilde{P} = \mathbf{REFINE}[P^a, f_{P^a}, \bar{u}_{P^a}]$ or a refinement of it, $\bar{u}_{\tilde{P}} \in \mathcal{S}_{\tilde{P}}$, $f_{\tilde{P}} \in H^{-1}(\Omega)$, $u_{\tilde{P}} := L_{\tilde{P}}^{-1}f_{\tilde{P}}$, and

$$\zeta_{\tilde{P}} \leq \bar{\delta}(1+C_4)[C_1\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \zeta_{P^a}], \tag{8.3}$$

where thus $\zeta_{\tilde{P}}$ denotes an upper bound on $\|f-f_{\tilde{P}}\|_{-1} + C_4|u_{\tilde{P}}-\bar{u}_{\tilde{P}}|_1$; then

$$|u-\bar{u}_{\tilde{P}}|_1 + C_5\zeta_{\tilde{P}} \leq \mu[|u-\bar{u}_{P^a}|_1 + C_5\zeta_{P^a}]. \tag{8.4}$$

Proof. With $\hat{u} := L^{-1} f_{P^a}$, (8.1) follows from Theorem 6.1 and Lemma 6.5 by

$$\begin{aligned}|u - \bar{u}_{P^a}|_1 &\le |u - \hat{u}|_1 + |\hat{u} - u_{P^a}|_1 + |u_{P^a} - \bar{u}_{P^a}|_1 \\ &\le \|f - f_{P^a}\|_{-1} + C_1 \mathcal{E}(P^a, f_{P^a}, u_{P^a}) + |u_{P^a} - \bar{u}_{P^a}|_1 \\ &\le \|f - f_{P^a}\|_{-1} + C_1 \mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + (1 + C_1 C_3)|u_{P^a} - \bar{u}_{P^a}|_1.\end{aligned}$$

In one direction, (8.2) follows immediately from (8.1), whereas in the other direction it is a consequence of Corollary 6.4 in combination with Lemma 6.5.

Theorem 6.7 shows that with $C_6 := \max\{\frac{1+2c_2C_3}{C_4}, 3\}$,

$$|u - \bar{u}_{\tilde{P}}|_1 + C_5 \zeta_{\tilde{P}} \le \left[1 - \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2\right]^{\frac{1}{2}} |u - \bar{u}_{P^a}|_1 + C_6(\zeta_{P^a} + \zeta_{\tilde{P}}) + C_5 \zeta_{\tilde{P}},$$

which, given a $\mu \in ([1 - \frac{1}{2}(\frac{c_2\theta}{C_1})^2]^{\frac{1}{2}}, 1)$, is less than or equal to $\mu[|u - \bar{u}_{P^a}|_1 + C_5 \zeta_{P^a}]$ if and only if

$$(C_6 + C_5)\zeta_{\tilde{P}} \le \left(\mu - \left[1 - \frac{1}{2}\left(\frac{c_2\theta}{C_1}\right)^2\right]^{\frac{1}{2}}\right)|u - \bar{u}_{P^a}|_1 + (\mu C_5 - C_6)\zeta_{P^a}.$$

Hence, by selecting the constant $C_5 > \frac{C_6}{\mu}$, the proof of (8.4) is completed by observing that for $\bar{\delta}$ small enough,

$$\bar{\delta}(1+C_4)[C_1 \mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \zeta_{P^a}] \le \frac{(\mu - [1 - \frac{1}{2}(\frac{c_2\theta}{C_1})^2]^{\frac{1}{2}})|u - \bar{u}_{P^a}|_1 + (\mu C_5 - C_6)\zeta_{P^a}}{C_6 + C_5},$$

which is a consequence of (8.2). □

We are ready to formulate the adaptive finite element method **SOLVE2** in which the tolerances are controlled by the a posteriori error estimator. Any faster convergence of the approximations produced by the **REFINE**, **RHS**, **GALSOLVE** triple than appears from a priori estimates can be expected to lead to better quantitative properties for **SOLVE2** than for **SOLVE1**.

SOLVE2$[f, \varepsilon, \bar{u}_{P_0}, \varepsilon_0] \to [P^a, \bar{u}_{P^a}]$:
% The following constants are fixed: $\bar{\delta}$ is small enough so that it corresponds to a
% $\mu < 1$ as in Proposition 8.1; $\gamma > t_1^{-\frac{1}{2}}$ with t_1 as in Proposition 5.3; and $\sigma \in (0,1)$.
% The input must satisfy $f \in H^{-1}(\Omega)$ such that a valid routine **RHS** *is available,*
% $\varepsilon > 0$, $\bar{u}_{P_0} \in \mathcal{S}_{P_0}$ and $\varepsilon_0 \ge |u - \bar{u}_{P_0}|_1$.
$P^a := P_0$, $f_{P^a} := f_{P_0}$, $\bar{u}_{P^a} := \bar{u}_{P_0}$, $\bar{e} := \tilde{e} := \varepsilon_0$
`while` $\bar{e} > \varepsilon$ `do`
  `if` *not first iteration* `then`
    $[P^a, \bar{u}_{P^a}] := \mathbf{COARSE}[P^a, \bar{u}_{P^a}, \gamma \lambda_{\bar{\Psi}}^{-\frac{1}{2}} \bar{e}]$, $\tilde{e} := (1+\gamma)\kappa_{\bar{\Psi}}^{\frac{1}{2}} \bar{e}$
  `fi`
  $[P^a, f_{P^a}] := \mathbf{RHS}[P^a, f, \bar{\delta}\tilde{e}]$
  $\bar{u}_{P^a} := \mathbf{GALSOLVE}[P^a, f_{P^a}, \bar{u}_{P^a}, \bar{\delta}\tilde{e}]$
  $\tilde{e} := C_1 \mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + (1 + C_4)\bar{\delta}\tilde{e}$
  `while` $\tilde{e} > \sigma \bar{e}$ `do`
    $P := \mathbf{REFINE}[P^a, f_{P^a}, \bar{u}_{P^a}]$
    $[P^a, f_{P^a}] := \mathbf{RHS}[P, f, \bar{\delta}\tilde{e}]$
    $\bar{u}_{P^a} := \mathbf{GALSOLVE}[P^a, f_{P^a}, \bar{u}_{P^a}, \bar{\delta}\tilde{e}]$
    $\tilde{e} := C_1 \mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + (1 + C_4)\bar{\delta}\tilde{e}$
  `od`
  $\bar{e} := \tilde{e}$
`od`

The next theorem shows that **SOLVE2** is an optimal method whenever this is allowed by the $(f, \mathbf{RHS})$ pair.

THEOREM 8.2. *$[P^a, \bar{u}_{P^a}] := \mathbf{SOLVE1}[f, \varepsilon, \bar{u}_{P_0}, \varepsilon_0]$ satisfies $|u - \bar{u}_{P^a}|_1 \leq \varepsilon$. Assuming $\varepsilon_0 \lesssim |u|_1$, if for some $s > 0$, $u \in \mathcal{A}^s$ and $(f, \mathbf{RHS})$ is s-optimal, then both $\#P^a$ and the number of arithmetic operations required by this call are $\lesssim \max\{1, \varepsilon^{-1/s}(c_f^{1/s} + |u|_{\mathcal{A}^s}^{1/s})\}$.*

Proof. At the beginning of a cycle of the outer while-loop, we have that $|u - \bar{u}_{P^a}|_1 \leq \bar{e}$, which for a cycle other than the first one is a consequence of Proposition 8.1. In particular, when the outer loop terminates, we have $|u - \bar{u}_{P^a}|_1 \leq \varepsilon$.

After the if-then-fi clause, we have that $|u - \bar{u}_{P^a}|_1 \leq \tilde{e}$, where $\tilde{e} = \bar{e}$ for the first iteration, and $\tilde{e} = (1+\gamma)\kappa_{\Psi}^{\frac{1}{2}}\bar{e}$ otherwise (apply Corollary 5.5 and (4.6)). After the call of **RHS**, by definition we have $\|f - f_{P^a}\|_{-1} \leq \bar{\delta}\tilde{e}$, and so as in (7.3), for $u_{P^a} := L_{P^a}^{-1} f_{P^a}$ we have $|u - u_{P^a}|_1 \leq 2\|f - f_{P^a}\|_{-1} + |u - \bar{u}_{P^a}|_1 \leq (2\bar{\delta} + 1)\tilde{e}$. After the call of **GALSOLVE**, by definition we have $|u_{P^a} - \bar{u}_{P^a}|_1 \leq \bar{\delta}\tilde{e}$, and so $|u - \bar{u}_{P^a}|_1 \leq (3\bar{\delta} + 1)\tilde{e}$. By applying (8.2), these estimates show that just before starting the inner while-loop, the new $\tilde{e}$ satisfies

$$\tilde{e} \leq C\bar{e} \tag{8.5}$$

for some absolute constant $C > 0$.

Let us now consider any newly computed $\bar{u}_{P^a}$ in the inner while-loop, and let us denote by τ_1, τ_2 the tolerances that were used in the corresponding calls of **RHS** and **GALSOLVE** and let $\zeta_{P^a} = \tau_1 + C_4\tau_2$. We have that ζ_{P^a} is equal to $(1 + C_4)\bar{\delta}[C_1\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \zeta_{P^a}]$, where in the latter expression P^a, f_{P^a}, $\bar{u}_{P^a}$, and ζ_{P^a} refer to the previous partition, right-hand side, approximate solution, and ζ_{P^a}, respectively. Since by assumption $\bar{\delta}$ corresponds to a $\mu < 1$ as in Proposition 8.1, formula (8.4) shows that in each iteration of the inner loop $|u - \bar{u}_{P^a}|_1 + C_5\zeta_{P^a}$ is multiplied by a factor $\leq \mu$. Since by (8.2), $C_1\mathcal{E}(P^a, f_{P^a}, \bar{u}_{P^a}) + \zeta_{P^a} \eqsim |u - \bar{u}_{P^a}|_1 + C_5\zeta_{P^a}$, the geometric decrease of $|u - \bar{u}_{P^a}|_1 + C_5\zeta_{P^a}$ together with (8.5) shows that the inner while-loop terminates within an (absolute) constant number of iterations. After termination of the inner while-loop, the new $\bar{e}$ will be less than or equal to $\sigma < 1$ times the previous $\bar{e}$, showing that **SOLVE2** terminates, with, as we have seen, $|u - \bar{u}_{P^a}|_1 \leq \varepsilon$.

Let us consider any cycle of the outer loop with $\bar{e} > \varepsilon$ being the value at the beginning of this cycle. After the if-then-fi clause, we have that $\#P^a \lesssim \bar{e}^{-1/s}|u|_{\mathcal{A}^s}^{1/s}$, which for the first iteration follows from $\#P_0 \lesssim 1$ and $\varepsilon_0 \lesssim |u|_1$ by assumption, and which for any other cycle follows from Corollary 5.5 analogously as in the proof of Theorem 7.4. The properties of **RHS** and **REFINE** and the fact that the inner while-loop terminates within a fixed number of iterations show that at termination of this outer cycle, $\#P^a \lesssim \bar{e}^{-1/s}(c_f^{1/s} + |u|_{\mathcal{A}^s}^{1/s})$, which, in particular, proves the statement about $\#P^a$ at termination of **SOLVE2**. Furthermore, the cost of all calls of **RHS** and **REFINE**, as well as the cost of **COARSE**, in the possibly next cycle are $\lesssim \bar{e}^{-1/s}(c_f^{1/s} + |u|_{\mathcal{A}^s}^{1/s})$. Assuming, for the moment, that the cost of any application of **GALSOLVE** in **SOLVE2** on a partition P^a is $\lesssim \#P^a$, by the geometric decrease of the values of $\bar{e}$ at the beginning of the outer while-loop we conclude that the total cost of **SOLVE2** is $\lesssim \varepsilon^{-1/s}(c_f^{1/s} + |u|_{\mathcal{A}^s}^{1/s})$.

As we have seen, just before the evaluation of $\mathbf{GALSOLVE}[P^a, f_{P^a}, \bar{u}_{P^a}, \bar{\delta}\tilde{e}]$ outside the inner while-loop, we have $|u - \bar{u}_{P^a}|_1 \leq \tilde{e}$, and with $u_{P^a} := L_{P^a}^{-1} f_{P^a}$, $|u - u_{P^a}|_1 \leq (2\bar{\delta} + 1)\tilde{e}$ and so $|u_{P^a} - \bar{u}_{P^a}|_1 \leq 2(\bar{\delta} + 1)\tilde{e}$. We conclude that the cost of this call is $\lesssim \#P^a$.

Analogously, just before an evaluation of **GALSOLVE**$[P^a, f_{P^a}, \bar{u}_{P^a}, \bar{\delta}\tilde{e}]$ inside the inner while-loop, we have $|u - \bar{u}_{P^a}|_1 \leq \tilde{e}$, $\|f - f_{P^a}\|_{-1} \leq \bar{\delta}\tilde{e}$, and so, as in (7.3), with $u_{P^a} := L_{P^a}^{-1} f_{P^a}$, $|u - u_{P^a}|_1 \leq 2\bar{\delta}\tilde{e} + \tilde{e}$ and so $|u_{P^a} - \bar{u}_{P^a}|_1 \leq 2(\bar{\delta}\tilde{e} + \tilde{e})$. We conclude that the cost of such a call is also $\lesssim \#P^a$. □

Acknowledgments. The author would like to thank Peter Binev (University of South Carolina) for his explanations concerning adaptive tree approximations and both referees for numerous valuable comments.

EFFICIENT COMPUTATION OF THE MATRIX EXPONENTIAL BY GENERALIZED POLAR DECOMPOSITIONS*

ARIEH ISERLES† AND ANTONELLA ZANNA‡

Abstract. In this paper we explore the computation of the matrix exponential in a manner that is consistent with Lie-group structure. Our point of departure is the method of generalized polar decompositions, which we modify and combine with similarity transformations that bring the underlying matrix to a form more amenable to efficient computation. We develop techniques valid for a range of Lie groups: the orthogonal group, the symplectic group, Lorentz, isotropy, and scaling groups. However, the GPD approach is equally promising in a more general context. Even when Lie-group structure is not at issue, our algorithm is more efficient in many settings than classical methods for the computation of the matrix exponential.

Key words. matrix exponential, Lie group, Lie algebra, generalized polar decomposition

1. Introduction.

The approximation of the matrix exponential is among the oldest and most extensively researched problems in numerical mathematics. Yet, nineteen dubious ways [15] and many efficient algorithms (cf., for example, [8]) later, the problem is far from being satisfactorily solved and many challenges remain. This is true in particular when we wish to approximate an exponential of a matrix Z, say, which resides in a *Lie algebra.* This is a central problem in *geometric integration,* which arises once we wish to discretize systems of differential equations evolving in *Lie groups* (smooth manifolds with group structure) and in *homogeneous manifolds* (smooth manifolds which are subjected to transitive group action).

While referring the reader to [10] for a substantive survey of Lie-group methods and their applications, and to section 2 for formal definitions, it is important to mention informally a number of salient features of such methods, since they motivate much of the work of the present paper.

- The tangent space $\mathrm{T}_x G$, where G is a Lie group and $x \in G$, is $\{Zx : Z \in \mathfrak{g}\}$, where $\mathfrak{g} = \mathrm{T}_I G$ and I is the identity of G. Therefore, once we know $\mathfrak{g}$, we can describe all vector fields (hence all differential equations) on G.
- The linear space $\mathfrak{g}$ is a Lie algebra: it is closed under an antisymmetric binary operation of *commutation.*
- The *exponential map* takes the Lie algebra to "its" Lie group, $\exp \mathfrak{g} \subseteq G$.
- Most finite-dimensional Lie groups in practical applications are comprised of matrices. Familiar examples are the general linear group $\mathrm{GL}(\mathbb{R}, n)$ ($n \times n$ nonsingular real matrices), the special linear group $\mathrm{SL}(\mathbb{R}, n)$ ($n \times n$ real matrices with unit determinant), and the orthogonal group $\mathrm{O}(\mathbb{R}, n)$ ($n \times n$ real orthogonal matrices).

• All finite-dimensional Lie algebras are isomorphic to Lie algebras of matrices. In particular, the Lie algebras corresponding to the three Lie groups above are $\mathfrak{gl}(\mathbb{R}, n)$ (the $n \times n$ real matrices), $\mathfrak{sl}(\mathbb{R}, n)$ ($n \times n$ real matrices with zero trace), and $\mathfrak{so}(\mathbb{R}, n)$ ($n \times n$ real skew-symmetric matrices), respectively.

• If G is a matrix group (hence $\mathfrak{g}$ is a matrix algebra) the operations of commutation and exponentiation are the familiar matricial commutator and exponent, respectively.

Therefore, once a differential equation evolves in a matrix Lie group, it can be always written in the form

$$y' = F(t, y)y, \quad t \geq 0, \qquad y(0) \in G, \tag{1.1}$$

where $F : \mathbb{R}_+ \times G \to \mathfrak{g}$. Moreover, its solution can be represented (subject to the usual caveats of convergence) in the form $y(t) = \exp(\Omega(t))y(0)$, where Ω evolves in the Lie algebra $\mathfrak{g}$. It is possible to replace (1.1) by an equation for Ω, which evolves in $\mathfrak{g}$ [10], and there are important benefits in solving the latter, returning to the Lie group in every time step by means of the exponential map. The main advantage is that $\mathfrak{g}$ is a linear space and, as long as we discretize equations therein employing exclusively linear-space operations and commutators, we can be assured that the numerical solution stays in $\mathfrak{g}$. Thus, once exponentiated, we obtain a numerical solution that evolves in the Lie group; this is important in the many instances when the preservation of Lie-group structure is important and in variance with most numerical methods applied directly in G [10].

The above argument is at the heart of many Lie-group methods (Runge–Kutta–Munthe-Kaas schemes, Magnus expansions). Other methods, based on different premises (e.g., Crouch–Grossman methods, Fer expansions and methods based upon canonical coordinates of the second kind) also require the computation (or approximation) of the matrix exponential. However, standard methods for the approximation of the matrix exponential, e.g., Padé approximations and Krylov subspace techniques, are not guaranteed to map elements from $\mathfrak{g}$ to G. Thus, having gone to a great length to respect Lie-algebraic structure, we might well loose the fruits of this endeavor while computing the exponential! On the positive side, diagonal Padé approximations map some Lie algebras ("quadratic" algebras: $\mathfrak{so}(\mathbb{R}, n)$, the symplectic algebra, the Lorentz algebra) to the underlying group. However, it is possible to show that the only analytic function f, that maps $\mathfrak{sl}(\mathbb{R}, n)$ into $\mathrm{SL}(\mathbb{R}, n)$ consistently with the exponential function (i.e., $f(z) = 1 + z + \mathcal{O}(z^2)$) is the exponential itself [11]. Also other classical methods for the approximation of the exponential fail in that case, and this motivates the development of new breeds of approximation algorithms.

Early inroads into the approximation of the exponential in a Lie-algebraic setting have been made in [2], using the splitting approach,

$$\mathrm{e}^{tZ} \approx \mathrm{e}^{tV_1}\mathrm{e}^{tV_2} \cdots \mathrm{e}^{tV_m},$$

where each V_k resides in $\mathfrak{g}$ and the computation of its exponential is easy. The latter is true when the V_ks are of low rank and this, indeed, was the approach introduced in [2].

Suppose that $\dim \mathfrak{g} = s$ and let $\boldsymbol{X} = \{X_1, X_2, \ldots, X_s\}$ be a basis of $\mathfrak{g}$. In that case it is possible to represent $\exp(tZ)$ for $Z \in \mathfrak{g}$ and sufficiently small $|t|$ in *canonical coordinates of the second kind,*

$$\mathrm{e}^{tZ} = \mathrm{e}^{g_1(t)X_1}\mathrm{e}^{g_2(t)X_2} \cdots \mathrm{e}^{g_s(t)X_s},$$

where the scalar functions g_k are analytic at the origin. Although the g_ks are implicitly defined, it is possible to approximate their truncated Taylor expansion, an approach adopted in [3]. A naive procedure of this kind might be excessively expensive, but the cost can be reduced by several orders of magnitude by a clever choice of the basis $\boldsymbol{X}$, exploiting the Lie-algebraic structure.

The work underlying the approach of the present paper, *generalized polar decompositions (GPD),* has been introduced in [16] and further elaborated on in [20, 21]. In section 2 we present a brief review of such methods. It suffices to state here that, while building upon former work in this area, they establish a general framework which leads to robust and affordable algorithms. Having said this, such algorithms can be fairly expensive when the required order is high, in particular when they need to be computed, perhaps repeatedly, in each time step. The purpose of this paper is to bring together generalized polar decompositions with techniques from numerical linear algebra, thereby leading to more efficient and cheaper algorithms.

At a conceptual level, we are attempting to marry two types of structures, which are often incompatible. For example, a viable approach to compute $\exp tZ$ for $Z \in \mathfrak{gl}(\mathbb{R}, n)$ is to represent $Z = VHV^*$, where V is a product of Householder reflections and H is upper Hessenberg. Since this is a similarity transformation, it is true that $\mathrm{e}^{tZ} = V\mathrm{e}^{tH}V^*$ and we need to compute an exponential of an upper-Hessenberg matrix. As we show in what follows, this can be done very efficiently indeed by a modification of the GPD technique. Unfortunately, this approach cannot be extended to other Lie algebras. Thus, suppose that Z resides in the *symplectic algebra*

$$\mathfrak{sp}(n) = \{Y \in \mathfrak{gl}(\mathbb{R}, 2n) : YJ + JY^\top = O\}, \quad \text{where } J = \begin{bmatrix} O & I \\ -I & O \end{bmatrix}.$$

In that case, in general, $H \notin \mathfrak{sp}(n)$: a Hessenberg form and symplecticity are incompatible! This is an illustration of a more general state of affairs, when numerical-algebraic and Lie-algebraic structures clash. In this paper we present numerical-algebraic structures which are compatible with a long list of matrix Lie algebras that occur in applications. Moreover, in each case we need to modify and fine tune the GPD algorithm to reduce its cost and improve its efficiency.

This is the time to mention that the GPD approach, combined with an upper-Hessenberg form and the "peel-up" technique, result in an algorithm that compares favorably, in terms of both cost and accuracy, with classical methods to compute the exponential of a matrix. Thus, a procedure motivated by retention of specialized differential-geometric structure, and based on mathematics which might be unfamiliar to many numerical analysts, is very valuable also in a general context, where Lie-group structure is not at issue.

The plan of this paper is as follows. In section 2 we consider in greater detail Lie groups and Lie algebras, introducing requisite theory and notation. This is followed by a brief review of generalized polar decompositions by means of involutory automorphisms. In section 3 we debate the computation, using GPD, of exponentials of tridiagonal matrices. We introduce a new approach (the "peel-up" algorithm) which renders the GPD method substantially more efficient in this setting. The theme of section 4 is how to bring matrices to an upper-Hessenberg form, or alternative forms that lend themselves to our approach, by means of similarity transformations. Thus, for example, symplectic matrices are converted into a so-called butterfly form. We

discuss the implementation and cost of the "peel-up" technique in all these settings. Section 5 is devoted to a divide-and-conquer strategy, which, approximating the exponential of a matrix by computations in lower-dimensional spaces, which can be performed in unison, lends itself to implementation in parallel architectures. This strategy is fully compatible with GPD and the retention of Lie-group structure and it again displays the merits of the "peel-up" approach. Finally, in section 6 we discuss the calculation of the exponential by GPD and the "peel-up" technique for a range of more "exotic" Lie groups: the Lorentz group, the isotropy group and the scaling group. The paper concludes with an appendix, to which we have relegated some of the more technical calculations.

The issue of stability and conditioning is outside the scope of this paper. Although much of the underlying framework, based upon similarity transformations by orthogonal matrices, is consistent with good conditioning, stability might become an issue. We plan to return to this subject area in a subsequent paper, where we will explore in detail the stability of the GPD technique.

Let us conclude this section anticipating that the proposed method has a complexity of $\mathcal{O}(n^3)$, both when the exponential is applied to a vector and a matrix. This might seem quite expensive especially in the case when one needs to compute $\exp(A)\mathbf{v}$ if compared to other techniques like Krylov subspace methods, which require generally $\mathcal{O}(n^2)$ operations instead [5, 8]. However, let us remind the reader that Krylov subspace methods also require about $18n^3$ operations when the exponential is applied to a matrix. In this case, our methods achieve at least a 50% improvement on the execution time, depending on the algebra under consideration.

Another important difference with Krylov methods is that while Krylov methods approximate the exponential to machine precision, the proposed method approximates the exponential to a given *order* of accuracy. This makes them particularly suited to exponential approximations within numerical integrators for ODEs, since the error is subsumed in that of the integration method and can be controlled by standard error control techniques for ODEs. For other applications, there exist global error bounds that depend on the scaling of the matrix [19]. We speculate that these bounds can be used efficiently in tandem with scaling and squaring to achieve a given accuracy and we plan to further explore this approach in the next future.

2. Background theory. The natural setting of GPD is Lie-group and Lie-algebra theory; therefore it is convenient to present the background theory in the language of differential geometry. To distinguish between group and algebra elements, it is usual in differential geometry to denote Lie-group elements with lower-case letters and Lie-algebra elements with upper-case letters, whether they represent matrices, vectors or scalars [7]. An arbitrary Lie group will be denoted by G and the corresponding Lie algebra by $\mathfrak{g}$. Subspaces of $\mathfrak{g}$ are also usually denoted by Gothic letters. We adopt this convention throughout this subsection. Later on, when most of the computations take place at the algebra level, we will revert to a language that is more familiar to the numerical analysis community and matrices (except when we want to emphasize the Lie-group context) will be denoted as usual with capital letters.

Let $G \subseteq \mathrm{GL}(\mathbb{R}, n)$ be a matrix Lie group with Lie algebra $\mathfrak{g}$. Given an involutive automorphism σ of G, i.e., a one-to-one map $G \to G$ such that

$$\sigma(x \cdot y) = \sigma(x) \cdot \sigma(y) \quad \forall x, y \in G,$$
$$\sigma(\sigma(x)) = x \quad \forall x \in G,\ \sigma \neq \mathrm{id},$$

it is possible to show that, for t sufficiently small, every element $z = \exp(tZ) \in G$,

$Z \in \mathfrak{g}$, can be factorized in the form

$$z = xy, \tag{2.1}$$

where $\sigma(y) = y$ and $\sigma(x) = x^{-1}$ [12, 16]. The decomposition (2.1) is called the GPD of z, in analogy with the case of real matrices with the special choice $\sigma(z) = z^{-\top}$, when it reduces to the familiar polar decomposition.

The automorphism σ induces in a natural manner an involutive automorphism $\mathrm{d}\sigma$ on the Lie algebra $\mathfrak{g}$,

$$\mathrm{d}\sigma(Z) = \frac{\mathrm{d}}{\mathrm{d}t}\Big|_{t=0} \sigma(\exp(tZ)), \tag{2.2}$$

which defines a splitting of $\mathfrak{g}$ into the direct sum of two linear spaces,

$$\mathfrak{g} = \mathfrak{p} \oplus \mathfrak{k}, \tag{2.3}$$

where $\mathfrak{k} = \{Z \in \mathfrak{g} : \mathrm{d}\sigma(Z) = Z\}$ is a subalgebra of $\mathfrak{g}$, while the set $\mathfrak{p} = \{Z \in \mathfrak{g} : \mathrm{d}\sigma(Z) = -Z\}$ has the structure of a Lie triple system, a linear space closed under the double commutator,

$$A, B, C \in \mathfrak{p} \qquad \Longrightarrow \qquad [A, [B, C]] \in \mathfrak{p},$$

where the bracket $[A, B] = AB - BA$ is the standard matrix commutator.

To show that (2.3) is true, denote by $\Pi_{\mathfrak{p}} : \mathfrak{g} \to \mathfrak{p}$ the canonical projection of $\mathfrak{g}$ onto the subspace $\mathfrak{p}$ and by $\Pi_{\mathfrak{k}} : \mathfrak{g} \to \mathfrak{k}$ its projection onto $\mathfrak{k}$. Set

$$P = \Pi_{\mathfrak{p}}(Z), \qquad K = \Pi_{\mathfrak{k}}(Z).$$

It is easily verified by direct computation that every element Z can be written in a unique manner as $Z = P + K$, where

$$P = \Pi_{\mathfrak{p}}(Z) = \frac{1}{2}(Z - \mathrm{d}\sigma(Z)), \qquad K = \Pi_{\mathfrak{k}}(Z) = \frac{1}{2}(Z + \mathrm{d}\sigma(Z)).$$

To keep our presentation relevant to the subject matter of this paper, we refer the reader to [16, 20] and references therein for a more extensive treatment of such decompositions. However, it is of fundamental importance to note that the sets $\mathfrak{k}$ and $\mathfrak{p}$ possess the following properties:

$$[\mathfrak{k}, \mathfrak{k}] \subseteq \mathfrak{k}, \qquad [\mathfrak{k}, \mathfrak{p}], [\mathfrak{p}, \mathfrak{k}] \subseteq \mathfrak{p}, \qquad [\mathfrak{p}, \mathfrak{p}] \subseteq \mathfrak{k}, \tag{2.4}$$

meaning that for all $K_1, K_2 \in \mathfrak{k}$ and $P_1, P_2 \in \mathfrak{p}$, it is true that $[K_1, K_2] \in \mathfrak{k}$, $[K_1, P_1], [P_2, K_2] \in \mathfrak{p}$, and $[P_1, P_2] \in \mathfrak{k}$.

How does the splitting of $Z = P + K$ relate to the factorization (2.1)? It is possible to show that, for t sufficiently small, the factors x and y in (2.1) are of the form $x = \exp(X(t))$ and $y = \exp(Y(t))$, where $X(t) \in \mathfrak{p}$ and $Y(t) \in \mathfrak{k}$, for all $t \in [0, t_0]$. Moreover they can be expanded in series

$$X(t) = \sum_{i=1}^{\infty} X_i t^i, \qquad Y(t) = \sum_{i=1}^{\infty} Y_i t^i,$$

where the coefficients X_i and Y_i can be calculated by means of explicit recurrence relations from the matrices P and K [20]. The first terms in the expansions of $X(t)$ and $Y(t)$ are

$$\begin{aligned} X = {} & Pt - \frac{1}{2}[P,K]t^2 - \frac{1}{6}[K,[P,K]]t^3 \\ & + \left(\frac{1}{24}[P,[P,[P,K]]] - \frac{1}{24}[K,[K,[P,K]]]\right)t^4 \\ & + \left(\frac{7}{360}[K,[P,[P,[P,K]]]] - \frac{1}{120}[K,[K,[K,[P,K]]]] \right. \\ & \left. - \frac{1}{180}[[P,K],[P,[P,K]]]\right)t^5 + \mathcal{O}\big(t^6\big), \\ Y = {} & Kt - \frac{1}{12}[P,[P,K]]t^3 + \left(\frac{1}{120}[P,[P,[P,[P,K]]]] + \frac{1}{720}[K,[K,[P,[P,K]]]] \right. \\ & \left. - \frac{1}{240}[[P,K],[K,[P,K]]]\right)t^5 + \mathcal{O}\big(t^7\big). \end{aligned} \tag{2.5}$$

Since $X(t)$ and $Y(t)$ and their truncations live in $\mathfrak{p}$ and $\mathfrak{k}$, respectively, it is clearly desirable to choose automorphisms σ such that exponentials of elements in $\mathfrak{p}$ (and eventually $\mathfrak{k}$) and repeated commutators of P and K are easy to compute.

Assume next that $\sigma_1, \sigma_2, \ldots, \sigma_m$ is a sequence of involutive automorphisms on G that satisfies the above conditions. Then, taking $\sigma \equiv \sigma_1$, we partition $\mathfrak{g} = \mathfrak{p}_1 \oplus \mathfrak{k}_1$, and approximate

$$\exp(tZ) \approx \exp(X^{[1]}(t)) \exp(Y^{[1]}(t)), \tag{2.6}$$

where $X^{[1]}$ and $Y^{[1]}$ are truncations of (2.5) of suitable order.

By the same token, $\mathfrak{k}_1$ is partitioned as $\mathfrak{p}_2 \oplus \mathfrak{k}_2$ by means of the automorphism σ_2, and

$$\exp(Y^{[1]}(t)) \approx \exp(X^{[2]}(t)) \exp(Y^{[2]}(t)),$$

where again $X^{[2]}$ and $Y^{[2]}$ are truncations of (2.5) of suitable order.

The procedure is iterated for m steps, say, so that $\mathfrak{k}_m$ is of low dimension and, therefore, exponentials of its elements are easy to compute exactly.

This algorithm approximates $\exp(tZ)$ to a given order of accuracy. In these circumstances, (2.6) will read

$$\exp(tZ) \approx F(t,Z) = \exp(X^{[1]}(t)) \cdots \exp(X^{[m]}(t)) \exp(Y^{[m]}(t)) \tag{2.7}$$

and it corresponds to the algebra direct-sum decomposition

$$\mathfrak{g} = \mathfrak{p}_1 \oplus \cdots \oplus \mathfrak{p}_m \oplus \mathfrak{k}_m. \tag{2.8}$$

In some circumstances, it might be more convenient to use a mirrored form of (2.7),

$$\exp(tZ) \approx \exp(\tilde{Y}^{[m]}(t)) \exp(\tilde{X}^{[m]}(t)) \cdots \exp(\tilde{X}^{[1]}(t)). \tag{2.9}$$

Clearly, the functions $\tilde{Y}(t)$ and $\tilde{X}(t)$ and their truncations are related to $Y(t)$ and $X(t)$. Indeed, in [16] it is easily verified that

$$\tilde{Y}(t) = Y(t), \qquad \tilde{X}(t) = -X(-t).$$

2.1. On the choice of the order of approximation. As we have mentioned earlier, one of the core applications of the splitting methods proposed in this paper is the numerical solution of ODEs on Lie groups by means of Lie-group methods [10] using exponentials. If, in this context, a numerical integrator of order p is used, it is reasonable to use an exponential approximation of the same order since the truncation error of the exponential approximation is subsumed in the truncation error of the numerical integrator. This is accomplished by truncating the expansions (2.5) to include all the terms up to $\mathcal{O}(t^p)$. For instance, if using a numerical integrator of order four, a reasonable approximation is

$$\begin{aligned} X(t) &\approx X_1 t + X_2 t^2 + X_3 t^3 + X_4 t^4 \\ &= Pt - \frac{1}{2}[P,K]t^2 - \frac{1}{6}[K,[P,K]]t^3 + \left(\frac{1}{24}[P,[P,[P,K]]] - \frac{1}{24}[K,[K,[P,K]]]\right) t^4 \end{aligned}$$

for $X(t)$, and, similarly,

$$Y(t) \approx Y_1 t + Y_3 t^3 = Kt - \frac{1}{12}[P,[P,K]]t^3$$

for $Y(t)$.

In other cases, for example, when the given matrix Z has large entries or is badly scaled, the methods we propose in this paper should be combined with other procedures like error control and scaling and squaring.

2.2. On the choice of automorphisms. From this point onward, we are mostly interested in the algebraic setting; therefore, we revert our notation to the more familiar in numerical analysis. Matrices (otherwise specified) will be denoted by capital letters, vectors by boldface letters, et cetera.

To obtain the algebra splitting (2.8), Zanna et al. [21] suggested using automorphisms of the type

$$\sigma(z) = \mathrm{Ad}_S Z = SzS, \quad z \in G, \tag{2.10}$$

(inner automorphisms), where $S \in \mathrm{O}(n) \cap G$ is a suitable involutory matrix (i.e., $S^2 = I$) such that $SzS \in G$. Note that, at the algebra level, (2.2) implies that

$$\mathrm{d}\sigma(Z) = \mathrm{Ad}_S Z = SZS,$$

in other words, $\mathrm{d}\sigma$ and σ are essentially of the same form.

Consider next an inner automorphism Ad_S, where

$$S = \mathrm{diag}(-1)^{\mathbf{s}} = \mathrm{diag}[(-1)^{s_1}, (-1)^{s_2}, \dots, (-1)^{s_n}] \qquad s_i \in \{0,1\}. \tag{2.11}$$

Given an arbitrary matrix Z, one has

$$(SZS)_{i,j} = (-1)^{s_i+s_j} Z_{i,j}$$

consequently,

$$P_{i,j} = \frac{1}{2}[1 - (-1)^{s_i+s_j}]Z_{i,j}, \qquad K_{i,j} = \frac{1}{2}[1 + (-1)^{s_i+s_j}]Z_{i,j}.$$

Hence, choosing appropriately the vector $\mathbf{s}$, it is possible to dispatch selected rows and columns of Z to the different subspaces.

For instance, choosing $s_i = 0$, $i \neq k$, and $s_k = 1$, we obtain subspaces $\mathfrak{p}$ and $\mathfrak{k}$ with the sparsity structure

$$\mathfrak{p} \ni \begin{bmatrix} 0 & \cdots & 0 & \times & 0 & 0 & \cdots & 0 \\ \vdots & & \vdots & \times & \vdots & \vdots & & \vdots \\ 0 & \cdots & 0 & \times & 0 & 0 & \cdots & 0 \\ \times & \times & \times & 0 & \times & \times & \times & \times \\ 0 & \cdots & 0 & \times & 0 & 0 & \cdots & 0 \\ 0 & \cdots & 0 & \times & 0 & 0 & & 0 \\ \vdots & & \vdots & \times & \vdots & & & \vdots \\ 0 & \cdots & 0 & \times & 0 & 0 & \cdots & 0 \end{bmatrix}, \quad \mathfrak{k} \ni \begin{bmatrix} \times & \cdots & \times & 0 & \times & \times & \cdots & \times \\ \vdots & & \vdots & 0 & \vdots & \vdots & & \vdots \\ \times & \cdots & \times & 0 & \times & \times & \cdots & \times \\ 0 & 0 & 0 & \times & 0 & 0 & 0 & 0 \\ \times & \cdots & \times & 0 & \times & \times & \cdots & \times \\ \times & \cdots & \times & 0 & \times & \times & \cdots & \times \\ \vdots & & \vdots & 0 & \vdots & \vdots & & \vdots \\ \times & \cdots & \times & 0 & \times & \times & \cdots & \times \end{bmatrix},$$

respectively.

3. Tridiagonal matrices. Let us assume that Z is a tridiagonal matrix,

$$Z = \begin{bmatrix} \alpha_1 & \gamma_1 & & \\ \beta_1 & \ddots & \ddots & \\ & \ddots & \ddots & \gamma_{n-1} \\ & & \beta_{n-1} & \alpha_n \end{bmatrix}, \tag{3.1}$$

and denote by $\mathbf{e}_i$ the ith unit vector in $\mathbb{R}^n$.

DEFINITION 3.1. *We say that the sequence of automorphisms*

$$\mathrm{Ad}_{S_i}, \quad S_i = \mathrm{diag}(-1)^{\mathbf{s}_i}, \quad i = 1, \dots, n-1, \tag{3.2}$$

constitutes a peel-down approach *if* $\mathbf{s}_1 = \mathbf{e}_1 = [1, 0, 0, \dots, 0]^\top$, $\mathbf{s}_2 = \mathbf{e}_2 = [0, 1, 0, \dots, 0]^\top$, $\dots$, $\mathbf{s}_{n-1} = \mathbf{e}_{n-1} = [0, 0, 0, \dots, 1, 0]^\top$. *The choice* $\mathbf{s}_1 = \mathbf{e}_n$, $\mathbf{s}_2 = \mathbf{e}_{n-1}, \dots, \mathbf{s}_{n-1} = \mathbf{e}_2$ *constitutes a* peel-up approach.

The above definition is motivated by the fact that the peel-down approach leads to the splitting in bordered matrices proposed in [21]; the bordered matrices are obtained by "peeling" the matrix Z from the top-left corner downwards. In the peel-up approach, we target rows and columns of Z starting from the bottom-right corner instead and proceed upwards.

In what follows, we apply a peel-up approach to (3.1) and discuss in detail the first stage, corresponding to the automorphism Ad_{S_1}, $\mathbf{s}_1 = \mathbf{e}_n$. The remaining stages of the peel-up approach share very similar features.

Using $\mathrm{Ad}_{\mathrm{diag}(-1)^{\mathbf{e}_n}}$ to perform the first algebra splitting we obtain $Z = P + K$, where

$$P = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & \ddots & \ddots & & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & 0 & 0 & \gamma_{n-1} \\ 0 & \cdots & 0 & \beta_{n-1} & 0 \end{bmatrix}, \quad K = \begin{bmatrix} \alpha_1 & \gamma_1 & 0 & \cdots & 0 \\ \beta_1 & \alpha_2 & \ddots & & \vdots \\ 0 & \ddots & \ddots & \gamma_{n-2} & 0 \\ \vdots & \ddots & \beta_{n-2} & \alpha_{n-1} & 0 \\ 0 & \cdots & 0 & 0 & \alpha_n \end{bmatrix}. \tag{3.3}$$

Next, we start computing commutators. We write

$$P = \gamma_{n-1}\mathbf{e}_{n-1}\mathbf{e}_n^\top + \beta_{n-1}\mathbf{e}_n\mathbf{e}_{n-1}^\top,$$

and commence our computations with

$$\begin{aligned}[P,K] = &-\gamma_{n-2}\gamma_{n-1}\mathbf{e}_{n-2}\mathbf{e}_n^\top + \beta_{n-2}\beta_{n-1}\mathbf{e}_n\mathbf{e}_{n-2}^\top\\ &+\gamma_{n-1}(\alpha_n-\alpha_{n-1})\mathbf{e}_{n-1}\mathbf{e}_n^\top - \beta_{n-1}(\alpha_n-\alpha_{n-1})\mathbf{e}_n\mathbf{e}_{n-1}^\top.\end{aligned} \tag{3.4}$$

It is immediate to observe that there appears a fill-in in the tridiagonal structure of $X(t) = Pt - \frac{1}{2}t^2[P,K] + \mathcal{O}(t^3)$. In general, the more commutators we take, the greater the fill-in: two extra nonzero elements (one in the nth row and one in the nth column) for every extra power of t. In principle, the whole nth row and column would eventually be filled in. But this is not such bad news as it might appear at a first glance. Below we explain the reason for this.

3.1. Dealing with fill-in. An important observation is that fill-in of $X(t)$ propagates only in the Lie triple-system $\mathfrak{p}$, which consists of rank-2 matrices of the form

$$\left[\begin{array}{c|c} O & \mathbf{a} \\ \hline \mathbf{b}^\top & 0 \end{array}\right], \quad \mathbf{a},\mathbf{b}\in\mathbb{R}^m. \tag{3.5}$$

Therefore, once $X(t)$ is approximated, its exponential can be computed exactly by means of an expression analogous to the Euler–Rodrigues formula for the exponential of a skew-symmetric matrix. Assume that $A\in\mathfrak{p}$ is of the form (3.5). Then,

$$\exp(A) = \begin{cases} I + \dfrac{\sinh\theta}{\theta}A + \dfrac{1}{2}\left[\dfrac{\sinh(\theta/2)}{\theta/2}\right]^2 A^2, & \mathbf{a}^\top\mathbf{b} > 0,\ \theta = \sqrt{\mathbf{a}^\top\mathbf{b}},\\ I + A + \dfrac{1}{2}A^2, & \mathbf{a}^\top\mathbf{b} = 0,\\ I + \dfrac{\sin\theta}{\theta}A + \dfrac{1}{2}\left[\dfrac{\sin(\theta/2)}{\theta/2}\right]^2 A^2, & \mathbf{a}^\top\mathbf{b} < 0,\ \theta = \sqrt{-\mathbf{a}^\top\mathbf{b}}\end{cases} \tag{3.6}$$

[21], where

$$A^2 = \left[\begin{array}{c|c} \mathbf{a}\mathbf{b}^\top & \mathbf{0} \\ \hline \mathbf{0}^\top & \mathbf{a}^\top\mathbf{b} \end{array}\right].$$

Setting to η_1, η_2 the coefficients of (3.6), application to a vector yields

$$\exp(A)\mathbf{v} = \mathbf{v} + \eta_1\begin{bmatrix} O & \mathbf{a}\\ \mathbf{b}^\top & 0\end{bmatrix}\mathbf{v} + \eta_2\begin{bmatrix}\mathbf{a}\mathbf{b}^\top & \mathbf{0}\\ \mathbf{0}^\top & \pm\theta^2\end{bmatrix}\mathbf{v},$$

where the sign of θ^2 is chosen according to (3.6). Assume next that $\mathbf{w},\mathbf{v}\in\mathbb{R}^{k+1}$, $\mathbf{a},\mathbf{b}\in\mathbb{R}^k$. Writing $\mathbf{v} = [\mathbf{v}_k, v]^\top$, $\mathbf{w} = [\mathbf{w}_k, w]^\top$, a direct computation reveals that

$$\begin{bmatrix}\mathbf{w}_k\\ w\end{bmatrix} = \exp(A)\mathbf{v} = \begin{bmatrix}\mathbf{v}_k + \zeta_1\mathbf{a}\\ \zeta_2\end{bmatrix}, \tag{3.7}$$

where

$$\begin{aligned}\zeta_1 &= [\eta_1 v + \eta_2(\mathbf{b}^\top\mathbf{v}_k)],\\ \zeta_2 &= (1\pm\eta_2\theta^2)v + \eta_1(\mathbf{b}^\top\mathbf{v}_k).\end{aligned}$$

TABLE 3.1

Cost of the computation (including both addition and multiplication) of the exponential (3.6). *The* (k,k) *column corresponds to the case when* $\mathbf{a},\mathbf{b}$ *are full, the* (k,p) *corresponds to the case when* $\mathbf{a}$ *is full while only the last* p *components of* $\mathbf{b}$ *are nonzero and, finally, the* (p,p) *column corresponds to both* $\mathbf{a}$ *and* $\mathbf{b}$ *having only the last* p *components nonzero.*

Cost of $\exp(A)$	(k,k)	(k,p)	(p,p)
$\mathbf{a}^\top\mathbf{b}$	$2k$	$2p$	$2p$
$\mathbf{b}^\top\mathbf{v}_k$	$2k$	$2p$	$2p$
$\zeta_1\mathbf{a}$	k	k	p
$\mathbf{w}_k$	k	k	p
total, stage k	$6k$	$2k+4p$	$6p$
total, summing $1\le k\le n$ (vector)	$3n^2$	n^2+4pn	$6pn$
matrix (n vectors)	$2n^3$	n^3+2pn^2	$4pn^2$

When the exponential is applied to a matrix, we apply (3.7) to each column vector. Note, however, that the scalar product $\mathbf{a}^\top\mathbf{b}$ need be computed only once, even if the matrix columns are distinct.

In passing, we mention that there exists another formula for the exact computation of the exponential of a matrix as in (3.5), due to Celledoni et al. [2],

$$\exp(A) = I + [\mathbf{e}_k, \mathbf{k}]\varphi(D)\begin{bmatrix}\mathbf{l}^\top\\ \mathbf{e}_k^\top\end{bmatrix}, \tag{3.8}$$

where

$$\mathbf{k} = \begin{bmatrix}\mathbf{a}\\ 0\end{bmatrix}, \qquad \boldsymbol{l} = \begin{bmatrix}\mathbf{b}\\ 0\end{bmatrix}, \qquad D = \begin{pmatrix}0 & \mathbf{b}^\top\mathbf{a}\\ 1 & 0\end{pmatrix},$$

$\mathbf{e}_k$ is the vector $[0,0,\dots,0,1]^\top \in \mathbb{R}^k$ and, finally, $\varphi(z) = (\mathrm{e}^z-1)/z$. This formula can be shown to have the same computational cost as (3.7).

If $\mathbf{a},\mathbf{b}$ have $p \ll n$ nonzero elements only, say $a_{n-p},\dots,a_{n-1},b_{n-p}\dots,b_{n-1}$, it is clear that the computation of exponentials of elements in $\mathfrak{p}$ requires just $\mathcal{O}(pn)$ operations, when the exponentials are multiplied by a vector, and $\mathcal{O}(pn^2)$ operations when a multiplication by a matrix is required (see Table 3.1). Therefore, the fill-in in the $\mathfrak{p}$ part is inconvenient (in principle one would have preferred to preserve the neater tridiagonal structure), but it is not dangerous insofar as the increase of the computational cost is concerned.

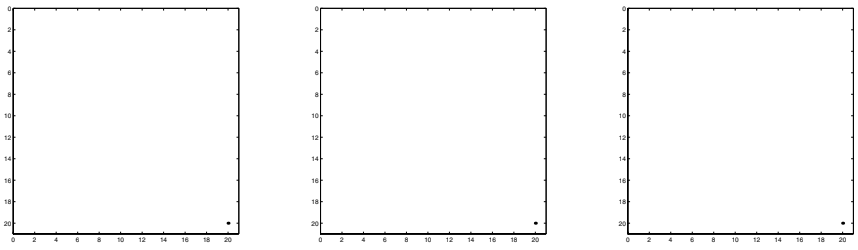

FIG. 3.1. *Fill-in in the tridiagonal structure at step one, two, and three in the peel-up procedure.*

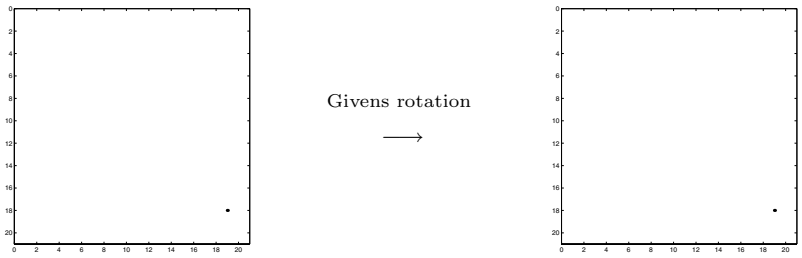

FIG. 3.2. *In the peel-up approach for skew-symmetric matrices, using a Givens rotation to annihilate sub-diagonal fill-in does not cause further fill-in.*

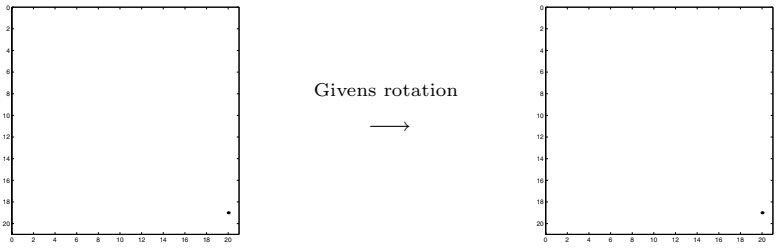

FIG. 3.3. *In the peel-down approach for skew-symmetric matrices, using a Givens rotation to annihilate sub-diagonal fill-in does cause fill-in that propagates downwards. If the rotations are chosen to annihilate* super-diagonal *fill-in instead, there is no fill-in propagation.*

More subtle is the case when the fill-in appears in $\mathfrak{k} \ni Y(t) = Kt - \frac{1}{12}t^3[P,[P,K]] +$ higher order terms. If such fill-in occurs and is not suitably dealt with, it will propagate further and the tridiagonal structure of the sub-matrices will be lost. The matrices then become increasingly full, and the cost of the splitting becomes $\mathcal{O}(n^3)$, as discussed in [21]. Such an instance is displayed below in Figure 3.1, in which we perform three steps of the peel-up procedure for a tridiagonal symmetric matrix. We compute the function $Y(t)$ given in (2.5) and truncate the expansion to order six. It is clearly observed that in each step the number of nonzero elements increases and that the sub-matrices have a tendency to become full. This is clearly not desirable, since we do not want to lose the benefits of the original tridiagonal form!

However, two important observations are the following:

- The fill-in in the $Y(t)$ part appears at order five only—truncations of order one to four are still tridiagonal.
- The number of fill-in elements is usually very small.

Hence it is reasonable to eliminate the fill-in at each step by means of similarity orthogonal transformations (for instance, Givens rotations). At each step this contributes only $\mathcal{O}(1)$ to the cost of the splitting, which is negligible compared to the total cost of the approximation.

If Z is a skew-symmetric matrix, the fill-in in the $Y(t)$ part is chess board-like. Givens rotations can be used to eliminate the sub-diagonal fill-in and their transpose takes care of the super-diagonal fill-in. This is precisely the point when our choice of the peel-up approach, in preference to peel-down, starts to pay dividends. Using a peel-down approach, Givens rotations that eliminate the sub-diagonal fill-in cause

further fill-in that is propagated downwards. However, no fill-in is caused if Givens rotations are targeted to annihilate super-diagonal fill-ins instead (see and compare Figures 3.2 and 3.3). For this reason we will restrict our attention to the peel-up approach instead of the peel-down approach of [21].

3.2. On the computation of commutators. We return to the computation of commutators and denote by $\mathrm{ad}_B = [B, \cdot]$ the operator that performs commutation with B, i.e., $\mathrm{ad}_B C = [B, C]$, $\mathrm{ad}_B^2 C = [B, [B, C]]$, etc.

Our first observation is that the involutions S are usually chosen so that $P = \Pi_{\mathfrak{p}}(Z)$ has low rank, hence only just a few nonzero eigenvalues. Thus, we can use the theory of minimal polynomials of matrices [9] so that few commutators need be computed. All the remaining commutators with P can be obtained as linear combinations of those.

LEMMA 3.2. *Consider the matrix A of the form* (3.5). *If $\mathbf{a}\mathbf{b}^\top \neq O$, then the minimal polynomial of* ad_A *is*

$$\begin{aligned} p(\lambda) &= \lambda(\lambda - 2\theta)(\lambda + 2\theta)(\lambda - \theta)(\lambda + \theta) \\ &= \lambda^5 - 5\mathbf{b}^\top\mathbf{a}\lambda^3 + 4(\mathbf{b}^\top\mathbf{a})^2\lambda, \end{aligned} \tag{3.9}$$

where $\theta = \sqrt{\mathbf{b}^\top\mathbf{a}}$.

If either $\mathbf{a}$ or $\mathbf{b}$ is zero, then the minimal polynomial is

$$p(\lambda) = \lambda^3. \tag{3.10}$$

Proof. Recall that if A has distinct eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_m$ with algebraic multiplicities $r_1, r_2, \ldots, r_m$, respectively, the minimal polynomial of A has the form

$$q(\lambda) = \prod_{i=1}^{m} (\lambda - \lambda_i)^{g_i},$$

where g_i is the order of the largest Jordan block of A corresponding to the eigenvalue λ_i [9].

Let us assume first that $\mathbf{b}^\top\mathbf{a} \neq 0$. Imposing $A\mathbf{v} = \lambda\mathbf{v}$, we deduce immediately that the eigenvalues of A are $\lambda = \pm\theta = \pm\sqrt{\mathbf{b}^\top\mathbf{a}}$ and $\lambda = 0$ with algebraic multiplicities one, one, and $n - 2$, respectively. It is easily verified that these are also their geometric multiplicities: for $\lambda = \pm\theta$, eigenvectors are of the form $[\mathbf{a}, \pm 1]^\top$; for the zero eigenvalues, eigenvectors are of the form $[\mathbf{v}_1, 0]^\top$, $\mathbf{0} \neq \mathbf{v}_1 \in \mathbb{R}^{n-1}$, satisfying $\mathbf{b}^\top\mathbf{v}_1 = 0$, furthermore, it is possible to find $n - 2$ of those that are linearly independent.

Since the eigenvalues and eigenvectors of ad_A are the form $\lambda_i - \lambda_j$ and $\mathbf{y}_i^\top\mathbf{x}_j$, respectively, the λ_is being eigenvalues of A with left and right eigenvector $\mathbf{y}_i$ and $\mathbf{x}_i$, respectively, we deduce that ad_A has eigenvalues

$$\lambda = \pm 2\theta, \qquad \lambda = \pm\theta$$

with algebraic/geometric multiplicities one each, and

$$\lambda = 0$$

with algebraic and geometric multiplicity $n^2 - 4$. This implies that all Jordan blocks have size one, from which it follows directly that the minimal polynomial of ad_A is of the form åq:minpoly.

Next, if $\theta = 0$ but $\mathbf{a}\mathbf{b}^\top \neq O$ (namely $\mathbf{a}, \mathbf{b} \neq \mathbf{0}$) the eigenvectors of A, that we write as $[\mathbf{v}_1, v_2]^\top$, must obey the conditions

$$\begin{aligned} \mathbf{a}v_2 &= \mathbf{0}, \\ \mathbf{b}^\top \mathbf{v}_1 &= 0. \end{aligned}$$

Since $\mathbf{a} \neq 0$, it must necessarily be $v_2 = 0$. Therefore, eigenvectors must be of the form $[\mathbf{v}_1, 0]$. Recall that $\mathbf{v}_1$ has $n-1$ entries ($n-1$ free parameters) while the second equation $\mathbf{b}^\top \mathbf{v}_1 = 0$ gives only a linear constraint. This means that we can find only $n-2$ linearly independent eigenvectors and two further linearly independent generalized eigenvectors. In terms of Jordan blocks, this means that A has a Jordan block of the form

$$J(0) = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix},$$

or two Jordan blocks of the form

$$J(0) = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}.$$

A simple discussion eliminates the second possibility: if there were two such Jordan blocks, the minimal polynomial would be λ^2, i.e., $A^2 = O$, which is clearly not the case by direct computation, being $\mathbf{a}\mathbf{b}^\top \neq O$. Hence, only the first 3×3 Jordan block is admissible. Therefore λ^3 is the minimal polynomial of A and, as a consequence, $A^3 = O$. Passing to the adjoint operator ad_A, recall that, for an arbitrary matrix C,

$$\mathrm{ad}_A^k C = \sum_{i=0}^{k} \binom{k}{i} (-1)^{k-i} A^i C A^{k-i}, \quad k = 1, 2, \ldots . \tag{3.11}$$

Clearly, $\mathrm{ad}_A^5 C = O$ since in all terms there appears a power A^i with $i \geq 3$. For lower order powers, there are always terms of the type $A^i C A^{k-i}$, where $i, k-i \leq 2$. This means that it is always possible to find a matrix C for which at least one of terms does not vanish. Hence the minimal polynomial of ad_A is

$$p(\lambda) = \lambda^5.$$

Finally, in the case when either $\mathbf{a} = \mathbf{0}$ or $\mathbf{b} = \mathbf{0}$, by direct computation,

$$A^2 = O,$$

corresponding to a Jordan block $J(0) = \left[\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right]$. Hence the minimal polynomial of A is λ^2. Insofar as ad_A is concerned, the first power to vanish in (3.11) is ad_A^3, and no lower power vanishes for arbitrary matrices C. Hence the minimal polynomial is

$$p(\lambda) = \lambda^3.$$

This completes the proof of the lemma. ∎

Trivially, in the case when both $\mathbf{a}$ and $\mathbf{b}$ are zero, both $A = O$ and $\mathrm{ad}_A = O$, hence their minimal polynomial is $p(\lambda) = \lambda$.

THEOREM 3.3. *Assume that the matrix A is of the form* (3.5). *Then, for every $k = 1, 2, \dots$, commutators by A can be computed as*

$$\mathrm{ad}_A^k = [C_1 + (-1)^k C_2] 2^k \theta^k + [C_3 + (-1)^k C_4] \theta^k, \quad k = 1, 2, \dots, \tag{3.12}$$

when $\theta = \sqrt{\mathbf{b}^\top \mathbf{a}} \neq 0$, and

$$\begin{aligned} C_1 - C_2 &= \frac{1}{6}\left(-\frac{\mathrm{ad}_A}{\theta} + \frac{\mathrm{ad}_A^3}{\theta^3}\right), & C_3 - C_4 &= \frac{1}{3}\left(\frac{4\mathrm{ad}_A}{\theta} - \frac{\mathrm{ad}_A^3}{\theta^3}\right), \\ C_1 + C_2 &= \frac{1}{12}\left(-\frac{\mathrm{ad}_A^2}{\theta^2} + \frac{\mathrm{ad}_A^4}{\theta^4}\right), & C_3 + C_4 &= \frac{1}{3}\left(\frac{4\mathrm{ad}_A^2}{\theta^2} - \frac{\mathrm{ad}_A^4}{\theta^4}\right). \end{aligned} \tag{3.13}$$

If $\theta = 0$ but $\mathbf{a}, \mathbf{b} \neq O$, then

$$\mathrm{ad}_A^k = O, \quad k = 5, 6, 7, \dots .$$

If either $\mathbf{a}$ or $\mathbf{b}$ is a zero vector, then

$$\mathrm{ad}_A^k = O, \quad k = 3, 4, 5, \dots .$$

Proof. Recall that the minimal polynomial is the least degree monic polynomial such that

$$p(\mathrm{ad}_A) = 0,$$

hence

$$\mathrm{ad}_A^5 - 5(\mathbf{b}^\top \mathbf{a})\mathrm{ad}_A^3 + 4(\mathbf{b}^\top \mathbf{a})^2 \mathrm{ad}_A = O.$$

Multiplying by $\mathrm{ad}_A, \mathrm{ad}_A^2, \dots$, we obtain the recurrence relation

$$\mathrm{ad}_A^{k+2} - 5(\mathbf{b}^\top \mathbf{a})\mathrm{ad}_A^k + 4(\mathbf{b}^\top \mathbf{a})^2 \mathrm{ad}_A^{k-2} = O, \quad k = 3, 4, 5, \dots,$$

whose general solution is (3.12). The unknowns C_1, C_2, C_3, C_4 are obtained by requiring that the formula (3.12) is correct for $k = 1, 2, 3, 4$. We obtain

$$\begin{aligned} (C_1 - C_2) + \frac{1}{2}(C_3 - C_4) &= \frac{1}{2\theta}\mathrm{ad}_A, \\ (C_1 + C_2) + \frac{1}{4}(C_3 + C_4) &= \frac{1}{4\theta^2}\mathrm{ad}_A^2, \\ (C_1 - C_2) + \frac{1}{8}(C_3 - C_4) &= \frac{1}{8\theta^3}\mathrm{ad}_A^3, \\ (C_1 + C_2) + \frac{1}{16}(C_3 + C_4) &= \frac{1}{16\theta^4}\mathrm{ad}_A^4, \end{aligned}$$

and (3.13) follows by direct computation. Thus, (3.12) is determined for both odd and even values of k. ∎

In other words, given an arbitrary matrix B, the commutator $\mathrm{ad}_A^k B$, $k \geq 5$, can be obtained as a mere linear combination of $B, \mathrm{ad}_A B, \dots, \mathrm{ad}_A^4 B$. In our case, taking $A \equiv P$ and taking into account the sparsity of P, the computation of ad_P^k, $k = 1, 2, 3, 4$, is particularly simple. Setting $E_{i,j} = \mathbf{e}_i \mathbf{e}_j^\top$, a matrix with 1 in the (i, j)

position and 0 otherwise, and applying ad_P to K (whose elements are as in (3.3)), we have

$$
\begin{aligned}
[P,K] &= c_{n-2,n}E_{n-2,n} + c_{n,n-2}E_{n,n-2} \\
&\quad + c_{n-1,n}E_{n-1,n} + c_{n,n-1}E_{n,n-1}, \\
[P,[P,K]] &= d_{n-2,n-1}E_{n-2,n-1} + d_{n-1,n-2}E_{n-1,n-2} \\
&\quad + d_{n-1,n-1}E_{n-1,n-1} + d_{n,n}E_{n,n}, \\
[P,[P,[P,K]]] &= e_{n-2,n}E_{n-2,n} + e_{n,n-2}E_{n,n-2} \\
&\quad + e_{n-1,n}E_{n-1,n} + e_{n,n-1}E_{n,n-1}, \\
[P,[P,[P,[P,K]]]] &= f_{n-2,n-1}E_{n-2,n-1} + f_{n-1,n-2}E_{n-1,n-2} \\
&\quad + f_{n-1,n-1}E_{n-1,n-1} + f_{n,n}E_{n,n}.
\end{aligned} \tag{3.14}
$$

The nonzero coefficients $c_{i,j}$, $d_{i,j}$, $e_{i,j}$, $f_{i,j}$ are given by

$$
\begin{aligned}
c_{n-2,n} &= -\gamma_{n-2}\gamma_{n-1}, & d_{n-2,n-1} &= -\beta_{n-1}c_{n-2,n}, \\
c_{n,n-2} &= \beta_{n-2}\beta_{n-1}, & d_{n-1,n-2} &= \gamma_{n-1}c_{n,n-2}, \\
c_{n-1,n} &= \gamma_{n-1}(\alpha_n - \alpha_{n-1}), & d_{n-1,n-1} &= \gamma_{n-1}c_{n,n-1} - \beta_{n-1}c_{n-1,n}, \\
c_{n,n-1} &= \beta_{n-1}(\alpha_n - \alpha_{n-1}), & d_{n,n} &= -d_{n-1,n-1}, \\
e_{n-2,n} &= -\gamma_{n-1}d_{n-2,n-1}, & f_{n-2,n-1} &= -\beta_{n-1}e_{n-2,n}, \\
e_{n,n-2} &= \beta_{n-1}d_{n-1,n-2}, & f_{n-1,n-2} &= \gamma_{n-1}e_{n,n-2}, \\
e_{n-1,n} &= 2\gamma_{n-1}d_{n,n}, & f_{n-1,n-1} &= \gamma_{n-1}e_{n,n-1} - \beta_{n-1}e_{n-1,n}, \\
e_{n,n-1} &= -2\beta_{n-1}d_{n-1,n-1}, & f_{n,n} &= -f_{n-1,n-1},
\end{aligned} \tag{3.15}
$$

where β_ks and γ_ks originate in (3.3).

Unfortunately, the theory of minimal polynomials is not equally insightful insofar as commutators with K are concerned. Instead, we have computed the first few such terms explicitly and they are also in a form that renders their evaluation cheap,

$$
\begin{aligned}
[K,[P,K]] &= g_{n,n-3}E_{n,n-3} + g_{n,n-2}E_{n,n-2} + g_{n,n-1}E_{n,n-1} \\
&\quad + g_{n-3,n}E_{n-3,n} + g_{n-2,n}E_{n-2,n} + g_{n-1,n}E_{n-1,n}, \\
[K,[K,[P,K]]] &= h_{n,n-4}E_{n,n-4} + h_{n,n-3}E_{n,n-3} + h_{n,n-2}E_{n,n-2} \\
&\quad + h_{n,n-1}E_{n,n-1} + h_{n-4,n}E_{n-4,n} + h_{n-3,n}E_{n-3,n} \\
&\quad + h_{n-2,n}E_{n-2,n} + h_{n-1,n}E_{n-1,n}, \\
[K,[P,[P,[P,K]]]] &= i_{n,n-3}E_{n,n-3} + i_{n,n-2}E_{n,n-2} + i_{n,n-1}E_{n,n-1} \\
&\quad + i_{n-3,n}E_{n-3,n} + i_{n-2,n}E_{n-2,n} + i_{n-1,n}E_{n-1,n}, \\
[K,[K,[K,[P,K]]]] &= j_{n,n-5}E_{n,n-5} + j_{n,n-5}E_{n,n-4} + j_{n,n-3}E_{n,n-3} \\
&\quad + j_{n,n-2}E_{n,n-2} + j_{n,n-1}E_{n,n-1} \\
&\quad + j_{n-5,n}E_{n-5,n} + j_{n-4,n}E_{n-4,n} + j_{n-3,n}E_{n-3,n} \\
&\quad + j_{n-2,n}E_{n-2,n} + j_{n-1,n}E_{n-1,n}, \\
[[P,K],[P,[P,K]]] &= k_{n,n-2}E_{n,n-2} + k_{n,n-1}E_{n,n-1} \\
&\quad + k_{n-2,n}E_{n-2,n} + k_{n-1,n}E_{n-1,n}, \\
[K,[K,[P,[P,K]]]] &= l_{n-1,n-4}E_{n-1,n-4} + l_{n-1,n-3}E_{n-1,n-3} \\
&\quad + l_{n-1,n-2}E_{n-1,n-2} + l_{n-1,n-1}E_{n-1,n-1} \\
&\quad + l_{n-2,n-3}E_{n-2,n-3} + l_{n-2,n-2}E_{n-2,n-2}
\end{aligned} \tag{3.16}
$$

$$
\begin{aligned}
&+ l_{n-2,n-1}E_{n-2,n-1} + l_{n-3,n-2}E_{n-3,n-2}\\
&+ l_{n-3,n-1}E_{n-3,n-1} + l_{n-4,n-1}E_{n-4,n-1},\\
[[P,K],[K,[P,K]]] &= m_{n,n}E_{n,n} + m_{n-1,n-3}E_{n-1,n-3}\\
&+ m_{n-1,n-2}E_{n-1,n-2} + m_{n-1,n-1}E_{n-1,n-1}\\
&+ m_{n-2,n-3}E_{n-2,n-3} + m_{n-2,n-2}E_{n-2,n-2}\\
&+ m_{n-2,n-1}E_{n-2,n-1} + m_{n-3,n-2}E_{n-3,n-2}\\
&+ m_{n-3,n-1}E_{n-3,n-1}.
\end{aligned}
$$

The nonzero coefficients of (3.16) are reported in the appendix.

Note that, when Z in (3.1) is symmetric or skew-symmetric, only about half of the coefficients in (3.14) and (3.16) need be computed. To see this, assume that Z is symmetric as well as P and K. Then, so is $[P,[P,K]],[K,[P,K]],\dots$, and in general all terms which include an even number of commutators. Those including an odd number of commutators, like $[P,K],[K,[K,[P,K]]],\dots$, are instead skew-symmetric. Symmetry and skew-symmetry can be transparently taken into account when computing the coefficients (3.15) and (A.1)–(A.6).

By the same token, when Z is skew-symmetric, so are P and K, and *all* their commutators. Again, this means that we only need to compute just the under-diagonal (or over-diagonal) coefficients in (3.14) and (3.16).

3.3. The reduction to a tridiagonal form: Symmetric and skew-symmetric matrices. For symmetric and skew-symmetric matrices, the problem of reduction to a tridiagonal form is classical, and we briefly review well-known techniques based on Householder reflections and Lanczos tridiagonalization.

Symmetric and skew-symmetric matrices can be reduced to a tridiagonal form by means of Householder reflections,

$$H = I - \beta \mathbf{v}\mathbf{v}^\top, \quad \beta = \frac{2}{\|\mathbf{v}\|^2},$$

which are orthogonal transformations. Since $H = H^\top$, it is easily verified that HZH is symmetric/skew-symmetric if Z is also. The above transformation can be computed very effectively for symmetric and skew-symmetric matrices thanks to an algorithm due to Wilkinson, which amounts to n^3 operations approximatively (counting both additions and multiplications) [6]. If counting only multiplications (or only *flops*, i.e., operations of the form $av + b$), the count reduces to $\frac{2}{3}n^3$, consistently with [6].

When Z is sparse and very large, a possible alternative is to use the Lanczos method, which is particularly attractive when it is cheap to form products of the form $Z\mathbf{v}$, where $\mathbf{v} \in \mathbb{R}^n$ [6, 18]. Denote by $Q = [\mathbf{q}_1, \mathbf{q}_2, \dots, \mathbf{q}_n]$ an orthogonal matrix that tridiagonalizes Z, i.e., $Q^\top ZQ = T$, where T is symmetric or skew-symmetric depending on Z, and tridiagonal. From

$$ZQ = QT,$$

one readily obtains the recurrences relations for the unknowns of the problem. The procedure may break down when, in exact arithmetics, T is reducible. In floating-point arithmetics it is also possible that the vectors $\mathbf{q}_j$ might become progressively

TABLE 3.2

less orthogonal, and, in such cases, a restart process is recommended. We refer the reader to [6, 18] for further details on the algorithm.

4. Other matrices. When Z is neither symmetric nor skew-symmetric, and, in particular, when it is not normal, the tridiagonalization process (nonsymmetric tridiagonalization, i.e., tridiagonalization by similarity transform, not necessarily orthonormal) might be either unstable or it might destroy the underlying algebraic structure [6]. For instance, the tridiagonalization of a matrix in the symplectic algebra $\mathfrak{sp}(n) := \{Z : ZJ = -JZ^\top\}$, where

$$J = \begin{bmatrix} O & I \\ -I & O \end{bmatrix}, \tag{4.1}$$

might not produce an output in $\mathfrak{sp}(n)$, and this is not desirable in many applications, for instance when conservation of Lie-group structure is important. To force the group structure, it might be more appropriate to look for other sparsity patterns that are (a) compatible with the algebra structure and (b) retained under commutation.

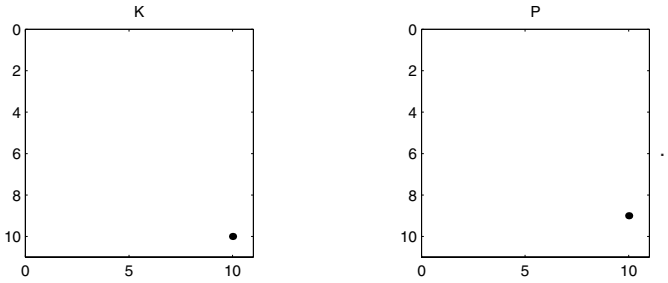
For matrices in $\mathfrak{gl}(n), \mathfrak{sl}(n)$ which do not strictly belong to other subalgebras, it is more convenient to reduce to an *upper-Hessenberg form*, by means of orthogonal transformations (e.g., Householder reflections). This is a more stable process

than nonsymmetric tridiagonalization [6]. For generic matrices, reduction to upper-Hessenberg form costs about $3\frac{1}{3}n^3$ operations [6].

For matrices belonging to other subalgebras, like the symplectic algebra, Lorentz-type algebras, quadratic algebras, etc., it is possible to consider other specific transformations that preserve the algebraic structure. These will be described at length in what follows.

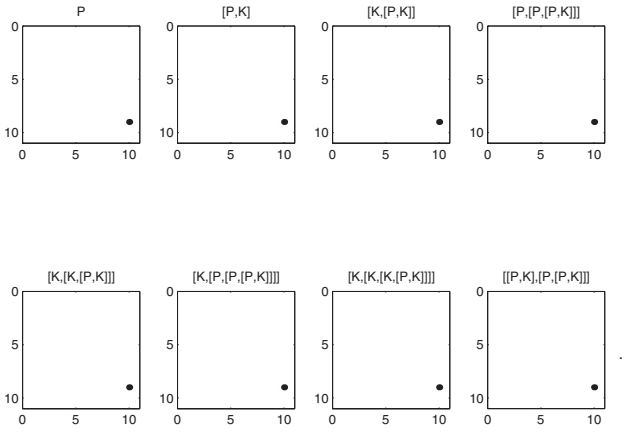
4.1. Upper Hessenberg matrices. In this subsection we analyze the first step of a peel-up approach, as in Definition 3.1, corresponding to the automorphism Ad_{S_1}, where $S_1 = \mathrm{diag}(-1)^{\mathbf{s}_1}$, $\mathbf{s}_1 = \mathbf{e}_n$. The remaining steps, corresponding to $\mathrm{Ad}_{S_2}, \mathrm{Ad}_{S_3}, \ldots$, corresponding to $\mathbf{s}_2 = \mathbf{e}_{n-1}$, $\mathbf{s}_3 = \mathbf{e}_{n-2}, \ldots$, share similar features. Therefore, Y_6 has the sparsity pattern displayed in Figure 4.2.

Assume that Z in $\mathfrak{gl}(n)$ or in $\mathfrak{sl}(n)$ is in an upper-Hessenberg form. The matrices P, K corresponding to the splitting induced by $\mathrm{Ad}_{\mathrm{diag}(-1)^{\mathbf{e}_n}}$ have the sparsity pattern



In Figure 4.1 we display the terms required in the generation of Y up to $\mathcal{O}(t^6)$, with just three filled-in entries, at the $(n-2, n-4)$, $(n-1, n-4)$ and $(n-1, n-3)$ positions. It thus takes just three Givens rotations to bring Y_6 to the same sparsity pattern as K via similarity transformations.

Next, we proceed to generate X. All the terms up to $\mathcal{O}(t^5)$ are



Therefore, the sparsity patterns of the truncations X_2, X_3, X_4, X_5 are

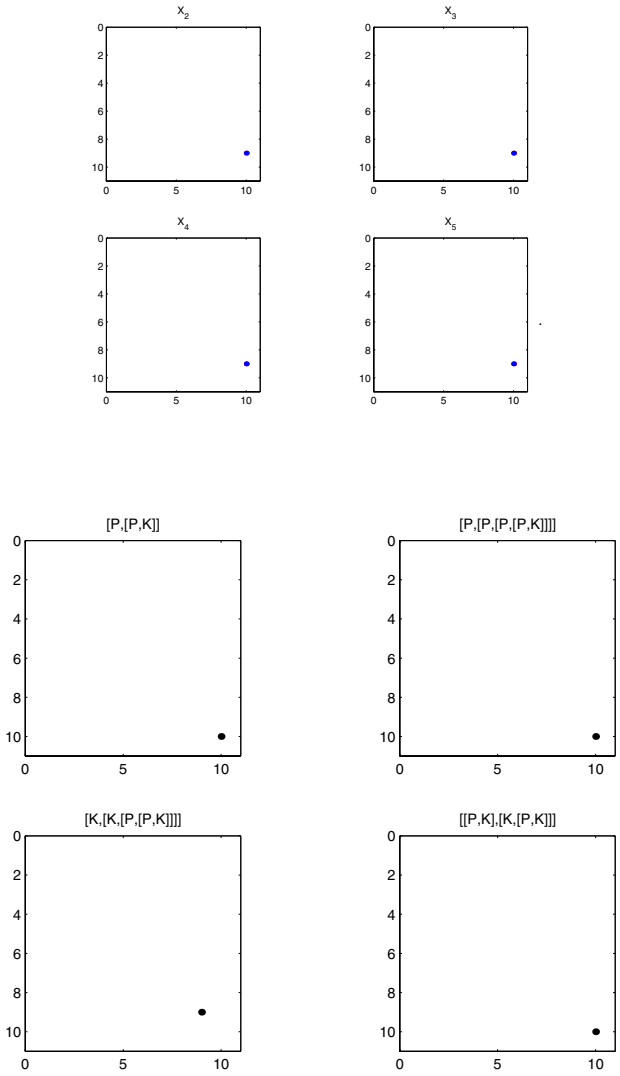


FIG. 4.1. *Commutators required for the generation of Y_6 for a matrix in a Hessenberg form.*

What about the exponential of X_p? Each such matrix is again of the form (3.5) and (3.6) still holds. Assume now that **a** has n nonzero elements, while **b** has only p nonzero elements, say $b_{n-p}, \ldots, b_{n-1}$. As displayed in Table 3.1, multiplying a vector by $n-1$ exponentials of matrices of decreasingly small dimension costs just $\mathcal{O}\big(pn^2\big)$ flops, while multiplying a matrix in a similar fashion carries the price tag of $\frac{1}{2}n^3 + \mathcal{O}\big(n^2\big)$ flops.

What is the cost of computing the commutators? Clearly, one has to take advantage of the sparsity of the matrices under consideration.

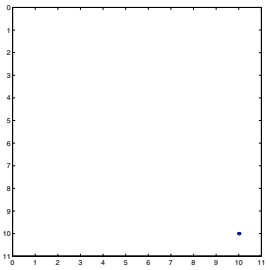

FIG. 4.2. *Sparsity pattern of Y_6 for a matrix in a Hessenberg form.*

We commence with the analysis of commutators of the type $[A, B]$, where $A \in \mathfrak{p}$ and $B \in \mathfrak{k}$. We write

$$A = \begin{bmatrix} O & \mathbf{a} \\ \mathbf{b}^\top & 0 \end{bmatrix}, \qquad B = \begin{bmatrix} B_1 & \mathbf{0} \\ \mathbf{0}^\top & B_2 \end{bmatrix},$$

where $\mathbf{b}^\top = [0, 0, \ldots, b_{n-q}, \ldots, b_{n-1}]$, has only q nonzero elements, B_1 is $(n-1) \times (n-1)$ and in a Hessenberg form, while B_2 has a single nonzero entry. We have

$$[A, B] = \begin{bmatrix} O & \mathbf{a}B_2 - B_1\mathbf{a} \\ \mathbf{b}^\top B_1 - B_2\mathbf{b}^\top & 0 \end{bmatrix}.$$

Thus, computing $[A, B]$ amounts to the following:

- about $n(n-1)$ operations for the computation of $B_1\mathbf{a}$, since B_1 is in a Hessenberg form. Note that this reduces to about $2qn$ operations if only the last q columns of B_1 are nonzero.
- $(n-1)$ operations for $\mathbf{a}B_2$ and further $n-1$ operations to compute $\mathbf{a}B_2 - B_1\mathbf{a}$,
- about $q(q-1)$ operations for $\mathbf{b}^\top B_1$, q to compute $B_2\mathbf{b}$ and further q to compute $\mathbf{b}^\top B_1 - B_2\mathbf{b}^\top$.

In total, we require about n^2 operations (assuming that $q \ll n$). Running the commutators over matrices of decreasing dimension, we have in total

$$\sum_{j=1}^{n-1} j^2 \approx \frac{1}{3}n^3$$

operations. This is the cost of the commutators $[P, K], [K, [P, K]], [K, [K, [P, K]]], \ldots$, namely of $\mathfrak{p}$-elements with K.

Next, we consider commutators of the form $[A_1, A_2]$, where $A_1, A_2 \in \mathfrak{p}$ are bordered matrices. Set

$$A_1 = \begin{bmatrix} O & \mathbf{a} \\ \mathbf{b}^\top & 0 \end{bmatrix}, \qquad A_2 = \begin{bmatrix} O & \mathbf{c} \\ \mathbf{d}^\top & 0 \end{bmatrix},$$

where only the last q elements of $\mathbf{b}$, $\mathbf{d}$ are nonzero. Since

$$[A_1, A_2] = \begin{bmatrix} \mathbf{a}\mathbf{c}^\top - \mathbf{d}\mathbf{b}^\top & \mathbf{0} \\ \mathbf{0}^\top & \mathbf{b}^\top\mathbf{d} - \mathbf{c}^\top\mathbf{a} \end{bmatrix},$$

it is evident that the computation of these commutators costs about $3q(n-1)$ operations, contributing a total of $\frac{3}{2}qn^2$ to the total cost (i.e., summing the contribution of similar terms over matrices of decreasing dimension). This is the cost of the commutators $[P,[P,K]],[P,[P,[P,[P,K]]]]$, etc. Finally, if $C_1, C_2 \in \mathfrak{k}$, with

$$C_1 = \begin{bmatrix} B_1 & \mathbf{0} \\ \mathbf{0}^\top & b_1 \end{bmatrix}, \qquad C_2 = \begin{bmatrix} B_2 & \mathbf{0} \\ \mathbf{0}^\top & b_2 \end{bmatrix},$$

with B_1, B_2 of dimension n, one has

$$[C_1, C_2] = \begin{bmatrix} [B_1, B_2] & \mathbf{0} \\ \mathbf{0}^\top & 0 \end{bmatrix}.$$

If only the last p (resp., r) columns of B_1, (resp., B_2) are nonzero, setting $r = \min\{p,q\}+1$, we deduce that the commutators $[C_1, C_2]$ cost about $6rn$ operations—an $\mathcal{O}\big(n^2\big)$ contribution when the count is carried over matrices of decreasing dimension.

Putting all the bricks together,

- Terms for order 2:

$$[P,K] \to \frac{1}{3}n^3.$$

- Order 3:

$$\begin{aligned} [K,[P,K]] &\to \frac{1}{3}n^3, \\ [P,[P,K]] &\to \mathcal{O}\big(n^2\big). \end{aligned}$$

- Order 4:

$$\begin{aligned} [P,[P,[P,K]]] &\to \mathcal{O}\big(n^2\big), \\ [K,[K,[P,K]]] &\to \frac{1}{3}n^3. \end{aligned}$$

- Order 5:

$$\begin{aligned} [K,[P,[P,[P,K]]]] &\to \frac{1}{3}n^3, \\ [K,[K,[K,[P,K]]]] &\to \frac{2}{3}n^3, \\ [[P,K],[P,[P,K]]] &\to \mathcal{O}\big(n^2\big), \\ [P,[P,[P,[P,K]]]] &\to \mathcal{O}\big(n^2\big), \\ [[P,K],[K,[P,K]]] &\to \mathcal{O}\big(n^2\big), \\ [K,[K,[P,[P,K]]]] &\to \mathcal{O}\big(n^2\big). \end{aligned}$$

In Table 4.1 we summarize the cost for the various stages of the exponential approximation of a generic matrix $Z \in \mathfrak{gl}(n)$ for orders $2, 3$, and 4 and compare our new algorithms with those proposed in [21]. For full matrices, it is evident that the benefits of our approach appear for orders greater than two. For order 4 the new

algorithm is almost 40% faster than the one without transformation to an upper-Hessenberg form.

4.2. Symplectic matrices. The symplectic group of matrices $\mathrm{Sp}(n)$ is the set of all invertible matrices M of dimension $2n$ such that $MJM^\top = J$ where J is as in (4.1). The symplectic algebra $\mathfrak{sp}(n)$ is the set of $2n \times 2n$ matrices such that $NJ = -JN^\top$.

A symplectic matrix $M \in \mathrm{Sp}(n)$ is said to be in a *butterfly form* if it can be written as

$$M = \begin{bmatrix} D_1 & B_1 \\ D_2 & B_2 \end{bmatrix},$$

where D_1, D_2 are $n \times n$ diagonal matrices and B_1, B_2 are $n \times n$ tridiagonal matrices. This butterfly form was considered by Benner et al. [1] as a starting point of a QR-type algorithm (the SR-algorithm) to compute the eigenvalues of a symplectic matrix so that the transformed matrix remains symplectic at each step.

The transformation of a given symplectic matrix to a butterfly form can be performed by the use of three different types of similarity mappings with the following

matrices:

- *Symplectic Givens transformations:*

$$G = \left[\begin{array}{cc|cc} I_{k-1} & & & \\ & c & & s \\ & & I_{n-k} & \\ \hline & & I_{k-1} & \\ & -s & & c \\ & & & & I_{n-k} \end{array}\right].$$

- *Symplectic Householder transformations:*

$$H = \left[\begin{array}{cc|cc} I_{k-1} & & & \\ & Q & & \\ \hline & & I_{k-1} & \\ & & & Q \end{array}\right], \quad Q = I_{n-k+1} - \beta \mathbf{v}\mathbf{v}^\top, \quad \beta = \frac{2}{\|\mathbf{v}\|^2}.$$

- *Symplectic Gauss transformations:*

$$L = \left[\begin{array}{ccc|ccc} I_{k-2} & & & & & \\ & c & & & d & \\ & & c & & & \\ & & & I_{n-k} & & \\ \hline & & & I_{k-2} & & \\ & & & & c^{-1} & \\ & & & & & c^{-1} \\ & & & & & & I_{n-k} \end{array}\right].$$

The following algorithm for reduction to a butterfly form is described in more detail in [4].

Given a $2n \times 2n$ symplectic matrix M, compute its reduction to a butterfly form. M will be overwritten by its butterfly form.

```
for j = 1 : n − 1
  for k = n : −1 : j + 1
    compute G_k such that (G_k M)_{k+n,j} = 0
    M = G_k M G_k^⊤
  end
  if j < n − 1 then
    compute H_j such that (H_j M)_{j+2:n,j} = 0
    M = H_j M H_j^⊤
  end
  compute L_{j+1} such that (L_{j+1} M)_{j+1,j} = 0
  M = L_{j+1} M L_{j+1}^{−1}
  for k = n : −1 : j + 1
    compute G_k such that (M G_k)_{j,k} = 0
    M = G_k^⊤ M G_k
  end
  if j < n − 1 then
    compute H_j such that (M H_j)_{j,j+2+n:2n} = 0
    M = H_j^⊤ M H_j
  end
end
```

The algorithm introduces zeros in the rows by applying one of the above-mentioned transformations from the right, while zeros in the columns are obtained by applying the transformations from the left. To maintain similarity, the inverse of each transformation is applied also on the other side. The basic idea of the algorithm is, at each step j, (i) to bring the jth column of M into the desired form; (ii) to bring the $(n+j)$th row of M into the desired form. For more details, see [4].

Clearly, symplectic transformations can also be used at the algebra level. Our idea is to reduce a symplectic matrix $A \in \mathfrak{sp}(n)$ to a butterfly form, using the same algorithm as above. Note that

$$A \in \mathfrak{sp}(n) \Leftrightarrow A = \begin{bmatrix} A_1 & A_2 \\ A_3 & -A_1^\top \end{bmatrix},$$

where A_1, A_2, A_3 are $n \times n$ matrices and A_2, A_3 are symmetric; therefore, a butterfly matrix $B \in \mathfrak{sp}(n)$ must be of the form

$$B = \begin{bmatrix} B_1 & B_2 \\ B_3 & -B_1^\top \end{bmatrix},$$

where B_1 and B_3 are now diagonal, and B_2 is tridiagonal and symmetric.

Assume next that $B \in \mathfrak{sp}(n)$ is in a butterfly form. To approximate $\exp(tB)$ we use again a peel-up approach. However, the matrices S_i need be appropriately modified to preserve the $\mathfrak{sp}(n)$ structure. Set

$$\tilde{S}_i = \operatorname{diag}(-1)^{\tilde{\mathbf{s}}_i}, \quad \tilde{\mathbf{s}}_i = [s_{i;1}, \dots, s_{i;n}, s_{i;1}, \dots, s_{i;n}]. \tag{4.2}$$

In other words, the $\tilde{S}_i$s can be taken as direct products $S_i \times S_i$ of the matrices S_i in (2.11), and they act in the same manner on the first and the second n rows and columns of the matrix B.

To have a mental picture of the splitting induced by the automorphisms $\mathrm{Ad}_{\tilde{S}_i}$, we set $i = n$ and obtain subspaces $\mathfrak{p}$ and $\mathfrak{k}$ with the sparsity structure

$$\mathfrak{p} \ni \begin{bmatrix} 0 & \cdots & 0 & \times & 0 & \cdots & 0 & \times \\ \vdots & & \vdots & \times & \vdots & & \vdots & \vdots \\ 0 & \cdots & 0 & \times & 0 & \cdots & 0 & \times \\ \times & \times & \times & 0 & \times & \times & \times & 0 \\ 0 & \cdots & 0 & \times & 0 & \cdots & 0 & \times \\ \vdots & & \vdots & \times & \vdots & & \vdots & \vdots \\ 0 & \cdots & 0 & \times & 0 & \cdots & 0 & \times \\ \times & \times & \times & 0 & \times & \times & \times & 0 \end{bmatrix}, \quad \mathfrak{k} \ni \begin{bmatrix} \times & \cdots & \times & 0 & \times & \cdots & \times & 0 \\ \vdots & & \vdots & 0 & \vdots & & \vdots & \vdots \\ \times & \cdots & \times & 0 & \times & \cdots & \times & 0 \\ 0 & 0 & 0 & \times & 0 & 0 & 0 & \times \\ \times & \cdots & \times & 0 & \times & \cdots & \times & 0 \\ \vdots & & \vdots & 0 & \vdots & & \vdots & \vdots \\ \times & \cdots & \times & 0 & \times & \cdots & \times & 0 \\ 0 & 0 & 0 & \times & 0 & 0 & 0 & \times \end{bmatrix},$$

respectively. Observe that the automorphism targets the $2n$th and nth rows and columns.

The sparsity pattern of the computed terms in the generation of $X(t)$ up to $\mathcal{O}(t^5)$ is displayed in Figure 4.3 below.

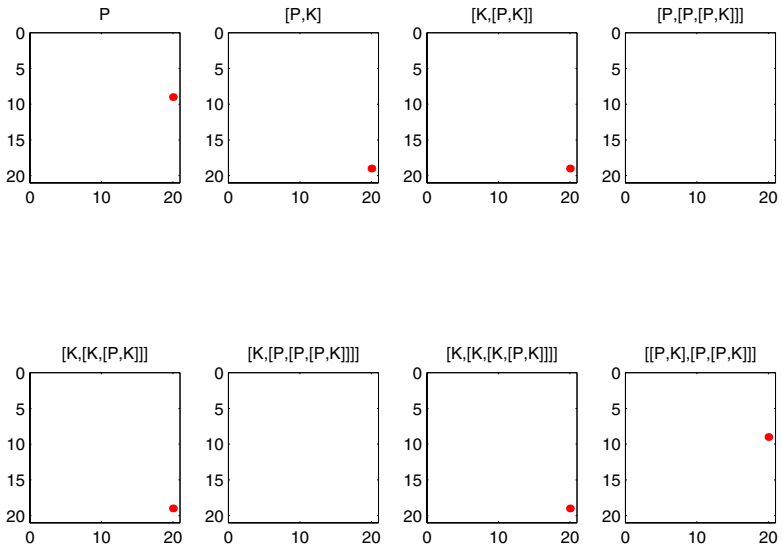

FIG. 4.3. *The sparsity pattern in the generation of* $X(t)$.

It is trivial to observe that $[P,[P,[P,K]]] = O$. This is not just a consequence of the reduction to a butterfly form, but of a more general result.

PROPOSITION 4.1. *Let* A *be a* $2n \times 2n$ *matrix, partitioned in* $n \times n$ *blocks, and assume that* A *is of the form*

$$\begin{bmatrix} O & A_{1,2} \\ O & O \end{bmatrix}.$$

Then, for any matrix $C \in M_{2n,2n}$, *it is true that*

$$[A,[A,[A,C]]] = O.$$

Proof. Let us partition the matrix C in blocks of the same size of those of A,

$$C = \begin{bmatrix} C_{1,1} & C_{1,2} \\ C_{2,1} & C_{2,2} \end{bmatrix}.$$

By direct computation, we observe that

$$[A,C] = \begin{bmatrix} D_{1,1} & D_{1,2} \\ O & D_{2,2} \end{bmatrix},$$

where $D_{1,1} = A_{1,2}C_{2,1}$, $D_{1,2} = A_{1,2}C_{2,2} - C_{1,1}A_{1,2}$, and $D_{2,2} = -C_{2,1}A_{1,2}$. Similarly,

$$[A,[A,C]] = \begin{bmatrix} O & F_{1,2} \\ O & O \end{bmatrix},$$

where $F_{1,2} = -2A_{1,2}C_{1,2}A_{1,2}$. Finally, it is immediate to check that $[A,[A,[A,C]]] = O$. ∎

Note that the lemma is valid in the more general case, when A is $n \times n$, $A1,2$ is $n_1 \times n_2$, and $n_1 + n_2 = n$. The (trivial) extension of the proof is left to the reader.

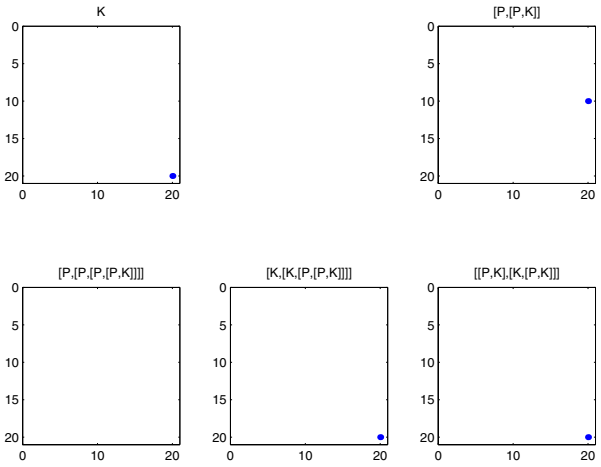

FIG. 4.4. *Commutators in the expansion of* $Y(t)$.

The terms required for the generation of $Y(t)$ are displayed in Figure 4.4 and the superposition of Y_5 (darker shade) and X_5 (lighter shade) is displayed in Figure 4.5 (for convenience, we have plotted X_5 with $\times$).

In Figure 4.5 we observe that no fill-in is introduced at least up to order 6. This is most welcome news because we do not need to use extra computation to annihilate further entries.

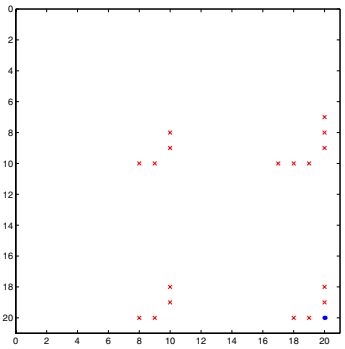

FIG. 4.5. *Superposition of* X_5 *(crosses) and* Y_5 *(dots). No fill-in is introduced in the* $\mathfrak{k}$ *subalgebra.*

4.3. The cost of reduction to a butterfly form. Assume that we have already partially reduced the matrix M to a butterfly form, where the blocks L_k, M_k, N_k have dimension k and N_k, M_k are symmetric (see Figure 4.6). To set to zero the terms in the leading column of N_k we apply symplectic Givens rotations from the left. Each of these rotations requires about $6k$ operations (multiplications and additions) for the update of L_k, M_k, and $3k$ operations for the update of N_k, for a total of $9k$ operations. When we apply their transpose from the right, we can take into account the symmetry of the $(1,2)$ and $(2,1)$ blocks, so that only L_k needs be updated, hence

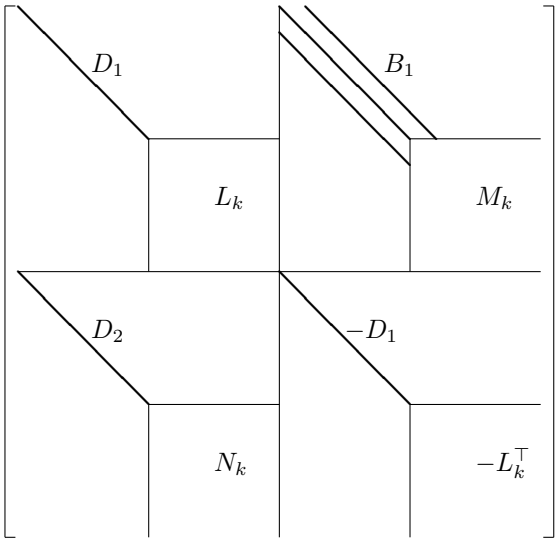

FIG. 4.6. *A matrix in* $\mathfrak{sp}(n)$ *partially reduced to a butterfly form.*

further $6k$ operations, for a total of $15k$ operations. A similar count holds for the Givens rotations that are applied to annihilate the top-row elements of L_k, hence *in toto* Givens rotations account for $30k$. Since for each column/row there are k of those Givens rotation, for matrices of decreasing dimension, neglecting lower order terms we have

$$\text{total cost of Givens rotations} \approx 30 \sum_{k=1}^{n} k^2 \approx 10n^3.$$

The application of Householder symplectic reflections reduces to the application of standard Householder to the blocks L_k, M_k, N_k, and costs $3\frac{1}{3}n^3$, n^3, and n^3, respectively, since the two latter blocks are symmetric. We need to apply two sets of such Householder reflections for a total of

$$\text{total cost of Householder reflections} \approx 10\frac{2}{3}n^3 \text{ operations.}$$

Since the cost of Gauss transformations is of a lower order of magnitude, the total cost of reduction to a butterfly form is

$$20\frac{2}{3}n^3 \text{ operations,}$$

which is not really prohibitive, given that the matrix has dimension $2n$.

5. A divide-and-conquer strategy. In what follows, we shall introduce an alternative approach that can be particularly useful in the context of very large n and parallel computing. The main idea is to choose an automorphism Ad_S so that the matrix Y_p is reducible, hence the exponential of each submatrix can be computed separately and possibly in parallel.

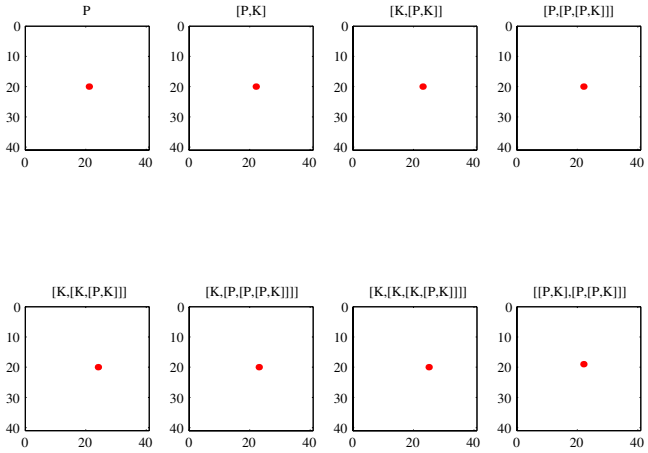

FIG. 5.1. *Sparsity pattern of matrices in* $\mathfrak{p}$ *in the divide-and-conquer approach for skew-symmetric matrices.*

5.1. Skew-symmetric matrices. We again commence our exposition with $Z \in \mathfrak{so}(n)$ and assume that it is already in tridiagonal form. Our point of departure is to consider an inner automorphism Ad_G where

$$G = \begin{bmatrix} I_{n_1 \times n_1} & O_{n_1 \times n_2} \\ O_{n_2 \times n_1} & -I_{n_2 \times n_2} \end{bmatrix},$$

where $n_1 + n_2 = n$: an obvious choice is $n_1 = \lfloor n/2 \rfloor$, however, other choices are possible, e.g., the index corresponding to the least off-diagonal element. Then,

$$\mathfrak{k} \ni \begin{bmatrix} K^{(1)}_{n_1 \times n_1} & O_{n_1 \times n_2} \\ O_{n_2 \times n_1} & K^{(2)}_{n_2 \times n_2} \end{bmatrix}, \qquad \mathfrak{p} \ni \begin{bmatrix} O_{n_1 \times n_1} & P^{(1)}_{n_1 \times n_2} \\ P^{(2)}_{n_2 \times n_1} & O_{n_2 \times n_2} \end{bmatrix}.$$

Therefore,

$$K = \begin{bmatrix} K_1 & O \\ O & K_2 \end{bmatrix}, \qquad P = \begin{bmatrix} O & P_1 \\ P_2 & O \end{bmatrix}.$$

We stress that both K_1 and K_2 are tridiagonal while P_1 and P_2 have a single nonzero entry, in the lower left and upper right corner, respectively. We write $P_1 = c_1 \mathbf{e}_{n_1,n_1} \mathbf{e}^\top_{n_2,1}$, $P_2 = c_2 \mathbf{e}_{n_2,1} \mathbf{e}^\top_{n_1,n_1}$, where $\mathbf{e}_{m,k} \in \mathbb{R}^m$ is the kth unit vector.

In Figures 5.1 and 5.2 we display the sparsity pattern of elements in $\mathfrak{p}$ and in $\mathfrak{k}$, respectively, while in Figure 5.3 the matrices X and Y for different orders are superposed (truncations of X are denoted in lighter shade, while the darker shade corresponds to truncations of Y).

The following observations form the basis for an efficient divide-and-conquer algorithm to compute the exponential function in $\mathfrak{so}(n)$:

- All the commutators, hence also X and Y (up to the requisite order), can be evaluated in $\mathcal{O}(1)$ flops.

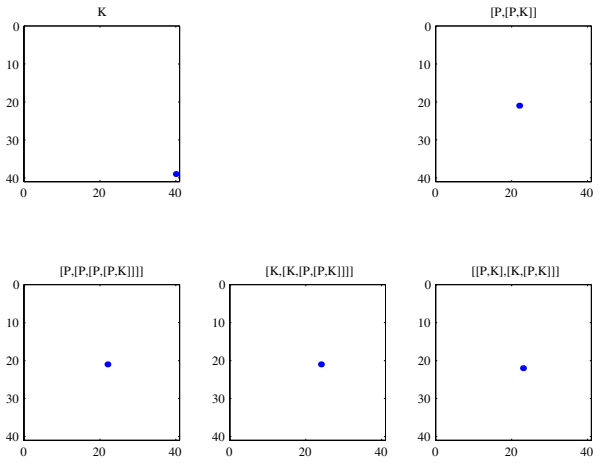

FIG. 5.2. *Sparsity pattern of matrices in* $\mathfrak{k}$ *in the divide-and-conquer approach for skew-symmetric matrices.*

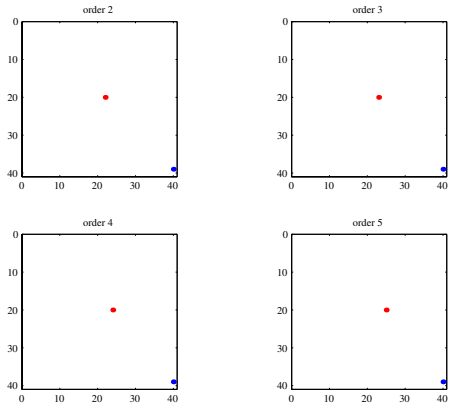

FIG. 5.3. *Superposition of truncations of* $X(t)$ *(lighter shade) and* $Y(t)$ *(darker shade) of order* $2, 3, 4, 5$ *in the divide-and-conquer approach for skew-symmetric matrices.*

- The exact exponential of X reduces to that of a small matrix, hence can be evaluated in $\mathcal{O}(1)$ flops.
- Y is a reducible matrix.
- The departure of Y from tridiagonal can be corrected in a small number of Givens rotations. Because of reducibility, we can act *separately* on each of the two components, hence the outcome is two tridiagonal matrices of size $n_1 \times n_1$ and $n_2 \times n_2$, respectively. Again, the cost is $\mathcal{O}(1)$ flops.

We can now continue with the two pieces of Y in a similar vain, splitting them into progressively smaller pieces. All this is similar to many familiar techniques in numerical linear algebra, not least domain decomposition. Altogether, we require

$\log_2 n$ stages to parcel out the exponential of a tridiagonal $Z \in \mathfrak{so}(n)$ into a product of rank-2 orthogonal matrices, although in practice this divide-and-conquer technique can terminate with matrices of higher rank.

5.2. General matrices. Let $Z \in \mathfrak{gl}(n)$ or $\mathfrak{sl}(n)$ and suppose that we have already brought it to an upper-Hessenberg form. Proceeding as before, P_1 is a dense matrix, while $P_2 = c\mathbf{e}_{n_2,1}\mathbf{e}_{n_1,n_1}^\top$.

Again, we can always bring Y into an upper-Hessenberg form in $\mathcal{O}(1)$ Givens rotations. More interesting is the evaluation of $\exp X$. Note that

$$X = \begin{bmatrix} O & X_1 \\ X_2 & O \end{bmatrix},$$

where X_1 is $n_1 \times n_2$ and dense, while X_2 is $n_2 \times n_1$ and zero except for a $q \times q$ block in the upper right corner, where $q \geq 1$. Let

$$V = X_1 X_2, \qquad W = X_2 X_1.$$

Then

$$X^{2m} = \begin{bmatrix} V^m & O \\ O & W^m \end{bmatrix}, \qquad X^{2m+1} = \begin{bmatrix} V^m & O \\ O & W^m \end{bmatrix} \begin{bmatrix} O & X_1 \\ X_2 & O \end{bmatrix}, \quad m \in \mathbb{Z}_+,$$

therefore,

$$\exp(X) = \begin{bmatrix} C(V) & S(V)X_1 \\ S(W)X_2 & C(W) \end{bmatrix},$$

where

$$C(Z) = \sum_{m=0}^{\infty} \frac{Z^m}{(2m)!} = \cosh Z^{1/2}, \qquad S(Z) = \sum_{m=0}^{\infty} \frac{Z^m}{(2m+1)!} = \sinh Z^{1/2}.$$

We write X_1 and X_2 in a compound form,

$$X_1 = \begin{bmatrix} T_{1,1} & T_{1,2} \\ T_{2,1} & T_{2,2} \end{bmatrix}, \qquad X_2 = \begin{bmatrix} O & R \\ O & O \end{bmatrix},$$

where

$$T_{1,1} \in \mathrm{M}_{(n_1-p)\times p}, \quad T_{1,2} \in \mathrm{M}_{(n_1-p)\times(n_2-p)}, \quad T_{2,1} \in \mathrm{M}_{p\times p}, \quad T_{2,2} \in \mathrm{M}_{p\times(n_2-p)}$$

and $R \in \mathrm{M}_{p\times p}$, where $\mathrm{M}_{n\times m}$ denotes the set of $n \times m$ matrices. Therefore,

$$V = \begin{bmatrix} O & V_1 \\ O & V_2 \end{bmatrix}, \qquad W = \begin{bmatrix} W_1 & W_2 \\ O & O \end{bmatrix},$$

where

$$\begin{aligned} V_1 &= T_{1,1}R \in \mathrm{M}_{(n_1-p)\times p}, \qquad V_2 = T_{2,1}R \in \mathrm{M}_{p\times p}, \\ W_1 &= RT_{2,1} \in \mathrm{M}_{p\times p}, \qquad W_2 = RT_{2,2} \in \mathrm{M}_{p\times(n_2-p)}. \end{aligned}$$

In particular, note that $V_2, W_1 \in \mathrm{M}_{p\times p}$, hence they are square and *small!*
We can easily prove by induction that

$$V^m = \begin{bmatrix} O & V_1 V_2^{m-1} \\ O & V_2^m \end{bmatrix}, \qquad W^m = \begin{bmatrix} W_1^m & W_1^{m-1} W_2 \\ O & O \end{bmatrix}, \quad m \in \mathbb{Z}.$$

Therefore, simple calculation affirms that

$$\begin{aligned} C(V) &= \begin{bmatrix} I & V_1 V_2^{-1}[C(V_2) - I] \\ O & C(V_2) \end{bmatrix}, \\ C(W) &= \begin{bmatrix} C(W_1) & [C(W_1) - I] W_1^{-1} W_2 \\ O & I \end{bmatrix}, \\ S(V)X_1 &= \begin{bmatrix} I & V_1[S(V_2) - I]V_2^{-1} \\ O & S(V_2) \end{bmatrix} \begin{bmatrix} T_{1,1} & T_{1,2} \\ T_{2,1} & T_{2,2} \end{bmatrix}, \\ S(W)X_2 &= \begin{bmatrix} O & S(W_1)R \\ O & O \end{bmatrix}. \end{aligned}$$

Given that $p \ll n_1, n_2$ and $n_1 + n_2 = n$, we have the following cost (disregarding lower order terms),

1. Computing $C(V)$: $n_1 p^2$ flops;
2. Computing $C(W)$: $n_2 p^2$ flops;
3. Computing $S(V)$: $n_1 p^2$ flops;
4. Multiplying $S(V)X_1$: $n_1 n_2 p + n p^2$;
5. Computing $S(W)X_2$: p^3 flops.[1]

Hence, altogether the cost is $n_1 n_2 p$: if $n_1 = n_2 = n/2$ then the entire cost of computing the exponential *exactly* is just $\frac{1}{4} n^2 p$.

Suppose that $n = 2^s$ and $n_1 = n_2 = 2^{s-1}$, whence the cost is $\approx p 2^{2s-2}$. Moreover, we continue with the divide-and-conquer technique. In the next stage we have two $2^{s-1} \times 2^{s-1}$ matrices, then four $2^{s-2} \times 2^{s-2}$ matrices and so on. The entire cost of computing all the exponentials then becomes

$$p \sum_{r=1}^{s} 2^{2s-r-1} = \frac{1}{2} pn(n-1) \approx \frac{1}{2} pn^2.$$

The above is true on a serial machine. If the calculations for different pieces of the matrix are performed in parallel, we have instead just a single $2^{s+1-r} \times 2^{s+1-r}$ matrix to deal with in the rth stage and the overall cost is

$$p \sum_{r=1}^{s} 2^{s+1-r} \approx 2p(n-1).$$

5.3. The cost of computing commutators. Assume that P and K are as in Figures 5.4 and 5.5,

$$P = \begin{bmatrix} O & P_1 \\ P_2 & O \end{bmatrix}, \qquad K = \begin{bmatrix} K_1 & O \\ O & K_2 \end{bmatrix}, \tag{5.1}$$

[1] Note that we do not need to compute $S(W)$ first—only $S(W_1)$.

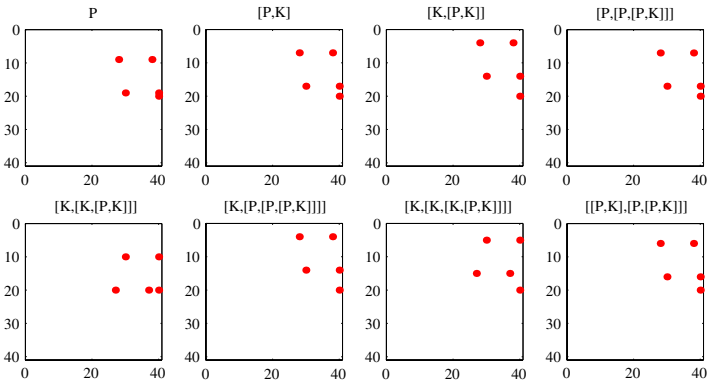

FIG. 5.4. *Sparsity structure for the first terms in* $\mathfrak{p}$ *in the divide-and-conquer approach (upper Hessenberg matrices).*

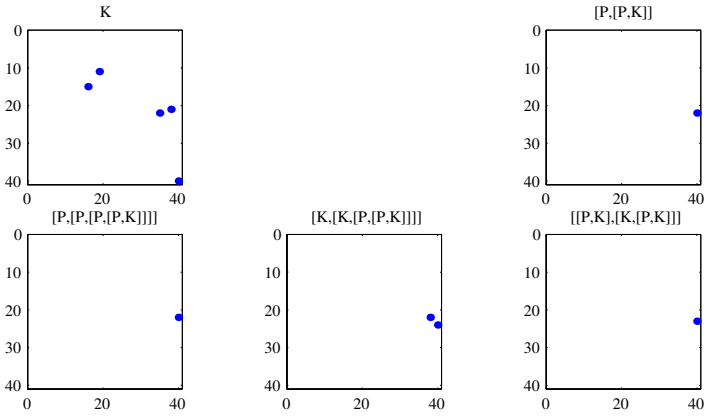

FIG. 5.5. *Sparsity structure for the first terms in* $\mathfrak{k}$ *in the divide-and-conquer approach (upper Hessenberg matrices).*

where the blocks P_i and K_i have dimension k. Note that

$$\begin{aligned}\left[\begin{bmatrix} O & P_1 \\ P_2 & O \end{bmatrix}, \begin{bmatrix} O & R_1 \\ R_2 & O \end{bmatrix}\right] &= \begin{bmatrix} O & P_1R_2 - R_1P_2 \\ P_2R_1 - R_2P_1 & O \end{bmatrix}, \\ \left[\begin{bmatrix} O & P_1 \\ P_2 & O \end{bmatrix}, \begin{bmatrix} K_1 & O \\ O & K_2 \end{bmatrix}\right] &= \begin{bmatrix} O & P_1K_2 - K_1P_1 \\ P_2K_1 - K_2P_1 & O \end{bmatrix}.\end{aligned} \tag{5.2}$$

From (5.2) we conclude that the most expensive commutators are those of the form $[P, K]$, for which we need to compute $P_1K_2 - K_1P_1$, amounting to about $2k^3$ operations (counting addition and multiplication). All the remaining commutators are of lower complexity, which we ignore. For a splitting of order 5 (as depicted in Figure 5.6), we need to compute seven such commutators, amounting to $14k^3$. Next, assume that $k = 2^s$ and that there are $2^{\log_2 n - s}$ such blocks. For order five, the total cost of

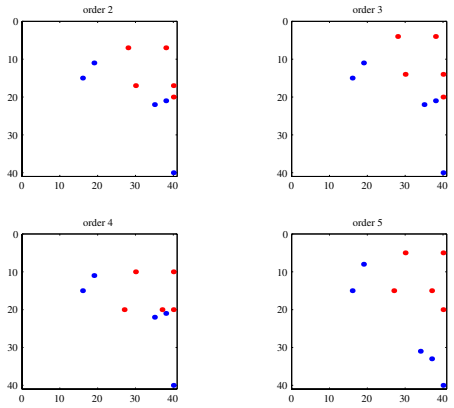

FIG. 5.6. *A superposition of X_5 and Y_5 in the divide-and-conquer approach (upper Hessenberg matrices).*

commutators (disregarding lower order terms) amounts to

$$14n \sum_{s=1}^{\log_2 n} 2^{2s} \approx 5n^3$$

operations on a serial machine. When implementing this in parallel on $\log_2 n$ processors (that is, when the commutators of blocks of dimension 2^s are evaluated simultaneously), the cost reduces to

$$14 \sum_{s=1}^{\log_2 n} 2^{3s} \approx 2n^3.$$

6. Other groups. In this section we discuss briefly GPD for a number of more unusual Lie groups which, nonetheless, feature in applications.

6.1. Lorentz-type groups SO(p, q). Let

$$J = \begin{pmatrix} I_p & O \\ O & -I_q \end{pmatrix},$$

and consider the group $\mathrm{SO}(p,q) = \{x : xJx^\top = J\}$. As is well known, the corresponding algebra is $\mathfrak{so}(p,q) = \{Z : ZJ = -JZ^\top\}$. The block form of Z is

$$Z = \begin{pmatrix} Z_1 & Z_2 \\ Z_2^\top & Z_3 \end{pmatrix},$$

where Z_1 and Z_3 are skew-symmetric. The most widespread Lorentz-type groups in applications are $\mathrm{SO}(3,1)$ and $\mathrm{SO}(5,2)$, for which it is not too costly to compute the exponential exactly given the low dimension. Algorithms for computing the exact exponential of these matrices have been proposed in [13].

In what follows, we focus instead on the less ordinary case when $p + q = n$ is large, yet $p \ll q$. The basic idea consists of splitting

$$Z = \begin{pmatrix} O & Z_2 \\ Z_2^\top & O \end{pmatrix} + \begin{pmatrix} Z_1 & O \\ O^\top & Z_3 \end{pmatrix} = P + K$$

so that the problem is reduced to computing the exponential of skew-symmetric matrices and that of a (symmetric) bordered matrix.

The only issue that can cause complications is the computation of commutators with P, K (especially if we desire high order). To do this in a cheaper manner, we consider the matrix

$$H = \begin{pmatrix} I & O \\ O^\top & H_2 \end{pmatrix},$$

where H_2 is the matrix that QR factorizes P (a product of p elementary Householder reflections). Computing commutators with P (ad_P) now costs $2p^2q$. Commutators with K are more expensive—at present we do not see how this can be avoided but perhaps one can exploit skew symmetry.

However, these order conditions are used only once. Once we have split into the symmetric and skew-symmetric parts, the problem reduces to the approximation of exponentials of skew-symmetric matrices, which has been described at length earlier in this paper.

6.2. Isotropy groups. In this section we consider the computation of the exponential in isotropy groups. Recall that the (left) isotropy group G_V at $V \in \mathrm{M}_{n\times m}$ is the group of matrices x that leaves V fixed under left multiplication,

$$G_V = \{x \in \mathrm{GL}(n) : xV = V\}$$

(see, for instance, [17]). The corresponding algebra can be easily computed,

$$\mathfrak{g}_V = \{X \in \mathfrak{gl}(n) : XV = V\}.$$

Let us assume that $m \le n$ and that V has rank m (if V has rank less then m then it is possible to ignore some of its columns so that the resulting matrix has full rank). In that case, the problem essentially reduces to the isotropy group (isomorphic to G_V)

$$G_{\tilde R} = \{y : y\tilde R = \tilde R\}, \quad \tilde R = \begin{bmatrix} R \\ O \end{bmatrix},$$

where R is $m \times m$ upper triangular and $G_{\tilde R} = Q^\top G_V Q$, Q being the orthogonal matrix that performs the QR factorization of V, i.e., $V = Q\tilde R$. In what follows, we abuse notation and write G_R instead of $G_{\tilde R}$, hoping that this does not cause confusion of types.

Let us study in greater detail the elements of G_R. Assume that

$$y = \begin{bmatrix} y_{1,1} & y_{1,2} \\ y_{2,1} & y_{2,2} \end{bmatrix},$$

where $y_{1,1}$ is $m \times m$, $y_{1,2}$ and $y_{2,1}^\top$ are $m \times (n-m)$, and $y_{2,2}$ is $(n-m) \times (n-m)$. Imposing $y\tilde R = \tilde R$ we obtain the following conditions:

$$\begin{aligned} y_{1,1}R = R \quad &\Rightarrow \quad y_{1,1} = I_{m\times m} \\ y_{2,1}R = O_{(n-m)\times m} \quad &\Rightarrow \quad y_{2,1} = O_{(n-m)\times m} \\ y_{1,2}, y_{2,2} \quad &\text{arbitrary} \end{aligned}$$

(recall that R has full rank, hence it is invertible).

Correspondingly, at the algebra level, we set

$$Y = \begin{bmatrix} Y_{1,1} & Y_{1,2} \\ Y_{2,1} & Y_{2,2} \end{bmatrix},$$

which, in tandem with the algebra conditions, implies

$$\begin{aligned} Y_{1,1} &= O_{m\times m}, \\ Y_{2,1} &= O_{(n-m)\times m}, \\ Y_{1,2}, Y_{2,2} &\quad \text{arbitrary.} \end{aligned}$$

Note that $Y_{1,2}$, $Y_{2,2}$ can be considered as free parameters. Although their action does not change $\tilde{R}$, they do move points around $\tilde{R}$. As a possible application, in [14] isotropy at a point is used to improve retention of qualitative features by numerical integrators for ODEs.

The exponential of Y can be evaluated exactly by the formula

$$\exp(tY) = \begin{bmatrix} I_{m\times m} & Y_{1,2}\phi(Y_{2,2}) \\ O & \exp(tY_{2,2}) \end{bmatrix},$$

where

$$\phi(Z) = Z^{-1}[\exp(Z) - I] = \sum_{k=0}^{\infty} \frac{1}{(k+1)!} Z^k.$$

Thus, the problem reduces to computing the exponential of $Y_{2,2}$, which is of dimension $(n-m)$. Now, $Y_{2,2}$ can be reduced to Hessenberg form and its exponential computed as in the general $\mathrm{GL}(n)$ case.

6.3. Scaling groups. We commence as in the case of the isotropy groups. A one-parameter curve in the scaling group G_V^{sc} of $V = (\mathbf{v}_1, \dots, \mathbf{v}_m) \in \mathbb{R}^{n\times m}$,

$$G_V^{\mathrm{sc}} = \{x : \exists \lambda_1, \lambda_2, \dots, \lambda_m \text{ such that } x\mathbf{v}_i = \lambda_i \mathbf{v}_i,\ i = 1, \dots, m\},$$

satisfies

$$x(t)V = V\Lambda(t),$$

where $\Lambda(t)$ is a smooth diagonal matrix function [17]. Again, performing a QR decomposition of V, we find that G_V^{sc} is isomorphic to $Q^\top G_V^{\mathrm{sc}} Q = G_{\tilde{R}}^{\mathrm{sc}}$, the scaling group of the upper triangular matrix $\tilde{R}$, where $Q\tilde{R} = V$.

At the algebra level $\mathfrak{g}_R^{\mathrm{sc}}$, we set

$$Y = \begin{bmatrix} Y_{1,1} & Y_{1,2} \\ Y_{2,1} & Y_{2,2} \end{bmatrix},$$

which, in tandem with the algebra condition

$$Y\tilde{R} = \tilde{R}\Lambda'(t)$$

implies that

$$\begin{aligned} Y_{1,1} &= R\Lambda'(t)R^{-1}, \\ Y_{2,1} &= O_{(n-m)\times m}, \\ Y_{1,2}, Y_{2,2} &\quad \text{arbitrary.} \end{aligned}$$

Again, $Y_{1,2}, Y_{2,2}$ can be considered as free parameters: their action does not move/scale $\tilde{R}$ but only the points in its neighborhood. It is also useful to note that $Y_{1,1}$ is upper triangular.

Thus, the problem reduces to computing exponentials of block-upper triangular matrices of the form

$$Y = \begin{bmatrix} Y_{1,1} & Y_{1,2} \\ O & Y_{2,2} \end{bmatrix},$$

where $Y_{1,1}$ is upper triangular.

In general, the exponential of a block triangular matrix can be evaluated exactly by the formula

$$\exp\left(t \begin{bmatrix} A & B \\ O & C \end{bmatrix}\right) = \begin{bmatrix} \exp(tA) & \int_0^t \mathrm{e}^{(t-\tau)A} B \mathrm{e}^{\tau C} \mathrm{d}\tau \\ 0 & \exp(tC) \end{bmatrix}, \tag{6.1}$$

however, the integral might be a difficult to compute exactly. It could be approximated by quadrature formulae, but this will require the computation of roots of matrices, adding an extra layer of complexity.

We could again use the *divide-and-conquer* approach, split

$$Y = K + P, \quad K = \begin{bmatrix} Y_{1,1} & O \\ O & Y_{2,2} \end{bmatrix}, \quad P = \begin{bmatrix} O & Y_{2,1} \\ O & O \end{bmatrix}.$$

It can be observed that Y is block upper triangular and so are K and P. Since triangular (and block triangular) matrices form subalgebras, $\mathfrak{k}$ and $\mathfrak{p}$ also consist of block triangular matrices (in other words, the lower (2,1) block never fills in the $\mathfrak{p}$ part).

Now,

$$[P, K] = \begin{bmatrix} O & Y_{1,2}Y_{2,2} - Y_{1,1}Y_{1,2} \\ O & O \end{bmatrix},$$

moreover, if $P_1, P_2 \in \mathfrak{p}$, it is easily verified that

$$O = [P_1, P_2] \in \mathfrak{k}.$$

In other words, K *does not need any order corrections* and the only nonzero commutators are those of the form

$$[K, [K, [\ldots, [K, [P, K]]]]]$$

in the $\mathfrak{p}$ part.

Moreover, observe that

$$\begin{bmatrix} O & B \\ O & O \end{bmatrix}^2 = O,$$

therefore,

$$\exp(t\tilde{P}) = I + t\tilde{P}, \quad \tilde{P} \in \mathfrak{p},$$

while, for matrix $\tilde{K} = \left[\begin{smallmatrix} A & O \\ O & C \end{smallmatrix}\right] \in \mathfrak{k}$, one has

$$\exp(t\tilde{K}) = \begin{bmatrix} \exp(tA) & O \\ O & \exp(tC) \end{bmatrix}.$$

An alternative is to expand the integral in (6.1) in Taylor series and truncate to appropriate order.

Appendix A. Herewith, we report the coefficients for the commutators in (3.16).

NUMERICAL ANALYSIS OF STOCHASTIC SCHEMES IN GEOPHYSICS*

BRIAN D. EWALD† AND ROGER TÉMAM‡

Abstract. We present and study the stability, convergence, and order of convergence of a numerical scheme used in geophysics, namely, the stochastic version of a deterministic "implicit leapfrog" scheme which has been developed for the approximation of the so-called barotropic vorticity model. Two other schemes which might be useful in the context of geophysical applications are also introduced and discussed.

Key words. numerical methods, stochastic differential equations, leapfrog scheme, Adams–Bashforth scheme, geophysical fluid dynamics

1. Introduction.

Much effort has been invested in studying numerical schemes for stochastic differential equations of the form

$$dU_t = a(U_t)\,dt + b(U_t)\,dW_t, \tag{1.1}$$

where $U_t \in \mathbb{R}^d$, a is a function from $\mathbb{R}^d$ into itself, W is a Wiener process on $\mathbb{R}^m$, and b is a function from $\mathbb{R}^d$ into $\mathbb{R}^{d\times m}$.

For the so-called weak approximation of (1.1), in which the approximation of the expectation of functions of U is considered, extensive work is due, for example, to Talay and his collaborators, work relying on probabilistic methods more involved than those used in this article (see, e.g., [1], [2], [12] and the references therein).

The question of strong approximation of (1.1), in which the approximation of sample paths of U is desired, has also been much studied. Mil'shtein, in [8], introduced the scheme

$$\begin{aligned} U_{n+1}^k = U_n^k &+ \sum_{j=1}^{d} b^{k,j}(U_n)\Delta W_n^j + a^k(U_n)\Delta t \\ &+ \sum_{j_1,j_2,\ell=1}^{d} b^{\ell,j_1}(U_n)\frac{\partial b^{k,j_2}}{\partial x^\ell}(U_n)\int_{t_n}^{t_{n+1}} (W_s^{j_1} - W_{t_n}^{j_1})\,dW_s^{j_2}, \end{aligned} \tag{1.2}$$

which converges to U to the order of Δt in mean-square error. His method involved the consideration of a functional analytic Taylor series for the infinitesimal generator of a semigroup corresponding to U and W. Rümelin later investigated a stochastic analogue of Runge–Kutta (RK) schemes in [10], in which he compared them to Mil'shtein's scheme. The RK schemes which he derives can be arranged to converge

to U when the stochastic integral is interpreted in the sense of Itô, Stratonovich, or in fact for any stochastic calculus whatsoever. However, the issue of the accuracy of these RK schemes (which is not the same as in the deterministic case) is not fully addressed in [10] and is mostly unresolved. In fact, there are indications that these stochastic RK schemes are of significantly lower orders of accuracy than their deterministic counterparts (see [3]).

The book by Kloeden and Platen [6] and the companion volume by Kloeden, Platen, and Schurz [7] offer a systematic investigation of numerical schemes for (1.1) in both the sense of Itô and of Stratonovich, the two stochastic calculi which in applications are by far the most useful. Their methods are analytic and are applicable to proving the convergence of a wide range of numerical schemes, and they derive a very general scheme (formula (12.6.2) of [6]) which, for various choices of parameters, includes stochastic analogues of such deterministic schemes as the explicit and implicit Euler schemes, the Crank–Nicholson scheme, and the leapfrog scheme.

In the geophysics community, an enormous amount of work has been spent in developing large, complex numerical models of the oceans and atmosphere. The questions therefore arise: Is it possible to add stochastic numerical noise to these already existing models in such a way that it is known to what the scheme converges (e.g., to the Itô or Stratonovich solution of some stochastic differential equation), to what order they may be expected to converge, etc.? While we certainly do not answer these complex questions here, we consider a simple "implicit leapfrog" scheme for a barotropic model (supplied to us by Cecile Penland and Prashant Sardeshmukh) and demonstrate one way of adding stochastic noise to it so that these questions can be answered for the resulting stochastic scheme (section 4).

This scheme and the scheme in section 5 have been applied in investigating El Niño (see [4]). In this paper, the schemes were used for the numerical timestepping to determine if a linear inverse model of El Niño (see [9]) can be reconciled with the observed skew toward warm events in the Pacific. It was found that the observed skew is well within the range predicted by the model, although the observed trend is not.

We also propose a stochastic analogue for the deterministic Adams–Bashforth scheme, using methods similar to those of [6], as an attempt to produce alternate schemes which are higher order in time (studied in section 3, following the preliminary results in section 2).

Last, we examine the derivatives of a and b which occur naturally in the above schemes, and which can prove to be troublesome in certain applications in which these functions, especially b, are given by physical parametrizations (i.e., by "tables") and not by analytic expressions. We consider how these derivatives can be replaced by finite differences derived from space-discretization while still maintaining the existing rate of convergence (section 5).

We realize that the results of this article, while very useful in our opinion, are just some small contribution to an outstanding problem, namely, the numerical analysis of stochastic differential equations which raise—with more difficulty—the same issues as in the deterministic case: consistency, convergence, and accuracy. All of these issues—partly due to the form of the stochastic Taylor formula—are considerably more difficult than in the deterministic case; in particular, consistency includes here the issue of the type of stochastic calculus (Itô, Stratonovich, or otherwise) to which the scheme converges.

In the case of the geoscience scheme, the scheme that we study in section 4 is the closest we could get, at this time, to a scheme actually used in the geo-

sciences, without any prior information on its consistency, convergence, and accuracy properties. The version of the Adams–Bashforth scheme studied in section 3 has given very good numerical results in simulations for simple (one-dimensional) stochastic differential equations; see section 6 and forthcoming articles. The numerical example in section 6 is actually based on a mistake: one of the stochastic processes involved in the scheme was mistakenly believed to be (and treated as) a Gaussian process; this did not affect the accuracy of the scheme, which remains at order two as predicted by the theory. This raises perhaps an interesting probabilistic problem about the approximation of certain non-Gaussian processes used in numerical schemes. Another issue of probabilistic nature is raised by the Adams–Bashforth-type scheme studied in section 3: in several or in high dimensions, a large number of stochastic processes need to be simulated, which could make the cost prohibitive. It is not excluded that future probabilistic developments will improve this situation. In particular, the first author, using some ideas of Gaines and Lyons [5], is trying at this time to develop methods of generating the needed stochastic increments.

As we have said, there are, of course, a great many mathematical difficulties which this paper does not address. However, methods involving stochastic noise are already in common use in numerical simulations for the geosciences and turbulence (and, no doubt, many other areas in science). As mathematicians, we can attempt to help these scientists develop the necessary numerical tools, or watch as they do it themselves.

2. Preliminary results. We consider a stochastic differential equation

$$dU_t = a(t, U_t)dt + b(t, U_t)dW_t \tag{2.1}$$

for $U = (u_1, \dots, u_d) \in \mathbb{R}^d$, where $a : \mathbb{R}^+ \times \mathbb{R}^d \to \mathbb{R}^d$, $b : \mathbb{R}^+ \times \mathbb{R}^d \to \mathbb{R}^{d\times m}$, and W is a Wiener process in $\mathbb{R}^m$ adapted to a filtration $\{\mathcal{F}_t\}_{t\geq 0}$.

We then have the Itô formula, which states that if $F : \mathbb{R}^+ \times \mathbb{R}^d \to \mathbb{R}^{\hat{d}}$, then $F_t = F(t, U_t)$ satisfies the stochastic differential equation

$$dF_t = \left[\frac{\partial F}{\partial t} + a^k(F_t)\frac{\partial F}{\partial u^k} + \frac{1}{2}b^{ij}(F_t)b^{kj}(F_t)\frac{\partial^2 F}{\partial u^i \partial u^k}\right]dt + b^{ij}(F_t)\frac{\partial F}{\partial u^i}dW_t^j; \tag{2.2}$$

here we use the Einstein convention for repeated indices.

We use the following notation from [6]: We call a row vector $\alpha = (j_1, j_2, \dots, j_l)$, where each $j_i \in \{0, 1, \dots, m\}$, a multi-index of length $l = \ell(\alpha) \in \{1, 2, \dots\}$. We also use ν to denote the multi-index of length 0, i.e., $\ell(\nu) = 0$. We define $n(\alpha)$ to be the number of entries of α which are 0. For adapted, right-continuous functions f, and stopping times ρ, τ such that $0 \leq \rho \leq \tau \leq T$ almost surely, we define

$$I_\alpha[f(\cdot)]_{\rho,\tau} = \begin{cases} f(\tau) & \text{if } \ell(\alpha) = 0, \\ \int_\rho^\tau I_{\alpha-}[f(\cdot)]_{\rho,s}\, ds & \text{if } \ell(\alpha) \geq 1,\ j_{\ell(\alpha)} = 0, \\ \int_p^\tau I_{\alpha-}[f(\cdot)]_{\rho,s}\, dW_s^{j_{\ell(\alpha)}} & \text{if } \ell(\alpha) \geq 1,\ j_{\ell(\alpha)} \neq 0. \end{cases} \tag{2.3}$$

Here $\alpha-$ is α with its final component removed.

We define the spaces $\mathcal{H}_\alpha$ as follows.

First, $\mathcal{H}_\nu$ is the space of adapted right-continuous stochastic processes f with left limits such that $|f(t)|$ is almost surely finite for each $t \geq 0$. Next, $\mathcal{H}_{(0)}$ contains those elements of $\mathcal{H}_\nu$ such that

$$\int_0^t |f(s)|\, ds < \infty \tag{2.4}$$

almost surely for each $t \geq 0$; and $\mathcal{H}_{(j)}$ for $j \neq 0$ contains those elements of $\mathcal{H}_\nu$ such that

$$\int_0^t |f(s)|^2 \, ds < \infty \tag{2.5}$$

almost surely for each $t \geq 0$. Finally, if $\ell(\alpha) \geq 2$, we define $\mathcal{H}_\alpha$ recursively as those elements of $\mathcal{H}_\nu$ that satisfy

$$I_{\alpha-}[f(\cdot)]_{0,t} \in \mathcal{H}_{(j_{\ell(\alpha)})} \tag{2.6}$$

almost surely for all $t \geq 0$.

We also define the operators

$$L^0 = \frac{\partial}{\partial t} + a^k \frac{\partial}{\partial u^k} + \frac{1}{2} b^{kj} b^{lj} \frac{\partial^2}{\partial u^k \partial u^l}, \tag{2.7}$$

$$L^j = b^{kj} \frac{\partial}{\partial u^k}, \tag{2.8}$$

and, if $f \in C^h(\mathbb{R}^+ \times \mathbb{R}^d, \mathbb{R})$, where $h \geq \ell(\alpha) + n(\alpha)$, we set

$$f_\alpha = \begin{cases} f & \text{if } \ell(\alpha) = 0, \\ L^{j_1} f_{-\alpha} & \text{if } \ell(\alpha) \geq 1. \end{cases} \tag{2.9}$$

Here $-\alpha$ is α with its first component removed.

We note that if $f(t,u) \equiv u$, then $f_{(0)} = a, f_{(j)} = b^j$, etc. In what follows, unless explicitly stated otherwise, we will assume that f is this identity function.

A set, $\mathcal{A}$, of multi-indices is said to be a hierarchical set if $\mathcal{A} \neq \emptyset$, $\sup_{\alpha \in \mathcal{A}} \ell(\alpha) < \infty$, and $-\alpha \in \mathcal{A}$ whenever $\alpha \in \mathcal{A} - \{\nu\}$. We then define the remainder set $\mathcal{B}(\mathcal{A})$ of $\mathcal{A}$ by $\mathcal{B}(\mathcal{A}) = \{\alpha \mid \alpha \notin \mathcal{A} \text{ and } -\alpha \in \mathcal{A}\}$. We can now provide a stochastic Taylor expansion for U satisfying (2.1): If $f : \mathbb{R}^+ \times \mathbb{R}^d \to \mathbb{R}$, then, provided the derivatives and integrals exist,

$$f(\tau, U_\tau) = \sum_{\alpha \in \mathcal{A}} I_\alpha[f_\alpha(\rho, U_\rho)]_{\rho,\tau} + \sum_{\alpha \in \mathcal{B}(\mathcal{A})} I_\alpha[f_\alpha(\cdot, U_\cdot)]_{\rho,\tau}, \tag{2.10}$$

where $\mathcal{A}$ is some hierarchical set.

Now, for $\gamma = 0.5, 1.0, 1.5, \ldots$, we set

$$\mathcal{A}_\gamma = \left\{ \alpha \,\middle|\, \ell(\alpha) + n(\alpha) \leq 2\gamma \text{ or } \ell(\alpha) = n(\alpha) = \gamma + \frac{1}{2} \right\}. \tag{2.11}$$

We call the stochastic Taylor expansion with $\mathcal{A} = \mathcal{A}_\gamma$ the stochastic Taylor expansion to order γ.

We will make use of the following lemmas in the succeeding sections. In each of them, U is the solution to (2.1), and $t_k = k\Delta t$ for $k = 0, 1, \ldots, N$ is an equipartition of $[0,T]$, so that $t_N = T$; we partly rely on [6] for the proofs.

LEMMA 2.1. *Suppose Y_n is a stochastic process adapted to the filtration $\mathcal{F}_t$ at the equipartition (i.e., Y_n is $\mathcal{F}_{t_n}$-measurable), the function f satisfies $|f(t,x) - f(t,y)| \leq K|x-y|$ for all $t \in [0,T]$ and $x, y \in \mathbb{R}$, and α is a multi-index with $\ell(\alpha) \geq 1$. Then*

$$\begin{aligned} &\mathbb{E} \sup_{0 \leq m \leq n} \left| \sum_{k=0}^{m-1} I_\alpha[f(t_k, U_{t_k}) - f(t_k, Y_k)]_{t_k, t_{k+1}} \right|^2 \\ &\qquad \leq C\Delta t \sum_{k=0}^{n-1} \mathbb{E} \sup_{0 \leq m \leq k} |U_{t_m} - Y_m|^2. \end{aligned} \tag{2.12}$$

Proof. For $\alpha = (0)$, we have

$$\begin{aligned}
&\mathbb{E} \sup_{0\le m\le n} \left| \sum_{k=0}^{m-1} (f(t_k, U_{t_k}) - f(t_k, Y_k))\Delta t \right|^2 \\
&\quad \le \Delta t^2 \mathbb{E} \sup_{0\le m\le n} m \sum_{k=0}^{m-1} |f(t_k, U_{t_k}) - f(t_k, Y_k)|^2 \\
&\quad \le n\Delta t^2 \mathbb{E} \sum_{k=0}^{n-1} K^2 |U_{t_k} - Y_k|^2 \\
&\quad \le K^2 T \Delta t \sum_{k=0}^{n-1} \mathbb{E} \sup_{0\le m\le k} |U_{t_m} - Y_m|^2.
\end{aligned} \tag{2.13}$$

For $\alpha = (j)$,

$$\begin{aligned}
&\mathbb{E} \sup_{0\le m\le n} \left| \sum_{k=0}^{m-1} (f(t_k, U_{t_k}) - f(t_k, Y_k))\Delta W_k^j \right|^2 \\
&\quad \le 4\mathbb{E} \left| \sum_{k=0}^{n-1} (f(t_k, U_{t_k}) - f(t_k, Y_k))\Delta W_k^j \right|^2 \\
&\quad \le 4 \sum_{k=0}^{n-1} \mathbb{E} |f(t_k, U_{t_k}) - f(t_k, Y_k)|^2 \Delta t \\
&\quad \le 4K^2 \Delta t \sum_{k=0}^{n-1} \mathbb{E} \sup_{0\le m\le k} |U_{t_k} - Y_k|^2.
\end{aligned} \tag{2.14}$$

For longer α's, we just repeat the above two arguments as necessary. ∎

LEMMA 2.2. *Suppose the function f satisfies $|f(t,x)|^2 \le K^2(1+|x|^2)$ for all $t \in [0,T]$ and $x \in \mathbb{R}$, and that α is a multi-index with $\ell(\alpha) \ge 1$. Then*

$$\mathbb{E} \sup_{0\le m\le n} \left| \sum_{k=0}^{m-1} I_\alpha[f(\cdot, U_\cdot)]_{t_k, t_{k+1}} \right|^2 \le \begin{cases} C\Delta t^{2(\ell(\alpha)-1)}(1 + \mathbb{E}|U_0|^2) & \text{if } \ell(\alpha) = n(\alpha), \\ C\Delta t^{\ell(\alpha)+n(\alpha)-1}(1 + \mathbb{E}|U_0|^2) & \text{if } \ell(\alpha) \ne n(\alpha). \end{cases} \tag{2.15}$$

Proof. The ideas of this proof are the same as those in the proof of Lemma 2.1, along with the following bound on the solution U_t (see equation (4.5.16) of [6]):

$$\mathbb{E} \sup_{t_0\le s\le T} |U_s|^2 \le C(1 + \mathbb{E}|U_{t_0}|^2). \tag{2.16}$$

If we apply Lemma 10.8.1 of [6] with $g(s) = f(s, U_s)$, we have

$$\begin{aligned}
&\mathbb{E} \sup_{0\le m\le n} \left| \sum_{k=0}^{m-1} I_\alpha[f(\cdot, U_\cdot)]_{t_k, t_{k+1}} \right|^2 \\
&\quad \le \begin{cases} C\Delta t^{2(\ell(\alpha)-1)} \displaystyle\int_{t_0}^{t_n} \mathbb{E} \sup_{t_0\le s\le t} |f(s, U_s)|^2 \, dt & \text{if } \ell(\alpha) = n(\alpha), \\ C\Delta t^{\ell(\alpha)+n(\alpha)-1} \displaystyle\int_{t_0}^{t_n} \mathbb{E} \sup_{t_0\le s\le t} |f(s, U_s)|^2 \, dt & \text{if } \ell(\alpha) \ne n(\alpha). \end{cases}
\end{aligned} \tag{2.17}$$

Here, the constant C depends only on the length of the time interval $T - t_0$ and on α.

We then apply (2.16) and the growth condition on f, and we have the desired result. ∎

LEMMA 2.3. *Suppose that the sequence of positive numbers Z_n for $n = 0, 1, \ldots, N$ satisfies the inequality*

$$Z_n \le C\left(\Delta t \sum_{k=0}^{n} Z_k + \Delta t^{\gamma}\right) \tag{2.18}$$

for some positive constant C and some $\gamma > 0$. Then $Z_N = O(\Delta t^{\gamma})$ as $\Delta t \to 0$.

Proof. Set $\xi_n = \Delta t \sum_{k=0}^{n} Z_k$, so $Z_n = \frac{1}{\Delta t}(\xi_n - \xi_{n-1})$, and we have

$$\frac{1}{\Delta t}(\xi_n - \xi_{n-1}) \le C\xi_n + C\Delta t^{\gamma}. \tag{2.19}$$

That is,

$$(1 - C\Delta t)\xi_n \le \xi_{n-1} + C\Delta t^{\gamma+1}. \tag{2.20}$$

Therefore,

$$\begin{aligned}
(1 - C\Delta t)^n \xi_n &\le (1 - C\Delta t)^{n-1}\xi_{n-1} + (1 - C\Delta t)^{n-1} C\Delta t^{\gamma+1},\\
(1 - C\Delta t)^{n-1}\xi_{n-1} &\le (1 - C\Delta t)^{n-2}\xi_{n-2} + (1 - C\Delta t)^{n-2} C\Delta t^{\gamma+1},\\
&\vdots\\
(1 - C\Delta t)\xi_1 &\le C\Delta t^{\gamma+1},
\end{aligned}$$

and, summing,

$$\begin{aligned}
(1 - C\Delta t)^n \xi_n &\le (1 + (1 - C\Delta t) + \cdots + (1 - C\Delta t)^{n-1}) C\Delta t^{\gamma+1}\\
&\le \frac{1 - (1 - C\Delta t)^n}{1 - (1 - C\Delta t)} C\Delta t^{\gamma+1}\\
&\le (1 - (1 - C\Delta t)^n)\Delta t^{\gamma}.
\end{aligned} \tag{2.21}$$

Since $(1 - C\Delta t)^N \to e^{-CT}$ as $N = T/\Delta t \to \infty$, we see that $\xi_n \le C\Delta t^{\gamma}$ for some (different) C. Thus, by (2.18),

$$Z_n \le C(\xi_n + \Delta t^{\gamma}) \le C\Delta t^{\gamma}. \qquad \blacksquare \tag{2.22}$$

3. A stochastic Adams–Bashforth scheme. The deterministic Adams–Bashforth scheme for the ordinary differential equation $\phi' = F(\phi)$ takes the form

$$\phi_{n+1} = \phi_n + \frac{\Delta t}{2}[3F(\phi_n) - F(\phi_{n-1})]. \tag{3.1}$$

This scheme is order Δt^2. We will derive a stochastic version of this scheme which maintains the same order.

We begin with the stochastic Taylor expansion to order $\gamma = 2.0$:

$$\begin{aligned}
U_{t+\Delta} &= U_t + b^j \Delta W^j + a\Delta + L^{j_1} b^{j_2} I_{(j_1,j_2)} + L^0 b^j I_{(0,j)} + L^j a I_{(j,0)}\\
&\quad + L^{j_1} L^{j_2} b^{j_3} I_{(j_1,j_2,j_3)} + \frac{1}{2} L^0 a \Delta^2 + L^0 L^{j_1} b^{j_2} I_{(0,j_1,j_2)} + L^{j_1} L^0 b^{j_2} I_{(j_1,0,j_2)}\\
&\quad + L^{j_1} L^{j_2} a I_{(j_1,j_2,0)} + L^{j_1} L^{j_2} L^{j_3} b^{j_4} I_{(j_1,j_2,j_3,j_4)} + \tilde{R}^{\Delta}_{2.0}(t)\\
&= U_t + a\Delta + \frac{1}{2} L^0 a \Delta^2 + M^{\Delta}(t),
\end{aligned} \tag{3.2}$$

where each coefficient is at the point (t, U_t), and each stochastic integral is from t to $t+\Delta$, $\Delta = \Delta t$. We have also used the Einstein summation convention.

Similarly, for $\gamma = 1.5$, we have

$$a(t+\Delta, U_{t+\Delta}) = a + L^0 a\Delta + N^\Delta(t), \tag{3.3}$$

where $N^\Delta(t) = \frac{1}{2}L^0L^0a\Delta^2 + L^j a\Delta W^j + L^0L^j aI_{(0,j)} + L^jL^0aI_{(j,0)} + L^{j_1}L^{j_2}aI_{(j_1,j_2)} + L^{j_1}L^{j_2}L^{j_3}aI_{(j_1,j_2,j_3)} + \tilde{R}^\Delta_{1.5}(t)$, and, for $\gamma = 1.0$,

$$L^0a(t+\Delta, U_{t+\Delta}) = L^0a + P^\Delta(t), \tag{3.4}$$

where $P^\Delta(t) = L^0L^0a\Delta + L^jL^0a\Delta W^j + L^{j_1}L^{j_2}L^0aI_{(j_1,j_2)} + \tilde{R}^\Delta_{1.0}(t)$.

Combining these results, we get

$$\begin{aligned} U_{t+\Delta} = U_t &+ [\alpha a(t+\Delta, U_{t+\Delta}) + (1-\alpha)a]\Delta \\ &+ \left(\frac{1}{2} - \alpha\right)[\beta L^0a(t+\Delta, U_{t+\Delta}) + (1-\beta)L^0a]\Delta^2 \\ &- \alpha\Delta N^\Delta(t) - \left(\frac{1}{2} - \alpha\right)\beta\Delta^2 P^\Delta(t) + M^\Delta(t). \end{aligned} \tag{3.5}$$

In particular, if $t = t_n, \Delta = 2\Delta t, \alpha = 0, \beta = 0$, and writing $U_n = U_{t_n}$,

$$U_{n+2} = U_n + 2a(t_n, U_n)\Delta t + 2L^0a(t_n, U_n)\Delta t^2 + M^{2\Delta t}(t_n), \tag{3.6}$$

and if $t = t_n, \Delta = \Delta t, \alpha = -\frac{3}{2}, \beta = 0$,

$$\begin{aligned} U_{n+1} = U_n &- \frac{3}{2}a(t_{n+1}, U_{n+1})\Delta t + \frac{5}{2}a(t_n, U_n)\Delta t \\ &+ 2L^0a(t_n, U_n)\Delta t^2 + \frac{3}{2}N^{\Delta t}(t_n)\Delta t + M^{\Delta t}(t_n). \end{aligned} \tag{3.7}$$

Therefore,

$$\begin{aligned} U_{n+2} &= U_{n+1} + (U_{n+2} - U_n) - (U_{n+1} - U_n) \\ &= U_{n+1} + \left[\frac{3}{2}a(t_{n+1}, U_{n+1}) - \frac{1}{2}a(t_n, U_n)\right]\Delta t \\ &\quad - \frac{3}{2}\Delta t N^{\Delta t}(t_n) + (M^{2\Delta t}(t_n) - M^{\Delta t}(t_n)). \end{aligned} \tag{3.8}$$

This leads us to consider the following stochastic Adams–Bashforth (SAB) scheme:

$$\begin{aligned} Y_{n+2} = Y_{n+1} &+ \left[\frac{3}{2}a(t_{n+1}, Y_{n+1}) - \frac{1}{2}a(t_n, Y_n)\right]\Delta t \\ &- \frac{3}{2}\Delta t A_n(t_n, Y_n) + B_n(t_n, Y_n), \end{aligned} \tag{3.9}$$

in which

$$A_n(t,x) = L^j a(t,x)\Delta W^j + L^{j_1}L^{j_2}a(t,x)I_{(j_1,j_2)}, \tag{3.10}$$

where the random intervals are from time t_n to t_{n+1}, and

$$\begin{aligned} B_n(t,x) = {} & b^j(t,x)\Delta W^j + L^0 b^j(t,x) I_{(0,j)} + L^j a(t,x) I_{(j,0)} \\ & + L^{j_1} b^{j_2}(t,x) I_{(j_1,j_2)} + L^0 L^{j_1} b^{j_2}(t,x) I_{(0,j_1,j_2)} \\ & + L^{j_1} L^0 b^{j_2}(t,x) I_{(j_1,0,j_2)} + L^{j_1} L^{j_2} a(t,x) I_{(j_1,j_2,0)} \\ & + L^{j_1} L^{j_2} b^{j_3}(t,x) I_{(j_1,j_2,j_3)} + L^{j_1} L^{j_2} L^{j_3} b^{j_4}(t,x) I_{(j_1,j_2,j_3,j_4)}, \end{aligned} \tag{3.11}$$

where the random intervals are those from time t_n to t_{n+2} minus those from time t_n to t_{n+1}.

We then have the following theorem.

THEOREM 3.1. *Suppose that the coefficient functions f_α satisfy*

$$|f_\alpha(t,x) - f_\alpha(t,y)| \le K|x-y| \tag{3.12}$$

for all $\alpha \in \mathcal{A}_{2.0}$, $t \in [0,T]$, and $x, y \in \mathbb{R}^d$;

$$f_{-\alpha} \in C^{1,2} \text{ and } f_\alpha \in \mathcal{H}_\alpha \tag{3.13}$$

for all $\alpha \in \mathcal{A}_{2.0} \cup \mathcal{B}(\mathcal{A}_{2.0})$; and

$$|f_\alpha(t,x)| \le K(1+|x|) \tag{3.14}$$

for all $\alpha \in \mathcal{A}_{2.0} \cup \mathcal{B}(\mathcal{A}_{2.0})$, $t \in [0,T]$, and $x \in \mathbb{R}^d$. Choose $\Delta t \le 1$ and set $N = T/\Delta t$, and define $t_n = n\Delta t$ for $n = 1, \dots, N$. Suppose that Y_0 is some (nonrandom) initial condition and that some appropriate numerical scheme is used to generate Y_1 such that $\mathbb{E}[|U_{t_1} - Y_1|^2 \mid \mathcal{F}_0]^{\frac{1}{2}} \le C\Delta t^2$. Then

$$\mathbb{E}\left[\sup_{0\le n\le N} |U_{t_n} - Y_n|^2 \mid \mathcal{F}_0\right]^{\frac{1}{2}} \le C\Delta t^2. \tag{3.15}$$

Proof. First, we note that

$$\begin{aligned} U_{n+2} = {} & U_{n+1} + \left[\frac{3}{2} a(t_{n+1} U_{n+1}) - \frac{1}{2} a(t_n, U_n)\right] \Delta t \\ & - \frac{3}{2} \Delta t A_n(t_n, U_n) + B_n(t_n, U_n) + R_n, \end{aligned} \tag{3.16}$$

where

$$\begin{aligned} R_n = {} & \frac{3}{2}\Delta t \left[\frac{1}{2} L^0 L^0 a(t_n, U_n)\Delta t^2 + L^0 L^j a(t_n, U_n) I_{(0,j)} + L^j L^0 a(t_n, U_n) I_{(j,0)} \right. \\ & \left. + L^{j_1} L^{j_2} L^{j_3} a(t_n, U_n) I_{(j_1,j_2,j_3)} + \tilde{R}^{\Delta t}_{1.5}(t_n)\right] + \tilde{R}^{2\Delta t}_{2.0}(t_n) - \tilde{R}^{\Delta t}_{2.0}(t_n). \end{aligned}$$

If we iterate (3.9) and (3.16), we arrive at

$$
\begin{cases}
U_n = U_1 + \Delta t \sum_{k=0}^{n-2} \left[\frac{3}{2} a(t_{k+1}, U_{k+1}) - \frac{1}{2} a(t_k, U_k) \right] \\
\qquad - \frac{3}{2} \Delta t \sum_{k=0}^{n-2} A_k(t_k, U_k) + \sum_{k=0}^{n-2} B_k(t_k, U_k) + \sum_{k=0}^{n-2} R_k, \\
Y_n = Y_1 + \Delta t \sum_{k=0}^{n-2} \left[\frac{3}{2} a(t_{k+1}, Y_{k+1}) - \frac{1}{2} a(t_k, Y_k) \right] \\
\qquad - \frac{3}{2} \Delta t \sum_{k=0}^{n-2} A_k(t_k, Y_k) + \sum_{k=0}^{n-2} B_k(t_k, Y_k).
\end{cases} \tag{3.17}
$$

Set $\zeta_n = U_n - Y_n$. Then

$$
\begin{aligned}
\zeta_n = \zeta_1 &+ \Delta t \sum_{k=0}^{n-2} \left[\frac{3}{2} (a(t_{k+1}, U_{k+1}) - a(t_{k+1}, Y_{k+1})) - \frac{1}{2} (a(t_k, U_k) - a(t_k, Y_k)) \right] \\
&- \frac{3}{2} \Delta t \sum_{k=0}^{n-2} (A_k(t_k, U_k) - A_k(t_k, Y_k)) \\
&+ \sum_{i=0}^{n-2} (B_k(t_k, U_k) - B_k(t_k, Y_k)) + \sum_{k=0}^{n-2} R_k.
\end{aligned} \tag{3.18}
$$

Set $Z_n = \mathbb{E}[\sup_{0 \le m \le n} |\zeta_m|^2 \,|\, \mathcal{F}_0]$.
Then we have

$$
\begin{aligned}
Z_n \le C \Bigg(& \mathbb{E}[|\zeta_1|^2 | \mathcal{F}_0] + \Delta t^2 \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} a(t_{k+1}, U_{k+1}) - a(t_{k+1}, Y_{k+1}) \right|^2 \,\middle|\, \mathcal{F}_0 \right] \\
& + \Delta t^2 \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} a(t_k, U_k) - a(t_k, Y_k) \right|^2 \,\middle|\, \mathcal{F}_0 \right] \\
& \left. \begin{aligned}
& + \Delta t^2 \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} (L^j a(t_k, U_k) - L^j a(t_k, Y_k)) \Delta W_k^j \right|^2 \,\middle|\, \mathcal{F}_0 \right] \\
& + \Delta t^2 \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} (L^{j1} L^{j2} a(t_k, U_k) - L^{j_1} L^{j_2} a(t_k, Y_k)) I_{(j_1, j_2)} \right|^2 \,\middle|\, \mathcal{F}_0 \right]
\end{aligned} \right\} \text{Terms from } A_k \\
& \left. \begin{aligned}
& + \sum_{\alpha \epsilon \mathcal{A}_2^*} \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} I_\alpha \left[f_\alpha(t_k, U_k) - f_\alpha(t_k, Y_k) \right]_{t_k, t_{k+2}} \right|^2 \,\middle|\, \mathcal{F}_0 \right] \\
& + \sum_{\alpha \epsilon \mathcal{A}_2^*} \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} I_\alpha \left[f_\alpha(t_k, U_k) - f_\alpha(t_k, Y_k) \right]_{t_k, t_{k+1}} \right|^2 \,\middle|\, \mathcal{F}_0 \right]
\end{aligned} \right\} \text{Terms from } B_k \\
& + \mathbb{E} \left[\sup_{0 \le m \le n} \left| \sum_{k=0}^{m-2} R_k \right|^2 \,\middle|\, \mathcal{F}_0 \right] \Bigg).
\end{aligned}
$$

We go term-by-term:

$$\begin{aligned}
&\Delta t^2\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} a(t_{k+1},U_{k+1})-a(t_{k+1},Y_{k+1})\right|^2\ \middle|\ \mathcal{F}_0\right]\\
&\quad\le \Delta t^2 n\ \mathbb{E}\left[\sup_{0\le m\le n}\sum_{k=0}^{m-2}\left|a(t_{k+1},U_{k+1})-a(t_{k+1},Y_{k+1})\right|^2\ \middle|\ \mathcal{F}_0\right]\\
&\quad\le T\Delta t\ \mathbb{E}\left[\sum_{k=0}^{n-2}\left|a(t_{k+1},U_{k+1})-a(t_{k+1},Y_{k+1})\right|^2\ \middle|\ \mathcal{F}_0\right] \qquad (3.19)\\
&\quad\le C\Delta t\sum_{k=0}^{n-2}\mathbb{E}\left[|U_{k+1}-Y_{k+1}|^2\mid\mathcal{F}_0\right]\\
&\quad\le C\Delta t\sum_{k=0}^{n-1} Z_k.
\end{aligned}$$

Similarly,

$$\Delta t^2\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} a(t_k,U_k)-a(t_k,Y_k)\right|^2\ \middle|\ \mathcal{F}_0\right]\le C\Delta t\sum_{k=0}^{n-1} Z_k. \qquad (3.20)$$

Next, we consider the terms from A_k. From Lemma 2.1 with $\alpha=(j)$,

$$\begin{aligned}
&\Delta t^2\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2}(L^j a(t_k,U_k)-L^j a(t_k,Y_k))\Delta W^j_{t_k,t_{k+1}}\right|^2\ \middle|\ \mathcal{F}_0\right] \qquad (3.21)\\
&\quad\le C\Delta t\sum_{k=0}^{n-2} Z_k,
\end{aligned}$$

and from Lemma 2.1 with $\alpha=(j_1,j_2)$,

$$\begin{aligned}
&\Delta t^2\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2}(L^{j1}L^{j2}a(t_k,U_k)-L^{j_1}L^{j_2}a(t_k,Y_k))I_{(j_1,j_2)t_k,t_{k+1}}\right|^2\ \middle|\ \mathcal{F}_0\right] \qquad (3.22)\\
&\quad\le C\Delta t\sum_{k=0}^{n-1} Z_k.
\end{aligned}$$

Now, we consider the terms from B_k. For $\alpha\in\mathcal{A}_2^*$ (i.e., $\alpha\in\mathcal{A}_2,\ell(\alpha)\ne n(\alpha)$),

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} I_\alpha\left[f_\alpha(t_k,U_k)-f_\alpha(t_k,Y_k)\right]_{t_k,t_{k+1}}\right|^2\ \middle|\ \mathcal{F}_0\right]\le C\Delta t\sum_{k=0}^{n-1} Z_k. \qquad (3.23)$$

The other terms from B_k are similar. This leaves only the terms from R_k. From Lemma 2.2 with $\alpha=(0)$,

$$\begin{aligned}
&\Delta t^2\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} L^0L^0a(t_n,U_n)\Delta t^2\right|^2\ \middle|\ \mathcal{F}_0\right]\\
&\quad\le \Delta t^4\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{n-2} L^0L^0a(t_n,U_n)\right|^2\ \middle|\ \mathcal{F}_0\right] \qquad (3.24)\\
&\quad\le C\Delta t^4(1+|U_0|^2).
\end{aligned}$$

For $\alpha = (0,j),(j,0),(j_1,j_2,j_3)$, by Lemma 2.2

$$\Delta t^2 \mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} I_\alpha\left[a_\alpha(t_k,U_k)\right]_{t_k,t_{k+1}}\right|^2 \,\middle|\, \mathcal{F}_0\right] \le C\Delta t^4(1+|U_0|^2), \text{ since } \ell(\alpha)+n(\alpha)=3. \tag{3.25}$$

If $\alpha \in \mathcal{B}(\mathcal{A}\gamma)$ (here $\gamma = 1.5$ or 2.0), we have by Lemma 2.2,

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} I_\alpha\left[\alpha(\cdot,U_\cdot)\right]_{t_k,t_{k+1}}\right|^2 \,\middle|\, \mathcal{F}_0\right] \le C(1+|U_0|^2)\Delta t^{2\gamma}. \tag{3.26}$$

Therefore, we have

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-2} R_k\right|^2 \,\middle|\, \mathcal{F}_0\right] \le C(1+|U_0|^2)\Delta t^4. \tag{3.27}$$

So, overall, we see that

$$Z_n \le C\left[Z_1 + (1+|U_0|^2)\Delta t^4 + \Delta t\sum_{k=0}^{n-1} Z_k\right]. \tag{3.28}$$

The result then follows from Lemma 2.3. □

Remark 3.1. If we truncate A_n and B_n to

$$A_n(t,x) = L^j a(t,x)\Delta W^j \tag{3.29}$$

and

$$\begin{aligned} B_n(t,x) = {} & b^j(t,x)\Delta W^j + L^0 b^j(t,x) I_{(0,j)} + L^j a(t,x) I_{(j,0)} \\ & + L^{j_1} b^{j_2}(t,x) I_{(j_1,j_2)} + L^{j_1} L^{j_2} b^{j_3}(t,x) I_{(j_1,j_2,j_3)}, \end{aligned} \tag{3.30}$$

the same proof will show that the convergence is now to order $\Delta t^{\frac{3}{2}}$. We note that although the order Δt^2 SAB scheme seems to have no obvious advantages over the standard Δt^2 strong one-step explicit scheme (as in [6]), the order $\Delta t^{\frac{3}{2}}$ SAB scheme does have an advantage over the order $\Delta t^{\frac{3}{2}}$ strong one-step explicit scheme in that the former lacks the terms involving the second derivative of a which are present in the latter.

Remark 3.2. It can be shown that the scheme

$$\begin{aligned} Y_{n+2} = {} & Y_{n+1} + \left[\frac{3}{2}a(t_{n+1},Y_{n+1}) - \frac{1}{2}a(t_n,Y_n)\right]\Delta t \\ & - \frac{3}{2}\Delta t A_n(t_n,Y_n) + B_n(t_n,Y_n), \end{aligned} \tag{3.31}$$

in which

$$A_n(t,x) = L^j a(t,x)\Delta W^j, \tag{3.32}$$

where the random intervals are from time t_n to t_{n+1}, and

$$\begin{aligned} B_n(t,x) = {} & b^j(t,x)\Delta W^j + L^0 b^j(t,x) I_{(0,j)} + L^j a(t,x) I_{(j,0)} \\ & + L^{j_1} b^{j_2}(t,x) I_{(j_1,j_2)}, \end{aligned} \tag{3.33}$$

where the random intervals are those from time t_n to t_{n+2} minus those from time t_n to t_{n+1}, converges to the Itô solution in the weak sense to order 2. As can be seen, this scheme is considerably simpler than the strong scheme, and it avoids the difficulties with generating the higher-order moments that the strong scheme has.

4. A stochastic "implicit leapfrog" scheme. The barotropic vorticity model supplied to us by Cecile Penland and Prashant Sardeshmukh of the National Oceanic and Atmospheric Administration in Boulder, Colorado (see [11]), takes the form

$$\frac{\partial \zeta}{\partial t} = -\nabla \cdot (v\zeta) + S - r\xi - \kappa \nabla^4 \xi, \tag{4.1}$$

where $\zeta = \nabla^2 \psi + f = \xi + f$ and $v = \hat{k} \times \nabla \psi$. Here, ζ is the total vorticity, v is the velocity vector, f is the Coriolis term, S is a (deterministic) forcing, r and κ are constants, and ξ is the local vorticity.

The numerical scheme they provided for this uses spherical harmonics, and, writing F for $-\nabla \cdot (v\zeta)$, the equation becomes

$$\frac{d}{dt}\zeta_n^m = F_n^m + S_n^m - r\xi_n^m - \kappa \left[\frac{n(n+1)}{a^2}\right]^2 \zeta_n^m. \tag{4.2}$$

Then the scheme has two steps. First, a leapfrog step,

$$\tilde{\zeta}_n^m(t + \Delta t) = \zeta_n^m(t - \Delta t) + 2\Delta t[F_n^m(t) + S_n^m(t)], \tag{4.3}$$

followed by an implicit step,

$$\zeta_n^m(t + \Delta t) = \frac{\tilde{\zeta}_n^m(t + \Delta t)}{1 + 2\Delta t \left[r + \kappa \left[\frac{n(n+1)}{a^2}\right]^2\right]}. \tag{4.4}$$

If we simplify notation and write a_1 for $F + S$ and a_2 for $-r\xi - \kappa\nabla^4\xi$, we see that this is just an "implicit leapfrog" scheme

$$\begin{cases} \tilde{Y}(t + \Delta t) = Y(t - \Delta t) + 2\Delta t a_1(t, Y(t)), \\ Y(t + \Delta t) = \tilde{Y}(t + \Delta t) + 2\Delta t a_2(t + \Delta t, Y(t + \Delta t)) \end{cases} \tag{4.5}$$

for the equation

$$dU(t) = [a_1(t, U(t)) + a_2(t, U(t))]\, dt. \tag{4.6}$$

Therefore, we consider a stochastic differential equation of the form

$$dU_t = (a_1(t, U_t) + a_2(t, U_t))\, dt + b(t, U_t)\, dW_t. \tag{4.7}$$

Note that we have simply added a general diffusion term to the deterministic differential equation (4.6).

We will consider the scheme

$$\begin{cases} \tilde{Y}_{n+2} = Y_n + 2a_1(t_{n+1}, Y_{n+1})\Delta t + M_n(Y_n) + M_{n+1}(Y_{n+1}), \\ Y_{n+2} = \tilde{Y}_{n+2} + 2a_2(t_{n+2}, Y_{n+2})\Delta t, \end{cases} \tag{4.8}$$

where

$$M_n(y) = b(t_n, y)\Delta W_n + bb'(t_n, y) I_{(1,1),n}. \tag{4.9}$$

THEOREM 4.1. *Suppose that the coefficient functions f_α satisfy*

$$|f_\alpha(t,x) - f_\alpha(t,y)| \le K|x-y| \tag{4.10}$$

for all $\alpha \in \mathcal{A}_{1.0}$, $t \in [0,T]$, and $x, y \in \mathbb{R}^d$;

$$f_{-\alpha} \in C^{1,2} \quad \text{and} \quad f_\alpha \in \mathcal{H}_\alpha \tag{4.11}$$

for all $\alpha \in \mathcal{A}_{1.0} \cup \mathcal{B}(\mathcal{A}_{1.0})$; and

$$|f_\alpha(t,x)| \le K(1+|x|) \tag{4.12}$$

for all $\alpha \in \mathcal{A}_{1.0} \cup \mathcal{B}(\mathcal{A}_{1.0})$, $t \in [0,T]$, and $x \in \mathbb{R}^d$. Choose $\Delta t \le 1$ and set $N = T/\Delta t$, and define $t_n = n\Delta t$ for $n = 1, \dots, N$. Suppose that some appropriate numerical scheme is used to generate Y_1 such that $\mathbb{E}[|U_{t_1} - Y_1|^2 \mid \mathcal{F}_0]^{\frac{1}{2}} \le C\Delta t$. Then

$$\mathbb{E}\left[\sup_{0\le n\le N} |U_{t_n} - Y_n|^2 \mid \mathcal{F}_0\right]^{\frac{1}{2}} \le C\Delta t. \tag{4.13}$$

Proof. We note first that, by Itô's formula (i.e., the Taylor expansion with $\gamma = 0.0$), the solution U to (4.7) satisfies the following equations (where for notational simplicity we have written U_n for U_{t_n}):

$$\begin{aligned} a_1(t_{n+1}, U_{n+1}) &= a_1(t_n, U_n) + R_{0.0}^{\Delta t, a_1}(t_n); \\ a_2(t_{n+2}, U_{n+2}) &= a_2(t_n, U_n) + R_{0.0}^{2\Delta t, a_2}(t_n); \\ a_2(t_{n+2}, U_{n+2}) &= a_2(t_{n+1}, U_{n+1}) + R_{0.0}^{\Delta t, a_2}(t_{n+1}). \end{aligned} \tag{4.14}$$

Therefore we have

$$\begin{aligned} U_{n+2} &= U_n + (U_{n+2} - U_{n+1}) + (U_{n+1} - U_n) \\ &= U_n + [b(t_{n+1}, U_{n+1})\Delta W_{n+1} + a_1(t_{n+1}, U_{n+1})\Delta t \\ &\quad + a_2(t_{n+1}, U_{n+1})\Delta t + bb'(t_{n+1}, U_{n+1})I_{(1,1),n+1} \\ &\quad + R_{1.0}^{\Delta t}(t_{n+1})] + [b(t_n, U_n)\Delta W_n + a_1(t_n, U_n)\Delta t \\ &\quad + a_2(t_n, U_n)\Delta t + bb'(t_n, U_n)I_{(1,1),n} + R_{1.0}^{\Delta t}(t_n)]. \end{aligned} \tag{4.15}$$

After substituting (4.14) into this, we see that

$$\begin{aligned} U_{n+2} = [U_n + 2a_1(t_{n+1}, U_{n+1})\Delta t + M_n(U_n) + M_{n+1}(U_{n+1})] \\ + 2a_2(t_{n+2}, U_{n+2})\Delta t + R_n; \end{aligned} \tag{4.16}$$

here

$$\begin{aligned} R_n = R_{1.0}^{\Delta t}(t_n) + R_{1.0}^{\Delta t}(t_{n+1}) - \Delta t[R_{0.0}^{\Delta t, a_1}(t_n) \\ + R_{0.0}^{2\Delta t, a_2}(t_n) + R_{0.0}^{\Delta t, a_2}(t_{n+1})]. \end{aligned} \tag{4.17}$$

If we iterate (4.16), we arrive at

$$\begin{aligned} U_n = U_{n^*} + 2\Delta t\left[\sum_{k=1}^{[n/2]} a_1(t_{2k-1+n^*}, U_{2k-1+n^*}) + \sum_{k=1}^{[n/2]} a_2(t_{2k+n^*}, U_{2k+n^*})\right] \\ + \sum_{k=n^*}^{n-1} M_n(U_n) + \sum_{k=0}^{[n/2]} R_{2k-2+n^*}; \end{aligned} \tag{4.18}$$

here n^* is 0 if n is even and 1 if n is odd.

Similarly, we have for Y

$$Y_n = Y_{n^*} + 2\Delta t \left[\sum_{k=1}^{[n/2]} a_1(t_{2k-1+n^*}, Y_{2k-1+n^*}) + \sum_{k=1}^{[n/2]} a_2(t_{2k+n^*}, Y_{2k+n^*}) \right] + \sum_{k=n^*}^{n-1} M_n(Y_n). \tag{4.19}$$

Let us set $Z_n = \mathbb{E}[\sup_{0\le m\le n} |U_m - Y_m|^2 \mid \mathcal{F}_0]$. Then, by subtracting (4.19) from (4.18) and then squaring and taking expectations, we find

$$Z_n \le C\mathbb{E}\left[\sup_{0\le m\le n} Z_{m^*} + \Delta t^2 A_{1,m}^2 + \Delta t^2 A_{2,m}^2 + \left(\sum_{k=m^*}^{m-1} M_k(U_k) - M_k(Y_k) \right)^2 + \left(\sum_{k=0}^{[m/2]} R_{2k-2+m^*} \right)^2 \Bigg| \mathcal{F}_0 \right]. \tag{4.20}$$

In (4.20),

$$A_{1,n} = \sum_{k=1}^{[n/2]} a_1(t_{2k-1+n^*}, U_{2k-1+n^*}) - a_1(t_{2k-1+n^*}, Y_{2k-1+n^*}) \tag{4.21}$$

and

$$A_{2,n} = \sum_{k=1}^{[n/2]} a_2(t_{2k+n^*}, U_{2k+n^*}) - a_2(t_{2k+n^*}, Y_{2k+n^*}). \tag{4.22}$$

We then have the following estimates (where we omit the dependence on t when it is clear):

$$\begin{aligned} \Delta t^2 \mathbb{E}\left[\sup_{0\le m\le n} A_{1,m}^2 \right] &\le \Delta t^2 \mathbb{E}\left[\sup_{0\le m\le n} \left[\frac{m}{2}\right] \sum_{k=1}^{[m/2]} [a_1(U_{2k-1+n^*}) - a_1(Y_{2k-1+n^*})]^2 \right] \\ &\le K\Delta t^2 n \mathbb{E}\left[\sum_{k=1}^{n} (U_k - Y_k)^2 \right] \le KT\Delta t \sum_{k=1}^{n} Z_k. \end{aligned} \tag{4.23}$$

Similarly,

$$\Delta t^2 \mathbb{E}\left[\sup_{0\le m\le n} A_{2,n}^2 \right] \le KT\Delta t \sum_{k=1}^{n} Z_k. \tag{4.24}$$

There are two terms in M_k. For the first one, from Lemma 2.1, with $\alpha = (1)$, we obtain

$$\mathbb{E}\left[\sup_{0\le m\le n} \left| \sum_{k=m^*}^{m-1} [b(U_k) - b(Y_k)]\Delta W_k \right|^2 \right] \le C\Delta t \sum_{k=0}^{n} Z_k. \tag{4.25}$$

The second term is similar, with $\alpha = (1,1)$.

Finally, we show a representative term from the remainder R. From Lemma 2.2, with $\alpha = (1, 0)$,

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{k=0}^{m-1}\int_{t_k}^{t_{k+1}}\int_{t_k}^{s} L^0 b(U_r)\,dr\,dW_s\right|^2\right] \le C\Delta t^2(1+U_0^2). \tag{4.26}$$

The remaining terms from R give similar bounds.

Taking all of these estimates into account, we have the inequality

$$Z_n \le K\left[Z_1 + \Delta t\sum_{k=0}^{n} Z_k + \Delta t^2\right]. \tag{4.27}$$

Therefore, from Lemma 2.3, we see that

$$\mathbb{E}\left[\sup_{o\le n\le N}|U_n - Y_n|^2 \,\middle|\, \mathcal{F}_0\right]^{\frac{1}{2}} = O(\Delta t). \qquad \square \tag{4.28}$$

Remark 4.1. It is possible to show that the scheme

$$\begin{cases} \tilde{Y}_{n+2} = Y_n + 2a_1(t_{n+1}, Y_{n+1})\Delta t + b(t_n, Y_n)\Delta W_n \\ \qquad\qquad + b(t_{n+1}, Y_{n+1})\Delta W_{n+1}, \\ Y_{n+2} = \tilde{Y}_{n+2} + 2a_2(t_{n+2}, Y_{n+2})\Delta t \end{cases} \tag{4.29}$$

converges to the Itô solution in the weak sense to order 1. Again, it can be seen that the weak scheme is simpler than the strong scheme to the same order. However, we also note that the weak order 1 Stratonovich scheme

$$\begin{cases} \tilde{Y}_{n+2} = Y_n + 2a_1(t_{n+1}, Y_{n+1})\Delta t + bb'(t_{n+1}, Y_{n+1})(\Delta W_{n+1})^2 \\ \qquad\qquad + b(t_n, Y_n)\Delta W_n + b(t_{n+1}, Y_{n+1})\Delta W_{n+1}, \\ Y_{n+2} = \tilde{Y}_{n+2} + 2a_2(t_{n+2}, Y_{n+2})\Delta t \end{cases} \tag{4.30}$$

is not appreciably simpler than the strong order 1 Stratonovich scheme

$$\begin{cases} \tilde{Y}_{n+2} = Y_n + 2a_1(t_{n+1}, Y_{n+1})\Delta t + M_n(Y_n) + M_{n+1}(Y_{n+1}), \\ Y_{n+2} = \tilde{Y}_{n+2} + 2a_2(t_{n+2}, Y_{n+2})\Delta t, \end{cases} \tag{4.31}$$

where

$$M_n(y) = b(t_n, y)\Delta W_n + \frac{1}{2}bb'(t_n, y)(\Delta W_n)^2. \tag{4.32}$$

5. Discretization of spatial derivatives by finite differences. It sometimes happens in applications that the functions a and b may only be known empirically (i.e., in tables) rather than analytically. In such cases, analytic derivatives of these functions can be difficult to obtain. It is therefore useful to replace these derivatives by discrete approximations. As a first example, consider this modification of Mil'shtein's scheme:

$$\begin{aligned} \hat{Y}_{n+1}^k &= \hat{Y}_n^k + \sum_{j=1}^{d} b^{k,j}(\hat{Y}_n)\Delta W_n^j + a^k(\hat{Y}_n)\Delta t \\ &\quad + \sum_{j_1,j_2,\ell=1}^{d} \frac{1}{\Delta x} b^{\ell,j_1}(\hat{Y}_n)(b^{k,j_2}(\hat{Y}_n + \Delta x e^\ell) - b^{k,j_2}(\hat{Y}_n))I_{(j_1,j_2),n}, \end{aligned} \tag{5.1}$$

where e^ℓ is the vector $(0,\dots,0,1,0,\dots,0)$, with 1 in the ℓth position, and we have chosen $\Delta x > 0$. We have also suppressed the dependence of a and b on time to simplify notation.

We then have the following theorem.

THEOREM 5.1. *Suppose that a and b have the regularity required for Mil'shtein's scheme to converge to the solution U to order Δt. Then*

$$\mathbb{E}\left[\sup_{0\le n\le N}|U_n-\hat{Y}_n|^2\right]^{\frac{1}{2}}=O(\max\{\Delta t,\Delta x\Delta t^{\frac{1}{2}}\}). \tag{5.2}$$

Note that if we want to maintain the order of convergence of Mil'shtein's scheme, we need that $\Delta x = O(\Delta t^{\frac{1}{2}})$.

Proof. We denote Mil'shtein's scheme by Y and recall that it satisfies

$$\mathbb{E}\left[\sup_{0\le n\le N}|Y_n-U_n|^2\right]^{\frac{1}{2}}=O(\Delta t). \tag{5.3}$$

First, we see that (using Einstein's summation convention on repeated indices)

$$\begin{aligned}\hat{Y}^k_{n+1}-Y^k_{n+1}&=\hat{Y}^k_n-Y^k_n+(b^{k,j}(\hat{Y}_n)-b^{k,j}(Y_n))\Delta W^j_n+(a^k(\hat{Y}_n)-a^k(Y_n))\Delta t\\&+\left[b^{\ell,j_1}(\hat{Y}_n)\frac{1}{\Delta x}(b^{k,j_2}(\hat{Y}_n+\Delta x e^\ell)-b^{k,j_2}(\hat{Y}_n))\right.\\&\left.-\ b^{\ell,j_1}(Y_n)\frac{\partial b^{k,j_2}}{\partial x^\ell}(Y_n)\right]I_{(j_1,j_2),n}.\end{aligned} \tag{5.4}$$

Iterating this, we have

$$\begin{aligned}\hat{Y}^k_n-Y^k_n&=\hat{Y}^k_0-Y^k_0+\sum_{i=0}^{n-1}(b^{k,j}(\hat{Y}_i)-b^{k,j}(Y_i))\Delta W^j_i+\sum_{i=0}^{n-1}(a^k(\hat{Y}_i)-a^k(Y_i))\Delta t\\&+\sum_{i=0}^{n-1}\left[b^{\ell,j_1}(\hat{Y}_i)\frac{1}{\Delta x}(b^{k,j_2}(\hat{Y}_i+\Delta x e^\ell)-b^{k,j_2}(\hat{Y}_i))\right.\\&\left.-\ b^{\ell,j_1}(Y_i)\frac{\partial b^{k,j_2}}{\partial x^\ell}(Y_i)\right]I_{(j_1,j_2),i}.\end{aligned} \tag{5.5}$$

Set

$$Z_n=\mathbb{E}\left[\sup_{0\le m\le n}|\hat{Y}_n-Y_n|^2\right]. \tag{5.6}$$

We then have the estimates

$$\begin{aligned}&\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{i=0}^{m-1}(b^{k,j}(\hat{Y}_i)-b^{k,j}(Y_i))\Delta W^j_i\right|^2\right]\\&\le 4\mathbb{E}\left[\left|\sum_{i=0}^{n-1}(b^{k,j}(\hat{Y}_i)-b^{k,j}(Y_i))\Delta W^j_i\right|^2\right]\\&\le 4\mathbb{E}\left[\sum_{i=0}^{n-1}|b^{k,j}(\hat{Y}_i)-b^{k,j}(Y_i)|^2\Delta t\right]\\&\le C\Delta t\sum_{i=0}^{n-1}Z_i,\end{aligned}$$

and

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{i=0}^{m-1}(a^k(\hat{Y}_i)-a^k(Y_i))\Delta t\right|^2\right]\le \Delta t^2 n\mathbb{E}\left[\sum_{i=0}^{n-1}|a^k(\hat{Y}_i)-a^k(Y_i)|^2\right]$$
$$\le C\Delta t\sum_{i=0}^{n-1}Z_i,$$

and, finally,

$$\mathbb{E}\left[\sup_{0\le m\le n}\left|\sum_{i=0}^{m-1}\left[b^{\ell,j_1}(\hat{Y}_i)\frac{1}{\Delta x}[b^{k,j_2}(\hat{Y}_i+\Delta x e^\ell)-b^{k,j_2}(\hat{Y}_i)]\right.\right.\right.$$
$$\left.\left.\left.-\ b^{\ell,j_1}(Y_i)\frac{\partial b^{k,j_2}}{\partial x^\ell}(Y_i)\right]I_{(j_1,j_2),i}\right|^2\right]$$
$$\le C\Delta t^2\sum_{i=0}^{n-1}\mathbb{E}\left[b^{\ell,j_1}(\hat{Y}_i)\frac{1}{\Delta x}[b^{k,j_2}(\hat{Y}_i+\Delta x e^\ell)-b^{k,j_2}(\hat{Y}_i)]-b^{\ell,j_1}(Y_i)\frac{\partial b^{k,j_2}}{\partial x^\ell}(Y_i)\right]^2$$
$$\le C\Delta t^2\sum_{i=0}^{n-1}\mathbb{E}\left[b^{\ell,j_1}(\hat{Y}_i)\frac{\partial b^{k,j_2}}{\partial x^\ell}(\hat{Y}_i)-b^{\ell,j_1}(Y_i)\frac{\partial b^{k,j_2}}{\partial x^\ell}(Y_i)\right]^2$$
$$+C\Delta t^2\sum_{i=0}^{n-1}b^{\ell,j_1}(\hat{Y}_i)^2\left[\frac{1}{\Delta x}(b^{k,j_2}(\hat{Y}_i+\Delta x e^\ell)-b^{k,j_2}(\hat{Y}_i))-\frac{\partial b^{k,j_2}}{\partial x^\ell}(\hat{Y}_i)\right]^2$$
$$\le C\Delta t^2\sum_{i=0}^{n-1}Z_i+C\Delta t\Delta x^2.$$

Therefore, altogether we have

$$Z_n\le C\Delta t\sum_{k=0}^{n-1}Z_k+C\Delta t\Delta x^2, \tag{5.7}$$

and an application of Lemma 2.3 implies that

$$\mathbb{E}\left[\sup_{0\le n\le N}|Y_n-\hat{Y}_n|^2\right]^{\frac{1}{2}}=O(\Delta x\Delta t^{\frac{1}{2}}). \tag{5.8}$$ □

We can apply a similar idea to the SAB scheme. That is, if we replace A_n and B_n in the order $\Delta t^{\frac{3}{2}}$ scheme (see Remark 3.1) by, for instance (with, again, Einstein's summation convention in effect),

$$A_n(t,x)=b^{kj}(t,x)\frac{1}{\Delta x}[a(t,x+\Delta x e^k)-a(t,x)]\Delta W^j, \tag{5.9}$$

where $e^k=(0,\dots,0,1,0,\dots,0)$, with the 1 in the kth position, and

$$
\begin{aligned}
B_n(t,x) = {} & b^j(t,x)\Delta W^j + \frac{1}{\Delta t}[b^j(t+\Delta t,x) - b^j(t,x)]I_{(0,j),n} \\
& + a^k(t,x)\frac{1}{\Delta x}[b^j(t,x+\Delta x e^k) - b^j(t,x)]I_{(0,j),n} \\
& + b^{ki}(t,x)b^{\ell i}(t,x)\frac{1}{8\Delta x^2}[b^j(t,x+\Delta x(e^i+e^\ell)) - b^j(t,x+\Delta x(e^i-e^\ell)) \\
& \quad - b^j(t,x+\Delta x(e^\ell-e^i)) + b^j(t,x-\Delta x(e^i+e^\ell))]I_{(0,j),n} \\
& + b^{kj_1}(t,x)\frac{1}{2\Delta x}[b^{j_2}(t,x+\Delta x e^k) - b^{j_2}(t,x-\Delta x e^k)]I_{(j_1,j_2),n} \\
& + b^{kj}(t,x)\frac{1}{\Delta x}[a(t,x+\Delta x e^k) - a(t,x)]I_{(j,0),n} \\
& + b^{k_1j_1}(t,x)\frac{1}{4\Delta x^2}[b^{k_2j_2}(t,x+\Delta x e^{k_1}) - b^{k_2j_2}(t-x+\Delta x e^{k_1})] \\
& \quad [b^{j_3}(t,x+\Delta x e^{k_2}) - b^{j_3}(t,x-\Delta x e^{k_1})]I_{(j_1,j_2,j_3),n} \\
& + b^{k_1j_1}(t,x)b^{k_2,j_2}(t,x)\frac{1}{4\Delta x^2} \\
& \quad [b^{j_3}(t,x+\Delta x(e^{k_1}+e^{k_2})) - b^{j_3}(t,x+\Delta x(e^{k_1}-e^{k_2})) \\
& \quad - b^{j_3}(t,x+\Delta x(e^{k_2}-e^{k_1})) + b^{j_3}(t,x-\Delta x(e^{k_1}+e^{k_2}))]I_{(j_1,j_2,j_3),n},
\end{aligned}
$$

we could then prove that this scheme converges to order $\max\{\Delta t^{\frac{3}{2}}, \Delta t^{\frac{1}{2}}\Delta x\}$ in a similar fashion.

6. Numerical simulation. The object of this section is to test numerically the accuracy of the scheme of section 3 and compare it to the theoretical result above (i.e., $O(\Delta t^2)$ accuracy) and to the accuracy of the Euler and Mil'shtein schemes (respectively, $O(\Delta t^{\frac{1}{2}})$ and $O(\Delta t)$). All the numerical results below are consistent with the theoretical ones.

We consider the following equation:

$$
dX_t = \beta^2 \sinh X_t \cosh^2 X_t \, dt + \beta \cosh^2 X_t \, dW_t, \tag{6.1}
$$

with $\beta = \frac{1}{10}$ and $X_0 = \frac{1}{2}$. This has the exact solution

$$
X_t = \operatorname{arctanh}(\beta W_t + \tanh X_0), \tag{6.2}
$$

respectively. This can be easily verified using Itô's formula and is just one of many possible examples listed in [6].

We computed approximate solutions Y_n using the Euler and Mil'shtein schemes and the SAB scheme from section 3. Then we computed the following error:

$$
e = \sqrt{\mathbb{E}\left(\sup_{0\le n\le N} |X_n - Y_n|^2\right)}. \tag{6.3}
$$

To estimate the mean value needed, we used 500 sample trajectories.

In Figure 6.1, the order of each scheme is given by the slope of the corresponding line. So we can see that the orders are $\frac{1}{2}$ for Euler, 1 for Mil'shtein, and 2 for the SAB of section 3.

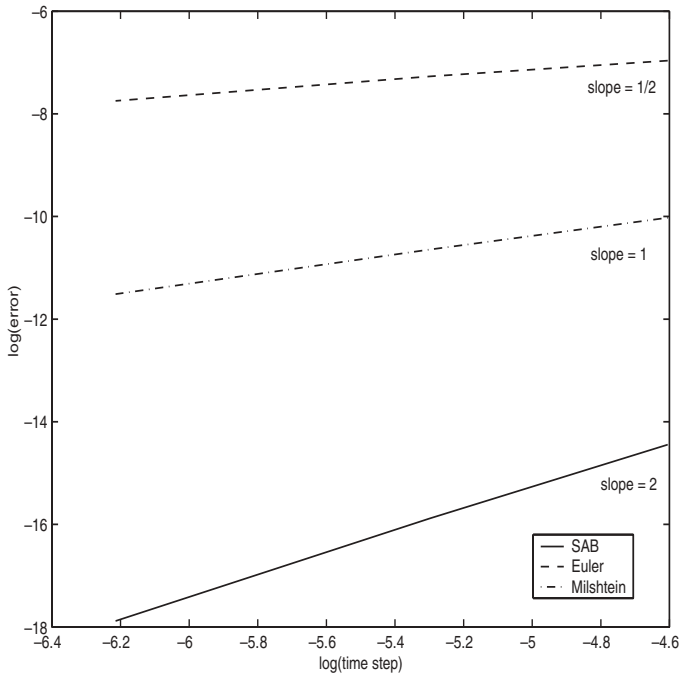

FIG. 6.1. *Results obtained with the stochastic equation* (6.1).

Note that for the SAB scheme, the stochastic integral $I_{(0,1,1)}$ (which is difficult to generate) was approximated by a normal law. The results tend to show that this does not affect the accuracy (at least in these two cases). We will try to improve this point, which seems to raise interesting probabilistic questions, as already mentioned in the introduction.

Acknowledgments. The authors are very grateful to Cecile Penland for bringing these issues to their attention, and they acknowledge very useful discussions with her and with Prashant Sardeshmukh. They are also indebted to Arnaud Debussche for several improvements on an earlier draft, and to Sylvain Faure, who provided the numerical simulations of section 6.

MULTIPLE SHOOTING FOR UNSTRUCTURED NONLINEAR DIFFERENTIAL-ALGEBRAIC EQUATIONS OF ARBITRARY INDEX*

PETER KUNKEL†, VOLKER MEHRMANN‡, AND RONALD STÖVER§

Abstract. We study multiple shooting methods for the numerical solution of nonlinear boundary value problems for unstructured nonlinear systems of differential-algebraic equations with arbitrary index. We give a convergence analysis and demonstrate the results with some numerical examples.

Key words. nonlinear boundary value problem, differential-algebraic equations, multiple shooting

1. Introduction. In this paper we consider the numerical solution of nonlinear boundary value problems for systems of differential-algebraic equations of arbitrary index by means of multiple shooting techniques. Multiple shooting is well studied and widely used for ordinary differential equations (see [1]) and also for special classes of systems of differential-algebraic equations (DAEs); see [15, 18].

In this paper we study general nonlinear DAE boundary value problems, i.e., problems of the form

$$\begin{array}{ll} \text{(a)} & F(t,x,\dot{x})=0, \\ \text{(b)} & r(x(\underline{t}),x(\bar{t}))=0, \end{array} \tag{1.1}$$

where $F:[\underline{t},\bar{t}]\times\mathbb{D}_x\times\mathbb{D}_{\dot{x}}\to\mathbb{R}^n$, $r:\mathbb{D}_x\times\mathbb{D}_x\to\mathbb{R}^d$ with $\mathbb{D}_x,\mathbb{D}_{\dot{x}}\subseteq\mathbb{R}^n$ open. The integer d denotes the number of differential components of x. A precise definition will follow in the next section.

The typical feature of shooting methods is that the solution of (1.1) is achieved through the solution of initial value problems, where it is implicitly assumed that they are well conditioned and can be solved sufficiently accurately. The boundary condition, together with the continuity conditions in the case of multiple shooting, then form a system of nonlinear equations for the initial values. In contrast to the application of shooting methods for the solution of ordinary differential equations, however, a problem arises for DAEs due to the fact that initial values have to be consistent with all explicit and hidden algebraic constraints. But even starting with a consistent initial guess, the iterative solver for the nonlinear equation will, in general, produce corrections that lead to inconsistent intermediate iterates. For this reason, shooting methods for nonlinear DAE boundary value problems were considered only

in very special cases, where the algebraic constraints are known explicitly [18], or where they can be accessed due to the special structure of the equation [5, 15].

For general linear problems with variable coefficients, the set of consistent initial values at a given point forms an affine space which is numerically accessible; see [9, 12]. Based on this knowledge, shooting methods were developed for this case in [20]. Generalizing this approach to the general nonlinear case is the subject of the present paper. The new method that we present is able to treat boundary value problems for general DAEs of a given arbitrary index, i.e., there are no assumptions on the structure of the equations besides the requirement that the DAE can be assigned a certain kind of index. Note that such an assumption is indispensable because we need existence and uniqueness results on which we can base our method.

The paper is organized as follows. In section 2, we state some preliminaries on the theory of DAEs. In particular, we give the basic index definition and some further results that we need for the construction and investigation of the presented approach. In section 3 we discuss the local uniqueness of solutions of (1.1) via single shooting. A multiple shooting approach is then presented in section 4 together with a special Gauß–Newton-like method. In particular, we show that the arising linear equations can be reduced to shooting systems as they are obtained by multiple shooting for a system of d ordinary differential equations. In section 5, we then discuss the results of a number of numerical experiments. Finally, we give some conclusions in section 6.

2. Preliminaries. In general, the solution of a DAE may depend on derivatives of (1.1a). In particular, we must perform so many differentiations such that we can deduce all algebraic constraints that (1.1a) imposes on possible values for $x(t)$. Assuming in the following that all occurring functions are sufficiently smooth, we first introduce the so-called derivative array functions (see [2, 3])

$$F_\ell(t,x,\dot{x},\dots,x^{(\ell+1)}) = \begin{bmatrix} F(t,x,\dot{x}) \\ \frac{d}{dt}F(t,x,\dot{x}) \\ \vdots \\ (\frac{d}{dt})^\ell F(t,x,\dot{x}) \end{bmatrix} \tag{2.1}$$

that are obtained from (1.1a) by successive differentiation with respect to t. Note that we treat $(t,x,\dot{x},\dots,x^{(\ell+1)})$ here as independent variables such that F_ℓ is a function from some subset of $\mathbb{R}^{(\ell+2)n+1}$ into $\mathbb{R}^{(\ell+1)n}$. Partial derivatives will be denoted by corresponding subscripts as, e.g., in

$$F_{\ell;x} = \tfrac{\partial}{\partial x}F_\ell, \quad F_{\ell;\dot{x},\dots,x^{(\ell+1)}} = \begin{bmatrix} \frac{\partial}{\partial \dot{x}}F_\ell & \cdots & \frac{\partial}{\partial x^{(\ell+1)}}F_\ell \end{bmatrix}.$$

The following hypothesis states the central requirements on the DAE (1.1a); see [10].

HYPOTHESIS 2.1. *There exist (nonnegative) integers μ, a, and d such that for all values $(t,x,\dot{x},\dots,x^{(\mu+1)}) \in \mathbb{L}_\mu$ with*

$$\mathbb{L}_\mu = \{(t,x,\dot{x},\dots,x^{(\mu+1)}) \in \mathbb{R}^{(\mu+2)n+1} \mid F_\mu(t,x,\dot{x},\dots,x^{(\mu+1)}) = 0\} \neq \emptyset \tag{2.2}$$

associated with F the following properties hold:

1. *We have*

$$\operatorname{rank} F_{\mu;\dot{x},\dots,x^{(\mu+1)}}(t,x,\dot{x},\dots,x^{(\mu+1)}) = (\mu+1)n - a$$

such that there exists a smooth matrix function $\hat{Z}_2$ *on* $\mathbb{L}_\mu$ *with orthonormal columns and size* $((\mu+1)n, a)$ *satisfying*

$$\hat{Z}_2^T F_{\mu;\dot{x},\ldots,x^{(\mu+1)}} = 0 \quad \text{on } \mathbb{L}_\mu.$$

2. *We have*

$$\operatorname{rank} \hat{Z}_2^T F_{\mu;x}(t, x, \dot{x}, \ldots, x^{(\mu+1)}) = a$$

such that there exists a smooth matrix function $\hat{T}_2$ *on* $\mathbb{L}_\mu$ *with orthonormal columns and size* (n, d)*, where* $d = n - a$*, satisfying*

$$\hat{Z}_2^T F_{\mu;x} \hat{T}_2 = 0 \quad \text{on } \mathbb{L}_\mu.$$

3. *We have*

$$\operatorname{rank} F_{\dot{x}} \hat{T}_2(t, x, \dot{x}, \ldots, x^{(\mu+1)}) = d$$

such that there exists a smooth matrix function $\hat{Z}_1$ *on* $\mathbb{L}_\mu$ *with orthonormal columns and size* (n, d) *satisfying*

$$\operatorname{rank} \hat{Z}_1^T F_{\dot{x}} \hat{T}_2 = d \quad \text{on } \mathbb{L}_\mu.$$

The minimal number μ (if it exists), such that Hypothesis 2.1 is fulfilled, is called the *strangeness index* of F. The numbers a and d denote the *size of the algebraic and differential part* of (1.1a). In particular, the choice of initial values is restricted by a algebraic constraints. More specific, for an initial value problem consisting of (1.1a) together with $x(t_0) = x_0$ to be solvable, the initial value x_0 must be extendable to a point $(t_0, x_0, \dot{x}_0, \ldots, x_0^{(\mu+1)})$ in $\mathbb{L}_\mu$. This requirement can be reduced to a conditions on x_0 itself; see [10] for more details.

A typical ingredient in the investigation of numerical methods for boundary value problems is the assumption that a solution of the given problem does exist. We therefore assume that there exists a sufficiently smooth solution $x^* \in C^1([\underline{t}, \overline{t}], \mathbb{R}^n)$ of (1.1) in the sense that

$$\begin{aligned} &\text{(a)} \quad F(t, x^*(t), \dot{x}^*(t)) = 0 \quad \text{for all } t \in [\underline{t}, \overline{t}], \\ &\text{(b)} \quad F_\mu(t, x^*(t), P(t)) = 0 \quad \text{for all } t \in [\underline{t}, \overline{t}], \\ &\text{(c)} \quad r(x^*(\underline{t}), x^*(\overline{t})) = 0, \end{aligned} \tag{2.3}$$

where $P : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\mu+1)n}$ is some smooth function that coincides with $\dot{x}^*$ in the first n components; see [11, Theorem 3] for sufficient conditions for such a function to exist.

Restricting the projectors $\hat{Z}_1$, $\hat{Z}_2$, $\hat{T}_2$ of Hypothesis 2.1 to the path $(t, x^*(t), P(t))$ which lies in $\mathbb{L}_\mu$ due to (2.3b), we obtain functions

$$Z_1 : [\underline{t}, \overline{t}] \to \mathbb{R}^{n,d}, \quad Z_2 : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\mu+1)n,a}, \quad T_2 : [\underline{t}, \overline{t}] \to \mathbb{R}^{n,d} \tag{2.4}$$

that satisfy

$$\begin{aligned} &\text{(a)} \quad Z_2(t)^T F_{\mu;\dot{x},\ldots,x^{(\mu+1)}}(t, x^*(t), P(t)) = 0 \quad \text{for all } t \in [\underline{t}, \overline{t}], \\ &\text{(b)} \quad Z_2(t)^T F_{\mu;x}(t, x^*(t), P(t)) T_2(t) = 0 \quad \text{for all } t \in [\underline{t}, \overline{t}], \\ &\text{(c)} \quad \operatorname{rank} Z_1(t)^T F_{\dot{x}}(t, x^*(t), \dot{x}^*(t)) T_2(t) = d \quad \text{for all } t \in [\underline{t}, \overline{t}]. \end{aligned} \tag{2.5}$$

In addition, there exist smooth functions

$$\begin{aligned} &Z_2' : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\mu+1)n,(\mu+1)n-a}, \qquad && T_1 : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\mu+1)n,a}, \\ &T_2' : [\underline{t}, \overline{t}] \to \mathbb{R}^{n,a}, && T_1' : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\mu+1)n,(\mu+1)n-a}, \end{aligned} \tag{2.6}$$

such that the matrix valued functions $[Z_2', Z_2]$, $[T_1', T_1]$, and $[T_2', T_2]$ are pointwise orthogonal and, furthermore,

$$Z_2'(t)^T F_{\mu;\dot{x},\ldots,x^{(\mu+1)}}(t, x^*(t), P(t))T_1(t) = 0 \quad \text{for all } t \in [\underline{t}, \overline{t}]. \tag{2.7}$$

It has been shown in [10] that for every

$$(t_0, x_0, \dot{x}_0, \ldots, x_0^{(\mu+1)}) \in \mathbb{L}_\mu$$

the DAE (1.1a), if it satisfies Hypothesis 2.1, locally defines a function x from a neighborhood of t_0 into $\mathbb{R}^n$. In particular, the x so obtained solves a DAE of differentiation index at most one that is extracted from the derivative array equations $F_\mu(t, x, \dot{x}, \ldots, x^{(\mu+1)}) = 0$. This solution can be extended until the boundary of the set where F_μ is defined is reached. Since

$$(t_0, x^*(t_0), P(t_0)) \in \mathbb{L}_\mu, \quad t_0 \in [\underline{t}, \overline{t}],$$

defines a solution on $[\underline{t}, \overline{t}]$, the same holds for every $(t_0, x_0, y_0) \in \mathbb{L}_\mu$ in a neighborhood of $(t_0, x^*(t_0), P(t_0))$.

In this section we have briefly presented some results on the solution and formulation of general nonlinear systems of DAEs. In the next section we use these results to analyze the single shooting method and the local uniqueness of solutions to the resulting nonlinear systems.

3. Single shooting and local uniqueness. In this section, which is of a more theoretical nature, we discuss the single shooting method. If initial value problems are uniquely solvable, then we can see the value of the solution at a certain point as a function of the initial value. This means that the boundary condition of a boundary value problem also becomes a function of the initial value. Therefore, a solution of a boundary value problem is said to be *locally unique* if the corresponding initial value is a locally unique solution of the boundary condition. For DAEs we must, of course, take into account that an initial condition must be consistent in the sense that there is a related point in the set $\mathbb{L}_\mu$.

For this reason we locally define a (nonlinear) projection onto $\mathbb{L}_\mu$ by considering the nonlinear system

$$\begin{aligned} &\text{(a)} \quad F_\mu(\underline{t}, \hat{x}, \hat{y}) = 0, \\ &\text{(b)} \quad T_2(\underline{t})^T(\hat{x} - x) = 0, \\ &\text{(c)} \quad T_1(\underline{t})^T(\hat{y} - y) = 0 \end{aligned} \tag{3.1}$$

in the unknowns $(x, y, \hat{x}, \hat{y})$.

If we write (3.1) as

$$H(x, y, \hat{x}, \hat{y}) = 0, \tag{3.2}$$

then a solution of this system is given by $(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t}))$. Since the Jacobian with respect to $\hat{x}, \hat{y}$ satisfies

$$\begin{aligned}
&\operatorname{rank} H_{\hat{x},\hat{y}}(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t})) \\
&\quad = \operatorname{rank} \begin{bmatrix} F_{\mu;x}(\underline{t}, x^*(\underline{t}), P(\underline{t})) & F_{\mu;y}(\underline{t}, x^*(\underline{t}), P(\underline{t})) \\ T_2(\underline{t})^T & 0 \\ 0 & T_1(\underline{t})^T \end{bmatrix} \\
&\quad = \operatorname{rank} \begin{bmatrix} Z_2'(\underline{t})^T F_{\mu;x}(\underline{t}, x^*(\underline{t}), P(\underline{t})) & Z_2'(\underline{t})^T F_{\mu;y}(\underline{t}, x^*(\underline{t}), P(\underline{t})) \\ Z_2(\underline{t})^T F_{\mu;x}(\underline{t}, x^*(\underline{t}), P(\underline{t})) & 0 \\ T_2(\underline{t})^T & 0 \\ 0 & T_1(\underline{t})^T \end{bmatrix},
\end{aligned}$$

and since by construction the matrices

$$\begin{bmatrix} Z_2'(t)^T F_{\mu;y}(t, x^*(t), P(t)) \\ T_1(t)^T \end{bmatrix}, \quad \begin{bmatrix} Z_2(t)^T F_{\mu;x}(t, x^*(t), P(t)) \\ T_2(t)^T \end{bmatrix}$$

are nonsingular for all $t \in [\underline{t}, \overline{t}]$, it follows that $H_{\hat{x},\hat{y}}(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t}))$ is nonsingular. We can therefore solve locally for $(\hat{x}, \hat{y})$ obtaining a function S according to

$$(\hat{x}, \hat{y}) = S(x, y). \tag{3.3}$$

Since $F_\mu(\underline{t}, S(x, y)) = 0$, we have that $(\underline{t}, S(x, y)) \in \mathbb{L}_\mu$ for every (x, y) in a neighborhood of $(x^*(\underline{t}), P(\underline{t}))$. Observing that the initial value problem for (1.1a) together with $(\underline{t}, S(x^*(\underline{t}), P(\underline{t}))) \in \mathbb{L}_\mu$ is solvable on the whole interval $[\underline{t}, \overline{t}]$, the initial value problem remains solvable on the whole interval $[\underline{t}, \overline{t}]$ with an initial condition given by $(\underline{t}, \underline{x}, \underline{y})$ from a neighborhood $\mathbb{L}_\mu \cap \mathbb{U}$ of $(\underline{t}, x^*(\underline{t}), P(\underline{t}))$. Thus the DAE defines a flow

$$\Phi : \mathbb{V} \to \mathbb{R}^n, \quad \mathbb{V} = \{(\underline{x}, \underline{y}) \mid (\underline{t}, \underline{x}, \underline{y}) \in \mathbb{L}_\mu \cap \mathbb{U}\} \tag{3.4}$$

that maps $(\underline{x}, \underline{y}) \in \mathbb{V}$ on the final value $x(\overline{t})$ of the solution x of the associated initial value problem.

