SOLVING MATRIX INEQUALITIES WHOSE UNKNOWNS ARE MATRICES*

JUAN F. CAMINO†, J. WILLIAM HELTON‡, AND ROBERT E. SKELTON§

Abstract. This paper provides algorithms for numerical solution of convex matrix inequalities in which the variables naturally appear as matrices. This includes, for instance, many systems and control problems. To use these algorithms, no knowledge of linear matrix inequalities is required. However, as tools, they preserve many advantages of the linear matrix inequality framework. Our method has two components: (1) a numerical algorithm that solves a large class of matrix optimization problems and (2) a symbolic "convexity checker" that automatically provides a region which, if convex, guarantees that the solution from (1) is a global optimum on that region. The algorithms are partly numerical and partly symbolic and since they aim at exploiting the matrix structure of the unknowns, the symbolic part requires the development of new computer techniques for treating noncommutative algebra.

Key words. matrix inequalities, convex optimization, semidefinite programming, noncommutative algebra, computer algebra

DOI. 10.1137/040613718

1. The basic idea.

Since the early 1990s, matrix inequalities (MIs) have become very important in engineering, particularly in control theory. If one has the ability to convert the MIs arising in a particular problem to a linear matrix inequality (LMI), then the problem can be solved up to substantial size. The wide acceptance of LMIs stems from the following advantages:

1. If a control problem is posed as an LMI, then any local solution is a global optimum.
2. Efficient numerical LMI solvers are readily available.
3. Once a control problem is posed as an LMI, adding constraints in the form of LMIs results in a LMI problem.

On the other hand, the LMI framework has the following disadvantages:

1. There is no systematic way to produce LMIs for general classes of problems.
2. There is no way of knowing whether it is possible to reduce a system problem to an LMI without actually doing it.
3. The user must possess the knowledge of manipulating LMIs, which takes considerable training. Indeed, if one does not have the ability to deal with LMIs, then it is not clear what one should do.
4. Transformations via Schur complements can lead to a large LMI representation.

1.1. Our method. The main objective for this paper is to provide a method for solving MIs that possesses similar advantages to the LMI framework but without its main disadvantages. Our method has two components:

1. a numerical algorithm, called NCSDP, that solves a large class of matrix optimization problems;
2. a symbolic "convexity checker" that automatically provides a region $\mathcal{G}$. If $\mathcal{G}$ is convex, then the solution from (1) is a global optimum on $\mathcal{G}$. Also, convexity ensures good numerical behavior of NCSDP on $\mathcal{G}$.

1.2. The convexity region algorithm. The symbolic convexity region algorithm receives as input a function $F(x)$ and gives as output a family of inequalities that determine a region $\mathcal{G}$ of x on which $F(x)$ is "matrix convex." Often, we just refer to matrix convexity as convexity and it is defined precisely in section 4.5. This algorithm produces sufficient conditions, which with some very weak hypotheses are necessary conditions for convexity. A concern is that the output might produce a "region of convexity $\mathcal{G}$" with several connected components, in which case the user must select one of them. (See section 3.1 for an example.)

1.3. The numerical solver for matrix inequalities. Our NCSDP solver can be used to solve optimization problems involving matrix inequalities. It is designed for situations where there are only a few unknown matrices and it attempts with symbolic manipulation (as well as numerics) to use the matrix structure to advantage. The solver has very reliable behavior in convex situations. The novel features of our algorithm that allow us to view the matrices as unknowns, rather than the entries of these matrices as unknowns, are discussed in sections 4.4, 7.2, and 8.

1.4. Combining the tools. Putting together the convexity checker and the NCSDP solver, we have a set of tools to solve many engineering problems that can be posed as matrix inequalities with matrix unknowns. Section 3 gives an example of these tools. Our method is effective on problems with few unknowns, but we reiterate that we can take each unknown to be a matrix. This is not a serious restriction for many system problems (e.g., most of the classics [23]).

1.5. LMI analogues. In some sense, there is a parallel between the conventional LMI approach and our approach. In the former, one needs to be able to convert the optimization problem over matrix functions into an equivalent LMI problem, so that some available LMI solver can be used. In our approach, the convexity checker provides a region $\mathcal{G}$ which, if convex, guarantees reliable behavior of our NCSDP solver and that a solution is a global optimum on $\mathcal{G}$.

1.6. Matrix unknowns. The advantage of dealing with matrices as single letters is that one letter z can stand for a matrix Z with n^2 commuting variables. In typical engineering situations, most problems have few matrix unknowns, often two or three, and few (not exceedingly complicated) constraints (usually fewer than 10). This contrasts with treating matrices in terms of their entries where one often has several thousand variables. A disadvantage is that matrix multiplication is not commutative and so we must develop computer tools for performing algebraic operations on noncommuting variables. The major focus of this research is how to use the matrix structure of the unknowns to advantage, and this will come out as the article unfolds. Our algorithms, including the NCSDP solver, combine symbolic and numerical manipulations and lead to several very natural open questions.

1.7. Software availability. The user interface of our NCSDP code is not polished and we do not yet distribute NCSDP. However, the convexity checker algorithm is well documented and available through NCAlgebra, a noncommutative algebra package that runs under Mathematica. This package provides a large number of useful commands and functions for symbolic computation. It can be downloaded from http://math.ucsd.edu/∼ncalg.

2. Nomenclature. We use uppercase letters (e.g., X) for matrices and lowercase letters (e.g., x) for symbolic variables. The notation $\mathcal{Q}, \mathcal{H}$ stands for the symbolic gradient and Hessian maps, and the notation $\mathbb{Q}, \mathbb{H}$ is used to indicate we have substituted matrices of compatible size for the symbolic variables in $\mathcal{Q}, \mathcal{H}$. The n-dimensional Euclidean space is denoted by $\mathbb{R}^n$. The space of $n \times m$ real matrices is denoted by $\mathbb{R}^{n\times m}$. The space of $n \times n$ symmetric matrices with real entries is denoted by $\mathbb{S}^n$. Let $(\mathbb{S}^n)^g$ stand for the direct product $\mathbb{S}^n \times \mathbb{S}^n \times \cdots \times \mathbb{S}^n$ of order g. The expression $A \geq B$ ($A > B$) means that $A - B$ is a positive semidefinite (positive definite) matrix. The associated spaces are respectively denoted by $\mathbb{S}_+$ and $\mathbb{S}_{++}$. The usual Kronecker product of two matrices A and B is denoted by $A \otimes B$ and the trace of A is $\mathrm{Tr}\,\{A\}$. To define the vec operation, let us associate the vector $\mathrm{vec}(X) \in \mathbb{R}^{nm}$ with each matrix $X \in \mathbb{R}^{n\times m}$ by listing the entries of the columns, column by column, that is, $\mathrm{vec}(X) = [X_{11}, X_{21}, \ldots, X_{n1}, X_{12}, \ldots, X_{n2}, \ldots, X_{1m}, \ldots, X_{nm}]^T$.

3. Introducing our approach by an example. Suppose one is given two matrices[1] A and S, where S is symmetric, and one needs to solve the following problem:

$$\max\{\mathrm{Tr}\,\{X\} \,:\, (X, Y, A, S) \in \mathrm{closure}(\mathcal{S})\}, \tag{P1}$$

where the domain $\mathcal{S}$ is given by

$$\mathcal{S} = \left\{(X, Y, A, S) \in \mathcal{V} \,:\, F(X, Y, A, S) < 0, \quad X^2 < I, \quad Y > 0, \quad Y^2 < I\right\}$$

with $\mathcal{V} = \mathbb{S}^n \times \mathbb{S}^n \times \mathbb{R}^{n\times n} \times \mathbb{S}^n$ and

$$\begin{aligned} F(X, Y, A, S) := &-AX(XA^TY^{-1}AX - Y)^{-1}XA^T \\ &- (Y^{-1}(XA^TY^{-1}AXY^{-1} - Y)Y^{-1})^{-1} - AX(Y^{-1}(XA^TY^{-1}AX - Y))^{-1} \\ &- ((XA^TY^{-1}AX - Y)Y^{-1})^{-1}XA^T + XA^TY^{-1}AX - S. \end{aligned}$$

To solve this problem, we apply our two-step methodology:

1. Determine a domain $\mathcal{G}$ on which the above problem is convex.
2. Solve numerically the optimization problem on $\mathcal{G}$ using NCSDP.

3.1. Step 1. Determining a region of convexity in problem (P1). This step is purely symbolic and we do not use the particular numerical values of A and S given in (3.1). We describe this step using standard TEX notation rather than displaying actual computer runs.

The problem (P1) is to maximize $\mathrm{Tr}\,\{X\}$ over the domain

$$\mathcal{S} := \mathcal{S}_1 \cap \mathcal{S}_2$$

[1] Ultimately, in our example we shall take the matrices A and S to be

$$A = \begin{bmatrix} 1 & -1 \\ 0 & 2 \end{bmatrix}, \qquad S = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}. \tag{3.1}$$

The matrices are chosen small to save space.

with

$$\mathcal{S}_1 := \{(X,Y,A,S) \in \mathcal{V} : Y^2 < I, \quad X^2 < I\}$$

and

$$\mathcal{S}_2 := \{(X,Y,A,S) \in \mathcal{V} : F(X,Y,A,S) < 0, \quad Y > 0\}.$$

This optimization problem will be convex whenever $\mathcal{S}$ is a convex domain, since the objective function $\mathrm{Tr}\{X\}$ is linear in X. It is clear that $\mathcal{S}_1$ is convex; we wish to show that $\mathcal{S}_2$ is convex so that we can conclude that $\mathcal{S}$ is convex. For this purpose, we use our symbolic package to find the region where $F(X,Y,A,S)$ is convex with respect to X, Y in the domain $\mathcal{S}_2$.

Since matrix multiplication is not commutative, we must treat the matrices X, Y, A, and S symbolically as noncommutative variables. Thus, we load the Mathematica package NCAlgebra, which contains our convexity checker software. We type in the function F just as we see it in the definition of F and apply the convexity checker algorithm **NCConvexityRegion[]** (see section 5) using its default set of permutations. One of the outputs is the list

$$\{2y^{-1},\ -2(xa^Ty^{-1}ax - y)^{-1},\ 2y^{-1},\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0,\ 0\}.$$

The interpretation of the output is that $F(X,Y,A,S)$ will be a convex function on the region consisting of all matrices that make each nonzero entry in the output list a positive definite expression, which, in this case, is the region given by

$$2Y^{-1} > 0 \qquad \text{and} \qquad -2(XA^TY^{-1}AX - Y)^{-1} > 0.$$

Thus, we conclude from this output that $F(X,Y,A,S)$ is simultaneously convex in X and Y whenever A, S, X, and Y are matrices of compatible dimension in the region $\mathcal{G}_{\mathcal{S}_2}$ given by

$$\mathcal{G}_{\mathcal{S}_2} := \{(X,Y,A,S) \in \mathcal{V} : Y > 0, \quad XA^TY^{-1}AX < Y\}. \tag{3.2}$$

To find if the above region $\mathcal{G}_{\mathcal{S}_2}$ is itself simultaneously convex in X and Y, we run the convexity checker once more on the function $G(X,Y,A) := XA^TY^{-1}AX - Y$,

NCConvexityRegion$[xa^Ty^{-1}ax - y, \{x,\ y\}]$.

This command outputs the list $\{2y^{-1},\ 0\}$. Thus, the region $\mathcal{G}$ is convex on matrices Y satisfying $Y > 0$. Thus, the region where the function G is convex consists of matrices Y satisfying $Y > 0$; consequently the region $\mathcal{G}_{\mathcal{S}_2}$ in (3.2) is convex. Thus, we can conclude that the optimization problem (P1) is convex inside the convex region

$$\mathcal{G} := \{(X,Y,A,S) \in \mathcal{V} : (X,Y,A,S) \in \mathcal{S} \cap \mathcal{G}_{\mathcal{S}_2}\}.$$

Equivalently

$$\mathcal{G} := \{(X,Y,A,S) \in \mathcal{V} : F(X,Y,A,S) < 0, \quad XA^TY^{-1}AX < Y, \quad Y > 0, \quad Y^2 < I, \quad X^2 < I\}.$$

Note that the region of convexity $\mathcal{G}$ for the optimization problem (P1) was determined without considering any specific numerical values for A and S. Thus, the set

of inequalities $\mathcal{G}$ characterizes a convex region for any arbitrary choice of two $n \times n$ matrices A and symmetric S no matter what value n is. Whether $\mathcal{G}$ is the biggest such region we have not said. In fact, the algorithm addresses this, requiring an interpretation, for which we refer to [5], or see section 5 for an abbreviated account. For the example above this gives that the largest subregion of matrix tuples (of large enough size) on which the Hessian is positive is the closure of $\mathcal{G}$.

3.2. Step 2. Invoking the NCSDP solver. Until this point, all calculations were symbolic. Now, we make the particular numerical choice for the matrices A, S given in (3.1). The optimization problem (P1) can now be solved with the NCSDP solver reliably and globally on the convex region of 2×2 matrices satisfying the constraints $\mathcal{G}$. We emphasize that this amounts to adding the following convex constraint

$$XA^TY^{-1}AX < Y \tag{3.3}$$

to the constraints defining $\mathcal{S}$. *Thus, we are not solving exactly the original problem, and the user must decide if this constraint meets his or her engineering needs.* Beware that declining to add the constraint (3.3) subjects one to the difficulties found in nonconvex situations, but one can still run numerical optimization routines.

To use NCSDP, we define the objective for this optimization problem as

$$\text{obj} := -\operatorname{Tr}\{X\},$$

subject to the constraint $G_i < 0$, where

$$\begin{aligned} G_1 &:= F(X, Y, A, S), \qquad G_2 := XA^TY^{-1}AX - Y, \\ G_3 &:= -Y, \qquad G_4 := YY - I, \qquad G_5 := XX - I, \end{aligned}$$

with

$$A = \begin{bmatrix} 1 & -1 \\ 0 & 2 \end{bmatrix}, \qquad S = \begin{bmatrix} 2 & 0 \\ 0 & 1 \end{bmatrix}.$$

Using this input, namely, (obj, $\{G_1, G_2, G_3, G_4, G_5\}$, $\{X, Y\}$), we run NCSDP. The solver finds the global optimizers over $\mathcal{G}$ to be

$$X^* = \begin{bmatrix} 0.3421 & 0.0263 \\ 0.0263 & 0.0788 \end{bmatrix}, \qquad Y^* = \begin{bmatrix} 0.8107 & 0.0016 \\ 0.0016 & 0.4255 \end{bmatrix}.$$

The optimal cost is therefore $\operatorname{Tr}\{-X^*\} = -0.4208$. We repeat that X^*, Y^* is a global optimum over the region

$$\mathcal{S} \cap \{(X, Y, A, S) \in \mathbb{S}^{2\times 2} \,:\, XA^TY^{-1}AX < Y, \quad Y > 0\}$$

with the matrices A and S as given above.

We emphasize there is no need to know much Mathematica to use NCSDP, unless one desires to use the convexity checker, and related symbolic algorithms, as we did in this example.

3.3. Scope of our methods. The method we shall describe here applies to problems of the form

$$\min_{X_i} \{\operatorname{Tr}\{X_1\} \,:\, X_i \in \text{closure}(\mathcal{G})\},$$

where the feasibility region $\mathcal{G}$ is given by

$$\mathcal{G} = \Big\{ (X_i, A_j) \,:\, F_1(X_i, A_j) > 0, \ldots, F_\ell(X_i, A_j) > 0 \Big\}$$

with $F_1(X_i, A_j), \ldots, F_\ell(X_i, A_j)$ rational expressions of noncommutative variables A_j, X_i, X_i^T. We assume the closure of the set $\mathcal{G}$ is compact. We can take some of the variables to be formally symmetric, like $X_7 = X_7^T$. The methods also apply to the feasibility problem, namely, determining if $\mathcal{G}$ is empty. We expect that (once refined) such methods will have advantages when the F_k are not highly complicated expressions.

An example of a problem we do not treat here is

$$\min \mathrm{Tr}\,\{X\} \qquad \text{subject to} \quad \mathrm{Tr}\,\big\{X^2\big\} \le 1.$$

However, we think our methods extend to such situations.

Space and expository considerations forced us to consider a single function $F(X)$ of a single symmetric variable $X = X^T$. The extension to the multivariate case stated above, found in [4], follows similar ideas, but it is too long to present here.

3.4. Comparing to the LMI approach. The optimization problem (P1) was actually selected to correspond to an LMI problem, so that we could compare approaches. There is not enough space to describe this in detail. (The corresponding LMI system has dimension 4×4.) We found that our approach produced exactly what was obtained using the LMI. Indeed our "extra condition" $XA^TY^{-1}AX < Y$ was a necessary condition for the LMI to be positive definite. Thus, from the LMI point of view, it is an essential constraint.

Since transformations via Schur complements can lead to an LMI representation with large constraint block matrices, the NCSDP solver has the potential to reduce the optimization time significantly compared to primal-dual solvers (see section 9).

3.5. Comparing to optimization over functions of commutative variables. If one has a complicated polynomial or rational function F, then there are typically many isolated regions on which the Hessian of F is positive definite. In our terminology, there are many "regions of convexity" for F. Thus, our technique requires selecting those convexity regions of interest and finding optima on them.

To those whose experience is with classical rational optimization, this seems odd, because there are many regions of convexity for F. However, our motivation comes from systems engineering problems, where we reemphasize that the number of matrix unknowns is small and that the rational functions are not terribly complicated; consequently F has a few connected regions of convexity. Moreover, the inequality constraints in a problem (e.g., $Y > 0$, $X^2 < I$) often select one convexity region.

4. Background on NC rational functions and convexity.

4.1. NC polynomials. We work with noncommutative (NC) polynomials with real numbers as coefficients in variables $x = \{x_1, \ldots x_g\}$. They cause little confusion, so a few examples suffice for an introduction:

$$p(x) = x_1x_2x_1 + x_1x_2 + x_2x_1, \qquad x_1^T = x_1, \quad x_2^T = x_2,$$

where the variables x_j are formally symmetric. In this next expression

$$p(x) = x_1^Tx_2x_1 + x_1^Tx_2 + x_2x_1, \qquad x_2^T = x_2,$$

the variable x_2 is formally symmetric but x_1 is not. Often, the term indeterminant is used instead of the term variable.

An NC polynomial p is symmetric provided that it is formally symmetric with respect to the involution ^{T}. Often, we shall substitute $n \times n$ matrices $X_1, \ldots, X_g$ into p for the variables $x_1, \ldots, x_g$. For a symmetric p, if the x_j are designated as symmetric variables, then the matrices X_j must be taken to be symmetric, and the resulting matrix $p(X_1, \ldots, X_g)$ is symmetric. The variables x_j which are not declared symmetric, if substituted by the matrix X_j, also result in the variables x_j^T being substituted by X_j^T.

4.2. NC rational functions. We shall discuss the notion of an NC rational function in terms of rational expressions. There is a technicality, "analytic at 0," which we include, since it makes formal definitions simpler. Casual readers can ignore it, since assuming analyticity elsewhere suffices.

An NC rational expression analytic at 0 is defined recursively. NC polynomials are NC rational expressions as are all sums and products of NC rational expressions. If r is a NC rational expression and $r(0) \neq 0$, then the inverse of r is a rational expression.

The notion of the formal domain of a rational expression r, denoted $\mathcal{F}_{r,\text{formal}}$, very roughly speaking, is

$$\mathcal{F}_{r,\text{formal}} := \{X \,:\, r(X) \text{ is defined } (\text{is not infinite})\}\,.$$

More precisely, the formal domain and the evaluation $r(X)$ of the rational expression at a tuple $X \in (\mathbb{S}^n)^g \bigcap \mathcal{F}_{r,\text{formal}}$ are both defined recursively.[2]

The following example illustrates it conveniently.

Example 4.1. Let the symmetric NC rational expressions $r(x)$ be given by

$$r(x_1, x_2) = (1 + x_1 - (3 + x_2)^{-1})^{-1}$$

with $x_1 = x_1^T$ and $x_2 = x_2^T$. The domain $\mathcal{F}_{r,\text{formal}}$ is

$$\bigcup_{n>0} \left\{ X_1, X_2 \in \mathbb{S}^n \,:\, I + X_1 - (3I + X_2)^{-1} \text{ and } 3I + X_2 \text{ are invertible} \right\}.$$

A difficulty is two different expressions, such as

$$r_1 = x_1(1 - x_2x_1)^{-1} \quad \text{and} \quad r_2 = (1 - x_1x_2)^{-1}x_1,$$

that can be converted into each other with algebraic manipulation. Thus they represent the same function and one needs to specify an equivalence relation on rational expressions to arrive at what are typically called NC rational functions. (This is standard and simple for commutative (ordinary) rational functions.) There are many alternate ways to describe NC rational functions and they go back 50 years or so in the algebra literature; cf. [17]. For engineering purposes, one need not be too concerned, since what happens is that two expressions r_1 and r_2 are equivalent whenever the usual manipulations one is accustomed to with matrix expressions convert r_1 to r_2. We say more on this in section 4.3.

[2]The formal domain of a polynomial p is all of $(\mathbb{S}^n)^g$ and $p(X)$ is defined as before. The formal domain of sums and products of rational expressions is the intersection of their respective formal domains. If r is an invertible rational expression analytic at 0 and $r(X)$ is invertible, then X is in the formal domain of r^{-1}.

For $\mathfrak{r}$ a rational function, that is, an "equivalence class of rational expressions r," we define its domain by

$$\mathcal{F}_{\mathfrak{r}} := \bigcup_{\{r \text{ represents } \mathfrak{r}\}} \mathcal{F}_{r,\text{formal}}.$$

Henceforth we do not distinguish between rational functions $\mathfrak{r}$ and rational expressions r, since this causes no confusion.

4.3. Partial fraction expansion of an NC rational. A computer algebra package must have a way to put functions into a canonical form. For example, if two rational expressions r_1 and r_2 represent the same rational function, then the canonical form of $r_1 - r_2$ would be 0. In NCAlgebra we have the command NCSimplifyRational, which in principle, when applied to a rational expression r, outputs what one might think of as a noncommutative partial fraction expansion of r; in practice, our command gives the true canonical form on a broad class of NC rational expressions but not all, since doing all of them is an infinite process. The theory behind producing this kind of canonical form is found in [11] and [24]. The idea is to generate what is called a Gröbner basis (GB) from the defining equations for inverses and store key elements of the GB as replacement rules in NCSimplifyRational. This is well suited to systems whose input operators B are left invertible, output operators C are right invertible, and state operators are generically invertible. Indeed they naturally lie in what is called a path algebra. It is not hard (for a GB expert) to prove that GB production respects the path algebra structure; thus, for example, the right inverse of B will never occur. See [10] for an extensive treatment of GBs in a path algebra.

4.4. Symbolic differentiation of noncommutative functions. Since our goal is to use symbolic computation to determine the gradient and the Hessian of functions in our optimization problems and to preserve the matrix structure of the unknowns, we need the notion of derivatives of function of variables which are symbolic noncommutative elements.

Noncommutative rational functions of x are polynomials in x and in inverses of polynomials in x. An example of a symmetric noncommutative function is

$$F(a, b, x) = ax + xa^T - \frac{3}{4}xbb^Tx, \quad x = x^T. \tag{4.1}$$

It is also assumed there is an involution on these rational functions which is denoted by the superscript ^{T} and which will play the role of transpose later when we substitute matrices for the indeterminates.

The *first directional derivative* of a noncommutative rational function $F(x)$ with respect to x in the direction δ_x is defined in the usual way

$$DF(x)[\delta_x] := \lim_{t\to 0} \frac{1}{t}\left(F(x + t\delta_x) - F(x)\right) = \frac{d}{dt}\, F(x + t\delta_x)\Big|_{t=0}.$$

For example, with F in (4.1),

$$DF(x)[\delta_x] = a\delta_x + \delta_x a^T - \frac{3}{4}\delta_x bb^T x - \frac{3}{4}xbb^T\delta_x,$$

and if $p(x) = x^4$,

$$Dp(x)[\delta_x] = \delta_x xxx + x\delta_x xx + xx\delta_x x + xxx\delta_x.$$

It is easy to check that derivatives of symmetric noncommutative rational functions always have the form

$$DF(x)[\delta_x] = \operatorname{sym}\left\{\sum_{i=1}^{k} a_i \delta_x b_i\right\}. \tag{4.2}$$

The sym operator is defined as $\operatorname{sym}\{M\} = M + M^T$.

The *second directional derivative* of a noncommutative rational function $F(x)$ with respect to x in the direction δ_x is defined by

$$D^2F(x)\left[\delta_x, \delta_x\right] = \frac{d^2}{dt^2} F(x + t\delta_x)\bigg|_{t=0}.$$

For example, if $p(x) = x^4$, then

$$D^2p(x)\left[\delta_x, \delta_x\right] = 2(\delta_x\delta_x xx + \delta_x x\delta_x x + \delta_x xx\delta_x + x\delta_x\delta_x x + x\delta_x x\delta_x + xx\delta_x\delta_x).$$

One can easily show that the second directional derivative of a symmetric noncommutative rational functions has the form

$$\begin{aligned} D^2F(x)\left[\delta_x, \delta_x\right] = \operatorname{sym}\Bigg\{ & \sum_{j=1}^{w_1} m_j \delta_x n_j \delta_x t_j \\ & + \sum_{j=1+w_1}^{w_2} m_j {\delta_x}^T n_j \delta_x t_j + \sum_{j=1+w_2}^{w_3} m_j \delta_x n_j {\delta_x}^T t_j \Bigg\}. \end{aligned} \tag{4.3}$$

For $r(x)$ given by $r(x_1, x_2) = (1 + x_1 - (3 + x_2)^{-1})^{-1}$, we have

$$Dr(x)[\delta_{x_1}] = -(1 + x_1 - (3 + x_2)^{-1})^{-1}\delta_{x_1}(1 + x_1 - (3 + x_2)^{-1})^{-1}$$

and

$$\begin{aligned} D^2r(x)\left[\delta_{x_1}, \delta_{x_1}\right] = 2(1 + x_1 - (3 + x_2)^{-1})^{-1} \cdots \\ \delta_{x_1}(1 + x_1 - (3 + x_2)^{-1})^{-1}\delta_{x_1}(1 + x_1 - (3 + x_2)^{-1})^{-1}. \end{aligned}$$

4.4.1. Symbolic NC differentiator algorithm. Derivatives of rational expressions can be defined recursively from the following rules:

1. If $r(x)$ is a polynomial, use the standard formula.
2. The product rule is, if $r(x) = r_1(x)r_2(x)$, then $Dr(x)[\delta_x] = Dr_1(x)[\delta_x]r_2(x) + r_1(x)Dr_2(x)[\delta_x]$.
3. The sum rule is, if $r(x) = r_1(x) + r_2(x)$, then $Dr(x)[\delta_x] = Dr_1(x)[\delta_x] + Dr_2(x)[\delta_x]$.
4. If $r(x)$ is the inverse $r(x) = f^{-1}(x)$ of an NC rational expression satisfying $f(0) \neq 0$, then $Dr(x)[\delta_x] := -f^{-1}(x)Df(x)[\delta_x]f^{-1}(x)$.

Our differentiation algorithm applies these rules (in a natural order) to an NC rational expression $r(x)$ and gives a new NC rational expression $Dr(x)[\delta_x]$, the directional derivative of the rational expression $r(x)$ in direction δ_x. Similarly, there are the natural formulas for the second directional derivative $D^2r(x)\left[\delta_x, \delta_x\right]$, for sums products and inverses. Our algorithm uses these recursively to compute our symbolic Hessian of $r(x)$.

4.5. Matrix convex functions. It will be shown that the definition just presented for the Hessian of a symmetric noncommutative rational function F is the key to determine the region of convexity for F. Therefore, it is the main ingredient of our NCConvexityRegion algorithm. There are several (almost equivalent) notions of noncommutative convexity; thus we define matrix convex functions as it is the definition used throughout the paper. For formal definitions, a detailed presentation, and an substantial theory behind the algorithm, see [5].

Let us suppose that F is the symmetric noncommutative rational function to be analyzed. Say F is a function of the noncommutative variables $x_1, \ldots, x_k$. Then, the function F is said to be matrix convex with respect to the variables $x_1, \ldots, x_k$ on a certain domain $\mathcal{G}$ provided its Hessian, denoted by $D^2F(X_1, \ldots, X_k)[\delta_{X_1}^2, \ldots, \delta_{X_k}^2]$, is a positive semidefinite matrix for all $X_1, \ldots, X_k$ in[3] $\mathcal{G}$ and all $\delta_{X_1}, \ldots, \delta_{X_k}$.

It is known (cf. [5]) that if $\mathcal{G}$ is a convex set, then this definition is equivalent to the usual notion of convexity, the geometrically matrix convex functions, which states that

$$F(\alpha X + (1-\alpha)Y) \leq \alpha F(X) + (1-\alpha)F(Y)$$

with $X := \{X_1, \ldots, X_k\}$ and $Y := \{Y_1, \ldots, Y_k\}$ tuples of matrices of compatible dimensions, and $0 \leq \alpha \leq 1$ a scalar. Of course, $\mathcal{G}$ might have separate components; then one often can focus on the component of primary interest with convexity on that component alone.

5. How the convexity checker algorithm works. With these notions of convexity, we now briefly introduce the algorithm underlying the command

NCConvexityRegion$[F, \{x\}]$

that provides a region $\mathcal{G}$ on which $F(X)$ is matrix convex. The main steps of the algorithm are as follows:

1. The second directional derivative with respect to $x_1, \ldots, x_k$, called the Hessian $D^2F[\delta_x, \delta_x]$ of the function F, is computed.
2. As the Hessian is always a quadratic function of the δ_x directions, it can be associated with a symmetric matrix $M_{D^2F[\delta_x, \delta_x]}$ with entries which are NC rational functions of x but not δ_x.
3. The noncommutative LDL$^{\mathrm{T}}$ factorization is applied to the coefficient matrix $M_{D^2F[\delta_x, \delta_x]}$.
4. And finally specifying positive definiteness of the resulting diagonal matrix $D(x_1, \ldots, x_k)$ gives inequalities describing a region $\mathcal{G}$ of variables on which F is matrix convex.
5. If a linear independence condition which is usually true holds and if the region $\mathcal{G}$ is nonempty for matrices of large enough size, then the closure of $\mathcal{G}$ is the largest domain on which $D^2F[\delta_x, \delta_x]$ is positive semidefinite. (See [5] for details on this rather complicated fact.)

Our implementation assumes that each pivot in the LDL$^{\mathrm{T}}$ decomposition is invertible. Possibly the most informative thing that could be done briefly is to give a simple example, presented in [5].

Example 5.1. Define the function $F(x)$ by

$$F(x) = g^T x^T a x g + x^T b x + g^T x^T c x + x^T c^T x g,$$

where $b = b^T$ and $a = a^T$.

[3] More precisely, for all X in the set $\mathcal{G}$ that intersect the domain of the rational function F.

1. The Hessian of $F(x)$ is given by
$$D^2F(X)\,[\delta_x,\delta_x] = 2({\delta_x}^T b\delta_x + {\delta_x}^T c^T\delta_x G + g^T{\delta_x}^T a\delta_x g + g^T{\delta_x}^T c\delta_x).$$
2. Equivalently, this quadratic expression takes the form
$$D^2F(X)\,[\delta_x,\delta_x] = V[\delta_x]^T M_{D^2F} V[\delta_x] = 2({\delta_x}^T, g^T{\delta_x}^T)\begin{pmatrix} b & c^T \\ c & a \end{pmatrix}\begin{pmatrix}\delta_x \\ \delta_x g\end{pmatrix}.$$
3. The LDL$^{\mathrm{T}}$ decomposition with no permutation applied to M_{D^2F} is
$$\begin{pmatrix} 1 & 0 \\ cb^{-1} & 1 \end{pmatrix}\begin{pmatrix} b & 0 \\ 0 & a - cb^{-1}c^T \end{pmatrix}\begin{pmatrix} 1 & b^{-1}c^T \\ 0 & 1 \end{pmatrix},$$
provided that b is invertible.[4]
4. Therefore, when b is invertible, sufficient conditions for the Hessian to be positive semidefinite are
$$b > 0 \quad \text{and} \quad a - cb^{-1}c^T > 0.$$
5. If the Hessian is "positive," then for large enough dimension, a, b, c are in the closure of the set described in step 4.

A finer property of our algorithm (and implementation) is that it includes the possibility of permutations. Thus, if we know that a (instead of b) in the example above is invertible, then a permutation can be applied before applying the LDL$^{\mathrm{T}}$ decomposition. This makes **NCConvexityRegion[]** somewhat delicate. In practice, the runs will finish with some choices of permutation and not with others. Also, the expressions that appear in the outputs from successful runs using different permutations can be different; however, the theory behind NCConvexityRegion tells us that the sets they describe are all the same.

Example 5.2. Let $p(x)$ be given by $p(x) = a^Tx^2b + b^Tx^2a$ with $x = x^T$. Its Hessian is $a^T{\delta_x}^2b + b^T{\delta_x}^2a$. Represent this as v^TMv with
$$v^T := \begin{pmatrix} a^T\delta_x & b^T\delta_x \end{pmatrix} \quad \text{and} \quad M = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$
whose eigenvalues are 1 and -1. Thus, we conclude from steps 4 and 5 that (for large enough n) there is no set $\mathcal{G}$ of matrices a and b, open in the set of pairs of $n \times n$ matrices, on which the Hessian is positive definite.

A related example is $p(x) = a^Tx^2a + a^Tx^2a$. Its Hessian is $a^T{\delta_x}^2a + a^T{\delta_x}^2a$; the representation above still works with $v^T := (a^T\delta_x, a^T\delta_x)$. However, the linear independence condition of step 4 on $v^T := (a^T\delta_x, a^T\delta_x)$ does not hold, that is, the condition $a^T\delta_x$ and $a^T\delta_x$ are linearly independent fails, and thus no definitive conclusion is possible. Another (more natural) representation is $a^T{\delta_x}^2a + a^T{\delta_x}^2a = 2a^T\delta_x 1\delta_x a$, that is, M is the 1×1 matrix 1. Thus step 4 implies, the Hessian of $p(x)$ is everywhere positive; note that in this case, linear independence holds. NCConvexityRegion does the later not the former calculation.

Our convexity region algorithm was new with [5], where it is described in detail, together with the proofs of its properties. The guarantee it produces for the nonnegativity of the NC Hessian (as in step 4) is straightforward to prove, while the converse (as in step 5) is quite surprising and not at all easy to prove.

[4]The list returned by **NCConvexityRegion** is $\{b, \quad a - cb^{-1}c^T\}$.

5.1. Noncommutativity is essential. A great advantage of our framework is that treating matrices as single letters is likely the only practical necessary and sufficient approach available for checking convexity of rational functions on matrices of large dimension. For a commutative rational function F, one might imagine a Parrilo type of sum of squares algorithm [22], which could affirm positivity of the Hessian of F, and thus convexity of F. Unfortunately, it would be practical with only a few dozen variables. If the unknown X and Y were symmetric matrices on even a 10-dimensional state-space, the entrywise representation would give about 100 commuting variables. This is prohibitive. On the other hand, our convexity checking method is insensitive to the dimension of the state-space.

6. Convex optimization over matrix functions. In this paper, the presentation of the numerical NCSDP optimization solver for matrix functions is limited to the single variable case. The extension to the multivariate case, found in [4], follows similar ideas, but it is too long to present here. This solver is based on an implementation of the method of centers.

There are in the literature few papers on solving nonlinear matrix inequalities. In [15], the authors presented and analyzed a numerical interior point trust region algorithm that can be used for solving a class of nonlinear (nonconvex) semidefinite programming problem. For MI problems that concern the minimization of the largest eigenvalue of a matrix (this is a convex but highly nonsmooth problem), the work by [21, 16] is a good source. See [1, 26, 6, 27, 28, 29] for general SDP problems and [3] for a comprehensive introduction to convex optimization.

The main distinctions between these approaches and ours is that our method focus on unknowns which themselves are treated as matrices. In our research, we deal with the entire matrix structure instead of dealing with the individual entries of the matrix unknowns. Also, the user does not need to calculate first and second derivatives by hand, since this is done automatically in our method.

The outline of our method is as follows. We compute the first and second derivatives of a potential function noncommutatively (symbolically) in a way that keeps the matrix structure and does not split up the matrices (see section 4.4). This step provides the Hessian map $\mathcal{H}(\delta_x)$ and the gradient map $\mathcal{Q}$. It is this step whose efficiency is improved by our MinimumSylvesterIndex algorithm for symbolically obtaining an efficient form for $\mathcal{H}(\delta_x)$ (this is described in section 8). After this, our algorithm turns numerical (by substituting matrices for the indeterminate that appears in the expressions for $\mathcal{H}(\delta_x)$ and $\mathcal{Q}$) and the code aims to solve the respective numerical linear system of equations $\mathbb{H}(\delta_X) = \mathbb{Q}$ in the direction δ_X. We find that the numerical linear subproblem has an elegant form, and it is an interesting open question how to fully exploit this form. We numerically solve this linear system for δ_X in a conventional way. The method successively iterates, at the numerical level, until the algorithm converges to an optimal solution.

As described above, one needs to compute derivatives of an auxiliary potential function. The formula for this potential function depends on which member of the family of penalty/barrier methods one wishes to adhere to. The approach we have selected is known as the *analytic method of centers*. Before describing this method in section 6.2, we characterize the optimization problem we are interested in section 6.1.

6.1. Constrained optimization problem. Throughout the paper, we shall be primarily concerned with the convex optimization problem

$$\text{(COP)} \qquad f^{\text{opt}} = \min \{\text{Tr}\,\{X\} \,:\, X \in \text{closure}(\mathcal{G})\}$$

with the feasibility domain $\mathcal{G}$ given by

$$\mathcal{G} = \Big\{ X \in \mathcal{V} \,:\, F(X) > 0 \Big\},$$

where we assume the closure of $\mathcal{G}$ is compact, the set $\mathcal{V}$ is a subspace of $\mathbb{R}^{p\times q}$, and $F : \mathcal{V} \to \mathbb{S}^n$ is a concave function. This type of problem incorporates the eigenvalue minimization problem as a particular case.

6.2. Review of the method of centers. The idea behind the method of centers ([2, 19] and references therein) is to replace the above constrained problem by a sequence of unconstrained minimization problems whose solutions eventually tend to the set of optimal solutions of (COP). This occurs in the context of *interior penalty methods*. It follows therefore, that under certain hypotheses, the original problem (COP) can be approximated by a sequence of unconstrained convex optimization problems of the form

$$X^*(\gamma) = \operatorname{argmin} \{ \phi_\gamma(X) \,:\, X \in \mathcal{G}_\gamma \} \tag{UOP}$$

with the auxiliary potential function $\phi_\gamma : \mathcal{G}_\gamma \to \mathbb{R}$ given by

$$\phi_\gamma(X) = \zeta \log \left(1/(\gamma - \operatorname{Tr}\{X\})\right) - \log\det F(X),$$

where ζ is a scalar satisfying $\zeta \geq 1$ and $\mathcal{G}_\gamma$ is the domain given by

$$\mathcal{G}_\gamma = \Big\{ X \in \mathcal{G} \,:\, \operatorname{Tr}\{X\} < \gamma \Big\}.$$

The decrease of the parameter γ has to be done in such a way that the method maintains feasibility at each iteration and that the sequence $\{\gamma^k\}$ is guaranteed to converge to f^{opt} (the minimum values of the objective function). The formula for updating γ at some iteration k is given by

$$\gamma^{k+1} = (1-\theta)\operatorname{Tr}\left\{X^k\right\} + \theta\gamma^k, \quad 0 < \theta < 1, \tag{6.1}$$

where X^k denotes $X^*(\gamma^k)$. Under mild conditions, the solution $X^*(\gamma)$ of (UOP) approaches the set of optimal solutions of (COP) for an appropriate sequence of decreasing centralization parameter γ (see [2, 7, 19]).

Using these facts, one possible algorithm based on the method of centers can be described by the following algorithm.

Algorithm 6.1. Method of centers.
Fix θ such that $0 < \theta < 1$;
Choose X^0 and γ^0 such that $X^0 \in \mathcal{G}_{\gamma^0}$;
$k \leftarrow 0$;
while not converged **do**
  $\gamma^{k+1} \leftarrow (1-\theta)\operatorname{Tr}\left\{X^k\right\} + \theta\gamma^k$;
  $X^{k+1} \leftarrow \operatorname{argmin}\left\{\phi_{\gamma^{k+1}}(X^k) \,:\, X^k \in \mathcal{G}_{\gamma^{k+1}}\right\}$;
  $k \leftarrow k+1$;
end while

There are some important comments concerning this algorithm:

1. The bound γ^{k+1} from (6.1), used in the determination of the analytic center of the potential $\phi_{\gamma^{k+1}}(X^k)$, never produces infeasible starting points X^k, γ^{k+1}.

2. It will be necessary to find feasible starting points X^0 and γ^0 to be used in Algorithm 6.1. This is a *feasibility problem* that can be solved by the same method of centers.
3. Evidently, the expensive part of the algorithm is the *inner loop*, the part that computes the *analytic center*.

6.3. An algorithm to solve the inner loop. This section sketches briefly a standard algorithm to solve the inner loop. The algorithm implemented in the NCSDP code to find the analytic center

$$X^{k+1} = \operatorname{argmin} \left\{ \phi_\gamma(X^k) \,:\, X^k \in \mathcal{G}_\gamma \right\}$$

for fixed scalar γ is based on a conventional modified Newton's method [19, 3, 20], as follows:

while not converged **do**
$X^{k+1} \leftarrow X^k + \sigma {\delta_X}^k$;
end while

where ${\delta_X}^k$ is the Newton direction (see section 7.1). The step length used in this algorithm [19] is given by

$$\sigma = \begin{cases} 1/(1+\tau) & \text{if } \tau > 1/4, \\ 1 & \text{otherwise} \end{cases}$$

for $\tau = \sqrt{g^T H^{-1} g}$ with g and H, respectively, the gradient and the Hessian of $\phi_\gamma(X^k)$. The stopping criteria used in our experiments was, stop as soon as $\sigma = 1$. In practice Newton's method works better with a line search instead of the above fixed step length. Certainly, we shall consider implementing a line search in a more elaborate version of the code.

7. Solving for the analytic center. In sections 7.1, 7.2, and 7.3 we discuss in depth the linear subproblem that provides the update direction δ_X, which is the core of the modified Newton's algorithm presented in section 6.3. Therefore, in these sections we show how to exploit the matrix structure of the unknowns to find an elegant formula for the linear subproblem.

7.1. Describing the main steps. The original convex optimization problem (COP) has now been replaced by a sequence of unconstrained convex minimization problems of the form (UOP) for a decreasing sequence of scalars $\{\gamma^k\}$ provided by formula (6.1). To find the update directions which lead toward the central path for fixed values of γ, Newton's method is applied by minimizing an approximation, the second-order Taylor series expansion, of the potential function $\phi_\gamma(X)$. In a vague sense, these procedures can be summarized as follows:

1. Compute symbolically the second-order Taylor expansion of the potential function $\phi_\gamma(x + \delta_x)$ in some direction δ_x

$$\phi_\gamma(x) + D\phi_\gamma(x)\,[\delta_x] + \frac{1}{2} D^2\phi_\gamma(x)\,[\delta_x, \delta_x]\,.$$

2. The Newton step ${\delta_x}^*$ must satisfy the necessary optimality conditions for the following quadratic minimization problem:

$$\min_{\delta_x} \; D\phi_\gamma(x)\,[\delta_x] + \frac{1}{2} D^2\phi_\gamma(x)\,[\delta_x, \delta_x]\,.$$

3. This first-order necessary optimality condition is algebraically[5] given by

$$0 = D\left[D\phi_\gamma(x)\,[\delta_x] + \frac{1}{2}D^2\phi_\gamma(x)\,[\delta_x,\delta_x]\right]\Big[\delta_v\Big] \quad \text{for all symmetric } \delta_v. \tag{7.1}$$

Which will be shown (in Theorem 7.1) to be equivalently[6] written as

$$\mathrm{Tr}\left\{\delta_v(\mathcal{H}(\delta_x)-\mathcal{Q})^T + (\mathcal{H}(\delta_x)-\mathcal{Q}){\delta_v}^T\right\} = 0 \quad \text{for all symmetric } \delta_v. \tag{7.2}$$

4. Finally, find a Newton update ${\delta_X}^*$ satisfying (7.1) or (7.2) for all δ_v.

Section 7.2 concerns steps 1 through 3, which are performed symbolically. On the other hand, step 4, presented in section 7.3, is completely numerical.

7.2. Obtaining the formulas for the linear subproblem. The main ingredient of our approach is how we use symbolic computation to determine the algebraic linear system of equations that provides the update direction δ_X toward the central paths. At the outset of this work, it was not obvious that we could find a clean symbolic formula for the linear subproblem which treated both known and unknown matrices as a whole and did not break them into entries. Fortunately, this is possible, as the next theorem shows.

THEOREM 7.1. *Let $\mathcal{V}$ be a subspace of $\mathbb{R}^{p\times q}$, and let the map $F : \mathcal{V} \to \mathbb{S}$ be concave. Consider the unconstrained auxiliary potential function $\phi_\gamma : \mathcal{G}_\gamma \to \mathbb{R}$ given by*

$$\phi_\gamma(X) = \zeta \log\Big(1/(\gamma - \mathrm{Tr}\,\{X\})\Big) - \log\det F(X),$$

where ζ is a scalar satisfying $\zeta \geq 1$ and the feasibility domains $\mathcal{G}$ and $\mathcal{G}_\gamma$ are respectively given by

$$\mathcal{G} = \Big\{X \in \mathcal{V} \,:\, F(X) > 0\Big\} \quad \textit{and} \quad \mathcal{G}_\gamma = \Big\{X \in \mathcal{G} \,:\, \mathrm{Tr}\,\{X\} < \gamma\Big\},$$

where we assume the closure of $\mathcal{G}$ is compact. Then, the update direction ${\delta_X}^*$ toward the central path for the above potential is the solution of the following symbolically[7] computable algebraic linear equation:

$$\mathrm{Tr}\left\{\delta_v(\mathcal{H}(\delta_x)-\mathcal{Q})^T + (\mathcal{H}(\delta_x)-\mathcal{Q}){\delta_v}^T\right\} = 0 \quad \textit{for all } \delta_v \in \mathcal{V}, \tag{7.3}$$

where $\mathcal{H}(\delta_x)$ is linear as regarded as a function of δ_x. Moreover, $\mathcal{Q}$ and $\mathcal{H}(\delta_x)$ are given by

$$\mathcal{Q} = \sum_{i=1}^{k} a_i^T F(x)^{-1} b_i^T - \frac{1}{2}\zeta\,(\gamma - \mathrm{Tr}\,\{x\})^{-1}\,\mathfrak{I}_d$$

[5] Assuming that all x belong to some space $\mathcal{V}$, then $\delta_x, \delta_v \in \mathcal{V}$. Cf. footnotes 6, 7.

[6] When we say $\mathrm{Tr}\,\{x\}$, we mean that the operation $\mathrm{Tr}\,\{\}$ is to be performed after x has been replaced by a matrix. Cf. footnote 7.

[7] When we say $\delta_v \in \mathcal{V}$, we mean that we will substitute matrices in $\mathcal{V}$ for the indeterminate δ_v. The same is true for $\mathrm{Tr}\,\{x\}$. Cf. footnote 6.

and

$$\begin{aligned}\mathcal{H}(\delta_x) = &\sum_{i=1}^{k}\sum_{j=1}^{k} a_i^T F(x)^{-1} a_j \delta_x b_j F(x)^{-1} b_i^T + \sum_{i=1}^{k}\sum_{j=1}^{k} a_i^T F(x)^{-1} b_j^T \delta_x^T a_j^T F(x)^{-1} b_i^T \\ &- \frac{1}{2}\sum_{j=1}^{w_1} n_j^T \delta_x^T m_j^T F(x)^{-1} t_j^T + m_j^T F(x)^{-1} t_j^T \delta_x^T n_j^T \\ &- \frac{1}{2}\sum_{j=1+w_1}^{w_2} n_j \delta_x t_j F(x)^{-1} m_j + n_j^T \delta_x m_j^T F(x)^{-1} t_j^T \\ &- \frac{1}{2}\sum_{j=1+w_2}^{w_3} t_j F(x)^{-1} m_j \delta_x n_j + m_j^T F(x)^{-1} t_j^T \delta_x n_j^T \\ &+ \frac{1}{2}\zeta \left(\gamma - \operatorname{Tr}\{x\}\right)^{-2} \operatorname{Tr}\{\delta_x\}\, \mathfrak{I}_d,\end{aligned}$$

where the terms a_i, b_i, m_i, n_i, t_i are obtained from the first and second directional derivatives of $F(x)$ as given by (4.2) *and* (4.3). *The term $\mathfrak{I}_d$ stands for the symbolic analogue of the identity matrix.*

Proof. The theorem follows from manipulations of (7.1). For a detailed presentation see [4]. □

The result of Theorem 7.1, the algebraic linear equation (7.3), can be further specialized depending upon the structure of the underlying subspace $\mathcal{V}$; in other words, if there is or is not some restriction imposed on X. Specifying various structures for the underlying subspace $\mathcal{V}$ is the subject of Corollary 7.2 which is the main result of this section.

COROLLARY 7.2. *Let $\mathcal{V}$ be a subspace of $\mathbb{R}^{p\times q}$ and $\mathcal{C}$ be a convex domain in $\mathcal{V}$. Let the map $F : \mathcal{C} \to \mathbb{S}$ be concave. Consider the unconstrained auxiliary potential function $\phi_\gamma : \mathcal{G}_\gamma \to \mathbb{R}$ given by*

$$\phi_\gamma(X) = \zeta \log\Big(1/(\gamma - \operatorname{Tr}\{X\})\Big) - \log\det F(X),$$

where ζ is a scalar satisfying $\zeta \geq 1$ and the feasibility domains $\mathcal{G}$ and $\mathcal{G}_\gamma$ are respectively given by

$$\mathcal{G} = \Big\{X \in \mathcal{C} \subset \mathcal{V} \,:\, F(X) > 0\Big\} \quad \textit{and} \quad \mathcal{G}_\gamma = \Big\{X \in \mathcal{G} \,:\, \operatorname{Tr}\{X\} < \gamma\Big\}.$$

Then, depending upon the structure of the underlying subspace $\mathcal{V}$, the update direction $\delta_x{}^*$ toward the central path for the above potential is the solution of one of the following symbolically computable algebraic linear equations:

1. *The subspace $\mathcal{V}$ equals $\mathbb{R}^{p\times q}$ so that the unknown X can be any matrix in $\mathbb{R}^{p\times q}$:*

$$\sum_{i=1}^{c_1} \mathfrak{a}_i \delta_x \mathfrak{b}_i + \sum_{j=c_1+1}^{c_2} \mathfrak{a}_j \delta_x^T \mathfrak{b}_j + \varrho \operatorname{Tr}\{\delta_x\} = \mathfrak{Q}.$$

2. *The subspace $\mathcal{V}$ equals $\mathbb{S}^p$ so that the unknown X is restricted to being symmetric:*

$$\sum_{i=1}^{c_2} \mathfrak{b}_i^T \delta_x \mathfrak{a}_i^T + \mathfrak{a}_i \delta_x \mathfrak{b}_i + \varrho \operatorname{Tr}\{\delta_x\} = \mathfrak{Q} + \mathfrak{Q}^T.$$

3. *The unknown X is restricted to being a scalar multiple of the identity, that is, $X = \sigma I$, for some scalar σ:*

$$\mathrm{Tr}\left\{\sum_{i=1}^{c_2} \mathfrak{a}_i \mathfrak{b}_i + \varrho \mathrm{Tr}\left\{\mathfrak{I}_d\right\}\right\} \delta_\sigma = \mathrm{Tr}\left\{\mathfrak{Q}\right\}, \qquad \delta_x = \delta_\sigma \mathfrak{I}_d, \quad \delta_\sigma \in \mathbb{R}.$$

For these expressions, $\mathfrak{Q}$ is the gradient term given by

$$\mathfrak{Q} = \sum_{i=1}^{k} a_i^T F(x)^{-1} b_i^T - \frac{1}{2}\zeta \left(\gamma - \mathrm{Tr}\left\{x\right\}\right)^{-1} \mathfrak{I}_d.$$

The term ϱ is the cost term given by $\varrho = \frac{1}{2}\zeta(\gamma - \mathrm{Tr}\left\{x\right\})^{-2}\mathfrak{I}_d$. And, by an appropriate relabeling, the terms $\mathfrak{a}_i$ and $\mathfrak{b}_i$ are obtained from the Hessian map $\mathcal{H}(\delta_x)$ presented in Theorem 7.1*.*

Proof. The corollary follows from Theorem 7.1 by expressing the linear system of equations (7.3) considering the structure of the underlying subspace $\mathcal{V}$. (See [4].) ∎

The above results provide the necessary conditions that the update δ_X must satisfy in order to be a Newton direction toward the central path of the unconstrained auxiliary potential function $\phi_\gamma(X)$.

We provide a tutorial example in appendix A to illustrate Theorem 7.1 and Corollary 7.2 and to give an idea of how they are proved.

7.3. Solving the linear subproblem. The algebraic linear subproblem[8] provided in Corollary 7.2 always has the form

$$\sum_{i}^{N} \mathfrak{a}_i \delta_x \mathfrak{b}_i + \varrho\, \mathrm{Tr}\left\{\delta_x\right\} = \bar{\mathfrak{Q}}, \tag{7.4}$$

where the $\mathfrak{a}_i$, $\mathfrak{b}_i$, and $\bar{\mathfrak{Q}}$ are rational functions of the known noncommutative variables given in the problem formulation and δ_x is the unknown variable (the update direction). The notation $\mathfrak{a}_i, \mathfrak{b}_i$ stands for symbolic Sylvester terms, and the notation $\mathcal{A}_i, \mathcal{B}_i$ will indicate we have substituted matrices of compatible size for the symbolic variables in $\mathfrak{a}_i, \mathfrak{b}_i$.

The integer N has been called the Sylvester index in [14]. A key point is that the same linear system can have several representations of the form (7.4), that is, the representation of the Hessian map $\mathcal{H}(\delta_x)$ in Theorem 7.1 is not unique. We will see later in section 8 that there is a substantial advantage to obtaining a representation with a small Sylvester index.

There are two main costs in treating the linear subproblem (7.4):

FE: evaluating the matrices $\mathfrak{a}_i$, $\mathfrak{b}_i$, and $\bar{\mathfrak{Q}}$ at each iteration, that is, converting them from symbols to numeric matrices whose entries are numbers is time-consuming (see section 8);

NLS: solving numerically the resulting linear system for δ_X.

[8] (a) Depending upon the structure of the underlying subspace $\mathcal{V}$, the term $\bar{\mathfrak{Q}}$ will be either $\bar{\mathfrak{Q}} = \mathfrak{Q}$ or $\bar{\mathfrak{Q}} = \mathfrak{Q} + \mathfrak{Q}^T$. (b) The third case in Corollary 7.2 behaves in a similar way, so we do not go through it.

After the evaluation step FE has been performed, we rewrite the linear subproblem (7.4) as

$$\sum_{i}^{N} \mathcal{A}_i \delta_X \mathcal{B}_i + \varrho \operatorname{Tr}\{\delta_X\} = \mathbb{Q}, \tag{7.5}$$

indicating that the indeterminate have already been substituted by matrices of compatible dimension. Then, using the vec operation (see [12]), the matrix system (7.5) can be transformed into the equivalent vector form

$$Hv = g, \tag{7.6}$$

where H is the Hessian matrix given by

$$H = \sum_{i}^{N} \mathcal{B}_i^T \otimes \mathcal{A}_i + \operatorname{vec}(\varrho)\operatorname{vec}(I)^T,$$

where the vector g is given by $g = \operatorname{vec}(\mathbb{Q})$, and v is the vector of unknowns given by $v = \operatorname{vec}(\delta_X)$. The symbol $\otimes$ denotes the Kronecker product.

Therefore, the cost of numerically solving the linear subproblem can be split into two distinct costs:

KP: applying Kronecker products to build the Hessian matrix H;

LS: numerically solving $Hv = g$ for the unknown vector v.

The above "brute force" procedure does not take advantage of the particular structure of $\mathcal{H}(\delta_x)$. Of course, Lyapunov equations are very special cases for which there are extremely fast algorithms (see [9, 14]). Naturally, an open question highly motivated by this research is how one uses this special Sylvester structure to solve efficiently (7.5).

Iterative methods are attractive for solving Sylvester-type linear equations. Related to this is [13] and references therein. However, in our paper, we do not investigate numerical linear solvers special to Sylvester forms. It is a separate topic and our focus was on our new noncommutative symbolic methodology. Consequently, we just used our brute force Kronecker product approach since it is reliable. However, in order to speed up the implementation of our linear solver, we plan a careful study of iterative methods like conjugate gradient in a separate project.

8. Improving the evaluation time for the linear subproblem. In this section, we illustrate by examples that for a system of linear equations, the Sylvester form (7.4) is not unique. Moreover, we show that the Sylvester index has a great influence on the evaluation cost given in Step FE of section 7.3.

Consider an expression in the Sylvester form

$$\mathcal{H}(\delta_x) = a\delta_x a^T + x^T\delta_x x + b\delta_x b^T - a\delta_x x - x^T\delta_x a^T + b\delta_x a^T + a\delta_x b^T. \tag{8.1}$$

The Sylvester index in this case is seven. This expression can be written in at least two different ways, having the same number of terms. One possibility is

$$\mathcal{H}(\delta_x) = (a - x^T)\delta_x(a - x^T)^T + (a + b)\delta_x(a + b)^T - a\delta_x a^T = \sum_{i=1}^{N=3} \mathfrak{a}_i \delta_x \mathfrak{b}_i$$

for $\mathfrak{a}_i$ and $\mathfrak{b}_i$ given by

$$\begin{aligned} \mathfrak{a}_1 &= (a - x^T), \qquad \mathfrak{a}_2 = (a + b), \qquad \mathfrak{a}_3 = -a, \\ \mathfrak{b}_1 &= (a - x^T)^T, \quad \mathfrak{b}_2 = (a + b)^T, \quad \mathfrak{b}_3 = a^T. \end{aligned}$$

Another one is

$$\mathcal{H}(\delta_x) = (a + b - x^T)\delta_x(a + b - x^T)^T + b\delta_x x + x^T\delta_x b^T = \sum_{i=1}^{N=3} \mathfrak{a}_i\delta_x\mathfrak{b}_i$$

for $\mathfrak{a}_i$ and $\mathfrak{b}_i$ given by

$$\begin{aligned} \mathfrak{a}_1 &= (a + b - x^T), \qquad \mathfrak{a}_2 = b, \qquad \mathfrak{a}_3 = x^T, \\ \mathfrak{b}_1 &= (a + b - x^T)^T, \quad \mathfrak{b}_2 = x, \qquad \mathfrak{b}_3 = b^T. \end{aligned}$$

In both cases, the Sylvester index is now three, going down by over one half. Thus, for a given Hessian map $\mathcal{H}(\delta_x)$, the Sylvester index is not unique. Moreover, the $\mathcal{H}(\delta_x)$ may have different representations for a specific Sylvester index (as illustrated above). It is also easy to see that a significant reduction in the Sylvester index might happen for an expression which contains a large number of Sylvester terms. Based on those ideas, a few natural questions can be formulated:

1. Given an expression for the Hessian map $\mathcal{H}(\delta_x)$, what is the minimum Sylvester index associated with this expression?
2. Is there a symbolic algorithm to compute a minimum Sylvester index representation?
3. How many different expressions which achieve this minimal Sylvester index are possible?
4. Does the evaluation time in Step FE vary substantially for small versus large Sylvester index N?

This section addresses the first two questions. We describe preliminarily a symbolic algorithm which is fast and which often reduces the Sylvester index N dramatically. Later, we describe a more powerful (but slower) symbolic algorithm which gives the minimal Sylvester index when the coefficients $\mathfrak{a}_j$ and $\mathfrak{b}_j$ are polynomials. For our problems, the coefficients are not polynomials, but this algorithm applies with no restrictions. However, we can no longer guarantee that we obtain the minimal Sylvester index.

As to question 4, we have found through examples (see section 8.3.1) that the overall computational time spent on numerically solving an optimization problem using our NCSDP code dramatically reduces when the Sylvester index of the Hessian map $\mathcal{H}(\delta_x)$ is reduced by one of these two algorithms. However, we should consider the time consumed at the symbolic level by the algorithm itself. We found that the first algorithm to be presented is faster than the second algorithm. (The second provides the minimal Sylvester index).

8.1. A Sylvester index reducing algorithm. We now describe our first Sylvester index reducing algorithm, which is denoted by

NCCollectSylvester[exp, var].

The implementation used in our NCSDP optimization code is a command that sequentially applies two commands, called NCRightSylvester[] and NCLeftSylvester[], to the expression. These two "sided" commands have analogous implementation,

which uses a pattern match that collects similar terms on the right (respectively, on the left) side of the expression. We now present the idea behind these commands.

ALGORITHM 8.1 (NCRIGHTSYLVESTER ALGORITHM).

1. IDENTIFY THE TERMS IN WHICH THE EXPRESSION SHOULD BE COLLECTED. In the example given by expression (8.1), this term is δ_x.
2. BUILD A RIGHT LIST. This list contains the terms that multiplies δ_x from the right side (including δ_x itself). For the expression (8.1), we would obtain
$$\text{RightList} = \{\delta_x a^T,\ \delta_x x,\ \delta_x b^T\}.$$
3. BUILD A COLLECTLIST. For each element inside RightList, we add together all the terms that multiply this element from the left side. For our example we obtain
$$\text{CollectList} = \{(a + b - x^T),\ (x^T - a),\ (a + b)\}.$$
4. COMBINE THE COLLECTLIST AND THE RIGHTLIST. This gives the answer. For our example it is
$$\mathcal{H}(\delta_x) = (a + b - x^T)\delta_x a^T + (x^T - a)\delta_x x + (a + b)\delta_x b^T.$$

The above right-sided implementation of the collecting algorithm begins by building a list of multipliers from the right side of δ_x. Clearly, a similar implementation can also be done by obtaining a left list of terms that multiplies δ_x from the left side, instead of the right side. In this way, we can implement two collect commands that differ only by the side in which the process of collecting begins; thus, we can have an **NCRightSylvester[]** command (described above) and an **NCLeftSylvester[]** command. As already mentioned, our implementation encompasses these two commands into a single command

NCCollectSylvester[exp, var]
:= NCRightSylvester[NCLeftSylvester[exp, vars], vars].

These algorithms, when applied to an expression in the Sylvester form, in practice provide a large reduction on the Sylvester index. However, these algorithms do not guarantee that one can obtain the lowest possible Sylvester index. On the other hand, in the next section, we provide an algorithm which under some hypothesis provides the lowest possible Sylvester index.

8.2. The minimum Sylvester index algorithm. Consider a function $L(\delta)$ of a noncommutative variable δ in the Sylvester form

$$L(\delta) := \sum_{j=1}^{N} \mathfrak{a}_j \, \delta \, \mathfrak{b}_j,$$

with the terms $\mathfrak{a}_j$ and $\mathfrak{b}_j$ polynomials in noncommutative variables. The algorithm proposed in this section has property that if the $\mathfrak{a}_j$ and $\mathfrak{b}_j$ are restricted to be polynomials, then it always gives the lowest possible Sylvester index. This fact is presented in Theorem 8.3. We now present the steps of the algorithm and give an example. For

this purpose, consider the following expression:

$$\begin{aligned}(8.2)\quad L(\delta) &= (xb+axb)\,\delta\,(-2axb+bxb)+(xb+axb)\,\delta\,(xb-axb+bxb)\\ &-(xb+axb)\,\delta\,(xb-axb+2xax)+(xb+axb)\,\delta\,(xb-2axb+bxb+xax)\\ &+(c-xb-bxb+xax)\,\delta\,(-axb+xax)+(c+axb-bxb+xax)\,\delta\,(xb+xax)\\ &+(c+xb+2axb-bxb+xax)\,\delta\,(2xb+bxb).\end{aligned}$$

The Sylvester index associated with this expression is $N = 7$. Using our algorithm, we will see that the minimum Sylvester index is $N^* = 2$.

Algorithm 8.2 (MinimumSylvesterIndex Algorithm).

1. Identify the terms in which the expression should be collected. In the example given by expression (8.2), this term is δ.
2. Build a right list. This list contains the terms that multiplies δ from the right side in $L(\delta)$. Denote this list by $\mathfrak{b}$. For our example, this list is

$$\begin{aligned}\mathfrak{b} = \{&(-2axb+bxb),\ (xb-axb+bxb),\ (xb-axb+2xax),\\ &(xb-2axb+bxb+xax),\ (-axb+xax),\ (xb+xax),\ (2xb+bxb)\}.\end{aligned}$$

3. Build a monomial list. This list contains the terms that appears in $\mathfrak{b}$. This list, denoted by $\mathfrak{m}$, contains only monomial that are linearly independents:

$$\mathfrak{m} = \{xb,\ axb,\ bxb,\ xax\}.$$

4. Find a matrix G such that $\mathfrak{b} = G\mathfrak{m}$. For our example, G is given by

$$G^T = \begin{bmatrix} 1 & 0 & 1 & 1 & 0 & 1 & 2\\ -1 & -2 & -1 & -2 & -1 & 0 & 0\\ 0 & 1 & 1 & 1 & 0 & 0 & 1\\ 2 & 0 & 0 & 1 & 1 & 1 & 0 \end{bmatrix}.$$

5. Build a left list. This list contains the terms that multiplies δ from the left side in $L(\delta)$. Denote this list by $\mathfrak{a}$:

$$\begin{aligned}\mathfrak{a} = \{&(xb+axb),\ (xb+axb),\ (xb+axb),\ -(xb+axb),\\ &(c-xb-bxb+xax),\ (c+axb-bxb+xax),\ (c+xb+2axb-bxb+xax)\}.\end{aligned}$$

6. The expression $L(\delta)$ can now be rewritten as

$$L(\delta) = \sum_{j=1}^{4} \mathfrak{c}_j\,\delta\,\mathfrak{m}_j$$

with $\mathfrak{c} = G^T\mathfrak{a}$ given by

$$\begin{aligned}\mathfrak{c} = \{&3(c+xb+2axb-bxb+xax),\ (-c-3xb-4axb+bxb-xax),\\ &(c+4xb+5axb-bxb+xax),\ 2(c-xb-bxb+xax)\}.\end{aligned}$$

7. Build a monomial list from $\mathfrak{c}$. For the above example:

$$\bar{\mathfrak{m}} = \{c,\ xb,\ axb,\ bxb,\ xax\}.$$

8. Find a transformation matrix $\bar{G}$ such that $\mathfrak{c} = \bar{G}\bar{\mathfrak{m}}$:

$$\bar{G} = \begin{bmatrix} 3 & 3 & 6 & -3 & 3 \\ -1 & -3 & -4 & 1 & -1 \\ 1 & 4 & 5 & -1 & 1 \\ 2 & -2 & 0 & -2 & 2 \end{bmatrix}.$$

9. Decompose matrix $\bar{G}$ as $\bar{G} = QR$, with Q and R full rank matrices:

$$Q^T = \frac{1}{5}\begin{bmatrix} 15 & -5 & 5 & 10 \\ 3 & -11 & 16 & -18 \end{bmatrix}, \quad R = \frac{1}{5}\begin{bmatrix} 5 & 4 & 9 & -5 & 5 \\ 0 & 5 & 5 & 0 & 0 \end{bmatrix}.$$

10. The minimal Sylvester index N^* is the rank of $\bar{G}$. Thus, the final expression is

$$L(\delta) = \sum_j^{N^*} [R\bar{\mathfrak{m}}]_j \, \delta \, [Q^T \mathfrak{m}]_j \,. \tag{8.3}$$

For our example (8.2), the result is

$$L(\delta) = \frac{1}{5}(5\,c + 4\,xb + 9\,axb - 5\,bxb + 5\,xax)\,\delta\,(3\,xb - axb + bxb + 2\,xax) + \frac{1}{5}(xb + axb)\,\delta\,(3\,xb - 11\,axb + 16\,bxb - 18\,xax)$$

with the minimum Sylvester index guaranteed to be $N^* = 2$.

The implementation of our **MinimumSylvesterIndex**$[L(\delta)$**,** $\delta]$ command is described by these steps. When the original expression $L(\delta)$ contains a large number of Sylvester terms, the time spent on generating the matrix G in step 4 might be long. However, we emphasize that the expression $L(\delta)$ provided in step 6 can alternatively be provided by **NCRightSylvester[],** which is significantly faster than steps 1 through 6. In fact, this is how the MinimumSylvesterIndex command was implemented.

Theorem 8.3. *Provided that the $\mathfrak{a}_j$ and $\mathfrak{b}_j$ are polynomials, the lowest Sylvester index for $L(\delta)$ is given by N^*, which is the dimension of the span of $\mathfrak{c}_j$ for $j = 1, \ldots, d_{\mathfrak{b}}$, i.e., the rank of $\bar{G}$.*

Proof. This theorem follows immediately from Lemmas 8.4 and 8.6. □

Lemma 8.4. *The representation* (8.3) *produced by the MinimumSylvesterIndex algorithm has the property that the polynomials $[R\bar{\mathfrak{m}}]_1, \ldots, [R\bar{\mathfrak{m}}]_{N^*}$ are linearly independent and that the polynomials $[Q^T\mathfrak{m}]_1, \ldots, [Q^T\mathfrak{m}]_{N^*}$ are also linearly independent.*

Proof. Since the vectors $\mathfrak{m}_j$ are linearly independent and Q has full rank, the vectors $[Q^T\mathfrak{m}]_j$ for $j = 1, \ldots, N^*$ are linearly independent. Similarly, since the vectors $\bar{\mathfrak{m}}_j$ are linearly independent and R has full rank, the vectors $[R\bar{\mathfrak{m}}]_j$ for $j = 1, \ldots, N^*$ are linearly independent. □

Definition 8.5. *We call a dependence free Sylvester representation any Sylvester expression $L(\delta) = \sum \mathfrak{a}_j \, \delta \, \mathfrak{b}_j$ with $\mathfrak{a}_j$ linearly independent and $\mathfrak{b}_j$ also linearly independent.*

Lemma 8.6. *Let $L(\delta)$ and $\widetilde{L}(\delta)$ be Sylvester representations such that*

$$L(\delta) := \sum_{j=1}^{N} \mathfrak{a}_j \, \delta \, \mathfrak{b}_j = \sum_{k=1}^{\widetilde{N}} \widetilde{\mathfrak{a}}_k \, \delta \, \widetilde{\mathfrak{b}}_k =: \widetilde{L}(\delta).$$

If the polynomials $\mathfrak{a}_j$ are linearly independent, and if the polynomials $\mathfrak{b}_j$ are linearly independent, then for each $k = 1, \ldots, \widetilde{N}$ we have

$$\mathfrak{a}_j \in \operatorname{span}\{\widetilde{\mathfrak{a}}_k\}_1^{\widetilde{N}} \qquad \textit{and} \qquad \mathfrak{b}_j \in \operatorname{span}\left\{\widetilde{\mathfrak{b}}_k\right\}_1^{\widetilde{N}}.$$

Consequently $N \leq \widetilde{N}$, and if $\widetilde{L}(\delta)$ is also a dependence free Sylvester representation, then their Sylvester indexes are the same, $\widetilde{N} = N$.

Proof. Let β denote the maximum of the degrees of all of the polynomials $\mathfrak{a}_j, \mathfrak{b}_j, \widetilde{\mathfrak{a}}_k, \widetilde{\mathfrak{b}}_k$ for $j = 1, \ldots, N$ and $k = 1, \ldots, \widetilde{N}$. Let $\mathcal{P}(y)$ denote the space of all polynomials of degree less than or equal to β in $y = \{y_1, \ldots, y_g\}$. Let $\mathcal{P}(y)\delta$ denote all polynomials in the variables $\{y_1, y_2, \ldots, y_g, \delta\}$ of the form $p(y)\delta$ for $p \in \mathcal{P}(y)$. Since $\{\mathfrak{b}_j\}$ for $j = 1, \ldots, N$ is a linearly independent subset of the finite dimensional vector space $\mathcal{P}(y)$, there is an inner product $(\ ,\ )$ defined on $\mathcal{P}(y)$ satisfying

$$(\mathfrak{b}_i, \mathfrak{b}_j) = \begin{cases} 0, & i \neq j, \\ 1, & i = j\,. \end{cases} \tag{8.4}$$

For each $p \in \mathcal{P}(y)$, let us define a map $E : \mathcal{P}(y) \to \mathcal{P}(y)\delta$ for any Sylvester form by

$$E(L(\delta), p) := \sum_{j=1}^{N} \mathfrak{a}_j\, \delta\, (\mathfrak{b}_j, p) = \sum_{j=1}^{N} (\mathfrak{b}_j, p)\mathfrak{a}_j\, \delta\,.$$

With this notation, for each $\ell \leq N$ we obtain

$$E(L(\delta), \mathfrak{b}_\ell) = \sum_{j=1}^{N} \mathfrak{a}_j\, \delta\, (\mathfrak{b}_j, \mathfrak{b}_\ell) = \mathfrak{a}_\ell\, \delta\,.$$

Since $L(\delta) = \widetilde{L}(\delta)$ we have

$$E(L(\delta), \mathfrak{b}_\ell) = E(\widetilde{L}(\delta), \mathfrak{b}_\ell) \longrightarrow \mathfrak{a}_\ell\, \delta = \sum_{k=1}^{\widetilde{N}} (\widetilde{\mathfrak{b}}_k, \mathfrak{b}_\ell)\widetilde{\mathfrak{a}}_k\, \delta\,.$$

Thus, the polynomial $\mathfrak{a}_\ell$ is a linear combination of the polynomials $\widetilde{\mathfrak{a}}_k$, i.e., $\mathfrak{a}_\ell \in \operatorname{span}\{\widetilde{\mathfrak{a}}_k\}$. In a similar way, we can define an inner product $(\mathfrak{a}_i, \mathfrak{a}_j)$ satisfying property (8.4) and apply it to $L(\delta)$ to obtain that $\mathfrak{b}_\ell \in \operatorname{span}\{\widetilde{\mathfrak{b}}_k\}$. ∎

8.2.1. Rational coefficients. We have presented an algorithm which has the property that if the $\mathfrak{a}_j$ and $\mathfrak{b}_j$ are polynomials, then it always gives the lowest possible Sylvester index. However, in our optimization application the $\mathfrak{a}_j$ and $\mathfrak{b}_j$ may be rational functions. Thus, we shall describe how one can extend the algorithm to rational functions rather than polynomials.

The conceptual idea is to think of inverses of expressions as new variables, say, w_j. Then any rational expression is a polynomial in the original variables together with the new letters w_j. In this way, one can apply directly the Sylvester index minimizing algorithm. As an example, suppose that $L(\delta)$ is given by

$$L(\delta) = x(1-x)^{-1}\,\delta\, x - (1-x)^{-1}\,\delta\, x + \delta\, x. \tag{8.5}$$

Using the change of variable

$$w = (1-x)^{-1} \tag{8.6}$$

this expression can be written as

$$L(\delta) = xw\delta x - w\delta x + \delta x.$$

Now, one can apply the MinimumSylvesterIndex command to obtain

$$L(\delta) = (xw - w + 1)\delta x.$$

In this way, the Sylvester index for $L(\delta)$ was reduced to $N = 1$.

That is how the MinimumSylvesterIndex command is used in NCSDP. Unpleasantly, the algorithm did not take into account the "side relationships" that w_j and the other variables might satisfy, which for the above example is

$$(1 - x)^{-1} \equiv x(1 - x)^{-1} + 1$$

or in terms of w

$$xw - w + 1 = 0.$$

Consequently $L(\delta)$ is identically zero. Thus, our algorithm when applied to rational functions fails to produce a minimal Sylvester representation.

To some extent, we are not optimistic about finding a practical exact algorithm for $L(\delta)$ having rational coefficients, because noncommutative Gröbner basis algorithms are very time-consuming. However, we are looking into more empirical methods. One effective test for linear dependence is as follows. Suppose that

$$L(\delta) = \sum_{j=1}^{N} \mathfrak{a}_j \delta \mathfrak{b}_j$$

has already been reduced with the command MinimumSylvesterIndex. Then we replace the symbols appearing in the expressions for $\mathfrak{a}_j$ and for $\mathfrak{b}_j$ by matrices of large dimensions generated randomly. In this way, we obtain random large matrices $\mathcal{A}_j$ and $\mathcal{B}_j$. After, we build numerically the matrices A and B as follows:

$$A = \begin{bmatrix} \operatorname{vec}(\mathcal{A}_1) & \operatorname{vec}(\mathcal{A}_2) & \cdots & \operatorname{vec}(\mathcal{A}_N) \end{bmatrix},$$
$$B = \begin{bmatrix} \operatorname{vec}(\mathcal{B}_1) & \operatorname{vec}(\mathcal{B}_2) & \cdots & \operatorname{vec}(\mathcal{B}_N) \end{bmatrix}.$$

Naturally, N is the number of columns of A and B. Denoting by r_A the rank of the matrix A (respectively, r_B for the rank of B), then the minimum Sylvester index for $L(\delta)$ will be $\min(r_A, r_B)$. If the $\mathcal{A}_j$ and $\mathcal{B}_j$ are polynomials, then we know that r_A and r_B remains N. However, when the $\mathcal{A}_j$ and $\mathcal{B}_j$ are rational functions rather than polynomial, this might not be the case, as described by the example (8.5).

An optimization problem will be presented in section 8.3.1 in which the Sylvester index of the Hessian map is $N = 1043$. After applying the MinimumSylvesterIndex command, the Sylvester index was reduced to $N = 26$. However, $N = 26$ is not the lowest possible index for this Hessian map. When we apply the empirical procedure just described, we found that $r_A = 22$ and $r_B = 22$. Therefore, we know that the minimum Sylvester index is less than or equal to $N = 22$. An empirical algorithm along these lines for actually computing the dependences is under investigation.

Remark 8.7. Another step is taken in order to improve the overall timing, and it is not related to the idea of simplifying expressions by collecting terms, but it is valuable. At the symbolic level we look for inverses of matrices which appear repeatedly inside the symbolic expressions for the Hessian map and we replace each occurrence of an inverse by a new variable. In this way, all numerical inverses are evaluated only once at the beginning of the linear subproblem. This can considerably improve the overall run times.

8.3. Experiments with MinimumSylvesterIndex. The previous examples were presented to illustrate methods for reducing the Sylvester index. Now, we present numerical evidence validating the usefulness of these ideas. For this purpose, let us consider the following eigenvalue minimization problem, whose numerical behavior is to be presented in section 9:

$$\text{(P2)} \qquad \begin{array}{l} \inf \lambda_{\max}(CXC^T) \\ \text{subject to} \end{array}$$
$$0 < X,$$
$$0 < G(X) := A_3X + XA_3^T - XR_3^{-1}X + S_3,$$
$$0 < F(X) := A_1X + XA_1^T - XR_1^{-1}X + S_1 - (A_2^TX + XA_2)G(X)^{-1}(A_2^TX + XA_2)$$

with all the matrices having dimension $n \times n$.

As already described, we need to compute symbolically the Hessian and the gradient of an auxiliary potential function. For the above example, this potential function is given by the symbolic formula

$$\phi_\gamma(x) = -\log\det x - \log\det F(x) - \log\det G(x) - \log\det(\gamma\mathfrak{I}_d - cxc^T),$$

where $\mathfrak{I}_d$ stand for the symbolic analogue of the identity matrix and γ is a scalar which is not relevant here. The expression $\phi_\gamma(x)$ is a function of the unknown x. If the update direction is taken to be δ_x, the Hessian map $\mathcal{H}(\delta_x)$ as a function of δ_x will have a structure of the form

$$\mathcal{H}(\delta_x) = \sum_i^N \mathfrak{a}_i\delta_x\mathfrak{b}_i,$$

where the $\mathfrak{a}_i$ and $\mathfrak{b}_i$ are noncommutative rational functions of the variables c, a_1, a_2, a_3, r_1, r_3, s_1, s_3, x. At this stage, one can apply the MinimumSylvesterIndex command to reduce the Sylvester index N. The gradient map $\mathcal{Q}$ is obtained from the first directional derivative of $\phi_\gamma(x)$ along the direction δ_x. Thus, for this symmetric case, one obtains a "symbolic" system given by

$$\mathcal{H}(\delta_x) = \mathcal{Q} + \mathcal{Q}^T. \tag{8.7}$$

The next step is to substitute for matrices of compatible dimensions the symbols appearing in $\mathcal{H}(\delta_x)$ and $\mathcal{Q}$. Thus, the code becomes numerical, and to find numerically the update direction δ_X, we must be able to solve the linear system of equations given by

$$\mathbb{H}(\delta_X) = \mathbb{Q} + \mathbb{Q}^T.$$

Using the vec operation, the above system can be equivalently written as

$$Hv = g, \tag{8.8}$$

where $H = \sum_i^N \mathcal{B}_i^T \otimes \mathcal{A}_i$, $g = \mathrm{vec}(\mathbb{Q} + \mathbb{Q}^T)$, and $v = \mathrm{vec}(\delta_X)$.

Therefore, in order to solve numerically the linear system given in (8.7), one needs

FE: to substitute matrices for the symbols appearing in $\mathcal{H}(\delta_x)$ and $\mathcal{Q}$;
KP: to evaluate the Hessian matrix H by applying N Kronecker products;
LS: to solve the system $Hv = g$ for the update direction v.

TABLE 8.1
Timing (seconds): formulas evaluation, Kronecker products, and linear solver.

SIZE	16			32			64		
	MSI	CS	UNT	MSI	CS	UNT	MSI	CS	UNT
FE	0.071	0.096	0.409	0.258	0.287	1.09	1.47	1.74	6.1
KP	0.039	0.061	1.341	0.603	0.974	21.47	9.74	15.71	344.3
LS	0.029	0.028	0.029	0.397	0.410	0.41	9.65	9.87	9.8
TOT	0.139	0.185	1.779	1.258	1.671	22.96	20.85	27.31	360.1

Ratio	UNT / MSI	UNT / MSI	UNT / MSI
FE	5.8	4.2	4.1
KP	34.4	35.6	35.3
TOT	12.8	18.3	17.3

The first two steps, namely, FE (formula evaluations) and KP (Kronecker products), are the two main steps where reducing the Sylvester index N of the expression for $\mathcal{H}(\delta_x)$ can significantly affect the evaluation time. We do not show the formulas for $\mathcal{H}(\delta_x)$ and $\mathcal{Q}$, since these expressions are quite large and would consume several pages. What is important is the fact that the formula for $\mathcal{H}(\delta_x)$ as computed originally, before applying any simplification rule, has $N = 1014$ Sylvester terms. However, after applying the NCCollectSylvester command to the original expression, the Sylvester index decreases to $N = 43$, and after applying our MinimumSylvesterIndex command to the original expression, we obtain the index $N = 26$ for this Hessian.

8.3.1. Time saved by applying MinimumSylvesterIndex. To find out how much time is actually saved at the numerical level, the NCSDP code is executed using the collected formulas for $\mathcal{H}(\delta_x)$ with $N = 26$ (MinimumSylvesterIndex command) and with $N = 43$ (NCCollectSylvester command) and the not collected formula for $\mathcal{H}(\delta_x)$ with $N = 1014$. For this set of experiments, the size n of the matrices involved assume the values $n = 16, 32, 64$. For each case, we execute the inner loop where the linear system (8.8) is numerically solved 20 times. Thus, we measure the CPU time per call (average over 20 iterations) spent on the above items, FE, KP, and LS (linear solver). In this way, we can analyze how the time spent on formula evaluations behaves as a function of the size of the matrices involved in the expressions, as well as the Sylvester index N.

The results are presented in Table 8.1, where MSI stands for the Hessian simplified by MinimumSylvesterIndex (the Sylvester index is $N = 26$), CS stands for the Hessian simplified by NCCollectSylvester (the Sylvester index is $N = 43$), and UNT stands for the untreated Hessian (the Sylvester index is $N = 1014$). In this table, the row labeled Ratio is the ratio between the untreated column and the MSI column. The time spent on solving the linear system, presented in the row labeled LS, is not affected by the expression being or not being collected. SIZE stands for matrix size, and TOT for the total time FE+KP+LS.

The results provided in Table 8.1 show that collecting terms in the expression for the Hessian map $\mathcal{H}(\delta_x)$ represents a huge saving, since the average time spent on substituting matrices for the symbols that appear in the expressions for the $\mathfrak{a}_i$ and $\mathfrak{b}_i$ when the expressions are not collected (UNT case) is approximately four to five times longer than the time for the MSI collected case (row FE in Ratio). Moreover, collecting the expressions significantly improved the time spent on evaluating Kronecker products, as seen from row KP under Ratio, where this timing improved by a factor ranging from 34.4 to 35.6.

For matrices of dimension 16 and 32, the time per call spent (over 20 iterations) on numerically solving the equation $Hv = g$ for the unknown v was relatively small, as seen from row LS. On the other hand, for matrices of dimension 64, the (LS) cost becomes significantly large. To understand this fact better, suppose the dimension of the matrices involved is chosen to be $n = 64$. Thus, the symmetric unknown matrix X having size 64×64 implies that the unknown vector v and the system to be solved will have size approximately $64^2/2 = 2048$.

Kronecker products are also extremely expensive, as seen from row KP for size 64. In fact, if we did not have a theory for decreasing the Sylvester index, our approach using Kronecker products would be intractable for matrices of large dimensions. If one could solve the linear system of equations for δ_X in its original structured form $\mathbb{H}(\delta_X) = \mathbb{Q}$, without applying Kronecker products and keeping the dimension of the linear system low, a huge saving on the numerical linear solver would probably be attained. This is an open area which we hope members of the community will pursue.

8.4. Some more experiments using MinimumSylvesterIndex. Another interesting experiment is to analyze how the Sylvester index behaves by applying our MinimumSylvesterIndex command to a variety of matrix inequalities which appear in control design. The example just presented, taken from section 9, has shown a great improvement since the Sylvester index reduced from $N = 1014$ to $N = 26$. Now, we present two more examples.

Example 8.8. For the standard Riccati inequality

$$AX + XA^T - XRX + S > 0$$

the Hessian map $\mathcal{H}(\delta_x)$ for the untreated case has a Sylvester index of $N = 20$, while our MinimumSylvesterIndex algorithm applied to it provides a Sylvester index of $N = 4$.

Example 8.9. Now, a more realistic example is used: a mixed H_2/H_∞ control problem

$$\text{(P3)} \qquad \begin{array}{l} \inf \operatorname{Tr}\{W\} \\ \text{subject to} \\ \qquad\qquad 0 < X, \\ \qquad 0 < W - (C_2X + D_{2u}F)X^{-1}(C_2X + D_{2u}F)^T, \\ 0 > AX + XA^T + B_uF + F^TB_u^T + B_wB_w^T \\ \qquad + \left[XC_1^T + F^TD_{1u}^T + B_wD_{1w}^T\right] R^{-1} \left[XC_1^T + F^TD_{1u}^T + B_wD_{1w}^T\right]^T \end{array}$$

with $R = \eta^2 I - D_{1w}D_{1w}^T > 0$.

For the above control problem, there are three unknowns denoted by $W = W^T$, $X = X^T$, and F (not symmetric). Thus, the linear subproblem to be solved will have dimension 3×3, and consequently each entry on this system will contain a Sylvester operator. For instance, the (1,1) entry will be an expression of the form

$$\sum_i^{N_{11}} \mathfrak{a}_i^{11} \delta_w \mathfrak{b}_i^{11} + \sum_i^{\hat{N}_{11}} \hat{\mathfrak{a}}_i^{11} {\delta_w}^T \hat{\mathfrak{b}}_i^{11}.$$

The (1,2) entry will have the form $\sum_i^{N_{12}} \mathfrak{a}_i^{12} \delta_x \mathfrak{b}_i^{12} + \sum_i^{\hat{N}_{12}} \hat{\mathfrak{a}}_i^{12} \delta_x^T \hat{\mathfrak{b}}_i^{12}$. The (1,3) entry will have the form $\sum_i^{N_{13}} \mathfrak{a}_i^{13} \delta_f \mathfrak{b}_i^{13} + \sum_i^{\hat{N}_{13}} \hat{\mathfrak{a}}_i^{13} \delta_f^T \hat{\mathfrak{b}}_i^{13}$. The (2,1) entry is the adjoint case

TABLE 8.2
Sylvester index N and $\hat{N}$ for the MSI Hessian $\mathcal{H}(\delta_w, \delta_x, \delta_f)$.

	Sylv. index N_{ij}			Sylv. index $\hat{N}_{ij}$		
i,j	1	2	3	1	2	3
1	1	2	1	0	0	1
2	2	10	4	0	0	4
3	1	4	2	1	4	4

TABLE 8.3
Sylvester index N and $\hat{N}$ for the UNT Hessian $\mathcal{H}(\delta_w, \delta_x, \delta_f)$.

	Sylv. index N_{ij}			Sylv. index $\hat{N}_{ij}$		
i,j	1	2	3	1	2	3
1	1	2	2	0	0	2
2	2	73	38	0	0	38
3	2	38	42	2	38	38

of the (1,2) entry. The (2,2) entry will have the form $\sum_i^{N_{22}} \mathfrak{a}_i^{22} \delta_x \mathfrak{b}_i^{22} + \sum_i^{\hat{N}_{22}} \hat{\mathfrak{a}}_i^{22} \delta_x^T \hat{\mathfrak{b}}_i^{22}$ and so forth. It should be noticed that the Sylvester index $\hat{N}_{11}$, $\hat{N}_{12}$, $\hat{N}_{21}$, and $\hat{N}_{22}$ are zero, since the corresponding variables w and x are symmetric.

For the matrix inequalities given in problem (P3), the set of Sylvester indexes N and $\hat{N}$ for the Hessian map $\mathcal{H}(\delta_w, \delta_x, \delta_f)$ simplified by MinimumSylvesterIndex (MSI case) and for the untreated Hessian (UNT case) are respectively presented in Table 8.2 and Table 8.3.

In Tables 8.2 and 8.3, the variables x and f are associated with the entries

$$\text{(i,j)} \in \{(2,2) \quad (2,3) \quad (3,2) \quad (3,3)\}$$

for each one of the subtables. If we only pay attention to the Sylvester index N, we see that the submatrix associated with x and f for the

UNT case $\begin{array}{|c|c|}\hline 73 & 38 \\ \hline 38 & 42 \\ \hline \end{array}$ reduces to only $\begin{array}{|c|c|}\hline 10 & 4 \\ \hline 4 & 2 \\ \hline \end{array}$ in the MSI case.

Similarly, a large reduction is also obtained for the Sylvester index $\hat{N}$. Thus, for the variables x and f, we found that a large reduction on the Sylvester index N and $\hat{N}$ are obtained after applying our MinimumSylvesterIndex command. Naturally, this will represent a considerable saving on the evaluation time for the numerical linear solver.

It is also true that the process of simplifying rational functions, at the symbolic level of Mathematica, can consume a considerable amount of time. However, this computation is performed only once at the beginning of the run. This is in contrast with the numerical part, where solving the linear system to provide the update direction takes place at each inner iteration (which occurs several times). Therefore, the ability to collect factors in an expression (decreasing the Sylvester index) plays a very important role.

9. Numerical experiment: Timing of NCSDP. In this section, our NCSDP code is numerically compared to some available semidefinite programming solvers.

TABLE 9.1
Total CPU time in seconds.

	Matrix Size			
	8	16	32	64
SDPT3	2.59	12.94	163.77	3132.68
LMI-Lab	0.43	2.58	66.03	2124.54
SeDuMi	0.79	2.20	33.63	1254.30
NCSDP	7.73	12.57	81.40	1224.49

TABLE 9.2
CPU time per iteration in seconds.

	Matrix Size					
	16		32		64	
	CPI	IT	CPI	IT	CPI	IT
SDPT3	1.62	8	18.20	9	348.08	9
SeDuMi	0.20	11	2.59	13	89.59	14
NCSDP	0.60	21	4.28	19	72.03	17

For this purpose, the optimization problem to be used is the following eigenvalue minimization problem (stated earlier in section 8.3.1):

$$\text{(P2)} \qquad \begin{array}{l} \inf \lambda_{\max}(CXC^T) \\ \text{subject to} \\ \qquad 10^{-1}I < X, \\ \qquad 0 < G(X) := A_3X + XA_3^T - XR_3^{-1}X + S_3, \\ 0 < F(X) := A_1X + XA_1^T - XR_1^{-1}X + S_1 - (A_2^TX + XA_2)G(X)^{-1}(A_2^TX + XA_2). \end{array}$$

The matrices C, A_1, A_2, and A_3 belong to $\mathbb{R}^{n\times n}$, the invertible matrices R_1, R_3 belong to $\mathbb{S}^n_{++}$ and the matrices S_1, S_3, and X belong to $\mathbb{S}^n$. We do not present the numerical values of those matrices since it would take considerable space. Note that by Schur complement techniques problem (P2) can be equivalently restated as an LMI problem.

The results of this experiment (shown in Table 9.1) show the overall CPU time spent by the solvers SDPT3, LMI-Lab, SeDuMi, and NCSDP to solve the above optimization problem (P2) within the required accuracy of 10^{-4} for the objective value. The LMI-Lab toolbox (Version 1.0.8) is based on the projective method of [8]. The SeDuMi solver (Version 1.02) from [25] implements the self-dual embedding technique for optimization over self-dual homogeneous cones. The SDPT3 solver (Version 3.0) from [28] implements an infeasible path-following algorithm that employs a predictor-corrector method. The starting feasible points were the same for all the solvers.

From Table 9.1, one sees that for matrices of size 64, the solvers SeDuMi and NCSDP were the fastest code for the eigenvalue minimization problem (P2). The CPU times per iteration (CPI) and number of (outer) iterations (IT) are presented in Table 9.2. We believe that NCSDP might be significantly faster than SeDuMi for matrices of dimensions larger than 64×64. However, we did not run this experiment

TABLE 9.3
Numerical behavior of NCSDP.

SIZE	IT/NeNe	FE	KP	LS	g	$\lambda_{\min}(H)$	$\lambda_{\max}(H)$
8	25/94	2.32	0.07	0.14	$1.14E+04$	$6.74E+03$	$2.59E+10$
16	21/75	3.05	2.88	2.16	$8.94E+03$	$1.62E+03$	$2.41E+10$
32	19/69	8.24	41.9	26.7	$7.38E+03$	$1.14E+03$	$2.24E+10$
64	17/61	43.4	595	580	$5.84E+03$	$9.81E+02$	$2.76E+10$

since the overall elapsed time would be extremely long and because of the requirement of large RAM memory availability. The computer used for our experiments was an Intel Celeron at 2800 MHz CPU clock, 512MB of RAM, 1GB of swap, running Linux (kernel 2.4.20-31.9), MATLAB Version 6.5.0 R13, Mathematica 4.0, and NCAlgebra Version 3.7.

We believe our NCSDP code, even in its raw stage, has been competitive mainly because it allows nonlinear matrix inequalities, so it avoids the increase in dimensions when converting to LMIs using Schur complements. Also, we think that the techniques in the paper allow the numerical Newton equations to be derived more efficiently. However, we did not take advantage of the special structure of the linear subproblem when solving it.

For these experiments, we installed the codes listed above using their default installer. However, since these codes are for general SDP problems, where the input data should be expressed in a "standard" SDP form, which is not the standard LMI form (like the input from LMILab), we make use of the package LMILab Translator (LMITrans) that translates from LMILab form to the SeDuMi and SDPT3 form. The timing presented in Table 9.1 did not incorporate the (modest amount of) time consumed by this interface.

We do not know if LMITrans does nearly the "optimal" conversion for each solver; this adds uncertainty to the experiments. It might be the case that there exists an optimal conversion for a particular solver, in this case, the solver would perform better than for the default options used in LMITrans. However, we also used YALMIP as a front-end for SeDuMi and SDPT3 at the suggestion of a referee after the paper was complete. In a few tests, we found that it did not affect the timings significantly: the timing was approximately the same as the timing obtained using LMITrans.

9.1. Numerical behavior of NCSDP. We now provide the numerical details of the results from NCSDP presented in Table 9.1. The trade-off between the number of inner iterations, NeNe, and the number of outer iterations, Iter (as seen from Table 9.3), is a characteristic of Barrier methods, in particular, the method of centers [2], and depends mainly on the centralization parameter θ, given in (6.1) from section 6.2. In practice, a smaller θ induces a higher number of inner iterations, NeNe. For all the experiments, θ was set to $\theta = 0.2$.

For matrices of small size, the most expensive part is the time spent on evaluating the Sylvester terms $\mathfrak{a}_i$, $\mathfrak{b}_i$, and $\mathcal{Q}$, presented in column FE. However, when the size of the matrices increases above 8, the time spent on Kronecker products, column KP, and the time spent on solving the linear system, column LS, begins to dominate.

In Table 9.3, the column g stands for the gradient, and columns $\lambda_{\min}(H)$ and $\lambda_{\max}(H)$ stand, respectively, for the minimum and the maximum eigenvalues of the

Hessian matrix H at the optimum. Those values show that the condition number of the Hessian is large at the optimal solution. This ill-conditioning in the Hessian is a well-known fact for classical barrier methods [30, 18], where it has been shown that this behavior is highly influenced by the set of constraints that are or are not active (binding) at the solution. However, it is not an immediate task to determine the set of active constraints in the semidefinite programming framework.

9.2. Implementation speed-ups. At this stage, the numeric part of our NCSDP code is "completely" implemented using MATLAB functions (not compiled). The only compiled part of our code is the Kronecker product, since the MATLAB function *kron.m* was extremely slow for our needs. On the other hand, most of the other solvers have their core subroutines written in either Fortran or C, which significantly improve their overall performance.

To make the experiment transparent, the stopping criteria for the inner loop in NCSDP is kept constant throughout all the iterations. We stop as soon as $\sigma = 1$ (see section 6.3). Changing dynamically this stopping criteria might also improve the timing of the solver.

Although in this paper we have focused on convex optimization problems over matrix inequalities, the extension of our numerical ideas to finding local solutions in nonconvex situations is immediate; however, reliability has not been tested [4].

We reiterate that fast methods for solving numerical linear equations of Sylvester form have not been investigated and are the main open question motivated by this paper. A big advance here would translate directly into a big reduction in run times.

Appendix A. Illustrating our methodology by an example. In this section we explain the ideas behind Theorem 7.1 and Corollary 7.2 through a simple optimization problem. The extrapolation to a more general case is straightforward, but it gives messy formulas. Let us consider the optimization problem

$$\min \{\mathrm{Tr}\,\{X\} \,:\, X \in \mathrm{closure}(\mathcal{G})\} \tag{A.1}$$

with $F(X) := AX + XA^T - XRX + Q$, and the domain $\mathcal{G}$ given by

$$\mathcal{G} = \{X \in \mathbb{S}^n \,:\, F(X) > 0\}\,.$$

We assume (1) all matrices have dimension $n \times n$; (2) the matrices X, R, Q are symmetric; (3) the closure of the set $\mathcal{G}$ is compact.

A.1. Describing the central path. Let us define the unconstrained auxiliary potential function $\phi_\gamma(X)$ as described in Theorem 7.1 as

$$\phi_\gamma(X) = \zeta \log\Big(1/(\gamma - \mathrm{Tr}\,\{X\})\Big) - \log\det F(X). \tag{A.2}$$

The analytic center for the potential $\phi_\gamma(X)$ is the path given by

$$X^*(\gamma^k) = \mathrm{argmin}\,\phi_{\gamma^k}(X). \tag{A.3}$$

A.2. Solving for the analytic center. The above optimization problem (A.1) has now been replaced by a sequence of unconstrained minimization problems in the form (A.3). In this way, we are interested in finding update directions which lead toward the central path of (A.3). To find those directions, Newton's method is applied to minimize the second-order Taylor series expansion of the potential function $\phi(x)$.

These procedures are summarized in section 7.1. Here, we go through each step precisely. For clarity of notation, we omit the subscript γ in $\phi_\gamma(x)$. To compute the quadratic approximation of $\phi(x)$, we take δ_x to be the update direction for x. Thus, assuming $x^* = x + \delta_x$, the series expansion of $\phi(x)$ up to the second term is given by

$$\tilde{\phi}(\delta_x) := \phi(x^*) - \phi(x) = D\phi(x)\,[\delta_x] + \frac{1}{2}D^2\phi(x)\,[\delta_x, \delta_x]\,. \tag{A.4}$$

A.3. Directional eerivatives of $F(x)$. In order to compute the derivatives in (A.4), we need to have at hand the first and second directional derivatives of $F(x)$. Recalling that x is symmetric, and therefore so is the update direction δ_x, the first directional derivative of $F(x)$ in the direction δ_x is given by

$$DF(x)\,[\delta_x] = (a - xr)\delta_x + \delta_x(a^T - rx) = \operatorname{sym}\{(a - xr)\delta_x\}$$

and the second directional derivative is

$$D^2F(x)\,[\delta_x, \delta_x] = -\operatorname{sym}\{\delta_x r \delta_x\}$$

A.4. Connection with Theorem 7.1. Comparing the above derivatives of $F(x)$ with the formulas (4.2) and (4.3), one readily verifies that $k = 1$, $a_1 = (a - xr)$, and $b_1 = 1$, for the first directional derivative, and that $w_1 = 1, w_2 = 0, w_3 = 0$, $m_1 = 1$, $n_1 = -r$, and $t_1 = 1$, for the second directional derivative. With this notation, we can directly apply Theorem 7.1 to obtain the algebraic linear system of equations. For the gradient term $\mathcal{Q}$ we have

$$\begin{aligned}\mathcal{Q} &= \sum_{i=1}^{k} a_i^T F(x)^{-1} b_i^T - \frac{1}{2}\zeta\,(\gamma - \operatorname{Tr}\{x\})^{-1}\,\mathfrak{I}_d \\ &= (a - xr)^T F(x)^{-1} - \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-1}\mathfrak{I}_d.\end{aligned}$$

For the Hessian $\mathcal{H}(\delta_x)$ we calculate

1. $\sum_{i=1}^{k}\sum_{j=1}^{k} a_i^T F(x)^{-1} a_j \delta_x b_j F(x)^{-1} b_i^T = (a - xr)^T F(x)^{-1}(a - xr)\delta_x F(x)^{-1}$;
2. $\sum_{i=1}^{k}\sum_{j=1}^{k} a_i^T F(x)^{-1} b_j^T \delta_x^T a_j^T F(x)^{-1} b_i^T = (a - xr)^T F(x)^{-1}\delta_x(a - xr)F(x)^{-1}$;
3. $-\sum_{j=1}^{w_1} n_j^T \delta_x^T m_j^T F(x)^{-1} t_j^T + m_j^T F(x)^{-1} t_j^T \delta_x^T n_j^T = r\delta_x F(x)^{-1} + F(x)^{-1}\delta_x r$.

Thus $\mathcal{H}(\delta_x)$ becomes

$$\begin{aligned}\mathcal{H}(\delta_x) = {} & \frac{1}{2}F(x)^{-1}\delta_x r + \frac{1}{2}r\delta_x F(x)^{-1} + (a - xr)^T F(x)^{-1}(a - xr)\delta_x F(x)^{-1} \\ & + (a - xr)^T F(x)^{-1}\delta_x(a - xr)^T F(x)^{-1} + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-2}\operatorname{Tr}\{\delta_x\}\,\mathfrak{I}_d.\end{aligned}$$

Consequently, the algebraic linear system of equations is described by

$$\operatorname{Tr}\left\{\delta_V(\mathcal{H}(\delta_x) - \mathcal{Q})^T + (\mathcal{H}(\delta_x) - \mathcal{Q})\delta_V\right\} = 0 \tag{A.5}$$

with $\mathcal{H}(\delta_X)$ and $\mathcal{Q}$ as given above

These are the steps someone would need in order to apply Theorem 7.1 directly. However, we shall go through the details of the manipulation that leads to this main result.

A.5. Directional derivatives of the barrier function. Having the above directional derivatives of $F(x)$ available, we are ready to take the directional derivatives needed in (A.4). However, to clarify the exposition, we split the potential function into two parts:

$$\phi_1(x) = -\log\det F(x) \quad \text{and} \quad \phi_2(x) = \zeta \log\Big(1/(\gamma - \operatorname{Tr}\{x\})\Big).$$

A.6. Symbolic directional derivatives of $\phi_1(x) = -\log\det F(x)$. The first and second directional derivative of $\phi_1(x)$ in the direction δ_x are given by

$$\begin{aligned} D\phi_1(x)[\delta_x] &= -\operatorname{Tr}\left\{F(x)^{-1} DF(x)[\delta_x]\right\} \\ &= -\operatorname{Tr}\left\{F(x)^{-1}\operatorname{sym}\{(a - xr)\delta_x\}\right\}, \end{aligned}$$

$$\begin{aligned} D^2\phi_1(x)[\delta_x,\delta_x] &= \operatorname{Tr}\left\{\left(F(x)^{-1}DF(x)[\delta_x]\right)^2\right\} - \operatorname{Tr}\left\{F(x)^{-1}D^2F(x)[\delta_x,\delta_x]\right\} \\ &= \operatorname{Tr}\left\{\left(F(x)^{-1}\operatorname{sym}\{(a-xr)\delta_x\}\right)^2\right\} \\ &\quad + \operatorname{Tr}\left\{F(x)^{-1}\operatorname{sym}\{\delta_x r \delta_x\}\right\}. \end{aligned}$$

A.7. Symbolic directional derivatives of $\phi_2(x) = \zeta\log(1/(\gamma - \operatorname{Tr}\{x\}))$. The first derivative is given by

$$D\phi_2(x)[\delta_x] = \zeta\left(\gamma - \operatorname{Tr}\{x\}\right)^{-1}\operatorname{Tr}\{\delta_x\}$$

and the second by

$$D^2\phi_2(x)[\delta_x,\delta_x] = \zeta\left(\left(\gamma - \operatorname{Tr}\{x\}\right)^{-1}\operatorname{Tr}\{\delta_x\}\right)^2.$$

A.8. Optimality conditions. Now we are ready to write the optimality conditions which will provide the update direction. These conditions are the first-order necessary optimality conditions for problem (A.3), obtained by taking directional derivatives of the Taylor expansion $\phi(x+\delta_x)$, given by (A.4), as a function of δ_x in the direction δ_V. To accomplish this step, we should compute $D\tilde{\phi}(\delta_x)[\delta_V]$ or equivalently

$$D\left(D\phi(x)[\delta_x] + \frac{1}{2}D^2\phi(x)[\delta_x,\delta_x]\right)[\delta_V] = 0. \tag{A.6}$$

Using the directional derivatives just computed in the previous sections, the expression for the second-order approximation $\tilde{\phi}(\delta_x)$ is given

$$\begin{aligned} \tilde{\phi}(\delta_x) &= -\operatorname{Tr}\left\{F(x)^{-1}\operatorname{sym}\{(a-xr)\delta_x\}\right\} + \frac{1}{2}\operatorname{Tr}\left\{\left(F(x)^{-1}\operatorname{sym}\{(a-xr)\delta_x\}\right)^2\right\} \\ &\quad + \frac{1}{2}\operatorname{Tr}\left\{F(x)^{-1}\operatorname{sym}\{\delta_x r\delta_x\}\right\} + \zeta\left(\gamma - \operatorname{Tr}\{x\}\right)^{-1}\operatorname{Tr}\{\delta_x\} \\ &\quad + \frac{1}{2}\zeta\left(\left(\gamma - \operatorname{Tr}\{x\}\right)^{-1}\operatorname{Tr}\{\delta_x\}\right)^2. \end{aligned} \tag{A.7}$$

To proceed, we now set to zero the directional derivative of $\tilde{\phi}(\delta_x)$ as a function of δ_x in the direction δ_V. After a few manipulations, the term $D\tilde{\phi}(\delta_x)\,[\delta_V]$ is given by

$$\begin{aligned}
D\tilde{\phi}(\delta_x)\,[\delta_V] = \operatorname{Tr}\Big\{ \delta_V \Big(& F(x)^{-1}\delta_x(a-xr)^T F(x)^{-1}(a-xr) - F(x)^{-1}(a-xr) \\
& + \frac{1}{2} r\delta_x F(x)^{-1} + \frac{1}{2} F(x)^{-1}\delta_x r \\
& + F(x)^{-1}(a-xr)\delta_x F(x)^{-1}(a-xr) \\
& + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-1}\mathfrak{I}_d + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-2}\operatorname{Tr}\{\delta_x\}\,\mathfrak{I}_d \Big) \\
+ \Big(& (a-xr)^T F(x)^{-1}(a-xr)\delta_x F(x)^{-1} - (a-xr)^T F(x)^{-1} \\
& + \frac{1}{2} F(x)^{-1}\delta_x r + \frac{1}{2} r\delta_x F(x)^{-1} \\
& + (a-xr)^T F(x)^{-1}\delta_x (a-xr)^T F(x)^{-1} \\
& + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-1}\mathfrak{I}_d + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-2}\operatorname{Tr}\{\delta_x\}\,\mathfrak{I}_d \Big)\delta_V \Big\}.
\end{aligned}$$

Therefore, the algebraic linear system of equations is described by

$$\operatorname{Tr}\left\{\delta_V(\mathcal{H}(\delta_x) - \mathcal{Q})^T + (\mathcal{H}(\delta_x) - \mathcal{Q})\delta_V\right\} = 0 \tag{A.8}$$

with $\mathcal{H}(\delta_X)$ and $\mathcal{Q}$ respectively given by

$$\mathcal{Q} = (a-xr)^T F(x)^{-1} - \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-1}\mathfrak{I}_d,$$

$$\begin{aligned}
\mathcal{H}(\delta_x) = & \frac{1}{2} F(x)^{-1}\delta_x r + \frac{1}{2} r\delta_x F(x)^{-1} + (a-xr)^T F(x)^{-1}(a-xr)\delta_x F(x)^{-1} \\
& + (a-xr)^T F(x)^{-1}\delta_x (a-xr)^T F(x)^{-1} + \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-2}\operatorname{Tr}\{\delta_x\}\,\mathfrak{I}_d.
\end{aligned}$$

A.9. Connection with Theorem 7.1. We shall emphasize that this illustrative example gives a reasonable idea of how the proof of Theorem 7.1 was constructed, since it follows very similar steps.

A.10. The algebraic linear system of equations. Since the unknown x is restricted to being symmetric (so is δ_x) the subspace $\mathcal{V}$ equals the space of symmetric matrices. Consequently, its orthogonal complement $\mathcal{V}^\perp$ is the set of all skew symmetric matrices. Therefore, we obtain the following linear system in δ_x:

$$\mathcal{H}(\delta_x) + \mathcal{H}(\delta_x)^T = \mathcal{Q} + \mathcal{Q}^T.$$

We can rewrite this equation using a suitable choice of variables $\mathfrak{a}_i$ and $\mathfrak{b}_i$ as follows:

$$\operatorname{sym}\left\{\sum_{i=1}^{4}\left(\mathfrak{a}_i\delta_x\mathfrak{b}_i\right)\right\} + \varrho\operatorname{Tr}\{\delta_x\} = \mathcal{Q} + \mathcal{Q}^T \tag{A.9}$$

with

$$\begin{aligned}
\mathfrak{a}_1 &= F(x)^{-1}(a - xr), & \mathfrak{b}_1 &= F(x)^{-1}(a - xr),\\
\mathfrak{a}_2 &= F(x)^{-1}, & \mathfrak{b}_2 &= (a - xr)^T F(x)^{-1}(a - xr),\\
\mathfrak{a}_3 &= \frac{1}{2}F(x)^{-1}, & \mathfrak{b}_3 &= r,\\
\mathfrak{a}_4 &= r, & \mathfrak{b}_4 &= \frac{1}{2}F(x)^{-1},
\end{aligned}$$

and

$$\mathcal{Q} = (a - xr)^T F(x)^{-1} - \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-1}\mathfrak{I}_d, \qquad \varrho = \frac{1}{2}\zeta(\gamma - \operatorname{Tr}\{x\})^{-2}\mathfrak{I}_d.$$

A.11. Connection with Corollary 7.2. These are the $\mathfrak{a}_i$ and $\mathfrak{b}_i$ described in the corollary for the specific case where the subspace $\mathcal{V}$ equals the space of symmetric matrices $\mathbb{S}^n$. The proof of Corollary 7.2 is illustrated by our example, since the proof mainly consists in determining the orthogonal complement of the subspace $\mathcal{V}$.

Acknowledgments. Thanks are due to M. C. de Oliveira for many ideas and suggestions. We also thank the referees for their very valuable comments and suggestions.

CONSTRUCTING GENERALIZED MEAN FUNCTIONS USING CONVEX FUNCTIONS WITH REGULARITY CONDITIONS*

YUN-BIN ZHAO†, SHU-CHERNG FANG‡, AND DUAN LI§

Abstract. The generalized mean function has been widely used in convex analysis and mathematical programming. This paper studies a further generalization of such a function. A necessary and sufficient condition is obtained for the convexity of a generalized function. Additional sufficient conditions that can be easily checked are derived for the purpose of identifying some classes of functions which guarantee the convexity of the generalized functions. We show that some new classes of convex functions with certain regularity (such as S^*-regularity) can be used as building blocks to construct such generalized functions.

Key words. convexity, mathematical programming, generalized mean function, self-concordant functions, S^*-regular functions

1. Introduction.

In this paper, we denote the n-dimensional Euclidean space by R^n, its nonnegative orthant by R^n_+, and its positive orthant by R^n_{++}.

In 1934, Hardy, Littlewood, and Pólya [13] considered the following function under the name of generalized mean:

$$\Upsilon_w(x) = \phi^{-1}\left(\sum_{i=1}^{n} w_i \phi(x_i)\right), \tag{1.1}$$

where $\phi(\cdot)$ is a real, strictly increasing, convex function defined on a subset of R and $w = (w_1, w_2, \ldots, w_n)^T$ is a given vector in R^n_+. Assuming that $\phi > 0$, $\phi' > 0$, and $\phi'' > 0$, they showed an equivalent condition for the convexity of Υ_w. When ϕ is three times differentiable, Ben-Tal and Teboulle [2] established another equivalent condition for Υ_w being convex (see section 2 for details).

The generalized mean function (1.1) has many applications in optimization. Ben-Tal and Teboulle [2] demonstrated an interesting application of (1.1) (in a continuous form) on penalty functions and duality formulation of stochastic nonlinear programming problems. However, the most widely used generalized means are the logorithmic-exponentional and p-norm functions:

$$f_w(x) = \log\left(\sum_{i=1}^{n} w_i e^{x_i}\right), \quad p_w(x) = \left(\sum_{i=1}^{n} w_i x_i^p\right)^{1/p} \quad \text{for } x = (x_1, \ldots, x_n)^T \in R^n.$$

They correspond to the special cases of Υ_w with $\phi(t) = e^t$ and $\phi(t) = t^p$, respectively.

Needless to say, the log-exp function has been widely used in convex analysis and mathematical programming. For example, a geometric program (see Duffin, Peterson, and Zener [8] and Boyd and Vandenberghe [6]) can be converted into a convex programming problem by using the log-exp function so that the interior-point algorithms can be developed to solve geometric programs with great efficiency (see Kortanek, Xu, and Ye [14]). Another example is concerned with the nondifferentiable minimax problem

$$\min_{y\in D} \max_{1\le i\le n} g_i(y),$$

where $g_i(\cdot)$, $i = 1, \ldots, n$, are real functions defined on a convex set D in R^m. Since the recession function of the log-exp function is the "max-function"(see Rockafellar [20]), i.e., $\max_{1\le i\le n} x_i = \lim_{\varepsilon\to 0_+} \varepsilon f(\frac{x}{\varepsilon})$ where $f(\cdot) = f_w(\cdot)$ and $w = (1, 1, \ldots, 1)$, the above nondifferential optimization problem can be approximated by solving the following optimization problem:

$$\min_{y\in D} \varepsilon \log\left(\sum_{i=1}^{n} e^{\frac{g_i(y)}{\varepsilon}}\right).$$

The objective function is differentiable and convex if every $g_i(y)$ is. Other applications of the log-exp function in optimization can be found in Ben-Tal [1], Ben-Tal and Teboulle [3], Zang [25], Bertsekas [4], Polyak [19], Fang [9], Fang and Tsao [10], Li and Fang [15], Peng and Lin [17], Birbil et al. [5], and Sun and Li [22, 23, 24].

It is worth mentioning that the conjugate function of the log-exp function happens to be the well-known Shannon entropy function [21] which plays a vital role in so many fields ranging from image enhancement to economics and from statistical mechanics to nuclear physics (see Buck and Macaulay [7] and Fang, Rajasekera, and Tsao [11]).

We consider in this paper a further generalization of (1.1) in the form

$$\Gamma_w(x) = \Psi^{-1}\left(\sum_{i=1}^{n} w_i\phi_i(x_i)\right), \tag{1.2}$$

where $\phi_i : \Omega \to R$, $i = 1, \ldots, n$, are convex, twice differentiable (but not necessarily strictly increasing) functions defined on an open convex set $\Omega \subset R$, $\Psi : \Omega \to R$ is convex, twice differentiable, and strictly increasing, and $w \in R^n_+$ is a given vector. Clearly, $\Upsilon_w(\cdot)$ is a special case of $\Gamma_w(\cdot)$ with $\phi_1 = \phi_2 = \cdots = \phi_n = \Psi = \phi$. For convenience, in this paper, we still call Γ_w given by (1.2) a generalized mean function, and we call ϕ_i the inner function and Ψ the outer function of Γ_w.

To ensure the well-definedness of Γ_w, we naturally require that $\sum_{i=1}^{n} Cone[\phi_i(\Omega)] \subseteq \Psi(\Omega)$, where $Cone[\phi_i(\Omega)]$ denotes the cone generated by the set $\phi_i(\Omega)$.

As in the case of Υ_w, we would like to derive certain sufficient and necessary conditions for the function Γ_w to be convex. Moreover, we hope to find a systematic way to explicitly construct some classes of convex Γ_w.

It is interesting to point out that Γ_w is by no means a new research subject. In fact, it was essentially studied by Fenchel in his lecture notes on *Convex Cones, Sets and Functions* in 1953 [12]. Based on the properties of level sets and characteristic roots of Hessian matrices of functions involved, Fenchel derived some sufficient and necessary conditions for the convexity of the generalized mean function Γ_w. The conditions he derived, however, are rather complicated, and there is no simple test to decide what

kind of functions may admit these complicated properties. Unlike Fenchel's approach, our analysis in this paper depends only on the function value, its first derivative, and its second derivative to provide a sufficient and necessary condition for Γ_w being convex. The necessary and sufficient condition we derive in this paper can be viewed as a generalization of that in [13] concerning the function (1.1). We can also use related sufficient conditions to explicitly construct concrete examples of convex Γ_w. Moreover, we show how the so-called S^*-regular functions (to be defined in this paper) can be used to construct convex generalized mean functions.

The rest of the paper is organized as follows. In section 2, we investigate the conditions that ensure the convexity of the generalized mean function Γ_w. In section 3, we identify some classes of functions that satisfy the conditions derived in section 2 and illustrate how the generalized mean function Γ_w can be explicitly constructed. Conclusions are given in the last section.

2. Necessary and sufficient conditions for the convexity of Γ_w. Let us start with a simple lemma (proof omitted) that shows that the inverse of an increasing convex function is concave and increasing.

LEMMA 2.1. *Let Ω be an open convex subset of R and $\Psi : \Omega \to R$ be a real function defined on Ω. Then Ψ is (strictly) convex and strictly increasing if and only if its inverse $\Psi^{-1} : R \to \Omega$ is (strictly) concave and strictly increasing.*

Notice that if $w_i = 0$ for some i, then the term $w_i\phi_i(x)$ can be removed from the expression of $\Gamma_w(x)$, and it suffices to consider Γ_w defined on R^{n-1}. Thus, without loss of generality, we may assume that the vector $w \in R^n_{++}$ throughout the rest of the paper.

To study the convexity of Γ_w, when assuming that ϕ_i, $i = 1, \ldots, n$, and Ψ^{-1} are twice differentiable, we need to check the properties of its Hessian matrix. Let

$$x_w = \sum_{i=1}^{n} w_i\phi_i(x_i).$$

Since $\frac{\partial x_w}{\partial x_i} = w_i\phi_i'(x_i)$, we have

$$\frac{\partial \Gamma_w}{\partial x_i} = (\Psi^{-1})'(x_w)w_i\phi_i'(x_i).$$

Moreover,

$$\frac{\partial^2 \Gamma_w}{\partial x_i^2} = (\Psi^{-1})''(x_w)(w_i\phi_i'(x_i))^2 + (\Psi^{-1})'(x_w)w_i\phi_i''(x_i),$$
$$\frac{\partial^2 \Gamma_w}{\partial x_i \partial x_j} = (\Psi^{-1})''(x_w)w_iw_j\phi_i'(x_i)\phi_j'(x_j) \quad \text{for} \quad i \neq j.$$

Consequently, the Hessian matrix of Γ_w becomes

$$\frac{\partial^2 \Gamma_w}{\partial x^2} = (\Psi^{-1})'(x_w) \begin{bmatrix} w_1\phi_1''(x_1) & 0 & \ldots & 0 \\ 0 & w_2\phi_2''(x_2) & \ldots & 0 \\ \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & \ldots & w_n\phi_n''(x_n) \end{bmatrix}$$
$$+ (\Psi^{-1})''(x_w) \begin{bmatrix} w_1\phi_1'(x_1) \\ w_2\phi_2'(x_2) \\ \ldots \\ w_n\phi_n'(x_n) \end{bmatrix} [w_1\phi_1'(x_1), w_2\phi_2'(x_2), \ldots, w_n\phi_n'(x_n)]. \tag{2.1}$$

Note that when ϕ_i, $i = 1, \ldots, n$, is convex and Ψ is convex and increasing, by Lemma 2.1, we see that the first term on the right-hand side of (2.1) is a positive semidefinite matrix multiplied by a positive coefficient $(\Psi^{-1})'(x_w)$, while the second is a rank one matrix multiplied by a negative coefficient $(\Psi^{-1})''(x_w)$.

Some conditions for convexity of the function $\Upsilon_w(x)$ have already been studied in [13] and [2]. We summarize their results here.

THEOREM 2.2 (see [13]). *Under the conditions of $\phi > 0$, $\phi' > 0$, and $\phi'' > 0$, the function $\Upsilon_w(x)$ defined by (1.1) is convex if and only if the following condition holds:*

$$\sum_{i=1}^{n} w_i \frac{[\phi'(x_i)]^2}{\phi''(x_i)} \le \frac{[\phi'(y)]^2}{\phi''(y)} \quad \textit{for} \quad y = \Upsilon_w(x).$$

Ben-Tal and Teboulle [2] also provided a different sufficient and necessary condition, under certain assumptions, for the convexity of the function $\Upsilon_w(x)$.

THEOREM 2.3 (see [2]). *Let $\phi(t) \in C^3$. $\Upsilon_w(x)$ is convex if and only if $1/\rho(t)$ is convex, where $\rho(t) = -\phi''/\phi'$.*

It is possible to extend the analysis in [2] for deriving sufficient conditions for the convexity of $\Gamma_w(x)$ defined by (1.2). For example, the following result is actually implied in [2] and can be proved along the line of the proof of "Lemma 1" and "Theorem 1" therein.

THEOREM 2.4 (see [2]). *Let $\Psi(t) \in C^3$ and $\phi_i(t) \in C^3$ be strictly increasing and $\rho(t) = -\Psi''(t)/\Psi'(t)$. If $1/\rho(t)$ is convex and $\Psi^{-1}(\phi_i(t))$ is convex for $i = 1, \ldots, n$, then $\Gamma_w(x)$ given by (1.2) is convex.*

Note that if ϕ is sufficiently smooth, $1/\rho(t)$ is convex, where $\rho(t) = -\phi''(t)/\phi'(t)$, if and only if its second derivative is nonnegative; i.e.,

$$\left(\frac{1}{\rho}\right)'' = \frac{(\phi'')^3\phi''' - 2\phi'\phi''(\phi''')^2 + \phi'(\phi'')^2\phi''''}{(\phi'')^2} \ge 0.$$

Thus, to check the convexity of $1/\rho(t)$, it is usually needed to check the above inequality involving the third and forth derivative of the function ϕ. Theorem 2.2 does not require the third or fourth differentiability of the function ϕ.

In what follows, we generalize the above Theorem 2.2 to the function $\Gamma_w(x)$. Although the basic idea of our proof is essentially tied to that of [13], the proof is not straightforward. For completeness, we give a detailed proof for the result.

THEOREM 2.5. *Let $\Omega \subset R$ be open and convex, $\Psi : \Omega \to R$ be convex, twice differentiable, and strictly increasing, $\phi_i : \Omega \to R$, $i = 1, \ldots, n$, be strictly convex and twice differentiable, and $w \in R^n_{++}$ be a given vector. Then the generalized mean function*

$$\Gamma_w(x) = \Psi^{-1}\left(\sum_{i=1}^{n} w_i \phi_i(x_i)\right)$$

is convex on $\Omega^n := \overbrace{\Omega \times \cdots \times \Omega}^{n}$ if and only if

$$\Psi''(y)\left(\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right) \le [\Psi'(y)]^2 \quad \textit{for} \quad x \in \Omega^n \ \textit{and} \ \ y = \Gamma_w(x). \tag{2.2}$$

Moreover, $\Gamma_w(x)$ is strictly convex if and only if the inequality in (2.2) holds strictly.

Proof. Let $y = \Gamma_w(x) = \Psi^{-1}(x_w)$. Then $x_w = \Psi(y)$ and

$$(\Psi^{-1})'(x_w)\Psi'(y) = 1. \tag{2.3}$$

Differentiating both sides with respect to y and using the above relations, we have

$$\begin{aligned} 0 &= (\Psi^{-1})''(x_w)[\Psi'(y)]^2 + (\Psi^{-1})'(x_w)\Psi''(y) \\ &= (\Psi^{-1})''(x_w)[\Psi'(y)]^2 + \frac{\Psi''(y)}{\Psi'(y)}. \end{aligned}$$

Therefore,

$$(\Psi^{-1})''(x_w) = -\frac{\Psi''(y)}{[\Psi'(y)]^3}. \tag{2.4}$$

Combining (2.3) and (2.4) yields

$$(\Psi^{-1})'(x_w) + (\Psi^{-1})''(x_w)\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)} = \frac{[\Psi'(y)]^2 - \left(\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right)\Psi''(y)}{[\Psi'(y)]^3}. \tag{2.5}$$

First we prove that $\Gamma_w(x)$ is convex if (2.2) holds. It suffices to show that the Hessian matrix of $\Gamma_w(x)$ is positive semidefinite.

For any $d \in R^n$ and $x \in \Omega^n$, the Cauchy–Schwarz inequality implies that

$$\begin{aligned} \left(\sum_{i=1}^{n} w_i \phi_i'(x_i) d_i\right)^2 &= \left(\sum_{i=1}^{n} \left[\sqrt{w_i \phi_i''(x_i)}\, d_i\right] \cdot \sqrt{\frac{w_i}{\phi_i''(x_i)}}\, \phi_i'(x_i)\right)^2 \\ &\le \left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right)\left(\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right). \end{aligned}$$

By Lemma 2.1, we know Ψ^{-1} is concave and hence $(\Psi^{-1})''(x_w) \le 0$ for all x_w. Combining this fact with the above inequality, we see that, for any $d \in R^n$,

$$\begin{aligned} & d^T \frac{\partial^2 \Gamma_w}{\partial x^2} d \\ &= (\Psi^{-1})'(x_w)\left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right) + (\Psi^{-1})''(x_w)\left(\sum_{i=1}^{n} w_i \phi_i'(x_i) d_i\right)^2 \\ &\ge (\Psi^{-1})'(x_w)\left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right) + (\Psi^{-1})''(x_w)\left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right)\left(\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right) \\ &= \left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right)\left[(\Psi^{-1})'(x_w) + (\Psi^{-1})''(x_w)\left(\sum_{i=1}^{n} \frac{w_i [\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right)\right] \\ &= \left(\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2\right) \frac{[\Psi'(y)]^2 - \left(\sum_{i=1}^{n} w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}\right)\Psi''(y)}{[\Psi'(y)]^3} \\ &\ge 0. \end{aligned}$$

The last equality follows from (2.5) and the last inequality follows from the fact that the first quantity on the right-hand side, i.e., $\sum_{i=1}^{n} w_i \phi_i''(x_i) d_i^2$, is nonnegative, and

the second quantity is also nonnegative due to our assumption. Consequently, we have proven that the Hessian matrix $\frac{\partial^2 \Gamma_w}{\partial x^2}$ is positive semidefinite, as desired.

Conversely, we would like to show that inequality (2.2) holds if $\Gamma_w(x)$ is convex. For any vector $0 \neq d \in R^n$, knowing (2.3), (2.4), and the convexity of $\Gamma_w(x)$, we have

$$\begin{aligned} 0 \leq d^T \frac{\partial^2 \Gamma_w}{\partial x^2} d &= (\Psi^{-1})'(x_w) \left(\sum_{i=1}^n w_i \phi_i''(x_i) d_i^2 \right) + (\Psi^{-1})''(x_w) \left(\sum_{i=1}^n w_i \phi_i'(x_i) d_i \right)^2 \\ &= \frac{1}{\Psi'(y)} \left(\sum_{i=1}^n w_i \phi_i''(x_i) d_i^2 \right) - \frac{\Psi''(y)}{\Psi'(y)^3} \left(\sum_{i=1}^n w_i \phi_i'(x_i) d_i \right)^2 \\ &= \left(\sum_{i=1}^n w_i \phi_i''(x_i) d_i^2 \right) \left[\frac{1}{\Psi'(y)} - \frac{\Psi''(y)}{\Psi'(y)^3} \frac{[\sum_{i=1}^n w_i \phi_i'(x_i) d_i]^2}{\sum_{i=1}^n w_i \phi_i''(x_i) d_i^2} \right]. \end{aligned} \tag{2.6}$$

Notice that the above inequality holds for any vector $d \in R^n$. In particular, let

$$d_i = \frac{\phi_i'(x_i)}{\phi_i''(x_i) \sum_{k=1}^n w_k \frac{[\phi_k'(x_k)]^2}{\phi_k''(x_k)}}, \ i = 1, \ldots, n.$$

Then, we have

$$\sum_{i=1}^n w_i \phi_i'(x_i) d_i = 1, \ \sum_{i=1}^n w_i \phi_i''(x_i) d_i^2 = \frac{1}{\sum_{i=1}^n w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}}.$$

As a result, the inequality (2.6) reduces to

$$0 \leq \left(\frac{1}{\sum_{i=1}^n w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)}} \right) \left[\frac{1}{\Psi'(y)} - \frac{\Psi''(y)}{\Psi'(y)^3} \left(\sum_{i=1}^n w_i \frac{[\phi_i'(x_i)]^2}{\phi_i''(x_i)} \right) \right].$$

We see that inequality (2.2) indeed holds. The result about strict convexity can be easily checked out. □

Theorem 2.5 generalizes the result of Theorem 2.2 (concerning $\Upsilon_w(x)$) to the more general function $\Gamma_w(x)$, while Theorem 2.4 generalizes the sufficient condition of Theorem 2.3 (concerning $\Upsilon_w(x)$) to the function $\Gamma_w(x)$. Except for some very simple cases, like e^t or x^p, these results do not give us the concrete class of functions which can be used to construct of the examples of generalized mean functions. The purpose of the remainder of this paper is to provide a way to identify the desired class of functions. Our analysis here is based only on the result of Theorem 2.5 instead of Theorem 2.4. We believe that there are also some systematic ways to identify the desired class of function based on Theorem 2.4.

To this end, two related sufficiency results of Theorem 2.5 are derived below for convenient usage in constructing convex Γ_w (see section 3).

THEOREM 2.6. *Let Ω be an open convex subset of R, $\Psi : \Omega \to R$ be strictly increasing, twice differentiable, and convex, $\phi_i : \Omega \to R$, $i = 1, \ldots, n$, be strictly convex and twice differentiable, and $w \in R^n_{++}$ be a given vector. Assume that there exists a scalar $\alpha \in R$ such that*

$$\alpha \Psi(t) \Psi''(t) \leq [\Psi'(t)]^2 \quad \textit{for } t \in \Omega. \tag{2.7}$$

Then the function Γ_w *is convex on* Ω^n *if*

$$\sum_{i=1}^{n} \frac{w_i[\phi_i'(x_i)]^2}{\phi_i''(x_i)} \le \alpha\Psi(y) \quad \text{for } x \in \Omega^n, \tag{2.8}$$

where $y = \Gamma_w(x)$.

Proof. Multiplying both sides of (2.8) by $\Psi''(y)$ and applying (2.7), we see that condition (2.2) holds. The result follows from Theorem 2.5 immediately. □

THEOREM 2.7. *Let* Ω *be an open convex subset of* R, $\Psi : \Omega \to R$ *be strictly increasing, twice differentiable, and convex,* $\phi_i : \Omega \to R$, $i = 1, \ldots, n$, *be strictly convex and twice differentiable, and* $w \in R^n_{++}$ *be a given vector. Assume that there exist* $0 \ne \alpha_i \in R$, $i = 1, \ldots, n$, *holding the same sign such that*

$$\alpha_i\phi_i(t)\phi_i''(t) \ge [\phi_i'(t)]^2 \quad \text{for } t \in \Omega, \tag{2.9}$$

and there exists an $\alpha \in R$ *such that the inequality* (2.7) *holds. Then the function* Γ_w *is convex if*

$$\alpha \ge \max_{1\le i\le n} \alpha_i \quad (\text{when } \alpha_i > 0 \text{ for all } i), \tag{2.10}$$

or

$$\alpha \le \min_{1\le i\le n} \alpha_i \quad (\text{when } \alpha_i < 0 \text{ for all } i). \tag{2.11}$$

Proof. Taking $y = \Gamma_w(x)$, we see two cases.

Case 1. $\alpha_i > 0$ for $i = 1, \ldots, n$. In this case, (2.9) implies that $\phi_i(t) \ge 0$ for $t \in \Omega$ and (2.10) implies that

$$\sum_{i=1}^{n} w_i \frac{[\phi_i'(t)]^2}{\phi_i''(x_i)} \le \sum_{i=1}^{n} w_i\alpha_i\phi_i(x_i) \le \left(\max_{1\le i\le n} \alpha_i\right) \sum_{i=1}^{n} w_i\phi_i(x_i) \le \alpha\Psi(y).$$

Case 2. $\alpha_i < 0$ for $i = 1, \ldots, n$. In this case, (2.9) implies that $\phi_i(t) \le 0$ for $t \in \Omega$ and (2.11) implies that

$$\sum_{i=1}^{n} w_i \frac{[\phi_i'(t)]^2}{\phi_i''(x_i)} \le \sum_{i=1}^{n} w_i\alpha_i\phi_i(x_i) \le \left(\min_{1\le i\le n} \alpha_i\right) \sum_{i=1}^{n} w_i\phi_i(x_i) \le \alpha\Psi(y).$$

Both cases yield (2.8) and the desired result follows from Theorem 2.2. □

A special case of $\phi_1(t) = \phi_2(t) = \cdots = \Psi(t)$ immediately leads to the next result.

COROLLARY 2.8. *Let* Ω *be an open convex set in* R, $\phi : \Omega \to R$ *be a convex, twice differentiable, and strictly increasing function, and* $w \in R^n_{++}$ *be a given vector. If there exists an* $\alpha \ne 0$ *such that*

$$[\phi'(t)]^2 = \alpha\phi(t)\phi''(t) \quad \text{for } t \in \Omega, \tag{2.12}$$

then the function $\Upsilon_w(x) = \phi^{-1}(\sum_{i=1}^{n} w_i\phi(x_i))$ *is convex on* Ω^n.

This result can also follow directly from the aforementioned Theorem 2.3 (due to Ben-Tal and Teboulle [2]). In fact, it is easy to verify that the relation (2.12) implies that the second derivative of ϕ'/ϕ'' is equal to zero, and thus by Theorem 2.3 the function $\Upsilon_w(x)$ is convex.

Remark 2.1. The functions satisfying a differential inequality such as (2.7) are related to the so-called self-concordant barrier function introduced by Nesterov and Nemirovskii [16]. Recall that a C^3 function $\xi : (0,\infty) \to R$ is said to be self-concordant if ξ is convex and there exists a constant $\mu_1 > 0$ such that

$$|\xi'''(t)| \le \mu_1(\xi''(t))^{\frac{3}{2}} \quad \text{for } t \in (0,\infty). \tag{2.13}$$

Moreover, the self-concordant function ξ is called a self-concordant barrier function if there exists a constant $\mu_2 > 0$ such that

$$|\xi'(t)| \le \mu_2[\xi''(t)]^{\frac{1}{2}} \quad \text{for } t \in (0,\infty). \tag{2.14}$$

Combining (2.13) and (2.14) yields

$$\xi'(t)\xi'''(t) \le \mu[\xi''(t)]^2.$$

This indicates that the first-order derivative function of a self-concordant barrier function, i.e., $g(t) := \xi'(t)$, satisfies the inequality (2.7). A self-concordant function $\xi(\cdot)$ itself may also satisfy an inequality like (2.7) or (2.9).

Remark 2.2. The functions satisfying a differential inequality such as (2.7) also appear in convexity theory. Given a twice differentiable function $\phi(t) > 0$ on its domain Ω, we consider the convexity of the function $h(t) := \frac{1}{\phi(t)}$ on Ω. Notice that

$$h''(t) = \frac{2[\phi'(t)]^2 - \phi(t)\phi''(t)}{[\phi(t)]^3} \quad \text{for} \quad t \in \Omega.$$

Hence the function $h(t) = \frac{1}{\phi(t)}$ is convex if and only if the inequality $\phi(t)\phi''(t) \le 2[\phi'(t)]^2$ holds on Ω. Moreover, if $\phi(t)\phi''(t) \le [\phi'(t)]^2$, the convex function $h(t)$ satisfies a reverse inequality, i.e., $h(t)h''(t) \ge [h'(t)]^2$ on Ω.

From this observation, a related question arises. Given a function $\phi(t) > 0$ on Ω and a constant $r > 0$, when will the function $h(t) := \frac{1}{\phi(t)^r}$ become convex and satisfy an inequality such as (2.9)? A straightforward analysis leads to the next result.

THEOREM 2.9. (i) *Let Ω be a convex subset of R and $\phi : \Omega \to (0,\infty)$ be a function. If $\phi(t)\phi''(t) \le [\phi'(t)]^2$ for $t \in \Omega$, then, for any $r > 0$, the function $h(t) := \frac{1}{\phi(t)^r}$ is convex and $h(t)h''(t) \ge [h'(t)]^2$ for $t \in \Omega$. Conversely, if there exists an $r > 0$ such that $h(t) := \frac{1}{\phi(t)^r}$ is convex and $h(t)h''(t) \ge [h'(t)]^2$ for $t \in \Omega$, then $\phi(t)\phi''(t) \le [\phi'(t)]^2$ for $t \in \Omega$.*

(ii) *Let Ω be a convex subset of R, $\tau > 0$, and $\phi : \Omega \to (\tau,\infty)$ be a function. If $\phi(t)\phi''(t) \le [\phi'(t)]^2$ for $t \in \Omega$, then, for any scalar $r > 0$ and $T > 0$, the function $h_T(t) := T + \frac{1}{\phi(t)^r}$ is convex and $\alpha h_T(t)h_T''(t) \ge [h_T'(t)]^2$ for $t \in \Omega$, where $\alpha = \frac{1}{T\tau^r+1}$.*

Proof. For case (i), it is sufficient to see that

$$h''(t) = \frac{r^2(\phi'(t))^2 + r[(\phi'(t))^2 - \phi(t)\phi''(t)]}{\phi(t)^{r+2}},$$

and

$$h(t)h''(t) - [h'(t)]^2 = \frac{r[(\phi'(t))^2 - \phi(t)\phi''(t)]}{\phi(t)^{2(r+1)}}.$$

For case (ii), it is easy to verify that $h_T''(t) = h''(t)$ and

$$\left(\frac{1}{T\phi(t)^r + 1}\right) h_T(t)h_T''(t) - [h_T'(t)]^2 = \frac{r[(\phi'(t))^2 - \phi(t)\phi''(t)]}{\phi(t)^{2(r+1)}}.$$

Then the desired result follows. ∎

The above results indicate that if we have a function ϕ satisfying the inequality (2.7) with $\alpha = 1$, then we may construct a function h from ϕ such that h satisfies the converse differentiable inequality $\alpha h(t)h''(t) \geq [h'(t)]^2$ for some constant α. Moreover, if we take a T-translation of the value of the function h, then the resulting function satisfies the converse differentiable inequality with an α that can be reduced to be smaller than any threshold given in (0,1) provided a suitable choice of $T > 0$. This fact will be used near the end of section 3.