For later use, we will need the derivatives of S at $(x^*(\underline{t}), P(\underline{t}))$. These are given by

$$\begin{aligned}
&H_{\hat{x},\hat{y}}(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t})) S_{x,y}(x^*(\underline{t}), P(\underline{t})) \\
&\quad = -H_{x,y}(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t})),
\end{aligned}$$

i.e.,

$$\begin{bmatrix} F_{\mu,x}(\underline{t}, x^*(\underline{t}), P(\underline{t})) & F_{\mu;y}(\underline{t}, x^*(\underline{t}), P(\underline{t})) \\ T_2(\underline{t})^T & 0 \\ 0 & T_1(\underline{t})^T \end{bmatrix} S_{x,y}(x^*(\underline{t}), P(\underline{t})) = \begin{bmatrix} 0 & 0 \\ T_2(\underline{t})^T & 0 \\ 0 & T_1(\underline{t})^T \end{bmatrix}.$$

Let the columns of W be orthonormal and span kernel $F_{\mu;x,y}(\underline{t}, x^*(\underline{t}), P(\underline{t}))$. Setting

$$\tilde{W} = \begin{bmatrix} T_2(\underline{t}) & 0 \\ 0 & T_1(\underline{t}) \end{bmatrix}, \tag{3.5}$$

we see that $\tilde{W}^T W$ is nonsingular, since $H_{\hat{x},\hat{y}}(x^*(\underline{t}), P(\underline{t}), x^*(\underline{t}), P(\underline{t}))$ is nonsingular, and we have

$$S_{x,y}(x^*(\underline{t}), P(\underline{t})) = W(\tilde{W}^T W)^{-1}\tilde{W}^T. \tag{3.6}$$

We then have the following theorem on the local uniqueness of solutions of boundary value problems for DAEs.

THEOREM 3.1. *The function x^* in* (2.3) *is a locally unique solution of the boundary value problem* (1.1) *in the sense that $(x^*(\underline{t}), P(\underline{t}))$ is a solution of*

$$\begin{aligned} &\text{(a)} \quad F_\mu(\underline{t}, \underline{x}, \underline{y}) = 0, \\ &\text{(b)} \quad T_1(\underline{t})^T(\underline{y} - P(\underline{t})) = 0, \\ &\text{(c)} \quad r(\underline{x}, \Phi(S(\underline{x}, \underline{y}))) = 0, \end{aligned} \tag{3.7}$$

with nonsingular Jacobian if and only if

$$\mathcal{E} = CT_2(\underline{t}) + D\Phi_{x,y}(x^*(\underline{t}), P(\underline{t}))S_x(x^*(\underline{t}), P(\underline{t}))T_2(\underline{t}) \tag{3.8}$$

is nonsingular, where $C = r_{x_a}(x^*(\underline{t}), x^*(\bar{t}))$ and $D = r_{x_b}(x^*(\underline{t}), x^*(\bar{t}))$.

Proof. Obviously, $(\underline{x}, \underline{y}) = (x^*(\underline{t}), P(\underline{t}))$ is a solution of (3.7). Moreover, the Jacobian J of (3.7) is given by

$$J = \begin{bmatrix} F_{\mu;x} & F_{\mu;y} \\ 0 & T_1(\underline{t})^T \\ C + D\Phi_{x,y}S_x & D\Phi_{x,y})S_y \end{bmatrix},$$

where we have omitted the arguments $\underline{t}, x^*(\underline{t}), P(\underline{t})$. So we have that $\operatorname{rank} J$ is equal to

$$\operatorname{rank} \begin{bmatrix} Z_2'^T F_{\mu;x} T_2' & Z_2'^T F_{\mu;x} T_2 & Z_2'^T F_{\mu;y} T_1' & 0 \\ Z_2^T F_{\mu;x} T_2' & 0 & 0 & 0 \\ 0 & 0 & 0 & I \\ (C + D\Phi_{x,y}S_x)T_2' & (C + D\Phi_{x,y}S_x)T_2 & D\Phi_{x,y}S_y T_1' & D\Phi_{x,y}S_y T_1 \end{bmatrix}.$$

Since

$$S_x = W(\tilde{W}^T W)^{-1}\begin{bmatrix} T_2^T \\ 0 \end{bmatrix}, \quad S_y = W(\tilde{W}^T W)^{-1}\begin{bmatrix} 0 \\ T_1^T \end{bmatrix}$$

by (3.5), we have $S_x T_2' = 0$ and $S_y T_1' = 0$ by (2.6). Moreover, $Z_2^T F_{\mu;x} T_2'$ and $Z_2'^T F_{\mu;y} T_1'$ are nonsingular by construction. Thus J has full rank if and only if

$$\mathcal{E} = (C + D\Phi_{x,y}S_x)T_2$$

has full rank. ∎

REMARK 3.2. *In the case of linear boundary value problems, i.e., problems* (1.1) *where F and r are linear, condition* (3.8) *coincides with that given in* [14, 20, 21] *and thus yields global uniqueness of the solution x^**

Proof. Since we do not need this result further in the course of this paper, we give the proof in the appendix. ∎

4. Multiple shooting. It is well known that in single shooting, one is faced with the difficulty that the arising initial value problems may be unstable. This may lead to large solution components or even to the problem that the solution does not extend until $\bar{t}$ due to errors in the initial guess. To overcome these difficulties, in multiple shooting the solution interval is split beforehand into smaller subintervals according to

$$\underline{t} = t_0 < t_1 < \cdots < t_{N-1} < t_N = \bar{t}, \quad N \in \mathbb{N}. \tag{4.1}$$

Given initial guesses

$$(x_i, y_i) \in \mathbb{R}^{(\mu+2)n}, \quad i = 0, \ldots, N, \tag{4.2}$$

at these points, the idea is to project (t_i, x_i, y_i) onto $\mathbb{L}_\mu$ and to solve the associated initial value problems on $[t_i, t_{i+1}]$, requiring that the pieces correspond to a continuous solution on the whole interval and that the boundary condition is satisfied.

In contrast to section 3 which was merely dedicated to a theoretical investigation, in this section we present a method that can actually be implemented. We therefore are not allowed to use functions such as Z_2 or T_2 in the definition of the procedure. Instead, we must look for computationally available quantities.

Given (t_i, x_i, y_i) as an initial guess for a point on $\mathbb{L}_\mu$, we can solve $F_\mu(t_i, x, y) = 0$ by the Gauß–Newton method (see, e.g., [16]) to obtain $(t_i, \tilde{x}_i, \tilde{y}_i) \in \mathbb{L}_\mu$. Of course, we must require that the guess (t_i, x_i, y_i) is good enough to guarantee convergence. Applying Hypothesis 2.1, we can then compute quantities $\tilde{Z}_{2,i}$ and $\tilde{T}_{2,i}$, where the columns form orthonormal bases of corange $F_{\mu;y}(t_i, \tilde{x}_i, \tilde{y}_i)$ and kernel $\tilde{Z}_{2,i}^T F_{\mu;x}(t_i, \tilde{x}_i, \tilde{y}_i)$, respectively. In the same way, we can determine quantities $\tilde{Z}'_{2,i}$ and $\tilde{T}_{1,i}$.

Similar to (3.1), the system

$$\begin{aligned} &\text{(a)} \quad F_\mu(t_i, \hat{x}_i, \hat{y}_i) = 0, \\ &\text{(b)} \quad \tilde{T}_{2,i}^T(\hat{x}_i - x_i) = 0, \\ &\text{(c)} \quad \tilde{T}_{1,i}^T(\hat{y}_i - y_i) = 0 \end{aligned} \tag{4.3}$$

locally defines functions S_i according to

$$(\hat{x}_i, \hat{y}_i) = S_i(x_i, y_i) \tag{4.4}$$

in such a way that $(t_i, S_i(x_i, y_i)) \in \mathbb{L}_\mu$. Defining W_i to have columns that form an orthonormal basis of kernel $F_{\mu;x,y}(t_i, \hat{x}_i, \hat{y}_i)$ with $(t_i, \hat{x}_i, \hat{y}_i) \in \mathbb{L}_\mu$ and setting

$$\tilde{W}_i = \begin{bmatrix} \tilde{T}_{2,i} & 0 \\ 0 & \tilde{T}_{1,i} \end{bmatrix}, \tag{4.5}$$

we obtain

$$S_{i;x,y}(\hat{x}_i, \hat{y}_i) = W_i(\tilde{W}_i^T W_i)^{-1} \tilde{W}_i^T \tag{4.6}$$

similar to (3.6) as long as $\tilde{W}_i^T W_i$ is invertible. As was done with Φ in section 3, we define flows Φ_i that map initial values $(\hat{x}_i, \hat{y}_i)$ with $(t_i, \hat{x}_i, \hat{y}_i) \in \mathbb{L}_\mu$ on the value $x(t_{i+1})$ of the solution x of the corresponding initial value problem.

The multiple shooting system is then given by

$$\begin{aligned} &\text{(a)} \quad F_\mu(t_i, x_i, y_i) = 0, && i = 0, \ldots, N, \\ &\text{(b)} \quad \tilde{T}_{2,i+1}^T(x_{i+1} - \Phi_i(S_i(x_i, y_i))) = 0, && i = 0, \ldots, N-1, \\ &\text{(c)} \quad r(x_0, x_N) = 0. \end{aligned} \tag{4.7}$$

Comparing with the single shooting method of section 3, (3.7a) is now required in (4.7a) at all mesh points t_i with corresponding unknowns (x_i, y_i). Besides the boundary condition (4.7c), we impose continuity conditions for the differential components in (4.7b). Condition (3.7b), which was responsible for local uniqueness of the solution in (3.7), cannot be used here because it involves knowledge of the actual solution. Thus, in the present form, system (4.7) is underdetermined. It is therefore solved by a Gauß–Newton-type iteration method which we present in what follows. In the course of the presentation, we will select a suitable generalized inverse of the Jacobian by additional conditions which will turn out to be the appropriate replacement for (3.7b).

Given approximations (x_i, y_i), the Gauß–Newton-type method is defined by the corrections $(\Delta x_i, \Delta y_i)$ that are added to (x_i, y_i) to get updated approximations. In the (underdetermined) ordinary Gauß–Newton method, these corrections satisfy the linearized equations

$$\begin{aligned}
&\text{(a)} \quad F_{\mu;x}(t_i, x_i, y_i)\Delta x_i + F_{\mu;y}(t_i, x_i, y_i)\Delta y_i = -F_\mu(t_i, x_i, y_i),\\
&\text{(b)} \quad \tilde{T}_{2,i+1}^T(\Delta x_{i+1} - \Phi_{i;x,y}(S_i(x_i, y_i))(S_{i;x}(x_i, y_i)\Delta x_i + S_{i;y}(x_i, y_i)\Delta y_i))\\
&\qquad\qquad = -\tilde{T}_{2,i+1}^T(x_{i+1} - \Phi_i(S_i(x_i, y_i))),\\
&\text{(c)} \quad r_{x_a}(x_0, x_N)\Delta x_0 + r_{x_b}(x_0, x_N)\Delta x_N = -r(x_0, x_N).
\end{aligned} \tag{4.8}$$

For an efficient numerical method, however, the structure and the properties of the Jacobian should be utilized. In the following, we will perturb the coefficient matrix in such a way that the system decouples into smaller systems of reasonable size. In particular, the perturbations that we apply will tend to zero when the (x_i, y_i) converge to a solution of (4.7) resulting in a Gauß–Newton-like process with superlinear convergence rate; cf. [4].

In a solution of (4.7), the matrices $F_{\mu;y}(t_i, x_i, y_i)$ will have rank deficiency a. We therefore perturb $F_{\mu;y}(t_i, x_i, y_i)$ to matrices $\tilde{M}_i$ with rank deficiency a. The only condition we must require is that these perturbations tend to zero when the matrices $F_{\mu;y}(t_i, x_i, y_i)$ tend to matrices with rank deficiency a. One possibility for achieving this is to neglect the a smallest singular values of $F_{\mu;y}(t_i, x_i, y_i)$; see, e.g., [6]. The equations (4.8a) are thus replaced by

$$F_{\mu;x}(t_i, x_i, y_i)\Delta x_i + \tilde{M}_i\Delta y_i = -F_\mu(t_i, x_i, y_i). \tag{4.9}$$

Let the columns of $Z_{2,i}$ form an orthonormal basis of corange $\tilde{M}_i$ and let $[Z'_{2,i}, Z_{2,i}]$ be orthogonal. Relation (4.9) then splits into

$$\begin{aligned}
&\text{(a)} \quad Z_{2,i}'^T F_{\mu;x}(t_i, x_i, y_i)\Delta x_i + Z_{2,i}'^T\tilde{M}_i\Delta y_i = -Z_{2,i}'^T F_\mu(t_i, x_i, y_i),\\
&\text{(b)} \quad Z_{2,i}^T F_{\mu;x}(t_i, x_i, y_i)\Delta x_i = -Z_{2,i}^T F_\mu(t_i, x_i, y_i).
\end{aligned} \tag{4.10}$$

Requiring in addition that

$$\tilde{T}_{1,i}^T\Delta y_i = 0 \tag{4.11}$$

as a substitute for (3.7b) and observing that

$$\begin{bmatrix} Z_{2,i}'^T\tilde{M}_i \\ \tilde{T}_{1,i}^T \end{bmatrix}$$

is nonsingular for sufficiently good initial guesses (x_i, y_i), it follows that we can solve (4.10a) with (4.11) for Δy_i in terms of Δx_i.

Let the columns of the matrix $T_{2,i}$ form an orthonormal basis of the space kernel $Z_{2,i}^T F_{\mu;x}(t_i, x_i, y_i)$. For sufficiently good initial guesses (x_i, y_i), $\tilde{T}_{2,i}^T T_{2,i}$ is also nonsingular. Thus, there exists a matrix $T'_{2,i}$ such that $[T'_{2,i}, T_{2,i}]$ is nonsingular and

$$\tilde{T}_{2,i}^T T'_{2,i} = 0. \tag{4.12}$$

Defining $\Delta v'_i$ and Δv_i by the relation

$$\Delta x_i = T'_{2,i} \Delta v'_i + T_{2,i} \Delta v_i, \tag{4.13}$$

(4.10b) becomes

$$Z_{2,i}^T F_{\mu;x}(t_i, x_i, y_i) T'_{2,i} \Delta v'_i = -Z_{2,i}^T F_{\mu}(t_i, x_i, y_i). \tag{4.14}$$

Since $Z_{2,i}^T F_{\mu;x}(t_i, x_i, y_i) T'_{2,i}$ is nonsingular by construction, (4.14) can be solved for $\Delta v'_i$.

Turning to (4.8b), we know that at a solution of (4.8), the relations

$$\begin{aligned} &\text{(a)}\ \ S_{i;x}(x_i, y_i)\Delta x_i = W_i(\tilde{W}_i^T W_i)^{-1} \begin{bmatrix} \tilde{T}_{2,i}^T \\ 0 \end{bmatrix} T_{2,i} \Delta v_i = S_{i;x}(x_i, y_i) T_{2,i} \Delta v_i, \\ &\text{(b)}\ \ S_{i;y}(x_i, y_i)\Delta y_i = W_i(\tilde{W}_i^T W_i)^{-1} \begin{bmatrix} 0 \\ \tilde{T}_{1,i}^T \end{bmatrix} \Delta y_i = 0 \end{aligned} \tag{4.15}$$

hold because of (4.11) and (4.12). Thus, we replace (4.8b) by

$$\begin{aligned} &\tilde{T}_{2,i+1}^T T_{2,i+1} \Delta v_{i+1} - \tilde{T}_{2,i+1}^T \Phi_{i;x,y}(S_i(x_i, y_i)) S_{i;x}(x_i, y_i) T_{2,i} \Delta v_i \\ &\quad = -\tilde{T}_{2,i+1}^T (x_{i+1} - \Phi_i(S_i(x_i, y_i))), \end{aligned} \tag{4.16}$$

which is again a perturbation that tends to zero when the iteration converges. The main advantage of (4.16) is that we need only the derivative $\Phi_{i;x,y}(S_i(x_i, y_i)) S_{i;x}(x_i, y_i)$ in the direction of the d columns of $T_{2,i}$. In particular, if we use numerical differentiation to approximate this derivative, then we need only solve d initial value problems.

Finally, we write (4.8c) in the form

$$\begin{aligned} &r_{x_a}(x_0, x_N) T_{2,0} \Delta v_0 + r_{x_b}(x_0, x_N) T_{2,N} \Delta v_N \\ &\quad = -r(x_0, x_N) - r_{x_a}(x_0, x_N) T'_{2,0} \Delta v'_0 - r_{x_b}(x_0, x_N) T'_{2,N} \Delta v'_N. \end{aligned} \tag{4.17}$$

Setting

$$\begin{aligned} &\text{(a)} \quad G_i = \tilde{T}_{2,i+1}^T \Phi_{i;x,y}(S_i(x_i, y_i)) S_{i;x}(x_i, y_i) T_{2,i}, \quad i = 0, \ldots, N-1, \\ &\text{(b)} \quad J_i = \tilde{T}_{2,i}^T T_{2,i}, \quad i = 1, \ldots, N, \\ &\text{(c)} \quad \tilde{C} = r_{x_a}(x_0, x_N) T_{2,0}, \quad \tilde{D} = r_{x_b}(x_0, x_N) T_{2,N}, \end{aligned} \tag{4.18}$$

the linear system that we have to solve for the unknowns Δv_i has the shooting-like coefficient matrix

$$\tilde{\mathcal{E}}_N = \begin{bmatrix} -G_0 & J_1 & & & \\ & -G_1 & J_2 & & \\ & & \ddots & \ddots & \\ & & & -G_{N-1} & J_N \\ \tilde{C} & & & & \tilde{D} \end{bmatrix}. \tag{4.19}$$

This system can be solved by standard methods such as Gaussian elimination with pivoting [6]. Since the blocks J_i are invertible for sufficiently good initial guesses (x_i, y_i), it follows that the matrix $\tilde{\mathcal{E}}_N$ is nonsingular if and only if

$$\mathcal{E}_N = \tilde{C} + \tilde{D}(J_N^{-1}G_{N-1})(J_{N-1}^{-1}G_{N-2})\cdots(J_2^{-1}G_1)(J_1^{-1}G_0) \tag{4.20}$$

is nonsingular. Thus, for the method to work, it suffices to show that this is the case at least at the solution and therefore in some neighborhood of it.

At a solution $(x_i, y_i) = (x^*(t_i), y_i^*)$, the matrix $\mathcal{E}_N$ takes the form

$$\begin{aligned}\mathcal{E}_N = CT_{2,0} + DT_{2,N} \prod_{i=N-1}^{i=0} \Big[&(\tilde{T}_{2,i+1}^T T_{2,i+1})^{-1} \tilde{T}_{2,i+1}^T \\ &\times \Phi_{i;x,y}(S_i(x_i, y_i)) S_{i;x}(x_i, y_i) T_{2,i} \Big].\end{aligned} \tag{4.21}$$

To take into account that $\Phi_i(S_i(x, y))$ is consistent at t_{i+1} for (x, y) in a neighborhood of (x_i, y_i) as the value of a solution of the DAE on $[t_i, t_{i+1}]$, we consider the system

$$\begin{aligned} &\text{(a)} \quad F_\mu(t_i, x, \hat{y}) + Z_{2,i}\alpha = 0, \\ &\text{(b)} \quad \tilde{T}_{1,i}^T(\hat{y} - y_i) = 0. \end{aligned} \tag{4.22}$$

Writing this as

$$H_i(x, \hat{y}, \alpha) = 0, \tag{4.23}$$

we know that $H_i(x_i, y_i, 0) = 0$. Since

$$\begin{aligned}&\operatorname{rank} H_{i;\hat{y},\alpha}(x_i, y_i, 0) \\ &\quad = \operatorname{rank} \begin{bmatrix} F_{\mu;y}(t_i, x_i, y_i) & Z_{2,i} \\ \tilde{T}_{1,i}^T & 0 \end{bmatrix} = \operatorname{rank} \begin{bmatrix} Z_{2,i}'^T F_{\mu;y}(t_i, x_i, y_i) & 0 \\ 0 & I \\ \tilde{T}_{1,i}^T & 0 \end{bmatrix},\end{aligned}$$

the construction of $Z_{2,i}'$ and $\tilde{T}_{1,i}$ guarantees that the matrix $H_{i;\hat{y},\alpha}(x_i, y_i, 0)$ is nonsingular. Thus, (4.22) locally defines functions K_i and L_i according to

$$\hat{y} = K_i(x), \quad \alpha = L_i(x). \tag{4.24}$$

For all x with $L_i(x) = 0$ we have $F_\mu(t_i, x, K_i(x)) = 0$ and x is consistent at t_i. Furthermore, differentiating

$$F_\mu(t_i, x, K_i(x)) + Z_{2,i}L_i(x) = 0,$$

evaluating at x_i and multiplying by $Z_{2,i}^T$ yields

$$L_{i;x}(x_i) = -Z_{2,i}^T F_{\mu;x}(t_i, x_i, y_i).$$

Hence, $L_{i;x}$ has full row rank in a neighborhood of x_i, and all solutions of $L_i(x) = 0$ form a manifold of dimension $d = n - a$ which is a submanifold of the manifold of consistent values at point t_i. Since the dimension of the latter manifold is also d (see [10]), they must coincide.

Thus, given an x that is consistent at t_i, the function K_i yields a $\hat{y}$ such that $(t_i, x, \hat{y}) \in \mathbb{L}_\mu$ while $L_i(x) = 0$. In particular,

$$F_\mu(t_{i+1}, \Phi_i(S_i(x, y)), K_{i+1}(\Phi_i(S_i(x, y)))) = 0 \tag{4.25}$$

holds in a neighborhood of (x_i, y_i). Differentiating this relation with respect to (x, y) and setting $(x, y) = (x_i, y_i)$, we obtain

$$\begin{aligned} &F_{\mu;x}(t_{i+1}, x_{i+1}, y_{i+1})\Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i) \\ &\quad + F_{\mu;y}(t_{i+1}, x_{i+1}, y_{i+1})K_{i+1;x}(x_{i+1})\Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i) = 0. \end{aligned}$$

Multiplying with $Z_{2,i+1}^T$ from the left finally yields

$$Z_{2,i+1}^T F_{\mu;x}(t_{i+1}, x_{i+1}, y_{i+1})\Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i) = 0. \tag{4.26}$$

Hence, the columns of $\Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i)$ lie in the kernel of the matrix $Z_{2,i+1}^T F_{\mu;x}(t_{i+1}, x_{i+1}, y_{i+1})$, which in turn is spanned by the columns of $T_{2,i+1}$. Since the expression $T_{2,i+1}(\tilde{T}_{2,i+1}^T T_{2,i+1})^{-1}\tilde{T}_{2,i+1}^T$ is a projector on this kernel, we have

$$\begin{aligned} &T_{2,i+1}(\tilde{T}_{2,i+1}^T T_{2,i+1})^{-1}\tilde{T}_{2,i+1}^T \Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i) \\ &\quad = \Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i). \end{aligned} \tag{4.27}$$

Thus, (4.21) reduces to

$$\mathcal{E}_N = CT_{2,0} + D\left[\prod_{i=N-1}^{i=0} \Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x}(x_i, y_i)\right] T_{2,0}. \tag{4.28}$$

Finally, defining

$$\Psi_i(x) = (x, K_i(x)) \tag{4.29}$$

and using $\tilde{T}_{1,i}^T K_{i;x}(x_i) = 0$, which holds due to (4.22b), we find that

$$\begin{aligned} &S_{i;x,y}(x_i, y_i)\Psi_{i;x}(x_i) \\ &\quad = W_i(\tilde{W}_i^T W_i)^{-1}\begin{bmatrix} \tilde{T}_{2,i}^T & 0 \\ 0 & \tilde{T}_{1,i}^T \end{bmatrix}\begin{bmatrix} I \\ K_{i;x}(x_i) \end{bmatrix} \\ &\quad = W_i(\tilde{W}_i^T W_i)^{-1}\begin{bmatrix} \tilde{T}_{2,i}^T \\ 0 \end{bmatrix} = S_{i;x}(x_i, y_i). \end{aligned}$$

Hence, (4.28) becomes

$$\mathcal{E}_N = CT_{2,0} + D\left[\prod_{i=N-1}^{i=0} \Phi_{i;x,y}(S_i(x_i, y_i))S_{i;x,y}(x_i, y_i)\Psi_{i;x}(x_i)\right] T_{2,0}. \tag{4.30}$$

Comparing with (3.8), the term in brackets in (4.30) is nothing more than the derivative $\Phi_{x,y}\tilde{S}_x$ of $\Phi \circ \tilde{S}$ decomposed according to

$$\Phi \circ \tilde{S} = (\Phi_{N-1} \circ S_{N-1}) \circ (\Psi_{N-1} \circ \Phi_{N-2} \circ S_{N-2}) \circ \cdots \circ (\Psi_1 \circ \Phi_0 \circ S_0), \tag{4.31}$$

where $\tilde{S}$ differs from S by replacing $T_1(\underline{t}), T_2(\underline{t})$ with $\tilde{T}_{1,0}, \tilde{T}_{2,0}$ in (3.1). This means that for sufficiently good initial guesses, the matrix $\mathcal{E}_N$ is nonsingular when $\mathcal{E}$ of (3.8) is nonsingular, i.e., when there is a locally unique solution of the boundary value problem in the sense of Theorem 3.1.

Summarizing the results obtained, we have the following convergence theorem.

THEOREM 4.1. *Suppose that the boundary value problem* (1.1) *satisfies Hypothesis* 2.1 *and that* (1.1) *has a locally unique solution according to Theorem* 3.1. *Then, for sufficiently good initial guesses, the iterates of the Gauß–Newton-like procedure developed in the course of this section converge superlinearly to a solution of* (4.7).

Proof. Writing the Gauß–Newton-like procedure for (4.7) in the form

$$z_{\nu+1} = z_\nu - \mathcal{A}_\nu^- \mathcal{F}(z_\nu),$$

where $\mathcal{A}_\nu$ is the chosen perturbation of $\mathcal{F}_z(z_\nu)$ and $\mathcal{A}_\nu^-$ denotes the chosen pseudoinverse due to (4.11), we have

$$\mathcal{A}_\nu \mathcal{A}_\nu^- = I,$$

since $\mathcal{A}_\nu^-$ yields a solution of the perturbed linear system. Thus, we get

$$\begin{aligned} z_{\nu+1} - z_\nu &= -\mathcal{A}_\nu^- \mathcal{F}(z_\nu) \\ &= -\mathcal{A}_\nu^- \big[\mathcal{F}(z_\nu) - \mathcal{F}(z_{\nu-1}) - \mathcal{A}_{\nu-1}(z_\nu - z_{\nu-1})\big] \\ &= -\mathcal{A}_\nu^- \big[\mathcal{F}(z_{\nu-1} + s(z_\nu - z_{\nu-1}))\big|_{s=0}^{s=1} - \mathcal{F}_z(z_{\nu-1})(z_\nu - z_{\nu-1}) \\ &\qquad -(\mathcal{A}_{\nu-1} - \mathcal{F}_z(z_{\nu-1}))(z_\nu - z_{\nu-1})\big] \\ &= -\mathcal{A}_\nu^- \big[\textstyle\int_0^1 (\mathcal{F}_z(z_{\nu-1}+s(z_\nu - z_{\nu-1})) - \mathcal{F}_z(z_{\nu-1}))(z_\nu - z_{\nu-1})\, ds \\ &\qquad -(\mathcal{A}_{\nu-1} - \mathcal{F}_z(z_{\nu-1}))(z_\nu - z_{\nu-1})\big]. \end{aligned}$$

Introducing constants β, γ, and δ_ν according to

$$\|\mathcal{A}_\nu^-\| \le \beta, \quad \|\mathcal{F}_z(u) - \mathcal{F}_z(v)\| \le \gamma\|u - v\|, \quad \|\mathcal{A}_\nu - \mathcal{F}_z(z_\nu)\| = \delta_\nu$$

for some vector norm and its corresponding matrix norm (recalling that we assume sufficient smoothness for the data), we obtain the estimate

$$\|z_{\nu+1} - z_\nu\| \le \frac{1}{2}\beta\gamma\|z_\nu - z_{\nu-1}\|^2 + \beta\delta_{\nu-1}\|z_\nu - z_{\nu-1}\|.$$

Since $\delta_\nu \to 0$ when z_ν converges to a solution, superlinear convergence follows as in [4]. ∎

REMARK 4.2. *In all steps of the above construction, we were forced to include the equation $F_\mu = 0$ in order to get hold of all algebraic constraints posed by the given DAE. For problems with structure it is often much easier to address these algebraic constraints. Sometimes one can even simply write them down. In both cases, the approach presented above can be simplified to obtain more efficient procedures. In particular, one can replace the equation $F_\mu = 0$ by a simpler one that determines the algebraic constraints, or even replace it by them if they are known explicitly.*

REMARK 4.3. *As already mentioned, the main problem in the construction of shooting methods for DAEs is how to deal with inconsistent intermediate iterates. In the method presented here, we used (locally defined) nonlinear projections on $\mathbb{L}_\mu$ to get consistent initial values. A second possibility would have been to shift the manifold $\mathbb{L}_\mu$ in such a way that the given inconsistent iterate then lies in the shifted manifold. In the case of single shooting, if*

$$(\hat{x}, \hat{y}) = S(x_0, y_0),$$

then we would define

$$\hat{\mathbb{L}}_\mu = \{(t, x, y) \in \mathbb{R}^{(\mu+2)n+1} \mid F_\mu(t, x - x_0 + \hat{x}, y - y_0 + \hat{y}) = 0\}$$

and solve the arising initial value problem with respect to $\hat{\mathbb{L}}_\mu$. The same idea is used by [18] *in the form of so-called relaxed algebraic constraints when these are explicitly*

available. One can show that using the technique of shifting the manifold would yield a method with the same properties as the new method we have presented. However, the method of shifting the manifold has the disadvantage that it requires modifying F_μ for use in the initial value solver.

5. Numerical experiments. The procedure of section 4 has been implemented in `FORTRAN` in the form of a research code. All rank decisions, computations of kernel and corange matrices and their complements, as well as the solution of linear equations, are performed on the basis of singular value decompositions. In particular, no concern was laid on efficiency questions. Due to that, all multiple shooting codes designed for special structured DAEs should outperform the present implementation. All computations were done on a `Sun Blade 100` workstation with 500 MHz in `IEEE` double precision.

The following examples cover a large variety of problem classes of different structure and differentiation index. In all examples, the Gauß–Newton-like procedure of Theorem 4.1 was terminated as soon as $\|\Delta z_\nu\|_2 \le 10^{-5}$, where $\Delta z_\nu = z_{\nu+1} - z_\nu$. The entries G_i of (4.19) were approximated by numerical differentiation according to

$$G_i e_j = \tfrac{1}{\eta} \tilde{T}_{2,i+1}^T [\Phi_i(S_i(x_i + \eta T_{2,i} e_j, y_i)) - \Phi_i(x_i, y_i)], \qquad j = 1, \dots, d,\ i = 0, \dots, N-1,$$

where e_j is the jth canonical basis vector of $\mathbb{R}^d$. We used the choice $\eta = 10^{-7}$. All initial value problems occurring were solved with `GENDA` of [13] using the tolerance 10^{-5}.

Example 5.1. In [7], the model of a periodically driven electronic amplifier is given. The equations with $n = 5$ for the unknowns $(U_1, \dots, U_5)$ read as

$$\begin{aligned}
&(U_E(t) - U_1)/R_0 + C_1(\dot{U}_2 - \dot{U}_1) = 0,\\
&(U_B - U_2)/R_2 - U_2/R_1 + C_1(\dot{U}_1 - \dot{U}_2) - 0.01 f(U_2 - U_3) = 0,\\
&f(U_2 - U_3) - U_3/R_3 - C_2\dot{U}_3 = 0,\\
&(U_B - U_4)/R_4 + C_3(\dot{U}_5 - \dot{U}_4) - 0.99 f(U_2 - U_3) = 0,\\
&-U_5/R_5 + C_3(\dot{U}_4 - \dot{U}_5) = 0
\end{aligned}$$

with

$$\begin{aligned}
U_E(t) &= 0.4 \sin(200\pi t), \quad U_B = 6,\\
f(U) &= 10^{-6}(\exp(U/0.026) - 1),\\
R_0 &= 1000, \quad R_1 = \cdots = R_5 = 9000,\\
C_1 &= 10^{-6}, \quad C_2 = 2 \cdot 10^{-6}, \quad C_3 = 3 \cdot 10^{-6}.
\end{aligned}$$

The problem is known to satisfy Hypothesis 2.1 with $\mu = 0$, $d = 3$, and $a = 2$. If we ask for the periodic response of the amplifier, we are led to the boundary conditions

$$U_l(0) = U_l(0.01), \quad l = 2, 3, 5;$$

thus $\underline{t} = 0$ and $\bar{t} = 0.01$. We used $N = 1$ and determined the initial guess for the unknowns (x_i, y_i), $i = 0, \dots, N$, by integration starting with

$$(0, V_1, V_1, U_B, 0, 0, 0, V_2, 0, 0) \in \mathbb{L}_\mu,$$

where $V_1 = U_B \frac{R_1}{R_1 + R_2}$ and $V_2 = -\frac{V_1}{R_3 C_2}$.

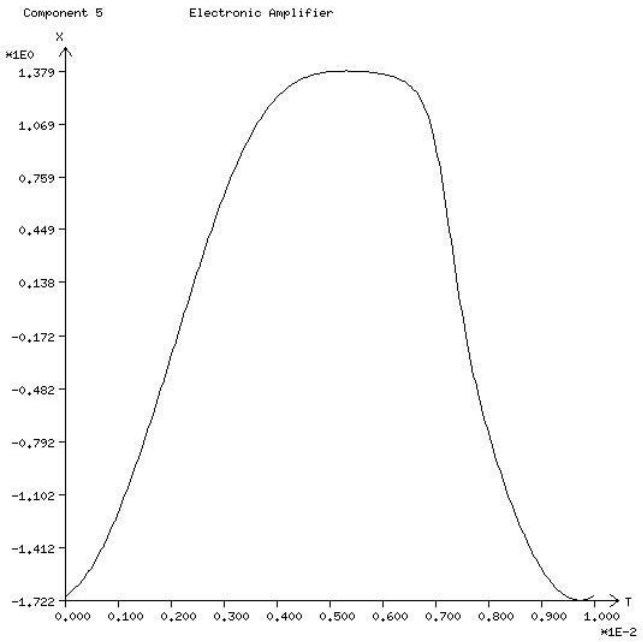

FIG. 5.1. *Periodic response for Example* 5.1.

Then the presented method successfully computed a periodic solution in about 3.1 seconds. The behavior of the Gauß–Newton-like method is given in Table 5.1. One component of the periodic response of the amplifier is shown in Figure 5.1.

Example 5.2. In [17], a multibody system with nonholonomic constraint is presented. The model equations for the unknowns $(\varphi, z_G, z_Z, \lambda)$ are given by

$$\begin{aligned} &I_R\ddot{\varphi} = u, \\ &m_G\ddot{z}_G + d_1(\dot{z}_G - \dot{z}_Z) + c_1(z_G - z_Z) = \lambda, \\ &m_Z\ddot{z}_Z + d_1(\dot{z}_Z - \dot{z}_G) + c_1(z_Z - z_G) = 0, \\ &\dot{z}_G = v_U\varphi, \end{aligned}$$

where

$$\begin{aligned} &I_R = 0.002, \qquad m_G = 3, \qquad m_Z = 10, \\ &v_U = 2.8, \qquad c_1 = 250, \qquad d_1 = 10. \end{aligned}$$

We ask for the time T when, starting from the trivial equilibrium, the maximal allowed $\varphi_{\max} = 0.27$ is reached for an external force $u = 0.001$. The boundary conditions are

TABLE 5.2
Results for Example 5.2.

ν	$\|\Delta z_\nu\|_2$
0	0.727D+00
1	0.405D-01
2	0.345D-04
3	0.107D-09

then given by

$$\varphi(0) = z_G(0) = z_Z(0) = \dot\varphi(0) = \dot z_Z(0) = 0, \quad \varphi(T) = 0.27.$$

Writing the model equations as a first order system and transforming the unknown interval $[0, T]$ to $[0, 1]$, thus introducing T as further unknown, we get a problem with $n = 8$ in the unknowns $(\varphi, z_G, z_Z, \dot\varphi, \dot z_G, \dot z_Z, \lambda, T)$. Hypothesis 2.1 is here satisfied with $\mu = 1$, $d = 6$, and $a = 2$. We set $N = 1$ and took $T = 1$ to get initial guesses for (x_i, y_i) by integration starting with the equilibrium state. Table 5.2 shows the behavior of the Gauß–Newton-like procedure. The computing time was about 4.3 seconds.

Example 5.3. A pendulum in two space dimensions is modeled by

$$\begin{aligned} &\dot p_1 = v_1, \quad \dot v_1 = 2p_1\lambda, \\ &\dot p_2 = v_2, \quad \dot v_2 = 2p_2\lambda - g, \\ &p_1^2 + p_2^2 = 1 \end{aligned}$$

with the gravity constant $g = 9.81$. The unknowns are $(p_1, p_2, v_1, v_2, \lambda)$. In [15] this problem, together with the boundary conditions

$$v_2(0) = 0, \quad p_1(0.55) = 0, \tag{5.1}$$

was used to test an implementation of a multiple shooting method for DAEs with $\mu = 1$. Since for the above formulation we have $\mu = 2$ together with $d = 2$ and $a = 3$, in [15] it was necessary to replace the constraint by its differentiated form

$$2p_1\dot p_1 + 2p_2\dot p_2 = 2p_1v_1 + 2p_2v_2 = 0$$

and to add a further boundary condition due to the additional dynamics introduced. Here we can solve this problem in its original formulation. Instead of (5.1), we also used the boundary conditions

$$v_2(0) = v_2(2.5) = 0, \tag{5.2}$$

thus seeking a periodic orbit. Observe that we must fix the phase of the solution, since the problem is autonomous.

Starting in both cases with the initial guess

$$\begin{aligned} &x_0 = (1, 0.3, 0, 0, 1), \qquad \dot x_0 = (0, 0, 0, -g, 0), \\ &\ddot x_0 = (0, -g, 0, 0, 0), \qquad x_0^{(3)} = (0, 0, 0, 0, 0) \end{aligned}$$

and using $N = 1$, we obtained solutions according to Table 5.3. The computing times were 3.5 and 14.6 seconds, respectively.

4	0.341D-02
5	0.120D-08

Example 5.4. In [19], the model of a (two-dimensional) truck is given. It has the form of a standard multibody system

$$\begin{aligned} \dot{p} &= v, \\ M\dot{v} &= f(p, v, u, \dot{u}) - g_p(p)^T \lambda, \\ g(p) &= 0, \end{aligned}$$

where p are the (generalized) positions, v the corresponding velocities, and λ the forces introduced by the constraint $g(p) = 0$. In the truck model, p and v have eleven components and λ is scalar. Hypothesis 2.1 is fulfilled with $\mu = 2$, $d = 20$, and $a = 3$. The (scalar) function u models the road profile and is chosen here to be

$$u(t) = \tau \sin(20\pi t).$$

Asking as in [20] for the periodic response of the system for $\tau = 0.05$, we require the boundary conditions

$$\begin{aligned} p_l(0) &= p_l(0.1), \quad l = 1, \ldots, 9, 11, \\ v_l(0) &= v_l(0.1), \quad l = 1, \ldots, 9, 11. \end{aligned}$$

This problem suffers from an extremely bad scaling and high nonlinearity. Therefore, we applied a (fixed) scaling to get reasonable condition numbers and used classical homotopy according to

$$\tau \in \{0.01, 0.02, 0.03, 0.04, 0.05\}$$

to get the desired solution. The homotopy was started with the equilibrium state for $\tau = 0$. The course of the Gauß–Newton-like procedure for $N = 2$ can be found in Table 5.4. The overall computing time was about 84 minutes, with roughly 10 seconds for the solution of a single initial value problem. In particular, more than 95% of the computing time is used for time integration, as is typical for a multiple shooting approach. In this respect, the efficiency of a multiple shooting code mostly depends on the efficiency of the initial value solver.

Example 5.5. The so-called Lotka–Volterra system is the simplest model for a predator/prey interaction and consists (in normalized form) of the two differential equations

$$\dot{x}_1 = x_1(1 - x_2), \quad \dot{x}_2 = -cx_2(1 - x_1)$$

with some constant $c > 0$. It is well known that the quantity

$$H = c(x_1 - \log x_1) + (x_2 - \log x_2)$$

TABLE 5.4

stays constant along every componentwise positive solution and that therefore every such solution is periodic. In order to compute a periodic orbit for a given value of H, we can use the above equation for H as the algebraic constraint for the Lotka–Volterra system. But then the system would be overdetermined. We therefore combine the two differential equations such that the resulting relation defines a flow on the manifold defined by the algebraic constraint. Observing that we must fix the phase of the periodic orbit in order to fix a locally unique solution, we obtain the boundary value problem

$$\begin{aligned}
&(1-x_1)\dot{x}_2 - c(1-x_2)\dot{x}_1 + cx_2(1-x_1)^2 + cx_1(1-x_2)^2 = 0,\\
&c(x_1 - \log x_1) + (x_2 - \log x_2) - H = 0,\\
&x_1(0) = x_1(T), \quad x_1(0) = 1.
\end{aligned}$$

Note that the derivatives $\dot{x}_1$ and $\dot{x}_2$ now have solution dependent factors. Transforming the problem finally to the unit interval and using $x_3 = H$ and $x_4 = T$ as further unknowns, the boundary value problem to solve reads as

$$\begin{aligned}
&(1-x_1)\dot{x}_2 - c(1-x_2)\dot{x}_1 + cx_2(1-x_1)^2x_4 + cx_1(1-x_2)^2x_4 = 0,\\
&c(x_1 - \log x_1) + (x_2 - \log x_2) - x_3 = 0, \quad \dot{x}_3 = 0, \quad \dot{x}_4 = 0,\\
&x_1(0) = x_1(1), \quad x_1(0) = 1, \quad x_3(0) = H.
\end{aligned}$$

It has differentiation index one and satisfies Hypothesis 2.1 with $\mu = 0$, $d = 3$, and $a = 1$. Starting with

$$x_0 = (1.0, 0.6, 2.1, 6.0), \quad \dot{x}_0 = (3.2, 0, 0, 0)$$

for the choice $c = 1$, $H = 2.2$ and using $N = 1$, we successfully obtained the solution which has a period $T = 6.4943$. The computation took about 0.8 seconds, and the convergence behavior is reported in Table 5.5.

In summary, we have demonstrated that the multiple shooting method presented is able to solve problems with different values of the index and different structures. The

tables show that the Gauß–Newton-like method developed has very good convergence properties. Indeed, for the examples presented they cannot be distinguished from quadratic convergence.

6. Conclusions. We have presented a multiple shooting approach for the solution of nonlinear boundary value problems for differential-algebraic systems of arbitrary index and without special structure requirements. Using a specific Gauß–Newton-like method for the solution of the nonlinear system of boundary and continuity conditions we have proved superlinear convergence of the method. We have implemented the method on the basis of a new general solver for DAEs of arbitrary index [13] and demonstrated the numerical properties of the method for several examples.

Appendix. Proof of Remark 3.2. In the linear case, the derivative array equations (2.1) have the form

$$M_\ell(t) \begin{bmatrix} \dot{x} \\ \vdots \\ x^{\ell+1} \end{bmatrix} = N_\ell(t)x + g_\ell(t)$$

with

$$M_\ell : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\ell+1)n,(\ell+1)n}, \quad N_\ell : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\ell+1)n,n}, \quad g_\ell : [\underline{t}, \overline{t}] \to \mathbb{R}^{(\ell+1)n}.$$

Defining

$$\begin{aligned} E_1(t) = Z_1(t)^T M_0(t), \quad A_1(t) = Z_1(t)^T N_0(t), \quad f_1(t) = Z_1(t)^T g_0(t), \\ A_2(t) = Z_2(t)^T N_\mu(t), \quad f_2(t) = Z_2(t)^T g_\mu(t), \end{aligned}$$

with Z_1, Z_2 as in the nonlinear case, the given solution x^* satisfies the linear DAE

$$\begin{bmatrix} E_1(t) \\ 0 \end{bmatrix} \dot{x} = \begin{bmatrix} A_1(t) \\ A_2(t) \end{bmatrix} x + \begin{bmatrix} f_1(t) \\ f_2(t) \end{bmatrix},$$

which has vanishing strangeness index; see [8, 9]. Following the theory presented there, pointwise nonsingular (smooth) matrix functions $P, Q : [\underline{t}, \overline{t}] \to \mathbb{R}^{n,n}$ exist such that

$$P(t) \begin{bmatrix} E_1(t) \\ 0 \end{bmatrix} Q(t) = \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix},$$

$$P(t) \begin{bmatrix} A_1(t) \\ A_2(t) \end{bmatrix} Q(t) - P(t) \begin{bmatrix} E_1(t) \\ 0 \end{bmatrix} \dot{Q}(t) = \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix},$$

transforming the DAE to

$$\begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \dot{\tilde{x}} = \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix} \tilde{x} + \begin{bmatrix} \tilde{f}_1(t) \\ \tilde{f}_2(t) \end{bmatrix}$$

with

$$x(t) = Q(t)\tilde{x}(t) = Q(t) \begin{bmatrix} \tilde{x}_1(t) \\ \tilde{x}_2(t) \end{bmatrix}, \quad \begin{bmatrix} \tilde{f}_1(t) \\ \tilde{f}_2(t) \end{bmatrix} = P(t) \begin{bmatrix} f_1(t) \\ f_2(t) \end{bmatrix}.$$

Hence, all solutions have the form

$$x(t) = Q(t) \begin{bmatrix} \tilde{x}_1(\underline{t}) + \int_{\underline{t}}^{t} \tilde{f}_1(s)\, ds \\ \\ -\tilde{f}_2(t) \end{bmatrix},$$

implying that

$$\Phi_{x,y}(x,y) = Q(\bar{t}) \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} Q(\underline{t})^{-1} & 0 \end{bmatrix}.$$

The equations (3.1) that define S take the form

$$M_\mu(\underline{t})\hat{y} - N_\mu(\underline{t})\hat{x} - g_\mu(\underline{t}) = 0, \quad T_2(\underline{t})^T(\hat{x} - x) = 0, \quad T_1(\underline{t})^T(\hat{y} - y) = 0.$$

Multiplying the first relation with $Z_2(\underline{t})^T$, we obtain

$$Z_2(\underline{t})^T N_\mu(\underline{t})\hat{x} = -Z_2(\underline{t})^T g_\mu(\underline{t})$$

and therefore (recalling the definition of A_2 and f_2)

$$\hat{x} = \begin{bmatrix} A_2(\underline{t}) \\ T_2(\underline{t})^T \end{bmatrix}^{-1} \begin{bmatrix} -f_2(\underline{t}) \\ T_2(\underline{t})^T x \end{bmatrix}.$$

A similar argument yields

$$\hat{y} = \begin{bmatrix} Z_2'(\underline{t})^T M_\mu(\underline{t}) \\ T_1(\underline{t})^T \end{bmatrix}^{-1} \begin{bmatrix} Z_2'(\underline{t})^T N_\mu(\underline{t})\hat{x} + Z_2'(\underline{t})^T g_\mu(\underline{t}) \\ T_1(\underline{t})^T y \end{bmatrix}.$$

Altogether, we have

$$\Phi_{x,y}(x,y) S_x(x,y) = Q(\bar{t}) \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} Q(\underline{t})^{-1} \begin{bmatrix} A_2(\underline{t}) \\ T_2(\underline{t})^T \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ T_2(\underline{t})^T \end{bmatrix}$$

and therefore

$$\mathcal{E} = C T_2(\underline{t}) + D Q(\bar{t}) \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} Q(\underline{t})^{-1} \begin{bmatrix} A_2(\underline{t}) \\ T_2(\underline{t})^T \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ I \end{bmatrix}.$$

Following [20], the transformation P has the block structure

$$P(t) = \begin{bmatrix} P_{11}(t) & P_{12}(t) \\ 0 & P_{22}(t) \end{bmatrix},$$

where $P_{22} : [\underline{t}, \bar{t}] \to \mathbb{R}^{a,a}$ is pointwise nonsingular. Hence,

$$P_{22}(\underline{t}) A_2(\underline{t}) Q(\underline{t}) = [\, 0 \; I \,]$$

and $Q(\underline{t})$ has the form

$$Q(\underline{t}) = [\, T_2(\underline{t}) U \; * \,]$$

with some nonsingular matrix $U \in \mathbb{R}^{d,d}$. In particular,

$$Q(\underline{t}) \begin{bmatrix} U^{-1} \\ 0 \end{bmatrix} = T_2(\underline{t}).$$

Defining $[\,C_{11}\ C_{12}\,] = CQ(\underline{t})$, $[\,D_{11}\ D_{12}\,] = DQ(\bar{t})$, and using

$$\begin{bmatrix} A_2(\underline{t}) \\ T_2(\underline{t})^T \end{bmatrix} T_2(\underline{t}) = \begin{bmatrix} 0 \\ I \end{bmatrix},$$

we find

$$\begin{aligned} \mathcal{E} &= CQ(\underline{t})Q(\underline{t})^{-1}T_2(\underline{t}) + DQ(\bar{t}) \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} Q(\underline{t})^{-1}T_2(\underline{t}) \\ &= [\,C_{11}\ C_{22}\,] \begin{bmatrix} U^{-1} \\ 0 \end{bmatrix} + [\,D_{11}\ D_{22}\,] \begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} U^{-1} \\ 0 \end{bmatrix} \\ &= (C_{11} + D_{11})U^{-1}. \end{aligned}$$

Thus, $\mathcal{E}$ is nonsingular if and only if $C_{11} + D_{11}$ is nonsingular.

HIGHER-ORDER FOURIER APPROXIMATION IN SCATTERING BY TWO-DIMENSIONAL, INHOMOGENEOUS MEDIA*

OSCAR P. BRUNO† AND E. MCKAY HYDE‡

Abstract. This paper provides a theoretical analysis of a higher-order, FFT-based integral equation method introduced recently [*IEEE Trans. Antennas and Propagation*, 48 (2000), pp. 1862–1864] for the evaluation of transverse electric–polarized electromagnetic scattering from a bounded, penetrable inhomogeneity in two-dimensional space. Roughly speaking, this method is based on Fourier smoothing of the integral operator and the refractive index $n(x)$. Here we *prove* that the solution of the resulting integral equation approximates the solution of the exact integral equation with higher-order accuracy, *even when* $n(x)$ *is a discontinuous function*—as suggested by the numerical experiments contained in the paper mentioned above. In detail, we relate the convergence rates of the computed interior and exterior fields to the regularity of the scatterer, and we demonstrate, with a few numerical examples, that the predicted convergence rates are achieved in practice.

Key words. Helmholtz equation, Lippmann–Schwinger integral equation, transverse electric scattering, TM scattering, fast Fourier transform

1. Introduction.

Scattering problems find application in a wide range of fields, including communications, materials science, plasma physics, biology, medicine, radar, and remote sensing. The evaluation of useful numerical solutions for scattering problems remains a highly challenging problem, requiring novel mathematical approaches and powerful computational tools. An integral equation method [7, 8] introduced recently for the evaluation of time-harmonic, transverse electric (TE)–polarized, electromagnetic scattering by bounded inhomogeneities in two dimensions has proven highly competitive with currently available approaches. (Note that there is some ambiguity in the naming of the polarization [28, p. R5], with some authors referring to this setting as transverse magnetic (TM)–polarized scattering. To be precise, we consider the case in which the electric field is parallel to the cylindrical axis of the scatterer.) In this paper, we provide a theoretical analysis of the higher-order convergence of this approach. More specifically, we *prove* that the approximating integral equation used in this method, which is based on Fourier approximation of the integral

operator, yields higher-order convergence in the L^∞-norm even when the refractive index $n(x)$ is a discontinuous function. Furthermore, we relate the convergence rates of the computed interior and exterior fields to the regularity of the scatterer, and we demonstrate, with a few numerical examples, that the predicted convergence rates are achieved in practice.

Given an incident field u^i, we denote by u the total electric field—which equals the sum of u^i and the resulting scattered field u^s:

$$u = u^i + u^s. \tag{1.1}$$

Calling λ the wavelength of the incident field and $\kappa = \frac{2\pi}{\lambda}$ the wavenumber, the total field u satisfies [9, p. 2]

$$\Delta u + \kappa^2 n^2(x) u = 0, \quad x \in \mathbb{R}^3, \tag{1.2}$$

where the given incident field u^i is assumed to satisfy

$$\Delta u^i + \kappa^2 u^i = 0, \quad x \in \mathbb{R}^3. \tag{1.3}$$

Finally, to guarantee that the scattered wave is outgoing, u^s is required to satisfy the Sommerfeld radiation condition [9, p. 67]

$$\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial u^s}{\partial r} - i\kappa u^s\right) = 0. \tag{1.4}$$

The algorithms available for computing solutions to this problem fall into two broad classes: (1) finite element and finite difference methods and (2) integral equation methods. Use of finite element and finite difference methods can be advantageous in that, unlike other methods, they lead to sparse linear systems. Their primary disadvantage, on the other hand, lies in the fact that in order to satisfy the Sommerfeld radiation condition (1.4), a relatively large computational domain containing the scatterer must be used, together with appropriate absorbing boundary conditions on the boundary of the computational domain (see, for example, [10, 17, 18, 26, 32]). Thus, these procedures give rise to very large numbers of unknowns and, thus, to very large linear systems.

A second class of algorithms is based on the use of integral equations. An appropriate integral formulation for our two-dimensional TE problem is given by the Lippmann–Schwinger integral equation [9, p. 214], [24],

$$u(x) = u^i(x) - \kappa^2 \int g(x-y) m(y) u(y) dy, \tag{1.5}$$

where $g(x) = \frac{i}{4} H_0^1(\kappa|x|)$ is the fundamental solution of the Helmholtz equation in two dimensions and m is the *compactly supported* function $m = 1 - n^2$. Integral equation approaches are advantageous in a number of ways: they require only discretization of the equation *on the scatterer itself*, and the solutions they produce satisfy the radiation condition at infinity *automatically*. Direct use of integral equation methods is costly, however, since they lead to dense linear systems: a straightforward computation of the required convolution requires $\mathcal{O}(N^2)$ operations per iteration of an iterative linear solver. As mentioned above, however, the *higher-order* integral method that we analyze in this paper, in which the complexity of the convolution evaluation

is reduced to $\mathcal{O}(N \log N)$ operations per iteration, is highly competitive with finite element or finite difference approaches.

Fast solvers for (1.5), based on the fast Fourier transform (FFT), have been available for some time [3, 31, 33]. In these solvers, the convolution with the fundamental solution is computed via Fourier transforms, which can, in turn, be evaluated with low complexity by means of FFTs. These methods do give rise to a reduced complexity for a given discretization but, unfortunately, they are only first-order accurate for discontinuous scatterers. Low-order accuracy results since, for a general nonsmooth and/or nonperiodic function, the FFT provides a poor approximation to the Fourier transform. Our approach also uses FFTs to achieve a reduced complexity but, unlike previous FFT methods, it yields, in addition, *higher-order accuracy*.

Despite the significant advantages exhibited by higher-order methods over their low-order counterparts (see, for example, Appendix B), only limited attempts have been made to develop higher-order methods for the problem under consideration. A higher-order method was proposed in [23] on the basis of a locally corrected Nyström discretization; the complexity of this method, however, is $\mathcal{O}(N^2)$, where N is the total number of unknowns used.

In [27], Vainikko presents two $\mathcal{O}(N \log N)$ methods for solving (1.5). The first applies to m in the Sobolev space $W^{\mu,2}$ and yields $\mathcal{O}(h^\mu)$ L^2-convergence in the near and the far fields. We instead consider piecewise-smooth $m \in C^{k,\alpha}$ (which are arguably the appropriate spaces for scatterers arising in practice). (For the precise definition of the function spaces that we consider, see Definitions 2.4 and 2.5.) In comparing Vainikko's approach with our method, note that a piecewise-smooth $m \in C^{0,\alpha}$ which does not belong to C^1 can, at best, belong to $W^{2,2}$ [22, p. 197], [11, p. 194], for which Vainikko's method predicts $\mathcal{O}(h^2)$ L^∞-convergence in both the near and the far field. Our method, on the other hand, achieves $\mathcal{O}(h^3)$ and $\mathcal{O}(h^5)$ L^∞-convergence in the near and far fields, respectively (see section 3.2 for our convergence results). More generally, a piecewise-smooth $m \in C^{k,\alpha}$ for $k \geq 1$ which does not belong to C^{k+1} can, at best, belong to $W^{k+2,2}$, for which Vainikko's result predicts $\mathcal{O}(h^{k+2})$ L^∞-convergence in both the near and far field, whereas our method achieves $\mathcal{O}(h^{k+3})$ L^∞-convergence in the near field and $\mathcal{O}(h^{k+6})$ L^∞-convergence in the far field.

The second method proposed in [27] applies to piecewise-smooth (possibly discontinuous) m and yields $\mathcal{O}(h^2(1+|\log h|))$ L^∞-convergence in the near and far fields. (This method requires evaluation of the volume fraction of each discretization cell on each side of a discontinuity in $m = 1 - n^2$.) For such inhomogeneities, our method yields $\mathcal{O}(h^2)$ and $\mathcal{O}(h^3)$ L^∞-convergence in the near and far fields, respectively. Thus, our approach, which applies to smooth as well as discontinuous refractive indices, is both fast—it runs in $\mathcal{O}(N \log N)$ operations—and higher-order accurate, substantially exceeding the convergence rates of Vainikko's approach, especially in the far field.

Our method is based on recasting the last term of the integral equation (1.5) by means of the polar coordinate form

$$(Ku)(a,\phi) = -\kappa^2 \int g(a,\phi;r,\theta) m(r,\theta) u(r,\theta) r \, dr \, d\theta. \tag{1.6}$$

An approximate integral equation is obtained from (1.6) by replacing the kernel g by a truncation of its Fourier representation with respect to its angular variables—which, as is known, is given by the addition theorem for the Hankel function; see section 2. As we show in this paper, the solution of this approximate integral equation approximates the solution of the exact integral equation with higher-order accuracy, even for discontinuous functions $n(x)$.

The higher-order convergence of this method relies on the following important fact: although the Fourier representation of the fundamental solution converges slowly, the resulting Fourier representation of the integral converges *rapidly*; clearly, such accuracy improvements for integrated quantities can only occur through a process of error cancellation. In this paper, we prove that this approach does indeed yield higher-order convergence (at least third-order in the exterior field) even in the case of discontinuous inhomogeneities. More precisely, we derive bounds on the convergence rates for the interior and exterior fields as they depend on the regularity of the scatterer (see Theorem 3.5 and Corollaries 3.9 and 3.10).

Our present analysis considers neither a specific numerical discretization for the radial integration nor the method used to solve the resulting linear system. Here we focus instead on the exact solution of the approximate integral equation resulting from the polar Fourier approximation of the fundamental solution, as described briefly above and in detail in section 2; this exact solution of the approximate equation is to be viewed as an approximate solution of the exact equation (1.5). The details of the complete numerical implementation are given in their original form in [7, 8] as well as in the more recent presentations [5, 14], which contain several significant improvements.

As discussed in section 4, our approximate integral formulation allows us to replace the (possibly discontinuous) function n in polar coordinates by its truncated Fourier series of certain orders *without introducing additional errors*. This fact allows us to compute the corresponding angular integrals *exactly* by means of FFTs. (In [14, 15, 16], similar ideas are used in the construction of a fast, higher-order method for the Helmholtz equation in three dimensions.) To conclude this paper we present a number of computational examples that demonstrate that the predicted convergence rates are achieved in practice.

(Note that a direct application of the methods presented in this paper to discontinuous scatterers for either TM or three-dimensional electromagnetic scattering would yield rates of convergence lower than those for the TE case considered here—since in such cases the normal derivatives of the solution are not continuous across surfaces of discontinuity of the refractive index. As shown in [6], however, the convergence rates of our method for all of these problems—TE, TM, and three-dimensional electromagnetic scattering—can be improved significantly by appropriate treatment of thin volumetric regions around surfaces where either discontinuities or reduced regularity of the refractive index occur.)

2. An approximate integral equation. As mentioned in the introduction, our approach produces numerical solutions of (1.5) through consideration of a sequence of approximate integral equations, which result as the fundamental solution is replaced by a truncated Fourier series in an angular variable. In this section we describe our approximate integral equations, and we show that (1) they admit unique solutions and (2) the inverse operators for the approximate problems are uniformly bounded.

To introduce our approximate integral equations we begin by recalling an addition theorem: using polar coordinates $x = ae^{i\phi}$ and $y = re^{i\theta}$, the addition theorem for the Hankel function reads [9, p. 67]

$$H_0^1(\kappa|ae^{i\phi} - re^{i\theta}|) = \sum_{\ell=-\infty}^{\infty} \mathcal{J}_\ell(a, r)e^{i\ell(\phi-\theta)},$$

where, calling J_ℓ and H^1_ℓ the Bessel and Hankel functions of order ℓ, we have denoted

$$\mathcal{J}_\ell(a,r) = H^1_\ell(\kappa \max(a,r))\ J_\ell(\kappa \min(a,r)). \tag{2.1}$$

This identity allows us to obtain another expression for the integral operator K of (1.5),

$$(Ku)(a,\phi) = -\frac{i\kappa^2}{4}\int H^1_0(\kappa|x-y|)m(y)u(y)dy = \sum_{\ell=-\infty}^{\infty}(K_\ell u)(a)e^{i\ell\phi},$$

where, using an annular region $R_0 \le a \le R_1$ containing the support of m, we have set

$$(K_\ell u)(a) = -\frac{i\kappa^2}{4}\int_{R_0}^{R_1}\mathcal{J}_\ell(a,r)\left[\int_0^{2\pi} m(r,\theta)u(r,\theta)e^{-i\ell\theta}d\theta\right] r\,dr. \tag{2.2}$$

Truncating this Fourier series as well as the corresponding Fourier series for the incident field, we obtain the approximate integral equation

$$v(a,\phi) = u^{i,M}(a,\phi) + (K^M v)(a,\phi), \tag{2.3}$$

where

$$u^{i,M}(a,\phi) = \sum_{\ell=-M}^{M} u^i_\ell(a)e^{i\ell\phi}, \tag{2.4}$$

$$(K^M v)(a,\phi) = \sum_{\ell=-M}^{M}(K_\ell v)(a)e^{i\ell\phi}. \tag{2.5}$$

Here and throughout this paper we use a superscript M to denote the truncated Fourier series of order M of a given function.

Decomposing (2.3) into Fourier modes, we observe that a solution of this equation must satisfy

$$v_\ell(a) = \begin{cases} u^i_\ell(a) + (K_\ell v)(a) & \text{for } |\ell| \le M, \\ 0 & \text{for } |\ell| > M. \end{cases} \tag{2.6}$$

Hence,

$$v(a,\phi) = v^M(a,\phi)$$

and solving (2.3) is equivalent to solving the following system of one-dimensional integral equations:

$$v_\ell(a) - (K_\ell v^M)(a) = u^i_\ell(a), \quad \ell = -M,\dots,M. \tag{2.7}$$

To prove existence and uniqueness for this approximate integral equation, we make use of the following technical lemma.

LEMMA 2.1. *There exists a constant $C > 0$ depending only on R_0, R_1, and κ such that*

$$\left\| \int_{R_0}^{R_1} |\mathcal{J}_\ell(a,r)| r\,dr \right\|_\infty \le \frac{C}{\ell^2},$$

where $\mathcal{J}_\ell(a,r)$ is defined in (2.1).

This result, which is proven in Appendix A, allows us to establish the following lemma. (Note: In the bound above and in all similar bounds in this paper, we abuse the notation slightly for $\ell = 0$, in which case the expression on the left-hand side is assumed to be bounded.)

LEMMA 2.2. *For any $m \in L^\infty$,*

$$\|K - K^M\|_\infty \to 0$$

as $M \to \infty$, where the operator norm is the one induced by the L^∞-norm.

Proof. Let $u \in L^\infty$. Then

$$\int_0^{2\pi} |m(r,\theta)u(r,\theta)e^{-i\ell\theta}|d\theta \le 2\pi\|m\|_\infty\|u\|_\infty.$$

Hence, for $M \ge 0$,

$$\begin{aligned}\|(K - K^M)u\|_\infty &\le \frac{\pi\kappa^2}{2}\|m\|_\infty\|u\|_\infty \sum_{|\ell|>M} \left\| \int_{R_0}^{R_1} |\mathcal{J}_\ell(a,r)|r\,dr \right\|_\infty \\ &= \mathcal{O}\left(\sum_{|\ell|>M} \frac{1}{\ell^2} \right) \|u\|_\infty \\ &= \mathcal{O}(M^{-1})\|u\|_\infty.\end{aligned}$$

Therefore, $\|K - K^M\|_\infty = \mathcal{O}(M^{-1}) \to 0$ as $M \to \infty$. ∎

Remark 2.3. The following proof of the existence and uniform boundedness of $(I-K^M)^{-1}$ depends crucially on the existence and boundedness of $(I-K)^{-1}$. By the Riesz–Fredholm theory (see, for example, [20, p. 29]), since K is a compact operator on L^∞, $(I-K)^{-1}$ exists and is bounded if $I-K$ is injective. The injectivity of this operator is equivalent to the uniqueness of solutions of the corresponding Helmholtz equation (1.2). The uniqueness result relevant for our setting follows from corresponding (more general) results for acoustic scattering proved in [30] under assumptions that we state more precisely below with the help of the following definitions.

DEFINITION 2.4. *Given a compact set $D \subset \mathbb{R}^n$, we say that a function f has piecewise continuous derivatives of order k on D, denoted by $f \in C^k_{pw}(D)$, if and only if there exist a finite number of open, disjoint subsets of D, denoted by $D_1, D_2, \dots, D_p$, such that $D = \bigcup_{i=1}^p \overline{D_i}$ and there exist functions $f_i \in C^k(\overline{D_i})$ such that $f|_{D_i} = f_i|_{D_i}$. In an entirely analogous fashion we define spaces of functions with piecewise-Hölder continuous derivatives of order k on D, denoted by $C^{k,\alpha}_{pw}(D)$.*

DEFINITION 2.5. *We say that the scattering inhomogeneity m belongs to $\mathcal{M}$ if and only if* (1) *$m \in C^{0,\alpha}_{pw}(D)$ for some compact set D that properly contains the support of m and* (2) *each of the corresponding subsets $D_1, D_2, \dots, D_p$, as defined in Definition* 2.4*, has a Lipschitz boundary.*

Remark 2.6. With these definitions, we can state the unique solvability result for (1.5), which is based on the uniqueness result of [30], more precisely: $I-K$ admits a bounded inverse on L^∞ for each $m \in \mathcal{M}$. Hence, throughout this paper, we will assume that $m \in \mathcal{M}$. Note that the uniqueness result of [30] makes use of a unique continuation result due to Heinz [13], which assumes C^1 boundary regularity of the subsets D_i defined above. However, more recent unique continuation results make much weaker assumptions (see [19] and the references therein) and hence allow us

to relax the C^1 regularity assumption to Lipschitz regularity (which suffices to allow integration by parts in obtaining the appropriate weak formulation).

We can now establish the following theorem.

THEOREM 2.7. *Given $m \in \mathcal{M}$, for M sufficiently large the operators $(I-K^M)^{-1}$ exist on L^∞ and are uniformly bounded. Thus, given any incident field u^i, (2.3) admits a unique solution $v \in L^\infty$ for all M sufficiently large.*

Proof. Since, by the discussion above, $I-K$ has a bounded inverse, Lemma 2.2 and [20, Theorem 10.1, p. 142] imply that for all sufficiently large M the inverse operators $(I-K^M)^{-1}$ exist and are uniformly bounded. ∎

3. Error bounds. The approximate integral equation (2.3) was obtained by truncating the Fourier series of both the incident field u^i and the integral operator K at each radius; as mentioned above, the exact solution v of this approximate equation is to be viewed as an approximate solution of the exact equation (1.5). As it happens, the function v is a *higher-order approximation* of the exact solution u of (1.5). Roughly speaking, this result follows from the fact that the integral operator Ku and the incident field u^i are smooth and periodic functions of the angular variable, which are thus approximated to higher-order by their truncated Fourier series.

In this section we derive bounds on the error implicit in the approximation of u by v. Of course the full numerical implementation of the method introduces additional errors (e.g., errors arising from radial numerical quadratures), but here we study the accuracy with which v approximates the exact solution u only. Higher-order methods for computing the required radial integrals are discussed in [5, 7, 8, 14].

3.1. Error in approximated Fourier modes. The error in the solution v^M of the approximate integral equation (2.3) at a point $x=(a,\phi)\in\mathbb{R}^2$ is given by

$$|u(x)-v^M(x)| \le |(u-u^M)(x)| + |u^M(x)-v^M(x)|, \tag{3.1}$$

where $(u-u^M)$ is the "tail" of the Fourier series of u,

$$(u-u^M)(a,\phi) = \sum_{|\ell|>M} u_\ell(a)e^{i\ell\phi}.$$

In this section, we derive a bound on the second term on the right-hand side of (3.1).

Subtracting the identities (see (2.6))

$$\begin{aligned} u^M &= u^{i,M} + K^M u, \\ v^M &= u^{i,M} + K^M v^M, \end{aligned}$$

we obtain

$$\begin{aligned} u^M - v^M &= K^M(u-v^M) \\ &= K^M(u^M-v^M) + K^M(u-u^M). \end{aligned}$$

In view of Theorem 2.7 and calling

$$\varepsilon_M = \|u^M - v^M\|_\infty, \tag{3.2}$$

we obtain

$$\varepsilon_M \le B\|K^M(u-u^M)\|_\infty$$

for sufficiently large M, where B is a uniform bound on $\|(I - K^M)^{-1}\|$.

To bound $K^M(u - u^M)$, we note that

$$\|K^M(u - u^M)\|_\infty \leq \sum_{\ell=-M}^{M} \|K_\ell(u - u^M)\|_\infty$$

and

$$\int_0^{2\pi} m(r,\theta)(u - u^M)(r,\theta)e^{-i\ell\theta}d\theta = 2\pi \sum_{|j|>M} m_{\ell-j}(r)u_j(r).$$

Therefore, by Lemma 2.1,

$$\|K_\ell(u - u^M)\|_\infty \leq \frac{C}{\ell^2} \sum_{|j|>M} \|m_{\ell-j}\|_\infty \|u_j\|_\infty. \tag{3.3}$$

We will bound this expression through consideration of bounds on the Fourier coefficients of m and u. To this end, we make use of the following lemma, which is a slight variation of a classical result [34, pp. 48, 71] and can be proved by multiple integrations by parts.

LEMMA 3.1. *If g is a 2π-periodic function such that $g \in C^k([0, 2\pi])$ with $g^{(n)}(0) = g^{(n)}(2\pi)$ for $n = 0, \ldots, k$, and $g^{(k+1)}$ is of bounded variation, then the Fourier coefficients c_ℓ of g satisfy $|c_\ell| \leq C|\ell|^{-(k+2)}$ for some constant C. If $g^{(1)}$ is of bounded variation on $[0, 2\pi]$, then $|c_\ell| \leq C|\ell|^{-1}$.*

The following useful theorem describes the dependence of the regularity of u on the regularity of m. Variations on the results for the Newtonian potential (see [2, p. 223], [11, pp. 78–80], and [12, pp. 53, 56]) give us the following result.

THEOREM 3.2. *Let D be an open set which properly contains the compact support of $m \in \mathcal{M}$, and let u be the solution of (1.5) on D for a given incident field u^i. Then $u \in C^{1,\alpha}(D)$. Furthermore, if Ω is an open subset of D and $m \in C^{k,\alpha}(\Omega)$, then $u \in C^{k+2,\alpha}(\Omega)$.*

Remark 3.3. Since Ω is an arbitrary bounded, open set, this theorem relates the *local* regularity of u to the *local* regularity of m.

To bound the discrete convolution in (3.3) we also need results on the decay rates of the Fourier coefficients of m and u.

LEMMA 3.4. *Let $m \in \mathcal{M}$. Define the annular region $A = \{(a, \phi) : 0 \leq R_0 \leq a \leq R_1\}$ such that A properly contains the support of m. If $m \in C^{k,\alpha}(A) \cap C^{k+2}_{pw}(A)$ for $k \geq 0$, then the Fourier coefficients of the total field u satisfy*

$$\|u_\ell\|_\infty \leq \frac{C}{|\ell|^{k+4}}.$$

If $m \in C^1_{pw}(A)$, then the Fourier coefficients of the total field u satisfy

$$\|u_\ell\|_\infty \leq \frac{C}{|\ell|^3}.$$

Proof. From (2.2), we see that the coefficients in the Fourier series representation of (1.5) are given by

$$u_\ell(a) = u^i_\ell(a) - \frac{i\pi\kappa^2}{2} \int_{R_0}^{R_1} \mathcal{J}_\ell(a, r)(mu)_\ell(r)r\, dr.$$

Since $m \in C^{k,\alpha}(A) \cap C^{k+2}_{pw}(A)$, Theorem 3.2 implies that $u \in C^{k+2,\alpha}(A)$ and hence, $mu \in C^{k,\alpha}(A) \cap C^{k+2}_{pw}(A)$. Therefore, by Lemma 3.1, the Fourier coefficients of mu satisfy

$$\|(mu)_\ell\|_\infty \leq \frac{C_1}{|\ell|^{k+2}}.$$

Again by Theorem 3.2, since u^i solves the homogeneous Helmholtz equation (1.3), $u^i \in C^\infty(\mathbb{R}^2)$. Thus, the Fourier coefficients u^i_ℓ decay faster than $|\ell|^{-p}$ for any positive integer p as $\ell \to \infty$. Therefore, by Lemma 2.1, we obtain

$$\begin{aligned}\|u_\ell\|_\infty &\leq \frac{C_2}{\ell^2}\frac{C_1}{|\ell|^{k+2}} \\ &\leq \frac{C}{|\ell|^{k+4}}.\end{aligned}$$

The proof for $m \in C^1_{pw}$ is similar. ∎

We can now establish the main result of this paper.

THEOREM 3.5. *Let $m \in \mathcal{M}$. Define the annular region $A = \{(a,\phi) : 0 \leq R_0 \leq a \leq R_1\}$ such that A properly contains the support of m.*

If $m \in C^1_{pw}(A)$, then as $M \to \infty$

$$\varepsilon_M = \|u^M - v^M\| \leq B\|K^M(u - u^M)\| = \mathcal{O}\left(\frac{1}{M^3}\right).$$

If $m \in C^{0,\alpha}(A) \cap C^2_{pw}(A)$, then as $M \to \infty$

$$\varepsilon_M = \mathcal{O}\left(\frac{1}{M^5}\right).$$

If $m \in C^{k,\alpha}(A) \cap C^{k+2}_{pw}(A)$ for $k \geq 1$, then as $M \to \infty$

$$\varepsilon_M = \mathcal{O}\left(\frac{1}{M^{k+6}}\right).$$

Proof. We seek a bound on $\|K^M(u - u^M)\|_\infty \leq \sum_{\ell=-M}^{M} \|K_\ell(u - u^M)\|_\infty$. By Lemma 3.4, we obtain

$$\begin{aligned}\|K_\ell(u - u^M)\|_\infty &\leq \frac{C_1}{\ell^2} \sum_{|j|>M} \frac{1}{|\ell - j|^{k+2}} \frac{1}{|j|^{k+4}} \\ &= \frac{C_1}{\ell^2} \sum_{j>M} \frac{1}{j^{k+4}} \left(\frac{1}{(j-\ell)^{k+2}} + \frac{1}{(j+\ell)^{k+2}}\right) \\ &\leq \frac{2C_1}{\ell^2} \sum_{j>M} \frac{1}{j^{k+4}} \frac{1}{(j - |\ell|)^{k+2}}\end{aligned}$$

for $\ell = -M, \ldots, M$. This expression also holds for $m \in C^{1,\alpha}_{pw}(A)$ with $k = -1$. Clearly, it suffices to bound $\|K_\ell(u - u^M)\|_\infty$ for $\ell = 0, \ldots, M$.

Thus, for $k \geq 0$, we obtain

$$\sum_{j>M} \frac{1}{j^{k+4}} \frac{1}{(j-\ell)^{k+2}} \leq \frac{1}{M^{k+4}} \frac{C_2}{(M+1-\ell)^{k+1}}.$$

For $k = -1 (m \in C^{1,\alpha}_{pw}(A))$, on the other hand, we find that

$$\begin{aligned}\sum_{j>M} \frac{1}{j^3}\frac{1}{j-\ell} &\le \frac{1}{M^2}\frac{1}{\ell}\sum_{j>M}\left(\frac{1}{j-\ell}-\frac{1}{j}\right)\\ &\le \frac{1}{M^2}\frac{C_3}{\ell}\log\left(\frac{M+1}{M+1-\ell}\right)\\ &\le \frac{1}{M^2}\frac{C_3}{M+1-\ell},\end{aligned}$$

since $\log x \le x-1$ for $x>0$.

To obtain the final result, it suffices to consider sums of the following form:

$$\sum_{\ell=1}^{M}\frac{1}{\ell^2}\frac{1}{(M+1-\ell)^p}$$

for $p = 1, 2, \ldots$. First, for $p \ge 2$,

$$\begin{aligned}\sum_{\ell=1}^{M}\frac{1}{\ell^2}\frac{1}{(M+1-\ell)^p} &\le \sum_{\ell=1}^{M}\frac{1}{\ell^2}\frac{1}{(M+1-\ell)^2}\\ &\le 2\sum_{\ell=1}^{\lceil \frac{M}{2}\rceil}\frac{1}{\ell^2}\frac{1}{(M+1-\ell)^2}\\ &= \mathcal{O}\left(\frac{1}{M^2}\right)\end{aligned}$$

as $M \to \infty$. Finally, for $p = 1$, we obtain

$$\begin{aligned}\sum_{\ell=1}^{M}\frac{1}{\ell^2}\frac{1}{M+1-\ell} &= \sum_{\ell=1}^{\lceil \frac{M}{2}\rceil}\frac{1}{\ell^2}\frac{1}{M+1-\ell} + \sum_{\ell=\lceil \frac{M}{2}\rceil+1}^{M}\frac{1}{\ell^2}\frac{1}{M+1-\ell}\\ &= \mathcal{O}\left(\frac{1}{M}\right)+\mathcal{O}\left(\frac{\log M}{M^2}\right)\\ &= \mathcal{O}\left(\frac{1}{M}\right)\end{aligned}$$

as $M \to \infty$. Combining these results, the theorem follows. ∎

Remark 3.6. Of course, there are many other conditions on m for which the corresponding convergence rates could be determined; for instance, one might remove the requirement of Hölder continuity. In every case, the convergence rates are directly determined by the rate of decay of the Fourier coefficients of m and u. We do not attempt to provide a comprehensive listing of all possible regularity conditions and their corresponding convergence rates.

Remark 3.7. Numerical experiments indicate that the bounds of Theorem 3.5 are tight. The resulting convergence rates depend on k in a particularly interesting way. As we have shown, the method exhibits *third-order* convergence for $m \in C^1_{pw}(A)$, *fifth-order* convergence for $m \in C^{0,\alpha}(A) \cap C^2_{pw}(A)$, and *seventh-order* convergence for $m \in C^{1,\alpha}(A) \cap C^3_{pw}(A)$. This rather interesting and unexpected k-dependence of the convergence rates is observed in the numerical examples of section 5.

3.2. Total error in the interior and exterior fields. Up to this point, we have computed only convergence rates for the approximated modes, i.e., the modes of order ℓ with $|\ell| \leq M$. Given these convergence rates, we can now easily estimate the total error. We make a distinction here between two types of error: the *interior field error* (the error on the domain of integration $A = \{(a, \phi) : 0 \leq R_0 \leq a \leq R_1\}$) and the *exterior field error* (the error outside of A). The interior field error is simply the difference between the true solution $u(x)$ and the solution $v^M(x)$ of (2.3) on A. Clearly, on A we have

$$\begin{aligned}\|u - v^M\|_\infty &\leq \|u^M - v^M\|_\infty + \|u - u^M\|_\infty \\ &\leq \varepsilon_M + \tau_M,\end{aligned}$$

where ε_M is defined in (3.2) and $\tau_M = \|u - u^M\|_\infty$.

Remark 3.8. Note that the decay rate of $(u - u^M)(x_0)$ for a particular point $x_0 \in A$, as opposed to the maximum error in all of A, depends on the regularity of m in a neighborhood of the circle with radius $r_0 = |x_0|$ centered at the origin. Hence, in general, the convergence rate of $v^M(x_0)$ to $u(x_0)$ may vary with the choice of $x_0 \in A$. In particular, the regularity of m in a neighborhood of the circle with radius $r_0 = |x_0|$ centered at the origin determines the regularity of u in that neighborhood and hence also determines the decay rate of the Fourier coefficients $u_\ell(r_0)$. This decay rate in turn determines whether ε_M or $(u - u^M)(x_0)$ dominates the convergence rate. The pointwise convergence rate is of limited usefulness, however; the following corollary to Theorem 3.5 provides a bound on the maximum error in the computed interior field.

COROLLARY 3.9 (interior field error). *If $m \in C^{k,\alpha}(A) \cap C^{k+2}_{pw}(A)$, then the interior field error is given by*

$$\|u - v^M\|_\infty = \mathcal{O}\left(\frac{1}{M^{k+3}}\right).$$

This result holds with $k = -1$ for $m \in C^1_{pw}(A)$.

Proof. By Lemma 3.4,

$$\tau_M = \sum_{\ell > M} \frac{C}{\ell^{k+4}} = \mathcal{O}\left(\frac{1}{M^{k+3}}\right)$$

as $M \to \infty$. Clearly, by Theorem 3.5, τ_M dominates ε_M for every k. The proof for $m \in C^1_{pw}(A)$ is similar. ∎

Before discussing convergence rates in the exterior field, we describe how to extend the approximate solution v^M, which we have computed only on the interior of A, to the exterior field. Since the integration in (1.5) is performed only over the support of m, one can easily see that, given the solution u on the boundary of A, the solution in the rest of $\mathbb{R}^2$ can be computed simply by an appropriate scaling of the Fourier modes of u^s on the (circular) inner and outer boundaries of A at radii R_0 and R_1, respectively. More precisely, we find that

$$u^s_\ell(a) = \begin{cases} \dfrac{J_\ell(\kappa a)}{J_\ell(\kappa R_0)} u^s_\ell(R_0) & \text{if } 0 \leq a < R_0, \\ \dfrac{H^1_\ell(\kappa a)}{H^1_\ell(\kappa R_1)} u^s_\ell(R_1) & \text{if } a > R_1. \end{cases} \tag{3.4}$$

Our approximate solution v^M is extended to the exterior of A by the same procedure.

COROLLARY 3.10 (exterior field error). *Let $m \in \mathcal{M}$. Given $x_0 \notin A$, extend the approximate solution v^M to the exterior of A by means of* (3.4) *above. More precisely, for $\ell = -M, \ldots, M$, let $r_0 = |x_0|$ and define*

$$v_\ell(r_0) = u_\ell^i(r_0) + \begin{cases} \dfrac{J_\ell(\kappa r_0)}{J_\ell(\kappa R_0)}[v_\ell(R_0) - u_\ell^i(R_0)] & \text{if } 0 \le r_0 < R_0, \\ \dfrac{H_\ell^1(\kappa r_0)}{H_\ell^1(\kappa R_1)}[v_\ell(R_1) - u_\ell^i(R_1)] & \text{if } r_0 > R_1. \end{cases}$$

(Note: If $R_0 = 0$, then the integration domain is a disc and, hence, only the part of the equation above corresponding to $r_0 > R_1$ applies.) Then, the exterior field error at $x_0 \notin A$ is given by

$$|u(x_0) - v^M(x_0)| = \mathcal{O}(\varepsilon_M)$$

as $M \to \infty$, where ε_M, defined in (3.2)*, has bounds given by Theorem* 3.5.

Proof. Assume that $r_0 > R_1$; the proof for $0 \le r_0 < R_0$ is similar. Defining the scaling factors $\beta_\ell(r_0)$ at radius r_0 by

$$\beta_\ell(r_0) = \frac{H_\ell^1(\kappa r_0)}{H_\ell^1(\kappa R_1)}, \tag{3.5}$$

we have

$$\begin{aligned} |u(x_0) - v^M(x_0)| &\le \sum_{\ell=-M}^{M} |\beta_\ell(r_0)|\,|u_\ell(R_1) - v_\ell(R_1)| + |(u - u^M)(x_0)| \\ &\le \varepsilon_M \sum_{\ell=-M}^{M} |\beta_\ell(r_0)| + |(u - u^M)(x_0)|. \end{aligned}$$

As before, let S denote the circle of radius r_0 about the origin. Since $r_0 = |x_0| > R_1$, there exists a neighborhood $N(S)$ of S such that $m|_{N(S)} = 0$. Therefore, $u \in C^\infty(N(S))$ and $|(u - u^M)(x_0)| \le \frac{C}{M^p}$ for *any* integer $p > 0$. This implies that $|(u - u^M)(x_0)|$ is always dominated by ε_M.

Since the Hankel function $H_\ell^1(z) = J_\ell(z) + i\,Y_\ell(z)$, where $Y_\ell(z)$ is the Neumann function of order ℓ, we complete the proof by using the asymptotic expressions for J_ℓ and Y_ℓ [1, p. 365] for fixed z and as $\ell \to \infty$ through positive real values,

$$\begin{aligned} J_\ell(z) &\sim \frac{1}{\sqrt{2\pi\ell}} \left(\frac{ez}{2\ell}\right)^\ell, \\ Y_\ell(z) &\sim -\sqrt{\frac{2}{\pi\ell}} \left(\frac{ez}{2\ell}\right)^{-\ell}. \end{aligned}$$

Therefore, from these asymptotic expressions and from (3.5), we obtain

$$\begin{aligned} |\beta_\ell(r_0)|^2 &= \left|\frac{Y_\ell(\kappa r_0)}{Y_\ell(\kappa R_1)}\right|^2 \frac{1 + \left|\frac{J_\ell(\kappa r_0)}{Y_\ell(\kappa r_0)}\right|^2}{1 + \left|\frac{J_\ell(\kappa R_1)}{Y_\ell(\kappa R_1)}\right|^2} \\ &\sim \left(\frac{R_1}{r_0}\right)^{2\ell} \end{aligned}$$

as $\ell \to \infty$. This implies that $|\beta_\ell(r_0)|$ is summable. We conclude that as $M \to \infty$

$$|u(x_0) - v^M(x_0)| = \mathcal{O}(\varepsilon_M). \qquad \square$$

Note that while $u \in C^\infty$ on the exterior of A, this function may be much less regular on the interior of A (in general, $u \in C^{1,\alpha}$ for $m \in \mathcal{M}$). Hence, the decay of $u - u^M$ on the exterior of A is superalgebraic, whereas $u - u^M$ may decay as slowly as $\mathcal{O}(M^{-2})$ on the interior of A. This fact is responsible for the interesting result that the method converges more rapidly on the exterior of A than on the interior (where $u - u^M$ may dominate ε_M).

These remarks are particularly relevant in the evaluation of radar cross sections, an important measure in many applications. The evaluation of radar cross sections requires the computation of the *far field*. Although Corollary 3.10 does not directly address the error in the far field, we obtain an approximate far field by a scaling of the Fourier modes of v^M just as in the computation of the exterior field. As in [4, p. 6], we define the far field, u_∞, by the asymptotic representation of the scattered field as $r \to \infty$, i.e.,

$$u^s(r,\phi) = e^{i(\kappa r - \frac{\pi}{4})}\sqrt{\frac{2}{\pi\kappa r}}[u_\infty(\phi) + \mathcal{O}(r^{-1})].$$

From (3.4) and the asymptotic expression for $H^1_\ell(z)$ for fixed ℓ as $z \to \infty$ [1, p. 364], we obtain the Fourier modes of u_∞ by a simple scaling of the Fourier modes of u^s:

$$(u_\infty)_\ell = \frac{u^s_\ell(R_1)}{i^\ell H^1_\ell(\kappa R_1)}.$$

If we define the approximate far field v_∞ in the same way, we can prove that

$$\|u_\infty - v_\infty\| = \mathcal{O}(\varepsilon_M)$$

as $M \to \infty$. The proof of this fact is nearly identical to that of Corollary 3.10.

The predicted convergence rates in both the interior field and the far field are verified through several computational examples in section 5.

4. Computation of the angular integral. We have proven that the solution to the approximate integral equation (2.3) provides a higher-order approximation to the solution of the exact integral equation (1.5) for the scattering problem. However, to this point, we have not discussed any methods for computing the required angular and radial integrals. This paper primarily addresses the theoretical aspects of the method; for a discussion of a particular efficient, higher-order radial integrator, we refer to [5, 7, 8, 14]. On the other hand, with regards to the angular integrals, we show below that the Fourier coefficients of $m(r,\theta)v^M(r,\theta)$ can be computed efficiently and *exactly* (except for roundoff) by means of FFTs.

The required angular integrals are given by

$$I_\ell(r) = \int_0^{2\pi} m(r,\theta)v^M(r,\theta)e^{-i\ell\theta}d\theta, \tag{4.1}$$

where v^M solves the approximate integral equation (2.3). We can express this integral

in terms of the Fourier coefficients of m and v, i.e.,

$$\begin{aligned} I_\ell(r) &= \int_0^{2\pi} \left(\sum_{j=-\infty}^{\infty} m_j(r) e^{ij\theta} \right) \left(\sum_{k=-M}^{M} v_k(r) e^{ik\theta} \right) e^{-i\ell\theta} d\theta \\ &= 2\pi \sum_{k=-M}^{M} m_{\ell-k}(r) v_k(r), \end{aligned} \tag{4.2}$$

where $\ell = -M, \ldots, M$. Hence, we obtain a finite discrete convolution of Fourier coefficients of m and v at each radius; since $|\ell| \le M$ and $|k| \le M$, we have $|\ell - k| \le 2M$. Thus, as stated above, given the Fourier coefficients $m_\ell(r)$ for $|\ell| \le 2M$, we can compute the required angular integrals *exactly*. Furthermore, as is well known, such discrete convolutions may be evaluated (with no discretization error) with the help of FFTs [25, pp. 531–537] so that the computational cost at each radius is of the order of $M \log M$.

This method of computing the angular integrals has an interesting implication concerning the dependence of the solution u on the inhomogeneity m. Indeed, since the computation involves only modes m_ℓ, $|\ell| \le 2M$, replacing m with m^{2M} in the integral equation yields no additional error, i.e.,

$$I_\ell(r) = \int_0^{2\pi} m^{2M}(r,\theta) v^M(r,\theta) e^{-i\ell\theta} d\theta. \tag{4.3}$$

Hence, in a sense, the truncation of the Fourier series of the integral operator *implies* an associated truncation of the Fourier series of the refractive index—as a result of the band-limited nature of the solution v^M. Thus, surprisingly, the low-order approximation of a discontinuous refractive index at each radius by its truncated Fourier series yields *no additional error* beyond that of our original, higher-order truncation of the Fourier series of K. This points to the interesting cancellation of errors phenomenon mentioned briefly in the introduction: the large errors in the Fourier approximation of the refractive index *cancel* in the discrete integration process yielding small errors—high-order accurate approximations—in the evaluation of $I_\ell(r)$.

Note that the discrete-convolution approach to the evaluation of $I_\ell(r)$ ($\ell = -M, \ldots, M$) is equivalent to trapezoidal rule integration of (4.3) with a sufficiently large number of integration points N_θ. This follows from the fact that the trapezoidal rule with N_θ points on the interval $[0, 2\pi]$ integrates the Fourier modes $e^{ik\theta}$ for $|k| < N_\theta$ exactly: using N_θ points in the trapezoidal rule to approximate $\int_0^{2\pi} e^{ik\theta} d\theta$, we obtain

$$\frac{2\pi}{N_\theta} \sum_{j=0}^{N_\theta - 1} e^{2\pi i j k / N_\theta} = \begin{cases} 2\pi & \text{if } k = pN_\theta \text{ for } p \in \mathbb{Z}, \\ 0 & \text{otherwise.} \end{cases}$$

Therefore, since the largest mode in the integrand of (4.3) is $2M + M + M = 4M$, if we choose $N_\theta = cM$, where $c > 4$, the trapezoidal rule computes (4.3) exactly (except for roundoff) and the use of FFTs yields a complexity of $\mathcal{O}(M \log M)$. Algorithmically, this is entirely equivalent to computing the discrete convolution (4.2) using FFTs.

5. Computational examples. In this section, we illustrate the performance of the two-dimensional algorithm for a variety of scattering configurations. We first study the convergence of the method for two scatterers for which analytical solutions

are known. We then verify that the algorithm achieves the predicted convergence rates for three scatterers of varying degrees of regularity.

In each case, we compute the near and far fields produced under plane wave incidence, $u^i(x,y) = e^{i\kappa x}$. To compute the maximum error in the near field, we evaluate the solution computed by our method on an evenly spaced polar grid. On this grid, we evaluate the maximum absolute error as compared with either the analytical solution (when it is available) or the solution computed with a finer discretization. The maximum error in the far field is computed similarly by interpolating to an evenly spaced angular grid.

The results for each example are given in the accompanying figures and tables. The figures include visualizations of $-m(x) = n^2(x) - 1$ and the computed near field intensity, $|v^M|^2$. The tables provide values for the number of modes M in the approximate solution v^M, the wall-clock time required, and the maximum absolute errors in the near and far field denoted by ϵ_u^{nf} and ϵ_u^{ff}, respectively. Additionally, the ratios of the errors at successive levels of discretization are listed to illustrate the convergence rates. For some discretizations, the accuracy in the computed solution has reached either machine-precision accuracy (actually just less than machine precision due to round-off errors), the accuracy of the radial integration, or the tolerance of the linear solver. In such a case, we observe no improvement in the error of the solution as we refine the discretization and hence, to indicate a converged solution, we write "Conv." in the ratio column.

Our main goal in this section is to verify the convergence rates established in Theorem 3.5 and Corollaries 3.9 and 3.10. Hence, in this section, we are primarily concerned with the convergence in the number of Fourier modes M, rather than the convergence in the number of radial points. We also seek to demonstrate the $\mathcal{O}(M \log M)$ complexity of the angular integration method. We therefore fix the number of radial points at a sufficiently large value and we hold the number of iterations of the linear solver (GMRES) fixed at a value that produces a sufficiently accurate solution of the linear system. This isolates the dependence of the times and errors on M and allows us to confirm the computational complexity and the predicted convergence rates. All of these results were computed using a 700 MHz Pentium III Xeon workstation.

We first compute the scattering by two obstacles for which an analytical solution is known: (1) a cylindrically symmetric scatterer centered at the origin with piecewise-constant refractive index and (2) a disc centered at $(1\lambda, 0)$ with constant refractive index.

The results for the first example are presented in Figure 5.1 and Table 5.1. Here the inner disc has a radius equal to 1λ and a refractive index $n = 2$; the outer annulus has an outer radius of 2λ and a refractive index $n = 3$. Thus, this scatterer has a diameter of 10 interior wavelengths. (Perhaps the best indication of the difficulty of a scattering problem is given by the size of the scatterer in terms of interior wavelengths, since the numerical method must resolve these wavelengths to provide any accuracy.) One may also observe that the method obtains an exponential convergence rate. This occurs despite the discontinuity in the refractive index because, at each radius, the refractive index is a C^∞ function of the angular variable. Finally, we observe that the time required is consistent with an $\mathcal{O}(M \log M)$ complexity.

The results for the second example are presented in Figure 5.2 and Table 5.2. Here the disc is centered at $(1\lambda, 0)$ and has a diameter of 1λ and a refractive index $n = \sqrt{2}$. Thus, it has a diameter of $\sqrt{2}$ interior wavelengths. As opposed to the previous

1920	898s	1.45e-6	7.17	3.83e-7	9.22

the angular variable. Since the analytical solution in this case is known, the off-center disc provides direct verification of the predicted convergence rates for a *discontinuous* refractive index. The table shows excellent agreement with the predicted third-order convergence in the far field. The convergence in the near field is less steady, but is consistent with the predicted second-order convergence in the near field. As in the previous example, we observe that the computing time scales appropriately with M.

We now illustrate the convergence of the method for a series of three simple scatterers of increasing degrees of regularity. In each case, $m(x) = 1 - n^2(x)$ is given in the following form:

$$m(r,\theta) = \begin{cases} -\dfrac{3}{2} - \dfrac{1}{2\pi} \displaystyle\sum_{|\ell|\geq 1} \left(\frac{i}{\ell}\right)^{k+2} e^{i\ell\theta} & \text{for } \dfrac{5}{2}\lambda \leq r \leq 5\lambda, \\ 0 & \text{otherwise.} \end{cases}$$

Note that for each integer k, this series becomes either a sine or cosine series with real coefficients. If $k = -1$, m is discontinuous and piecewise smooth as a function of θ. Further, for any integer $k \geq 0$, $m \in C^{k,\alpha} \cap C^{\infty}_{pw}$ as a function of θ. The three examples that follow illustrate the convergence of the method for $k = -1, 0, 1$. Because these scatterers are fully inhomogeneous, their size in terms of interior wavelengths is not easily defined. Note, however, that each annular scatterer has a radial thickness of 2.5λ in terms of incident wavelengths; if the refractive index were constant within the annulus and equal to the maximum, then the radial thickness of the annulus would be approximately 4.33, 4.15, and 4.54 interior wavelengths for $k = -1, 0, 1$, respectively.

The results for $k = -1$ are found in Figure 5.3 and Table 5.3. The predicted second-order convergence in the near field is exceeded and the third-order convergence

in the far field is readily observed. The results of $k = 0$ are found in Figure 5.4 and Table 5.4. In this case, the predicted third-order convergence in the near field and

fifth-order convergence in the far field are both matched quite precisely. This example clearly illustrates the interesting jump in the far field convergence rate from third-order for a discontinuous refractive index to *fifth-order* for a $C^{0,\alpha}$ refractive index. Finally, the results for $k = 1$ are found in Figure 5.5 and Table 5.5. In this case, the predicted fourth- and seventh-order convergence rates in the near and far fields, respectively, are clearly exceeded. However, because convergence is so rapid, it is difficult to observe a definite pattern, especially in the far field convergence. In each of these cases, we note that the computing time scales appropriately with M. Finally, we mention that even the largest of these examples required less than 20 minutes and less than 700 MB of memory.

Appendix A. Bound on Fourier coefficients of the fundamental solution. To prove that solutions to the approximate integral equation (2.3) exist and to bound the convergence rate of the method, we need a bound on the decay rate of the Fourier coefficients of the fundamental solution $\mathcal{J}_\ell(a, r)$ defined in (2.1). This decay rate is given in Lemma 2.1.

According to [1, p. 362], for all integers $\ell \geq 0$ and for any real, nonnegative z,

$$|J_\ell(z)| \leq \frac{1}{\ell!}\left(\frac{z}{2}\right)^\ell \leq \frac{z^\ell}{\ell!}. \tag{A.1}$$

The following lemma provides a similar bound for $|Y_\ell(z)|$.

LEMMA A.1. *Let $z \in \mathbb{R}$ with $0 \leq z \leq R$. For all integers $\ell \geq 1$,*

$$|Y_\ell(z)| \leq C\frac{(\ell-1)!}{z^\ell},$$

and for $\ell = 0$,

$$|Y_\ell(z)| \leq C|\log(z)|,$$

where $C > 0$ depends only on R.

Proof. By [4, p. 51], $Y_\ell(z)$ is given for any nonnegative integer ℓ by

$$\begin{aligned} Y_\ell(z) = {} & \frac{2}{\pi}J_\ell(z)\log\left(\frac{z}{2}\right) - \frac{1}{\pi}\sum_{k=0}^{\ell-1}\frac{(\ell-k-1)!}{k!}\left(\frac{z}{2}\right)^{2k-\ell} \\ & -\frac{1}{\pi}\sum_{k=0}^{\infty}\frac{\psi(\ell+k)+\psi(k)}{(-1)^k k!(k+\ell)!}\left(\frac{z}{2}\right)^{2k+\ell}, \end{aligned} \tag{A.2}$$

where $\psi(0) = -\gamma \approx -0.5772$ and $\psi(k) = -\gamma + \sum_{j=1}^{k}\frac{1}{j}$ for $k \geq 1$.

To bound the second term in (A.2), we find that

$$\begin{aligned} \sum_{k=0}^{\ell-1}\frac{(\ell-k-1)!}{k!}\left(\frac{z}{2}\right)^{2k} &\leq (\ell-1)!\sum_{k=0}^{\infty}\frac{1}{k!}\left[\left(\frac{z}{2}\right)^2\right]^k \\ &\leq (\ell-1)!\, e^{\left(\frac{R}{2}\right)^2} \leq C_1(R)(\ell-1)!. \end{aligned}$$

Now note that for $k \geq 1$, $|\psi(0)| \leq 1$ and $0 \leq \psi(k) \leq -\gamma + k \leq k$.

Hence, for a bound on the third term in (A.2), we obtain

$$\sum_{k=0}^{\infty}\frac{|\psi(\ell+k)+\psi(k)|}{k!(k+\ell)!}\left(\frac{z}{2}\right)^{2k+\ell} \leq 2\sum_{k=0}^{\infty}\frac{1}{k!}\frac{[(R/2)^2]^{\frac{\ell}{2}+k}}{(\ell+k-1)!} \leq C_2(R),$$

since

$$\frac{[(R/2)^2]^{\frac{\ell}{2}+k}}{(\ell+k-1)!} \le C_3(R).$$

These bounds together with (A.1) yield the desired result. ∎

We now turn to the proof of the main lemma.

Proof of Lemma 2.1. First note that

$$\begin{aligned}\int_{R_0}^{R_1} |\mathcal{J}_\ell(a,r)|r\,dr &= |H_\ell^1(\kappa a)| \int_{R_0}^{a} |J_\ell(\kappa r)|r\,dr + |J_\ell(\kappa a)| \int_a^{R_1} |H_\ell^1(\kappa r)|r\,dr \\ &\le |J_\ell(\kappa a)| \int_{R_0}^{R_1} |J_\ell(\kappa r)|r\,dr + |J_\ell(\kappa a)| \int_a^{R_1} |Y_\ell(\kappa r)|r\,dr \\ &\quad + |Y_\ell(\kappa a)| \int_{R_0}^{a} |J_\ell(\kappa r)|r\,dr \\ &\le I_{J,J} + I_{J,Y} + I_{Y,J},\end{aligned}$$

where

$$\begin{aligned}I_{J,J} &= |J_\ell(\kappa a)| \int_0^{R_1} |J_\ell(\kappa r)|r\,dr, \\ I_{J,Y} &= |J_\ell(\kappa a)| \int_a^{R_1} |Y_\ell(\kappa r)|r\,dr, \\ I_{Y,J} &= |Y_\ell(\kappa a)| \int_0^{a} |J_\ell(\kappa r)|r\,dr.\end{aligned}$$

Note that $|J_{-\ell}(z)| = |(-1)^\ell J_\ell(z)| = |J_\ell(z)|$ and similarly $|Y_{-\ell}(z)| = |Y_\ell(z)|$. Hence, it suffices to bound these integrals for $\ell \ge 0$.

Thus, for $\ell \ge 0$, by (A.1),

$$I_{J,J} \le \frac{1}{(\ell!)^2} R_1^2 (\kappa R_1)^{2l} \le \frac{C_{J,J}}{\ell^2},$$

where $C_{J,J} > 0$ depends only on κ and R_1. By (A.1) and Lemma A.1, we find that for $\ell > 2$,

$$\begin{aligned}I_{J,Y} &\le C \frac{(\kappa a)^\ell}{\ell!} \int_a^{R_1} \frac{(\ell-1)!}{(\kappa r)^\ell} r\,dr \\ &= C \frac{{R_1}^2}{\ell(\ell-2)} \left[\left(\frac{a}{R_1}\right)^2 - \left(\frac{a}{R_1}\right)^\ell \right] \le \frac{C_{J,Y}}{\ell^2}.\end{aligned}$$

A similar argument shows that $I_{J,Y}$ is also bounded for $\ell = 0, 1, 2$. Finally, for $\ell \ge 1$, we find that

$$\begin{aligned}I_{Y,J} &\le C \frac{(\ell-1)!}{(\kappa a)^\ell} \int_0^{a} \frac{(\kappa r)^\ell}{\ell!} r\,dr \\ &= \frac{a^2}{\ell(\ell+2)} \le \frac{C_{Y,J}}{\ell^2}.\end{aligned}$$

It is not difficult to show that this same bound holds for $\ell = 0$. ∎

TABLE B.1
Relative errors in trapezoidal rule integration.

N	Error	Ratio
1	2.5e-1	
2	9.5e-2	2.6
4	3.5e-2	2.7
8	1.3e-2	2.7
8192	4.2e-7	

(a) $\int_0^{1/2} \sqrt{x}dx \approx 0.2357$

N	Error	Ratio
1	4.8e-2	
2	1.2e-2	4.0
4	2.9e-3	4.1
8	7.4e-4	3.9
8192	7.0e-10	

(b) $\int_0^{\pi/4} e^{\cos^2 x}dx \approx 1.8009$

1	5.5e-1	
2	6.0e-2	9.2
4	3.1e-4	1.9e+2
8	7.2e-10	4.3e+5
16	2.1e-23	3.4e+13

(c) $\int_0^{\pi} e^{\cos^2 x}dx \approx 5.5084$

Appendix B. Higher-order integration via the trapezoidal rule. When used to integrate a smooth and periodic function over its period, the trapezoidal rule obtains a truly extraordinary convergence rate (see [21, section 9.4] and [29]). As with our numerical method, this convergence behavior is due to the rapid decay of the function's Fourier coefficients (see Lemma 3.1). Since this fact may yet be unfamiliar to some readers, we illustrate trapezoidal rule convergence through three simple, one-dimensional integrals.

In Table B.1, we give the relative errors obtained when computing the integrals of the functions $\sqrt{x}$ and $e^{\cos^2 x}$ by means of the trapezoidal rule with N points. In Table B.1(a), we observe less than second-order convergence when computing $\int_0^{1/2} \sqrt{x}dx$, which is a result of the singularity in its first derivative at the origin. Table B.1(b) shows second-order convergence when computing $\int_0^{\pi/4} e^{\cos^2 x}dx$, which agrees with the well-known convergence rate predicted for the trapezoidal rule when integrating C^2 functions. Finally, in Table B.1(c), we observe an *exponential* convergence rate when computing $\int_0^{\pi} e^{\cos^2 x}$, the same function integrated in Table B.1(b). Note that in this example a relative error of 7×10^{-10} is obtained with 8 points, whereas in Table B.1(b), 8192 points are required for similar accuracy. This extraordinary convergence rate results because we are integrating a *smooth and periodic function over its period*.

ROBUST A POSTERIORI ERROR ESTIMATION FOR NONCONFORMING FINITE ELEMENT APPROXIMATION*

MARK AINSWORTH†

Abstract. The equilibrated residual method for a posteriori error estimation is extended to nonconforming finite element schemes for the approximation of linear second order elliptic equations where the permeability coefficient is allowed to undergo large jumps in value across interfaces between differing media. The estimator is shown to provide a computable upper bound on the error and, up to a constant depending only on the geometry, provides two-sided bounds on the error. The robustness of the estimator is also studied and the dependence of the constant on the jumps in permeability is given explicitly.

Key words. robust a posteriori error estimation, nonconforming finite element, Crouzeix–Raviart element, saturation assumption

1. Introduction.

A posteriori error estimation for *conforming* finite element schemes has been the subject of extensive investigation, and such methods are now routinely incorporated in adaptive finite element procedures by the engineering and scientific computing communities. In contrast, the treatment of *nonconforming* methods [8] has been subject to sporadic yet sustained attention over the past decade.

The early work of Agouzal [1] was concerned with a posteriori error estimation for nonconforming finite element approximation of Poisson-type problems. The important contribution of Dari et al. [10] presented an explicit a posteriori error estimator based on evaluation of norms of residuals supplemented by jumps in fluxes across interelement edges and showed that the estimator provides two-sided bounds on the error up to generic, unknown constants that are independent of the mesh size. This was subsequently extended to nonconforming mixed finite element approximation of Stokes flow [9] and non-Newtonian flow [3]. The application of hierarchic basis estimators to nonconforming finite element approximation was considered by Hoppe and Wohlmuth [16], where the usual hierarchic basis estimator is augmented with an additional term comparing the nonconforming approximation with a smoothed approximation. Two-sided bounds were obtained [16] under the assumption that a saturation condition is valid. In a related approach, Schieweck [18] proposed a residual-based estimator supplemented with the same additional term as in [16]. However, the analysis of efficiency in [18] was based on additional rather strong assumptions on the regularity of the mesh and the true solution. Carstensen, Bartels, and Jansche [6] derived estimators based on *gradient* averaging (or smoothing) techniques and obtained two-sided bounds. All of the above estimators involve generic, unknown constants and as such provide refinement indicators rather than actual numerical bounds on the error.

Destuynder and Métivet [12] derived a posteriori bounds for the error in a conforming approximation obtained by smoothing the nonconforming approximation. Explicit, computable upper bounds on the error measured in the energy norm were obtained for approximation of Poisson's equation. To show that the bounds are efficient, the authors made additional regularity assumptions on the mesh and the true solution and showed that the estimator decays at the same rate as the true error. Unfortunately, these regularity assumptions on the mesh and the true solution generally fail to hold in the context of the solution of practical problems on adaptively refined meshes.

A technique that has proved particularly effective and robust for a posteriori estimation of the error in *conforming* finite element schemes is the *equilibrated residual method*, as described, for example, in [2]. One goal of the present work is to extend the equilibrated residual method to nonconforming finite element schemes for the approximation of a linear second order elliptic problem with variable permeability. The permeability is assumed to be piecewise constant on subdomains corresponding to different media but is allowed to undergo large jumps across interfaces. Particular attention is paid to the robustness of the a posteriori error estimator with respect to the size of the jumps. This issue has also been studied in the setting of conforming finite element approximation by Bernardi and Verfürth [4].

The approach is based on the idea of Dari et al. [10] involving an orthogonal (Helmholtz) decomposition of the error into a conforming part and a nonconforming part. The conforming part is treated using a modification of the standard equilibrated residual method where the weakened continuity requirements for a nonconforming element are fully exploited. Indeed, the usual procedure for conforming approximation can be dramatically simplified to the extent that in its final form the estimator resembles an explicit estimator, but with the advantage that there are no unknown constants. The remaining nonconforming part of the error is estimated using the difference between the nonconforming approximation and a smoothed nonconforming approximation, similarly to [16], and this is shown to give an upper bound without recourse to unknown constants. The final form of the estimator resembles those derived in [10, 12, 16, 18]. However, one byproduct of the method of derivation is that the estimator can be shown to provide computable upper bounds on the error—a feature characteristic of the equilibrated residual method. Furthermore, the bounds are shown to be efficient in the sense that the estimator is bounded above by the true error up to a constant depending only on the shape of the elements. This result is proved without additional assumptions on the regularity of the true solution and the mesh is allowed to be locally refined, as would be the case of adaptive refinements. However, in order to circumvent the saturation assumption [16], we shall assume that the oscillation of the data is sufficiently small. This extends the ideas of Dörfler and Nochetto [13] to nonconforming finite element approximation. Moreover, the analysis takes full account of the large jumps in the permeability across material interfaces and shows that the estimator is robust with respect to the jumps in certain circumstances (such as if the hypothesis assumed by Bernardi and Verfürth [4] is satisfied).

Gradient smoothing procedures are frequently adopted in the setting of conforming finite element approximation. However, for the nonconforming schemes considered here, smoothing is applied directly to the (discontinuous) finite element approximation, as opposed to its gradient. Interestingly, in the case of Laplace's equation, the exact solution of the local residual problem vanishes identically. This means that the estimator reduces to a recovery-based estimator, and in view of the upper bound

property, we arrive at the somewhat surprising observation[1] that the recovery-based estimator provides a guaranteed upper bound on the error (even though the true solution may have singularities and the mesh may be highly unstructured).

The remainder of this paper is organized as follows. After describing the details of the finite element scheme and the conditions on the mesh, the decomposition of the error into a conforming and nonconforming component is presented. The main results of the paper are then outlined, and illustrative numerical examples are presented. Subsequent sections are concerned with the derivation of the upper and lower bounds for each source of error.

2. Preliminaries.

2.1. Model problem.

Consider the model problem

$$-\mathbf{div}(A\,\mathbf{grad}\,u) = f \text{ in } \Omega \tag{2.1}$$

subject to $u = q$ on Γ_D and $\boldsymbol{n} \cdot A\,\mathbf{grad}\,u = g$ on Γ_N, where Ω is a plane polygonal domain, and the disjoint sets Γ_D and Γ_N form a partitioning of the boundary $\Gamma = \partial\Omega$ of the domain. The data satisfy $f \in L_2(\Omega)$, $g \in L_2(\Gamma_N)$, $q \in H^1(\Gamma_D)$ and $A \in L_\infty(\Omega; \mathbb{R}^{2\times 2})$ is positive definite. For simplicity, it will be assumed that the permeability matrix A is piecewise constant on subdomains of Ω. However, the value of A across a subdomain boundary may undergo jumps of many orders of magnitude, corresponding to transition between regions of widely differing permeability.

The variational form of the problem consists of finding $u \in H^1(\Omega)$ such that $u = q$ on Γ_D and

$$(A\,\mathbf{grad}\,u, \mathbf{grad}\,v) = (f, v) + \int_{\Gamma_N} gv\,\mathrm{d}s \quad \forall v \in H^1_E(\Omega), \tag{2.2}$$

where $H^1_E(\Omega) = \{v \in H^1(\Omega) : v = 0 \text{ on } \Gamma_D\}$. In general, we shall use the notation $(\cdot,\cdot)_\omega$ to denote the integral inner product over a region ω, and omit the subscript in the case where ω is the physical domain Ω.

Consider a family of partitions $\{\mathcal{P}\}$ of the domain Ω into the union of nonoverlapping, shape regular triangular elements such that the nonempty intersection of a distinct pair of elements is a single common node or single common edge. The family of partitions is assumed to be locally quasi-uniform in the sense that the ratio of the diameters of any pair of neighboring elements is uniformly bounded above and below over the whole family.

In addition, whenever possible, the partitioning is chosen to reflect the structure of the permeability matrix in the sense that individual elements do not straddle a subdomain boundary where the value of A undergoes a large jump. This requirement is reflected in the assumption that, for every element $K \in \mathcal{P}$, there exist positive constants λ_K and Λ_K satisfying

$$\lambda_K \|\boldsymbol{p}\|^2_{L_2(K)} \le (A\boldsymbol{p}, \boldsymbol{p})_K \le \Lambda_K \|\boldsymbol{p}\|^2_{L_2(K)}, \quad \boldsymbol{p} \in L_2(K)^2, \tag{2.3}$$

such that the ratio $\Upsilon_K = \Lambda_K/\lambda_K$ is uniformly bounded over the whole family of partitions. It will be important to develop a posteriori error estimators whose reliability and efficiency is insensitive to the magnitude of the jumps in permeability between differing regions but which are allowed to depend on the variation of A within a region.

[1] We are grateful to an anonymous reviewer for drawing our attention to the fact that this observation was first reported in [14].

2.2. Nonconforming finite element approximation. Let $\mathcal{N}$ index the set of element vertices, let $\partial\mathcal{P}$ denote the set of element edges, let $\mathcal{M} = \{\boldsymbol{m}_\gamma : \gamma \in \partial\mathcal{P}\}$ denote the set of points located at midpoints of edges, and let $\mathbb{P}_1$ denote the space of polynomials of total degree at most one. The *Crouzeix–Raviart* finite element space [8] is defined by

$$X^{\mathsf{nc}} = \left\{ v : \Omega \to \mathbb{R} : v_{|K} \in \mathbb{P}_1 \quad \forall K \in \mathcal{P}, \quad v \text{ is continuous at } \boldsymbol{m}_\gamma \in \mathcal{M}\backslash\Gamma \right\},$$

with the subspace X_E^{nc} defined by

$$X_E^{\mathsf{nc}} = \{ v \in X^{\mathsf{nc}} : v(\boldsymbol{m}_\gamma) = 0 \text{ for } \gamma \subset \Gamma_D \}.$$

Functions belonging to the space X^{nc} and X_E^{nc} may have discontinuities across element interfaces, meaning that X^{nc} is not a subspace of $H^1(\Omega)$ and therefore constitutes a *nonconforming* approximation space [5, 7]. The nonconforming finite element approximation of problem (2.2) consists of finding $u_{\mathsf{nc}} \in X^{\mathsf{nc}}$ such that

$$\begin{aligned} (A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}_{\mathsf{nc}}\, v) &= (f, v) + \textstyle\int_{\Gamma_N} g v \,\mathrm{d}s \quad \forall v \in X_E^{\mathsf{nc}}, \\ u_{\mathsf{nc}}(\boldsymbol{m}_\gamma) &= q(\boldsymbol{m}_\gamma) \quad \forall \gamma \subset \Gamma_D, \end{aligned} \tag{2.4}$$

where $\mathbf{grad}_{\mathsf{nc}}$ denotes the operator defined by

$$(\mathbf{grad}_{\mathsf{nc}}\, v)_{|K} = \mathbf{grad}(v_{|K}), \quad K \in \mathcal{P}.$$

A Lagrange-type basis $\{\theta_\gamma\}$ for the space X^{nc} may be constructed by choosing $\theta_\gamma \in X^{\mathsf{nc}}$ to be the function uniquely defined by the conditions

$$\theta_\gamma(\boldsymbol{m}_{\gamma'}) = \delta_{\gamma\gamma'}, \quad \gamma' \in \partial\mathcal{P}. \tag{2.5}$$

A nonconforming interpolation operator $\Pi_{\mathsf{nc}} : H^1(\Omega) \to X^{\mathsf{nc}}$ is defined by the conditions

$$\int_\gamma \Pi_{\mathsf{nc}}\, v \,\mathrm{d}s = \int_\gamma v \,\mathrm{d}s \quad \forall \gamma \in \partial\mathcal{P}. \tag{2.6}$$

The representation of the operator relative to the basis (2.5) is given by

$$\Pi_{\mathsf{nc}}\, v = \sum_{\gamma \subset \partial\mathcal{P}} \overline{v}_\gamma \theta_\gamma, \tag{2.7}$$

where $\overline{v}_\gamma$ denotes the average value of v on an edge γ. Observe that the restriction of $\Pi_{\mathsf{nc}}\, v$ to a particular element K is defined entirely in terms of the averages of the function v on the edges of the element and, moreover, Π_{nc} locally preserves constants. These properties (in conjunction with standard scaling arguments) may be used to deduce that there exists a positive constant C depending only on the shape of the element such that the following local elementwise approximation property holds:

$$\|v - \Pi_{\mathsf{nc}}\, v\|_{L_2(K)} + h_K^{1/2} \|v - \Pi_{\mathsf{nc}}\, v\|_{L_2(\partial K)} \le C h_K \|\mathbf{grad}\, v\|_{L_2(K)}. \tag{2.8}$$

2.3. Data oscillation. It will be necessary to impose some notion of regularity on the underlying problem. Often, a *saturation condition* [16] is assumed, but this assumption makes reference to the (unknown) true solution u, meaning that it is difficult to verify a priori. Dörfler and Nochetto [13], working in the context of conforming piecewise affine approximation, showed that the saturation assumption can be removed in favor of an assumption on the magnitude of the *data oscillation*. This condition has the advantage of being formulated directly in terms of the known data for the problem and can therefore be verified a priori. We shall show that a similar conclusion holds in the nonconforming setting considered here.

The oscillation of the data $f \in L_2(\Omega)$ over the finite element partition $\mathcal{P} = \{K\}$ is defined by

$$\operatorname{osc}(f, \{K : K \in \mathcal{P}\})^2 = \sum_{K \in \mathcal{P}} \operatorname{meas}(K) \left\| f - \overline{f}_K \right\|^2_{L_2(K)}, \tag{2.9}$$

where $\overline{f}_K$ is the average value of f over element K. The data oscillation quantifies the variation in the data f with respect to the partition $\mathcal{P}$. Likewise, the oscillation of the Neumann data g is defined by

$$\operatorname{osc}(g, \{\gamma : \gamma \subset \Gamma_N\})^2 = \sum_{\gamma \subset \Gamma_N} \operatorname{meas}(\gamma) \left\| g - \overline{g}_\gamma \right\|^2_{L_2(\gamma)}. \tag{2.10}$$

The appropriate quantity for the Dirichlet data turns out to be

$$\operatorname{osc}\left(\partial q/\partial s, \{\gamma : \gamma \subset \Gamma_D\}\right)^2 = \sum_{\gamma \subset \Gamma_D} \operatorname{meas}(\gamma) \left\| \frac{\partial q}{\partial s} - \mu_\gamma \right\|^2_{L_2(\gamma)}.$$

Here $\overline{g}_\gamma$ and μ_γ denote the average value of g and $\partial q/\partial s$ on edge γ.

2.4. Path permeability. Let Ω_n denote the patch composed from those elements with a vertex located at $\boldsymbol{x}_n$, and let K, $K' \subset \Omega_n$ be distinct elements. It is useful to introduce the notion of permeability $\lambda_{KK'}$ between a pair of elements. Roughly speaking, this measures the permeability of the "most permeable" route between the elements. The precise definition is based on the observation that there is always at least one connected path $\wp(K, K') \subset \mathcal{P}$ passing from K to K' through adjacent elements belonging to the patch Ω_n. The smallest permeability of all the elements in the path $\wp(K, K')$ is given by $\min\{\lambda_M : M \in \wp(K, K')\}$. If $\boldsymbol{x}_n$ is an interior vertex, then there are two such paths, and in this case we take $\wp(K, K')$ to be the path $\wp^*(K, K')$, which maximizes the value of this quantity, and define

$$\lambda_{KK'} = \min\{\lambda_M : M \in \wp^*(K, K')\}. \tag{2.11}$$

If a vertex $\boldsymbol{x}_n$ of element K lies on the Dirichlet boundary Γ_D, then the element may be linked to Γ_D by a connected path $\wp(K, \Gamma_D)$ passing through adjacent elements as before. The permeability $\lambda_{K\Gamma_D}$ between element K and the Dirichlet boundary is then defined using (2.11) with $\wp^*(K, \Gamma_D)$ in place of $\wp^*(K, K')$. The ratio

$$\Upsilon_{KK'} = \frac{\min(\Lambda_K, \Lambda_{K'})}{\lambda_{KK'}} \tag{2.12}$$

measures path permeability relative to the least permeable of the two elements K and K' at the endpoints of the path.

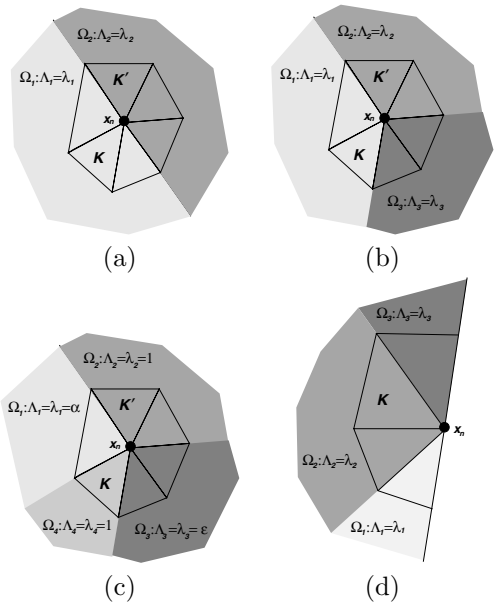

FIG. 2.1. *Value of relative path permeability* (2.12) *for some typical configurations.* (a) *Node on interface:* $\Upsilon_{KK'} = 1$. (b) *Node at crosspoint of three subdomains.* $\Upsilon_{KK'} = 1$. (c) *Node at crosspoint of four subdomains* ($\epsilon \ll 1$). $\Upsilon_{KK'} = 1/\max(\min(1,\alpha),\epsilon)$. (d) *Node on Dirichlet boundary.* $\Upsilon_{K\Gamma_D} = \Lambda_2/\max(\min(\lambda_1,\lambda_2),\min(\lambda_2,\lambda_3))$.

If Ω_n is contained either within a subdomain, on the interface between two subdomains, or at the crosspoint of three subdomains, then the relative path permeability is always unity; see Figure 2.1(a)–(b). However, the relative path permeability may be arbitrarily large at crosspoints where four or more subdomains meet, as would be the case in Figure 2.1(c) if $\alpha \ll 1$. This means that the relative path permeability remains bounded only under additional hypotheses. For example, if, as in Bernardi and Verfürth [4, Hypothesis 2.7], it is assumed that there is always a path between any two elements on which the permeability increases monotonically, then the relative path permeability is always unity, even at boundary nodes $\boldsymbol{x}_n \in \Gamma_D$.

3. A posteriori error estimator.

3.1. Decomposition of the error. The purpose of the present work is to develop methods for obtaining computable estimators for the error $e = u - u_{\mathsf{nc}}$ in the nonconforming approximation measured in the energy norm denoted by $(A\,\mathbf{grad}_{\mathsf{nc}}\, e, \mathbf{grad}_{\mathsf{nc}}\, e)^{1/2}$. The following Helmholtz-type decomposition is essentially taken from Dari et al. [10].

LEMMA 3.1. *Let*

$$\mathcal{H} = \left\{ w \in H^1(\Omega) : \int_\Omega w \,\mathrm{d}\boldsymbol{x} = 0 \text{ and } \frac{\partial w}{\partial s} = 0 \text{ on } \Gamma_N \right\}.$$

The error e may be decomposed into the form

$$A\,\mathbf{grad}_{\mathsf{nc}}\, e = A\,\mathbf{grad}\,\phi + \mathbf{curl}\,\psi, \tag{3.1}$$

where $\phi \in H^1_E(\Omega)$ satisfies

$$(A\,\mathbf{grad}\,\phi, \mathbf{grad}\, v) = (A\,\mathbf{grad}_{\mathsf{nc}}\, e, \mathbf{grad}\, v) \quad \forall v \in H^1_E(\Omega) \tag{3.2}$$

and $\psi \in \mathcal{H}$ satisfies

$$(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,w) = (\mathbf{grad}_{\mathsf{nc}}\,e, \mathbf{curl}\,w) \quad \forall w \in \mathcal{H}. \tag{3.3}$$

Moreover,

$$(A\,\mathbf{grad}_{\mathsf{nc}}\,e, \mathbf{grad}_{\mathsf{nc}}\,e) = (A\,\mathbf{grad}\,\phi, \mathbf{grad}\,\phi) + (A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi). \tag{3.4}$$

Proof. An application of the Lax–Milgram lemma shows that ϕ exists and is unique. Denote $\boldsymbol{w} = A(\mathbf{grad}_{\mathsf{nc}}\,e - \mathbf{grad}\,\phi) \in L_2(\Omega)^2$. With the aid of Green's formula and (3.2), we deduce that

$$0 = \int_\Omega v\,\mathbf{div}\boldsymbol{w}\,\mathrm{d}\boldsymbol{x} + \int_\Gamma v\,\boldsymbol{n}\cdot\boldsymbol{w}\,\mathrm{d}s \quad \forall v \in H^1_E(\Omega).$$

Consequently, $\boldsymbol{w}$ is divergence free in Ω and $\boldsymbol{n}\cdot\boldsymbol{w} = 0$ on Γ_N. Applying Theorem 3.1 in [15] shows that there exists $\psi \in H^1(\Omega)/\mathbb{R}$ such that

$$A(\mathbf{grad}_{\mathsf{nc}}\,e - \mathbf{grad}\,\phi) = \boldsymbol{w} = \mathbf{curl}\,\psi.$$

Furthermore, $\boldsymbol{n}\cdot\mathbf{curl}\,\psi = \boldsymbol{n}\cdot\boldsymbol{w} = 0$ on Γ_N, and we conclude that $\psi \in \mathcal{H}$. The characterization (3.3) and the orthogonality property (3.4) hold, provided that

$$\int_\Omega \mathbf{grad}\,\phi\cdot\mathbf{curl}\,w\,\mathrm{d}\boldsymbol{x} = 0 \quad \forall w \in \mathcal{H}.$$

This follows directly from an integration by parts on recalling that ϕ vanishes on Γ_D while $\boldsymbol{n}\cdot\mathbf{curl}\,w$ vanishes on Γ_N. ∎

Lemma 3.1 means that the error e in the nonconforming approximation may be split into two parts, as in (3.1). The nature of the contributions ψ and ϕ defined in Lemma 3.1 may be identified as follows. First, suppose that the nonconforming approximation u_{nc} happens to be conforming, by which we mean $u - u_{\mathsf{nc}} \in H^1_E(\Omega)$. The right-hand side of (3.3) then simplifies to

$$(\mathbf{grad}_{\mathsf{nc}}\,e, \mathbf{curl}\,w) = (\mathbf{grad}\,e, \mathbf{curl}\,w) = \int_\Gamma e\,\boldsymbol{n}\cdot\mathbf{curl}\,w\,\mathrm{d}s = 0,$$

since e vanishes on Γ_D and $\boldsymbol{n}\cdot\mathbf{curl}\,w = 0$ on Γ_N for $w \in \mathcal{H}$. Hence, if the approximation u_{nc} is conforming, then the contribution ψ vanishes. For this reason, we shall refer to ψ as the *nonconforming error*. The remaining contribution, ϕ, is referred to as the *conforming error*.

The splitting of the error into nonconforming and conforming components defines an orthogonal decomposition in the sense that the Pythagorean identity (3.4) holds. This means that the problem of obtaining a posteriori error estimators for the total error reduces to the derivation of estimators for the conforming and nonconforming errors *independently*. An estimator for the total error is then given by summing the estimators for the independent contributions.

3.2. Statement of main result. We summarize the results to be proved in sections 5 and 6. For $K \in \mathcal{P}$, let $\boldsymbol{\sigma}_K$ denote the function $\boldsymbol{\sigma}_K = -\frac{1}{2}\overline{f}_K(\boldsymbol{x} - \boldsymbol{x}_K)$, where $\boldsymbol{x}_K$ denotes the element centroid. The estimator for the conforming error is defined in terms of $\boldsymbol{\sigma}_K$ as follows:

$$\eta^2_{\mathsf{cf},K} = \big(A^{-1}\boldsymbol{\sigma}_K, \boldsymbol{\sigma}_K\big)_K = \frac{1}{48}\,\mathrm{meas}(K)\overline{f}^2_K \sum_{\ell=1}^{3} \boldsymbol{w}_\ell^\top A^{-1}\boldsymbol{w}_\ell, \tag{3.5}$$

where $\boldsymbol{w}_\ell$ is the position vector of vertex ℓ of the element relative to the centroid.

The estimator for the nonconforming error is defined in terms of a piecewise affine function $S(u_{\mathsf{nc}})$ on $\mathcal{P}$ obtained by smoothing the nonconforming approximation with values at vertices given by

$$S(u_{\mathsf{nc}})(\boldsymbol{x}_n) = \begin{cases} q(\boldsymbol{x}_n) & \text{if } \boldsymbol{x} \in \Gamma_D, \\ \displaystyle\sum_{K\in\Omega_n} \omega_{K,n}\, u_{\mathsf{nc}|K}(\boldsymbol{x}_n) & \text{otherwise,} \end{cases} \tag{3.6}$$

where the weights $\omega_{K,n}$ are defined by

$$\omega_{K,n} = \frac{\Lambda_K^{1/2}}{\sum_{K'\subset\Omega_n} \Lambda_{K'}^{1/2}}. \tag{3.7}$$

The estimator on element K is then given by

$$\eta_{\mathsf{nc},K}^2 = \left(A\,\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}} - S(u_{\mathsf{nc}})), \mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}} - S(u_{\mathsf{nc}}))\right)_K. \tag{3.8}$$

The main result may now be stated. For ease of exposition, we suppose the Dirichlet data is homogeneous, although this assumption is subsequently relaxed.

THEOREM 3.2. *Let Δ_K denote the local data oscillation on element K given by*

$$\Delta_K = \operatorname{osc}(f,K) + \operatorname{osc}(g, \{\gamma \subset \Gamma_N \cap \partial K\}), \tag{3.9}$$

and let $\Upsilon_{KK'}$ be the relative path permeability defined in (2.12)*. Then the conforming error may be estimated as*

$$(A\,\mathbf{grad}\,\phi, \mathbf{grad}\,\phi) \le \sum_{K\in\mathcal{P}} (\eta_{\mathsf{cf},K} + C\lambda_K^{-1/2}\Delta_K)^2 \tag{3.10}$$

and

$$c\eta_{\mathsf{cf},K} \le \Upsilon_K^{1/2} (A\,\mathbf{grad}\,\phi, \mathbf{grad}\,\phi)_K^{1/2} + \lambda_K^{-1/2} \operatorname{osc}(f,K). \tag{3.11}$$

Furthermore, the nonconforming error may be estimated as

$$(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi) \le \sum_{K\in\mathcal{P}} \eta_{\mathsf{nc},K}^2 \tag{3.12}$$

and

$$c\eta_{\mathsf{nc},K}^2 \le (A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi)_{\widetilde{K}} \sum_{K'\subset\widetilde{K}} \Upsilon_{KK'}, \tag{3.13}$$

where $\widetilde{K}$ denotes the patch formed from those elements sharing a common vertex with element K, and c and C are positive constants that depend only on the element geometry. Consequently, the total error may be estimated as

$$(A\,\mathbf{grad}_{\mathsf{nc}}\, e, \mathbf{grad}_{\mathsf{nc}}\, e) \le \sum_{K\in\mathcal{P}} (\eta_{\mathsf{cf},K} + C\lambda_K^{-1/2}\Delta_K)^2 + \eta_{\mathsf{nc},K}^2 \tag{3.14}$$

along with a corresponding lower bound on the total error.

Proof. The estimates for the conforming error are proved in Lemmas 5.2 and 5.3, while the estimates for the nonconforming error are proved in Lemma 6.2 and Theorem 6.4. The upper and lower bounds on the total error follow at once from (3.4). ∎

The resulting estimator is reminiscent of the estimators found in [10, 12, 16, 18]. Here, it is shown that the estimator provides a numerical upper bound for the total global error which does not involve unknown constants. Moreover, the estimator is shown to be efficient and robust (provided the relative path permeability remains bounded) without additional assumptions on the regularity of the true solution or on the mesh.

4. Numerical examples. The behavior of the estimator (3.14) is illustrated for some simple representative problems in this section.

4.1. Laplacian on L-shaped domain. Figure 4.1 shows the sequence of adaptively refined meshes for the solution of Laplace's equation on an L-shaped domain with pure Dirichlet boundary conditions chosen so that the solution is given by $u(r,\theta) = r^{2/3}\sin(2\theta/3)$. The conforming error vanishes in this case and the local error estimator on element K reduces to $\eta_{\mathsf{nc},K}$.

The effectivity index is found to vary in the range 1.5–1.6 in this example, as shown in Table 4.1. The sequence of meshes was constructed adaptively by selecting for refinement all elements where the local error indicator exceeds 30% of the value of the largest local indicator.

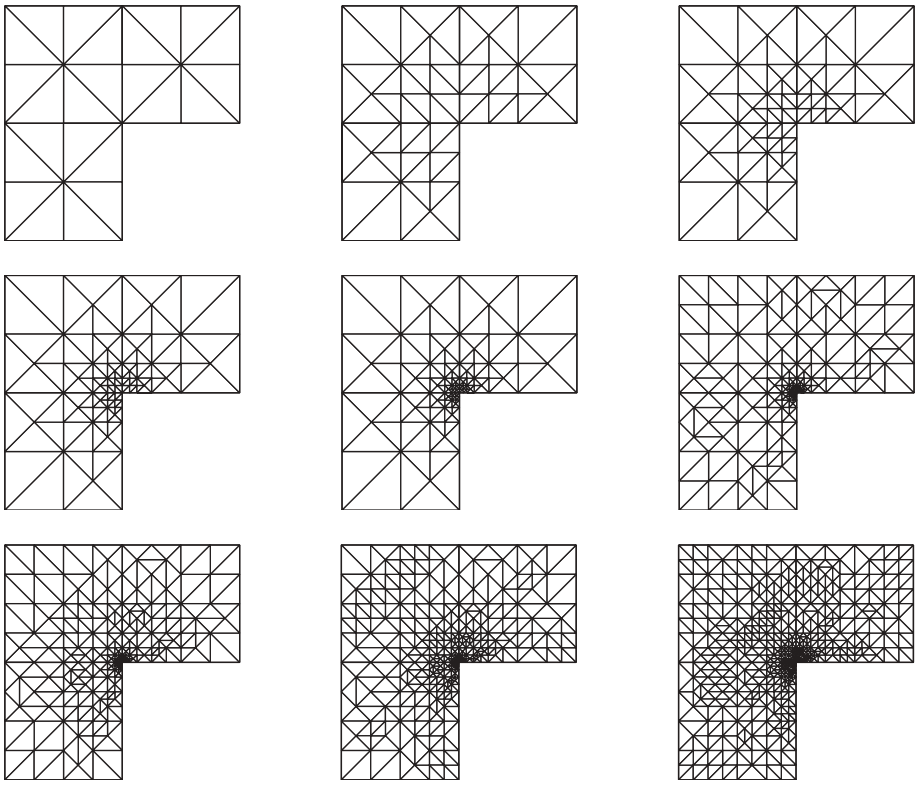

FIG. 4.1. *Sequence of adaptively refined meshes for Laplace example.*

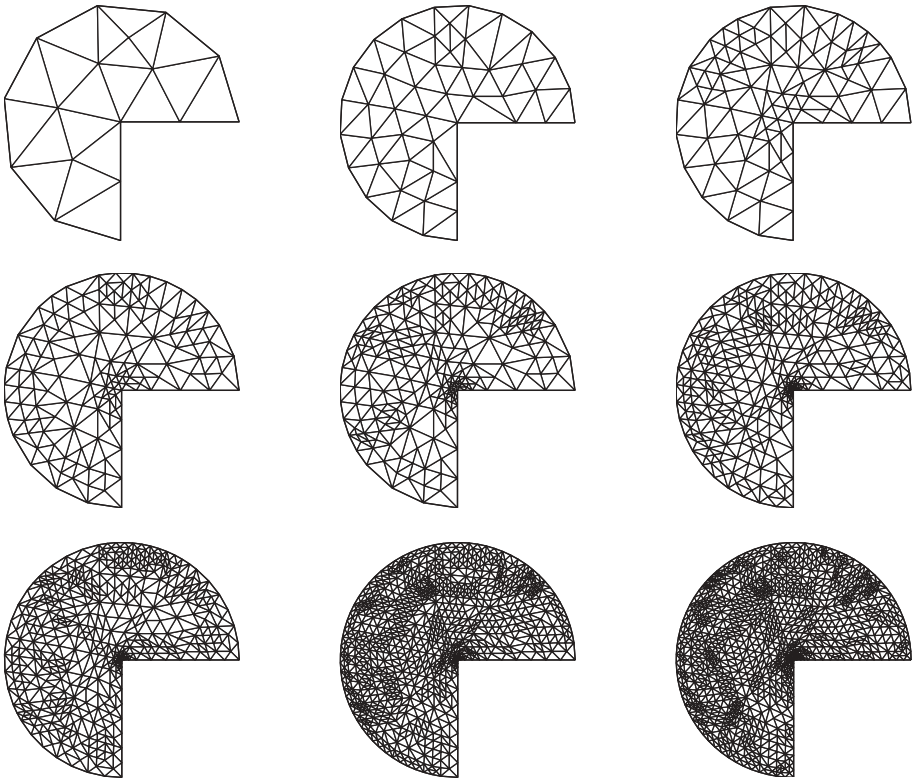

FIG. 4.2. *Sequence of adaptively refined meshes for Poisson problem.*

4.2. Nonzero source term. Figure 4.2 shows the sequence of adaptively refined meshes for the solution of Poisson's equation with homogeneous Dirichlet boundary conditions and source term chosen so that the solution is given by $u(r,\theta) = (r^{2/3} - r^2)\sin(2\theta/3)$. In this example, the conforming and nonconforming errors are both nonzero. The performance of the error estimator is shown in Table 4.2 along with the contributions from the conforming and nonconforming components of the error.

4.3. Variable permeability. The performance of the estimator in the case of variable permeability will be illustrated by considering the simple problem on the domain shown in Figure 4.3 with scalar permeability $A = a_\ell I$ on Ω_ℓ and prescribed flux $g = \boldsymbol{n} \cdot \mathbf{grad}(x^2 - y^2)$ on $\partial\Omega$. The true solution on subdomain Ω_ℓ is given by

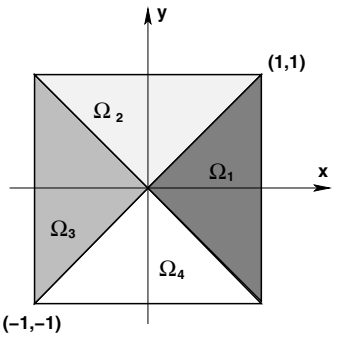

FIG. 4.3. *Geometry and subdomains for problem with variable permeability.*

$u(x,y) = (x^2 - y^2)/a_\ell$. Consider the situation where the local permeability is given by $a_1 = 1$, $a_2 = \alpha^2$, $a_3 = 1$, and $a_4 = \alpha^4$ with an initial mesh consisting of four elements coinciding with the subdomains shown in Figure 4.3.

The smoothing operator S may in principle be constructed using any choice of weights satisfying the condition

$$\sum_{K \subset \Omega_n} \omega_{K,n} = 1. \tag{4.1}$$

This requirement leaves considerable latitude in the selection of the weights. For instance, one might even choose all but one of weights to vanish, as suggested by Schieweck [18]. The obvious choice whereby the weights are chosen to be equal has been utilized by Oswald [17] in the context of multigrid methods. An alternative choice, advocated by Destuynder and Métivet [12, eqn. (17)], is to take $\omega_{K,n}$ proportional to the area of element K. If the mesh is locally quasi-uniform, then the latter two choices are not significantly different. Here, we are specifically concerned with the approximation of problems with highly varying local permeability, and the choice of weights given in (3.7) reflects this by depending on the value of the local permeability. The weights (3.7) are equal if the node $\boldsymbol{x}_n$ is located inside a subdomain where the local permeability is constant but differ markedly on interfaces and crosspoints between subdomains.

The ratio of the estimated error to the true error, $\mathrm{Eff}(\alpha)$, of the estimators obtained using the standard smoothing operator S with equal weighting and the estimator obtained using the weighted smoothing operator with weights depending on the permeability as in (3.7) can be computed explicitly on the initial mesh. For the

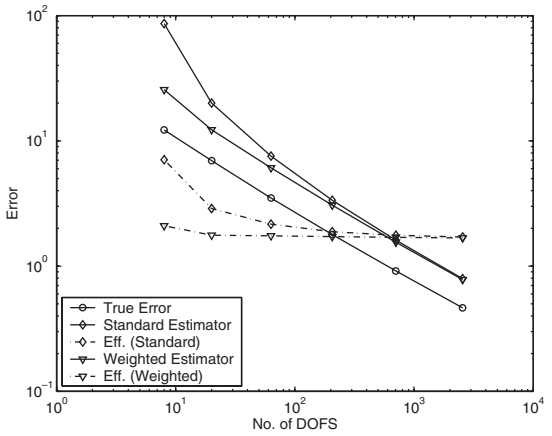

FIG. 4.4. *Comparison of standard estimator with weighted scheme for model problem with variable permeability.*

standard scheme, we obtain

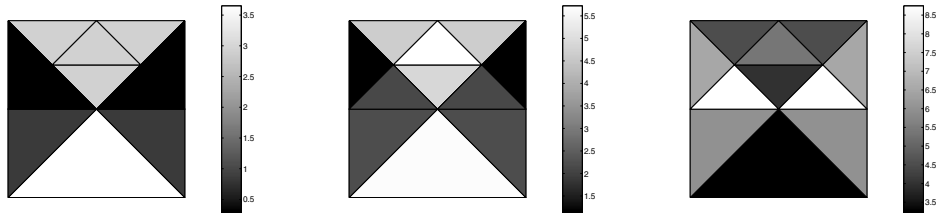
$$\mathrm{Eff}(\alpha)^2 = \begin{cases} \dfrac{3}{8}\alpha^4 + \mathcal{O}(1) & \text{as } \alpha \to \infty, \\ \dfrac{15}{32}\alpha^{-4} + \mathcal{O}(\alpha^{-2}) & \text{as } \alpha \to 0, \end{cases}$$

while for the weighted estimator,

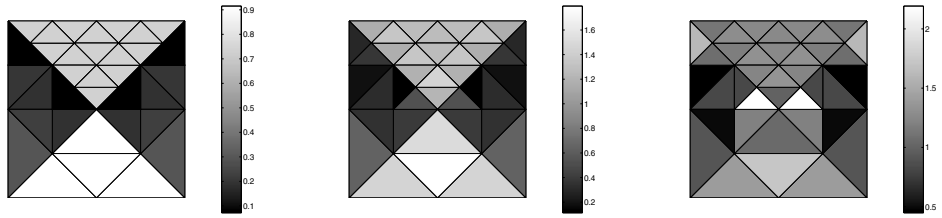
$$\mathrm{Eff}(\alpha)^2 = \begin{cases} \dfrac{27}{4} + \mathcal{O}(\alpha^{-1}) & \text{as } \alpha \to \infty, \\ \dfrac{39}{8} + \mathcal{O}(\alpha) & \text{as } \alpha \to 0. \end{cases}$$

The performance of the standard estimator clearly degenerates rapidly as the local permeability α is varied. The performance of the estimators when α^2 is taken to be 0.1 is presented in Figure 4.4. As would be expected, as the mesh is refined, both estimators tend to give the same value. However, even with this relatively modest value of α, the standard scheme provides very poor estimates for the error on the coarser meshes. The distribution of the local error estimates is compared with the actual local errors, as shown in Figure 4.5. Obviously, the estimators coincide away from interfaces. However, on interfaces and at the crosspoint, it is observed that the weighted estimator gives a more accurate picture of the distribution of the true error. Here, the true error was used to construct the sequence of adaptively refined meshes. Essentially the same sequence of meshes would be obtained if the weighted estimator were used, while if the standard estimator were to be used, then one would obtain a completely different sequence of meshes.

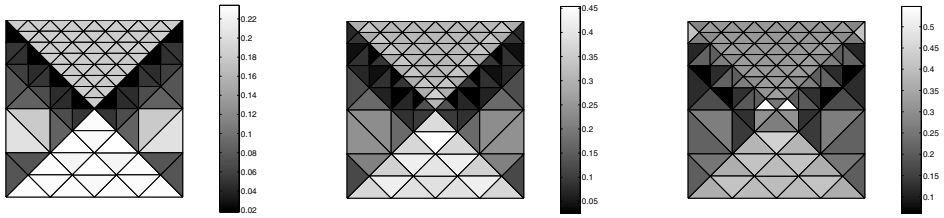
4.4. Neither term can be dropped from the estimator. The fact that the estimator provides an upper bound for the solution of the Laplace equation shows that the nonconforming term must be present in the estimator. It is less clear that the interior residual term must also be present. Consider the Poisson equation on a unit square with pure Neumann data chosen so that the true solution is given by $3x^2 - 2xy + 3y^2$. Observe that the oscillation of f vanishes. Suppose that the



(a) Mesh 2



(b) Mesh 3



(c) Mesh 4

FIG. 4.5. *Distribution of true local error (left) and estimated local error for weighted (center) and standard (right) estimators applied to model problem with variable permeability.*

solution is approximated using the mesh obtained by subdividing the square into a uniform mesh of right-angled triangles with hypotenuse in the direction $(1,1)$. In this scenario, it is found that the nonconforming finite element approximation u_{nc} is actually *conforming*, which means that the nonconforming term vanishes, yet the true error is obviously nonzero. This example shows that the interior residual term is essential for the upper bound and therefore cannot be removed in general.

5. Estimation of the conforming error.

5.1. Upper bound. Our objective is to derive a representation formula for the conforming component ϕ of the error in terms of quantities that can be evaluated explicitly or estimated in terms of the data oscillation. The following preparatory result will be useful in this direction. Let $\overline{\boldsymbol{x}}_K$ denote the centroid of element K, and define

$$\boldsymbol{\sigma}_K = -\frac{1}{2}\overline{f}_K(\boldsymbol{x} - \overline{\boldsymbol{x}}_K), \tag{5.1}$$

where $\overline{f}_K$ denotes the (constant) average value of the data f on element K. The function $\boldsymbol{\sigma}_K$ has the following property.

LEMMA 5.1. *Let $\boldsymbol{\sigma}_K$ be defined as in* (5.1). *Then*

$$(\boldsymbol{\sigma}_K, \mathbf{grad}\, v)_K = (\overline{f}_K, v - \Pi_{\mathsf{nc}}\, v)_K \quad \forall v \in H^1_E(K), \tag{5.2}$$

where Π_{nc} *is the nonconforming interpolation operator defined in* (2.6).

Proof. Let $v \in H^1_E(K)$. Then integration by parts gives

$$(\boldsymbol{\sigma}_K, \mathbf{grad}\, v)_K = -\int_K v\, \mathbf{div}\, \boldsymbol{\sigma}_K \,\mathrm{d}\boldsymbol{x} + \int_{\partial K} v \boldsymbol{n}_K \cdot \boldsymbol{\sigma}_K \,\mathrm{d}s,$$

where $\boldsymbol{n}_K$ denotes the unit outward normal on ∂K. Inserting the expression for $\boldsymbol{\sigma}_K$ into the first term on the right-hand side gives

$$-\int_K v\, \mathbf{div}\, \boldsymbol{\sigma}_K \,\mathrm{d}\boldsymbol{x} = (\overline{f}_K, v)_K$$

since $\overline{f}_K$ is constant. It therefore suffices to show that the second term satisfies

$$\int_{\partial K} v \boldsymbol{n}_K \cdot \boldsymbol{\sigma}_K \,\mathrm{d}s = -(\overline{f}_K, \Pi_{\mathsf{nc}}\, v)_K. \tag{5.3}$$

Substituting the expression for $\boldsymbol{\sigma}_K$ gives

$$\int_{\partial K} v \boldsymbol{n}_K \cdot \boldsymbol{\sigma}_K \,\mathrm{d}s = -\frac{1}{2}\overline{f}_K \sum_{\gamma \subset \partial K} \int_\gamma v \boldsymbol{n}_K \cdot (\boldsymbol{x} - \overline{\boldsymbol{x}}_K) \,\mathrm{d}s.$$

Elementary geometry reveals that $\boldsymbol{n}_K \cdot (\boldsymbol{x} - \overline{\boldsymbol{x}}_K)|_\gamma = 2\,\mathrm{meas}(K)/3\,\mathrm{meas}(\gamma)$, and hence

$$\int_\gamma v \boldsymbol{n}_K \cdot (\boldsymbol{x} - \overline{\boldsymbol{x}}_K) \,\mathrm{d}s = \frac{2}{3}\,\mathrm{meas}(K)\overline{v}_\gamma,$$

where $\overline{v}_\gamma$ denotes the average value of v on the edge γ, and the left-hand side of (5.3) may therefore be written in the form

$$\int_{\partial K} v \boldsymbol{n}_K \cdot \boldsymbol{\sigma}_K \,\mathrm{d}s = -\frac{1}{3}\,\mathrm{meas}(K)\overline{f}_K \sum_{\gamma \subset \partial K} \overline{v}_\gamma. \tag{5.4}$$

An elementary computation using (2.6) reveals that

$$\int_K \Pi_{\mathsf{nc}}\, v \,\mathrm{d}\boldsymbol{x} = \frac{1}{3}\,\mathrm{meas}(K) \sum_{\gamma \subset \partial K} \overline{v}_\gamma,$$

and the identity (5.3) now follows by combining this result with (5.4). ∎

We now turn to the error representation formula. Let $v \in H^1_E(\Omega)$ be given; then, using (3.2) and (2.2), we have

$$\begin{aligned}(A\,\mathbf{grad}\,\phi, \mathbf{grad}\, v) &= (A\,\mathbf{grad}_{\mathsf{nc}}\, e, \mathbf{grad}\, v)\\ &= (f, v) + \textstyle\int_{\Gamma_N} gv \,\mathrm{d}s - (A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}\, v).\end{aligned} \tag{5.5}$$

By integrating by parts and observing that $\mathbf{div}(A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}})$ vanishes, we obtain

$$(A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}(v - \Pi_{\mathsf{nc}}\, v))_K = \int_{\partial K} \boldsymbol{n}_K \cdot A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}|_K\, (v - \Pi_{\mathsf{nc}}\, v) \,\mathrm{d}s = 0, \tag{5.6}$$

where the final step follows from the definition of Π_{nc} and the fact that the normal component of $A\,\mathbf{grad}_{\mathsf{nc}}\,u_{\mathsf{nc}}$ is piecewise constant on the element edges. Accumulating contributions over all elements shows that, in view of (2.4),

$$\begin{aligned}(A\,\mathbf{grad}_{\mathsf{nc}}\,u_{\mathsf{nc}},\mathbf{grad}\,v) &= (A\,\mathbf{grad}_{\mathsf{nc}}\,u_{\mathsf{nc}},\mathbf{grad}\,\Pi_{\mathsf{nc}}\,v)\\ &= (f,\Pi_{\mathsf{nc}}\,v)+\textstyle\int_{\Gamma_N} g\,\Pi_{\mathsf{nc}}\,v\,\mathrm{d}s.\end{aligned}\tag{5.7}$$

Equation (5.5) may therefore be rewritten as

$$(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,v)=(f,v-\Pi_{\mathsf{nc}}\,v)+\int_{\Gamma_N} g(v-\Pi_{\mathsf{nc}}\,v)\,\mathrm{d}s.\tag{5.8}$$

Thanks to Lemma 5.1,

$$(f,v-\Pi_{\mathsf{nc}}\,v)_K=(\boldsymbol{\sigma}_K,\mathbf{grad}\,v)_K+(f-\overline{f}_K,v-\Pi_{\mathsf{nc}}\,v)_K,$$

while properties of the nonconforming interpolation operator mean that

$$\int_\gamma \overline{g}_\gamma(v-\Pi_{\mathsf{nc}}\,v)\,\mathrm{d}s=0,$$

where $\overline{g}_\gamma$ is the (constant) average value of g on an edge $\gamma\subset\Gamma_N$. With the aid of these results, we arrive at the following representation formula for the conforming component of the error:

$$(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,v)=\sum_{K\in\mathcal{P}} R_K(v)\tag{5.9}$$

for all $v\in H^1_E(\Omega)$, where

$$R_K(v)=(\boldsymbol{\sigma}_K,\mathbf{grad}\,v)_K+(f-\overline{f}_K,v-\Pi_{\mathsf{nc}}\,v)_K+\sum_{\gamma\subset\Gamma_N\cap\partial K}\int_\gamma(g-\overline{g}_\gamma)(v-\Pi_{\mathsf{nc}}\,v)\,\mathrm{d}s.$$

The first term is estimated using a Cauchy–Schwarz inequality to obtain

$$(\boldsymbol{\sigma}_K,\mathbf{grad}\,v)_K\le(A^{-1}\boldsymbol{\sigma}_K,\boldsymbol{\sigma}_K)^{1/2}(A\,\mathbf{grad}\,v,\mathbf{grad}\,v)_K^{1/2},$$

while the remaining terms are estimated in terms of the data oscillation (2.9) and (2.10) using (2.3) and (2.8) to derive

$$(f-\overline{f}_K,v-\Pi_{\mathsf{nc}}\,v)_K\le C\lambda_K^{-1/2}\,\mathrm{osc}(f,K)(A\,\mathbf{grad}\,v,\mathbf{grad}\,v)_K^{1/2}$$

and

$$\begin{aligned}&\sum_{\gamma\subset\Gamma_N\cap\partial K}\int_\gamma(g-\overline{g}_\gamma)(v-\Pi_{\mathsf{nc}}\,v)\,\mathrm{d}s\\ &\le C\lambda_K^{-1/2}\,\mathrm{osc}(g,\{\gamma\subset\Gamma_N\cap\partial K\})(A\,\mathbf{grad}\,v,\mathbf{grad}\,v)_K^{1/2}.\end{aligned}$$

By inserting these bounds into (5.9), choosing $v=\phi$, and using a discrete Cauchy–Schwarz inequality, we arrive at the following estimate for the conforming component of the error.

LEMMA 5.2. *Let $\boldsymbol{\sigma}_K$ be defined as in* (5.1)*; then there exists a positive constant C depending only on the element geometry, such that*

$$(A\,\mathbf{grad}\,\phi, \mathbf{grad}\,\phi) \le \sum_{K\in\mathcal{P}} \left\{ (A^{-1}\boldsymbol{\sigma}_K, \boldsymbol{\sigma}_K)^{1/2} + C\lambda_K^{-1/2}\Delta_K \right\}^2, \tag{5.10}$$

where

$$\Delta_K = \operatorname{osc}(f, K) + \operatorname{osc}(g, \{\gamma \subset \Gamma_N \cap \partial K\}) \tag{5.11}$$

measures the local data oscillation over element K.

Remark 1. The estimator for the conforming error derived above may be regarded as the generalization of the equilibrated residual method [2] to nonconforming finite element approximation. Specifically, we define piecewise constant flux functions $g_K \in L_2(\partial K)$ by the rule

$$g_K = \frac{1}{h_\gamma}\left\{(\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}_{\mathsf{nc}}\,\theta_\gamma)_K - (f, \theta_\gamma)_K\right\} \text{ on } \gamma \subset \partial K \backslash \Gamma_N \tag{5.12}$$

with $g_K = g$ on $\gamma \subset \partial K \cap \Gamma_N$. Choosing $v = \theta_\gamma$ in (2.4) shows that $g_K + g_{K'} = 0$ on $\partial K \cap \partial K'$. An elementary computation using properties (2.6) and (5.6) reveals that

$$\begin{aligned}&(f, v - \Pi_{\mathsf{nc}}\, v)_K + \int_{\partial K\cap\Gamma_N} g(v - \Pi_{\mathsf{nc}}\, v)\,\mathrm{d}s \\ &= (f, v)_K + \int_{\partial K} g_K v\,\mathrm{d}s - (A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}\, v)_K \quad \forall v \in H^1_E(K),\end{aligned}$$

where $H^1_E(K) = \{v|_K : v \in H^1_E(\Omega)\}$, and it is trivially seen that both sides vanish whenever v is an affine function. It follows that $\{g_K\}$ is a set of equilibrated fluxes in the sense of [2] and, thanks to (5.8), the conforming error may be decomposed into local contributions,

$$(A\,\mathbf{grad}\,\phi, \mathbf{grad}\, v) = \sum_{K\in\mathcal{P}} \left\{ (f, v)_K + \int_{\partial K} g_K v\,\mathrm{d}s - (A\,\mathbf{grad}_{\mathsf{nc}}\, u_{\mathsf{nc}}, \mathbf{grad}\, v)_K \right\}$$

for all $v \in H^1_E(\Omega)$, which is the starting point for the analysis of the equilibrated residual method.

5.2. Local lower bounds. The next result shows that the estimator suggested by Lemma 5.2 provides a lower bound for the conforming component of the error up to local data oscillation.

LEMMA 5.3. *There exists positive constant c depending only on the element geometry, such that*

$$c(A^{-1}\boldsymbol{\sigma}_K, \boldsymbol{\sigma}_K)_K^{1/2} \le \Upsilon_K^{1/2}(A\,\mathbf{grad}\,\phi, \mathbf{grad}\,\phi)_K^{1/2} + \lambda_K^{-1/2}\operatorname{osc}(f, K). \tag{5.13}$$

Proof. Let $\chi \in H^1_0(K)$ be the cubic (bubble) function whose value is unity at the element centroid. Then, up to constants independent of the element size h_K,

$$\int_K \chi\,\mathrm{d}\boldsymbol{x} \approx h_K^2; \quad \|\chi\|_{L_2(K)} \approx h_K; \quad \|\mathbf{grad}\,\chi\|_{L_2(K)} \approx 1.$$

Thanks to (2.3), the latter estimate implies that $(A\,\mathbf{grad}\,\chi,\mathbf{grad}\,\chi)_K \le C\Lambda_K$. Choosing $v=\chi$ in (5.8) gives

$$(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,\chi)=(f,\chi)_K$$

since $\Pi_{\mathsf{nc}}\,\chi=0$. Equally well, for constant $\overline{f}_K$,

$$\overline{f}_K(1,\chi)_K=(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,\chi)_K-(f-\overline{f}_K,\chi)_K,$$

and so, applying Cauchy–Schwarz inequalities and the properties of χ recorded above, we deduce that

$$\left|\overline{f}_K(1,\chi)_K\right|\le C\left\{\Lambda_K^{1/2}(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,\phi)_K^{1/2}+h_K\left\|f-\overline{f}_K\right\|_{L_2(K)}\right\}.$$

Again exploiting properties of χ, we deduce that, up to constants depending only on the element geometry, $h_K\left\|\overline{f}_K\right\|_{L_2(K)}\approx\left|\overline{f}_K(1,\chi)_K\right|$ and hence

$$h_K\left\|\overline{f}_K\right\|_{L_2(K)}\le C\left\{\Lambda_K^{1/2}(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,\phi)_K^{1/2}+\operatorname{osc}(f,K)\right\}. \tag{5.14}$$

Using (2.3) and (3.5), we deduce that

$$(A^{-1}\boldsymbol{\sigma}_K,\boldsymbol{\sigma}_K)_K\le C\lambda_K^{-1}h_K^2\left\|\overline{f}_K\right\|^2_{L_2(K)},$$

and then, thanks to (5.14), we obtain

$$(A^{-1}\boldsymbol{\sigma}_K,\boldsymbol{\sigma}_K)_K^{1/2}\le C\left\{\Upsilon_K^{1/2}(A\,\mathbf{grad}\,\phi,\mathbf{grad}\,\phi)_K^{1/2}+\lambda_K^{-1/2}\operatorname{osc}(f,K)\right\}$$

as claimed. ∎

6. Estimation of the nonconforming error. We turn to the problem of estimation of the nonconforming component of the total error defined by (3.3). The following result forms the basis for developing upper bounds.

LEMMA 6.1. *Let ψ be defined in* (3.3). *Then*

$$(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi)=\min_{\substack{u^*\in H^1(\Omega):\\ u^*=q\text{ on }\Gamma_D}}(A\,\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}}),\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}})). \tag{6.1}$$

Proof. Let $u^*\in H^1(\Omega)$ satisfy $u^*=q$ on Γ_D. In particular, $u-u^*\in H^1_E(\Omega)$, and hence, applying Green's formula gives for each $w\in\mathcal{H}$,

$$(\mathbf{grad}_{\mathsf{nc}}(u-u^*),\mathbf{curl}\,w)=\int_{\partial\Omega}(u-u^*)\frac{\partial w}{\partial s}\,\mathrm{d}s=0$$

since the first term vanishes on Γ_D, while the second vanishes on Γ_N. Consequently,

$$(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,w)=(\mathbf{grad}_{\mathsf{nc}}\,e,\mathbf{curl}\,w)=(\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}}),\mathbf{curl}\,w).$$

Therefore, choosing $w=\psi$ and applying a Cauchy–Schwarz inequality reveals that

$$(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi)\le(A\,\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}}),\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}})).$$

It remains to show that the lower bound is attained. Let $\phi\in H^1_E(\Omega)$ be defined as in (3.2), and choose u^* to be the function $u-\phi$. Identity (3.1) reveals that

$$A\,\mathbf{grad}_{\mathsf{nc}}(u^*-u_{\mathsf{nc}})=A\,\mathbf{grad}_{\mathsf{nc}}(e-\phi)=\mathbf{curl}\,\psi,$$

which shows the lower bound is attained. ∎

The significance of Lemma 6.1 is, given *any* admissible function u^* in (6.1), we immediately obtain an upper bound on the nonconforming error. The accuracy of the bound will of course depend on the particular choice of function u^*. Equally well, the ease with which the bound may be evaluated will depend on the actual form of the function. Simple choices of u^* are ruled out by the condition on the Dirichlet boundary (except those where the Dirichlet data q is trivial), and it will be worthwhile to relax this restriction (at the expense of introducing an oscillation term for the Dirichlet data). We shall base our choice of u^* on a continuous, piecewise affine function $\mathcal{S}(u_{\mathsf{nc}})$ obtained by postprocessing the nonconforming approximation. The restriction of the function $\mathcal{S}(u_{\mathsf{nc}})$ to the Dirichlet boundary is chosen to be the continuous piecewise linear interpolant q_I of the Dirichlet data q at element vertices on Γ_D.

LEMMA 6.2. *Let $\mathcal{S}(u_{\mathsf{nc}})$ be any piecewise affine function whose restriction to the Dirichlet boundary Γ_D coincides with q_I. Then there exists a constant C depending only on the shape of the elements, such that*

$$\begin{aligned}(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi)^{1/2} &\le (A\,\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}})),\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}})))^{1/2}\\ &\quad + C\Lambda_{\Gamma_D}^{1/2}\operatorname{osc}\left(\partial q/\partial s,\{\gamma:\gamma\subset\Gamma_D\}\right),\end{aligned}\tag{6.2}$$

where $\Lambda_{\Gamma_D}=\max\{\Lambda_K : K$ has an edge on $\Gamma_D\}$.

Proof. First, let $\gamma\subset\partial\mathcal{P}\cap\Gamma_D$ and observe that $q-q_I\in H_{00}^{1/2}(\gamma)$. Moreover, the convexity of the $H_{00}^{1/2}$-norm and standard (one-dimensional) approximation properties of the interpolant reveal that

$$\|q-q_I\|^2_{H_{00}^{1/2}(\gamma)}\le Ch_\gamma\,\|\partial q/\partial s\|^2_{L_2(\gamma)}\,.$$

The same argument applies if we replace q by $q-\alpha s$, where $\alpha\in\mathbb{R}$ is arbitrary and s denotes the arc-length, yielding the estimate

$$\|q-q_I\|_{H_{00}^{1/2}(\gamma)}\le C\operatorname{meas}(\gamma)\inf_{\alpha\in\mathbb{R}}\|\partial q/\partial s-\alpha\|^2_{L_2(\gamma)}=C\operatorname{osc}(\partial q/\partial s,\gamma)^2.\tag{6.3}$$

The function u^* is then chosen to be $u^*=\mathcal{S}(u_{\mathsf{nc}})+\xi$. The function $\xi\in H^1(\Omega)$ is defined elementwise by $\xi_{|K}=q-q_I$ on $\partial K\cap\Gamma_D$, $\xi_{|K}=0$ on $\partial K\backslash\Gamma_D$ and extended onto the domain interior as a harmonic function so that $\|\xi\|_{H^1(K)}\le C\,\|q-q_I\|_{H_{00}^{1/2}(\partial K\cap\Gamma_D)}$. Hence, thanks to (2.3) and (6.3),

$$(A\,\mathbf{grad}\,\xi,\mathbf{grad}\,\xi)^{1/2}\le C\Lambda_K^{1/2}\operatorname{osc}(\partial q/\partial s,\{\gamma:\gamma\subset\Gamma_D\}).$$

Inserting this choice of u^* in Lemma 6.1 and applying the triangle inequality gives the result claimed. ∎

6.1. Local smoothing operator. Given a particular choice of the function $S(u_{\mathsf{nc}})$, Lemma 6.2 shows how to obtain a computable upper bound. The tightness of the bound and the efficiency of the resulting estimator will hinge on the particular construction chosen for S.

The affine function $\mathcal{S}(u_{\mathsf{nc}})$ is uniquely defined by the values at the nodes of the partition given in (3.6). It is clear that S is a linear operator. The next result shows that S is continuous and can be bounded in terms of the choice of weights and the path permeability between elements discussed in section 2.4.

LEMMA 6.3. *Let $n \in \mathcal{N}$ and $K \in \Omega_n$. Then*

$$\begin{aligned}&\left|u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n)\right| \\ &\leq C \begin{cases} \left(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi\right)_{\Omega_n}^{1/2} \sum_{K' \subset \Omega_n} \omega_{K',n} \lambda_{KK'}^{-1/2} & \text{if } \boldsymbol{x}_n \notin \Gamma_D, \\ \lambda_{K\Gamma_D}^{-1/2} \left(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi\right)_{\Omega_n}^{1/2} + \operatorname{osc}(\partial q/\partial s, \{\gamma \in \mathcal{E}_n \cap \Gamma_D\}) & \\ \qquad\qquad \text{if } \boldsymbol{x}_n \in \Gamma_D. \end{cases}\end{aligned}$$

Proof. Case (i): $\boldsymbol{x}_n \notin \Gamma_D$. Inserting definition (3.6) and using property (4.1), we obtain

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n) = \sum_{K' \subset \Omega_n} \omega_{K',n} \left(u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - u_{\mathsf{nc}|K'}(\boldsymbol{x}_n)\right). \tag{6.4}$$

To begin with, we consider the contribution to this quantity arising when an element K' shares a common edge γ with element K.

An elementary computation reveals that

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - u_{\mathsf{nc}|K'}(\boldsymbol{x}_n) = \frac{h_\gamma}{2} \left[\frac{\partial\, u_{\mathsf{nc}}}{\partial s}\right]_\gamma, \quad \gamma = \partial K \cap \partial K'. \tag{6.5}$$

Let β_γ denote the continuous piecewise quadratic function that takes the value $3/4$ at the midpoint of edge γ and vanishes at all remaining nodes and midpoints. The function β_γ is supported on the patch $K \cup K'$. In (3.3), we choose $w \in \mathcal{H}$ to be the difference between β_γ and its (constant) average value over the domain Ω to obtain

$$(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\beta_\gamma)_{K\cup K'} = (\mathbf{grad}_{\mathsf{nc}}\, e, \mathbf{curl}\,\beta_\gamma).$$

Integration by parts allows the right-hand side to be rewritten in the form

$$(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\beta_\gamma)_{K\cup K'} = \int_\gamma \left[\frac{\partial\, u_{\mathsf{nc}}}{\partial s}\right]_\gamma \beta_\gamma \,\mathrm{d}s = \frac{h_\gamma}{2} \left[\frac{\partial\, u_{\mathsf{nc}}}{\partial s}\right]_\gamma,$$

where the fact that the jump is constant on an interior edge has been used. Together with (6.5), this identity implies

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - u_{\mathsf{nc}|K'}(\boldsymbol{x}_n) = (A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\beta_\gamma)_{K\cup K'}. \tag{6.6}$$

This relation is valid for pairs of elements K and K' sharing a common edge γ. More generally, suppose elements K and K' share only a common node $\boldsymbol{x}_n$. The path $\wp^*(K, K')$ appearing in (2.11) links the elements K and K' by a set of elements having a common endpoint at $\boldsymbol{x}_n$. The set of edges shared by these elements is denoted by $\partial\wp^*(K, K')$. Relation (6.6) holds on each edge along the path, and so, by summing (6.6) over edges, we obtain a telescoping sum of differences of u_{nc} across neighboring edges, which simplifies to give

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - u_{\mathsf{nc}|K'}(\boldsymbol{x}_n) = \left(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\beta_{KK'}\right),$$

where $\beta_{KK'} = \sum_{\gamma \in \partial\wp^*(K,K')} \beta_\gamma$. Applying the Cauchy–Schwarz inequality gives the upper bound

$$\begin{aligned}&\left|u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - u_{\mathsf{nc}|K'}(\boldsymbol{x}_n)\right| \\ &\leq \left(A^{-1}\,\mathbf{curl}\,\psi, \mathbf{curl}\,\psi\right)_{\Omega_n}^{1/2} \left(A^{-1}\,\mathbf{curl}\,\beta_{KK'}, \mathbf{curl}\,\beta_{KK'}\right)^{1/2}.\end{aligned} \tag{6.7}$$

The permeability on each element in the path $\wp^*(K, K')$ is bounded below by $\lambda_{KK'}$, implying that

$$\left(A^{-1}\,\mathbf{curl}\;\beta_{KK'}, \mathbf{curl}\;\beta_{KK'}\right) \leq \lambda_{KK'}^{-1}\,\|\mathbf{curl}\;\beta_{KK'}\|^2 \leq C\lambda_{KK'}^{-1},$$

where C depends only on the shape of the elements. Inserting this estimate into (6.7) and recalling (6.4) completes the proof in the first case.

Case (ii). If $\boldsymbol{x}_n \in \Gamma_D$, then $\mathcal{S}(u_{\mathsf{nc}})$ interpolates the Dirichlet data q at the node, so

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n) = u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - q(\boldsymbol{x}_n).$$

First consider the case when element K abuts the Dirichlet boundary Γ_D. It is not difficult to show that

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - q(\boldsymbol{x}_n) = \frac{h_\gamma}{2}\left.\frac{\partial\, u_{\mathsf{nc}}}{\partial s}\right|_\gamma - \left(q(\boldsymbol{x}_n) - q(\boldsymbol{m}_\gamma)\right). \tag{6.8}$$

Let μ_γ denote the average value of $\partial q/\partial s$ on edge γ,

$$\left(A^{-1}\,\mathbf{curl}\;\psi, \mathbf{curl}\;\beta_\gamma\right) = \frac{h_\gamma}{2}\left.\frac{\partial\, u_{\mathsf{nc}}}{\partial s}\right|_\gamma - \int_\gamma \left(\frac{\partial q}{\partial s} - \mu_\gamma\right)\beta_\gamma\,\mathrm{d}s - \frac{1}{2}\left(q(\boldsymbol{x}_n) - q(\boldsymbol{x}_m)\right).$$

Subtracting this from (6.8) gives

$$\begin{aligned} &u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n) \\ &= \left(A^{-1}\,\mathbf{curl}\;\psi, \mathbf{curl}\;\beta_\gamma\right) + \int_\gamma \left(\frac{\partial q}{\partial s} - \mu_\gamma\right)\beta_\gamma\,\mathrm{d}s + q(\boldsymbol{m}_\gamma) - \frac{1}{2}\left(q(\boldsymbol{x}_n) + q(\boldsymbol{x}_m)\right). \end{aligned}$$

Applying the Peano kernel theorem [11], we write

$$q(\boldsymbol{m}_\gamma) - \frac{1}{2}\left(q(\boldsymbol{x}_n) + q(\boldsymbol{x}_m)\right) = \int_\gamma \frac{\partial q}{\partial s} w\,\mathrm{d}s = \int_\gamma \left(\frac{\partial q}{\partial s} - \mu_\gamma\right) w\,\mathrm{d}s,$$

where $w = 1/2$ on $(\boldsymbol{x}_m, \boldsymbol{m}_\gamma)$ and $w = -1/2$ on $(\boldsymbol{m}_\gamma, \boldsymbol{x}_n)$. As a consequence, we obtain

$$u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n) = \left(A^{-1}\,\mathbf{curl}\;\psi, \mathbf{curl}\;\beta_\gamma\right) + \int_\gamma \left(\frac{\partial q}{\partial s} - \mu_\gamma\right)(\beta_\gamma - w)\;\mathrm{d}s.$$

Bounding the second term above by the oscillation of $\partial q/\partial s$ on γ leads to the estimate

$$\begin{aligned} &\left|u_{\mathsf{nc}|K}(\boldsymbol{x}_n) - \mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n)\right| \\ &\leq C\lambda_{K\Gamma_D}^{-1/2}\left(A^{-1}\,\mathbf{curl}\;\psi, \mathbf{curl}\;\psi\right)_{\Omega_n}^{1/2} + C\,\mathrm{osc}(\partial q/\partial s, \gamma). \end{aligned}$$

This proves the result in the case of an element $K \in \Omega_n$ which has an edge γ on Γ_D. The result may be extended to cover a general element $K' \subset \Omega_n$ by connecting to the exterior boundary along the path $\wp^*(K, \Gamma_D)$ and arguing as before. ∎

6.2. Efficiency of the estimator. The next result concerns the efficiency of the estimator when the weights are chosen as in (3.7).

THEOREM 6.4. *Let $\mathcal{S}(u_{\mathsf{nc}})$ denote the postprocessed approximation defined in (3.6). If $K \in \mathcal{P}$ has no vertices belonging to Γ_D, then there exists a positive constant c, independent of any mesh size, such that*

$$\begin{aligned} &c\left(A\,\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}})),\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}}))\right)_K \\ &\leq (A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi)_{\widetilde{K}}\sum_{K'\subset\widetilde{K}}\Upsilon_{KK'}, \end{aligned} \tag{6.9}$$

where $\widetilde{K}$ denotes the patch formed from those elements sharing a common vertex with element K. In the case where K has a vertex $\boldsymbol{x}_n \in \Gamma_D$, then the same estimate holds if the right-hand side is supplemented with the term

$$\Upsilon_{K\Gamma_D}(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi)_{\widetilde{K}}+\operatorname{osc}(\partial q/\partial s,\{\gamma\in\mathcal{E}_n\cap\Gamma_D\})^2, \tag{6.10}$$

where $\mathcal{E}_n$ denotes the set of edges having an endpoint at $\boldsymbol{x}_n$.

Proof. Applying (2.3) and an inverse estimate shows that the left-hand side of (6.9) is bounded above by

$$C\Lambda_K h_K^{-2}\left\|u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}})\right\|^2_{L_2(K)},$$

and then evaluating this integral (using, for instance, the quadrature rule based on edge midpoints which is exact for quadratic functions) gives

$$C\Lambda_K\sum_{\gamma\subset\partial K}\left|u_{\mathsf{nc}}(\boldsymbol{m}_\gamma)-\mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{m}_\gamma)\right|^2.$$

The restriction of $u_{\mathsf{nc}|K}-\mathcal{S}(u_{\mathsf{nc}})$ to an edge $\gamma\subset\partial K$ is a linear function of arc-length, which means that the value at the midpoint $\boldsymbol{m}_\gamma$ is the average of the values at the endpoints of the edge, and therefore

$$\left|u_{\mathsf{nc}}(\boldsymbol{m}_\gamma)-\mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{m}_\gamma)\right|\leq\frac{1}{2}\sum_{\boldsymbol{x}_n\in\gamma}\left|u_{\mathsf{nc}|K}(\boldsymbol{x}_n)-\mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n)\right|.$$

Hence,

$$\begin{aligned} &\left(A\,\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}})),\mathbf{grad}_{\mathsf{nc}}(u_{\mathsf{nc}}-\mathcal{S}(u_{\mathsf{nc}}))\right)_K \\ &\leq C\Lambda_K\sum_{\boldsymbol{x}_n\in K}\left|u_{\mathsf{nc}|K}(\boldsymbol{x}_n)-\mathcal{S}(u_{\mathsf{nc}})(\boldsymbol{x}_n)\right|^2. \end{aligned} \tag{6.11}$$

Suppose that no vertex of K belongs to Γ_D; then the first estimate in Lemma 6.3 gives the following upper bound for (6.11)

$$\sum_{\boldsymbol{x}_n\in K}\left(A^{-1}\,\mathbf{curl}\,\psi,\mathbf{curl}\,\psi\right)_{\Omega_n}\leq\sum_{K'\subset\Omega_n}\frac{\min(\Lambda_K,\Lambda_{K'})}{\lambda_{KK'}},$$

which in turn may be bounded above by the right-hand side of (6.11). If K has a vertex $\boldsymbol{x}_n\in\Gamma_D$, then the second estimate in Lemma 6.3 must be used, which gives rise to the additional term (6.10). ∎

Acknowledgment. It is a pleasure to thank Prof. Dr. Willy Dörfler for his comments on an earlier version of the manuscript.

PERTURBATIONS OF FORMS AND ERROR ESTIMATES FOR THE FINITE ELEMENT METHOD AT A POINT, WITH AN APPLICATION TO IMPROVED SUPERCONVERGENCE ERROR ESTIMATES FOR SUBSPACES THAT ARE SYMMETRIC WITH RESPECT TO A POINT*

ALFRED H. SCHATZ†

Abstract. We first derive a variety of local error estimates for $u - u_h$ at a point x_0, where u_h belongs to a finite element space S_r^h and is an approximation to u satisfying the local equations $A(u - u_h, \varphi) = F(\varphi)$ for all φ in S_r^h with compact support in a neighborhood of x_0. Here the $A(\cdot, \cdot)$ are bilinear forms associated with second order elliptic equations and the F are linear functionals. In the case that $F \equiv 0$ our results coincide with those of Schatz [*SIAM J. Numer. Anal.*, 38 (2000), pp. 1269–1293] but are improvements when $F \neq 0$. We apply these results to improve the superconvergence error estimates obtained by Schatz, Sloan, and Wahlbin [*SIAM J. Numer. Anal.*, 33 (1996), pp. 505–521] at points x_0 where the subspaces are symmetric with respect to x_0.

Key words. finite elements, weighted pointwise estimates, superconvergence, symmetry

DOI. 10.1137/S0036142902408131

1. Introduction, preliminaries, and statement of results. Our aim here is twofold. On the one hand we shall extend part of the results in Schatz [11] on finite element error estimates at a point, in particular those that deal with the perturbations of forms. These will then be applied to improve the results by Schatz, Sloan, and Wahlbin [12] on superconvergence at so-called symmetry points of subspaces.

The paper [11] dealt with two types of interior error estimates at a point for finite element approximations of solutions of second order elliptic problems. Roughly speaking, let $B_d \subset\subset \Omega \subset\subset \mathbb{R}^N$, $N \geq 2$, and let $A(\cdot, \cdot)$ be the usual type of locally defined bilinear form associated with the weak formulation of a second order elliptic problem on B_d (see below for a precise definition). Suppose further that u_h is a finite element approximation to a solution u. The first type of estimates derived in [11] were for $u - u_h$ satisfying, for all φ in an appropriate finite element space on B_d,

$$A(u - u_h, \varphi) = 0. \tag{1.1}$$

We shall be concerned with the second type of estimate, extensions of the first, that deal with $u - u_h$ satisfying a more general equation of the form

$$A(u - u_h, \varphi) = F(\varphi). \tag{1.2}$$

Here $F(\varphi)$ is a linear functional with certain technical properties which will be described in detail below. We remark that $F(\phi)$ may depend on $u - u_h$.

Typically, nonvanishing F arise in a variety of different problems. They often may be identified as perturbation terms of the bilinear form A. This includes some problems that, in the literature, are called "variational crimes" (see, e.g., Brenner and Scott [2]). As an example related to superconvergence, we note that in Nitsche and Schatz [8], they arose in proving superconvergence estimates for difference quotients of $u - u_h$ on translation invariant meshes. In general, for $u - u_h$ satisfying (1.1), difference quotients of $u - u_h$ do not satisfy (1.1) but rather an equation of the form (1.2).

In this paper the application we give is to prove superconvergence at a point with respect to which the mesh is symmetric. As in [12], we shall use the odd and even parts of the error to prove our results. In general the odd and even parts do not satisfy an equation of the form (1.1) but rather an equation of the form (1.2). For additional relevant problems see [2] and [18].

There are a great many papers in the literature devoted to maximum norm estimates on irregular grids. We shall mention a few where additional references may be found. In addition to the papers referred to above, we cite Natterer [6], Scott [16], Nitsche [7], Rannacher and Scott [9], Schatz and Wahlbin [14], and Schatz [10]. The paper most relevant to our work here is [11].

There is an enormous literature on superconvergence. Besides the main reference [12] given above, we mention two monographs devoted to superconvergence, namely, [5] and [18].

In section 1.1 we give some preliminaries for interior estimates, and section 1.2 contains statements of the main results on error estimates at a point with perturbed forms. Theorem 1 is concerned with estimates for the error $u - u_h$, and Theorem 2 deals with first derivatives of the error. Corollaries 1 and 2 are so-called asymptotic expansion inequalities that are useful for our application to superconvergence. These expansions are simple consequences of Theorems 1 and 2. Section 1.3 contains preliminaries for our study of the symmetry theory of superconvergence, and section 1.4 contains statements of the main results. In particular, Theorem 3 is concerned with superconvergence of $u - u_h$, and Theorem 4 deals with superconvergence for first derivatives of $u - u_h$. In section 1.5 we give applications of the estimates to specific boundary value problems.

Section 2 contains a proof of Theorem 1, and a discussion of the proof of Theorem 2 is given in section 2.1. Theorem 3 is proved in section 3, and Theorem 4 is proved in section 4. Finally, the appendix contains the main assumptions on the subspaces.

1.1. Notation and preliminaries. Let Ω be a bounded domain in $\mathbb{R}^N$, $N \geq 1$. For $m \geq 0$ an integer, and $1 \leq p \leq \infty$, $W_p^m(\Omega)$ will denote the usual Sobolev space of functions having distributional derivatives up to order m in L_p. The norm is given for $1 \leq p < \infty$ by

$$\|u\|_{W_p^m(\Omega)} = \left(\sum_{|\alpha| \leq m} \|D^\alpha u\|^p_{L_p(\Omega)} \right)^{1/p}$$

with the usual modification for $p = \infty$. $\mathring{W}_p^m(\Omega)$ is the closure of $C_0^\infty(\Omega)$ with respect to the norm of $W_p^m(\Omega)$. Furthermore, $|u|_{W_p^m(\Omega)}$ will denote the seminorm

$$|u|_{W_p^m(\Omega)} = \left(\sum_{|\alpha| = m} \|D^\alpha u\|^p_{L_p(\Omega)} \right)^{1/p}.$$

For $m > 0$, $W_p^{-m}(\Omega)$ is the dual of $\mathring{W}_q^m(\Omega)$ with the norm

$$\|u\|_{W_p^{-m}(\Omega)} = \sup_{\substack{v \in \mathring{W}_q^m(\Omega) \\ \|v\|_{W_q^m(\Omega)}=1}} \int_\Omega uv dx, \quad \frac{1}{p} + \frac{1}{q} = 1.$$

For given $x_0 \in \mathbb{R}^N$ and $d > 0$, let

$$B_d = B_d(x_0) = \{x \in \mathbb{R}^N : |x - x_0| < d\},$$

the ball of radius d centered at x_0. Suppose now that u satisfies the local equation in $B_d(x_0) \subset\subset \Omega$,

$$Lu = -\sum_{i,j=1}^N \frac{\partial}{\partial x_j}\Big(a_{ij}(x)\frac{\partial u}{\partial x_i}\Big) + \sum_{i=1}^N b_i(x)\frac{\partial u}{\partial x_i} + c(x)u = f \text{ in } B_d(x_0). \tag{1.3}$$

It will be assumed that the coefficients of L are smooth and that L is uniformly elliptic in $\overline{B}_d(x_0)$. That is, there exists a constant $C_{\text{ell}} > 0$, independent of $x \in \overline{B_d(x_0)}$ such that for all $\zeta \in \mathbb{R}^N$

$$C_{\text{ell}}|\zeta|^2 \le \sum_{i,j=1}^N a_{ij}\zeta_i\zeta_j.$$

In weak form, $u \in W_2^1(B_d(x_0))$ satisfies the local equations

$$\begin{aligned} A(u,v) &\equiv \int_{B_d}\left(\sum_{i,j=1}^N a_{ij}\frac{\partial u}{\partial x_i}\,\frac{\partial v}{\partial x_j} + \sum_{i=1}^N b_i\frac{\partial u}{\partial x_i}v + cuv\right)dx \\ &= \int_{B_d} fv dx \equiv (f,v) \text{ for all } v \in \mathring{W}_2^1(B_d(x_0)). \end{aligned} \tag{1.4}$$

Consider now a finite element approximation u_h of u. To this end, for each $0 < h < \frac{1}{2}$ and integer $r \ge 2$, let $S_r^h(\Omega) \subset W_\infty^1(\Omega)$ be a one-parameter family of finite element spaces defined on a disjoint partition $\{\tau_h\}$ of Ω that covers $B_d(x_0)$. It will be assumed that the partition is quasi-uniform of size h. Furthermore, it will be assumed that Assumptions A.1–A.4 of the appendix are satisfied. These are essentially the same assumptions as in [11]. They are satisfied by large classes of finite element spaces, e.g., by conforming piecewise polynomials defined on quasi-uniform partitions of Ω of size h, whose restriction to each disjoint set τ_h of the partition contains all polynomials of degree $\le r-1$. The spaces we use have the standard approximation property that they can approximate functions to order h^r and derivatives to order h^{r-1} in L_∞.

We shall consider approximations $u_h \in S_r^h(B_d)$ satisfying the local equations

$$A(u - u_h, \varphi) = F(\varphi) \text{ for all } \varphi \in \mathring{S}_r^h(B_d), \tag{1.5}$$

where $F(\varphi)$ is a linear functional on $\mathring{S}_r^h(B_d)$. Here $\mathring{S}_r^h(B_d)$ is the subspace of functions $\varphi \in S_r^h(B_d)$, whose support is contained in B_d.

Before stating our first results, we shall need to introduce various weighted Sobolev norms. Let $x_0 \in \mathbb{R}^N$ and $s \in \mathbb{R}$ be fixed and let $y \in \mathbb{R}^N$ be arbitrary. Consider the weight function

$$\sigma_{x_0,h}^s(y) = \Big(\frac{h}{|x_0 - y| + h}\Big)^s \tag{1.6}$$

and, for $p = 1, \infty$ the weighted seminorms

$$|u|_{W_p^j(B_d),x_0,s} = \sum_{|\alpha|=j} \|\sigma_{x_0,h}^s(y) D^\alpha u(y)\|_{L_p(B_d)} \tag{1.7}$$

and the norms

$$\|u\|_{W_p^m(B_d),x_0,s} = \sum_{j=0}^m |u|_{W_p^j(B_d),x_0,s}. \tag{1.8}$$

We shall need some norms for the linear functional F that will allow us to obtain estimates for $(u - u_h)(x_0)$ and $\frac{\partial}{\partial x_i}(u - u_h)(x_0)$. We shall first introduce these norms and then try to motivate their choice, after stating our main results in section 1.2.

We begin with the simplest. For $u \in \mathring{W}_1^1(B_d)$ and $s \in \mathbb{R}$ let

$$\|u\|_{W_1^{0,1}(B_d),x_0,s} = h^{-1}\|u\|_{L_1(B_d),x_0,s+1} + \|\nabla u\|_{L_1(B_d),x_0,s}. \tag{1.9}$$

Then we define the norm of a linear functional bounded with respect to this norm,

$$|||F|||_{W_\infty^{0,-1}(B_d),x_0,s} = \sup_{\substack{\varphi \in \varphi \in \mathring{W}_1^1(B_d) \\ \|\varphi\|_{W_1^{0,1}(B_d),x_0,-s} = 1}} F(\varphi). \tag{1.10}$$

Furthermore, let $\ell > k$ be an arbitrary but fixed integer, where $k = 1, 2$.

For $u \in \mathring{W}_1^\ell(B_d)$, we define the norm

$$\|u\|_{W_j^{0,\ell,k}(B_d),x_0} = \sum_{j=0}^{\ell} \sum_{|\alpha|=j} \Big(\ln \frac{1}{h}\Big)^{\overline{j}} \int_{B_d} (|x - x_0| + h)^{j-k} |D^\alpha u| dx, \tag{1.11}$$

where $\overline{j} = 1$ if $N = 2$, $k = 2$, and $j = 0$ and $\overline{j} = 0$ otherwise. Then we define the norm of a linear functional bounded with respect to this norm,

$$|||F|||_{W_\infty^{0,-\ell,k}(B_d),x_0} = \sup_{\substack{\varphi \in \mathring{W}_1^\ell(B_d) \\ \|\varphi\|_{W_1^{0,\ell,k}(B_d),x_0} = 1}} F(\varphi). \tag{1.12}$$

We are now in a position to state our main results for interior estimates.

1.2. A statement of results for interior error estimates. We begin with error estimates for $(u - u_h)$.

THEOREM 1. *Suppose that the assumptions on the finite element spaces $S_r^h(B_d)$ given in* A.1–A.4 *are satisfied on $B_d(x_0)$. Let $1 \le p \le \infty$, t be a nonnegative integer and $0 \le s \le r - 2$ be given. There exist positive constants C and k, which depend at most on p, t, N, s, C_{ell}, the maximum norms of the coefficients of A and a sufficient number of their derivatives in $\overline{B}_d(x_0)$, and the constants in Assumptions* A.1–A.4, *such that if $u \in W_\infty^1(B_d(x_0))$ and $u_h \in S_r^h(B_d)$ satisfy* (1.5), *where $d \ge kh$, then*

$$\begin{aligned} \|u - u_h\|_{L_\infty(B_h(x_0))} \le{}& Ch\Big(\ln \frac{d}{h}\Big)^{\overline{s}} \min_{\chi \in S_r^h(B_d(x_0))} \|u - \chi\|_{W_\infty^1(B_d(x_0)),x_0,s} \\ &+ Cd^{-t-N/p}\|u - u_h\|_{W_p^{-t}(B_d(x_0))} \\ &+ C\Big(h\Big(\ln \frac{d}{h}\Big)^{\overline{s}} |||F|||_{W_\infty^{0,-1}(B_d(x_0)),x_0,s} \\ &\quad + \Big(\ln \frac{d}{h}\Big)|||F|||_{W_\infty^{0,-r,2}(B_d(x_0)),x_0}\Big). \end{aligned} \tag{1.13}$$

Here $\overline{s} = 0$ if $0 \le s < r - 2$, and $\overline{s} = 1$ if $s = r - 2$.

We again remark that in the case that $F \equiv 0$, Theorem 1 coincides with Theorem 1.1 of [11]. However, in the case that $F \not\equiv 0$, then Theorem 1 is an improvement in that the norms of F are weaker.

The next result is the analogue of Theorem 1 for first derivatives of $u - u_h$.

THEOREM 2. *Suppose that* A.1–A.4, *the assumptions on the finite element spaces* $S_1^h(\infty)$ *given in the appendix, are satisfied on* $B_d(x_0)$. *Let* $1 \le p \le \infty$, t *be a nonnegative integer and* $0 \le s \le r-1$ *be given. There exist positive constants* C *and* k, *which depend at most on* p, t, N, s, C_{ell}, *the maximum norms of the coefficients of* A *and a sufficient number of their derivatives in* $B_d(x_0)$, *and the constants in* A.1–A.4, *such that if* $u \in W_\infty^1(B_d(x_0))$ *and* $u_h \in S_r^h(B_d(x_0))$ *satisfy* (1.5) *with* $d \ge kh$, *then*

$$
\begin{aligned}
&\|u-u_h\|_{W_\infty^1(B_h(x_0))} \\
&\quad \le C\Big(\ln\frac{d}{h}\Big)^{\overline{\overline{s}}} \min_{\chi\in S_r^h(B_d(x_0))} \Big(|u-\chi|_{W_\infty^1(B_d(x_0)),x_0,s} + d^{-1}|u-\chi|_{L_\infty(B_d(x_0)),x_0,s}\Big) \\
&\quad + Cd^{-t-N/p-1}\|u-u_h\|_{W_p^{-t}(B_d(x_0))} \qquad (1.14)\\
&\quad + C\Big(\ln\frac{d}{h}\Big)^{\overline{\overline{s}}} |||F|||_{W_\infty^{0,-1}(B_d(x_0)),x_0,s} \\
&\quad + C\Big(\ln\frac{d}{h}\Big) |||F|||_{W_\infty^{0,-r,1}(B_d(x_0)),x_0}.
\end{aligned}
$$

Here $\overline{\overline{s}} = 0$ *if* $0 \le s < r-1$, *and* $\overline{\overline{s}} = 1$ *if* $s = r-1$.

Analogous to the remark made for Theorem 1, we remark that in the case that $F \equiv 0$, Theorem 2 coincides with Theorem 1.2 of [11], and in the case $F \neq 0$, Theorem 2 is an improvement in that the norms of F are weaker.

Let us digress to motivate the choice of norms for the functional F. We limit ourselves to a discussion of Theorem 1. The choice in Theorem 2 follows in an analogous fashion. In Theorem 1, the contribution to the error $|(u-u_h)(x_0)|$ made by the functional F may be seen in (2.14), in the case $d=1$, to be a term of the form

$$|F(wg_h^{x_0}(x))|.$$

Here $w(x) \in C_0^\infty(B_{1/2}(x_0))$ is a cutoff function, and $g_h^{x_0}(x)$ is the Galerkin approximation to $g^{x_0}(x)$ on $B_1(x_0)$, where $g^{x_0}(x)$ is a smoothed Green's function for a certain auxilliary problem. Using the triangle inequality we have

$$|F(wg_h^{x_0}(x))| \le |F(wg^{x_0}(x))| + |F(w(g^{x_0}(x) - g_h^{x_0}(x))|.$$

The idea now is to treat these two terms separately, requiring F to have different properties in each case.

For the first term on the right we can require that F be bounded when acting on any space in which $g^{x_0}(x)$ is bounded. We shall prove in Lemma 2 that

$$\|g^{x_0}(\cdot)\|_{W_1^{0,r,2}(B_1(x_0)),x_0} \le C\ln\frac{1}{h}.$$

Note that this norm was designed to capture the behavior of the smoothed Green's function and it is natural to bound $F(wg^{x_0}(x))$ by

$$
\begin{aligned}
|F(wg^{x_0}(x))| &\le |||F|||_{W_\infty^{0,-r,2}(B_1(x_0)),x_0} \|wg\|_{W_1^{0,r,2}(B_1(x_0)),x_0} \\
&\le C\ln\frac{1}{h} |||F|||_{W_\infty^{0,-r,2}(B_1(x_0)),x_0}.
\end{aligned}
$$

Similarly for the second term $F(w(g^{x_0}-g_h^{x_0}))$, we seek a norm with respect to which $w(g^{x_0}(x)-g_h^{x_0}(x))$ is bounded. From (2.11) we have that for $0\le s\le r-2$, $g_h^{x_0}(x)$ approximates $g^{x_0}(x)$ according to

$$\|g^{x_0}(x)-g_h^{x_0}(x)\|_{W_1^{0,1}(B_d(x_0)),x_0,-s}\le Ch\Big(\ln\frac{1}{h}\Big)^{\overline{s}}.$$

Using this we easily obtain

$$\begin{aligned}|F(w(g^{x_0}(x)-g_h^{x_0}(x)))|&\le |||F|||_{W_\infty^{0,-1}(B_d(x_0)),x_0,s}\|w(g^{x_0}(x)-g_h^{x_0}(x))\|_{W_1^{0,1}(B_1(x_0)),x_0,-s}\\&\le Ch\Big(\ln\frac{1}{h}\Big)^{\overline{s}}|||F|||_{W_\infty^{0,-1}(B_d(x)),x_0,s}.\end{aligned}$$

We shall now state some simple consequences of Theorems 1 and 2, so-called error expansion inequalities, that will be the basic estimates used in our superconvergence study to be given in section 1.4. We shall need a strengthened form of A.1 that we state here as a separate assumption.

Assumption A.5. Assume that for $p=\infty$ and for $D_1\subset\subset D\subset B_d(x_0)$, with $\operatorname{dist}(D_1,\partial D)\ge k_0h$, the function $\chi\in S_r^h(D)$ in A.1 satisfies

$$\|u-\chi\|_{W_\infty^1(D_1)}\le Ch^{r-1}|u|_{W_\infty^r(D)},\tag{1.15}$$

where $|\cdot|_{W_\infty^r(D)}$ is the seminorm defined in (1.7).

COROLLARY 1. *Suppose that the conditions of Theorem* 1 *hold and in addition Assumption* A.5 *holds. Let $u\in W^\gamma(B_d(x_0))$, where γ is an integer $r+1\le\gamma\le 2r-2$. Let $\widehat{C}>0$ be a fixed but arbitrary constant with $\widehat{C}h\le d$, and let $\widehat{x}$ satisfy $|x_0-\widehat{x}|\le\widehat{C}h$. Then* (1.13) *holds with*

$$Ch\Big(\ln\frac{d}{h}\Big)^{\overline{s}}\min_{\chi\in S_r^h(B_d(x_0))}\|u-\chi\|_{W_\infty^1(B_d(x_0)),x_0,s}\tag{1.16}$$

in (1.14) *replaced by*

$$C\Big(\ln\frac{d}{h}\Big)^{\overline{\gamma}}\bigg(h^r\sum_{|\alpha|=r}|D^\alpha u(\widehat{x})|+\cdots+h^{\gamma-1}\sum_{|\alpha|=\gamma-1}|D^\alpha u(\widehat{x})|+h^\gamma|u|_{W_\infty^\gamma(B_d(x_0))}\bigg).\tag{1.17}$$

Here $\overline{\gamma}=0$ if $r+1\le\gamma<2r-2$ and $\overline{\gamma}=1$ if $\gamma=2r-2$. C is the same as in Theorem 1 *except that it also depends on $\widehat{C}$.*

The corresponding error expansion inequality for first derivatives of the error is as follows.

COROLLARY 2. *Suppose that the conditions of Theorem* 2 *hold and in addition Assumption* A.5 *holds. Let $u\in W_\infty^{\gamma+1}(B_d(x_0))$, where γ is an integer $r\le\gamma\le 2r-2$. Let $\widehat{C}$ be an arbitrary but fixed positive constant with $\widehat{C}h<d$, and let $\widehat{x}$ satisfy $|x_0-\widehat{x}|\le\widehat{C}h$. Then* (1.14) *holds with*

$$C\Big(\ln\frac{d}{h}\Big)^{\overline{\overline{s}}}\min_{\chi\in S_r^h(B_d(x_0))}\big(|u-\chi|_{W_\infty^1(B_d(x_0)),x_0,s}+d^{-1}|u-\chi|_{L_\infty(B_d(x_0)),x_0,s}\big)\tag{1.18}$$

replaced by

$$C\Big(\ln\frac{d}{h}\Big)^{\overline{\overline{\gamma}}}\bigg(h^{r-1}\sum_{|\alpha|=r}|D^\alpha u(\widehat{x})|+\cdots+h^{\gamma-1}\sum_{|\alpha|=\gamma}|D^\alpha u(\widehat{x})|+h^\gamma|u|_{W_\infty^{\gamma+1}(B_d(x_0))}\bigg).\tag{1.19}$$

Here $\overline{\overline{\gamma}} = 0$ *if* $r \le \gamma < 2r-2$ *and* $\overline{\overline{\gamma}} = 1$ *if* $\gamma = 2r-2$. C *is the same as in Theorem* 2 *except that it also depends on* $\widehat{C}$.

1.3. Superconvergence and subspaces symmetric with respect to a point—preliminaries. In [12], a new theory was presented for obtaining superconvergence. Assuming now that $u - u_h$ satisfies

$$A(u-u_h,\varphi) = 0 \quad \text{for all} \quad \varphi \in \mathring{S}_r^h(B_d(x_0)), \tag{1.20}$$

superconvergence at a point x_0 was achieved by requiring the subspaces to be symmetric with respect to x_0 in $B_d(x_0)$, which is defined as follows.

Assumption A.6. Let x_0 and $d > 0$ be given with $B_d(x_0) \subset\subset \Omega$. Assume that whenever $\varphi(x) \in S_r^h(B_d(x_0))$, then $\overline{\varphi}(x) = \varphi(x_0 - (x - x_0))$ also belongs to $S_r^h(B_d(x_0))$. In this case we shall call x_0 a symmetry point of $S_r^h(B_d(x_0))$.

Let us now turn to some simple examples of finite element spaces that satisfy Assumptions A.1–A.6. Let $\{\tau_h\}$ be a quasi-uniform partition of size h of Ω (which obviously covers $B_d(x_0)$). For our finite element spaces $S_r^h(B_d(x_0))$, we shall start with the set of functions that are in $C^\ell(B_d(x_0))$ for some integer $0 \le \ell \le r-2$ and that, on each element τ_h, are polynomials of the form

$$\varphi(x) = \sum_{\alpha \in I} C_\alpha x^\alpha, \ C_\alpha \text{ arbitrary constants.} \tag{1.21}$$

Here, I is a fixed set of multi-indices. Many well-known finite element spaces fitting this description satisfy Assumptions A.1–A.5. It is easy to see that A.6 is satisfied if and only if

(i) the partition $\{\tau_h\}$ is invariant under the antipodal mapping $x \to x_0 - (x - x_0)$, and

(ii) functions of the form (1.21) are invariant in form under the same antipodal mapping $x \to x_0 - (x - x_0)$.

We refer the reader to the examples of partitions $\{\tau_h\}$ satisfying (i) that are given in [12], and granting these we only have to check (ii). If $\alpha \in I$, $\alpha = (\alpha_1, \dots, \alpha_N)$, a multi-index, then x^α transforms to $(2x_0 - x)^\alpha$, and it is easy to see via a binomial expansion that $\alpha \in I$, if and only if $\beta \in I$ for every multi-index $\beta \le \alpha$. This is a necessary and sufficient condition that functions of the form (1.21), defined on partitions satisfying (i), satisfy A.6. A simple example is $P_{r-1}(\tau_h)$, the set of polynomials of degree $\le r-1$. In this case $\alpha \in I$, if and only if $|\alpha| \le r-1$. Another simple example is $Q_{r-1}(\tau_h)$, the tensor products of one-dimensional polynomials of degree $r-1$. In this case $\alpha \in I$ if and only if $\alpha_i \le r-1$ for $i = 1, \dots, N$.

1.4. Statement of results for superconvergence at symmetry points. We are now in a position to state our main superconvergence results. Applications to specific boundary value problems are given in section 1.5. We begin with estimates for the error $(u - u_h)(x_0)$ at a symmetry point x_0.

THEOREM 3. *Suppose that the conditions of Corollary* 1 *hold and in addition* A.6 *is satisfied. Then if* $r \ge 3$ *is odd,*

$$|(u-u_h)(x_0)| \le C\Big[h^{r+1}\Big(\ln\frac{d}{h}\Big)^2 \|u\|_{W_\infty^{r+1}(B_d(x_0))} + \Big(\ln\frac{d}{h}\Big) d^{-t-N/p} \|e\|_{W_p^{-t}(B_d(x_0))}\Big]. \tag{1.22}$$

Remark. We point out that the first term on the right side of (1.22) is superconvergent of order $h^{r+1}(\ln \frac{d}{h})^2$ and hence superconvergence of the same order will occur

at x_0 provided a similar bound holds for the second term on the right which measures the effects of the discretization error from outside of $B_d(x_0)$. As is customary, this can be determined separately for each particular global problem. Examples are given in the next section.

Our next result involves superconvergent approximations to first derivatives at symmetry points x_0. As noted in [12], u_h may not be differentiable at x_0, in which case our result will give many possible approximations to $\frac{\partial u}{\partial x_i}(x_0)$ given by $\frac{\partial \widehat{u}_h(x_0,\beta)}{\partial x_i}$, where β is any unit vector such that for $0 \le s \le s_0$ sufficiently small, $\frac{\partial u_h}{\partial x_i}$ has both left- and right-hand limits as $s \to 0$ along the line $x = x_0 + s\beta$. We then define

$$\frac{\partial \widehat{u}_h}{\partial x_i}(x_0,\beta) = \frac{1}{2}\lim_{s\to 0}\Big(\frac{\partial u_h(x_0+s\beta)}{\partial x_i} + \frac{\partial u_h(x-s\beta)}{\partial x_i}\Big).$$

Our result is then as follows.

THEOREM 4. *Suppose that the conditions of Corollary* 2 *hold and in addition* A.6 *is satisfied. Then if* $r \ge 2$ *is even and* $i = 1, \dots, N$,

$$\begin{aligned}&\Big|\frac{\partial u}{\partial x_i}(x_0) - \frac{\partial \widehat{u}(x_0,\beta)}{\partial x_i}\Big| \\ &\quad \le C\Big(h^r\Big(\ln\frac{d}{h}\Big)^2\|u\|_{W_\infty^{r+1}(B_{d(x_0)})} + \ln\Big(\frac{d}{h}\Big)d^{-1-t-N/p}\|e\|_{W_p^{-t}(B_{d(x_0)})}\Big).\end{aligned} \tag{1.23}$$

Remark. The first term on the right side of (1.23) is superconvergent of order $h^r(\ln\frac{d}{h})^2$, and we now give specific examples in which the second term on the right also exhibits superconvergent behavior.

1.5. Examples: Applications to specific boundary value problems. In this section we apply our results to the finite element method for approximating the solutions of various boundary value problems. For simplicity we restrict ourselves to the examples treated in section 3 of [12]. The superconvergence results given below are all significant improvements of those given there. Our boundary value problems will be of the form

$$Lu = -\sum_{i,j=1}^{N}\frac{\partial}{\partial x_j}\Big(a_{ij}(x)\frac{\partial u}{\partial x_i}\Big) + \sum_{i=1}^{N} b_i(x)\frac{\partial u}{\partial x_i} + c(x)u = f \text{ in } \Omega \tag{1.24}$$

with some boundary condition on $\partial\Omega$.

It will be assumed that the coefficients of L are smooth and satisfy a uniform ellipticity conditon on Ω.

Example 1. Let the form (1.4) be defined on all of Ω and coercive on $W_2^1(\Omega)$ so that it corresponds to a problem with homogeneous conormal derivative boundary conditions. Suppose that $\partial\Omega$ is smooth and that the triangulations fit the boundary exactly. Furthermore, suppose that the subspaces have the property that for any $1 \le q \le \infty$,

$$\min_{\chi\in S_r^h(\Omega)}\|u-\chi\|_{W_q^1(\Omega)} \le Ch^{r-1}\|u\|_{W_q^r(\Omega)}. \tag{1.25}$$

We investigate the standard finite element method

$$A(u-u_h,\varphi) = 0 \text{ for all } \varphi \in S_r^h(\Omega). \tag{1.26}$$

It is well known (see, for example, [12, Example 3.1]) that

$$\|e\|_{W_\infty^{2-r}(\Omega)} \le Ch^{2r-2}\Big(\ln\frac{1}{h}\Big)\|u\|_{W_\infty^r(\Omega)}. \tag{1.27}$$

Applying (1.29) to Theorem 3, we obtain at symmetry points x_0 that if $r \ge 3$ is odd and u is sufficiently smooth, then

$$\begin{aligned} |e(x_0)| &\le C(u)\Big(\ln\frac{1}{h}\Big)^2(h^{r+1} + d^{2-r}h^{2r-2}) \\ &\le C(u)\Big(\ln\frac{1}{h}\Big)^2 h^{r+1} \text{ for } d \ge h^{1-\frac{1}{r-2}} \quad (r \ge 3 \text{ odd}). \end{aligned} \tag{1.28}$$

Thus if we disregard logarithmic factors we have superconvergence of one order higher than the global optimal rate, provided the subspace satisfies the symmetry condition in an $0\big(h^{1-\frac{1}{r-2}}\big)$ neighborhood of x_0.

The corresponding result for first derivatives is for $r \ge 2$ and even. In this case it follows from (1.27) and (1.23) that

$$\begin{aligned} &\Big|\frac{\partial u}{\partial x_i}(x_0) - \frac{\partial \widehat{u}_h(x_0,\beta)}{\partial x_i}\Big| \\ &\qquad \le C(u)\Big(\ln\frac{1}{h}\Big)^2(h^r + d^{1-r}h^{2r-2}) \\ &\qquad \le C(u)\Big(\ln\frac{1}{h}\Big)^2(h^r) \quad \text{for} \quad d \ge h^{1-\frac{1}{r-1}} \quad (r \ge 2, \text{ even}). \end{aligned} \tag{1.29}$$

We also note that a superconvergence rate of order $h^{r+\varepsilon}$ for $e(x_0)$ can be achieved with $d \ge h^{1-\frac{\varepsilon}{r-2}}$, and a superconvergence rate of order $h^{r-1+\varepsilon}$ for first derivatives can be achieved with $d \ge h^{1-\frac{\varepsilon}{r-1}}$. This indicates that we can obtain superconvergence fairly close to boundaries.

Example 2 (Dirichlet's problem on smooth domains in $\mathbb{R}^N$). Here we consider homogeneous Dirichlet boundary conditions $u = 0$ on $\partial\Omega$. For our finite element spaces we take isoparametric elements defined on a mesh that approximates the boundary to order h^r and that vanish on the approximate boundary. For u sufficiently smooth it was proved in Schatz and Wahlbin [15] that

$$\|e\|_{L_\infty(\Omega)} \le Ch^r\Big(\ln\frac{1}{h}\Big)^{\overline{r}}. \tag{1.30}$$

Applying this to (1.23) we obtain for the derivatives

$$\begin{aligned} \Big|\frac{\partial u(x_0)}{\partial x_i} - \frac{\partial \widehat{u}_h(x_0,\beta)}{\partial x_i}\Big| &\le C\Big(\ln\frac{1}{h}\Big)^2\big(h^r\|u\|_{W_\infty^{r+1}(B_{d(x_0)})} + h^r d^{-1}\big) \\ &\le C\Big(\ln\frac{1}{h}\Big)^2 h^r \end{aligned} \tag{1.31}$$

for $r \ge 2$ even and $d = 0(1)$.

Results analogous to (1.28) and (1.29) would hold if (1.27) were satisfied. This can be accomplished, for example, by using superparametric elements that approximate the boundary to order h^{2r-2}.

Example 3 (Dirichlet problems on smooth plane domains). Scott [16], [17] treated Dirichlet problems on plane smooth domains in a special way so that

$$\|e\|_{W_2^{2-r}(\Omega)} \le Ch^{2r-2}. \tag{1.32}$$

In this case it is easily seen that the superconvergence estimate (1.28) holds this time with $d \ge Ch^{\frac{r-3}{r-1}}$. Furthermore, (1.29) holds with $d \ge Ch^{\frac{r-2}{r}}$.

Example 4 (Dirichlet problems on plane polygonal domains). Consider the problem

$$-\Delta u = f \text{ in } \Omega,\ u = 0 \text{ on } \partial\Omega,$$

where Ω is a plane polygonal domain. The behavior of solutions for f sufficiently smooth is well known (see, for example, Grisvard [3, Theorem 5.1.3.5]), and using suitable mesh refinements if necessary [1], we can assume that

$$\min_{\chi \in S_r^h(\Omega)} \|u - \chi\|_{W_2^1(\Omega)} \le Ch^{r-1}\|f\|_{W_2^{r-2}(\Omega)}.$$

A standard duality argument gives that (1.32) holds.

Then for $B_d(x) \subset\subset \Omega$ on which the meshes are not refined and for which Corollaries 1 and 2 hold, the same results as for Example 3 hold.

2. A proof of Theorem 1. The proof of Theorem 1 is quite lengthy. Parts of it have a great deal in common with the proof of Theorem 1.1 of [11]. We give an outline of the common parts and details on what is new. We shall simplify by considering only the case $d = 1$. The case $d < 1$ follows from this by a scaling argument. Without loss of generality we may assume that A is coercive on $W_2^1(B_1)$. The case of noncoercive A can be easily reduced to this case (see, e.g., [11]) Furthermore, the proof may be reduced in a now-standard way to estimates for an auxilliary Neumann problem with homogeneous conormal derivative boundary conditions as follows. Let $w(x) \in C_0^\infty(\mathbb{R}^N)$ be a cutoff function with $0 \le w(x) \le 1$, $w(x) \equiv 1$ for $|x - x_0| \le .25$, and $w(x) \equiv 0$ for $|x - x_0| \ge .5$. Set $\widehat{u} = wu$ and let $(\widehat{u})_h$ be the finite element approximation of $\widehat{u}$ defined by

$$A(\widehat{u} - (\widehat{u})_h, \varphi) = F(w\varphi) \quad \text{for all} \quad \varphi \in S_r^h(B_1). \tag{2.1}$$

Using the triangle inequality,

$$\|u - u_h\|_{L_\infty(B_h)} \le \|\widehat{u} - (\widehat{u})_h\|_{L_\infty(B_h)} + \|(\widehat{u})_h - u_h\|_{L_\infty(B_h)}. \tag{2.2}$$

The remainder of this section is devoted to proving the following lemma, from which (1.13) follows.

LEMMA 1. *With u, u_h, $\widehat{u}$, and $(\widehat{u})$ defined above,*

$$\begin{aligned}\|\widehat{u} - (\widehat{u})_h\|_{L_\infty(B_h)} \le C\Big(&h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}\|\widehat{u}\|_{W_\infty^1(B_1),x_0,s} \\ &+ h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}|||F|||_{W_\infty^{0,-1}(B_1),x_0,s} \\ &+ \Big(\ln\frac{1}{h}\Big)|||F|||_{W_\infty^{0,-r,2}(B_1),x_0}\Big)\end{aligned} \tag{2.3}$$

and

$$\|(\widehat{u})_h - u_h\|_{L_\infty(B_h)} \le C\Big(h\|\widehat{u}\|_{W^1_\infty(B_1),x_0,s} + \|u-u_h\|_{W_p^{-t}(B_1)} + h|||F|||_{W^{0,-1}_\infty(B_1),x_0,s} + |||F|||_{W^{0,-r,2}_\infty(B_1),x_0}\Big). \tag{2.4}$$

Before proceeding with a proof of this lemma, let us show how Theorem 1 follows. Since

$$\|\widehat{u}\|_{W^1_\infty(B_1),x_0,s} \le C\|u\|_{W^1_\infty(B_1)x_0,s},$$

from (2.3), (2.4), and (2.2), we have that

$$\|u-u_h\|_{L_\infty(B_h)} \le C\Big(h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}\|u\|_{W^1_\infty(B_1),x_0,s} + \|u-u_h\|_{W_p^{-t}(B_1)} + h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}|||F|||_{W^{0,-1}_\infty(B_1),x_0,s} + \Big(\ln\frac{1}{h}\Big)|||F|||_{W^{0,-r,2}_\infty(B_1),x_0}\Big). \tag{2.5}$$

The inequality (1.14) follows easily on applying (2.5) to $u-u_h \equiv u-\chi-(u_h-\chi)$ for any $\chi \in S^h_r(B_1)$.

We first prove the estimate (2.3). For this purpose let k be a fixed positive integer, and let $\psi \in \mathring{W}_2^{r-2}(B_{kh})$ with $\|\psi\|_{W_2^{r-2}(B_{kh})} = 1$. Define $g^{x_0}(y)$ as the unique solution of

$$A(v, g^{x_0}) = (v, h^{-N/2+2-r}\psi) \quad \text{for all} \quad v \in W^1_2(B_1(x_0)). \tag{2.6}$$

Note that $g^{x_0}(y) \in W^r_2(B_1)$ and $h^{-N/2+2-r}\|\psi\|_{L_1(B_{kh})} \le C$, so that g^{x_0} may be thought of as a smoothed and renormalized Green's function, in general smoother than that defined in [11]. Furthermore, let $g^{x_0}_h \in S^h_r(B_1)$ be its finite element approximation defined by

$$A(\varphi, g^{x_0} - g^{x_0}_h) = 0 \quad \text{for all} \quad \varphi \in S^h_r(B_1). \tag{2.7}$$

The following estimates play a critical role in our new results.

LEMMA 2. *For g^{x_0} and $g^{x_0}_h$ as defined above,*

$$\|g^{x_0}\|_{W^j_2(B_1)} \le Ch^{-N/2-j+2} \quad \textit{for} \quad j = 2, \dots, r \tag{2.8}$$

and

$$\|g^{x_0}\|_{W^{0,r,2}_1(B_1),x_0} \le C\ln\frac{1}{h}. \tag{2.9}$$

Furthermore,

$$\|g^{x_0} - g^{x_0}_h\|_{W^1_1(B_1),x_0,-s} \le Ch\Big(\ln\frac{1}{h}\Big)^{\overline{s}} \tag{2.10}$$

and

$$\|g^{x_0} - g^{x_0}_h\|_{W^{0,1}_1(B_{.5}),x_0,-s} \le Ch\Big(\ln\frac{1}{h}\Big)^{\overline{s}}, \tag{2.11}$$

where the constants C are independent of ψ.

Let us first show how, using this, one may estimate $\|\widehat{u} - (\widehat{u})_h\|_{L_\infty(B_h)}$ in (2.2). Letting $\widehat{e} = \widehat{u} - (\widehat{u})_h$ and using standard inverse properties of $S_r^h(B_1)$, we have for any $\chi \in S_r^h(B_1)$ that there is a $k > 0$, sufficiently large but fixed, such that

$$\|\widehat{e}\|_{L_\infty(B_h)} \le C\|\widehat{u} - \chi\|_{L_\infty(B_{kh})} + Ch^{-N/2+2-r}\|\widehat{e}\|_{W_2^{2-r}(B_{kh})}. \tag{2.12}$$

Then by duality,

$$h^{-N/2+2-r}\|\widehat{e}\|_{W_2^{2-r}(B_{kh})} = \sup_{\substack{\psi \in \mathring{W}_2^{r-2}(B_{kh}) \\ \|\psi\|_{W_2^{r-2}(B_{kh})}=1}} (\widehat{e}, h^{-N/2+2-r}\psi). \tag{2.13}$$

Now for each such ψ, we have in view of (2.1) and (2.7) that

$$\begin{aligned}(\widehat{e}, h^{-N/2+2-r}\psi) &= A(\widehat{e}, g^{x_0}) = A(\widehat{e}, g^{x_0} - g_h^{x_0}) + F(wg_h^{x_0}) \\ &= A(\widehat{u} - \chi, g^{x_0} - g_h^{x_0}) + F(w(g_h^{x_0} - g^{x_0})) + F(wg^{x_0}).\end{aligned} \tag{2.14}$$

Combining (2.12), (2.13), and (2.14) with Lemma 2 we arrive at

$$\begin{aligned}\|\widehat{e}\|_{L_\infty(B_h)} &\le C\Big(\|\widehat{u} - \chi\|_{L_\infty(B_{kh})} + \|\widehat{u} - \chi\|_{W_\infty^1(B_1),x_0,s}\|g^{x_0} - g_h^{x_0}\|_{W_1^1(B_1),x_0,-s} \\ &\quad + |||F|||_{W_\infty^{0,-1}(B_{.5}),x_0,s}\|g^{x_0} - g_h^{x_0}\|_{W_1^{0,1}(B_{.5}),x_0,-s} \\ &\quad + |||F|||_{W_\infty^{0,-r,2}(B_1),x_0}\|g^{x_0}\|_{W_1^{0,r,2}(B_1),x_0}\Big) \\ &\le C\Big(h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}\|\widehat{u}\|_{W_\infty^1(B_1),x_0,s} + h\Big(\ln\frac{1}{h}\Big)^{\overline{s}}|||F|||_{W_\infty^{0,-1}(B_1),x_0,s} \\ &\quad + \Big(\ln\frac{1}{h}\Big)|||F|||_{W_\infty^{0,-r,2}(B_1),x_0}\Big),\end{aligned}$$

which completes the proof of (2.3), once we have proved Lemma 2.

Proof of Lemma 2. The inequality (2.8) follows from a standard a priori estimate and Poincaré's inequality. In fact, for $j = 2, \dots, r$,

$$\|g^{x_0}\|_{W_2^j(B_1)} \le Ch^{-N/2+2-r}\|\psi\|_{W_2^{j-2}(B_{kh})} \le Ch^{-N/2-j}\|\psi\|_{W_2^{r-2}(B_{kh})}.$$

We prove (2.9) in three steps. Set

$$M_\alpha = \int_{B_1} (|x - x_0| + h)^{j-2}|D^\alpha g^{x_0}|dx, \quad |\alpha| = j.$$

Step 1. We begin by estimating M_α for $j = 2, \dots, r$:

$$\begin{aligned}M_\alpha &\le \int_{B_{2kh}} (|x - x_0| + h)^{j-2}|D^\alpha g^{x_0}|dx + \sum_{j=0}^{J}\int_{\Omega_\ell} (|x - x_0| + h)^{j-2}|D^\alpha g^{x_0}|dx \\ &= I_{in} + \sum_{\ell=0}^{J} I_\ell.\end{aligned} \tag{2.15}$$

Here for $\ell = 0, \dots, J = [\ln_2 \frac{1}{kh}] + 1$, Ω_ℓ is the annulus

$$\Omega_\ell = \{x : 2^{\ell-1} \le |x - x_0| \le 2^{-\ell}\}.$$

Now using (2.8),

$$|I_{in}| \le Ch^{j-2+N/2} \|g^{x_0}\|_{W_2^j(B_1)} \le C. \tag{2.16}$$

Furthermore, for any $\ell = 0, \dots, J$ and any $j = 2, \dots, r$, and $d_\ell = 2^{-\ell}$,

$$|I_\ell| \le Cd_\ell^{j+N} \|D_x^\alpha g^{x_0}\|_{L_\infty(\Omega_\ell)}. \tag{2.17}$$

Now let $G^x(y)$ be the Green's function for the auxilliary Neumann problem. It follows that since $x \in \Omega_\ell$ and $\Omega_\ell \cap B_{kh} = \phi$, then

$$D_x^\alpha g^{x_0}(x) = h^{-N/2+2-r} \int_{B_{kh}} \psi(y) D_x^\alpha G^x(y) dy.$$

By an estimate of Krasovskii [4] we have for $N \ge 2$,

$$|D_x^\alpha D_y^\beta G^x(y)| \le C \begin{cases} \left(\ln \dfrac{1}{|x-y|}\right) + 1 & \text{if } N = 2 \text{ and } |\alpha| + |\beta| = 0, \\ \dfrac{1}{|x-y|^{N-2+|\alpha|+|\beta|}} & \text{otherwise.} \end{cases} \tag{2.18}$$

Thus for $|\alpha| = j \ge 2$

$$\|D_x^\alpha G^x(y)\|_{L_\infty(\Omega_\ell)} \le \frac{C}{d_\ell^{N-2+j}}, \ x \in \Omega_\ell, \quad y \in B_{kh}.$$

Hence it follows from this that

$$\|D_x^\alpha g^{x_0}\|_{L_\infty(\Omega_\ell)} \le h^{-N/2+2-r} \|\psi\|_{L_1(B_{kh})} d_\ell^{-N-j+2} \le Cd_\ell^{-N-j+2},$$

where we used the Cauchy–Schwarz and Poincaré inequalities. Combining this last inequality with (2.17) we arrive at

$$|I_\ell| \le C. \tag{2.19}$$

Summing (2.19) over ℓ and adding the result to (2.16) we finally obtain from (2.15) that for any $|\alpha| = j$ and $j = 2, \dots, r$,

$$M_\alpha \le C \ln \frac{1}{h}, \tag{2.20}$$

which completes Step 1.

Step 2. We estimate M_α for $j = 1$ and $N \ge 2$, or $j = 0$ and $N \ge 3$. In this case

$$\begin{aligned} M_\alpha &\le h^{-N/2+2-r} \int_{B_1} (|x - x_0| + h)^{j-2} \left(\int_{B_{kh}} |\psi(y)| \ |D^\alpha G^x(y)| dy \right) dx \\ &\le h^{-N/2+2-r} \int_{B_{kh}} |\psi(y)| \left(\int_{B_1} (|x - x_0| + h)^{j-2} |D^\alpha G^x(y)| dx \right) dy, \end{aligned}$$

where we interchanged orders of integration. Setting $\rho = |x-y|$ and $\sigma = |x-x_0|$ it follows that

$$M_\alpha \le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_0^{3/2}(\sigma+h)^{j-2}\rho^{1-j}d\rho\Big)dy,$$

where we used (2.18). Now let $j=1$; then

$$\begin{aligned} M_\alpha &\le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_0^{2}(\sigma+h)^{-1}d\sigma\Big) \\ &\le Ch^{-N/2+2-r}\ln\frac{1}{h}\|\psi\|_{L_1(B_{kh})} \le C\ln\frac{1}{h}. \end{aligned} \tag{2.21}$$

In the case that $j=0$ and $N\ge 3$, it follows from (2.18) that

$$\begin{aligned} M_\alpha &\le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_0^{3/2}\frac{\rho}{(\sigma+h)^2}d\rho\Big)dy \\ &\le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_0^{2}(\sigma+h)^{-1}d\sigma\Big)dy \\ &\le C\ln\frac{1}{h}, \end{aligned} \tag{2.22}$$

where we used $\rho \le \sigma + 2kh \le 2k(\sigma+h)$. This completes Step 2.

Step 3. $j=0$ and $N=2$. Again using (2.18) we have

(2.23)

$$\begin{aligned} M_\alpha &\le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_{B_1}\frac{\big(\ln\frac{1}{|x-y|}+1\big)}{(|x-x_0|+h)^2}\,dx\Big)dy \\ &\le Ch^{-N/2+2-r}\int_{B_{kh}} |\psi(y)|\Big(\int_0^{h}\frac{\rho\big(\ln\frac{1}{\rho}+1\big)}{(\sigma+h)^2}d\rho + \int_h^{1.5}\frac{\rho\big(\ln\frac{1}{\rho}+1\big)}{(\sigma+h)^2}d\rho\Big)dy. \end{aligned}$$

Furthermore,

$$\int_0^h \frac{\rho\big(\ln\frac{1}{\rho}+1\big)}{(\sigma+h)^2}d\rho \le \frac{1}{h^2}\int_0^h \rho\Big(\ln\frac{1}{\rho}+1\Big)d\rho \le C\ln\frac{1}{h}, \tag{2.24}$$

which is obtained by integrating the last integral by parts. Again, since $\rho \le 2k(\sigma+h)$,

$$\int_h^{1.5}\frac{\rho\big(\ln\frac{1}{\rho}+1\big)}{(\sigma+h)^2}d\rho \le C\Big(\ln\frac{1}{h}\Big)\int_0^2(\sigma+h)^{-1}d\sigma \le C\Big(\ln\frac{1}{h}\Big)^2. \tag{2.25}$$

Substituting (2.24) and (2.25) into (2.23) we obtain for $j=0$ and $N=2$,

$$M_\alpha \le C\Big(\ln\frac{1}{h}\Big)^2 \text{ for } |\alpha| = j = 0 \text{ and } N=2, \tag{2.26}$$

which completes Step 3. The inequality (2.9) now easily follows from (2.20), (2.21), (2.22), and (2.26).

We next note that the inequality (2.10) was proved in Lemma 2.7 of [11] for a less smoothed Green's function than that treated here. The proof given there yields the result (2.10). This completes the proof of Lemma 2.

Remark. The extra smoothness of the smoothed Green's function constructed here was used in the inequalities (2.8) and (2.9) and could be used to estimate higher derivatives of the error in (2.11).

We now turn to the proof of (2.4). To begin with, notice that $(\widehat{u})_h - u_h$, where $\widehat{u} = wu$, is discrete "A harmonic" on $B_{.25}$; i.e., it satisfies

$$A((\widehat{u})_h - u_h, \varphi) = 0 \quad \text{for all} \quad \varphi \in \mathring{S}_r^h(B_{.25}). \tag{2.27}$$

It was proved in [13] (see also [11]) that

$$\begin{aligned} \|(\widehat{u})_h - u_h\|_{L_\infty(B_h)} &\le C\|(\widehat{u})_h - u_h\|_{W_{p'}^{-t'}(B_{.25})} \\ &\le C\Big(\|u - u_h\|_{W_{p'}^{-t'}(B_1)} + \|\widehat{u} - (\widehat{u})_h\|_{W_{p'}^{-t'}(B_1)}\Big), \end{aligned} \tag{2.28}$$

where $t' \ge 0$ and $1 \le p' \le \infty$ are arbitrary. Now t' may be chosen so large and $p' = 1$, so that for arbitrary $t \ge 0$ and $1 \le p \le \infty$ (2.28) becomes

$$\|(\widehat{u})_h - u_h\|_{L_\infty(B_h)} \le C\Big(\|u - u_h\|_{W_p^{-t}(B_1)} + \|\widehat{u} - (\widehat{u})_h\|_{W_2^{-\lambda}(B_1)}\Big), \tag{2.29}$$

where $\lambda = \max(r-2, [N/2])$ and $[N/2]$ denotes the integer part of $N/2$. The proof of (2.4), and hence of Theorem 1, is complete once we have shown that

$$\begin{aligned} &\|\,\widehat{u} - (\widehat{u})_h\|_{W_2^{-\lambda}(B_1)} \\ &\quad \le C\Big(h\|\widehat{u}\|_{W_\infty^1(B_1),x_0,s} + h|||F|||_{W_\infty^{0,-1}(B_1),x_0,s} + \ln\frac{1}{h}|||F|||_{W_\infty^{0,-r,2}(B_1),x_0}\Big). \end{aligned} \tag{2.30}$$

The proof of this follows by a standard duality argument that we shall just outline.

$$\|\widehat{e}\|_{W_2^{-\lambda}(B_1)} = \sup_{\substack{\eta \in \mathring{W}_2^{\lambda}(B_1) \\ \|\eta\|_{W_2^{\lambda}(B_1)} = 1}} (\widehat{e}, \eta). \tag{2.31}$$

For each such η let $z \in W_2^r(B_1)$ satisfy

$$A(v, z) = (v, \eta) \quad \text{for all} \quad v \in W_2^1(B_1) \tag{2.32}$$

and let $z_h \in S_r^h(B_1)$ satisfy

$$A(\varphi, z - z_h) = 0 \quad \text{for all} \quad \varphi \in S_r^h(B_1). \tag{2.33}$$

Then

$$\begin{aligned} (\widehat{e}, \eta) = A(\widehat{e}, z) &= A(\widehat{e}, z - z_h) + F(wz_h) \\ &= A(\widehat{u}, z - z_h) + F(w(z_h - z)) + F(wz). \end{aligned}$$

This together with (2.31) yields

$$\begin{aligned} \|\widehat{e}\|_{W_2^{-\lambda}(B_1)} \le C\ \Big(&\|\widehat{u}\|_{W_\infty^1(B_1),x_0,s}\|z - z_h\|_{W_1^1(B_1),x_0,-s} \\ &+ |||F|||_{W_\infty^{0,-1}(B_{.5}),x_0,s}\|z - z_h\|_{W_1^{0,1}(B_{.5}),x_0,s} \\ &+ |||F|||_{W_\infty^{0,-r,2}(B_{.5}),x_0}\|z\|_{W_1^{0,r,2}(B_{.5}),x_0}\Big). \end{aligned} \tag{2.34}$$

The inequality (2.30) now easily follows from (2.34) and the following lemma.

LEMMA 3. *With z and z_h defined as above,*

$$\|z - z_h\|_{W_1^1(B_1),x_0,-s} \le Ch, \tag{2.35}$$

$$\|z - z_h\|_{W_1^{0,1}(B_{.5}),x_0,-s} \le Ch, \tag{2.36}$$

$$\|z\|_{W_1^{0,r,2}(B_1),x_0} \le C\Big(\ln\frac{1}{h}\Big). \tag{2.37}$$

Proof. We begin by noting that

$$\|z\|_{W_2^{\lambda+2}(B_1)} \le C\|\eta\|_{W_2^{\lambda}(B_1)} \le C. \tag{2.38}$$

Then a crude estimate yields

$$\|z - z_h\|_{W_1^1(B_1),x_0,-s} \le Ch^{-s}\|z - z_h\|_{W_2^1(B_1)} \le Ch^{r-1-s}\|z\|_{W_2^r(B_1)} \le Ch, \tag{2.39}$$

where we used (2.38) and the fact that $0 \le s \le r-2$. This proves (2.35). We leave the proof of (2.36) to the reader.

To prove (2.37) we let

$$P_\alpha = \int_{B_1} (|x - x_0| + h)^{j-2}|D^\alpha(\omega z)|dx,\ |\alpha| = j,\ j = 0, \dots, r.$$

When $j = 2, \dots, r$,

$$P_\alpha \le C\|D^\alpha(\omega z)\|_{L_2(B_1)} \le C\|\eta\|_{W_2^{r-2}(B_1)} \le C. \tag{2.40}$$

In the case that $j = 0, 1$ we have

$$P_\alpha = \|(|x - x_0| + h)^{j-2}\|_{L_1(B_1)}\|D^\alpha(\omega z)\|_{L_\infty(B_1)}.$$

Now

$$\|(|x - x_0| + h)^{j-2}\|_{L_1(B_1)} \le C\begin{cases}\ln\dfrac{1}{h} & \text{when } j = 0 \text{ and } N = 2,\\ 1 & \text{when } j = 0 \text{ and } N \ge 3 \text{ or } j = 1 \text{ and } N \ge 2.\end{cases}$$

Thus in this case we certainly have

$$P_\alpha \le C\ln\frac{1}{h},\ j = 0, 1,\ |\alpha| = j. \tag{2.41}$$

The inequality (2.37) now easily follows from (2.40) and (2.41).

This completes the proof of Lemma 3 and Theorem 1. ∎

2.1. A sketch of the proof of Theorem 2. In general outline, the proof of Theorem 2 follows that of Theorem 1. We give only a sketch of the proof and indicate the differences. We again restrict ourselves to the case $d = 1$ and this time, using $\widehat{u} - (\widehat{u})_h$, the solution of (2.1), we have instead of (2.2), that for any $i = 1, \dots, N$,

$$\Big\| \frac{\partial}{\partial x_i}(u - u_h) \Big\|_{L_\infty(B_h)} \le \Big\| \frac{\partial}{\partial x_i}(\widehat{u} - (\widehat{u})_h) \Big\|_{L_\infty(B_h)} + \Big\| \frac{\partial}{\partial x_i}((\widehat{u})_h - u_h) \Big\|_{L_\infty(B_h)}. \tag{2.42}$$

Then instead of Lemma 1 we have the following lemma.

LEMMA 4. *With u, u_h, $\widehat{u}$, and $\widehat{u}_h$ as in Lemma 1,*

$$\begin{aligned} &\Big\| \frac{\partial}{\partial x_i}(\widehat{u} - (\widehat{u})_h) \Big\|_{L_\infty(B_h)} \\ &\quad \le C\Big(\Big(\ln \frac{1}{h} \Big)^{\overline{\overline{s}}} \|\widehat{u}\|_{W^1_\infty(B_1),x_0,s} + \Big(\ln \frac{1}{h} \Big)^{\overline{\overline{s}}} |||F|||_{W^{0,-1}_\infty(B_1),x_0,s} \\ &\qquad + \Big(\ln \frac{1}{h} \Big) |||F|||_{W^{0,-r,1}_\infty(B_1),x_0} \Big) \end{aligned} \tag{2.43}$$

and

$$\begin{aligned} &\Big\| \frac{\partial}{\partial x_i}((\widehat{u})_h - u_h) \Big\|_{L_\infty(B_n)} \\ &\quad \le C\Big(\|u\|_{W^1_\infty(B_1),x_0,s} + \|u - u_h\|_{W_p^{-t}(B_1)} \\ &\qquad + |||F|||_{W^{0,-1}_\infty(B_1),x_0,s} + |||F|||_{W^{0,-r,1}_\infty(B_1),x_0} \Big). \end{aligned} \tag{2.44}$$

The proof of Theorem 2 follows easily from (2.40), (2.43), and (2.44). Therefore we need only prove (2.43) and (2.44).

To prove (2.43), let $\psi \in \mathring{W}_2^{r-1}(B_{kh})$ with $\|\psi\|_{W_2^{r-1}(B_{kh})} = 1$, and define $\widetilde{g}^{x_0}$ as the solution of

$$A(v, \widetilde{g}^{x_0}) = \Big(v, -h^{-N/2-r+1} \frac{\partial \psi}{\partial x_i} \Big). \tag{2.45}$$

Furthermore, let $\widetilde{g}_h^{x_0}$ be the finite element approximation defined by

$$A(v, \widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}) = 0 \quad \text{for all} \quad v \in W_2^1(B_1). \tag{2.46}$$

The analogue of Lemma 2 is as follows.

LEMMA 5. *Let $\widetilde{g}^{x_0}$ and $\widetilde{g}_h^{x_0}$ as defined above. Then*

$$\|\widetilde{g}^{x_0}\|_{W_2^j(B_1)} \le C h^{-N/2-j+1} \quad \textit{for} \quad j = 1, \dots, r, \tag{2.47}$$

$$\|\widetilde{g}^{x_0}\|_{W_1^{0,r,1}(B_1),x_0} \le C \ln \frac{1}{h}, \tag{2.48}$$

$$\|\widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}\|_{W_1^1(B_1),x_0,-s} \le C\Big(\ln\frac{1}{h}\Big)^{\overline{\overline{s}}}, \tag{2.49}$$

$$\|\widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}\|_{W_1^{0,1}(B_{1/2}),x_0,-s} \le C\Big(\ln\frac{1}{h}\Big). \tag{2.50}$$

The proof of Lemma 5 follows along the lines of Lemma 2 and is left for the reader.

To prove (2.43) we first find, with $\widehat{e} = \widehat{u} - (\widehat{u})_h$, that for any $\chi \in S_r^h(B_1)$,

$$\Big\|\frac{\partial\widehat{e}}{\partial x_i}\Big\|_{L_\infty(B_h)} \le \Big\|\frac{\partial(\widehat{u}-\chi)}{\partial x_i}\Big\|_{L_\infty(B_{kh})} + h^{-N/2+1-r}\Big\|\frac{\partial\widehat{e}}{\partial x_i}\Big\|_{W_2^{1-r}(B_{kh})}. \tag{2.51}$$

By duality and integration by parts

$$h^{-N/2+1-r}\Big\|\frac{\partial\widehat{e}}{\partial x_i}\Big\|_{W_2^{1-r}(B_{kh})} = \sup_{\substack{\psi\in\mathring{W}_2^{r-1}(B_{kh})\\ \|\psi\|_{W_2^{r-1}(B_{kh})}=1}} \Big(\widehat{e}, -h^{-N/2+1-r}\frac{\partial\psi}{\partial x_i}\Big). \tag{2.52}$$

For each such ψ

$$\Big(\widehat{e}, -h^{N/2+1-r}\frac{\partial\psi}{\partial x_i}\Big) = A(\widehat{e}, \widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}) + F(\widetilde{w(g_h^{x_0} - \widetilde{g}^{x_0})}) + F(w\widetilde{g}^{x_0}).$$

It follows that

$$\begin{aligned}
&\Big|\Big(\widehat{e}, -h^{N/2+1-r}\frac{\partial\psi}{\partial x_i}\Big)\Big| \\
&\quad\le C\Big(\|\widehat{u}-\chi\|_{W_\infty^1(B_1),x_0,s}\|\widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}\|_{W_1^1(B_1),x_0,-s} \\
&\qquad + |||F|||_{W_\infty^{0,-1}(B_1),x_0,s}\|\widetilde{g}^{x_0} - \widetilde{g}_h^{x_0}\|_{W_1^{0,1}(B_{1/2}),x_0,-s} \\
&\qquad + |||F|||_{W_\infty^{0,-r,1}(B_1),x_0}\|\widetilde{g}^{x_0}\|_{W_1^{0,r,1}(B_1),x_0}\Big).
\end{aligned} \tag{2.53}$$

The inequality (2.43) now follows by combining (2.48), (2.52), and (2.53) with Lemma 5.

The proof of (2.44) follows the proof of (2.4) very closely except that instead of (2.21), we now use

$$\Big\|\frac{\partial}{\partial x_i}((\widehat{u})_h - u_h)\Big\|_{L_\infty(B_h)} \le C\|(\widehat{u})_h - u_h\|_{W_p^{-t}(B_{.25})},$$

which was proved in [14] (see also [11]). We leave the details to the reader.

3. A proof of Theorem 3. Consider $\overline{e}(x) = e(x_0 - (x - x_0))$, where $e(x) = u(x) - u_h(x)$. For any $\varphi \in \mathring{S}_r^h(B_d(x_0))$, $\overline{e}(x)$ satisfies (after a change of variables

$y = x_0 - (x - x_0))$

$$
\begin{aligned}
A(\overline{e},\varphi) &= \int_{B_d(x_0)} \left(\sum_{i,j=1}^{N} a_{ij} \frac{\partial \overline{e}}{\partial x_i} \frac{\partial \varphi}{\partial x_j} + \sum_{i=1}^{N} b_i \frac{\partial \overline{e}}{\partial x_i} \varphi + c\overline{e}\varphi \right) dx \\
&= (-1)^N \int_{B_d(x_0)} \left(\sum_{i,j=1}^{N} \overline{a}_{ij} \frac{\partial e}{\partial y_i} \frac{\partial \overline{\varphi}}{\partial y_j} - \sum_{i=1}^{N} \overline{b}_i \frac{\partial e}{\partial y} \overline{\varphi} + \overline{C} e \overline{\varphi} \right) dy \\
&= (-1)^N A(e,\overline{\varphi}) \\
&\quad + (-1)^N \int_{B_d(x_0)} \left(\sum_{i,j=1}^{N} (\overline{a}_{ij} - a_{ij}) \frac{\partial e}{\partial y_i} \frac{\partial \overline{\varphi}}{\partial y_j} - \sum_{i=1}^{N} (\overline{b}_i + b_i) \frac{\partial e}{\partial y_i} \overline{\varphi} \right) dy \\
&\quad + (-1)^N \textstyle\int_{B_d(x_0)} (\overline{C} - C) e \overline{\varphi} dy.
\end{aligned} \tag{3.1}
$$

Since $\overline{\varphi} \in \mathring{S}_r^h(B_d(x_0)), A(e,\overline{\varphi}) = 0$, and it follows that (3.1) may be rewritten as

$$
\begin{aligned}
A(\overline{e},\varphi) &= 2(-1)^N \int_{B_d(x_0)} \left(\sum_{i,j=1}^{N} a_{ij,\mathrm{odd}} \frac{\partial e}{\partial y_i} \frac{\partial \overline{\varphi}}{\partial y_j} - \sum_{i=1}^{N} b_{i,\mathrm{even}} \frac{\partial e}{\partial y_i} \overline{\varphi} + C_{\mathrm{odd}} e \overline{\varphi} \right) dy \\
&= 2(-1)^n [F_1(\varphi) + F_2(\varphi) + F_3(\varphi)] \equiv F(\varphi).
\end{aligned} \tag{3.2}
$$

Here, for any function $w(x)$

$$
w_{\mathrm{even}} = \frac{w(x) + \overline{w}(x)}{2}, \qquad w_{\mathrm{odd}} = \frac{w(x) - \overline{w}(x)}{2}.
$$

Note that since $A(e,\varphi) = 0$ for all $\varphi \in \mathring{S}_r^h(B_d(x_0))$, then

$$
A(e_{\mathrm{even}},\varphi) = F(\varphi) \quad \text{for all} \quad \varphi \in \mathring{S}_r^h(B_d(x_0)). \tag{3.3}
$$

Applying Corollary 1 to $e_{\mathrm{even}} = u_{\mathrm{even}} - u_{h,\mathrm{even}}$ with the choice $\gamma = r+1$, we obtain that at the symmetry point x_0 where $e_{\mathrm{even}}(x_0) = e(x_0)$,

$$
\begin{aligned}
|e(x_0)| \le C &\left[\left(\ln \frac{d}{h} \right)^{\overline{r}} \left(h^r \sum_{|\alpha|=r} |D^\alpha u_{\mathrm{even}}(x_0)| + h^{r+1} \|u_{\mathrm{even}}\|_{W_\infty^{r+1}(B_d(x_0))} \right) \right. \\
&\left. + d^{-t-N/p} \|e_{\mathrm{even}}\|_{W_p^{-t}(B_d(x_0))} \right] \\
&+ C \ln \left(\frac{d}{h} \right) \left[h |||F|||_{W_\infty^{0,-1}(B_d(x_0)),x_0,r-2} + |||F|||_{W_\infty^{0,-r,1}(B_d(x_0)),x_0} \right].
\end{aligned}
$$

Here $\overline{r} = 1$ if $r = 3$, and $\overline{r} = 0$ otherwise. Since r is odd, $D^\alpha u_{\mathrm{even}}(x_0) = 0$ for all $|\alpha| = r$ and it easily follows that

$$
\begin{aligned}
|e(x_0)| \le C &\left[\left(\ln \frac{d}{h} \right)^{\overline{r}} h^{r+1} \|u\|_{W_\infty^{r+1}(B_d(x_0))} + d^{-t-N/p} \|e\|_{W_p^{-t}(B_d(x_0))} \right] \\
&+ C \left(\ln \frac{d}{h} \right) \left[h |||F|||_{W_\infty^{0,-1}(B_d(x_0),x_0,r-2} + |||F|||_{W_\infty^{0,-r,1}(B_d(x_0)),x_0} \right].
\end{aligned} \tag{3.4}
$$

We now estimate the last two terms on the right side of (3.4).

We begin by estimating $F_3(\varphi)$ defined in (3.2). Setting $B_d \equiv B_d(x_0)$,

$$
\begin{aligned}
|F_3(\varphi)| &= \Big| \int_{B_d} C_{\text{odd}} e\varphi dy \Big| \le C\|e\|_{W_\infty^{-1}(B_d)} \|\varphi\|_{W_1^1(B_d)} \\
&\le C\|e\|_{W_\infty^{-1}(B_d)} \|\varphi\|_{W_1^{0,-1}(B_d),x_0,r-2} \quad \text{for all} \quad \varphi \in \mathring{W}_1^r(B_d).
\end{aligned} \tag{3.5}
$$

On the other hand,

$$
\begin{aligned}
|F_3(\varphi)| &\le C\|e\|_{W_\infty^{-2}(B_d)} \|\varphi\|_{W_1^2(B_d)} \\
&\le C\|e\|_{W_\infty^{-2}(B_d)} \|\varphi\|_{W_1^{0,r,2}(B_d),x_0} \quad \text{for all} \quad \varphi \in \mathring{W}_1^r(B_d).
\end{aligned} \tag{3.6}
$$

Hence taken together, (3.5) and (3.6) imply

$$
\begin{aligned}
&\Big(\ln \frac{d}{h} \Big) \Big[h|||F_3|||_{W_\infty^{0,-1}(B_d),x_0,r-2} + |||F_3|||_{W_\infty^{0,-r}(B_d),x_0} \Big] \\
&\qquad \le C\Big(\ln \frac{d}{h} \Big) \big[h\|e\|_{W_\infty^{-1}(B_d)} + \|e\|_{W_\infty^{-2}(B_d)} \big].
\end{aligned} \tag{3.7}
$$

To estimate $F_2(\varphi)$ we use the triangle inequality and integration by parts to obtain

$$
\begin{aligned}
|F_2(\varphi)| &\le \sum_{i=1}^N \Big| \int_{B_d} b_{i,\text{even}} \frac{\partial e}{\partial y_i} \varphi dy \Big| \\
&\le \sum_{i=1}^N \Big(\Big| \int_{B_d} e\Big(b_{i,\text{even}} \frac{\partial \varphi}{\partial y_i} \Big) dy \Big| + \Big| \int_{B_d} e \frac{\partial b_{i,\text{even}}}{\partial x_i} \varphi dy \Big| \Big) \\
&\le C\|e\|_{L_\infty(B_d)} \|\varphi\|_{W_1^1(B_d)} \le C\|e\|_{L_\infty(B_d)} \|\varphi\|_{W_1^{0,1}(B_d),x_0,r-2}.
\end{aligned} \tag{3.8}
$$

Furthermore,

$$
|F_2(\varphi)| \le C\|e\|_{W_\infty^{-1}(B_d)} \|\varphi\|_{W_1^2(B_d)} \le C\|e\|_{W_\infty^{-1}(B_d)} \|\varphi\|_{W_1^{0,r,2}(B_d),x_0}. \tag{3.9}
$$

Taken together, (3.8) and (3.9) imply

$$
\begin{aligned}
&\Big(\ln \frac{d}{h} \Big) \Big[h|||F_2|||_{W_\infty^{0,-1}(B_d)x_0,r-2} + |||F_2|||_{W_\infty^{0,-r,2}(B_d),x_0} \Big] \\
&\qquad \le C\Big(\ln \frac{d}{h} \Big) \Big[h\|e\|_{L_\infty(B_d)} + \|e\|_{W_\infty^{-1}(B_d)} \Big].
\end{aligned} \tag{3.10}
$$

Last, we estimate $F_1(\varphi)$. On the one hand we have

$$
\begin{aligned}
|F_1(\varphi)| &\le \sum_{i,j=1}^N \Big| \int_{B_d} a_{ij,\text{odd}} \frac{\partial e}{\partial y_i} \frac{\partial \varphi}{\partial y_j} dy \Big| \\
&\le \sum_{i,j=1}^N \Big\| \frac{\partial e}{\partial y_i} \Big\|_{L_\infty(B_d)} \Big\| a_{ij,\text{odd}} \frac{\partial \varphi}{\partial y_j} \Big\|_{L_1(B_d)} \\
&\le Ch\|e\|_{W_\infty^1(B_d)} \|\varphi\|_{W_1^1(B_d),x_0,-1},
\end{aligned} \tag{3.11}
$$

where in the last step we used

$$
|a_{ij,\text{odd}}| \le C|x - x_0|. \tag{3.12}
$$

Furthermore, using integration by parts and the triangle inequality,

$$|F_1(\varphi)| \le \sum_{i,j=1}^{N} \left(\left| \int_{B_d} e \frac{\partial a_{ij,\text{odd}}}{\partial y_i} \frac{\partial \varphi}{\partial y_j} dy \right| + \left| \int_{B_d} e a_{ij,\text{odd}} \frac{\partial^2 \varphi}{\partial y_i \partial y_j} dy \right| \right)$$
$$\le C \|e\|_{W_\infty^{-1}(B_d)} \left(\|\varphi\|_{W_1^2(B_d)} + \sum_{i,j=1}^{N} \left\| a_{ij,\text{odd}} \frac{\partial^2 \varphi}{\partial y_i \partial y_j} \right\|_{W_1^1(B_d)} \right).$$

A simple calculation shows that

$$\sum_{i,j=1}^{N} \left\| a_{ij,\text{odd}} \frac{\partial^2 \varphi}{\partial y_i \partial y_j} \right\|_{W_1^1(B_d)} \le C \|\varphi\|_{W_1^{0,r,2}(B_d),x_0},$$

where we again used (3.12). This leads to

$$|F_1(\varphi)| \le C \|e\|_{W_\infty^{-1}(B_d)} \|\varphi\|_{W_1^{0,r,2}(B_d),x_0}. \tag{3.13}$$

Taken together, (3.11) and (3.13) imply that

$$\left(\ln \frac{d}{h} \right) \left[h |||F_1|||_{W_\infty^{0,-1}(B_d),x_0,r-2} + |||F_1|||_{W_\infty^{0,-r,2}(B_d),x_0} \right]$$
$$\le C \left(\ln \frac{d}{h} \right) \left[h^2 \|e\|_{W_\infty^1(B_d)} + \|e\|_{W_\infty^{-1}(B_d)} \right]. \tag{3.14}$$

Combining (3.14), (3.10), and (3.7) we arrive at

$$\left(\ln \frac{d}{h} \right) \left[h |||F|||_{W_\infty^{0,-1}(B_d),x_0,r-2} + |||F|||_{W_\infty^{0,-r,2}(B_d),x_0} \right]$$
$$\le C \left(\ln \frac{d}{h} \right) \left[h^2 \|e\|_{W_\infty^1(B_d)} + h\|e\|_{L_\infty(B_d)} + \|e\|_{W_\infty^{-1}(B_d)} \right]. \tag{3.15}$$

Now with an inconsequential change in domains, it follows from (3.4) and (3.15) that

$$|e(x_0)| \le C \left(h^{r+1} \left(\ln \frac{d}{h} \right)^{\overline{r}} \|u\|_{W_\infty^{r+1}(B_{d/2})} + d^{-t-N/p} \|e\|_{W_p^{-t}(B_{d/2})} \right)$$
$$+ \left(\ln \frac{d}{h} \right) \left(h^2 \|e\|_{W_\infty^1(B_{d/2})} + h\|e\|_{L_\infty(B_{d/2})} + \|e\|_{W_\infty^{-1}(B_{d/2})} \right). \tag{3.16}$$

Now it was proved in [14], and may be seen from (1.15), that for $r \ge 3$ and $d \ge kh$

$$h^2 \|e\|_{W_\infty^1(B_{d/2})} \le C \left(h^{r+1} \|u\|_{W_\infty^r(B_d)} + h^2 d^{-1-N/p-t} \|e\|_{W_p^{-t}(B_d)} \right), \tag{3.17}$$

and from (1.13),

$$h\|e\|_{L_\infty(B_{d/2})} \le C \left(h^{r+1} \|u\|_{W_\infty^r(B_d)} + h d^{-N/p-t} \|e\|_{W_p^{-t}(B_d)} \right). \tag{3.18}$$

Furthermore, it is not difficult to show by a local duality argument that for $t \ge 1$ and $r \ge 3$

$$\|e\|_{W_\infty^{-1}(B_{d/2})} \le C \left(h^{r+1} \left(\ln \frac{d}{h} \right) \|u\|_{W_\infty^r(B_d)} + d^{1-N/p-t} \|e\|_{W_p^{-t}(B_d)} \right). \tag{3.19}$$

Substituting (3.17), (3.18), and (3.19) into (3.16), we easily arrive at

$$|e(x_0)| \le C \left(\left(\ln \frac{d}{h} \right)^2 h^{r+1} \|u\|_{W_\infty^{r+1}(B_d)} + \left(\ln \frac{d}{h} \right) d^{-N/p-t} \|e\|_{W_p^{-t}(B_d)} \right). \tag{3.20}$$

This completes the proof of Theorem 3.

4. A proof of Theorem 4. In view of (3.2) and (1.20), we have that

$$A(e_{\rm odd},\varphi) = -F(\varphi) \quad \text{for all} \quad \varphi \in \mathring{S}_r^h(B_d(x_0)). \tag{4.1}$$

Then using (1.20) of Corollary 2 and the fact that since $r \geq 2$ is even, $D^\alpha u_{\rm odd}(x_0) = 0$ for all $|\alpha| = r$, we obtain

$$\begin{aligned} &\| e_{\rm odd}\|_{W_\infty^1(B_h(x_0))} \\ &\quad \leq C\Big[h^r\Big(\ln\frac{d}{h}\Big)^{\overline{\overline{r}}}\|u\|_{W_\infty^{r+1}(B_d(x_0))} + d^{-1-t-N/p}\|e\|_{W_p^{-t}(B_d(x_0))}\Big] \\ &\qquad + \Big(\ln\frac{d}{h}\Big)\Big[|||F|||_{W_\infty^{0,-1}(B_d(x_0)),x_0,r-1} + |||F|||_{W_\infty^{0,-r,1}(B_d(x_0)),x_0}\Big]. \end{aligned} \tag{4.2}$$

Proceeding as in the proof of (3.7) we arrive at

$$\begin{aligned} &\Big(\ln\frac{d}{h}\Big)\Big(|||F|||_{W_\infty^{0,-1}(B_d),x_0,r-1} + |||F|||_{W_\infty^{0,-r,1}(B_d),x_0}\Big) \\ &\qquad \leq \Big(\ln\frac{d}{h}\Big)\Big(\|e\|_{L_\infty(B_d)} + h\|e\|_{W_\infty^1(B_d)}\Big). \end{aligned} \tag{4.3}$$

Using (3.17) and (3.18) in (4.3), again after an inconsequential change in domains, and substituting the result into (4.2) we obtain

$$\begin{aligned} &\| e_{\rm odd}\|_{W_\infty^1(B_h(x_0))} \\ &\quad \leq C\Big(h^r\Big(\ln\frac{d}{h}\Big)^2\|u\|_{W_\infty^{r+1}(B_d)} + \Big(\ln\frac{d}{h}\Big)d^{-1-N/p-t}\|e\|_{W_p^{-t}(B_d)}\Big). \end{aligned} \tag{4.4}$$

By definition,

$$\frac{\partial}{\partial x_i}e_{\rm odd}(x) = \left(\frac{\frac{\partial e(x)}{\partial x_i} + \frac{\partial e}{\partial x_i}(x_0 - (x - x_0))}{2}\right),$$

wherever these derivatives exist. The inequality (1.23) now follows on setting $x - x_0 = s\beta$ for an appropriate direction β and scalar $0 \leq s \leq s_0$ and taking the limit as $s \to 0$. This completes the proof of Theorem 4.

Appendix. Assumed properties of finite element spaces. We now state our assumptions on the finite element spaces used in this paper. They are the same as those used in [11], which in turn are essentially the same, with some simplifications, as those used in [13] and [14].

Let $\mathcal{D} \subset\subset \Omega \subset \mathbb{R}^N$ and for $r \geq 2$ an integer and $0 < h < 1$ a parameter, $S_r^h(\mathcal{D})$ will denote a family of finite dimensional subspaces of $W_\infty^1(\mathcal{D})$. For $G \subseteq \mathcal{D}$, $S_r^h(G)$ is the restriction of $S_r^h(\mathcal{D})$ to G and

$$\mathring{S}_r^h(G) = \varphi : \varphi \in S_r^h(G), \operatorname{supp}(\varphi) \subset G.$$

We assume that there exist positive constants k_0, δ, c_1, c_2, c_3 so that the following Assumptions A.1–A.4 are satisfied for any $\mathcal{D}_1 \subset\subset \mathcal{D}_2 \subset\subset \mathcal{D}_3 \subset\subset \mathcal{D}_4$ with $\operatorname{dist}(\mathcal{D}_i, \partial\mathcal{D}_{i+1}) \geq k_0 h$, $i = 1, 2, 3$.

Assumption A.1 (approximation). For each $v \in W_p^\ell(\mathcal{D}_2)$ there exists a $\chi \in S_r^h(\mathcal{D}_2)$ such that if $t = 0, 1$, $1 \leq \ell \leq r$, and $1 \leq p \leq \infty$,

$$\|w - \chi\|_{W_p^t(\mathcal{D}_1)} \leq c_1 h^{\ell - t}\|v\|_{W_p^\ell(\mathcal{D}_2)}. \tag{A.1}$$

In addition there exists a χ such that

$$\|v-\chi\|_{W^1_\infty(\mathcal{D}_1)} \le c_1 h^{r-1-N/p}\|v\|_{W^r_p(\mathcal{D}_2)}. \tag{A.2}$$

Furthermore, if $\operatorname{supp}(v) \subseteq \mathcal{D}_1$, then $\chi \in \mathring{S}^h(\mathcal{D}_2)$.

Assumption A.2 (inverse properties). For $\ell = 0, 1$, $t \ge 0$ an integer, and $1 \le q \le p \le \infty$,

$$\|\chi\|_{W^\ell_p(\mathcal{D}_1)} \le c_2 h^{-[\frac{N}{q}-\frac{N}{p}]-\ell-t}\|\chi\|_{W^{-t}_q(\mathcal{D}_2)} \text{ for all } \chi \in S^h_r(\mathcal{D}_2). \tag{A.3}$$

Furthermore, for any $\tau_h \subset B_d$ and integer $j = 1, \dots, r-2$,

$$\|\chi\|_{W^{1+j}_1(\tau_h)} \le Ch^{-j}\|\chi\|_{W^1_1(\tau_h)}. \tag{A.4}$$

Assumption A.3 (superapproximation). Let $\omega \in C^\infty_0(\mathcal{D}_3)$; then for each $\chi \in S^h_r(\mathcal{D}_4)$ there exists an $\eta \in \mathring{S}^h_r(\mathcal{D}_4)$ such that for $\ell = 0, 1$

$$\|\omega\chi - \eta\|_{W^\ell_2(\mathcal{D}_4)} \le c_3 h\|\omega\|_{W^\delta_\infty(\mathcal{D}_3)}\|\chi\|_{W^\ell_2(\mathcal{D}_4)}. \tag{A.5}$$

Furthermore, if $\omega \equiv 1$ on $\mathcal{D}_2$, then $\eta = \chi$ in $\mathcal{D}_1$ and

$$\|\omega\chi - \eta\|_{W^\ell_2(\mathcal{D}_4)} \le c_3 h\|\omega\|_{W^\delta_\infty(\mathcal{D}_3)}\|\chi\|_{W^\ell_2(\mathcal{D}_4\setminus\mathcal{D}_1)}. \tag{A.6}$$

Assumption A.4 (scaling). Let $x \in \mathcal{D}$ and $d \ge k_0 h$ be such that $B_d(x) \subseteq \mathcal{D}$. The linear transformation $z = (y-x)/d$ takes $B_d(x) = \{y : |y-x| < d\}$ into a new domain $\widehat{B}_1(x)$ and $S^h_r(B_d(x))$ into a new function space $\widehat{S}^{h/d}_r(\widehat{B}_1(x))$. Then $\widehat{S}^{h/d}_r(\widehat{B}_1(x))$ satisfies A.1, A.2, and A.3 with h replaced by h/d. The constants occurring in A.1, A.2, and A.3 remain the same and are independent of d.

For a discussion of these properties see [13].

ANALYSIS OF A NEW ERROR ESTIMATE FOR COLLOCATION METHODS APPLIED TO SINGULAR BOUNDARY VALUE PROBLEMS*

WINFRIED AUZINGER†, OTHMAR KOCH†, AND EWA WEINMÜLLER†

Abstract. We discuss an a posteriori error estimate for the numerical solution of boundary value problems for nonlinear systems of ordinary differential equations with a singularity of the first kind. The estimate for the global error of an approximation obtained by collocation with piecewise polynomial functions is based on the defect correction principle. We prove that for collocation methods which are not superconvergent, the error estimate is asymptotically correct. As an essential prerequisite we derive convergence results for collocation methods applied to nonlinear singular problems.

Key words. boundary value problems, singularity of the first kind, collocation methods, error estimate, defect correction, asymptotical correctness

1. Introduction.

In this paper, we discuss the numerical solution of singular boundary value problems of the form

$$z'(t) = \frac{M(t)}{t} z(t) + f(t, z(t)), \quad t \in (0, 1], \tag{1.1a}$$

$$B_a z(0) + B_b z(1) = \beta, \tag{1.1b}$$

$$z \in C[0, 1], \tag{1.1c}$$

where z is an n-dimensional real function, M is a smooth $n \times n$ matrix, and f is an n-dimensional smooth function on a suitable domain. B_a and B_b are constant $r \times n$ matrices, with $r < n$. In section 3 we will demonstrate that condition (1.1c) is equivalent to a set of $n - r$ linearly independent conditions $z(0)$ must satisfy. These boundary conditions are augmented by (1.1b) to yield an isolated solution z. In this paper, we restrict our attention to the class of singular boundary value problems which are equivalent to a well-posed singular initial value problem, where all boundary conditions are posed at $t = 0$. In this case, a shooting argument can be used to derive a representation of the solution convenient for our analysis. This implies certain restrictions on the spectrum of the matrix $M(0)$, which will be discussed in section 3.

The search for an efficient numerical method to solve problems (1.1) is strongly motivated by numerous applications from physics, chemistry, mechanics, or ecology; see, for example, [15], [28]. Also, research activities in related fields, like the computation of connecting orbits in dynamical systems [21] or singular Sturm–Liouville problems [6], may benefit from techniques developed for problems of the form (1.1). The problem class discussed in this paper, where $M(0)$ has no eigenvalues with positive real parts, arises in applications from mechanics (buckling of spherical shells

[22], [25]), chemical reactor theory (cf. [14]), and avalanche dynamics (see [18] and [19]). Moreover, Dirichlet problems for certain nonlinear elliptic equations lead to this problem class when certain symmetries are present; see [23]. The computation of self-similar solution profiles for the nonlinear Schrödinger equation is also essentially reduced to this problem type; see [7]. However, our restriction on the spectrum of $M(0)$ excludes problems of the type

$$y''(t) + \frac{1}{t}y'(t) - \frac{1}{t^2}y(t) = f(t)$$

(see [20], [22]) from the treatment. The first order system resulting from the Euler transformation $z(t) = (y(t), ty'(t))$ does not belong to the class considered here.

To compute the numerical solution of (1.1), we use polynomial collocation at collocation points placed in the interior of every collocation interval. Collocation has been used in one of the best established standard codes for (regular) boundary value problems, COLSYS (COLNEW); see [1] and [2]. In COLSYS, (superconvergent) collocation at Gaussian points is used; cf. [8]. Our decision to use collocation was motivated by its advantageous convergence properties for (1.1), while in the presence of a singularity other high order methods show order reductions and become inefficient (see, for example, [11]). For linear problems (1.1) which can equivalently be posed as initial value problems, it was shown in [10] that the convergence order of collocation methods is at least equal to the *stage order* of the method. We will discuss the restrictions implied by the latter requirement in section 3. For the general class (1.1), numerical evidence suggests that the convergence order is at least equal to the stage order for both the linear and the nonlinear case;[1] cf. [5]. However, we cannot expect to observe superconvergence (cf. [8]) when collocation is applied to (1.1) in general. At most, a convergence order of $O(|\ln(h)|^{n_0-1}h^{m+1})$, for some positive integer n_0, holds for a method of stage order m; see [10]. Consequently, a restriction to collocation at an even number of equidistant points, which implies that the convergence order is at most $O(h^m)$, does not limit the method's accuracy significantly. We use these collocation nodes in practice, since it turns out that the error of the error estimate we propose in this paper is $O(|\ln(h)|^{n_0-1}h^{m+1})$. This means that the estimate is asymptotically correct when the order of the collocation method is not higher than the stage order.

Our main aim was to construct an efficient asymptotically correct error estimate for the global error of the numerical solution obtained by collocation. This estimate, introduced in [5], is based on the defect correction principle, which was first considered in [29] for the estimation of the global error of Runge–Kutta methods. In [29], the estimate for the error at the mesh points is obtained by applying the (high order) basic numerical scheme twice, to the original and to a suitably defined "neighboring problem." An extension of this idea proposed in [12], [24] avoids the second application of the high order scheme, using a cheap low order method instead. Again, this estimate is asymptotically correct at the mesh points only. A further modification proposed by the authors provides an error estimate which is asymptotically correct at both the mesh and the collocation points. The analysis of this estimate in the context of nonlinear regular problems was given in [5]. It could be shown that for a collocation method of stage order $O(h^m)$, the error of the estimate (the difference between the global error and its estimate) is of order $O(h^{m+1})$. Numerical evidence suggests that

[1] The analysis given in [26] for second order problems might provide tools to prove this assertion.

this is also true for singular problems. In this paper, we will prove this assertion for the class of singular problems (1.1).

The collocation method and error estimate described in this paper were also implemented in the MATLAB code `sbvp` designed especially to solve singular boundary value problems. The error estimate yields a reliable basis for a mesh selection procedure which enables an efficient computation of the numerical solution. A description of the code and experimental evidence of its advantageous properties are given in [4].

The paper is organized as follows: The analytical properties of (1.1) which were discussed in detail in [9] are briefly recapitulated in section 3. In section 4.1, the results for collocation methods according to [10] are given. Using these results, we derive new, refined bounds for the errors of the numerical solution and its derivative, and we extend these results to the nonlinear case. This analysis is carried out in section 4.2. In section 5 we use these estimates for the collocation solution in order to prove that our version of the error estimate is asymptotically correct for problem (1.1). Finally, in section 6 we give a numerical example which illustrates the theory.

2. Preliminaries. Throughout the paper, the following notation is used. We denote by $\mathbb{R}^n$ the space of real vectors of dimension n and use $|\cdot|$,

$$|x| = |(x_1, x_2, \ldots, x_n)^T| := \max_{1\le i\le n} |x_i|,$$

to denote the maximum norm in $\mathbb{R}^n$. $C_n^p[0,1]$ is the space of real vector-valued functions which are p times continuously differentiable on $[0,1]$. For functions $y \in C_n^0[0,1]$ we define the maximum norm,

$$\|y\|_{[0,1]} := \max_{0\le t\le 1} |y(t)|,$$

or more generally for an interval $J \subseteq [0,1]$,

$$\|y\|_J := \max_{t\in J} |y(t)|.$$

$C_{n\times n}^p[0,1]$ is the space of real $n \times n$ matrices with columns in $C_n^p[0,1]$. For a matrix $A = (a_{ij})_{i,j=1}^n$, $A \in C_{n\times n}^0[0,1]$, $\|A\|_{[0,1]}$ is the induced norm,

$$\|A\|_{[0,1]} = \max_{0\le t\le 1} |A(t)| = \max_{0\le t\le 1} \left(\max_{1\le i\le n} \sum_{j=1}^{n} |a_{ij}(t)| \right).$$

Where there is no confusion, we will omit the subscripts n and $n \times n$ and denote $C[0,1] = C^0[0,1]$.

For the numerical analysis, we define meshes

$$\Delta := (\tau_0, \tau_1, \ldots, \tau_N),$$

and $h_i := \tau_{i+1} - \tau_i,\ i = 0, \ldots, N-1,\ \tau_0 = 0,\ \tau_N = 1$. On Δ, we define corresponding grid vectors

$$u_\Delta := (u_0, \ldots, u_N) \in \mathbb{R}^{(N+1)n}.$$

The norm on the space of grid vectors is given by

$$\|u_\Delta\|_\Delta := \max_{0\le k\le N} |u_k|.$$

For a continuous function $y \in C[0,1]$, we denote by R_Δ the pointwise projection onto the space of grid vectors,

$$R_\Delta(y) := (y(\tau_0), \dots, y(\tau_N)).$$

For collocation, m points spaced at distances $h_i\delta_j,\ j = 1, \dots, m$, are inserted in each subinterval $J_i := [\tau_i, \tau_{i+1}]$. This yields the (fine) grid[2] (see Figure 2.1)

$$\Delta^m := \left\{ t_{i,j} :\ t_{i,j} = \tau_i + h_i \sum_{k=0}^{j} \delta_k,\ i = 0, \dots, N-1,\ j = 0, \dots, m+1 \right\}. \tag{2.1}$$

We restrict ourselves to grids where $\delta_1 > 0$ to avoid a special treatment of the singular point $t = 0$. For the analysis of collocation methods, we allow $\delta_{m+1} = 0$. In the discussion of the error estimate, we use the further restriction $\delta_{m+1} > 0$. This requirement is satisfied for equidistant collocation points which we use in practice (see section 1), where

$$\delta_j := \frac{1}{m+1}, \quad j = 1, \dots, m+1. \tag{2.2}$$

For a grid Δ^m, u_{Δ^m}, $\|\cdot\|_{\Delta^m}$, and R_{Δ^m} are defined accordingly.

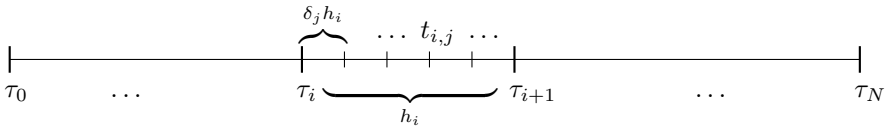

FIG. 2.1. *The computational grid.*

3. Analytical results. In this section we discuss the analytical properties of (1.1); cf. [9]. Here, we assume all eigenvalues of $M(0)$ have nonpositive real parts. Moreover, the only eigenvalue of $M(0)$ on the imaginary axis is zero. These restrictions are necessary to ensure that we can use a shooting argument to derive a representation of the solution convenient for our theory.[3]

First, we treat the linear case,

$$z'(t) = \frac{M(t)}{t} z(t) + f(t), \quad t \in (0,1], \tag{3.1a}$$

$$B_a z(0) + B_b z(1) = \beta, \tag{3.1b}$$

$$z \in C[0,1], \tag{3.1c}$$

where $B_a, B_b \in \mathbb{R}^{r\times n},\ r < n$, are constant matrices, and $\beta \in \mathbb{R}^r$ is a constant vector.

Throughout, we assume $M \in C^1[0,1]$. Consequently, we can rewrite $M(t)$ and obtain

$$M(t) = M(0) + tC(t) \tag{3.2}$$

[2]For convenience, we denote τ_i by $t_{i,0} \equiv t_{i-1,m+1},\ i = 1, \dots, N-1$. Moreover, we define $\delta_0 := 0,\ \delta_{m+1} := (t_{i,m+1} - t_{i,m})/h_i$. Note that we choose the same distribution of collocation points in every subinterval J_i, and that $\sum_{j=0}^{m+1} \delta_j = 1$ holds for $i = 0, \dots, N-1$.

[3]Note, however, that we do not use shooting when we actually compute the numerical solution.

with a continuous matrix $C(t)$.

Let X_0 be the kernel of $M(0)$ and let R be a projection onto X_0, where the rank of R is equal to r. We define

$$S := I_n - R,$$

where we denote by I_n the $n \times n$ identity matrix. The necessary and sufficient condition for z to be continuous on $[0,1]$ is

$$Sz(0) = 0.$$

This yields

$$z(0) = (S+R)z(0) = Rz(0),$$

and due to

$$M(0)z(0) = MRz(0) = 0$$

it follows that (3.1c) is equivalent to $z(0) \in \ker(M(0))$. These conditions are augmented by (3.1b) to yield a unique solution.

We denote by $\tilde{E}$ the $n \times r$ matrix consisting of a maximal set of linearly independent columns of R. Moreover, let $Z(t) = (Z_1(t), \ldots, Z_r(t))$ be the fundamental solution matrix of the initial value problem

$$Z'(t) = \frac{M(t)}{t} Z(t), \quad t \in (0,1], \tag{3.3a}$$

$$Z(0) = \tilde{E}. \tag{3.3b}$$

The necessary and sufficient condition for problem (3.1) to have a unique solution is that the $r \times r$ matrix Q,

$$Q := B_a \tilde{E} + B_b Z(1), \tag{3.4}$$

be nonsingular. In this case, we can represent the solution z of (3.1) by

$$z(t) = \sum_{k=1}^{r} a_k Z_k(t) + \tilde{z}(t), \tag{3.5}$$

where $\tilde{z}$ is the solution of

$$\tilde{z}'(t) = \frac{M(t)}{t} \tilde{z}(t) + f(t), \quad t \in (0,1], \tag{3.6a}$$

$$\tilde{z}(0) = 0. \tag{3.6b}$$

The coefficients $a = (a_1, \ldots, a_r)$ are uniquely determined by $Qa = \beta - B_b \tilde{z}(1)$.

For the solution of the linear problem (3.1), $z \in C^{k+1}[0,1]$ holds if $f \in C^k[0,1]$ and $M \in C^{k+1}[0,1]$.

Now we discuss the nonlinear problem[4]

$$z'(t) = \frac{M(t)}{t} z(t) + f(t, z(t)), \quad t \in (0,1], \tag{3.7a}$$

$$B_a z(0) + B_b z(1) = \beta, \tag{3.7b}$$

$$M(0)z(0) = 0. \tag{3.7c}$$

In order to formulate analogous smoothness properties for z, we make the following assumptions:

[4]Again, we assume that $M(0)$ has only eigenvalues with negative real parts or the eigenvalue 0.

1. $f : D_1 \to \mathbb{R}^n$ is a nonlinear mapping, where $D_1 \subseteq [0,1] \times \mathbb{R}^n$ is a suitable set.
2. Equation (3.7) has a solution $z \in C[0,1] \cap C^1(0,1]$. With this solution and a $\rho > 0$ we associate the closed balls

$$S_\rho(z(t)) := \{x \in \mathbb{R}^n : \ |z(t) - x| \le \rho\}$$

and the tube

$$T_\rho(z) := \{(t,x) : \ t \in [0,1], \ x \in S_\rho(z(t))\}.$$

3. $f(t,z)$ is continuously differentiable with respect to z, and $\frac{\partial f(t,z)}{\partial z}$ is continuous on $T_\rho(z)$.
4. The solution z is isolated. This means that

$$\begin{aligned} &u'(t) = \frac{M(t)}{t}u(t) + A(t)u(t), \quad t \in (0,1], \\ &B_a u(0) + B_b u(1) = 0, \\ &M(0)u(0) = 0, \end{aligned}$$

where

$$A(t) := \frac{\partial f}{\partial z}(t, z(t))$$

has only the trivial solution.

Under these assumptions and for $f \in C^k(T_\rho(z)), \ M \in C^{k+1}[0,1]$, the solution z of (3.7) satisfies $z \in C^{k+1}[0,1]$.

For further details and proofs see [9].

4. Collocation methods. In this section, we derive new, refined error bounds for collocation methods applied to (1.1), relying on earlier results formulated in [10]. Moreover, we extend the convergence analysis to the nonlinear case. For reasons of simplicity, we restrict the discussion to equidistant meshes, $h_i = h, \ i = 0, \dots, N-1$, because the results from [10] are formulated for this situation. However, the results also hold for nonuniform meshes which have a limited variation in the stepsizes; see [10, section 6].

Let us denote by B the Banach space of continuous, piecewise polynomial functions $q \in \mathbb{P}_m$ of degree $\le m, \ m \in \mathbb{N}$ (m is called the *stage order* of the method), equipped with the norm $\|\cdot\|_{[0,1]}$. As an approximation for the exact solution z of (1.1), we define an element of B which satisfies the differential equation (1.1a) at a finite number of points and which is subject to the same boundary conditions. Since we require the numerical solution to satisfy (1.1c), we introduce the space $B_1 \subset B$, such that $M(0)q(0) = 0 \ \forall\, q \in B_1$. Thus, we are seeking a function $p(t) = p_i(t), \ t \in J_i, \ i = 0, \dots, N-1$, in B_1 which satisfies

$$p_i'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} p_i(t_{i,j}) + f(t_{i,j}, p_i(t_{i,j})), \quad i = 0, \dots, N-1, \ j = 1, \dots, m, \tag{4.1a}$$

$$B_a p(0) + B_b p(1) = \beta. \tag{4.1b}$$

We consider collocation on general grids Δ^m as defined in section 1, subject to the restriction $\delta_1 > 0$.

4.1. Earlier results. In [10], collocation methods for linear problems were studied. For the analysis of the nonlinear case in section 4.2, bounds for the collocation solution $p \in B_1$ need to be specified. Here, the relevant preliminaries from [10] are recapitulated.

Thus, we consider the solution $p \in B_1$ of

$$p'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} p(t_{i,j}) + f(t_{i,j}), \quad i = 0, \dots, N-1,\ j = 1, \dots, m, \tag{4.2a}$$

$$B_a p(0) + B_b p(1) = \beta. \tag{4.2b}$$

LEMMA 4.1. *For $\mu, \beta \in \{0, 1\}$ and arbitrary constants $c_{i,j}$, there exists a unique $p \in B_1$ which satisfies*

$$p'(t_{i,j}) = \frac{M(0)}{t_{i,j}} p(t_{i,j}) + \frac{M(0)^\mu}{t_{i,j}^\beta} c_{i,j}, \quad i = 0, \dots, N-1,\ j = 1, \dots, m, \tag{4.3a}$$

$$p(0) = 0. \tag{4.3b}$$

Furthermore,

$$\|p\|_{J_i} \le \text{const.}\, \tau_{i+1}^{1-\beta} |\ln(h)|^{(\beta(n_0-\mu))_+} C_i, \quad i = 0, \dots, N-1, \tag{4.4}$$

where n_0 is the dimension of the largest Jordan block of $M(0)$ corresponding to the eigenvalue 0,

$$(x)_+ := \begin{cases} x, & x \ge 0, \\ 0, & x < 0, \end{cases}$$

and

$$C_i := \max_{\substack{l = 0, \dots, i \\ j = 1, \dots, m}} |c_{l,j}|.$$

Proof. See [10, Lemma 4.4]. ∎

The following result is a slightly modified version of [10, Theorem 4.1].

THEOREM 4.2. *For $\mu, \beta \in \{0, 1\}$, consider the problem*

$$p'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} p(t_{i,j}) + \frac{M(0)^\mu}{t_{i,j}^\beta} c_{i,j}, \quad i = 0, \dots, N-1,\ j = 1, \dots, m, \tag{4.5a}$$

$$p(0) = \delta \in \ker(M(0)). \tag{4.5b}$$

There exists a unique solution of (4.5) when h is sufficiently small, and this solution satisfies

$$\|p\|_{J_i} \le \text{const.}\, (|\delta| + \tau_{i+1}^{1-\beta} |\ln(h)|^{(\beta(n_0-\mu))_+} C_i), \quad i = 0, \dots, i_0, \tag{4.6}$$

for a suitable $i_0 \le N-1$.

Proof. In [10, Theorem 4.1], the estimate following [10, formula (4.15)] can be replaced by

$$\|p\|_{J_i} \le \kappa(\tau_{i+1} \|p\|_{[0,\tau_{i+1}]} + |\delta| + \tau_{i+1}^{1-\beta} |\ln(h)|^{(\beta(n_0-\mu))_+} C_i), \quad i = 0, \dots, i_0, \tag{4.7}$$

if the results of [10, Lemma 4.4] are suitably applied. Substitution of the bound for p derived in [10, Theorem 4.1] into the right-hand side of (4.7) yields the result. ∎

Note that the existence of the solution of (4.5) and the estimate (4.6) are shown only on an interval $[0, b]$, where b is sufficiently small (but independent of h). Thus, we need to use classical theory for regular problems to ensure the existence of the solution on the whole interval. In what follows, we treat the underlying singular problems only on the restricted interval, and we apply classical results for collocation from [3], and the error estimate analysis for regular problems from [5], to complete the proofs.

4.2. New error bounds. First, we use Theorem 4.2 to derive bounds for the solution $p \in B_1$ of the general linear problem (4.2) and for its derivative p'. By the superposition principle, p can be written in the form

$$p(t) = \sum_{k=1}^{r} b_k P_k(t) + \tilde{p}(t), \tag{4.8}$$

analogous to (3.5) for the exact solution. Here, $P(t) = (P_1(1), \ldots, P_r(t))$ is the $n \times r$ matrix solution of

$$P'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} P(t_{i,j}), \quad i = 0, \ldots, N-1,\ j = 1, \ldots, m, \tag{4.9a}$$

$$P(0) = \tilde{E}, \tag{4.9b}$$

whose columns are in B_1, and $\tilde{p}$ satisfies

$$\tilde{p}'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} \tilde{p}(t_{i,j}) + f(t_{i,j}), \quad i = 0, \ldots, N-1,\ j = 1, \ldots, m, \tag{4.10a}$$

$$\tilde{p}(0) = 0. \tag{4.10b}$$

It was shown in [10, Theorem 4.4] that the representation (4.8) is well defined. Of course, the coefficients b_k could be computed in principle from the boundary conditions, as in the case of the analytical problem; the representation (4.8) is used only to describe the structure of the solution p, and therefore we refrain from specifying b_k explicitly. Next, we derive convergence results for the quantities appearing in the representation (4.8) using arguments similar to those given in [10, Theorem 4.2].

Consider the solutions z and q of (3.1a) and (4.2a), respectively, subject to the initial conditions $z(0) = q(0) = \delta \in \ker(M(0))$. We define an error function $e \in B_1$ by

$$\begin{aligned} &e'(t_{i,j}) = z'(t_{i,j}) - q'(t_{i,j}), \quad i = 0, \ldots, N-1,\ j = 1, \ldots, m, \\ &e(0) = 0. \end{aligned}$$

From standard results for interpolation (see, for example, [13]), we conclude that

$$e(t) = z(t) - q(t) + tO(h^m)$$

if z is sufficiently smooth, whence

$$e'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} e(t_{i,j}) + O(h^m), \quad i = 0, \ldots, N-1,\ j = 1, \ldots, m, \tag{4.11a}$$

$$e(0) = 0. \tag{4.11b}$$

Now, Theorem 4.2 yields

$$\|e\|_{J_i} \le \tau_{i+1} O(h^m), \quad i = 0, \ldots, i_0, \tag{4.12}$$

and consequently

$$\|z-q\|_{J_i} \le \tau_{i+1} O(h^m), \quad i = 0, \dots, i_0. \tag{4.13}$$

It follows from (4.11a) and (4.12) that $e'(t_{i,j}) = O(h^m)$, which implies

$$\|z' - q'\|_{[0,1]} = O(h^m). \tag{4.14}$$

Finally, we show that the residual of q with respect to (3.1a) has the same asymptotic quality. Since $q \in C[0,1]$ and q' has only a finite number of jump discontinuities in $[0,1]$, we can use the representations

$$q(t) = \delta + t \int_0^1 q'(st)\, ds, \tag{4.15a}$$

$$z(t) = \delta + t \int_0^1 z'(st)\, ds \tag{4.15b}$$

to conclude that

$$\begin{aligned} q'(t) - \frac{M(t)}{t} q(t) - f(t) &= q'(t) - z'(t) + \frac{M(t)}{t} t \int_0^1 (q'(st) - z'(st))\, ds \\ &= O(h^m), \quad t \in [0,1]. \end{aligned} \tag{4.16}$$

This means that the refined bounds (4.13), (4.14), and (4.16) hold for the fundamental modes P_k and the particular solution $\tilde{p}$ in (4.8). To show that these bounds also hold for the solution p of (4.2), we have to estimate the differences $|a_k - b_k|$ for $k = 1, \dots, r$. We substitute (3.5) and (4.8) into (3.1b) and obtain a system of linear equations for $a_k - b_k$. This system is nonsingular since Q from (3.4) is nonsingular and $P(1) = Z(1) + O(h^m)$. This implies

$$b_k = a_k + O(h^m), \quad k = 1, \dots, r; \tag{4.17}$$

see also [10, Theorem 4.5].

Consequently, the following result holds.

THEOREM 4.3. *Consider the solution $p \in B_1$ of (4.2) as an approximation of the (sufficiently smooth[5]) solution z of (3.1). Then, for a sufficiently small stepsize h and a suitable $i_0 \le N-1$, the following bounds hold:*

$$z(t) - p(t) = \tilde{E} O(h^m) + \tau_{i+1} O(h^m), \quad t \in J_i,\ i = 0, \dots, i_0, \tag{4.18a}$$

$$\|z' - p'\|_{[0,1]} = O(h^m), \tag{4.18b}$$

$$\left| p'(t) - \frac{M(t)}{t} p(t) - f(t) \right| = O(h^m), \quad t \in [0,1]. \tag{4.18c}$$

Proof. The result follows immediately on noting that $P(t)$ can also be written in a form given by (4.15a), and therefore

$$\begin{aligned} z(t) - p(t) &= \sum_{k=1}^{r} a_k (Z_k(t) - P_k(t)) + \sum_{k=1}^{r} (a_k - b_k) P_k(t) + \tilde{z}(t) - \tilde{p}(t) \\ &= \tau_{i+1} O(h^m) + (\tilde{E} + tO(1)) O(h^m) + \tau_{i+1} O(h^m), \quad t \in J_i. \end{aligned}$$

[5] We require that $z \in C^{m+1}[0,1]$, which holds if $f \in C^m[0,1]$ and $M \in C^{m+1}[0,1]$.

The bounds (4.18b) and (4.18c) are direct consequences of this representation. ∎

To prove the analogous convergence results for nonlinear problems, we use techniques developed in [17]. In order to show the existence of the solution and derive the error bounds, we rewrite the problem in an abstract Banach space setting and apply the Banach fixed point theorem. The arguments are similar to those given in the proof of [17, Theorem 3.6], but we cannot use this theorem directly, because some of the assumptions made there are violated and, also, a refined error estimate is required. Therefore, we need to repeat the main steps of the proof.

We write the collocation problem as an operator equation

$$F(p) = 0, \tag{4.19}$$

where $F : B_1 \to B_2$ is defined by

$$F(p) = \begin{pmatrix} p'(t_{i,j}) - \frac{M(t_{i,j})}{t_{i,j}} p(t_{i,j}) - f(t_{i,j}, p(t_{i,j})), \quad i = 0, \dots, N-1,\ j = 1, \dots, m \\ B_a p(0) + B_b p(1) - \beta \end{pmatrix},$$

and B_1 and B_2 are Banach spaces,

$$B_1 = (\{q \in \mathbb{P}_m :\ M(0)q(0) = 0\}, \|\cdot\|_{[0,1]}), \quad B_2 = (\mathbb{R}^{Nmn+r}, |\cdot|).$$

For $p \in B_1$, the Fréchet derivative $DF(p) : B_1 \to B_2$ of F is given by

$$DF(p)q = \begin{pmatrix} q'(t_{i,j}) - \frac{M(t_{i,j})}{t_{i,j}} q(t_{i,j}) - D_2 f(t_{i,j}, p(t_{i,j}))q(t_{i,j}), \quad i = 0, \dots, N-1,\ j = 1, \dots, m \\ B_a q(0) + B_b q(1) \end{pmatrix},$$

where $D_2 f(t, z)$ is the Fréchet derivative of f with respect to z.

If $D_2 f$ is Lipschitz, then DF also satisfies a Lipschitz condition with the same constant,

$$\begin{aligned} |(DF(p_1) - DF(p_2))q| &= \left| \begin{pmatrix} (D_2 f(t_{i,j}, p_1(t_{i,j})) - D_2 f(t_{i,j}, p_2(t_{i,j})))q(t_{i,j}) \ \ \forall\, i, j \\ 0 \end{pmatrix} \right| \\ &\le L \|p_1 - p_2\|_{[0,1]} \|q\|_{[0,1]}. \end{aligned}$$

For the convergence proof, we require all assumptions from section 3 to hold. In particular, this means that an isolated, smooth solution z of (1.1) exists. Using this function, we now construct an auxiliary element $p_{\mathrm{ref}} \in B_1$ for the proof of the existence of a solution p of (4.1). We require that p_{ref} satisfy

$$p'_{\mathrm{ref}}(t_{i,j}) = z'(t_{i,j}), \quad i = 0, \dots, N-1,\ j = 1, \dots, m, \tag{4.20a}$$

$$B_a p_{\mathrm{ref}}(0) + B_b p_{\mathrm{ref}}(1) = \beta. \tag{4.20b}$$

Since p'_{ref} is a piecewise polynomial of degree $\le m-1$, it is uniquely defined by the system (4.20a). Moreover,

$$\|z' - p'_{\mathrm{ref}}\|_{[0,1]} = O(h^m). \tag{4.21}$$

Representing p_{ref} by means of (4.15a), we conclude that

$$z(t) - p_{\mathrm{ref}}(t) = \tilde{E}(r_1 - r_2) + tO(h^m), \quad r_1, r_2 \in \mathbb{R}^r.$$

Substitution into (4.20b) yields

$$(B_a + B_b)\tilde{E}(r_1 - r_2) = O(h^m).$$

For further analysis, we assume that

$$\tilde{Q} := (B_a + B_b)\tilde{E} \quad \text{is nonsingular.} \tag{4.22}$$

This implies $r_1 - r_2 = O(h^m)$, and consequently

$$z(t) - p_{\mathrm{ref}}(t) = \tilde{E}O(h^m) + tO(h^m). \tag{4.23}$$

Remark. Assumption (4.22) is quite natural. If we require that boundary value problems consisting of (1.1a) posed on intervals $(0, b]$, $0 < b \leq 1$, and boundary conditions $M(0)z(0) = 0$ and $B_a z(0) + B_b z(b) = \beta$ have unique, continuous solutions, then (4.22) follows. Moreover, we can interpret (4.20) as the (regular) collocation problem associated with the boundary value problem

$$\begin{aligned} &y'(t) = z'(t), \quad t \in (0, 1], \\ &B_a y(0) + B_b y(1) = \beta, \\ &M(0)y(0) = 0. \end{aligned}$$

Obviously, $y(t) = z(t)$ is a solution of this reconstruction problem, and if we require the solution to be unique, then (4.22) must hold. Note that (4.22) always holds for problems with separated boundary conditions.

We now use (4.23) to derive the following relation:

$$\begin{aligned} F(p_{\mathrm{ref}}) &= \begin{pmatrix} p'_{\mathrm{ref}}(t_{i,j}) - \frac{M(t_{i,j})}{t_{i,j}} p_{\mathrm{ref}}(t_{i,j}) - f(t_{i,j}, p_{\mathrm{ref}}(t_{i,j})) \ \ \forall\, i,j \\ B_a p_{\mathrm{ref}}(0) + B_b p_{\mathrm{ref}}(1) - \beta \end{pmatrix} \\ &= \begin{pmatrix} p'_{\mathrm{ref}}(t_{i,j}) - z'(t_{i,j}) - \frac{M(t_{i,j})}{t_{i,j}} (p_{\mathrm{ref}}(t_{i,j}) - z(t_{i,j})) \\ \qquad\qquad -f(t_{i,j}, p_{\mathrm{ref}}(t_{i,j})) + f(t_{i,j}, z(t_{i,j})) \ \ \forall\, i,j \\ 0 \end{pmatrix} \\ &= \begin{pmatrix} \frac{M(0)}{t_{i,j}} (\tilde{E}O(h^m) + t_{i,j}O(h^m)) + O(h^m) \ \ \forall\, i,j \\ 0 \end{pmatrix} \\ &= \begin{pmatrix} O(h^m) \\ 0 \end{pmatrix}. \end{aligned} \tag{4.24}$$

Finally, we give an estimate for $DF^{-1}(p_{\mathrm{ref}})$. Note that

$$q := DF^{-1}(p_{\mathrm{ref}}) \left(\begin{pmatrix} \gamma_{i,j} \ \ \forall\, i,j \\ \tilde{\beta} \end{pmatrix} \right)$$

is the solution of the linear collocation problem

$$q'(t_{i,j}) = \frac{M(t_{i,j})}{t_{i,j}} q(t_{i,j}) + D_2 f(t_{i,j}, p_{\mathrm{ref}}(t_{i,j}))q(t_{i,j}) + \gamma_{i,j} \ \ \forall\, i,j, \tag{4.25a}$$

$$B_a q(0) + B_b q(1) = \tilde{\beta}. \tag{4.25b}$$

Since for sufficiently small h, p_{ref} is in $T_\rho(z)$, this problem is well defined. Finally, from Theorem 4.2, we have

$$\|q\|_{J_i} \leq \text{const.}\, (|\tilde{\beta}| + \tau_{i+1}\gamma_i), \tag{4.26}$$

where

$$\gamma_i = \max_{\substack{l=0,\dots,i \\ j=1,\dots,m}} |\gamma_{l,j}|.$$

With these preliminary results we can prove the next theorem.

THEOREM 4.4. *Let z be an isolated, sufficiently smooth solution of* (1.1). *For sufficiently small h and $\rho > 0$, the nonlinear collocation scheme* (4.1) *has a unique solution p in the tube $T_\rho(z)$ around z. Moreover, the estimates* (4.18) *hold.*

Proof. We proceed in a manner similar to the proof of [17, Theorem 3.6]. Define a mapping $G : B_1 \to B_1$,

$$G(q) := q - DF^{-1}(p_{\mathrm{ref}})F(q). \tag{4.27}$$

Obviously, $F(p) = 0$ is equivalent to the fixed point equation $G(p) = p$. We use the Banach fixed point theorem to show that this equation has a unique solution in a suitably chosen closed ball

$$K := K(p_{\mathrm{ref}}, \rho_0) := \{q \in B_1 : \ \|q - p_{\mathrm{ref}}\|_{[0,1]} \le \rho_0\}.$$

To show that G is a contraction, we write

$$q := G(p_1) - G(p_2) = DF^{-1}(p_{\mathrm{ref}})(DF(p_{\mathrm{ref}}) - \widehat{DF}(p_1, p_2))(p_1 - p_2)$$

for $p_1, p_2 \in K$, where

$$\widehat{DF}(p_1, p_2) := \int_0^1 DF(\tau p_1 + (1-\tau)p_2)\, d\tau.$$

Consequently, q is the solution of the scheme (4.25), where

$$\begin{aligned}\left|\begin{pmatrix} \gamma_{i,j} \ \ \forall\, i,j \\ \tilde{\beta} \end{pmatrix}\right| &= \left|\int_0^1 (DF(p_{\mathrm{ref}}) - DF(\tau p_1 + (1-\tau)p_2))\, d\tau (p_1 - p_2)\right| \\ &\le L\rho_0 \|p_1 - p_2\|_{[0,1]}\end{aligned}$$

due to the Lipschitz condition which DF satisfies. Thus, it follows from (4.26) that G is a contraction with constant $\tilde{L} < 1$ if ρ_0 is sufficiently small. To show that G maps K into itself, we estimate for $q \in K$,

$$\|p_{\mathrm{ref}} - G(q)\|_{[0,1]} \le \|p_{\mathrm{ref}} - G(p_{\mathrm{ref}})\|_{[0,1]} + \|G(p_{\mathrm{ref}}) - G(q)\|_{[0,1]},$$

where $p_{\mathrm{ref}} - G(p_{\mathrm{ref}}) = DF^{-1}(p_{\mathrm{ref}})F(p_{\mathrm{ref}})$ is the solution of (4.25) with $\gamma_{i,j} = O(h^m)$ and $\tilde{\beta} = 0$; cf. (4.24). Thus,

$$\|p_{\mathrm{ref}} - G(q)\|_{[0,1]} \le O(h^m) + \tilde{L}\rho_0 \le \rho_0, \tag{4.28}$$

provided that h is sufficiently small. The Banach fixed point theorem now implies that a solution $p \in B_1$ of (4.1) exists.

We now prove the convergence results (4.18). From

$$\begin{aligned}\|p_{\mathrm{ref}} - p\|_{J_i} = \|p_{\mathrm{ref}} - G(p)\|_{J_i} &\le \|p_{\mathrm{ref}} - G(p_{\mathrm{ref}})\|_{J_i} + \|G(p_{\mathrm{ref}}) - G(p)\|_{J_i} \\ &\le \tau_{i+1} O(h^m) + \tilde{L}\|p_{\mathrm{ref}} - p\|_{J_i}\end{aligned}$$

we have $\|p_{\rm ref} - p\|_{J_i} \le \tau_{i+1} O(h^m)$, which together with (4.23) yields

$$\begin{aligned} z(t) - p(t) &= z(t) - p_{\rm ref}(t) + p_{\rm ref}(t) - p(t) \\ &= \tilde{E} O(h^m) + t O(h^m) + \tau_{i+1} O(h^m), \quad t \in J_i. \end{aligned} \tag{4.29}$$

Consequently, (4.18a) follows. Next, we choose a piecewise polynomial function $e \in B_1$ satisfying $e'(t_{i,j}) = z'(t_{i,j}) - p'(t_{i,j})$. Therefore, $e'(t) = z'(t) - p'(t) + O(h^m)$. Moreover, (4.29) implies

$$\begin{aligned} e'(t_{i,j}) &= z'(t_{i,j}) - p'(t_{i,j}) \\ &= \frac{M(t_{i,j})}{t_{i,j}} (z(t_{i,j}) - p(t_{i,j})) + f(t_{i,j}, z(t_{i,j})) - f(t_{i,j}, p(t_{i,j})) \\ &= O(h^m), \quad i = 0, \dots, N-1,\ j = 1, \dots, m. \end{aligned}$$

Thus $e'(t) = O(h^m) = z'(t) - p'(t) + O(h^m)$ and (4.18b) follows. Finally, (4.18c) is shown by using (4.18b), (4.29), and the Lipschitz condition for f in

$$\begin{aligned} p'(t) - \frac{M(t)}{t} p'(t) - f(t, p(t)) \\ = p'(t) - z'(t) + \frac{M(t)}{t} (p(t) - z(t)) - f(t, p(t)) + f(t, z(t)) \\ = O(h^m), \quad t \in [0, 1]. \qquad \square \end{aligned}$$

Under the previous assumptions we can also show that Newton's method converges quadratically when it is applied to compute the collocation solution p, provided that the starting approximation $p^{[0]}$ is chosen sufficiently close to $p_{\rm ref}$.

THEOREM 4.5. *Let all assumptions of Theorem* 4.4 *hold. Newton's method converges quadratically to the solution* $p \in K(p_{\rm ref}, \rho_0)$ *of* (4.1) *if the starting iterate* $p^{[0]}$ *is chosen in a ball* $K(p_{\rm ref}, \rho_1)$, $\rho_1 \le \rho_0$, *provided that* ρ_0, ρ_1, *and the stepsize* h *are sufficiently small.*

Proof. The proof is analogous to that of [17, Theorem 3.7], taking into account the modifications made earlier in the proof of Theorem 4.4.

We write[6]

$$DF(q) = DF(p_{\rm ref})(I + DF^{-1}(p_{\rm ref})(DF(q) - DF(p_{\rm ref})))$$

for $q \in K(p_{\rm ref}, \rho_0)$ and use the bound for $DF^{-1}(p_{\rm ref})$, the Lipschitz condition for DF, and the Banach lemma to show that $DF^{-1}(q)$ is bounded if ρ_0 is sufficiently small,

$$\|DF^{-1}(q)\|_{[0,1]} \le K_{\rho_0}, \tag{4.30}$$

where K_{ρ_0} is a constant depending on ρ_0. Furthermore, let $p^{[0]} \in K(p_{\rm ref}, \rho_1)$; then

$$\begin{aligned} p^{[1]} - p^{[0]} &= -DF^{-1}(p^{[0]}) F(p^{[0]}) \\ &= -DF^{-1}(p^{[0]}) F(p_{\rm ref}) + DF^{-1}(p^{[0]}) (\widehat{DF}(p_{\rm ref}, p^{[0]})(p_{\rm ref} - p^{[0]})) \end{aligned}$$

[6] I is the identical mapping on the space of operators mapping $B_1 \to B_2$, that is, $I : DF(p_{\rm ref}) \mapsto DF(p_{\rm ref})$.

holds, with $\widehat{DF}(p_1, p_2)$ specified in Theorem 4.4. Using the Lipschitz condition for DF, we obtain

$$\begin{aligned}
&\|DF^{-1}(p^{[0]})\widehat{DF}(p_{\mathrm{ref}}, p^{[0]})(p_{\mathrm{ref}} - p^{[0]})\|_{[0,1]} \\
&\quad = \|p_{\mathrm{ref}} - p^{[0]} + DF^{-1}(p^{[0]})(\widehat{DF}(p_{\mathrm{ref}}, p^{[0]}) - DF(p^{[0]}))(p_{\mathrm{ref}} - p^{[0]})\|_{[0,1]} \\
&\quad \le \left(1 + \frac{L\rho_1}{2} K_{\rho_0}\right) \rho_1 =: C\rho_1.
\end{aligned}$$

Finally, we conclude

$$\|p^{[1]} - p^{[0]}\|_{[0,1]} \le K_{\rho_0} O(h^m) + C\rho_1.$$

Consider a ball $K(p^{[0]}, r)$. For a sufficiently small ρ_1 it is possible to choose the radius $r \le \rho_0$ in such a way that $K(p^{[0]}, r) \subseteq K(p_{\mathrm{ref}}, \rho_0)$. Moreover, let

$$\|DF^{-1}(p^{[0]})(DF(q_1) - DF(q_2))\|_{[0,1]} \le \omega(\|q_1 - q_2\|_{[0,1]}) \quad \forall\, q_1, q_2 \in K(p^{[0]}, r),$$

and choose r such that the condition $\omega(r) = 2K_{\rho_0} L r \le 1/2$ holds. Consequently,

$$\|p^{[1]} - p^{[0]}\|_{[0,1]} \le K_{\rho_0} O(h^m) + C\rho_1 \le (1 - 2\omega(r))r,$$

provided that ρ_1 and h are sufficiently small; cf. [16, formula (6c)]. This implies that the assumptions of [16, Theorem 1] are satisfied and the quadratic convergence of Newton's method in $K(p^{[0]}, r)$ follows. ∎

5. The error estimate. In this section, we analyze an error estimate based on the defect correction principle for the numerical solution p on the collocation grid Δ^m. For reasons explained in section 1, it is sufficient for practical purposes to consider equidistant collocation (cf. (2.2)), where we choose m even. However, the argument is valid on any collocation grid with $t_{i,m} < t_{i,m+1},\ i = 0, \ldots, N-1$.

Our estimate was introduced in [5], where it was shown to be asymptotically correct for regular problems. The numerical solution p obtained by collocation is used to define a "neighboring problem" to (1.1). The original and neighboring problems are solved by the backward Euler method at the points $t_{i,j},\ i = 0, \ldots, N-1,\ j = 1, \ldots, m+1$. This yields the grid vectors[7] $\xi_{i,j}$ and $\pi_{i,j}$ as the solutions of the following schemes, subject to boundary conditions (1.1b) and (1.1c):

$$\frac{\xi_{i,j} - \xi_{i,j-1}}{t_{i,j} - t_{i,j-1}} = \frac{M(t_{i,j})}{t_{i,j}} \xi_{i,j} + f(t_{i,j}, \xi_{i,j}), \quad \text{and} \tag{5.1a}$$

$$\frac{\pi_{i,j} - \pi_{i,j-1}}{t_{i,j} - t_{i,j-1}} = \frac{M(t_{i,j})}{t_{i,j}} \pi_{i,j} + f(t_{i,j}, \pi_{i,j}) + \bar{d}_{i,j}, \tag{5.1b}$$

where $\bar{d}_{i,j}$ is a defect term defined by

$$\bar{d}_{i,j} := \frac{p(t_{i,j}) - p(t_{i,j-1})}{t_{i,j} - t_{i,j-1}} - \sum_{k=1}^{m+1} \alpha_{j,k} \left(\frac{M(t_{i,k})}{t_{i,k}} p(t_{i,k}) + f(t_{i,k}, p(t_{i,k})) \right). \tag{5.2}$$

Here, the coefficients $\alpha_{j,k}$ are chosen in such a way that the quadrature rules given by

$$\frac{1}{t_{i,j} - t_{i,j-1}} \int_{t_{i,j-1}}^{t_{i,j}} \varphi(\tau)\, d\tau \approx \sum_{k=1}^{m+1} \alpha_{j,k} \varphi(t_{i,k})$$

[7] Here and in Theorem 5.1, we assume throughout $i = 0, \ldots, N-1,\ j = 1, \ldots, m+1$.

have precision $m+1$.

In the next theorem, we show that the difference $\xi_{\Delta^m} - \pi_{\Delta^m}$ is an asymptotically correct estimate for the global error of the collocation solution, $R_{\Delta^m}(z) - R_{\Delta^m}(p)$.

THEOREM 5.1. *Assume that the singular boundary value problem* (1.1) *has an isolated (sufficiently smooth*[8]*) solution z. Then, provided that h is sufficiently small, the following estimate holds:*

$$\|(R_{\Delta^m}(z) - R_{\Delta^m}(p)) - (\xi_{\Delta^m} - \pi_{\Delta^m})\|_{\Delta^m} = O(|\ln(h)|^{n_0-1} h^{m+1}), \tag{5.3}$$

with n_0 specified in Lemma 4.1.

Proof. The general idea of the proof is similar to that for regular problems. In particular, the smooth nonlinear part in the right-hand side of (1.1a) can be treated analogously. Therefore, we give a general outline of the proof here and discuss those aspects which are crucial for the singular case. For further technical details we refer the reader to [5].

Let

$$\varepsilon_{\Delta^m} := \xi_{\Delta^m} - R_{\Delta^m}(z), \quad \bar{\varepsilon}_{\Delta^m} := \pi_{\Delta^m} - R_{\Delta^m}(p); \tag{5.4}$$

then the quantity to be estimated is

$$\tilde{\varepsilon}_{\Delta^m} := (R_{\Delta^m}(p) - R_{\Delta^m}(z)) - (\pi_{\Delta^m} - \xi_{\Delta^m}) = \varepsilon_{\Delta^m} - \bar{\varepsilon}_{\Delta^m}. \tag{5.5}$$

Here, ε_{Δ^m}, the error of the backward Euler scheme applied to the original problem, satisfies

$$\begin{aligned} \frac{\varepsilon_{i,j} - \varepsilon_{i,j-1}}{t_{i,j} - t_{i,j-1}} &= \frac{M(t_{i,j})}{t_{i,j}} \xi_{i,j} + f(t_{i,j}, \xi_{i,j}) - \frac{z(t_{i,j}) - z(t_{i,j-1})}{t_{i,j} - t_{i,j-1}} \\ &= \frac{M(t_{i,j})}{t_{i,j}} \xi_{i,j} + f(t_{i,j}, \xi_{i,j}) \\ &\quad - \sum_{k=1}^{m+1} \alpha_{j,k} \left(\frac{M(t_{i,k})}{t_{i,k}} z(t_{i,k}) + f(t_{i,k}, z(t_{i,k})) \right) + O(h^{m+1}), \end{aligned} \tag{5.6}$$

since the $\alpha_{j,k}$ define quadrature rules of precision $O(h^{m+1})$. Moreover, $\bar{\varepsilon}_{\Delta^m}$ satisfies

$$\begin{aligned} \frac{\bar{\varepsilon}_{i,j} - \bar{\varepsilon}_{i,j-1}}{t_{i,j} - t_{i,j-1}} &= \frac{M(t_{i,j})}{t_{i,j}} \pi_{i,j} + f(t_{i,j}, \pi_{i,j}) + \bar{d}_{i,j} - \frac{p(t_{i,j}) - p(t_{i,j-1})}{t_{i,j} - t_{i,j-1}} \\ &= \frac{M(t_{i,j})}{t_{i,j}} \pi_{i,j} + f(t_{i,j}, \pi_{i,j}) \\ &\quad - \sum_{k=1}^{m+1} \alpha_{j,k} \left(\frac{M(t_{i,k})}{t_{i,k}} p(t_{i,k}) + f(t_{i,k}, p(t_{i,k})) \right). \end{aligned} \tag{5.7}$$

Both (5.6) and (5.7) hold for $i = 0, \ldots, N-1$, $j = 1, \ldots, m+1$, and ε_{Δ^m} as well as $\bar{\varepsilon}_{\Delta^m}$ satisfy homogeneous boundary conditions.

In order to proceed, we use Taylor's theorem to conclude that

$$\begin{aligned} f(t_{i,j}, \xi_{i,j}) - f(t_{i,j}, z(t_{i,j})) &= \int_0^1 D_2 f(t_{i,j}, z(t_{i,j}) + \tau(\xi_{i,j} - z(t_{i,j}))) \, d\tau \cdot \varepsilon_{i,j} \\ &=: A(t_{i,j}) \varepsilon_{i,j}, \end{aligned} \tag{5.8}$$

[8] In fact, we require $z \in C^{m+2}[0,1]$.

and analogously

$$f(t_{i,j},\pi_{i,j}) - f(t_{i,j},p(t_{i,j})) =: \bar{A}(t_{i,j})\bar{\varepsilon}_{i,j}. \tag{5.9}$$

Next, we note that due to (4.18c),

$$\begin{aligned}\bar{d}_{i,j} &= \frac{p(t_{i,j}) - p(t_{i,j-1})}{t_{i,j} - t_{i,j-1}} - \sum_{k=1}^{m+1} \alpha_{j,k} \left(\frac{M(t_{i,k})}{t_{i,k}} p(t_{i,k}) + f(t_{i,k}, p(t_{i,k})) \right) \\ &= \frac{1}{t_{i,j} - t_{i,j-1}} \int_{t_{i,j-1}}^{t_{i,j}} p'(\tau)\, d\tau - \sum_{k=1}^{m+1} \alpha_{j,k} p'(t_{i,k}) \\ &\quad + \alpha_{j,m+1} \left(p'(t_{i,m+1}) - \frac{M(t_{i,m+1})}{t_{i,m+1}} p(t_{i,m+1}) - f(t_{i,m+1}, p(t_{i,m+1})) \right) \\ &= O(h^m). \end{aligned} \tag{5.10}$$

From this we conclude that $\xi_{i,j} = \pi_{i,j} + O(h^m)$ using the following argument.

The backward Euler schemes (5.1a) and (5.1b) can be written as collocation methods with $m = 1$ and the collocating condition posed at the right endpoint of each interval $[t_{i,j-1}, t_{i,j}]$. Thus, we discuss the collocation solutions $\xi(t)$, $\pi(t)$ of two singular boundary value problems whose right-hand sides differ by a term $O(h^m)$. This term can be assumed to be smooth if a suitable interpolant g of $\bar{d}_{i,j}$ is used. More precisely, $\xi(t)$ is an approximation to the solution z of (1.1), and $\pi(t)$ is an approximation to the solution of

$$\begin{aligned} & z'_{\mathrm{def}}(t) = \frac{M(t)}{t} z_{\mathrm{def}}(t) + f(t, z_{\mathrm{def}}(t)) + g(t), \quad t \in (0,1], \\ & B_a z_{\mathrm{def}}(0) + B_b z_{\mathrm{def}}(1) = \beta, \\ & M(0) z_{\mathrm{def}}(0) = 0. \end{aligned}$$

For (1.1), we make the assumption that the analytical problem is stable in the sense that

$$\|z - z_{\mathrm{def}}\|_{[0,1]} \le \text{const.}\, \|g\|_{[0,1]} = O(h^m)$$

holds. For results on this type of stability analysis, see [27].

As in section 4 we can prove that (locally) unique solutions $\xi(t)$ and $\pi(t)$ of (5.1a) and (5.1b) exist in a neighborhood of z and z_{def}, respectively.

Subtracting (5.1b) from (5.1a) and using Taylor expansion about $\pi(t_{i,j})$, we can show that $q(t) := \xi(t) - \pi(t)$ satisfies the linear scheme

$$\frac{q(t_{i,j}) - q(t_{i,j-1})}{t_{i,j} - t_{i,j-1}} = \frac{M(t_{i,j}) + t_{i,j} B(t_{i,j})}{t_{i,j}} q(t_{i,j}) + O(h^m),$$

with a suitable, bounded matrix B and homogeneous boundary conditions. Since this is equivalent to a collocation scheme, we may use [10, Theorem 4.4] with $\gamma = \delta = 0$ (or alternatively a combination of stability results from section 4) to conclude that $\|R_{\Delta^m}(q)\|_{\Delta^m} = \|\xi_{\Delta^m} - \pi_{\Delta^m}\|_{\Delta^m} = O(h^m)$.

Since $\varepsilon_{i,j} = O(h)$ and $\bar{\varepsilon}_{i,j} = O(h)$, we may finally write (see [5])

$$\bar{A}(t_{i,j})\bar{\varepsilon}_{i,j} = A(t_{i,j})\bar{\varepsilon}_{i,j} + (\bar{A}(t_{i,j}) - A(t_{i,j}))\bar{\varepsilon}_{i,j} = A(t_{i,j})\bar{\varepsilon}_{i,j} + O(h^{m+1}).$$

Now we use (5.8), (5.9) to rewrite (5.6), (5.7) and obtain

$$\begin{aligned}\frac{\varepsilon_{i,j}-\varepsilon_{i,j-1}}{t_{i,j}-t_{i,j-1}} &= \frac{M(t_{i,j})}{t_{i,j}}\varepsilon_{i,j} + A(t_{i,j})\varepsilon_{i,j} + \frac{M(t_{i,j})}{t_{i,j}}z(t_{i,j}) + f(t_{i,j},z(t_{i,j})) \\ &\quad - \sum_{k=1}^{m+1}\alpha_{j,k}\left(\frac{M(t_{i,k})}{t_{i,k}}z(t_{i,k}) + f(t_{i,k},z(t_{i,k}))\right) + O(h^{m+1}) \qquad (5.11)\end{aligned}$$

and

$$\begin{aligned}\frac{\bar\varepsilon_{i,j}-\bar\varepsilon_{i,j-1}}{t_{i,j}-t_{i,j-1}} &= \frac{M(t_{i,j})}{t_{i,j}}\bar\varepsilon_{i,j} + A(t_{i,j})\bar\varepsilon_{i,j} + \frac{M(t_{i,j})}{t_{i,j}}p(t_{i,j}) + f(t_{i,j},p(t_{i,j})) \\ &\quad - \sum_{k=1}^{m+1}\alpha_{j,k}\left(\frac{M(t_{i,k})}{t_{i,k}}p(t_{i,k}) + f(t_{i,k},p(t_{i,k}))\right) + O(h^{m+1}). \qquad (5.12)\end{aligned}$$

Systems (5.11) and (5.12) are a pair of "parallel" backward Euler schemes, with related inhomogeneous terms. Let us use the shorthand notation $\phi(t) := f(t,p(t)) - f(t,z(t))$. It can be shown that for the difference in the smooth parts of the inhomogeneous terms, the estimate

$$\begin{aligned}|\phi(t_{i,j}) - \sum_{k=1}^{m+1}\alpha_{j,k}\phi(t_{i,k})| &\le \text{const.}\, h_i\|\phi'\|_{J_i} \\ &\le \text{const.}\, h_i(\|z-p\|_{J_i} + \|z'-p'\|_{J_i}) \le O(h^{m+1}) \qquad (5.13)\end{aligned}$$

holds. To see this we use Taylor expansion of $\phi(t_{i,k})$ about $t_{i,j}$ and the fact that $\sum_{k=1}^{m+1}\alpha_{j,k} = 1\ \forall j$; see [5]. The estimate finally follows from Theorem 4.4.

In the next step, we derive a representation for the difference in the singular terms occurring in the inhomogeneous parts of schemes (5.11) and (5.12). With $\epsilon(t) := z(t) - p(t)$ and with $\sigma := t_{i,j} + \tau(t_{i,k} - t_{i,j})$, we rewrite

$$\begin{aligned}&\frac{M(t_{i,j})}{t_{i,j}}\epsilon(t_{i,j}) - \sum_{k=1}^{m+1}\alpha_{j,k}\frac{M(t_{i,k})}{t_{i,k}}\epsilon(t_{i,k}) \qquad (5.14)\\ &\quad= \frac{M(t_{i,j})}{t_{i,j}}\epsilon(t_{i,j}) - \sum_{k=1}^{m+1}\alpha_{j,k}\left(\frac{M(t_{i,j})}{t_{i,j}}\epsilon(t_{i,j})\right.\\ &\qquad\left. + \int_0^1 \frac{d}{d\sigma}\left(\frac{M(\sigma)}{\sigma}\epsilon(\sigma)\right)\,d\tau(t_{i,k}-t_{i,j})\right)\\ &\quad= \sum_{k=1}^{m+1}\alpha_{j,k}(t_{i,j}-t_{i,k})\int_0^1\left(\frac{M(0)}{\sigma}\epsilon'(\sigma)\right.\\ &\qquad\left. - \frac{M(0)}{\sigma^2}\epsilon(\sigma) + C'(\sigma)\epsilon(\sigma) + C(\sigma)\epsilon'(\sigma)\right)d\tau\\ &\quad= \frac{M(0)}{t_{i,j}}O(h^{m+1}) + O(h^{m+1})\end{aligned}$$

on noting that

$$\frac{1}{\sigma} \le \frac{m}{t_{i,j}}, \quad k = 1,\dots,m+1,\ j = 1,\dots,m,\ \tau\in[0,1],$$

and using the results of Theorem 4.4.

Altogether, we have shown that the error of the error estimate $\tilde{\varepsilon}_{\Delta^m}$ (cf. (5.5)) satisfies a linear Euler difference scheme

$$\frac{\tilde{\varepsilon}_{i,j}-\tilde{\varepsilon}_{i,j-1}}{t_{i,j}-t_{i,j-1}} = \frac{M(t_{i,j})}{t_{i,j}}\tilde{\varepsilon}_{i,j} + A(t_{i,j})\tilde{\varepsilon}_{i,j} + \frac{M(0)}{t_{i,j}}O(h^{m+1}) + O(h^{m+1}) \ \forall\, i,j, \tag{5.15a}$$

$$B_a\tilde{\varepsilon}_{0,0} + B_b\tilde{\varepsilon}_{N-1,m+1} = 0, \tag{5.15b}$$

$$M(0)\tilde{\varepsilon}_{0,0} = 0. \tag{5.15c}$$

This scheme can also be interpreted as a collocation scheme with $m = 1$ where the only collocation point is the right endpoint of every collocation interval. To estimate the solution of (5.15) we use a representation according to (4.8) for $\tilde{\varepsilon}_{\Delta^m}$. Then we apply Theorem 4.2 to derive bounds for the quantities occurring in (4.8), and we conclude that altogether the estimate (5.3) holds for the solution of (5.15). ∎

Remark. Obviously, the arguments used to prove the last theorem are valid for any choice of collocation nodes. The only necessary restriction is $t_{i,m+1} > t_{i,m}$. However, if we consider superconvergent schemes, the error estimate is no longer asymptotically correct, because the basic collocation solution has a higher convergence order in that case. Therefore we restrict ourselves to an even number of equidistant collocation points. This restriction is not severe, since in the case of singular problems, the highest convergence order that can generally be expected at the mesh points τ_i is $O(|\ln(h)|^{n_0-1}h^{m+1})$; see [10].

Finally, we would like to mention an alternative variant of our error estimate closely related to the so-called version B of defect correction according to Stetter [24]. If instead of (5.1) we solve

$$\frac{\zeta_{i,j}-\zeta_{i,j-1}}{t_{i,j}-t_{i,j-1}} = \frac{M(t_{i,j})}{t_{i,j}}\zeta_{i,j} + D(t_{i,j})\zeta_{i,j} - \bar{d}_{i,j}, \tag{5.16}$$

where

$$D(t_{i,j}) := D_2 f(t_{i,j}, p(t_{i,j})),$$

then $\zeta_{i,j}$ is an asymptotically correct error estimate. To see this, we note that the difference between this error estimate and the estimate analyzed earlier in this paper,

$$x_{i,j} := (\xi_{i,j} - \pi_{i,j}) - \zeta_{i,j},$$

satisfies

$$\begin{aligned}\frac{x_{i,j}-x_{i,j-1}}{t_{i,j}-t_{i,j-1}} &= \frac{M(t_{i,j})}{t_{i,j}}x_{i,j} + f(t_{i,j},\xi_{i,j}) - f(t_{i,j},\pi_{i,j}) - D(t_{i,j})\zeta_{i,j}\\ &= \frac{M(t_{i,j})}{t_{i,j}}x_{i,j} + O(h^{m+1}).\end{aligned}$$

Consequently, the error of this error estimate has a bound analogous to (5.3). Note that for linear problems, this alternative error estimate coincides with the variant discussed earlier in the paper. For nonlinear problems, the practical usability and numerical stability of the new estimate still has to be carefully assessed.

6. Numerical examples. To illustrate the theory, we first consider the following nonlinear problem:

$$z'(t) = \frac{1}{t}\begin{pmatrix} 0 & 1 \\ 0 & -1 \end{pmatrix} z(t) + t \begin{pmatrix} 0 \\ -\frac{2(t^2+2)+8}{(t^2+2)^2} z_1^2(t) + \frac{8t^2}{(t^2+2)^2} z_1^3(t) \end{pmatrix}, \tag{6.1a}$$

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} z(0) + \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} z(1) = \begin{pmatrix} 0 \\ 1/\ln(3) \end{pmatrix}. \tag{6.1b}$$

Its exact solution is

$$z(t) = \left(\frac{1}{\ln(t^2+2)}, -\frac{2t^2}{(t^2+2)\ln^2(t^2+2)} \right)^T.$$

The computations were carried out with the subroutines from our MATLAB code `sbvp` (cf. [4]) on fixed, equidistant grids. For the purpose of determining the empirical convergence orders the mesh adaptation strategy was disabled. The tests were performed in IEEE double precision with EPS $\approx 1.11 \cdot 10^{-16}$. In Table 6.1, we give the exact global errors $\mathrm{err}_{\mathrm{coll}}$ of the collocation solutions for the respective mesh width h and the convergence orders p_{coll} computed from the errors for two consecutive stepsizes. Moreover, the errors of the error estimate with respect to the exact global errors, $\mathrm{err}_{\mathrm{est}}$, are recorded, together with associated empirical convergence orders p_{est}. In accordance with the theoretical results from sections 4 and 5, convergence orders $O(h^4)$ for collocation and $O(h^5)$ for the error estimate are observed. This illustrates the asymptotical correctness of the error estimate analyzed in this paper. Test runs given in [4] demonstrate that this error estimate can be used as a dependable basis for a mesh adaptation algorithm, providing an efficient, high precision numerical solver.

TABLE 6.1
Convergence orders of collocation and error estimate for (6.1).

h	$\mathrm{err}_{\mathrm{coll}}$	p_{coll}	$\mathrm{err}_{\mathrm{est}}$	p_{est}
2^{-2}	1.5763e−04		2.2232e−05	
2^{-3}	9.5865e−06	4.04	6.5978e−07	5.07
2^{-4}	5.9574e−07	4.01	1.7873e−08	5.21
2^{-5}	3.7189e−08	4.00	5.1077e−10	5.13
2^{-6}	2.3237e−09	4.00	1.5205e−11	5.07
2^{-7}	1.4522e−10	4.00	4.6274e−13	5.04
2^{-8}	9.0772e−12	4.00	1.4655e−14	4.98

Finally, we demonstrate the favorable performance of our error estimate for a practically relevant example from applications. The following boundary value problem is a model from the theory of shallow spherical shells; see [22], [25]. The transformation of the original two-dimensional system of second order to the first order form yields

$$z'(t) = \frac{1}{t}\begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -2 & 0 \\ 0 & 0 & 0 & -2 \end{pmatrix} z(t) + t \begin{pmatrix} 0 \\ 0 \\ z_2(t)(-\mu^2 + z_1(t)) - 2\gamma \\ z_1(t)(\mu^2 - \frac{1}{2} z_1(t)) \end{pmatrix}, \tag{6.2}$$

where the eigenvalues of $M(0)$ are $\lambda = 0,\ 0,\ -2,\ -2$. The boundary conditions read $z_3(0) = z_4(0) = z_1(1) = 0,\ z_4(1) + 2/3 z_2(1) = 0$, and the parameters are chosen as $\mu = 9,\ \gamma = 6000$. We solve (6.2) using our code `sbvp` [4] equipped with the

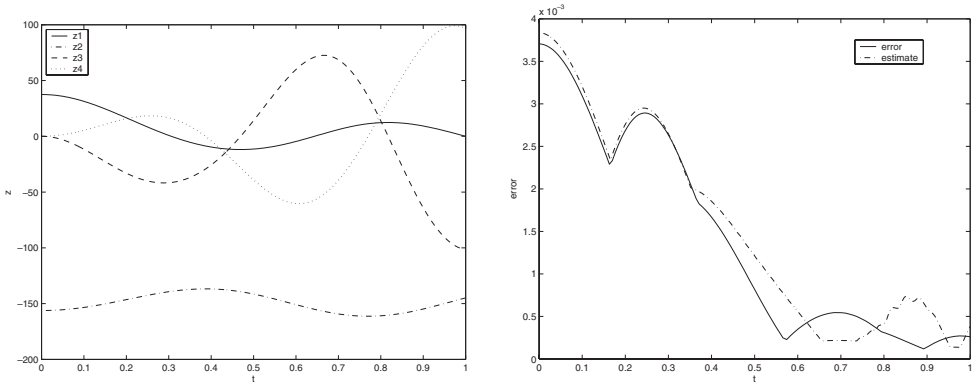

FIG. 6.1. *Solution, global error, and error estimate for* (6.2).

error estimate from section 5 and the adaptive mesh selection routine. The numerical solution satisfies a mixed tolerance requirement with absolute and relative tolerance equal to 10^{-4} at a mesh containing 124 mesh points, where the variation in the mesh width is just below 2. In Figure 6.1 four components of the numerical solution are given, and the estimate of the global error on the final mesh is compared with the error of the collocation solution. In order to calculate the error of the collocation solution we used a reference solution computed with tolerances $5 \cdot 10^{-6}$. The maximum of the error estimate is 0.0038367, and the maximum of the error with respect to the reference solution is 0.003706. For most of the integration interval, the estimate slightly overestimates the "true" error.

Acknowledgment. We wish to thank the referees for their valuable suggestions, in particular for pointing out the alternative variant (5.16).

A FIRST-ORDER SYSTEM LEAST SQUARES FINITE ELEMENT METHOD FOR THE SHALLOW WATER EQUATIONS*

GERHARD STARKE†

Abstract. A least squares finite element method for the first-order system of the shallow water equations is proposed and studied. The method combines a characteristic-based time discretization with a least squares finite element approach which approximates the water level and the velocity field in H^1 and $H(\mathrm{div})$, respectively. The linearized least squares functional is shown to be elliptic, uniformly as the time-step size τ approaches zero, with respect to a suitably weighted norm. Moreover, Lipschitz continuity of the Fréchet derivative is shown with respect to this norm. This implies that the local evaluation of the nonlinear least squares functional constitutes an a posteriori error estimator on which an adaptive refinement technique may be based. The efficiency of such an adaptive finite element approach is tested numerically for a test problem involving the surface flow in a widening channel leading to a recirculating velocity field.

Key words. least squares finite element method, first-order system, shallow water equations, method of characteristics

1. Introduction.

The numerical simulation of surface flow by the system of shallow water equations is of interest for the prediction of, for example, water levels in coastal regions or flood zones. The shallow water equations which are obtained from depth-averaging the Navier–Stokes equations for fluid flow simplify the flow model to a two-dimensional situation. This reduction is permissible under certain assumptions including the fact that the horizontal dimension of the domain is much larger than the vertical one. A lot of effort has been dedicated to the development of accurate and efficient numerical methods for the approximate solution of shallow water equations in recent years. Time discretization based on characteristics has become a standard approach to the numerical simulation of surface flows in the meantime; see, e.g., [18, 9, 14, 17, 2, 12, 8, 10]. The discretization in time based on a coordinate transformation along the characteristics is also used in the analytical study of a numerical approach to the shallow water equations in [7].

Most often, the finite element discretization of the shallow water system uses piecewise quadratic approximations for the velocity components and piecewise linear elements for the elevation (see, e.g., [11]). This combination of finite element spaces constitutes the well-known Taylor–Hood elements and is known to be stable for the mixed variational formulation of the Stokes problem. If viscosity is neglected in the shallow water model, the velocity field need only be $H(\mathrm{div})$-conforming and Raviart–Thomas elements may be used for its approximation. The lowest-order Raviart–Thomas spaces for the velocity field combined with piecewise constants for the elevation are used in [12, 8] for this purpose. The resulting mixed finite element approach for the two-dimensional shallow water equations is contained as a special case in the more general Quasi-three-dimensional multilayer approach treated in [12, 8].

The mixed finite element method by Raviart and Thomas was also employed in [10] where the emphasis was on the incorporation of transparent boundary conditions into the weak formulation.

In this paper, we present a least squares finite element method for the system of shallow water equations. This method does not require the finite element spaces for velocity and elevation to satisfy a compatibility condition. Raviart–Thomas spaces (of arbitrary degree) for the velocity field may be combined with H^1-conforming elements (of arbitrary degree) for the elevation, for example. The elementwise evaluation of the least squares functional constitutes an a posteriori error estimator at no additional cost. This a posteriori error estimator gives rise to adaptive refinement strategies which dramatically increase the accuracy and efficiency of numerical methods in many practical situations (see [3] for a study of such techniques in the least squares finite element context). The use of the local evaluation of nonlinear least squares functionals as an a posteriori error estimator was previously studied in connection to subsurface flow problems in [16, 15]. For surface flow in domains with complicated boundaries, like coastal regions, adaptivity is mandatory to achieve satisfactory results at reasonable computational cost. Adaptive mesh refinement techniques based on error indicators which are conceptually different from the ones derived in this paper are proposed and tested for shallow water flow in [11].

For the above reasons, among others, least squares finite element methods have become increasingly popular in recent years for a number of different application problems; see [5] for an overview. Several least squares formulations for the Navier–Stokes equations have been studied in [4, 6] where the partial derivatives of the velocity field are introduced as additional variables.

In section 2 we introduce the system of shallow water equations and describe the time discretization using a coordinate transformation along the characteristics. The least squares variational formulation in the space of the resulting system is investigated in section 3. In particular, ellipticity of the linearized least squares functional and Lipschitz continuity of the Fréchet derivative is shown with respect to a properly weighted norm. Section 4 treats the discretization by appropriate finite element spaces including adaptive refinement strategies and the solution of the resulting nonlinear least squares problems by Gauss–Newton iterations. Finally, computational results for a test problem modelling recirculating shallow water flow in a channel are presented in section 5.

2. The shallow water equations and method of characteristics. The process variables to be determined are H, the total elevation above the sea bottom, and $\mathbf{u}$, the depth-averaged horizontal velocities. The system of the shallow water equations is then given by

$$\begin{aligned} \partial_t H + \operatorname{div}(H\mathbf{u}) &= 0, \\ \partial_t \mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u} + g\nabla(H - H_b) + c_f \frac{\mathbf{u}|\mathbf{u}|}{H} + \mathbf{F} &= \mathbf{0}, \end{aligned} \tag{2.1}$$

to be satisfied in a region $\Omega \subset \mathbb{R}^2$, where H_b denotes the bathymetric depth under the reference plane, g is the acceleration due to gravity, c_f is the so-called Chezy coefficient for the bottom friction term, and $\mathbf{F}$ comprises additional body and surface forces (cf. [7]). Note that we have neglected the fluid viscosity in (2.1), an assumption that is often admissible in practical situations (see, e.g., [8, 12, 10]).

In order to properly take into account the hyperbolic nature of system (2.1), characteristic-based time discretizations are widely used for the shallow water equa-

tions. To this end, the system (2.1) is reformulated with respect to transformed time-space coordinates. The time coordinate is replaced by the local direction of the characteristics while the spatial coordinates remain unchanged. The characteristic curves $\mathbf{X}(t;s,\mathbf{x})$ associated with the system (2.1) are given by

$$\frac{d}{dt}\mathbf{X}(t;s,\mathbf{x}) = \mathbf{u}(t,\mathbf{X}(t;s,\mathbf{x})) \quad \text{for } t>0,$$
$$\mathbf{X}(s;s,\mathbf{x}) = \mathbf{x},$$

where $\mathbf{X}(t;s,\mathbf{x})$ is the characteristic curve, parametrized by t, passing through the time-space point $(s,\mathbf{x})$. For the transformed process variables

$$\hat{H}(t,\mathbf{x}) = H(t,\mathbf{X}(t;s,\mathbf{x})) \quad \text{and} \quad \hat{\mathbf{u}}(t,\mathbf{x}) = \mathbf{u}(t,\mathbf{X}(t;s,\mathbf{x})),$$

we have

$$\partial_t \hat{H} = \partial_t H + \mathbf{u}\cdot\nabla H,$$
$$\partial_t \hat{\mathbf{u}} = \partial_t \mathbf{u} + (\mathbf{u}\cdot\nabla)\mathbf{u}.$$

With respect to the transformed coordinates, (2.1) therefore turns into

$$\partial_t \hat{H} + \hat{H}\,\mathrm{div}\,\hat{\mathbf{u}} = 0,$$
$$\partial_t \hat{\mathbf{u}} + g\nabla(\hat{H}-H_b) + c_f\frac{\hat{\mathbf{u}}|\hat{\mathbf{u}}|}{\hat{H}} + \mathbf{F} = \mathbf{0}.$$

Using an implicit Euler time discretization we end up with a first-order system of the form

$$\begin{aligned} &\frac{H-\hat{H}^{\mathrm{old}}}{\tau} + H\,\mathrm{div}\,\mathbf{u} = 0 \quad \text{for all } \mathbf{x}\in\Omega,\\ &\frac{\mathbf{u}-\hat{\mathbf{u}}^{\mathrm{old}}}{\tau} + g\nabla(H-H_b) + c_f\frac{\mathbf{u}|\mathbf{u}|}{H} + \mathbf{F} = \mathbf{0} \quad \text{for all } \mathbf{x}\in\Omega \end{aligned} \tag{2.2}$$

for each time step. Here, τ denotes the time-step length, H and $\mathbf{u}$ stand for the unknown solutions at the current time t, while $\hat{H}^{\mathrm{old}}$ and $\hat{\mathbf{u}}^{\mathrm{old}}$ are the solutions at the previous time level $t-\tau$ evaluated at the point $\hat{\mathbf{x}}$ backwards along the characteristic. An implicit Euler scheme is usually sufficient for the approximation of the characteristics. In that case we obtain $\hat{\mathbf{x}} = \mathbf{x} - \tau\mathbf{u}$.

Initial conditions prescribed for H and $\mathbf{u}$ allow the time-stepping procedure to start from time $t=0$. Furthermore, we consider the boundary conditions

$$\begin{aligned} &H = H^D \quad \text{for all } \mathbf{x}\in\Gamma_D,\\ &\mathbf{u}\cdot\mathbf{n} = 0 \quad \text{for all } \mathbf{x}\in\Gamma_N, \end{aligned} \tag{2.3}$$

where Γ_D and Γ_N are boundary segments such that $\Gamma_D\cup\Gamma_N = \partial\Omega$. Physically, this means that at each boundary point either the elevation is prescribed or the normal velocity is set to zero.

3. Least squares formulation of the time-discretized first-order system. Our variational formulation for the solution of the first-order system (2.2) with boundary conditions (2.3) will be based on the spaces

$$H^1_{\Gamma_D}(\Omega) = \{\eta\in H^1(\Omega) : \eta = 0 \text{ on } \Gamma_D\},$$
$$H_{\Gamma_N}(\mathrm{div},\Omega) = \{\mathbf{v}\in H(\mathrm{div},\Omega) : \mathbf{v}\cdot\mathbf{n} = 0 \text{ on } \Gamma_N\}.$$

In addition to the standard norm in $L^2(\Omega)$ which we denote by $\|\cdot\|_{0,\Omega}$, we will also make use of the supremum norm $\|\cdot\|_{\infty,\Omega}$ on $L^\infty(\Omega)$ and the Sobolev space

$$W^{1,\infty}(\Omega) = \{\eta \in L^\infty(\Omega) : \nabla\eta \in L^\infty(\Omega)^2\}.$$

Multiplying the first-order system (2.2) with τ leads to

$$\mathcal{R}(H, \mathbf{u}; \hat{H}^{\mathrm{old}}, \hat{\mathbf{u}}^{\mathrm{old}}) = \begin{pmatrix} H - \hat{H}^{\mathrm{old}} + \tau H \operatorname{div} \mathbf{u} \\ \mathbf{u} - \hat{\mathbf{u}}^{\mathrm{old}} + \tau \left(g\nabla(H - H_b) + c_f \dfrac{\mathbf{u}|\mathbf{u}|}{H} + \mathbf{F} \right) \end{pmatrix} = \mathbf{0}. \tag{3.1}$$

Our aim is to solve (3.1) for $H = H^D + \hat{H}$ with $\hat{H} \in H^1_{\Gamma_D}(\Omega)$ and for $\mathbf{u} \in H_{\Gamma_N}(\operatorname{div}, \Omega)$. To this end, we consider the least squares minimization problem of finding $(\hat{H}, \mathbf{u}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div}, \Omega)$ such that

$$\|\mathcal{R}(H^D + \hat{H}, \mathbf{u}; \hat{H}^{\mathrm{old}}, \hat{\mathbf{u}}^{\mathrm{old}})\|^2_{0,\Omega} \le \|\mathcal{R}(H^D + \eta, \mathbf{v}; \hat{H}^{\mathrm{old}}, \hat{\mathbf{u}}^{\mathrm{old}})\|^2_{0,\Omega} \tag{3.2}$$

holds for all $(\eta, \mathbf{v}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div}, \Omega)$.

For the linearization, the Fréchet derivative of $\mathcal{R}$ with respect to $(H, \mathbf{u})$ is of interest. It is given by

$$\mathcal{J}(H, \mathbf{u})[\eta, \mathbf{v}] = \begin{pmatrix} \eta + \tau(H \operatorname{div} \mathbf{v} + \eta \operatorname{div} \mathbf{u}) \\ \mathbf{v} + \tau g \nabla\eta + \tau c_f \left(\dfrac{|\mathbf{u}|}{H}\mathbf{v} + \dfrac{\mathbf{u}}{|\mathbf{u}|H}(\mathbf{u} \cdot \mathbf{v}) \right) - \tau c_f \dfrac{\mathbf{u}|\mathbf{u}|}{H^2}\eta \end{pmatrix}. \tag{3.3}$$

For the well-posedness of the least squares minimization problem (3.2) we need to establish an equivalence of the type

$$\alpha |||(\eta, \mathbf{v})|||^2 \le \|\mathcal{J}(H, \mathbf{u})[\eta, \mathbf{v}]\|^2_{0,\Omega} \le \beta |||(\eta, \mathbf{v})|||^2$$

for all $(\eta, \mathbf{v}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div}, \Omega)$ with positive constants α, β which are independent of τ and with respect to a suitable norm $|||(\cdot, \cdot)|||$. Such an equivalence will also be needed in the next section for the well-posedness of the linear subproblems in a Gauss–Newton iteration and for deriving the property of the least squares functional as an a posteriori error estimator.

Let us start by considering the special case $H \equiv \bar{H} > 0$, $\mathbf{u} \equiv \mathbf{0}$ which is the unique solution of a stationary problem with constant water level. For this rather simple situation we obtain

$$\mathcal{J}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}] = \begin{pmatrix} \eta + \tau \bar{H} \operatorname{div} \mathbf{v} \\ \mathbf{v} + \tau g \nabla\eta \end{pmatrix},$$

which is obviously uniformly equivalent to

$$\tilde{\mathcal{J}}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}] = \begin{pmatrix} \bar{H}^{-1/2}\eta + \tau \bar{H}^{1/2} \operatorname{div} \mathbf{v} \\ g^{-1/2}\mathbf{v} + \tau g^{1/2} \nabla\eta \end{pmatrix}$$

in the sense that

$$\min\{\bar{H}, g\} \|\tilde{\mathcal{J}}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}]\|^2_{0,\Omega} \le \|\mathcal{J}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}]\|^2_{0,\Omega} \le \max\{\bar{H}, g\} \|\tilde{\mathcal{J}}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}]\|^2_{0,\Omega}$$

holds for all $(\eta, \mathbf{v}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div}, \Omega)$. The identity

$$\|\tilde{\mathcal{J}}(\bar{H}, \mathbf{0})[\eta, \mathbf{v}]\|^2_{0,\Omega} = \bar{H}^{-1}\|\eta\|^2_{0,\Omega} + \tau^2\bar{H}\|\operatorname{div}\mathbf{v}\|^2_{0,\Omega} + g^{-1}\|\mathbf{v}\|^2_{0,\Omega} + \tau^2 g\|\nabla\eta\|^2_{0,\Omega}$$

(the cross terms vanish due to integration by parts) suggests the use of the norm

$$|||(\eta, \mathbf{v})||| = (\|\eta\|^2_{0,\Omega} + \tau^2\|\operatorname{div}\mathbf{v}\|^2_{0,\Omega} + \|\mathbf{v}\|^2_{0,\Omega} + \tau^2\|\nabla\eta\|^2_{0,\Omega})^{1/2} \tag{3.4}$$

on $H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div}, \Omega)$.

For the investigation of the general case, it is convenient to use a transformation of variables. To this end, we write (3.3) as

$$\mathcal{J}(H, \mathbf{u})[\eta, \mathbf{v}] = \begin{pmatrix} (1 + \tau\operatorname{div}\mathbf{u})\eta + \tau H\operatorname{div}\mathbf{v} \\ D(H, \mathbf{u})\mathbf{v} + \tau g\nabla\eta - \tau c_f\dfrac{\mathbf{u}|\mathbf{u}|}{H^2}\eta \end{pmatrix}, \tag{3.5}$$

where the matrix

$$D(H, \mathbf{u}) = \left(1 + \tau c_f\frac{|\mathbf{u}|}{H}\right)\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \frac{\tau c_f}{|\mathbf{u}|H}\begin{pmatrix} u_1^2 & u_1u_2 \\ u_1u_2 & u_2^2 \end{pmatrix}$$

is invertible with

$$D(H, \mathbf{u})^{-1} = \frac{1}{1 + \tau c_f\frac{|\mathbf{u}|}{H}}\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} - \frac{\tau c_f}{|\mathbf{u}|H(1 + \tau c_f\frac{|\mathbf{u}|}{H})(1 + 2\tau c_f\frac{|\mathbf{u}|}{H})}\begin{pmatrix} u_1^2 & u_1u_2 \\ u_1u_2 & u_2^2 \end{pmatrix}.$$

Of course, this formula is valid only for $\mathbf{u} \neq \mathbf{0}$, and for vanishing $\mathbf{u}$ we simply have $D(H, \mathbf{u}) = I$. Note that, in particular,

$$D(H, \mathbf{u})^{-1}\mathbf{u} = \frac{1}{1 + \tau c_f\frac{|\mathbf{u}|}{H}}\left(1 - \frac{\tau c_f\frac{|\mathbf{u}|}{H}}{1 + 2\tau c_f\frac{|\mathbf{u}|}{H}}\right)\mathbf{u} = \frac{1}{1 + 2\tau c_f\frac{|\mathbf{u}|}{H}}\mathbf{u}. \tag{3.6}$$

Obviously, for any $\mathbf{z} \in H_{\Gamma_N}(\operatorname{div}, \Omega)$,

$$\mathbf{z} \cdot D(H, \mathbf{u})\mathbf{z} = \left(1 + \tau c_f\frac{|\mathbf{u}|}{H}\right)|\mathbf{z}|^2 + \tau c_f\frac{1}{|\mathbf{u}|H}(\mathbf{u} \cdot \mathbf{z})^2 \geq \left(1 + \tau c_f\frac{|\mathbf{u}|}{H}\right)|\mathbf{z}|^2. \tag{3.7}$$

Similarly, for $D(H, \mathbf{u})^{-1}$ the estimate

$$\begin{aligned} \mathbf{z} \cdot D(H, \mathbf{u})^{-1}\mathbf{z} &= \frac{1}{1 + \tau c_f\frac{|\mathbf{u}|}{H}}\left(|\mathbf{z}|^2 - \frac{\tau c_f(\mathbf{u} \cdot \mathbf{z})^2}{|\mathbf{u}|H(1 + 2\tau c_f\frac{|\mathbf{u}|}{H})}\right) \\ &\geq \frac{1}{1 + \tau c_f\frac{|\mathbf{u}|}{H}}|\mathbf{z}|^2\left(1 - \tau c_f\frac{|\mathbf{u}|}{H(1 + 2\tau c_f\frac{|\mathbf{u}|}{H})}\right) = \frac{|\mathbf{z}|^2}{1 + 2\tau c_f\frac{|\mathbf{u}|}{H}} \end{aligned} \tag{3.8}$$

holds.

In what follows, we abbreviate our notation by omitting the dependence of D on H and $\mathbf{u}$. Inserting

$$\mathbf{v} = \mathbf{w} + \tau c_f \frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta$$

into (3.5), $\mathcal{J}(H,\mathbf{u})[\eta,\mathbf{v}]$ turns into

$$\tilde{\mathcal{J}}(H,\mathbf{u})[\eta,\mathbf{w}] = \begin{pmatrix} (1+\tau \operatorname{div}\mathbf{u})\eta + \tau H \operatorname{div}\mathbf{w} + \tau^2 c_f H \operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta\right) \\ D\mathbf{w} + \tau g \nabla\eta \end{pmatrix}. \tag{3.9}$$

LEMMA 3.1. *If $H \in W^{1,\infty}(\Omega)$, $\mathbf{u} \in W^{1,\infty}(\Omega)^2$, and $H \geq H_*$ with a constant $H_* > 0$, then, for any $\eta \in H^1_{\Gamma_D}(\Omega)$, the mapping*

$$\mathbf{v} \mapsto \mathbf{v} - \tau c_f \frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta =: \mathbf{w}$$

is bijective in $H_{\Gamma_N}(\operatorname{div},\Omega)$. Moreover, there is a constant $\gamma > 0$ which is independent of τ such that, under the above transformation,

$$\frac{1}{\gamma}|||(\eta,\mathbf{v})||| \leq |||(\eta,\mathbf{w})||| \leq \gamma|||(\eta,\mathbf{v})||| \tag{3.10}$$

holds, uniformly as $\tau \to 0$, for all $(\eta,\mathbf{v}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div},\Omega)$.

Proof. Since $\mathbf{n}\cdot\mathbf{u} = 0$ on Γ_N, (3.6) implies that also $\mathbf{n}\cdot(D^{-1}\mathbf{u}) = 0$ on Γ_N. Therefore, $\mathbf{n}\cdot\mathbf{v} = 0$ on Γ_N if and only if $\mathbf{n}\cdot\mathbf{w} = 0$ on Γ_N. Moreover, from (3.6) we obtain

$$\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u}) = \frac{|\mathbf{u}|}{H(H+2\tau c_f|\mathbf{u}|)}\mathbf{u} \tag{3.11}$$

leading to

$$\left\|\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right\|_{\infty,\Omega} \leq \left\|\frac{\mathbf{u}}{H}\right\|^2_{\infty,\Omega} \leq \left(\frac{\|\mathbf{u}\|_{\infty,\Omega}}{H_*}\right)^2 =: C_1. \tag{3.12}$$

From (3.11) we also obtain

$$\begin{aligned}\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right) &= \mathbf{u}\cdot\nabla\left(\frac{|\mathbf{u}|}{H(H+2\tau c_f|\mathbf{u}|)}\right) + \frac{|\mathbf{u}|}{H(H+2\tau c_f|\mathbf{u}|)}\operatorname{div}\mathbf{u} \\ &= \frac{\mathbf{u}\cdot(H^2\nabla(|\mathbf{u}|) - 2|\mathbf{u}|(H+\tau c_f|\mathbf{u}|)\nabla H)}{H^2(H+2\tau c_f|\mathbf{u}|)^2} + \frac{|\mathbf{u}|}{H(H+2\tau c_f|\mathbf{u}|)}\operatorname{div}\mathbf{u}.\end{aligned}$$

Using $|\nabla(|\mathbf{u}|)| \leq |\nabla\mathbf{u}|$ the above identity leads to

$$\begin{aligned}&\left\|\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right)\right\|_{\infty,\Omega} \\ &\quad\leq \left\|\frac{|\mathbf{u}|\,|\nabla\mathbf{u}|}{H^2}\right\|_{\infty,\Omega} + 2\left\|\frac{|\mathbf{u}|^2|\nabla H|}{H^3}\right\|_{\infty,\Omega} + \left\|\frac{|\mathbf{u}|\,|\operatorname{div}\mathbf{u}|}{H^2}\right\|_{\infty,\Omega} \\ &\quad\leq 2\left\|\frac{\mathbf{u}}{H}\right\|_{\infty,\Omega}\left(\left\|\frac{\nabla\mathbf{u}}{H}\right\|_{\infty,\Omega} + \left\|\frac{\mathbf{u}}{H}\right\|_{\infty,\Omega}\left\|\frac{\nabla H}{H}\right\|_{\infty,\Omega}\right) \\ &\quad\leq 2\frac{\|\mathbf{u}\|_{\infty,\Omega}}{H_*}\left(\frac{\|\nabla\mathbf{u}\|_{\infty,\Omega}}{H_*} + \frac{\|\mathbf{u}\|_{\infty,\Omega}\|\nabla H\|_{\infty,\Omega}}{H_*^2}\right) =: C_2.\end{aligned} \tag{3.13}$$

Therefore,

$$\begin{aligned}\|\mathbf{w}\|_{0,\Omega} &= \left\|\mathbf{v} - \tau c_f \frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta\right\|_{0,\Omega} \le \|\mathbf{v}\|_{0,\Omega} + \tau c_f \left\|\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right\|_{\infty,\Omega} \|\eta\|_{0,\Omega} \\ &\le \|\mathbf{v}\|_{0,\Omega} + \tau c_f C_1 \|\eta\|_{0,\Omega}\end{aligned}$$

and

$$\begin{aligned}\|\operatorname{div}\mathbf{w}\|_{0,\Omega} &= \left\|\operatorname{div}\mathbf{v} - \tau c_f \operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right)\eta - \tau c_f \frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\cdot\nabla\eta\right\|_{0,\Omega} \\ &\le \|\operatorname{div}\mathbf{v}\|_{0,\Omega} + \tau c_f \left\|\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right)\right\|_{\infty,\Omega} \|\eta\|_{0,\Omega} \\ &\quad + \tau c_f \left\|\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right\|_{\infty,\Omega} \|\nabla\eta\|_{0,\Omega} \\ &\le \|\operatorname{div}\mathbf{v}\|_{0,\Omega} + \tau c_f C_2 \|\eta\|_{0,\Omega} + c_f C_1 \tau \|\nabla\eta\|_{0,\Omega},\end{aligned}$$

which leads to

$$\begin{aligned}|||(\eta,\mathbf{w})|||^2 &= \|\eta\|_{0,\Omega}^2 + \tau^2\|\nabla\eta\|_{0,\Omega}^2 + \|\mathbf{w}\|_{0,\Omega}^2 + \tau^2\|\operatorname{div}\mathbf{w}\|_{0,\Omega}^2 \\ &\le (1 + 2\tau^2 c_f^2(C_1^2 + C_2^2))\|\eta\|_{0,\Omega}^2 + (1 + 2c_f^2 C_1^2)\tau^2\|\nabla\eta\|_{0,\Omega}^2 \\ &\quad + 2\|\mathbf{v}\|_{0,\Omega}^2 + 2\tau^2\|\operatorname{div}\mathbf{v}\|_{0,\Omega}^2.\end{aligned}$$

This proves the right inequality in (3.10) with $\gamma = 1 + \max\{1, 2\tau^2 c_f^2(C_1^2 + C_2^2), 2c_f^2 C_1^2\}$. The left inequality follows similarly. ∎

Remark. The linear first-order operator in (3.9) may be reformulated as a second-order operator with respect to η alone. For the resulting second-order differential equation

$$(1 + \tau \operatorname{div}\mathbf{u})\eta + \tau^2 H \operatorname{div}\left(c_f \frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta - gD^{-1}\nabla\eta\right) = 0,$$

however, the unique solvability can only be guaranteed under additional conditions on the coefficients of the operator. In the following theorem ellipticity of the associated least squares functional is established under suitable conditions on the coefficients which are formulated as restrictions on the time-step size.

THEOREM 3.2. *Assume as in Lemma* 3.1 *that* $H \in W^{1,\infty}(\Omega)$, $\mathbf{u} \in W^{1,\infty}(\Omega)^2$, *and that there is a positive constant* H_* *such that* $H \ge H_*$ *holds. If, moreover, the time-step size* τ *satisfies the condition*

$$\tau \le \min\left\{\frac{1}{2\|\operatorname{div}\mathbf{u}\|_{\infty,\Omega}}, \frac{1}{(8c_f C_2 H^*)^{1/2}}, \frac{g}{4c_f C_1 (H^*(1 + 2\tau c_f C_1^{1/2}))^{1/2}}\right\}, \tag{3.14}$$

where $H^* = \|H\|_{\infty,\Omega}$ *and* C_1 *and* C_2 *are the constants defined in* (3.12) *and* (3.13), *respectively, then there are positive constants* α *and* β *such that*

$$\alpha|||(\eta,\mathbf{v})|||^2 \le \|\mathcal{J}(H,\mathbf{u})[\eta,\mathbf{v}]\|_{0,\Omega}^2 \le \beta|||(\eta,\mathbf{v})|||^2 \tag{3.15}$$

holds for all $(\eta,\mathbf{v}) \in H^1_{\Gamma_D}(\Omega) \times H_{\Gamma_N}(\operatorname{div},\Omega)$, *uniformly as* $\tau \to 0$.

Proof. In view of Lemma 3.1 we only need to show that

$$\tilde{\alpha}|||(\eta,\mathbf{w})|||^2 \le \|\tilde{\mathcal{J}}(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \le \tilde{\beta}|||(\eta,\mathbf{w})|||^2$$

holds for all $(\eta,\mathbf{w}) \in H^1_{\Gamma_D}(\Omega)\times H_{\Gamma_N}(\operatorname{div},\Omega)$, uniformly in τ. Moreover, $\tilde{\mathcal{J}}(H,\mathbf{u})[\eta,\mathbf{w}]$ is equivalent to

$$\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}] = \begin{pmatrix} \left(\dfrac{1+\tau\operatorname{div}\mathbf{u}}{H}\right)^{1/2}\eta + \tau\left(\dfrac{H}{1+\tau\operatorname{div}\mathbf{u}}\right)^{1/2}\operatorname{div}\mathbf{w} + \cdots \\ \cdots + \tau^2 c_f\left(\dfrac{H}{1+\tau\operatorname{div}\mathbf{u}}\right)^{1/2}\operatorname{div}\left(\dfrac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta\right) \\ \dfrac{1}{(2g)^{1/2}}D^{1/2}\mathbf{w} + \tau\left(\dfrac{g}{2}\right)^{1/2}D^{-1/2}\nabla\eta \end{pmatrix}$$

in the sense that

$$\begin{aligned} &\min\left\{H_*(1-\tau\|\operatorname{div}\mathbf{u}\|_{\infty,\Omega}), 2g\left(1-\tau c_f\frac{\|\mathbf{u}\|_{\infty,\Omega}}{H_*}\right)\right\}\|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \\ &\quad\le \|\tilde{\mathcal{J}}(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \\ &\quad\le \max\left\{H^*(1+\tau\|\operatorname{div}\mathbf{u}\|_{\infty,\Omega}), 2g\left(1+2\tau c_f\frac{\|\mathbf{u}\|_{\infty,\Omega}}{H_*}\right)\right\}\|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \end{aligned}$$

holds for all $(\eta,\mathbf{w}) \in H^1_{\Gamma_D}(\Omega)\times H_{\Gamma_N}(\operatorname{div},\Omega)$, uniformly in τ. Note that it is possible to take the square roots above since $1+\tau\operatorname{div}\mathbf{u} > 0$ in Ω due to (3.14). Therefore, all that is left to show is that

$$\alpha^\circ|||(\eta,\mathbf{w})|||^2 \le \|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \le \beta^\circ|||(\eta,\mathbf{w})|||^2 \tag{3.16}$$

holds for all $(\eta,\mathbf{w}) \in H^1_{\Gamma_D}(\Omega)\times H_{\Gamma_N}(\operatorname{div},\Omega)$ with constants α° and β° which are independent of τ. We only prove the left inequality in (3.16) which is the hard part.

Using (3.12) and (3.13) again, we obtain

$$\begin{aligned} &\left\|\left(\frac{H}{1+\tau\operatorname{div}\mathbf{u}}\right)^{1/2}\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta\right)\right\|_{0,\Omega} \\ &\le \left\|\frac{H}{1+\tau\operatorname{div}\mathbf{u}}\right\|_{\infty,\Omega}^{1/2}\left(\left\|\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right)\right\|_{\infty,\Omega}\|\eta\|_{0,\Omega} + \left\|\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\right\|_{\infty,\Omega}\|\nabla\eta\|_{0,\Omega}\right) \\ &\le \left(\frac{H^*}{1-\tau\|\operatorname{div}\mathbf{u}\|_{\infty,\Omega}}\right)^{1/2}(C_2\|\eta\|_{0,\Omega} + C_1\|\nabla\eta\|_{0,\Omega}). \end{aligned}$$

Combined with the restriction on the time-step size (3.14), this leads to

$$\left\|\left(\frac{H}{1+\tau\operatorname{div}\mathbf{u}}\right)^{1/2}\operatorname{div}\left(\frac{|\mathbf{u}|}{H^2}(D^{-1}\mathbf{u})\eta\right)\right\|_{0,\Omega} \le (2H^*)^{1/2}(C_2\|\eta\|_{0,\Omega} + C_1\|\nabla\eta\|_{0,\Omega}).$$

This implies

$$
\begin{aligned}
&\|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \\
&\quad\geq \frac{1}{2}\left\|\left(\frac{1+\tau\,\mathrm{div}\,\mathbf{u}}{H}\right)^{1/2}\eta+\tau\left(\frac{H}{1+\tau\,\mathrm{div}\,\mathbf{u}}\right)^{1/2}\mathrm{div}\,\mathbf{w}\right\|_{\Omega}^2 \\
&\qquad-2\tau^4c_f^2H^*(C_2\|\eta\|_{0,\Omega}+C_1\|\nabla\eta\|_{0,\Omega})^2+\left\|\frac{1}{(2g)^{1/2}}D^{1/2}\mathbf{w}+\tau\left(\frac{g}{2}\right)^{1/2}D^{-1/2}\nabla\eta\right\|_{0,\Omega}^2 \\
&\quad=\frac{1}{2}\left\|\left(\frac{1+\tau\,\mathrm{div}\,\mathbf{u}}{H}\right)^{1/2}\eta\right\|_{0,\Omega}^2+\frac{\tau^2}{2}\left\|\left(\frac{H}{1+\tau\,\mathrm{div}\,\mathbf{u}}\right)^{1/2}\mathrm{div}\,\mathbf{w}\right\|_{0,\Omega}^2 \\
&\qquad-2\tau^4c_f^2H^*(C_2\|\eta\|_{0,\Omega}+C_1\|\nabla\eta\|_{0,\Omega})^2+\frac{1}{2g}\|D^{1/2}\mathbf{w}\|_{0,\Omega}^2+\frac{g}{2}\tau^2\|D^{-1/2}\nabla\eta\|_{0,\Omega}^2,
\end{aligned}
$$

where we used the identity $(\eta,\mathrm{div}\,\mathbf{w})_{0,\Omega}+(\mathbf{w},\nabla\eta)_{0,\Omega}=0$. Using (3.7) and (3.8), this may be further bounded from below to obtain

$$
\begin{aligned}
&\|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2 \\
&\quad\geq\frac{1-\tau\|\,\mathrm{div}\,\mathbf{u}\|_{\infty,\Omega}}{2H^*}\|\eta\|_{0,\Omega}^2+\frac{\tau^2H_*}{2(1+\tau\|\,\mathrm{div}\,\mathbf{u}\|_{\infty,\Omega})}\|\,\mathrm{div}\,\mathbf{w}\|_{0,\Omega}^2 \\
&\qquad-4\tau^4c_f^2H^*(C_2^2\|\eta\|_{0,\Omega}^2+C_1^2\|\nabla\eta\|_{0,\Omega}^2)+\frac{1}{2g}\|\mathbf{w}\|_{0,\Omega}^2+\frac{g\tau^2}{2(1+2\tau c_fC_1^{1/2})}\|\nabla\eta\|_{0,\Omega}^2 \\
&\quad\geq\left(\frac{1}{4H^*}-4\tau^4c_f^2H^*C_2^2\right)\|\eta\|_{0,\Omega}^2+\left(\frac{g\tau^2}{2(1+2\tau c_fC_1^{1/2})}-4\tau^4c_f^2H^*C_1^2\right)\|\nabla\eta\|_{0,\Omega}^2 \\
&\qquad+\frac{1}{2g}\|\mathbf{w}\|_{0,\Omega}^2+\frac{\tau^2H_*}{2(1+\tau\|\,\mathrm{div}\,\mathbf{u}\|_{\infty,\Omega})}\|\,\mathrm{div}\,\mathbf{w}\|_{0,\Omega}^2.
\end{aligned}
$$

The restriction on the time-step size (3.14) leads finally to

$$
\begin{aligned}
\|\mathcal{J}^\circ(H,\mathbf{u})[\eta,\mathbf{w}]\|_{0,\Omega}^2\geq{}&\frac{1}{8H^*}\|\eta\|_{0,\Omega}^2+\frac{g}{4(1+2\tau c_fC_1^{1/2})}\tau^2\|\nabla\eta\|_{0,\Omega}^2 \\
&+\frac{1}{2g}\|\mathbf{w}\|_{0,\Omega}^2+\frac{H_*}{2(1+\tau\|\,\mathrm{div}\,\mathbf{u}\|_{\infty,\Omega})}\tau^2\|\,\mathrm{div}\,\mathbf{w}\|_{0,\Omega}^2. \qquad \square
\end{aligned}
$$

Remark. Theorem 3.2 shows that the least squares minimization problem (3.2) is well-posed in a neighborhood of the solution $(H,\mathbf{u})$ of the nonlinear elliptic problem (3.1).

We end this section by showing that the Fréchet derivative $\mathcal{J}$ associated with our least squares formulation is Lipschitz continuous. The derivation of a posteriori error estimators in the next section will be done on the basis of this result. It is also useful in the convergence study of Gauss–Newton methods for the iterative solution of the discrete nonlinear variational problems.

LEMMA 3.3. *For* $\mathbf{u},\bar{\mathbf{u}}\in L^2(\Omega)^2$,

$$
\left\|\frac{1}{|\bar{\mathbf{u}}|}\begin{pmatrix}\bar{u}_1^2 & \bar{u}_1\bar{u}_2\\ \bar{u}_1\bar{u}_2 & \bar{u}_2^2\end{pmatrix}-\frac{1}{|\mathbf{u}|}\begin{pmatrix}u_1^2 & u_1u_2\\ u_1u_2 & u_2^2\end{pmatrix}\right\|_{0,\Omega}\leq 3\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}. \tag{3.17}
$$

Proof. Using elementary matrix calculations,

$$\left|\frac{1}{|\bar{\mathbf{u}}|}\begin{pmatrix}\bar{u}_1^2 & \bar{u}_1\bar{u}_2\\ \bar{u}_1\bar{u}_2 & \bar{u}_2^2\end{pmatrix}-\frac{1}{|\mathbf{u}|}\begin{pmatrix}u_1^2 & u_1u_2\\ u_1u_2 & u_2^2\end{pmatrix}\right|^2=\left|\frac{\bar{\mathbf{u}}\bar{\mathbf{u}}^T}{|\bar{\mathbf{u}}|}-\frac{\mathbf{u}\mathbf{u}^T}{|\mathbf{u}|}\right|^2$$

$$\begin{aligned}&=|\bar{\mathbf{u}}|^2+|\mathbf{u}|^2-2\frac{(\mathbf{u}^T\bar{\mathbf{u}})^2}{|\mathbf{u}|\,|\bar{\mathbf{u}}|}\\ &=|\mathbf{u}+(\bar{\mathbf{u}}-\mathbf{u})|^2+|\mathbf{u}|^2-2\frac{(\mathbf{u}^T(\mathbf{u}+(\bar{\mathbf{u}}-\mathbf{u})))^2}{|\mathbf{u}|\,|\mathbf{u}+(\bar{\mathbf{u}}-\mathbf{u})|}\\ &=2|\mathbf{u}|^2+2\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+|\bar{\mathbf{u}}-\mathbf{u}|^2-2\frac{|\mathbf{u}|^4+2|\mathbf{u}|^2\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+(\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u}))^2}{|\mathbf{u}|^2(1+\frac{2}{|\mathbf{u}|^2}\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+\frac{|\bar{\mathbf{u}}-\mathbf{u}|^2}{|\mathbf{u}|^2})^{1/2}}\end{aligned}\tag{3.18}$$

is obtained. The two cases $|\bar{\mathbf{u}}-\mathbf{u}|\geq|\mathbf{u}|$ and $|\bar{\mathbf{u}}-\mathbf{u}|\leq|\mathbf{u}|$ are considered separately. For the first case, $|\bar{\mathbf{u}}-\mathbf{u}|\geq|\mathbf{u}|$ implies

$$\left|\frac{\bar{\mathbf{u}}\bar{\mathbf{u}}^T}{|\bar{\mathbf{u}}|}-\frac{\mathbf{u}\mathbf{u}^T}{|\mathbf{u}|}\right|^2\leq 2|\mathbf{u}|^2+2\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+|\bar{\mathbf{u}}-\mathbf{u}|^2\leq 5|\bar{\mathbf{u}}-\mathbf{u}|^2.\tag{3.19}$$

For the second case, $|\bar{\mathbf{u}}-\mathbf{u}|\leq|\mathbf{u}|$ implies

$$\frac{2}{|\mathbf{u}|^2}\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+\frac{1}{|\mathbf{u}|^2}|\bar{\mathbf{u}}-\mathbf{u}|^2\leq 3$$

which leads to

$$\left(1+\frac{2}{|\mathbf{u}|^2}\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+\frac{1}{|\mathbf{u}|^2}|\bar{\mathbf{u}}-\mathbf{u}|^2\right)^{-1/2}\geq 1-\frac{1}{|\mathbf{u}|^2}\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})-\frac{1}{2|\mathbf{u}|^2}|\bar{\mathbf{u}}-\mathbf{u}|^2.$$

Combined with (3.18), we therefore obtain

$$\begin{aligned}&\left|\frac{\bar{\mathbf{u}}\bar{\mathbf{u}}^T}{|\bar{\mathbf{u}}|}-\frac{\mathbf{u}\mathbf{u}^T}{|\mathbf{u}|}\right|^2\\ &\quad\leq 2|\mathbf{u}|^2+2\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+|\bar{\mathbf{u}}-\mathbf{u}|^2\\ &\quad-2\left(|\mathbf{u}|^2+2\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})+\frac{(\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u}))^2}{|\mathbf{u}|^2}\right)\left(1-\frac{1}{|\mathbf{u}|^2}\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})-\frac{|\bar{\mathbf{u}}-\mathbf{u}|^2}{2|\mathbf{u}|^2}\right)\\ &\quad=2\frac{(\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u}))^2}{|\mathbf{u}|^2}+2\frac{(\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u}))^3}{|\mathbf{u}|^4}+2|\bar{\mathbf{u}}-\mathbf{u}|^2+\frac{\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u})|\bar{\mathbf{u}}-\mathbf{u}|^2}{|\mathbf{u}|^4}\\ &\qquad+2\frac{(\mathbf{u}^T(\bar{\mathbf{u}}-\mathbf{u}))^2|\bar{\mathbf{u}}-\mathbf{u}|^2}{|\mathbf{u}|^2}\leq 4|\bar{\mathbf{u}}-\mathbf{u}|^2+4\frac{|\bar{\mathbf{u}}-\mathbf{u}|^3}{|\mathbf{u}|}+\frac{|\bar{\mathbf{u}}-\mathbf{u}|^4}{|\mathbf{u}|^2}\leq 9|\bar{\mathbf{u}}-\mathbf{u}|^2.\end{aligned}\tag{3.20}$$

The estimate (3.17) follows from integrating (3.19) and (3.20) over Ω. ∎

THEOREM 3.4. *Assume that $\mathbf{u},\bar{\mathbf{u}}\in W^{1,\infty}(\Omega)^2$ with $\mathbf{u}\cdot\mathbf{n}=0$ on Γ_N, $H,\bar{H}\in H^1(\Omega)$ with $H=\bar{H}=H^D$ on Γ_D, and that there is a positive constant H_* such that $H\geq H_*$ and $\bar{H}\geq H_*$ uniformly in Ω. Then,*

$$\|\mathcal{J}(\bar{H},\bar{\mathbf{u}})[\eta,\mathbf{v}]-\mathcal{J}(H,\mathbf{u})[\eta,\mathbf{v}]\|_{0,\Omega}\leq L|||(\bar{H}-H,\bar{\mathbf{u}}-\mathbf{u})|||\,|||(\eta,\mathbf{v})|||,\tag{3.21}$$

uniformly as $\tau\to 0$, for all $(\eta,\mathbf{v})\in H^1_{\Gamma_D}(\Omega)\times H_{\Gamma_N}(\mathrm{div},\Omega)$, where the constant L does not depend on τ.

Proof. Equation (3.5) implies

$$
\begin{aligned}
&\|\mathcal{J}(\bar H,\bar{\mathbf{u}})[\eta,\mathbf{v}]-\mathcal{J}(H,\mathbf{u})[\eta,\mathbf{v}]\|_{0,\Omega}\\
&\quad=\left\|\begin{pmatrix}\tau\operatorname{div}(\bar{\mathbf{u}}-\mathbf{u})\eta+\tau(\bar H-H)\operatorname{div}\mathbf{v}\\ (D(\bar H,\bar{\mathbf{u}})-D(H,\mathbf{u}))\mathbf{v}-\tau c_f\left(\dfrac{\bar{\mathbf{u}}|\bar{\mathbf{u}}|}{\bar H^2}-\dfrac{\mathbf{u}|\mathbf{u}|}{H^2}\right)\eta\end{pmatrix}\right\|_{0,\Omega}\\
&\quad\le\tau\|\operatorname{div}(\bar{\mathbf{u}}-\mathbf{u})\|_{0,\Omega}\|\eta\|_{0,\Omega}+\tau\|\bar H-H\|_{0,\Omega}\|\operatorname{div}\mathbf{v}\|_{0,\Omega}\\
&\qquad+\|D(\bar H,\bar{\mathbf{u}})-D(H,\mathbf{u})\|_{0,\Omega}\|\mathbf{v}\|_{0,\Omega}+\tau c_f\left\|\frac{\bar{\mathbf{u}}|\bar{\mathbf{u}}|}{\bar H^2}-\frac{\mathbf{u}|\mathbf{u}|}{H^2}\right\|_{0,\Omega}\|\eta\|_{0,\Omega}\\
&\quad\le\sqrt{2}\left(\tau^2\|\operatorname{div}(\bar{\mathbf{u}}-\mathbf{u})\|_{0,\Omega}^2+\|\bar H-H\|_{0,\Omega}^2\right.\\
&\qquad\left.+\|D(\bar H,\bar{\mathbf{u}})-D(H,\mathbf{u})\|_{0,\Omega}^2+\tau^2c_f^2\left\|\frac{\bar{\mathbf{u}}|\bar{\mathbf{u}}|}{\bar H^2}-\frac{\mathbf{u}|\mathbf{u}|}{H^2}\right\|_{0,\Omega}^2\right)^{1/2}|||(\eta,\mathbf{v})|||.
\end{aligned}
\tag{3.22}
$$

The definition of $D(H,\mathbf{u})$ (cf. (3.5)) implies

$$
\begin{aligned}
D(\bar H,\bar{\mathbf{u}})-D(H,\mathbf{u})=\tau c_f\left(\left(\frac{|\bar{\mathbf{u}}|}{\bar H}-\frac{|\mathbf{u}|}{H}\right)\begin{pmatrix}1&0\\0&1\end{pmatrix}\right.\\
\left.+\frac{1}{|\bar{\mathbf{u}}|\bar H}\begin{pmatrix}\bar u_1^2&\bar u_1\bar u_2\\ \bar u_1\bar u_2&\bar u_2^2\end{pmatrix}-\frac{1}{|\mathbf{u}|H}\begin{pmatrix}u_1^2&u_1u_2\\ u_1u_2&u_2^2\end{pmatrix}\right)
\end{aligned}
$$

and therefore

$$
\begin{aligned}
&\|D(\bar H,\bar{\mathbf{u}})-D(H,\mathbf{u})\|_{0,\Omega}\\
&\quad\le\tau c_f\left(\sqrt{2}\left\|\frac{|\bar{\mathbf{u}}|}{\bar H}-\frac{|\mathbf{u}|}{H}\right\|_{0,\Omega}+\left\|\left(\frac{1}{\bar H}-\frac{1}{H}\right)\frac{1}{|\mathbf{u}|}\begin{pmatrix}u_1^2&u_1u_2\\ u_1u_2&u_2^2\end{pmatrix}\right\|_{0,\Omega}\right.\\
&\qquad\left.+\left\|\frac{1}{\bar H}\left(\frac{1}{|\bar{\mathbf{u}}|}\begin{pmatrix}\bar u_1^2&\bar u_1\bar u_2\\ \bar u_1\bar u_2&\bar u_2^2\end{pmatrix}-\frac{1}{|\mathbf{u}|}\begin{pmatrix}u_1^2&u_1u_2\\ u_1u_2&u_2^2\end{pmatrix}\right)\right\|_{0,\Omega}\right)\\
&\quad\le\tau c_f\left(\frac{\sqrt{2}}{H_*}\||\bar{\mathbf{u}}|-|\mathbf{u}|\|_{0,\Omega}+(1+\sqrt{2})\|\mathbf{u}\|_{\infty,\Omega}\left\|\frac{1}{\bar H}-\frac{1}{H}\right\|_{0,\Omega}\right.\\
&\qquad\left.+\frac{1}{H_*}\left\|\frac{1}{|\bar{\mathbf{u}}|}\begin{pmatrix}\bar u_1^2&\bar u_1\bar u_2\\ \bar u_1\bar u_2&\bar u_2^2\end{pmatrix}-\frac{1}{|\mathbf{u}|}\begin{pmatrix}u_1^2&u_1u_2\\ u_1u_2&u_2^2\end{pmatrix}\right\|_{0,\Omega}\right)\\
&\quad\le\tau c_f\left(\frac{\sqrt{2}}{H_*}\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}+\frac{1+\sqrt{2}}{H_*^2}\|\mathbf{u}\|_{\infty,\Omega}\|\bar H-H\|_{0,\Omega}+\frac{3}{H_*}\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}\right),
\end{aligned}
$$

where we used (3.17) for estimating the last term. Moreover,

$$
\begin{aligned}
\left\|\frac{\bar{\mathbf{u}}|\bar{\mathbf{u}}|}{\bar H^2}-\frac{\mathbf{u}|\mathbf{u}|}{H^2}\right\|_{0,\Omega}&=\left\|\frac{|\bar{\mathbf{u}}|}{\bar H^2}(\bar{\mathbf{u}}-\mathbf{u})+\frac{\mathbf{u}}{\bar H^2}(|\bar{\mathbf{u}}|-|\mathbf{u}|)+\mathbf{u}|\mathbf{u}|\left(\frac{1}{\bar H}+\frac{1}{H}\right)\frac{H-\bar H}{\bar H H}\right\|_{0,\Omega}\\
&\le\frac{\|\bar{\mathbf{u}}\|_{\infty,\Omega}+\|\mathbf{u}\|_{\infty,\Omega}}{H_*^2}\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}+2\frac{\|\mathbf{u}\|_{\infty,\Omega}^2}{H_*^3}\|\bar H-H\|_{0,\Omega}.
\end{aligned}
$$

Inserting all this into (3.22) implies

$$\begin{aligned}
&\|\mathcal{J}(\bar H,\bar{\mathbf{u}})[\eta,\mathbf{v}]-\mathcal{J}(H,\mathbf{u})[\eta,\mathbf{v}]\|_{0,\Omega}\\
&\quad\le\sqrt{2}\left(\tau^2\|\operatorname{div}(\bar{\mathbf{u}}-\mathbf{u})\|_{0,\Omega}^2+\|\bar H-H\|_{0,\Omega}^2\right.\\
&\qquad+2\tau^2c_f^2\left(\frac{11}{H_*^2}\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}^2+\frac{6}{H_*^4}\|\mathbf{u}\|_{\infty,\Omega}^2\|\bar H-H\|_{0,\Omega}^2\right)\\
&\qquad+2\tau^2c_f^2\left(\frac{(\|\bar{\mathbf{u}}\|_{\infty,\Omega}+\|\mathbf{u}\|_{\infty,\Omega})^2}{H_*^4}\|\bar{\mathbf{u}}-\mathbf{u}\|_{0,\Omega}^2\right.\\
&\qquad\left.\left.+4\frac{\|\mathbf{u}\|_{\infty,\Omega}^4}{H_*^6}\|\bar H-H\|_{0,\Omega}^2\right)\right)^{1/2}|||(\eta,\mathbf{v})|||
\end{aligned}$$

which proves (3.21). ∎

We end this section with an investigation of the behavior of the least squares functional near the solution $(H,\mathbf{u})$ of (3.1). Using the fact that $\mathcal{R}(H,\mathbf{u};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}})=0$ and the Lipschitz continuity shown in Theorem 3.4, it can be shown that for $(\bar H,\bar{\mathbf{u}})$, $(\tilde H,\tilde{\mathbf{u}})$ sufficiently close to $(H,\mathbf{u})$, up to quadratic terms in $(\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}})$,

$$\begin{aligned}
&(\mathcal{R}(\bar H,\bar{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\bar H,\bar{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&\quad-(\mathcal{R}(\tilde H,\tilde{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\tilde H,\tilde{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&=(\mathcal{R}(\bar H,\bar{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}})-\mathcal{R}(H,\mathbf{u};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\bar H,\bar{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&\quad-(\mathcal{R}(\tilde H,\tilde{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}})-\mathcal{R}(H,\mathbf{u};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\tilde H,\tilde{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&\approx(\mathcal{J}(H,\mathbf{u})[\bar H-H,\bar{\mathbf{u}}-\mathbf{u}],\mathcal{J}(H,\mathbf{u})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&\quad-(\mathcal{J}(H,\mathbf{u})[\tilde H-H,\tilde{\mathbf{u}}-\mathbf{u}],\mathcal{J}(H,\mathbf{u})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&=(\mathcal{J}(H,\mathbf{u})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}],\mathcal{J}(H,\mathbf{u})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}.
\end{aligned}$$

Combined with (3.15), this implies that

$$\begin{aligned}
&(\mathcal{R}(\bar H,\bar{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\bar H,\bar{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\\
&\quad-(\mathcal{R}(\tilde H,\tilde{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}}),\mathcal{J}(\tilde H,\tilde{\mathbf{u}})[\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}}])_{0,\Omega}\ge\breve\alpha|||(\bar H-\tilde H,\bar{\mathbf{u}}-\tilde{\mathbf{u}})|||^2
\end{aligned}$$

holds with a constant $\breve\alpha>0$. This condition is equivalent to the statement that the least squares functional $\|\mathcal{R}(\bar H,\bar{\mathbf{u}};\hat H^{\mathrm{old}},\hat{\mathbf{u}}^{\mathrm{old}})\|_{0,\Omega}^2$ is uniformly convex in a neighborhood of $(H,\mathbf{u})$ (cf. [1, section 4.3.4]).

4. Finite element discretization, approximate mass balance, and Gauss–Newton iteration. The least squares finite element method consists in setting the minimization problem (3.2) in finite-dimensional subspaces $Q_h\subset H^1_{\Gamma_D}(\Omega)$ and $\mathbf{V}_h\subset H_{\Gamma_N}(\operatorname{div},\Omega)$. Suitable finite element spaces are standard H^1-conforming piecewise polynomial functions for Q_h and the $H(\operatorname{div})$-conforming Raviart–Thomas elements for $\mathbf{V}_h$. The minimization problem in these finite-dimensional spaces has a unique solution in a neighborhood of $(H,\mathbf{u})$ since the least squares functional is uniformly convex (cf. [1, section 3.2.2]).

The following general relation holds between the residual $\mathcal{R}$ and its derivative $\mathcal{J}$:

$$\begin{aligned}\mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}}) &= \mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}}) - \mathcal{R}(H,\mathbf{u};\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\\ &= \mathcal{J}(H,\mathbf{u})[H_h-H,\mathbf{u}_h-\mathbf{u}]\\ &\quad + \int_0^1 \left(\mathcal{J}(H+s(H_h-H),\mathbf{u}+s(\mathbf{u}_h-\mathbf{u})) - \mathcal{J}(H,\mathbf{u})\right)[H_h-H,\mathbf{u}_h-\mathbf{u}]\,ds.\end{aligned}$$

Using the Lipschitz continuity of $\mathcal{J}$ shown in Theorem 3.4, this leads to

$$\|\mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,\Omega} \le \|\mathcal{J}(H,\mathbf{u})[H_h-H,\mathbf{u}_h-\mathbf{u}]\|_{0,\Omega} + \frac{L}{2}|||(H_h-H,\mathbf{u}_h-\mathbf{u})|||^2$$

and

$$\|\mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,\Omega} \ge \|\mathcal{J}(H,\mathbf{u})[H_h-H,\mathbf{u}_h-\mathbf{u}]\|_{0,\Omega} - \frac{L}{2}|||(H_h-H,\mathbf{u}_h-\mathbf{u})|||^2.$$

Combined with Theorem 3.2, this implies that there exist positive constants $\ddot{\alpha}$ and $\dddot{\beta}$, such that

$$\ddot{\alpha}|||(H_h-H,\mathbf{u}_h-\mathbf{u})|||^2 \le \|\mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,\Omega}^2 \le \dddot{\beta}|||(H_h-H,\mathbf{u}_h-\mathbf{u})|||^2 \tag{4.1}$$

holds if $|||(H_h-H,\mathbf{u}_h-\mathbf{u})|||$ is sufficiently small. The practical implication of (4.1) is that for a given triangulation $\mathcal{T}_h$ of Ω, the local evaluation of the least squares functional,

$$\|\mathcal{R}(H_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,T}^2 \quad \text{for each } T\in\mathcal{T}_h,$$

serves as an a posteriori error estimator. Note that only the constants $\ddot{\alpha}$ and $\dddot{\beta}$ affect the sharpness of this a posteriori error estimator.

For some applications, it is of special importance that the mass balance error which is associated with the first equation in (2.2) is small. More precisely, let $\mathcal{T}$ be a fixed triangulation of Ω, then a measure for the local mass balance error is given by

$$\mathcal{M}(H_h,\mathbf{u}_h) = \sum_{K\in\mathcal{T}} \left| \int_K (H_h - \hat{H}^{\text{old}} + \tau H_h \operatorname{div}\mathbf{u}_h)\,d\mathbf{x} \right|. \tag{4.2}$$

For the Raviart–Thomas mixed finite element method employed in [8, 12], this mass balance error is zero (up to interpolation errors for $\hat{H}^{\text{old}}$ on the current triangulation). In our least squares approach $\mathcal{M}(H_h,\mathbf{u}_h)$ does not vanish, in general, but it is rather small, and decreases with refinement, as illustrated by the numerical results in the next section. Similar results were observed in connection to the study of mass conservation of a least squares mixed finite element method applied to variably saturated subsurface flow (see [16]).

For the solution of the discrete version of (3.2), i.e., to find $(\hat{H}_h,\mathbf{u}_h)\in Q_h\times\mathbf{V}_h$ such that

$$\|\mathcal{R}(H^D+\hat{H}_h,\mathbf{u}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,\Omega}^2 \le \|\mathcal{R}(H^D+\eta_h,\mathbf{v}_h;\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}})\|_{0,\Omega}^2 \tag{4.3}$$

holds for all $(\eta_h,\mathbf{v}_h)\in Q_h\times\mathbf{V}_h$, we use a Gauss–Newton iteration with suitable stopping criterion (see [16, 15]). The kth Gauss–Newton step consists of computing $\delta_h^H\in Q_h$ and $\boldsymbol{\delta}_h^u\in\mathbf{V}_h$ such that

$$\left\| \mathcal{R}\left(H_h^{(k)},\mathbf{u}_h^{(k)};\hat{H}^{\text{old}},\hat{\mathbf{u}}^{\text{old}}\right) + \mathcal{J}\left(H_h^{(k)},\mathbf{u}_h^{(k)}\right)[\delta_h^H,\boldsymbol{\delta}_h^u] \right\|_{0,\Omega}^2$$

is minimized, and setting

$$H_h^{(k+1)} = H_h^{(k)} + \delta_h^H, \qquad \mathbf{u}_h^{(k+1)} = \mathbf{u}_h^{(k)} + \boldsymbol{\delta}_h^u.$$

This is equivalent to the variational formulation of finding $\delta_h^H \in Q_h$ and $\boldsymbol{\delta}_h^u \in \mathbf{V}_h$ such that

(4.4)
$$\left(\mathcal{J}\left(H_h^{(k)}, \mathbf{u}_h^{(k)}\right)[\delta_h^H, \boldsymbol{\delta}_h^u] + \mathcal{R}\left(H_h^{(k)}, \mathbf{u}_h^{(k)}; \hat{H}^{\text{old}}, \hat{\mathbf{u}}^{\text{old}}\right), \mathcal{J}\left(H_h^{(k)}, \mathbf{u}_h^{(k)}\right)[\eta_h, \mathbf{v}_h]\right)_{0,\Omega} = 0$$

for all $\eta_h \in Q_h$ and $\mathbf{v}_h \in \mathbf{V}_h$. The size of the algebraic residual

$$\left(\mathcal{R}\left(H_h^{(k)}, \mathbf{u}_h^{(k)}; \hat{H}^{\text{old}}, \hat{\mathbf{u}}^{\text{old}}\right), \mathcal{J}\left(H_h^{(k)}, \mathbf{u}_h^{(k)}\right)[\eta_h, \mathbf{v}_h]\right)_{0,\Omega}$$

may be used as a stopping criterion for the Gauss–Newton iteration (cf. [15]). In general, the Gauss–Newton iteration converges only locally, i.e., if $(H_h^{(0)}, \mathbf{u}_h^{(0)})$ is already sufficiently close to $(H_h, \mathbf{u}_h)$. Therefore, the scheme has to be combined with a line search or trust region strategy to ensure convergence (cf. [13, Chapter 10]). The linear variational problems (4.4) arising in each Gauss–Newton step may most efficiently be solved by multilevel methods (see [15] for such a strategy for a related nonlinear least squares formulation). Embedding such an inexact Gauss–Newton iteration into a full multigrid framework can lead to an overall method with a computational cost which grows only linearly in the dimension of the system. This requires the careful adjustment of the different tolerances for the linear and nonlinear algebraic errors with respect to the discretization error (cf. [15]).

5. Computational results. This section is concerned with the validation of our least squares approach by numerical results obtained for a test example of shallow water flow taken from [8]. The recirculation of the flow behind an abrupt widening of a channel is only captured by sufficiently fine meshes. Adaptive refinement strategies are helpful for this purpose.

The domain Ω is best defined by its boundary $\partial\Omega = \Gamma_D \cup \Gamma_N$ with Γ_D and Γ_N given by

$$\begin{aligned}
\Gamma_D &= \{\mathbf{x} = (x_1, x_2) : x_1 = 100,\ 0 \le x_2 \le 100\} \\
&\quad \cup \{\mathbf{x} = (x_1, x_2) : x_1 = 1100,\ 0 \le x_2 \le 200\}, \\
\Gamma_N &= \{\mathbf{x} = (x_1, x_2) : x_2 = 0,\ 100 \le x_1 \le 1100\} \\
&\quad \cup \{\mathbf{x} = (x_1, x_2) : x_2 = 100,\ 100 \le x_1 \le 200\} \\
&\quad \cup \{\mathbf{x} = (x_1, x_2) : x_1 = 200,\ 100 \le x_2 \le 200\} \\
&\quad \cup \{\mathbf{x} = (x_1, x_2) : x_2 = 200,\ 200 \le x_1 \le 1100\}.
\end{aligned}$$

As boundary conditions on Γ_D we have

$$\begin{aligned}
H(\mathbf{x}) &= 2 + \frac{1}{4}\sin\left(\frac{t\pi}{300}\right) \quad \text{if } x_1 = 100, \\
H(\mathbf{x}) &= 2 \quad \text{if } x_1 = 1100,
\end{aligned}$$

modelling a water level that varies with t at the left end of Ω while keeping the elevation constant at the right boundary. On Γ_N the normal component of the velocity, $\mathbf{u} \cdot \mathbf{n}$, is set to zero. The Chezy coefficient was chosen as $c_f = 0.002725$ which is taken from [8]. The initial conditions at $t = 0$ are $H \equiv 2$ and $\mathbf{u} \equiv \mathbf{0}$.

The time discretization is done with a time-step size τ of 5 seconds. These rather small time steps are chosen in order to resolve the variation of the inflow

boundary conditions with sufficient accuracy. Moreover, our experiments showed that for larger time-step sizes the cost associated with the Gauss–Newton iteration for solving the nonlinear systems in each time step is growing significantly. For the space discretization, piecewise quadratic functions are used for Q_h and combined with quadratic Raviart–Thomas spaces for $\mathbf{V}_h$. Starting from a coarse initial triangulation, four steps of adaptive refinement based on the local evaluation of the least squares functional described in the previous section are performed. With a given tolerance ε for the desired value of the functional minimum, all triangles are refined which satisfy

$$\|\mathcal{R}(H_h, \mathbf{u}_h; \hat{H}^{\text{old}}, \hat{\mathbf{u}}^{\text{old}})\|_{0,T}^2 > \frac{\varepsilon}{\#\text{elements}}$$

for the local contribution to the least squares functional.

We present the results of our computations at various stages of the time evolution. As it can be seen in Figures 5.1 and 5.2, at $t = 100$ a sink begins to form behind the reentrant corner. At $t = 200$ the recirculation phase starts, gaining in strength until $t = 300$. Afterwards, at $t = 400$, the flow starts turning until it is directed backwards at $t = 500$. For $t = 600$ this cycle starts again resembling the results for $t = 100$. Figure 5.3 shows the local distribution of the least squares functional for the same times on a logarithmic scale. For each of the shown time steps lighter zones starting from the reentrant corner with relatively large contributions to the least squares functional can be clearly identified. The use of this error estimator results in the adaptively refined triangulations shown in Figure 5.4. Obviously, a high level of refinement is reached primarily in the recirculation zone in order to resolve the local variation of the water level and velocity field in this area.

Tables 5.1 to 5.6 show the reduction of the least squares functional on the resulting sequence of adaptively refined triangulations. The dimensions of the finite element spaces Q_h and $\mathbf{V}_h$ are denoted by N_Q and N_V, respectively. The optimal convergence behavior achievable with piecewise quadratic finite elements would result in a reduction of the least squares functional proportional to $(N_Q + N_V)^{-2}$. Such a behavior is only reached in our numerical tests for $t = 200$ and 300. For the other times only $(N_Q + N_V)^{-\mu}$ with μ well below 2 is reached in average for the reduction of the least squares functional. This suboptimal convergence behavior indicates that the adaptive refinement strategy based on a fixed tolerance for the local contribution of the functional may not be appropriate at these time steps. On the other hand, this phenomenon may also be due to the nonlinear nature of the problem which is possibly not resolved on all refinement levels shown. Note that the reduction exponent μ moves somewhat closer to 2 on finer levels in most of the time steps shown. Interestingly, the largest deviation from the expected optimal convergence behavior is seen at those time steps where relative large recirculation zones are present.

Also shown is the mass balance error $\mathcal{M}(H_h, \mathbf{u}_h)$ associated with these time steps. The coarsest triangulation (level 0) is used for $\mathcal{T}$ in the definition of $\mathcal{M}(H_h, \mathbf{u}_h)$ in (4.2). Our numerical results indicate that the decrease in the mass balance error is at least as fast as for the least squares functional. Note that the computed mass balance error needs to be related to the typical size of the mass variation

$$\left| \int_\Omega (H - \hat{H}^{\text{old}})\, d\mathbf{x} \right| \approx |\Omega|\, |\Delta H| = 1.7 \cdot 10^5 |\Delta H|.$$

The inflow boundary conditions suggest that ΔH is in the range of $10^{-3}\tau = 5 \cdot 10^{-3}$ which leads to an overall mass variation in the range of 10^3. The relative mass balance error in Tables 5.1 to 5.6 is therefore on the order of 10^{-4} to 10^{-3} on the finest level.

RECONSTRUCTION OF CLOSELY SPACED SMALL INCLUSIONS*

HABIB AMMARI†, HYEONBAE KANG‡, EUNJOO KIM‡, AND MIKYOUNG LIM‡

Abstract. In this paper we establish an explicit asymptotic formula for the steady state voltage perturbations caused by closely spaced small conductivity inhomogeneities. Based on this new formula we design a very effective numerical method to identify the location and some geometric features of these inhomogeneities from a finite number of boundary measurements. The viability of our approach is documented by numerical examples.

Key words. conductivity imaging, closely spaced small inhomogeneities, polarization tensors of multiple inclusions, numerical reconstruction algorithms

1. Introduction.

The problem of determining interior information about a medium from boundary field measurements is one that is not, in general, well posed. If, however, in advance we have additional structural information about the medium, then we may be able to determine specific features with higher resolution. One particular very promising line of work has been concerned with the reconstruction of small *well-separated* inhomogeneities. While efficient algorithms to determine the location and/or shape of the small inhomogeneities have been developed in that case [3, 5, 6, 7, 8, 10, 17, 18, 23, 28, 4], it remains an interesting open problem to adapt these numerical methods to the close-to-touching case. In this paper, we will concentrate on the reconstruction of conductivity inhomogeneities in a specific setting, namely a bounded domain consisting of a homogeneous conducting background medium in which are embedded *closely spaced* conducting inhomogeneities of small diameter. We believe that our results can be extended, with some modifications, to the case of the Helmholtz equation, the full Maxwell equations, and the Lamé system, as well as to the setting of thin inhomogeneities.

Our objective in this work is threefold. Our first goal is to provide an explicit derivation of the leading order boundary perturbations resulting from the presence of an arbitrary number of closely spaced small conductivity inhomogeneities. This formula expresses the voltage potential in terms of the background potential, a certain Neumann function, and the relevant *polarization tensors of multiple inclusions* and, in a most natural way, generalizes those already derived for a finite set of well-separated small inhomogeneities [1, 10, 16]. Our second goal is to investigate some important properties of these new polarization tensors such as symmetry and positivity. We also estimate their eigenvalues in terms of the total volume of the inclusions and explicitly compute them in the multidisk case. These results do not seem to be available in the literature. In the case of a single inhomogeneity these polarization tensors are reduced

to the classical Pólya–Szegö polarization tensor which has been extensively studied [10, 16, 21, 25, 26] and higher-order polarization tensors which have been introduced in [1, 2]. It should also be noted that Cheng and Greengard gave in Theorem 2.2 of their interesting paper [11] a solution to the two- and three-disk conductivity problem based on a method of images. Our calculations provide a more general way of solving the multidisk problem.

Our third goal is to apply our explicit asymptotic formula for the purpose of identifying the location and the polarization tensor of closely spaced small inhomogeneities from finitely many current-voltage pairs measured on the boundary.

To fix notation, consider a homogeneous conducting object which occupies a bounded Lipschitz domain $\Omega \subset \mathbb{R}^d$, $d = 2$ or 3. We will assume, for the sake of simplicity, that its conductivity is equal to 1. The background voltage potential, U, is the solution to the boundary value problem

$$\begin{cases} \Delta U = 0 \quad \text{in } \Omega, \\ \dfrac{\partial U}{\partial \nu}\Big|_{\partial\Omega} = g. \end{cases}$$

Here ν denotes the unit outward normal to the domain Ω and g represents the applied boundary current; it belongs to the set $L^2_0(\partial\Omega) = \{g \in L^2(\partial\Omega), \int_{\partial\Omega} g = 0\}$.

Let D denote a set of m closely spaced inhomogeneities inside Ω

$$D = \cup_{l=1}^m D_l := \cup_{l=1}^m (\epsilon B_l + z),$$

where $z \in \Omega$, $\epsilon > 0$ is small, and B_l for $l = 1, \dots, m$ is a bounded Lipschitz domain in $\mathbb{R}^d$. Throughout this paper we suppose that

(H1) the set D is well separated from the boundary $\partial\Omega$ (i.e., $\operatorname{dist}(D, \partial\Omega) > d_0 > 0$);

(H2) there exist positive constants C_1 and C_2 such that

$$C_1 \le \operatorname{diam} B_l \le C_2, \quad \text{and} \quad C_1 \le \operatorname{dist}(B_l, B_{l'}) \le C_2, \quad l \ne l';$$

(H3) and the conductivity of the inhomogeneity D_l for $l = 1, \dots, m$ is equal to some positive constant $k_l \ne 1$.

The conductivity profile of Ω is then

$$\gamma(x) = \begin{cases} k_l, & x \in D_l, \\ 1, & x \in \Omega \setminus \overline{D}. \end{cases} \tag{1.1}$$

The voltage potential in the presence of the set D of conductivity inhomogeneities is denoted u. It is the solution to

$$\begin{cases} \nabla \cdot \left(\chi\left(\Omega \setminus \bigcup_{l=1}^m \overline{D_l} \right) + \sum_{l=1}^m k_l \chi(D_l) \right) \nabla u = 0 \quad \text{in } \Omega, \\ \dfrac{\partial u}{\partial \nu}\Big|_{\partial\Omega} = g. \end{cases}$$

We normalize both the potentials U and u by requiring that $\int_{\partial\Omega} u = \int_{\partial\Omega} U = 0$.

It should be noted that Capdeboscq and Vogelius, in their interesting paper [9], derived a very general representation formula for the boundary voltage perturbations caused by internal conductivity inhomogeneities of small volume fraction. Rather than directly applying this general formula for finding the location and geometric

features of D we derive a more *explicit* one in the particular case of close-to-touching small inhomogeneities from which it is possible to extract *very specific information* about D. The numerical examples presented in this paper show that this explicit formula leads to a *very effective computational algorithm*.

This paper is organized as follows. In section 2, we review some basic facts on the layer potentials of the Laplacian which constitute the basic tools of the present work. In section 3, we give mathematical definitions of the polarization tensors of multiple inclusions. In particular, we rigorously establish some useful properties of these new polarization tensors, carefully study their properties of symmetry and positivity, and estimate their eigenvalues in terms of the total volume of the inclusions. In section 4, we explicitly compute these polarization tensors in the multidisk case. In section 5, we visualize the first-order polarization tensor of multiple inclusions in terms of an equivalent ellipse. In section 6, we rigorously justify the derivation of our asymptotic formula. In section 7, we propose a numerical algorithm based on the asymptotic formula to detect the location and size of closely spaced inclusions. This algorithm makes it possible to find the first-order polarization tensor as well.

2. Layer potentials for the Laplacian. In this section, let us review some well-known properties of the layer potentials for the Laplacian and prove a decomposition formula of the solution u to the following transmission problem:

$$\begin{cases} \nabla \cdot \left(\chi\left(\Omega \setminus \bigcup_{l=1}^{m} \overline{B_l} \right) + \sum_{l=1}^{m} k_l \chi(B_l) \right) \nabla u = 0 \quad \text{in } \mathbb{R}^d, \\ u(x) - H(x) = O(|x|^{1-d}) \quad \text{as } |x| \to \infty, \end{cases} \tag{2.1}$$

where H is a harmonic function in $\mathbb{R}^d$.

The theory of layer potentials has been developed in relation to the boundary value problems. Let D be a bounded domain in $\mathbb{R}^d, d \geq 2$. We assume that ∂D is Lipschitz. Let $\Gamma(x)$ be the fundamental solution of the Laplacian Δ:

$$\Gamma(x) = \begin{cases} \dfrac{1}{2\pi} \ln |x|, & d = 2, \\ \dfrac{1}{(2-d)\omega_d} |x|^{2-d}, & d \geq 3, \end{cases} \tag{2.2}$$

where ω_d is the area of the $(d-1)$-dimensional unit sphere. The single and double layer potentials of the density function ϕ on D are defined by

$$\mathcal{S}_D \phi(x) := \int_{\partial D} \Gamma(x-y) \phi(y) d\sigma(y), \quad x \in \mathbb{R}^d, \tag{2.3}$$

$$\mathcal{D}_D \phi(x) := \int_{\partial D} \frac{\partial}{\partial \nu_y} \Gamma(x-y) \phi(y) d\sigma(y), \quad x \in \mathbb{R}^d \setminus \partial D. \tag{2.4}$$

For a function u defined on $\mathbb{R}^d \setminus \partial D$, we denote

$$\frac{\partial}{\partial \nu^{\pm}} u(x) := \lim_{t \to 0^+} \langle \nabla u(x \pm t\nu_x), \nu_x \rangle, \quad x \in \partial D,$$

if the limit exists. Here ν_x is the outward unit normal to ∂D at x.

The proof of the following trace formula can be found in [14, 15, 24] (for Lipschitz domains, see [27]):

$$\frac{\partial}{\partial \nu^{\pm}} \mathcal{S}_D \phi(x) = \left(\pm \frac{1}{2} I + \mathcal{K}_D^* \right) \phi(x), \quad x \in \partial D, \tag{2.5}$$

$$(\mathcal{D}_D \phi)|_{\pm} = \left(\mp \frac{1}{2} I + \mathcal{K}_D \right) \phi(x), \quad x \in \partial D, \tag{2.6}$$

where

$$\mathcal{K}_D \phi(x) = \frac{1}{\omega_d} \text{p.v.} \int_{\partial D} \frac{\langle y - x, \nu_y \rangle}{|x - y|^d} \phi(y) d\sigma(y)$$

and $\mathcal{K}_D^*$ is the L^2-adjoint of $\mathcal{K}_D$. When ∂D is Lipschitz, $\mathcal{K}_D$ is a singular integral operator and known to be bounded on $L^2(\partial\Omega)$ [12]. Let $L_0^2(\partial D) := \{f \in L^2(\partial D) : \int_{\partial D} f d\sigma = 0\}$. The following results are due to Verchota and Escauriaza, Fabes, and Verchota.

THEOREM 2.1 (see [13], [27]). *$\lambda I - \mathcal{K}_D^*$ is invertible on $L_0^2(\partial D)$ if $|\lambda| \geq \frac{1}{2}$, and for $\lambda \in (-\infty, -\frac{1}{2}] \cup (\frac{1}{2}, \infty)$, $\lambda I - \mathcal{K}_D^*$ is invertible on $L^2(\partial D)$.*

The following theorem will be very useful in the next section.

THEOREM 2.2. *Let H be a harmonic function in $\mathbb{R}^d$ for $d = 2$ or 3. Let u be the solution of the transmission problem (2.1). There are unique functions $\varphi^{(j)} \in L_0^2(\partial B_j)$, $j = 1, \ldots, m$, such that*

$$u(x) = H(x) + \sum_{j=1}^{m} \mathcal{S}_{B_j} \varphi^{(j)}(x). \tag{2.7}$$

The potential $\varphi^{(j)}$, $j = 1, \ldots, m$, satisfy

$$(\lambda_j I - \mathcal{K}_{B_j}^*)\varphi^{(j)} - \sum_{k \neq j} \frac{\partial (\mathcal{S}_{B_k} \varphi^{(k)})}{\partial \nu^{(j)}}\bigg|_{\partial B_j} = \frac{\partial H}{\partial \nu^{(j)}}\bigg|_{\partial B_j} \quad \text{on } \partial B_j, \quad j = 1, \ldots, m, \tag{2.8}$$

where $\nu^{(j)}$ denotes the outward unit normal to ∂B_j and

$$\lambda_j = \frac{k_j + 1}{2(k_j - 1)}, \quad j = 1, \ldots, m.$$

Proof. It is easy to see from (2.5) that u defined by (2.7) and (2.8) is the solution of (2.1). Thus it is enough to show that the integral equation (2.8) has a unique solution.

Let $X := L_0^2(\partial B_1) \times \cdots \times L_0^2(\partial B_m)$. We prove that the operator $T : X \to X$ defined by

$$\begin{aligned} T(\varphi^{(1)}, \ldots, \varphi^{(m)}) &= T_0(\varphi^{(1)}, \ldots, \varphi^{(m)}) + T_1(\varphi^{(1)}, \ldots, \varphi^{(m)}) \\ &:= \left((\lambda_1 I - \mathcal{K}_{B_1}^*)\varphi^{(1)}, \ldots, (\lambda_m I - \mathcal{K}_{B_m}^*)\varphi^{(m)} \right) \\ &\quad - \left(\sum_{k \neq 1} \frac{\partial (\mathcal{S}_{B_k} \varphi^{(k)})}{\partial \nu^{(1)}}\bigg|_{\partial B_1}, \ldots, \sum_{k \neq m} \frac{\partial (\mathcal{S}_{B_k} \varphi^{(k)})}{\partial \nu^{(m)}}\bigg|_{\partial B_m} \right) \end{aligned}$$

is invertible. By Theorem 2.1, T_0 is invertible on X. On the other hand, it is easy to see that T_1 is a compact operator on X. Thus, by the Fredholm alternative, it suffices to show that T is injective on X. If $T(\varphi^{(1)}, \dots, \varphi^{(m)}) = 0$, then $u(x) := \sum_{j=1}^m \mathcal{S}_{B_j}\varphi^{(j)}(x)$, $x \in \mathbb{R}^d$, is the solution of (2.1) with $H = 0$. By the uniqueness of the solution to (2.1), we get $u \equiv 0$. In particular, $\mathcal{S}_{B_j}\varphi^{(j)}$ is smooth across ∂B_j, $j = 1, \dots, m$. Therefore, $\varphi^{(j)} = \frac{\partial(\mathcal{S}_{B_j}\varphi^{(j)})}{\partial\nu^{(j)}}\big|_+ - \frac{\partial(\mathcal{S}_{B_j}\varphi^{(j)})}{\partial\nu^{(j)}}\big|_- = 0$. This completes the proof. ∎

3. Polarization tensors of multiple inclusions. Our aim in this section is to introduce new concepts of polarization tensors of multiple inclusions which generalize the Pólya–Szegö tensor. These concepts are defined in a way analogous to the generalized polarization tensors introduced in [1, 2]. A novel result of this paper is a proof of symmetry and positive-definiteness of these polarization tensors. We also obtain estimations of their eigenvalues in terms of the total volume of the inclusions. These results will turn out to be crucial for our approach to determine the location and some geometric features of closely spaced small conductivity inclusions.

DEFINITION 3.1. *Let $\alpha = (\alpha_1, \dots, \alpha_d), \beta = (\beta_1, \dots, \beta_d) \in \mathbb{N}^d$ be multi-indices. For $l = 1, \dots, m$ let $\varphi_\alpha^{(l)}$ be the solution of*

$$(\lambda_l I - \mathcal{K}_{B_l}^*)\varphi_\alpha^{(l)} - \sum_{k\neq l} \frac{\partial(\mathcal{S}_{B_k}\varphi_\alpha^{(k)})}{\partial\nu^{(l)}}\bigg|_{\partial B_l} = \frac{\partial x^\alpha}{\partial\nu^{(l)}}\bigg|_{\partial B_l} \quad \text{on } \partial B_l. \tag{3.1}$$

Then the polarization tensor $M = (m_{\alpha\beta})$ is defined to be

$$m_{\alpha\beta} = \sum_{l=1}^m \int_{\partial B_l} x^\beta \varphi_\alpha^{(l)}(x) d\sigma. \tag{3.2}$$

If $|\alpha| = |\beta| = 1$, we denote $m_{\alpha\beta}$ by m_{ij}, $i, j = 1, \dots, d$. We call m_{ij} the first-order polarization tensor.