3. Constructing convex generalized mean functions Γ_w. In this section, we try to identify some classes of functions that satisfy inequality (2.7) and/or inequality (2.9) so that we have building blocks for constructing the concrete convex function $\Gamma_w(x)$. First, we give a result that identifies functions satisfying (2.12). Obviously, this class of functions satisfies both inequalities (2.7) and (2.9).

THEOREM 3.1. *Let Ω be an open set in R and $\phi : \Omega \to R$ be a convex, twice differentiable, and strictly increasing function satisfying* (2.12) *with a constant $\alpha \neq 0$. Then, the following hold:*

(i) *When $\alpha = 1$, ϕ is in the form of $\phi(t) = \gamma e^{\frac{t}{\beta}}$ for some $\gamma > 0$ and $\beta > 0$.*

(ii) *When $0 < \alpha \neq 1$ with $v^* := \sup_{t\in\Omega} \frac{1-\alpha}{\alpha} t$ being finite, ϕ is in the form of*

$$\phi(t) = \gamma \left(\frac{\alpha - 1}{\alpha} t + \beta \right)^{\frac{\alpha}{\alpha-1}}$$

for some $\gamma > 0$ and $\beta \geq v^*$.

(iii) *When $\alpha < 0$ with $u^* := \sup_{t\in\Omega} \frac{\alpha-1}{\alpha} t$ being finite, ϕ is in the form of*

$$\phi(t) = -\gamma \left(\beta - \frac{\alpha - 1}{\alpha} t \right)^{\frac{\alpha}{\alpha-1}}$$

for some $\gamma > 0$ and $\beta \geq u^*$.

Note that results (i) and (ii) were pointed out in [2] and [13] and result (iii) can be easily derived. The above result leads to the following consequence related to Υ_w.

COROLLARY 3.2. *The following functions can be used to explicitly construct a convex generalized mean function $\Upsilon_w(x) = \phi^{-1}(\sum_{i=1}^n w_i \phi(x_i))$ over Ω^n:*

(i) *$\phi(t) = \gamma e^{\frac{t}{\beta}}$ over $\Omega = R$ with $\gamma > 0$ and $\beta > 0$.*

(ii) *$\phi(t) = \gamma\left(\frac{1}{p}t + \beta\right)^p$ over $\Omega = (\eta, \infty)$ with $p > 1$, $\gamma > 0$, and $\beta \geq -\frac{\eta}{p}$.*

(iii) *$\phi(t) = \frac{\gamma}{\left(\beta - \frac{1}{p}t\right)^p}$ over $\Omega = (-\infty, \eta)$ with $p > 0$, $\gamma > 0$, and $\beta \geq -\frac{\eta}{p}$.*

(iv) *$\phi(t) = -\gamma(\beta - \frac{1}{p}t)^p$ over $\Omega = (-\infty, \eta)$ with $0 < p < 1$, $\gamma > 0$, and $\beta \geq \frac{\eta}{p}$.*

Again, results (i) and (ii) were given in [2] and [13] and results (iii) and (iv) can be easily derived. The functions listed in Corollary 3.2 actually form a complete basis in the sense that the function ϕ in case (i) satisfies condition (2.12) with $\alpha = 1$; the function ϕ in case (ii) satisfies condition (2.12) with $\alpha = \frac{p}{p-1} > 1$; the function ϕ in case (iii) satisfies condition (2.12) with $\alpha = \frac{p}{p+1} \in (0, 1)$; and the function ϕ in (iv) satisfies condition (2.12) with $\alpha = \frac{p}{p-1} < 0$.

We now try to identify some class of functions that satisfies inequalities (2.7) and/or (2.9). For simplicity, we consider only convex, twice differentiable, strictly increasing functions ϑ on $\Omega = (0, \infty)$. Let us first define the following four categories of such functions:

$$\mathcal{U}_1 = \{\vartheta : \text{There exists } \alpha \in R \text{ such that } \alpha\vartheta(t)\vartheta''(t) \geq [\vartheta'(t)]^2 \text{ for } t \in \Omega\};$$

$\mathcal{U}_2 = \{\vartheta : \text{There exists } \alpha \in R \text{ such that } \alpha\vartheta(t)\vartheta''(t) \le [\vartheta'(t)]^2 \text{ for } t \in \Omega\}$;
$\mathcal{U}_3 = \{\vartheta : \text{There exist } \alpha_1 \le \alpha_2 \text{ such that } \alpha_1\vartheta(t)\vartheta''(t) \le [\vartheta'(t)]^2 \le \alpha_2\vartheta(t)\vartheta''(t)$ for $t \in \Omega\}$;
$\mathcal{U}_4 = \{\vartheta : \text{There exists } \alpha \in R \text{ such that } \alpha\vartheta(t)\vartheta''(t) = [\vartheta'(t)]^2 \text{ for all } t \in \Omega\}$.

It is evident that

$$\mathcal{U}_4 \subset \mathcal{U}_3 \subset (\mathcal{U}_2 \cap \mathcal{U}_1).$$

As pointed out in Theorem 3.1, the class $\mathcal{U}_4$ can be given explicitly. By allowing $\alpha_1 \neq \alpha_2$, we show that $\mathcal{U}_3$ is much broader than $\mathcal{U}_4$. In fact, many convex functions with certain regularities fall into the category $\mathcal{U}_3$. To start, we introduce a new class of functions with certain regularity properties.

DEFINITION 3.3. *A convex, twice differentiable, strictly increasing function* $\delta(t) : (0,\infty) \to R$ *is called an* S^*-regular function *if* (i) $\delta(t)$ *vanishes at* $t = 0$ *in the sense of*

$$\lim_{t\to 0_+} \delta(t) = \lim_{t\to 0_+} \delta'(t) = \lim_{t\to 0_+} \delta''(t) = 0;$$

and (ii) *there exist positive constants* $0 < \beta_1 \le \beta_2$, $p \ge 1$, *and* $q \ge 1$ *such that*

$$\beta_1[(t+1)^{p-1} - (t+1)^{-1-q}] \le \delta''(t) \le \beta_2[(t+1)^{p-1} - (t+1)^{-1-q}],\ t > 0. \tag{3.1}$$

Note that condition (3.1) actually implies the strict convexity of an S^*-regular function on $(0,\infty)$. In particular, setting $\beta_1 = \beta_2$, condition (3.1) reduces to an equation

$$\delta''(t) = (t+1)^{p-1} - (t+1)^{-1-q}. \tag{3.2}$$

Taking integration twice and noting that $\lim_{t\to 0_+} \delta(t) = \lim_{t\to 0_+} \delta'(t) = 0$, the unique solution to (3.2) is

$$\Delta_{p,q}(t) = \frac{(t+1)^{p+1} - 1}{p(p+1)} - \frac{(t+1)^{1-q} - 1}{q(q-1)} - \frac{p+q}{pq}t \quad \text{for } p \ge 1 \text{ and } \ q > 1. \tag{3.3}$$

In addition, since $\lim_{q\to 1_+}[1 - (t+1)^{1-q}]/(q-1) = \ln(t+1)$, we have

$$\Delta_{p,1}(t) = \frac{(t+1)^{p+1} - 1}{p(p+1)} + \ln(t+1) - \frac{p+1}{p}t \quad \text{for } p \ge 1. \tag{3.4}$$

Taking $p = 1$ in (3.4), we have

$$\Delta_{1,1}(t) = \frac{(t+1)^2 - 1}{2} + \ln(t+1) - 2t = \frac{1}{2}t^2 - t + \ln(t+1). \tag{3.5}$$

Moreover, taking $p = 1$ and $q = 2$ in (3.3) yields

$$\Delta_{1,2}(t) = \frac{1}{2}\left[(t+1)^2 - (t+1)^{-1} - 3t\right]. \tag{3.6}$$

In terms of this particular solution $\Delta_{p,q}(t)$, condition (3.1) can be written as

$$\beta_1\Delta''_{p,q}(t) \le \delta''(t) \le \beta_2\Delta''_{p,q}(t). \tag{3.7}$$

By integrating and noting that $\lim_{t\to 0_+}\delta'(t)=\lim_{t\to 0_+}\delta(t)=0$, we further have

$$\beta_1\Delta'_{p,q}(t)\le\delta'(t)\le\beta_2\Delta'_{p,q}(t) \tag{3.8}$$

and

$$\beta_1\Delta_{p,q}(t)\le\delta(t)\le\beta_2\Delta_{p,q}(t). \tag{3.9}$$

Therefore, we can see that the class of S^*-regular functions is quite broad. Later, by using (3.7)–(3.9), we show that S^*-regular functions fall into the category $\mathcal{U}_3$.

It is worth mentioning that for any $p\ge 1, q>1$ (including the case of $q\to 1_+$) the S^*-regular function $\Delta_{p,q}(t)$ is not self-concordant. In fact, the function $\Delta_{p,q}(t)$ does not satisfy the inequality (2.13) since $\delta''(t)\to 0$ and $\delta'''(t)\to p+q$ as $t\to 0_+$.

S^*-regular functions are somewhat analogous to (but different from) the self-regular functions defined in [18]. As we have mentioned above, S^*-regular functions are not self-concordant; however, the class of self-regular functions has a large overlap with self-concordant functions. In what follows, we display the relation among the first and second derivatives of S^*-regular functions, which shows that any S^*-regular function belongs to the category $\mathcal{U}_3$. It should be mentioned that the relations among the first and second derivative for the self-regular function have been studied in [18].

THEOREM 3.4. *Let $\delta(t):(0,\infty)\to R$ be S^*-regular on $(0,\infty)$. Then there exist $c_2\ge c_1>0$ such that*

$$c_1\le\frac{\delta(t)\delta''(t)}{[\delta'(t)]^2}\le c_2\quad \textit{for all } t\in(0,\infty), \tag{3.10}$$

i.e., the function $\delta(t)\in\mathcal{U}_3$.

Proof. We show only that an S^*-regular function $\Delta_{p,q}(t)$ satisfies the property (3.10). Actually, we have

$$\frac{\Delta_{p,q}(t)\Delta''_{p,q}(t)}{[\Delta'_{p,q}(t)]^2}=\frac{\left(\frac{(t+1)^{p+1}-1}{p(p+1)}-\frac{(t+1)^{1-q}-1}{q(q-1)}-\frac{p+q}{pq}t\right)\left[(t+1)^{p-1}-(t+1)^{-1-q}\right]}{\left(\frac{(t+1)^p}{p}+\frac{(t+1)^{-q}}{q}-\frac{p+q}{pq}\right)^2}.$$

Dividing the numerator and denominator of the right-hand side of the above equation by $(t+1)^{2p}=(t+1)^{p+1}(t+1)^{p-1}$, we have

$$\frac{\Delta_{p,q}(t)\Delta''_{p,q}(t)}{[\Delta'_{p,q}(t)]^2}=\frac{\left(\frac{1-(t+1)^{-(p+1)}}{p(p+1)}+\frac{(t+1)^{-(p+1)}-(t+1)^{-(p+q)}}{q(q-1)}-\frac{(p+q)t}{pq(t+1)^{(p+1)}}\right)\left(1-\frac{1}{(t+1)^{(p+q)}}\right)}{\left(\frac{1}{p}+\frac{1}{q(t+1)^{(p+q)}}-\frac{p+q}{pq(t+1)^p}\right)^2}.$$

Therefore,

$$\lim_{t\to\infty}\frac{\Delta_{p,q}(t)\Delta''_{p,q}(t)}{[\Delta'_{p,q}(t)]^2}=\frac{p}{p+1}. \tag{3.11}$$

Since $\Delta''_{p,q}(t)=(t+1)^{p-1}-(t+1)^{-1-q}$, we have $\lim_{t\to 0_+}\Delta'''_{p,q}(t)=p+q$. Since $\Delta''_{p,q}(t)\to 0$, $\Delta'_{p,q}(t)\to 0$, and $\Delta_{p,q}(t)\to 0$ as $t\to 0_+$, we have

$$\lim_{t\to 0_+}\frac{(\Delta''_{p,q}(t))^2}{\Delta'_{p,q}(t)}=\lim_{t\to 0_+}\frac{[(\Delta''_{p,q}(t))^2]'}{[\Delta'_{p,q}(t)]'}=\lim_{t\to 0_+}\frac{2\Delta''_{p,q}(t)\Delta'''_{p,q}(t)}{\Delta''_{p,q}(t)}=2(p+q).$$

Hence, we have

$$\lim_{t\to 0_+}\frac{\Delta_{p,q}(t)}{2\Delta'_{p,q}(t)\Delta''_{p,q}(t)}=\lim_{t\to 0_+}\frac{\Delta'_{p,q}(t)}{2[\Delta''_{p,q}(t)]^2+2\Delta'_{p,q}(t)\Delta'''_{p,q}(t)}=\frac{1}{6(p+q)}.$$

Using the above relations, we further have

$$\begin{aligned}\lim_{t\to 0_+}\frac{\Delta_{p,q}(t)\Delta''_{p,q}(t)}{[\Delta'_{p,q}(t)]^2}&=\lim_{t\to 0_+}\frac{\Delta'_{p,q}(t)\Delta''_{p,q}(t)+\Delta_{p,q}(t)\Delta'''_{p,q}(t)}{2\Delta'_{p,q}(t)\Delta''_{p,q}(t)}\\&=\frac{1}{2}+\lim_{t\to 0_+}\frac{\Delta_{p,q}(t)}{2\Delta'_{p,q}(t)\Delta''_{p,q}(t)}\lim_{t\to 0_+}\Delta'''_{p,q}(t)=\frac{2}{3}.\end{aligned}\tag{3.12}$$

Notice that $\Delta_{p,q}(t)>0, \Delta''_{p,q}(t)>0$, and $\Delta'_{p,q}(t)>0$ in $(0,\infty)$. From (3.11) and (3.12), we can see by continuity that there exist two constants $\mu_2\ge\mu_1>0$ such that

$$\mu_1\le\frac{\Delta_{p,q}(t)\Delta''_{p,q}(t)}{[\Delta'_{p,q}(t)]^2}\le\mu_2\quad\text{for } t\in(0,\infty).$$

Together with (3.7) through (3.9), this implies that an S^*-regular function $\delta(t)$ satisfies the following inequality:

$$0<\mu_1\beta_1\le\frac{\delta(t)\delta''(t)}{[\delta'(t)]^2}\le\beta_2\mu_2.$$

Therefore, (3.10) holds with $c_1:=\mu_1\beta_1$ and $c_2:=\mu_2\beta_2$. □

A fact that should be pointed out here is that new functions in $\mathcal{U}_1$ or $\mathcal{U}_2$ can be constructed by using the basic operations (addition, multiplication, division, and composition) on known functions. The proof of the following fact is omitted.

LEMMA 3.5. (i) *If $\phi:(0,\infty)\to(0,\infty)$, $\phi\in\mathcal{U}_1$ with $\alpha=\alpha_1$, and $\varphi:(0,\infty)\to(0,\infty)$, $\varphi\in\mathcal{U}_1$ with $\alpha=\alpha_2$, then $\phi+\varphi\in\mathcal{U}_1$ with $\alpha=2\max\{\alpha_1,\alpha_2\}$.*

(ii) *If $\phi:(0,\infty)\to(0,\infty)$, $\phi\in\mathcal{U}_1$ with $\alpha_1\in(0,1]$, and $\varphi:(0,\infty)\to(0,\infty)$, $\varphi\in\mathcal{U}_1$ with $\alpha_2\in(0,1]$, then the multiplicative function $\phi(t)\cdot\varphi(t)\in\mathcal{U}_1$ with $\alpha=1$. Similarly, if $\phi\in\mathcal{U}_2$ with $\alpha_1\ge 1$ and $\varphi\in\mathcal{U}_2$ with $\alpha_2\ge 1$, then $\phi(t)\cdot\varphi(t)\in\mathcal{U}_2$ with $\alpha=1$.*

(iii) *If $\phi:(0,\infty)\to(0,\infty)$, $\phi\in\mathcal{U}_2$ with $\alpha_1\ge 1$, and $\varphi:(0,\infty)\to(0,\infty)$, $\varphi\in\mathcal{U}_1$ with $\alpha_2\in(0,1]$, then the function $\frac{\phi}{\varphi}\in\mathcal{U}_2$ with $\alpha=1$. Similarly, if $\phi\in\mathcal{U}_1$ with $\alpha_1\in(0,1]$ and $\varphi\in\mathcal{U}_2$ with $\alpha_2\ge 1$, then $\frac{\phi}{\varphi}\in\mathcal{U}_1$ with $\alpha=1$.*

(iv) *Let $\varphi:(0,\infty)\to\Omega_1\subset R$ and $\phi:\Omega_1\to(0,\infty)$ be two convex functions. If $\phi\in\mathcal{U}_1$ with $\alpha>0$, then the composite function $(\phi\circ\varphi)(t)=\phi(\varphi(t))\in\mathcal{U}_1$ with the same constant α.*

The next result shows that the composite functions of e^t belong to $\mathcal{U}_3$.

LEMMA 3.6. *Denote the exponential function e^t by $\exp(t)$ and the composition of m ($m\ge 1$) exponential functions by*

$$\theta_m(t):=\overbrace{(\exp\circ\exp\circ\cdots\circ\exp)}^{m}(t).$$

Then

$$\frac{1}{m}\theta_m(t)\theta''_m(t)\le[\theta'_m(t)]^2\le\theta_m(t)\theta''_m(t)\quad\text{for } t\in R.\tag{3.13}$$

Proof. Let $\alpha_m(t) := [\theta'_m(t)]^2/(\theta_m(t)\theta''_m(t))$ for $t \in R$. Since $\alpha_1(t) \equiv 1$, we can prove the right-hand side inequality of (3.13) using (iv) of Lemma 3.5 and mathematical induction. For the left-hand side inequality, notice that

$$\theta'_m(t) = \theta_m(t)\theta'_{m-1}(t),\ \theta''_m(t) = \theta_m(t)(\theta'_{m-1}(t))^2 + \theta_m(t)\theta''_{m-1}(t) \ \text{ for } t \in R.$$

This indicates that

$$\alpha_m(t) = \frac{1}{1 + \frac{1}{\alpha_{m-1}(t)\theta_{m-1}(t)}} > \frac{1}{1 + \frac{1}{\alpha_{m-1}(t)}} \ \text{ for } t \in R.$$

It is easy to check that $\alpha_2(t) \in (\frac{1}{2}, 1)$. The desired result follows by induction. ∎

To construct examples of the convex function Γ_w, Theorem 2.7 tells us that it suffices to find functions satisfying the inequalities (2.7) and (2.9) and compare their α values. The next result is to estimate the α values, or, equivalently, to estimate the values of c_1 and c_2 in (3.10). For simplicity, we use the S^*-regular functions with $p = 1$ and $q = 1, 2$ to estimate the required c_1 and c_2. In fact, we have the following result. Its proof was omitted here.

LEMMA 3.7. *The S^*-regular functions $\Delta_{1,1}(t)$ and $\Delta_{1,2}(t)$ given by* (3.5) *and* (3.6)*, respectively, satisfy condition* (3.10) *with $c_1 = \frac{1}{2}$ and $c_2 = \frac{2}{3}$; that is,*

$$\frac{3}{2}\Delta_{1,1}(t)\Delta''_{1,1}(t) \le [\Delta'_{1,1}(t)]^2 \le 2\Delta_{1,1}(t)\Delta''_{1,1}(t), \tag{3.14}$$

$$\frac{3}{2}\Delta_{1,2}(t)\Delta''_{1,2}(t) \le [\Delta'_{1,2}(t)]^2 \le 2\Delta_{1,2}(t)\Delta''_{1,2}(t) \tag{3.15}$$

for $t \in (0, \infty)$.

We now give the last result on how to construct some convex functions Γ_w.

THEOREM 3.8. *Let Ω be an open convex subset of R.*

(i) *Let $\phi : \Omega \to (0, \infty)$ be a convex, twice differentiable, strictly increasing function on Ω. If $\phi(t)\phi''(t) \le [\phi'(t)]^2$ for $t \in \Omega$, then the generalized mean function*

$$\Gamma_w^{(1)}(x) := \phi^{-1}\left(\sum_{i=1}^n \frac{w_i}{\phi(x_i)^r}\right)$$

is convex on Ω^n for any given $w \in R^n_{++}$ and $r > 0$.

(ii) *Let $\kappa > 0$ be a constant and $\phi : \Omega \to (\kappa, \infty)$ be a convex, twice differentiable, strictly increasing function satisfying the inequality $\phi(t)\phi''(t) \le [\phi'(t)]^2$ for $t \in \Omega$. Then, for any given $w \in R^n_{++}$ and $T > 0, r > 0$, the function*

$$\Gamma_w^{(2)}(x) := \overbrace{\ln \circ \ln \circ \cdots \circ \ln}^{\ell}\left(\sum_{i=1}^n w_i\left(T + \frac{1}{\phi(x_i)^r}\right)\right)$$

is convex on Ω^n for any positive integer $\ell \le T\kappa^r + 1$.

In fact, result (i) comes from part (i) of Theorem 2.9 and Theorem 2.7. Result (ii) follows from Lemma 3.6, Theorem 2.7, and part (ii) of Theorem 2.9. In fact, it suffices to take the inner function $h_T(t) = T + \frac{1}{\phi(t)^r}$ and outer function $\theta_m(t)$, as defined in Lemma 3.6, whose inverse function is given by $\overbrace{\ln \circ \ln \cdots \circ \ln}^{m}(t)$.

The above result partially answers the following interesting question: *Given a convex function, how many times can* log*-transformations be applied while retaining the convexity?*

Using Theorems 2.7, 2.9, and 3.8 and Lemma 3.7, we have the following examples of convex Γ_w.

Example 3.1.

(i) $\Delta_{1,j}^{-1}\left[\sum_{i=1}^{n}\frac{1}{\Delta_{1,j}(x_i)^r}\right]$,

(ii) $\ln\left(\sum_{i=1}^{n}\frac{1}{\Delta_{1,j}(x_i)^r}\right)$,

(iii) $\overbrace{\ln\circ\ln\circ\cdots\circ\ln}^{\ell\le m+1}\left(\sum_{i=1}^{n}\left(m+e^{-rx_i}\right)\right),\ x\in(0,\infty)^n.$

(iv) $\overbrace{\ln\circ\ln\circ\cdots\circ\ln}^{\ell}\left[\sum_{i=1}^{n}\left(m+\frac{1}{\Delta_{1,1}(x_i)^r}\right)\right],\ x\in(\tau,\infty)^n, \ell\le m\Delta_{1,1}(\tau)^r+1, \tau>0.$

It follows from Corollary 3.2 that the function x^p over $(0,\infty)$ satisfies (2.12) with $\alpha=\frac{p}{p-1}$. Hence, when $1<p\le 2$, we have $\alpha\ge 2$, and when $1<p\le\frac{29}{17}$, we have $\alpha\ge\frac{29}{12}\ge\frac{9}{4}$. By Lemma 3.7, both $\Delta_{1,2}(t)$ and $\Delta_{1,1}(t)$ satisfy condition (2.9) with $\alpha=2$. From Theorem 2.7, we see that the functions below are examples of convex Γ_w.

Example 3.2. Let $1<p\le 2$ and $\delta_i(t)=\Delta_{1,2}(t)$ or$\Delta_{1,1}(t)$ for $t\in(0,\infty)$ and $i=1,\ldots,n$. Then $\Gamma_w(x)=(\sum_{i=1}^{n}w_i\delta_i(x_i))^{\frac{1}{p}}$ is convex on $(0,\infty)^n$.

Before closing this section, we briefly illustrate a possible application of involving function Γ_w in the regularization method for solving a nonlinear programming problem:

$$\min\{f_0(x): x\in C\}.$$

For simplicity, we assume that C is a convex set and f_0 is a convex function. Let $\mu>0$ be a positive parameter. Given a strictly convex function Γ_w, we consider the following problem:

$$\min\{f_0(x)+\mu\Gamma_w(x): x\in C\}.$$

This problem becomes a strictly convex programming problem with a unique solution, denoted by $x(\mu)$, which comprises a continuation trajectory $\{x(\mu):\mu>0\}$. Under suitable conditions of f_0,Φ, and ϕ, this trajectory becomes bounded. In this case, by setting $\mu\to 0$, any accumulation point of $x(\mu)$, as $\mu\to 0$, is a solution to the original problem. Thus, a path-following algorithm can be designed to follow this trajectory to achieve the solution of the original problem. The performance of such a path-following algorithm certainly depends on the choice of the function Γ_w with regularity conditions.

4. Conclusions. In this paper, we have further extended the theoretical foundation for the generalized mean function. We have established a necessary and sufficient condition for such a generalization to be convex. Moreover, a systematic way to explicitly construct convex Γ_w has been illustrated. To this end, the concept of S^*-regular functions has been introduced. It should be noted that any S^*-regular function is not self-concordant [16].

Acknowledgments. We would like to thank the two anonymous referees for their insightful comments which helped improve significantly the results and presentation of the paper. We are especially grateful to one of the referees who brought the references [2] and [13] to our attention and provided Theorem 2.4 in this paper.

INTERIOR METHODS FOR MATHEMATICAL PROGRAMS WITH COMPLEMENTARITY CONSTRAINTS*

SVEN LEYFFER†, GABRIEL LÓPEZ-CALVA‡, AND JORGE NOCEDAL§

Abstract. This paper studies theoretical and practical properties of interior-penalty methods for mathematical programs with complementarity constraints. A framework for implementing these methods is presented, and the need for adaptive penalty update strategies is motivated with examples. The algorithm is shown to be globally convergent to strongly stationary points, under standard assumptions. These results are then extended to an interior-relaxation approach. Superlinear convergence to strongly stationary points is also established. Two strategies for updating the penalty parameter are proposed, and their efficiency and robustness are studied on an extensive collection of test problems.

Key words. mathematical programs with complementarity constraints, nonlinear programming, interior-point methods, exact penalty, equilibrium constraints, complementarity constraints

1. Introduction.

In this paper we study the numerical solution of mathematical programs with complementarity constraints (MPCCs) of the form

$$\begin{aligned}
&\text{minimize} && f(x) && \text{(1.1a)}\\
&\text{subject to} && c_i(x) = 0, \quad i \in \mathcal{E}, && \text{(1.1b)}\\
& && c_i(x) \geq 0, \quad i \in \mathcal{I}, && \text{(1.1c)}\\
& && 0 \leq x_1 \perp x_2 \geq 0. && \text{(1.1d)}
\end{aligned}$$

The variables have been divided as $x = (x_0, x_1, x_2)$, with $x_0 \in \mathbb{R}^n$, $x_1, x_2 \in \mathbb{R}^p$. The complementarity condition (1.1d) stands for

$$x_1 \geq 0,\ x_2 \geq 0 \ \text{ and either } \ x_{1i} = 0 \ \text{ or } \ x_{2i} = 0 \ \text{ for } \ i = 1, \ldots, p, \tag{1.2}$$

where x_{1i}, x_{2i} are the ith components of vectors x_1 and x_2, respectively.

Complementarity (1.2) represents a logical condition (a disjunction) and must be expressed in analytic form if we wish to solve the MPCC using nonlinear programming

methods. A popular reformulation of the MPCC is

$$\begin{aligned}
&\text{minimize} && f(x) && \text{(1.3a)}\\
&\text{subject to} && c_i(x) = 0, \quad i \in \mathcal{E}, && \text{(1.3b)}\\
& && c_i(x) \geq 0, \quad i \in \mathcal{I}, && \text{(1.3c)}\\
& && x_1 \geq 0, \quad x_2 \geq 0, && \text{(1.3d)}\\
& && x_{1i}x_{2i} \leq 0, \quad i = 1, \ldots, p. && \text{(1.3e)}
\end{aligned}$$

This formulation preserves the solution set of the MPCC but is not totally adequate because it violates the Mangasarian–Fromowitz constraint qualification (MFCQ) at any feasible point. This lack of regularity can create problems when applying *classical* nonlinear programming algorithms. For example, sequential quadratic programming (SQP) methods can give rise to inconsistent constraint linearizations. Interior methods exhibit inefficiencies caused by the conflicting goals of enforcing complementarity while keeping the variables x_1, x_2 away from their bounds.

Modern nonlinear programming algorithms include, however, regularization techniques and other safeguards to deal with degeneracy, and one cannot rule out the possibility that they can cope with the difficulties created by the formulation (1.3) without having to exploit the special structure of MPCCs. If this level of robustness could be attained (and this is a laudable goal) there might be no need to develop algorithms specifically for MPCCs.

Numerical experiments by Fletcher and Leyffer [12] suggest that this goal is almost achieved by modern active-set SQP methods. In [12], FILTERSQP [11] was used to solve the problems in the MacMPEC collection [18], which contains more than a hundred MPCCs, and fast convergence was almost always observed. The reason for this practical success is that, even though the formulation (1.3) fails to satisfy MFCQ, it is locally equivalent to a nonlinear program that satisfies MFCQ, and a robust SQP solver is able to identify the right set of active constraints in the well-behaved program and converge to a solution. Failures, however, are still possible for the SQP approach. Fletcher et al. [13] give several examples that illustrate ways in which an SQP method may fail to converge.

Interior methods are less successful when applied directly to the nonlinear programming formulation (1.3). Fletcher and Leyffer [12] tested LOQO [25] and KNITRO [4] and observed that they were slower and less reliable than the SQP solvers FILTERSQP and SNOPT [15] (all codes as of 2002). This result contrasts starkly with the experience in nonlinear programming, where interior methods compete well with SQP methods. These studies have stimulated considerable interest in developing interior methods for MPCCs that guarantee both global convergence and efficient practical performance. The approaches can be broadly grouped into two categories.

The first category comprises relaxation approaches, where (1.3) is replaced by a family of problems in which (1.3e) is changed to

$$x_{1i}x_{2i} \leq \theta, \quad i = 1, \ldots, p, \tag{1.4}$$

and the relaxation parameter $\theta > 0$ is driven to zero. This type of approach has been studied from a theoretical perspective by Scholtes [24] and Ralph and Wright [22]. Interior methods based on the relaxation (1.4) have been proposed by Liu and Sun [19] and Raghunathan and Biegler [21]. In both studies, the parameter θ is proportional to the barrier parameter μ and is updated only at the end of each barrier problem. Raghunathan and Biegler focus on local analysis and report very good numerical

results on the MacMPEC collection. Liu and Sun analyze global convergence of their algorithm and report limited numerical results. Numerical difficulties may arise when the relaxation parameter gets small, since the interior of the regularized problem shrinks toward the empty set.

DeMiguel et al. [8] address this problem by proposing a different relaxation scheme where, in addition to (1.4), the nonnegativity bounds on the variables are relaxed to

$$x_{1i} \geq -\delta, \quad x_{2i} \geq -\delta. \tag{1.5}$$

Under fairly general assumptions, their algorithm drives either θ or δ, but not both, to zero. This provides the resulting family of problems with a strict interior, even when the appropriate relaxation parameters are approaching zero, which is a practical advantage over the previous relaxation approach. The drawback is that the algorithm has to correctly identify the parameters that must be driven to zero, a requirement that can be difficult to meet in some cases.

The second category involves a regularization technique based on an exact-penalty reformulation of the MPCC. Here, (1.3e) is moved to the objective function in the form of an ℓ_1-penalty term, so that the objective becomes

$$f(x) + \pi x_1^T x_2, \tag{1.6}$$

where $\pi > 0$ is a penalty parameter. If π is chosen large enough, the solution of the MPCC can be recast as the minimization of a single penalty function. The appropriate value of π is, however, unknown in advance and must be estimated during the course of the minimization.

This approach was first studied by Anitescu [1] in the context of active-set SQP methods, although it had been used before to solve engineering problems (see, e.g., [10]). It has been adopted as a heuristic to solve MPCCs with interior methods in LOQO by Benson et al. [3], who present very good numerical results on the MacMPEC set. A more general class of exact penalty functions was analyzed by Hu and Ralph [17], who derive global convergence results for a sequence of penalty problems that are solved exactly. Anitescu [2] derives similar global results in the context of inexact subproblem solves.

In this paper, we focus on the penalization approach, because we view it as a general tool for handling degenerate nonlinear programs. Our goal is to study global and local convergence properties of interior-penalty methods for MPCCs and to propose efficient and robust practical implementations.

In section 2 we present the interior-penalty framework; some examples motivate the need for proper updating strategies for the penalty parameter. Section 3 shows that the proposed interior-penalty method converges globally to strongly stationary points, under standard assumptions. These results are then extended to the interior-relaxation approaches considered in [19] and [21]. In section 4 we show that, near a solution that satisfies some standard regularity properties, the penalty parameter is not updated and the iterates converge superlinearly to the solution. Section 5 presents two practical implementations of the interior-penalty method with different updating strategies for the penalty parameter. Our numerical experiments, reported in the same section, favor a dynamic strategy that assesses the magnitude of the penalty parameter at every iteration.

2. An interior-penalty method for MPCCs. To circumvent the difficulties caused by the complementarity constraints, we replace (1.3) by the ℓ_1-penalty problem

$$\begin{aligned} &\text{minimize} && f(x) + \pi x_1^T x_2, \\ &\text{subject to} && c_i(x) = 0, \quad i \in \mathcal{E}, \\ &&& c_i(x) \geq 0, \quad i \in \mathcal{I}, \\ &&& x_1 \geq 0,\ x_2 \geq 0, \end{aligned} \tag{2.1}$$

where $\pi > 0$ is a penalty parameter. In principle, the ℓ_1-penalty term should have the form $\sum_i \max\{0, x_{1i}x_{2i}\}$, but we can write it as $x_1^T x_2$ if we enforce the nonnegativity of x_1, x_2. This exact penalty reformulation of MPCCs has been studied in [1, 2, 3, 17, 22, 23]. Since problem (2.1) is smooth, we can safely apply standard nonlinear programming algorithms, such as interior methods, to solve it. The barrier problem associated to (2.1) is

$$\begin{aligned} &\text{minimize} && f(x) + \pi x_1^T x_2 - \mu \sum_{i \in \mathcal{I}} \log s_i - \mu \sum_{i=1}^{p} \log x_{1i} - \mu \sum_{i=1}^{p} \log x_{2i} \\ &\text{subject to} && c_i(x) = 0, \quad i \in \mathcal{E}, \\ &&& c_i(x) - s_i = 0, \quad i \in \mathcal{I}, \end{aligned} \tag{2.2}$$

where $\mu > 0$ is the barrier parameter and $s_i > 0$, $i \in \mathcal{I}$, are slack variables. The Lagrangian of this barrier problem is given by

$$\begin{aligned} \mathcal{L}_{\mu,\pi}(x, s, \lambda) = f(x) + \pi x_1^T x_2 - \mu \sum_{i \in \mathcal{I}} \log s_i - \mu \sum_{i=1}^{p} \log x_{1i} - \mu \sum_{i=1}^{p} \log x_{2i} \\ - \sum_{i \in \mathcal{E}} \lambda_i c_i(x) - \sum_{i \in \mathcal{I}} \lambda_i (c_i(x) - s_i), \end{aligned} \tag{2.3}$$

and the first-order Karush–Kuhn–Tucker (KKT) conditions of (2.2) can be written as

$$\begin{aligned} \nabla f(x) - \nabla c_{\mathcal{E}}(x)^T \lambda_{\mathcal{E}} - \nabla c_{\mathcal{I}}(x)^T \lambda_{\mathcal{I}} - \begin{pmatrix} 0 \\ \mu X_1^{-1} e - \pi x_2 \\ \mu X_2^{-1} e - \pi x_1 \end{pmatrix} = 0, \\ s_i \lambda_i - \mu = 0, \quad i \in \mathcal{I}, \\ c_i(x) = 0, \quad i \in \mathcal{E}, \\ c_i(x) - s_i = 0, \quad i \in \mathcal{I}, \end{aligned} \tag{2.4}$$

where we have grouped the components $c_i(x), i \in \mathcal{E}$, into the vector $c_{\mathcal{E}}(x)$, and similarly for $c_{\mathcal{I}}(x), \lambda_{\mathcal{E}}, \lambda_{\mathcal{I}}$. We also define $\lambda = (\lambda_{\mathcal{E}}, \lambda_{\mathcal{I}})$. X_1 denotes the diagonal matrix containing the elements of x_1 on the diagonal (the same convention is used for X_2 and S), and e is a vector of ones of appropriate dimension.

The KKT conditions (2.4) can be expressed more compactly as

$$\nabla_x \mathcal{L}_{\mu,\pi}(x, s, \lambda) = 0, \tag{2.5a}$$

$$S\lambda_{\mathcal{I}} - \mu e = 0, \tag{2.5b}$$

$$c(x, s) = 0, \tag{2.5c}$$

where we define

$$c(x,s) = \begin{pmatrix} c_{\mathcal{E}}(x) \\ c_{\mathcal{I}}(x) - s \end{pmatrix}. \tag{2.6}$$

In Figure 1, we describe an interior method for MPCCs based on the ℓ_1-penalty formulation. Here, and in the rest of the paper, $\|\cdot\|$ denotes the infinity norm. This is consistent with our implementation; it also simplifies the exposition, without compromising the generality of our results.

In addition to requiring that the optimality conditions (2.7) of the barrier problem are satisfied approximately, we impose a reduction in the complementarity term by means of (2.8). For now, the only requirement on the sequence of barrier parameters $\{\mu^k\}$ and the stopping tolerances $\{\epsilon^k_{pen}\}, \{\epsilon^k_{comp}\}$ is that they all converge to 0 as $k \to \infty$. Later, in the local analysis of section 4, we impose further conditions on the relative rate of convergence of these sequences.

Algorithm I: Interior-Penalty Method for MPCCs

Initialization: Let x^0, s^0, λ^0 be the initial primal and dual variables. Set $k = 1$.

repeat

1. Choose a barrier parameter μ^k, stopping tolerances ϵ^k_{pen} and ϵ^k_{comp}
2. Find π^k and an approximate solution (x^k, s^k, λ^k) of problem (2.2) with parameters μ^k and π^k that satisfy $x^k_1 > 0, x^k_2 > 0, s^k > 0, \lambda^k_{\mathcal{I}} > 0$ and the following conditions:

$$\|\nabla_x \mathcal{L}_{\mu^k,\pi^k}(x^k, s^k, \lambda^k)\| \le \epsilon^k_{pen}, \tag{2.7a}$$

$$\|S^k \lambda^k_{\mathcal{I}} - \mu^k e\| \le \epsilon^k_{pen}, \tag{2.7b}$$

$$\|c(x^k, s^k)\| \le \epsilon^k_{pen}, \tag{2.7c}$$

and

$$\|\min\{x^k_1, x^k_2\}\| \le \epsilon^k_{comp} \tag{2.8}$$

3. Let $k \leftarrow k + 1$

until a stopping test for the MPCC is satisfied.

FIG. 1. *An interior-penalty method for MPCCs.*

We use $\|\min\{x^k_1, x^k_2\}\|$ in (2.8) as a measure of complementarity, rather than $x^{kT}_1 x^k_2$, because it is less sensitive to the scaling of the problem and is independent of the number of variables. Moreover, this measure is accurate even when both x^k_{1i} and x^k_{2i} converge to zero.

Our formulation of Algorithm I is sufficiently general to permit various updating strategies for the penalty parameter in step 2. One option is to choose μ^k and solve (2.2) with $\pi^k = \pi^{k-1}$, until conditions (2.7) are satisfied. If condition (2.8) also holds, then we proceed to step 3. Otherwise, we increase π^k and solve (2.2) again using the same barrier parameter μ^k. The process is repeated, if necessary, until (2.8) is satisfied. We show in section 5 that Algorithm I with this penalty update strategy is much more robust and efficient than the direct application of an interior method to (1.3). Nevertheless, there are some flaws in a strategy that holds the penalty

parameter fixed throughout the minimization of a barrier problem, as illustrated by the following examples.

The results reported next were obtained with an implementation of Algorithm I that uses the penalty update strategy described in the previous paragraph. The initial parameters are $\pi^1 = 1, \mu^1 = 0.1$, and we set $\epsilon^k_{comp} = (\mu^k)^{0.4}$ for all k. When the penalty parameter is increased, it is multiplied by 10. The other details of the implementation are discussed in section 5 and are not relevant to the discussion that follows.

Example 1 (`ralph2`). Consider the MPCC

$$\begin{aligned} &\text{minimize} && x_1^2 + x_2^2 - 4x_1x_2 \\ &\text{subject to} && 0 \le x_1 \perp x_2 \ge 0, \end{aligned} \tag{2.9}$$

whose solution is $(0, 0)$. The associated penalty problem is

$$\begin{aligned} &\text{minimize} && (x_1 - x_2)^2 + (\pi - 2)x_1x_2 \\ &\text{subject to} && x_1 \ge 0,\ x_2 \ge 0, \end{aligned} \tag{2.10}$$

which is unbounded for any $\pi < 2$. Starting with $\pi^1 = 1$, the first barrier problem is never solved. The iterates increase monotonically because, by doing so, the objective function is reduced and feasibility is maintained for problem (2.10). Eventually, the iterates diverge. Table 1 shows the values of x_1x_2 during the first eight iterations of the inner algorithm in step 2.

TABLE 1
Complementarity values for problem `ralph2`.

Iterate	1	2	3	4	5	6	7	8
Complementarity	0.0264	0.0916	0.1480	51.70	63.90	79.00	97.50	120.0

The upward trend in complementarity should be taken as a warning sign that the penalty parameter is not large enough, since no progress is made toward satisfaction of (2.8). This suggests that we should be prepared to increase the penalty parameter dynamically. How to do so, in a robust manner, is not a simple question because complementarity can oscillate. We return to this issue in section 5, where we describe a dynamic strategy for updating the penalty parameter. □

Example 2 (`scale1`). Even if the penalty problem is bounded, there are cases where efficiency can be improved with a more flexible strategy for updating π^k. For example, consider the MPCC

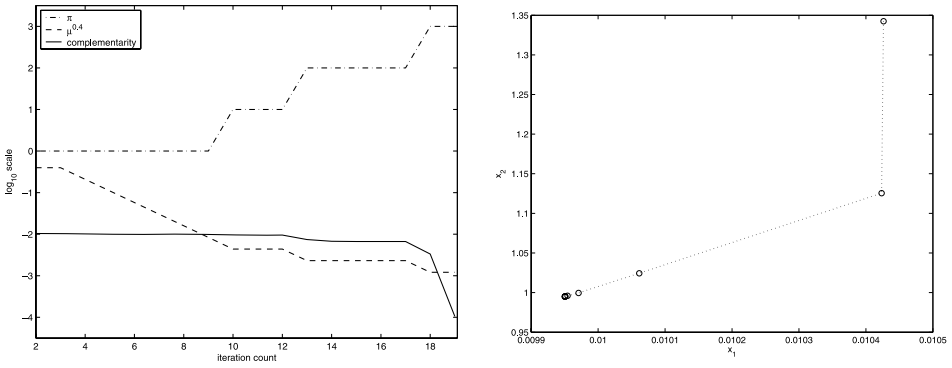
$$\begin{aligned} &\text{minimize} && (100x_1 - 1)^2 + (x_2 - 1)^2 \\ &\text{subject to} && 0 \le x_1 \perp x_2 \ge 0, \end{aligned} \tag{2.11}$$

which has two local solutions: $(0.01, 0)$ and $(0, 1)$. Table 2 shows the first seven values of x^k satisfying (2.7) and (2.8), and the corresponding values of μ^k.

We observe that complementarity, as measured by $\min\{x_1^k, x_2^k\}$, stagnates. This result is not surprising because the minimum penalty parameter required to recover the solution $(0, 1)$ is $\pi^* = 200$ and we have used the value $\pi^1 = 1$. In fact, for any $\pi < 200$, there is a saddle point close to $(0, 1)$, and the iterates approach that saddle point. Seven barrier problems must be solved before the test (2.8) is violated for the first time, triggering the first update of π^k.

TABLE 2
Solutions of 7 *consecutive barrier-penalty problems for* `scale1`.

k	1	2	3	4	5	6	7
μ^k	0.1	0.02	0.004	0.0008	0.00016	0.000032	0.0000064
x_1^k	0.010423	0.010061	0.009971	0.009954	0.009951	0.009950	0.009950
x_2^k	1.125463	1.024466	0.999634	0.995841	0.995186	0.995057	0.995031
ϵ_{comp}^k	0.398107	0.209128	0.109856	0.057708	0.030314	0.015924	0.008365



(a) Complementarity gap. (b) Solution path.

FIG. 2. *A numerical solution of problem* `scale1`.

The behavior of the algorithm is illustrated in Figure 2(a), which plots three quantities as a function of the inner iterations. Complementarity (continuous line) stalls at a nonzero value during the first 10 iterations, while μ^k (dashed line) decreases monotonically. The penalty parameter (dashed-dotted line) is increased for the first time at iteration 9. It must be increased three times to surpass the threshold value $\pi^* = 200$, which finally forces complementarity down to zero. Figure 2(b) shows the path of the iterates up to the solution of the seventh barrier problem. There is a clear pattern of convergence to the stationary point where none of the variables is zero. If this convergence pattern can be identified early, the penalty parameter can be increased sooner, saving some iterations in the solution of the MPCC. □

One could ask whether the penalty parameter needs to be updated at all, or whether choosing a very large value of π and holding it fixed during the execution of Algorithm I could prove to be an effective strategy. In section 5 we show that excessively large penalty parameters can result in substantial loss of efficiency. More important, no matter how large π is, for some problems the penalty function is unbounded outside a small neighborhood of the solution, and a bad initial point makes the algorithm diverge if π is kept fixed (see [20] for an example).

In section 5, we describe a dynamic strategy for updating the penalty parameter. We show that it is able to promptly identify the undesirable behavior described in these examples and to react accordingly.

3. Global convergence analysis. In this section, we present the global convergence analysis of an interior-penalty method. We start by reviewing an MPCC constraint qualification that suffices to derive first-order optimality conditions for MPCCs. We then review stationarity concepts.

DEFINITION 3.1. *We say that the* MPCC linear independence constraint qualification *(MPCC-LICQ) holds at a feasible point x for the MPCC* (1.1) *if and only if the standard LICQ holds at x for the set of constraints*

$$\begin{aligned} c_i(x) &= 0, \quad i \in \mathcal{E}, \\ c_i(x) &\geq 0, \quad i \in \mathcal{I}, \\ x_1 \geq 0, &\quad x_2 \geq 0. \end{aligned} \tag{3.1}$$

We denote indices of the active constraints at a feasible point x by

$$\begin{aligned} \mathcal{A}_c(x) &= \{i \in \mathcal{I} : c_i(x) = 0\}, \\ \mathcal{A}_1(x) &= \{i \in \{1, \ldots, p\} : x_{1i} = 0\}, \\ \mathcal{A}_2(x) &= \{i \in \{1, \ldots, p\} : x_{2i} = 0\}. \end{aligned} \tag{3.2}$$

For ease of notation, we use $i \notin \mathcal{A}_1(x)$ as shorthand for $i \in \{1, \ldots, p\} \setminus \mathcal{A}_1(x)$ (likewise for $\mathcal{A}_2, \mathcal{A}_c$). We sometimes refer to variables satisfying $x_{1i} + x_{2i} > 0$ as *branch variables*; those for which $x_{1i} + x_{2i} = 0$, that is, variables indexed by $\mathcal{A}_1(x) \cap \mathcal{A}_2(x)$, are called *corner variables*.

The next theorem establishes the existence of multipliers for minimizers that satisfy MPCC-LICQ. It can be viewed as a counterpart for MPCCs of the first-order KKT theorem for nonlinear programs.

THEOREM 3.2. *Let x^* be a minimizer of the MPCC* (1.1), *and suppose MPCC-LICQ holds at x^*. Then, there exist multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$ that, together with x^*, satisfy the system*

$$\nabla f(x) - \nabla c_{\mathcal{E}}(x)^T \lambda_{\mathcal{E}} - \nabla c_{\mathcal{I}}(x)^T \lambda_{\mathcal{I}} - \begin{pmatrix} 0 \\ \sigma_1 \\ \sigma_2 \end{pmatrix} = 0, \tag{3.3a}$$

$$c_i(x) = 0, \quad i \in \mathcal{E}, \tag{3.3b}$$

$$c_i(x) \geq 0, \quad i \in \mathcal{I}, \tag{3.3c}$$

$$x_1 \geq 0, x_2 \geq 0, \tag{3.3d}$$

$$x_{1i} = 0 \text{ or } x_{2i} = 0, \quad i = 1, \ldots, p, \tag{3.3e}$$

$$c_i(x)\lambda_i = 0, \quad i \in \mathcal{I}, \tag{3.3f}$$

$$\lambda_i \geq 0, \quad i \in \mathcal{I}, \tag{3.3g}$$

$$x_{1i}\sigma_{1i} = 0 \quad \text{and} \quad x_{2i}\sigma_{2i} = 0, \quad i = 1, \ldots, p, \tag{3.3h}$$

$$\sigma_{1i} \geq 0, \sigma_{2i} \geq 0, \quad i \in \mathcal{A}_1(x) \cap \mathcal{A}_2(x). \tag{3.3i}$$

For a proof of this theorem, see [23] or an alternative proof in [20].

We note that the multipliers σ_1, σ_2 are required to be nonnegative only for corner variables. This requirement reflects the geometry of the feasible set: If $x_{1i} > 0$, then $x_{2i} = 0$ acts like an equality constraint, and the corresponding multiplier can be positive or negative. Theorem 3.2 motivates the following definition.

DEFINITION 3.3. (a) *A point x^* is called a* strongly stationary point *of the MPCC* (1.1) *if there exist multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$ such that* (3.3) *is satisfied.* (b) *A point x^* is called a* C-stationary point *of the MPCC* (1.1) *if there exist multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$ such that conditions* (3.3a)–(3.3h) *hold and*

$$\sigma_{1i}^* \sigma_{2i}^* \geq 0, \quad i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*). \tag{3.4}$$

Strong stationarity implies the absence of first-order feasible descent directions. These are the points that the algorithms should aim for. Although C-stationarity does not characterize the solutions of an MPCC, since it allows descent directions if $\sigma_{1i} < 0$ or $\sigma_{2i} < 0$, we consider C-stationary points because they are attractors of iterates generated by Algorithm I. One can find examples in which a sequence of stationary points of the penalty problem converge to a C-stationary point where descent directions exist, and this phenomenon can actually be observed in practice (see case 1 of Example 3.1 in [17] and the comments on problem `scale4` in section 5). The reader further interested in stationarity for MPCCs is referred to [23].

3.1. Global convergence of the interior-penalty algorithm. Many algorithms have been proposed to solve the barrier problem in step 2; see, for example, [7, 14] and the references therein. As is well known, these inner algorithms may fail to satisfy (2.7), and therefore Algorithm I can fail to complete step 2. The analysis of the inner algorithm is beyond the scope of this paper, and we concentrate only on the analysis of the outer iterations in Algorithm I. We assume that the inner algorithm is always successful and that Algorithm I generates an infinite sequence of iterates $\{x^k, s^k, \lambda^k\}$ that satisfies conditions (2.7) and (2.8).

We present the following result in the slightly more general setting in which a vector of penalties $\pi = (\pi_1, \ldots, \pi_p)$ is used, with the objective function as

$$f(x) + \pi^T X_1 x_2, \tag{3.5}$$

and with minor changes in the Lagrangian of the problem. This allows us to extend the global convergence result to the relaxation approach in the next subsection. For the implementation, however, we use a uniform (i.e., scalar-valued) penalty.

THEOREM 3.4. *Suppose that Algorithm* I *generates an infinite sequence of iterates* $\{x^k, s^k, \lambda^k\}$ *and parameters* $\{\pi^k, \mu^k\}$ *that satisfies conditions* (2.7) *and* (2.8), *for sequences* $\{\epsilon^k_{pen}\}, \{\epsilon^k_{comp}\}, \{\mu^k\}$ *converging to zero. If* x^* *is a limit point of the sequence* $\{x^k\}$, *and* f *and* c *are continuously differentiable in an open neighborhood* $\mathcal{N}(x^*)$ *of* x^*, *then* x^* *is feasible for the MPCC* (1.1). *If, in addition, MPCC-LICQ holds at* x^*, *then* x^* *is a C-stationary point of* (1.1). *Moreover, if* $\pi^k_i x^k_{ji} \to 0$ *for* $j = 1, 2$ *and* $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$, *then* x^* *is a strongly stationary point of* (1.1).

Proof. Let x^* be a limit point of the sequence $\{x^k\}$ generated by Algorithm I, and let $\mathcal{K}$ be an infinite index set such that $\{x^k\}_{k\in\mathcal{K}} \to x^*$. Then, $x^k \in \mathcal{N}(x^*)$ for all k sufficiently large; from the assumption of continuous differentiability on $\mathcal{N}(x^*)$, and $\{x^k\}_{k\in\mathcal{K}} \to x^*$, we conclude that the sequences $\{f(x^k)\}$, $\{c(x^k)\}$, $\{\nabla f(x^k)\}$, $\{\nabla c_{\mathcal{E}}(x^k)\}$, $\{\nabla c_{\mathcal{I}}(x^k)\}$, $k \in \mathcal{K}$, have limit points and are therefore bounded.

Since the inner algorithm used in Step 2 enforces positivity of the slacks s^k, by continuity of c and the condition $\epsilon^k_{pen} \to 0$ we have

$$c_i(x^*) = 0, \quad i \in \mathcal{E},$$

$$c_i(x^*) = s^*_i \geq 0, \quad i \in \mathcal{I},$$

where $s^*_i = \lim_{k\in\mathcal{K}} s^k_i$. Therefore x^* satisfies (3.3b) and (3.3c), and it also satisfies (3.3d) because the inner algorithm enforces the positivity of x^k. The complementarity condition (3.3e) follows directly from (2.8) and $\epsilon^k_{comp} \to 0$. Therefore, x^* is feasible for the MPCC (1.1).

Existence of multipliers. Let us define

$$\sigma_{1i}^k = \frac{\mu^k}{x_{1i}^k} - \pi_i^k x_{2i}^k, \qquad \sigma_{2i}^k = \frac{\mu^k}{x_{2i}^k} - \pi_i^k x_{1i}^k \tag{3.6}$$

and

$$\alpha^k = \|(\lambda^k, \sigma_1^k, \sigma_2^k)\|. \tag{3.7}$$

(Recall $\|\cdot\|$ denotes the infinity norm.) We first show that $\{\alpha^k\}_{k\in\mathcal{K}}$ is bounded, a result that implies that the sequence of multipliers $(\lambda^k, \sigma_1^k, \sigma_2^k)$ has a limit point. Then we show that any limit point satisfies C-stationarity at x^*.

We can assume, without loss of generality, that $\alpha_k \geq \tau > 0$ for all $k \in \mathcal{K}$. Indeed, if there were a further subsequence $\{\alpha_k\}_{k\in\mathcal{K}'}$ converging to 0, this subsequence would be trivially bounded, and we would apply the analysis below to $\{\alpha_k\}_{k\in\mathcal{K}\setminus\mathcal{K}'}$, which is bounded away from 0, to prove the boundedness of the entire sequence $\{\alpha_k\}_{k\in\mathcal{K}}$.

Let us define the "normalized multipliers"

$$\hat{\lambda}^k = \frac{\lambda^k}{\alpha^k}, \quad \hat{\sigma}_1^k = \frac{\sigma_1^k}{\alpha^k}, \quad \hat{\sigma}_2^k = \frac{\sigma_2^k}{\alpha^k}. \tag{3.8}$$

We now show that the normalized multipliers corresponding to inactive constraints converge to 0 for $k \in \mathcal{K}$. Consider an index $i \notin \mathcal{A}_c(x^*)$, where $\mathcal{A}_c$ is defined by (3.2). Since $s_i^k \to c_i(x^*) > 0$ and $s_i^k \lambda_i^k \to 0$ by (2.7b), we have that λ_i^k converges to 0, and so does $\hat{\lambda}_i^k$.

Next consider an index $i \notin \mathcal{A}_1(x^*)$. We want to show that $\hat{\sigma}_{1i}^k \to 0$. If $i \notin \mathcal{A}_1(x^*)$, then $x_{1i}^k \to x_{1i}^* > 0$, which implies that $x_{2i}^k \to 0$, by (2.8) and $\epsilon_{comp}^k \to 0$. We also have, from (3.6), that for any $k \in \mathcal{K}$,

$$\sigma_{1i}^k \neq 0 \quad \Rightarrow \quad \frac{\mu^k}{x_{1i}^k} - \pi_i^k x_{2i}^k \neq 0 \quad \Rightarrow \quad \frac{\mu^k}{x_{2i}^k} - \pi_i^k x_{1i}^k \neq 0 \quad \Rightarrow \quad \sigma_{2i}^k \neq 0. \tag{3.9}$$

Using this and the fact that $|\sigma_{2i}^k| \leq \alpha^k$, we have that, if there is any subsequence of indices k for which $\sigma_{1i}^k \neq 0$, then

$$\begin{aligned} |\hat{\sigma}_{1i}^k| = \frac{|\sigma_{1i}^k|}{\alpha^k} \leq \frac{|\sigma_{1i}^k|}{|\sigma_{2i}^k|} &= \frac{\left|\frac{\mu^k}{x_{1i}^k} - \pi_i^k x_{2i}^k\right|}{\left|\frac{\mu^k}{x_{2i}^k} - \pi_i^k x_{1i}^k\right|} \\ &= \frac{\left|\frac{\mu^k - \pi_i^k x_{1i}^k x_{2i}^k}{x_{1i}^k}\right|}{\left|\frac{\mu^k - \pi_i^k x_{1i}^k x_{2i}^k}{x_{2i}^k}\right|} = \frac{x_{2i}^k}{x_{1i}^k} \to 0. \end{aligned}$$

Since clearly $\hat{\sigma}_{1i}^k \to 0$ for those indices with $\sigma_{1i}^k = 0$, we have that the whole sequence $\hat{\sigma}_{1i}^k$ converges to zero for $i \notin \mathcal{A}_1(x^*)$. The same argument can be applied to show that $\hat{\sigma}_{2i}^k \to 0$ for $i \notin \mathcal{A}_2(x^*)$. Therefore we have shown that the normalized multipliers (3.8) corresponding to the inactive constraints converge to zero for $k \in \mathcal{K}$.

To prove that $\{\alpha^k\}_{k\in\mathcal{K}}$ is bounded, we proceed by contradiction and assume that there exists $\mathcal{K}' \subseteq \mathcal{K}$ such that $\{\alpha^k\}_{k\in\mathcal{K}'} \to \infty$. By definition, the sequences of normalized multipliers (3.8) are bounded, so we restrict $\mathcal{K}'$ further, if necessary, so that the sequences of normalized multipliers are convergent within $\mathcal{K}'$. Given that

$\mathcal{K}' \subseteq \mathcal{K}$, all the sequences of gradients $\{\nabla f(x^k)\}$, $\{\nabla c_{\mathcal{E}}(x^k)\}$, $\{\nabla c_{\mathcal{I}}(x^k)\}$, $k \in \mathcal{K}'$, are convergent. We can then divide both sides of (2.7a) by α^k and take limits to get

$$\lim_{k\to\infty, k\in\mathcal{K}'} \left\| \frac{1}{\alpha^k} \nabla_x \mathcal{L}_{\mu^k,\pi^k}(x^k, s^k, \lambda^k) \right\| \leq \lim_{k\to\infty, k\in\mathcal{K}'} \frac{\epsilon^k_{pen}}{\alpha^k} = 0$$

or

$$\lim_{k\to\infty, k\in\mathcal{K}'} \left[\frac{1}{\alpha^k} \nabla f^k - \sum_{i\in\mathcal{E}\cup\mathcal{I}} \hat{\lambda}^k_i \nabla c_i(x^k) - \begin{pmatrix} 0 \\ \hat{\sigma}^k_1 \\ \hat{\sigma}^k_2 \end{pmatrix} \right] = 0. \tag{3.10}$$

It is immediate that the first term of (3.10) converges to 0. We showed that the coefficients (the normalized multipliers (3.8)) of the inactive constraints also converge to zero. Since the corresponding sequences of gradients have limits (hence are bounded), all the terms corresponding to inactive constraints get cancelled in the limit, and we have

$$\sum_{i\in\mathcal{E}\cup\mathcal{A}_c(x^*)} \hat{\lambda}^*_i \nabla c_i(x^*) + \sum_{i\in\mathcal{A}_1(x^*)} \hat{\sigma}^*_{1i} \begin{pmatrix} 0 \\ e_i \\ 0 \end{pmatrix} + \sum_{i\in\mathcal{A}_2(x^*)} \hat{\sigma}^*_{2i} \begin{pmatrix} 0 \\ 0 \\ e_i \end{pmatrix} = 0.$$

If the limit point x^* satisfies MPCC-LICQ, then the constraint gradients involved in this expression are linearly independent, and we get

$$\hat{\lambda}^* = 0, \;\; \hat{\sigma}^*_1 = 0, \;\; \hat{\sigma}^*_2 = 0.$$

This result, however, contradicts the fact that $\|(\hat{\lambda}^k, \hat{\sigma}^k_1, \hat{\sigma}^k_2)\| = 1$ for all $k \in \mathcal{K}'$, which follows from (3.7), (3.8), and the assumption that $\lim_{k\to\infty, k\in\mathcal{K}'} \alpha^k \to \infty$. Therefore, we conclude that no such unbounded subsequence exists, and hence all the sequences $\{\lambda^k\}, \{\sigma^k_1\}, \{\sigma^k_2\}$, with $k \in \mathcal{K}$, are bounded and have limit points.

C-stationarity. Choose any such limit point $(\lambda^*, \sigma^*_1, \sigma^*_2)$ and restrict $\mathcal{K}$, if necessary, so that

$$(x^k, s^k, \lambda^k, \sigma^k_1, \sigma^k_2) \to (x^*, s^*, \lambda^*, \sigma^*_1, \sigma^*_2).$$

By (2.7a) and (2.4) and by continuity of f and c, we have that

$$\nabla f(x^*) - \nabla c_{\mathcal{E}}(x^*)^T \lambda^*_{\mathcal{E}} - \nabla c_{\mathcal{I}}(x^*)^T \lambda^*_{\mathcal{I}} - \begin{pmatrix} 0 \\ \sigma^*_1 \\ \sigma^*_2 \end{pmatrix} = 0,$$

which proves (3.3a). We have already shown that the limit point x^* satisfies conditions (3.3b) through (3.3e). The nonnegativity of $\lambda^*_{\mathcal{I}}$, condition (3.3g), follows from the fact that the inner algorithm maintains $\lambda^k_i > 0$ for $i \in \mathcal{I}$. Condition (3.3f) holds because, for any $i \in \mathcal{I}$, if $c_i(x^*) = s^*_i > 0$, then since $s^k_i \lambda^k_i \to 0$, we must have $\lambda^*_i = 0$.

We now establish that conditions (3.3h) hold at the limit point $(x^*, s^*, \lambda^*, \sigma^*_1, \sigma^*_2)$. They are clearly satisfied when $i \in \mathcal{A}_1(x^*)$ and $i \in \mathcal{A}_2(x^*)$. Consider an index $i \notin \mathcal{A}_1(x^*)$. If there is any infinite subset $\mathcal{K}'' \subseteq \mathcal{K}$ with $\sigma^k_{1i} \neq 0$ for all $k \in \mathcal{K}''$, then, as argued in (3.9), $\sigma^k_{1i} \neq 0 \Rightarrow \sigma^k_{2i} \neq 0$ for all $k \in \mathcal{K}''$ and

$$\lim_{k\to\infty, k\in\mathcal{K}''} \frac{|\sigma^k_{1i}|}{|\sigma^k_{2i}|} = \lim_{k\to\infty, k\in\mathcal{K}''} \frac{\left| \frac{\mu^k}{\pi^k_i x^k_{1i}} - x^k_{2i} \right|}{\left| \frac{\mu^k}{\pi^k_i x^k_{2i}} - x^k_{1i} \right|} = \lim_{k\to\infty, k\in\mathcal{K}''} \frac{x^k_{2i}}{x^k_{1i}} = 0, \tag{3.11}$$

where the limit follows from the fact that $x_{1i}^* > 0$, which implies that $x_{2i}^k \to 0$. $\{\sigma_{2i}^k\}$ has a limit and is therefore bounded. Hence, (3.11) can hold only if $\lim_{k\to\infty, k\in\mathcal{K}''} \sigma_{1i}^k = 0$ and, by definition, $\sigma_{1i}^k = 0$ for all $k \in \mathcal{K} \setminus \mathcal{K}''$. We conclude that $\sigma_{1i}^* = 0$ for $i \notin \mathcal{A}_1(x^*)$. A similar argument can be used to get $\sigma_{2i}^* = 0$ if $i \notin \mathcal{A}_2(x^*)$.

To prove (3.4), we consider an index $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$. If $\sigma_{1i}^* = 0$, we immediately have $\sigma_{1i}^*\sigma_{2i}^* = 0$. If $\sigma_{1i}^* > 0$, then for all $k \in \mathcal{K}$ large enough, $\sigma_{1i}^k > 0$. Then

$$\frac{\mu^k}{x_{1i}^k} > \pi_i^k x_{2i}^k \quad \Rightarrow \quad \frac{\mu^k}{x_{2i}^k} > \pi_i^k x_{1i}^k,$$

or $\sigma_{2i}^k > 0$. Hence, $\sigma_{1i}^*\sigma_{2i}^* \geq 0$, as desired. The same argument can be used to show that if $\sigma_{1i}^* < 0$, then $\sigma_{2i}^* < 0$, and hence $\sigma_{1i}^*\sigma_{2i}^* \geq 0$. Therefore, condition (3.4) holds, and x^* is a C-stationary point of the MPCC.

Strong stationarity. Let $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$. If $\pi_i^k x_{2i}^k \to 0$, then

$$\sigma_{1i}^* = \lim_{k\in\mathcal{K}} \sigma_{1i}^k = \lim_{k\in\mathcal{K}} \left(\frac{\mu^k}{x_{1i}^k} - \pi_i^k x_{2i}^k \right) = \lim_{k\in\mathcal{K}} \frac{\mu^k}{x_{1i}^k} \geq 0. \tag{3.12}$$

A similar argument shows that $\sigma_{2i}^* \geq 0$. Therefore, condition (3.3i) holds, and x^* is a strongly stationary point for the MPCC (1.1). □

The proof of Theorem 3.4 builds on a similar proof in [17], where an analogous result is derived for *exact* subproblem solves. Our result is related to the analysis in [2] (derived independently), except that we explicitly work within an interior-method framework and we do not analyze the convergence of the inner algorithm. In [2], stronger assumptions are required (e.g., that the lower-level problem satisfies a mixed-P property) to guarantee that the inner iteration always terminates.

For strong stationarity, we require a condition on the behavior of the penalty parameter, relative to the sequences converging to the corners. This is the same condition that Scholtes required for strong stationarity in [24]. A simpler, though stronger, assumption on the penalties is a boundedness condition, which we use for the following corollary that corresponds to the particular case of our implementations.

COROLLARY 3.5. *Suppose Algorithm* I *is applied with a uniform (i.e., scalar-valued) penalty parameter, and let the assumptions of Theorem* 3.4 *hold. Then, if the sequence of penalty parameters* $\{\pi^k\}$ *is bounded,* x^* *is a strongly stationary point for* (1.1). □

In our algorithmic framework, the sequence of penalty parameters does not have to be monotone, although practical algorithms usually generate nondecreasing sequences. Monotonicity is required neither in the description of the algorithm nor in the proof. This flexibility could be exploited to correct unnecessarily large penalty parameters in practice. For theoretical purposes, on the other hand, this nonmonotonicity property is important for the derivation of Theorem 3.6 in the next subsection.

3.2. Relationship to interior-relaxation methods. An alternative to exact penalization for regularizing the complementarity constraints of an MPCC is to relax the complementarity constraints. This approach has been combined with interior methods in [19, 21]; we refer to it as the "interior-relaxation" method. The objective of this subsection is to show that there is a correspondence between interior-penalty and interior-relaxation approaches and that this correspondence can be exploited to give an alternative global convergence proof for an interior-relaxation method, based on Theorem 3.4.

Interior-relaxation methods solve a sequence of barrier subproblems associated with (1.3) with one modification; namely, the complementarity constraints (1.3e) are relaxed by introducing a parameter $\theta^k > 0$ that goes to 0 as the barrier parameter μ^k approaches 0. Effectively, a sequence of problems

$$\begin{aligned} \text{minimize} \quad & f(x) - \mu^k \sum_{i\in\mathcal{I}} \log s_i - \mu^k \sum_{i=1}^{p} \log s_{ci} - \mu^k \sum_{i=1}^{p} \log x_{1i} - \mu^k \sum_{i=1}^{p} \log x_{2i} \\ \text{subject to} \quad & c_i(x) = 0, \qquad i \in \mathcal{E}, \\ & c_i(x) - s_i = 0, \qquad i \in \mathcal{I}, \\ & \theta^k - x_{1i}x_{2i} - s_{ci} = 0, \qquad i = 1,\dots,p, \end{aligned} \tag{3.13}$$

has to be solved, where s_c are the slacks for the relaxed complementarity constraints, the multipliers of which are denoted by ξ. Let $\mathcal{L}_{\mu^k,\theta^k}$ denote the Lagrangian of (3.13).

An approximate solution of (3.13), for some μ^k and θ^k, is given by variables $x^k, s^k, s_c^k, \lambda^k, \xi^k$, with $x_1^k > 0, x_2^k > 0, s^k > 0, s_c^k > 0, \lambda_{\mathcal{I}}^k > 0, \xi^k > 0$, satisfying the following inexact KKT system, where $\epsilon_{rel}^k > 0$ is some tolerance

$$\|\nabla_x \mathcal{L}_{\mu^k,\theta^k}(x^k, s^k, \lambda^k, \xi^k)\| \le \epsilon_{rel}^k, \tag{3.14a}$$

$$\|S^k \lambda_{\mathcal{I}}^k - \mu^k e\| \le \epsilon_{rel}^k, \tag{3.14b}$$

$$\|S_c^k \xi^k - \mu^k e\| \le \epsilon_{rel}^k, \tag{3.14c}$$

$$\|c(x^k, s^k)\| \le \epsilon_{rel}^k, \tag{3.14d}$$

$$\|\theta^k e - X_1^k x_2^k - s_c^k\| \le \epsilon_{rel}^k. \tag{3.14e}$$

THEOREM 3.6. *Suppose an interior-relaxation method generates an infinite sequence of solutions* $\{x^k, s^k, s_c^k, \lambda^k, \xi^k\}$ *and parameters* $\{\mu^k, \theta^k\}$ *that satisfies conditions* (3.14) *for sequences* $\{\mu^k\}, \{\theta^k\}$, *and* $\{\epsilon_{rel}^k\}$, *all converging to 0. If* x^* *is a limit point of the sequence* $\{x^k\}$, *and* f *and* c *are continuously differentiable in an open neighborhood* $\mathcal{N}(x^*)$ *of* x^*, *then* x^* *is feasible for the MPCC* (1.1). *If, in addition, MPCC-LICQ holds at* x^*, *then* x^* *is a C-stationary point of* (1.1). *Moreover, if* $\xi_i^k x_{ji}^k \to 0$ *for* $j = 1, 2$ *and* $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$, *then* x^* *is a strongly stationary point of* (1.1).

Proof. We provide an indirect proof. Given sequences of variables $\{x^k,\ s^k,\ s_c^k,\ \lambda^k,\ \xi^k\}$, parameters $\{\mu^k, \theta^k\}$, and tolerances $\{\epsilon_{rel}^k\}$ satisfying the assumptions, we define sequences of parameters $\{\mu^k, \pi^k := \xi^k\}$ and tolerances $\{\epsilon_{pen}^k := \epsilon_{rel}^k, \epsilon_{comp}^k := (\theta^k + \epsilon_{rel}^k)^{1/2}\}$; for the variables, we keep $\{x^k, s^k, \lambda^k\}$ only. Note that we have not changed the sequence of decision variables $\{x^k\}$, so the limit points are unchanged. We show that the sequences that we just defined satisfy the assumptions of Theorem 3.4. Observe that there is no reason why the sequence of multipliers $\{\xi^k\}$ should be monotone. This is not a problem, however, because there is no monotonicity requirement for the sequence $\{\pi^k\}$ in Theorem 3.4, as noted earlier.

First, $\{\mu^k\}, \{\epsilon_{pen}^k\}, \{\epsilon_{comp}^k\}$ all converge to 0, by construction. Next, it is easy to see that

$$\nabla_x \mathcal{L}_{\mu^k,\pi^k}(x^k, s^k, \lambda^k) = \nabla_x \mathcal{L}_{\mu^k,\theta^k}(x^k, s^k, \lambda^k, \xi^k).$$

This, together with conditions (3.14a), (3.14b), and (3.14d), yields (2.7).

Recall that the infinity norm is used for (2.8) (without loss of generality). Combining (3.14e) with $\min\{x_1^k, x_2^k\} \le x_1^k$ and $\min\{x_1^k, x_2^k\} \le x_2^k$, we get

$$\begin{aligned} 0 &\le \min\{x_{1i}^k, x_{2i}^k\} \le (x_{1i}^k x_{2i}^k)^{1/2} \\ &\le (x_{1i}^k x_{2i}^k + s_{ci}^k)^{1/2} \le (\theta^k + \epsilon_{rel}^k)^{1/2} = \epsilon_{comp}^k. \end{aligned}$$

Therefore, the sequence $\{x^k, s^k, \lambda^k\}$, with corresponding parameters $\{\mu^k, \pi^k\}$, satisfies conditions (2.7) and (2.8) for all k. The conclusions follow from a direct application of Theorem 3.4. ∎

A similar global result is proved directly in [19], under somewhat different assumptions. The key for the proof presented here is that there exists a one-to-one correspondence between KKT points of problems (2.2) and (3.13), which is easily seen by comparing the corresponding first-order conditions. In fact, this one-to-one relation between KKT points of relaxation and penalization schemes can be extended to general nonlinear programs. Such an extension is useful because some convergence results can be derived directly for one approach only and then extended to the alternative regularization scheme in a simple way.

4. Local convergence analysis. In this section, we show that if the iterates generated by Algorithm I approach a solution x^* of the MPCC that satisfies certain regularity conditions and if the penalty parameter is sufficiently large, then this parameter is never updated and the iterates converge to x^* at a superlinear rate.

We start by defining a second-order sufficient condition (SOSC) for MPCCs (see [23]). For this purpose, we define the Lagrangian

$$\mathcal{L}(x, \lambda, \sigma_1, \sigma_2) = f(x) - \lambda_{\mathcal{E}}^T c_{\mathcal{E}}(x) - \lambda_{\mathcal{I}}^T c_{\mathcal{I}}(x) - \sigma_1^T x_1 - \sigma_2^T x_2. \tag{4.1}$$

DEFINITION 4.1. *The* MPCC second-order sufficient condition *(MPCC-SOSC) holds at x^* if x^* is a strongly stationary point of* (1.1) *with multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$ and*

$$d^T \nabla_{xx}^2 \mathcal{L}(x^*, \lambda^*, \sigma_1^*, \sigma_2^*)\, d > 0 \tag{4.2}$$

for all critical directions d, with $\|d\| = 1$, satisfying

$$\nabla f(x)^T d = 0, \tag{4.3a}$$

$$\nabla c_i(x)^T d = 0 \ \ \textit{for all} \ \ i \in \mathcal{E}, \tag{4.3b}$$

$$\nabla c_i(x)^T d \geq 0 \ \ \textit{for all} \ \ i \in \mathcal{A}_c(x), \tag{4.3c}$$

$$\min_{\{j : x_{ji} = 0\}} \{d_{ji}\} = 0 \ \ \textit{for all} \ \ i = 1, \ldots, p. \tag{4.3d}$$

Notice that (4.3d) is a convenient way to summarize the following conditions, which characterize the set of feasible directions with respect to the complementarity constraints: If $x_{1i} = 0, x_{2i} > 0$, then $d_{1i} = 0$ and d_{2i} is free; if $x_{2i} = 0, x_{1i} > 0$, then $d_{2i} = 0$ and d_{1i} is free; and if $x_{1i} = x_{2i} = 0$, then $0 \leq d_{1i} \perp d_{2i} \geq 0$.

For the local analysis, we make the following assumptions.

Assumptions 4.2. There exists a strongly stationary point x^* of the MPCC (1.1), with multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$, satisfying the following conditions:

1. f and c are twice Lipschitz continuously differentiable in an open neighborhood of x^*.
2. MPCC-LICQ holds at x^*.
3. The following primal-dual strict complementarity holds at x^*: $\lambda_i^* \neq 0$ for all $i \in \mathcal{E} \cup \mathcal{A}_c(x^*)$, and $\sigma_{ji}^* > 0$ for all $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$, for $j = 1, 2$.
4. MPCC-SOSC holds at x^*.

The following lemma shows that the penalty formulation inherits the desirable properties of the MPCC for a sufficiently large penalty parameter. The multipliers for the bound constraints $x_1 \geq 0, x_2 \geq 0$ of the penalty problem (2.1) are denoted by $\nu_1 \geq 0, \nu_2 \geq 0$, respectively.

LEMMA 4.3. *If Assumptions* 4.2 *hold at* x^* *and* $\pi > \pi^*$, *where*

$$\pi^* = \pi^*(x^*, \sigma_1^*, \sigma_2^*) = \max\left\{0, \max_{\{i:x_{1i}^*>0\}} \frac{-\sigma_{2i}^*}{x_{1i}^*}, \max_{\{i:x_{2i}^*>0\}} \frac{-\sigma_{1i}^*}{x_{2i}^*}\right\}, \tag{4.4}$$

then it follows that

1. *LICQ holds at* x^* *for* (2.1);
2. x^* *is a KKT point of* (2.1);
3. *primal-dual strict complementarity holds at* x^* *for* (2.1); *that is,* $\lambda_i^* \neq 0$ *for all* $i \in \mathcal{E} \cup \mathcal{A}_c(x^*)$ *and* $\nu_{ji}^* > 0$ *for all* $i \in \mathcal{A}_j(x^*)$, *for* $j = 1, 2$;
4. *SOSC holds at* x^* *for* (2.1).

Proof. LICQ at x^* for (2.1) follows from the definition of MPCC-LICQ.

The proof of part 2 is similar to the proof of Proposition 4.1 in [13]. The key for the proof is the relationship between the multipliers σ_1^*, σ_2^* of (1.1) and $\nu_1^* \geq 0, \nu_2^* \geq 0$ of (2.1), given by

$$\nu_1^* = \sigma_1^* + \pi x_2^* \quad \text{and} \quad \nu_2^* = \sigma_2^* + \pi x_1^*. \tag{4.5}$$

The result is evident when the strong stationarity conditions (3.3) and the first-order KKT conditions of (2.1) are compared, except for the nonnegativity of ν_1^* and ν_2^*. To see that $\nu_1^*, \nu_2^* \geq 0$, suppose first that $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$. In that case, from (4.5), we have $\nu_{ji} = \sigma_{ji}, j = 1, 2$, and the nonnegativity follows directly from (3.3i). If, on the other hand, $i \notin \mathcal{A}_2(x^*)$, then (4.5) and $\pi > \pi^*$ imply

$$\nu_{1i}^* = \sigma_{1i}^* + \pi x_{2i}^* > \sigma_{1i}^* + \frac{-\sigma_{1i}^*}{x_{2i}^*} x_{2i}^* = 0. \tag{4.6}$$

The same argument applies for $i \notin \mathcal{A}_1(x^*)$, which completes the proof of part 2.

Note that $\pi \geq \pi^*$ suffices for the nonnegativity of ν_1, ν_2. The strict inequality $\pi > \pi^*$ is required for part 3; that is, we need it for primal-dual strict complementarity at x^* for (2.1). In fact, (4.6) yields primal-dual strict complementarity for $i \notin \mathcal{A}_2(x^*)$ (and a similar argument works for $i \notin \mathcal{A}_1(x^*)$). For $i \in \mathcal{E} \cup \mathcal{A}_c(x^*)$, strict complementarity comes directly from the assumptions. For $i \in \mathcal{A}_2(x^*) \cap \mathcal{A}_1(x^*)$, relation (4.5) shows that $\nu_{ji}^* = \sigma_{ji}^*, j = 1, 2$, which is positive by Assumption 4.2(3).

For part 4, Assumption 4.2(3) implies that the multipliers of the complementarity variables satisfy $\nu_{1i}^* + \nu_{2i}^* > 0$ for all $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$, which, together with $\pi > \pi^*$, constitutes a sufficient condition for SOSC of the penalty problem (2.1); see [20] for details. Therefore, SOSC holds at x^* for (2.1). ∎

We note that Assumption 4.2(3) can be weakened and still get SOSC for the penalized problem (2.1). In [20], two alternative sufficient conditions for SOSC of (2.1) are given. The first involves $\nu_{1i}^* + \nu_{2i}^* > 0$ for all $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$ (which is called partial strict complementarity in [22]) and $\pi > \pi^*$. The second condition involves a possibly larger penalty parameter and shows how the curvature term of the complementarity constraint $x_1^T x_2$ can be exploited to ensure the penalized problem satisfies a second-order condition. We state the result here for completeness (the proof can be found in [20]).

LEMMA 4.4. *Let MPCC-SOSC hold at* x^*. *If either*

1. $\pi > \pi^*$ *and* $\nu_{1i}^* + \nu_{2i}^* > 0$ *for all* $i \in \mathcal{A}_1(x^*) \cap \mathcal{A}_2(x^*)$, *or*
2. $\pi > \max\{\pi^*, \pi_{SO}\}$, *for a (possibly higher) value* π_{SO} *defined in* [20],

then SOSC holds at x^* *for* (2.1). ∎

We now show that an adequate penalty parameter stabilizes near a regular solution and superlinear convergence takes place.

We group primal and dual variables in a single vector $z = (x, s, \lambda)$. Given a strongly stationary point x^* with multipliers $\lambda^*, \sigma_1^*, \sigma_2^*$, we associate to it the triplet $z^* = (x^*, s^*, \lambda^*)$, where $s^* = c_{\mathcal{I}}(x^*)$. We also group the left-hand side of (2.5) in the function

$$F_\mu(z;\pi) = \begin{pmatrix} \nabla_x \mathcal{L}_{\mu,\pi}(x,\lambda) \\ S\lambda_{\mathcal{I}} - \mu e \\ c(x,s) \end{pmatrix}. \tag{4.7}$$

At every inner iteration in step 2 of Algorithm I, a step d is computed by solving a system of the form

$$\nabla F_\mu(z;\pi) d = -F_\mu(z;\pi). \tag{4.8}$$

Note that (2.7) is equivalent to $\|F_\mu(z;\pi)\| \le \epsilon_{pen}$.

The following theorem shows that there are practical implementations of Algorithm I that, near a regular solution x^* of the MPCC and for a sufficiently large penalty parameter, satisfy the stopping tests (2.7) and (2.8) at every iteration, with no backtracking and no updating of the penalty parameter. Using this fact, one can easily show that the iterates converge to x^* superlinearly. To state this result, we introduce the following notation. Let z be an iterate satisfying $\|F_\mu(z;\pi)\| \le \epsilon_{pen}$ and $\|\min\{x_1, x_2\}\| \le \epsilon_{comp}$. We define z^+ to be the new iterate computed using a barrier parameter $\mu^+ < \mu$, namely,

$$z^+ = z + d, \qquad \text{with} \quad F_{\mu^+}(z;\pi) d = -F_{\mu^+}(z;\pi). \tag{4.9}$$

THEOREM 4.5. *Suppose that Assumptions* 4.2 *hold at a strongly stationary point* x^*. *Assume that* $\pi > \pi^*$, *with* π^* *given by* (4.4), *and that the tolerances* $\epsilon_{pen}, \epsilon_{comp}$ *in Algorithm* I *are functions of* μ *that converge to* 0 *as* $\mu \to 0$. *Furthermore, assume that the barrier parameter and these tolerances are updated so that the following limits hold as* $\mu \to 0$*:*

$$\frac{(\epsilon_{pen} + \mu)^2}{\epsilon_{pen}^+} \to 0, \tag{4.10a}$$

$$\frac{(\epsilon_{pen} + \mu)^2}{\mu^+} \to 0, \tag{4.10b}$$

$$\frac{\mu^+}{\epsilon_{comp}^+} \to 0. \tag{4.10c}$$

Assume also that

$$\frac{\mu^+}{\|F_0(z;\pi)\|} \to 0 \ \ as \ \ \|F_0(z;\pi)\| \to 0. \tag{4.11}$$

Then, if μ *is sufficiently small and* z *is sufficiently close to* z^*, *the following conditions hold:*

1. *The stopping criteria* (2.7) *and* (2.8), *with parameters* $\mu^+, \epsilon_{pen}^+, \epsilon_{comp}^+$ *and* π, *are satisfied at* z^+.
2. $\|z^+ - z^*\| = o(\|z - z^*\|)$.

Proof. By the implicit function theorem, Assumptions 4.2, the condition $\pi > \pi^*$, and Lemma 4.3, it follows that, for all sufficiently small μ, there exists a solution

$z^*(\mu)$ of problem (2.2); see, for example, [14]. If, in addition, z is close to z^*, then

$$L_1\mu \leq \|z^* - z^*(\mu)\| \leq U_1\mu, \tag{4.12}$$

$$L_2\|F_\mu(z;\pi)\| \leq \|z - z^*(\mu)\| \leq U_2\|F_\mu(z;\pi)\|. \tag{4.13}$$

(Condition (4.12) is Corollary 3.14 in [14], and (4.13) is Lemma 2.4 in [5].) Here and in the rest of the proof L_i and U_i denote positive constants; recall that $\|\cdot\|$ denotes the infinity norm (without loss of generality). By standard Newton analysis (see, e.g., Theorem 2.3 in [5]) we have that

$$\|z^+ - z^*(\mu^+)\| \leq U_3\|z - z^*(\mu^+)\|^2. \tag{4.14}$$

We also use the inequality

$$\|z^+ - z^*(\mu^+)\| \leq U_4(\epsilon_{pen} + \mu)^2, \tag{4.15}$$

which is proved as follows:

$$\begin{aligned}
\|z^+ - z^*(\mu^+)\| &\leq U_3\|z - z^*(\mu^+)\|^2 \quad \text{(from (4.14))} \\
&\leq U_3\left(\|z - z^*(\mu)\| + \|z^*(\mu) - z^*\| + \|z^* - z^*(\mu^+)\|\right)^2 \\
&\leq U_3\left(U_2\|F_\mu(z;\pi)\| + U_1\mu + U_1\mu^+\right)^2 \quad \text{(from (4.13) and (4.12))} \\
&\leq U_4\left(\epsilon_{pen} + \mu\right)^2,
\end{aligned}$$

where the last inequality holds because z satisfies (2.7) with μ, ϵ_{pen}, π and because $\mu^+ < \mu$.

We now show that (2.7) holds at z^+, with parameters $\mu^+, \epsilon^+_{pen}, \pi$, as follows:

$$\begin{aligned}
\|F_{\mu^+}(z^+;\pi)\| &\leq L_2^{-1}\|z^+ - z^*(\mu^+)\| \quad \text{(from (4.13))} \\
&\leq L_2^{-1}U_4(\epsilon_{pen} + \mu)^2 \quad \text{(from (4.15))} \\
&= L_2^{-1}U_4\frac{(\epsilon_{pen} + \mu)^2}{\epsilon^+_{pen}}\epsilon^+_{pen} \\
&\leq \epsilon^+_{pen} \quad \text{(from (4.10a)).}
\end{aligned}$$

To see that $x_1^+ > 0$, we can apply (4.15) componentwise to get

$$|x^+_{1i} - x^*_{1i}(\mu^+)| \leq U_4(\epsilon_{pen} + \mu)^2,$$

from which we have that

$$x^+_{1i} \geq x^*_{1i}(\mu^+) - U_4(\epsilon_{pen} + \mu)^2. \tag{4.16}$$

If $x^*_{1i} = 0$, we have by (4.12) and the positivity of $x^*_{1i}(\mu^+)$ that $x^*_{1i}(\mu^+) \geq L_1\mu^+$. Therefore

$$\begin{aligned}
x^+_{1i} &\geq L_1\mu^+ - U_4\frac{(\epsilon_{pen} + \mu)^2}{\mu^+}\mu^+ \quad \text{(from (4.12))} \\
&\geq L_5\mu^+ \quad \text{(from (4.10b)).}
\end{aligned}$$

If, on the other hand, $x^*_{1i} > 0$, then from (4.12) and (4.16), we get

$$\begin{aligned}
x^+_{1i} &\geq x^*_{1i} - U_1\mu^+ - U_4(\epsilon_{pen} + \mu)^2 \\
&= x^*_{1i} - U_1\mu^+ - U_4\frac{(\epsilon_{pen} + \mu)^2}{\mu^+}\mu^+ \\
&> 0 \quad \text{(from (4.10b)).}
\end{aligned}$$

Similar arguments can be applied to get $x_2^+ > 0, s^+ > 0, \lambda_{\mathcal{I}}^+ > 0$.

To prove that x^+ satisfies (2.8), we first observe that

$$\begin{aligned}\|z^+ - z^*\| &\le \|z^+ - z^*(\mu^+)\| + \|z^*(\mu^+) - z^*\| \\ &\le U_4(\epsilon_{pen} + \mu)^2 + U_1\mu^+ \quad \text{(from (4.15) and (4.12))} \\ &= U_4\frac{(\epsilon_{pen} + \mu)^2}{\mu^+}\mu^+ + U_1\mu^+ \\ &\le U_5\mu^+ \quad \text{(from (4.10b)).} \end{aligned} \tag{4.17}$$

Let $i \in \{1, \ldots, p\}$, and assume, without loss of generality, that $x_{1i}^* = 0$. Then,

$$\begin{aligned}|\min\{x_{1i}^+, x_{2i}^+\}| &= \min\{x_{1i}^+, x_{2i}^+\} \quad \text{(because } x_1^+ > 0, x_2^+ > 0) \\ &\le x_{1i}^+ = |x_{1i}^+ - x_{1i}^*| \\ &\le U_5\mu^+ \quad \text{(from (4.17))} \\ &= U_5\frac{\mu^+}{\epsilon_{comp}^+}\epsilon_{comp}^+ \le \epsilon_{comp}^+, \end{aligned}$$

where the last inequality follows from (4.10c). Since this argument applies to all $i \in \{1, \ldots, p\}$, we have that (2.8) is satisfied. This concludes the proof of part 1 of the theorem.

For part 2, we have that

$$\begin{aligned}\|z^+ - z^*\| &\le \|z^+ - z^*(\mu^+)\| + \|z^*(\mu^+) - z^*\| \\ &\le U_3\|z - z^*(\mu^+)\|^2 + U_1\mu^+ \quad \text{(from (4.14) and (4.12))} \\ &\le U_3\left(\|z - z^*\| + \|z^* - z^*(\mu^+)\|\right)^2 + U_1\mu^+ \\ &\le U_3\left(2\|z - z^*\|^2 + 2\|z^* - z^*(\mu^+)\|^2\right) + U_1\mu^+ \\ &\le 2U_3\|z - z^*\|^2 + 2U_3(U_1\mu^+)^2 + U_1\mu^+ \quad \text{(from (4.14))} \\ &\le U_6\left(\|z - z^*\|^2 + \mu^+\right). \end{aligned}$$

This implies that

$$\frac{\|z^+ - z^*\|}{\|z - z^*\|} \le U_6\left(\|z - z^*\| + \frac{\mu^+}{\|z - z^*\|}\right).$$

We apply the left-hand inequality in (4.13), evaluated at z and with barrier parameter 0, to get

$$\frac{\|z^+ - z^*\|}{\|z - z^*\|} \le U_6\left(\|z - z^*\| + \frac{1}{L_2}\frac{\mu^+}{\|F_0(z;\pi)\|}\right). \tag{4.18}$$

Note that, from (4.13), if $\|z - z^*\|$ is sufficiently small, so is $\|F_0(z;\pi)\|$, which in turn, by (4.11), implies that the second term in the right-hand side is also close to 0. Hence, if $\|z - z^*\|$ is sufficiently small, it follows that the new iterate z^+ is even closer to z^*. Moreover, by applying (4.18) recursively, we conclude that the iterates converge to z^*. From the same relation, it is clear that this convergence happens at a superlinear rate, which concludes the proof. □

Many practical updating rules for μ and ϵ_{pen} satisfy conditions (4.10a)–(4.11). For example, we can define $\epsilon_{pen} = \theta\mu$ with $\theta \in [0, \sqrt{|\mathcal{I}|})$. In this case, it is not

difficult to show [5] that (4.10a), (4.10b), and (4.11) are satisfied if we update μ by the rule

$$\mu^+ = \mu^{1+\delta}, \quad 0 < \delta < 1.$$

The same is true for the rule

$$\mu^+ = \|F_\mu(z;\pi)\|^{1+\delta}, \quad 0 < \delta < 1.$$

A simple choice for ϵ_{comp} that ensures (4.10c) is μ^γ, with $0 < \gamma < 1$.

5. Implementation and numerical results. We begin by describing two practical implementations of Algorithm I that use different strategies for updating the penalty parameter. The first algorithm, *Classic*, is described in Figure 3; it updates the penalty parameter only after the barrier problem is solved, and provided the complementarity value has decreased sufficiently as stipulated in step 3. We index by k the major iterates that satisfy (2.7) and (2.8); this notation is consistent with that of section 2. We use j to index the sequence of all minor iterates generated by the algorithm Classic. Since $\gamma \in (0,1)$, the tolerance ϵ^k_{comp} defined in step 1 converges to 0 more slowly than does $\{\mu^k\}$; this is condition (4.10c) in Theorem 4.5.

In the numerical experiments, we use $\gamma = 0.4$ for the following reason: The distance between iterates x^k and the solution x^* is proportional to $\sqrt{\mu^k}$, if primal-dual strict complementarity does not hold at x^*. By choosing the complementarity tolerance to be $\epsilon^k_{comp} = (\mu^k)^{0.4}$, we ensure that the test (2.8) can be satisfied in this case. All other details of the interior method are described below.

Algorithm Classic: A Practical Interior-Penalty Method for MPCCs

Initialization: Let $z^0 = (x^0, s^0, \lambda^0)$ be the initial primal and dual variables. Choose an initial penalty π^0 and a parameter $\gamma \in (0,1)$. Set $j = 0, k = 1$.

repeat (barrier loop)

1. Choose a barrier parameter μ^k, a stopping tolerance ϵ^k_{pen}, let $\epsilon^k_{comp} = (\mu^k)^\gamma$ and let $\pi^k = \pi^{k-1}$.
2. **repeat** (inner iteration)
   (a) Let $j \leftarrow j + 1$ and let the current point be $z^c = z^{j-1}$.
   (b) Using a globally convergent method, compute a primal-dual step d^j based on the KKT system (2.4), with $\mu = \mu^k, \pi = \pi^k$ and $z = z^c$.
   (c) Let $z^j = z^c + d^j$.
   until conditions (2.7) are satisfied for ϵ^k_{pen}.
3. **If** $\|\min\{x^j_1, x^j_2\}\| \le \epsilon^k_{comp}$, let $z^k = z^j$, set $k \leftarrow k + 1$;
   else set $\pi^k \leftarrow 10\pi^k$ and go to Step 2

until a stopping test for the MPCC is satisfied.

FIG. 3. *Description of the algorithm Classic.*

The second algorithm we implemented, *Dynamic*, is described in Figure 4. It is more flexible than Classic in that it allows changes in the penalty parameter at every iteration of the inner algorithm. The strategy of step 2(c) is based on the following considerations: If the complementarity pair is relatively small according to the preset tolerance ϵ^k_{comp}, then there is no need to increase π. Otherwise, we check whether the current complementarity value, $x_1^{jT} x_2^j$, is less than a fraction of the maximum

value attained in the m previous iterations (in our tests, we use $m = 3$ and $\eta = 0.9$). If not, we increase the penalty parameter. We believe that it is appropriate to look back at several previous steps, and not require decrease at every iteration, because the sequence $\{x_1^{jT} x_2^j\}$ is frequently nonmonotone, especially for problems in which primal-dual strict complementarity is violated (see, e.g., Figure 6(a)). Note that the algorithms Classic and Dynamic are both special cases of Algorithm I of section 2.

Algorithm Dynamic: A Practical Interior-Penalty Method for MPCCs

Initialization: Let $z^0 = (x^0, s^0, \lambda^0)$ be the initial primal and dual variables. Choose an initial penalty π^0, parameters $\gamma, \eta \in (0, 1)$, and an integer $m \geq 1$. Set $j = 0$, $k = 1$.

repeat (barrier loop)

1. Choose a barrier parameter μ^k, a stopping tolerance ϵ_{pen}^k and let $\epsilon_{comp}^k = (\mu^k)^\gamma$.
2. **repeat** (inner iteration)
   (a) Set $j \leftarrow j + 1$, let the current point be $z^c = z^{j-1}$, and let $\pi^j = \pi^{j-1}$.
   (b) Using a globally convergent method, compute a primal-dual step d^j based on the KKT system (2.4), with $\mu = \mu^k, \pi = \pi^j$ and $z = z^c$.
   (c) If $\| \min\{x_1^j, x_2^j\} \| > \epsilon_{comp}^k$ and

$$x_1^{jT} x_2^j > \eta \max \left\{ x_1^{jT} x_2^j, \ldots, x_1^{(j-m+1)T} x_2^{(j-m+1)} \right\}, \tag{5.1}$$

   then set $\pi^j \leftarrow 10\pi^j$, adjust λ^j and go to Step 2.
   until conditions (2.7) are satisfied for ϵ_{pen}^k.
3. **If** $\| \min\{x_1^j, x_2^j\} \| \leq \epsilon_{comp}^k$, let $z^k = z^j$ and $k = k + 1$
   else set $\pi^k \leftarrow 10\pi^k$ and go to Step 2

until a stopping test for the MPCC is satisfied.

FIG. 4. *Description of the algorithm Dynamic.*

We implemented these two algorithms as an extension of our MATLAB solver IPM-D. This solver is based on the interior algorithm for nonlinear programming described in [26], with one change: IPM-D handles negative curvature by adding a multiple of the identity to the Hessian of the Lagrangian, as in [25], instead of switching to conjugate-gradient iterations. We chose to work with IPM-D because it is a simple interior solver that does not employ the regularizations, scalings, and other heuristics used in production packages that alter the MPCC, making it harder to assess the impact of the approach proposed in this paper.

In our implementation, all details of the interior-point iteration, such as the update of the barrier parameter, the step selection, and the choice of merit function, are handled by IMP-D. The main point of this section is to demonstrate how to adapt an existing interior-point method to solve MPCCs efficiently and reliably.

We tested the algorithms on a collection of 74 problems, listed in Table 3, where we report the number of variables n (excluding slacks), the number of constraints m (excluding complementarity constraints), and the number of complementarity constraints p. These problems are taken from the MacMPEC collection [18]; we added a few problems to test the sensitivity of our implementations to bad scalings in the MPCC. All the methods tested were implemented in IPM-D, and since this MATLAB program is not suitable for very large problems, we restricted our test set to a sample

of problems with fewer than 1,000 variables. We report results for four methods, which are labeled in the figures as follows:

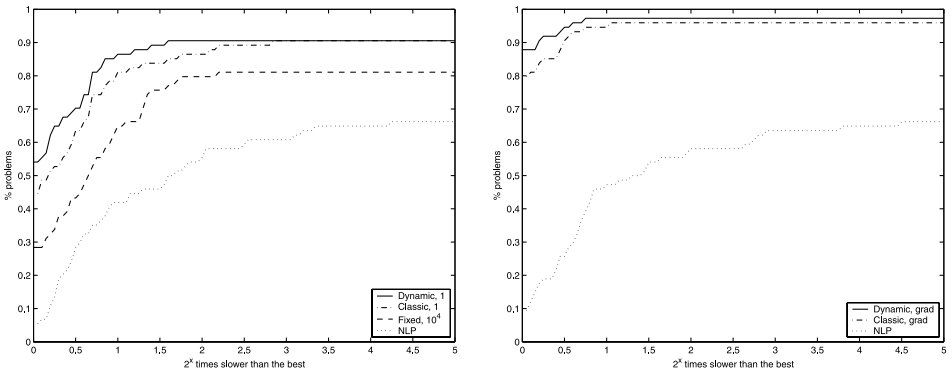
NLP is the direct application of the interior code IPM-D to the nonlinear programming formulation (1.3) of the MPCC.

Fixed is a penalty method in which IPM-D is applied to (2.1) with a fixed penalty of 10^4. The penalty parameter is not changed.

Classic is the algorithm given in Figure 3, implemented in the IPM-D solver.

Dynamic is the algorithm given in Figure 4, implemented in the IPM-D solver.

In Figure 5 we report results for these four methods in terms of total number of iterations (indexed by j). The figures use the logarithmic performance profiles described in [9]. An important choice in the algorithms Classic and Dynamic is the initial value of π. In Figure 5(a) we show results for $\pi^0 = 1$, and in Figure 5(b)



(a) $\pi = 1$, initially. (b) Initial π based on gradient norm.

FIG. 5. *Performance profiles.*

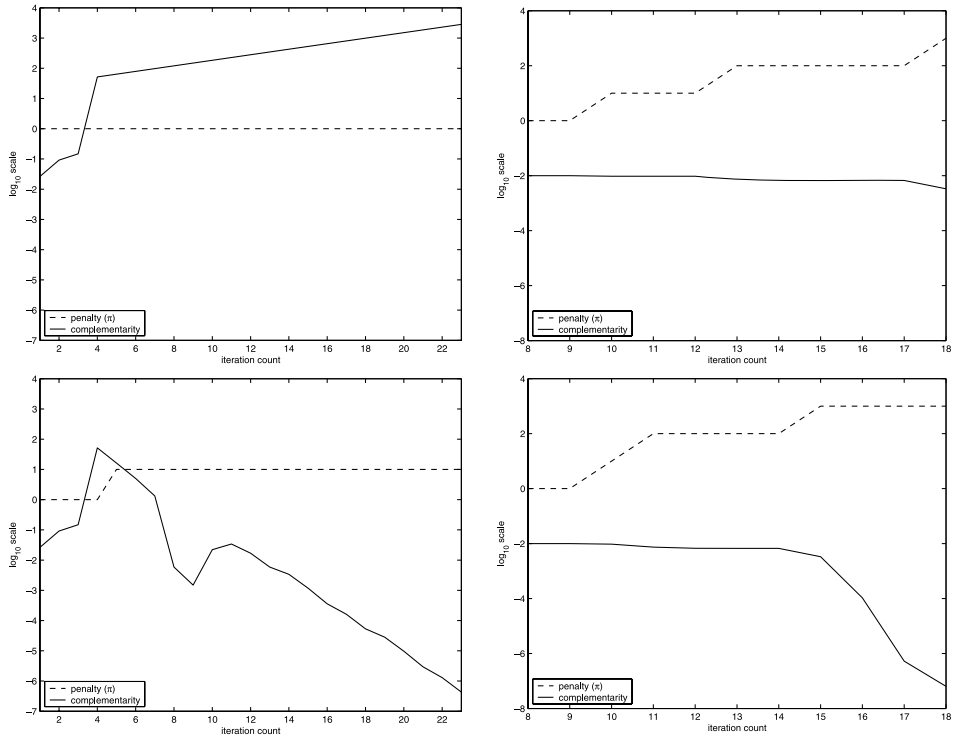
for $\pi^0 = \|\nabla f(x^0)\|$ (the latter rule is also used, for example, in the elastic phase of SNOPT [15]). Note that every time π is updated, a new barrier subproblem has to be solved, where the initial point is the current iterate and the barrier parameter is the current value of μ. The discrepancy in initial conditions when π is reset explains the difference in performance of the choices $\pi^0 = 1$ and $\pi^0 = \|\nabla f(x^0)\|$, for both Classic and Dynamic.

Comparing the results in Figure 5, we note that the direct application of the interior method, option NLP, gives the poorest results. Option Fixed (dashed curve in Figure 5(a)) is significantly more robust and efficient than option NLP, but it is clearly surpassed by the Classic and Dynamic methods. Option Fixed fails more often than Classic and Dynamic and it requires, in general, more iterations to solve each barrier problem. In extreme cases, such as `bar-truss-3`, Dynamic (with $\pi^0 = 1$) solves the first barrier problem in 15 iterations, whereas Fixed needs 43 iterations. Moreover, we frequently find that, near a solution, the algorithms Classic and Dynamic take one iteration per barrier problem, as expected, whereas Fixed keeps taking several steps to find a solution every time μ is updated.

Classic and Dynamic perform remarkably well with the seemingly naive initial value $\pi^0 = 1$ (Figure 5(a)). Both algorithms adjust π efficiently, especially Dynamic. The choice $\pi^0 = \|\nabla f(x^0)\|$, on the other hand, attempts to estimate the norm of the multipliers and can certainly be unreliable. Nonetheless, it performed very well on this test set. We note from Figure 5(b) that the performance of both algorithms improves for $\pi^0 = \|\nabla f(x^0)\|$.

The MacMPEC collection is composed almost exclusively of well-scaled problems, and `ralph2` is the only problem that becomes unbounded for the initial penalty (with either initialization of π). As a result, Dynamic does not differ significantly from Classic on this test set. We therefore take a closer look at the performance of these methods on problems `ralph2` and `scale1` discussed in section 2. We believe that the results for these examples support the choice of Dynamic over Classic for practical implementations.

Example 1 *(*`ralph2`*), revisited.* Figure 6(a) plots the complementarity measure $(x_1^{jT} x_2^j)$ (continuous line) and the value of the penalty parameter π^j (dashed line) for problem (2.9) (using a $\log_{10}$ scale). The top figure corresponds to Classic and the bottom figure to Dynamic; both used an initial penalty parameter of 1. Recall



(a) `ralph2`. (b) `scale1`.

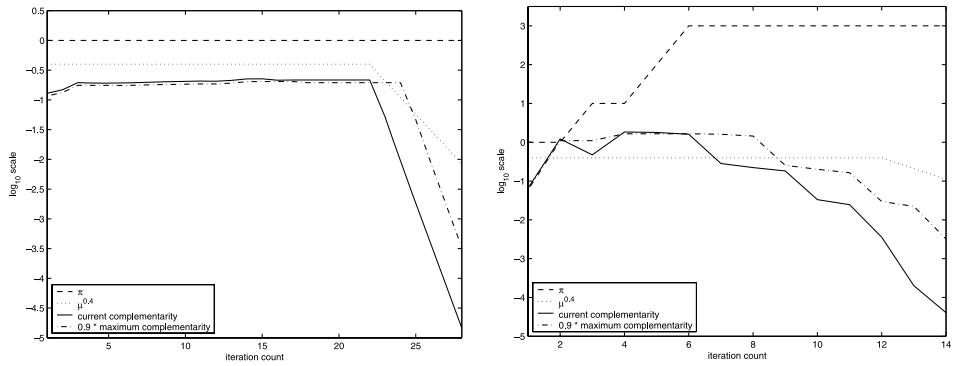
FIG. 6. *Evolution of penalty and complementarity values (*$\log_{10}$ *scale). Classic (top) versus Dynamic (bottom).*

that $\pi = 1$ gives rise to an unbounded penalty problem. The two algorithms perform identically up to iteration 4. Then, the Dynamic algorithm increases π, whereas the Classic algorithm never changes π, because it never solves the first barrier problem. Classic fails on this problem, and complementarity grows without bound. □

Example 2 *(*`scale1`*), revisited.* Problem (2.11) requires $\pi \geq 200$ so that the penalty problem recovers the solution of the MPCC. We again initialize Dynamic and Classic with $\pi = 1$. Figure 6(b) plots the complementarity measure and the penalty parameter values for both implementations. The two algorithms increase π three times (from 1 to 10, to 100, to 1000). While the Classic implementation (top figure) is performing the third update of π, the Dynamic implementation (bottom figure) has converged to the solution. The Dynamic algorithm detects earlier that complementarity has stagnated (and is not sufficiently small) and takes corrective action by increasing π. Not all plateaus mean that π needs to be changed, however, as we discuss next. □

To study in more detail the algorithm Dynamic, we consider two other problems, `bard3` and `bilin`, from the MacMPEC collection (we initialize the penalty parameter to 1, as before).

Example 3 (`bard3`). Figure 7(a) shows the results for problem `bard3`. The continuous line plots $x_1^{jT} x_2^j$, and the dashed-dotted line plots 0.9 times the maximum value of $x_1^{iT} x_2^i$ over the last three iterations. Note that the complementarity measure increases at the beginning and does not decrease during the first 20 iterations.



(a) Problem `bard3`. (b) Problem `bilin`.

FIG. 7. *Illustration of the Dynamic updating strategy.*

However, Dynamic does not increase the value of π (dashed line) because the value of complementarity is small enough, compared to the threshold $\mu^{0.4}$ (dotted line). This is the correct action; if the algorithm increased π simply because the maximum value of complementarity over the last three iterations is not decreasing, π would take on large values that would slow the iteration and could even cause failure. □

Example 4 (`bilin`). A different behavior is observed for problem `bilin`; see Figure 7(b). The value of complementarity (continuous line) not only lies above the line that plots 0.9 times the maximum complementarity over the last three iterations (dashed-dotted line), but is also above the line plotting $(\mu^j)^{0.4}$. Thus the penalty parameter is increased quickly (dashed line). The sufficient reduction condition is satisfied at iteration 3 but is then again violated, so π is increased again, until complementarity finally starts converging to zero. □

These results suggest that Dynamic constitutes an effective technique for handling the penalty parameter in interior-penalty methods for MPCCs.

We conclude this section by commenting on some of the failures of our algorithms. All implementations converge to a C-stationary point for problem `scale4` (which is a rescaling of problem `scholtes3`). We find it interesting that convergence to C-stationary points is possible in practice and is not simply allowed by the theory. We note that convergence to C-stationary points cannot be ruled out for SQP methods, and in this sense interior-point methods are no less robust than SQP methods applied to MPCCs. Another failure, discussed already, is problem `ralph2` for the algorithm Classic.

The rest of the failures can be attributed to various forms of problem deficiencies beyond the MPCC structure. All implementations have difficulties solving problems for which the minimizer is not a strongly stationary point, that is, problems for which there are no multipliers at the solution. This is the case in `ex9.2.2`, where our algorithms obtain good approximations of the solution but the penalty parameter diverges, and for `ralphmod`, where our algorithms fail to find a stationary point. These difficulties are not surprising because the algorithms strongly rely upon the existence of multipliers at the solution. SQP methods also fail to find strongly stationary solutions to these problems, and generate a sequence of multipliers that diverge to infinity.

Test problems in the groups `incid-set`$*$, `pack-rig`$*$, and `pack-comp`$*$ include degenerate constraints other than those defining complementarity. Our implementa-

tions are able to solve most of these problems, but the number of iterations is high, and the performance is very sensitive to changes in the implementation. In some of these problems our algorithms have difficulty making progress near the solution. Problem `tap-09` has a rank-deficient constraint Jacobian that causes difficulties for our algorithms. All of these point to the need for more general regularization schemes for interior methods that can cope with both MPCCs and with other forms of degeneracy. This topic is the subject of current investigation [6, 16].

6. Conclusions. Interior methods can be an efficient and robust tool for solving MPCCs, when appropriately combined with a regularization scheme. In this article, we have studied an interior-penalty approach and have carefully addressed issues related to efficiency and robustness. We have provided global and local convergence analysis to support the interior-penalty methods proposed here. We have also shown how to extend our global convergence results to interior methods based on the relaxation approach described by [19, 21].

We have presented two practical implementations. The first algorithm, Classic, is more flexible than the approach studied in [2, 17], which solves the penalty problem (2.1) with a fixed penalty parameter and then updates π if necessary. The approach in [2, 17] has the advantage that it can be used in combination with any off-the-shelf nonlinear programming solver; the disadvantage is that it can be very wasteful in terms of iterations if the initial penalty parameter is not appropriate. The second algorithm, Dynamic, improves on Classic by providing a more adaptive penalty update strategy. This can be particularly important in dealing with unbounded penalty problems and also yields an improvement in efficiency when the scaling of the problem complicates the detection of complementarity violation. The numerical results presented in this paper are highly encouraging. We plan to implement the penalty method for MPCCs in the KNITRO package, which will allow us to solve large-scale MPCCs.

The penalty methods considered here are designed specifically for MPCCs. However, lack of regularity other than that caused by complementarity constraints often occurs in practice, and a more general class of interior-penalty methods for degenerate nonlinear programs is the subject of current research [6, 16]. Some of the techniques proposed here may be useful in that more general context.

DISCRETE MONOTONIC OPTIMIZATION WITH APPLICATION TO A DISCRETE LOCATION PROBLEM*

HOANG TUY†, MICHEL MINOUX‡, AND N. T. HOAI-PHUONG†

Abstract. A general discrete optimization problem is investigated that includes integer polynomial programs as special cases. To exploit the discrete monotonic structure of these problems, a special class of cuts called monotonicity cuts are developed and then adjusted according to a suitable procedure to accommodate discrete requirements. As illustration, the method is applied to solve a discrete location problem which is also a variant of the well known engineering problem of design centering. Computational results are reported for instances of the latter problem with up to 100 variables and 500 constraints.

Key words. discrete optimization, differences of increasing functions, monotonic optimization, polyblock approximation, monotonicity cuts, branch-reduce-and-bound algorithm, discrete location, design centering

DOI. 10.1137/04060932X

1. Introduction.

Throughout this paper, for any two vectors $x, y \in \mathbb{R}^n$ we write $x \leq y$ ($x < y$, resp.) to mean $x_i \leq y_i$ ($x_i < y_i$, resp.) for every $i = 1, \ldots, n$. If $a \leq b$ then the box $[a, b]$ ($(a, b]$, resp.) is the set of all $x \in \mathbb{R}^n$ satisfying $a \leq x \leq b$ ($a < x \leq b$, resp.).

A function $f : [a, b] \to \mathbb{R}$ is said to be *increasing* (*decreasing,* resp.) if

$$a \leq x \leq y \leq b \Rightarrow f(x) \leq f(y) \quad (f(x) \geq f(y), \text{ resp.}).$$

Monotonic functions, i.e., functions which are either increasing or decreasing, and more generally, *d.m. functions*, i.e., functions which are differences of monotonic functions, abound in economics and engineering: production function, cost function, profit function, performance function, etc. As can easily be proved (see [10]) the set of d.m. functions is dense in the space $\mathbf{C}([a, b])$ of continuous functions with the supnorm topology. Recently a general mathematical framework has been developed [10], [11], for the numerical study of monotonic optimization problems, i.e., mathematical programming problems described by means of monotonic or d.m. functions.

Since any generalized polynomial $P(x) = \sum_{\alpha \in I} c_\alpha x^\alpha$, where $c_\alpha \in \mathbb{R}$, $\alpha = (\alpha_1, \ldots, \alpha_n) \in \mathbb{R}^n_+$, and $x^\alpha := x_1^{\alpha_1} x_2^{\alpha_2} \cdots x_n^{\alpha_n}$, can be written as a difference of two generalized polynomials with positive coefficients,

$$P(x) = \sum_{\alpha \in I_+} c_\alpha x^\alpha - \sum_{\alpha \in I_-} (-c_\alpha) x^\alpha,$$

where $I_+ = \{\alpha \in I | c_\alpha > 0\}$, $I_- = \{\alpha \in I |\ c_\alpha < 0\}$, and each generalized polynomial with positive coefficients is obviously increasing on $\mathbb{R}^n_+$, the class of monotonic

optimization problems includes as special cases generalized polynomial mathematical programs which have received increasing attention in recent years due to their applications in various fields (see, e.g., [7], [2], [15]).

It has been shown in [10] that any mathematical programming problem dealing with differences of increasing functions on a box $[a, b] \subset \mathbb{R}^n$ can be reduced to an equivalent constrained monotonic optimization problem of the following *canonical form*:

$$\text{(MO)} \qquad \max\{f(x)|\ g(x) \le 0 \le h(x),\ x \in [a, b]\},$$

where $f, g, h : [a, b] \to \mathbb{R}$ are given increasing functions on $[a, b]$. (Without loss of generality we may assume, as we will do in what follows, that $[a, b] \subset \mathbb{R}^n_+$.) An easily implementable cutting algorithm called the *polyblock algorithm* has been proposed for solving (MO). Applications of this approach to certain classes of difficult nonconvex optimization problems have demonstrated its efficiency when these problems, originally of large scale, can be converted into problems (MO) in low-dimensional space by a suitable change of variables [5], [12], [13], [15]. For larger problems a branch and bound approach, using polyblock approximation for bounding, has also been proposed and recently extended to a branch-reduce-and-bound method [11].

If a problem involves discrete constraints, e.g., boolean constraints like $x_i \in \{0, 1\},\ i = 1, \dots, s\ (s \le n)$, then these constraints can be written as $\sum_{i=1}^s x_i(1-x_i) \le 0,\ 0 \le x_i \le 1\ (i = 1, \dots, s)$, i.e., $\sum_{i=1}^s x_i - \sum_{i=1}^s x_i^2 \le 0,\ 0 \le x_i \le 1\ (i = 1, \dots, s)$, where the functions $\sum_{i=1}^s x_i,\ \sum_{i=1}^s x_i^2$ are increasing on $\mathbb{R}^n_+$. Therefore, a monotonic optimization problem with discrete constraints can in principle be reformulated and solved as one with only continuous monotonic constraints. However, so far this approach has never been implemented; moreover, its potential drawback is that, since the basic algorithms for continuous monotonic optimization are iterative procedures, by this approach only an approximate optimal solution can be computed in finitely many steps.

The aim of the present paper is to suggest an alternative, more practical, approach to monotonic optimization problems with discrete constraints. Specifically, given a box $[a, b] \subset \mathbb{R}^n_+$ with $a < b$, a finite set $S \subset \mathbb{R}^s_+,\ s \le n$, and increasing functions $f(x), g(x), h(x)$ on $[a, b]$, we will consider the general optimization problem

$$\max\{f(x)|\ g(x) \le 0 \le h(x),\ x \in [a, b],\ (x_1, \dots, x_s) \in S\}.$$

We will refer to this problem as the *canonical discrete monotonic optimization problem* (DMO). Setting

$$\text{(1)} \qquad G = \{x \in [a, b]|\ g(x) \le 0\}, H = \{x \in [a, b]|\ h(x) \ge 0\},$$

$$\text{(2)} \qquad S^* = \{x \in [a, b]|\ (x_1, \dots, x_s) \in S\},$$

we can rewrite it as

$$\text{(DMO)} \qquad \max\{f(x)|\ x \in G \cap H \cap S^*\}.$$

In what follows we propose to extend the basic algorithm for continuous monotonic optimization [11] to obtain an algorithm for (DMO) which is *finite* in the important special case when $s = n$ (so that S is a finite set in $\mathbb{R}^n_+$). It turns out that in this special case, by suitable modifications of the basic continuous algorithm, an exact optimal solution of (DMO) can be computed in finitely many iterations. Furthermore, for

certain continuous monotonic optimization problems, although the optimum may be known a priori to be achieved on a certain finite set S, quite often an exact optimal solution can be obtained only through infinitely many iterations of the basic iterative algorithm of the continuous approach. The discrete version to be proposed will help in many cases to turn this infinite procedure into a finite one, thus allowing the exact optimum in these continuous problems to be found in finitely many iterations, too.

The paper is organized as follows. First, in sections 2 and 3, we review some necessary concepts and results from monotonic optimization as presented in [10]. In section 4 two types of cuts exploiting the monotonic structure are described. The first type, introduced earlier in [10], is based on a special separation property of normal sets and plays a role very similar to that of convexity cuts in convex maximization. The second type, to be referred to as reduction cuts, is a further development of a procedure already used in [10] for reducing the size of the solution set of a system of monotonic inequalities. After this review of the essentials about continuous monotonic optimization, the next sections present the new theory of discrete monotonic optimization. A key operation, called S-adjustment, designed to accommodate the continuous monotonicity cuts to discrete constraints, is described in section 5. Next, a procedure for discrete optimization, to be referred to as the discrete polyblock algorithm, is presented in section 6. Some implementation issues are discussed, while the convergence of this algorithm in the general case $s \leq n$ and its finiteness when $s = n$ are established. To enhance efficiency for large scale problems, a branch-reduce-and-bound version of the method is developed in section 7. Finally in section 8, the method is specialized to solve a discrete maximin problem encountered in location, design centering, and some other applications. Computational experiments on problems with up to 100 variables and 500 constraints are reported which demonstrate the practicability of the method at least for this class of discrete optimization problems.

As a matter of notation, for any two vectors $x, y \in \mathbb{R}^n$, we write $u = x \vee y$, to mean $u_i = \max\{x_i, y_i\},\ i = 1, \ldots, n$, and $v = x \wedge y$, to mean $v_i = \min\{x_i, y_i\},\ i = 1, \ldots, n$; e^i denotes the ith unit vector of $\mathbb{R}^n$, i.e., a vector such that $e^i_i = 1, e^i_j = 0\ \forall j \neq i$, while $e \in \mathbb{R}^n$ is a vector of all ones, i.e., $e = \sum_{i=1}^n e^i$.

2. Some geometric concepts. In this and the next two sections we review some basic concepts and essential results of continuous monotonic optimization [10] which are needed for the development of discrete monotonic optimization. For the convenience of the reader, most of the proofs will be provided, although they are rather simple and can be found in [10].

A set $G \subset [a, b]$ is said to be *normal* if $x \in G \Rightarrow [a, x] \subset G$. A set $H \subset [a, b]$ is *conormal (reverse normal)* if $x \in H \Rightarrow [x, b] \subset H$. Thus the set $G = \{x \in [a, b] |\ g(x) \leq 0\}$ defined above (with an increasing function $g(x)$) is normal, whereas the set $H = \{x \in [a, b] |\ h(x) \geq 0\}$ (with an increasing function $h(x)$) is conormal.

Given a set $A \subset [a, b]$, the *normal hull* of A, written $A^\rceil$, is the smallest normal set containing A. The *conormal hull* of A, written $\lfloor A$, is the smallest conormal set containing A.

PROPOSITION 1. (i) *The normal hull of a set $A \subset [a, b] \subset R^n_+$ is the set $A^\rceil = \cup_{z \in A}[a, z]$. If A is compact, then so is $A^\rceil$.*

(ii) *The conormal hull of a set $A \subset [a, b] \subset R^n_+$ is the set $\lfloor A = \cup_{z \in A}[z, b]$. If A is compact, then so is $\lfloor A$.*

Proof. It suffices to prove (i), because the proof of (ii) is similar. Let $P = \cup_{z \in A}[a, z]$. Clearly P is normal and $P \supset A$; hence $P \supset A^\rceil$. Conversely, if $x \in P$, then $x \in [a, z]$ for some $z \in A \subset A^\rceil$; hence $x \in A^\rceil$ by normality of $A^\rceil$, so that $P \subset A^\rceil$

and therefore, $P = A^{\rceil}$. If A is compact, then A is contained in a ball B centered at 0, and if $x^k \in A^{\rceil}, k = 1, 2, \dots$, then since $x^k \in [a, z^k] \subset B$, there exists a subsequence $\{k_\nu\} \subset \{1, 2, \dots\}$ such that $z^{k_\nu} \to z^0 \in A,\ x^{k_\nu} \to x^0 \in [a, z^0]$, and hence $x^0 \in A^{\rceil}$, proving the compactness of $A^{\rceil}$. □

The normal hull of a finite set $T \subset [a, b]$ is called a *polyblock* P, with *vertex set* T. By Proposition 1, $P = \cup_{z \in T}[a, z]$. A vertex z of a polyblock is called *proper* if there is no vertex $z' \neq z$ "dominating" z, i.e., such that $z' \geq z$. An *improper* vertex or improper element of T is an element of T which is not a proper vertex. Obviously, a polyblock is fully determined by its proper vertex set; more precisely, *a polyblock is the normal hull of its proper vertices.*

Similarly, the conormal hull of a finite set $T \subset [a, b]$ is called a *copolyblock (reverse polyblock)* Q with *vertex set* T. By Proposition 1, $Q = \cup_{z \in T}[z, b]$. A vertex z of a copolyblock is called *proper* if there is no vertex $z' \neq z$ "dominated" by z, i.e., such that $z' \leq z$. An *improper* vertex or improper element of T is an element of T which is not a proper vertex. Obviously, a copolyblock is fully determined by its proper vertex set; more precisely, *a copolyblock is the conormal hull of its proper vertices.*

PROPOSITION 2. (i) *The intersection of finitely many polyblocks is a polyblock.*

(ii) *The intersection of finitely many copolyblocks is a copolyblock.*

Proof. If T_1, T_2 are the vertex sets of two polybocks P_1, P_2, respectively, then $P_1 \cap P_2 = (\cup_{z \in T_1}[a, z]) \cap (\cup_{y \in T_2}[a, y]) = \cup_{z \in T_1, y \in T_2}[a, z] \cap [a, y] = \cup_{z \in T_1, y \in T_2}[a, z \wedge y]$. Thus, $P_1 \cap P_2$ is a polyblock of vertex set $\{z \wedge y |\ z \in T_1, y \in T_2\}$. Similarly, if T_1, T_2 are the vertex sets of two copolyblocks Q_1, Q_2, respectively, then $Q_1 \cap Q_2 = \cup_{z \in T_1, y \in T_2}[z, b] \cap [y, b] = \cup_{z \in T_1, y \in T_2}[z \vee y, b]$, so $Q_1 \cap Q_2$ is a copolyblock with vertex set $\{z \vee y |\ z \in T_1, y \in T_2\}$. □

PROPOSITION 3. (i) *The maximum of an increasing function $f(x)$ over a polyblock is achieved at a proper vertex of this polyblock.*

(ii) *The minimum of an increasing function $f(x)$ over a copolyblock is achieved at a proper vertex of this copolyblock.*

Proof. We prove (i). Let $\bar{x}$ be a maximizer of $f(x)$ over a polyblock P. Since a polyblock is the normal hull of its proper vertices, there exists a proper vertex z of P such that $\bar{x} \in [a, z]$. Then $f(z) \geq f(\bar{x})$ because $z \geq \bar{x}$, so z also must be an optimal solution. The proof of (ii) is similar. □

LEMMA 4. (i) *If $a < x < b$, then the set $[a, b] \setminus (x, b]$ is a polyblock with vertices*

$$u^i = b + (x_i - b_i)e^i, \quad i = 1, \dots, n. \tag{3}$$

(ii) *If $a < x < b$, then the set $[a, b] \setminus [a, x)$ is a copolyblock with vertices*

$$v^i = a + (x_i - a_i)e^i, \quad i = 1, \dots, n.$$

Proof. We prove (i). Let $K_i = \{z \in [a, b] |\ x_i < z_i\}$. Since $(x, b] = \cap_{i=1,\dots,n} K_i$, we have $[a, b] \setminus (x, b] = \cup_{i=1,\dots,m}([a, b] \setminus K_i)$, proving the assertion because $[a, b] \setminus K_i = \{z |\ a_i \leq z_i \leq x_i,\ a_j \leq z_j \leq b_j\ \forall j \neq i\} = [a, u^i]$. The proof of (ii) is similar. □

Note that $u^1, \dots, u^n$ are the n vertices of the hyperrectangle $[x, b]$ that are adjacent to b, while $v^1, \dots, v^n$ are the n vertices of the hyperrectangle $[a, x]$ that are adjacent to a.

3. Monotonic functions. It has been shown in [10] that by simple transformations, any optimization problem dealing with d.m. functions can be converted to the canonical form (MO), where f, g, h are increasing functions. These transformations are based on the following properties of monotonic functions [10].

PROPOSITION 5. *If $f_i,\ i = 1, \dots, m$, are d.m. functions, then their upper and lower envelopes*

$$\max_{i=1,\dots,m} f_i(x), \qquad \min_{i=1,\dots,m} f_i(x)$$

are also d.m.

Proof. Let $f_i(x) = g_i(x) - h_i(x)$, where g_i, h_i are increasing. It is easily seen that

$$\max_{i=1,\dots,m}\{g_i - h_i\} = \sum_{k=1,\dots,m} g_k - \min_{i=1,\dots,m}\left\{\sum_{k\neq i} g_k + h_i\right\},$$

$$\min_{i=1,\dots,m}\{g_i - h_i\} = \sum_{k=1,\dots,m} g_k - \max_{i=1,\dots,m}\left\{\sum_{k\neq i} g_k + h_i\right\}.$$

The conclusion follows, because the sum and the upper and lower envelopes of finitely many increasing functions are obviously increasing. ∎

COROLLARY 6. *Any conjunctive or disjunctive system of d.m. inequalities is equivalent to a single d.m. inequality:*

$$f_i(x) \le 0\ \forall i = 1, \dots, m \qquad \Leftrightarrow \max_{i=1,\dots,m} f_i(x) \le 0,$$
$$f_i(x) \le 0 \text{ for at least one } i = 1, \dots, m \Leftrightarrow \min_{i=1,\dots,m} f_i(x) \le 0.$$

PROPOSITION 7. *Any constrained d.m. optimization problem*

$$\max\{f_0(x)|\ f_i(x) \le 0,\ i = 1, \dots, m,\ x \in [a, b] \subset \mathbb{R}^n_+\}, \tag{4}$$

with d.m. functions $f_i : [a, b] \to \mathbb{R},\ i = 0, 1, \dots, m$, can be transformed into a monotonic optimization problem in canonical form.

Proof. Since $f_0(x) = f_{01}(x) - f_{02}(x)$, with increasing functions $f_{01}(x), f_{02}(x)$, by writing the problem (4) as

$$\max\{f_{01}(x) + t - f_{02}(b)|\ t - f_{02}(b) + f_{02}(x) \le 0, f_i(x) \le 0, i = 1, \dots, m,$$
$$0 \le t \le f_{02}(b) - f_{02}(a), a \le x \le b\}$$

and changing the notation, one can assume that the objective function, i.e., the function $f_0(x)$ in (4), is increasing. Furthermore, by Corollary 6, the set of d.m. inequalities $f_i(x) \le 0,\ i = 1, \dots, m$, can be rewritten as a single inequality $g(x) - h(x) \le 0$, with increasing functions g, h. In turn, it is easily verified that the inequality $g(x) - h(x) \le 0$ has a solution $x \in [a, b]$ if and only if $h(b) - g(a) \ge 0$ and there exists $x_{n+1} \in \mathbb{R}$ such that

$$0 \le x_{n+1} \le h(b) - g(a), \quad g(x) + x_{n+1} \le h(b) \le h(x) + x_{n+1}.$$

Therefore, setting $z = (x, x_{n+1}),\ w(z) = f_0(x),\ u(z) = g(x) + x_{n+1} - h(b),\ v(z) = h(x) + x_{n+1} - h(b),\ c = (a, 0),$ *and* $d = (b, h(b) - g(a))$, we obtain the problem in z

$$\max\{w(z)|\ u(z) \le 0 \le v(z),\ z \in [c, d]\}$$

which is identical to (MO) except for the notation. ∎

4. Monotonicity cuts. A popular method for exploiting special structure in nonconvex optimization problems is to develop cuts that allow one to successively remove unfit portions of the region of the feasible set currently of interest.

For the problem (MO), two kinds of cuts can be introduced. Cuts of the first kind are based on a special separation property of normal sets similar to the separation property of convex sets and are, therefore, called *separation cuts*. Cuts of the second kind aim at tightening the box containing the feasible portion currently still of interest and are referred to as *reduction cuts*.

I. *Separation cut*. This cut was developed earlier in [5] and [10]. For a closed normal set G in $[a,b]$, a point $\bar{x} \in G$ is called an *upper boundary point* if the cone $K_{\bar{x}} := \{x|\ x > \bar{x}\}$ contains no point $x \in G$. The set of all upper boundary points of G is called its *upper boundary* and is denoted by $\partial^+ G$. Clearly, if $\bar{z} \in [a,b] \setminus G$, then the first point of G in the line segment joining $\bar{z}$ to a is an upper boundary point of G.

PROPOSITION 8 (see [10]). *Let G be a closed normal set in a box $[a,b]$, and $\bar{z} \in [a,b] \setminus G$. If $\bar{x}$ is any point on $\partial^+ G$ such that $\bar{x} < \bar{z}$ then the cone $K_{\bar{x}} := \{x|\ x > \bar{x}\}$ contains $\bar{z}$ but is disjoint from G.* (We say that this cone separates strictly $\bar{z}$ from G.)

Proof. If there were $x \in G$ such that $x > \bar{x}$, then by normality, $[\bar{x}, x] \subset G$; hence $G \cap K_{\bar{x}} \supset [\bar{x}, x] \cap K_{\bar{x}} \neq \emptyset$, conflicting with $\bar{x}$ being an upper boundary point. □

We shall refer to the cone $K_{\bar{x}}$ as a *separation cut with vertex* $\bar{x}$. Since, by Lemma 2, $[a,b] \setminus K_x = [a,b] \setminus (x,b]$ is a polyblock, Proposition 8 also says that for any $\bar{z} \in [a,b] \setminus G$, there exists a polyblock $P \supset G$ such that $z \notin P$.

The next corollary shows that with respect to compact normal sets, polyblocks play a role similar to that of polytopes with respect to compact convex sets.

COROLLARY 9 ([10]). *Any compact normal set $G \subset [a,b]$ is the intersection of a family of polyblocks.*

Proof. Clearly, $P_0 := [a,b]$ is a polyblock containing G. Let $\{P_i, i \in I\}$ be the family of all polyblocks containing G. We have $G = \cap_{i \in I} P_i$ because if there were $z \in \cap_{i \in I} P_i \setminus G$, there would exist, by Proposition 8, a polyblock $P \supset G$ (i.e., $P = P_i$ for some $i \in I$) such that $z \notin P$, a contradiction. □

Sometimes we need to perform a sequence of conjunctive separation cuts. The following proposition, which is an improved version of an earlier result ([10, Proposition 18]) indicates how to compute the proper vertex set of the resulting polyblock.

PROPOSITION 10. *Let P be a polyblock with proper vertex set $T \subset [a,b]$, let $x \in [a,b]$ be such that $T_* := \{z \in T|\ z > x\} \neq \emptyset$. For every $z \in T_*$ and every $i = 1, \ldots, n$, define $z^i = z + (x_i - z_i)e^i$. Then the vertex set of the polyblock $P \setminus (x,b]$ is*

$$T' = (T \setminus T_*) \bigcup \{z^i = z + (x_i - z_i)e^i|\ z \in T_*, i \in \{1, \ldots, n\}\}. \tag{5}$$

The improper elements of T' are those $z^i = z + (x_i - z_i)e^i$, with $z \in T_*$, for which there exists $y \in T$ such that $y \geq x$ and the set $J(z,y) := \{j|\ z_j > y_j\}$ has i as its unique element.

Proof. Since $[a,z] \cap (x,b] = \emptyset$ for every $z \in T \setminus T_*$, it follows that $P \setminus (x,b] = P_1 \cup P_2$, where P_1 is the polyblock generated by $T \setminus T_*$ and $P_2 = (\cup_{z \in T_*}[a,z]) \setminus (x,b] = \cup_{z \in T_*}([a,z] \setminus (x,b])$. Noting that $[a,b] \setminus (x,b]$ is a polyblock with vertices $u^i = b + (x_i - b_i)e^i,\ i = 1, \ldots, n$ (see (3)), we can then write $[a,z] \setminus (x,b] = [a,z] \cap ([a,b] \setminus (x,b]) = [a,z] \cap (\cup_{i=1,\ldots,n}[a,u^i]) = \cup_{i=1,\ldots,n}[a,z] \cap [a,u^i] = \cup_{i=1,\ldots,n}[a, z \wedge u^i]$; hence $P_2 = \cup\{[a, z \wedge u^i]|\ z \in T_*, i = 1, \ldots, n\}$, which shows that the vertex set of $P \setminus (x,b]$ is the set T' given by (5).

It remains to show that every $z \in T \setminus T_*$ is proper, while a $z^i = z + (x_i - z_i)e^i$ with $z \in T_*$ is improper if and only if $J(z,y) = \{i\}$ for some $y \in T$ such that $y \geq x$.

Since every $y \in T \setminus T_*$ is proper in T, while $z^i \leq z \in T$ for every $z^i = z + (x_i - z_i)e^i$, it is clear that every $y \in T \setminus T_*$ is proper in T'. Therefore, an improper element of T' must be some z^i such that $z^i \leq y$ for some $y \in T' \setminus \{z^i\}$. Two cases are possible: either $y \in T$ or $y \in T' \setminus T$. In the former case ($y \in T$), since obviously $x \leq z^i$ we must have $x \leq y$; furthermore, $z_j = z^i_j \leq y_j \ \forall j \neq i$; hence, since $z \not\leq y$, it follows that $z_i > y_i$, i.e., $J(z,y) = \{i\}$. In the latter case ($y \in T' \setminus T$), $z^i \leq y^l = y + (x_l - y_l)e^l$ for some $y \in T_*$ and some $l \in \{1, \ldots, n\}$. Then, since $y^l \neq z^i$, we must have $y \neq z$ and $z^i_j \leq y^l_j \ \forall j = 1, \ldots, n$. If $l = i$, then this implies that $z_j = z^i_j \leq y^i_j = y_j \ \forall j \neq i$; hence, since $z \not\leq y$ it follows that $z_i > y_i$ and $J(z,y) = \{i\}$. On the other hand, if $l \neq i$, then from $z^i_j \leq y^l_j \ \forall j = 1, \ldots, n$ we have $z_j \leq y_j \ \forall j \neq i$ and, again, since $z \not\leq y$, we must have $z_i > y_i$, so $J(z,y) = \{i\}$. Thus an improper $z^i = z + (x_i - z_i)e^i$ must satisfy $J(z,y) = \{i\}$ for some $y \in T$ such that $y \geq x$. Conversely, if $J(z,y) = \{i\}$ for some $y \in T$ such that $y \geq x$, then $z^i_j = z_j \leq y_j \ \forall j \neq i$; hence $z^i \leq y$ (because $z^i_i = x_i \leq y_i$) and so, noting that $y \in T'$ if $y \notin T_*$, while $y \leq y^i \in T'$ otherwise, we see that z^i is improper in T'. This completes the proof of the proposition. □

II. *Reduction cuts.* Consider any box $[p,q] \subset [a,b]$ and the problem (MO) restricted to $[p,q]$:

$$\max\{f(x) |\ g(x) \leq 0 \leq h(x),\ x \in [p,q]\}. \tag{6}$$

If a feasible solution of (MO) is known with objective function value γ, then we would like to recognize whether or not the box $[p,q]$ contains a feasible solution to (MO) with objective function value at least equal to γ. Furthermore, if a feasible solution x to (MO) satisfies $g(x) < 0$, then the intersection point x' of the half-line $\{p + \lambda(x-p) |\ \lambda > 0\}$ with the surface $g(x) = 0$ will give a better feasible solution to (MO), so we are interested only in feasible solutions satisfying $g(x) = 0$. Therefore, we can replace the problem (6) by

$$\max\{f(x) |\ g(x) \leq 0 \leq \min\{h(x), g(x), f(x) - \gamma\},\ x \in [p,q]\}. \tag{7}$$

Define

$$h_\gamma(x) := \min\{h(x), g(x), f(x) - \gamma\}, \tag{8}$$

$$H_\gamma := \{x \in [p,q] |\ h_\gamma(x) \geq 0\}. \tag{9}$$

PROPOSITION 11. (i) *Let* $h_\gamma(q) \geq 0$ *and* $p' = q - \sum_{i=1}^n \alpha_i(q_i - p_i)e^i$, *where*

$$\alpha_i = \sup\{\alpha |\ 0 \leq \alpha \leq 1,\ h_\gamma(q - \alpha(q_i - p_i)e^i) \geq 0\}, \quad i = 1, \ldots, n. \tag{10}$$

Then the box $[p', q]$ *still contains all feasible solutions of the problem* (7).

(ii) *Let* $g(p) \leq 0$ *and* $q' = p + \sum_{i=1}^n \beta_i(q_i - p_i)e^i$, *where*

$$\beta_i = \sup\{\beta |\ 0 \leq \beta \leq 1,\ g(p + \beta(q_i - p_i)e^i) \leq 0\}, \quad i = 1, \ldots, n. \tag{11}$$

Then the box $[p, q']$ *still contains all feasible solutions of the problem* (7).