THEOREM 3.2. *The polarization tensor M is symmetric. More precisely, if a_α and b_β are constants such that $\sum_\alpha a_\alpha y^\alpha$ and $\sum_\beta b_\beta y^\beta$ are harmonic polynomials, then*

$$\sum_{\alpha,\beta} a_\alpha b_\beta m_{\alpha\beta} = \sum_{\alpha,\beta} a_\alpha b_\beta m_{\beta\alpha}. \tag{3.3}$$

Proof. Put $f(y) := \sum_\alpha a_\alpha y^\alpha$, $g(y) := \sum_\beta b_\beta y^\beta$, $\varphi^{(l)} := \sum_\alpha a_\alpha \varphi_\alpha^{(l)}$, and $\psi^{(l)} := \sum_\beta b_\beta \varphi_\beta^{(l)}$. Then one can easily see that

$$\sum_{\alpha,\beta} a_\alpha b_\beta m_{\alpha\beta} = \sum_{l=1}^m \int_{\partial B_l} g\varphi^{(l)} d\sigma \quad \text{and} \quad \sum_{\alpha,\beta} a_\alpha b_\beta m_{\beta\alpha} = \sum_{l=1}^m \int_{\partial B_l} f\psi^{(l)} d\sigma.$$

We also put

$$\Phi(x) := \sum_{l=1}^m \mathcal{S}_{B_l}\varphi^{(l)} \quad \text{and} \quad \Psi(x) := \sum_{l=1}^m \mathcal{S}_{B_l}\psi^{(l)}.$$

From the definition of $\varphi_\alpha^{(l)}$, one can readily get

$$k_j \frac{\partial(f+\Phi)}{\partial\nu^{(j)}}\bigg|_- = \frac{\partial(f+\Phi)}{\partial\nu^{(j)}}\bigg|_+ \quad \text{on } \partial B_j, \tag{3.4}$$

and the same relation holds for $g+\Psi$. From (3.1) we obtain

$$\begin{aligned}\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu^{(l)}}\Big|_+ - k_l\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu^{(l)}}\Big|_- &= \sum_\alpha a_\alpha\left[\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)}_\alpha)}{\partial\nu^{(l)}}\Big|_+ - k_l\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)}_\alpha)}{\partial\nu^{(l)}}\Big|_-\right]\\ &= (k_l-1)\sum_\alpha a_\alpha\frac{\partial}{\partial\nu^{(l)}}\left[x^\alpha+\sum_{j\neq l}\mathcal{S}_{B_j}\varphi^{(j)}_\alpha\right]\\ &= (k_l-1)\frac{\partial}{\partial\nu^{(l)}}\left[f+\sum_{j\neq l}\mathcal{S}_{B_j}\varphi^{(j)}_\alpha\right].\end{aligned}$$

Thus, it follows from (3.4) that

$$\varphi^{(l)} = \frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu^{(l)}}\Big|_+ - \frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu^{(l)}}\Big|_- = (k_l-1)\frac{\partial(f+\Phi)}{\partial\nu^{(l)}}\Big|_- \quad \text{on } \partial B_l. \tag{3.5}$$

Therefore, we get

$$\begin{aligned}\sum_{\alpha,\beta}a_\alpha b_\beta m_{\alpha\beta} &= \sum_{l=1}^m(k_l-1)\int_{\partial B_l} g\frac{\partial(f+\Phi)}{\partial\nu}\Big|_- d\sigma\\ &= \sum_{l=1}^m(k_l-1)\int_{\partial B_l}(g+\Psi)\frac{\partial(f+\Phi)}{\partial\nu}\Big|_- d\sigma - \sum_{l=1}^m(k_l-1)\int_{\partial B_l}\Psi\frac{\partial(f+\Phi)}{\partial\nu}\Big|_- d\sigma\\ &= \sum_{l=1}^m(k_l-1)\int_{\partial B_l}(g+\Psi)\frac{\partial(f+\Phi)}{\partial\nu}\Big|_- d\sigma\\ &\quad - \sum_{l=1}^m\int_{\partial B_l}\Psi\left[\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu}\Big|_+ - \frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu}\Big|_-\right]d\sigma.\end{aligned} \tag{3.6}$$

Observe now that

$$\begin{aligned}&\sum_{l=1}^m\int_{\partial B_l}\Psi\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu}\Big|_+ d\sigma = \sum_{j,l}\int_{\partial B_l}\mathcal{S}_{B_j}\psi^{(j)}\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu}\Big|_+ d\sigma\\ &\quad = -\sum_{l=1}^m\int_{\mathbb{R}^d\setminus\overline{B}_l}\nabla\mathcal{S}_{B_l}\psi^{(l)}\cdot\nabla\mathcal{S}_{B_l}\varphi^{(l)}dx - \frac{1}{2}\sum_{l\neq j}\int_{\mathbb{R}^d\setminus\overline{B_l\cup B_j}}\nabla\mathcal{S}_{B_j}\psi^{(j)}\cdot\nabla\mathcal{S}_{B_l}\varphi^{(l)}dx,\end{aligned}$$

and

$$\begin{aligned}\sum_{l=1}^m\int_{\partial B_l}\Psi\frac{\partial(\mathcal{S}_{B_l}\varphi^{(l)})}{\partial\nu}\Big|_- d\sigma &= \sum_{j,l}\int_{B_l}\nabla\mathcal{S}_{B_j}\psi^{(j)}\cdot\nabla\mathcal{S}_{B_l}\varphi^{(l)}dx\\ &= \sum_{l=1}^m\int_{B_l}\nabla\mathcal{S}_{B_l}\psi^{(l)}\cdot\nabla\mathcal{S}_{B_l}\varphi^{(l)}dx + \frac{1}{2}\sum_{j\neq l}\int_{B_l\cup B_j}\nabla\mathcal{S}_{B_j}\psi^{(j)}\cdot\nabla\mathcal{S}_{B_l}\varphi^{(l)}dx,\end{aligned}$$

to finally arrive at

$$\begin{aligned}\sum_{\alpha,\beta}a_\alpha b_\beta m_{\alpha\beta} &= \sum_{l=1}^m(k_l-1)\langle(g+\Psi),(f+\Phi)\rangle_{B_l} + \sum_{l=1}^m\langle\mathcal{S}_{B_l}\psi^{(l)},\mathcal{S}_{B_l}\varphi^{(l)}\rangle_{\mathbb{R}^d}\\ &\quad + \frac{1}{2}\sum_{j\neq l}\langle\mathcal{S}_{B_j}\psi^{(j)},\mathcal{S}_{B_l}\varphi^{(l)}\rangle_{\mathbb{R}^d}.\end{aligned} \tag{3.7}$$

Here, the notation $\langle u, v\rangle_D := \int_D \nabla u \cdot \nabla v dx$ has been used. The symmetry (3.3) follows immediately from (3.7) and the proof is complete. ∎

THEOREM 3.3. *Suppose that either $k_l - 1 > 0$ or $k_l - 1 < 0$ for all $l = 1, \dots, m$. Let*

$$\kappa := \max_{1 \le l \le m} \left| 1 - \frac{1}{k_l} \right|.$$

For any a_α such that $\sum_\alpha a_\alpha y^\alpha$ is harmonic,

$$\left| \sum_{\alpha,\beta} a_\alpha a_\beta m_{\alpha\beta} \right| \ge \frac{|\kappa - 1|}{m+1} \sum_{l=1}^m |k_l - 1| \int_{B_l} \left| \nabla \left(\sum_\alpha a_\alpha y^\alpha \right) \right|^2 dy. \tag{3.8}$$

In particular, if $k_l - 1 > 0$ (resp., < 0) for all $l = 1, \dots, m$, then (m_{ij}) is positive (resp., negative) definite and if $\sum_{i=1}^d a_i^2 = 1$, then

$$\left| \sum_{i,j} a_i a_j m_{ij} \right| \ge \frac{|\kappa - 1|}{m+1} \sum_{l=1}^m |k_l - 1||B_l|. \tag{3.9}$$

Here $|B|$ is the volume of B.

Proof. Suppose that either $k_l - 1 > 0$ or $k_l - 1 < 0$ for all $l = 1, \dots, m$. Define the quadratic form $Q_D(u)$ by

$$Q_D(u) := \langle u, u\rangle_D.$$

It then follows from (3.7) that

$$\begin{aligned} \sum_{\alpha,\beta} a_\alpha a_\beta m_{\alpha\beta} &= \sum_{l=1}^m (k_l - 1) Q_{B_l}(f + \Phi) + \sum_{l=1}^m Q_{\mathbb{R}^d}(\mathcal{S}_{B_l} \varphi^{(l)}) \\ &\quad + \frac{1}{2} \sum_{j \ne l} \langle \mathcal{S}_{B_j} \varphi^{(j)}, \mathcal{S}_{B_l} \varphi^{(l)} \rangle_{\mathbb{R}^d} \\ &= \sum_{l=1}^m (k_l - 1) Q_{B_l}(f + \Phi) + Q_{\mathbb{R}^d}(\Phi). \end{aligned} \tag{3.10}$$

On the other hand, because of (3.4), we get

$$(k_j - 1) \frac{\partial f}{\partial \nu^{(j)}} = \frac{\partial \Phi}{\partial \nu^{(j)}}\bigg|_+ - k_j \frac{\partial \Phi}{\partial \nu^{(j)}}\bigg|_- \quad \text{on } \partial B_j, \quad j = 1, \dots, d.$$

Thus, it follows from (3.5) that

$$\begin{aligned} \sum_{\alpha,\beta} a_\alpha a_\beta m_{\alpha\beta} &= \sum_{l=1}^m (k_l - 1) \int_{\partial B_l} f \frac{\partial (f + \Phi)}{\partial \nu}\bigg|_- d\sigma \\ &= \sum_{l=1}^m (k_l - 1) Q_{B_l}(f) + \sum_{l=1}^m (k_l - 1) \int_{\partial B_l} \frac{\partial f}{\partial \nu} \Phi d\sigma \\ &= \sum_{l=1}^m (k_l - 1) Q_{B_l}(f) + \sum_{l=1}^m \int_{\partial B_l} \frac{\partial \Phi}{\partial \nu}\bigg|_+ \Phi d\sigma - \sum_{l=1}^m k_l \int_{\partial B_l} \frac{\partial \Phi}{\partial \nu}\bigg|_- \Phi d\sigma \\ &= \sum_{l=1}^m (k_l - 1) Q_{B_l}(f) - \sum_{l=1}^m Q_{\mathbb{R}^d}(\Phi) - \sum_{l=1}^m (k_l - 1) Q_{B_l}(\Phi). \end{aligned} \tag{3.11}$$

By equating (3.10) and (3.11) we have

$$\begin{aligned}&\sum_{l=1}^{m}(k_l-1)Q_{B_l}(f+\Phi)+Q_{\mathbb{R}^d}(\Phi)\\&=\sum_{l=1}^{m}(k_l-1)Q_{B_l}(f)-\sum_{l=1}^{m}Q_{\mathbb{R}^d}(\Phi)-\sum_{l=1}^{m}(k_l-1)Q_{B_l}(\Phi).\end{aligned}\tag{3.12}$$

Since the left-hand side of (3.12) is positive, one can claim that

$$\sum_{l=1}^{m}(k_l-1)Q_{B_l}(f)\geq\sum_{l=1}^{m}k_lQ_{B_l}(\Phi).\tag{3.13}$$

It also follows from (3.12) that

$$Q_{\mathbb{R}^d}(\Phi)=\frac{1}{m+1}\sum_{l=1}^{m}(k_l-1)\left[Q_{B_l}(f)-Q_{B_l}(f+\Phi)-Q_{B_l}(\Phi)\right].\tag{3.14}$$

Substituting (3.14) into (3.10), we obtain

$$\sum_{\alpha,\beta}a_\alpha a_\beta m_{\alpha\beta}=\frac{m}{m+1}\sum_{l=1}^{m}(k_l-1)Q_{B_l}(f+\Phi)+\frac{1}{m+1}\sum_{l=1}^{m}(k_l-1)\left[Q_{B_l}(f)-Q_{B_l}(\Phi)\right],\tag{3.15}$$

and hence

$$\sum_{\alpha,\beta}a_\alpha a_\beta m_{\alpha\beta}\geq\frac{1}{m+1}\sum_{l=1}^{m}(k_l-1)\left[Q_{B_l}(f)-Q_{B_l}(\Phi)\right].\tag{3.16}$$

By (3.13) we get

$$\begin{aligned}\sum_{l=1}^{m}(k_l-1)Q_{B_l}(\Phi)&=\sum_{l=1}^{m}\frac{(k_l-1)}{k_l}k_lQ_{B_l}(\Phi)\\&\leq\kappa\sum_{l=1}^{m}k_lQ_{B_l}(\Phi)\leq\kappa\sum_{l=1}^{m}(k_l-1)Q_{B_l}(f),\end{aligned}$$

and hence (3.8) follows immediately from (3.16). This completes the proof. ∎

4. Explicit formulae for the polarization tensors of multiple disks. In this section, we explicitly compute the solution $\varphi^{(l)}$ of the integral equation (2.8) in the case where all of the domains B_l are two-dimensional disks. Let $B_l=B(z_l,r_l)$ be the disk with center z_l and radius r_l for $l=1,\dots,m$. Let R_l, $l=1,\dots,m$, be the reflection with respect to the disk B_l, i.e.,

$$R_l(x):=\frac{r_l^2(x-z_l)}{|x-z_l|^2}+z_l.$$

We also define the reflection of a function f by

$$(R_lf)(x)=f(R_l(x)),\quad x\in\mathbb{R}^2,\quad l=1,\dots,m.$$

The following lemma will be useful later.

LEMMA 4.1. *For a function u harmonic in $\overline{B_l}$, we have*

$$\mathcal{S}_{B_l}\left(\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\partial B_l}\right)(x) = -\frac{1}{2}R_l u(x) + \frac{1}{2}u(z_l) \quad \text{for } x \in \mathbb{R}^2 \setminus \overline{B_l}. \tag{4.1}$$

Proof. By (2.5), we have

$$\frac{\partial}{\partial \nu}\mathcal{S}_{B_l}\left(\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\P B_l}\right)(x) = \left(\frac{1}{2}I + \mathcal{K}_{B_l}^*\right)\left(\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\partial B_l}\right) + (x).$$

Since B_l is a disk and $\int_{\partial B_l} \frac{\partial u}{\partial \nu} d\sigma = 0$, one can get that $\mathcal{K}_{B_l}^*(\frac{\partial u}{\partial \nu^{(l)}}\big|_{\partial B_l}) = 0$ on ∂B_l. We refer the reader to [19] for a proof of this fact. Therefore, we get

$$\frac{\partial}{\partial \nu}\mathcal{S}_{B_l}\left(\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\partial B_l}\right)(x) = \frac{1}{2}\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\partial B_l} + (x),$$

and thus

$$\mathcal{S}_{B_l}\left(\frac{\partial u}{\partial \nu^{(l)}}\Big|_{\partial B_l}\right)(x) = -\frac{1}{2}R_l u(x) + C$$

for some constant C. Since $\int_{\partial B_l} \frac{\partial u}{\partial \nu^{(l)}} d\sigma = 0$ and hence $\mathcal{S}_{B_l}(\frac{\partial u}{\partial \nu^{(l)}}\big|_{\partial B_l})(x) \to 0$ as $|x| \to \infty$, we have $C = (1/2)u(z_l)$. This completes the proof. ∎

Our main result in this section is the following.

THEOREM 4.2. *For $l = 1, \dots, m$, let*

$$S_l = \{\Theta = (k_1, \dots, k_n) \mid n \in \mathbb{N},\ k_i \in \{1, \dots, m\} \text{ such that } k_1 \neq l \text{ and } k_i \neq k_{i+1}\}.$$

For $\Theta = (k_1, \dots, k_n) \in S_l$, let

$$R_\Theta = R_{k_1} R_{k_2} \cdots R_{k_n} \text{ and } \Lambda_\Theta = \prod_{i=1}^{n}\left(-\frac{1}{2\lambda_{k_i}}\right).$$

Then, for a given harmonic function H, the solution of (2.8) *is given by*

$$\varphi^{(l)} = \frac{1}{\lambda_l}\sum_{\Theta \in S_l} \Lambda_\Theta \frac{\partial}{\partial \nu_l}(R_\Theta H)\big|_{\partial B_l} + \frac{1}{\lambda_l}\frac{\partial H}{\partial \nu_l}\Big|_{\partial B_l}, \quad l = 1, \dots, m, \tag{4.2}$$

provided that

$$\min_{1 \le i \neq j \le m} dist(B_i, B_j) > (\sqrt{m-1} - 1)\max_{1 \le i \le m} r_i. \tag{4.3}$$

The series in (4.2) *converges absolutely.*

Proof. We first prove that the series in (4.2) converges absolutely on ∂B_l. Observe that

$$|\nabla(R_\Theta H)(x)| \le |R_\Theta \nabla H(x)| \prod_{i=1}^{n} |DR_{k_i}(R_{k_{i-1}} \dots R_{k_1}(x))|. \tag{4.4}$$

Assuming (4.3) and using

$$|DR_j(x)| \leq \frac{r_j^2}{|x - z_j|^2}, \quad x \in \mathbb{R}^2 \setminus B_j, \quad j = 1, \dots, m, \tag{4.5}$$

it follows from (4.4) that for $x \in \partial B_l$ we have

$$|\nabla(R_\Theta H)(x)| \leq M \cdot \prod_{i=1}^{n} \frac{r_{k_i}^2}{(d + r_{k_i})^2} \leq M \cdot \left(\frac{r_{max}}{(d + r_{max})}\right)^{2n} < M \left(\frac{s}{m-1}\right)^n \tag{4.6}$$

for some $s < 1$, where

$$d = \min_{1 \leq i \neq j \leq m} \operatorname{dist}(B_i, B_j), \quad r_{max} = \max_{1 \leq i \leq m} r_i, \quad \text{and } M = \|\nabla H\|_{L^\infty(\bigcup_{k=1}^m \overline{B_k})}.$$

Note that the number of those Θ's which have n components is $(m-1)^n$. It can be deduced from (4.6) that for $x \in \partial B_l$,

$$\sum_{\Theta \in S_l} \left| \Lambda_\Theta \frac{\partial}{\partial \nu_l} (R_\Theta H)(x) \right| \leq M \sum_{n=1}^{\infty} \left(\frac{s}{m-1}\right)^n (m-1)^n < C$$

for some constant C independent of x.

We now prove that $\varphi^{(l)}$ satisfies (2.8). Let us first observe the following: for each $l = 1, \dots, m$,

$$\cup_{k \neq l} \{(k, \Theta),\ (k) \mid \Theta \in S_k\} = S_l. \tag{4.7}$$

Recalling that $\mathcal{K}_{B_l}^* \varphi^{(l)} = 0$, $l = 1, \dots, m$, and using (4.1), (4.2), and (4.7), we arrive at

$$\begin{aligned}
\sum_{k \neq l} \frac{\partial(\mathcal{S}_{B_k} \varphi^{(k)})}{\partial \nu^{(l)}}\Big|_{B_l} &= \sum_{k \neq l} \frac{\partial}{\partial \nu^{(l)}} \left(\frac{-1}{2\lambda_k} R_k \left[\sum_{\Theta \in S_k} \Lambda_\Theta (R_\Theta H) + H \right] \right) \\
&= \sum_{\Theta \in S_l} \Lambda_\Theta \frac{\partial}{\partial \nu^{(l)}} (R_\Theta H) \\
&= \lambda_l \varphi^{(l)} - \frac{\partial H}{\partial \nu^{(l)}}\Big|_{\partial B_l},
\end{aligned}$$

which is exactly the desired result. ∎

As an immediate application of the above theorem we obtain the following explicit form of the first-order polarization tensor.

THEOREM 4.3. *Suppose $d = 2$. The first-order polarization tensor m_{ij} is given by*

$$m_{ij} = \sum_{l=1}^{m} |B_l| \frac{1}{\lambda_l} \left[\sum_{\Theta \in S_l} \Lambda_\Theta \frac{\partial}{\partial x_j} (R_\Theta(x_i))(z_l) + \delta_{ij} \right], \quad i, j = 1, 2. \tag{4.8}$$

Proof. Let $H(x) = x_i$ and $\varphi_i^{(l)}$ be the corresponding solution of (2.8). Then by (4.2), we have

$$\varphi_i^{(l)} = \frac{1}{\lambda_l} \frac{\partial}{\partial \nu^{(l)}} \left[\sum_{\Theta \in S_l} \Lambda_\Theta (R_\Theta(x_i)) + H \right], \quad i = 1, 2,\ l = 1, \dots, m.$$

It then follows from the divergence theorem and the mean value property of harmonic functions that

$$\begin{aligned}\int_{\partial B_l} x_j \varphi_i^{(l)} d\sigma &= \frac{1}{\lambda_l}\left[\sum_{\Theta\in S_l}\Lambda_\Theta \int_{\partial B_l} x_j \frac{\partial}{\partial \nu^{(l)}}(R_\Theta(x_i))(x)d\sigma + \int_{\partial B_l} x_j \frac{\partial}{\partial \nu^{(l)}} x_i d\sigma\right]\\ &= \frac{1}{\lambda_l}\left[\sum_{\Theta\in S_l}\Lambda_\Theta \int_{B_l} \frac{\partial}{\partial x_j}(R_\Theta(x_i))(x)d\sigma + \delta_{ij}|B_l|\right]\\ &= |B_l|\frac{1}{\lambda_l}\left[\sum_{\Theta\in S_l}\Lambda_\Theta \frac{\partial}{\partial x_j}(R_\Theta(x_i))(z_l) + \delta_{ij}\right].\end{aligned}$$

Thus we get the explicit expression (4.8) as desired. ∎

Let us now write formulae (4.2) and (4.8) in a more explicit way assuming that there are only two inclusions. We note that in this case the assumption (4.3) is trivially fulfilled. If $m = 2$, then R_Θ for $\Theta \in S_1$ takes the form

$$R_\Theta = (R_2R_1)^k R_2 R_1^n \quad \text{for some } k = 0, 1, \dots, \text{ and } n = 0, 1, \tag{4.9}$$

and R_Θ for $\Theta \in S_2$ takes the form

$$R_\Theta = (R_1R_2)^k R_1 R_2^n \quad \text{for some } k = 0, 1, \dots, \text{ and } n = 0, 1. \tag{4.10}$$

Here $R_j^0 = I$, $j = 1, 2$.

COROLLARY 4.4. *If $m = 2$, then*

$$\begin{aligned}\varphi^{(1)} &= \frac{1}{\lambda_1}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\frac{\partial}{\partial\nu^{(1)}}\left[(R_2R_1)^k\left(I - \frac{1}{2\lambda_2}R_2\right)H\right]\Big|_{\partial B_1},\\ \varphi^{(2)} &= \frac{1}{\lambda_2}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\frac{\partial}{\partial\nu^{(2)}}\left[(R_1R_2)^k\left(I - \frac{1}{2\lambda_1}R_1\right)H\right]\Big|_{\partial B_2}.\end{aligned} \tag{4.11}$$

Proof. It follows from (4.2), (4.9), and (4.10) that

$$\begin{aligned}\varphi^{(1)} &= \frac{1}{\lambda_1}\frac{\partial}{\partial\nu^{(1)}}\left[\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}(R_2R_1)^k\left(-\frac{1}{2\lambda_2}R_2 + \frac{1}{4\lambda_1\lambda_2}R_2R_1\right)H + H\right]\Big|_{\partial B_1},\\ \varphi^{(2)} &= \frac{1}{\lambda_2}\frac{\partial}{\partial\nu^{(2)}}\left[\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}(R_1R_2)^k\left(-\frac{1}{2\lambda_1}R_1 + \frac{1}{4\lambda_1\lambda_2}R_1R_2\right)H + H\right]\Big|_{\partial B_2}.\end{aligned}$$

By rearranging the summations, we get (4.11). ∎

COROLLARY 4.5. *Let $m = 2$. Suppose that the centers of the disks B_1 and B_2 are on the x_1-axis. Then the polarization tensor m_{ij} is given by*

$$
\begin{aligned}
&m_{12} = m_{21} = 0,\\
&m_{11} = \frac{|B_1|}{\lambda_1} + \frac{|B_2|}{\lambda_2}\\
&+ \frac{|B_1|}{\lambda_1}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\left[(R_2R_1)^k\left(\frac{1}{2\lambda_2}g_2 + \frac{1}{4\lambda_1\lambda_2}R_2(g_1)g_2\right)\prod_{i=0}^{k-1}(R_2R_1)^i(R_2(g_1)g_2)\right](z_1)\\
&+ \frac{|B_2|}{\lambda_2}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\left[(R_1R_2)^k\left(\frac{1}{2\lambda_1}g_1 + \frac{1}{4\lambda_1\lambda_2}R_1(g_2)g_1\right)\prod_{i=0}^{k-1}(R_1R_2)^i(R_1(g_2)g_1)\right](z_2),\\
&m_{22} = \frac{|B_1|}{\lambda_1} + \frac{|B_2|}{\lambda_2}\\
&+ \frac{|B_1|}{\lambda_1}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\left[(R_2R_1)^k\left(-\frac{1}{2\lambda_2}g_2 + \frac{1}{4\lambda_1\lambda_2}R_2(g_1)g_2\right)\prod_{i=0}^{k-1}(R_2R_1)^i(R_2(g_1)g_2)\right](z_1)\\
&+ \frac{|B_2|}{\lambda_2}\sum_{k=0}^{\infty}\frac{1}{(4\lambda_1\lambda_2)^k}\left[(R_1R_2)^k\left(-\frac{1}{2\lambda_1}g_1 + \frac{1}{4\lambda_1\lambda_2}R_1(g_2)g_1\right)\prod_{i=0}^{k-1}(R_1R_2)^i(R_1(g_2)g_1)\right](z_2),
\end{aligned}
$$

where the functions g_1 and g_2 are defined by

$$g_j(x) := \frac{r_j^2}{|x - z_j|^2}, \quad x \in \mathbb{R}^2 \setminus \overline{B_j},\ j = 1, 2.$$

Proof. By Theorem 4.3, (4.9), and (4.10), we have

$$
\begin{aligned}
m_{ij} =& \frac{|B_1|}{\lambda_1}\left[\sum_{k=0}^{\infty}(4\lambda_1\lambda_2)^{-k}\frac{\partial}{\partial x_j}\left((R_2R_1)^k\left(-\frac{1}{2\lambda_2}R_2 + \frac{1}{4\lambda_1\lambda_2}R_2R_1\right)(x_i)\right)(z_1) + \delta_{ij}\right]\\
&+ \frac{|B_2|}{\lambda_2}\left[\sum_{k=0}^{\infty}(4\lambda_1\lambda_2)^{-k}\frac{\partial}{\partial x_j}\left((R_1R_2)^k\left(-\frac{1}{2\lambda_1}R_1 + \frac{1}{4\lambda_1\lambda_2}R_1R_2\right)(x_i)\right)(z_2) + \delta_{ij}\right].
\end{aligned}
$$

Easy computations show that for x on the x_1-axis,

$$DR_{B_j}(x) = g_j(x)\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad j = 1, 2,$$

and

$$\nabla R_j f(x) = (R_j \nabla f)(x) g_j(x)\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \quad j = 1, 2.$$

Therefore, we get for $H = x_i$

$$
\begin{aligned}
&\nabla\Big((R_2R_1)^kR_2(H)\Big)(x) = \nabla H \cdot \left[(R_2R_1)^k g_2(x)\prod_{i=0}^{k-1}(R_2R_1)^i(R_2(g_1)g_2)(x)\right]\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},\\
&\nabla\Big((R_2R_1)^kR_2R_1(H)\Big)(x) = \nabla H \cdot \left[\prod_{i=0}^{k}(R_2R_1)^i(R_2(g_1)g_2)(x)\right]\begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}.
\end{aligned}
$$

One can get similar formulae for $\nabla((R_1R_2)^kR_1(H))$ and $\nabla((R_1R_2)^kR_1R_2(H))$. By substituting these formulae into the first equation of the proof, we obtain Corollary 4.5. ∎

5. Representation by equivalent ellipses. Let m_{ij} be the first-order polarization tensor of the inclusions $\cup_{l=1}^m B_l$. We define the *overall conductivity* $\bar{k}$ of $B = \cup_{l=1}^m B_l$ by

$$\frac{\bar{k}-1}{\bar{k}+1}\sum_{l=1}^{m}|B_l| := \sum_{l=1}^{m}\frac{k_l-1}{k_l+1}|B_l|, \tag{5.1}$$

and its *center* $\bar{z}$ by

$$\frac{\bar{k}-1}{\bar{k}+1}\bar{z}\sum_{l=1}^{m}|B_l| = \sum_{l=1}^{m}\frac{k_l-1}{k_l+1}\int_{B_l} x dx. \tag{5.2}$$

Note that if k_l is the same for all l, then $\bar{k} = k_l$ and $\bar{z}$ is the center of mass of B. Figure 7.1, at the end of the last section, shows that the center $\bar{z}$ is a very good match with the center reconstructed by the boundary measurements.

In this section we represent and visualize the multiple inclusions $\cup_{l=1}^m B_l$ by means of an ellipse, $\mathcal{E}$, of center $\bar{z}$ with the same polarization tensor. We call $\mathcal{E}$ the *equivalent ellipse* of $\cup_{l=1}^m B_l$. It will turn out that if we consider the problem of determining the collection D of the closely spaced small inhomogeneities D_l, the only information of real interest that could be reconstructed from boundary measurements is exactly $\mathcal{E}$. This will be shown in the last section.

At this point let us review a method to find an ellipse from a given first-order polarization tensor. This method is due to Brühl et al. [8]. Let $\mathcal{E}'$ be an ellipse whose focal line is on either the x_1- or the x_2-axis. We suppose that its semimajor axis is of length a and its semiminor axis is of length b. Let $\mathcal{E} = R\mathcal{E}'$, where $R = \left(\begin{smallmatrix}\cos\theta & -\sin\theta \\ \sin\theta & \cos\theta\end{smallmatrix}\right)$. Let M be the polarization tensor of $\mathcal{E}$. We want to recover a, b, and θ from M knowing the conductivity $k = \bar{k}$.

The polarization tensor M' for $\mathcal{E}'$ takes the form

$$M' = (k-1)|\mathcal{E}'|\begin{pmatrix}\frac{a+b}{a+kb} & 0 \\ 0 & \frac{a+b}{b+ka}\end{pmatrix}, \tag{5.3}$$

and that of $\mathcal{E}$ is given by $M = RM'R^T$. Suppose that the eigenvalues of M are λ_1 and λ_2 and the corresponding eigenvectors of unit length are $(e_{11}, e_{12})^T$ and $(e_{21}, e_{22})^T$. Then it is shown in [8] that

$$a = \sqrt{\frac{p}{\pi q}}, \quad b = \sqrt{\frac{pq}{\pi}}, \quad \theta = \arctan\frac{e_{21}}{e_{11}}, \tag{5.4}$$

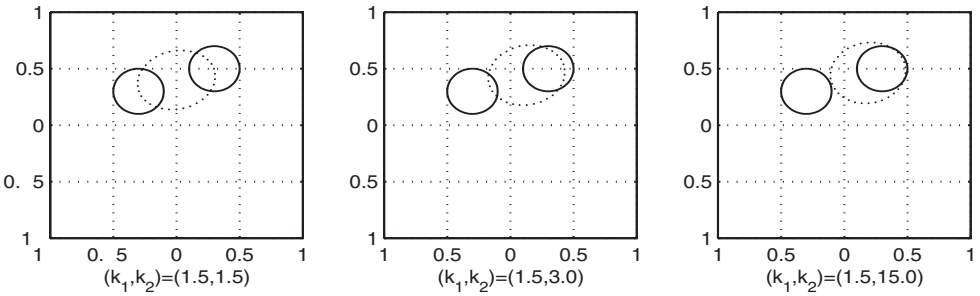
where

$$\frac{1}{p} = \frac{k-1}{k+1}\left(\frac{1}{\lambda_1}+\frac{1}{\lambda_2}\right) \quad \text{and} \quad q = \frac{\lambda_2 - k\lambda_1}{\lambda_1 - k\lambda_2}. \tag{5.5}$$

We now show some numerical examples of equivalent ellipses. We represent the set of inclusions $B = \cup_{l=1}^m B_l$ by an equivalent ellipse of center $\bar{z}$ and conductivity $\bar{k}$. We assume that the inclusion B_l takes the following form:

$$\partial B_l = \{\big(a_0^l + a_1^l\cos(t) + a_2^l\cos(2t), b_0^l + b_1^l\sin(t) + b_2^l\sin(2t)\big)\,|0 \le t < 2\pi\}.$$

In order to evaluate the first-order polarization tensor of multiple inclusions, we solve



$a_0^i, a_1^i, a_2^i, b_0^i, b_1^i, b_2^i$	k_i	$\bar{k}$	a	b	θ	$\bar{z}$

the integral equation (6.4) with $H(x) = x_i$ to find $\varphi_i^{(l)}$ for $i = 1, 2$ and $l = 1, \ldots, m$ and then calculate $m_{ij} = \sum_{l=1}^{m} \int_{\partial B_l} x_j \varphi_i^{(l)}(x) d\sigma$.

Figures 5.1 and 5.2 show how the equivalent ellipse changes as the conductivities and the sizes of the inhomogeneities B_l vary. The solid line represents the actual inhomogeneities and the dash lines are the effective ellipses. Figure 7.1 exhibits equivalent ellipses of other configurations.

6. Derivation of the asymptotic formula. In the remainder of this paper, we consider the problem of determining the location and the polarization tensor of a set of closely spaced small inclusions from boundary measurements. Our algorithm makes use of a new asymptotic expansion of the voltage potentials in the presence of a set of close-to-touching small conductivity inhomogeneities. Since this formula can be obtained following the arguments presented in [1], we only outline its derivation leaving the details to the reader.

In this section, we use the notation stated at the beginning of this paper and suppose that assumptions (H1), (H2), and (H3) hold.

Based on the arguments given in [19, 20], the following theorem was proved in [22].

THEOREM 6.1. *The solution u of the problem*

$$\begin{cases} \nabla \cdot \left(\chi\left(\Omega \setminus \bigcup_{j=1}^{m} \overline{D_j} \right) + \sum_{j=1}^{m} k_j \chi(D_j) \right) \nabla u = 0 \quad \text{in } \Omega, \\ \dfrac{\partial u}{\partial \nu}\Big|_{\partial\Omega} = g \end{cases} \tag{6.1}$$

can be represented as

$$u(x) = H(x) + \sum_{j=1}^{m} \mathcal{S}_{D_j} \psi^{(j)}(x), \quad x \in \Omega, \tag{6.2}$$

where the harmonic function H is given by

$$H(x) = -\mathcal{S}_\Omega(g)(x) + \mathcal{D}_\Omega(f)(x), \quad x \in \Omega, \quad f := u|_{\partial\Omega}, \tag{6.3}$$

and $\psi^{(j)} \in L^2_0(\partial D_j)$, $j = 1, \dots, m$, satisfies the integral equation

$$(\lambda_j I - \mathcal{K}^*_{D_j})\psi^{(j)} - \sum_{k \neq j} \frac{\partial(\mathcal{S}_{D_k}\psi^{(k)})}{\partial \nu^{(j)}}\Big|_{\partial D_j} = \frac{\partial H}{\partial \nu^{(j)}}\Big|_{\partial D_j} \quad \text{on } \partial D_j, \quad j = 1, \dots, m. \tag{6.4}$$

Moreover, for all $n \in \mathbb{N}$, there exist a constant $C_n = C(n, \Omega, dist(D, \partial\Omega))$ independent of $|D|$ and the conductivities $k_j, j = 1, \dots, m$, such that

$$\|H\|_{\mathcal{C}^n(\overline{D})} \leq C_n \|g\|_{L^2(\partial\Omega)}. \tag{6.5}$$

Let $N(x, z)$ be the Neumann function for Δ in Ω corresponding to a Dirac mass at z; that is, N is the solution to

$$\begin{cases} \Delta_x N(x, z) = -\delta_z \quad \text{in } \Omega, \\ \dfrac{\partial N}{\partial \nu}\Big|_{\partial\Omega} = -\dfrac{1}{|\partial\Omega|}. \end{cases} \tag{6.6}$$

In addition, we assume that

$$\int_{\partial\Omega} N(x, y) d\sigma(x) = 0 \quad \text{for } y \in \Omega. \tag{6.7}$$

Let us fix one more notation. For D, a subset of Ω, let

$$N_D f(x) := \int_{\partial D} N(x, y) f(y) d\sigma(y).$$

Then following the same lines of [1], one can prove the following theorem.

THEOREM 6.2. *Let U be the background solution, i.e., the solution of*

$$\begin{cases} \Delta U = 0 \quad \text{in } \Omega, \\ \dfrac{\partial U}{\partial \nu}\big|_{\partial\Omega} = g \in L^2_0(\partial\Omega), \\ \displaystyle\int_{\partial\Omega} U(x)d\sigma(x) = 0. \end{cases} \tag{6.8}$$

Then the solution u of (6.1) *can be represented as*

$$u(x) = U(x) - \sum_{j=1}^{m} N_{D_j}\psi^{(j)}(x), \quad x \in \partial\Omega, \tag{6.9}$$

where $\psi^{(j)}$, $j = 1, \dots, m$, is defined by (6.4).

For $x \in \partial\Omega$, by using the change of variables $y = \frac{x-z}{\epsilon}$ we may write

$$\sum_{j=1}^{m} N_{D_j}\psi^{(j)}(x) = \epsilon^{d-1}\sum_{j=1}^{m}\int_{\partial B_j} N(x, \epsilon y + z)\psi^{(j)}(\epsilon y + z)d\sigma(y). \tag{6.10}$$

As in [1], we expand the Neumann function as

$$N(x, \epsilon y + z) = \sum_{|\beta|=0}^{\infty} \frac{1}{\beta!}\epsilon^{|\beta|}\partial_z^\beta N(x, z)y^\beta. \tag{6.11}$$

We then use the uniqueness of the solution to the integral equation (3.1) and the expansion of the harmonic function H,

$$H(x) := H(z) + \sum_{|\alpha|=1}^{\infty} \frac{1}{\alpha!}(\partial^\alpha H)(z)(x-z)^\alpha, \quad x \in \overline{D},$$

to show that

$$\psi^{(j)}(\epsilon y + z) = \sum_{|\alpha|=1}^{\infty} \frac{\epsilon^{|\alpha|-1}}{\alpha!}(\partial^\alpha H)(z)\varphi_\alpha^{(j)}(y), \quad y \in \partial B_j, \tag{6.12}$$

where $\varphi_\alpha^{(j)}$ is the solution of (3.1). Substituting (6.11) and (6.12) into (6.10), we obtain

$$\sum_{j=1}^{m} N_{D_j}\psi^{(j)}(x) = \sum_{|\alpha|=1}^{\infty}\sum_{|\beta|=0}^{\infty} \frac{\epsilon^{|\alpha|+|\beta|+d-2}}{\alpha!\beta!}(\partial^\alpha H)(z)\partial_z^\beta N(x, z)\sum_{j=1}^{m}\int_{\partial B_j} y^\beta \varphi_\alpha^{(j)}(y)d\sigma(y).$$

If $\beta = 0$, then $\int_{\partial B_j} \varphi_\alpha^{(j)}(y)d\sigma(y) = 0$ for $j = 1, \dots, m$, and hence we get

$$\sum_{j=1}^{m} N_{D_j}\psi^{(j)}(x) = \sum_{|\alpha|=1}^{\infty}\sum_{|\beta|=1}^{\infty} \frac{\epsilon^{|\alpha|+|\beta|+d-2}}{\alpha!\beta!}(\partial^\alpha H)(z)\partial_z^\beta N(x, z)m_{\alpha\beta}, \tag{6.13}$$

where $m_{\alpha\beta}$ is the polarization tensor.

We now convert the formula (6.13) to the one given solely by U and its derivatives, not H. Using formula (4.10) of [1], one can show that

$$|\partial^\alpha H(z) - \partial^\alpha U(z)| \leq C\epsilon^d \|g\|_{L^2(\partial\Omega)} \quad \text{for } \alpha \in \mathbb{N},$$

where C is independent of ϵ and g. We finally have the following theorem.

THEOREM 6.3. *The following pointwise asymptotic expansion holds uniformly in $x \in \partial\Omega$ for $d = 2$ or 3:*

$$u(x) = U(x) - \sum_{|\alpha|=1}^{d} \sum_{|\beta|=1}^{d} \frac{\epsilon^{|\alpha|+|\beta|+d-2}}{\alpha!\beta!} (\partial^\alpha U)(z) \partial_z^\beta N(x,z) m_{\alpha\beta} + O(\epsilon^{2d}), \tag{6.14}$$

where the remainders $O(\epsilon^{2d})$ are dominated by $C\epsilon^{2d}\|g\|_{L^2(\partial\Omega)}$ for some constant C independent of $x \in \partial\Omega$.

7. Detection of closely spaced inclusions. In this section, we present an algorithm to reconstruct the first-order polarization tensor and the center of closely spaced small inclusions from a finite number of boundary measurements and show some results of numerical experiments. The algorithm is based on the asymptotic expansion formula (6.14) and represents the generalization of the numerical methods derived in [6] and [17] for determining well-separated conductivity inhomogeneities. For $g \in L_0^2(\partial\Omega)$, define the harmonic function $H[g](x)$, $x \in \mathbb{R}^d \setminus \overline{\Omega}$, by

$$H[g](x) := -\mathcal{S}_\Omega(g)(x) + \mathcal{D}_\Omega(u|_{\partial\Omega})(x), \quad x \in \mathbb{R}^d \setminus \bar{\Omega}, \tag{7.1}$$

where u is the solution of (6.1). Then by substituting (6.14) into (7.1) and using a simple formula $\mathcal{D}_\Omega(N(\cdot - z))(x) = \Gamma(x - z)$ for $z \in \Omega$ and $x \in \mathbb{R}^d \setminus \overline{\Omega}$, we get

$$H[g](x) = -\sum_{|\alpha|=1}^{d} \sum_{|\beta|=1}^{d} \frac{\epsilon^{|\alpha|+|\beta|+d-2}}{\alpha!\beta!} (\partial^\alpha U)(z) \partial_z^\beta \Gamma(x - z) m_{\alpha\beta} + O(\epsilon^{2d}). \tag{7.2}$$

Assume for the sake of simplicity that $d = 2$. Our reconstruction procedure is the following.

DETECTION ALGORITHM.

(D1) For $g_j = \frac{\partial x_j}{\partial \nu}$, $j = 1, 2$, measure $u|_{\partial\Omega}$.

(D2) Compute the first-order polarization tensor $\epsilon^2 M = \epsilon^2 (m_{ij})$ for D by

$$\epsilon^2 m_{ij} = \lim_{t\to\infty} 2\pi t H[g_i](te_j). \tag{7.3}$$

(D3) Compute $h_j = \lim_{t\to\infty} 2\pi t H[g_3](te_j)$ for $g_3 = \frac{\partial(x_1 x_2)}{\partial \nu}$, $j = 1, 2$. Then the center is estimated by solving

$$z = (h_1, h_2)(\epsilon^2 M)^{-1}. \tag{7.4}$$

(D4) Let the overall conductivity $\bar{k} = \infty$ if the polarization tensor M is positive definite. Otherwise assume $\bar{k} = 0$. Using the similar method in [8] as explained in section 5, we obtain the shape of the equivalent ellipse.

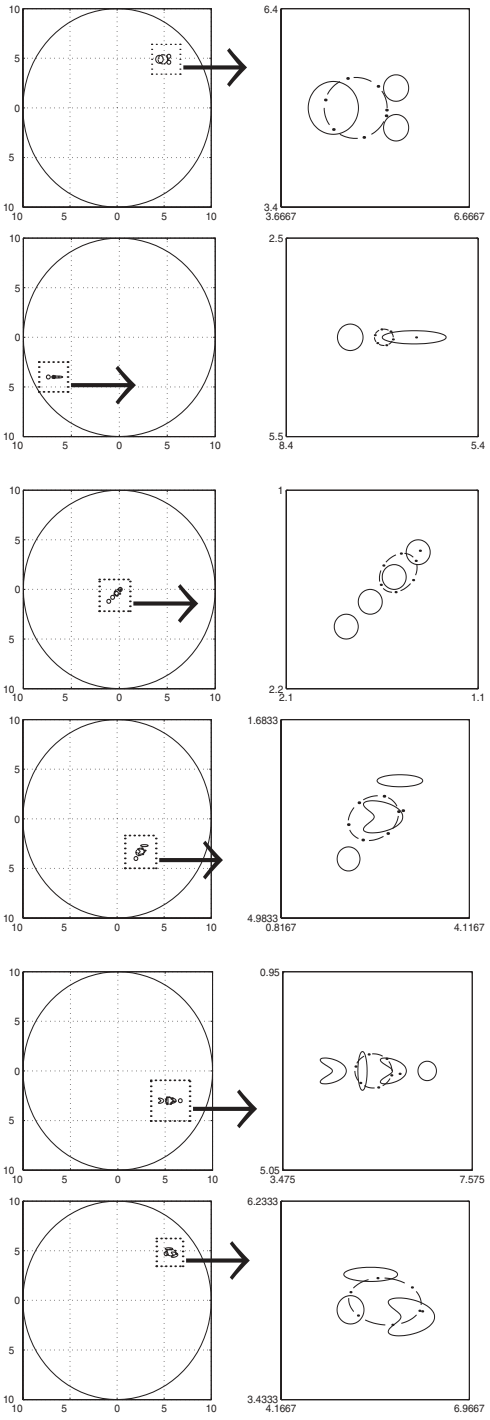

FIG. 7.1. *Reconstruction of closely spaced small inhomogeneities. The dash line is the equivalent ellipse and the dash-dot line is the detected ellipse. The table for numerical values is given in Table* 7.1.

TABLE 7.1

In order to collect data $u|_{\partial\Omega}$ in step (D1), we solve the direct problem (6.1) as follows: Using the formula (6.2) and the jump relations (2.5) and (2.6), we have the following equation:

(7.5)
$$\begin{cases} u = \dfrac{u}{2} + \mathcal{K}_\Omega u - \mathcal{S}_\Omega g + \displaystyle\sum_{i=1}^{m} \mathcal{S}_{D_i}\psi^{(i)} \quad \text{on } \partial\Omega, \\ (\lambda_j I - \mathcal{K}_{D_j}^*)\psi^{(j)} - \displaystyle\sum_{k\neq j} \frac{\partial(\mathcal{S}_{D_k}\psi^{(k)})}{\partial\nu^{(j)}}\bigg|_{\partial D_j} = \frac{\partial H}{\partial\nu^{(j)}}\bigg|_{\partial D_j} \quad \text{on } \partial D_j, \quad j = 1, \dots, m. \end{cases}$$

We solve the integral equation using the collocation method and obtain $u|_{\partial\Omega}$ on $\partial\Omega$ for given data g.

A few words are required for the step (D4). In order to find the overall conductivity, it is necessary to know the individual conductivity k_l and the size of B_l, $l = 1, \dots, m$, which seems impossible. Thus we assume a priori that $\bar{k}$ is either ∞ or 0 depending upon the sign of the detected polarization tensor. Therefore, it is natural that our algorithm gives better information when the conductivity contrast between the background and inclusions is high.

We illustrate in Figure 7.1 the viability of this algorithm. For rigorous justification of the validity of this algorithm the reader is referred to [6, 17]. It should also be noted that although our algorithm is only described and tested in the two-dimensional case, we are confident that it works in the three-dimensional case as well.

Acknowledgment. We would like to thank June-Yub Lee for helpful conversation on numerical computations.

QUADRILATERAL $H(\mathrm{div})$ FINITE ELEMENTS*

DOUGLAS N. ARNOLD†, DANIELE BOFFI‡, AND RICHARD S. FALK§

Abstract. We consider the approximation properties of quadrilateral finite element spaces of vector fields defined by the Piola transform, extending results previously obtained for scalar approximation. The finite element spaces are constructed starting with a given finite dimensional space of vector fields on a square reference element, which is then transformed to a space of vector fields on each convex quadrilateral element via the Piola transform associated to a bilinear isomorphism of the square onto the element. For affine isomorphisms, a necessary and sufficient condition for approximation of order $r+1$ in L^2 is that each component of the given space of functions on the reference element contain all polynomial functions of total degree at most r. In the case of bilinear isomorphisms, the situation is more complicated and we give a precise characterization of what is needed for optimal order L^2-approximation of the function and of its divergence. As applications, we demonstrate degradation of the convergence order on quadrilateral meshes as compared to rectangular meshes for some standard finite element approximations of $\boldsymbol{H}(\mathrm{div})$. We also derive new estimates for approximation by quadrilateral Raviart–Thomas elements (requiring less regularity) and propose a new quadrilateral finite element space which provides optimal order approximation in $\boldsymbol{H}(\mathrm{div})$. Finally, we demonstrate the theory with numerical computations of mixed and least squares finite element approximations of the solution of Poisson's equation.

1. Introduction.

Many mixed finite element methods are based on variational principles employing the space $\boldsymbol{H}(\mathrm{div},\Omega)$ consisting of $\boldsymbol{L}^2$ vector fields with divergence in L^2. For such methods, finite element subspaces of $\boldsymbol{H}(\mathrm{div},\Omega)$ are generally constructed starting from a space of reference shape functions on a reference element, typically the unit simplex or unit square in two dimensions. See, e.g., [4] for numerous examples. These shape functions are then transformed to general triangular, rectangular, or quadrilateral elements via polynomial diffeomorphisms and the Piola transform. For the case of triangular and rectangular (or more generally parallelogram) elements, i.e., the case of affine isomorphisms, the order of approximation so achieved can be easily determined from the highest degree of complete polynomial space contained in the space of reference shape functions. In the case of arbitrary convex quadrilaterals with bilinear diffeomorphisms, the situation is less well understood. In this paper, we determine precisely what reference shape functions are needed to obtain a given order of approximation in $\boldsymbol{L}^2$ and $\boldsymbol{H}(\mathrm{div},\Omega)$ by such elements. It turns out that the accuracy of some of the standard $\boldsymbol{H}(\mathrm{div},\Omega)$ finite elements is lower for general quadrilateral elements than for rectangular elements.

Let $\hat{K}$ be a reference element, the closure of an open set in $\mathbb{R}^2$, and let $\boldsymbol{F}:\hat{K}\to\mathbb{R}^2$ be a diffeomorphism of $\hat{K}$ onto an actual element $K=\boldsymbol{F}(\hat{K})$. For functions in

$\boldsymbol{H}(\mathrm{div},\Omega)$ the natural way to transform functions from $\hat{K}$ to K is via the *Piola transform*. Namely, given a function $\hat{\boldsymbol{u}} : \hat{K} \to \mathbb{R}^2$, we define $\boldsymbol{u} = \boldsymbol{P}_F\hat{u} : K \to \mathbb{R}^2$ by

$$\boldsymbol{u}(\boldsymbol{x}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1} D\boldsymbol{F}(\hat{\boldsymbol{x}})\hat{\boldsymbol{u}}(\hat{\boldsymbol{x}}), \tag{1.1}$$

where $\boldsymbol{x} = \boldsymbol{F}(\hat{\boldsymbol{x}})$, and $D\boldsymbol{F}(\hat{\boldsymbol{x}})$ is the Jacobian matrix of the mapping $\boldsymbol{F}$ and $J\boldsymbol{F}(\hat{\boldsymbol{x}})$ its determinant. The transform has the property that if $\boldsymbol{u} = \boldsymbol{P}_F\hat{\boldsymbol{u}}$, $p = \hat{p} \circ \boldsymbol{F}^{-1}$ for some $\hat{p} : \hat{K} \to \mathbb{R}$, and $\boldsymbol{n}$ and $\hat{\boldsymbol{n}}$ denote the unit outward normals on ∂K and $\partial\hat{K}$, respectively, then

$$\int_K \operatorname{div} \boldsymbol{u} p \, d\boldsymbol{x} = \int_{\hat{K}} \hat{\operatorname{div}}\, \hat{\boldsymbol{u}}\hat{p} \, d\hat{\boldsymbol{x}}, \qquad \int_{\partial K} \boldsymbol{u}\cdot\boldsymbol{n} p \, ds = \int_{\partial\hat{K}} \hat{\boldsymbol{u}}\cdot\hat{\boldsymbol{n}}\hat{p} \, d\hat{s}.$$

Since continuity of $\boldsymbol{u}\cdot\boldsymbol{n}$ is necessary for finite element subspaces of $\boldsymbol{H}(\mathrm{div},\Omega)$, use of the Piola transform facilitates the definition of finite element subspaces of $\boldsymbol{H}(\mathrm{div},\Omega)$ by mapping from a reference element. Another important property of the Piola transform, which follows directly from the chain rule and which we shall use frequently below, is that if $\boldsymbol{G}$ is a diffeomorphism whose domain is K, then

$$\boldsymbol{P}_{G\circ F} = \boldsymbol{P}_G \circ \boldsymbol{P}_F. \tag{1.2}$$

Using the Piola transform, a standard construction of a finite element subspace proceeds as follows. Let $\hat{K}$ be a fixed reference element, typically either the unit simplex or the unit square. Let $\hat{\boldsymbol{V}} \subset \boldsymbol{H}(\mathrm{div},\hat{K})$ be a finite-dimensional space of vector fields on $\hat{K}$, typically polynomial, the space of reference *shape functions*. Now suppose we are given a mesh $\mathcal{T}_h$ consisting of elements K, each of which is the image of $\hat{K}$ under some given diffeomorphism: $K = \boldsymbol{F}_K(\hat{K})$. Via the Piola transform we then obtain the space $\boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$ of shape functions on K. Finally we define the finite element space as

$$\boldsymbol{S}_h = \{\boldsymbol{v} \in \boldsymbol{H}(\mathrm{div},\Omega) \mid \boldsymbol{v}|_K \in \boldsymbol{P}_{F_K}\hat{\boldsymbol{V}} \ \forall K \in \mathcal{T}_h\}.$$

Recall that $\boldsymbol{S}_h$ may be characterized as the subspace of

$$\boldsymbol{V}_h := \{\boldsymbol{v} \in \boldsymbol{L}^2(\Omega) \mid \boldsymbol{v}|_K \in \boldsymbol{P}_{F_K}\hat{\boldsymbol{V}} \ \forall K \in \mathcal{T}_h\},$$

consisting of vector fields whose normal component is continuous across interelement edges.

We now recall a few examples of this construction in the case where $\hat{K}$ is the unit square. If we restrict to linear diffeomorphisms $\boldsymbol{F}$, the resulting finite elements $K = \boldsymbol{F}(\hat{K})$ will be parallelograms (or, with the further restriction to diagonal linear diffeomorphisms, rectangles). If we allow general bilinear diffeomorphisms, the resulting finite elements can be arbitrary convex quadrilaterals. The best known example of shape functions on the reference square for construction of $\boldsymbol{H}(\mathrm{div},\Omega)$ finite element spaces is the Raviart–Thomas space of index $r \geq 0$ for which $\hat{\boldsymbol{V}}$ is taken to be $\boldsymbol{\mathcal{RT}}_r := \mathcal{P}_{r+1,r}(\hat{K}) \times \mathcal{P}_{r,r+1}(\hat{K})$. Here and below $\mathcal{P}_{s,t}(\hat{K})$ denotes the space of polynomial functions on $\hat{K}$ of degree at most s in $\hat{x}_1$ and at most t in $\hat{x}_2$. Thus a basis for $\boldsymbol{\mathcal{RT}}_r$ is given by the $2(r+1)(r+2)$ vector fields

$$(\hat{x}_1^i\hat{x}_2^j, 0), \quad (0, \hat{x}_1^j\hat{x}_2^i), \quad 0 \leq i \leq r+1, \ 0 \leq j \leq r. \tag{1.3}$$

A second example is given by choosing $\hat{\boldsymbol{V}}$ to be the Brezzi–Douglas–Marini space of index $r \geq 1$, $\hat{\boldsymbol{V}} = \boldsymbol{\mathcal{BDM}}_r$, which is the span of $\boldsymbol{\mathcal{P}}_r(\hat{K})$ and the two additional vector fields $\mathrm{curl}(\hat{x}_1^{r+1}\hat{x}_2)$ and $\mathrm{curl}(\hat{x}_1\hat{x}_2^{r+1})$. Another possibility is the Brezzi–Douglas–Fortin–Marini space $\hat{\boldsymbol{V}} = \boldsymbol{\mathcal{BDFM}}_{r+1}$, $r \geq 0$, which is the subspace of codimension 2 of $\boldsymbol{\mathcal{P}}_{r+1}(\hat{K})$ spanned by $(\hat{x}_1^i\hat{x}_2^j, 0)$ and $(0, \hat{x}_1^j\hat{x}_2^i)$ for nonnegative i and j with $i+j \leq r+1$ and $j \leq r$. We note that for each of these choices $\hat{\boldsymbol{V}}$ strictly contains $\boldsymbol{\mathcal{P}}_r(\hat{K})$ but does not contain $\boldsymbol{\mathcal{P}}_{r+1}(\hat{K})$. Note that $\boldsymbol{\mathcal{BDM}}_0$ is not defined, $\boldsymbol{\mathcal{BDFM}}_1 = \boldsymbol{\mathcal{RT}}_0$, and $\boldsymbol{\mathcal{BDM}}_r \subsetneq \boldsymbol{\mathcal{BDFM}}_{r+1} \subsetneq \boldsymbol{\mathcal{RT}}_r$ for $r \geq 1$. More information about these spaces can be found in [4, section III.3.2].

One of the basic issues in finite element theory concerns the approximation properties of finite element spaces. Namely, under certain regularity assumptions on the mesh $\mathcal{T}_h$, for a given smooth vector field $\boldsymbol{u} : \Omega \to \mathbb{R}^2$ one usually estimates the error (in some norm to be made more precise) in the best approximation of $\boldsymbol{u}$ by vector fields in $\boldsymbol{S}_h$ as a quantity involving powers of h, the maximum element diameter. For instance, given a shape-regular sequence of triangular or parallelogram meshes $\mathcal{T}_h$ of Ω with $\boldsymbol{S}_h$ the corresponding Raviart–Thomas spaces of index $r \geq 0$, then for any vector field $\boldsymbol{u}$ smooth enough that the right-hand sides of the next expressions make sense, there exists $\boldsymbol{\pi}_h\boldsymbol{u} \in \boldsymbol{S}_h$ such that (cf. [4])

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u}\|_{L^2(\Omega)} \leq Ch^{r+1}|\boldsymbol{u}|_{H^{r+1}(\Omega)},$$
$$\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u})\|_{L^2(\Omega)} \leq Ch^{r+1}|\operatorname{div}\boldsymbol{u}|_{H^{r+1}(\Omega)}.$$

In the case of more general shape-regular convex quadrilaterals, the best known estimate appears to be the one obtained by Thomas in [12]:

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u}\|_{L^2(\Omega)} \leq Ch^{r+1}[|\boldsymbol{u}|_{H^{r+1}(\Omega)} + h|\operatorname{div}\boldsymbol{u}|_{H^{r+1}(\Omega)}],$$
$$\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u})\|_{L^2(\Omega)} \leq Ch^{r}|\operatorname{div}\boldsymbol{u}|_{H^{r+1}(\Omega)}.$$

Note that the order in h for the L^2 estimate on $\boldsymbol{u}$ is the same as for the parallelogram meshes, but additional regularity is required, while the estimate for $\operatorname{div}\boldsymbol{u}$ is one order lower in h. As we shall see below, the latter estimate cannot be improved. However, in section 4 of this paper, we use a modification of the usual scaling argument to obtain the improved L^2 estimate

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u}\|_{L^2(\Omega)} \leq Ch^{r+1}|\boldsymbol{u}|_{H^{r+1}(\Omega)}.$$

We restrict our presentation to two-dimensional domains, the three-dimensional case being considerably more complicated. We hope to address this issue in future work. We observe that in [9] the construction of $\boldsymbol{H}(\mathrm{div}, \Omega)$ elements on hexahedrons has been considered. The point of view of [9] is somewhat different from ours in that the elements are not obtained by applying the Piola transform starting from a fixed set of basis functions on the unit cube. Other papers dealing with modifications of standard shape functions for the approximation of vector fields are [11, 8]; in the first paper a simple lowest-order two-dimensional element is proposed (which is not obtained via the Piola transform), while in the second paper a construction based on macroelements is presented.

In this paper, we adapt the theory presented in [1] to the case of vector elements defined by the Piola transform, seeking necessary conditions for L^2-approximation of order $r+1$ for $\boldsymbol{u}$ and $\operatorname{div}\boldsymbol{u}$. More specifically, we shall prove in section 3 that in order for the $\boldsymbol{L}^2$ error in the best approximation of $\boldsymbol{u}$ by functions in $\boldsymbol{V}_h$ to be of order

$r+1$, the space $\hat{\boldsymbol{V}}$ must contain $\boldsymbol{\mathcal{S}}_r$, where $\boldsymbol{\mathcal{S}}_r$ is the subspace of codimension one of $\boldsymbol{\mathcal{RT}}_r$ spanned by the vector fields in (1.3) except that the two fields $(\hat{x}_1^{r+1}\hat{x}_2^r, 0)$ and $(0, \hat{x}_1^r\hat{x}_2^{r+1})$ are replaced by the single vector field $(\hat{x}_1^{r+1}\hat{x}_2^r, -\hat{x}_1^r\hat{x}_2^{r+1})$. To establish this result, we shall exhibit a domain Ω and a sequence $\mathcal{T}_h$ of meshes of it, and prove that whenever $\boldsymbol{\mathcal{S}}_r$ is not contained in $\hat{\boldsymbol{V}}$, there exists a smooth vector field $\boldsymbol{u}$ on Ω such that

$$\inf_{\boldsymbol{v}\in\boldsymbol{V}_h} \|\boldsymbol{u}-\boldsymbol{v}\|_{L^2(\Omega)} \neq o(h^r).$$

The example is far from pathological. The domain is simply a square, the mesh sequence does not degenerate in any sense—in fact all the elements of all the meshes in the sequence are similar to a single right trapezoid—and the function $\boldsymbol{u}$ is a polynomial. We use the same mesh sequence to establish a necessary condition for order $r+1$ approximation to $\operatorname{div}\boldsymbol{u}$, namely that $\operatorname{div}\hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$, where $\mathcal{R}_r$ is the subspace of codimension one of $\mathcal{Q}_{r+1}$, the space of polynomials of degree $\leq r+1$ in each variable separately, spanned by the monomials in $\mathcal{Q}_{r+1}$ except $\hat{x}_1^{r+1}\hat{x}_2^{r+1}$. A consequence of these results, also discussed in section 3, is that while the Raviart–Thomas space of index r achieves order $r+1$ approximation in $\boldsymbol{L}^2$ for quadrilateral meshes as for rectangular meshes, the order of approximation of the divergence is only of order r in the quadrilateral case (but of order $r+1$ for rectangular meshes). Thus, in the case $r=0$, there is no convergence in $\boldsymbol{H}(\operatorname{div},\Omega)$. For the Brezzi–Douglas–Marini and Brezzi–Douglas–Fortin–Marini spaces, the order of convergence is severely reduced on general quadrilateral meshes not only for $\operatorname{div}\boldsymbol{u}$ but also for $\boldsymbol{u}$.

In section 4, we show that the necessary conditions for order $r+1$ approximation of $\boldsymbol{u}$ and $\operatorname{div}\boldsymbol{u}$ established in section 3 are also sufficient. The argument used allows us to obtain the previously mentioned improved estimate for approximation by quadrilateral Raviart–Thomas elements. In section 5, we devise a new finite element subspace of $\boldsymbol{H}(\operatorname{div},\Omega)$ which gives optimal order approximation in both $\ll^2$ and $\boldsymbol{H}(\operatorname{div},\Omega)$ on general convex quadrilaterals. In sections 6 and 7, we present applications of these results to the approximation of second order elliptic partial differential equations by mixed and least squares finite element methods. In particular, we show that despite the lower order of approximation of the divergence by Raviart–Thomas quadrilateral elements, the mixed method approximation of the scalar and vector variable retain optimal order convergence orders in L^2. By contrast, error estimates for the least squares method indicate a possible loss of convergence for both the scalar and vector variable. In the final section, we illustrate the positive results with some numerical examples and confirm the degradation of accuracy on quadrilateral meshes in the cases predicted by our theory.

2. Approximation theory of vector fields on rectangular meshes. In this preliminary section of the paper we adapt to vector fields the results presented in the corresponding section of [1] for scalar functions. Although the Piola transform is used in the definition of the finite elements, its simple expression on rectangular meshes requires only minor changes in the proof given in [1] and so we give only a statement of the results.

Let K be any square with edges parallel to the axes, namely $K = \boldsymbol{F}_K(\hat{K})$ with

$$\boldsymbol{F}_K(\hat{\boldsymbol{x}}) = \boldsymbol{x}_K + h_K\hat{\boldsymbol{x}}, \tag{2.1}$$

where $\boldsymbol{x}_K \in \mathbb{R}^2$ is the lower left corner of K and $h_K > 0$ is its side length. The Piola transform of $\hat{\boldsymbol{u}} \in \boldsymbol{L}^2(\hat{K})$ is simply given by $(\boldsymbol{P}_{F_K}\hat{\boldsymbol{u}})(\boldsymbol{x}) = h_K^{-1}\hat{\boldsymbol{u}}(\hat{\boldsymbol{x}})$ where

$\boldsymbol{x} = \boldsymbol{F}_K\hat{\boldsymbol{x}}$. We also have the simple expressions $\operatorname{div}(\boldsymbol{P}_{F_K}\hat{\boldsymbol{u}})(\boldsymbol{x}) = h_K^{-2}\,\hat{\operatorname{div}}\,\hat{\boldsymbol{u}}(\hat{\boldsymbol{x}})$ and $\|\boldsymbol{P}_{F_K}\hat{\boldsymbol{u}}\|_{L^2(K)} = \|\hat{\boldsymbol{u}}\|_{L^2(\hat{K})}$.

Let Ω denote the unit square (Ω and $\hat{K}$ both denote the unit square, but we use the notation Ω when we think of it as a domain, while we use $\hat{K}$ when we think of it as a reference element), and for n a positive integer, let $\mathcal{U}_h$ be the uniform mesh of Ω into n^2 subsquares of side length $h = 1/n$. Given a subspace $\hat{\boldsymbol{V}}$ of $\boldsymbol{L}^2(\hat{K})$ we define

$$\boldsymbol{V}_h = \{\boldsymbol{u} : \Omega \to \mathbb{R}^2 \mid \boldsymbol{u}|_K \in \boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}\ \forall K \in \mathcal{U}_h\}. \tag{2.2}$$

In this definition, when we write $\boldsymbol{u}|_K \in \boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$ we mean only that $\boldsymbol{u}|_K$ agrees with a function in $\boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$ almost everywhere, and so do not impose any interelement continuity. Then we have the following approximation results.

THEOREM 2.1. *Let $\hat{\boldsymbol{V}}$ be a finite-dimensional subspace of $\boldsymbol{L}^2(\hat{K})$ and r be a nonnegative integer. The following conditions are equivalent:*

(i) *There is a constant C such that $\inf_{\boldsymbol{v}\in\boldsymbol{V}_h}\|\boldsymbol{u}-\boldsymbol{v}\|_{L^2(\Omega)} \le Ch^{r+1}|\boldsymbol{u}|_{H^{r+1}(\Omega)}$ for all $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(\Omega)$.*

(ii) $\inf_{\boldsymbol{v}\in\boldsymbol{V}_h}\|\boldsymbol{u}-\boldsymbol{v}\|_{L^2(\Omega)} = o(h^r)$ *for all $\boldsymbol{u} \in \boldsymbol{\mathcal{P}}_r(\Omega)$.*

(iii) $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(\hat{K})$.

THEOREM 2.2. *Let $\hat{\boldsymbol{V}}$ be a finite-dimensional subspace of $\boldsymbol{L}^2(\hat{K})$ and r be a nonnegative integer. The following conditions are equivalent:*

(i) *There is a constant C such that*

$$\inf_{\boldsymbol{v}\in\boldsymbol{V}_h}\|\operatorname{div}\boldsymbol{u}-\operatorname{div}\boldsymbol{v}\|_{L^2(\Omega)} \le Ch^{r+1}|\operatorname{div}\boldsymbol{u}|_{H^{r+1}(\Omega)}$$

for all $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(\Omega)$ with $\operatorname{div}\boldsymbol{u} \in H^{r+1}(\Omega)$.

(ii) $\inf_{\boldsymbol{v}\in\boldsymbol{V}_h}\|\operatorname{div}\boldsymbol{u}-\operatorname{div}\boldsymbol{v}\|_{L^2(\Omega)} = o(h^r)$ *for all $\boldsymbol{u}$ with $\operatorname{div}\boldsymbol{u} \in \mathcal{P}_r(\Omega)$.*

(iii) $\hat{\operatorname{div}}\,\hat{\boldsymbol{V}} \supseteq \mathcal{P}_r(\hat{K})$.

Remark. Since we do not impose interelement continuity in the definition of $\boldsymbol{V}_h$, in Theorem 2.2 $\operatorname{div}\boldsymbol{v}$ should be interpreted as the divergence applied elementwise to $\boldsymbol{v} \in \boldsymbol{V}_h$.

3. A necessary condition for optimal approximation of vector fields on general quadrilateral meshes. In this section, we determine the properties of the finite element approximating spaces that are necessary for order $r+1$ L^2-approximation of a vector field and its divergence on quadrilateral meshes. The construction of the finite element spaces proceeds as in the previous section. We start with the reference shape functions, a finite-dimensional space $\hat{\boldsymbol{V}}$ of vector fields on the unit square $\hat{K} = [0,1]\times[0,1]$ (typically $\hat{\boldsymbol{V}}$ consists of polynomials). Given an arbitrary convex quadrilateral K and a bilinear isomorphism $\boldsymbol{F}_K$ of the reference element $\hat{K}$ onto K, the shape functions on K are then taken to be $\boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$. (Note that there are eight possible choices for the bilinear isomorphism $\boldsymbol{F}_K$, but the space $\boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$ does not depend on the particular choice whenever $\hat{\boldsymbol{V}}$ is invariant under the symmetries of the square, which is usually the case in practice. When that is not the case, which we shall allow, it is necessary to specify not only the elements K but for each a choice of bilinear isomorphism from the reference element to K.) Finally, given a quadrilateral mesh $\mathcal{T}$ of a two-dimensional domain Ω, we can then construct the space of vector fields $\boldsymbol{V}(\mathcal{T})$ consisting of functions on Ω which belong to $\boldsymbol{P}_{F_K}\hat{\boldsymbol{V}}$ when restricted to a generic quadrilateral $K \in \mathcal{T}$.

It follows from the results of the previous section that if we consider the sequence $\mathcal{T}_h = \mathcal{U}_h$ of meshes of the unit square into congruent subsquares of side length $h = 1/n$,

then the approximation estimate

$$\inf_{\boldsymbol{v}\in\boldsymbol{V}(\mathcal{T}_h)} \|\boldsymbol{u}-\boldsymbol{v}\|_{L^2(\Omega)} = o(h^r) \quad \forall\ \boldsymbol{u}\in\boldsymbol{\mathcal{P}}_r(\Omega) \tag{3.1}$$

is valid only if $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(\hat{K})$ and the estimate

$$\inf_{\boldsymbol{v}\in\boldsymbol{V}(\mathcal{T}_h)} \|\operatorname{div}\boldsymbol{u} - \operatorname{div}\boldsymbol{v}\|_{L^2(\Omega)} = o(h^r) \quad \forall\ \boldsymbol{u} \text{ with } \operatorname{div}\boldsymbol{u}\in\mathcal{P}_r(\Omega) \tag{3.2}$$

is valid only if $\hat{\operatorname{div}}(\hat{\boldsymbol{V}}) \supseteq \mathcal{P}_r(\hat{K})$. In this section we show that for these estimates to hold for more general quadrilateral mesh sequences $\mathcal{T}_h$, stronger conditions on $\hat{\boldsymbol{V}}$ are required.

Before stating the main results of this section, we briefly recall a measure for the shape regularity of a convex quadrilateral K, cf. [7, A.2, pp. 104–105] or [13]. From the quadrilateral K we obtain four triangles by the four possible choices of three vertices from the vertices of K, and we define ρ_K as the smallest diameter of the inscribed circles to these four triangles. The *shape constant* of K is then $\sigma_K := h_K/\rho_K$, where $h_K = \operatorname{diam}(K)$. A bound on σ_K implies a bound on the ratio of any two sides of K and also a bound away from 0 and π for its angles (and conversely such bounds imply an upper bound on σ_K). It also implies bounds on the Lipschitz constant of $h_K^{-1}\boldsymbol{F}_K$ and its inverse. The shape constant of a mesh $\mathcal{T}_h$ consisting of convex quadrilaterals is then defined to be the supremum of the shape constants σ_K for $K\in\mathcal{T}_h$, and a family $\mathcal{T}_h$ of such meshes is called shape-regular if the shape constants for the meshes can be uniformly bounded.

The following two theorems give necessary conditions on the shape functions in order to ensure estimates like (3.1) and (3.2) on arbitrary quadrilateral mesh sequences. The spaces $\boldsymbol{\mathcal{S}}_r$ and $\mathcal{R}_r$ were defined in section 1.

THEOREM 3.1. *Suppose that the estimate* (3.1) *holds whenever $\mathcal{T}_h$ is a shape-regular sequence of quadrilateral meshes of a two-dimensional domain Ω. Then $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$.*

THEOREM 3.2. *Suppose that the estimate* (3.2) *holds whenever $\mathcal{T}_h$ is a shape-regular sequence of quadrilateral meshes of a two-dimensional domain Ω. Then $\hat{\operatorname{div}}\,\hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$.*

In order to establish the theorems, we shall make use of two results analogous to Theorem 4 of [1]. To state these results, we introduce some specific bilinear mappings. For $\alpha > 0$, let $\boldsymbol{F}^\alpha$ and $\boldsymbol{G}^\alpha$ denote the mappings

$$\boldsymbol{F}^\alpha(\hat{\boldsymbol{x}}) = (\hat{x}_1, (\alpha+\hat{x}_1)\hat{x}_2), \qquad \boldsymbol{G}^\alpha(\hat{\boldsymbol{x}}) = \boldsymbol{F}^\alpha(\hat{x}_2,\hat{x}_1), \tag{3.3}$$

each of which maps the unit square $\hat{K}$ to the quadrilateral K^α with vertices $(0,0)$, $(1,0)$, $(1,\alpha+1)$, and $(0,\alpha)$.

LEMMA 3.3. *Let $\hat{\boldsymbol{V}}$ be a space of vector fields on $\hat{K}$ such that $\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(\boldsymbol{F}(\hat{K}))$ when $\boldsymbol{F}$ is any of the four bilinear isomorphisms $\boldsymbol{F}^1$, $\boldsymbol{F}^2$, $\boldsymbol{G}^1$, and $\boldsymbol{G}^2$. Then $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$.*

LEMMA 3.4. *Let $\hat{\boldsymbol{V}}$ be a space of vector fields on $\hat{K}$ such that $\operatorname{div}\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \mathcal{P}_r(\boldsymbol{F}(\hat{K}))$ when $\boldsymbol{F}$ is any of the four bilinear isomorphisms $\boldsymbol{F}^1$, $\boldsymbol{F}^2$, $\boldsymbol{G}^1$, and $\boldsymbol{G}^2$. Then $\hat{\operatorname{div}}\,\hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$.*

We postpone the proof of these lemmas to the end of the section. Now, based on Lemma 3.3 and Theorem 2.1, we establish Theorem 3.1.

Proof of Theorem 3.1. To establish the theorem, we assume that $\hat{\boldsymbol{V}} \not\supseteq \boldsymbol{\mathcal{S}}_r$ and exhibit a sequence $\mathcal{T}_h$ of shape regular meshes ($h = 1, 1/2, 1/3, \dots$) of the unit square

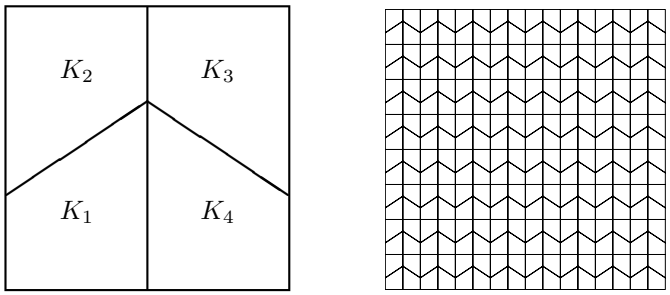

FIG. 1. (a) *The mesh* $\mathcal{T}_1$ *of the unit square into four trapezoids.* (b) *The mesh* $\mathcal{T}_h$ *(here* $h = 1/8$*) composed of translated dilates of* $\mathcal{T}_1$.

for which the estimate (3.1) does not hold. We know, by Lemma 3.3, that for either $\alpha = 1$ or $\alpha = 2$ either $\boldsymbol{P}_{F^\alpha}\hat{\boldsymbol{V}}$ or $\boldsymbol{P}_{G^\alpha}\hat{\boldsymbol{V}}$ does not contain $\boldsymbol{\mathcal{P}}_r(K^\alpha)$. We fix this value of α and, without loss of generality, suppose that

$$\boldsymbol{P}_{F^\alpha}\hat{\boldsymbol{V}} \not\supseteq \boldsymbol{\mathcal{P}}_r(K^\alpha). \tag{3.4}$$

Set $\beta = \alpha/(1+2\alpha)$. As shown in Figure 1(a), we define a mesh $\mathcal{T}_1$ consisting of four congruent elements $K_1, \ldots, K_4$, with the vertices of K_1 given by $(0,0)$, $(1/2,0)$, $(1/2, 1-\beta)$, and $(0,\beta)$. For $h = 1/n$, we construct the mesh $\mathcal{T}_h$ by partitioning the unit square into n^2 subsquares K and meshing each subsquare K with the mesh obtained by applying $\boldsymbol{F}_K$, given by (2.1), to $\mathcal{T}_1$ as shown in Figure 1(b). For each element T of the mesh $\mathcal{T}_h$ there is a natural way to construct a bilinear mapping $\boldsymbol{F}$ from the unit square onto T based on the mapping $\boldsymbol{F}^\alpha$. The first step is to compose $\boldsymbol{F}^\alpha$ with the linear isomorphism $\boldsymbol{E}(\boldsymbol{x}) = (x_1/2, x_2/(1+2\alpha))$ to obtain a bilinear map from the unit square onto the trapezoid K_1. Composing further with the natural isometries of K_1 onto K_2, K_3, and K_4, we obtain bilinear maps $\boldsymbol{F}_j$ from the unit square onto each of the trapezoids K_j, $j = 1, \ldots, 4$. Finally, further composition with the map $\boldsymbol{F}_K$ (consisting of dilation and translation) taking the unit square onto the subsquare K containing T, defines a bilinear diffeomorphism of the unit square onto T.

Having specified the mesh $\mathcal{T}_h$ and a bilinear map from the unit square onto each element of the mesh, we have determined the space $\boldsymbol{V}(\mathcal{T}_h)$ based on the shape functions in $\hat{\boldsymbol{V}}$. We need to show that the estimate (3.1) does not hold. To do so, we observe that $\boldsymbol{V}(\mathcal{T}_h)$ coincides precisely with the space $\boldsymbol{V}_h$ constructed at the start of section 2 (see (2.2)) if we use $\boldsymbol{V}(\mathcal{T}_1)$ as the space of shape functions on the unit square to begin the construction. This observation is easily verified in view of the composition property (1.2) of the Piola transform. Thus we may invoke Theorem 2.1 to conclude that (3.1) does not hold if we can show that $\boldsymbol{V}(\mathcal{T}_1) \not\supseteq \boldsymbol{\mathcal{P}}_r(\hat{K})$. Now, by construction, the functions in $\boldsymbol{V}(\mathcal{T}_1)$ restrict to functions in $\boldsymbol{P}_{F_1}\hat{\boldsymbol{V}}$ on $K_1 = \boldsymbol{F}_1\hat{K}$, so it is enough to show that $\boldsymbol{P}_{F_1}\hat{\boldsymbol{V}} \not\supseteq \boldsymbol{\mathcal{P}}_r(K_1)$. But $\boldsymbol{F}_1 = \boldsymbol{E} \circ \boldsymbol{F}^\alpha$ and, hence, $\boldsymbol{P}_{F_1}\hat{\boldsymbol{V}} = \boldsymbol{P}_E(\boldsymbol{P}_{F^\alpha}\hat{\boldsymbol{V}})$. Now $\boldsymbol{E}$ is a linear isomorphism of K^α onto K_1, and so $\boldsymbol{P}_E$ is a linear isomorphism of $\boldsymbol{\mathcal{P}}_r(K^\alpha)$ onto $\boldsymbol{\mathcal{P}}_r(K_1)$. Thus $\boldsymbol{P}_{F_1}\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(K_1)$ if and only if $\boldsymbol{P}_{F^\alpha}\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(K^\alpha)$ and so the theorem is complete in view of (3.4). ∎

Proof of Theorem 3.2. The proof is essentially identical to the preceding one, except that Lemma 3.4 and Theorem 2.2 are used in place of Lemma 3.3 and Theorem 2.1. ∎

Before turning to the proof of Lemmas 3.3 and 3.4, we draw some implications from Theorems 3.1 and 3.2 for the approximation properties of the extensions of stan-

dard finite element subspaces of $\boldsymbol{H}(\mathrm{div},\Omega)$ from rectangular meshes to quadrilateral meshes. By definition, $\boldsymbol{\mathcal{S}}_r \subseteq \boldsymbol{\mathcal{RT}}_r$, so Theorem 3.1 does not contradict the possibility that the Raviart–Thomas space of index r achieves order $r+1$ approximation in $\boldsymbol{L}^2$ on quadrilateral meshes, just as for rectangular meshes. This is indeed the case (see the discussion in section 1). But $\mathrm{div}\,\boldsymbol{\mathcal{RT}}_r = \mathcal{Q}_r$ which contains $\mathcal{R}_{r-1}$ but not $\mathcal{R}_r$. Thus we may conclude from Theorem 3.2 that the best possible order of approximation to the divergence in L^2 for the Raviart–Thomas space of index r is only r on quadrilateral meshes, one degree lower than for rectangular meshes, and, in particular, there is no convergence for $r=0$. (This lower order is achieved, as discussed in section 1.) In contrast to the Raviart–Thomas spaces, for the Brezzi–Douglas–Marini and Brezzi–Douglas–Fortin–Marini spaces there is a loss of L^2-approximation order on quadrilateral meshes. Both $\boldsymbol{\mathcal{BDM}}_r$ and $\boldsymbol{\mathcal{BDFM}}_{r+1}$ contain $\boldsymbol{\mathcal{P}}_r$, which is enough to ensure order $r+1$ approximation in $\boldsymbol{L}^2$ on rectangular meshes. However, it is easy to check that $\boldsymbol{\mathcal{BDM}}_r$ contains $\boldsymbol{\mathcal{S}}_{\lfloor (r-1)/2\rfloor}$ but not $\boldsymbol{\mathcal{S}}_{\lfloor (r+1)/2\rfloor}$ so that the best possible order of approximation for the Brezzi–Douglas–Marini space of index r on general quadrilateral meshes is $\lfloor (r+1)/2\rfloor$, a substantial loss of accuracy in comparison to the rectangular case. For the divergence, we have $\hat{\mathrm{div}}\,\boldsymbol{\mathcal{BDM}}_r = \mathcal{P}_{r-1}(\hat{K})$ which contains $\mathcal{R}_{\lfloor (r-2)/2\rfloor}$ but not $\mathcal{R}_{\lfloor r/2\rfloor}$. Therefore the best possible order of approximation for the divergence for the Brezzi–Douglas–Marini space of index r on general quadrilateral meshes is $\mathcal{R}_{\lfloor r/2\rfloor}$. Similarly, the best possible order of L^2-approximation for the Brezzi–Douglas–Fortin–Marini space of index $r+1$ on general quadrilateral meshes is $\lfloor (r+2)/2\rfloor$, while since $\hat{\mathrm{div}}\,\boldsymbol{\mathcal{BDFM}}_{r+1} = \mathcal{P}_r(\hat{K})$, the best possible rate for the divergence is $\lfloor (r+1)/2\rfloor$. We specifically note that in the lowest index cases, namely when $\hat{\boldsymbol{V}} = \boldsymbol{\mathcal{RT}}_0$, $\boldsymbol{\mathcal{BDM}}_1$, or $\boldsymbol{\mathcal{BDFM}}_1$ (which is identical to $\boldsymbol{\mathcal{RT}}_0$), *the best approximation in* $\boldsymbol{H}(\mathrm{div},\Omega)$ *does not converge in* $\boldsymbol{H}(\mathrm{div},\Omega)$ *for general quadrilateral mesh sequences.* Section 8 of this paper contains a numerical confirmation of this result.

We conclude this section with the proofs of Lemmas 3.3 and 3.4.

Proof of Lemma 3.3. By hypothesis $\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(\boldsymbol{F}(\hat{K}))$ or, equivalently, $\hat{\boldsymbol{V}} \supseteq \boldsymbol{P}_F^{-1}[\boldsymbol{\mathcal{P}}_r(\boldsymbol{F}(\hat{K}))]$, for $\boldsymbol{F} = \boldsymbol{F}^1$, $\boldsymbol{F}^2$, $\boldsymbol{G}^1$, and $\boldsymbol{G}^2$. Thus it is sufficient to prove that

$$\boldsymbol{\mathcal{S}}_r \subseteq \boldsymbol{\Sigma}_r := \boldsymbol{P}_{F^1}^{-1}[\boldsymbol{\mathcal{P}}_r(K^1)] + \boldsymbol{P}_{F^2}^{-1}[\boldsymbol{\mathcal{P}}_r(K^2)] + \boldsymbol{P}_{G^1}^{-1}[\boldsymbol{\mathcal{P}}_r(K^1)] + \boldsymbol{P}_{G^2}^{-1}[\boldsymbol{\mathcal{P}}_r(K^2)]. \tag{3.5}$$

We will prove this using induction on r.

Now for any diffeomorphism $\boldsymbol{F}:\hat{K}\to K$ and any $\boldsymbol{u}:K\to\mathbb{R}^2$, we have, directly from the definition of the Piola transform, that

$$(\boldsymbol{P}_F^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})DF(\hat{\boldsymbol{x}})^{-1}\boldsymbol{u}(\boldsymbol{x}) = \begin{pmatrix} \dfrac{\partial F_2}{\partial \hat{x}_2}(\hat{\boldsymbol{x}}) & -\dfrac{\partial F_1}{\partial \hat{x}_2}(\hat{\boldsymbol{x}}) \\ -\dfrac{\partial F_2}{\partial \hat{x}_1}(\hat{\boldsymbol{x}}) & \dfrac{\partial F_1}{\partial \hat{x}_1}(\hat{\boldsymbol{x}}) \end{pmatrix} \boldsymbol{u}(\boldsymbol{x}). \tag{3.6}$$

Specializing to the case where $\boldsymbol{F} = \boldsymbol{F}^\alpha$ or $\boldsymbol{G}^\alpha$ given by (3.3), we have

$$(\boldsymbol{P}_{F^\alpha}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = \begin{pmatrix} \alpha+\hat{x}_1 & 0 \\ -\hat{x}_2 & 1 \end{pmatrix}\boldsymbol{u}(\boldsymbol{x}), \qquad (\boldsymbol{P}_{G^\alpha}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = \begin{pmatrix} \hat{x}_1 & -1 \\ -\alpha-\hat{x}_2 & 0 \end{pmatrix}\boldsymbol{u}(\boldsymbol{x}).$$

Thus, when $u(\boldsymbol{x})$ is the constant vector field $(1,0)$, $(\boldsymbol{P}_{F^1}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = (1+\hat{x}_1, -\hat{x}_2)$, and when $u(\boldsymbol{x}) \equiv (0,1)$, $(\boldsymbol{P}_{F^1}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = (0,1)$ and $(\boldsymbol{P}_{G^1}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = (-1,0)$. These three vector fields span $\boldsymbol{\mathcal{S}}_0$, which establishes (3.5) in the case $r=0$.

Suppose now that $\boldsymbol{\mathcal{S}}_{r-1} \subseteq \boldsymbol{\Sigma}_{r-1}$ for some $r \geq 1$. To complete the induction we need to show that $\boldsymbol{\mathcal{S}}_r \subseteq \boldsymbol{\Sigma}_r$. Now $\boldsymbol{\mathcal{S}}_r$ is spanned by $\boldsymbol{\mathcal{S}}_{r-1}$ plus the $4r+4$ additional

vector fields

$$\begin{array}{llll}(\hat{x}_1^i\hat{x}_2^r,0) & \text{and} & (0,\hat{x}_1^r\hat{x}_2^i), & 0\le i\le r,\\ (\hat{x}_1^{r+1}\hat{x}_2^j,0) & \text{and} & (0,\hat{x}_1^j\hat{x}_2^{r+1}), & 0\le j\le r-1,\\ (\hat{x}_1^r\hat{x}_2^{r-1},0) & \text{and} & (\hat{x}_1^{r+1}\hat{x}_2^r,-\hat{x}_1^r\hat{x}_2^{r+1}).\end{array}$$

Pick $0\le i\le r$, and set $\boldsymbol{F}=\boldsymbol{G}^\alpha$ and $\boldsymbol{u}(\boldsymbol{x})=(0,-x_1^{r-i}x_2^i)\in\boldsymbol{\mathcal{P}}_r(K^\alpha)$. Note that $\boldsymbol{x}=\boldsymbol{G}^\alpha\hat{\boldsymbol{x}}=(\hat{x}_2,(\alpha+\hat{x}_2)\hat{x}_1)$. Then

$$(\boldsymbol{P}_{G^\alpha}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}})=(x_1^{r-i}x_2^i,0)=(\hat{x}_2^{r-i}(\alpha+\hat{x}_2)^i\hat{x}_1^i,0)=(\hat{x}_1^i\hat{x}_2^r,0)+i\alpha(\hat{x}_1^i\hat{x}_2^{r-1},0)\pmod{\boldsymbol{\mathcal{S}}_{r-1}}.$$

Since $\boldsymbol{\mathcal{S}}_{r-1}\subseteq\boldsymbol{\Sigma}_r$ by the inductive hypothesis, and since we may take both $\alpha=1$ and $\alpha=2$, we conclude that $(\hat{x}_1^i\hat{x}_2^r,0)\in\boldsymbol{\Sigma}_r$ (for $0\le i\le r$) and also that $(\hat{x}_1^r\hat{x}_2^{r-1},0)\in\boldsymbol{\Sigma}_r$.

In a similar way, setting $\boldsymbol{F}=\boldsymbol{F}^\alpha$ and $\boldsymbol{u}(\boldsymbol{x})=(0,x_1^{r-i}x_2^i)$, we conclude that $(0,\hat{x}_1^r\hat{x}_2^i)\in\boldsymbol{\Sigma}_r$, $0\le i\le r$. The choice $\boldsymbol{F}=\boldsymbol{F}^\alpha$ and $\boldsymbol{u}(\boldsymbol{x})=(x_1^{r-j}x_2^j,0)$ together with the fact that $\boldsymbol{\Sigma}_r\supseteq\mathcal{Q}_r\times\mathcal{Q}_r$, which is a consequence of the proof thus far, implies that $(\hat{x}_1^{r+1}\hat{x}_2^j,0)\in\boldsymbol{\Sigma}_r$ for $0\le j\le r-1$. The choice $\boldsymbol{F}=\boldsymbol{G}^\alpha$ with the same choice of $\boldsymbol{u}$ similarly implies that $(0,\hat{x}_1^j\hat{x}_2^{r+1})\in\boldsymbol{\Sigma}_r$ for $0\le j\le r-1$.

Finally, with $\boldsymbol{u}(\boldsymbol{x})=(x_2^r,0)$, we find that $(\boldsymbol{P}_{F^1}^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}})=(\hat{x}_1^{r+1}\hat{x}_2^r,-\hat{x}_1^r\hat{x}_2^{r+1})$ (mod $\mathcal{Q}_r\times\mathcal{Q}_r$), which completes the proof of (3.5) and so the lemma. ∎

Proof of Lemma 3.4. The hypothesis is that $\operatorname{div}\boldsymbol{P}_F\hat{\boldsymbol{V}}\supseteq\mathcal{P}_r(\boldsymbol{F}(\hat{K}))$ for $\boldsymbol{F}=\boldsymbol{F}^1$, $\boldsymbol{F}^2$, $\boldsymbol{G}^1$, and $\boldsymbol{G}^2$. Now $\hat{\operatorname{div}}\,\hat{\boldsymbol{u}}(\hat{\boldsymbol{x}})=J\boldsymbol{F}(\hat{\boldsymbol{x}})\operatorname{div}(\boldsymbol{P}_F\hat{\boldsymbol{u}})(\boldsymbol{F}\hat{\boldsymbol{x}})$, so $\hat{\operatorname{div}}\,\hat{\boldsymbol{V}}$ contains all functions on $\hat{K}$ of the form $\hat{\boldsymbol{x}}\mapsto J\boldsymbol{F}(\hat{\boldsymbol{x}})p(\boldsymbol{F}\hat{\boldsymbol{x}})$ with $p\in\mathcal{P}_r(\boldsymbol{F}(\hat{K}))$ and $\boldsymbol{F}\in\{\boldsymbol{F}^1,\boldsymbol{F}^2,\boldsymbol{G}^1,\boldsymbol{G}^2\}$. To prove the lemma, it suffices to show that the span of such functions, call it Σ_r, contains $\mathcal{R}_r$. Note that $J\boldsymbol{F}^\alpha(\hat{\boldsymbol{x}})=\alpha+\hat{x}_1$ and $J\boldsymbol{G}^\alpha(\hat{\boldsymbol{x}})=-\alpha-\hat{x}_2$.

For $r=0$, we take $p\equiv1$ and $\boldsymbol{F}=\boldsymbol{F}^1$, $\boldsymbol{F}^2$, and $\boldsymbol{G}^1$, and find that Σ_r contains $1+\hat{x}_1$, $2+\hat{x}_1$, and $-1-\hat{x}_2$. These three functions span $\mathcal{R}_0$, so $\Sigma_0\supseteq\mathcal{R}_0$.

We continue the proof that $\Sigma_r\supseteq\mathcal{R}_r$ by induction on r. Now $\mathcal{R}_r$ is the span of $\mathcal{R}_{r-1}$ and the $2r+3$ additional functions $\hat{x}_1^{r+1}\hat{x}_2^i$ and $\hat{x}_1^i\hat{x}_2^{r+1}$, $0\le i\le r$, and $\hat{x}_1^r\hat{x}_2^r$. Taking $p(\boldsymbol{x})=x_1^{r-i}x_2^i$ and $\boldsymbol{F}=\boldsymbol{F}^\alpha$ we find that the function $\hat{\boldsymbol{x}}\mapsto\hat{x}_1^{r-i}(\alpha+\hat{x}_1)^{i+1}\hat{x}_2^i$ belongs to Σ_r. Modulo $\mathcal{R}_{r-1}$ (which is contained in Σ_r by the inductive hypothesis), this is equal to the function $\hat{\boldsymbol{x}}\mapsto\hat{x}_1^{r+1}\hat{x}_2^i+(i+1)\alpha\hat{x}_1^r\hat{x}_2^i$. Using both $\alpha=1$ and 2, we conclude that $\hat{x}_1^{r+1}\hat{x}_2^i$ belongs to Σ_r for $0\le i\le r$ and that $\hat{x}_1^r\hat{x}_2^r$ does as well. The same choice of p with $\boldsymbol{F}=\boldsymbol{G}^\alpha$ shows that Σ_r contains the functions $\hat{x}_1^i\hat{x}_2^{r+1}$, $0\le i\le r$, and completes the proof. ∎

4. Sufficient conditions for optimal order approximation. In this section we show that the necessary conditions we have obtained in the previous section are also sufficient for approximation of order $r+1$ in $\boldsymbol{L}^2$ and $\boldsymbol{H}(\mathrm{div},\Omega)$. To state this more precisely, we recall the construction of projection operators for $\boldsymbol{H}(\mathrm{div})$ finite elements. We suppose that we are given a bounded projection $\hat{\boldsymbol{\pi}}:\boldsymbol{H}^{r+1}(\hat{K})\to\hat{\boldsymbol{V}}$ (typically this operator is specified via a unisolvent set of degrees of freedom for $\hat{\boldsymbol{V}}$). We then define the corresponding projection $\boldsymbol{\pi}_K:\boldsymbol{H}^{r+1}(K)\to\boldsymbol{P}_F\hat{\boldsymbol{V}}$ for an arbitrary element $K=\boldsymbol{F}(\hat{K})$ via the Piola transform, as expressed in this commuting diagram:

$$\begin{array}{ccc}\boldsymbol{H}^{r+1}(\hat{K}) & \xrightarrow{\hat{\boldsymbol{\pi}}} & \hat{\boldsymbol{V}}\\ \Big\downarrow{\scriptstyle\boldsymbol{P}_F} & & \Big\downarrow{\scriptstyle\boldsymbol{P}_F}\\ \boldsymbol{H}^{r+1}(K) & \xrightarrow[\boldsymbol{\pi}_K]{} & \boldsymbol{P}_F\hat{\boldsymbol{V}}\end{array}.$$

That is, $\boldsymbol{\pi}_K = \boldsymbol{P}_F \circ \hat{\boldsymbol{\pi}} \circ \boldsymbol{P}_F^{-1}$. Finally a global projection operator $\boldsymbol{\pi}_h : \boldsymbol{H}^{r+1}(\Omega) \to \boldsymbol{V}(\mathcal{T}_h)$ is defined piecewise: $(\boldsymbol{\pi}_h \boldsymbol{u})|_K = \boldsymbol{\pi}_K(\boldsymbol{u}|_K)$. (The degrees of freedom used to define $\hat{\boldsymbol{\pi}}$ will determine the degree of interelement continuity enjoyed by $\boldsymbol{\pi}_h \boldsymbol{u}$. In particular, for the standard $\boldsymbol{H}(\mathrm{div})$ finite element spaces discussed previously, the degrees of freedom ensure that on any edge $\hat{e}$ of $\hat{K}$, $(\hat{\boldsymbol{\pi}}\hat{\boldsymbol{u}}) \cdot \hat{\boldsymbol{n}}$ on $\hat{e}$ depends only on $\boldsymbol{u} \cdot \boldsymbol{n}$ on $\hat{e}$. From this it results that $\boldsymbol{\pi}_h \boldsymbol{u} \in \boldsymbol{H}(\mathrm{div})$.)

The following two theorems contain the main results of this section.

THEOREM 4.1. *Let $\hat{\boldsymbol{\pi}} : \boldsymbol{H}^{r+1}(\hat{K}) \to \hat{\boldsymbol{V}}$ be a bounded projection operator. Given a quadrilateral mesh $\mathcal{T}_h$ of a domain Ω, let $\boldsymbol{\pi}_h : \boldsymbol{H}^{r+1}(\Omega) \to \boldsymbol{V}(\mathcal{T}_h)$ be defined as above. Suppose that $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$. Then there exists a constant C depending only on the bound for $\hat{\boldsymbol{\pi}}$ and on the shape regularity of $\mathcal{T}_h$, such that*

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)} \le C h^{r+1} |\boldsymbol{u}|_{H^{r+1}(\Omega)} \tag{4.1}$$

for all $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(\Omega)$.

THEOREM 4.2. *Let $\hat{\boldsymbol{\pi}} : \boldsymbol{H}^{r+1}(\hat{K}) \to \hat{\boldsymbol{V}}$ be a bounded projection operator. Given a quadrilateral mesh $\mathcal{T}_h$ of a domain Ω, let $\boldsymbol{\pi}_h : \boldsymbol{H}^{r+1}(\Omega) \to \boldsymbol{V}(\mathcal{T}_h)$ be defined as above. Suppose that $\hat{\mathrm{div}}\, \hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$. Suppose also that there exists a bounded projection operator $\hat{\Pi} : H^{r+1}(\hat{K}) \to \hat{\mathrm{div}}\, \hat{\boldsymbol{V}}$ such that*

$$\hat{\mathrm{div}}\, \hat{\boldsymbol{\pi}} \hat{\boldsymbol{u}} = \hat{\Pi}\, \hat{\mathrm{div}}\, \hat{\boldsymbol{u}} \quad \forall \hat{\boldsymbol{u}} \in \boldsymbol{H}^{r+1}(\hat{K}) \text{ with } \hat{\mathrm{div}}\, \hat{\boldsymbol{u}} \in H^{r+1}(\hat{K}). \tag{4.2}$$

Then there exists a constant C depending only on the bounds for $\hat{\boldsymbol{\pi}}$ and $\hat{\Pi}$ and on the shape regularity of $\mathcal{T}_h$, such that

$$\|\mathrm{div}\, \boldsymbol{u} - \mathrm{div}\, \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)} \le C h^{r+1} |\mathrm{div}\, \boldsymbol{u}|_{H^{r+1}(\Omega)} \tag{4.3}$$

for all $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(\Omega)$ with $\mathrm{div}\, \boldsymbol{u} \in H^{r+1}(\Omega)$.

Remarks. 1. It follows immediately that if the hypotheses of both theorems are met, then $\boldsymbol{\pi}_h$ furnishes order $r+1$ approximation in $\boldsymbol{H}(\mathrm{div}, \Omega)$:

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{\boldsymbol{H}(\mathrm{div},\Omega)} \le C h^{r+1} (|\boldsymbol{u}|_{H^{r+1}(\Omega)} + |\mathrm{div}\, \boldsymbol{u}|_{H^{r+1}(\Omega)})$$

for all $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(\Omega)$ with $\mathrm{div}\, \boldsymbol{u} \in H^{r+1}(\Omega)$.

2. The commutativity hypothesis involving the projection $\hat{\Pi}$ plays a major role in the theory of $\boldsymbol{H}(\mathrm{div}, \Omega)$ finite elements. It is satisfied in the case of the Raviart–Thomas, Brezzi–Douglas–Marini, and Brezzi–Douglas–Fortin–Marini elements, as well as for the new elements introduced in the next sections, with $\hat{\Pi}$ equal to the L^2 projection onto $\hat{\mathrm{div}}\, \hat{\boldsymbol{V}}$.

3. When applied to the Raviart–Thomas elements of index r, Theorem 4.1 gives

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)} \le C h^{r+1} |\boldsymbol{u}|_{H^{r+1}(\Omega)}$$

and Theorem 4.2 gives

$$\|\mathrm{div}\, \boldsymbol{u} - \mathrm{div}\, \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)} \le C h^{r} |\mathrm{div}\, \boldsymbol{u}|_{H^{r+1}(\Omega)}.$$

The latter estimate is proved in [12], but the former estimate appears to be new. It improves on the estimate given in [12]:

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)} \le C h^{r+1} [|\boldsymbol{u}|_{H^{r+1}(\Omega)} + h |\mathrm{div}\, \boldsymbol{u}|_{H^{r+1}(\Omega)}].$$

The proofs of the theorems depend on the following two lemmas which are strengthened converses of Lemmas 3.3 and 3.4.

LEMMA 4.3. *Let $\hat{\boldsymbol{V}}$ be a space of vector fields on $\hat{K}$ containing $\boldsymbol{\mathcal{S}}_r$. Then $\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{P}}_r(K)$ for all bilinear isomorphisms $\boldsymbol{F}$ of $\hat{K}$ onto convex quadrilaterals $K = \boldsymbol{F}(\hat{K})$.*

Proof. It is sufficient to show that $\boldsymbol{\mathcal{S}}_r \supseteq \boldsymbol{P}_F^{-1}[\boldsymbol{\mathcal{P}}_r(K)]$, since then the hypothesis $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$ implies that

$$\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \boldsymbol{P}_F\boldsymbol{\mathcal{S}}_r \supseteq \boldsymbol{P}_F\boldsymbol{P}_F^{-1}[\boldsymbol{\mathcal{P}}_r(K)] = \boldsymbol{\mathcal{P}}_r(K).$$

Now (3.6) tells us that

$$\boldsymbol{P}_F^{-1}\boldsymbol{u} = \begin{pmatrix} \partial F_2/\partial\hat{x}_2 & -\partial F_1/\partial\hat{x}_2 \\ -\partial F_2/\partial\hat{x}_1 & \partial F_1/\partial\hat{x}_1 \end{pmatrix} (\boldsymbol{u}\circ\boldsymbol{F}).$$

Since $\boldsymbol{u} \in \boldsymbol{\mathcal{P}}_r(K)$ and $\boldsymbol{F}$ is bilinear, $\boldsymbol{u}\circ\boldsymbol{F} \in \boldsymbol{\mathcal{Q}}_r(\hat{K})$. Also, again in view of the bilinearity of $\boldsymbol{F}$, the matrix appearing in this equation is the sum of a constant matrix field and one of the form $(\hat{x}_1, -\hat{x}_2)^T(a_2, -a_1)$ (where $a_i \in \mathbb{R}$ is the coefficient of $\hat{x}_1\hat{x}_2$ in F_i). It follows immediately that $\boldsymbol{P}_F^{-1}\boldsymbol{u} \in \boldsymbol{\mathcal{S}}_r$. ∎

LEMMA 4.4. *Let $\hat{\boldsymbol{V}}$ be a space of vector fields on $\hat{K}$ such that $\hat{\operatorname{div}}\,\hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$. Then $\operatorname{div}\boldsymbol{P}_F\hat{\boldsymbol{V}} \supseteq \mathcal{P}_r(K)$ for all bilinear isomorphisms $\boldsymbol{F}$ of $\hat{K}$ onto convex quadrilaterals $K = \boldsymbol{F}(\hat{K})$.*

Proof. Let $p \in \mathcal{P}_r(K)$ be arbitrary. Choose any $\boldsymbol{u} \in \boldsymbol{H}(\operatorname{div},\Omega)$ such that $\operatorname{div}\boldsymbol{u} = p$. From the identity

$$(\hat{\operatorname{div}}\,\boldsymbol{P}_F^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})(\operatorname{div}\boldsymbol{u})(\boldsymbol{x}),$$

we have $\hat{\operatorname{div}}\,\boldsymbol{P}_F^{-1}\boldsymbol{u} = J\boldsymbol{F}\cdot(p\circ\boldsymbol{F})$. Now $p \in \mathcal{P}_r(K)$ and $\boldsymbol{F}$ is bilinear, so $p\circ\boldsymbol{F}$ belongs to $\mathcal{Q}_r(\hat{K})$ and $J\boldsymbol{F}$ is linear. Thus $\hat{q} := \hat{\operatorname{div}}\,\boldsymbol{P}_F^{-1}\boldsymbol{u} \in \mathcal{R}_r$.

Invoking the hypothesis that $\mathcal{R}_r \subseteq \hat{\operatorname{div}}\,\hat{\boldsymbol{V}}$, we can find $\hat{\boldsymbol{v}} \in \hat{\boldsymbol{V}}$ such that $\hat{\operatorname{div}}\,\hat{\boldsymbol{v}} = \hat{q}$. Then

$$\begin{aligned} p(\boldsymbol{x}) &= \operatorname{div}\boldsymbol{u}(\boldsymbol{x}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1}(\hat{\operatorname{div}}\,\boldsymbol{P}_F^{-1}\boldsymbol{u})(\hat{\boldsymbol{x}}) \\ &= J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1}\hat{q}(\hat{\boldsymbol{x}}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1}\,\hat{\operatorname{div}}\,\hat{\boldsymbol{v}}(\hat{\boldsymbol{x}}) = \operatorname{div}\boldsymbol{P}_F\hat{\boldsymbol{v}}(\boldsymbol{x}). \end{aligned}$$

This shows that $p \in \operatorname{div}\boldsymbol{P}_F\hat{\boldsymbol{V}}$ as required. ∎

Proof of Theorem 4.1. We will show that if $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$ and K is any convex quadrilateral, then

$$\|\boldsymbol{u} - \boldsymbol{\pi}_K\boldsymbol{u}\|_{L^2(K)} \le Ch_K^{r+1}|\boldsymbol{u}|_{H^{r+1}(K)} \quad \forall\boldsymbol{u} \in \boldsymbol{H}^{r+1}(K), \tag{4.4}$$

where $h_K = \operatorname{diam}(K)$ and the constant C depends only on $\hat{\boldsymbol{\pi}}$ and the shape constant for K. The theorem follows easily by squaring both sides and summing over the elements.

We establish (4.4) in two steps. First we prove it under the additional assumption that $h_K = 1$, and then we use a simple scaling argument to obtain it for arbitrary K.

For the first part we use the Bramble–Hilbert lemma. In view of Lemma 4.3 and the fact that $\hat{\boldsymbol{\pi}}$ is a projection onto $\hat{\boldsymbol{V}}$, it follows that $\boldsymbol{\pi}_K\boldsymbol{u} = \boldsymbol{u}$ for all $\boldsymbol{u} \in \boldsymbol{\mathcal{P}}_r(K)$. Now under the assumption that $h_K = 1$, the Piola transform $\boldsymbol{P}_{F_K}$ is bounded and invertible both from $\boldsymbol{L}^2(\hat{K})$ to $\boldsymbol{L}^2(K)$ and from $\boldsymbol{H}^{r+1}(\hat{K})$ to $\boldsymbol{H}^{r+1}(K)$ with bounds in both norms depending only on the shape constant. A similar statement holds for $\boldsymbol{P}_{F_K}^{-1}$.

Since $\hat{\boldsymbol{\pi}}$ is bounded from $\boldsymbol{H}^{r+1}(\hat{K})$ to $\boldsymbol{L}^2(\hat{K})$, it follows that $\boldsymbol{\pi}_K = \boldsymbol{P}_{F_K} \circ \hat{\boldsymbol{\pi}} \circ \boldsymbol{P}_{F_K}^{-1}$ is bounded from $\boldsymbol{H}^{r+1}(K)$ to $\boldsymbol{L}^2(K)$ with bound depending only on the bound for $\hat{\boldsymbol{\pi}}$ and the shape constant for K. The map $\boldsymbol{u} \mapsto \boldsymbol{u} - \boldsymbol{\pi}_K \boldsymbol{u}$ is then similarly bounded and moreover vanishes on $\boldsymbol{\mathcal{P}}_r(K)$. Therefore,

$$\|\boldsymbol{u} - \boldsymbol{\pi}_K \boldsymbol{u}\|_{L^2(K)} \le \|\boldsymbol{I} - \boldsymbol{\pi}_K\|_{\mathcal{L}(\boldsymbol{H}^{r+1}(K), \boldsymbol{L}^2(K))} \inf_{\boldsymbol{p} \in \boldsymbol{\mathcal{P}}_r(K)} \|\boldsymbol{u} - \boldsymbol{p}\|_{H^{r+1}(K)}.$$

Now the Bramble–Hilbert lemma states that the last infimum can be bounded by $c|\boldsymbol{u}|_{H^{r+1}(K)}$, where c depends only on r and the shape regularity of K (see, e.g., [2, Lemma 4.3.8]). The estimate (4.4) then follows for $h_K = 1$ with $C = c\|\boldsymbol{I} - \boldsymbol{\pi}_K\|_{\mathcal{L}(\boldsymbol{H}^{r+1}(K), \ll^2(K))}$.

To complete the proof, let K be an arbitrary convex quadrilateral, and denote by $\boldsymbol{M} : K \to \tilde{K} := h_K^{-1} K$ the dilation $\boldsymbol{M}(\boldsymbol{x}) = h_K^{-1} \boldsymbol{x}$. Then the bilinear maps $\boldsymbol{F}_K$ and $\boldsymbol{F}_{\tilde{K}}$ of the reference element $\hat{K}$ onto K and $\tilde{K}$, respectively, are related by the equation $\boldsymbol{F}_{\tilde{K}} = \boldsymbol{M} \circ \boldsymbol{F}_K$, from which it follows easily that $\boldsymbol{\pi}_{\tilde{K}} = \boldsymbol{P}_M \circ \boldsymbol{\pi}_K \circ \boldsymbol{P}_M^{-1}$. Of course, $\boldsymbol{P}_M$ has a very simple form:

$$\boldsymbol{P}_M \boldsymbol{u}(\tilde{\boldsymbol{x}}) = h_K \boldsymbol{u}(h_K \tilde{\boldsymbol{x}}).$$

Now for any $\boldsymbol{u} \in \boldsymbol{H}^{r+1}(K)$, let $\tilde{\boldsymbol{u}} = \boldsymbol{P}_M \boldsymbol{u} \in \boldsymbol{H}^{r+1}(\tilde{K})$. It is then easy to check that

$$\begin{aligned} \|\boldsymbol{u} - \boldsymbol{\pi}_K \boldsymbol{u}\|_{L^2(K)} &= \|\boldsymbol{P}_M^{-1}(\tilde{\boldsymbol{u}} - \boldsymbol{\pi}_{\tilde{K}} \tilde{\boldsymbol{u}})\|_{L^2(K)} = \|\tilde{\boldsymbol{u}} - \boldsymbol{\pi}_{\tilde{K}} \tilde{\boldsymbol{u}}\|_{L^2(\tilde{K})} \\ &\le C|\tilde{\boldsymbol{u}}|_{H^{r+1}(\tilde{K})} = C h_K^{r+1} |\boldsymbol{u}|_{H^{r+1}(K)}, \end{aligned}$$

where we obtained the inequality from the already established result for elements of unit diameter. ∎

Proof of Theorem 4.2. As for the previous theorem, it suffices to prove a local result:

$$\begin{aligned} \|\operatorname{div} \boldsymbol{u} - \operatorname{div} \boldsymbol{\pi}_K \boldsymbol{u}\|_{L^2(K)} &\le C h_K^{r+1} |\operatorname{div} \boldsymbol{u}|_{H^{r+1}(K)} \\ &\qquad \forall \boldsymbol{u} \in \boldsymbol{H}^{r+1}(K) \text{ with } \operatorname{div} \boldsymbol{u} \in H^{r+1}(K), \end{aligned} \tag{4.5}$$

where C depends only on the bounds for $\hat{\boldsymbol{\pi}}$ and $\hat{\Pi}$ and the shape constant of K.

Define $\Lambda_K : L^2(K) \to L^2(K)$ by

$$\Lambda_K p(\boldsymbol{x}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1} \hat{\Pi}[J\boldsymbol{F} \cdot (p \circ \boldsymbol{F})](\hat{\boldsymbol{x}}), \tag{4.6}$$

i.e., $\Lambda_K p = \{J\boldsymbol{F}^{-1} \cdot \hat{\Pi}[J\boldsymbol{F} \cdot (p \circ \boldsymbol{F})]\} \circ \boldsymbol{F}^{-1}$. Then

$$\begin{aligned} \operatorname{div} \boldsymbol{\pi}_K \boldsymbol{u}(\boldsymbol{x}) &= \operatorname{div}(\boldsymbol{P}_{F_K} \hat{\boldsymbol{\pi}} \boldsymbol{P}_{F_K}^{-1} \boldsymbol{u})(\boldsymbol{x}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1} \hat{\operatorname{div}}(\hat{\boldsymbol{\pi}} \boldsymbol{P}_{F_K}^{-1} \boldsymbol{u})(\hat{\boldsymbol{x}}) \\ &= J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1} \hat{\Pi}(\hat{\operatorname{div}} \boldsymbol{P}_{F_K}^{-1} \boldsymbol{u})(\hat{\boldsymbol{x}}) = J\boldsymbol{F}(\hat{\boldsymbol{x}})^{-1} \hat{\Pi}[J\boldsymbol{F} \cdot (\operatorname{div} \boldsymbol{u}) \circ \boldsymbol{F}](\hat{\boldsymbol{x}}). \end{aligned}$$

That is, $\operatorname{div} \boldsymbol{\pi}_K \boldsymbol{u} = \Lambda_K(\operatorname{div} \boldsymbol{u})$. Thus,

$$\|\operatorname{div} \boldsymbol{u} - \operatorname{div} \boldsymbol{\pi}_K \boldsymbol{u}\|_{L^2(K)} = \|\operatorname{div} \boldsymbol{u} - \Lambda_K(\operatorname{div} \boldsymbol{u})\|_{L^2(K)}$$

and (4.5) will hold if we can prove that

$$\|p - \Lambda_K p\|_{L^2(K)} \le C h_K^{r+1} |p|_{H^{r+1}(K)} \quad \forall p \in H^{r+1}(K). \tag{4.7}$$

The proof of (4.7) is again given first in the case of elements of unit diameter. Then Λ_K is bounded uniformly from $H^{r+1}(K)$ to $L^2(K)$ for elements K with uniformly

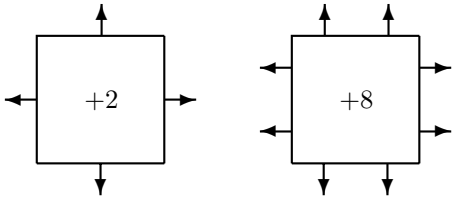

FIG. 2. *Element diagrams indicating the degrees of freedom for* $\boldsymbol{\mathcal{ABF}}_0$ *and* $\boldsymbol{\mathcal{ABF}}_1$.

bounded shape constant. Now, as noted in the proof of Lemma 4.4, if $p \in \mathcal{P}_r(K)$, then $J\boldsymbol{F} \cdot (p \circ \boldsymbol{F}) \in \mathcal{R}_r \subseteq \hat{\mathrm{div}}\, \hat{\boldsymbol{V}}$. Since $\hat{\Pi}$ is a projection onto $\hat{\mathrm{div}}\, \hat{\boldsymbol{V}}$, it follows that $\Lambda_K p = p$ for $p \in \mathcal{P}_r(K)$. Thus the Bramble–Hilbert lemma implies (4.7) under the restriction $h_K = 1$. To extend to elements of arbitrary diameter, we again use a dilation. ∎

5. Construction of spaces with optimal order $\boldsymbol{H}(\mathrm{div}, \Omega)$ approximation. We have previously shown that none of the standard finite element approximations of $\boldsymbol{H}(\mathrm{div}, \Omega)$ (i.e., the Raviart–Thomas, Brezzi–Douglas–Marini, or Brezzi–Douglas–Fortin–Marini spaces) maintain the same order of approximation on general convex quadrilaterals as they do on rectangles. In this section, we use the conditions determined in the previous sections to construct finite element subspaces of $\boldsymbol{H}(\mathrm{div}, \Omega)$ which do have this property. To obtain approximation of order $r+1$ in $\boldsymbol{H}(\mathrm{div}, \Omega)$ on general convex quadrilaterals, we require that the space of reference shape functions $\hat{\boldsymbol{V}} \supseteq \boldsymbol{\mathcal{S}}_r$ and $\hat{\mathrm{div}}\, \hat{\boldsymbol{V}} \supseteq \mathcal{R}_r$. A space with this property is $\boldsymbol{\mathcal{ABF}}_r := \mathcal{P}_{r+2,r}(\hat{K}) \times \mathcal{P}_{r,r+2}(\hat{K})$, for which $\hat{\mathrm{div}}\, \boldsymbol{\mathcal{ABF}}_r = \mathcal{R}_r$.

As degrees of freedom for $\boldsymbol{\mathcal{ABF}}_r$ on the reference element, we take

$$\int_{\hat{e}} \hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{n}} \hat{q}\, d\hat{s}, \quad \hat{q} \in \mathcal{P}_r(\hat{e}) \text{ for each edge } \hat{e} \text{ of } \hat{K} \tag{5.1}$$

$$\int_{\hat{K}} \hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{\phi}}\, d\hat{\boldsymbol{x}}, \quad \hat{\boldsymbol{\phi}} \in \mathcal{P}_{r-1,r}(\hat{K}) \times \mathcal{P}_{r,r-1}(\hat{K}), \tag{5.2}$$

$$\int_{\hat{K}} \hat{\mathrm{div}}\, \hat{\boldsymbol{u}} \hat{x}_1^{r+1} \hat{x}_2^i\, d\hat{\boldsymbol{x}}, \quad \int_{\hat{K}} \hat{\mathrm{div}}\, \hat{\boldsymbol{u}} \hat{x}_1^i \hat{x}_2^{r+1}\, d\hat{\boldsymbol{x}}, \quad i = 0, \ldots, r. \tag{5.3}$$

Note that (5.1) and (5.2) are the standard degrees of freedom for the Raviart–Thomas elements on the reference square. In all we have specified $4(r+1)+2r(r+1)+2(r+1) = 2(r+3)(r+1) = \dim \boldsymbol{\mathcal{ABF}}_r$ degrees of freedom. Since the new degrees of freedom, with respect to the standard Raviart–Thomas elements, are local, we remark that the implementation of the new space $\boldsymbol{\mathcal{ABF}}_r$ should not be more expensive than that of $\boldsymbol{\mathcal{RT}}_r$. Figure 2 indicates the degrees of freedom for the first two cases $r = 0$ and 1.

In order to see that these choices of $\hat{\boldsymbol{V}}$ and degrees of freedom determine a finite element subspace of $\boldsymbol{H}(\mathrm{div}, \Omega)$, we need to show that the degrees of freedom are unisolvent, and that if the degrees of freedom on an edge $\hat{e}$ vanish, then $\hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{n}}$ vanishes on e (this will ensure that the assembled finite element space belongs to $\boldsymbol{H}(\mathrm{div}, \Omega)$). The second point is immediate. On any edge $\hat{e}$ of $\hat{K}$, $\boldsymbol{u} \cdot \boldsymbol{n} \in \mathcal{P}_r(\hat{e})$, so the vanishing of the degrees of freedom (5.1) associated to $\hat{e}$ does indeed ensure that $\hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{n}} \equiv 0$.

We now verify unisolvence by showing that if $\hat{\boldsymbol{u}} \in \boldsymbol{\mathcal{ABF}}_r$ and all the quantities (5.1)–(5.3) vanish, then $\hat{\boldsymbol{u}} = 0$. If $\hat{q} \in \mathcal{Q}_r(\hat{K})$, then $\hat{q}|_{\hat{e}} \in \mathcal{P}_r(\hat{e})$ for any edge $\hat{e}$ of

$\hat{K}$, and $\hat{\nabla}\hat{q} \in \mathcal{P}_{r-1,r}(\hat{K}) \times \mathcal{P}_{r,r-1}(\hat{K})$. Therefore,

$$\int_{\hat{K}} \hat{\operatorname{div}}\, \hat{\boldsymbol{u}}\hat{q}\, d\hat{\boldsymbol{x}} = \int_{\partial\hat{K}} \hat{\boldsymbol{u}} \cdot \hat{\boldsymbol{n}}\hat{q}\, ds - \int_{\hat{K}} \hat{\boldsymbol{u}} \cdot \hat{\nabla}\hat{q}\, d\hat{\boldsymbol{x}} = 0, \quad \hat{q} \in \mathcal{Q}_r(\hat{K}).$$

In view of (5.3) we then have that

$$\int_{\hat{K}} \hat{\operatorname{div}}\, \hat{\boldsymbol{u}}\hat{q}\, d\hat{\boldsymbol{x}} = 0, \quad \hat{q} \in \mathcal{R}_r.$$

Since $\hat{\operatorname{div}}\, \hat{\boldsymbol{u}} \in \mathcal{R}_r$ we conclude that $\hat{\operatorname{div}}\, \hat{\boldsymbol{u}} = 0$. Now we may write

$$\hat{\boldsymbol{u}} = \sum_{i=0}^{r} [a_i(\hat{x}_1^{r+2}\hat{x}_2^i, 0) + b_i(0, \hat{x}_1^i\hat{x}_2^{r+2})] + \hat{\boldsymbol{v}}$$

with $\hat{\boldsymbol{v}} \in \boldsymbol{\mathcal{RT}}_r$. Since

$$0 = \hat{\operatorname{div}}\, \hat{\boldsymbol{u}} = \sum_{i=1}^{r} (r+2)(a_i\hat{x}_1^{r+1}\hat{x}_2^i + b_i\hat{x}_1^i\hat{x}_2^{r+1}) + \hat{\operatorname{div}}\, \hat{\boldsymbol{v}},$$

and $\hat{\operatorname{div}}\, \hat{\boldsymbol{v}} \in \mathcal{Q}_r$, it follows that $a_i = b_i = 0$ and so $\hat{\boldsymbol{u}} = \hat{\boldsymbol{v}} \in \boldsymbol{\mathcal{RT}}_r$. Since (5.1), (5.2) are unisolvent degrees of freedom for $\boldsymbol{\mathcal{RT}}_r$ [4, Proposition III.3.4], we conclude that $\hat{\boldsymbol{u}} = 0$.

We also note that a small variant of the first part of this argument establishes the commutativity property (4.2) with $\hat{\boldsymbol{\pi}} : \boldsymbol{H}^1(\hat{K}) \to \boldsymbol{\mathcal{ABF}}_r$ the projection determined by the degrees of freedom (5.1)–(5.3) and $\hat{\Pi}$ the L^2-projection onto $\mathcal{R}_r = \hat{\operatorname{div}}\, \boldsymbol{\mathcal{ABF}}_r$. Thus, all the hypotheses of Theorems 4.1 and 4.2 are satisfied and the estimates (4.1) and (4.3) hold on general quadrilateral meshes for finite element spaces based on $\boldsymbol{\mathcal{ABF}}_r$.

6. Application to mixed finite element methods. One of the main applications of finite element subspaces of $\boldsymbol{H}(\operatorname{div}, \Omega)$ is to the approximation of second order elliptic boundary value problems by mixed finite element methods. For the model problem $\Delta p = f$ in Ω, $p = 0$ on $\partial\Omega$, the mixed formulation is the following: Find $\boldsymbol{u} \in \boldsymbol{H}(\operatorname{div}, \Omega)$ and $p \in L^2(\Omega)$ such that

$$\begin{aligned} (\boldsymbol{u}, \boldsymbol{v}) + (p, \operatorname{div} \boldsymbol{v}) &= 0 \quad \forall \boldsymbol{v} \in \boldsymbol{H}(\operatorname{div}, \Omega), \\ (\operatorname{div} \boldsymbol{u}, q) &= (f, q) \quad \forall q \in L^2(\Omega), \end{aligned}$$

where $(\cdot, \cdot)$ denotes the $L^2(\Omega)$ inner product. For $\boldsymbol{S}_h \subseteq \boldsymbol{H}(\operatorname{div}, \Omega)$ and $W_h \subseteq L^2(\Omega)$, the mixed finite element approximation seeks $\boldsymbol{u}_h \in \boldsymbol{S}_h$ and $p_h \in W_h$ such that

$$\begin{aligned} (\boldsymbol{u}_h, \boldsymbol{v}) + (p_h, \operatorname{div} \boldsymbol{v}) &= 0 \quad \forall \boldsymbol{v} \in \boldsymbol{S}_h, \\ (\operatorname{div} \boldsymbol{u}_h, q) &= (f, q) \quad \forall q \in W_h. \end{aligned}$$

The pair $(\boldsymbol{S}_h, W_h)$ is said to be stable if the following conditions are satisfied:

$$(\boldsymbol{v}, \boldsymbol{v}) \geq c\|\boldsymbol{v}\|^2_{\boldsymbol{H}(\operatorname{div},\Omega)} \quad \forall \boldsymbol{v} \in \boldsymbol{Z}_h = \{\boldsymbol{v} \in \boldsymbol{S}_h : (\operatorname{div} \boldsymbol{v}, q) = 0\ \forall q \in W_h\}, \tag{6.1}$$

$$\sup_{\boldsymbol{v} \in \boldsymbol{S}_h} \frac{(\operatorname{div} \boldsymbol{v}, q)}{\|\boldsymbol{v}\|_{\boldsymbol{H}(\operatorname{div},\Omega)}} \geq c\|q\|_{L^2(\Omega)} \quad \forall q \in W_h. \tag{6.2}$$

By Brezzi's theorem [3], if $(\boldsymbol{S}_h, W_h)$ is a stable pair, then the quasioptimality estimate

(6.3)
$$\|\boldsymbol{u}-\boldsymbol{u}_h\|_{\boldsymbol{H}(\mathrm{div},\Omega)}+\|p-p_h\|_{L^2(\Omega)}\le C\Big(\inf_{\boldsymbol{v}\in\boldsymbol{S}_h}\|\boldsymbol{u}-\boldsymbol{v}\|_{\boldsymbol{H}(\mathrm{div},\Omega)}+\inf_{q\in W_h}\|p-q\|_{L^2(\Omega)}\Big)$$

holds with C depending only on Ω and the constant c entering into the stability conditions.

For the space $\boldsymbol{S}_h$ we will take $\boldsymbol{V}(\mathcal{T}_h)\cap\boldsymbol{H}(\mathrm{div},\Omega)$, where $\mathcal{T}_h$ is an arbitrary quadrilateral mesh and $\boldsymbol{V}(\mathcal{T}_h)$ is constructed as described at the start of section 3 starting from a space of reference shape functions $\hat{\boldsymbol{V}}$ on the unit square. To specify the corresponding space W_h, we first define a space of reference shape functions $\hat{W}=\hat{\mathrm{div}}\,\hat{\boldsymbol{V}}$, next define the space of shape functions on K by $W_K=\{\hat{w}\circ\boldsymbol{F}_K^{-1}\mid\hat{w}\in\hat{W}\}$, and then set

$$W_h=\{w\in L^2(\Omega)\mid w|_K\in W_K\}.$$

Now suppose that $\hat{\boldsymbol{V}}$ is any one of the previously considered spaces $\boldsymbol{\mathcal{RT}}_r$, $\boldsymbol{\mathcal{BDM}}_r$, $\boldsymbol{\mathcal{BDFM}}_{r+1}$, or $\boldsymbol{\mathcal{ABF}}_r$. Associated with each of these spaces is a unisolvent set of degrees of freedom. These are given in (5.1) and (5.2) for $\boldsymbol{\mathcal{RT}}_r$, by (5.1)–(5.3) for $\boldsymbol{\mathcal{ABF}}_r$, and, for $\boldsymbol{\mathcal{BDM}}_r$ and $\boldsymbol{\mathcal{BDFM}}_{r+1}$, by (5.1) and $\int_{\hat{K}}\hat{\boldsymbol{u}}\cdot\hat{\boldsymbol{\phi}}\,d\hat{\boldsymbol{x}}$ with $\hat{\boldsymbol{\phi}}$ in $\boldsymbol{\mathcal{P}}_{r-2}(\hat{K})$ or $\boldsymbol{\mathcal{P}}_{r-1}(\hat{K})$, respectively. These degrees of freedom determine the projection $\hat{\boldsymbol{\pi}}:\boldsymbol{H}^1(\hat{K})\to\hat{\boldsymbol{V}}$ and then, by the construction described at the start of section 4, the projection $\boldsymbol{\pi}_h:\boldsymbol{H}^1(\Omega)\to\boldsymbol{S}_h$. Moreover, the degrees of freedom ensure the commutativity property (4.2) where $\hat{\Pi}$ is the $L^2(\hat{K})$ projection onto $\hat{W}$. From these observations it is straightforward to derive the stability conditions (6.1) and (6.2), as we shall now do.

Given $\boldsymbol{v}\in\boldsymbol{Z}_h$ and $K\in\mathcal{T}_h$, let $\hat{\boldsymbol{v}}=\boldsymbol{P}_{F_K}^{-1}(\boldsymbol{v}|_K)\in\hat{\boldsymbol{V}}$, $\hat{q}=\hat{\mathrm{div}}\,\hat{\boldsymbol{v}}\in\hat{W}$, and $q=\hat{q}\circ\boldsymbol{F}_K^{-1}\in W_K$. Then $(\mathrm{div}\,\boldsymbol{v},q)_{L^2(K)}=0$ (because we can extend q to Ω by zero and obtain a function in W_h and $\mathrm{div}\,\boldsymbol{v}$ is orthogonal to W_h since $\boldsymbol{v}\in\boldsymbol{Z}_h$). But $(\mathrm{div}\,\boldsymbol{v},q)_{L^2(K)}=(\hat{\mathrm{div}}\,\hat{\boldsymbol{v}},\hat{q})_{L^2(\hat{K})}=\|\hat{\mathrm{div}}\,\hat{\boldsymbol{v}}\|^2_{L^2(K)}$, so $\hat{\mathrm{div}}\,\hat{\boldsymbol{v}}=0$ and therefore $\mathrm{div}\,\boldsymbol{v}=[(J\boldsymbol{F}_K)^{-1}\hat{\mathrm{div}}\,\hat{\boldsymbol{v}}]\circ\boldsymbol{F}_K^{-1}=0$. Thus, if $\boldsymbol{v}\in\boldsymbol{Z}_h$, then $\mathrm{div}\,\boldsymbol{v}=0$, and (6.1) follows immediately with $c=1$.

To prove (6.2), we shall show that for any given $q\in W_h$ there exists $\boldsymbol{v}\in\boldsymbol{S}_h$ with

$$(\mathrm{div}\,\boldsymbol{v},q)=\|q\|_{L^2(\Omega)}\tag{6.4}$$

and

$$\|\boldsymbol{v}\|_{\boldsymbol{H}(\mathrm{div},\Omega)}\le C\|q\|_{L^2(\Omega)}.\tag{6.5}$$

As usual, we start by noting that there exists $\boldsymbol{u}\in\boldsymbol{H}^1(\Omega)$ with $\mathrm{div}\,\boldsymbol{u}=q$ and $\|\boldsymbol{u}\|_{H^1(\Omega)}\le C\|q\|_{L^2(\Omega)}$ and letting $\boldsymbol{v}=\boldsymbol{\pi}_h\boldsymbol{u}$. Now $(\mathrm{div}\,\boldsymbol{\pi}_h\boldsymbol{u},q)=(\mathrm{div}\,\boldsymbol{u},q)$ whenever $q\in W_h$, as follows directly from the construction of $\boldsymbol{\pi}_h$, the commutativity property (4.2), and the properties of the Piola transform. Therefore (6.4) holds. To prove (6.5) we note that in each case $\hat{\boldsymbol{V}}\supseteq\boldsymbol{\mathcal{S}}_0$, so Theorem 4.1 gives the estimate $\|\boldsymbol{u}-\boldsymbol{\pi}_h\boldsymbol{u}\|_{L^2(\Omega)}\le Ch\|\boldsymbol{u}\|_{H^1(\Omega)}$, and so, by the triangle inequality, $\|\boldsymbol{v}\|_{L^2(\Omega)}\le C\|q\|_{L^2(\Omega)}$. Also, on any element K, $\mathrm{div}\,\boldsymbol{v}=\mathrm{div}\,\boldsymbol{\pi}_K\boldsymbol{u}=\Lambda_K(\mathrm{div}\,\boldsymbol{u})=\Lambda_K q$, where Λ_K is defined by (4.6), which implies that $\|\mathrm{div}\,\boldsymbol{v}\|_{L^2(\Omega)}\le C\|q\|_{L^2(\Omega)}$. This establishes (6.5) and completes the proof of stability.

Remark. Note that we do not have $W_h = \operatorname{div} \boldsymbol{S}_h$ on general quadrilateral meshes, although this is the case on rectangular meshes. With that choice of W_h it would be easy to prove (6.1) but the proof of (6.2) would not be clear.

We now turn our attention to error estimates for mixed methods. Having established stability, we can combine the quasioptimality estimate (6.3) with the bounds for the approximation error given by Theorems 4.1 and 4.2 (and Theorem 1 of [1] for the approximation error for p) to obtain error bounds. For the $\boldsymbol{\mathcal{ABF}}_r$ method this gives

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_{\boldsymbol{H}(\operatorname{div},\Omega)} + \|p - p_h\|_{L^2(\Omega)} \le Ch^{r+1}(|u|_{H^{r+1}(\Omega)} + |\operatorname{div} \boldsymbol{u}|_{H^{r+1}(\Omega)} + |p|_{H^{r+1}(\Omega)}).$$

But for the $\boldsymbol{\mathcal{RT}}_r$ method it gives only an $O(h^r)$ bound, and no convergence at all for $r = 0$, because of the decreased approximation for the divergence (and the approximation orders are even lower for $\boldsymbol{\mathcal{BDM}}_r$ and $\boldsymbol{\mathcal{BDFM}}_{r+1}$).

It is possible to improve on this by following the approach of [6] and [5], as we now do. First we define $\Pi_K : L^2(K) \to W_K$ by $\Pi_K p = (\hat{\Pi}\hat{p}) \circ \boldsymbol{F}_K^{-1}$ with $\hat{p} = p \circ \boldsymbol{F}_K$, and then we define $\Pi_h : L^2(\Omega) \to W_h$ by $\Pi_h p|_K = \Pi_K(p|_K)$. It follows that $(p - \Pi_K p, \operatorname{div} \boldsymbol{v})_{L^2(K)} = (\hat{p} - \hat{\Pi}\hat{p}, \hat{\operatorname{div}}\, \boldsymbol{P}_{F_K}^{-1}\boldsymbol{v})_{L^2(K)}$, so

$$(p - \Pi_h p, \operatorname{div} \boldsymbol{v}) = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{S}_h.$$

We then have the following error estimates.

THEOREM 6.1.

$$\begin{aligned}
\|\boldsymbol{u} - \boldsymbol{u}_h\|_{L^2(\Omega)} &\le \|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)},\\
\|\operatorname{div} \boldsymbol{u}_h\|_{L^2(\Omega)} &\le C\|\operatorname{div} \boldsymbol{u}\|_{L^2(\Omega)},\\
\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(\Omega)} &\le C\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u})\|_{L^2(\Omega)},\\
\|\Pi_h p - p_h\|^2_{L^2(\Omega)} &= (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{U} - \boldsymbol{\pi}_h \boldsymbol{U}) + (\operatorname{div}[\boldsymbol{u} - \boldsymbol{u}_h], P - \Pi_h P),
\end{aligned}$$

where P is the solution to the Dirichlet problem $-\Delta P = \Pi_h p - p_h$ in Ω, $P = 0$ on $\partial\Omega$ and $\boldsymbol{U} = \operatorname{grad} P$.

Proof. Using the error equations

$$(\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{v}) + (p - p_h, \operatorname{div} \boldsymbol{v}) = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{S}_h, \qquad (\operatorname{div}[\boldsymbol{u} - \boldsymbol{u}_h], q) = 0 \quad \forall q \in W_h,$$

we obtain

$$\begin{aligned}
(\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{\pi}_h \boldsymbol{u} - \boldsymbol{u}_h) &= (p - p_h, \operatorname{div}[\boldsymbol{u}_h - \boldsymbol{\pi}_h \boldsymbol{u}]) = (\Pi_h p - p_h, \operatorname{div}[\boldsymbol{u}_h - \boldsymbol{\pi}_h \boldsymbol{u}])\\
&= (\Pi_h p - p_h, \operatorname{div}[\boldsymbol{u}_h - \boldsymbol{u}]) = 0.
\end{aligned}$$

Hence, $\|\boldsymbol{u} - \boldsymbol{u}_h\|^2_{L^2(\Omega)} = (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u})$ and it easily follows that

$$\|\boldsymbol{u} - \boldsymbol{u}_h\|_{L^2(\Omega)} \le \|\boldsymbol{u} - \boldsymbol{\pi}_h \boldsymbol{u}\|_{L^2(\Omega)}.$$

To estimate $\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(\Omega)}$, we observe that if $v \in \boldsymbol{S}_h$ and we define

$$q(\boldsymbol{x}) = \begin{cases} |J\boldsymbol{F}_K(\hat{\boldsymbol{x}})| \operatorname{div} \boldsymbol{v}(\boldsymbol{x}), & \boldsymbol{x} \in K,\\ 0, & \boldsymbol{x} \in \Omega \setminus K, \end{cases}$$

then $q \in W_h$. Therefore, from the error equation we have

$$(\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h), |J\boldsymbol{F}_K| \operatorname{div} \boldsymbol{v})_K = 0.$$

Choosing $\boldsymbol{v} = \boldsymbol{u}_h$, it easily follows that

$$\||J\boldsymbol{F}_K|^{1/2}\operatorname{div}\boldsymbol{u}_h\|_{L^2(K)} \le \||J\boldsymbol{F}_K|^{1/2}\operatorname{div}\boldsymbol{u}\|_{L^2(K)},$$

and so $\|\operatorname{div}\boldsymbol{u}_h\|_{L^2(K)} \le C\|\operatorname{div}\boldsymbol{u}\|_{L^2(K)}$ with C depending on the shape constant for K. Choosing $\boldsymbol{v} = \boldsymbol{\pi}_h\boldsymbol{u} - \boldsymbol{u}_h$, it also follows that

$$\||J\boldsymbol{F}_K|^{1/2}\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(K)} \le \||J\boldsymbol{F}_K|^{1/2}\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u})\|_{L^2(K)},$$

so $\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(K)} \le C\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u})\|_{L^2(K)}$. Summing over all quadrilaterals, we obtain

$$\|\operatorname{div}\boldsymbol{u}_h\|_{L^2(\Omega)} \le C\|\operatorname{div}\boldsymbol{u}\|_{L^2(\Omega)}, \qquad \|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(\Omega)} \le C\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u})\|_{L^2(\Omega)}.$$

To estimate $\|p - p_h\|_{L^2(\Omega)}$, we define P as the solution to the Dirichlet problem $\Delta P = \Pi_h p - p_h$ in Ω, $P = 0$ on $\partial\Omega$, and set $\boldsymbol{U} = \operatorname{grad} P$. Then

$$\begin{aligned}\|\Pi_h p - p_h\|^2_{L^2(\Omega)} &= (\operatorname{div}\boldsymbol{U}, \Pi_h p - p_h) = (\operatorname{div}\boldsymbol{\pi}_h\boldsymbol{U}, \Pi_h p - p_h) = -(\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{\pi}_h\boldsymbol{U})\\ &= (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{U} - \boldsymbol{\pi}_h\boldsymbol{U}) - (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{U})\\ &= (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{U} - \boldsymbol{\pi}_h\boldsymbol{U}) + (\operatorname{div}[\boldsymbol{u} - \boldsymbol{u}_h], P)\\ &= (\boldsymbol{u} - \boldsymbol{u}_h, \boldsymbol{U} - \boldsymbol{\pi}_h\boldsymbol{U}) + (\operatorname{div}[\boldsymbol{u} - \boldsymbol{u}_h], P - \Pi_h P). \qquad \square\end{aligned}$$

To obtain order of convergence estimates, one needs to apply the approximation properties of a particular space. For the Raviart–Thomas elements of index r we obtain the following estimates.

THEOREM 6.2. *Suppose $(\boldsymbol{u}_h, p_h)$ is the mixed method approximation to $(\boldsymbol{u}, p)$ obtained when $\hat{\boldsymbol{V}}$ is the Raviart–Thomas reference space of index r and suppose that the domain Ω is convex. Then for $p \in H^{r+2}(\Omega)$,*

$$\begin{aligned}\|\boldsymbol{u} - \boldsymbol{u}_h\|_{L^2(\Omega)} &\le Ch^{r+1}\|\boldsymbol{u}\|_{H^{r+1}(\Omega)},\\ \|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(\Omega)} &\le Ch^{r}\|\operatorname{div}\boldsymbol{u}\|_{H^{r}(\Omega)},\\ \|p - p_h\|_{L^2(\Omega)} &\le \begin{cases} Ch^{r+1}\|p\|_{H^{r+1}(\Omega)} & (r \ge 1),\\ Ch\|p\|_{H^2(\Omega)} & (r = 0).\end{cases}\end{aligned}$$

Proof. It follows from [7, section I.A.2] that $\|p - \Pi_h p\|_{L^2(\Omega)} \le Ch^{k+1}\|p\|_{k+1,\Omega}$, $0 \le k \le r$, and it follows from Theorems 4.1 and 4.2 that, for $0 \le k \le r$,

$$\|\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u}\|_{L^2(\Omega)} \le Ch^{k+1}\|\boldsymbol{u}\|_{H^{k+1}(\Omega)}, \qquad \|\operatorname{div}[\boldsymbol{u} - \boldsymbol{\pi}_h\boldsymbol{u}]\|_{L^2(\Omega)} \le Ch^{k}\|\operatorname{div}\boldsymbol{u}\|_{H^{k}(\Omega)}.$$

Inserting these results in Theorem 6.1, we immediately obtain the first two estimates of Theorem 6.2. From the last estimate of Theorem 6.1, we also obtain

$$\|\Pi_h p - p_h\|_{L^2(\Omega)} \le C(h\|\boldsymbol{u} - \boldsymbol{u}_h\|_{L^2(\Omega)} + h^{\min(1+r,2)}\|\operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h)\|_{L^2(\Omega)}).$$

Here we have used elliptic regularity, which holds under the assumption that Ω is convex, to bound $\|\boldsymbol{U}\|_{H^1(\Omega)} = \|P\|_{H^2(\Omega)}$ by $\|\Pi_h p - p_h\|_{L^2(\Omega)}$. Hence, for $r \ge 1$ and $0 \le k \le r$, we obtain

$$\|\Pi_h p - p_h\|_{L^2(\Omega)} \le Ch^{k+2}(\|\boldsymbol{u}\|_{H^{k+1}(\Omega)} + \|\operatorname{div}\boldsymbol{u}\|_{H^k(\Omega)}) \le Ch^{k+2}\|\boldsymbol{u}\|_{H^{k+1}(\Omega)}.$$

Choosing $k = r - 1$ and $k = r$, we obtain for $r \ge 1$

$$\|\Pi_h p - p_h\|_{L^2(\Omega)} \le Ch^{r+1}\|\boldsymbol{u}\|_{H^r(\Omega)}, \qquad \|\Pi_h p - p_h\|_{L^2(\Omega)} \le Ch^{r+2}\|\boldsymbol{u}\|_{H^{r+1}(\Omega)},$$

and for $r = 0$, $\|\Pi_h p - p_h\|_{L^2(\Omega)} \le Ch\|\boldsymbol{u}\|_{1,\Omega}$. The final estimates of the theorem now follow directly by the triangle inequality. $\square$

7. Application to least squares methods. A standard finite element least squares approximation of the Dirichlet problem $\Delta p = f$ in Ω, $p = 0$ on $\partial\Omega$ seeks $p_h \in W_h \subseteq H_0^1(\Omega)$ and $\boldsymbol{u}_h \in \boldsymbol{S}_h \subseteq \boldsymbol{H}(\operatorname{div}, \Omega)$ minimizing

$$J(q, \boldsymbol{v}) = \|\boldsymbol{v} - \operatorname{grad} q\|^2_{L^2(\Omega)} + \|\operatorname{div} \boldsymbol{v} + f\|^2_{L^2(\Omega)}$$

over $W_h \times \boldsymbol{S}_h$. For any choices of subspaces this satisfies the quasioptimality estimate (cf. [10])

$$\|p - p_h\|_{H^1(\Omega)} + \|\boldsymbol{u} - \boldsymbol{u}_h\|_{\boldsymbol{H}(\operatorname{div},\Omega)} \le C\Big(\inf_{p \in W_h} \|p - q\|_{H^1(\Omega)} + \inf_{\boldsymbol{v} \in \boldsymbol{S}_h} \|\boldsymbol{u} - \boldsymbol{v}\|_{\boldsymbol{H}(\operatorname{div},\Omega)} \Big).$$

If we take W_h to be the standard H^1 finite element space based on reference shape functions $\mathcal{Q}_{r+1}$ and use the $\boldsymbol{\mathcal{ABF}}_r$ space for $\boldsymbol{S}_h$, we immediately obtain

$$\|p - p_h\|_{H^1(\Omega)} + \|\boldsymbol{u} - \boldsymbol{u}_h\|_{\boldsymbol{H}(\operatorname{div},\Omega)} \le C h^{r+1} (\|p\|_{H^{r+1}(\Omega)} + \|\boldsymbol{u}\|_{H^{r+1}(\Omega)} + \|\operatorname{div} \boldsymbol{u}\|_{H^{r+1}(\Omega)}).$$

However, the quasioptimality estimate suggests that if we choose the same W_h but use the $\boldsymbol{\mathcal{RT}}_r$ elements for $\boldsymbol{S}_h$, the lower rate of approximation of $\operatorname{div} \boldsymbol{u}$ may negatively influence the approximation of both variables.

Next, we use a duality argument to obtain a second estimate, which provides improved convergence for p in L^2 when the $\boldsymbol{\mathcal{ABF}}$ spaces are used, but again suggests difficulties for the $\boldsymbol{\mathcal{RT}}$ spaces. We shall henceforth assume that the domain Ω is convex so that we have 2-regularity for the Dirichlet problem for the Laplacian. Define $\boldsymbol{w} \in \boldsymbol{H}(\operatorname{div}, \Omega)$ and $r \in H_0^1(\Omega)$ as solution of the dual problem

$$\int_\Omega (\boldsymbol{w} - \nabla r) \cdot \boldsymbol{v}\, d\boldsymbol{x} + \int_\Omega \operatorname{div} \boldsymbol{w} \operatorname{div} \boldsymbol{v}\, d\boldsymbol{x} = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{H}(\operatorname{div}, \Omega), \tag{7.1}$$

$$\int_\Omega (\boldsymbol{w} - \nabla r) \cdot \nabla q\, d\boldsymbol{x} = -\int_\Omega (p - p_h) q\, d\boldsymbol{x} \quad \forall q \in H_0^1(\Omega). \tag{7.2}$$

This problem has a unique solution, since if $p - p_h$ were to vanish, then we could take $\boldsymbol{v} = \boldsymbol{w}$ and $q = r$, subtract the equations, and conclude that $\boldsymbol{w} = \nabla r$, $\operatorname{div} \boldsymbol{w} = 0$ with $r \in H_0^1(\Omega)$, which implies that $\boldsymbol{w}$ and r vanish. For general $p - p_h$, the solution of the dual problem may be written as $\boldsymbol{w} = \nabla(r + g)$ where $g \in H^2(\Omega) \cap H_0^1(\Omega)$ satisfies $\Delta g = p - p_h$ and $r \in H^2(\Omega) \cap H_0^1(\Omega)$ satisfies $\Delta r = g - p + p_h$ (so $\operatorname{div} \boldsymbol{w} = g$). Note that $\|r\|_{H^2(\Omega)} + \|\boldsymbol{w}\|_{H^1(\Omega)} + \|\operatorname{div} \boldsymbol{w}\|_{H^2(\Omega)} \le C \|p - p_h\|_{L^2(\Omega)}$. Choosing $q = p - p_h$, $\boldsymbol{v} = \boldsymbol{u} - \boldsymbol{u}_h$, subtracting (7.2) from (7.1), and using the error equations

$$\int_\Omega (\boldsymbol{u} - \boldsymbol{u}_h - \nabla[p - p_h]) \cdot \boldsymbol{v}\, d\boldsymbol{x} + \int_\Omega \operatorname{div}(\boldsymbol{u} - \boldsymbol{u}_h) \operatorname{div} \boldsymbol{v}\, d\boldsymbol{x} = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{S}_h,$$

$$\int_\Omega (\boldsymbol{u} - \boldsymbol{u}_h - \nabla[p - p_h]) \cdot \nabla q\, d\boldsymbol{x} = 0 \quad \forall q \in W_h,$$

one obtains the estimate

$$\|p - p_h\|^2_{L^2(\Omega)} \le C(\|r - r_I\|_{H^1(\Omega)} + \|\boldsymbol{w} - \boldsymbol{w}_I\|_{\boldsymbol{H}(\operatorname{div},\Omega)})(\|p - p_h\|_{H^1(\Omega)} + \|\boldsymbol{u} - \boldsymbol{u}_h\|_{\boldsymbol{H}(\operatorname{div},\Omega)})$$

for all $\boldsymbol{w}_I \in \boldsymbol{S}_h$ and $r_I \in W_h$. This estimate will furnish an improved order of convergence for p in L^2 as compared to H^1 if $\boldsymbol{S}_h$ has good approximation properties in $\boldsymbol{H}(\operatorname{div}, \Omega)$. For the $\boldsymbol{\mathcal{ABF}}_r$ space (still with W_h based on $\mathcal{Q}_{r+1}$) we obtain

$$\|p - p_h\|_{L^2(\Omega)} \le C h^{r+2} (\|p\|_{H^{r+1}(\Omega)} + \|\boldsymbol{u}\|_{H^{r+r}(\Omega)} + \|\operatorname{div} \boldsymbol{u}\|_{H^{r+1}(\Omega)}).$$

But for the $\boldsymbol{\mathcal{RT}}_0$ space we obtain no convergence whatsoever. Numerical computations reported in the next section verify these findings for both the scalar and the vector variable: with W_h taken to be the usual four node H^1 elements based on $\mathcal{Q}_1$ and $\boldsymbol{S}_h$ based on $\boldsymbol{\mathcal{ABF}}_0$, we obtain convergence of order 1 for $\boldsymbol{u}$ in $\boldsymbol{H}(\mathrm{div},\Omega)$ and of order 2 for p in $L^2(\Omega)$, but if we use $\boldsymbol{\mathcal{RT}}_0$ elements instead there is no L^2 convergence for $\boldsymbol{u}$ or p.

The numerical computations of the next section also exhibit second order convergence for $\operatorname{div}\boldsymbol{u}$ in $\boldsymbol{L}^2(\Omega)$ when approximated by the $\boldsymbol{\mathcal{ABF}}_0$ method on square meshes. We close this section by showing that

$$\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)} = O(h^{r+2})$$

when the $\boldsymbol{\mathcal{ABF}}_r$ elements are used on rectangular meshes. Now define $\boldsymbol{w}\in\boldsymbol{H}(\mathrm{div},\Omega)$ and $r\in H_0^1(\Omega)$ by

$$\int_\Omega (\boldsymbol{w}-\nabla r)\cdot\boldsymbol{v}\,d\boldsymbol{x} + \int_\Omega \operatorname{div}\boldsymbol{w}\operatorname{div}\boldsymbol{v}\,d\boldsymbol{x} = \int_\Omega \operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\operatorname{div}\boldsymbol{v}\,d\boldsymbol{x} \quad \forall \boldsymbol{v}\in\boldsymbol{H}(\mathrm{div},\Omega),$$
$$\int_\Omega (\boldsymbol{w}-\nabla r)\cdot\nabla q\,d\boldsymbol{x} = 0 \quad \forall q\in H_0^1(\Omega).$$

Then $\Delta r = \operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)$ and $\boldsymbol{w}=\nabla r$, and so $\|r\|_{H^2(\Omega)} + \|\boldsymbol{w}\|_{H^1(\Omega)} \le C\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)}$. Taking $\boldsymbol{v}=\boldsymbol{u}-\boldsymbol{u}_h$, $q=p-p_h$ and using the error equations, we obtain

$$\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|^2_{L^2(\Omega)} = \int_\Omega (\boldsymbol{w}-\boldsymbol{w}_I-\nabla[r-r_I])\cdot(\boldsymbol{u}-\boldsymbol{u}_h-\nabla[p-p_h])\,d\boldsymbol{x} + \int_\Omega \operatorname{div}(\boldsymbol{w}-\boldsymbol{w}_I)\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\,d\boldsymbol{x}$$

for any $\boldsymbol{w}_I\in\boldsymbol{S}_h$ and $r_I\in W_h$. Taking $\boldsymbol{w}_I=\boldsymbol{\pi}_h\boldsymbol{w}$ and r_I a standard interpolant of r, the first integral on the right-hand side is bounded by

$$\begin{aligned} &Ch\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)}(\|p-p_h\|_{H^1(\Omega)} + \|\boldsymbol{u}-\boldsymbol{u}_h\|_{\boldsymbol{H}(\mathrm{div},\Omega)}) \\ &\quad\le Ch^{r+2}\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)}(\|p\|_{H^{r+1}(\Omega)} + \|\boldsymbol{u}\|_{H^{r+1}(\Omega)} + \|\operatorname{div}\boldsymbol{u}\|_{H^{r+1}(\Omega)}). \end{aligned}$$

To bound the second integral, we note that, in the rectangular case, $\operatorname{div}\boldsymbol{\pi}_h\boldsymbol{w} = \Pi_h\operatorname{div}\boldsymbol{w}$ with Π_h the L^2-projection into $\operatorname{div}\boldsymbol{V}_h$, and also, in the rectangular case, $\operatorname{div}\boldsymbol{V}_h$ contains all piecewise polynomials of degree at most $r+1$, so $\|q-\Pi_h q\|_{L^2(\Omega)} \le Ch^{r+2}\|q\|_{H^{r+2}(\Omega)}$ for all q. Therefore,

$$\begin{aligned} \int_\Omega \operatorname{div}(\boldsymbol{w}-\boldsymbol{w}_I)\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\,d\boldsymbol{x} &= \int_\Omega \operatorname{div}\boldsymbol{w}[\operatorname{div}\boldsymbol{u}-\Pi_h(\operatorname{div}\boldsymbol{u})]\,d\boldsymbol{x} \\ &\le C\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)}h^{r+2}\|\operatorname{div}\boldsymbol{u}\|_{H^{r+2}(\Omega)}. \end{aligned}$$

Combining these estimates, we conclude that

$$\|\operatorname{div}(\boldsymbol{u}-\boldsymbol{u}_h)\|_{L^2(\Omega)} \le Ch^{r+2}(\|p\|_{H^{r+1}(\Omega)} + \|\boldsymbol{u}\|_{H^{r+1}(\Omega)} + \|\operatorname{div}\boldsymbol{u}\|_{H^{r+2}(\Omega)}).$$

8. Numerical results. In this section, we illustrate our results with several numerical examples using two sequences of meshes. The first is a uniform mesh of the unit square into n^2 subsquares and the second is a mesh of trapezoids as shown in Figure 1(b) (with the notation of Theorem 3.1, here $\alpha=1$ and $\beta=1/3$). In the first of

these examples (see Table 1), we demonstrate the decreased orders of convergence of the $\boldsymbol{\mathcal{BDM}}_1$ and $\boldsymbol{\mathcal{BDFM}}_2$ spaces by computing the piecewise $\boldsymbol{H}(\mathrm{div},\Omega)$ projection of a simple smooth function, $\boldsymbol{u}=\operatorname{grad}[x_1(1-x_1)x_2(1-x_2)]$, into the discontinuous versions of these spaces. On a rectangular mesh, the space $\boldsymbol{\mathcal{BDFM}}_2$ gives second order approximation of both components of the vector and of its divergence. This is

confirmed in the approximation of the piecewise $\boldsymbol{H}(\mathrm{div},\Omega)$ projection. On a trapezoidal mesh, $\boldsymbol{\mathcal{BDFM}}_2$ gives only first order approximation of both components of the vector and of its divergence, and this is also confirmed in the approximation of the piecewise $\boldsymbol{H}(\mathrm{div},\Omega)$ projection. On a rectangular mesh, the space $\boldsymbol{\mathcal{BDM}}_1$ gives second order approximation of both components of the vector, but only first order approximation of its divergence. On a trapezoidal mesh these orders of convergence are reduced to first order for the approximation of both components of the vector and the approximation of the divergence shows no convergence. These theoretical convergence orders are also confirmed in the computations. Although we do not in-

clude the details of the computations, the same convergence orders are observed in computations of the $\boldsymbol{L}^2(\Omega)$, rather than the piecewise $\boldsymbol{H}(\operatorname{div},\Omega)$ projection.

The second computation, reported in Table 2, illustrates our results on the convergence orders of $\boldsymbol{\mathcal{RT}}_0$ and $\boldsymbol{\mathcal{ABF}}_0$ for the approximation of Poisson's equation by the standard mixed finite element method. The exact solution is $p = x_1(1-x_1)x_2(1-x_2)$. As expected, on a trapezoidal mesh, $\boldsymbol{\mathcal{RT}}_0$ gives a first order approximation to the scalar and vector variable (the same as on a rectangular mesh), but there is no con-

vergence of the approximation of the divergence of the vector variable in contrast to the standard first order approximation seen on rectangles. When $\boldsymbol{\mathcal{ABF}}_0$ is used instead, there is an improvement in the convergence order of the divergence of the vector variable.

Finally, Table 3 shows the difference in the convergence orders of $\boldsymbol{\mathcal{RT}}_0$ and $\boldsymbol{\mathcal{ABF}}_0$ coupled with $\mathcal{Q}_1$ for the scalar variable for the approximation of Poisson's equation by a standard least squares finite element method. Again the exact solution is $p = x_1(1-x_1)x_2(1-x_2)$. When $\boldsymbol{\mathcal{RT}}_0$ is used, the poor approximation of the divergence on trapezoidal meshes results in poor approximation of both the scalar and vector variable, while on a rectangle the scalar variable is approximated to second order and the vector variable and its divergence to first order. When $\boldsymbol{\mathcal{ABF}}_0$ is used instead, one achieves second order convergence for the scalar variable and first order convergence for the vector variable on both rectangular and quadrilateral meshes. The divergence of the vector variable is approximated to second order on rectangles and to first order on trapezoids, as predicted by the theory.

LEAST-SQUARES GALERKIN METHODS FOR PARABOLIC PROBLEMS III: SEMIDISCRETE CASE FOR SEMILINEAR PROBLEMS*

MOHAMMAD MAJIDI†

Abstract. This is the third part of a series of papers on least-squares Galerkin methods for parabolic initial-boundary value problems. These methods are based on the minimization of a least-squares functional for an equivalent first-order system over space and time with respect to suitable discrete spaces. This paper presents the derivation and analysis of one-step methods for semidiscretization in time from least-squares principles for semilinear parabolic problems. One of the most important features of the least-squares methodology is a built-in a posteriori estimate for the approximation error. For the presentation in this paper, we focus our attention on the specific combination of piecewise linear, not necessarily continuous, functions in time with continuous piecewise linear for the flux and scalar variables, respectively. For the resulting method, a convergence result is shown for the scalar variable.

Key words. least-squares Galerkin method, first-order system, a posteriori error estimate, adaptive time-step control, semilinear parabolic problems

AMS subject classifications. 65M60, 65M15

1. Introduction.

Efficient computation of accurate approximations to initial-boundary value problems for parabolic partial differential equations requires adaptive techniques. Both the step-size for the discretization in time as well as the choice of mesh for the spatial discretization need to be adapted to local features of the solution using appropriate error estimators. One of the strengths of the least-squares Galerkin approach presented in this series of papers is that it provides such an a posteriori error estimator automatically by evaluating the associated least-squares functional. The purpose of this third paper is to prove convergence of the least-squares method for the semilinear case with respect to the time discretization. For this semilinear case we will observe an order reduction. Adaptive strategies for time-step control, based on a posteriori error estimators, were derived for the backward Euler discretization in [13] and in the framework of discontinuous Galerkin methods in a series of papers [6, 7, 8, 9, 10] for linear and nonlinear parabolic problems. See also [25, section 12] for the linear case. A different approach to adaptive time-stepping based on extrapolation principles was established for the linear case in [2, 3, 4] and for the nonlinear case in [15]. In [26], four least-squares Galerkin approaches are used to approximate a numerical solution of a first-order convection-diffusion system in $H^1(\Omega) \times H(\mathrm{div}, \Omega)$.

The least-squares Galerkin methodology presented here is conceptually different from all these previous approaches to adaptivity for parabolic problems. Our approach is based on the reformulation of the parabolic problem as a first-order system by introducing the flux u as an additional variable. A suitable least-squares functional is then minimized with respect to discrete spaces in order to construct approximations for the scalar variable p and for the flux u simultaneously. In [18] the equivalence

†Institute for Applied Mathematics, University of Hannover, D-30177 Hannover, Germany (majidi@ifam.uni-hannover.de).

of the least-squares functional to the consistency error for the linear case is proved, which implies that it provides an a posteriori error estimator to be used for the adaptive control of the time steps. In the semilinear case, the equivalence of the least-squares functional to the consistency error is an open problem. In this case we have only numerical evidence (cf. [17]), which implies that it provides an a posteriori error estimator to be used for the adaptive control of the time steps. In the fully discrete case, which will be considered in the fourth part of this series of papers, the least-squares functional provides an a posteriori error estimator for the approximation error in time and space. The use of least-squares functionals associated with first-order systems for a posteriori error estimation for elliptic boundary value problems is studied in [1] and, in particular for nonlinear problems, in [23]. At first sight, it may seem that the extension to more variables by changing to the first-order system formulation leads to an increase in computational work which would make the least-squares approach inefficient. However, a fair comparison of different methods is not so simple since the overall goal is to gain a certain required accuracy at minimal cost. For example, the discontinuous Galerkin method using piecewise linear functions has similar approximation properties in time for p (second order in the semilinear case) to the method discussed in this paper. The discontinuous Galerkin method requires two spatial approximations for p in this case, while the least-squares method described below needs one for p and two for u. A detailed comparison of the amount of work involved in the computation would also need to account for the availability of fast solvers for the elliptic subproblems. However, such a detailed study is far beyond the scope of this paper. In many practical applications, the flux u is actually of interest in itself and the approximation property of the least-squares Galerkin method for this variable then becomes important.

In the rest of this paper, we proceed as follows. First we introduce in section 2 the spaces that will be used in this work. To define the derivative for L^2-functions we need to introduce a tool called *distributions*. Section 3 presents the least-squares Galerkin framework and derives the associated variational formulations. In section 4, the representation of the discrete evolution in terms of solution of a nonlinear equation is derived which is the basis for the convergence analysis. The convergence analysis of the approximation error in time with respect to the H^1-norm is carried out in section 5. Finally, section 6 addresses the issues related to the solution of the elliptic problems at each time step.

2. Distributions and other spaces. Distributions give a useful tool to define and handle with Sobolev space and derivation in the weak form. Next, we will use the same notation as that of [22]. In this section, we give some definition of standard spaces using distributions. For $d \in \mathbb{N}$, let $\Omega \subset \mathbb{R}^d$ be a bounded domain with smooth boundary and let us define, for short,

$$\mathcal{D}(\Omega) = C_0^\infty(\Omega).$$

In $\mathcal{D}(\Omega)$ we observe the following concept of convergence: for a sequence $(\varphi_n)_{n\in\mathbb{N}} \subset \mathcal{D}(\Omega)$ and $\varphi \in \mathcal{D}(\Omega)$ we say the sequence φ_n *converges* in $\mathcal{D}(\Omega)$ to φ or $\varphi_n \xrightarrow{\mathcal{D}} \varphi$ iff there is a compact $K \subset \Omega$, where $\mathrm{supp}\varphi_n \subset K$ for all $n \in \mathbb{N}$, and for all α,

$$\partial^\alpha \varphi_n \longrightarrow \partial^\alpha \varphi \text{ uniformly in } \Omega.$$

Now we are in the position to define $\mathcal{D}'(\Omega)$ as the space of linear and continuous functionals on $\mathcal{D}(\Omega)$. The functionals contained in $\mathcal{D}'(\Omega)$ are called *distributions*. We

call $F : \mathcal{D}(\Omega) \to \mathbb{R}$ *continuous* iff for all $(\varphi_n)_{n\in\mathbb{N}} \subset \mathcal{D}(\Omega)$ and $\varphi \in \mathcal{D}(\Omega)$ with $\varphi_n \xrightarrow{\mathcal{D}} \varphi$ it follows that $F(\varphi_n) \xrightarrow{\mathbb{R}} F(\varphi)$. Now we observe the following concept of convergence on $\mathcal{D}'(\Omega)$: For $(F_n)_{n\in\mathbb{N}} \subset \mathcal{D}'(\Omega)$ and $F \in \mathcal{D}'(\Omega)$, we say $F_n \xrightarrow{\mathcal{D}'} F$ iff $F_n(\varphi) \xrightarrow{\mathbb{R}} F(\varphi)$ for all $\varphi \in \mathcal{D}(\Omega)$. Obviously each $f \in L^p(\Omega) \cup C^m(\Omega), 1 \le p \le \infty$, $m \in \mathbb{N}_0 \cup \{\infty\}$, could generate the following distribution:

$$F_f : \mathcal{D}(\Omega) \to \mathbb{R},$$

where

$$F_f(\varphi) := \langle F_f, \varphi\rangle := \int_\Omega f(x)\varphi(x)\,dx.$$

For such a function we identify f with its generated distribution F_f. In the above equation, F_f operates on the left-hand side like a functional and on the middle and right-hand sides like a function in the inner product $\langle\cdot,\cdot\rangle$. We will prefer the inner product notation $\langle\cdot,\cdot\rangle$, but we will use both notations whenever the situation could be better understood.

For $\alpha = (\alpha_1, \ldots, \alpha_d) \in \mathbb{N}_0^d$, we set $|\alpha| := \sum_{i=1}^d \alpha_i$ and for $F \in \mathcal{D}'(\Omega)$, we define the (*weak*) *derivation* as the following distribution:

$$\partial^\alpha F : \mathcal{D}(\Omega) \to \mathbb{R},$$
$$\langle \partial^\alpha F, \varphi\rangle = (-1)^{|\alpha|} \langle F, \partial^\alpha \varphi\rangle .$$

Notice that this "new definition" is an expansion of the definition of derivation in the classical sense. For $F \in \mathcal{D}'(\Omega)$ we say $\partial^\alpha F \in L^p(\Omega)$ iff there is $g_\alpha \in L^p(\Omega)$, where

$$\partial^\alpha F(\varphi) = \int_\Omega g_\alpha(x)\varphi(x)\,dx \quad \forall \varphi \in \mathcal{D}(\Omega).$$

2.1. Sobolev spaces. Now we are able to define Sobolev spaces: For $k \in \mathbb{N}_0$ let

$$H^k(\Omega) = \left\{ v \in L^2(\Omega) \;\middle|\; \partial^\alpha v \in L^2(\Omega) \quad \forall \alpha \in \mathbb{N}_0^d,\ |\alpha| \le k \right\}$$

be the Sobolev space of order k.

2.2. H(div)-space. Now we define for a distribution $F \in (\mathcal{D}'(\Omega))^d$ the *distributive divergence* $\mathrm{div}F \in \mathcal{D}'(\Omega)$,

$$\mathrm{div}F(\varphi) = -F(\nabla\varphi) \quad \forall \varphi \in \mathcal{D}(\Omega),$$

that will be used in the next sections. We can now introduce the $H(\mathrm{div})$-space as

$$H(\mathrm{div}, \Omega) = \left\{ v \in (L^2(\Omega))^d \;\middle|\; \mathrm{div} v \in L^2(\Omega) \right\}.$$

3. Least-squares Galerkin formulation in time. In this section we introduce the parabolic semilinear problem. Furthermore we formulate the Galerkin approximation in time. For detailed information, the reader is referred to [18].

Let $\Omega \subset \mathbb{R}^2$ be a bounded polygonal domain and assume the boundary of Ω is divided in Γ_D and Γ_N. Furthermore let n be the exterior unit normal on Γ_N. Assume $a,\ c \in L^\infty(\Omega)$ and that $a(x) \ge \underline{a},\ c(x) \ge \underline{c}$ for all $x \in \Omega$ with positive constants $\underline{a}, \underline{c}$.

For $\hat{f} : \Omega \times \mathbb{R} \times \mathbb{R}^2 \to \mathbb{R}$ and $\Lambda : \Omega \to \mathbb{R}$, we consider the first-order system formulation of the semilinear parabolic equation,

$$\begin{aligned} c(x)\,\partial_t p(t,x) + \operatorname{div} u(t,x) + \hat{f}(x, p(t,x), \nabla p(t,x)) &= 0 \quad \forall (t,x) \in (0,T)\times\Omega, \\ u(t,x) + a(x)\,\nabla p(t,x) &= 0 \quad \forall (t,x) \in (0,T)\times\Omega, \\ u(t,x)\cdot n(x) &= 0 \quad \forall (t,x) \in (0,T)\times\Gamma_N, \\ p(t,x) &= 0 \quad \forall (t,x) \in (0,T)\times\Gamma_D, \\ p(0,x) &= \Lambda(x) \quad \forall x \in \Omega, \end{aligned} \tag{3.1}$$

with some $T > 0$. We are interested in a scalar function $p : [0,T]\times\Omega \to \mathbb{R}$ and a vector function $u : [0,T]\times\Omega \to \mathbb{R}^2$ that solve (3.1). More general boundary conditions can be handled in the standard way by a suitable modification of the right-hand side $\hat{f}$. Obviously, the system in (3.1) does not always have a solution. In the following observation we restrict $\hat{f}$ and Λ such that the existence of a unique solution can be guaranteed. Let us define the following spaces:

$$\begin{aligned} H_{\Gamma_N}(\operatorname{div},\Omega) &= \{ v \in H(\operatorname{div},\Omega) \mid n\cdot v = 0 \text{ on } \Gamma_N \}, \\ H^1_{\Gamma_D}(\Omega) &= \{ q \in H^1(\Omega) \mid q = 0 \text{ on } \Gamma_D \}, \end{aligned}$$

where $H^1(\Omega)$ and $H(\operatorname{div},\Omega)$ were defined in the last section. Furthermore we define for a Hilbert space H the following spaces:

$$\begin{aligned} L^2((0,T);H) &= \left\{ v : (0,T) \to H \;\middle|\; \int_0^T \|v\|_H^2 < \infty \right\}, \\ H^1((0,T);H) &= \left\{ v : (0,T) \to H \;\middle|\; \partial_t v \in L^2((0,T);H) \right\}. \end{aligned}$$

For each $q \in H^1_{\Gamma_D}(\Omega)$, we define

$$\begin{aligned} &\mathcal{I}_q : \Omega \to \mathbb{R}, \\ &\mathcal{I}_q(x) = \hat{f}(x, q(x), \nabla q(x)), \end{aligned}$$

for short, and set

$$f(q) := \mathcal{I}_q.$$

Assuming $f \in C^1(H^1_{\Gamma_D}(\Omega); L^2(\Omega))$ and $\Lambda \in H^1_{\Gamma_D}(\Omega)$, we now replace (3.1) by

$$\begin{aligned} c\partial_t p + \operatorname{div} u + f(p) &= 0 \quad \text{in } (0,T)\times\Omega, \\ u + a\,\nabla p &= 0 \quad \text{in } (0,T)\times\Omega, \\ u\cdot n &= 0 \quad \text{on } (0,T)\times\Gamma_N, \\ p &= 0 \quad \text{on } (0,T)\times\Gamma_D, \\ p(0) &= \Lambda \quad \text{in } \Omega, \end{aligned} \tag{3.2}$$

which has a unique solution $(u,p) \in L^2((0,T); H_{\Gamma_N}(\operatorname{div},\Omega)) \times H^1((0,T); H^1_{\Gamma_D}(\Omega))$ depending continuously on the given initial and boundary data (see, e.g., [24, section 15.1]). For symmetry, we replace the first and second equations of (3.2) with the equivalent first-order system

$$\begin{aligned} c^{1/2}\partial_t p + c^{-1/2}\operatorname{div} u + c^{-1/2} f(p) &= 0, \\ a^{-1/2} u + a^{1/2}\,\nabla p &= 0. \end{aligned} \tag{3.3}$$

Obviously, the solution $(u,p) \in L^2\left((0,T); H_{\Gamma_N}(\mathrm{div},\Omega)\right) \times H^1\left((0,T); H^1_{\Gamma_D}(\Omega)\right)$ of (3.3) minimizes the least-squares functional

$$\tilde{\mathcal{F}}(u,p) = \int_0^T \left(\alpha \left\| c^{1/2}\partial_t p + c^{-1/2}(\mathrm{div} u + f(p)) \right\|^2_{0,\Omega} + \left\| a^{-1/2}\, u + a^{1/2}\nabla p \right\|^2_{0,\Omega} \right) ds\,,$$

where $\alpha > 0$ has to be chosen later. The choice of the weight α was in the first part of this series of papers the main decision to get a functional that could be used as an a posteriori error estimator (see [18, 19]). On the other hand, if $\tilde{\mathcal{F}}(u,p) = 0$, then (u,p) is a solution of (3.3).

For the time discretization, we choose subspaces

$$V_\tau((0,T); H_{\Gamma_N}(\mathrm{div},\Omega)) \subset L^2((0,T); H_{\Gamma_N}(\mathrm{div},\Omega))\,, \tag{3.4}$$

$$Q_\tau((0,T); H^1_{\Gamma_D}(\Omega)) \subset H^1((0,T); H^1_{\Gamma_D}(\Omega)) \tag{3.5}$$

and perform the minimization of the least-squares functional in these spaces. The subindex τ emphasizes that these spaces are semidiscrete spaces. Appropriate choices include the combination of piecewise polynomial, not necessarily continuous, functions for V_τ with piecewise polynomial continuous functions for Q_τ on a subdivision $\triangle = \{0 = t_0 < t_1 < \cdots < t_M = T\}$ of $[0,T]$ with step-sizes $\tau_j = t_j - t_{j-1}, j = 1,\ldots,M$. However, due to the continuity requirement for Q_τ, minimizing the least-squares functional with respect to these spaces generally leads to a coupling of all $M+1$ time-levels. Now we set $\alpha = \tau$ and consider one-step methods that consist of stepping only from one time-level t to the next $t+\tau$ by minimizing the least-squares functional

$$\begin{aligned} \hat{\mathcal{F}}(u_\tau, p_\tau) = \int_t^{t+\tau} \Big(& \tau \Big\| c^{1/2}\partial_t(p_\tau(s)) + c^{-1/2}\Big[\mathrm{div}(u_\tau(s)) + f(p_\tau(s))\Big] \Big\|^2_{0,\Omega} \\ & + \Big\| a^{-1/2} u_\tau(s) + a^{1/2}\nabla(p_\tau(s)) \Big\|^2_{0,\Omega} \Big) ds. \end{aligned} \tag{3.6}$$

Throughout the rest of this paper, the symbols $\lesssim$ and $\gtrsim$ indicate that the inequality holds up to constants that are independent of the discretization parameter τ. Similarly, the symbol $\eqsim$ stands for equivalence independently of discretization parameters.

4. Variational formulation for the nonlinear least-squares functional. In this section, the representation of the discrete evolution in terms of solution of a nonlinear equation is derived which is the basis for the convergence analysis. Our aim is to minimize the least-squares functional (3.6) in $\tilde{V}_\tau \times \tilde{Q}_\tau$, where

$$\begin{aligned} \tilde{V}_\tau &= \left\{ \left(1 - \frac{\sigma}{\tau}\right) v_1 + \frac{\sigma}{\tau} v_2 \;\middle|\; v_1, v_2 \in H_{\Gamma_N}(\mathrm{div},\Omega) \right\}, \\ \tilde{Q}_\tau &= \left\{ \frac{\sigma}{\tau}\, q \;\middle|\; q \in H^1_{\Gamma_D}(\Omega) \right\}. \end{aligned}$$

For short, let us set

$$p_\tau(t+\sigma) = \left(1 - \frac{\sigma}{\tau}\right) p_\tau(t) + \hat{p}_\tau(\sigma)$$

and

$$q_\tau(\sigma) = \left(1 - \frac{\sigma}{\tau}\right) p_\tau(t) + \hat{q}_\tau(\sigma),$$

where $\hat{p}_\tau, \hat{q}_\tau \in \tilde{Q}_\tau$.

Our aim is to find $(u_\tau, \hat{p}_\tau) \in \tilde{V}_\tau \times \tilde{Q}_\tau$ with

$$\hat{\mathcal{F}}\,(u_\tau, p_\tau) = \min_{(v_\tau, \hat{q}_\tau) \in \tilde{V}_\tau \times \tilde{Q}_\tau} \hat{\mathcal{F}}\,(v_\tau, q_\tau)\,. \tag{4.1}$$

Roughly speaking, our one-step method assumes a given $p_\tau(t)$ (for $t = 0$, we start with $p_\tau(0) = p(0) = \Lambda$) and computes in each step a $p_\tau(t+\tau) = (1-\frac{\tau}{\tau})p_\tau(t)+\hat{p}_\tau(\tau) = \hat{p}_\tau(\tau)$, $\hat{p}_\tau \in \tilde{Q}_\tau$, for the next step. Actually, this assumption leads to a coupling of all $M+1$ time-levels with respect to the scalar variable p_τ. With the choice of the above spaces, we can simplify the minimization problem (4.1) to analyze the observed method. We are interested in the exact evolution operator. Let us define the operator A as

$$\begin{aligned} &A : D_A \subset H^1_{\Gamma_D}(\Omega) \to L^2(\Omega), \\ &\quad (c^{1/2}\, A\, c^{1/2} p, q)_{0,\Omega} = (a\, \nabla p, \nabla q)_{0,\Omega} \qquad \forall q \in H^1_{\Gamma_D}(\Omega)\,. \end{aligned} \tag{4.2}$$

Formally, we may write $A = -c^{-1/2}\mathrm{div}\,(a\,\nabla)\,c^{-1/2}$. Note that the operator A is bijective as a mapping from

$$D_A = \{ q \in H^1_{\Gamma_D}(\Omega)\,|\, a\,\nabla q \in H_{\Gamma_N}(\mathrm{div}, \Omega)\,\}$$

to $L^2(\Omega)$. Now we can define the evolution operator. We deduce from [24, Chapter 15.1] that

$$\begin{aligned} &E(t+\tau;t) : H^1_{\Gamma_D}(\Omega) \to H^1_{\Gamma_D}(\Omega), \\ &E(t+\tau;t)\, p(t) = p(t+\tau) = c^{-1/2} \exp(-\tau A)\, c^{1/2} p(t) \\ &\qquad\qquad - c^{-1/2} \int_0^\tau (\exp(-(\tau-\sigma)A)) c^{-1/2} f(p(t+\sigma))\, d\sigma\,. \end{aligned} \tag{4.3}$$

Next, we define the discrete evolution operator

$$\begin{aligned} E_d(t+\tau;t) :& H^1_{\Gamma_D}(\Omega) \to H^1_{\Gamma_D}(\Omega), \\ & E_d(t+\tau;t) p_\tau(t) = p_\tau(t+\tau), \end{aligned} \tag{4.4}$$

where $p_\tau(t)$ is the initial value of our one-step method and $p_\tau(t+\tau)$ its solution using the minimization method (4.1). We will see later that a unique solution exists if τ is small enough. The following theorem gives $p_\tau(t+\tau) = E_d(t+\tau;t)p_\tau(t)$ as a solution of a nonlinear equation depending on $p_\tau(t)$.

THEOREM 4.1. *The solution $E_d(t+\tau;t)p_\tau(t)$ of the minimization method* (4.1) *fulfills the following nonlinear equation (in the sense of distributions):*

$$\begin{aligned} \int_0^\tau c^{1/2} \Big[I + \sigma \Big(c^{-1/2} f'(p_\tau(t+\sigma)) c^{-1/2} + A \Big) \Big] \Big[& c^{1/2} \frac{p_\tau(t+\tau) - p_\tau(t)}{\tau} \\ & + A c^{1/2} p_\tau(t+\sigma) + c^{-1/2} f(p_\tau(t+\sigma)) \Big]\, d\sigma = 0, \end{aligned}$$

where f' is the derivation of f.

Proof. We will separate the minimization problem (4.1) in two different variational problems. From the first variational problem we gain a formula for $c^{-1/2}\mathrm{div}u$. Setting that formula in the second variational problem and simplifying leads finally to our result.

The minimization problem (4.1) is equivalent to the variational problem: Find $(u_\tau, p_\tau) \in \tilde{V}_\tau \times \tilde{Q}_\tau$, such that

$$\begin{aligned}\int_0^\tau \Big[\tau\Big(&c^{1/2}\partial_t p_\tau(t+\sigma) + c^{-1/2}\mathrm{div}u_\tau(t+\sigma) + c^{-1/2}f(p_\tau(t+\sigma)),\\ &c^{1/2}\partial_t q(\sigma) + c^{-1/2}\,\mathrm{div}v(\sigma) + c^{-1/2}f'(p_\tau(t+\sigma))q(\sigma)\Big)_{0,\Omega}\\ &+\Big(a^{-1/2}u_\tau(t+\sigma) + a^{1/2}\nabla p_\tau(t+\sigma), a^{-1/2}v(\sigma) + a^{1/2}\nabla q(\sigma)\Big)_{0,\Omega}\Big]d\sigma = 0\end{aligned} \tag{4.5}$$

for all $(v, q) \in \tilde{V}_\tau \times \tilde{Q}_\tau$. This formula includes two different variational formulations in spaces $\tilde{V}_\tau$ and $\tilde{Q}_\tau$, which we will separate. We deduce the first equation from (4.5) and (3.2) as

$$\begin{aligned}\int_0^\tau \Big[\tau\Big(&c^{1/2}\partial_t p_\tau(t+\sigma) + c^{-1/2}\mathrm{div}u_\tau(t+\sigma) + c^{-1/2}f(p_\tau(t+\sigma)), c^{-1/2}\mathrm{div}v(\sigma)\Big)_{0,\Omega}\\ &+\Big(a^{-1/2}u_\tau(t+\sigma) + a^{1/2}\nabla p_\tau(t+\sigma), a^{-1/2}v(\sigma)\Big)_{0,\Omega}\Big]d\sigma = 0\end{aligned}$$

for all $v \in \tilde{V}_\tau$. If we define

$$D_{A^2} = \{q \in D_A \mid Aq \in D_A\},$$

$$\hat{D}_\tau = \Big\{\frac{\sigma}{\tau}\, q_1 + \Big(1 - \frac{\sigma}{\tau}\Big) q_2 \;\mid q_1, q_2 \in D_{A^2}\Big\}$$

and set $v = -a\nabla q$, where $q \in \hat{D}_\tau$, then we get $c^{-1/2}\mathrm{div}v = Ac^{1/2}q$. Hence, we obtain

$$\begin{aligned}\int_0^\tau \Big[\tau\Big(&c^{1/2}\partial_t p_\tau(t+\sigma) + c^{-1/2}[\mathrm{div}u_\tau(t+\sigma) + f(p_\tau(t+\sigma))], Ac^{1/2}q(\sigma)\Big)_{0,\Omega}\\ &-\Big(a^{-1/2}u_\tau(t+\sigma) + a^{1/2}\nabla p_\tau(t+\sigma), a^{1/2}\nabla q(\sigma)\Big)_{0,\Omega}\Big]d\sigma = 0\end{aligned} \tag{4.6}$$

for all $q \in \hat{D}_\tau$. Again using the definition of A, we write

$$\begin{aligned}\int_0^\tau \Big[\Big(&c^{1/2}\partial_t p_\tau(t+\sigma) + c^{-1/2}f(p_\tau(t+\sigma)) + \frac{1}{\tau}\, c^{1/2}p_\tau(t+\sigma), \tau Ac^{1/2}q(\sigma)\Big)_{0,\Omega}\\ &+\Big(c^{-1/2}\mathrm{div}u_\tau(t+\sigma), (I+\tau A)c^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma = 0\end{aligned}$$

for all $q \in \hat{D}_\tau$. Furthermore, we use the fact that the operators $(I + \tau A)$ and τA are bijective and self-adjoint to make the equivalent reformulation

$$\begin{aligned}\int_0^\tau \Big[\Big(&(I+\tau A)^{-1}\Big[c^{1/2}\partial_t p_\tau(t+\sigma) + c^{-1/2}f(p_\tau(t+\sigma))\\ &+\frac{1}{\tau}\, c^{1/2}p_\tau(t+\sigma)\Big], (I+\tau A)(\tau A)c^{1/2}q(\sigma)\Big)_{0,\Omega}\\ &+\Big((\tau A)^{-1}c^{-1/2}\mathrm{div}u_\tau(t+\sigma), (\tau A)(I+\tau A)c^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma = 0\end{aligned}$$

to obtain

$$\int_0^\tau \Big[\Big((I+\tau A)^{-1}\Big[c^{1/2}\partial_t p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))+\frac{1}{\tau}\,c^{1/2}p(t+\sigma)\Big] + (\tau A)^{-1}c^{-1/2}\mathrm{div}u_\tau(t+\sigma),(I+\tau A)\tau A c^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma=0 \tag{4.7}$$

for all $q\in\hat{D}_\tau$. Defining

$$\hat{L}_\tau=\Big\{\frac{\sigma}{\tau}\,q_1+\Big(1-\frac{\sigma}{\tau}\Big)\,q_2 \;\Big|\; q_1,q_2\in L^2(\Omega)\Big\},$$

we observe that $(I+\tau A)\tau Ac^{1/2}:\hat{D}_\tau\to\hat{L}_\tau$ is one-to-one. Hence, (4.7) leads to

$$c^{-1/2}\mathrm{div}u_\tau=-(I+\tau A)^{-1}\Big(\tau A[c^{1/2}\partial_t p_\tau+c^{-1/2}f(p_\tau)]+Ac^{1/2}p_\tau\Big) \tag{4.8}$$

in $\hat{L}_\tau$.

Now, we obtain the second equation from (4.5):

$$\int_0^\tau\Big[\tau\Big(c^{1/2}\partial_t p_\tau(t+\sigma)+c^{-1/2}[\mathrm{div}u_\tau(t+\sigma)+f(p_\tau(t+\sigma))],c^{-1/2}\partial_t q(\sigma) + f'(p_\tau(t+\sigma))\,c^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma + \underbrace{\int_0^\tau\Big[\Big(a^{-1/2}u_\tau(t+\sigma)+a^{1/2}\nabla p_\tau(t+\sigma),a^{1/2}\nabla q(\sigma)\Big)_{0,\Omega}\Big]d\sigma}_{=:K}=0 \tag{4.9}$$

for all $q\in\tilde{Q}_\tau$. Restricting (4.9) to $q\in\tilde{Q}_\tau\cap\hat{D}_\tau$ and using (4.6) lead to

$$K=\int_0^\tau\Big[\tau\Big(c^{1/2}\partial_t p_\tau(t+\sigma)+c^{-1/2}[\mathrm{div}u_\tau(t+\sigma)+f(p_\tau(t+\sigma))],Ac^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma$$

for all $q\in\tilde{Q}_\tau\cap\hat{D}_\tau$. Hence, we obtain

$$\int_0^\tau\Big[\tau\Big(c^{1/2}\partial_t p_\tau(t+\sigma)+c^{-1/2}[\mathrm{div}u_\tau(t+\sigma)+f(p_\tau(t+\sigma))],c^{1/2}\partial_t q(\sigma) + c^{-1/2}f'(p_\tau(t+\sigma))q(\sigma)+Ac^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma=0$$

for all $q\in\tilde{Q}_\tau\cap\hat{D}_\tau$. If we replace $c^{-1/2}\mathrm{div}u$ by the right-hand side of (4.8) and note that $1-\frac{z}{1+z}=\frac{1}{1+z}$, we deduce

$$\int_0^\tau\Big[\tau\Big((I+\tau A)^{-1}\Big[c^{1/2}\partial_t p_\tau(t+\sigma)+Ac^{1/2}p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))\Big],c^{1/2}\partial_t q(\sigma) + c^{-1/2}f'(p_\tau(t+\sigma))q(\sigma)+A\,c^{1/2}q(\sigma)\Big)_{0,\Omega}\Big]d\sigma=0$$

for all $q\in\tilde{Q}_\tau\cap\hat{D}_\tau$. Since $q\in\tilde{Q}_\tau\cap\hat{D}_\tau$ (i.e., $q(\sigma)=\frac{\sigma}{\tau}\hat{q},\hat{q}\in D_{A^2}$), we have

$$\int_0^\tau\Big[\tau\Big((I+\tau A)^{-1}\Big[c^{1/2}\partial_t p_\tau(t+\sigma)+Ac^{1/2}p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))\Big],\frac{1}{\tau}\,c^{1/2}\hat{q} + c^{-1/2}f'(p_\tau(t+\sigma))c^{-1/2}\frac{\sigma}{\tau}\,c^{1/2}\hat{q}+A\,\frac{\sigma}{\tau}\,c^{1/2}\hat{q}\Big)_{0,\Omega}\Big]d\sigma=0$$

for all $\hat{q} \in D_{A^2}$. Equivalence reformulation leads to

$$\left\langle \int_0^\tau c^{1/2}\Big[I+\sigma\Big(c^{-1/2}f'(p_\tau(t+\sigma))c^{-1/2}+A\Big)\Big]\Big[c^{1/2}\partial_t p_\tau(t+\sigma) + Ac^{1/2}p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))\Big]d\sigma, (I+\tau A)^{-1}\hat{q}\Big)\right\rangle = 0$$

for all $\hat{q} \in D_{A^2}$. Since $C_0^\infty(\Omega) \subset (I+\tau A)^{-1}D_{A^2} = D_{A^3}$, we obtain

$$\left\langle \int_0^\tau c^{1/2}\Big[I+\sigma\Big(c^{-1/2}f'(p_\tau(t+\sigma))c^{-1/2}+A\Big)\Big]\Big[c^{1/2}\partial_t p_\tau(t+\sigma) + Ac^{1/2}p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))\Big]d\sigma, \varphi\Big\rangle\right\rangle = 0$$

for all $\varphi \in C_0^\infty(\Omega)$. □

To construct a numerical method, we should replace the integral

$$\int_0^\tau c^{1/2}\Big[I+\sigma\Big(c^{-1/2}f'(p_\tau(t+\sigma))c^{-1/2}+A\Big)\Big]\Big[c^{1/2}\partial_t p_\tau(t+\sigma) + Ac^{1/2}p_\tau(t+\sigma)+c^{-1/2}f(p_\tau(t+\sigma))\Big]d\sigma$$

by computable terms. For simplicity, we assume $a \equiv c \equiv 1$. We could get the general case by modifying this special case. We deduce from Theorem 4.1 that

$$\int_0^\tau \big[I+\sigma(A+f'(p_\tau(t+\sigma)))\big]\big[\partial_t p_\tau(t+\sigma)+Ap_\tau(t+\sigma)+f(p_\tau(t+\sigma))\big]\,d\sigma = 0.$$

Computing the integral, we obtain

$$\begin{aligned} p_\tau(t+\tau) = {} & r_{2,2}(\tau A)p_\tau(t) - r_{0,2}(\tau A)\Bigg[\int_0^\tau (I+\sigma A)f(p_\tau(t+\sigma))\,d\sigma \\ & - \int_0^\tau \sigma f'(p_\tau(t+\sigma))(\partial_t p_\tau(t+\sigma)+Ap_\tau(t+\sigma)+f(p_\tau(t+\sigma)))\,d\sigma\Bigg], \end{aligned} \tag{4.10}$$

where

$$r_{2,2}(z) = \frac{1-\frac{z^2}{6}}{1+z+\frac{z^2}{3}}$$

and

$$r_{0,2}(z) = \frac{1}{1+z+\frac{z^2}{3}}.$$

The above operators are defined in the sense of the standard definition by eigenvalues of A. For further information the reader is referred to [18, 19]. If we now set $f(p) \equiv$ const, we observe the same result as in [18, Lemma 3.1]. Hence, Theorem 4.1 is a generalization of [18, Lemma 3.1].

5. Convergence theory. In this section, the convergence analysis of the approximation error in time with respect to the H^1-norm is observed, which is the main result of this paper. Define for a mesh $\triangle = \{0 = t_0^\triangle < t_1^\triangle < \cdots < t_{M_\triangle}^\triangle = T\}$ with step-sizes $\tau_j^\triangle = t_j^\triangle - t_{j-1}^\triangle$, $j = 1, \ldots, M_\triangle$:

$$\tau_{\min,\triangle} := \min_{j=1}^{M_\triangle} \tau_j^\triangle$$

and

$$\tau_\triangle := \max_{j=1}^{M_\triangle} \tau_j^\triangle.$$

We use $\triangle$ as an index for the mesh points t_j, step-sizes τ_j, and the number of mesh points M of an observed mesh $\triangle$ whenever we would like to emphasize that the choice of these parameters depends on the mesh $\triangle$.

Furthermore, we assume that

$$\frac{\tau_\triangle}{\tau_{\min,\triangle}} \eqsim 1 \tag{5.1}$$

for each observed $\triangle \subset [0,T]$. The following theorem shows the second-order convergence of the minimizing method (4.1).

Let us define for $\tilde{\alpha} \geq 0$

$$H_{\tilde{\alpha}} := D_{A^{\tilde{\alpha}/2}} \subset L^2(\Omega).$$

$H_{\tilde{\alpha}}$ is a Hilbert space with respect to the inner product

$$\langle q_1, q_2 \rangle_{\tilde{\alpha}} := (A^{\frac{\tilde{\alpha}}{2}} q_1, A^{\frac{\tilde{\alpha}}{2}} q_2)_{0,\Omega}$$

(cf. [21, p. 195]). Let $\|\cdot\|_{\tilde{\alpha}} := (\langle \cdot, \cdot \rangle_{\tilde{\alpha}})^{\frac{1}{2}}$ be the associated norm. Furthermore, put

$$H_{-\tilde{\alpha}} := (H_{\tilde{\alpha}})' = \left\{ \tilde{q} \in \mathcal{D}' \;\middle|\; \sup_{q \in H_{\tilde{\alpha}}} \frac{\langle \tilde{q}, q \rangle}{\|q\|_{\tilde{\alpha}}} < \infty \right\}$$

as the dual space of $H_{\tilde{\alpha}}$. Our assumption $f \in C^1(H^1_{\Gamma_D}(\Omega); L^2(\Omega))$ leads to the fact that f is local Lipschitz. Next, consider the exact solution $p \in H^1((0,T); H^1_{\Gamma_D}(\Omega))$ of (3.1). Let L_t be the Lipschitz constant of f in a neighborhood $B(p(t), \delta_t) \subset H^1_{\Gamma_D}(\Omega)$ (i.e., the open ball with center $p(t)$ and radius δ_t in $H^1_{\Gamma_D}(\Omega)$) of the exact solution $p(t)$ of (3.1). Furthermore set $L = \sup_{t \in [0,T]} L_t < \infty$ and $\delta = \inf_{t \in [0,T]} \delta_t > 0$. To prepare a short notation for the next theorem, we define

$$g(\tau, \sigma, q) = r_{0,2}(\tau A)\, \sigma f'(q)\, [Aq \;\; + f(q)] \quad \forall q \in H^1_{\Gamma_D}(\Omega). \tag{5.2}$$

Generally, with our current assumptions, $g(\tau, \sigma, \cdot)$ is not well-posed. If we assume that $f : H_{-1} \to H_{-2}$ and $f(H_1) \subset H_0 = L^2(\Omega)$, we receive a well-posed $g(\tau, \sigma, \cdot)$: Starting with

$$q \in H_1 \underbrace{=}_{\text{cf. [14, Theorem 2.23]}} H^1_{\Gamma_D}(\Omega),$$

we get

$$\underbrace{Aq}_{\in H_{-1}} + \underbrace{f(q)}_{\in H_0} \in H_{-1}.$$

For each $\hat{q} \in H_{-1}$ the linear operator $f'(\hat{q})$ maps H_{-1} into H_{-2}, since we assume $f : H_{-1} \to H_{-2}$, and hence $\sigma f'(q)\,[Aq \ + f(q)] \in H_{-2}$. Finally we have $r_{0,2}(\tau A) : H_{-2} \to H_2 \subset H_1 = H^1_{\Gamma_D}(\Omega)$, which leads to $g(\tau,\sigma,q) = r_{0,2}(\tau A)\,\sigma f'(q)\,[Aq \ + f(q)] \in H^1_{\Gamma_D}(\Omega)$. Furthermore, we assume that the function $g(\tau,\sigma,\cdot)$ is local Lipschitz for all $\sigma,\tau \in [0,T],\ \sigma \le \tau$.

Let $\tilde{L}_{t,\tau,\sigma}$ be the Lipschitz constant of $g(\tau,\sigma,\cdot)$ in a neighborhood $B(p(t),\tilde{\delta}_{t,\tau,\sigma}) \subset H^1_{\Gamma_D}(\Omega)$ of the solution $p(t)$ of (3.2). Defining

$$\tilde{L} = \max_{t,\tau,\sigma\in[0,T]}\{\tilde{L}_{t,\tau,\sigma}\} < \infty,$$

$$\tilde{\delta} = \min_{t,\tau,\sigma\in[0,T]}\{\tilde{\delta}_{t,\tau,\sigma}\} > 0,$$

$$\hat{\delta} = \min\{\tilde{\delta}, \delta\},$$

and

$$\hat{L} = \max\{\tilde{L}, L\},$$

we deduce

$$\|f(q) - f(p(t))\|_{0,\Omega} \le \hat{L}\|q - p(t)\|_{1,\Omega}$$

and

$$\|g(\tau,\sigma,q) - g(\tau,\sigma,p(t))\|_{1,\Omega} \le \hat{L}\|q - p(t)\|_{1,\Omega}$$

for all $q \in H^1_{\Gamma_D}(\Omega)$ with $\|q - p(t)\|_{1,\Omega} < \hat{\delta}$.

Before we formulate the theorem, we recall the well-known Gronwall lemma.

LEMMA 5.1 (Gronwall's lemma (for weakly singular kernels)). *Assume $\hat{a}, \hat{b}, \hat{\alpha}, \hat{\beta}$ are nonnegative constants, with $\hat{\alpha}, \hat{\beta} < 1$, and $0 < T < \infty$. There is a constant $C = C(\hat{a}, \hat{b}, \hat{\alpha}, \hat{\beta}) < \infty$ such that for any integrable function $v : [0,T] \to \mathbb{R}$ satisfying*

$$0 \le v(t) \le \hat{a}t^{-\hat{\alpha}} + \hat{b}\int_0^t (t-s)^{-\hat{\beta}} v(s)ds$$

for t a.e. in $[0,T]$, we have

$$v(t) \le \hat{a}Ct^{-\hat{\alpha}}$$

a.e. on $0 < t \le T$.

Proof. This is a special case of [12, Lemma 7.1.1]. The proof is an elementary iteration argument, followed by Lebesgue's dominated convergence theorem. ∎

Finally, we present the main convergence theorem of this paper.

THEOREM 5.2. *Assume that $f : H_{-1} \to H_{-2}$, where its restriction on $H^1_{\Gamma_D}(\Omega)$ is in $C^1(H^1_{\Gamma_D}(\Omega); L^2(\Omega))$, i.e.,*

$$f_{\big|_{H^1_{\Gamma_D}(\Omega)}} \in C^1(H^1_{\Gamma_D}(\Omega); L^2(\Omega)).$$

Furthermore, let $p \in C^2([0,T]; H^1_{\Gamma_D}(\Omega))$ be the exact solution of (3.2) and assume that the function $g(\tau,\sigma,\cdot)$ defined in (5.2) is local Lipschitz for all $\sigma,\tau \in [0,T]$, $\sigma \le \tau$. There are a τ^* and a constant C, such that for all observed meshes $\triangle$ which satisfy (5.1) $\big($remember that $\triangle = \{0 < t_1^\triangle < \cdots < t^\triangle_{M_\triangle - 1} < T\} \subset [0,T]$ with step-sizes $\tau_j^\triangle = t_j^\triangle - t_{j-1}^\triangle$, $j = 1,\ldots,M_\triangle$, and $\tau_\triangle \le \tau^*\big)$, the solution of our minimizing problem (4.1) $p_\tau(t_n^\triangle)$ satisfies

$$\|p_\tau(t_n^\triangle) - p(t_n^\triangle)\|_{1,\Omega} \le C\,\tau_\triangle^2 \tag{5.3}$$

for all $0 \le n \le M_\triangle$.

Proof. We will separate the proof in three parts: In parts (a) and (c) we show

$$\max_{t\in[0,T]} \|q_\tau(t) - p(t)\|_{1,\Omega} < \hat\delta$$

for sufficiently small $\tau_\triangle$. We need this result to use the Lipschitz property of f and $g(\tau,\sigma,\cdot)$. Due to this Lipschitz property we show in part (b) an upper estimation

$$\|p_\tau(t_n^\triangle) - p(t_n^\triangle)\|_{1,\Omega} \le \text{const.}\ \tau_\triangle^2 + \text{const.}\ \tau_\triangle \sum_{j=1}^{n-1} ((n-j+1)\tau_\triangle)^{-\frac12} \|p_\tau(t_j^\triangle) - p(t_j^\triangle)\|_{1,\Omega}$$

and use Gronwall's lemma (Lemma 5.1) to get the main result.

(a) In this part of the proof we will show that there is a $q_\tau \in Q_\tau$ such that

$$\max_{t\in[0,T]} \|q_\tau(t) - p(t)\|_{1,\Omega} < \hat\delta. \tag{5.4}$$

Remember that Q_τ defined in (3.5) is a subset of $H^1((0,T); H^1_{\Gamma_D}(\Omega))$ with piecewise linear continuous functions on the observed subdivision $\triangle \subset [0,T]$. For a given mesh $\{0 < t_1^\triangle < \cdots < t^\triangle_{M_\triangle - 1} < T\} = \triangle \subset [0,T]$, we define $I_\triangle p$ to be the linear spline of p. It is known from the interpolation theory (cf. [5, Theorem 7.3]) that $\max_{t\in[0,T]} \|I_\triangle p(t) - p(t)\|_{1,\Omega} \le C_1 \tau_\triangle^2$, where C_1 is a constant which only depends on $\sup_{t\in[0,T]} \|\partial_t^2 p(t)\|_{1,\Omega} < \infty$. Setting $\tau^* \le \min\{1, \frac{\hat\delta}{2C_1}\} =: \varepsilon_0$, we have

$$\max_{t\in[0,T]} \|I_\triangle p(t) - p(t)\|_{1,\Omega} \le C_1\varepsilon_0^2 \le C_1\varepsilon_0 \le \frac{\hat\delta C_1}{2C_1} \le \frac{\hat\delta}{2}.$$

Let $q_j \in H^1_{\Gamma_D}(\Omega)$ such that $\|q_j - p(t_j^\triangle)\|_{1,\Omega} < \frac{\hat\delta}{2}$ for $j = 1,\ldots,M_\triangle$ and $q_0 = p_0$. If we define

$$q_\tau(t) = \frac{t - t_{j-1}^\triangle}{\tau_j^\triangle}\, q_j + \left(1 - \frac{t - t_{j-1}^\triangle}{\tau_j^\triangle}\right) q_{j-1}$$

for given $t \in [t_{j-1}^\triangle, t_j^\triangle]$, $1 \le j \le M_\triangle$, then we get

$$\max_{t\in[0,T]} \|q_\tau(t) - p(t)\|_{1,\Omega} \le \max_{t\in[0,T]} \|I_\triangle p(t) - p(t)\|_{1,\Omega} + \max_{t\in[0,T]} \|q_\tau(t) - I_\triangle p(t)\|_{1,\Omega} < \delta.$$

If we assume that τ^* is chosen, such that

$$\|p_\tau(t_j^\triangle) - p(t_j^\triangle)\|_{1,\Omega} \le j\frac{\hat{\delta}}{3M_\triangle} \tag{5.5}$$

for $j = 0, \dots, M_\triangle$, then we get, together with the above considerations,

$$\max_{t\in[0,T]} \|p_\tau(t) - p(t)\|_{1,\Omega} < \hat{\delta} \tag{5.6}$$

for all observed $\triangle$. We will prove (5.5) later in part (c). We should note that the result in (5.6) allows us to use the local Lipschitz property of f and g.

(b) In this part, our goal is to prove the main result using the so-called defect equation.

(i) First we reformulate the defect equation in a form where estimation with powers of $\tau_\triangle$ becomes obvious. Set $\hat{p}_n = p(t_n^\triangle)$, $n = 0, \dots, M_\triangle$, for short. For $0 < n \le M_\triangle$, we get

$$\hat{p}_n = E_d(t_n^\triangle; t_{n-1}^\triangle)\hat{p}_{n-1} \underbrace{-E_d(t_n^\triangle; t_{n-1}^\triangle)\hat{p}_{n-1} + \hat{p}_n}_{=:d_n}, \tag{5.7}$$

where d_n is the so-called *defect* and the discrete evolution operator $E_d(t_n^\triangle; t_{n-1}^\triangle)$ was defined in (4.4). Hence, using Theorem 4.1 and (4.10) to reformulate the defect, we obtain

$$\begin{aligned} d_n = &- r_{2,2}(\tau_n^\triangle A)\hat{p}_{n-1} + \hat{p}_n \\ &- r_{0,2}(\tau_n^\triangle A)\bigg[\int_0^{\tau_n^\triangle} (I + \sigma A)(\partial_t p(t_{n-1}^\triangle + \sigma) + Ap(t_{n-1}^\triangle + \sigma))\, d\sigma \\ &- \int_0^{\tau_n^\triangle} \sigma f'(p(t_n^\triangle + \sigma)) \underbrace{(\partial_t p(t_n^\triangle + \sigma) + Ap(t_n^\triangle + \sigma) + f(p(t_n^\triangle + \sigma)))}_{=0}\, d\sigma\bigg]. \end{aligned} \tag{5.8}$$

Integration by parts leads to

$$\begin{aligned} & r_{0,2}(\tau_n^\triangle A)\int_0^{\tau_n^\triangle} \underbrace{(I + \sigma A)}_{=:\mathcal{U}(\sigma)} \underbrace{\partial_t p(t_n^\triangle + \sigma)}_{=:\mathcal{V}'(\sigma)}\, d\sigma \\ &\quad = r_{0,2}(\tau_n^\triangle A)\left[\mathcal{U}(\sigma)\mathcal{V}(\sigma)\Big|_0^{\tau_n^\triangle} - \int_0^{\tau_n^\triangle} \mathcal{U}'(\sigma)\mathcal{V}(\sigma)d\sigma\right] \\ &\quad = r_{0,2}(\tau_n^\triangle A)\left[(I + \tau_n^\triangle A)\hat{p}_n - \hat{p}_{n-1} - \int_0^{\tau_n^\triangle} Ap(t_{n-1}^\triangle + \sigma)\, d\sigma\right]. \end{aligned} \tag{5.9}$$

Using (5.9) in (5.8) and simplifying, we get

$$\begin{aligned} d_n = &(r_{0,2}(\tau_n^\triangle A) - r_{2,2}(\tau_n^\triangle A))\hat{p}_{n-1} + (I - (I + \tau_n^\triangle A)\, r_{0,2}(\tau_n^\triangle A))\hat{p}_n \\ &- r_{0,2}(\tau_n^\triangle A)\int_0^{\tau_n^\triangle} \sigma A^2 p(t_{n-1}^\triangle + \sigma)\, d\sigma. \end{aligned} \tag{5.10}$$

If we notice that

(5.11)
$$r_{0,2}(\tau_n^{\triangle}A)\int_0^{\tau_n^{\triangle}}\sigma A^2 I_{\triangle}p(t_{n-1}^{\triangle}+\sigma)\,d\sigma = r_{0,2}(\tau_n^{\triangle}A)\left(\frac{{\tau_n^{\triangle}}^2}{3}A^2\hat{p}_n + \frac{{\tau_n^{\triangle}}^2}{6}A^2\hat{p}_{n-1}\right),$$

we can expand (5.10) with $I_{\triangle}p$ as follows:

$$d_n = -\int_0^{\tau_n^{\triangle}}\sigma A^2 r_{0,2}(\tau_n^{\triangle}A)(p(t_{n-1}^{\triangle}+\sigma) - I_{\triangle}p(t_{n-1}^{\triangle}+\sigma))\,d\sigma. \tag{5.12}$$

Again, using [5, Theorem 7.3], for $\sigma\in[0,\tau_n^{\triangle}]$, we have

(5.13)
$$p(t_{n-1}^{\triangle}+\sigma) - I_{\triangle}p(t_{n-1}^{\triangle}+\sigma) = \frac{1}{2}\,\partial_t^2 p(t_{n-1}^{\triangle}+\theta_\sigma)\sigma(\sigma-\tau_n^{\triangle}), \quad \text{where } \theta_\sigma\in(0,\tau_n^{\triangle})\ .$$

(ii) Our next goal is to get an estimation like

$$\|e_n\|_{1,\Omega} \le \text{const.}\ \tau_{\triangle}^2 + \text{const.}\ \tau_{\triangle}\sum_{j=1}^{n-1}((n-j+1)\tau_{\triangle})^{-\frac{1}{2}}\|e_j\|_{1,\Omega},$$

and use Gronwall's lemma (Lemma 5.1) to get the main result.

First we use the chain rule to write $\partial_t f(q(t)) = f'(q(t))\ \partial_t q(t)$ for all $q\in H^1((0,T)\,;H^1_{\Gamma_D}(\Omega))$. Hence, integration by parts leads to

$$\begin{aligned}
&\int_0^{\tau_n^{\triangle}} \underbrace{\sigma}_{=:\mathcal{U}(\sigma)} \underbrace{[f'(p_\tau(t_{n-1}^{\triangle}+\sigma))\ \partial_t p_\tau(t_{n-1}^{\triangle}+\sigma) - f'(p(t_{n-1}^{\triangle}+\sigma))\ \partial_t p(t_{n-1}^{\triangle}+\sigma)]}_{=:\mathcal{V}'(\sigma)}\,d\sigma \\
&\quad = \mathcal{U}(\sigma)\mathcal{V}(\sigma)\Big|_0^{\tau_n^{\triangle}} - \int_0^{\tau_n^{\triangle}}\mathcal{U}'(\sigma)\mathcal{V}(\sigma)d\sigma \\
&\quad = \tau_n^{\triangle}\,(f(p_n)-f(\hat{p}_n)) - \int_0^{\tau_n^{\triangle}} f(p_\tau(t_{n-1}^{\triangle}+\sigma)) - f(p(t_{n-1}^{\triangle}+\sigma))\,d\sigma.
\end{aligned} \tag{5.14}$$

Now define

$$R(t_j^{\triangle},t_n^{\triangle}) = \prod_{i=j+1}^{n} r_{2,2}(\tau_i^{\triangle}A),$$

$$\Sigma_{j+1}(\sigma) = f(p_\tau(t_j^{\triangle}+\sigma)) - f(I_{\triangle}p(t_j^{\triangle}+\sigma)),$$

and

$$\hat{\Sigma}_{j+1}(\sigma) = f(I_{\triangle}p(t_j^{\triangle}+\sigma)) - f(p(t_j^{\triangle}+\sigma)).$$

Let $e_j = p_\tau(t_j^{\triangle}) - p(t_j^{\triangle})$ be the error for $j=0,\dots,M_{\triangle}$. Hence, we deduce the

following from (5.14), (4.10), the defect equation (5.7), and the definition of g in (5.2):

$$\begin{aligned} e_n = {} & r_{2,2}(\tau_n^{\triangle} A)e_{n-1} - \tau_n^{\triangle} r_{0,2}(\tau_n^{\triangle} A)(f(p_n) - f(\hat{p}_n)) \\ & - \int_0^{\tau_n^{\triangle}} r_{0,2}(\tau_n^{\triangle} A)\sigma A \Sigma_n(\sigma)\, d\sigma - \int_0^{\tau_n^{\triangle}} r_{0,2}(\tau_n^{\triangle} A)\sigma A \hat{\Sigma}_n(\sigma)\, d\sigma \\ & - \int_0^{\tau_n^{\triangle}} \underbrace{g(\tau_n^{\triangle}, \sigma, p_\tau(t_{n-1}^{\triangle} + \sigma)) - g(\tau_n^{\triangle}, \sigma, p(t_{n-1}^{\triangle} + \sigma))}_{=:\mathcal{G}_n(\sigma)} d\sigma + d_n. \end{aligned}$$

This way we get recursively (noting that $e_0 = 0$)

$$\begin{aligned} e_n = {} & \sum_{j=0}^{n-1} R(t_{j+1}^{\triangle}, t_n^{\triangle}) \Big[d_{j+1} + \tau_n^{\triangle} r_{0,2}(\tau_n^{\triangle} A)(f(p_n) - f(\hat{p}_n)) \\ & - \int_0^{\tau_{j+1}^{\triangle}} r_{0,2}(\tau_{j+1}^{\triangle} A)(\sigma A)(\Sigma_{j+1}(\sigma) + \hat{\Sigma}_{j+1}(\sigma)) + \mathcal{G}_{j+1}(\sigma) d\sigma \Big]. \end{aligned} \tag{5.15}$$

For short, we set

$$S(t_{j+1}^{\triangle}, t_n^{\triangle}) = (I + \tau_{j+1}^{\triangle} A) r_{0,2}(\tau_{j+1}^{\triangle} A) R(t_{j+1}^{\triangle}, t_n^{\triangle})$$

and notice that

$$\|\sigma A\, r_{0,2}(\tau A) q\|_{1,\Omega} \le \|(I + \sigma A)\, r_{0,2}(\tau A) q\|_{1,\Omega} \le \|(I + \tau A)\, r_{0,2}(\tau A) q\|_{1,\Omega}$$

for all $j = 1, \dots, M_{\triangle}$, $q \in H^1_{\Gamma_D}(\Omega)$, and $\sigma \in [0, \tau]$. Hence, we can deduce from (5.15) and the local Lipschitz property of $g(\tau_j^{\triangle}, \sigma, \cdot)$ that

$$\begin{aligned} \|e_n\|_{1,\Omega} \lesssim {} & \left\| \sum_{j=0}^{n-1} S(t_{j+1}^{\triangle}, t_n^{\triangle}) \left(\int_0^{\tau_{j+1}^{\triangle}} \hat{\Sigma}_{j+1}(\sigma) d\sigma + \tau_{j+1}^{\triangle} \hat{\Sigma}_{j+1}(\tau_{j+1}^{\triangle}) \right) \right\|_{1,\Omega} \\ & + \left\| \sum_{j=0}^{n-1} R(t_{j+1}^{\triangle}, t_n^{\triangle}) d_{j+1} \right\|_{1,\Omega} \\ & + \left\| \sum_{j=0}^{n-1} S(t_{j+1}^{\triangle}, t_n^{\triangle}) \left(\int_0^{\tau_{j+1}^{\triangle}} \Sigma_{j+1}(\sigma)\, d\sigma + \tau_{j+1}^{\triangle} \Sigma_{j+1}(\tau_{j+1}^{\triangle}) \right) \right\|_{1,\Omega} \\ & + \left\| \sum_{j=0}^{n-1} \int_0^{\tau_{j+1}^{\triangle}} p_\tau(t_j^{\triangle} + \sigma) - p(t_j^{\triangle} + \sigma) d\sigma \right\|_{1,\Omega} \\ =: {} & \|I_1\|_{1,\Omega} + \|I_2\|_{1,\Omega} + \|I_3\|_{1,\Omega} + \|I_4\|_{1,\Omega}. \end{aligned}$$

Now, our aim is to estimate each of the terms $\|I_i\|_{1,\Omega}$, $i = 1, 2, 3, 4$. To estimate $\|I_1\|_{1,\Omega}$, let us define

$$\rho_{2,2}(z) = \frac{1 + \frac{5}{6} z + \frac{z^2}{6}}{1 + z + \frac{z^2}{3}},$$

$$\tilde{\rho}_{2,2}(z) = \frac{1 - \frac{z^2}{6}}{1 + \frac{5}{6}z + \frac{z^2}{6}},$$

and

$$\xi(t_j^{\triangle}, t_n^{\triangle}) = \prod_{i=j+1}^{n} \rho_{2,2}(\tau_i^{\triangle} A), \quad j = 0, \ldots, M_{\triangle} - 1.$$

The Poincaré–Friedrichs inequality leads to

$$\|I_1\|_{1,\Omega} \lesssim \|\nabla I_1\|_{0,\Omega} \lesssim \|AI_1\|_{0,\Omega}.$$

The local Lipschitz property of f, along with (5.4) and (5.13), leads to

$$\max_{\sigma \in [0, t_n^{\triangle}]} \|\hat{\Sigma}_{j+1}(\sigma)\|_{0,\Omega} \leq L \max_{\sigma \in [0, t_n^{\triangle}]} \|I_{\triangle} p(t_j^{\triangle} + \sigma) - p(t_j^{\triangle} + \sigma)\|_{1,\Omega} \lesssim \tau_{\triangle}^2. \tag{5.16}$$

For Hilbert spaces $(\mathcal{H}, \|\cdot\|_{\mathcal{H}})$ and $(\hat{\mathcal{H}}, \|\cdot\|_{\hat{\mathcal{H}}})$, let $\mathcal{L}(\mathcal{H}, \hat{\mathcal{H}})$ be the space of linear continuous operators $\mathcal{T} : \mathcal{H} \to \hat{\mathcal{H}}$ and let

$$\|\mathcal{T}\|_{\mathcal{H} \to \hat{\mathcal{H}}} = \sup_{0 \neq q \in \mathcal{H}} \frac{\|\mathcal{T} q\|_{\hat{\mathcal{H}}}}{\|q\|_{\mathcal{H}}}$$

be the underlying operator norm on $\mathcal{L}(\mathcal{H}, \hat{\mathcal{H}})$. Observing that $\rho_{2,2}$ is positive and decreases on $[0, \infty)$ and that $\sup_{x \in (0,\infty)} |\tilde{\rho}_{2,2}(x)| = 1$, together with the fact that $r_{2,2} = \rho_{2,2}\tilde{\rho}_{2,2}$, we could easily deduce the following by the formula of the geometric series:

(5.17)

$$\begin{aligned}
\|I_1\|_{1,\Omega} \lesssim & \|AI_1\|_{0,\Omega} \lesssim \tau_{\triangle}^2 \left\| \sum_{j=0}^{n-1} S(t_{j+1}^{\triangle}, t_n^{\triangle}) \tau_{j+1}^{\triangle} A \right\|_{L^2 \to L^2} \\
& \lesssim \tau_{\triangle}^2 \left\| \sum_{j=0}^{n-1} \xi(t_{j+1}^{\triangle}, t_n^{\triangle}) r_{0,2}(\tau_{\min,\triangle}\, A) \tau_{\triangle}\, A \right\|_{L^2 \to L^2} \\
& \lesssim \tau_{\triangle}^2 \left\| \sum_{j=0}^{n-1} \rho_{2,2}(\tau_{\min,\triangle}\, A)^{n-j-1} r_{0,2}(\tau_{\min,\triangle}\, A) \tau_{\triangle}\, A \right\|_{L^2 \to L^2} \\
& \lesssim \tau_{\triangle}^2 \left\| (I - \rho_{2,2}(\tau_{\min,\triangle}\, A))^{-1} r_{0,2}(\tau_{\min,\triangle}\, A) \tau_{\triangle} A \right\|_{L^2 \to L^2} \\
& = \tau_{\triangle}^2 \left\| 6(\tau_{\min,\triangle}\, A + \tau_{\min,\triangle}^2\, A^2)^{-1} r_{0,2}(\tau_{\min,\triangle}\, A)^{-1} r_{0,2}(\tau_{\min,\triangle}\, A) \tau_{\triangle} A \right\|_{L^2 \to L^2} \\
& \lesssim \tau_{\triangle}^2 \left\| (I + \tau_{\min,\triangle}\, A)^{-1} \right\|_{L^2 \to L^2} \lesssim \tau_{\triangle}^2.
\end{aligned}$$

To estimate $\|I_2\|_{1,\Omega}$, we define

$$\varphi_{2,2}(z) = \frac{1 + z + \frac{z^2}{6}}{1 + z + \frac{z^2}{3}}$$

and

$$\tilde{\varphi}_{2,2}(z) = \frac{1 - \frac{z^2}{6}}{1 + z + \frac{z^2}{6}},$$

and we note that $\varphi_{2,2}$ is a positive decreasing function on $[0,\infty)$, that $\sup_{x\in(0,\infty)}|\tilde{\varphi}_{2,2}(x)| = 1$, and that $r_{2,2} = \varphi_{2,2}\tilde{\varphi}_{2,2}$. Again, using the geometric series, (5.12) and (5.13) lead to

$$\begin{aligned}
\|I_2\|_{1,\Omega} &\lesssim \left\| \sum_{j=0}^{n-1} R(t_{j+1}^{\triangle}, t_n^{\triangle})\, r_{0,2}(\tau_{j+1}^{\triangle} A) \int_0^{\tau_{j+1}^{\triangle}} A^2\sigma^2(\sigma - \tau_{j+1}^{\triangle}) d\sigma \right\|_{H^1_{\Gamma_D}\to H^1_{\Gamma_D}} \\
&= \left\| \sum_{j=0}^{n-1} R(t_{j+1}^{\triangle}, t_n^{\triangle})\, r_{0,2}(\tau_{j+1}^{\triangle} A)\, \frac{1}{12}\, {\tau_{j+1}^{\triangle}}^4 A^2 \right\|_{H^1_{\Gamma_D}\to H^1_{\Gamma_D}} \\
&\underbrace{\leq}_{\sup\limits_{x\in(0,\infty)} |\tilde{\varphi}_{2,2}(x)|=1} \left\| \sum_{j=0}^{n-1} \varphi_{2,2}(\tau_{\min,\triangle}\, A)^{n-j-1}\, r_{0,2}(\tau_{\min,\triangle}\, A)\tau_{\triangle}^4 A^2 \right\|_{H^1_{\Gamma_D}\to H^1_{\Gamma_D}} \\
&\lesssim \tau_{\triangle}^2 \left\| (I - r_{2,2}((\tau_{\min,\triangle}\, A))^{-1}\, r_{0,2}(\tau_{\min,\triangle}\, A)\tau_{\triangle}^2 A^2 \right\|_{H^1_{\Gamma_D}\to H^1_{\Gamma_D}} \\
&= \tau_{\triangle}^2 \left\| 6(\tau_{\min,\triangle}\, A)^{-2} r_{0,2}(\tau_{\min,\triangle}\, A)^{-1}\, r_{0,2}(\tau_{\min,\triangle}\, A)\tau_{\triangle}^2 A^2 \right\|_{H^1_{\Gamma_D}\to H^1_{\Gamma_D}} \\
&= \tau_{\triangle}^2\, 6 \left(\frac{\tau_{\triangle}}{\tau_{\min,\triangle}} \right)^2 \lesssim \tau_{\triangle}^2.
\end{aligned} \tag{5.18}$$

To estimate $\|I_3\|_{1,\Omega}$ we proceed as in (5.18) with

$$\|I_3\|_{1,\Omega} \lesssim \left\| \sum_{j=0}^{n-1} Op_j \left(\int_0^{\tau_{j+1}^{\triangle}} \Sigma_{j+1}(\sigma) d\sigma + \tau_{j+1}^{\triangle} \Sigma_{j+1}(\tau_{j+1}^{\triangle}) \right) \right\|_{1,\Omega}, \tag{5.19}$$

where we set

$$Op_j = \varphi_{2,2}(\tau_{\min,\triangle} A)^{n-j-1}(I + \tau_{\triangle} A) r_{0,2}(\tau_{\triangle} A), \quad j = 0, \ldots, n-1,$$

for short. Again, using the local Lipschitz property of f and the inequality (5.4), we deduce

$$\begin{aligned}
\int_0^{\tau_{j+1}^{\triangle}} \|\Sigma_{j+1}(\sigma)\|_{0,\Omega}\, d\sigma &\leq \hat{L} \int_0^{\tau_{j+1}^{\triangle}} \|p_\tau(t_j^{\triangle} + \sigma) - I_{\triangle} p(t_j^{\triangle} + \sigma)\|_{1,\Omega}\, d\sigma \\
&= \hat{L}\, \frac{\tau_{j+1}^{\triangle}}{2} (\|e_j\|_{1,\Omega} + \|e_{j+1}\|_{1,\Omega}).
\end{aligned} \tag{5.20}$$

Combining (5.19) and (5.20) leads to

$$\|I_3\|_{1,\Omega} \lesssim \tau_{\triangle} \sum_{j=0}^{n-1} \|Op_j\|_{L^2\to H^1_{\Gamma_D}} (\|e_{j+1}\|_{1,\Omega} + \|e_j\|_{1,\Omega}). \tag{5.21}$$

For $j = n-1$, we get

$$\|Op_{n-1}\|_{L^2\to H^1_{\Gamma_D}} = \|(I + \tau_{\triangle} A) r_{0,2}(\tau_{\triangle} A)\|_{L^2\to H^1_{\Gamma_D}} \lesssim \tau_{\triangle}^{-1/2}.$$

Assumption (5.1), the inequality $n\tau_{\min,\triangle} \le t_n^{\triangle} \le n\tau_{\triangle}$, and the fact that $\varphi_{2,2}(\infty) = \frac{1}{2}$ lead to

$$\begin{aligned}\|Op_j\|_{L^2\to H^1_{\Gamma_D}} &\lesssim \|\varphi_{2,2}(\tau_{\min,\triangle}A)^{n-j-1} - 2^{j+1-n}\|_{L^2\to H^1_{\Gamma_D}} \\ &\quad + \|2^{j+1-n}(I+\tau_{\triangle}A)r_{0,2}(\tau_{\triangle}A)\|_{L^2\to H^1_{\Gamma_D}} \\ &\lesssim {t_{n-j+1}^{\triangle}}^{-1/2} + \| \underbrace{2^{j+1-n}}_{\lesssim (n-j+1)^{-1/2}} (I+\tau_{\triangle}A)r_{0,2}(\tau_{\triangle}A)\|_{L^2\to H^1_{\Gamma_D}} \lesssim {t_{n-j+1}^{\triangle}}^{-1/2}\end{aligned}$$

for $j = 0, \dots, n-2$ (cf. [11, Theorem 1.1]). For the last term $\|I_4\|_{1,\Omega}$, we immediately see the following:

$$\|I_4\|_{1,\Omega} \lesssim \tau_{\triangle}^2 + \tau_{\triangle} \sum_{j=0}^{n-1} (\|e_j\|_{1,\Omega} + \|e_{j+1}\|_{1,\Omega}).$$

Putting all our estimations together, we deduce

$$\begin{aligned}\|e_n\|_{1,\Omega} &\lesssim \|I_1\|_{1,\Omega} + \|I_2\|_{1,\Omega} + \|I_3\|_{1,\Omega} + \|I_4\|_{1,\Omega} \\ &\lesssim \tau_{\triangle}^2 + \tau_{\triangle} \sum_{j=0}^{n-1} {t_{n-j+1}^{\triangle}}^{-1/2} (\|e_j\|_{1,\Omega} + \|e_{j+1}\|_{1,\Omega}) \\ &\lesssim \tau_{\triangle}^2 + \tau_{\triangle} \sum_{j=1}^{n} {t_{n-j+1}^{\triangle}}^{-1/2} \|e_j\|_{1,\Omega}.\end{aligned}$$

This means that the error satisfies

$$\|e_n\|_{1,\Omega} \le C_2\tau_{\triangle}^2 + C_2\tau_{\triangle} \sum_{j=1}^{n} \hat{t}_{n-j+1}^{-1/2} \|e_j\|_{1,\Omega},$$

with $\hat{t}_j = j\tau_{\triangle}$, $j = 0, \dots, n$, where C_2 is a constant. Now we get $(1 - C_2\tau_{\triangle}^{1/2}) \ge \frac{1}{2} > 0$ if we choose τ^* small enough, say $\tau^* \le \min\{\varepsilon_3, \frac{1}{4C_2^2}\}$, where we will give ε_3 in part (c) of the proof. Setting $C = 2C_2$ we easily get

$$\begin{aligned}\|e_n\|_{1,\Omega} &\le \underbrace{\frac{C_2}{1 - C_2\tau_{\triangle}^{1/2}}}_{\le \frac{C_2}{1-\frac{C_2}{2C_2}} = 2C_2} \tau_{\triangle}^2 + \frac{C_2\tau_{\triangle}}{1 - C_2\tau_{\triangle}^{1/2}} \sum_{j=1}^{n-1} \hat{t}_{n-j+1}^{-1/2} \|e_j\|_{1,\Omega} \\ &\le C\tau_{\triangle}^2 + C\tau_{\triangle} \sum_{j=1}^{n-1} \hat{t}_{n-j+1}^{-1/2} \|e_j\|_{1,\Omega}.\end{aligned} \tag{5.22}$$

Now, let us define $v(t) = \|e_j\|_{1,\Omega}$ for $t \in [\hat{t}_{j-1}, \hat{t}_j)$, $j = 1, \dots, n$. One may deduce

$$\begin{aligned}\int_0^t (t-s)^{-1/2} v(s)\, ds &\ge \sum_{j=1}^{m-1} \int_{\hat{t}_{j-1}}^{\hat{t}_j} (\underbrace{t-s}_{\le \hat{t}_m - \hat{t}_{j-1}})^{-1/2}\, ds\, \|e_j\|_{1,\Omega} \\ &\ge \tau_{\triangle} \sum_{j=1}^{m-1} \hat{t}_{m-j+1}^{-1/2} \|e_j\|_{1,\Omega}\end{aligned} \tag{5.23}$$

for $m = 1, \dots, n$ and $t \in [\hat{t}_{m-1}, \hat{t}_m)$. For each $t \in [0, \hat{t}_n)$, we choose $m \in \{1, \dots, n\}$, such that $t \in [\hat{t}_{m-1}, \hat{t}_m)$. From (5.22) and (5.23) we obtain

$$v(t) = \|e_m\|_{1,\Omega} \le C\,\tau_\triangle^2 + C\,\tau_\triangle \sum_{j=1}^{n-1} \hat{t}_{n-j+1}^{-1/2} \|e_j\|_{1,\Omega} \le C\,\tau_\triangle^2 + C \int_0^t (t-s)^{-1/2} v(s)\,ds.$$

Setting $\hat{a} = C\,\tau_\triangle^2$, $\hat{b} = C$, $\hat{\alpha} = 0$, and $\hat{\beta} = \frac{1}{2}$, Gronwall's lemma (Lemma 5.1) leads to

$$\|e_n\|_{1,\Omega} \lesssim \tau_\triangle^2.$$

(c) Our aim now is to choose τ^* to prove (5.5) for $j = 0, \dots, M_\triangle$. We show this by induction on $j \in \{0, 1, \dots, M_\triangle\}$.

Initial step. For $j = 0$, we have $p_\tau(0) = p(0) = p_0$, and hence (5.5) is true.

Inductive step. To show (5.5) for $j+1$, set $\gamma_1 := \frac{\hat{\delta}}{6M_\triangle} < \frac{\hat{\delta}}{2}$ and $\gamma_2 := \frac{(2j+1)\hat{\delta}}{6M_\triangle} < \frac{\hat{\delta}}{2}$. Consider the function

$$D : \overline{B(p(t_{j+1}^\triangle), \gamma_1)} \subset H^1_{\Gamma_D}(\Omega) \to \overline{B(p(t_{j+1}^\triangle), \gamma_1)},$$

$$D(q) := r_{2,2}(\tau_{j+1}^\triangle A) p(t_j^\triangle) - \int_0^{\tau_{j+1}^\triangle} r_{0,2}(\tau_{j+1}^\triangle A)\sigma A f(\tilde{q}(\sigma)) + g(\tau_{j+1}^\triangle, \sigma, \tilde{q}(\sigma))d\sigma,$$

where $\tilde{q}(\sigma) := (1 - (\sigma/\tau_{j+1}^\triangle))p(t_j^\triangle) + (\sigma/\tau_{j+1}^\triangle)\, q$ ($\overline{B(p(t_{j+1}^\triangle), \gamma_1)}$ is the closed ball with center $p(t_{j+1}^\triangle)$ and radius γ_1). From

$$\begin{aligned}\|p(t_j^\triangle + \sigma) - \tilde{q}(\sigma)\|_{1,\Omega} &\le \|p(t_j^\triangle + \sigma) - I_\triangle p(t_j^\triangle + \sigma)\|_{1,\Omega} + \|\tilde{q}(\sigma) - I_\triangle p(t_j^\triangle + \sigma)\|_{1,\Omega} \\ &\le \underbrace{C_1 \tau_\triangle^2}_{\le \frac{\hat{\delta}}{2}\text{ , because } \tau^* \le \varepsilon_0} + \underbrace{\|q - p(t_{j+1}^\triangle)\|_{1,\Omega}}_{\le \gamma_1 < \frac{\hat{\delta}}{2}} < \hat{\delta}\end{aligned}$$

we obtain by basic estimations

$$\begin{aligned}&\|p(t_{j+1}^\triangle) - D(q)\|_{1,\Omega} \\ &\quad\le \frac{c_1}{2}\,{\tau_{j+1}^\triangle}^{-1/2} \int_0^{\tau_{j+1}^\triangle} \|f(p(t_j^\triangle + \sigma)) - f(\tilde{q}(\sigma))\|_{0,\Omega} \\ &\qquad\qquad + \|g(\tau_{j+1}^\triangle, \sigma, p(t_j^\triangle + \sigma)) - g(\tau_{j+1}^\triangle, \sigma, \tilde{q}(\sigma))\|_{1,\Omega}\, d\sigma + \underbrace{\|d_{j+1}\|_{1,\Omega}}_{\le \hat{C}{\tau_{j+1}^\triangle}^2 \text{ cf. (5.18)}} \\ &\quad\le c_1 \hat{L} \tau_{j+1}^\triangle {}^{-1/2} \int_0^{\tau_{j+1}^\triangle} \underbrace{\|p(t_j^\triangle + \sigma) - \tilde{q}(\sigma)\|_{1,\Omega}}_{<\hat{\delta}} + \hat{C}{\tau_{j+1}^\triangle}^{1/2} \le {\tau_{j+1}^\triangle}^{1/2}(c_1 \hat{L}\hat{\delta} + \hat{C}),\end{aligned}$$

where c_1 and $\hat{C}$ are constants. On the one hand, for $\tau^* \le \min\{\varepsilon_0, (\gamma_1/(c_1\hat{L}\hat{\delta} + \hat{C}))^2\} =: \varepsilon_1$, $D(q) \in \overline{B(p(t_{j+1}^\triangle), \gamma_1)}$. So D is well-defined. One the other hand, we get

$$\|D(q_1) - D(q_2)\|_{1,\Omega} \le c_1 \hat{L} {\tau_{j+1}^\triangle}^{1/2} \|q_1 - q_2\|_{1,\Omega}.$$

For $\tau^* \le \min\{\varepsilon_1, (1/2c_1\hat{L})^2\} =: \varepsilon_2$ and all $q_1, q_2 \in \overline{B(p(t_{j+1}^{\triangle}), \gamma_1)}$ we obtain

$$\|D(q_1) - D(q_2)\|_{1,\Omega} \le \frac{1}{2}\,\|q_1 - q_2\|_{1,\Omega}.$$

Hence, Banach's fixed-point theorem leads to convergence of the sequence $q_{m+1} := D(q_m)$, where $q_0 \in \overline{B(p(t_{j+1}^{\triangle}), \gamma_1)}$.

Setting $p^{\bullet} := \lim_{m\to\infty} q_m$, we deduce

$$\|p^{\bullet} - p(t_{j+1}^{\triangle})\|_{1,\Omega} \le \gamma_1. \tag{5.24}$$

Furthermore, define the function

$$\tilde{D} : \overline{B(p^{\bullet}, \gamma_2)} \subset H^1_{\Gamma_D}(\Omega) \to \overline{B(p^{\bullet}, \gamma_2)},$$

where

$$\tilde{D}(q) = r_{2,2}(\tau_{j+1}^{\triangle}A)p_\tau(t_j^{\triangle}) - \int_0^{\tau_{j+1}^{\triangle}} r_{0,2}(\tau_{j+1}^{\triangle}A)\sigma A f(\hat{q}(\sigma)) + g(\tau_{j+1}^{\triangle}, \sigma, \hat{q}(\sigma))d\sigma,$$

and $\hat{q}(\sigma) := (1 - (\sigma/\tau_{j+1}^{\triangle}))p_\tau(t_j^{\triangle}) + (\sigma/\tau_{j+1}^{\triangle})\,q$. Using the assumption of the induction for j, we obtain

$$\|\tilde{p}^{\bullet}(\sigma) - \hat{q}(\sigma)\|_{1,\Omega} \le \max\{\underbrace{\|p_\tau(t_j^{\triangle}) - p(t_j^{\triangle})\|_{1,\Omega}}_{\le \frac{j\hat{\delta}}{3M_{\triangle}}}, \|p^{\bullet} - q\|_{1,\Omega}\} < \frac{\hat{\delta}}{2},$$

which leads to

$$\begin{aligned}
\|p^{\bullet} - \tilde{D}(q)\|_{1,\Omega} = \ & \|D(p^{\bullet}) - \tilde{D}(q)\|_{1,\Omega} \le \ \|p(t_j^{\triangle}) - p_\tau(t_j^{\triangle})\|_{1,\Omega} \\
& + \frac{c_1}{2}{\tau_{j+1}^{\triangle}}^{-1/2} \int_0^{\tau_{j+1}^{\triangle}} \|f(\tilde{p}^{\bullet}(\sigma)) - f(\hat{q}(\sigma))\|_{0,\Omega} \\
& + \|g(\tau_{j+1}^{\triangle}, \sigma, \tilde{p}^{\bullet}(\sigma)) - g(\tau_{j+1}^{\triangle}, \sigma, \hat{q}(\sigma))\|_{1,\Omega}\, d\sigma \\
\le \ & \frac{j\delta}{3M_{\triangle}} + c_1\hat{L}{\tau_{j+1}^{\triangle}}^{1/2}\gamma_2.
\end{aligned}$$

For $\tau^* \le \min\{\varepsilon_2, (\hat{\delta}/c_1\hat{L}\gamma_2 6M_{\triangle})^2\} =: \varepsilon_3$, we obtain

$$\frac{j\hat{\delta}}{3M_{\triangle}} + c_1\hat{L}{\tau_{j+1}^{\triangle}}^{1/2}\gamma_2 \le \frac{j\hat{\delta}}{3M_{\triangle}} + \frac{\hat{\delta}}{6M_{\triangle}} = \frac{(2j+1)\hat{\delta}}{6M_{\triangle}} = \gamma_2.$$

Hence, $\tilde{D}$ is well-defined. On the other hand, for $\tau^* \le \varepsilon_2$ and all $q_1, q_2 \in \overline{B(p^{\bullet}, \gamma_2)}$ we get

$$\|\tilde{D}(q_1) - \tilde{D}(q_2)\|_{1,\Omega} \le \frac{1}{2}\,\|q_1 - q_2\|_{1,\Omega}.$$

This leads to convergence of the sequence $q_{m+1} := \tilde{D}(q_m)$ using Banach's fixed-point theorem, where again $q_0 \in \overline{B(p^{\bullet}, \gamma_2)}$. Hence, for the limit of the fixed-point iteration

we know $p_\tau(t^\triangle_{j+1}) = \lim_{m\to\infty} q_{m+1}$, and so we have $\|p^\bullet - p_\tau(t^\triangle_{j+1})\|_{1,\Omega} \le \gamma_2$. Putting this result together with (5.24), we get

$$\|p(t^\triangle_{j+1}) - p_\tau(t^\triangle_{j+1})\|_{1,\Omega} \le \|p^\bullet - p(t^\triangle_{j+1})\|_{1,\Omega} + \|p^\bullet - p_\tau(t^\triangle_{j+1})\|_{1,\Omega} \le \gamma_1 + \gamma_2 = \frac{(j+1)\hat{\delta}}{3M_\triangle}. \quad \square$$

Now we are interested in a result for the whole interval $[0,T]$.

COROLLARY 5.3. *With the conditions of Theorem* 5.2*, we get*

$$\max_{t\in[0,T]} \|p(t) - p_\tau(t)\|_{1,\Omega} \le C\tau^2_\triangle.$$

Proof. Let $\hat{t} \in [0,T]$ such that

$$\max_{t\in[0,T]} \|p(t) - p_\tau(t)\|_{1,\Omega} = \|p(\hat{t}) - p_\tau(\hat{t})\|_{1,\Omega}.$$

From the triangle inequality we obtain

$$\|p(\hat{t}) - p_\tau(\hat{t})\|_{1,\Omega} \le \|p(\hat{t}) - I_\triangle p(\hat{t})\|_{1,\Omega} + \|I_\triangle p(\hat{t}) - p_\tau(\hat{t})\|_{1,\Omega}. \tag{5.25}$$

To estimate the first term on the right-hand side, we use the interpolation theory to get

$$\|p(\hat{t}) - I_\triangle p(\hat{t})\|_{1,\Omega} \le C_1\tau^2_\triangle.$$

Now choose $0 \le n \le M_\triangle$ such that $\hat{t} \in [t^\triangle_n, t^\triangle_{n+1}]$. The functions $I_\triangle p$ and p_τ are linear on $[t^\triangle_n, t^\triangle_{n+1}]$; hence we get

$$\|I_\triangle p(\hat{t}) - p_\tau(\hat{t})\|_{1,\Omega} \le \max\{\|e_n\|_{0,\Omega}, \|e_{n+1}\|_{1,\Omega}\} \underbrace{\le}_{\text{cf. Theorem 5.2}} C^*\tau^2_\triangle. \quad \square$$

6. The minimization problem. This section addresses the issues related to the solution of the elliptic problems at each time step. We approximate now the least-squares functional $\hat{\mathcal{F}}$ with Simpson's rule and get

$$\begin{aligned}
\hat{\mathcal{F}}(u_\tau, p_\tau) \approx{}& \frac{1}{6}\|p^+_\tau - p_\tau(t) + \tau \operatorname{div} u^-_\tau + \tau f(p_\tau(t))\|^2_{0,\Omega} \\
&+ \frac{2}{3}\left\|p^+_\tau - p_\tau(t) + \tau\frac{1}{2}(\operatorname{div} u^-_\tau + \operatorname{div} u^+_\tau) + \tau f\left(\frac{p^+_\tau + p_\tau(t)}{2}\right)\right\|^2_{0,\Omega} \\
&+ \frac{1}{6}\|p^+_\tau - p_\tau(t) + \tau \operatorname{div} u^+_\tau + \tau f(p^+_\tau)\|^2_{0,\Omega} \\
&+ \frac{\tau}{6}\|u^-_\tau + a^{1/2}\nabla p_\tau(t)\|^2_{0,\Omega} + \frac{\tau}{6}\|u^+_\tau + \nabla p^+_\tau\|^2_{0,\Omega} \\
&+ \frac{\tau}{6}\|(u^-_\tau + u^+_\tau) + (\nabla p_\tau(t) + \nabla p^+_\tau)\|^2_{0,\Omega} = \mathcal{F}(u^-_\tau, u^+_\tau, p^+_\tau; p_\tau(t)).
\end{aligned} \tag{6.1}$$

Now our goal is to minimize the least-squares functional $\mathcal{F}$ in $H_{\Gamma_N}(\operatorname{div},\Omega)^2 \times H^1_{\Gamma_D}(\Omega)$.

Obviously we see

$$\mathcal{F}(u^-_\tau, u^+_\tau, p^+_\tau; p_\tau(t)) = \|\mathcal{R}(u^-_\tau, u^+_\tau, p^+_\tau; p_\tau(t))\|^2_{0,\Omega}, \tag{6.2}$$

where

$$\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)) = \begin{pmatrix} \frac{1}{\sqrt{6}}\,(p_\tau^+ - p_\tau(t) + \tau \mathrm{div} u_\tau^- + \tau\, f(p_\tau(t))) \\ \sqrt{\frac{2}{3}}\,(p_\tau^+ - p_\tau(t) + \frac{\tau}{2}\mathrm{div}(u_\tau^- + u_\tau^+) + \tau\, f(\frac{p_\tau^+ + p_\tau(t)}{2})) \\ \frac{1}{\sqrt{6}}\,(p_\tau^+ - p_\tau(t) + \tau \mathrm{div} u_\tau^+ + \tau f(p_\tau^+)) \\ \sqrt{\frac{\tau}{6}}\,(\,u_\tau^- + \nabla p_\tau(t)) \\ \sqrt{\frac{\tau}{6}}\,(\,u_\tau^- + u_\tau^+ + \nabla p_\tau(t) + \nabla p_\tau^+) \\ \sqrt{\frac{\tau}{6}}\,(\,u_\tau^+ + \nabla p_\tau^+) \end{pmatrix}.$$

Considering $\mathcal{F}$ on $H_{\Gamma_N}(\mathrm{div}, \Omega)^2 \times H^1_{\Gamma_D}(\Omega)$ and (4.1) lead to

$$\mathcal{F}'(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)) \equiv 0 \quad \text{in } H_{\Gamma_N}(\mathrm{div}, \Omega)^2 \times H^1_{\Gamma_D}(\Omega), \tag{6.3}$$

where

$$\mathcal{F}'(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)) \,:\, H_{\Gamma_N}(\mathrm{div}, \Omega)^2 \times H^1_{\Gamma_D}(\Omega) \longrightarrow \mathbb{R},$$

$$\begin{aligned} &\mathcal{F}'(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)) \begin{pmatrix} v_\tau^- \\ v_\tau^+ \\ q_\tau \end{pmatrix} \\ &\quad = \left(\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)), \mathcal{J}_\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+) \begin{pmatrix} v_\tau^- \\ v_\tau^+ \\ q_\tau \end{pmatrix} \right)_{0,\Omega}, \end{aligned} \tag{6.4}$$

and

$$\mathcal{J}_\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+) = (\partial_j \mathcal{R}_i)_{i=1,\ldots,6, j=1,\ldots,3}$$

is the *Jacobi matrix* of $\mathcal{R}$ at the point $(u_\tau^-, u_\tau^+, p_\tau^+)$. Elementary calculus leads to

$$\mathcal{J}_\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+) \,:\, H_{\Gamma_N}(\mathrm{div}, \Omega)^2 \times H^1_{\Gamma_D}(\Omega) \longrightarrow (L^2(\Omega))^9,$$

where

$$\mathcal{J}_\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+) = \frac{1}{\sqrt{6}} \begin{pmatrix} \tau\mathrm{div} & 0 & 1 \\ 2\,\tau\mathrm{div} & 2\,\tau\mathrm{div} & 4 + 2\tau f'(\frac{p_\tau^+ + p_\tau(t)}{2}) \\ 0 & \tau\mathrm{div} & 1 + \tau f'(p_\tau^+) \\ \sqrt{\tau} & 0 & 0 \\ \sqrt{\tau} & \sqrt{\tau} & \sqrt{\tau}\nabla \\ 0 & \sqrt{\tau} & \sqrt{\tau}\nabla \end{pmatrix}.$$

Now we obtain from (6.3) and (6.4) that (4.1) is equivalent to

$$\left(\mathcal{R}(u_\tau^-, u_\tau^+, p_\tau^+; p_\tau(t)), \mathcal{J}_{\mathcal{R}}(u_\tau^-, u_\tau^+, p_\tau^+) \begin{pmatrix} v_\tau^- \\ v_\tau^+ \\ q_\tau \end{pmatrix} \right)_{0,\Omega} = 0 \tag{6.5}$$

for all $(v_\tau^-, v_\tau^+, q_\tau) \in V_\tau^2 \times Q_\tau$.

There are several solution methods which directly use this nonlinear variational formulation. One of them is the nonlinear conjugate gradient method (cf. [20, section 5.2]), which in each step constructs a descent direction with the help of the gradient (6.4). The study of this solution is beyond the scope of this paper. Alternatively, one can first linearize this nonlinear minimization problem to use methods of Newton or Gauss–Newton type. We will choose this way to receive the fully discrete approximation in the next part of this paper.

The minimization problem of this paper could also be generalized for nonautonomous problems. The proof of the convergence result in this case is a little different from the technique observed here. Interested readers are referred to [16, Chapters 3, 4].

Acknowledgments. The author would like to thank Travis Austin, Michael Florig, and Gerhard Starke for reading this manuscript and for their suggestions. Furthermore the author is very thankful to the anonymous referees for helpful comments and suggestions.

A $\mathcal{V}$-CYCLE MULTIGRID APPROACH FOR MORTAR FINITE ELEMENTS*

BARBARA I. WOHLMUTH†

Abstract. Mortar methods, based on dual Lagrange multipliers, provide a flexible tool for the numerical approximation of partial differential equations. The associated finite element spaces are, in general, nonconforming and nonnested. Optimal multigrid results have previously been established for $\mathcal{W}$-cycle and the variable $\mathcal{V}$-cycle multigrid methods. In this paper, we introduce a new multigrid method based on a nested sequence of modified mortar spaces for which we can establish that the $\mathcal{V}$-cycle with one smoothing step has contraction numbers uniformly bounded away from one. To obtain nested mortar spaces, we apply a product form of certain corrections at the interfaces. Numerical results demonstrate the efficiency of the resulting multigrid solver.

Key words. dual space, mortar finite elements, multigrid methods, nonmatching triangulations

AMS subject classifications. 65N30, 65N55

DOI. 10.1137/S003614290343092X

1. Introduction.

Nonconforming domain decomposition techniques, such as mortar methods, provide a more flexible approach than standard conforming approximations of elliptic problems. Different physical models, discretization schemes, and nonmatching triangulations of the domain can be coupled across interior interfaces by using mortar methods. There has also been substantial progress in establishing a theoretical foundation. The central issue is the choice of interface conditions that ensure stable and optimal discretization schemes for the problem as a whole. Within the framework of mortar methods, the information transfer across the interfaces is given in terms of a weak continuity condition. The jump of the solution at the interfaces is controlled by suitable Lagrange multiplier spaces [6, 7] satisfying an approximation property and a uniform inf-sup condition [5].

In this paper, we will use dual Lagrange multipliers which yield locally defined basis functions; see, e.g., [26]. Dual Lagrange multipliers provide the same accuracy as standard multipliers [6, 7] and give rise to more efficient iterative solvers and sparser local stiffness matrices. In particular, no mass matrices have to be inverted at the interfaces, and the mortar projection can be computed locally. The numerical solution of the resulting linear systems can be based on a symmetric positive definite system or on an equivalent saddle point formulation. Many different iterative solvers have been introduced and analyzed, among them iterative substructuring methods, which have been applied successfully to mortar finite elements; see [1, 2, 3, 17]. The Schur complement plays an important role in the construction of efficient iterative solvers based on the saddle point formulation. Using the techniques introduced in [12], multigrid methods for the indefinite system have been successfully analyzed in the mortar setting; see [8, 9]. The exact solution of an approximative Schur complement can be replaced by an inexact solution; see [25, 30]. A cascadic multigrid method is analyzed

in [10]. A first optimal multigrid convergence result for the positive definite formulation on the constrained space can be found in [18, 19]. Convergence rates which are uniformly bounded away from one are established for a variable $\mathcal{V}$-cycle result and numerical results illustrate the performance. In [28], a positive definite mesh dependent bilinear form is considered on the unconstrained product space. Based on a modified transfer operator and a modified smoother, level independent $\mathcal{W}$-cycle convergence results can be established if the number of smoothing steps is large enough. General results for multigrid algorithms for nonconforming finite elements are also given in [14, 15].

In this paper, we will work with the positive definite system and consider a modified multigrid approach. Our new iterative solver is based on a nested sequence of finite element spaces. To obtain a hierarchy of nested spaces, the nonconforming mortar spaces have to be modified at the interfaces. To preserve the complexity of a standard multigrid algorithm, such modifications must be kept local. The construction of the nested spaces is based on a multiplicative correction on each level. A suitable modification of the spaces at the crosspoints yields optimal best approximations results and a condition number which is bounded as in the standard conforming case. As a result we obtain contraction numbers uniformly bounded away from one with respect to the refinement level for the $\mathcal{V}$-cycle with one smoothing step. For simplicity of notation, we will talk about level independent convergence rates. The algebraic formulation of the prolongation can be easily obtained from the standard transfer operator and a local postprocessing of smaller complexity.

The rest of this paper is organized as follows: In section 2, we briefly review the mortar finite element method. We introduce a hierarchy of nested spaces in section 3. These spaces satisfy the mortar condition with respect to the finest triangulation. In section 4, we establish optimal multigrid convergence results in terms of a best approximation property and a bound on the condition number. In section 5, we consider the algebraic formulation of the problem in more detail and show that the modifications can easily be carried out in a local postprocessing step. Finally in section 6, we illustrate the numerical performance of our new multigrid approach.

2. The elliptic problem and the mortar method. We will consider the following elliptic second order boundary value problem:

$$\begin{aligned} -\mathrm{div}(a\nabla u) &= f \quad \text{in } \Omega, \\ u &= 0 \quad \text{on } \partial\Omega. \end{aligned} \tag{2.1}$$

Here, $0 < a_0 \leq a \in L^\infty(\Omega)$, $f \in L^2(\Omega)$, and $\Omega \subset \mathbb{R}^2$ is a bounded polygonal domain. Let Ω be decomposed into K nonoverlapping polygonal subdomains Ω_k such that $\overline{\Omega} = \bigcup_{k=1}^{K} \overline{\Omega}_k$. The intersection between the boundaries of any pair of subdomains $\partial\Omega_l \cap \partial\Omega_k$, $k \neq l$, is assumed to be either empty, a vertex, or a common edge. We will talk about an interface only in the latter case. A point is a crosspoint if it is in Ω and an endpoint of an interface. The set of crosspoints is denoted by $\mathcal{C}$. On each subdomain, we define a quasi-uniform simplicial triangulation $\mathcal{T}_k$ and denote the finite-dimensional space of conforming piecewise linear finite elements on $\mathcal{T}_k$, with homogeneous Dirichlet boundary conditions on $\partial\Omega \cap \partial\Omega_k$, by X_k. The mortar method can now be characterized by discrete Lagrange multiplier spaces M_m defined on the interfaces γ_m, $1 \leq m \leq M$, of the decomposition. For each interface, there exists a pair $1 \leq l(m) < k(m) \leq K$ such that $\overline{\gamma}_m = \partial\Omega_{l(m)} \cap \partial\Omega_{k(m)}$. Moreover, each interface γ_m is associated with a one-dimensional mesh $\mathcal{S}_m$, inherited from either $\mathcal{T}_{k(m)}$ or $\mathcal{T}_{l(m)}$. Thus, the elements of $\mathcal{S}_m$ are boundary edges of either $\mathcal{T}_{l(m)}$ or

$\mathcal{T}_{k(m)}$. The subdomain from which the interface γ_m inherits its mesh is called the slave subdomain $\Omega_{s(m)}$ and the one opposite is the master subdomain $\Omega_{m(m)}$. We denote the trace space, $X_{s(m)}$, restricted to γ_m, and with zero boundary conditions by W_m; i.e., $W_m := \{w \in H_0^1(\gamma_m),\ w = v_{|\gamma_m} \text{ with } v \in X_{s(m)}\}$.

Following the approach in [6, 7], the mortar approximation u_h can be obtained as the solution of a positive definite nonconforming variational problem. It is defined on a subspace V_h of the unconstrained product space $X_h := \{v \in L^2(\Omega) \mid \ v_{|\Omega_k} \in X_k,\ 1 \le k \le K\}$. The elements of V_h satisfy a weak matching condition across the interfaces, and V_h is given by

$$V_h := \big\{v \in X_h \mid b(v,\mu) = 0,\ \mu \in M_h\big\},$$

where $M_h := \prod_{m=1}^{M} M_m$ and

$$b(v,\mu) := \sum_{m=1}^{M} \int_{\gamma_m} [v]\ \mu\ d\sigma, \quad \mu \in M_h, v \in X_h.$$

Here, the jump is defined as $[v]_{|\gamma_m} := v_{|\Omega_{m(m)}} - v_{|\Omega_{s(m)}}$; see, e.g., [6, 7]. The nonconforming formulation of the mortar method can then be written in terms of the constrained space V_h: find $u_h \in V_h$ such that

$$a(u_h, v_h) = (f, v_h)_0, \quad v_h \in V_h, \tag{2.2}$$

where the bilinear form $a(\cdot,\cdot)$ is defined as

$$a(v,w) := \sum_{k=1}^{K} \int_{\Omega_k} a \nabla v \cdot \nabla w\ dx, \quad v, w \in X := \prod_{k=1}^{K} H^1(\Omega_k).$$

It is obvious that the quality of the nonconforming approach (2.2) and the properties of V_h depend on the discrete Lagrange multiplier space. We will work with the dual Lagrange multiplier space introduced in [26] which satisfy $n_m := \dim M_m = \dim W_m$. The basis functions $\{\mu_i\}_{1 \le i \le n_m}$ of M_m and the nodal basis functions $\{\varphi_i\}_{1 \le i \le n_m}$ of the trace space W_m satisfy the following biorthogonality relation:

$$\int_{\gamma_m} \mu_i\ \varphi_j\, d\sigma = \delta_{ij} \int_{\gamma_m} \varphi_j\, d\sigma, \quad 1 \le i, j \le n_m.$$

Such locally defined dual Lagrange multiplier spaces can also be defined for higher order finite elements; see [24]. In this paper, we use piecewise linear but discontinuous Lagrange multiplier basis functions, but we note that there also exist continuous Lagrange multiplier basis functions; see [27].

3. New nested spaces. In the following, we denote the unconstrained product spaces associated with a nested sequence of quasi-uniform and shape regular triangulations $\mathcal{T}^l$, $l = 0, \dots, L$, by $X^l := \prod_{k=1}^{K} X_k^l$. We assume that $\mathcal{T}^{l+1}$ is obtained from $\mathcal{T}^l$ by uniform refinement and that the mesh sizes satisfy $2\, h_{l+1} = h_l$. The constrained mortar spaces are denoted by V^l, the dual Lagrange multiplier spaces by $M^l := \prod_{m=1}^{M} M_m^l$, and the trace spaces having zero boundary conditions by $W^l := \prod_{m=1}^{M} W_m^l$. We note that, in general, the global triangulations $\mathcal{T}^l$, $l = 0, \dots, L$, do not match across the interfaces. The corresponding nodal basis functions of X^l,

V^l, and M^l on level l are denoted by $\{\theta_p^l\}_{p\in\mathcal{N}_u^l}$, $\{\phi_p^l\}_{p\in\mathcal{N}_c^l}$, and $\{\lambda_p^l\}_{p\in\mathcal{N}_s^l}$, respectively, where $\mathcal{N}_u^l$, $\mathcal{N}_c^l$, and $\mathcal{N}_s^l$ denote the sets of nodes. We note that $\mathcal{N}_u^l = \mathcal{N}_c^l \cup \mathcal{N}_s^l$ and that $\{\theta_p^l\}_{p\in\mathcal{N}_s^l}$ restricted to the interfaces defines a basis of W_h which is biorthogonal to $\{\lambda_p^l\}_{p\in\mathcal{N}_s^l}$. In contrast to the unconstrained product spaces X^l, the nonconforming mortar spaces V^l are nonnested; i.e., $V^l \not\subset V^{l+1}$. In our multigrid analysis, we will assume that the problem is H^2-regular.

The central idea is to replace V^l in a first step by $\widetilde{V}^l$ yielding a nested sequence of finite element spaces, i.e., with $\widetilde{V}^0 \subset \widetilde{V}^1 \subset \cdots \subset \widetilde{V}^L := V^L$, while maintaining the same approximation properties. Then, in a second step, we replace $\widetilde{V}^l$, $0 \le l < L$, by a smaller space $\widehat{V}^l$ that is continuous at the crosspoints. We note that each element v in V^l with $[v] = 0$ for all interfaces is an element in V^{l+1}. But, generally, $v \in V^l$ will not guarantee that $b(v,\mu) = 0$ for all $\mu \in M^{l+1}$ and thus $v \notin V^{l+1}$.

On each level, we therefore introduce a locally defined linear operator $Q^l : X^l \longrightarrow X^l$ by

$$Q^l v := v - \sum_{p\in\mathcal{N}_s^l} \frac{b(v,\lambda_p^l)}{b(\theta_p^l,\lambda_p^l)}\theta_p^l. \tag{3.1}$$

Due to the duality of the Lagrange multiplier space, we find for each λ_q^l, $q \in \mathcal{N}_s^l$,

$$b(Q^l v,\lambda_q^l) = b(v,\lambda_q^l) - \sum_{p\in\mathcal{N}_s^l} \frac{b(v,\lambda_p^l)}{b(\theta_p^l,\lambda_p^l)}\, b(\theta_p^l,\lambda_q^l) = b(v,\lambda_q^l) - b(v,\lambda_q^l) = 0,$$

and thus $Q^l v \in V^l$. Moreover, Q^l restricted to V^l is the identity, and the kernel of Q^l is span $\{\theta_p^l, p \in \mathcal{N}_s^l\}$. We now define our new spaces by $\widetilde{V}^l := \text{span}\,\{\varphi_p^l, p \in \mathcal{N}_c^l\}$, where the basis functions φ_p^l are given by

$$\varphi_p^l := Q^L\ Q^{L-1}\ \ldots\ Q^{l+1}\ \phi_p^l, \quad p \in \mathcal{N}_c^l. \tag{3.2}$$

By construction, we have $\widetilde{V}^L = V^L$ and $\dim \widetilde{V}^l \le \dim V^l$. Moreover, we find that $\varphi_p^l(q) = \delta_{pq}$, $p,q \in \mathcal{N}_c^l$, and thus the φ_p^l are linearly independent yielding $\dim \widetilde{V}^l = \dim V^l$. We note that the elements of $\widetilde{V}^l$ are, in general, not level l functions. Observing that $\phi_p^l = Q^l\theta_p^l$, $p \in \mathcal{N}_c^l$, the new basis functions φ_p^l can also be written in terms of a subset of the nodal basis functions θ_p^l

$$\varphi_p^l = P^l\ \theta_p^l := Q^L\ Q^{l-1}\ \ldots\ Q^{l+1}\ Q^l\ \theta_p^l, \quad p \in \mathcal{N}_c^l.$$

Using the definition of P^l, it is easy to see that $\widetilde{V}^l = P^l V^l$. By construction, the elements of $\widetilde{V}^l$ satisfy the mortar condition with respect to the finest level L and thus $\widetilde{V}^l \subset V^L$. The application of P^l is illustrated in Figure 3.1. For each level $k = l, \ldots, L$, we add a local level k correction to $v \in X^l$ on the slave sides. These level k corrections are nonzero only in a strip of width h_k in the slave subdomains; see Figure 3.1

To see that the spaces $\widetilde{V}^l$ are nested, we consider the basis functions in more detail. Using the definition (3.1), we obtain $Q^l\theta_q^l = \sum_{p\in\mathcal{N}_u^{l+1}} \alpha_p^q \theta_p^{l+1}$. Observing that $Q^{l+1}\theta_p^{l+1} = 0$ for $p \in \mathcal{N}_s^{l+1}$, we find

$$\varphi_q^l = P^l\theta_q^l = P^{l+1} \sum_{p\in\mathcal{N}_u^{l+1}} \alpha_p^q \theta_p^{l+1} = \sum_{p\in\mathcal{N}_c^{l+1}} \alpha_p^q P^{l+1}\theta_p^{l+1} = \sum_{p\in\mathcal{N}_c^{l+1}} \alpha_p^q \varphi_p^{l+1},$$

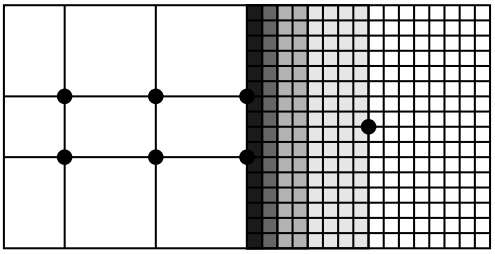

FIG. 3.1. *Action of P^l, where the master side is on the left and $l = L - 3$.*

and thus $\widetilde{V}^l \subset \widetilde{V}^{l+1}$.

The definition of P^l as a product provides the natural framework within a multigrid approach. We find that P^l is closely related to the mortar projection. Introducing the mortar projection $\pi_m^l : L^2(\gamma_m) \longrightarrow W_m^l$, by

$$\int_{\gamma_m} \pi_m^l v \mu \, d\sigma = \int_{\gamma_m} v \mu \, d\sigma, \quad \mu \in M_m^l, \tag{3.3}$$

and $\Pi^l : X^l \longrightarrow W^l$, by $(\Pi^l v)_{|\gamma_m} := \pi_m^l([v]_{|\gamma_m})$, we can rewrite the projection Q^l as

$$Q^l = \mathrm{Id} \; - E^l \Pi^l,$$

where $E^l : W^l \longrightarrow X^l$ is defined by $E^l := \sum_{m=1}^M E_m^l$, and E_m^l denotes the trivial extension by zero from W_m^l into $X_{s(m)}^l \subset X^l$; i.e., all coefficients in the basis representation being not associated with nodes in the interior of γ_m are set to be zero. We note that π_m^l restricted to W_m^l is the identity. The operator Q^l plays a crucial role in the multigrid analysis. In the next lemma, we briefly recall the essential properties of the mortar projection (3.3). For a proof in the dual Lagrange multiplier setting, we refer to [26].

LEMMA 3.1. *The mortar projection π_m^l satisfies the following properties with constants independent of the refinement level* l*:*

- *It is $H_{00}^{1/2}$-stable, i.e.,*

$$\|\pi_m^l v\|_{H_{00}^{1/2}(\gamma_m)} \leq C \|v\|_{H_{00}^{1/2}(\gamma_m)}, \quad v \in H_{00}^{1/2}(\gamma_m).$$

- *It satisfies an approximation property*

$$\|v - \pi_m^l v\|_{0;\gamma_m} \leq C h_l |v|_{1;\gamma_m}, \quad v \in H_0^1(\gamma_m).$$

To establish level independent multigrid convergence rates, we have to consider the spaces $\widetilde{V}^l$ in more detail. In particular, appropriate approximation properties are essential. As a preliminary step in this direction, we give an equivalent formulation of P^l.

LEMMA 3.2. *The operator P^l, defined in terms of a product, can also be expressed as a sum over different levels,*

$$P^l = \mathrm{Id} \; - \sum_{k=l+1}^{L} E^k (\Pi^k - \Pi^{k-1}) - E^l \Pi^l.$$

Proof. The proof is obtained by induction. By definition, we have $Q^l = \mathrm{Id} - E^l\Pi^l$. Let us assume that $Q^j \dots Q^l = \mathrm{Id} - \sum_{k=l+1}^{j} E^k(\Pi^k - \Pi^{k-1}) - E^l\Pi^l$ holds. We then get

$$Q^{j+1}\, Q^j \dots Q^l = (\mathrm{Id} - E^{j+1}\Pi^{j+1}) \left(\mathrm{Id} - \sum_{k=l+1}^{j} E^k(\Pi^k - \Pi^{k-1}) - E^l\Pi^l \right)$$

$$= \mathrm{Id} - \sum_{k=l+1}^{j} E^k(\Pi^k - \Pi^{k-1}) - E^l\Pi^l - E^{j+1}\Pi^{j+1} \tag{3.4}$$

$$+ \sum_{k=l+1}^{j} E^{j+1}\Pi^{j+1}E^k(\Pi^k - \Pi^{k-1}) + E^{j+1}\Pi^{j+1}E^l\Pi^l.$$

We recall that $E^k\Pi^k$ and $E^k\Pi^{k-1}$ when restricted to the interfaces are Π^k and Π^{k-1}, respectively. Moreover, the trace spaces are nested; i.e., $W^k \subset W^{k+1}$, and thus $\Pi^{k+i}E^k\Pi^k = \Pi^k$, $i \geq 0$. Using these observations in (3.4), we find

$$Q^{j+1}\, Q^j \dots Q^l = \mathrm{Id} - \sum_{k=l+1}^{j} E^k(\Pi^k - \Pi^{k-1}) - E^l\Pi^l - E^{j+1}\Pi^{j+1}$$

$$+ \sum_{k=l+1}^{j} E^{j+1}(\Pi^k - \Pi^{k-1}) + E^{j+1}\Pi^l$$

$$= \mathrm{Id} - \sum_{k=l+1}^{j} E^k(\Pi^k - \Pi^{k-1}) - E^{j+1}(\Pi^{j+1} - \Pi^j) - E^l\Pi^l. \qquad \square$$

4. $\boldsymbol{\mathcal{V}}$-cycle multigrid convergence analysis. The two basic tools to establish level independent multigrid convergence rates are an approximation and a smoothing property. The approximation property for the mortar space V^l is well known; see, e.g., [26]. Here, we have to consider the modified spaces $\widetilde{V}^l$. In the following, we work with the broken H^1-norm which is defined by $\|\cdot\|_1^2 := \sum_{k=1}^{K} \|\cdot\|_{1;\Omega_k}^2$.

LEMMA 4.1. *The modified spaces $\widetilde{V}^l$, $0 \leq l \leq L$, satisfy an approximation property, i.e.,*

$$\inf_{v \in \widetilde{V}^l} \|u - v\|_1 \leq C h_l |u|_2, \quad u \in H^2(\Omega) \cap H_0^1(\Omega),$$

where the constant $C < \infty$ does not depend on L and h_l.

Proof. The starting point for the proof is Lemma 3.2. We define $w := Q^l I^l u$, where I^l is the broken Lagrange interpolation operator onto X^l. Then, it is well known that

$$\|u - w\|_1 \leq C h_l |u|_2, \quad u \in H_0^1(\Omega) \cap H^2(\Omega);$$

see [26]. An analogous result for standard Lagrange multipliers can be found in [6, 7]. We recall that $w \in V^l$ and thus $\Pi^l w = 0$. Defining $v := P^l w \in \widetilde{V}^l$ and using the additive structure of P^l, we find

$$\|u - v\|_1 = \|u - w + \sum_{k=l+1}^{L} E^k(\Pi^k - \Pi^{k-1})w\|_1$$

$$\leq \|u - w\|_1 + \sum_{k=l+1}^{L} \|E^k(\Pi^k - \Pi^{k-1})w\|_1.$$

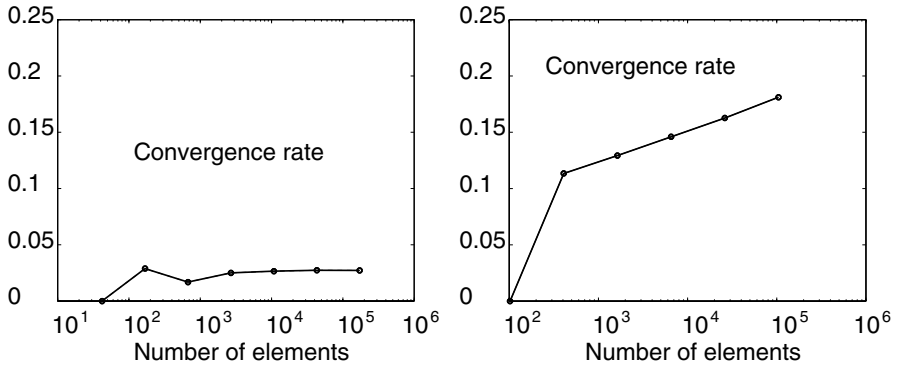

FIG. 4.1. *Convergence rates based on $\widetilde{V}^l$, no crosspoints (left) and crosspoints (right).*

A standard inverse estimate provides for the trivial extension on level k

$$\|E^k(\Pi^k - \Pi^{k-1})w\|_1 \leq \frac{C}{\sqrt{h_k}}\|(\Pi^k - \Pi^{k-1})w\|_{0;\mathcal{S}},$$

where $\mathcal{S} := \cup_{m=1}^M \gamma_m$. In what follows, we denote by $\|\cdot\|_{t;\mathcal{S}}$ and $|\cdot|_{t;\mathcal{S}}$ the broken H^t-norm and H^t-seminorm on $\mathcal{S}$; i.e.,

$$\|v\|_{t;\mathcal{S}}^2 := \sum_{m=1}^M \|v\|_{t;\gamma_m}^2, \text{ and } \quad |v|_{t;\mathcal{S}}^2 := \sum_{m=1}^M |v|_{t;\gamma_m}^2,$$

respectively. The definition of w guarantees that $[w]_{|\gamma_m} \in H_0^1(\gamma_m)$, and thus we are in the setting of Lemma 3.1. In terms of the approximation property, we find

$$\begin{aligned}\|(\Pi^k - \Pi^{k-1})w\|_{0;\mathcal{S}} &\leq \|\Pi^k w - [w]\|_{0;\mathcal{S}} + \|\Pi^{k-1}w - [w]\|_{0;\mathcal{S}} \\ &\leq Ch_k|[w]|_{1;\mathcal{S}} \;=\; Ch_k|[w-u]|_{1;\mathcal{S}}.\end{aligned}$$

Combining these results and using $2h_k = h_{k-1}$, we obtain

$$\begin{aligned}\|u-v\|_1 &\leq C\left(\|u-w\|_1 + \sum_{k=l+1}^L \sqrt{h_k}|[w-u]|_{1;\mathcal{S}}\right) \\ &\leq C\left(\|u-w\|_1 + \sqrt{h_l}|[w-u]|_{1;\mathcal{S}}\right) \\ &\leq C\left(\|u-w\|_1 + \sqrt{h_l}|[I^l u - u]|_{1;\mathcal{S}} + \sqrt{h_l}|[\Pi^l I^l u]|_{1;\mathcal{S}}\right) \\ &\leq C\left(\|u-w\|_1 + h_l|u|_{3/2;\mathcal{S}}\right) \;\leq\; Ch_l|u|_2.\end{aligned}$$

To bound $|[\Pi^l I^l u]|_{1;\mathcal{S}}$, we have used an inverse estimate and the stability of the mortar projection in the $H_{00}^{1/2}$-norm. ∎

Unfortunately, the nested spaces $\widetilde{V}^l$ do not, in general, provide optimal multigrid results. Figure 4.1 shows the asymptotic convergence rates of a $\mathcal{V}$-cycle with one smoothing step.

In the left picture, the domain is decomposed into two subdomains and there are no crosspoints. For this situation, we observe level independent convergence rates.

However, in the more general case of many subdomains, this does not hold. This is illustrated in the right picture. For a decomposition into 13 subdomains and with six crosspoints, we find that the convergence rates depend on the refinement level. To advance our understanding, we consider the stiffness matrix $\widetilde{A}^l$ associated with $\widetilde{V}^l$ in more detail. As in the standard case, its smallest eigenvalue is of order $1/(h_l)^2$ but its largest eigenvalue is not uniformly bounded independently of the refinement level. This is caused by the modified basis functions φ_p^l, associated with the crosspoints, for which the energy is not bounded by a constant. As a consequence, the condition number of $\widetilde{A}^l$ is not of order $1/(h_l)^2$, and we do not obtain level independent convergence rates.

To obtain better numerical results, we have to work with different spaces. We introduce a subspace of $\widetilde{V}^l$. Let $\widehat{V}^l$ be defined by

$$\begin{aligned}\widehat{V}^L &:= V^L,\\ \widehat{V}^l &:= \{v \in \widetilde{V}^l \mid [v]_{|\gamma_m} \in H_{00}^{1/2}(\gamma_m), 1 \le m \le M\}, \quad 0 \le l \le L-1.\end{aligned}$$

The condition $[v]_{|\gamma_m} \in H_{00}^{1/2}(\gamma_m)$ for all interfaces is equivalent to making v continuous at the crosspoints. We note that $\widehat{V}^l \not\subset H_0^1(\Omega)$ and as a consequence, the Galerkin orthogonality does not hold. The proof of Lemma 4.1 gives rise to the following corollary. By definition $w := Q^l I^l u$ is continuous at the crosspoints and thus $v := P^l w \in \widehat{V}^l$.

COROLLARY 4.2. *The nested spaces $\widehat{V}^l$, $0 \le l \le L$, satisfy an approximation property, i.e.,*

$$\inf_{v \in \widehat{V}^l} \|u - v\|_1 \le C h_l |u|_2, \quad u \in H^2(\Omega) \cap H_0^1(\Omega),$$

where the constant $C < \infty$ does not depend on L and h_l.

We now define $\widehat{u}^l \in \widehat{V}^l$ as the solution of the following positive definite variational problem: find $\widehat{u}^l \in \widehat{V}^l$ such that

$$a(\widehat{u}^l, v) = (f, v)_0, \quad v \in \widehat{V}^l.$$

To obtain optimal a priori estimates, the consistency error has to be of order h_l.

LEMMA 4.3. *The discrete finite element solution $\widehat{u}^l$, $0 \le l \le L$, satisfies the following a priori estimate for $u \in H_0^1(\Omega) \cap H^2(\Omega)$:*

$$\|u - \widehat{u}^l\|_1 + \frac{1}{h_l}\|u - \widehat{u}^l\|_0 \le C h_l |u|_2,$$

where the constant does not depend on L and h_l.

Proof. We start with the jump of an element $w \in \widehat{V}^l$. Using the orthogonality of $[w]$ to M^L, we find

$$\|[w]\|_{0;\mathcal{S}}^2 = ([w],[w])_{0;\mathcal{S}} \le \|[w]\|_{0;\mathcal{S}} \inf_{\mu \in M^L} \|[w] - \mu\|_{0;\mathcal{S}} \le C\sqrt{h_L}\, |[w]|_{1/2;\mathcal{S}}\, \|[w]\|_{0;\mathcal{S}}.$$

In terms of the approximation property of M^L and the orthogonality of $[w]$ to M^L, the upper bound for the jump results in a bound on the consistency error given by

$$\sup_{\substack{w \in \widehat{V}^l \\ w \neq 0}} \frac{\int_{\mathcal{S}} \frac{\partial u}{\partial n}[w]\, d\sigma}{\|w\|_1} \le C\sqrt{h_L} \inf_{\mu \in M^L} \|\frac{\partial u}{\partial n} - \mu\|_{0;\mathcal{S}} \sup_{\substack{w \in \widehat{V}^l \\ w \neq 0}} \frac{|[w]|_{1/2;\mathcal{S}}}{\|w\|_1} \le C h_L |u|_2.$$

We note that the consistency error of an element in $\widehat{V}^l$ is, in general, smaller than for an element in V^l. It is of order h_L for all $v \in \widehat{V}^l$, $0 \le l \le L$, whereas it is of order h_l for $v \in V^l$. This is due to the fact that the jump is orthogonal to M^L and not only to M^l. The space M^l is associated with the mesh on level l whereas M^L is associated with that on level L and $\dim M^L > \dim M^l$. Then, the a priori estimate in the energy norm follows from Corollary 4.2. The a priori estimate in the L^2-norm can easily be obtained by using the H^2-regularity and the Aubin–Nitsche trick for nonconforming elements. In that case, the consistency error of the dual problem enters additionally in the upper bound. ∎

Although the spaces $\widehat{V}^l$ are nested, we are in a nonconforming setting. In contrast to standard conforming approaches, no Galerkin orthogonality holds, and we cannot bound $\|u - \widehat{u}^l\|_0$ by $Ch_l\|u - \widehat{u}^l\|_1$. However, a weaker result can be established.

COROLLARY 4.4. *There exists a constant independent of the level L such that*

$$\|\widehat{u}^l - \widehat{u}^{l-1}\|_0 \le Ch_l\|\widehat{u}^l - \widehat{u}^{l-1}\|_1, \quad 0 \le l \le L.$$

Proof. We start with a discrete Galerkin orthogonality

$$a(\widehat{u}^l - \widehat{u}^{l-1}, v) = 0, \quad v \in \widehat{V}^{l-1}.$$

Introducing $w \in H_0^1(\Omega)$ by $a(w, v) = (\widehat{u}^l - \widehat{u}^{l-1}, v)_0$, $v \in H_0^1(\Omega)$ and $\widehat{w}^k \in \widehat{V}^k$ by $a(\widehat{w}^k, v) = (\widehat{u}^l - \widehat{u}^{l-1}, v)_0$, $v \in \widehat{V}^k$, we find

$$\begin{aligned}\|\widehat{u}^l - \widehat{u}^{l-1}\|_0^2 &= a(\widehat{w}^l, \widehat{u}^l - \widehat{u}^{l-1}) = a(\widehat{w}^l - \widehat{w}^{l-1}, \widehat{u}^l - \widehat{u}^{l-1}) \\ &\le C\|\widehat{u}^l - \widehat{u}^{l-1}\|_1\|\widehat{w}^l - \widehat{w}^{l-1}\|_1 \le C\|\widehat{u}^l - \widehat{u}^{l-1}\|_1(\|\widehat{w}^l - w\|_1 + \|\widehat{w}^{l-1} - w\|_1).\end{aligned}$$

Then, the a priori estimate in the energy norm and the H^2-regularity yield the upper bound for $\|\widehat{u}^l - \widehat{u}^{l-1}\|_0$. ∎

Following the approach in [16], we have to consider the condition number of the modified stiffness matrix $\widehat{A}^l$ associated with the nested spaces $\widehat{V}^l$ to obtain level independent convergence rates. The ellipticity of the bilinear form $a(\cdot, \cdot)$ on $\widehat{V}^l \times \widehat{V}^l$ guarantees

$$c\|v\|_0^2 \le a(v, v) \le C\|v\|_1^2, \quad v \in \widehat{V}^l, \quad 0 \le l \le L.$$

We define $\widehat{\mathcal{N}}_c^l$ as a subset of $\mathcal{N}_c^l$ such that $p \in \widehat{\mathcal{N}}_c^l$ if p does not coincide geometrically with a crosspoint. We now use the following basis of $\widehat{V}^l \subset \widetilde{V}^l$:

$$\{\varphi_p^l, \ p \in \widehat{\mathcal{N}}_c^l\} \cup \left\{ \sum_{p \in \mathcal{C}_q} \varphi_p^l, \ q \in \mathcal{C} \right\},$$

where $\mathcal{C}$ is the set of crosspoints of the domain decomposition, and $p \in \mathcal{C}_q$ if and only if $p \in \mathcal{N}_c^l$ coincides geometrically with the crosspoint $q \in \mathcal{C}$. In what follows, we use the same symbol for the function v as an element in the finite element space S, $S \in \{X^l, \widetilde{V}^l, \widehat{V}^l\}$, and its vector representation $v \in \mathbb{R}^{\dim S}$ with respect to the specified basis functions of S.

We denote by $\|\cdot\|_S$ the Euclidean vector norm. Then for the L^2-norm of $v \in \widehat{V}^l$, we find the standard estimate

$$\|v\|_0 \ge \frac{c}{h_l}\|v\|_{\widehat{V}^l}, \quad 0 \le l \le L,$$

where the constant $c > 0$ does not depend on the level L. We recall that the operator P^l does not modify the values at the interior and master nodes on level l. The following lemma provides an upper bound for the condition number of the stiffness matrix $\widehat{A}^l$.

LEMMA 4.5. *There exists a constant $C < \infty$ independent of the level L such that*

$$\kappa(\widehat{A}^l) \leq \frac{C}{h_l^2}, \quad 0 \leq l \leq L.$$

Proof. It is sufficient to establish a suitable upper bound for the energy norm of $v \in \widehat{V}^l$. Each $v \in \widehat{V}^l$ can be written as

$$v = Q^L \; Q^{L-1} \; \ldots \; Q^{l+1} \; Q^l w,$$

where $w \in X^l$ is continuous at the crosspoints and vanishes at all nodes $p \in \mathcal{N}_s^l$. We note that w is uniquely defined. Lemma 3.2 and the triangle inequality yield

$$\|v\|_1 \leq \|w - E^l \Pi^l w\|_1 + \sum_{j=l+1}^{L} \|E^j(\Pi^j - \Pi^{j-1})w\|_1. \tag{4.1}$$

In a first step, we establish an upper bound for $\|w - E^l\Pi^l w\|_1$. The definition of E^l and Π^l gives $z := w - E^l\Pi^l w \in V^l$. Applying an inverse estimate and using the continuity of z, we obtain

$$\begin{aligned} \|z\|_1^2 \leq \frac{C}{h_l^2}\|z\|_0^2 &\leq C \sum_{p \in \mathcal{N}_u^l} z(p)^2 \leq C\left(\sum_{p \in \mathcal{N}_c^l} z(p)^2 + \sum_{p \in \mathcal{N}_s^l} z(p)^2 \right) \\ &\leq C\left(\|z\|_{V^l}^2 + \sum_{p \in \mathcal{N}_s^l} z(p)^2 \right). \end{aligned}$$

The second term on the right-hand side can be bounded as follows: For each node $p \in \mathcal{N}_s^l$, we find due to the mortar condition on level l that

$$z(p) = \sum_{q \in \mathcal{N}_c^l} \frac{\int_{\mathcal{S}} z(q)[\phi_q^l]\mu_p^l \, d\sigma}{\int_{\mathcal{S}} \phi_p^l \, d\sigma}.$$

We denote the set of nodes $q \in \mathcal{N}_c^l$ such that supp $\phi_q^l \cap$ supp μ_p^l has a nonzero measure by $\mathcal{I}_p$. Moreover, the number of elements in $\mathcal{I}_p$ is bounded independently of p and L. Now, $z(p)$ can be bounded by

$$z(p)^2 \leq C \sum_{q \in \mathcal{I}_p} z(q)^2,$$

and as a result, we find $\sum_{p \in \mathcal{N}_s^l} z(p)^2 \leq C\|z\|_{V^l}^2$. Observing that Q^j, $j > l$, does not modify the values at the mortar nodes on level l, we get $z(p) = v(p)$ for all $p \in \mathcal{N}_c^l$. We note that dim $V^l \geq$ dim $\widehat{V}^l$ and thus $\|z\|_{V^l} \geq \|v\|_{\widehat{V}^l}$. However, by construction, z is continuous at the crosspoints and therefore $\|z\|_{V^l} \leq C\|v\|_{\widehat{V}^l}$. In a second step, we have to consider the second term on the right-hand side in (4.1). A standard inverse inequality shows

$$\begin{aligned} \|E^j(\Pi^j - \Pi^{j-1})w\|_1 &\leq \frac{C}{h_j}\|E^j(\Pi^j - \Pi^{j-1})w\|_0 \leq \frac{C}{\sqrt{h_j}}\|(\Pi^j - \Pi^{j-1})w\|_{0;\mathcal{S}} \\ &\leq \frac{C}{\sqrt{h_j}}\left(\|\Pi^j w - [w]\|_{0;\mathcal{S}} + \|\Pi^{j-1}w - [w]\|_{0;\mathcal{S}} \right). \end{aligned}$$

The continuity of w at the crosspoints guarantees that $[w]_{|\gamma_m} \in H_{00}^{1/2}(\gamma_m)$ for all interfaces γ_m, $1 \le m \le M$. Thus, we can apply Lemma 3.1 and get

$$\|E^j(\Pi^j - \Pi^{j-1})w\|_1 \le C\sqrt{h_j}|[w]|_{1;\mathcal{S}} \le C\frac{\sqrt{h_j}}{h_l}|[w]|_{0;\mathcal{S}} \le C\frac{\sqrt{h_j}}{\sqrt{h_l}}\|v\|_{\widehat{V}^l}.$$

Here, we have used $w \in X^l$ with $w(p) = v(p)$ for all interior and master nodes on level l and $w(p) = 0$ for all slave nodes $p \in \mathcal{N}_s^l$. In terms of (4.1), we obtain

$$\|v\|_1 \le C\sum_{j=l}^{L}\frac{\sqrt{h_j}}{\sqrt{h_l}}\|v\|_{\widehat{V}^l} \le C\sum_{j=0}^{\infty}\sqrt{2}^{-j}\|v\|_{\widehat{V}^l} \le C\|v\|_{\widehat{V}^l}. \qquad \square$$

We can now formulate our main result. Here, u_n^L stands for the nth multigrid iterate, and u^L is the mortar finite element solution on level L. Our multigrid method is based on the nested sequence $\widehat{V}^0 \subset \widehat{V}^1 \subset \cdots \subset \widehat{V}^{L-1} \subset V^L$. Moreover, we use the natural embedding to define the prolongation operator, and the restriction matrix is its transpose. We apply a damped Richardson iteration as the smoothing operator, and the damping factor ω on level l is bounded by $c/\widehat{\lambda}_{\max}^l \le \omega \le 1/\widehat{\lambda}_{\max}^l$, where $\widehat{\lambda}_{\max}^l$ is the maximal eigenvalue of the stiffness matrix associated with the nodal basis of $\widehat{V}^l$.

THEOREM 4.6. *There exists a constant independent of the refinement level L such that the $\mathcal{V}$-cycle multigrid convergence rate is given by*

$$a(u^L - u_n^L, u^L - u_n^L) \le \left(\frac{C}{C+m}\right)^2 a(u^L - u_{n-1}^L, u^L - \widehat{u}_{n-1}^L),$$

where m denotes the number of smoothing steps.

The condition number bound in combination with the approximation property and the construction of the nested sequence of spaces yields level independent convergence rates for the $\mathcal{V}$-cycle multigrid method with one smoothing step; see [11, 13, 20]. Using the approach given in [16], the proof follows from Corollary 4.4 and Lemma 4.5. The results can also be extended to other multigrid variants such as, e.g., the $\mathcal{W}$-cycle.

Remark 4.7. We note that on the finest level no continuity at the crosspoints is required.

5. Algebraic formulation. The multigrid method proposed in the previous section is based on the natural embedding of the spaces. In this section, we consider the algebraic representation of the prolongation and restriction and show how the stiffness matrix $\widehat{A}^l$ from Lemma 4.5 can be recursively assembled. We start by describing how to obtain the stiffness matrix associated with the nodal basis of V^L. Let us denote by A the stiffness matrix associated with the unconstrained product space X^L. For simplicity, we suppress the level index L. Then A has a block diagonal structure. We use a decomposition of the matrix into block matrices and three different sets of nodes: $\mathcal{N}_s^l$, $\mathcal{N}_m^l$, and $\mathcal{N}_i^l$. The index set $\mathcal{N}_i^l$ contains all nodes not on the interfaces $\overline{\gamma}_m$, $1 \le m \le M$. All nodes being on the master sides and all nodes coinciding geometrically with a crosspoint are in $\mathcal{N}_m^l$; i.e., $\mathcal{N}_m^l = \mathcal{N}_c^l \setminus \mathcal{N}_i^l$. We recall that the set $\mathcal{N}_s^l$ stands for the nodes on level l associated with the vertices in the interior of the slave sides. Now, each vector $x \in \mathbb{R}^{n_L}$, $n_L := \dim X^L$, can be decomposed according to the three different blocks in $x = (x_i, x_m, x_s)^T$. Then, each

element in $v \in V^L$ can be written in terms of the nodal basis of X^L, and we find for the algebraic representation

$$x = \begin{pmatrix} x_i \\ x_m \\ x_s \end{pmatrix} = \begin{pmatrix} \mathrm{Id} & 0 \\ 0 & \mathrm{Id} \\ 0 & M \end{pmatrix} \begin{pmatrix} v_i \\ v_m \end{pmatrix} =: Bv,$$

where M is a sparse mass matrix associated with the mortar projection. We note that x and v as functions are the same, but their algebraic representations differ. We observe that each $x \in X^L$ is in V^L if and only if it has the algebraic form $x = (x_i, x_m, Mx_m)^T$ with respect to the nodal basis of X^L. We now define the stiffness matrix A^{c} by

$$A^{\mathrm{c}} := \begin{pmatrix} A_{ii} & A_{im} + A_{is}M \\ A_{mi} + M^T A_{si} & A_{\mathrm{mod}} \end{pmatrix},$$

where A_{kl}, $k, l \in \{s, m, i\}$, are the block matrices of the stiffness matrix A associated with the nodal basis functions of X^L, and $A_{\mathrm{mod}} := A_{mm} + M^T A_{ss} M + A_{ms} M + M^T A_{sm}$.

LEMMA 5.1. *The variational problem* (2.1) *on level* L *is equivalent to the algebraic system*

$$A^{\mathrm{c}} u_L = f^{\mathrm{c}} := \begin{pmatrix} f_i \\ f_m + M^T f_s \end{pmatrix}.$$

Proof. Observing that each test function $v \in V^L$ has the algebraic form $v = (v_i, v_m, Mv_m)^T$ with respect to the nodal basis of X^L, we obtain $v^T f = (v_i, v_m)(f_i, f_m + M^T f_s)^T$, where f is the algebraic representation of the right-hand side with respect to the nodal basis of X^L. Thus, the variational problem (2.1) can be written as $(Bv)^T A(Bu_L) = v^T (B^T AB) u_L = (Bv)^T f = v^T (B^T f)$. It is now easy to verify that $A^{\mathrm{c}} = (B^T AB)$ and $f^{\mathrm{c}} = (B^T f)$. ∎

Remark 5.2. In contrast to standard mortar approaches the matrix A^{c} can easily be assembled from A by local post processing. A crucial role is played by the structure of M. Only in the case of a dual Lagrange multiplier space is M a sparse scaled mass matrix. In the case of standard Lagrange multipliers, M has the form $M = M_s^{-1} M_m$, where M_m is a rectangular mass matrix and M_s is tridiagonal.

In the rest of this section, we focus on the prolongation operator. Let I_l^{l+1} be the algebraic representation of the natural embedding of X^l in X^{l+1}, and let W_l be the matrix representation of the projection operator Q^l. Using the definition of $Q^l : X^l \longrightarrow X^l$, we find

$$W_l := \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & 0 \\ 0 & M & 0 \end{pmatrix}. \tag{5.1}$$

The following lemma shows that the natural embedding of $\widetilde{V}^l$ in $\widetilde{V}^{l+1}$ can be expressed in terms of I_l^{l+1} and W_l.

LEMMA 5.3. *Let the interpolation matrix* Z_l^{l+1} *be defined by*

$$Z_l^{l+1} := \begin{pmatrix} (I_l^{l+1})_{ii} & (I_l^{l+1})_{im} + (I_l^{l+1})_{is} M_l \\ 0 & (I_l^{l+1})_{mm} \end{pmatrix},$$

where $(I_l^{l+1})_{jk}$, $j,k \in \{i,m,s\}$, *denote the block components of* I_l^{l+1}. *Then,* Z_l^{l+1} *is the matrix representation of the natural embedding of* $\widetilde{V}^l$ *in* $\widetilde{V}^{l+1}$.

Proof. We start by considering the nodal basis functions of $\widetilde{V}^l$ and $\widetilde{V}^{l+1}$ in more detail. The algebraic representation of φ_p^l in the nodal basis of X^L is given by

$$W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_l^{l+1} W_l e_p^l,$$

where e_p^l denotes the unit vector of $\mathbb{R}^{n_l}$, $n_l := \dim X^l$, associated with the node p on level l. Analogously, the algebraic presentation of φ_p^{l+1} in the nodal basis of X^L is given by

$$W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_{l+1}^{l+2} W_{l+1} e_p^{l+1},$$

where e_p^{l+1} denotes the unit vector of $\mathbb{R}^{n_{l+1}}$, $n_{l+1} := \dim X^{l+1}$, associated with the node p on level $l+1$. We now consider the natural embedding $\widetilde{V}^l \subset \widetilde{V}^{l+1}$. Each element $v \in \widetilde{V}^l \subset \widetilde{V}^{l+1} \subset X^L$ can be written uniquely as a linear combination of the nodal basis functions φ_p^l, φ_p^{l+1}, and θ_p^L

$$v = \sum_{p \in \mathcal{N}_c^l} v_p^l \varphi_p^l = \sum_{p \in \mathcal{N}_c^{l+1}} v_p^{l+1} \varphi_p^{l+1} = \sum_{p \in \mathcal{N}_u^L} x_p^L \theta_p^L.$$

We define $w^l \in \mathbb{R}^{n_l}$ by $w_p^l := v_p^l$, $p \in \mathcal{N}_c^l$ and $w_p^l := 0$, $p \in \mathcal{N}_s^l$, and $w^{l+1} \in \mathbb{R}^{n_{l+1}}$ by $w_p^{l+1} = v_p^{l+1}$, $p \in \mathcal{N}_c^{l+1}$ and $w_p^{l+1} = 0$, $p \in \mathcal{N}_s^{l+1}$. We then find

$$W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_l^{l+1} W_l w^l = W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_{l+1}^{l+2} W_{l+1} w^{l+1}.$$

In the next step, we decompose $I_l^{l+1} W_l w^l = c^{l+1} + y^{l+1}$, where $c_p^{l+1} = 0$, $p \in \mathcal{N}_s^{l+1}$ and $y_p^{l+1} = 0$, $p \in \mathcal{N}_c^{l+1}$. We note that this decomposition is unique. Moreover, the definition of W_{l+1} yields $W_{l+1} y^{l+1} = 0$ and thus $W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_l^{l+1} W_l w^l = W_L I_{L-1}^L W_{L-1} I_{L-2}^{L-1} \dots I_{l+1}^{l+2} W_{l+1} c^{l+1}$. Observing that the kernel of W_j, $1 \le j \le L$, is associated with the nodes $p \in \mathcal{N}_s^j$, we find $c^{l+1} = w^{l+1}$. A straightforward computation shows that

$$\begin{aligned} c^{l+1} &= \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} (I_l^{l+1})_{ii} & (I_l^{l+1})_{im} & (I_l^{l+1})_{is} \\ 0 & (I_l^{l+1})_{mm} & 0 \\ 0 & (I_l^{l+1})_{sm} & (I_l^{l+1})_{ss} \end{pmatrix} \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & 0 \\ 0 & M_l & 0 \end{pmatrix} w^l \\ &= \begin{pmatrix} (I_l^{l+1})_{ii} & (I_l^{l+1})_{im} + (I_l^{l+1})_{is} M_l & 0 \\ 0 & (I_l^{l+1})_{mm} & 0 \\ 0 & 0 & 0 \end{pmatrix} w^l. \end{aligned}$$

Using the structure of w^{l+1} and w^l, we find

$$\begin{pmatrix} v^{l+1} \\ 0 \end{pmatrix} = \begin{pmatrix} Z_l^{l+1} & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} v^l \\ 0 \end{pmatrix},$$

and thus $v^{l+1} = Z_l^{l+1} v^l$. ∎

Figure 5.1 illustrates the prolongation operator. For simplicity, we restrict ourselves to a function in $\widetilde{V}^l$ which vanishes at all interior vertices. The support of such a function is marked by the shadowed region. Then, the function, as an element in $\widetilde{V}^l$, is uniquely defined by its values at the vertices on the master side, which are

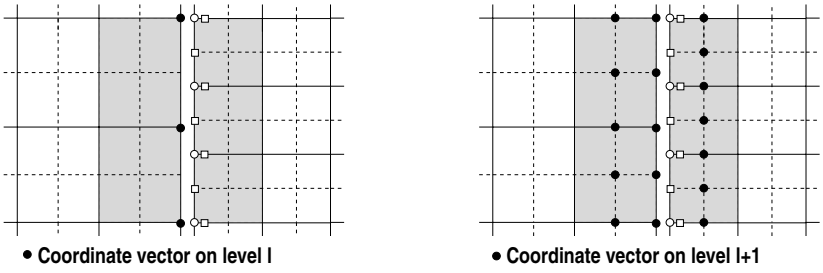

FIG. 5.1. *Prolongation operator from* $\widetilde{V}^l$ *onto* $\widetilde{V}^{l+1}$, $L := l+1$.

marked by filled circles in the left picture of Figure 5.1. The values on the master side are extended on the slave side in the prescribed multiplicative way such that the constraints at the interface on level L are satisfied. The vertices on the slave side on level l are marked by empty circles and on level $L := l+1$ by empty squares. We now interpret the function as an element in $\widetilde{V}^{l+1}$. In the right picture, the relevant vertices to specify the function are shown by filled circles. The values at the filled circles in the interior of the slave subdomain are obtained from the values at the empty circles and the standard prolongation. We note that the values at the empty squares do not contribute.

Remark 5.4. Although the spaces M^l are nonnested, we can assemble the scaled mass matrices M_l, $0 \le l \le L-1$, recursively. We note that M^l can be embedded in a higher dimensional but locally defined space. These macro spaces are nested and can be used for the assembly process. Thus, we have to compute the intersection of the edges on the slave and master sides only on the highest level.

Additionally, we have to consider the spaces $\widehat{V}^l$ which are continuous at the crosspoints. By definition, we have $\widehat{V}^l \subset \widetilde{V}^l$. We start by introducing new sets of nodes. Let $\mathcal{C}^l$ be the set of nodes which coincide geometrically with one crosspoint. For each crosspoint $c \in \mathcal{C}$, we define one master node p_c such that $p_c \in \mathcal{C}^l$ coincides geometrically with the crosspoint c. The choice is arbitrary but should be fixed. Moreover, we set $\mathcal{N}_g^l := \mathcal{N}_m^l \setminus \mathcal{C}^l$ and $\mathcal{C}_m^l := \cup_{c\in\mathcal{C}}\ p_c$. Now, each element $v \in \widetilde{V}^l$ and $v \in \widehat{V}^l$ can be written as (v_i, v_g, v_d) and (v_i, v_g, v_c), respectively. Here, the block vectors are connected to the basis functions associated with the nodes in $\mathcal{N}_i^l$, $\mathcal{N}_g^l$, $\mathcal{C}^l$ and $\mathcal{N}_i^l$, $\mathcal{N}_g^l$, $\mathcal{C}_m^l$, respectively. We note that $\mathcal{N}_m^l = \mathcal{N}_g^l \cup \mathcal{C}^l$. Then, the natural embedding $\widehat{V}^l \subset \widetilde{V}^l$ has the algebraic form

$$\begin{pmatrix} v_i \\ v_g \\ v_d \end{pmatrix} = \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & 0 \\ 0 & 0 & C \end{pmatrix} \begin{pmatrix} v_i \\ v_g \\ v_c \end{pmatrix} =: R_l \begin{pmatrix} v_i \\ v_g \\ v_c \end{pmatrix},$$

where C is a block diagonal matrix. Each block diagonal entry C_{ii} corresponds to one crosspoint $c_i \in \mathcal{C}$ and has the form $C_{ii} := (1, 1, \ldots, 1)^T$, where the number of ones is equal to the number of nodes coinciding geometrically with the crosspoint c_i. We note that the number of columns of C is equal to the number of crosspoints and the number of rows is equal to the number of elements in $\mathcal{C}^l$. Thus the size of C does not depend on the level. On the other hand, each element $v \in \widehat{V}^l$, $l < L$, can be written

as

$$\begin{pmatrix} v_i \\ v_g \\ v_c \end{pmatrix} = \begin{pmatrix} \mathrm{Id} & 0 & 0 \\ 0 & \mathrm{Id} & 0 \\ 0 & 0 & DC^T \end{pmatrix} \begin{pmatrix} v_i \\ v_g \\ v_d \end{pmatrix} =: \widehat{R}_l^T \begin{pmatrix} v_i \\ v_g \\ v_d \end{pmatrix},$$

where $D \in \mathbb{R}^{n_c \times n_c}$ is a diagonal matrix, and n_c is the number of crosspoints. The entries are defined by $d_{ii} := 1/k_i$, where k_i is the number of nodes coinciding geometrically with the crosspoint c_i. We point out that DC^T does not depend on the level, and we set formally $\widehat{R}_L^T := \mathrm{Id}$. Then, the algebraic representation of the embedding of $\widehat{V}^l \subset \widehat{V}^{l+1}$, $0 \le l \le L-1$, is given by

$$\widehat{Z}_l^{l+1} = \widehat{R}_{l+1}^T Z_l^{l+1} R_l.$$

The coarse stiffness matrices $\widehat{A}_l$ are obtained recursively by a Galerkin assembly

$$\widehat{A}_l := (\widehat{Z}_l^{l+1})^T \widehat{A}_{l+1} \widehat{Z}_l^{l+1}, \quad 0 \le l \le L-1,$$

where $\widehat{A}_L := A^c$. We recall that A^c is the stiffness matrix associated with the constrained space V_L. The restriction of the defect d_{l+1} is given by $d_l := \widehat{Z}_l^T d_{l+1}$. We note that all modifications can be carried out locally. Additionally, they are of smaller complexity than one matrix vector multiplication, and only the nodes on the interfaces are involved.

Remark 5.5. In contrast to the approach given in [19], we work with a nested sequence of nonconforming spaces. The coarse spaces satisfy the constraints with respect to the highest level. As a result, we can use the natural embedding operator as prolongation. Using a Gauß–Seidel smoother, this yields a monotone variant. A combination of monotone multigrid techniques for Signorini problems [21, 22, 23] with our approach gives a globally convergent monotone multigrid strategy for variational inequalities based on interface constraints; see [29].

Remark 5.6. The construction of the spaces $\widehat{V}^l$ is restricted to the two-dimensional situation and has to be generalized in three dimensions (3D). In 3D, we cannot, in general, require continuity on the wirebasket. However, as in two dimensions, we can impose continuity at the crosspoints. Additionally, we have to impose a weak matching condition on the edges of the wire basket. This can be realized in terms of one master edge.

6. Numerical results. In this section, we present some numerical results for our multigrid method. They confirm the theoretical results and illustrate the performance of the method. In particular, we consider three different examples with several crosspoints. The numerical realization is based on the finite element toolbox ug [4],and uniform refinement is applied in each refinement step. In all our examples, we compare two different smoothers and show the influence of the number of smoothing steps on the convergence rates. On each level, the initial iterate is set to be zero. As stopping criteria, we use a relative tolerance of 5e−15.

In our first example, we consider a decomposition of the unit square $\Omega = (0,1) \times (0,1)$ into nine squares $\Omega_{ij} := ((i-1)/3, i/3) \times ((j-1)/3, j/3)$, $1 \le i,j \le 3$. The right-hand side f and the boundary conditions of $-\Delta u = f$ are chosen such that the exact solution is given by $u(x,y) = \sin(2\pi y)\exp(-x^{-2})\exp(-0.1(1-x)^{-2}) + \sin(\pi x)\exp(-1.25y^{-2})\exp(-0.1(1-y)^{-2})$. Figure 6.1 shows the decomposition into subdomains, the nonmatching triangulations and the isolines of the solution. The initial triangulation has 72 elements and is nonmatching at the interface.

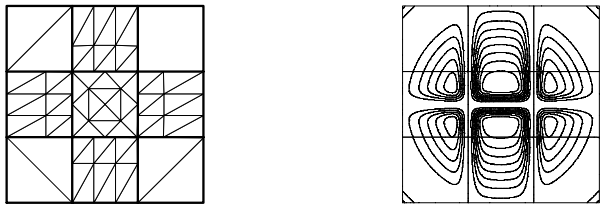

FIG. 6.1. *Decomposition into nine subdomains and initial triangulation (left), isolines of the solution (right) (Example* 1*).*

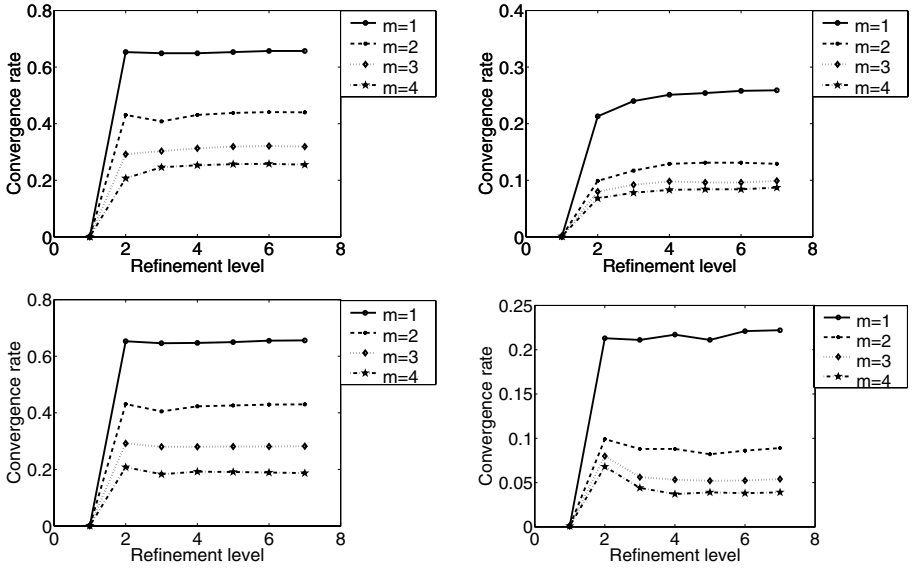

FIG. 6.2. *Asymptotic convergence rates for a damped Jacobi smoother (left) and a symmetric Gauß–Seidel one (right) (Example* 1*). In the first row the $\mathcal{V}(m,m)$-cycle results are shown, and in the second row those of the $\mathcal{W}(m,m)$-cycle results.*

We observe level independent convergence rates for all our tests. In particular, we compare two different types of smoothers. As expected the symmetric Gauß–Seidel smoother yields considerably better results than the damped Jacobi smoother, for $\omega = 0.8$. In each case, we apply m pre- and m postsmoothing steps, $1 \leq m \leq 4$. Increasing the number of smoothing steps gives better results. The first row in Figure 6.2 shows our numerical results for the $\mathcal{V}$-cycle and in the second row those of the $\mathcal{W}$-cycle. There is no big difference between the $\mathcal{V}$-cycle and $\mathcal{W}$-cycle results.

In our second example, we consider a nonconvex domain which is decomposed into 13 subdomains; see Figure 6.3 for the decomposition and the isolines of the solution. We find six crosspoints having four adjacent subdomains.

As in our first example, we observe asymptotically constant convergence rates. In the case of the Jacobi smoother the asymptotic starts later than in the case of the symmetric Gauß–Seidel smoother. We set the numerical convergence rate to be the reduction factor of the residual in the last iteration step. At the beginning of the iteration, $\|r^{l+1}\|/\|r^l\|$ is increasing. However, asymptotically this ratio tends to be a constant value on each refinement level. This constant value is not yet reached on

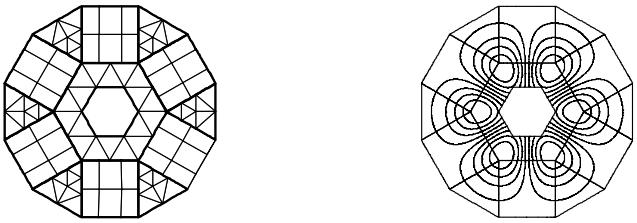

FIG. 6.3. *Decomposition into* 13 *subdomains and initial triangulation (left) and isolines of the solution (right) (Example* 2*).*

the higher levels for the $\mathcal{V}(1,1)$-cycle with the Gauß–Seidel smoother. As a result, we observe, in the right upper picture of Figure 6.4, a decreasing convergence rate. Comparing the multigrid convergence rates of $m = 1$ and $m = 2$, we find a big difference in the case of the Gauß–Seidel smoother. This is also true if we compare $m = 2$ and $m = 4$ in the case of the Jacobi smoother. Taking into account that the symmetric Gauß–Seidel smoother is more expensive than the Jacobi smoother, we cannot compare the results for the same m directly. Comparing the symmetric Gauß–Seidel smoother with $m = 2$ and the Jacobi smoother with $m = 4$, we find that the Gauß–Seidel smoother yields better convergence rates.

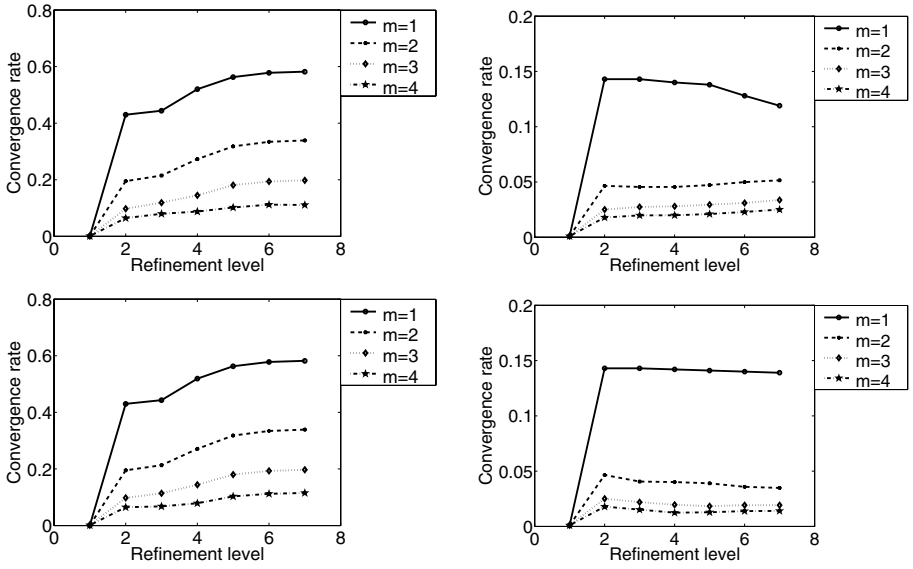

FIG. 6.4. *Asymptotic convergence rates for a damped Jacobi smoother (left) and a symmetric Gauß–Seidel one (right) (Example* 2*). In the first row the $\mathcal{V}(m,m)$-cycle results are shown and in the second row those of the $\mathcal{W}(m,m)$-cycle results.*

In our third example, we consider a decomposition of the unit square $(-0.5, 0.5)^2$ into three subdomains. Two of the subdomains are nonconvex. Figure 6.5 shows the decomposition into the subdomains, the nonmatching triangulations, and the isolines of the solution. The slave sides are chosen to be on the middle subdomain. The right-hand side f and the Dirichlet boundary conditions of $-\Delta u = f$ are chosen such that the exact solution is given by $x(x-y)\exp(-10(x^2+0.6y^2))$.

In this example, the differences between the $\mathcal{V}(m,m)$-cycle and $\mathcal{W}(m,m)$-cycle results are extremely small for the Jacobi smoother; see Figure 6.6. Moreover, the number of iteration steps is the same. The Gauß–Seidel smoother results in better convergence rates for the $\mathcal{W}(m,m)$-cycle. The $\mathcal{V}(1,1)$-cycle and the $\mathcal{W}(2,2)$-cycle show the same effect as the $\mathcal{V}(1,1)$-cycle in Example 2. We observe for all our examples considerably better results if the number of smoothing steps is greater than one.

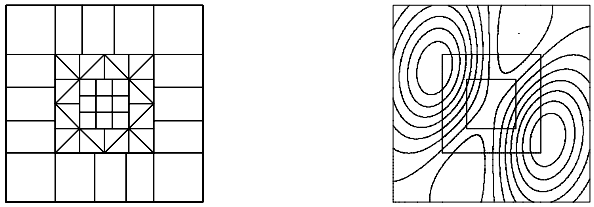

FIG. 6.5. *Decomposition into three subdomains and initial triangulation (left) and isolines of the solution (right) (Example* 3*).*

In contrast to the right picture in Figure 4.1, we observe level independent convergence rates for the $\mathcal{V}$-cycle. A comparison of Figures 4.1 and 6.4 shows the influence of the modification of the nonconforming spaces. The numerical results of Figure 4.1 are based on the nested sequence $\widetilde{V}^0 \subset \widetilde{V}^1 \subset \cdots \subset \widetilde{V}^L$. The condition number of the stiffness matrix associated with these spaces is not bounded by Ch_l^{-2}. As a result, we do not observe level independent convergence rates for the $\mathcal{V}(1,1)$-cycle.

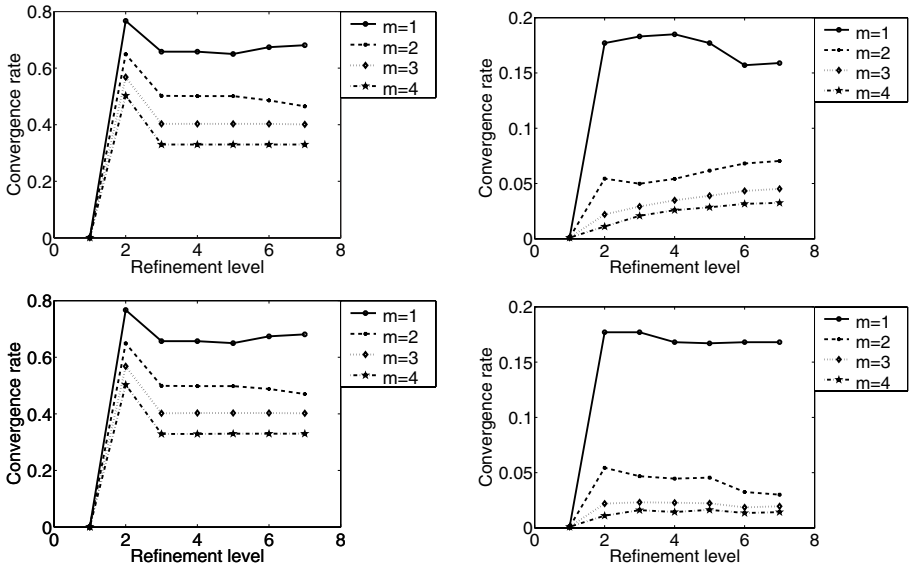

FIG. 6.6. *Asymptotic convergence rates for a damped Jacobi smoother (left) and a symmetric Gauß–Seidel one (right) (Example* 3*). In the first row the $\mathcal{V}(m,m)$-cycle results are shown and in the second row those of the $\mathcal{W}(m,m)$-cycle results.*

Compared to the more general saddlepoint multigrid method analyzed in [9, 25], the performance of this multigrid variant applied to a mortar discretization with dual Lagrange multipliers is considerably better. This is due to the fact that we can exploit the biorthogonality of the Lagrange multiplier and the trace space for the construction

of the solver. In case of the saddlepoint variant this cannot be done, and we have to include an inner iteration loop in the multigrid scheme. Applying this new variant to standard Lagrange multipliers increases the computational cost. The modified stiffness matrices can be easily obtained by local static condensation in the case of dual Lagrange multipliers. This does not hold for standard Lagrange multipliers. In this situation the multiplication with a diagonal matrix has to be replaced by the multiplication with the inverse of a mass matrix, and the resulting stiffness matrix is not as sparse. In both cases, we obtain a condition number which is bounded by Ch_l^{-2}. Compared to [28], the $\mathcal{V}(1,1)$-cycle of this multigrid variant is more robust. In contrast to the two variants discussed in [25, 28], this multigrid variant can also be used in combination with monotone techniques to solve nonlinear multibody contact problems [29]. The monotonicity and thus the convergence of the nonlinear algorithm cannot be guaranteed if we do not work with nested spaces and a positive definite formulation.

EXPLICIT AND AVERAGING A POSTERIORI ERROR ESTIMATES FOR ADAPTIVE FINITE VOLUME METHODS*

C. CARSTENSEN†, R. LAZAROV‡, AND S. TOMOV§

Abstract. Local mesh-refining algorithms known from adaptive finite element methods are adopted for locally conservative and monotone finite volume discretizations of boundary value problems for steady-state convection-diffusion-reaction equations. The paper establishes residual-type explicit error estimators and averaging techniques for a posteriori finite volume error control with and without upwind in global H^1- and L^2-norms. Reliability and efficiency are verified theoretically and confirmed empirically with experimental support for the superiority of the suggested adaptive mesh-refining algorithms over uniform mesh refining. A discussion of adaptive computations in the simulation of contaminant concentration in a nonhomogeneous water reservoir concludes the paper.

Key words. convection-diffusion-reaction equations, 3-D problems, finite volume approximation, a posteriori error estimators, residual estimators, averaging estimators, ZZ refinement indicator

1. Introduction.

We consider the following convection-diffusion-reaction problem: Find $u = u(x)$ such that

$$\begin{cases} Lu \equiv \nabla \cdot (-A\nabla u + \underline{b}u) + \gamma u = f & \text{in } \Omega, \\ u = 0 & \text{on } \Gamma_D, \\ (-A\nabla u + \underline{b}u) \cdot \underline{n} = g & \text{on } \Gamma_N^{\text{in}}, \\ -(A\nabla u) \cdot \underline{n} = 0 & \text{on } \Gamma_N^{\text{out}}. \end{cases} \tag{1.1}$$

Here Ω is a bounded polygonal domain in R^d, $d = 2, 3$; $A = A(x)$ is $d \times d$ symmetric, bounded, and uniformly positive definite matrix in Ω; $\underline{b}$ is a given vector function; $\underline{n}$ is the unit outer vector normal to $\partial\Omega$; and f is a given source function. We have also used the notation ∇u for the gradient of a scalar function u and $\nabla \cdot \underline{b}$ for the divergence of a vector function $\underline{b}$ in R^d. The boundary of Ω, $\partial\Omega$ is split into Dirichlet, Γ_D and Neumann, Γ_N parts. Further, the Neumann boundary is divided into two parts: $\Gamma_N = \Gamma_N^{\text{in}} \cup \Gamma_N^{\text{out}}$, where $\Gamma_N^{\text{in}} = \{x \in \Gamma_N : \underline{n}(x) \cdot \underline{b}(x) < 0\}$ and $\Gamma_N^{\text{out}} = \{x \in \Gamma_N : \underline{n}(x) \cdot \underline{b}(x) \geq 0\}$. We assume that Γ_D has positive surface measure.

This problem is a prototype for flow and transport in porous media. For example, $u(x)$ can represent the pressure head in an aquifer or the concentration of a chemical that is dissolved and distributed in groundwater due to the processes of diffusion, dispersion, and absorption. In many cases $A = \epsilon I$, where I is the identity matrix in

R^d and $\epsilon > 0$ is a small parameter. This corresponds to the important and difficult class of singularly perturbed convection-diffusion problems (see, e.g., the monograph of Ross, Stynes, and Tobiska [31]). In our computations we have used our approach for grid adaptation for this type of problem as well. However, we do not claim that the developed theory in this paper covers this important practical case. Further, $u(x)$ can be viewed as a limit for $t = \infty$ of the solution $u = u(x,t)$ of the corresponding time-dependent problem

$$u_t + Lu = f,\ t > 0,\ x \in \Omega \tag{1.2}$$

with boundary conditions as above and an initial condition $u(x,0) = u_0(x)$, where u_0 is a given function in Ω. Various generalizations, mostly considering nonlinear terms, are possible and widely used in the applications. For example, γu is replaced by a nonlinear reaction term $\gamma(u)$, or the linear convective term $\underline{b}u$ is replaced by a nonlinear flux $\underline{b}(u)$. In this work we follow the framework of the model problem (1.1) and focus on its 3-D setting.

The development of efficient solution methods featuring error control is important for various applications. Our study has been motivated by the research in groundwater modeling and petroleum reservoir simulations (see, e.g., [19]). The solutions of problems in that area exhibit steep gradients and rapid changes due to localized boundary data, discontinuities in the coefficients of the differential equation, and/or other local phenomena (for example, extraction/injection wells, faults, etc.). In order to accurately resolve such local behavior, the numerical method should be able to detect the regions in which the solution changes significantly and to refine the grid locally in a balanced manner so that the overall accuracy is uniform in the whole domain.

Equation (1.1) expresses conservation of the properly scaled quantity u over any subdomain contained in Ω. In the context of groundwater, fluid flow $u(x)$ is in general either the water mass or the mass of the chemical dissolved in the water. Numerical methods that have this property over a number of nonoverlapping subdomains that cover the whole domain are called locally conservative. Finite volumes (control volumes, box schemes), mixed finite elements, and discontinuous Galerkin methods have this highly desirable property. The simplicity of the finite volume approximations combined with their local conservation property and flexibility motivated our study.

There are few works related to a posteriori error estimates for finite volume methods. In [2] Angermann studied a balanced a posteriori error estimate for finite volume discretizations for convection-diffusion equations in two dimensions on Voronoi meshes. The derivation of the error estimator is based on the idea of his previous work [3] on the finite element method. The estimator for the finite volume method contains two new terms which have been studied previously. Some extensions to Angermann's work related to more general situations in respect to space dimension and type of control volumes can be found in Thiele's dissertation [35]. Again, the ideas from the finite element method were exploited in deriving an upper error estimate for the space discretization of parabolic problems. In our paper we use a similar approach; namely, the error estimates for the finite volume method are derived by using the relation between the finite volume and finite element methods (see, e.g., [8]). We note that, despite recent progress (see, e.g., the monographs [23, 26]), the theory of finite volume methods is still under development. This in turn raises certain difficulties in establishing an independent and sharp a posteriori error analysis for the finite volume approximations.

A posteriori error indicators and estimators for the finite element method have been used and studied in the past two decades. Since the pioneering paper of Babuška and Rheinboldt [6], the research in this field has expanded in various directions that include the *residual-based* method (see the survey paper of Verfürth [36]), *hierarchical-based* error estimators [9], estimators based on postprocessing of the approximate solution gradient [37, 38], error estimators that control the error or its gradient in the maximum norm, etc. One popular approach is to evaluate certain local residuals and obtain the a posteriori error indicator by solving local Dirichlet or Neumann problems by taking the local residuals as data [6, 9]. Another variation of the method that controls the global L^2- and H^1-norms of the error uses the Galerkin orthogonality, a priori interpolation estimates, and global stability (see, for example, [21]). Furthermore, solving appropriate dual problems, instead of using the a priori interpolation estimates, leads to error estimators controlling various kinds of error functionals [11]. Solving finite element problems in a space enriched by hierarchical bases functions gives rise to *hierarchical-based* error estimators [9]. There are error estimators based on optimal a priori estimates in a maximum norm [22]. Another type of error estimator/indicator, widely (and in most cases heuristically) used in many adaptive finite element codes, is based on postprocessing (averaging) of the approximate solution gradient (see [37, 38]). In the context of the finite element method for elliptic partial differential equations, averaging or recovery techniques are justified in [10, 14, 30]. Finally, for an extensive study of the efficiency and the reliability of the local estimators and indicators for finite element approximations, we refer to the recent monograph of Babuska and Strouboulis [7].

In this paper we adapt the finite element local error estimation techniques to the case of finite volume approximations. We consider mainly the *residual-based* a posteriori error estimators and analyze the one that uses Galerkin orthogonality, a priori interpolation estimates, and global stability in L^2- and H^1-norms. Our theoretical and experimental findings are similar to those in [2] and could be summarized as follows. The a posteriori error estimates in the finite volume element method are quite close to those in the finite element method, and the mathematical tools from finite element theory can be successfully applied for their analysis. Our computational experiments with various model problems confirm this conclusion. For more computational examples we refer to [25].

The paper is organized as follows. We start with the finite volume element formulation in section 2. The section defines the used notation and approximations and gives some general results from the finite volume approximations. Section 3 studies the *residual-based* error estimator, followed by a short description of the used adaptive refinement strategy (in section 4). Finally, in section 5, we present numerous computational results for 2-D and 3-D test problems which illustrate the adaptive strategy and support our theoretical findings.

2. Finite volume element approximation. Subsection 2.1 introduces the notation used in the paper. In subsection 2.2 we define the finite volume element approximations and give an a priori estimate for the error.

2.1. Notation. We denote by $L^2(K)$ the square-integrable real-valued functions over $K \subset \Omega$, by $(\cdot,\cdot)_{L^2(K)}$ the inner product in $L^2(K)$, and by $|\cdot|_{H^1(K)}$ and $||\cdot||_{H^1(K)}$, respectively, the seminorm and norm of the Sobolev space $H^1(K)$, namely,

$$||u||_{L^2(K)} := (u,u)^{1/2}_{L^2(K)}, \qquad |u|_{H^1(K)} := (\nabla u, \nabla u)^{1/2}_{L^2(K)},$$
$$||u||^2_{H^1(K)} := ||u||^2_{L^2(K)} + |u|^2_{H^1(K)}.$$

In addition, if $K = \Omega$, we suppress the index K and also write $(\cdot,\cdot)_{L^2(\Omega)} := (\cdot,\cdot)$ and $||\cdot||_{L^2} := ||\cdot||$. Further, we use the Hilbert space $H^1_D(\Omega) = \{v \in H^1(\Omega) :\ v|_{\Gamma_D} = 0\}$. Finally, we denote by $H^{1/2}(\partial K)$ the space of the traces of functions in $H^1(K)$ on the boundary ∂K.

To avoid writing unknown constants we use the notation $a \lesssim b$ instead of the inequality $a \le Cb$, where the constant C is independent of the mesh size h.

In our analysis we shall use the following simple inequality valid for $\Omega \subset R^d$, $d > 1$, with Lipschitz continuous boundary $\partial\Omega$ (called Ilin's inequality; cf., e.g., [28]): Let Ω_δ be a strip along $\partial\Omega$ of width δ. Then

$$
\begin{aligned}
&||u||_{L^2(\Omega_\delta)} \lesssim \delta^{1/2}||u||_{H^1(\Omega)} \quad \text{for all } u \in H^1(\Omega);\\
&||u||_{L^2(\Omega_\delta)} \lesssim \delta^{s}||u||_{H^s(\Omega)} \quad \text{for all } u \in H^s(\Omega),\ 0 < s < 1/2.
\end{aligned}
\tag{2.1}
$$

The first inequality is trivial in the case where Ω is a half-space and u has a compact support. The proof in the general case will follow easily by using partition of unity and transforming each subdomain into half-space. The second inequality is obtained using the fact that $||u||_{L^2(\Omega_\delta)} \lesssim \delta||u||_{H^1(\Omega)}$ for all $u \in H^1_0(\Omega)$ and interpolation of Banach spaces (cf., e.g., [1]).

Next, we introduce the bilinear form $a(\cdot,\cdot)$ defined on $H^1_D(\Omega) \times H^1_D(\Omega)$ as

$$
a(u,v) := (A\nabla u - \underline{b}u, \nabla v) + (\gamma u, v) + \int_{\Gamma_N^{\text{out}}} \underline{b}\cdot\underline{n}\ u\ v\, ds. \tag{2.2}
$$

We assume that the coefficients of problem (1.1) are such that

(a) the form is $H^1_D(\Omega)$-elliptic (coercive); i.e., there is a constant $c_0 > 0$ such that

$$
c_0||u||_{H^1} \le a(u,u) \quad \text{for all } u \in H^1_D(\Omega); \tag{2.3}
$$

(b) the form is bounded (continuous) on $H^1_D(\Omega)$; i.e., there is a constant $c_1 > 0$ such that

$$
a(u,v) \le c_1||u||_{H^1}||v||_{H^1} \quad \text{for all } u,\ v \in H^1_D(\Omega). \tag{2.4}
$$

The above two conditions guarantee that the expression $a(u,u)$ is equivalent to the norm in $H^1_D(\Omega)$. Further, we shall use the notation $||u||_a^2 = a(u,u)$ and call this expression the "energy" norm.

A sufficient condition for the coercivity of the bilinear form is $\gamma(x)+0.5\nabla\cdot\underline{b}(x) \ge 0$ for all $x \in \Omega$, while a sufficient condition for the continuity is boundedness of the coefficients $A(x)$, $\underline{b}(x)$, and $\gamma(x)$ in Ω. Further in the paper we assume that these conditions are satisfied. Then (1.1) has the following weak form: Find $u \in H^1_D(\Omega)$ such that

$$
a(u,v) = F(v) := (f,v) - \int_{\Gamma_N^{\text{in}}} gv\, ds \quad \text{for all } v \in H^1_D(\Omega). \tag{2.5}
$$

2.2. Approximation method. The domain Ω is partitioned into triangular (for the 2-D case) or tetrahedral (for the 3-D case) finite elements denoted by K. The

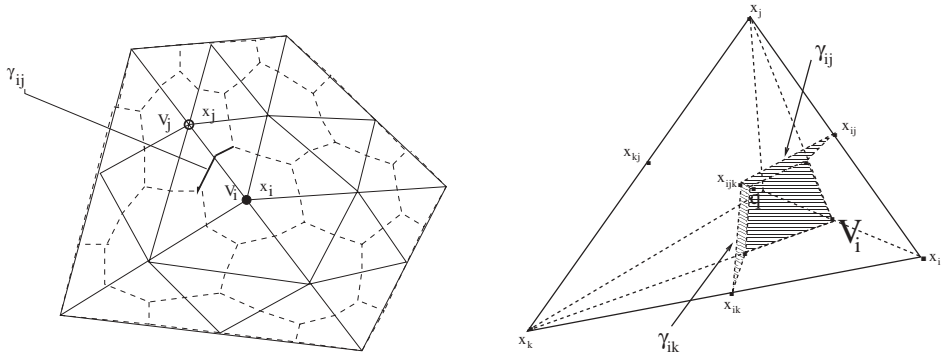

FIG. 1. *Left: Finite element and finite volume partitions in two dimensions. Right: Contribution from one element to control volume V_i, γ_{ij}, and γ_{ik} in three dimensions; point q is the element's medicenter. Internal points for the faces are the medicenters of the faces.*

elements are considered to be closed sets and the splitting, often called triangulation of Ω, is denoted by $\mathcal{T}$. We assume that the mesh is aligned with the discontinuities of the coefficients of the differential equation (if any), with the data f and g, and with the interfaces between Γ_D, Γ_N^{out}, and Γ_N^{in}.

We note that our analysis will be valid also for domains with smooth boundaries. In this case we have to modify the triangulation so that the methods do not lose accuracy due to approximation of the domain. Such schemes have been discussed in [18].

We introduce the set $N_h = \{x_i : x_i \text{ is a vertex of element } K \in \mathcal{T}\}$ and denote by N_h^0 the set of all vertices in N_h except those on Γ_D. For a given vertex x_i we denote by $\Pi(i)$ the index set of all neighbors of x_i in N_h, i.e., all vertices that are connected to x_i by an edge.

For a given finite element triangulation $\mathcal{T}$, we construct a dual mesh $\mathcal{T}^*$ (based upon $\mathcal{T}$), whose elements are called control volumes (boxes, finite volumes, etc.). There are various ways to introduce the control volumes. Almost all approaches can be described in the following general scheme. In each element $K \in \mathcal{T}$ a point q is selected. For the 3-D case, on each of the four faces $\overline{x_i x_j x_k}$ of K a point x_{ijk} is selected and on each of the six edges $\overline{x_i x_j}$ a point x_{ij} is selected. Then q is connected to the points x_{ijk}, and in the corresponding faces, the points x_{ijk}, are connected to the points x_{ij} by straight lines (see Figure 1). Control volume associated with a vertex x_i is denoted by V_i and defined as the union of the "quarter" elements $K \in \mathcal{T}$, which have x_i as a vertex (see Figure 1). The interface between two control volumes, V_i and V_j, is denoted by γ_{ij}, i.e., $\overline{V}_i \cap \overline{V}_j = \gamma_{ij}$.

We assume that $\mathcal{T}$ is locally quasi uniform, that is, for $K \in \mathcal{T}$, $|K| \lesssim \rho(K)^d$, where $\rho(K)$ is the radius of the largest ball contained in K and $|K|$ denotes the area or volume of K. In the context of locally refined grids, this means that the smallest interior angle is bounded away from zero and any two neighboring finite elements are of approximately the same size, whereas elements that are far away may have quite different sizes.

In our 3-D computations q is the center of gravity of the element K, x_{ijk} are the centers of gravity of the corresponding faces, and x_{ij} are the mid-points (centers of gravity) of the corresponding edges (as shown on Figure 1).

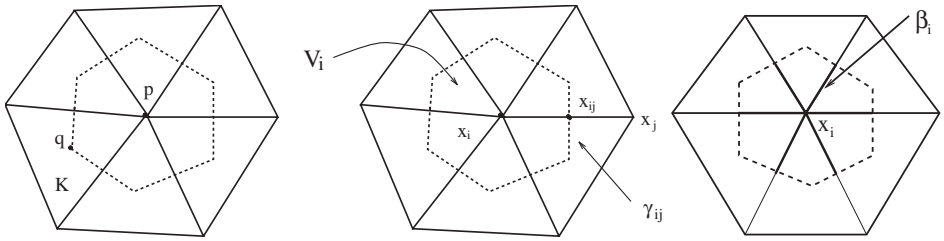

FIG. 2. *Control volumes with circumcenters as internal points (Voronoi meshes) and interface γ_{ij} of V_i and V_j. The rightmost picture shows the segments β_i in bold.*

In two dimensions, another possibility is to choose q to be the center of the circumscribed circle of K. These types of control volumes form Voronoi or perpendicular bisector (PEBI) meshes (see, e.g. [23, pp. 764, 825]). Then obviously, γ_{ij} are the PEBIs of the three edges of K (see Figure 2). This construction requires that all finite elements are triangles of acute type, which we shall assume whenever such triangulation is used.

We define the linear finite element space S_h as

$$S_h = \{v \in C(\Omega) : v|_K \text{ is affine for all } K \in \mathcal{T} \text{ and } v|_{\Gamma_D} = 0\}$$

and its dual volume element space S_h^* by

$$S_h^* = \{v \in L^2(\Omega) : v|_V \text{ is constant for all } V \in \mathcal{T}^* \text{ and } v|_{\Gamma_D} = 0\}.$$

Obviously, $S_h = \text{span}\{\phi_i : x_i \in N_h^0\}$ and $S_h^* = \text{span}\{\chi_i : x_i \in N_h^0\}$, where ϕ_i denotes the standard nodal linear basis function associated with the node x_i, and χ_i denotes the characteristic function of the volume V_i. Let $I_h : C(\Omega) \cap H_D^1(\Omega) \to S_h$ be the interpolation operator and $I_h^* : C(\Omega) \cap H_D^1(\Omega) \to S_h^*$ and $P_h^* : C(\Omega) \cap H_D^1(\Omega) \to S_h^*$ be the piecewise constant interpolation and projection operators:

$$I_h u = \sum_{x_i \in N_h} u(x_i)\phi_i(x),\ I_h^* u = \sum_{x_i \in N_h} u(x_i)\chi_i(x),\ \text{and } P_h^* u = \sum_{x_i \in N_h} \bar{u}_i \chi_i(x).$$

Here $\bar{u}_i$ is the averaged value of u over the volume V_i for $x_i \in N_h^0$, i.e., $\bar{u}_i = \int_{V_i} u\,dx/|V_i|$, and $\bar{u}_i = 0$ for $x_i \in \Gamma_D$. In fact, I_h also makes sense as an interpolation operator from S_h^* to S_h. Namely, if $v^* \in S_h^*$, then $I_h v^* \in S_h$ and $I_h v^*(x_i) = v^*(x_i)$.

Further, for $v^* \in S_h^*$, we use the notation $v_i^* = v^*(x_i)$. We also define the "total flux" and its approximation by

$$\underline{\sigma} := -A\nabla u + \underline{b}u, \qquad \underline{\sigma}_h := -A\nabla_h u_h + \underline{b}u_h$$

and assume that the coefficients $A(x)$ and $\underline{b}(x)$ are elementwise smooth. Also, we denote by $\nabla_h \cdot$ the $\mathcal{T}$-piecewise divergence and by ∇_h the $\mathcal{T}$-piecewise gradient. Integrals involving piecewise quantities are considered as sums over the pieces where the quantities are defined.

The finite volume element approximation u_h of (1.1) is the solution to the following problem: Find $u_h \in S_h$ such that

$$a_h(u_h, v_h^*) := A(u_h, v_h^*) + C(u_h, v_h^*) = F(v_h^*) \quad \text{for all } v_h^* \in S_h^*. \tag{2.6}$$

Here the bilinear forms $A(u_h, v^*)$ and $C(u_h, v^*)$ are defined on $S_h \times S_h^*$ and the linear form $F(v^*)$ is defined on S_h^*. They are given by

$$A(u_h, v^*) = \sum_{x_i \in N_h^0} v_i^* \left(- \int_{\partial V_i \setminus \Gamma_N} (A \nabla_h u_h) \cdot \underline{n} ds + \int_{V_i} \gamma u_h dx \right), \tag{2.7}$$

$$C(u_h, v^*) = \sum_{x_i \in N_h^0} v_i^* \int_{\partial V_i \setminus \Gamma_N^{\text{in}}} (\underline{b} \cdot \underline{n})\ u_h \, ds, \tag{2.8}$$

$$F(v^*) = \sum_{x_i \in N_h^0} v_i^* \left\{ \int_{V_i} f dx - \int_{\partial V_i \cap \Gamma_N^{\text{in}}} g \, ds \right\}. \tag{2.9}$$

Obviously, $\nabla \cdot \underline{\sigma}_h$ is well defined over $V_i \cap K$ for all $V_i \in \mathcal{T}^*$ and $K \in \mathcal{T}$. This ensures, in particular, that the surface integrals in (2.7) and (2.8) exist.

In addition to $C(u_h, v^*)$ we introduce the form $C^{\text{up}}(u_h, v^*)$ that uses upwind approximation. Approximation (2.7)–(2.9) can be used for moderate convection fields and dominating diffusion. For small diffusion, for example, when $A = \epsilon I$ with ϵ small, approximation (2.7)–(2.9) gives oscillating numerical results, which we would like to avoid. We are interested in approximation methods that produce solutions satisfying the maximum principle and are locally conservative. Such schemes are also known as monotone schemes (see, e.g., [24, 31]). A well-known sufficient condition for a scheme to be monotone is that the corresponding stiffness matrix be an M-matrix (see [33, pp. 182, 260] and [31, p. 202]).

The upwind approximation that we use for problems with large convection (or small diffusion) is locally mass conservative and gives the desired stabilization. We split the integral over ∂V_i on integrals over $\gamma_{ij} = \partial V_i \cap \partial V_j$ (see Figure 1) and introduce out-flow and in-flow parts of the boundary of the volume V_i. This splitting can be characterized by the quantities $(\underline{b} \cdot \underline{n})_+ = \max(0,\ \underline{b} \cdot \underline{n})$ and $(\underline{b} \cdot \underline{n})_- = \min(0,\ \underline{b} \cdot \underline{n})$, where $\underline{n}$ is the outer unit vector normal to ∂V_i. Then we introduce

$$C^{\text{up}}(u_h, v^*) = \sum_{x_i \in N_h^0} v_i^* \Bigg\{ \sum_{j \in \Pi(i)} \int_{\gamma_{ij}} \left((\underline{b} \cdot \underline{n})_+ u_h(x_i) + (\underline{b} \cdot \underline{n})_- u_h(x_j) \right) ds + \int_{\Gamma_N^{\text{out}} \cap \partial V_i} (\underline{b} \cdot \underline{n})\, u_h(x_i)\ ds \Bigg\}. \tag{2.10}$$

This approximation is well defined for any $\underline{b}$. In order to avoid technicalities in our analysis we assume that the vector field $\underline{b}$ is piecewise smooth and has small variation over each finite element. Thus, the quantity $\underline{b} \cdot \underline{n}$ does not change sign over γ_{ij}.

The upwind finite volume element approximation u_h of (1.1) becomes the following: Find $u_h \in S_h$ such that

$$a_h^{\text{up}}(u_h, v^*) := A(u_h, v^*) + C^{\text{up}}(u_h, v^*) = F(v^*) \text{ for all } v^* \in S_h^*. \tag{2.11}$$

This is an extension of the classical upwind approximation of the convection term and is closely related to the discontinuous Galerkin approximation (see, e.g., [22]) or to the Tabata scheme for the Galerkin finite element method [34]. It is also related to the scheme on Voronoi meshes derived by Mishev [27]. A different type of weighted upwind approximation on Voronoi meshes in two dimensions has been studied by Angermann [2].

3. A posteriori error analysis. This section is devoted to the mathematical derivation of computable error bounds in the energy norm. Throughout this section, $u \in H^1_D$ denotes the exact solution of (2.5) and $u_h \in S_h$ denotes the discrete solution of either (2.6) or (2.11). Then, $e := u - u_h \in H^1_D(\Omega)$ is the (unknown) error and $\overline{e} := P^*_h e \in S^*_h$ is its $\mathcal{T}^*$-piecewise integral mean. We denote by $\mathcal{E}$ the set of all interior edges/faces in $\mathcal{T}$, respectively, in two/three dimensions. Also, for a vertex $x_i \in N^0_h$ let $\beta_i := V_i \cap \mathcal{E}$ (see Figure 2). For any $E \in \mathcal{E}$ let $[\underline{\sigma}_h] \cdot \underline{n}$ denote the jump of $\underline{\sigma}_h$ across E in normal to E direction $\underline{n}$. The orientation of $\underline{n}$ is not important as long as the jump is in the same direction. In general, if $\underline{n}$ is present in a boundary integral, it will denote the outward unit vector normal to the boundary. With every element $K \in \mathcal{T}$, edge/face $E \in \mathcal{E}$, and volume $V_i \in \mathcal{T}^*$ we associate local mesh size denoted correspondingly by h_K, h_E, and h_i. Since the mesh is locally quasi uniform the introduced mesh sizes are locally equivalent, i.e., bound each other from above and below with constants independent of the mesh size. Then, we introduce a global discontinuous mesh size function $h(x)$, $x \in \Omega$, that assumes value h_K, h_E, and h_i depending on $x \in K \setminus \partial K$, $x \in E$, or $x = x_i$, respectively. Finally, we use the following shorthand notation for integration over all faces E in $\mathcal{E}$:

$$\int_{\mathcal{E}} v ds := \sum_{E \in \mathcal{E}} \int_E v ds, \qquad \|v\|_{L^2(\mathcal{E})} := \sum_{E \in \mathcal{E}} \int_E v^2 ds.$$

3.1. Energy-norm a posteriori error estimate of the scheme without upwind. We consider problem (2.6) and begin our analysis with the case when the form $C(\cdot,\cdot)$ is evaluated by (2.8). We first give a representation of the error and introduce some locally computable quantities. In Theorem 3.1 we show that these quantities give a reliable estimate for the error. Further, we introduce the error estimator, based on local "averaging" of the "total flux" $\underline{\sigma}$ over the control volumes, and show that this estimator is reliable up to higher order terms.

The following lemma gives a representation of the error.

LEMMA 3.1. *Assume that the bilinear form $a(\cdot,\cdot)$ satisfies* (2.3) *and* (2.4). *Then for the error $e = u - u_h$, where u is the solution of* (2.5) *and u_h is the solution of* (2.6), *we have*

$$\begin{aligned} \|e\|_a^2 &= (f - \nabla_h \cdot \underline{\sigma}_h - \gamma u_h,\ e - \overline{e}) - \int_{\mathcal{E}} [\underline{\sigma}_h] \cdot \underline{n}\, (e - \overline{e})\, ds \\ &\quad - \int_{\Gamma_N^{\mathrm{in}}} (g - \underline{\sigma}_h \cdot \underline{n})\, (e - \overline{e})\, ds - \int_{\Gamma_N^{\mathrm{out}}} (A \nabla_h u_h) \cdot \underline{n}\, (e - \overline{e})\, ds. \end{aligned} \tag{3.1}$$

Proof. We take $v = e \in H^1_D(\Omega)$ in (2.5) and use the definition of $a(\cdot,\cdot)$ by (2.2) to get

$$\begin{aligned} a(e,e) &= a(u,e) - a(u_h,e) \\ &= (f - \gamma u_h, e) + (\underline{\sigma}_h, \nabla e) - \int_{\Gamma_N^{\mathrm{in}}} g e\, ds - \int_{\Gamma_N^{\mathrm{out}}} (\underline{b} \cdot \underline{n})\, u_h\, e\, ds. \end{aligned}$$

We integrate the second term on the right-hand side by parts on each element $K \in \mathcal{T}$:

$$\int_K \underline{\sigma}_h \cdot \nabla e\, ds = \int_{\partial K} (\underline{\sigma}_h \cdot \underline{n}) e\, ds - \int_K e \nabla \cdot \underline{\sigma}_h\, dx.$$

The sum over all elements yields the jump contributions $[\underline{\sigma}_h]\cdot\underline{n}$ along $\mathcal{E}$ and eventually proves

$$
\begin{aligned}
a(e,e) &= (f-\nabla_h\cdot\underline{\sigma}_h-\gamma u_h,e)-\int_{\mathcal{E}}[\underline{\sigma}_h]\cdot\underline{n}\,e\,ds\\
&\quad-\int_{\Gamma_N^{\mathrm{in}}}(g-\underline{\sigma}_h\cdot\underline{n})e\,ds-\int_{\Gamma_N^{\mathrm{out}}}(A\nabla_h u_h)\cdot\underline{n}\,e\,ds.
\end{aligned}
\tag{3.2}
$$

It remains to be shown that the preceding right-hand side vanishes if e is replaced by $\overline{e}$. For each control volume V_i we have from (2.6)–(2.8) that

$$
\int_{\partial V_i\setminus\Gamma_N}\underline{\sigma}_h\cdot\underline{n}\,ds=\int_{V_i}(f-\gamma u_h)\,dx-\int_{\partial V_i\cap\Gamma_N^{\mathrm{out}}}(\underline{b}\cdot\underline{n})\,u_h\,ds-\int_{\partial V_i\cap\Gamma_N^{\mathrm{in}}}g\,ds.
$$

The Gauss divergence theorem is applied to each nonvoid $K\cap V_i$, $K\in\mathcal{T}$, so that the left-hand side of the above inequality becomes

$$
\int_{\partial V_i\setminus\Gamma_N}\underline{\sigma}_h\cdot\underline{n}\,ds=\int_{V_i}\nabla_h\cdot\underline{\sigma}_h\,dx+\int_{\beta_i}[\underline{\sigma}_h]\cdot\underline{n}\,ds-\int_{\partial V_i\cap\Gamma_N}\underline{\sigma}_h\cdot\underline{n}\,ds.
$$

The difference of the preceding two identities is multiplied by $\overline{e}(x_i)$ and summed over all control volumes. This results in

$$
0=(f-\nabla_h\cdot\underline{\sigma}_h-\gamma u_h,\overline{e})-\int_{\mathcal{E}}[\underline{\sigma}_h]\cdot\underline{n}\,\overline{e}\,ds-\int_{\Gamma_N^{\mathrm{in}}}(g-\underline{\sigma}_h\cdot\underline{n})\,\overline{e}\,ds-\int_{\Gamma_N^{\mathrm{out}}}A\nabla_h u_h\cdot\underline{n}\,\overline{e}\,ds.
$$

Subtracting this identity from (3.2) concludes the proof of (3.1). ∎

Motivated by the above considerations we introduce the following locally computable quantities that play a major role in the design of adaptive algorithms and their a posteriori error analysis.

DEFINITION 3.1. *Set*

$$
\begin{aligned}
R_K(x)&:=(f-\nabla\cdot\underline{\sigma}_h-\gamma u_h)(x),\ x\in K,\\
R_E(x)&:=([\underline{\sigma}_h]\cdot\underline{n})(x),\ x\in E,\ \textit{for } E\cap\Gamma_N=\emptyset,\\
R_E^{\mathrm{in}}(x)&:=(g-\underline{\sigma}_h\cdot\underline{n})(x),\ x\in E,\ \textit{for } E\subset\Gamma_N^{\mathrm{in}},\\
R_E^{\mathrm{out}}(x)&:=(A\nabla u_h\cdot\underline{n})(x),\ x\in E,\ \textit{for } E\subset\Gamma_N^{\mathrm{out}}
\end{aligned}
$$

and define

$$
\begin{aligned}
\eta_R&:=\|h\,R_K\|_{L^2(\Omega)},\ \eta_E:=\|h^{1/2}\,R_E\|_{L^2(\mathcal{E})},\\
\eta_N&:=\|h^{1/2}\,R_E^{\mathrm{in}}\|_{L^2(\Gamma_N^{in})}+\|h^{1/2}\,R_E^{\mathrm{out}}\|_{L^2(\Gamma_N^{\mathrm{out}})}.
\end{aligned}
$$

LEMMA 3.2. *Suppose that $R_E\in L^2(\mathcal{E})$ and that the partitioning $\mathcal{T}$ of Ω is locally quasi uniform. Then*

$$
\int_{\mathcal{E}}[\underline{\sigma}_h]\cdot\underline{n}(e-\overline{e})\,ds\lesssim\eta_E\,\|\nabla e\|\ \textit{for any } e\in H^1_D(\Omega),
$$

where the constant in the notation $\lesssim$ depends only on the shape of the elements in $\mathcal{T}$ and the volumes in $\mathcal{T}^*$.

Proof. A well-established trace inequality (cf., e.g., [12, Theorem 1.6.6] or [15, Theorem 1.4]) and scaling argument lead to

$$h_E^{1/2}\|v\|_{L^2(E)} \lesssim \|v\|_{L^2(K)} + h_E\|\nabla v\|_{L^2(K)} \tag{3.3}$$

for all $v \in H^1(K)$ and edges E of an element $K \in \mathcal{T}$. An application to $v := e - \overline{e}$ on each $K \cap V_i$, where $K \in \mathcal{T}$ and $x_i \in N_h$, leads to

$$\begin{aligned}\int_{\beta_i} [\underline{\sigma}_h]\cdot\underline{n}(e-\overline{e})\,ds &\le \|[\underline{\sigma}_h]\cdot\underline{n}\|_{L^2(\beta_i)}\|e-\overline{e}\|_{L^2(\beta_i)}\\ &\lesssim h_i^{1/2}\|[\underline{\sigma}_h]\cdot\underline{n}\|_{L^2(\beta_i)}(h_i^{-1}\|e-\overline{e}\|_{L^2(V_i)} + \|\nabla e\|_{L^2(V_i)}).\end{aligned}$$

Further, Poincaré's inequality for $x_i \in N_h^0$ (in which case $\int_{V_i}(e-\overline{e})\,dx = 0$) or Friedrichs's inequality for $x_i \in N_h\backslash N_h^0$ (in which case $\overline{e} = 0$ on V_i and $e = 0$ on $\partial V_i \cap \Gamma_D$) shows that

$$h_i^{-1}\|e-\overline{e}\|_{L^2(V_i)} \lesssim \|\nabla e\|_{L^2(V_i)}. \tag{3.4}$$

Poincaré's, respectively, Friedrichs's, inequality is valid in this case because the volumes V_i are star shaped w.r.t. a ball of radius $\sim h_i$, which follows from the quasi uniformity of $\mathcal{T}$ and our choice of $\mathcal{T}^*$. Substituting the last result into the preceding inequality yields

$$\int_{\beta_i} [\underline{\sigma}_h]\cdot\underline{n}(e-\overline{e})\,ds \lesssim \|h^{1/2}\ [\underline{\sigma}_h]\cdot\underline{n}\|_{L^2(\beta_i)}\|\nabla e\|_{L^2(V_i)}$$

for all $x_i \in N_h$. A summation over all vertices yields the assertion. ∎

Below we establish that the sum of the quantities η_R, η_E, and η_N gives a reliable estimate for the error in the global energy norm.

THEOREM 3.1. *Assume that the coefficients of the bilinear form $a(\cdot,\cdot)$ are such that* (2.3) *and* (2.4) *are satisfied, and that the partitioning $\mathcal{T}$ of Ω is locally quasi uniform. Then*

$$\|e\|_a \lesssim \eta_R + \eta_E + \eta_N.$$

The constant in this inequality depends on the constants c_0 in (2.3) *and c_1 in* (2.4)*, and on the shape of the elements in $\mathcal{T}$ and $\mathcal{T}^*$, but is independent of h.*

Proof. The identity (3.1) of Lemma 3.1 represents $\|e\|_a^2$ as a sum of four terms. We bound the first term using Cauchy's inequality, the second one using Lemma 3.2, and the remaining two terms using again Cauchy's inequality:

$$\|e\|_a^2 \lesssim \eta_R\|h^{-1}(e-\overline{e})\| + \eta_E\|\nabla e\| + \eta_N\|h^{-1/2}(e-\overline{e})\|_{L^2(\Gamma_N)}.$$

Inequality (3.4) is combined with the trace inequality (3.3) to obtain

$$\|h^{-1/2}(e-\overline{e})\|_{L^2(\Gamma_N)}^2 + \|h^{-1}(e-\overline{e})\|^2 \lesssim \sum_{x_i\in N_h}(h_i^{-2}\|e-\overline{e}\|_{L^2(V_i)}^2 + \|\nabla e\|_{L^2(V_i)}^2) \lesssim \|\nabla e\|^2.$$

Condition (2.3) yields $\|\nabla e\| \lesssim \|e\|_a$ and this concludes the proof of the theorem. ∎

Now we introduce an error estimator that is based on local averaging (post-processing) of the "total flux" $\underline{\sigma}_h$. For finite element approximations this estimator,

often called the ZZ-estimator, has been justified by Carstensen and Bartels [10, 14] and Rodriguez [30].

DEFINITION 3.2. *Let P_i be the L^2-projection onto the affine functions on V_i. We define the error indicator η_Z for $A(x)$ and $\underline{b}(x)$ smooth over the volumes $V_i \in \mathcal{T}^*$ as*

$$\eta_Z := \left(\sum_{x_i \in N_h} \|\underline{\sigma}_h - P_i \underline{\sigma}_h\|^2_{L^2(V_i)} \right)^{1/2}.$$

Remark 3.1. In our numerical experiments we have allowed $A(x)$ to have jumps that are aligned with the partition $\mathcal{T}$. In such cases we have changed the projection P_i. For example, if $V_i = V_i^1 \cup V_i^2$ and $A(x)$ is smooth on V_i^1 and V_i^2 but has jumps across their interface, then P_i is defined in a piecewise way as

$$\|\underline{\sigma}_h - P_i \underline{\sigma}_h\|^2_{L^2(V_i)} = \|\underline{\sigma}_h - P_i^1 \underline{\sigma}_h\|^2_{L^2(V_i^1)} + \|\underline{\sigma}_h - P_i^2 \underline{\sigma}_h\|^2_{L^2(V_i^2)},$$

where P_i^1 and P_i^2 are the L^2-projections on the affine functions on V_i^1 and V_i^2, respectively.

To simplify our notation we shall use the concept of "higher order terms" (h.o.t.). Since the finite volume scheme at hand is of first order for $u \in H^2(\Omega)$, i.e., $\|e\|_a \lesssim h$, then it is reasonable to denote all terms that tend to zero faster than $O(h)$ by h.o.t. Below, we shall refer to the following quantities as h.o.t.:

(a) $\|h^2\ \nabla(\gamma u_h)\|_{L^2(\Omega)}$ for $\gamma \in H^1(\Omega)$;
(b) $\|h^2\ \nabla f\|_{L^2(\Omega)}$ if $f \in H^1(\Omega)$;
(c) $\|hf\|_{L^2(\Omega_D)}$ if $f \in H^s(\Omega)$, $s > 0$, and $\Omega_D := \cup\{V_i : x_i \in N_h \cap \Gamma_D\}$ is a strip of width h around Γ_D (to show that this quantity is h.o.t. we apply Ilin's inequality (2.1) and get $\|hf\|_{L^2(\Omega_D)} \lesssim h^{1+s}\|f\|_{H^s(\Omega)}$, $s < 1/2$);
(d) $h_E^{1/2}\|g - \bar{g}\|_{L^2(E)}$ for $\bar{g} = \int_E g ds/|E|$ and $g \in H^1(E)$ for $E \subset \Gamma_N^{\text{out}}$;
(e) denote by $\tilde{r}(x)$ a linear approximation of $r(x)$ on K. Thus, $\widetilde{\nabla \cdot A}$ and $\widetilde{\nabla \cdot \underline{b}}$ are linear approximations on K of $\nabla \cdot A$ and $\nabla \cdot \underline{b}$, respectively. Here $\nabla \cdot A$ is understood as a vector with components divergence of the rows of $A(x)$. If A and $\underline{b}$ are sufficiently smooth on K, then $\nabla \cdot A - \widetilde{\nabla \cdot A}$ and $\nabla \cdot \underline{b} - \widetilde{\nabla \cdot \underline{b}}$ are h.o.t.

More generally, if functions $\alpha(h)$, $\beta(h)$, and $\gamma(h)$ satisfy $\alpha(h) \le \beta(h) + \gamma(h)$ and $\gamma(h)/\beta(h) \to 0$ as $h \to 0$, we will denote $\gamma(h)$ as h.o.t. compared to $\beta(h)$. In the case above we have $\beta(h) = h$.

In the analysis that follows we derive a posteriori error estimates based on averaging techniques. In the estimates derived the constants in $\lesssim$ depend only on c_0 from (2.3), c_1 from (2.4), and the shape of the elements in $\mathcal{T}$ and $\mathcal{T}^*$. The h.o.t. will account for the smoothness of the coefficients of the differential equation. The smoothness requirements, as stated in the theorems below, yield h.o.t. of order $O(h^2)$, i.e., one order higher than needed. Using standard results from interpolation of Banach spaces (cf., e.g., [1]) we can weaken the assumptions, requiring smoothness of order $\epsilon > 0$ less than that stated.

LEMMA 3.3. *Let the coefficients A and $\underline{b}$ be $C^1(\Omega)$-functions and let P_i be the L^2-projection onto the affine functions on $V_i \in \mathcal{T}^*$. Then*

$$h_i^{1/2}\|[\underline{\sigma}_h] \cdot \underline{n}\|_{L^2(\beta_i)} \lesssim \|\underline{\sigma}_h - P_i \underline{\sigma}_h\|_{L^2(V_i)} + \text{h.o.t.} \quad \text{for all } V_i \in \mathcal{T}^*. \tag{3.5}$$

The multiplicative constants in the notation $\lesssim$ depend on the shape of the elements in $\mathcal{T}$ and the shape of the control volumes in $\mathcal{T}^*$, while the h.o.t. depend on the smoothness of the coefficients A and $\underline{b}$.

Proof. If A and $\underline{b}$ are polynomials, then $\underline{\sigma}_h|_K$ is in a finite dimensional space for any $K \in \mathcal{T}$. In this case we easily prove (3.5) without h.o.t. by an equivalence-of-norm argument on finite dimensional spaces. Namely, both sides of (3.5) define seminorms for finite dimensional $\underline{\sigma}_h$. If $\|\underline{\sigma}_h - P_i\underline{\sigma}_h\|_{L^2(V_i)} = 0$ for some $\underline{\sigma}_h$, then $\underline{\sigma}_h = P_i\underline{\sigma}_h$ on V_i. Since $P_i\underline{\sigma}_h$ is linear on V_i, this shows that $\underline{\sigma}_h$ is also linear. Therefore, the jump $[\underline{\sigma}_h]$ is zero on β_i, i.e., the left-hand side of (3.5) vanishes as well. This proves that the seminorm on the right-hand side is stronger than the seminorm on the left-hand side and so proves (3.5). A scaling argument shows that the multiplicative constant behind $\lesssim$ is independent of h_i.

The case when A and $\underline{b}$ are smooth functions but $\underline{\sigma}_h|_K$ is not finite dimensional over $K \in \mathcal{T}$ is treated using approximation. Namely, we introduce polynomial approximations $\overline{\underline{\sigma}}_h$ of $\underline{\sigma}_h$ for any $K \in \mathcal{T}$ based on approximations of A and $\underline{b}$, taking into account that

$$\|\underline{\sigma}_h - \overline{\underline{\sigma}}_h\|_{L^2(V_i)} = \text{h.o.t.} \quad \text{and} \quad \|[\underline{\sigma}_h - \overline{\underline{\sigma}}_h] \cdot \underline{n}\|_{L^2(V_i)} = \text{h.o.t.},$$

and use the result for the finite dimensional case to get (3.5). ∎

As a corollary we get the following inequality.

COROLLARY 3.1. *Let the assumptions of Lemma* 3.3 *be satisfied. Then*

$$\eta_E \lesssim \eta_Z + \textit{h.o.t.} \tag{3.6}$$

The above inequality follows directly by squaring (3.5) and summing over all $x_i \in N_h$.

Recall that η_Z is defined for internal vertex nodes. Below we show that η_Z together with η_N can be used as an estimator for the H^1-norm of the error modulus of h.o.t.

THEOREM 3.2. *Let the assumptions of Lemma* 3.3 *be satisfied and let* $f \in H^1(\Omega)$. *Then*

$$\|e\|_a \lesssim \eta_Z + \eta_N + \textit{h.o.t.} \tag{3.7}$$

Proof. We use again the error representation from Lemma 3.1. In Theorem 3.1 we have bounded the third and fourth sums from the error representation by $\eta_N\|\nabla e\|$ and the second sum by $\eta_E\|\nabla e\|$. Further, η_E was bounded in Lemma 3.3 by η_Z + h.o.t., so it remains to establish the bound

$$(f - \nabla \cdot \underline{\sigma}_h - \gamma u_h,\ e - \overline{e}) \lesssim (\eta_Z + \text{h.o.t.})\|\nabla e\|.$$

For $x_i \in N_h^0$ denote by $\overline{f}$ and $\overline{\gamma u_h}$ the integral means over V_i of f and γu_h, respectively. Then we have

$$\begin{aligned}\int_{V_i} (f - \nabla_h \cdot \underline{\sigma}_h - \gamma u_h)(e - \overline{e})\,dx &= \int_{V_i} (f - \overline{f})(e - \overline{e})\,dx \\ &\quad - \int_{V_i} \nabla_h \cdot (\underline{\sigma}_h - P_i\underline{\sigma}_h)(e - \overline{e})\,dx - \int_{V_i} (\gamma u_h - \overline{\gamma u_h})(e - \overline{e})\,dx \\ &\le \|e - \overline{e}\|_{L^2(V_i)}\big(\|f - \overline{f}\|_{L^2(V_i)} + \|\nabla_h \cdot (\underline{\sigma}_h - P_i\underline{\sigma}_h)\|_{L^2(V_i)} \\ &\qquad + \|\gamma u_h - \overline{\gamma u_h}\|_{L^2(V_i)}\big).\end{aligned} \tag{3.8}$$

Poincaré's inequality gives

$$\begin{aligned}\|e - \overline{e}\|_{L^2(V_i)} &\lesssim h_i\|\nabla e\|_{L^2(V_i)}, \\ \|f - \overline{f}\|_{L^2(V_i)} &\lesssim h_i\|\nabla f\|_{L^2(V_i)}, \\ \|\gamma u_h - \overline{\gamma u_h}\|_{L^2(V_i)} &\lesssim h_i\|\nabla(\gamma u_h)\|_{L^2(V_i)}.\end{aligned} \tag{3.9}$$

The term $\|\nabla_h \cdot (\underline{\sigma}_h - P_i\underline{\sigma}_h)\|_{L^2(V_i)}$ is treated by the inverse estimate

$$\|\nabla_h \cdot (\underline{\sigma}_h - P_i\underline{\sigma}_h)\|_{L^2(V_i)} \lesssim h_i^{-1}\|\underline{\sigma}_h - P_i\underline{\sigma}_h\|_{L^2(V_i)} + \text{h.o.t.} \tag{3.10}$$

As in the proof of Lemma 3.3, we first prove (3.10) when $\underline{\sigma}_h$ is finite dimensional by equivalence of norms followed by a scaling argument and then, for the general case, by a perturbation analysis. The combination of (3.8)–(3.10) shows

$$\int_{V_i} (f - \nabla_h \cdot \underline{\sigma}_h - \gamma u_h)(e - \overline{e})\, dx \lesssim \|\nabla e\|_{L^2(V_i)} \left(\|\underline{\sigma}_h - P_i\underline{\sigma}_h\|_{L^2(V_i)} + \text{h.o.t.}\right). \tag{3.11}$$

So far (3.11) holds for $x_i \in N_h^0$. For $x_i \in N_h \cap \Gamma_D$ we replace $\overline{e}$, $\overline{f}$, and $\overline{\gamma u_h}$ by zero and deduce the first and third inequalities of (3.9) from Friedrichs's inequality (notice that e and γu_h vanish on $\Gamma_D \cap V_i$). The inverse estimate (3.10) holds for $x_i \in N_h \cap \Gamma_D$ as well. The aforementioned arguments prove (3.11) with $\|h^2\ \nabla f\|_{L^2(V_i)}$ replaced by $\|h\, f\|_{L^2(V_i)}$. This shows

$$(f - \nabla_h \cdot \underline{\sigma}_h - \gamma u_h, e - \overline{e}) \lesssim (\eta_Z + \|hf\|_{L^2(\Omega_D)} + \text{h.o.t.})\|\nabla e\|.$$

The last result, the discussion at the beginning of the theorem, Ilin's inequality (2.1), and the ellipticity assumption conclude the proof of the theorem. ∎

THEOREM 3.3. *Suppose that the coefficients A and $\underline{b}$ are $C^1(\Omega)$-functions, $f \in H^1(\Omega)$, $\gamma \in H^1(\Omega)$, $g \in H^{1/2}(\mathcal{E})$, and that the partitioning $\mathcal{T}$ of Ω is locally quasi uniform. Then*

$$\eta_Z + \eta_R + \eta_E + \eta_N \lesssim \|e\|_a + h.o.t.$$

Proof. We will prove that the quantities η_R, η_E, η_N, and η_Z are bounded by $C\ \|e\|_a + \text{h.o.t.}$ The h.o.t. appear by applying averaging techniques as in the proof of Lemma 3.3 and therefore we will consider only the case when $\underline{\sigma}_h$ is finite dimensional. First, we will bound the contributions to η_N due to Γ_N^{in}, namely, we will prove

$$\|h^{1/2}\,(g - \underline{\sigma}_h \cdot \underline{n})\|_{L^2(\Gamma_N^{\text{in}})} \lesssim \|e\|_a + \text{h.o.t.} \tag{3.12}$$

We consider an element $K \in \mathcal{T}$ that has an edge/face $E \subset \Gamma_N^{\text{in}}$. We will use the pair (K, E) in the rest of the proof (see Figure 3).

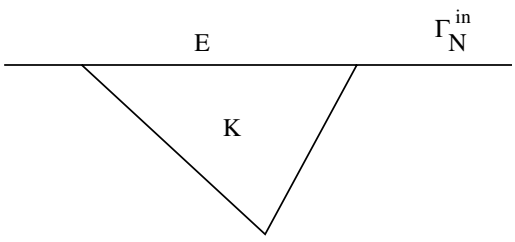

FIG. 3. *The pair (K, E) of edge $E \subset \Gamma_N^{\text{in}}$ and element K used in the proof of inequality* (3.12).

First, we note that

$$h_E^{1/2}\|g-\overline{g}\|_{L^2(E)} = \text{h.o.t.} \quad \text{for} \quad \overline{g} := \int_E g\,ds/|E|.$$

Then

$$\|g-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} \le \|g-\overline{g}\|_{L^2(E)} + \|\overline{g}-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} \lesssim \|\overline{g}-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} + \text{h.o.t.}$$

We prove below that

$$\|\overline{g}-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} \lesssim h_E^{-1/2}\|\underline{\sigma}-\underline{\sigma}_h\|_{L^2(K)} + \text{h.o.t.}$$

so that summation over all $E\subset\Gamma_N^{\text{in}}$ yields (3.12).

Consider an edge-bubble function $b_E\in H^1(\Omega)$, $b_E\ge 0$, $b_E(x)=0$ on $\Omega\setminus K$ and $\partial K\setminus E$, with properties

$$\int_E b_E\,ds = \int_E ds,\ \|b_E\|_{L^\infty(K)}\lesssim 1,\ \|\nabla b_E\|_{L^\infty(K)}\lesssim 1/h_E. \tag{3.13}$$

A 2-D example of such a bubble is $b_E = 6\phi_1\phi_2$, where ϕ_1 and ϕ_2 are the standard linear nodal basis functions associated with the end points of the edge E. Let $z\in H^1(K)$ be the harmonic extension of $(\overline{g}-\underline{\sigma}_h\cdot\underline{n})b_E$ from ∂K to K. The extension is bounded in H^1 [29, Theorem 4.1.1] on a reference element $\hat{K}$ by the $H^{1/2}(\hat{E})$-norm of the extended quantity and, since all norms are equivalent on a finite dimensional space, by its $L^2(\hat{E})$-norm. Therefore, a scaling argument gives

$$h_E^{1/2}\|\nabla z\|_{L^2(K)} + h_E^{-1/2}\|z\|_{L^2(K)} \lesssim \|b_E(\overline{g}-\underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}. \tag{3.14}$$

We define the linear operator P_K into the space of polynomials of degree 2 on an element $K\in\mathcal{T}$ as

$$(b_K\ P_K z, p_h)_{L^2(K)} = (z,p_h)_{L^2(K)}$$

for all polynomials p_h of degree 2. Here $b_K\in H^1(\Omega)$, $b_K\ge 0$, is an element-bubble function with properties

$$\text{supp } b_K\subset K,\ \int_K b_K\,ds = \int_K ds,\ \|b_K\|_{L^\infty(K)}\lesssim 1,\ \|\nabla b_K\|_{L^\infty(K)}\lesssim 1/h_K.$$

A 2-D example of such a bubble is $b_K = 60\phi_1\phi_2\phi_3$, where ϕ_1, ϕ_2, and ϕ_3 are the standard linear nodal basis functions associated with the vertices of the element K. Then $\tilde{z} := z - b_K\,P_K z$ by construction has the properties

$$\tilde{z} = (\overline{g}-\underline{\sigma}_h\cdot\underline{n})b_E \quad \text{on } E, \qquad \tilde{z}=0 \quad \text{on } \partial K\backslash E,$$
$$(\tilde{z},\,p_h)_{L^2(K)} = 0 \quad \text{for all polynomials } p_h \text{ of degree 2.}$$

Inequality (3.14) remains valid for z replaced by $\tilde{z}$ because of the following. Choosing $p_h = P_K z$ in the definition of P_K yields

$$\|b_K^{1/2}P_K z\|_{L^2(K)}^2 = (z,P_K z)_{L^2(K)} \lesssim \|z\|_{L^2(K)}\|P_K z\|_{L^2(K)}.$$

We use norm equivalence on finite dimensional spaces on a reference element and scaling to K to get that the quantities $||b_K P_K z||_{L^2(K)}$, $\|b_K^{1/2}P_K z\|_{L^2(K)}$, and $\|P_K z\|_{L^2(K)}$

are equivalent up to constants independent of h, and therefore $\|b_K P_K z\|_{L^2(K)} \lesssim \|z\|_{L^2(K)}$. We use again the equivalence-of-norms argument, inverse inequality, and the properties of z to get that

$$\begin{aligned}\|\nabla(b_K P_K z)\|_{L^2(K)} &\lesssim \|\nabla b_K\|_{L^2(K)}\|P_K z\|_{L^2(K)} + \|b_K \nabla(P_K z)\|_{L^2(K)}\\ &\lesssim h_E^{-1}\|P_K z\|_{L^2(K)} + h_E^{-1}\|z\|_{L^2(K)}\\ &\lesssim h_E^{-1/2}\|b_E(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}.\end{aligned}$$

Combined with the bound for $\|b_K P_K z\|_{L^2(K)}$, this completes the proof of (3.12) for $z = \tilde{z}$.

Given a polynomial p_h of degree 2, using the Gauss divergence theorem and the properties of $\tilde{z}$, we deduce

$$\begin{aligned}&\int_E b_E(\overline{g} - \underline{\sigma}_h\cdot\underline{n})(\underline{\sigma} - \underline{\sigma}_h)\cdot\underline{n}\,ds = \int_{\partial K}\tilde{z}(\underline{\sigma} - \underline{\sigma}_h)\cdot\underline{n}\,ds\\ &\quad= \int_K(\underline{\sigma} - \underline{\sigma}_h)\cdot\nabla\tilde{z}\,dx + \int_K \tilde{z}(\nabla\cdot(\underline{\sigma} - \underline{\sigma}_h) - p_h)\,dx\\ &\quad\lesssim \big(\|\underline{\sigma} - \underline{\sigma}_h\|_{L^2(K)} + h_E\|\nabla\cdot(\underline{\sigma} - \underline{\sigma}_h) - p_h\|_{L^2(K)}\big)\, h_E^{-1/2}\|b_E(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}.\end{aligned}$$

Choosing proper p_h in the second term of the last inequality makes that term h.o.t. Indeed, write down first the equality (see the basic problem (1.1))

$$\nabla\cdot(\underline{\sigma} - \underline{\sigma}_h) - p_h = \gamma u - f - (\nabla\cdot A)\cdot\nabla u_h + u_h\,\nabla\cdot\underline{b} + \underline{b}\cdot\nabla u_h - p_h. \tag{3.15}$$

Here $\nabla\cdot A$ is understood as a vector with component divergence on the rows of $A(x)$. Let $\tilde{f}$, $\widetilde{\gamma u}$, $\widetilde{\nabla\cdot\underline{b}}$, $\tilde{\underline{b}}$, and $\widetilde{\nabla\cdot A}$ be the linear approximations on K of f, γu, $\nabla\cdot\underline{b}$, $\underline{b}$, and $\nabla\cdot A$, respectively.

Now, we choose p_h to be the following polynomial of degree 2 on K,

$$p_h = \widetilde{\gamma u} - \tilde{f} - (\widetilde{\nabla\cdot A})\cdot\nabla u_h + u_h\widetilde{\nabla\cdot\underline{b}} + \tilde{\underline{b}}\cdot\nabla u_h,$$

take the $L^2(K)$-norm of (3.15), and use the triangle's inequality to get

$$\begin{aligned}\|\nabla\cdot(\sigma - \underline{\sigma}_h) - p_h\|_{L^2(K)} &\le \|f - \tilde{f}\|_{L^2(K)} + \|\gamma u - \widetilde{\gamma u}\|_{L^2(K)} + \|u_h(\nabla\cdot\underline{b} - \widetilde{\nabla\cdot\underline{b}})\|_{L^2(K)}\\ &\quad + \|(\underline{b} - \tilde{\underline{b}})\cdot\nabla u_h\|_{L^2(K)} + \|\nabla u_h\cdot(\nabla\cdot A - \widetilde{\nabla\cdot A})\|_{L^2(K)}\\ &\lesssim \big(\|u\|_{H^2(K)} + \|u_h\|_{H^1(K)}\big)\ \text{h.o.t.} + \|h_K\nabla f\|_{L^2(K)}.\end{aligned}$$

Therefore (note that $g = \underline{\sigma}\cdot\underline{n}$ on Γ_N^{in}),

$$\begin{aligned}\|b_E^{1/2}(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}^2 &= \int_E \tilde{z}(\overline{g} - g)\,ds + \int_E\tilde{z}(\underline{\sigma} - \underline{\sigma}_h)\cdot\underline{n}\,ds\\ &\lesssim h_E^{-1/2}\big(\|\underline{\sigma} - \underline{\sigma}_h\|_{L^2(K)} + \text{h.o.t.}\big)\ \|b_E^{1/2}(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}\end{aligned}$$

and so

$$\|b_E^{1/2}(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)} \lesssim h_E^{-1/2}\|\underline{\sigma} - \underline{\sigma}_h\|_{L^2(K)} + \text{h.o.t.}$$

Using again the equivalence-of-norms estimate (equivalence of norms on finite dimensional spaces on reference element and scaling)

$$\|\overline{g} - \underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} \lesssim \|b_E^{1/2}(\overline{g} - \underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}$$

we finally prove that

$$\begin{aligned}\|g-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)} &\le \|g-\overline{g}\|_{L^2(E)}+\|\overline{g}-\underline{\sigma}_h\cdot\underline{n}\|_{L^2(E)}\\ &\lesssim \|b_E^{1/2}(\overline{g}-\underline{\sigma}_h\cdot\underline{n})\|_{L^2(E)}+\text{h.o.t.}\\ &\lesssim h_E^{-1/2}\|\underline{\sigma}-\underline{\sigma}_h\|_{L^2(K)}+\text{h.o.t.}\end{aligned}$$

Similarly, $\|A\nabla u_h\cdot\underline{n}\|_{L^2(E)}\lesssim h_E^{-1/2}\|\underline{\sigma}-\underline{\sigma}_h\|_{L^2(K)}+\text{h.o.t.}$ for $E\subset\Gamma_N^{\text{out}}$, which, combined with the result for $E\subset\Gamma_N^{\text{in}}$, proves that $\eta_N\lesssim ||e||_a+\text{h.o.t.}$

A similar technique shows that $\eta_E\lesssim\|e\|_a+\text{h.o.t.}$

The inequality $\eta_R\lesssim\|e\|_a+\text{h.o.t.}$ can be proved in the following way. Take the average $\bar{R}_K$ of the residual $R_K:=f-\nabla\cdot\underline{\sigma}_h-\gamma u_h$ over an element K to derive

$$\|\bar{R}_K\|_{L^2(K)}\le\|R_K-\bar{R}_K\|_{L^2(K)}+\|R_K\|_{L^2(K)}=\ \text{h.o.t.}+\|R_K\|_{L^2(K)}.$$

Further, apply the technique from Lemma 3.1 to deduce the equality $(R_K,b_K\bar{R}_K)_{L^2(K)}=a(e,b_K\bar{R}_K)$ and therefore

$$\begin{aligned}(R_K,b_K\bar{R}_K)_{L^2(K)}&=\|b_K^{1/2}R_K\|^2_{L^2(K)}-(R_K,b_K(R_K-\bar{R}_K))_{L^2(K)}=a(e,b_K\bar{R}_K)\\ &\lesssim\|e\|_{H^1(K)}\|b_K\bar{R}_K\|_{H^1(K)}\lesssim\|e\|_{H^1(K)}h_K^{-1}\|\bar{R}_K\|_{L^2(K)}\\ &\lesssim h_K^{-1}\|e\|_{H^1(K)}\|R_K\|_{L^2(K)}+\text{h.o.t.}\end{aligned}$$

Here we used the inverse inequality and the boundedness of the coefficients of the differential equation (1.1). Then we take the term $(R_K,b_K(R_K-\bar{R}_K))_{L^2(K)}$ to the right-hand side and consider it as h.o.t. Finally, use that $\|b_K^{1/2}R_K\|_{L^2(K)}\approx\|R_K\|_{L^2(K)}$ to obtain

$$\|R_K\|_{L^2(K)}\lesssim h_K^{-1}\|e\|_{H^1(K)}+\text{h.o.t.}$$

A summation over all $K\in\mathcal{T}$ yields the inequality $\eta_R\lesssim\|e\|_a+\text{h.o.t.}$

Now we prove the remaining inequality, $\eta_Z\lesssim\|e\|_a+\text{h.o.t.}$ Since P_i is a linear $L^2(V_i)$ projector, we have that

$$\|\underline{\sigma}_h-P_i\underline{\sigma}_h\|_{L^2(V_i)}\le\|\underline{\sigma}_h-P_i\underline{\sigma}\|_{L^2(V_i)}.$$

Adding and subtracting $\underline{\sigma}$ in the right-hand side and applying the triangle's inequality we get

$$\|\underline{\sigma}_h-P_i\underline{\sigma}\|_{L^2(V_i)}\le\|\underline{\sigma}_h-\underline{\sigma}\|_{L^2(V_i)}+\|\underline{\sigma}-P_i\underline{\sigma}\|_{L^2(V_i)}=\|\underline{\sigma}_h-\underline{\sigma}\|_{L^2(V_i)}+\text{h.o.t.}$$

since $\|\underline{\sigma}-P_i\underline{\sigma}\|_{L^2(V_i)}=\text{h.o.t.}$ for $\underline{\sigma}$ smooth. The summation over all x_i concludes the proof of the theorem. ∎

3.2. Analysis of the upwind scheme in the H^1-norm. This section is devoted to the case when an upwind approximation is applied to the convection term, namely, we consider problem (2.11).

DEFINITION 3.3. *For an element $K\in\mathcal{T}$ we denote by $\gamma_K:=\cup_{\gamma_{ij}}(K\cap\gamma_{ij})$ and set*

$$\eta_E^{\text{up}}:=\left(\sum_{K\in\mathcal{T}}\sum_{\gamma_{ij}\subset\gamma_K}\|h^{1/2}\underline{b}\cdot\underline{n}\,(u_h(x_i)-u_h)\|^2_{L^2(\gamma_{ij})}\right)^{1/2},$$

$$\eta_N^{\text{up}}:=\|h^{1/2}\underline{b}\cdot\underline{n}\,\nabla u_h\|_{L^2(\Gamma_N^{\text{out}})}.$$

THEOREM 3.4. *Let the assumptions of Theorems* 3.1 *and* 3.2 *be satisfied, and let the upwind approximation be applied to the convection term. Then*

$$\|e\|_a \lesssim \eta_Z + \eta_N + \eta_E^{\mathrm{up}} + \eta_N^{\mathrm{up}} + h.o.t. \tag{3.16}$$

Proof. Since $a_h^{\mathrm{up}}(u_h, v^*) = F(v^*)$ and $a_h(u, v^*) = F(v^*)$ for $v^* \in S_h^*$ we have the orthogonality condition $a_h(u, v^*) - a_h^{\mathrm{up}}(u_h, v^*) = 0$. Choosing $v^* = \bar{e}$ we get the following representation for the energy norm of the error:

$$\begin{aligned}\|e\|_a^2 &= a(e,e) - a_h(u,\bar{e}) + a_h^{\mathrm{up}}(u_h,\bar{e}) \\ &= \{a(e,e) - a_h(e,\bar{e})\} + \{a_h^{\mathrm{up}}(u_h,\bar{e}) - a_h(u_h,\bar{e})\} \\ &= \{a(e,e) - a_h(e,\bar{e})\} + \{C_h^{\mathrm{up}}(u_h,\bar{e}) - C_h(u_h,\bar{e})\}.\end{aligned}$$

For the first term, $a(e,e) - a_h(e,\bar{e})$, we use the same approach as in the analysis of the scheme without upwind (see Lemma 3.1) and show that

$$\begin{aligned}a(e,e) - a_h(u,\bar{e}) &= (f - \nabla_h \cdot \underline{\sigma}_h - \gamma u_h,\ e - \bar{e}) - \int_{\mathcal{E}} [\underline{\sigma}_h] \cdot \underline{n}\,(e - \bar{e})\,ds \\ &\quad - \int_{\Gamma_N^{\mathrm{in}}} (g - \underline{\sigma}_h \cdot \underline{n})\,(e - \bar{e})\,ds - \int_{\Gamma_N^{\mathrm{out}}} (A\nabla_h u_h) \cdot \underline{n}\,(e - \bar{e})\,ds.\end{aligned} \tag{3.17}$$

This presentation allows us to use estimate (3.7) of Theorem 3.2.

For the second term, $C_h^{\mathrm{up}}(u_h,\bar{e}) - C_h(u_h,\bar{e})$, we get

$$\begin{aligned}C_h^{\mathrm{up}}(u_h,\bar{e}) - C_h(u_h,\bar{e}) = \sum_{x_i \in N_h^0} \bar{e}_i \Bigg\{ &\sum_{j \in \Pi(i)} \int_{\gamma_{ij}} ((\underline{b}\cdot\underline{n})_+ u_h(x_i) + (\underline{b}\cdot\underline{n})_- u_h(x_j) - \underline{b}\cdot\underline{n} u_h)\,ds \\ &+ \int_{\partial V_i \cap \Gamma_N^{\mathrm{out}}} (\underline{b}\cdot\underline{n}\ u_h(x_i) - \underline{b}\cdot\underline{n}\ u_h)\ ds \Bigg\}.\end{aligned}$$

Here the unit normal vector $\underline{n}$ on γ_{ij} is oriented in such a way that $\underline{b}\cdot\underline{n} \geq 0$. We want to express the above sum as a sum over the elements. To do so we specify that the indexes (ij) are oriented so that $(x_i - x_j)\cdot\underline{n} \leq 0$. We get that

$$\begin{aligned}C_h^{\mathrm{up}}(u_h,\bar{e}) - C_h(u_h,\bar{e}) = \sum_{K \in \mathcal{T}_h} \Bigg\{ &\sum_{\gamma_{ij} \subset K} (\bar{e}_i - \bar{e}_j) \int_{\gamma_{ij}} \underline{b}\cdot\underline{n}\,(u_h(x_i) - u_h)\,ds \\ &+ \sum_{V_i \cap K} \bar{e}_i \int_{\partial V_i \cap \Gamma_N^{\mathrm{out}}} \underline{b}\cdot\underline{n}\ (u_h(x_i) - u_h)\ ds \Bigg\}.\end{aligned}$$

We denote by $[\bar{e}] := e_i - \bar{e}_j$ the jump of $\bar{e}$ across γ_{ij} and take into account that $[\bar{e} - e] = [\bar{e}]$. Then, by the Schwarz inequality, the term involving the integral over γ_{ij} is bounded by $C\|[e - \bar{e}]\|_{L^2(\gamma_{ij})}\ \|\underline{b}\cdot\underline{n}\,(u_h(x_i) - u_h)\|_{L^2(\gamma_{ij})}$. As before, using trace, Poincaré's, and/or Friedrichs's inequalities we get

$$\|[e - \bar{e}]\|_{L^2(\gamma_{ij})} \lesssim h_i^{1/2} \|\nabla e\|_{L^2(V_i)},$$

which bounds the integrals over γ_{ij} in the error representation with η_E^{up}.

For the terms involving integration over Γ_N^{out} we have

$$|u_h(x_i) - u_h(x)| \leq |\nabla u_h \cdot \underline{t}(x)|.|x_i - x|.$$

Here $\underline{t}(x)$ is a unit vector along $\partial V_i \cap K$, an edge in two dimensions, or a face in three dimensions. Then in two dimensions $\underline{t}$ is simply a unit vector perpendicular to $\underline{n}$, while in three dimensions $\underline{t}(x)$ depends on the position of x on the face and is again perpendicular to $\underline{n}$. In both cases $|u_h(x_i) - u_h(x)| \leq |h_K \nabla u_h|$. Using the Schwarz inequality we bound the term involving integration over Γ_N^{out} in the following way:

$$\sum_{V_i \cap K} \bar{e}_i \int_{\partial V_i \cap \Gamma_N^{\text{out}}} \underline{b} \cdot \underline{n}\, (u_h(x_i) - u_h)\, ds \leq C \|\nabla e\|.\|h^{1/2} \underline{b} \cdot \underline{n}\, \nabla u_h\|_{L^2(\Gamma_N^{\text{out}})},$$

which eventually gives the term η_N^{up} in (3.16) and completes the proof. ∎

3.3. Error estimates in L^2. We use duality techniques to get error estimators for different quantities of the error. In this subsection we will show how to use the duality technique in order to derive an error estimator in the global $L^2(\Omega)$-norm for the scheme without upwinding. The main assumption in this section is that the solution of problem (1.1) is H^2 regular.

DEFINITION 3.4. *We define the residual L^2 a posteriori error estimator $\tilde{\rho}$ as*

$$\tilde{\rho} := (\tilde{\eta}_R^2 + \tilde{\eta}_E^2 + \tilde{\eta}_N^2)^{1/2}, \tag{3.18}$$

where

$$\begin{aligned}
\tilde{\eta}_R^2 &:= \|h\,(R_K - \bar{R}_K)\|^2 + \|h^2\, R_K\|^2, \\
\tilde{\eta}_E^2 &:= \|h^{1/2}\,(R_E - \bar{R}_E)\|_{L^2(\mathcal{E})}^2 + \|h^{3/2}\, R_E\|_{L^2(\mathcal{E})}^2, \\
\tilde{\eta}_N^2 &:= \|h^{1/2}\,(R_E^{\text{in}} - \bar{R}_E^{\text{in}})\|_{L^2(\Gamma_N^{\text{in}})}^2 + \|h^{3/2}\, R_E^{\text{in}}\|_{L^2(\Gamma_N^{\text{in}})}^2 \\
&\quad + \|h^{1/2}\,(R_E^{\text{out}} - \bar{R}_E^{\text{out}})\|_{L^2(\Gamma_N^{\text{out}})}^2 + \|h^{3/2}\, R_E^{\text{out}}\|_{L^2(\Gamma_N^{\text{out}})}^2,
\end{aligned}$$

and $\bar{R}_K$, $\bar{R}_E$, $\bar{R}_E^{\text{in}}$, and $\bar{R}_E^{\text{out}}$ are the $K \in \mathcal{T}$, $E \in \mathcal{E}$, $E \in \Gamma_N^{\text{in}}$, and $E \in \Gamma_N^{\text{out}}$ piecewise mean values of, correspondingly, R_K, R_E, R_E^{in}, and R_E^{out} introduced in Definition 3.1.

Our aim is to show that the estimator $\tilde{\rho}$ is reliable in the $L^2(\Omega)$-norm. The a posteriori $L^2(\Omega)$ error analysis involves the following continuous dual problem: Find $\tilde{e} \in H_D^1(\Omega)$ such that

$$a(v, \tilde{e}) = (e, v) \text{ for any } v \in H_D^1(\Omega), \tag{3.19}$$

where e is the exact error, defined as before.

THEOREM 3.5. *Let the solution $\tilde{e}$ of the dual problem* (3.19) *be $H^2(\Omega)$ regular. If the coefficients of our basic problem* (1.1) *are sufficiently regular, namely R_K, R_E, R_E^{in}, and R_E^{out} are correspondingly in $H^1(K)$, $H^{1/2}(E)$, $H^{1/2}(\Gamma_N^{\text{in}})$, and $H^{1/2}(\Gamma_N^{\text{out}})$, then the residual L^2 a posteriori error estimator* (3.18) *from Definition* 3.4 *is reliable, i.e., $\|e\| \lesssim \tilde{\rho}$.*

Proof. Let $v = e$ in (3.19) and argue as in the proof of Lemma 3.1 to show

$$\begin{aligned}
\|e\|^2 = a(e, \tilde{e}) &= (R_K, \tilde{e} - e^*) - (R_E, \tilde{e} - e^*)_{L^2(\mathcal{E})} \\
&\quad - (R_E^{\text{in}}, \tilde{e} - e^*)_{L^2(\Gamma_N^{\text{in}})} - (R_E^{\text{out}}, \tilde{e} - e^*)_{L^2(\Gamma_N^{\text{out}})}
\end{aligned} \tag{3.20}$$

for an arbitrary $e^* \in S_h^*$. To evaluate the right-hand side of this identity we use the nodal interpolation operator I_h and its properties. If $\tilde{e} \in H^2(\Omega)$, the Sobolev inequalities [12, Theorem 4.3.4] guarantee that $I_h\tilde{e}$ is well defined. The properties of the interpolant are well established in the finite element literature (see, for example, [12]), namely,

(3.21)
$$h_K^{-2}\|\tilde{e} - I_h\tilde{e}\|_{L^2(K)} + h_K^{-1}|\tilde{e} - I_h\tilde{e}|_{H^1(K)} + h_K^{-3/2}\|\tilde{e} - I_h\tilde{e}\|_{L^2(\partial K)} \leq C_{I,K}|\tilde{e}|_{H^2(K)}.$$

Now, in (3.20) we choose $e^* = I_h^* I_h\tilde{e}$ so that $\tilde{e} - e^* = (\tilde{e} - I_h\tilde{e}) + (I_h\tilde{e} - I_h^* I_h\tilde{e})$. Further, we apply the Schwarz inequality on the integrals involving $\tilde{e} - I_h\tilde{e}$ and use (3.21) to get the bound

$$\begin{aligned}(R_K, \tilde{e} - I_h\tilde{e}) - (R_E, \tilde{e} - I_h\tilde{e})_{L^2(\mathcal{E})} - (R_E^{\text{in}}, \tilde{e} - I_h\tilde{e})_{L^2(\Gamma_N^{\text{in}})} - (R_E^{\text{out}}, \tilde{e} - I_h\tilde{e})_{L^2(\Gamma_N^{\text{out}})}\\ \lesssim \big(\|h^2\ R_K\| + \|h^{3/2}\ R_E\|_{L^2(\mathcal{E})} + \|h^{3/2}\ R_E^{\text{in}}\|_{L^2(\Gamma_N^{\text{in}})} + \|h^{3/2}\ R_E^{\text{out}}\|_{L^2(\Gamma_N^{\text{out}})}\big)|\tilde{e}|_{H^2(\Omega)}.\end{aligned}$$

For the integrals involving $I_h\tilde{e} - I_h^* I_h\tilde{e}$ we first note that if K is a fixed element in $\mathcal{T}$, then for every vertex x_i of K, the quantities $|K \cap V_i|$ (volume in three dimensions and area in two dimensions) are equal. Also, for vertices x_i on the face/edge E we have that the boundary quantities $|E \cap V_i|$ (area in three dimensions and length in two dimensions) are also equal. Therefore,

$$\int_K (I_h\tilde{e} - I_h^* I_h\tilde{e})dx = 0, \qquad \int_E (I_h\tilde{e} - I_h^* I_h\tilde{e})ds = 0.$$

We apply the last fact to the integrals involving $I_h\tilde{e} - I_h^* I_h\tilde{e}$ in order to subtract from R_K, R_E, R_E^{in}, and R_E^{out} their mean values $\bar{R}_K$, $\bar{R}_E$, $\bar{R}_E^{\text{in}}$, and $\bar{R}_E^{\text{out}}$. Then, using Schwarz and Poincaré inequalities we bound the term involving $I_h\tilde{e} - I_h^* I_h\tilde{e}$, namely,

$$\begin{aligned}&|(R_K, I_h^* I_h\tilde{e} - I_h\tilde{e}) - (R_E, I_h^* I_h\tilde{e} - I_h\tilde{e})_{L^2(\mathcal{E})} - (R_E^{\text{in}}, I_h^* I_h\tilde{e} - I_h\tilde{e})_{L^2(\Gamma_N^{\text{in}})}\\ &\qquad - (R_E^{\text{out}}, I_h^* I_h\tilde{e} - I_h\tilde{e})_{L^2(\Gamma_N^{\text{out}})}|\\ &\lesssim \big(\|h\ (R_K - \bar{R}_K)\| + \|h^{1/2}(R_E - \bar{R}_E)\|_{L^2(\mathcal{E})}\\ &\qquad + \|h^{1/2}\ (R_E^{\text{in}} - \bar{R}_E^{\text{in}})\|_{L^2(\Gamma_N^{\text{in}})} + \|h^{1/2}\ (R_E^{\text{out}} - \bar{R}_E^{\text{out}})\|_{L^2(\Gamma_N^{\text{out}})}\big)\|\tilde{e}\|_{H^2(K)},\end{aligned}$$

where we have used the inequality

$$\begin{aligned}\|I_h\tilde{e} - I_h^* I_h\tilde{e}\|_{L^2(K)} &\lesssim h_K|I_h\tilde{e}|_{H^1(K)} \lesssim h_K|\tilde{e} - I_h\tilde{e}|_{H^1(K)} + h_K|\tilde{e}|_{H^1(K)}\\ &\lesssim h_K^2|\tilde{e}|_{H^2(K)} + h_K|\tilde{e}|_{H^1(K)} \lesssim h_K|\tilde{e}|_{H^2(K)}.\end{aligned}$$

Applying the above estimates, the stability of the dual problem with respect to the right-hand side, $\|\tilde{e}\|_{H^2(\Omega)} \leq C\|e\|$, and obvious manipulations, we get that the L^2 a posteriori error estimator $\tilde{\rho}$ is reliable. Moreover, since the coefficients of (1.1) are sufficiently regular we can apply Poincaré's inequality to the terms $\|R_K - \bar{R}_K\|_{L^2(K)}$, $\|R_E - \bar{R}_E\|_{L^2(E)}$, $\|R_E^{\text{in}} - \bar{R}_E^{\text{in}}\|_{L^2(E)}$, and $\|R_E^{\text{out}} - \bar{R}_E^{\text{out}}\|_{L^2(E)}$ to get one additional power of h that will make the error estimator of second order.

Note that we did not explicitly apply Poincaré's inequality in the definition of the error estimator in order to make it well defined for problems with less than that stated in the theorem regularity. ∎

4. Adaptive grid refinement and solution strategy. In this section we present the adaptive mesh refinement strategy that we use. It is based on the grid refinement approach in the finite element methods (see, e.g., [11, 36]). A different grid adaptation strategy, again in the finite element method, has been proposed, justified, and used in [20].

For a given finite element partitioning $\mathcal{T}$, desired error tolerance ρ, and a norm in which the tolerance to be achieved is, say $|||\cdot|||$, do the following:

- compute the finite volume approximation $u_h \in S_h$, as given in subsection 2.2;
- using the a posteriori error analysis, compute the errors ρ_K for all $K \in \mathcal{T}$;
- mark those finite elements K for which $\rho_K \geq \rho/\sqrt{N}$; here N is the number of elements in $\mathcal{T}$;
- if $\sum_{K\in\mathcal{T}} \rho_K^2 > \rho^2$, then refine the marked elements;
- additionally refine until a conforming mesh is reached;
- repeat the above process until no elements have been refined.

For the 2-D case we refine marked elements by uniformly splitting the marked triangles into four. The refinement to conformity is done by bisection through the longest edge. For the 3-D version of the code the elements (tetrahedrons) are refined using the algorithm described by Arnold, Mukherjee, and Pouly in [5].

The described procedure yields error control and optimal mesh (heuristics), which are the goals in the adaptive algorithm. The nested meshes obtained in the process are used to define multilevel preconditioners. The initial guess for every new level is taken to be the interpolation of u_h from the previous level.

5. Numerical examples. Here we present two sets of numerical examples to test the our theoretical results. The first two examples are simple 2-D elliptic problems while the remaining tests illustrate our approach on 3-D problems of flow and transport in porous media.

5.1. 2-D test problems. In Example 1 we consider problems with known solutions and compare the behavior of the error estimators with the exact errors. Example 2 is for discontinuous matrix $A(x)$ with an unknown solution.

Example 1. We consider three Dirichlet problems for the Poisson equation on an L-shaped domain with known exact solutions $u = r^{4/3}\sin\frac{4\theta}{3}$ (Problem 1), $u = r^{2/3}\sin\frac{2\theta}{3}$ (Problem 2), and $u = r^{1/2}\sin\frac{\theta}{2}$ (Problem 3). These functions belong to $H^{1+s}(\Omega)$ with s almost $4/3$, $2/3$, and $1/2$, respectively. In Figure 4 we show the mesh and the error for Problem 2 after four levels of local refinement.

The theory shows that the a posteriori error estimators η_E and η_Z are equivalent to the H^1-norm of the error. This theoretical result is confirmed by our computations, which are summarized in Figure 5. The left picture gives the exact error (solid line) and the a posteriori error estimators η_Z (dashed line) and η_E (dash-dotted line) for the three problems over the different levels of the mesh. The levels are obtained by uniform refinement (splitting every triangle into 4) and have 65, 255, 833, 3,201, 12,545, 49,665, and 197,633 nodes correspondingly for levels $1, \ldots, 7$. The errors are printed in logarithmic scale in order to demonstrate the linear behavior of the error as a function of the level. For exact solutions in $H^{1+1/2-\epsilon}$, $H^{1+2/3-\epsilon}$, and $H^{1+4/3-\epsilon}$ ($\epsilon > 0$) one can see the theoretically expected rate of error reduction over the levels of $1/2$, $2/3$, and 1 correspondingly. One can observe that both η_Z and η_E are equivalent to the exact error, as proved in the theoretical section. The same is true when the local refinement method from section 4 is applied. The numerical results are given in Figure 5, right. The y scale is again the error, and the x scale is the refinement level.

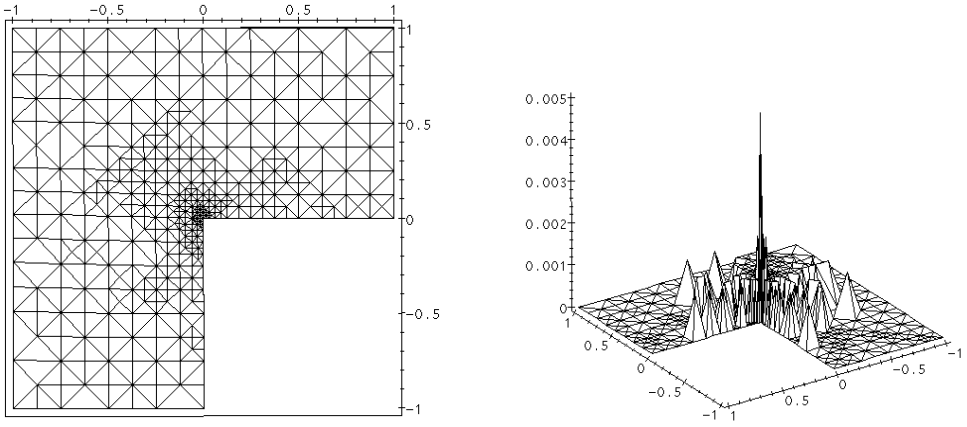

FIG. 4. *Locally refined mesh and the corresponding error after four levels of refinement.*

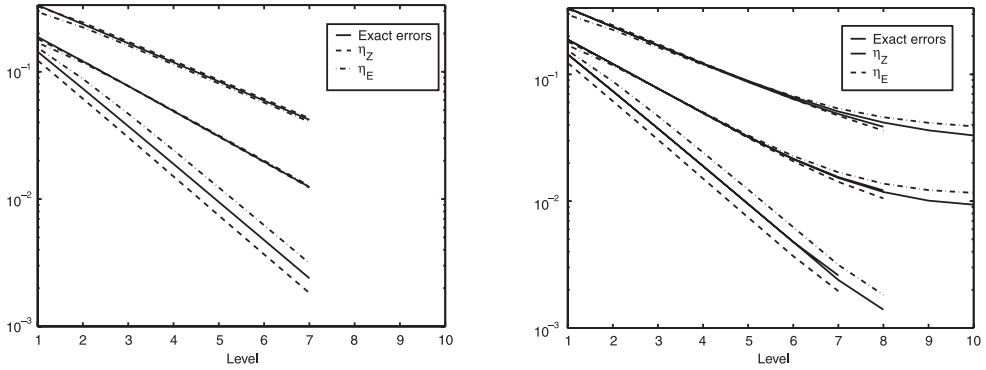

FIG. 5. *Comparison of the H^1-norm of the error for solutions $H^{1+4/3-\epsilon}$ (Problem 1), $H^{1+2/3-\epsilon}$ (Problem 2), and $H^{1+1/2-\epsilon}$ (Problem 3) on a sequence of uniformly refined grids and for grids refined locally by using the a posteriori error estimates. Left: Exact error, η_Z, and η_E for uniformly refined grids. Right: Exact error, η_Z, and η_E for locally refined grids.*

The error tolerances supplied to the refinement procedures are 0.0026 for Problem 1, 0.0122 for Problem 2, and 0.0385 for Problem 3. These are the exact errors for the problems considered on level 7 of the uniformly refined mesh. The result shows that, on the locally refined meshes, as in the uniform refinement case, both η_Z and η_E are equivalent to the exact error. Another observation is that, although the meshes are refined, only locally is the rate of error reduction over the refinement levels the same as on the uniformly refined meshes (compare the error reduction slopes with the ones in Figure 5, left).

Finally, we demonstrate the efficiency of the adaptive error control by giving the number of the degrees of freedom (DOF) on the locally refined mesh levels from Figure 5, right, and comparing them with the number of DOF on the uniformly refined mesh levels (see Table 5.1). Note the difference in the order of the mesh sizes for uniform refinement and local refinement for Problems 2 and 3. For Problem 1 we have full elliptic regularity, and η_Z/η_E are supposed to lead to uniform refinement, which is confirmed by the numerical experiment. The results demonstrate the efficiency of

TABLE 5.1

Number of DOF for the levels resulting from local refinement based on the η_Z and η_E error estimators. The error tolerances supplied to the refinement procedures are 0.0026 *for Problem* 1, 0.0122 *for Problem* 2, *and* 0.0385 *for Problem* 3 (*see Example* 1).

Level	Uniform mesh	Problem 1		Problem 2		Problem 3

applying local refinement based on η_Z and η_E for problems with singular solutions.

Example 2. We consider problem (1.1) with Ω shown in Figure 6. In this problem Γ_D is the upper boundary, $\underline{b} = (1, -0.5)$, and $f = 0$. The domain is taken to have three layers (see Figure 6) with $A(x) = 0.01\ I$ in the top layer, $0.05\ I$ in the internal layer, and $0.001\ I$ at the bottom. The Dirichlet boundary value is 1 for $x < 0.2$ and 0 otherwise. On the Neumann boundary we take $g = 0$. In this problem we have used the upwind approximation (2.11) and the local refinement procedures based on η_Z and η_E.

Since the exact solution is not known we judge the quality of the error estimators η_Z and η_E by comparing the results with the ones on uniformly refined meshes. Also, when choosing problems with known local behavior we expect the estimators to lead to refinement that closely follows the local behavior of the solution profile. This is a standard testing approach (see, for example, [4]).

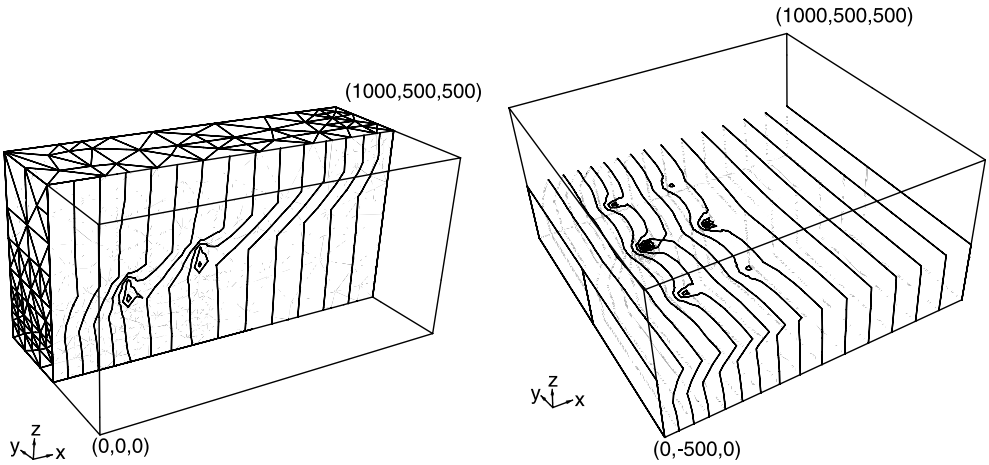

FIG. 7. *Pressure computations for a nonhomogeneous reservoir. Left: Contour curves of the pressure for the cross section* $x_2 = 250$. *Right: Contour curves of the pressure for the cross section* $x_3 = 200$.

Figure 6 shows the mesh on level 4 (left) with 3,032 nodes and 5,910 triangles. On the right are the solution level curves. This particular mesh was obtained by refinement based on η_Z with $\rho = 4\%$ of $|u_h|_1$ (≈ 0.1616, i.e., $\rho = 0.006464$). The mesh obtained by four levels of uniform refinement has 38,257 DOF. The discrete solutions have the same qualitative behavior in both cases. As expected, the mesh refinement follows the discrete solution profile. Refinement based on η_E, compared to η_Z, leads to slightly different, but qualitatively and quantitatively similar, meshes.

5.2. 3-D problems of flow and transport in porous media. This test is very similar to the 2-D Example 2. Here we test the error estimators η_Z and η_E on a real 3-D application in fluid flow and transport in porous media. Again, the exact solution is unknown but we know its local behavior, which is due to boundary layers, discontinuities of coefficients, and localized sources. The problem is described as follows.