Proof. It suffices to prove (i) because the proof of (ii) is similar. Since $p'_i = \alpha_i p_i + (1 - \alpha_i)q_i$ with $0 \leq \alpha_i \leq 1$, it follows that $p_i \leq p'_i \leq q_i \ \forall i = 1, \ldots, n$, i.e., $[p', q] \subset [p, q]$. For any $x \in H_\gamma \cap [p,q]$ we have, by conormality, $[x, q] \subset H_\gamma$, so if we define $x^i := q - (q_i - x_i)e^i$, then $x^i \in H_\gamma, i = 1, \ldots, n$. But $x_i \leq q_i$, so

$x^i = q - \alpha(q_i - p_i)e^i$ for some α (depending on i) such that $0 \le \alpha \le 1$. This implies that $\alpha \le \alpha_i$, i.e., $x^i \ge q - \alpha_i(q_i - p_i)e^i,\ i = 1, \dots, n$, and consequently $x \ge p'$, i.e., $x \in [p', q]$. Thus, $H_\gamma \cap [p, q] \subset H_\gamma \cap [p', q]$, which completes the proof because the converse inclusion is obvious from the fact that $[p', q] \subset [p, q]$. □

Clearly the box $[p', q]$ defined in (i) is obtained from $[p, q]$ by applying the cut $\cup_{i=1}^n \{x|\ x_i < p'_i\}$, while the box $[p, q']$ defined in (ii) is obtained from $[p, q]$ by applying the cut $\cup_{i=1}^n \{x|\ x_i > q'_i\}$. The former cut is referred to as a *lower cut with vertex* p' and the latter cut as an *upper cut with vertex* q'.

Given the problem (6) and a box $[p, q]$ satisfying $g(p) \le 0 \le h_\gamma(q)$, let p' be the vertex of the lower cut defined above.

If $g(p') \le 0$ and q' is the vertex of the upper cut for $[p', q]$, i.e., $q' = p' + \sum_{i=1}^n \beta_i(q_i - p'_i)e^i$, where

$$\beta_i = \sup\{\beta|\ 0 \le \beta \le 1,\ g(p' + \beta(q_i - p'_i)e^i) \le 0\}, \quad i = 1, \dots, n,$$

then the box $[p', q']$ is called a γ-*reduction* of $[p, q]$, written $[p', q'] = \text{red}_\gamma[p, q]$.

If $g(p') > 0$, then we set $\text{red}_\gamma[p, q] = \emptyset$.

By Proposition 11 the set $\text{red}_\gamma[p, q]$ still contains all feasible solutions x to (MO) satisfying $x \in [p, q], f(x) \ge \gamma$. In other words, by replacing the box $[p, q]$ with $\text{red}_\gamma[p, q]$ no feasible solution $x \in [p, q]$ satisfying $f(x) \ge \gamma$ is lost.

5. The *S*-adjustment operation. The above cuts are valid for the general monotonic optimization problem (MO). We now extend these cuts to the discrete optimization problem (DMO).

As we saw by Propositions 8 and 11, a separation cut is determined by the vertex $\bar{x} \in \partial^+ G$ of the cone to be removed, while a lower (upper) cut is determined by the vertex p' (or q') of the cone complementary to the part to be removed. Since the feasible set of (DMO) is smaller than that of (MO), these cuts can be adjusted to take account of the discrete constraint. The adjustment consists of moving the vertex of the cut (i.e., $\bar{x}, q'$, or p') to a suitable point inside, so that the new cut is deeper but still leaves unaffected the set of feasible solutions in $[p, q]$ with objective function value no less than γ.

The following proposition transforms the discrete problem (DMO) into a continuous problem with an implicitly defined monotonic constraint.

PROPOSITION 12. *Define* $\tilde{G} = (G \cap S^*)^\rceil$, *the normal hull of the set* $G \cap S^*$. *Then problem* (DMO) *is equivalent to*

$$\max\{f(x)|\ x \in \tilde{G} \cap H\}. \tag{12}$$

Proof. Since the feasible set of (DMO) is contained in the feasible set of (12), the optimal value of (DMO) cannot exceed that of problem (12). Conversely, if $\bar{x}$ solves (12), then $\bar{x} \in \tilde{G} \cap H$, but $\tilde{G} = \cup_{z \in G \cap S^*}[0, z]$ by Proposition 1, so $\bar{x} \in [0, z]$ for some $z \in G \cap S^*$; furthermore, since $\bar{x} \in H$ and $\bar{x} \le z$ we must also have $z \in H$ by conormality of H. Consequently, $\bar{x} \le z \in G \cap S^* \cap H$, and hence $f(\bar{x}) \le f(z)$ for some z feasible to (DMO). This implies that the optimal value of (12) cannot exceed that of (DMO). Therefore, the two problems (DMO) and (12) have the same optimal value. □

Solving problem (DMO) is thus reduced to solving (12) which is a monotonic optimization problem without explicit discrete constraint. The new difficulty, however, is how to handle the polyblock $\tilde{G}$ which is defined only implicitly as the normal hull of $G \cap S^*$.

Fortunately, as we will see shortly, the monotonicity cuts developed in the previous section for the continuous problem (MO) can be adjusted to yield valid cuts for the problem (12) equivalent to the discrete problem (DMO).

Consider a box $[p,q] \subset [a,b]$. Given any point $x \in [p,q]$, we define the *lower S-adjustment* of x to be the point

(13)
$$\lfloor x \rfloor_{S^*} = \tilde{x}, \text{ with } \tilde{x}_i = \begin{cases} \max\{y_i |\ y \in S^* \cup \{p\},\ y_i \le x_i\}, & i = 1,\dots,s, \\ x_i, & i = s+1,\dots,n \end{cases}$$

and the *upper S-adjustment* of x to be the point

(14)
$$\lceil x \rceil_{S^*} = \hat{x}, \text{ with } \hat{x}_i = \begin{cases} \min\{y_i |\ y \in S^* \cup \{q\},\ y_i \ge x_i\}, & i = 1,\dots,s, \\ x_i, & i = s+1,\dots,n. \end{cases}$$

A frequently encountered special case is when $S = S_1 \times \cdots \times S_s$ and every S_i is a finite set of real numbers. In this case

$$\tilde{x}_i = \begin{cases} \max\{\xi |\ \xi \in S_i \cup \{p_i\},\ \xi \le x_i\}, & i = 1,\dots,s, \\ x_i, & i = s+1,\dots,n, \end{cases} \tag{15}$$

$$\hat{x}_i = \begin{cases} \min\{\xi |\ \xi \in S_i \cup \{q_i\},\ x_i \le \xi\}, & i = 1,\dots,s, \\ x_i, & i = s+1,\dots,n. \end{cases} \tag{16}$$

(For example, if each S_i is the set of integers and $p_i, q_i \in S_i$, then $\tilde{x}_i$ is the largest integer no larger than x_i while $\hat{x}_i$ is the smallest integer no less than x_i.)

PROPOSITION 13. (i) *If $\bar{x}$ is the vertex of a separation cut for the problem* (MO), *then $\tilde{x} := \lfloor \bar{x} \rfloor_{S^*}$ is the vertex of a separation cut for the problem* (12).

(ii) *If q' is the vertex of an upper cut for* (MO), *then $\lfloor q' \rfloor_{S^*}$ is the vertex of an upper cut for the problem* (12).

(iii) *If p' is the vertex of a lower cut for* (MO), *then $\lceil p' \rceil_{S^*}$ is the vertex of a lower cut for the problem* (12).

Proof. We prove (i). If $\bar{x}$ is the vertex of a separation cut for the problem (MO), then $(\bar{x}, b] \cap G = \emptyset$. For any $y \in (\tilde{x}, b] \cap G \cap S^*$, since $y \in (\tilde{x}, b]$ we have $y_i > \tilde{x}_i$ for every $i = 1,\dots,n$. But $\tilde{x}_i = \bar{x}_i$ for $i = s+1,\dots,n$, so $y_i > \bar{x}_i,\ i = s+1,\dots,n$. On the other hand, since $y \in G \cap S^*$ while $(\bar{x}, b] \cap G = \emptyset$, it follows that $y \notin (\bar{x}, b]$; i.e., there is at least one $i_0 \in \{1,\dots,n\}$ such that $y_{i_0} \le \bar{x}_{i_0}$. Hence $i_0 \in \{1,\dots,s\}$. Since $y \in S^*$ and $y_{i_0} \le x_{i_0}$, it follows from the definition of $\tilde{x}$ that $\tilde{x}_{i_0} \ge y_{i_0}$, conflicting with $y_i > \tilde{x}_i\ \forall i$. Therefore $(\tilde{x}, b] \cap G \cap S^* = \emptyset$, as was to be proved. Analogously we can prove (ii) and (iii). □

Thus any monotonicity cut for the continuous problem (MO) can be adjusted to yield a monotonicity cut for the discrete problem (DMO).

6. The discrete polyblock algorithm. In an earlier paper [10] a polyblock approximation algorithm was developed for solving continuous monotonic optimization problems. Using the S-adjustment operation we now extend this algorithm to solve the discrete monotonic optimization problem (DMO).

Since the feasible set of (DMO) is obviously contained in the box $[a^*, b^*]$, where $a^* = \lceil a \rceil_{S^*}$ (upper S-adjustment of a), $b^* = \lfloor b \rfloor_{S^*}$ (lower S-adjustment of b), we can assume, without loss of generality, that $a = a^*, b = b^*$. If $g(a) > 0$, i.e., $a \notin G$,

then, since $g(x)$ is increasing, it follows that $g(x) > 0\ \forall x \in [a,b]$, and the problem is infeasible. Similarly, if $h(b) < 0$, i.e., $b \notin H$, then $h(x) < 0\ \forall x \in [a,b]$, and the problem is infeasible. Therefore, we also assume that

$$a \in G, \quad b \in H. \tag{17}$$

Now to solve (DMO) we will construct a sequence of polyblocks $P_0 \supset P_1 \supset \cdots$, together with a sequence of numbers $\gamma_0 \le \gamma_1 \le \cdots$, satisfying two conditions:

(C1) $\gamma_k = f(\hat{x}^k)$ for some $\hat{x}^k \in \tilde{G} \cap H$ if $\gamma_k > -\infty$,

(C2) $P_k \supset \tilde{G}_k \cap H$,

where $\tilde{G}_k = (G \cap S_k^*)^\rceil$, $S_k^* = \{x \in S^* |\ f(x) > \gamma_k\}$.

Start with an initial polyblock $P_0 \supset \tilde{G} \cap H$, e.g., $P_0 = [a,b]$, with vertex set $T_0 = \{b\}$ and $\gamma_0 = -\infty$. At iteration $k = 0, 1, \ldots$, let P_k be the current polyblock, T_k its proper vertex set, γ_k the current best value, and $\hat{x}^k$ the current best solution, satisfying (C1) and (C2). Perform the following transformation (*) of T_k:

(*) For every $v \in T_k$ define $\mathrm{red}^*_{\gamma_k}[a,v]$ to be the γ_k-reduction of the box $[a,v]$, S-adjusted as indicated above. If $\mathrm{red}^*_{\gamma_k}[a,v] = \emptyset$, then drop v (in particular delete any $v \notin H$); if $\mathrm{red}^*_{\gamma_k}[a,v] \neq \emptyset$, denote the highest vertex of $\mathrm{red}^*_{\gamma_k}[a,v]$ again by v, and if $f(v) \le \gamma_k$, then drop v.

Let $\tilde{T}_k$ be the set that results from T_k upon the transformation (*) (note that $\tilde{T}_k \subset H$). If $\tilde{T}_k = \emptyset$, the procedure terminates: the current best feasible solution is optimal (if $\gamma_k > -\infty$) or the problem is infeasible (if $\gamma_k = -\infty$). If $\tilde{T}_k \neq \emptyset$, let P_k be the polyblock with vertex set $\tilde{T}_k$ and select

$$v^k \in \mathrm{argmax}\{f(x) |\ x \in \tilde{T}_k\}.$$

Two cases may occur:

Case 1. $v^k \in G \cap S^*$. Since $v^k \in H$ we have $v^k \in G \cap H \cap S_k^*$, so v^k is a feasible solution of (DMO) with objective function value no less than γ_k. We set $\hat{x}^{k+1} = v^k, \gamma_{k+1} = f(v^k)$, and define P_{k+1} to be the polyblock with vertex set $T_{k+1} = \tilde{T}_k \setminus \{v^k\}$. Also in this case we define $\tilde{v}^k = v^k$.

Case 2. $v^k \notin G \cap S^*$. Then we find $x^k = \pi_G(v^k)$, the first point of G on the line segment joining v^k to a. If $x^k \in S_k^*$, then set $\tilde{v}^k = x^k$; otherwise, set $\tilde{v}^k = \lfloor x^k \rfloor_{S_k^*}$. Perform the cut with vertex at $\tilde{v}^k$, yielding a polyblock P_{k+1}. Compute the proper vertex set T_{k+1} of P_{k+1} according to Proposition 10.

If a new feasible solution has appeared with a better objective function value than γ_k, then let $\hat{z}^{k+1}$ be the best among such solutions, and set $\gamma_{k+1} = f(\hat{z}^{k+1})$; otherwise, set $\hat{z}^{k+1} = \hat{z}^k, \gamma_{k+1} = \gamma_k$.

PROPOSITION 14. *Let $\gamma_{k+1} = f(\hat{x}^{k+1})$, where $\hat{x}^{k+1}$ is the new current best feasible solution. The polyblock P_{k+1} still contains $G \cap H \cap S_{k+1}^*$ and $P_{k+1} \subset P_k \setminus (\tilde{v}^k, b]$ (so conditions* (C1), (C2) *still hold for $k \leftarrow k+1$).*

Proof. In Case 1, we have $P_{k+1} \supset P_k \setminus [a, v^k]$, but $P_k \supset G \cap H \cap S_k^*$, while $[0, v^k] \subset \{x \in P_k |\ f(x) \le f(v^k) = \gamma_{k+1}\}$, and hence $P_{k+1} \supset G \cap H \cap S_{k+1}^*$; furthermore, since $v^k = \tilde{v}^k, (v^k, b] \cap P_k = \emptyset$ (v^k is a proper vertex of P_k), we have $P_k \setminus (\tilde{v}^k, b] = P_k \supset P_{k+1}$. In Case 2, if $v^k \in G \setminus S^*$, then, since v^k is a proper vertex of P_k and $v^k \in G$, one must have $v^k \in \partial^+ G$, i.e., $(v^k, b] \cap G = \emptyset$; hence, by Proposition 13, $(\tilde{v}^k, b] \cap G \cap S_k^* = \emptyset$, and consequently, $P_{k+1} \supset G \cap H \cap S_k^* \supset G \cap H \cap S_{k+1}^*$. On the other hand, if $v^k \notin G$, then $(v^k, b] \cap G = \emptyset$; hence, again by Proposition 13, $(\tilde{v}^k, b] \cap G \cap S_k^* = \emptyset$, and $P_{k+1} \supset G \cap H \cap S_k^* \supset G \cap H \cap S_{k+1}^*$. That $P_{k+1} \subset P_k \setminus (\tilde{v}^k, b]$ follows from Proposition 10. □

Thus, P_{k+1} and γ_{k+1} will still satisfy (C1), (C2) (for $k \leftarrow k+1$). We can then go to iteration $k+1$.

In a formal way, assuming that $a, b \in S^*$, we can state the following algorithm.

ALGORITHM 1 (discrete polyblock algorithm).

Initialization. Take an initial polyblock $P_0 \supset G \cap H$, with proper vertex set T_0. Let $\hat{x}^0$ be the best feasible solution available (the current best feasible solution), $\gamma_0 := f(\hat{x}^0)$. If no feasible solution is available, let $\gamma_0 := -\infty$. Set $k := 0$.

Step 1. Perform the transformation (*) of T_k. Let $\tilde{T}_k$ be the resulting set ($\tilde{T}_k \subset H$). Reset $T_k := \tilde{T}_k$.

Step 2. If $T_k = \emptyset$, terminate: if $\gamma_k = -\infty$, the problem is infeasible; if $\gamma_k > -\infty$, $\hat{x}^k$ is an optimal solution.

Step 3. If $T_k \neq \emptyset$, select $v^k \in \operatorname{argmax}\{f(v) |\ v \in T_k\}$.

If $v^k \in G \cap S^*$, terminate: v^k is an optimal solution.

Step 4. If $v^k \in G \setminus S^*$, compute $\tilde{v}^k := \lfloor v^k \rfloor_{S_k^*}$ (using formula (13) for $S^* := S_k^*$).

If $v^k \notin G$, compute $x^k := \pi_G(v^k)$ and define $\tilde{v}^k := x^k$ if $x^k \in S_k^*$, $\tilde{v}^k := \lfloor x^k \rfloor_{S_k^*}$ if $x^k \notin S_k^*$.

Step 5. Let $T_{k,*} := \{z \in T_k |\ z > \tilde{v}^k\}$. Compute

$$T_k' := (T_k \setminus T_{k,*}) \bigcup \{z^{k,i} = z + (\tilde{v}_i^k - z_i)e^i |\ z \in T_{k,*}, i = 1, \dots, n\}. \tag{18}$$

Let T_{k+1} be the set obtained from T_k' by removing every z^i such that $\{j |\ z_j > y_j\} = \{i\}$ for some $z \in T_{k,*}$ and $y \in T_{k,*}^+$.

Step 6. Determine the new current best feasible solution $\hat{x}^{k+1}$ and $\gamma_{k+1} := f(\hat{x}^{k+1})$. Increment k and return to Step 1.

To prove the convergence of Algorithm 1 assume that either $s = n$ (so that S is a finite subset of $\mathbb{R}^n$) or there exists a constant $\alpha > 0$ such that

$$\min_{i=s+1,\dots,n} (x_i - a_i) \geq \alpha \quad \forall x \in H. \tag{19}$$

THEOREM 15. *If $s = n$, then Algorithm* 1 *is finite. If $s < n$ and condition* (19) *holds, then either Algorithm* 1 *is finite or it generates an infinite sequence of feasible solutions converging to an optimal solution.*

Proof. At each iteration k a pair $v^k, \tilde{v}^k$ is generated such that $v^k \notin (G \cap S_k^*)^\rceil$, $\tilde{v}^k \in (G \cap S_k^*)^\rceil$ and the rectangle $(\tilde{v}^k, b]$ contains no point of P_l with $l > k$ and hence no $\tilde{v}^l$ with $l > k$. Therefore, there can be no repetition in the sequence $\{\tilde{v}^0, \tilde{v}^1, \dots, \tilde{v}^k, \dots\} \subset S^*$. This implies finiteness of the algorithm in the case $s = n$ since then $S^* = S$ is finite. In the case $s < n$, if the sequence $\{v^k\}$ is infinite, it follows from the fact $(\tilde{v}_1^k, \dots, \tilde{v}_s^k) \in S^*$ that for some sufficiently large k_0,

$$\tilde{v}_i^k = \tilde{v}_i, \quad i = 1, \dots, s, \quad \forall k \geq k_0. \tag{20}$$

On the other hand, since $v^k \in H$ we have from (19) that

$$\min_{i=s+1,\dots,n} (v_i^k - a_i) \geq \alpha \quad \forall k. \tag{21}$$

We show that $v^k - x^k \to 0$ as $k \to \infty$. Suppose the contrary, that there exist $\eta > 0$ and an infinite sequence k_l such that $\|v^{k_l} - x^{k_l}\| \geq \eta > 0$ $\forall l$. For all $\mu > l$ we have $v^{k_\mu} \notin (\tilde{v}^{k_l}, v^{k_l}]$ because $P_{k_\mu} \subset P_{k_l} \setminus (\tilde{v}^{k_l}, b]$. Since $\tilde{v}_i^k = x_i^k$ $\forall i > s$, we then derive

$$\|v^{k_\mu} - v^{k_l}\| \geq \min_{i=s+1,\dots,n} |v_i^{k_l} - \tilde{v}_i^{k_l}| = \min_{i=s+1,\dots,n} |v_i^{k_l} - x_i^{k_l}|.$$

On the other hand, $\min\{v_i^{k_l} - a_i |\ i = s+1, \ldots, n\} \geq \alpha$ by (21) because $v^{k_l} \in H$, while x^{k_l} lies on the line segment joining a to v^{k_l}; thus

$$v_i^{k_l} - x_i^{k_l} = \frac{v_i^{k_l} - a_i}{\|v^{k_l} - a\|} \|v^{k_l} - x^{k_l}\| \geq \frac{\alpha\eta}{\|b - a\|} \quad \forall i > s.$$

Therefore,

$$\|v^{k_\mu} - v^{k_l}\| \geq \min_{i=s+1,\ldots,n} |v_i^{k_l} - x_i^{k_l}| \geq \frac{\alpha\eta}{\|b - a\|},$$

conflicting with the boundedness of the sequence $\{v^{k_l}\} \subset [a, b]$. Thus, $\|v^k - x^k\| \to 0$ and by boundedness we may assume, by passing to subsequences if necessary, that $x^k \to \bar{x},\ v^k \to \bar{x}$. Then, since $v^k \in H,\ x^k \in G\ \ \forall k$, it follows that $\bar{x} \in G \cap H$ and hence, $\bar{v} \in G \cap H \cap S^*$ for $\bar{v}$ defined by $\bar{v}_i = \tilde{v}_i\ (i = 1, \ldots, s),\ \bar{v}_i = \bar{x}_i\ (i = s+1, \ldots, n)$. Furthermore, $f(v^k) \geq f(v)\ \forall v \in P_k \supset G \cap H \cap S_k$; hence by letting $k \to +\infty$, we have $f(\bar{x}) \geq f(x)\ \forall x \in G \cap H \cap S_{\bar{\gamma}}$, for $\bar{\gamma} = \lim_{k\to\infty} \gamma_k$. The latter in turn implies that $\bar{v} \in \operatorname{argmax}\{f(x) |\ x \in G \cap H \cap S\}$, i.e., $\bar{v}$ is an optimal solution. □

Remark 1. A discrete monotonic *minimization* problem

$$\min\{f(x) |\ g(x) \leq 0 \leq h(x), x \in [a, b] \cap S^*\}$$

can be reduced, by the change of variables $x = b - y$, to the discrete maximization problem

$$\max\{\tilde{f}(y) |\ \tilde{h}(y) \leq 0 \leq \tilde{g}(y), y \in [0, b - a] \cap (b - S^*)\},$$

where $\tilde{f}(y) = -f(b-y),\ \tilde{g}(y) = -g(b-y),\ \tilde{h}(x) = -h(b-y)$ are increasing functions on $[0, b - a]$.

7. Branch-reduce-and-bound algorithm. Algorithm 1 can be interpreted as a branch and bound algorithm in which a node z of the branch and bound tree represents a box $[a, z]$ and branching is performed by splitting a node into n descendants, while the bound over a node z is taken to be $f(z)$. An attractive feature of this algorithm is that, though the bounds are rather rough, the convergence is guaranteed because monotonicity cuts are used in each step to progressively reduce the feasible portion currently of interest. However, since each node has n descendants, the vertex set T_k of the polyblock at iteration k may grow rapidly and reach a prohibitively large size. Furthermore, since this approach requires the problem to be put in the canonical form (MO), some preliminary transformations are necessary which, as we saw in section 3, would introduce a number of additional variables and might increase the dimension of the problem considerably. Therefore, for large scale problems not necessarily in the canonical form we propose an alternative branch and bound version of the algorithm in which each node has only a small number of descendants (typically two descendants).

Consider a discrete d.m. optimization problem in the general form

$$\text{(DDM)}, \qquad \max\{f(x) |\ g(x) - h(x) \leq 0, x \in [a, b] \cap S^*\},$$

where $f(x) = f^+(x) - f^-(x)$ and $f^+, f^-, g, h : \mathbb{R}^n_+ \to \mathbb{R}$ are increasing functions, while S^* is defined by (2); i.e., $S^* = \{x \in \mathbb{R}^n_+ |\ (x_1, \ldots, x_s) \in S\}$ with S being a given discrete subset of $\mathbb{R}^s_+$.

Instead of converting this problem to the canonical form (DMO), we now develop an alternative version of Algorithm 1 for solving it directly.

This alternative algorithm, to be referred to as a *branch-reduce-and-bound algorithm*, is a procedure involving in each iteration three basic operations: branching, reduction, and bounding.

We next describe these operations.

I. *Branching.* Starting from the initial box $M_1 = [a, b]$, we successively bisect it into smaller and smaller boxes using the following subdivision rule:

Let $M = [p, q]$ be a box candidate for subdivision. Compute the numbers $\delta(M) = \max_{i=1,\dots,n}(q_i - p_i) = q_{i_M} - p_{i_M}$, $r_{i_M} = (p_{i_M} + q_{i_M})/2$ and divide M into two boxes

$$M_+ = \{x \in M |\ x_{i_M} \geq (r_{i_M})^{X_i}\},$$
$$M_- = \{x \in M |\ x_{i_M} \leq (r_{i_M})_{X_i}\},$$

where $X_i = \{\xi \in \mathbb{R} |\ \xi = x_i, x \in S\}$ and r^{X_i}, r_{X_i} denote, respectively, the smallest element of $X_i \cup \{q_i\}$ no less than r and the largest element of $X_i \cup \{p_i\}$ no larger than r.

II. *Reduction.* At each iteration we will have a current best value γ of the objective function, together with a set of newly generated boxes that remain for exploration. If $M = [p, q]$ is such a box, to check whether M contains a feasible solution x with $f(x) \geq \gamma$, we use the following lemma.

LEMMA 16. *There exists a feasible solution $x \in [p, q]$ to* (DDM) *satisfying $f(x) \geq \gamma$ only if*

$$h(q) - g(p) \geq 0, \qquad f^+(q) - f^-(p) \geq \gamma, \tag{22}$$

and any such x must be contained in the box $[p', q'] \subset [p, q]$ defined by

$$p' = q - \sum_{i=1}^{n} \alpha_i (q_i - p_i) e^i, \qquad q' = p' + \sum_{i=1}^{n} \beta_i (q_i - p'_i) e^i, \tag{23}$$

where, for $i = 1, \dots, n$,

$$\alpha_i = \sup\{\alpha |\ 0 \leq \alpha \leq 1,\ h(q - \alpha(q_i - p_i)e^i) - g(p) \geq 0,$$
$$f^+(q - \alpha(q_i - p_i)e^i) - \gamma \geq f^-(p)\}, \tag{24}$$
$$\beta_i = \inf\{\beta |\ 0 \leq \beta \leq 1,\ g(p' + \beta(q_i - p'_i)e^i) - h(q) \leq 0,$$
$$f^-(p' + \beta(q_i - p'_i)e^i) \leq f^+(q) - \gamma\}. \tag{25}$$

Proof. Consider any $x \in [p, q]$ satisfying

$$g(x) - h(x) \leq 0, \qquad f(x) = f^+(x) - f^-(x) \geq \gamma. \tag{26}$$

Since $f^+(.), f^-(.), g(.), h(.)$ are increasing, $g(p) \leq g(x) \leq h(x) \leq h(q), f^+(q) \geq f^+(x) \geq f^-(x) + \gamma \geq f^-(p) + \gamma$; hence $h(q) \geq g(p), f^+(q) - \gamma \geq f^-(p)$, so (22) holds.

If $x \not\geq p'$, then there is i such that $x_i < p'_i = q_i - \alpha_i(q_i - p_i)$, i.e., $x_i = q_i - \alpha(q_i - p_i)$ with some $\alpha > \alpha_i$. By virtue of the definition of α_i, this implies that

$$\text{either} \quad h(q - (q_i - x_i)e^i) = h(q - \alpha(q_i - p_i)e^i) < g(p),$$
$$\text{or} \quad f^+(q - (q_i - x_i)e^i) = f^+(q - \alpha(q_i - p_i)e^i) < \gamma + f^-(p).$$

Since $x \le q-(q_i-x_i)e^i$, in the former case $h(x) \le h(q-(q_i-x_i)e^i) < g(p)$, conflicting with $h(x) \ge g(x) \ge g(p)$, while in the second case $f^+(x) \le f^+(q-(q_i-x_i)e^i) < \gamma + f^-(p)$, conflicting with $f^+(x) - \gamma \ge f^-(x) \ge f^-(p)$. Therefore, $x \ge p'$. In a similar way, from $x \in [p', q]$ and (26) we show that $x \le q'$, and thus $x \in [p', q']$. □

We shall denote by $\mathrm{red}^*_\gamma[p, q]$ the box obtained from $[p', q']$ by replacing p', q' with their lower and upper S-adjustments, respectively. It follows from the above that by replacing $[p, q]$ with $\mathrm{red}^*_\gamma[p, q]$ no feasible solution $x \in [p, q]$ with $f(x) \ge \gamma$ is lost.

Remark 2. When there are more than one d.m. constraint $g_j(x) - h_j(x) \le 0,\ j = 1, \dots, m$, the formulas (23)–(24) should be replaced by the following:

$$\alpha_i = \sup\{\alpha |\ 0 < \alpha \le 1,\ h_j(q - \alpha(q_i - p_i)e^i) \ge g_j(p),\ j = 1, \dots, m, \tag{27}$$
$$f^+(q - \alpha(q_i - p_i)e^i) - \gamma \ge f^-(p)\},$$

$$\beta_i = \sup\{\beta |\ 0 < \beta \le 1,\ g_j(p' + \beta(q_i - p'_i)e^i) \le h_j(q),\ j = 1, \dots, m, \tag{28}$$
$$f^-(p' + \beta(q_i - p'_i)e^i) \le f^+(q) - \gamma\}.$$

III. *Bounding.* For every given box $M = [p, q]$ compute a number $\mu(M)$ such that

$$\mu(M) \ge \gamma(M) := \max\{f(x) |\ g(x) - h(x) \le 0, x \in M \cap S^*\}.$$

To ensure convergence, this upper bound must be consistent in the sense that for any infinite nested sequence of boxes $\{M_{k_\nu}\}$ shrinking to a single point x^*,

$$\lim_{\nu \to +\infty} \mu(M_{k_\nu}) = f(x^*). \tag{29}$$

Since $f(x) = f^+(x) - f^-(x)$ with $f^+(x), f^-(x)$ increasing, an obvious bound is $f^+(q_{k_\nu}) - f^-(p_{k_\nu})$, and any bound such that

$$\mu(M_{k_\nu}) \le f^+(q_{k_\nu}) - f^-(p_{k_\nu}) \tag{30}$$

will satisfy (29). Therefore, one can always take $\mu(M) = f^+(q) - f^-(p)$ when a better bound is expensive to compute. In a formal way we can state the following algorithm.

ALGORITHM 2 (branch-reduce-and-bound algorithm for (DDM)).

Initialization. Let $\mathcal{P}_1 := \{M_1\}, M_1 := [a, b], \mathcal{R}_1 := \emptyset$. If some feasible solutions are available, let CBV denote the value of $f(x)$ at the best of them (current best value). Otherwise, set $CBV := -\infty$. Set $k := 1$.

Step 1. Apply S-adjusted reduction to reduce each box $[p, q] \in \mathcal{P}_k$. In particular delete every box $[p, q]$ such that $h(q) - g(p) < 0$. Let $\mathcal{P}'_k := \{\mathrm{red}^*_\gamma[p, q] |\ \ [p, q] \in \mathcal{P}_k\}$ for $\gamma = CBV$.

Step 2. For each box $M \in \mathcal{P}'_k$ compute a bound $\mu(M)$ satisfying (29).

Step 3. Let $\mathcal{S}_k := \mathcal{R}_k \cup \mathcal{P}'_k$. Update CBV, using the new feasible solutions encountered in Steps 1 and 2, if any. Delete every $M \in \mathcal{S}_k$ such that $\mu(M) < CBV$ and let $\mathcal{R}_{k+1}$ be the collection of remaining boxes.

Step 4. If $\mathcal{R}_{k+1} = \emptyset$, then terminate: if $CBV = -\infty$, the problem is infeasible; otherwise, CBV is the optimal value and the feasible solution $\bar{x}$ with $f(\bar{x}) = CBV$ is an optimal solution.

Step 5. If $\mathcal{R}_{k+1} \ne \emptyset$, let $M_k \in \mathrm{argmax}\{\mu(M) |\ M \in \mathcal{R}_{k+1}\}$. Divide M_k into two boxes according to the above described rule. Let $\mathcal{P}_{k+1}$ be the collection of these two subboxes of M_k.

Step 6. Increment k and return to Step 1.

THEOREM 17. *If $s = n$, Algorithm 2 terminates after finitely many iterations, yielding an optimal solution or establishing the infeasibility of the problem. If $s < n$, either Algorithm 2 terminates after finitely many iterations, yielding an optimal solution or establishing the infeasibility of the problem, or it generates an infinite sequence of feasible solutions converging to an optimal solution.*

Proof. If $s = n$, the set S^* is finite. But due to S-adjustment reduction, every box $M = [p, q] \in \mathcal{S}_k$ satisfies $p = \wedge\{x|\ x \in S^* \cap M\},\ q = \vee\{x|\ x \in S^* \cap M\}$. Therefore, the total number of nodes of the branch and bound tree is finite, which implies finiteness of the algorithm itself.

If $s < n$, the subdivision rule implies that the algorithm, whenever infinite, generates a sequence of boxes $\{M_{k_\nu} := [p^{k_\nu}, q^{k_\nu}]\}$ shrinking to a point $x^* = \lim q^{k_\nu} \in S^*$. Since the deletion rule in Step 3 implies, by condition (22) in Lemma 16, that $g(p^{k_\nu}) - h(q^{k_\nu}) \leq 0$, we must have $g(x^*) - h(x^*) \leq 0$; hence $x^* \in \Omega$, the feasible set of (DDM). On the other hand, by the selection rule in Step 5,

$$\mu(M_{k_\nu}) \geq \max\{\mu(M)|\ M \in \mathcal{R}_k\} \geq f(x) \quad \forall x \in \Omega,$$

while by (29), $\mu(M_{k_\nu}) \to f(x^*)$, and hence $f(x^*) \geq f(x)\ \forall x \in \Omega$; i.e., x^* is an optimal solution. If $\hat{x}^k$ is the current best solution at iteration k, then by passing to a subsequence if necessary we may assume $\hat{x}^k \to \hat{x}$ with $f(\hat{x}) = f(x^*)$; i.e., $\hat{x}$ is also an optimal solution. □

Remark 3. The above proof shows that Algorithm 2 converges, even if in Step 2 we always take $\mu(M) = f^+(q) - f^-(p)$ for every box $M = [p, q]$ (so that condition (29) is ensured). Furthermore, in the general case when there are more than one d.m. constraints, the algorithm can be applied without having to convert a system of several d.m. constraints into a single one (and accordingly increase the dimension of the problem). As was mentioned in Remark 2, it suffices in that case to replace, in the reduction operation, the formulas (23)–(24) by (27)–(28). We thus have an extremely simple method for solving any discrete optimization problem of the form (DDM).

Remark 4. The performance of Algorithm 2 critically depends on the reduction operation in Step 1 and also the bounding operation in Step 2. Therefore, although the bound $\mu(M) = f^+(q) - f^-(p)$ (for a box $M = [p, q]$) is sufficient for guaranteeing convergence, tighter bounds are often necessary to achieve reasonable efficiency.

For example, if a polytope D containing the feasible portion in $M = [p, q]$ can be found together with a linear overestimator $L(x)$ of $f(x)$ such that $L(x^M) = f(x^M)$ at a point $x^M \in M = [p, q]$, then an upper bound satisfying (29) is provided by the optimal value of the linear program

$$\max\{L(x)|\ x \in D \cap M\}.$$

In any case, if the problem has the form (DMO), then tighter bounds than $f(q)$ can be computed by either of the following methods based on polyblock approximation.

Method 1: Apply a truncated version of Algorithm 1 (i.e., perform a given number of k iterations of this algorithm) to problem $\max\{f(x)|\ x \in G \cap H \cap [p, q]\}$ (usually $k = 1$ or $k = 2$). If T_k is the vertex set of the last polyblock obtained, then let $\mu(M) = \max\{f(z)|\ z \in T_k\}$.

Method 2: Consider a grid $U = \{c^0, c^1, \ldots, c^n\} \subset \{x \in R^n_+|\ \sum_{i=1}^n x_i = 1\}$, for example, $U = \{c^0, c^1, \ldots, c^k\}$ with

$$c^0 = e/n, \quad c^k = \frac{(n+1)e - ne^k}{n^2}, \quad k = 1, \ldots, n.$$

For each $k = 0, 1, \ldots, n$, let $x^k = \pi(c^k) := p + \lambda_k c^k$, with $\lambda_k = \sup\{\alpha |\ p + \alpha c^k \in G\}$. Next construct a set T as follows:

Step 0. Let $T = \{u^1, \ldots, u^n\}$ with $u^i = q + (x_i^0 - q_i)e^i, i = 1, \ldots, n$. Set $k = 1$.

Step k. Compute $x^k = \pi(c^k)$, let $T_* = \{z \in T |\ z > x^k\}$, and compute

$$T' = (T \setminus T_*) \bigcup \{z^i = z + (x_i^k - z_i)e^i |\ z \in T_*, i \in \{1, \ldots, n\}\}$$

and from T' remove all z^i for which there exists $y \in T_*^+ := \{z \in T |\ z \geq x^k\}$ such that $\{j |\ z_j > y_j\} = \{i\}$. Reset T equal to the set of remaining elements of T'. If $k < n$, let $k \leftarrow k + 1$ and go back to Step k. If $k = n$, stop.

If T is the last set obtained by the above procedure then let $\mu(M) = \max\{f(z) |\ z \in T \cap H\}$.

8. Application: A discrete location problem. As an application, let us consider the following discrete location problem:

(DL) *Given m balls in $\mathbb{R}^n$ of centers $a^i \in R_{++}^n$ and radii $\alpha_i (i = 1, \ldots, m)$, and a bounded discrete set $S \subset \mathbb{R}_+^n$, find the largest ball that has center in S and is disjoint from any of these m balls.* In other words,

$$\begin{array}{l} \text{maximize } z \quad \text{subject to} \\ \|x - a^i\| - \alpha_i \geq z, \quad i = 1, \ldots, m, \\ x \in S \subset R_+^n,\ z \in \mathbb{R}_+. \end{array} \tag{31}$$

This problem is encountered in various applications. For example, in location theory (see, e.g., [4], [1]), it can be interpreted as a "maximin location problem": $a^i,\ i = 1, \ldots, m$, are the locations of m obnoxious facilities, and $\alpha_i > 0$ is the radius of the polluted region of facility i, while an optimal solution is a location $x \in S$ outside all polluted regions and as far as possible from the nearest of these obnoxious facilities. In engineering design (DL) appears as a variant of the "design centering problem" [16], [8], an important special case of which, when $\alpha_i = 0, i = 1, \ldots, m$, is the "largest empty ball problem" [6]: given m points $a^1, \ldots, a^m$ in $\mathbb{R}_{++}^n$ and a bounded set S, find the largest ball that has center in $S \subset \mathbb{R}_+^n$ and contains none of these points.

As a first step toward solving (DL) one can study the following feasibility problem:

(Q(r)) Given a number $r \geq 0$, find a point $x(r) \in S$ lying outside any one of the m balls of centers a^i and radii $\theta_i = \alpha_i + r$.

It has been shown in [14] that this problem can be reduced to

$$\max\{\|x\|^2 - h(x) |\ x \in S\},$$

where $h(x) = \max_{i=1,\ldots,m}(2\langle a^i, x\rangle + \theta_i^2 - \|a^i\|^2)$. Since both $\|x\|^2$ and $h(x)$ are obviously increasing functions, this is a discrete d.m. optimization problem that can be solved by the above presented method.

Clearly if $\bar{r}$ is the maximal value of r such that (Q(r)) is feasible, then $\bar{x} = x(\bar{r})$ will solve (DL). Noting that $\bar{r} \geq 0$ and for any $r > 0$ one has $\bar{r} \geq r$ or $\bar{r} < r$ according to whether (Q(r)) is feasible or not, the value $\bar{r}$ can be found by a Bolzano binary search scheme: starting from an interval $[0, s]$ containing $\bar{r}$, one reduces it by a half at each step by solving a (Q(r)) with a suitable r. Quite encouraging computational results with this scheme have been reported in [14], where each subproblem (Q(r)) was solved by a preliminary version of Algorithm 2 described in [3]. However, it turns out that more complete and much better results can be obtained by a direct application of Algorithm 2 to problem (31). Next we describe this method.

Observe that

$$\begin{aligned} &\|x-a^i\|-\alpha_i \geq z, \quad i=1,\dots,m,\\ \Leftrightarrow\ &\|x\|^2+\|a^i\|^2-2\langle a^i,x\rangle \geq (z+\alpha_i)^2, \quad i=1,\dots,m,\\ \Leftrightarrow\ &\max_{i=1,\dots,m}\{(z+\alpha_i)^2+2\langle a^i,x\rangle-\|a^i\|^2\} \leq \|x\|^2. \end{aligned}$$

Therefore, by setting

$$\varphi(x,z)=\max_{i=1,\dots,m}((z+\alpha_i)^2+2\langle a^i,x\rangle-\|a^i\|^2), \tag{32}$$

problem (31) can be restated as

$$\max\{z|\ \varphi(x,z)-\|x\|^2\leq 0,\ x\in[a,b]\cap S,\ z\geq 0\}, \tag{33}$$

where $\varphi(x,z)$ and $\|x\|^2$ are increasing functions and $[a,b]$ is a box containing S.

To apply Algorithm 2 for solving this problem, observe that the value of z is determined when x is fixed. Therefore, branching should be performed upon the variables x only, using the subdivision rule described in section 6.

Another key operation in Algorithm 2 is bounding: given a box $[p,q]\subset[a,b]$, compute an upper bound $\mu(M)$ for the optimal value of the subproblem

$$\max\{z|\ \varphi(x,z)-\|x\|^2\leq 0,\ x\in S\cap[p,q],\ 0\leq z\}. \tag{34}$$

If $CBV=r>0$ is the largest thus far known value of z at a feasible solution (x,z), then only feasible points (x,z) with $z>r$ are still of interest. Therefore, to obtain a tighter value of $\mu(M)$ one should consider, instead of (34), the problem

$$\max\{z|\ \varphi(x,z)-\|x\|^2\leq 0,\ x\in S\cap[p,q],\ z\geq r\}. \tag{DL(M,r)}$$

Because $\varphi(x,z)$ and $\|x\|^2$ are both increasing, the constraints of (DL(M,r)) can be relaxed to $\varphi(p,z)-\|q\|^2$, so an obvious upper bound is

$$c(p,q):=\max\{z|\ \varphi(p,z)-\|q\|^2\leq 0\}. \tag{35}$$

Although this bound is easy to compute (it is the zero of the increasing function $z\mapsto\varphi(p,z)-\|q\|^2$), it is often not sufficiently efficient. A better bound can be computed by solving a linear relaxation of (DL(M,r)) obtained by omitting the discrete constraint $x\in S$ and replacing $\varphi(x,z)$ with a linear underestimator. Since

$$(z+\alpha_i)^2\geq(r+\alpha_i)^2+2(r+\alpha_i)(z-r),$$

a linear underestimator of $\varphi(x,z)$ is

$$\psi(x,z):=\max_{i=1,\dots,n}\{2(r+\alpha_i)(z-r)+(r+\alpha_i)^2+2\langle a^i,x\rangle-\|a^i\|^2\}.$$

On the other hand,

$$\|x\|^2\leq\sum_{j=1}^{n}[(p_j+q_j)x_j-p_jq_j]\quad\forall x\in[p,q],$$

so by (32) the constraint $\varphi(x,z)-\|x\|^2\leq 0$ can be relaxed to

$$\psi(x,z)-\sum_{j=1}^{n}[(p_j+q_j)x_j-p_jq_j]\leq 0,$$

which is equivalent to the system of linear constraints

$$\max_{i=1,\dots,m}\{2(r+\alpha_i)(z-r)+(r+\alpha_i)^2+2\langle a^i,x\rangle-\|a^i\|^2\}\le\sum_{j=1}^{n}[(p_j+q_j)x_j-p_jq_j].$$

Therefore,

$$\text{(LP}(M,r)\text{)}\qquad \begin{aligned}\mu(M)=\max\Big\{z|\ & 2(r+\alpha_i)(z-r)+(r+\alpha_i)^2+2\langle a^i,x\rangle-\|a^i\|^2\\ & -\sum_{j=1}^{n}[(p_j+q_j)x_j-p_jq_j]\le 0,\ i=1,\dots,m,\\ & z\ge r,\ p\le x\le q\Big\}.\end{aligned}$$

The bounds can be further improved by using valid reduction operations. For this, observe that, since $\varphi(x,r)\le\varphi(x,z)$ for $r\le z$, the feasible set of (DL(M,r)) is contained in the set

$$\{x|\ \varphi(x,r)-\|x\|^2\le 0,\ x\in[p,q]\},$$

so, according to Lemma 16, if p',q' are defined by (23)–(25) with

$$g(x)=\varphi(x,r),\quad h(x)=\|x\|^2,$$

and $\tilde p=\lceil p'\rceil_{S^*},\tilde q=\lfloor q'\rfloor_{S^*}$, then the box $[\tilde p,\tilde q]\subset[p,q]$ is a valid reduction of $[p,q]$.

Thus, Algorithm 2 specialized to problem (DL) becomes the following algorithm.

Algorithm 3 (branch-reduce-and-bound algorithm for (DL)).

Initialization. Let $\mathcal{P}_1:=\{M_1\},M_1:=[a,b],\mathcal{R}_1:=\emptyset$. If some feasible solution $(\bar x,\bar z)$ is available, let $r:=\bar z$ be CBV, the current best value. Otherwise, let $r:=0$. Set $k:=1$.

Step 1. Apply S-adjusted reduction cuts to reduce each box $M:=[p,q]\in\mathcal{P}_k$. In particular delete any box $[p,q]$ such that $\varphi(p,r)-\|q\|^2\ge 0$. Let $\mathcal{P}'_k$ be the resulting collection of reduced boxes.

Step 2. For each $M:=[p,q]\in\mathcal{P}'_k$ compute $\mu(M)$ by solving LP(M,r). If LP(M,r) is infeasible or $\mu(M)=r$, then delete M. Let $\mathcal{P}^*_k:=\{M\in\mathcal{P}'_k|\ \mu(M)>r\}$. For every $M\in\mathcal{P}^*_k$ if a basic optimal solution of LP(M,r) can be S-adjusted to derive a feasible solution (x^M,z^M) with $z^M>r$, then use it to update CBV.

Step 3. Let $\mathcal{S}_k:=\mathcal{R}_k\cup\mathcal{P}^*_k$. Reset $r:=CBV$. Delete every $M\in\mathcal{S}_k$ such that $\mu(M)<r$ and let $\mathcal{R}_{k+1}$ be the collection of remaining boxes.

Step 4. If $\mathcal{R}_{k+1}=\emptyset$, then terminate: if $r=0$, the problem is infeasible; otherwise, r is the optimal value and the feasible solution $(\bar x,\bar z)$ with $\bar z=r$ is an optimal solution.

Step 5. If $\mathcal{R}_{k+1}\ne\emptyset$, let $M_k\in\operatorname{argmax}\{\mu(M)|\ M\in\mathcal{R}_{k+1}\}$. Divide M_k into two boxes according to the rule described in section 6. Let $\mathcal{P}_{k+1}$ be the collection of these two subboxes of M_k.

Step 6. Increment k and return to Step 1.

Theorem 18. *Algorithm* 3 *solves the problem* (DL) *in finitely many iterations.*

Proof. Although the variable z is not explicitly required to take on discrete values, this is actually a discrete variable, since the constraint (31) amounts to requiring that $z=\min_{i=1,\dots,m}(\|x-a^i\|-\alpha_i)$ for $x\in S$. The finiteness of Algorithm 3 then follows from Theorem 17. □

Algorithm 3 was coded in C++ and tested on a number of problem instances of dimension ranging from 10 to 100 (10 problems for each instance of n). Points a^j were randomly generated in the square $1000 \leq x_i \leq 90000,\ i = 1, \ldots, n$, while S was taken to be the lattice of points with integral coordinates. The program was run on a PC Pentium IV (2.53GHz with 256Mb of DDR RAM), with linear subproblems solved by the LP software CPLEX 8.0.

The computational results (with relative error ≤ 0.01 for the optimal value) are summarized in Table 1 with the following notation:

n: dimension,

m: number of given points a^j,

It: average number of iterations,

Time: average running time in seconds,

max$N$: average maximal number of active nodes of the branch and bound tree.

These results suggest that the method is quite practical for this class of discrete optimization problems. The computational cost increases much more rapidly with n (dimension of space or number of variables) than with m (number of balls). Also, when compared with the results preliminarily reported in [14], they show that the performance of the method can be drastically improved by using a more suitable monotonic reformulation. To give a more precise idea of the improvement, Table 2 reports the computational results obtained in the two versions of the method on the 50 first problems tested (the columns A, B refer to performances of the version used in [14] and the present version, respectively).

Finally, we note that, although variants of the problem (DL) have been known for years, the literature on numerical results for this problem appear to be very poor. To the best of our knowledge, prior to the paper [14], the problem was studied only for n and/or m very small (see, e.g., [16], [8], where, however, ellipsoids rather than balls were considered). A d.c. optimization method proposed in [6] for the largest empty ball problem has never been implemented. It seems that [14] was the first numerical study for the problem (DL) with fairly large values of n and m.

Acknowledgment. The authors are grateful to the referees for several helpful comments and suggestions.

ON THE SOLUTION OF THE TIKHONOV REGULARIZATION OF THE TOTAL LEAST SQUARES PROBLEM*

AMIR BECK† AND AHARON BEN-TAL†

Abstract. *Total least squares* (TLS) is a method for treating an overdetermined system of linear equations $\mathbf{Ax} \approx \mathbf{b}$, where both the matrix $\mathbf{A}$ and the vector $\mathbf{b}$ are contaminated by noise. *Tikhonov regularization* of the TLS (TRTLS) leads to an optimization problem of minimizing the sum of fractional quadratic and quadratic functions. As such, the problem is nonconvex. We show how to reduce the problem to a single variable minimization of a function $\mathcal{G}$ over a closed interval. Computing a value and a derivative of $\mathcal{G}$ consists of solving a single trust region subproblem. For the special case of regularization with a squared Euclidean norm we show that $\mathcal{G}$ is unimodal and provide an alternative algorithm, which requires only one spectral decomposition. A numerical example is given to illustrate the effectiveness of our method.

Key words. total least squares, Tikhonov regularization, fractional programming, nonconvex optimization, trust region subproblem

1. Introduction.

Many problems in data fitting and estimation give rise to an overdetermined system of linear equations $\mathbf{Ax} \approx \mathbf{b}$, where both the matrix $\mathbf{A} \in \mathbb{R}^{m\times n}$ and the vector $\mathbf{b} \in \mathbb{R}^m$ are contaminated by noise. The total least squares (TLS) approach to this problem [11, 12, 19] is to seek a perturbation matrix $\mathbf{E} \in \mathbb{R}^{m\times n}$ and a perturbation vector $\mathbf{r} \in \mathbb{R}^m$ that minimize $\|\mathbf{E}\|^2 + \|\mathbf{r}\|^2$ subject to the consistency equation $(\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{r}$ (here and elsewhere in this paper a matrix norm is always the Frobenius norm and a vector norm is the Euclidean one). The TLS approach was extensively used in a variety of scientific disciplines such as signal processing, automatic control, statistics, physics, economic, biology, and medicine (see, e.g., [19] and the references therein). The TLS problem has essentially an explicit solution, expressed by the singular value decomposition of the augmented matrix $(\mathbf{A}, \mathbf{b})$ (see, e.g., [11, 19]).

In practical situations, the original (noise-free) linear system is often ill-conditioned. For example, this happens when the system is obtained via discretization of ill-posed problems such as integral equations of the first kind (see, e.g., [10] and the references therein). In these cases the least squares (LS) solution as well as the TLS solution can be physically meaningless, and thus regularization is essential for stabilizing the solution.

There are two well-established approaches (among many others) to stabilize the LS solution: (i) *Tikhonov regularization*, where a quadratic penalty is appended to the LS objective function [4, 33], and (ii) *regularized least squares* (abbreviated RLS and LSQI), where a quadratic constraint bounding the size of the solution is added [4, 8].

The research of the first author was partially supported by ISF grant 729/04. The research of the second author was partially supported by BSF grant 2002038.

For the TLS problem the situation is different. Stabilization by introducing a quadratic constraint was extensively studied [1, 10, 14, 28, 24]. On the other hand, Tikhonov regularization of the TLS (TRTLS) problem has not yet been considered.

In this paper we adopt the Tikhonov regularization concept to stabilize the TLS solution; i.e., we consider the problem

$$\text{(TRTLS)} \quad \min_{\mathbf{E},\mathbf{r},\mathbf{x}} \left\{ \|\mathbf{E}\|^2 + \|\mathbf{r}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 : (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{r} \right\}, \tag{1}$$

where $\mathbf{L} \in \mathbb{R}^{k\times n}, k \le n$, is a full row rank matrix and $\rho > 0$ is a penalty parameter. $\mathbf{L}$ is a matrix that defines a (semi)norm on the solution through which its "size" is measured. A common example where $\mathbf{L}$ is not square is when $\mathbf{L}$ is an approximation matrix of the first or second order derivative [10, 16, 18].

The main difficulty associated with problem (TRTLS) is its nonconvexity. Nevertheless, we show in this paper that the problem can be solved efficiently to global optimality. First, in section 2 we reduce problem (TRTLS) to one involving only the $\mathbf{x}$ variables:

$$\min_{\mathbf{x}\in\mathbb{R}^n} \left\{ \frac{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2}{\|\mathbf{x}\|^2+1} + \rho\|\mathbf{L}\mathbf{x}\|^2 \right\}. \tag{2}$$

In section 3 we derive an extremely mild condition for the attainability of an optimal solution to (2). An algorithm for solving problem (TRTLS) is then described in section 4. The algorithm consists of minimizing a single variable continuous (and differentiable under a mild condition) function $\mathcal{G}(\alpha)$ on a closed interval. Computing $\mathcal{G}(\alpha)$ and its derivative involves the solution of a single trust region subproblem. The interesting special case, where the matrix $\mathbf{L}$ in problem (TRTLS) is the identity matrix, is studied in section 5, where we prove that in this case $\mathcal{G}$ is unimodal and provide an alternative algorithm for solving the TRTLS problem requiring a single spectral decomposition. Finally, we provide in section 6 a detailed algorithm for the solution of the TRTLS problem (with a general regularization matrix) and demonstrate our method through an image deblurring example.

2. Simplified formulation of the TRTLS problem. In order to simplify problem (1), we use a derivation similar to the one used in [1].[1] Problem (TRTLS) can be written as a double minimization problem:

$$\min_{\mathbf{x}} \min_{\mathbf{E},\mathbf{r}} \left\{ \|\mathbf{E}\|^2 + \|\mathbf{r}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 : (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{r} \right\}. \tag{3}$$

Consider the inner minimization problem

$$\min_{\mathbf{E},\mathbf{r}} \left\{ \|\mathbf{E}\|^2 + \|\mathbf{r}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 : (\mathbf{A}+\mathbf{E})\mathbf{x} = \mathbf{b}+\mathbf{r} \right\}. \tag{4}$$

The Lagrangian of problem (4) is given by

$$\mathcal{L}(\mathbf{E},\mathbf{r},\boldsymbol{\lambda}) = \|\mathbf{E}\|^2 + \|\mathbf{r}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2 + 2\boldsymbol{\lambda}^T((\mathbf{A}+\mathbf{E})\mathbf{x} - \mathbf{b} - \mathbf{r}).$$

Note that problem (4) is a linearly constrained convex problem with respect to the variables $\mathbf{E}$ and $\mathbf{r}$. Thus, the KKT conditions are necessary and sufficient [3, Proposition 3.4.1], and we conclude that $(\mathbf{E},\mathbf{r})$ is an optimal solution of (4) if and only if

[1] We thank Marc Teboulle for his contribution to this derivation.

there exists $\boldsymbol{\lambda} \in \mathbb{R}^m$ such that

$$2\mathbf{E} + 2\boldsymbol{\lambda}\mathbf{x}^T = \mathbf{0} \quad (\nabla_{\mathbf{E}}\mathcal{L} = 0), \tag{5}$$

$$2\mathbf{r} - 2\boldsymbol{\lambda} = \mathbf{0} \qquad (\nabla_{\mathbf{r}}\mathcal{L} = 0), \tag{6}$$

$$(\mathbf{A} + \mathbf{E})\mathbf{x} = \mathbf{b} + \mathbf{r} \quad \text{(feasibility)}. \tag{7}$$

From (6) we have $\boldsymbol{\lambda} = \mathbf{r}$. Substituting this into (5) we have

$$\mathbf{E} = -\mathbf{r}\mathbf{x}^T. \tag{8}$$

Combining (8) with (7) we obtain $(\mathbf{A} - \mathbf{r}\mathbf{x}^T)\mathbf{x} = \mathbf{b} + \mathbf{r}$, so

$$\mathbf{r} = \frac{\mathbf{A}\mathbf{x} - \mathbf{b}}{\|\mathbf{x}\|^2 + 1} \tag{9}$$

and consequently

$$\mathbf{E} = -\frac{(\mathbf{A}\mathbf{x} - \mathbf{b})\mathbf{x}^T}{\|\mathbf{x}\|^2 + 1}. \tag{10}$$

Finally, by substituting (9) and (10) into the objective function of problem (4) we obtain that the value of problem (4) is equal to $\frac{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2}{\|\mathbf{x}\|^2+1} + \rho\|\mathbf{L}\mathbf{x}\|^2$. Consequently, the TRTLS problem (1) reduces to

$$f^* = \min_{\mathbf{x}\in\mathbb{R}^n} \left\{ \mathcal{H}(\mathbf{x}) \equiv \frac{\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2}{\|\mathbf{x}\|^2 + 1} + \rho\|\mathbf{L}\mathbf{x}\|^2 \right\}. \tag{11}$$

For a given optimal solution $\mathbf{x}$ to the simplified TRTLS problem (11), the optimal pair $(\mathbf{E}, \mathbf{r})$ to the original TRTLS problem is given by (9) and (10).

3. Attainability of the minimum. In this section, we find a sufficient condition for the attainability of the minimum in (11). First, notice that if $k = n$, then $\mathbf{L}$ has full rank and as a result the objective function is a coercive function[2] and the minimum is attained (see [3]). On the other hand, if $k < n$, then the minimum in (11) might not be attained. This is illustrated by the following example.

Example. Consider problem (11) with data

$$m = 3, \quad n = 2, \quad \mathbf{A} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{pmatrix}, \ \mathbf{b} = \begin{pmatrix} 4 \\ 0 \\ 0 \end{pmatrix}, \ \mathbf{L} = \begin{pmatrix} 1 & 0 \end{pmatrix}, \ \rho = 1.$$

The TRTLS problem (11) in this case is

$$\min_{x_1,x_2} \left\{ \underbrace{\frac{(x_1-4)^2 + x_2^2}{1 + x_1^2 + x_2^2} + x_1^2}_{\mathcal{H}(x_1,x_2)} \right\}. \tag{12}$$

To show the nonattainment of the minimum, suppose on the contrary that the minimum is attained at a point (x_1^*, x_2^*). Notice that

$$(x_1^*)^2 \le \mathcal{H}(x_1^*, x_2^*) \le \mathcal{H}(0, x_2) \quad \forall x_2 \in \mathbb{R}.$$

[2] A real valued function $f : \mathbb{R}^n \to \mathbb{R}$ is coercive if $\lim_{\|\mathbf{x}\|\to\infty} f(\mathbf{x}) = \infty$.

Since $\mathcal{H}(0,x_2)=\frac{16+x_2^2}{1+x_2^2}\overset{x_2\to\infty}{\longrightarrow}1$ we conclude that $|x_1^*|\le 1$, which implies the inequality $(x_1^*-4)^2>1+(x_1^*)^2$. Therefore, the function $\varphi(y)=\mathcal{H}(x_1^*,y)=\frac{(x_1^*-4)^2+y^2}{1+(x_1^*)^2+y^2}+(x_1^*)^2$ is strictly decreasing and as a result we have, for example, $\mathcal{H}(x_1^*,x_2^*+1)<\mathcal{H}(x_1^*,x_2^*)$, which is a contradiction to the assumption that the minimum is attained at (x_1^*,x_2^*). We therefore conclude that the minimum (12) is not attained. ∎

Theorem 3.1 introduces a sufficient condition for the attainability of the minimum of the TRTLS problem (11).

THEOREM 3.1. *Consider problem* (11) *with* $\mathbf{A}\in\mathbb{R}^{m\times n},\mathbf{b}\in\mathbb{R}^m$, *and* $\mathbf{L}\in\mathbb{R}^{k\times n},n>k$. *Let* $\mathbf{F}\in\mathbb{R}^{n\times k}$ *be a matrix whose columns form an orthogonal basis for the null space of* $\mathbf{L}$. *If the following condition is satisfied,*

$$\lambda_{min}\begin{pmatrix}\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F} & \mathbf{F}^T\mathbf{A}^T\mathbf{b}\\ \mathbf{b}^T\mathbf{A}\mathbf{F} & \|\mathbf{b}\|^2\end{pmatrix}<\lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}), \tag{13}$$

then

(i)

$$f^*\le\lambda_{min}\begin{pmatrix}\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F} & \mathbf{F}^T\mathbf{A}^T\mathbf{b}\\ \mathbf{b}^T\mathbf{A}\mathbf{F} & \|\mathbf{b}\|^2\end{pmatrix}; \tag{14}$$

(ii) *the minimum of* (11) *is attained.*

Proof. (i) Let $\mathbf{d}\in\mathbb{R}^{p+1}$ be an eigenvector corresponding to the minimum eigenvalue of the matrix

$$\mathbf{H}=\begin{pmatrix}\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F} & \mathbf{F}^T\mathbf{A}^T\mathbf{b}\\ \mathbf{b}^T\mathbf{A}\mathbf{F} & \|\mathbf{b}\|^2\end{pmatrix}.$$

Then

$$\frac{\mathbf{d}^T\mathbf{H}\mathbf{d}}{\|\mathbf{d}\|^2}=\lambda_{min}(\mathbf{H}). \tag{15}$$

d_{p+1} must be different from zero since otherwise we would have

$$\lambda_{min}(\mathbf{H})\overset{\mathbf{d}=(\tilde{\mathbf{d}}^T,0)^T}{=}\frac{\mathbf{d}^T\mathbf{H}\mathbf{d}}{\|\mathbf{d}\|^2}=\frac{\tilde{\mathbf{d}}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\tilde{\mathbf{d}}}{\|\tilde{\mathbf{d}}\|^2}\ge\lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}),$$

which is in contradiction to (13). Therefore, $d_{p+1}\neq 0$. Let $\mathbf{y}\in\mathbb{R}^p$ be such that $\frac{\mathbf{d}}{-d_{p+1}}=(\mathbf{y}^T,-1)^T$. Then

$$\begin{aligned}\lambda_{min}(\mathbf{H})&\overset{(15)}{=}\frac{\mathbf{d}^T\mathbf{H}\mathbf{d}}{\|\mathbf{d}\|^2}=\frac{\left(\frac{\mathbf{d}}{d_{n+1}}\right)^T\mathbf{H}\left(\frac{\mathbf{d}}{d_{n+1}}\right)}{\left\|\left(\frac{\mathbf{d}}{d_{n+1}}\right)\right\|^2}\\ &=\frac{\begin{pmatrix}\mathbf{y}^T & -1\end{pmatrix}\mathbf{H}\begin{pmatrix}\mathbf{y}\\ -1\end{pmatrix}}{\left\|\begin{pmatrix}\mathbf{y}^T & -1\end{pmatrix}\right\|^2}=\frac{\mathbf{y}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{y}-2\mathbf{y}^T\mathbf{F}^T\mathbf{A}^T\mathbf{b}+\|\mathbf{b}\|^2}{\|\mathbf{y}\|^2+1}\\ &\overset{\mathbf{F}^T\mathbf{F}=\mathbf{I},\mathbf{L}\mathbf{F}=0}{=}\frac{\mathbf{y}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{y}-2\mathbf{y}^T\mathbf{F}^T\mathbf{A}^T\mathbf{b}+\|\mathbf{b}\|^2}{\mathbf{y}^T\mathbf{F}^T\mathbf{F}\mathbf{y}+1}+\rho\|\mathbf{L}\mathbf{F}\mathbf{y}\|^2\\ &=\mathcal{H}(\mathbf{F}\mathbf{y})\ge f^*,\end{aligned}$$

thus proving (i). To prove (ii), suppose on the contrary that the minimum value of (11), f^*, is not attained, which implies that there exists a sequence $\mathbf{x}_k, k \geq 1$, such that

$$\|\mathbf{x}_k\| \to \infty, \quad \underbrace{q(\mathbf{x}_k) + h(\mathbf{x}_k)}_{\mathcal{H}(\mathbf{x}_k)} \to f^*, \tag{16}$$

where $q(\mathbf{x}_k) \equiv \frac{\|\mathbf{A}\mathbf{x}_k - \mathbf{b}\|^2}{\|\mathbf{x}_k\|^2+1}$ and $h(\mathbf{x}_k) \equiv \rho\|\mathbf{L}\mathbf{x}_k\|^2$. Since both the sequences $q(\mathbf{x}_k)$ and $\frac{\mathbf{x}_k}{\|\mathbf{x}_k\|}$ are bounded, there exists a subsequence $\mathbf{x}_{n_k}$ for which the subsequences $q(\mathbf{x}_{n_k})$ and $\frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|}$ converge to a finite value. That is, there exist η and $\mathbf{d}$ such that

$$q(\mathbf{x}_{n_k}) \to \eta, \quad \frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|} \to \mathbf{d}.$$

Now, from (16) it follows that

$$\frac{q(\mathbf{x}_{n_k}) + h(\mathbf{x}_{n_k})}{\|\mathbf{x}_{n_k}\|^2} \to 0$$

and since $q(\mathbf{x}_{n_k})$ is bounded we have that $\frac{h(\mathbf{x}_{n_k})}{\|\mathbf{x}_{n_k}\|^2} \to 0$. But, on the other hand, $\frac{h(\mathbf{x}_{n_k})}{\|\mathbf{x}_{n_k}\|^2} \to \rho\|\mathbf{L}\mathbf{d}\|^2$ and as a result we have that $\|\mathbf{L}\mathbf{d}\|^2 = 0$, which is equivalent to $\mathbf{d} \in \text{Null}(\mathbf{L})$. To summarize, we have found a subsequence $\mathbf{x}_{n_k}$ for which $q(\mathbf{x}_{n_k})$ converges and $\frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|} \to \mathbf{d}$, where $\mathbf{d} \in \text{Null}(\mathbf{L})$ and $\|\mathbf{d}\| = 1$. Now,

$$\begin{aligned}
f^* &= \lim_{k\to\infty} \{q(\mathbf{x}_{n_k}) + h(\mathbf{x}_{n_k})\} \\
&\overset{h(\cdot)\geq 0}{\geq} \lim_{k\to\infty} q(\mathbf{x}_{n_k}) = \lim_{k\to\infty} \frac{\|\mathbf{A}\mathbf{x}_{n_k} - \mathbf{b}\|^2}{\|\mathbf{x}_{n_k}\|^2 + 1} \\
&= \lim_{k\to\infty} \frac{\mathbf{x}_{n_k}^T\mathbf{A}^T\mathbf{A}\mathbf{x}_{n_k} - 2\mathbf{b}^T\mathbf{A}\mathbf{x}_{n_k} + \|\mathbf{b}\|^2}{\|\mathbf{x}_{n_k}\|^2 + 1} \\
&= \lim_{k\to\infty} \frac{\left(\frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|}\right)^T \mathbf{A}^T\mathbf{A}\left(\frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|}\right) - 2\frac{1}{\|\mathbf{x}_{n_k}\|}\mathbf{b}^T\mathbf{A}\left(\frac{\mathbf{x}_{n_k}}{\|\mathbf{x}_{n_k}\|}\right) + \frac{\|\mathbf{b}\|^2}{\|\mathbf{x}_{n_k}\|^2}}{1 + \frac{1}{\|\mathbf{x}_{n_k}\|^2}} \\
&= \mathbf{d}^T\mathbf{A}^T\mathbf{A}\mathbf{d}.
\end{aligned}$$

Since $\mathbf{d} \in \text{Null}(\mathbf{L})$ we can write $\mathbf{d} = \mathbf{F}\mathbf{v}$, and therefore we obtain the following lower bound on f^*:

$$f^* \geq \min_{\mathbf{v}^T\mathbf{F}^T\mathbf{F}\mathbf{v}=1} \mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{v} \overset{\mathbf{F}^T\mathbf{F}=\mathbf{I}}{=} \min_{\|\mathbf{v}\|^2=1} \mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{v} = \lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}).$$

On the other hand, by condition (13), $\lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}^T) > \lambda_{min}(\mathbf{H})$, and therefore we have that

$$f^* > \lambda_{\min}(\mathbf{H}),$$

which is a contradiction to part (i). □

Remarks.

1. Weak inequality is always satisfied in (13): the matrix in the right-hand side of (13) is a principal submatrix of the one in the left-hand side. Hence, by the interlacing theorem of eigenvalues [34, Theorem 7.8], weak inequality holds.
2. Condition (13) is invariant to the specific choice of the orthogonal basis of the null space of $\mathbf{L}$.
3. For $\mathbf{L} = \mathbf{0}$ problem (11) reduces to the classical TLS problem. In this case we can take $\mathbf{F} = \mathbf{I}$ in condition (13), which then reduces to the well-known condition [11, 19] for the attainability of the minimum in the TLS problem:

$$\lambda_{min}\begin{pmatrix} \mathbf{A}^T\mathbf{A} & \mathbf{A}^T\mathbf{b} \\ \mathbf{b}^T\mathbf{A} & \|\mathbf{b}\|^2 \end{pmatrix} < \lambda_{min}\left(\mathbf{A}^T\mathbf{A}\right). \tag{17}$$

   Incidentally, for the nonregularized version of problem (12), i.e.,

$$\min_{x_1,x_2}\left\{\frac{(x_1-4)^2+x_2^2}{1+x_1^2+x_2^2}\right\}, \tag{18}$$

   condition (17) does hold since

$$\lambda_{min}\begin{pmatrix} \mathbf{A}^T\mathbf{A} & \mathbf{A}^T\mathbf{b} \\ \mathbf{b}^T\mathbf{A} & \|\mathbf{b}\|^2 \end{pmatrix} = 0 < 1 = \lambda_{min}\left(\mathbf{A}^T\mathbf{A}\right)$$

   and indeed (18) attains an optimal solution $x_1^* = 4, x_2^* = 0$.
4. The TRTLS problem (12), for which nonattainability of the minimum was established, indeed does not satisfy condition (13). $\mathbf{F}$ can be chosen to be $\binom{0}{1}$, and we have

$$\lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}) = 1$$

   and

$$\lambda_{min}\begin{pmatrix} \mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F} & \mathbf{F}^T\mathbf{A}^T\mathbf{b} \\ \mathbf{b}^T\mathbf{A}\mathbf{F} & \|\mathbf{b}\|^2 \end{pmatrix} = \lambda_{min}\begin{pmatrix} 1 & 0 \\ 0 & 4 \end{pmatrix} = 1.$$

4. Solving the TRTLS problem with general L. In this section we consider the TRTLS problem (11) with a full row rank $k \times n$ regularization matrix $\mathbf{L}$. We will assume that condition (13) is satisfied, and therefore the minimum is attained.

Problem (11) can be formulated as a double minimization problem in the following way:

$$\min_{\alpha\geq 1}\min_{\|\mathbf{x}\|^2=\alpha-1}\left\{\frac{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2}{\alpha}+\rho\|\mathbf{L}\mathbf{x}\|^2\right\},$$

which can be written as

$$\min_{\alpha\geq 1}\{\mathcal{G}(\alpha)\}, \tag{19}$$

where

$$\mathcal{G}(\alpha) \equiv \min_{\|\mathbf{x}\|^2=\alpha-1}\left\{\frac{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2}{\alpha}+\rho\|\mathbf{L}\mathbf{x}\|^2\right\}. \tag{20}$$

Calculating function values of $\mathcal{G}$ requires solving a minimization problem with a quadratic objective function and a norm equality constraint. In section 4.1 we briefly review known results on this problem including necessary and sufficient optimality conditions. In section 4.2 continuity and differentiability of $\mathcal{G}$ are established under standard second order sufficiency conditions. In section 4.3 an upper bound $\bar{\alpha}$ on the value of the optimal α is derived. Thus, the TRTLS problem (11) is reduced to a one dimensional minimization of $\mathcal{G}$ over a finite interval $[1, \bar{\alpha}]$.

4.1. Minimization of a quadratic function subject to a norm equality constraint. In this section we consider the minimization problem

$$\min_{\|\mathbf{x}\|^2=\beta} \left\{ \mathbf{x}^T \mathbf{Q} \mathbf{x} - 2\mathbf{f}^T \mathbf{x} + c \right\}. \tag{21}$$

We do not assume that $\mathbf{Q}$ is positive semidefinite, and therefore the objective function need not be convex. Problem (21) is the well-known *trust region subproblem* (TRS); it has been extensively studied from both theoretical and algorithmic aspects [2, 5, 7, 23, 27, 31].[3] Necessary and sufficient conditions for a (global) solution of (21) are well established [5, 7, 32].

THEOREM 4.1 (see [5, 7, 32]). *Consider problem* (21) *with a symmetric matrix* $\mathbf{Q} \in \mathbb{R}^{n \times n}, \mathbf{f} \in \mathbb{R}^n, c \in \mathbb{R}, \beta \in \mathbb{R}^+$. *Then* $\mathbf{x}^*$ *is an optimal solution of* (21) *if and only if there exists* $\lambda^* \in \mathbb{R}$ *such that*

$$(\mathbf{Q} - \lambda^* \mathbf{I})\mathbf{x}^* = \mathbf{f}, \tag{22}$$

$$\|\mathbf{x}^*\|^2 = \beta, \tag{23}$$

$$\mathbf{Q} - \lambda^* \mathbf{I} \succeq \mathbf{0}. \tag{24}$$

Moreover, if $\mathbf{f} \notin Null(\mathbf{Q} - \lambda_{\min}(\mathbf{Q})\mathbf{I})^{\perp}$, *then the solution of problem* (21) *is unique.*

Many algorithms have been suggested to solve the TRS. A solution based on the complete spectral decomposition can be found in [8]. For medium and large-scale problems the latter approach is not applicable. Thus, several methods have been devised for these scenarios [5, 7, 13, 23, 25, 30, 29].

4.2. Continuity and differentiability of $\mathcal{G}$.

4.2.1. Continuity. The continuity of $\mathcal{G}(\alpha)$ for $\alpha > 1$ follows from a theorem by Gauvin and Dubeau [9, Theorem 3.3] . The notation in [9] is quite different from the notation in this paper, and therefore we will present the three sufficient conditions for continuity of $\mathcal{G}$ at a point $\bar{\alpha}$ from [9] in our terminology (the quotation from [9] is in italic).

1. *The feasible set* $\{\mathbf{x} : \|\mathbf{x}\|^2 = \bar{\alpha} - 1\}$ *is nonempty.* This condition is naturally satisfied for $\bar{\alpha} > 1$.
2. *There exists* $\epsilon > 0$ *such that* $\bigcup_{|\alpha - \bar{\alpha}| < \epsilon} \{\mathbf{x} : \|\mathbf{x}\|^2 = \alpha - 1\}$ *is compact.* This is also true in our problem since the union is equal to $\{\mathbf{x} : \bar{\alpha} - 1 - \epsilon \leq \|\mathbf{x}\|^2 \leq \bar{\alpha} - 1 + \epsilon\}$, which is obviously compact.
3. *The Mangasarian–Fromovitz regularity conditions are satisfied (see* [22]*).* In our problem, this means that the gradient of the constraint is different from zero at the optimal solution, i.e., $\mathbf{x}^* \neq 0$. This is true for $\bar{\alpha} > 1$ since $\|\mathbf{x}^*\|^2 = \bar{\alpha} - 1$.

[3] The TRS is usually considered with an inequality constraint $\|\mathbf{x}\|^2 \leq \beta$ instead of an equality one; however, all known results can be trivially converted to the equality case.

What is left to prove is that $\mathcal{G}$ is continuous at $\alpha = 1$ (from the right). This is proved next.

LEMMA 4.1. *$\mathcal{G}$ is continuous at $\alpha = 1$ from the right.*

Proof. First, $\mathcal{G}(1) = \|\mathbf{b}\|^2$. Now, for every $\alpha > 1$ let $\mathbf{x}_\alpha$ be such that $\mathcal{H}(\mathbf{x}_\alpha) = \mathcal{G}(\alpha)$ and $\|\mathbf{x}_\alpha\|^2 = \alpha - 1$. Then

$$\begin{aligned}
|\mathcal{G}(\alpha) - \mathcal{G}(1)| &= |\mathcal{H}(\mathbf{x}_\alpha) - \|\mathbf{b}\|^2| \\
&= \left| \frac{\|\mathbf{A}\mathbf{x}_\alpha - \mathbf{b}\|^2}{\alpha} + \rho\|\mathbf{L}\mathbf{x}_\alpha\|^2 - \|\mathbf{b}\|^2 \right| \\
&= \left| \left(\frac{1}{\alpha} - 1\right)\|\mathbf{b}\|^2 + \frac{\mathbf{x}_\alpha^T\mathbf{A}^T\mathbf{A}\mathbf{x}_\alpha - 2\mathbf{b}^T\mathbf{A}\mathbf{x}_\alpha}{\alpha} + \rho\mathbf{x}_\alpha^T\mathbf{L}^T\mathbf{L}\mathbf{x}_\alpha \right| \\
&\leq \left(1 - \frac{1}{\alpha}\right)\|\mathbf{b}\|^2 + \left(\frac{\lambda_{max}(\mathbf{A}^T\mathbf{A})}{\alpha} + \rho\lambda_{max}(\mathbf{L}^T\mathbf{L})\right)\|\mathbf{x}_\alpha\|^2 \\
&\quad + 2\frac{\|\mathbf{A}^T\mathbf{b}\|}{\alpha}\|\mathbf{x}_\alpha\| \\
&\overset{\|\mathbf{x}_\alpha\|^2 = \alpha - 1}{=} \left(1 - \frac{1}{\alpha}\right)\|\mathbf{b}\|^2 + \left(\frac{\lambda_{max}(\mathbf{A}^T\mathbf{A})}{\alpha} + \rho\lambda_{max}(\mathbf{L}^T\mathbf{L})\right)(\alpha - 1) \\
&\quad + 2\frac{\|\mathbf{A}^T\mathbf{b}\|}{\alpha}\sqrt{\alpha - 1} \\
&\overset{\alpha \to 1^+}{\longrightarrow} 0.
\end{aligned}$$

Therefore, $\lim_{\alpha \to 1^+} \mathcal{G}(\alpha) = \mathcal{G}(1)$. ∎

COROLLARY 4.1. *$\mathcal{G}$ is continuous over $[1, \infty)$.*

4.2.2. Differentiability. The function $\mathcal{G}$ is of the general form

$$\mathcal{G}(\alpha) = \min_{g(\mathbf{x}) = \alpha - 1} f(\mathbf{x}, \alpha), \tag{25}$$

where

$$f(\mathbf{x}, \alpha) \equiv \mathbf{x}^T\mathbf{Q}_\alpha\mathbf{x} - 2\mathbf{f}_\alpha^T\mathbf{x} + c_\alpha$$

and

$$g(\mathbf{x}) = \|\mathbf{x}\|^2,\ \mathbf{Q}_\alpha = \frac{1}{\alpha}\mathbf{A}^T\mathbf{A} + \rho\mathbf{L}^T\mathbf{L},\ \mathbf{f}_\alpha = \frac{1}{\alpha}\mathbf{A}^T\mathbf{b},\ c_\alpha = \frac{1}{\alpha}\|\mathbf{b}\|^2. \tag{26}$$

The single variable function $\mathcal{G}$ is not necessarily differentiable. In this subsection we show that under a suitable condition, $\mathcal{G}$ is differentiable of any order.

Our argument is the same as the one used in the sensitivity analysis of minimization problems (see, e.g., [3, 26] and the references therein). Theorem 4.2 establishes the differentiability of $\mathcal{G}$ under a suitable regularity condition.

THEOREM 4.2. *For every $\alpha > 1$ that satisfies the condition*

$$\mathbf{f}_\alpha \notin \mathit{Null}(\mathbf{Q}_\alpha - \lambda_{min}(\mathbf{Q}_\alpha)\mathbf{I})^\perp, \tag{27}$$

$\mathcal{G}(\alpha)$ is differentiable of any order and its first derivative is given by

$$\mathcal{G}'(\alpha) = \lambda(\alpha) + f'_\alpha(\mathbf{x}(\alpha), \alpha) = \lambda(\alpha) - \frac{\|\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b}\|^2}{\alpha^2}, \tag{28}$$

where $\mathbf{x}(\alpha)$ *and* $\lambda(\alpha)$ *are the unique solutions of the KKT conditions* (22) *and* (23).

Proof. Let $\alpha > 1$ be such that condition (27) is satisfied. By Theorem 4.1, condition (27) implies the uniqueness of the solution of the minimization problem (25). Consider the system of equations

$$(\mathbf{Q}_\alpha - \lambda \mathbf{I})\mathbf{x} = \mathbf{f}_\alpha, \tag{29}$$

$$\|\mathbf{x}\|^2 = \alpha - 1. \tag{30}$$

By Theorem 4.1, $x(\alpha)$ and $\lambda(\alpha)$ are the solutions of the system for the given α. The Jacobian matrix associated with the system of equations (29) and (30) with respect to $(\mathbf{x}, \lambda)$ at $(\mathbf{x}(\alpha), \lambda(\alpha))$ is given by

$$J = \begin{pmatrix} \mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I} & \mathbf{x}(\alpha) \\ \mathbf{x}(\alpha)^T & 0 \end{pmatrix}.$$

To show that J is nonsingular note first that condition (27) implies also that

$$\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I} \succ \mathbf{0}. \tag{31}$$

This is true since (29) implies that $\mathbf{f}_\alpha \in \text{Range}(\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I}) = \text{Null}(\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I})^\perp$. This condition combined with (27) and (24) implies that $\lambda(\alpha) < \lambda_{min}(\mathbf{Q}_\alpha)$. To show the nonsingularity of J, we will prove that the only solution of the system

$$J \begin{pmatrix} \mathbf{w} \\ t \end{pmatrix} = \mathbf{0}, \quad \mathbf{w} \in \mathbb{R}^n,\ t \in \mathbb{R},$$

is the trivial solution. Indeed, the system can be written explicitly as

$$(\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I})\mathbf{w} + 2t\mathbf{x}(\alpha) = \mathbf{0}, \tag{32}$$

$$2\mathbf{x}(\alpha)^T\mathbf{w} = \mathbf{0}. \tag{33}$$

Multiplying (32) by $\mathbf{w}^T$ from the left and using (33), we obtain $\mathbf{w}^T(\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I})\mathbf{w} = 0$. Since $\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I} \succ \mathbf{0}$ we conclude that $\mathbf{w} = 0$. Substituting this into (32) we have $t = 0$, proving the nonsingularity of J. Invoking the implicit function theorem, the differentiability of any order of $\mathbf{x}(\alpha)$ and $\lambda(\alpha)$ in a neighborhood of α follows. Now $\mathbf{x}(\alpha)$ and $\lambda(\alpha)$ satisfy the identities (in α)

$$f'_{\mathbf{x}}(\mathbf{x}(\alpha), \alpha) - \lambda(\alpha) g'_{\mathbf{x}}(\mathbf{x}(\alpha)) = 0, \tag{34}$$

$$g(\mathbf{x}(\alpha)) = \alpha - 1. \tag{35}$$

Differentiating both sides of (35) yields the equation

$$\dot{\mathbf{x}}(\alpha)^T g'_{\mathbf{x}}(\mathbf{x}(\alpha)) = 1. \tag{36}$$

Multiplying (34) from the left by $\dot{\mathbf{x}}(\alpha)^T$ we obtain

$$\dot{\mathbf{x}}(\alpha)^T f'_{\mathbf{x}}(\mathbf{x}(\alpha), \alpha) - \lambda(\alpha)\dot{\mathbf{x}}(\alpha)^T g'_{\mathbf{x}}(\mathbf{x}(\alpha)) = 0. \tag{37}$$

By substituting (36) into (37) we obtain

$$\dot{\mathbf{x}}(\alpha)^T f'_{\mathbf{x}}(\mathbf{x}(\alpha), \alpha) = \lambda(\alpha). \tag{38}$$

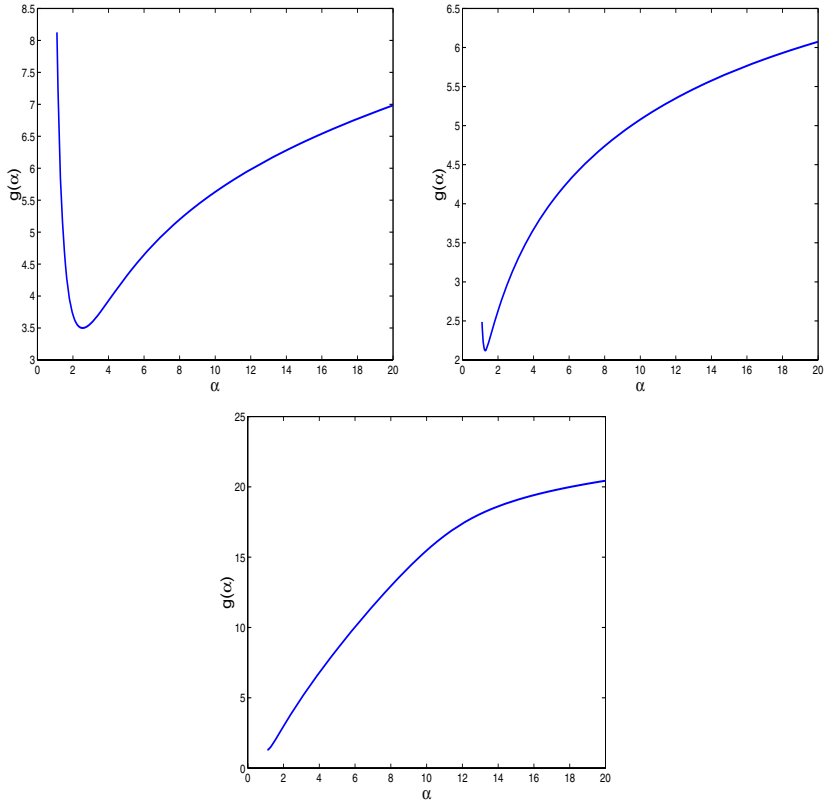

FIG. 1. *Examples of* $\mathcal{G}(\alpha)$.

$\mathcal{G}(\alpha)$ and its derivatives are given by

$$\begin{aligned} \mathcal{G}(\alpha) &= f(\mathbf{x}(\alpha), \alpha), \\ \mathcal{G}'(\alpha) &= \dot{\mathbf{x}}(\alpha)^T f'_{\mathbf{x}}(\mathbf{x}(\alpha), \alpha) + f'_{\alpha}(\mathbf{x}(\alpha), \alpha). \end{aligned} \tag{39}$$

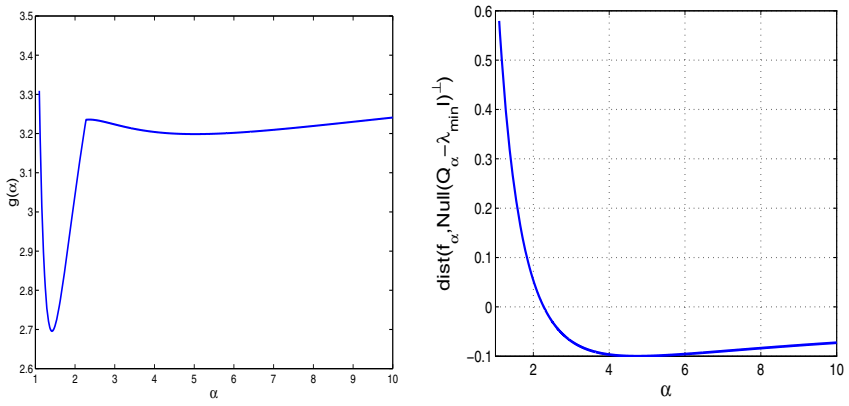
Substituting (38) into (39), the expression for the derivative (28) follows. ∎

Example. Some examples of $\mathcal{G}(\alpha)$ are given in Figure 1. These examples were randomly generated with dimensions $m = n = 4$ and $k = 3$.

In all of these examples $\mathcal{G}$ is continuous and differentiable. Note that in most examples the function $\mathcal{G}$ seems to be "well behaved" in the sense that it is strictly unimodal. A "bad" example is given in Figure 2(a), where we see an example of a nondifferentiable function. The point of nondifferentiability is $\bar{\alpha} = 2.275$. Figure 2(b) plots the quantity $dist(\mathbf{f}_\alpha, \text{Null}(\mathbf{Q}_\alpha - \lambda_{min}(\mathbf{Q}_\alpha)\mathbf{I})^\perp)$ versus α. It can be readily seen that the point in which the distance is zero is exactly the point $\bar{\alpha}$.

So far we have shown how to reduce the TRTLS problem (11) to a one dimensional problem $\min_{\alpha \geq 1} \mathcal{G}(\alpha)$. One of the problems frequently arising in one dimensional (line search) methods is determining an initial interval of search in which the optimum is known to reside. At this point, we have only shown that a lower bound on α is 1. Next we derive an upper bound.

4.3. Upper bound on the norm of optimal solutions. Let $\mathbf{x}^*$ be an optimal solution of problem (11). In this section we find an upper bound for $\|\mathbf{x}^*\|$. We recall



(a) (b)

FIG. 2. *An example of a nondifferentiable* $\mathcal{G}(\alpha)$.

the assumption that $\mathbf{L}$ is full row rank. In the case where $k = n$, it is very easy to bound the $\|\mathbf{x}^*\|$, as can be seen from the following lemma.

LEMMA 4.2. *Suppose that* $k = n$, *and let* $\mathbf{x}^*$ *be an optimal solution of* $\min_{\mathbf{x}\in\mathbb{R}^n} \mathcal{H}(\mathbf{x})$. *Then* $\|\mathbf{x}^*\|^2 \leq \frac{\|\mathbf{b}\|^2}{\rho\lambda_{min}(\mathbf{L}\mathbf{L}^T)}$.

Proof. First, notice that $\lambda_{min}(\mathbf{L}\mathbf{L}^T) > 0$ since $\mathbf{L}$ has full row rank. Now,

$$\rho\|\mathbf{L}\mathbf{x}^*\|^2 \leq \mathcal{H}(\mathbf{x}^*) \leq \mathcal{H}(0) = \|\mathbf{b}\|^2,$$

and the result follows from the simple observation that $\|\mathbf{L}\mathbf{x}^*\|^2 = (\mathbf{x}^*)^T\mathbf{L}^T\mathbf{L}\mathbf{x}^* \geq \lambda_{min}(\mathbf{L}\mathbf{L}^T)\|\mathbf{x}^*\|^2 > 0$. □

The case in which $k < n$ is much harder. In this case, we assume that condition (13) is satisfied.

THEOREM 4.3. *Suppose that condition* (13) *is satisfied, and let* $\mathbf{x}^*$ *be an optimal solution of* $\min_{\mathbf{x}\in\mathbb{R}^n} \mathcal{H}(\mathbf{x})$. *Then*

$$\|\mathbf{x}^*\|^2 \leq \max\left\{1, \frac{\|\mathbf{b}\|^2 + \lambda_{max}(\mathbf{A}^T\mathbf{A})(\delta + 2\sqrt{\delta}) + \|\mathbf{A}^T\mathbf{b}\|(\delta + 2\sqrt{\delta}) + l_1(1+\delta))}{l_1 - l_2}\right\}^2 + \delta, \tag{40}$$

where

$$l_2 = \lambda_{min}\begin{pmatrix} \mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F} & \mathbf{F}^T\mathbf{A}^T\mathbf{b} \\ \mathbf{b}^T\mathbf{A}\mathbf{F} & \|\mathbf{b}\|^2 \end{pmatrix},$$
$$l_1 = \lambda_{min}(\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}),$$

$\delta = \frac{l_2}{\lambda_{min}(\mathbf{L}\mathbf{L}^T)\rho}$, *and* $\mathbf{F}$ *is a matrix whose columns form an orthogonal base of Null*$(\mathbf{L})$.

Proof. Consider the decomposition

$$\mathbf{x}^* = \mathbf{F}\mathbf{v} + \mathbf{L}^T\mathbf{w}, \tag{41}$$

where $\mathbf{v} \in \mathbb{R}^{n-k}$ and $\mathbf{w} \in \mathbb{R}^n$ (such decomposition is possible since $\text{Null}(\mathbf{L}) = (\text{Range}(\mathbf{L}^T))^\perp$). Now,

$$\|\mathbf{x}^*\|^2 = \|\mathbf{v}\|^2 + \mathbf{w}^T\mathbf{L}\mathbf{L}^T\mathbf{w}. \tag{42}$$

By (14),

$$\mathcal{H}(\mathbf{x}^*) = f^* \leq l_2.$$

As a result,

$$\rho\|\mathbf{L}\mathbf{x}^*\|^2 \leq l_2. \tag{43}$$

Substituting (41) into (43) we obtain

$$\rho\mathbf{w}^T(\mathbf{L}\mathbf{L}^T)^2\mathbf{w} \leq l_2,$$

which implies the following inequality:

$$\mathbf{w}^T\mathbf{L}\mathbf{L}^T\mathbf{w} = \mathbf{w}^T(\mathbf{L}\mathbf{L}^T)^2\mathbf{w}\frac{\mathbf{w}^T\mathbf{L}\mathbf{L}^T\mathbf{w}}{\mathbf{w}^T(\mathbf{L}\mathbf{L}^T)^2\mathbf{w}} \leq \frac{l_2}{\rho}\lambda_{max}((\mathbf{L}\mathbf{L}^T)^{-1}(\mathbf{L}\mathbf{L}^T)(\mathbf{L}\mathbf{L}^T)^{-1}) = \delta. \tag{44}$$

We assume for now that $\|\mathbf{v}\| \geq 1$. Substituting the decomposition (41) into the objective function $\mathcal{H}$ we have

$$\begin{aligned}
&\mathcal{H}(\mathbf{x}^*)\\
&= \frac{\|\mathbf{A}\mathbf{x}^* - \mathbf{b}\|^2}{\|\mathbf{x}^*\|^2 + 1} + \rho\|\mathbf{L}\mathbf{x}^*\|^2\\
&\geq \frac{\|\mathbf{A}\mathbf{x}^* - \mathbf{b}\|^2}{\|\mathbf{x}^*\|^2 + 1} = \frac{\|\mathbf{A}(\mathbf{F}\mathbf{v} + \mathbf{L}^T\mathbf{w}) - \mathbf{b}\|^2}{\|\mathbf{F}\mathbf{v} + \mathbf{L}^T\mathbf{w}\|^2 + 1}\\
&= \frac{\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{v} + 2\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w} - 2\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{b} + \mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w} - 2\mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{b} + \|\mathbf{b}\|^2}{1 + \|\mathbf{v}\|^2 + \mathbf{w}^T\mathbf{L}\mathbf{L}^T\mathbf{w}}\\
&= \frac{\frac{\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{F}\mathbf{v}}{\|\mathbf{v}\|^2} + \beta}{1 + \gamma} \geq \frac{l_1 + \beta}{1 + \gamma},
\end{aligned}$$

where

$$\gamma = \frac{1 + \mathbf{w}^T\mathbf{L}\mathbf{L}^T\mathbf{w}}{\|\mathbf{v}\|^2},$$

$$\beta = \frac{2\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w} - 2\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{b} + \mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w} - 2\mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{b} + \|\mathbf{b}\|^2}{\|\mathbf{v}\|^2}.$$

We have thus proven that $\mathcal{H}(\mathbf{x}^*) \geq \theta$, where $\theta = \frac{l_1+\beta}{1+\gamma}$. Combining this with Theorem 3.1 and condition (13) we have $\theta \leq l_2 < l_1$. Now,

$$l_1 - l_2 \leq l_1 - \theta = |\theta - l_1| = \left|\frac{l_1 + \beta}{1 + \gamma} - l_1\right| = \left|\frac{\beta - l_1\gamma}{1 + \gamma}\right| \leq \beta + l_1\gamma. \tag{45}$$

Also,

(46)

$$\begin{aligned}
\gamma &\leq \frac{1 + \delta}{\|\mathbf{v}\|^2} \overset{\|\mathbf{v}\|\geq 1}{\leq} \frac{1 + \delta}{\|\mathbf{v}\|},\\
\beta &\leq \frac{2|\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w}| + 2|\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{b}| + |\mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w}| + 2|\mathbf{w}^T\mathbf{L}\mathbf{A}^T\mathbf{b}| + \|\mathbf{b}\|^2}{\|\mathbf{v}\|^2}\\
&\overset{(*)}{\leq} \frac{2}{\|\mathbf{v}\|}\left(\lambda_{max}(\mathbf{A}^T\mathbf{A})\sqrt{\delta} + \|\mathbf{A}^T\mathbf{b}\|\right) + \frac{1}{\|\mathbf{v}\|^2}\left(\|\mathbf{b}\|^2 + \lambda_{max}(\mathbf{A}^T\mathbf{A})\delta + 2\|\mathbf{A}^T\mathbf{b}\|\sqrt{\delta}\right)
\end{aligned}$$

$$\begin{aligned}
&\overset{\|\mathbf{v}\|\geq 1}{\leq} \frac{2}{\|\mathbf{v}\|}\left(\lambda_{max}(\mathbf{A}^T\mathbf{A})\sqrt{\delta}+\|\mathbf{A}^T\mathbf{b}\|\right)+\frac{1}{\|\mathbf{v}\|}\left(\|\mathbf{b}\|^2+\lambda_{max}(\mathbf{A}^T\mathbf{A})\delta+2\|\mathbf{A}^T\mathbf{b}\|\sqrt{\delta}\right)\\
&= \frac{1}{\|\mathbf{v}\|}\left(\|\mathbf{b}\|^2+\lambda_{max}(\mathbf{A}^T\mathbf{A})(\delta+2\sqrt{\delta})+\|\mathbf{A}^T\mathbf{b}\|(2+2\sqrt{\delta})\right),
\end{aligned} \tag{47}$$

where inequality (*) is true due to the Cauchy–Schwarz inequality and trivial linear algebra inequalities. For example, $|\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w}|$ is bounded as follows:

$$\begin{aligned}
|\mathbf{v}^T\mathbf{F}^T\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w}| &\overset{\text{C-S}}{\leq} \|\mathbf{F}\mathbf{v}\|\cdot\|\mathbf{A}^T\mathbf{A}\mathbf{L}^T\mathbf{w}\| \overset{\lambda_{max}(\mathbf{F})\leq 1}{\leq} \|\mathbf{v}\|\lambda_{max}(\mathbf{A}^T\mathbf{A})\|\mathbf{L}^T\mathbf{w}\|\\
&\overset{(44)}{\leq} \lambda_{max}(\mathbf{A}^T\mathbf{A})\|\mathbf{v}\|\sqrt{\delta}.
\end{aligned}$$

Using the upper bound on β (47) and the upper bound on γ (46), we conclude that if $\|\mathbf{v}\|\geq 1$, then

$$\begin{aligned}
l_1-l_2 &\overset{(45)}{\leq} \beta+l_1\gamma\\
&\leq \frac{1}{\|\mathbf{v}\|}\left(\|\mathbf{b}\|^2+\lambda_{max}(\mathbf{A}^T\mathbf{A})(\delta+2\sqrt{\delta})+\|\mathbf{A}^T\mathbf{b}\|(2+2\sqrt{\delta})+l_1(1+\delta)\right).
\end{aligned}$$

Therefore,

$$\|\mathbf{v}\|\leq \max\left\{1,\frac{\|\mathbf{b}\|^2+\lambda_{max}(\mathbf{A}^T\mathbf{A})(\delta+2\sqrt{\delta})+\|\mathbf{A}^T\mathbf{b}\|(\delta+2\sqrt{\delta})+l_1(1+\delta)}{l_1-l_2}\right\}. \tag{48}$$

Finally,

$$\begin{aligned}
&\|\mathbf{x}^*\|^2\\
&= \|\mathbf{v}\|^2+\|\mathbf{L}^T\mathbf{w}\|^2\\
&\overset{(44),(48)}{\leq} \max\left\{1,\frac{\|\mathbf{b}\|^2+\lambda_{max}(\mathbf{A}^T\mathbf{A})(\delta+2\sqrt{\delta})+\|\mathbf{A}^T\mathbf{b}\|(\delta+2\sqrt{\delta})+l_1(1+\delta)}{l_1-l_2}\right\}^2+\delta. \qquad \square
\end{aligned}$$

Remark. Recall that the sufficient condition for attainability is that $l_2<l_1$. Note that if l_2 is very close to l_1, then the upper bound on $\|\mathbf{x}^*\|^2$ might be very large.

5. The case $\mathbf{L}=\mathbf{I}$.

5.1. Strict unimodality of $\mathcal{G}$. In this section we show that in the case in which $\mathbf{L}=\mathbf{I}$, the function $\mathcal{G}$ defined in (20) has a very attractive property: *strictly unimodal*. A strictly unimodal function over an interval $[a,b]$ is a function that has a unique global minimum α^* and is strictly decreasing over $[a,\alpha^*]$ and strictly increasing over $[\alpha^*,b]$ (α^* can be equal to a or b and in that case the function is monotone). The fact that $\mathcal{G}$ is strictly unimodal implies that we can solve the one dimensional minimization problem efficiently (with, e.g., the golden section method; see [3]).

THEOREM 5.1. *Consider problem* (11) *with* $\mathbf{L}=\mathbf{I}$. *If* $\mathbf{A}^T\mathbf{b}\notin$ *Null*$(\mathbf{A}^T\mathbf{A}-\lambda_{\min}(\mathbf{A}^T\mathbf{A})\mathbf{I})^{\perp}$, *then* $\mathcal{G}$, *defined in* (20), *is differentiable for every* $\alpha>1$ *and strictly unimodal.*

Proof. First, by substituting $\mathbf{Q}_\alpha=\frac{1}{\alpha}\mathbf{A}^T\mathbf{A}+\rho\mathbf{I}$ and $\mathbf{f}_\alpha=\frac{1}{\alpha}\mathbf{A}^T\mathbf{b}$ into (27) we obtain the following sufficient condition for differentiability of $\mathcal{G}$ at α:

$$\mathbf{A}^T\mathbf{b}\notin \text{Null}(\mathbf{A}^T\mathbf{A}-\lambda_{\min}(\mathbf{A}^T\mathbf{A})\mathbf{I})^{\perp}.$$

Now, in order to prove the strict unimodality of $\mathcal{G}$, it is sufficient to prove the following property of $\mathcal{G}$: *if* $\mathcal{G}'(\alpha) = 0$, *then* $\mathcal{G}''(\alpha) > 0$. By differentiating both sides of (39), we obtain

$$\mathcal{G}''(\alpha) = \ddot{\mathbf{x}}(\alpha)^T f'_{\mathbf{x}}(\mathbf{x}(\alpha),\alpha) + \dot{\mathbf{x}}(\alpha)^T f''_{\mathbf{x}^2}(\mathbf{x}(\alpha),\alpha)\dot{\mathbf{x}}(\alpha) + 2\dot{\mathbf{x}}(\alpha)^T f''_{\mathbf{x}\alpha}(\mathbf{x}(\alpha),\alpha) + f''_{\alpha^2}(\mathbf{x}(\alpha),\alpha). \tag{49}$$

Differentiating (36), we have

$$\ddot{\mathbf{x}}(\alpha)^T g'_{\mathbf{x}}(\mathbf{x}(\alpha)) + \dot{\mathbf{x}}(\alpha)^T g''_{\mathbf{x}^2}(\mathbf{x}(\alpha))\dot{\mathbf{x}}(\alpha) = 0. \tag{50}$$

Therefore,

$$\begin{aligned}
\mathcal{G}''(\alpha) &= \mathcal{G}''(\alpha) - \lambda(\alpha)\cdot 0 \\
&\overset{(50)}{=} \mathcal{G}''(\alpha) - \lambda(\alpha)(\ddot{\mathbf{x}}(\alpha)^T g'_{\mathbf{x}}(\mathbf{x}(\alpha)) + \dot{\mathbf{x}}(\alpha)^T g''_{\mathbf{x}^2}(\mathbf{x}(\alpha))\dot{\mathbf{x}}(\alpha)) \\
&\overset{(49)}{=} \overbrace{\ddot{\mathbf{x}}(\alpha)^T \left(f'_{\mathbf{x}}(\mathbf{x}(\alpha),\alpha) - \lambda(\alpha) g'_{\mathbf{x}}(\mathbf{x}(\alpha))\right)}^{A} \\
&\quad + \overbrace{\dot{\mathbf{x}}(\alpha)^T \left(f''_{\mathbf{x}^2}(\mathbf{x}(\alpha),\alpha) - \lambda(\alpha) g''_{\mathbf{x}^2}(\mathbf{x}(\alpha))\right)\dot{\mathbf{x}}(\alpha)}^{B} \\
&\quad + \underbrace{2\dot{\mathbf{x}}(\alpha)^T f''_{\mathbf{x}\alpha}(\mathbf{x}(\alpha),\alpha) + f''_{\alpha^2}(\mathbf{x}(\alpha),\alpha)}_{C}.
\end{aligned}$$

By (34) we have $A = 0$ and

$$B = \dot{\mathbf{x}}(\alpha)^T \left(f''_{\mathbf{x}^2}(\mathbf{x}(\alpha),\alpha) - \lambda(\alpha) g''_{\mathbf{x}^2}(\mathbf{x}(\alpha))\right)\dot{\mathbf{x}}(\alpha) = \dot{\mathbf{x}}(\alpha)^T(\mathbf{Q}_\alpha - \lambda(\alpha)\mathbf{I})\dot{\mathbf{x}}(\alpha) \overset{(31)}{>} 0.$$

The latter inequality is true since by (36) $\dot{\mathbf{x}}(\alpha) \neq \mathbf{0}$. Suppose that $\mathcal{G}'(\alpha) = 0$; then

$$\dot{\mathbf{x}}(\alpha)^T f'_{\mathbf{x}}(\mathbf{x}(\alpha),\alpha) + f'_{\alpha}(\mathbf{x}(\alpha),\alpha) = 0,$$

which can also be written as

$$2\dot{\mathbf{x}}(\alpha)^T \left(\frac{\mathbf{A}^T(\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b})}{\alpha}\right) - \frac{\|\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b}\|^2}{\alpha^2} = -2\rho\dot{\mathbf{x}}(\alpha)^T \mathbf{L}^T\mathbf{L}\mathbf{x}(\alpha). \tag{51}$$

Now,

$$\begin{aligned}
C &= 2\dot{\mathbf{x}}(\alpha)^T f''_{\mathbf{x}\alpha}(\mathbf{x}(\alpha),\alpha) + f''_{\alpha^2}(\mathbf{x}(\alpha),\alpha) \\
&= -4\dot{\mathbf{x}}(\alpha)^T \frac{\mathbf{A}^T(\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b})}{\alpha^2} + 2\frac{\|\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b}\|^2}{\alpha^3} \\
&\overset{(51)}{=} 4\rho\frac{\dot{\mathbf{x}}(\alpha)^T\mathbf{L}^T\mathbf{L}\mathbf{x}(\alpha)}{\alpha}.
\end{aligned}$$

In our case $\mathbf{L} = \mathbf{I}$, and thus $C = 4\rho\frac{\dot{\mathbf{x}}(\alpha)^T\mathbf{x}(\alpha)}{\alpha} \overset{(36)}{=} \frac{2\rho}{\alpha} > 0$ and we conclude that, when $\mathcal{G}'(\alpha) = 0$, then $\mathcal{G}''(\alpha) = A + B + C > 0$, proving the unimodality property. ∎

5.2. Another approach to the case $\mathbf{L} = \mathbf{I}$.

5.2.1. The schematic algorithm. In the case $\mathbf{L} = \mathbf{I}$ the problem is given by

$$\min_{\mathbf{x}\in\mathbb{R}^n} \left\{ \mathcal{H}(\mathbf{x}) \equiv \frac{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2}{\|\mathbf{x}\|^2+1} + \rho\|\mathbf{x}\|^2 \right\}. \tag{52}$$

We use the following simple observation, which goes back to Dinkelbach [6]: For every $t \in \mathbb{R}$, the following two statements are equivalent:

$$\min_{\mathbf{x}\in\mathbb{R}^n} \mathcal{H}(\mathbf{x}) \le t,$$

$$\min_{\mathbf{x}\in\mathbb{R}^n} \{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2 + \rho\|\mathbf{x}\|^4 + \rho\|\mathbf{x}\|^2 - t(\|\mathbf{x}\|^2+1)\} \le 0. \tag{53}$$

The minimization problem (53) also seems hard to solve; however, we will show in section 5.2.2 that it is in fact a very simple problem having essentially an explicit solution. Consider the function $\phi : \mathbb{R} \to \mathbb{R}$ defined by

$$\phi(t) = \min_{\mathbf{x}\in\mathbb{R}^n} \{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2 + \rho\|\mathbf{x}\|^4 + \rho\|\mathbf{x}\|^2 - t(\|\mathbf{x}\|^2+1)\}.$$

We claim that ϕ is strictly decreasing. To prove this suppose that $t_1 < t_2$, and let $\mathbf{x}_{t_1} \equiv \operatorname{argmin}_{\mathbf{x}\in\mathbb{R}^n}\{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2 + \rho\|\mathbf{x}\|^4 + \rho\|\mathbf{x}\|^2 - t_1(\|\mathbf{x}\|^2+1)\}$. Then

$$\begin{aligned}\phi(t_1) &= \|\mathbf{A}\mathbf{x}_{t_1}-\mathbf{b}\|^2 + \rho\|\mathbf{x}_{t_1}\|^4 + \rho\|\mathbf{x}_{t_1}\|^2 - t_1(\|\mathbf{x}_{t_1}\|^2+1)\\ &> \|\mathbf{A}\mathbf{x}_{t_1}-\mathbf{b}\|^2 + \rho\|\mathbf{x}_{t_1}\|^4 + \rho\|\mathbf{x}_{t_1}\|^2 - t_2(\|\mathbf{x}_{t_1}\|^2+1) \ge \phi(t_2).\end{aligned}$$

From the above observation we also have that $t^* \equiv \min_{\mathbf{x}\in\mathbb{R}^n} \mathcal{H}(\mathbf{x})$ is the unique root of $\phi(\cdot)$. Moreover, $t^* \in [0, \|\mathbf{b}\|^2]$ since

$$\phi(0) = \min_{\mathbf{x}\in\mathbb{R}^n} \{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2 + \rho\|\mathbf{x}\|^4 + \rho\|\mathbf{x}\|^2\} \ge 0$$

and

$$\begin{aligned}\phi(\|\mathbf{b}\|^2) &= \min_{\mathbf{x}\in\mathbb{R}^n} \{\|\mathbf{A}\mathbf{x}-\mathbf{b}\|^2 + \rho\|\mathbf{x}\|^4 + (\rho-\|\mathbf{b}\|^2)\|\mathbf{x}\|^2 - \|\mathbf{b}\|^2\}\\ &\le \min_{\mathbf{x}\in\mathbb{R}^n} \{\|\mathbf{A}\mathbf{0}-\mathbf{b}\|^2 + \rho\|\mathbf{0}\|^4 + (\rho-\|\mathbf{b}\|^2)\|\mathbf{0}\|^2 - \|\mathbf{b}\|^2\} = 0.\end{aligned}$$

As a result, the optimal t^* can be found by, e.g., a simple bisection algorithm with an initial interval $[0, \|\mathbf{b}\|^2]$.

5.2.2. Solving the subproblem. The subproblem can also be written as

$$\min_{\mathbf{x}\in\mathbb{R}^n} \left\{\mathbf{x}^T\mathbf{A}^T\mathbf{A}\mathbf{x} + (\rho-t)\|\mathbf{x}\|^2 + \rho\|\mathbf{x}\|^4 - 2\mathbf{b}^T\mathbf{A}\mathbf{x} + \|\mathbf{b}\|^2 - t\right\}.$$

Making the change of variables $\mathbf{x} = \mathbf{U}\mathbf{z}$, where $\mathbf{U}$ is orthogonal matrix diagonalizing $\mathbf{A}^T\mathbf{A}$, i.e., $\mathbf{U}^T\mathbf{A}^T\mathbf{A}\mathbf{U} = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$, the problem then reduces to

$$\min_{\mathbf{z}\in\mathbb{R}^n} \sum_{j=1}^{n} \left\{\lambda_j z_j^2 + (\rho-t)z_j^2 + \rho z_j^4 - 2f_j z_j\right\}, \tag{54}$$

where $\mathbf{f} = \mathbf{U}^T\mathbf{A}^T\mathbf{b}$. Note that since ρ canbe smaller than t, (54) might be a nonconvex problem. But, in fact, this does not really matter since this is a separable problem in its variables. Therefore, the solution of (54) requires solving n independent minimization problems:

$$\min_{\mathbf{z}_j\in\mathbb{R}} \left\{(\lambda_j + \rho - t)z_j^2 + \rho z_j^4 - 2f_j z_j\right\}. \tag{55}$$

The scalar objective function is a coercive function (since the dominating factor is z_j^4). Therefore, the minimum of (55) is attained at a point satisfying $g_j'(z_j) = 0$, where $g_j(z_j) = (\lambda_j + \rho - t)z_j^2 + \rho z_j^4 - 2f_j z_j$. Therefore, the minimum is attained at one of the real roots of

$$4\rho z_j^3 + 2(\lambda_j + \rho - t)z_j - 2f_j = 0. \tag{56}$$

This is a cubic equation and therefore can be solved explicitly by Cardano's formula. More precisely, the roots of the cubic equation $x^3 + 3Qx - 2R = 0$ are given by

$$x_1 = (R + \sqrt{Q^3 + R^2})^{1/3} + (R - \sqrt{Q^3 + R^2})^{1/3}$$

and

$$\begin{aligned} x_{2,3} = &-\frac{1}{2}\left[(R + \sqrt{Q^3 + R^2})^{1/3} + (R - \sqrt{Q^3 + R^2})^{1/3}\right] \\ &\pm \frac{\sqrt{3}}{2} i \left[(R + \sqrt{Q^3 + R^2})^{1/3} - (R - \sqrt{Q^3 + R^2})^{1/3}\right]. \end{aligned}$$

In any case, it has three real roots if $Q^3 + R^2 \leq 0$ and only one real root (and two complex roots) otherwise. The minimum of (55) is attained at one of the roots of the cubic equation (56). Therefore, the initial step of the algorithm is to diagonalize the matrix $\mathbf{A}^T\mathbf{A}$, and then a bisection algorithm is invoked to find the unique root of the strictly decreasing function ϕ. The calculation of a function value of ϕ requires solving n cubic equations.

The algorithm described in this section is summarized below.

ALGORITHM TRTLSI.

Input: $\mathbf{A} \in \mathbb{R}^{m\times n}, \mathbf{b} \in \mathbb{R}^m, \rho > 0$, and ϵ—a tolerance parameter.

Output: $\mathbf{x}^*$—a solution (up to some tolerance) of the TRTLS problem (11) with $\mathbf{L} = \mathbf{I}$.

1. **Set** $t_{\min} \leftarrow 0$ and $t_{\max} \leftarrow \|\mathbf{b}\|^2$.
2. Compute the spectral decomposition of $\mathbf{A}^T\mathbf{A}$: $\mathbf{U}^T\mathbf{A}^T\mathbf{A}\mathbf{U} = \operatorname{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$.
3. **Set** $\mathbf{f} \leftarrow \mathbf{U}^T\mathbf{A}^T\mathbf{b}$.
4. **While** $|t_{\max} - t_{\min}| > \epsilon$ **repeat** steps (a), (b), and (c):
   (a) For every $j = 1, 2, \ldots, n$ compute the solutions $z_1^j, \ldots, z_{p_j}^j$ of the one dimensional cubic equation (56). Here p_j denotes the number of different real solutions of the jth cubic equation.
   (b) For every $j = 1, 2, \ldots, n$ **set**
   $$\beta_j \leftarrow \min_{k=1,\ldots,p_j} \{(\lambda_j + \rho - t)(z_k^j)^2 + \rho(z_k^j)^4 - 2f_j z_k^j\}.$$
   (c) **If** $\sum_{j=1}^n \beta_j - t < 0$, **then** $t_{\max} = t$; **else** $t_{\min} = t$.
5. **Set**
   $$m_j \leftarrow \operatorname*{argmin}_{k=1,\ldots,p_j} \{(\lambda_j + \rho - t)(z_k^j)^2 + \rho(z_k^j)^4 - 2f_j z_k^j\}.$$
6. Let $\mathbf{w}$ be such that $w_j = z_{m_j}^j$ for every $j = 1, \ldots, n$.
7. Set $\mathbf{x}^* = \mathbf{U}\mathbf{w}$.

The dominant computational effort when applying algorithm TRTLSI is the single calculation of the spectral decomposition of $\mathbf{A}^T\mathbf{A}$, which requires $O(n^3)$ operations. At each iteration the computational cost of solving n cubic equations is $O(n)$. For problems with up to several hundreds of variables, algorithm TRTLSI is therefore applicable. However, for problems with thousands or even tens of thousands of variables, algorithm TRTLSI cannot be implemented. Nevertheless, it is still possible to use the approach of solving the one dimensional minimization problem (19) since large-scale TRSs can be solved efficiently (see, e.g., [5, 7] and the references therein). A specific implementation of the algorithm for a general regularization matrix is given in the subsequent section.

6. Implementation and example. We have shown that solving the TRTLS problem (11) (for a general regularization matrix $\mathbf{L}$) reduces to a problem of solving a one dimensional minimization problem over a closed interval. The specific details of the algorithm (for a general regularization matrix) depend on the choice of the one dimensional solver and the selection of a method for solving the TRS. In section 6.1 we describe a specific implementation—algorithm TRTLSG. We then apply the proposed algorithm in section 6.2 to an image deblurring example.

6.1. A detailed algorithm for the TRTLS problem. We use the method of Moré and Sorensen for solving the TRS (21). The method is based on applying Newton's method to the problem

$$\frac{1}{\phi(\lambda)} - \frac{1}{\beta} = 0, \tag{57}$$

where $\phi(\lambda) \equiv \mathbf{f}^T(\mathbf{Q} - \lambda\mathbf{I})^{-1}\mathbf{f}$. The main computational effort at each iteration is the calculation of a Cholesky factorization of a matrix of the form $\mathbf{Q} - \lambda\mathbf{I}$. For large-scale problems the Cholesky factorization is not affordable, and other nondirect methods, such as Krylov subspace methods, can be employed (see, e.g., [29] and the references in [5, 7]). In our example $n = 1024$ so that Moré and Sorensen's method is appropriate.

Algorithm TRTLSG.

Input: $\mathbf{A} \in \mathbb{R}^{m\times n}, \mathbf{b} \in \mathbb{R}^m, \mathbf{L} \in \mathbb{R}^{k\times n}, \rho > 0$, and ϵ_1, ϵ_2—tolerance parameters.

Output: $\mathbf{x}^*$—a solution (up to some tolerance) of the TRTLS problem (11).

1. **Set** $\alpha_{\min} \leftarrow 1 + \epsilon_1$.
2. **If** $k = n$, **set** $\alpha_{\max}$ to be the upper bound given in Lemma 4.2; **else** $\alpha_{\max}$ is equal to the upper bound given in Theorem 4.3.
3. **While** $|\alpha_{\max} - \alpha_{\min}| > \epsilon_2$ **repeat** steps (a), (b), and (c):
   (a) **Set** $\alpha \leftarrow \frac{\alpha_{min}+\alpha_{max}}{2}$.
   (b) Solve the following TRS:

$$\min_{\|\mathbf{x}\|^2=\alpha-1} \left\{\mathbf{x}^T\mathbf{Q}_\alpha\mathbf{x} - 2\mathbf{f}_\alpha^T\mathbf{x}\right\},$$

   where $\mathbf{Q}_\alpha$ and $\mathbf{f}_\alpha$ are given in (26), and obtain a solution $\mathbf{x}(\alpha)$ and a multiplier $\lambda(\alpha)$ that satisfy conditions (22), (23), and (24) (with $\mathbf{Q} = \mathbf{Q}_\alpha, \mathbf{f}_\alpha, \mathbf{x}^* = \mathbf{x}(\alpha)$, and $\lambda^* = \lambda(\alpha)$).
   (c) **If** $\underbrace{\lambda(\alpha) - \frac{\|\mathbf{A}\mathbf{x}(\alpha) - \mathbf{b}\|^2}{\alpha^2}}_{\mathcal{G}'(\alpha)} > 0$, **then** $\alpha_{\max} = \alpha$; **else** $\alpha_{\min} = \alpha$.
4. Set $\mathbf{x}^* = \mathbf{x}(\alpha_{\max})$.

In our implementation the tolerance parameters take the values $\epsilon_1 = 10^{-1}$ and $\epsilon_2 = 10^{-6}$.

The one dimensional solver in algorithm TRTLSG is a simple bisection algorithm applied to the derivative of $\mathcal{G}(\alpha)$. To *guarantee* global convergence of the algorithm, the function $\mathcal{G}$ should be unimodal. For the case $\mathbf{L} = \mathbf{I}$ the unimodality property was proven in section 5.1. We observed through numerous random examples of the TRTLS problem of different dimensions ($4 \leq n, m, k \leq 1024$) that the unimodality property almost always holds even for $\mathbf{L} \neq \mathbf{I}$. The "bad" example in Figure 2 (with $m = n = 4, k = 3$) is an exceptional example. Moreover, for $n > 10$ we have not been able to find a single example which is not unimodal. Thus, for all practical purposes, algorithm TRTLSG finds the global optimum. If, for some reason, the function $\mathcal{G}$ is not unimodal, then algorithm TRTLSG does not necessarily converge to a global minimum and more sophisticated one dimensional global solvers should be employed.

6.2. Example. To illustrate the effectiveness of the TRTLS approach, we consider an image deblurring example. The TRTLS problems arising in this example were solved by algorithm TRTLSG implemented in MATLAB.

The choice of the regularization parameter ρ in our experiments was done by using the L-curve method [16, 21]. This method was originally devised as a method for choosing the regularization parameter for a regularized *least squares* problem. The L-curve is a plot of the L-norm $\|\mathbf{L}\mathbf{x}_\rho\|$ versus the residual $\|\mathbf{A}\mathbf{x}_\rho - \mathbf{b}\|$, where $\mathbf{x}_\rho$ is the solution of the regularization method with parameter ρ. The obtained plot usually has an L-shape appearance, and the chosen parameter is the one which is the closest to the left bottom corner. For the TLS problem, we follow the L-curve approach described in [24]: we plot the L-norm $\|\mathbf{L}\mathbf{x}_\rho\|^2$ versus the *fractional residual* $\|\mathbf{A}\mathbf{x}_\rho - \mathbf{b}\|^2/(1 + \|\mathbf{x}_\rho\|^2)$ for a various number of regularization parameters and pick the parameter closest to the L-shaped corner.

Let X be a 32×32 two dimensional image obtained from the sum of three harmonic oscillations:

$$X(z_1, z_2) = \sum_{l=1}^{3} a_i \cos(w_{l,1} z_1 + w_{l,2} z_2 + \phi_l), \quad \left(w_{l,i} = \frac{2\pi k_{l,i}}{n} \right), \ 1 \leq z_1, z_2 \leq 32,$$

where $k_{l,i} \in \mathbb{Z}^2$ (see Figure 3—true image). The specific values of the parameters are given in Table 1.

TABLE 1
Image parameters.

l	a_l	$w_{l,1}$	$w_{l,2}$	ϕ_l
1	1.3936	0.1473	0.0982	5.8777
2	0.5579	0.0982	0.0982	5.7611
3	0.8529	0.0491	0.0982	2.5778

We consider the square system

$$\mathbf{A}_{\text{true}}\mathbf{x}_{\text{true}} = \mathbf{b}_{\text{true}},$$

where $\mathbf{x}_{\text{true}} \in \mathbb{R}^{1024}$ is obtained by stacking the columns of the 32×32 image X. The vector $\mathbf{x}_{\text{true}}$ was normalized so that $\|\mathbf{x}_{\text{true}}\| = 1$. The 1024×1024 matrix $\mathbf{A}_{\text{true}}$ represents an atmospheric turbulence blur originating from [15] and implemented in the function blur(n,3) from the "Regularization Tools" [17]. The observed matrix

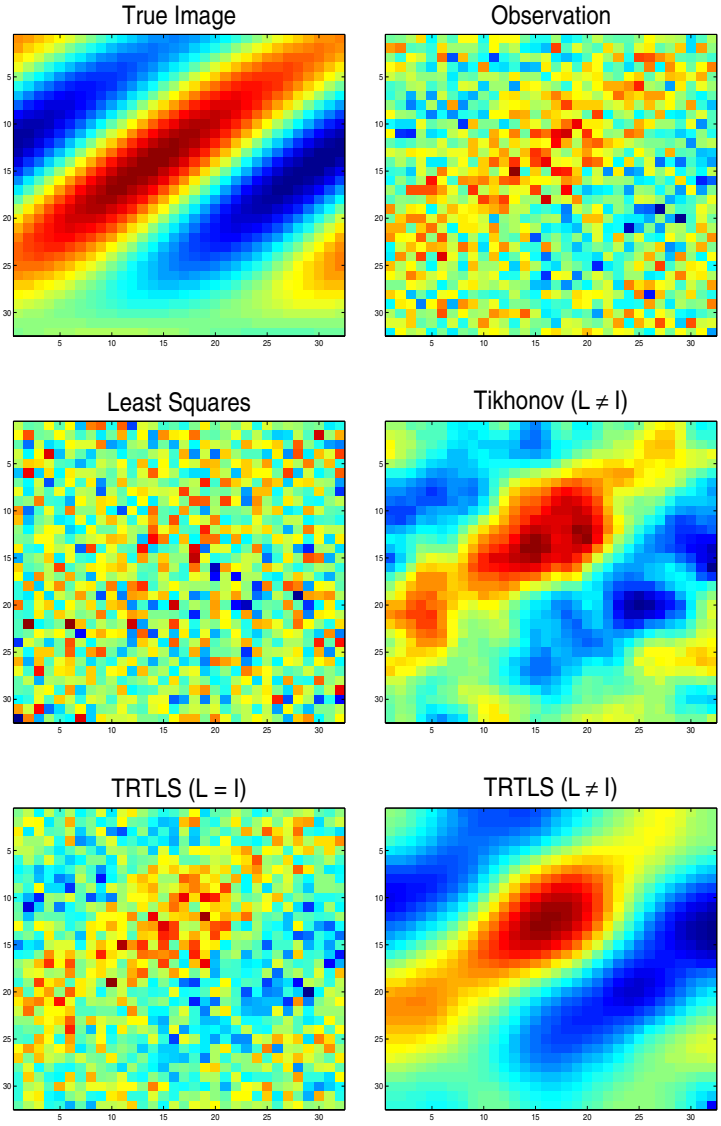


FIG. 3. *Results for different regularization solvers.*

and vector were generated by adding white noise to the data: $\mathbf{A} = \mathbf{A}_{true} + \sigma\mathbf{E}$ and $\mathbf{b} = \mathbf{b}_{\text{true}} + \sigma\mathbf{e}$, where each component of $\mathbf{E} \in \mathbb{R}^{1024\times 1024}$ and $\mathbf{e} \in \mathbb{R}^{1024}$ was generated from a standard normal distribution.

In our experiment the standard deviation σ was chosen to be 0.05, which results in a highly noisy image (see Figure 3—observation). The LS estimator was implemented in the function lsqr from [17]; it can be readily observed that it produces a poor image.

The choice of regularization matrix has a major influence on the quality of the obtained image. The solution of the TRTLS problem with *standard regularization* produces an unsatisfactory image (see Figure 3—TRTLS with $L = I$).

To produce a better result, we use a regularization matrix that accounts for the

smoothness property of this image. In particular, the matrix $\mathbf{L}$ was chosen to satisfy the relation

$$\mathbf{L}^T\mathbf{L} = \mathbf{R}^T\mathbf{R} + \mathbf{I}, \tag{58}$$

where $\mathbf{R}$ is a discrete approximation of the Laplace operator, which is a two dimensional convolution with the following mask:

$$\begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix}.$$

This operator is standard in image processing [20]. With this choice of $\mathbf{L}$, the TRTLS algorithm gave the much better image (see Figure 3—TRTLS with $L \neq I$). We also compared our results to the one obtained by the classic Tikhonov regularization of the least squares, i.e., the solution of the minimization problem

$$\min_{\mathbf{x}}\{\|\mathbf{A}\mathbf{x} - \mathbf{b}\|^2 + \rho\|\mathbf{L}\mathbf{x}\|^2\}$$

with the same regularization matrix given in (58). Tikhonov regularization of the *least squares* (see Figure 3—Tikhonov $\mathbf{L} \neq \mathbf{I}$) provides a better image than the least squares, but its quality is inferior to the one obtained by the corresponding TRTLSG algorithm.

Acknowledgment. We give special thanks to the referees for their constructive comments and suggestions.

CONSTRAINT REDUCTION FOR LINEAR PROGRAMS WITH MANY INEQUALITY CONSTRAINTS*

ANDRÉ L. TITS†, P.-A. ABSIL‡, AND WILLIAM P. WOESSNER§

Abstract. Consider solving a linear program in standard form where the constraint matrix A is $m \times n$, with $n \gg m \gg 1$. Such problems arise, for example, as the result of finely discretizing a semi-infinite program. The cost per iteration of typical primal-dual interior-point methods on such problems is $O(m^2 n)$. We propose to reduce that cost by replacing the normal equation matrix, AD^2A^T, where D is a diagonal matrix, with a "reduced" version (of same dimension), $A_Q D_Q^2 A_Q^T$, where Q is an index set including the indices of M most nearly active (or most violated) dual constraints at the current iterate, with $M \geq m$ a prescribed integer. This can result in a speedup of close to $n/|Q|$ at each iteration. Promising numerical results are reported for constraint-reduced versions of a dual-feasible affine-scaling algorithm and of Mehrotra's predictor-corrector method [S. Mehrotra, *SIAM J. Optim.*, 2 (1992), pp. 575–601]. In particular, while it could be expected that neglecting a large portion of the constraints, especially at early iterations, may result in a significant deterioration of the search direction, it appears that the total number of iterations typically remains essentially constant as the size of the reduced constraint set is decreased down to some threshold. In some cases this threshold is a small fraction of the total set. In the case of the affine-scaling algorithm, global convergence and local quadratic convergence are proved.

Key words. linear programming, constraint reduction, column generation, primal-dual interior-point methods, affine scaling, Mehrotra's predictor-corrector

1. Introduction.

Consider a primal-dual linear programming pair in standard form, i.e.,

$$\min\ c^T x \text{ subject to } Ax = b,\ x \geq 0, \tag{1.1}$$

$$\max\ b^T y \text{ subject to } A^T y + s = c,\ s \geq 0, \tag{1.2}$$

where A has dimensions $m \times n$. The dual problem is equivalently written as

$$\max\ b^T y \text{ subject to } A^T y \leq c. \tag{1.3}$$

§Department of Computer Science and Institute for Systems Research, University of Maryland, College Park, MD 20742.

Most algorithms that have been proposed for the numerical solution of such problems belong to one of two classes: simplex methods and interior-point methods. For background on such methods, see, e.g., [NS96] and [Wri97]. In both classes of algorithms, the main computational task at each iteration is the solution of a linear system of equations. In the simplex case, the system has dimension m; in the interior-point case it has dimensions $2n + m$, but can readily be reduced ("normal equations") to one of size m at the cost of forming the matrix $H := AS^{-1}XA^T$. Here S and X are diagonal but vary from iteration to iteration, and the cost of forming H, when A is dense, is of the order of m^2n operations at each iteration.

The focus of the present paper is the solution of (1.1)–(1.2) when $n \gg m \gg 1$, i.e., when there are many more variables than equality constraints in the primal, many more inequality constraints than variables in the dual. This includes fine discretizations of "semi-infinite" problems of the form

$$\max\ b^T y \text{ subject to } a(\omega)^T y \le c(\omega)\ \forall \omega \in \Omega, \tag{1.4}$$

where, in the simplest cases, Ω is an interval of the real line. Network problems may also have a disproportionately large number of inequality constraints: For many network problems in dual form, there is one variable for each node of the network and one constraint for each arc or link, so that a linear program associated with a network with m nodes could have up to $O(m^2)$ constraints. Clearly, for such problems one iteration of a standard interior-point method would be computationally much more costly than one iteration of a simplex method. On the other hand, given the large number of vertices in the polyhedral feasible set of (1.3), the number of iterations needed to approach a solution with an interior-point method is likely to be significantly smaller than that needed when a simplex method is used.

Intuitively, when $n \gg m$, most of the constraints in (1.3) are of little or no relevance. Conceivably, if an interior-point search direction were computed based on a much smaller problem, with only a small subset of the constraints, significant progress could still be made toward a solution, provided this subset were astutely selected. Motivated by such consideration, in the present paper we aim at devising interior-point methods for the solution of (1.1)–(1.2) with $n \gg m \gg 1$, with drastically reduced computational cost per iteration. In a sense, such an algorithm would combine the best aspects of simplex methods and interior-point methods in the context of problems for which $n \gg m \gg 1$: each iteration would be effected at low computational cost, yet the iterates would follow an "interior" trajectory rather than being constrained to proceed along edges.

The issue of computing search directions for linear programs of the form (1.3) with $n \gg m$—or for semi-infinite linear programs (with a continuum of inequality constraints)—based on a small subset of the constraints has been an active area of research for many years. In most cases, the proposed schemes are based on logarithmic barrier ("primal") interior-point methods. In one approach, known as "column generation" (for the A matrix) or "build-up" (see, e.g., [Ye92, dHRT92, GLY94, Ye97]), constraints are added to (but never deleted from) the constraint set iteratively as they are deemed critical. In particular, the scheme studied in [Ye97] allows for more than one constraint (column) to be added at each step, and it is proved that the algorithm terminates in polynomial time with a bound whose dependence on the constraints is limited to those that are eventually included in the constraint set. In [Ye92, GLY94, Ye97], in the spirit of cutting-plane methods, the successive iterates are infeasible for (1.3) and the algorithm stops as soon as a feasible point is achieved;

while in the approach proposed in [dHRT92] all iterates are feasible for (1.3). Another approach is the "build-down" process (e.g., [Ye90]) by which columns of A are discarded when it is determined that the corresponding constraints are guaranteed not to be active at the solution. Both build-up [dHRT92] and build-down [Ye90] approaches were subsequently combined in [dHRT94], and a complexity analysis for the semi-infinite case was carried out in [LRT99].

In the present paper, a constraint reduction scheme is proposed in the context of *primal-dual* interior-point methods. Global and local quadratic convergence are proved in the case of a primal-dual affine-scaling (PDAS) method. (An early version of this analysis appeared in [Tit99].) Distinctive merits of the proposed scheme are its simplicity and the fact that it can be readily incorporated into other primal-dual interior-point methods. In the scheme's simplest embodiment, the constraint set is determined "from scratch" at the beginning of each iteration, rather than being updated in a build-up/build-down fashion. Promising numerical results are reported with constraint-reduced versions of the PDAS method and of Mehrotra's predictor-corrector (MPC) algorithm [Meh92]. Strikingly, while (consistent with conventional wisdom) the unreduced version of MPC significantly outperformed that of PDAS in our random experiments, the reduced version of PDAS performed essentially at the same level, in terms of CPU time, as that of MPC.

The remainder of the paper is organized as follows. In section 2, the basics of primal-dual interior-point methods are reviewed and the computational cost per iteration is analyzed, with special attention paid to possible gains to be achieved in certain steps by ignoring most constraints. Section 3 contains the heart of this paper's contribution. There, a dual-feasible PDAS algorithm is proposed that features a constraint-reduction scheme. Global and local quadratic convergence of this algorithm are proved, and numerical results are reported that suggest that, even with a simplistic implementation, the constraint-reduction scheme may lead to significant speedup. In section 4, promising numerical results are reported for a similarly reduced MPC algorithm, both with a dual-feasible initial point and with an infeasible initial point. Finally, section 5 is devoted to concluding remarks.

2. Preliminaries. Let

$$\mathbf{n} := \{1, 2, \ldots, n\};$$

for $i \in \mathbf{n}$, let $a_i \in \mathbb{R}^m$ denote the ith column of A; let F be the feasible set for (1.3), i.e.,

$$F := \{y : A^T y \leq c\},$$

and let $F^{\mathrm{o}} \subseteq \mathbb{R}^m$ denote the dual strictly feasible set

$$F^{\mathrm{o}} := \{y : A^T y < c\}.$$

Also, given $y \in F$, let $I(y)$ denote the index set of active constraints at y, i.e.,

$$I(y) := \{i \in \mathbf{n} : a_i^T y = c_i\}.$$

Given any index set $Q \subseteq \mathbf{n}$, let A_Q denote the $m \times |Q|$ matrix obtained from A by deleting all columns a_i with $i \notin Q$; similarly let x_Q and s_Q denote the vectors of size $|Q|$ obtained from x and s by deleting all entries x_i and s_i with $i \notin Q$. Further, following standard practice, let X denote $\mathrm{diag}(x_i, i \in \mathbf{n})$, and S denotes $\mathrm{diag}(s_i, i \in \mathbf{n})$.

When subscripts, superscripts, or diacritical signs are attached to x and s, they are inherited by x_Q, s_Q, X, and S. The rest of the notation is standard. In particular, $\|\cdot\|$ denotes the Euclidean norm.

Primal-dual interior-point algorithms use search directions based on the Newton step for the solution of the equalities in the Karush–Kuhn–Tucker (KKT) conditions for (1.2), or a perturbation thereof, while maintaining positivity of x and s. Given $\mu > 0$, the perturbed KKT conditions of interest are

$$A^T y + s - c = 0, \tag{2.1a}$$

$$Ax - b = 0, \tag{2.1b}$$

$$Xs = \mu e, \tag{2.1c}$$

$$x, s \geq 0, \tag{2.1d}$$

with $\mu = 0$ yielding the true KKT conditions. Given a current guess (x, y, s), the Newton step of interest is the solution to the linear system

$$\begin{bmatrix} 0 & A^T & I \\ A & 0 & 0 \\ S & 0 & X \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \\ \Delta s \end{bmatrix} = \begin{bmatrix} -r_c \\ -r_b \\ -Xs + \mu e \end{bmatrix}, \tag{2.2}$$

where

$$r_b := Ax - b, \quad r_c := A^T y + s - c$$

are the primal and dual *residuals*. Applying block Gaussian elimination to eliminate Δs yields the system (usually referred to as "augmented system")

$$\begin{bmatrix} 0 & A \\ XA^T & -S \end{bmatrix} \begin{bmatrix} \Delta y \\ \Delta x \end{bmatrix} = \begin{bmatrix} -r_b \\ -Xr_c + Xs - \mu e \end{bmatrix}, \tag{2.3a}$$

$$\Delta s = -A^T \Delta y - r_c. \tag{2.3b}$$

With $s > 0$, further elimination of Δx results in the "normal equations"

$$AS^{-1}XA^T \Delta y = -r_b + A(-S^{-1}Xr_c + x - \mu S^{-1}e), \tag{2.4a}$$

$$\Delta s = -A^T \Delta y - r_c, \tag{2.4b}$$

$$\Delta x = -x + \mu S^{-1}e - S^{-1}X\Delta s. \tag{2.4c}$$

Note that (2.4a) is equivalently written as

$$AS^{-1}XA^T \Delta y = b - AS^{-1}(Xr_c + \mu e).$$

For ease of reference, define the Jacobian and "augmented" Jacobian

$$J(A, x, s) := \begin{bmatrix} 0 & A^T & I \\ A & 0 & 0 \\ S & 0 & X \end{bmatrix}, \quad J_{\mathrm{a}}(A, x, s) := \begin{bmatrix} 0 & A \\ XA^T & -S \end{bmatrix}. \tag{2.5}$$

The following result is proven in the appendix.[1]

[1] Concerning the second claim of Lemma 1, only sufficiency is used in the convergence analysis, but the fact that the listed conditions are in fact necessary and sufficient may be of independent interest. We could not find this result (or even the sufficiency portion) in the literature, so are providing a proof for completeness. We would be grateful to anyone who would point us to a reference for the result.