A steady-state flow, with Darcy velocity $\underline{v}$ measured in ft/yr, has been established in a parallelepiped-shaped reservoir $\Omega = [0, 1000] \times [-500, 500] \times [0, 500]$ (see Figure 7, right). First, we determine the pressure $p(x)$ in Ω as the solution $u(x)$ of problem (1.1) with $\underline{b} = 0$, $\gamma = 0$, and $A(x) = D(x)$, where $D(x)$ is the permeability tensor. The pressure at faces $x_1 = 0$ and $x_1 = 1000$ is constant (correspondingly, 2,000 and 0). The rest of the boundary is subject to a no-flow condition. We take the permeability $D(x)$ to be 32 I everywhere in Ω except in the layer (see Figure 7, middle) where $D(x)$ is taken to be 10 times smaller than in the rest of the domain, i.e., in the layer $D(x) = 3.2\ I$.

Also, we have six production wells. For all of them x_3 is in the range $0, \ldots, 400$. Their (x_1, x_2) coordinates are correspondingly (200, -250), (400, -250), (200, 0), (400, 0), (200, 250), and (400, 250). We treat a well simply as a line-delta function (sink) along the well axis. Production rates $Q = 16{,}000$ l/yr for wells in plane $x_2 = 0$, and $Q = 8{,}000$ l/yr for the rest, are the intensities of the sink. Figure 7 shows half of the mesh and the contour curves of the pressure for the cross section $x_2 = 250$ (left) after five levels of local refinement. It has 19,850 tetrahedrons and 3,905 nodes. The right picture shows the contour curves for the cross section $x_3 = 200$.

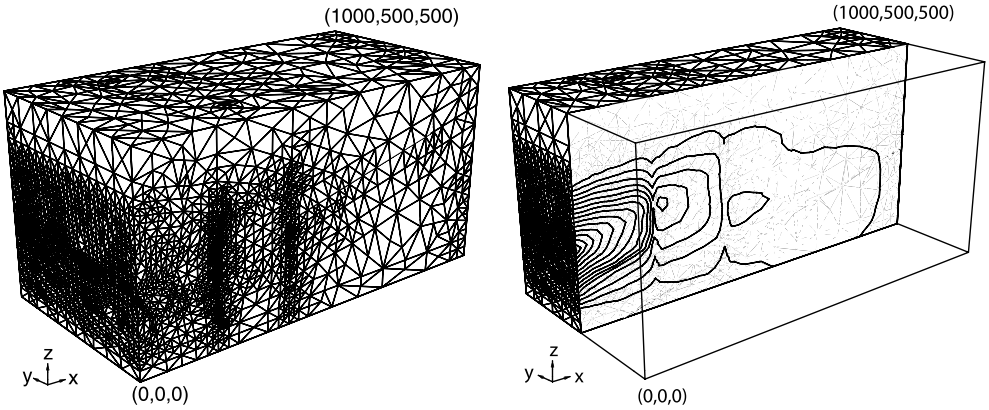

FIG. 8. *Concentration computations for a nonhomogeneous reservoir. Left: The* 3*-D mesh on refinement level* 11 *with* 219,789 *tetrahedrons and* 39,752 *nodes. Right: Concentration contour curves for cross section* $x_2 = 250$.

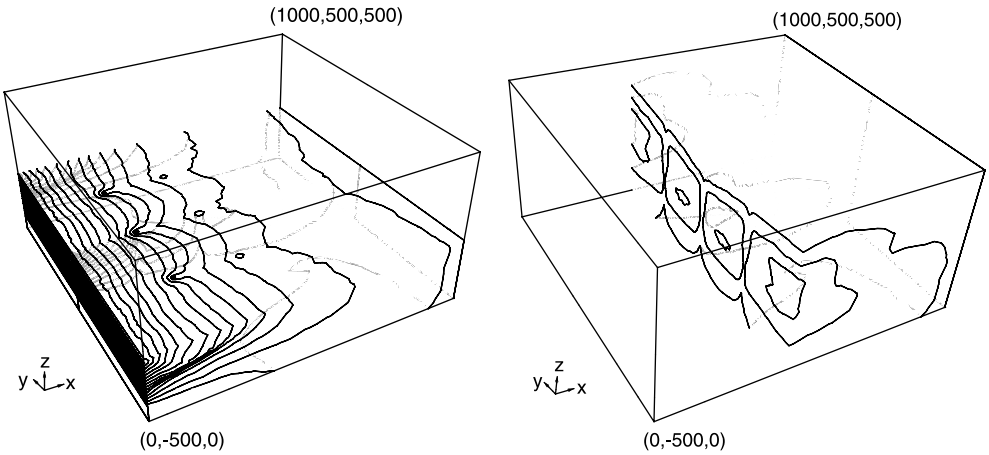

FIG. 9. *Concentration level curves at cross sections* $x_3 = 200$ (*left*) *and* $x_1 = 400$ (*right*).

The weighted pressure gradient $-D\nabla p$ forces the groundwater to flow. The transport of a contaminant dissolved in the water (in our case, benzene) is described by the convection-diffusion-reaction equation (1.1), where $u(x)$ represents the benzene concentration, $\underline{b}$ is the Darcy velocity $\underline{v} = -D\nabla p$, γ is the biodegradation rate, and $A(x)$ is the diffusion-dispersion tensor:

$$A(x) = k_{\text{diff}} I + k_t \underline{v}^T \underline{v}/|\underline{v}| + k_l(|\underline{v}|^2 I - \underline{v}^T \underline{v})/|\underline{v}|.$$

Here $k_{\text{diff}} = 0.0001$, $k_t = 21$, and $k_l = 2.1$ are the coefficients of diffusion, transverse, and longitudinal dispersions, respectively. A steady piecewise linear in x_3 and constant in x_2 leakage of benzene of maximum 30 mg/l is applied on the boundary strip $x_1 = 0$ and $50 \le x_3 \le 350$. The leakage is 30 mg/l at $x_3 = 200$ and drops linearly to 0 at $x_3 =$ 50 and 350. The rest of the boundary is subject to a homogeneous Neumann boundary condition. The dispersion/convection process causes the dissolved benzene to disperse in the reservoir. The biodegradation transforms it into a solid substance which is absorbed by the soil. This leads to a decrease in the benzene. The computations are

for the case of low absorption rate $\gamma = 0.05$. We approximate the convection term using the upwind approximation (2.10).

Figure 8 shows the obtained mesh in half of the domain (left) on refinement level 11. The mesh has 219,789 tetrahedrons and 39,752 nodes. The first five level of refinement are for the pressure equation, the rest for the concentration. Figure 8 (right) shows the level curves for the concentration in the reservoir cross section $x_2 = 250$ on the same refinement level. Figure 9 gives the level curves at two more cross sections, $x_3 = 200$ (left) and $x_1 = 400$ (right).

FLOQUET THEORY AS A COMPUTATIONAL TOOL*

GERALD MOORE†

Abstract. We describe how classical Floquet theory may be utilized, in a continuation framework, to construct an efficient Fourier spectral algorithm for approximating periodic orbits. At each continuation step, only a single square matrix, whose size equals the dimension of the phase-space, needs to be factorized; the rest of the required numerical linear algebra just consists of back-substitutions with this matrix. The eigenvalues of this key matrix are the Floquet exponents, whose crossing of the imaginary axis indicates bifurcation and change-in-stability. Hence we also describe how the new periodic orbits created at a period-doubling bifurcation point may be efficiently computed using our approach.

Key words. Floquet, Fourier, periodic orbit, continuation, period doubling

DOI. 10.1137/S0036142903434175

1. Introduction.

Floquet theory is the mathematical theory of linear, periodic systems of ordinary differential equations (ODEs) and as such appears in every standard book on ODEs, e.g., [1, 20]. (We especially recommend, however, the extensive elementary discussion in [19].) In this paper we wish to utilize Floquet theory in order to efficiently compute approximations to periodic orbits of nonlinear autonomous systems. The basic equations defining a periodic orbit are nonlinear, but applying a Newton-like method for their solution will lead to linear, periodic systems. It is for this reason that Floquet theory is so important for us.

The nonlinear, autonomous system we shall consider is

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{F}(\boldsymbol{x}(t), \lambda), \qquad \boldsymbol{F} : \mathbb{R}^n \times \mathbb{R} \mapsto \mathbb{R}^n; \tag{1.1}$$

i.e., $\boldsymbol{F}$ is a smooth function on $\mathbb{R}^n$ and depends on a parameter λ. For the rest of this section (and sections 2 and 4), however, we shall temporarily consider

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{F}(\boldsymbol{x}(t)), \qquad \boldsymbol{F} : \mathbb{R}^n \mapsto \mathbb{R}^n. \tag{1.2}$$

The simplest solutions of (1.2) are the stationary points $\boldsymbol{x}^\star \in \mathbb{R}^n$ defined by

$$\boldsymbol{F}(\boldsymbol{x}^\star) = \boldsymbol{0}.$$

We will only be interested in stationary points at which periodic orbits are created, i.e., the famous Hopf bifurcation points considered in section 3. It is the next simplest solution of (1.2) that this paper is concerned with.

DEFINITION. *$\boldsymbol{u}^\star : \mathbb{R} \mapsto \mathbb{R}^n$ is a* periodic orbit *for* (1.2)*, with (minimal) period $2\pi T^\star > 0$, if*

$$\begin{aligned} &\dot{\boldsymbol{u}}^\star(t) = \boldsymbol{F}(\boldsymbol{u}^\star(t)) \quad \forall t \in \mathbb{R}, \\ &\boldsymbol{u}^\star(0) = \boldsymbol{u}^\star(2\pi T^\star), \\ &\boldsymbol{u}^\star(t) \neq \boldsymbol{u}^\star(0) \quad \forall t \in (0, 2\pi T^\star). \end{aligned}$$

*Received by the editors August 28, 2003; accepted for publication (in revised form) June 19, 2004; published electronically March 31, 2005.

†Department of Mathematics, Imperial College of Science, Technology and Medicine, 180 Queen's Gate, London SW7 2AZ, UK (g.moore@imperial.ac.uk).

In order to set up an appropriate set of equations for computing a periodic orbit, two key facts should be kept in mind:

- $T^\star$ that defines the period is also unknown;
- for any $c \in \mathbb{R}$, $\boldsymbol{u}^\star(t+c)$ describes the "same" periodic orbit.

(More precisely, $\boldsymbol{u}^\star(t)$ and $\boldsymbol{u}^\star(t+c)$ differ only by *phase*.)

The problem of working with an unknown period is dealt with by defining

$$\boldsymbol{v}^\star(\theta) \equiv \boldsymbol{u}^\star(T^\star\theta).$$

Hence $\boldsymbol{v}^\star$ has period 2π and satisfies

$$\dot{\boldsymbol{v}}^\star(\theta) = T^\star \boldsymbol{F}(\boldsymbol{v}^\star(\theta)).$$

Thus we should solve

$$\dot{\boldsymbol{v}}(\theta) = T\boldsymbol{F}(\boldsymbol{v}(\theta)), \qquad \boldsymbol{v}(0) = \boldsymbol{v}(2\pi) \tag{1.3}$$

for both the function $\boldsymbol{v}$ and the scalar T. Since there is an extra unknown, i.e., T, we must have an extra scalar equation. This fits in with the fact that $\boldsymbol{v}^\star(\theta+c)$ is a solution for any $c \in \mathbb{R}$. The modern way of "fixing the phase," i.e., constructing an extra scalar equation which determines a unique c, is as follows.

- We assume that we know a nearby periodic orbit $\boldsymbol{v}^0(\theta)$ of period 2π. This is a natural assumption to make in a continuation framework.
- We *fix* the phase by seeking the value of c which makes $\boldsymbol{v}^\star(\theta+c)$ as close as possible to $\boldsymbol{v}^0(\theta)$, e.g.,

$$\min_{c\in\mathbb{R}} \int_0^{2\pi} \|\boldsymbol{v}^\star(\theta+c) - \boldsymbol{v}^0(\theta)\|_2^2 \,\mathrm{d}\theta.$$

- Setting the derivative with respect to c equal to zero gives

$$\int_0^{2\pi} \boldsymbol{v}^0(\theta) \cdot \dot{\boldsymbol{v}}^\star(\theta+c) \,\mathrm{d}\theta = 0,$$

but it is convenient to integrate-by-parts and write

$$\int_0^{2\pi} \dot{\boldsymbol{v}}^0(\theta) \cdot \boldsymbol{v}^\star(\theta+c) \,\mathrm{d}\theta = 0.$$

Hence our final set of equations for a periodic orbit is

$$\begin{aligned} &\dot{\boldsymbol{v}}(\theta) = T\boldsymbol{F}(\boldsymbol{v}(\theta)), \qquad \boldsymbol{v}(0) = \boldsymbol{v}(2\pi), \\ &\int_0^{2\pi} \dot{\boldsymbol{v}}^0(\theta) \cdot \boldsymbol{v}(\theta) \,\mathrm{d}\theta = 0. \end{aligned} \tag{1.4}$$

We shall follow this idea later in section 4, but using a more appropriate inner product.

As we shall see, Floquet theory is best combined with a Fourier method to approximate periodic orbits. This leads to the question, why aren't Fourier spectral methods more popular, compared to the completely dominant collocation with piecewise-polynomials [11, 14, 23, 24]? (Of course, Fourier approximation of periodic orbits has been considered in a few papers, e.g., [9, 10], but *not* using the present approach. For example, in [30] it is suggested that an approximation to the monodromy matrix be

computed using an initial-value algorithm, which we regard as generally unacceptable.) So long as the solution one is trying to approximate is smooth, the standard advantage of spectral methods has always been their approximation power, and the standard disadvantage has been that they require the solution of linear equations with nonsparse coefficient matrices. The key task of the present paper is to emphasize that this disadvantage is *not* present when using Fourier spectral methods to approximate periodic orbits *in a continuation framework*. The underlying reason can be split into three parts.

- Fourier mode decoupling occurs for linear, constant-coefficient differential equations, as described in section 2.
- Floquet theory transforms linear, periodic differential equations into constant-coefficient form, as described in section 4.
- The Floquet variables required for this transformation can be updated efficiently as part of the continuation process, as described in section 5.

The practical difference between piecewise-polynomial and Fourier approximation becomes clear if one considers the linear, periodic system

$$-\dot{\boldsymbol{y}}(\theta) + \mathsf{A}(\theta)\boldsymbol{y}(\theta) = \boldsymbol{f}(\theta),$$

where $\boldsymbol{f} : [0, 2\pi] \mapsto \mathbb{R}^n$ and $\mathsf{A} : [0, 2\pi] \mapsto \mathbb{R}^{n\times n}$ is given periodic data, and we wish to determine a periodic solution $\boldsymbol{y} : [0, 2\pi] \mapsto \mathbb{R}^n$. Applying a piecewise-polynomial collocation method at the N mesh-points

$$0 = \theta_0 < \theta_1 < \cdots < \theta_{N-1} < \theta_N = 2\pi$$

leads to an $Nn \times Nn$ coefficient matrix with the almost block-bidiagonal structure

$$\begin{pmatrix} \square & \square & & & & \\ & \square & \square & & & \\ & & \ddots & \ddots & & \\ & & & \ddots & \ddots & \\ & & & & \square & \square \\ \square & & & & & \square \end{pmatrix}, \tag{1.5}$$

where each $\square$ is of size $n \times n$. (We assume that *condensation of local parameters* has been applied, as in [3].) With a spectral method based on Fourier modes, however, just a *single* $n \times n$ matrix needs to be factorized; all other matrix operations are just back-substitutions with quasi-upper triangular matrices. We must admit, however, that it *is* necessary to use a small multiple of Nn^2 locations for storing Floquet information, i.e., roughly the same number of nonzero elements as in (1.5).

To conclude this introduction, we describe the contents of this paper. In section 2, we show how mode-decoupling occurs for Fourier approximation of constant-coefficient problems, not only for 2π-periodic equations but also for another form of periodicity that is (in general) required by the Floquet theory. Some of these results are then applied in section 3 in order to efficiently calculate periodic orbits created at a Hopf bifurcation point. In section 4, we describe Floquet theory in the practical form that we shall utilize it. It is then immediately employed, in section 5, to advance a periodic orbit over a single continuation step. To illustrate the performance of the previous algorithms, we present some numerical results in section 6. Finally, section 7 shows how the Floquet theory makes it very easy to move onto the new periodic orbits created at a period-doubling point. For a background to many of the topics discussed in this paper, we recommend [12, 13].

2. Constant-coefficient equations. For periodic, constant-coefficient equations, Fourier analysis is especially simple because the Fourier modes decouple. We shall require two spaces of periodic functions, which we denote by $\mathcal{Y}_+$ and $\mathcal{Y}_-$, respectively. The first of these is just the usual space of 2π-periodic functions, spanned by

$$1,\ \cos\theta,\ \sin\theta,\ \cos 2\theta,\ \sin 2\theta,\ \ldots.$$

The second of these is the subspace of 4π-periodic functions which satisfy

$$y(\theta) = -y(\theta + 2\pi)$$

and is therefore spanned by

$$\cos\tfrac{\theta}{2},\ \sin\tfrac{\theta}{2},\ \cos\tfrac{3\theta}{2},\ \sin\tfrac{3\theta}{2},\ \ldots.$$

Of course, the direct sum

$$\mathcal{Y}_+ \oplus \mathcal{Y}_-$$

gives *all* 4π-periodic functions. The key reason why the space $\mathcal{Y}_-$ is important to us is that the product of two of its elements lies in $\mathcal{Y}_+$, and such products will arise naturally in section 4. Similarly, the product of an element of $\mathcal{Y}_+$ with an element of $\mathcal{Y}_-$ lies in $\mathcal{Y}_-$.

We mention here that, throughout this paper, Fourier series will be described using real trigonometric functions rather than the mathematically more elegant complex exponentials. This is solely because we wish to remain close to the practical implementation of our algorithms.

2.1. Equations in $\mathcal{Y}_+^n$. For a constant $n \times n$ matrix A, consider the linear, periodic, homogeneous differential equation

$$-\dot{\boldsymbol{z}}(\theta) + \mathsf{A}\boldsymbol{z}(\theta) = \boldsymbol{0}, \qquad \boldsymbol{z} \in \mathcal{Y}_+^n,$$

which means that each component of $\boldsymbol{z}$ is in $\mathcal{Y}_+$. If the set $\{m\mathrm{i} : m \in \mathbb{Z}\}$ does *not* contain any eigenvalue of A, then this equation only has the trivial solution $\boldsymbol{z}(\theta) \equiv \boldsymbol{0}$. Under this assumption, consider the linear, periodic, inhomogeneous differential equation

$$-\dot{\boldsymbol{z}}(\theta) + \mathsf{A}\boldsymbol{z}(\theta) = \boldsymbol{f}(\theta), \qquad \boldsymbol{z} \in \mathcal{Y}_+^n, \tag{2.1}$$

for a given $\boldsymbol{f} \in \mathcal{Y}_+^n$. If

$$\boldsymbol{f}(\theta) \equiv \boldsymbol{f}_0^c + \sum_{m=1}^{\infty} \bigl\{\boldsymbol{f}_m^c \cos m\theta + \boldsymbol{f}_m^s \sin m\theta\bigr\},$$

then the Fourier coefficients of

$$\boldsymbol{z}(\theta) \equiv \boldsymbol{z}_0^c + \sum_{m=1}^{\infty} \bigl\{\boldsymbol{z}_m^c \cos m\theta + \boldsymbol{z}_m^s \sin m\theta\bigr\}$$

are given by

$$\mathsf{A}\boldsymbol{z}_0^c = \boldsymbol{f}_0^c \tag{2.2a}$$

and

$$\begin{pmatrix} \mathsf{A} & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{A} \end{pmatrix} \begin{pmatrix} \boldsymbol{z}_m^c \\ \boldsymbol{z}_m^s \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_m^c \\ \boldsymbol{f}_m^s \end{pmatrix}, \quad m = 1, 2, \ldots. \tag{2.2b}$$

Since the eigenvalues of $\left(\begin{smallmatrix} \mathsf{A} & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{A} \end{smallmatrix}\right)$ are related to those of A through the mapping

$$\mu \to \mu \pm m\mathrm{i},$$

the above eigenvalue assumption means that $\left(\begin{smallmatrix} \mathsf{A} & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{A} \end{smallmatrix}\right)$ is nonsingular for all $m \in \mathbb{N}$.

2.2. Equations in $\mathcal{Y}_-^n$. Similarly, if we ask the question whether the linear, periodic, homogeneous differential equation

$$-\dot{\boldsymbol{z}}(\theta) + \mathsf{A}\boldsymbol{z}(\theta) = \boldsymbol{0}, \qquad \boldsymbol{z} \in \mathcal{Y}_-^n,$$

has any nontrivial solution, then the answer is that it does *not*, provided that the set $\left\{[m - \frac{1}{2}]\mathrm{i} : m \in \mathbb{Z}\right\}$ contains no eigenvalue of A. Furthermore, if $\boldsymbol{f} \in \mathcal{Y}_-^n$ is given, the linear, periodic, inhomogeneous differential equation

$$-\dot{\boldsymbol{z}}(\theta) + \mathsf{A}\boldsymbol{z}(\theta) = \boldsymbol{f}(\theta), \qquad \boldsymbol{z} \in \mathcal{Y}_-^n, \tag{2.3}$$

has a unique solution under this assumption. If

$$\boldsymbol{f}(\theta) \equiv \sum_{m=1}^{\infty} \left\{ \boldsymbol{f}_m^c \cos[m - \tfrac{1}{2}]\theta + \boldsymbol{f}_m^s \sin[m - \tfrac{1}{2}]\theta \right\},$$

then the Fourier coefficients of

$$\boldsymbol{z}(\theta) \equiv \sum_{m=1}^{\infty} \left\{ \boldsymbol{z}_m^c \cos[m - \tfrac{1}{2}]\theta + \boldsymbol{z}_m^s \sin[m - \tfrac{1}{2}]\theta \right\}$$

are given by

$$\begin{pmatrix} \mathsf{A} & -[m - \frac{1}{2}]\mathsf{I} \\ [m - \frac{1}{2}]\mathsf{I} & \mathsf{A} \end{pmatrix} \begin{pmatrix} \boldsymbol{z}_m^c \\ \boldsymbol{z}_m^s \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_m^c \\ \boldsymbol{f}_m^s \end{pmatrix}, \quad m = 1, 2, \ldots. \tag{2.4}$$

2.3. Computational algorithm in $\mathcal{Y}_+^n$. Now we show how to efficiently compute spectral approximations to the solution of (2.1). This is achieved by restricting to a finite number of Fourier modes ($m \le M$) and using accurate numerical quadrature to approximate the Fourier coefficients of $\boldsymbol{f}$.

Thus $\boldsymbol{f}$ in (2.1) is approximated by

$$\boldsymbol{f}(\theta) \approx \tilde{\boldsymbol{f}}_0^c + \sum_{m=1}^{M} \left\{ \tilde{\boldsymbol{f}}_m^c \cos m\theta + \tilde{\boldsymbol{f}}_m^s \sin m\theta \right\}, \tag{2.5}$$

where

- $\tilde{\boldsymbol{f}}_0^c \equiv \dfrac{1}{N} \displaystyle\sum_{j=1}^{N} \boldsymbol{f}(\theta_j),$
- $\tilde{\boldsymbol{f}}_m^c \equiv \dfrac{2}{N} \displaystyle\sum_{j=1}^{N} \boldsymbol{f}(\theta_j) \cos m\theta_j, \qquad m = 1, 2, \ldots, M,$
- $\tilde{\boldsymbol{f}}_m^s \equiv \dfrac{2}{N} \displaystyle\sum_{j=1}^{N} \boldsymbol{f}(\theta_j) \sin m\theta_j, \qquad m = 1, 2, \ldots, M,$

and $N \equiv 2M+1$ with $\theta_j = \frac{2\pi j}{N}, \quad j = 1, \ldots, N$. In other words, we are using the fact that

$$\frac{1}{2\pi}\int_0^{2\pi} f(\theta)g(\theta)\,\mathrm{d}\theta = \frac{1}{N}\sum_{j=1}^{N} f(\theta_j)g(\theta_j) \tag{2.6}$$

when f and g are both in the subspace of $\mathcal{Y}_+$ spanned by

$$1,\ \cos\theta,\ \sin\theta,\ \cos 2\theta,\ \sin 2\theta,\ \ldots\ ,\ \cos M\theta,\ \sin M\theta.$$

Also the above transformation from function values to approximate Fourier coefficients can be written in matrix form

$$\mathsf{Q}_+ \boldsymbol{g}^p = \sqrt{N/2}\,\tilde{\boldsymbol{g}}^m,$$

where

$$\begin{aligned}\boldsymbol{g}^p &\equiv (g(\theta_1), g(\theta_2), \ldots g(\theta_N))^T,\\ \tilde{\boldsymbol{g}}^m &\equiv (\sqrt{2}\tilde{g}_0^c, \tilde{g}_1^c, \tilde{g}_1^s, \ldots \tilde{g}_M^c, \tilde{g}_M^s)^T\end{aligned}$$

with

$$g(\theta) \approx \tilde{g}_0^c + \sum_{m=1}^{M}\left\{\tilde{g}_m^c \cos m\theta + \tilde{g}_m^s \sin m\theta\right\},$$

and Q_+ is the $N \times N$ orthogonal matrix with (i,j)th component

$i = 1$	odd $i \geq 3$	even i
$1/\sqrt{N}$	$\sqrt{2/N}\sin\frac{i-1}{2}\theta_j$	$\sqrt{2/N}\cos\frac{i}{2}\theta_j$

.

Thus it can be applied to the point values of each component of $\boldsymbol{f}$ to obtain (2.5). (For large M, it is more efficient to map between point values and approximate modal values of $\boldsymbol{f}$ using the fast Fourier transform [17, 29]. In this case it may be preferable to choose N to be slightly greater than $2M+1$, i.e., so as to be a highly composite integer. The standard techniques for dealing with this situation are described in [6, 29].) Now the approximate Fourier coefficients for $\boldsymbol{z}$ in (2.1),

$$\boldsymbol{z}(\theta) \approx \tilde{\boldsymbol{z}}_0^c + \sum_{m=1}^{M}\left\{\tilde{\boldsymbol{z}}_m^c \cos m\theta + \tilde{\boldsymbol{z}}_m^s \sin m\theta\right\},$$

may be computed as in (2.2). Note that this is especially efficient when A has already been reduced to Schur form [17]; i.e.,

$$\mathsf{A} = \mathsf{Q}\hat{\mathsf{U}}\mathsf{Q}^T, \tag{2.7}$$

where $\hat{\mathsf{U}} \in \mathbb{R}^{n\times n}$ is a quasi-upper triangular matrix and $\mathsf{Q} \in \mathbb{R}^{n\times n}$ is an orthogonal matrix. Then, if $\tilde{\boldsymbol{z}}_0^c = \mathsf{Q}\hat{\boldsymbol{z}}_0^c$, $\tilde{\boldsymbol{f}}_0^c = \mathsf{Q}\hat{\boldsymbol{f}}_0^c$, and

$$\left.\begin{aligned}\tilde{\boldsymbol{z}}_m^{c/s} &= \mathsf{Q}\hat{\boldsymbol{z}}_m^{c/s}\\ \tilde{\boldsymbol{f}}_m^{c/s} &= \mathsf{Q}\hat{\boldsymbol{f}}_m^{c/s}\end{aligned}\right\}, \quad m = 1, \ldots, M,$$

we have only to solve the systems

$$\hat{\mathsf{U}}\hat{\boldsymbol{z}}_0^c = \hat{\boldsymbol{f}}_0^c \quad \text{and} \quad \begin{pmatrix} \hat{\mathsf{U}} & -m\mathsf{I} \\ m\mathsf{I} & \hat{\mathsf{U}} \end{pmatrix} \begin{pmatrix} \hat{\boldsymbol{z}}_m^c \\ \hat{\boldsymbol{z}}_m^s \end{pmatrix} = \begin{pmatrix} \hat{\boldsymbol{f}}_m^c \\ \hat{\boldsymbol{f}}_m^s \end{pmatrix}, \quad m = 1, \ldots, M.$$

The first is just back-substitution, starting with $\hat{u}_{nn}$ or the 2×2 block

$$\begin{pmatrix} \hat{u}_{n-1,n-1} & \hat{u}_{n-1,n} \\ \hat{u}_{n,n-1} & \hat{u}_{nn} \end{pmatrix},$$

while the second only requires solving 2×2 or 4×4 systems like

$$\begin{pmatrix} \hat{u}_{nn} & -m \\ m & \hat{u}_{nn} \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} \hat{u}_{n-1,n-1} & \hat{u}_{n-1,n} & -m & 0 \\ \hat{u}_{n,n-1} & \hat{u}_{nn} & 0 & -m \\ m & 0 & \hat{u}_{n-1,n-1} & \hat{u}_{n-1,n} \\ 0 & m & \hat{u}_{n,n-1} & \hat{u}_{nn} \end{pmatrix}.$$

2.4. Computational algorithm in $\mathcal{Y}_-^n$. Now we show how to efficiently compute spectral approximations to the solution of (2.3). Again this is achieved by restricting to a finite number of Fourier modes ($m \le M$) and using accurate numerical quadrature to approximate the Fourier coefficients of $\boldsymbol{f}$. Thus $\boldsymbol{f}$ in (2.3) is approximated by

$$\boldsymbol{f}(\theta) \approx \sum_{m=1}^{M} \left\{ \tilde{\boldsymbol{f}}_m^c \cos\left[m - \tfrac{1}{2}\right]\theta + \tilde{\boldsymbol{f}}_m^s \sin\left[m - \tfrac{1}{2}\right]\theta \right\}, \tag{2.8}$$

where

- $\tilde{\boldsymbol{f}}_m^c \equiv \dfrac{2}{N} \displaystyle\sum_{j=1}^{N} \boldsymbol{f}(\theta_j) \cos\left[m - \tfrac{1}{2}\right]\theta_j, \qquad m = 1, 2, \ldots, M,$
- $\tilde{\boldsymbol{f}}_m^s \equiv \dfrac{2}{N} \displaystyle\sum_{j=1}^{N} \boldsymbol{f}(\theta_j) \sin\left[m - \tfrac{1}{2}\right]\theta_j, \qquad m = 1, 2, \ldots, M,$

and $\theta_j = \frac{2\pi j}{N}, \quad j = 1, \ldots, N$. In other words, we are now using the fact that (2.6) also holds when f and g are both in the subspace of $\mathcal{Y}_-$ spanned by

$$\cos\tfrac{\theta}{2},\ \sin\tfrac{\theta}{2},\ \cos\tfrac{3\theta}{2},\ \sin\tfrac{3\theta}{2},\ \ldots\ ,\ \cos\left[M - \tfrac{1}{2}\right]\theta,\ \sin\left[M - \tfrac{1}{2}\right]\theta.$$

Again the above transformation from function values to approximate Fourier coefficients can be written in matrix form

$$\mathsf{Q}_- \boldsymbol{g}^p = \sqrt{N/2}\, \tilde{\boldsymbol{g}}^m,$$

where

$$\boldsymbol{g}^p \equiv (g(\theta_1), g(\theta_2), \ldots g(\theta_N))^T,$$
$$\tilde{\boldsymbol{g}}^m \equiv (\tilde{g}_1^c, \tilde{g}_1^s, \ldots \tilde{g}_M^c, \tilde{g}_M^s)^T$$

with

$$g(\theta) \approx \sum_{m=1}^{M} \left\{ \tilde{g}_m^c \cos\left[m - \tfrac{1}{2}\right]\theta + \tilde{g}_m^s \sin\left[m - \tfrac{1}{2}\right]\theta \right\},$$

and Q_- is the $2M \times N$ matrix with orthonormal rows and (i,j)th component

i even	i odd
$\sqrt{2/N}\sin\frac{i-1}{2}\theta_j$	$\sqrt{2/N}\cos\frac{i}{2}\theta_j$

;

the inverse transformation similarly being

$$\boldsymbol{g}^p = \sqrt{N/2}\,\mathsf{Q}_-^T\,\tilde{\boldsymbol{g}}^m.$$

Thus it can be applied to the point values of each component of $\boldsymbol{f}$ to obtain (2.8). (Again, for large M, the mapping between point values and approximate modal values of $\boldsymbol{f}$ is more efficiently carried out by a variant of the fast Fourier transform.) Now the approximate Fourier coefficients for $\boldsymbol{z}$ in (2.3),

$$\boldsymbol{z}(\theta) \approx \sum_{m=1}^{M} \left\{\tilde{\boldsymbol{z}}_m^c \cos[m-\tfrac{1}{2}]\theta + \tilde{\boldsymbol{z}}_m^s \sin[m-\tfrac{1}{2}]\theta\right\},$$

may be computed as in (2.4) above. Note that this is again especially efficient when A has already been reduced to Schur form as in (2.7). Then, if

$$\left.\begin{aligned}\tilde{\boldsymbol{z}}_m^{c/s} &= \mathsf{Q}\hat{\boldsymbol{z}}_m^{c/s}\\ \tilde{\boldsymbol{f}}_m^{c/s} &= \mathsf{Q}\hat{\boldsymbol{f}}_m^{c/s}\end{aligned}\right\}, \quad m = 1,\ldots,M,$$

we have only to solve the systems

$$\begin{pmatrix}\hat{\mathsf{U}} & -[m-\frac{1}{2}]\mathsf{I}\\ [m-\frac{1}{2}]\mathsf{I} & \hat{\mathsf{U}}\end{pmatrix}\begin{pmatrix}\hat{\boldsymbol{z}}_m^c\\ \hat{\boldsymbol{z}}_m^s\end{pmatrix} = \begin{pmatrix}\hat{\boldsymbol{f}}_m^c\\ \hat{\boldsymbol{f}}_m^s\end{pmatrix}, \quad m = 1,\ldots,M.$$

This just involves back-substitution, e.g., starting with the 2×2 system

$$\begin{pmatrix}\hat{u}_{nn} & -[m-\frac{1}{2}]\\ [m-\frac{1}{2}] & \hat{u}_{nn}\end{pmatrix}$$

or the 4×4 system

$$\begin{pmatrix}\hat{u}_{n-1,n-1} & \hat{u}_{n-1,n} & -[m-\frac{1}{2}] & 0\\ \hat{u}_{n,n-1} & \hat{u}_{nn} & 0 & -[m-\frac{1}{2}]\\ [m-\frac{1}{2}] & 0 & \hat{u}_{n-1,n-1} & \hat{u}_{n-1,n}\\ 0 & [m-\frac{1}{2}] & \hat{u}_{n,n-1} & \hat{u}_{nn}\end{pmatrix}.$$

3. Hopf bifurcation. In this section we look at a straightforward application of the ideas in sections 2.1 and 2.3. We were surprised that this does not seem to have appeared in the literature before, the closest example we have found being [16], which does not, however, take full advantage of the mode-decoupling.

Hopf bifurcation refers to the creation of small amplitude periodic orbits at a particular point on a curve of stationary points. For the parameter-dependent equation (1.1), we shall consider a stationary point $(\boldsymbol{x}^\star, \lambda^\star)$ satisfying the following properties.[1]

[1]For simplicity, we assume that the curve of stationary points is parametrizable by λ; cf. [18].

(a) $\boldsymbol{F}(\boldsymbol{x}^\star, \lambda^\star) = \boldsymbol{0}$ and the Jacobian matrix $\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)$ is nonsingular. Thus the implicit function theorem tells us that there is a locally unique curve of stationary points passing through $(\boldsymbol{x}^\star, \lambda^\star)$. This may be parametrized by λ, and so we denote it by $(\boldsymbol{x}^\star(\lambda), \lambda)$.

(b) $\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)$ has a pair of simple purely imaginary eigenvalues

$$\pm \mathrm{i}\omega^\star, \quad \omega^\star > 0,$$

and no other eigenvalues of the form $\{m\mathrm{i}\omega^\star : m \in \mathbb{Z}\}$. Hence the right eigenvector pair $\boldsymbol{\varphi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\varphi}^\star_{\Im}$ satisfies

$$\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)[\boldsymbol{\varphi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\varphi}^\star_{\Im}] = \pm \mathrm{i}\omega^\star[\boldsymbol{\varphi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\varphi}^\star_{\Im}],$$

i.e.,

$$\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)\boldsymbol{\varphi}^\star_{\Re} = -\omega^\star \boldsymbol{\varphi}^\star_{\Im}, \qquad \mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)\boldsymbol{\varphi}^\star_{\Im} = \omega^\star \boldsymbol{\varphi}^\star_{\Re},$$

and the left eigenvector pair $\boldsymbol{\psi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\psi}^\star_{\Im}$ satisfies

$$\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)^T[\boldsymbol{\psi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\psi}^\star_{\Im}] = \mp \mathrm{i}\omega^\star[\boldsymbol{\psi}^\star_{\Re} \pm \mathrm{i}\boldsymbol{\psi}^\star_{\Im}],$$

i.e.,

$$\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)^T\boldsymbol{\psi}^\star_{\Re} = \omega^\star \boldsymbol{\psi}^\star_{\Im}, \qquad \mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)^T\boldsymbol{\psi}^\star_{\Im} = -\omega^\star \boldsymbol{\psi}^\star_{\Re}.$$

A suitable choice of normalization is that

$$\begin{aligned} \boldsymbol{\varphi}^\star_{\Re} \cdot \boldsymbol{\varphi}^\star_{\Im} &= 0, & \|\boldsymbol{\varphi}^\star_{\Re}\|_2^2 + \|\boldsymbol{\varphi}^\star_{\Im}\|_2^2 &= 1, \\ \boldsymbol{\psi}^\star_{\Re} \cdot \boldsymbol{\varphi}^\star_{\Re} &= 1, & \boldsymbol{\psi}^\star_{\Re} \cdot \boldsymbol{\varphi}^\star_{\Im} &= 0, \\ \boldsymbol{\psi}^\star_{\Im} \cdot \boldsymbol{\varphi}^\star_{\Re} &= 0, & \boldsymbol{\psi}^\star_{\Im} \cdot \boldsymbol{\varphi}^\star_{\Im} &= 1. \end{aligned}$$

(c) If the $n \times n$ matrix $\mathsf{K}^\star$ is defined by

$$\mathsf{K}^\star \equiv \frac{\mathrm{d}}{\mathrm{d}\lambda}\Big\{\mathsf{J}(\boldsymbol{x}^\star(\lambda), \lambda)\Big\}\Big|_{\lambda=\lambda^\star},$$

then

$$\boldsymbol{\psi}^\star_{\Re} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Re} + \boldsymbol{\psi}^\star_{\Im} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Im} \neq 0. \tag{3.1}$$

This means that, as λ moves away from $\lambda^\star$, the eigenvalues of $\mathsf{J}(\boldsymbol{x}^\star(\lambda), \lambda)$ corresponding to $\pm\mathrm{i}\omega^\star$ are no longer purely imaginary; i.e., if these eigenvalues are denoted

$$\mu^\star(\lambda) \pm \mathrm{i}\omega^\star(\lambda),$$

then (3.1) is equivalent to $\frac{\mathrm{d}\mu^\star}{\mathrm{d}\lambda}(\lambda^\star) \neq 0$, since (from [22])

$$\begin{aligned} \gamma^\star_{\Re} &\equiv \frac{\mathrm{d}\mu^\star}{\mathrm{d}\lambda}(\lambda^\star) = \frac{\boldsymbol{\psi}^\star_{\Re} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Re} + \boldsymbol{\psi}^\star_{\Im} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Im}}{2}, \\ \gamma^\star_{\Im} &\equiv \frac{\mathrm{d}\omega^\star}{\mathrm{d}\lambda}(\lambda^\star) = \frac{\boldsymbol{\psi}^\star_{\Re} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Im} - \boldsymbol{\psi}^\star_{\Im} \cdot \mathsf{K}^\star \boldsymbol{\varphi}^\star_{\Re}}{2}. \end{aligned} \tag{3.2}$$

If, for λ near $\lambda^\star$, we look for a periodic orbit of (1.1) near $\boldsymbol{x}^\star$, then first we make our usual change-of-variable

$$\boldsymbol{v}(\theta) \equiv \boldsymbol{u}(T\theta),$$

which switches from $\boldsymbol{u}(t)$ with unknown period $2\pi T$ to $\boldsymbol{v}(\theta)$ with period 2π, and (1.1) transforms to

$$\dot{\boldsymbol{v}}(\theta) = T\boldsymbol{F}(\boldsymbol{v}(\theta), \lambda), \qquad \boldsymbol{v} \in \mathcal{Y}^n_+. \tag{3.3}$$

Since $\boldsymbol{F}(\boldsymbol{x}^\star, \lambda^\star) = \boldsymbol{0}$,

$$\boldsymbol{v}(\theta) \equiv \boldsymbol{x}^\star + \boldsymbol{z}(\theta), \qquad \boldsymbol{z} \in \mathcal{Y}^n_+,$$

will be an *approximate* periodic orbit (of period $2\pi T$) if $\boldsymbol{z}(\theta)$ is "small" and satisfies

$$-\dot{\boldsymbol{z}}(\theta) + T\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)\boldsymbol{z}(\theta) = \boldsymbol{0}. \tag{3.4}$$

But for $T = \frac{1}{\omega^\star}$, we know that (3.4) has solutions

$$\boldsymbol{z}(\theta) = C\boldsymbol{a}^\star(\theta + c)$$

for arbitrary constants C & c, where

$$\boldsymbol{a}^\star(\theta) \equiv \boldsymbol{\varphi}^\star_{\Re} \sin\theta + \boldsymbol{\varphi}^\star_{\Im} \cos\theta.$$

Thus we seek solutions of (3.3) in the form

$$\boldsymbol{v}(\theta) \equiv \boldsymbol{x}^\star(\lambda) + \varepsilon[\boldsymbol{a}^\star(\theta) + \boldsymbol{z}(\theta)] \tag{3.5}$$

for small nonzero ε, with

$$\frac{1}{\pi}\int_0^{2\pi} \boldsymbol{a}^\star(\theta) \cdot \boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0 \tag{3.6a}$$

and

$$\frac{1}{\pi}\int_0^{2\pi} \boldsymbol{p}^\star(\theta) \cdot \boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0, \tag{3.6b}$$

where

$$\boldsymbol{p}^\star(\theta) \equiv \frac{\mathrm{d}\boldsymbol{a}^\star}{\mathrm{d}\theta}(\theta) = \boldsymbol{\varphi}^\star_{\Re} \cos\theta - \boldsymbol{\varphi}^\star_{\Im} \sin\theta.$$

Equation (3.6a) fixes the amplitude of the periodic orbit, so we are using ε as a parametrization, and (3.6b) fixes the phase.

We shall soon require properties of the constant coefficient differential operator

$$-\frac{\mathrm{d}}{\mathrm{d}\theta} + \mathsf{A}^\star \tag{3.7}$$

on $\mathcal{Y}^n_+$, where

$$\mathsf{A}^\star \equiv T^\star \mathsf{J}(\boldsymbol{x}^\star, \lambda^\star) \quad \text{and} \quad T^\star \equiv \frac{1}{\omega^\star}.$$

The right null-space of (3.7) is spanned by $\boldsymbol{p}^\star(\theta)$ and $\boldsymbol{a}^\star(\theta)$, while its left null-space is spanned by

$$\tilde{\boldsymbol{a}}^\star(\theta) \equiv \boldsymbol{\psi}^\star_{\Re} \sin\theta + \boldsymbol{\psi}^\star_{\Im} \cos\theta \quad \text{and} \quad \tilde{\boldsymbol{p}}^\star(\theta) \equiv \boldsymbol{\psi}^\star_{\Re} \cos\theta - \boldsymbol{\psi}^\star_{\Im} \sin\theta.$$

If we consider the augmented linear equation

$$\begin{aligned} -\dot{\boldsymbol{z}}(\theta) + \mathsf{A}^\star \boldsymbol{z}(\theta) + \tfrac{T}{T^\star} \boldsymbol{p}^\star(\theta) + \lambda T^\star \mathsf{K}^\star \boldsymbol{a}^\star(\theta) &= \boldsymbol{0}, \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{a}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta &= 0, \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{p}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta &= 0 \end{aligned} \tag{3.8}$$

for unknowns $(\boldsymbol{z}(\theta), T, \lambda)$, as a mapping from $\mathcal{Y}^n_+ \times \mathbb{R}^2$ to itself; then (3.8) will only have the trivial solution $(\boldsymbol{0}, 0, 0)$ if the determinant of

$$\begin{bmatrix} \frac{1}{T^\star} \int_0^{2\pi} \tilde{\boldsymbol{a}}^\star(\theta) \cdot \boldsymbol{p}^\star(\theta)\, \mathrm{d}\theta & T^\star \int_0^{2\pi} \tilde{\boldsymbol{a}}^\star(\theta) \cdot \mathsf{K}^\star \boldsymbol{a}^\star(\theta)\, \mathrm{d}\theta \\ \frac{1}{T^\star} \int_0^{2\pi} \tilde{\boldsymbol{p}}^\star(\theta) \cdot \boldsymbol{p}^\star(\theta)\, \mathrm{d}\theta & T^\star \int_0^{2\pi} \tilde{\boldsymbol{p}}^\star(\theta) \cdot \mathsf{K}^\star \boldsymbol{a}^\star(\theta)\, \mathrm{d}\theta \end{bmatrix}$$

is nonzero. Since

$$\int_0^{2\pi} \tilde{\boldsymbol{a}}^\star(\theta) \cdot \boldsymbol{p}^\star(\theta)\, \mathrm{d}\theta = 0 \quad \text{and} \quad \int_0^{2\pi} \tilde{\boldsymbol{p}}^\star(\theta) \cdot \boldsymbol{p}^\star(\theta)\, \mathrm{d}\theta \neq 0,$$

this depends only on

$$\int_0^{2\pi} \tilde{\boldsymbol{a}}^\star(\theta) \cdot \mathsf{K}^\star \boldsymbol{a}^\star(\theta)\, \mathrm{d}\theta \neq 0,$$

which is equivalent to (3.1).

If the smooth mapping

$$\boldsymbol{G} : (\mathcal{Y}^n_+ \times \mathbb{R}^2) \times \mathbb{R} \mapsto \mathcal{Y}^n_+ \times \mathbb{R}^2$$

is constructed by the following:

- for $\varepsilon \neq 0$, $\boldsymbol{G}(\boldsymbol{z}, T, \lambda; \varepsilon)$ is defined by

$$\begin{aligned} -[\dot{\boldsymbol{a}}^\star(\theta) + \dot{\boldsymbol{z}}(\theta)] + \frac{1}{\varepsilon} T \boldsymbol{F}(\boldsymbol{x}^\star(\lambda) + \varepsilon[\boldsymbol{a}^\star(\theta) + \boldsymbol{z}(\theta)], \lambda) \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{a}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{p}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta, \end{aligned}$$

- $\boldsymbol{G}(\boldsymbol{z}, T, \lambda; 0)$ is defined by

$$\begin{aligned} -[\dot{\boldsymbol{a}}^\star(\theta) + \dot{\boldsymbol{z}}(\theta)] + T \mathsf{J}(\boldsymbol{x}^\star(\lambda), \lambda)[\boldsymbol{a}^\star(\theta) + \boldsymbol{z}(\theta)] \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{a}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta \\ \frac{1}{\pi} \int_0^{2\pi} \boldsymbol{p}^\star(\theta) \cdot \boldsymbol{z}(\theta)\, \mathrm{d}\theta; \end{aligned}$$

then the zeroes $(\boldsymbol{z}(\theta), T, \lambda)$ of $\boldsymbol{G}$ for nonzero ε correspond to periodic orbits of (3.3) through (3.5). It is immediate, however, that $\boldsymbol{G}(\boldsymbol{0}, T^\star, \lambda^\star; 0) = \boldsymbol{0}$, and (3.8) also tells us that, at $\varepsilon = 0$, the linearization of $\boldsymbol{G}$ with respect to $(\boldsymbol{z}, T, \lambda)$ at $(\boldsymbol{0}, T^\star, \lambda^\star)$ has no nontrivial solution. Hence the implicit function theorem applies to $\boldsymbol{G}$ at $(\boldsymbol{0}, T^\star, \lambda^\star; 0)$ and tells us there is a locally unique solution curve of periodic orbits for (3.3), parametrized by ε. (We note that, from a practical point of view, it is more efficient to replace $\boldsymbol{x}^\star(\lambda)$ above with the first-order approximation

$$\boldsymbol{x}^\star + [\lambda - \lambda^\star]\boldsymbol{\ell}^\star,$$

where $\boldsymbol{\ell}^\star$ is defined by

$$\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)\boldsymbol{\ell}^\star = -\boldsymbol{F}_\lambda(\boldsymbol{x}^\star, \lambda^\star).$$

For simplicity, however, we do not include this extra trick.)

Rearranging the equation for zeroes of $\boldsymbol{G}$ enables us to define the following Newton-chord iteration for obtaining these periodic orbits.

- Choose small $\varepsilon \neq 0$ and set

$$\boldsymbol{y}^{(0)}(\theta) = \boldsymbol{a}^\star(\theta), \quad T^{(0)} = T^\star, \quad \lambda^{(0)} = \lambda^\star.$$

- Solve

$$\begin{aligned} \left[-\frac{\mathrm{d}}{\mathrm{d}\theta} + \mathsf{A}^\star\right]\boldsymbol{z}(\theta) + \tfrac{\delta T}{T^\star}\boldsymbol{p}^\star(\theta) + \delta\lambda\, T^\star \mathsf{K}^\star \boldsymbol{a}^\star(\theta) &= \tfrac{1}{\varepsilon}\boldsymbol{r}^{(k)}(\theta), \\ \frac{1}{\pi}\int_0^{2\pi} \boldsymbol{a}^\star(\theta)\cdot\boldsymbol{z}(\theta)\,\mathrm{d}\theta &= 0, \\ \frac{1}{\pi}\int_0^{2\pi} \boldsymbol{p}^\star(\theta)\cdot\boldsymbol{z}(\theta)\,\mathrm{d}\theta &= 0 \end{aligned} \tag{3.9}$$

  for $\boldsymbol{z} \in \mathcal{Y}_+^n$, δT, and $\delta\lambda$, where

$$\boldsymbol{r}^k(\theta) \equiv \dot{\boldsymbol{y}}^{(k)}(\theta) - T^{(k)}\boldsymbol{F}(\boldsymbol{x}^\star(\lambda^{(k)}) + \varepsilon\boldsymbol{y}^{(k)}(\theta), \lambda^{(k)}).$$

- Set

$$\begin{aligned} \boldsymbol{y}^{(k+1)}(\theta) &= \boldsymbol{y}^{(k)} + \boldsymbol{z}(\theta), \\ T^{(k+1)} &= T^{(k)} + \delta T, \\ \lambda^{(k+1)} &= \lambda^{(k)} + \delta\lambda. \end{aligned}$$

Note that only the same augmented constant-coefficient differential equation, with varying right-hand sides, needs to be solved at each iteration.

3.1. Fourier approximation. Finally, we show how to efficiently compute accurate approximations to the periodic orbits of (3.3), using the above Newton-chord iteration and the results of section 2.3. The key step is how to calculate the approximate Fourier coefficients

$$\boldsymbol{z}(\theta) \approx \tilde{\boldsymbol{z}}_0^c + \sum_{m=1}^{M}\left\{\tilde{\boldsymbol{z}}_m^c \cos m\theta + \tilde{\boldsymbol{z}}_m^s \sin m\theta\right\}$$

from the right-hand side

$$\begin{aligned}\boldsymbol{f}(\theta) &\equiv \tfrac{1}{\varepsilon}\boldsymbol{r}^{(k)}(\theta)\\ &\approx \tilde{\boldsymbol{f}}_0^c + \sum_{m=1}^{M}\left\{\tilde{\boldsymbol{f}}_m^c \cos m\theta + \tilde{\boldsymbol{f}}_m^s \sin m\theta\right\}\end{aligned}$$

in (3.9), and we see that matching Fourier coefficients gives the modal equations

- for $m = 0$

$$\mathsf{A}^\star \tilde{\boldsymbol{z}}_0^c = \tilde{\boldsymbol{f}}_0^c,$$

- for $m = 1$

$$\begin{bmatrix} \mathsf{A}^\star & -\mathsf{I} & \frac{1}{T^\star}\boldsymbol{\varphi}_{\Re}^\star & T^\star \mathsf{K}^\star \boldsymbol{\varphi}_{\Im}^\star \\ \mathsf{I} & \mathsf{A}^\star & -\frac{1}{T^\star}\boldsymbol{\varphi}_{\Im}^\star & T^\star \mathsf{K}^\star \boldsymbol{\varphi}_{\Re}^\star \\ \boldsymbol{\varphi}_{\Im}^{\star\,T} & \boldsymbol{\varphi}_{\Re}^{\star\,T} & 0 & 0 \\ \boldsymbol{\varphi}_{\Re}^{\star\,T} & -\boldsymbol{\varphi}_{\Im}^{\star\,T} & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{\boldsymbol{z}}_1^c \\ \tilde{\boldsymbol{z}}_1^s \\ \delta T \\ \delta\lambda \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{f}}_1^c \\ \tilde{\boldsymbol{f}}_1^s \\ 0 \\ 0 \end{bmatrix},$$

- for $2 \le m \le M$

$$\begin{bmatrix} \mathsf{A}^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{A}^\star \end{bmatrix} \begin{bmatrix} \tilde{\boldsymbol{z}}_m^c \\ \tilde{\boldsymbol{z}}_m^s \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{f}}_m^c \\ \tilde{\boldsymbol{f}}_m^s \end{bmatrix}.$$

Hence the extra scalar unknowns δT and $\delta\lambda$ are solved for as part of the $m = 1$ system, while the other modal equations remain the same as in section 2.3. Thus, by applying

$$\begin{bmatrix} \boldsymbol{\psi}_{\Im}^\star \\ \boldsymbol{\psi}_{\Re}^\star \\ 0 \\ 0 \end{bmatrix}^T \qquad \text{and} \qquad \begin{bmatrix} \boldsymbol{\psi}_{\Re}^\star \\ -\boldsymbol{\psi}_{\Im}^\star \\ 0 \\ 0 \end{bmatrix}^T$$

to the $m = 1$ equation, we immediately determine δT and $\delta\lambda$ from

$$\begin{bmatrix} 0 & T^\star\gamma_{\Re}^\star \\ \frac{1}{T^\star} & T^\star\gamma_{\Im}^\star \end{bmatrix} \begin{bmatrix} \delta T \\ \delta\lambda \end{bmatrix} = \frac{1}{2}\begin{bmatrix} \boldsymbol{\psi}_{\Im}^\star \cdot \tilde{\boldsymbol{f}}_1^c + \boldsymbol{\psi}_{\Re}^\star \cdot \tilde{\boldsymbol{f}}_1^s \\ \boldsymbol{\psi}_{\Re}^\star \cdot \tilde{\boldsymbol{f}}_1^c - \boldsymbol{\varphi}_{\Im}^\star \cdot \tilde{\boldsymbol{f}}_1^s \end{bmatrix};$$

i.e.,

$$\delta\lambda = \frac{1}{T^\star} d_\lambda \quad \text{and} \quad \delta T = T^\star d_T,$$

where

$$\begin{aligned} d_\lambda &\equiv \frac{\boldsymbol{\psi}_{\Im}^\star \cdot \tilde{\boldsymbol{f}}_1^c + \boldsymbol{\psi}_{\Re}^\star \cdot \tilde{\boldsymbol{f}}_1^s}{2\gamma_{\Re}^\star},\\ d_T &\equiv \frac{\gamma_{\Re}^\star\left(\boldsymbol{\psi}_{\Re}^\star \cdot \tilde{\boldsymbol{f}}_1^c - \boldsymbol{\varphi}_{\Im}^\star \cdot \tilde{\boldsymbol{f}}_1^s\right) - \gamma_{\Im}^\star\left(\boldsymbol{\psi}_{\Im}^\star \cdot \tilde{\boldsymbol{f}}_1^c + \boldsymbol{\psi}_{\Re}^\star \cdot \tilde{\boldsymbol{f}}_1^s\right)}{2\gamma_{\Re}^\star} \end{aligned}$$

and $\gamma_{\Re}^\star, \gamma_{\Im}^\star$ are defined in (3.2).

If $\mathsf{A}^\star$ has already been reduced to Schur form by

$$\mathsf{A}^\star \mathsf{Q}^\star = \mathsf{Q}^\star \mathsf{U}^\star,$$

where $\mathsf{U}^\star \in \mathbb{R}^{n\times n}$ is a quasi-upper triangular matrix and $\mathsf{Q}^\star \in \mathbb{R}^{n\times n}$ is an orthogonal matrix, then it can be arranged that $\mathsf{U}^\star$ has its eigenvalues $\pm\mathrm{i}$ in the top left corner, i.e.,

$$\mathsf{U}^\star = \begin{bmatrix} 0 & \beta & \cdots & & & \\ -\beta^{-1} & 0 & \cdots & & & \\ 0 & 0 & \ddots & \ddots & \ddots & \ddots \\ \vdots & \vdots & \ddots & \ddots & \ddots & \ddots \\ \vdots & \vdots & \ddots & \ddots & \ddots & \ddots \\ 0 & 0 & \ddots & \ddots & \ddots & \ddots \end{bmatrix}$$

for some nonzero β, as in the LAPACK standard form [2]. This means that

$$\boldsymbol{\varphi}^\star_{\Re} \equiv \frac{\beta}{\sqrt{1+\beta^2}}\boldsymbol{q}^\star_1 \qquad \text{and} \qquad \boldsymbol{\varphi}^\star_{\Im} \equiv \frac{1}{\sqrt{1+\beta^2}}\boldsymbol{q}^\star_2,$$

where $\boldsymbol{q}^\star_j$ denotes the jth column of $\mathsf{Q}^\star$. Hence, under the transformations $\tilde{\boldsymbol{z}}^c_0 = \mathsf{Q}^\star\hat{\boldsymbol{z}}^c_0$, $\tilde{\boldsymbol{f}}^c_0 = \mathsf{Q}^\star\hat{\boldsymbol{f}}^c_0$, and

$$\left.\begin{aligned} \tilde{\boldsymbol{z}}^{c/s}_m &= \mathsf{Q}^\star\hat{\boldsymbol{z}}^{c/s}_m \\ \tilde{\boldsymbol{f}}^{c/s}_m &= \mathsf{Q}^\star\hat{\boldsymbol{f}}^{c/s}_m \end{aligned}\right\}, \quad m = 1,\ldots,M,$$

we have only to solve the systems

- for $m = 0$

$$\mathsf{U}^\star\hat{\boldsymbol{z}}^c_0 = \hat{\boldsymbol{f}}^c_0;$$

- for $m = 1$

$$\begin{bmatrix} \mathsf{U}^\star & -\mathsf{I} \\ \mathsf{I} & \mathsf{U}^\star \\ \boldsymbol{e}_2^T & \beta\boldsymbol{e}_1^T \\ \beta\boldsymbol{e}_1^T & -\boldsymbol{e}_2^T \end{bmatrix} \begin{bmatrix} \hat{\boldsymbol{z}}^c_1 \\ \hat{\boldsymbol{z}}^s_1 \end{bmatrix} = \begin{bmatrix} \hat{\boldsymbol{f}}^c_1 - d_T\frac{\beta}{\sqrt{1+\beta^2}}\boldsymbol{e}_1 - d_\lambda\frac{1}{\sqrt{1+\beta^2}}\boldsymbol{c}^\star_2 \\ \hat{\boldsymbol{f}}^s_1 + d_T\frac{1}{\sqrt{1+\beta^2}}\boldsymbol{e}_2 - d_\lambda\frac{\beta}{\sqrt{1+\beta^2}}\boldsymbol{c}^\star_1 \\ 0 \\ 0 \end{bmatrix},$$

  where the components of $\boldsymbol{c}^\star_1$ and $\boldsymbol{c}^\star_2$ are the coefficients of $\mathsf{K}^\star\boldsymbol{q}^\star_1$ and $\mathsf{K}^\star\boldsymbol{q}^\star_2$, respectively, with respect to the orthonormal basis of $\mathbb{R}^n$ formed by the columns of $\mathsf{Q}^\star$, i.e.,

$$\mathsf{Q}^\star\boldsymbol{c}^\star_1 \equiv \mathsf{K}^\star\boldsymbol{q}^\star_1 \quad \text{and} \quad \mathsf{Q}^\star\boldsymbol{c}^\star_2 \equiv \mathsf{K}^\star\boldsymbol{q}^\star_2;$$

- for $2 \le m \le M$

$$\begin{bmatrix} \mathsf{U}^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{U}^\star \end{bmatrix} \begin{bmatrix} \hat{\boldsymbol{z}}^c_m \\ \hat{\boldsymbol{z}}^s_m \end{bmatrix} = \begin{bmatrix} \hat{\boldsymbol{f}}^c_m \\ \hat{\boldsymbol{f}}^s_m \end{bmatrix}$$

by back-substitution. The systems for $m = 0$ and $m \ge 2$ are the same as in section 2.3 and nonsingular because of the eigenvalue conditions satisfied by $\mathsf{J}(\boldsymbol{x}^\star, \lambda^\star)$ in (b) on page 2530. The system for $m = 1$ is overdetermined, but consistent by construction,

and the last $n-2$ components for $\hat{\boldsymbol{z}}_1^{c/s}$ can again be solved by back-substitution. We are then left with the simple system

$$\begin{bmatrix} 0 & \beta & -1 & 0 \\ 1 & 0 & 0 & \beta \\ 0 & 1 & \beta & 0 \\ \beta & 0 & 0 & -1 \end{bmatrix} \begin{bmatrix} \hat{z}_{11}^c \\ \hat{z}_{12}^c \\ \hat{z}_{11}^s \\ \hat{z}_{12}^s \end{bmatrix} = \begin{bmatrix} \star \\ \star \\ 0 \\ 0 \end{bmatrix},$$

where $\hat{z}_{11}^{c/s}$ and $\hat{z}_{12}^{c/s}$ refer to the first two components of $\hat{\boldsymbol{z}}_1^{c/s}$.

4. Practical Floquet theory. Now let $\mathsf{A}(\theta)$ be a 2π-periodic $n \times n$ matrix, i.e.,

$$\mathsf{A}(\theta + 2\pi) = \mathsf{A}(\theta) \qquad \forall \theta \in \mathbb{R}.$$

At first glance the periodic differential equation

$$-\dot{\boldsymbol{v}}(\theta) + \mathsf{A}(\theta)\boldsymbol{v}(\theta) = \boldsymbol{f}(\theta), \qquad \boldsymbol{v} \in \mathcal{Y}_+^n, \tag{4.1}$$

for a given $\boldsymbol{f} \in \mathcal{Y}_+^n$, seems much more difficult to analyze and solve than (2.1). It is the fundamental result of *Floquet theory*, however, that there is a change-of-variable

$$\boldsymbol{v}(\theta) = \mathsf{P}(\theta)\boldsymbol{w}(\theta)$$

which transforms (4.1) to constant-coefficient form. The price one has to pay to remain within real arithmetic, however, is that some of the components of the solution to the constant-coefficient problem may lie in $\mathcal{Y}_-$ rather than $\mathcal{Y}_+$: i.e., some of the components of $\boldsymbol{w}(\theta)$ may be in $\mathcal{Y}_-$, with the corresponding columns of the $n \times n$ matrix $\mathsf{P}(\theta)$ in $\mathcal{Y}_-^n$, but this still means that the product $\mathsf{P}(\theta)\boldsymbol{w}(\theta)$ is in $\mathcal{Y}_+^n$. In conclusion then, our constant-coefficient equations may be a combination of (2.1) and (2.3).

To see how this occurs, let $\mathsf{X}(\theta)$ be the principal fundamental solution matrix for the differential operator

$$-\frac{\mathrm{d}}{\mathrm{d}\theta} + \mathsf{A}(\theta); \tag{4.2}$$

i.e., $\mathsf{X}(0) = \mathsf{I}$ and

$$\dot{\mathsf{X}}(\theta) = \mathsf{A}(\theta)\mathsf{X}(\theta) \quad \forall \theta \in \mathbb{R},$$

and thus the jth column of $\mathsf{X}(\theta)$ solves the homogeneous initial value problem formed from (4.2), with $\boldsymbol{e}_j$ as the initial value. The columns of $\mathsf{X}(\theta)$ remain linearly independent, and so $\mathsf{X}(\theta)$ is always nonsingular. (There is, of course, no necessity for X to have any periodicity property!) $\mathsf{X}(2\pi)$ is called the *monodromy* matrix, and solutions of the fundamental algebraic eigenproblem

$$\mathsf{X}(2\pi)\boldsymbol{y} = \lambda \boldsymbol{y}$$

lead to the following three possibilities for solutions of the differential eigenproblem

$$-\dot{\boldsymbol{p}}(\theta) + \mathsf{A}(\theta)\boldsymbol{p}(\theta) = \mu \boldsymbol{p}(\theta),$$

with either $\boldsymbol{p} \in \mathcal{Y}_+^n$ or $\boldsymbol{p} \in \mathcal{Y}_-^n$.

1. For real $\lambda > 0$, we may define $\mu \in \mathbb{R}$ by $\lambda = \mathrm{e}^{2\pi\mu}$ and set

$$\boldsymbol{p}(\theta) \equiv \mathrm{e}^{-\mu\theta}\mathsf{X}(\theta)\boldsymbol{y},$$

so $\boldsymbol{p} \in \mathcal{Y}^n_+$ and

$$-\dot{\boldsymbol{p}}(\theta) + \mathsf{A}(\theta)\boldsymbol{p}(\theta) = \mu\boldsymbol{p}(\theta).$$

2. For real $\lambda < 0$, we may define $\mu \in \mathbb{R}$ by $-\lambda = \mathrm{e}^{2\pi\mu}$ and set

$$\boldsymbol{p}(\theta) \equiv \mathrm{e}^{-\mu\theta}\mathsf{X}(\theta)\boldsymbol{y},$$

so $\boldsymbol{p} \in \mathcal{Y}^n_-$ and

$$-\dot{\boldsymbol{p}}(\theta) + \mathsf{A}(\theta)\boldsymbol{p}(\theta) = \mu\boldsymbol{p}(\theta).$$

3. For a complex conjugate pair $\lambda_\Re \pm \mathrm{i}\lambda_\Im$ and $\boldsymbol{y}_\Re \pm \mathrm{i}\boldsymbol{y}_\Im$, so that

$$\mathsf{X}(2\pi)[\boldsymbol{y}_\Re, \boldsymbol{y}_\Im] = [\boldsymbol{y}_\Re, \boldsymbol{y}_\Im] \begin{bmatrix} \lambda_\Re & \lambda_\Im \\ -\lambda_\Im & \lambda_\Re \end{bmatrix},$$

we can do either of the following. (We describe below how to make a sensible choice!)

- Define $\mu \equiv \mu_\Re + \mathrm{i}\mu_\Im \in \mathbb{C}$ by $\lambda = \mathrm{e}^{2\pi\mu}$ and set

$$[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] \equiv \mathrm{e}^{-\mu_\Re\theta}\mathsf{X}(\theta)[\boldsymbol{y}_\Re, \boldsymbol{y}_\Im] \begin{bmatrix} \cos\mu_\Im\theta & -\sin\mu_\Im\theta \\ \sin\mu_\Im\theta & \cos\mu_\Im\theta \end{bmatrix}.$$

Then $\boldsymbol{p}_\Re, \boldsymbol{p}_\Im \in \mathcal{Y}^n_+$, with $\boldsymbol{p}_\Re(0) = \boldsymbol{y}_\Re$ and $\boldsymbol{p}_\Im(0) = \boldsymbol{y}_\Im$, and

$$-\frac{\mathrm{d}}{\mathrm{d}\theta}[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] + \mathsf{A}(\theta)[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] = [\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] \begin{bmatrix} \mu_\Re & \mu_\Im \\ -\mu_\Im & \mu_\Re \end{bmatrix}.$$

- Define $\mu \equiv \mu_\Re + \mathrm{i}\mu_\Im \in \mathbb{C}$ by $-\lambda = \mathrm{e}^{2\pi\mu}$ and again set

$$[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] \equiv \mathrm{e}^{-\mu_\Re\theta}\mathsf{X}(\theta)[\boldsymbol{y}_\Re, \boldsymbol{y}_\Im] \begin{bmatrix} \cos\mu_\Im\theta & -\sin\mu_\Im\theta \\ \sin\mu_\Im\theta & \cos\mu_\Im\theta \end{bmatrix}.$$

Now $\boldsymbol{p}_\Re, \boldsymbol{p}_\Im \in \mathcal{Y}^n_-$, but we still have $\boldsymbol{p}_\Re(0) = \boldsymbol{y}_\Re$ and $\boldsymbol{p}_\Im(0) = \boldsymbol{y}_\Im$, and

$$-\frac{\mathrm{d}}{\mathrm{d}\theta}[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] + \mathsf{A}(\theta)[\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] = [\boldsymbol{p}_\Re(\theta), \boldsymbol{p}_\Im(\theta)] \begin{bmatrix} \mu_\Re & \mu_\Im \\ -\mu_\Im & \mu_\Re \end{bmatrix}.$$

The eigenvalues λ of $\mathsf{X}(2\pi)$ are called the *Floquet multipliers* for (4.2), while the corresponding μ are called the *Floquet exponents*. (This is *not quite* the standard terminology but is certainly what we require for a practical algorithm!) Note that each μ, and hence also the corresponding $\boldsymbol{p}(\theta)$, is not uniquely defined by the above construction; i.e., for any $\ell \in \mathbb{Z}$ we may set $\mu \to \mu + \mathrm{i}\ell$ and $\boldsymbol{p}(\theta) \to \boldsymbol{p}(\theta)\mathrm{e}^{\mathrm{i}\ell\theta}$. We shall always choose the size of the imaginary parts of the Floquet exponents to be as small

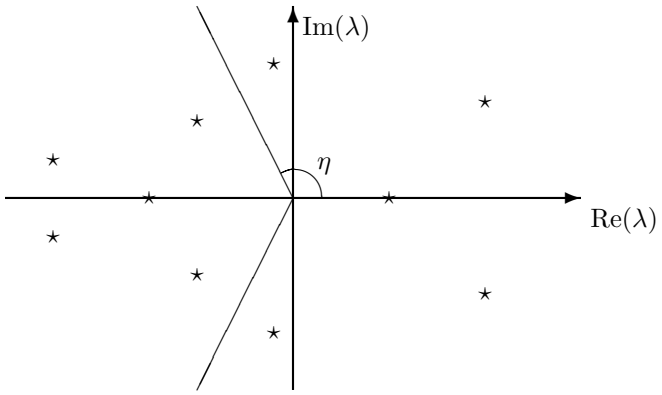

FIG. 1. *Splitting of the complex plane for Floquet multipliers.*

as possible in modulus. In conclusion, if the Floquet multipliers and exponents are denoted by

$$\lambda \equiv |\lambda| \mathrm{e}^{\mathrm{i}\theta} \quad \text{and} \quad \mu \equiv \mu_{\Re} + \mathrm{i}\mu_{\Im},$$

respectively, with $-\pi < \theta \leq \pi$, then the following table gives the mappings between them for $\mathcal{Y}_+$ and $\mathcal{Y}_-$.

$\mathcal{Y}_+$	$\lambda = \mathrm{e}^{2\pi\mu}$	$\mu_{\Re} = \frac{1}{2\pi}\ln\lvert\lambda\rvert, \quad \mu_{\Im} = \frac{\theta}{2\pi}$
$\mathcal{Y}_-$	$-\lambda = \mathrm{e}^{2\pi\mu}$	$\mu_{\Re} = \frac{1}{2\pi}\ln\lvert\lambda\rvert, \quad \mu_{\Im} = \begin{cases} \frac{\theta-\pi}{2\pi}, & \theta > 0, \\ \frac{\theta+\pi}{2\pi}, & \theta < 0 \end{cases}$

Instead of considering individual eigenvalues and eigenvectors for the monodromy matrix $\mathsf{X}(2\pi)$, the above argument can be better applied to well-conditioned invariant subspaces. Thus we choose some $0 < \eta < \pi$, such that no eigenvalue λ of $\mathsf{X}(2\pi)$ has $\arg\lambda = \eta$, and split the spectrum of $\mathsf{X}(2\pi)$ into two parts (see Figure 1), i.e.,

$$\mathsf{X}(2\pi)\mathsf{Y}_+ = \mathsf{Y}_+\Lambda_+ \quad \text{and} \quad \mathsf{X}(2\pi)\mathsf{Y}_- = \mathsf{Y}_-\Lambda_-,$$

where, for some $n_\pm \geq 0$ with $n_+ + n_- = n$, $\mathsf{Y}_+ \in \mathbb{R}^{n\times n_+}$, $\Lambda_+ \in \mathbb{R}^{n_+\times n_+}$, $\mathsf{Y}_- \in \mathbb{R}^{n\times n_-}$, $\Lambda_- \in \mathbb{R}^{n_-\times n_-}$. Here the columns of Y_+ span the invariant subspace of $\mathsf{X}(2\pi)$ corresponding to all the eigenvalues λ of $\mathsf{X}(2\pi)$ satisfying $-\eta < \arg\lambda < \eta$, while the columns of Y_- span the invariant subspace of $\mathsf{X}(2\pi)$ corresponding to all the eigenvalues λ of $\mathsf{X}(2\pi)$ satisfying $\eta - \pi < \arg[-\lambda] < \pi - \eta$. Therefore, defining $\mathsf{E}_+ \in \mathbb{R}^{n_+\times n_+}$ and $\mathsf{P}_+(\theta) \in \mathbb{R}^{n\times n_+}$ by

$$\Lambda_+ = \mathrm{e}^{2\pi\mathsf{E}_+}, \qquad \mathsf{P}_+(\theta) = \mathsf{X}(\theta)\mathsf{Y}_+\mathrm{e}^{-\mathsf{E}_+\theta}$$

and $\mathsf{E}_- \in \mathbb{R}^{n_-\times n_-}$ and $\mathsf{P}_-(\theta) \in \mathbb{R}^{n\times n_-}$ by

$$-\Lambda_- = \mathrm{e}^{2\pi\mathsf{E}_-}, \qquad \mathsf{P}_-(\theta) = \mathsf{X}(\theta)\mathsf{Y}_-\mathrm{e}^{-\mathsf{E}_-\theta},$$

we finally have

$$-\dot{\mathsf{P}}(\theta) + \mathsf{A}(\theta)\mathsf{P}(\theta) = \mathsf{P}(\theta)\mathsf{E}, \tag{4.3}$$

where

$$\mathsf{P}(\theta) = [\mathsf{P}_+(\theta), \mathsf{P}_-(\theta)]$$

and

$$\mathsf{E} = \begin{pmatrix} \mathsf{E}_+ & \mathsf{O} \\ \mathsf{O} & \mathsf{E}_- \end{pmatrix}.$$

Each column of $\mathsf{P}_+(\theta)$ is in $\mathcal{Y}_+^n$ and each column of $\mathsf{P}_-(\theta)$ is in $\mathcal{Y}_-^n$, but the $n \times n$ matrix $\mathsf{P}(\theta)$ must be nonsingular for all θ. The choice of η is not critical but, in order for our linear algebra problems to be uniformly well-posed, we shall

- keep η away from 0 and π, so that the moduli of the imaginary parts of the eigenvalues of $\mathsf{E}_\pm$ are all less than $\frac{1}{2}$,
- let η correspond to a "gap" in the arguments of the Floquet multipliers, so that the sum of the largest imaginary part of an eigenvalue from E_+ with the largest imaginary part of an eigenvalue from E_- stays below $\frac{1}{2}$.

We shall see later that it is easy to adapt η within a continuation framework for periodic orbits.

The above differential equation for P, i.e., (4.3), should be regarded as an eigenproblem. This makes it clear that there is an indeterminacy in the choice of $\mathsf{P}(\theta)$ and E, although the eigenvalues of E are invariants. Thus, for any orthogonal matrix $\mathsf{Q} \in \mathbb{R}^{n\times n}$, we have

$$-\frac{\mathrm{d}}{\mathrm{d}\theta}\left[\mathsf{P}(\theta)\mathsf{Q}\right] + \mathsf{A}(\theta)\left[\mathsf{P}(\theta)\mathsf{Q}\right] = \left[\mathsf{P}(\theta)\mathsf{Q}\right]\left[\mathsf{Q}^T\mathsf{E}\mathsf{Q}\right],$$

and therefore we can choose

$$\mathsf{Q} \equiv \begin{pmatrix} \mathsf{Q}_+ & \mathsf{O} \\ \mathsf{O} & \mathsf{Q}_- \end{pmatrix}, \qquad \mathsf{Q}_+ \in \mathbb{R}^{n_+\times n_+}, \qquad \mathsf{Q}_- \in \mathbb{R}^{n_-\times n_-},$$

so that the transformations

$$\begin{aligned} \mathsf{P}(\theta) &\mapsto \mathsf{P}(\theta)\mathsf{Q}, \\ \mathsf{E} &\mapsto \mathsf{Q}^T\mathsf{E}\mathsf{Q} \end{aligned}$$

mean that we can assume E_+ and E_- are in real Schur (i.e., quasi-upper triangular) form. It would also be possible to ensure that

$$\frac{1}{4\pi}\int_0^{4\pi} \mathsf{P}(\theta)^T\mathsf{P}(\theta)\,\mathrm{d}\theta = \mathsf{I},$$

and so (4.3) could be regarded as a *dynamic* Schur factorization; but this is of more theoretical than practical interest.

If we now return to the problem of solving (4.1), then we can use the change-of-variable

$$\boldsymbol{v}(\theta) = \mathsf{P}(\theta)\boldsymbol{w}(\theta) \equiv \mathsf{P}(\theta)\begin{pmatrix} \boldsymbol{w}_+(\theta) \\ \boldsymbol{w}_-(\theta) \end{pmatrix},$$

where $\boldsymbol{w}_+ \in \mathcal{Y}_+^{n_+}$ and $\boldsymbol{w}_- \in \mathcal{Y}_-^{n_-}$, and obtain

$$-\mathsf{P}(\theta)\dot{\boldsymbol{w}}(\theta) + \left\{-\dot{\mathsf{P}}(\theta) + \mathsf{A}(\theta)\mathsf{P}(\theta)\right\}\boldsymbol{w}(\theta) = \boldsymbol{f}(\theta).$$

This simplifies to

$$-\dot{\boldsymbol{w}}(\theta) + \mathsf{E}\boldsymbol{w}(\theta) = \mathsf{P}(\theta)^{-1}\boldsymbol{f}(\theta),$$

and so we merely have to solve

$$\begin{aligned} -\dot{\boldsymbol{w}}_+(\theta) + \mathsf{E}_+\boldsymbol{w}_+(\theta) &= \boldsymbol{g}_+(\theta), \\ -\dot{\boldsymbol{w}}_-(\theta) + \mathsf{E}_-\boldsymbol{w}_-(\theta) &= \boldsymbol{g}_-(\theta), \end{aligned} \tag{4.4}$$

where

$$\mathsf{P}(\theta)\boldsymbol{g}(\theta) \equiv \mathsf{P}(\theta)\begin{pmatrix}\boldsymbol{g}_+(\theta)\\ \boldsymbol{g}_-(\theta)\end{pmatrix} = \boldsymbol{f}(\theta)$$

and thus $\boldsymbol{g}_+ \in \mathcal{Y}_+^{n_+}$ and $\boldsymbol{g}_- \in \mathcal{Y}_-^{n_-}$; i.e., we have reduced the problem of solving (4.1) to the simpler problem of solving (2.1) and (2.3). Equation (4.4) is nonsingular so long as E_+ has no eigenvalues of the form $m\mathrm{i}$ for $m \in \mathbb{Z}$ and E_- has no eigenvalues of the form $(m - \frac{1}{2})\mathrm{i}$ for $m \in \mathbb{Z}$. Hence, by our construction of E_+ and E_-, singularity can only occur when 0 is an eigenvalue of E_+, i.e., there is a Floquet multiplier equal to 1.

4.1. Application to periodic orbits. Just as for stationary points, it is important to distinguish between regular periodic orbits and singular ones. For stationary points $\boldsymbol{x}^\star$, we have only to look at the Jacobian matrix $\mathsf{J}(\boldsymbol{x}^\star)$: however, for a periodic orbit $\boldsymbol{u}^\star(t)$, with period $2\pi T^\star$, we must consider whether a linear differential equation has any nontrivial solutions. Looking at (1.4), we see that $(\boldsymbol{v}^\star(\theta), T^\star)$ satisfies

$$\begin{aligned} \dot{\boldsymbol{v}}(\theta) &= T\boldsymbol{F}(\boldsymbol{v}(\theta)), \qquad \boldsymbol{v} \in \mathcal{Y}_+^n, \\ \int_0^{2\pi} \dot{\boldsymbol{v}}^\star(\theta)\cdot\boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0. \end{aligned} \tag{4.5}$$

Hence we consider whether the linearization of this equation at the solution $(\boldsymbol{v}^\star, T^\star)$, i.e.,

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + T^\star\mathsf{J}(\boldsymbol{v}^\star(\theta))\boldsymbol{v}(\theta) + T\boldsymbol{F}(\boldsymbol{v}^\star(\theta)) &= \boldsymbol{0}, \qquad \boldsymbol{v} \in \mathcal{Y}_+^n, \\ \int_0^{2\pi} \dot{\boldsymbol{v}}^\star(\theta)\cdot\boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0, \end{aligned} \tag{4.6}$$

has any nonzero solutions $(\boldsymbol{v}(\theta), T)$.

We investigate (4.6) by applying the above Floquet theory to the linear periodic differential operator

$$-\dot{\boldsymbol{v}}(\theta) + \mathsf{A}^\star(\theta)\boldsymbol{v}(\theta), \qquad \boldsymbol{v} \in \mathcal{Y}_+^n, \tag{4.7}$$

where $\mathsf{A}^\star(\theta) \equiv T^\star\mathsf{J}(\boldsymbol{v}^\star(\theta))$; i.e., there exist $n \times n$ matrices

$$\mathsf{P}^\star(\theta) = \left[\mathsf{P}_+^\star(\theta), \mathsf{P}_-^\star(\theta)\right] \quad \text{and} \quad \mathsf{E}^\star = \begin{pmatrix}\mathsf{E}_+^\star & \mathsf{O}\\ \mathsf{O} & \mathsf{E}_-^\star\end{pmatrix}$$

so that the change-of-variable

$$\boldsymbol{v}(\theta) = \mathsf{P}^\star(\theta)\boldsymbol{w}(\theta) \equiv \mathsf{P}^\star(\theta)\begin{pmatrix}\boldsymbol{w}_+(\theta)\\ \boldsymbol{w}_-(\theta)\end{pmatrix}$$

transforms (4.6) to

$$-\dot{\boldsymbol{w}}(\theta) + \mathsf{E}^\star \boldsymbol{w}(\theta) + T\mathsf{P}^\star(\theta)^{-1}\boldsymbol{F}(\boldsymbol{v}^\star(\theta)) = \mathbf{0}, \qquad \boldsymbol{w}_\pm \in \mathcal{Y}_\pm^{n_\pm},$$
$$\int_0^{2\pi} \dot{\boldsymbol{v}}^\star(\theta) \cdot [\mathsf{P}^\star(\theta)\boldsymbol{w}(\theta)]\, \mathrm{d}\theta = 0.$$

Since we know that

$$-\dot{\boldsymbol{v}}(\theta) + T^\star \mathsf{J}(\boldsymbol{v}^\star(\theta))\boldsymbol{v}(\theta) = \mathbf{0}, \qquad \boldsymbol{v} \in \mathcal{Y}_+^n,$$

has the nontrivial solution $\boldsymbol{v}(\theta) = \dot{\boldsymbol{v}}^\star(\theta)$, we can choose the first column of $\mathsf{P}^\star(\theta)$ to be a normalization of $\dot{\boldsymbol{v}}^\star(\theta)$, i.e.,

$$\alpha^\star \mathsf{P}^\star(\theta)\boldsymbol{e}_1 \equiv \tfrac{1}{T^\star}\dot{\boldsymbol{v}}^\star(\theta)$$

for some nonzero $\alpha^\star \in \mathbb{R}$; hence, $\mathsf{E}_+^\star$ is in quasi-upper triangular form with zero first column and

$$\mathsf{P}^\star(\theta)^{-1}\boldsymbol{F}(\boldsymbol{v}^\star(\theta)) = \tfrac{1}{T^\star}\mathsf{P}^\star(\theta)^{-1}\dot{\boldsymbol{v}}^\star(\theta)$$
$$= \alpha^\star \boldsymbol{e}_1.$$

Thus to answer our question about (4.6), we only have to determine whether the much simpler problem

$$\begin{aligned} -\dot{\boldsymbol{w}}_+(\theta) + \mathsf{E}_+^\star \boldsymbol{w}_+(\theta) + T\alpha^\star \boldsymbol{e}_1 = \mathbf{0}, &\qquad \boldsymbol{w}_+ \in \mathcal{Y}_+^{n_+}, \\ -\dot{\boldsymbol{w}}_-(\theta) + \mathsf{E}_-^\star \boldsymbol{w}_-(\theta) = \mathbf{0}, &\qquad \boldsymbol{w}_- \in \mathcal{Y}_-^{n_-}, \\ \int_0^{2\pi} [\mathsf{P}^\star(\theta)\boldsymbol{e}_1] \cdot [\mathsf{P}^\star(\theta)\boldsymbol{w}(\theta)]\, \mathrm{d}\theta = 0 & \end{aligned} \tag{4.8}$$

has any nontrivial solutions $(\boldsymbol{w}(\theta), T)$. Since, by our construction of $\mathsf{E}_\pm^\star$, it is only possible for a nontrivial solution to appear in the constant Fourier mode for $\boldsymbol{w}_+$, this leads us to the following key definition.

DEFINITION. $\boldsymbol{u}^\star : \mathbb{R} \mapsto \mathbb{R}^n$ *is called a* nonsingular *or* regular *periodic orbit of* (1.2) *if zero is a* simple *eigenvalue of* $\mathsf{E}_+^\star$.

The justification for this definition is that if zero *is* a simple eigenvalue of $\mathsf{E}_+^\star$, with corresponding right and left eigenvectors $\boldsymbol{\varphi}^\star$ and $\boldsymbol{\psi}^\star$ say, then we know that the conditions [23]

$$\boldsymbol{\psi}^\star \cdot \boldsymbol{e}_1 \neq 0,$$
$$\int_0^{2\pi} [\mathsf{P}^\star(\theta)\boldsymbol{e}_1] \cdot [\mathsf{P}^\star(\theta)\boldsymbol{\varphi}^\star]\, \mathrm{d}\theta \neq 0$$

are both necessary and sufficient for (4.8) to have only the zero solution. However, since $\boldsymbol{\varphi}^\star \equiv \boldsymbol{e}_1$, both these conditions are immediately satisfied. Similarly, if zero is *not* a simple eigenvalue of $\mathsf{E}_+^\star$, then it is simple to check that (4.8) *does* have nontrivial solutions. Hence the basis of the above definition is the following conclusion.

CONCLUSION. *A necessary and sufficient condition for* (4.6) *to have only the trivial solution* $(\boldsymbol{v}, T) = (\mathbf{0}, 0)$ *is that zero is a simple eigenvalue of the matrix* $\mathsf{E}_+^\star$.

Of course, this is in complete agreement with the standard definition of a nonsingular periodic orbit, i.e., that 1 is a simple Floquet multiplier for (4.7) [1, 20].

Since, however, our algorithm in the next section works explicitly with $\mathsf{E}_+^\star$, the above definition is more appropriate for us.

Finally, it is also clear that, when using Floquet theory and working with $\boldsymbol{w}(\theta)$ instead of $\boldsymbol{v}(\theta)$, we can simplify our phase condition in (4.5); i.e., the second equation there can be replaced by

$$\frac{1}{2\pi}\int_0^{2\pi} \dot{\boldsymbol{v}}^\star(\theta)\cdot\left[\mathsf{P}^\star(\theta)\mathsf{P}^\star(\theta)^T\right]^{-1}\boldsymbol{v}(\theta)\,\mathrm{d}\theta = 0,$$

which is equivalent to the final equation of (4.8) being replaced by

$$\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1\cdot\boldsymbol{w}_+(\theta)\,\mathrm{d}\theta = 0. \tag{4.9}$$

(As we shall see in the next section, the 2π is a convenient normalization.) It is this phase condition that we shall use as part of our continuation algorithm in the next section, which connects with the fact that the bordered matrix

$$\begin{bmatrix}\mathsf{E}_+^\star & \alpha^\star\boldsymbol{e}_1\\ \boldsymbol{e}_1^T & 0\end{bmatrix}$$

is invertible for a nonsingular periodic orbit.

5. Continuation of periodic orbits. From our Floquet point of view, we describe a standard strategy for following a curve of periodic orbits for (1.1), commonly called pseudo-arclength [23]. Thus we assume that the equation

$$\dot{\boldsymbol{v}}(\theta) = T\boldsymbol{F}(\boldsymbol{v}(\theta),\lambda), \qquad \boldsymbol{v}\in\mathcal{Y}_+^n, \tag{5.1}$$

has a solution $\boldsymbol{v}^\star(\theta)$ with period $2\pi T^\star$ at $\lambda=\lambda^\star$. We also assume that the linearization

$$-\frac{\mathrm{d}}{\mathrm{d}\theta}+\mathsf{A}^\star(\theta),$$

where

$$\mathsf{A}^\star(\theta)\equiv T^\star\mathsf{J}(\boldsymbol{v}^\star(\theta),\lambda^\star),$$

has invariant subspaces defined by

$$-\dot{\mathsf{P}}^\star(\theta)+\mathsf{A}^\star(\theta)\mathsf{P}^\star(\theta)=\mathsf{P}^\star(\theta)\mathsf{E}^\star,$$

where

- $\mathsf{P}^\star(\theta)\equiv\left[\mathsf{P}_+^\star(\theta),\mathsf{P}_-^\star(\theta)\right]$ with each column of the $n\times n_+$ matrix $\mathsf{P}_+^\star$ in $\mathcal{Y}_+^n$ and each column of the $n\times n_-$ matrix $\mathsf{P}_-^\star$ in $\mathcal{Y}_-^n$;
- $\mathsf{E}^\star$ is quasi-upper triangular, with

$$\mathsf{E}^\star\equiv\begin{bmatrix}\mathsf{E}_+^\star & \mathsf{O}\\ \mathsf{O} & \mathsf{E}_-^\star\end{bmatrix},$$

  where $\mathsf{E}_+^\star\in\mathbb{R}^{n_+\times n_+}$ and $\mathsf{E}_-^\star\in\mathbb{R}^{n_-\times n_-}$;
- the sum of the largest imaginary part of an eigenvalue of $\mathsf{E}_+^\star$ with the largest imaginary part of an eigenvalue of $\mathsf{E}_-^\star$ is less than $\frac{1}{2}$;

- the first column of $\mathsf{P}^\star(\theta)$ is a normalization of $\dot{\boldsymbol{v}}^\star(\theta)$ and the first column of $\mathsf{E}^\star$ is zero.

If our periodic orbit $\boldsymbol{v}^\star(\theta)$ of period $2\pi T^\star$ is nonsingular at $\lambda = \lambda^\star$, according to the definition in section 4.1, then the implicit function theorem applies. This follows from considering the linearization of (5.1) with respect to $\boldsymbol{v}(\theta), T$ at $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$ and adding the phase condition (4.9): thus the equation

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + \mathsf{A}^\star(\theta)\boldsymbol{v}(\theta) + T\boldsymbol{p}^\star(\theta) &= \boldsymbol{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{e}_1 \cdot \boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0 \end{aligned}$$

for $(\boldsymbol{v}(\theta), T) \in \mathcal{Y}^n_+ \times \mathbb{R}$, where

$$\boldsymbol{p}^\star(\theta) \equiv \tfrac{1}{T^\star}\dot{\boldsymbol{v}}^\star(\theta) = \boldsymbol{F}(\boldsymbol{v}^\star(\theta), \lambda^\star),$$

has only the zero solution; or equivalently, the equation

$$\begin{aligned} -\dot{\boldsymbol{w}}_+(\theta) + \mathsf{E}^\star_+\boldsymbol{w}_+(\theta) + \alpha^\star T\boldsymbol{e}_1 &= \boldsymbol{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1 \cdot \boldsymbol{w}_+(\theta)\,\mathrm{d}\theta &= 0, \\ -\dot{\boldsymbol{w}}_-(\theta) + \mathsf{E}^\star_-\boldsymbol{w}_-(\theta) &= \boldsymbol{0} \end{aligned}$$

for $(\boldsymbol{w}_+(\theta), \boldsymbol{w}_-(\theta), T) \in \mathcal{Y}^{n_+}_+ \times \mathcal{Y}^{n_-}_- \times \mathbb{R}$, where

$$\alpha^\star \mathsf{P}^\star(\theta)\boldsymbol{e}_1 \equiv \boldsymbol{p}^\star(\theta),$$

has only the zero solution. Hence there is a unique curve of periodic orbits through $(\boldsymbol{v}^\star(\theta), T^\star)$, and this curve is parametrizable by λ.

We do not, however, wish to restrict ourselves to curves of periodic orbits which are parametrizable by λ. Thus we consider the full linearization of (5.1) with respect to $\boldsymbol{v}(\theta), T, \lambda$ at $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$, and our basic assumption is that the equation

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + \mathsf{A}^\star(\theta)\boldsymbol{v}(\theta) + T\boldsymbol{p}^\star(\theta) + \lambda\boldsymbol{k}^\star(\theta) &= \boldsymbol{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{e}_1 \cdot \boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0 \end{aligned} \tag{5.2}$$

for $(\boldsymbol{v}(\theta), T, \lambda) \in \mathcal{Y}^n_+ \times \mathbb{R}^2$, where

$$\boldsymbol{k}^\star(\theta) \equiv T^\star \boldsymbol{F}_\lambda(\boldsymbol{v}^\star(\theta), \lambda^\star),$$

has a one-dimensional solution set spanned by $(\boldsymbol{v}^\star_t(\theta), T^\star_t, \lambda^\star_t)$. (This will be normalized in (5.7) below.) So the augmented equation

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + T\boldsymbol{F}(\boldsymbol{v}(\theta), \lambda) &= \boldsymbol{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{e}_1 \cdot \boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0, \\ \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{v}^\star_t(\theta)\cdot[\boldsymbol{v}(\theta) - \boldsymbol{v}^\star(\theta)]\,\mathrm{d}\theta & \\ + T^\star_t[T - T^\star] + \lambda^\star_t[\lambda - \lambda^\star] - \varepsilon &= 0 \end{aligned} \tag{5.3}$$

has the solution $[\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star]$ for $\varepsilon = 0$; and the full linearization of (5.3) at this point gives the equation

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + \mathsf{A}^\star(\theta)\boldsymbol{v}(\theta) + T\boldsymbol{p}^\star(\theta) + \lambda\boldsymbol{k}^\star(\theta) &= \mathbf{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{e}_1 \cdot \boldsymbol{v}(\theta)\,\mathrm{d}\theta &= 0, \\ \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{v}_t^\star(\theta)\cdot\boldsymbol{v}(\theta)\,\mathrm{d}\theta + T_t^\star T + \lambda_t^\star\lambda &= 0, \end{aligned} \tag{5.4}$$

which has only the zero solution. Hence, the implicit function theorem tells us that (5.3) has a locally unique solution for all $|\varepsilon|$ sufficiently small, and this gives us a curve of periodic orbits $[\boldsymbol{v}(\theta), T, \lambda]$ parametrized by ε.

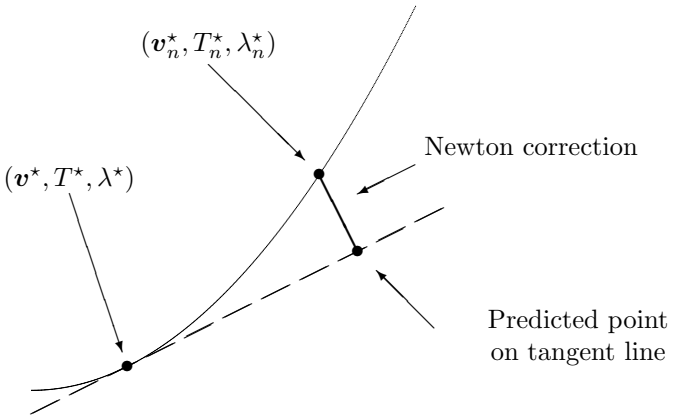

FIG. 2. *Continuing a curve of periodic orbits.*

Geometrically, our basic assumption on (5.2) is saying that the curve of periodic orbits has a unique tangent line. Thus, in section 5.1, we use our Floquet transformation to compute a Fourier approximation to this tangent line. Then, in section 5.2, we solve (5.3) using a Newton-chord iteration whose starting value is a point on this tangent line; see Figure 2. By using a simplified Newton's method, which keeps the linearization fixed, we sacrifice the quadratic convergence of the full Newton's method; this is more than compensated, however, by only having to apply our Floquet theory at $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$. Thus we have an efficient algorithm for computing the Fourier approximation of a new point, $(\boldsymbol{v}_n^\star(\theta), T_n^\star, \lambda_n^\star)$ say, on the curve of periodic orbits. Having obtained this new point, we require the new Floquet variables $\mathsf{P}_n^\star(\theta), \mathsf{E}_n^\star$ there; i.e., we must efficiently update from $\mathsf{P}^\star(\theta), \mathsf{E}^\star$ to $\mathsf{P}_n^\star(\theta), \mathsf{E}_n^\star$. The algorithm for obtaining a Fourier approximation of $\mathsf{P}_n^\star(\theta), \mathsf{E}_n^\star$ is described in section 5.3. Finally, in section 5.4 we explain how the crucial bound on the size of the imaginary parts of the Floquet exponents is maintained, while in section 5.5 we show how to start the continuation method at a Hopf point.

5.1. Tangent predictor. First, we consider what the assumption (5.2) means in terms of our Floquet variables; i.e., if we set

$$\boldsymbol{v}(\theta) \equiv \mathsf{P}_+^\star(\theta)\boldsymbol{w}_+(\theta) + \mathsf{P}_-^\star(\theta)\boldsymbol{w}_-(\theta),$$

then we are assuming that

$$\begin{aligned} -\dot{\boldsymbol{w}}_+(\theta) + \mathsf{E}_+^\star \boldsymbol{w}_+(\theta) + \alpha^\star T \boldsymbol{e}_1 + \lambda \boldsymbol{k}_+^\star(\theta) &= \boldsymbol{0}, \\ \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1 \cdot \boldsymbol{w}_+(\theta)\,\mathrm{d}\theta &= 0, \\ -\dot{\boldsymbol{w}}_-(\theta) + \mathsf{E}_-^\star \boldsymbol{w}_-(\theta) + \lambda \boldsymbol{k}_-^\star(\theta) &= \boldsymbol{0}, \end{aligned} \tag{5.5}$$

where

$$\mathsf{P}^\star(\theta)\begin{bmatrix}\boldsymbol{k}_+^\star(\theta)\\ \boldsymbol{k}_-^\star(\theta)\end{bmatrix} \equiv \boldsymbol{k}^\star(\theta),$$

has a one-dimensional solution space. It is clear that this assumption rests on the equation for the constant mode of $\boldsymbol{w}_+(\theta)$; i.e., that the $(n_+ + 1)\times(n_+ + 2)$ coefficient matrix

$$\begin{bmatrix}\mathsf{E}_+^\star & \alpha^\star \boldsymbol{e}_1 & \boldsymbol{k}_0^c \\ \boldsymbol{e}_1^T & 0 & 0\end{bmatrix},$$

where

$$\boldsymbol{k}_0^c \equiv \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{k}_+^\star(\theta)\,\mathrm{d}\theta,$$

has full rank. Using the bordered matrix

$$\begin{bmatrix}\mathsf{E}_+^\star & \alpha^\star \boldsymbol{e}_1 \\ \boldsymbol{e}_1^T & 0\end{bmatrix}, \tag{5.6}$$

this can arise in three different ways.

- If (5.6) is nonsingular, then $\boldsymbol{v}^\star(\theta)$ is a nonsingular periodic orbit as described in section 4.1.
- If (5.6) has rank n_+, with $\mathsf{E}_+^\star$ having rank $n_+ - 1$, then this corresponds to zero being an eigenvalue of $\mathsf{E}_+^\star$ of geometric multiplicity one and algebraic multiplicity greater than one; in addition $\boldsymbol{k}_0^c$ is not in the range of $\mathsf{E}_+^\star$. (Generically, we would expect this zero eigenvalue of $\mathsf{E}_+^\star$ to have algebraic multiplicity two [15, 21].)
- If (5.6) has rank n_+, with $\mathsf{E}_+^\star$ having rank $n_+ - 2$, then this corresponds to zero being an eigenvalue of $\mathsf{E}_+^\star$ of geometric multiplicity two, but $\boldsymbol{e}_1$ is not in the range of $\mathsf{E}_+^\star$; in addition $\boldsymbol{k}_0^c$ is not in the range of $\mathsf{E}_+^\star$ and not parallel to $\boldsymbol{e}_1$. (Generically, we would not expect these conditions to appear [21].)

This analysis also shows that a suitable normalization for the solution of (5.2) or (5.5) is

$$\|\hat{\boldsymbol{t}}^\star\|^2 + [T_t^\star]^2 + [\lambda_t^\star]^2 = 1, \tag{5.7}$$

where $\hat{\boldsymbol{t}}^\star \in \mathbb{R}^{n_+}$ is the constant mode of $\boldsymbol{w}_+(\theta)$; i.e.,

$$\hat{\boldsymbol{t}}^\star \equiv \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{w}_+(\theta)\,\mathrm{d}\theta.$$

We shall also require $\boldsymbol{t}^\star \in \mathbb{R}^n$ later, which is just $\hat{\boldsymbol{t}}^\star$ padded out with zeroes.

Discretizing (5.5), our Fourier approximations

$$\boldsymbol{w}_+(\theta) \approx \boldsymbol{w}_0^c + \sum_{m=1}^{M} \left\{ \boldsymbol{w}_m^c \cos m\theta + \boldsymbol{w}_m^s \sin m\theta \right\},$$
$$\boldsymbol{k}_+^\star(\theta) \approx \boldsymbol{k}_0^c + \sum_{m=1}^{M} \left\{ \boldsymbol{k}_m^c \cos m\theta + \boldsymbol{k}_m^s \sin m\theta \right\}$$

give us

$$\begin{pmatrix} \mathsf{E}_+^\star & \alpha^\star \boldsymbol{e}_1 & \boldsymbol{k}_0^c \\ \boldsymbol{e}_1^T & 0 & 0 \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_0^c \\ T_t^\star \\ \lambda_t^\star \end{pmatrix} = \begin{pmatrix} \boldsymbol{0} \\ 0 \end{pmatrix} \tag{5.8}$$

for $m = 0$ and

$$\begin{pmatrix} \mathsf{E}_+^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_+^\star \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_m^c \\ \boldsymbol{w}_m^s \end{pmatrix} = -\lambda_t^\star \begin{pmatrix} \boldsymbol{k}_m^c \\ \boldsymbol{k}_m^s \end{pmatrix} \tag{5.9}$$

for $m = 1, \ldots, M$; similarly, our Fourier approximations

$$\boldsymbol{w}_-(\theta) \approx \sum_{m=1}^{M} \left\{ \boldsymbol{w}_m^c \cos [m - \tfrac{1}{2}]\theta + \boldsymbol{w}_m^s \sin [m - \tfrac{1}{2}]\theta \right\},$$
$$\boldsymbol{k}_-^\star(\theta) \approx \sum_{m=1}^{M} \left\{ \boldsymbol{k}_m^c \cos [m - \tfrac{1}{2}]\theta + \boldsymbol{k}_m^s \sin [m - \tfrac{1}{2}]\theta \right\}$$

give us

$$\begin{pmatrix} \mathsf{E}_-^\star & -[m - \frac{1}{2}]\mathsf{I} \\ [m - \frac{1}{2}]\mathsf{I} & \mathsf{E}_-^\star \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_m^c \\ \boldsymbol{w}_m^s \end{pmatrix} = -\lambda_t^\star \begin{pmatrix} \boldsymbol{k}_m^c \\ \boldsymbol{k}_m^s \end{pmatrix} \tag{5.10}$$

for $m = 1, \ldots, M$. The one-dimensional null-space for the full-rank structured matrix in (5.8) may be efficiently obtained by employing algorithms from [17, Chap. 5].

- First, we construct the $n \times (n+1)$ quasi-upper triangular matrix

$$\begin{pmatrix} \alpha^\star \boldsymbol{e}_1 & \hat{\mathsf{E}}_+^\star & \boldsymbol{k}_0^c \end{pmatrix}, \tag{5.11}$$

  where $\hat{\mathsf{E}}_+^\star$ is obtained from $\mathsf{E}_+^\star$ by removing the zero first column.
- Second, Givens rotations are used to annihilate the nonzero elements below the diagonal and thus change (5.11) into an $n \times (n+1)$ upper triangular matrix.
- Third, post-multiplication with Householder matrices is used to annihilate the final column of (5.11).

We can then solve (5.9) and (5.10), since the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_\pm^\star$ makes these systems nonsingular.

5.2. Newton correction. Our Newton correction will solve the system

$$\begin{aligned} -\dot{\boldsymbol{v}}(\theta) + T\boldsymbol{F}(\boldsymbol{v}(\theta), \lambda) &= \boldsymbol{0}, \\ \frac{1}{2\pi} \int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T} \boldsymbol{e}_1 \cdot \boldsymbol{v}(\theta)\, \mathrm{d}\theta &= 0, \\ \frac{1}{2\pi} \int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T} \boldsymbol{t}^\star \cdot [\boldsymbol{v}(\theta) - \boldsymbol{v}^\star(\theta)]\, \mathrm{d}\theta & \\ + T_t^\star [T - T^\star] + \lambda_t^\star [\lambda - \lambda^\star] - \varepsilon &= 0. \end{aligned} \tag{5.12}$$

Thus, for the same reason as in (4.9), we have replaced the final equation for the tangent line step in (5.3) by the more convenient equation above. Our Newton-chord iteration for solving (5.12) is defined from the starting values

$$\begin{aligned} \boldsymbol{v}^{(0)}(\theta) &= \boldsymbol{v}^\star(\theta) + \varepsilon \boldsymbol{v}_t^\star(\theta), \\ T^{(0)} &= T^\star + \varepsilon T_t^\star, \\ \lambda^{(0)} &= \lambda^\star + \varepsilon \lambda_t^\star \end{aligned}$$

for chosen small $|\varepsilon|$, and consists of

$$\begin{aligned} \boldsymbol{v}^{(k+1)}(\theta) &= \boldsymbol{v}^{(k)}(\theta) + \boldsymbol{z}(\theta), \\ T^{(k+1)} &= T^{(k)} + \delta T, \\ \lambda^{(k+1)} &= \lambda^{(k)} + \delta\lambda, \end{aligned}$$

where $(\boldsymbol{z}(\theta), \delta T, \delta\lambda) \in \mathcal{Y}_+^n \times \mathbb{R}^2$ satisfy

$$\begin{aligned} -\dot{\boldsymbol{z}}(\theta) + \mathsf{A}^\star(\theta)\boldsymbol{z}(\theta) + \delta T \boldsymbol{p}^\star(\theta) + \delta\lambda \boldsymbol{k}^\star(\theta) &= \boldsymbol{r}^{(k)}(\theta), \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{e}_1 \cdot \boldsymbol{z}(\theta)\,\mathrm{d}\theta &= 0, \\ \frac{1}{2\pi}\int_0^{2\pi} \mathsf{P}^\star(\theta)^{-T}\boldsymbol{t}^\star \cdot \boldsymbol{z}(\theta)\,\mathrm{d}\theta + T_t^\star \delta T + \lambda_t^\star \delta\lambda &= 0, \end{aligned} \tag{5.13}$$

with

$$\boldsymbol{r}^{(k)}(\theta) \equiv \dot{\boldsymbol{v}}^{(k)}(\theta) - T^{(k)}\boldsymbol{F}(\boldsymbol{v}^{(k)}(\theta), \lambda^{(k)}).$$

Hence, under the Floquet transformations

$$\begin{aligned} \boldsymbol{z}(\theta) &\equiv \mathsf{P}_+^\star(\theta)\boldsymbol{w}_+(\theta) + \mathsf{P}_-^\star(\theta)\boldsymbol{w}_-(\theta), \\ \boldsymbol{r}^{(k)}(\theta) &\equiv \mathsf{P}_+^\star(\theta)\boldsymbol{f}_+(\theta) + \mathsf{P}_-^\star(\theta)\boldsymbol{f}_-(\theta), \end{aligned}$$

our equation in $\mathcal{Y}_+^{n_+}$ becomes

$$\begin{aligned} -\dot{\boldsymbol{w}}_+(\theta) + \mathsf{E}_+^\star \boldsymbol{w}_+(\theta) + \delta T \alpha^\star \boldsymbol{e}_1 + \delta\lambda \boldsymbol{k}_+^\star(\theta) &= \boldsymbol{f}_+(\theta), \\ \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1 \cdot \boldsymbol{w}_+(\theta)\,\mathrm{d}\theta &= 0, \\ \frac{1}{2\pi}\int_0^{2\pi} \hat{\boldsymbol{t}}^\star \cdot \boldsymbol{w}_+(\theta)\,\mathrm{d}\theta + T_t^\star \delta T + \lambda_t^\star \delta\lambda &= 0, \end{aligned}$$

and our equation in $\mathcal{Y}_-^{n_-}$ is

$$-\dot{\boldsymbol{w}}_-(\theta) + \mathsf{E}_-^\star \boldsymbol{w}_-(\theta) + \delta\lambda \boldsymbol{k}_-^\star(\theta) = \boldsymbol{f}_-(\theta).$$

Hence our Fourier approximation in $\mathcal{Y}_+^{n_+}$ is

$$\begin{aligned} \boldsymbol{w}_+(\theta) &\approx \boldsymbol{w}_0^c + \sum_{m=1}^M \{\boldsymbol{w}_m^c \cos m\theta + \boldsymbol{w}_m^s \sin m\theta\}, \\ \boldsymbol{f}_+(\theta) &\approx \boldsymbol{f}_0^c + \sum_{m=1}^M \{\boldsymbol{f}_m^c \cos m\theta + \boldsymbol{f}_m^s \sin m\theta\}, \\ \boldsymbol{k}_+^\star(\theta) &\approx \boldsymbol{k}_0^c + \sum_{m=1}^M \{\boldsymbol{k}_m^c \cos m\theta + \boldsymbol{k}_m^s \sin m\theta\}, \end{aligned}$$

leading to

$$\begin{pmatrix} \mathsf{E}_+^\star & \alpha^\star \boldsymbol{e}_1 & \boldsymbol{k}_0^c \\ \boldsymbol{e}_1^T & 0 & 0 \\ (\hat{\boldsymbol{t}}^\star)^T & T_t^\star & \lambda_t^\star \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_0^c \\ \delta T \\ \delta\lambda \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_0^c \\ 0 \\ 0 \end{pmatrix} \tag{5.14}$$

for $m = 0$ and

$$\begin{pmatrix} \mathsf{E}_+^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_+^\star \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_m^c \\ \boldsymbol{w}_m^s \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_m^c - \delta\lambda \boldsymbol{k}_m^c \\ \boldsymbol{f}_m^s - \delta\lambda \boldsymbol{k}_m^s \end{pmatrix} \tag{5.15}$$

for $m = 1, \ldots, M$; while our Fourier approximation in $\mathcal{Y}_-^{n_-}$ is

$$\begin{aligned} \boldsymbol{w}_-(\theta) &\approx \sum_{m=1}^{M} \left\{ \boldsymbol{w}_m^c \cos\left[m - \tfrac{1}{2}\right]\theta + \boldsymbol{w}_m^s \sin\left[m - \tfrac{1}{2}\right]\theta \right\}, \\ \boldsymbol{f}_-(\theta) &\approx \sum_{m=1}^{M} \left\{ \boldsymbol{f}_m^c \cos\left[m - \tfrac{1}{2}\right]\theta + \boldsymbol{f}_m^s \sin\left[m - \tfrac{1}{2}\right]\theta \right\}, \\ \boldsymbol{k}_-^\star(\theta) &\approx \sum_{m=1}^{M} \left\{ \boldsymbol{k}_m^c \cos\left[m - \tfrac{1}{2}\right]\theta + \boldsymbol{k}_m^s \sin\left[m - \tfrac{1}{2}\right]\theta \right\}, \end{aligned}$$

giving us

$$\begin{pmatrix} \mathsf{E}_-^\star & -[m - \frac{1}{2}]\mathsf{I} \\ [m - \frac{1}{2}]\mathsf{I} & \mathsf{E}_-^\star \end{pmatrix} \begin{pmatrix} \boldsymbol{w}_m^c \\ \boldsymbol{w}_m^s \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}_m^c - \delta\lambda \boldsymbol{k}_m^c \\ \boldsymbol{f}_m^s - \delta\lambda \boldsymbol{k}_m^s \end{pmatrix} \tag{5.16}$$

for $m = 1, \ldots, M$. By our construction of $(\hat{\boldsymbol{t}}^\star, T_t^\star, \lambda_t^\star)$, the coefficient matrix in (5.14) is nonsingular. Our linear algebra at the end of section 5.1 also means that we can solve (5.14) efficiently. We can then solve (5.15) and (5.16), since the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_\pm^\star$ makes these systems nonsingular.

5.3. Floquet continuation. After having calculated $\boldsymbol{v}_n^\star(\theta)$, $T_n^\star$, and $\lambda_n^\star$, we need to update from

$$-\dot{\mathsf{P}}^\star(\theta) + \mathsf{A}^\star(\theta)\mathsf{P}^\star(\theta) = \mathsf{P}^\star(\theta)\mathsf{E}^\star \tag{5.17}$$

to

$$-\dot{\mathsf{P}}_n^\star(\theta) + \mathsf{A}_n^\star(\theta)\mathsf{P}_n^\star(\theta) = \mathsf{P}_n^\star(\theta)\mathsf{E}_n^\star, \tag{5.18}$$

where

$$\mathsf{A}_n^\star(\theta) \equiv T_n^\star \mathsf{J}(\boldsymbol{v}_n^\star(\theta), \lambda_n^\star).$$

We seek $\mathsf{P}_n^\star(\theta)$ in the Floquet form

$$\mathsf{P}_n^\star(\theta) \equiv \mathsf{P}^\star(\theta)\mathsf{P}(\theta),$$

with the normalization

$$\frac{1}{2\pi} \int_0^{2\pi} \mathsf{P}(\theta)\, \mathrm{d}\theta = \mathsf{I}. \tag{5.19}$$

Hence we can apply a Newton-chord method to solve (5.18) for $\mathsf{P}(\theta)$ and $\mathsf{E}_n^\star$, analogous to that described theoretically in [28] and practically in [7], and make use of our known Floquet variables for (5.17). Thus our Newton iteration starts from $\mathsf{P}^{(0)}(\theta) \equiv \mathsf{I}$ and $\mathsf{E}^{(0)} \equiv \mathsf{E}^\star$ and computes

$$\begin{aligned} \mathsf{P}^{(k+1)}(\theta) &= \mathsf{P}^{(k)}(\theta) + \mathsf{Z}(\theta), \\ \mathsf{E}^{(k+1)} &= \mathsf{E}^{(k)} + \delta\mathsf{E} \end{aligned}$$

from

$$-\dot{\mathsf{Z}}(\theta) + \mathsf{E}^\star\mathsf{Z}(\theta) - \mathsf{Z}(\theta)\mathsf{E}^\star - \delta\mathsf{E} = \mathsf{R}^{(k)}(\theta), \tag{5.20}$$

where

$$\mathsf{R}^{(k)}(\theta) \equiv \mathsf{P}^\star(\theta)^{-1}\left\{\frac{\mathrm{d}}{\mathrm{d}\theta}\left[\mathsf{P}^\star(\theta)\mathsf{P}^{(k)}(\theta)\right] - \mathsf{A}_n^\star(\theta)\mathsf{P}^\star(\theta)\mathsf{P}^{(k)}(\theta) + \mathsf{P}^\star(\theta)\mathsf{P}^{(k)}(\theta)\mathsf{E}^{(k)}\right\}.$$

We now make use of the decompositions

$$\mathsf{E}^\star \equiv \begin{bmatrix} \mathsf{E}_+^\star & \mathsf{O} \\ \mathsf{O} & \mathsf{E}_-^\star \end{bmatrix}, \qquad \delta\mathsf{E} \equiv \begin{bmatrix} \delta\mathsf{E}_+ & \mathsf{O} \\ \mathsf{O} & \delta\mathsf{E}_- \end{bmatrix}$$

and the fact that $\mathsf{P}^\star(\theta) \equiv \left[\mathsf{P}_+^\star(\theta)|\mathsf{P}_-^\star(\theta)\right]$ leads to

$$\mathsf{Z}(\theta) \equiv \begin{bmatrix} \mathsf{Z}_{++}(\theta) & \mathsf{Z}_{+-}(\theta) \\ \mathsf{Z}_{-+}(\theta) & \mathsf{Z}_{--}(\theta) \end{bmatrix} \quad \text{and} \quad \mathsf{R}^{(k)}(\theta) \equiv \begin{bmatrix} \mathsf{R}_{++}^{(k)}(\theta) & \mathsf{R}_{+-}^{(k)}(\theta) \\ \mathsf{R}_{-+}^{(k)}(\theta) & \mathsf{R}_{--}^{(k)}(\theta) \end{bmatrix}.$$

Here $\mathsf{Z}_{++}(\theta) \in \mathbb{R}^{n_+ \times n_+}$ and $\mathsf{Z}_{--}(\theta) \in \mathbb{R}^{n_- \times n_-}$ have components in $\mathcal{Y}_+$, while $\mathsf{Z}_{+-}(\theta) \in \mathbb{R}^{n_+ \times n_-}$ and $\mathsf{Z}_{-+}(\theta) \in \mathbb{R}^{n_- \times n_+}$ have components in $\mathcal{Y}_-$, and similarly for the decomposition of $\mathsf{R}^{(k)}(\theta)$. Hence we can decompose (5.20) into two equations with components in $\mathcal{Y}_+$,

$$-\dot{\mathsf{Z}}_{++}(\theta) + \mathsf{E}_+^\star\mathsf{Z}_{++}(\theta) - \mathsf{Z}_{++}(\theta)\mathsf{E}_+^\star - \delta\mathsf{E}_+ = \mathsf{R}_{++}^{(k)}(\theta) \tag{5.21}$$

and

$$-\dot{\mathsf{Z}}_{--}(\theta) + \mathsf{E}_-^\star\mathsf{Z}_{--}(\theta) - \mathsf{Z}_{--}(\theta)\mathsf{E}_-^\star - \delta\mathsf{E}_- = \mathsf{R}_{--}^{(k)}(\theta), \tag{5.22}$$

and two equations with components in $\mathcal{Y}_-$,

$$-\dot{\mathsf{Z}}_{+-}(\theta) + \mathsf{E}_+^\star\mathsf{Z}_{+-}(\theta) - \mathsf{Z}_{+-}(\theta)\mathsf{E}_-^\star = \mathsf{R}_{+-}^{(k)}(\theta) \tag{5.23}$$

and

$$-\dot{\mathsf{Z}}_{-+}(\theta) + \mathsf{E}_-^\star\mathsf{Z}_{-+}(\theta) - \mathsf{Z}_{-+}(\theta)\mathsf{E}_+^\star = \mathsf{R}_{-+}^{(k)}(\theta). \tag{5.24}$$

Each of (5.21), (5.22), (5.23), and (5.24) can be replaced by the analogous Fourier approximation, which leads to mode-decoupling as we see below. We then obtain Sylvester equations [17], which can be solved by the Bartels–Stewart algorithm [4, 17]. Most of the work in this algorithm is devoted to reducing the appropriate matrices to Schur form, but here $\mathsf{E}_\pm^\star$ already have this form! Otherwise, only back-substitutions are required. Of course the product to form $\mathsf{R}^{(k)}(\theta)$ in (5.20) is carried out in point-space.

- To obtain $\mathsf{Z}_{++}(\theta)$, we set

$$\mathsf{Z}_{++}(\theta) \approx \sum_{m=1}^{M} \{\mathsf{Z}_m^c \cos m\theta + \mathsf{Z}_m^s \sin m\theta\},$$
$$\mathsf{R}_{++}^{(k)}(\theta) \approx \mathsf{R}_0^c + \sum_{m=1}^{M} \{\mathsf{R}_m^c \cos m\theta + \mathsf{R}_m^s \sin m\theta\},$$

and so (5.21) gives us

$$\delta \mathsf{E}_+ = -\mathsf{R}_0^c \tag{5.25}$$

for $m = 0$ and

$$\begin{bmatrix} \mathsf{E}_+^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_+^\star \end{bmatrix} \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} - \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} \mathsf{E}_+^\star = \begin{bmatrix} \mathsf{R}_m^c \\ \mathsf{R}_m^s \end{bmatrix} \tag{5.26}$$

for $m = 1, \ldots, M$. The Sylvester equations in (5.26) are nonsingular, because the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_+^\star$ means that

$$\begin{bmatrix} \mathsf{E}_+^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_+^\star \end{bmatrix} \quad \text{and} \quad \mathsf{E}_+^\star$$

have no common eigenvalue.

- To obtain $\mathsf{Z}_{--}(\theta)$, we set

$$\mathsf{Z}_{--}(\theta) \approx \sum_{m=1}^{M} \{\mathsf{Z}_m^c \cos m\theta + \mathsf{Z}_m^s \sin m\theta\},$$
$$\mathsf{R}_{--}^{(k)}(\theta) \approx \mathsf{R}_0^c + \sum_{m=1}^{M} \{\mathsf{R}_m^c \cos m\theta + \mathsf{R}_m^s \sin m\theta\},$$

and so (5.22) gives us

$$\delta \mathsf{E}_- = -\mathsf{R}_0^c \tag{5.27}$$

for $m = 0$ and

$$\begin{bmatrix} \mathsf{E}_-^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_-^\star \end{bmatrix} \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} - \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} \mathsf{E}_-^\star = \begin{bmatrix} \mathsf{R}_m^c \\ \mathsf{R}_m^s \end{bmatrix} \tag{5.28}$$

for $m = 1, \ldots, M$. The Sylvester equations in (5.28) are nonsingular, because the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_-^\star$ means that

$$\begin{bmatrix} \mathsf{E}_-^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_-^\star \end{bmatrix} \quad \text{and} \quad \mathsf{E}_-^\star$$

have no common eigenvalue.

- To obtain $\mathsf{Z}_{+-}(\theta)$, we set

$$\mathsf{Z}_{+-}(\theta) \approx \sum_{m=1}^{M} \left\{ \mathsf{Z}_m^c \cos\left[m-\tfrac{1}{2}\right]\theta + \mathsf{Z}_m^s \sin\left[m-\tfrac{1}{2}\right]\theta \right\},$$
$$\mathsf{R}_{+-}^{(k)}(\theta) \approx \sum_{m=1}^{M} \left\{ \mathsf{R}_m^c \cos\left[m-\tfrac{1}{2}\right]\theta + \mathsf{R}_m^s \sin\left[m-\tfrac{1}{2}\right]\theta \right\},$$

and so (5.23) gives us

$$\begin{bmatrix} \mathsf{E}_+^\star & -[m-\frac{1}{2}]\mathsf{I} \\ [m-\frac{1}{2}]\mathsf{I} & \mathsf{E}_+^\star \end{bmatrix} \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} - \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} \mathsf{E}_-^\star = \begin{bmatrix} \mathsf{R}_m^c \\ \mathsf{R}_m^s \end{bmatrix} \tag{5.29}$$

for $m = 1, \ldots, M$. The Sylvester equations in (5.29) are nonsingular, because of the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_+^\star$ and $\mathsf{E}_-^\star$ means that

$$\begin{bmatrix} \mathsf{E}_+^\star & -[m-\frac{1}{2}]\mathsf{I} \\ [m-\frac{1}{2}]\mathsf{I} & \mathsf{E}_+^\star \end{bmatrix} \quad \text{and} \quad \mathsf{E}_-^\star$$

have no common eigenvalue.

- To obtain $\mathsf{Z}_{-+}(\theta)$, we set

$$\mathsf{Z}_{-+}(\theta) \approx \sum_{m=1}^{M} \left\{ \mathsf{Z}_m^c \cos\left[m-\tfrac{1}{2}\right]\theta + \mathsf{Z}_m^s \sin\left[m-\tfrac{1}{2}\right]\theta \right\},$$
$$\mathsf{R}_{-+}^{(k)}(\theta) \approx \sum_{m=1}^{M} \left\{ \mathsf{R}_m^c \cos\left[m-\tfrac{1}{2}\right]\theta + \mathsf{R}_m^s \sin\left[m-\tfrac{1}{2}\right]\theta \right\},$$

and so (5.24) gives us

$$\begin{bmatrix} \mathsf{E}_-^\star & -[m-\frac{1}{2}]\mathsf{I} \\ [m-\frac{1}{2}]\mathsf{I} & \mathsf{E}_-^\star \end{bmatrix} \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} - \begin{bmatrix} \mathsf{Z}_m^c \\ \mathsf{Z}_m^s \end{bmatrix} \mathsf{E}_+^\star = \begin{bmatrix} \mathsf{R}_m^c \\ \mathsf{R}_m^s \end{bmatrix} \tag{5.30}$$

for $m = 1, \ldots, M$. The Sylvester equations in (5.30) are nonsingular, because the restriction on the size of the imaginary parts of the eigenvalues of $\mathsf{E}_-^\star$ and $\mathsf{E}_+^\star$ means that

$$\begin{bmatrix} \mathsf{E}_-^\star & -[m-\frac{1}{2}]\mathsf{I} \\ [m-\frac{1}{2}]\mathsf{I} & \mathsf{E}_-^\star \end{bmatrix} \quad \text{and} \quad \mathsf{E}_+^\star$$

have no common eigenvalue.

Finally, we note that our limit

$$\mathsf{E}_n^\star \equiv \lim_{k\to\infty} \begin{bmatrix} \mathsf{E}_+^{(k)} & \mathsf{O} \\ \mathsf{O} & \mathsf{E}_-^{(k)} \end{bmatrix}$$

will not generally be quasi-upper triangular, and so we will have to perform a last Schur factorization with

$$\mathsf{Q} \equiv \begin{pmatrix} \mathsf{Q}_+ & \mathsf{O} \\ \mathsf{O} & \mathsf{Q}_- \end{pmatrix}, \qquad \mathsf{Q}_+ \in \mathbb{R}^{n_+ \times n_+}, \qquad \mathsf{Q}_- \in \mathbb{R}^{n_- \times n_-},$$

so that the transformations

$$\begin{aligned}\mathsf{P}_n^\star(\theta) &\mapsto \mathsf{P}_n^\star(\theta)\mathsf{Q},\\ \mathsf{E}_n^\star &\mapsto \mathsf{Q}^T\mathsf{E}_n^\star\mathsf{Q}\end{aligned}$$

mean that the diagonal blocks of $\mathsf{E}_n^\star$ are now in real Schur form.

5.4. Controlling the Floquet exponents. On page 2539 we stated the conditions on our Floquet exponents, the eigenvalues of

$$\mathsf{E} \equiv \begin{bmatrix}\mathsf{E}_+ & \mathsf{O}\\ \mathsf{O} & \mathsf{E}_-\end{bmatrix},$$

that must be maintained during the continuation process. Basically, this means that the sum of any imaginary part of an eigenvalue of E_+ with any imaginary part of an eigenvalue of E_- must be less than $\frac{1}{2}$. We now show what to do if this condition is found either to fail or to be dangerously close to failing at the end of a continuation step.

Suppose we have

$$-\dot{\mathsf{P}}(\theta) + \mathsf{A}(\theta)\mathsf{P}(\theta) = \mathsf{P}(\theta)\mathsf{E},$$

with

$$\mathsf{P}(\theta) \equiv [\mathsf{P}_+(\theta), \mathsf{P}_-(\theta)] \quad \text{and} \quad \mathsf{E} \equiv \begin{bmatrix}\mathsf{E}_+ & \mathsf{O}\\ \mathsf{O} & \mathsf{E}_-\end{bmatrix}.$$

If the imaginary parts of a pair of complex conjugate eigenvalues of E_- are too large, we could [17]

- move them to the top left of E_-,
- block-diagonalize E_-

(altering $\mathsf{P}_-(\theta)$ in consequence), so that now E_- has the form

$$\mathsf{E}_- = \begin{bmatrix}\alpha & \beta_1 & 0 & \cdots & \cdots & 0\\ -\beta_2 & \alpha & 0 & \cdots & \cdots & 0\\ 0 & 0 & \ddots & \ddots & \ddots & \ddots\\ \vdots & \vdots & \ddots & \ddots & \ddots & \ddots\\ \vdots & \vdots & \ddots & \ddots & \ddots & \ddots\\ 0 & 0 & \ddots & \ddots & \ddots & \ddots\end{bmatrix},$$

where β_1, β_2 are positive. Now, if we denote the first two columns of $\mathsf{P}_-(\theta)$ by $\boldsymbol{p}_1(\theta)$ and $\boldsymbol{p}_2(\theta)$, then transforming them by

$$\begin{bmatrix}\boldsymbol{p}_1(\theta) & \boldsymbol{p}_2(\theta)\end{bmatrix} \to \begin{bmatrix}\boldsymbol{p}_1(\theta) & \boldsymbol{p}_2(\theta)\end{bmatrix} \begin{bmatrix}\sqrt{\beta_1}\cos\frac{1}{2}\theta & \sqrt{\beta_1}\sin\frac{1}{2}\theta\\ -\sqrt{\beta_2}\sin\frac{1}{2}\theta & \sqrt{\beta_2}\cos\frac{1}{2}\theta\end{bmatrix}$$

will transform the leading 2×2 block of E_- into

$$\begin{bmatrix}\alpha & \sqrt{\beta_1\beta_2} - \frac{1}{2}\\ \frac{1}{2} - \sqrt{\beta_1\beta_2} & \alpha\end{bmatrix},$$

thus decreasing the size of the imaginary parts of the eigenvalues by $\frac{1}{2}$. Now the new $\boldsymbol{p}_1(\theta), \boldsymbol{p}_2(\theta)$ are in $\mathcal{Y}_+^n$, and so we increase n_+ by 2 and decrease n_- by 2.

Similarly, if the imaginary parts of a pair of complex conjugate eigenvalues of E_+ are too large, we carry out the analogous procedure to transfer them to E_-; e.g.,

- moving them to the bottom right of E_+,
- block-diagonalizing E_+,
- transforming the final two columns of $\mathsf{P}_+(\theta)$, so that the size of the imaginary parts of the dangerous eigenvalues is decreased by $\frac{1}{2}$.

We have described above the simplest situations, where there is only a single pair of dangerous eigenvalues. We omit the obvious extensions, where a larger block of eigenvalues has to be controlled.

5.5. Starting at a Hopf point. Finally, we show how $\mathsf{E}^\star$ and $\mathsf{P}^\star(\theta)$ may be constructed at a Hopf bifurcation point in order to start the continuation process; so $(\boldsymbol{x}^\star, \lambda^\star)$ is a Hopf bifurcation point for (1.1), satisfying the conditions at the beginning of section 3. Hence we have a Schur factorization

$$\mathsf{A}^\star \mathsf{Q}^\star = \mathsf{Q}^\star \mathsf{U}^\star$$

for

$$\mathsf{A}^\star \equiv T^\star \mathsf{J}(\boldsymbol{x}^\star, \lambda^\star).$$

1. Block-diagonalize $\mathsf{A}^\star$ to obtain

$$\mathsf{A}^\star \mathsf{S}^\star = \mathsf{S}^\star \mathsf{D}^\star,$$

where $\mathsf{D}^\star$ is the $n \times n$ block-diagonal matrix

$$\mathsf{D}^\star \equiv \begin{bmatrix} \mathsf{U}_+^\star & \mathsf{O} \\ \mathsf{O} & \mathsf{U}_-^\star \end{bmatrix}$$

with quasi-upper triangular $\mathsf{U}_+^\star \in \mathbb{R}^{n_+ \times n_+}$ and $\mathsf{U}_-^\star \in \mathbb{R}^{n_- \times n_-}$. In fact each of $\mathsf{U}_+^\star$ and $\mathsf{U}_-^\star$ is itself block-diagonal with

$$\mathsf{U}_+^\star \equiv \begin{bmatrix} \mathsf{U}_0 & & & & \\ & \mathsf{U}_1 & & & \\ & & \mathsf{U}_2 & & \\ & & & \ddots & \\ & & & & \ddots \end{bmatrix}$$

and

$$\mathsf{U}_-^\star \equiv \begin{bmatrix} \mathsf{U}_{\frac{1}{2}} & & & & \\ & \mathsf{U}_{\frac{3}{2}} & & & \\ & & \mathsf{U}_{\frac{5}{2}} & & \\ & & & \ddots & \\ & & & & \ddots \end{bmatrix},$$

so that the eigenvalues of $\mathsf{U}_j, j \geq 0$, have an imaginary part "close to" $\pm j$ and the eigenvalues of $\mathsf{U}_{\frac{j}{2}}, j \geq 1$, have an imaginary part "close to" $\pm \frac{j}{2}$.

2. If $\left[\begin{smallmatrix} \alpha & \beta_1 \\ -\beta_2 & \alpha \end{smallmatrix}\right]$ is a 2×2 diagonal block of U_j or $\mathsf{U}_{\frac{j}{2}}$ for $j \geq 1$, with β_1, β_2 positive and $\boldsymbol{s}_\ell^\star, \boldsymbol{s}_{\ell+1}^\star$ denoting the corresponding columns of $\mathsf{S}^\star$, then we can transform these columns by

$$\widetilde{\boldsymbol{s}}_\ell^\star \to \sqrt{\beta_1}\boldsymbol{s}_\ell^\star - \sqrt{\beta_2}\boldsymbol{s}_{\ell+1}^\star,$$
$$\widetilde{\boldsymbol{s}}_{\ell+1}^\star \to \sqrt{\beta_1}\boldsymbol{s}_\ell^\star + \sqrt{\beta_2}\boldsymbol{s}_{\ell+1}^\star.$$

Thus we obtain

$$\mathsf{A}^\star\widetilde{\mathsf{S}}^\star = \widetilde{\mathsf{S}}^\star\widetilde{\mathsf{D}}^\star,$$

where

$$\widetilde{\mathsf{D}}^\star \equiv \begin{bmatrix} \widetilde{\mathsf{U}}_+^\star & \mathsf{O} \\ \mathsf{O} & \widetilde{\mathsf{U}}_-^\star \end{bmatrix}$$

with

$$\widetilde{\mathsf{U}}_+^\star \equiv \begin{bmatrix} \mathsf{U}_0 & & & & \\ & \widetilde{\mathsf{U}}_1 & & & \\ & & \widetilde{\mathsf{U}}_2 & & \\ & & & \ddots & \\ & & & & \ddots \end{bmatrix}$$

and

$$\widetilde{\mathsf{U}}_-^\star \equiv \begin{bmatrix} \widetilde{\mathsf{U}}_{\frac{1}{2}} & & & & \\ & \widetilde{\mathsf{U}}_{\frac{3}{2}} & & & \\ & & \widetilde{\mathsf{U}}_{\frac{5}{2}} & & \\ & & & \ddots & \\ & & & & \ddots \end{bmatrix},$$

so that the 2×2 diagonal blocks of $\widetilde{\mathsf{U}}_j, \widetilde{\mathsf{U}}_{\frac{j}{2}},\ j \geq 1$, have the form $\left[\begin{smallmatrix} \alpha & \sqrt{\beta_1\beta_2} \\ -\sqrt{\beta_1\beta_2} & \alpha \end{smallmatrix}\right]$.

3. Finally, if $\left[\begin{smallmatrix} \alpha & \sqrt{\beta_1\beta_2} \\ -\sqrt{\beta_1\beta_2} & \alpha \end{smallmatrix}\right]$ is now a 2×2 diagonal block of $\widetilde{\mathsf{U}}_j, j \geq 1$, with corresponding columns $\widetilde{\boldsymbol{s}}_\ell^\star, \widetilde{\boldsymbol{s}}_{\ell+1}^\star$ of $\widetilde{\mathsf{S}}^\star$, then $\mathsf{P}_+^\star(\theta) \in \mathbb{R}^{n\times n_+}$ is obtained by replacing these columns with

$$\widetilde{\boldsymbol{s}}_\ell^\star \cos j\theta - \widetilde{\boldsymbol{s}}_{\ell+1}^\star \sin j\theta \quad \text{and} \quad \widetilde{\boldsymbol{s}}_\ell^\star \sin j\theta + \widetilde{\boldsymbol{s}}_{\ell+1}^\star \cos j\theta.$$

Similarly, if $\left[\begin{smallmatrix} \alpha & \sqrt{\beta_1\beta_2} \\ -\sqrt{\beta_1\beta_2} & \alpha \end{smallmatrix}\right]$ is now a 2×2 diagonal block of $\widetilde{\mathsf{U}}_{\frac{j}{2}}, j \geq 1$, with corresponding columns $\widetilde{\boldsymbol{s}}_\ell^\star, \widetilde{\boldsymbol{s}}_{\ell+1}^\star$ of $\widetilde{\mathsf{S}}^\star$, then $\mathsf{P}_-^\star(\theta) \in \mathbb{R}^{n\times n_-}$ is obtained by replacing these columns with

$$\widetilde{\boldsymbol{s}}_\ell^\star \cos j\theta/2 - \widetilde{\boldsymbol{s}}_{\ell+1}^\star \sin j\theta/2 \quad \text{and} \quad \widetilde{\boldsymbol{s}}_\ell^\star \sin j\theta/2 + \widetilde{\boldsymbol{s}}_{\ell+1}^\star \cos j\theta/2.$$

Hence the columns of $\mathsf{P}_+^\star$ are in $\mathcal{Y}_+^n$ and the columns of $\mathsf{P}_-^\star$ are in $\mathcal{Y}_-^n$, with $\mathsf{P}^\star(\theta) \equiv \left[\mathsf{P}_+^\star(\theta), \mathsf{P}_-^\star(\theta)\right]$ satisfying

$$-\dot{\mathsf{P}}^\star(\theta) + \mathsf{A}^\star(\theta)\mathsf{P}^\star(\theta) = \mathsf{P}^\star(\theta)\mathsf{E}^\star.$$

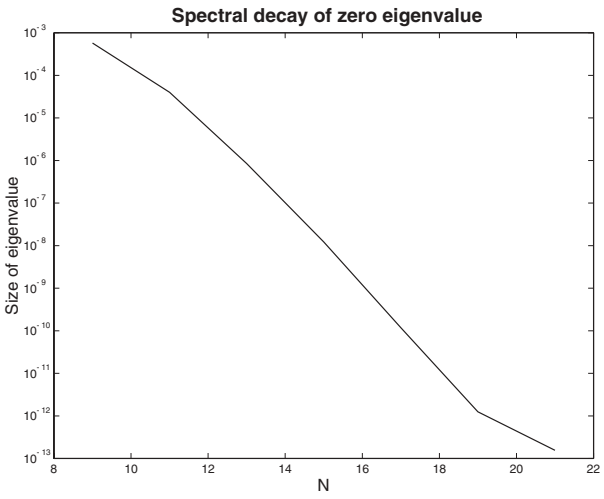

FIG. 3. *Approximating the zero Floquet exponent.*

Here

$$\mathsf{E}^\star \equiv \begin{bmatrix} \mathsf{E}^\star_+ & \mathsf{O} \\ \mathsf{O} & \mathsf{E}^\star_- \end{bmatrix}$$

is constructed from $\widetilde{\mathsf{U}}^\star_+$ and $\widetilde{\mathsf{U}}^\star_-$. The imaginary parts of the eigenvalues of $\mathsf{E}^\star$ are close to zero.

6. Numerical results. Now we illustrate the above algorithms with some well-known examples.

6.1. The Lorenz equations.

$$\begin{aligned} \dot{x} &= \sigma(y - x), \\ \dot{y} &= \lambda x - y - xz, \\ \dot{z} &= xy - bz. \end{aligned}$$

For $\sigma > b + 1$ there is a subcritical Hopf bifurcation from the stationary solution curves

$$\left(\pm\sqrt{b(\lambda-1)}, \pm\sqrt{b(\lambda-1)}, \lambda - 1\right), \quad \lambda > 1,$$

at

$$\lambda_H \equiv \frac{\sigma(\sigma + b + 3)}{\sigma - b - 1}.$$

We use the parameter values $(\sigma, b) = (10, \frac{8}{3})$, which gives $\lambda_H \approx 24.74$, and follow the branch of periodic orbits in the range $\lambda_H \geq \lambda \geq 24$. For $N \equiv 2 * M + 1$, where M is the number of Fourier modes, we plot in Figure 3 the maximum size of the smallest Floquet exponent (which should be zero) over this range of λ. The exponential decay is clear. For this example, it is necessary only to work in $\mathcal{Y}_+$.

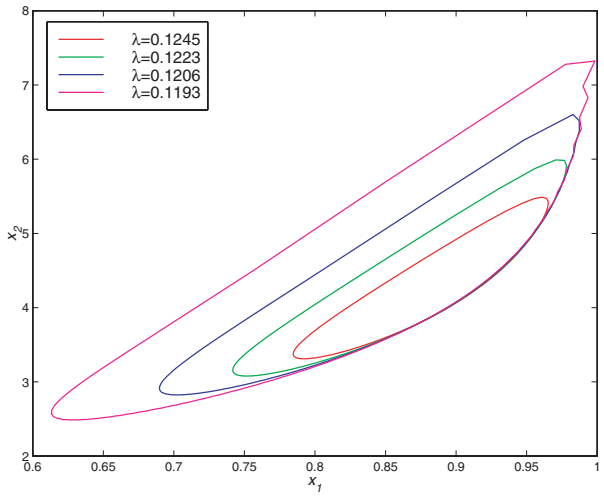

FIG. 4. *Approximating four periodic orbits.*

6.2. The A → B reaction equations.

$$\dot{x}_1 = -x_1 + \lambda(1 - x_1)\exp x_2,$$
$$\dot{x}_2 = -x_2 + \lambda a(1 - x_1)\exp x_2 - bx_2.$$

This system is used as an example in [14], in particular for the parameter values $a = 14$ and $b = 2$. In this case, the stationary solution curve through $(\boldsymbol{x}, \lambda) = (\mathbf{0}, 0)$ has two turning points as λ increases, and then there is a Hopf bifurcation point at

$$\lambda \approx 0.1309, \quad x_1 \approx 0.8951, \quad x_2 \approx 4.177.$$

The curve of periodic orbits created here exists, with λ decreasing, until $\lambda \approx 0.1055$, where it ends in a homoclinic orbit connected to the stationary solution curve. Again it is only necessary to work in $\mathcal{Y}_+$.

We use this example to illustrate how our algorithm may perform badly when applied to periodic orbits which lack smoothness or are poorly conditioned. In Figure 4, we show approximations to periodic orbits at four different values of λ, using the algorithm in section 5 with $M = 50$. We see oscillations appearing in the approximations as they try to cope with the lack of smoothness developing as $\boldsymbol{x} = (1, 10)$ is approached. As is shown in [14], this point is reached at $\lambda \approx 0.1055$, when the homoclinic orbit appears. (If results for smaller λ were shown, the oscillations would be more violent.) We exhibit this lack of smoothness differently in Figure 5, where the size of the Fourier modes is shown for $m = 1, \ldots, M$. It is clear that, as λ decreases, the exponential decay of these modes is gradually being lost. Similar conclusions can be drawn when we plot the "zero" Floquet exponent against λ in Figure 6. By the time $\lambda \approx 0.1193$ is reached, the two exponents are almost equal! Finally, and most tellingly, we examine $\mathrm{cond}\,(\mathsf{P}^\star(\theta))$ in Figure 7. Theoretically $\mathsf{P}^\star(\theta)$ can never be singular, and its condition number is a measure of the conditioning of the boundary value problem defining the periodic orbit. Here, however, we see $\mathrm{cond}\,(\mathsf{P}^\star(\theta))$ reaching 10^8! It is therefore no surprise that our algorithm, which *explicitly* works with $\mathsf{P}^\star(\theta)$, has difficulties in this situation. Collocation with piecewise-polynomials and an adaptive mesh, as used in [14], will obviously perform better in such cases.

6.3. The fourth order Lorenz equations.

$$\begin{aligned}
\dot{y}_1 &= -y_1 + 2\lambda - y_2^2 + (y_3^2 + y_4^2)/2,\\
\dot{y}_2 &= -y_2 + (y_1 y_2 - y_3 y_4) + (y_4^2 - y_3^2)/2,\\
\dot{y}_3 &= -y_3 + (y_2 - y_1)(y_3 + y_4)/2,\\
\dot{y}_4 &= -y_4 + (y_2 + y_1)(y_3 - y_4)/2.
\end{aligned}$$

This system is described in [27]. There is a stationary solution curve

$$\boldsymbol{y}(\lambda) \equiv (2\lambda, 0, 0, 0),$$

which has a supercritical bifurcation at $\lambda = \frac{1}{2}$ into the two stationary solution curves

$$\boldsymbol{y}_{\pm}(\lambda) \equiv (1, \pm\sqrt{2\lambda - 1}, 0, 0).$$

At $\lambda = 3$, the new solution curves bifurcate again, and there is then a supercritical Hopf bifurcation at

$$\lambda_H \approx 3.8531.$$

We follow the branch of periodic orbits for $\lambda_H \le \lambda \le 17$ and plot the behavior of the critical Floquet exponent in the three graphs of Figure 8. Of course one Floquet exponent is always zero, but another uninteresting one remains real and strictly negative. Thus it is the other two that we are concerned with. They are plotted in the complex plane for $\lambda_H \le \lambda \le 10$ in the first graph of Figure 8. (Since they become a complex conjugate pair for $\lambda \approx 4$, we only plot the one with positive imaginary part.) In this range of λ we can take $n_+ = n = 4$, but when λ reaches 10, this imaginary part has become greater than 0.3. Thus we decide to switch this pair of Floquet exponents from E_+ to E_-, as described in section 5.4, and so $n_+ = 2$ and $n_- = 2$. In the second graph of Figure 8, we continue to plot the critical Floquet exponent in the complex plane, but now for $10 \le \lambda \le 14.3$. Note that the imaginary part of the exponent at $\lambda = 10$ differs by $\frac{1}{2}$ in these two graphs ($\pm.33$ and $\pm.17$) as

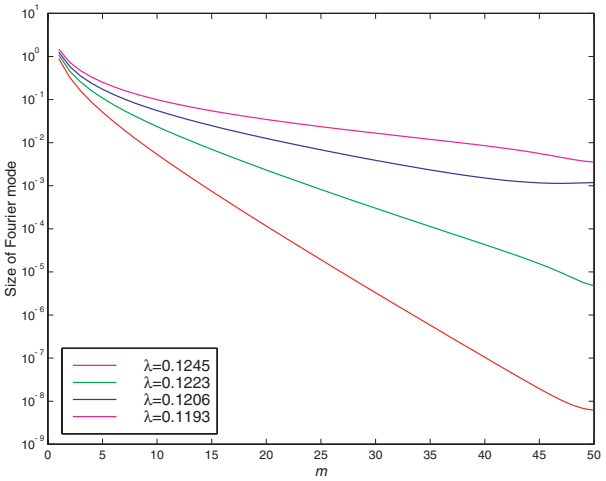

FIG. 5. *Decay of Fourier modes for periodic orbits.*

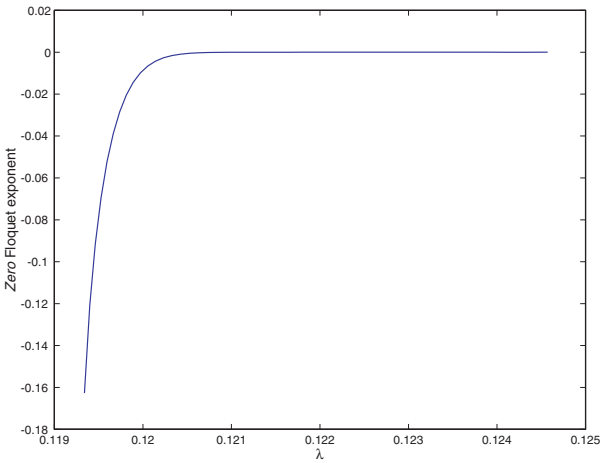

FIG. 6. *Degeneration of "zero" Floquet exponent.*

described in section 5.4. At $\lambda \approx 14.3$, this complex pair of critical Floquet exponents become real and negative, thus corresponding to negative real Floquet multipliers as described in section 4. We follow the interesting real Floquet exponent in the third graph of Figure 8, this time plotting it against λ. It quickly passes through zero, thus corresponding to a period-doubling bifurcation as described in section 7, and then continues to increase.

7. Period-doubling bifurcation. A further advantage of using Floquet theory to continue periodic orbits is that the occurrence of nonhyperbolic behavior is always obvious; i.e., because we always have $\mathsf{E}^\star$ available in quasi-upper triangular form, we can immediately see when a Floquet exponent crosses the imaginary axis. The three simplest types of bifurcation that can occur are as follows.

1. Saddle-node bifurcation (turning points): when $\mathsf{E}^\star_+$ has a geometrically single,

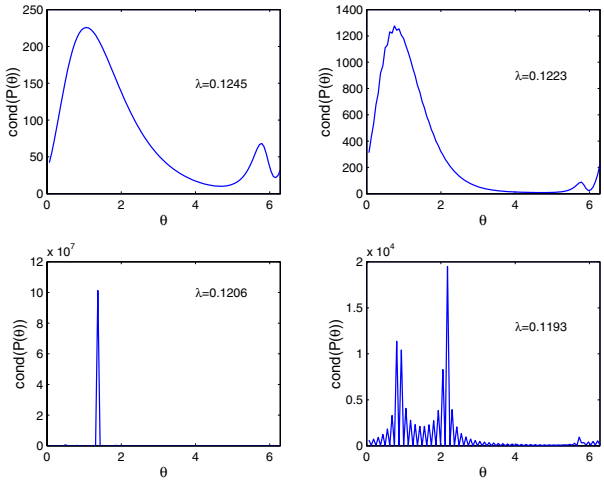

FIG. 7. *Ill-conditioning of periodic orbits.*

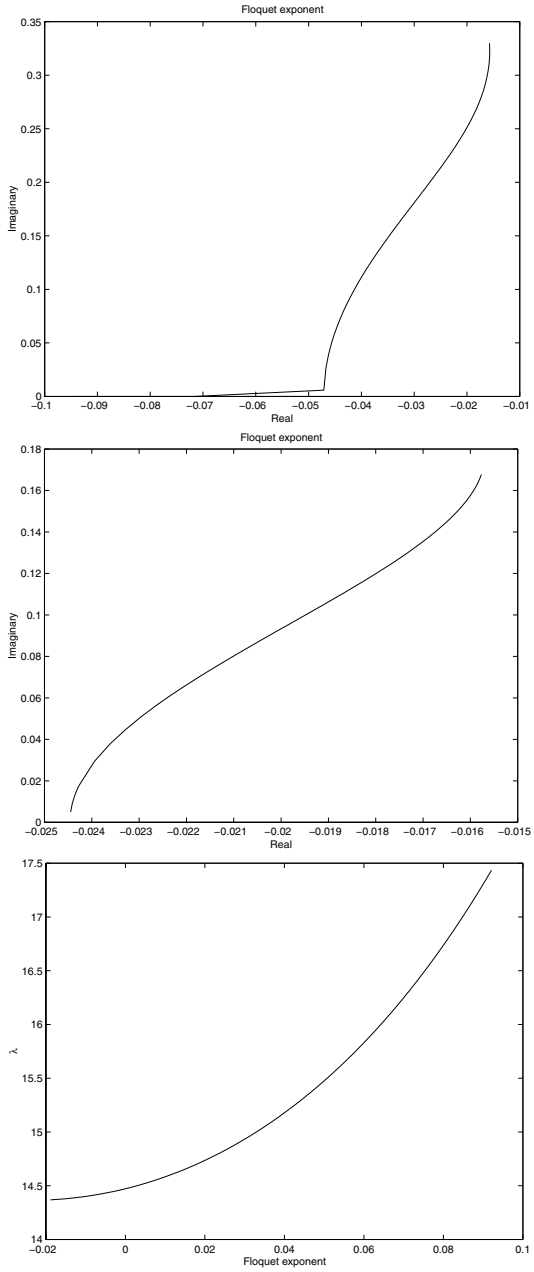

FIG. 8. *Movement of critical Floquet exponent.*

but algebraically double, zero eigenvalue, as mentioned in section 5.

2. Period-doubling bifurcation: when both $\mathsf{E}^{\star}_{+}$ and $\mathsf{E}^{\star}_{-}$ have a simple zero eigenvalue.
3. Neimark–Sacker (torus) bifurcation: when either $\mathsf{E}^{\star}_{+}$ or $\mathsf{E}^{\star}_{-}$ has a conjugate pair of purely imaginary simple eigenvalues.

If any of these occur during the continuation process, we may wish to determine the bifurcation point more precisely, which can be achieved by two different means.

- After having determined two values of the continuation parameter that bracket the bifurcation point, we may use a secant-like method to determine the parameter value at which the critical Floquet exponent is zero or has zero real part.
- We may set up a special augmented system of equations, whose solution will give the bifurcation point immediately! Modern algorithms for the above three types of bifurcation have recently been described in [15], and Floquet–Fourier versions of these algorithms could be constructed.

In addition, after having located a period-doubling or torus bifurcation point accurately, we may wish to follow these newly created objects. We do not consider Neimark–Sacker bifurcation here, since this is rather complicated [8, 21] and a treatment combining Floquet theory with the ideas in [25] would be quite lengthy. In this section, however, we do wish to present an algorithm for moving onto the new periodic orbits created at a period-doubling bifurcation point. In particular, we will see how this fits in very neatly with the spaces $\mathcal{Y}_\pm$ used in section 4 to describe our general Floquet theory and with the symmetry-breaking framework within which period-doubling is usually described [10].

The conditions that $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$ must satisfy in order to be a period-doubling bifurcation point are as follows.[2]

(a) At $\lambda = \lambda^\star$ we have a nonsingular periodic orbit $\boldsymbol{v}^\star(\theta)$ of period $2\pi T^\star$, so that

$$\dot{\boldsymbol{v}}^\star(\theta) = T^\star \boldsymbol{F}(\boldsymbol{v}^\star(\theta), \lambda^\star)$$

and the solution space in $\mathcal{Y}^n_+$ for

$$-\dot{\boldsymbol{v}}(\theta) + T^\star \mathsf{J}(\boldsymbol{v}^\star(\theta), \lambda^\star)\boldsymbol{v}(\theta) = \boldsymbol{0} \tag{7.1}$$

is one-dimensional and spanned by $\dot{\boldsymbol{v}}^\star(\theta)$. Hence the implicit function theorem applies and there is a locally unique curve of periodic orbits through $\lambda^\star$, parametrized by λ, which we denote by $(\boldsymbol{v}^\star(\theta;\lambda), T^\star(\lambda))$ and which satisfies

$$\frac{\partial \boldsymbol{v}^\star}{\partial \theta}(\theta;\lambda) = T^\star(\lambda)\boldsymbol{F}(\boldsymbol{v}^\star(\theta;\lambda),\lambda). \tag{7.2}$$

(b) If $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$ is a period-doubling bifurcation point; however, the solution space of (7.1) must also be one-dimensional in $\mathcal{Y}^n_-$, spanned by $\boldsymbol{\varphi}^\star(\theta)$ say.

(c) The final condition for period-doubling to occur is that

$$\int_0^{2\pi} \boldsymbol{\psi}^\star(\theta) \cdot \mathsf{K}^\star(\theta)\boldsymbol{\varphi}^\star(\theta)\,\mathrm{d}\theta \neq 0, \tag{7.3}$$

where

$$\mathsf{K}^\star(\theta) \equiv \frac{\mathrm{d}}{\mathrm{d}\lambda}\Big\{T^\star(\lambda)\mathsf{J}(\boldsymbol{v}^\star(\theta;\lambda),\lambda)\Big\}\,\Big|_{\lambda=\lambda^\star}$$

and $\boldsymbol{\psi}^\star \in \mathcal{Y}^n_-$ is the left null-vector satisfying

$$\dot{\boldsymbol{\psi}}^\star(\theta) + T^\star \mathsf{J}(\boldsymbol{v}^\star(\theta),\lambda^\star)^T \boldsymbol{\psi}^\star(\theta) = \boldsymbol{0}.$$

[2] As with Hopf bifurcation, we assume that the curve of periodic orbits is parametrizable by λ; cf. [15].

If $\mu^\star(\lambda)$ were a simple real eigenvalue equaling zero at $\lambda = \lambda^\star$ and satisfying

$$-\frac{\partial \boldsymbol{v}}{\partial \theta}(\theta;\lambda) + T^\star(\lambda)\mathsf{J}(\boldsymbol{v}^\star(\theta;\lambda),\lambda)\boldsymbol{v}(\theta;\lambda) = \mu^\star(\lambda)\boldsymbol{v}(\theta;\lambda)$$

for some nonzero $\boldsymbol{v}(\theta;\lambda) \in \mathcal{Y}^n_-$ such that $\boldsymbol{v}(\theta;\lambda^\star) \equiv \boldsymbol{\varphi}^\star(\theta)$, then (7.3) is equivalent to the transversal crossing condition

$$\frac{\mathrm{d}\mu^\star}{\mathrm{d}\lambda}(\lambda^\star) \neq 0,$$

since

$$\frac{\mathrm{d}\mu^\star}{\mathrm{d}\lambda}(\lambda^\star) \equiv \frac{\int_0^{2\pi} \boldsymbol{\psi}^\star(\theta)\cdot \mathsf{K}^\star(\theta)\boldsymbol{\varphi}^\star(\theta)\,\mathrm{d}\theta}{\int_0^{2\pi} \boldsymbol{\psi}^\star(\theta)\cdot \boldsymbol{\varphi}^\star(\theta)\,\mathrm{d}\theta}.$$

It is not necessary, however, for this eigenvalue to be simple.

In terms of our Floquet variables we have

$$-\dot{\mathsf{P}}^\star(\theta) + T^\star\mathsf{J}(\boldsymbol{v}^\star(\theta),\lambda^\star)\mathsf{P}^\star(\theta) = \mathsf{P}^\star(\theta)\mathsf{E}^\star;$$

where

$$\mathsf{P}^\star(\theta) \equiv [\mathsf{P}^\star_+(\theta), \mathsf{P}^\star_-(\theta)],$$

with $\mathsf{P}^\star_+(\theta) \in \mathbb{R}^{n\times n_+}$ and $\mathsf{P}^\star_-(\theta) \in \mathbb{R}^{n\times n_-}$, and

$$\mathsf{E}^\star \equiv \begin{bmatrix} \mathsf{E}^\star_+ & \mathsf{O} \\ \mathsf{O} & \mathsf{E}^\star_- \end{bmatrix},$$

with $\mathsf{E}^\star_+ \in \mathbb{R}^{n_+\times n_+}$ and $\mathsf{E}^\star_- \in \mathbb{R}^{n_-\times n_-}$. As usual, $n_+ + n_- = n$, with the columns of $\mathsf{P}^\star_+(\theta)$ in $\mathcal{Y}^n_+$ and the columns of $\mathsf{P}^\star_-(\theta)$ in $\mathcal{Y}^n_-$. Since $\mathsf{E}^\star_+$ has a simple zero eigenvalue, this matrix can be chosen to be in quasi-upper triangular form with first column zero. Hence the first column of $\mathsf{P}^\star_+(\theta)$ is a multiple of $\dot{\boldsymbol{v}}^\star(\theta)$, i.e., $\alpha^\star \boldsymbol{p}^\star(\theta) = \dot{\boldsymbol{v}}^\star(\theta)$. Similarly, since $\mathsf{E}^\star_-$ has a one-dimensional null-space, it too can be chosen to be in quasi-upper triangular form with first column zero, so that the first column of $\mathsf{P}^\star_-(\theta)$ is $\boldsymbol{\varphi}^\star(\theta)$. We thus have

$$\boldsymbol{p}^\star(\theta) = \mathsf{P}^\star_+(\theta)\boldsymbol{e}_1 \quad \text{and} \quad \boldsymbol{\varphi}^\star(\theta) = \mathsf{P}^\star_-(\theta)\boldsymbol{e}_1.$$

Hence the key period-doubling condition (7.3) is equivalent to the last n_- components of

$$\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{k}^\star(\theta)\,\mathrm{d}\theta$$

not lying in the range of $\mathsf{E}^\star_-$, where $\boldsymbol{k}^\star(\theta) \in \mathbb{R}^n$ is defined by

$$\mathsf{P}^\star(\theta)\boldsymbol{k}^\star(\theta) \equiv \mathsf{K}^\star(\theta)\boldsymbol{\varphi}^\star(\theta).$$

Note that $\mathsf{K}^\star(\theta)\boldsymbol{\varphi}^\star(\theta) \in \mathcal{Y}^n_-$ and so the first n_+ components of $\boldsymbol{k}^\star(\theta)$ lie in $\mathcal{Y}^{n_+}_-$ while the last n_- components lie in $\mathcal{Y}^{n_-}_+$.

From now on, we will be interested in a doubling of $\boldsymbol{v}^\star(\theta)$; i.e., we define

$$\boldsymbol{v}^\star_d(\theta) \equiv \boldsymbol{v}^\star(2\theta) \quad \text{and} \quad T^\star_d \equiv 2T^\star,$$

and so $(\boldsymbol{v}_d^\star(\theta), T_d^\star)$ satisfies

$$\dot{\boldsymbol{v}}(\theta) = T\boldsymbol{F}(\boldsymbol{v}(\theta), \lambda^\star).$$

(Thus we are offending against the minimality condition usually considered as part of the definition of a periodic orbit; cf. page 2522.) The Floquet variables for this period-doubled orbit are

$$\mathsf{P}_d^\star(\theta) \equiv \mathsf{P}^\star(2\theta) \equiv [\mathsf{P}_+^\star(2\theta), \mathsf{P}_-^\star(2\theta)] \quad \text{and} \quad \mathsf{E}_d^\star \equiv 2\,\mathsf{E}^\star \equiv 2\begin{bmatrix} \mathsf{E}_+^\star & \mathsf{O} \\ \mathsf{O} & \mathsf{E}_-^\star \end{bmatrix},$$

and thus they satisfy the equation

$$-\dot{\mathsf{P}}_d^\star(\theta) + \mathsf{A}_d^\star(\theta)\mathsf{P}_d^\star(\theta) = \mathsf{P}_d^\star(\theta)\mathsf{E}_d^\star,$$

where

$$\mathsf{A}_d^\star(\theta) \equiv T_d^\star \mathsf{J}(\boldsymbol{v}_d^\star(\theta), \lambda^\star). \tag{7.4}$$

Note that *all* the columns of $\mathsf{P}_d^\star(\theta)$ are now in $\mathcal{Y}_+^n$, but if $\boldsymbol{q}^\star(\theta)$ is one of the first n_+ columns, then it is *symmetric*, i.e.,

$$\boldsymbol{q}^\star(\theta) = \boldsymbol{q}^\star(\theta + \pi) \quad \forall \theta \in \mathbb{R},$$

while if $\boldsymbol{q}^\star(\theta)$ is one of the last n_- columns, then it is *antisymmetric*, i.e.,

$$\boldsymbol{q}^\star(\theta) = -\boldsymbol{q}^\star(\theta + \pi) \quad \forall \theta \in \mathbb{R}.$$

If we use (7.2) to define

$$\boldsymbol{v}_d^\star(\theta; \lambda) \equiv \boldsymbol{v}^\star(2\theta; \lambda) \quad \text{and} \quad T_d^\star(\lambda) \equiv 2T^\star(\lambda),$$

then $(\boldsymbol{v}_d^\star(\theta; \lambda), T_d^\star(\lambda), \lambda)$ is a curve of periodic orbits passing through $(\boldsymbol{v}_d^\star(\theta), T_d^\star, \lambda^\star)$. It is symmetric and parametrizable by λ and satisfies

$$\frac{\partial \boldsymbol{v}_d^\star}{\partial \theta}(\theta; \lambda) = T_d^\star(\lambda)\boldsymbol{F}(\boldsymbol{v}_d^\star(\theta; \lambda), \lambda).$$

It is important to realize that, since the imaginary parts of the eigenvalues of $\mathsf{E}^\star$ are bounded below $\frac{1}{2}$ in size, the imaginary parts of the eigenvalues of $\mathsf{E}_d^\star$ are correspondingly bounded below 1 in size. As we will only be using $\mathsf{E}_d^\star$ in connection with equations in $\mathcal{Y}_+^n$, as in section 2.1, this will be sufficient.

Now we look for a *new* curve of periodic orbits passing through $(\boldsymbol{v}_d^\star(\theta), T_d^\star, \lambda^\star)$ of the form

$$\boldsymbol{v}(\theta) \equiv \boldsymbol{v}_d^\star(\theta; \lambda) + \varepsilon\,[\boldsymbol{a}_d^\star(\theta) + \boldsymbol{z}(\theta)]$$

with period $T_d^\star(\lambda) + \varepsilon T$. Here ε is a small scalar which parametrizes the new curve, and $(\boldsymbol{z}(\theta), T, \lambda) \in (\mathcal{Y}_+^n, \mathbb{R}^2)$ are to be determined. $\boldsymbol{a}_d^\star(\theta)$ is the $(n_+ + 1)$th column of $\mathsf{P}_d^\star(\theta)$, and the amplitude of $\boldsymbol{v}(\theta)$ is fixed by insisting that

$$\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{a}_d^\star(\theta) \cdot \left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1} \boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0. \tag{7.5a}$$

Note that $\boldsymbol{a}_d^\star(\theta) \equiv \boldsymbol{\varphi}^\star(2\theta)$ is antisymmetric according to the above definition, and so we are *breaking the symmetry* of $\boldsymbol{v}_d^\star(\theta;\lambda)$. Similarly, the phase of $\boldsymbol{v}(\theta)$ is fixed by insisting that

$$\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{p}_d^\star(\theta)\cdot\left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1}\boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0, \tag{7.5b}$$

where $\boldsymbol{p}_d^\star(\theta) \equiv \boldsymbol{p}^\star(2\theta)$ is the first column of $\mathsf{P}_d^\star(\theta)$, i.e., $2\alpha^\star \boldsymbol{p}_d^\star(\theta) = \dot{\boldsymbol{v}}_d^\star(\theta)$. The system of equations $(\boldsymbol{z}(\theta), T, \lambda)$ must satisfy is therefore

$$-\dot{\boldsymbol{v}}(\theta) + [T_d^\star(\lambda) + \varepsilon T]\,\boldsymbol{F}(\boldsymbol{v}(\theta),\lambda) = \boldsymbol{0}, \tag{7.6}$$

together with (7.5). In order to apply the implicit function theorem, we may adopt the strategy used for Hopf bifurcation in section 3 and construct the smooth mapping

$$\boldsymbol{G} : (\mathcal{Y}_+^n \times \mathbb{R}^2) \times \mathbb{R} \mapsto \mathcal{Y}_+^n \times \mathbb{R}^2$$

by the following:

- for $\varepsilon \neq 0$, $\boldsymbol{G}(\boldsymbol{z}, T, \lambda; \varepsilon)$ is defined by

$$\begin{aligned} &-[\dot{\boldsymbol{a}}_d^\star(\theta) + \dot{\boldsymbol{z}}(\theta)] + \tfrac{1}{\varepsilon}\Big\{[T_d^\star(\lambda) + \varepsilon T] \\ &\qquad \boldsymbol{F}(\boldsymbol{v}_d^\star(\theta;\lambda) + \varepsilon[\boldsymbol{a}_d^\star(\theta) + \boldsymbol{z}(\theta)],\lambda) - T_d^\star(\lambda)\boldsymbol{F}(\boldsymbol{v}_d^\star(\theta;\lambda),\lambda)\Big\} \end{aligned} \tag{7.7}$$

  plus the two scalar conditions (7.5),

- $\boldsymbol{G}(\boldsymbol{z}, T, \lambda; 0)$ is defined by

$$-[\dot{\boldsymbol{a}}_d^\star(\theta) + \dot{\boldsymbol{z}}(\theta)] + T_d^\star(\lambda)\mathsf{J}(\boldsymbol{v}_d^\star(\theta;\lambda),\lambda)[\boldsymbol{a}_d^\star(\theta) + \boldsymbol{z}(\theta)] + T\boldsymbol{F}(\boldsymbol{v}_d^\star(\theta;\lambda),\lambda) \tag{7.8}$$

  plus the two scalar conditions (7.5).

Thus the zeroes $(\boldsymbol{z}(\theta), T, \lambda)$ of $\boldsymbol{G}$ for nonzero ε define nonsymmetric periodic orbits near $(\boldsymbol{v}_d^\star(\theta), T_d^\star, \lambda^\star)$. It is immediate, however, that $\boldsymbol{G}(\boldsymbol{0}, 0, \lambda^\star; 0) = \boldsymbol{0}$, and we can determine whether the linearization of $\boldsymbol{G}$ at this point has any nontrivial solutions by considering the system

$$\begin{aligned} &-\dot{\boldsymbol{z}}(\theta) + \mathsf{A}_d^\star(\theta)\boldsymbol{z}(\theta) + T\tfrac{\alpha^\star}{T^\star}\boldsymbol{p}_d^\star(\theta) + \lambda\mathsf{K}_d^\star(\theta)\boldsymbol{a}_d^\star(\theta) = \boldsymbol{0}, \\ &\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{a}_d^\star(\theta)\cdot\left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1}\boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0, \\ &\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{p}_d^\star(\theta)\cdot\left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1}\boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0 \end{aligned} \tag{7.9}$$

for $(\boldsymbol{z}(\theta), T, \lambda)$, where $\mathsf{A}_d^\star(\theta)$ is defined in (7.4) and

$$\mathsf{K}_d^\star(\theta) \equiv \frac{\mathrm{d}}{\mathrm{d}\lambda}\Big\{T_d^\star(\lambda)\mathsf{J}(\boldsymbol{v}_d^\star(\theta;\lambda),\lambda)\Big\}\,\Big|_{\lambda=\lambda^\star} \equiv \mathsf{K}^\star(2\theta).$$

Using the Floquet transformation

$$\boldsymbol{z}(\theta) \equiv \mathsf{P}_d^\star(\theta)\boldsymbol{w}(\theta) \quad \text{with } \boldsymbol{w} \in \mathcal{Y}_+^n,$$

(7.9) becomes

$$\begin{aligned} &-\dot{\boldsymbol{w}}(\theta) + \mathsf{E}_d^\star\boldsymbol{w}(\theta) + T\tfrac{\alpha^\star}{T^\star}\boldsymbol{e}_1 + \lambda\boldsymbol{k}_d^\star(\theta) = \boldsymbol{0}, \\ &\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1\cdot\boldsymbol{w}(\theta)\,\mathrm{d}\theta = 0, \\ &\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_{n_+ +1}\cdot\boldsymbol{w}(\theta)\,\mathrm{d}\theta = 0, \end{aligned}$$

where

$$\mathsf{P}_d^\star(\theta)\boldsymbol{k}_d^\star(\theta) \equiv \mathsf{K}_d^\star(\theta)\boldsymbol{a}_d^\star(\theta) \equiv 2\mathsf{K}^\star(2\theta)\boldsymbol{\varphi}^\star(2\theta).$$

From (7.3) and the fact that zero is a simple eigenvalue of $\mathsf{E}_+^\star$, we know that neither of the two linearly independent vectors

$$\boldsymbol{e}_1 \quad \text{and} \quad \frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{k}_d^\star(\theta)\,\mathrm{d}\theta$$

are in the range of $\mathsf{E}_d^\star$. Hence (7.9) has no nontrivial solution, and the implicit function theorem applies to $\boldsymbol{G}$ at $(\boldsymbol{0}, 0, \lambda^\star; 0)$ and tells us that $\boldsymbol{G}(\boldsymbol{z}, T, \lambda; \varepsilon) = \boldsymbol{0}$ has a locally unique solution curve parametrized by ε.

Thus we define the following Newton-chord iteration for obtaining these nonsymmetric period-doubled orbits.

- Set

$$\boldsymbol{y}^{(0)}(\theta) = \boldsymbol{a}_d^\star(\theta), \quad T^{(0)} = 0, \quad \lambda^{(0)} = \lambda^\star.$$

- Solve

$$\begin{aligned}
&\left[-\frac{\mathrm{d}}{\mathrm{d}\theta} + \mathsf{A}_d^\star(\theta)\right]\boldsymbol{z}(\theta) + \delta T\frac{\alpha^\star}{T^\star}\boldsymbol{p}_d^\star(\theta) + \delta\lambda\mathsf{K}_d^\star(\theta)\boldsymbol{a}_d^\star(\theta) = \frac{1}{\varepsilon}\boldsymbol{r}^{(k)}(\theta),\\
&\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{p}_d^\star(\theta)\cdot\left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1}\boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0,\\
&\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{a}_d^\star(\theta)\cdot\left[\mathsf{P}_d^\star(\theta)\mathsf{P}_d^\star(\theta)^T\right]^{-1}\boldsymbol{z}(\theta)\,\mathrm{d}\theta = 0
\end{aligned} \tag{7.10}$$

  for $\boldsymbol{z} \in \mathcal{Y}_+^n$, δT, and $\delta\lambda$, where

$$\begin{aligned}
\boldsymbol{r}^k(\theta) \equiv\ &\dot{\boldsymbol{v}}_d^\star(\theta;\lambda^{(k)}) + \varepsilon\dot{\boldsymbol{y}}^{(k)}(\theta)\\
&- \left[T_d^\star(\lambda^{(k)}) + \varepsilon T^{(k)}\right]\boldsymbol{F}(\boldsymbol{v}_d^\star(\theta;\lambda^{(k)}) + \varepsilon\boldsymbol{y}^{(k)}(\theta), \lambda^{(k)}).
\end{aligned}$$

- Set

$$\begin{aligned}
\boldsymbol{y}^{(k+1)}(\theta) &= \boldsymbol{y}^{(k)} + \boldsymbol{z}(\theta),\\
T^{(k+1)} &= T^{(k)} + \delta T,\\
\lambda^{(k+1)} &= \lambda^{(k)} + \delta\lambda.
\end{aligned}$$

Note that only the same augmented linear periodic differential equation, with varying right-hand sides, needs to be solved, at each iteration.

7.1. Fourier approximation. Finally, we show how to efficiently compute accurate approximations to the periodic orbits of (7.6), using the above Newton-chord iteration and the results of section 2.3. Floquet transforming the basic linear iteration (7.10), we obtain

$$\begin{aligned}
&-\dot{\boldsymbol{w}}(\theta) + \mathsf{E}_d^\star\boldsymbol{w}(\theta) + \delta T\tfrac{\alpha^\star}{T^\star}\boldsymbol{e}_1 + \delta\lambda\boldsymbol{k}_d^\star(\theta) = \boldsymbol{f}(\theta),\\
&\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_1\cdot\boldsymbol{w}(\theta)\,\mathrm{d}\theta = 0,\\
&\frac{1}{2\pi}\int_0^{2\pi} \boldsymbol{e}_{n_++1}\cdot\boldsymbol{w}(\theta)\,\mathrm{d}\theta = 0,
\end{aligned} \tag{7.11}$$

where

$$\begin{aligned} \boldsymbol{z}(\theta) &\equiv \mathsf{P}_d^\star(\theta)\boldsymbol{w}(\theta), \\ \tfrac{1}{\varepsilon}\boldsymbol{r}^{(k)}(\theta) &\equiv \mathsf{P}_d^\star(\theta)\boldsymbol{f}(\theta) \end{aligned}$$

with $\boldsymbol{w}(\theta), \boldsymbol{f}(\theta) \in \mathcal{Y}_+^n$.

Using the approximate Fourier coefficients

$$\begin{aligned} \boldsymbol{w}(\theta) &\approx \tilde{\boldsymbol{w}}_0^c + \sum_{m=1}^{M} \left\{ \tilde{\boldsymbol{w}}_m^c \cos m\theta + \tilde{\boldsymbol{w}}_m^s \sin m\theta \right\}, \\ \boldsymbol{f}(\theta) &\approx \tilde{\boldsymbol{f}}_0^c + \sum_{m=1}^{M} \left\{ \tilde{\boldsymbol{f}}_m^c \cos m\theta + \tilde{\boldsymbol{f}}_m^s \sin m\theta \right\}, \end{aligned}$$

and

$$\boldsymbol{k}_d^\star(\theta) \approx \tilde{\boldsymbol{k}}_0^c + \sum_{m=1}^{M} \left\{ \tilde{\boldsymbol{k}}_m^c \cos m\theta + \tilde{\boldsymbol{k}}_m^s \sin m\theta \right\}$$

and then matching coefficients, gives us the modal equations

- for $m = 0$

$$\begin{bmatrix} \mathsf{E}_d^\star & \frac{\alpha^\star}{T^\star}\boldsymbol{e}_1 & \tilde{\boldsymbol{k}}_0^c \\ \boldsymbol{e}_1^T & 0 & 0 \\ \boldsymbol{e}_{n_+ + 1}^T & 0 & 0 \end{bmatrix} \begin{bmatrix} \tilde{\boldsymbol{w}}_0^c \\ \delta T \\ \delta\lambda \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{f}}_0^c \\ 0 \\ 0 \end{bmatrix},$$

- for $1 \le m \le M$

$$\begin{bmatrix} \mathsf{E}_d^\star & -m\mathsf{I} \\ m\mathsf{I} & \mathsf{E}_d^\star \end{bmatrix} \begin{bmatrix} \tilde{\boldsymbol{w}}_m^c \\ \tilde{\boldsymbol{w}}_m^s \end{bmatrix} = \begin{bmatrix} \tilde{\boldsymbol{f}}_m^c - \delta\lambda\tilde{\boldsymbol{k}}_m^c \\ \tilde{\boldsymbol{f}}_m^s - \delta\lambda\tilde{\boldsymbol{k}}_m^s \end{bmatrix}.$$

Hence the extra scalar unknowns δT and $\delta\lambda$ are solved for as part of the nonsingular $m = 0$ system, while the other modal equations remain the same as in section 2.3, and nonsingular because of the eigenvalue conditions imposed on $\mathsf{E}^\star$.

The above iteration only moves us onto the curve of period-doubled orbits near $(\boldsymbol{v}^\star(\theta), T^\star, \lambda^\star)$. If we want to follow this new curve, using the techniques in section 5, then we must update the Floquet information as in section 5.3. Since the imaginary parts of the eigenvalues of $\mathsf{E}_d^\star$ may exceed $\frac{1}{2}$ in size, it may first be necessary to apply section 5.4 to $\mathsf{P}_d^\star(\theta)$, thus introducing some components in $\mathcal{Y}_-$.

7.2. Numerical example. As an illustration of period-doubling bifurcation, we continue using the fourth order Lorenz equations as an example. The third graph in Figure 8 shows the critical Floquet exponent passing through zero for λ slightly greater than 14.3, and a simple secant iteration quickly locates the bifurcation point at

$$\lambda^\star \approx 14.4722024 \quad \text{and} \quad T^\star \approx 0.1530674\,.$$

Now we apply the algorithm developed in this section to move onto the period-doubled orbit with $\varepsilon = \frac{1}{2}$. Since the phase-space is four-dimensional, Figure 9 shows two different three-dimensional projections. The number of Fourier modes used in the approximation is $M = 50$.

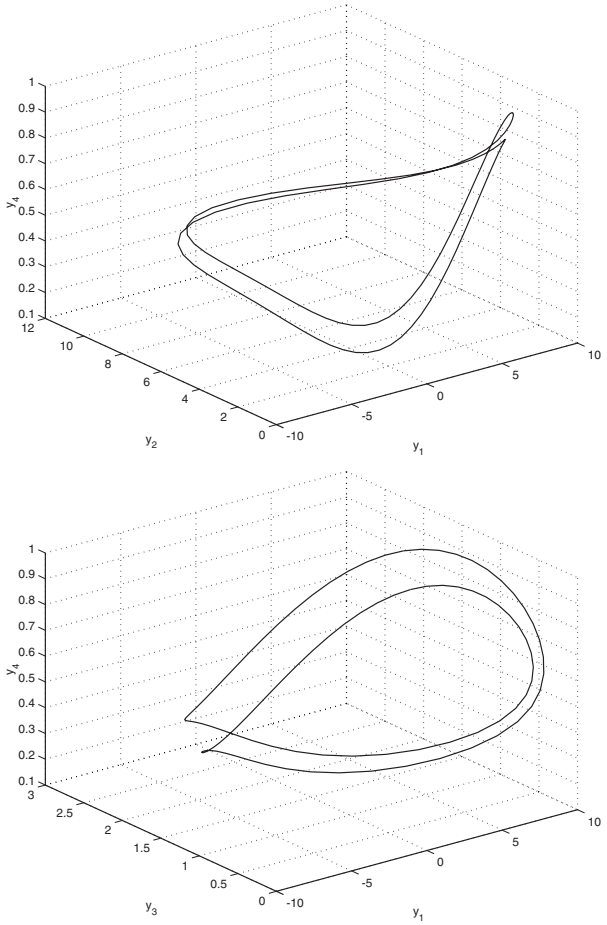

FIG. 9. *Period-doubled orbit with* $\varepsilon = \frac{1}{2}$.

8. Conclusion. We have shown how Floquet theory may be utilized in order to compute Fourier approximations of periodic orbits. The key result is that the size of the linear systems which must be solved is independent of the number M of Fourier modes used in the approximation. The overhead is that the Floquet variables $\mathsf{P}(\theta)$ must also be carried along in the continuation process, and this extra work is proportional to n, the dimension of the phase-space. Consequently, when $n \ll M$, we have a highly efficient and accurate algorithm for smooth and well-conditioned periodic orbits.

Of course, it would be silly to assert that the present algorithm can replace the AUTO package in [14], and we make no such claim! AUTO has been gradually refined over 20 years, and was developed from collocation and adaptive mesh ideas of an even earlier vintage, e.g., COLSYS [3]. What we do claim is that (just as in other areas of differential equations) spectral approximation of periodic orbits has its place alongside finite difference and piecewise polynomial approximation. Spectral methods are not trivial to implement efficiently and accurately on nonlinear problems, and further work is necessary before practical conclusions can be drawn. For example, if the basic linear algebra philosophy of [29] were used, Floquet theory could be thought of as an

efficient way of (approximately) factorizing the structured $Nn \times Nn$ matrix obtained from collocation [6].

Perhaps the most pleasing feature of the present algorithm is that it exploits the full mathematical structure of the periodic orbit problem. The fact that Floquet theory provides a *constant* matrix means that many algorithms for questions about stationary solutions (where the Jacobian matrix is constant of course) can easily be adapted for similar questions about periodic orbits.

- The algorithm for Hopf bifurcation in section 3 can be adapted to apply when invariant tori are created at a Neimark–Sacker bifurcation, as mentioned near the beginning of section 7.
- The algorithms for stable manifolds of stationary solutions and connecting orbits in [26] can be adapted to apply to stable manifolds of periodic orbits and periodic connections [5].
- Fourier approximation was recommended in [9, 10] to exploit spatial-temporal symmetries of periodic orbits. The analysis of such symmetries becomes even clearer when Floquet theory is utilized as well.

Papers devoted to these three applications of Floquet theory are currently being prepared.

NONLINEAR STABILITY ANALYSIS FOR THE METHOD OF TRANSPORT FOR THE ELASTIC-PLASTIC WAVE EQUATION*

GUIDO GIESE†

Abstract. In this paper we present an analytic assessment of the stability and convergence of the so-called method of transport for solving the elastic-plastic wave equation, which is a nonlinear hyperbolic partial differential equation. For the purely elastic wave equation, which is a linear hyperbolic conservation law, one can use von Neumann analysis for proving that stability and convergence immediately follow from the Lax equivalence theorem. For plastic deformation, however, nonlinear stability proofs require greater effort.

Key words. nonlinear stability, convergence, hyperbolic conservation laws, elasticity, plasticity

1. Introduction.

There exist a large number of numerical schemes for hyperbolic conservation laws (cf. [2], [7], [9], [10], [22], [23]), some of which have been used for the simulation of waves in solids (e.g., [11], [12], [13], [14], [15], [16]). In [5] we followed the ansatz of Fey, who developed in [3], [4], and [8] a high order scheme called method of transport for solving the multidimensional Euler equations, to develop a numerical scheme for solving the elastic-plastic wave equation, which is not a pure conservation law anymore, since only the equations describing the conservation of momentum are in conservation form.

For linear conservation laws—as for linear PDEs in general—convergence proofs of numerical schemes are quite common, e.g., the Lax equivalence theorem (cf. [19]) for linear (schemes for) hyperbolic conservation laws, which also applies to the elastic wave equation due to its linearity. The Lax equivalence theorem basically states the equivalence of convergence of a linear numerical scheme on the one hand and consistency and stability on the other. For nonlinear PDEs, however, such as the elastic-plastic wave equation, convergence results are rare, mostly because a proof of stability is not possible.

In this paper, we will present analytic stability results for the method of transport for solving the elastic-plastic wave equation in one and two dimensions. We will start with an introduction to the method of transport for the elastic-plastic wave equation in the case of so-called antiplane shear in two space dimensions. Then we present the concepts of defining linear and nonlinear stability and their implications on the convergence of a numerical scheme. Afterwards, we analyze the stability of the linear scheme for elastic waves and the nonlinear stability of the scheme for plastic waves, including convergence considerations.

We will abstain from presenting computational examples, since they can be found in [3] or [5], reconfirming the convergence property for the scheme in one and two dimensions by various numerical computations.

2. Antiplane shear waves. We consider the propagation of shear waves in a plane. Let $\boldsymbol{u} \in \mathbb{R}^3$ denote the vector of displacements. Then

$$\epsilon = \frac{\partial u_3}{\partial x},$$
$$\gamma = \frac{\partial u_3}{\partial y},$$
$$w = \frac{\partial u_3}{\partial t}$$

are the strain components in x- and y-directions and the velocity component in the z-direction. Of the symmetric stress tensor $\underline{\boldsymbol{\sigma}}$ we need only the stress components $\sigma = (\underline{\boldsymbol{\sigma}})_{13}$ and $\tau = (\underline{\boldsymbol{\sigma}})_{23}$ in the x- and y-directions. The physical equations for the description of shear waves consist of three equations, the first one containing the conservation of momentum and two compatibility relations between velocity and strain,

$$\begin{pmatrix} w \\ \epsilon \\ \gamma \end{pmatrix}_t = \begin{pmatrix} \sigma/\rho \\ w \\ 0 \end{pmatrix}_x + \begin{pmatrix} \tau/\rho \\ 0 \\ w \end{pmatrix}_y, \tag{2.1}$$

where ρ denotes the density of the material. Our description of waves in solids is based on the model of small-strains, which is a linearization of the general flow-equations (cf. [18]). Equation (2.1) models an elastic medium that corresponds to a membrane with no coupling between longitudinal and transversal deformation, as would be the case in a solid with nonzero Poisson ratio.

Analogous to gas dynamics, we need an equation connecting stress and strain components, where we will distinguish between elastic and plastic deformation in the following.

2.1. Elastic shear waves. In the elastic case, Hook's law relates the stresses to the strains by

$$\sigma = \mu\epsilon,$$
$$\tau = \mu\gamma$$

with the elastic shear modulus μ. The wave-speed c is given by

$$c = \sqrt{\frac{\mu}{\rho}}. \tag{2.2}$$

Thus, we can write (2.1) in the well-known form of the wave equation as

$$\begin{pmatrix} w \\ \sigma \\ \tau \end{pmatrix}_t = \nabla \cdot c \begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ \rho c w & 0 \\ 0 & \rho c w \end{pmatrix}. \tag{2.3}$$

Defining the vector of conserved quantities as $\boldsymbol{U}$ and the "flux" as $c\underline{\boldsymbol{L}}$, we get the simple form for (2.3):

$$\boldsymbol{U}_t + \nabla \cdot c\underline{\boldsymbol{L}} = 0. \tag{2.4}$$

2.2. Plastic shear waves. In regions of plastic deformation, however, the stress-strain relation contains only a relationship between infinitesimal changes of stress and strain components in time:

$$\begin{pmatrix} \dot{\epsilon} \\ \dot{\gamma} \end{pmatrix} = \underline{\mathcal{C}}(\sigma, \tau) \begin{pmatrix} \dot{\sigma} \\ \dot{\tau} \end{pmatrix}. \tag{2.5}$$

There exist quite a lot of different models for describing plastic deformation (cf. [18], [20]). For our further investigations we make use of the well-known Prandtl–Reuss equations, which we will present briefly in the following (for details, see [21] or [5], [11]).

The model uses the most commonly used yield function, i.e., the von Mises yield function, which reads in the special case of antiplane shear:

$$f(\sigma, \tau) = \sigma^2 + \tau^2 =: \kappa^2. \tag{2.6}$$

This yield function enables us to distinguish between plastic and elastic deformation, i.e., with

$$\kappa_0(t) = \max_{t_0 \le t' \le t} \kappa(t')$$

three different cases may occur:

- $\kappa(t) < \kappa_0$: elastic deformation.
- $\kappa(t) = \kappa_0$ and $\dot{\kappa} \le 0$: elastic unloading.
- $\kappa(t) = \kappa_0$ and $\dot{\kappa} > 0$: plastic loading.

In the elastic case, the stress-strain relationship is described by Hooke's law (cf. section 2.1). In the plastic region, the model of Prandtl–Reuss (for details, see [21]) yields the following matrix $\underline{\mathcal{C}}(\sigma, \tau)$ used in the stress-strain relationship (2.5):

$$\underline{\mathcal{C}}(\sigma, \tau) = \begin{pmatrix} \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma^2 & \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau \\ \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau & \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\tau^2 \end{pmatrix}, \tag{2.7}$$

where the function $\mu_p(\sigma)$ is the plastic shear modulus which can be measured in experiments. In the following we always assume that the occurrence of plasticity decreases the wave-speed, which is the case for almost all materials (cf. [18]), and hence

$$\mu_p(\sigma) \le \mu \quad \forall \sigma \in \mathbb{R}^+.$$

Using this stress-strain relationship in order to replace the time derivatives of strain variables in (2.1) by derivatives of stress variables, the wave equation describing plastic deformation has the form

$$\begin{pmatrix} w \\ \sigma \\ \tau \end{pmatrix}_t - \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma^2 & \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau \\ 0 & \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau & \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\tau^2 \end{pmatrix}^{-1} \nabla \cdot c \begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \end{pmatrix} = 0, \tag{2.8}$$

or simply

$$\begin{pmatrix} w \\ \sigma \\ \tau \end{pmatrix}_t - \underline{\boldsymbol{\mathcal{A}}}(\sigma,\tau)\nabla\cdot c \begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \end{pmatrix} = 0. \tag{2.9}$$

Since $\underline{\boldsymbol{\mathcal{A}}}(\sigma,\tau)$ is not a Jacobian matrix, we no longer have a conservation law. Equation (2.8) can be written in divergence form with "source term":

$$\boldsymbol{U}_t + \nabla\cdot c\underline{\boldsymbol{L}} = \boldsymbol{P}(\sigma,\tau,\sigma_x,\sigma_y,\tau_x,\tau_y) \tag{2.10}$$

with

$$\begin{aligned} \underline{\boldsymbol{L}} &= -\underline{\boldsymbol{\mathcal{A}}}(\sigma,\tau)\begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \end{pmatrix}, \\ \boldsymbol{P}(\sigma,\tau,\sigma_x,\sigma_y,\tau_x,\tau_y) &= \underline{\boldsymbol{\mathcal{A}}}(\sigma,\tau)\nabla\cdot c\begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \end{pmatrix} \\ &\quad - \nabla\cdot c\underline{\boldsymbol{\mathcal{A}}}(\sigma,\tau)\begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \end{pmatrix}. \end{aligned}$$

Another interpretation of the equation is to rewrite it as a system for five state variables:

$$\begin{pmatrix} w \\ \epsilon \\ \gamma \\ \sigma \\ \tau \end{pmatrix}_t - \nabla\cdot c\begin{pmatrix} \sigma/(\rho c) & \tau/(\rho c) \\ w/c & 0 \\ 0 & w/c \\ 0 & 0 \\ 0 & 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ \underline{\boldsymbol{\mathcal{C}}}^{-1}(\sigma,\tau)\begin{pmatrix} \epsilon \\ \gamma \end{pmatrix}_t \end{pmatrix}. \tag{2.11}$$

This formula will be the basis for the numerical scheme presented below. It shows that the velocity and strain variables have to be updated by computing fluxes, e.g., by using the method of transport and the stress variables σ and τ can be computed by integrating the stress-strain relationship, which will be done by applying a high order ODE solver.

The idea of the method of transport for solving a hyperbolic conservation law consists of decomposing the conservation law into advection equations which can be solved numerically. We will develop such decompositions for the wave equation under antiplane in the following sections, first for elastic waves where the system under consideration is a linear conservation law, and then for plastic waves, where not all variables are conserved.

2.3. Decomposition of the elastic wave equation. For elasticity the wave equation (2.3) (or the abbreviated version (2.4)) is a linear hyperbolic conservation law. We define new vectors $\boldsymbol{R}_i$,

$$\boldsymbol{R}_i = \boldsymbol{U} + \underline{\boldsymbol{L}}\vec{\boldsymbol{n}}_i, \quad i = 1,\dots,k, \tag{2.12}$$

where $\vec{\boldsymbol{n}}_i \in \mathbb{R}^2$ are k constant vectors, not necessarily of unit length. Then (2.4) can be rewritten in the strictly equivalent form

$$\boldsymbol{U}_t + \nabla\cdot c\underline{\boldsymbol{L}} = \frac{1}{k}\sum_{i=1}^{k}\left[(\boldsymbol{R}_i)_t + \nabla\cdot\left(\boldsymbol{R}_i\vec{\boldsymbol{n}}_i^T c\right)\right] = 0, \tag{2.13}$$

provided the vectors $\vec{\boldsymbol{n}}_i$ satisfy the following two conditions:

$$\sum_{i=1}^{k} \vec{\boldsymbol{n}}_i = 0, \tag{2.14}$$

$$\frac{1}{k} \sum_{i=1}^{k} \vec{\boldsymbol{n}}_i \vec{\boldsymbol{n}}_i^T = \underline{\boldsymbol{I}}.$$

The right-hand side of (2.13) can be reinterpreted as a coupled system of advection equations, transporting the quantity $\boldsymbol{R}_i$ at speed $c\vec{\boldsymbol{n}}_i$. Relation (2.14) is necessary and sufficient for this reinterpretation and the following numerical scheme to be consistent with the original equation.

Our numerical approximation for (2.3) consists of decoupling the system, i.e., solving each advection equation in (2.13) independently on the time interval $[t^n, t^{n+1}]$ of time-step n, which leads to

$$(\boldsymbol{R}_i)_t + \nabla \cdot \left(\boldsymbol{R}_i \vec{\boldsymbol{n}}_i^T c \right) = 0, \quad i = 1, \ldots, k, \tag{2.15}$$

and consequently our approximate update for the state vector $\boldsymbol{U}$ reads

$$\boldsymbol{U}(t^{n+1}) = \frac{1}{k} \sum_{i=1}^{k} \boldsymbol{R}_i(t^{n+1}). \tag{2.16}$$

This decomposition into decoupled advection equations is a first order approximation in time, which is easy to prove:

$$\boldsymbol{U}_t = \frac{1}{k} \sum_{i=1}^{k} (\boldsymbol{R}_i)_t = -\frac{1}{k} \sum_{i=1}^{k} \nabla \cdot \left(c \boldsymbol{R}_i \vec{\boldsymbol{n}}_i^T \right) = -\nabla \cdot c\underline{\boldsymbol{L}}.$$

To obtain approximations of order two or higher in the time integration with the same one-step method, additional correction terms in the numerical fluxes are needed, which can be found by comparing the Taylor of the exact solution and the numerical solution (cf. [3], [4], [5]). We omit these correction terms in the following, since we focus our stability analysis on the first order scheme. The application of our analysis to higher order schemes including correction terms in the numerical fluxes is in principle analogous to the one-dimensional (1-D) case, but more complicated due to the more complex form of the numerical fluxes and hence beyond the scope of this paper.

It is noteworthy that the decomposition into advection equations according to (2.13) is a generalization of the decomposition of a linear conservation law into right eigenvectors in one dimension, which we will further analyze in our stability analysis for the scheme in one dimension.

2.4. Decomposition of the elastic-plastic wave equation. For plastic waves, the scheme described above with a decomposition of the form (2.13) is no longer possible since the plastic wave equation in the form (2.10) or (2.11) has no conservation form.

One approach is to use the same transported quantities $\boldsymbol{R}_i$ as defined in (2.12) and decompose the term on the right-hand side of (2.10) as well. Unfortunately, this formulation leads to severe numerical problems since the "source term" on the right-hand side of (2.10) depends on the spatial derivatives of $\boldsymbol{U}$. Moving derivatives

change the flux and thus the jump conditions, which means that the wave equation in divergence form with "source term" does not have the correct physical discontinuities.

Another idea is to start with (2.11). Our numerical approach consists of "extracting" the stress-strain relationship out of the flux computation, i.e., we write (2.1) as

$$\boldsymbol{V}_t + \nabla \cdot c\underline{\boldsymbol{L}}(\boldsymbol{U}) = 0 \tag{2.17}$$

with

$$\boldsymbol{V} = \begin{pmatrix} w \\ \epsilon \\ \gamma \end{pmatrix}, \qquad \boldsymbol{U} = \begin{pmatrix} w \\ \sigma \\ \tau \end{pmatrix}, \qquad \underline{\boldsymbol{L}} = -\frac{1}{c}\begin{pmatrix} \sigma/\rho & \tau/\rho \\ w & 0 \\ 0 & w \end{pmatrix}.$$

According to this ansatz, our numerical scheme will possess two steps:

- First, we decompose (2.17) into advection equations (analogously to the elastic wave equation) by defining

$$\boldsymbol{R}_i := \boldsymbol{V} + \underline{\boldsymbol{L}}(\boldsymbol{U})\vec{\boldsymbol{n}}_i. \tag{2.18}$$

The corresponding advection equations

$$(\boldsymbol{R}_i)_t + \nabla \cdot \left(\boldsymbol{R}_i \vec{\boldsymbol{n}}_i^T c\right) = 0 \tag{2.19}$$

are solved independently for the time-step $[t^n, t^{n+1}]$ to compute the update

$$\boldsymbol{V}^{n+1} = \frac{1}{k}\sum_{i=1}^{k} \boldsymbol{R}_i(t^{n+1}) \tag{2.20}$$

of the velocity and strain variables.

- Afterwards, the stress variables contained in $\boldsymbol{U}$ have to be updated by integrating (2.5) in the stress space, which means integrating the ODE

$$\begin{pmatrix} \dot\sigma \\ \dot\tau \end{pmatrix} = \begin{pmatrix} \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma^2 & \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau \\ \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\sigma\tau & \frac{1}{\mu} + \frac{1}{\kappa^2}\left(\frac{1}{\mu_p(\kappa)} - \frac{1}{\mu}\right)\tau^2 \end{pmatrix}^{-1} \begin{pmatrix} \dot\epsilon \\ \dot\tau \end{pmatrix}, \tag{2.21}$$

or in simple form

$$\begin{pmatrix} \dot\sigma \\ \dot\tau \end{pmatrix} = \underline{\boldsymbol{C}}^{-1}(\sigma,\tau)\begin{pmatrix} \dot\epsilon \\ \dot\tau \end{pmatrix}, \tag{2.22}$$

which is an equivalent formulation of (2.5) for $\dot\sigma$ and $\dot\tau$ on the given time interval $[t^n, t^{n+1}]$ of time-step n. The problem arises that $\dot\epsilon(t)$ and $\dot\gamma(t)$ are not known $\forall t \in [t^n, t^{n+1}]$. We only know $\Delta\epsilon := \epsilon^{n+1} - \epsilon^n$ and $\Delta\gamma := \gamma^{n+1} - \gamma^n$ from the flux updates.

In order to solve the ODE (2.22) we have to reconstruct the strain path, i.e., the evolution of the strain variables on the time interval $t \in [0, t^{n+1} - t^n]$:

$$\begin{pmatrix} \epsilon^{n+1} \\ \gamma^{n+1} \end{pmatrix} - \begin{pmatrix} \epsilon^{n} \\ \gamma^{n} \end{pmatrix} = \boldsymbol{a}t + \boldsymbol{b}t^2 + \boldsymbol{c}t^3 + \cdots. \tag{2.23}$$

Since we can compute the time derivatives of the strain variables at times t^n and t^{n+1} by using

$$\dot{\epsilon}(t^*) = \partial_x w(t^*),$$
$$\ddot{\epsilon}(t^n) = \partial_x \dot{w}(t^n) = \frac{1}{\rho}\left(\frac{\partial^2}{\partial x^2}\sigma + \frac{\partial^2}{\partial x \partial y}\tau\right)(t^n), \tag{2.24}$$
$$\dot{\gamma}(t^*) = \partial_y w(t^*),$$
$$\ddot{\gamma}(t^n) = \partial_y \dot{w}(t^n) = \frac{1}{\rho}\left(\frac{\partial^2}{\partial x \partial y}\sigma + \frac{\partial^2}{\partial y^2}\tau\right)(t^n) \tag{2.25}$$
$$\text{at} \quad t^* = t^n \quad \text{or} \quad t^{n+1}$$

(w is known at times t^n and t^{n+1} and σ and τ are known at time t^n), we can reconstruct the strain variables up to order four and the time derivatives of the strain variables (and thus the right-hand side of the ODE (2.22)) up to order three—higher order can be achieved by using higher spatial derivatives.

If the matrix function $\underline{\boldsymbol{\mathcal{C}}}(\sigma, \tau)$ is not smooth at the transition from elasticity to plasticity, one has to restart the integration on the yield surface. The exact point on the yield surface where the transition from elasticity to plasticity takes place can be found by iteration, e.g., bisection (cf. [5]).

2.5. Boundary conditions. Throughout this paper we will consider the Cauchy-type problem for the elastic-plastic wave equation (2.11), i.e., the computational domain is $\mathbb{R}$ for the 1-D equation and $\mathbb{R}^2$ for the two-dimensional (2-D) equation, and we prescribe an initial solution for the velocity, strain, and stress variables at a certain time t_0 and then advance the solution forward in time. Consequently, the physical domain under consideration has no spatial boundaries and does not require the prescription of spatial boundary conditions.

3. Definition of stability. The classical proof of convergence for numerical schemes consists of proving consistency and stability. For explicit numerical schemes for solving a PDE of the form

$$\boldsymbol{W}^{n+1} = \boldsymbol{\Psi}[\boldsymbol{W}^n] \tag{3.1}$$

with the discrete solution $\boldsymbol{W}^n$ calculated using a grid $\Delta x \times \Delta t$ at time t^n, we define linear stability as follows.

DEFINITION 3.1 (linear stability). *A linear scheme of the form* (3.1) *is called stable if there exist constants* $C(T)$, Δx_0, *and* Δt_0 *independent of* Δt, Δx *with*

$$\|\boldsymbol{W}^N\| \le C\|\boldsymbol{W}^0\| \quad \forall \Delta t \le \Delta t_0,\ \forall \Delta x \le \Delta x_0 \tag{3.2}$$

with $N = T/\Delta t$.

This definition of stability (together with the requirement that the physical problem is well-posed) is sufficient for the Lax equivalence (cf. [19]) theorem to hold and to ensure convergence of a consistent linear scheme. Of course, a sufficient condition for linear stability is that the update operator $\boldsymbol{\Psi}$ is bounded by one, i.e.,

$$\left\|\boldsymbol{W}^{n+1}\right\| \le \|\boldsymbol{W}^n\|, \tag{3.3}$$

which one can prove for linear schemes with von Neumann analysis.

However, for nonlinear schemes a reasonable definition of nonlinear stability is more difficult. Our goal is to apply the convergence results for nonlinear schemes

obtained in [1], [17]. The following definition of nonlinear stability is sufficient for the convergence proof obtained by [1], [17] to be applicable to a consistent numerical scheme of the form (3.1).

DEFINITION 3.2 (nonlinear stability). *A consistent numerical scheme of the form* (3.1) *is called stable if for two arbitrary state vectors* W_1 *and* W_2 *there exists a constant* C *independent of* Δx *and* Δt *such that*

$$\|\boldsymbol{\Psi}(\boldsymbol{W}_1) - \boldsymbol{\Psi}(\boldsymbol{W}_2)\| \leq (1 + C\Delta t)\|\boldsymbol{W}_1 - \boldsymbol{W}_2\| \quad \forall \boldsymbol{W}_1, \boldsymbol{W}_2. \tag{3.4}$$

The definition of nonlinear stability is constructed in such a way that consistency and stability will be sufficient for convergence to the exact solution. However, consistency and stability in this sense will not be necessary for convergence, as in the linear case (cf. [24]).

Simply put, we define a scheme to be nonlinearly stable if the evolution of the difference in time t of two states is bounded by an expression proportional to e^{Ct}, which is sufficient (together with consistency) to show convergence. The convergence follows from [24] using the L_2-norm of the approximate solution $\boldsymbol{W}^n$ at a grid level, which is defined as the sum over the L_2-norm of all grid cells:

$$\|\boldsymbol{W}^n\| := \Delta x \sum_i \|\boldsymbol{W}_i^n\|_2 \quad \text{in one dimension,}$$

$$\|\boldsymbol{W}^n\| := \Delta x \Delta y \sum_{i,j} \|\boldsymbol{W}_{i,j}^n\|_2 \quad \text{in two dimensions.}$$

The system under consideration in (2.11) contains physical constants such as ρ and μ, which make the application of the L_2-norm problematic, as we show in the following.

Remark 3.3 (variable transform). When using the L_2-norm for the state-vector containing velocity, stress, and strain variables for the physical system as presented in (2.11), the problem occurs that the different components of the state-vector are measured in different physical units (since we left physical constants such as ρ and μ in the system) and hence the L_2-norm is meaningless, since it contains the sum of (squared) physical quantities measured in different physical units. Hence, we either have to use a weighed L_2-norm (i.e., an energy norm) or apply a method often used in physics (cf. [11]): transforming physical quantities and time so that all components of the state-vector are denoted in the same unit. To be more precise, we apply the following transformation:

$$\begin{aligned}
\text{Transformed variables} \qquad & \text{Physical variables} \\
t' &= ct \Longrightarrow \frac{\partial}{\partial t} = c\frac{\partial}{\partial t'}, \\
w' &= cw, \\
(\sigma', \tau') &= \left(\frac{\sigma}{\rho}, \frac{\tau}{\rho}\right), \\
(\epsilon', \gamma') &= (c^2\epsilon, c^2\gamma), \\
\kappa' &= \frac{\kappa}{\rho}, \\
\mu_p'(\kappa') &:= \frac{\mu_p(\kappa)}{\rho c^2}.
\end{aligned}$$

Rewriting our physical system (2.11) in these "transformed variables" yields a system of the same form, but $\rho' = c' = \mu' = 1$, measuring all quantities in the same unit,

which will be used throughout the following stability analysis. For simplicity we will drop the $'$ used for the transformed variables.