LEMMA 1. *$J_a(A,x,s)$ is nonsingular if and only if $J(A,x,s)$ is. Further, suppose that $x \geq 0$ and $s \geq 0$.*[2] *Then $J(A,x,s)$ is nonsingular if and only if the following three conditions hold: (i) $|x_i| + |s_i| > 0$ for all i, (ii) $\{a_i : s_i = 0\}$ is linear independent, and (iii) $\{a_i : x_i \neq 0\}$ spans $\mathbb{R}^m$.*

In the next two sections, two types of primal-dual interior-point methods are considered: first, a dual-feasible (but primal-infeasible) PDAS algorithm, then a version of MPC. In the former, at each iteration the normal equations (2.4) are solved once, with $\mu = 0$, and $r_c = 0$. In the latter, the normal equations are solved twice per iteration with different right-hand sides.

We assume that A is dense. For large m and $n \gg m$, the bulk of the CPU cost is consumed by the solution of the normal equations (2.4). Indeed, the number of operations (per iteration) in other computations amounts to at most a small multiple of n. As for the operations involved in solving the normal equations, the operation count is roughly as follows:

- Forming $H := AS^{-1}XA^T$: m^2n;
- Forming $v := b - AS^{-1}(Xr_c + \mu e)$: $2mn$;
- Solving $H\Delta y = v$ (Cholesky factorization): $m^3/3$;
- Computing $\Delta s := -A^T\Delta y - r_c$: $2mn$;
- Computing $\Delta x := -x + S^{-1}(-X\Delta s + \mu e)$: $2n$.

(Because both algorithms we consider update y and s by taking a common step $\hat{t}$ along Δy and Δs, r_c is updated at no cost: the new value is $(1 - \hat{t})$ times the old value.)

The above suggests that maximum CPU savings should be obtained by replacing, in the definition of H, matrix A by its submatrix A_Q, corresponding to a suitably chosen index set Q. The cost of forming H would then be reduced to $m^2|Q|$ operations. In this paper, we investigate the effect of making that modification only, and leaving all else unchanged, so as to least "perturb" the original algorithms.

A central issue is then the choice of Q. Given $y \in \mathbb{R}^m$ and $M \geq m$, let $\mathcal{Q}_M(y)$ be the set of all subsets of $\mathbf{n}$ that contain the indexes of M leftmost components of $c - A^Ty$. More precisely (some components of $c - A^Ty$ may be equal, so "M leftmost" may not be uniquely defined), let

(2.6)
$$\mathcal{Q}_M(y) := \{Q \subseteq \mathbf{n} : \exists Q' \subseteq Q \text{ s.t. } |Q'| = M \text{ and } c_i - a_i^Ty \leq c_j - a_j^Ty \ \forall i \in Q', j \notin Q'\}.$$

Consequently, the statement "$Q \in \mathcal{Q}_M(y)$," to be used later, means that the index set Q contains the indices of M components of the vector $c - A^Ty$ that are smaller or equal to all other components of $c - A^Ty$. The convergence analysis of section 3.2 guarantees that our reduced PDAS algorithm will perform appropriately (under certain assumptions involving M) as long as Q is in $\mathcal{Q}_M(y)$. Given that $n \gg m$, this leaves a lot of leeway in choosing Q. We have two competing goals. On the one hand, we want $|Q|$ to be small enough that the iterations are significantly faster than when $Q = \mathbf{n}$. On the other hand, we want to include enough well chosen constraints that the iteration count remains low. In the numerical experiments we report toward the end of this paper, we restrict ourselves to a very simple scheme: we let Q be precisely the set of indexes of M leftmost components of $c - A^Ty$. Note that the "M leftmost" rule is inexpensive to apply: it takes at most $O(n \log n)$ operations—comparisons,

[2] The result still holds, and the same proof applies, under the milder but less intuitive assumption "$x_is_i \geq 0$ for all i." The result as stated is sufficient for our present purpose.

which are faster than additions or multiplications. (For small M, it takes even fewer comparisons.)

The following assumption will be needed in order for the proposed algorithms to be well defined.

ASSUMPTION 1. *All $m \times M$ submatrices of A have full row rank.*

LEMMA 2. *Suppose Assumption 1 holds. Let $x > 0$, $s > 0$, and $Q \subseteq \mathbf{n}$ with $|Q| \geq M$. Then $A_Q S_Q^{-1} X_Q A_Q^T$ is positive definite.*

Proof. Follows from positive definiteness of $S_Q^{-1} X_Q$ and full row rank of A_Q. ∎

3. A reduced, dual-feasible PDAS algorithm.

3.1. Algorithm statement. The proposed reduced primal-dual interior-point affine scaling (rPDAS) iteration is strongly inspired from the iteration described in [TZ94], a dual-feasible primal-dual iteration based on the Newton system discussed above, with $\mu = 0$ and $r_c = 0$. In particular, the normal equations for the algorithm of [TZ94] are given by

$$AS^{-1}XA^T\Delta y = b, \tag{3.1a}$$

$$\Delta s = -A^T\Delta y, \tag{3.1b}$$

$$\Delta x = -x - S^{-1}X\Delta s. \tag{3.1c}$$

The iteration focuses on the dual variables. Note that the iteration requires the availability of an initial $y^0 \in F^o$.

Iteration rPDAS.

Parameters. $\beta \in (0,1)$, $x_{\max} > 0$, $\underline{x} > 0$, integer M satisfying $m \leq M \leq n$.

Data. $y \in F^o$, $s := c - A^T y$, $x > 0$, with $x_i \leq x_{\max}$, $i = 1, \ldots, n$, $Q \in \mathcal{Q}_M(y)$.

Step 1. Compute search direction:

$$\text{Solve} \quad A_Q S_Q^{-1} X_Q A_Q^T \Delta y = b, \tag{3.2a}$$

$$\text{and compute} \qquad \Delta s := -A^T\Delta y, \tag{3.2b}$$

$$\Delta x := -x - S^{-1}X\Delta s. \tag{3.2c}$$

Set $\tilde{x} := x + \Delta x$ and, for $i \in \mathbf{n}$, set

$$(\tilde{x}_-)_i := \min\{\tilde{x}_i, 0\}.$$

Step 2. Updates:

(i) Compute the largest dual feasible step size

$$\bar{t} := \begin{cases} \infty & \text{if } \ \Delta s_i \geq 0 \ \ \forall i \in \mathbf{n}, \\ \min\{(-s_i/\Delta s_i) : \Delta s_i < 0, i \in \mathbf{n}\} & \text{otherwise.} \end{cases} \tag{3.3}$$

Set

$$\hat{t} := \min\{\max\{\beta\bar{t},\ \bar{t}\text{–}\|\Delta y\|\},\ 1\}. \tag{3.4}$$

Set $y^+ := y + \hat{t}\Delta y$, $s^+ := s + \hat{t}\Delta s$.

(ii) Set

$$x_i^+ := \min\{\max\{\min\{\|\Delta y\|^2 + \|\tilde{x}_-\|^2, \underline{x}\},\ \tilde{x}_i\},\ x_{\max}\}\ \forall i \in \mathbf{n}. \tag{3.5}$$

(iii) Pick $Q^+ \in \mathcal{Q}_M(y)$.

It should be noted that $(\Delta x_Q, \Delta y, \Delta s_Q)$ constructed by Iteration rPDAS also satisfies

$$\Delta s_Q = -A_Q^T \Delta y, \tag{3.6a}$$

$$\Delta x_Q = -x_Q - S_Q^{-1} X_Q \Delta s_Q, \tag{3.6b}$$

i.e., it satisfies the full set of normal equations associated with the constraint-reduced system. Equivalently, they satisfy the Newton system (with $\mu = 0$ and $r_c = 0$)

$$\begin{bmatrix} 0 & A_Q^T & I \\ A_Q & 0 & 0 \\ S_Q & 0 & X_Q \end{bmatrix} \begin{bmatrix} \Delta x_Q \\ \Delta y \\ \Delta s_Q \end{bmatrix} = \begin{bmatrix} 0 \\ b - A_Q x_Q \\ -X_Q s_Q \end{bmatrix}. \tag{3.7}$$

Remark 1. Primal update rule (3.5) is identical to the "dual" update rule used in [AT06] in the context of indefinite quadratic programming. (The "primal" problem in [AT06] can be viewed as a direct generalization of the *dual* (1.3).) As explained in [AT06], imposing the lower bound $\|\Delta y\|^2 + \|\tilde{x}_-\|^2$, which is a key to our global convergence analysis, precludes updating of x by means of a step in direction Δx; further, the specific form of this lower bound simplifies the global convergence analysis while, together with the bound $\bar{t} - \|\Delta y\|$ in (3.4), allowing for a quadratic convergence rate. Also key to our global convergence analysis (though in our experience not needed in practice) is the upper bound $x_{\max}$ imposed on all components of the primal variable x; it should be stressed that global convergence of the sequence of vectors $\tilde{x}$ to a solution is guaranteed regardless of the value of $x_{\max} > 0$. Finally, replacing in (3.5) $\min\{\|\Delta y\|^2 + \|\tilde{x}_-\|^2, \underline{x}\}$ simply with $\|\Delta y\|^2 + \|\tilde{x}_-\|^2$ would not affect the theoretical convergence properties of the algorithm. However, allowing small values of x_i^+ even when $\|\Delta y\|^2 + \|\tilde{x}_-\|^2$ is large proved beneficial in practice, especially in early iterations.

3.2. Convergence analysis. Before embarking on a convergence analysis, we introduce two more definitions. First, let $F^* \subseteq \mathbb{R}^m$ be the set of solutions of (1.3), i.e.,

$$F^* := \{y^* \in F : b^T y^* \geq b^T y \ \forall y \in F\}.$$

Of course, F^* is the set of y for which (2.1) holds with $\mu = 0$ for some $x, s \in \mathbb{R}^n$. Second, given $y \in F$, we will say that y is *stationary* for (1.3) whenever there exists $x \in \mathbb{R}^n$ such that

$$Ax = b \tag{3.8}$$

and

$$X(c - A^T y) = 0, \tag{3.9}$$

with no sign constraint imposed on x; equivalently, with $s := c - A^T y$ (≥ 0), (2.1a)–(2.1c) hold with $\mu = 0$ for some $x \in \mathbb{R}^n$. We will refer to such x as a *multiplier vector* associated with y. Clearly, every point in F^* is stationary, but not all stationary points are in F^*: in particular, all vertices of F are stationary.

3.2.1. Global convergence. We now show that, under certain nondegeneracy assumptions, the sequence of dual iterates generated by Iteration rPDAS converges to F^*. First, on the basis of Lemma 2, it is readily verified that, under Assumption 1, Iteration rPDAS is well defined. That it can be repeated *ad infinitum* then follows from the next proposition.

PROPOSITION 3. *Suppose Assumption* 1 *holds. Then Iteration rPDAS generates quantities with the following properties:* (i) $\Delta y \neq 0$ *if and only if* $b \neq 0$*;* (ii) $\hat{t} > 0$*,* $y^+ \in F^o$*,* $s^+ = c - A^T y^+ > 0$*, and* $x^+ > 0$*.*

Proof. The first claim is a direct consequence of Lemma 2 and (3.2a); the other claims are immediate. ∎

Now, let $y^0 \in F^o$, let $s^0 = c - A^T y^0$, let $x^0 > 0$, $Q^0 \subseteq \mathbf{n}$ with $|Q^0| \geq M$, and let $\{(x^k, y^k, s^k)\}$, $\{Q^k\}$, $\{\Delta y^k\}$, $\{\tilde{x}^k\}$, $\{\bar{t}^k\}$, and $\{\hat{t}^k\}$ be generated by successive applications of Iteration rPDAS starting at (x^0, y^0, s^0). Our analysis focuses on the dual sequence $\{y^k\}$.

In view of Proposition 3, $s^k = c - A^T y^k > 0$ for all k, so $y^k \in F^o$ for all k. We first note that, under no additional assumptions, the sequence of dual objective values is monotonic nondecreasing, strictly so if $b \neq 0$. This fact plays a central role in our global convergence analysis.

LEMMA 4. *Suppose Assumption* 1 *holds. If* $b \neq 0$*, then* $b^T \Delta y^k > 0$ *for all* k*. In particular,* $\{b^T y\}$ *is nondecreasing.*

Proof. The claim follows from (3.2a), Lemma 2, Proposition 3, and Step 2(i) of Iteration rPDAS. ∎

The remainder of the global convergence analysis is carried out under two additional assumptions. The first one implies that $\{y^k\}$ is bounded.

ASSUMPTION 2. *The dual solution set* F^* *is nonempty and bounded.*

Equivalently, the superlevel sets $\{y \in F : b^T y \geq \alpha\}$ are bounded for all α. Boundedness of $\{y^k\}$ then follows from its feasibility and monotonicity of $\{b^T y^k\}$ (Lemma 4 and Step 2(i) of Iteration rPDAS).

LEMMA 5. *Suppose Assumptions* 1 *and* 2 *hold; then* $\{y^k\}$ *is bounded.*

Our final nondegeneracy assumption ensures that small values of $\|\Delta y^k\|$ indicate that a stationary point of (1.3) is being approached (Lemma 6).

ASSUMPTION 3. *For all* $y \in F$*,* $\{a_i : i \in I(y)\}$ *is a linear independent set of vectors.*

LEMMA 6. *Suppose Assumptions* 1 *and* 3 *hold. Let* $y^* \in \mathbb{R}^m$ *and suppose that* K*, an infinite index set, is such that* $\{y^k\}$ *converges to* y^* *on* K*. If* $\{\Delta y^k\}$ *converges to zero on* K*, then* y^* *is stationary and* $\{\tilde{x}^k\}$ *converges to* x^* *on* K*, where* x^* *is the unique multiplier vector associated with* y^**.*

Proof. Suppose $\{\Delta y^k\} \to 0$ as $k \to \infty$, $k \in K$. Without loss of generality (by going down to a further subsequence if necessary), assume that, for some Q^*, $Q_k = Q^*$ for all $k \in K$. Equation (3.7) implies that

$$A_{Q^*} \tilde{x}^k_{Q^*} - b = 0 \quad \forall k \in K, \tag{3.10}$$

and (3.2b)–(3.2c) yield

$$x^k_i a_i^T \Delta y^k - s^k_i \tilde{x}^k_i = 0 \quad \forall i, \forall k. \tag{3.11}$$

Let $s^* = c - A^T y^*$, so $s^k \to s^*$ as $k \to \infty$, $k \in K$. Since $\{x^k\}$ is bounded ($x^k_i \in [0, x_{\max}]$ $\forall i$ by construction), it follows from (3.11) that for all $i \notin I(y^*)$ (i.e., all i for which $s^*_i > 0$), $\{\tilde{x}^k_i\} \to 0$ as $k \to \infty$, $k \in K$. Now, in view of Assumption 3 (linear

independence of the active constraints), $|I(y^*)| \leq m$ and, since $Q^k \in \mathcal{Q}_M(y^k)$ for all k, $M \geq m$, $I(y^*) \subseteq Q^*$. Hence, (3.10) yields

$$\sum_{i \in I(y^*)} \tilde{x}_i^k a_i - b \to 0 \text{ as } k \to \infty,\ k \in K,$$

and Assumption 3 implies that, for all $i \in I(y^*)$, $\{\tilde{x}_i^k\}$ converges on K, say, to x_i^*. Taking limits in (3.10)–(3.11) then yields

$$Ax^* - b = 0,$$

$$X^* s^* = 0,$$

implying that y^* is stationary, with multiplier vector x^*. Uniqueness of x^* again follows from Assumption 3. □

Proving that $\{y^k\}$ converges to F^* will be achieved in two main steps. The first objective is to show that $\{y^k\}$ converges to the set of *stationary points* of (1.3) (Lemma 9). This will be proved via a contradiction argument: if, for some infinite index set K, $\{y^k\}$ were to converge on K to a *nonsolution* point—for instance, to a nonstationary point—then $\{\Delta y^k\}$ would have to go to zero on K (Lemma 8), in contradiction with Lemma 6. The heart of the argument lies in the following lemma.

LEMMA 7. *Suppose Assumptions* 1, 2, *and* 3 *hold. Let K be an infinite index set such that*

$$\inf\{\|\Delta y^{k-1}\|^2 + \|\tilde{x}_-^{k-1}\|^2 :\ k \in K\} > 0.$$

Then $\{\Delta y^k\} \to 0$ as $k \to \infty,\ k \in K$.

Proof. In view of (3.5), for all $i \in \mathbf{n}$, x_i^k is bounded away from zero on K. Proceeding by contradiction, assume that, for some infinite index set $K' \subseteq K$, $\inf_{k \in K'} ||\Delta y^k|| > 0$. Since $\{y^k\}$ (see Lemma 5) and $\{x^k\}$ (see (3.5)) are bounded, we may assume, without loss of generality, that for some y^* and x^*, with $x_i^* > 0$ for all i, and some Q^* with $|Q^*| \geq M$,

$$\{y^k\} \to y^* \text{ as } k \to \infty, \quad k \in K',$$

$$\{x^k\} \to x^* \text{ as } k \to \infty, \quad k \in K',$$

and

$$Q^k = Q^* \quad \forall k \in K'.$$

Let $s^* := c - A^T y^*$; since $s^k = c - A^T y^k$ for all k, it follows that $\{s^k\} \to s^*$, $k \in K'$. Since in view of Lemma 1, of Assumptions 1 and 3, and of the fact that $x_i^* > 0$ for all i, the matrix $J(A_{Q^*}, x_{Q^*}^*, s_{Q^*}^*)$ is nonsingular, it follows from (3.7) that, for some v^* and $\tilde{x}_i^*$, $i \in Q^*$, with $v^* \neq 0$ (since $\inf_{k \in K'} \|\Delta y^k\| > 0$),

$$\{\Delta y^k\} \to v^* \text{ as } k \to \infty, \quad k \in K',$$

$$\{x_i^k\} \to \tilde{x}_i^* \text{ as } k \to \infty, \quad k \in K', \quad i \in Q^*.$$

In view of linear independence Assumption 3, since $\{s^k\} \to s^* = c - A^T y^*$, and since, by definition of $\mathcal{Q}_M$, $I(y^*) \subseteq Q^*$, it follows that s_i^k is bounded away from zero when $i \notin Q^*$, $k \in K'$. It then follows from (3.2b) and (3.2c) that, for some $\tilde{x}^*$,

$$\{\tilde{x}^k\} \to \tilde{x}^* \text{ as } k \to \infty, \quad k \in K'. \tag{3.12}$$

Now, Step 2(i) of Iteration rPDAS and (3.2c) yield

$$\bar{t}^k = -\frac{s_{i_k}^k}{\Delta s_{i_k}^k} = \frac{x_{i_k}^k}{\tilde{x}_{i_k}^k} \quad \text{for some } i_k,$$

for all $k \in K'$ such that $\bar{t}^k < \infty$. Since the components of $\{x^k\}$ are bounded away from zero on K' (since $x_i^* > 0$ for all i), it follows from (3.12) that $\bar{t}^k$ is bounded away from zero on K', and from Step 2(i) in Iteration rPDAS that the same holds for $\hat{t}^k$. Thus, for some $\underline{t} > 0$, $\hat{t}^k \geq \underline{t}$ for all $k \in K'$. Also, (3.2b)–(3.2c) yield, for all k,

$$\tilde{x}^k = (S^k)^{-1} X^k A^T \Delta y^k \tag{3.13}$$

which together with (3.2)(a) yields

$$b^T \Delta y^k = (\Delta y^k)^T A_{Q^k} X_{Q^k}^k (S_{Q^k}^k)^{-1} A_{Q^k}^T \Delta y^k = (\tilde{x}_{Q^k}^k)^T A_{Q^k}^T \Delta y^k \quad \forall k. \tag{3.14}$$

In view of Lemma 4, it follows that

$$b^T y^{k+1} = b^T (y^k + \hat{t}^k \Delta y^k) \geq b^T y^k + \underline{t} b^T \Delta y^k = b^T y^k + \underline{t} (A_{Q^k} \tilde{x}_{Q^k}^k)^T \Delta y^k \quad \forall k \in K'. \tag{3.15}$$

Now, since $v^* \neq 0$ and $|Q^*| \geq M$, it follows from Assumption 1 that $A_{Q^*}^T v^* \neq 0$. Further, taking limits in (3.13) as $k \to \infty$, $k \in K'$, we get

$$X_{Q^*}^* A_{Q^*}^T v^* - S_{Q^*}^* \tilde{x}_{Q^*}^* = 0.$$

Positivity of x_i^* and nonnegativity of s_i^* for all i then imply that $\left(\tilde{x}_{Q^*}^*\right)_i$ and $(A_{Q^*}^T v^*)_i$ have the same sign whenever the latter is nonzero, in which case the former is nonzero as well. It follows that $(\tilde{x}_{Q^*}^*)^T A_{Q^*}^T v^* > 0$. Thus there exists $\delta > 0$ such that $(A_{Q^*} \tilde{x}_{Q^*}^k)^T (\Delta y^k) > \delta$ for k large enough, $k \in K'$. Since, in view of Lemma 4, $\{b^T y^k\}$ is monotonic nondecreasing, it follows from (3.15) that $b^T y^k \to \infty$ as $k \to \infty$, a contradiction since y^k is bounded. ∎

LEMMA 8. *Suppose Assumptions* 1, 2, *and* 3 *hold. Suppose there exists an infinite index set K such that $\{y^k\}$ is bounded away from F^* on K. Then $\{\Delta y^k\}$ goes to zero on K.*

Proof. Let us again proceed by contradiction, i.e., suppose $\{\Delta y^k\}$ does not converge to zero as $k \to \infty$, $k \in K$. In view of Lemma 7, there exists an infinite index set $K' \subseteq K$ such that

$$\tilde{x}_-^{k-1} \to 0 \text{ as } k \to \infty, \ k \in K' \tag{3.16}$$

and

$$\Delta y^{k-1} \to 0 \text{ as } k \to \infty, \ k \in K'. \tag{3.17}$$

Further, since $\{y^k\}$ is bounded, and bounded away from F^*, there is no loss of generality in assuming that, for some $y^* \notin F^*$, $\{y^k\} \to y^*$ as $k \to \infty$, $k \in K'$.

Since $\|y^k - y^{k-1}\| = \|\hat{t}^{k-1}\Delta y^{k-1}\| \leq \|\Delta y^{k-1}\|$, it follows that $\{y^{k-1}\} \to y^*$ as $k \to \infty$, $k \in K'$ which implies, in view of (3.17) and of Lemma 6, that y^* is stationary and $\{\tilde{x}^{k-1}\} \to x^*$ as $k \to \infty$, $k \in K'$, where x^* is the corresponding multiplier vector. From (3.16) it follows that $x^* \geq 0$, thus that $y^* \in F^*$, a contradiction. ∎

LEMMA 9. *Suppose Assumptions* 1, 2, *and* 3 *hold. Then* $\{y^k\}$ *converges to the set of stationary points of* (1.3).

Proof. Suppose the claim does not hold. Because $\{y^k\}$ is bounded, there exist an infinite index set K and some nonstationary y^* such that $y^k \to y^*$ as $k \to \infty$, $k \in K$. By Lemma 6, $\{\Delta y^k\}$ does not converge to zero on K. This contradicts Lemma 8. ∎

We are now ready to embark on the final step in the global convergence analysis: prove convergence of $\{y^k\}$ to the *solution set* for (1.3). The key to this result is Lemma 11, which establishes that the multiplier vectors associated with all limit points of $\{y^k\}$ are the same. Thus, let

$$L := \left\{y \in \mathbb{R}^m : y \text{ is a limit point of } \{y^k\}\right\}.$$

(In view of Lemma 9, every $y \in L$ is a stationary point of (P).) The set L is bounded (since $\{y^k\}$ is bounded) and, as a limit set, it is closed, and thus compact. We first prove an auxiliary lemma.

LEMMA 10. *Suppose Assumptions* 1, 2, *and* 3 *hold. If* $\{y^k\}$ *is bounded away from* F^*, *then* L *is connected.*

Proof. Suppose the claim does not hold. Since L is compact, there must exist compact sets $E_1, E_2 \subset \mathbb{R}^n$, both nonempty, such that $L = E_1 \cup E_2$ and $E_1 \cap E_2 = \emptyset$. Thus $\delta := \min_{y \in E_1, y' \in E_2} \|y - y'\| > 0$. A simple contradiction argument based on the fact that $\{y^k\}$ is bounded shows that, for k large enough, $\min_{y \in L} \|y^k - y\| \leq \delta/3$, i.e., either $\min_{y \in E_1} \|y^k - y\| \leq \delta/3$ or $\min_{y \in E_2} \|y^k - y\| \leq \delta/3$. Moreover, since both E_1 and E_2 are nonempty (i.e., contain limit points of $\{y^k\}$), each of these situations occurs infinitely many times. Thus $K := \{k : \min_{y \in E_1} \|y^k - y\| \leq \delta/3, \min_{y \in E_2} \|y^{k+1} - y\| \leq \delta/3\}$ is an infinite index set and $\|\Delta y^k\| \geq \delta/3 > 0$ for all $k \in K$. In view of Lemma 8, this is a contradiction. ∎

LEMMA 11. *Suppose Assumptions* 1, 2, *and* 3 *hold. Suppose* $\{y^k\}$ *is bounded away from* F^*. *Let* $y, y' \in L$. *Let* x *and* x' *be the associated multiplier vectors. Then* $x = x'$.

Proof. Given any $y \in L$, let $x(y)$ be the multiplier vector associated with y, let $s(y) = c - A^T y$, and let $J(y)$ be the index set of "binding" constraints at y, i.e.,

$$J(y) = \{i \in \mathbf{n} : x_i(y) \neq 0\}.$$

We first show that, if $y, y' \in L$ are such that $J(y) = J(y')$, then $x(y) = x(y')$. Indeed, from (2.1b),

$$\sum_{j \in J(y)} x_j(y) a_j = b = \sum_{j \in J(y)} x_j(y') a_j,$$

and the claim follows from linear independence Assumption 3. To conclude the proof, we show that, for any $y, y' \in L$, $J(y) = J(y')$. Let $\tilde{y} \in L$ be arbitrary and let $E_1 := \{y \in L : J(y) = J(\tilde{y})\}$ and $E_2 := \{y \in L : J(y) \neq J(\tilde{y})\}$. We show that both E_1 and E_2 are closed. Let $\{\xi^\ell\} \subseteq L$ be a convergent sequence, say to $\hat{\xi}$, such that $J(\xi^\ell) = J$ for all ℓ, for some J. It follows from the first part of this proof that $x(\xi^\ell) = x$ for all ℓ for some x. Now, for all ℓ, $s_j(\xi^\ell) = 0$ for all j such that $x_j \neq 0$, so

that $s_j(\hat{\xi}) = 0$ for all j such that $x_j \neq 0$. Thus $J \subseteq I(\hat{\xi})$, and from linear independence Assumption 3 it follows that $x(\hat{\xi}) = x$ and thus $J(\hat{\xi}) = J$. Also, since L is closed, $\hat{\xi} \in L$. Thus, if $\{\xi^\ell\} \subseteq E_1$, then $\hat{\xi} \in E_1$ and, if $\{\xi^\ell\} \subseteq E_2$, then $\hat{\xi} \in E_2$, proving that both E_1 and E_2 are closed. Since E_1 is nonempty (it contains $\tilde{y}$), connectedness of L (Lemma 10) implies that E_2 is empty. Thus $J(y) = J(\tilde{y})$ for all $y \in L$, and the proof is complete. ∎

With all the tools in hand, we present the final theorem of this section. The essence of its proof is that if $\{y_k\}$ does not converge to F^*, complementary slackness will not be satisfied.

THEOREM 12. *Suppose Assumptions* 1, 2, *and* 3 *hold. Then* $\{y^k\}$ *converges to* F^*.

Proof. Proceeding again by contradiction, suppose that some limit point of $\{y^k\}$ is not in F^* and thus, since $y^k \in F$ for all k and since, in view of the monotonicity of $\{b^T y^k\}$ (Lemma 4), $b^T y^k$ takes on the same value at all limit points of $\{y^k\}$, that $\{y^k\}$ is bounded away from F^*. In view of Lemma 8, $\{\Delta y^k\} \to 0$. Let x^* be the common multiplier vector associated with all limit points of $\{y^k\}$ (see Lemma 11). A simple contradiction argument shows that Lemma 6 then implies that $\{\tilde{x}^k\} \to x^*$. Since $\{y^k\}$ is bounded away from F^*, $x^* \not\geq 0$. Let i_0 be such that $x^*_{i_0} < 0$. Then $\tilde{x}^k_{i_0} < 0$ for all k large enough. The definition of $\tilde{x}^k$ in Step 1 of Iteration rPDAS, together with (3.2c), then implies that $\Delta s^k_{i_0} > 0$ for k large enough, and it then follows from the update rule for s^k in Step 2(i) that, for k large enough,

$$0 < s^k_{i_0} < s^{k+1}_{i_0} < \cdots .$$

On the other hand, since $x^*_{i_0} < 0$, complementary slackness (3.9) implies that $(c - A^T\hat{y})_{i_0} = 0$ for all limit points $\hat{y}$ of $\{y^k\}$ and thus, since $\{y^k\}$ is bounded, $\{s^k_{i_0}\} \to 0$. This is a contradiction. ∎

3.2.2. Local rate of convergence. We prove q-quadratic convergence of the pair (x^k, y^k) (when $x_{\max}$ is large enough) under one additional assumption, which supersedes Assumption 2. (A sequence $\{z^k\}$ is said to converge q-quadratically to z^* if it converges to z^* and there exists a constant θ such that $\|z^{k+1} - z^*\| \leq \theta\|z^k - z^*\|^2$ for all k large enough.)

ASSUMPTION 4. *The dual solution set* F^* *is a singleton.*

Let y^* denote the unique solution to (1.3), i.e., $F^* = \{y^*\}$, let $s^* := c - A^T y^*$, and let x^* be the corresponding multiplier vector (unique in view of Assumption 3). Of course, under Assumptions 1, 3, and 4, it follows from Theorem 12 that $\{y^k\} \to y^*$ as $k \to \infty$. Further, under Assumption 3, Assumption 4 implies that strict complementarity holds, i.e.,

$$x^*_i > 0 \quad \forall i \in I(y^*). \tag{3.18}$$

Moreover, Assumption 4 implies that

$$\operatorname{span}(\{a_i : i \in I(y^*)\}) = \mathbb{R}^m. \tag{3.19}$$

LEMMA 13. *Suppose Assumptions* 1, 3, *and* 4 *hold and let* $Q \supseteq I(y^*)$ *and* $Q^{\mathrm{c}} = \mathbf{n} \setminus Q$. *Then* $J_{\mathrm{a}}(A_Q, x^*_Q, s^*_Q)$ *and* $J(A_Q, x^*_Q, s^*_Q)$ *are nonsingular and* $A^T_{Q^{\mathrm{c}}} y^* < c_{Q^{\mathrm{c}}}$.

Proof. The last claim is immediate. Since $s^* = c - A^T y^*$, it follows from linear independence Assumption 3 that $\{a_i : s_i = 0\}$ is linear independent, hence its subset

retaining only the columns whose indices are in Q is also linear independent. The first two claims now follow directly from Lemma 1. ∎

The following preliminary result is inspired from [PTH88, Proposition 4.2].

LEMMA 14. *Suppose Assumptions* 1, 3, *and* 4 *hold. Then* (i) $\{\Delta y^k\} \to 0$; (ii) $\{\tilde{x}^k\} \to x^*$; *and* (iii) *if* $x_i^* \leq x_{\max}$ *for all* $i \in \mathbf{n}$, *then* $\{x^k\} \to x^*$.

Proof. To prove Claim (i), proceed by contradiction. Specifically, suppose that, for some infinite index set K, $\inf_{k\in K}\|\Delta y^k\| > 0$. Without loss of generality, assume that, for some Q^*, $Q^k = Q^*$ for all $k \in K$. Since $Q^* \in \mathcal{Q}_M(y^k)$ for all $k \in K$, since $\{y^k\} \to y^*$ as $k \to \infty$, and since, in view of Assumption 3, $|I(y^*)| \leq m \leq M$, it must hold that $Q^* \supseteq I(y^*)$. On the other hand, Lemma 7 implies that there exists an infinite index set $K' \subseteq K$ such that $\{\Delta y^{k-1}\}_{k\in K'}$ and $\{\tilde{x}_-^{k-1}\}_{k\in K'}$ go to zero. In view of Lemma 6 it follows that $\{\tilde{x}^{k-1}\}_{k\in K'} \to x^*$. It then follows from (3.5) that, for all i, $\{x_i^k\}_{k\in K'} \to \xi_i^* := \min\{x_i^*, x_{\max}\}$. Since $Q^* \supseteq I(y^*)$, it follows from Lemma 1, Assumption 3, (3.18), and (3.19) that $J(A_{Q^*}, \xi_{Q^*}^*, s_{Q^*}^*)$ is nonsingular. Now note that, in view of (3.7), it holds that (see (2.5))

$$J(A_{Q^k}, x_{Q^k}^k, s_{Q^k}^k) \begin{bmatrix} \tilde{x}_{Q^k}^k \\ \Delta y^k \\ \Delta s_{Q^k}^k \end{bmatrix} = \begin{bmatrix} 0 \\ b \\ 0 \end{bmatrix} \quad \forall k \in K'. \tag{3.20}$$

On the other hand, by feasibility of x^* and complementarity slackness,

$$J(A_{Q^*}, \xi_{Q^*}^*, s_{Q^*}^*) \begin{bmatrix} x_{Q^*}^* \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ b \\ 0 \end{bmatrix}. \tag{3.21}$$

From (3.20) and (3.21), nonsingularity of $J(A_{Q^*}, \xi_{Q^*}^*, s_{Q^*}^*)$ thus implies that $\{\Delta y^k\} \to 0$ as $k \to \infty$, $k \in K'$, a contradiction since $K' \subseteq K$. Claim (i) is thus proved. Claim (ii) then directly follows from Lemma 6 and Claim (iii) follows from (3.5). ∎

To prove q-quadratic convergence of $\{(y^k, x^k)\}$, the following property of Newton's method will be used. It is borrowed from [TZ94, Proposition 3.10].

PROPOSITION 15. *Let* $\Phi : \mathbb{R}^n \to \mathbb{R}^n$ *be twice continuously differentiable and let* $\hat{z} \in \mathbb{R}^n$ *be such that* $\Phi(\hat{z}) = 0$ *and* $\frac{\partial\Phi}{\partial z}(\hat{z})$ *is nonsingular. Let* $\rho > 0$ *be such that* $\frac{\partial\Phi}{\partial z}(z)$ *is nonsingular whenever* $z \in B(\hat{z}, \rho) := \{z : \|z - \hat{z}\| \leq \rho\}$. *Let* $d^{\mathrm{N}} : B(\hat{z}, \rho) \to \mathbb{R}^n$ *be the Newton increment* $d^{\mathrm{N}}(z) := -\left(\frac{\partial\Phi}{\partial z}(z)\right)^{-1}\Phi(z)$. *Then given any* $c_1 > 0$ *there exists* $c_2 > 0$ *such that the following statement holds:*

For all $z \in B(\hat{z}, \rho)$ *and* $z^+ \in \mathcal{R}^n$ *such that, for each* $i \in \{1, \ldots, n\}$, *either*

(i) $|z_i^+ - \hat{z}_i| \leq c_1\|d^{\mathrm{N}}(z)\|^2$

or

(ii) $|z_i^+ - (z_i + d_i^{\mathrm{N}}(z))| \leq c_1\|d^{\mathrm{N}}(z)\|^2$,

it holds that

$$\|z^+ - \hat{z}\| \leq c_2\|z - \hat{z}\|^2. \tag{3.22}$$

We will apply this proposition to the equality portion of the KKT conditions (2.1) (with $\mu = 0$). Eliminating s from this system of equations yields $\Phi(x, y) = 0$, with Φ given by

$$\Phi(x, y) := \begin{bmatrix} Ax - b \\ X(c - A^T y) \end{bmatrix}. \tag{3.23}$$

It is readily verified that (2.3a), with $\mu = 0$, $r_c = 0$, and s replaced by $c - A^T y$, is the Newton iteration for the solution of $\Phi(x, y) = 0$. In particular, $J_{\mathrm{a}}(A, x, c - A^T y)$ is the Jacobian of $\Phi(x, y)$.

Of course, Iteration rPDAS does not make use of the Newton direction for Φ, since it is based on a reduced set of constraints. Lemma 16 below relates the direction computed in Step 1 of Iteration rPDAS to the Newton direction.

In what follows, we use z (possibly with subscripts, superscripts, or diacritical signs) to denote (x, y) (with the same subscripts, superscripts, or diacritical signs on both x and y). Also, let

$$G^o := \{z : x > 0, y \in F^{\mathrm{o}}\}$$

and, given $z \in G^o$ and $Q \in \mathcal{Q}_M(y)$, let $\Delta x(z, Q)$, $\Delta y(z, Q)$, $x^+(z, Q)$, $y^+(z, Q)$, $\tilde{x}(z, Q)$, $\bar{t}(z, Q)$, and $\hat{t}(z, Q)$ denote the quantities defined by Iteration rPDAS, and let $\Delta z(z, Q) := (\Delta x(z, Q), \Delta y(z, Q))$ and $z^+(z, Q) := (x^+(z, Q), y^+(z, Q))$. Further, let $Q^{\mathrm{c}} := \mathbf{n} \setminus Q$, let $d^{\mathrm{N}}(z) := \Delta z(z, \mathbf{n})$ denote the Newton increment for Φ, and, given $\rho > 0$, let $B(z^*, \rho) := \{z : \|z - z^*\| \le \rho\}$. The following lemma was inspired from an idea of O'Leary [O'L04]. (Existence of $\rho > 0$ follows from Lemma 13.)

LEMMA 16. *Suppose Assumptions* 1, 3, *and* 4 *hold. Let $\rho > 0$ be such that, for all $(x, y) \in B(z^*, \rho) \cap G^o$ and for all $Q \in \mathcal{Q}_M(y)$, $J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y)$ is nonsingular and $A_{Q^{\mathrm{c}}}^T y < c_{Q^{\mathrm{c}}}$. Then there exists $\gamma > 0$ such that, for all $z \in B(z^*, \rho) \cap G^o$, $Q \in \mathcal{Q}_M(y)$,*

$$\|\Delta z(z, Q) - d^{\mathrm{N}}(z)\| \le \gamma \|z - z^*\| \cdot \|d^{\mathrm{N}}(z)\|.$$

Proof. Let $z \in B(z^*, \rho) \cap G^o$, $Q \in \mathcal{Q}_M(y)$ and let $s := c - A^T y$. Then, $\Delta y(z, Q)$ and $\Delta x_Q(z, Q)$ satisfy (direct consequence of (3.7))

$$\begin{bmatrix} 0 & A_Q \\ X_Q A_Q^T & -S_Q \end{bmatrix} \begin{bmatrix} \Delta y(z, Q) \\ \Delta x_Q(z, Q) \end{bmatrix} = \begin{bmatrix} b - A_Q x_Q \\ X_Q s_Q \end{bmatrix}. \tag{3.24}$$

On the other hand, $\Delta y(z, \mathbf{n})$ and $\Delta x(z, \mathbf{n})$ satisfy (see (2.3a), with $\mu = 0$ and $r_c = 0$)

$$\begin{bmatrix} 0 & A \\ X A^T & -S \end{bmatrix} \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x(z, \mathbf{n}) \end{bmatrix} = \begin{bmatrix} b - Ax \\ Xs \end{bmatrix},$$

and eliminating $\Delta x_{Q^{\mathrm{c}}}(z, \mathbf{n})$ in the latter yields

$$\begin{bmatrix} A_{Q^{\mathrm{c}}} S_{Q^{\mathrm{c}}}^{-1} X_{Q^{\mathrm{c}}} A_{Q^{\mathrm{c}}}^T & A_Q \\ X_Q A_Q^T & -S_Q \end{bmatrix} \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix} = \begin{bmatrix} b - A_Q x_Q \\ X_Q s_Q \end{bmatrix}. \tag{3.25}$$

Equating the left-hand sides of (3.24) and (3.25) yields

$$\begin{bmatrix} \Delta y(z, Q) \\ \Delta x_Q(z, Q) \end{bmatrix} = J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y)^{-1} \begin{bmatrix} A_{Q^{\mathrm{c}}} S_{Q^{\mathrm{c}}}^{-1} X_{Q^{\mathrm{c}}} A_{Q^{\mathrm{c}}}^T & A_Q \\ X_Q A_Q^T & -S_Q \end{bmatrix} \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix}. \tag{3.26}$$

Expressing $\begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix}$ as $J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y)^{-1} J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y) \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix}$ and subtracting from (3.26) then yields

$$\begin{bmatrix} \Delta y(z, Q) \\ \Delta x_Q(z, Q) \end{bmatrix} - \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix}$$

$$= J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y)^{-1} \begin{bmatrix} A_{Q^{\mathrm{c}}} S_{Q^{\mathrm{c}}}^{-1} X_{Q^{\mathrm{c}}} A_{Q^{\mathrm{c}}}^T & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \Delta y(z, \mathbf{n}) \\ \Delta x_Q(z, \mathbf{n}) \end{bmatrix}.$$

Further, it follows from (3.1b) and (3.1c) and from (3.2b) and (3.2c) that

$$\Delta x_{Q^{\mathrm{c}}}(z, Q) - \Delta x_{Q^{\mathrm{c}}}(z, \mathbf{n}) = S_{Q^{\mathrm{c}}}^{-1} X_{Q^{\mathrm{c}}} A_{Q^{\mathrm{c}}}^T (\Delta y(z, Q) - \Delta y(z, \mathbf{n})).$$

Since $S_{Q^{\mathrm{c}}}$ and $J_{\mathrm{a}}(A_Q, x_Q, c_Q - A_Q^T y)$ are continuous and nonsingular over the closed ball $B(z^*, \rho)$, and since $\|X_{Q^{\mathrm{c}}}\| = \|X_{Q^{\mathrm{c}}} - X_{Q^{\mathrm{c}}}^*\| \leq \|z - z^*\|$ (since $c_{Q^{\mathrm{c}}} - A_{Q^{\mathrm{c}}}^T z^* > 0$, i.e., $I(y^*) \cap Q^{\mathrm{c}}$ is empty), in view of the fact that $\{Q^{\mathrm{c}} : Q \in \mathcal{Q}_M(y)\}$ is finite (since $\mathcal{Q}_M(y)$ is) the claim follows. ∎

We are now ready to prove q-quadratic convergence.

THEOREM 17. *Suppose Assumptions* 1, 3, *and* 4 *hold. If* $x_i^* < x_{\max}$ *for all* $i \in \mathbf{n}$, *then* $\{(x^k, y^k)\}$ *converges to* (x^*, y^*) *q-quadratically.*

Proof. We aim at establishing that the conditions in Proposition 15 hold for Φ given by (3.23) and with $\hat{z} := z^*(= (x^*, y^*))$, $z^+ := z^+(z, Q)$, $Q \in \mathcal{Q}_M(y)$, and $\rho > 0$ small enough. First, note that

$$\frac{\partial \Phi}{\partial z}(z) = J_{\mathrm{a}}(A, x, c - A^T y),$$

so, in view of (3.18), (3.19), and linear independence Assumption 3, it follows from Lemma 1 that $\frac{\partial \Phi}{\partial z}(z^*)$ is nonsingular. Next, let $i \in I(y^*)$ and consider Step 2(ii) in Iteration rPDAS. Let $Q \supseteq I(y^*)$. From Lemma 13, we know that $J(A_Q, x_Q^*, s_Q^*)$ is nonsingular. Since, by feasibility of x^* and complementarity slackness,

$$J(A_Q, x_Q^*, s_Q^*) \begin{bmatrix} x_Q^* \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ b \\ 0 \end{bmatrix},$$

it follows from (3.7), (3.2), and the fact that $s_j := c_j - a_j^T y$ is bounded away from zero in a neighborhood of z^* for $j \notin Q$ (Lemma 13), that

$$\Delta y(z, Q) \to 0 \text{ as } z \to z^* \tag{3.27}$$

and

$$\tilde{x}(z, Q) \to x^* \text{ as } z \to z^*. \tag{3.28}$$

Note that, for $z \in G^o$ close enough to z^*, $Q \supseteq I(y^*)$ for all $Q \in \mathcal{Q}_M(y)$. Since $x_i^* > 0$ (from (3.18)) and $x^* \geq 0$, it follows that for $z \in G^o$ close enough to z^*,

$$\|\Delta y(z, Q)\|^2 + \|\tilde{x}_-(z, Q)\|^2 < \tilde{x}_i(z, Q) \quad \forall Q \in \mathcal{Q}_M(y),$$

which, in view of the update rule for x in Step 2(ii) of Iteration rPDAS, since $x_i^* < x_{\max}$, implies that, for $z \in G^o$ close enough to z^*,

$$x_i^+(z, Q) = \tilde{x}_i(z, Q) = x_i + \Delta x_i(z, Q) \quad \forall Q \in \mathcal{Q}_M(y),$$

yielding, for $z \in G^o$ close enough to z^*,

$$x_i^+(z, Q) - (x_i + \Delta x_i(z, \mathbf{n})) = \Delta x_i(z, Q) - \Delta x_i(z, \mathbf{n}) \quad \forall Q \in \mathcal{Q}_M(y). \tag{3.29}$$

In view of Lemma 16, it follows that, for z close enough to z^*, $z \in G^o$,

$$|x_i^+(z,Q) - (x_i + \Delta x_i(z,\mathbf{n}))| \leq \gamma \|z - z^*\| \cdot \|d^{\mathrm{N}}(z)\| \quad \forall Q \in \mathcal{Q}_M(y). \tag{3.30}$$

Next, let $i \notin I(y^*)$, so that $x_i^* = 0$, and again consider Step 2(ii) in Iteration rPDAS. Then for every $z \in G^o$ close enough to z^*, and every $Q \in \mathcal{Q}_M(y)$, either again

$$x_i^+(z,Q) = x_i + \Delta x_i(z,Q),$$

yielding again (3.29) and (3.30), or

$$x_i^+(z,Q) = \|\Delta y(z,Q)\|^2 + \|\tilde{x}_-(z,Q)\|^2, \leq \|\Delta z(z,Q)\|^2$$

yielding, since $x_i^* = 0$,

(3.31)
$$\|x_i^+(z,Q) - x_i^*\| \leq \|\Delta z(z,Q) - d^{\mathrm{N}}(z) + d^{\mathrm{N}}(z)\|^2 \leq (\gamma\|z - z^*\| \cdot \|d^{\mathrm{N}}(z)\| + \|d^{\mathrm{N}}(z)\|)^2$$

for every $z \in G^o$ close enough to z^*, $Q \in \mathcal{Q}_M(y)$. Finally, consider the "y" components of z. From (3.2b)–(3.2c) we know that, for $z \in G^o$ close enough to z^*, for all $Q \in \mathcal{Q}_M(y)$, and for all i such that $\Delta s_i(z,Q) := -a_i^T \Delta y(z,Q) \neq 0$,

$$\frac{s_i}{a_i^T \Delta y(z,Q)} = -\frac{s_i}{\Delta s_i(z,Q)} = \frac{x_i}{\tilde{x}_i(z,Q)}.$$

In view of Lemma 14(i), we conclude that, for $i \notin I(y^*)$,

$$\frac{|x_i|}{|\tilde{x}_i(z,Q)|} \to \infty \quad \text{as } z \to z^*, Q \in \mathcal{Q}_M(y).$$

Step 2(i) in Iteration rPDAS then yields

$$\bar{t}(z,Q) = \min\left\{ \frac{x_i}{\tilde{x}_i(z,Q)} : \ i \in I(y^*) \right\}$$

for $z \in G^o$ close enough to z^*, $Q \in \mathcal{Q}_M(y)$. Step 2(i) in Iteration rPDAS further yields, for $z \in G^o$ close enough to z^* (using (3.27)), $Q \in \mathcal{Q}_M(y)$,

$$\hat{t}(z,Q) = \min\left\{1, \frac{x_{i(z,Q)}}{\tilde{x}_{i(z,Q)}(z,Q)} - \|\Delta y(z,Q)\|\right\},$$

for some $i(z,Q) \in I(y^*)$. (Nonemptiness of $I(y^*)$ is insured by Assumption 4.) Thus, for $z \in G^o$ close enough to z^*, $Q \in \mathcal{Q}_M(y)$, and some $i(z,Q) \in I(y^*)$,

$$\begin{aligned}\|y^+(z,Q) - (y + \Delta y(z,Q))\| &= |\hat{t}(z,Q) - 1| \|\Delta y(z,Q)\| \\ &\leq \left| \ \|\Delta y(z,Q)\| + \frac{\tilde{x}_{i(z,Q)}(z,Q) - x_{i(z,Q)}}{\tilde{x}_{i(z,Q)}(z,Q)} \right| \ \|\Delta y(z,Q)\|.\end{aligned}$$

Since $x_i^* > 0$ for all $i \in I(y^*)$, it follows that for some $c_0 > 0$ and $z \in G^o$ close enough to z^*,

$$\begin{aligned}\|y^+(z,Q) - (y + \Delta y(z,Q))\| &\leq (\|\Delta y(z,Q)\| + c_0\|\Delta x(z,Q)\|)\|\Delta y(z,Q)\| \\ &\leq (1 + c_0)\|\Delta z(z,Q)\|^2 \\ &\leq (1 + c_0)(\|\Delta z(z,Q) - d^{\mathrm{N}}(z)\| + \|d^{\mathrm{N}}(z)\|)^2 \\ &\leq (1 + c_0)(\gamma\|z - z^*\| \cdot \|d^{\mathrm{N}}(z)\| + \|d^{\mathrm{N}}(z)\|)^2\end{aligned}$$

for all $Q \in \mathcal{Q}_M(y)$. It follows from Lemma 16 that

$$\|y^+(z,Q) - (y + \Delta y(z,\mathbf{n}))\| \le (1+c_0)(\gamma\|z-z^*\| \cdot \|d^{\mathrm{N}}(z)\| + \|d^{\mathrm{N}}(z)\|)^2$$

$$+\gamma\|z-z^*\| \cdot \|d^{\mathrm{N}}(z)\|$$

$$\le c_1 \max\{\|d^{\mathrm{N}}(z)\|^2, \|z-z^*\|^2\} \tag{3.32}$$

for some $c_1 > 0$ independent of z for all $z \in G^o$ close enough to z^*, $Q \in \mathcal{Q}_M(y)$. Equations (3.30), (3.31), and (3.32) are the key to the completion of the proof.

For $z \in G^o$ (close enough to z^*) such that $\|z-z^*\| \le \|d^{\mathrm{N}}(z)\|$, in view of Proposition 15, (3.30), (3.31), and (3.32) imply that, for some $c_2 > 0$ independent of z, and for all $Q \in \mathcal{Q}_M(y)$,

$$\|z^+(z,Q) - z^*\| \le c_2\|z-z^*\|^2.$$

On the other hand, for $z \in G^o$ close enough to z^* such that $\|d^{\mathrm{N}}(z)\| < \|z-z^*\|$, (3.30) yields, for some $c_3 > 0$ independent of z and for all $Q \in \mathcal{Q}_M(y)$,

$$|x_i^+(z,Q) - x_i^*| \le \gamma\|z-z^*\| \cdot \|d^{\mathrm{N}}(z)\| + \|x_i + \Delta x_i(z,\mathbf{n}) - x_i^*\| \le c_3\|z-z^*\|^2$$

for all $i \in I(y^*)$, where we have invoked quadratic convergence of the Newton iteration; (3.31) yields, for some $c_4 > 0$ independent of z,

$$|x_i^+(z,Q) - x_i^*| \le c_4\|z-z^*\|^2$$

for all $i \notin I(y^*)$; and (3.32) yields, for some $c_5 > 0$ independent of z,

$$\|y^+(z,Q) - y^*\| \le c_1\|z-z^*\|^2 + \|y_i + \Delta y(z,\mathbf{n}) - y^*\| \le c_5\|z-z^*\|^2.$$

In particular, they together imply again that, for all $z \in G^o$ close enough to z^*, $Q \in \mathcal{Q}_M(y)$,

$$\|z^+(z,Q) - z^*\| \le c_2\|z-z^*\|^2$$

for some $c_2 > 0$ independent of z. Since, in view of Lemma 14, z^k converges to z^*, it follows that z^k converges to z^* q-quadratically. □

3.3. Numerical results. Algorithm rPDAS was implemented in MATLAB and run on an Intel(R) Pentium(R) III CPU 733MHz machine with 256 KB cache, 512 MB RAM, Linux kernel 2.6.11, and MATLAB 7 (R14).[3]

Parameters were chosen as $\beta := 0.99$, $x_{\max} := 10^{15}$, $\underline{x} := 10^{-4}$. The code was supplied with strictly feasible initial dual points (i.e., $y^0 \in F^{\mathrm{o}}$). The initial primal vector, x^0, was chosen using the heuristic in [Meh92, p. 589] modified to accommodate dual feasibility. Specifically, $x^0 := \hat{x}^0 + \hat{\delta}_x$, where $\hat{x}^0$ is the minimum norm solution of $Ax = b$, $\hat{\delta}_x := \delta_x + (\hat{x}^0 + \delta_x e)^T s^0/(2\sum_{i=1}^n s_i^0)$, $\delta_x := \max\{-1.5 \cdot \min(x), 0\}$, where $s^0 := x - A^T y^0$ and e is the vector of all ones. The "M most active" heuristic (Q consists of the indexes of the M leftmost components of $c - A^T y$) was used to select the index set Q. The code uses MATLAB's "Cholesky-Infinity" factorization (`cholinc` function) to solve the normal equations (3.2a). A safeguard $s_i := \max\{10^{-14}, s_i\}$ was

[3]The code is available from the authors.

applied before Step 1; this prevents the matrix $A_Q S_Q^{-1} X_Q A_Q^T$ in (3.2a) from being excessively ill-conditioned and avoids inaccuracies in the ratios $s_i/\Delta s_i$ involved in (3.3) that could lead to unnecessarily small steps. We used a stopping criterion, adapted from [Meh92, p. 592], based on the error in the primal-dual equalities (2.1b)–(2.1a) and the duality gap. Specifically, convergence was declared when

$$\frac{\|b - Ax\|}{1 + \|x\|} + \frac{\|c - A^T y - s\|}{1 + \|s\|} + \frac{|c^T x - b^T y|}{1 + |b^T y|} < tol,$$

where *tol* was set to 10^{-8}. Notice that, in the case of iteration rPDAS, $\|c - A^T y - s\|$ vanishes throughout, up to numerical errors.

Execution times strongly depend on how the computation of $H^Q := A_Q D_Q^2 A_Q^T$ (where $D_Q^2 := S_Q^{-1} X_Q$ is diagonal), involved in (3.2a), is implemented in MATLAB. Storing the $|Q| \times |Q|$ matrix D_Q^2 as a full matrix is inefficient, or even impossible (even when $|Q|$ is much smaller than n, it may still be large). We are left with two options: Either (i) compute an auxiliary matrix $D_Q^2 A_Q^T$ using a "for" loop over the $|Q|$ rows of A_Q^T, then compute $A_Q * D_Q^2 A_Q^T$, or (ii) create a sparse matrix D_Q^2 using the `spdiags` function, then compute $A_Q * D_Q^2 * A_Q^T$. If the matrix A is in sparse form with sufficiently few nonzero elements, then the second option is (much) more efficient. If the matrix A is dense, then both options have comparable speed. Consequently, we used the second option in all experiments.

Numerical results obtained with algorithm rPDAS on several types of problems (to be discussed below) are presented in Figures 1 through 4. The points on the plots, as well as those on the plots of Figures 5 through 12 discussed in section 4, correspond to different runs on the same problem. The runs differ only by the number of constraints M that are retained in Q; this information is indicated on the horizontal axis in relative value. The rightmost point thus corresponds to the experiment without constraint reduction, while the points on the extreme left correspond to the most drastic constraint reduction. The plots are built as follows: the execution script picks progressively smaller values of M from a predefined list of values until it reaches the end of the list, or early, abnormal termination occurs. The latter was always caused by either (i) the number of iterations reaching a predefined limit of 100 (this is an ad hoc choice to stop the execution script when it reaches values of M where the number of iterations become high), or (ii) MATLAB generating `NaN` values, which happens when the normal matrix becomes numerically singular. Abnormal termination did occur in the numerical experiment presented in Figure 3 due to (ii) and in a few other instances due to (i).

In the lower plot of each figure, the vertical axis indicates CPU times to solution (total time, as well as time expended in the computation of H^Q and time used for the solution of the normal equation) as returned by the MATLAB function `cputime`. We emphasize that these results are valid only for the specific MATLAB implementation described above. Results could vary widely, depending on the programming language, the possible use of the BLAS, and the hardware. In contrast, the number of iterations shown on the upper plot has more meaning.

The first test problem is of the finely discretized semi-infinite type: the dual feasible set F is a polytope whose faces are tangent to the unit sphere. Contact points on the sphere were selected from the uniform distribution by first generating vectors of numbers distributed according to $\mathcal{N}(0, 1)$—normal distribution with mean zero and standard deviation one—and then normalizing these vectors. These points form the columns of A, and c was selected as the vector of all ones. Each entry of the objective vector, b, was chosen from $\mathcal{N}(0, 1)$, and y^0 was selected as the zero vector.

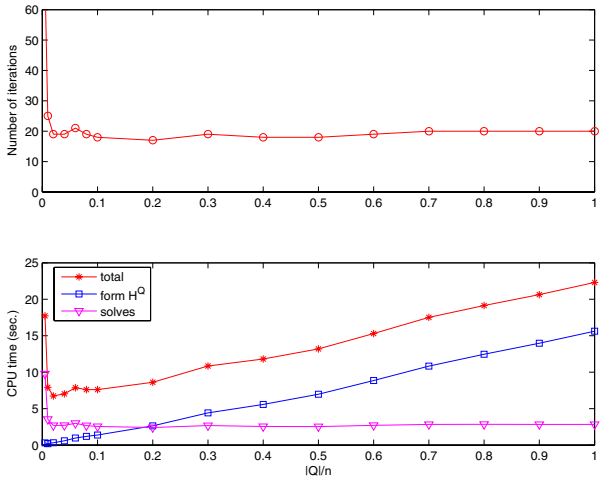

FIG. 1. *rPDAS on the problem with constraints tangent to the unit sphere.*

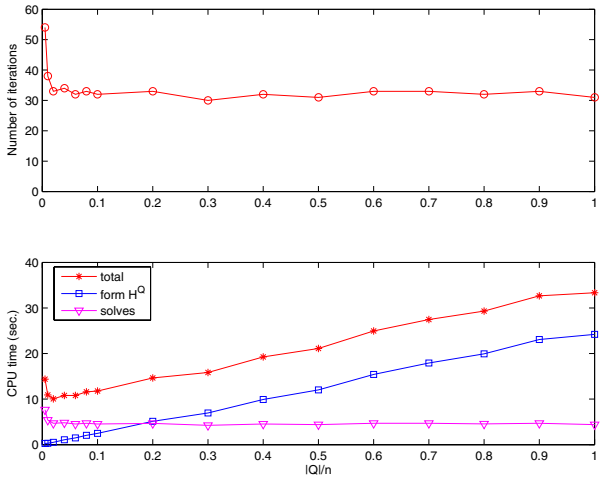

FIG. 2. *rPDAS on the "fully random" problem.*

This yields a problem that lends itself nicely to constraint reduction, since $n \gg m$ (we chose $m = 50$ and $n = 20000$), A is dense, and Assumption 1 on the full rank of submatrices of A holds for M as low as m. Numerical results are presented in Figure 1.

Arguably the most remarkable result in this paper is that observed on the upper plot of Figure 1 (and again in other figures discussed below): the number of iterations shows little variation over a significant range of values of $|Q|$. We tested the algorithm on several problems randomly generated, as explained above, and always observed that only very low values of $|Q|$ produce a significant increase in the number of iterations.

The second test problem is "fully random." The entries of A and b were generated from $\mathcal{N}(0, 1)$. To ensure a dual-feasible initial point, y^0 and s^0 were chosen from a uniform distribution on $(0, 1)$ and the vector c was generated by taking $c := A^T y^0 + s^0$. We again chose $m = 50$ and $n = 20000$. Results are displayed in Figure 2.

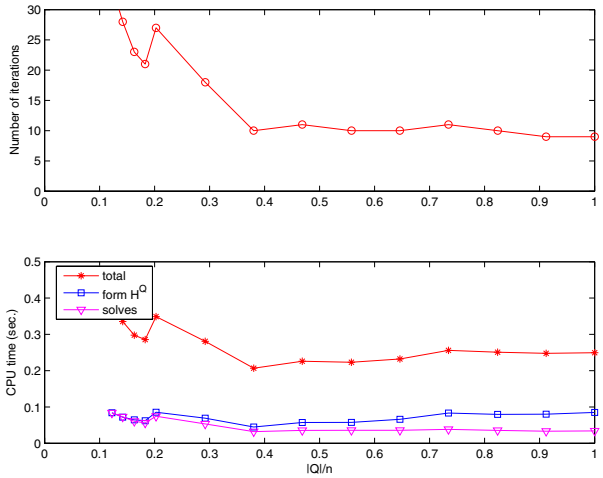

FIG. 3. *rPDAS on SCSD*1.

Note that these results are qualitatively similar to those of Figure 1. Here again, the number of iterations is stable over a wide range of values of $|Q|$. Experiments conducted on other test problems drawn from the same distribution produced similar results.

Next, we searched the Netlib LP library for problems where n is significantly greater than m and Assumption 1 is satisfied for reasonably small M. This left us with the SCSD problems. These problems, however, are very sparse. The computation of the normal matrix AD^2A^T involves only sparse matrix multiplications that can be performed efficiently and account only for a small portion of the total execution time. Therefore, the constraint reduction strategy, which focuses on reducing the cost of forming the normal matrix, has little effect on the overall execution time. (If the computation of H^Q is done with a `for` loop as explained above, then an important speedup is observed.) We tested algorithm rPDAS on SCSD1 ($m = 77$, $n = 760$) and SCSD6 ($m = 147$, $n = 1350$). For both problems, we set y^0 to $0 \in F^o$. Results are displayed in Figures 3 and 4. Here again, the number of iterations is quite stable over a wide range of values of $|Q|$.

4. A reduced MPC algorithm.

4.1. Algorithm statement. We consider a constraint-reduced version of Mehrotra's predictor-corrector (MPC) method [Meh92]—or rather of the simplified version of that algorithm found in [Wri97].

Iteration rMPC.

Parameters. $\beta \in (0,1)$, integer M satisfying $m \le M \le n$.

Data. $y \in \mathbb{R}^m$, $s > 0$, $x > 0$, $Q \in \mathcal{Q}_M(y)$, $\mu := x^T s/n$.

Step 1. Compute affine scaling direction:

Solve

$$A_Q S_Q^{-1} X_Q A_Q^T \Delta y = -r_b + A(-S^{-1} X r_c + x)$$

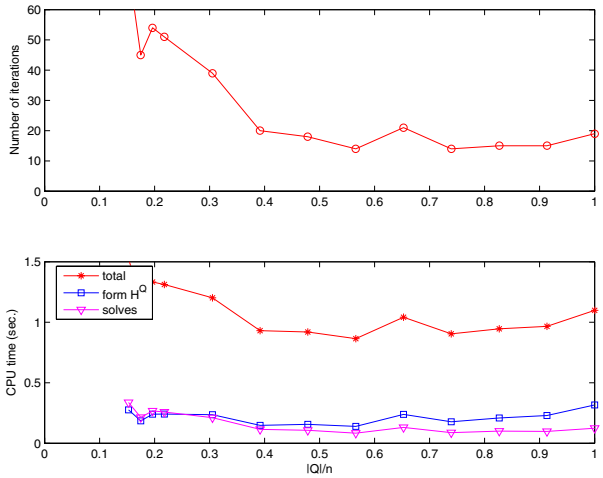

FIG. 4. *rPDAS on SCSD6.*

and compute

$$\Delta s := -A^T \Delta y - r_c,$$
$$\Delta x := -x - S^{-1} X \Delta s,$$

and let

$$t_{\text{aff}}^{\text{pri}} := \arg\max\{t \in [0,1] \mid x + t\Delta x \geq 0\},$$
$$t_{\text{aff}}^{\text{dual}} := \arg\max\{t \in [0,1] \mid s + t\Delta s \geq 0\}.$$

Step 2. Compute centering parameter:

$$\mu_{\text{aff}} := (x + t_{\text{aff}}^{\text{pri}} \Delta x)^T (s + t_{\text{aff}}^{\text{dual}} \Delta s)/n,$$
$$\sigma := (\mu_{\text{aff}}/\mu)^3.$$

Step 3. Compute centering/corrector direction:

Solve

$$A_Q S_Q^{-1} X_Q A_Q^T \Delta y^{\text{cc}} = -AS^{-1}(\sigma\mu e - \Delta X \Delta s)$$

and compute

$$\Delta s^{\text{cc}} := -A^T \Delta y^{\text{cc}},$$
$$\Delta x^{\text{cc}} := S^{-1}(\sigma\mu e - \Delta X \Delta s) - S^{-1} X \Delta s^{\text{cc}}.$$

Step 4. Compute MPC step:

$$\Delta x^{\text{mpc}} := \Delta x + \Delta x^{\text{cc}},$$
$$\Delta y^{\text{mpc}} := \Delta y + \Delta y^{\text{cc}},$$
$$\Delta s^{\text{mpc}} := \Delta s + \Delta s^{\text{cc}},$$

$$t^{\rm pri}_{\rm max} := \arg\max\{t \in [0,1] \mid x + t\Delta x^{\rm mpc} \geq 0\},$$
$$t^{\rm dual}_{\rm max} := \arg\max\{t \in [0,1] \mid s + t\Delta s^{\rm mpc} \geq 0\},$$

$$t^{\rm pri} := \min\{\beta t^{\rm pri}_{\rm max},\ 1\},$$
$$t^{\rm dual} := \min\{\beta t^{\rm dual}_{\rm max},\ 1\}.$$

Step 5. Updates:

$$x^+ := x + t^{\rm pri}\Delta x^{\rm mpc},$$
$$y^+ := y + t^{\rm dual}\Delta y^{\rm mpc},$$
$$s^+ := s + t^{\rm dual}\Delta s^{\rm mpc}.$$

Pick $Q^+ \in \mathcal{Q}_M(y^+)$.

As compared with the case of Iteration rPDAS, the speed-up per iteration achieved by rMPC over MPC is not as striking. This is due to the presence of two additional matrix-vector products in the iteration (see Step 3) for a total of three matrix-vector products per iteration. Further, these products involve the full A matrix and require $O(mn)$ flops, which can be substantial.

4.2. Numerical results: Dual-feasible initial point. We report on numerical results obtained with a MATLAB implementation of the reduced MPC (rMPC) algorithm.[4] The hardware, software, test problems, initial points, and presentation of the results are the same as in section 3.3. Figures 5, 6, 7, and 8 are the counterparts of Figures 1, 2, 3, and 4, respectively.

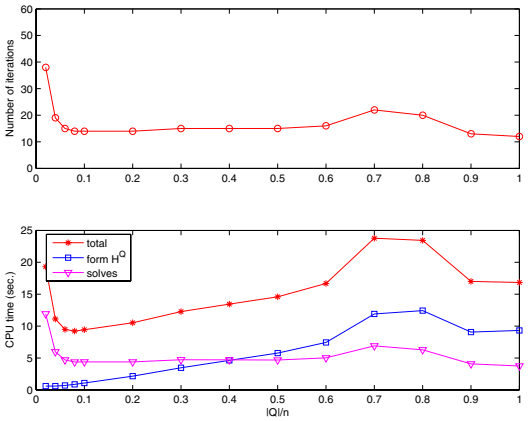

FIG. 5. *rMPC on the problem with constraints tangent to the unit sphere, with dual-feasible initial point.*

4.3. Numerical results: Infeasible initial point. We now report on numerical experiments that differ from the ones in section 4.2 only by the choice of the initial

[4]The code is available from the authors.

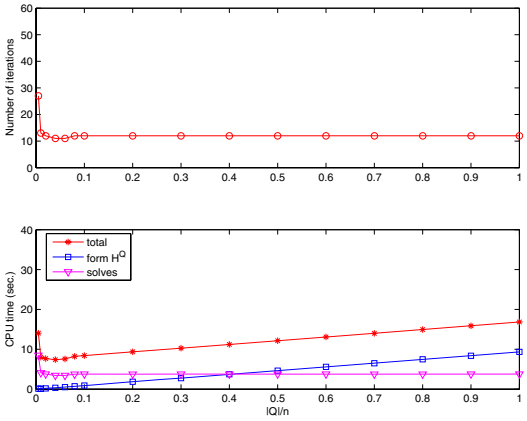

FIG. 6. *rMPC on the "fully random" problem, with dual-feasible initial point.*

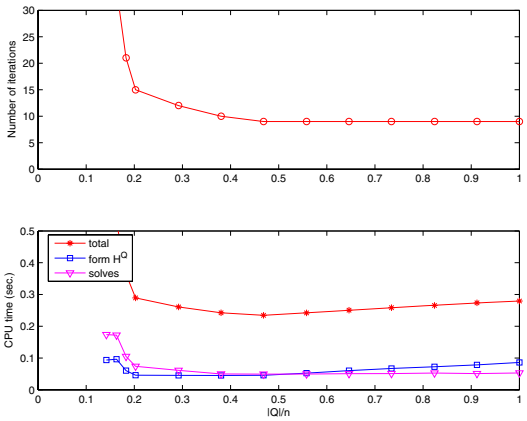

FIG. 7. *rMPC on SCSD*1*, with dual-feasible initial point.*

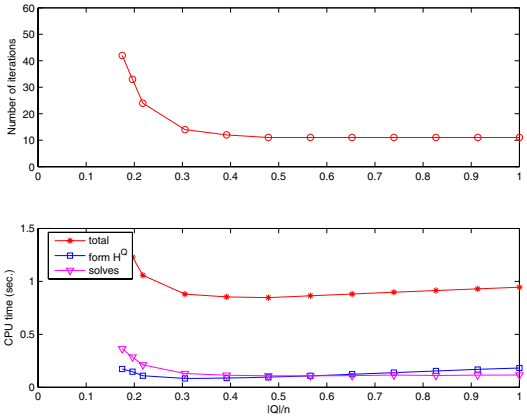

FIG. 8. *rMPC on SCSD*6*, with dual-feasible initial point.*

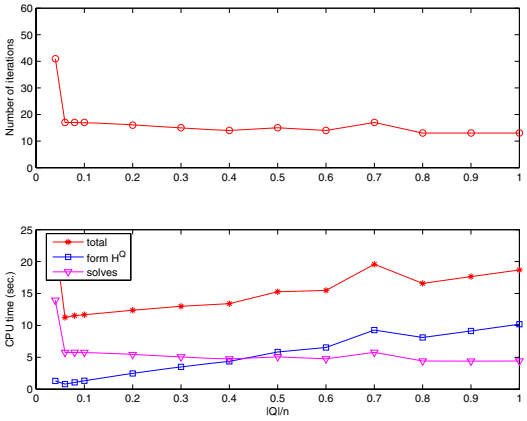

FIG. 9. *rMPC on the problem with constraints tangent to the unit sphere, with infeasible initial point.*

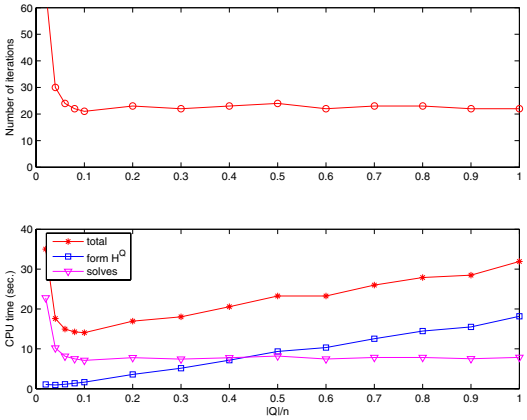

FIG. 10. *rMPC on the "fully random" problem, with infeasible initial point.*

variables. Here we select the initial variables as in [Meh92, p. 589], without modification. Consequently, there is no guarantee that the initial point will be dual-feasible; and indeed, in most experiments, the initial point was dual-infeasible (in addition to being primal-infeasible, as in all the previous experiments). Figures 9, 10, 11, and 12 are the counterparts of Figures 5, 6, 7, 8, respectively.

5. Discussion. In the context of primal-dual interior-point methods for linear programming, a scheme was proposed, aimed at significantly decreasing the computational effort at each iteration when solving problems which, when expressed in dual standard form, have many more constraints than (dual) variables. The core idea is to compute the dual search direction based only on a small subset of the constraints, carefully selected in an attempt to preserve the quality of the search direction. Global and local quadratic convergence was proved for a class of schemes in the case of a simple dual-feasible affine scaling algorithm. Promising numerical results were reported both on this "reduced" affine scaling algorithm and a similarly "reduced" version of the MPC algorithm, using a rather simplistic heuristic: for a prescribed $M > m$, keep only the M most nearly active (or most violated) constraints. In particular,

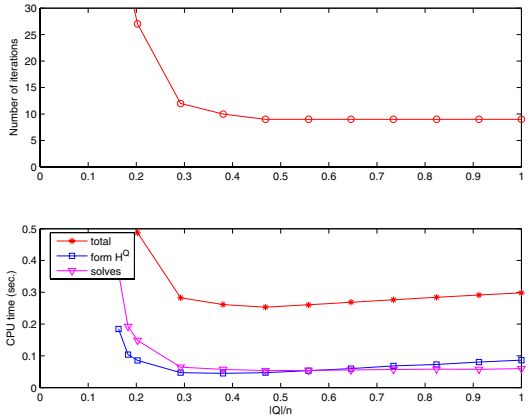

FIG. 11. *rMPC on SCSD1, with infeasible initial point.*

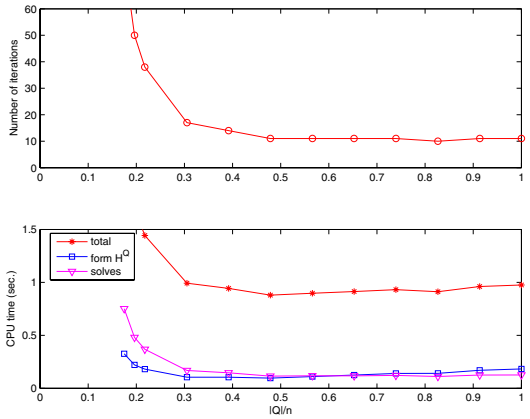

FIG. 12. *rMPC on SCSD6, with infeasible initial point.*

rather unexpectedly, it was observed that, on a number of problems, the number of iterations to solutions did not increase when the size of the reduced constraint set was decreased, down to a small fraction of the total number of constraints! Accordingly, all savings in computational effort per iteration directly translate to savings in total computational effort for the solution of the problem. Another interesting finding is that, in our MATLAB implementation, the reduced affine scaling algorihtm rPDAS works as well as the reduced MPC algorithm on random problems in terms of CPU time; however, CPU times may vary widely over implementations.

The (unreduced) MPC algorithm has remarkable invariance properties. Let $\{(x^k, y^k, s^k)\}$ be a sequence generated by MPC on the problem defined by (A, b, c). Let P be an invertible $m \times m$ matrix, let R be a diagonal positive-definite $n \times n$ matrix, let v belong to $\mathbb{R}^m$, and define $\mathbf{A} := PAR$, $\mathbf{b} := Pb$, $\mathbf{c} := Rc + RA^T P^T v$, $\mathbf{x}^0 := R^{-1}x^0$, $\mathbf{y}^0 := P^{-T}y^0 + v$, and $\mathbf{s}^0 := Rs^0$. Then the sequence $\{(\mathbf{x}^k, \mathbf{y}^k, \mathbf{z}^k)\}$ generated by MPC on the problem defined by $(\mathbf{A}, \mathbf{b}, \mathbf{c})$ satisfies $\mathbf{x}^k = R^{-1}x^k$, $\mathbf{y}^k = P^{-T}y^k + v$, and $\mathbf{s}^k = Rs^k$.[5] The reduced algorithm rMPC is still invariant under the action of

[5]Note, however, that the procedure recommended in [Meh92] for generating x^0 and s^0, while

P and v, but it is no longer invariant under the action of R, because the relation $\mathbf{s} = Rs$ affects the choice of the set Q. A simple way to recover invariance under R is to redefine $\mathcal{Q}_M$ based on $(c_i - a_i^T y)/s_i^0$ instead of $c_i - a_i^T y$.

The rPDAS and PDAS algorithms (rPDAS with $Q = \mathbf{n}$) have weaker invariance properties than MPC. While they are invariant under the action of v and of orthogonal P (that is, Euclidean transformations of the dual space), they are neither invariant under the action of nonorthogonal P, because of the presence of $\|\Delta y\|$ in (3.4) and (3.5), nor under the action of R, because of (3.5) containing the quantity $\|\tilde{x}_-\|$ and fixed bounds on x (and also, for rPDAS, because of the way $\mathcal{Q}_M$ is defined).[6] Algorithms rPDAS and PDAS can be modified to achieve other invariance properties. If $\|\Delta y\|$ is replaced[7] by $\|(\Delta Y^0)^{-1}\Delta y\|$, where $\Delta Y^0 = \operatorname{diag}(\Delta y_i^0,\ i = 1, \ldots, m)$, then the algorithms are invariant under v and nonsingular diagonal P. If instead $\|\Delta y\|$ is replaced by $\|\Delta y\|/\|\Delta y^0\|$, then the algorithms are invariant under Euclidean transformation and uniform scaling of the dual (i.e., P is a nonzero scalar multiple of an orthogonal matrix). If (3.5) is replaced by

$$x_i^+ := \min\{\max\{\min\{(\|\Delta y\|^2 + \|(X^0)^{-1}\tilde{x}_-\|^2)x_i^0, \underline{x}x_i^0\},\ \tilde{x}_i\},\ x_{\max}x_i^0\}\ \forall i \in \mathbf{n},$$

then PDAS is invariant under R; if, moreover, $\mathcal{Q}_M$ is redefined based on $(c_i - a_i^T y)/s_i^0$ instead of $c_i - a_i^T y$, then rPDAS becomes invariant under R, too.

We have focused on a constraint selection rule that requires that, at each iteration, the M "most nearly active" (or "most violated") constraints all be included in the reduced set. It should be clear, however, that nearness to activity can be measured differently for each constraint, and indeed differently at each iteration. In fact, only two conditions must be satisfied in order for our convergence analysis to go through: (i) A_Q must have full row rank at each iteration, which is required in order for the algorithm to be well defined, and (ii) constraints must be included in the reduced set whenever y is "close enough" to the corresponding constraint boundary.

Appendix. Proof of Lemma 1.

The first claim is a direct consequence of the equivalence between (2.2) and (2.3). Let us now prove the sufficiency portion of the second claim. Thus suppose conditions (i) through (iii) hold, and let $(\xi, \eta, \sigma)^T$ be in the nullspace of $J(A, x, s)$. We show that it must be identically zero. We have

$$A^T\eta + \sigma = 0, \tag{A.1}$$

$$A\xi = 0, \tag{A.2}$$

$$S\xi + X\sigma = 0. \tag{A.3}$$

Equation (A.1) yields

$$\xi^T A^T \eta + \xi^T \sigma = 0, \tag{A.4}$$

which, in view of (A.2), yields

$$\xi^T \sigma = 0. \tag{A.5}$$

invariant under the action of P and v, is not invariant under that of R.

[6] Note that simpler versions of PDAS that do not aim at superlinear convergence enjoy v, P, and R invariance as defined above (see, e.g., [MAR90]).

[7] Assuming that no component of Δy^0 vanishes.

Also, (A.3) yields

$$\sigma_i = -\frac{s_i}{x_i}\xi_i$$

whenever $x_i \neq 0$, and $\xi_i = 0$ otherwise (since $|x_i| + |s_i| > 0$), so that (A.5) yields

$$-\sum_{i:x_i\neq 0} \frac{s_i}{x_i}\xi_i^2 = 0.$$

Since $s_i/x_i \geq 0$ whenever $x_i \neq 0$, it follows that $s_i\xi_i = 0$ whenever $x_i \neq 0$. It then follows from (A.3) that $x_i\sigma_i = 0$ whenever $x_i \neq 0$, yielding

$$X\sigma = 0 \tag{A.6}$$

and, from (A.3),

$$S\xi = 0. \tag{A.7}$$

Since $\{a_i : s_i = 0\}$ is linear independent, it follows from (A.2) and (A.7) that $\xi = 0$. Equation (A.1) and (A.6) now yield $XA^T\eta = 0$, so that $a_i^T\eta = 0$ whenever $x_i \neq 0$. Since $\{a_i : x_i \neq 0\}$ spans $\mathbb{R}^m$, we conclude that $\eta = 0$. Finally, it now follows from (A.1) that $\sigma = 0$, concluding the proof of the sufficiency portion of the second claim.

As for the necessity portion of the second claim, first, inspection of the last n rows, then of the first n columns of $J(A, x, s)$, shows that the first two conditions are needed in order for $J(A, x, s)$ to be nonsingular. As for the third condition, suppose it does not hold, i.e., suppose that $\{a_i : x_i \neq 0\}$ does not span $\mathbb{R}^m$. Then there exists $\eta \neq 0$ such that $a_i^T\eta = 0$ for all i such that $x_i \neq 0$. Further, let $\xi := 0$ and let $\sigma := -A^T\eta$, so that $\sigma_i = 0$ for all i such that $x_i \neq 0$. It is readily checked that (ξ, η, σ) is in the nullspace of $J(A, x, s)$. Since $\eta \neq 0$, $J(A, x, s)$ must be singular. This completes the proof of the necessity portion of the second claim.

Acknowledgments. The authors wish to thank Dianne O'Leary for helpful discussions. Further, they wish to thank two anonymous referees for their careful reading of the paper and for their many helpful comments.

ON THE STABILITY OF CONVEX-VALUED MAPPINGS AND THEIR RELATIVE BOUNDARY AND EXTREME POINTS SET MAPPINGS*

MIGUEL A. GOBERNA†, MAXIM I. TODOROV‡, AND VIRGINIA N. VERA DE SERIO§

Abstract. This paper deals with the transmission of the main stability properties (lower and upper semicontinuity in Berge sense, and closedness) from a given closed–convex-valued mapping to its corresponding relative boundary and extreme point set mappings, and vice versa. The domain of the mappings considered in this paper are locally metrizable spaces and the images range on Euclidean spaces. Important examples of the class of mappings considered in this paper are the feasible set mapping and the optimal set mapping of convex optimization problems, for which the space of parameters is the result of perturbing a given nominal problem.

Key words. stability theory, set-valued mappings, convex hull mappings, relative boundary mappings, extreme points set mappings

AMS subject classifications. 49K40, 28B20

DOI. 10.1137/050632476

1. Introduction.

The main objective of the paper is to analyze the relationships between important pairs of mappings, one of them being the convex hull of the other, which frequently arise in convex optimization (convex systems), where, as a consequence of measurement or roundoff errors, the nominal problem y_0 (system y_0) is usually replaced in practice by perturbed problems (systems, respectively) having the same structure. Let us denote by Y the set of all possible perturbed problems (systems) equipped with a certain pseudometric measuring the size of the perturbations and let $\mathcal{F} : Y \rightrightarrows \mathbb{R}^n$ be the set-valued mapping associating with each $y \in Y$ its feasible set or its optimal set (its solution set, respectively). Under mild conditions, $\mathcal{F}(y)$ is the convex hull of its boundary set $\operatorname{bd}\mathcal{F}(y)$, its relative boundary set $\operatorname{rbd}\mathcal{F}(y)$, and/or its extreme points set $\operatorname{extr}\mathcal{F}(y)$ for all $y \in Y$. We denote these mappings from Y to $\mathbb{R}^n$ as $\operatorname{bd}\mathcal{F}$, $\operatorname{rbd}\mathcal{F}$, and $\operatorname{extr}\mathcal{F}$, which are called *boundary mapping*, *relative boundary mapping*, and *extreme points set mapping* of $\mathcal{F}$, respectively. The connections between the stability properties of $\mathcal{F}$, $\operatorname{bd}\mathcal{F}$, and $\operatorname{extr}\mathcal{F}$ have been already analyzed in the particular context of linear semi-infinite systems ([3] and [4], respectively), where Y is equipped with the pseudometric of the uniform convergence.

Throughout this paper we consider given an arbitrary convex-valued mapping $\mathcal{F} : Y \rightrightarrows \mathbb{R}^n$, where the domain Y is a locally metrizable space (i.e., Y is equipped with the topology induced by an extended distance on Y, δ, taking values on $\mathbb{R}_+ \cup \{+\infty\}$), and its boundary mapping, relative boundary mapping, and extreme points set mapping,

$\operatorname{bd}\mathcal{F}$, $\operatorname{rbd}\mathcal{F}$, and $\operatorname{extr}\mathcal{F}$. The relationships between $\mathcal{F}$ and $\operatorname{bd}\mathcal{F}$, assuming that $\mathcal{F} = \operatorname{conv}\operatorname{bd}\mathcal{F}$, have been studied in [5]. In the same vein, this paper considers the relationships between the stability properties of $\mathcal{F}$, $\operatorname{rbd}\mathcal{F}$, and $\operatorname{extr}\mathcal{F}$, assuming that $\mathcal{F} = \operatorname{conv}\operatorname{rbd}\mathcal{F}$ and $\mathcal{F} = \operatorname{conv}\operatorname{extr}\mathcal{F}$, respectively. The finite dimension of the image space plays a crucial role in those arguments based on the compactness of the unit sphere or on Carathéodory's theorem.

Some of these relationships are direct consequences of basic results about arbitrary mappings $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ and their corresponding *convex hull mappings*, $\operatorname{conv}\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$, which associates to each $y \in Y$ the convex hull of $\mathcal{A}(y)$, i.e., $(\operatorname{conv}\mathcal{A})(y) = \operatorname{conv}\mathcal{A}(y)$ for all $y \in Y$. Although some results on the transmission of stability properties between $\mathcal{A}$ and $\operatorname{conv}\mathcal{A}$ are already known (see, e.g., [6] and [1]), we provide proofs of other results which will be used in what follows. Thus, for each stability property, we start analyzing the relationships between $\mathcal{A}$ and $\operatorname{conv}\mathcal{A}$, and then we exploit the properties of the images of $\mathcal{F}$, $\operatorname{rbd}\mathcal{F}$, and $\operatorname{extr}\mathcal{F}$ in order to obtain the relationships between these mappings; section 3 deals with the lower semicontinuous (lsc) property and section 4 with the upper semicontinuous (usc) property and closedness.

Let us introduce some additional notation. Given $X \subset \mathbb{R}^n$, $\operatorname{aff} X$ denotes the affine hull of X. From the topological side, $\operatorname{bd} X$, $\operatorname{rbd} X$, $\operatorname{int} X$, $\operatorname{rint} X$, and $\operatorname{cl} X$ represent the boundary, the relative boundary, the interior, the relative interior, and the closure of X, respectively. If X is convex, its set of extreme points is denoted by $\operatorname{extr} X$. The Euclidean norm in $\mathbb{R}^n$ will be denoted by $\|.\|$ and the open ball centered at x and radius $\varepsilon > 0$ by $B(x;\varepsilon)$. If X is a convex set and $x \in X$, then

$$B(x;\varepsilon) \cap \operatorname{rbd} X = \emptyset \Longrightarrow B(x;\varepsilon) \cap \operatorname{aff} X \subset \operatorname{rint} X \tag{1.1}$$

for all $\varepsilon > 0$.

The standard simplex in $\mathbb{R}^{n+1}$ is

$$S := \left\{ (\lambda_1, \ldots, \lambda_{n+1}) \in \mathbb{R}^{n+1}_+ \mid \sum_{i=1}^{n+1} \lambda_i = 1 \right\}.$$

For the sake of completeness, we recall the stability concepts and some basic results for set-valued mappings that we shall consider in this paper. Let $\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ be a set-valued mapping with its domain $\operatorname{dom}\mathcal{M} := \{y \in Y \mid \mathcal{M}(y) \neq \emptyset\}$. The following semicontinuity concepts are due to Bouligand and Kuratowski (see [1, section 1.4]).

We say that $\mathcal{M}$ is *lower semicontinuous* at $y_0 \in Y$ *in the Berge sense* if, for each open set $W \subset \mathbb{R}^n$ such that $W \cap \mathcal{M}(y_0) \neq \emptyset$, there exists an open set $V \subset Y$, containing y_0, such that $W \cap \mathcal{M}(y) \neq \emptyset$ for each $y \in V$. Obviously, $\mathcal{M}$ is lsc at $y_0 \notin \operatorname{dom}\mathcal{M}$ and $y_0 \in \operatorname{int}\operatorname{dom}\mathcal{M}$ if $\mathcal{M}$ is lsc at $y_0 \in \operatorname{dom}\mathcal{M}$.

$\mathcal{M}$ is *upper semicontinuous* at $y_0 \in Y$ *in the Berge sense* if, for each open set $W \subset \mathbb{R}^n$ such that $\mathcal{M}(y_0) \subset W$, there exists an open set $V \subset Y$, containing y_0, such that $\mathcal{M}(y) \subset W$ for each $y \in V$. If $\mathcal{M}$ is usc at $y_0 \notin \operatorname{dom}\mathcal{M}$, then $y_0 \in \operatorname{int}(Y \setminus \operatorname{dom}\mathcal{M})$.

If $\mathcal{M}$ is simultaneously lsc and usc at y_0 we say that $\mathcal{M}$ is *continuous* at this point.

$\mathcal{M}$ is *closed* at $y_0 \in \operatorname{dom}\mathcal{M}$ if for all sequences $\{y_r\}_{r=1}^{\infty} \subset Y$ and $\{x_r\}_{r=1}^{\infty} \subset \mathbb{R}^n$ satisfying $x_r \in \mathcal{M}(y_r)$ for all $r \in \mathbb{N}$, $\lim_{r\to\infty} y_r = y_0$ and $\lim_{r\to\infty} x_r = x_0$ (in brief, $y_r \to y_0$ and $x_r \to x_0$) one has $x_0 \in \mathcal{M}(y_0)$. If $\mathcal{M}$ is usc at $y_0 \in \operatorname{dom}\mathcal{M}$ and $\mathcal{M}(y_0)$ is closed, then $\mathcal{M}$ is closed at y_0. Conversely, if $\mathcal{M}$ is closed and *locally bounded* at

$y_0 \in \operatorname{dom} \mathcal{M}$ (i.e., if there is a neighborhood of y_0, say V, and a bounded set $A \subset \mathbb{R}^n$ containing $\mathcal{M}(y)$ for every $y \in V$), then $\mathcal{M}$ is usc at y_0.

Finally, $\mathcal{M}$ is lsc (usc, closed, locally bounded) if it is lsc (usc, closed, locally bounded) at y for all $y \in Y$.

Without entering in details we would like to mention that there are other notions of lower and upper semicontinuity as lsc and usc in the sense of Hausdorff (see, e.g., [2]) or inner and outer semicontinuity (see, e.g., [8], where it is shown that the last two concepts are equivalent to lsc in Berge sense and closedness when $\mathcal{M}(y)$ is closed for all $y \in Y$).

2. Preliminaries. We say that $\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ is *locally convex* at $y_0 \in Y$ if there exists an open set $V \subset Y$, containing y_0, such that $\mathcal{M}(y)$ is convex for all $y \in V$. We shall use the following sufficient condition for $\mathcal{M}$ to be locally bounded.

PROPOSITION 2.1. *Let $\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ and let $y_0 \in \operatorname{dom} \mathcal{M}$ such that $\mathcal{M}(y_0)$ is bounded and $\mathcal{M}$ is lsc, closed, and locally convex at y_0. Then $\mathcal{M}$ is locally bounded and continuous at y_0.*

Proof. Let $r_0 \in \mathbb{N}$ such that

$$\mathcal{M}(y_0) \subset B(0_n; r_0). \tag{2.1}$$

Since $\mathcal{M}$ is lsc and locally convex at y_0 there exists an open set $V \subset Y$, containing y_0, such that $\mathcal{M}(y)$ is convex and

$$B(0_n; r_0) \cap \mathcal{M}(y) \neq \emptyset \text{ for each } y \in V. \tag{2.2}$$

If $\mathcal{M}$ is not locally bounded at y_0, given $r \in \mathbb{N}$ there exists $y_r \in Y$, with $\delta(y_r, y) \leq \frac{1}{r}$, such that $\mathcal{M}(y_r) \nsubseteq B(0_n; r)$. Thus there exists a sequence $\{x_r\}$ such that

$$x_r \in \mathcal{M}(y_r), \|x_r\| \geq r, r = 1, 2, \ldots .$$

Let $r_1 \geq r_0$ such that $y_r \in V$ for all $r \geq r_1$. In this case, due to (2.2), we can take $z_r \in B(0_n; r_0) \cap \mathcal{M}(y_r)$. Since $x_r \in \mathcal{M}(y_r) \setminus B(0_n; r_0)$ and $\mathcal{M}(y_r)$ is convex, there exists $u_r \in]x_r, z_r] := \{(1-\lambda) x_r + \lambda z_r \mid 0 < \lambda \leq 1\}$ such that

$$u_r \in \mathcal{M}(y_r), \|u_r\| = r_0, r \leq r_1. \tag{2.3}$$

By the compactness of the spheres in $\mathbb{R}^n$, there exists a subsequence $\{u_{r_k}\}$ such that $u_{r_k} \in \mathcal{M}(y_{r_k})$, $k = 1, 2, \ldots$, and $\lim_k u_{r_k} = u_0$, with $\|u_0\| = r_0$. Since $\mathcal{M}$ is closed at y_0 and $\lim_k y_{r_k} = y_0$, we must have $u_0 \in \mathcal{M}(y_0)$, which contradicts (2.1).

We have shown that $\mathcal{M}$ is locally bounded at y_0. Since we are assuming that $\mathcal{M}$ is closed at y_0, it is also usc at y_0. Hence it is continuous at y_0. ∎

The condition of $\mathcal{M}$ being locally convex above is not superfluous as the following example shows.

Example 2.2. If $Y = [0, 1]$ and $\mathcal{M} : Y \rightrightarrows \mathbb{R}$ is defined by $\mathcal{M}(y) = \{0, 1/y\}$ for $y \neq 0$ and $\mathcal{M}(0) = \{0\}$, then $\mathcal{M}$ is neither locally bounded nor continuous at $y_0 = 0$, in spite of $\mathcal{M}(y_0)$ being bounded and being $\mathcal{M}$ lsc and closed at y_0.

The *truncated mapping* of $\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ with radius $\rho > 0$ is $\mathcal{M}_\rho : Y \rightrightarrows \mathbb{R}^n$ defined such as

$$\mathcal{M}_\rho(y) := \mathcal{M}(y) \cap \operatorname{cl} B(0_n; \rho) \text{ for all } y \in Y.$$

The following result (Lemma 2 in [5]), which establishes the relationships between $\mathcal{M}$ and $\mathcal{M}_\rho$, will be useful in the next sections.

PROPOSITION 2.3. *Let $\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ and let $y_0 \in \operatorname{dom} \mathcal{M}$. Then the following*

statements hold:
(i) $\mathcal{M}$ *is closed at* y_0 *if and only if* $\mathcal{M}_\rho$ *is closed at* y_0 *for all* $\rho > 0$ *such that* $\mathcal{M}_\rho(y_0) \neq \emptyset$.
(ii) *If* $\mathcal{M}$ *is usc at* y_0 *and* $\mathcal{M}(y_0)$ *is closed, then* $\mathcal{M}_\rho$ *is usc at* y_0 *for all* $\rho > 0$ *such that* $\mathcal{M}_\rho(y_0) \neq \emptyset$.
(iii) *If* $\mathcal{M}$ *is usc at* y_0, *then there exist a positive scalar* $\overline{\rho}$ *and an open neighborhood of* y_0, V, *such that*

$$\mathcal{M}(y) \setminus \mathcal{M}_{\overline{\rho}}(y) \subset \mathcal{M}(y_0) \setminus \mathcal{M}_{\overline{\rho}}(y_0) \quad \text{for all } y \in V. \tag{2.4}$$

The converse statement holds when $\mathcal{M}$ *is closed at* y_0.
(iv) *If* $\mathcal{M}_\rho$ *is lsc at* y_0 *for every* ρ *such that* $\mathcal{M}(y_0) \cap B(0_n; \rho) \neq \emptyset$, *then* $\mathcal{M}$ *is lsc at* y_0. *The converse statement holds if* $\mathcal{M}(y_0)$ *is convex.*

As an immediate consequence of the following result we obtain characterizations of the identities $\mathcal{F} = \operatorname{conv} \operatorname{bd} \mathcal{F}$, $\mathcal{F} = \operatorname{conv} \operatorname{rbd} \mathcal{F}$, and $\mathcal{F} = \operatorname{conv} \operatorname{extr} \mathcal{F}$. Recall that an edge is a one-dimensional face whereas a half-flat is the intersection of a flat (also called affine manifold) with a closed halfspace which meets it, but does not contain it.

PROPOSITION 2.4. *Given a convex set* $F \subset \mathbb{R}^n$, *the following statements hold:*
(i) $F = \operatorname{conv} \operatorname{bd} F$ *if and only if* F *is a closed set which does not contain halfspaces.*
(ii) $F = \operatorname{conv} \operatorname{rbd} F$ *if and only if* F *is a closed set which does not contain half-flats of the same dimension.*
(iii) *If* $F = \operatorname{conv} \operatorname{extr} F$, *then* F *contains neither lines nor unbounded edges. The converse holds if* F *is closed.*

Proof. Obviously, if $F = \emptyset$, then

$$\operatorname{conv} \operatorname{bd} F = \operatorname{conv} \operatorname{rbd} F = \operatorname{conv} \operatorname{extr} F = \emptyset.$$

So we can assume that $F \neq \emptyset$ without loss of generality.

(i) It is a straightforward consequence of Lemma 2 in [3].

(ii) If $F = \operatorname{conv} \operatorname{rbd} F$, then $\operatorname{rbd} F \subset F$ and so F is closed for each $y \in Y$. If F contains a half-flat of the same dimension, then it is either a flat or a half-flat, with $\operatorname{conv} \operatorname{rbd} F \neq F$ in both cases.

Conversely, since F is a closed and convex set which is neither a flat nor a half-flat, then $F = \operatorname{conv} \operatorname{rbd} F$ by Theorem 2.6.12 in [9].

(iii) Suppose that $F = \operatorname{conv} \operatorname{extr} F$. $F \neq \emptyset$ entails $\operatorname{extr} F \neq \emptyset$ and so F does not contain lines. We shall obtain a contradiction assuming the existence of a halfline edge of F, say A.

Let $A = \{\overline{x} + \lambda v \mid \lambda \geq 0\}$ be an edge of F. Then $v \neq 0_n$ and $\overline{x} \in \operatorname{extr} F$. We shall prove that no element of $A \setminus \{\overline{x}\}$ belongs to $\operatorname{conv} \operatorname{extr} F$. We assume the contrary, i.e., that there exists $\lambda > 0$ such that $\overline{x} + \lambda v \in \operatorname{conv} \operatorname{extr} F$.

If $\overline{x} + \lambda v = x_1 \in \operatorname{extr} F$, then $x_1 = \frac{1}{2}\overline{x} + \frac{1}{2}(\overline{x} + 2\lambda v)$, with $\overline{x}, \overline{x} + 2\lambda v \in F$, making this impossible. Thus we can write $\overline{x} + \lambda v = \sum_{i=1}^{p} \lambda_i x_i$, where $p \geq 2$, $\sum_{i=1}^{p} \lambda_i = 1$ and $\lambda_i > 0$, and $x_i \in \operatorname{extr} F$, $i = 1, \ldots, p$, with $x_i \neq x_j$ if $i \neq j$. Then we can write

$$\overline{x} + \lambda v = \lambda_1 x_1 + (1 - \lambda_1) \sum_{i=2}^{p} \left(\frac{\lambda_i}{1 - \lambda_1} \right) x_i, \tag{2.5}$$

which yields x_1, $\sum_{i=2}^{p} \left(\frac{\lambda_i}{1-\lambda_1}\right) x_i \in A$ because A is a face of F. Since $A \cap \operatorname{extr} F = \{\overline{x}\}$, $x_1 = \overline{x}$, and so from (2.5) we get

$$\overline{x} + \frac{\lambda}{1-\lambda_1} v = \sum_{i=2}^{p} \left(\frac{\lambda_i}{1-\lambda_1} \right) x_i. \tag{2.6}$$

By taking into account again that A is a face of F, we get the following contradiction: $x_2, \ldots, x_p \in A \cap \operatorname{extr} F = \{\overline{x}\}$.

We have shown that $(A \setminus \{\overline{x}\}) \cap \operatorname{conv} \operatorname{extr} F = \emptyset$. Since $\emptyset \neq A \setminus \{\overline{x}\} \subset F$, we conclude that $\operatorname{conv} \operatorname{extr} F \subsetneq F$.

Conversely, if F is closed and does not contain lines, it is the convex hull of its extreme points and extreme directions (Corollary 2.6.15 in [9]). Since the assumption precludes the existence of extreme directions, we have $\operatorname{conv} \operatorname{extr} F = F$. □

Remark 2.5. According to Proposition 2.4, if $\mathcal{F} = \operatorname{conv} \operatorname{bd} \mathcal{F}$ ($\mathcal{F} = \operatorname{conv} \operatorname{rbd} \mathcal{F}$), then we have $\mathcal{F}_\rho = \operatorname{conv} \operatorname{bd} \mathcal{F}_\rho$ ($\mathcal{F}_\rho = \operatorname{conv} \operatorname{rbd} \mathcal{F}_\rho$, respectively) for all $\rho > 0$. Nevertheless, in the case of $\mathcal{F} = \operatorname{conv} \operatorname{extr} \mathcal{F}$, we need to show that $\mathcal{F}_\rho = \operatorname{conv} \operatorname{extr} \mathcal{F}_\rho$ because $\mathcal{F}$ could be not closed-valued. In order to do this, it is enough to prove that if $\mathcal{F}(y) := F = \operatorname{conv} \operatorname{extr} F$ and $x \in F_\rho$ with $\|x\| < \rho$, then $x \in \operatorname{conv} \operatorname{extr} F_\rho$. We can write

$$x = \sum_{j \in J} \lambda_j x_j, |J| < \infty, \sum_{j \in J} \lambda_j = 1, \lambda_j > 0 \text{ and } x_j \in \operatorname{extr} F \text{ for all } j \in J.$$

Let $I = \{j \in J \mid \|x_j\| > \rho\}$. If $I = \emptyset$, then $x_j \in [\operatorname{extr} F]_\rho \subset \operatorname{extr} F_\rho$ for all $j \in J$ and so $x \in \operatorname{conv} \operatorname{extr} F_\rho$. Otherwise take an arbitrary $k \in I$. Let $x'_k \in [x, x_k] \subset F$ such that $\|x'_k\| = \rho$, so that $x'_k \in \operatorname{extr} F_\rho$. If $x'_k = (1-\mu)\, x + \mu x_k$, with $0 < \mu < 1$, and we denote $y_j = x_j$ for all $j \in J$, $j \neq k$, and $y_k = x'_k$, we get an expression $x = \sum_{j \in J} \alpha_j y_j$, where $\sum_{j \in J} \alpha_j = 1, \alpha_j > 0$ and $y_j \in \operatorname{extr} F$ for all $j \in J$, but now the cardinality of the set $\{j \in J \mid \|y_j\| > \rho\}$ is $|I| - 1$. After $|I|$ iterations of this procedure we get x expressed as a convex combination of elements of $\operatorname{extr} F_\rho$. In fact, if Φ is any operator that transforms convex sets in $\mathbb{R}^n$ into sets in $\mathbb{R}^n$ satisfying $[\Phi(\mathcal{F})]_\rho \subset \Phi(\mathcal{F}_\rho) \subset \mathcal{F}_\rho$ and $\{x \in \mathcal{F}(y) \mid \|x\| = \rho\} \subset \Phi(\mathcal{F}_\rho(y))$ for all $y \in Y$, then

$$\mathcal{F} = \operatorname{conv} \Phi(\mathcal{F}) \Longrightarrow \mathcal{F}_\rho = \operatorname{conv} \Phi(\mathcal{F}_\rho).$$

Observe that $\Phi(\mathcal{F}) = \operatorname{bd} \mathcal{F}$, $\operatorname{rbd} \mathcal{F}$, and $\operatorname{extr} \mathcal{F}$ satisfy these conditions.

3. Lower semicontinuity. We shall use the following classical result ([6, Proposition 2.6]).

THEOREM 3.1. *If $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ is lsc at $y_0 \in \operatorname{dom} \mathcal{A}$, then $\operatorname{conv} \mathcal{A}$ is also lsc at y_0.*

In particular, taking $\mathcal{A} = \operatorname{bd} \mathcal{F}$ we get the direct statement of Proposition 1 in [5], whose corresponding converse statement establishes that, if $\mathcal{F} = \operatorname{conv} \operatorname{bd} \mathcal{F}$ is lsc and closed at $y_0 \in \operatorname{dom} \mathcal{F}$, then $\operatorname{bd} \mathcal{F}$ is also lsc at y_0. The next two results are counterparts of this converse statement for $\operatorname{rbd} \mathcal{F}$ and $\operatorname{extr} \mathcal{F}$ (instead of $\operatorname{bd} \mathcal{F}$). Example 3 in [5], where $\operatorname{bd} \mathcal{F} = \operatorname{rbd} \mathcal{F} = \operatorname{extr} \mathcal{F}$, shows that the closedness of $\mathcal{F}$ is not superfluous in these results. The following example shows that, in general, if $\operatorname{conv} \mathcal{A}$ is lsc and closed at y_0, then $\mathcal{A}$ is not necessarily lsc at y_0. Accordingly, the proofs must appeal to the specific properties of the sets $\operatorname{rbd} \mathcal{F}(y)$ and $\operatorname{extr} \mathcal{F}(y)$.

Example 3.2. Let $\mathcal{A} : \mathbb{R} \rightrightarrows \mathbb{R}$ such that

$$\mathcal{A}(y) = \begin{cases} \{-1, 0, 1\}, & y = 0, \\ \{-1, 1\}, & y \neq 0. \end{cases}$$

It is easy to see that $\operatorname{conv}\mathcal{A}$ is constant (so that it is continuous and closed) whereas $\mathcal{A}$ is not lsc at $y_0 = 0$.

THEOREM 3.3. *Let $\mathcal{F} : Y \rightrightarrows \mathbb{R}^n$ be such that $\mathcal{F} = \operatorname{conv}\operatorname{rbd}\mathcal{F}$ and $\mathcal{F}$ is lsc and closed at $y_0 \in \operatorname{dom}\mathcal{F}$. Then $\operatorname{rbd}\mathcal{F}$ is lsc at y_0.*

Proof. Let us denote $\mathcal{R} = \operatorname{rbd}\mathcal{F}$. Since $\mathcal{F}(y_0)$ cannot be singleton (otherwise $\mathcal{R}(y_0) = \emptyset$, contradicting the assumptions), we have $|\mathcal{F}(y_0)| > 1$.

We assume that $\mathcal{R}$ is not lsc at y_0 and we shall obtain a contradiction. This assumption entails the existence of an open convex set W and a sequence $\{y_r\}$ such that $y_r \to y_0$,

$$W \cap \mathcal{R}(y_0) \neq \emptyset, \tag{3.1}$$

and

$$W \cap \mathcal{R}(y_r) = \emptyset, r = 1, 2, \ldots . \tag{3.2}$$

Since $y_0 \in \operatorname{int}\operatorname{dom}\mathcal{F}$, we can assume that $y_r \in \operatorname{dom}\mathcal{F}, r = 1, 2, \ldots$. By (3.1), we can choose a point $\widehat{x} \in W \cap \mathcal{R}(y_0)$. Fix $\overline{x} \in \operatorname{rint}\mathcal{F}(y_0)$. Then

$$\widehat{x} - \lambda(\overline{x} - \widehat{x}) \notin \mathcal{F}(y_0) \text{ for all } \lambda > 0. \tag{3.3}$$

Because $\mathcal{F}$ is lsc at y_0 and $\overline{x}, \widehat{x} \in \mathcal{F}(y_0)$, there exist two sequences, $\{\overline{x}_r\}$ and $\{\widehat{x}_r\}$, with $\overline{x}_r, \widehat{x}_r \in \mathcal{F}(y_r)$ for all r, $\overline{x}_r \to \overline{x}$, and $\widehat{x}_r \to \widehat{x}$. Let $\delta > 0$ such that $B(\widehat{x}; \delta) \subset W$ and take $r_0 \in \mathbb{N}$ such that $\widehat{x}_r \in B(\widehat{x}; \frac{\delta}{2})$ for all $r \geq r_0$. Given $r \geq r_0$, (3.2) yields $B(\widehat{x}; \frac{\delta}{2}) \cap \mathcal{R}(y_r) = \emptyset$ and so, by (1.1), $B(\widehat{x}; \frac{\delta}{2}) \cap \operatorname{aff}\mathcal{F}(y_r) \subset \mathcal{F}(y_r)$. Hence

$$\widehat{x}_r - \frac{\delta}{4\|\overline{x}_r - \widehat{x}_r\|}(\overline{x}_r - \widehat{x}_r) \in \mathcal{F}(y_r) \quad \text{for all } r \geq r_0.$$

Taking limits as $r \to \infty$ we get, by the closedness of $\mathcal{F}$ at y_0, that

$$\widehat{x} - \frac{\delta}{4\|\overline{x} - \widehat{x}\|}(\overline{x} - \widehat{x}) \in \mathcal{F}(y_0),$$

in contradiction with (3.3). □

THEOREM 3.4. *Let $\mathcal{F} : Y \rightrightarrows \mathbb{R}^n$ be such that $\mathcal{F} = \operatorname{conv}\operatorname{extr}\mathcal{F}$ and $\mathcal{F}$ is lsc and closed at $y_0 \in \operatorname{dom}\mathcal{F}$. Then $\operatorname{extr}\mathcal{F}$ is lsc at y_0.*

Proof. We denote $\mathcal{E} = \operatorname{extr}\mathcal{F}$ and consider two possible cases.

Case 1. $\mathcal{F}(y_0)$ is bounded.

$\mathcal{F}$ is locally bounded at y_0 according to Proposition 2.1. Let V be an open set in Y, $y_0 \in V$, and $\rho > 0$ such that $\mathcal{F}(y) \subset \operatorname{cl} B(0_n; \rho)$ for all $y \in V$.

We assume that $\mathcal{E}$ is not lsc at y_0 and we shall get a contradiction.

Let W be an open set and let $\{y_r\} \subset V$, with $y_r \to y_0$, be such that

$$W \cap \mathcal{E}(y_0) \neq \emptyset \tag{3.4}$$

and

$$W \cap \mathcal{E}(y_r) = \emptyset \text{ for all } r \in \mathbb{N}. \tag{3.5}$$

By (3.4) we can select a point $x_0 \in W \cap \mathcal{E}(y_0)$.

Given $k \in \mathbb{N}$, since $x_0 \in B(x_0; k^{-1}) \cap \mathcal{F}(y_0)$ and $\mathcal{F}$ is lsc at y_0, there exists $r_k \in \mathbb{N}$ such that $B(x_0; k^{-1}) \cap \mathcal{F}(y_{r_k}) \neq \emptyset$. We can assume that $\{y_{r_k}\}$ is a subsequence of $\{y_r\}$. Let

$$z_k \in B(x_0; k^{-1}) \cap \mathcal{F}(y_{r_k}), \quad k = 1, 2, \ldots . \tag{3.6}$$

For any $k \in \mathbb{N}$, we can write

$$z_k = \sum_{i=1}^{n+1} \lambda_i^k e_i^k, \quad (\lambda_1^k, \ldots, \lambda_{n+1}^k) \in S, \quad e_i^k \in \mathcal{E}(y_{r_k}), \quad i = 1, \ldots, n+1, \tag{3.7}$$

because $\mathcal{F}(y_{r_k}) = \operatorname{conv} \mathcal{E}(y_{r_k})$.

By the compactness of the simplex S, we can assume without loss of generality that $(\lambda_1^k, \ldots, \lambda_{n+1}^k) \to (\lambda_1, \ldots, \lambda_{n+1}) \in S$. Analogously, since for any $i \in \{1, \ldots, n+1\}$,

$$\left\{e_i^k\right\} \subset \mathcal{E}(y_{r_k}) \subset \mathcal{F}(y_{r_k}) \subset \operatorname{cl} B(0_n; \rho),$$

we can assume that $e_i^k \to e_i \in \operatorname{cl} B(0_n; \rho)$, $i = 1, \ldots, n+1$. Since $\mathcal{F}$ is closed at y_0 and $e_i^k \in \mathcal{F}(y_{r_k})$ for all $k \in \mathbb{N}$, we get $e_i \in \mathcal{F}(y_0)$. Now, taking $\lim_k$ in (3.7) and recalling (3.6), we obtain

$$x_0 = \sum_{i=1}^{n+1} \lambda_i e_i, \quad (\lambda_1^k, \ldots, \lambda_{n+1}^k) \in S, \quad e_i \in \mathcal{F}(y_0), \quad i = 1, \ldots, n+1. \tag{3.8}$$

Since $x_0 \in \mathcal{E}(y_0) = \operatorname{extr} \mathcal{F}(y_0)$, we must have in (3.8) all the coefficients $\lambda_i = 0$ except one, $\lambda_j = 1$, in which case $x_0 = e_j$. Since $e_j = \lim_k e_j^k$, $\{e_j^k\} \subset \mathcal{E}(y_{r_k}) \subset \mathbb{R}^n \backslash W$ by (3.5), and $\mathbb{R}^n \backslash W$ is closed, we have $x_0 = e_j \in \mathbb{R}^n \backslash W$, i.e., $x_0 \notin W$. This contradicts the selection of x_0 in $W \cap \mathcal{E}(y_0)$.

Case 2. $\mathcal{F}(y_0)$ is unbounded.

The plan of the proof is to consider the truncated mapping $\mathcal{F}_\rho$, for a certain $\rho > 0$. Since $\mathcal{F}_\rho = \operatorname{conv} \operatorname{extr} \mathcal{F}_\rho$ by Remark 2.5 and $\mathcal{F}_\rho(y_0)$ is bounded, we are in case 1 and so $\operatorname{extr} \mathcal{F}_\rho$ will be lsc at y_0. This will allow us to conclude that $\mathcal{E} = \operatorname{extr} \mathcal{F}$ is lsc at y_0.

First we show that if $\mathcal{E}_\rho$ is the truncated mapping of $\mathcal{E}$ of radius $\rho > 0$, then

$$\operatorname{extr} \mathcal{F}_\rho(y) = \mathcal{E}_\rho(y) \cup \{x \in \mathcal{F}(y) \mid \|x\| = \rho\} \text{ for all } y \in Y. \tag{3.9}$$

In fact, the inclusion $\operatorname{extr} \mathcal{F}_\rho(y) \supset \mathcal{E}_\rho(y) \cup \{x \in \mathcal{F}(y) \mid \|x\| = \rho\}$ is obvious. For the reverse inclusion take $x \in \operatorname{extr} \mathcal{F}_\rho(y)$ such that $\|x\| < \rho$. Assume that $x = \lambda u + (1-\lambda)v$ with $0 < \lambda < 1$ and $u, v \in \mathcal{F}(y), u \neq v$. We may assume without loss of generality that $\|u\|, \|v\| < \rho$ which contradicts the fact that x is an extreme point of $\mathcal{F}_\rho(y)$. Therefore, $x \in \mathcal{E}_\rho(y)$.

Now, in order to prove that $\mathcal{E}$ is lsc at y_0, assume that $\mathcal{E}$ is not. Then there exist $x_0 \in \mathcal{E}(y_0)$, $\delta > 0$, and a sequence $\{y_r\}$ such that $y_r \to y_0$ and $\mathcal{E}(y_r) \cap B(x_0; \delta) = \emptyset$ for every $r \in \mathbb{N}$. Take $\rho = \|x_0\| + \delta$ and observe that $x_0 \in \operatorname{extr} \mathcal{F}_\rho(y_0)$ according to (3.9). $\mathcal{F}_\rho$ is lsc and closed at y_0, and so, by case 1, $\operatorname{extr} \mathcal{F}_\rho$ is lsc at y_0, which implies that there exists a sequence $\{x_r\}$ such that $x_r \to x_0$, $x_r \in \operatorname{extr} \mathcal{F}_\rho(y_r)$, and $\|x_r\| < \rho$ for r large enough. This yields the contradiction $\mathcal{E}(y_r) \cap B(x_0; \delta) \neq \emptyset$. □

4. Upper semicontinuity and closedness. In contrast with the lower semicontinuity, the closedness of a set-valued mapping $\mathcal{A}$ is not inherited by $\operatorname{conv}\mathcal{A}$ (even though $\mathcal{A}=\operatorname{bd}\mathcal{F},\operatorname{rbd}\mathcal{F},\operatorname{extr}\mathcal{F}$, as Example 3 in [5] shows). On the other hand, Proposition 4 in [5] establishes that, if $\operatorname{bd}\mathcal{F}$ is usc at y_0, then $\mathcal{F}$ is usc at y_0. In this section we shall prove that a similar statement holds for $\operatorname{rbd}\mathcal{F}$, but not for $\operatorname{extr}\mathcal{F}$ even though $\operatorname{extr}\mathcal{F}$ is either locally bounded or closed (nevertheless, according to the next Theorem 4.3, these two properties together entail the upper semicontinuity and the closedness of $\mathcal{F}$).

Example 4.1. Let $\mathcal{E}:Y\rightrightarrows\mathbb{R}^2$, where $Y=[2,+\infty[$ and

$$\mathcal{E}(y)=\left\{x\in\mathbb{R}^2\mid\|x\|=1,x_1<y^{-1}\right\}\cup\{(y,0)\}\ \text{ for all } y\in Y.$$

It is easy to see that $\mathcal{E}$ is locally bounded and continuous but not closed at $y_0=2$, and that it is the extreme points set mapping of $\mathcal{F}=\operatorname{conv}\mathcal{E}$. We shall prove that $\mathcal{F}$ is not usc at y_0. Let

$$W:=\{x\in\mathbb{R}^2\mid\sqrt{3}\,|x_2|<2-x_1,x_1<2\}\cup B\left((2,0);\frac{1}{2}\right),$$

$\mathcal{F}(y_0)\subset W$. If $y>2$, then $\overline{x}=(1,\frac{1}{\sqrt{3}})\in\mathcal{F}(y)\setminus W$. Observe also that $\mathcal{F}$ cannot be closed at y_0 (because $\mathcal{F}(y_0)$ is not closed).

Example 4.2. Let $\mathcal{E}:\mathbb{R}\rightrightarrows\mathbb{R}^3$ be such that

$$\mathcal{E}(y)=\left\{(x_1,x_2,0)\in\mathbb{R}^3\mid x_2=x_1^2\right\}\cup\{(0,0,y)\}\ \text{ for all } y\in\mathbb{R}.$$

As in the previous example, $\mathcal{E}=\operatorname{extr}\mathcal{F}$ for $\mathcal{F}=\operatorname{conv}\mathcal{E}$ and $\mathcal{E}$ is continuous at $y_0=0$, but now $\mathcal{E}$ is also closed and $\mathcal{E}(y_0)$ is unbounded. In order to prove that $\mathcal{F}$ is not usc at y_0, let us consider the convex plane set $C:=\left\{x\in\mathbb{R}^2\mid x_2\geq x_1^2\right\}$ and the open set

$$W:=\mathbb{R}^3\setminus\left\{x\in\mathbb{R}^3\mid x_3\geq x_2^{-1},x_2>0\right\}.$$

Obviously, $\mathcal{F}(y_0)=C\times\{0\}\subset W$. Moreover, if $y>0$ and $y>4/r^2$ for $0\neq r\in\mathbb{R}$, we have

$$\left(0,\frac{r^2}{2},\frac{y}{2}\right)=\frac{1}{2}(0,0,y)+\frac{1}{4}[(-r,r^2,0)+(r,r^2,0)]\in\mathcal{F}(y)\setminus W,$$

so that $\mathcal{F}(y)\not\subseteq W$. Hence $\mathcal{F}$ is not usc at y_0.

Finally, we show that $\mathcal{F}$ is closed at y_0. Let $y_r\to y_0$ and $x^r\to x^0$ be such that $x^r\in\mathcal{F}(y_r)$, $r=1,2,\ldots$. Since $\mathcal{F}(y_r)=\operatorname{conv}[(C\times\{0\})\cup\{(0,0,y_r)\}]$, for any $r\in\mathbb{N}$, we can write

$$x^r=\lambda_r(c^r,0)+(1-\lambda_r)(0,0,y_r)=(\lambda_r c^r,(1-\lambda_r)y_r),c^r\in C,0\leq\lambda_r\leq 1.$$

Observe that $c^r\in C$ and $(0,0)\in C$ entail $\lambda_r c^r\in C$. On the other hand, $x_3^r=(1-\lambda_r)y_r\in\operatorname{conv}\{0,y_r\}$. Taking limits we get $x^0=\lim_r x^r\in C\times\{0\}=\mathcal{F}(y_0)$.

The next result is a reformulation of a well-known result ([1, Lemma 1.1.9]), taking into account the mentioned equivalence between closedness and outer semicontinuity.

THEOREM 4.3. *If $\mathcal{A}:Y\rightrightarrows\mathbb{R}^n$ is closed and locally bounded at $y_0\in\operatorname{dom}\mathcal{A}$, then $\operatorname{conv}\mathcal{A}$ is closed and usc at y_0.*

Observe that it is not possible to replace in Theorem 4.3 above the condition "$\mathcal{A}$ is closed and locally bounded at y_0" by just "$\mathcal{A}$ is closed and usc at y_0" (recall Example 4.2).

Given two set-valued mappings $\mathcal{M}, \mathcal{N} : Y \rightrightarrows \mathbb{R}^n$, we say that $\mathcal{M}$ is *contained* in $\mathcal{N}$ (in brief, $\mathcal{M} \subset \mathcal{N}$) *locally at* y_0 if there exists an open set $V \subset Y$, containing y_0, such that $\mathcal{M}(y) \subset \mathcal{N}(y)$ for all $y \in V$. We also define the *closure* of $\mathcal{M}$ as the mapping $\operatorname{cl}\mathcal{M} : Y \rightrightarrows \mathbb{R}^n$ such that $(\operatorname{cl}\mathcal{M})(y) = \operatorname{cl}\mathcal{M}(y)$ for all $y \in Y$.

COROLLARY 4.4. *Let $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ and let $y_0 \in \operatorname{dom}\mathcal{A}$ be such that $\mathcal{A}(y_0)$ is bounded and $\mathcal{A}$ is usc at y_0. Then each of the following conditions guarantees that* $\operatorname{conv}\mathcal{A}$ *is closed and usc at* y_0*:*
(i) $\mathcal{A}(y_0)$ *is closed.*
(ii) $\operatorname{cl}\mathcal{A} \subset \operatorname{conv}\mathcal{A}$ *locally at* y_0.

Proof. (i) Since $\mathcal{A}$ is usc at y_0 and $\mathcal{A}(y_0)$ is bounded, then $\mathcal{A}$ is locally bounded at y_0. The conclusion follows from Theorem 4.3.

(ii) First we prove that $\operatorname{cl}\mathcal{A}$ is usc at y_0. In fact, given an open set W such that $\operatorname{cl}\mathcal{A}(y_0) \subset W$, we have

$$\mathcal{A}(y_0) \subset U := \operatorname{cl}\mathcal{A}(y_0) + B(0_n; \varepsilon),$$

where

$$\varepsilon := \frac{1}{2} d\left(\operatorname{cl}\mathcal{A}(y_0), \mathbb{R}^n \setminus W\right) > 0.$$

Since U is open, there exists an open set $V \subset Y$, $y_0 \in V$, such that $\mathcal{A}(y) \subset U$ for all $y \in V$. Then $\operatorname{cl}\mathcal{A}(y) \subset \operatorname{cl} U \subset W$.

Now we show that $\operatorname{conv}\mathcal{A}$ is usc at y_0.

Since $\operatorname{cl}\mathcal{A}$ is usc at y_0 and $\operatorname{cl}\mathcal{A}(y_0)$ is compact we can assert, applying statement (i) to $\operatorname{cl}\mathcal{A}$, that $\operatorname{conv}\operatorname{cl}\mathcal{A}$ is closed and usc at y_0. Since the assumption implies that $\operatorname{conv}\operatorname{cl}\mathcal{A} = \operatorname{conv}\mathcal{A}$ locally at y_0, we conclude that $\operatorname{conv}\mathcal{A}$ is closed and usc at y_0. ∎

The boundedness assumption in Corollary 4.4 is not superfluous even for the extreme points set mapping (recall again Example 4.2, where (i) holds).

Now, we give a condition that assures that if $\mathcal{A}$ is usc at y_0, then $\operatorname{conv}\mathcal{A}$ is usc at y_0 as well.

PROPOSITION 4.5. *Let $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ and let $y_0 \in \operatorname{dom}\mathcal{A}$ be such that*

$$\operatorname{rbd}\operatorname{conv}\mathcal{A} \subset \mathcal{A} \subset \operatorname{conv}\operatorname{rbd}\operatorname{conv}\mathcal{A}$$

locally at y_0 and $\operatorname{conv}\mathcal{A}$ *is closed at y_0. If $\mathcal{A}$ is usc at y_0, then* $\operatorname{conv}\mathcal{A}$ *is usc at y_0.*

Proof. Let $\mathcal{F} := \operatorname{conv}\mathcal{A}$ and let $\mathcal{R} = \operatorname{rbd}\mathcal{F}$. We assume that $\mathcal{A}$ is usc at y_0.

Let V_1 be a neighborhood of y_0 such that $\mathcal{R}(y) \subset \mathcal{A}(y) \subset \operatorname{conv}\mathcal{R}(y)$ for all $y \in V_1$. Then we have $\mathcal{F}(y) = \operatorname{conv}\mathcal{R}(y)$ for all $y \in V_1$.

By Proposition 2.3, there exists $\overline{\rho} > 0$ and a neighborhood of y_0, $V_2 \subset V_1$, such that

$$\mathcal{A}(y) \setminus \mathcal{A}_{\overline{\rho}}(y) \subset \mathcal{A}(y_0) \setminus \mathcal{A}_{\overline{\rho}}(y_0) \quad \text{for all } y \in V_2. \tag{4.1}$$

We shall prove that we can replace $\mathcal{A}$ with $\mathcal{F}$ in (4.1), so that $\mathcal{F}$ will be usc at y_0 because $\mathcal{F}$ is closed at y_0 (again by Proposition 2.3). Let $\overline{y} \in V_2$ and $\overline{x}$ be such that

$$\overline{x} \in \mathcal{F}(\overline{y}) \text{ and } \|\overline{x}\| > \overline{\rho}.$$

If $\overline{x} \in \mathcal{A}(\overline{y})$, then $\overline{x} \in \mathcal{A}(\overline{y}) \setminus \mathcal{A}_{\overline{\rho}}(\overline{y})$ and so

$$\overline{x} \in \mathcal{A}(y_0) \setminus \mathcal{A}_{\overline{\rho}}(y_0) \subset \mathcal{A}(y_0) \subset \mathcal{F}(y_0).$$

Suppose that $\overline{x} \notin \mathcal{A}(\overline{y})$ and $\overline{x} \notin \mathcal{F}(y_0)$. Now, $\mathcal{R}(\overline{y}) \subset \mathcal{A}(\overline{y})$ implies that

$$\overline{x} \in \mathcal{F}(\overline{y}) \setminus \mathcal{A}(\overline{y}) \subset \mathcal{F}(\overline{y}) \setminus \mathcal{R}(\overline{y}) = \operatorname{rint} \mathcal{F}(\overline{y}). \tag{4.2}$$

Since $\mathcal{F}(y_0)$ is closed and convex, there exist $a \neq 0_n$ and a scalar α such that

$$a'\overline{x} = \alpha \text{ and } a'x < \alpha \text{ for all } x \in \mathcal{F}(y_0). \tag{4.3}$$

Consider the flat $H := \{x \in \operatorname{aff} \mathcal{F}(\overline{y}) \mid a'x = \alpha\}$. Obviously $a'c = 0$ for all $c \in H - \overline{x}$ (the linear subspace parallel to H).

We shall get a contradiction if we are able to prove that $H \subset \mathcal{F}(\overline{y})$. In fact, in this case if $a'x = \alpha$ for all $x \in \operatorname{aff} \mathcal{F}(\overline{y})$, then $H = \operatorname{aff} \mathcal{F}(\overline{y})$ and so $\mathcal{F}(\overline{y}) = \operatorname{aff} \mathcal{F}(\overline{y})$, i.e., $\mathcal{F}(\overline{y})$ is a flat. Otherwise $\mathcal{F}(\overline{y})$ is a half-flat. In both cases $\mathcal{F}(\overline{y}) \neq \operatorname{conv} \mathcal{R}(\overline{y})$ despite of $\overline{y} \in V_1$.

In order to prove that $H \subset \mathcal{F}(\overline{y})$ we associate with each $c \in (H - \overline{x}) \setminus \{0_n\}$ the halfline $S(c) := \{\overline{x} + \lambda c \mid \lambda \geq 0\} \subset H$. Now we prove that

$$S(c) \cap \operatorname{cl} B(0_n; \overline{\rho}) = \emptyset \Rightarrow S(c) \subset \operatorname{rint} \mathcal{F}(\overline{y}). \tag{4.4}$$

Assume that $S(c) \cap \operatorname{cl} B(0_n; \overline{\rho}) = \emptyset$ and $S(c) \not\subseteq \operatorname{rint} \mathcal{F}(\overline{y})$. By (4.2) we have

$$0 < \overline{\lambda} := \sup \{\lambda \in \mathbb{R}_+ \mid \overline{x} + \lambda c \in \operatorname{rint} \mathcal{F}(\overline{y})\} < +\infty.$$

Thus $\overline{x} + \overline{\lambda} c \in \mathcal{R}(\overline{y}) \subset \mathcal{A}(\overline{y})$ and, by (4.1), we have

$$\begin{aligned} \overline{x} + \overline{\lambda} c \in \mathcal{A}(\overline{y}) \setminus \operatorname{cl} B(0_n; \overline{\rho}) &= \mathcal{A}(\overline{y}) \setminus \mathcal{A}_{\overline{\rho}}(\overline{y}) \\ &\subset \mathcal{A}(y_0) \setminus \mathcal{A}_{\overline{\rho}}(y_0) \subset \mathcal{F}(y_0), \end{aligned}$$

so that by (4.3) $a'\overline{x} = \alpha$ and $a'\overline{x} = a'(\overline{x} + \overline{\lambda} c) < \alpha$. This is a contradiction.

Finally, we prove that $H \subset \mathcal{F}(\overline{y})$ by means of a discussion based on the set $C := H \cap \operatorname{cl} B(0_n; \overline{\rho})$.

If $C = \emptyset$, then H is the union of halflines emanating from $\overline{x}$ in all directions parallel to H, and these halflines are contained in $\operatorname{rint} \mathcal{F}(\overline{y})$, according to (4.4). Then $H \subset \operatorname{rint} \mathcal{F}(\overline{y}) \subset \mathcal{F}(\overline{y})$.

If $|C| = 1$, then all the halflines mentioned above are contained in $\operatorname{rint} \mathcal{F}(\overline{y})$, except one. Thus $H \subset \mathcal{F}(\overline{y})$.

If $|C| > 1$, then C is a closed ball in H and all the halflines in H emanating from $\overline{x}$ which do not meet C are contained in $\operatorname{rint} \mathcal{F}(\overline{y})$. Then $\mathcal{F}(\overline{y})$ contains the complement, relative to H, of a pointed cone with apex $\overline{x}$. Hence we have again $H \subset \mathcal{F}(\overline{y})$. □

Given $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ and $\rho > 0$, we denote by $\mathcal{A}_\rho$ and by $(\operatorname{conv} \mathcal{A})_\rho$ the truncated mappings of $\mathcal{A}$ and $\operatorname{conv} \mathcal{A}$, respectively, with radius ρ. We also define the mapping $\mathcal{A}^\rho : Y \rightrightarrows \mathbb{R}^n$ such that

$$\mathcal{A}^\rho(y) = \mathcal{A}_\rho(y) \cup \{x \in \operatorname{conv} \mathcal{A}(y) \mid \|x\| = \rho\}.$$

If $\mathcal{F} = \operatorname{conv} \operatorname{rbd} \mathcal{F}$ ($\mathcal{F} = \operatorname{conv} \operatorname{bd} \mathcal{F}$), and $\mathcal{A} = \operatorname{rbd} \mathcal{F}$ ($\mathcal{A} = \operatorname{bd} \mathcal{F}$, respectively), then $(\operatorname{conv} \mathcal{A})_\rho = \operatorname{conv} \mathcal{A}^\rho$. The inclusion $(\operatorname{conv} \mathcal{A})_\rho \subset \operatorname{conv} \mathcal{A}^\rho$ follows from the fact that any convex combination $x = (1 - \lambda) u + \lambda v$, $0 \leq \lambda \leq 1$, $x, u, v \in \operatorname{conv} \mathcal{A}(y)$,

$\|x\| \leq \rho$ and $\|v\| > \rho$, can be expressed as $x = (1-\alpha)\,u + \alpha w$, where $0 \leq \alpha \leq 1$ and $w \in [x, v] \subset \operatorname{conv} \mathcal{A}(y)$, with $\|w\| = \rho$.

LEMMA 4.6. *Let $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ and let $y_0 \in \operatorname{dom} \mathcal{A}$ be such that $\mathcal{A}(y_0)$ and $\operatorname{conv} \mathcal{A}(y_0)$ are closed and $\mathcal{A}$ is usc at y_0. Then $\{\rho > 0 \mid \mathcal{A}^\rho$ is closed at $y_0\}$ is unbounded.*

Proof. We will prove that, under the assumptions, $\mathcal{A}^\rho$ is closed at y_0 for all $\rho \in I := \{\rho > 0 \mid \mathcal{A}_\rho(y_0) \neq \emptyset\}$ (I is a halfline). We denote $\mathcal{F} = \operatorname{conv} \mathcal{A}$.

Let $\rho \in I$, $y_k \to y_0$ and $x_k \to x_0$ be such that $x_k \in \mathcal{A}^\rho(y_k)$, $k = 1, 2, \ldots$.

Since $\mathcal{A}^\rho(y_k) \subset \operatorname{cl} B(0_n; \rho)$ for all $k \in \mathbb{N}$, $\|x_0\| \leq \rho$.

If there exists an increasing sequence $\{k_r\} \subset \mathbb{N}$ such that $x_{k_r} \in \mathcal{A}(y_{k_r})$, $r = 1, 2, \ldots$, then $x_0 \in \mathcal{A}(y_0)$ (because $\mathcal{A}$ is closed at y_0) and so $x_0 \in \mathcal{A}_\rho(y_0) \subset \mathcal{A}^\rho(y_0)$.

Thus we can assume without loss of generality that $x_k \notin \mathcal{A}(y_k)$, $k = 1, 2, \ldots$.

Given $k \in \mathbb{N}$, we have $x_k \in \mathcal{A}^\rho(y_k) \setminus \mathcal{A}_\rho(y_k) \subset \{x \in \mathcal{F}(y_k) \mid \|x\| = \rho\}$. Since $\|x_k\| = \rho$ for all k, we have $\|x_0\| = \rho$.

If $x_0 \in \mathcal{F}(y_0)$, then $x_0 \in \mathcal{A}^\rho(y_0)$ and we have finished. So we assume that $x_0 \notin \mathcal{F}(y_0)$. Since this set is closed, $\varepsilon := \frac{1}{2} d(x_0, \mathcal{F}(y_0)) > 0$. Let us consider the open convex set $W := \mathcal{F}(y_0) + B(0_n; \varepsilon)$. Since $\mathcal{A}(y_0) \subset \mathcal{F}(y_0) \subset W$ and $\mathcal{A}$ is usc at y_0, there exists a neighborhood of y_0, say V, such that $\mathcal{A}(y) \subset W$ for all $y \in V$. Then, taking convex hulls, we get $\mathcal{F}(y) \subset W$ for all $y \in V$.

Let $k_0 \in \mathbb{N}$ be such that $y_k \in V$ for all $k \geq k_0$. For such a k we have $x_k \in \mathcal{A}^\rho(y_k) \subset \mathcal{F}(y_k) \subset W$ whereas $x_0 \notin \mathcal{F}(y_0)$, so that $d(x_k, x_0) \geq \varepsilon$. This contradicts $x_k \to x_0$. ∎

LEMMA 4.7. *Let $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ be such that $(\operatorname{conv} \mathcal{A})_\rho = \operatorname{conv} \mathcal{A}^\rho$ for all $\rho > 0$ sufficiently large and let $y_0 \in \operatorname{dom} \mathcal{A}$ such that $\{\rho > 0 \mid \mathcal{A}^\rho$ is closed at $y_0\}$ is unbounded. Then $\operatorname{conv} \mathcal{A}$ is closed at y_0.*

Proof. Let $\mathcal{F} := \operatorname{conv} \mathcal{A}$. Let $y_r \to y_0$ and $x_r \to x_0$ be such that $x_r \in \mathcal{F}(y_r)$, $r = 1, 2, \ldots$.

Since the convergent sequence $\{x_r\}$ is bounded, and by the assumptions on $\{\mathcal{A}^\rho \mid \rho > 0\}$, there exists $\rho > 0$ such that $\|x_r\| \leq \rho$ for all $r \in \mathbb{N}$, $\mathcal{F}_\rho = \operatorname{conv} \mathcal{A}^\rho$ and $\mathcal{A}^\rho$ is closed at y_0. Since $\mathcal{A}^\rho$ is closed and locally bounded at y_0, by Theorem 4.3, $\mathcal{F}_\rho = \operatorname{conv} \mathcal{A}^\rho$ is closed and usc at y_0. Then, since $x_r \in \mathcal{F}_\rho(y_r)$ for all $r \in \mathbb{N}$, we have $x_0 \in \mathcal{F}_\rho(y_0) \subset \mathcal{F}(y_0)$. ∎

PROPOSITION 4.8. *Let $\mathcal{A} : Y \rightrightarrows \mathbb{R}^n$ be such that $(\operatorname{conv} \mathcal{A})_\rho = \operatorname{conv} \mathcal{A}^\rho$ for all $\rho > 0$ sufficiently large and let $y_0 \in \operatorname{dom} \mathcal{A}$ such that $\mathcal{A}(y_0)$ is closed,*

$$\operatorname{rbd} \operatorname{conv} \mathcal{A} \subset \mathcal{A} \subset \operatorname{conv} \operatorname{rbd} \operatorname{conv} \mathcal{A}$$

locally at y_0 and $\mathcal{A}$ is usc at y_0. Then $\operatorname{conv} \mathcal{A}$ is usc at y_0.

Proof. By assumption $\operatorname{rbd} \operatorname{conv} \mathcal{A}(y_0) \subset \mathcal{A}(y_0) \subset \operatorname{conv} \mathcal{A}(y_0)$, so that $\operatorname{conv} \mathcal{A}(y_0)$ is closed. Then, by Lemma 4.6, $\{\rho > 0 \mid \mathcal{A}^\rho$ is closed at $y_0\}$ is unbounded and, by Lemma 4.7, $\operatorname{conv} \mathcal{A}$ is closed at y_0. We conclude that $\operatorname{conv} \mathcal{A}$ is usc at y_0 by Proposition 4.5. ∎

THEOREM 4.9. *Let $\mathcal{F} : Y \rightrightarrows \mathbb{R}^n$ be such that $\mathcal{F} = \operatorname{conv} \operatorname{rbd} \mathcal{F}$ and $\operatorname{rbd} \mathcal{F}$ is usc at $y_0 \in \operatorname{dom} \mathcal{F}$. Then $\mathcal{F}$ is usc at y_0.*

Proof. It is a straightforward consequence of Proposition 4.8, taking $\mathcal{A} = \operatorname{rbd} \mathcal{F}$. ∎

The last four results are also valid replacing "rbd" everywhere with "bd" (see [5]). The final example illustrates the results in sections 3 and 4 and shows that there is no usc counterpart for Theorems 3.3 and 3.4.

Example 4.10. Let us identify the complex field $\mathbb{C}$ with $\mathbb{R}^2$ and let us take as Y the set of polynomials of degree $q \in \mathbb{N}$ (fixed) with complex coefficients equipped with the Euclidean distance on $\mathbb{R}^{2q+2}$. Given $y \in Y$, we denote by $\mathcal{A}(y)$ its set of complex zeros and by $\mathcal{F}(y)$ its convex hull, i.e., the polytope $\mathcal{F}(y) = \operatorname{conv} \mathcal{A}(y)$. By the fundamental theorem of algebra, $\mathcal{A}(y) \neq \emptyset$ for all $y \in Y$, so that $\operatorname{dom} \mathcal{A} = Y$. Let us denote by $\mathcal{B}$, $\mathcal{R}$, and $\mathcal{E}$ the boundary mapping, the relative boundary mapping, and the extreme points set mapping of $\mathcal{F}$, respectively. By Proposition 2.4, we have

$$\mathcal{F} = \operatorname{conv} \mathcal{B} = \operatorname{conv} \mathcal{R} = \operatorname{conv} \mathcal{E}.$$

$\mathcal{A}$ is lsc and usc as a consequence of a well-known consequence of Rolle's theorem for complex polynomials (see, e.g., [7]) and, since it has closed images, it is also closed. By Theorem 3.1 and Corollary 4.4, $\mathcal{F}$ is also lsc, usc, and closed. Consequently, $\mathcal{B}$, $\mathcal{R}$, and $\mathcal{E}$ are lsc by Propositions 1 in [4] and Theorems 3.3 and 3.4 in this paper (the direct proofs of these statements are rather involved). Now we show that $\mathcal{R}$ and $\mathcal{E}$ are neither usc nor closed if $q = 3$.

Let $y_0 = x^3 + x$, with $\mathcal{A}(y_0) = \{0, \pm i\}$, and let $y_r = x^3 - \frac{2}{r}x^2 + (1 + \frac{1}{r^2})x$, with $\mathcal{A}(y_r) = \left\{0, \frac{1}{r} \pm i\right\}$, $r = 1, 2, \ldots$. Obviously, $y_r \to y_0$. Taking the constant sequence $x_r = 0$, $r = 1, 2, \ldots$, we have $x_r \in \mathcal{E}(y_r) \subset \mathcal{F}(y_r)$ for all r, whereas $0 \notin \mathcal{E}(y_0) = \mathcal{R}(y_0) = \{\pm i\}$. Thus neither $\mathcal{R}$ nor $\mathcal{E}$ is closed (usc) at y_0.

Acknowledgment. The authors wish to thank the referees for their valuable comments and suggestions.

PATH-FOLLOWING METHODS FOR A CLASS OF CONSTRAINED MINIMIZATION PROBLEMS IN FUNCTION SPACE*

MICHAEL HINTERMÜLLER†‡ AND KARL KUNISCH‡

Abstract. Path-following methods for primal-dual active set strategies requiring a regularization parameter are introduced. Existence of a primal-dual path and its differentiability properties are analyzed. Monotonicity and convexity of the primal-dual path value function are investigated. Both feasible and infeasible approximations are considered. Numerical path-following strategies are developed and their efficiency is demonstrated by means of examples.

Key words. semismooth Newton methods, path-following methods, active set strategy, primal-dual methods

DOI. 10.1137/040611598

1. Introduction.

Primal-dual active set strategies or, in some cases equivalently, semismooth Newton methods, were proved to be efficient methods for solving constrained variational problems in function space [1, 9, 10, 11, 12, 13]. In certain cases regularization is required, resulting in a family of approximating problems with more favorable properties than those of the original one, [12, 13]. In previous work [13] convergence, and in some cases rate of convergence, with respect to the regularization parameter was proved. In the numerical work the adaptation of these parameters was heuristic, however. The focus of the present investigation is on an efficient control of the regularization parameter in the primal-dual active set strategy for a class of constrained variational problems. To explain the involved issues we proceed mostly formally in this section and consider the problem

$$\left\{\begin{array}{l} \min \mathcal{J}(v) \quad \text{over } v \in X \\ \text{s.t. } G\,v \le \psi, \end{array}\right. \tag{1}$$

where $\mathcal{J}$ is a quadratic functional on a Hilbert space X, and $G\colon X \to Y$. It is assumed that $Y \subset L^2(\Omega)$ is a Hilbert lattice with ordering $\le$ induced by the natural ordering of $L^2(\Omega)$. We note that (1) subsumes problems of very different nature. For example, for the control constrained optimal control problem

$$\left\{\begin{array}{l} \min \frac{1}{2}|y-z|_{L^2}^2 + \frac{\alpha}{2}|u|_{L^2}^2 \\ \text{s.t. } -\Delta y = u \ \text{ in } \ \Omega, \quad y = 0 \ \text{ on } \ \partial\Omega, \\ \qquad u \le \psi \ \text{ a.e. in } \Omega, \end{array}\right.$$

with Ω a bounded domain in $\mathbb{R}^n$, $z \in L^2(\Omega)$, $\alpha > 0$, one can use $y = (-\Delta)^{-1}u$, where Δ denotes the Laplacian with homogenous Dirichlet boundary conditions, and arrive

at

$$\begin{cases} \min \frac{1}{2}|(-\Delta)^{-1}u - z|^2 + \frac{\alpha}{2}|u|^2 \\ \text{s.t. } u \le \psi \text{ a.e. in } \Omega, \end{cases}$$

which is clearly of the form (1). For $\mathcal{J}(v) = \frac{1}{2}\int_\Omega |\nabla v|^2 dx - \int_\Omega f\, v$, $X = H_0^1(\Omega)$, and $G = I$ we obtain the classical obstacle problem. For state constrained control problems with $y \le \psi$ one has

$$\begin{cases} \min \frac{1}{2}|(-\Delta)^{-1}u - z|^2 + \frac{\alpha}{2}|u|^2 \\ \text{s.t. } (-\Delta)^{-1}u \le \psi \text{ a.e. in } \Omega, \end{cases}$$

which is also of the form (1). From the point of view of duality theory these three problems are very different. While it is straightforward to argue the existence of a Lagrange multiplier in $L^2(\Omega)$ for the control constrained optimal control problem, it is already more involved and requires additional assumptions to guarantee its existence in $L^2(\Omega)$ for obstacle problems, and for state constrained problems the Lagrange multiplier is only a measure. If we resort to a formal discussion, then in either of these cases we arrive at the optimality system of the form

$$\begin{cases} \mathcal{J}'(v) + G^*\lambda = 0, \\ \lambda = \max(0, \lambda + c(G(v) - \psi)\,) \end{cases} \tag{2}$$

for any fixed $c > 0$. Here, G^* denotes the adjoint of G. The second equation in (2) is equivalent to $\lambda \ge 0$, $G(v) \le \psi$, and $\lambda(G(v) - \psi) = 0$.

Continuing formally, the primal-dual active set strategy determines the active set at iteration level k by means of

$$\mathcal{A}_{k+1} = \{x \in \Omega \colon \lambda_k(x) + c(G(v_k)(x) - \psi(x)\,) > 0\},$$

assigns the inactive set $\mathcal{I}_{k+1} = \Omega \setminus \mathcal{A}_{k+1}$, and updates (v, λ) by means of

$$\begin{cases} \mathcal{J}'(v_{k+1}) + G^*\lambda_{k+1} = 0, \\ \lambda_{k+1} = 0 \ \text{ on } \ \mathcal{I}_{k+1}, \quad (G(v_{k+1}) - \psi)(x) = 0 \ \text{ for } \ x \in \mathcal{A}_{k+1}. \end{cases} \tag{3}$$

These auxiliary problems require special attention. For obstacle problems the constraint $v_{k+1} = \psi$ on $\mathcal{A}_{k+1}$ induces that the associated Lagrange multiplier λ_{k+1} is in general less regular than the Lagrange multiplier associated with $v \le \psi$ for the original problem; see, e.g., [13]. For problems with combined control and state constraints it may happen that due to the assignment on $\mathcal{I}_{k+1}$ and $\mathcal{A}_{k+1}$, (3) has no solution while the original problem does. For these reasons in, e.g., [9, 12, 13] the second equation in (2) was regularized, resulting in the family of equations

$$\begin{cases} \mathcal{J}'(v) + G^*\lambda = 0, \\ \lambda = \max(0, \bar{\lambda} + \gamma(G(v) - \psi)), \end{cases} \tag{4}$$

where $\bar{\lambda}$ is fixed, possibly $\bar{\lambda} = 0$, and $\gamma \in \mathbb{R}^+$. In the above-mentioned references it was shown that under appropriate conditions the solutions $(v_\gamma, \lambda_\gamma)$ to (4) exist, the quantity λ_γ enjoys extra regularity, and $(v_\gamma, \lambda_\gamma)$ converge to the solution of (2) as $\gamma \to \infty^+$.

In previous numerical implementations the increase of γ to infinity was heuristic. As the system (4) becomes increasingly ill-conditioned as γ tends to ∞, in this paper a framework for a properly controlled increase of γ-values will be developed in order to cope with the conditioning problem. In fact, in a typical algorithmic regime for solving (1) one uses the solution $(v_\gamma, \lambda_\gamma)$ to (4) for some γ as the initial guess for the solution to (4) for the updated γ-value $\gamma^+ > \gamma$. Typically, if $\gamma^+ \gg \gamma$, then $(v_\gamma, \lambda_\gamma)$ is only a poor approximation of $(v_{\gamma^+}, \lambda_{\gamma^+})$, which in addition to numerical linear algebra issues (like ill-conditioned system matrices) causes severe stability problems for iterative solvers for (4) such as semismooth Newton methods. Together with developing a new γ-update strategy, we aim at solving the auxiliary problems (4) only inexactly to keep the overall computational cost low. To this end we define neighborhoods of the path which allow inexact solutions and which contract in a controlled way towards the path as the iteration proceeds. Our work is inspired by concepts from path-following methods in finite dimensional spaces [4, 5, 16, 18, 19]. We first guarantee the existence of a sufficiently smooth path $\gamma \to (v_\gamma, \lambda_\gamma)$, with $\gamma \in (0, \infty)$ in appropriately chosen function spaces. Once the path is available it can be used as the basis for updating strategies of the path parameter. Given a current value γ_k, with associated primal and dual states $(v_{\gamma_k}, \lambda_{\gamma_k})$, the γ-update should be sufficiently large to make good progress towards satisfying the complementarity conditions. On the other hand, since we are not solving the problems along the path exactly, we have to use safeguards against steps which would lead us too far off the path. Of course, these goals are impeded by the fact that the path is not available numerically. To overcome this difficulty we use qualitative properties of the value function, like monotonicity and convexity, which can be verified analytically. These suggest the introduction of model functions which will be shown to approximate the value functional along the path very well. We use these model functions for our updating strategies of γ. In the case of exact path-following we can even prove convergence of the resulting strategy. In the present paper the program just described is carried out for a class of problems corresponding to contact problems. State constrained optimal control problems require a different approach that will be considered independently. As we shall see, the (infinite dimensional) parameter $\bar{\lambda}$ can be used to guarantee that the iterates of the primal variable are feasible. Further, it turns out that the numerical behavior of infeasible approximations is superior to the feasible ones from the point of view of iteration numbers.

Interior point methods also require an additional parameter, which, however, enters into (2) differently. For the problem under consideration here, the interior-point relaxation replaces the second equation in (2) by

$$\lambda(x)\,(\psi - G(v))(x) = \frac{1}{\gamma} \quad \text{for } x \in \Omega. \tag{5}$$

Path-following interior-point methods typically start strictly feasible, with iterates which are required to stay strictly feasible during the iterations while satisfying, or satisfying approximately, the first equation in (2) and (5). Path-following interior-point methods have not received much attention for infinite dimensional problems yet. In fact, we are aware of only [17], where such methods are analyzed for optimal control problems related to ordinary differential equations. For the problem classes that we outlined at the beginning of this section, the primal-dual active set strategy proved to be an excellent competitor to interior-point methods, as was demonstrated, for example, in [1] comparing these two methods.

This paper is organized as follows. Section 2 contains the precise problem formulation and the necessary background on the primal-dual active set strategy. The

existence and regularity of the primal-dual path is discussed in section 3. Properties of the primal-dual path value functional are analyzed in section 4. Section 5 contains the derivation of the proposed model functions for the primal-dual path value functional. Exact as well as inexact path-following algorithms are proposed in section 6, and their numerical behavior is discussed there as well.

2. Problem statement, regularization, and its motivation. We consider

$$\text{(P)} \qquad \begin{cases} \min \frac{1}{2}\, a(y,y) - (f,y) \quad \text{over} \quad y \in H_0^1(\Omega) \\ \text{s.t. } y \le \psi, \end{cases}$$

where $f \in L^2(\Omega)$, $\psi \in H^1(\Omega)$, with $\psi_{|\partial\Omega} \ge 0$, where Ω is a bounded domain in $\mathbb{R}^n$ with Lipschitz continuous boundary $\partial\Omega$. Throughout, $(\cdot,\cdot)$ denotes the standard $L_2(\Omega)$-inner product, and we assume that $a(\cdot,\cdot)$ is a bilinear form on $H_0^1(\Omega) \times H_0^1(\Omega)$ satisfying

$$a(v,v) \ge \nu |v|^2_{H_0^1} \ \text{ and } \ a(w,z) \le \mu |w|_{H^1} |z|_{H^1} \tag{6}$$

for some $\nu > 0$, $\mu > 0$ independent of $v \in H_0^1(\Omega)$ and $w, z \in H^1(\Omega)$. Here and throughout we use $|v|_{H_0^1} = |\nabla v|_{L^2}$ for $v \in H_0^1(\Omega)$, which defines a norm on $H_0^1(\Omega)$ due to Friedrichs' inequality, and $|w|_{H^1} = (|w|^2_{L^2} + |\nabla w|^2_{L^2})^{1/2}$ denotes the standard H^1-norm; see, e.g., [2]. Moreover, let $A\colon H_0^1(\Omega) \to H^{-1}(\Omega)$ be defined by

$$a(v,w) = \langle A\, v, w \rangle_{H^{-1}, H_0^1} \quad \text{for all } v, w \in H_0^1(\Omega).$$

It is well known that (P) admits a unique solution $y^* \in H_0^1(\Omega)$ with associated Lagrange multiplier $\lambda^* = -Ay^* + f$, satisfying the optimality system

$$\begin{cases} a(y^*, v) + \langle \lambda^*, v \rangle_{H^{-1}, H_0^1} = (f, v), \\ \langle \lambda^*, y^* - \psi \rangle_{H^{-1}, H_0^1} = 0, \quad y^* \le \psi, \langle \lambda^*, v \rangle \le 0 \ \text{ for all } \ v \le 0. \end{cases} \tag{7}$$

This also holds with $f \in H^{-1}(\Omega)$. Under well-known additional requirements on a, ψ, and Ω, as for example

$$\begin{cases} a(v,w) = \int_\Omega (\sum a_{ij} v_{x_i} w_{x_j} + d\, v\, w), \ \text{ with } \ a_{ij} \in C^1(\bar\Omega), d \in L^\infty(\Omega), \\ d \ge 0, \quad \psi \in H^2(\Omega), \partial\Omega \quad \text{is } \ C^{1,1}, \ \text{ or } \ \Omega \ \text{ is a convex polyhedron}, \end{cases} \tag{8}$$

we have $(y^*, \lambda^*) \in H^2(\Omega) \times L^2(\Omega)$, and the optimality system can be expressed as

$$\begin{cases} A\, y^* + \lambda^* = f \ \text{ in } \quad L^2(\Omega), \\ \lambda^* = (\lambda^* + c(y^* - \psi))^+ \quad \text{for some } \ c > 0, \end{cases} \tag{9}$$

where $(v)^+ = \max(0, v)$; for details see, e.g., [14].

Our aim is the development of Newton-type methods for solving (7) or (9), which is complicated by the system of inequalities in (7) and the nondifferentiable max-operator in (9). In the recent past significant progress was made in the investigation of semismooth Newton methods and primal-dual active set methods for coping with nondifferentiable functionals in infinite dimensional spaces; see, for instance, [10, 15]. A direct application of these techniques to (9) results in the following algorithm.

ALGORITHM A.

(i) Choose $c > 0$, (y_0, λ_0); set $k = 0$.
(ii) Set $\mathcal{A}_{k+1} = \{x \in \Omega\colon \lambda_k(x) + c(y_k(x) - \psi(x)) > 0\}$.
(iii) Compute $y_{k+1} = \arg\min \{\frac{1}{2}\, a(y, y) - (f, y)\colon y = \psi \text{ on } \mathcal{A}_{k+1}\}$.
(iv) Let λ_{k+1} be the Lagrange multiplier associated with the constraint in (iii), with $\lambda_{k+1} = 0$ on $\Omega \setminus \mathcal{A}_{k+1}$.
(v) Set $k := k + 1$ and go to (ii).

The optimality system for the variational problem in (iii) is given by

$$\text{(10)} \qquad \begin{cases} a(y_{k+1}, v) + \langle \lambda_{k+1}, v\rangle_{H^{-1}, H_0^1} = (f, v) \ \text{ for all } \ v \in H_0^1(\Omega), \\ y_{k+1} = \psi \ \text{ on } \ \mathcal{A}_{k+1}, \quad \lambda_{k+1} = 0 \ \text{ on } \ \mathcal{I}_{k+1} = \Omega \setminus \mathcal{A}_{k+1}. \end{cases}$$

This corresponds to (3) in our introductory discussion. The Lagrange multiplier associated with the constraint $y = \psi$ on $\mathcal{A}_{k+1}$ is in general only a distribution in $H^{-1}(\Omega)$ and is not in $L^2(\Omega)$. In fact, λ_{k+1} is related to the jumps in the normal derivatives of y across the interface between $\mathcal{A}_{k+1}$ and $\mathcal{I}_{k+1}$ [13]. This complicates the convergence analysis for Algorithm A since the calculus of Newton (or slant) differentiability [10] does not apply. We note that these difficulties are not present if (7) or (9) is discretized. However, they are crucial for the treatment of infinite dimensional problems, and as such they are generic. Analogous difficulties arise for state constrained optimization problems, for inverse problems with BV-regularization, and for elasticity problems with contract and friction, to mention a few. This suggests the introduction of regularized problems, which in our case are chosen as

$$(P_\gamma) \qquad \min \frac{1}{2}\, a(y, y) - (f, y) + \frac{1}{2\gamma} \int_\Omega |(\bar\lambda + \gamma(y - \psi))^+|^2 \quad \text{over } y \in H_0^1(\Omega),$$

where $\gamma > 0$ and $\bar\lambda \in L^2(\Omega)$, $\bar\lambda \geq 0$ are fixed. For later use we denote the objective functional of (P_γ) by $J(y; \gamma)$. The choice of $\bar\lambda$ will be used to influence the feasibility of the solution y_γ of (P_γ). Using Lebesgue's bounded convergence theorem to differentiate the max under the integral in $J(y; \gamma)$, the first order optimality condition associated with (P_γ) is given by

$$(\mathrm{OC}_\gamma) \qquad \begin{cases} a(y_\gamma, v) + (\lambda_\gamma, v) = (f, v) \ \text{ for all } \ v \in H_0^1(\Omega), \\ \lambda_\gamma = (\bar\lambda + \gamma(y_\gamma - \psi))^+, \end{cases}$$

where $(y_\gamma, \lambda_\gamma) \in H_0^1(\Omega) \times L^2(\Omega)$. With (8) holding, we have $y_\gamma \in H^2(\Omega)$. The primal-dual active set strategy, or equivalently the semismooth Newton method, for (P_γ) is given next. For its statement and for later use we introduce $\chi_{\mathcal{A}^{k+1}}$, the characteristic function of the set $\mathcal{A}^{k+1} \subseteq \Omega$.

ALGORITHM B.

(i) Choose $\bar\lambda \geq 0$, (y_0, λ_0); set $k = 0$.
(ii) Set $\mathcal{A}_{k+1} = \{x \in \Omega\colon \bar\lambda(x) + \gamma(y_k(x) - \psi(x)) > 0\}$, $\mathcal{I}_{k+1} = \Omega \setminus \mathcal{A}_{k+1}$.
(iii) Solve for $y_{k+1} \in H_0^1(\Omega)$: $a(y_{k+1}, v) + ((\bar\lambda + \gamma(y_{k+1} - \psi))\chi_{\mathcal{A}_{k+1}}, v) = (f, v)$ for all $v \in H_0^1(\Omega)$.
(iv) Set

$$\lambda_{k+1} = \begin{cases} 0 & \text{on } \mathcal{I}_{k+1}, \\ \bar\lambda + \gamma(y_{k+1} - \psi) & \text{on } \mathcal{A}_{k+1}. \end{cases}$$

Algorithm B was analyzed in [13], where global as well as locally superlinear convergence for every fixed $\gamma > 0$ were established. However, the choice and adaptation (increase) of γ was heuristic in [13] and earlier work. The focus of the present investigation is the automatic adaptive choice of γ. We shall utilize the following two results, which we recall from [13] where the proofs can also be found.

PROPOSITION 2.1. *The solutions* $(y_\gamma, \lambda_\gamma)$ *to* (OC_γ) *converge to* (y^*, λ^*) *in the sense that* $y_\gamma \to y^*$ *strongly in* $H_0^1(\Omega)$ *and* $\lambda_\gamma \rightharpoonup \lambda^*$ *weakly in* $H^{-1}(\Omega)$ *as* $\gamma \to \infty$.

We say that a satisfies the weak maximum principle if for any $v \in H_0^1(\Omega)$

$$a(v, v^+) \le 0 \text{ implies } v^+ = 0. \tag{11}$$

PROPOSITION 2.2. *Assume that* (11) *holds and let* $0 < \gamma_1 \le \gamma_2 < \infty$.

(a) *In the* infeasible case, *i.e., for* $\bar\lambda = 0$, *we have* $y^* \le y_{\gamma_2} \le y_{\gamma_1}$.

(b) *In the* feasible case, *i.e., if*

$$\bar\lambda \ge 0 \ \text{ and } \ \langle \bar\lambda - f + A\psi, v\rangle_{H^{-1}, H_0^1} \ge 0 \ \text{ for all } \ v \in H_0^1(\Omega), \tag{12}$$

with $v \ge 0$, *then* $y_{\gamma_1} \le y_{\gamma_2} \le y^* \le \psi$.

3. The primal-dual path. In this section we introduce the primal-dual path and discuss its smoothness properties.

DEFINITION 3.1. *The family of solutions* $\mathcal{C} = \{(y_\gamma, \lambda_\gamma) \colon \gamma \in (0, \infty)\}$ *to* (OC_γ), *considered as subset of* $H_0^1(\Omega) \times H^{-1}(\Omega)$, *is called the primal-dual path associated with* (P).

For $r \ge 0$ we further set $\mathcal{C}_r = \{(y_\gamma, \lambda_\gamma) \colon \gamma \in [r, \infty)\}$, and with some abuse of terminology we also refer to $\mathcal{C}_r$ as a path. In the following lemma we denote by $\hat y$ the solution to the unconstrained problem

$$\min J(y) = \frac{1}{2}\, a(y, y) - (f, y) \quad \text{ over } y \in H_0^1(\Omega). \tag{$\hat{\mathrm{P}}$}$$

Subsequently, in connection with convergence of a sequence in function space we use the subscript "weak" together with the space to indicate convergence in the weak sense.

LEMMA 3.2. *For each* $r > 0$ *the path* $\mathcal{C}_r$ *is bounded in* $H_0^1(\Omega) \times H^{-1}(\Omega)$, *with* $\lim_{\gamma\to\infty}(y_\gamma, \lambda_\gamma) = (y^*, \lambda^*)$ *in* $H_0^1(\Omega) \times H^{-1}(\Omega)_{weak}$. *For* $\bar\lambda = 0$ *the path* $\mathcal{C}_0$ *is bounded in* $H_0^1(\Omega) \times H^{-1}(\Omega)$, *with* $\lim_{\gamma\to 0^+}(y_\gamma, \lambda_\gamma) = (\hat y, 0)$ *in* $H_0^1(\Omega) \times L^2(\Omega)$.

Proof. From (OC_γ) we have for every $\gamma > 0$

$$a(y_\gamma, y_\gamma - y^*) + (\lambda_\gamma, y_\gamma - y^*) = (f, y_\gamma - y^*). \tag{13}$$

Since $\lambda_\gamma = \max(0, \bar\lambda + \gamma(y_\gamma - \psi)) \ge 0$ and $\psi - y^* \ge 0$ we have

$$\begin{aligned}(\lambda_\gamma, y_\gamma - y^*) &= \left(\lambda_\gamma, \frac{\bar\lambda}{\gamma} + y_\gamma - \psi + \psi - y^* - \frac{\bar\lambda}{\gamma}\right)\\ &\ge \frac{1}{\gamma}(\lambda_\gamma, \bar\lambda + \gamma(y_\gamma - \psi)) - \frac{1}{\gamma}(\lambda_\gamma, \bar\lambda)\\ &= \frac{1}{\gamma}\left[|\lambda_\gamma|_{L^2}^2 - (\lambda_\gamma, \bar\lambda)\right].\end{aligned}$$

Combined with (13) this implies that

$$a(y_\gamma, y_\gamma) + \frac{1}{\gamma}\,|\lambda_\gamma|_{L^2}^2 \le a(y_\gamma, y^*) + (f, y_\gamma - y^*) + \frac{1}{\gamma}\,(\bar\lambda, \lambda_\gamma). \tag{14}$$

This estimate, (6), (OC_γ), and the Poincaré–Friedrichs inequality imply that $\mathcal{C}_r$ is bounded in $H_0^1(\Omega) \times H^{-1}(\Omega)$ for every $r > 0$. In fact, for $\omega > 0$ satisfying $\omega|y|_{H^1}^2 \leq |y|_{H_0^1}^2$, we have

$$\begin{aligned}
\omega|y_\gamma|_{H^1}^2 + \frac{1}{\gamma}\,|\lambda_\gamma|_{L^2}^2 &\leq a(y_\gamma, y_\gamma) + \frac{1}{\gamma}\,|\lambda_\gamma|_{L^2}^2 \\
&\leq \mu|y_\gamma|_{H^1}\,|y^*|_{H^1} + |f|_{H^{-1}}\,(|y_\gamma|_{H^1} + |y^*|_{H^1}) + \frac{1}{\gamma}\,|\bar\lambda|_{L^2}\,|\lambda_\gamma|_{L^2} \\
&\leq \frac{\omega}{4}\,|y_\gamma|_{H^1}^2 + \frac{\mu^2}{\omega}\,|y^*|_{H^1}^2 + \frac{\omega}{2}|y_\gamma|_{H^1}^2 + \frac{1}{2\omega}|f|_{H^{-1}}^2 \\
&\quad + \frac{1}{2\gamma}|\lambda_\gamma|_{L^2}^2 + \frac{1}{2\gamma}|\bar\lambda|_{L^2}^2 + |f|_{H^{-1}}\,|y^*|_{H^1},
\end{aligned}$$

and hence

$$\frac{\omega}{4}|y_\gamma|_{H^1}^2 + \frac{1}{2\gamma}\,|\lambda_\gamma|_{L^2}^2 \leq \frac{\mu^2}{\omega}|y^*|_{H^1}^2 + \frac{1}{2\omega}\,|f|_{H^{-1}} + |f|_{H^{-1}}\,|y^*|_{H^1} + \frac{1}{2\gamma}\,|\bar\lambda|_{L^2}^2.$$

This estimate implies that $\{y_\gamma : \gamma \geq r\}$ is bounded in $H_0^1(\Omega)$ for every $r > 0$. The first equation of (OC_γ) implies that $\{\lambda_\gamma : \gamma \geq r\}$ is bounded in $H^{-1}(\Omega)$ as well. From Proposition 2.1 we have that $\lim_{\gamma\to\infty}(y_\gamma, \lambda_\gamma) = (y^*, \lambda^*)$ in $H_0^1(\Omega) \times H^{-1}(\Omega)_{weak}$. If $\bar\lambda = 0$, then from (14), (6), and (OC_γ) the path $\mathcal{C}_o$ is bounded in $H_0^1(\Omega) \times H^{-1}(\Omega)$ and $\lambda_\gamma \to 0$ in $L^2(\Omega)$ for $\gamma \to 0^+$. From (OC_γ) and the optimality condition for ($\hat{\mathrm{P}}$) we have

$$a(y_\gamma - \hat y, y_\gamma - \hat y) + (\lambda_\gamma, y_\gamma - \hat y) = 0,$$

and hence $\lim_{\gamma\to 0^+} y_\gamma = \hat y$ in $H_0^1(\Omega)$. ∎

PROPOSITION 3.3. *The path $\mathcal{C}_r$ is globally Lipschitz in $H_0^1(\Omega)\times H^{-1}(\Omega)$ for every $r > 0$. If $\bar\lambda = 0$, then $\mathcal{C}_0$ is globally Lipschitz continuous.*

Proof. Let $\gamma, \bar\gamma \in [r, \infty)$ be arbitrary. Then

$$A(y_\gamma - y_{\bar\gamma}) + (\bar\lambda + \gamma(y_\gamma - \psi))^+ - (\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+ = 0.$$

Taking the inner-product with $y_\gamma - y_{\bar\gamma}$ and using the monotonicity and Lipschitz continuity (with constant $L = 1$) of $x \mapsto \max(0, x)$, we find

$$\begin{aligned}
a(y_\gamma - y_{\bar\gamma},\quad & y_\gamma - y_{\bar\gamma}) \\
&\leq \left|\left((\bar\lambda + \gamma(y_\gamma - \psi))^+ - (\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+, y_\gamma - y_{\bar\gamma}\right)\right| \\
&\leq |\gamma - \bar\gamma|\,|y_\gamma - \psi|_{L^2}|y_\gamma - y_{\bar\gamma}|_{L^2}.
\end{aligned}$$

By Lemma 3.2 the set $\{y_\gamma\}_{\gamma\geq r}$ is bounded in $H_0^1(\Omega)$. Hence there exists $K_1 > 0$ such that

$$\nu|y_\gamma - y_{\bar\gamma}|_{H_0^1}^2 \leq K_1|\gamma - \bar\gamma| \cdot |y_\gamma - y_{\bar\gamma}|_{L^2},$$

and by Poincaré's inequality there exists $K_2 > 0$ such that

$$|y_\gamma - y_{\bar\gamma}|_{H_0^1} \leq K_2|\gamma - \bar\gamma| \quad \text{for all} \quad \gamma \geq r, \bar\gamma \geq r.$$

Let us recall here that $|y|_{H_0^1} = |\nabla y|_{L^2}$. Lipschitz continuity of $\gamma \mapsto \lambda_\gamma$ from $[r,\infty)$ to $H^{-1}(\Omega)$ follows from the first equation in (OC_γ). For $\bar\lambda = 0$ the set $\{y_\gamma\}_{\gamma\geq 0}$ is bounded in $H_0^1(\Omega)$. The remainder of the proof remains identical. ∎

LEMMA 3.4. *For every subset $I \subset [r,\infty)$, $r > 0$, the mapping $\gamma \mapsto \lambda_\gamma$ is globally Lipschitz from I to $L^2(\Omega)$.*

Proof. For $0 < \gamma_1 \leq \gamma_2$ we have by (OC_γ)

$$\begin{aligned}|\lambda_{\gamma_1} - \lambda_{\gamma_2}|_{L^2} &= |(\bar\lambda + \gamma_1(y_{\gamma_1} - \psi))^+ - (\bar\lambda + \gamma_2(y_{\gamma_2} - \psi))^+|_{L^2} \\ &\leq (K_3\gamma_1 + K_1 + |\psi|_{L^2})\,|\gamma_1 - \gamma_2|\end{aligned}$$

for some constant $K_3 > 0$. ∎

We shall use the following notation:

$$S_\gamma = \{x \in \Omega\colon \bar\lambda(x) + \gamma(y_\gamma - \psi)(x) > 0\}.$$

Further we set

$$g(\gamma) = \bar\lambda + \gamma(y_\gamma - \psi). \tag{15}$$

Since $\gamma \mapsto y_\gamma \in H_0^1(\Omega)$ is Lipschitz continuous by Proposition 3.3, there exists a weak accumulation point $\dot y (= \dot y_\gamma)$ of $\frac{1}{\bar\gamma - \gamma}(y_{\bar\gamma} - y_\gamma)$ as $\bar\gamma \to \gamma > 0$, which is also a strong accumulation point in $L^2(\Omega)$. Further $\frac{1}{\bar\gamma - \gamma}(g(\bar\gamma) - g(\gamma))$ has $\dot g(\gamma) := y_\gamma - \psi + \gamma\,\dot y_\gamma$ as a strong accumulation point in $L^2(\Omega)$ as $\bar\gamma \to \gamma$. In case $\bar\gamma$ approaches γ from above (or below), the associated accumulation points $\dot y_\gamma^r$ (or $\dot y_\gamma^l$) satisfy certain properties which are described next. In what follows we use $\dot g^r(\gamma)$ or $\dot g^l(\gamma)$ whenever $\dot y_\gamma$ in $\dot g(\gamma)$ is replaced by $\dot y_\gamma^r$ and $\dot y_\gamma^l$, respectively.

PROPOSITION 3.5. *Let $\gamma > 0$, and denote by $\dot y_\gamma^r$ any weak accumulation point of $\frac{1}{\bar\gamma - \gamma}(y_{\bar\gamma} - y_\gamma)$ in $H_0^1(\Omega)$ as $\bar\gamma \downarrow \gamma$. Set*

$$S_\gamma^+ = S_\gamma \cup \{x\colon \bar\lambda(x) + \gamma(y_\gamma(x) - \psi(x)) = 0 \wedge \dot g^r(\gamma)(x) \geq 0\}.$$

Then $\dot y_\gamma^r$ satisfies

$$a(\dot y_\gamma^r, v) + ((y_\gamma - \psi + \gamma\dot y_\gamma^r)\chi_{S_\gamma^+}, v) = 0 \quad \textit{for all} \quad v \in H_0^1(\Omega). \tag{16}$$

Proof. By (OC_γ) we have for every $v \in H_0^1(\Omega)$

$$a(y_{\bar\gamma} - y_\gamma, v) + ((\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+ - (\bar\lambda + \gamma(y_\gamma - \psi))^+, v) = 0. \tag{17}$$

We multiply (17) by $(\bar\gamma - \gamma)^{-1}$ and discuss separately the two terms in (17). Clearly, we have

$$\lim_{\bar\gamma \downarrow \gamma} (\bar\gamma - \gamma)^{-1} a(y_{\bar\gamma} - y_\gamma, v) = a(\dot y_\gamma^r, v).$$

Here and below the limit is taken on the sequence of $\bar\gamma$-values, which provides the accumulation point. Lebesgue's bounded convergence theorem allows us to consider the pointwise limits of the integrands. Considering separately the cases $g(\gamma)(x) < 0$, $g(\gamma)(x) > 0$, and $g(\gamma)(x) = 0$, we have

$$\begin{aligned}&(\bar\gamma - \gamma)^{-1}((g(\bar\gamma))^+ - (g(\gamma))^+, v) \\ &\quad \to ((y_\gamma - \psi + \gamma\,\dot y_\gamma^r)\chi_{S_\gamma^+}, v) \ \text{ as } \ \bar\gamma \downarrow \gamma,\end{aligned} \tag{18}$$

which ends the proof. ∎

As a consequence of the proof we obtain the following result.

COROLLARY 3.6. *Let $\gamma > 0$, and denote by $\dot{y}_\gamma^l$ any weak accumulation point of $\frac{1}{\bar\gamma-\gamma}(y_{\bar\gamma} - y_\gamma)$ in $H_0^1(\Omega)$ as $\bar\gamma \uparrow \gamma$. Set $S_\gamma^- = S_\gamma \cup \{x\colon \bar\lambda(x) + \gamma(y_\gamma(x) - \psi(x)) = 0 \wedge \dot g^l(\gamma)(x) \geq 0\}$. Then $\dot{y}_\gamma^l$ satisfies*

$$a(\dot{y}_\gamma^l, v) + ((y_\gamma - \psi + \gamma\,\dot{y}_\gamma^l)\chi_{S_\gamma^-}, v) = 0 \quad \text{for all } v \in H_0^1(\Omega). \tag{19}$$

Another corollary of Proposition 3.5 treats the case $\bar\lambda = 0$.

COROLLARY 3.7. *Let $\bar\lambda = 0$, and assume that (11) holds. Then the right- and left- derivatives $\dot{y}_\gamma^r$ and $\dot{y}_\gamma^l$ of $\gamma \mapsto y_\gamma$, $\gamma \in (0,\infty)$, exist and are given by*

$$a(\dot{y}_\gamma^r, v) + ((y_\gamma - \psi + \gamma\,\dot{y}_\gamma^r)\chi_{\{y_\gamma > \psi\}}, v) = 0 \quad \text{for all } v \in H_0^1(\Omega), \tag{20}$$

$$a(\dot{y}_\gamma^l, v) + ((y_\gamma - \psi + \gamma\,\dot{y}_\gamma^l)\chi_{\{y_\gamma \geq \psi\}}, v) = 0 \quad \text{for all } v \in H_0^1(\Omega). \tag{21}$$

Proof. Let $\bar\gamma \downarrow \gamma$. By Proposition 2.2 any accumulation point $\dot{y}_\gamma^r$ of $(\bar\gamma-\gamma)^{-1}(y_{\bar\gamma} - y_\gamma)$ satisfies $\dot{y}_\gamma^r \leq 0$ and hence

$$S_\gamma^+ = \{x \in \Omega\colon y_\gamma(x) > \psi(x)\} \cup \{x \in \Omega\colon y_\gamma(x) = \psi(x) \wedge \dot{y}_\gamma^r(x) = 0\}.$$

Observe that

$$(y_\gamma - \psi + \gamma\dot{y}_\gamma^r)\chi_{S_\gamma^+} = (y_\gamma - \psi + \gamma\dot{y}_\gamma^r)\chi_{\{y_\gamma > \psi\}}.$$

This implies that every accumulation point $\dot{y}_\gamma^r$ satisfies (20). Since the solution to (20) is unique, the directional derivative from the right exists.

Similarly, if $\bar\gamma \uparrow \gamma$, by Proposition 2.2 we have $S_\gamma^- = \{x \in \Omega\colon y_\gamma(x) \geq \psi(x)\}$, and (21) follows. ∎

Henceforth we set

$$S_\gamma^\circ = \{x \in \Omega\colon \bar\lambda(x) + \gamma(y_\gamma - \psi)(x) = 0\}.$$

COROLLARY 3.8. *If $\operatorname{meas}(S_\gamma^\circ) = 0$, then $\gamma \mapsto y_\gamma \in H_0^1(\Omega)$ is differentiable at γ, and the derivative $\dot{y}_\gamma$ satisfies*

$$a(\dot{y}_\gamma, v) + ((y_\gamma - \psi + \gamma\,\dot{y}_\gamma)\chi_{S_\gamma}, v) = 0 \quad \textit{for all } v \in H_0^1(\Omega). \tag{22}$$

Proof. Let z denote the difference of two accumulation points of $(\bar\gamma - \gamma)^{-1}(y_{\bar\gamma} - y_\gamma)$ as $\bar\gamma \to \gamma$. As a consequence of (16) and (19)

$$a(z, v) + \gamma(z\chi_{S_\gamma}, v) = 0 \quad \text{for all } v \in H_0^1(\Omega).$$

This implies that $z = 0$ by (6). Consequently, accumulation points are unique, and by (16), (19) they satisfy (22). ∎

The assumption $\operatorname{meas}(S_\gamma^o) = 0$ in Corollary 3.8 reflects the lack of differentiability of the max-operation in (OC_γ).

4. The primal-dual path value functional. In this section we investigate the value function associated with (P_γ) and study its monotonicity and smoothness properties.

DEFINITION 4.1. *The functional*

$$\gamma \mapsto V(\gamma) = J(y_\gamma;\gamma) = \frac{1}{2}a(y_\gamma, y_\gamma) - (f, y_\gamma) + \frac{1}{2\gamma}|(\bar\lambda + \gamma(y_\gamma - \psi))^+|_{L^2}^2$$

defined on $(0,\infty)$ *is called the primal-dual path value functional.*

Let us start by studying first order differentiability properties of V.

PROPOSITION 4.2. *The value function* V *is differentiable with*

$$\dot V(\gamma) = -\frac{1}{2\gamma^2}\int_\Omega |(\bar\lambda + \gamma(y_\gamma - \psi))^+|^2 \;+\; \frac{1}{\gamma}\int_\Omega (\bar\lambda + \gamma(y_\gamma - \psi))^+(y_\gamma - \psi).$$

COROLLARY 4.3. *For* $\bar\lambda = 0$ *we have* $\dot V(\gamma) = \frac{1}{2}\int_\Omega |(y_\gamma - \psi)^+|^2 \geq 0$ *and* $\dot V(\gamma) > 0$ *unless* y_γ *is feasible. For* $\bar\lambda$ *satisfying* (12) *and with* (11) *holding, we have* $y_\gamma \leq \psi$ *and hence* $\dot V(\gamma) \leq 0$ *for* $\gamma \in (0,\infty)$.

In either of the two cases $\dot V(\gamma) = 0$ *implies that* y_γ *solves* ($\hat{\mathrm{P}}$).

Proof. We show only that $\dot V(\gamma) = 0$ implies that y_γ solves ($\hat{\mathrm{P}}$). The rest of the assertion follows immediately from Proposition 4.2.

If $\bar\lambda = 0$, then $\dot V(\gamma) = 0$ yields $y_\gamma \leq \psi$. Thus, $\lambda_\gamma = 0$, and hence y_γ solves ($\hat{\mathrm{P}}$).

If (11) and (12) are satisfied, then $y_\gamma \leq \psi$ and $\dot V(\gamma) = 0$ implies $\gamma(y_\gamma - \psi) \leq \bar\lambda + \gamma(y_\gamma - \psi) \leq 0$. As a consequence $\lambda_\gamma = 0$, and y_γ solves ($\hat{\mathrm{P}}$). ∎

Proof of Proposition 4.2. For $\bar\gamma, \gamma \in (0,\infty)$ we find

$$\begin{aligned}\frac{1}{2}\, & a(y_{\bar\gamma} + y_\gamma, y_{\bar\gamma} - y_\gamma) - (f, y_{\bar\gamma} - y_\gamma) \\ & + \tfrac{1}{2}((\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+ + (\bar\lambda + \gamma(y_\gamma - \psi))^+, y_{\bar\gamma} - y_\gamma) = 0,\end{aligned} \tag{23}$$

and consequently

$$\begin{aligned} V(\bar\gamma) - V(\gamma) &= \frac{1}{2}a(y_{\bar\gamma}, y_{\bar\gamma}) - \frac{1}{2}a(y_\gamma, y_\gamma) - (f, y_{\bar\gamma} - y_\gamma) \\ &\quad + \frac{1}{2\bar\gamma}\int_\Omega |(\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+|^2 - \frac{1}{2\gamma}\int_\Omega |(\bar\lambda + \gamma(y_\gamma - \psi))^+|^2 \\ &= \frac{1}{2\bar\gamma}\int_\Omega |(\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+|^2 + \frac{1}{2\gamma}\int_\Omega -|(\bar\lambda + \gamma(y_\gamma - \psi))^+|^2 \\ &\quad + \frac{1}{2}\int_\Omega -((\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^+ + (\bar\lambda + \gamma(y_\gamma - \psi))^+)(y_{\bar\gamma} - y_\gamma) \\ &= \int_{P_{\bar\gamma}\cap P_\gamma} z + \int_{P_{\bar\gamma}\cap N_\gamma} z + \int_{P_\gamma \cap N_{\bar\gamma}} z = \mathcal{I}_1 + \mathcal{I}_2 + \mathcal{I}_3, \end{aligned}$$

where z stands for the sum of the kernels on the left of the above equalities,

$$P_\gamma = \{x\colon \bar\lambda + \gamma(y_\gamma - \psi) > 0\}, \qquad N_\gamma = \{x\colon \bar\lambda + \gamma(y_\gamma - \psi) < 0\},$$

and $P_{\bar\gamma}$, $N_{\bar\gamma}$ are defined analogously. For $\mathcal{I}_2$ we have

$$\begin{aligned} |\mathcal{I}_2| &\leq \frac{1}{2}\int_{P_{\bar\gamma}\cap N_\gamma} \frac{1}{\bar\gamma}(\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi))^2 + |\bar\lambda + \bar\gamma(y_{\bar\gamma} - \psi)|\,|y_{\bar\gamma} - y_\gamma| \\ &\leq \frac{1}{2}\int_\Omega \frac{1}{\bar\gamma}(\bar\gamma(y_{\bar\gamma} - \psi) - \gamma(y_\gamma - \psi))^2 + |y_{\bar\gamma} - y_\gamma|(|\bar\gamma y_{\bar\gamma} - \gamma\, y_\gamma| + |\bar\gamma - \gamma|\,|\psi|), \end{aligned}$$

and hence by Proposition 3.3

$$\lim_{\bar\gamma\to\gamma} \frac{1}{\bar\gamma - \gamma} \quad |\mathcal{I}_2| = 0. \tag{24}$$

Analogously one verifies that

$$\lim_{\bar\gamma\to\gamma} \frac{1}{\bar\gamma-\gamma} \quad |\mathcal{I}_3| = 0. \tag{25}$$

On $P_{\bar\gamma}\cap P_\gamma$ we have

$$\begin{aligned} z &= \frac{1}{2\bar\gamma}\,(\bar\lambda+\bar\gamma(y_{\bar\gamma}-\psi))^2 \\ &\qquad -\frac{1}{2\gamma}\,(\bar\lambda+\gamma(y_\gamma-\psi))^2 - \frac{1}{2}\,(2\bar\lambda+\bar\gamma(y_{\bar\gamma}-\psi)+\gamma(y_\gamma-\psi))(y_{\bar\gamma}-y_\gamma) \\ &= \frac{\gamma-\bar\gamma}{2\bar\gamma\gamma}\,(\bar\lambda+\bar\gamma(y_{\bar\gamma}-\psi))^2 \\ &\qquad +\frac{1}{2\gamma}\,\left[2\bar\lambda(\bar\gamma(y_{\bar\gamma}-\psi)-\gamma(y_\gamma-\psi))+\bar\gamma^2(y_{\bar\gamma}-\psi)^2-\gamma^2(y_\gamma-\psi)^2\right] \\ &\qquad -\frac{1}{2}\,(2\bar\lambda+\bar\gamma(y_{\bar\gamma}-\psi)+\gamma(y_\gamma-\psi))(y_{\bar\gamma}-y_\gamma) \\ &= \frac{\gamma-\bar\gamma}{2\bar\gamma\gamma}\,(\bar\lambda+\bar\gamma(y_{\bar\gamma}-\psi))^2+\frac{\bar\lambda}{\gamma}\,[\bar\gamma(y_{\bar\gamma}-\psi)-\gamma(y_{\bar\gamma}-\psi)] \\ &\qquad +\frac{1}{2}\,\left[\frac{\bar\gamma^2}{\gamma}(y_{\bar\gamma}-\psi)^2-\bar\gamma(y_{\bar\gamma}-\psi)^2+(\bar\gamma-\gamma)(y_{\bar\gamma}-\psi)(y_\gamma-\psi)\right], \end{aligned}$$

and thus on $P_{\bar\gamma}\cap P_{\bar\gamma}$

$$\begin{aligned} (\bar\gamma-\gamma)^{-1}z &= \frac{-1}{2\bar\gamma\gamma}(\bar\lambda+\bar\gamma(y_\gamma-\psi))^2+\frac{\bar\lambda}{\gamma}(y_{\bar\gamma}-\psi) \\ &\qquad +\frac{1}{2}\left[\frac{\bar\gamma}{\gamma}(y_{\bar\gamma}-\psi)^2+(y_{\bar\gamma}-\psi)(y_\gamma-\psi)\right]. \end{aligned}$$

By Lebesgue's bounded convergence theorem,

$$\begin{aligned} &\lim_{\bar\gamma\to\gamma}\frac{1}{\bar\gamma-\gamma}\;\mathcal{I}_1 = \lim_{\bar\gamma\to\gamma}\frac{1}{\bar\gamma-\gamma}\int_\Omega z\,\chi_{P_{\bar\gamma}\cap P_\gamma} \\ &= -\frac{1}{2\gamma^2}\int_\Omega((\bar\lambda+\gamma(y_\gamma-\psi))^+)^2+\frac{1}{\gamma}\int_\Omega(\bar\lambda+\gamma(y_\gamma-\psi))^+(y_\gamma-\psi). \end{aligned}$$

Together with (24) and (25), this implies the claim. ∎

Remark 4.1. Note that $\dot V$ is characterized without recourse to $\dot y_\gamma$.

The boundedness of $\{\gamma^2\dot V(\gamma)\}_{\gamma\ge0}$ is established next. In what follows we use $(v)^- = -\min(0,v)$.

PROPOSITION 4.4. *If $\bar\lambda = 0$ and $a(v^+,v^-) = 0$ for all $v\in H_0^1(\Omega)$, then $\{\gamma^2\dot V(\gamma)\}_{\gamma\ge0}$ is bounded. If* (11) *and* (12) *hold, then again $\{\gamma^2\dot V(\gamma)\}_{\gamma\ge0}$ is bounded.*

Proof. In the case $\bar\lambda = 0$ we have

$$a(y_\gamma-\psi,v)+\gamma((y_\gamma-\psi)^+,v) = (f,v)-a(\psi,v) \quad \text{for all } v\in H_0^1(\Omega).$$

Since $(y_\gamma-\psi)\in H_0^1(\Omega)$ and $a((y_\gamma-\psi)^+,(y_\gamma-\psi)^-) = 0$ we have, using (6) with $v = (y_\gamma-\psi)^+$,

$$\nu|(y_\gamma-\psi)^+|^2_{H_0^1(\Omega)}+\gamma|(y_\gamma-\psi)^+|^2_{L^2}\le|f|_{L^2}|(y_\gamma-\psi)^+|_{H_0^1}+\mu|\psi|_{H^1}|y_\gamma-\psi|_{H^1}.$$

This implies the existence of a constant K, depending on $|\psi|_{H^1}$ and $|f|_{L^2}$ but independent of $\gamma \geq 0$, such that $\gamma|(y_\gamma - \psi)^+|_{L^2} \leq K$. Since $\dot{V}(\gamma) = \frac{1}{2}\int_\Omega |(y_\gamma - \psi)^+|^2$ the claim follows.

Turning to the feasible case with (11) and (12) holding, we have that $y_\gamma \leq \psi$ for every $\gamma > 0$, and hence $(\bar{\lambda} + \gamma(y_\gamma - \psi))(x) > 0$ if and only if $\bar{\lambda}(x) > \gamma(\psi - y_\gamma)(x)$. Consequently,

$$\begin{aligned}|\dot{V}(\gamma)| &\leq \frac{1}{2\gamma^2}\int_\Omega |(\bar{\lambda} + \gamma(y_\gamma - \psi))^+|^2 + \frac{1}{\gamma}\int_\Omega (\bar{\lambda} + \gamma(y_\gamma - \psi))^+(\psi - y_\gamma) \\ &\leq \frac{3}{2\gamma^2}|\bar{\lambda}|^2_{L^2},\end{aligned}$$

which again implies the claim. ∎

Before we investigate $\ddot{V}$, we state a result which connects $\gamma\dot{V}(\gamma)$, $|y^* - y_\gamma|_{H^1_0}$, and $V^* - V(\gamma)$, where $V^* = \lim_{\gamma\to\infty} V(\gamma)$. It will be used in section 6.1 for designing a γ-update strategy.

PROPOSITION 4.5. *In the feasible and infeasible cases the following estimate holds true:*

$$|y^* - y_\gamma|^2_{H^1_0} \leq \frac{2}{\nu}\left(V^* - V(\gamma) - \gamma\dot{V}(\gamma)\right).$$

Proof. We have $V^* - V(\gamma) = J(y^*) - J(y_\gamma;\gamma)$ and

$$\begin{aligned}J(y^*) - J(y_\gamma;\gamma) \geq\ & \frac{\nu}{2}|y^* - y_\gamma|^2_{H^1_0} + a(y_\gamma, y^* - y_\gamma) - (f, y^* - y_\gamma) \\ & - \frac{1}{2\gamma}|(\bar{\lambda} + \gamma(y_\gamma - \psi))^+|^2_{L^2},\end{aligned}$$

where we have used (6). From (OC_γ) we have

$$a(y_\gamma, y^* - y_\gamma) - (f, y^* - y_\gamma) = -((\bar{\lambda} + \gamma(y_\gamma - \psi))^+, y^* - y_\gamma),$$

and hence

$$\begin{aligned}J(y^*) - J(y_\gamma;\gamma) \geq\ & \frac{\nu}{2}|y^* - y_\gamma|^2_{H^1_0} - ((\bar{\lambda} + \gamma(y_\gamma - \psi))^+, y^* - y_\gamma) \\ & - \frac{1}{2\gamma}|(\bar{\lambda} + \gamma(y_\gamma - \psi))^+|^2_{L^2} \\ \geq\ & \frac{\nu}{2}|y^* - y_\gamma|^2_{H^1_0} - \frac{1}{2\gamma}|(\bar{\lambda} + \gamma(y_\gamma - \psi))^+|^2_{L^2} \\ & + ((\bar{\lambda} + \gamma(y_\gamma - \psi))^+, y_\gamma - \psi) \\ =\ & \frac{\nu}{2}|y^* - y_\gamma|^2_{H^1_0} + \gamma\dot{V}(\gamma).\end{aligned}$$

This completes the proof. ∎

Below we shall assume that $y_\gamma - \psi \in C(\bar{\Omega})$. Recall that for dimension $n \leq 3$ and with (6) and (8) holding, we have $y_\gamma \in H^2(\Omega) \subset C(\bar{\Omega})$.

PROPOSITION 4.6. *Let $\dot{y}_\gamma$ denote any accumulation point of $(\bar{\gamma} - \gamma)^{-1}(y_{\bar{\gamma}} - y_\gamma)$ as $\bar{\gamma} \to \gamma$.*

(a) *If $\bar{\lambda} = 0$, $y_\gamma - \psi \in C(\bar{\Omega})$, and (8) is satisfied, then $\gamma \mapsto V(\gamma)$ is twice differentiable at γ with*

$$\ddot{V}(\gamma) = \int_\Omega (y_\gamma - \psi)^+\dot{y}_\gamma. \tag{26}$$

(b) *For arbitrary* $\bar\lambda$, *if* $\operatorname{meas}(S_\gamma^\circ)=0$, *then* $\gamma\mapsto V(\gamma)$ *is twice differentiable at* γ *with*

$$\begin{aligned}\ddot V(\gamma)&=\frac{1}{\gamma^3}\int_\Omega|(\bar\lambda+\gamma(y_\gamma-\psi))^+|^2\\&\quad-\frac{2}{\gamma^2}\int_\Omega(\bar\lambda+\gamma(y_\gamma-\psi))^+(y_\gamma-\psi)\\&\quad+\frac{1}{\gamma}\int_\Omega(y_\gamma-\psi)(y_\gamma-\psi+\gamma\,\dot y_\gamma)\chi_{S_\gamma}.\end{aligned}\tag{27}$$

Proof. (a) On the subsequence γ_n realizing the accumulation point, we have that $\lim_{n\to\infty}(\gamma_n-\gamma)^{-1}(\dot V(\gamma_n)-\dot V(\gamma))$ equals the right-hand side of (26). The claim will be established by verifying that the accumulation points $\dot y_\gamma$ restricted to $S_\gamma=\{x\colon y_\gamma(x)-\psi(x)>0\}$ are unique. Let z denote the difference of two accumulation points. By (16) and (19) we have

$$a(z,v)+\gamma(z,v)=0\ \text{ for all }\ v\in H_0^1(\Omega)\ \text{ with }\ v=0\ \text{ on }\ \Omega\setminus S_\gamma.$$

Using (8) and the fact that S_γ is an open set relative to Ω due to the continuity of $y_\gamma-\psi$, we find that $z=0$ in S_γ, as desired.

(b) Let $\dot y_\gamma$ denote any accumulation point of $(\bar\gamma-\gamma)^{-1}(y_{\bar\gamma}-y_\gamma)$ as $\bar\gamma\downarrow\gamma$, and recall the notation $g(\gamma)=\bar\lambda+\gamma(y_\gamma-\psi)$ and S_γ^+ from section 3. On the subsequence realizing the accumulation point we find

$$\begin{aligned}\lim_{\bar\gamma\to\gamma}\frac{1}{\bar\gamma-\gamma}(\dot V(\bar\gamma)-\dot V(\gamma))&=\frac{1}{\gamma^3}\int_\Omega|(\bar\lambda+\gamma(y_\gamma-\psi))^+|^2\\&\quad-\frac{2}{\gamma^2}\int_\Omega(\bar\lambda+\gamma(y_\gamma-\psi))^+(y_\gamma-\psi)\\&\quad+\frac{1}{\gamma}\int_\Omega(y_\gamma-\psi)(y_\gamma-\psi+\gamma\,\dot y_\gamma)\chi_{S_\gamma^+}.\end{aligned}\tag{28}$$

By assumption, $\operatorname{meas}(S_\gamma^\circ)=0$ and, hence the right-hand sides of (27) and (28) coincide. Since $\dot y_\gamma$ is unique by Corollary 3.8 the claim is established. ∎

5. Model functions. In this section we derive low-parameter families of functions which approximate the value functional V and share some of its qualitative properties. We will make use of these models in the numerics section when devising path-following algorithms.

5.1. Infeasible case. Throughout this subsection we assume (8) and

$$\bar\lambda=0,\ y_\gamma-\psi\in C(\bar\Omega)\quad\text{ for all }\ \gamma\in(0,\infty).\tag{29}$$

Observe that (8), together with the general assumption (6), implies (11). In fact, for any $v\in H_0^1(\Omega)$ we have $a(v,v^+)\ge\gamma|v^+|^2$, and hence $0\ge a(v,v^+)$ implies $v^+=0$.

PROPOSITION 5.1. *The value function* V *satisfies* $\dot V(\gamma)\ge0$ *and* $\ddot V(\gamma)\le0$ *for* $\gamma\in(0,\infty)$.

Proof. Proposition 4.2 implies that $\dot V(\gamma)\ge0$. Moreover, $y_{\gamma_2}\le y_{\gamma_1}$ for $\gamma_2\ge\gamma_1>0$ and hence $\dot y_\gamma\le0$ a.e. on S_γ. Consequently $\ddot V(\gamma)\le0$ by Proposition 4.6. ∎

A model function m for the value function V should reflect the sign properties of V and its derivatives. Moreover, $V(0)$ gives the value of $(\hat{\mathrm P})$, and hence we shall require that $m(0)=V(0)$. Finally from Lemma 3.2 we conclude that V is bounded on $[0,\infty)$. All these properties are satisfied by functions of the form

$$m(\gamma)=C_1-\frac{C_2}{E+\gamma}\tag{30}$$

with $C_1 \in \mathbb{R}$. Here $C_2 \geq 0$, $E > 0$ satisfy

$$m(0) = V(0) = C_1 - \frac{C_2}{E}. \tag{31}$$

Other choices for model functions are also conceivable, for example, $\gamma \to C_1 - \frac{C_1}{(E+\gamma)^r}$ with $r > 1$. Note, however, that the asymptotic behavior of the model in (30) is such that $\gamma^2 \dot{m}(\gamma)$ is bounded for $\gamma \to \infty$. This is consistent with the boundedness of $\gamma^2 \dot{V}(\gamma)$ for $\gamma \to \infty$ asserted in Proposition 4.4.

Another reason for choosing (30) is illustrated next. Choosing $v = (y_\gamma - \psi)^+$ in (OC_γ), we find

$$a(\dot{y}_\gamma, (y_\gamma - \psi)^+) + |(y_\gamma - \psi)^+|^2_{L^2} + \gamma \int_\Omega (y_\gamma - \psi)^+ \dot{y}_\gamma = 0. \tag{32}$$

For the following discussion we

$$\text{replace } a(\cdot,\cdot) \text{ by } E(\cdot,\cdot) \text{ with } E > 0 \text{ a constant, and } V \text{ by } m. \tag{33}$$

By Proposition 4.2 and (26) the following ordinary differential equation is obtained for m:

$$(E + \gamma)\, \ddot{m}(\gamma) + 2\, \dot{m}(\gamma) = 0. \tag{34}$$

The solutions to (34) are given by (30). To get an account for the quality of our model in (30) we refer to the left-hand plot of Figure 4 in section 6.

5.2. Feasible case. Throughout this subsection we assume

$$(11), \quad \bar{\lambda} \text{ satisfies (12)}, \quad \text{and meas}\,(S^\circ_\gamma) = 0 \ \text{ for all } \ \gamma \in (0, \infty). \tag{35}$$

PROPOSITION 5.2. *The value function V satisfies $\dot{V}(\gamma) \leq 0$ and $\ddot{V}(\gamma) \geq 0$ for $\gamma \in (0, \infty)$.*

Proof. By Proposition 2.2 we have $y_\gamma \leq \psi$ and hence $\dot{V}(\gamma) \leq 0$ by Proposition 4.2. A short computation based on (27) shows that

$$\ddot{V}(\gamma) = \frac{1}{\gamma^3} \int_\Omega \chi \bar{\lambda}^2 + \int_\Omega \chi (y_\gamma - \psi) \dot{y}_\gamma \geq \frac{1}{\gamma} \int_\Omega \chi (y_\gamma - \psi)^2 + \int_\Omega \chi\, (y_\gamma - \psi) \dot{y}_\gamma, \tag{36}$$

where χ is the characteristic function of the set $S_\gamma = \{\bar{\lambda} + \gamma(y_\gamma - \psi) > 0\}$. From (22) we have

$$\gamma |\dot{y}_\gamma|_{L^2(S_\gamma)} \leq |\psi - y_\gamma|_{L^2(S_\gamma)},$$

and hence $\ddot{V}(\gamma) \geq 0$. ∎

An immediate consequence is stated next.

LEMMA 5.3. *If the solution to the unconstrained problem is not feasible, then* $\lim_{\gamma \downarrow 0} V(\gamma) = \infty$.

Proof. Assume that $\lim_{\gamma \downarrow 0} V(\gamma)$ is finite. Then, using (P_γ), there exists a sequence $\gamma_n \to 0$ and $\tilde{y} \in H^1_0(\Omega)$ such that $y_{\gamma_n} \rightharpoonup \tilde{y}$ weakly in $H^1_0(\Omega)$, with y_{γ_n} the solution to (P_{γ_n}), and $\lambda_{\gamma_n} = \max(0, \bar{\lambda} + \gamma_n(y_n - \psi)) \to 0$ in $L^2(\Omega)$. Consequently $\tilde{y} \leq \psi$. Taking the limit with respect to n in (OC_{γ_n}), it follows that $\tilde{y} \leq \psi$ is the solution to ($\hat{\mathrm{P}}$), which contradicts our assumption. ∎

From Lemmas 3.2 and 5.3 and Proposition 5.2 it follows that $\gamma \mapsto V(\gamma)$, $\gamma \in (0,\infty)$, is a monotonically strictly decreasing convex function with $\lim_{\gamma\to 0^+} V(\gamma) = \infty$. All these properties are also satisfied by functions of the form

$$m(\gamma) = C_1 \; - \; \frac{C_2}{E+\gamma} \; + \; \frac{B}{\gamma}, \tag{37}$$

provided that $C_1 \in \mathbb{R}$, $C_2 \geq 0$, $E > 0$, $B > 0$, and $C_2 \leq B$.

We now give the motivation for choosing the model function m for V as in (37). From (22) with $v = (y_\gamma - \psi)\chi$ we get

$$a(\dot{y}_\gamma, (y-\psi)\chi) + \gamma(\dot{y}_\gamma\chi, y_\gamma - \psi) + ((y_\gamma - \psi)\chi, y_\gamma - \psi) = 0,$$

where $\chi = \chi_{S_\gamma}$. As in the infeasible case we replace $a(\cdot,\cdot)$ by $E(\cdot,\cdot)$, with E a constant, and using (22), we arrive at

$$(E+\gamma)(\dot{y}_\gamma\chi, v) + ((y_\gamma - \psi)\chi, v) = 0.$$

The choice $v = y_\gamma - \psi$ implies

$$(E+\gamma)(\dot{y}_\gamma\chi, y_\gamma - \psi) + ((y_\gamma - \psi)\chi, y_\gamma - \psi) = 0. \tag{38}$$

Note that $\dot{V}(\gamma)$ can be expressed as

$$\dot{V}(\gamma) = -\frac{1}{2\gamma^2}\int_\Omega \bar{\lambda}^2\chi + \frac{1}{2}\int_\Omega (y_\gamma - \psi)^2\chi. \tag{39}$$

Using (36) and (39) in (38), and replacing V by m, due to the substitution for $a(\cdot,\cdot)$, we find

$$(E+\gamma)\ddot{m} + 2\dot{m} - E\,\gamma^{-3}\int_\Omega \chi\,\bar{\lambda}^2 = 0.$$

We further replace $\int_\Omega \chi\bar{\lambda}^2$, which is a bounded quantity depending on γ, by $2B$, and obtain, as the ordinary differential equation that we propose for the model function m in the feasible case,

$$(E+\gamma)\ddot{m} + 2\dot{m} - 2\gamma^{-3}E\,B = 0. \tag{40}$$

The family of solutions is given by (37). In the right-hand plot of Figure 4 in section 6 we depict the approximation quality of $m(\gamma)$.

6. Path-following algorithms. In this section we study the basic Algorithm B together with a variety of adjustment schemes for the path parameter γ. For this purpose recall that, depending on the shift parameter $\bar{\lambda}$, the elements y_γ along the primal-dual path are feasible or infeasible. As we have seen in the previous section, this implies different models for approximating the value function V. We will see, however, that for $\gamma > 0$ in both cases similar strategies for updating γ may be used. When referring to the infeasible or feasible case, (29), respectively (35), is assumed to hold.

The subsequent discussion is based on the following two-dimensional test problems. We point out that the bound ψ in problem P1 below does not satisfy $\psi \in H^1(\Omega)$. However, as we shall see, the feasible and infeasible primal-dual path as well as the algorithms introduced subsequently still perform satisfactorily. We include this example since discontinuous obstacles are of practical relevance.

Test problem P1. We consider (8) with $a_{ij} = \delta_{ij}$, with δ_{ij} the Kronecker symbol, $d = 0$, and $\Omega = (0,1)^2$. We choose

$$f(x_1, x_2) = 500x_1 \sin(5x_1)\cos(x_2)$$

and $\psi \equiv 10$ on $\Omega \setminus K$, and $\psi \equiv 1$ on K with $K = \{x \in \Omega : \frac{1}{5} \le \|x - (\frac{1}{2}, \frac{1}{2})^\top\|_2 \le \frac{2}{5}\}$. The solution y^*, the obstacle ψ, and the active set $\mathcal{A}^*$ at the solution are shown in Figure 1.

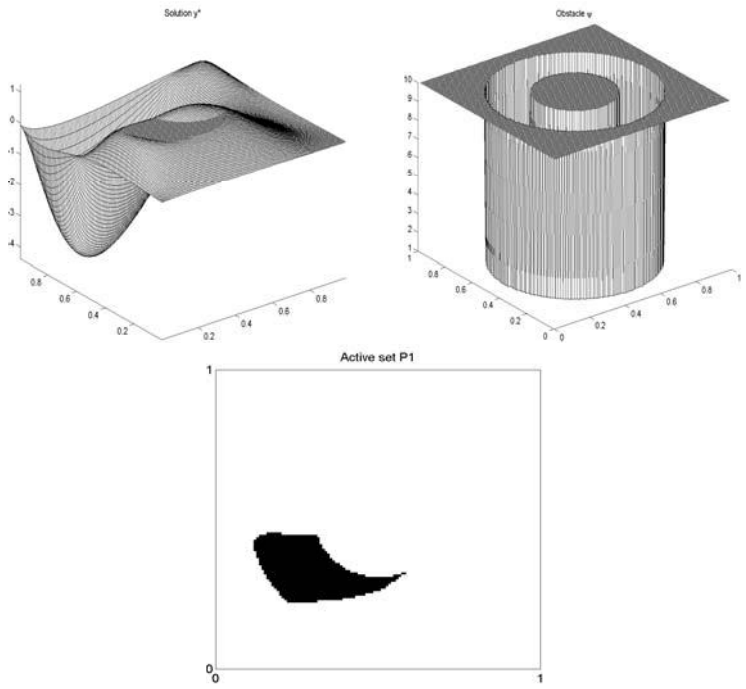

FIG. 1. *Optimal solution y^* (upper left plot), obstacle ψ (upper right plot), and the active set $\mathcal{A}^*$ (lower plot) for test problem* P1.

Test problem P2. Again we consider (8), with a_{ij}, d, and Ω as before, and define

$$y^\dagger := \begin{cases} x_1 & \text{on } T_1 := \{x \in \Omega : x_2 \le x_1 \wedge x_2 \le 1 - x_1\}, \\ 1 - x_2 & \text{on } T_2 := \{x \in \Omega : x_2 \le x_1 \wedge x_2 \ge 1 - x_1\}, \\ 1 - x_1 & \text{on } T_3 := \{x \in \Omega : x_2 \ge x_1 \wedge x_2 \ge 1 - x_1\}, \\ x_2 & \text{on } T_4 := \{x \in \Omega : x_2 \ge x_1 \wedge x_2 \le 1 - x_1\}. \end{cases} \tag{41}$$

The obstacle ψ is defined by $\psi \equiv y^\dagger$ on $S_1 := \{x \in \Omega : \|x - (\frac{1}{2}, \frac{1}{2})^\top\|_\infty \le \frac{1}{4}\}$, $\psi \equiv \frac{1}{4}$ on $S_2 \setminus S_1$, and

$$\psi := \begin{cases} 2x_1 & \text{on } T_1 \cap (\Omega \setminus S_2), \\ \frac{1}{4} - 2(x_2 - \frac{7}{8}) & \text{on } T_2 \cap (\Omega \setminus S_2), \\ \frac{1}{4} - 2(x_1 - \frac{7}{8}) & \text{on } T_3 \cap (\Omega \setminus S_2), \\ 2x_2 & \text{on } T_4 \cap (\Omega \setminus S_2), \end{cases}$$

with $S_2 := \{x \in \Omega : \|x - (\frac{1}{2}, \frac{1}{2})^\top\|_\infty \le \frac{3}{8}\}$. The forcing term is given by

$$(f, \phi)_{L^2} = \int_{\Omega^+} \phi(s)ds + (\chi_{S_1}, \phi)_{L^2} + \int_{S_1 \cap \Omega^+} \phi(s)ds \qquad \text{for all } \phi \in H_0^1(\Omega),$$

where $\Omega^+ := \{x \in \Omega : x_2 = x_1\} \cup \{x \in \Omega : x_2 = 1 - x_1\}$. We recall that for $\phi \in H_0^1(\Omega)$, $\Omega \subset \mathbb{R}^2$, the traces along smooth curves are well defined. The solution y^* is given by $y^* = y^\dagger$. The active or coincidence set at the solution is $\mathcal{A}^* = S_1$. The Lagrange multiplier $\lambda^* = f + \Delta y^*$ is in $H^{-1}(\Omega)$ and enjoys no extra regularity. In Figure 2 we display the optimal solution y^*, the obstacle ψ, and the active set $\mathcal{A}^*$.

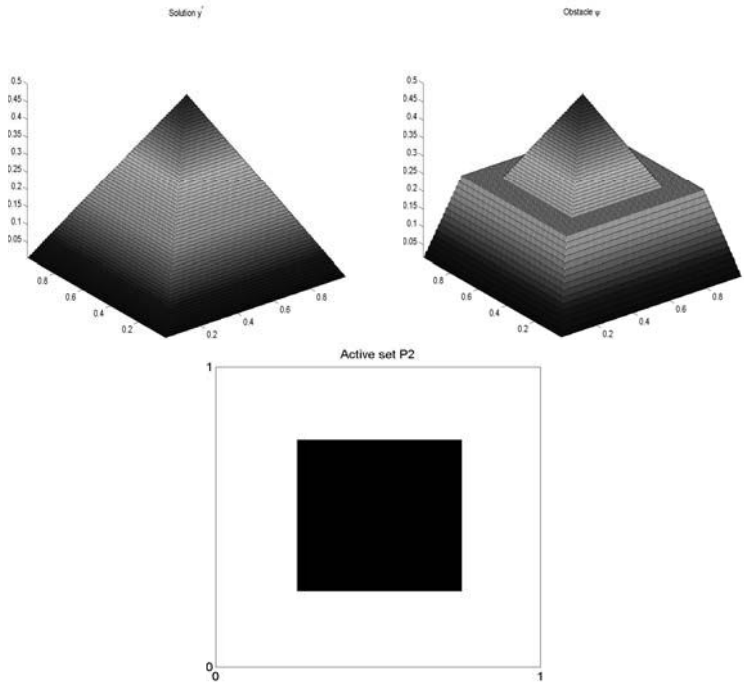

FIG. 2. *Optimal solution y^* (upper left plot), obstacle ψ (upper right plot), and the active set $\mathcal{A}^*$ (lower plot) for test problem* P2.

Test problem P3. For this test problem (8) is satisfied. We therefore obtain $y^* \in H^2(\Omega)$ and $\lambda^* \in L^2(\Omega)$. The coefficients a_{ij} and d as well as Ω are as before. The volume force f is given by $f = -\Delta v$ with $v(x_1, x_2) = \sin(3\pi x_1)\sin(3\pi x_2)$. Further, we have $\psi = \frac{1}{4} - \frac{1}{10}\sin(\pi x_1)\sin(\pi x_2)$. The optimal solution y^*, the Lagrange multiplier λ^*, and the active set at y^* are displayed in Figure 3.

Unless specified otherwise, the subsequent algorithms are initialized by $y_0 = (-\Delta)^{-1} f$, where $-\Delta$ denotes the Laplacian with homogeneous Dirichlet boundary conditions. The initial Lagrange multiplier is chosen as $\lambda_0 = \gamma_0 \chi_{\{y_0 > \psi\}}(y_0 - \psi)$.

The discretization of $-\Delta$ is based on the classical five-point finite difference stencil. We denote the mesh size by h, which we occasionally drop for convenience. The forcing term f in P2 is discretized by $f = -\Delta y^\dagger + \chi_{S_1} e + \chi_{S_1}(-\Delta y^\dagger)$, where e is the vector of all ones and χ_{S_1} represents a diagonal matrix with entry $(\chi_{S_1})_{ii} = 1$ for grid points $x_i \in S_1$ and $(\chi_{S_1})_{ii} = 0$ otherwise. Above $y^\dagger$ denotes the grid function corresponding to (41).

6.1. A strategy based on model functions—exact path-following. As outlined in section 5, there are good reasons to trust our model functions (30) and (37) in the infeasible and feasible cases, respectively. Let us start by focusing on the infeasible case. The model is given by $m(\gamma) = C_1 - C_2(E + \gamma)^{-1}$. For determining

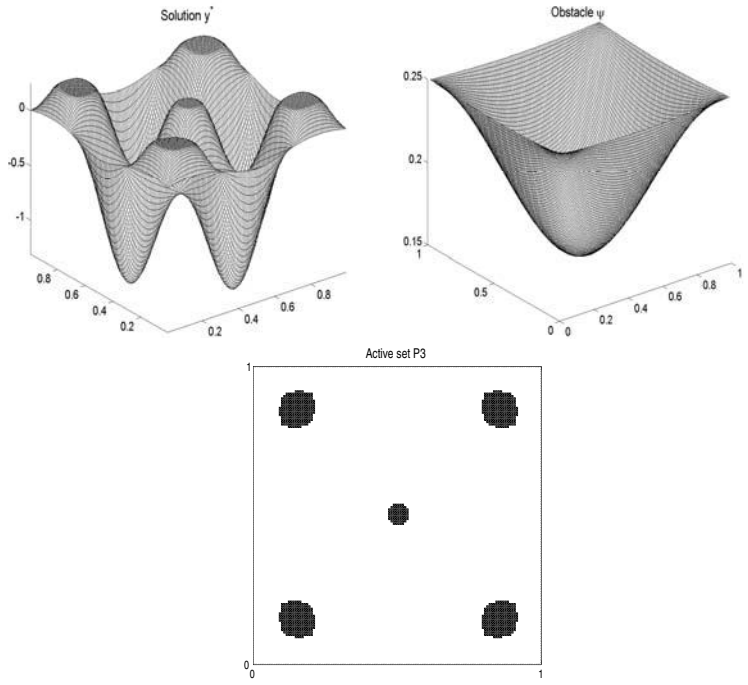

FIG. 3. *Optimal solution y^* (upper left plot), obstacle ψ (upper right plot), and the active set $\mathcal{A}^*$ (lower plot) for test problem* P3.

the three parameters C_1, C_2, and E, we use the information $V(0), V(\gamma), \dot{V}(\gamma)$, which, by Proposition 4.2, is available from one solve of the unconstrained problem ($\hat{\text{P}}$) and one solve for (Pγ). The conditions

$$m(0) = V(0), \quad m(\gamma) = V(\gamma), \quad \dot{m}(\gamma) = \dot{V}(\gamma) \tag{42}$$

yield

$$\begin{aligned} E &= \gamma^2 \dot{V}(\gamma) \left(V(\gamma) - V(0) - \gamma \dot{V}(\gamma) \right)^{-1}, \\ C_2 &= \gamma^{-1} E(E+\gamma) \left(V(\gamma) - V(0) \right), \\ C_1 &= V(0) + C_2 E^{-1}. \end{aligned} \tag{43}$$

We could have used an alternative reference value $\gamma_r \in (0, \gamma)$ and computed $m(\gamma_r) = V(\gamma_r)$ instead of $m(0) = V(0)$. In Figure 4 we compare $V(\gamma)$ to $m(\gamma)$ for different values of the coefficients (C_1, C_2, E). These coefficients depend on different values y_f for γ (in (42)) produced by Algorithm EP (see below) for problem P1. The solid line corresponds to $V(\gamma)$. The corresponding γ-values γ_f for (42) are depicted in the legend of the left plot in Figure 4. The dotted and dashed line belong to rather small γ-values, and the dashed-dotted and the circled lines to large γ_f in (42). As we can see, the dotted line is accurate in the range of relatively small γ_f, while the other lines are more accurate for large γ_f. From now on we consider only the choices $\gamma_r = 0$ and $\gamma = \gamma_k$ in (42) when updating γ_k.

Next we discuss properties of the model parameters E, C_1, C_2 according to (43). For this purpose assume that the solution $\hat{y}$ to ($\hat{\text{P}}$) is not feasible for (P). Then

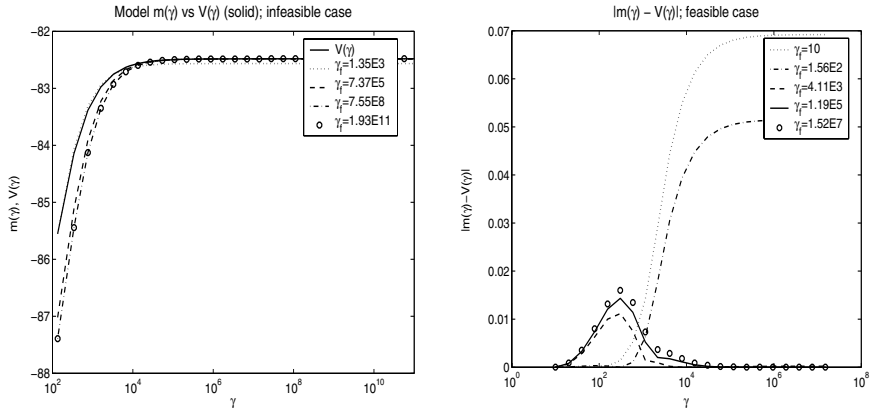

FIG. 4. *Left: Model $m(\gamma)$ vs. $V(\gamma)$ (solid) in the infeasible case for* P1. *Right: Model $m(\gamma)$ vs. $V(\gamma)$ in the feasible case.*

by Corollary 4.3 we have $\dot{V}(\gamma) > 0$ for all $\gamma > 0$. Consequently $V(\gamma) > V(0)$ and $V(\gamma) - V(0) - \gamma\dot{V}(\gamma) = -\int_0^\gamma \int_s^\gamma \ddot{V}(\sigma) d\sigma ds > 0$, and hence $E > 0$ and $C_2 > 0$ for all $\gamma \in (0, +\infty)$. This implies $m(\gamma) \leq C_1$ and $m(\gamma) \to C_1$ for $\gamma \to +\infty$.

We propose the following update strategy for γ: Let $\{\tau_k\}$ satisfy $\tau_k \in (0,1)$ for all $k \in \mathbb{N}$ and $\tau_k \downarrow 0$ as $k \to \infty$, and assume that $V(\gamma_k)$ is available. Then, given γ_k, the updated value γ_{k+1} should ideally satisfy

$$|V^* - V(\gamma_{k+1})| \leq \tau_k |V^* - V(\gamma_k)|. \tag{44}$$

Since V^* and $V(\gamma_{k+1})$ are unknown, we use $C_{1,k}$ and our model $m_k(\gamma) = C_{1,k} - C_{2,k}/(E_k + \gamma)$ at $\gamma = \gamma_{k+1}$ instead. Thus, (44) is replaced by

$$|C_{1,k} - m_k(\gamma_{k+1})| \leq \tau_k |C_{1,k} - V(\gamma_k)| =: \beta_k. \tag{45}$$

Solving the equation $C_{1,k} - m_k(\gamma_{k+1}) = \beta_k$, we obtain

$$\gamma_{k+1} = \frac{C_{2,k}}{\beta_k} - E_k. \tag{46}$$

In Theorem 6.1 we shall show that $\gamma_{k+1} \geq \kappa\gamma_k$, with $\kappa > 1$, independently of $k \in \mathbb{N}$.

Before we turn to the feasible case, we interpret (44) in view of Proposition 4.5 in the infeasible case. Recall that $V^* \geq V(\gamma)$, and observe that $|V^* - V(\gamma)| = \mathcal{O}(|y^* - y_\gamma|_{H_0^1})$. Proposition 4.5 yields

$$|y^* - y_\gamma|_{H_0^1}^2 \leq \frac{2}{\nu} (V^* - V(\gamma))$$

since $\dot{V}(\gamma) > 0$. Setting $\tau_k = \omega_k^2 |V^* - V(\gamma_k)|$, with $\omega_k \to 0$, in (44) yields

$$|y^* - y_{\gamma_{k+1}}|_{H_0^1}^2 \leq C_\tau \omega_k^2 |y^* - y_{\gamma_k}|_{H_0^1}^2.$$

Consequently, we obtain

$$\frac{|y^* - y_{\gamma_{k+1}}|_{H_0^1}}{|y^* - y_{\gamma_k}|_{H_0^1}} \leq C_\tau \omega_k,$$

which implies q-superlinear convergence of $\{y_{\gamma_k}\}$ in $H_0^1(\Omega)$.

In the feasible case, i.e., when $\bar{\lambda}$ satisfies (12), we use the model $m(\gamma) = C_1 - C_2(E+\gamma)^{-1} + B\gamma^{-1}$ with $C_2 \geq 0$ and $E, B > 0$; see (37). Let $\gamma_r > 0$, $\gamma_r \neq \gamma$, denote a reference γ-value; then we use the conditions

$$m(\gamma_r) = V(\gamma_r), \quad \dot{m}(\gamma_r) = \dot{V}(\gamma_r), \quad m(\gamma) = V(\gamma), \quad \dot{m}(\gamma) = \dot{V}(\gamma)$$

for fixing B, $C1$, $C2$, E. Solving the corresponding system of nonlinear equations, we get

$$E = \frac{\Big(\Big((\gamma_r - \gamma)(\dot{V}(\gamma_r)\gamma_r^2 + \dot{V}(\gamma)\gamma^2) + 2\gamma_r\gamma(V(\gamma) - V(\gamma_r)\Big)\Big)}{\Big((\dot{V}(\gamma)\gamma + \dot{V}(\gamma_r)\gamma_r)(\gamma - \gamma_r) + (\gamma_r + \gamma)(V(\gamma_r) - V(\gamma))\Big)}$$

and

$$B = \frac{\gamma_r^2\gamma^2\left((V(\gamma) - V(\gamma_r))^2 - \dot{V}(\gamma)\dot{V}(\gamma_r)(\gamma - \gamma_r)^2\right)}{\Big((\gamma - \gamma_r)^2(\dot{V}(\gamma_r)\gamma_r^2 + \dot{V}(\gamma)\gamma^2) + 2(\gamma - \gamma_r)\gamma_r\gamma(V(\gamma_r) - V(\gamma))\Big)}$$

Then the parameters C_1 and C_2 are given by

$$C_2 = (E+\gamma)^2\left(\frac{B}{\gamma^2} + \dot{V}(\gamma)\right),$$

$$C_1 = V(\gamma) + \frac{C_2}{E+\gamma} - \frac{B}{\gamma}.$$

In the right plot of Figure 4 we show $|m(\gamma) - V(\gamma)|$ with $m(\gamma)$ produced by the iterates of Algorithm EP for P1 similar to the infeasible case. Again we can see that our model yields a close approximation of the value function V.

If we require that (45) be satisfied in the feasible case, then we obtain the following update strategy for γ:

$$\gamma_{k+1} = -\frac{D_k}{2} + \sqrt{\frac{D_k^2}{4} + \frac{B_k E_k}{\beta_k}}, \tag{47}$$

where $D_k = E_k + (C_{2,k} - B_k)/\beta_k$. In Theorem 6.1 we shall establish $\gamma_{k+1} \geq \kappa\gamma_k$ for all $k \in \mathbb{N}_0$ with $\kappa > 1$ independent of k.

Next we describe an **e**xact **p**ath-following version of Algorithm B, which utilizes the update strategy (45) for updating γ.

ALGORITHM EP.

(i) Select γ_r. Compute $V(\gamma_r)$, and choose $\gamma_0 > \max(1, \gamma_r)$; set $k = 0$.
(ii) Apply Algorithm B to obtain y_{γ_k}.
(iii) Compute $V(\gamma_k)$, $\dot{V}(\gamma_k)$, and γ_{k+1} according to (46) in the infeasible case or (47) in the feasible case.
(iv) Set $k = k + 1$, and go to (ii).

Concerning the choice of γ_r note that in the infeasible case we have $\gamma_r \geq 0$, and in the feasible case $\gamma_r > 0$. Convergence of Algorithm EP is addressed next.

THEOREM 6.1. *Assume that the solution to* ($\hat{\text{P}}$) *is not feasible for* (P). *Then the iterates* γ_k *of Algorithm EP tend to* ∞ *as* $k \to \infty$, *and consequently* $\lim_{k\to\infty}(y_{\gamma_k}, \lambda_{\gamma_k}) = (y^*, \lambda^*)$ *in* $H_0^1(\Omega) \times H^{-1}(\Omega)_{weak}$.

Proof. Let us consider the infeasible case. Then (45) is equivalent to

$$0 < C_{1,k} - m_k(\gamma_{k+1}) < \tau_k(C_{1,k} - m_k(\gamma_k)). \tag{48}$$

Since $\gamma \mapsto m_k(\gamma)$ is strictly increasing and $\tau_k \in (0,1)$, it follows that $\gamma_{k+1} > \gamma_k$ for every $k = 0, 1, \ldots$. If $\lim_{k\to\infty} \gamma_k = \infty$, then $\lim_{k\to\infty}(y_{\gamma_k}, \lambda_{\gamma_k}) = (y^*, \lambda^*)$. Otherwise there exists $\bar\gamma$ such that $\lim_{k\to\infty} \gamma_k = \bar\gamma$. Since $\gamma \mapsto V(\gamma)$ and $\gamma \mapsto \dot V(\gamma)$ are continuous on $(0,\infty)$, it follows from (42) and (43) that $\lim_{k\to\infty} E_k = E(\bar\gamma)$, $\lim_{k\to\infty} C_{1,k} = C_1(\bar\gamma)$, and $\lim_{k\to\infty} C_{2,k} = C_2(\bar\gamma)$, where $E(\bar\gamma)$, $C_1(\bar\gamma)$, $C_2(\bar\gamma)$ are given by (43) with γ replaced by $\bar\gamma$. Taking the limit with respect to k in (48), we arrive at

$$\frac{C_2(\bar\gamma)}{E(\bar\gamma) + \bar\gamma} = 0,$$

which is impossible, since $C_2(\bar\gamma) > 0$ and $E(\bar\gamma) > 0$ if the solution to $(\hat{\mathrm{P}})$ is not feasible for (P). Thus $\lim_{k\to\infty} \gamma_k = \infty$. The feasible case is treated analogously. ∎

Numerically we stop the algorithm as soon as $\|(r_k^{1,h}, r_k^{2,h}, r_k^{3,h})^\top\|_2 \le \sqrt{\epsilon_M}$, where

$$\begin{aligned}
r_k^{1,h} &= \|y_{\gamma_k}^h + (-\Delta^h)^{-1}(\lambda_{\gamma_k}^h - f^h)\|_{H^{-1,h}} / \|f^h\|_{H^{-1,h}},\\
r_k^{2,h} &= \|\lambda_{\gamma_k}^h - \max(0, \lambda_{\gamma_k}^h + y_{\gamma_k}^h - \psi^h)\|_{H^{-1,h}},\\
r_k^{3,h} &= \|\max(0, y_{\gamma_k}^h - \psi^h)\|_{L_2^h},
\end{aligned}$$

and ϵ_M denotes the machine accuracy. Here $|\cdot|_{H^{-1,h}}$ denotes the discrete version of $|\cdot|_{H^{-1}}$. For some vector v it is realized as $|v|_{H^{-1}} = |\nabla^h(-\Delta^h)^{-1}v|_{L_2^h}$ with $|\cdot|_{L_2^h}$ the discrete L^2-norm and ∇^h a forward difference approximation of the gradient operator; see [8]. The inner iteration, i.e., Algorithm B for $\gamma = \gamma^k$, is terminated if successive active sets coincide or

$$\frac{\|-\Delta^h y_{\gamma_k}^{h,l} + \lambda_{\gamma_k}^{h,l} - f^h\|_{H^{-1,h}}}{\|f^h\|_{H^{-1,h}}} \le \sqrt{\epsilon_M}.$$

Here the superscript $l = l(k)$ denotes the iteration index of Algorithm B for fixed k. For a discussion and numerical results in the case where the approximation errors due to the discretization of the underlying function space problems are incorporated into the algorithmic framework, e.g., when stopping the algorithm, we refer to the next section 6.2.

The initialization of γ is as follows: In the infeasible case we propose a choice of γ_0 based on the deviation of the linearization of $V(\gamma)$ at $\gamma = \gamma_r$ from the objective value of the unconstrained problem $(\hat{\mathrm{P}})$ at the projection of y_{γ_r} onto the feasible set. In our realization of this heuristic we choose $\gamma_r = 0$ and compute $\hat y$, $V(0)$, and $\dot V(0)$. Then we set

$$\gamma_0 = \max\left\{1, \zeta\frac{J(y_b) - V(0)}{\dot V(0)}\right\}, \tag{49}$$

where $\zeta \in (0,1]$ is some fixed constant, $y_b(x) = \min(\hat y, \psi(x))$, and J denotes the objective function of $(\hat{\mathrm{P}})$. Note that $\hat y$ is the minimizer of the unconstrained problem $(\hat{\mathrm{P}})$. For the examples below we use $\zeta = 1$. In the feasible case we choose a reference value γ_r, e.g., $\gamma_r = 1$, and solve the path problem (P_γ). Then we choose

$$\gamma_0 = \gamma_r + \frac{J(\hat y) - V(\gamma_r)}{\dot V(\gamma_r)}, \tag{50}$$

where $\hat{y}$ denotes the minimizer of the discretized unconstrained problem $(\hat{\mathrm{P}})$. If $\hat{y}$ is not feasible for (P), then one has $J(\hat{y}) < V(\gamma_r)$ and hence $\gamma_0 > \gamma_r$.

When applied to P1, P2, and P3 for $h = 1/128$ and with $\tau_k = 0.01^{k+1}$, we obtain the results shown in Figure 5 and Table 6.1.

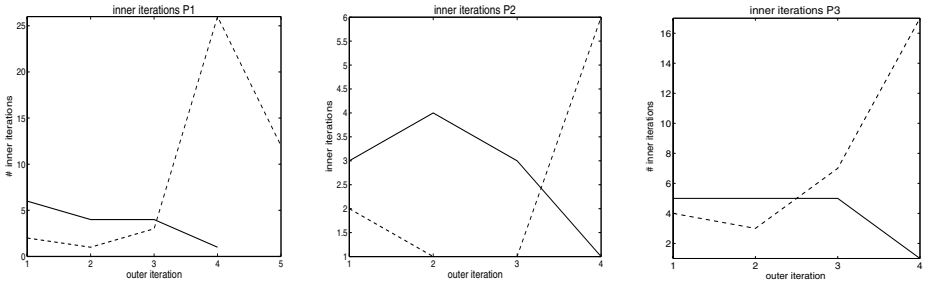

FIG. 5. *Number of inner iterations (vertical axis) per outer iteration for* P1 *(left plot),* P2 *(middle plot), and* P3 *(right plot); solid line – infeasible case, dashed line – feasible case.*

TABLE 6.1
Comparison of iteration counts.

	P1		P2		P3	
Version	# outer	# inner	# outer	# inner	# outer	# inner
Feasible	5	44	4	10	4	31
Infeasible	4	15	4	11	4	16

From our test runs, also for other test problems, we observe the following characteristics:

- For the feasible version the number of inner iterations exhibits an increasing tendency until a saturation value is reached, and then, unless the algorithm stops at an approximate solution, it starts to decrease. For the infeasible version we typically observe that the first couple of iterations require several inner iterations. As the outer iterations proceed the number of inner iterations drops eventually to one. We also tested less aggressive γ-updates compared to the ones used here, e.g., updates based on $\gamma_{k+1} = \xi\gamma_k$ with $\xi > 1$ fixed.
- The numerically observable convergence speed of y_{γ_k} towards y^* in $H_0^1(\Omega)$ is typically superlinear. This can be seen from Figure 6, where the plots for the discrete versions q_k^h of the quotients

$$q_k = \frac{|y_{\gamma_{k+1}} - y^*|_{H_0^1}}{|y_{\gamma_k} - y^*|_{H_0^1}}$$

are shown. Note that the vertical axis uses a logarithmic scale. In the first row, for P1 we depict the behavior of q_k^h for $h = 2^{-i}$, $i = 5, 6, 7, 8$, for the infeasible case (left plot) and the feasible case (right plot). We observe that the convergence rate is stable with respect to decreasing mesh size h. In the second row we see the behavior of q_k^h for P2 and P3, with $h = 2^{-7}$. Again, we observe a superlinear rate of convergence. With respect to decreasing h the same conclusion as for P1 holds true. These stability results provide a link between our function space theory and the numerical realization of the algorithms.

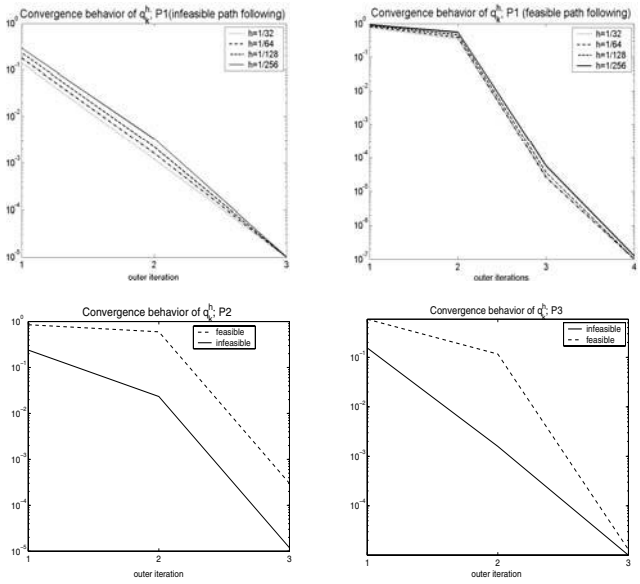

FIG. 6. *Discrete quotients* q_k^h *for* P1 *and various mesh sizes* h *(upper row) and for* P2 *(lower left) and* P3 *(lower right) for* $h = 1/128$.

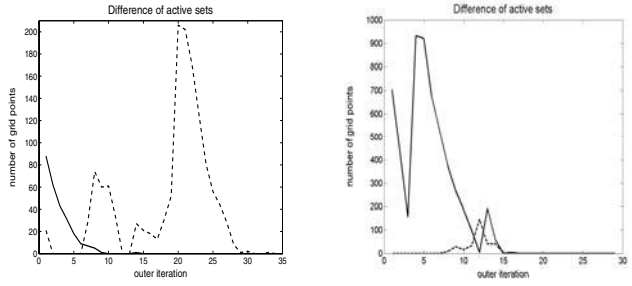

FIG. 7. *Difference in active sets for* P1 *and* P2*; solid line – infeasible case, dashed line – feasible case.*

- In connection with the convergence speed it is of interest how the detection process of the correct active set works. For the rather aggressive γ-updates used in Algorithm EP the difference between two successive active sets is zero typically only in the last iteration. However, if a less aggressive strategy for updating γ is used, then it is to be expected, that the difference of active sets might become zero earlier along the iteration. In Figure 7, for the strategy $\gamma_{k+1} = 2\gamma_k$, we show the difference of successive active sets; i.e., the vertical axis relates to the number of grid points that are in $\mathcal{A}_{k+1}$ but not in $\mathcal{A}_k$ and vice versa. We detect that for the infeasible case there exists an iteration index $\bar{k}$ after which the difference is constantly zero. This behavior is a strong indication that the correct active set was detected. It suggests that we fix this set $\mathcal{A}_{\bar{k}}$ and set $\bar{y}_{|\mathcal{A}_{\bar{k}}} = \psi_{|\mathcal{A}_{\bar{k}}}$, $\mathcal{I}_{\bar{k}} = \Omega \setminus \mathcal{A}_{\bar{k}}$, and $\bar{\lambda}_{\mathcal{I}_{\bar{k}}} = 0$. Then one computes $\bar{y}_{|\mathcal{I}_{\bar{k}}}$ and $\bar{\lambda}_{\mathcal{A}_{\bar{k}}}$ such that $a(\bar{y}, v) + \langle \bar{\lambda}, v \rangle_{H^{-1}, H_0^1} = (f, v)$ for all $v \in H_0^1(\Omega)$, and checks whether $(\bar{y}, \bar{\lambda})$ satisfies (7). If this is the case, then the solution is

found; otherwise $\gamma_{\bar{k}}$ is updated and the iteration continued. If we apply this technique for P1 in the infeasible case, then the algorithm stops at iteration 15 (35 inner iterations) with the exact discrete solution, as compared to 28 outer and 47 inner iterations without the additional stopping rule. There were four iterations where the additional system solve was necessary but without obtaining the numerical solution. Hence, with respect to system solves, the amount of work drops from 47 solves to 39 ($= 35 + 4$). A similar observation is true for P2 and P3. In the feasible case, however, this strategy yields no reduction of iterations. Here, typically the correct active set is determined in the last iteration (for large enough γ).

- The dependence of the iteration number on the mesh size of the discretization for P1 is depicted in Table 6.2 (those for P2 and P3 are similar). In parenthesis we show the number of inner iterations. The results clearly indicate that the outer iterations are mesh independent, while the number of inner iterations increases as the mesh size decreases. In the third row we display the results obtained by applying Algorithm A for the solution of the unregularized problem (P) with data according to P1. If we compare these results with those of the infeasible exact path-following algorithm, we find that for sufficiently small mesh sizes h the infeasible version of Algorithm EP requires significantly fewer iterations than does Algorithm A, which is also an infeasible algorithm. Also, the number of iterations required by Algorithm A exhibits a relatively strong dependence on h when compared to Algorithm EP in the infeasible case. Similar observations apply also to P2 and P3. This shows that taking into account the function space theoretic properties when regularizing problem (P) results in an algorithmic framework which performs stably with respect to decreasing mesh size of the discretization.

TABLE 6.2
Comparison of iteration counts for different mesh sizes.

Algorithm A	4	8	14	26	48

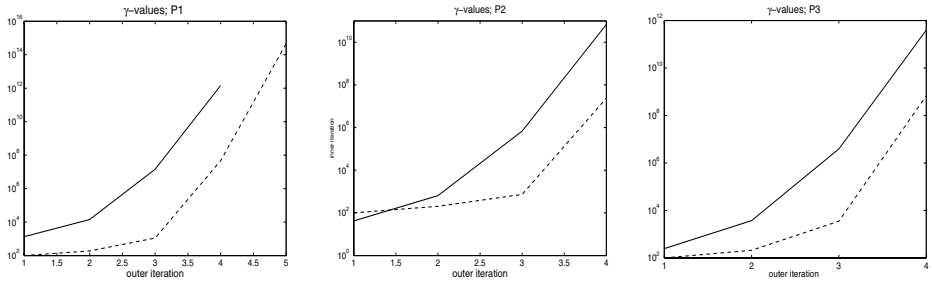

FIG. 8. *γ-updates; solid line – infeasible case, dashed line – feasible case.*

- From the plots in Figure 8, where the y-axis again has a logarithmic scale, it can be seen that our strategy (45) produces a rapidly increasing sequence

$\{\gamma_k\}$. The plots in Figure 8 depict the increase of γ_k as a function of the iteration number. The question arises of whether one could increase γ more rapidly. Numerical examples employing an ad hoc strategy show that if γ is increased too quickly, then the numerical error may prevent the residuals of the first order system from dropping below $\sqrt{\epsilon_M}$. This effect is due to the ill-conditioning of the linear systems for large γ. On the other hand, small increases in γ result in a slow convergence speed of Algorithm EP. Further, in our test runs and as can be seen from Figure 8, the feasible version of Algorithm EP is less aggressive in enlarging γ_k.

6.2. Inexact path-following. While exact path-following is primarily of theoretical interest, the development of inexact path-following techniques that keep the number of iterations as small as possible is of more practical importance. The strategy in the previous section relies on the fact that for every γ_k the corresponding point on the primal-dual path is computed. This, however, is not the case for inexact techniques and, as a consequence, a different update strategy for the path parameter γ is necessary. A common concept in inexact path-following methods is based on the definition of an appropriate neighborhood of the path; see, e.g., [3] and the references therein for a noninterior neighborhood-based path-following method, or [5, 16, 18, 19] for path-following techniques related to interior point methods. It is typically required that the primal-dual iterates stay within the neighborhood of the path, with the goal to reduce the computational burden while still maintaining convergence of the method.

We define

$$r_\gamma^1(y,\lambda) = \| -\Delta y + \lambda - f\|_{H^{-1}}, \tag{51a}$$

$$r_\gamma^2(y,\lambda) = \|\lambda - \max(0, \lambda + \gamma(y-\psi))\|_{H^{-1}}, \tag{51b}$$

and the neighborhood

$$\mathcal{N}(\gamma) := \left\{ (y,\lambda) \in H_0^1(\Omega) \times L^2(\Omega) : \|(r_\gamma^1(y,\lambda), r_\gamma^2(y,\lambda))^\top\|_2 \le \frac{\tau}{\sqrt{\gamma}} \right\} \tag{52}$$

in the infeasible case and

$$\mathcal{N}(\gamma) := \left\{ (y,\lambda) \in H_0^1(\Omega) \times L^2(\Omega) : \|(r_\gamma^1(y,\lambda), r_\gamma^2(y,\lambda))^\top\|_2 \le \frac{\tau}{\sqrt{\gamma}} \right.$$
$$\left. \wedge \frac{\partial}{\partial\gamma} J(y;\gamma) \le 0 \right\} \tag{53}$$

in the feasible case. Above, $\tau > 0$ denotes some fixed parameter. Note that adding the condition $\frac{\partial}{\partial\gamma} J(y;\gamma) \ge 0$ in (52) yields no further restriction, since this condition is automatically satisfied by the structure of $J(y;\gamma)$. We also point out that the conditions on the derivative of $J(y;\gamma)$ are included in (52) and (53), respectively, in order to qualitatively capture (up to first order) the analytical properties of the primal-dual path.

Next we specify our framework for an **i**nexact **p**ath-following algorithm.

ALGORITHM IP.

(i) Initialize γ_0 according to (49) in the infeasible case or (50) in the feasible case; set $k := 0$.

(ii) Apply Algorithm B to find $(y_{k+1}, \lambda_{k+1}) \in \mathcal{N}(\gamma_k)$.
(iii) Update γ_k to obtain γ_{k+1}.
(iv) Set $k = k + 1$, and go to (ii).

Note that if in step (ii) the path-problem (P_γ) is solved, then $r^1_\gamma(y_\gamma, \lambda_\gamma) = r^2_\gamma(y_\gamma, \lambda_\gamma) = 0$.

As is the case with primal-dual path-following interior point methods, the update strategy for γ in step (iii) of Algorithm IP is a delicate issue. If the increase of γ from one iteration to the next is rather small, then we follow the path closely, and the convergence speed is slow. If the γ-update is too aggressive, then step (ii) requires many iterations of Algorithm B to produce iterates in the neighborhood. We propose the following strategy, which performed very well in our numerical tests.

We introduce the *primal infeasibility measure* ρ^F and the *complementarity measure* ρ^C as follows:

$$\rho^F_{k+1} := \int_\Omega (y_{k+1} - \psi)^+ dx, \tag{54}$$

$$\rho^C_{k+1} := \int_{\mathcal{I}_{k+1}} (y_{k+1} - \psi)^+ dx + \int_{\mathcal{A}_{k+1}} (y_{k+1} - \psi)^- dx, \tag{55}$$

where $(\cdot)^- = -\min(0, \cdot)$ and $(\cdot)^+ = \max(0, \cdot)$. Note that at the optimal solution both measures vanish. Further, we point out that ρ^C is related to the duality measure well known from primal-dual path-following interior point methods. These measures are used in the following criterion for updating γ:

$$\gamma_{k+1} \geq \max\left(\gamma_k \max\left(\tau_1, \frac{\rho^F_{k+1}}{\rho^C_{k+1}}\right), \frac{1}{(\max(\rho^F_{k+1}, \rho^C_{k+1}))^q}\right) \tag{56}$$

with $\tau_1 > 1$ and $q \geq 1$. The first term in the outermost max-expression is used because of our observation that $\rho^F_{k+1} \geq \rho^C_{k+1}$ in the infeasible case. If ρ^C is small compared to ρ^F, we find that the iterates primarily lack feasibility as compared to complementarity. Therefore, a strong increase in γ, which aims at reducing constraint infeasibility, is favorable. If both measures are of almost the same size and rather small, then the second term in the outer max-expression should yield a significant increase in γ. Typically $q \in [\frac{3}{2}, 2]$ is chosen, which induces growth rates for γ.

If there is still a significant change in the active sets from one iteration to the next and the update γ_{k+1} based on (56) would be too large compared to γ_k, then many inner iterations would be necessary to keep track of the path, or very conservative γ-updates in the following iterations have to be chosen. We safeguard the γ-updates by utilizing our model function $m(\gamma)$, which was found to be a reliable tool. In fact, in updating γ, large deviations from $m(\gamma)$ are prohibited by comparing the value of the tangent to $J(y; \gamma)$ at $\gamma = \gamma_k$ with the actual model value. If necessary and as long as γ_{k+1} is much larger than γ_k, we reduce the actual γ-value until

$$|t_k(\gamma_{k+1}) - m_k(\gamma_{k+1})| \leq \tau_3 |J(y_{k+1}; \gamma_k) - J(y_k; \gamma_{k-1})| \tag{57}$$

with $0 < \tau_3 < 1$, $t_k(\gamma) = J(y_{k+1}; \gamma_k) + \frac{\partial J}{\partial \gamma}(y_{k+1}; \gamma_k)(\gamma - \gamma_k)$, and $m_k(\gamma)$ the model related to γ_k. Recall that $m_k(\gamma_k) = J(y_{k+1}; \gamma_k)$. The motivation of this strategy utilizes the good approximation qualities of our models. Indeed, for small γ the distance between t_k and m_k might be large, but so is $|J(y_{k+1}; \gamma_k) - J(y_k; \gamma_{k-1})|$ since the change in the function value is expected to be relatively large for small γ. For large γ, however, both difference measures tend to be small.

Concerning the numerical realization of Algorithm IP in the discrete setting we point out that by an a posteriori analysis of the discretization errors one finds that the norm of the residuals in (51a) and (51b) can be approximated typically to the order of h. This can be used as an upper bound for γ in the discrete versions of (52) and (53), respectively. However, since, on a fixed grid, our discrete versions of (P) and (P_γ) are consistent (as $\gamma \to \infty$) and admit unique solutions in $\mathbb{R}^{N_h}$, where $N_h \in \mathbb{N}$ depends on the mesh size of discretization h, it is of interest to consider $\gamma \to \infty$. On a fixed grid, this allows us also to study the behavior of our discretized algorithms as finite dimensional solvers for problems similar to the discrete versions of the ones under consideration. With respect to the latter aspect, below we report on test runs of Algorithm IP when applied to our test problems P1, P2, and P3. The parameters had values $q = 1.5$, $\tau_1 = 10$, $\tau_3 = 0.999$, $\tau = 1e6$. The stopping rule for the outer iteration is as before.

P1. The infeasible version of Algorithm IP requires 9 outer iterations and at most 2 inner iterations per outer iteration. In particular, in many iterations the criterion $(y_{k+1}, \lambda_{k+1}) \in \mathcal{N}(\gamma_k)$ was satisfied within 1 inner iteration. The feasible version of Algorithm IP stops after 11 iterations. With respect to inner iterations in the feasible case we note that more than 1 or 2 inner iterations were necessary only in the last 3 outer iterations with 3, 4, and 6 inner iterations, respectively. For both runs, the behavior of the measures ρ^F and ρ^C is shown in Figure 9. Note that the vertical scale is a logarithmic one. The left plot corresponds to the infeasible case. The feasibility measure ρ^F and the complementarity measure ρ^C are both convergent at a superlinear rate. In the feasible case, which is depicted in the right plot, we observe that ρ^C is only linearly convergent. In some iterations we have $\rho_k^F > 0$. However, the constraint violation is of the order of the machine precision and thus negligible.

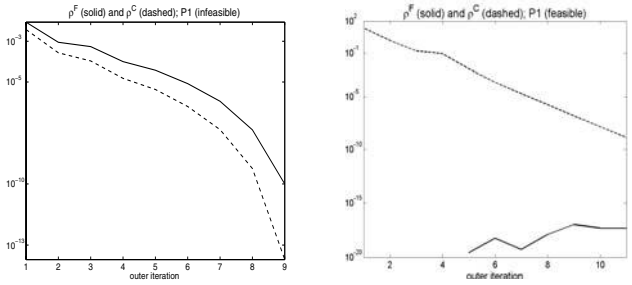

FIG. 9. *Behavior of the measures ρ^F (solid) and ρ^C (dashed) for* P1*, left plot – infeasible case, right plot – feasible case.*

P2. For this test problem the infeasible version of Algorithm IP required 11 iterations with one inner iteration per outer iteration. The feasible version needed 6 outer iterations and 9 inner iterations.

P3. The behavior of Algorithm IP for solving P3 is comparable to its behavior for P1 and P2. In fact, the infeasible version required 11 outer iterations and 11 inner iterations for solving the discrete problem. The feasible variant of Algorithm IP stopped successfully after 9 outer and 19 inner iterations. For the latter run, in the next-to-last iteration 5 inner iterations were necessary; otherwise at most 2 inner iterations were needed. With respect to the behavior of the decrease of the measures ρ^C and ρ^F, an observation similar to the one obtained from Figure 9 for P1 holds true. We remark only that in the feasible case ρ^C exhibits an almost superlinear

convergence behavior.

Compared to the exact path-following strategy of Algorithm EP, the inexact path-following concept of Algorithm IP is in many cases more efficient. In Table 6.3 we provide the number of outer and inner iterations for exact versus inexact path-following. In parenthesis we write the number of inner iterations.

TABLE 6.3
Comparison of iteration counts between exact and inexact path-following.

	Infeasible case			Feasible case		
	P1	P2	P3	P1	P2	P3
EP	4 (15)	4 (11)	4 (16)	5 (44)	4 (10)	4 (31)
IP	9 (12)	11 (11)	11 (11)	11 (25)	6 (9)	9 (19)

Finally we address the issue of how to incorporate the approximation error due to the discretization of function space quantities; see [6, 7]. First note that with (8) holding (which is the case for P3), the discretization of the residual in the definition of the neighborhoods (52), respectively (53), approximates the original one to the order of h. Hence, in our discrete version of Algorithm IP the neighborhood criterion

$$\|(r_\gamma^1(y,\lambda), r_\gamma^2(y,\lambda))^\top\|_2 \leq \frac{\tau}{\sqrt{\gamma}}$$

becomes

$$\|(r_\gamma^{1,h}(y,\lambda), r_\gamma^{2,h}(y,\lambda))^\top\|_2 \leq \max\left\{\sqrt{\epsilon_M}, \kappa_{\text{in}} h, \frac{\tau}{\sqrt{\gamma}}\right\},$$

with some constant $\kappa_{\text{in}} > 0$. We stop the outer iteration as soon as the discrete residual drops below $\max\{\kappa_{\text{out}} h, \sqrt{\epsilon_M}\}$, where $\kappa_{\text{out}} > 0$ is fixed. In our tests we use $\kappa_{\text{in}} = 1$ and $\kappa_{\text{out}} = 10$. Applying this strategy for the solution of P3, we obtain (outer) iteration numbers as displayed in Table 6.4. Here, in parenthesis we give the total number of inner iterations.

TABLE 6.4
Inexact path-following with h-dependent stopping of inner and outer iterations.

MESH ADAPTIVE DIRECT SEARCH ALGORITHMS FOR CONSTRAINED OPTIMIZATION*

CHARLES AUDET† AND J. E. DENNIS, JR.‡

Abstract. This paper addresses the problem of minimization of a nonsmooth function under general nonsmooth constraints when no derivatives of the objective or constraint functions are available. We introduce the mesh adaptive direct search (MADS) class of algorithms which extends the generalized pattern search (GPS) class by allowing local exploration, called *polling*, in an asymptotically dense set of directions in the space of optimization variables. This means that under certain hypotheses, including a weak constraint qualification due to Rockafellar, MADS can treat constraints by the extreme *barrier* approach of setting the objective to infinity for infeasible points and treating the problem as unconstrained.

The main GPS convergence result is to identify limit points $\hat{x}$, where the Clarke generalized derivatives are nonnegative in a finite set of directions, called *refining directions*. Although in the unconstrained case, nonnegative combinations of these directions span the whole space, the fact that there can only be finitely many GPS refining directions limits rigorous justification of the barrier approach to finitely many linear constraints for GPS. The main result of this paper is that the general MADS framework is flexible enough to allow the generation of an asymptotically dense set of refining directions along which the Clarke derivatives are nonnegative.

We propose an instance of MADS for which the refining directions are dense in the hypertangent cone at $\hat{x}$ with probability 1 whenever the iterates associated with the refining directions converge to a single $\hat{x}$. The instance of MADS is compared to versions of GPS on some test problems. We also illustrate the limitation of our results with examples.

1. Introduction.

We present and analyze a new *mesh adaptive direct search* (MADS) class of algorithms for minimizing a nonsmooth function $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ under general constraints $x \in \Omega \neq \emptyset \subseteq \mathbb{R}^n$. For the form of the algorithm given here, the feasible region Ω may be defined through blackbox constraints given by an oracle, such as a computer code that returns a yes or no indicating whether or not a specified trial point is feasible.

In the unconstrained case, where $\Omega = \mathbb{R}^n$, this new class of algorithms occupies a position somewhere between the generalized pattern search (GPS) class [30], as organized in [8], and the Coope and Price frame-based methods [12]. A key advantage of MADS over GPS for both unconstrained and linearly constrained optimization is that local exploration of the space of variables is not restricted to a finite number of directions (called *poll directions*). This is the primary drawback of GPS algorithms in our opinion, and our main motivation in defining MADS was to overcome this

restriction. MADS algorithms are frame-based methods. We propose a less general choice of frames than the choices allowed by Coope and Price. Our MADS frames are easy to implement, and they are specifically aimed at ensuring an asymptotically dense set of polling directions. We illustrate our ideas with an example algorithm that we call LTMADS because it is based on a random lower triangular matrix.

The convergence analysis here is based on Clarke's calculus [10] for nonsmooth functions. The analysis evolved from our previous work on GPS [3] where we gave a hierarchy of convergence results for GPS that show the limitations inherent in the restriction to finitely many directions. Specifically, we showed that for unconstrained optimization, GPS produces a limit point at which the gradient is zero if the function at that point is strictly differentiable [20]. Strict differentiability is just the requirement that the generalized gradient is a singleton, i.e., that $\partial f(\hat{x}) = \{\nabla f(\hat{x})\}$ in addition to the requirement that f is Lipschitz near $\hat{x}$. But if the function f is only Lipschitz near such a limit point $\hat{x}$, then Clarke's generalized directional derivatives [10] are provably nonnegative only for a finite set of directions $\hat{D} \subset \mathbb{R}^n$ (called the set of *refining directions*) whose nonnegative linear combinations span the whole space

$$f^\circ(\hat{x}; d) := \limsup_{y \to \hat{x},\ t \downarrow 0} \frac{f(y + td) - f(y)}{t} \geq 0 \quad \text{for all } d \in \hat{D}. \tag{1.1}$$

This result (1.1) for GPS is not as strong as stating that the generalized derivative is nonnegative for every direction in $\mathbb{R}^n$, i.e., that the limit point is a Clarke stationary point, or equivalently that $0 \in \partial f(\hat{x})$, the generalized gradient of f at $\hat{x}$ defined by

$$f^\circ(\hat{x}; v) \geq 0 \ \text{ for all } v \in \mathbb{R}^n \Leftrightarrow 0 \in \partial f(\hat{x}) := \{s \in \mathbb{R}^n : f^\circ(\hat{x}; v) \geq v^T s \text{ for all } v \in \mathbb{R}^n\}. \tag{1.2}$$

Example F in [2] shows that indeed the GPS algorithm does not necessarily produce a Clarke stationary point for Lipschitz functions because of the restriction to finitely many poll directions. This is so even if the gradient exists at the limit point $\hat{x}$. For the unconstrained case, this restriction can be overcome by assuming more smoothness for f, e.g., strict differentiability at $\hat{x}$ [3] as mentioned above.

However, even in the presence of simple bound constraints, the directional dependence of GPS cannot be overcome by any amount of smoothness, by using penalty functions, or by the use of the filter approach for handling constraints [4]. In contrast, MADS produces a limit point at which the Clarke derivatives are nonnegative for every direction in the tangent cone. The class of problems that MADS is designed for is similar but not the same as that of Lucidi, Sciandrone, and Tseng [23] and Price, Coope, and Dennis [27]. They also target nonlinear optimization but require that all functions be continuously differentiable and that the constraint derivatives be available.

Besides the advantages of an asymptotically dense set of refining directions, MADS can also treat a wide class of nonlinear constraints by the "barrier" approach. By this we mean that the algorithm is not applied directly to f but to the barrier function f_Ω, defined to be equal to f on Ω and $+\infty$ outside Ω. This way of rejecting infeasible points was shown to be effective for GPS with finitely many linear constraints by Lewis and Torczon [21]. However, their proof requires that the tangent cone generators of the feasible region at boundary points near an iterate be known at each iteration.

For LTMADS, a specific implementation of the general framework MADS, no special effort is needed for the barrier approach to be provably effective with probability 1 on nonlinear constraints satisfying a mild constraint qualification due to Rockafellar

[29]—that there exists a hypertangent vector at the limit point. A key advantage of the barrier approach is that one can avoid expensive function calls to f whenever a constraint is violated. Indeed, the question of feasibility of a trial point needs only a yes or no answer—the constraints do not need to be given by a known algebraic condition. Marsden [24] exploited this capability in an insightful way to avoid a significant number of full 3D LES turbulence simulations when the nonlinear constraints were violated in MADS applied to a trailing edge design problem.

The class of algorithms presented here differs significantly from previous GPS extensions [4, 22] to nonlinear constraints. Treating constraints as we do motivates us to use the generalization of the Clarke derivative presented in Jahn [18]. Jahn's approach is aimed at a case like ours where the evaluation of f is restricted to points in the feasible domain Ω. Thus instead of (1.1) we use the following definition of the Clarke generalized derivative at $\hat{x} \in \Omega$ in the direction $v \in \mathbb{R}^n$:

$$f^\circ(\hat{x}; v) := \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{f(y + tv) - f(y)}{t}. \tag{1.3}$$

Both definitions (1.1) and (1.3) coincide when $\Omega = \mathbb{R}^n$ or when $\hat{x} \in int(\Omega)$.

The main theoretical objective of this paper is to show that under appropriate assumptions, a MADS algorithm produces a constrained Clarke stationary point, i.e., a limit point $\hat{x} \in \Omega$ satisfying the following necessary optimality condition:

$$f^\circ(\hat{x}; v) \ \geq \ 0 \text{ for all } v \in T_\Omega^{Cl}(\hat{x}), \tag{1.4}$$

where $T_\Omega^{Cl}(\hat{x})$ is the Clarke tangent cone to Ω at $\hat{x}$ (see [10] or Definition 3.5).

The paper is organized into two main parts. First, sections 2 and 3 present the abstract MADS algorithm class and its convergence analysis. The analysis revolves around three types of tangent cones. This allows us to tie some convergence results to local differentiability of the function f at limit points satisfying certain constraint qualifications. We present sufficient conditions under which (1.4) holds. We discuss the consequences of this when the algorithm is applied to an unconstrained problem, or when the set Ω is regular in the sense of Definition 3.7 or [10]. We also give a stronger constraint qualification ensuring that MADS produces a contingent KKT stationary point (Definition 3.11) if f is strictly differentiable. The reader will find a quite different algorithm analyzed using the same concepts in [15].

Then in sections 4 and 5, we give an instance of MADS along with numerical experiments to compare MADS with standard GPS. On an artificial example, where GPS is well known to stagnate, we show that MADS reaches the global optimum. We give a comparison on a parameter fitting problem in catalytic combustion kinetics on which we know that GPS performs well [17]. We also give an example illustrating the power of being able to handle even simple nonlinear constraints by the barrier approach. We also use this example to illustrate that MADS can cope surprisingly well as the dimension of the problem increases. The final example shows the value of randomly generated polling directions for a problem with a narrowing feasible region.

Notation. $\mathbb{R}, \mathbb{Z}$, and $\mathbb{N}$, respectively, denote the sets of real numbers, integers, and nonnegative integers. For $x \in \mathbb{R}^n$ and $\delta \in \mathbb{R}_+$, $B_\delta(x)$ denotes the open ball of radius δ centered at x. For a matrix D, the notation $d \in D$ indicates that d is a column of D. The iteration numbers are denoted by the index k.

2. Mesh adaptive direct search algorithms. MADS is an iterative feasible-point algorithm. Given an initial iterate $x_0 \in \Omega$, a MADS algorithm attempts to

locate a minimizer of the function f over Ω by evaluating f_Ω at some trial points. The algorithm does not require any derivative information for f. This is essential when ∇f is unavailable, either because it does not exist, or it cannot be accurately estimated due to noise in f or other reasons. At each iteration, a finite number of trial points are generated and the infeasible trial points are discarded. The objective function values at the feasible trial points are compared with the current incumbent value $f_\Omega(x_k)$, i.e., the best feasible objective function value found so far. Each of these trial points lies on the *current mesh*, constructed from a finite set of n_D directions $D \subset \mathbb{R}^n$ scaled by a *mesh size parameter* $\Delta_k^m \in \mathbb{R}_+$. Just as in GPS, this mesh is not actually constructed, it just underlies the algorithm.

There are two restrictions on the set D. First, D must be a positive spanning set [14], i.e., nonnegative linear combinations of its elements must span $\mathbb{R}^n$. Second, each direction $d_j \in D$ (for $j = 1, 2, \ldots, n_D$) must be the product Gz_j of some fixed nonsingular generating matrix $G \in \mathbb{R}^{n\times n}$ by an integer vector $z_j \in \mathbb{Z}^n$. For convenience, the set D is also viewed as a real $n \times n_D$ matrix.

DEFINITION 2.1. *At iteration k, the current mesh is defined to be the following union:*

$$M_k = \bigcup_{x\in S_k} \{x + \Delta_k^m Dz : z \in \mathbb{N}^{n_D}\},$$

where S_k is the set of points where the objective function f had been evaluated by the start of iteration k.

In the definition above, the mesh is defined to be the union of sets over S_k. Defining the mesh this way ensures that all previously visited points lie on the mesh, and that new trial points can be selected around any of them using the directions in D. This definition of the mesh is identical to the one in [4] and generalizes the one in [3].

The mesh is conceptual in the sense that it is never actually constructed. In practice, one can easily make sure that the strategy for generating trial points is such that they all belong to the mesh. One simply has to verify in Definition 2.1 that x belongs to S_k and that z is an integer vector. The objective of the iteration is to find a feasible trial mesh point with a lower objective function value than the current incumbent value $f_\Omega(x_k)$. Such a trial point is called an *improved mesh point*, and the iteration is called a *successful iteration*. There are no sufficient decrease requirements on the objective function value.

The evaluation of f_Ω at a trial point x is done as follows. First, the constraints defining Ω are tested to determine if x is feasible or not. Indeed, since some of the constraints defining Ω might be expensive or inconvenient to test, one would order the constraints to test the easiest ones first. If $x \notin \Omega$, then $f_\Omega(x)$ is set to $+\infty$ without evaluating $f(x)$, and perhaps without evaluating all the constraints defining Ω. In effect, this means we discard the infeasible trial points. On the other hand, if $x \in \Omega$, then $f(x)$ is evaluated. This remark may seem obvious, but it saves computation [24], and it is needed in the proof of Theorem 3.12.

Each iteration is divided into two steps. The first, called the SEARCH step, has the same flexibility as in GPS. It allows evaluation of f_Ω at any finite number of mesh points. Any strategy can be used in the SEARCH step to generate a finite number of trial mesh points. Restricting the SEARCH points to lie on the mesh is a way in which MADS is less general than the frame methods of Coope and Price [12]. The SEARCH is said to be empty when no trial points are considered. The drawback to the SEARCH flexibility is that it cannot be used in the convergence analysis—except to provide counterexamples as in [2]. More discussion of SEARCH steps is given in [1, 8].

When an improved mesh point is generated, then the iteration may stop, or it may continue if the user hopes to find a more improved mesh point. In either case, the next iteration will be initiated with a new incumbent solution $x_{k+1} \in \Omega$ with $f_\Omega(x_{k+1}) < f_\Omega(x_k)$ and with a mesh size parameter Δ^m_{k+1} equal to or larger than Δ^m_k (the exact rules for updating this parameter are presented in (2.1)). Coarsening the mesh when improvements in f_Ω are obtained can speed convergence.

Whenever the SEARCH step fails to generate an improved mesh point, then the second step, called the POLL, is invoked before terminating the iteration. The POLL step consists of a local exploration of the space of optimization variables near the current incumbent solution x_k. The difference between the MADS and the GPS algorithms lies exactly in this POLL step. For this reason, our numerical comparisons in what follows use empty, or very simple, SEARCH steps in order to illustrate the value of the MADS POLL step.

When the iteration fails in generating an improved mesh point, then the next iteration is initiated from any point $x_{k+1} \in S_{k+1}$ with $f_\Omega(x_{k+1}) = f_\Omega(x_k)$. There is usually a single such incumbent solution, and x_{k+1} is set to x_k. The mesh size parameter Δ^m_{k+1} is reduced to increase the mesh resolution in order to allow the evaluation of f at trial points closer to the incumbent solution. More precisely, given a fixed rational number $\tau > 1$, and two integers $w^- \le -1$ and $w^+ \ge 0$, the mesh size parameter is updated as follows:

$$\Delta^m_{k+1} = \tau^{w_k}\Delta^m_k \quad \text{for some } w_k \in \begin{cases} \{0, 1, \ldots, w^+\} & \text{if an improved mesh} \\ & \text{point is found} \\ \{w^-, w^- + 1, \ldots, -1\} & \text{otherwise.} \end{cases} \tag{2.1}$$

Everything up to this point in the section applies to both GPS and MADS. We now present the key difference between both classes of algorithms. For MADS, we introduce the *poll size parameter* $\Delta^p_k \in \mathbb{R}_+$ for iteration k. This new parameter dictates the magnitude of the distance from the trial points generated by the POLL step to the current incumbent solution x_k. In GPS, there is a single parameter to represent these quantities: $\Delta_k = \Delta^p_k = \Delta^m_k$. In MADS, the strategy for updating Δ^p_k must be such that $\Delta^m_k \le \Delta^p_k$ for all k, and moreover, it must satisfy

$$\lim_{k \in K} \Delta^m_k = 0 \text{ if and only if } \lim_{k \in K} \Delta^p_k = 0 \text{ for any infinite subset of indices } K. \tag{2.2}$$

An implementable updating strategy satisfying these requirements is presented in section 4.

We now move away from the GPS terminology, and toward that of Coope and Price because it is better suited to describe MADS. The set of trial points considered during the POLL step is called a *frame*. The frames of Coope and Price can be more general than MADS frames in a way not important to the present discussion. For this reason, we do not digress to discuss their general definition here [11].

The MADS frame is constructed using a current incumbent solution x_k (called the *frame center*) and the poll and mesh size parameters Δ^p_k and Δ^m_k to obtain a positive spanning set of directions D_k. Unlike GPS, generally the MADS set of directions D_k is not a subset of D.

DEFINITION 2.2. *At iteration k, the MADS frame is defined to be the set*

$$P_k = \{x_k + \Delta^m_k d : d \in D_k\} \subset M_k,$$

where D_k is a positive spanning set such that $0 \notin D_k$ and for each $d \in D_k$,

- *d can be written as a nonnegative integer combination of the directions in D: $d = Du$ for some vector $u \in \mathbb{N}^{n_{D_k}}$ that may depend on the iteration number k*
- *the distance from the frame center x_k to a frame point $x_k + \Delta_k^m d \in P_k$ is bounded above by a constant times the poll size parameter: $\Delta_k^m \|d\| \leq \Delta_k^p \max\{\|d'\| : d' \in D\}$*
- *limits (as defined in Coope and Price [11]) of the normalized sets $\mathcal{D}_k = \left\{\frac{d}{\|d\|} : d \in D_k\right\}$ are positive spanning sets.*

The set of all poll directions $\mathcal{D} = \bigcup_{k=1}^{\infty} \mathcal{D}_k$ is said to be asymptotically dense if the closure of the cone generated by $\mathcal{D}$ equals $\mathbb{R}^n$.

If the POLL step fails to generate an improved mesh point, then the frame is said to be a *minimal frame*, and the frame center x_k is said to be a *minimal frame center*. This leads to mesh refinement: $\Delta_{k+1} < \Delta_k$ (see (2.1)).

The algorithm is stated formally below. It is very similar to GPS, with differences in the POLL step, and in the new poll size parameter.

A GENERAL MADS ALGORITHM

- INITIALIZATION: Let $x_0 \in \Omega$, $\Delta_0^m \leq \Delta_0^p$, D, G, τ, w^- and w^+ satisfy the requirements given above.
  Set the iteration counter $k \leftarrow 0$.
- SEARCH AND POLL STEP: Perform the SEARCH and possibly the POLL steps (or only part of them) until an improved mesh point x_{k+1} is found on the mesh M_k (see Definition 2.1).
  - OPTIONAL SEARCH: Evaluate f_Ω on a finite subset of trial points on the mesh M_k.
  - LOCAL POLL: Evaluate f_Ω on the frame P_k (see Definition 2.2).
- PARAMETER UPDATE: Update Δ_{k+1}^m according to (2.1), and Δ_{k+1}^p so that (2.2) is satisfied.
  Set $k \leftarrow k + 1$ and go back to the SEARCH and POLL step.

The crucial distinction and advantage of MADS over GPS is that the MADS mesh size parameter Δ_k^m may go to zero more rapidly than Δ_k^p. Consequently, the directions in D_k used to define the frame may be selected in a way so that asymptotically they are not confined to a finite set. Note that in GPS both Δ_k^m and Δ_k^p are equal: a single parameter plays the role of the mesh and poll size parameters, and therefore, the number of positive spanning sets that can be formed by subsets of D is constant over all iterations.

For example, suppose that in $\mathbb{R}^2$ the set D is composed of the eight directions $\{(d_1, d_2)^T \neq (0, 0)^T : d_1, d_2 \in \{-1, 0, 1\}\}$. There are a total of eight distinct positive bases containing three directions that can be constructed from D. Figures 2.1 and 2.2 illustrate some possible frames in $\mathbb{R}^2$ for three values of Δ_k^m. The frames in Figure 2.1 are generated by a GPS instance, and are such that $\Delta_k^p = \Delta_k^m$. Regardless of k and of the mesh or poll size parameters, each direction in D_k is confined to be selected in D.

The frames in Figure 2.2 are generated by an instance of MADS with $\Delta_k^p = n\sqrt{\Delta_k^m}$. One can see that the new MADS algorithm may select the directions of D_k from a larger set. With the new algorithm, the frame may be chosen among the mesh points lying inside the square with the dark contour. We will present in section 4 an implementation of MADS ensuring that given any directions in $\mathbb{R}^n$, the

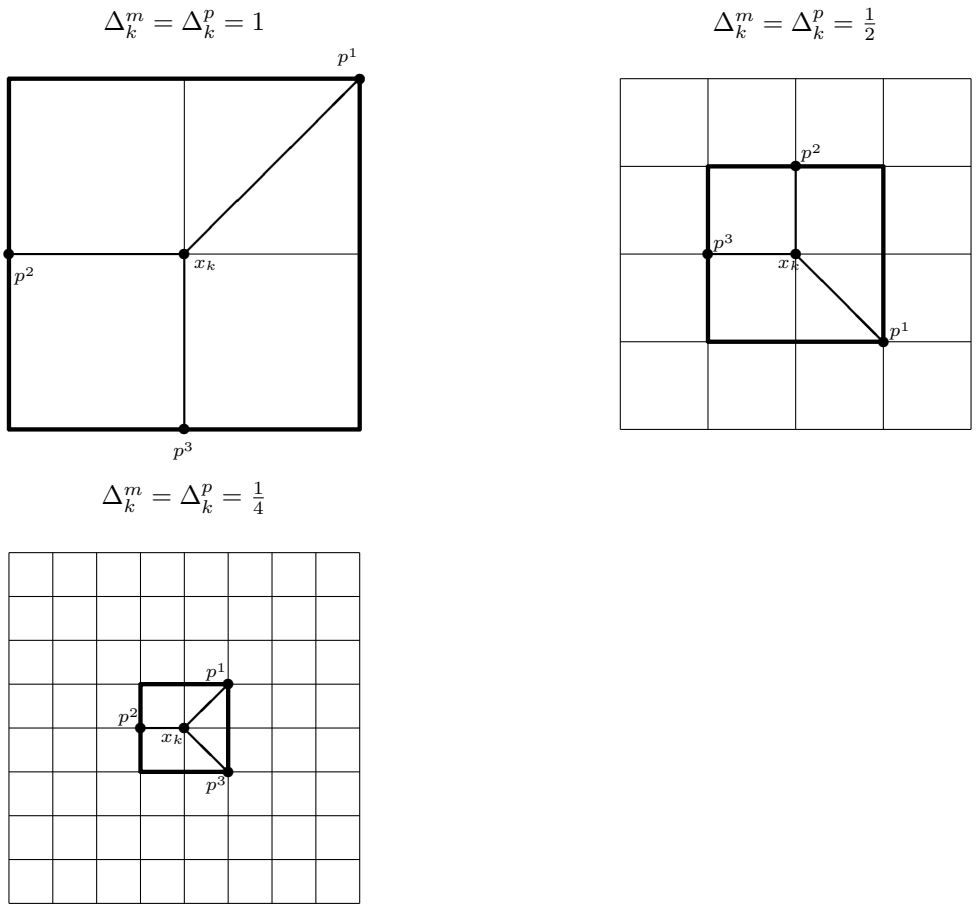

FIG. 2.1. *Example of GPS frames* $P_k = \{x_k + \Delta_k^m d : d \in D_k\} = \{p^1, p^2, p^3\}$ *for different values of* $\Delta_k^m = \Delta_k^p$. *In all three figures, the mesh* M_k *is the intersection of all lines.*

algorithm generates arbitrarily close poll directions, i.e., that the set of poll directions is asymptotically dense in $\mathbb{R}^n$.

We have presented above a general framework for MADS algorithms. The next section contains a detailed convergence analysis for that general framework. It presents sufficient conditions to ensure a hierarchy of convergence results based on the local differentiability of f (using the Clarke nonsmooth calculus) and on the local properties of Ω (using three types of tangent cones). The results rely on the assumption that a specific set of directions (called the refining directions—see Definition 3.2) be dense in a tangent cone. Then, in section 4 we propose a specific implementation called LTMADS, and give sufficient conditions to satisfy this assumption.

3. MADS convergence analysis. The convergence analysis below relies on the assumptions that $x_0 \in \Omega$, that $f(x_0)$ is finite, and that all iterates $\{x_k\}$ produced by the MADS algorithm lie in a compact set. Future work will relax the first assumption by incorporating the filter approach given in [4].

The section is divided into three subsections. The first recalls Torczon's [30] analysis of the behavior of the mesh size parameter and defines refining sequences as

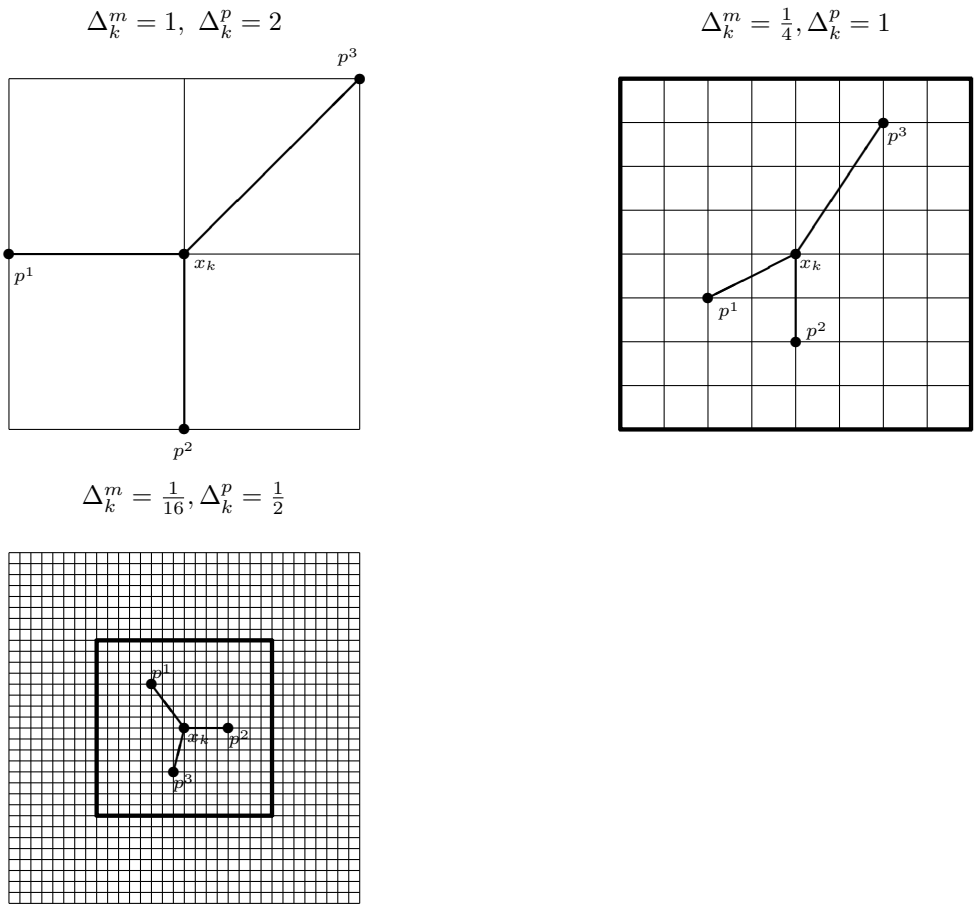

FIG. 2.2. *Example of MADS frames* $P_k = \{x_k + \Delta_k^m d : d \in D_k\} = \{p^1, p^2, p^3\}$ *for different values of* Δ_k^m *and* Δ_k^p. *In all three figures, the mesh* M_k *is the intersection of all lines.*

in [3]. It also defines the idea of a refining subsequence and a refining direction. The second subsection recalls the definitions of the hypertangent, Clarke, and contingent cones in addition to some results on generalized derivatives. The third contains a hierarchy of convergence results based on local properties of the feasible region Ω.