4. Stability for elastic-plastic waves in 1-D. The physical behavior of a solid undergoing stress can be classified according to three categories—elastic loading, elastic unloading, and plastic loading. Analogous to the physical behavior, our stability analysis in one dimension consists of three steps. First, we assume that we have purely elastic deformation only, which means that the stress-strain relationship is described by the line $0 \to A$ according to Figure 4.1, and hence our system, as well as our numerical scheme, is linear, and stability in the sense of Definition 3.1 can be proved with von Neumann analysis (cf. [10]).

In the second step, we still consider elastic deformation, but this time the stress-strain values may lie on a line which does not necessarily pass through the origin, e.g., line $B \to C$ according to Figure 4.1. Physically speaking, the material is assumed to be in an elastic state everywhere, but having a different plasticity history in the past, explaining why different cells have a different linear stress-strain relationship (e.g., in Figure 4.1 one cell can be in an elastic unloading process, described by a straight line not passing through the origin).

In the last step, we allow plastic deformation. First of all, we will prove boundedness (i.e., (3.3)) of the solution for plastic deformation, provided $0 < \mu_p(\kappa) \leq \mu$. However, a severe problem occurs for plastic deformation, explained in the following remark, leading to restriction of our further analysis.

Remark 4.1 (restriction of analysis). In the general case of plasticity described by a hysteresis model as outlined in section 2.2, it is no longer possible to write the update operator in the form

$$\boldsymbol{W}^{n+1} = \boldsymbol{\Psi}[\boldsymbol{W}^n] \tag{4.1}$$

since the yield condition depends on $\kappa_0(t) = \max_{t_0 \leq t' \leq t} \kappa(t')$; i.e., it depends on all past state vectors $\boldsymbol{W}^0, \boldsymbol{W}^1, \ldots, \boldsymbol{W}^n$. In order to analyze nonlinear stability for plastic waves in the sense of (3.4), we will restrict our analysis to the following special cases:

- Nonlinear elastic waves (cf. Figure 4.2): The stress-strain relationship is described by a nonlinear function $\epsilon = h(\sigma)$.
- Ideal plastic deformation (cf. Figure 4.1): $\kappa_0 \equiv \text{const}$ and $\mu_p(\kappa) \equiv 0$.

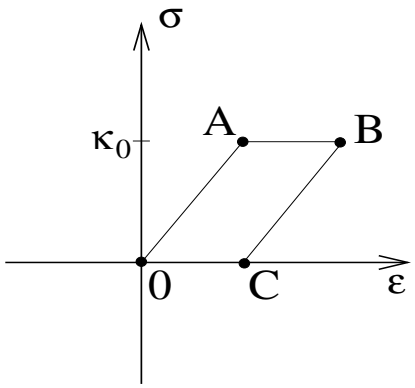

FIG. 4.1. *Hysteresis curve of an ideal plastic material. We consider three steps in our stability analysis: Elastic loading* $0 \to A$*, elastic unloading* $B \to C$*, and plastic loading along* $A \to B$*.*

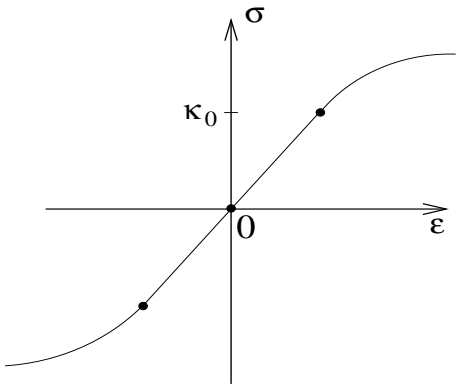

FIG. 4.2. *Stress-strain relationship of a nonlinear elastic material: The wave-speed decreases if* $|\sigma| > \kappa_0$.

In both cases the operator $\boldsymbol{\Psi}$ is of the form (4.1), as used in our definition of nonlinear stability (Definition 3.2).

4.1. Purely elastic waves. The first step of our analysis starts with the 1-D elastic wave equation (i.e., (2.3) restricted to one space dimension)

$$\boldsymbol{U}_t = \begin{pmatrix} w \\ \sigma \end{pmatrix}_t = \begin{pmatrix} \sigma \\ w \end{pmatrix}_x \quad \text{with } \mu = 1 \text{ (cf. Remark 3.3)}, \tag{4.2}$$

where the method of transport for elasticity is equivalent to the decomposition of the linear conservation law into right eigenvectors (cf. [10]). Hence, the 1-D right eigenvectors

$$\boldsymbol{R}^{\pm} = \frac{1}{2}\begin{pmatrix} w \pm \sigma \\ \sigma \pm w \end{pmatrix} \tag{4.3}$$

allow us to decompose the state- and flux-vectors as follows:

$$\begin{aligned} \boldsymbol{U} &= \boldsymbol{R}^{+} + \boldsymbol{R}^{-}, \\ \begin{pmatrix} \sigma \\ w \end{pmatrix}_x &= (\boldsymbol{R}^{+})_x - (\boldsymbol{R}^{-})_x. \end{aligned}$$

The cell update for a first order scheme with constant values in each cell reads

$$\boldsymbol{U}_i^{n+1} = (1-\lambda)\boldsymbol{U}_i^n + \lambda(\boldsymbol{R}_{i-1}^{+,n} + \boldsymbol{R}_{i+1}^{-,n}) \tag{4.4}$$

(λ = CFL-number), which can be written in the form

$$\boldsymbol{U}_i^{n+1} = (1-\lambda)\boldsymbol{U}_i^n + \lambda(\underline{\boldsymbol{A}}^{+}\boldsymbol{U}_{i-1}^n + \underline{\boldsymbol{A}}^{-}\boldsymbol{U}_{i+1}^n) \tag{4.5}$$

with the matrices

$$\underline{\boldsymbol{A}}^{\pm} := \frac{1}{2}\begin{pmatrix} 1 & \pm 1 \\ \pm 1 & 1 \end{pmatrix}.$$

Due to the linearity of the scheme, stability can be proven with von Neumann analysis, which consists of analyzing the norm of the solution $\boldsymbol{U}(x,t)$ in the Fourier space. The Fourier transform of the approximate solution reads

$$\mathcal{F}[\boldsymbol{U}](k,t^n) = \hat{\boldsymbol{U}}(k,t^n) = \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} \boldsymbol{U}(x,t^n)e^{-ikx}\,dx. \tag{4.6}$$

Furthermore we need the identity

$$\mathcal{F}[\boldsymbol{U}(x + l\Delta x, t^n)](k, t^n) = \hat{\boldsymbol{U}}(k, t^n)e^{-il\xi} \tag{4.7}$$

with $\xi = k\Delta x$. Applying the Fourier transform to (4.4) leads to the amplification matrix

$$\underline{\boldsymbol{G}}(\xi) = (1 - \lambda)\underline{\boldsymbol{I}} + \lambda(e^{i\xi}\underline{\boldsymbol{A}}^+ + e^{-i\xi}\underline{\boldsymbol{A}}^-), \tag{4.8}$$

which has the eigenvalues $r_{1,2}$,

$$r_{1,2} = 1 - \lambda(1 - e^{\pm i\xi}). \tag{4.9}$$

Obviously, we have $|r_{1,2}| \leq 1$ for $\lambda \in [0, 1]$, which is necessary for stability.

Moreover, a sufficient condition for stability is that the L_2-norm of the matrix $\underline{\boldsymbol{G}}(\xi)$ is bounded by one; i.e., all eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ are bounded by one. We have the following.

LEMMA 4.2. *For $\lambda = 1$, the scheme* (4.4) *satisfies*

$$\|\boldsymbol{U}^{n+1}\|_2 = \|\boldsymbol{U}^n\|_2. \tag{4.10}$$

Proof. For $\lambda = 1$, the two eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ are

$$r_{1,2} = 1. \qquad \square$$

PROPOSITION 4.3. *Scheme* (4.4) *is stable according to Definition* 3.1 $\forall\lambda \in [0, 1]$.

Proof. We consider the L_2-norm of $\boldsymbol{U}^{n+1}$ computed according to (4.4). Obviously, the squared norm $\|\boldsymbol{U}^{n+1}\|_2^2$ is a polynomial of degree 2 in λ. Since

$$\begin{aligned} \|\boldsymbol{U}^{n+1}\|_2^2(\lambda) &\geq 0 \quad \forall\lambda \in \mathbb{R}, \\ \|\boldsymbol{U}^{n+1}\|_2^2(\lambda = 0) &= \|\boldsymbol{U}^n\|_2^2, \\ \|\boldsymbol{U}^{n+1}\|_2^2(\lambda = 1) &= \|\boldsymbol{U}^n\|_2^2, \end{aligned}$$

and because of $\lim_{\lambda\to\pm\infty} \|\boldsymbol{U}^{n+1}\|_2^2(\lambda) = \infty$, this polynomial has to be convex. Hence,

$$\|\boldsymbol{U}^{n+1}\|_2(\lambda) \leq \|\boldsymbol{U}^n\|_2 \quad \forall\lambda \in [0, 1]. \qquad \square \tag{4.11}$$

4.2. Elastic loading and unloading waves. The second step of the stability analysis, as sketched in Figure 4.1, focuses on the case when the stress-strain relationship is still linear, but not necessarily on a straight line through the origin (e.g., line $B \to C$); for example, a cell could be in an elastic unloading process.

Our numerical scheme consists of two steps now—updating velocity and strain by the method of transport and then updating the stress. To apply the method of transport (cf. (2.19) and (2.20) in two dimensions), we decompose the PDE in the 1-D case,

$$\boldsymbol{V}_t = \begin{pmatrix} w \\ \epsilon \end{pmatrix}_t = \begin{pmatrix} \sigma \\ w \end{pmatrix}_x, \tag{4.12}$$

into transported quantities $\boldsymbol{R}^\pm$ as follows:

$$\boldsymbol{R}^\pm := \frac{1}{2}\begin{pmatrix} w \pm \sigma \\ \epsilon \pm w \end{pmatrix}. \tag{4.13}$$

Thus, we update the velocity and strain variables in each cell by solving the advection equations,

$$\boldsymbol{R}_t^+ + (\boldsymbol{R}^+)_x = 0,$$
$$\boldsymbol{R}_t^- - (\boldsymbol{R}^-)_x = 0,$$

which yields an update formula for $\boldsymbol{V} = (w, \epsilon)$ with the CFL-number λ:

$$\boldsymbol{V}_i^{n+1} = (1-\lambda)\boldsymbol{V}_i^n + \lambda(\boldsymbol{R}_{i-1}^{+,n} + \boldsymbol{R}_{i+1}^{-,n}). \tag{4.14}$$

Afterwards, the stress is updated according to Hooke's law (with $\mu = 1$ due to Remark 3.3),

$$\sigma_i^{n+1} = \sigma_i^n + (\epsilon_i^{n+1} - \epsilon_i^n). \tag{4.15}$$

The stress-strain relationship is obviously linear but can be described by a different linear equation in each cell, which generalizes the analysis of the previous section, where each cell was described by the same linear stress-strain relationship. Physically speaking, each cell can be in a different elastic loading or unloading process. We will write these two steps (4.14), (4.15) as a one-step update for the vector $\boldsymbol{W}_i^n = (w_i^n, \epsilon_i^n, \sigma_i^n)$.

With the matrices $\underline{\boldsymbol{A}}^+$, $\underline{\boldsymbol{A}}^-$, $\underline{\boldsymbol{A}}^0$, and $\underline{\boldsymbol{E}}$ defined as follows:

$$\underline{\boldsymbol{A}}^\pm := \frac{1}{2}\begin{pmatrix} 1 & 0 & \pm 1 \\ \pm 1 & 1 & 0 \\ \pm 1 & 1 & 0 \end{pmatrix},$$
$$\underline{\boldsymbol{A}}^0 := \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & -1 & 1 \end{pmatrix},$$
$$\boldsymbol{E} := \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

We can write the scheme (4.14), (4.15) as one step:

$$\boldsymbol{W}_i^{n+1} = \lambda[\underline{\boldsymbol{A}}^+\boldsymbol{W}_{i-1}^n + \underline{\boldsymbol{A}}^-\boldsymbol{W}_{i+1}^n]\boldsymbol{W}_i^n + \underline{\boldsymbol{A}}^0\boldsymbol{W}_i^n + (1-\lambda)\underline{\boldsymbol{E}}\boldsymbol{W}_i^n. \tag{4.16}$$

Since the scheme (4.16) is still linear, we apply von Neumann analysis, which means we analyze the amplification matrix

$$\underline{\boldsymbol{G}}(\xi) = \lambda[\underline{\boldsymbol{A}}^+ e^{i\xi} + \underline{\boldsymbol{A}}^- e^{-i\xi}] + \underline{\boldsymbol{A}}^0 + (1-\lambda)\underline{\boldsymbol{E}}. \tag{4.17}$$

The eigenvalues r_i of the complex non-Hermitian matrix $\underline{\boldsymbol{G}}(\xi)$ turn out to be

$$r_1 = 1,$$
$$r_{2,3} = 1 - \lambda + \lambda e^{\pm i\xi},$$

which are all bounded by one $\forall \lambda \in [0,1]$, which is necessary for stability.

A sufficient condition for stability is that the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ are bounded by one. The calculation of the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ yields lengthy expressions for the eigenvalues, which are too complicated to be discussed analytically. Thus, we perform a computational analysis to verify the following.

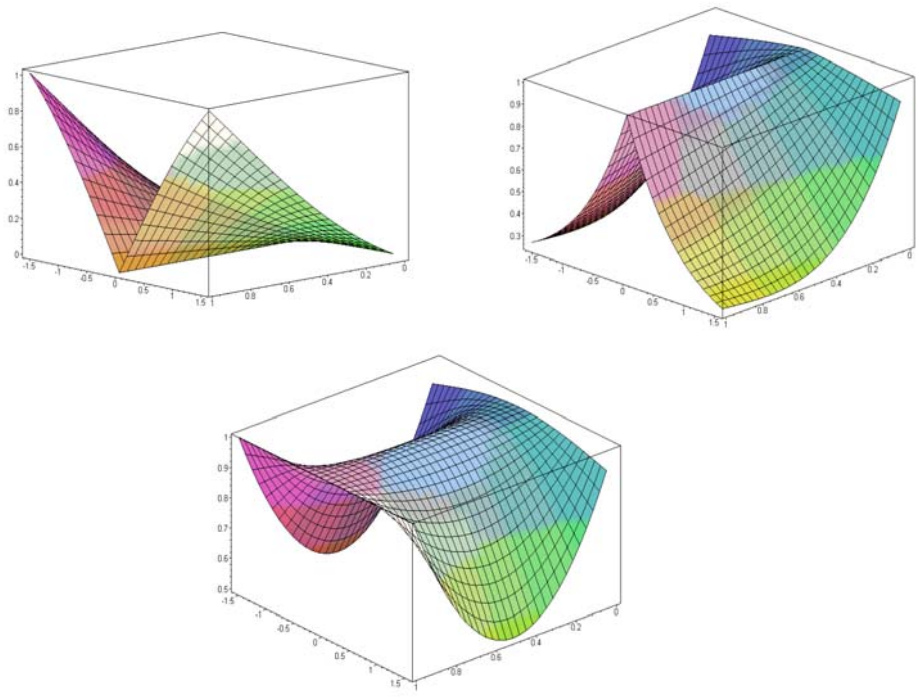

FIG. 4.3. *Three eigenvalues of the matrix* $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$*, plotted over the region* $(\lambda,\xi) \in [0,1] \times [-\pi/2,\pi/2]$*, showing their boundedness between zero and one.*

Conjecture 4.4 (boundedness of eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$). The eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ with the amplification matrix defined in (4.17) are bounded by one $\forall\lambda \in [0,1]$.

Proof. The three eigenvalues of the matrix $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ plotted in Figure 4.3 for $(\lambda,\xi) \in [0,1] \times [-\pi/2,\pi/2]$ show that these three eigenvalues are bounded by one. ∎

Consequently, we can conclude that

$$\|\boldsymbol{W}^{n+1}\|_2 \leq \|\boldsymbol{W}^n\|_2. \tag{4.18}$$

It is important to mention that our further investigations for plastic waves are independent of this result for the method of transport; i.e., the following results can be applied to any numerical scheme fulfilling the stability condition (4.18) for elastic waves.

4.3. Boundedness for elastic-plastic waves. The third step of our stability analysis generalizes to the case of plastic deformation, i.e., the stress update in (4.15) has to be replaced by the integral equation

$$\sigma_i^{n+1} = \sigma_i^n + \int_{\epsilon_i^n}^{\epsilon_i^{n+1}} \mu_p(\sigma(\epsilon))d\epsilon, \tag{4.19}$$

which yields an update for σ. For most materials (cf. [18]) $\mu_p(\sigma)$ is smaller for plasticity than for elasticity, i.e.,

$$\mu_p(\sigma) = \begin{cases} \mu = 1 & \text{if } |\sigma| \leq \kappa_0, \\ \leq \mu = 1 & \text{otherwise,} \end{cases} \tag{4.20}$$

with

$$\kappa_0(t) = \max_{0 \leq t' \leq t} |\sigma(t)|,$$

which will be used as an assumption in the following proposition. Equation (4.20) shows that the following analysis covers not only purely plastic deformation but also the case where deformation is first elastic and then becomes plastic.

PROPOSITION 4.5. *If* (4.18) *holds for elastic waves* $\forall \lambda \in [0,1]$ *and* $0 < \mu_p(\kappa) \leq \mu = 1$ $\forall \kappa \in \mathbb{R}^+$*, then the update operator* $\boldsymbol{\Psi}$ *of the scheme is also bounded by one for plasticity* $\forall \lambda \in [0,1]$*, i.e.,*

$$\|\boldsymbol{W}^{n+1}\|_2 \leq \|\boldsymbol{W}^n\|_2.$$

Proof. The basic idea of the proof is simple: With a given solution $\boldsymbol{W}^n$ at time level t^n we compute two different updates: one purely elastic update $\boldsymbol{W}_{el}^{n+1}$ computed according to (4.15) neglecting the existence of plasticity, and the plastic update $\boldsymbol{W}_{pl}^{n+1}$ computed according to (4.19). Since the elastic update of the stress σ_{el}^{n+1} cannot be smaller than the plastic update if $\mu_p(\kappa) \leq \mu = 1$, i.e.,

$$|\sigma_{pl}^{n+1}| \leq |\sigma_{el}^{n+1}|, \tag{4.21}$$

the norm of the plastic update of the vector $\boldsymbol{W}_{pl}^{n+1}$ cannot be larger than the elastic update $\boldsymbol{W}_{el}^{n+1}$:

$$\|\boldsymbol{W}_{pl}^{n+1}\|_2 \leq \|\boldsymbol{W}_{el}^{n+1}\|_2 \leq \|\boldsymbol{W}^n\|_2. \qquad \square$$

Hence, boundedness by one of the update operator for elasticity implies boundedness for plastic waves as well. It is noteworthy that this result is independent of the numerical scheme used for solving the fluxes, e.g., the method of transport.

4.4. Nonlinear stability for elastic-plastic waves. However, since we have a nonlinear scheme for plastic waves, boundedness of the operator is no longer sufficient for stability in the sense of Definition 3.2.

Therefore, we have to use (3.4) from Definition 3.2, which means that we have to investigate the difference between two solutions $\Delta \boldsymbol{W}_i^n = \bar{\boldsymbol{W}}_i^n - \boldsymbol{W}_i^n$ with

$$\begin{aligned} \boldsymbol{W}_i^n &:= (w_i^n, \epsilon_i^n, \sigma_i^n), \\ \bar{\boldsymbol{W}}_i^n &:= (\bar{w}_i^n, \bar{\epsilon}_i^n, \bar{\sigma}_i^n) \end{aligned}$$

in order to prove nonlinear stability.

As for the proof of boundedness, the basic idea is to prove that plasticity can only decrease the norm of the difference between two states relative to elasticity. Therefore, one computes an elastic update for both $\boldsymbol{W}_i$ and $\bar{\boldsymbol{W}}_i$ ignoring the existence of plasticity and then compares it to the plastic update. Provided the stability condition (4.18) holds for elastic waves, then we can already conclude a relation of the form

$$\|\Delta \boldsymbol{W}^{n+1}\|_2 \leq \|\Delta \boldsymbol{W}^n\|_2 \tag{4.22}$$

for elastic waves, since in that case $\boldsymbol{\Psi}[\boldsymbol{W}^n - \bar{\boldsymbol{W}}^n] = \boldsymbol{\Psi}[\boldsymbol{W}^n] - \boldsymbol{\Psi}[\bar{\boldsymbol{W}}^n]$ due to the linearity of the scheme for elastic waves. Thus, it is sufficient to show that plasticity can only reduce the norm of $\|\Delta \boldsymbol{W}^{n+1}\|_2$; i.e., we have to show

$$(\Delta\sigma_{pl}^{n+1})^2 \le (\Delta\sigma_{el}^{n+1})^2 \tag{4.23}$$

in each cell, where the indices *el* and *pl* distinguish between an elastic and a plastic stress update.

For reasons explained above in Remark 4.1, we will analyze only the special cases of an ideal plastic material and nonlinear elastic material.

4.4.1. Ideal plastic material. For such material, the stress-strain relationship can be described as follows:

$$\begin{aligned} \kappa(t) &= \sqrt{\sigma^2(t)}, \\ d\sigma &= \begin{cases} 0 & \text{if } \kappa = \kappa_0 \text{ and } \dot{\kappa} > 0, \\ d\epsilon & \text{otherwise,} \end{cases} \end{aligned} \tag{4.24}$$

which implies

$$\kappa_0 \equiv \text{const} \quad \text{and} \quad |\sigma(t)| \le \kappa_0. \tag{4.25}$$

We have the following proposition.

PROPOSITION 4.6. *The update operator* $\boldsymbol{\Psi}$ *for plastic waves in a material with the plasticity model described in* (4.24) *is nonlinearly stable in the sense of Definition* 3.2*; i.e., for the difference between two solutions* $\Delta \boldsymbol{W}^n$ *we have*

$$\|\Delta \boldsymbol{W}^{n+1}\|_2 \le \|\Delta \boldsymbol{W}^n\|_2.$$

Proof. If σ_{el}^{n+1} and $\bar{\sigma}_{el}^{n+1}$ denote the elastic stress update in a cell i neglecting the occurrence of plasticity, then the plastic update in this cell reads

$$\begin{aligned} \sigma_{pl}^{n+1} &= \operatorname{sgn}(\sigma_{el}^{n+1}) \min\{|\sigma_{el}^{n+1}|, \kappa_0\}, \\ \bar{\sigma}_{pl}^{n+1} &= \operatorname{sgn}(\bar{\sigma}_{el}^{n+1}) \min\{|\bar{\sigma}_{el}^{n+1}|, \kappa_0\}. \end{aligned}$$

Thus, one easily verifies

$$|\sigma_{pl}^{n+1} - \bar{\sigma}_{pl}^{n+1}| \le |\sigma_{el}^{n+1} - \bar{\sigma}_{el}^{n+1}|, \tag{4.26}$$

which implies

$$\|\Delta \boldsymbol{W}_{pl}^{n+1}\|_2 \le \|\Delta \boldsymbol{W}_{el}^{n+1}\|_2 \le \|\Delta \boldsymbol{W}^n\|_2. \qquad \square \tag{4.27}$$

4.4.2. Nonlinear elastic material. The second case we want to study is a nonlinear elastic material, where the stress-strain relationship is described by a nonlinear function $\sigma = h(\epsilon)$ (cf. Figure 4.2). If the elastic shear modulus $\mu = 1$ is a Lipschitz constant for the function f (which implies that the nonlinear wave-speed is smaller than the elastic speed), then we have the following.

PROPOSITION 4.7. *For stress-strain relationship of the form* $\sigma = h(\epsilon)$ *with* $\mu = 1$ *being a Lipschitz constant of the function* $h(\cdot)$*, the operator* $\boldsymbol{\Psi}$ *is stable in the sense of Definition* 3.2.

Proof. Let the index pl and el distinguish between the nonlinear and the linear elastic updates, whence in a cell i we have

$$|\sigma_{pl}^{n+1} - \bar{\sigma}_{pl}^{n+1}| = |h(\epsilon^{n+1}) - h(\bar{\epsilon}^{n+1})| \leq |\epsilon^{n+1} - \bar{\epsilon}^{n+1}| = |\sigma_{el}^{n+1} - \bar{\sigma}_{el}^{n+1}| \tag{4.28}$$

and thus

$$\|\Delta \boldsymbol{W}_{pl}^{n+1}\|_2 \leq \|\Delta \boldsymbol{W}_{el}^{n+1}\|_2 \leq \|\Delta \boldsymbol{W}^{n}\|_2. \tag{4.29}$$ ∎

It is noteworthy that these two results for nonlinear stability are independent of the method used for solving the PDE; i.e., they can be used for schemes other than the method of transport as well.

5. Stability for elastic-plastic waves in two dimensions. In this section, we will analyze the stability of our scheme in two dimensions. In principle, one can follow the same three steps and the same ideas as for one dimension. In two dimensions, the method of transport based on the decomposition of the PDE into advection equations is a generalization of the decomposition of a linear conservation law into right eigenvectors in one dimension.

5.1. Stability for elastic waves. As in one dimension, the first step of our stability analysis focuses on an purely elastic material. As mentioned above (cf. (2.13)–(2.16)), the idea of the method of transport is to decompose a PDE into advection equations describing the transport of some quantities $\boldsymbol{R}_i$. For elastic waves, these quantities can be written as

$$\boldsymbol{R}_i := \boldsymbol{U} + \underline{\boldsymbol{L}}\vec{\boldsymbol{n}}_i = \underline{\boldsymbol{A}}_i \boldsymbol{U} \tag{5.1}$$

with

$$\underline{\boldsymbol{A}}_i = \begin{pmatrix} 1 & n_i^1 & n_i^2 \\ n_i^1 & 1 & 0 \\ n_i^2 & 0 & 1 \end{pmatrix} \quad \text{and} \quad \vec{\boldsymbol{n}}_i = \begin{pmatrix} n_i^1 \\ n_i^2 \end{pmatrix}. \tag{5.2}$$

We call λ the CFL-number of the scheme. In the following we use four diagonal waves, i.e.,

$$\vec{\boldsymbol{n}}_1 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \qquad \vec{\boldsymbol{n}}_2 = \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \qquad \vec{\boldsymbol{n}}_3 = \begin{pmatrix} -1 \\ 1 \end{pmatrix}, \qquad \vec{\boldsymbol{n}}_4 = \begin{pmatrix} -1 \\ -1 \end{pmatrix}, \tag{5.3}$$

which fulfill the consistency relation (2.14).

We assume a Cartesian grid, and consequently λ^2 is the part of the quantity $\boldsymbol{R}_i$ in a certain cell which is transported into the corner neighbors and $\lambda(1-\lambda)$ is the part which is transported into the direct neighbor cells (cf. Figure 5.1).

With the above assumptions, the update formula of the scheme for the state vector $\boldsymbol{U}_{ij}$ in the cell (i,j) can be formulated:

$$\begin{aligned} \boldsymbol{U}_{ij}^{n+1} = {} & [1 - \lambda^2 - 2\lambda(1-\lambda)]\boldsymbol{U}_{i,j}^n \\ & + \{\lambda^2[(\boldsymbol{R}_1^n)_{i-1,j-1} + (\boldsymbol{R}_3^n)_{i+1,j-1} + (\boldsymbol{R}_2^n)_{i-1,j+1} + (\boldsymbol{R}_4^n)_{i+1,j+1}] \\ & + \lambda(1-\lambda)[(\boldsymbol{R}_1^n)_{i-1,j} + (\boldsymbol{R}_4^n)_{i-1,j} + (\boldsymbol{R}_2^n)_{i-1,j} + (\boldsymbol{R}_3^n)_{i+1,j}] \\ & + \lambda(1-\lambda)[(\boldsymbol{R}_3^n)_{i,j-1} + (\boldsymbol{R}_4^n)_{i,j+1} + (\boldsymbol{R}_1^n)_{i,j-1} + (\boldsymbol{R}_2^n)_{i,j+1}]\}/4. \end{aligned} \tag{5.4}$$

Taking into account (5.1) and (5.2), the quantities $\boldsymbol{R}_k$ used in (5.4) can be expressed by the $\boldsymbol{U}_{ij}^n$.

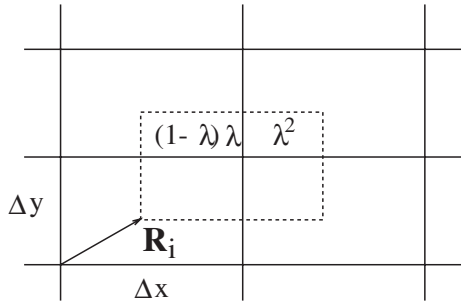

FIG. 5.1. *Advection of the quantity $\boldsymbol{R}_i$ in a cell into the direction $\vec{\boldsymbol{n}}_1 = (1,1)^T$. The part transported into the corner cell is λ^2, and the part transported into each of the two direct neighboring cells is $\lambda(1-\lambda)$, where λ denotes the CFL-number.*

Since the scheme is linear, we can apply the well-known von Neumann analysis to show stability for the scheme (5.4). Therefore, we analyze the Fourier transform of $\boldsymbol{U}(x,y,t)$,

$$\begin{aligned}\mathcal{F}[\boldsymbol{U}](k_1,k_2,t^n) &= \hat{\boldsymbol{U}}(k_1,k_2,t^n)\\ &= \frac{1}{2\pi}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\boldsymbol{U}(x,y,t^n)e^{-i(k_1x+k_2y)}\,dx\,dy.\end{aligned} \tag{5.5}$$

Obviously we have

$$\mathcal{F}[\boldsymbol{U}(x+l\Delta x, y+m\Delta y, t^n)](k_1,k_2,t^n) = \hat{\boldsymbol{U}}(k_1,k_2,t^n)e^{-i(l\xi+m\eta)} \tag{5.6}$$

with $\xi = k_1\Delta x$ and $\eta = k_2\Delta y$. Hence, in the Fourier space the update scheme can be written as

$$\hat{\boldsymbol{U}}(k_1,k_2,t^{n+1}) = \underline{\boldsymbol{G}}(\xi,\eta)\hat{\boldsymbol{U}}(k_1,k_2,t^n). \tag{5.7}$$

In order to prove stability for the scheme (5.4) it is sufficient to show that the amplification matrix $\underline{\boldsymbol{G}}(\xi,\eta)$ is bounded in the L_2-norm; i.e., the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ are less than or equal to one. We have the following.

PROPOSITION 5.1 (boundedness for $CFL = 1$). *For $CFL = 1$, the eigenvalues of $\underline{\boldsymbol{G}}^H(\xi,\eta)\underline{\boldsymbol{G}}(\xi,\eta)$ on a Cartesian grid are bounded by one, and hence the scheme is linearly stable according to Definition* 3.1.

Proof. Using (5.5) in (5.4), the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ can be found:

$$\begin{aligned}r_1 &= -\frac{1}{8}\cos(2\xi+2\eta) + \frac{1}{4}\cos(2\eta) - \frac{1}{8}\cos(2\eta-2\xi) + \frac{1}{4}\cos(2\xi) + \frac{3}{4},\\ r_{2,3} &= \frac{1}{8}\cos(2\xi+2\eta) + \frac{1}{4}\cos(2\eta) + \frac{1}{8}\cos(2\eta-2\xi) + \frac{1}{4}\cos(2\xi) + \frac{1}{4},\end{aligned}$$

which are bounded by one. Hence, for $CFL = 1$ the scheme is stable.

Further, numerical plots of the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ confirm that stability holds $\forall\lambda \in [0;1]$. We omit the plots of eigenvalues in this step, since we show them below in the more general context of the second step. ∎

5.2. Stability for elastic loading and unloading waves. As in one dimension, the second step of our analysis still focuses on elastic waves, but now allowing

different cells to be in a different hysteresis state (i.e., different cells have different linear stress-strain relationships, as indicated in Figure 4.1). Again, we can rewrite our two-step scheme:

- Updating w, ϵ, and γ using the method of transport, i.e., (2.18)–(2.20).
- Then updating σ and τ using the stress-strain relationship

$$\sigma_{ij}^{n+1} = \sigma_{ij}^{n} + (\epsilon_{ij}^{n+1} - \epsilon_{ij}^{n}),$$
$$\tau_{ij}^{n+1} = \tau_{ij}^{n} + (\gamma_{ij}^{n+1} - \gamma_{ij}^{n})$$

as a one-step update scheme for the vector $\boldsymbol{W} = (w, \epsilon, \gamma, \sigma, \tau)$. With the matrix

$$\underline{\boldsymbol{A}}_i := \frac{1}{4}\begin{pmatrix} 1 & 0 & 0 & n_i^1 & n_i^2 \\ n_i^1 & 1 & 0 & 0 & 0 \\ n_i^2 & 0 & 1 & 0 & 0 \\ n_i^1 & 1 & 0 & 0 & 0 \\ n_i^2 & 0 & 1 & 0 & 0 \end{pmatrix} \tag{5.8}$$

we can define the transported quantities

$$\boldsymbol{R}_i := \underline{\boldsymbol{A}}_i \boldsymbol{W}, \tag{5.9}$$

where i is the index of one of the four diagonal waves according to (5.3). Furthermore, we define

$$\underline{\boldsymbol{A}}_0 := \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{pmatrix},$$

$$\underline{\boldsymbol{B}} := \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 1 & 0 \\ 0 & 0 & -1 & 0 & 1 \end{pmatrix}.$$

Hence, our scheme for the update of $\boldsymbol{W}_{ij}^n$ in cell (i, j) reads

$$\begin{aligned} \boldsymbol{W}_{ij}^{n+1} = {} & [1 - \lambda^2 - 2\lambda(1-\lambda)]\underline{\boldsymbol{A}}_0 \boldsymbol{W}_{i,j}^n + \underline{\boldsymbol{B}} \boldsymbol{W}_{i,j}^n \\ & + \{\lambda^2[(\boldsymbol{R}_1^n)_{i-1,j-1} + (\boldsymbol{R}_3^n)_{i+1,j-1} + (\boldsymbol{R}_2^n)_{i-1,j+1} + (\boldsymbol{R}_4^n)_{i+1,j+1}] \\ & + \lambda(1-\lambda)[(\boldsymbol{R}_1^n)_{i-1,j} + (\boldsymbol{R}_4^n)_{i+1,j} + (\boldsymbol{R}_2^n)_{i-1,j} + (\boldsymbol{R}_3^n)_{i+1,j}] \\ & + \lambda(1-\lambda)[(\boldsymbol{R}_3^n)_{i,j-1} + (\boldsymbol{R}_4^n)_{i,j+1} + (\boldsymbol{R}_1^n)_{i,j-1} + (\boldsymbol{R}_2^n)_{i,j+1}]\}/4. \end{aligned} \tag{5.10}$$

Analogous to the 1-D case, we compute the amplification matrix as

$$\begin{aligned} \underline{\boldsymbol{G}}(\xi, \eta) = {} & [1 - \lambda^2 - 2\lambda(1-\lambda)]\underline{\boldsymbol{A}}_0 + \underline{\boldsymbol{B}} \\ & + \{\lambda^2[e^{i\xi+i\eta}\underline{\boldsymbol{A}}_1 + e^{-i\xi+i\eta}\underline{\boldsymbol{A}}_3 + e^{i\xi-i\eta}\underline{\boldsymbol{A}}_2 + e^{-i\xi-i\eta}\underline{\boldsymbol{A}}_4] \\ & + \lambda(1-\lambda)[e^{i\xi}\underline{\boldsymbol{A}}_1 + e^{-i\xi}\underline{\boldsymbol{A}}_4 + e^{i\xi}\underline{\boldsymbol{A}}_2 + e^{-i\xi}\underline{\boldsymbol{A}}_3] \\ & + \lambda(1-\lambda)[e^{i\eta}\underline{\boldsymbol{A}}_3 + e^{-i\eta}\underline{\boldsymbol{A}}_4 + e^{i\eta}\underline{\boldsymbol{A}}_1 + e^{-i\eta}\underline{\boldsymbol{A}}_2]\}/4, \end{aligned} \tag{5.11}$$

which is a complex non-Hermitian matrix. As in one dimension, we come to the following conjecture.

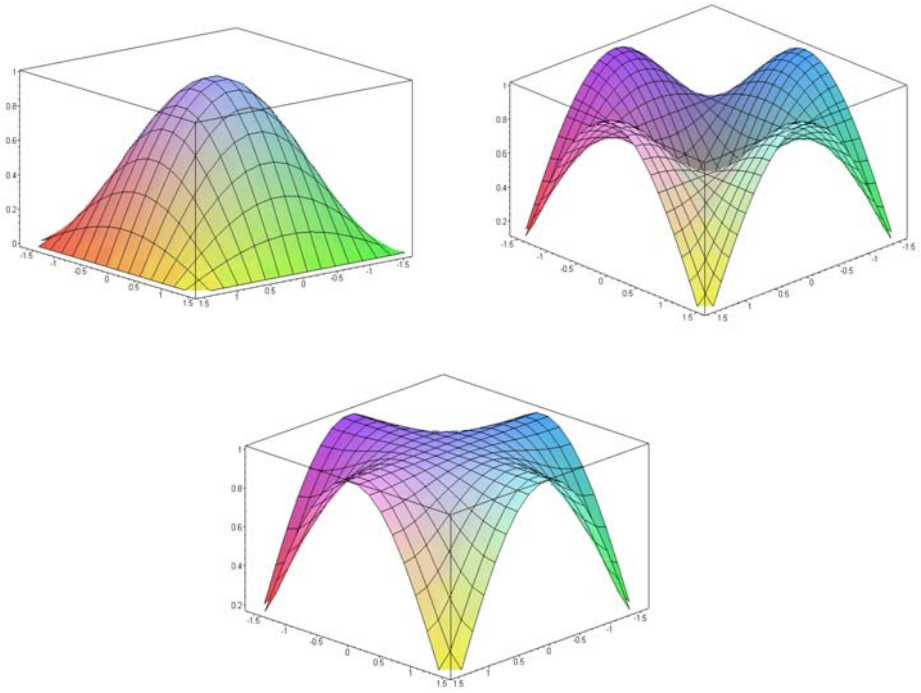

FIG. 5.2. *Three eigenvalues of the matrix* $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ *for* $CFL = \lambda = 1$*, plotted over the region* $(\xi, \eta) \in [-\pi/2, \pi/2]^2$*, showing their boundedness between zero and one. The remaining two eigenvalues are omitted, since they are constantly one.*

Conjecture 5.2 (boundedness of eigenvalues of amplification matrix). *The eigenvalues of the update matrix* $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ *with the amplification matrix defined in* (5.11) *on a Cartesian grid are bounded by one for* $CFL = \lambda = 1$.

Proof. The eigenvalues of the amplification matrix $\underline{\boldsymbol{G}}^H(\xi, \eta)\underline{\boldsymbol{G}}(\xi, \eta)$ plotted in Figure 5.2 show the eigenvalues for $\lambda = 1$, which are bounded by one.

It is important to mention that further computations of the eigenvalues of $\underline{\boldsymbol{G}}^H\underline{\boldsymbol{G}}$ for CFL-numbers between zero and one illustrates that stability holds $\forall\lambda \in [0, 1]$. □

5.3. Stability for elastic-plastic waves. Analogous to the 1-D case, one can argue that the norm of the difference of two solutions $\Delta\boldsymbol{W}$ can only decrease when plasticity occurs if we make similar assumptions for the stress-strain relationship as in 1-D, i.e., ideal plasticity. The argument used is the same as in one dimension: Plasticity yields smaller stress updates than elasticity as long as the plastic wavespeed is not greater than the elastic one.

6. Conclusion. The "classical" convergence proof for ODE and linear PDE solvers is based on two properties of a numerical scheme—consistency and stability. For our numerical scheme for solving the (nonlinear) elastic-plastic wave equation using the method of transport as underlying numerical scheme, we used a definition of nonlinear stability, which is based on a limit for the evolution of the difference between two numerical solutions in time. On the basis of this stability

definition it is straightforward to obtain convergence proofs for a consistent numerical scheme.

For purely elastic waves where our scheme is linear, and hence boundedness of the update operator is sufficient for stability, we were able to show stability with von Neumann analysis in one and two dimensions. For plastic waves, where the system to be simulated nonlinear, as, consequently, is our scheme, we were able to show boundedness of the update operator, provided that the plastic wave-speed is not higher than the elastic wave-speed in one dimension. Furthermore, we showed nonlinear stability for two special cases in one dimension—nonlinear elastic waves and ideal plastic waves, where the shear modulus reduces to zero in the plastic zone. The basic idea for the proof of boundedness and nonlinear stability is the observation that plasticity only decreases the value of the stress variables, provided the material "weakens" in plastic zones. Furthermore, it is straightforward to generalize this argument to two dimensions.

It is noteworthy that our stability results in the nonlinear (i.e., plastic) case are very general in the sense that they are independent of the numerical scheme used for solving the PDE, and they are based on the observation that the occurrence of plasticity only "improves" stability, provided the material becomes weaker in the plastic zone, which is the case for almost all materials. Moreover, the analysis performed is not restricted to one or two space dimensions—a generalization to the wave equation in three dimensions is straightforward.

DUAL-PRIMAL FETI ALGORITHMS FOR EDGE ELEMENT APPROXIMATIONS: TWO-DIMENSIONAL H AND P FINITE ELEMENTS ON SHAPE-REGULAR MESHES*

ANDREA TOSELLI† AND XAVIER VASSEUR†

Abstract. A family of dual-primal finite element tearing and interconnecting (FETI) methods for edge element approximations in two dimensions is proposed and analyzed. The primal constraints here are averages over subdomain edges. It is shown that the condition number of the corresponding method is independent of the number of substructures and grows only polylogarithmically with the number of unknowns associated with individual substructures. The estimate is also independent of the jumps of both of the coefficients of the original problem. Numerical results validating our theoretical bounds are given.

Key words. edge elements, Maxwell's equations, finite elements, spectral elements, domain decomposition, FETI, preconditioners, heterogeneous coefficients

1. Introduction.

In this paper, we consider the boundary value problem

$$\begin{aligned} L\mathbf{u} := \mathbf{curl}\,(a\ \mathrm{curl}\,\mathbf{u}) + A\ \mathbf{u} = \mathbf{f} \quad &\text{in } \Omega, \\ \mathbf{u}\cdot\mathbf{t} = 0 \quad &\text{on } \partial\Omega, \end{aligned} \tag{1.1}$$

with Ω a bounded polygonal domain in $\mathbb{R}^2$. The domain Ω has unit diameter and $\mathbf{t}$ is its unit tangent. We have

$$\mathbf{curl}\, v := \left[\frac{\partial v}{\partial x_2}, -\frac{\partial v}{\partial x_1}\right]^T, \qquad \mathrm{curl}\,\mathbf{u} := \frac{\partial u_2}{\partial x_1} - \frac{\partial u_1}{\partial x_2};$$

see, e.g., [19]. The coefficient matrix A is a symmetric uniformly positive definite matrix-valued function with entries $A_{ij} \in L^\infty(\Omega)$, $1 \le i,\, j \le 2$, and $a \in L^\infty(\Omega)$ is a positive function bounded away from zero.

The weak formulation of problem (1.1) requires the introduction of the Hilbert space $H(\mathrm{curl}\,;\Omega)$, defined by

$$H(\mathrm{curl}\,;\Omega) := \{\mathbf{v} \in (L^2(\Omega))^2 \mid \mathrm{curl}\,\mathbf{v} \in L^2(\Omega)\}.$$

The space $H(\mathrm{curl}\,;\Omega)$ is equipped with the inner product and graph norm

$$(\mathbf{u},\mathbf{v})_{\mathrm{curl}} := \int_\Omega \mathbf{u}\cdot\mathbf{v}\ dx + \int_\Omega \mathrm{curl}\,\mathbf{u}\,\mathrm{curl}\,\mathbf{v}\ dx, \qquad \|\mathbf{u}\|^2_{\mathrm{curl}} := (\mathbf{u},\mathbf{u})_{\mathrm{curl}},$$

and the tangential component $\mathbf{u}\cdot\mathbf{t}$, of a vector $\mathbf{u} \in H(\mathrm{curl}\,;\Omega)$ on the boundary $\partial\Omega$, belongs to the space $H^{-\frac{1}{2}}(\partial\Omega)$; see [6, 19]. The subspace of vectors in $H(\mathrm{curl}\,;\Omega)$ with vanishing tangential component on $\partial\Omega$ is denoted by $H_0(\mathrm{curl}\,;\Omega)$.

For any $\mathcal{D} \subset \Omega$, we define the bilinear form

$$a_{\mathcal{D}}(\mathbf{u},\mathbf{v}) := \int_{\mathcal{D}} (a \operatorname{curl}\mathbf{u} \operatorname{curl}\mathbf{v} + A\, \mathbf{u}\cdot\mathbf{v})\, dx, \quad \mathbf{u},\, \mathbf{v} \in H(\operatorname{curl};\Omega). \tag{1.2}$$

The variational formulation of (1.1) is as follows.

Find $\mathbf{u} \in H_0(\operatorname{curl};\Omega)$ such that

$$a_{\Omega}(\mathbf{u},\mathbf{v}) = \int_{\Omega} \mathbf{f}\cdot\mathbf{v}\, dx, \quad \mathbf{v} \in H_0(\operatorname{curl};\Omega). \tag{1.3}$$

The purpose of this work is to construct and analyze a dual-primal finite element tearing and interconnecting (FETI-DP) preconditioner for h and p finite element approximations of problem (1.3). Neumann–Neumann (NN) and finite element tearing and interconnecting (FETI) algorithms are particular domain decomposition (DD) methods of iterative substructuring type; they rely on a nonoverlapping partition into subdomains. They are among the most popular and heavily tested DD methods and are now employed for the solution of huge problems on parallel architectures; see, e.g., [16, 9, 8, 31, 4]. The rate of convergence is often independent of possibly large jumps of the coefficients.

FETI methods rely on the reformulation of the original algebraic problem into an equivalent saddle point problem, involving discontinuous functions across the subdomain boundaries and a continuity constraint for the solution; see (3.3). In the original one-level FETI methods, completely discontinuous vectors are employed; the elimination of the primal variable thus requires the solution of local (generally singular) Neumann problems, and an equation for the Lagrange multipliers is then obtained. A first step consists in the elimination of the components belonging to a suitable coarse space, constructed from local subdomain kernels or suitable functions (constants for the Laplace equation and rigid body modes for linear elasticity, for example). This elimination employs a projection, constructed with a suitable scaling matrix. A preconditioner for the resulting equation is then constructed by solving local Dirichlet problems on the subdomains and by employing a set of scaling matrices which have the purpose of making convergence independent of possibly large jumps of the coefficients. We recall that one-level FETI methods actually consist of both coarse and local components; in the context of FETI methods the term "one-level" is in contrast to two-level methods that were developed primarily for biharmonic and shell element problems and that involve satisfying some of the continuity constraints at each step of the iterations.

The more recently developed FETI-DP methods employ a smaller space for the solution, where a certain number of degrees of freedom or linear functionals is continuous across the subdomains. These so-called *primal constraints* ensure that a nonsingular global problem needs to be solved in order to obtain an equation for the Lagrange multipliers; this step requires the solution of modified nonsingular Neumann problems and the solution of a coarse problem the size of which equals the number of primal constraints. As before, a preconditioner is constructed by solving local Dirichlet problems. FETI-DP algorithms present considerable advantages: the same code can now be employed for a wider class of problems, much less dense coarse matrices need to be inverted, they do not require the characterization of the kernels of local Neumann operators or the introduction of an additional scaling matrix for the construction of the coarse component of the preconditioner, and they may start the conjugate gradient (CG) iteration from an arbitrary initial guess. For these reasons,

they have now almost completely replaced one-level FETI methods for large scale computations. Connections between NN and FETI methods are being investigated; see [13].

The motivation of this work lies in the fact that no iterative substructuring methods (and, in particular, no NN or FETI preconditioners) that are robust with respect to the number of unknowns, the number of subdomains, and large jumps of the coefficients are presently available for edge element approximations of three-dimensional problems.

Some methods are available for two-dimensional approximations.

In [30], a DD preconditioner was proposed, which is based on a standard coarse space and local spaces associated to the subdomain edges. NN preconditioners with standard coarse spaces were studied in [24]. One-level FETI methods were developed in [26, 21], thanks to the introduction of suitable local functions which are the analogue of constants and rigid body modes for the Laplace equation and linear elasticity, respectively. These functions were then employed to construct a Balancing NN method in [25]. Standard coarse spaces, however, are not in general suitable for quasi-optimal preconditioners in three dimensions, and the search for suitable local functions in three dimensions for balancing NN and one-level FETI methods has produced no results so far. For these reasons we believe that FETI-DP algorithms will turn out to be easier to devise for three-dimensional problems. The scope of this work is then to begin to understand a good set of primal constraints in *two dimensions*, which have not been available so far. It turns out that the natural choice of edge averages on the subdomain edges leads to a robust preconditioner.

For the analysis, we employ the tools developed in [30]. We note that more general tools were later devised in [32], which consisted in decomposition results for trace functions in $H(\mathrm{curl}\,;\Omega)$ in two dimensions or $H(\mathrm{div}\,;\Omega)$ and stable curl/divergence-free extensions from the subdomain boundaries. Here, we have chosen to employ the results in [30], since we have in mind extensions to anisotropic meshes which are often needed for problems in conductor materials with high jumps in the conductivity. The work in [27, 28, 29] for scalar problems showed that when dealing with highly anisotropic meshes the analysis cannot employ trace norms or stable extensions, since the latter are not available in this case. The approach in [30], which does not rely on trace norms or stable extensions, but only on results for scalar problems (see Lemma 4.1 and its proof in section 5), appears more promising for edge element approximations on anisotropic meshes. This generalization is left to a future work.

We recall that effective multilevel strategies have also been developed for problems involving the curl-curl operator in three dimensions. We refer to, e.g., [1, 12, 22, 5].

This paper is organized as follows. In section 2, we introduce our discrete problems, the subdomain partition, and local and global finite element spaces. In section 3, we introduce our FETI-DP algorithms. Condition number bounds are given in section 4. First we give the technical tools necessary to prove them in subsection 4.1. These are the decomposition lemma, Lemma 4.1, and the abstract framework for the analysis of FETI-DP methods originally proposed in [15]. Our main result is the stability property in Lemma 4.6 in subsection 4.2. Lemma 4.1 is proven in [30] for h approximations, and we provide a proof for the case of p finite elements in section 5. A practical implementation of our algorithm is given in section 6 and some numerical results in section 7.

2. Discrete spaces. In this paper, we consider both h and p version finite elements. We discretize this problem using edge elements, which are also known as

Nédélec elements; see [20]. These are vector finite elements that ensure only the continuity of the tangential component across the elements, as is physically required for the electric and magnetic fields, solutions of Maxwell's equations. We refer to [19] for a general introduction of approximations of electromagnetic problems, the Sobolev space $H(\mathrm{curl}\,;\Omega)$, and edge elements.

2.1. Triangulations and subdomain partitions. We introduce a shape-regular triangulation $\mathcal{T} = \mathcal{T}_h$ of the domain Ω, made of affinely mapped quadrilaterals. In particular, if $\widehat{Q} = (-1,1)^2$ is a reference square, for each element $K \in \mathcal{T}$, there exists an affine mapping $F_K : \widehat{Q} \to K$, such that K is the image of $\widehat{Q}$. Here we consider only quadrilateral meshes for simplicity but note that our results are equally valid for h approximations on triangular meshes.

Let $\mathcal{E} = \mathcal{E}_h$ be the set of edges of $\mathcal{T}$. For every edge $e \in \mathcal{E}$, we fix a direction, given by a unit vector $\mathbf{t}_e$, tangent to e. The length of the edge e is denoted by $|e|$.

We next consider a nonoverlapping partition of the domain Ω,

$$\mathcal{F}_H = \left\{ \Omega_i \mid 1 \le i \le N,\ \bigcup_{i=1}^{N} \overline{\Omega_i} = \overline{\Omega} \right\},$$

such that each Ω_i is connected. The elements of $\mathcal{F}_H$ are called *subdomains* or *substructures*. For the h version, we take the substructures Ω_i as unions of fine elements. We denote the diameter of Ω_i by H_i and define H as the maximum of the diameters of the subdomains:

$$H := \max_{1 \le i \le N} \{H_i\}.$$

In this case $h < H$. For the p version we take $\mathcal{F}_H = \mathcal{T}_h$ and thus $H = h$.

We always assume that the substructures are images of a reference square under sufficiently regular maps, which effectively means that their aspect ratios remain uniformly bounded. In addition, we assume that the ratio of the diameters of two adjacent subregions is bounded away from zero and infinity. Further assumptions, necessary for the analysis but not for the definition of the algorithms, are made at the beginning of section 4.1.

We define the *edges* of the partition as the interior E_{ij} of the intersections

$$\overline{E}_{ij} := \partial\Omega_i \cap \partial\Omega_j, \quad i \ne j,\ |E_{ij}| > 0,$$

where $|E_{ij}|$ denotes the measure of E_{ij} and $\overline{E}_{ij}$ its closure. We note that $E_{ji} = E_{ij}$. We introduce a unit vector $\mathbf{t}_{E_{ij}}$ that is tangent to E_{ij}. Let $\mathcal{E}_H$ be the set of edges of $\mathcal{F}_H$, and let the interface Γ be the union of the edges of $\mathcal{F}_H$ or, equivalently, the parts of the subdomain boundaries that do not belong to $\partial\Omega$:

$$\Gamma := \bigcup_{i=1}^{N} \partial\Omega_i \setminus \partial\Omega.$$

For every subdomain Ω_i, let $\mathcal{I}_i$ be the set of indices j, such that E_{ij} is an edge of Ω_i:

$$\mathcal{I}_i := \{j \mid E_{ij} \subset \partial\Omega_i,\ E_{ij} \in \mathcal{E}_H\}.$$

Our assumptions on the partition $\mathcal{F}_H$ ensure that the the number of edges $|\mathcal{I}_i|$ is uniformly bounded.

We assume that the coefficients a and A are constant in each substructure Ω_i and denote them by a_i and A_i, respectively. We also assume that

$$0 < \beta_i |\mathbf{x}|^2 \leq \mathbf{x}^t A_i \mathbf{x} \leq \gamma_i |\mathbf{x}|^2, \quad \mathbf{x} \in \mathbb{R}^2, \tag{2.1}$$

for $i = 1, \ldots, N$, where $|\cdot|$ denotes the standard Euclidean norm.

2.2. Edge element functions. We next define the local spaces

$$\mathrm{H}_\star(\mathrm{curl}\,;\Omega_i) := \{\mathbf{u}_i \in \mathrm{H}(\mathrm{curl}\,;\Omega_i) \mid \mathbf{u}_i \cdot \mathbf{t} = 0 \text{ on } \partial\Omega \cap \partial\Omega_i\}$$

and the following polynomial spaces on the reference square for $k \geq 1$:

$$\mathcal{R}_k(\widehat{Q}) = \mathbb{Q}_{k-1,k}(\widehat{Q}) \otimes \mathbb{Q}_{k,k-1}(\widehat{Q}),$$

with $\mathbb{Q}_{k_1,k_2}(\widehat{Q})$ the space of polynomials of degree k_i in the ith variable. On an affinely mapped element $K \in \mathcal{T}$, we take

$$\mathcal{R}_k(K) = \{\mathbf{u} = J_{F_K}^{-T} \widehat{\mathbf{u}} \mid \widehat{\mathbf{u}} \in \mathcal{R}_k(\widehat{Q})\}, \tag{2.2}$$

with J_{F_K} the Jacobian of the transformation F_K. We note that the tangential component of a vector in $\mathcal{R}_k(K)$ is a function of $\mathbb{Q}_{k-1}$ over each edge of K.

For the h version, we employ the lowest-order Nédélec finite element spaces, originally introduced in [20], defined on each subdomain Ω_i:

$$X_i = X^h(\Omega_i) := \{\mathbf{u} \in \mathrm{H}_\star(\mathrm{curl}\,;\Omega_i) \mid \mathbf{u}_{|K} \in \mathcal{R}_1(K),\ K \in \mathcal{T}_h,\ K \subset \Omega_i\}.$$

Higher polynomial degrees can also be considered and our results and bounds will remain valid with constants that depend on the polynomial degree. See, e.g., [19] for more details. Functions in X_i have a constant tangential component over the fine edges in $\mathcal{E}$. The degrees of freedom for X_i are the constant values of the tangential component on the fine edges in $\mathcal{E}$ contained in $\overline{\Omega}_i$.

For the p version, we choose

$$X_i = X^k(\Omega_i) := \mathcal{R}_k(\Omega_i) \cap \mathrm{H}_\star(\mathrm{curl}\,;\Omega_i).$$

The basis functions can be associated to the (mapped) Gauss–Lobatto nodes on Ω_i, and the corresponding degrees of freedom are in this case the values at these nodes. Other basis functions are also possible, however. We refer to, e.g., [3, 11, 18, 7, 19] for more details on spectral and p finite element approximations of electromagnetic problems. The results in this paper for the p version are independent of the particular basis chosen.

We next consider the product space

$$X = X(\Omega) := \prod_{i=1}^{N} X_i \subset \prod_{i=1}^{N} \mathrm{H}_\star(\mathrm{curl}\,;\Omega_i),$$

which consists of vectors that have in general a discontinuous tangential component along the subdomain edges. The discrete solution is sought in the conforming space

$$\widehat{X} := X \cap \mathrm{H}_0(\mathrm{curl}\,;\Omega)$$

of vectors with a continuous tangential component along the edges in $\mathcal{E}_H$.

We now introduce some trace spaces consisting of tangential components on the boundaries of the substructures. A scalar function u, defined on $\partial\Omega_i \setminus \partial\Omega$, belongs to W_i if and only if there exists $\mathbf{u} \in X_i$ such that, for each edge,

$$u_{|_{E_{ij}}} = \mathbf{u} \cdot \mathbf{t}_{E_{ij}}, \quad E_{ij} \in \mathcal{E}_H,\ j \in \mathcal{I}(i).$$

For h approximations these are piecewise constant (or piecewise polynomial of degree $k-1$ if higher-order Nédélec elements are considered) along the edges E_{ij}. For p approximations they are polynomials of degree $k-1$ on each edge E_{ij}. We will employ the product space of functions defined on Γ, $W := \prod_i W_i$, and its continuous subspace $\widehat{W}$ consisting of tangential traces of vectors in $\widehat{X}$.

The scalar functions in the spaces W_i and W are uniquely defined by the degrees of freedom of the spaces X_i and X involving the tangential components along edges in $\mathcal{E}_H$. Throughout this paper, we will use the following notation: we denote a generic vector function in X_i using a bold letter with the superscript (i), e.g., $\mathbf{u}^{(i)}$, and employ the same notation for the corresponding column vector of degrees of freedom. Its tangential component $u^{(i)}$ is an element of W_i and is defined by

$$u^{(i)}{}_{|_{E_{ij}}} := \mathbf{u}^{(i)} \cdot \mathbf{t}_{E_{ij}}, \quad E_{ij} \in \mathcal{E}_H,\ j \in \mathcal{I}(i).$$

It is uniquely determined by the degrees of freedom $\mathbf{u}^{(i)}$ involving the tangential component along $\partial\Omega_i \setminus \partial\Omega$. We use the same notation $u^{(i)}$ for the column vector of these tangential degrees of freedom and the same notation for the spaces of functions X_i and W_i and for the corresponding spaces of degrees of freedom. We use similar notation for global functions in X and W.

We remark that a vector $\mathbf{u}$ belongs to the continuous space $\widehat{X}$ (and consequently its tangential component to $\widehat{W}$) if

$$u^{(i)}{}_{|_{E_{ij}}} = u^{(j)}{}_{|_{E_{ij}}}, \quad E_{ij} \in \mathcal{E}_H. \tag{2.3}$$

Finally, for $i = 1, \ldots, N$, we define the extensions into the interior of the Ω_i,

$$\mathcal{H}_i : W_i \longrightarrow X_i,$$

that are discrete harmonic with respect to the bilinear forms $a_{\Omega_i}(\cdot,\cdot)$. We recall that $\mathbf{u}^{(i)} = \mathcal{H}_i u^{(i)}$ minimizes the energy $a_{\Omega_i}(\mathbf{u}^{(i)}, \mathbf{u}^{(i)})$ among all the vectors of X_i with tangential component equal to $u^{(i)}$ on $\partial\Omega_i \setminus \partial\Omega$. We will refer to $\mathcal{H}_i$ as the *Maxwell* discrete harmonic extension.

2.3. Continuous finite element spaces. In the following we will also need the standard finite element spaces of scalar, continuous, piecewise polynomial functions. With

$$\mathrm{H}^1_\star(\Omega_i) := \{\phi \in \mathrm{H}^1(\Omega_i) \mid \phi = 0 \text{ on } \partial\Omega \cap \partial\Omega_i\},$$

we define, for the h version, the space of continuous piecewise bilinear functions

$$Q_i = Q^h(\Omega_i) := \{\phi \in \mathrm{H}^1_\star(\Omega_i)\ \phi \in \mathbb{Q}_{1,1}(K),\ K \in \mathcal{T}_h,\ K \subset \Omega_i\}.$$

For the p version, we employ

$$Q_i = Q^k(\Omega_i) := \mathbb{Q}_{k,k}(\Omega_i) \cap \mathrm{H}^1_\star(\Omega_i).$$

We note that in both cases $\operatorname{grad} Q_i \subset X_i$.

Discrete harmonic functions in Q_i will be referred to as *Laplace* discrete harmonic in the following.

3. FETI-DP methods. In this section, we introduce a FETI-DP method for the solution of the linear system arising from the edge element discretization of problem (1.3). In section 6, we give a practical implementation of the algorithm. Throughout the paper, we denote the Euclidean scalar product in l^2 by $\langle \cdot, \cdot \rangle$. We recall that FETI-DP methods were originally introduced in [8]. The first theoretical result was given in [17] for two-dimensional problems and then later in [15] for three dimensions. Some theoretical results for linear elasticity can be found in [14].

We first assemble the local stiffness matrices, relative to the bilinear forms $a_{\Omega_i}(\cdot, \cdot)$, and the local load vectors. The degrees of freedom that belong only to one substructure can be eliminated in parallel by block Gaussian elimination. We note that these are degrees of freedom associated to edges or nodes in the interior of the substructures, on $\partial\Omega$, and, in case polynomial spaces with $k > 0$ are employed, they also consist of values of the normal component on the subdomain boundaries. We are then left with the degrees of freedom involving the *tangential* component along the substructure boundaries. Let $f^{(i)}$ be the resulting right-hand sides and $S^{(i)}$ the Schur complement matrices

$$S^{(i)} : W_i \longrightarrow W_i,$$

relative to the tangential degrees of freedom on $\partial\Omega_i \setminus \partial\Omega$.

We recall that the local Schur complements satisfy the property

$$|u^{(i)}|^2_{S^{(i)}} := \langle u^{(i)}, S^{(i)} u^{(i)} \rangle = a_{\Omega_i}(\mathcal{H}_i u^{(i)}, \mathcal{H}_i u^{(i)}); \tag{3.1}$$

see, e.g., [23, 24]. Since the local bilinear forms are positive definite, so are the local Schur complements $S^{(i)}$.

We write

$$u := \begin{bmatrix} u^{(1)} \\ \vdots \\ u^{(N)} \end{bmatrix} \in W, \qquad S := \operatorname{diag}\{S^{(1)}, \ldots, S^{(N)}\}, \qquad f := \begin{bmatrix} f^{(1)} \\ \vdots \\ f^{(N)} \end{bmatrix}.$$

The solution $u \in W$ to the discrete problem can then be found by minimizing the energy

$$\frac{1}{2}\langle u, Su \rangle - \langle f, u \rangle$$

subject to the constraint that u is continuous, i.e., it belongs to $\widehat{W}$.

For FETI-DP methods we work in a subspace $\widetilde{W} \subset W$ of functions satisfying a certain number of continuity constraints. We have

$$\widetilde{W} = \widehat{W}_\Pi \oplus \widetilde{W}_\Delta.$$

Here the primal space $\widehat{W}_\Pi \subset \widehat{W}$ consists of continuous functions determined by degrees of freedom associated to the substructures. We choose a space of constant functions on the subdomain edges.

$$\widehat{W}_\Pi = \widehat{W}^H := \{u \in \widehat{W} \mid u_{|_{E_{ij}}} \in \mathbb{Q}_0,\ E_{ij} \in \mathcal{E}_H\}. \tag{3.2}$$

The degrees of freedom (*primal variables*) associated to this space are the averages of tangential components over the subdomain edges:

$$\bar{u}_{E_{ij}} = \frac{\int_{E_{ij}} u\, ds}{|E_{ij}|} = \frac{\int_{E_{ij}} \mathbf{u}\cdot\mathbf{t}_{E_{ij}}\, ds}{|E_{ij}|}.$$

These are the same degrees of freedom associated to a standard coarse space in case the substructures are elements of a coarse mesh; see [30, 24] and section 4.1.

The dual space $\widetilde{W}_\Delta$ is the product space of spaces associated to the substructures

$$\widetilde{W}_\Delta := \prod_{i=1}^{N} \widetilde{W}_{\Delta,i}$$

of functions for which the functional given by the primal variables vanish:

$$\widetilde{W}_{\Delta,i} := \{u \in W_i \mid \bar{u}_{E_{ij}} = 0,\ j \in \mathcal{I}(i)\}.$$

Therefore, $\widetilde{W}$ consists of functions that have a continuous average along the substructure edges; i.e., the averages are the same regardless of which substructure is considered for the calculation.

The primal degrees of freedom can then be eliminated together with the internal ones, at the expense of solving one coarse problem. We are then left with a problem involving interface functions with vanishing mean value along the substructure edges and, consequently, in the dual space, $\widetilde{W}_\Delta$. Let $\widetilde{S} : \widetilde{W}_\Delta \to \widetilde{W}_\Delta$ be the corresponding Schur complement and $\widetilde{f}_\Delta$ the corresponding load vector. We then look for $u_\Delta \in \widetilde{W}_\Delta$, such that

$$\frac{1}{2}\langle u_\Delta, \widetilde{S}u_\Delta\rangle - \langle \widetilde{f}_\Delta, u_\Delta\rangle \longrightarrow \min$$

subject to the constraint that u_Δ is continuous. The continuity constraint is expressed by the equation

$$B_\Delta u_\Delta = 0,$$

where B_Δ is constructed from $\{0, 1, -1\}$ and evaluates the difference between all the corresponding tangential degrees of freedom on Γ; cf. (2.3). We employ the same matrix as in our previous paper [26] and then enforce redundant conditions. The matrix B_Δ has the following block structure:

$$B_\Delta = [B_\Delta^{(1)} \quad B_\Delta^{(2)} \quad \cdots \quad B_\Delta^{(N)}],$$

where each block corresponds to a substructure.

We obtain the saddle point problem

$$\begin{aligned} \widetilde{S}u_\Delta + B_\Delta^T\lambda &= \widetilde{f}_\Delta, \\ B_\Delta u_\Delta &= 0, \end{aligned} \tag{3.3}$$

with $u_\Delta \in \widetilde{W}_\Delta$ and $\lambda \in V := \mathrm{Range}(B_\Delta)$.

We note that $\widetilde{S}$ can be obtained from the restriction of S to the space $\widetilde{W}$, by eliminating the primal degrees of freedom. We have therefore the minimization property

$$\langle u_\Delta, \widetilde{S}u_\Delta\rangle = \min\langle u, Su\rangle, \tag{3.4}$$

where the minimum is taken over all the functions $u = u_\Delta + w_\Pi$, $w_\Pi \in \widehat{W}_\Pi$. This property ensures that $\widetilde{S}$ is also positive definite.

Since the Schur complement $\widetilde{S}$ is invertible, an equation for λ can easily be found:

$$F\lambda = d, \tag{3.5}$$

with

$$F := B_\Delta \widetilde{S}^{-1} B_\Delta^T, \qquad d := B_\Delta \widetilde{S}^{-1} \widetilde{f}_\Delta. \tag{3.6}$$

In section 6, we provide explicit formulas for F and d. Once λ is found, the primal variables are given by

$$u_\Delta = \widetilde{S}^{-1}(\widetilde{f}_\Delta - B_\Delta^T \lambda) \in \widetilde{W}_\Delta.$$

In order to define a preconditioner for (3.5), we need to define scaling matrices and functions defined on the subdomain boundaries. As in our previous work they are constructed with the coefficient A only. For each substructure, we define $\delta_i^\dagger \in W_i$, such that on the edge E_{ij}, $j \in \mathcal{I}(i)$,

$$\delta_i^\dagger = \frac{\gamma_i^\chi}{\gamma_i^\chi + \gamma_j^\chi} \tag{3.7}$$

for an arbitrary but fixed $\chi \in [1/2, +\infty)$; see (2.1). By direct calculation, we find

$$\gamma_i {\delta_j^\dagger}^2 \leq \min(\gamma_i, \gamma_j). \tag{3.8}$$

For each substructure Ω_i, we next introduce a diagonal matrix $D_\Delta^{(i)} : V \to V$. The diagonal entry corresponding to the Lagrange multipliers that enforce the continuity along an edge E_{ij} is set equal to the (constant) value of $\delta_j^\dagger$ along E_{ji}

$$\delta_{ji}^\dagger := \delta_{j|_{E_{ji}}}^\dagger = \frac{\gamma_j^\chi}{\gamma_i^\chi + \gamma_j^\chi}.$$

We next define the scaled matrix

$$B_{D,\Delta} = [D_\Delta^{(1)} B_\Delta^{(1)} \quad D_\Delta^{(2)} B_\Delta^{(2)} \ \cdots \ D_\Delta^{(N)} B_\Delta^{(N)}] : \widetilde{W}_\Delta \to V.$$

We solve the dual system (3.5) using the preconditioned CG algorithm with the preconditioner

$$M^{-1} := B_{D,\Delta} S B_{D,\Delta}^T = \sum_{i=1}^N D_\Delta^{(i)} B_\Delta^{(i)} S^{(i)} B_\Delta^{(i)T} D_\Delta^{(i)}; \tag{3.9}$$

see [8, 17, 15].

4. Condition number bounds.

4.1. Technical tools. The analysis of the FETI-DP methods presented here relies on a decomposition result. We first need to introduce coarse spaces on the

subdomains. As is often customary in the analysis of iterative substructuring methods, we require that the substructures are elements of a shape-regular coarse mesh $\mathcal{T}_H$. This is always the case for p finite elements. We next define

$$X^H(\Omega_i) := \mathcal{R}_1(\Omega_i), \tag{4.1}$$

the lowest-order edge element space on the coarse element Ω_i; see (2.2). We note that the tangential traces of vectors in $X^H(\Omega_i)$ are restrictions of functions in the space $\widehat{W}^H$, defined in (3.2), to the boundary of Ω_i.

The following result can be found in [30, Lem. 4.2] for h approximations. The proof for the p finite element case is given in section 5. We need the scaled norm

$$\|\mathbf{u}\|^2_{\mathrm{curl},\Omega_i} := \|\mathbf{u}\|^2_{L^2(\Omega_i)} + H_i^2\|\mathrm{curl}\,\mathbf{u}\|^2_{L^2(\Omega_i)}, \quad \mathbf{u} \in X_i.$$

LEMMA 4.1. *Let Ω_i be a substructure. Then, for every $\mathbf{u} \in X_i$ there exists a unique decomposition*

$$\mathbf{u} = \mathbf{u}_H + \sum_{j\in\mathcal{I}(i)} \mathbf{u}_{ij} + \mathbf{u}^{int} \tag{4.2}$$

such that the following hold:

1. *$\mathbf{u}_H$ is a coarse function in $X^H(\Omega_i)$;*
2. *$\mathbf{u}_{ij} = \nabla\phi_{ij}$, with $\phi_{ij} \in Q_i$, is a Laplace discrete harmonic function that vanishes on $\partial\Omega_i \setminus E_{ij}$;*
3. *$\mathbf{u}^{int}$ has a vanishing tangential component on $\partial\Omega_i$.*

In addition, for $j \in \mathcal{I}(i)$,

$$\int_{E_{ij}} (\mathbf{u} - \mathbf{u}_H)\cdot\mathbf{t}_{E_{ij}}\,ds = \int_{E_{ij}} \nabla\phi_{ij}\cdot\mathbf{t}_{E_{ij}}\,ds = 0, \tag{4.3}$$

and

$$\|\nabla\phi_{ij}\|^2_{L^2(\Omega_i)} \le C\omega^2\|\mathbf{u}\|^2_{\mathrm{curl},\Omega_i}, \tag{4.4}$$

with $\omega = (1+\log(H/h))$ for h approximations and $\omega = (1+\log k)$ for p approximations.

We note that bounds for the components $\mathbf{u}_H$ and $\mathbf{u}^{int}$ can also be found, but they will not be necessary for the analysis in this paper.

The following result is a straightforward application of the existence of a stable finite element extension and of a trace theorem; see, in particular, [2] for the p version.

LEMMA 4.2. *Let Ω_i and Ω_j be two substructures that share an edge E_{ij}. Let $\phi^{(i)} \in Q_i$ and $\phi^{(j)} \in Q_j$ be two Laplace discrete harmonic functions that have a common trace on E_{ij} and vanish on $\partial\Omega_i \setminus E_{ij}$ and $\partial\Omega_j \setminus E_{ij}$, respectively. Then there exists a constant C, independent of h, k, H_i, and H_j, such that*

$$\|\nabla\phi^{(j)}\|^2_{L^2(\Omega_j)} \le C\|\nabla\phi^{(i)}\|^2_{L^2(\Omega_i)}.$$

We now recall an abstract framework for the analysis of FETI-DP algorithms, which was originally given in [15]. It turns out that condition number bounds rely on one stability estimate for the following jump operator:

$$P_\Delta := B^T_{D,\Delta}B_\Delta : \widetilde{W} \longrightarrow \widetilde{W}.$$

We summarize the properties of P_Δ proven in [15, sect. 6] in the following lemma.

LEMMA 4.3. *The operator P_Δ is a projection and preserves the jump of any function $w \in \widetilde{W}$, i.e.,*

$$B_\Delta P_\Delta w = B_\Delta w.$$

If $v := P_\Delta w$ for $w \in \widetilde{W}$, then on every edge E_{ij} of a substructure Ω_i, we have

$$v^{(i)} = \delta_j^\dagger (w^{(i)} - w^{(j)}). \tag{4.5}$$

Finally, $P_\Delta w = 0$ if $w \in \widehat{W}$.

The following fundamental result can be found in [15, Th. 1]. It employs the norms

$$|v|_S^2 := \langle v, Sv\rangle = \sum_{i=1}^N \langle v^{(i)}, S^{(i)} v^{(i)}\rangle, \quad |v|_{\widetilde{S}}^2 := \langle v, \widetilde{S} v\rangle. \tag{4.6}$$

THEOREM 4.4. *Let C_{P_Δ} be such that*

$$|P_\Delta w_\Delta|_S^2 \le C_{P_\Delta} |w_\Delta|_{\widetilde{S}}^2, \quad w_\Delta \in \widetilde{W}_\Delta. \tag{4.7}$$

Then, if $\widetilde{S}$ and M^{-1} are invertible,

$$\langle M\lambda, \lambda\rangle \le \langle F\lambda, \lambda\rangle \le C_{P_\Delta} \langle M\lambda, \lambda\rangle, \quad \lambda \in V. \tag{4.8}$$

4.2. Main results. We now present two lemmas. The first one is trivial for our approximations and ensures that the Schur complement $\widetilde{S}$ and the preconditioner M^{-1} are invertible. The second provides a key stability estimate in order to bound the largest eigenvalue of the preconditioned operator $M^{-1}F$. Our main result is given in Theorem 4.7.

LEMMA 4.5. *The Schur complement $\widetilde{S}$ and the preconditioner M^{-1} are invertible.*

Proof. The result for $\widetilde{S}$ is an immediate consequence of the fact that the local bilinear forms $a_{\Omega_i}(\cdot,\cdot)$ are positive definite. Indeed the Schur complement S is invertible and so is $\widetilde{S}$ thanks to (3.4).

In order to prove the invertibility of M^{-1}, we assume that there is a $\lambda = B_\Delta w_\Delta$, $w_\Delta \in \widetilde{W}$, such that

$$0 = M^{-1}\lambda = B_{D,\Delta} S B_{D,\Delta}^T B_\Delta w_\Delta.$$

This implies

$$0 = \langle \lambda, M^{-1}\lambda\rangle = |P_\Delta w_\Delta|_S^2.$$

Since the local Schur complements $S^{(i)}$ are invertible, this implies $P_\Delta w_\Delta = 0$. Lemma 4.3 then implies

$$\lambda = B_\Delta w_\Delta = B_\Delta P_\Delta w_\Delta = 0. \qquad \square$$

LEMMA 4.6. *There is a constant C, such that, for $w_\Delta \in \widetilde{W}_\Delta$,*

$$|P_\Delta w_\Delta|_S^2 \le C\, \eta\, \omega^2\, |w_\Delta|_{\widetilde{S}}^2,$$

where ω is the same as in Lemma 4.1 *and*

$$\eta := \max_{1\le i\le N} \frac{\gamma_i}{\beta_i}\left(1+\frac{H_i^2\beta_i}{a_i}\right).$$

Proof. Using the minimization property in (3.4), we consider the element $w = w_\Delta + w_\Pi$, $w_\Pi \in \widehat{W}_\Pi$, such that

$$|w_\Delta|_{\tilde{S}}^2 = |w|_S^2. \tag{4.9}$$

We note that, since w_Π is continuous,

$$v := P_\Delta w_\Delta = P_\Delta w.$$

We then need to calculate

$$|P_\Delta w|_S^2 = \sum_{i=1}^N |v^{(i)}|_{S^{(i)}}^2 = \sum_{i=1}^N a_{\Omega_i}(\mathcal{H}_i v^{(i)}, \mathcal{H}_i v^{(i)}).$$

On an edge E_{ij} of a substructure Ω_i, we employ the representation in (4.5). We recall that the function $\delta_j^\dagger$ is constant along an edge E_{ij} and $\delta_{ji}^\dagger$ is this value. We then decompose $v^{(i)}$ into contributions supported on single edges:

$$v^{(i)} = \sum_{j\in\mathcal{I}(i)} \theta_{E_{ij}}\delta_{ji}^\dagger(w^{(i)} - w^{(j)}), \tag{4.10}$$

where $\theta_{E_{ij}} \in W_i$ is identically one on E_{ij} and vanishes on $\partial\Omega_i \setminus E_{ij}$. We consider each contribution in this sum separately. Since, in addition, w is an element of $\widetilde{W}$, its average $\bar{w}_{E_{ij}}$ is the same whether it is calculated using $w^{(i)}$ or $w^{(j)}$. We can therefore write

$$\theta_{E_{ij}}\delta_{ji}^\dagger(w^{(i)} - w^{(j)}) = \theta_{E_{ij}}\delta_{ji}^\dagger(w^{(i)} - \bar{w}_{E_{ij}}) - \theta_{E_{ij}}\delta_{ji}^\dagger(w^{(j)} - \bar{w}_{E_{ij}}). \tag{4.11}$$

We consider the two terms in (4.11) separately.

In order to bound the first, we employ the decomposition in Lemma 4.1 for the vector $\mathbf{u} := \mathcal{H}_i w^{(i)}$. We recall that the tangential component of $\mathbf{u}_{ij} = \nabla\phi_{ij}$ vanishes on $\partial\Omega_i \setminus E_{ij}$ and, thanks to (4.3), it is equal to $\theta_{E_{ij}}(w^{(i)} - \bar{w}_{E_{ij}})$. Using (3.8), the minimizing property of the Maxwell discrete harmonic extension in (3.1), (2.1), and (4.4), we find

$$\begin{aligned} |\theta_{E_{ij}}\delta_{ji}^\dagger(w^{(i)} - \bar{w}_{E_{ij}})|_{S^{(i)}}^2 &\le \gamma_i \|\nabla\phi_{ij}\|_{L^2(\Omega_i)}^2 \\ &\le C\gamma_i\omega^2(\|\mathbf{u}\|_{L^2(\Omega_i)}^2 + H_i^2\|\operatorname{curl}\mathbf{u}\|_{L^2(\Omega_i)}^2) \\ &\le C\,\eta\,\omega^2\,a_{\Omega_i}(\mathcal{H}_i w^{(i)}, \mathcal{H}_i w^{(i)}) = C\,\eta\,\omega^2\,|w^{(i)}|_{S^{(i)}}^2. \end{aligned} \tag{4.12}$$

We then consider the second term in (4.11). The vector

$$\mathbf{u}^{(i)} := \mathcal{H}_i(\theta_{E_{ij}}(w^{(j)} - \bar{w}_{E_{ij}}))$$

can be decomposed according to Lemma 4.1, into the sum of two contributions $\mathbf{u}_{ij} = \nabla\phi_{ij}$ and $\mathbf{u}^{int}$. We next apply Lemma 4.1 to the function $\mathcal{H}_j w^{(j)}$ and obtain

$$\mathbf{u}^{(j)} := \mathcal{H}_j w^{(j)} = \mathbf{u}_H + \sum_{k\in\mathcal{I}(j)} \mathbf{u}_{jk} + \widetilde{\mathbf{u}}^{int}.$$

We note that the functions $\mathbf{u}_{ji} = \nabla\phi_{ji}$ and $\mathbf{u}_{ij} = \nabla\phi_{ij}$ have the same tangential component along the common edge E_{ij}, which is equal to $\theta_{E_{ij}}(w^{(j)} - \bar{w}_{E_{ij}})$. Using (3.8), the minimizing property of the Maxwell discrete harmonic extension, Lemma 4.2, (2.1), and (4.4), we find

$$
\begin{aligned}
|\theta_{E_{ij}}\delta_{ji}^{\dagger}(w^{(j)} - \bar{w}_{E_{ij}})|_{S^{(i)}}^2 &\leq \gamma_j \|\nabla\phi_{ij}\|_{L^2(\Omega_i)}^2 \\
&\leq C\gamma_j \|\nabla\phi_{ji}\|_{L^2(\Omega_j)}^2 \\
&\leq C\gamma_j\omega^2(\|\mathbf{u}^{(j)}\|_{L^2(\Omega_j)}^2 + H_j^2\|\operatorname{curl}\mathbf{u}^{(j)}\|_{L^2(\Omega_j)}^2) \\
&\leq C\,\eta\,\omega^2\, a_{\Omega_j}(\mathcal{H}_j w^{(j)}, \mathcal{H}_j w^{(j)}) = C\,\eta\,\omega^2\,|w^{(j)}|_{S^{(j)}}^2.
\end{aligned}
\tag{4.13}
$$

Combining (4.10), (4.12), and (4.13) and summing over the edges E_{ij}, we finally find

$$
|v^{(i)}|_{S^{(i)}}^2 \leq C\,\eta\,\omega^2\,|w^{(i)}|_{S^{(i)}}^2 + C\,\eta\,\omega^2 \sum_{j\in\mathcal{I}(i)} |w^{(j)}|_{S^{(j)}}^2.
$$

The proof is then concluded by summing over the substructures Ω_i and using (4.9). ∎

By combining Lemmas 4.6 and 4.5 and Theorem 4.4, we obtain our final result.

THEOREM 4.7. *The condition number of the preconditioned system $M^{-1}F$ satisfies*

$$
\kappa(M^{-1}F) \leq C\,\eta\,(1 + \log(H/h))^2
$$

for h finite element approximations and

$$
\kappa(M^{-1}F) \leq C\,\eta\,(1 + \log k)^2
$$

for p finite elements. Here, η is defined in Lemma 4.6.

5. Proof of Lemma 4.1. As already mentioned, the proof of Lemma 4.1 for the case of finite elements is given in [30, Lemma 4.2]. In this section we provide a proof for the case of p finite elements. The proof follows that of [30, Lemma 4.2] and is given here for completeness. It employs suitable orthogonal decomposition of edge element functions into gradients of scalar functions and *discrete curl free* functions.

Let $X_i^0 \subset X^k(\Omega_i)$ be the subspace of vectors with vanishing tangential component of $\partial\Omega_i$. If $Q_i^0 \subset Q_i$ is the subspace of functions that vanish on $\partial\Omega_i$, then $\operatorname{grad} Q_i^0 \subset X_i^0$ and the following orthogonal decomposition is well defined:

$$
X_i^0 = \operatorname{grad} Q_i^0 \oplus X_i^{0,\perp}. \tag{5.1}
$$

Proofs of the following fundamental result for a substructure of unit diameter can be found in [10, Th. 7.18] and in [18, sect. 4]. The case of a subdomain of diameter H_i can be treated by a scaling argument. We recall that its proof employs an interpolation operator on the edge element space.

LEMMA 5.1. *Let $\mathbf{u} \in X_i^{0,\perp}$. Then there is a constant, independent of H_i and k, such that*

$$
\|\mathbf{u}\|_{L^2(\Omega_i)} \leq C H_i \|\operatorname{curl}\mathbf{u}\|_{L^2(\Omega_i)}.
$$

We also need a decomposition result for polynomial functions. It is a classical result that is available in the literature in various forms. Since we did not find it in

exactly the form that we need, we have included a proof which employs the tools in [2] in order to help the reader.

LEMMA 5.2. *Let $\psi_H \in \mathbb{Q}_{1,1}(\Omega_i)$ and, for $j \in \mathcal{I}(i)$, let $\psi_{ij} \in Q^k(\Omega_i)$ be a Laplace discrete harmonic function that vanishes on $\partial\Omega_i \setminus E_{ij}$. If*

$$\psi := \psi_H + \sum_{j\in\mathcal{I}(i)} \psi_{ij},$$

then

$$|\psi_{ij}|^2_{H^1(\Omega_i)} \leq C(1+\log k)^2 |\psi|^2_{H^1(\Omega_i)},$$

with a constant that is independent of k and H_i.

Proof. We consider the case of a substructure of unit diameter. The more general case $H_i < 1$ can be treated by a scaling argument. The function ψ_{ij} belongs to $H^{1/2}_{00}(E_{ij})$, the subspace of $H^{1/2}(\partial\Omega)$ of functions that vanish on $\partial\Omega_i \setminus E_{ij}$; see, e.g., [2, sect. 2] for the definition of these spaces and the corresponding norms. Using the stable extension in [2, Th. 7.5], we find

$$|\psi_{ij}|^2_{H^1(\Omega_i)} \leq C\|\psi_{ij}\|^2_{H^{1/2}(\partial\Omega_i)} \leq C\|\psi_{ij}\|^2_{H^{1/2}_{00}(E_{ij})},$$

and, using [2, Th. 6.6],

$$\|\psi_{ij}\|^2_{H^{1/2}_{00}(E_{ij})} \leq \|\psi_{ij}\|^2_{H^{1/2}(E_{ij})} + C(1+\log k)\|\psi_{ij}\|^2_{L^\infty(E_{ij})}.$$

Combining these two inequalities yields

$$|\psi_{ij}|^2_{H^1(\Omega_i)} \leq C(1+\log k)\|\psi-\psi_H\|^2_{L^\infty(E_{ij})} + \|\psi-\psi_H\|^2_{H^{1/2}(E_{ij})}. \tag{5.2}$$

We note that ψ_H is the nodal interpolant of ψ on the linear space $\mathbb{Q}_{1,1}$, and therefore the inverse inequality in [2, Th. 6.2] can be employed. We obtain

$$(1+\log k)\|\psi-\psi_H\|^2_{L^\infty(E_{ij})} \leq C(1+\log k)^2\|\psi\|^2_{H^{1/2}(E_{ij})} \tag{5.3}$$

and

$$\|\psi-\psi_H\|^2_{H^{1/2}(E_{ij})} \leq C(1+\log k)\|\psi\|^2_{H^{1/2}(E_{ij})}. \tag{5.4}$$

Combining (5.2), (5.3), (5.4), and a trace estimate, we find

$$|\psi_{ij}|^2_{H^1(\Omega_i)} \leq C(1+\log k)^2\|\psi\|^2_{H^1(\Omega_i)}.$$

We note that if we add a constant to ψ, the left-hand side does not change. A quotient space argument then allows us to replace the full norm with the seminorm on the left-hand side. ∎

We recall that the coarse space $X^H(\Omega_i)$ was defined in (4.1). We now introduce the coarse interpolant

$$\rho_H : X^k(\Omega_i) \longrightarrow X^H(\Omega_i).$$

Here, $\rho_H\mathbf{u}$ is the unique vector that satisfies

$$\int_{E_{ij}} (\rho_H\mathbf{u}-\mathbf{u})\cdot\mathbf{t}_{E_{ij}}\,ds = 0, \quad j \in \mathcal{I}(i). \tag{5.5}$$

We also define $X_{ij} \subset X^k(\Omega_i)$ as the space of functions $\nabla\phi_{ij}$, where $\phi_{ij} \in Q^k(\Omega_i)$ is Laplace discrete harmonic and vanishes on $\partial\Omega_i \setminus E_{ij}$.

We are now ready to give a proof of Lemma 4.1. It is immediate to see that, for the substructure Ω_i and for $j \in \mathcal{I}(i)$, $l \in \mathcal{I}(i)$, $j \neq l$,

$$X^H(\Omega_i) \cap X_i^0 = X^H(\Omega_i) \cap X_{ij} = X_{ij} \cap X_i^0 = X_{ij} \cap X_{il} = \{0\}.$$

Counting the degrees of freedom, we see that

$$X^k(\Omega_i) = X^H(\Omega_i) \oplus \sum_{j \in \mathcal{I}(i)} X_{ij} \oplus X_i^0 \tag{5.6}$$

is a direct sum. We have therefore proved the existence and the uniqueness of the decomposition (4.2).

The first equality in (4.3) is a consequence of the fact that the tangential component of $\mathbf{u}_i := \mathbf{u}^{int}$ and of $\mathbf{u}_{il}$ for $l \neq j$ vanishes on the edge E_{ij}. The second one comes from the fact that ϕ_{ij} vanishes at the endpoints of E_{ij}.

We are then left with the proof of the stability property (4.4). Since the decomposition is unique, thanks to (5.5), we find $\mathbf{u}_H = \rho_H \mathbf{u}$. We now decompose each term into a gradient of a scalar function and a remainder. Since the coarse space $X^H(\Omega_i)$ is $\mathcal{R}_1(\Omega_i)$, we can write

$$\mathbf{u}_H = \nabla\phi_H + \alpha \begin{bmatrix} y - y_i \\ x_i - x \end{bmatrix} =: \nabla\phi_H + \mathbf{u}_H^\perp,$$

with $\phi_H \in \mathbb{Q}_{1,1}$ bilinear and (x_i, y_i) the center of gravity of Ω_i. By direct calculation, we find that this is an L^2 orthogonal decomposition and that

$$\|\mathbf{u}_H^\perp\|_{L^2(\Omega_i)} \leq C H_i \|\mathrm{curl}\, \mathbf{u}_H^\perp\|_{L^2(\Omega_i)}. \tag{5.7}$$

For the term $\mathbf{u}_i := \mathbf{u}^{int} \in X_i^0$, we employ the orthogonal decomposition in (5.1) and find

$$\mathbf{u}_i = \nabla\phi_i + \mathbf{u}_i^\perp.$$

Finally, by definition, $\mathbf{u}_{ij} = \nabla\phi_{ij}$ for each edge E_{ij}. We then group the gradient terms and the remainders and set

$$\phi := \phi_H + \sum_{j \in \mathcal{I}(i)} \phi_{ij} + \phi_i, \qquad \mathbf{u}^\perp := \mathbf{u}_H^\perp + \mathbf{u}_i^\perp.$$

We have therefore the decomposition

$$\mathbf{u} = \nabla\phi + \mathbf{u}^\perp. \tag{5.8}$$

We need to bound the $\nabla\phi_{ij}$ in terms of $\mathbf{u}$. Since ϕ_H and the $\{\phi_{il}\}$ are Laplace discrete harmonic, we can apply Lemma 5.2 and find

$$|\phi_{ij}|^2_{H^1(\Omega_i)} \leq C(1 + \log k)^2 \left| \phi_H + \sum_{l \in \mathcal{I}(i)} \phi_{il} \right|^2_{H^1(\Omega_i)} \leq C(1 + \log k)^2 |\phi|^2_{H^1(\Omega_i)}. \tag{5.9}$$

For the last step we also have used that fact that ϕ_i vanishes on $\partial\Omega_i$ and is thus orthogonal to Laplace discrete harmonic functions.

The last step is to bound $\nabla\phi$ in terms of $\mathbf{u}$. We first note that, using (5.7) and Lemma 5.1, we obtain

$$\|\mathbf{u}^{\perp}\|^2_{L^2(\Omega_i)} \leq CH_i^2(\|\operatorname{curl}\mathbf{u}_H^{\perp}\|^2_{L^2(\Omega_i)} + \|\operatorname{curl}\mathbf{u}_i^{\perp}\|^2_{L^2(\Omega_i)}).$$

Since $\operatorname{curl}\mathbf{u}_H^{\perp}$ is constant and $\operatorname{curl}\mathbf{u}_i^{\perp}$ has a vanishing mean value on Ω_i, these two functions are L^2 orthogonal and thus

$$\|\mathbf{u}^{\perp}\|^2_{L^2(\Omega_i)} \leq C_{\perp}H_i^2\|\operatorname{curl}\mathbf{u}^{\perp}\|^2_{L^2(\Omega_i)}. \tag{5.10}$$

Using (5.8), (5.10), and Young's inequality, we find

$$\begin{aligned}\|\mathbf{u}\|^2_{\operatorname{curl},\Omega_i} &= |\phi|^2_{H^1(\Omega_i)} + \|\mathbf{u}^{\perp}\|^2_{\operatorname{curl},\Omega_i} + 2\int_{\Omega_i}\nabla\phi\cdot\mathbf{u}^{\perp}\,dx \\ &\geq (1-\epsilon)|\phi|^2_{H^1(\Omega_i)} + (1+(1-\epsilon^{-1})C_{\perp})H_i^2\|\operatorname{curl}\mathbf{u}^{\perp}\|^2_{L^2(\Omega_i)}\end{aligned} \tag{5.11}$$

for $\epsilon\in(0,1)$. The choice $\epsilon = C_{\perp}/(C_{\perp}+1)$ ensures

$$|\phi|^2_{H^1(\Omega_i)} \leq (C_{\perp}+1)\|\mathbf{u}\|^2_{\operatorname{curl},\Omega_i},$$

which, combined with (5.9), concludes the proof.

6. Implementation aspects. In this section, we describe how we can efficiently implement the preconditioned algorithm described in this paper. Indeed, we need to construct the matrix F, the vector d (see (3.5) and (3.6)), and the preconditioner M^{-1} in (3.9).

In principle, a change of basis should be performed and the degrees of freedom partitioned into I (interior to the substructures), Π (common averages along the subdomain edges), and Δ. However, such change of basis is not trivial or advisable. Since the basis functions associated to the Δ block are not local in general, this would spoil the sparsity of certain matrices. In practice we will work with full vectors in the original product space consisting of all the degrees of freedom on Γ, satisfying no continuity constraint. We will then make sure that these degrees of freedom belong to the dual space $\widetilde{W}_{\Delta}$; i.e., the averages along all the subdomain edges vanish. For this reason, as already pointed out in section 3, the matrix $B_{\Delta} = B$ is the same as that of the one-level FETI method in [26]; it is constructed from $\{0,1,-1\}$ and evaluates the difference between all the corresponding tangential degrees of freedom on Γ.

We then consider an initial vector of Lagrange multipliers λ_0. We note that since we work with the matrix B which acts on the whole space W, in order to ensure that $\lambda_0 \in V = \operatorname{Range}(B_{\Delta})$, we need to choose $\lambda_0 = Bu_0$, with $u_0 \in \widetilde{W}$.

We work with the matrix $K : X \to X$, which acts on the product space and is block diagonal; each block $K^{(i)}$ corresponds to a substructure Ω_i and is the representation of the local bilinear form $a_{\Omega_i}(\cdot,\cdot)$. We also work with global vectors $\mathbf{u}\in X$ and the load vector, still denoted by $\mathbf{f}$, which represents the linear functional

$$\int_{\Omega}\mathbf{f}\cdot\mathbf{w}\,dx, \quad \mathbf{w}\in X. \tag{6.1}$$

In addition, if $w\in W$ is a vector of degrees of freedom on Γ, let

$$\widetilde{R}^T : W \to X$$

be the extension by zero from Γ into the whole of Ω.

We can then write the system for the solution $\mathbf{u} \in X$ as

$$\begin{aligned} K\mathbf{u} + C^T\mu + (B\widetilde{R})^T\lambda &= \mathbf{f}, \\ C\mathbf{u} &= 0, \\ (B\widetilde{R})\mathbf{u} &= 0. \end{aligned} \tag{6.2}$$

Here $C\mathbf{u} = 0$ imposes the constraint to a vector $\mathbf{u} \in X$ that it have vanishing averages along the subdomain edges and μ is a vector of Lagrange multipliers associated to these constraints. We note that the last condition imposes then redundant constraints. An equation for λ is obtained by eliminating $\mathbf{u}$ and μ. We obtain

$$\mathbf{u} = K^{-1}(I - C^T(CK^{-1}C^T)^{-1}CK^{-1})(\mathbf{f} - (B\widetilde{R})^T\lambda) =: H(\mathbf{f} - (B\widetilde{R})^T\lambda)$$

and thus

$$B\widetilde{R}\,H\,\widetilde{R}^T B^T\lambda = B\widetilde{R}\,H\,\mathbf{f}.$$

We finally find

$$\begin{aligned} F &= B\widetilde{R}\,H\,\widetilde{R}^T B^T, \\ d &= B\widetilde{R}\,H\,\mathbf{f}. \end{aligned}$$

We note that $\widetilde{R}\,H\,\widetilde{R}^T$ gives an expression for $\widetilde{S}^{-1}$. In addition, the application of H to a vector requires *two* applications of K^{-1} (and then the solution of two Neumann problems on each substructure) and *one* application of $(CK^{-1}C^T)^{-1}$. If we partition

$$C = [C^{(1)}\ C^{(2)}\ \cdots\ C^{(N)}],$$

with each block corresponding to a substructure, we can write

$$F_0 := CK^{-1}C^T = \sum_{i=1}^{N} C^{(i)}{K^{(i)}}^{-1}{C^{(i)}}^T.$$

Since the number of constraints (and thus of nonzero columns in ${C^{(i)}}^T$) is equal to the number of edges of Ω_i, we need to apply ${K^{(i)}}^{-1}$ only to these nonzero columns in order to calculate F_0. The matrix F_0 is then factored once and for all and its inversion provides a coarse problem, the size of which is equal to the number of edges of the subdomain partition. Finally, by construction, the operator H always returns a vector in the kernel of C, which therefore has vanishing mean value on the subdomain edges. We note that, in case the subdomain partition coincides with a coarse mesh the coarse matrix F_0 has the same size and stencil as the coarse one for the balancing NN method in [24], for which coarse degrees of freedom are also associated to the edges of a coarse mesh.

Concerning the preconditioner M^{-1} in (3.9), the local Schur complements $S^{(i)}$ are the same as those employed for the one-level FETI method in [26] and are obtained from the local stiffness matrices in the standard way; see, e.g., [24, Eq. 3.3].

With the exception of the coarse problem, which is here larger, the cost of the setup of the algorithm is the same as that in [26] since the matrices for the same local Dirichlet and Neumann problems need to be inverted. A similar consideration holds for the cost of each iteration. Each step of our algorithm requires the solution of one coarse and two local Neumann problems per subdomain for the application of F and one Dirichlet problem per subdomain for the application of the preconditioner. The same is true for the algorithm in [26].

TABLE 7.1

FETI-DP method. Estimated condition number and number of CG iterations necessary to obtain a relative preconditioned residual less than 10^{-12} (in parentheses), versus H/h and n. Case of $a = 1$, $b = 1$. The asterisks denote the cases for which we had not enough memory to run the corresponding algorithm.

$n = 256$	4.265 (17)	3.337 (14)	2.500 (12)	*	*

7. Numerical results. We consider the same mesh, partitions, and coefficient distribution as in [26, sect. 6] in order to allow a comparison with the one-level FETI. The domain $\Omega := (0,1)^2$ is partitioned into two uniform meshes $\mathcal{T}_h$ and $\mathcal{T}_H$. The fine triangulation is made of triangles and the coarse one of squares that are unions of fine triangles. The substructures Ω_i are the elements of the coarse triangulation $\mathcal{T}_H$. The fine triangulation $\mathcal{T}_h$ consists of $2 * n^2$ triangles, with $h = 1/n$. We choose

$$A = \begin{bmatrix} b & 0 \\ 0 & b \end{bmatrix}, \qquad \mathbf{f} = [\exp(-x/3 + y^2), -3\cos(2x - 5y - 10)]^T,$$

and we use the value $\chi = 1/2$ for the definition of the scaling matrices $D_\Delta^{(i)}$; see (3.7). We consider a CG algorithm and estimate the condition number of the preconditioned operator using the quantities provided by the CG. Since, however, convergence is much faster here, we employ a more restrictive stopping criterion than in [26] in order to obtain good condition number estimates: we stop the iteration when $\|z_k\|/\|f\|$ is less than 10^{-12} instead of 10^{-6}. Here, z_k is the kth preconditioned residual $M^{-1}(d - F\lambda_k)$. The estimated condition numbers here can then be compared with those in [26, sect. 6], while in order to compare the iteration counts we need to consider the double of those in [26].

In Table 7.1, we show the estimated condition number and the number of iterations as functions of the dimensions of the fine and coarse meshes for $a = b = 1$. For a fixed ratio H/h, the condition number and the number of iterations are quite insensitive to the dimension of the fine mesh and are consistent with a quadratic logarithmic growth; see Theorem 4.7. The condition numbers here can be compared with those in [26, Table 1]. Those for the FETI-DP method are generally slightly smaller than those for the one-level method. This is related to the fact that a coarse problem of larger size is solved here. For the uniform partition into square substructures, we have one coarse function for each substructure for one-level FETI and two for FETI-DP (four degrees of freedom for the four edges of each subdomain, shared by two substructures).

On the other hand, comparison of the iteration counts shows a faster convergence for the FETI-DP algorithm. This is related to the smaller condition number and also to the fact that there is basically no freedom for the initial guess of one-level FETI methods (cf., e.g., the algorithm in [21, p. 100]); this may often give a quite high initial residual. An arbitrary initial guess can be employed for FETI-DP and the null vector employed here provides a relatively small initial residual for our tests.

In Table 7.2, we show some results when the coefficient b has jumps across the interface. We consider a 4×4 checkerboard distribution, where b assumes two values,

TABLE 7.2
4×4 checkerboard distribution for $b : (b_1, b_2)$. Estimated condition number and number of CG iterations to obtain a relative preconditioned residual less than 10^{-12} (in parentheses), versus H/h and b_2. Case of $n = 128$, $a = 1$, and $b_1 = 100$.

$b2 = 1e-4$	3.777 (21)	5.395 (28)	7.633 (32)
$b2 = 1e-3$	3.760 (20)	5.382 (27)	7.606 (30)
$b2 = 1e-2$	3.713 (20)	5.308 (25)	7.504 (29)
$b2 = 1e-1$	3.561 (18)	5.089 (23)	7.196 (27)
$b2 = 1$	3.155 (16)	4.502 (20)	6.364 (25)
$b2 = 1e+1$	2.355 (13)	3.338 (17)	4.692 (20)
$b2 = 1e+2$	1.800 (10)	2.436 (13)	3.068 (15)
$b2 = 1e+3$	2.298 (13)	3.059 (15)	3.798 (17)
$b2 = 1e+4$	2.612 (14)	3.036 (16)	3.435 (17)
$b2 = 1e+5$	2.203 (12)	2.630 (14)	2.918 (15)
$b2 = 1e+6$	2.085 (12)	2.593 (13)	2.820 (14)

b_1 and b_2. For a fixed value of $n = 128$, $b_1 = 100$, and $a = 1$, the estimated condition number and the number of iterations are shown as a function of H/h and b_2. Similar behavior as in [26, Table 2] is observed here. For $b_2 = 100$, the coefficient b has a uniform distribution, and this corresponds to a local minimum for the condition number and the number of iterations. When b_2 decreases or increases, the condition number and the number of iterations normally increase, but they can still be bounded independently of b_2. We note, however, that for some very large values of b_2, convergence may be faster than in the uniform case. We also remark that, when b_2 is large, the local ratio b_2/a is also large; see η in Theorem 4.7. In this case, however, our results remain good and the condition number even appears to be less sensitive to H/h. We remark that condition numbers and iteration counts are smaller than the corresponding ones in [26, Table 2] for one-level FETI.

In Table 7.3, we show some results when the coefficient a has jumps. We consider the same 4×4 checkerboard distribution shown as for the previous tests. For a fixed value of $n = 128$, $a_1 = 0.01$, and $b = 1$, the estimated condition number and the number of iterations are shown as a function of H/h and a_2. For $a_2 = 0.01$, the

$b2 = 1e+6$	107.7 (36)	2.87 (14)	1.82 (10)

coefficient a has a uniform distribution. A slight increase in the number of iterations and the condition number may be observed for some larger or smaller values of a_2 and when H/h is large. As for the previous table, when a_2 is small, the local ratio b/a_2 is large and our results remain good. The condition numbers and the iteration counts are smaller than the corresponding ones in [26, Table 3].

We finally present a test case where coefficient discontinuities do not coincide with the subdomain interfaces. We consider a 5×5 checkerboard distribution for the coefficient b. For a fixed value of $n = 128$, $b_1 = 100$, and $a = 1$, the estimated condition number and the number of iterations are shown in Table 7.4 as a function of $H/h = 4, 8, 16$ (corresponding to 32×32, 16×16, and 8×8 subdomains) and b_2. We see that there are cases corresponding to a large number of subdomains and small values of b for which convergence may deteriorate; the assumption that the coefficient b does not vary much in each subdomain may be therefore required in practice. The analogous case for jumps in the coefficient a, on the other hand, produces results that are similar to those in Table 7.3, and they are not presented here.

FAST SWEEPING METHODS FOR STATIC HAMILTON–JACOBI EQUATIONS*

CHIU-YEN KAO†, STANLEY OSHER†, AND YEN-HSI TSAI‡

Abstract. We propose a new sweeping algorithm which discretizes the Legendre transform of the numerical Hamiltonian using an explicit formula. This formula yields the numerical solution at a grid point using only its immediate neighboring grid values and is easy to implement numerically. The minimization that is related to the Legendre transform in our sweeping scheme can either be solved analytically or numerically. We illustrate the efficiency and accuracy approach with several numerical examples in two and three dimensions.

Key words. fast sweeping method, Godunov Hamiltonian, static Hamilton–Jacobi equation

1. Introduction.

The Hamilton–Jacobi equation

$$\psi_t(x,t) + H(x, \nabla\psi(x,t)) = 0 \tag{1.1}$$

arises in many applications ranging from classical mechanics to contemporary problems of optimal control. These include geometrical optics, crystal growth, etching, computer vision, obstacle navigation, path planning, photolithography, and seismology. In general, these nonlinear PDEs cannot be solved analytically. The solutions usually develop singularities in their derivatives even with smooth initial conditions. In these cases, the solutions do not satisfy the equation in the classical sense. The weak solution that is usually sought is called the viscosity solution [10]. Numerically, in general, one looks for a consistent and monotone scheme to construct approximate viscosity solutions [27].

In this paper, we focus on static Hamilton–Jacobi equations of the following form:

$$\begin{cases} H(x, \nabla\phi(x)) = R(x) & \text{for } x \in \Omega, \\ \phi(x) = q(x) & \text{for } x \in \Gamma \subset \partial\Omega, \end{cases} \tag{1.2}$$

where H, q, and $R > 0$ are Lipschitz continuous and H is also convex and homogeneous of degree one in $\nabla\phi(x)$. A special case of this type of equation is the eikonal equation,

$$|\nabla\phi| = r(x) \tag{1.3}$$

with the same type of Dirichlet boundary condition as in (1.2). Many numerical methods have been developed for this problem. Rouy and Tourin [24] used an iterative method to solve the discretized eikonal equation and proved that it converges to the viscosity solution. The key is to use an upwind, monotone, and consistent discretization for $|\nabla\phi|$. Instead of using iterative methods, Tsitsiklis [29], later Sethian [25],

and Helmsen et. al. [14] proposed single-pass methods. Based on the monotonicity of the solution along the characteristics, they combined the heap-sort data structure with a variation of the classical Dijkstra algorithm to solve the steady state equation $|\nabla\phi| = r(\mathbf{x})$. This became known as the fast marching method whose complexity is $O(N \log N)$, where N is the total number of grid points in the domain. Later Sethian and Vladimirsky [26] generalized the method of [29] to solve (1.2).

Osher [18] provided a link between time-independent and time-dependent Hamilton–Jacobi equations. The zero level set of the viscosity solution ψ of (1.1) with suitable initial conditions at various time t is the solution $\phi(x, y) = t$ of (1.2). This gives an approach that one can try to solve the time-dependent equation by the level set formulation [19] with high order approximations on the partial derivatives [20], [15]. Falcone and Ferretti studied a class of semi-Lagrangian schemes which can be interpreted as a discrete version of the Hopf–Lax–Oleinik representation formula for first order time-dependent Hamilton–Jacobi equations. In semi-Lagrangian schemes, ψ needs to be interpolated using its grid values, the Legendre transformation of H needs to be obtained, and the minimum must be computed on an unbounded set. See [11] and the references therein for more details.

Another approach to obtaining a "time-dependent" Hamilton–Jacobi equation from a time-independent Hamilton–Jacobi equation comes by using the so-called paraxial formulation, i.e., by assuming that there is a preferred direction in the wave propagation. In [13], the paraxial formulation was first proposed for the eikonal equation (1.3). Later in [22], [23], a paraxial formulation was proposed for the static general eikonal equation (1.2) in geophysical applications.

An important application for (1.2) is obtaining geodesic distance on a manifold. Suppose that $P = (x, y)$ is a point on a manifold M defined as the graph of a smooth function $f(x, y)$ and that γ are the curves connecting P and $\Gamma \subset M$ on the manifold. The minimizing curve of γ is called the geodesic. Let ϕ be the distance function such that

$$\phi(x, y) = \min_{\gamma \subset M} \int_\gamma ds.$$

Then ϕ is the solution of

$$\sqrt{\left(\frac{1+f_y^2}{f_x^2+f_y^2+1}\right)\phi_x^2 + \left(\frac{1+f_x^2}{f_x^2+f_y^2+1}\right)\phi_y^2 - 2\frac{f_x f_y}{f_x^2+f_y^2+1}\phi_x\phi_y} = 1, \quad \phi|_\Gamma = 0. \tag{1.4}$$

This equation can be easily generalized to higher dimensions. For example, in three dimensions we again write down the formula for M as the graph of a smooth function $f(x, y, z)$. The distance function ϕ then satisfies

$$\sqrt{a\phi_x^2 + b\phi_y^2 + c\phi_z^2 - 2d\phi_x\phi_y - 2e\phi_y\phi_z - 2f\phi_z\phi_x} = 1, \quad \phi|_\Gamma = 0, \tag{1.5}$$

where

$$a = \frac{1+f_y^2+f_z^2}{1+f_x^2+f_y^2+f_z^2}, \quad b = \frac{1+f_x^2+f_z^2}{1+f_x^2+f_y^2+f_z^2}, \quad c = \frac{1+f_x^2+f_y^2}{1+f_x^2+f_y^2+f_z^2},$$
$$d = \frac{f_x f_y}{1+f_x^2+f_y^2+f_z^2}, \quad e = \frac{f_y f_z}{1+f_x^2+f_y^2+f_z^2}, \quad f = \frac{f_z f_x}{1+f_x^2+f_y^2+f_z^2}.$$

We will apply our new algorithm to compute the geodesic distance later. There are other approaches that are designed to compute geodesic distances on manifolds. Kimmel and Sethian [16] extended the fast marching method to triangulated manifolds and provided an algorithm for computing the geodesic distances, thereby extracting shortest paths on triangulated manifolds. Barth [2] used the discontinuous Galerkin method to find the distance on graphs of functions that are represented by spline functions. In [7], the authors embeded the manifold as the zero level set of a Lipschitz continuous function and solved the corresponding eikonal equation (1.4) in the embedding space. In [17], the authors based their work on the theory of geodesics on Riemannian manifolds with boundaries and adapted the standard fast marching method to compute weighted distance functions and geodesics on implicit surfaces efficiently. Tsai et. al. [28] used a fast Gauss–Seidel-type iteration method and a monotone upwind Godunov flux for the numerical Hamiltonian.

We propose a new interpretation of the monotone upwind Godunov flux for the numerical Hamiltonian to solve (1.2). The complexity of our method appears to be $O(N)$. We illustrate the approach with several numerical examples in two and three dimensions.

2. A new numerical scheme for convex Hamiltonians. Our new numerical algorithm for static Hamilton–Jacobi equations is composed of a sweeping process and an update formula. The sweeping process we use here is a version of Gauss–Seidel iteration. It is motivated originally by Boué and Dupuis [3], who first suggested that the complexity of this approach for the eikonal case is $O(N)$. In [31], the fast sweeping algorithm was first formulated in PDE framework for the eikonal equation and was used to compute the distance function. In the sweeping process, we sweep through the grids with alternating directions in order to follow the characteristics and use the most recent values as we update the solution. This means that we overwrite an old value with its new value as soon as we obtain the latter. In one dimension, we sweep through the grids from left to right followed by right to left because the characteristics have only two possible directions. In two dimensions, the characteristics may have an infinite number of possible directions. We use four sweeping directions so that a specific sweeping direction covers a group of characteristics at the same time. We denote these four sweeping directions as one iteration. In n dimensions, we will use 2^n alternating directions per iteration. We stop our iterations when the L_1 norm of the difference of two successive iteration results is less than the given tolerance, which is $O(h)$, where h is the grid size.

The new update formula we derive here comes from using the Legendre transformation. The Legendre transformation can be applied to the Wulff problem [21], which is usedto determine the equilibrium shape of crystalline materials. We give the definitions in the following.

DEFINITION 2.1. *Let $\gamma : S^{d-1} \to R^+$ be a continuous function defined on a curved space S^{d-1}.*

1. The first Legendre transformation of γ is

$$\gamma_*(\nu) = \min_{\theta\cdot\nu>0,\,|\theta|=1} \left[\frac{\gamma(\theta)}{(\theta\cdot\nu)}\right].$$

2. The second Legendre transformation of γ is

$$\gamma^*(\nu) = \max_{\theta\cdot\nu>0,\,|\theta|=1} [\gamma(\theta)(\theta\cdot\nu)].$$

The first and second Legendre transformations are dual to each other in a certain sense, i.e., $(\gamma_*)^* = \gamma$ if γ is convex and $(\gamma^*)_* = \gamma$ if γ is polar-convex. See, e.g., [21]. We can extend γ to the whole space R^d by defining

$$\widetilde{\gamma}(x) = |x|\gamma\left(\frac{x}{|x|}\right),$$

where the extension $\widetilde{\gamma}$ is homogeneous to degree 1 and $x \in R^d$.

The convex Hamiltonian using the Bellman formula or the Legendre transformation is

$$H(\nabla\phi(x)) = \max_{\theta}[(\nabla\phi \cdot \theta)w(\theta)], \quad \theta \in S^{d-1},$$

where

$$w(\theta) = \min_{\nu\cdot\theta>0,\,|\nu|=1}\left[\frac{H(\nu)}{(\nu\cdot\theta)}\right] \quad \text{and} \quad \nu = \frac{\nabla\phi(x)}{|\nabla\phi(x)|}. \tag{2.1}$$

We define the numerical Hamiltonian as follows:

$$\hat{H}(D_-^i\phi; D_+^j\phi) = \max_{\theta}\left\{\left(\sum_k D_{\mp}^k\phi\cdot\theta_k^{\pm}\right)w(\theta)\right\},$$

where $D_-^i\phi$ ($D_+^j\phi$) are the backward (forward) difference in i (j) direction, $\theta^+ = \max(\theta, 0)$, and $\theta^- = \min(\theta, 0)$. This numerical Hamiltonian is monotone and consistent. It also turns out to be Godunov's numerical Hamiltonian. In order to describe this clearly without loss of generality, we discuss the two-dimensional case here,

$$H(\phi_x, \phi_y) = \max_{\theta}(\phi_x\cos\theta + \phi_y\sin\theta)w(\theta),$$

where

$$w(\theta) = \min_{-\frac{\pi}{2}\le\nu-\theta\le\frac{\pi}{2}}\frac{H(\cos\nu, \sin\nu)}{\cos(\nu-\theta)}.$$

The new numerical Hamiltonian is

$$\hat{H}(D_-^x\phi, D_+^x\phi; D_-^y\phi, D_+^y\phi) = \max_{\theta}\{((\cos\theta)^{\pm}D_{\mp}^x\phi + (\sin\theta)^{\pm}D_{\mp}^y\phi)w(\theta)\}.$$

We say a function $H(x_1, x_2, \dots, x_n)$ is nondecreasing in x_j by writing $H(x_1, x_2, \dots, x_{j-1}, \uparrow, x_{j+1}, \dots, x_n)$ and nonincreasing by writing $H(x_1, x_2, \dots, x_{j-1}, \downarrow, x_{j+1}, \dots, x_n)$.

LEMMA 2.2. *$\hat{H}$ is monotone; i.e., $\hat{H}(\uparrow, \downarrow, \uparrow, \downarrow)$.*

Proof. Since $w > 0$, this conclusion is straightforward. ∎

LEMMA 2.3. *$\hat{H}$ is consistent; i.e., $\hat{H}(p, p; q, q) = H(p, q)$.*

Proof. This is a simple manipulation of the following definitions:

$$\begin{aligned}
\hat{H}(p_-, p_+; q_-, q_+) &:= \max_{\theta}\{((\cos\theta)^{\pm}p_{\mp} + (\sin\theta)^{\pm}q_{\mp})w(\theta)\},\\
\hat{H}(p, p; q, q) &= \max_{\theta}\{((\cos\theta)^{\pm}p + (\sin\theta)^{\pm}q)w(\theta)\}\\
&= \max_{\theta}\{(p\cos\theta + q\sin\theta)w(\theta)\}\\
&=: H(p, q). \qquad ∎
\end{aligned}$$

By solving the Riemann problem for Hamilton–Jacobi equations (a generalization of Godunov's procedure), Bardi and Osher [1] proved the following result for Godunov's scheme:

$$H^G(p_-, p_+; q_-, q_+) = \operatorname{ext}_{p\in I[p_-,p_+]} \operatorname{ext}_{q\in I[q_-,q_+]} H(p,q), \tag{2.2}$$

where

$$\begin{aligned}
\operatorname{ext}_{p\in I[a,b]} &= \min_{p\in[a,b]} \quad \text{if } a \le b,\\
\operatorname{ext}_{p\in I[a,b]} &= \max_{p\in[b,a]} \quad \text{if } a > b,\\
H^G(D^x_- \phi_{ij}, D^x_+ \phi_{ij}; D^y_- \phi_{ij}, D^y_+ \phi_{ij}) &= H^G(p_-, p_+; q_-, q_+),
\end{aligned}$$

and $I[a,b]$ denotes the closed interval bounded by a and b.

PROPOSITION 2.4. *$\hat{H}$ is Godunov's numerical Hamiltonian; i.e., $\hat{H} = H^G$.*

Proof. We first assume $p_- < p_+$ and $q_- < q_+$,

$$\begin{aligned}
H^G(p_-, p_+; q_-, q_+) &:= \min_{p_-\le p\le p_+} \min_{q_-\le q\le q_+} H(p,q)\\
&= \min_{p_-\le p\le p_+} \min_{q_-\le q\le q_+} \left\{ \max_\theta \{(p\cos\theta + q\sin\theta) w(\theta)\} \right\}\\
&= \max_\theta \left\{ \min_{p_-\le p\le p_+} \min_{q_-\le q\le q_+} (p\cos\theta + q\sin\theta) w(\theta) \right\}\\
&= \max_\theta \{((\cos\theta)^{\pm} p_{\mp} + (\sin\theta)^{\pm} q_{\mp}) w(\theta)\}\\
&=: \hat{H}(p_-, p_+; q_-, q_+).
\end{aligned}$$

The proof for the other 3 cases is equally straightforward. ∎

Now we use our new numerical Hamiltonian to solve (1.2). In order to write our scheme in an explicit form, we prove the following property first.

LEMMA 2.5. *$\max_\theta (a f(\theta) - g(\theta)) = 0$ with $f(\theta) > 0 \iff a = \min_\theta \frac{g(\theta)}{f(\theta)}$.*

Proof.

$$\max_\theta (a f(\theta) - g(\theta)) = \max_\theta f(\theta) \left(a - \frac{g(\theta)}{f(\theta)} \right) = 0.$$

Since $f(\theta) > 0$, we have $\max_\theta (a - \frac{g(\theta)}{f(\theta)}) = 0$, which implies $a = \min_\theta \frac{g(\theta)}{f(\theta)}$. ∎

Apply this property to

$$\hat{H}(D^x_- \phi, D^x_+ \phi; D^y_+ \phi, D^y_- \phi) = R(x,y).$$

Let $\phi_0 = \phi_{i,j}$, $\phi_W = \phi_{i-1,j}$, $\phi_E = \phi_{i+1,j}$, $\phi_S = \phi_{i,j-1}$, and $\phi_N = \phi_{i,j+1}$. Breaking down the expressions, we have

$$\max_{\theta,\phi_{W,E,S,N}} \left\{ \begin{Bmatrix} (\cos\theta)^+(\phi_O - \phi_W) \\ -(\cos\theta)^-(\phi_O - \phi_E) \end{Bmatrix} + \begin{Bmatrix} (\sin\theta)^+(\phi_O - \phi_S) \\ -(\sin\theta)^-(\phi_O - \phi_N) \end{Bmatrix} \right\} w(\theta) - hR(x_i, y_j) = 0,$$

$$\max_{\theta,\phi_{W,E,S,N}} \phi_O((\cos\theta)^+ - (\cos\theta)^- + (\sin\theta)^+ - (\sin\theta)^-) w(\theta)$$

$$+ \begin{Bmatrix} -(\cos\theta)^+ \phi_W \\ (\cos\theta)^- \phi_E \end{Bmatrix} + \begin{Bmatrix} -(\sin\theta)^+ \phi_S \\ (\sin\theta)^- \phi_N \end{Bmatrix} w(\theta) = hR(x_i, y_j).$$

Thus

$$\begin{aligned}\phi_O &= \min_{\theta}\left\{\frac{\begin{Bmatrix}(\cos\theta)^+\phi_W & + & (\sin\theta)^+\phi_S\\ -(\cos\theta)^-\phi_E & + & -(\sin\theta)^-\phi_N\end{Bmatrix} w(\theta) + hR(x_i,y_j)}{(|\cos\theta|+|\sin\theta|)w(\theta)}\right\}\\ &= \min_{\theta} K(\theta).\end{aligned} \tag{2.3}$$

We can also derive the three-dimensional numerical Hamiltonian and the update formula in the same way. Let $\phi_0 = \phi_{i,j.k}$, $\phi_W = \phi_{i-1,j,k}$, $\phi_E = \phi_{i+1,j,k}$, $\phi_S = \phi_{i,j-1,k}$, $\phi_N = \phi_{i,j+1,k}$, $\phi_D = \phi_{i,j,k-1}$, and $\phi_U = \phi_{i,j,k+1}$. We have

$$\begin{aligned}&\hat{H}(D^x_-\phi, D^x_+\phi; D^y_-\phi, D^y_+\phi; D^z_-\phi, D^z_+\phi)\\ &\quad = \max_{\theta_1,\theta_2}\{((\sin\theta_1\cos\theta_2)^{\pm}D^x_{\mp}\phi + (\sin\theta_1\sin\theta_2)^{\pm}D^y_{\mp}\phi + (\cos\theta_1)^{\pm}D^z_{\mp}\phi)w(\theta_1,\theta_2)\},\\ &\phi_O = \min_{\theta_1,\theta_2}\left\{\frac{\begin{Bmatrix}(\sin\theta_1\cos\theta_2)^+\phi_W & + & (\sin\theta_1\sin\theta_2)^+\phi_S & + & (\cos\theta_1)^+\phi_D\\ -(\sin\theta_1\cos\theta_2)^-\phi_E & + & -(\sin\theta_1\sin\theta_2)^-\phi_N & + & -(\cos\theta_1)^-\phi_U\end{Bmatrix} w + hR}{(|\sin\theta_1\cos\theta_2|+|\sin\theta_1\cos\theta_2|+|\cos\theta_1|)w}\right\}.\end{aligned} \tag{2.4}$$

Sometimes it is possible to obtain explicit expression for w from (2.1), but in general, one has to use numerical approximations by the fast Legendre transform developed by Brenier [4] and Corrias [9]. The minimization in the update formulas (2.3) and (2.4) can be achieved either analytically or numerically. For a Hamiltonian of quadratic form in the gradient, we solve the minimization analytically in the next section. For other cases, we find the minimizer by using some well-developed numerical optimization techniques, e.g., L-BFGS-B [5], [32] and trust region methods that employ quadratic interpolation [12], [8].

3. Analytically solving a class of Hamilton–Jacobi equations. The quadratic form Hamiltonian

$$\sqrt{a(x,y)\phi_x^2 + b(x,y)\phi_y^2 - 2c(x,y)\phi_x\phi_y} = R(x,y) \tag{3.1}$$

is of special interest because computing geodesic distances on a manifold leads to this type of equation. Here we show that the minimization of (2.3) can be solved explicitly. Using the Legendre transformation, we have (after some simple calculations)

$$H(\cos\nu,\sin\nu) = \sqrt{a\cos^2\nu + b\sin^2\nu - 2c\sin\nu\cos\nu}$$

and

$$w(\theta) = \sqrt{\frac{ab-c^2}{a\sin^2\theta + b\cos^2\theta + 2c\cos\theta\sin\theta}}.$$

Finding the minimum of (2.3) when $0 < \theta < \pi/2$ first, $\frac{dK}{d\theta} = 0$ leads to

$$(-\phi_W + \phi_S)w^2 - hR[(\cos\theta + \sin\theta)w' + (-\sin\theta + \cos\theta)w] = 0. \tag{3.2}$$

Thus

$$\frac{-\phi_W+\phi_S}{hR}=\frac{-a\sin\theta+b\cos\theta+c(\sin\theta-\cos\theta)}{\sqrt{(ab-c^2)(a\sin^2\theta+b\cos^2\theta+2c\sin\theta\cos\theta)}}=T(\theta) \tag{3.3}$$

and

$$T'(\theta)=-\frac{\sqrt{ab-c^2}(\cos\theta+\sin\theta)}{(a\sin^2\theta+b\cos^2\theta+2c\sin\theta\cos\theta)^{3/2}}<0.$$

The solvability condition for θ_1 is

$$\frac{c-a}{\sqrt{a(ab-c^2)}}<\frac{-\phi_W+\phi_S}{hR}<\frac{b-c}{\sqrt{b(ab-c^2)}}. \tag{3.4}$$

If (3.4) is satisfied, we will have a unique solution for $0<\theta<\pi/2$ because of the monotonicity of T. Let $m=(-\phi_W+\phi_S)/hR$. We have

$$\theta=\tan^{-1}\left(\frac{-cm^2(ab-c^2)-(a-c)(b-c)\pm m(ab-c^2)\sqrt{(a+b-2c)-m^2(ab-c^2)}}{am^2(ab-c^2)-(a-c)^2}\right)$$

if both m and the denominator are not zero. Here we have two choices for θ because we square both sides while we do the calculation. We need to plug in (3.3) and pick up the right one. Also

$$\theta=\tan^{-1}\left(\frac{b-a}{c-a}\right)$$

if the denominator is zero, and

$$\theta=\tan^{-1}\left(\frac{c-b}{c-a}\right)$$

if $m=0$. Using similar arguments, we can write down solvability conditions and explicit formulas for θ in other ranges. This can be summarized in the following algorithm.

Algorithm (Quadratic Hamilton–Jacobi solver using the Bellman formula). We assume that $\phi(i,j)$ is given in a small neighborhood of Γ. We initialize the unknown ϕ by setting $\phi(i,j)$ to ∞[1] and mask $(i,j)=$ unknown.

We begin by setting $\phi^{(0)}=\phi$.

Do the following steps while $|\phi^{(n+1)}-\phi^{(n)}|>\delta$: ($\delta>0$ is the given tolerance which is $O(h)$).

Sweeping Process: A compact way of writing these sweeping iterations in C/C++ is

```
for(s1=-1;s1<=1;s1+=2)
for(s2=-1;s2<=1;s2+=2)
for(i=(s1<0?nx:0);(s1<0?i>=0:i<=nx);i+=s1)
for(j=(s2<0?ny:0);(s2<0?j>=0:j<=ny);j+=s2)
  update φ_{i,j}
```

Update Formula: For each grid point (i,j) visited in the sweeping iteration, if mask $(i,j)=$ unknown, do the following:

For $(s_x,s_y)=(\pm1,\pm1)$

[1]Notice that we only need to use a large value in actual implementation.

1. Check the solvability condition

$$m = \frac{s_x s_y(\phi^{(n)}(i, j - s_y) - \phi^{(n)}(i - s_x, j))}{hR},$$
$$\text{check } \frac{c-a}{\sqrt{a(ab-c^2)}} < m < \frac{b-c}{\sqrt{b(ab-c^2)}} \quad \text{when } s_x s_y > 0,$$
$$\text{check } \frac{-(b+c)}{\sqrt{b(ab-c^2)}} < m < \frac{a+c}{\sqrt{a(ab-c^2)}} \quad \text{when } s_x s_y < 0.$$

2. If the condition is satisfied,

$$\theta = \tan^{-1}\left(\frac{-cm^2(ab-c^2) - (as_x - cs_y)(bs_y - cs_x)}{am^2(ab-c^2) - (as_x - cs_y)^2} \pm \frac{m(ab-c^2)\sqrt{(a+b-2cs_x s_y) - m^2(ab-c^2)}}{am^2(ab-c^2) - (as_x - cs_y)^2}\right) + (1 - s_x)\frac{\pi}{2}$$

if both m and the denominator are not zero. Plug in the test function

$$T(\theta) = \frac{(-as_x + cs_y)\sin\theta + (bs_y - cs_x)\cos\theta}{\sqrt{(ab-c^2)(a\sin^2\theta + b\cos^2\theta + 2c\sin\theta\cos\theta)}}$$

and pick up the right one which equals m, not $-m$. Also

$$\theta = \tan^{-1}\left(\frac{b-a}{c - as_x s_y}\right) + (1 - s_x)\frac{\pi}{2}$$

if the denominator is zero, and

$$\theta = \tan^{-1}\left(\frac{cs_x - bs_y}{cs_y - as_x}\right) + (1 - s_x)\frac{\pi}{2}$$

if $m = 0$.

3. Add

$$\phi_{tmp} = \frac{(s_x\phi(i - s_x, j)\cos\theta + s_y\phi(i, j - s_y)\sin\theta)w(\theta) + hR}{(|\cos\theta| + |\sin\theta|)w(\theta)}$$

to the list `phi_candidate`.

4. Add $K(0)$, $K(\frac{\pi}{2})$, $K(\pi)$, $K(\frac{3\pi}{2})$ to the list `phi_candidate`.
5. Let $\phi_{\min}$ be the minimum element of `phi_candidate`.
6. Update

$$\phi^{(n+1)}(i, j) = \min(\phi^{(n)}(i, j), \phi_{\min}).$$

4. Numerical minimization. For a more general sweeping algorithm, we use numerical optimization to calculate ϕ_0. There are many minimization methods that are readily available to us. Some methods need only evaluations of the function while others also require evaluations of the derivative of the function. For our multidimensional cases, we use the L-BFGS-B method [5], [32], [6] because the cost of the iteration is low and the storage requirements of the algorithm are modest. L-BFGS-B is a limited memory quasi-Newton method for a large-scale bound-constrained

problem. The minimizer $\widetilde{\theta}$ of (2.3) and the minimizer $(\widetilde{\theta_1}, \widetilde{\theta_2})$ of (2.4) at a grid point is constructed to be within a given tolerance through iterations, and the number of iterations depends on the initial condition and the tolerance. In our algorithm, we use the minimizer obtained in the previous sweep as our initial guess. In the first sweep, we use the minimizers of the upwind neighboring grid pronts as initial conditions for the quasi-Newton method. This implies that the initial conditions that we end up using are, in most cases, close enough to the minimizers. In practice, with the tolerance of 10^{-6}, we observed that, in average, only four to five iterations are needed. There is an alternative approach of discretizing θ and then searching for the minimum in the corresponding discretized space. Take the two-dimensional case, for example,

$$\phi_O = \min_{\theta} K(\theta) = K(\widetilde{\theta}) \sim \min_{\theta_j} k(\theta_j), \tag{4.1}$$

where $\theta_j = j \triangle \theta / 2\pi$. Used in a straightforward manner, this kind of approach would require that the grid size $\triangle\theta$ is comparable to the given tolerance. In the following, we briefly describe how the L-BFGS-B method works.

Consider finding a minimum by Newton's method to search for a zero of the gradient of the function $f(\theta) : R^n \to R$. The iteration formula is given by

$$\theta^{K+1} = \theta^k - A^{-1} \cdot \nabla f(\theta),$$

where A is the Hessian matrix of f. The BFGS method is a quasi-Newton method because it doesn't use the actual Hessian matrix of f, but it constructs a sequence of H^k to approximate A^{-1}. The iteration formula for unconstrained optimization is given by

$$\theta^{k+1} = \theta^k - \lambda^k H^k g^k, \quad k = 0, 1, 2, \dots,$$

where λ^k is a step size, g^k is the gradient of f at θ^k, and H^k is updated at every iteration by the following formula:

$$H^{k+1} = (V^k)^T H^k V^k + \rho^k s^k (s^k)^T, \tag{4.2}$$

where

$$\rho^k = 1/(y^k)^T s^k, \qquad V^k = I - \rho^k y^k (s^k)^T,$$

and

$$s^k = \theta^{k+1} - \theta^k, \qquad y^k = g^{k+1} - g^k.$$

The limited memory BFGS method only stores the m most recent pairs $\{s^i, y^i\}_{i=k-m}^{k-1}$ to update H^k. Suppose that the current iteration is θ^k and the initial limited memory matrix $H_{(0)}^k$ (usually a diagonal matrix) is updated by $\{s^i, y^i\}_{i=k-m}^{k-1}$. From (4.2) we have

$$\begin{aligned} H^k = {} & ((V^{k-1})^T \cdots (V^{k-m})^T) H_{(0)}^k (V^{k-m} \cdots V^{k-1}) \\ & + \rho^{k-m} ((V^{k-1})^T \cdots (V^{k-m+1})^T) s^{k-m} (s^{k-m})^T (V^{k-m+1} \cdots V^{k-1}) \\ & + \rho^{k-m+1} ((V^{k-1})^T \cdots (V^{k-m+2})^T) s^{k-m+1} (s^{k-m+1})^T (V^{k-m+2} \cdots V^{k-1}) \\ & + \cdots + \rho^{k-1} s^{k-1} (s^{k-1})^T. \end{aligned} \tag{4.3}$$

For bound constrained problems, the direct Hessian approximation $B^k = (H^k)^{-1}$ is used. The detail derivation and efficient algorithm for computing H^k and B^k are found in [6]. This B^k is used to define a quadratic model of f at θ^k,

$$Q^k(\theta) = f(\theta^k) + (g^k)^T(\theta - \theta^k) + \frac{1}{2}(\theta - \theta^k)^T B^k(\theta - \theta^k).$$

In order to find the minimizer of Q^k subject to the bound constrained, the gradient projection method is first used to determine a set of active bounds. Suppose we have $\Theta = \{\theta \mid l_i \le \theta_i \le u_i,\ i = 1, \dots, n\}$; the ith coordinate of the projection of vector θ is given by

$$P(\theta, l, u)_i = \begin{cases} l_i & \text{if } \theta_i \le l_i, \\ u_i & \text{if } \theta_i \ge u_i, \\ \theta_i & \text{otherwise.} \end{cases}$$

We can then find the generalized Cauchy point that is the first local minimizer θ^c of

$$Q_L^k(t) = Q^k(P(\theta^k - tg^k, l, u)).$$

Use θ^c to identify a set of active variables and then find the minimizer $\overline{\theta}^{k+1}$of the quadratic model with respect to the free variables. Perform a line search

$$\theta^{k+1} = \theta^k + \alpha^k \left(\overline{\theta}^{k+1} - \theta^k\right), \tag{4.4}$$

where α^k is the step size, to find θ^{k+1} that satisfies the sufficient decrease condition

$$f(\theta^{k+1}) \le f(\theta^k) + 10^{-4}(g^k)^T \left(\overline{\theta}^{k+1} - \theta^k\right).$$

For more details, please refer to [5]. In our calculation, we choose $m = 5$ and the stopping criterion is then

$$\|P(\theta^k - g^k, l, u) - \theta^k\|_\infty < 10^{-6}.$$

5. Examples. We implement our new numerical scheme in the following examples. We choose $\delta = 10^{-15}$ for two dimensional cases and $\delta = 10^{-12}$ for three dimensional cases for simplicity. Ideally the δ should be chosen as a small constant times the grid size. We test an anisotropic case with constant coefficients a, b, and c in Figures 1 and 2 to show a very degenerate case with varied coefficients and a box-shape boundary condition. The equation is

$$\sqrt{0.375\phi_x^2 + 0.25\phi_y^2 - 0.58\phi_x\phi_y} = (2.1 - \cos(4\pi^2 xy))/4.$$

Thus $a = 0.375$, $b = 0.25$, $c = 0.29$, and $R(x, y) = (2.1 - \cos(4\pi^2 xy))/4$. Notice that in this case, $ab = 0.0938$ is barely greater than $c^2 = 0.0841$ and R is highly oscillatory. That is why it needs more iterations. In general, we usually need more iterations when the characteristics are very curvy. Figures 3 and 4 show the geodesic distances on manifolds. In Figure 3, there are two boundary points. The contour plot has kinks on the equal distance places. In Figure 4, the boundary point is in the center and on the

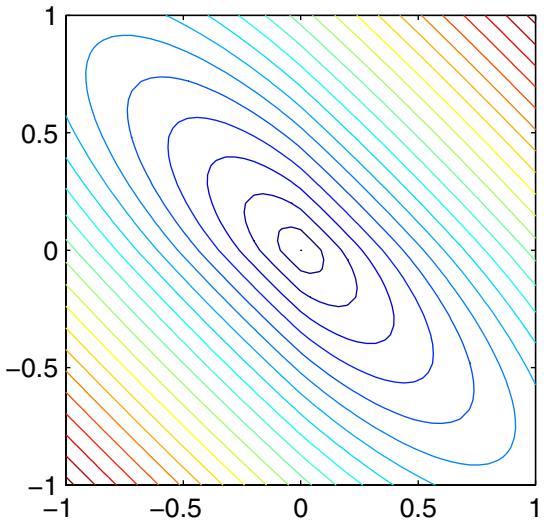

FIG. 1. *A sweeping result after* 2 *sweeping iterations on a* 50×50 *grid. The boundary is a single point in the center.* $a = 1.0$, $b = 1.0$, $c = 0.9$, *and* $R = 1$.

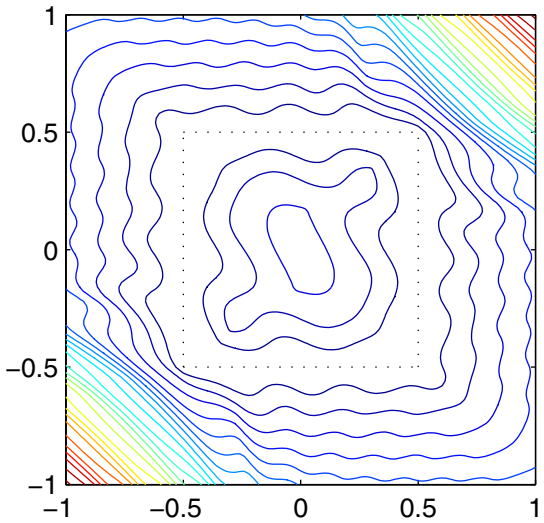

FIG. 2. $a = 0.375$, $b = 0.25$, $c = 0.29$, *and* $R(x, y) = (2.1 - \cos(4\pi^2 xy))/4.0$ *on a* 100×100 *grid. Convergence is reached after* 45 *sweeping iterations.*

top of the mountain-shaped manifold. The contour plot shows the geodesic distance to the boundary point. Figure 5 is an example of the first arrival travel times to seismic imaging. The computational domain suggests material layering under a sinusoidal profile with layer shapes $C(x) = 0.1225 \sin(4\pi x)$. Suppose the domain is split into four parts by $y_i(x) = 0.1225 \sin(4\pi x) + p_i$ where $i = 1, 2, 3,$ and $p_i = (-0.25, 0, 0.25)$. In each layer, the anisotropic speed at (x, y) is given by an ellipse with the long axis (of length $2F_2$) tangential to the curve $C(x)$ and the short axis (of length $2F_1$) normal

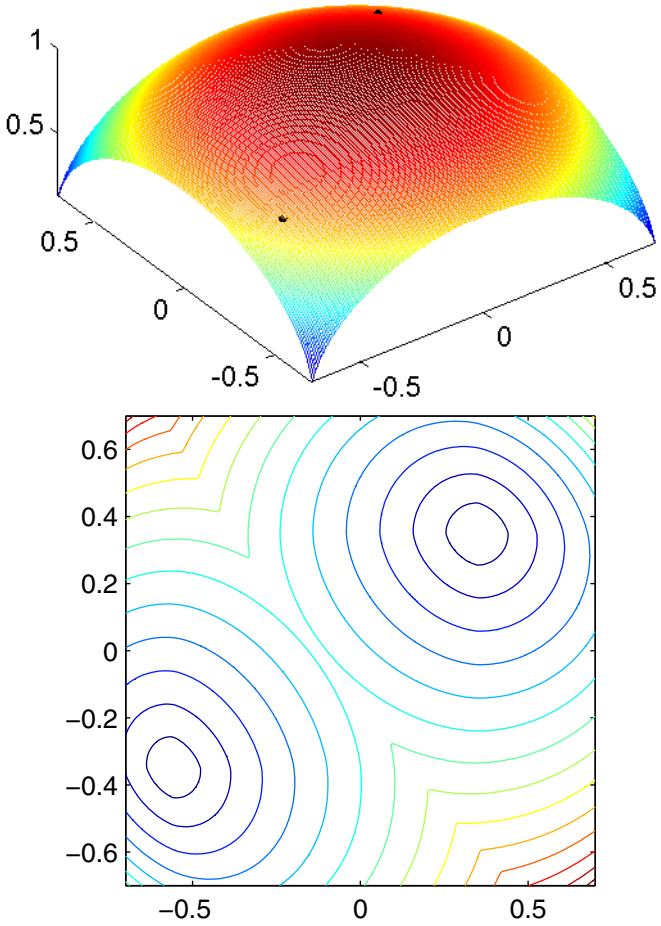

FIG. 3. *This is an example of the distance on a half sphere. The sweeping algorithm was applied to the graph of* $f(x,y) = \sqrt{1.0 - (x^2 + y^2)}$ *with* $\phi(-0.56, -0.35) = \phi(0.35, 0.35) = 0$ *as a boundary condition on a* 200×200 *grid. to the curve. F_1 and F_2 are constants in each layer. This leads to

$$F_2\sqrt{((1+n^2)\phi_x^2 + (1+m^2)\phi_y^2 - 2mn\phi_x\phi_y)/(1+m^2+n^2)} = 1,$$

where

$$(m,n) = \frac{\sqrt{(F_2/F_1)^2 - 1}}{\sqrt{1 + \left(\frac{dC(x)}{dx}\right)^2}}\left(\frac{dC(x)}{dx}, -1\right).$$

From the results, we know that the algorithm is stable even with discontinuous coefficients. Figures 6 and 7 are the solutions for three-dimensional eikonal equation with one and two point boundary conditions. Figures 8 and 9 are the more general cases for

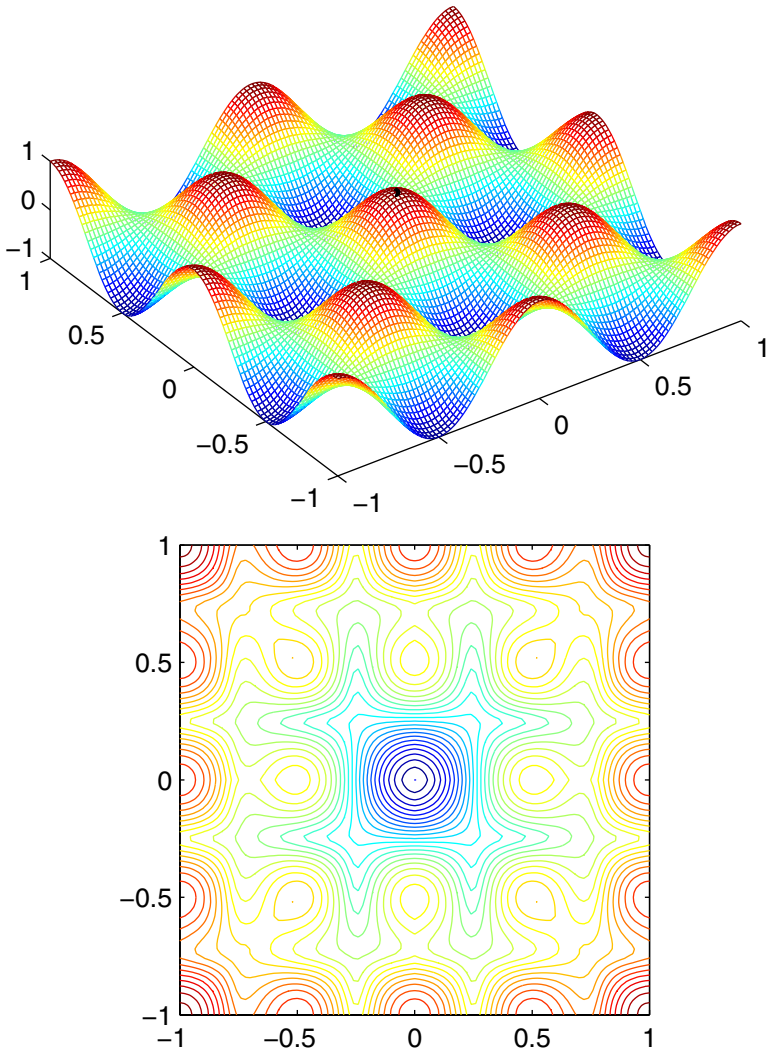

FIG. 4. *The distance contour from* $(0,0)$ *on the graph of* $f(x,y) = \cos(2\pi x)\cos(2\pi y)$. *The convergence was obtained after* 12 *iterations on a* 100×100 *grid.*

three dimensions. Figure 8 has a boundary point $\phi(0,0,0) = 0$ and Figure 9 has a cubic boundary condition with sides of length one. The governing equation we solved is

$$\sqrt{a\phi_x^2 + b\phi_y^2 + c\phi_z^2 - 2d\phi_x\phi_y - 2e\phi_y\phi_z - 2f\phi_z\phi_x} = 1,$$

where

$$a = \frac{1 + f_y^2 + f_z^2}{1 + f_x^2 + f_y^2 + f_z^2}, \quad b = \frac{1 + f_x^2 + f_z^2}{1 + f_x^2 + f_y^2 + f_z^2}, \quad c = \frac{1 + f_x^2 + f_y^2}{1 + f_x^2 + f_y^2 + f_z^2},$$

$$d = \frac{f_x f_y}{1 + f_x^2 + f_y^2 + f_z^2}, \quad e = \frac{f_y f_z}{1 + f_x^2 + f_y^2 + f_z^2}, \quad f = \frac{f_z f_x}{1 + f_x^2 + f_y^2 + f_z^2},$$

and $f(x,y,z) = \cos(2\pi x)\cos(2\pi y)\cos(2\pi z)$, and the corresponding

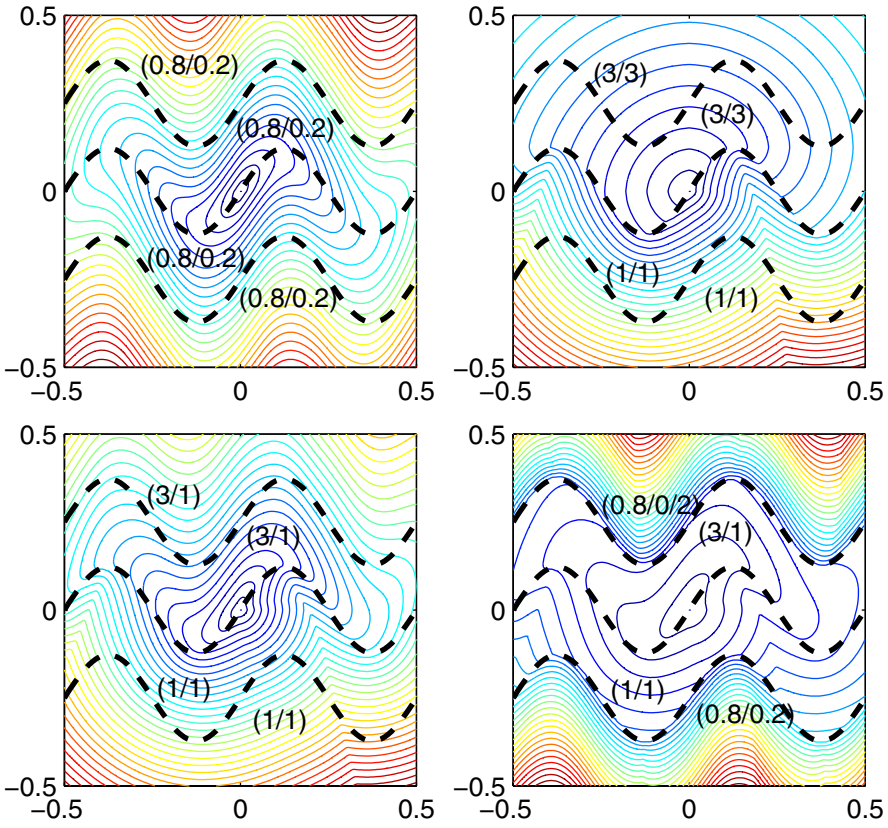

FIG. 5. *This is an example of first arrival travel times in seismic imaging* [26]. *The* (F_2, F_1) *pair for each layer is given in the above figures. The convergence was obtained after* $5, 4, 16,$ *and* 16 *iterations on a* 200×200 *grid.*

$$w(\theta_1, \theta_2) = \sqrt{\frac{1}{1 + (f_x \sin\theta_1 \cos\theta_2 + f_y \sin\theta_1 \sin\theta_2 + f_z \cos\theta_1)^2}}.$$

This seems to be the first successful rapid computation in three dimensions for such problems. In [30], it was proved that the results from the fast sweeping method for the eikonal equation with $R(x) = 1$ need only one iteration, which is exactly 2^n Gauss–Seidel alternating sweepings for the problem in R^n, to reach a solution with global error $O(h \log(1/h))$. We provide the numerical evidence by testing our methods on an eikonal equation with $R(x) = 1$ on two and three dimensions. The results are given in Tables 1 and 2. For anisotropic cases, we found out that the number of iterations depend on the anisotropy of the Hamiltonian, but it is always reasonable and appears to be independent of the grid size.

6. Conclusion. In this paper, we have presented a new numerical method for Hamilton–Jacobi equations written in the form of Bellman's formula. We proved that the numerical Hamiltonian we proposed is monotone and consistent and is in fact also the Godunov Hamiltonian. We implemented this new scheme and showed some results in two- and three-dimensional cases.

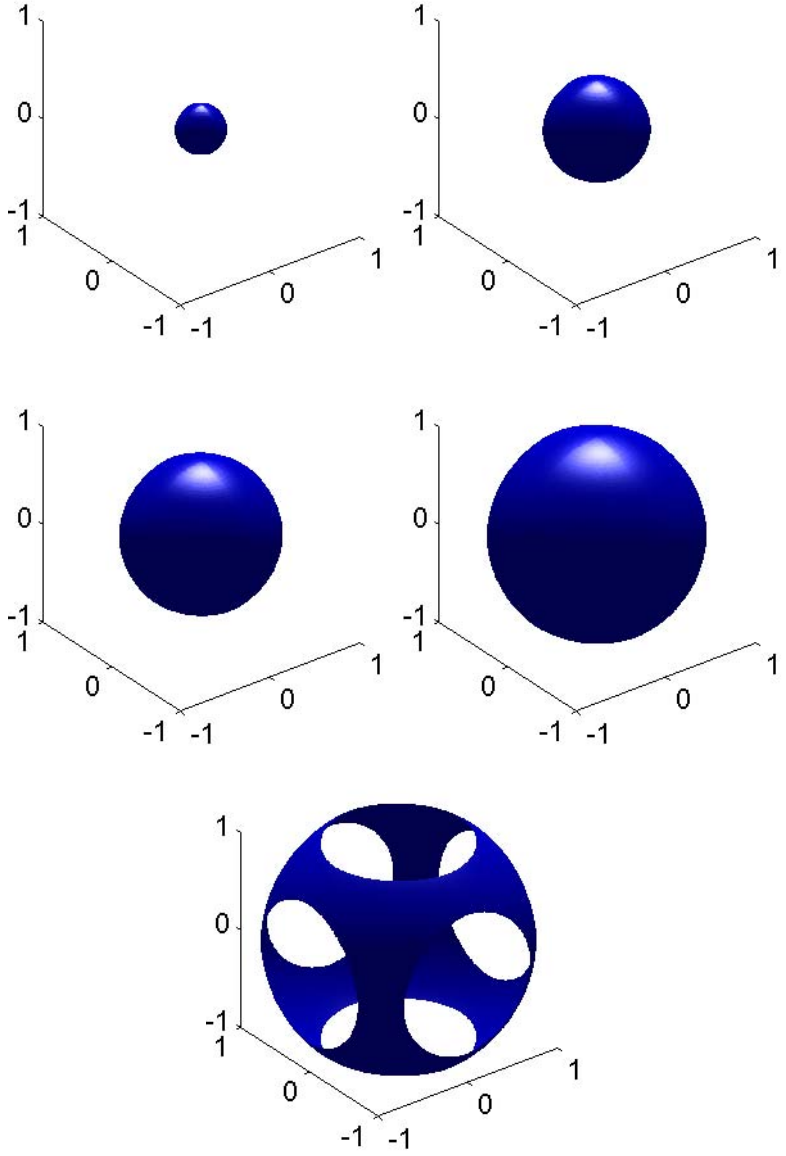

FIG. 6. *This is the one-iteration result of the* $3D$ *eikonal equation with the boundary* $(0, 0)$ *in the center of the graph. The corresponding contours are* 0.25, 0.5, 0.75, 1.0, *and* 1.25.

NUMERICAL ANALYSIS FOR A MACROSCOPIC MODEL IN MICROMAGNETICS*

CARSTEN CARSTENSEN† AND DIRK PRAETORIUS‡

Abstract. The macroscopic behavior of stationary micromagnetic phenomena can be modeled by a relaxed version of the Landau–Lifshitz minimization problem. In the limit of large and soft magnets Ω, it is reasonable to exclude the exchange energy and convexify the remaining energy densities. The numerical analysis of the resulting minimization problem,

$$\min E_0^{**}(\mathbf{m}) \text{ amongst } \mathbf{m} : \Omega \to \mathbb{R}^d \text{ with } |\mathbf{m}(x)| \le 1 \text{ for almost every } x \in \Omega,$$

for $d = 2, 3$, faces difficulties caused by the pointwise side-constraint $|\mathbf{m}| \le 1$ and an integral over the whole space $\mathbb{R}^d$ for the stray field energy. This paper involves a penalty method to model the side-constraint and reformulates the exterior Maxwell equation via a nonlocal integral operator $\mathcal{P}$ acting on functions exclusively defined on Ω. The discretization with piecewise constant discrete magnetizations leads to edge-oriented boundary integrals, the implementation of which and related numerical quadrature are discussed, as are adaptive algorithms for automatic mesh-refinement. A priori and a posteriori error estimates provide a thorough rigorous error control of certain quantities. Three classes of numerical experiments study the penalization, empirical convergence rates, and performance of the uniform and adaptive mesh-refining algorithms.

1. Introduction.

Numerical simulations of stationary micromagnetic phenomena are most frequently based on a mathematical model named after Landau and Lifshitz [2, 11]. Therein, one minimizes the energy functional

$$E_\alpha(\mathbf{m}) := \int_\Omega \phi(\mathbf{m})\,dx - \int_\Omega \mathbf{f}\cdot\mathbf{m}\,dx + \frac{1}{2}\int_{\mathbb{R}^d} |\nabla u|^2\,dx + \alpha\int_\Omega |\nabla \mathbf{m}|^2\,dx \tag{1.1}$$

over some admissible vector-valued magnetizations $\mathbf{m} : \Omega \to \mathbb{R}^d$ on the magnet Ω; $\mathbf{m}(x) := 0$ for $x \in \mathbb{R}^d\backslash\overline{\Omega}$. Moreover, $\phi \in \mathcal{C}^\infty(\mathbb{R}^d; \mathbb{R}_{\ge 0})$ denotes the anisotropy density (it models material properties on a crystalline level), $\mathbf{f} \in L^2(\Omega; \mathbb{R}^d)$ denotes an applied exterior magnetic field, $\alpha \ge 0$ is the very small exchange parameter, and u is the magnetic potential related to $\mathbf{m}$ by Maxwell's equation

$$\operatorname{div}(-\nabla u + \mathbf{m}) = 0 \quad \text{in } \mathcal{D}'(\mathbb{R}^d). \tag{1.2}$$

The model description is completed by a nonconvex side-constraint given by the pointwise length condition on the magnetization vector, namely,

$$|\mathbf{m}(x)| = 1 \quad \text{for almost every } x \in \Omega. \tag{1.3}$$

Any of the summands in (1.1) favors another property of an energy-minimizing magnetization. First, uniaxial materials such as cobalt allow the *uniaxial* anisotropy energy

$$\phi(x) = \frac{1}{2}\big(1 - (x \cdot \mathbf{e})^2\big) \quad \text{for all } |x| = 1 \tag{1.4}$$

with given *easy axis* $\mathbf{e} \in \mathbb{R}^d$, a fixed unit vector, which favors magnetizations $\mathbf{m}$ aligned with $\mathbf{e}$. Second, the *exterior energy* favors magnetizations $\mathbf{m}$ aligned to the exterior field $\mathbf{f}$. Third, the *magnetic energy* vanishes for divergence-free magnetizations, as seen in (1.2); notice that (1.2) involves a boundary condition $[\partial u/\partial \mathbf{n}] = -\mathbf{m} \cdot \mathbf{n}$ for the jump $[\cdot]$ on $\partial\Omega$, where $\mathbf{n}$ denotes the outer normal vector on $\partial\Omega$. Fourth, the *exchange energy* penalizes changes in the magnetization $\mathbf{m}$ and so yields Weissian domains and rapidly changes at the Bloch walls between those.

The macroscopic material behavior for large and soft magnets, however, is conserved in the case $\alpha = 0$. Then, the model lacks classical solutions in general [12] and hence has to be relaxed by considering measure-valued solutions [17] or by convexification [6, 21]. Notice that the convexified problem is the mathematical foundation of the so-called *phase theory* [11, p. 184].

Throughout this paper, the focus is on the numerical approximation of macroscopic quantities such as the magnetic potential u or the space-averages of the magnetization vector $\mathbf{m}$. In fact, in a certain limit configuration of soft-large bodies, $\alpha \to 0$, and then E_0 is the correct model with generalized solutions. The well-posed macroscopic values of E_0 are u and $\mathbf{m}$, which minimize the convexified model E_0^{**}. We refer to [6, 21] for justifications of this and the proof of

$$E_0^{**}(\mathbf{m}) := \int_\Omega \phi^{**}(\mathbf{m})\, dx - \int_\Omega \mathbf{f} \cdot \mathbf{m}\, dx + \frac{1}{2}\int_{\mathbb{R}^d} |\nabla u|^2\, dx \tag{1.5}$$

with the side-constraint (1.2) and

$$|\mathbf{m}(x)| \le 1 \quad \text{for almost every } x \in \Omega. \tag{1.6}$$

Here, ϕ^{**} is the convexified density defined by

$$\phi^{**}(x) = \sup\big\{\varphi(x) \,\big|\, \varphi : \mathbb{R}^d \to \mathbb{R} \text{ convex and } \varphi|_{\mathbb{S}} \le \phi\big\} \quad \text{for } |x| \le 1,$$

where $\mathbb{S} = \big\{x \in \mathbb{R}^d \,\big|\, |x| = 1\big\}$ denotes the unit sphere. Then the relaxed problem (RP) reads as follows:

$$\text{Minimize } E_0^{**}(\mathbf{m}) \text{ over } \mathcal{A} := \big\{\mathbf{m} \in L^\infty(\Omega;\mathbb{R}^d) \,\big|\, \|\mathbf{m}\|_{L^\infty} \le 1\big\}.$$

In contrast to the ill-posed problem E_0, its convexification is well-posed. In particular, the minimum of $E_0^{**}(\mathcal{A})$ is attained in $\mathcal{A}$.

The numerical analysis of the model in [5, 20] considers $d = 2$ only, replaces the entire space $\mathbb{R}^d$ in (1.2) by a bounded Lipschitz domain $\widehat{\Omega}$ containing Ω, and solves for $u \in H_0^1(\widehat{\Omega})$. The potential u is discretized by a nonconforming u_h and a piecewise constant $\mathbf{m}_h$ on Ω. The choice of u_h as a conforming, piecewise affine, and globally continuous finite element scheme leads to instabilities [5, 20]. In this paper, we treat (1.2) exactly via an integral representation, i.e., $u = \mathcal{L}\mathbf{m}$ with a linear convolution operator $\mathcal{L}$ and $\mathcal{P}\mathbf{m} := \nabla(\mathcal{L}\mathbf{m})$; cf. Theorem 2.1. The algorithmic realization of

$\mathcal{P}$ is less obvious and discussed in subsection 4.1. The advantage is that the resulting model requires only one discretization, e.g., by piecewise constant approximations $\mathbf{m}_h$. Those allow exact fulfillment of the side-constraint $|\mathbf{m}_h| \le 1$ involved approximately by a penalization procedure. The resulting discrete minimization problem is to minimize

$$E^{**}_{\varepsilon,h}(\mathbf{m}_h) := \int_\Omega \phi^{**}(\mathbf{m}_h)\,dx - \int_\Omega \mathbf{f}\cdot\mathbf{m}_h\,dx + \frac{1}{2}\int_{\mathbb{R}^d} |\mathcal{P}\mathbf{m}_h|^2\,dx + \frac{1}{2}\int_\Omega \frac{1}{\varepsilon}(|\mathbf{m}_h|-1)_+^2\,dx \tag{1.7}$$

over all $\mathcal{T}$-piecewise constant magnetizations $\mathbf{m}_h \in \mathcal{L}^0(\mathcal{T})^d$, where $\mathcal{T}$ is a partition of Ω. According to the a priori error analysis, the $\mathcal{T}$-piecewise constant penalization function $\varepsilon \in \mathcal{L}^0(\mathcal{T};\mathbb{R}_{>0})$ will be a power of the local mesh-size later on. It turns out that the error analysis of [5] essentially carries over to the situation presented in section 3 and generalizes to $d = 2, 3$.

The remaining part of the paper is organized as follows: Section 2 states the Euler–Lagrange equations related to (RP) and gives an alternate proof of the uniqueness of the solution of (RP) in the uniaxial case. The discrete problem $(RP_{\varepsilon,h})$ is formulated and unique existence of discrete solutions is discussed. Section 3 presents the assertion and proofs of a priori and a posteriori error estimates. Section 4 displays details on a possible implementation: the computation of a discrete solution by a Newton–Raphson scheme (subsection 4.1), an indicator-based adaptive mesh-refinement (subsection 4.2), the implementation of the proposed refinement indicators (subsection 4.3), and the efficient realization of the involved integral operator $\mathcal{P}$ by an $\mathcal{H}$-matrix approach (subsection 4.4). Sections 5–7 report on the results of careful numerical studies. The first and second examples provide a closed formula for the smooth and nonsmooth exact solution with a computable error $\|\mathbf{m} - \mathbf{m}_h\|_{L^2(\Omega)}$. Empirical evidence supports the choice of the penalty parameter $\varepsilon = h^{3/2}$ and the superiority of adaptive mesh-refining strategies over uniform meshes. The real-life scientific computing in section 7 with unknown solution shows, very much in surprising contrast to [5], that almost no local mesh-refinement is required.

2. Preliminaries. This section is devoted to the Euler–Lagrange equations related to (RP) which characterize the minimizers and introduces the proposed discretization by a penalization strategy. For (RP) and the discrete problem $(RP_{\varepsilon,h})$ we prove unique existence of solutions in the uniaxial case.

The magnetic potential is modeled via a Newton integral representation as in [14, 13]. The subsequent theorem gathers the required properties of the respective integral operator. Proofs can be found in [19] although we expect that the result is known to the experts. The Newtonian kernel $G : \mathbb{R}^d\backslash\{0\} \to \mathbb{R}$ is defined by

$$G(x) := \begin{cases} \frac{1}{\gamma_d}\log|x| & \text{for } d = 2 \\ \frac{1}{(2-d)\gamma_d}|x|^{2-d} & \text{for } d > 2 \end{cases} \quad \text{for } x \neq 0, \tag{2.1}$$

where the constant $\gamma_d := |\mathbb{S}| > 0$ denotes the surface measure of the unit sphere.

THEOREM 2.1. *Given any $\mathbf{m} \in L^\infty(\Omega;\mathbb{R}^d)$, there exists (up to an additive constant) a unique magnetic potential $u = \mathcal{L}\mathbf{m} \in H^1_{\ell oc}(\mathbb{R}^d)$ such that*

$$\nabla u \in L^2(\mathbb{R}^d;\mathbb{R}^d) \quad \textit{and} \quad \operatorname{div}(-\nabla u + \mathbf{m}) = 0 \quad \textit{in } \mathcal{D}'(\mathbb{R}^d). \tag{2.2}$$

The (extended) operator $\mathcal{P} : L^2(\mathbb{R}^d;\mathbb{R}^d) \to L^2(\mathbb{R}^d;\mathbb{R}^d), \mathbf{m} \mapsto \nabla(\mathcal{L}\mathbf{m})$ *is an* L^2 *orthogonal projection. The potential* $\mathcal{L}\mathbf{m}$ *can be represented as a convolution operator*

$$\mathcal{L}\mathbf{m} = \sum_{j=1}^{d} \frac{\partial G}{\partial x_j} * \mathbf{m}_j, \tag{2.3}$$

where $\mathbf{m} = (\mathbf{m}_1, \dots, \mathbf{m}_d)$ *is trivially extended (by zero) from* Ω *to* $\mathbb{R}^d$ *(so that the convolution is formally well-defined).*

Remark 2.1. For $d = 3$ it can be shown that the convolution $\mathcal{L}\mathbf{m}$ from (2.3) already is in $H^1(\mathbb{R}^d)$. Further details on the case $\mathbf{m} \in L^p(\mathbb{R}^d;\mathbb{R}^d)$ for $1 < p < \infty$ are found in [19].

Since the energy functional E_0^{**} from (1.5) is convex and (Gâteaux-)differentiable, the minima are equivalently characterized by the corresponding Euler–Lagrange equations [6]. Thus, problem (RP) reads as follows: Find $(\lambda, \mathbf{m}) \in L^2(\Omega) \times L^2(\Omega;\mathbb{R}^d)$ such that

$$\mathcal{P}\mathbf{m} + D\phi^{**}(\mathbf{m}) + \lambda\mathbf{m} = \mathbf{f} \quad \text{a.e. in } \Omega, \tag{2.4}$$

$$\lambda \geq 0,\ |\mathbf{m}| \leq 1,\ \lambda(1 - |\mathbf{m}|) = 0 \quad \text{a.e. in } \Omega. \tag{2.5}$$

Remark 2.2. For the uniaxial model case (1.4), direct calculations show $\phi^{**}(x) = \frac{1}{2}\sum_{j=2}^{d}(x \cdot \mathbf{z}_j)^2$, where $\mathbf{e} \in \mathbb{R}^d$ is the easy axis and $\{\mathbf{e}, \mathbf{z}_2, \dots, \mathbf{z}_d\}$ is an orthonormal basis of $\mathbb{R}^d$. Thus, $D\phi^{**}(x) = \sum_{j=1}^{d}(x \cdot \mathbf{z}_j)\mathbf{z}_j$.

THEOREM 2.2. *Problem* (RP) *has at least one solution* $(\lambda, \mathbf{m})$. *For any two solutions* $(\lambda_1, \mathbf{m}_1), (\lambda_2, \mathbf{m}_2)$ *of* (RP), *the magnetic potentials coincide (modulo an additive constant),* $\mathcal{L}\mathbf{m}_1 = \mathcal{L}\mathbf{m}_2$. *In the uniaxial model case* (1.4) *the solution is unique, i.e.,* $(\lambda_1, \mathbf{m}_1) = (\lambda_2, \mathbf{m}_2)$ *a.e.*

Proof. Existence of solutions of (RP) is obtained by the direct method of the calculus of variations. For any solutions $(\lambda_j, \mathbf{m}_j)$ of (RP) and $\boldsymbol{\delta} = \mathbf{m}_2 - \mathbf{m}_1$, (2.4) yields

$$\langle \mathcal{P}\boldsymbol{\delta}\,;\,\boldsymbol{\delta}\rangle_{L^2(\Omega)} + \langle D\phi^{**}(\mathbf{m}_2) - D\phi^{**}(\mathbf{m}_1)\,;\,\boldsymbol{\delta}\rangle_{L^2(\Omega)} + \langle \lambda_2\mathbf{m}_2 - \lambda_1\mathbf{m}_1\,;\,\boldsymbol{\delta}\rangle_{L^2(\Omega)} = 0. \tag{2.6}$$

By orthogonality of $\mathcal{P}$, we have $\langle \mathcal{P}\boldsymbol{\delta}\,;\,\boldsymbol{\delta}\rangle_{L^2(\Omega)} = \|\mathcal{P}\boldsymbol{\delta}\|_{L^2(\Omega)} \geq 0$. Further, convexity yields that the second term in (2.6) is nonnegative. Direct calculation shows the same for the last term [5, Proof of Theorem 2.1]. Thus, all three terms vanish. Hence, $\mathcal{P}\boldsymbol{\delta} = 0$; i.e., the potentials coincide and moreover $\boldsymbol{\delta}$ is (weakly) divergence free in $\mathbb{R}^d$ by definition of $\mathcal{P}$ (and $\mathcal{L}$); see (2.2) in Theorem 2.1.

In the model case we may assume that the easy axis $\mathbf{e} = \mathbf{e}_1$ is the first standard unit vector. The vanishing second term in (2.6) shows that $\boldsymbol{\delta}$ vanishes in all but the $\mathbf{e}_1$ direction. Now we use a standard mollification argument: For any test function $\psi \in \mathcal{D}(\mathbb{R}^d)$, we have $\psi * \boldsymbol{\delta} \in \mathcal{D}(\mathbb{R}^d)$ with $0 = \psi * (\mathrm{div}\boldsymbol{\delta}) = \mathrm{div}(\psi * \boldsymbol{\delta}) = \partial(\psi * \boldsymbol{\delta})/\partial x_1$. Hence $\psi * \boldsymbol{\delta}$ is constant in the $\mathbf{e}_1$ direction and must therefore vanish. This shows $\boldsymbol{\delta} = 0$. From (2.4) and (2.5) we infer that λ_j is uniquely determined by $(\mathbf{m}_j, \mathbf{f})$. Therefore uniqueness of $\mathbf{m}_j$ implies uniqueness of λ_j. ∎

Let $\mathcal{T} = \{T_1, \dots, T_N\}$ be a finite family of pairwise disjoint nonempty open sets T_j which satisfy $\overline{\Omega} = \bigcup_{j=1}^{N} \overline{T_j}$. The space of all $\mathcal{T}$-piecewise constant functions is denoted by $\mathcal{L}^0(\mathcal{T})$, and $h \in \mathcal{L}^0(\mathcal{T})$ is the mesh-size function, $h|_T := h_T := \mathrm{diam}(T)$. For $f \in L^2(\Omega)$, let $f_{\mathcal{T}} \in \mathcal{L}^0(\mathcal{T})$ be the $\mathcal{T}$-piecewise integral mean given by

$$f_{\mathcal{T}}|_T := \frac{1}{|T|}\int_T f\,dx \quad \text{for all } T \in \mathcal{T}.$$

The map $(\cdot)_{\mathcal{T}} : L^2(\Omega) \to \mathcal{L}^0(\mathcal{T}), f \mapsto f_{\mathcal{T}}$ is the L^2 orthogonal projection.

The discrete problem $(RP_{\varepsilon,h})$ reads as follows: Given a penalization parameter $\varepsilon \in \mathcal{L}^0(\mathcal{T})$ with $\varepsilon > 0$, find $\mathbf{m}_h \in \mathcal{L}^0(\mathcal{T})^d$ such that

$$\langle \mathcal{P}\mathbf{m}_h + D\phi^{**}(\mathbf{m}_h) + \lambda_h \mathbf{m}_h \,;\, \boldsymbol{\nu}_h \rangle_{L^2(\Omega)} = \langle \mathbf{f} \,;\, \boldsymbol{\nu}_h \rangle_{L^2(\Omega)} \quad \text{for all } \boldsymbol{\nu}_h \in \mathcal{L}^0(\mathcal{T})^d, \tag{2.7}$$

where $\lambda_h \in \mathcal{L}^0(\mathcal{T})$ is defined by

$$\lambda_h = \varepsilon^{-1} \frac{(|\mathbf{m}_h| - 1)_+}{|\mathbf{m}_h|} \quad \text{with } (\cdot)_+ := \max\{\cdot, 0\}. \tag{2.8}$$

Remark 2.3. Problem $(RP_{\varepsilon,h})$ are the Euler–Lagrange equations of the minimization problem related to the convex functional from (1.7) and the finite-dimensional space $\mathcal{A} = \mathcal{L}^0(\mathcal{T})^d$. Thus, the existence of solutions of the discrete problem $(RP_{\varepsilon,h})$ follows by the direct method of the calculus of variations.

THEOREM 2.3. *The discrete problem $(RP_{\varepsilon,h})$ has at least one solution. For any two solutions $(\lambda_1, \mathbf{m}_1), (\lambda_2, \mathbf{m}_2)$ of $(RP_{\varepsilon,h})$, the magnetic potentials $\mathcal{L}\mathbf{m}_j$ coincide. In the uniaxial model case* (1.4)*, we have uniqueness of the discrete solution, i.e., $(\lambda_1, \mathbf{m}_1) = (\lambda_2, \mathbf{m}_2)$.*

Proof. The same proof as for Theorem 2.2 applies for the discrete setting as well. ∎

Remark 2.4. (a) If the elements $T \in \mathcal{T}$ are rectangular, it can easily be shown that (independent of ϕ^{**}) the solution $(\lambda_h, \mathbf{m}_h)$ of $(RP_{\varepsilon,h})$ is unique. The easy proof just needs that for two discrete solutions $(\lambda_1, \mathbf{m}_1), (\lambda_2, \mathbf{m}_2)$ the difference $\boldsymbol{\delta} := \mathbf{m}_2 - \mathbf{m}_1 \in \mathcal{L}^0(\mathcal{T})^d$ is (weakly) divergence free in $\mathbb{R}^d$. Consider the set $\mathcal{T}^* := \{T \in \mathcal{T} \,|\, \boldsymbol{\delta}|_T \neq 0\}$ and $\Omega^* := \bigcup \{\overline{T} \,|\, T \in \mathcal{T}^*\}$ and argue by contradiction: If $\mathcal{T}^*$ is not empty, we have $\boldsymbol{\delta} \cdot \mathbf{n} = 0$ a.e. by the Gauss divergence theorem, where $\mathbf{n}$ is the outer normal vector on $\partial\Omega^*$. Using that $\boldsymbol{\delta}$ is $\mathcal{T}^*$-piecewise constant, the contradiction easily follows.

(b) The preceding argument applies to more general (but not all) triangulations $\mathcal{T}$.

3. A priori and a posteriori error control. This section provides an a priori and a posteriori error analysis for the proposed discrete scheme $(RP_{\varepsilon,h})$ with or without a further monotonicity assumption (3.4) on ϕ^{**} valid in the uniaxial case (1.4).

THEOREM 3.1. *Let $(\lambda, \mathbf{m})$ and $(\lambda_h, \mathbf{m}_h)$ solve (RP) and $(RP_{\varepsilon,h})$, respectively. Then*

$$\begin{aligned} &\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + 2\langle D\phi^{**}(\mathbf{m}) - D\phi^{**}(\mathbf{m}_h) \,;\, \mathbf{m} - \mathbf{m}_h \rangle_{L^2(\Omega)} + \|\sqrt{\varepsilon}\,\lambda_h \mathbf{m}_h\|^2_{L^2(\Omega)} \\ &\quad \le 3\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|^2_{L^2(\Omega)} + \|D\phi^{**}(\mathbf{m}) - (D\phi^{**}(\mathbf{m}))_{\mathcal{T}}\|^2_{L^2(\Omega)} + \|\lambda\mathbf{m} - (\lambda\mathbf{m})_{\mathcal{T}}\|^2_{L^2(\Omega)} \\ &\qquad + \|\sqrt{\varepsilon}\,\lambda\mathbf{m}\|^2_{L^2(\Omega)}. \end{aligned} \tag{3.1}$$

(Note that according to convexity, the second term on the left-hand side is also nonnegative.)

Proof. To abbreviate notation, define $\mathbf{d} := D\phi^{**}(\mathbf{m})$ and $\mathbf{d}_h := D\phi^{**}(\mathbf{m}_h)$. Using the orthogonal projection $\mathcal{P}$ and the Cauchy inequality, we infer

$$\begin{aligned} \|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} \le{}& \frac{1}{2}\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + \frac{1}{2}\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|^2_{L^2(\Omega)} \\ &+ \langle \mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h \,;\, \mathbf{m}_{\mathcal{T}} - \mathbf{m}_h \rangle_{L^2(\Omega)}. \end{aligned} \tag{3.2}$$

According to the Galerkin orthogonality

$$\langle \mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h + \mathbf{d} - \mathbf{d}_h + \lambda\mathbf{m} - \lambda_h\mathbf{m}_h \,;\, \boldsymbol{\nu}_h\rangle_{L^2(\Omega)} = 0 \quad \text{for all } \boldsymbol{\nu}_h \in \mathcal{L}^0(\mathcal{T})^d, \tag{3.3}$$

the last term in (3.2) may be written as

$$\begin{aligned}
&\langle \mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h \,;\, \mathbf{m}_\mathcal{T} - \mathbf{m}_h\rangle_{L^2(\Omega)} \\
&\quad = -\langle \mathbf{d} - \mathbf{d}_h \,;\, \mathbf{m} - \mathbf{m}_h\rangle_{L^2(\Omega)} - \langle \lambda\mathbf{m} - \lambda_h\mathbf{m}_h \,;\, \mathbf{m} - \mathbf{m}_h\rangle_{L^2(\Omega)} \\
&\qquad + \langle \mathbf{d} - \mathbf{d}_h \,;\, \mathbf{m} - \mathbf{m}_\mathcal{T}\rangle_{L^2(\Omega)} + \langle \lambda\mathbf{m} - \lambda_h\mathbf{m}_h \,;\, \mathbf{m} - \mathbf{m}_\mathcal{T}\rangle_{L^2(\Omega)}.
\end{aligned}$$

Since $(\cdot)_\mathcal{T}$ is an orthogonal projection, $\mathbf{d}_h$ and $\lambda_h\mathbf{m}_h$ may be replaced by $\mathbf{d}_\mathcal{T}$ and $(\lambda\mathbf{m})_\mathcal{T}$ in the third and fourth terms. Pointwise evaluation [5, Proof of Theorem 4.3] shows

$$-\langle \lambda\mathbf{m} - \lambda_h\mathbf{m}_h \,;\, \mathbf{m} - \mathbf{m}_h\rangle_{L^2(\Omega)} \le \frac{1}{2}\|\sqrt{\varepsilon}\,\lambda\mathbf{m}\|^2_{L^2(\Omega)} - \frac{1}{2}\|\sqrt{\varepsilon}\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}.$$

Combining the last two results with two Cauchy inequalities, we conclude (3.1). ∎

THEOREM 3.2. *Let $(\lambda, \mathbf{m})$ and $(\lambda_h, \mathbf{m}_h)$ solve (RP) and $(RP_{\varepsilon,h})$, respectively, and assume that there is a constant $c_1 > 0$ such that, for all $\mathbf{m}_1, \mathbf{m}_2 \in L^2(\Omega;\mathbb{R}^d)$, the following holds:*

$$c_1\|D\phi^{**}(\mathbf{m}_1) - D\phi^{**}(\mathbf{m}_2)\|^2_{L^2(\Omega)} \le \langle D\phi^{**}(\mathbf{m}_1) - D\phi^{**}(\mathbf{m}_2) \,;\, \mathbf{m}_1 - \mathbf{m}_2\rangle_{L^2(\Omega)}. \tag{3.4}$$

Then there is a constant $c_2 > 0$ which depends only on c_1 such that

$$\begin{aligned}
&\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + \|D\phi^{**}(\mathbf{m}) - D\phi^{**}(\mathbf{m}_h)\|^2_{L^2(\Omega)} + \|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)} \\
&\quad \le c_2\Big((1 + \|\varepsilon\|_{L^\infty(\Omega)})\Big\{\|\mathbf{m} - \mathbf{m}_\mathcal{T}\|^2_{L^2(\Omega)} + \|D\phi^{**}(\mathbf{m}) - (D\phi^{**}(\mathbf{m}))_\mathcal{T}\|^2_{L^2(\Omega)} \\
&\qquad + \|\lambda\mathbf{m} - (\lambda\mathbf{m})_\mathcal{T}\|^2_{L^2(\Omega)}\Big\} + \|\varepsilon\|_{L^\infty(\Omega)}\|\sqrt{\varepsilon}\,\lambda\mathbf{m}\|^2_{L^2(\Omega)}\Big).
\end{aligned} \tag{3.5}$$

Proof. Use notation from the proof of Theorem 3.1. Direct calculation with Galerkin orthogonality, orthogonal projections $(\cdot)_\mathcal{T}$ and $\mathcal{P}$, and simple use of the Cauchy inequality shows

$$\begin{aligned}
&\|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)} \\
&\qquad \le 4\big(\|\lambda\mathbf{m} - (\lambda\mathbf{m})_\mathcal{T}\|^2_{L^2(\Omega)} + \|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + \|\mathbf{d} - \mathbf{d}_h\|^2_{L^2(\Omega)}\big),
\end{aligned} \tag{3.6}$$

whence the left-hand side of (3.5) $\le 5\times$ the right-hand side of (3.6). Assumption (3.4) allows us to dominate the last two terms by Theorem 3.1, which leads to $c_3\big(\|\sqrt{\varepsilon}\,\lambda\mathbf{m}\|^2_{L^2(\Omega)} - \|\sqrt{\varepsilon}\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}\big)$ on the right-hand side with $c_3 := 5\max\{1, c_1^{-1}\}$. Elementary calculations for scalars $a, b, c \in \mathbb{R}$ show $c\,(a^2 - b^2) = c\,(a+b)(a-b) \le \sqrt{2}\,c\,(a^2+b^2)^{1/2}|a-b| \le c^2\,(a^2+b^2) + |a-b|^2/2$, whence

$$\begin{aligned}
&c_3\big(\|\sqrt{\varepsilon}\,\lambda\mathbf{m}\|^2_{L^2(\Omega)} - \|\sqrt{\varepsilon}\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}\big) \\
&\qquad \le c_3^2\big(\|\varepsilon\lambda\mathbf{m}\|^2_{L^2(\Omega)} + \|\varepsilon\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}\big) + \frac{1}{2}\|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}
\end{aligned}$$

by pointwise application and integration over Ω. Finally, the second term is dominated by $\|\varepsilon\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)} \le \|\varepsilon\|_{L^\infty(\Omega)}\|\sqrt{\varepsilon}\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)}$ and a second application of Theorem 3.1. ∎

Remark 3.1. Theorem 3.2 applies in particular to the uniaxial case, where we have equality with $c_1 = 1$ in the monotonicity assumption (3.4).

Remark 3.2. Assume the monotonicity assumption (3.4) and that the exact solution is sufficiently smooth. Whereas Theorem 3.1 leads to an estimate of order $O(\varepsilon^{1/2} + h)$ for the error $\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|_{L^2(\mathbb{R}^d)} + \|D\phi^{**}(\mathbf{m}) - D\phi^{**}(\mathbf{m}_h)\|_{L^2(\Omega)}$, Theorem 3.2 leads to $O(\varepsilon+h)$. This favors the choice $\varepsilon = h$ for the penalization parameter.

Remark 3.3. Note that the full L^2 convergence of $\mathbf{m}_h$ towards $\mathbf{m}$ could not be proven, although it is observed in the numerical experiments. For the uniaxial case, Theorem 3.2 yields the L^2 convergence in all directions orthogonal to the easy axis; cf. Remark 2.2.

THEOREM 3.3. *Let* $(\lambda, \mathbf{m})$ *and* $(\lambda_h, \mathbf{m}_h)$ *solve* (RP) *and* $(RP_{\varepsilon,h})$*, respectively, and assume monotonicity as in* (3.4)*. Then*

(3.7)
$$\begin{aligned}
&\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + c_1\|D\phi^{**}(\mathbf{m}) - D\phi^{**}(\mathbf{m}_h)\|^2_{L^2(\Omega)}\\
&\quad\le (1 + 1/c_1)\,\|\varepsilon\,\lambda_h\mathbf{m}_h\|^2_{L^2(\Omega)} + 2\|\varepsilon|\lambda_h\mathbf{m}_h|\{(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\}\|_{L^1(\Omega)}\\
&\qquad + 2\langle(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\,;\,\mathbf{m} - \mathbf{m}_\mathcal{T}\rangle_{L^2(\Omega)}.
\end{aligned}$$

Remark 3.4. (a) In fact, the last term on the right-hand side of (3.7) is *not* an a posteriori term but can always be dominated by an application of the Hölder inequality and (1.6)

$$\begin{aligned}
&\langle(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\,;\,\mathbf{m} - \mathbf{m}_\mathcal{T}\rangle_{L^2(\Omega)}\\
&\quad\le 2\|(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\|_{L^1(\Omega)},
\end{aligned}$$

where we used the side-constraint $\|\mathbf{m}\|_{L^\infty(\Omega)} \le 1$.

(b) For $\mathbf{m} \in W^{1,\infty}(\Omega;\mathbb{R}^d)$ and $C = C_P\,\|\mathbf{m}\|_{W^{1,\infty}(\Omega)}$, Poincaré's inequality yields

$$\begin{aligned}
&\langle(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\,;\,\mathbf{m} - \mathbf{m}_\mathcal{T}\rangle_{L^2(\Omega)}\\
&\quad\le\ C\,\|h\{(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\}\|_{L^1(\Omega)}.
\end{aligned}$$

Remark 3.5. We did not succeed in deriving an a posteriori bound for the a priori term $\|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h\|_{L^2(\Omega)}$.

Proof of Theorem 3.3. Adopt notation from the proof of Theorem 3.1. By definition of the discretization scheme, we have

(3.8)
$$\mathbf{f} - \mathbf{f}_\mathcal{T} = (\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h) + (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T}) + (\mathbf{d} - \mathbf{d}_h) + (\lambda\mathbf{m} - \lambda_h\mathbf{m}_h) \quad \text{a.e. in } \Omega.$$

This and the elementary inequality [5, Proof of Theorem 5.2]

$$-\langle\lambda\mathbf{m} - \lambda_h\mathbf{m}_h\,;\,\mathbf{m} - \mathbf{m}_h\rangle_{L^2(\Omega)} \le \int_\Omega \varepsilon|\lambda_h\mathbf{m}_h|\,|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h|\,dx$$

allow us to dominate the left-hand side of (3.7),

$$\begin{aligned}
&\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|^2_{L^2(\mathbb{R}^d)} + c_1\|\mathbf{d} - \mathbf{d}_h\|^2_{L^2(\Omega)}\\
&\quad\le \langle(\mathbf{f} - \mathbf{f}_\mathcal{T}) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_\mathcal{T})\,;\,\mathbf{m} - \mathbf{m}_h\rangle_{L^2(\Omega)} + \int_\Omega \varepsilon|\lambda_h\mathbf{m}_h|\,|\lambda\mathbf{m} - \lambda_h\mathbf{m}_h|\,dx.
\end{aligned}$$

In the scalar product, $\mathbf{m}-\mathbf{m}_h$ may be replaced my $\mathbf{m}-\mathbf{m}_{\mathcal{T}}$ due to orthogonality of $(\cdot)_{\mathcal{T}}$. Inserting $\lambda\mathbf{m}-\lambda_h\mathbf{m}_h$ from (3.8) into the integrand and serious use of the Cauchy inequality yield the assertion. ∎

4. Numerical algorithms. This section is devoted to the implementation of $(RP_{\varepsilon,h})$ for the uniaxial case (1.4) in MATLAB. The discrete problem $(RP_{\varepsilon,h})$ leads to a nonlinear systems of equations solved by a Newton–Raphson scheme. Subsections 4.2 and 4.3 describe an adaptive mesh-refinement based on refinement indicators motivated by Theorem 3.3 and the practical computation of the refinement indicators. The computation of both—the Galerkin element and the refinement indicators—involves the integral operator $\mathcal{P}$ and hence leads to dense matrices. Subsection 4.4 gives
an outlook of their efficient approximation with an $\mathcal{H}$-matrix approach.

4.1. Computation of the discrete solution $\mathbf{m_h}$. Given $\mathcal{T}=\{T_1,\dots,T_N\}$, the set $\mathcal{B}:=\big\{\chi_{T_j}\mathbf{e}_k\,\big|\,1\le j\le N,1\le k\le d\big\}$ is a basis of $\mathcal{L}^0(\mathcal{T})^d$, where $\mathbf{e}_k$ denotes the kth standard unit vector in $\mathbb{R}^d$. The computation of a discrete solution $\mathbf{m}_h=\sum_{j=1}^{dN}\mu_j\varphi_j$ is done via a Newton–Raphson scheme. To abbreviate notation and fix a numbering of the basis elements $\varphi_\ell\in\mathcal{B}$, let

$$\begin{cases}[j,1]:=j\\ [j,2]:=j+N\end{cases}\quad\text{for } d=2\quad\text{and}\quad\begin{cases}[j,1]:=j\\ [j,2]:=j+N\\ [j,3]:=j+2N\end{cases}\quad\text{for } d=3,$$

respectively, and for all $1\le j\le N$. Further let $\varphi_{[j,k]}:=\chi_{T_j}\mathbf{e}_k\in\mathcal{B}$. With $\mathbf{x}\in\mathbb{R}^{dN}$ and

$$\mathbf{m}_h=\sum_{j=1}^{N}\sum_{k=1}^{d}\mathbf{x}_{[j,k]}\varphi_{[j,k]},\tag{4.1}$$

equation (2.7) is equivalent to the nonlinear system $\mathbf{F}(\mathbf{x})=0$ with

$$\mathbf{F}:\mathbb{R}^{dN}\to\mathbb{R}^{dN},\quad \mathbf{F}_\ell=\langle\mathcal{P}\mathbf{m}_h\,;\,\varphi_\ell\rangle_{L^2(\Omega)}+\langle\lambda_h\mathbf{m}_h+D\phi^{**}(\mathbf{m}_h)-\mathbf{f}\,;\,\varphi_\ell\rangle_{L^2(\Omega)}.\tag{4.2}$$

Thus, the discrete scheme needs the computation of the matrix

$$\mathbf{A}\in\mathbb{R}^{dN\times dN},\quad \mathbf{A}_{mn}:=\langle\mathcal{P}\varphi_m\,;\,\varphi_n\rangle_{L^2(\Omega)}\quad\text{for basis functions }\varphi_m,\varphi_n\in\mathcal{B}.\tag{4.3}$$

Provided all $T_j\in\mathcal{T}$ are bounded Lipschitz domains, the following lemma allows for the *exact* computation of (4.3).

LEMMA 4.1 (see [10, 19]). *Let $\mathbf{m},\widetilde{\mathbf{m}}\in\mathbb{R}^d$ and let $\omega,\widetilde{\omega}\subseteq\mathbb{R}^d$ be bounded Lipschitz domains with outer normals $\mathbf{n},\widetilde{\mathbf{n}}$, respectively. Then $A(\chi_\omega\mathbf{m},\chi_{\widetilde{\omega}}\widetilde{\mathbf{m}}):=\langle\mathcal{P}(\chi_\omega\mathbf{m});\chi_{\widetilde{\omega}}\widetilde{\mathbf{m}}\rangle_{L^2(\mathbb{R}^d)}$ satisfies*

$$\begin{aligned}A(\chi_\omega\mathbf{m},\chi_{\widetilde{\omega}}\widetilde{\mathbf{m}})&=A(\chi_{\widetilde{\omega}}\widetilde{\mathbf{m}},\chi_\omega\mathbf{m})=A(\chi_\omega\widetilde{\mathbf{m}},\chi_{\widetilde{\omega}}\mathbf{m})\\&=-\int_\omega\int_{\widetilde{\omega}}G(x-y)(\mathbf{n}(x)\cdot\mathbf{m})(\widetilde{\mathbf{n}}(y)\cdot\widetilde{\mathbf{m}})\,ds_y\,ds_x.\end{aligned}\tag{4.4}$$

Remark 4.1. In the context of the boundary element method, boundary integrals

$$\int_E\int_{\widetilde{E}}G(x-y)\,ds_y\,ds_x$$

occur for the computation of the Galerkin elements for Symm's integral equation and piecewise constant ansatz functions. Analytic formulas are known for $E, \widetilde{E}$ being affine boundary pieces ($d = 2$) [15, 16, 4] or axis-orientated flat rectangles ($d = 3$) [15, 16, 9].

4.2. Adaptive mesh-refinement. Theorem 3.3 gives rise to the error estimators

$$\mu := \left(\sum_{T \in \mathcal{T}} \mu_T^2 \right)^{1/2} \quad \text{and} \quad \eta := \left(\sum_{T \in \mathcal{T}} \eta_T^2 \right)^{1/2}, \tag{4.5}$$

where the refinement indicators μ_T, η_T, for $T \in \mathcal{T}$, are defined by

$$\begin{aligned} \ell_T &:= (\varepsilon \lambda_h |\mathbf{m}_h|)|_T = (|\mathbf{m}_h|_T| - 1)_+, \\ \mu_T^2 &:= (1 + \ell_T) \|(\mathbf{f} - \mathbf{f}_T) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_T)\|_{L^1(T)} + |T| \ell_T^2, \\ \eta_T^2 &:= (h_T + \ell_T) \|(\mathbf{f} - \mathbf{f}_T) - (\mathcal{P}\mathbf{m}_h - (\mathcal{P}\mathbf{m}_h)_T)\|_{L^1(T)} + |T| \ell_T^2. \end{aligned} \tag{4.6}$$

Remark 4.2. (a) The estimator μ is reliable, i.e., an upper bound for the error $\|\mathcal{P}\mathbf{m} - \mathcal{P}\mathbf{m}_h\|_{L^2(\mathbb{R}^d)} + \|D\phi^{**}(\mathbf{m}) - D\phi^{**}(\mathbf{m}_h)\|_{L^2(\Omega)}$ up to a multiplicative constant.

(b) μ cannot be efficient, i.e., a lower bound for the error.

(c) η is reliable for $\mathbf{m} \in W^{1,\infty}(\Omega; \mathbb{R}^d)$, but not in general.

(d) Efficiency of η is expected but could not be proven.

ALGORITHM 4.2 (adaptive mesh-refinement). *Let $\mathcal{T}^{(0)}$ be the initial triangulation, $n = 0$, $\alpha > 0$, and $0 \le \theta \le 1$.*

(i) *For $T_j \in \mathcal{T}^{(n)} = \{T_1, \dots, T_N\}$ choose a penalization parameter $\varepsilon_j = h_{T_j}^{\alpha} > 0$.*

(ii) *Compute approximation $\mathbf{m}_h$ with respect to the current triangulation $\mathcal{T}^{(n)}$ and $\varepsilon \in \mathcal{L}^0(\mathcal{T}^{(n)})$, $\varepsilon|_{T_j} := \varepsilon_j$, by the Newton–Raphson scheme.*

(iii) *Compute error estimators μ and η from* (4.5) *and refinement indicators $\eta_j := \eta_{T_j}$ and $\mu_j := \mu_{T_j}$ from* (4.6).

(iv) *Mark an element $T_j \in \mathcal{T}^{(n)}$ provided $\eta_j \ge \theta \max_{1 \le k \le N} \eta_k$ for η-adaptive mesh-refinement and provided $\mu_j \ge \theta \max_{1 \le k \le N} \mu_k$ for μ-adaptive mesh-refinement.*

(v) *Refine the marked elements, update $n \mapsto n + 1$, and go to* (i).

Remark 4.3. The choice $\theta = 0$ in Algorithm 4.2 leads to uniform mesh-refinement, whereas $\theta \approx 1$ leads to highly adapted meshes. In the numerical experiments, $\theta = 0$ or $\theta = 1/2$.

Remark 4.4. To lower the computational cost for the Newton–Raphson scheme, we used *nested iterations*: In step (ii) of Algorithm 4.2, the Newton–Raphson scheme was started with the prolonged discrete solution $\mathbf{m}_h^{(n-1)}$ for the previous grid $\mathcal{T}^{(n-1)}$.

4.3. Implementation of the refinement indicators. The L^1 norm in the definition of μ_T and η_T, respectively, was computed by a (2×2)-tensor Gauss quadrature rule. The following lemma shows that the point evaluation of $\mathcal{P}\mathbf{m}_h$ is well-defined outside the skeleton of $\mathcal{T}$.

LEMMA 4.3. *For $\mathbf{m}_h \in \mathcal{L}^0(\mathcal{T}; \mathbb{R}^d)$, the corresponding potential satisfies $\mathcal{L}\mathbf{m}_h \in \mathcal{C}(\mathbb{R}^d) \cap \mathcal{C}^1(\mathbb{R}^d \backslash \mathcal{S})$, where $\mathcal{S} := \bigcup \{\partial T \,|\, T \in \mathcal{T}\}$ denotes the skeleton of the triangulation. Moreover, the derivative $\mathcal{P}\mathbf{m}_h = \nabla(\mathcal{L}\mathbf{m}_h)$ can be computed pointwise by*

$$\mathcal{P}\mathbf{m}_h(x) = \frac{1}{|\mathbb{S}|} \sum_{T \in \mathcal{T}} \int_{\partial T} \frac{\mathbf{m}_h|_T \cdot (x - y)}{|x - y|^d} \, \mathbf{n}(y) \, ds_y \quad \text{for } x \in \mathbb{R}^d \backslash \mathcal{S}, \tag{4.7}$$

where $\mathbf{n}(y)$ *denotes the outer normal with respect to* $T \in \mathcal{T}$ *and* $\mathbb{S} \subseteq \mathbb{R}^d$ *the unit sphere.*

Proof. For the Lipschitz domain $T \in \mathcal{T}$, the Newtonian potential of the characteristic function satisfies $G * \chi_T \in \mathcal{C}^1(\mathbb{R}^d) \cap \mathcal{C}^2(\operatorname{int} T)$ with

$$\frac{\partial^2}{\partial x_j \partial x_k}\big(G * \chi_T\big)(x) = \frac{\partial}{\partial x_k}\big((\partial G/\partial x_j) * \chi_T\big)(x) = \int_{\partial T} \frac{\partial G}{\partial x_j}(x-y)\, n_k(y)\, ds_y; \tag{4.8}$$

see [8, Lemma 4.2]. With the abbreviated notation $\mathbf{m}^{(T)} := \mathbf{m}_h|_T$, we have

$$\mathcal{L}\mathbf{m}_h = \sum_{T\in\mathcal{T}} \sum_{j=1}^{d} m_j^{(T)}\, \frac{\partial G}{\partial x_j} * \chi_T = \sum_{T\in\mathcal{T}} \mathbf{m}^{(T)} \cdot \big((\nabla G) * \chi_T\big).$$

Computing the kth partial derivative of $\mathcal{L}\mathbf{m}_h$ via (4.8), we verify the assertion. ∎

Remark 4.5. Note that the singularities of $\mathcal{P}\mathbf{m}_h$ on the skeleton $\mathcal{S}$ are quite weak since it can be shown that $\mathcal{P}\mathbf{m}_h \in L^p(\Omega;\mathbb{R}^d)$ for all $1 < p < \infty$; see [19]. This seems to justify the computation of the L^1 norms by a simple quadrature rule.

Remark 4.6. In the context of the boundary element method, boundary integrals as in (4.7) occur for the computation of the double layer potential for piecewise constants. If one replaces ∂T by a bounded boundary piece E, the analytic formulas are known for E being affine ($d = 2$) [15, 16, 4] and being a triangle or rectangle ($d = 3$) [15, 16, 9].

4.4. Efficient realization of the involved integral operator $\boldsymbol{\mathcal{P}}$. The dense matrix $\mathbf{A} \in \mathbb{R}^{dN\times dN}_{sym}$ from (4.3) has certain symmetry properties. To decrease computation time and memory, $\mathcal{H}$- and $\mathcal{H}^2$-matrix approaches can be used [1, 10, 19, 18], where $\mathbf{A}$ is replaced by an approximation $\widetilde{\mathbf{A}}$.

LEMMA 4.4. *For any bounded open sets* $\omega, \widetilde{\omega} \subseteq \mathbb{R}^d$ *with* $\operatorname{dist}(\omega;\widetilde{\omega}) > 0$*, for* $\alpha, \beta = 1, \dots, d$*, and the* ℓ*th canonical unit vector* $\mathbf{e}_\ell \in \mathbb{R}^d$*, the bilinear form* $A(\cdot,\cdot)$ *from Lemma* 4.1 *satisfies*

$$A(\chi_\omega \mathbf{e}_\alpha, \chi_{\widetilde{\omega}} \mathbf{e}_\beta) = \int_\omega \int_{\widetilde{\omega}} \frac{\partial^2 G}{\partial x_\alpha \partial x_\beta}(x-y)\, dy\, dx.$$

Proof. The lemma follows from standard results on convolutions. ∎

The idea of the $\mathcal{H}^2$-matrix approach is to approximate the kernel

$$g_{\alpha\beta}(x,y) := \frac{\partial^2 G}{\partial x_\alpha \partial x_\beta}(x-y)$$

based on panel clustering. For certain $\sigma, \tau \subseteq \mathcal{T}$ with $\operatorname{dist}(\cup\sigma, \cup\tau) > 0$, let vectors $x_{m_1}^{(\sigma)} \in \cup\sigma$, $y_{m_2}^{(\tau)} \in \cup\tau$ and polynomials $p_{m_1}^{(\sigma)}, p_{m_2}^{(\tau)}$ on $\cup\sigma$, respectively, $\cup\tau$, be given and define

$$\widetilde{g}_{\alpha\beta}(x,y) := \sum_{m_1=1}^{M_1} \sum_{m_2=1}^{M_2} g_{\alpha\beta}(x_m^{(\sigma)}, y_{m_2}^{(\tau)})\, p_{m_1}^{(\sigma)}(x)\, p_{m_2}^{(\tau)}(y) \quad \text{for } (x,y) \in \cup\sigma \times \cup\tau.$$

For $T_j \in \sigma$ and $T_k \in \tau$ there holds the approximation

$$\int_{T_j}\int_{T_k} g_{\alpha\beta}(x,y)\, dy\, dx \approx \sum_{m_1=1}^{M_1} \sum_{m_2=1}^{M_2} \underbrace{g_{\alpha\beta}(x_{m_1}^{(\sigma)}, y_{m_2}^{(\tau)})}_{=:D_{m_1 m_2}} \underbrace{\Big\{\int_{T_j} p_{m_1}^{(\sigma)}(x)\, dx\Big\}}_{=:C_{jm_1}^{(\sigma)}} \underbrace{\Big\{\int_{T_k} p_{m_2}^{(\tau)}(y)\, dy\Big\}}_{=:C_{km_2}^{(\tau)}}. \tag{4.9}$$

For fixed α, β, consider the matrix $B \in \mathbb{R}^{N\times N}_{sym}$, $B_{jk} := A(\chi_{T_j}\mathbf{e}_\alpha, \chi_{T_k}\mathbf{e}_\beta)$. With the matrices $C^{(\sigma)} \in \mathbb{R}^{|\sigma|\times M_1}$, $C^{(\tau)} \in \mathbb{R}^{|\tau|\times M_2}$, and $D \in \mathbb{R}^{M_1\times M_2}$ defined in (4.9), the submatrix $B|_{\sigma\times\tau}$ from B satisfies

$$B|_{\sigma\times\tau} \approx C^{(\sigma)} D (C^{(\tau)})^T. \tag{4.10}$$

The use of the latter approximation significantly reduces the computational cost for assembling the matrix $B|_{\sigma\times\tau}$, provided $\max\{M_1, M_2\} < \min\{|\sigma|, |\tau|\}$.

Remark 4.7. Notice that only the matrix D in (4.9) depends on α and β and the matrix $\mathbf{A}$ can be approximated by the block-matrix $\widetilde{\mathbf{A}}$ with blocks of $\mathcal{H}^2$-matrix type. The time to assemble the matrix $\mathbf{A}$ could be highly decreased by use of the indicated $\mathcal{H}^2$-matrix approach. However, all experiments in this paper have been made using the *exactly computed* matrix $\mathbf{A}$, but the much cheaper $\mathcal{H}^2$-matrix approach leads to (almost) the same accuracy, in (almost) linear complexity. (Since the present implementation is in MATLAB, comparisons will appear in [18].)

Remark 4.8. The computation of the refinement indicators can also be based on an $\mathcal{H}$-matrix approach since the computation of $\mathcal{P}\mathbf{m}_h(x)$ corresponds to a collocation method with the double layer potential; cf. Lemma 4.3.