3.1. Preliminaries. Torczon [30] first showed the following result for unconstrained pattern search algorithms. Then Audet and Dennis [3] used the same technique for a description of GPS that is much closer to our description of MADS. The proof of this result for MADS is identical to that of GPS. The element necessary to the proof is that for any integer $N \geq 1$, the iterate x_N may be written as $x_N = x_0 + \sum_{k=0}^{N-1} \Delta_k^m D z_k$ for some vectors $z_k \in \mathbb{N}^{n_D}$. This is still true with our new way of defining the mesh and the frame (see Definitions 2.1 and 2.2).

PROPOSITION 3.1. *The poll and mesh size parameters produced by a MADS instance satisfy*

$$\liminf_{k \to +\infty} \Delta_k^p \ = \ \liminf_{k \to +\infty} \Delta_k^m \ = \ 0.$$

Price and Coope [26] propose a frame-based method for linearly constrained problems in which trial points are not confined to be on an underlying mesh. The price of this greater flexibility is that their convergence analysis is based upon the assumption that the frame size parameter (which plays a role similar to the MADS poll size parameter) goes to zero.

Since the mesh size parameter shrinks only at minimal frames, Proposition 3.1 guarantees that there are infinitely many minimal frame centers. The following definition specifies the subsequences of iterates and limit directions we use.

DEFINITION 3.2. *A subsequence of the MADS iterates consisting of minimal frame centers, $\{x_k\}_{k\in K}$ for some subset of indices K, is said to be a* refining subsequence *if $\{\Delta_k^p\}_{k\in K}$ converges to zero.*

Let $\hat{x}$ be the limit of a convergent refining subsequence. If the limit $\lim_{k\in L} \frac{d_k}{\|d_k\|}$ exists for some subset $L \subseteq K$ with poll direction $d_k \in D_k$, and if $x_k + \Delta_k^m d_k \in \Omega$ for infinitely many $k \in L$, then this limit is said to be a refining direction for $\hat{x}$.

It is shown in [3], that there exists at least one convergent refining subsequence. We now present some definitions that will be used later to guarantee the existence of refining directions.

3.2. Three types of tangent cones. Three different types of tangent cones play a central role in our analysis. Their definition, and equivalent ones, may be found in [29, 10, 18]. After presenting them, we supply an example where the three cones differ to illustrate some of our results. The first cone that we present is the hypertangent cone.

DEFINITION 3.3 (Hypertangent cone). *A vector $v \in \mathbb{R}^n$ is said to be a hypertangent vector to the set $\Omega \subseteq \mathbb{R}^n$ at the point $x \in \Omega$ if there exists a scalar $\epsilon > 0$ such that*

$$y + tw \in \Omega \qquad \text{for all } y \in \Omega \cap B_\epsilon(x), \quad w \in B_\epsilon(v) \quad \text{and} \quad 0 < t < \epsilon. \tag{3.1}$$

The set of hypertangent vectors to Ω at x is called the hypertangent cone to Ω at x *and is denoted by $T_\Omega^H(x)$.*

The hypertangent cone is a useful concept for understanding the behavior of the MADS algorithm. When analyzing MADS, we will be concerned with the following specific subsequences:

- minimal frame centers $x_k \to \hat{x}$;
- mesh size parameters $\Delta_k^m \searrow 0$ and step sizes $\Delta_k^m \|d_k\| \searrow 0$;
- normalized refining directions $\frac{d_k}{\|d_k\|} \to v \neq 0$.

These subsequences will be chosen in a way so that $x_k \in \Omega$ and $x_k + (\Delta_k^m \|d_k\|)\frac{d_k}{\|d_k\|} \in \Omega$. The connection with the hypertangent definition is obvious by noticing that the roles of y, t, and w are played by $x_k, \Delta_k^m\|d_k\|$, and $\frac{d_k}{\|d_k\|}$, respectively. The connection with the Clarke derivative (1.3) will be made explicit in Theorem 3.12.

Since the definition of a hypertangent is rather technical and crucial to our results, we will pause for a short discussion. The reader could easily show that if Ω is a full dimensional polytope defined by linear constraints, then every direction from a point $\hat{x} \in \Omega$ into the interior of Ω is a hypertangent. That follows immediately from the following result relating hypertangents to the constraint qualification suggested by Gould and Tolle [16]; see also [6] for a discussion of the Gould and Tolle constraint qualification and the closely related one of Mangasarian and Fromovitz.

THEOREM 3.4. *Let $C : \mathbb{R}^n \to \mathbb{R}^m$ be continuously differentiable at a point $\hat{x} \in \Omega = \{x \in \mathbb{R}^n \ : \ C(x) \leq 0\}$, and let $\mathcal{A}(\hat{x}) = \{i \in \{1, 2, \ldots, m\} : c_i(\hat{x}) = 0\}$ be the*

active set at $\hat{x}$. If $v \in \mathbb{R}^n$ is a hypertangent vector to Ω at $\hat{x}$, then $\nabla c_i(\hat{x})^T v < 0$ for each $i \in \mathcal{A}(\hat{x})$ such that $\nabla c_i(\hat{x}) \neq 0$. Furthermore, if $\nabla c_i(\hat{x})^T v < 0$ for each $i \in \mathcal{A}(\hat{x})$, then $v \in \mathbb{R}^n$ is a hypertangent vector to Ω at $\hat{x}$.

Proof. Let v be a hypertangent vector to Ω at $\hat{x}$. Then, there exists an $\epsilon > 0$ such that $\hat{x} + tv \in \Omega$ for any $0 < t < \epsilon$. Let $i \in \mathcal{A}(\hat{x})$. Continuous differentiability of c_i at $\hat{x}$ implies that

$$\nabla c_i(\hat{x})^T v = \lim_{t \to 0} \frac{c_i(\hat{x} + tv) - c_i(\hat{x})}{t} \leq 0.$$

It only remains to show that $\nabla c_i(\hat{x})^T v \neq 0$ when $\nabla c_i(\hat{x}) \neq 0$. Suppose by way of contradiction that $\nabla c_i(\hat{x})^T v = 0$ and $\nabla c_i(\hat{x}) \neq 0$. Since the hypertangent cone is an open set [29], for any nonnegative $\delta \in \mathbb{R}$ sufficiently small, $v + \delta \nabla c_i(\hat{x})$ is a hypertangent vector to Ω at $\hat{x}$. It follows that

$$0 \ \geq \ \nabla c_i(\hat{x})^T (v + \delta \nabla c_i(\hat{x})) \ = \ \delta \|\nabla c_i(\hat{x})\|_2^2 \ > \ 0,$$

which is a contradiction. Thus, $\nabla c_i(\hat{x})^T v < 0$ when $\nabla c_i(\hat{x}) \neq 0$.

To prove the converse, let $i \in \mathcal{A}(\hat{x})$ be such that $\nabla c_i(\hat{x}) \neq 0$ and $v \in \mathbb{R}^n$ be such that $\|v\| = 1$ and $\nabla c_i(\hat{x})^T v < 0$. The product $\nabla c_i(y)^T w$ is a continuous function at $(y;\ w) = (\hat{x};\ v)$, and so there is some $\epsilon_1 > 0$ such that

$$\nabla c_i(y)^T w < 0 \ \text{ for all } \ y \in B_{\epsilon_1}(\hat{x}) \text{ and } w \in B_{\epsilon_1}(v). \tag{3.2}$$

Take $\epsilon = \min\{1, \frac{\epsilon_1}{3}\}$ and let y, w be in $B_\epsilon(\hat{x})$ and $B_\epsilon(v)$, respectively, with $y \in \Omega$, and let $0 < t < \epsilon$. We will show that $y + tw \in \Omega$. Our construction ensures that $c_i(y) \leq 0$ and $\epsilon < \epsilon_1$, and so by the mean value theorem, we have

$$c_i(y + tw) \leq c_i(y + tw) - c_i(y) = \nabla c_i(y + \theta tw)^T (tw) \ \text{ for some } \theta \in [0, 1]. \tag{3.3}$$

But, $\|y + \theta tw - \hat{x}\| \leq \|y - \hat{x}\| + \theta t(\|w - v\| + \|v\|) < \epsilon + \epsilon(\epsilon + 1) \leq 3\epsilon \leq \epsilon_1$, thus $y + \theta tw \in B_{\epsilon_1}(\hat{x})$, and $w \in B_\epsilon(v) \subseteq B_{\epsilon_1}(v)$. It follows that (3.2) applies and therefore $\nabla c_i(y + \theta tw)^T w < 0$. This is combined with (3.3) and with the fact that $t > 0$ implies that $c_i(y + tw) \leq 0$. But c_i was any active component function, and so $C(y + tw) \leq 0$ and thus $y + tw \in \Omega$. ∎

We would like to culminate our hierarchy of convergence results by providing necessary conditions to ensure contingent stationarity. In order to do so, we present two other types of tangent cones.

DEFINITION 3.5 (Clarke tangent cone). *A vector $v \in \mathbb{R}^n$ is said to be a Clarke tangent vector to the set $\Omega \subseteq \mathbb{R}^n$ at the point x in the closure of Ω if for every sequence $\{y_k\}$ of elements of Ω that converges to x and for every sequence of positive real numbers $\{t_k\}$ converging to zero, there exists a sequence of vectors $\{w_k\}$ converging to v such that $y_k + t_k w_k \in \Omega$. The set $T_\Omega^{Cl}(x)$ of all Clarke tangent vectors to Ω at x is called the Clarke tangent cone to Ω at x.*

DEFINITION 3.6 (Contingent cone). *A vector $v \in \mathbb{R}^n$ is said to be a tangent vector to the set $\Omega \subseteq \mathbb{R}^n$ at the point x in the closure of Ω if there exists a sequence $\{y_k\}$ of elements of Ω that converges to x and a sequence of positive real numbers $\{\lambda_k\}$ for which $v = \lim_k \lambda_k(y_k - x)$. The set $T_\Omega^{Co}(x)$ of all tangent vectors to Ω at x is called the contingent cone (or sequential Bouligand tangent cone) to Ω at x.*

DEFINITION 3.7. *The set Ω is said to be regular at x provided $T_\Omega^{Cl}(x) = T_\Omega^{Co}(x)$.*

Any convex set is regular at each of its points [10]. Both $T_\Omega^{Co}(x)$ and $T_\Omega^{Cl}(x)$ are closed cones, and both $T_\Omega^{Cl}(x)$ and $T_\Omega^{H}(x)$ are convex cones. Moreover, $T_\Omega^{H}(x) \subseteq T_\Omega^{Cl}(x) \subseteq T_\Omega^{Co}(x)$. Rockafellar [29] showed that $T_\Omega^{H}(x) = int(T_\Omega^{Cl}(x))$ whenever $T_\Omega^{H}(x)$ is nonempty. Moreover, since the closure of the interior of a closed convex set is the set itself [28], it follows that $T_\Omega^{Cl}(x) = \mathrm{cl}(T_\Omega^{H}(x))$ whenever $T_\Omega^{H}(x)$ is nonempty.

3.3. Generalized derivatives. Recall that we are using Jahn's definition (1.3) of the Clarke derivative instead of (1.1), and therefore we cannot directly use the calculus theory developed in [10]. The next lemma and proposition extend previously known calculus results in the unconstrained case.

LEMMA 3.8. *Let f be Lipschitz near $\hat{x} \in \Omega$ with Lipschitz constant λ. If u and v belong to $T_\Omega^{H}(\hat{x})$, then*

$$f^\circ(\hat{x}; u) \geq f^\circ(\hat{x}; v) - \lambda\|u - v\|.$$

Proof. Let f be Lipschitz near $\hat{x} \in \Omega$ with Lipschitz constant λ and let u and v belong to $T_\Omega^{H}(\hat{x})$. Let $\epsilon > 0$ be such that $y + tw \in \Omega$ whenever $y \in \Omega \cap B_\epsilon(\hat{x})$, $w \in B_\epsilon(u) \cup B_\epsilon(v)$ and $0 < t < \epsilon$. This can be done by taking ϵ to be the smaller of the values for u and v guaranteed by the definition of a hypertangent. In particular, if $y \in \Omega \cap B_\epsilon(\hat{x})$ and if $0 < t < \epsilon$, then both $y + tu$ and $y + tv$ belong to Ω. This allows us to go from the first to the second equality of the following chain:

$$\begin{aligned}
f^\circ(\hat{x}; u) &= \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y + tu \in \Omega}} \frac{f(y+tu) - f(y)}{t} \\
&= \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{f(y+tu) - f(y)}{t} \\
&= \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{f(y+tv) - f(y)}{t} + \frac{f(y+tu) - f(y+tv)}{t} \\
&= f^\circ(\hat{x}; v) + \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{f(y+tu) - f(y+tv)}{t} \geq f^\circ(\hat{x}; v) - \lambda\|u - v\|. \qquad \square
\end{aligned}$$

Based on the previous lemma, the next proposition shows that the Clarke generalized derivative is continuous with respect to v on the Clarke tangent cone. The result is necessary to the proofs of Theorems 3.12 and 3.13.

PROPOSITION 3.9. *Let f be Lipschitz near $\hat{x} \in \Omega$. If $T_\Omega^{H}(\hat{x}) \neq \emptyset$ and if $v \in T_\Omega^{Cl}(\hat{x})$ then*

$$f^\circ(\hat{x}; v) = \lim_{\substack{w \to v, \\ w \in T_\Omega^{H}(\hat{x})}} f^\circ(\hat{x}; w).$$

Proof. Let λ be a Lipschitz constant for f near $\hat{x} \in \Omega$ and let $\{w_k\} \subset T_\Omega^{H}(\hat{x})$ be a sequence of directions converging to a vector $v \in T_\Omega^{Cl}(\hat{x})$. By definition of the hypertangent cone, let $0 < \epsilon_k < \frac{1}{k}$ be such that

$$y + tw \in \Omega \text{ whenever } y \in \Omega \cap B_{\epsilon_k}(\hat{x}), w \in B_{\epsilon_k}(w_k) \text{ and } 0 < t < \epsilon_k. \tag{3.4}$$

We first show the inequality $f^\circ(\hat{x}; v) \leq \lim_k f^\circ(\hat{x}; w_k)$. Equation (3.4) implies that

$$
\begin{aligned}
f^\circ(\hat{x};v) = & \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y+tv \in \Omega}} \frac{f(y+tv)-f(y)}{t} \\
= & \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y+tv \in \Omega \\ y+tw_k \in \Omega}} \frac{f(y+tv)-f(y)}{t} \\
\leq & \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y+tw_k \in \Omega}} \frac{f(y+tw_k)-f(y)}{t} - \frac{f(y+tw_k)-f(y+tv)}{t} \\
= & \ f^\circ(\hat{x};w_k) \ + \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y+tw_k \in \Omega}} \frac{f(y+tw_k)-f(y+tv)}{t}.
\end{aligned}
$$

As k goes to infinity, $\left|\frac{f(y+tw_k)-f(y+tv)}{t}\right| \leq \lambda\|w_k - v\|$ goes to zero. Since $\{w_k\}$ was arbitrary in the hypertangent cone, it follows that

$$
f^\circ(\hat{x};v) \leq \lim_{\substack{w \to v, \\ w \in T_\Omega^H(\hat{x})}} f^\circ(\hat{x};w).
$$

Second, we show the reverse inequality: $f^\circ(\hat{x};v) \geq \lim_k f^\circ(\hat{x};w_k)$. Let us define $u_k = \frac{1}{k}w_k + (1-\frac{1}{k})v = w_k + (1-\frac{1}{k})(v-w_k)$. Since the hypertangent cone is a convex set, and since v lies in the closure of the hypertangent cone, it then follows that $u_k \in T_\Omega^H(\hat{x})$ for every $k = 1, 2, \ldots$

We now consider the generalized directional derivative

$$
f^\circ(\hat{x};u_k) = \limsup_{\substack{y \to \hat{x},\ y \in \Omega \\ t \downarrow 0,\ y+tu_k \in \Omega}} \frac{f(y+tu_k)-f(y)}{t}.
$$

The fact that $u_k \in T_\Omega^H(\hat{x})$ implies that there exists $y_k \in \Omega \cap B_{\epsilon_k}(\hat{x})$ and $0 < \frac{t_k}{k} < \epsilon_k$ such that $y_k + t_k u_k \in \Omega$ and

$$
\frac{f(y_k + t_k u_k) - f(y_k)}{t_k} \geq f^\circ(\hat{x};u_k) - \epsilon_k, \tag{3.5}
$$

where ϵ_k is the constant from (3.4). We now define the sequence $z_k = y_k + \frac{t_k}{k}w_k \in \Omega$ converging to $\hat{x}$, and the sequence of scalars $h_k = (1-\frac{1}{k})t_k > 0$ converging to zero. Notice that

$$
z_k + h_k v = y_k + t_k\left(\frac{1}{k}w_k + \left(1-\frac{1}{k}\right)v\right) = y_k + t_k u_k \ \in \ \Omega,
$$

and therefore

$$
\begin{aligned}
f^\circ(\hat{x};v) = & \limsup_{\substack{z \to \hat{x},\ z \in \Omega \\ h \downarrow 0,\ z+hv \in \Omega}} \frac{f(z+hv)-f(z)}{t} \\
& \geq \lim_k \frac{f(z_k+h_k v)-f(z_k)}{h_k} \\
& = \lim_k \frac{f(y_k+t_k u_k)-f(y_k)}{(1-\frac{1}{k})t_k} + \frac{f(y_k)-f(y_k+\frac{t_k}{k}w_k)}{(1-\frac{1}{k})t_k} \\
\text{by (3.5):} \quad & \geq \lim_k f^\circ(\hat{x};u_k) - \epsilon_k + \frac{f(y_k)-f(y_k+\frac{t_k}{k}w_k)}{(1-\frac{1}{k})t_k} \\
\text{by Lemma 3.8:} \quad & \geq \lim_k f^\circ(\hat{x};w_k) - \lambda\|u_k - w_k\| - \epsilon_k - \frac{\frac{\lambda}{k}\|w_k\|}{(1-\frac{1}{k})} \\
& = \lim_k f^\circ(\hat{x};w_k) - \lambda\|v - w_k\| - \tfrac{\lambda}{k}\|v\| \ = \ \lim_k f^\circ(\hat{x};w_k). \qquad \square
\end{aligned}
$$

Unfortunately, the above proposition is not necessarily true when the hypertangent cone is empty: $f^\circ(\hat{x};v)$ may differ from $\lim_{w\to v} f^\circ(\hat{x};w)$. The above proof breaks as we cannot show in (3.4) that $y+tw_k$ belongs to Ω when $y\in\Omega$ is close to $\hat{x}$ and when $t>0$ is small. The following example in $\mathbb{R}^2$ illustrates that in this case, the Clarke generalized derivative is not necessarily upper semicontinuous on the contingent cone.

Example 3.10. Consider a feasible region $\Omega\subset\mathbb{R}^2$ that is the union of

$$\Omega_1=\{(a,b)^T : a\geq 0,\ b\geq 0\} \ \text{ with } \ \Omega_2=\{(-a,b)^T : b=-a^2,\ a\geq 0\}.$$

One can verify that at the origin

$$T_\Omega^H(0)=\emptyset,\ \ T_\Omega^{Cl}(0)=\{(a,0)^T : a\geq 0\}\subset\Omega_1 \ \text{ and } \ T_\Omega^{Co}(0)=\Omega_1\cup\{(-a,0)^T : a\geq 0\},$$

and therefore Ω is not regular at the origin.

Consider the continuous concave function in $\mathbb{R}^2$: $f(a,b)=-\max\{0,a\}$. Notice that $f(a,b)=0$ for $(a,b)^T\in\Omega_2$, and $f(a,b)=-a\leq 0$ on Ω_1. We will show that $f^\circ(0;w)$ is nonnegative for w in the interior of the contingent cone but $f^\circ(0;e_1)=-1$ with $e_1=(1,0)^T$ in the Clarke tangent cone.

Let $w=(w_1,w_2)^T$ be any direction in $int(T_\Omega^{Co}(0))=int(\Omega_1)$. We will construct appropriate subsequences in order to compute a valid lower bound on $f^\circ(0;w)$. For every positive integer k, define

$$y_k=\left(\frac{-w_1}{k},\ \frac{-w_1^2}{k^2}\right)^T \ \text{ and } \ t_k=\frac{1}{k}.$$

One can easily check that $y_k\in\Omega_2\subset\Omega$, and hence $f(y_k)=0$ for every k. Also, for every $k>\frac{w_1^2}{w_2}$, we have $y_k+t_kw=\left(0,\ \frac{1}{k^2}(kw_2-w_1^2)\right)^T\in\Omega_1\subset\Omega$ is on the nonnegative b axis. It follows that $f(y_k+t_kw)=0$ for every such k, and so

$$f^\circ(0;w)\geq\lim_{k\to\infty}\tfrac{f(y_k+t_kw)-f(y_k)}{t_k} \ = \ \lim_{k\to\infty} k\cdot(0-0) \ = \ 0.$$

In particular, taking $w=(1,\epsilon)$, we have that $f^\circ(0;(1,\epsilon)^T)$ is nonnegative for any $\epsilon>0$.

However, let us compute the Clarke generalized directional derivative $f^\circ(0;e_1)$ at the origin in the direction $e_1=(1,0)^T\in T_\Omega^{Cl}(0)$. The origin cannot be approached by points $y_k=(a_k,b_k)^T\in\Omega$ with the properties that $b_k<0$, and $y_k+t_ke_1\in\Omega$ with $t_k>0$. This is easy to see from a picture because y_k would have to be in Ω_2, and then $y_k+t_ke_1$ cannot possibly be in Ω. A necessary condition for both sequences to be in Ω is that y_k belongs to Ω_1, where $f(a,b)=-a$. But then every difference quotient in the definition of $f^\circ(0;e_1)$ is -1, and therefore $f^\circ(0;e_1)=-1$.

This example shows that when the hypertangent cone at $\hat{x}$ is empty, the Clarke tangent cone is not. It is possible that $f^\circ(\hat{x};w)$ is nonnegative for every w in the interior of the contingent cone and drops discontinuously to a negative value on the boundary of the contingent cone: $f^\circ(\hat{x};e_1)<\limsup_{w\to e_1} f^\circ(\hat{x};w)$.

3.4. A hierarchy of convergence results for MADS. We now present different necessary optimality conditions based on the tangent cone definitions.

DEFINITION 3.11. *Let f be Lipschitz near $\hat{x}\in\Omega$. Then, $\hat{x}$ is said to be a Clarke or contingent stationary point of f over Ω, if $f^\circ(\hat{x};v)\geq 0$ for every direction v in the Clarke or contingent cone of Ω at $\hat{x}$, respectively.*

In addition, $\hat{x}$ is said to be a Clarke or contingent KKT stationary point of f over Ω, if $-\nabla f(\hat{x})$ exists and belongs to the polar of the Clarke or contingent cone of Ω at $\hat{x}$, respectively.

This leads to our basic result on refining directions from which all our hierarchy of results are derived. The proof of these results also illustrates the close connection between the MADS framework, the Clarke calculus, and the definition of a hypertangent vector.

THEOREM 3.12. *Let f be Lipschitz near a limit $\hat{x} \in \Omega$ of a refining subsequence, and let $v \in T_\Omega^H(\hat{x})$ be a refining direction for $\hat{x}$. Then the generalized directional derivative of f at $\hat{x}$ in the direction v is nonnegative,* i.e., *$f^\circ(\hat{x}; v) \geq 0$.*

Proof. Let $\{x_k\}_{k \in K}$ be a refining subsequence converging to $\hat{x}$ and $v = \lim_{k \in L} \frac{d_k}{\|d_k\|} \in T_\Omega^H(\hat{x})$ be a refining direction for $\hat{x}$, with $d_k \in D_k$ for every $k \in L$. Since f is Lipschitz near $\hat{x}$, Proposition 3.9 ensures that $f^\circ(\hat{x}; v) = \lim_{k \in L} f^\circ(\hat{x}; \frac{d_k}{\|d_k\|})$. But, for any $k \in L$, one can apply the definition of the Clarke generalized derivative with the roles of y and t played by x_k and $\Delta_k^m \|d_k\|$, respectively. Note that this last quantity indeed converges to zero since Definition 2.2 ensures that it is bounded above by $\Delta_k^p \max\{\|d'\| : d' \in D\}$, where D is a finite set of directions, and (2.2) states that Δ_k^p goes to zero. Therefore

$$\begin{aligned} f^\circ(\hat{x}; v) &\geq \limsup_{k \in L} \frac{f(x_k + \Delta_k^m \|d_k\| \frac{d_k}{\|d_k\|}) - f(x_k)}{\Delta_k^m \|d_k\|} \\ &= \limsup_{k \in L} \frac{f(x_k + \Delta_k^m d_k) - f(x_k)}{\Delta_k^m \|d_k\|} \;\geq\; 0. \end{aligned}$$

The last inequality follows from the fact that for each sufficiently large $k \in L$, $x_k + \Delta_k^m d_k \in \Omega$ and $f(x_k + \Delta_k^m d_k) = f_\Omega(x_k + \Delta_k^m d_k)$ was evaluated and compared by the algorithm to $f(x_k)$, but x_k is a minimal frame center, so the inequality holds. ∎

We now show that Clarke directional derivatives of f at the limit $\hat{x}$ of minimal frame centers, for meshes that get infinitely fine, are nonnegative for all directions in the hypertangent cone, i.e., we show that MADS generates a Clarke stationary point.

THEOREM 3.13. *Let f be Lipschitz near a limit $\hat{x} \in \Omega$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$. If the set of refining directions for $\hat{x}$ is dense in $T_\Omega^H(\hat{x})$, then $\hat{x}$ is a Clarke stationary point of f on Ω.*

Proof. The proof follows directly from Theorem 3.12 and Proposition 3.9. ∎

Note that even though the algorithm is applied to f_Ω instead of f, the convergence results are linked to the local smoothness of f and not f_Ω, which is obviously discontinuous on the boundary of Ω. This is because we use (1.3) as the definition of the Clarke generalized derivative instead of (1.1). The constraint qualification used in these results is that the hypertangent cone is nonempty at the feasible limit point $\hat{x}$. Further discussion of nonempty hypertangent cones is found in Rockafellar [29].

A corollary to this last theorem is that if f is strictly differentiable at $\hat{x}$, then it is a Clarke KKT point.

COROLLARY 3.14. *Let f be strictly differentiable at a limit $\hat{x} \in \Omega$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$. If the set of refining directions for $\hat{x}$ is dense in $T_\Omega^H(\hat{x})$, then $\hat{x}$ is a Clarke KKT stationary point of f over Ω.*

Proof. Strict differentiability ensures that the gradient $\nabla f(\hat{x})$ exists and that $\nabla f(\hat{x})^T v = f^\circ(\hat{x}; v)$ for all directions. It follows directly from the previous proposition that $-\nabla f(\hat{x})^T v \leq 0$ for every direction v in $T_\Omega^{Cl}(\hat{x})$, thus $\hat{x}$ is a Clarke KKT stationary point. ∎

Our next two results are based on the definition of set regularity (see Definition 3.7).

PROPOSITION 3.15. *Let f be Lipschitz near a limit $\hat{x} \in \Omega$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$. If the set of refining directions for $\hat{x}$ is dense in $T_\Omega^H(\hat{x})$, and if Ω is regular at $\hat{x}$, then $\hat{x}$ is a contingent stationary point of f over Ω.*

Proof. The definition of regularity of the set Ω ensures that $f^\circ(\hat{x}; w) \geq 0$ for all w in $T_\Omega^{Co}(\hat{x})$. ∎

The following result is the counterpart to Corollary 3.14 for contingent stationarity. The proof is omitted since it is essentially the same.

COROLLARY 3.16. *Let f be strictly differentiable at a limit $\hat{x} \in \Omega$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$. If the set of refining directions for $\hat{x}$ is dense in $T_\Omega^H(\hat{x})$, and if Ω is regular at $\hat{x}$, then $\hat{x}$ is a contingent KKT stationary point of f over Ω.*

Example F in [2] presents an instance of a GPS algorithm such that when applied to a given unconstrained optimization problem, it generates a single limit point $\hat{x}$ which is not a Clarke stationary point. In fact, it is shown that f is differentiable but not strictly differentiable at $\hat{x}$ and $\nabla f(\hat{x})$ is nonzero. This unfortunate circumstance is due to the fact that GPS uses a finite number of poll directions while MADS can use infinitely many.

The following result shows that the algorithm ensures strong optimality conditions for unconstrained optimization, or when $\hat{x}$ is in the interior of Ω.

THEOREM 3.17. *Let f be Lipschitz near a limit $\hat{x}$ of a refining subsequence. If $\Omega = \mathbb{R}^n$, or if $\hat{x} \in int(\Omega)$, and if the set of refining directions for $\hat{x}$ is dense in $\mathbb{R}^n$, then $0 \in \partial f(\hat{x})$.*

Proof. Let $\hat{x}$ be as in the statement of the result, then $T_\Omega^H(\hat{x}) = \mathbb{R}^n$. Combining Definition 3.11 and Theorem 3.13 with (1.2) yields the result. ∎

Newton's method uses second derivatives, and the standard analysis of Newton's method assumes Lipschitz continuity of the second derivatives. Correspondingly, MADS is an algorithm that uses only function values, and we assume only that the function f is Lipschitz near $\hat{x}$.

In the general statement of the algorithm we did not present a strategy that would guarantee a dense set of refining directions in the hypertangent cone. We want to keep the algorithm framework as general as possible. There are different strategies that could be used to generate a dense set of poll directions. The selection of the set D_k could be done in a deterministic way or may use some randomness. In the remainder of the paper, we present, analyze, and test one MADS strategy that uses some randomness. We do this because we have not found a deterministic strategy that achieves a satisfying distribution of poll directions when the process is terminated after a reasonable number of iterations.

4. Practical implementation—LTMADS.

We now present two variants of a stochastic implementation of the MADS algorithm. We call either variant LTMADS, because of the underlying lower triangular basis construction, and we show that with probability 1, the set of poll directions generated by the algorithm is dense in the whole space, and in particular in the hypertangent cone.

4.1. Implementable instances of a MADS algorithm.

Let $G = I$, the identity matrix, and let $D = [I \ -I], \tau = 4, w^- = -1$ and $w^+ = 1$ be the fixed algorithmic parameters. Choose $\Delta_0^m = 1, \Delta_0^p = 1$ to be the initial mesh and poll size

parameters, and define the update rules as follows:

$$\Delta_{k+1}^m = \begin{cases} \frac{\Delta_k^m}{4} & \text{if } x_k \text{ is a minimal frame center} \\ 4\Delta_k^m & \text{if an improved mesh point is found, and if } \Delta_k^m \leq \frac{1}{4} \\ \Delta_k^m & \text{otherwise.} \end{cases}$$

A consequence of these rules is that the mesh size parameter is always a power of 4 and never exceeds 1. Thus, $\frac{1}{\sqrt{\Delta_k^m}} \geq 1$ is always a nonnegative power of 2 and hence integral.

We now present a strategy to randomly generate the poll directions. In what follows, every random generation is done uniformly with equal probabilities. In order to ensure that the set of refining directions is dense in the hypertangent cone, one of these directions must be selected in a different way. This direction must depend only on the value of the mesh size parameter, and not on the iteration number. The direction is denoted by $b(\ell)$ where ℓ is an integer related to the mesh size parameter. An additional counter, called ℓ_c, is initially set to zero and is used to keep track of the values of ℓ for which $b(\ell)$ was created. The construction of $b(\ell)$ is as follows.

GENERATION OF THE DIRECTION $b(\ell)$ FOR A GIVEN NONNEGATIVE INTEGER ℓ.

- VERIFICATION IF $b(\ell)$ WAS ALREADY CREATED:
  If $\ell_c > \ell$, then exit this procedure with the existing vector $b(\ell) \in \mathbb{Z}^n$.
  Otherwise, set $\ell_c \leftarrow \ell_c + 1$, and continue to the next step.
- INDEX OF ENTRY WITH LARGEST COMPONENT:
  Let $\hat{\imath}$ be an integer randomly chosen in the set $N = \{1, 2, \ldots, n\}$.
- CONSTRUCTION OF $b(\ell)$:
  Randomly set $b_{\hat{\imath}}(\ell)$ to either plus or minus 2^ℓ, and $b_i(\ell)$ for $i \in N \setminus \{\hat{\imath}\}$ to be an integer in $\{-2^\ell + 1, -2^\ell + 2, \ldots, 2^\ell - 1\}$. Record $b(\ell)$ and exit this procedure.

The above procedure returns a vector $b(\ell) \in \mathbb{Z}^n$ such that all elements but one are integers between $-2^\ell + 1$ and $2^\ell - 1$. The other element is either -2^ℓ or 2^ℓ. Moreover, when two iterations have the same mesh size parameter, then the corresponding vectors $b(\ell)$ are identical.

To each mesh size parameter Δ_k^m, we assign an integer $\ell = -\log_4(\Delta_k^m) \in \mathbb{N}$ so that $\Delta_k^m = 4^{-\ell}$. Note that the mesh size parameter in LTMADS takes the values $1, \frac{1}{4}, \frac{1}{16}, \ldots$, and therefore ℓ is necessarily a nonnegative integer.

We now present a procedure that extends $b(\ell)$ to a positive spanning set of either $2n$ or $n+1$ poll directions. The procedure first generates an $(n-1) \times (n-1)$ lower triangular matrix, and then combines it with $b(\ell)$ to create a basis in $\mathbb{R}^n$. Finally, this basis is extended to a positive basis by either mirroring the directions (for a maximal $2n$ basis), or by taking the negative sum of the directions (for a $n+1$ basis).

The rows of a lower triangular matrix L are randomly permuted, and a row of zeroes is inserted in position $\hat{\imath}$, where $\hat{\imath}$ is the index defined in the construction of the vector $b(\ell)$. This results in a $n \times (n-1)$ matrix. The column $b(\ell)$ is appended to it, and this leads to a basis B in $\mathbb{R}^n$. The permutation of the rows ensures that the zeroes of the triangular matrix are not mostly located in the upper part of B. Afterwards, the columns of B are randomly permuted to ensure that the zeroes are not mostly located in the right part of B'. This construction ensures that $|\det(B)| = |\det(B')| = 2^{\ell n}$. The completion to a positive basis D_k appends to B' either the negative sum of the columns of B', or the negative of each column.

GENERATION OF THE POSITIVE BASIS D_k AND UPDATE OF Δ_k^p.

- CONSTRUCTION OF THE DIRECTION $b(\ell)$ AND INDEX $\hat{\imath}$:
  Let $\ell = -\log_4(\Delta_k^m)$, and construct $b(\ell)$ by the above procedure.
  Set $\hat{\imath}$ to be the integer in N such that $|b_{\hat{\imath}}(\ell)| = 2^\ell$.
- BASIS CONSTRUCTION IN $\mathbb{R}^{n-1}$:
  Let L be a lower triangular $(n-1) \times (n-1)$ matrix where each term on the diagonal is either plus or minus 2^ℓ, and the lower components are randomly chosen in $\{-2^\ell + 1, -2^\ell + 2, \ldots, 2^\ell - 1\}$.
  L is a basis in $\mathbb{R}^{n-1}$ with $|\det(L)| = 2^{\ell(n-1)}$.
- PERMUTATION OF THE LINES OF L, AND COMPLETION TO A BASIS IN $\mathbb{R}^n$:
  Let $\{p_1, p_2, \ldots, p_{n-1}\}$ be random permutations of the set $N \setminus \{\hat{\imath}\}$. Set

$$\begin{array}{ll} B_{p_i,j} = L_{i,j} & \text{for } i, j = 1, 2, \ldots, n-1 \\ B_{\hat{\imath},j} = 0 & \text{for } j = 1, 2, \ldots, n-1 \\ B_{i,n} = b_i(\ell) & \text{for } i = 1, 2, \ldots, n. \end{array}$$

  B is a basis in $\mathbb{R}^n$ with $|\det(B)| = 2^{\ell n}$.
- PERMUTATION OF THE COLUMNS OF B:
  Let $\{q_1, q_2, \ldots, q_n\}$ be random permutations of the set N.
  Set $B'_{i,q_j} = B_{i,j}$ for each i and j in N. B' is a basis in $\mathbb{R}^n$ with $|\det(B')| = 2^{\ell n}$.
- COMPLETION TO A POSITIVE BASIS:
  - Minimal positive basis: Set $D_k = [B' \; d]$ with $d_i = -\sum_{j \in N} B'_{ij}$.
    Set the poll size parameter to $\Delta_k^p = n\sqrt{\Delta_k^m} \geq \Delta_k^m$.
  - Maximal positive basis: Set $D_k = [B' \; -B']$.
    Set the poll size parameter to $\Delta_k^p = \sqrt{\Delta_k^m} \geq \Delta_k^m$.

The construction also ensures that $b(\ell)$ is necessarily a column of the positive basis D_k. Our convergence analysis will show that as k goes to infinity, the union of all directions $b(\ell)$ is dense in $\mathbb{R}^n$ with probability 1. We will also show that if the entire sequence of iterates converges, then the set of refining directions is also dense in $\mathbb{R}^n$ with probability 1.

The following example in $\mathbb{R}^5$ highlights the features of the positive basis construction.

Example 4.1. Consider an iteration k with $\Delta_k^m = \frac{1}{16}$. The step CONSTRUCTION OF THE DIRECTION $b(\ell)$ AND INDEX $\hat{\imath}$ fixed $\ell = -\log_4(\Delta_k^m) = 2$. Suppose that the randomly defined vector $b(\ell)$ is $(-3, 2, 4, -1, 0)^T$. It follows that $\hat{\imath} = 3$ since $b_3(\ell) = 4$. Observe that all other components of $b(\ell)$ are integers between $-2^2 + 1$ and $2^2 - 1$.

Suppose that the step BASIS CONSTRUCTION IN $\mathbb{R}^{n-1}$ generates the random lower triangular matrix

$$L = \begin{bmatrix} -4 & 0 & 0 & 0 \\ 3 & 4 & 0 & 0 \\ -1 & 2 & -4 & 0 \\ 1 & -2 & 0 & 4 \end{bmatrix} \in \mathbb{Z}^{4\times 4}.$$

Now, if the two permutation steps generate the row permutation vector $(p_1, p_2, p_3, p_4) = (4, 1, 2, 5)$, and the column permutation vector $(q_1, q_2, q_3, q_4, q_5) = (5, 1, 3, 2, 4)$, then the bases constructed from L and $b(\ell)$ are

$$B = \begin{bmatrix} \mathbf{3} & \mathbf{4} & \mathbf{0} & \mathbf{0} & -3 \\ \mathbf{-1} & \mathbf{2} & \mathbf{-4} & \mathbf{0} & 2 \\ 0 & 0 & 0 & 0 & 4 \\ \mathbf{-4} & \mathbf{0} & \mathbf{0} & \mathbf{0} & -1 \\ \mathbf{1} & \mathbf{-2} & \mathbf{0} & \mathbf{4} & 0 \end{bmatrix} \quad \text{and} \quad B' = \begin{bmatrix} \mathbf{4} & \mathbf{0} & \mathbf{0} & -3 & \mathbf{3} \\ \mathbf{2} & \mathbf{0} & \mathbf{-4} & 2 & \mathbf{-1} \\ 0 & 0 & 0 & 4 & 0 \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & -1 & \mathbf{-4} \\ \mathbf{-2} & \mathbf{4} & \mathbf{0} & 0 & \mathbf{1} \end{bmatrix}$$

(the entries copied from L appear in boldface characters). One may easily verify that $|\det(B)| = |\det(B')| = 4^5$ and that the four terms B'_{p_i,q_i} for $i = 1, 2, 3, 4$ as well as B'_{3,q_5} are equal to either 4 or -4.

Finally, depending on if the minimal or maximal positive basis is selected, the COMPLETION TO A POSITIVE BASIS step generates the set D_k composed of the columns of either

$$\begin{bmatrix} 4 & 0 & 0 & -3 & 3 & -4 \\ 2 & 0 & -4 & 2 & -1 & 1 \\ 0 & 0 & 0 & 4 & 0 & -4 \\ 0 & 0 & 0 & -1 & -4 & 5 \\ -2 & 4 & 0 & 0 & 1 & -3 \end{bmatrix}$$

$$\text{or} \quad \begin{bmatrix} 4 & 0 & 0 & -3 & 3 & -4 & 0 & 0 & 3 & -3 \\ 2 & 0 & -4 & 2 & -1 & -2 & 0 & 4 & -2 & 1 \\ 0 & 0 & 0 & 4 & 0 & 0 & 0 & 0 & -4 & 0 \\ 0 & 0 & 0 & -1 & -4 & 0 & 0 & 0 & 1 & 4 \\ -2 & 4 & 0 & 0 & 1 & 2 & -4 & 0 & 0 & -1 \end{bmatrix}.$$

A key point of this construction is that any iteration with a mesh size parameter equal to $\frac{1}{16}$ will have $b(\ell)$ as the q_{5th} column of D_k. In this particular example, $b(\ell)$ is the fourth column of D_k. The other columns will usually differ from one iteration to another.

Since MADS is allowed to be *opportunistic* and end a POLL step as soon as a better point is found, we want to randomize the POLL directions. Thus, the purpose of the second step is to permute the rows of the matrix B so that the zeroes in the upper triangular part of the matrix are randomly positioned, and to permute the columns so that the dense column is not always the first in D_k. The name LTMADS is based on the lower triangular matrix at the heart of the construction of the frames.

The following result shows that the frames generated by the LTMADS algorithm satisfy the conditions of Definition 2.2.

PROPOSITION 4.2. *At each iteration k, the procedure above yields a D_k and a MADS frame P_k such that*

$$P_k = \{x_k + \Delta_k^m d : d \in D_k\} \subset M_k,$$

where M_k is given by Definition 2.1 *and D_k is a positive spanning set such that for each $d \in D_k$,*

- *d can be written as a nonnegative integer combination of the directions in D: $d = Du$ for some vector $u \in \mathbb{N}^{n_D}$ that may depend on the iteration number k;*
- *the distance from the frame center x_k to a frame point $x_k + \Delta_k^m d \in P_k$ is bounded above by a constant times the poll size parameter: $\Delta_k^m \|d\| \leq \Delta_k^p \max\{\|d'\| : d' \in D\}$;*

- *limits (as defined in Coope and Price* [11]*) of the normalized sets $\mathcal{D}_k$ are positive spanning sets.*

Proof. The first n columns of D_k form a basis of $\mathbb{R}^n$ because they are obtained by permuting rows and columns of the lower triangular matrix B, which is nonsingular because it has nonzero terms on the diagonal. Moreover, taking the last direction to be the negative of the sum of the others leads to a minimal positive basis, and combining the first n columns of D_k with their negatives gives a maximal positive basis [14].

Again by construction, D_k has all integral entries in the interval $[-2^\ell, 2^\ell]$ $\left(\text{with } 2^\ell = \frac{1}{\sqrt{\Delta_k^m}}\right)$, and so clearly each column d of D_k can be written as a nonnegative integer combination of the columns of $D = [I, -I]$. Hence, the frame defined by D_k is on the mesh M_k.

Now the ℓ_∞ distance from the frame center to any frame point is $\|\Delta_k^m d\|_\infty = \Delta_k^m \|d\|_\infty$. There are two cases. If the maximal positive basis construction is used, then $\Delta_k^m \|d\|_\infty = \sqrt{\Delta_k^m} = \Delta_k^p$. If the minimal positive basis construction is used, then $\Delta_k^m \|d\|_\infty \le n\sqrt{\Delta_k^m} = \Delta_k^p$. The proof of the second bullet follows by noticing that $\max\{\|d'\|_\infty : d' \in [I \ -I]\} = 1$.

The frame can be rewritten in the equivalent form $\{x_k + \sqrt{\Delta_k^m} v : v \in \mathcal{V}\}$, where $\mathcal{V}$ is a set whose columns are the same as those of B after permutation and multiplication by $\sqrt{\Delta_k^m}$.

Coope and Price [11] show that a sufficient condition for the third bullet to hold is that each element of $\mathcal{V}$ is bounded above and below by positive constants that are independent of k. This is trivial to show with our construction. Indeed, each entry of $\mathcal{V}$ lies between -1 and 1 and every term on the diagonal is ± 1. B is a triangular matrix, and therefore $|det(\mathcal{V})| = 1$. ∎

The frames given in Figure 2.2 were generated using minimal positive bases with direction sets D_k: $\{(-1,0)^T, (0,-1)^T, (1,1)^T\}$, $\{(-2,-1)^T, (0,-2)^T, (2,3)^T\}$, and $\{(-3,4)^T, (4,0)^T, (-1,-4)^T\}$. One can see that as Δ_k^m and Δ_k^p go to zero, the number of candidates for frame points increases rapidly. For the three examples illustrated in the figure, the number of distinct possible frames that LTMADS may choose from is 4, 20, and 44, respectively (the frames D_k are interpreted as sets and not matrices). For example, in the case depicted in the rightmost figure, the $\hat{\imath}th$ row of the matrix B is $[0 \ \pm 4]$, the other row is $[\pm 4 \ \beta]$, where β is an integer between -3 and 3. It follows that for a given $\hat{\imath}$, there are $2 \times 2 \times 7 = 28$ possibilities for B. The index $\hat{\imath}$ is either 1 or 2, and thus the number of possibilities for B' is 56. Permuting the columns does not change the points in the frames. However, some different values of B' lead to the same frame D_k when viewed as a set. For examples, when B' is

$$\begin{bmatrix} 4 & -1 \\ 0 & -4 \end{bmatrix} \text{ or } \begin{bmatrix} -3 & 4 \\ 4 & 0 \end{bmatrix},$$

then in both cases the set of directions in the frame D_k is $\{(-3,4)^T, (4,0)^T, (-1,-4)^T\}$. This leads to a total of 44 different frames.

In addition to an opportunistic strategy, i.e., terminating a POLL step as soon as an improved mesh point is detected, a standard trick we use in GPS to improve the convergence speed consists of promoting a successful poll direction to the top of the list of directions for the next POLL step. We call this *dynamic ordering* of the polling directions. This strategy cannot be directly implemented in MADS since

at a successful iteration $k-1$, the poll size parameter is increased, and therefore a step of Δ_k^m in the successful direction will often be outside the mesh. The way we mimic GPS dynamic ordering in MADS is that when the previous iteration succeeded in finding an improved mesh point, we execute a simple one point *dynamic search* in the next iteration as follows. Suppose that $f_\Omega(x_k) < f_\Omega(x_{k-1})$ and that d is the direction for which $x_k = x_{k-1} + \Delta_{k-1}^m d$. Then, the trial point produced by the SEARCH step is $s_k = x_{k-1} + 4\Delta_{k-1}^m d$. Note that with this construction, if $\Delta_{k-1}^m < 1$, then $s_k = x_{k-1} + \Delta_k^m d$ and otherwise, $s_k = x_{k-1} + 4\Delta_k^m d$. In both cases s_k lies on the current mesh M_k. If this SEARCH finds a better point, then we go on to the next iteration, but if not, then we proceed to the POLL step. The reader will see in the numerical results below that this seems to be a good strategy.

4.2. Convergence analysis. The convergence results in section 3.4 are based on the assumption that the set of refining directions for the limit of a refining sequence is asymptotically dense in the hypertangent cone at that limit. The following result shows that the above instances of LTMADS generates an asymptotically dense set of poll directions with probability 1. Therefore, the convergence results based on the local smoothness of the objective function f and on the local topology of the feasible region Ω can be applied to LTMADS.

THEOREM 4.3. *Let $\hat{x} \in \Omega$ be the limit of a refining subsequence produced by either instance of LTMADS. Then the set of poll directions for the subsequence converging to $\hat{x}$ is asymptotically dense in $T_\Omega^H(\hat{x})$ with probability* 1.

Proof. Let $\hat{x}$ be the limit of a refining subsequence $\{x_k\}_{k\in K}$ produced by one of the above instances of LTMADS (either with the minimal or maximal positive basis). Consider the sequence of positive bases $\{D_k\}_{k\in K}$. Each one of these bases is generated independently.

We use the notation $P[E]$ to denote the probability that E occurs. Let v be a direction in $\mathbb{R}^n$ with $\|v\|_\infty = 1$ such that $P[|v_j| = 1] \geq \frac{1}{n}$ and $P[v_j = 1 \mid |v_j| = 1] = P[v_j = -1 \mid |v_j| = 1] = \frac{1}{2}$. We will find a lower bound on the probability that a normalized direction in D_k is arbitrarily close to the vector v.

Let k be an index of K, and let $\ell = -\log_4(\Delta_k^m)$. Recall that in the generation of the positive basis D_k, the column $b(\ell)$ is such that $|b_{\hat{\imath}}(\ell)| = 2^\ell$, and the other components of $b(\ell)$ are random integers between $-2^\ell + 1$ and $2^\ell - 1$. Set $u = \frac{b(\ell)}{\|b(\ell)\|_\infty}$. It follows by construction that $u = 2^{-\ell} b(\ell)$ and $\|u\|_\infty = |u_{\hat{\imath}}| = 1$. We will now show for any $0 < \epsilon < 1$, that the probability that $\|u - v\|_\infty < \epsilon$ is bounded below by some nonnegative number independent of k, as $k \in K$ goes to infinity. Let us estimate the probability that $|u_j - v_j| < \epsilon$ for each j. For $j = \hat{\imath}$ we have

$$\begin{aligned} P[|u_{\hat{\imath}} - v_{\hat{\imath}}| < \epsilon] &\geq P[u_{\hat{\imath}} = v_{\hat{\imath}} = 1] + P[u_{\hat{\imath}} = v_{\hat{\imath}} = -1] \\ &= P[u_{\hat{\imath}} = 1] \times P[v_{\hat{\imath}} = 1] + P[u_{\hat{\imath}} = -1] \times P[v_{\hat{\imath}} = -1] \\ &\geq \frac{1}{2} \times \frac{1}{2n} + \frac{1}{2} \times \frac{1}{2n} \;=\; \frac{1}{2n}. \end{aligned}$$

For $j \in N \setminus \{\hat{\imath}\}$ we have

$$P[|u_j - v_j| < \epsilon] = P[v_j - \epsilon < u_j < v_j + \epsilon] \;=\; P\left[2^\ell(v_j - \epsilon) < b_j(\ell) < 2^\ell(v_j + \epsilon)\right].$$

We will use the fact that the number of integers in the interval $[2^\ell(v_j - \epsilon), 2^\ell(v_j + \epsilon)] \cap [-2^\ell + 1, 2^\ell - 1]$ is bounded below by the value $2^\ell\epsilon - 1$. Now, since the bases D_k are independently generated, and since $b_j(\ell)$ is an integer randomly chosen with equal

probability among the $2^{\ell+1}-1$ integers in the interval $[-2^\ell+1, 2^\ell-1]$, then it follows that

$$P[|u_j - v_j| < \epsilon] \geq \frac{2^\ell\epsilon - 1}{2^{\ell+1}-1} \;>\; \frac{2^\ell\epsilon - 1}{2^{\ell+1}} \;=\; \frac{\epsilon - 2^{-\ell}}{2}.$$

Recall that $\hat{x}$ is the limit of a refining subsequence, and so there exists an integer α such that $\sqrt{\Delta_k^m} = 2^{-\ell} \leq \frac{\epsilon}{2}$ whenever $\alpha \leq k \in K$, and so

$$P[|u_j - v_j| < \epsilon] \geq \frac{\epsilon - \sqrt{\Delta_k^m}}{2} \;\geq\; \frac{\epsilon}{4} \qquad \text{for any } k \in K \text{ with } k \geq \alpha.$$

It follows that

$$P[\|u - v\|_\infty < \epsilon] \;=\; \prod_{j=1}^{n} P[|u_j - v_j| < \epsilon] \geq \frac{\left(\frac{\epsilon}{4}\right)^{n-1}}{2n} \qquad \text{for any } k \in K \text{ with } k \geq \alpha.$$

We have shown when k is sufficiently large that $P[\|u - v\|_\infty < \epsilon]$ is larger than a strictly positive constant which is independent of Δ_k^m. Thus, there will be a poll direction in D_k for some $k \in K$ arbitrarily close to any direction $v \in \mathbb{R}^n$, and in particular to any direction $v \in T_\Omega^H(\hat{x})$. ∎

The proof of the previous result shows that the set of directions consisting of the $b(\ell)$ directions over all iterations is dense in $\mathbb{R}^n$. Nevertheless, we require the algorithm to use a positive spanning set at each iteration instead of a single poll direction. This ensures that any limit of a refining subsequence is the limit of minimal frame centers on meshes that get infinitely fine. At this limit point, the set of refining directions is generated from the set of poll directions which is dense in LTMADS and finite in GPS. Therefore with both MADS and GPS, the set of directions for which the Clarke generalized derivatives are nonnegative positively span the whole space. However, GPS does not allow the possibility that the set of refining directions is dense, since it is finite.

Finally, we give a condition that ensures dense MADS refining directions with probability 1.

THEOREM 4.4. *Suppose that the entire sequence of iterates produced by either instance of LTMADS converges to $\hat{x} \in \Omega$. Then the set of refining directions for the entire sequence of iterates is asymptotically dense in $T_\Omega^H(\hat{x})$ with probability* 1.

Proof. Let K be the set of indices of iterations that are minimal frame centers. If the entire sequence of iterates produced by an instance of LTMADS converges to $\hat{x} \in \Omega$, then the subsequence $\{x_k\}_{k\in K}$ also converges to $\hat{x}$. Therefore, $\{b(\ell)\}_{\ell=1}^\infty$ is a subsequence of refining directions. This subsequence was shown in Theorem 4.3 to be asymptotically dense in $T_\Omega^H(\hat{x})$ with probability 1. ∎

5. Numerical results. We consider four test problems in this section. Each problem is intended to make a point about MADS. We give results for GPS with a POLL step only and with a simple Latin hypercube SEARCH step. The GPS results all use a POLL ordering we have found to be advantageous in our experience using GPS.

The first problem is unconstrained, but GPS is well known to stagnate on this problem if it is given an unsuitable set of directions. MADS has no problem converging quickly to a global optimizer. The second problem is a bound constrained chemical engineering problem where GPS is known to behave well enough to justify publication of the results [17]. Still, on the whole, MADS does better. The third is a simple

nonlinearly constrained problem where GPS and another filter version of GPS are both known to converge short of an optimizer. As the theory given here predicts, MADS has no difficulty. We also use this problem to show that MADS does well as the number of variables increases.

The last example is such that the feasible region gets narrow very quickly. This is meant to be a test for any derivative-free feasible point algorithm—like GPS or MADS with the extreme barrier approach to constraints. MADS does better than GPS with the filter or the barrier, both of which stagnate due to the limitation of finitely many POLL directions. MADS stops making progress when the mesh size gets smaller than the precision of the arithmetic.

Of course, even when one tries to choose carefully, four examples are not conclusive evidence. However, we believe that these numerical results coupled with the more powerful theory for MADS make a good case for MADS versus GPS. In addition, there is the evidence in [24] that MADS was effective on a problem in which each function evaluation took weeks to perform. In [5] MADS was used in a context of identifying optimal algorithmic trust-region parameters. In [7] MADS was used to optimize spent potliner treatment process in aluminium production. Furthermore, MADS has recently been added as an option in the MATLAB GADS toolbox [25].

5.1. An unconstrained problem where GPS does poorly. Consider the unconstrained optimization problem in $\mathbb{R}^2$ presented in [19] where GPS algorithms are known to converge to nonstationary points:

$$f(x) \;=\; \big(1-\exp(-\|x\|^2)\big)\times\max\{\|x-c\|^2,\|x-d\|^2\},$$

where $c=-d=(30,40)^T$. Figure 5.1 shows level sets of this function. It can be shown that f is locally Lipschitz and strictly differentiable at its global minimizer $(0,0)^T$.

The GPS and MADS runs are initiated at $x_0=(-2.1,1.7)^T$, depicted by a diamond in the right part of Figure 5.1. The gradient of f exists and is nonzero at that point, and therefore both GPS and MADS will move away from it. Since there is some randomness involved in the MADS instance described in section 4.1, we ran it a total of 5 times, to see how it compares to our standard NOMAD [13] implementation of GPS. Figure 5.2 shows a log plot of the progress of the objective function value for each set of runs. All POLL steps were opportunistic, and the runs were stopped when a minimal frame with poll size parameter less than 10^{-10} was detected. For GPS, the maximal $2n$ positive basis refers to the set of positive and negative coordinate directions, and the two minimal $n+1$ positive bases are $\{(1,0)^T,(0,1)^T,(-1,-1)^T\}$ and $\{(1,0)^T,(-0.5,0.866025)^T,(-0.5,-0.866025)^T\}$, and the termination criteria are the same, i.e., when Δ_k drops below 10^{-10}.

Without a search strategy, every GPS run converged to a point on the line $x_2=-\frac{3}{4}x_1$, where f is not differentiable. These three limit points are denoted by stars in Figure 5.1. As proved in [3], the limit points for GPS satisfy the necessary optimality condition that the Clarke generalized directional derivatives are nonnegative for D at these limit points, but they are not local optimizers. One can see by looking at the level sets of f that no descent directions can be generated by the GPS algorithm using the above directions.

However, when adding a search strategy (by randomly selecting $2n$ mesh points at each SEARCH step) or when using LTMADS, all runs eventually generated good directions and converged to the origin, the global optimal solution. Figure 5.2 suggests that the MADS convergence is faster than GPS. Also, even if randomness appears in

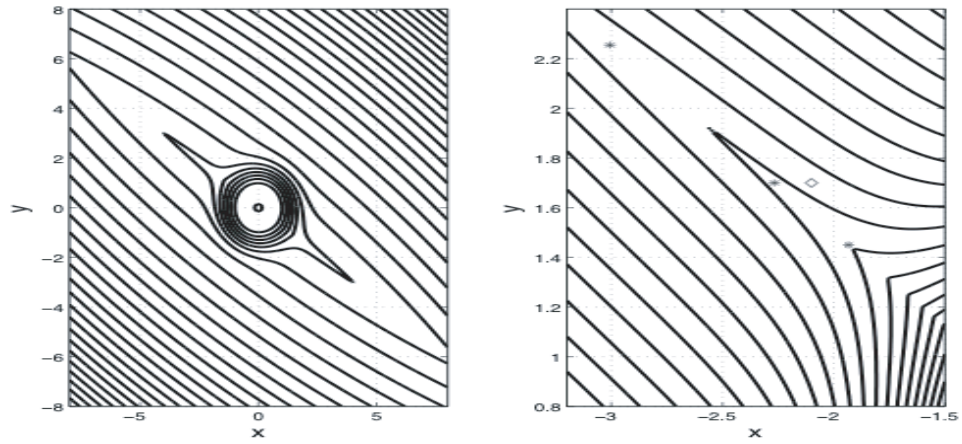

FIG. 5.1. *Level sets of* $f(x) = \left(1 - \exp(-\|x\|^2)\right) \times \max\{\|x - c\|^2, \|x - d\|^2\}$.

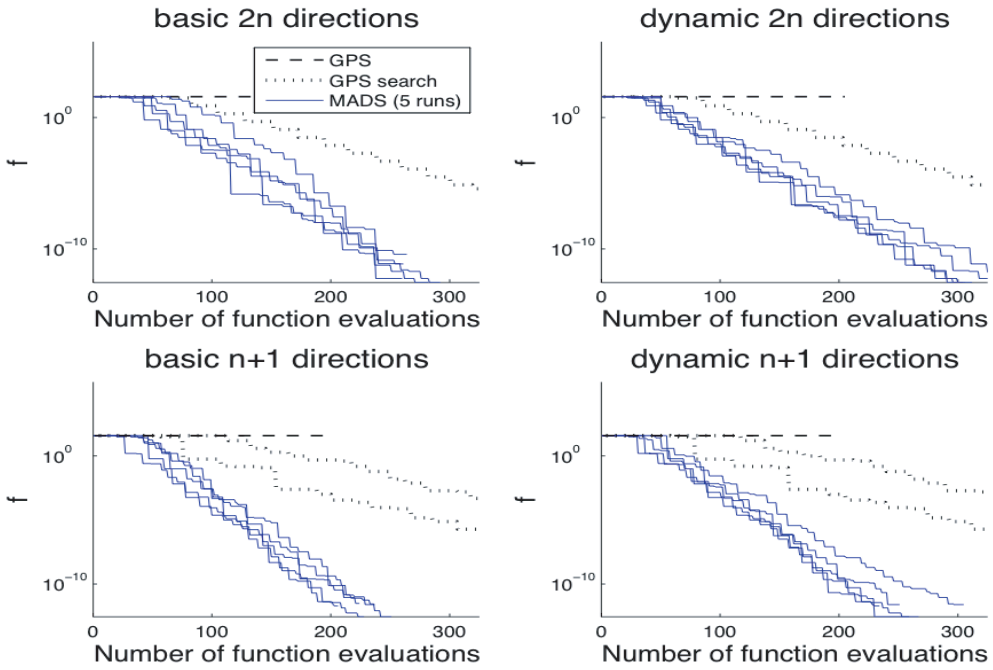

FIG. 5.2. *Progression of the objective function value vs the number of evaluations.*

these instances of LTMADS, the behavior of the algorithm is very stable in converging quickly to the origin.

5.2. A test problem where GPS does well. The academic example above was one of our motivations for developing MADS. We now apply MADS to an example from the chemical engineering literature for which GPS was shown to be preferable to a conjugate-direction approach. Hayes et al. [17] describe a method for evaluating the kinetic constants in a rate expression for catalytic combustion applications using experimental light-off curves. The method uses a transient one-dimensional single

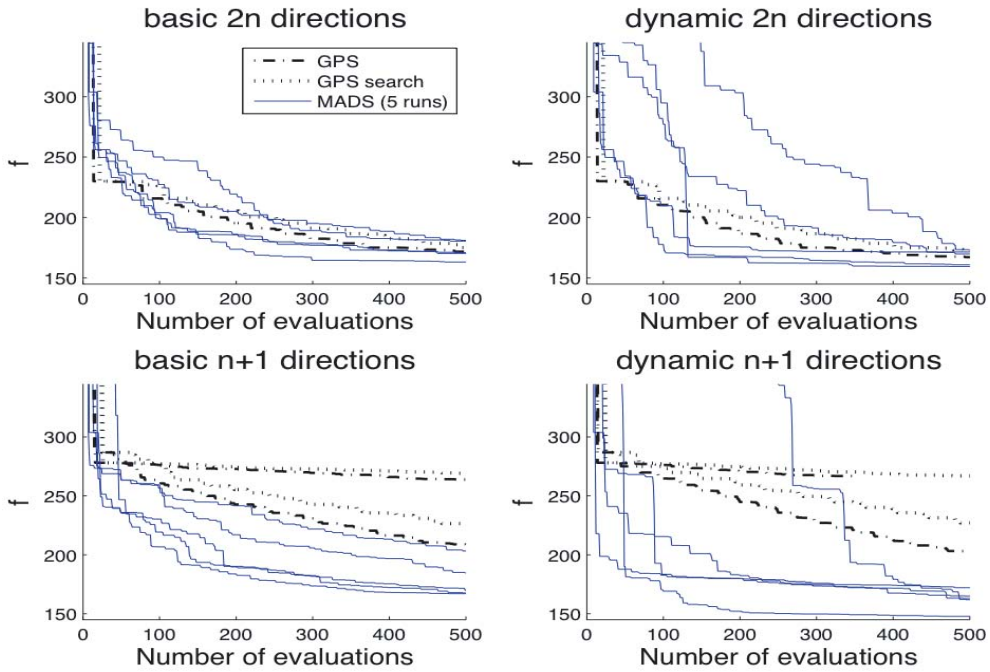

FIG. 5.3. *Data set* 1—*Progression of the objective function value vs the number of evaluations.*

channel monolith finite element reactor model to simulate reactor performance. The objective is to find the values of four parameters in a way such that the model estimates as closely as possible (in a weighted least square sense) an experimental conversion rate. This is a bound constrained nonsmooth optimization problem in $\mathbb{R}^4_+$, where the objective function measures the error between experimental data and values predicted by the model.

For the three sets of experimental data analyzed in [17], we compared the instances of GPS and MADS discussed above. The algorithms terminate whenever a minimal frame center with $\Delta_k^p \leq 2^{-6}$ (for MADS) or $\Delta_k \leq 2^{-6}$ (for GPS) is detected, or whenever 500 functions evaluations are performed, whichever comes first. Figures 5.3, 5.4, and 5.5 show the progression of the objective function value versus the number of evaluations for each data set.

The plots suggest that the objective function value decreases more steadily with GPS than with MADS. This is because GPS uses a fixed set of poll directions that we know to be an excellent choice for this problem. By allowing more directions, MADS eventually generates a steeper descent direction, and the dynamic runs capitalize on this by evaluating f further in that direction thus sharply reducing the objective function value in a few evaluations. In general, if the number of function evaluations is limited to a fixed number, then it appears that MADS with the dynamic strategy gives a better result than GPS.

For all three data sets, the dynamic runs are preferable to the basic runs. It also appears that for this problem, MADS runs with minimal $n+1$ directions perform better than the maximal $2n$ runs. GPS with a 2 point random search at each iteration systematically gave worst results than GPS without a search. In each of the three

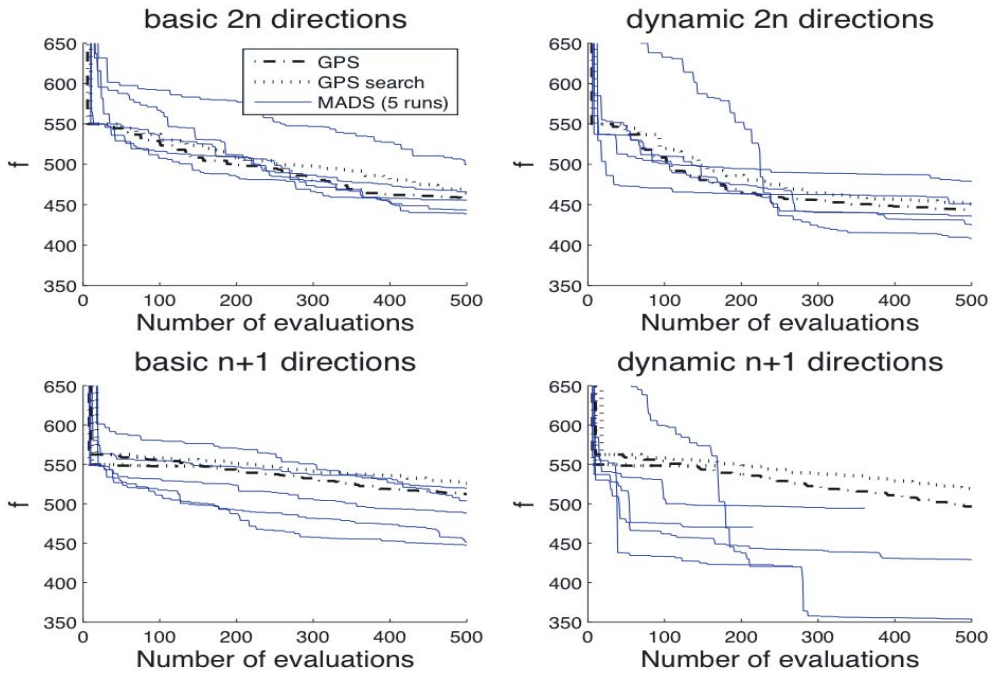

FIG. 5.4. *Data set* 2*—Progression of the objective function value vs the number of evaluations.*

data sets, the best overall solution was always produced by MADS with the dynamic $n+1$ directions.

The quality of the best solutions produced by GPS and MADS can be visualized in Figure 5.6 where the difference between the experimental and predicted conversions are plotted versus time. A perfect model with perfectly tuned parameters would have had a difference of zero everywhere. The superiority of the solution produced by MADS versus GPS is mostly visible for the second data set near the time 170 sec and the third data set near the time 190 sec where in both cases the fit is better by approximately 1%.

5.3. Linear optimization on an hypersphere. The third example shows again the difficulty caused by being restricted to a finite number of polling directions. It also illustrates the effect of dimension. This is a problem with a linear objective and strictly convex full-dimensional feasible region, surely the simplest nonlinearly constrained problem imaginable.

$$\begin{aligned} \min_{x\in\mathbb{R}^n} \quad & \sum_{i=1}^{n} x_i \\ \text{s.t.} \quad & \sum_{i=1}^{n} x_i^2 \le 3n. \end{aligned}$$

There is a single optimal solution to that problem: every component of the vector x is $-\sqrt{3}$ and the optimal value is $-\sqrt{3}n$.

The starting point is the origin, and the algorithm terminates when $\Delta_k^p \le 10^{-12}$ (for MADS) or $\Delta_k \le 10^{-12}$ (for GPS), or when the number of function evaluations exceeds $600n$, whichever comes first. The algorithm was run with four values of n.

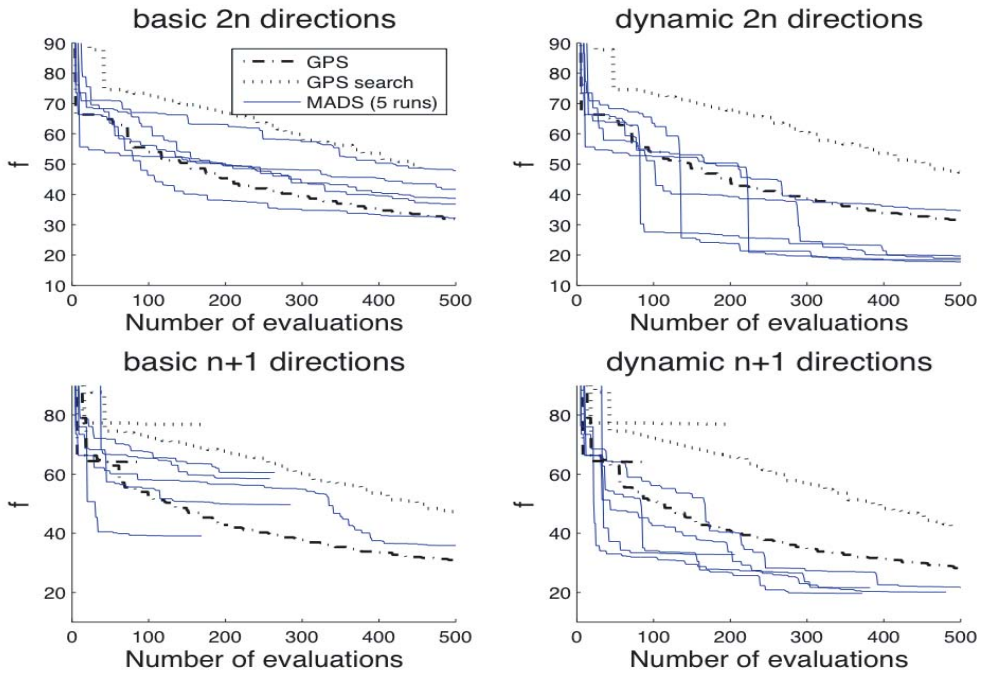

FIG. 5.5. *Data set* 3*—Progression of the objective function value vs the number of evaluations.*

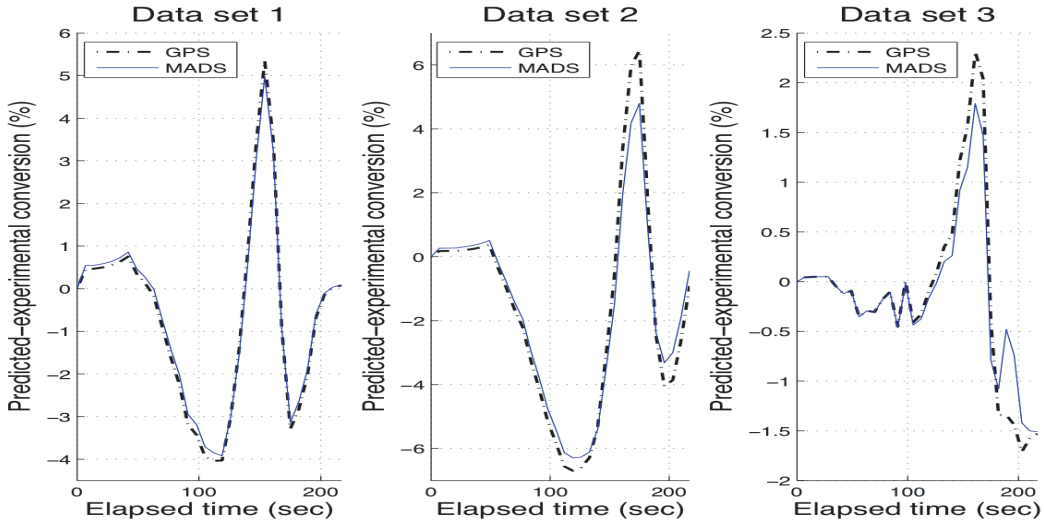

FIG. 5.6. *Conversion rate error versus time.*

For the GPS method we always used $D_k = D = [I, -I]$ with dynamic ordering. The GPS filter method is described in [4]. We used a search strategy, which we often use with the GPS filter method, consisting of a $5n$ point Latin hypercube sample at the first iteration, and a $n/5$ random search at other iterations.

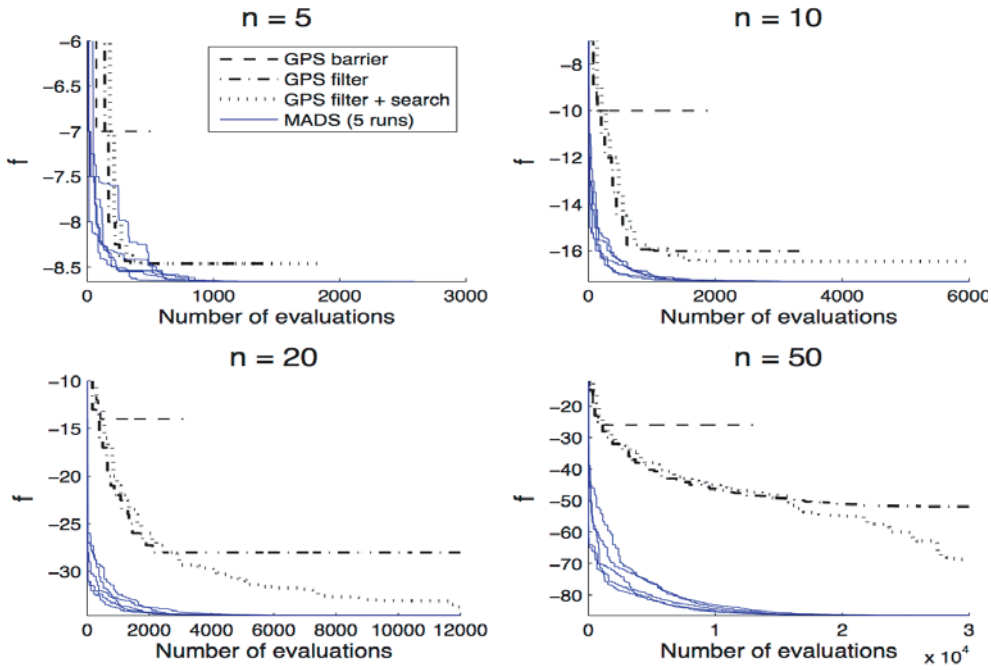

FIG. 5.7. *Progression of the objective function value vs the number of evaluations on an easy nonlinear problem.*

The behavior of LTMADS is comparable for every value of n. In every case, that MADS algorithm converged to the global optimal solution. The GPS barrier approach quickly moved to a point on the boundary of the domain and stalled there. The GPS filter approach was able to move away from that point, but it converged to a better suboptimal solution. The absence of a SEARCH strategy, and the restriction to a finite number of POLL directions traps the iterates at a nonoptimal solution. The addition of a random SEARCH strategy allows GPS with the filter, when n is $10, 20$, or 50, to move away from this solution, but it still was short of finding the optimal solution in the number of function calls allowed. The "GPS search" label below applies to the GPS with the filter and random SEARCH, because this combination performed better than GPS with a random SEARCH step. The progression of the runs is illustrated in Figure 5.7.

5.4. Numerical limitations. The optimal solution in this last example does not satisfy the hypotheses of any GPS or MADS theorems because it is located at $-\infty$. However, the example is intended to show how well the various algorithms track a feasible region that gets narrow quickly. Consider the following problem in $\mathbb{R}^2$:

$$\begin{aligned} \min_{x=(a,b)^T} \quad & a \\ \text{s.t.} \quad & e^a \le b \le 2e^a. \end{aligned}$$

The starting point is $(0,1)^T$, and the algorithm terminates when $\Delta_k^m < 10^{-323}$ (for MADS) or $\Delta_k < 10^{-323}$ (for GPS) i.e., when the mesh size parameter drops below the smallest positive representable number in double precision arithmetic. We admit that this is excessive, but we wanted to run the algorithms to their limits. The same strategies as in section 5.3 are used.

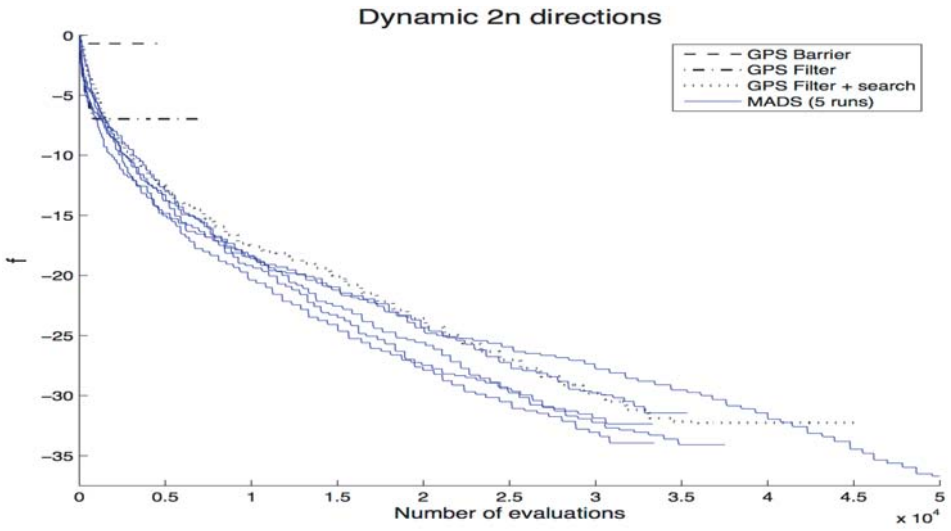

FIG. 5.8. *Progression of the objective function value versus the number of evaluations on a difficult nonlinear problem.*

The progression of the algorithms is illustrated in Figure 5.8. GPS with both the barrier and filter approaches to constraints converged quickly to points where the standard 2n basis does not contain a feasible descent direction. The filter GPS (without search) approach to constraints did better than the GPS barrier (without search) approach because it is allowed to become infeasible.

All 5 runs of the LTMADS method of the previous section ended with roughly the same solution, a point where $a \pm \Delta_k^p = a$ in finite arithmetic, which is all one can ask. The same behavior is observed for GPS with a random SEARCH (similar results were generated with or without the filter). The fact that LTMADS generates an asymptotically dense set of poll directions, and that a SEARCH step is conducted at each GPS iteration explain why both the GPS with a search and LTMADS do better than the GPS barrier or filter approach.

The feasible region is very narrow, and therefore it gets quite improbable that the MADS poll directions generate a feasible point. When such a feasible point is generated it is always very close to the frame center since the mesh and poll parameters are very small.

Even if the algorithm instances failed to solve this problem to optimality and converged to points that are not Clarke stationary points, the GPS and MADS convergence theory is not violated—yet. In all cases, there is a set of directions that positively span $\mathbb{R}^2$ such that for each direction either the Clarke generalized derivative is nonnegative or is an infeasible direction.

6. Discussion. GPS is a valuable algorithm, but the application of nonsmooth analysis techniques in [3] showed its limitations due to the finite choice of directions in [2]. MADS removes the GPS restriction to finitely many poll directions. We have long felt that this was the major impediment to stronger proofs of optimality for GPS limit points (and better behavior on nonsmooth problems), and in this paper we find more satisfying optimality conditions for MADS in addition to opening new options for handling nonlinear constraints.

It would be easy to define a GPS algorithm that contains a randomized selection of POLL directions. It would suffice to define the set of directions D to be large enough to contain more than one positive basis, as illustrated in Figure 2.1. But since that number would still remain finite and the directions would not fill the space, the theory would remain limited. Introducing randomness to GPS in this way or to MADS as in LTMADS does not make either into random search methods as viewed by that community. The interested reader can refer to [31] and Chapter 2 of [32] for the distinction.

MADS is a general framework which also contains both deterministic and randomized instances of polling direction choices. But most importantly, MADS allows infinitely many different polling directions. To illustrate the MADS generality, we proposed here a randomized way to choose polling directions. This method, which we called LTMADS, performed well, especially for a first implementation. Of course, this implies that the convergence analysis of LTMADS (and not that of the general framework MADS) requires probabilistic arguments.

We could have used a deterministic strategy to define our first instance of MADS, but the deterministic ways that we tried were such that when the algorithm was halted after finitely many iterations, the set of poll directions was often far from being uniformly distributed in $\mathbb{R}^n$. This convinced us to present LTMADS here rather than our early deterministic efforts despite being able to prove the same theorems without the need for probabilistic arguments.

We expect that more, and perhaps better, instances of MADS will be found, and we hope this paper will facilitate that. To have a MADS instance be backed by our convergence analysis, one needs to show that the new instance generates a dense set of refining directions.

When n is small, our examples suggested that GPS with a random SEARCH behaved similarly to MADS. Of course, it is well known [32] that random searches that sample the space using a uniform distribution get worse as the dimension of the problem increases, and the probability of improvement for a fixed dimension decreases as the function value decreases. Thus, for larger n, we would not recommend using a pure random search step with either GPS or MADS.

We think that the ideas here can be readily applied to choosing templates for implicit filtering [9], another very successful algorithm for nasty nonlinear problems.

7. Acknowledgments. Finally, we wish to thank Gilles Couture for coding NOMAD, the C++ implementation of MADS and GPS, and to acknowledge useful discussions with Andrew Booker, Mark Abramson, and Sébastien Le Digabel, and constructive comments by the associate editor Margaret Wright and by an anonymous referee.

ERRATUM: MESH ADAPTIVE DIRECT SEARCH ALGORITHMS FOR CONSTRAINED OPTIMIZATION*

CHARLES AUDET†, A. L. CUSTÓDIO‡, AND J. E. DENNIS, JR.§

Abstract. In [*SIAM J. Optim.*, 17 (2006), pp. 188–217] Audet and Dennis proposed the class of *mesh adaptive direct search* (MADS) *algorithms* for minimization of a nonsmooth function under general nonsmooth constraints. The notation used in the paper evolved since the preliminary versions, and, unfortunately, even though the statement of Proposition 4.2 is correct, it is not compatible with the final notation. The purpose of this note is to show that the proposition is valid.

Key words. mesh adaptive direct search algorithms, constrained optimization, nonsmooth optimization

AMS subject classifications. 90C30, 90C56, 65K05, 49J52

DOI. 10.1137/060671267

In [1] Audet and Dennis proposed the class of *mesh adaptive direct search* (MADS) *algorithms* for minimization of a nonsmooth function under general nonsmooth constraints. The paper contains a convergence analysis for this class of methods and proposes two variants of an implementable instance called LTMADS.

The proof that LTMADS is indeed an instance of MADS is not compatible with the notation used in the rest of the paper. We restate the proposition and propose a consistent proof.

PROPOSITION 0.1 (Proposition 4.2 of [1]). *At each iteration k, the procedure above yields a D_k and a MADS frame P_k such that*

$$P_k = \{x_k + \Delta_k^m d : d \in D_k\} \subset M_k,$$

where $\Delta_k^m > 0$ is the mesh size parameter, M_k is given by Definition 2.1 of [1], and D_k is a positive spanning set such that for each $d \in D_k$,

- *d can be written as a nonnegative integer combination of the directions in D: $d = Du$ for some vector $u \in \mathbb{N}^{n_D}$ that may depend on the iteration number k;*
- *the distance from the frame center x_k to a frame point $x_k + \Delta_k^m d \in P_k$ is bounded above by a constant times the poll size parameter: $\Delta_k^m \|d\|_\infty \leq \Delta_k^p \max\{\|d'\|_\infty : d' \in D\}$;*
- *limits (as defined in Coope and Price [2]) of convergent subsequences of the normalized sets $\overline{D_k} := \{\frac{d}{\|d\|_\infty} : d \in D_k\}$ are positive spanning sets.*

Proof. In order to construct the set of directions D_k, the algorithm builds matrices at iteration k that should be called L_k, B_k, and B'_k. To ease the presentation, we omit the index k in the proof of the two first bullets. The index k reappears in the proof of the last bullet since this last result involves limits as k goes to infinity.

By the construction in [1], L is a lower triangular $(n-1)\times(n-1)$ matrix where each term on the diagonal is either plus or minus 2^ℓ, and the lower components are randomly chosen from the discrete set $\{-2^\ell+1,-2^\ell+2,\ldots,2^\ell-1\}$, with ℓ an integer that satisfies $2^\ell = 1/\sqrt{\Delta_k^m}$. The rules for updating the mesh size parameter Δ_k^m ensure that $\ell \in \mathbb{N}$. It follows that L is a basis in $\mathbb{R}^{n-1}$ with $|\det(L)| = 2^{\ell(n-1)}$. Let $\{p_1, p_2, \ldots, p_{n-1}\}$ be a random permutation of the set $\{1,2,\ldots,n\}\setminus\{\hat{\imath}\}$, where $\{\hat{\imath}\}$ is defined in [1]. The elements of the matrix B are defined as

$$\begin{array}{ll} B_{p_i,j} = L_{i,j} & \text{for } i,j = 1,2,\ldots,n-1,\\ B_{\hat{\imath},j} = 0 & \text{for } j = 1,2,\ldots,n-1,\\ B_{i,n} = b_i(\ell) & \text{for } i = 1,2,\ldots,n,\end{array}$$

where $b_i(\ell)$ is a vector that depends only on the value of the mesh size parameter and not on the iteration number (see section 4.1 of [1]). It follows that B is a permutation of the rows and the columns of a lower triangular matrix whose diagonal elements are either -2^ℓ or 2^ℓ. Therefore B is a basis in $\mathbb{R}^n$ and $|\det(B)| = 2^{\ell n}$.

The square matrix B' is obtained by permuting the columns of B, and therefore the columns of B' form a basis of $\mathbb{R}^n$. Furthermore, $|\det(B')| = |\det(B)| = 2^{\ell n}$.

One of the proposed versions of LTMADS uses a minimal positive basis at every iteration, and the other variant uses a maximal positive basis at every iteration. The columns of $[B' \;\; -b']$ with $b'_i = \sum_{j\in N} B'_{ij}$ define a minimal positive basis, and the columns of $[B' \;\; -B']$ define a maximal positive basis [3].

Therefore, if $D_k = [B' \;\; -b']$ or if $D_k = [B' \;\; -B']$, then all entries of D_k are integers in the interval $[-n2^\ell, n2^\ell]$ or in the interval $[-2^\ell, 2^\ell]$, respectively. It follows that each column d of D_k can be written as a nonnegative integer combination of the columns of $D = [I \;\; -I]$. Hence, the frame defined by D_k is on the mesh M_k.

Two cases must be considered to show the second bullet. Recall that with LTMADS, the poll size parameter Δ_k^p (see [1]) is defined differently depending on whether minimal or maximal positive bases are used. If the maximal positive basis construction is used, then $\|\Delta_k^m d\|_\infty = \Delta_k^m \|d\|_\infty = \sqrt{\Delta_k^m} = \Delta_k^p$. If the minimal positive basis construction is used, then $\|\Delta_k^m d\|_\infty = \Delta_k^m \|d\|_\infty \le n\sqrt{\Delta_k^m} = \Delta_k^p$. The proof of the second bullet follows by noticing that $\max\{\|d'\|_\infty : d' \in [I \;\; -I]\} = 1$.

To show the third bullet, we will verify that the limit of the normalized sets $\overline{D_k} := \{\frac{d}{\|d\|_\infty} : d \in D_k\}$ forms a positive basis. It suffices to show that the conditions (1a), (1b), and (C1) or (C2) of Coope and Price [2] hold.

- Conditions (1a) and (1b) ensure that the limit of any convergent subsequence of the sequence of bases $\overline{B'_k} := \{\frac{d}{\|d\|_\infty} : d \in B'_k\}$ is also a basis. Condition (1a) requires that $|\det(\overline{B'_k})|$ be bounded below by a positive constant that is independent of k. In our context, $|\det(\overline{B'_k})| = 1$ for all k, and therefore this condition is satisfied. Condition (1b) is also easily satisfied since normalized directions are used. It follows that the limit of $\overline{B'_k}$ is a basis.
- Conditions (C1) and (C2) involve the columns added to each basis B'_k to form a positive basis. In the case of the maximal bases, condition (C1) is easily satisfied. For the minimal bases, (C2) holds since all the structure constants ξ (again following the definition of Coope and Price [2]) satisfy $-1 \le \xi \le -\frac{1}{n}$.

This concludes the proof. ∎

SUMS OF SQUARES AND SEMIDEFINITE PROGRAM RELAXATIONS FOR POLYNOMIAL OPTIMIZATION PROBLEMS WITH STRUCTURED SPARSITY*

HAYATO WAKI†, SUNYOUNG KIM‡, MASAKAZU KOJIMA†, AND MASAKAZU MURAMATSU§

Abstract. Unconstrained and inequality constrained sparse polynomial optimization problems (POPs) are considered. A correlative sparsity pattern graph is defined to find a certain sparse structure in the objective and constraint polynomials of a POP. Based on this graph, sets of the supports for sums of squares (SOS) polynomials that lead to efficient SOS and semidefinite program (SDP) relaxations are obtained. Numerical results from various test problems are included to show the improved performance of the SOS and SDP relaxations.

Key words. polynomial optimization problem, sparsity, global optimization, Lagrangian relaxation, Lagrangian dual, sums of squares optimization, semidefinite program relaxation

1. Introduction.

Polynomial optimization problems (POPs) arise from various applications in science and engineering. Recent developments [9, 15, 18, 19, 22, 25, 27, 31, 32] in semidefinite program (SDP) and sums of squares (SOS) relaxations for POPs have attracted a lot of research from diverse directions. These relaxations have been extended to polynomial SDPs [11, 12, 17] and POPs over symmetric cones [20]. In particular, SDP and SOS relaxations have been popular for their theoretical convergence to the optimal value of a POP [22, 25]. From a practical point of view, improving the computational efficiency of SDP and SOS relaxations using the sparsity of polynomials in POPs has become an important issue [15, 19].

A polynomial f in real variables $x_1, x_2, \ldots, x_n$ of a positive degree d can have all monomials of the form $x_1^{\alpha_1} x_2^{\alpha_2} \cdots x_n^{\alpha_n}$ with nonnegative integers α_i $(i = 1, 2, \ldots, n)$ such that $\alpha_i \geq 0$ and $\sum_{i=1}^n \alpha_i \leq d$; all monomials of different form add up to $\binom{n+d}{d}$. We call such a polynomial *fully dense*. When we examine polynomials in POPs from applications, we notice in many cases that they are *sparse* polynomials having a few or some of all possible monomials as defined in [19]. The sparsity provides a computational edge if it is handled properly when deriving SDP and SOS relaxations. More precisely, taking advantage of the sparsity of POPs is essential to obtaining an optimal value of a POP by applying SDP and SOS relaxations in practice.

For sparse POPs, generalized Lagrangian duals and their SOS relaxations were proposed in [15]. The relaxations are derived using SOS polynomials for the Lagrangian multipliers with sparsity similar to that of the associated constraint poly-

nomials. Then the relaxations are converted into equivalent SDPs. As a result, the size of the resulting relaxations is reduced and computational efficiency is improved. This approach is shown to have an advantage in implementation over the SDP relaxation given in [22] whose size depends only on the degrees of objective and constraint polynomials of the POP.

The aim of this paper is to propose new practical SOS and SDP relaxations for a sparse POP and show their performance for various test problems. The framework of SOS and SDP relaxations presented here is based on the one proposed in [15]. The main idea here is that we define sparsity of a POP more precisely by finding a structure of the polynomials in the POP to obtain sparse SOS and SDP relaxations accordingly. Specifically, we introduce *correlative sparsity*, which is a special case of the sparsity [19] mentioned above; the correlative sparsity implies the sparsity, but the converse is not necessarily true. The correlative sparsity is described in terms of an $n \times n$ symmetric matrix $\boldsymbol{R}$, which we call the *correlative sparsity pattern matrix* (*csp matrix*) of the POP. Each element R_{ij} of the csp matrix $\boldsymbol{R}$ is either 0 or $\star$ representing a nonzero value. We assign $\star$ to every diagonal element R_{ii} $(i = 1, 2, \ldots, n)$, and also to each offdiagonal element $R_{ij} = R_{ji}$ $(1 \leq i < j \leq n)$ if and only if either (i) the variables x_i and x_j appear simultaneously in a term of the objective function or (ii) they appear in an inequality constraint. The csp matrix $\boldsymbol{R}$ constructed in this way represents the sparsity pattern of the Hessian matrix of the generalized Lagrangian function of [15] (or the Hessian matrix of the objective function in unconstrained cases) except for the diagonal elements; some diagonal elements of the Hessian matrix may vanish while $R_{ii} = \star$ $(i = 1, 2, \ldots, n)$ by definition. We say that the POP is *correlatively sparse* if the csp matrix $\boldsymbol{R}$ (or the Hessian matrix of the generalized Lagrangian function) is sparse.

From the csp matrix $\boldsymbol{R}$, it is natural to induce graph $G(N, E)$ with the node set $N = \{1, 2, \ldots, n\}$ and the edge set $E = \{\{i, j\} : R_{ij} = \star,\ i < j\}$ corresponding to the nonzero offdiagonal elements of $\boldsymbol{R}$. We call $G(N, E)$ the *correlative sparsity pattern graph* (*csp graph*) of the POP. We employ some results of graph theory regarding maximal cliques of chordal graphs [1]. A key idea in this paper is to use the maximal cliques of a chordal extension of the csp graph $G(N, E)$ to construct sets of supports for a sparse SOS relaxation. This idea is motivated by the recent work [5] that proposed positive semidefinite matrix completion techniques for exploiting sparsity in primal-dual interior-point methods for SDPs.

Theoretically, the proposed sparse SOS and SDP relaxations are not guaranteed to generate lower bounds of the same quality as the dense SDP relaxation [22] for general POPs. Practical experiences, however, show that the performance gap between the two relaxations is small as we will observe in section 6. In particular, the definition of a structured sparsity based on the csp matrix $\boldsymbol{R}$ and the csp graph $G(N, E)$ make it possible to achieve the same quality of lower bounds for quadratic optimization problems (QOPs) where all polynomials in the objective function and constraints are quadratic. More precisely, the proposed sparse relaxation of order 1 obtains lower bounds of the same quality as the dense SOS relaxation of order 1, as shown in section 4.5.

The remainder of the paper is organized as follows. After introducing basic notation and symbols of polynomials, we define SOS polynomials in section 2. In section 3, we first describe the dense SOS relaxation of unconstrained POPs and then the sparse SOS relaxation. We show how a csp matrix is defined from a given unconstrained POP and how a sparse SOS relaxation is constructed using the maximal cliques of a chordal extension of a csp graph induced from the csp matrix. Section 4 contains the

description of an SOS relaxation of an inequality constrained POP with a structured sparsity characterized by a csp matrix and a csp graph. We introduce a generalized Lagrangian dual for the inequality constrained POP and a sparse SOS relaxation. Section 5 discusses some additional techniques which enhance the practical performance of the sparse SOS relaxation such as computing optimal solutions, handling equality constraints, and scaling. Section 6 includes numerical results on various test problems. We show that the proposed sparse SOS and SDP relaxations exhibit much better performance in practice. Finally, we give concluding remarks in section 7.

2. Polynomials and SOS polynomials. Let $\mathbb{R}$ be the set of real numbers, and let $\mathbb{Z}_+$ be the set of nonnegative integers. $\mathbb{R}[\boldsymbol{x}]$ is the set of real-valued multivariate polynomials in x_i $(i = 1, 2, \ldots, n)$. Each polynomial $f \in \mathbb{R}[\boldsymbol{x}]$ is represented as $f(\boldsymbol{x}) = \sum_{\boldsymbol{\alpha}\in\mathcal{F}} c(\boldsymbol{\alpha})\boldsymbol{x}^{\boldsymbol{\alpha}}$, where $\mathcal{F} \subset \mathbb{Z}^n_+$ is a nonempty finite subset, $c(\boldsymbol{\alpha})$ $(\boldsymbol{\alpha} \in \mathcal{F})$ are real coefficients, and $\boldsymbol{x}^{\boldsymbol{\alpha}} = x_1^{\alpha_1}x_2^{\alpha_2}\cdots x_n^{\alpha_n}$. The *support* of f is defined by $\mathrm{supp}(f) = \{\boldsymbol{\alpha} \in \mathcal{F} : c(\boldsymbol{\alpha}) \neq 0\} \subset \mathbb{Z}^n_+$, and the *degree* of $f \in \mathbb{R}[\boldsymbol{x}]$ is defined by $\deg(f) = \max\{\sum_{i=1}^n \alpha_i : \boldsymbol{\alpha} \in \mathrm{supp}(f)\}$.

For every nonempty finite set $\mathcal{G} \subset \mathbb{Z}^n_+$, $\mathbb{R}[\boldsymbol{x}, \mathcal{G}]$ denotes the set of polynomials in x_i $(i = 1, 2, \ldots, n)$ whose support is in $\mathcal{G}$; i.e., $\mathbb{R}[\boldsymbol{x}, \mathcal{G}] = \{f \in \mathbb{R}[\boldsymbol{x}] : \mathrm{supp}(f) \subset \mathcal{G}\}$. We denote $\mathbb{R}[\boldsymbol{x}, \mathcal{G}]^2$ as the set of SOS polynomials in $\mathbb{R}[\boldsymbol{x}, \mathcal{G}]$. By construction, we see that $\mathrm{supp}(g) \subset \mathcal{G} + \mathcal{G}$ if $g \in \mathbb{R}[\boldsymbol{x}, \mathcal{G}]^2$, where $\mathcal{G} + \mathcal{G}$ denotes the Minkowski sum of two $\mathcal{G}$'s.

Let $\mathbb{R}^{\mathcal{G}}$ denote the $|\mathcal{G}|$-dimensional Euclidean space whose coordinates are indexed by $\boldsymbol{\alpha} \in \mathcal{G}$. Each vector of $\mathbb{R}^{\mathcal{G}}$ is denoted as $\boldsymbol{w} = (w_{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \mathcal{G})$. We use the symbol $\mathcal{S}(\mathcal{G})$ for the set of $|\mathcal{G}| \times |\mathcal{G}|$ symmetric matrices with coordinates $\boldsymbol{\alpha} \in \mathcal{G}$. Let $\mathcal{S}_+(\mathcal{G})$ be the set of positive semidefinite matrices in $\mathcal{S}(\mathcal{G})$; if $V \in \mathcal{S}_+(\mathcal{G})$,

$$\boldsymbol{w}^T\boldsymbol{V}\boldsymbol{w} = \sum_{\boldsymbol{\alpha}\in\mathcal{G}}\sum_{\boldsymbol{\beta}\in\mathcal{G}} V_{\boldsymbol{\alpha}\boldsymbol{\beta}}w_{\boldsymbol{\alpha}}w_{\boldsymbol{\beta}} \geq 0 \quad \text{for every } \boldsymbol{w} = (w_{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \mathcal{G}) \in \mathbb{R}^{\mathcal{G}}.$$

The symbol $\boldsymbol{u}(\boldsymbol{x}, \mathcal{G})$ is used for the $|\mathcal{G}|$-dimensional column vector consisting of elements $\boldsymbol{x}^{\boldsymbol{\alpha}}$ $(\boldsymbol{\alpha} \in \mathcal{G})$. Then, the set $\mathbb{R}[\boldsymbol{x}, \mathcal{G}]^2$ can be rewritten as

$$\mathbb{R}[\boldsymbol{x}, \mathcal{G}]^2 = \left\{\boldsymbol{u}(\boldsymbol{x}, \mathcal{G})^T\boldsymbol{V}\boldsymbol{u}(\boldsymbol{x}, \mathcal{G}) : \boldsymbol{V} \in \mathcal{S}_+(\mathcal{G})\right\}. \tag{2.1}$$

For more details, see [4, 25]. Let $N = \{1, 2, \ldots, n\}$, $\emptyset \neq C \subset N$, and

$$\mathcal{A}^C_\omega = \left\{\boldsymbol{\alpha} \in \mathbb{Z}^n_+ : \alpha_i = 0 \text{ if } i \notin C \text{ and } \sum_{i\in C}\alpha_i \leq \omega\right\}.$$

Then we observe that $\mathcal{A}^C_\omega + \mathcal{A}^C_\omega = \mathcal{A}^C_{2\omega}$ for every nonempty $C \subset N$ and $\omega \in \mathbb{Z}_+$.

3. SOS relaxations of unconstrained POPs. In this section, we consider an unconstrained POP,

$$\text{minimize } f_0(\boldsymbol{x}). \tag{3.1}$$

Let $\zeta^* = \inf\{f_0(\boldsymbol{x}) : \boldsymbol{x} \in \mathbb{R}^n\}$. Throughout this section, we assume that $\zeta^* > -\infty$. Then $\deg(f_0)$ must be an even integer, i.e., $\deg(f_0) = 2\omega_0$ for some $\omega_0 \in \mathbb{Z}_+$. By the lemma in section 3 of [29], we also know that $\mathcal{F}_0 = \mathrm{supp}(f_0) \subset \mathrm{conv}(\mathcal{F}^e_0)$, where $\mathcal{F}^e_0 = \{\boldsymbol{\alpha} \in \mathcal{F}_0 : \alpha_i \text{ is an even nonnegative integer } (i = 1, 2, \ldots, n)\}$.

3.1. An outline of sparse SOS relaxations. We first convert the POP (3.1) into an equivalent problem,

$$\text{maximize } \zeta \text{ subject to } f_0(\boldsymbol{x}) - \zeta \geq 0. \tag{3.2}$$

We fix a positive integer $\omega \geq \omega_0$, and replace the constraint of the problem (3.2) by an SOS constraint to obtain

$$\text{maximize } \zeta \text{ subject to } f_0(\boldsymbol{x}) - \zeta \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^N]^2. \tag{3.3}$$

The SOS optimization problem (3.3) serves as a relaxation of the POP (3.1). See [26] and the references therein for more details of this relaxation. We can rewrite the SOS constraint of (3.2) using the relation (2.1) as

$$f_0(\boldsymbol{x}) - \zeta = \boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^N)^T \boldsymbol{V} \boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^N) \quad \text{and} \quad \boldsymbol{V} \in \mathcal{S}_+(\mathcal{A}_\omega^N). \tag{3.4}$$

We call the parameter $\omega \in \mathbb{Z}_+$ in (3.3) the *(relaxation) order*. In fact, we can fix $\omega = \omega_0$ in the unconstrained case. Nevertheless, we regard ω as a parameter to be consistent with the notation of the constrained case.

We call a polynomial $f_0 \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{2\omega}^N]$ *sparse* if the number of elements in its support $\mathcal{F}_0 = \text{supp}(f_0)$ is much smaller than the number of elements in $\mathcal{A}_{2\omega}^N$ that forms a support of fully dense polynomials in $\mathbb{R}[\boldsymbol{x}, \mathcal{A}_{2\omega}^N]$. When the objective function f_0 is a sparse polynomial in $\mathbb{R}[\boldsymbol{x}, \mathcal{A}_{2\omega}^N]$, the size of the SOS constraint (3.3) can be reduced by eliminating redundant elements from $\mathcal{A}_\omega^N$. In fact, by applying Theorem 1 of [29], $\mathcal{A}_\omega^N$ in problem (3.3) can be replaced by

$$\mathcal{G}_0^0 = \text{conv}\left\{\frac{\boldsymbol{\alpha}}{2} : \boldsymbol{\alpha} \in \mathcal{F}_0^e \bigcup \{\boldsymbol{0}\}\right\} \cap \mathbb{Z}_+^n \subset \mathcal{A}_\omega^N.$$

Note that $\{\boldsymbol{0}\}$ is added as the support for the real number variable ζ.

A method that can further reduce the size of the SOS optimization problem by eliminating redundant elements in $\mathcal{G}_0^0$ was proposed by Kojima, Kim, and Waki in [19]. We write the resulting SOS constraint from their method as

$$f_0(\boldsymbol{x}) - \zeta \in \mathbb{R}[\boldsymbol{x}, \mathcal{G}_0^*]^2, \tag{3.5}$$

where $\mathcal{G}_0^* \subset \mathcal{G}_0^0 \subset \mathcal{A}_\omega^N$ denotes the set obtained by applying the method.

We now outline a new sparse relaxation. Using the structure obtained from the correlative sparsity, we generate multiple support sets $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_p \subset \mathbb{Z}_+^n$ such that

$$\mathcal{F}_0 \bigcup \{\boldsymbol{0}\} \subset \bigcup_{\ell=1}^p (\mathcal{G}_\ell + \mathcal{G}_\ell), \tag{3.6}$$

and replace the SOS constraint (3.5) by

$$f_0(\boldsymbol{x}) - \zeta \in \sum_{\ell=1}^p \mathbb{R}[\boldsymbol{x}, \mathcal{G}_\ell]^2, \tag{3.7}$$

where $\sum_{\ell=1}^p \mathbb{R}[\boldsymbol{x}, \mathcal{G}_\ell]^2 = \left\{\sum_{\ell=1}^p h_\ell : h_\ell \in \mathbb{R}[\boldsymbol{x}, \mathcal{G}_\ell]^2 \ (\ell = 1, 2, \ldots, p)\right\}$. The support of $f_0(\boldsymbol{x}) - \zeta$ is $\mathcal{F}_0 \bigcup \{\boldsymbol{0}\}$, while the support of each polynomial in $\sum_{\ell=1}^p \mathbb{R}[\boldsymbol{x}, \mathcal{G}_\ell]^2$ is contained in $\bigcup_{\ell=1}^p (\mathcal{G}_\ell + \mathcal{G}_\ell)$. Hence (3.6) is necessary for the SOS constraint (3.7) to be feasible although it is not sufficient. If the size of each $\mathcal{G}_\ell$ is much smaller than the size of $\mathcal{G}_0^*$ and if the number of the support sets p is not large, the size of the SOS constraint (3.7) is smaller than the size of the SOS constraint of (3.3).

3.2. Correlative sparsity pattern matrix. The sparsity considered here is measured by the number of different kinds of cross terms in the objective polynomial f_0. We will call this type of sparsity *correlative sparsity*. The correlative sparsity is represented with the $n \times n$ (symbolic, symmetric) *correlative sparsity pattern matrix* (abbreviated as *csp matrix*) $\boldsymbol{R}$ whose (i,j)th element R_{ij} is given by

$$R_{ij} = \begin{cases} \star & \text{if } i = j, \\ \star & \text{if } \alpha_i \geq 1 \ \text{ and } \alpha_j \geq 1 \ \text{ for some } \boldsymbol{\alpha} \in \mathcal{F}_0 = \mathrm{supp}(f_0), \\ 0 & \text{otherwise} \end{cases}$$

$(i = 1, 2, \ldots, n, \ j = 1, 2, \ldots, n)$. Here $\star$ stands for some nonzero element. If the csp matrix $\boldsymbol{R}$ of f_0 is sparse, then f_0 is sparse as defined in [19], but the converse is not true. We say that f_0 is *correlatively sparse* if the associated csp matrix is sparse. As mentioned in the introduction, the correlative sparsity of an objective function $f_0(\boldsymbol{x})$ is equivalent to the sparsity of its Hessian matrix with some additional nonzero diagonal elements.

3.3. Correlative sparsity pattern graphs. We describe a method to determine the sets of supports $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_p$ for the target SOS relaxation (3.7) of the unconstrained POP (3.1). The basic idea is to use the structure of the csp matrix $\boldsymbol{R}$ and some results from graph theory.

Given a csp matrix $\boldsymbol{R}$, the undirected graph $G(N,E)$ with $N = \{1, 2, \ldots, n\}$ and $E = \{\{i,j\} : i,j \in N, \ i < j, \ R_{ij} = \star\}$ is called the *correlative sparsity pattern graph* (abbreviated as *csp graph*). Let $C_1, C_2, \ldots, C_p \subset N$ denote the maximal cliques of the csp graph $G(N,E)$. Then, choose the sets of supports $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_p$ such that $\mathcal{G}_\ell = \mathcal{A}_\omega^{C_\ell}$ $(\ell = 1, 2, \ldots, p)$. We can easily verify that the relation (3.6) holds. However, the method described above for choosing $\mathcal{G}_1, \mathcal{G}_2, \ldots, \mathcal{G}_p$ has a critical disadvantage since finding all maximal cliques of a graph is a difficult problem in general. In fact, finding a single maximum clique is an NP-hard problem. To resolve this difficulty, we generate a chordal extension $G(N,E')$ of the csp graph $G(N,E)$ and use the extended csp graph $G(N,E')$ instead of $G(N,E)$. See [1, 7] for chordal graphs and finding all maximal cliques.

Consequently, we obtain a sparse SOS relaxation of the POP (3.1):

$$\text{maximize} \quad \zeta \quad \text{subject to} \quad f_0(\boldsymbol{x}) - \zeta \in \sum_{\ell=1}^{p} \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell}]^2, \tag{3.8}$$

where C_ℓ $(\ell = 1, 2, \ldots, p)$ denote the maximal cliques of a chordal extension $G(N,E')$ of the csp graph $G(N,E)$.

There may be several different chordal extensions of a graph $G(N,E)$, and any of them is valid for deriving the sparse relaxation presented in this paper. The chordal extension with the least number of edges, called the minimum chordal extension, serves best for the resulting sparse relaxation. We remark that finding a chordal extension of a graph is equivalent to calculating symbolic sparse Cholesky factorization of its adjacency matrix; the resulting sparse matrix represents the chordal extension. The minimum chordal extension corresponds to the sparse Cholesky factorization with the minimum fill-ins. Finding the minimum chordal extension is difficult in general, but fortunately, several heuristics, such as the minimum degree ordering, are known to efficiently produce a good approximation. For more information on symbolic Cholesky factorization with minimum degree ordering and a chordal extension, see [6].

It should be noted that the number of the maximal cliques of $G(N, E')$ does not exceed n, which is equivalent to the number of nodes of the graph $G(N, E')$ as well as to the number of variables of the objective polynomial f_0.

Let us consider a few typical examples. Suppose that the objective polynomial function $f_0 \in \mathbb{R}[\boldsymbol{x}]_{2\omega}$ of the unconstrained POP (3.1) is a separable polynomial of the form $f_0(\boldsymbol{x}) = \sum_{i=1}^{n} h_i(x_i)$, where each $h_i(x_i)$ denotes a polynomial in a single variable $x_i \in \mathbb{R}$ with $\deg(h_i(x_i)) = 2\omega$. In this case, the csp matrix $\boldsymbol{R}$ becomes an $n \times n$ diagonal matrix so that $C_i = \{i\}$ $(i = 1, 2, \ldots, n)$. Hence we take $\mathcal{G}_\ell = \{\rho \boldsymbol{e}^\ell : \rho = 0, 1, 2, \ldots, \omega\}$ $(\ell = 1, 2, \ldots, n)$ in the sparse SOS relaxation (3.8). Here $\boldsymbol{e}^\ell \in \mathbb{R}^n$ denotes the ℓth unit vector with 1 at the ℓth coordinate and 0 elsewhere. The resulting SOS optimization problem inherits the separability from the separable polynomial objective function f_0, and is subdivided into n independent subproblems; each subproblem forms an SOS relaxation of the corresponding subproblem of the POP (3.1), minimizing $h_\ell(x_\ell)$ in a single variable. We remark here that if we directly apply the sparse SOS relaxation proposed in [19], we obtain the dense relaxation of the form (3.3). Therefore, this case shows a critical difference between the sparse SOS relaxation proposed in this paper and the one given in [19]. See Proposition 5.1 of [19] for more details.

Suppose that $f_0(\boldsymbol{x}) = \sum_{i=1}^{n-1}(a_i x_i^4 + b_i x_i^2 x_{i+1} + c_i x_i x_{i+1})$, where $a_i,\ b_i$, and c_i are nonzero real numbers $(i = 1, 2, \ldots, n-1)$. Then, the csp matrix turns out to be the $n \times n$ tridiagonal matrix which induces in fact a chordal graph; hence there is no need to extend. In this case, the maximal cliques of the chordal graph are $C_\ell = \{\ell,\ \ell+1\}$ $(\ell = 1, 2, \ldots, n-1)$.

For another example, let us consider $f_0(\boldsymbol{x}) = \sum_{i=1}^{n-1}(a_i x_i^4 + b_i x_i^2 x_n + c_i x_i x_n)$, where $a_i,\ b_i$, and c_i are nonzero real numbers $(i = 1, 2, \ldots, n-1)$. In this case, we have the csp matrix

$$\boldsymbol{R} = \begin{pmatrix} \star & 0 & \ldots & 0 & \star \\ 0 & \star & & 0 & \star \\ \vdots & & \ddots & & \vdots \\ 0 & 0 & \ldots & \star & \star \\ \star & \star & \ldots & \star & \star \end{pmatrix},$$

which gives a chordal graph with the maximal cliques $C_\ell = \{\ell,\ n\}$ $(\ell = 1, 2, \ldots, n-1)$.

4. SOS relaxations of inequality constrained POPs. Let $f_k \in \mathbb{R}[\boldsymbol{x}]$ $(k = 0, 1, 2, \ldots, m)$. Consider the following POP:

$$\text{(4.1)} \qquad \text{minimize} \quad f_0(\boldsymbol{x}) \quad \text{subject to} \quad f_k(\boldsymbol{x}) \geq 0 \ (k = 1, 2, \ldots, m).$$

Let $\zeta^* = \inf\{f_0(\boldsymbol{x}) : f_k(\boldsymbol{x}) \geq 0 \ (k = 1, 2, \ldots, m)\}$. With the correlative sparsity of the POP (4.1), we determine the generalized Lagrangian function with the same sparsity and proper sets of supports in an SOS relaxation. A sparse SOS relaxation is proposed in two steps. In the first step, we convert the POP (4.1) into an unconstrained minimization of the generalized Lagrangian function according to [15]. In the second step, we apply the sparse SOS relaxation given in the previous section for unconstrained POPs to the resulting minimization problem. A key point of utilizing the correlative sparsity of the POP (4.1) is that the POP (4.1) and its generalized Lagrangian function have the same correlative sparsity.

4.1. Correlative sparsity in inequality constrained POPs. Let $F_k = \{i : \alpha_i \geq 1 \text{ for some } \boldsymbol{\alpha} \in \mathrm{supp}(f_k)\}$ $(k = 1, 2, \ldots, m)$. Each F_k is regarded as the index set of variables x_i of the polynomial f_k. For example, if $n = 4$ and $f_k(\boldsymbol{x}) = x_1^3 + 3x_1x_4 - 2x_4^2$, then $F_k = \{1, 4\}$. Define the $n \times n$ (symbolic, symmetric) csp matrix $\boldsymbol{R}$ such that

$$R_{ij} = \begin{cases} \star & \text{if } i = j, \\ \star & \text{if } \alpha_i \geq 1 \text{ and } \alpha_j \geq 1 \text{ for some } \boldsymbol{\alpha} \in \mathrm{supp}(f_0), \\ \star & \text{if } i \in F_k \text{ and } j \in F_k \text{ for some } k \in \{1, 2, \ldots, m\}, \\ 0 & \text{otherwise.} \end{cases}$$

When the csp matrix $\boldsymbol{R}$ is sparse, we say that the POP (4.1) is correlatively sparse.

4.2. Generalized Lagrangian duals. The generalized Lagrangian function [15] is defined as

$$L(\boldsymbol{x}, \boldsymbol{\varphi}) = f_0(\boldsymbol{x}) - \sum_{k=1}^{m} \varphi_k(\boldsymbol{x}) f_k(\boldsymbol{x}),$$

where $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{\varphi} = (\varphi_1, \varphi_2, \ldots, \varphi_m) \in \Phi$, and

$$\Phi = \left\{ \boldsymbol{\varphi} = (\varphi_1, \varphi_2, \ldots, \varphi_m) : \begin{array}{l} \varphi_k \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^N]^2 \text{ for some } \omega \in \mathbb{Z}_+ \\ (k = 1, 2, \ldots, m) \end{array} \right\}.$$

Then, for each fixed $\boldsymbol{\varphi} \in \Phi$, the problem of minimizing $L(\boldsymbol{x}, \boldsymbol{\varphi})$ over $\boldsymbol{x} \in \mathbb{R}^n$ serves as a Lagrangian relaxation problem; its optimal value, $L^*(\boldsymbol{\varphi}) = \inf\{L(\boldsymbol{x}, \boldsymbol{\varphi}) : \boldsymbol{x} \in \mathbb{R}^n\}$, bounds the optimal value ζ^* of the POP (4.1) from below.

If our aim is to preserve the correlative sparsity of the POP (4.1) in the resulting SOS relaxation, we need to have the Lagrangian function L that inherits the correlative sparsity from the POP (4.1). Notice that $\boldsymbol{\varphi}$ can be chosen for this purpose. In [15], Kim, Kojima, and Waki proposed choosing a polynomial of the same variables as the variables x_i $(i \in F_k)$ in the polynomial f_k for each multiplier polynomial φ_k, i.e., $\mathrm{supp}(\varphi_k) \subset \{\boldsymbol{\alpha} \in \mathbb{Z}_+^n : \alpha_i = 0 \ (i \notin F_k)\}$. Let $\omega_k = \lceil \deg(f_k)/2 \rceil$ $(k = 0, 1, 2, \ldots, m)$ and $\omega_{\max} = \max\{\omega_k : k = 0, 1, \ldots, m\}$. For every nonnegative integer $\omega \geq \omega_{\max}$, define

$$\Phi_\omega = \left\{ \boldsymbol{\varphi} = (\varphi_1, \varphi_2, \ldots, \varphi_m) : \varphi_k \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{\omega-\omega_k}^{F_k}]^2 \ (k = 1, 2, \ldots, m) \right\}.$$

Here the parameter $\omega \in \mathbb{Z}_+$ serves as the (relaxation) order of the SOS relaxation of the POP (4.1) that is derived in the next subsection. Then a generalized Lagrangian dual (with the Lagrangian multiplier $\boldsymbol{\varphi}$ restricted to Φ_ω) [15] is defined as

$$\text{maximize} \quad \zeta \quad \text{subject to} \quad L(\boldsymbol{x}, \boldsymbol{\varphi}) - \zeta \geq 0 \text{ and } \boldsymbol{\varphi} \in \Phi_\omega. \tag{4.2}$$

Let L_ω^* denote the optimal value of this problem: $L_\omega^* = \sup\{L^*(\boldsymbol{\varphi}) : \boldsymbol{\varphi} \in \Phi_\omega\}$. Then $L_\omega^* \leq \zeta^*$. If the POP (4.1) includes the box inequality constraint of the form $\rho - x_i^2 \geq 0$ $(i = 1, 2, \ldots, n)$ for some $\rho > 0$, we know by Theorem 3.1 of [15] that L_ω^* converges to ζ^* as $\omega \to \infty$.

4.3. Sparse SOS relaxations. We show how a sparse SOS relaxation is formulated using the sets of supports constructed from the csp matrix $\boldsymbol{R}$. Let $\omega \geq \omega_{\max}$ be fixed. Suppose that $\boldsymbol{\varphi} \in \Phi_\omega$. Then $L(\cdot, \boldsymbol{\varphi})$ forms a polynomial in x_i $(i = 1, 2, \ldots, n)$

with $\deg(L(\cdot,\boldsymbol{\varphi})) = 2\omega$. We also observe from the construction of the csp matrix $\boldsymbol{R}$ and Φ_ω that the polynomial $L(\cdot,\boldsymbol{\varphi})$ has the same csp matrix as the csp matrix $\boldsymbol{R}$ constructed for the POP (4.1). As in section 3.4, the csp matrix $\boldsymbol{R}$ induces the csp graph $G(N,E)$. By construction, we know that each F_k forms a clique of the csp graph $G(N,E)$. Let $C_1, C_2, \ldots, C_p$ be the maximal cliques of a chordal extension $G(N,E')$ of $G(N,E)$. Then, a sparse SOS relaxation of the POP (4.1) is written as

$$\text{(4.3)} \qquad \text{maximize} \quad \zeta \quad \text{subject to} \quad L(\boldsymbol{x},\boldsymbol{\varphi}) - \zeta \in \sum_{\ell=1}^{p} \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell}]^2 \ \text{ and } \boldsymbol{\varphi} \in \Phi_\omega.$$

Let ζ_ω denote the optimal objective value of this SOS optimization problem. Then $\zeta_\omega \le L_\omega^* \le \zeta^*$ for every $\omega \ge \omega_{\max}$, but the convergence of ζ_ω to ζ^* as $\omega \to \infty$ is not guaranteed in theory.

The above idea of the SOS relaxation of the constrained POP (4.1) using the generalized Lagrangian function stems from Putinar's lemma [28] and was first used in [22]. In fact, if we replace every index subset F_k of N $(k = 1, 2, \ldots, m)$ by the entire index set N and if we take $p = 1$ and $C_1 = N$, then the resulting SOS relaxation (4.3) of the POP (4.1) essentially coincides with the dense SOS relaxation (4.10) of Lasserre [22], and in this case, it was shown in [22] that $\zeta_\omega \to \zeta^*$ as $\omega \to \infty$ under moderate assumptions.

4.4. Primal approach. We have formulated a sparse SOS relaxation (4.3) of the inequality constrained POP (4.1) in the previous subsection. For numerical computation, we convert the SOS optimization problem (4.3) into an SDP, which serves as an SDP relaxation of the POP (4.1). We may regard this way of deriving an SDP relaxation from the POP (4.1) as the dual approach. We briefly mention below the so-called primal approach to the POP (4.1) whose sparsity is characterized by the csp matrix $\boldsymbol{R}$ and the csp graph $G(N,E)$. We use the same symbols and notation as in section 4.3. Let $\omega \ge \omega_{\max}$. To derive a primal SDP relaxation, we first transform the POP (4.1) into an equivalent polynomial SDP,

$$\text{(4.4)} \qquad \left.\begin{array}{ll} \text{minimize} & f_0(\boldsymbol{x}) \\ \text{subject to} & \boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_{\omega-\omega_k}^{F_k})\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_{\omega-\omega_k}^{F_k})^T f_k(\boldsymbol{x}) \in \mathcal{S}_+(\mathcal{A}_{\omega-\omega_k}^{F_k}) \\ & (k = 1, 2, \ldots, m), \\ & \boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell})\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell})^T \in \mathcal{S}_+(\mathcal{A}_\omega^{C_\ell}) \ (\ell = 1, 2, \ldots, p). \end{array}\right\}$$

The matrices $\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_{\omega-\omega_k}^{F_k})\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_{\omega-\omega_k}^{F_k})^T$ $(k = 1, 2, \ldots, m)$ and $\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell})\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell})^T$ $(\ell = 1, 2, \ldots, p)$ are positive semidefinite symmetric matrices of rank 1 for any $\boldsymbol{x} \in \mathbb{R}^n$, and have 1 as a diagonal element. These facts ensure the equivalence between the POP (4.1) and the polynomial SDP above. Let

$$\begin{aligned}
\widetilde{\mathcal{F}} &= \left(\bigcup_{\ell=1}^{p} \mathcal{A}_\omega^{C_\ell} \right) \setminus \{\boldsymbol{0}\}, \\
\widetilde{\mathcal{S}} &= \mathcal{S}(\mathcal{A}_{\omega-\omega_1}^{F_1}) \times \cdots \times \mathcal{S}(\mathcal{A}_{\omega-\omega_m}^{F_m}) \times \mathcal{S}(\mathcal{A}_\omega^{C_1}) \times \cdots \times \mathcal{S}(\mathcal{A}_\omega^{C_p}) \\
&\quad \text{(the set of block diagonal matrices of matrices in } \mathcal{S}(\mathcal{A}_{\omega-\omega_k}^{F_k}) \\
&\quad\ (k = 1, \ldots, m) \text{ and } \mathcal{S}(\mathcal{A}_\omega^{C_\ell}) \ (\ell = 1, \ldots, p) \text{ on their diagonal blocks)}, \\
\widetilde{\mathcal{S}}_+ &= \{\boldsymbol{M} \in \widetilde{\mathcal{S}} : \text{positive semidefinite}\}.
\end{aligned}$$

Then we can rewrite the polynomial SDP above as

$$\text{minimize} \quad \sum_{\boldsymbol{\alpha}\in\widetilde{\mathcal{F}}} \tilde{c}_0(\boldsymbol{\alpha})\boldsymbol{x}^{\boldsymbol{\alpha}} \quad \text{subject to} \quad \boldsymbol{M}(\boldsymbol{0}) + \sum_{\boldsymbol{\alpha}\in\widetilde{\mathcal{F}}} \boldsymbol{M}(\boldsymbol{\alpha})\boldsymbol{x}^{\boldsymbol{\alpha}} \in \widetilde{\mathcal{S}}_+$$

for some $\tilde{c}_0(\boldsymbol{\alpha}) \in \mathbb{R}$ ($\boldsymbol{\alpha} \in \widetilde{\mathcal{F}}$), $\boldsymbol{M}(\boldsymbol{0}) \in \widetilde{\mathcal{S}}$, and $\boldsymbol{M}(\boldsymbol{\alpha}) \in \widetilde{\mathcal{S}}$ ($\boldsymbol{\alpha} \in \widetilde{\mathcal{F}}$). Now, replacing each monomial $\boldsymbol{x}^{\boldsymbol{\alpha}}$ by a single real variable $y_{\boldsymbol{\alpha}}$, we have an SDP relaxation problem of (4.1):

$$\text{minimize} \quad \sum_{\boldsymbol{\alpha}\in\widetilde{\mathcal{F}}} \tilde{c}_0(\boldsymbol{\alpha})y_{\boldsymbol{\alpha}} \quad \text{subject to} \quad \boldsymbol{M}(\boldsymbol{0}) + \sum_{\boldsymbol{\alpha}\in\widetilde{\mathcal{F}}} \boldsymbol{M}(\boldsymbol{\alpha})y_{\boldsymbol{\alpha}} \in \widetilde{\mathcal{S}}_+. \tag{4.5}$$

We denote the optimal objective value by $\hat{\zeta}_\omega$.

The primal approach described in this section is based on the moment formulation proposed by [22], which is the dual to the SOS relaxation of the constrained POP (4.1). More precisely, if we replace every index subset F_k of N ($k = 1, 2, \ldots, m$) by the entire index set N and if we take $p = 1$ and $C_1 = N$, then we have the SDP relaxation of the POP (4.1) which corresponds to the SDP (4.6) of Lasserre [22]. In this case, the linearization of the matrix $\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}^N_\omega)\boldsymbol{u}(\boldsymbol{x}, \mathcal{A}^N_\omega)^T$ forms the moment matrix $M_\omega(y)$ of the SDP (4.5) of Lasserre [22].

4.5. SOS and SDP relaxations of quadratic optimization problems with order 1. Consider a QOP

$$\left.\begin{array}{ll} \text{minimize} & \boldsymbol{x}^T\boldsymbol{Q}_0\boldsymbol{x} + 2\boldsymbol{q}_0^T\boldsymbol{x} \\ \text{subject to} & \boldsymbol{x}^T\boldsymbol{Q}_k\boldsymbol{x} + 2\boldsymbol{q}_k^T\boldsymbol{x} + \gamma_k \geq 0 \ (k = 1, 2, \ldots, m). \end{array}\right\} \tag{4.6}$$

Here $\boldsymbol{Q}_k$ denotes an $n \times n$ symmetric matrix, $\boldsymbol{q}_k \in \mathbb{R}^n$, and $\gamma_k \in \mathbb{R}$. In this case, we show that the proposed sparse SOS relaxation (4.3) of order $\omega = 1$ using any chordal extension of the csp graph $G(N, E)$ attains the same optimal value as the dense SOS relaxation [22] of order $\omega = 1$. This demonstrates an advantage of using the set of maximal cliques of a chordal extension of the csp graph $G(N, E)$ instead of the set of maximal cliques of $G(N, E)$ itself.

We formulate the dense [22] and sparse relaxations of order $\omega = 1$ using SOS polynomials from the dual side. Consider the Lagrangian dual of (4.6):

$$\text{maximize} \quad \zeta \quad \text{subject to} \quad L(\boldsymbol{x}, \boldsymbol{\varphi}) - \zeta \geq 0 \ (\forall \boldsymbol{x} \in \mathbb{R}^n) \ \text{ and } \boldsymbol{\varphi} \in \mathbb{R}^m_+, \tag{4.7}$$

where L denotes the Lagrangian function such that

$$L(\boldsymbol{x}, \boldsymbol{\varphi}) = \boldsymbol{x}^T \left(\boldsymbol{Q}_0 - \sum_{k=1}^m \varphi_k \boldsymbol{Q}_k\right)\boldsymbol{x} + 2\left(\boldsymbol{q}_0 - \sum_{k=1}^m \varphi_k \boldsymbol{q}_k\right)^T \boldsymbol{x} - \sum_{k=1}^m \varphi_k\gamma_k.$$

Then we replace the constraint $L(\boldsymbol{x}, \boldsymbol{\varphi}) - \zeta \geq 0$ ($\forall \boldsymbol{x} \in \mathbb{R}^n$) by an SOS condition $L(\boldsymbol{x}, \boldsymbol{\varphi}) - \zeta \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}^N_1]^2$ to obtain the dense relaxation [22] of order $\omega = 1$,

$$\text{maximize} \quad \zeta \quad \text{subject to} \quad L(\boldsymbol{x}, \boldsymbol{\varphi}) - \zeta \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}^N_1]^2 \ \text{ and } \boldsymbol{\varphi} \in \mathbb{R}^m_+. \tag{4.8}$$

Now consider the aggregated sparsity pattern matrix $\tilde{\boldsymbol{R}}$ over the coefficient matrices $\boldsymbol{Q}_0, \boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_m$ such that

$$\tilde{R}_{ij} = \begin{cases} \star & \text{if } i = j, \\ \star & \text{if } i \neq j \text{ and } [Q_k]_{ij} \neq 0 \ \text{ for some } k \in \{0, 1, 2, \ldots, m\}, \\ 0 & \text{otherwise,} \end{cases}$$

which coincides with the csp matrix of the Lagrangian function $L(\cdot,\boldsymbol{\varphi})$ with $\boldsymbol{\varphi} \in \mathbb{R}^m_+$. Let $G(N,E')$ be a chordal extension of the csp graph $G(N,E)$ from $\tilde{\boldsymbol{R}}$, and let C_ℓ $(\ell = 1,2,\ldots,p)$ be the maximal cliques of $G(N,E')$. Then we can apply the sparse relaxation (3.8) to the unconstrained minimization of the Lagrangian function $L(\cdot,\boldsymbol{\varphi})$ with $\boldsymbol{\varphi} \in \mathbb{R}^m_+$. Thus, replacing $\mathbb{R}[\boldsymbol{x},\mathcal{A}_1^N]^2$ in the dense SOS relaxation (4.8) by $\sum_{\ell=1}^p \mathbb{R}[\boldsymbol{x},\mathcal{A}_1^{C_\ell}]^2$, we obtain the sparse SOS relaxation

$$\left.\begin{array}{ll} \text{maximize} & \zeta \\ \text{subject to} & L(\boldsymbol{x},\boldsymbol{\varphi}) - \zeta \in \displaystyle\sum_{\ell=1}^{p} \mathbb{R}[\boldsymbol{x},\mathcal{A}_1^{C_\ell}]^2 \ \text{ and } \boldsymbol{\varphi} \in \mathbb{R}^m_+. \end{array}\right\} \tag{4.9}$$

Note that $L(\cdot,\boldsymbol{\varphi})$ is a quadratic function in $\boldsymbol{x} \in \mathbb{R}^n$ which results in the same csp graph $G(N,E)$ for each $\boldsymbol{\varphi} \in \mathbb{R}^m_+$, and that C_ℓ $(\ell = 1,2,\ldots,p)$ are the maximal cliques of a chordal extension $G(N,E')$ of the csp graph $G(N,E)$. Hence, if φ is chosen so that the Hessian matrix $\nabla_{xx}L(\boldsymbol{x},\varphi)$ of $L(\boldsymbol{x},\varphi)$ is positive semidefinite, $\nabla_{xx}L(\boldsymbol{x},\varphi)$ can be factorized using a Cholesky factorization such that $\nabla_{xx}L(\boldsymbol{x},\varphi) = \boldsymbol{M}\boldsymbol{M}^T$ for some $n \times n$ matrix $\boldsymbol{M}$ with the property $\{i \in N : M_{ij} \neq 0\} \subset C'_j$ for some maximal clique C'_j of $G(N,E')$ $(j = 1,2,\ldots,n)$. If in addition $L(\boldsymbol{x},\boldsymbol{\varphi}) - \zeta$ is an SOS polynomial or the constraint of the dense relaxation (4.8) is satisfied, then $L(\boldsymbol{x},\boldsymbol{\varphi}) - \zeta$ is represented as

$$L(\boldsymbol{x},\boldsymbol{\varphi}) - \zeta = (1,\boldsymbol{x}^T)\widetilde{\boldsymbol{M}}\widetilde{\boldsymbol{M}}^T \begin{pmatrix} 1 \\ \boldsymbol{x} \end{pmatrix} = \sum_{\ell=1}^{n} \left(\widetilde{\boldsymbol{M}}_{\cdot\ell+1}^T \begin{pmatrix} 1 \\ \boldsymbol{x} \end{pmatrix} \right)^2 + \alpha^2$$

for some $\alpha \geq 0$ and some $(1+n) \times (1+n)$ matrix $\widetilde{\boldsymbol{M}}$ of the form

$$\widetilde{\boldsymbol{M}} = \begin{pmatrix} \alpha & \boldsymbol{b} \\ \boldsymbol{0} & \boldsymbol{M} \end{pmatrix}.$$

Here $\widetilde{\boldsymbol{M}}_{\cdot\ell+1}$ denotes the $(\ell+1)$st column of $\widetilde{\boldsymbol{M}}$. It should be noted that each $\widetilde{\boldsymbol{M}}_{\cdot\ell+1}^T \binom{1}{\boldsymbol{x}}$ is an affine function whose support is contained in

$$\mathcal{A}_1^{C'_\ell} = \left\{ \boldsymbol{\alpha} \in \mathbb{Z}^n_+ : \alpha_i = 0 \ (i \notin C'_\ell) \right\}$$

as a polynomial. Therefore we have shown that the dense SOS relaxation (4.8) with order $\omega = 1$ is equivalent to the sparse SOS relaxation (4.9) with order $\omega = 1$.

5. Some technical issues.

5.1. Computing optimal solutions. Henrion and Lasserre [10] presented a linear algebra method that computes multiple optimal solutions of the POP (4.1). The moment matrix of full size induced from $\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^N)\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^N)^T$ plays an essential role in their method. In the proposed sparse relaxation, however, the moment matrix of full size is not available; instead multiple but partial moment matrices from $\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^{C_\ell})\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^{C_\ell})^T$ $(\ell = 1,2,\ldots,p)$, where the monomials in variables x_i $(i \in C_\ell)$ with degree up to ω are taken for the elements of the column vector $\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^{C_\ell})$, are generated. As mentioned in the previous sections, we further apply the method [19] that eliminates redundant monomials from $\boldsymbol{u}(\boldsymbol{x},\mathcal{A}_\omega^{C_\ell})$ to reduce the size of the partial moment matrices. Because of these reasons, it is difficult to utilize the linear algebra method in the sparse relaxation.

We present a different technique. The basic idea is to perturb the POP (4.1) so that the projection of optimal solutions of the resulting primal SDP relaxation (4.5) onto the space of the variables x_i $(i = 1, 2, \ldots, n)$ consists of a unique point, which is the unique optimal solution of the perturbed POP. This technique is originally proposed in section 6.7 of [9]. We may assume without loss of generality that the objective polynomial function f_0 of the POP (4.1) is linear; if f_0 is not linear, we may replace $f_0(\boldsymbol{x})$ by a new variable x_0 and add the inequality constraint $f_0(\boldsymbol{x}) \leq x_0$.

We consider

$$\text{minimize } f_0(\boldsymbol{x}) + \boldsymbol{p}^T\boldsymbol{x} \text{ subject to } f_k(\boldsymbol{x}) \geq 0 \ (k = 1, 2, \ldots, m). \tag{5.1}$$

Here $\boldsymbol{p} \in \mathbb{R}^n$ denotes a perturbation vector. We then focus on the primal SDP relaxation of the perturbed POP (5.1), which can be described as the problem of minimizing $f_0(y_{e^1}, y_{e^2}, \ldots, y_{e^n}) + \sum_{i=1}^n p_i y_{e^i}$ subject to the constraint of the SDP (4.5). Define

$$\widetilde{D} = \{(y_{\boldsymbol{e}^1}, y_{\boldsymbol{e}^2}, \ldots, y_{\boldsymbol{e}^n}) \in \mathbb{R}^n : (y_{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \widetilde{\mathcal{F}}) \text{ is a feasible solution of (4.5)}\}.$$

Note that $\widetilde{D}$ is a convex subset of $\mathbb{R}^n$. Then the primal SDP relaxation of the perturbed POP (5.1) is equivalent to the convex program

$$\text{minimize } f_0(\boldsymbol{x}) + \boldsymbol{p}^T\boldsymbol{x} \text{ subject to } \boldsymbol{x} \in \widetilde{D}, \tag{5.2}$$

which may be regarded as the projection of the primal SDP relaxation of the perturbed POP (5.1) onto the space of the variables of (5.1). Now we assume a certain weak stability for the optimal solution set of the convex program (5.2): there exist $\epsilon > 0$ and $\rho > 0$ such that the optimal solution set of the convex program (5.2) is nonempty and is contained in the ball $B(\rho) = \{\boldsymbol{x} \in \mathbb{R}^n : \|\boldsymbol{x}\| \leq \rho\}$ for any perturbation with $\|\boldsymbol{p}\| \leq \epsilon$. In this case, we can replace the feasible region $\widetilde{D}$ of the convex program (5.2) by $\widetilde{D} \cap B(\rho)$. Now $\widetilde{D} \cap B(\rho)$ is convex and bounded. Hence, the convex program (5.2) has a unique solution for almost every $\boldsymbol{p}$ with $\|\boldsymbol{p}\| \leq \epsilon$ by Theorem 2.2.9 of [30].

Consequently, under the assumption on its optimal solution set, the convex program (5.2) has a unique optimal solution for almost every small $\boldsymbol{p}$. Suppose that

(a) $\boldsymbol{p}$ is sufficiently small;
(b) the convex program (5.2) has a unique optimal solution $\hat{\boldsymbol{x}}$; this means that $\hat{\boldsymbol{x}} = (\hat{y}_{e^1}, \hat{y}_{e^2}, \ldots, \hat{y}_{e^n})^T$ is obtained from any optimal solution $(\hat{y}_{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \widetilde{\mathcal{F}})$ of the primal SDP relaxation of the perturbed POP (5.1);
(c) the optimal value of the primal SDP relaxation of (5.1) coincides with the value $f_0(\hat{\boldsymbol{x}}) + \boldsymbol{p}^T\hat{\boldsymbol{x}}$; when f_0 is linear, this condition always holds;
(d) $\hat{\boldsymbol{x}}$ is a feasible solution of the perturbed POP (5.1).

Then $\hat{\boldsymbol{x}}$ is an optimal solution of the perturbed POP (5.1), which may be regarded as an approximate optimal solution of the original POP (4.1).