5. Numerical example with exact solution $\mathbf{m} \in \boldsymbol{W^{1,\infty}(\Omega;\mathbb{R}^2)}$. The unit square $\Omega = (0,1)^2$ is filled with a uniaxial magnetic material (1.4) with easy axis $\mathbf{e} = (-1,1)/\sqrt{2}$, i.e., $\mathbf{z} = (1,1)/\sqrt{2}$ in Remark 2.2. Define

$$\mathbf{m}(x) := \begin{cases} x & \text{for } |x| \le 1, \\ x/|x| & \text{for } |x| \ge 1 \end{cases} \quad \text{and} \quad \lambda(x) := \begin{cases} 0 & \text{for } |x| < 1, \\ 1 & \text{for } |x| \ge 1. \end{cases} \tag{5.1}$$

Then $(\mathbf{m}, \lambda) \in W^{1,\infty}(\Omega;\mathbb{R}^2) \times L^\infty(\Omega)$ solves (2.4)–(2.5) with given right-hand side

$$\mathbf{f} := \mathcal{P}\mathbf{m} + (\mathbf{m}\cdot\mathbf{z})\mathbf{z} + \lambda\mathbf{m} \in L^2(\Omega;\mathbb{R}^2). \tag{5.2}$$

In all our numerical experiments, we replaced $\mathcal{P}\mathbf{m}$ on the right-hand side of (5.2) by $\mathcal{P}\mathbf{m}_\mathcal{T}$ for the elementwise integral means $\mathbf{m}_\mathcal{T}$ of $\mathbf{m}$. Recall that Lemma 4.1 allows the exact integration of $\mathcal{P}\mathbf{m}_\mathcal{T}$. Figure 1 shows discrete solutions $\mathbf{m}_h$ for the penalization parameter $\alpha = 1$.

For a given sequence of h-uniform meshes with $N = h^{-2}$ elements in $\mathcal{T}^{(n)}$, the first set of experiments studies the choice of the parameter $\alpha > 0$ in the penalization $\varepsilon = h^\alpha$. Figure 2 displays the L^2 error of the magnetization vectors as a function of the mesh-size $h = N^{-2}$ for 12 values of α. Any choice of $\alpha \ge 1$ seems to result in a linear convergence, while values $\alpha < 1$ seem to result in smaller experimental convergence rates (until $\alpha = 1/4$ with almost no convergence). The length $|\mathbf{m}_h(x)|$ for $|x| > 1$ and $\alpha = 1/2$ are about 1.1, compared to ≤ 1.01 for $\alpha = 3/2$. The value $\alpha = 3/2$ is recommended throughout all examples of this paper. Theoretical estimates concern the $\mathbf{z}$ direction of $\mathbf{m} - \mathbf{m}_h$ exclusively. In the numerical examples, however, linear convergence is observed also for the easy axis direction $\mathbf{e}$. Notice that $\mathbf{m}$ is essentially smooth, and hence adaptive mesh-refinements cannot improve the experimental convergence rates further.

In conclusion, the first example gives empirical support for the a priori analysis and the choice of the penalization parameter. As indicated by Theorem 3.2, the choice of $\varepsilon = h^\alpha$ with $\alpha \ge 1$ appears to be necessary for optimal experimental convergence

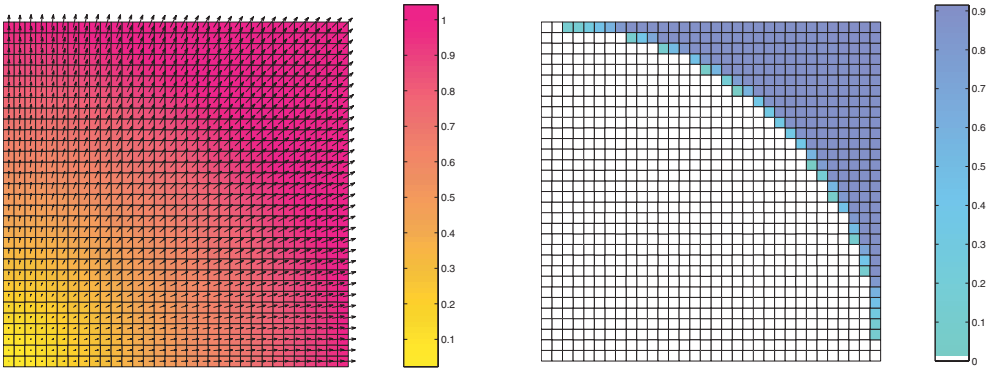

FIG. 1. *Discrete solution* $(\mathbf{m}_h, \lambda_h)$ *in section* 5 *on* $\mathcal{T}_4$ *(with* $N = 1024$*) for penalization parameter* $\varepsilon = h$*:* $\mathbf{m}_h$ *as vectors* $\mathbf{m}_h|_T$ *and* $|\mathbf{m}_h|_T|$ *in grayscale (left) and* λ_h *in grayscale (right).*

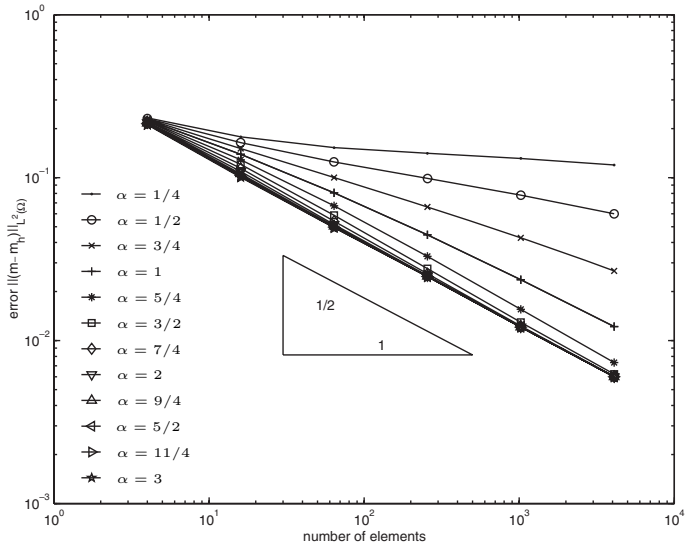

FIG. 2. *Error* $\|\mathbf{m} - \mathbf{m}_h\|_{L^2(\Omega)}$ *versus the number of elements* $N = 4, 16, \ldots, 4096$ *for various choices of the penalization parameter* $\varepsilon = h^\alpha$ *for uniform meshes with* $\alpha = .25, .5, .75, 1, 1.25, 1.5, 1.75, 2, 2.25, 2.5, 2.75, 3$*. The results for* $\alpha = 1.5, 1.75, \ldots, 3$ *essentially coincide and lead to the linear convergence in* h *indicated by the slope* $1/2$*.*

behavior. The lower order of convergence for a choice of $\alpha < 1$ can be explained as follows: Theorem 3.2 shows the L^2 convergence $\lambda_h \mathbf{m}_h \to \lambda \mathbf{m}$ in Ω, particularly on the restricted domain $\omega := \{x \in \Omega \,|\, |x| \geq 1\}$; i.e., the smaller α, the larger the length $|\mathbf{m}_h|$:

$$h^{-\alpha}(|\mathbf{m}_h| - 1)_+ = \lambda_h |\mathbf{m}_h| \to \lambda |\mathbf{m}| = 1 \quad \text{in } L^2(\omega).$$

6. Numerical example with exact solution $\mathbf{m} \notin \boldsymbol{H^1(\Omega)}$. This section is devoted to the numerical approximation of a more singular magnetization,

$$(\mathbf{m}(x), \lambda(x)) := \begin{cases} (\mathbf{y}(x), 0) & \text{for } x \in \omega, \\ (x_1 x_2 (1 - y_1(x))^{-1} (1 - y_2(x))^{-2} \mathbf{y}(x), 1) & \text{for } x \in \Omega \backslash \omega \end{cases} \tag{6.1}$$

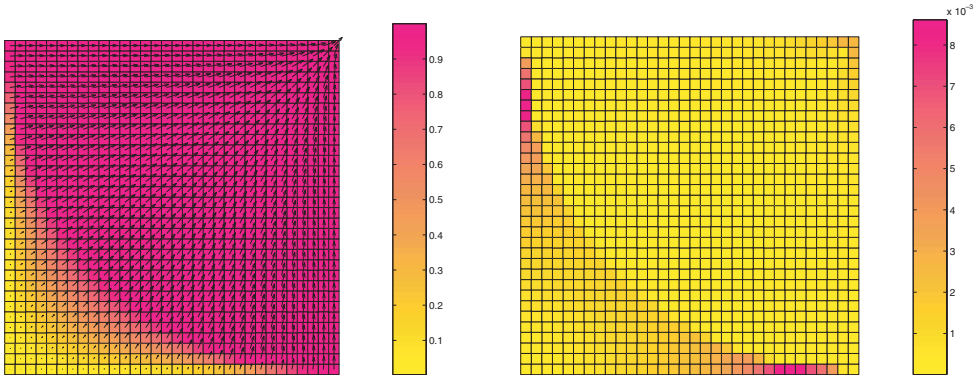

FIG. 3. *Best approximation* $\mathbf{m}_{\mathcal{T}}$ *(left) of the magnetization vector* $\mathbf{m}$ *in section* 6 *on a uniform mesh (with* $N = 1024$*), and elementwise distribution of the corresponding best approximation error* $\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(T_j)}$ *(right). FIG. 4. *Best approximation* $\mathbf{m}_{\mathcal{T}}$ *(left) in section* 6 *on an error adapted generated mesh (with* $N = 1717$*), and elementwise distribution of the corresponding best approximation error* $\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(\Omega)}$ *(right). For the adaptive mesh-refinement, we used Algorithm* 4.2 *with refinement indicators* $\varrho_j = \|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(T_j)}$*. Notice that the grayscale displays values multiplied with* 1 *(left) and* $10^{-4} = 1/10000$ *(right).*

with a singular gradient at the three vertices $(0,1)$, $(1,0)$, $(1,1)$ on the boundary of the magnetic body $\Omega = (0,1)^2$. Here,

$$\mathbf{y}(x) := \frac{(1,1) - x}{|(1,1) - x|} \quad \text{and} \quad \omega := \big\{x \in \Omega \,\big|\, |(1,1) - x| < 1\big\}.$$

The remaining data ϕ, $\mathbf{z}$, and $\mathbf{f}$ are as in section 5. The magnetization vector $\mathbf{m}$ (6.1) and the error by the piecewise integral means are depicted in Figure 3. We observe a larger elementwise L^2 error in $\Omega\backslash\omega$ and hence expect the necessity of adaptive mesh-refining for an effective computation. For a comparison, Figure 4 displays the best approximation $\mathbf{m}_{\mathcal{T}}$ and its elementwise L^2 errors $\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(T)}$ on an adapted mesh. The latter was generated by Algorithm 4.2 with the refinement indicator $\varrho_j := \|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(T_j)}$; i.e., an element T_j is marked in step (iv) if $\varrho_j \geq 1/2 \max_{1 \leq k \leq n} \varrho_k$. The singularity at $(1,1)$ is visible in Figures 3 and 4, as is a refinement near the arc $\big\{x \in \Omega \,\big|\, |(1,1) - x| = 1\big\}$. There is no theoretical support

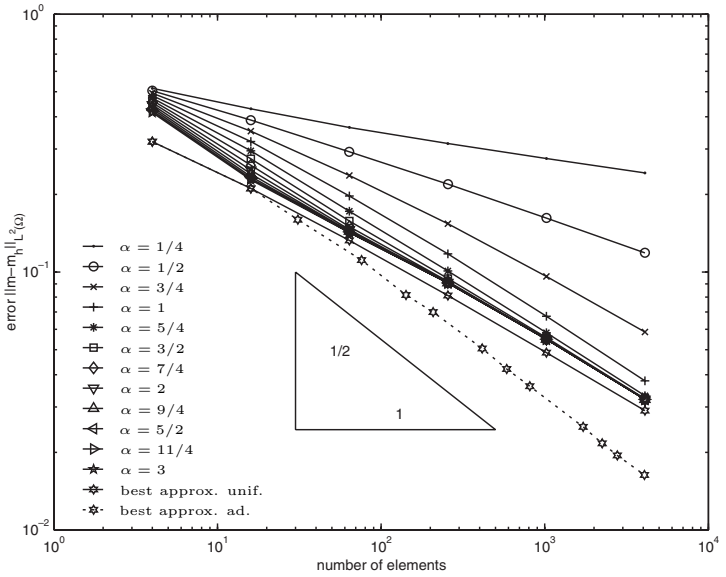

FIG. 5. *Error* $\|\mathbf{m}-\mathbf{m}_h\|_{L^2(\Omega)}$ *and dependence from penalization parameter* $\varepsilon = h^\alpha$ *for uniform mesh-refinement. For comparison, the best approximation errors on uniform and adapted meshes from Figure* 4 *are also shown.*

that the refinement indicator ϱ_j leads to optimal meshes, but it allows an interesting theoretical comparison. Also, heuristically we expect optimal meshes (asymptotically) since the mesh-refinement with respect to ϱ leads to meshes on which the best approximation errors are equidistributed.

A comparison between Figures 3 and 4 (keeping in mind the different scalings in the right figures) shows that adaptive meshes have the potential for improvement. Numerical evidence for this is provided in Figure 5: Besides various choices of penalization parameter α with conclusions similar to those of section 5, the sequence of uniform and ϱ-adapted mesh-refining are compared. The adaptive meshes yield linear convergence in a reference mesh-size $h := N^{-2}$ even in all components of $\|\mathbf{m} - \mathbf{m}_{\mathcal{T}}\|_{L^2(\Omega)}$. The sequence of uniform meshes shows a suboptimal convergence rate.

Figures 6 and 7 display the L^2 error $\|\mathbf{m} - \mathbf{m}_h\|_{L^2(\Omega)}$ and the error estimators μ and η from (4.5) as functions of the number of elements N for various sequences of meshes. Those are generated by Algorithm 4.2 with refinement indicators η_j and μ_j from (4.6) and penalizations $\varepsilon = h^\alpha$ for $\alpha = 1$ and $\alpha = 3/2$. The two penalizations show similar convergence rates; the overall recommendation of $\alpha = 3/2$ is again supported in Figure 6 by better results. Each of the two adaptive algorithms leads to optimal convergence rates and is (asymptotically) factor 2 for $\alpha = 1$, respectively, 1.3, for $\alpha = 3/2$ worse than the best approximation errors.

Figure 7 illustrates the reliability-efficiency gap [3]: What is reliable is not efficient and what is efficient is not (known to be) reliable. Theorem 3.2 and Remark 3.1 show that the error terms are bounded from above by $c_1\mu$ and $c_2(\mathbf{m})\eta$, and the latter bound is of higher order but valid only for a smooth magnetization. The second estimate is also expected to be efficient (up to higher-order terms in the magnetization). Figure 7 displays η and μ and clearly shows their different convergence rates. From Figure 7 there is no support that adaptive is more effective than uniform mesh-refining.

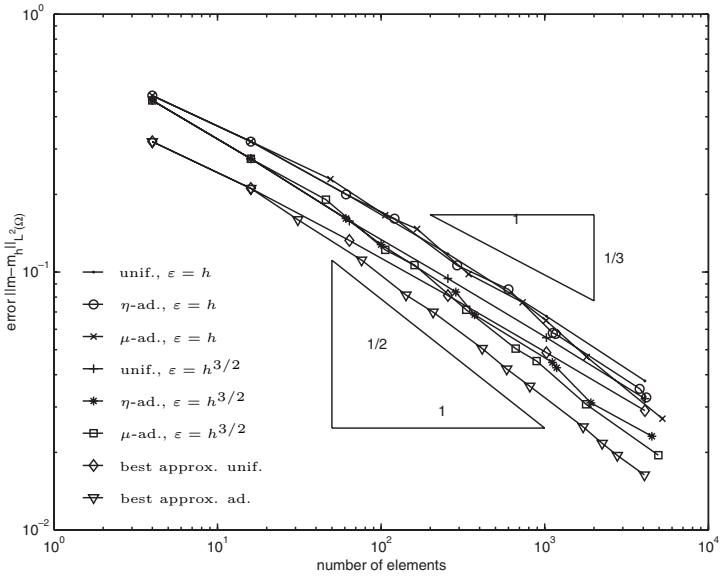

FIG. 6. *Error* $\|\mathbf{m} - \mathbf{m}_h\|_{L^2(\Omega)}$ *for uniform,* μ*-adaptive, and* η*-adaptive mesh-refinement with penalization parameter* $\varepsilon = h^\alpha$ *or* $\varepsilon = h^{3/2}$*. For comparison, the best approximation error is shown for uniform and optimal adapted meshes as well. Both adaptive strategies lead to optimal experimental convergence rate* $1/2$ *in terms of numbers of elements.*

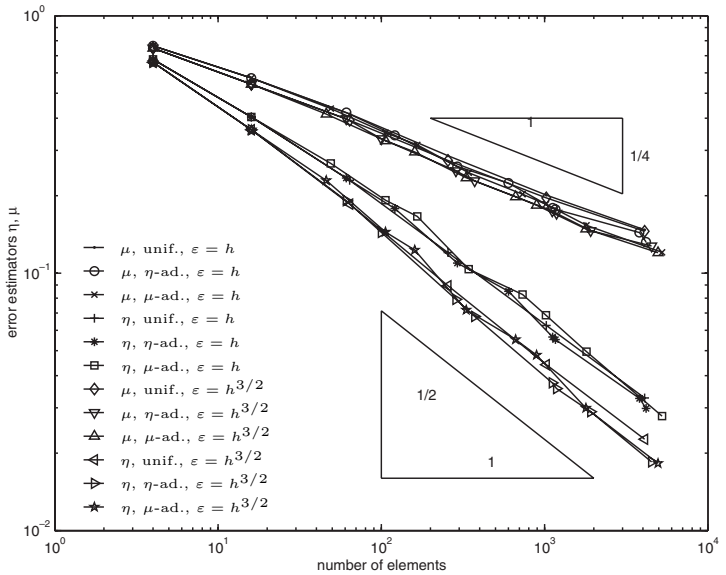

FIG. 7. *Illustration of the reliability-efficiency gap: Experimental convergence of the error estimators* η *and* μ *in section* 6 *for uniform,* η*-adaptive, and* μ*-adaptive mesh-refinement with penalization parameter* $\varepsilon = h$ *or* $\varepsilon = h^{3/2}$*. The improvement of the error by adaptive mesh-refinement strategies as shown in Figure* 6 *is not reflected by the estimators. There is (up to a multiplicative constant) no improvement of the convergence behavior by the adaptive mesh-refinement.*

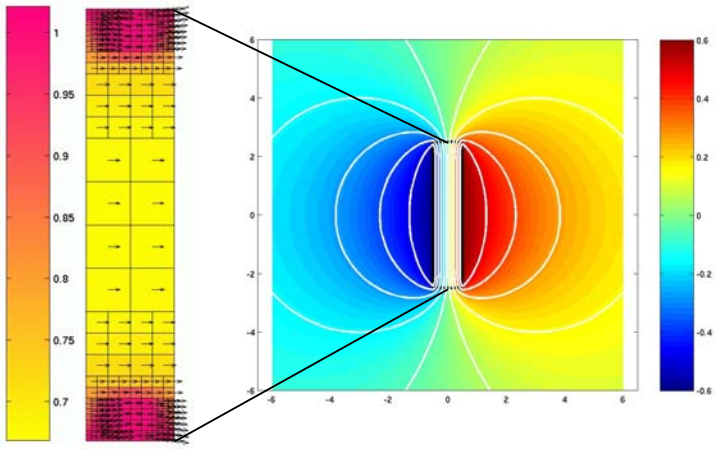

FIG. 8. *Discrete magnetization* $\mathbf{m}_h$ *(zoom on the left) on the* η*-adaptively generated mesh* $\mathcal{T}_4$ *(with* $N = 236$*) and corresponding potential* u_h *(right) for constant exterior field* $\mathbf{f} = (.6, 0)$*, easy axis* $\mathbf{e} = (1, 0)$*, and penalization parameter* $\varepsilon = h^{3/2}$*. The grayscale in the zoomed magnet displays the length* $|\mathbf{m}_h|$ *of the discrete magnetization. On the right, the pointwise value of* u_h *is shown by the grayscale and some isolines have been drawn.*

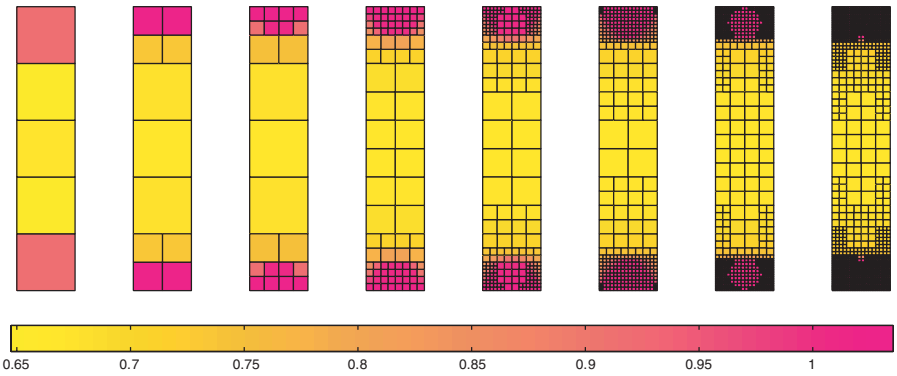

FIG. 9. η*-adaptively generated meshes* $\mathcal{T}_0$ *(with* $N = 5$*) till* $\mathcal{T}_7$ *(with* $N = 1604$*) in section 7 for* $\mathbf{f} = (.6, 0)$*,* $\mathbf{e} = (1, 0)$*, and* $\varepsilon = h^{3/2}$*. The grayscale shows the length* $|\mathbf{m}_h|$ *of the discrete solution.*

7. Real-life scientific computing. The ferromagnetic body $\Omega = (-1/2, 1/2) \times (-5/2, 5/2)$ is loaded with a constant applied magnetic field $\mathbf{f} := (0.6, 0)$ aligned with the easy axis $\mathbf{e} = (1, 0)$. Figure 8 displays the magnetic potential $u_h = \mathcal{L}\mathbf{m}_h$ and the magnetization vectors $\mathbf{m}_h$ on an adaptively generated mesh. The exact solution $\mathbf{m}$ is unknown. The first numerical computations for this example have been performed in [5]. Although there the potential equation

$$\operatorname{div}(-\nabla u + \mathbf{m}) = 0 \quad \text{in } \mathbb{R}^2$$

is discretized and solved by a finite element scheme for a *bounded* domain that surrounds Ω instead of the full space, we obtain similar results.

The initial mesh $\mathcal{T}_0$ consists of 5 congruent squares with side-length 1. Figure 9 shows η-adaptively generated meshes $\mathcal{T}_0, \dots, \mathcal{T}_7$ with $N = 5, \dots, 1604$ elements. We observe some mesh-refinement towards the 4 vertices of Ω which we might expect to be caused by singularities in the stray field. However, this refinement seems to be

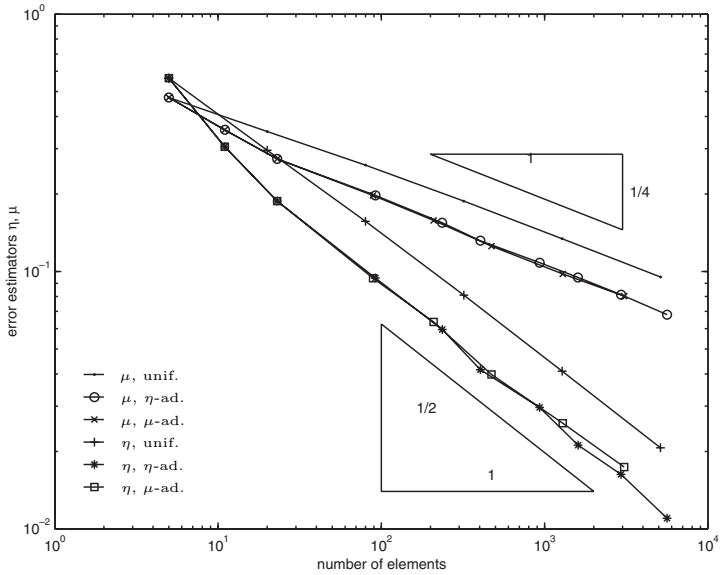

FIG. 10. *Experimental convergence of the error estimators η and μ in section 7 for uniform, η-adaptive, and μ-adaptive mesh-refinement and penalization parameter $\varepsilon = h^{3/2}$. There is (up to a multiplicative constant) no improvement of the convergence behavior by the adaptive mesh-refinement, although we obtain some local mesh-refinement towards the corners in Figure 9.*

accomplished in $\mathcal{T}_0, \dots, \mathcal{T}_6$ as $\mathcal{T}_7$ and $\mathcal{T}_8$ show a refinement of a more global zone. Figure 8 displays the discrete solution which follows the exterior field $\mathbf{f}$ and develops some flowering at the tips of Ω. One observes large curvatures of the magnetization near the top and bottom of the magnet Ω but no strong point singularity there. Furthermore, Figure 8 displays the corresponding magnetic potential $u_h = \mathcal{L}\mathbf{m}_h$ computed analytically by

$$\mathcal{L}\mathbf{m}_h(x) = \sum_{k=1}^{N} \int_{\partial T_k} G(x-y)\, \mathbf{m}_h|_{T_k} \cdot \mathbf{n}(y)\, ds_y \qquad \text{for all } x \in \mathbb{R}^d, \tag{7.1}$$

as follows from partial integration of (2.3). In comparison with a corresponding numerical experiment in [5], we see that the potential lines of the magnetic potential are not perpendicular on the boundary of the domain displayed. This is a consequence of the correct treatment of the stray field in the full space $\mathbb{R}^2$. More important, the discretization in [5] shows a strong refinement towards the vertices, much stronger than those visible in Figures 8 or 10. To monitor the asymptotic behavior, Figure 10 displays the error estimators μ and η. In comparison with uniform and η- and μ-adaptive mesh-refinement one deduces that, in this example, adaptivity is not important—there is a small improvement, but one obtains essentially the same convergence rate for all three strategies. Our interpretation is that, to our great surprise, there is no singularity in the integral-operator model at hand and so the formulation is indeed superior to that of [5].

Finally, Figure 11 shows the discrete Lagrange multipliers λ_h corresponding to the triangulations from Figure 9. They do not indicate some particular resolution of the set $\{x \in \Omega : \lambda_h(x) = 0\}$ (or some other level set of λ_h).

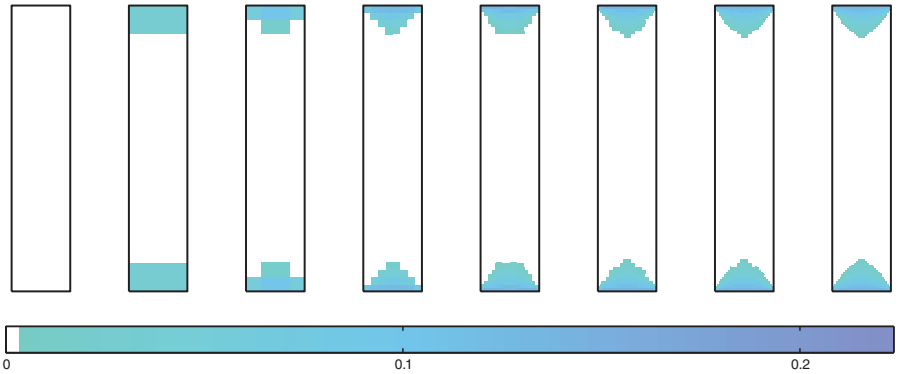

FIG. 11. *Discrete Lagrange multiplier λ_h on η-adaptively generated meshes $\mathcal{T}_0$ (with $N = 5$) till $\mathcal{T}_7$ (with $N = 1604$) in section 7 for $\mathbf{f} = (.6, 0)$, $\mathbf{e} = (1, 0)$, and $\varepsilon = h^{3/2}$. The grayscale shows the pointwise value of λ_h. In the white region we have $\lambda_h \equiv 0$, i.e., $|\mathbf{m}_h| \leq 1$.*

A CONVOLUTION-THRESHOLDING APPROXIMATION OF GENERALIZED CURVATURE FLOWS*

RICHARDS GRZHIBOVSKIS† AND ALEXEI HEINTZ†

Abstract. We construct a convolution-thresholding approximation scheme for the geometric surface evolution in the case when the velocity of the surface at each point is a given function of the mean curvature. Conditions for the monotonicity of the scheme are found and the convergence of the approximations to the corresponding viscosity solution is proved. We also discuss some aspects of the numerical implementation of such schemes and present several numerical results.

Key words. generalized curvature flow, convolution-thresholding scheme, viscosity solution, level-set equation

1. Introduction.

The topic of curvature flows of different types was popular during the last 20 years and is still popular in both pure and applied mathematics. By curvature flow we mean a family $\{\Gamma_t\}_{t\geq 0}$ of hypersurfaces in $\mathbb{R}^n$ depending on time t with local normal velocity equal to the mean curvature or a function of it for generalized curvature flows. The mean curvature in turn denotes here the sum of principal curvatures.

In the three-dimensional case a smooth initial surface can develop singularities after some finite time. There have been several successful attempts to deal with singularities and topological complications: the varifold approach [7], [2], the phase field method [14], [8], and the level-set method. This approach was suggested in the physical literature [26] and was extensively developed for numerical purposes by Osher and Sethian [27]. The main idea of this method is to evolve some continuous function $u : [0,\infty)\times\mathbb{R}^n \mapsto \mathbb{R}$ in such a way that $\Gamma_t \subset \mathbb{R}^n$ would always be a level-set of $u(x,t)$, i.e., $\Gamma_t = \{x \in \mathbb{R}^n : u(x,t) = 0\}$ for all $t \geq 0$. In the case of the mean curvature flow, the evolution equation for u turns out to be

$$u_t = |Du| \operatorname{div}\left(\frac{Du}{|Du|}\right). \tag{1.1}$$

The evolution equation for a function u with each point of a level-set moving along the normal with velocity equal to some function G of the mean curvature is the so-called generalized mean curvature evolution PDE

$$u_t = |Du|\, G\left(\operatorname{div}\left(\frac{Du}{|Du|}\right)\right). \tag{1.2}$$

†Department of Mathematics, Chalmers University of Technology, 41296 Göteborg, Sweden (richards@math.chalmers.se, heintz@math.chalmers.se).

This equation is degenerate parabolic. The existence and uniqueness of generalized viscosity solutions (see [12]) to the initial value problem

$$\begin{cases} u_t = |Du|\, G\left(\operatorname{div}\left(\frac{Du}{|Du|}\right)\right) & \text{in } \mathbb{R}^n \times (0,T), \\ u = g(x) \in BUC(\mathbb{R}^n) & \text{on } \mathbb{R}^n \times \{0\} \end{cases} \tag{1.3}$$

was investigated in [17], [11], [22].

Curvature flows arise naturally in various problems. Among these are the fast reaction–slow diffusion problem [29], [4], [16], [19] and image processing [1].

In the present work we construct a class of approximations of a convolution-thresholding type to the generalized curvature flows. By this we mean the following. Assume that, initially, the surface under consideration is a boundary of a compact set $C \in \mathbb{R}^n$. Take compactly supported functions $\tilde{\rho}_i : \mathbb{R}_+, \longmapsto \mathbb{R}_+, i = 1,2$ (in fact, one can also take $\tilde{\rho}_i$ with unbounded support decreasing fast for large x). We define $\rho_i : \mathbb{R}^n \mapsto \mathbb{R}_+$,

$$\rho_i(x) = \frac{1}{h^{n/2}} \tilde{\rho}_i\left(|x| / \sqrt{h}\right),$$

and introduce a convolution

$$M_i(C)(x,h) = \int_{\mathbb{R}^n} \chi_C(y)\, \rho_i(x-y)\, dy.$$

Now $M_i(C)(x,h)$ are functions of x, and we define a new position of the surface as a boundary of the set

$$\mathcal{H}_h C = \{x \in \mathbb{R}^n : F(M_1(C)(x,h), M_2(C)(x,h)) \geq 0\}, \tag{1.4}$$

where F is some (thresholding) function. Next we follow Evans [15] and introduce an operator on the space of bounded functions $\mathbb{B}(\mathbb{R}^n)$: $H(h) : \mathbb{B}(\mathbb{R}^n) \mapsto \mathbb{B}(\mathbb{R}^n)$ by

$$[H(h)\, u](x) = \sup\{\lambda \in \mathbb{R} : x \in \mathcal{H}_h [u \geq \lambda]\}. \tag{1.5}$$

The purpose of the present study is, for a given function G in (1.3), to find a corresponding thresholding function F in (1.4) so that $H(t/m)^m g(x)$ converges to the unique viscosity solution of (1.3) as $m \to \infty$.

Such a function in the case when G is linear was proposed by Merriman, Bence, and Osher in [25]. This result is often referred to as the Bence–Merriman–Osher method. Rigorous proofs of the convergence of such approximations can be found in [15], [20], and [3]. In this case it is enough to take a thresholding function depending only on one convolution.

Suppose that G is nonlinear. As we show in section 3, in this case one has to use two convolutions M_1 and M_2 and a thresholding function depending on two variables $F(M_1, M_2)$. This is necessary to ensure that the operator H is consistent with the PDE in (1.3). We also show how to choose convolution kernels in order to get a monotone H. These two conditions—monotonicity and consistency—are crucial for the convergence.

Using our approach we also suggest a new construction of higher order schemes for the classical curvature flows. The numerical experiments with these schemes show a considerable improvement in the accuracy.

Finite difference approximations for (1.3) have been studied in [27], [31], [13].

Another class of approximation operators, the so-called Matheron filters, comes from image processing. The connection between such operators and the mean curvature evolution PDE (1.2) was established in [10]. This result was then extended in [18] and [9].

Threshold dynamics models, introduced earlier in [21], lead to approximations of the solution of the Cauchy problem to a nonlinear parabolic equation, where the right-hand side can be interpreted as a general elliptic operator on a level set of the solution. This is a generalization of the curvature flow, but it does not entirely include (1.3) as a special case.

Another generalization of the Bence–Merriman–Osher method can be found in [23]. The author suggests an approximation procedure that allows tracking the surface evolution when the velocity of the surface depends also on the coordinates. The convergence of this approximation is also proved.

Outline. This paper is organized as follows. After introducing the basic notions and stating some results for viscosity solutions in section 2, we turn to our method of approximation for such solutions. In section 3, we construct F to get the convergence of the convolution-thresholding approximation to the viscosity solution of (1.3) with a monotone continuous function G. This is the main result of the paper. More precisely, the following local uniform convergence is proved:

$$\left(\left(H\left(t/m\right)\right)^m g\right)(x) \to u\left(x,t\right), \qquad m \to \infty,$$

where H is defined by (1.5) and $u\left(x,t\right)$ is the viscosity solution of (1.3).

We use this construction for numerical calculation for some cases of the generalized curvature flows in $\mathbb{R}^2$ and $\mathbb{R}^3$. Numerical results and two approaches to the implementation are described in section 4.

2. The viscosity solution framework. Consider the nonlinear equation (1.2) on an open set $\Omega \times (0,T)$ with function G continuous and nondecreasing. This is the second order equation with a right-hand side that is monotonic and degenerate elliptic (see [12]) provided that G is nondecreasing and $Du \neq 0$. Viscosity solution to (1.2) was defined by Evans and Spruck in [17] and by Chen, Giga, and Goto in [11]. In our presentation we will use a somewhat more general definition of viscosity solutions introduced by Ishii and Souganidis in [22] to allow for a wider class of functions G in (1.2). For the general degenerate elliptic equation

$$u_t + \mathcal{G}\left(Du, D^2u\right) = 0, \tag{2.1}$$

they introduce a special class of test functions and adapt the definition of viscosity solution for possible singularities of the right-hand side. Representation of (1.3) in the form of (2.1) gives

$$\mathcal{G}(p,X) = -|p| G\left(\frac{1}{|p|}\mathrm{tr}\left(\left(I - \frac{p\otimes p}{|p|^2}\right)X\right)\right).$$

Let us begin by introducing an auxiliary subclass of $C^2\left([0,\infty)\right)$. We say that $f : [0,\infty) \mapsto \mathbb{R}$ lies in $\mathcal{F} \subset C^2$ if $f\left(0\right) = f'\left(0\right) = f''\left(0\right) = 0$, $f''\left(r\right) > 0$ for $r > 0$ and the following limits hold:

$$\lim \frac{f'\left(|p|\right)}{|p|}\mathcal{G}\left(p,I\right) = \lim \frac{f'\left(|p|\right)}{|p|}\mathcal{G}\left(p,-I\right) = 0.$$

As was shown in [22], this set of functions is a nonempty cone, provided that the right-hand side lies in $C((\mathbb{R}^n \setminus \{0\}) \times \mathbb{S}(n))$. The class of test functions $\mathcal{A}(\mathcal{G})$ depends on $\mathcal{G}$ and is defined as follows.

DEFINITION 2.1. *A function ϕ is admissible if it is in $C^2(\mathbb{R}^n \times (0,T))$ and if, for each $\acute{z} = (\acute{x}, \acute{t})$ where $D\phi(\acute{z}) = 0$, there is $\delta > 0$, $f \in \mathcal{F}$, and $\omega \in C([0,\infty))$ such that $\omega = o(r)$ and for all $(x,t) \in B(\acute{z}, \delta)$*

$$\left|\phi(x,t) - \phi(\acute{z}) - \phi_t(\acute{z})\left(t - \acute{t}\right)\right| \leq f\left(|x - \acute{x}|\right) + \omega\left(\left|t - \acute{t}\right|\right).$$

Let us also denote by u^* and u_* the upper and lower semicontinuous envelopes of u:

$$u^*(x,t) = \limsup_{(y,s)\to(x,t)} u(y,s), \quad u_*(x,t) = \liminf_{(y,s)\to(x,t)} u(y,s).$$

The definition of viscosity solution follows.

DEFINITION 2.2. *Take an open set $\tilde{\mathcal{O}} \subset \mathbb{R}^n$ and $\mathcal{O} = \tilde{\mathcal{O}} \times (0,T)$. $u : \mathcal{O} \subset \mathbb{R}^n \times (0,T) \mapsto \mathbb{R} \cup \{-\infty\}$ is a viscosity subsolution (supersolution) of* (1.2) *in an open $\mathcal{O}$ if $u^* < \infty$ ($u_* > -\infty$) and for all $\phi \in \mathcal{A}(G)$ and all local maximum (minimum) points (z_0, t_0) of $u^* - \phi$ ($u_* - \phi$),*

$$\begin{cases} \phi_t(z_0,t_0) \leq (\geq) |D\phi(z_0,t_0)| \, G\left(\operatorname{div} \dfrac{\mathrm{D}\phi(\mathrm{z}_0,\mathrm{t}_0)}{|\mathrm{D}\phi(\mathrm{z}_0,\mathrm{t}_0)|}\right) & \text{if } D\phi(z) \neq 0, \\ \phi_t(z_0,t_0) \leq (\geq) 0 & \text{otherwise.} \end{cases}$$

Consequently, a viscosity solution is a function that is sub- and supersolution simultaneously.

The result by Ishii and Souganidis presented in [22] can be restated in terms of the level-set equation (see [28]) as follows.

THEOREM 2.3. *Assume that G is continuous and nondecreasing. Then the initial value problem* (1.3) *has a unique viscosity solution $u \in BUC(\mathbb{R}^n \times (0,T))$.*

In what follows, we also use another result by Ishii and Souganidis [22] concerning locally uniform perturbations of the right-hand side of the equation. One can restate this result in the case of (1.2) as follows (see [28]).

THEOREM 2.4. *Assume that G is continuous and nondecreasing. Suppose also that $\{G_m\}_1^\infty$ is a sequence of continuous, nondecreasing functions on $\mathbb{R}$ and $G_m \to G$ locally uniformly. For any m, let $\mathcal{F}(G) \subset \mathcal{F}(G_m)$ and for any $f \in \mathcal{F}(G)$,*

$$\liminf_{p\to,\, m\to\infty} f'(|p|)\, G_m(1/p) \geq 0,$$
$$\left(resp., \ \limsup_{p\mapsto 0,\, m\to\infty} f'(|p|)\, G_m(-1/p) \leq 0\right).$$

Let u_m be a subsolution (resp., supersolution) of

$$\frac{\partial u_m}{\partial t} = |Du_m| \, G_m\left(\operatorname{div} \frac{Du_m}{|Du_m|}\right) \text{ in } \mathcal{O}.$$

Then

$$u^+(z) = \limsup_{r\mapsto 0} \{u_m(y), |y - z| \leq r, \ m > 1/m\}, \tag{2.2}$$

$$\left(resp., u_+(z) = \liminf_{r\to 0} \{u_m(y), |y - z| \leq r, \ m > 1/m\}\right) \tag{2.3}$$

is a subsolution (resp., supersolution) of (1.2) *in $\mathcal{O}$ provided that $u^+ < \infty$ (resp., $u_+ > -\infty$).*

3. A convolution-thresholding method for a generalized curvature flow.

3.1. Convergence of approximation schemes. Here we make use of a theorem by Barles and Souganidis proved in [5]. In order to base the proof of our main result on this theorem, we follow Pasquignon [28] and restate it in terms of (1.2).

Let $H(h)$ be the approximation operator, i.e.,

$$u_h(x,(n+1)h) = H(h)\,u_h(x,nh) = H(h)^{n+1}\,u_0(x),$$
$$u_h(x,0) = u_0(x).$$

Definition 3.1.

1. *Consistency.*
   An approximation operator $H(h)$, $h>0$, is consistent with (1.2) if for any $\phi \in C^\infty\left(\bar{\Omega}\right)$ and for any $x \in \bar{\Omega}$, the following holds:

$$\frac{(H(h)\,\phi)(x) - \phi(x)}{h} = |D\phi|\, G\left(\operatorname{div}\frac{\mathrm{D}\phi}{|\mathrm{D}\phi|}\right) + o_x(1) \text{ for } D\phi \neq 0. \tag{3.1}$$

   If the convergence of $o_x(1)$ is locally uniform on sets, where $D\phi \neq 0$, then $H(h)$ is said to be uniformly consistent with the PDE.
2. *Monotonicity.*
   An operator $H(h)$, $h>0$, is locally monotone if there exists $r>0$ such that for any functions $u(y), v(y) \in \mathbb{B}\left(\bar{\Omega}\right)$ with $u \geq v$ on $B(x,r)\setminus\{x\}$, the following holds:

$$H(h)\,u(y) \geq H(h)\,v(y) + o(h),$$

   where the convergence of $o(h)$ is uniform on $B(x,r)\setminus\{x\}$.
3. *Stability.*
   An approximation scheme $H(h)$ is stable if $H(h)^n u \in \mathbb{B}\left(\bar{\Omega}\right)$ for every $u \in B\left(\bar{\Omega}\right), n \in \mathbb{N}, h>0$, with a bound independent of h and n.

In this setting the result of Barles and Souganidis reads as follows.

Theorem 3.2. *Consider a monotone, stable approximation operator $H(h)$ that commutes with additions of constants (i.e., $H(h)(u+C) = H(h)\,u + C$ for all $C \in \mathbb{R}$) and is uniformly consistent with (1.2). Suppose also that*

$$\lim_{h\to 0} \frac{H(h)\,(f(|x-x_0|))(x_0)}{h} = 0 \tag{3.2}$$

for any $f \in \mathcal{F}(G)$. Then $u_h(x,nh)$ converges locally uniformly to the unique viscosity solution $u(x,t)$ of (1.2) as $nh \mapsto t$.

3.2. Properties of $\mathcal{H}$. We consider a convolution generated motion of a hypersurface in $\mathbb{R}^n$ defined by (1.4) and the corresponding evolution of an initially bounded function $g : \mathbb{R}^n \mapsto \mathbb{R}$ defined by (1.5). Consider also the initial value problem (1.3) with given G and g. We are looking for such a thresholding function F in (1.4) so that $H^m_{t/m} g(x)$ would converge (in some sense) to the unique viscosity solution of (1.3).

For example, set $F(M_1, M_2) = M_1 - \frac{1}{2}$ and $\tilde{\rho}_1(x) = \frac{1}{(4\pi)^{n/2}} e^{-x^2/4}$ to get corresponding operators $\mathcal{H}_h$ and $H(h)$ by (1.4) and (1.5). Then we get the Bence–Merriman–Osher procedure to which the main result of [15] applies, and $H(h)^n u_0$ converges locally uniformly to the unique viscosity solution of (1.3) with $G(k) = k$.

We will see that it is necessary to compute two convolutions M_1 and M_2 and use the thresholding function depending on both these values to resolve the problem when G is not linear.

Let us now consider an operator $H(h)$ defined by (1.5) with the help of an operator $\mathcal{H}_h$ with an arbitrary thresholding function (1.4). We look for requirements on F sufficient to fulfill the conditions of Theorem 3.2.

Stability. Suppose $u(x) \in \mathbb{B}(\mathbb{R}^n)$. We show that $H(h)u \in \mathbb{B}(\mathbb{R}^n)$. Intuitively, we require

$$\mathcal{H}_h\mathbb{R}^n = \mathbb{R}^n, \tag{3.3}$$

$$\mathcal{H}_h\emptyset = \emptyset, \tag{3.4}$$

and denote $A = \max|u|$. With these settings, we have $[u \le A] = \mathbb{R}^n$ and

$$-A \le H(h)u(x) = \inf\{\lambda \in \mathbb{R} : x \in \mathcal{H}_h[u \le \lambda]\} \le A.$$

It remains to find out for which F the conditions (3.3) and (3.4) are satisfied. To do this, we substitute the corresponding sets into the definition of $\mathcal{H}$:

$$\begin{aligned}
\mathcal{H}_h\mathbb{R}^n &= \{x \in \mathbb{R}^n : F(M_1\mathbb{R}^n(x,h), M_2\mathbb{R}^n(x,h)) \ge 0\} \\
&= \left\{x \in \mathbb{R}^n : F\left(\int_{\mathbb{R}^n}\rho_1 dx, \int_{\mathbb{R}^n}\rho_2 dx\right) \ge 0\right\} = \mathbb{R}^n \\
\mathcal{H}_h\emptyset &= \{x \in \mathbb{R}^n : F(M_1\emptyset(x,h), M_2\emptyset(x,h)) \ge 0\} \\
&= \{x \in \mathbb{R}^n : F(0,0) \ge 0\} = \emptyset.
\end{aligned}$$

Thus, the requirements on F become

$$\begin{aligned}
F\left(\int_{\mathbb{R}^n}\rho_1 dx, \int_{\mathbb{R}^n}\rho_2 dx\right) \ge 0, \\
F(0,0) < 0.
\end{aligned}$$

Monotonicity. Let us now show that if $\mathcal{H}_h$ satisfies the so-called inclusion principle, then H_h is monotonous.

LEMMA 3.3. *Assume, that $\mathcal{H}_h$ satisfies the inclusion principle, i.e.,*

$$\forall C_1, C_2 \subseteq \mathbb{R}^n : C_1 \subseteq C_2 \text{ we have } \mathcal{H}_h C_1 \subseteq \mathcal{H}_h C_2; \tag{3.5}$$

then H_h is monotone, that is,

$$\forall u, v \in \mathbb{C}(\mathbb{R}^n) : v \le u \text{ we have } H_h(v) \le H_h(u).$$

Proof. Suppose, there exists x_0 s.t. $H(h)u(x_0) < H(h)v(x_0)$. We denote $\lambda_1 = H(h)u(x_0)$, $\lambda_2 = H(h)v(x_0)$, and $\epsilon = \frac{\lambda_2 - \lambda_1}{2} > 0$. Since

$$\lambda_1 + \epsilon < \inf\{\lambda \in \mathbb{R} : x_0 \in \mathcal{H}_h[v \le \lambda]\},$$

we have $x_0 \notin \mathcal{H}_h[v \le \lambda_1 + \epsilon]$, but

$$\mathcal{H}_h[v \le \lambda_1 + \epsilon] \supseteq \mathcal{H}_h[u \le \lambda_1 + \epsilon].$$

Therefore $x_0 \notin \mathcal{H}_h[u \le \lambda_1 + \epsilon]$, which contradicts the definition of λ_1. ∎

Consistency. We sum up some calculations in the following lemma.

LEMMA 3.4. *Let* $\phi \in C^\infty(\mathbb{R}^n)$ $\phi(0) = 0$ *and* $D\phi(0) = (0, 0, \ldots, \beta)$. *Then the consistency of an operator* $H(h)$ *with* (1.3) *is equivalent to*

$$\gamma(h, 0) = hG(-\Delta\gamma(h, 0)) + o(h), \tag{3.6}$$

where $\Delta\gamma(h, 0) = \sum_{i=1}^{n-1} \partial^2\gamma/\partial x_i^2(0)$ *and* $x_n = \gamma(h, \acute{x})$ *is a parameterization of the surface*

$$\{x \in \mathbb{R}^n : \phi(x) = H(h)\phi(0)\}$$

near $\acute{x} = 0$.

We observe that in these settings $-\Delta\gamma(h, 0) \equiv k$ *is the mean curvature of the graph of* γ *at the point* $(0, \gamma(h, 0))$.

Proof. Without loss of generality, one can consider the consistency condition (3.1) only for ϕ as in the statement. We rewrite (3.1) in a more convenient form:

$$(H(h)\phi)(0) = h|D\phi(0)| G\left(\operatorname{div}\frac{D\phi}{|D\phi|}(0)\right) + o(h). \tag{3.7}$$

We use the equality

$$\operatorname{div}\left(\frac{D\phi}{|D\phi|}\right) = \frac{1}{|D\phi|}\sum_{i,j=1}^{n}\left(\delta_{i,j} - \frac{\phi_{x_i}\phi_{x_j}}{|D\phi|^2}\right)\phi_{x_ix_j}.$$

Since $\phi(0) = 0$ and $\phi_{x_i}(0) = \delta_{ni}\beta$,

$$\begin{aligned}\operatorname{div}\frac{D\phi}{|D\phi|}\bigg|_{x=0} &= \frac{1}{\beta}\left[\sum_{i=1}^{n}\phi_{x_ix_i}(0) - \frac{\phi_{x_n}(0)\phi_{x_n}(0)}{\beta^2}\phi_{x_nx_n}(0)\right] \\ &= \frac{1}{\beta}\Delta'\phi(0). \end{aligned} \tag{3.8}$$

Here $\Delta'\phi = \sum_{i=1}^{n-1}\phi_{x_ix_i}$. Our next step is to take small $\acute{x}$, namely $|\acute{x}| < Rh$. For such $\acute{x}$ we apply the inverse function theorem to ϕ,

$$H(h)\phi(0) = \phi(\acute{x}, \gamma(h, \acute{x})) = \phi(0) + \beta\gamma(h, 0) + O\left(h^2\right). \tag{3.9}$$

Putting (3.9) and (3.8) into (3.7) we get

$$\gamma(h, 0) = hG\left(\frac{1}{\beta}\Delta'\phi(0)\right) + o(h). \tag{3.10}$$

Furthermore, differentiating both sides of $H(h)\phi(0) = \phi(\acute{x}, \gamma(h, \acute{x}))$ gives

$$\begin{aligned}\phi_{x_i} + \phi_{x_n}\gamma_{x_i} &= 0, \\ \phi_{x_ix_j} + \phi_{x_ix_n}\gamma_{x_j} + \phi_{x_nx_j}\gamma_{x_i} + \phi_{x_nx_n}\gamma_{x_j}\gamma_{x_i} + \phi_{x_n}\gamma_{x_ix_j} &= 0\end{aligned}$$

for $j, i = 1, \ldots, n-1$. We deduce $\gamma_{x_i}(h, 0) = 0$ from the first equality and rewrite the second one for $i = j$,

$$\phi_{x_jx_j}(0) + \phi_{x_n}(0)\gamma_{x_jx_j}(h, 0) = 0.$$

After a summation over j this becomes

$$\frac{1}{\beta}\Delta'\phi(0) = -\Delta\gamma(h, 0).$$

It remains to put this relation into (3.10) to get the desired equality (3.6). ∎

3.3. The convergence result for general G. In this subsection we construct the thresholding function $F(M_1, M_2)$ and show that the corresponding convolution thresholding scheme (1.4), (1.5) converges to the viscosity solution $u(x,t)$ of (1.3),

$$H_{\frac{t}{m}}^{m} g(x) \to u(x,t) \text{ as } m \to \infty.$$

We start with $F(M_1 C(x,h), M_2 C(x,h))$, where

$$M_i C(x,h) = \int_C \rho_i(x-y)\, dy.$$

For each ρ_i we expand this integral into the power series in h (see (3.19)), i.e.,

$$M_i[\phi \le H(h)\phi(0)](0,h) = A_i + \sqrt{h} v C_i + \sqrt{h}\Delta\gamma(h,0) B_i + O\left(h^{3/2}\right), \tag{3.11}$$

where

$$A_i = \int_{\mathbb{R}^{n-1}} \int_{-\infty}^{0} \rho_i(|y|)\, dy_n d\acute{y}, \tag{3.12}$$

$$B_i = \frac{1}{2} \int_{\mathbb{R}^{n-1}} y_k^2 \rho_i(\acute{y}, 0)\, d\acute{y}, \tag{3.13}$$

$$C_i = \int_{\mathbb{R}^{n-1}} \rho_i(\acute{y}, 0)\, d\acute{y}, \tag{3.14}$$

and $i = 1, 2$. This is a system of linear algebraic equations for $\Delta\gamma(h,0)$ and v. We choose the kernels so that the determinant of this system is positive,

$$D = C_1 B_2 - C_2 B_1 > 0,$$

denote $N_i = M_i[\phi \le H(h)\phi(0)](0,h) - A_i$, and write the solution

$$v = \frac{\gamma(h,0)}{h} = \frac{1}{\sqrt{h}} \frac{N_1 B_2 - N_2 B_1}{C_1 B_2 - C_2 B_1} + O(h),$$

$$\Delta\gamma(h,0) = \frac{1}{\sqrt{h}} \frac{N_2 C_1 - N_1 C_2}{C_1 B_2 - C_2 B_1} + O(h).$$

Lemma 3.4 implies that the operator H is consistent with the PDE in (1.3) if we take

$$\begin{aligned} F(N_1, N_2) &= v - G(-\Delta\gamma(h,0)) \\ &= \frac{1}{\sqrt{h}} \frac{N_1 B_2 - N_2 B_1}{D} - G\left(\frac{1}{\sqrt{h}} \frac{N_1 C_2 - N_2 C_1}{D}\right). \end{aligned} \tag{3.15}$$

In the case of the thresholding function of one variable, the inclusion principle (3.5) holds for $\mathcal{H}$ when F is nondecreasing. In the case of two variables we require

$$\frac{\partial F}{\partial N_1} = \frac{B_2}{D} - \frac{C_2}{D} G' \ge 0, \tag{3.16}$$

$$\frac{\partial F}{\partial N_2} = -\frac{B_1}{D} + \frac{C_1}{D} G' \ge 0. \tag{3.17}$$

This implies

$$\frac{B_1}{C_1} \leq G^{'} \leq \frac{B_2}{C_2}. \tag{3.18}$$

Therefore, for awhile we restrict ourselves with G having a bounded and positive derivative. Comparing (3.14) with (3.13) one sees that it is possible to make the lower bound in (3.18) small by choosing ρ_1 with mass concentration close to the origin. The upper bound will be large if the mass of ρ_2 is concentrated relatively far from the origin.

Next, we state some auxiliary results.

LEMMA 3.5. *Suppose* (3.16) *and* (3.17) *hold and* $\mathcal{H}$ *is defined by* (1.4)*; then for all* $h \in \mathbb{R}_+$,

1. $\mathcal{H}(h)(\mathbb{R}^n) = \mathbb{R}^n$, $\mathcal{H}(h)(\emptyset) = \emptyset$,
2. *for all* $a, b \in \mathbb{X} : a \subseteq b \Rightarrow \mathcal{H}(h) a \subseteq \mathcal{H}(h) b$.

Proof.

1. It is enough to show that $F\left(M_1(\mathbb{R}^n)(x,h), M_2(\mathbb{R}^n)\left(x,h\right)\right) \geq 0$, and $F\big(M_1(\emptyset)\left(x,h\right), M_2(\emptyset)(x,h)\big) < 0$. First we observe that $F(A_1, A_2) = 0$, $M_i(\mathbb{R}^n)(x,h) \geq A_i$, and $M_i(\emptyset)(x,h) = 0 < A_i$. This, together with $\frac{\partial F}{\partial N_i} > 0$, gives the desired inequalities.
2. Since $M_i(b) \geq M_i(a)$, $F(M_1(b), M_2(b)) \geq F(M_1(a), M_2(a))$, therefore $[F(M_1(a), M_2(a)) \geq 0] \subseteq [F(M_1(b), M_2(b)) \geq 0]$, which is equivalent to $\mathcal{H}(h) a \subseteq \mathcal{H}(h) b$. □

PROPOSITION 3.6. *Define* H *by* (1.5) *and* $\mathcal{H}$ *by* (1.4)*; then for each* $h > 0$ *and* $u \in \mathbb{B}(\mathbb{R}^n)$ *one has* $H(h) u \in \mathbb{B}(\mathbb{R}^n)$.

Proof. Without loss of generality we assume that $S_1 \leq u(x) \leq S_2$ for some $S_1, S_2 \in \mathbb{R}$. From

$$\forall h \in \mathbb{R}_+ \quad \mathcal{H}(h)(\mathbb{R}^n) = \mathbb{R}^n \text{and } \mathcal{H}(h)(\emptyset) = \emptyset$$

it follows that $x \in \mathcal{H}(h)[u \leq S_2]$ and $x \notin \mathcal{H}(h)[u \leq S_1]$. Therefore, we see that

$$S_1 \leq H(h) u(x) = \inf\{\lambda \in \mathbb{R} : x \in \mathcal{H}(h)[u \leq \lambda]\} \leq S_2. \qquad \square$$

With the results above, we are ready to state the convergence of the approximations $H(t/m)^m g$ to the unique viscosity solution of (1.3).

THEOREM 3.7. *Let* $H(h)$ *be defined by*

$$[H(h) u](x) = \sup\{\lambda \in \mathbb{R} : x \in \mathcal{H}_h[u \geq \lambda]\}$$

with

$$\mathcal{H}_h C = \{x \in \mathbb{R}^n : F(M_1(C)(x,h), M_2(C)(x,h)) \geq 0\},$$

where

$$F(N_1, N_2) = \frac{1}{\sqrt{h}} \frac{N_1 B_2 - N_2 B_1}{D} - G\left(\frac{1}{\sqrt{h}} \frac{N_2 C_1 - N_1 C_2}{D}\right),$$

and where $\tilde{\rho}_1, \tilde{\rho}_2$ *have compact support and* G *is continuous nondecreasing satisfying* (3.18). *Then*

$$H_{t/m}^m g(x) \to u(x,t)$$

locally uniformly when $m \to \infty$. *Here* $u(x,t)$ *is the unique viscosity solution of* (1.3) *with* G *satisfying* (3.18).

Proof. Our aim is to show here that the operator $H(h)$ satisfies the conditions of Theorem 3.2. The *monotonicity* of H_h is ensured by Lemmas 3.3 and 3.5.

The *stability* of H is exactly the result of Proposition 3.6: $H(h) u \in \mathbb{B}\left(\bar{\Omega}\right)$.

Another requirement in Theorem 3.2 is that $H(h)$ must commute with the addition of constants, i.e.,

$$\forall a \in \mathbb{R} \quad H(h)(u(x) + a) = H(h) u(x) + a.$$

This follows from the very definition of $H(h)$:

$$\begin{aligned} H(h)(u(x) + a) &= \inf\{\lambda \in \mathbb{R} : x \in \mathcal{H}(h)[u(x) + a \le \lambda]\} \\ &= \inf\{\beta + a \in \mathbb{R} : x \in \mathcal{H}(h)[u(x) \le \beta]\} = H(h) u(x) + a. \end{aligned}$$

The operator $H(h)$ has to fulfill (3.2) as well. The limit we are interested in is

$$\lim_{h \to 0} \frac{H(h) u(x_0)}{h} = 0$$

for u of the form $u(x) = f(|x - x_0|)$, where $f \in C^2([0,\infty))$ with $f(0) = f'(0) = f''(0) = 0$ and $f''(r) > 0$ for $r > 0$.

It is enough to show that this is true for $x_0 = 0$. First, we observe that $\mathcal{H}_h^{-1}[\{0\}] = \{u \le \lambda_1\}$, where $\lambda_1 = H(h) u(0)$. Since both ρ_1 and ρ_2 have compact support, we can be sure that there exists R s.t. $\left\{|x| \le R\sqrt{h}\right\} \supseteq \mathcal{H}_h^{-1}[\{0\}]$. Now we observe, that $\left\{|x| \le R\sqrt{h}\right\} = \{u \le \lambda_2\}$ for some $\lambda_2 > \lambda_1$. From the latter equality we deduce $\lambda_2 = O\left(h^{3/2}\right)$ and conclude with

$$\lim_{h \to 0} \frac{H(h) u(x_0)}{h} \le \lim_{h \to 0} \frac{O\left(h^{3/2}\right)}{h} = 0.$$

To show that our approximation operator is *consistent* with the PDE, we use Lemma 3.4. It is enough to prove the following:

$$\gamma(h,0) = hG(-\Delta\gamma(h,0)) + o(h),$$

where $x_n = \gamma(h, \acute{x})$ is a parameterization of the surface

$$\{x \in \mathbb{R}^n : u(x) = H(h) u(0)\}$$

near $\acute{x} = 0$. To show this, we use the fact that

$$F(M_1[u \le \mu], M_2[u \le \mu])|_{x=0} = 0.$$

We begin by writing the expressions for M_i in detail:

$$M_i = \left(\chi_{[u\le\mu]} \star \frac{1}{h^{n/2}}\rho_i\left(\frac{|\cdot|}{\sqrt{h}}\right)\right)(0) = \int_{\mathbb{R}^n} \chi_{[u\le\mu]}(y)\,\frac{1}{h^{n/2}}\rho_i\left(\frac{|y|}{\sqrt{h}}\right)dy$$

$$= \int_{\mathbb{R}^{n-1}}\int_{-\infty}^{\gamma(h,\acute{y})} \frac{1}{h^{n/2}}\rho_i\left(\frac{|y|}{\sqrt{h}}\right)dy_n d\acute{y} = A_i + \int_{\mathbb{R}^{n-1}}\int_0^{(1/\sqrt{h})\gamma\left(h,\sqrt{h}\acute{y}\right)} \rho_i(|y|)\,dy_n d\acute{y}.$$

Here A_i is given by (3.12). Expanding $\gamma\left(h,\sqrt{h}\acute{y}\right)$ in the Taylor series with respect to the spatial variables (keeping h as a parameter) we get

$$\frac{1}{\sqrt{h}}\gamma\left(h,\sqrt{h}\acute{y}\right) = \sqrt{h}\frac{\gamma(h,0)}{h} + \frac{\sqrt{h}}{2}\sum_{i,j=1}^{n-1}\gamma_{y_iy_j}(h,0)\,y_iy_j + \frac{h}{6}\sum_{i,j,l=1}^{n-1}\gamma_{y_iy_jy_l}(h,0)\,y_iy_jy_l + O\left(h^{3/2}\acute{y}^4\right).$$

Observing that $\gamma(h,0) = O\left(\sqrt{h}\right)$, we denote $\frac{\gamma(h,0)}{h} = v$. The expression for M_i becomes

$$M_i = A_i + \int_{\mathbb{R}^{n-1}}\rho_i(\acute{y},0)\left[\sqrt{h}v + \frac{\sqrt{h}}{2}\sum_{i,j=1}^{n-1}\gamma_{y_iy_j}(h,0)\,y_iy_j + O\left(h^{3/2}\acute{y}^4\right)\right]dy_n d\acute{y}$$

$$= A_i + \sqrt{h}vC_i + \sqrt{h}\Delta\gamma(h,0)\,B_i + O\left(h^{3/2}\right), \tag{3.19}$$

where we have used the fact that $\rho_i(\acute{x},x_n)$ is smooth and radially symmetric, in particular,

$$\frac{\partial\rho_i}{\partial x_n}(\acute{x},0) = 0.$$

The constants B_i, C_i depend only on ρ_i and are given by (3.13) and (3.14).

Remark 1. At this point it is easy to see that a scheme with a thresholding depending only on one variable can be consistent with the PDE (1.2) only in the case of linear G. The thresholding condition becomes

$$F\left(A + \sqrt{h}vC + \sqrt{h}\Delta\gamma(h,0)\,B + O\left(h^{3/2}\right)\right) = 0.$$

As was required by the inclusion principle, the function F is nondecreasing. This implies

$$A + \sqrt{h}vC + \sqrt{h}\Delta\gamma(h,0)\,B + O\left(h^{3/2}\right) = a,$$

where a is the unique solution of $F(a) = 0$. Thus

$$v = \frac{\gamma(h,0)}{h} = -\frac{B}{C}\Delta\gamma(h,0) - \frac{a-A}{\sqrt{h}C} + o\left(\sqrt{h}\right).$$

Comparing this relationship with the one in Lemma 3.4, we see that the only G's we can resolve by thresholding depending on one variable are the linear ones: $G(k) = \text{const}\cdot k + \text{const}$.

Let us denote here $k = \Delta\gamma(h,0)$.

Now we can express v and k in terms of M_i and constants A_i, B_i, and C_i :

$$v = \frac{1}{\sqrt{h}} \frac{N_1 B_2 - N_2 B_1}{C_1 B_2 - C_2 B_1} + O(h),$$
$$k = \frac{1}{\sqrt{h}} \frac{N_2 C_1 - N_1 C_2}{C_1 B_2 - C_2 B_1} + O(h).$$

Since $F(M_1, M_2) = v - G(-k) = 0$, we have

$$\gamma(h,0) = hG(-\Delta\gamma(h,0)) + o(h).$$

Remark 2. As was already mentioned above, convolution kernels $\tilde{\rho}_i$ can also be taken with unbounded support. For example, the exponential decay for large arguments is sufficient in order for Theorem 3.7 to hold.

The requirement (3.18) is quite restrictive. Our next result shows that it is enough to take G_ϵ satisfying (3.18) and uniformly close to G in order to approximate the solutions of (1.3).

PROPOSITION 3.8. *Suppose G_ϵ, G are continuous and $G_\epsilon \to G$ uniformly on $\mathbb{R}$ as $\epsilon \to 0$. Then $\mathcal{F}(G) = \mathcal{F}(G_\epsilon)$.*

Proof. Suppose $f \in \mathcal{F}(G)$. It means that $f(0) = f'(0) = f''(0)$, $f(r) > 0$ for $r > 0$, and

$$\lim_{p\to 0} f'(p)\, G\left(\frac{1}{p}\right) = \lim_{p\to 0} f'(p)\, G\left(\frac{-1}{p}\right) = 0.$$

Since $G_\epsilon \to G$ uniformly, $G(k) = G_\epsilon(k) + o_\epsilon(1)\,\alpha(k)$, where $\alpha \in \mathbb{B}(\mathbb{R})$. We write

$$\begin{aligned} 0 &= \lim_{p\mapsto 0} f'(p)\, G\left(\frac{1}{p}\right) \\ &= \lim_{p\to 0} f'(p)\left(G_\epsilon\left(\frac{1}{p}\right) + o_\epsilon(1)\,\alpha\left(\frac{1}{p}\right)\right) = \lim_{p\to 0} f'(p)\, G_\epsilon\left(\frac{1}{p}\right) \end{aligned}$$

to see that $f \in \mathcal{F}(G_\epsilon)$.

The proof of the reverse inclusion is analogous. □

LEMMA 3.9. *Suppose G_ϵ, G are nondecreasing continuous and $G_\epsilon \to G$ uniformly on $\mathbb{R}$ as $\epsilon \to 0$. Suppose also that for each $\epsilon > 0$ the operator H_ϵ is monotone, stable, commuting with additions of constants, and consistent with*

$$\frac{\partial u_\epsilon}{\partial t} = |Du_\epsilon|\, G_\epsilon\left(\operatorname{div}\frac{\mathrm{Du}_\epsilon}{|\mathrm{Du}_\epsilon|}\right). \tag{3.20}$$

Additionally, let the following limit hold:

$$\lim_{h\to} \frac{H_h(h)(f(|x - x_0|))(x_0)}{h} = 0 \tag{3.21}$$

for each $f \in \mathcal{F}(G)$. Then

$$H^m_{t/m}(t/m)\, u_0(x) \to u(x,t)$$

locally uniformly as $m \to \infty$, where $u(x,t)$ is the unique viscosity solution of (1.3).

Proof. We show here that the operator $H_h(h)$ satisfies the conditions of Theorem 3.2. This operator commutes with additions of constants and satisfies limit (3.21) by the assumption. Since the operator H_ϵ is stable for all $\epsilon > 0$, it is particularly stable for $\epsilon = h$ for each $h > 0$.

Since the operator H_ϵ is monotonic for all $\epsilon > 0$, it is particularly monotonic for $\epsilon = h$ for each $h > 0$.

We have to show consistency; i.e., for each $\phi \in C^\infty(\mathbb{R}^n)$ at each point where $|D\phi| \neq 0$,

$$H_h(h)\phi(x) - \phi(x) = h|D\phi(x)| G\left(\operatorname{div}\frac{D\phi(x)}{|D\phi(x)|}\right) + o(h) \tag{3.22}$$

has to hold. Since the operator H_ϵ is consistent with (3.20) and $G_h(k) = G(k) + o_h(1)\alpha(k)$ for some $\alpha \in \mathbb{B}(\mathbb{R})$, we write

$$\begin{aligned} H_h(h)\phi(x) - \phi(x) &= h|D\phi(x)| G_h\left(\operatorname{div}\frac{D\phi(x)}{|D\phi(x)|}\right) + o(h) \\ = h|D\phi(x)| \left(G\left(\operatorname{div}\frac{D\phi(x)}{|D\phi(x)|}\right) + o_h(1)\alpha\left(\operatorname{div}\frac{D\phi(x)}{|D\phi(x)|}\right)\right) &+ o(h) \\ &= h|D\phi(x)| G\left(\operatorname{div}\frac{D\phi(x)}{|D\phi(x)|}\right) + o(h); \end{aligned}$$

here $o_h(1) \to 0$ as $h \to 0$. ∎

THEOREM 3.10. *Consider a convolution-thresholding scheme*

$$\begin{aligned} H_\epsilon(h)u(x) &= \inf\{\lambda \in \mathbb{R} : x \in \mathcal{H}_\epsilon(h)[u \leq \lambda]\}, \\ \mathcal{H}_\epsilon(h)C &= \{x \in \mathbb{R}^n : F_\epsilon(M_1(C)(x,h), M_2(C)(x,h)) \geq 0\}, \end{aligned}$$

where the thresholding function $F_\epsilon(M_1, M_2)$ is chosen so that the scheme is monotone and consistent with (3.20) *and the convolution kernels have compact support. If $G_\epsilon \to G$ uniformly, then*

$$H^m_{t/m}(t/m)u_0(x) \to u(x,t)$$

locally uniformly as $m \to \infty$, where $u(x,t)$ is the unique viscosity solution of (1.3).

Proof. The convergence follows form Lemma 3.9 if we show that the limit (3.21) holds. Let us set $x_0 = 0$; then the set $[f(|x|) \leq \lambda]$ is a ball centered at the origin with radius $O(\lambda^{1/3})$. We denote $H_h(h)f(0) = \lambda_1$. Observe that λ_1 can be characterized as a number for which $\mathcal{H}_h(h)[f \leq \lambda_1] = \{0\}$. Since we know that $F_h(A_1, A_2) > 0$, the radius of $[f \leq \lambda_1]$ must be less than or equal to the radius of the greatest support of the kernel: $O(\lambda_1^{1/3}) \leq R\sqrt{h}$. From this inequality we deduce $H_h(h)f(0) = \lambda_1 \leq O(h^{3/2})$. This establishes the desired limit (3.21). ∎

Let us now consider the particular interesting case with $G(k) = k|k|^{\alpha-1}$ with $\alpha > 1$. We set

$$G_m(k) = \begin{cases} (1-\alpha)m^\alpha + \alpha m^{\alpha-1}k & \text{for } k < -n, \\ m^{1-\alpha}k & \text{for } |k| < 1/n, \\ -(1-\alpha)m^\alpha + \alpha m^{\alpha-1}k & \text{for } k > n, \\ k|k|^{\alpha-1} & \text{elsewhere.} \end{cases}$$

G_m is continuous, increasing, and its derivative is bounded from below and above: $m^{1-\alpha} \le G_m' \le \alpha m^{\alpha-1}$. Moreover, $G_m \to k\,|k|^{\alpha-1}$ locally uniformly as $m \to \infty$. Using Theorem 2.4 it is easy to show the following.

THEOREM 3.11. *Let u_m be the viscosity solution of*

$$\frac{\partial u_m}{\partial t} = |Du_m|\, G_m\left(\operatorname{div}\frac{Du_m}{|Du_m|}\right) \text{ in } \mathcal{O},$$

where G_m is defined above. Then $u_m \to u$ locally uniformly as $m \to \infty$, where u is the viscosity solution of (1.2) *in $\mathcal{O}$, with $G(k) = k\,|k|^{\alpha-1}$, $\alpha > 1$.*

Proof. First we establish the inclusion $\mathcal{F}(G) \subset \mathcal{F}(G_m)$. Take $f \in \mathcal{F}(G)$. By the definition of $\mathcal{F}(G)$, $f'(x) = o(x^\alpha)$. This immediately gives

$$\lim_{p\to 0} f'(p)\, G_m(1/p) = \lim_{p\to 0} f'(p)/p = 0,$$

since $\alpha > 1$. We observe also that the remaining conditions of Theorem 2.4 are satisfied. Hence a subsolution and a supersolution u^+ and u_+ can be constructed by means of (2.2) and (2.3). Since the equation has the strong comparison property (see [12]), $u^+ = u_+$ and the result follows. □

Remark 3. In a more general case when $G(k) = O(k^\alpha)$, $\alpha > 1$, one can pick a sequence of increasing functions with derivative bounded below and above and apply Theorem 2.4 to get a result similar to Theorem 3.11.

4. Numerical implementation. This section is devoted to a description of our numerical implementations of the convolution-thresholding scheme developed in section 3.

Given a compact set $C \subset \mathbb{R}^n$, we fix convolution kernels ρ_1, ρ_2 and the time step h and approximate C_t at a time moment $t = mh$ by $(\mathcal{H}(h))^m C$. The algorithm of computations consists of the following steps:

1. Compute convolutions and the thresholding function

$$M_i C(x,h) = \int_{\mathbb{R}^n} \chi_C(y)\, \rho_i(x-y)\, dy, \qquad i = 1,2, \tag{4.1}$$

$$F(x,h) = F(M_1 C(x,h), M_2 C(x,h)). \tag{4.2}$$

2. Find the evolved set $\mathcal{H}(h)C = \{x \in \mathbb{R}^n : F(x,h) \ge 0\}$.
3. Repeat the procedure with the evolved set to get $\mathcal{H}^2(h)C$ and so on.

We used two different algorithms for the calculation of the convolution step, which constitutes the main computational part of the algorithm.

4.1. Spatial discretization. We assume that initially the surface is closed and contained in a unit cube. The surface under consideration is always an isosurface of some function. In our implementation we use a modification of the so-called marching cubes algorithm for extracting an isosurface. The algorithm was originally proposed in [24] and was first applied for the mean curvature flow calculations in [30]. The algorithm creates an adaptive spatial discretization of C (see Figure 4.1).

By our implementation, we significantly reduce the number of grid points. In addition, the accurate piecewise polynomial approximation of the ∂C can be arranged.

4.2. Spectral method. One can use a Fourier series to calculate the convolutions (4.1). Numerical aspects of this approach have been presented by Ruuth in [30].

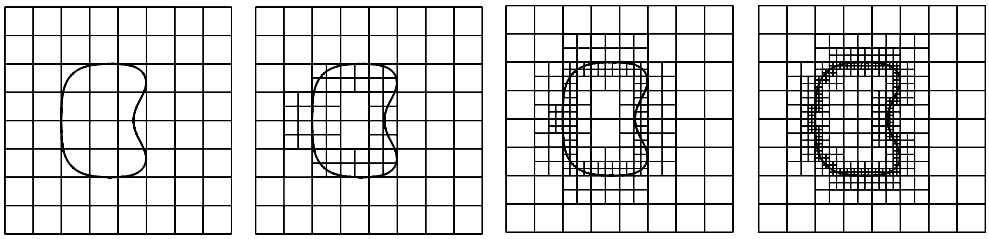

FIG. 4.1. *On the spatial discretization.*

In order to compute Fourier coefficients of χ_C given on a nonuniform grid, the unequally spaced approximate fast Fourier transform algorithm [6] is used. The numerical cost of this transform algorithm combined with the marching cubes procedure is (see [30]) $O\big(m^n N_p + N_f^n \log(N_f)\big)$, where m is a constant depending on a desired accuracy in the calculation of the Fourier coefficients (in case $m = 23$, the accuracy is comparable with the machine truncation error), N_f is a number of the Fourier modes along each axis, and N_p is the number of nodes in the grid.

4.3. Direct method. If ρ_1 and ρ_2 are simple enough and have compact support, their convolutions with χ_C can be calculated explicitly. Let us choose

$$\tilde{\rho}_1(x) = \begin{cases} \frac{1}{|\mathcal{B}_1|} & \text{if } x < 1, \\ 0 & \text{otherwise,} \end{cases}$$

$$\tilde{\rho}_2(x) = \frac{1}{\alpha^n} \tilde{\rho}_1\left(\frac{x}{\alpha}\right),$$

where $|\mathcal{B}_1|$ is the Lebesgue measure of a unit ball in $\mathbb{R}^n$ and $\alpha \in \mathbb{R}_+$, $\alpha < 1$. In this case, convolution values (4.1) are proportional to the measure of the intersection of C with a ball of radius proportional to $\sqrt{h}$ centered at the point x.

We present expressions for the thresholding function $F(M_1, M_2)$ in the case $n = 2$:

$$F(M_1, M_2) = v - G(k), \text{ where}$$

$$v = \frac{\pi\alpha(2\alpha M_1 - 2M_2 - \alpha + 1)}{4\sqrt{h}(\alpha^2 - 1)},$$

$$k = \frac{-3\pi(2M_1 - 2\alpha M_2 + \alpha - 1)}{2\sqrt{h}(\alpha^2 - 1)}.$$

In this case convolutions M_1 and M_2 can be calculated as follows. We represent C as a disjoint union of squares and triangles (or cubes in tetrahedron in case $n = 3$) using the marching cubes method and calculate the area (volume) of intersection of the ball (supp ρ) with each square and triangle. The numerical cost of each step of the evolution can be estimated by $O(N_p * N_i + N_p)$, where N_i is the number of points inside the ball of radius $\sqrt{h}$ with the center at some grid point. When h is large, the accuracy of the method is low; therefore one can take less grid points. Thus, N_i is entirely determined by the desired accuracy.

4.4. Computed examples. In the case of the mean curvature curve evolution in $\mathbb{R}^2$, the accuracy of calculations can be monitored with the help of the Von Neumann–Mullins parabolic law. It asserts that $dS/dt = -2\pi$, where S is the area enclosed by the curve.

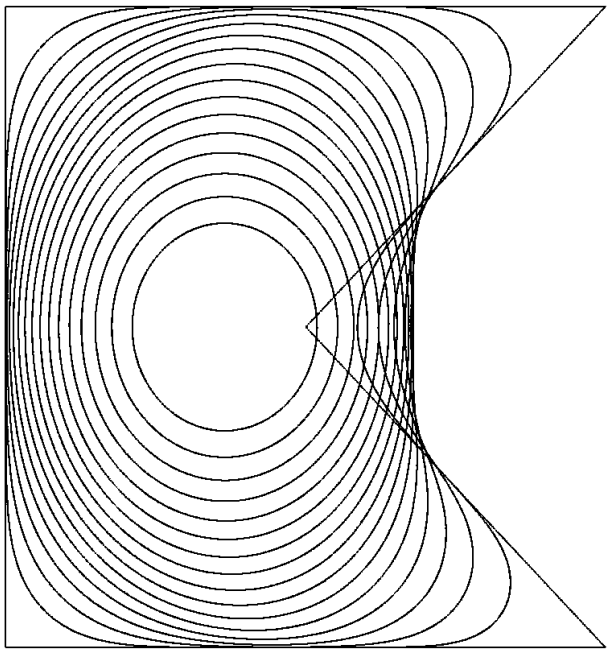

FIG. 4.2. *The mean curvature evolution of a nonsmooth, nonconvex curve.*

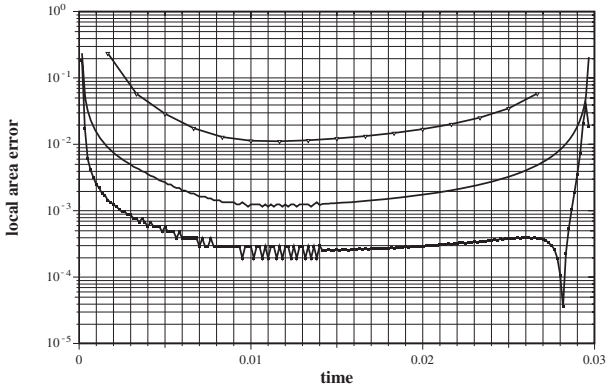

FIG. 4.3. *Local area error dependence on time. The first order method with time step* 1/600*—the line with triangle markers; the first order method with time step* 1/6000*—the thin line; the second order method with time step* 1/6000*—the line with square markers.*

Consider a nonconvex, nonsmooth initial curve, depicted in Figure 4.2. The mean curvature evolution of this curve was calculated using the direct method with time step values $dt = 1/600$ and $1/6000$. The shape of the curve is plotted in Figure 4.2 for times $t = 1/600,\ 2/600, \ldots$ when calculated with the fine time step. The comparison between local relative errors

$$e_i = \frac{|S_i - S_{i+1} - 2\pi dt|}{2\pi dt} \tag{4.3}$$

for calculations with different time steps is seen in Figure 4.3. One can observe that the error indeed depends linearly on the time step.

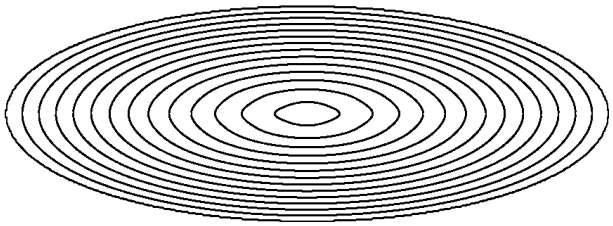

FIG. 4.4. *The evolution $v = k^{1/3}$ of an ellipse.*

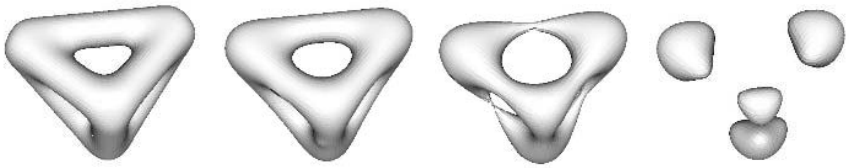

FIG. 4.5. *Computed mean curvature evolution.*

The evolution with the velocity $v = k^{1/3}$ is depicted in Figure 4.4. In this case the flow is affine invariant [1]; hence the eccentricity e of the evolving ellipse remains constant. In this particular example, the curvature is bounded from above and below by some positive constants for some evolution time. This means that we never use the parts of $G(k) = k^{1/3}$, where its derivative is too large or too small. This allows us to apply the thresholding procedure without any approximation of G.

In Figures 4.5 and 4.6 computed three-dimensional evolution of a nonconvex surface is represented for curvature flow and for a flow with velocity $v = G(k)$, as in Figure 4.7 with ~ 200000 triangles approximating the surface.

4.5. On the higher order schemes for the mean curvature motion. Let us now look at approximations to the mean curvature evolution. It is easy to see that if the surface is smooth, the Bence–Merriman–Osher method gives the first order approximation in time for a curvature flow. A higher order scheme by an extrapolation argument in time was proposed by Ruuth in [30]. We propose here higher order approximations to the mean curvature evolution using some properties of functions M_i.

We rewrite the equations (3.11) and keep an additional term of order $h^{3/2}$ in each equation with a kernel-dependent multiplier E_i to get the error term of order $h^{5/2}$. Considering two equations we get the relation

$$E_2N_1 - E_1N_2 = \sqrt{h}[(E_2C_1 - E_1C_2)v + (E_2B_1 - E_1B_2)\gamma''(h,0)] + O\big(h^{5/2}\big). \tag{4.4}$$

This relationship motivates us to take the thresholding function $F(N_1, N_2) = E_2N_1 - E_1N_2$ to approximate the mean curvature evolution with the second order accuracy for smooth curves. However, this thresholding function does not simultaneously satisfy (3.16) and (3.17) and, therefore, the stability of the numerical scheme is not guaranteed by the previous argument.

The calculations with the above thresholding function were performed. No sign of instability was observed in the numerical experiments and, as one can see in Figure 4.3, the accuracy was increased by approximately one order. This increase agrees with the construction (4.4).

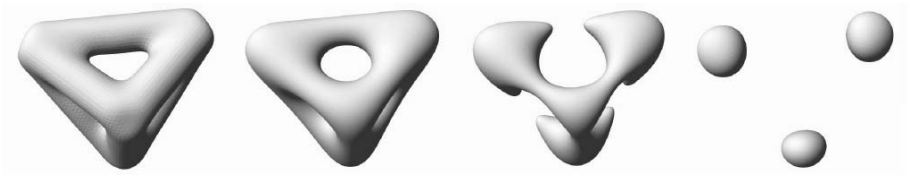

FIG. 4.6. *Computed generalized mean curvature evolution.*

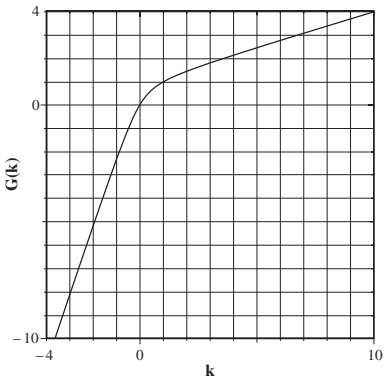

FIG. 4.7. *Function $G(k)$ used in the computation.*

Acknowledgments. A part of this work was completed during our visit to the University of South Carolina. We are grateful to Professor Björn Jawerth for the opportunity to work there and for fruitful discussions. We would also like to thank the anonymous referees for pointing out necessary corrections in the formulation of Theorem 3.2, for clarifying some key points in the text, and for suggesting additional references.

A SMOOTH TRANSITION MODEL BETWEEN KINETIC AND DIFFUSION EQUATIONS*

PIERRE DEGOND† AND SHI JIN‡

Abstract. This paper presents a model which provides a smooth transition between a kinetic and a diffusion domain. The idea is to use a buffer zone, in which both diffusion and kinetic equations will be solved. The solution of the original kinetic equation will be recovered as the *sum* of the solutions of these two equations. We use an artificial connecting function which makes the equation on each domain degenerate at the end of the buffer zone. Thus no boundary condition is needed at the transition point. This model avoids the delicate issue of finding the interface condition or iteration in a typical domain decomposition method that couples a kinetic equation with hydrodynamic equations. A new asymptotic-preserving method for this model is introduced, and numerical examples are used to validate this new model and the new numerical method.

Key words. kinetic-fluid coupling, transport equation, diffusion approximation, asymptotic preserving schemes

1. Introduction.

The collision transition rate in a kinetic transport process is often position dependent and varies from order unity in certain parts of the domain to an order of magnitude much smaller in other parts of the domain. For instance, in radiative transfer, the transition from a transparent to an opaque medium involves a change of collision rate by several orders of magnitude. Similarly, in stellar astrophysics, the magnitude of the photon transition rate can change by decades from the core of a star to its surface. When the collision rate is large, the diffusion equation is valid and much more efficient to solve numerically. In the domain where the collision rate is small, solving the more expensive kinetic transport equation in the phase space is necessary. Although one can solve the transport equation in the entire domain, to reduce the computational cost it is more advantageous to use a domain decomposition method that couples the diffusion equation with the transport equation.

Domain decomposition methods matching kinetic with hydrodynamic or diffusion models have received much attention in the past 15 years. Some methods have been proposed in [3], [7], [14], [15], [18], [19], [25], [26], [27], [28], [29], [33], [34], [37]. Typically a domain decomposition is done by an iteration procedure at each time step in which the diffusion and transport equations are solved alternately until convergence of the successive approximation is reached, or through an interface condition which provides the boundary conditions for each subdomain [18].

Other strategies include hybrid strategies, in which two equations are solved simultaneously, such as a fluid equation for the equilibrium part of the distribution function and a kinetic equation for perturbation to the equilibrium part. Recently, hybrid methods have been derived by a domain decomposition method *in velocity*

space [11], [12], [13]. These methods bear similarities with the δf method developed by plasma physicists [8].

In this paper we present a new approach to the domain decomposition method using a buffer zone, in which both diffusion and kinetic equations will be solved. The solution of the original transport equation will be recovered as the *sum* of the solutions of these two equations. In this way, our strategy departs from strategies based on domain decomposition with overlap, in which *each* of the models represents the *full* solution. Unlike a typical domain decomposition, where an interface condition has to be worked out in order to provide the boundary condition for each decomposed domain [18], we use an artificial connecting function which makes the equation on each domain degenerate at the end of the buffer zone; thus no boundary condition is needed at the transition point. Thus the delicate issue of finding the interface condition is completely avoided, and this method will not require any iteration at any given time step to match the solution of the two subdomains.

The paper is organized as follows. In the next section, we introduce the coupling technique and carry out some elementary analysis on its properties. A new asymptotic-preserving numerical scheme for this coupling model is derived in section 3. In section 5, we present numerical experiments to validate this new model and the numerical method introduced and state our conclusions.

2. The coupling methodology.

2.1. The transport equation and its diffusion limit. We present the method on a simple kinetic equation, the one-group transport equation in slab geometry [10]. Let $f(x,\mu,t)$ represent the particle phase-space density, where $x \in \mathbb{R}$ is the (one-dimensional) position variable, $\mu \in [-1,1]$ is the cosine of the angle between the velocity and the x-axis, and t is the time. In this model, the magnitude of the particle velocities are equal and normalized to 1. Then, the transport equation is

$$\partial_t f + \mu \partial_x f = Q(f)\,, \tag{2.1}$$

$$Q(f) = \int_{-1}^{1} S(x,\mu,\mu')(f(x,\mu',t) - f(x,\mu,t))\,d\mu'\,. \tag{2.2}$$

The left-hand side of (2.1) describes the motion of the particles along the x-axis with velocity μ while the operator Q takes into account the particle interactions with the medium. $S(x,\mu,\mu')$ is the collision transition rate from μ to μ' at point x. In the formulation (2.2), we implicitly assumed that these interactions preserve particle number, i.e.,

$$\int_{-1}^{1} Q(f)\,d\mu = 0\,. \tag{2.3}$$

This will be sufficient for our purpose. In practical cases, like neutron transport or radiative transfer, it is necessary to include nonconservative cases (like neutron multiplication or photon absorption/emission), but these effects are not essential and can be easily incorporated into our formulation if needed. Equation (2.1) must be supplemented with an initial condition $f_0(x,\mu)$ and suitable boundary conditions. A particular case is when S does not depend on μ and μ': $S(x,\mu,\mu') = \sigma(x)/2$, where σ is the collision frequency. Then

$$Q(f) = \sigma(x)\left[\frac{1}{2}\int_{-1}^{1} f(x,\mu',t)\,d\mu' - f(x,\mu,t)\right] \tag{2.4}$$

is (up to a multiplicative factor) a projection operator onto the functions independent of μ.

When the particle interactions with the medium are very frequent, i.e., when Q is "large," the numerical resolution of (2.1) becomes extremely time consuming, and it is worth using the asymptotic model obtained when Q "tends to infinity." We introduce a new set of "macroscopic variables" x' and t' according to

$$x' = \varepsilon x\,, \quad t' = \varepsilon^2 t\,,$$

where ε denotes the ratio of the microscopic to the macroscopic scale. Typically, ε is the ratio of the particle mean-free path (related to a typical value of S) to the size of the problem under consideration and is called the Knudsen number. After using this change of variables and dropping the primes for simplicity, one gets

$$\varepsilon^2 \partial_t f^\varepsilon + \varepsilon \mu \partial_x f^\varepsilon = Q(f^\varepsilon). \tag{2.5}$$

In the limit $\varepsilon \to 0$, f^ε converges towards the solution of a diffusion equation. More precisely, we have the following (see, e.g., [5], [6]).

LEMMA 2.1. *$f^\varepsilon \to n(x,t)$, where n is a solution of*

$$\partial_t n - \partial_x (D(x) \partial_x n) = 0\,, \tag{2.6}$$

with initial condition $n|_{t=0} = \frac{1}{2}\int f_0(x,\mu)\,d\mu$. The diffusion constant D is related to Q by

$$D(x) = -\frac{1}{2}\int_{-1}^{1} Q^{-1}(\mu)\,\mu\,d\mu > 0\,. \tag{2.7}$$

We shall not be more precise on the functional spaces and instead refer readers to [5], [17] for details. The definition of Q^{-1} needs a few words of explanation. We first note that Q only operates with respect to the variable μ, while x is just a parameter. As an operator acting on functions of μ, Q has the following properties (see, e.g., [5]).

LEMMA 2.2. *Suppose that $0 < C_0 \le S \le C_1 < \infty$. Then Q is a bounded self-adjoint nonpositive operator on $L^2(-1,1)$. Furthermore*

(i) $\mathrm{Ker\,Q}$ *consists of constant functions with respect to μ.*

(ii) $\mathrm{Im\,Q} = (\mathrm{Ker\,Q})^\perp = \{\mathrm{g}\ s.t. \int \mathrm{g}\,\mathrm{d}\mu = 0\}$.

(iii) *Q is invertible from $(\mathrm{Ker\,Q})^\perp$ to $(\mathrm{Ker\,Q})^\perp$. Its (pseudo-)inverse is denoted by Q^{-1}.*

It is worth summarizing the main steps of the proof.

Proof of Lemma 2.1. We use the Hilbert expansion

$$f^\varepsilon = f^{(0)} + \varepsilon f^{(1)} + \varepsilon^2 f^{(2)} + O(\varepsilon^3)\,. \tag{2.8}$$

We insert this expansion into (2.5) and identify terms of equal powers of ε. This leads to the sequence of equations

$$Q(f^{(0)}) = 0\,, \tag{2.9}$$

$$Q(f^{(1)}) = \mu \partial_x f^{(0)}\,, \tag{2.10}$$

$$Q(f^{(2)}) = \mu \partial_x f^{(1)} + \partial_t f^{(0)}\,. \tag{2.11}$$

With (2.9) and Lemma 2.2(i), we deduce that $f^{(0)}$ does not depend on μ. We denote $n(x,t) = f^{(0)}(x,\mu,t)$.

Equation (2.10) simplifies into

$$Q(f^{(1)}) = \mu \partial_x n \,. \tag{2.12}$$

Its right-hand side is an odd function of μ and therefore, integrated against any constant function, yields 0. Therefore, it belongs to $(\mathrm{Ker}\, Q)^\perp$. By Lemma 2.2(iii), we can invert (2.12) in $(\mathrm{Ker}\, Q)^\perp$ and get

$$f^{(1)} = Q^{-1}(\mu)\partial_x n \,. \tag{2.13}$$

For the most general solution of (2.12), we should add an element of $(\mathrm{Ker}\, Q)$, i.e., a function of (x,t) only. We fix this function to be zero to ensure that n is an $O(\varepsilon^2)$ approximation to the true density $n^\varepsilon = (1/2)\int f^\varepsilon \, d\mu$ (since then $\int f^{(1)}\, d\mu = 0$).

Equation (2.11) is solvable for $f^{(2)}$ if and only if its right-hand side is orthogonal to the functions independent of μ. Therefore, the solvability condition of (2.11) reads

$$\partial_t n + \partial_x j = 0 \tag{2.14}$$

with

$$j = \frac{1}{2}\int_{-1}^{1} f^{(1)} \mu \, d\mu \,. \tag{2.15}$$

Inserting (2.13) into (2.15), we get that $j = -D\partial_x n$ with D given by (2.7). Finally, with (2.14), we get (2.6). The fact that D is positive comes from the positive definiteness of $-Q$ on $(\mathrm{Ker}\, Q)^\perp$. □

Note that in the case (2.4), $D = 1/(3\sigma)$.

The proof of Lemma 2.1 relies on the fact that S (or σ) is everywhere of order unity (with respect to ε). However, S is position dependent and there are numerous situations in which it is of order unity in certain parts of the domain, while it is much smaller (of order ε or ε^2) in other parts of the domain. The diffusion equation is only valid when S is of order unity. If S is smaller, solving the transport equation is necessary. Therefore, one needs to couple the diffusion equation in the regions where S is of order unity to the transport equation in the regions where it is smaller.

2.2. The coupling method. This problem has been addressed by many authors with many methods (see the references in the introduction). Our approach is novel and consists of introducing a buffer zone in which both diffusion and kinetic equations will be solved. The solution of the initial transport equation will be recovered as the *sum* of the solutions of these two equations. In this way, our strategy departs from strategies based on domain decomposition with overlap, in which *each* of the models represents the *full* solution. The buffer interval is denoted by $[a,b]$. We introduce a smooth function $h(x)$ such that

$$\begin{cases} h(x) = 1 & \text{for} \quad x \le a \,, \\ h(x) = 0 & \text{for} \quad x \ge b \,, \\ h(x) \in (0,1) & \text{for} \quad a \le x \le b \,. \end{cases}$$

We consider the following coupled system for two distribution functions f_L and f_R:

$$\varepsilon^2 \partial_t f_L^\varepsilon + \varepsilon h \mu \partial_x f_L^\varepsilon + \varepsilon h \mu \partial_x f_R^\varepsilon = h(Q(f_L^\varepsilon) + Q(f_R^\varepsilon)) \,, \tag{2.16}$$

$$\varepsilon^2 \partial_t f_R^\varepsilon + \varepsilon (1-h) \mu \partial_x f_L^\varepsilon + \varepsilon (1-h) \mu \partial_x f_R^\varepsilon = (1-h)(Q(f_L^\varepsilon) + Q(f_R^\varepsilon)) \tag{2.17}$$

with initial data

$$f_L^\varepsilon|_{t=0} = hf_0, \quad f_R^\varepsilon|_{t=0} = (1-h)f_0\,. \tag{2.18}$$

We first note the following.

LEMMA 2.3. *If f_L^ε and f_R^ε are the solution of problem* (2.16), (2.17) *with initial data* (2.18)*, then $f = f_L^\varepsilon + f_R^\varepsilon$ is the solution of problem* (2.5) *with initial condition f_0.*

Proof. For the proof, simply add up (2.16) and (2.17). ∎

We note that, in reality, (2.16) is posed on the interval $(-\infty, b)$ and (2.17) on $(a, +\infty)$ since h vanishes for $x > b$ and $1-h$ for $x < a$. Additionally, since h (resp., $1-h$) multiplies the space derivative operator in (2.16) (resp., (2.17)), *no boundary condition is required for f_L^ε at $x = b$ (resp., for f_R^ε at $x = a$).*

Now, we assume that S is of order ε^2 in the interval $(-\infty, a)$, while it is of order 1 in $(a, +\infty)$. Therefore, we shall only be allowed to perform the diffusion approximation on f_R^ε, while f_L^ε will have to stay untouched. For this purpose, we rewrite (2.17) according to

$$\begin{aligned} &\varepsilon^2\partial_t f_R^\varepsilon + \varepsilon(1-h)\mu\partial_x f_R^\varepsilon - (1-h)Q(f_R^\varepsilon) \\ &\quad = -\varepsilon(1-h)\mu\partial_x f_L^\varepsilon + (1-h)Q(f_L^\varepsilon)\,, \end{aligned} \tag{2.19}$$

and we consider the terms on the right-hand side to be of order ε^2. The following proposition states the diffusion approximation $\varepsilon \to 0$ of this equation.

PROPOSITION 2.4. *Consider* (2.19)*, where the right-hand side is treated as an $O(\varepsilon^2)$ term. Then as $\varepsilon \to 0$, $f_R^\varepsilon \sim n_R^\varepsilon$ where $n_R^\varepsilon = n_R^\varepsilon(x,t)$ is a solution of the following diffusion equation:*

$$\partial_t n_R^\varepsilon - (1-h)\partial_x[D(x)\partial_x n_R^\varepsilon] + (1-h)\partial_x j_L^\varepsilon = 0, \tag{2.20}$$

where D is given by (2.7) *and*

$$j_L^\varepsilon = \frac{1}{2\varepsilon}\int_{-1}^{1} f_L^\varepsilon \mu\, d\mu\,. \tag{2.21}$$

Since ε tends to 0 only in some terms and not in others, we cannot speak of convergence but rather of asymptotic equivalence; hence the use of the symbol $\sim$. Again, (2.20) is a diffusion equation on the interval $[a, +\infty)$. However, since $1-h$ vanishes at $x = a$, *the diffusion operator is degenerate at this point and no boundary condition is required.*

Proof. We again write the Hilbert expansion $f_R^\varepsilon = f_R^{(0)} + \varepsilon f_R^{(1)} + \varepsilon^2 f_R^{(2)} + O(\varepsilon^3)$. The computations of $f_R^{(0)} = n_R$ and of $f_R^{(1)}$ are the same as in Lemma 2.1. Indeed, the right-hand side of (2.19) being of order ε^2 does not contribute anything to (2.9) and (2.10). The only change is in (2.11), which becomes

$$\begin{aligned} (1-h)Q(f_R^{(2)}) &= (1-h)\mu\partial_x f_R^{(1)} + \partial_t f_R^{(0)} \\ &\quad + \frac{1}{\varepsilon}(1-h)\mu\partial_x f_L^\varepsilon - \frac{1}{\varepsilon^2}(1-h)Q(f_L^\varepsilon)\,. \end{aligned} \tag{2.22}$$

We note that the sum of the last two terms is of order 1 by our hypothesis, despite their apparent dependence on ε. Integrating (2.22) with respect to μ in order to express the solvability condition for f_R^2, we obtain

$$\partial_t n_R^\varepsilon + (1-h)\partial_x j_R^\varepsilon = -(1-h)\partial_x\left(\frac{1}{2\varepsilon}\int_{-1}^{1} f_L^\varepsilon \mu\, d\mu\right)$$

because the contribution of $Q(f_L^\varepsilon)$ vanishes after integration with respect to μ by (2.3). This leads to (2.20) and concludes the proof. □

The coupled kinetic-diffusion model is now written as follows:

$$\varepsilon^2\partial_t f_L^\varepsilon + \varepsilon h\mu\partial_x f_L^\varepsilon + \varepsilon h\mu\partial_x f_R^\varepsilon = h(Q(f_L^\varepsilon) + Q(f_R^\varepsilon))\,, \qquad -\infty < x \le b, \tag{2.23}$$

$$\partial_t n_R^\varepsilon - (1-h)\partial_x(D(x)\partial_x n_R^\varepsilon) + (1-h)\partial_x j_L^\varepsilon = 0\,, \quad a \le x < \infty, \tag{2.24}$$

$$f_R^\varepsilon = n_R^\varepsilon + \varepsilon Q^{-1}(\mu)\partial_x n_R^\varepsilon\,, \tag{2.25}$$

$$j_L^\varepsilon = \frac{1}{2\varepsilon}\int_{-1}^{1} f_L^\varepsilon \mu\, d\mu\,, \tag{2.26}$$

with initial data

$$f_L^\varepsilon|_{t=0} = hf_0\,, \quad f_R^\varepsilon|_{t=0} = (1-h)f_0\,, \quad n_R^\varepsilon|_{t=0} = \frac{1}{2}(1-h)\int_{-1}^{1} f_0\, d\mu\,. \tag{2.27}$$

So far we use ε to perform the asymptotic analysis more conveniently. In numerical implementation, one should drop ε in the coupling model (2.23)–(2.26) by setting $\varepsilon = 1$. The domain is diffusive if $Q \approx O(1/\varepsilon)$.

2.3. Properties of the coupling. The reconstruction of the distribution function f_R^ε from the solution of the diffusion equation n_R^ε retains both the zeroth and first order terms of the Hilbert expansion. This is necessary in order to recover the diffusion equation on the entire real line when both regions are diffusive (see below). Equations (2.23) and (2.25) can be combined into

$$\varepsilon^2\partial_t f_L^\varepsilon + \varepsilon h\mu\partial_x f_L^\varepsilon - hQ(f_L^\varepsilon) = \varepsilon^2 h\mu\partial_x(Q^{-1}(\mu)\partial_x n_R^\varepsilon)\,, \tag{2.28}$$

showing that the n_R^ε enters the equation for f_L^ε in an order $O(\varepsilon^2)$ term. In the case where $S = \sigma(x)/2$ does not depend on μ, this equation becomes

$$\varepsilon^2\partial_t f_L^\varepsilon + \varepsilon h\mu\partial_x f_L^\varepsilon - hQ(f_L^\varepsilon) = \varepsilon^2 h\mu^2\partial_x(\sigma^{-1}\partial_x n_R^\varepsilon)\,. \tag{2.29}$$

We now prove that if both regions are diffusive, we recover the global diffusion equation (2.6) for $n = n_L + n_R$.

PROPOSITION 2.5. *As $\varepsilon \to 0$, the solution f_L^ε, n_R^ε of system* (2.23)–(2.27) *converges to the pair n_L, n_R, the solution of the diffusion system*

$$\partial_t n_L - h[\partial_x(D(x)\partial_x n_L) + \partial_x(D(x)\partial_x n_R)] = 0\,, \tag{2.30}$$

$$\partial_t n_R - (1-h)[\partial_x(D(x)\partial_x n_R) + \partial_x(D(x)\partial_x n_L)] = 0\,, \tag{2.31}$$

with initial data

$$n_L|_{t=0} = hn_0\,, \quad n_R|_{t=0} = (1-h)n_0\,, \quad n_0 = \frac{1}{2}\int_{-1}^{1} f_0\, d\mu\,. \tag{2.32}$$

In particular, $n = n_L + n_R$ is the solution of the diffusion equation (2.6) *with initial condition n_0.*

Proof. The proof is similar to that of Proposition 2.4. The term involving n_R^ε in the transport equation for f_L^ε is of order $O(\varepsilon^2)$. Therefore, it does not induce any change in the expression of the first two equations of the Hilbert expansion (2.9)–(2.10). Equation (2.11) is modified into

$$hQ(f_L^{(2)}) = h\mu\partial_x f_L^{(1)} + \partial_t f_L^{(0)} + h\mu\partial_x(Q^{-1}(\mu)\partial_x n_R)\,. \tag{2.33}$$

Integrating it with respect to μ in order to express the solvability condition for $f_L^{(2)}$, we obtain

$$\partial_t n_L^\varepsilon + h\partial_x j_L^\varepsilon = -h\partial_x \left(\left(\frac{1}{2} \int Q^{-1}(\mu)\mu \, d\mu \right) \partial_x n_R \right) ,$$

thus leading to (2.30). We use the expression of j_L from (2.15), (2.13), giving $j_L = -D\partial_x n_L$. Inserting this expression into (2.24) yields (2.31), which concludes the proof. ∎

Therefore, our coupled kinetic-diffusion model is consistent with the diffusion equation on the entire real line when the kinetic region $(-\infty, a)$ is also in the diffusive regime.

An important issue is positivity. Indeed, a distribution function being a density in phase space is a positive quantity. Therefore, we should ensure that $f_L^\varepsilon + f_R^\varepsilon$, which is our approximation of f, remains positive, or at least close to positive. Since the signs of the coupling terms in (2.23)–(2.24) are not determined, both f_L^ε and n_R^ε could become negative. In fact, outside the buffer zone, i.e., in the intervals $(-\infty, a]$ or $(b, +\infty]$, the coupling terms vanish identically, and we solve either a standard transport equation or a standard diffusion equation. Therefore, loss of positivity can originate only from the buffer zone $[a, b]$. This region is a diffusive region for both f_L^ε and f_R^ε since the conditions which ensure that the diffusion approximation is valid for f_R^ε (i.e., $Q = O(1)$) also make the diffusion approximation valid for f_L^ε. In this case, both f_L^ε and f_R^ε are close (at order ε) to the solutions n_R and n_L of the diffusion equations (2.30), (2.31). But since $n_R + n_L$ solves the classical diffusion equation, it remains positive. Therefore, in the buffer zone, $f_L^\varepsilon + f_R^\varepsilon$ are close, up to order $0(\varepsilon)$ terms, to a positive function.

Consequently, if losses of positivity occur in the buffer zone, they will remain small, i.e., of order ε. If they are ultimately propagated outside the buffer zone, they will remain small and of this order everywhere. Therefore, although we cannot prove that our method preserves positivity, we have solid indications that negative values, if they occur, will remain small. Our numerical simulations did not exhibit any loss of positivity so far (see next section).

Remark 2.1. There is an alternate coupling strategy to (2.23)–(2.27). It consists of the following system:

$$\varepsilon^2 \partial_t f_L^\varepsilon + \varepsilon h\mu \partial_x f_L^\varepsilon + \varepsilon h\mu \partial_x n_R^\varepsilon = Q(f_L^\varepsilon) , \tag{2.34}$$

$$\partial_t n_R^\varepsilon - \partial_x((1-h)D(x)\partial_x n_R^\varepsilon) - \partial_x((1-h)D(x)\partial_x n_L^\varepsilon) + (1-h)\partial_x j_L^\varepsilon = 0 , \tag{2.35}$$

$$n_L^\varepsilon = \frac{1}{2}\int_{-1}^{1} f_L^\varepsilon \, d\mu , \quad j_L^\varepsilon = \frac{1}{2\varepsilon}\int_{-1}^{1} f_L^\varepsilon \mu \, d\mu . \tag{2.36}$$

This model is more heuristic since it is not obtained from a diffusion approximation of the coupled kinetic equations (2.16), (2.17). However, it shares with (2.23)–(2.27) the property of relaxing towards the solution of the diffusion equation on the whole real line when both regions are diffusive (we leave the details of the proof to the reader).

Remark 2.2. A rigorous convergence analysis of this coupling strategy is outside the scope of the present paper, which focuses more on the practical feasibility of the method. The convergence analysis, as well as a rigorous study of the loss of positivity, will be investigated in future work.

3. Numerical method. In this section we introduce a new (spatially discrete) numerical method for the coupling problem. In fact, this numerical scheme can be

used for a discretization of the transport equation, with different order of magnitude in ϵ, in the spirit of the *asymptotic-preserving method* [9], [17], [20], [21], [22], [23], [24], [26], [30], [31], [32] that works uniformly with respect to the mean-free path. However, this new asymptotic-preserving spatial discretization method has not been reported in the literature.

This goal of this scheme to is verify the validity of the coupling method numerically. It remains a future research topic to find the best numerical scheme for the coupling problem.

3.1. Parity formulation. We explain the new scheme using the transport equation with isotropic scattering (2.4). It is based on the parity form of the transport equation. This is a standard form used to construct the asymptotic-preserving scheme [1], [24], [36]. For anisotropic scattering, if $S(x,\mu,\mu')$ is even in both μ and μ', one can also use the parity form. For isotropic scattering (2.4), the coupling problem (2.23)–(2.26) becomes

$$\begin{aligned}&\varepsilon^2\partial_t f_L+\varepsilon h\mu\partial_x f_L+\varepsilon h\mu\partial_x f_R\\ &\qquad=h\sigma\left[\frac{1}{2}\int_{-1}^{1}(f_L(\mu')+f_R(\mu'))d\mu'-f_L(\mu)-f_R(\mu)\right],\end{aligned}\tag{3.1}$$

$$\partial_t n_R-\frac{1}{3}(1-h)\partial_x(\sigma(x)^{-1}\partial_x n_R)+(1-h)\partial_x j_L=0\,,\tag{3.2}$$

$$f_R=n_R-\varepsilon\frac{\mu}{\sigma}\partial_x n_R\,,\tag{3.3}$$

$$j_L^{\varepsilon}=\frac{1}{\varepsilon}\int_0^1 f_L\mu\,d\mu\,.\tag{3.4}$$

Applying (3.3) in (3.1) one gets

$$\varepsilon^2\partial_t f_L+\varepsilon h\mu\partial_x f_L-\varepsilon^2 h\mu^2\partial_x(\sigma^{-1}\partial_x n_R)=h\sigma\left[\frac{1}{2}\int_{-1}^{1}f_L(\mu')d\mu'-f_L(\mu)\right],\tag{3.5}$$

$$\partial_t n_R-\frac{1}{3}(1-h)\partial_x(\sigma(x)^{-1}\partial_x n_R)+(1-h)\partial_x j_L=0\,,\tag{3.6}$$

$$j_L=\frac{1}{\varepsilon}\int_0^1 f_L\mu\,d\mu\,.\tag{3.7}$$

Define the even and odd parities, for $\mu>0$, as

$$f^E(t,x,\mu)=\frac{1}{2}\left[f(t,x,\mu)+f(t,x,-\mu)\right],\tag{3.8}$$

$$f^O(t,x,\mu)=\frac{1}{2\epsilon}\left[f(t,x,\mu)-f(t,x,-\mu)\right].\tag{3.9}$$

Then

$$n(t,x)=\frac{1}{2}\int_{-1}^{1}f(t,x,\mu)\,d\mu=\int_0^1 f^E(t,x,\mu)\,d\mu\,,\tag{3.10}$$

$$j(t,x)=\frac{1}{2\epsilon}\int_{-1}^{1}f(t,x,\mu)\mu\,d\mu=\int_0^1 f^O(t,x,\mu)\mu\,d\mu\,.\tag{3.11}$$

With the parities, from now on we only consider $\mu>0$. First, we split (3.1) and

(3.2), i.e., one for μ and one for $-\mu$ (from now on we omit the superscript):

$$\begin{aligned}&\varepsilon^2\partial_t f_L(\mu)+\varepsilon h\mu\partial_x f_L(\mu)-\varepsilon^2 h\mu^2\partial_x(\sigma^{-1}\partial_x n_R)\\&\quad=h\sigma\left[\frac{1}{2}\int_{-1}^{1} f_L(\mu')d\mu'-f_L(\mu)\right]\quad\text{for}\quad x<b\,,\end{aligned}\tag{3.12}$$

$$\begin{aligned}&\varepsilon^2\partial_t f_L(\mu)+\varepsilon h\mu\partial_x f_L(-\mu)-\varepsilon^2 h\mu^2\partial_x(\sigma^{-1}\partial_x n_R)\\&\quad=h\sigma\left[\frac{1}{2}\int_{-1}^{1} f_L(\mu')d\mu-f_L(-\mu)\right]\quad\text{for}\quad x<b\,,\end{aligned}\tag{3.13}$$

$$\partial_t n_R-\frac{1}{3}(1-h)\partial_x(\sigma(x)^{-1}\partial_x n_R^{\varepsilon})+(1-h)\partial_x j_L^{\varepsilon}=0\quad\text{for}\quad x>a\,,\tag{3.14}$$

$$j_L=\frac{1}{\varepsilon}\int_0^1 f_L^O\,\mu\,d\mu\,.\tag{3.15}$$

Adding and subtracting the two equations in (3.12) and (3.13) leads to

$$\epsilon^2\partial_t f_L^E+\epsilon h\mu\partial_x f_L^O-\varepsilon^2 h\mu^2\partial_x(\sigma^{-1}\partial_x n_R)=h\sigma\left(\int_0^1 f_L^E\,d\mu-f_L^E\right),\tag{3.16}$$

$$\epsilon^2\partial_t f_L^O+\epsilon h\mu\partial_x f_L^E=-h\sigma f_L^O\quad\text{for}\quad x<b.\tag{3.17}$$

Our system now consists of (3.16), (3.17), (3.14), and (3.15).

3.2. Asymptotic-preserving spatial discretization using staggered grids. For spatial discretization, let x_j be the mesh point for $i=0,1,\dots,J$. The even parity will be defined on these mesh points, namely, $f_i^E=f^E(x_i), n_{R,i}=n_R(x_i)$. For the odd parity we define them on a staggered mesh point $x_{i+1/2}=(x_i+x_{i+1})/2$: $f_{i+1/2}^O=f^O(x_{i+1/2})$. This definition guarantees that, when $\epsilon\to 0$, one ends up at a three-point rather than five-point scheme for the diffusion equation. This has better resolution than the previous asymptotic-preserving schemes [23], [24], [26] for diffusive transport equations that yield five-point stencils in this limit. However, we point out that using staggered mesh is restricted to one space dimension. For a higher dimension, the classical asymptotic-preserving schemes can still be applied, but this is beyond scope of this paper.

Let $\sigma_i=\sigma(x_i),\sigma_{i+1/2}=\frac{1}{2}(\sigma_i+\sigma_{i+1}), h_i=h(x_i), h_{i+1/2}=h(x_{i+1/2})$. The spatially discrete scheme for the coupling problem (3.16), (3.17), (3.14), (3.15) is given by center difference on a staggered grid:

$$\begin{aligned}&\epsilon^2\partial_t f_{L,i}^E+\epsilon h_i\mu\frac{f_{L,i+1/2}^O-f_{L,i-1/2}^O}{\Delta x}\\&\quad-\epsilon h_i\mu^2\frac{1}{(\Delta x)^2}\left[\sigma_{i+1/2}^{-1}(n_{R,i+1}-n_{R,i})-\sigma_{i-1/2}^{-1}(n_{R,i}-n_{R,i-1})\right]\\&\quad=h_i\sigma_i\left[\int_0^1 f_{L,i}^E\,d\mu-f_{L,i}^E\right],\end{aligned}\tag{3.18}$$

$$\epsilon^2\partial_t f_{L,i+1/2}^O+\epsilon h_{i+1/2}\,\mu\frac{f_{L,i+1}^E-f_{L,i}^E}{\Delta x}=-h_{i+1/2}\sigma_{i+1/2}f_{L,i+1/2}^O,\tag{3.19}$$

$$\begin{aligned}&\partial_t n_{R,i}-(1-h_i)\frac{1}{(\Delta x)^2}\left[\sigma_{i+1/2}^{-1}\,(n_{R,i+1}-n_{R,i})-\sigma_{i-1/2}^{-1}\,(n_{R,i}-n_{R,i-1})\right]\\&\quad+(1-h_i)\frac{j_{L,i+1/2}-j_{L,i-1/2}}{\Delta x}=0\,,\end{aligned}\tag{3.20}$$

$$j_{L,i+1/2} = \frac{1}{\varepsilon}\int_0^1 f^O_{L,i+1/2}\mu\, d\mu\,. \tag{3.21}$$

This is a second order approximation. To verify that it is asymptotic preserving, for $\epsilon \ll 1$, the leading order approximation of (3.18) gives

$$f^E_{L,i} = \int_0^1 f^E_{L.i}\, d\mu \equiv n_{L,i}, \tag{3.22}$$

while (3.19) gives

$$f^O_{L,i+1/2} = -\epsilon\frac{\mu}{\sigma_{i+1/2}}\frac{f^E_{L,i+1} - f^E_{L,i}}{\Delta x}\,. \tag{3.23}$$

Applying (3.22) and (3.23) into (3.18) and integrating over μ, we get

$$\begin{aligned}&\partial_t\rho^E_{L,i} - h_i\frac{1}{3(\Delta x)^2}\left[\sigma^{-1}_{i+1/2}(n_{L,i+1} - n_{L,i}) - \sigma^{-1}_{i-1/2}(n_{L,i} - n_{L,i-1})\right]\\ &- h_i\frac{1}{3(\Delta x)^2}\left[\sigma^{-1}_{i+1/2}(n_{R,i+1} - n_{R,i}) - \sigma^{-1}_{i-1/2}(n_{R,i} - n_{R,i-1})\right] = 0\,,\end{aligned} \tag{3.24}$$

which is a three-point second order approximation to (2.20) with $D = \sigma^{-1}$.

Since the space discretization is a centered-difference one, in order to ensure stability of the time discretization, one can use a so-called *I-stable* ODE solver. An I-stable solver is a scheme for ODEs whose stability region contains part of the imaginary axis. The third and fourth order explicit Runge–Kutta methods, among other schemes, are I-stable. An I-stable ODE solver is particularly well suited for convection problems where the convection term is discretized using centered differences, since the spectrum of a centered difference operator is purely imaginary and an I-stable scheme, unlike the forward Euler method, will be stable with a suitable choice of the time step [4], [16], [38]. We would like to remark that for steady state computations, the convergence to the steady state for such an explicit solver is very slow, and some acceleration techniques, such as the diffusion synthetic acceleration [2], can be used but will not be explored in this paper.

For discretization in the velocity space, we use the standard discrete-ordinate method with Gaussian quadrature over $(0, 1)$ [35].

4. Numerical examples. In this section we present several numerical examples on the coupling model (3.1)–(3.4) by the numerical schemes described in the previous section. We solve the problem in domain $[0, 1]$ with Dirichlet boundary condition

$$f(t, 0, \mu) = f_l(\mu)\,, \qquad f(t, 1, -\mu) = f_r(-\mu)\,, \qquad \mu > 0\,.$$

In these examples $\epsilon = 1$, and the value of σ characterizes the nature of the regime (transport or diffusive). We use 1001 points to solve the transport equation in the entire domain as the "exact" solution and 25 points for the numerical approximations. We use three choices of h that are piecewise linear: 1 for $x \le a$; 0 at $x > b$; and a line connecting 1 at a and 0 at b with $a = 0.2912, b = 0.7072$; $a = 0.416, b = 0.5824$; and $a = b = 0.5$, respectively. The last set gives a step function. The buffer zone is always chosen to be symmetric and centered at $x = 0.5$. The "exact" solution is given by the solid line, while the numerical results are given by o, x, and * for the three different sets of a and b, respectively. We compare both transient and steady state solutions.

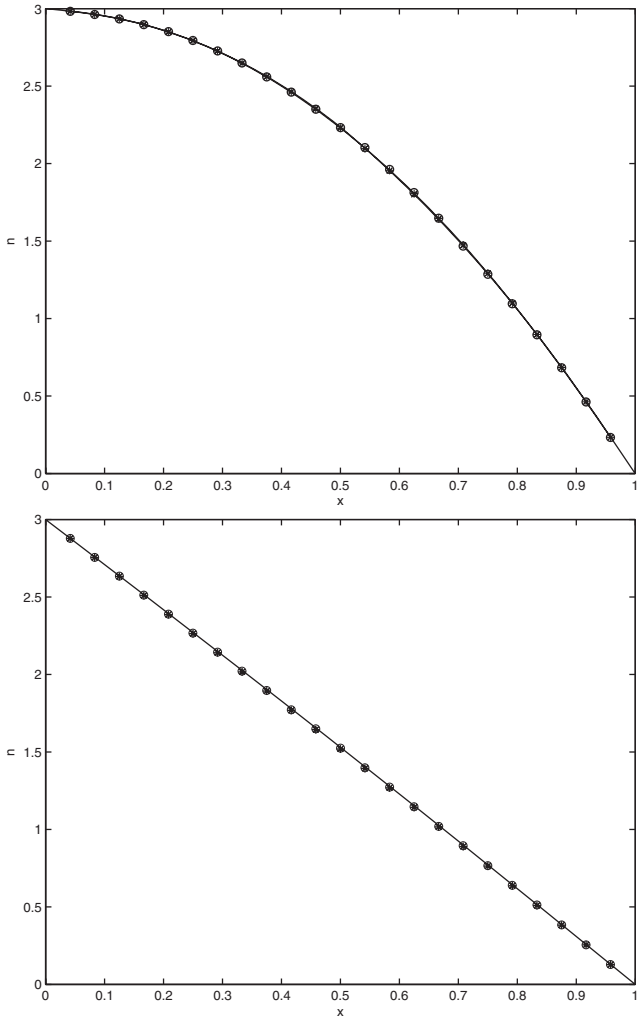

FIG. 1. *The numerical solution of n for Example* 1 *at* $t = 1$ *(top) and at steady state (bottom) of Example* 1. *The solid line is the solution of the transport equation in the entire domain computed using* 1001 *points, while the other three symbols represent numerical solution of the coupling model with* 25 *grid points and three different sizes of the buffer zone. Circles represent the solution for the larger buffer zone,* x*'s for the intermediate one, and * for the smaller one (when it reduces to one single point).*

Remark 4.1. When h is a step function, one may wonder if the advantage of the coupling model—avoiding the boundary condition at the buffer zone—is lost. Note that we solve only f_L^ε for $x \le b$, and n_R^ε for $x \ge a$, and set $f_L^\varepsilon = 0$ for $x > b$ and $n_R^\varepsilon = 0$ for $x < a$. This provides the numerical boundary condition for f_L^ε and n_R^ε at the interface. Although there is no theoretical justification for this numerical boundary condition, the numerical experiments in this section (where $\sigma(x)$ is continuous) suggests that h being a step function is still acceptable.

Example 1. We first test the case when both sides of the domain are diffusive in the entire domain, namely, $\sigma(x) \gg 1$. We take $\sigma(x) \equiv 100$, $f_l(\mu) = 3$, $f_r(\mu) = 0$, and

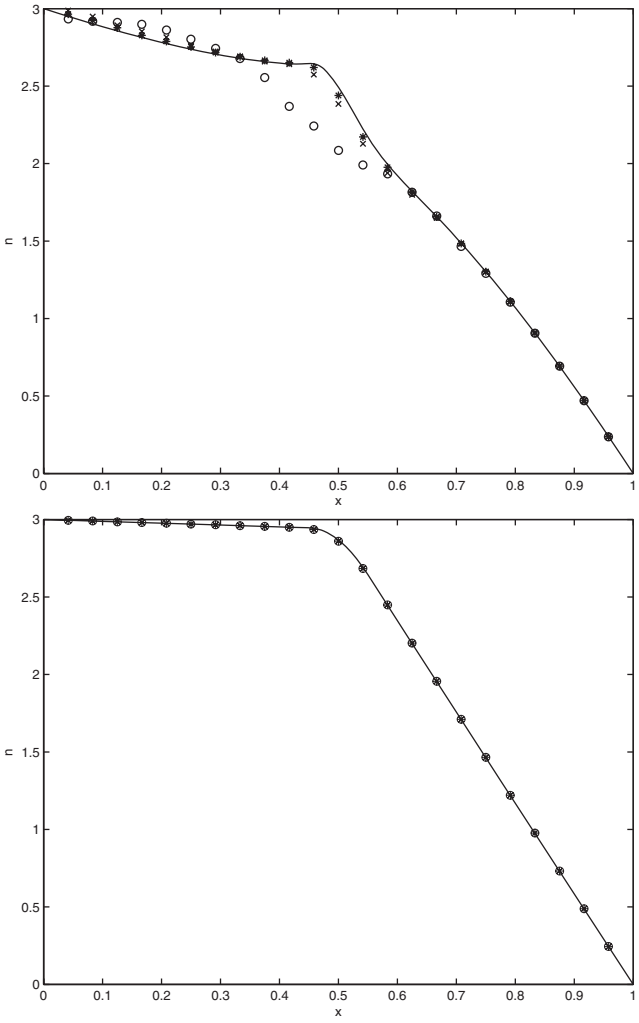

FIG. 2. *The numerical solution of* n *at* $t = 0.5$ *(top) and at steady state (bottom) for Example* 2. *The solid line is the solution of the transport equation in the entire domain computed using* 1001 *points, while the other three symbols represent numerical solutions of the coupling model with* 25 *grid points and three different sizes of buffer zone. Circles represent the solution for the larger buffer zone,* x*'s for the intermediate one, and * for the smaller one (when it reduces to one single point).*

the initial condition

$$f(0, x, \mu) = 3x^2 \, .$$

The solution to the diffusion equation (2.20) with $D = \sigma^{-1}$ should be a line connecting 3 to 0. The numerical results at $t = 1$ and at steady state are plotted in Figure 1.

One can see that the numerical results match the "exact" solution quite well, while the choice of h seems to have little influence on the numerical solution.

Example 2. We take $\sigma(x) = 2$ for $x < 0.45$, $\sigma(x) = 100$ for $x > 0.55$. $\sigma(x)$ is a linear function interpolating 2 and 100 for $0.45 \leq x \leq 0.55$. The boundary and initial conditions are the same as in Example 1. Thus the domain $[0, 0.45]$ is in the kinetic regime, while the domain $[0.55, 1]$ is diffusive. The results at $t = 0.5$ and

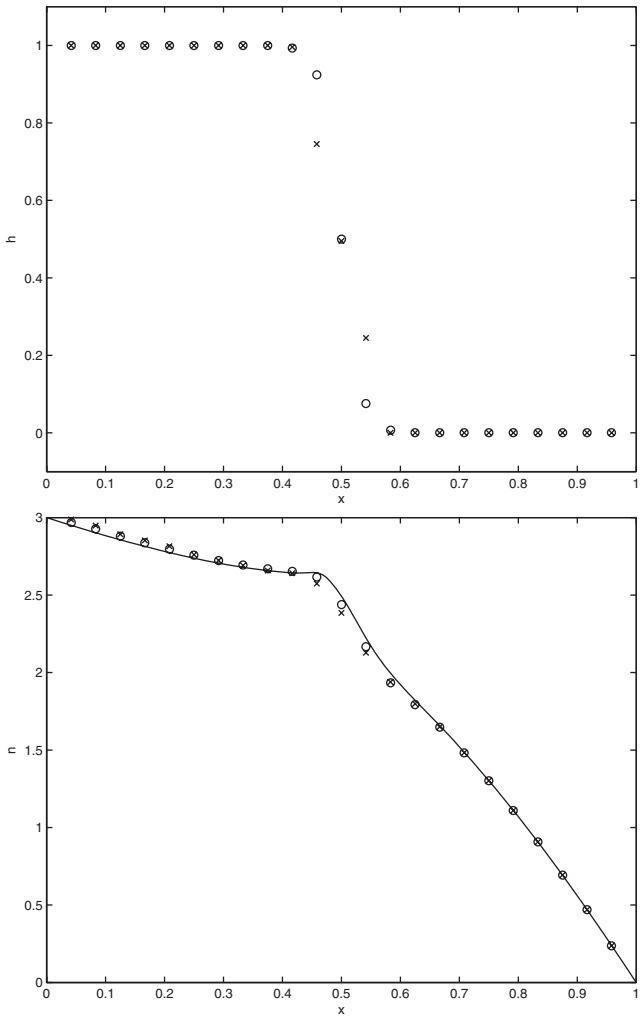

FIG. 3. *Example* 2. *Top: Comparison of different* h*: piecewise linear* x*,* C^∞*,* o*. Bottom: The corresponding numerical results for these* h*-functions versus the "exact" solution at* $t = 0.5$.

at steady state for $n = n_L + n_R$ are depicted in Figure 2 (top) for several different choices of a and b. As one can see, for the steady state solution, the choice of h has little influence on the numerical results, which match well with the "exact" solution. For the transient solution, the first set of parameters for the buffer zone (which is much larger than the domain for nonconstant σ) yields poor approximation in both the buffer zone and the transport domain, while in the diffusion domain the accuracy is as good as the other two buffer zones. This experiment indicates that the buffer zone should be within the transition region of σ.

In order to compare the effect of regularity of h on the numerical solution, we compare the piecewise linear h corresponding to $a = 0.2912, b = 0.7072$ (x in Figure 3, top) and $h = 0.5(1 - \tanh(30(x - 0.5))) \in C^\infty$ (o in Figure 3, top). The numerical results at $t = 0.5$ are given in the bottom of Figure 3. The numerical results are comparable.

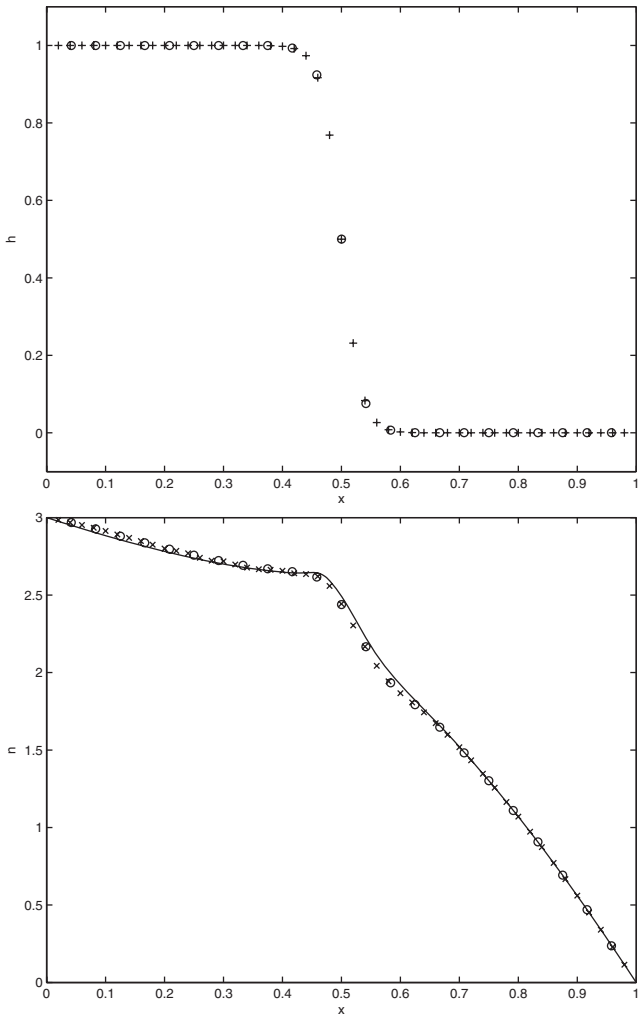

FIG. 4. *Example* 2. *Top: Comparison of same* C^∞*-function* h *with different mesh sizes. o:* 25 *grid points. x:* 50 *grid points. Bottom: The corresponding numerical results for these* h*-functions versus the "exact" solution at* $t = 0.5$.

For the same C^∞-function h, we compare the effect of mesh refinement on the numerical solution. In Figure 4 we compare the numerical results obtained by 25 and 50 points, respectively. The discrete h looks more regular in the finer mesh. The numerical results look similar, indicating that the regularity of h plays an insignificant role in the coupling algorithm.

Example 3. This problem is the same as Example 2 except for the boundary condition at $x = 0$, where we take an anisotropic one $f_l(\mu) = 3\mu + 1$ at $x = 0$. The numerical results at the steady state for the three piecewise linear h corresponding to the three different sizes of the buffer zone are given in Figure 5 and match quite well with the "exact" solution.

5. Conclusion. In this paper, we have presented a model which allows us to handle the transition between a kinetic and a diffusive region in a smooth way. In

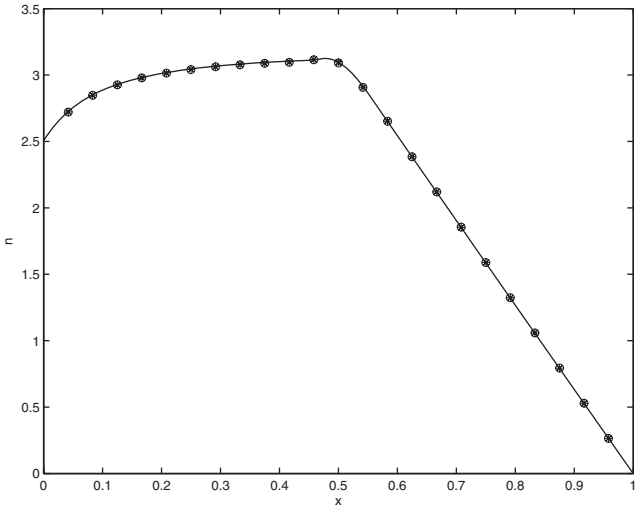

FIG. 5. *The numerical steady state solutions* $n = n_L + n_R$ *of Example* 3. *The solid line shows the solution of the transport equation in the entire domain cumputed using* 1001 *points, while the other three symbols represent numerical solution of the coupling model with* 25 *grid points and three different sizes of the buffer zone. Circles represent the solution for the larger buffer zone,* x*'s for the intermediate one, and * for the smaller one (when it reduces to one single point).*

the transition region both models are solved and the solution of the original transport equation is recovered by adding up the solutions of each model. The advantage of this coupling is that no boundary condition nor any iteration process at the overlapping zone is needed, as is the case for a typical domain decomposition method. The numerical discretization in the kinetic region is based on the parity formulation of the transport equation and the use of a new asymptotic-preserving scheme. Numerical experiments show that the coupling model describes quantitatively the behavior of the original transport equation, for both transient and steady state solutions, if the buffer zone is chosen inside the transition zone.

Further development of this work will include more robust time and space discretizations, multidimensional problems, and extensions to more complex kinetic models such as drift-diffusion or energy-transport models in semiconductors or the Boltzmann–BGK (Bhatnagar–Gross–Krook) model of rarefied gas dynamics.

A LOW-ORDER NONCONFORMING FINITE ELEMENT FOR REISSNER–MINDLIN PLATES*

C. LOVADINA†

Abstract. We propose a locking-free element for plate bending problems, based on the use of nonconforming piecewise linear functions for both rotations and deflections. We prove optimal error estimates with respect to both the meshsize and the analytical solution regularity.

Key words. nonconforming finite elements, plate bending problems, convergence analysis

1. Introduction. Nowadays, a *wide* choice of reliable finite element schemes for the approximation of Reissner–Mindlin plate problems is available in the engineering and mathematical literature (see, for instance, [7], [8], [9], [10], [11], [14], [17], [26], [27], [28], [29], [30] and the references therein). However, the extension to the more complex (and more interesting) shell problems appears to be a difficult task. Indeed, only *very few and not completely satisfactory* results have been established in this direction (cf., e.g., [3], [19], [20], [21], [22], and [24]).

In this paper we propose and analyze a new low-order Reissner–Mindlin plate element, some properties of which seem to be favorable for its generalization to shell problems. This triangular mixed element can be considered as a simplified variant of the one presented in [18], and it is based on the use of nonconforming piecewise linear functions for both rotations and deflections, while the shear stresses are approximated by piecewise constant functions. In actual computations the shear stress variables can be easily eliminated at the element level, and the final system to be solved involves only rotation and deflection unknowns, which *share the same nodes* (the midpoints of the edges). Compared with the element detailed in [18], the one we are going to study has the following features:

- no additional bubble functions are required;
- no additional sophisticated "reduction" operator on the shear term (other than the simple L^2-projection operator on piecewise constant functions) needs to be introduced.

In view of a possible extension to shell problems, the promising features of our element are the same as the ones met by the scheme presented in [18], i.e.,

- it is a simple low-order method;
- once the shear stresses have been eliminated, all the variables into play share the same nodes;
- the element has optimal order of approximation and is locking-free.

An outline of the paper is as follows. In section 2 we briefly present the Reissner–Mindlin plate problem. In section 3 we introduce the nonconforming element, together

with the necessary definitions and notation. In section 4 we develop the stability analysis, while in section 5 we perform the error analysis. The final results (cf. Theorem 5.1 and Corollary 5.1) show that our element is locking-free and is optimally convergent with respect to both the meshsize and the analytical solution regularity.

Furthermore, throughout the paper we will use standard notation for Sobolev spaces and norms (cf. [16] and [25], for instance). Finally, we will denote by C a generic constant, independent of h and t, which may differ in different occurrences.

2. The Reissner–Mindlin problem. The Reissner–Mindlin equations for a clamped plate with convex polygonal midplane Ω require us to find $(\boldsymbol{\theta}, w, \boldsymbol{\gamma})$ such that

$$-\operatorname{div} \mathbf{C}\,\varepsilon(\boldsymbol{\theta}) - \boldsymbol{\gamma} = 0 \quad \text{in } \Omega, \tag{2.1}$$

$$-\operatorname{div} \boldsymbol{\gamma} = g \quad \text{in } \Omega, \tag{2.2}$$

$$\boldsymbol{\gamma} = \lambda t^{-2}(\boldsymbol{\nabla} w - \boldsymbol{\theta}) \quad \text{in } \Omega, \tag{2.3}$$

$$\boldsymbol{\theta} = 0,\ w = 0 \quad \text{on } \partial\Omega. \tag{2.4}$$

In (2.1)–(2.3), t is the plate thickness, λ is the shear modulus, and $\mathbf{C}$ is the tensor of bending moduli, given by (for isotropic materials)

$$\mathbf{C}\tau := \frac{E}{12(1-\nu^2)}\Big((1-\nu)\tau + \nu \operatorname{tr}(\tau)\mathbf{I}\Big), \tag{2.5}$$

where τ is a generic second-order symmetric tensor, $\operatorname{tr}(\tau)$ its trace, $\mathbf{I}$ is the second-order identity tensor, while E and ν are Young's modulus and Poisson's ratio, respectively. Moreover, $\boldsymbol{\theta}$ represents the rotations, w the transversal displacement, $\boldsymbol{\gamma}$ the scaled shear stresses, and g a given transversal load. Finally, ε is the usual symmetric gradient operator. The classical variational formulation of problem (2.1)–(2.4) is

$$\begin{cases} \text{Find } (\boldsymbol{\theta}, w, \boldsymbol{\gamma}) \in \Theta \times W \times (L^2(\Omega))^2 : \\ a(\boldsymbol{\theta}, \boldsymbol{\eta}) + (\boldsymbol{\nabla} v - \boldsymbol{\eta}, \boldsymbol{\gamma}) = (g, v), \qquad (\boldsymbol{\eta}, v) \in \Theta \times W, \\ (\boldsymbol{\nabla} w - \boldsymbol{\theta}, \boldsymbol{\tau}) - \lambda^{-1} t^2 (\boldsymbol{\gamma}, \boldsymbol{\tau}) = 0, \qquad \boldsymbol{\tau} \in (L^2(\Omega))^2, \end{cases} \tag{2.6}$$

where $\Theta = (H_0^1(\Omega))^2$, $W = H_0^1(\Omega)$, $(\cdot,\cdot)$ is the inner-product in $L^2(\Omega)$, and

$$a(\boldsymbol{\theta}, \boldsymbol{\eta}) := \int_\Omega \mathbf{C}\,\varepsilon(\boldsymbol{\theta}) : \varepsilon(\boldsymbol{\eta}) \mathrm{d}x. \tag{2.7}$$

It is well known that for problem (2.6) the following inf-sup condition holds (cf. [16], for instance):

$$\begin{aligned} &\exists\, \beta > 0 \text{ such that} \\ &\sup_{(\boldsymbol{\eta}, v) \in \Theta \times W} \frac{(\boldsymbol{\nabla} v - \boldsymbol{\eta}, \boldsymbol{\tau})}{(||\boldsymbol{\eta}||_{1,\Omega}^2 + ||v||_{1,\Omega}^2)^{1/2}} \geq \beta ||\boldsymbol{\tau}||_\Gamma \qquad \forall \boldsymbol{\tau} \in \Gamma, \end{aligned} \tag{2.8}$$

where

$$\Gamma = H^{-1}(\mathrm{div}, \Omega) \quad \text{and} \quad ||\boldsymbol{\tau}||_{\Gamma} := (||\boldsymbol{\tau}||^2_{-1,\Omega} + ||\,\mathrm{div}\,\boldsymbol{\tau}||^2_{-1,\Omega})^{1/2}. \tag{2.9}$$

Moreover, the following regularity result is valid (cf., e.g., [7] and [23]).

PROPOSITION 2.1. *Suppose that Ω is a convex polygon and $g \in L^2(\Omega)$. Let $(\boldsymbol{\theta}, w, \boldsymbol{\gamma})$ be the solution of problem* (2.6)*. Then the following estimate holds:*

$$||\boldsymbol{\theta}||_{2,\Omega} + ||w||_{2,\Omega} + ||\boldsymbol{\gamma}||_{H(\mathrm{div})} + t||\boldsymbol{\gamma}||_{1,\Omega} \leq C||g||_{0,\Omega}, \tag{2.10}$$

where

$$||\boldsymbol{\gamma}||^2_{H(\mathrm{div})} = ||\boldsymbol{\gamma}||^2_{0,\Omega} + ||\,\mathrm{div}\,\boldsymbol{\gamma}||^2_{0,\Omega}.$$

3. The new nonconforming element. We now introduce a nonconforming finite element approximation of problem (2.1)–(2.4) using the approach detailed in [18]. Then let $\mathcal{T}_h$ be a decomposition of Ω into triangular elements T and let us set

$$H^1(\mathcal{T}_h) := \prod_{T \in \mathcal{T}_h} H^1(T). \tag{3.1}$$

We now define suitable jump and average operators. We first denote by $\mathcal{E}_h$ the set of all the edges in $\mathcal{T}_h$, and by $\mathcal{E}_h^{\mathrm{in}}$ the set of internal edges. Let e be an internal edge of $\mathcal{T}_h$, shared by two elements T^+ and T^-, and let φ denote a function in $H^1(\mathcal{T}_h)$, or a vector in $(H^1(\mathcal{T}_h))^2$, or a tensor in $(H^1(\mathcal{T}_h))^4_s$. We define the average as usual:

$$\{\varphi\} = \frac{\varphi^+ + \varphi^-}{2} \quad \forall e \in \mathcal{E}_h^{\mathrm{in}}. \tag{3.2}$$

For a scalar function $\varphi \in H^1(\mathcal{T}_h)$ we define its jump as

$$[\varphi] = \varphi^+ \mathbf{n}^+ + \varphi^- \mathbf{n}^- \quad \forall e \in \mathcal{E}_h^{\mathrm{in}}, \tag{3.3}$$

while the jump of a vector $\boldsymbol{\varphi} \in (H^1(\mathcal{T}_h))^2$ is given by

$$[\boldsymbol{\varphi}] = (\boldsymbol{\varphi}^+ \otimes \mathbf{n}^+)_S + (\boldsymbol{\varphi}^- \otimes \mathbf{n}^-)_S \quad \forall e \in \mathcal{E}_h^{\mathrm{in}}, \tag{3.4}$$

where $(\boldsymbol{\varphi} \otimes \mathbf{n})_S$ denotes the symmetric part of the tensor product, and $\mathbf{n}^+$ (resp., $\mathbf{n}^-$) is the outward unit normal to ∂T^+ (resp., to ∂T^-). On the boundary edges we define jumps of scalars as $[\varphi] = \varphi \mathbf{n}$, and jumps of vectors as $[\boldsymbol{\varphi}] = (\boldsymbol{\varphi} \otimes \mathbf{n})_S$, where $\mathbf{n}$ is the outward unit normal to $\partial\Omega$. We also define averages of vectors and tensors as $\{\boldsymbol{\varphi}\} = \boldsymbol{\varphi}$. It can be easily checked that, if $\boldsymbol{\varphi}$ is a smooth tensor and $\boldsymbol{\eta}$ a piecewise smooth vector, the following equality holds (see, e.g., [4] and [5] for a similar computation):

$$\sum_{T \in \mathcal{T}_h} \int_{\partial T} \boldsymbol{\varphi}\mathbf{n} \cdot \boldsymbol{\eta}\, ds = \sum_{e \in \mathcal{E}_h} \int_e \{\boldsymbol{\varphi}\} : [\boldsymbol{\eta}]\, ds. \tag{3.5}$$

In order to introduce our scheme, we first consider the finite element spaces:

$$\Theta_h = \left\{ \boldsymbol{\eta} : \boldsymbol{\eta}_{|T} \in (P_1(T))^2, \ \int_e [\boldsymbol{\eta}] ds = 0 \quad \forall e \in \mathcal{E}_h \right\}, \tag{3.6}$$

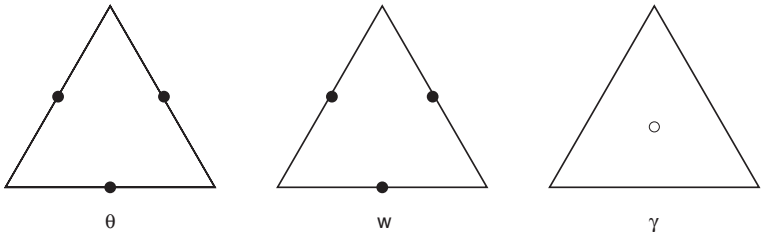

FIG. 3.1. *Local degrees of freedom for the three variables.*

$$W_h = \left\{ v : v_{|T} \in P_1(T), \ \int_e [v] ds = 0 \quad \forall e \in \mathcal{E}_h \right\}, \tag{3.7}$$

$$\Gamma_h = \left\{ \boldsymbol{\tau} : \boldsymbol{\tau}_{|T} \in (P_0(T))^2 \right\}, \tag{3.8}$$

where $P_k(T)$ is the space of polynomials of degree at most k defined on T. We also notice that

$$\boldsymbol{\nabla}_h W_h \subset \Gamma_h, \tag{3.9}$$

where $\boldsymbol{\nabla}_h$ denotes the gradient element by element. The local degrees of freedom for the three variables are depicted in Figure 3.1.

Moreover, we introduce a penalty on the jumps of functions in Θ_h as

$$p_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}) := \sum_{e \in \mathcal{E}_h} \frac{\kappa_e}{|e|} \int_e [\boldsymbol{\theta}] : [\boldsymbol{\eta}] \, ds, \tag{3.10}$$

where $|e|$ denotes the length of the side e, and κ_e is a positive constant having the same physical dimension as $\mathbf{C}$ (for smooth $\mathbf{C}$, one could take κ_e as $|\mathbf{C}|$ evaluated at the midpoint of e). We then define

$$a_T(\boldsymbol{\theta}, \boldsymbol{\eta}) := \int_T \mathbf{C}\, \varepsilon(\boldsymbol{\theta}) : \varepsilon(\boldsymbol{\eta}) \, dx, \tag{3.11}$$

and we finally set

$$a_h(\boldsymbol{\theta}, \boldsymbol{\eta}) := \sum_{T \in \mathcal{T}_h} a_T(\boldsymbol{\theta}, \boldsymbol{\eta}) + p_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}). \tag{3.12}$$

Following the ideas of [18], the discrete problem is then

$$\begin{cases} \text{Find } (\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h) \in \Theta_h \times W_h \times \Gamma_h : \\ a_h(\boldsymbol{\theta}_h, \boldsymbol{\eta}_h) + (\boldsymbol{\gamma}_h, \boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h) = (g, v_h), \quad (\boldsymbol{\eta}_h, v_h) \in \Theta_h \times W_h, \\ (\boldsymbol{\nabla}_h w_h - \boldsymbol{\theta}_h, \boldsymbol{\tau}_h) - \lambda^{-1} t^2 (\boldsymbol{\gamma}_h, \boldsymbol{\tau}_h) = 0, \qquad \boldsymbol{\tau}_h \in \Gamma_h. \end{cases} \tag{3.13}$$

We will use norms $||\cdot||_{\Theta_h}$ and $||\cdot||_{W_h}$ for functions in Θ_h and W_h, defined as

$$||\boldsymbol{\eta}_h||_{\Theta_h} := \left(\sum_{T \in \mathcal{T}_h} \int_T |\boldsymbol{\nabla} \boldsymbol{\eta}_h|^2 \right)^{1/2} = ||\boldsymbol{\nabla}_h \boldsymbol{\eta}_h||_{0,\Omega}, \tag{3.14}$$

$$||v_h||_{W_h} := \left(\sum_{T \in \mathcal{T}_h} \int_T |\boldsymbol{\nabla} v_h|^2 \right)^{1/2} = ||\boldsymbol{\nabla}_h v_h||_{0,\Omega}. \tag{3.15}$$

Due to the discrete Poincaré inequality, both $||\cdot||_{\Theta_h}$ and $||\cdot||_{W_h}$ are indeed *norms* on Θ_h and W_h, not only seminorms.

Remark 3.1. The discrete Poincaré inequality is known to hold for the *scalar-valued* space W_h, as detailed, for instance, in [7] (see also [6] and [12] for related and more general results). However, the same techniques can be applied to obtain the corresponding version for the *vector field* space Θ_h.

It has been proved in [6] (see also [13]) that there exist positive constants α and M such that

$$a_h(\boldsymbol{\eta}_h, \boldsymbol{\eta}_h) \geq \alpha ||\boldsymbol{\eta}_h||^2_{\Theta_h} \qquad \forall\, \boldsymbol{\eta}_h \in \Theta_h, \tag{3.16}$$

$$a_h(\boldsymbol{\theta}_h, \boldsymbol{\eta}_h) \leq M ||\boldsymbol{\theta}_h||_{\Theta_h} ||\boldsymbol{\eta}_h||_{\Theta_h} \qquad \forall\, \boldsymbol{\theta}_h\,, \boldsymbol{\eta}_h \in \Theta_h. \tag{3.17}$$

For functions in Γ_h we will work with the (natural) norms (cf. also (2.9))

$$||\boldsymbol{\tau}_h||_\Gamma \qquad \text{and} \qquad t||\boldsymbol{\tau}_h||_{0,\Omega}. \tag{3.18}$$

Remark 3.2. We remark that the coercivity property (3.16) can be easily deduced from the nontrivial Korn-type inequality (see [6] and [13])

$$\|\boldsymbol{\nabla}_h \boldsymbol{\eta}\|^2_{0,\Omega} \leq C \left(\|\varepsilon_h(\boldsymbol{\eta})\|^2_{0,\Omega} + \sum_{e \in \mathcal{E}_h} \frac{1}{|e|} \|[\boldsymbol{\eta}]\|^2_{0,e} \right), \qquad \boldsymbol{\eta} \in (H^1(\mathcal{T}_h))^2, \tag{3.19}$$

where ε_h denotes the symmetric gradient element by element. We point out that estimate (3.19) holds for a *generic* piecewise smooth function $\boldsymbol{\eta} \in (H^1(\mathcal{T}_h))^2$, not only for functions in Θ_h. Therefore, the coercivity of the form $a_h(\cdot,\cdot)$ is valid essentially for all the boundary conditions arising in actual applications. We finally stress that property (3.16) cannot hold without inserting the jump term (3.10) into the bilinear form $a_h(\cdot,\cdot)$ (cf. (3.12)). More precisely, the form

$$\widetilde{a}_h(\boldsymbol{\theta}, \boldsymbol{\eta}) := \int_\Omega \mathbf{C} \varepsilon_h(\boldsymbol{\theta}) : \varepsilon_h(\boldsymbol{\eta})\, dx \tag{3.20}$$

is *not* coercive on the nonconforming space Θ_h. Indeed, consider a square plate meshed into four triangles by means of the diagonals. The *nonvanishing* function $\boldsymbol{\eta}_h \in \Theta_h$ shown in Figure 3.2 verifies $\varepsilon_h(\boldsymbol{\eta}_h) = 0$, since in each element it represents an infinitesimal rotation about the corresponding boundary edge midpoint. As a consequence, coercivity for $\widetilde{a}_h(\cdot,\cdot)$ fails.

Remark 3.3. For Dirichlet boundary conditions on the whole $\partial\Omega$, one might take advantage of the relation

$$\operatorname{div} \varepsilon(\boldsymbol{\theta}) = \frac{1}{2} \left(\operatorname{div} \boldsymbol{\nabla} \boldsymbol{\theta} + \boldsymbol{\nabla} \operatorname{div} \theta \right) \tag{3.21}$$

to write the discrete problem (3.13) using the *modified* bilinear form (cf. also (2.5))

$$a_m(\boldsymbol{\theta}_h, \boldsymbol{\eta}_h) := \frac{E}{24(1-\nu^2)} \sum_{T \in \mathcal{T}_h} \int_T \Big((1-\nu) \boldsymbol{\nabla} \boldsymbol{\theta}_h : \boldsymbol{\nabla} \boldsymbol{\eta}_h + (1+\nu) \operatorname{div} \boldsymbol{\theta}_h \operatorname{div} \boldsymbol{\eta}_h \Big). \tag{3.22}$$

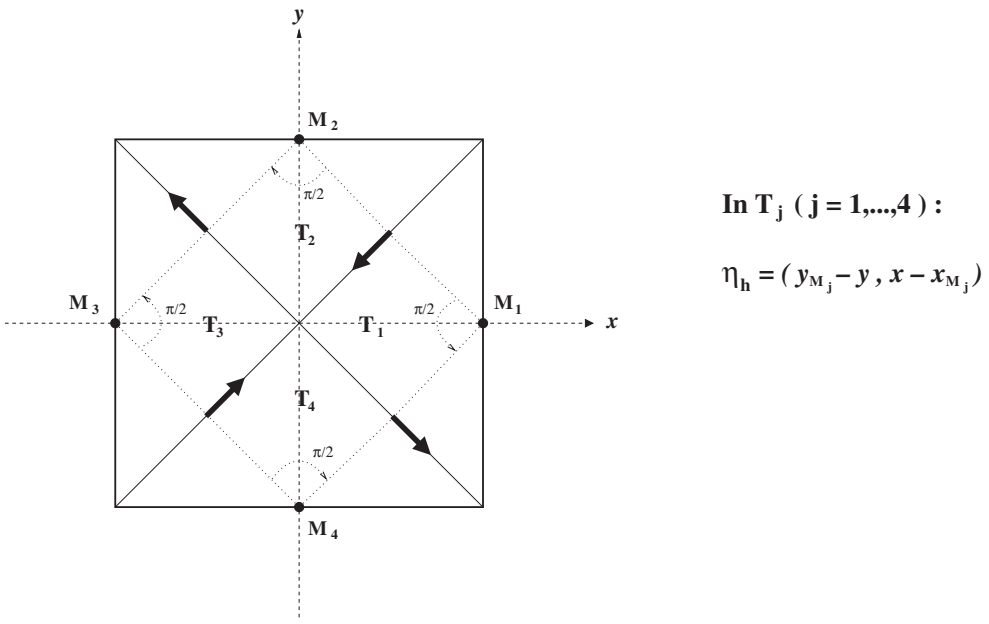

FIG. 3.2. *Rotational spurious mode* $\boldsymbol{\eta}_h$ *on a mesh with four triangles.*

Due to the discrete Poincaré inequality (see Remark 3.1), the bilinear form $a_m(\cdot,\cdot)$ is now coercive on Θ_h and we do not need to insert the penalty term (3.10) in the finite element method. We remark, however, that this approach is limited to the case of Dirichlet boundary conditions on the whole $\partial\Omega$. Since we have in mind a method applicable to *every* reasonable boundary condition (we consider the clamped plate *only* for the sake of simplicity), we have chosen to work with a formulation involving the bilinear form $a_h(\cdot,\cdot)$ (see (3.10)–(3.12) and Remark 3.2).

Remark 3.4. We point out that by eliminating $\boldsymbol{\gamma}_h$ from system (3.13), our scheme is equivalent to the following problem involving only the rotations and the vertical displacements:

$$\text{(3.23)}\quad \begin{cases} \text{Find } (\boldsymbol{\theta}_h, w_h) \in \Theta_h \times W_h : \\ a_h(\boldsymbol{\theta}_h, \boldsymbol{\eta}_h) + \lambda t^{-2}(\boldsymbol{\nabla}_h w_h - P_0\boldsymbol{\theta}_h, \boldsymbol{\nabla}_h v_h - P_0\boldsymbol{\eta}_h) \\ \qquad\qquad = (g, v_h) \qquad \forall (\boldsymbol{\eta}_h, v_h) \in \Theta_h \times W_h, \end{cases}$$

where P_0 denotes the L^2-projection operator on the piecewise constant functions. From (3.23) we may notice that the method implementation turns out to be rather simple.

4. Stability analysis. In this section we will prove a stability result for the discretized problem (3.13), using a macroelement technique essentially developed in [28]. In what follows it will be useful to set $V := \Theta \times W$ and $V_h := \Theta_h \times W_h$, equipped with the usual product norms. We first need the following preliminary result.

PROPOSITION 4.1. *The approximation spaces defined in* (3.6)–(3.8) *satisfy the following properties:*

(P1) *There exists a linear operator* $\pi_h : W \longrightarrow W_h$ *such that*

$$||\pi_h v||_{W_h} \leq c||v||_{1,\Omega},\ c \text{ independent of } h$$
$$\int_\Omega \boldsymbol{\nabla}_h(v - \pi_h v)\cdot\boldsymbol{\tau}_h = 0 \qquad \forall \boldsymbol{\tau}_h \in \Gamma_h.$$

(P2) *If the mesh* $\mathcal{T}_h$ *contains at least three triangles, then for* $\boldsymbol{\tau}_h \in \Gamma_h$ *condition*

$$\int_\Omega (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h)\cdot\boldsymbol{\tau}_h = 0 \qquad \forall (\boldsymbol{\eta}_h, v_h) \in V_h \tag{4.1}$$

implies $\boldsymbol{\tau}_h = \mathbf{0}$.

Proof. Consider the usual nonconforming interpolating operator $\pi_h : W \longrightarrow W_h$, defined by

$$(\pi_h v)(m) = \frac{1}{|e|}\int_e v\, ds \qquad \forall e \in \mathcal{E}_h \quad (\text{with } m \text{ the midpoint of } e).$$

It is easily seen that property (P1) is fulfilled.

To verify (P2), for a given internal edge $e \in \mathcal{E}_h^{\text{in}}$ we first choose one of the two possible normal (resp., tangential) vectors to e, indicated in what follows as $\mathbf{n}_e$ (resp., $\mathbf{t}_e$). Let us take $\boldsymbol{\tau}_h \in \Gamma_h$ satisfying condition (4.1).

By choosing $(\mathbf{0}, v_h) \in V_h$, integrating by parts yields

$$0 = \int_\Omega \boldsymbol{\nabla}_h v_h \cdot \boldsymbol{\tau}_h = \sum_{T\in\mathcal{T}_h}\int_{\partial T} v_h\, \boldsymbol{\tau}_h\cdot\mathbf{n}_T. \tag{4.2}$$

Since (4.2) is true for every $(\mathbf{0}, v_h) \in V_h$, it follows that $\boldsymbol{\tau}_h\cdot\mathbf{n}_e$ is continuous across every internal edge $e \in \mathcal{E}_h^{\text{in}}$. Therefore $\boldsymbol{\tau}_h \in H(\text{div};\Omega)$ and, obviously, $\text{div}\,\boldsymbol{\tau}_h = 0$. As a consequence, there exists φ_h (defined up to a constant) such that

$$\varphi_h \in \mathcal{L}_1^1(\Omega;\mathcal{T}_h), \qquad \boldsymbol{\tau}_h = \mathbf{curl}\,\varphi_h, \tag{4.3}$$

where $\mathcal{L}_1^1(\Omega;\mathcal{T}_h)$ is the usual space of piecewise linear and continuous functions on Ω.

Fix now a generic internal edge $e \in \mathcal{E}_h^{\text{in}}$ with midpoint m, and denote with T_e^+, T_e^- the triangles sharing e as common side. Recalling that $\mathbf{curl}\,\varphi_h\cdot\mathbf{n}_e$ is constant and continuous across e, we consider $(\boldsymbol{\eta}_h, 0) \in V_h$, where $\boldsymbol{\eta}_h$ is uniquely defined by

$$\begin{cases} (\boldsymbol{\eta}_h\cdot\mathbf{t}_e)(m) = 0, \quad (\boldsymbol{\eta}_h\cdot\mathbf{n}_e)(m) = \mathbf{curl}\,\varphi_h\cdot\mathbf{n}_e, \\ \boldsymbol{\eta}_h(m') = 0 \qquad \forall\, e' \in \mathcal{E}_h^{\text{in}}, \quad e' \neq e \quad (\text{with } m' \text{ the midpoint of } e'). \end{cases} \tag{4.4}$$

Since $\boldsymbol{\tau}_h = \mathbf{curl}\,\varphi_h$ satisfies (4.1), using (4.4) we have

$$\begin{aligned} 0 &= \int_\Omega \boldsymbol{\eta}_h\cdot\mathbf{curl}\,\varphi_h = \int_{T_e^+\cup T_e^-}\boldsymbol{\eta}_h\cdot\mathbf{curl}\,\varphi_h = \frac{|T_e^+|+|T_e^-|}{3}(\boldsymbol{\eta}_h\cdot\mathbf{curl}\,\varphi_h)(m) \\ &= \frac{|T_e^+|+|T_e^-|}{3}\,|\mathbf{curl}\,\varphi_h\cdot\mathbf{n}_e|^2. \end{aligned} \tag{4.5}$$

Repeating the same argument for every $e \in \mathcal{E}_h^{\text{in}}$, from (4.5) we infer that

$$\mathbf{curl}\,\varphi_h\cdot\mathbf{n}_e = \boldsymbol{\nabla}\varphi_h\cdot\mathbf{t}_e = 0 \qquad \text{for every } e \in \mathcal{E}_h^{\text{in}}. \tag{4.6}$$

Equation (4.6) implies that $\boldsymbol{\tau}_h = \mathbf{curl}\,\varphi_h$ vanishes in all the triangles $T \in \mathcal{T}_h$ having at least two sides in $\mathcal{E}_h^{\text{in}}$. Therefore, it remains to show that $\mathbf{curl}\,\varphi_h = \mathbf{0}$ also on the triangles sharing two sides with the boundary $\partial\Omega$ if there are any in the mesh $\mathcal{T}_h$. Consider then any such triangle T, and denote with e its *unique* side belonging to $\mathcal{E}_h^{\text{in}}$ and with T^{in} the triangle sharing the side e with T. Since Ω is a regular domain and $\mathcal{T}_h$ contains at least three triangles, it follows that T^{in} has at least two sides in $\mathcal{E}_h^{\text{in}}$. Hence we already know that

$$(\mathbf{curl}\,\varphi_h)_{|T^{\text{in}}} = \mathbf{0}. \tag{4.7}$$

Recalling that $\mathbf{curl}\,\varphi_h$ is constant in T, let us now take $(\boldsymbol{\eta}_h, 0) \in V_h$, where $\boldsymbol{\eta}_h$ is uniquely defined by

$$\begin{cases} \boldsymbol{\eta}_h(m) = (\mathbf{curl}\,\varphi_h)_{|T} & \text{(with } m \text{ the midpoint of } e\text{)}, \\ \boldsymbol{\eta}_h(m') = 0 \qquad \forall\, e' \in \mathcal{E}_h^{\text{in}}\,, \quad e' \neq e & \text{(with } m' \text{ the midpoint of } e'\text{)}. \end{cases} \tag{4.8}$$

Again, since $\boldsymbol{\tau}_h = \mathbf{curl}\,\varphi_h$ satisfies (4.1), by (4.7) and (4.8) we obtain

$$\begin{aligned} 0 &= \int_\Omega \boldsymbol{\eta}_h \cdot \mathbf{curl}\,\varphi_h = \int_{T \cup T^{\text{in}}} \boldsymbol{\eta}_h \cdot \mathbf{curl}\,\varphi_h = \int_T \boldsymbol{\eta}_h \cdot \mathbf{curl}\,\varphi_h \\ &= \frac{|T|}{3}\,|(\mathbf{curl}\,\varphi_h)_{|T}|^2, \end{aligned} \tag{4.9}$$

so that $\mathbf{curl}\,\varphi_h = \mathbf{0}$ also in T and the proof is complete. ∎

Remark 4.1. We remark that property (P2) can be written in the following equivalent form:

(P2′) For every $\boldsymbol{\varphi} \in (L^2(\Omega))^2$, the problem

$$\begin{cases} \text{Find } (\boldsymbol{\eta}_h, v_h) \in \Theta_h \times W_h : \\ \displaystyle\int_\Omega (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h) \cdot \boldsymbol{\tau}_h = \int_\Omega \boldsymbol{\varphi} \cdot \boldsymbol{\tau}_h \qquad \forall \boldsymbol{\tau}_h \in \Gamma_h \end{cases}$$

is solvable.

4.1. Macroelement decomposition. We start by recalling some standard definitions and notation we will use in what follows. First of all, we say that a family $\{\mathcal{T}_h\}_{h>0}$ of triangular meshes of Ω is *regular* (see [25]) if there exists a constant $\sigma > 0$ such that

$$h_T \leq \sigma \rho_T \qquad \forall\, T \in \bigcup_{h>0} \mathcal{T}_h, \tag{4.10}$$

where h_T is the diameter of the element T and ρ_T is the maximum diameter of the circles contained in T. Furthermore, a *macroelement* M is a set with connected interior part, formed by the union of a fixed number of neighboring triangles along a well-defined pattern (cf. [31]). A macroelement $M = \cup_{i=1}^m T_i$ is said to be equivalent to a reference macroelement $\widehat{M} = \cup_{i=1}^m \widehat{T}_i$ if there is a mapping $F_M : \widehat{M} \longrightarrow M$ for which the following conditions are fulfilled (cf. [31]):

1. F_M is a continuous bijection.
2. $T_i = F_M(\widehat{T}_i)\ \forall\, i,\ 1 \le i \le m$.
3. $F_{M|\widehat{T}_i} = F_{T_i} \circ F_{\widehat{T}_i}^{-1}$, where F_{T_i} and $F_{\widehat{T}_i}$ are the usual functions mapping the standard reference triangle (of vertices $(0,0)$, $(1,0)$, and $(0,1)$) onto T_i and $\widehat{T}_i$, respectively.

From a given mesh $\mathcal{T}_h$ of Ω it is always possible to derive (obviously not in a unique manner) a "macroelement mesh" $\mathcal{M}_h$ in such a way that each $T \in \mathcal{T}_h$ is covered by some macroelement M in $\mathcal{M}_h$ and each macroelement M is equivalent to a certain reference macroelement $\widehat{M}$.

Associated with every macroelement M in $\mathcal{M}_h$, the following spaces are relevant for the stability analysis (cf. [28]):

$$V_{0,M} := \big\{(\boldsymbol{\eta}_h, v_h) \in V_h : \quad (\boldsymbol{\eta}_h, v_h) = (\mathbf{0}, 0) \quad \text{in}\,\Omega \setminus M\big\}, \tag{4.11}$$

$$\Gamma_M := \big\{\boldsymbol{\tau}_h \in \Gamma_h : \quad \boldsymbol{\tau}_h = 0 \quad \text{in}\,\Omega \setminus M\big\}. \tag{4.12}$$

4.2. Fortin's trick by macroelements. The aim of this subsection is to prove that Fortin's trick (cf. [16]) applies to our finite element scheme, leading therefore to a suitable inf-sup condition with respect to the natural norms (see (2.8)). Indeed, we have the following result.

PROPOSITION 4.2. *Suppose that the family $\{\mathcal{T}_h\}_{h>0}$ is regular and choose a corresponding macroelement family $\{\mathcal{M}_h\}_{h>0}$ such that*

1. *each macroelement M contains at least three triangles;*
2. *there is only a fixed finite number of reference macroelements $\{\widehat{M}_1, \dots, \widehat{M}_r\}$ to which each macroelement $M \in \cup_{h>0}\mathcal{M}_h$ is equivalent.*

Then for the approximation spaces defined in (3.6)–(3.8) *the following inf-sup condition holds*

$$\exists\, \beta > 0 \text{ independent of } h, \text{ such that}$$
$$\sup_{(\boldsymbol{\eta}_h, v_h) \in V_h} \frac{(\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h, \boldsymbol{\tau}_h)}{||(\boldsymbol{\eta}_h, v_h)||_{V_h}} \ge \beta ||\boldsymbol{\tau}_h||_\Gamma \qquad \forall \boldsymbol{\tau}_h \in \Gamma_h. \tag{4.13}$$

Proof. Let $(\boldsymbol{\eta}, v) \in V$ be given. Fix an arbitrary macroelement $M \in \mathcal{M}_h$ and set

$$h_M := \max_{1 \le i \le m} h_{T_i} \quad \text{if} \quad M = \bigcup_i^m T_i. \tag{4.14}$$

Let us denote by i_M the index $1 \le i_M \le r$ such that M is equivalent to $\widehat{M}_{i_M}$.

Consider the problem of finding $(\boldsymbol{\eta}_M, v_M) \in V_{0,M}$ solution of

$$\int_M (\boldsymbol{\nabla}_h v_M - \boldsymbol{\eta}_M) \cdot \boldsymbol{\tau}_M = \int_M (\Pi_1 \boldsymbol{\eta} - \boldsymbol{\eta}) \cdot \boldsymbol{\tau}_M \qquad \forall \boldsymbol{\tau}_M \in \Gamma_M, \tag{4.15}$$

where $\Pi_1 \boldsymbol{\eta}$ is the usual nonconforming interpolated of $\boldsymbol{\eta}$, defined by

$$(\Pi_1 \boldsymbol{\eta})(m) = \frac{1}{|e|} \int_e \boldsymbol{\eta}\, ds \qquad \forall e \in \mathcal{E}_h \quad (\text{with } m \text{ the midpoint of } e).$$

By property (P2) of Proposition 4.1, applied to the macroelement M, it follows that system (4.15) is solvable, since M contains at least three triangles (cf. also

Remark 4.1). Let us take the solution of minimal V_h-norm. A scaling argument and the features of the interpolating operator Π_1 show that there exists $c(\widehat{M}_{i_M}) > 0$ such that

$$\exists\, c_1(\widehat{M}_{i_M}) > 0 : \quad ||\,\boldsymbol{\eta}_M\,||^2_{\Theta_h} + ||\,v_M\,||^2_{W_h} \le c_1(\widehat{M}_{i_M})\,||\,\boldsymbol{\eta}\,||^2_{1,M}. \tag{4.16}$$

Let us set

$$\boldsymbol{\eta}_F = \Pi_1\boldsymbol{\eta} + \sum_M \boldsymbol{\eta}_M, \tag{4.17}$$

$$v_F = \pi_h v + \sum_M v_M, \tag{4.18}$$

where π_h is the operator as in property (P1) of Proposition 4.1 (i.e., the standard nonconforming interpolation operator). We now notice that every $\boldsymbol{\tau}_h \in \Gamma_h$ can be uniquely written as $\boldsymbol{\tau}_h = \sum_M \boldsymbol{\tau}_M$, where $\boldsymbol{\tau}_M \in \Gamma_M$. Hence, recalling (4.15), from (4.17)–(4.18) we have

$$\begin{aligned}
\int_\Omega (\boldsymbol{\nabla}_h v_F - \boldsymbol{\eta}_F)\cdot\boldsymbol{\tau}_h &= \sum_M \int_M \Big[\,\boldsymbol{\nabla}_h(\pi_h v + v_M) - \Pi_1\boldsymbol{\eta} - \boldsymbol{\eta}_M\,\Big]\cdot\boldsymbol{\tau}_M \\
&= \sum_M \Big[\int_M \boldsymbol{\nabla}_h\pi_h v\cdot\boldsymbol{\tau}_M + \int_M (\boldsymbol{\nabla}_h v_M - \Pi_1\boldsymbol{\eta} - \boldsymbol{\eta}_M)\cdot\boldsymbol{\tau}_M\Big] \\
&= \sum_M \Big(\int_M \boldsymbol{\nabla}\, v\cdot\boldsymbol{\tau}_M - \int_M \boldsymbol{\eta}\cdot\boldsymbol{\tau}_M\Big) \\
&= \int_\Omega (\boldsymbol{\nabla}\, v - \boldsymbol{\eta})\cdot\boldsymbol{\tau}_h.
\end{aligned} \tag{4.19}$$

Therefore, for every $(\boldsymbol{\eta}, v) \in V$ we have found $\Pi_h(\boldsymbol{\eta}, v) = (\boldsymbol{\eta}_F, v_F) \in V_h$ such that

$$\int_\Omega (\boldsymbol{\nabla}_h v_F - \boldsymbol{\eta}_F)\cdot\boldsymbol{\tau}_h = \int_\Omega (\boldsymbol{\nabla}\, v - \boldsymbol{\eta})\cdot\boldsymbol{\tau}_h \qquad \forall\boldsymbol{\tau}_h \in \Gamma_h. \tag{4.20}$$

Let us estimate $||\boldsymbol{\eta}_F||^2_{\Theta_h} + ||v_F||^2_{W_h}$. By using the continuity of Π_1 and π_h, and estimate (4.16), we get

$$\begin{aligned}
||\boldsymbol{\eta}_F||^2_{\Theta_h} + ||v_F||^2_{W_h} &= \Big\|\,\Pi_1\boldsymbol{\eta} + \sum_M \boldsymbol{\eta}_M\Big\|^2_{\Theta_h} + \Big\|\,\pi_h v + \sum_M v_M\Big\|^2_{W_h} \\
&\le 2\left(\,||\Pi_1\boldsymbol{\eta}||^2_{\Theta_h} + ||\pi_h v||^2_{W_h} + \sum_M \big(||\,\boldsymbol{\eta}_M\,||^2_{\Theta_h} + ||\,v_M\,||^2_{W_h}\big)\right) \\
&\le 2\left(\,c\,\big(||v||^2_{1,\Omega} + ||\boldsymbol{\eta}||^2_{1,\Omega}\big) + \sum_M c_1(\widehat{M}_{i_M})||\boldsymbol{\eta}||^2_{1,M}\right).
\end{aligned} \tag{4.21}$$

Since there is only a finite number of reference macroelements $\{\widehat{M}_1, \ldots, \widehat{M}_r\}$, we obtain

$$||\boldsymbol{\eta}_F||^2_{\Theta_h} + ||v_F||^2_{W_h} \le C_1\big(||v||^2_{1,\Omega} + ||\boldsymbol{\eta}||^2_{1,\Omega}\big) \tag{4.22}$$

with $C_1 = 2\max\{c,\ c_1(\widehat{M}_1), \ldots, c_1(\widehat{M}_r)\}$. Therefore, we finally have

$$||\Pi_h(\boldsymbol{\eta}, v)||_{V_h} \leq C\left(||\boldsymbol{\eta}||^2_{1,\Omega} + ||v||^2_{1,\Omega}\right)^{1/2} \tag{4.23}$$

with C independent of h. It is well known (cf. [16], for instance) that (4.20) together with (4.23) implies condition (4.13), and the proof is complete. ∎

Remark 4.2. Note that it is always possible to derive, from a given regular family $\{\mathcal{T}_h\}_{h>0}$, a macroelement family $\{\mathcal{M}_h\}_{h>0}$ which fulfills the assumption of Proposition 4.2, provided in each $\mathcal{T}_h$ there are at least three triangles.

4.3. The stability result. Once the inf-sup condition (4.13) has been established, suitable stability estimates can be derived using standard techniques (see, for instance, [9] and [23] for their application to Reissner–Mindlin plate problems). For the sake of completeness, we develop such a stability analysis in full detail.

First, it is useful to set

$$\begin{aligned}\mathcal{A}_h(\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h; \boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) := a_h(\boldsymbol{\theta}_h, \boldsymbol{\eta}_h) + (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h, \boldsymbol{\gamma}_h)\\ - (\boldsymbol{\nabla}_h w_h - \boldsymbol{\theta}_h, \boldsymbol{\tau}_h) + \lambda^{-1}t^2(\boldsymbol{\gamma}_h, \boldsymbol{\tau}_h).\end{aligned} \tag{4.24}$$

Therefore, the discrete problem (3.13) reads

$$\begin{cases}\text{Find } (\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h) \in \Theta_h \times W_h \times \Gamma_h \text{ such that}\\ \mathcal{A}_h(\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h; \boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) = (g, v_h) \qquad \forall (\boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) \in \Theta_h \times W_h \times \Gamma_h.\end{cases} \tag{4.25}$$

We have the following result.

PROPOSITION 4.3. *Given* $(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h) \in \Theta_h \times W_h \times \Gamma_h$, *there exists* $(\boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) \in \Theta_h \times W_h \times \Gamma_h$ *such that*

$$\begin{aligned}||\boldsymbol{\eta}_h||_{\Theta_h} + ||v_h||_{W_h} + ||\boldsymbol{\tau}_h||_\Gamma + t||\boldsymbol{\tau}_h||_{0,\Omega}\\ \leq C\Big(||\boldsymbol{\beta}_h||_{\Theta_h} + ||z_h||_{W_h} + ||\boldsymbol{\rho}_h||_\Gamma + t||\boldsymbol{\rho}_h||_{0,\Omega}\Big)\end{aligned} \tag{4.26}$$

and

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) \geq C\Big(||\boldsymbol{\beta}_h||^2_{\Theta_h} + ||z_h||^2_{W_h} + ||\boldsymbol{\rho}_h||^2_\Gamma + t^2||\boldsymbol{\rho}_h||^2_{0,\Omega}\Big). \tag{4.27}$$

Proof. Let $(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h)$ be given in $\Theta_h \times W_h \times \Gamma_h$. The proof is performed in three steps.

Step 1. Let us first choose $(\boldsymbol{\eta}_1, v_1, \boldsymbol{\tau}_1) \in \Theta_h \times W_h \times \Gamma_h$ as

$$\boldsymbol{\eta}_1 = \boldsymbol{\beta}_h, \qquad v_1 = z_h, \qquad \boldsymbol{\tau}_1 = \boldsymbol{\rho}_h.$$

It is obvious that

$$\begin{aligned}||\boldsymbol{\eta}_1||_{\Theta_h} + ||v_1||_{W_h} + ||\boldsymbol{\tau}_1||_\Gamma + t||\boldsymbol{\tau}_1||_{0,\Omega}\\ = ||\boldsymbol{\beta}_h||_{\Theta_h} + ||z_h||_{W_h} + ||\boldsymbol{\rho}_h||_\Gamma + t||\boldsymbol{\rho}_h||_{0,\Omega}.\end{aligned} \tag{4.28}$$

Furthermore, it holds that

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_1, v_1, \boldsymbol{\tau}_1) = a_h(\boldsymbol{\beta}_h, \boldsymbol{\beta}_h) + \lambda^{-1}t^2||\boldsymbol{\gamma}_h||^2_{0,\Omega}. \tag{4.29}$$

By the coercivity of $a_h(\cdot,\cdot)$ (cf. (3.16)) it follows that

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_1, v_1, \boldsymbol{\tau}_1) \geq C_1\Big(||\boldsymbol{\beta}_h||^2_{\Theta_h} + t^2||\boldsymbol{\rho}_h||^2_0\Big). \tag{4.30}$$

Step 2. Notice that from (4.13) it follows that there exists $(\boldsymbol{\eta}_2, v_2) \in \Theta_h \times W_h$ such that

$$||\boldsymbol{\eta}_2||_{\Theta_h} + ||v_2||_{W_h} \leq C||\boldsymbol{\rho}_h||_\Gamma \tag{4.31}$$

and

$$(\boldsymbol{\nabla}_h v_2 - \boldsymbol{\eta}_2, \boldsymbol{\rho}_h) = ||\boldsymbol{\rho}_h||^2_\Gamma. \tag{4.32}$$

Choose $(\boldsymbol{\eta}_2, v_2, \boldsymbol{\tau}_2) \in \Theta_h \times W_h \times \Gamma_h$ with $\boldsymbol{\tau}_2 = 0$. We have

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_2, v_2, \boldsymbol{\tau}_2) = a_h(\boldsymbol{\beta}_h, \boldsymbol{\eta}_2) + (\boldsymbol{\nabla}_h v_2 - \boldsymbol{\eta}_2, \boldsymbol{\rho}_h), \tag{4.33}$$

so that by (4.32) it follows that

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_2, v_2, \boldsymbol{\tau}_2) = a_h(\boldsymbol{\beta}_h, \boldsymbol{\eta}_2) + ||\boldsymbol{\rho}_h||^2_\Gamma. \tag{4.34}$$

To control the first term on the right-hand side of (4.34), we note that (see also (3.17))

$$a_h(\boldsymbol{\beta}_h, \boldsymbol{\eta}_2) \geq -\frac{M}{2\delta}||\boldsymbol{\beta}_h||^2_{\Theta_h} - \frac{\delta M}{2}||\boldsymbol{\eta}_2||^2_{\Theta_h} \geq -\frac{M}{2\delta}||\boldsymbol{\beta}_h||^2_{\Theta_h} - \frac{\delta C M}{2}||\boldsymbol{\rho}_h||^2_\Gamma. \tag{4.35}$$

Taking δ sufficiently small, we get

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_2, v_2, \boldsymbol{\tau}_2) \geq C_2||\boldsymbol{\rho}_h||^2_\Gamma - C_3||\boldsymbol{\beta}_h||^2_{\Theta_h}. \tag{4.36}$$

Step 3. Choose $(\boldsymbol{\eta}_3, v_3, \boldsymbol{\tau}_3) \in \Theta_h \times W_h \times \Gamma_h$ as

$$\boldsymbol{\eta}_3 = 0, \qquad v_3 = 0, \qquad \boldsymbol{\tau}_3 = -\boldsymbol{\nabla}_h z_h.$$

Notice that by (3.9) the choice above is admissible.

On one hand it is easily seen that

$$||\boldsymbol{\tau}_3||_\Gamma \leq C||z_h||_{\Theta_h}. \tag{4.37}$$

On the other hand it holds that

$$\begin{aligned}\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_3, v_3, \boldsymbol{\tau}_3) &= (\boldsymbol{\nabla}_h z_h - \boldsymbol{\beta}_h, \boldsymbol{\nabla}_h z_h) - \lambda^{-1}t^2(\boldsymbol{\rho}_h, \boldsymbol{\nabla}_h z_h)\\ &= ||z_h||^2_{W_h} - (\boldsymbol{\beta}_h, \boldsymbol{\nabla}_h z_h) - \lambda^{-1}t^2(\boldsymbol{\rho}_h, \boldsymbol{\nabla}_h z_h)\\ &\geq \left(1 - \frac{\delta}{2}\right)||z_h||^2_{W_h} - \frac{C}{2\delta}||\boldsymbol{\beta}_h||^2_{\Theta_h} - \lambda^{-1}t^2(\boldsymbol{\rho}_h, \boldsymbol{\nabla}_h z_h).\end{aligned} \tag{4.38}$$

Moreover, one has

$$-\lambda^{-1}t^2(\boldsymbol{\rho}_h, \boldsymbol{\nabla}_h z_h) \geq -t^2\left(\frac{\lambda^{-1}}{2\varepsilon}||\boldsymbol{\rho}_h||^2_{0,\Omega} + \frac{\lambda^{-1}\varepsilon}{2}||z_h||^2_{W_h}\right). \tag{4.39}$$

By (4.38)–(4.39), and taking δ and ε sufficiently small, one finally gets

$$\mathcal{A}_h(\boldsymbol{\beta}_h, z_h, \boldsymbol{\rho}_h; \boldsymbol{\eta}_3, v_3, \boldsymbol{\tau}_3) \geq C_4||z_h||^2_{W_h} - C_5||\boldsymbol{\beta}_h||^2_{\Theta_h} - C_6 t^2||\boldsymbol{\rho}_h||^2_{0,\Omega}. \tag{4.40}$$

Now it suffices to take a suitable linear combination of $\{(\boldsymbol{\eta}_i, v_i, \boldsymbol{\tau}_i)\}_{i=1}^3$ so that by (4.28), (4.30), (4.34), (4.36), (4.37), and (4.40) it follows that (4.26) and (4.27) hold. The proof is then complete. ∎

5. Error analysis. In this section we develop a convergence analysis for our scheme, taking advantage of Proposition 4.3.

We shall need the following result (see [1], [2]): let T be a triangle, and let e be an edge of T. Then $\exists C > 0$ only depending on the minimum angle of T such that

$$||\varphi||_{0,e}^2 \le C\big(|e|^{-1}||\varphi||_{0,T}^2 + |e||\varphi|_{1,T}^2\big), \qquad \varphi \in H^1(\mathcal{T}_h). \tag{5.1}$$

Clearly, (5.1) also holds for vector-valued functions $\boldsymbol{\varphi} \in (H^1(\mathcal{T}_h))^2$. Moreover, we shall use the estimate (see [6])

$$\left(\sum_{e\in\mathcal{E}_h} |e|^{-1}\,|||[\boldsymbol{\eta}_h]|||_{0,e}^2\right)^{1/2} \le C||\boldsymbol{\eta}_h||_{\Theta_h} \qquad \forall \boldsymbol{\eta}_h \in \Theta_h. \tag{5.2}$$

We can now prove the following theorem.

THEOREM 5.1. *Let $(\boldsymbol{\theta}, w, \boldsymbol{\gamma})$ be the solution of problem* (2.1)–(2.4). *Furthermore, let $(\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h)$ be the solution of the discretized problem* (4.25). *The following error estimate holds*

$$\begin{aligned} &||\boldsymbol{\theta} - \boldsymbol{\theta}_h||_{\Theta_h} + ||w - w_h||_{W_h} + ||\boldsymbol{\gamma} - \boldsymbol{\gamma}_h||_\Gamma + t||\boldsymbol{\gamma} - \boldsymbol{\gamma}_h||_{0,\Omega} \\ &\qquad \le Ch\Big(||\boldsymbol{\theta}||_{2,\Omega} + ||w||_{2,\Omega} + ||\boldsymbol{\gamma}||_{H(\mathrm{div})} + t||\boldsymbol{\gamma}||_{1,\Omega}\Big). \end{aligned} \tag{5.3}$$

Proof. By Proposition 4.3, given $(\boldsymbol{\theta}_h - \boldsymbol{\theta}_I, w_h - w_I, \boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I) \in \Theta_h \times W_h \times \Gamma_h$, there exists $(\boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) \in \Theta_h \times W_h \times \Gamma_h$ such that

$$\begin{aligned} &||\boldsymbol{\eta}_h||_{\Theta_h} + ||v_h||_{W_h} + ||\boldsymbol{\tau}_h||_\Gamma + t||\boldsymbol{\tau}_h||_{0,\Omega} \\ &\le C\Big(||\boldsymbol{\theta}_h - \boldsymbol{\theta}_I||_{\Theta_h} + ||w_h - w_I||_{W_h} + ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_\Gamma + t||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_{0,\Omega}\Big) \end{aligned} \tag{5.4}$$

and

$$\begin{aligned} &C\Big(||\boldsymbol{\theta}_h - \boldsymbol{\theta}_I||_{\Theta_h}^2 + ||w_h - w_I||_{W_h}^2 + ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_\Gamma^2 + t^2||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_{0,\Omega}^2\Big) \\ &\quad \le \mathcal{A}_h(\boldsymbol{\theta}_h - \boldsymbol{\theta}_I, w_h - w_I, \boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I; \boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) \\ &\quad = a_h(\boldsymbol{\theta}_h - \boldsymbol{\theta}_I, \boldsymbol{\eta}_h) + (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h, \boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I) \\ &\qquad - \big(\boldsymbol{\nabla}_h(w_h - w_I) - (\boldsymbol{\theta}_h - \boldsymbol{\theta}_I), \boldsymbol{\tau}_h\big) + \lambda^{-1}t^2(\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I, \boldsymbol{\tau}_h). \end{aligned} \tag{5.5}$$

Multiplying (2.1) by $\boldsymbol{\eta}_h$, integrating by parts, and using $[\boldsymbol{\theta}] = 0$, we obtain

$$a_h(\boldsymbol{\theta}, \boldsymbol{\eta}_h) - (\boldsymbol{\gamma}, \boldsymbol{\eta}_h) = c_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}_h), \tag{5.6}$$

where, using (3.5),

$$c_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}_h) := \sum_{T\in\mathcal{T}_h} \int_{\partial T} \mathbf{C}\,\varepsilon(\boldsymbol{\theta})\mathbf{n} \cdot \boldsymbol{\eta}_h\, ds = \sum_{e\in\mathcal{E}_h} \int_e \{\mathbf{C}\,\varepsilon(\boldsymbol{\theta})\} : [\boldsymbol{\eta}_h]\, ds. \tag{5.7}$$

Multiplying (2.2) by v_h and integrating by parts, we have

$$(\boldsymbol{\gamma}, \boldsymbol{\nabla}_h v_h) = (g, v_h) + c_W(\boldsymbol{\gamma}, v_h), \tag{5.8}$$

where

$$c_W(\boldsymbol{\gamma}, v_h) := \sum_{T\in\mathcal{T}_h} \int_{\partial T} \boldsymbol{\gamma}\cdot\mathbf{n} v_h \, ds = \sum_{e\in\mathcal{E}_h} \int_e \{\boldsymbol{\gamma}\}\cdot[v_h]\, ds. \tag{5.9}$$

Multiplying (2.3) by $\boldsymbol{\tau}_h$ and integrating, we obtain

$$(\boldsymbol{\nabla} w - \boldsymbol{\theta}, \boldsymbol{\tau}_h) - \lambda^{-1} t^2 (\boldsymbol{\gamma}, \boldsymbol{\tau}_h) = 0. \tag{5.10}$$

Therefore, from (5.6)–(5.10) we get that

$$\mathcal{A}_h(\boldsymbol{\theta}, w, \boldsymbol{\gamma}; \boldsymbol{\eta}_h, v_h, \boldsymbol{\tau}_h) = (g, v_h) + c_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}_h) + c_W(\boldsymbol{\gamma}, v_h). \tag{5.11}$$

By recalling that $(\boldsymbol{\theta}_h, w_h, \boldsymbol{\gamma}_h)$ solves (4.25), from (5.5) and (5.11) we obtain

$$\begin{aligned} C\Big(||\boldsymbol{\theta}_h - \boldsymbol{\theta}_I||^2_{\Theta_h} + ||w_h - w_I||^2_{W_h} + ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||^2_\Gamma + t^2||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||^2_{0,\Omega}\Big) \\ \le a_h(\boldsymbol{\theta} - \boldsymbol{\theta}_I, \boldsymbol{\eta}_h) - c_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}_h) + (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h, \boldsymbol{\gamma} - \boldsymbol{\gamma}_I) - c_W(\boldsymbol{\gamma}, v_h) \\ - \big(\boldsymbol{\nabla}_h(w - w_I) - (\boldsymbol{\theta} - \boldsymbol{\theta}_I), \boldsymbol{\tau}_h\big) + \lambda^{-1} t^2 (\boldsymbol{\gamma} - \boldsymbol{\gamma}_I, \boldsymbol{\tau}_h) \\ = T_1 + T_2 + T_3 + T_4, \end{aligned} \tag{5.12}$$

where

$$\begin{cases} T_1 = a_h(\boldsymbol{\theta} - \boldsymbol{\theta}_I, \boldsymbol{\eta}_h) - c_\Theta(\boldsymbol{\theta}, \boldsymbol{\eta}_h), \\ T_2 = (\boldsymbol{\nabla}_h v_h - \boldsymbol{\eta}_h, \boldsymbol{\gamma} - \boldsymbol{\gamma}_I) - c_W(\boldsymbol{\gamma}, v_h), \\ T_3 = \big(\boldsymbol{\nabla}_h(w - w_I) - (\boldsymbol{\theta} - \boldsymbol{\theta}_I), \boldsymbol{\tau}_h\big), \\ T_4 = \lambda^{-1} t^2 (\boldsymbol{\gamma} - \boldsymbol{\gamma}_I, \boldsymbol{\tau}_h). \end{cases} \tag{5.13}$$

In order to estimate the four terms above, we need to choose $\boldsymbol{\theta}_I$, w_I, and $\boldsymbol{\gamma}_I$. For $\boldsymbol{\theta}_I$ and w_I we take the usual nonconforming piecewise linear interpolated of $\boldsymbol{\theta}$ and w, respectively. A suitable choice of $\boldsymbol{\gamma}_I$ is more involved and requires the introduction of the Helmholtz decomposition for $\boldsymbol{\gamma}$ (see [15] or [16], for instance). More precisely we write

$$\boldsymbol{\gamma} = \boldsymbol{\nabla} r + \mathbf{curl}\, p, \qquad r \in H^2(\Omega)\cap H^1_0(\Omega), \quad p \in H^1(\Omega)/\mathbf{R}. \tag{5.14}$$

It is easily seen that

$$\big(||r||^2_{2,\Omega} + ||p||^2_{1,\Omega}\big)^{1/2} \le C||\boldsymbol{\gamma}||_{H(\mathrm{div})}. \tag{5.15}$$

We now take r_I as the piecewise linear and continuous Lagrange interpolation of r, and p_I as the Clemént interpolation of p. Following [23], we finally set $\boldsymbol{\gamma}_I \in \Gamma_h$ as

$$\boldsymbol{\gamma}_I = \boldsymbol{\nabla} r_I + \mathbf{curl}\, p_I. \tag{5.16}$$

We have (see [23])

$$||\boldsymbol{\gamma} - \boldsymbol{\gamma}_I||_\Gamma \le Ch\, ||\boldsymbol{\gamma}||_{H(\mathrm{div})} \tag{5.17}$$

and

$$||\boldsymbol{\gamma} - \boldsymbol{\gamma}_I||_{0,\Omega} \le Ch\, ||\boldsymbol{\gamma}||_{1,\Omega}. \tag{5.18}$$

We are ready to estimate the terms in (5.13).

Estimate for T_1. Using (3.17), we have

$$a_h(\boldsymbol{\theta}-\boldsymbol{\theta}_I,\boldsymbol{\eta}_h)\le Ch\,||\boldsymbol{\theta}||_{2,\Omega}||\boldsymbol{\eta}_h||_{\Theta_h} \tag{5.19}$$

and (cf. [18])

$$c_\Theta(\boldsymbol{\theta},\boldsymbol{\eta}_h)\le Ch\,||\boldsymbol{\theta}||_{2,\Omega}||\boldsymbol{\eta}_h||_{\Theta_h}. \tag{5.20}$$

Therefore

$$T_1\le Ch\,||\boldsymbol{\theta}||_{2,\Omega}||\boldsymbol{\eta}_h||_{\Theta_h}. \tag{5.21}$$

Estimate for T_2. Using (5.14) and (5.16) we get

$$\begin{aligned} T_2 &= \big(\boldsymbol{\nabla}_h v_h-\boldsymbol{\eta}_h,\boldsymbol{\nabla}(r-r_I)+\mathbf{curl}\,(p-p_I)\big)-c_W(\boldsymbol{\gamma},v_h)\\ &= \big(\boldsymbol{\nabla}_h v_h,\boldsymbol{\nabla}(r-r_I)\big)+\Big\{\big(\boldsymbol{\nabla}_h v_h,\mathbf{curl}\,(p-p_I)\big)-c_W(\boldsymbol{\gamma},v_h)\Big\}\\ &\quad-\big(\boldsymbol{\eta}_h,\boldsymbol{\nabla}(r-r_I)\big)-\big(\boldsymbol{\eta}_h,\mathbf{curl}\,(p-p_I)\big)\\ &= T_2^1+T_2^2+T_2^3+T_2^4. \end{aligned} \tag{5.22}$$

• From standard approximation theory and (5.15), we have

$$T_2^1\le Ch\,||r||_{2,\Omega}||v_h||_{W_h}\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}||v_h||_{W_h}. \tag{5.23}$$

• We now treat the term T_2^2: since $v_h\in W_h$ and p_I is a piecewise linear and continuous function, the discrete Helmholtz decomposition proved in [7] gives

$$(\boldsymbol{\nabla}_h v_h,\mathbf{curl}\,p_I)=0,$$

so that, using also (5.9), we obtain

$$T_2^2=\sum_{T\in\mathcal{T}_h}\int_T\boldsymbol{\nabla}_h v_h\cdot\mathbf{curl}\,p-\sum_{e\in\mathcal{E}_h}\int_e\{\mathbf{curl}\,p\}\cdot[v_h]-\sum_{e\in\mathcal{E}_h}\int_e\{\boldsymbol{\nabla}r\}\cdot[v_h]. \tag{5.24}$$

Since

$$\sum_{T\in\mathcal{T}_h}\int_T\boldsymbol{\nabla}_h v_h\cdot\mathbf{curl}\,p-\sum_{e\in\mathcal{E}_h}\int_e\{\mathbf{curl}\,p\}\cdot[v_h]=0,$$

it follows that

$$T_2^2=-\sum_{e\in\mathcal{E}_h}\int_e\{\boldsymbol{\nabla}r\}\cdot[v_h]. \tag{5.25}$$

By a standard nonconforming approximation result and (5.15), we have

$$T_2^2\le Ch\,||\boldsymbol{\nabla}r||_{1,\Omega}||v_h||_{W_h}\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}||v_h||_{W_h}. \tag{5.26}$$

• To bound T_2^3 we simply observe that

$$T_2^3=-\big(\boldsymbol{\eta}_h,\boldsymbol{\nabla}(r-r_I)\big)\le Ch\,||\boldsymbol{\nabla}r||_{1,\Omega}||\boldsymbol{\eta}_h||_{0,\Omega}\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}||\boldsymbol{\eta}_h||_{\Theta_h}. \tag{5.27}$$

• Integrating by parts the term T_2^4, we get

$$\begin{aligned} T_2^4 &= -\sum_{T\in\mathcal{T}_h}\left\{\int_T \operatorname{rot}\,\boldsymbol{\eta}_h(p-p_I)+\int_{\partial T}\boldsymbol{\eta}_h\cdot\mathbf{t}_T\,(p-p_I)\right\} \\ &= -\sum_{T\in\mathcal{T}_h}\int_T \operatorname{rot}\,\boldsymbol{\eta}_h(p-p_I)-\sum_{e\in\mathcal{E}_h}\int_e \mathbf{t}_e\otimes\mathbf{n}_e : [\boldsymbol{\eta}_h]\{p-p_I\}. \end{aligned} \tag{5.28}$$

On one hand, we have

$$-\sum_{T\in\mathcal{T}_h}\int_T \operatorname{rot}\,\boldsymbol{\eta}_h(p-p_I)\le Ch\,||p||_{1,\Omega}||\boldsymbol{\eta}_h||_{\Theta_h}\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}||\boldsymbol{\eta}_h||_{\Theta_h}. \tag{5.29}$$

On the other hand, using (5.1) and (5.2) we get

$$\begin{aligned} &-\sum_{e\in\mathcal{E}_h}\int_e \mathbf{t}_e\otimes\mathbf{n}_e : [\boldsymbol{\eta}_h]\{p-p_I\} \\ &\qquad\le\left(\sum_{e\in\mathcal{E}_h}|e|\,||\{p-p_I\}||_{0,e}^2\right)^{1/2}\left(\sum_{e\in\mathcal{E}_h}|e|^{-1}\,|||[\boldsymbol{\eta}_h]|||_{0,e}^2\right)^{1/2} \\ &\qquad\le C\left(\sum_{T\in\mathcal{T}_h}\left(||p-p_I||_{0,T}^2+h_T^2|p-p_I|_{1,T}^2\right)\right)^{1/2}||\boldsymbol{\eta}_h||_{\Theta_h} \\ &\qquad\le Ch\,||p||_{1,\Omega}||\boldsymbol{\eta}_h||_{\Theta_h}. \end{aligned} \tag{5.30}$$

Therefore, from (5.28)–(5.30) and (5.15) we obtain

$$T_2^4\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}||\boldsymbol{\eta}_h||_{\Theta_h}. \tag{5.31}$$

Collecting (5.23), (5.26), (5.27), and (5.31), we conclude that

$$T_2\le Ch\,||\boldsymbol{\gamma}||_{H(\mathrm{div})}\Big(||\boldsymbol{\eta}_h||_{\Theta_h}+||v_h||_{W_h}\Big). \tag{5.32}$$

Estimate for T_3. Since $\boldsymbol{\tau}_h$ is piecewise constant, it follows that

$$\big(\boldsymbol{\nabla}_h(w-w_I),\boldsymbol{\tau}_h\big)=0.$$

Hence

$$\begin{aligned} T_3=-(\boldsymbol{\theta}-\boldsymbol{\theta}_I,\boldsymbol{\tau}_h) &\le\left(\sum_{T\in\mathcal{T}_h}h_T^{-2}||\boldsymbol{\theta}-\boldsymbol{\theta}_I||_{0,T}^2\right)^{1/2}\left(\sum_{T\in\mathcal{T}_h}h_T^2||\boldsymbol{\tau}_h||_{0,T}^2\right)^{1/2} \\ &\le Ch\,||\boldsymbol{\theta}||_{2,\Omega}||\boldsymbol{\tau}_h||_{-1,\Omega}\le Ch\,||\boldsymbol{\theta}||_{2,\Omega}||\boldsymbol{\tau}_h||_{\Gamma}, \end{aligned} \tag{5.33}$$

where we have used both the inverse inequality

$$\sum_{T\in\mathcal{T}_h}h_T^2||\boldsymbol{\tau}_h||_{0,T}^2\le C||\boldsymbol{\tau}_h||_{-1,\Omega}^2$$

and the definition of the Γ-norm (see (2.9)).

Estimate for T_4. We have, using (5.18),

$$T_4 = \lambda^{-1} t^2 (\boldsymbol{\gamma} - \boldsymbol{\gamma}_I, \boldsymbol{\tau}_h) \le Ch\, t ||\boldsymbol{\gamma}||_{1,\Omega}\, t ||\boldsymbol{\tau}_h||_{0,\Omega}. \tag{5.34}$$

Collecting (5.21), (5.32) (5.33), and (5.34), from (5.12) we obtain

$$\begin{aligned} &\Big(||\boldsymbol{\theta}_h - \boldsymbol{\theta}_I||^2_{\Theta_h} + ||w_h - w_I||^2_{W_h} + ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||^2_{\Gamma} + t^2 ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||^2_{0,\Omega} \Big) \\ &\le Ch \Big(||\boldsymbol{\theta}||_{2,\Omega} + ||\boldsymbol{\gamma}||_{H(\mathrm{div})} + t||\boldsymbol{\gamma}||_{1,\Omega} \Big) \\ &\qquad \times \Big(||\boldsymbol{\eta}_h||_{\Theta_h} + ||v_h||_{W_h} + ||\boldsymbol{\tau}_h||_{\Gamma} + t||\boldsymbol{\tau}_h||_{0,\Omega} \Big). \end{aligned} \tag{5.35}$$

Using (5.4) we get

$$\begin{aligned} &||\boldsymbol{\theta}_h - \boldsymbol{\theta}_I||_{\Theta_h} + ||w_h - w_I||_{W_h} + ||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_{\Gamma} + t||\boldsymbol{\gamma}_h - \boldsymbol{\gamma}_I||_{0,\Omega} \\ &\qquad \le Ch \Big(||\boldsymbol{\theta}||_{2,\Omega} + ||\boldsymbol{\gamma}||_{H(\mathrm{div})} + t||\boldsymbol{\gamma}||_{1,\Omega} \Big), \end{aligned} \tag{5.36}$$

and estimate (5.3) follows from the triangle inequality.

Using Proposition 2.1, from Theorem 5.1 we get an optimal error estimate with respect to h and independent of t.

COROLLARY 5.1. *Suppose that* Ω *is a convex polygon and* $g \in L^2(\Omega)$. *Then it holds that*

$$||\boldsymbol{\theta} - \boldsymbol{\theta}_h||_{\Theta_h} + ||w - w_h||_{W_h} + ||\boldsymbol{\gamma} - \boldsymbol{\gamma}_h||_{\Gamma} + t||\boldsymbol{\gamma} - \boldsymbol{\gamma}_h||_{0,\Omega} \le Ch\, ||g||_{0,\Omega}. \tag{5.37}$$

Acknowledgments. The author is grateful to F. Brezzi, L. D. Marini, and G. Sangalli for very valuable discussions on the subject of this paper.