5.2. Equality constraints. Consider the POP

$$\left.\begin{array}{ll} \text{minimize} & f_0(\boldsymbol{x}) \\ \text{subject to} & f_k(\boldsymbol{x}) \geq 0 \ (k = 1, 2, \ldots, m), \ h_j(\boldsymbol{x}) = 0 \ (j = 1, 2, \ldots, q). \end{array}\right\} \tag{5.3}$$

Here $h_j \in \mathbb{R}[\boldsymbol{x}]$. Replacing each $h_j(\boldsymbol{x}) = 0$ by two inequality constraints $h_j(\boldsymbol{x}) \geq 0$ and $-h_j(\boldsymbol{x}) \geq 0$, we reduce the POP (5.3) to the inequality constrained POP:

$$\left.\begin{array}{ll} \text{minimize} & f_0(\boldsymbol{x}) \\ \text{subject to} & f_k(\boldsymbol{x}) \geq 0 \ (k = 1, 2, \ldots, m), \\ & h_j(\boldsymbol{x}) \geq 0, \ -h_j(\boldsymbol{x}) \geq 0 \ (j = 1, 2, \ldots, q). \end{array}\right\} \tag{5.4}$$

Let

$$\begin{aligned} \omega_k &= \lceil \deg(f_k)/2 \rceil \ (k = 0, 1, 2, \ldots, m), \\ \chi_j &= \lceil \deg(h_j)/2 \rceil \ (j = 1, 2, \ldots, q), \\ \omega_{\max} &= \max\{\omega_k \ (k = 0, 1, 2, \ldots, m), \ \chi_j \ (j = 1, 2, \ldots, q)\}, \\ F_k &= \{i : \alpha_i \geq 1 \text{ for some } \boldsymbol{\alpha} \in \mathrm{supp}(f_k)\} \ (k = 1, 2, \ldots, m), \\ H_j &= \{i : \alpha_i \geq 1 \text{ for some } \boldsymbol{\alpha} \in \mathrm{supp}(h_j)\} \ (j = 1, 2, \ldots, q). \end{aligned}$$

We construct the csp matrix $\boldsymbol{R}$ and the csp graph $G(N, E)$ of the POP (5.4). Let $C_1, C_2, \ldots, C_p$ be the maximal cliques of a chordal extension of $G(N, E)$, and let $\omega \geq \omega_{\max}$. Applying the SOS relaxation in section 4 to the POP (5.4), we have

$$\begin{array}{ll} \text{maximize} & \zeta \\ \text{subject to} & f_0(\boldsymbol{x}) - \displaystyle\sum_{k=1}^{m} \varphi_k(\boldsymbol{x}) f_k(\boldsymbol{x}) - \sum_{j=1}^{q} \left(\psi_j^+(\boldsymbol{x}) - \psi_j^-(\boldsymbol{x})\right) h_j(\boldsymbol{x}) - \zeta \\ & \in \sum_{\ell=1}^{p} \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell}]^2, \\ & \boldsymbol{\varphi} \in \Phi_\omega, \ \psi_j^+, \psi_j^- \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{\omega-\chi_j}^{H_j}]^2 \ (j = 1, 2, \ldots, q). \end{array}$$

Since $\mathbb{R}[\boldsymbol{x}, \mathcal{A}_{\omega-\chi_j}^{H_j}]^2 - \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{\omega-\chi_j}^{H_j}]^2 = \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{2(\omega-\chi_j)}^{H_j}]$, this problem is equivalent to

$$\left.\begin{array}{ll} \text{maximize} & \zeta \\ \text{subject to} & f_0(\boldsymbol{x}) - \displaystyle\sum_{k=1}^{m} \varphi_k(\boldsymbol{x}) f_k(\boldsymbol{x}) - \sum_{j=1}^{q} \psi_j(\boldsymbol{x}) h_j(\boldsymbol{x}) - \zeta \\ & \in \sum_{\ell=1}^{p} \mathbb{R}[\boldsymbol{x}, \mathcal{A}_\omega^{C_\ell}]^2, \\ & \boldsymbol{\varphi} \in \Phi_\omega, \ \psi_j \in \mathbb{R}[\boldsymbol{x}, \mathcal{A}_{2(\omega-\chi_j)}^{H_j}] \ (j = 1, 2, \ldots, q). \end{array}\right\} \tag{5.5}$$

We can solve the SOS optimization problem (5.5) as an SDP with free variables.

5.3. Reducing the sizes of SOS relaxations. In [19], a method of reducing the size of the SOS relaxation is proposed by exploiting sparsity. The method consists of two phases. Suppose that, given an SOS polynomial f whose support is $\mathcal{F}$, we want to represent f using unknown polynomials $\phi_i \in \mathbb{R}[\boldsymbol{x}, \mathcal{G}]$ $(i = 1, 2, \ldots, k)$ with some support $\mathcal{G}$ such that $f = \sum_{i=1}^{k} \phi_i^2$. In phase 1 of the method in [19], we compute $\mathcal{G}^0 = \mathrm{conv}\left\{\frac{\boldsymbol{\alpha}}{2} : \boldsymbol{\alpha} \in \mathcal{F}^e\right\} \bigcap \mathbb{Z}_+^n$, where $\mathcal{F}^e = \{\boldsymbol{\alpha} \in \mathcal{F} : \alpha_i \text{ is even } (i = 1, 2, \ldots, n)\}$. It is known in [29] that $\mathrm{supp}(\phi_i) \subset \mathcal{G}^0$ for any SOS representation of $f = \sum_{i=1}^{k} \phi_i^2$. In phase 2, we eliminate redundant elements from $\mathcal{G}^0$ that are unnecessary in any SOS representation of f.

In the sparse SOS relaxations (3.8) and (4.3), we can apply phase 2 of the method with some modification to eliminate redundant elements from $\mathcal{A}_\omega^{C_\ell}$ $(\ell = 1, 2, \ldots, p)$. Let $\mathcal{F}$ denote the support of a polynomial f which we want to represent as

$$f = \sum_{\ell=1}^{p} \psi_\ell \quad \text{for some } \psi_\ell \in \mathbb{R}[\boldsymbol{x}, \mathcal{G}_\ell]^2 \ (\ell = 1, 2, \ldots, p). \tag{5.6}$$

The polynomial f can be either $f_0 - \zeta$ in the unconstrained POP (3.1), or $L(\cdot, \boldsymbol{\varphi}) - \zeta$ with $\boldsymbol{\varphi} \in \Phi_\omega$ in the constrained POP (4.1). In both cases, we assume that the family of supports $\mathcal{G}_\ell = \mathcal{A}_\omega^{C_\ell}$ $(\ell = 1, 2, \ldots, p)$ is sufficient to represent f as in (5.6); hence phase 1 is not implemented. Let $\mathcal{F}^e = \{\boldsymbol{\alpha} \in \mathcal{F} : \alpha_i \text{ is even } (i = 1, 2, \ldots, n)\}$. For each $\boldsymbol{\alpha} \in \bigcup_{\ell=1}^p \mathcal{G}_\ell$, we check whether the following relations are true:

$$2\boldsymbol{\alpha} \notin \mathcal{F}^e \ \text{ and } 2\boldsymbol{\alpha} \notin \bigcup_{\ell=1}^{p} \{\boldsymbol{\beta} + \boldsymbol{\gamma} : \boldsymbol{\beta} \in \mathcal{G}_\ell,\ \boldsymbol{\gamma} \in \mathcal{G}_\ell,\ \boldsymbol{\beta} \neq \boldsymbol{\alpha}\}.$$

If an $\boldsymbol{\alpha} \in \mathcal{G}_\ell$ satisfies these relations, we can eliminate $\boldsymbol{\alpha}$ from $\mathcal{G}_\ell$ and continue this process until no $\boldsymbol{\alpha} \in \bigcup_{\ell=1}^p \mathcal{G}_\ell$ satisfies these two relations. See [19] for more details.

5.4. Supports for Lagrange multiplier polynomials. In the generalized Lagrangian dual (4.2) and the sparse SOS relaxation (4.3), each multiplier polynomial φ_k has been chosen from the SOS polynomials with the support $\mathcal{A}_{\omega-\omega_k}^{F_k}$ to inherit the correlative sparsity from the original POP (4.1). For each k, let $J_k = \{\ell : F_k \subset C_\ell\}$ $(k = 1, 2, \ldots, m)$. By construction, $J_k \neq \emptyset$. Now we can replace the support $\mathcal{A}_{\omega-\omega_k}^{F_k}$ of SOS polynomials for φ_k by a union of $\mathcal{A}_{\omega-\omega_k}^{C_\ell}$ over some $\ell \in J_k$ in the sparse SOS relaxation (4.3). This modification strengthens the SOS relaxation (4.3) without losing much of the correlative sparsity of the other part.

5.5. Valid polynomial inequalities and their linearization. By adding appropriate valid polynomial inequalities to the constrained POP (4.1), we can strengthen its SDP relaxation (4.5). This idea has been used in many convex relaxation methods. See [18] and the references therein. We consider two types of valid polynomial inequalities that occur frequently in practice. These inequalities are used for some test problems in the numerical experiments in section 6. Suppose that (4.1) involves the nonnegative and upper bound constraints on all variables: $0 \leq x_i \leq \rho_i$ $(i = 1, 2, \ldots, n)$, where ρ_i denotes a nonnegative number $(i = 1, 2, \ldots, n)$. In this case, $0 \leq \boldsymbol{x}^{\boldsymbol{\alpha}} \leq \boldsymbol{\rho}^{\boldsymbol{\alpha}}$ $(\boldsymbol{\alpha} \in \widetilde{\mathcal{F}})$ form valid inequalities, where $\boldsymbol{\rho} = (\rho_1, \rho_2, \ldots, \rho_n) \in \mathbb{R}^n$. Therefore we can add their linearizations $0 \leq y_{\boldsymbol{\alpha}} \leq \boldsymbol{\rho}^{\boldsymbol{\alpha}}$ to the primal SDP relaxation (4.5). The complementarity condition $x_i x_j = 0$ is another example. If $\alpha_i \geq 1$ and $\alpha_j \geq 1$ for some $\boldsymbol{\alpha} \in \mathbb{Z}_+^n$, then $\boldsymbol{x}^{\boldsymbol{\alpha}} = 0$ forms a valid equality in this case; hence we can add $y_{\boldsymbol{\alpha}} = 0$ to the primal SDP relaxation or we can reduce the size of the primal SDP relaxation by eliminating the variable $y_{\boldsymbol{\alpha}} = 0$.

5.6. Scaling. High degree of polynomials in POPs can cause numerical problems. Even when the degrees of objective and constrained polynomials are small, the polynomial SDP (4.4) involves high degree monomials $\boldsymbol{x}^{\boldsymbol{\alpha}}$ as the order ω gets larger. Note that each variable $y_{\boldsymbol{\alpha}}$ corresponds to a monomial $\boldsymbol{x}^{\boldsymbol{\alpha}}$. More precisely, if $\boldsymbol{x}$ is a feasible solution of the POP (4.1), then $(y_{\boldsymbol{\alpha}} = \boldsymbol{x}^{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \widetilde{\mathcal{F}})$ is a feasible solution of the primal SDP relaxation (4.5) with the same objective value as (4.1). Therefore, if the magnitudes of some components of a feasible (or optimal) solution $\boldsymbol{x}$ of (4.1) are much larger (or smaller) than 1, the magnitude of some components of the corresponding solution $(y_{\boldsymbol{\alpha}} = \boldsymbol{x}^{\boldsymbol{\alpha}} : \boldsymbol{\alpha} \in \widetilde{\mathcal{F}})$ can be huge (or tiny). This may be the source of numerical difficulties. To avoid such unbalanced magnitudes in the components of feasible (or optimal) solutions of the primal SDP relaxation (4.5), it would be ideal to scale the POP (4.1) so that the magnitudes of all nonzero components of optimal solutions of the scaled problem are near 1. Practically such an ideal scaling is impossible.

Here we restrict our discussion to a POP of the form (4.1) with additional finite lower and upper bounds on variables x_i $(i = 1, 2, \ldots, n)$: $\eta_i \leq x_i \leq \rho_i$ $(i = 1, 2, \ldots)$,

where η_i and ρ_i denote real numbers such that $\eta_i < \rho_i$. In this case, we can perform a linear transformation to the variables x_i such that $z_i = (x_i - \eta_i)/(\rho_i - \eta_i)$. Then we have objective and constrained polynomials $g_k \in \mathbb{R}[\boldsymbol{z}]$ $(k = 0, 1, \ldots, m)$ such that

$$g_k(z_1, z_2, \ldots, z_n) = f_k((\rho_1 - \eta_1)z_1 + \eta_1, (\rho_2 - \eta_2)z_2 + \eta_2, \ldots, (\rho_n - \eta_n)z_n + \eta_n).$$

We further normalize the coefficients of each $g_k \in \mathbb{R}[\boldsymbol{z}]$ such that $g'_k(\boldsymbol{z}) = g_k(\boldsymbol{z})/\nu_k$. Here ν_k denotes the maximum magnitude of the coefficients of the polynomial $g_k \in \mathbb{R}[\boldsymbol{z}]$ $(k = 0, 1, 2, \ldots, m)$. Consequently, we obtain a scaled POP which is equivalent to the POP (4.1) with the additional bounding constraint on variables x_i $(i = 1, 2, \ldots, n)$:

$$\left.\begin{array}{ll} \text{minimize} & g'_0(\boldsymbol{z}) \\ \text{subject to} & g'_k(\boldsymbol{z}) \geq 0 \ (k = 1, 2, \ldots, m), \ 0 \leq z_i \leq 1 \ (i = 1, 2, \ldots, n). \end{array}\right\} \tag{5.7}$$

We note that the scaled POP (5.7) provides the same csp matrix as the original POP (4.1). Furthermore, we can add the constraints $0 \leq y_{\boldsymbol{\alpha}} \leq 1$ $(\boldsymbol{\alpha} \in \widetilde{\mathcal{F}})$ to its primal SDP (4.5) to strengthen the relaxation. A similar technique can be found in [9].

6. Numerical results. In this section, we present numerical results of the proposed sparse relaxation for unconstrained and constrained problems. The focus is on verifying the efficiency of the sparse relaxation compared with the dense relaxation in [22]. The sparse and dense relaxations were implemented with MATLAB for constructing SDP problems and then a software package SeDuMi 1.05 was used to solve the SDP problems. All the experiments were done on a 2.4GHz AMD Opteron cpu with 8.0GB memory. Unconstrained problems that we deal with are benchmark test problems from [3, 21, 24] and randomly generated test problems with artificial correlative sparsity. Constrained test problems (section 6.2) are chosen from [8] and optimal control problems [2].

We employ the techniques described in section 5.1 for finding an optimal solution. In particular, we use the random perturbation techniques with the parameter $\epsilon = 10^{-5}$ in all the experiments presented here. After an optimal solution $\hat{\boldsymbol{y}}$ of an SDP relaxation of the POP is found by SeDuMi, the linear part $\hat{\boldsymbol{x}}$ is considered for a candidate of an optimal solution of the POP.

With regard to computing the accuracy of an obtained solution, we use the following for an unconstrained POP with an objective function f_0:

$$\epsilon_{\text{obj}} = \frac{|\text{the optimal value of SDP} - (f_0(\hat{\boldsymbol{x}}) + \boldsymbol{p}^T\hat{\boldsymbol{x}})|}{\max\{1, |f_0(\hat{\boldsymbol{x}}) + \boldsymbol{p}^T\hat{\boldsymbol{x}}|\}}.$$

Here $\boldsymbol{p} \in \mathbb{R}^n$ denotes a randomly generated perturbation vector such that $|p_j| < \epsilon = 10^{-5}$ $(j = 1, 2, \ldots, n)$. For an inequality and equality constrained POP of the form (5.3), we need another measure for feasibility in addition to ϵ_{obj} defined above. The following feasibility measure is used:

$$\epsilon_{\text{feas}} = \min\{f_k(\hat{\boldsymbol{x}}) \ (k = 1, \ldots, m), \ -|h_j(\hat{\boldsymbol{x}})| \ (j = 1, \ldots, q)\}.$$

We use the technique given in section 5.2 for every equality constrained problem and the technique in section 5.3 of reducing the size of an SOS relaxation for all test problems. In addition, we apply the techniques presented in sections 5.4, 5.5, and 5.6 to every constrained problem from the literature [8]. Specifically, we use $\cup_{\ell \in J_k} \mathcal{A}^{C_\ell}_{\omega - \omega_k}$ as the supports of ψ_k discussed in section 5.4.

TABLE 6.1
Notation.

n	the number of variables of a POP
d	the degree of a POP
sparse	cpu time in seconds consumed by the proposed sparse relaxation
dense	cpu time in seconds consumed by the dense relaxation [22]
cl.str	the structure of the maximal cliques
#clique	the average number of cliques found in randomly generated problems
#solved	the number of problems solved among randomly generated problems
max.cl	the number of the maximal cliques
max	the maximum of cpu time consumed by randomly generated problems
avr	the average of cpu time consumed by randomly generated problems
min	the minimum of cpu time consumed by randomly generated problems
cpu	cpu time in seconds
ω	the relaxation order

400	3*398	3.6e-7	19.3	—	10	7*4	6.2e-8	348.7	8399.4

Table 6.1 shows notation used in the description of numerical experiments in the following subsections. The notation "cl.str" indicates the structure of the maximal cliques obtained by applying MATLAB functions "symamd" and "chol" to the csp matrix. For example, $4*3+5*2$ means three cliques of size 4 and two cliques of size 5.

6.1. Unconstrained cases. The problems presented here are from the literature [3, 21, 24] and randomly generated problems. Table 6.2 displays the numerical results of the following two functions.

- The chained singular function [3]

$$f_{\rm cs}(\boldsymbol{x}) = \sum_{i\in J} \big((x_i + 10x_{i+1})^2 + 5(x_{i+2} - x_{i+3})^2 + (x_{i+1} - 2x_{i+2})^4 + 10(x_i - 10x_{i+3})^4\big),$$

  where $J = \{1, 3, 5, \ldots, n-3\}$ and n is a multiple of 4.
- The Broyden banded function [21]

$$f_{\rm Bb}(\boldsymbol{x}) = \sum_{i=1}^{n} \left(x_i(2 + 5x_i^2) + 1 - \sum_{j\in J_i} (1 + x_j)x_j \right)^2,$$

  where $J_i = \{j \mid j \neq i, \max(1, i-5) \leq j \leq \min(n, i+1)\}$.

The above two problems of relatively small size could be solved by the dense relaxation as shown in Table 6.2, and their results can be used for the comparison of the performance of the sparse and dense relaxations. In the case of the chained singular function $f_{\rm cs}$, its csp matrix $\boldsymbol{R}$ has nonzero elements near the diagonal; i.e.,

TABLE 6.3
Numerical results of Broyden tridiagonal function, the chained Wood function, and the generalized Rosenbrock function.

	Broyden tridiagonal			Chained Wood			Generalized Rosenbrock		
n	cl.str	$\epsilon_{\rm obj}$	cpu	cl.str	$\epsilon_{\rm obj}$	cpu	cl.str	$\epsilon_{\rm obj}$	cpu

700	3*698	9.0e-7	10.9	2*699	1.6e-5	1.1	2*699	7.5e-9	4.0
800	3*798	2.2e-7	12.6	2*799	1.8e-5	1.3	2*799	2.1e-7	5.1
900	3*898	1.3e-7	14.4	2*899	3.4e-5	1.4	2*899	2.1e-7	5.6
1000	3*998	2.6e-7	16.0	2*999	3.8e-5	1.6	2*999	4.5e-7	5.9

$R_{ij} = 0$ if $|j - i| > 3$. This means that $f_{\rm cs}$ is correlatively sparse. The "cl.str" column of Table 6.2 shows that the sparsity can be detected correctly. As a result, the sparse relaxation is much more efficient than the dense relaxation. We could successfully solve the problem of 100 variables in a few seconds, while the dense relaxation could not handle the problem of 20 or 30 variables.

If we look at the result of the Broyden banded function $f_{\rm Bb}$ in Table 6.2, we observe that there is virtually no difference in performance between the proposed sparse and dense relaxations for $n = 6$ and $n = 7$. Because the csp matrix of this function has the bandwidth 7, it is fully dense when $n = 6$ and $n = 7$; the sparse relaxation is identical to the dense relaxation in these cases. As n increases, however, a sparse structure such as 7*2 for $n = 8$ can be found, and the sparse relaxation takes advantage of the structured sparsity, providing an optimal solution faster than the dense relaxation.

In Table 6.3, we present the numerical results of the following functions.

- The Broyden tridiagonal function [21]

$$f_{\rm Bt}(\boldsymbol{x}) = ((3-2x_1)x_1 - 2x_2 + 1)^2 + \sum_{i=2}^{n-1} ((3-2x_i)x_i - x_{i-1} - 2x_{i+1} + 1)^2 + ((3-2x_n)x_n - x_{n-1} + 1)^2.$$

- The chained Wood function [3]

$$f_{\rm cW}(\boldsymbol{x}) = 1 + \sum_{i\in J} \big(100(x_{i+1} - x_i^2)^2 + (1-x_i)^2 + 90(x_{i+3} - x_{i+2}^2)^2 + (1-x_{i+2})^2 + 10(x_{i+1} + x_{i+3} - 2)^2 + 0.1(x_{i+1} - x_{i+3})^2\big),$$

  where $J = \{1, 3, 5, \ldots, n-3\}$ and n is a multiple of 4.
- The generalized Rosenbrock function [24]

$$f_{\rm gR}(\boldsymbol{x}) = 1 + \sum_{i=2}^{n} \{100\left(x_i - x_{i-1}^2\right)^2 + (1-x_i)^2\}.$$

Each of the above three functions has a band structure in its csp matrix, and, therefore, the problems of large sizes can be handled efficiently. For example, the Broyden tridiagonal function $f_{\rm Bt}$ with 1000 variables could be solved in 16 seconds with the accuracy of 2.6e-07. Note that the solutions are accurate in all tested cases.

Next, we present the numerical results of randomly generated problems. The aim of the test using randomly generated problems is to observe the effects of increasing the

number of variables, the degree of the polynomials, and the maximal size of cliques of the csp graph of a POP. The dense relaxation could not handle the randomly generated problems of the sizes reported here, and we include only the numerical results from the sparse relaxation.

Let us describe how an unconstrained problem with artificial correlative sparsity is generated randomly. We begin by constructing a chordal graph randomly such that the size of every maximal clique is not less than 2 and not greater than max.cl. From the chordal graph, we derive the set of maximal cliques $\{C_1, \ldots, C_\ell\}$ with $2 \leq |C_i| \leq$ max.cl $(i = 1, \ldots, \ell)$. We let $\boldsymbol{v}_{C_i}(\boldsymbol{x}) = (x_k^d \colon k \in C_i)$, where $2d$ is the degree of the polynomial, and generate a positive definite matrix $\boldsymbol{V}_i \in \mathcal{S}_{++}(C_i)$ and a vector $\boldsymbol{g}_i \in [-1, 1]^{|\mathcal{A}^{C_i}_{2d-1}|}$ $(i = 1, 2, \ldots, \ell)$ randomly such that the minimum eigenvalue σ of $\boldsymbol{V}_1, \ldots, \boldsymbol{V}_\ell$ satisfies the relation

$$\sigma \geq \sum_{i=1}^{\ell} \left(\|\boldsymbol{g}_i\|_2 \sqrt{|\mathcal{A}^{C_i}_{2d-1}|} \right).$$

By using $\boldsymbol{V}_i$ and $\boldsymbol{g}_i$, we define the objective function:

$$f_{\rm rand}(\boldsymbol{x}) = \sum_{i=1}^{\ell} \left(\boldsymbol{v}_{C_i}(\boldsymbol{x})^T \boldsymbol{V}_i \boldsymbol{v}_{C_i}(\boldsymbol{x}) + \boldsymbol{g}_i^T \boldsymbol{u}\big(\boldsymbol{x}, \mathcal{A}^{C_i}_{2d-1}\big) \right).$$

This unconstrained POP is guaranteed to have an optimal solution in the compact set $\{\boldsymbol{x} = (x_1, \ldots, x_n) \in \mathbb{R}^n \mid \max_{i=1,\ldots,n} |x_i| \leq 1\}$. A scaling with the maximum of the absolute values of the coefficients of $f_{\rm rand}(\boldsymbol{x})$ is used in numerical experiments.

The numerical results are shown in Tables 6.4, 6.5, and 6.6. Table 6.4 exhibits how the sparse relaxation performs for a varying number of variables, Table 6.5 for raising the degree of the unconstrained problems, and Table 6.6 for increasing bounds of sizes of the cliques. For each choice of n, d, and max.cl, we generated 50 problems. Each column of #solved indicates the number of the problems whose optimal solutions were obtained with $\epsilon_{\rm obj} \leq 10^{-5}$ out of 50 problems. All problems tested were solved.

In Table 6.4, we notice that the number of cliques increases with n. For problems of large numbers of variables and cliques such as $n = 100$ and #clique= 80.3, the sparse relaxation provides optimal solutions in 8.8 average cpu seconds.

TABLE 6.6
Randomly generated polynomials with $2d = 4$ and $n = 30$.

max.cl	#clique	max	avr	min	#solved
4	22.7	1.1	0.6	0.3	50/50
6	20.0	31.5	6.4	1.3	50/50
8	17.3	497.9	79.8	4.0	50/50

The numerical results in Table 6.5 display the performance of the sparse relaxation for the problem of $n = 30$ with degrees up to 8. The maximum size of cliques is fixed to 4. As mentioned before, the size of the SDP relaxation of the POP of increasing degree becomes large rapidly even if the POP remains correlatively sparse. When $2d = 8$, the average cpu time is 74.7 and the maximum is 624.2.

A large size of cliques used during problem generation also increases the complexity of the problem as shown in Table 6.6. We tested with the maximum size of cliques 4, 6, and 8, and observe that cpu time to solve the corresponding problems grows very rapidly, e.g., 79.8 average cpu seconds and 497.9 maximum cpu seconds for max.cl = 8. From the increase of work measured by cpu time, we notice that the impact of the maximum size of cliques is comparable to that of degree, and bigger than that of the number of variables.

6.2. Constrained cases. In this subsection, we deal with the following constrained POPs:

- small-sized POPs from the literature [8],
- optimal control problems [2].

The numerical results on POPs from [8] are presented in Table 6.7. All problems are quadratic optimization problems except "alkyl," which involves polynomials of degree 3 in its equality constraints. We also added lower and upper bounds for the variables. In preliminary numerical experiments for some of the test problems, severe numerical difficulties occurred in badly scaled problems or problems with the complementarity condition. We incorporate all the techniques in sections 5.4, 5.5, and 5.6 into the dense and sparse relaxations for these problems.

In Table 6.7, ϵ'_{feas} denotes the feasibility for the scaled problems at the approximate optimal solutions obtained by the sparse and dense relaxations. We see that ϵ'_{feas} is small in most of the problems while the feasibility ϵ_{feas} for the original problems at the approximate optimal solutions becomes larger. The lower bounds obtained by the sparse relaxation are as good as the ones obtained by the dense relaxation except for the five problems ex5_2_2_cases1, 2, and 3, ex5_3_2, and ex9_1_4. In the first three cases, the dense relaxation with order $\omega = 2$ succeeds in computing accurate bounds while the sparse relaxation with order $\omega = 3$ computes accurate bounds with the same quality.

When we compare the performance of the sparse relaxation with the dense relaxation using these problems in Table 6.7, we observe that the sparse relaxation is much faster than the dense relaxation in large-dimensional problems. In some problems, however, the technique given in section 5.3 for reducing the sizes of relaxations worked so effectively that the difference between the dense and sparse relaxations decreased. For example, without incorporating this reduction technique, the sparse and dense relaxations of ex2_1_3 took 0.9 and 464.5 seconds, respectively, while 0.2 and 2.8 seconds, respectively, were consumed with the technique, as shown in Table 6.7. We will present more detailed comparison between the dense relaxation with the technique and the dense relaxation without the technique in section 6.3.

We present numerical results from discrete-time optimal control problems in [2]. The problem tested first (Problem 1 of [2]) is

$$\left.\begin{array}{ll} \min & \displaystyle\sum_{i=1}^{M-1}\left(\sum_{j=1}^{n_y}\left(y_{i,j}+\frac{1}{4}\right)^4+\sum_{j=1}^{n_x}\left(x_{i,j}+\frac{1}{4}\right)^4\right) \\ & \displaystyle+\sum_{j=1}^{n_y}\left(y_{M,j}+\frac{1}{4}\right)^4 \\ \text{subject to} & \boldsymbol{y}_{i+1}=\boldsymbol{A}\boldsymbol{y}_i+\boldsymbol{B}\boldsymbol{x}_i+(\boldsymbol{y}_i^T\boldsymbol{C}\boldsymbol{x}_i)\boldsymbol{e}\ (i=1,\ldots,M-1), \\ & \boldsymbol{y}_1=\boldsymbol{0},\ \boldsymbol{y}_i\in\mathbb{R}^{n_y}\ (i=1,\ldots,M), \\ & \boldsymbol{x}_i\in\mathbb{R}^{n_x}\ (i=1,\ldots,M-1), \end{array}\right\} \tag{6.1}$$

where $\boldsymbol{A} \in \mathbb{R}^{n_y \times n_y}$, $\boldsymbol{B} \in \mathbb{R}^{n_y \times n_x}$, and $\boldsymbol{C} \in \mathbb{R}^{n_y \times n_x}$ are given by

$$A_{i,j} = \begin{cases} 0.5 & \text{if } j = i, \\ 0.25 & \text{if } j = i+1, \\ -0.25 & \text{if } j = i-1, \\ 0 & \text{otherwise,} \end{cases} \qquad B_{i,j} = \frac{i-j}{n_y + n_x}, \quad C_{i,j} = \mu \frac{i+j}{n_y + n_x},$$

respectively. Here, $\boldsymbol{e}$ denotes a vector of ones in $\mathbb{R}^{n_y}$.

The numerical results of the problem (6.1) are shown in Tables 6.8, 6.9, and 6.10, which display the results of the problem (6.1) with $(n_x, n_y, \mu) = (2, 4, 0)$, the problem (6.1) with $(n_x, n_y, \mu) = (2, 4, 0.5)$ and the problem (6.1) with $(n_x, n_y, \mu) = (1, 2, 1)$, respectively. The values of n_x, n_y, and M determine the size of the problem, and μ is a parameter in $C_{i,j}$. The relaxation order 2 was used for all cases. As we increase M from 6 to 30, the number of variables becomes larger as indicated in the column of n. In all cases, the optimal solutions are obtained with good accuracy.

Depending on the choice of μ, it results in different clique structures and the size of the resulting SDP varies. This size can greatly affect the performance of the relaxations. When we take $\mu = 0$ in (6.1), the constraints are linear since $\boldsymbol{C} = \boldsymbol{O}$. Then, the cliques have smaller numbers of elements than the ones from the constraints with nonlinear terms, which enables the sparse relaxation to perform better in terms of cpu time. To see this, compare the column of cl.str of Table 6.8 with that of Table 6.9. For example, when $M = 30$ in Table 6.8, it took 122.7 cpu seconds to have an optimal solution, whereas it took 501.7 seconds in Table 6.9. Similarly, if we compare Tables 6.9 and 6.10, we notice that the size of the cliques in Table 6.10 is half the size of those in Table 6.9, while the cpu time of Table 6.10 is 1/100 of the cpu time of Table 6.9. This shows how much efficiency can be improved using appropriate clique structures.

In [2], the optimal values of the problem (6.1) with $\mu = 0, 0.5, 1$ and $n = 10, 50$ are shown as numerical results. We also solved the same problems with the sparse relaxation and obtained the same optimal values for each problem. Efficiency could not be compared because no cpu time was reported in [2].

TABLE 6.10

The second problem (Problem 5 of [2]) is

$$\left.\begin{array}{ll} \text{min} & \dfrac{1}{M}\displaystyle\sum_{i=1}^{M-1}\left(y_i^2 + x_i^2\right) \\ \text{subject to} & y_{i+1} = y_i + \dfrac{1}{M}(y_i^2 - x_i) \quad (i = 1, \ldots, M-1), \quad y_1 = 1. \end{array}\right\} \tag{6.2}$$

Table 6.11 shows the results of (6.2) for various M.

From the column cl.str, we notice that the set of cliques has very few elements. The sparse relaxation can solve large-sized problems since they have plenty of correlative sparsity. In fact, the sparse relaxation provides optimal solutions for the problems with almost 2000 variables, where the size of the clique is 2 or 3.

From all numerical experiments in subsections 6.1 and 6.2, we have observed that the sparse relaxation is much faster than the dense relaxation with relatively accurate solutions. The sparse relaxation can handle large POPs with more than a hundred variables; this is impossible with the dense relaxation. The correlative sparsity has been the key to solve such large problems.

6.3. Performance comparison with some optimization software. In Table 6.12, we compare the performance of the sparse relaxation whose numerical results have been reported in the previous two subsections with optimization solvers LINGO (free version) [14], PENNON [16], LOQO [36], and GloptiPoly [9]. We have chosen the test problems that can show differences for the optimization solvers. We use the symbols ◯, △, and × to denote the accuracy of the optimal value obtained:

$$\begin{aligned} &\bigcirc\text{: } \frac{|\text{known best value} - \text{obtained value}|}{\max\{1, |\text{known best value}|\}} < \text{1.0e-5}, \\ &\triangle\text{: 1.0e-5} < \frac{|\text{known best value} - \text{obtained value}|}{\max\{1, |\text{known best value}|\}} < \text{1.0e-3}, \\ &\times\text{: otherwise.} \end{aligned}$$

LINGO is a global optimizer. The free version of LINGO was not able to handle large-sized problems; $n = 20$ was the largest size of the problems that it could handle. Although PENNON and LOQO are local optimizers, we include these solvers because they often attain global optimal values in the numerical experiments. We note that

TABLE 6.12

× in a column of PENNON or LOQO does not necessarily mean that the corresponding local optimizer fails to "solve" the problem in its own context. GloptiPoly is a MATLAB implementation of the SDP relaxation method proposed by Lasserre [22] for solving POPs.

GloptiPoly needed larger memory as the number of variables increased for the Broyden tridiagonal and generalized Rosenbrock functions; hence, optimal values could not be obtained for $n \geq 20$. The problems ex5_2_2_case1 and st_e05 are badly scaled and could not be solved with GloptiPoly. We also note that the generalized Rosenbrock function has two distinct minimizers. As a result, the sparse relaxation with a perturbation resulted in less accurate approximate solutions. In contrast, GloptiPoly can obtain more accurate optimal solutions because of the special technique for detecting multiple optimal solutions developed by [10]. From Table 6.12, we observe that the proposed sparse relaxation provides more accurate optimal values than other software in most cases.

In Table 6.13, we compare our dense relaxation with that of GloptiPoly. Note that the dense relaxation without the reduction technique [19] stated in section 5.3 and

GloptiPoly are essentially the same relaxation; the difference lies in some additional techniques given in section 5 such as adding valid inequalities and scaling. Our dense relaxation was tested in two ways: with and without the reduction technique. In both cases, we did not perturb the objective function. The relaxation order $\omega = 2$ was used for all the problems, except ex2_2_1 where $\omega = 3$. It was shown that GloptiPoly is faster than the dense relaxation without the reduction in obtaining optimal values except for the problems ex9_2_5 and st_e05, and that the dense relaxation with the reduction is much faster than the others. The latter observation confirms that the reduction technique [19] is very effective in the dense relaxation.

7. Concluding discussions. The computational efficiency of the proposed sparse relaxations depends on the sparsity of a chordal extension of the csp graph. We note that the following two conditions are equivalent: (i) a chordal extension of the csp graph is sparse and (ii) Cholesky factorization of the Hessian matrix of the generalized Lagrangian function, or the Hessian matrix of the objective function in unconstrained problems, is sparse. When we compare the condition (ii) with the standard condition of traditional numerical methods, such as Newton's method for convex optimization, to be efficient for large-scale problems, we notice a difference between the generalized Lagrangian function and the usual Lagrangian function in their multipliers. SOS polynomials are the Lagrangian multipliers in the former whereas they are nonnegative real numbers in the latter. If a linear inequality constraint, the simplest polynomial constraint, is involved in a POP, it is multiplied by an SOS polynomial in the former. As a result, the Hessian matrix of the former can become denser than the Hessian matrix of the latter. In this sense, the condition (ii) in the proposed sparse relaxations is a stronger requirement on the sparsity in the POP than the standard condition for traditional numerical methods. This stronger requirement, however, can be justified if we understand the study of nonconvex and large-scale POPs in global optimization as a more complicated issue.

The proposed sparse relaxation for a correlatively sparse POP leads to an SDP that can maintain the sparsity for primal-dual interior-point methods. This is due to the fact that if a POP is correlatively sparse, the resulting SDP relaxation inherits the structured sparsity. In each iteration of a primal-dual interior-point method for solving an SDP, a system of linear equations, which is often called the Schur complement equation, is solved to compute a search direction. The coefficient matrix of this system is positive definite and fully dense in general. However, the sparse SDP relaxation of a correlatively sparse POP possesses sparsity in the coefficient matrix. This is an important advantage of our sparse relaxation. Among software packages implementing primal-dual interior-point methods, SeDuMi [33] handles SDPs with this sparsity in the coefficient matrix of the Schur complement equation while the current version of Semidefinite Programming Algorithm (SDPA) [37] developed by the authors' group is not equipped with the sparse Cholesky factorization for the Schur complement equation, showing slow performance for POPs with the correlative sparsity. This is the main reason that SeDuMi has been a choice for the numerical experiments instead of SDPA.

We encountered numerical difficulties during preliminary numerical experiments. The techniques presented in section 5 were very effective in overcoming the difficulties and in enhancing the performance of the sparse and dense relaxations. Some problems from [8], however, could not be solved because of numerical troubles resulting from SeDuMi. The failure has to be investigated more rigorously, but some SDPs generated as relaxations of POPs may be very difficult to solve. Additional techniques for

resolving this difficulty are to be developed, including the approach for formulating the SDP differently that was proposed in [23].

We mention that the proposed sparse SOS relaxation can be applied to the problems with rational objective functions in [13]. It is also interesting to extend the sparse SOS relaxation to optimization problems described with partially separable polynomial functions [34, 35]. These will be a future subject of study.

Acknowledgments. The authors would like to thank Phillipe L. Toint for discussion on a possible extension of the sparse SOS relaxation to partially separable optimization problems, and the anonymous referees for their valuable suggestions that considerably improved the presentation of this paper.

GENERALIZED LEVITIN–POLYAK WELL-POSEDNESS IN CONSTRAINED OPTIMIZATION*

X. X. HUANG† AND X. Q. YANG‡

Abstract. In this paper, we consider Levitin–Polyak-type well-posedness for a general constrained optimization problem. We introduce generalized Levitin–Polyak well-posedness and strongly generalized Levitin–Polyak well-posedness. Necessary and sufficient conditions for these types of well-posedness are given. Relations among these types of well-posedness are investigated. Finally, we consider convergence of a class of penalty methods and a class of augmented Lagrangian methods under the assumption of strongly generalized Levitin–Polyak well-posedness.

Key words. constrained optimization, generalized minimizing sequence, generalized Levitin–Polyak well-posedness, penalty-type methods

DOI. 10.1137/040614943

1. Introduction.

The study of well-posedness originates from Tykhonov [26] in dealing with unconstrained optimization problems. Its extension to the constrained case was developed by Levitin and Polyak [18]. Since then, various notions of well-posedness have been defined and extensively studied (see, e.g., [22, 6, 24, 28, 29, 9, 24, 30]). It is worth noting that recent research on well-posedness has been extended to vector optimization problems (see, e.g., [3, 20, 21, 12, 13, 7]).

Let (X, d_1) and (Y, d_2) be two metric spaces, and let $X_1 \subset X$ and $K \subset Y$ be two nonempty and closed sets. Consider the following constrained optimization problem:

$$\begin{aligned} (\mathrm{P}) \qquad & \min f(x) \\ & \text{s.t. } x \in X_1, \quad g(x) \in K, \end{aligned}$$

where $f : X \to R^1$ is a lower semicontinuous function and $g : X \to Y$ is a continuous function. Denote by X_0 the set of feasible solutions of (P), i.e.,

$$X_0 = \{x \in X_1 : g(x) \in K\}.$$

Denote by $\bar{X}$ and $\bar{v}$ the optimal solution set and the optimal value of (P), respectively. Throughout the paper, we always assume that $X_0 \neq \emptyset$ and $\bar{v} > -\infty$.

Let (Z, d) be a metric space and $Z_1 \subset Z$. We denote by $d_{Z_1}(z) = \inf\{d(z, z') : z' \in Z_1\}$ the distance from the point z to the set Z_1.

Levitin–Polyak (LP) well-posedness of (P) in the usual sense (when the optimal set of (P) is not necessarily a singleton) says that, for any sequence $\{x_n\} \subset X_1$ satisfying (i) $d_{X_0}(x_n) \to 0$ and (ii) $f(x_n) \to \bar{v}$, there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$.

It should be noted that many optimization algorithms, such as penalty-type methods, e.g., penalty function methods and augmented Lagrangian methods, terminate when the constraint is approximately satisfied; i.e., $d_K(g(\bar{x})) \leq \epsilon$ for some $\epsilon > 0$ sufficiently small, and $\bar{x}$ is taken as an approximate solution of (P). These methods may generate sequences $\{x_n\} \subset X_1$ that satisfy $d_K(g(x_n)) \to 0$, not necessarily $d_{X_0}(x_n) \to 0$, as shown in the following simple example.

Example 1.1. Let $\alpha > 0$. Let $X = R^1$, $X_1 = R^1_+$, $K = R^1_-$, and

$$f(x) = \begin{cases} -x^\alpha & \text{if } x \in [0,1]; \\ -1/x^\alpha & \text{if } x \geq 1, \end{cases}$$

$$g(x) = \begin{cases} x & \text{if } x \in [0,1]; \\ 1/x^2 & \text{if } x \geq 1. \end{cases}$$

Consider the following penalty problem:

$$(PP_\alpha(n)) \quad \min_{x \in X_1} f(x) + n\left[\max\{0, g(x)\}\right]^\alpha, \quad n \in N.$$

It is easily verified that $x_n = 2^{1/\alpha} n^{1/\alpha}$ is the unique global solution to $(PP_\alpha(n))$ for each $n \in N$. Note that $X_0 = \{0\}$. It follows that we have $d_K(g(x_n)) = 1/(2^{2/\alpha} n^{2/\alpha}) \to 0$, while $d_{X_0}(x_n) = 2^{1/\alpha} n^{1/\alpha} \to +\infty$.

Thus, it is useful to consider sequences that satisfy $d_K(g(x_n)) \to 0$ instead of $d_{X_0}(x_n) \to 0$ as $n \to \infty$ in order to study convergence of penalty-type methods.

The sequence $\{x_n\}$ satisfying (i) and (ii) above is called an LP minimizing sequence. In what follows, we introduce two more types of generalized LP well-posedness.

DEFINITION 1.1. (P) *is called LP well-posedness in the generalized sense if, for any sequence* $\{x_n\} \subset X_1$ *satisfying* (i) $d_K(g(x_n)) \to 0$ *and* (ii) $f(x_n) \to \bar{v}$, *there exist a subsequence* $\{x_{n_k}\}$ *of* $\{x_n\}$ *and some* $\bar{x} \in \bar{X}$ *such that* $x_{n_k} \to \bar{x}$. *The sequence* $\{x_n\}$ *is called a generalized LP minimizing sequence.*

DEFINITION 1.2. (P) *is called LP well-posedness in the strongly generalized sense if, for any sequence* $\{x_n\} \subset X_1$ *satisfying* (i) $d_K(g(x_n)) \to 0$ *and* (ii) $\limsup_{n\to+\infty} f(x_n) \leq \bar{v}$, *there exist a subsequence* $\{x_{n_k}\}$ *of* $\{x_n\}$ *and some* $\bar{x} \in \bar{X}$ *such that* $x_{n_k} \to \bar{x}$. *The sequence* $\{x_n\}$ *is called a weakly generalized LP minimizing sequence.*

Remark 1.1. (i) The study of well-posedness for optimization problems with explicit constraints dates back to [17] when the abstract set X_1 does not appear. In [17], it was assumed that X is a Banach space and Y is a Banach space ordered by a closed and convex cone with some special properties; see [17] for details. What is worth emphasizing is that [17] studied only the case when (P) is a convex program. However, it is well known that penalty-type methods such as penalization methods and augmented Lagrangian methods are mostly developed for constrained nonconvex optimization problems. This is the main motivation of this paper.

(ii) The LP well-posedness in the strongly generalized sense defined above was called well-posedness in the strongly generalized sense in [17], while a weakly generalized LP minimizing sequence in the above definition is called a generalized minimizing sequence in [17].

(iii) It is obvious that LP well-posedness in the strongly generalized sense implies LP well-posedness in the generalized sense because a generalized LP minimizing sequence is a weakly generalized LP minimizing sequence.

(iv) If there exists some $\delta_0 > 0$ such that g is uniformly continuous on the set

$$\{x \in X_1 : d_{X_0}(x) \leq \delta_0\},$$

then it is not difficult to see that LP well-posedness in the generalized sense implies LP well-posedness.

(v) Any one type of (generalized) LP well-posedness defined above implies that the optimal set $\bar{X}$ of (P) is nonempty and compact.

The paper is organized as follows. In section 2, we investigate characterizations and criteria for the three types of (generalized) LP well-posednesses. In section 3, we establish relations among the three types of (generalized) LP well-posednesses. In section 4, we obtain convergence of a class of penalty methods and a class of augmented Lagrangian methods under the assumption of strongly generalized LP well-posedness.

2. Necessary and sufficient conditions for three types of (generalized) LP well-posedness. In this section, we present some criteria and characterizations for the three types of (generalized) LP well-posedness defined in section 1.

Consider the following statement:

(1)
$[\bar{X} \neq \emptyset$ and, for any LP minimizing sequence (resp., generalized LP minimizing sequence, weakly generalized LP minimizing sequence) $\{x_n\}$, we have $d_{\bar{X}}(x_n) \to 0]$.

The proof of the following proposition is elementary and thus omitted.

PROPOSITION 2.1. *If* (P) *is LP well-posed (resp., LP well-posed in the generalized sense and LP well-posed in the strongly generalized sense), then* (1) *holds. Conversely, if* (1) *holds and* $\bar{X}$ *is compact, then* (P) *is LP well-posed (resp., LP well-posed in the generalized sense and LP well-posed in the strongly generalized sense).*

Consider a real-valued function $c = c(t, s)$ defined for $t, s \geq 0$ sufficiently small, such that

$$c(t,s) \geq 0 \quad \forall t, s, \quad c(0,0) = 0, \tag{2}$$

$$s_k \to 0, t_k \geq 0, c(t_k, s_k) \to 0 \text{ imply } t_k \to 0. \tag{3}$$

THEOREM 2.1. *If* (P) *is LP well-posed, then there exists a function* c *satisfying* (2) *and* (3) *such that*

$$|f(x) - \bar{v}| \geq c(d_{\bar{X}}(x), d_{X_0}(x)) \quad \forall x \in X_1. \tag{4}$$

Conversely, suppose that $\bar{X}$ *is nonempty and compact, and* (4) *holds for some* c *satisfying* (2) *and* (3). *Then* (P) *is LP well-posed.*

Proof. Define

$$c(t,s) = \inf\{|f(x) - \bar{v}| : x \in X_1, d_{\bar{X}}(x) = t, d_{X_0}(x) = s\}.$$

It is obvious that $c(0,0) = 0$. Moreover, if $s_n \to 0$, $t_n \geq 0$ and $c(t_n, s_n) \to 0$, then there exists a sequence $\{x_n\} \subset X_1$ with

$$d_{\bar{X}}(x_n) = t_n, \tag{5}$$

$$d_{X_0}(x_n) = s_n \tag{6}$$

such that

$$|f(x_n) - \bar{v}| \to 0. \tag{7}$$

Note that $s_n \to 0$. Equations (6) and (7) jointly imply that $\{x_n\}$ is an LP minimizing sequence. By Proposition 2.1, we have $t_n \to 0$. This completes the proof of the first half of the theorem. Conversely, let $\{x_n\}$ be an LP minimizing sequence. Then, by (4), we have

$$|f(x_n) - \bar{v}| \geq c(d_{\bar{X}}(x_n), d_{X_0}(x_n)) \quad \forall x \in X_1. \tag{8}$$

Let

$$t_n = d_{\bar{X}}(x_n), \quad s_n = d_{X_0}(x_n).$$

Then $s_n \to 0$. In addition, $|f(x_n) - \bar{v}| \to 0$. These facts together with (8) as well as the properties of the function c imply that $t_n \to 0$. By Proposition 2.1, we see that (P) is LP well-posed. □

THEOREM 2.2. *If* (P) *is LP well-posed in the generalized sense, then there exists a function c satisfying* (2) *and* (3) *such that*

$$|f(x) - \bar{v}| \geq c(d_{\bar{X}}(x), d_K(g(x))) \quad \forall x \in X_1. \tag{9}$$

Conversely, suppose that $\bar{X}$ is nonempty and compact, and (9) *holds for some c satisfying* (2) *and* (3). *Then* (P) *is LP well-posed in the generalized sense.*

Proof. The proof is almost the same as that of Theorem 2.1. The only difference lies in the proof of the first part of Theorem 2.1. Here we define

$$c(t, s) = \inf\{|f(x) - \bar{v}| : x \in X_1, d_{\bar{X}}(x) = t, d_K(g(x)) = s\}. \qquad \square$$

Next we give a necessary and sufficient condition in the form of Furi and Vignoli [10] to characterize the LP well-posedness in the strongly generalized sense.

Let

$$\Omega(\epsilon) = \{x \in X_1 : f(x) \leq \bar{v} + \epsilon, d_K(g(x)) \leq \epsilon\}.$$

Let (X, d_1) be a complete metric space. Recall that the Kuratowski measure of noncompactness for a subset A of X is defined as

$$\alpha(A) = \inf\left\{\epsilon > 0 : A \subset \bigcup_{1 \leq i \leq n} C_i, \text{ for some } C_i, diam(C_i) \leq \epsilon\right\},$$

where $diam(C_i)$ is the diameter of C_i defined by

$$diam(C_i) = \sup\{d_1(x_1, x_2) : x_1, x_2 \in C_i\}.$$

The next theorem can be proved analogously to [17, Theorem 5.5].

THEOREM 2.3. *Let (X, d_1) be a complete metric space and f be bounded below on X_0. Then* (P) *is LP well-posed in the strongly generalized sense if and only if*

$$\alpha(\Omega(\epsilon))) \to 0 \text{ as } \epsilon \to 0.$$

DEFINITION 2.1. *Let Z be a topological space and $Z_1 \subset Z$ be nonempty. Suppose that $h : Z \to R^1 \cup \{+\infty\}$ is an extended real-valued function. h is said to be level-compact on Z_1 if, for any $s \in R^1$, the subset $\{z \in Z_1 : h(z) \leq s\}$ is compact.*

For any $\delta \geq 0$, define

$$X_1(\delta) = \{x \in X_1 : d_K(g(x)) \leq \delta\}. \tag{10}$$

The following proposition gives sufficient conditions that guarantee LP well-posedness in the strongly generalized sense.

PROPOSITION 2.2. *Let one of the following conditions hold.*

(i) *There exists $\delta_0 > 0$ such that $X_1(\delta_0)$ is compact.*

(ii) *f is level-compact on X_1.*

(iii) *X is a finite dimensional normed space and*

$$\lim_{x \in X_1, \|x\| \to +\infty} \max\{f(x), d_K(g(x))\} = +\infty. \tag{11}$$

(iv) *There exists $\delta_0 > 0$ such that f is level-compact on $X_1(\delta_0)$.*

Then (P) *is LP well-posed in the strongly generalized sense.*

Proof. Let $\{x_n\} \subset X_1$ be a weakly generalized LP minimizing sequence. Then

$$\limsup_{n \to +\infty} f(x_n) \leq \bar{v}, \tag{12}$$

$$d_K(g(x_n)) \to 0. \tag{13}$$

The proof of (i) is elementary. It is obvious that condition (ii) implies (iv). Now we show that (iii) implies (iv). Indeed, we need only to show that for any $s \in R^1$ and any $\delta > 0$, the set

$$A = \{x \in X_1(\delta) : f(x) \leq s\}$$

is bounded since X is a finite dimensional space. Suppose to the contrary that there exist $\delta > 0$, $s > 0$, and $\{x'_n\} \subset X_1(\delta)$ such that

$$\|x'_n\| \to +\infty \text{ and } f(x'_n) \leq s.$$

By $\{x'_n\} \subset X_1(\delta)$, we have $\{x'_n\} \subset X_1$ and

$$d_K(g(x'_n)) \leq \delta.$$

As a result,

$$\max\{f(x'_n), d_K(g(x'_n))\} \leq \max\{s, \delta\},$$

contradicting (11).

Thus, we need only to prove that if (iv) holds, then (P) is LP well-posed in the strongly generalized sense. By (13), it is apparent that we can assume without loss of generality that $\{x_n\} \subset X_1(\delta_0)$. By (12), we can assume without loss of generality that

$$\{x_n\} \subset \{x \in X_1 : f(x) \leq \bar{v} + 1\}.$$

By the level-compactness of f on $X_1(\delta_0)$, we deduce that there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and $\bar{x} \in X_1$ such that $x_{n_k} \to \bar{x}$. It is obvious from (13) that $\bar{x} \in X_0$. Furthermore, from (12), we deduce that $f(\bar{x}) \leq \bar{v}$. So we have $f(\bar{x}) = \bar{v}$. That is, $\bar{x} \in \bar{X}$. Hence, (P) is LP well-posed in the strongly generalized sense. ∎

Now we consider the case when Y is a normed space and K is a closed and convex cone with nonempty interior $\text{int}K$. Arbitrarily fix an $e \in \text{int}K$. Let $t \geq 0$ and consider the following perturbed problem of (P):

$$(P_t) \qquad \min f(x)$$
$$\text{s.t. } x \in X_1, \quad g(x) \in K - te. \tag{14}$$

Let

$$X_2(t) = \{x \in X_1 : g(x) \in K - te\}. \tag{15}$$

PROPOSITION 2.3. *Let one of the following conditions hold.*
(i) *There exists $t_0 > 0$ such that $X_2(t_0)$ is compact.*
(ii) *f is level-compact on X_1.*
(iii) *X is a finite dimensional normed space and*

$$\lim_{x \in X_1, \|x\| \to +\infty} \max\{f(x), d_K(g(x))\} = +\infty.$$

(iv) *There exists $t_0 > 0$ such that f is level-compact on $X_2(t_0)$.*
Then (P) *is LP well-posed in the strongly generalized sense.*
Proof. The proof is similar to that of Proposition 2.2. □
Now we make the following assumption.

ASSUMPTION 2.1. *X is a finite dimensional normed space, Y is a normed space, $X_1 \subset X$ is a nonempty, closed, and convex set, $K \subset Y$ is a closed, and convex cone with nonempty interior* $\text{int}K$ *and $e \in \text{int}K$, f and g are continuous on X_1, f is a convex function on X_1, and g is K-concave on X_1 (namely, for any $x_1, x_2 \in X_1$ and any $\theta \in (0,1)$, there holds that $g(\theta x_1 + (1-\theta)x_2) - \theta g(x_1) - (1-\theta)g(x_2) \in K$).*

It is obvious that under Assumption 2.1, (P) is a convex program.
The next lemma can be proved similarly to that of [16, Proposition 2.4].

LEMMA 2.1. *Let Assumption* 2.1 *hold. Then the following two statements are equivalent.*
(i) *The optimal set $\bar{X}$ of* (P) *is nonempty and compact.*
(ii) *For any $t \geq 0$, f is level-compact on the set $X_2(t)$.*

THEOREM 2.4. *Let Assumption* 2.1 *hold. Then* (P) *is LP well-posed in the strongly generalized sense if and only if the optimal set $\bar{X}$ of* (P) *is nonempty and compact.*

Proof. The sufficiency part follows directly from Lemma 2.1 and Proposition 2.3, while the necessity part is obvious by Remark 1.1. □
The next two lemmas will be used to derive Theorem 2.5.

LEMMA 2.2 (see [1]). *Let (Z, d) be a complete metric space and $h : Z \to R^1 \cup \{+\infty\}$ be lower semicontinuous and bounded below. Let $\epsilon > 0$. Suppose that $z_0 \in Z$ satisfies $h(z_0) \leq \inf\{h(z) : z \in Z\} + \epsilon$. Then there exists $z_\epsilon \in Z$ such that*
(i) *$h(z_\epsilon) \leq h(z_0)$;*
(ii) *$d(z_\epsilon, z_0) \leq \sqrt{\epsilon}$;*
(iii) *$h(z_\epsilon) < h(z) + \sqrt{\epsilon} d(z, z_\epsilon)$ $\forall z \in Z \backslash \{z_\epsilon\}$.*

LEMMA 2.3. *Let Y be a normed space and $K \subset Y$ be a closed and convex cone with* $\text{int}K \neq \emptyset$ *and $e \in \text{int}K$. Suppose that $\{y_n\} \subset Y$. Then $d_K(y_n) \to 0$ if and only if there exists a sequence $\{t_n\} \subset R^1_+$ with $t_n \to 0$ such that $y_n \in K - t_n e$.*

Proof. For the necessity part, from $d_K(y_n) \to 0$, we have $\{u_n\} \subset K$ such that $\|y_n - u_n\| \to 0$. Let $y'_n = y_n - u_n$. Then $\|y'_n\| \to 0$. Let $t_n = \sqrt{\|y'_n\|}$. Then $\{t_n\} \subset R^1_+$,

$t_n \to 0$ and $y_n'/t_n \to 0$. Since $e \in \text{int}K$, it follows that $e + y_n'/t_n \in K$ when n is sufficiently large. Consequently, $y_n' \in K - t_n e$. Hence, $y_n = u_n + y_n' \in K - t_n e$.

For the sufficiency part, as $y_n \in K - t_n e$, we have $y_n + t_n e \in K$. Thus,

$$d_K(y_n) \le \|y_n - (y_n + t_n e)\| = t_n \|e\|.$$

Hence, $d_K(y_n) \to 0$. □

Suppose that K is a cone. We denote by K^* the positive polar cone of K, i.e.,

$$K^* = \{\mu \in Y^* : \mu(u) \ge 0 \ \forall u \in K\}.$$

THEOREM 2.5. *Assume that X is a Banach space, Y is a normed space, and $X_1 \subset X$ is nonempty, closed, and convex. $K \subset Y$ is a closed and convex cone with $\text{int}K \ne \emptyset$ and $e \in \text{int}K$. Suppose that $f : X \to R^1$ is convex and continuously differentiable on X_1 and $g : X \to Y$ is K-concave and continuously differentiable on X_1. Let Slater constraint qualification for* (P) *hold: there exists $x_0 \in X_1$ such that $g(x_0) \in \text{int}K$. Assume that the optimal set $\bar{X}$ of* (P) *is nonempty. Further assume that there exists a convergent subsequence of $\{x_n\}$ for any sequences $\{x_n\} \subset X_1$ and $\{\mu_n\} \subset K^*$ satisfying the following.*

(i) $\lim_{n \to +\infty} d_K(g(x_n)) = 0$.

(ii) *There exists a subsequence $\{\mu_{n_k}\}$ such that $\mu_{n_k} = 0 \ \forall k$ or $\lim_{n \to +\infty} \mu_n(g(x_n))/\|\mu_n\| = 0$.*

(iii) $\lim_{n \to +\infty} d_{(-N_{X_1}(x_n))}(\bigtriangledown f(x_n) - \mu_n(\bigtriangledown g(x_n))) = 0$, *where $N_{X_1}(x_n)$ is the normal cone of X_1 at x_n.*

Then, (P) is LP well-posed in the strongly generalized sense.

Proof. Suppose that $\bar{x} \in \bar{X}$. Since Slater constraint qualification holds, we have $\bar{\mu} \in K^*$ such that

$$f(\bar{x}) \le f(x) - \bar{\mu}(g(x)) \quad \forall x \in X_1 \tag{16}$$

and

$$\bar{\mu}(g(\bar{x})) = 0. \tag{17}$$

Let $\{x_n\} \subset X_1$ be a weakly generalized LP minimizing sequence for (P). Then, by Lemma 2.3,

$$\limsup_{n \to +\infty} f(x_n) \le \bar{v} \tag{18}$$

and

$$g(x_n) \in K - t_n e \tag{19}$$

for some $\{t_n\} \subset R^1_+$ with $t_n \to 0$. From (16), we have

$$f(\bar{x}) \le f(x) - \bar{\mu}(g(x)) \quad \forall x \in X_2(t_n).$$

Note that

$$-\bar{\mu}(g(x)) \le t_n \bar{\mu}(e) \quad \forall x \in X_2(t_n).$$

Thus,

$$f(\bar{x}) \le f(x) + t_n \bar{\mu}(e) \quad \forall x \in X_2(t_n). \tag{20}$$

Hence,

$$\inf_{x\in X_2(t_n)} f(x) > -\infty. \tag{21}$$

The combination of (19) and (20) gives

$$f(\bar{x}) \le f(x_n) + t_n\bar{\mu}(e).$$

Consequently,

$$f(\bar{x}) \le \liminf_{n\to+\infty} f(x_n).$$

This together with (18) yields

$$\lim_{n\to+\infty} f(x_n) = f(\bar{x}). \tag{22}$$

This combined with (20) implies that there exists $\epsilon_n \to 0^+$ such that

$$f(x_n) \le f(x) + \epsilon_n \quad \forall x \in X_2(t_n).$$

Note that $X_2(t_n) \subset X$ is nonempty and closed. $(X_2(t_n), \|\cdot\|)$ can be seen as a complete (metric) subspace of X. Applying Lemma 2.2, we obtain

$$x'_n \in X_2(t_n) \tag{23}$$

such that

$$\|x_n - x'_n\| \le \sqrt{\epsilon_n} \tag{24}$$

and

$$f(x'_n) \le f(x) + \sqrt{\epsilon_n}\|x - x'_n\| \quad \forall x \in X_2(t_n). \tag{25}$$

Note that Slater constraint qualification also holds for the following constrained optimization problem:

$$\begin{aligned} (P_n) \qquad & \min\ f(x) + \sqrt{\epsilon_n}\|x - x'_n\| \\ & \text{s.t. } x \in X_1, \quad g(x) \in K - t_n e, \end{aligned}$$

and by (25), x'_n is an optimal solution of (P_n). Hence, there exists $\mu_n \in K^*$ such that

$$0 \in \bigtriangledown f(x'_n) - \mu_n(\bigtriangledown g(x'_n)) + \sqrt{\epsilon_n}B^* + N_{X_1}(x'_n) \tag{26}$$

and

$$\mu_n(g(x'_n) + t_n e) = \mu_n(g(x'_n)) + t_n\mu_n(e) = 0, \tag{27}$$

where B^* is the closed unit ball of X^*. Equation (26) implies that

$$\lim_{n\to+\infty} d_{(-N_{X_1}(x'_n))}(\bigtriangledown f(x'_n) - \mu_n(\bigtriangledown g(x'_n))) = 0. \tag{28}$$

From (27), we see that if there does not exist a subsequence $\{\mu_{n_k}\}$ such that $\mu_{n_k} = 0\ \forall k$, then

$$\lim_{n\to+\infty} \mu_n(g(x_n))/\|\mu_n\| = 0. \tag{29}$$

The combination of (24), (28), and (29) implies that $\{x'_n\}$ and $\{\mu_n\}$ satisfy conditions (i)–(iii) of the theorem. Thus, $\{x'_n\}$ has a subsequence $\{x'_{n_k}\}$ which converges to some $\bar{x}' \in X_0$. From (24), we deduce that $x_{n_k} \to \bar{x}' \in X_0$. This combined with (22) implies $\bar{x}' \in \bar{X}$. Hence, (P) is LP well-posed in the strongly generalized sense. □

Remark 2.1. Conditions (i)–(iii) of Theorem 2.5 can be seen as the well-known Palais–Smale condition (C) [1] in the case of constrained optimization.

3. Relations among three types of (generalized) LP well-posedness. Simple relationships among the three types of LP well-posedness were mentioned in Remark 1.1. Now we investigate further relationships among them.

The proof of next theorem is elementary and is omitted.

THEOREM 3.1. *Suppose that there exist $\delta > 0$, $\alpha > 0$, and $c > 0$ such that*

$$d_{X_0}(x) \le c d_K^{\alpha}(g(x)) \quad \forall x \in X_1(\delta), \tag{30}$$

where $X_1(\delta)$ is defined by (10). *If* (P) *is LP well-posed, then* (P) *is LP well-posed in the generalized sense.*

Remark 3.1. Equation (30) is an error bound condition for the set X_0 in terms of the residual function

$$r(x) = d_K(g(x)) \quad \forall x \in X_1.$$

When $X = R^l, Y = R^m$, $X_1 = X$, and $X_0 \neq \emptyset$, by Theorem 5 of [23], (30) holds if and only if, for any $y \in R^m$ with $\|y\| \le \delta$,

$$\Psi(y) \subset \Psi(0) + c\|y\|^{\alpha} B,$$

where

$$\Psi(y) = \{x \in R^l : g(x) \in K + y\}, \quad y \in R^m,$$

and B is the closed unit ball of Y. Sufficient conditions guaranteeing (30) were given in numerous papers on error bounds for systems of inequalities and metric regularity of set-valued maps (when (30) holds locally with $\alpha = 1$) in finite and infinite dimensional spaces (see, e.g., [5, 8, 18] and the references therein).

DEFINITION 3.1 (see [4]). *Let W be a topological space and $F : W \to 2^X$ be a set-valued map. F is said to be upper Hausdorff semicontinuous (u.H.c.) at $w \in W$ if, for any $\epsilon > 0$, there exists a neighborhood U of w such that $F(U) \subset B(F(w), \epsilon)$, where, for $Z \subset X$ and $r > 0$,*

$$B(Z, r) = \{x \in X : d_Z(x) \le r\}.$$

DEFINITION 3.2 (see [1]). *Let W be a topological space and $F : W \to 2^X$ be a set-valued map. F is said to be upper semicontinuous (u.s.c.) in the Berge's sense at $w \in W$ if, for any neighborhood Ω of $F(w)$, there exists a neighborhood U of w such that $F(U) \subset \Omega$.*

It is obvious that the notion of u.s.c. (in Berge's sense) is stronger than u.H.c.

Clearly, $X_1(\delta)$ given by (10) can be seen as a set-valued map from R^1_+ to X. The next two theorems use conditions similar to those for the general stability results presented in section 3 of [4], where the uniform continuity of the objective function around the feasible set and the u.H.c. of the perturbation set-valued map were considered.

THEOREM 3.2. *Assume that the set-valued map $X_1(\delta)$ defined by* (10) *is u.H.c. at $0 \in R^1_+$. If* (P) *is LP well-posed, then* (P) *is LP well-posed in the generalized sense.*

Proof. Let $\{x_n\} \subset X_1$ be a generalized LP minimizing sequence. That is,

$$f(x_n) \to \bar{v}, \tag{31}$$

$$d_K(g(x_n)) \to 0. \tag{32}$$

Equation (32), together with the u.H.c. of $X_1(\delta)$ at 0, implies that $d_{X_0}(x_n) \to 0$. This fact combined with (31) implies that $\{x_n\}$ is an LP minimizing sequence. Thus,

there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$. Hence, (P) is LP well-posed in the generalized sense. □

THEOREM 3.3. *Assume that there exists $\epsilon_0 > 0$ such that f is uniformly continuous on $B(X_0, \epsilon_0)$ and the set-valued map $X_1(\delta)$ is u.H.c. at 0. If (P) is LP well-posed, then it is LP well-posed in the strongly generalized sense.*

Proof. Let $\{x_n\}$ be a weakly generalized LP minimizing sequence. That is,

$$\limsup_{n\to+\infty} f(x_n) \le \bar{v}, \tag{33}$$

$$d_K(g(x_n)) \to 0. \tag{34}$$

Note that $X_1(\delta)$ is u.H.c. at 0. This fact together with (34) implies that $d_{X_0}(x_n) \to 0$. Note that f is uniformly continuous on $B(X_0, \epsilon_0)$. It follows that

$$\liminf_{n\to+\infty} f(x_n) \ge \bar{v}. \tag{35}$$

The combination of (33) and (35) yields that

$$f(x_n) \to \bar{v}.$$

Hence, $\{x_n\}$ is an LP minimizing sequence. Thus, there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$. So, (P) is LP well-posed in the strongly generalized sense. □

Let $\delta \ge 0$. Consider the perturbed problem of (P):

$$(P_\delta) \qquad \begin{aligned} &\min\ f(x) \\ &\text{s.t. } x \in X_1, \quad d_K(g(x)) \le \delta. \end{aligned}$$

Denote by $v_1(\delta)$ the optimal value of (P_δ). Clearly, $v_1(0) = \bar{v}$.

THEOREM 3.4. *Consider problems* (P) *and* (P_δ). *Suppose that* (P) *is LP well-posed in the generalized sense and*

$$\liminf_{\delta\to 0^+} v_1(\delta) = \bar{v}. \tag{36}$$

Then (P) *is LP well-posed in the strongly generalized sense.*

Proof. Let $\{x_n\} \subset X_1$ be a weakly generalized LP minimizing sequence. Then

$$\limsup_{n\to+\infty} f(x_n) \le \bar{v} \tag{37}$$

and

$$\lim_{n\to+\infty} d_K(g(x_n)) = 0.$$

Let $\delta_n = d_K(g(x_n))$. Then x_n is feasible for (P_{δ_n}). Thus,

$$v_1(\delta_n) \le f(x_n).$$

Passing to the lower limit, we get

$$\liminf_{n\to+\infty} v_1(\delta_n) \le \liminf_{n\to+\infty} f(x_n).$$

This together with (37) and (36) yields

$$\lim_{n\to+\infty} f(x_n) = \bar{v}.$$

It follows that $\{x_n\}$ is a generalized LP minimizing sequence. Thus, there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$. So, (P) is LP well-posed in the strongly generalized sense. □

Remark 3.2. If the set-valued map $X_1(\delta)$ defined by (10) is u.s.c. at $0 \in R^1_+$, by Theorem 4.2.3 (1) of [2], (36) holds. In this case, the generalized LP well-posedness of (P) implies the strongly generalized LP well-posedness of (P).

Now let Y be a normed space and $y \in Y$. Consider the following perturbed problem of (P):

$$(P_y) \qquad \begin{aligned} &\min f(x) \\ &\text{s.t. } x \in X_1, \quad g(x) \in K + y. \end{aligned}$$

Denote by

$$X_3(y) = \{x \in X_1 : g(x) \in K + y\} \tag{38}$$

the feasible set of (P_y) and $v_3(y)$ the optimal value of (P_y). Here we note that if $X_3(y) = \emptyset$, we set $v_3(y) = +\infty$. It is obvious that $X_3(y)$ can be seen as a set-valued map from Y to X. Corresponding to Theorems 3.2–3.4, respectively, we have the following theorems.

THEOREM 3.5. *Assume that Y is a normed space and that the set-valued map $X_3(y)$ is u.H.c. at $0 \in Y$. If* (P) *is LP well-posed, then* (P) *is LP well-posed in the generalized sense.*

THEOREM 3.6. *Assume that Y is a normed space and that there exists $\epsilon_0 > 0$ such that f is uniformly continuous on $B(X_0, \epsilon_0)$ and the set-valued map $X_3(y)$ is u.H.c. at $0 \in Y$. If* (P) *is LP well-posed, then it is LP well-posed in the strongly generalized sense.*

THEOREM 3.7. *Assume that Y is a normed space. Consider problems* (P) *and* (P_y). *Suppose that* (P) *is LP well-posed in the generalized sense and*

$$\liminf_{y\to 0} v_3(y) = \bar{v}. \tag{39}$$

Then (P) *is LP well-posed in the strongly generalized sense.*

Similar to Remark 3.2, when the set-valued map X_3 is u.s.c. at $0 \in Y$, then (39) holds. Thus, the generalized LP well-posedness of (P) implies its strongly generalized LP well-posedness.

In the special case when K is a closed and convex cone with nonempty interior $\mathrm{int}K$, arbitrarily fix an $e \in \mathrm{int}K$. It is obvious that $X_2(t)$ defined by (15) can be seen as a set-valued map from R^1_+ to X. Denote by $v_2(t)$ the optimal value of (P_t).

THEOREM 3.8. *Assume that K is a closed and convex cone with nonempty interior* $\mathrm{int}K$ *and that the set-valued map $X_2(t)$ is u.H.c. at $0 \in R^1_+$. If* (P) *is LP well-posed, then* (P) *is LP well-posed in the generalized sense.*

THEOREM 3.9. *Assume that K is a closed and convex cone with nonempty interior* $\mathrm{int}K$ *and that there exists $\epsilon_0 > 0$ such that f is uniformly continuous on $B(X_0, \epsilon_0)$ and the set-valued map $X_2(t)$ is u.H.c. at $0 \in R^1_+$. If* (P) *is LP well-posed, then it is LP well-posed in the strongly generalized sense.*

THEOREM 3.10. *Assume that K is a closed and convex cone with nonempty interior* $\mathrm{int}K$. *Consider problems* (P) *and* (P_t). *Suppose that* (P) *is LP well-posed in the generalized sense and*

$$\liminf_{t\to 0^+} v_2(t) = \bar{v}. \tag{40}$$

Then (P) *is LP well-posed in the strongly generalized sense.*

Again, as noted in Remark 3.2, when the set-valued map X_2 is u.s.c. at $0 \in R^1_+$, then (39) holds. Thus, the generalized LP well-posedness of (P) implies its strongly generalized LP well-posedness.

4. Applications to penalty-type methods. In this section, we consider the convergence of a class of penalty methods and a class of augmented Lagrangian methods under the assumption of strongly generalized LP well-posedness of (P).

4.1. Penalty methods. Let $\alpha > 0$. Consider the following penalty problem:

$$(PP_\alpha(r)) \quad \min_{x\in X_1} f(x) + r d_K^\alpha(g(x)), \quad r > 0.$$

Denote by $v_4(r)$ the optimal value of $(PP_\alpha(r))$. It is clear that

$$v_4(r) \le \bar{v} \quad \forall r > 0. \tag{41}$$

Remark 4.1. When $\alpha \in (0,1)$, $X = R^l$, $Y = R^m$, $K = R^{m_1}_- \times \{0_{m-m_1}\}$, where $m \ge m_1$ and 0_{m-m_1} is the origin of the space R^{m-m_1}, this class of penalty functions was applied to the study of mathematical programs with equilibrium constraints [19]. Necessary and sufficient conditions for the exact penalization of this class of penalty functions were derived in [14]. This class of penalty methods was also applied to mathematical programs with complementarity constraints [27] and nonlinear semidefinite programs [15]. An important advantage of this class of penalty methods is that it requires weaker conditions to guarantee its exact penalization property than the usual l_1 penalty function method (see [19]).

THEOREM 4.1. *Let* $0 < r_n \to +\infty$. *Consider problems* (P) *and* $(PP_\alpha(r_n))$. *Assume that there exist* $\bar{r} > 0$ *and* $m_0 \in R^1$ *such that*

$$f(x) + \bar{r} d_K^\alpha(g(x)) \ge m_0 \quad \forall x \in X_1. \tag{42}$$

Let $0 < \epsilon_n \to 0$. Suppose that each $x_n \in X_1$ satisfies

$$f(x_n) + r_n d_K^\alpha(g(x_n)) \le v_4(r_n) + \epsilon_n. \tag{43}$$

Further assume that (P) is LP well-posed in the strongly generalized sense. Then there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$.

Proof. From (41) and (43), we have

$$f(x_n) \le \bar{v} + \epsilon_n.$$

Thus,

$$\limsup_{n\to+\infty} f(x_n) \le \bar{v}. \tag{44}$$

Moreover, from (41)–(43), we deduce that

$$f(x_n) + \bar{r} d_K^\alpha(g(x_n)) + (r_n - \bar{r}) d_K^\alpha(g(x_n)) \le \bar{v} + \epsilon_n.$$

Thus,

$$m_0 + (r_n - \bar{r}) d_K^{\alpha}(g(x_n)) \leq \bar{v} + \epsilon_n,$$

implying

$$d_K(g(x_n)) \leq \left[\frac{\bar{v} + \epsilon_n - m_0}{r_n - \bar{r}} \right]^{1/\alpha}.$$

Passing to the limit, we get

$$\lim_{n \to +\infty} d_K(g(x_n)) = 0. \tag{45}$$

It follows from (44) and (45) that $\{x_n\}$ is a weakly generalized LP minimizing sequence. Hence, there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$. □

4.2. Augmented Lagrangian methods. Let (X, d_1) be a metric space, let $Y = R^m$, and let $K \subset Y$ be a nonempty, closed, and convex set. Let $\sigma : R^m \to R^1 \cup \{+\infty\}$ be an augmenting function; namely, it is a lower semicontinuous, convex function satisfying

$$\min_{y \in R^m} \sigma(y) = 0 \text{ and } \sigma \text{ attains its unique minimum at } y = 0.$$

Following Example 11.46 in [25], we define the dualizing parametrization function by setting $X = X_1$ and $\theta = \delta_K$:

$$\bar{f}(x, u) = f(x) + \delta_{X_1}(x) + \delta_K(g(x) + u),$$

where δ_A is the indicator function of a subset A of a space Z, i.e.,

$$\delta_A(a) = \begin{cases} 0 & \text{if } a \in A, \\ +\infty & \text{if } a \in Z \backslash A. \end{cases}$$

Constructing the augmented Lagrangian as in Definition 11.55 of [25], we obtain the augmented Lagrangian:

$$\bar{l}(x, y, r) = \inf_{u \in R^m} \left\{ \bar{f}(x, u) + r\sigma(u) - \langle y, u \rangle \right\}, x \in X, y \in R^m, r > 0.$$

The augmented Lagrangian problem is

$$(ALP(y, r)) \quad \min_{x \in X} \bar{l}(x, y, r), \quad y \in R^m, r > 0.$$

Denote by $v_5(y, r)$ the optimal value of $(ALP(y, r))$.

We have the following result.

THEOREM 4.2. *Let $\{y_n\} \subset R^m$ be bounded and $0 < r_n \to +\infty$. Consider* (P) *and $(ALP(y_n, r_n))$. Assume that there exist $(\bar{y}, \bar{r}) \in R^m \times (0, +\infty)$ and $m_0 \in R^1$ such that*

$$\bar{l}(x, \bar{y}, \bar{r}) \geq m_0 \quad \forall x \in X. \tag{46}$$

Let $0 < \epsilon_n \to 0$. Suppose that each x_n satisfies

$$\bar{l}(x_n, y_n, r_n) \leq v_5(y_n, r_n) + \epsilon_n, \tag{47}$$

$v_5(y_n, r_n) > -\infty \ \forall n$, and (P) *is LP well-posed in the strongly generalized sense. Then there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$.*

Proof. By the definition of $\bar{l}(x, y, r)$, it is easy to see that

$$\bar{l}(x, y, r) = f(x) \quad \forall x \in X_0.$$

It follows that

$$v_5(y, r) \leq \bar{v} \quad \forall y \in R^m, r > 0.$$

Thus,

$$v_5(y_n, r_n) \leq \bar{v} \quad \forall n. \tag{48}$$

By the definition of $\bar{l}(x_n, y_n, r_n)$ and (47), $\{x_n\} \subset X_1$ and there exists $\{u_n\} \subset R^m$ satisfying

$$g(x_n) + u_n \in K \quad \forall n \tag{49}$$

such that

$$f(x_n) + r_n\sigma(u_n) - \langle y_n, u_n\rangle \leq v_5(y_n, r_n) + 2\epsilon_n. \tag{50}$$

This combined with (46) and (48) implies that

$$(r_n - \bar{r})\sigma(u_n) - \langle y_n - \bar{y}, u_n\rangle \leq \bar{v} + 2\epsilon_n - m_0. \tag{51}$$

We assert that $\{u_n\}$ is bounded. Otherwise, we assume without loss of generality that $\|u_n\| \to +\infty$. Since the lower semicontinuous and convex function σ has a unique minimum, by Proposition 3.2.5 in IV of [11] and Corollary 3.27 of [25], $\liminf_{n\to+\infty} \sigma(u_n)/\|u_n\| > 0$. As $\{y_n\}$ is bounded, (51) cannot hold. So, $\{u_n\}$ should be bounded. Assume without loss of generality that $u_n \to u_0$. We deduce from (51) that

$$\sigma(u_0) \leq \liminf_{n\to+\infty} \sigma(u_n) = 0.$$

It follows that $u_0 = 0$. We deduce from (48) and (50) that

$$f(x_n) - \langle y_n, u_n\rangle \leq \bar{v} + 2\epsilon_n.$$

Passing to the limit, we get

$$\limsup_{n\to+\infty} f(x_n) \leq \bar{v}.$$

From (49) and the fact that $u_n \to 0$, we obtain

$$\lim_{n\to+\infty} d_K(g(x_n)) = 0.$$

Thus, $\{x_n\}$ is a weakly generalized LP minimizing sequence. Hence, there exist a subsequence $\{x_{n_k}\}$ of $\{x_n\}$ and some $\bar{x} \in \bar{X}$ such that $x_{n_k} \to \bar{x}$. □

LOCAL CONVERGENCE OF SQP METHODS FOR MATHEMATICAL PROGRAMS WITH EQUILIBRIUM CONSTRAINTS*

ROGER FLETCHER†, SVEN LEYFFER‡, DANNY RALPH§, AND STEFAN SCHOLTES§

Abstract. Recently, nonlinear programming solvers have been used to solve a range of mathematical programs with equilibrium constraints (MPECs). In particular, sequential quadratic programming (SQP) methods have been very successful. This paper examines the local convergence properties of SQP methods applied to MPECs. SQP is shown to converge superlinearly under reasonable assumptions near a strongly stationary point. A number of examples are presented that show that some of the assumptions are difficult to relax.

Key words. nonlinear programming, sequential quadratic programming (SQP), mathematical programs with equilibrium constraints (MPEC), mathematical programs with complementarity constraints (MPCC), equilibrium constraints

AMS subject classifications. 90C30, 90C33, 90C55, 49M37, 65K10

DOI. 10.1137/S1052623402407382

1. Introduction.

We consider mathematical programs with equilibrium constraints (MPECs) of the form

$$\begin{array}{ll} \text{minimize} & f(z) \\ \text{subject to} & c_{\mathcal{E}}(z) = 0, \\ & c_{\mathcal{I}}(z) \geq 0, \\ & 0 \leq z_1 \ \perp \ z_2 \geq 0, \end{array} \tag{1.1}$$

where $z = (z_0, z_1, z_2)$ is a decomposition of the problem variables into controls $z_0 \in \mathbb{R}^n$ and states $(z_1, z_2) \in \mathbb{R}^{2p}$. The equality constraints $c_i(z) = 0,\ i \in \mathcal{E}$, are abbreviated as $c_{\mathcal{E}}(z) = 0$, and similarly, $c_{\mathcal{I}}(z) \geq 0$ represents the inequality constraints. Problems of this type arise frequently in applications; see [7, 16, 17] for references. (Problem (1.1) is also referred to as a mathematical program with complementarity constraints (MPCC).)

Clearly, an MPEC with a more general complementarity condition such as

$$0 \leq G(z) \perp H(z) \geq 0 \tag{1.2}$$

can be written in the form (1.1) by introducing slack variables. One can easily show that the reformulated MPEC has the same properties (such as constraint qualifications or second-order conditions) as the original MPEC. In this sense, nothing is lost by introducing slack variables.

One attractive way of solving (1.1) is to consider its equivalent nonlinear programming (NLP) formulation,

$$\begin{array}{ll} \text{minimize} & f(z) \\ \text{subject to} & c_{\mathcal{E}}(z) = 0, \\ & c_{\mathcal{I}}(z) \geq 0, \\ & z_1 \geq 0, \\ & z_2 \geq 0, \\ & z_1^T z_2 \leq 0, \end{array} \tag{1.3}$$

and solve (1.3) with existing NLP solvers. This paper examines the local convergence properties of sequential quadratic programming (SQP) methods applied to (1.3).

The NLP (1.3) obviously has no feasible point that satisfies the inequalities strictly. This fact implies that the Mangasarian–Fromovitz constraint qualification (MFCQ) is violated at every feasible point; see [4, 19]. There are other, MPEC-specific constraint qualifications, such as the MPEC-LICQ explained below, which guarantee the existence of multipliers at local optima of (1.3) and are not overly stringent; see [21]. MFCQ, however, is a sufficient condition for stability of an NLP, and the lack thereof has been advanced as a theoretical argument against the use of standard NLP solvers for MPECs.

Numerical experience with (1.3) has also been disappointing. Bard [2] reports failure on 50–70% of some bilevel problems for a gradient projection method. Conn, Gould, and Toint [5] and Ferris and Pang [7] attribute certain failures of lancelot to the fact that the problem contains a complementarity constraint. In contrast, Fletcher and Leyffer [10] recently reported encouraging numerical results on a large collection of MPECs [15]. They solved over 150 MPECs with an SQP solver and observed *quadratic* convergence for all but two problems. The two problems that did not give quadratic convergence violate certain MPEC regularity conditions and are rather pathological. The present work complements these numerical observations by giving a theoretical explanation for the good performance of the SQP method on apparently ill-posed problems of the type (1.3). We show that SQP is guaranteed to converge quadratically near a stationary point under relatively mild assumptions.

Recently, researchers have expressed renewed interest in the global convergence of algorithms for MPECs. Scholtes [20] analyzes a regularization scheme in which a sequence of parametric NLPs is solved. Fukushima and Tseng [11] analyze an algorithm that computes approximate KKT points for a sequence of active sets.

The paper also complements the recently renewed interest in the convergence properties of SQP under weaker assumptions. See, for example, [8, 13, 22]. These studies suggest modifications to enable SQP solvers to handle NLP problems for which the constraint gradients are linearly dependent at the solution and/or for which strict complementarity fails to hold.

Anitescu [1] extends Wright's analysis [22] to NLPs with unbounded multiplier sets. The fact that (1.3) violates MFCQ implies that the multiplier set at stationary solutions will be unbounded. Anitescu's work therefore applies to MPECs in the given form. However, his assumptions differ from ours, and neither set of assumptions is implied by the others. Most notably, Anitescu assumes that the QP solver employs an elastic mode, relaxing constraint linearizations if they are inconsistent. We do not require such a modification and provide a local analysis of the SQP method in its pure form.

In this paper, we argue that the introduction of slack variables is not just a convenience but plays an important role in ensuring convergence. In section 7.2 we present an example with a nonlinear complementarity constraint for which SQP converges to a nonstationary point. All QP approximations remain consistent during the solve. With the introduction of slack variables, on the other hand, SQP converges to a stationary point. Of course, this does not mean that the use of slacks makes an elastic mode or a feasibility restoration unnecessary. The example in section 2.2 clearly shows that NLP solvers must be able to handle inconsistent QPs.

This paper is organized as follows. The next section gives a few simple motivating examples that highlight the key ideas of our approach and illustrate the numerical difficulties associated with MPECs. In section 3 we review optimality conditions and constraint qualifications for MPECs. Section 4 shows that the optimality conditions of the MPEC and its equivalent NLP are related by a simple formula. In section 5 we show that SQP converges quadratically in two distinct situations. The first arises when SQP is started close to a complementary stationary point. If the starting point is not complementary, then we show convergence under the assumption that all QP subproblems remain consistent. Sufficient conditions for this assumption are introduced in section 6. In section 7 we present small examples that illustrate the necessity of some of these assumptions. We conclude by briefly emphasizing the importance of degeneracy handling at the QP level and pointing to future research directions.

Notation. Throughout the paper, $g(z) = \nabla f(z)$ is the objective gradient and the constraint gradients are denoted by $a_i(z) = \nabla c_i(z)$. Superscripts refer to the point at which functions or gradients are evaluated, for example, $a_i^{(k)} = a_i(z^{(k)}) = \nabla c_i(z^{(k)})$. The Jacobian matrices are denoted by $A_{\mathcal{E}} := [a_i]_{i\in\mathcal{E}}$ and $A_{\mathcal{I}} := [a_i]_{i\in\mathcal{I}}$, respectively.

2. Examples. The fact that the NLP formulation (1.3) of an MPEC violates MFCQ at any feasible point implies that (1.3) has certain features that pose numerical challenges to NLP solvers.

1. The active constraint normals are *linearly dependent* at any feasible point.
2. The set of multipliers is *unbounded*.
3. Arbitrarily close to a stationary point, the linearizations of (1.3) can be *inconsistent*.

These features are illustrated by the following examples. The examples also motivate the analysis in subsequent sections. The main conclusion of this section is that while MPECs possess these unpleasant properties, they arise in a well-structured way that allows SQP solvers to tackle MPECs successfully.

In the remainder of this paper, `*.mod` refers to the AMPL model of the problem in MacMPEC, an AMPL collection of MPECs [15].

2.1. Dependent constraint normals and unbounded multipliers. In this section we use a small example from Jiang and Ralph [14] (see also `jr*.mod`) to illustrate the key idea of our approach. Consider the two MPECs

$$\begin{cases} \underset{z}{\text{minimize}} & f_i(z) \\ \text{subject to} & 0 \le z_2 \ \perp \ z_2 - z_1 \ge 0 \end{cases} \tag{2.1}$$

with $f_1(z) = (z_1 - 1)^2 + z_2^2$ and $f_2(z) = z_1^2 + (z_2 - 1)^2$. The problems differ only in their objectives. The solution to both problems is $z^* = (1/2, 1/2)^T$; see Figure 1.

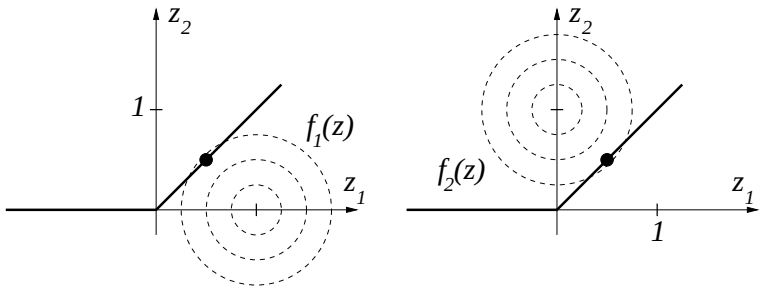

FIG. 1. *MPEC examples* 1 *and* 2.

The equivalent NLP problem to these MPECs is given by

$$\left\{\begin{array}{lll} \underset{z}{\text{minimize}} & f_i(z) & \text{multiplier} \\ \text{subject to} & z_2 \geq 0, & \nu \geq 0, \\ & z_2 - z_1 \geq 0, & \lambda \geq 0, \\ & z_2\,(z_2 - z_1) \leq 0, & \xi \geq 0. \end{array}\right. \tag{2.2}$$

The first-order conditions for these NLPs differ only in the objective gradient and are

$$\begin{pmatrix} -1 \\ 1 \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} 1 \\ -1 \end{pmatrix} \;=\; \lambda^* \begin{pmatrix} -1 \\ 1 \end{pmatrix} \;-\; \xi^* \begin{pmatrix} -\frac{1}{2} \\ \frac{1}{2} \end{pmatrix}.$$

Clearly, the two active constraint normals are linearly dependent. Since $z_2^* = \frac{1}{2} > 0$ it follows that $\nu^* = 0$. The multiplier sets, given by

$$\mathcal{M}_1 \;=\; \left\{(\lambda,\xi) \mid \xi \geq 0,\; \lambda - \frac{1}{2}\xi = 1\right\},$$

$$\mathcal{M}_2 \;=\; \left\{(\lambda,\xi) \mid \lambda \geq 0,\; -\lambda + \frac{1}{2}\xi = 1\right\},$$

are unbounded, as expected. The sets are shown in Figure 2.

This situation is typical for MPECs that satisfy a strong stationarity condition (see Definition 3.3). The multiplier set is a ray, and there is exactly one degree of freedom in the choice of multipliers.

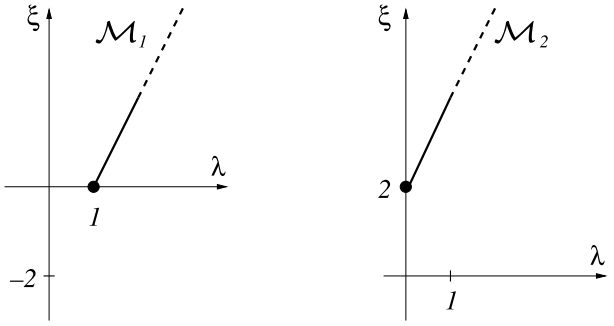

FIG. 2. *Multiplier sets of MPEC examples* 1 *and* 2.

Note, however, that if we restrict our attention to multipliers that correspond to a *linearly independent set* of constraint normals, then the following reduced sets are obtained:

$$\tilde{\mathcal{M}}_1 = \left\{\begin{pmatrix} 1 \\ 0 \end{pmatrix}\right\},$$

$$\tilde{\mathcal{M}}_2 = \left\{\begin{pmatrix} 0 \\ 2 \end{pmatrix}\right\}.$$

These multipliers are bounded and well behaved. We should expect SQP to converge if started near such a stationary point. The KKT multipliers that correspond to a solution with linearly independent strictly active constraints are illustrated by the black circles in Figure 2. The half-line shows the unbounded multiplier set.

Observe that in the first example, $\lambda \geq 0$ at the solution, which implies that this is also the solution for the NLP with the complementarity condition removed. In the second example, no $\lambda \geq 0$ can on its own satisfy the stationarity conditions, and $\xi > 0$ is required. If we had interpreted $z_2 - z_1 \geq 0$ as an equality constraint, then we could have chosen $\lambda = -1$ in the stationarity conditions. However, an NLP solver would never return $\lambda < 0$ for an inequality constraint, and hence $\xi = 2$ ensures that the stationarity conditions are satisfied.

The effect of the multiplier of the complementarity constraint is to relax the condition that $\lambda, \nu \geq 0$ for what is essentially an equality constraint. This is exploited in section 4, where we show that certain MPEC multipliers correspond to multipliers of (1.3). This situation is typical for MPECs under certain assumptions. The key idea is to show that SQP converges to a solution provided the QP solver chooses a linearly independent basis.

2.2. Inconsistent linearizations. The following example illustrates a possible pitfall for NLP solvers attempting to solve MPECs as NLPs. Consider `sl4.mod`:

$$\begin{cases} \underset{z}{\text{minimize}} & z_1 + z_2 \\ \text{subject to} & z_2^2 \geq 1, \\ & 0 \leq z_1 \ \perp \ z_2 \geq 0. \end{cases} \tag{2.3}$$

Its solution is $z^* = (0,1)^T$ with NLP multipliers $\lambda^* = 0.5$ of $z_2^2 \geq 1$, $\nu_1^* = 1$ of $z_1 \geq 0$, and $\xi^* = 0$ of $z_1 z_2 \leq 0$. In particular, this solution is a strongly stationary point (see Definition 3.3). However, linearizing the constraints about a point that satisfies the simple bounds and is *arbitrarily close to the solution*, such as $z^{(0)} = (\epsilon, 1-\delta)^T$ (with $\epsilon, \delta > 0$), gives a QP that is *inconsistent*. The linearizations are

$$(1-\delta)^2 + 2(1-\delta)(z_2 - (1-\delta)) \geq 1, \tag{2.4}$$

$$z_1 \geq 0,$$

$$z_2 \geq 0,$$

$$(1-\delta)\epsilon + (1-\delta)(z_1 - \epsilon) + \epsilon(z_2 - (1-\delta)) \leq 0. \tag{2.5}$$

One can show that

$$(2.4) \Rightarrow z_2 \geq \frac{1 + (1-\delta)^2}{2(1-\delta)} > 1,$$

$$(2.5) \Rightarrow z_2 \leq 1 - \delta < 1,$$

which indicates that the QP approximation is inconsistent. This is also observed during our filter solves (we enter restoration at this point).

Clearly, any NLP solver hoping to tackle MPECs will have to deal with this situation. The solver snopt [12] uses an *elastic mode* that relaxes the linearizations of the QP; filter [9] has a restoration phase. In section 5 convergence of SQP methods without modifications is analyzed. This analysis is closer in spirit to the results obtained using filter.

3. Optimality conditions for MPECs. This section reviews stationarity concepts for MPECs in the form (1.1) and introduces a second-order condition. It follows loosely the development of Scheel and Scholtes [19], although the presentation is slightly different.

Given two index sets $\mathcal{Z}_1,\ \mathcal{Z}_2 \subset \{1,\dots,p\}$ with

$$\mathcal{Z}_1 \cup\ \mathcal{Z}_2\ =\ \{1,\dots,p\}\,, \tag{3.1}$$

we denote their respective complements in $\{1,\dots,p\}$ by $\mathcal{Z}_1^c$ and $\mathcal{Z}_2^c$. For any such pair of index sets, we define the *relaxed NLP corresponding to the MPEC* (1.1) as

$$\begin{array}{lll} \underset{z}{\text{minimize}} & f(z) & \\ \text{subject to} & c_{\mathcal{E}}(z) = 0, & \\ & c_{\mathcal{I}}(z) \geq 0, & \\ & z_{1j} = 0 & \forall j \in \mathcal{Z}_2^c, \\ & z_{2j} = 0 & \forall j \in \mathcal{Z}_1^c, \\ & z_{1j} \geq 0 & \forall j \in \mathcal{Z}_2, \\ & z_{2j} \geq 0 & \forall j \in \mathcal{Z}_1. \end{array} \tag{3.2}$$

Concepts such as constraint qualifications, stationarity, and a second-order condition for MPECs will be defined in terms of the relaxed NLPs. The term "relaxed NLP" stems from the observation that if z^* is a local solution of a relaxed NLP (3.2) *and* satisfies complementarity ${z_1^*}^T z_2^* = 0$, then z^* is also a local solution of the original MPEC (1.1). One can naturally associate with every feasible point $\hat{z} = (\hat{z}_0, \hat{z}_1, \hat{z}_2)$ of the MPEC a relaxed NLP (3.2) by choosing $\mathcal{Z}_1$ and $\mathcal{Z}_2$ to contain the indices of the vanishing components of $\hat{z}_1$ and $\hat{z}_2$, respectively. In contrast to [19], our definition of the relaxed NLP is independent of a specific point; however, it will occasionally be convenient to identify the above sets of vanishing components associated with a specific point $\hat{z}$, in which case we denote them by $\mathcal{Z}_1(\hat{z})$, $\mathcal{Z}_2(\hat{z})$, or use suitable superscripts. Note that for these sets the condition (3.1) is equivalent to $\hat{z}_1^T \hat{z}_2 = 0$.

The indices that are both in $\mathcal{Z}_1$ and $\mathcal{Z}_2$ are referred to as the *biactive components* (or second-level degenerate indices) and are denoted by

$$\mathcal{D}(z) := \mathcal{Z}_1(z) \cap \mathcal{Z}_2(z) \ \text{ or } \ \mathcal{D} := \mathcal{Z}_1 \cap \mathcal{Z}_2.$$

Obviously, in view of (3.1), $(\mathcal{Z}_1^c, \mathcal{Z}_2^c, \mathcal{D})$ is a partition of $\{1,\dots,p\}$. A solution z^* to the problem (1.1) is said to be *second-level nondegenerate* if $\mathcal{D}(z^*) = \emptyset$.

First, the linear independence constraint qualification (LICQ) is extended to MPECs.

DEFINITION 3.1. *Let $z_1, z_2 \geq 0$, and define*

$$\mathcal{Z}_j := \{i\ :\ z_{ji} = 0\} \quad \textit{for}\ \ j = 1, 2.$$

The MPEC (1.1) *is said to satisfy an* MPEC-LICQ *at z if the corresponding relaxed NLP* (3.2) *satisfies an LICQ.*

In [19], four stationarity concepts are introduced for MPEC (1.1). The stationarity definition that allows the strongest conclusions is Bouligand or B-stationarity.

DEFINITION 3.2. *A point z^* is called* Bouligand*, or* B-stationary*, if $d = 0$ solves the linear program with equilibrium constraints (LPEC) obtained by linearizing f and c about z^*,*

$$\begin{array}{ll} \underset{d}{\text{minimize}} & {g^*}^T d \\ \text{subject to} & c^*_{\mathcal{E}} + {A^*_{\mathcal{E}}}^T d = 0, \\ & c^*_{\mathcal{I}} + {A^*_{\mathcal{E}}}^T d \geq 0, \\ & 0 \leq z^*_1 + d_1 \ \perp \ z^*_2 + d_2 \geq 0. \end{array}$$

We note that B-stationarity implies feasibility because if $d = 0$ solves the above LPEC, then $c^*_{\mathcal{E}} = 0$, $c^*_{\mathcal{I}} \geq 0$, and $0 \leq z^*_1 \ \perp \ z^*_2 \geq 0$. B-stationarity is difficult to check because it involves the solution of an LPEC that is a combinatorial problem and may require the solution of an exponential number of LPs, unless *all* these LPs share a common multiplier vector. Such a common multiplier vector exists if an MPEC-LICQ holds.

The results of this paper relate to the following notion of strong stationarity.

DEFINITION 3.3. *A point z^* is called* strongly stationary *if there exist multipliers λ, $\hat{\nu}_1$, and $\hat{\nu}_2$ such that*

$$\begin{aligned} g^* - \left[{A^*_{\mathcal{E}}}^T \ : \ {A^*_{\mathcal{I}}}^T\right]\lambda - \begin{pmatrix} 0 \\ \hat{\nu}_1 \\ \hat{\nu}_2 \end{pmatrix} &= 0, \\ c^*_{\mathcal{E}} &= 0, \\ c^*_{\mathcal{I}} &\geq 0, \\ z^*_1 &\geq 0, \\ z^*_2 &\geq 0, \\ z^*_{1j} = 0 \ \ \textit{or} \ \ z^*_{2j} &= 0, \\ \lambda_{\mathcal{I}} &\geq 0, \\ c^*_i \lambda_i &= 0, \\ z^*_{1j} \hat{\nu}_{1j} &= 0, \\ z^*_{2j} \hat{\nu}_{2j} &= 0, \\ \textit{if } z^*_{1j} = z^*_{2j} = 0, \ \ \textit{then} \ \ \hat{\nu}_{1j} \geq 0 \ \ \textit{and} \ \ \hat{\nu}_{2j} &\geq 0, \end{aligned} \tag{3.3}$$

where $g^* = \nabla f(z^*)$, $A^*_{\mathcal{E}} = \nabla c^T_{\mathcal{E}}(x^*)$, and $A^*_{\mathcal{I}} = \nabla c^T_{\mathcal{I}}(x^*)$.

Note that (3.3) are the stationarity conditions of the relaxed NLP (3.2) at z^*. B-stationarity is equivalent to strong stationarity if the MPEC-LICQ holds (e.g., [19]).

Next, a second-order sufficient condition (SOSC) for MPECs is given. Since strong stationarity is related to the relaxed NLP (3.2), it seems plausible to use the same NLP to define a second-order condition. For this purpose, let $\mathcal{A}^*$ denote the set of active constraints of (3.2) and $\mathcal{A}^*_+ \subset \mathcal{A}^*$ the set of active constraints with nonzero multipliers (some could be negative). Let A denote the matrix of active constraint normals, that is,

$$A = \begin{bmatrix} & & 0 & & 0 \\ A^*_{\mathcal{E}} \ : \ A^*_{\mathcal{I}\cap\mathcal{A}^*} \ : & & I^*_1 & : & 0 \\ & & 0 & & I^*_2 \end{bmatrix} =: \ [a^*_i]_{i\in\mathcal{A}^*},$$

where $A^*_{\mathcal{I}\cap\mathcal{A}^*}$ are the active inequality constraint normals and

$$I_1^* := [e_i]_{i\in\mathcal{Z}_1^*} \quad \text{and} \quad I_2^* := [e_i]_{i\in\mathcal{Z}_2^*}$$

are parts of the $p \times p$ identity matrices corresponding to active bounds. Define the set of feasible directions of zero slope of the relaxed NLP (3.2) as

$$S^* = \{s \mid s \neq 0\ ,\ {g^*}^T s = 0\ ,\ {a_i^*}^T s = 0\ ,\ i \in \mathcal{A}_+^*\ ,\ {a_i^*}^T s \geq 0\ ,\ i \in \mathcal{A}^*\backslash\mathcal{A}_+^*\}.$$

We can now give an MPEC-SOSC. This condition is also sometimes referred to as the strong-SOSC.

DEFINITION 3.4. *A strongly stationary point z^* with multipliers $(\lambda^*, \hat{\nu}_1^*, \hat{\nu}_2^*)$ satisfies the* MPEC-SOSC *if for every direction $s \in S^*$ it follows that*

$$s^T \nabla^2 \mathcal{L}^* s > 0,$$

where $\nabla^2\mathcal{L}^*$ is the Hessian of the Lagrangian of (3.2) *evaluated at $(z^*, \lambda^*, \hat{\nu}_1^*, \hat{\nu}_2^*)$.*

The definitions of this section are readily extended to the case where a more general complementarity condition such as (1.2) is used. Moreover, any reformulation using slacks preserves all of these definitions. In that sense, there is no loss of generality in assuming that slacks are being used.

4. Strong stationarity and NLP stationarity. This section shows that there exists a relationship between strong stationarity of the MPEC (1.1) and NLP stationarity conditions for (1.3). In particular, their respective multipliers are shown to be related by a simple formula.

The NLP stationarity conditions of (1.3) are that there exist multipliers $\mu := (\lambda, \nu_1, \nu_2, \xi)$ such that

$$\begin{aligned}
g(z) - \left[A_{\mathcal{E}}^T(z) : A_{\mathcal{I}}^T(z)\right]\lambda - \begin{pmatrix} 0 \\ \nu_1 \\ \nu_2 \end{pmatrix} + \xi \begin{pmatrix} 0 \\ z_2 \\ z_1 \end{pmatrix} &= 0, \\
c_{\mathcal{E}}(z) &\geq 0, \\
c_{\mathcal{I}}(z) &\geq 0, \\
z_1 &\geq 0, \\
z_2 &\geq 0, \\
z_1^T z_2 &\leq 0, \\
\lambda_{\mathcal{I}} &\geq 0, \\
\nu_1 &\geq 0, \\
\nu_2 &\geq 0, \\
\xi &\geq 0, \\
c_i(z)\lambda_i &= 0, \\
z_{1j}\nu_{1j} &= 0, \\
z_{2j}\nu_{2j} &= 0.
\end{aligned} \tag{4.1}$$

The complementarity condition $\xi z_1^T z_2 = 0$ is implied by the feasibility of z_1, z_2. This condition has been omitted.

We examine the difference between (4.1) and the strong-stationarity condition (3.3). In (3.3), the multipliers $\hat{\nu}_1$ and $\hat{\nu}_2$ may be negative for components that satisfy

second-level nondegeneracy, while in (4.1) $\nu_1 \geq 0, \nu_2 \geq 0$ is required. We will relate the multipliers of (3.3) and (4.1) to show that stationarity in both senses is equivalent.

The main observation in proving the following result is that the first-order condition of (4.1) can be written as

$$g(z) - \left[A_{\mathcal{E}}^T(z) : A_{\mathcal{I}}^T(z)\right] \lambda - \begin{pmatrix} 0 \\ \nu_1 - \xi z_2 \\ 0 \end{pmatrix} - \begin{pmatrix} 0 \\ 0 \\ \nu_2 - \xi z_1 \end{pmatrix} = 0,$$

which is equivalent to the corresponding first-order condition in (3.3) if

$$\hat{\nu}_1 = \nu_1 - \xi z_2, \tag{4.2}$$

$$\hat{\nu}_2 = \nu_2 - \xi z_1. \tag{4.3}$$

PROPOSITION 4.1. *A point z is strongly stationary in the MPEC* (1.1) *if and only if it is a stationary point of the NLP* (1.3).

Proof. First we show that (4.1) $\Rightarrow$ (3.3) by distinguishing three cases:

(a) If $z_{1j} > 0$, then $z_{2j} = 0 = \nu_{1j}$ from complementarity and slackness. From (4.2) it follows that $\hat{\nu}_{1j} = 0$ and $\hat{\nu}_{2j} = \nu_{2j} - \xi z_{1j}$ satisfies (3.3).

(b) If $z_{2j} > 0$, then transpose the above argument.

(c) If $z_{1j} = z_{2j} = 0$, then (4.2) and (4.3) imply that $\hat{\nu}_{1j} = \nu_{1j} \geq 0$ and $\hat{\nu}_{2j} = \nu_{2j} \geq 0$. Combining (a)–(c), one sees that (4.1) implies (3.3).

Next we show that (3.3) $\Rightarrow$ (4.1) by distinguishing three cases:

(d) If $z_{1j} > 0$, then $\hat{\nu}_{1j} = 0$ and $z_{2j} = 0$. This implies that $\nu_{1j} = \xi z_{2j} + \hat{\nu}_{1j} = 0 \geq 0$ for any ξ. To ensure that $\nu_{2j} = \xi z_{1j} + \hat{\nu}_{2j}$ is nonnegative, we need to choose ξ such that $\xi z_{1j} + \hat{\nu}_{2j} \geq 0 \; \forall j$, or equivalently that $\xi \geq -\hat{\nu}_{2j}/z_{1j} \; \forall j$.

(e) If $z_{2j} > 0$, then transpose the above argument.

(f) If $z_{1j} = z_{2j} = 0$, then $\nu_{1j} = \hat{\nu}_{1j} \geq 0$ and $\nu_{2j} = \hat{\nu}_{2j} \geq 0$, for any ξ.

From parts (d) and (e) it follows that choosing ξ to be at least

$$\xi = \max\left\{0, \max_{i \in \mathcal{Z}_2^c} \frac{-\hat{\nu}_{1i}}{z_{2i}^*}, \max_{i \in \mathcal{Z}_1^c} \frac{-\hat{\nu}_{2i}}{z_{1i}^*}\right\} \tag{4.4}$$

will ensure that $\nu_1, \nu_2 \geq 0$. Examining the expressions on the right-hand side of (4.4), one can see that ξ is bounded. Combining cases (d) to (f) it follows that (3.3) implies (4.1). ∎

The interesting point about the proof is that it relates the multiplier ξ to the fact that the NLP conditions (4.1) are more restrictive in the sense that they enforce $\nu_1, \nu_2 \geq 0$, while $\hat{\nu}_1, \hat{\nu}_2$ may be negative. In a way, ξ compensates for this: if, for instance, $\hat{\nu}_{1j} < 0$, then $z_{2j} > 0$, and we can get the corresponding NLP multiplier $\nu_{1j} = \hat{\nu}_{1j} + \xi z_{2j}$ nonnegative by choosing ξ sufficiently large.

Clearly, any value $\hat{\xi} > \xi$ in (4.4) would also satisfy the stationarity conditions (4.1), and this is how the unboundedness of the multiplier set arises. However, any such $\hat{\xi} > \xi$ would not correspond to a *basic solution*, in the sense that the constraint normals corresponding to nonzero multipliers are linearly dependent. The main argument in our convergence analysis is to show that an SQP solver that works with a nonsingular basis will pick the multiplier defined in (4.4).

DEFINITION 4.2. *The multiplier defined by* (4.4) *is referred to as the* basic multiplier.

The terminology of this definition is justified by the following lemma, which shows that if MPEC-LICQ holds, then the MPEC multipliers and the multiplier in (4.4) are unique and correspond to a linearly independent set of constraint normals.

LEMMA 4.3. *If MPEC-LICQ holds at a local minimizer of* (1.1), *then it is strongly stationary, and the multipliers in* (3.3) *and the basic multiplier defined by* (4.4) *are unique. Moreover, the set of constraint normals corresponding to nonzero multipliers is linearly independent.*

Proof. MPEC-LICQ implies the uniqueness of the MPEC multipliers (3.3); see [19]. The uniqueness of the MPEC multiplier implies that all expressions on the right-hand side of (4.4) are unique, hence implying the uniqueness of ξ. Finally, the uniqueness of the corresponding NLP multipliers follows from (4.2) and (4.3) (if the NLP multipliers were not unique, then we could find other MPEC multipliers).

To show that the constraint normals corresponding to nonzero multipliers are linearly independent, we distinguish two cases: $\xi = 0$ and $\xi > 0$.

If $\xi = 0$, then the linear independence of constraint normals corresponding to nonzero multipliers follows from MPEC-LICQ.

If $\xi > 0$, then there exists at least one component $i \in \mathcal{Z}_1^c$ or $i \in \mathcal{Z}_2^c$ such that $\nu_{2i} = 0$ or $\nu_{1i} = 0$.

It remains to show that the set of constraint normals corresponding to nonzero multipliers is linearly independent. By MPEC-LICQ, this is true for all but the complementarity constraint. Then we can exchange the normal of the complementarity constraint for any normal whose multiplier is driven to zero by (4.4) and (4.2) or (4.3) in the basis as explained in Lemma 5.8 below. ∎

The conclusions of this section can be readily extended to cover the case where the complementarity condition is of the more general form (1.2).

5. Local convergence of SQP methods. This section shows that SQP methods converge quadratically near a strongly stationary point under mild conditions. Section 7 discusses the assumptions and provides counterexamples for situations where (some of) these assumptions are not satisfied. In particular, we are interested in the situation where $z^{(k)}$ is close to a strongly stationary point, z^*, but ${z_1^{(k)}}^T z_2^{(k)}$ is *not* necessarily zero. SQP then solves a sequence of quadratic programming approximations, given by

$$(QP^k) \qquad \begin{cases} \underset{d}{\text{minimize}} & {g^{(k)}}^T d + \frac{1}{2} d^T W^{(k)} d \\ \text{subject to} & c_{\mathcal{E}}^{(k)} + {A_{\mathcal{E}}^{(k)}}^T d = 0, \\ & c_{\mathcal{I}}^{(k)} + {A_{\mathcal{I}}^{(k)}}^T d \geq 0, \\ & z_1^{(k)} + d_1 \geq 0, \\ & z_2^{(k)} + d_2 \geq 0, \\ & {z_1^{(k)}}^T z_2^{(k)} + {z_2^{(k)}}^T d_1 + {z_1^{(k)}}^T d_2 \leq 0, \end{cases}$$

where $W^{(k)} = \nabla^2 \mathcal{L}(z^{(k)}, \mu^{(k)})$ is the Hessian of the Lagrangian of (1.3) and $\mu^{(k)} = (\lambda^{(k)}, \nu_1^{(k)}, \nu_2^{(k)}, \xi^{(k)})$. The last constraint of (QP^k) is the linearization of the complementarity condition $z_1^T z_2 \leq 0$.

Assumption 5.1. The following assumptions are made:

[A1] f and c are twice Lipschitz continuously differentiable.

[A2] The MPEC (1.1) satisfies an MPEC-LICQ (Definition 3.1).

[A3] z^* is a strongly stationary point of (1.1) with multipliers $\lambda^*, \nu_1^*, \nu_2^*$ (Definition 3.3), and z^* satisfies the MPEC-SOSC (Definition 3.4).

[A4] $\lambda_i^* \neq 0 \; \forall i \in \mathcal{E}^*$, $\lambda_i^* > 0 \; \forall i \in \mathcal{A}^* \cap \mathcal{I}$, and both $\nu_{1j}^* > 0$ and $\nu_{2j}^* > 0 \; \forall j \in \mathcal{D}^*$.

[A5] The QP solver always chooses a linearly independent basis.

The most restrictive assumption is strong stationarity in [A3], which follows if z^* is a local minimizer from [A2]. That is, [A3] (or [A2]) removes the combinatorial nature of the problem. It is not clear that [A2] can readily be relaxed in the present context, since it allows us to check B-stationarity by solving exactly one LP or QP. Without assumption [A2] it would not be possible to verify B-stationarity without solving several LPs (one for every possible combination of second-level degenerate indices $i \in \mathcal{D}^*$). It seems unlikely, therefore, that a method that solves only a single LP or QP per outer iteration can be shown to be convergent to B-stationary points for problems that violate MPEC-LICQ. Note that we do *not* assume that the MPEC (1.1) is second-level nondegenerate; in other words, we do *not* assume that $z_1^* + z_2^* > 0$.

The strict complementarity Assumption [A4] can in fact be weakened for all the results of section 5.1 to require positivity only of the biactive multipliers ν_{1j}^* and ν_{2j}^*, because Proposition 5.2, which underlies our convergence analysis there, does not require $\lambda_i^* \neq 0 \; \forall i \in \mathcal{E}^*$ and $\lambda_i^* > 0 \; \forall i \in \mathcal{A}^* \cap \mathcal{I}$; see [3]. Section 5.2, however, requires all the conditions of [A4]. Assumption [A5] is a reasonable assumption in practice, as most modern SQP solvers are based on active set QP solvers that guarantee this.

This section is divided into two parts. First, we consider the case where complementarity is satisfied at a point sufficiently close to a stationary point. This case corresponds to the situation where all iterates (ultimately) remain on the same face of $0 \leq z_1 \perp z_2 \geq 0$. The key idea is to show that SQP applied to (1.3) behaves identical to SQP applied to (3.2).

The second case considered arises when ${z_1^{(k)}}^T z_2^{(k)} > 0$ for all iterates k. In this case, the previous ideas cannot be applied, and a separate proof is required. We make the additional assumption that all QP subproblems remain consistent. This assumption appears to be rather strong, especially in light of example (2.3), which shows that the QP approximation may be inconsistent *arbitrarily close to a solution*. However, we will give several sufficient conditions for it later that show that it is not unduly restrictive.

5.1. Local convergence for exact complementarity. In this section we make the following additional assumption:

[A6] For some k we have that ${z_1^{(k)}}^T z_2^{(k)} = 0$ and $(z^{(k)}, \mu^{(k)})$ is sufficiently close to a strongly stationary point.

Assumption [A6] implies that the correct face has been identified except for degenerate or biactive constraints. Thus, for given index sets $\mathcal{Z}_j = \{i : z_{ji}^{(k)} = 0\}$, $j = 1, 2$, the following holds:

$$\begin{aligned} z_{1j}^{(k)} &= 0 && \forall j \in \mathcal{Z}_2^c, \\ z_{2j}^{(k)} &= 0 && \forall j \in \mathcal{Z}_1^c, \\ z_{1j}^{(k)} &= 0 \quad \text{and} \quad z_{2j}^{(k)} = 0 && \forall j \in \mathcal{D}. \end{aligned}$$

In particular, it is *not* assumed that the biactive complementarity constraints $\mathcal{D}^*$ are active at $z^{(k)}$. Thus it may be possible that $\mathcal{Z}_1 \neq \mathcal{Z}_1^*$ (and similarly for $\mathcal{Z}_2$). However, it will be shown that the biactive constraints become active after one step of the SQP method as a consequence of [A4] (the positivity of biactive multipliers); see Proposition 5.2.

An important consequence of [A6] is that $\mathcal{Z}_1$ and $\mathcal{Z}_2$ satisfy

$$\begin{aligned} \mathcal{Z}_1^{*^c} \subset \mathcal{Z}_1^c \subset \mathcal{Z}_1^{*^c} \cup \mathcal{D}^*, \\ \mathcal{Z}_2^{*^c} \subset \mathcal{Z}_2^c \subset \mathcal{Z}_2^{*^c} \cup \mathcal{D}^*, \\ \mathcal{D} \subset \mathcal{D}^*; \end{aligned} \tag{5.1}$$

in other words, the indices $\mathcal{Z}_1^{*^c}$ and $\mathcal{Z}_2^{*^c}$ of the nondegenerate complementarity constraints have been identified correctly.

The key idea of the proof is to show that SQP applied to (1.3) is equivalent to SQP applied to the relaxed NLP (3.2) on a face. For a given partition $(\mathcal{Z}_1^c, \mathcal{Z}_2^c, \mathcal{D})$, an SQP step for (3.2) is obtained by solving the following QP:

$$(QP_R(z^{(k)}) \qquad \begin{cases} \underset{d}{\text{minimize}} & g^{(k)^T} d + \frac{1}{2} d^T \widehat{W^{(k)}} d & \\ \text{subject to} & c_{\mathcal{E}}^{(k)} + A_{\mathcal{E}}^{(k)^T} d = 0, & \\ & c_{\mathcal{I}}^{(k)} + A_{\mathcal{I}}^{(k)^T} d \geq 0, & \\ & d_{1j} = 0 & \forall j \in \mathcal{Z}_2^c, \\ & d_{2j} = 0 & \forall j \in \mathcal{Z}_1^c, \\ & z_{1j}^{(k)} + d_{1j} \geq 0 & \forall j \in \mathcal{Z}_2, \\ & z_{2j}^{(k)} + d_{2j} \geq 0 & \forall j \in \mathcal{Z}_1, \end{cases}$$

where

$$\widehat{W^{(k)}} = \nabla^2 f(z^{(k)}) - \sum \lambda_i^{(k)} \nabla^2 c_i(z^{(k)}) = W^{(k)} - \xi^{(k)} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & I \\ 0 & I & 0 \end{bmatrix}$$

is the Hessian of the Lagrangian of the relaxed NLP (3.2). Note that the relaxed NLP (3.2) is never set up nor is $(QP_R(z^{(k)}))$ ever solved. These two problems are merely used in the convergence proof. The key idea is to show that SQP applied to the ill-conditioned NLP (1.3) is equivalent to SQP applied to the well-behaved relaxed NLP (3.2), given by the sequence defined by $(QP_R(z^{(k)}))$.

The following proposition states the fact that SQP applied to the relaxed NLP converges quadratically and identifies the correct index sets $\mathcal{Z}_1^*$ and $\mathcal{Z}_2^*$ in one step.

PROPOSITION 5.2. *Let Assumptions* [A1]–[A6] *hold, and consider the relaxed NLP for any index sets* $\mathcal{Z}_1$, $\mathcal{Z}_2$ *(satisfying* (5.1) *by virtue of* [A6]*). Then it follows that*

1. *there exists a neighborhood* U *of* $(z^*, \lambda^*, \nu_1^*, \nu_2^*)$ *and a sequence of iterates generated by SQP applied to the relaxed NLP* (3.2), $\{(z^{(l)}, \lambda^{(l)}, \nu_1^{(l)}, \nu_2^{(l)})\}_{l>k}$, *that lies in* U *and converges Q-quadratically to* $(z^*, \lambda^*, \nu_1^*, \nu_2^*)$*;*
2. *the sequence* $\{z^{(l)}\}_{l>k}$ *converges Q-superlinearly to* z^**; and*
3. $\mathcal{Z}_1^{(l)} = \mathcal{Z}_1^*$ *and* $\mathcal{Z}_2^{(l)} = \mathcal{Z}_2^*$ *for* $l > k$.

Proof. The relaxed NLP satisfies LICQ and an SOSC. Therefore, there exists a neighborhood U of $(z^*, \lambda^*, \nu_1^*, \nu_2^*)$ such that for any $(z^{(l)}, \lambda^{(l)}, \nu_1^{(l)}, \nu_2^{(l)}) \in U$, there exists an SQP iterate $(z^{(l+1)}, \lambda^{(l+1)}, \nu_1^{(l+1)}, \nu_2^{(l+1)})$ that also lies in U; and any sequence of SQP iterates $\{z^{(l)}\}_{l>k} \subset U$ converges at second-order rate when applied to the relaxed NLP. In fact part 1 is a standard result whose proof can be found, for instance, in [6, Theorem 15.2.2] or in [3]. Part 2 is due to [3]. Part 3 follows from the fact

that SQP identifies the correct active set in one step by the strict complementarity assumption [A4]. ∎

Next, we show that the sequence of steps generated by SQP applied to the relaxed NLP (3.2) is identical to the sequence of steps generated by applying SQP to the equivalent NLP (1.3), provided that $z_1^{(k)^T} z_2^{(k)} = 0$, that is, [A6] holds for some k. If $z_1^{(k)^T} z_2^{(k)} = 0$, then an SQP step for (1.3) is obtained by solving the following (QP^k) with $z_1^{(k)^T} z_2^{(k)} = 0$ in the last constraint.

The two QPs (QP^k) and $(QP_R(z^{(k)}))$ have different constraints and Hessians. The Hessian of (QP^k) is

$$W^{(k)} = \widehat{W^{(k)}} + \xi^{(k)} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & I \\ 0 & I & 0 \end{bmatrix}.$$

Despite these differences, however, one can show that the two QPs have the same solution (from which second-order convergence follows). The following lemma shows that the constraint sets are the same.

LEMMA 5.3. *Let Assumptions* [A1]–[A6] *hold. Then, a step d is feasible in (QP^k) if and only if it is feasible in $(QP_R(z^{(k)}))$.*

Proof. The constraint sets differ only in the way in which indices $j \in \mathcal{Z}_2^c$ and $j \in \mathcal{Z}_1^c$ are handled. Thus it suffices to consider those constraints.

(a) *Let d be feasible in $(QP_R(z^{(k)}))$.* Then it follows in particular that d satisfies

$$\begin{aligned} d_{1j} &= 0 \quad \forall j \in \mathcal{Z}_2^c, \\ d_{2j} &= 0 \quad \forall j \in \mathcal{Z}_1^c. \end{aligned}$$

If these constraints are split into two inequalities, we have that d satisfies

$$d_{1j} \geq 0 \quad \forall j \in \mathcal{Z}_2^c, \tag{5.2}$$

$$d_{1j} \leq 0 \quad \forall j \in \mathcal{Z}_2^c, \tag{5.3}$$

$$d_{2j} \geq 0 \quad \forall j \in \mathcal{Z}_1^c, \tag{5.4}$$

$$d_{2j} \leq 0 \quad \forall j \in \mathcal{Z}_1^c. \tag{5.5}$$

Summing (5.3) over all $j \in \mathcal{Z}_2^c$ weighted with $z_{2j}^{(k)} > 0$ and (5.5) over all $j \in \mathcal{Z}_1^c$ weighted with $z_{1j}^{(k)} > 0$, it follows that d satisfies the last constraint of (QP^k) (the simple bounds follow from (5.2) and (5.4)).

(b) *Let d be feasible in (QP^k).* Since $z_{2j}^{(k)} > 0 \ \forall j \in \mathcal{Z}_2^c$ and $z_{1j}^{(k)} > 0 \ \forall j \in \mathcal{Z}_1^c$, it follows from [A6] that $z_{1j}^{(k)} = 0 \ \forall j \in \mathcal{Z}_2^c$ and that $z_{2j}^{(k)} = 0 \ \forall j \in \mathcal{Z}_1^c$. Thus, (QP^k) contains the constraints

$$d_{1j} \geq 0 \ \forall j \in \mathcal{Z}_2^c \quad \text{and} \quad d_{2j} \geq 0 \ \forall j \in \mathcal{Z}_1^c.$$

By [A6], the linearization of the complementarity constraint in (QP^k) simplifies to

$$\sum_{j \in \mathcal{Z}_2^c} z_{2j}^{(k)} d_{1j} + \sum_{j \in \mathcal{Z}_1^c} z_{1j}^{(k)} d_{2j} \leq 0.$$

Since $z_{2j}^{(k)} > 0$, and $z_{1j}^{(k)} > 0$ in this sum, it follows that

$$d_{1j} \leq 0 \ \forall j \in \mathcal{Z}_2^c \quad \text{and} \quad d_{2j} \leq 0 \ \forall j \in \mathcal{Z}_1^c.$$

Thus, d is feasible in $(QP_R(z^{(k)}))$. ∎

Next, we show that near z^*, the stationary points of (QP^k) and $(QP_R(z^{(k)}))$ are identical.

LEMMA 5.4. *Under Assumptions* [A1]–[A6], *any stationary point of* $(QP_R(z^{(k)}))$ *near zero is also a stationary point of* (QP^k), *and vice versa.*

Proof. From above, $(QP_R(z^{(k)}))$ and (QP_k) share the same feasible set. Consider a feasible point $\bar{d}$ that satisfies $\bar{d}_{ij} = 0$ for $j \in \mathcal{D}$, $i = 1, 2$. Since all feasible points d have $d_{1j} = 0$ for $j \in \mathcal{Z}_2^c$, then $\bar{d}_{1j} = 0$ for $j \in \mathcal{Z}_2^c \cup \mathcal{D} = \mathcal{Z}_1$. Likewise, $\bar{d}_{2j} = 0$ for $j \in \mathcal{Z}_2$. That is, we have orthogonality between $\bar{d}_1$ and d_2, and between $\bar{d}_2$ and d_1, for any feasible d. Thus the gradients of the objective functions of $(QP_R(z^{(k)}))$ and (QP_k) at $\bar{d}$, which differ only by $\xi^{(k)}(0, \bar{d}_2, \bar{d}_1)$, cannot be distinguished on the feasible set. It follows that $\bar{d}$ is stationary for $(QP_R(z^{(k)}))$ if and only if it is stationary for (QP_k). To complete the proof we show that any stationary point, near zero, of either QP does indeed satisfy the above conditions on $\bar{d}$.

From part 3 of Proposition 5.2, any stationary point $\bar{d}$ of $(QP_R(z^{(k)}))$, near zero, satisfies $z_{ij}^{(k)} + \bar{d}_{ij} = 0$ for $j \in \mathcal{D}^*$ and $i = 1, 2$. As $\mathcal{D}^* \supset \mathcal{D} \subset \mathcal{Z}_1$, we get for $j \in \mathcal{D}$ that $\bar{d}_{1j} = 0$. Likewise $\bar{d}_{2j} = 0$ for $j \in \mathcal{D}$.

Conversely let $\bar{d}$ be a stationary point, near zero, of (QP_k). The associated KKT conditions include

$$g^{(k)} + W^{(k)}\bar{d} - \left[{A_{\mathcal{E}}^{(k)}}^T : {A_{\mathcal{I}}^{(k)}}^T \right] \bar{\lambda} - \begin{pmatrix} 0 \\ \bar{\nu}_1 \\ \bar{\nu}_2 \end{pmatrix} + \bar{\xi} \begin{pmatrix} 0 \\ z_2^{(k)} \\ z_1^{(k)} \end{pmatrix} = 0$$

for some multipliers $\bar{\lambda}, \bar{\nu}_1, \bar{\nu}_2, \bar{\xi}$. As $z^{(k)}$ and $\bar{d}$ approach z^* and zero, respectively, where $\mu^{(k)}$ is within a given radius of $(\lambda^*, \nu_1^*, \nu_2^*, 0)$, we deduce from MPEC-LICQ and the first equation of (3.3) that $\bar{\nu}_1 - \bar{\xi} z_2^{(k)}$ and $\bar{\nu}_2 - \bar{\xi} z_1^{(k)}$ approach ν_1^* and ν_2^*, respectively. Therefore Assumption [A4], with nonnegativity of $z_1^{(k)}$, $z_2^{(k)}$, and $\bar{\xi}$, ensures that $\bar{\nu}_{ij} > 0$, hence $z_{ij}^{(k)} + \bar{d}_{ij} = 0$, for $j \in \mathcal{D}^*$ and $i = 1, 2$. The argument that $\bar{d}_{ij} = 0$ for $j \in \mathcal{D}$ and $i = 1, 2$ is given in the previous paragraph. ∎

LEMMA 5.5. *Let Assumptions* [A1]–[A6] *hold. Let* $(\lambda, \widehat{\nu}_1, \widehat{\nu}_2)$ *be the multipliers of* $(QP_R(z^{(k)}))$ *(corresponding to a step d near zero). Then it follows that the multipliers of* (QP^k), *corresponding to the same step d, are* $\mu = (\lambda, \nu_1, \nu_2, \xi)$, *where*

$$\xi = \max\left(0, \max_{j \in \mathcal{Z}_1 \setminus \mathcal{D}} \frac{-\widehat{\nu_{1j}} - \xi^{(k)} d_{2j}}{z_{2j}^{(k)}}, \max_{j \in \mathcal{Z}_2 \setminus \mathcal{D}} \frac{-\widehat{\nu_{2j}} - \xi^{(k)} d_{1j}}{z_{1j}^{(k)}}\right), \tag{5.6}$$

$$\nu_{1j} = \widehat{\nu_{1j}} > 0 \quad \forall j \in \mathcal{D}, \tag{5.7}$$

$$\nu_{2j} = \widehat{\nu_{2j}} > 0 \quad \forall j \in \mathcal{D}, \tag{5.8}$$

$$\nu_{1j} = \widehat{\nu_{1j}} + \xi^{(k)} d_{2j} + \xi z_{2j}^{(k)} \quad \forall j \in \mathcal{Z}_1 \setminus \mathcal{D}, \tag{5.9}$$

$$\nu_{2j} = \widehat{\nu_{2j}} + \xi^{(k)} d_{1j} + \xi z_{1j}^{(k)} \quad \forall j \in \mathcal{Z}_2 \setminus \mathcal{D}. \tag{5.10}$$

Conversely, given a solution d and multipliers μ *of* (QP^k), (5.7)–(5.10) *show how to construct multipliers so that* $(d, \lambda, \widehat{\nu}_1, \widehat{\nu}_2)$ *solves* $(QP_R(z^{(k)}))$.

Proof. If $z^{(k)}$ is sufficiently close to z^*, then the sign of the multipliers in (5.7) and (5.8) follows from [A4], and the value for the multipliers of (QP^k) follows similarly to Proposition 4.1. Similarly, the multipliers of (QP^k) in (5.9) and (5.10) are nonnegative by construction and satisfy first-order conditions by Lemma 5.4. ∎

Next, we show that both QPs have the same (unique) solution in a neighborhood of $d = 0$.

LEMMA 5.6. *The solution d of $(QP_R(z^{(k)}))$ is the only strict local minimizer in a neighborhood of $d = 0$ that is independent of k, and its corresponding multipliers (λ, ν_1, ν_2) are unique. Moreover, d is also the only strict local minimizer in a neighborhood of $d = 0$ of (QP^k).*

Proof. The result for $(QP_R(z^{(k)}))$ is due to Robinson [18] (see also Conn, Gould, and Toint [6]), since the relaxed NLP satisfies [A1]–[A4]. The statement for (QP^k) follows in two parts. First-order conditions are established in Lemma 5.5. Second-order conditions for (QP^k) follow from second-order conditions of $(QP_R(z^{(k)}))$, as we explain now. The critical cone at a stationary point is the set of directions in the tangent cone to the feasible set that are orthogonal to the gradient of the objective function. From Lemma 5.3 and the proof of Lemma 5.4, it can be seen that the critical cones of $(QP_R(z^{(k)}))$ and (QP^k) coincide; denote this cone C. Next, we use a standard fact that relates an inequality constraint with a positive multiplier to any direction d in the critical cone of (QP^k), namely, $d_{ij} = 0$ if $\bar{\nu}_{ij} > 0$. Hence, using the proof of Lemma 5.4, we have that $d_1^T d_2 = 0$ for $d \in C$. It follows that the Hessian matrices of $(QP_R(z^{(k)}))$ and (QP^k) are indistinguishable on C, hence that the SOSC of the former transfers to the latter, and the stationary point must be a local minimizer of the latter. ∎

The following theorem summarizes the results of this section. As remarked earlier, these results holds under a weak version of Assumption [A4] in which only positivity of the biactive multipliers ν_{1j}^* and ν_{2j}^* is required.

THEOREM 5.7. *If Assumptions* [A1]–[A6] *hold, then SQP applied to* (1.3) *generates a sequence $\{(z^{(k)}, \lambda^{(k)}, \nu_1^{(k)}, \nu_2^{(k)}, \xi^{(k)})\}_{l>k}$ that converges Q-quadratically to a solution $\{(z^*, \lambda^*, \nu_1^*, \nu_2^*, \xi^*)\}$ of* (4.1), *satisfying strong stationarity. Moreover, the sequence $\{z^{(k)}\}_{l>k}$ converges Q-superlinearly to z^* and $z_1^{(l)^T} z_2^{(l)} = 0 \ \forall l \geq k$.*

Proof. Under Assumptions [A1]–[A4], SQP converges quadratically when applied to the relaxed NLP (3.2); see Proposition 5.2. Lemmas 5.3–5.6 show that the sequence of iterates generated by this SQP method is equivalent to the sequence of steps generated by SQP applied to (1.3). This implies Q-superlinear convergence of $\{z^{(k)}\}_{l>k}$. Convergence of the multipliers follows by considering (5.6)–(5.10). Clearly, the multipliers in (5.7) and (5.8) converge, as they are just the multipliers of the relaxed NLP, which converge by virtue of Proposition 5.2. Now observe that (5.6) becomes

$$\widehat{\xi}^{(k+1)} = \max\left(0, \max_{j \in \mathcal{Z}_2^{*c}} \frac{-\widehat{\nu_{1j}^{(k+1)}} - \xi^{(k)} d_{2j}^{(k)}}{z_{2j}^{(k)}}, \max_{j \in \mathcal{Z}_1^{*c}} \frac{-\widehat{\nu_{2j}^{(k+1)}} - \xi^{(k)} d_{1j}^{(k)}}{z_{1j}^{(k)}}\right).$$

The right-hand side of this expression converges, since $\widehat{\nu_{1j}^{(k+1)}}, \widehat{\nu_{2j}^{(k+1)}}$ and $z_{1j}^{(k)}, z_{2j}^{(k)}$ converge and $d_{1j}^{(k)}, d_{2j}^{(k)} \to 0$. Note that the limit of (5.6) is the basic multiplier (4.4). Finally, (5.9) and (5.10) converge to (4.2) and (4.3) by a similar argument.

Now $z_1^{(l)^T} z_2^{(l)} = 0 \ \ \forall l \geq k$ follows from the convergence of SQP for the relaxed NLP (3.2) and the fact that SQP retains feasibility with respect to linear constraints. Assumption [A4] ensures that $d_{1j}^{(k)} = d_{2j}^{(k)} = 0 \ \forall j \in \mathcal{D}^*$, since $\nu_{1j}^{(k)}, \nu_{2j}^{(k)} > 0$ for biactive complementarity constraints. Thus SQP will not move out of the corner but will stay on the same face. ∎

5.2. Local convergence for nonzero complementarity. This section shows that SQP converges superlinearly even if complementarity does not hold at the starting point, that is, if $z_1^{(k)^T} z_2^{(k)} > 0$. Example (2.3) shows that the QP approximations can be inconsistent arbitrarily close to a stationary point. To avoid this problem, we make the following assumption, which often holds in practice.

[A7] All QP approximations (QP^k) are consistent.

This is clearly an undesirable assumption because it makes an assumption about the progress of the method. However, we show in the next section that this assumption is satisfied for some important practical applications.

Without loss of generality, we assume that $\mathcal{Z}_1^{*^c} = \emptyset$, that is, we will assume that the solution has the form $z_1^* = 0$ and $z_2^* = (0, z_{22}^*)$ and that $z_{22}^* > 0$. This assumption greatly simplifies the notation.

Our convergence analysis is concerned with showing that for any "basic" active set, SQP converges. To this end, we introduce the set of basic constraints

$$\mathcal{B}(z) := \mathcal{E} \cup \mathcal{I} \cap \mathcal{A}^* \cup \mathcal{Z}_1(z) \cup \mathcal{Z}_2(z) \cup \{z_1^T z_2 = 0\}$$

and the set of strictly active constraints (defined in terms of the basic multiplier, μ)

$$\mathcal{B}_+(z) \ := \ \{i \in \mathcal{B}(z) \mid \mu_i \neq 0\}.$$

Moreover, we let $B_+^{(k)}$ denote the matrix of strictly active constraint normals at $z = z^{(k)}$, namely,

$$B_+^{(k)} \ := \ \left[a_i^{(k)}\right]_{i \in \mathcal{B}_+(z^{(k)})}.$$

Note that Lemma 4.3 shows that the optimal multiplier is unique. However, it may be possible that for some iterates $\mathcal{B}_+^{(k)} \neq \mathcal{B}_+(z^*)$, and our analysis will have to allow for this.

The failure of any constraint qualification at a solution z^* of the equivalent NLP (1.3) implies that the active constraint normals at z^* are linearly dependent. However, the linear dependence occurs in a special form that can be exploited to prove fast convergence.

LEMMA 5.8. *Let Assumptions* [A1]–[A4] *hold, and let z^* be a solution of the MPEC* (1.1). *Let $\mathcal{I}^*$ denote the set of* active *inequalities $c_{\mathcal{I}}(x)$, and consider the matrix of active constraint normals at z^*,*

$$B^* \ = \ \begin{bmatrix} & & 0 & 0 & 0 \\ A_{\mathcal{E}}^* & A_{\mathcal{I}^*}^* & I & 0 & \begin{pmatrix} 0 \\ z_{22}^* \end{pmatrix} \\ & & 0 & \begin{bmatrix} I \\ 0 \end{bmatrix} & \begin{pmatrix} 0 \\ 0 \end{pmatrix} \end{bmatrix}, \tag{5.11}$$

where we have assumed without loss of generality that $\mathcal{Z}_1^{c^*} = \emptyset$. Note that the last column is the gradient of the complementarity constraint.

Then it follows that B is linearly dependent and any submatrix of columns of B has full rank, provided that it contains $[A_{\mathcal{E}}^* \ A_{\mathcal{I}}^*]$ and that either the last column of B is missing or any column corresponding to $z_{12} = 0$ is missing.

Proof. The fact that the columns of B are linearly dependent is clear by looking at the last three columns of B. Assumption [A2], MPEC-LICQ, implies that B without

the last column has full rank. The final statement follows by exchanging any column corresponding to $z_{12}^* = 0$ with the final column of B and observing that $z_{22}^* > 0$. ∎

The proof shows that in order to obtain a linearly independent basis, any column of $z_{12} = 0$ can be exchanged with the normal of the complementarity constraint. This idea is precisely what lies behind (4.2) and (4.3). The corresponding basic multipliers are shown as dots in Figure 2.

Next, we show that if we are close to z^* and the QP solver chooses the full basis B, then exact complementarity holds for all subsequent iterations. Thus, in this case the development of the previous section shows second-order convergence.

LEMMA 5.9. *Let $z^{(k)}$ be sufficiently close to z^*, and let Assumptions* [A1]–[A5] *and* [A7] *hold. If the QP solver chooses the full basis B^k, given by*

$$B^{(k)} = \begin{bmatrix} & & 0 & 0 & 0 \\ A_{\mathcal{E}}^{(k)} & A_{\mathcal{I}^*}^{(k)} & I & 0 & \begin{pmatrix} z_{21}^{(k)} \\ z_{22}^{(k)} \end{pmatrix} \\ & & 0 & \begin{bmatrix} I \\ 0 \end{bmatrix} & \begin{pmatrix} z_{11}^{(k)} \\ z_{12}^{(k)} \end{pmatrix} \end{bmatrix},$$

then it follows that $z_1^{(k)^T} z_2^{(k)} > 0$ and that after the QP step, $z_1^{(k+1)^T} z_2^{(k+1)} = 0$.

Proof. Assume that $z_1^{(k)^T} z_2^{(k)} = 0$, and seek a contradiction. Since $z^{(k)}$ is sufficiently close to z^*, it follows that there exists $\tau > 0$ such that $z_{22}^{(k)} \geq \tau > 0$. Hence, $z_{12}^{(k)} = 0$. Now consider the final three columns of $B^{(k)}$, and observe that if $z_{12}^{(k)} = 0$, then the last column lies in the range of the other two. Hence the basis would be singular, thus contradicting Assumption [A5], and so $z_1^{(k)^T} z_2^{(k)} > 0$.

Now, $z_1^{(k+1)^T} z_2^{(k+1)} = 0$ follows simply by observing that the full basis B implies that $0 = z_1^{(k)} + d_1 = z_1^{(k+1)}$. ∎

Thus, once a full basis is chosen, the corresponding step will give $z_1^{(k+1)^T} z_2^{(k+1)} = 0$ for a point close to z^*. Second-order convergence then follows from Theorem 5.7.

COROLLARY 5.10. *Let $z^{(k)}$ be sufficiently close to z^*, and let Assumptions* [A1]–[A5] *and* [A7] *hold. If the QP solver chooses the full basis B, then it follows that SQP converges quadratically from iteration $k+1$.*

In the remainder we can therefore concentrate on the case in which the full basis B is never chosen and $z_1^{(k)^T} z_2^{(k)} > 0$ for all iterates k (otherwise, we have convergence from the results of the previous section).

Next, we show that for $z^{(k)}$ sufficiently close to z^*, the basis at $z^{(k)}$ contains both $\mathcal{E}$ and $\mathcal{I}^*$.

LEMMA 5.11. *Let $z^{(k)}$ be sufficiently close to z^*, and let Assumptions* [A1]–[A5] *and* [A7] *hold. Then it follows that the optimal basis B of (QP^k) contains the normals $A_{\mathcal{E}}^{(k)}$ and $A_{\mathcal{I}^*}^{(k)}$ of active constraints at the solution.*

Proof. The proof follows by considering the gradient of the Lagrangian of (QP^k),

$$0 = g^{(k)} + \hat{W}^{(k)} d^{(k)} - \left[A_{\mathcal{E}}^{(k)^T} : A_{\mathcal{I}}^{(k)^T} \right] \lambda^{(k+1)} - \begin{pmatrix} 0 \\ \nu_1^{(k+1)} - \xi^{(k+1)} z_2^{(k)} \\ \nu_2^{(k+1)} - \xi^{(k+1)} z_1^{(k)} \end{pmatrix} + \xi^{(k)} \begin{pmatrix} 0 \\ d_2^{(k)} \\ d_1^{(k)} \end{pmatrix},$$

where $\hat{W}^{(k)}$ is the Hessian of the Lagrangian without the term corresponding to the complementarity constraint (the last term above). For $z^{(k)}$ sufficiently close to z^*, it follows from [A4] that $\lambda_i^{(k+1)} \neq 0 \ \forall i \in \mathcal{E} \cup \mathcal{I}^*$. ∎

Thus, as long as the QP approximations remain consistent, the optimal basis of (QP^k) will be a subset of B satisfying the conditions in Lemma 5.9. The key idea is now to show that for any such basis, there exists an equality constrained problem for which SQP converges quadratically. Since there exist only a finite number of bases, this implies convergence for SQP.

We now introduce the *reduced NLP*, which is an equality constraint NLP. Its constraints correspond to a linearly independent subset of the basis B^* in (5.11) of Lemma 5.8:

$$\begin{array}{lll} \text{minimize} & f(z) & \\ \text{subject to} & c_{\mathcal{E}}(z) = 0, & \\ & c_{\mathcal{I}^*}(z) = 0, & \\ & z_{11} = 0, & \\ & z_{21} = 0, & \\ & z_{12} = 0 & \Big\} \text{ subset of } B^* \text{ satisfying Lemma 5.8.} \\ & z_1^T z_2 = 0 & \end{array} \tag{5.12}$$

The next lemma shows that any reduced NLP satisfies an LICQ and an SOSC.

LEMMA 5.12. *Let Assumptions* [A1]–[A4] *and* [A7] *hold. Then it follows that any reduced NLP satisfies an LICQ and an SOSC.*

Proof. Lemma 5.8 shows that the normals of the equality constraints of each reduced NLP are linearly independent. The SOSC follows from the MPEC-SOSC and the observation that the MPEC and the reduced NLP have the same nullspace. ∎

Thus, applying SQP to the reduced NLP results in second-order convergence.

PROPOSITION 5.13. *Let Assumptions* [A1]–[A4] *and* [A7] *hold. Then it follows that SQP applied to any reduced NLP converges locally and quadratically to* (z^*, μ^*).

Proof. Lemma 5.12 shows that the reduced NLP satisfies LICQ and SOSC. Therefore, convergence of SQP follows. In particular, it follows that for a given reduced NLP corresponding to a basis $\mathcal{B}$, there exists a constant $c_{\mathcal{B}} > 0$ such that

$$\left\| \left(z^{(k+1)}, \mu^{(k+1)}\right) - \left(z^*, \mu^*\right) \right\| \le c_{\mathcal{B}} \left\| \left(z^{(k)}, \mu^{(k)}\right) - \left(z^*, \mu^*\right) \right\|^2. \tag{5.13}$$ ∎

Summarizing the results of this section, we obtain the following theorem.

THEOREM 5.14. *Let Assumptions* [A1]–[A5] *and* [A7] *hold. Then it follows that SQP applied to the NLP formulation* (1.3) *of the MPEC* (1.1) *converges quadratically near a solution* (z^*, μ^*).

Proof. Proposition 5.13 shows that SQP converges quadratically for any possible choice of basis $\mathcal{B}$, and Assumption [A7] shows that (QP^k) is consistent and remains consistent. Therefore, there exists a basis for which quadratic convergence follows. Thus, for each basis, a step is computed that satisfies a contraction condition like (5.13) for a constant $c_{\mathcal{B}} > 0$ that depends on the basis. Since there exists a finite number of bases, this condition holds also for $c = \max c_{\mathcal{B}}$ independent of the basis, and SQP converges quadratically independent of the basis. ∎

5.3. Discussion of the proofs. An interesting observation about the convergence proofs of this section is that if ${z_1^{(k)}}^T z_2^{(k)} = 0$, then the actual value of $\xi^{(k)}$ has no effect on the step computed by SQP. This shows that the curvature information contained in the complementarity constraint $z_1^T z_2 \le 0$ is not important. Consequently, one could omit this contribution to the Hessian of the Lagrangian. This can be easily implemented, and convergence results follow along lines similar to the observation above.

The conclusions and proofs presented in this section also carry through for linear complementarity constraints but *not* for general nonlinear complementarity constraints. The reason is that the implication

$$z_1^{(k)^T} z_2^{(k)} = 0 \Rightarrow z_1^{(k+1)^T} z_2^{(k+1)} = 0$$

holds for linear complementarity problems but *not* for nonlinear complementarity problems, because in general an SQP method would move off a nonlinear constraint. This is one reason for introducing slacks to deal with complementarity of the form (1.2).

Similar conclusions can easily be derived for other NLP formulations of the MPEC (1.1). For instance, the complementarity constraint in (1.3) can be replaced by

$$z_{1j} z_{2j} \leq 0 \quad \forall j = 1, \ldots, p.$$

In this case, a similar construction to (5.6) is possible, where $\widehat{\xi}$ is replaced by a vector of complementarity multipliers, one for each constraint. Equations (4.2) and (4.3) then become componentwise conditions and, similarly, (5.9) and (5.10). In addition, one can now see that a basis that satisfies the conditions of Lemma 5.9 satisfies a complementarity condition between the multipliers ξ_i and ν_{1i} (and ν_{2i}).

The strongest assumption in the present convergence analysis is Assumption [A7], namely, that all (QP^k) remain consistent. We show in the next section that this assumption holds for several interesting cases. We also show that a simple restoration procedure always ensures consistency after one step.

6. Sufficient conditions for consistency of (QP^k). Example (2.3) shows that the QP approximation to an MPEC can be inconsistent arbitrarily close to a stationary point. This section gives two situations in which consistency of (QP^k) can be guaranteed under Assumptions [A1]–[A5]. The first such situation arises when there are no general constraints on control and state variables. Next, we show that one step of a simple restoration procedure is guaranteed to find an iterate with $z_1^{(k)^T} z_2^{(k)} = 0$, thus ensuring consistency.

6.1. Vertical complementarity constraints. This section shows that the QP approximations (QP^k) are consistent arbitrarily close to a strongly stationary point, provided that the MPEC has the following form:

$$\begin{array}{ll} \text{minimize} & f(z) \\ \text{subject to} & c(z_0) = 0, \\ & 0 \leq G(z) \ \perp \ H(z) \geq 0, \end{array} \tag{6.1}$$

where $G, H : \mathbb{R}^{n+2p} \to \mathbb{R}^p$ are twice continuously differentiable. We note that the general constraints are on the control variables only and that the only complementarity constraint takes the form of a vertical complementarity constraints. This case was brought to our attention by Mihai Anitescu.

In this section, we make the following additional assumption, which is related to the mixed P_0 property (e.g., [16]).

[A8] The matrix $[\nabla c(z_0^*) : \nabla G(z^*) : \nabla H(z^*)]$ has full rank.

The motivation for considering this form of problem (6.1) is that the simple complementarity constraint $0 \leq z_1 \ \perp \ z_2 \geq 0$ always produces feasible linearization if there are no other constraints on z_1, z_2.

To see the relationship between Assumption [A8] and the mixed P_0 property, consider the equivalent MPEC with slacks defined by

$$\begin{array}{ll} \text{minimize} & f(z) \\ \text{subject to} & F(z,s) = 0, \\ & 0 \le s_1 \ \perp \ s_2 \ge 0, \end{array} \tag{6.2}$$

where

$$F(z,s) = \begin{pmatrix} c(z_0) \\ G(z) - s_1 \\ H(z) - s_2. \end{pmatrix}.$$

One can see that a sufficient condition for Assumption [A8] is that the Jacobian matrix

$$\begin{bmatrix} \nabla_{s_1} F \\ \nabla_{s_2} F \\ \nabla_z F \end{bmatrix} = \begin{bmatrix} 0 & -I & 0 \\ 0 & 0 & -I \\ & \nabla_z F & \end{bmatrix}$$

satisfy the mixed P_0 property. This assumption has been used, for instance, in the convergence analysis of MPEC solvers and holds for a range of test problems, such as those arising from obstacle or packaging problems [17, Chapter 9].

LEMMA 6.1. *Let Assumptions* [A1]–[A5] *and* [A8] *hold. Then it follows that* (QP^k) *is consistent* $\forall z^{(k)}$ *in a neighborhood of* z^* *where* $G^{(k)^T} H^{(k)} \ge 0$. *If, in addition, the functions* $G(z)$ *and* $H(z)$ *are convex, then* $G^{(k+1)^T} H^{(k+1)} \ge 0$.

Proof. Let $z^{(k)}$ be sufficiently close to z^* so that the Jacobian matrix

$$\left[\nabla c(z_0^{(k)}) : \nabla G(z^{(k)}) : \nabla H(z^{(k)})\right]$$

has full rank.

The linearizations of the QP approximation to (6.1) has the following constraints:

$$c^{(k)} + \nabla c^{(k)^T} d_0 = 0, \tag{6.3}$$

$$G^{(k)} + \nabla G^{(k)^T} d \ge 0, \tag{6.4}$$

$$H^{(k)} + \nabla H^{(k)^T} d \ge 0, \tag{6.5}$$

$$G^{(k)^T} H^{(k)} + G^{(k)^T} \nabla H^{(k)^T} d + H^{(k)^T} \nabla G^{(k)^T} d \le 0. \tag{6.6}$$

We need to show that these constraints are consistent. By [A8] it follows that there exists $\hat{d}$ such that constraints (6.3)–(6.5) hold with equality (this corresponds to the origin in the $G - H$ coordinate system).

It can be shown that $\hat{d}$ is also feasible in (6.6). The constraints (6.3) and (6.4) hold with equality, thus implying that $\nabla G^{(k)^T} \hat{d} = -G^{(k)}$ and $\nabla H^{(k)^T} \hat{d} = -H^{(k)}$. Substituting these last two equations into (6.6) simplifies that constraint to

$$G^{(k)^T} H^{(k)} + G^{(k)^T} \nabla H^{(k)^T} \hat{d} + H^{(k)^T} \nabla G^{(k)^T} \hat{d} \ = \ -G^{(k)^T} H^{(k)} \ \le \ 0,$$

where the last inequality follows from the assumption that $G^{(k)^T} H^{(k)} \ge 0$.

To show that the QP step d^* maintains nonnegative complementarity, we observe that for $z^{(k)}$ sufficiently close to z^*, SQP converges and identifies the correct active set. Thus, there exists a partition

$$\mathcal{G} := \{i \ : \ G_i(z^*) = 0\} \quad \text{and} \quad \mathcal{H} := \{i \ : \ H_i(z^*) = 0\},$$

and

$$G_i^{(k)} + \nabla G_i^{(k)^T} d^* = 0, i \in \mathcal{G}, \tag{6.7}$$

$$H_i^{(k)} + \nabla H_i^{(k)^T} d^* = 0, i \in \mathcal{H}. \tag{6.8}$$

Note that d^* is feasible for an LPEC approximation, because $\mathcal{G} \cup \mathcal{H} \supset \{1, \ldots, p\}$ implies that

$$\left(G^{(k)} + \nabla G^{(k)^T} d^*\right)^T \left(H^{(k)} + \nabla H^{(k)^T} d^*\right) = 0. \tag{6.9}$$

Hence, if $G(z)$ and $H(z)$ are convex, it follows that

$$G^{(k+1)} = G(z^{(k)} + d) \geq G^{(k)} + \nabla G^{(k)^T} d,$$

and similarly for $H^{(k+1)}$. Combining this with (6.9) implies that

$$G^{(k+1)^T} H^{(k+1)} \geq \left(G^{(k)} + \nabla G^{(k)^T} d\right)^T \left(H^{(k)} + \nabla H^{(k)^T} d\right) \geq 0. \qquad \square$$

The main conclusion of this section is that Assumption [A8] turns out to be satisfied for a range of practical problems as long as the vertical complementarity problem has certain properties. This assumption is satisfied, for instance, for obstacle and packaging problems.

6.2. Feasibility restoration for complementarity. This section examines the properties of (QP^k) where $z_1^{(k)^T} z_2^{(k)} > 0$. In this case, (QP^k) may be inconsistent. This section describes a simple restoration procedure that can be invoked if (QP^k) is inconsistent. The procedure finds a new iterate $z^{(k+1)}$ with $z_1^{(k+1)^T} z_2^{(k+1)} = 0$. Thus, after one step, all subsequent iterates retain feasibility of the QP approximations by virtue of Theorem 5.7.

If (QP^k) is inconsistent, then we consider solving the following LP:

$$(LP_F^k) \qquad \begin{cases} \underset{d,\theta}{\text{minimize}} & \theta \\ \text{subject to} & c_{\mathcal{E}}^{(k)} + A_{\mathcal{E}}^{(k)^T} d = 0, \\ & c_{\mathcal{I}}^{(k)} + A_{\mathcal{I}}^{(k)^T} d \geq 0, \\ & z_1^{(k)} + d_1 \geq 0, \\ & z_2^{(k)} + d_2 \geq 0, \\ & z_1^{(k)^T} z_2^{(k)} + z_2^{(k)^T} d_1 + z_1^{(k)^T} d_2 \leq \theta. \end{cases}$$

It follows from Assumption [A2] that any QP approximation to the relaxed NLP (3.2) is consistent for $z^{(k)}$ sufficiently close to z^* and thus that (LP_F^k) is consistent (since it is a relaxation of the relaxed QP). If $z^{(k)}$ is far away from z^*, then clearly (LP_F^k) need not be consistent. In that case we enter a restoration phase.

The following lemma shows that the solution d of (LP_F^k) satisfies $(z_1^{(k)}+d_1)^T(z_2^{(k)}+d_2) = 0$. The key idea of the proof is to show that the optimal active set includes $\mathcal{Z}_1$ and $\mathcal{Z}_2$.

LEMMA 6.2. *Let Assumptions* [A1]–[A5] *hold, and assume that $z^{(k)}$ is sufficiently close to z^* so that the linearizations of $c_{\mathcal{E}}(z)$, $c_{\mathcal{I}}(z)$ are consistent and $z_1^{(k)}, z_2^{(k)} \geq 0$.*

Then it follows that (LP_F^k) *has a solution* d *such that* $z^{(k+1)} = z^{(k)} + d$ *satisfies* ${z_1^{(k+1)}}^T z_2^{(k+1)} = 0$.

Proof. Assume without loss of generality that $\mathcal{Z}_1^c = \emptyset$, namely, that $z_1^* = 0$, and consider the dual feasibility conditions of (LP_F^k) (primal feasibility follows from Assumption [A2]),

$$\begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix} - \left[\begin{array}{c|cc|c} & 0 & 0 & 0 \\ A_{\mathcal{A}}^{(k)} & I_1 & 0 & z_2^{(k)} \\ & 0 & I_2 & z_1^{(k)} \\ \hline 0 & 0 & 0 & -1 \end{array}\right] \begin{pmatrix} \lambda_{\mathcal{A}} \\ \nu_1 \\ \nu_2 \\ \xi \end{pmatrix} = 0, \tag{6.10}$$

where $A_{\mathcal{A}}^{(k)}$ is the matrix of active constraint normals of $c_{\mathcal{E}}(z)$, $c_{\mathcal{I}}(z)$ at z^*, $I_2 = [e_i]_{i \in \mathcal{Z}_2}$ and $I_1 = [e_i]_{i \in \mathcal{Z}_1}$.

It follows immediately that $\xi = -1$ and that this active set gives rise to a primal feasible solution. Moreover, the columns of the basis matrix in (6.10) are linearly independent by Assumption [A2]. Thus there exists a unique solution to (6.10). Assumption [A2] implies in particular that the following block of (6.10) has full column rank:

$$\left[\begin{array}{c|cc} & 0 & 0 \\ A_{\mathcal{A}}^{(k)} & I_1 & 0 \\ & 0 & I_2 \end{array}\right].$$

This implies that the block of $A_{\mathcal{A}}^{(k)}$ corresponding to the first equation in (6.10) has full column rank, and thus $\lambda_{\mathcal{A}} = 0$ follows. This implies that

$$\nu_1 = z_2^{(k)} \geq 0 \quad \text{and} \quad \nu_2 = z_1^{(k)} \geq 0.$$

Complementary slackness of (LP_F^k) implies that ${z_1^{(k+1)}}^T z_2^{(k+1)} = 0$. To see how this follows, consider three cases:

Case 1. $i \in \mathcal{Z}_2^c$ implies that $z_{2i}^{(k)} > 0$. This implies that $\nu_{1i} > 0$, and thus $z_{1i}^{(k)} + d_{1i} = 0$.

Case 2. $i \in \mathcal{Z}_2$ and $z_{1i}^{(k)}, z_{2i}^{(k)} > 0$. This implies that $\nu_{1i}, \nu_{2i} > 0$, and thus $z_{1i}^{(k)} + d_{1i} = 0$ and $z_{2i}^{(k)} + d_{2i} = 0$.

Case 3. $i \in \mathcal{Z}_2$ and $z_{1i}^{(k)} > 0$ but $z_{2i}^{(k)} = 0$. This implies that $\nu_{2i} > 0$, and thus $z_{1i}^{(k)} + d_{1i} = 0$. The case where $z_{1i}^{(k)} = 0$ but $z_{2i}^{(k)} > 0$ is analogous.

Putting all three cases together and recalling that $\mathcal{Z}_1 = \emptyset$, one then has that ${z_1^{(k+1)}}^T z_2^{(k+1)} = 0$.

It remains to prove that there exist multipliers λ with $\lambda_{\mathcal{I}} \geq 0$ such that (6.10) holds. If $\lambda_{\mathcal{I} \cap \mathcal{A}} \geq 0$, there is nothing to show. Hence assume that there exists a multiplier $\lambda_i < 0$ for $i \in \mathcal{I} \cap \mathcal{A}$. Then one can perform an iteration of an active set method on (LP_F^k) that will not remove any columns of I_1 or I_2 from the basis. Since (LP_F^k) is bounded ($\theta > 0$, since (QP^k) is inconsistent), after a finite number of such pivots a basis is found with ν_1, ν_2 as above, and the conclusion follows. ∎

Solving (LP_F^k), if (QP^k) is inconsistent, is related to the elastic mode of snopt. In the elastic mode, some of the constraints are relaxed and an l_∞-QP is solved. The application of snopt to MPECs is explored in [1]. Unlike snopt, however, the present restoration will occur only at one iteration.

An alternative to solving (LP_F^k) would be to move $z^{(k)}$ onto the "nearest" axis. This is the effect of (LP_F^k), as can be seen from Lemma 6.2. However, solving (LP_F^k) avoids the need to choose tolerances to break ties between "close" values.

We note that this restoration does not address the wider issue of *global* convergence. It may be possible that the solution to (LP_F^k) is not acceptable to the global convergence criterion of the SQP method. Clearly, this possibility has to be taken into account in designing a globally convergent SQP method. This is beyond the scope of the present paper, which deals exclusively with local convergence issues.

7. Discussion of assumptions. This section discusses some of the assumptions made in the proof above. In particular, examples are presented showing that SQP will fail to converge at second-order rate if some or all of the assumptions are removed. The following table shows which assumptions seem difficult to remove. Below, each example is presented in turn.

Example	[A2]	MFCQ	[A3]	Slacks	SOSC	Comments
`scholtes4`	no	yes	no	yes	yes	$\xi \to \infty$, linear convergence
`sl2`	yes	yes	yes	no	yes	$\xi \to \infty$, nonstationary limit
`ralph2`	yes	yes	yes	yes	no	$\xi < \infty$, linear convergence

7.1. Unbounded multipliers and slow convergence. The following MPEC shows that if we remove Assumption [A2] and, in particular, Assumption [A3], then the NLP multipliers are not bounded (and may not even exist). Despite this, SQP converges linearly to the solution in the example presented here, although quadratic convergence is lost.

Consider the following MPEC (`scholtes4.mod`) from MacMPEC (see also [19]):

$$(P) \qquad \begin{cases} \underset{z}{\text{minimize}} & z_1 + z_2 - z_0 \\ \text{subject to} & -4z_1 + z_0 \le 0, \\ & -4z_2 + z_0 \le 0, \\ & 0 \le z_1 \ \perp \ z_2 \ge 0\,, \end{cases}$$

whose optimal solution is $z^* = (0,0,0)^T$. Writing (P) as an NLP gives

$$(P') \qquad \begin{cases} \underset{z}{\text{minimize}} & z_1 + z_2 - z_0 & & \text{multiplier} \\ \text{subject to} & -4z_1 + z_0 \le 0, & & \lambda_1 \ge 0, \\ & -4z_2 + z_0 \le 0, & & \lambda_2 \ge 0, \\ & z_1 z_2 \le 0, & & \xi \ge 0, \\ & z_1 \ge 0, & & \nu_1 \ge 0, \\ & z_2 \ge 0, & & \nu_2 \ge 0. \end{cases}$$

Next, we show that SQP converges linearly for this problem.

PROPOSITION 7.1. *SQP applied to (P') generates the following sequence of iterates:*

$$z^{(k)} = \begin{pmatrix} 2^{2-k} \\ 2^{-k} \\ 2^{-k} \end{pmatrix},\ \lambda^{(k)} = \begin{pmatrix} \frac{1}{2} \\ \frac{1}{2} \end{pmatrix},\ \xi^{(k)} = 2^{k-1} + \xi^{(k-1)}/2 = \sum_{j=0}^{k-1} 2^{(k-1)-2j}$$

for suitable starting values (e.g., $z = (4,1,1)^T$). Moreover, SQP converges linearly.

Proof. the proof is by induction. The assertion holds trivially for $k = 0$ (i.e., the starting point). Now assume the assertion holds for k, and show that it also holds for $k + 1$. At iteration k, SQP solves the following QP for a step d:

$$(QP^{(k)}) \qquad \begin{cases} \underset{z}{\text{minimize}} & d_1\xi^{(k)}d_2 + d_1 + d_2 - d_0 \\ \text{subject to} & -4d_1 + d_0 \le 0, \\ & -4d_2 + d_0 \le 0, \\ & z_1^{(k)}z_2^{(k)} + z_2^{(k)}d_1 + z_1^{(k)}d_2 \le 0, \\ & z_1^{(k)} + d_1 \ge 0, \\ & z_2^{(k)} + d_2 \ge 0. \end{cases}$$

We note that all QP approximations are consistent and that the first three constraints are active. Subtracting the second from the first constraint, we have that $d_1 = d_2$. Substituting into the third constraint, we get $d_1 = d_2 = -2^{-(k+1)}$, from which it follows that $d_0 = 4(-2^{-(k+1)})$. We verify the KKT conditions of $(QP^{(k)})$:

$$0 = \begin{pmatrix} -1 \\ 1 \\ 1 \end{pmatrix} + \begin{pmatrix} 0 \\ -2^{-(k+1)}\xi^{(k)} \\ -2^{-(k+1)}\xi^{(k)} \end{pmatrix} + \lambda_1 \begin{pmatrix} 1 \\ -4 \\ 0 \end{pmatrix} + \lambda_2 \begin{pmatrix} 1 \\ 0 \\ -4 \end{pmatrix} + \xi \begin{pmatrix} 0 \\ 2^{-k} \\ 2^{-k} \end{pmatrix}.$$

Subtracting the second from the first equation shows that $\lambda_1 = \lambda_2$. Substituting into the third equation then verifies that $\lambda_1^{(k+1)} = \lambda_2^{(k+1)} = \frac{1}{2}$.

Finally, the second equation shows $\xi^{(k)} = 2^{k-1} + \xi^{(k-1)}/2$, the recurrence relation for ξ. The explicit formula for ξ follows easily. The iterates clearly converge linearly to the solution. ∎

Note that (P) satisfies an MPEC-MFCQ [20] but violates an MPEC-LICQ (as can be seen easily by observing that four constraints are active at the solution). In addition, (P) fails to satisfy strong complementarity. For strong complementarity, it would be necessary that $\lambda_i \ge 0$ and $\nu_i \ge 0$, since $z_1 = z_2 = 0$. Checking the first-order condition,

$$0 = \begin{pmatrix} -1 \\ 1 \\ 1 \end{pmatrix} + \lambda_1 \begin{pmatrix} 1 \\ -4 \\ 0 \end{pmatrix} + \lambda_2 \begin{pmatrix} 1 \\ 0 \\ -4 \end{pmatrix} - \hat{\nu}_1 \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} - \hat{\nu}_2 \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

one can see that the system is underdetermined. Setting $\lambda_1 = t$, we obtain $\lambda_2 = 1 - t$, $\nu_1 = 1 - 4t$, and $\nu_2 = -3 + 4t$. The condition $\nu_i \ge 0$ now implies that $t \le \frac{1}{4}$ *and* $t \ge \frac{3}{4}$, which cannot hold simultaneously. Thus the solution of (P) is not strongly stationary.

The linear inequalities always ensure that $z_1^{(0)} = z_2^{(0)} \ge 0$, and the above analysis goes through for alternative starting points. It is not clear what would happen if we allowed $z_1 < 0$, but sensible NLP solvers will always project the starting point into the set of linear constraints (or at least the set of box constraints). The solvers filter, snopt, and lancelot behave in this way.

7.2. Formulations without slacks. The next example shows that SQP methods can converge to nonstationary points if slacks are not added to replace nonlinear complementarity conditions. Consider the following MPEC (`s12.mod`) from

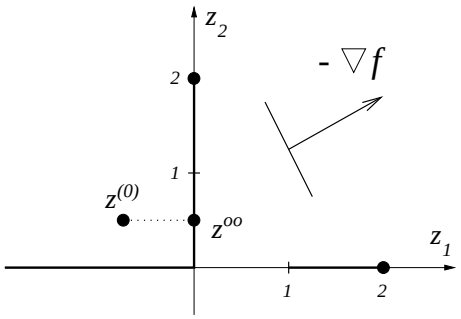

FIG. 3. *Example* `sl2`.

MacMPEC, which involves a nonlinear expression in the complementarity condition:

$$(P) \qquad \begin{cases} \underset{z}{\text{minimize}} & -z_1 - \frac{1}{2}z_2 \\ \text{subject to} & z_1 + z_2 \le 2, \\ & 0 \le z_1^2 - z_1 \ \perp \ z_2 \ge 0. \end{cases}$$

The problem has a global solution at $z^* = (2,0)^T$ with $f^* = -2$ and a local solution at $z^* = (0,2)^T$ with $f^* = -1$. Both solutions satisfy Assumptions [A1]–[A4]. The feasible set is illustrated by the bold lines in Figure 3.

Starting at $z^{(0)} = (-\epsilon, t)^T$ gives convergence to the nonstationary point $z^\infty = (0,t)^T$, where $t \ge 0$ is arbitrary. Moreover, one can show that $\xi \to \infty$ and that *both* the complementarity constraint *and* $0 \le z_1^2 + z_1$ remain in the active set. Thus, the active set is singular in the limit. Nevertheless, second-order convergence is observed!

It is straightforward to prove quadratic convergence to a nonstationary limit. Let $z^{(k)} = (-\epsilon, t)^T$ with $t \le 1$. Then the following problem is solved for a step of the SQP method:

$$(P) \qquad \begin{cases} \underset{d}{\text{minimize}} & -d_1 - \frac{1}{2}d_2 \\ \text{subject to} & d_1 + d_2 \le 2 + \epsilon - t, \\ & (\epsilon^2 + \epsilon) - (2\epsilon + 1)d_1 \ge 0, \\ & t + d_2 \ge 0, \\ & t(\epsilon^2 + \epsilon) - t(2\epsilon + 1)d_1 + (\epsilon^2 + \epsilon) \le 0, \end{cases}$$

whose solution is

$$d = \begin{pmatrix} \frac{\epsilon^2+\epsilon}{2\epsilon+1} \\ 0 \end{pmatrix}, \quad \xi = \frac{1}{2(\epsilon^2+\epsilon)}, \quad \nu_1 = \frac{1}{2\epsilon+1} + \xi t.$$

One can see that $z^{(k+1)} = (-\mathcal{O}(\epsilon^2), t)^T$ and quadratic convergence occurs to $z^\infty = (0,t)^T$. On the other hand, the multiplier ξ clearly diverges to infinity. Note that including the Hessian of the Lagrangian leads to a similar conclusion. This example shows that it is not sufficient to trigger the elastic mode only when QP become inconsistent. Clearly, the elastic mode is also required if the multipliers become too large. The introduction of slacks avoids the need for the elastic mode in this example.

When a slack variable is introduced, SQP converges quadratically. The SQP solver `filter` exhibits this behavior, while `lancelot` and `loqo` converge even for the problem *without* slacks. The reason for this apparently better behavior is that both introduce slacks internally before solving the problem!

Another reason for using slacks (rather than linear or even nonlinear complementarity) is that SQP solvers maintain linear feasibility throughout the iteration. Thus they *guarantee* that $z_1^{(k)} \geq 0,\ z_2^{(k)} \geq 0$ for all iterations k in *exact* arithmetic. In *inexact* arithmetic, one can truncate QP steps such that $z_1^{(k)} \geq 0,\ z_2^{(k)} \geq 0$ for all iterations k. This approach is *not* possible for general *linear* complementarity conditions even if iterative refinement were used.

Thus the use of slacks ensures that ${z_1^{(k)}}^T z_2^{(k)} \geq 0$ for all iterations k, and the trivial pitfall of [4], where it was observed that perturbing the right-hand side of the complementarity constraint to $-\epsilon$ renders an inconsistent QP, cannot occur.

7.3. Lack of second-order condition. The following MPEC (`ralph2.mod`) shows that if the second-order sufficient condition [A3] is violated, then SQP may converge only linearly:

$$(P) \qquad \begin{cases} \underset{z}{\text{minimize}} & z_1^2 + z_2^2 - 4z_1 z_2 \\ \text{subject to} & 0 \leq z_1 \ \perp \ z_2 \geq 0. \end{cases}$$

The problem has a global solution at $(0,0)$. Starting at $z = (1,1)$ causes SQP to converge linearly to the solution. Note that (P) also violates any upper-level strict complementarity condition.

The MPEC-SOSC is stronger than needed for MPECs in the sense that the set of directions over which positive curvature is required for SQP is larger than the set of MPEC-feasible directions. We illustrate this by the following example. The set of MPEC-feasible directions at $(0,0)$ is

$$S_M^* = \left\{ \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix} \right\},$$

while the set of directions over which curvature is required to be positive for SQP to converge is the whole positive orthant (i.e., $\text{conv}(S_M^*)$). The linear rate of convergence is due to the fact that the curvature in the direction $(1,1)$ is negative.

8. Conclusions and future work. We have presented a convergence analysis that shows that SQP methods converge quadratically when applied to the NLP equivalent of an MPEC. This analysis goes some way toward explaining the extraordinary success of SQP solvers applied to MPECs, as we have observed. The result is remarkable because MPECs violate the MFCQ.

Conditions are identified under which local second-order convergence occurs. These conditions include the assumption that all QP approximations remain consistent. It can be shown that this assumption always holds if ${z_1^{(k)}}^T z_2^{(k)} = 0$ (i.e., for iterates which satisfy complementarity), and this is often observed in practice. We have also shown that MPECs whose lower-level problem is a certain vertical complementarity problem generate consistent QP approximations. Further we have given a restoration phase that ensures that this can always be guaranteed sufficiently close to a solution.

We have also experimented with an alternative to the restoration problem. In this approach, the linearization of the complementarity condition is relaxed as

$$(8.1) \qquad {z_1^{(k)}}^T z_2^{(k)} + {z_2^{(k)}}^T d_1 + {z_1^{(k)}}^T d_2 \leq \delta \left({z_1^{(k)}}^T z_2^{(k)} \right)^{1+\kappa},$$

where $0 < \delta, \kappa < 1$ are constants. Note that the perturbation to the right-hand side of the complementarity condition is $o(\|d_{NR}\|)$, where d_{NR} is the Newton step. This form of perturbation allows the superlinear convergence proof to be extended by virtue of the Dennis–Moré characterization theorem.

However, the perturbation alone is not sufficient to guarantee consistency of (QP^k). The following example illustrates the need for further assumptions. Consider the following feasible set:

$$z_1 + z_2 - 1 \geq 0\,, \quad 0 \leq z_1 \perp z_2 \geq 0.$$

It is easy to see that for any $z = (\epsilon^4, 1-\epsilon)$, the (QP^k) relaxed by using (8.1) with $\delta = \kappa = 0.5$ is inconsistent. Note that if we restrict our attention to points z that satisfy the linear constraints (e.g., $z = (\epsilon, 1-\epsilon)$), then (QP^k) using (8.1) is consistent in a neighborhood of $z = (0, 1)$. Thus (8.1) seems to ensure consistency of (QP^k) as long as $z^{(k)}$ satisfies the linearizations of $c_{\mathcal{E}}(z)$, $c_{\mathcal{I}}(z)$ about $z^{(k-1)}$. Unfortunately, we have been unable to prove any general results along those lines. Such a proof would clearly allow us to bootstrap a convergence of SQP for MPECs with the relaxed equation (8.1).

We finish this paper with some observations on the role of degeneracy and point to some future work. It has been observed that any QP approximation about a feasible point of (1.3) is degenerate. Moreover, approximations about points that satisfy $z_1^T z_2 = \epsilon > 0$ are near-degenerate, and we would expect this property to play a role in the SQP method. In our numerical experiment we use two SQP solvers, snopt and filter.

The solver `snopt` uses `EXPAND` to handle degeneracy. This procedure perturbs the bounds of (QP^k) to *remove* degeneracy. Some numerical experiments suggest that this is not the best way to handle degeneracy in the case of MPECs. The QP solver in filter, `bqpd`, applies a different methodology to handle degeneracy. It *creates* degeneracy whenever *near-degeneracy* is detected and then handles the degenerate situation. This approach has two implications:

1. If *exact degeneracy* exists (i.e., if ${z_1^{(k)}}^T z_2^{(k)} = 0$), then `bqpd` will deal with it.
2. If *near-degeneracy* exists (i.e., if ${z_1^{(k)}}^T z_2^{(k)} = \epsilon > 0$), then `bqpd` *creates degeneracy* by perturbing the bound ϵ to zero. This has the effect of *pushing* the solution onto the axis. As we have shown, this is a favorable situation for SQP methods.

Future work will focus on relaxing some assumptions and providing a global convergence analysis. Some numerical results suggest that SQP converges under even weaker assumptions than those made above, and it may be possible to pursue the ideas of [22] in this context. Another important question concerns the global convergence of SQP methods. Anitescu [1] provides a framework for convergence (possibly under additional assumptions) of Sl_∞QP methods. However, the numerical results suggest that a similar proof may be possible for filter methods.

AN ITERATIVE SOLVER-BASED INFEASIBLE PRIMAL-DUAL PATH-FOLLOWING ALGORITHM FOR CONVEX QUADRATIC PROGRAMMING*

ZHAOSONG LU†, RENATO D. C. MONTEIRO‡, AND JEROME W. O'NEAL§

Abstract. In this paper we develop a long-step primal-dual infeasible path-following algorithm for convex quadratic programming (CQP) whose search directions are computed by means of a preconditioned iterative linear solver. We propose a new linear system, which we refer to as the *augmented normal equation* (ANE), to determine the primal-dual search directions. Since the condition number of the ANE coefficient matrix may become large for degenerate CQP problems, we use a maximum weight basis preconditioner introduced in [A. R. L. Oliveira and D. C. Sorensen, *Linear Algebra Appl.*, 394 (2005), pp. 1–24; M. G. C. Resende and G. Veiga, *SIAM J. Optim.*, 3 (1993), pp. 516–537; P. Vaida, *Solving Linear Equations with Symmetric Diagonally Dominant Matrices by Constructing Good Preconditioners*, Tech. report, Department of Computer Science, University of Illinois at Urbana-Champaign, Urbana, IL, 1990] to precondition this matrix. Using a result obtained in [R. D. C. Monteiro, J. W. O'Neal, and T. Tsuchiya, *SIAM J. Optim.*, 15 (2004), pp. 96–100], we establish a uniform bound, depending only on the CQP data, for the number of iterations needed by the iterative linear solver to obtain a sufficiently accurate solution to the ANE. Since the iterative linear solver can generate only an approximate solution to the ANE, this solution does not yield a primal-dual search direction satisfying all equations of the primal-dual Newton system. We propose a way to compute an inexact primal-dual search direction so that the equation corresponding to the primal residual is satisfied exactly, while the one corresponding to the dual residual contains a manageable error which allows us to establish a polynomial bound on the number of iterations of our method.

1. Introduction.

In this paper we develop an interior-point long-step primal-dual infeasible path-following (PDIPF) algorithm for convex quadratic programming (CQP) whose search directions are computed by means of an iterative linear solver. We will refer to this algorithm as an *inexact* algorithm, in the sense that the Newton system which determines the search direction will be solved only approximately at each iteration. The problem we consider is

$$\min_x \left\{ \frac{1}{2} x^T Q x + c^T x : \quad Ax = b,\ x \geq 0 \right\}, \tag{1}$$

where the data are $Q \in \Re^{n\times n}$, $A \in \Re^{m\times n}$, $b \in \Re^m$, and $c \in \Re^n$, and the decision vector is $x \in \Re^n$. We also assume that Q is positive semidefinite and that a factorization $Q = VE^2V^T$ is explicitly given, where $V \in \Re^{n\times l}$ and E is an $l \times l$ positive diagonal matrix.

A similar algorithm for solving the special case of linear programming (LP), i.e., problem (1) with $Q = 0$, was developed by Monteiro and O'Neal in [16]. The algorithm studied in [16] is essentially the long-step PDIPF algorithm studied in [9, 28], the only difference being that the search directions are computed by means of an iterative linear solver. We refer to the iterations of the iterative linear solver as the *inner iterations* and to the ones performed by the interior-point method itself as the *outer iterations*. The main step of the algorithm studied in [9, 16, 28] is the computation of the primal-dual search direction $(\Delta x, \Delta s, \Delta y)$, whose Δy component can be found by solving a system of the form $AD^2A^T\Delta y = g$, referred to as the *normal equation*, where $g \in \Re^m$ and the positive diagonal matrix D depends on the current primal-dual iterate. In contrast to [9, 28], the algorithm studied in [16] uses an iterative linear solver to obtain an approximate solution to the normal equation. Since the condition number of the normal matrix AD^2A^T may become excessively large on degenerate LP problems (see e.g., [13]), the maximum weight basis (MWB) preconditioner T introduced in [19, 22, 25] is used to better condition this matrix, and an approximate solution of the resulting equivalent system with coefficient matrix $TAD^2A^TT^T$ is then computed. By using a result obtained in [17], which establishes that the condition number of $TAD^2A^TT^T$ is uniformly bounded by a quantity depending only on A, Monteiro and O'Neal [16] showed that the number of inner iterations of the algorithm in [16] can be uniformly bounded by a constant depending on n and A.

In the case of CQP, the standard normal equation takes the form

$$A(Q + X^{-1}S)^{-1}A^T\Delta y = g \tag{2}$$

for some vector g. When Q is not diagonal, the matrix $(Q+X^{-1}S)^{-1}$ is not diagonal, and hence the coefficient matrix of (2) does not have the form required for the result of [17] to hold. To remedy this difficulty, we develop in this paper a new linear system, referred to as the *augmented normal equation* (ANE), to determine a portion of the primal-dual search direction. This equation has the form $\tilde{A}\tilde{D}^2\tilde{A}^Tu = w$, where $w \in \Re^{m+l}$, $\tilde{D}$ is an $(n+l)\times(n+l)$ positive diagonal matrix, and $\tilde{A}$ is a 2×2 block matrix of dimension $(m+l)\times(n+l)$ whose blocks consist of A, V^T, the zero matrix, and the identity matrix (see (21)). As was done in [16], a MWB preconditioner $\tilde{T}$ for the ANE is computed and an approximate solution of the resulting preconditioned equation with coefficient matrix $\tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T$ is generated using an iterative linear solver. Using the result of [17], which claims that the condition number of $\tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T$ is uniformly bounded regardless of $\tilde{D}$, we obtain a uniform bound (depending only on $\tilde{A}$) on the number of inner iterations performed by the iterative linear solver to find a desirable approximate solution to the ANE (see Theorem 3.5).

Since the iterative linear solver can generate only an approximate solution to the ANE, it is clear that not all equations of the Newton system, which determines the primal-dual search direction, can be satisfied simultaneously. In the context of LP, Monteiro and O'Neal [16] proposed a recipe to compute an inexact primal-dual search direction so that the equations of the Newton system corresponding to the primal and dual residuals were both satisfied. In the context of CQP, such an approach is no longer possible. Instead, we propose a way to compute an inexact primal-dual search direction so that the equation corresponding to the primal residual is satisfied

exactly, while the one corresponding to the dual residual contains a manageable error which allows us to establish a polynomial bound on the number of outer iterations of our method. Interestingly, the presence of this error on the dual residual equation implies that the primal and dual residuals go to zero at different rates. This is a unique feature of the convergence analysis of our algorithm in that it contrasts with the analysis of other interior-point PDIPF algorithms, where the primal and dual residuals are required to go to zero at the same rate.

The use of inexact search directions in interior-point methods has been extensively studied in the context of cone programming problems (see e.g., [1, 2, 7, 11, 12, 15, 18, 29]). Moreover, the use of iterative linear solvers to compute the primal-dual Newton search directions of interior-point path-following algorithms has also been extensively investigated in [1, 3, 4, 7, 12, 18, 19, 20, 22, 24]. For feasibility problems of the form $\{x \in \mathcal{H}_1 : \mathcal{A}x = b, x \in \mathcal{C}\}$, where $\mathcal{H}_1$ and $\mathcal{H}_2$ are Hilbert spaces, $\mathcal{C} \subseteq \mathcal{H}_1$ is a closed convex cone satisfying some mild assumptions, and $\mathcal{A} : \mathcal{H}_1 \to \mathcal{H}_2$ is a continuous linear operator, Renegar [21] has proposed an interior-point method where the Newton system that determines the search directions is approximately solved by performing a uniformly bounded number of iterations of the conjugate gradient (CG) method. To our knowledge, no one has used the ANE system in the context of CQP to obtain either an exact or inexact primal-dual search direction.

Our paper is organized as follows. In subsection 1.1, we give the terminology and notation which will be used throughout our paper. Section 2 describes the outer iteration framework for our algorithm and the complexity results we have obtained for it, along with presenting the ANE as a means to determine the search direction. In section 3, we discuss the use of iterative linear solvers to obtain a suitable approximate solution to the ANE and the construction of an inexact search direction based on this solution. Section 4 gives the proofs of the results presented in sections 2 and 3. Finally, we present some concluding remarks in section 5.

1.1. Terminology and notation. Throughout this paper, uppercase roman letters denote matrices, lowercase roman letters denote vectors, and lowercase Greek letters denote scalars. We let $\Re^n$, $\Re^n_+$, and $\Re^n_{++}$ denote the set of n-dimensional vectors having real, nonnegative real, and positive real components, respectively. Also, we let $\Re^{m\times n}$ denote the set of $m \times n$ matrices with real entries. For a vector $v \in \Re^n$, we let $|v|$ denote the vector whose ith component is $|v_i|$ for every $i = 1, \ldots, n$, and we let $\mathrm{Diag}(v)$ denote the diagonal matrix whose ith diagonal element is v_i for every $i = 1, \ldots, n$. In addition, given vectors $u \in \Re^m$ and $v \in \Re^n$, we denote by (u, v) the vector $(u^T, v^T)^T \in \Re^{m+n}$.

Certain matrices bear special notation, namely the matrices X, ΔX, S, D, and $\tilde{D}$. These matrices are the diagonal matrices corresponding to the vectors x, Δx, s, d, and $\tilde{d}$, respectively, as described in the previous paragraph. The symbol 0 will be used to denote a scalar, vector, or matrix of all zeros; its dimensions should be clear from the context. Also, we denote by e the vector of all 1's, and by I the identity matrix; their dimensions should be clear from the context.

For a symmetric positive definite matrix W, we denote its condition number by $\kappa(W)$, i.e., its maximum eigenvalue divided by its minimum eigenvalue. We will denote sets by uppercase calligraphic letters (e.g., $\mathcal{B}, \mathcal{N}$). For a finite set $\mathcal{B}$, we denote its cardinality by $|\mathcal{B}|$. Given a matrix $A \in \Re^{m\times n}$ and an ordered set $\mathcal{B} \subseteq \{1, \ldots, n\}$, we let $A_{\mathcal{B}}$ denote the submatrix whose columns are $\{A_i : i \in \mathcal{B}\}$ arranged in the same order as $\mathcal{B}$. Similarly, given a vector $v \in \Re^n$ and an ordered set $\mathcal{B} \subseteq \{1, \ldots, n\}$, we let $v_{\mathcal{B}}$ denote the subvector consisting of the elements $\{v_i : i \in \mathcal{B}\}$ arranged in the same

order as $\mathcal{B}$.

We will use several different norms throughout the paper. For a vector $z \in \Re^n$, $\|z\| = \sqrt{z^T z}$ is the Euclidian norm, $\|z\|_1 = \sum_{i=1}^n |z_i|$ is the "1-norm," and $\|z\|_\infty = \max_{i=1,\ldots,n} |z_i|$ is the "infinity norm." For a matrix $V \in \Re^{m\times n}$, $\|V\|$ denotes the operator norm associated with the Euclidian norm: $\|V\| = \max_{z:\|z\|=1} \|Vz\|$. Finally, $\|V\|_F$ denotes the Frobenius norm: $\|V\|_F = (\sum_{i=1}^m \sum_{j=1}^n V_{ij}^2)^{1/2}$.

2. Outer iteration framework. In this section, we introduce our PDIPF algorithm based on a class of inexact search directions and discuss its iteration complexity. This section is divided into two subsections. In subsection 2.1, we discuss an exact PDIPF algorithm, which will serve as the basis for the inexact PDIPF algorithm given in subsection 2.2, and we give its iteration complexity result. We also present an approach based on the ANE to determine the Newton search direction for the exact algorithm. To motivate the class of inexact search directions used by our inexact PDIPF algorithm, we describe in subsection 2.2 a framework for computing an inexact search direction based on an approximate solution to the ANE. We then introduce the class of inexact search directions, state a PDIPF algorithm based on it, and give its iteration complexity result.

2.1. An exact PDIPF algorithm and the ANE. Consider the following primal-dual pair of CQP problems:

$$\min_x \left\{ \frac{1}{2} x^T V E^2 V^T x + c^T x : \quad Ax = b,\ x \geq 0 \right\}, \tag{3}$$

$$\max_{(\hat{x},s,y)} \left\{ -\frac{1}{2} \hat{x}^T V E^2 V^T \hat{x} + b^T y : \quad A^T y + s - V E^2 V^T \hat{x} = c,\ s \geq 0 \right\}, \tag{4}$$

where the data are $V \in \Re^{n\times l}$, $E \in \mathrm{Diag}(\Re^l_{++})$, $A \in \Re^{m\times n}$, $b \in \Re^m$, and $c \in \Re^n$, and the decision variables are $x \in \Re^n$ and $(\hat{x}, s, y) \in \Re^n \times \Re^n \times \Re^m$. We observe that the Hessian matrix Q is already given in factored form $Q = VE^2V^T$.

It is well known that if x^* is an optimal solution for (3) and $(\hat{x}^*, s^*, y^*)$ is an optimal solution for (4), then (x^*, s^*, y^*) is also an optimal solution for (4). Now, let $\mathcal{S}$ denote the set of all vectors $w := (x, s, y, z) \in \Re^{2n+m+l}$ satisfying

$$Ax = b, \quad x \geq 0, \tag{5}$$

$$A^T y + s + Vz = c, \quad s \geq 0, \tag{6}$$

$$Xs = 0, \tag{7}$$

$$EV^T x + E^{-1} z = 0. \tag{8}$$

It is clear that $w \in \mathcal{S}$ if and only if x is optimal for (3), (x, s, y) is optimal for (4), and $z = -E^2V^Tx$. (Throughout this paper, the symbol w will always denote the quadruple (x, s, y, z), where the vectors lie in the appropriate dimensions; similarly, $\Delta w = (\Delta x, \Delta s, \Delta y, \Delta z)$, $w^k = (x^k, s^k, y^k, z^k)$, $\bar{w} = (\bar{x}, \bar{s}, \bar{y}, \bar{z})$, etc.)

We observe that the presentation of the PDIPF algorithm based on exact Newton search directions in this subsection differs from the classical way of presenting it in that we introduce an additional variable z as above. Clearly, it is easy to see that the variable z is completely redundant and can be eliminated, thereby reducing the method described below to the usual way of presenting it. The main reason for introducing the variable z is due to the development of the ANE presented at the end of this subsection.

We will make the following two assumptions throughout the paper.

Assumption 1. A has full row rank.

Assumption 2. The set $\mathcal{S}$ is nonempty.

For a point $w \in \Re^{2n}_{++} \times \Re^{m+l}$, let us define

$$\mu := \mu(w) \;=\; x^T s/n, \tag{9}$$

$$r_p := r_p(w) \;=\; Ax - b, \tag{10}$$

$$r_d := r_d(w) \;=\; A^T y + s + Vz - c, \tag{11}$$

$$r_V := r_V(w) \;=\; EV^T x + E^{-1} z, \tag{12}$$

$$r := r(w) \;=\; (r_p(w), r_d(w), r_V(w)). \tag{13}$$

Moreover, given $\gamma \in (0,1)$ and an initial point $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$, we define the following neighborhood of the central path:

$$\mathcal{N}_{w^0}(\gamma) := \left\{ w \in \Re^{2n}_{++} \times \Re^{m+l} : Xs \geq (1-\gamma)\mu e,\ r = \eta r^0 \right. \\ \left. \text{for some } 0 \leq \eta \leq \min\left[1, \frac{\mu}{\mu_0}\right] \right\}, \tag{14}$$

where $r := r(w)$, $r^0 := r(w^0)$, $\mu := \mu(w)$, and $\mu_0 := \mu(w^0)$.

We are now ready to state the PDIPF algorithm based on exact Newton search directions.

Exact PDIPF algorithm.

1. **Start:** Let $\epsilon > 0$ and $0 < \underline{\sigma} \leq \overline{\sigma} < 1$ be given. Let $\gamma \in (0,1)$ and $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ be such that $w^0 \in \mathcal{N}_{w^0}(\gamma)$. Set $k = 0$.
2. **While** $\mu_k := \mu(w^k) > \epsilon$ **do**
   (a) Let $w := w^k$ and $\mu := \mu_k$; choose $\sigma := \sigma_k \in [\underline{\sigma}, \overline{\sigma}]$.
   (b) Let $\Delta w = (\Delta x, \Delta s, \Delta y, \Delta z)$ denote the solution of the linear system

$$A\Delta x = -r_p, \tag{15}$$

$$A^T \Delta y + \Delta s + V \Delta z = -r_d, \tag{16}$$

$$X\Delta s + S\Delta x = -Xs + \sigma\mu e, \tag{17}$$

$$EV^T \Delta x + E^{-1}\Delta z = -r_V. \tag{18}$$

   (c) Let $\tilde{\alpha} = \operatorname{argmax}\{\alpha \in [0,1] : w + \alpha'\Delta w \in \mathcal{N}_{w^0}(\gamma),\ \forall \alpha' \in [0,\alpha]\}$.
   (d) Let $\bar{\alpha} = \operatorname{argmin}\left\{(x + \alpha\Delta x)^T (s + \alpha\Delta s) : \alpha \in [0, \tilde{\alpha}]\right\}$.
   (e) Let $w^{k+1} = w + \bar{\alpha}\Delta w$, and set $k \leftarrow k + 1$.

   End (while)

A proof of the following result, under slightly different assumptions, can be found in [28].

Theorem 2.1. *Assume that the constants γ, $\underline{\sigma}$, and $\overline{\sigma}$ are such that*

$$\max\left\{\gamma^{-1}, (1-\gamma)^{-1}, \underline{\sigma}^{-1}, (1-\overline{\sigma})^{-1}\right\} = \mathcal{O}(1),$$

and that the initial point $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ satisfies $(x^0, s^0) \geq (x^*, s^*)$ for some $w^* \in \mathcal{S}$. Then, the exact PDIPF algorithm finds an iterate $w^k \in \Re^{2n}_{++} \times \Re^{m+l}$ satisfying $\mu_k \leq \epsilon\mu_0$ and $\|r^k\| \leq \epsilon\|r^0\|$ within $\mathcal{O}(n^2 \log(1/\epsilon))$ iterations.

A few approaches have been suggested in the literature for computing the Newton search direction (15)–(18). Instead of using one of them, we will discuss below a new

approach, referred to in this paper as the ANE approach, that we believe to be suitable not only for direct solvers but especially for iterative linear solvers, as we will see in section 3.

Let us begin by defining the following matrices:

$$D := X^{1/2}S^{-1/2}, \tag{19}$$

$$\tilde{D} := \begin{pmatrix} D & 0 \\ 0 & E^{-1} \end{pmatrix} \in \Re^{(n+l)\times(n+l)}, \tag{20}$$

$$\tilde{A} := \begin{pmatrix} A & 0 \\ V^T & I \end{pmatrix} \in \Re^{(m+l)\times(n+l)}. \tag{21}$$

Suppose that we first solve the following system of equations for $(\Delta y, \Delta z)$:

$$\tilde{A}\tilde{D}^2\tilde{A}^T \begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} = \tilde{A} \begin{pmatrix} x - \sigma\mu S^{-1}e - D^2 r_d \\ 0 \end{pmatrix} + \begin{pmatrix} -r_p \\ -E^{-1}r_V \end{pmatrix} =: h. \tag{22}$$

This system is what we refer to as the ANE. Next, we obtain Δs and Δx according to

$$\Delta s = -r_d - A^T\Delta y - V\Delta z, \tag{23}$$

$$\Delta x = -D^2\Delta s - x + \sigma\mu S^{-1}e. \tag{24}$$

Clearly, the search direction $\Delta w = (\Delta x, \Delta s, \Delta y, \Delta z)$ computed as above satisfies (16) and (17) in view of (23) and (24). Moreover, it also satisfies (15) and (18) due to the fact that by (20)–(24), we have that

$$\begin{aligned}
\tilde{A} \begin{pmatrix} \Delta x \\ E^{-2}\Delta z \end{pmatrix} &= \tilde{A} \begin{pmatrix} -D^2\Delta s - x + \sigma\mu S^{-1}e \\ E^{-2}\Delta z \end{pmatrix} \\
&= \tilde{A} \begin{pmatrix} D^2 r_d + D^2 A^T\Delta y + D^2 V\Delta z - x + \sigma\mu S^{-1}e \\ E^{-2}\Delta z \end{pmatrix} \\
&= \tilde{A} \begin{pmatrix} D^2 A^T\Delta y + D^2 V\Delta z \\ E^{-2}\Delta z \end{pmatrix} + \tilde{A} \begin{pmatrix} D^2 r_d - x + \sigma\mu S^{-1}e \\ 0 \end{pmatrix} \\
&= \tilde{A}\tilde{D}^2\tilde{A}^T \begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} + \tilde{A} \begin{pmatrix} D^2 r_d - x + \sigma\mu S^{-1}e \\ 0 \end{pmatrix} \\
&= \begin{pmatrix} -r_p \\ -E^{-1}r_V \end{pmatrix}. \qquad (25)
\end{aligned}$$

Theorem 2.1 assumes that Δw is the exact solution of (22), which is usually obtained by computing the Cholesky factorization of the coefficient matrix of the ANE. In this paper, we will consider a variant of the exact PDIPF algorithm whose search directions are approximate solutions of (22) and ways of determining these inexact search directions by means of a suitable preconditioned iterative linear solver.

2.2. An inexact PDIPF algorithm for CQP. In this subsection, we describe a PDIPF algorithm based on a family of search directions that are approximate solutions to (15)–(18) and discuss its iteration complexity properties.

Clearly, an approximate solution to the ANE can yield only an approximate solution to (15)–(18). In order to motivate the class of inexact search directions used by the PDIPF algorithm presented in this subsection, we present a framework for

obtaining approximate solutions to (15)–(18) based on an approximate solution to the ANE.

Suppose that the ANE is solved only inexactly, i.e., that the vector $(\Delta y, \Delta z)$ satisfies

$$\tilde{A}\tilde{D}^2\tilde{A}^T \begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} = h + f \tag{26}$$

for some error vector f. If Δs and Δx were computed by (23) and (24), respectively, then it is clear that the search direction Δw would satisfy (16) and (17). However, (15) and (18) would not be satisfied, since by an argument similar to (25), we would have that

$$\begin{aligned} \tilde{A} \begin{pmatrix} \Delta x \\ E^{-2}\Delta z \end{pmatrix} = \cdots &= \tilde{A}\tilde{D}^2\tilde{A}^T \begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} + \tilde{A} \begin{pmatrix} D^2 r_d - x + \sigma\mu S^{-1} e \\ 0 \end{pmatrix} \\ &= \begin{pmatrix} -r_p \\ -E^{-1} r_V \end{pmatrix} + f. \end{aligned}$$

Instead, suppose we use (23) to determine Δs as before, but now we determine Δx as

$$\Delta x = -D^2\Delta s - x + \sigma\mu S^{-1} e - S^{-1} p, \tag{27}$$

where the correction vector $p \in \Re^n$ will be required to satisfy some conditions which we will now describe.

To motivate the conditions on p, we note that (23), (26), and (27) imply that

(28)

$$\begin{aligned} &\tilde{A} \begin{pmatrix} \Delta x \\ E^{-2}\Delta z \end{pmatrix} + \begin{pmatrix} r_p \\ E^{-1} r_V \end{pmatrix} \\ &= \tilde{A} \begin{pmatrix} -D^2\Delta s - x + \sigma\mu S^{-1} e - S^{-1} p \\ E^{-2}\Delta z \end{pmatrix} + \begin{pmatrix} r_p \\ E^{-1} r_V \end{pmatrix} \\ &= \tilde{A} \begin{pmatrix} D^2 r_d + D^2 A^T \Delta y + D^2 V \Delta z - x + \sigma\mu S^{-1} e - S^{-1} p \\ E^{-2}\Delta z \end{pmatrix} + \begin{pmatrix} r_p \\ E^{-1} r_V \end{pmatrix} \\ &= \tilde{A}\tilde{D}^2 \begin{pmatrix} A^T \Delta y + V \Delta z \\ \Delta z \end{pmatrix} + \tilde{A} \begin{pmatrix} D^2 r_d - x + \sigma\mu S^{-1} e \\ 0 \end{pmatrix} - \tilde{A} \begin{pmatrix} S^{-1} p \\ 0 \end{pmatrix} \\ &\qquad + \begin{pmatrix} r_p \\ E^{-1} r_V \end{pmatrix} \\ &= \tilde{A}\tilde{D}^2\tilde{A}^T \begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} + \tilde{A} \begin{pmatrix} D^2 r_d - x + \sigma\mu S^{-1} e \\ 0 \end{pmatrix} - \tilde{A} \begin{pmatrix} S^{-1} p \\ 0 \end{pmatrix} + \begin{pmatrix} r_p \\ E^{-1} r_V \end{pmatrix} \\ &= f - \tilde{A} \begin{pmatrix} S^{-1} p \\ 0 \end{pmatrix}. \end{aligned}$$

Based on the above equation, one is naturally tempted to choose p so that the right-hand side of (28) is zero, and consequently (15) and (18) are satisfied exactly. However, the existence of such p cannot be guaranteed and, even if it exists, its magnitude might not be sufficiently small to yield a search direction which is suitable for the development of a polynomially convergent algorithm. Instead, we consider an alternative approach where p is chosen so that the first component of (28) is zero and the second

component is small. More specifically, by partitioning $f = (f_1, f_2) \in \Re^m \times \Re^l$, we choose $p \in \Re^n$ such that

$$AS^{-1}p = f_1. \tag{29}$$

It is clear that p is not uniquely defined. Note that (21) implies that (29) is equivalent to

$$f \;=\; \tilde{A}\begin{pmatrix} S^{-1}p \\ E^{-1}q \end{pmatrix}, \tag{30}$$

where $q := E(f_2 - V^T S^{-1}p)$. Then, using (21), (28), and (30), we conclude that

$$\begin{aligned} \tilde{A}\begin{pmatrix} \Delta x \\ E^{-2}\Delta z \end{pmatrix} + \begin{pmatrix} r_p \\ E^{-1}r_V \end{pmatrix} &= f - \tilde{A}\begin{pmatrix} S^{-1}p \\ E^{-1}q \end{pmatrix} + \tilde{A}\begin{pmatrix} 0 \\ E^{-1}q \end{pmatrix} \\ &= \tilde{A}\begin{pmatrix} 0 \\ E^{-1}q \end{pmatrix} = \begin{pmatrix} 0 \\ E^{-1}q \end{pmatrix}, \end{aligned} \tag{31}$$

from which we see that the first component of (28) is set to 0 and the second component is exactly $E^{-1}q$.

In view of (23), (27), and (31), the above construction yields a search direction Δw satisfying the following modified Newton system of equations:

$$A\Delta x = -r_p, \tag{32}$$

$$A^T\Delta y + \Delta s + V\Delta z = -r_d, \tag{33}$$

$$X\Delta s + S\Delta x = -Xs + \sigma\mu e - p, \tag{34}$$

$$EV^T\Delta x + E^{-1}\Delta z = -r_V + q. \tag{35}$$

As far as the outer iteration complexity analysis of our algorithm is concerned, all we require of our inexact search directions is that they satisfy (32)–(35) and that p and q be relatively small in the following sense.

DEFINITION 1. *Given a point $w \in \Re^{2n}_{++} \times \Re^{m+l}$ and positive scalars τ_p and τ_q, an inexact direction Δw is referred to as a* (τ_p, τ_q)-search direction *if it satisfies* (32)–(35) *for some p and q satisfying $\|p\|_\infty \le \tau_p\mu$ and $\|q\| \le \tau_q\sqrt{\mu}$, where μ is given by* (9).

We next define a generalized central path neighborhood which is used by our inexact PDIPF algorithm. Given a starting point $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ and parameters $\eta \ge 0$, $\gamma \in [0,1]$, and $\theta > 0$, define the following set:

$$\mathcal{N}_{w^0}(\eta,\gamma,\theta) = \left\{ w \in \Re^{2n}_{++} \times \Re^{m+l} : \begin{array}{ccc} Xs \ge (1-\gamma)\mu e, & & (r_p, r_d) = \eta(r_p^0, r_d^0), \\ \|r_V - \eta r_V^0\| \le \theta\sqrt{\mu}, & & \eta \le \mu/\mu_0 \end{array} \right\}, \tag{36}$$

where $\mu = \mu(w)$, $\mu_0 = \mu(w^0)$, $r = r(w)$, and $r^0 = r(w^0)$. The generalized central path neighborhood is then given by

$$\mathcal{N}_{w^0}(\gamma,\theta) \;=\; \bigcup_{\eta\in[0,1]} \mathcal{N}_{w^0}(\eta,\gamma,\theta). \tag{37}$$

We observe that the neighborhood given by (37) agrees with the neighborhood given by (15) when $\theta = 0$.

We are now ready to state our inexact PDIPF algorithm.

INEXACT PDIPF ALGORITHM.

1. **Start:** Let $\epsilon > 0$ and $0 < \underline{\sigma} \leq \overline{\sigma} < 4/5$ be given. Choose $\gamma \in (0,1)$, $\theta > 0$, and $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ such that $w^0 \in \mathcal{N}_{w^0}(\gamma, \theta)$. Set $k = 0$.
2. **While** $\mu_k := \mu(w^k) > \epsilon$ **do**
   (a) Let $w := w^k$ and $\mu := \mu_k$; choose $\sigma \in [\underline{\sigma}, \overline{\sigma}]$.
   (b) Set

$$\tau_p = \gamma\sigma/4 \quad \text{and} \tag{38}$$

$$\tau_q = \left[\sqrt{1 + (1 - 0.5\gamma)\,\sigma} - 1\right]\theta. \tag{39}$$

   (c) Set $r_p = Ax - b$, $r_d = A^T y + s + Vz - c$, $r_V = EV^T x + E^{-1}z$, and $\eta = \|r_p\|/\|r_p^0\|$.
   (d) Compute a (τ_p, τ_q)-search direction Δw.
   (e) Compute $\tilde{\alpha} := \operatorname{argmax}\{\alpha \in [0,1] : w + \alpha'\Delta w \in \mathcal{N}_{w^0}(\gamma,\theta),\ \forall \alpha' \in [0,\alpha]\}$.
   (f) Compute $\bar{\alpha} := \operatorname{argmin}\{(x + \alpha\Delta x)^T(s + \alpha\Delta s) : \alpha \in [0,\tilde{\alpha}]\}$.
   (g) Let $w^{k+1} = w + \bar{\alpha}\Delta w$, and set $k \leftarrow k + 1$.

   End (while)

The following result gives a bound on the number of iterations needed by the inexact PDIPF algorithm to obtain an ϵ-solution to the KKT conditions (5)–(8). Its proof will be given in subsection 4.2.

THEOREM 2.2. *Assume that the constants γ, $\underline{\sigma}$, $\overline{\sigma}$, and θ are such that*

$$\max\left\{\gamma^{-1},\, (1-\gamma)^{-1},\, \underline{\sigma}^{-1},\, \left(1 - \frac{5}{4}\overline{\sigma}\right)^{-1}\right\} = \mathcal{O}(1),\ \ \theta = \mathcal{O}(\sqrt{n}), \tag{40}$$

and that the initial point $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ satisfies $(x^0, s^0) \geq (x^*, s^*)$ for some $w^* \in \mathcal{S}$. Then, the inexact PDIPF algorithm generates an iterate $w^k \in \Re^{2n}_{++} \times \Re^{m+l}$ satisfying $\mu_k \leq \epsilon\mu_0$, $\|(r_p^k, r_d^k)\| \leq \epsilon\|(r_p^0, r_d^0)\|$, and $\|r_V^k\| \leq \epsilon\|r_V^0\| + \epsilon^{1/2}\theta\mu_0^{1/2}$ within $\mathcal{O}\left(n^2 \log(1/\epsilon)\right)$ iterations.

3. Determining an inexact search direction via an iterative solver. The results in subsection 2.2 assume we can obtain a (τ_p, τ_q)-search direction Δw, where τ_p and τ_q are given by (38) and (39), respectively. In this section, we will describe a way to obtain a (τ_p, τ_q)-search direction Δw using a uniformly bounded number of iterations of a suitable preconditioned iterative linear solver applied to the ANE. It turns out that the construction of this Δw is based on the recipe given at the beginning of subsection 2.2, together with a specific choice of the perturbation vector p.

This section is divided into two subsections. In subsection 3.1, we introduce the MWB preconditioner which will be used to precondition the ANE. In addition, we also introduce a family of iterative linear solvers used to solve the preconditioned ANE. Subsection 3.2 gives a specific approach for constructing a pair (p, q) satisfying (30), and an approximate solution to the ANE so that the recipe described at the beginning of subsection 2.2 yields a (τ_p, τ_q)-search direction Δw. It also provides a uniform bound on the number of iterations that any member of the family of iterative linear solvers needs to perform to obtain such a direction Δw when applied to the preconditioned ANE.

3.1. MWB preconditioner and a family of solvers. In this subsection we introduce the MWB preconditioner, and we discuss its use as a preconditioner in

solving the ANE via a family of iterative linear solvers. Since the condition number of the ANE matrix $\tilde{A}\tilde{D}^2\tilde{A}^T$ may "blow up" for points w near an optimal solution, the direct application of a generic iterative linear solver for solving the ANE without first preconditioning it is generally not effective. We discuss a natural remedy to this problem which consists of using a preconditioner $\tilde{T}$, namely the MWB preconditioner, such that $\kappa(\tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T)$ remains uniformly bounded regardless of the iterate w. Finally, we analyze the complexity of the resulting approach to obtain a suitable approximate solution to the ANE.

We start by describing the MWB preconditioner. Its construction essentially consists of building a basis B of $\tilde{A}$ which gives higher priority to the columns of $\tilde{A}$ corresponding to larger diagonal elements of $\tilde{D}$. More specifically, the MWB preconditioner is determined by the following algorithm.

MAXIMUM WEIGHT BASIS ALGORITHM.

Start: Given $\tilde{d} \in \Re^{(n+l)}_{++}$, and $\tilde{A} \in \Re^{(m+l)\times(n+l)}$ such that $\text{rank}(\tilde{A}) = m + l$,

1. Order the elements of $\tilde{d}$ so that $\tilde{d}_1 \geq \cdots \geq \tilde{d}_{n+l}$; order the columns of $\tilde{A}$ accordingly.
2. Let $\mathcal{B} = \emptyset$, $j = 1$.
3. **While** $|\mathcal{B}| < m + l$ **do**
   (a) If $\tilde{A}_j$ is linearly independent of $\{\tilde{A}_i : i \in \mathcal{B}\}$, set $\mathcal{B} \leftarrow \mathcal{B} \cup \{j\}$.
   (b) $j \leftarrow j + 1$.
4. Return to the original ordering of $\tilde{A}$ and $\tilde{d}$; determine the set $\mathcal{B}$ according to this ordering and set $\mathcal{N} := \{1, \ldots, n + l\}\backslash\mathcal{B}$.
5. Set $B := \tilde{A}_{\mathcal{B}}$ and $\tilde{D}_{\mathcal{B}} := \text{Diag}(\tilde{d}_{\mathcal{B}})$.
6. Let $\tilde{T} = \tilde{T}(\tilde{A}, \tilde{d}) := \tilde{D}_{\mathcal{B}}^{-1}B^{-1}$.

end

Note that the above algorithm can be applied to the matrix $\tilde{A}$ defined in (21) since this matrix has full row rank due to Assumption 1. The MWB preconditioner was originally proposed by Vaidya [25] and Resende and Veiga [22] in the context of the minimum cost network flow problem. In this case, $\tilde{A} = A$ is the node-arc incidence matrix of a connected digraph (with one row deleted to ensure that $\tilde{A}$ has full row rank), the entries of $\tilde{d}$ are weights on the edges of the graph, and the set $\mathcal{B}$ generated by the above algorithm defines a maximum spanning tree on the digraph. Oliveira and Sorensen [19] later proposed the use of this preconditioner for general matrices $\tilde{A}$. Boman et al. [5] have proposed variants of the MWB preconditioner for diagonally dominant matrices, using the fact that they can be represented as $D_1 + AD_2A^T$, where D_1 and D_2 are nonnegative diagonal and positive diagonal matrices, respectively, and A is a node-arc incidence matrix.

For the purpose of stating the next result, we now introduce some notation. Let us define

$$\varphi_{\tilde{A}} := \max\{\|B^{-1}\tilde{A}\|_F : B \text{ is a basis of } \tilde{A}\}. \tag{41}$$

The constant $\varphi_{\tilde{A}}$ is related to the well-known condition number $\bar{\chi}_{\tilde{A}}$ (see [26]), defined as

$$\bar{\chi}_{\tilde{A}} := \sup\{\|\tilde{A}^T(\tilde{A}\tilde{E}\tilde{A}^T)^{-1}\tilde{A}\tilde{E}\| : \tilde{E} \in \text{Diag}(\Re^{(n+l)}_{++})\}.$$

Specifically, $\varphi_{\tilde{A}} \leq (n + l)^{1/2}\bar{\chi}_{\tilde{A}}$, in view of the facts that $\|C\|_F \leq (n + l)^{1/2}\|C\|$ for any matrix $C \in \Re^{(m+l)\times(n+l)}$ and, as shown in [23] and [26],

$$\bar{\chi}_{\tilde{A}} = \max\{\|B^{-1}\tilde{A}\| : B \text{ is a basis of } \tilde{A}\}.$$

The following result, which establishes the theoretical properties of the MWB preconditioner, follows as a consequence of Lemmas 2.1 and 2.2 of [17].

PROPOSITION 3.1. *Let $\tilde{T} = \tilde{T}(\tilde{A}, \tilde{d})$ be the preconditioner determined according to the maximum weight basis algorithm, and define $W := \tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T$. Then, $\|\tilde{T}\tilde{A}\tilde{D}\| \leq \varphi_{\tilde{A}}$ and $\kappa(W) \leq \varphi_{\tilde{A}}^2$.*

Note that the bound $\varphi_{\tilde{A}}^2$ on $\kappa(W)$ is independent of the diagonal matrix $\tilde{D}$ and depends only on $\tilde{A}$. This will allow us to obtain a uniform bound on the number of iterations needed by any member of the family of iterative linear solvers described below to obtain a suitable approximate solution of (22). This topic is the subject of the remainder of this subsection.

Instead of dealing directly with (22), we consider the application of an iterative linear solver to the preconditioned ANE:

$$Wu = v, \tag{42}$$

where

$$W := \tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T, \qquad v := \tilde{T}h. \tag{43}$$

For the purpose of our analysis below, the only thing we will assume regarding the iterative linear solver when applied to (42) is that it generates a sequence of iterates $\{u^j\}$ such that

$$\|v - Wu^j\| \;\leq\; c(\kappa)\left[1 - \frac{1}{\psi(\kappa)}\right]^j \|v - Wu^0\| \;\; \forall\; j = 0, 1, 2, \ldots, \tag{44}$$

where c and ψ are positive, nondecreasing functions of $\kappa \equiv \kappa(W)$.

Examples of solvers which satisfy (44) include the steepest descent (SD) and CG methods, with the values for $c(\kappa)$ and $\psi(\kappa)$ given in Table 3.1.

TABLE 3.1

Solver	$c(\kappa)$	$\psi(\kappa)$
SD	$\sqrt{\kappa}$	$(\kappa+1)/2$
CG	$2\sqrt{\kappa}$	$(\sqrt{\kappa}+1)/2$

The justification for Table 3.1 follows from section 7.6 and Exercise 10 of section 8.8 of [14].

The following result gives an upper bound on the number of iterations that any iterative linear solver satisfying (44) needs to perform to obtain a *ξ-approximate solution of* (42), i.e., an iterate u^j such that $\|v - Wu^j\| \leq \xi\sqrt{\mu}$ for some constant $\xi > 0$.

PROPOSITION 3.2. *Let u^0 be an arbitrary starting point. Then, a generic iterative linear solver with a convergence rate given by* (44) *generates an iterate u^j satisfying $\|v - Wu^j\| \leq \xi\sqrt{\mu}$ in*

$$\mathcal{O}\left(\psi(\kappa)\log\left(\frac{c(\kappa)\|v - Wu^0\|}{\xi\sqrt{\mu}}\right)\right) \tag{45}$$

iterations, where $\kappa \equiv \kappa(W)$.

Proof. Let j be any iteration such that $\|v - Wu^j\| > \xi\sqrt{\mu}$. We use relation (44) and the fact that $1 + \omega \le e^\omega$ for all $\omega \in \Re$ to observe that

$$\xi\sqrt{\mu} < \|v - Wu^j\| \;\le\; c(\kappa)\left[1 - \frac{1}{\psi(\kappa)}\right]^j \|v - Wu^0\| \;\le c(\kappa)\exp\left\{\frac{-j}{\psi(\kappa)}\right\}\|v - Wu^0\|.$$

Rearranging the first and last terms of the inequality, it follows that

$$j \;<\; \psi(\kappa)\log\left(\frac{c(\kappa)\|v - Wu^0\|}{\xi\sqrt{\mu}}\right),$$

and the result is proven. ∎

From Proposition 3.2, it is clear that different choices of u^0 and ξ lead to different bounds on the number of iterations performed by the iterative linear solver. In subsection 3.2, we will describe a suitable way of selecting u^0 and ξ so that (i) the bound (45) is independent of the iterate w and (ii) the approximate solution $\tilde{T}^T u^j$ of the ANE, together with a suitable pair (p, q), yields a (τ_p, τ_q)-search direction Δw through the recipe described in subsection 2.2.

3.2. Computation of the inexact search direction Δw. In this subsection, we use the results of subsections 2.2 and 3.1 to build a (τ_p, τ_q)-search direction Δw, where τ_p and τ_q are given by (38) and (39), respectively. In addition, we describe a way of choosing u^0 and ξ which ensures that the number of iterations of an iterative linear solver satisfying (44) applied to the preconditioned ANE is uniformly bounded by a constant depending on n and $\varphi_{\tilde{A}}$.

Suppose that we solve (42) inexactly according to subsection 3.1. Then our final solution u^j satisfies $Wu^j - v = \tilde{f}$ for some vector $\tilde{f}$. Letting

$$\begin{pmatrix} \Delta y \\ \Delta z \end{pmatrix} = \tilde{T}^T u^j, \tag{46}$$

we easily see from (43) that (26) is satisfied with $f := \tilde{T}^{-1}\tilde{f}$. We can then apply the recipe of subsection 2.2 to this approximate solution, using the pair (p, q) which we will now describe.

First, note that (30) with f as defined above is equivalent to the system

$$\tilde{f} \;=\; \tilde{T}\tilde{A}\begin{pmatrix} S^{-1}p \\ E^{-1}q \end{pmatrix} \;=\; \tilde{T}\tilde{A}\tilde{D}\begin{pmatrix} (XS)^{-1/2} & 0 \\ 0 & I \end{pmatrix}\begin{pmatrix} p \\ q \end{pmatrix}. \tag{47}$$

Now, let $\mathcal{B} = (\mathcal{B}_1, \ldots, \mathcal{B}_{m+l})$ be the ordered set of basic indices computed by the MWB algorithm applied to the pair $(\tilde{A}, \tilde{d})$ and note that, by step 6 of this algorithm, the $\mathcal{B}_i$th column of $\tilde{T}\tilde{A}\tilde{D}$ is the ith unit vector for every $i = 1, \ldots, m + l$. Then, the vector $t \in \Re^{n+l}$ defined as $t_{\mathcal{B}_i} = \tilde{f}_i$ for $i = 1, \ldots, m + l$ and $t_j = 0$ for every $j \notin \{\mathcal{B}_1, \ldots, \mathcal{B}_{m+l}\}$ clearly satisfies

$$\tilde{f} \;=\; \tilde{T}\tilde{A}\tilde{D}\; t. \tag{48}$$

We then obtain a pair $(p, q) \in \Re^n \times \Re^l$ satisfying (30) by defining

$$\begin{pmatrix} p \\ q \end{pmatrix} \;:=\; \begin{pmatrix} (XS)^{1/2} & 0 \\ 0 & I \end{pmatrix} t. \tag{49}$$

It is clear from (49) and the fact that $\|t\| = \|\tilde{f}\|$ that

$$\|p\| \;\le\; \|XS\|^{1/2}\|\tilde{f}\|, \qquad \|q\| \;\le\; \|\tilde{f}\|. \tag{50}$$

As an immediate consequence of this relation, we obtain the following result.

LEMMA 3.3. *Suppose that $w \in \Re^{2n}_{++} \times \Re^{m+l}$ and positive scalars τ_p and τ_q are given. Assume that w^j is a ξ-approximate solution of* (42) *or, equivalently, $\tilde{f} \le \xi\sqrt{\mu}$, where $\xi := \min\{n^{-1/2}\tau_p, \tau_q\}$. Let Δw be determined according to the recipe given in subsection* 2.2 *using the approximate solution* (46) *and the pair (p, q) given by* (49). *Then Δw is a (τ_p, τ_q)-search direction.*

Proof. It is clear from the previous discussion that Δw and the pair (p, q) satisfy (32)–(35). Next, relation (50) and the facts that $\xi \le n^{-1/2}\tau_p$ and $\|XS\|^{1/2} \le \sqrt{n\mu}$ imply that

$$\|p\|_\infty \;\le\; \|p\| \;\le\; \|XS\|^{1/2}\|\tilde{f}\| \;\le\; \sqrt{n\mu}\,\xi\sqrt{\mu} \;\le\; \tau_p\mu.$$

Similarly, (50) and the fact that $\xi \le \tau_q$ imply that $\|q\| \le \tau_q\sqrt{\mu}$. Thus, Δw is a (τ_p, τ_q)-search direction as desired. ∎

Lemma (3.3) implies that to construct a (τ_p, τ_q)-search direction Δw as in step 2(d) of the inexact PDIPF algorithm, it suffices to find a ξ-approximate solution to (42), where

$$\xi \;:=\; \min\left\{ \frac{\gamma\sigma}{4\sqrt{n}}\,,\; \left[\sqrt{1 + \left(1 - \frac{\gamma}{2}\right)\sigma} - 1\right]\theta \right\}. \tag{51}$$

We next describe a suitable way of selecting u^0 so that the number of iterations required by an iterative linear solver satisfying (44) to find a ξ-approximate solution of (42) can be uniformly bounded by a universal constant depending only on the quantities n and $\varphi_{\tilde{A}}$. First, compute a point $\bar{w} = (\bar{x}, \bar{s}, \bar{y}, \bar{z})$ such that

$$\tilde{A}\begin{pmatrix} \bar{x} \\ E^{-2}\bar{z} \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix}, \qquad A^T\bar{y} + \bar{s} + V\bar{z} = c. \tag{52}$$

Note that vectors $\bar{x}$ and $\bar{z}$ satisfying the first equation in (52) can be easily computed once a basis of $\tilde{A}$ is available (e.g., the one computed by the maximum weight basis algorithm in the first outer iteration of the inexact PDIPF algorithm). Once $\bar{y}$ is arbitrarily chosen, a vector $\bar{s}$ satisfying the second equation of (52) is immediately available. We then define

$$u^0 \;=\; -\eta\,\tilde{T}^{-T}\begin{pmatrix} y^0 - \bar{y} \\ z^0 - \bar{z} \end{pmatrix}. \tag{53}$$

The following lemma gives a bound on the size of the initial residual $\|Wu^0 - v\|$. Its proof will be given in subsection 4.1.

LEMMA 3.4. *Assume that $\tilde{T} = \tilde{T}(\tilde{A}, \tilde{d})$ is given and that $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ and $\bar{w}$ are such that $(x^0, s^0) \ge |(\bar{x}, \bar{s})|$ and $(x^0, s^0) \ge (x^*, s^*)$ for some $w^* \in \mathcal{S}$. Further, assume that $w \in \mathcal{N}_{w^0}(\gamma, \theta)$ for some $\gamma \in [0, 1]$ and $\theta > 0$, and that W, v, and u^0 are given by* (43) *and* (53), *respectively. Then, the initial residual in* (44) *satisfies $\|v - Wu^0\| \le \Psi\sqrt{\mu}$, where*

$$\Psi \;:=\; \left[\frac{7n + \theta^2/2}{\sqrt{1-\gamma}} + \theta\right]\varphi_{\tilde{A}}. \tag{54}$$

As an immediate consequence of Proposition 3.2 and Lemmas 3.3 and 3.4, we can bound the number of inner iterations required by an iterative linear solver satisfying (44) to yield a (τ_p, τ_q)-search direction Δw.

THEOREM 3.5. *Assume that ξ is defined in* (51)*, where σ, γ, θ are such that*

$$\max\{\sigma^{-1}, \gamma^{-1}, (1-\gamma)^{-1}, \theta, \theta^{-1}\}$$

is bounded by a polynomial of n. Assume also that $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ and $\bar{w}$ are such that $(x^0, s^0) \geq |(\bar{x}, \bar{s})|$ and $(x^0, s^0) \geq (x^*, s^*)$ for some $w^* \in \mathcal{S}$. Then, a generic iterative linear solver with a convergence rate given by (44) *generates a ξ-approximate solution, which leads to a (τ_p, τ_q)-search direction Δw in*

$$\mathcal{O}\left(\psi(\varphi^2_{\tilde{A}}) \log\left(c(\varphi^2_{\tilde{A}}) n \varphi_{\tilde{A}}\right)\right) \tag{55}$$

iterations. As a consequence, the SD and CG methods generate this approximate solution u^j in $\mathcal{O}(\varphi^2_{\tilde{A}} \log(n\varphi_{\tilde{A}}))$ and $\mathcal{O}(\varphi_{\tilde{A}} \log(n\varphi_{\tilde{A}}))$ iterations, respectively.

Proof. The proof of the first part of Theorem 3.5 immediately follows from Propositions 3.1 and 3.2 and Lemmas 3.3 and 3.4. The proof of the second part of Theorem 3.5 follows immediately from Table 3.1 and Proposition 3.1. ∎

Using the results of sections 2 and 3, we see that the number of "inner" iterations of an iterative linear solver satisfying (44) is uniformly bounded by a constant depending on n and $\varphi_{\tilde{A}}$, while the number of "outer" iterations in the inexact PDIPF algorithm is polynomially bounded by a constant depending on n and $\log \epsilon^{-1}$.

4. Technical results. This section is devoted to the proofs of Lemma 3.4 and Theorem 2.2. Subsection 4.1 presents the proof of Lemma 3.4, and subsection 4.2 presents the proof of Theorem 2.2.

4.1. Proof of Lemma 3.4. In this subsection, we will provide the proof of Lemma 3.4. We begin by establishing three technical lemmas.

LEMMA 4.1. *Suppose that $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$, $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$ for some $\eta \in [0,1]$, $\gamma \in [0,1]$, and $\theta > 0$, and $w^* \in \mathcal{S}$. Then*

$$(x - \eta x^0 - (1-\eta)x^*)^T (s - \eta s^0 - (1-\eta)s^*) \geq -\frac{\theta^2}{4}\mu. \tag{56}$$

Proof. Let us define $\tilde{w} := w - \eta w^0 - (1-\eta)w^*$. Using the definitions of $\mathcal{N}_{w^0}(\eta, \gamma, \theta)$, r, and $\mathcal{S}$, we have that

$$\begin{aligned} A\tilde{x} &= 0, \\ A^T\tilde{y} + \tilde{s} + V\tilde{z} &= 0, \\ V^T\tilde{x} + E^{-2}\tilde{z} &= E^{-1}(r_V - \eta r_V^0). \end{aligned}$$

Multiplying the second relation by $\tilde{x}^T$ on the left and using the first and third relations along with the fact that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$, we see that

$$\begin{aligned} \tilde{x}^T\tilde{s} = -\tilde{x}^T V\tilde{z} &= [E^{-2}\tilde{z} - E^{-1}(r_V - \eta r_V^0)]^T\tilde{z} = \|E^{-1}\tilde{z}\|^2 - (E^{-1}\tilde{z})^T(r_V - \eta r_V^0) \\ &\geq \|E^{-1}\tilde{z}\|^2 - \|E^{-1}\tilde{z}\|\|r_V - \eta r_V^0\| = \left(\|E^{-1}\tilde{z}\| - \frac{\|r_V - \eta r_V^0\|}{2}\right)^2 - \frac{\|r_V - \eta r_V^0\|^2}{4} \\ &\geq -\frac{\|r_V - \eta r_V^0\|^2}{4} \geq -\frac{\theta^2}{4}\mu. \end{aligned}$$

∎

LEMMA 4.2. *Suppose that* $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ *such that* $(x^0, s^0) \geq (x^*, s^*)$ *for some* $w^* \in \mathcal{S}$. *Then, for any* $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$ *with* $\eta \in [0,1]$, $\gamma \in [0,1]$, *and* $\theta > 0$, *we have*

$$\eta(x^T s^0 + s^T x^0) \leq \left(3n + \frac{\theta^2}{4}\right)\mu. \tag{57}$$

Proof. Using the fact $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$ and (56), we obtain

$$\begin{aligned} x^T s - \eta(x^T s^0 + s^T x^0) + \eta^2 {x^0}^T s^0 - (1-\eta)(x^T s^* + s^T x^*) \\ + \eta(1-\eta)({x^*}^T s^0 + {s^*}^T x^0) + (1-\eta)^2 {x^*}^T s^* \ \geq \ -\frac{\theta^2}{4}\mu. \end{aligned}$$

Rearranging the terms in this equation and using the facts that $\eta \leq x^T s / {x^0}^T s^0$, ${x^*}^T s^* = 0$, $(x,s) \geq 0$, $(x^*, s^*) \geq 0$, $(x^0, s^0) > 0$, $\eta \in [0,1]$, $x^* \leq x^0$, and $s^* \leq s^0$, we conclude that

$$\begin{aligned} \eta(x^T s^0 + s^T x^0) &\leq \eta^2 {x^0}^T s^0 + x^T s + \eta(1-\eta)({x^*}^T s^0 + {s^*}^T x^0) + \frac{\theta^2}{4}\mu \\ &\leq \eta^2 {x^0}^T s^0 + x^T s + 2\eta(1-\eta){x^0}^T s^0 + \frac{\theta^2}{4}\mu \\ &\leq 2\eta {x^0}^T s^0 + x^T s + \frac{\theta^2}{4}\mu \\ &\leq 3x^T s + \frac{\theta^2}{4}\mu \ = \ \left(3n + \frac{\theta^2}{4}\right)\mu. \qquad \square \end{aligned}$$

LEMMA 4.3. *Suppose* $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$, $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$ *for some* $\eta \in [0,1]$, $\gamma \in [0,1]$, *and* $\theta > 0$, *and* $\bar{w}$ *satisfies* (52). *Let* W, v, *and* u^0 *be given by* (43) *and* (53), *respectively. Then,*

$$Wu^0 - v \ = \ \tilde{T}\tilde{A}\begin{pmatrix} -x + \sigma\mu S^{-1}e + \eta(x^0 - \bar{x}) + \eta D^2(s^0 - \bar{s}) \\ E^{-1}(r_V - \eta r_V^0) \end{pmatrix}. \tag{58}$$

Proof. Using the fact that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$ along with (21), (36), and (52), we easily obtain that

$$\begin{aligned} \begin{pmatrix} r_p \\ E^{-1}r_V \end{pmatrix} &= \begin{pmatrix} \eta r_p^0 \\ \eta E^{-1} r_V^0 + E^{-1}(r_V - \eta r_V^0) \end{pmatrix} \\ &= \eta\tilde{A}\begin{pmatrix} x^0 - \bar{x} \\ E^{-2}(z^0 - \bar{z}) \end{pmatrix} + \tilde{A}\begin{pmatrix} 0 \\ E^{-1}(r_V - \eta r_V^0) \end{pmatrix}, \end{aligned} \tag{59}$$

$$s^0 - \bar{s} = -A^T(y^0 - \bar{y}) - V(z^0 - \bar{z}) + r_d^0. \tag{60}$$

Using relations (20), (21), (43), (36), (53), (59), and (60), we obtain

$$\begin{aligned}
Wu^0 - v &= \tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\tilde{T}^T u^0 - \tilde{T}\tilde{A}\begin{pmatrix} x - \sigma\mu S^{-1}e - D^2 r_d \\ 0 \end{pmatrix} + \tilde{T}\begin{pmatrix} r_p \\ E^{-1}r_V \end{pmatrix} \\
&= -\eta\tilde{T}\tilde{A}\tilde{D}^2\tilde{A}^T\begin{pmatrix} y^0 - \bar{y} \\ z^0 - \bar{z} \end{pmatrix} - \tilde{T}\tilde{A}\begin{pmatrix} x - \sigma\mu S^{-1}e - \eta D^2 r_d^0 \\ 0 \end{pmatrix} + \tilde{T}\begin{pmatrix} r_p \\ E^{-1}r_V \end{pmatrix} \\
&= -\eta\tilde{T}\tilde{A}\begin{pmatrix} D^2A^T(y^0 - \bar{y}) + D^2V(z^0 - \bar{z}) - D^2 r_d^0 \\ E^{-2}(z^0 - \bar{z}) \end{pmatrix} \\
&\quad - \tilde{T}\tilde{A}\begin{pmatrix} x - \sigma\mu S^{-1}e \\ 0 \end{pmatrix} + \tilde{T}\begin{pmatrix} r_p \\ E^{-1}r_V \end{pmatrix}, \\
&= -\eta\tilde{T}\tilde{A}\begin{pmatrix} -D^2(s^0 - \bar{s}) \\ E^{-2}(z^0 - \bar{z}) \end{pmatrix} - \tilde{T}\tilde{A}\begin{pmatrix} x - \sigma\mu S^{-1}e \\ 0 \end{pmatrix} \\
&\quad + \eta\tilde{T}\tilde{A}\begin{pmatrix} x^0 - \bar{x} \\ E^{-2}(z^0 - \bar{z}) \end{pmatrix} + \tilde{T}\tilde{A}\begin{pmatrix} 0 \\ E^{-1}(r_V - \eta r_V^0) \end{pmatrix},
\end{aligned}$$

which yields (58), as desired. ∎

We now turn to the proof of Lemma 3.4.

Proof. Since $w \in \mathcal{N}_{w^0}(\gamma, \theta)$, we have that $x_i s_i \geq (1-\gamma)\mu$ for all i, which implies

$$\|(XS)^{-1/2}\| \;\leq\; \frac{1}{\sqrt{(1-\gamma)\mu}}. \tag{61}$$

Note that $\|Xs - \sigma\mu e\|$, when viewed as a function of $\sigma \in [0,1]$, is convex. Hence, it is maximized at one of its endpoints, which, together with the facts $\|Xs - \mu e\| < \|Xs\|$ and $\sigma \in [\underline{\sigma}, \overline{\sigma}] \subset [0,1]$, immediately implies that

$$\|Xs - \sigma\mu e\| \;\leq\; \|Xs\| \;\leq\; \|Xs\|_1 \;=\; x^T s \;=\; n\mu. \tag{62}$$

Using the fact that $(x^0, s^0) \geq |(\bar{x}, \bar{s})|$ together with Lemma 4.2, we obtain that

$$\begin{aligned}
\eta\|S(x^0 - \bar{x}) + X(s^0 - \bar{s})\| &\leq \eta\big\{\|S(x^0 - \bar{x})\| + \|X(s^0 - \bar{s})\|\big\} \;\leq\; 2\eta\big\{\|Sx^0\| + \|Xs^0\|\big\} \\
&\leq 2\eta(x^T s^0 + x^T s^0) \;\leq\; \left(6n + \frac{\theta^2}{2}\right)\mu. \qquad (63)
\end{aligned}$$

Since $w \in \mathcal{N}_{w^0}(\gamma, \theta)$, there exists $\eta \in [0,1]$ such that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$. It is clear that the requirements of Lemma 4.3 are met, so (58) holds. By (19), (20), and (58), we see that

$$\begin{aligned}
\|v - Wu^0\| &= \left\|\tilde{T}\tilde{A}\tilde{D}\begin{pmatrix} (XS)^{-1/2}\{Xs - \sigma\mu e - \eta[S(x^0 - \bar{x}) + X(s^0 - \bar{s})]\} \\ r_V - \eta r_V^0 \end{pmatrix}\right\| \\
&\leq \|\tilde{T}\tilde{A}\tilde{D}\|\Big\{\|(XS)^{-1/2}\|\Big[\|Xs - \sigma\mu e\| + \eta\|X(s^0 - \bar{s}) + S(x^0 - \bar{x})\|\Big] \\
&\quad + \|r_V - \eta r_V^0\|\Big\}, \\
&\leq \varphi_{\tilde{A}}\left\{\frac{1}{\sqrt{(1-\gamma)\mu}}\left[n\mu + \left(6n + \frac{\theta^2}{2}\right)\mu\right] + \theta\sqrt{\mu}\right\} \;=\; \Psi\sqrt{\mu},
\end{aligned}$$

where the last inequality follows from Proposition 3.1, relations (61), (62), (63), and the assumption that $w \in \mathcal{N}_{w^0}(\gamma, \theta)$. ∎

4.2. "Outer" iteration results—Proof of Theorem 2.2. In this subsection, we will present the proof of Theorem 2.2. Specifically, we will show that the inexact PDIPF algorithm obtains an ϵ-approximate solution to (5)–(8) in $\mathcal{O}(n^2 \log(1/\epsilon))$ outer iterations.

Throughout this section, we use the following notation:

$$w(\alpha) := w + \alpha \Delta w, \quad \mu(\alpha) := \mu(w(\alpha)), \quad r(\alpha) := r(w(\alpha)).$$

LEMMA 4.4. *Assume that Δw satisfies* (32)–(35) *for some $\sigma \in \Re$, $w \in \Re^{2n+m+l}$, and $(p, q) \in \Re^n \times \Re^l$. Then, for every $\alpha \in \Re$, we have*

(a) $X(\alpha)s(\alpha) = (1-\alpha)Xs + \alpha\sigma\mu e - \alpha p + \alpha^2 \Delta X \Delta s$;
(b) $\mu(\alpha) = [1 - \alpha(1-\sigma)]\mu - \alpha p^T e/n + \alpha^2 \Delta x^T \Delta s/n$;
(c) $(r_p(\alpha), r_d(\alpha)) = (1-\alpha)(r_p, r_d)$;
(d) $r_V(\alpha) = (1-\alpha) r_V + \alpha q$.

Proof. Using (34), we obtain

$$\begin{aligned} X(\alpha)s(\alpha) &= (X + \alpha\Delta X)(s + \alpha \Delta s) \\ &= Xs + \alpha(X\Delta s + S\Delta x) + \alpha^2 \Delta X \Delta s \\ &= Xs + \alpha(-Xs + \sigma\mu e - p) + \alpha^2 \Delta X \Delta s \\ &= (1-\alpha)Xs + \alpha\sigma\mu e - \alpha p + \alpha^2 \Delta X \Delta s, \end{aligned}$$

thereby showing that (a) holds. Left multiplying the above equality by e^T and dividing the resulting expression by n, we easily conclude that (b) holds. Statement (c) can be easily verified by means of (32) and (33), while statement (d) follows from (35). ∎

LEMMA 4.5. *Assume that Δw satisfies* (32)–(35) *for some $\sigma \in \Re$, $w \in \Re^{2n}_{++} \times \Re^{m+l}$, and $(p, q) \in \Re^n \times \Re^l$ such that $\|p\|_\infty \le \gamma\sigma\mu/4$. Then, for every scalar α satisfying*

$$0 \le \alpha \le \min\left\{1, \frac{\sigma\mu}{4\,\|\Delta X \Delta s\|_\infty}\right\}, \tag{64}$$

we have

$$\frac{\mu(\alpha)}{\mu} \;\ge\; 1 - \alpha. \tag{65}$$

Proof. Since $\|p\|_\infty \le \gamma\sigma\mu/4$, we easily see that

$$|p^T e/n| \;\le\; \|p\|_\infty \;\le\; \sigma\mu/4. \tag{66}$$

Using this result and Lemma 4.4(b), we conclude for every α satisfying (64) that

$$\begin{aligned} \mu(\alpha) &= [1 - \alpha(1-\sigma)]\mu - \alpha p^T e/n + \alpha^2 \Delta x^T \Delta s/n \\ &\ge [1 - \alpha(1-\sigma)]\mu - \frac{1}{4}\alpha\sigma\mu + \alpha^2 \Delta x^T \Delta s/n \\ &\ge (1-\alpha)\mu + \frac{1}{4}\alpha\sigma\mu - \alpha^2 \|\Delta X \Delta s\|_\infty \\ &\ge (1-\alpha)\mu. \qquad \blacksquare \end{aligned}$$

LEMMA 4.6. *Assume that Δw is a (τ_p, τ_q)-search direction, where τ_p and τ_q are given by* (38) *and* (39)*, respectively. Assume also that $\sigma > 0$ and that $w \in \mathcal{N}_{w^0}(\gamma, \theta)$*

with $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$, $\gamma \in [0,1]$, *and* $\theta \geq 0$. *Then,* $w(\alpha) \in \mathcal{N}_{w^0}(\gamma,\theta)$ *for every scalar* α *satisfying*

$$0 \leq \alpha \leq \min\left\{1\,,\ \frac{\gamma\sigma\mu}{4\,\|\Delta X\Delta s\|_\infty}\right\}. \tag{67}$$

Proof. Since $w \in \mathcal{N}_{w^0}(\gamma,\theta)$, there exists $\eta \in [0,1]$ such that $w \in \mathcal{N}_{w^0}(\eta,\gamma,\theta)$. We will show that $w(\alpha) \in \mathcal{N}_{w^0}((1-\alpha)\eta,\gamma,\theta) \subseteq \mathcal{N}_{w^0}(\gamma,\theta)$ for every α satisfying (67).

First, we note that $(r_p(\alpha), r_d(\alpha)) = (1-\alpha)\eta(r_p^0, r_d^0)$ by Lemma 4.4(c) and the definition of $\mathcal{N}_{w^0}(\eta,\gamma,\theta)$. Next, it follows from Lemma 4.5 that (65) holds for every α satisfying (64), and hence (67) due to $\gamma \in [0,1]$. Thus, for every α satisfying (67), we have

$$(1-\alpha)\eta \leq \ \frac{\mu(\alpha)}{\mu}\eta \ \leq \ \frac{\mu(\alpha)}{\mu}\,\frac{\mu}{\mu_0} \ = \ \frac{\mu(\alpha)}{\mu_0}. \tag{68}$$

Now, it is easy to see that for every $u \in \Re^n$ and $\tau \in [0,n]$, there holds $\|u - \tau(u^Te/n)e\|_\infty \leq (1+\tau)\|u\|_\infty$. Using this inequality twice, the fact that $w \in \mathcal{N}_{w^0}(\eta,\gamma,\theta)$, relation (38), and statements (a) and (b) of Lemma 4.4, we conclude for every α satisfying (67) that

$$\begin{aligned}
&X(\alpha)s(\alpha) - (1-\gamma)\,\mu(\alpha)e \\
&= (1-\alpha)\,[Xs - (1-\gamma)\mu e] + \alpha\gamma\sigma\mu e - \alpha\left[p - (1-\gamma)\left(\frac{p^Te}{n}\right)e\right] \\
&\quad + \alpha^2\left[\Delta X\Delta s - (1-\gamma)\left(\frac{\Delta x^T\Delta s}{n}\right)e\right] \\
&\geq \alpha\left[\gamma\sigma\mu - \left\|p - (1-\gamma)\frac{p^Te}{n}\,e\right\|_\infty - \alpha\left\|\Delta X\Delta s - (1-\gamma)\frac{\Delta x^T\Delta s}{n}\,e\right\|_\infty\right]e \\
&\geq \alpha\,(\gamma\sigma\mu - 2\|p\|_\infty - 2\alpha\|\Delta X\Delta s\|_\infty)\,e \ \geq \ \alpha\left(\gamma\sigma\mu - \frac{1}{2}\gamma\sigma\mu - \frac{1}{2}\gamma\sigma\mu\right)e \ = \ 0.
\end{aligned}$$

Next, by Lemma 4.4(d), we have that

$$r_V(\alpha) = (1-\alpha)r_V + \alpha q = \ (1-\alpha)\eta r_V^0 + \hat{a},$$

where $\hat{a} = (1-\alpha)(r_V - \eta r_V^0) + \alpha q$. To complete the proof, it suffices to show that $\|\hat{a}\| \leq \theta\sqrt{\mu(\alpha)}$ for every α satisfying (67). By using equation (39) and Lemma 4.4(b) along with the facts that $\|r_V - \eta r_V^0\| \leq \theta\sqrt{\mu}$ and $\alpha \in [0,1]$, we have

$$\begin{aligned}
\|\hat{a}\|^2 - \theta^2\mu(\alpha) &= (1-\alpha)^2\|r_V - \eta r_V^0\|^2 + 2\alpha(1-\alpha)[r_V - \eta r_V^0]^Tq + \alpha^2\|q\|^2 - \theta^2\mu(\alpha) \\
&\leq (1-\alpha)^2\theta^2\mu + 2\alpha(1-\alpha)\theta\sqrt{\mu}\|q\| + \alpha^2\|q\|^2 \\
&\quad - \theta^2\left\{[1-\alpha(1-\sigma)]\mu - \alpha\frac{p^Te}{n} + \alpha^2\frac{\Delta x^T\Delta s}{n}\right\} \\
&\leq \alpha^2\|q\|^2 + 2\alpha\theta\sqrt{\mu}\|q\| - \alpha\theta^2\sigma\mu + \alpha\theta^2\frac{p^Te}{n} - \alpha^2\theta^2\frac{\Delta x^T\Delta s}{n} \\
&\leq \alpha\left[\|q\|^2 + 2\theta\sqrt{\mu}\|q\| - \left(1 - \frac{\gamma}{4}\right)\theta^2\sigma\mu + \theta^2\alpha\|\Delta X\Delta s\|_\infty\right] \\
&\leq \alpha\left[\|q\|^2 + 2\theta\sqrt{\mu}\|q\| - \left(1 - \frac{\gamma}{2}\right)\theta^2\sigma\mu\right] \ \leq \ 0,
\end{aligned}$$

where the last inequality follows from the quadratic formula and the fact that $\|q\| \leq \tau_q$, where τ_q is given by (39). ∎

Next, we derive a lower bound on the step size of the inexact PDIPF algorithm.

LEMMA 4.7. *In every iteration of the inexact PDIPF algorithm, the step length* $\bar{\alpha}$ *satisfies*

$$\bar{\alpha} \;\geq\; \min\left\{1, \frac{\min\{\gamma\sigma, 1-\frac{5}{4}\sigma\}\mu}{4\,\|\Delta X \Delta s\|_\infty}\right\} \tag{69}$$

and

$$\mu(\bar{\alpha}) \;\leq\; \left[1-\left(1-\frac{5}{4}\,\sigma\right)\frac{\bar{\alpha}}{2}\right]\mu. \tag{70}$$

Proof. We know that Δw is a (τ_p, τ_q)-search direction in every iteration of the inexact PDIPF algorithm, where τ_p and τ_q are given by (38) and (39). Hence, by Lemma 4.6, the quantity $\tilde{\alpha}$ computed in step (g) of the inexact PDIPF algorithm satisfies

$$\tilde{\alpha} \;\geq\; \min\left\{1, \frac{\gamma\sigma\mu}{4\,\|\Delta X \Delta s\|_\infty}\right\}. \tag{71}$$

Moreover, by (66), it follows that the coefficient of α in the expression for $\mu(\alpha)$ in Lemma 4.4(b) satisfies

$$\begin{aligned} -(1-\sigma)\mu - \frac{p^T e}{n} \;\leq\; -(1-\sigma)\mu + \|p\|_\infty \;&\leq\; -(1-\sigma)\mu + \frac{1}{4}\,\gamma\sigma\mu \\ &=\; -\left(1-\frac{5}{4}\,\sigma\right)\mu \;<\; 0, \end{aligned} \tag{72}$$

since $\sigma \in (0, 4/5)$. Hence, if $\Delta x^T \Delta s \leq 0$, it is easy to see that $\bar{\alpha} = \tilde{\alpha}$ and hence that (69) holds in view of (71). Moreover, by Lemma 4.4(b) and (72), we have

$$\mu(\bar{\alpha}) \;\leq\; [1-\bar{\alpha}(1-\sigma)]\mu - \bar{\alpha}\frac{p^T e}{n} \;\leq\; \left[1-\left(1-\frac{5}{4}\,\sigma\right)\bar{\alpha}\right]\mu \;\leq\; \left[1-\left(1-\frac{5}{4}\,\sigma\right)\frac{\bar{\alpha}}{2}\right]\mu,$$

showing that (70) also holds. We now consider the case where $\Delta x^T \Delta s > 0$. In this case, we have $\bar{\alpha} = \min\{\alpha_{\min}\,,\, \tilde{\alpha}\}$, where $\alpha_{\min}$ is the unconstrained minimum of $\mu(\alpha)$. It is easy to see that

$$\alpha_{\min} = \frac{n\mu(1-\sigma) + p^T e}{2\Delta x^T \Delta s} \;\geq\; \frac{n[\mu(1-\sigma) - \frac{1}{4}\sigma\mu]}{2\Delta x^T \Delta s} \;\geq\; \frac{\mu(1-\frac{5}{4}\sigma)}{2\,\|\Delta X \Delta s\|_\infty}.$$

The last two observations together with (71) imply that (69) holds in this case too. Moreover, since the function $\mu(\alpha)$ is convex, it must lie below the function $\phi(\alpha)$ over the interval $[0, \alpha_{\min}]$, where $\phi(\alpha)$ is the affine function interpolating $\mu(\alpha)$ at $\alpha = 0$ and $\alpha = \alpha_{\min}$. Hence,

$$\mu(\bar{\alpha}) \;\leq\; \phi(\bar{\alpha}) \;=\; \left[1-(1-\sigma)\frac{\bar{\alpha}}{2}\right]\mu - \bar{\alpha}\frac{p^T e}{2n} \;\leq\; \left[1-\left(1-\frac{5}{4}\,\sigma\right)\frac{\bar{\alpha}}{2}\right]\mu, \tag{73}$$

where the second inequality follows from (72). We have thus shown that $\bar{\alpha}$ satisfies (70). ∎

Our next task will be to show that the step size $\bar{\alpha}$ remains bounded away from zero. In view of (69), it suffices to show that the quantity $\|\Delta X \Delta s\|_\infty$ can be suitably bounded. The next lemma addresses this issue.

LEMMA 4.8. *Let $w^0 \in \Re^{2n}_{++} \times \Re^{m+l}$ be such that $(x^0, s^0) \geq (x^*, s^*)$ for some $w^* \in \mathcal{S}$, and let $w \in \mathcal{N}_{w^0}(\gamma, \theta)$ for some $\gamma \geq 0$ and $\theta \geq 0$. Then, the inexact search direction Δw used in the inexact PDIPF algorithm satisfies*

$$\begin{aligned} \max(\|D^{-1}\Delta x\|, \|D\Delta s\|) \leq & \left(1 - 2\sigma + \frac{\sigma^2}{1-\gamma}\right)^{1/2} \sqrt{n\mu} \\ & + \frac{1}{\sqrt{1-\gamma}} \left(\frac{\gamma\sigma}{4}\sqrt{n} + 6n + \frac{\theta^2}{2}\right) \sqrt{\mu} + \theta\sqrt{\mu}. \end{aligned} \tag{74}$$

Proof. Since $w \in \mathcal{N}_{w^0}(\gamma, \theta)$, there exists $\eta \in [0, 1]$ such that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$. Let $\widetilde{\Delta w} := \Delta w + \eta(w^0 - w^*)$. Using relations (32), (33), (35), and the fact that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$, we easily see that

$$A\widetilde{\Delta x} = 0, \tag{75}$$

$$A^T\widetilde{\Delta y} + \widetilde{\Delta s} + V\widetilde{\Delta z} = 0, \tag{76}$$

$$V^T\widetilde{\Delta x} + E^{-2}\widetilde{\Delta z} = E^{-1}(q - r_V + \eta r_V^0). \tag{77}$$

Premultiplying (76) by $\widetilde{\Delta x}^T$ and using (75) and (77), we obtain

$$\begin{aligned} \widetilde{\Delta x}^T\widetilde{\Delta s} = -\widetilde{\Delta x}^T V\widetilde{\Delta z} \;&=\; [E^{-2}\widetilde{\Delta z} - E^{-1}(q - r_V + \eta r_V^0)]^T\widetilde{\Delta z} \\ &= \|E^{-1}\widetilde{\Delta z}\|^2 - (q - r_V + \eta r_V^0)^T(E^{-1}\widetilde{\Delta z}) \\ &\geq \|E^{-1}\widetilde{\Delta z}\|^2 - \|q - r_V + \eta r_V^0\|\,\|E^{-1}\widetilde{\Delta z}\| \;\geq\; -\frac{\|q - r_V + \eta r_V^0\|^2}{4}. \end{aligned} \tag{78}$$

Next, we multiply (34) by $(XS)^{-1/2}$ to obtain $D^{-1}\Delta x + D\Delta s = H(\sigma) - (XS)^{-1/2}p$, where $H(\sigma) := -(XS)^{1/2}e + \sigma\mu(XS)^{-1/2}e$. Equivalently, we have that

$$D^{-1}\widetilde{\Delta x} + D\widetilde{\Delta s} = H(\sigma) - (XS)^{-1/2}p + \eta\left[D(s^0 - s^*) + D^{-1}(x^0 - x^*)\right] \;=:\; g.$$

Taking the squared norm of both sides of the above equation and using (78), we obtain

$$\begin{aligned} \|D^{-1}\widetilde{\Delta x}\|^2 + \|D\widetilde{\Delta s}\|^2 = \|g\|^2 - 2\widetilde{\Delta x}^T\widetilde{\Delta s} \;&\leq\; \|g\|^2 + \frac{\|q - r_V + \eta r_V^0\|^2}{2} \\ &\leq \left(\|g\| + \frac{\|q\| + \|r_V - \eta r_V^0\|}{\sqrt{2}}\right)^2 \;\leq\; \left(\|g\| + \theta\sqrt{\mu}\right)^2, \end{aligned}$$

since $\|q\| + \|r_V - \eta r_V^0\| \leq \left[\sqrt{2} - 1\right]\theta\sqrt{\mu} + \theta\sqrt{\mu} = \sqrt{2}\theta\sqrt{\mu}$ by (36), (39), and the fact that $1 + (1 - \gamma/2)\sigma \leq 2$. Thus, we have

$$\begin{aligned} &\max(\|D^{-1}\widetilde{\Delta x}\|\,,\, \|D\widetilde{\Delta s}\|) \;\leq\; \|g\| + \theta\sqrt{\mu} \\ &\leq\; \|H(\sigma)\| + \|(XS)^{-1/2}\|\,\|p\| + \eta\left[\|D(s^0 - s^*)\| + \|D^{-1}(x^0 - x^*)\|\right] + \theta\sqrt{\mu}. \end{aligned}$$

This, together with the triangle inequality, the definitions of D and $\widetilde{\Delta w}$, and the fact that $w \in \mathcal{N}_{w^0}(\eta, \gamma, \theta)$, implies that

(79)
$$\begin{aligned}
&\max(\|D^{-1}\Delta x\|, \|D\Delta s\|) \\
&\le \|H(\sigma)\| + \|(XS)^{-1/2}\|\,\|p\| + 2\eta\left[\|D(s^0 - s^*)\| + \|D^{-1}(x^0 - x^*)\|\right] + \theta\sqrt{\mu} \\
&\le \|H(\sigma)\| + \|(XS)^{-1/2}\|\,\|p\| + 2\eta\|(XS)^{-1/2}\|\left[\|X(s^0 - s^*)\| + \|S(x^0 - x^*)\|\right] + \theta\sqrt{\mu} \\
&\le \|H(\sigma)\| + \frac{1}{\sqrt{(1-\gamma)\mu}}\left[\|p\| + 2\eta\left(\|X(s^0 - s^*)\| + \|S(x^0 - x^*)\|\right)\right] + \theta\sqrt{\mu}.
\end{aligned}$$

It is well known (see, e.g., [10]) that

$$\|H(\sigma)\| \le \left(1 - 2\sigma + \frac{\sigma^2}{1-\gamma}\right)^{1/2}\sqrt{n\mu}. \tag{80}$$

Moreover, using the fact that $s^* \le s^0$ and $x^* \le x^0$ along with Lemma 4.2, we obtain

$$\eta\left(\|X(s^0 - s^*)\| + \|S(x^0 - x^*)\|\right) \;\le\; \eta(s^T x^0 + x^T s^0) \;\le\; \left(3n + \frac{\theta^2}{4}\right)\mu. \tag{81}$$

The result now follows by noting that $\|p\| \le \sqrt{n}\|p\|_\infty$ and by incorporating inequalities (80), (81), and (38) into (79). ∎

We are now ready to prove Theorem 2.2.

Proof. Let Δw^k denote the search direction, and let $r^k = r(w^k)$ and $\mu_k = \mu(w^k)$ at the kth iteration of the inexact PDIPF algorithm. Clearly, $w^k \in \mathcal{N}_{w^0}(\gamma, \theta)$. Hence, using Lemma 4.8, assumption (40), and the inequality

$$\|\Delta X^k \Delta s^k\|_\infty \;\le\; \|\Delta X^k \Delta s^k\| \;\le\; \|(D^k)^{-1}\Delta x^k\|\,\|D^k \Delta s^k\|,$$

we easily see that $\|\Delta X^k \Delta s^k\|_\infty = \mathcal{O}(n^2)\mu_k$. Using this conclusion together with assumption (40) and Lemma 4.7, we see that, for some universal constant $\beta > 0$, we have

$$\mu_{k+1} \;\le\; \left(1 - \frac{\beta}{n^2}\right)\mu_k \quad \forall k \ge 0.$$

Using this observation and some standard arguments (see, for example, Theorem 3.2 of [27]), we easily see that the inexact PDIPF algorithm generates an iterate $w^k \in \mathcal{N}_{w^0}(\gamma, \theta)$ satisfying $\mu_k/\mu_0 \le \epsilon$ within $\mathcal{O}\left(n^2 \log(1/\epsilon)\right)$ iterations. The theorem now follows from this conclusion and the definition of $\mathcal{N}_{w^0}(\gamma, \theta)$. ∎

5. Concluding remarks. We have shown that the long-step PDIPF algorithm for LP based on an iterative linear solver presented in [16] can be extended to the context of CQP. This was not immediately obvious at first since the standard normal equation for CQP does not fit into the mold required for the results of [17] to hold. By considering the ANE, we were able to use the results about the MWB preconditioner developed in [17] in the context of CQP. Another difficulty we encountered was the proper choice of the starting iterate u^0 for the iterative linear solver. By choosing $u^0 = 0$ as in the LP case, we obtain $\|v - Wu^0\| = \|v\|$, which can only be shown to be $\mathcal{O}(\max\{\mu, \sqrt{\mu}\})$. In this case, for every $\mu > 1$, Proposition 3.2 would guarantee that the number of inner iterations of the iterative linear solver is

$$\mathcal{O}\left(\psi(\varphi_{\tilde{A}}^2)\max\left\{\log\left(c(\varphi_{\tilde{A}}^2)n\varphi_{\tilde{A}}\right), \log\mu\right\}\right),$$

a bound which depends on the logarithm of the current duality gap. On the other hand, Theorem 3.5 shows that choosing u^0 as in (53) results in a bound that does not depend on the current duality gap.

We observe that under exact arithmetic, the CG algorithm applied to $Wu = v$ generates an exact solution in at most $m + l$ iterations (since $W \in \Re^{(m+l)\times(m+l)}$). It is clear, then, that the bound (55) is generally worse than the well-known finite termination bound for CG. However, our results in section 3 were given for a family of iterative linear solvers, only one member of which is CG. Also, under finite precision arithmetic, the CG algorithm loses its finite termination property, and its convergence rate behavior in this case is still an active topic of research (see, e.g., [8]). Certainly, the impact of finite precision arithmetic on our results is an interesting open issue.

Clearly, the MWB preconditioner is not suitable for dense CQP problems since, in this case, the cost to construct the MWB is comparable to the cost to form and factorize $\tilde{A}\tilde{D}^2\tilde{A}^T$, and each inner iteration would require $\Theta((m+l)^2)$ arithmetic operations, the same cost as a forward and backward substitution. There are, however, some classes of CQP problems for which the method proposed in this paper might be useful. One class of problems for which PDIPF methods based on MWB preconditioners might be useful are those for which bases of $\tilde{A}$ are sparse, but the ANE coefficient matrices $\tilde{A}\tilde{D}^2\tilde{A}^T$ are dense; this situation generally occurs in sparse CQP problems for which n is much larger than $m + l$. Other classes of problems for which our method might be useful are network flow problems. The paper [22] developed interior-point methods for solving the minimum cost network flow problem based on iterative linear solvers with maximum spanning tree preconditioners. Related to this work, we believe that the following two issues could be investigated: (i) whether the incorporation of the correction term p defined in (29) in the algorithm implemented in [22] will improve the convergence of the method; (ii) whether our algorithm might be efficient for network flow problems where the costs associated with the arcs are quadratic functions of the arc flows. Identification of other classes of CQP problems which could be efficiently solved by the method proposed in this paper is another topic for future research.

Regarding the second question above, it is easy to see (after a suitable permutation of the variables) that $V^T = \begin{pmatrix} I & 0 \end{pmatrix}$ and E^2 is a positive diagonal matrix whose diagonal elements are the positive quadratic coefficients. In this case, it can be shown that $\tilde{A}$ is totally unimodular; hence $\varphi_{\tilde{A}}^2 \leq (m+l)(n-m+1)$ by Cramer's rule (see [17]).

The usual way of defining the dual residual is as the quantity

$$R_d := A^T y + s - VE^2V^T x - c,$$

which, in view of (11) and (12), can be written in terms of the residuals r_d and r_V as

$$R_d = r_d - VEr_V. \tag{82}$$

Note that, along the iterates generated by the inexact PDIPF algorithm, we have $r_d = \mathcal{O}(\mu)$ and $r_V = \mathcal{O}(\sqrt{\mu})$, implying that $R_d = \mathcal{O}(\sqrt{\mu})$. Hence, while the usual primal residual converges to 0 according to $\mathcal{O}(\mu)$, the usual dual residual does so according to $\mathcal{O}(\sqrt{\mu})$. This is a unique feature of the convergence analysis of our algorithm in that it contrasts with the analysis of other interior-point PDIPF algorithms, where the primal and dual residuals are required to go to zero at the same rate. The convergence analysis under these circumstances is possible due to the specific form of the $\mathcal{O}(\sqrt{\mu})$-term present in (82), i.e., one that lies in the range space of VE.

CQP problems where V is explicitly available arise frequently in the literature. One important example arises in portfolio optimization (see [6]), where the rank of V is often small. In such problems, l represents the number of observation periods used to estimate the data for the problem. We believe that the inexact PDIPF algorithm could be of particular use for this type of application.

OPTIMIZING OVER CONSECUTIVE 1'S AND CIRCULAR 1'S CONSTRAINTS*

DORIT S. HOCHBAUM† AND ASAF LEVIN‡

Abstract. We consider packing and covering optimization problems over constraints in consecutive and circular 1's. Such problems arise in the context of shift scheduling, and in problems related to interval graphs. Previous approaches to this problem depended on solving several minimum cost network flow problems. We devise here substantially more efficient and strongly polynomial algorithms based on parametric shortest paths approaches. The objective function in the covering and packing problems is to either minimize or maximize the number of sets that satisfy the constraints. The various problems studied are classified according to whether the constraints are all consecutive 1's or if there are also circular 1's constraints, and according to whether the constraints are all of covering type; all of packing type, or mixed. The running time of our algorithm for a pure covering all consecutive 1's constraints problem on n variables and m constraints is $O(m+n)$. For the pure packing problem with consecutive 1's constraints we present an $O(m+n\log n)$ time algorithm. For the "mixed" case with both covering and packing consecutive 1's constraints we present an $O(mn)$ time algorithm. An $O(mn+n^2\log n)$-time algorithm is presented for the case where the constraints are *circular* (consecutive 1's constraint is also circular) of pure type—either all covering constraints or all packing constraints. Finally, we show an $O(n\min\{mn, n^2\log n + m\log^2 n\})$ time algorithm for the most general problem of mixed covering and packing case where the constraints are *circular*. All our algorithms are strongly polynomial and improve on the nonstrongly polynomial parametric minimum cost network flow or the (strongly polynomial) linear programming known approaches.

Key words. circular scheduling problems, consecutive 1's constraints, parametric optimization, parametric shortest path

1. Introduction.

Here we study optimization problems over constraints with $0,1$ coefficients that have the consecutive and circular 1's property. The basic consecutive 1's problem is formulated for a given set of m pairs, or intervals, $A = A_{cover} \cup A_{pack}$. Each interval (p,q) for $p<q$ corresponds to the $0,1$ vector, $[0,\ldots,0,1,\ldots,1,0,\ldots,0]$ with the positions $p+1,\ldots,q$ with value 1 and all others with value 0. A constraint (p,q) is said to be in consecutive 1's if it is of the covering form $\sum_{j=p+1}^{q} x_j \geq b_{pq}$ or packing form, $\sum_{j=p+1}^{q} x_j \leq b_{pq}$. The formulation of the consecutive 1's problem on a mixed set of covering and packing constraints is

$$\text{(Consec)} \qquad \begin{array}{lll} \min & \sum_{j=1}^{n} x_j & \\ \text{subject to:} & \sum_{j=p+1}^{q} x_j \geq b_{pq} & \text{for } 0\leq p<q\leq n \text{ and } (p,q)\in A_{cover} \\ & \sum_{j=p+1}^{q} x_j \leq b_{pq} & \text{for } 0\leq p<q\leq n \text{ and } (p,q)\in A_{pack} \\ & x_j \geq 0 \ \text{ integer} & j=1,\ldots,n. \end{array}$$

Although not explicitly stated, the packing and covering constraints allow modeling of upper and lower bounds on the variables, respectively. So the nonnegativity need

not be listed explicitly, as we have in the formulation. When $A_{pack} = \emptyset$ the problem is the well known *set cover* problem.

When substituting the variables $y_q = \sum_{i=1}^{q} x_i$ in (Consec) the constraints of the problem become $y_q - y_p \geq b_{pq}$ and $y_q - y_p \leq b_{pq}$. (Detailed discussion of this transformation is provided in section 2.) Such constraints are recognized as the dual of the minimum cost network flow problem, and previous techniques for solving the problem are indeed based on solving minimum cost network flow problems.

The circular 1's problem (Circular) includes, in addition to consecutive 1's constraints, also at least one constraint of the type

$$\sum_{j=1}^{q'} x_j + \sum_{j=p'+1}^{n} x_j \geq b_{q'p'} \quad \text{for } 0 \leq q' < p' \leq n,$$

or

$$\sum_{j=1}^{q'} x_j + \sum_{j=p'+1}^{n} x_j \leq b_{q'p'} \quad \text{for } 0 \leq q' < p' \leq n.$$

Such constraints, called *circular*, are characterized by having an entry 1 in the first and last columns of the constraint coefficient. That is, a circular constraint corresponding to (p', q') for $p' > q'$ is represented by a $0,1$ vector $[1, \ldots, 1, 0, \ldots, 0, 1, \ldots, 1]$ with positions $q'+1$ through p' having 0 value, and the rest are 1. We refer to the problem with constraints that include consecutive 1's and circular 1's as (Circular).

We study here problems (Consec) and (Circular) with either $\max \sum_{j=1}^{n} x_j$ or $\min \sum_{j=1}^{n} x_j$ as the objective function. These problems have applications ranging from problems on interval and circular-arc graphs, to staff scheduling. Problems on interval and circular-arc graphs that can be modeled using (Consec) and (Circular) include the minimum dominating set where all the constraints are covering constraints with the right-hand side equaling 1, and the maximum independent set where all the constraints are packing constraints with the right-hand side equaling 1. The reader is referred to [BOR80] for details on the application of staff scheduling.

The recognition problem of whether the constraint matrix is of consecutive 1's or circular 1's type is polynomially solvable. Booth and Lueker, [BL76] showed that given a $0,1$ matrix of size $m \times n$ with f 1's, one can verify in linear time, $O(m+n+f)$, whether the matrix has the consecutive 1's property . It is also possible to test quickly whether the matrix has the circular 1's property in O(m+n+2f), [Boo75].

We present here combinatorial and strongly polynomial time algorithms which are not based on flow and yield improved run times for (Consec) and (Circular) as reported in Table 1.1.

Veinott and Wagner [VW62] studied the problem (Consec) and established its relationship to the minimum cost network flow problem. We use this relationship to conclude the known result for mixed (Consec) problem reported in Table 1.1. The pure covering (Consec) problem and the pure packing (Consec) problem were solved by Tamir [Ta03]. He considered these problems when each row of the constraint matrix corresponds to a neighborhood in a tree. For this general problem he designed an $O((m+n)\log^2 n)$ time algorithm, and noted that in the special case of neighborhoods on a line (i.e., each row is consecutive 1's) the time complexity reduced to $O((m+n)\log n)$. His results were obtained for the problem where the coefficient matrix is not given as a set of intervals of the consecutive 1's, and therefore the $\log n$ factor is essential to transform the problem into the set of intervals we have as our input.

TABLE 1.1
Complexity of algorithms for optimizing over consecutive 1*'s and circular* 1*'s matrices.*

Problem	**Known best result**	**Running time here**
Consecutive covering constraints	$O((m+n)\log n)$ [Ta03]	$O(m+n)$
Consecutive packing constraints	$O((m+n)\log n)$ [Ta03]	$O(m+n\log n)$
Consecutive packing and covering constraints	MCNF [VW62]	$O(mn)$
Circular covering constraints	$O(mn\log n)$ [KO81]	$O(nm+n^2\log n)$
Circular packing constraints	LP, or $O(\log b \cdot MCNF)$ [BOR80]	$O(nm+n^2\log n)$
Circular packing and covering constraints	LP, or $O(\log b \cdot MCNF)$ [BOR80]	$O(n^2\min\{m, n\log n\})$

Legend: **MCNF**, the complexity of solving minimum cost network flow. **LP**, the complexity of linear programming with $0,1$ constraint coefficients. $b=\sum_{(p,q)\in A} b_{pq}$.

Shah and Farach-Colton [SF02] presented an $O((m+n)\log n)$ time algorithm that finds the optimal solution value (not the solution itself) of the pure covering and pure packing problems where each row of the constraint matrix corresponds to a neighborhood in a tree.

Bartholdi, Orlin, and Ratliff [BOR80] were the first to propose a polynomial time algorithm for a generalization of the (Circular) problem in which the cost coefficients are not identical, and demonstrated that the linear optimization problem over constraints with circular 1's is solvable in polynomial time as well although the constraint matrix is no longer totally unimodular. Although they studied the problem with only covering constraints, their results hold also for problems with packing constraints as well, as we show in section 4. The running time of their algorithm is $\log b$ times the complexity of solving a minimum cost network flow problem (MCNF), where b is the sum of the right-hand sides. A second algorithm they devised solves the problem by calling twice to the linear programming relaxation (in the second linear programming relaxation they fix the value of $\sum_j x_j$). They showed that for the special objective function $\min \sum_j x_j$ and pure covering, it is enough to solve a single linear programming relaxation and then round-up the fractional solution vector to obtain an optimal integral solution. A similar result holds also for pure packing constraints but the fractional solution vector is rounded-down. For the mixed case we need to check the two possible solutions obtained by rounding-up and by rounding-down the optimal fractional solution. One of these solutions is guaranteed to be feasible if the problem itself is feasible. Then, we need to check whether these solutions are feasible, and if both are feasible the optimal integral solution is the better one.

A combinatorial linear program with all entries in the constraint matrix that are "small" is solvable in strongly polynomial time, [Tar86]. Thus the second, LP-based algorithm of [BOR80] is strongly polynomial. The drawback of employing this linear programming algorithm is that in order to achieve strongly polynomial time one has to use the Ellipsoid method which is neither efficient nor practical. We will show how the first algorithm of [BOR80] that is based on MCNF can be transformed into a strongly-polynomial time algorithm, albeit with run time that is still inferior to the run time of the algorithm reported here.

Karp and Orlin [KO81] solved problem (Circular) when all the constraints are covering constraints using parametric shortest path method in $O(mn\log n)$ time.

A related problem to the ones studied here is the optimization over constraints with circular 1's in *columns*. Hochbaum and Levin [HL03] showed that this problem is

at least as difficult as the *exact matching* problem, and thus harder than the problem in circular 1's in *rows* investigated here. They gave a 2-approximation algorithm for the problem, and presented an $O(n^3 \log B + n^4)$-time algorithm for the special case where right-hand sides are uniform and equal to B.

Paper overview. In section 2 we provide a description of Veinott and Wagner's [VW62] transformation. In section 3, we describe the parametric method of Megiddo [Meg83] and Cole [Col87] which is used to improve the running time of several of the algorithms presented. In section 4 and in the appendix we show how the results of Bartholdi, Orlin, and Ratliff [BOR80] are extended to the mixed case where there are packing constraints and covering constraints (rather than the pure covering constraints they investigated). We also devise a strongly-polynomial variant of the [BOR80]'s algorithm based on the parametric method. In section 5, we address the problem (Consec) with pure covering constraints and present an $O(m + n)$-time algorithm that solves it, and in section 6 we derive for (Consec) with pure packing constraints an $O(m + n \log n)$-time algorithm. In section 7 we show that pure packing problems are at least as difficult as pure covering problems. In section 8 we show an $O(mn)$-time algorithm for the *mixed* problem (Consec). In section 9 we discuss the pure packing circular 1's problem and present an algorithm with complexity $O(mn + n^2 \log n)$. Finally, in section 10 we present an algorithm for the general circular 1's case with both covering and packing constraints. The total time complexity of that algorithm is $O(n \min\{mn, n^2 \log n + m \log^2 n\})$.

Notation. For $i < j$, $[i, j]$ is the interval of integers $\{i, i+1, \ldots, j\}$. We use the notation convention $\mathbf{x}$ to refer to the *vector* $\{x_j\}_{j=1}^n$. The vector $\mathbf{e}_j$ is the vector of $n-1$ zeros and one 1 in the jth position.

2. The transformation and definitions. Veinott and Wagner [VW62] suggested the following transformation for problems on consecutive ones. Let the set of variables y_j be defined as follows: $y_0 = x_0 \equiv 0$, $y_j = \sum_{i=0}^{j} x_i$ for $j = 1, 2, \ldots, n$. The set of constraints of (Consec) in terms of the new variables are

$$\begin{aligned} y_j - y_i &\geq b_{ij} \quad \forall\ (i,j) \in A_{cover}, \\ y_j - y_i &\leq b_{ij} \quad \forall\ (i,j) \in A_{pack}, \\ y_j - y_{j-1} &\geq 0 \quad \forall j. \end{aligned}$$

This set of constraints has one 1 and one -1 in each row. The coefficient matrix of such a set of constraints is totally unimodular, and furthermore it forms the constraints of the dual of MCNF problem. This implies the following polynomial time algorithm for (Consec): Take the dual of the transformed problem, solve it with a minimum cost network flow procedure, and construct the dual solution (node potentials, in minimum cost network flow terminology) by a shortest paths procedure. We note that the dual node potentials are computed explicitly as part of Orlin's [Orl93] minimum cost network flow procedure. Therefore, if we use Orlin's algorithm, then the last step of computing the shortest paths is redundant.

Using the transformation above for the (Circular) problem, a circular 1's covering constraint $\sum_{j=1}^{q'} x_j + \sum_{j=p'+1}^{n} x_j \geq b_{q'p'}$ is mapped into $y_{q'} - y_{p'} + y_n \geq b_{q'p'}$. So circular constraints have, in addition to one 1 and one -1, also an additional coefficient 1 for the variable y_n. This renders the constraint matrix no longer totally unimodular. Writing the transformed constraint as $y_{q'} - y_{p'} \geq b_{q'p'} - y_n$, or equivalently as $y_{p'} - y_{q'} \leq y_n - b_{q'p'}$, it is possible to treat y_n as a parameter and solve the problem

as a parametric dual of minimum cost network flow. Thus a parametric approach plays a crucial role in solving circular problems.

3. The parametric method. In a parametric optimization problem some right-hand sides and some cost coefficients are given as linear functions of a single common parameter λ. The parametric method, introduced by Megiddo [Meg83] and improved for some special cases by Cole [Col87], solves a parametric optimization problem. The goal is to find an optimal value λ^* so that for the instance of the optimization problem where each linear function of λ is evaluated at λ^* the optimal solution has a maximum cost (among all values of λ).

The parametric shortest path problem and the parametric minimum cost network flow problem are defined on a graph $G = (V, E)$, where each arc $e \in E$ has a cost c_e that is a linear function of a common parameter λ. In the minimum cost network flow we are also given a demand vector d. The goal in the parametric shortest path problem is to compute a value λ^* for which the length of the shortest path between s and t is maximized. Similarly, the goal for the parametric MCNF problem is to compute a value λ^* that maximizes the optimal cost of the minimum cost network flow problem instance.

The methods of [Col87, Meg83] both use a parallel algorithm with $O(f(n))$ processors and $O(g(n))$ parallel time that solves the optimization problem for a single value of λ (the nonparametric problem). The method "simulates" the execution of this parallel algorithm for $\lambda = \lambda^*$ without the knowledge of λ^*. A rough sketch of the idea is as follows: In each parallel time unit a set of $O(f(n))$ comparisons needs to be answered. For a single comparison, Megiddo [Meg83] proposed to use an algorithm that solves the nonparametric problem in the breakpoint of the two linear functions (of λ) that we have to compare (this is done by a call to a serial algorithm with time complexity $T(n)$). Megiddo [Meg83] suggested using a binary search over these comparisons to evaluate the $O(f(n))$ comparisons of a single parallel time unit using only $O(\log f(n))$ comparisons. This results in time complexity of $O(f(n)g(n) + (\log f(n))g(n)T(n))$ for the parametric problem.

Cole [Col87] suggested that one should "slow down" the comparisons that this algorithm evaluates, and use a sorting network instead of the comparisons. Using Cole's method the number of comparisons that the algorithm evaluates is only $O(\log f(n) + g(n))$. Therefore, the total complexity is $O(f(n)g(n) + [\log f(n) + g(n)]T(n))$. Cole's improvement is suitable only for cases when the parallel algorithm is based on sorting. Cole explicitly stated that his improvement cannot be applied to a general parametric problem but only to special cases. Cole also designed an algorithm with time complexity of $O(n^3 \log n + (\log^2 n)T(n))$ for the parametric shortest path problem where $T(n)$ is the time complexity of a single comparison. His algorithm was designed for the minimum ratio cycle problem where a comparison is answered using a negative cycle detector. The result, however, holds also for other applications of the parametric shortest path problem.

Since Orlin's [Orl93] algorithm for the minimum cost network flow uses $O(n \log n)$ shortest path computations, the parametric MCNF problem can be solved in $O(n^4 \log^2 n + n \log^3 nT(n))$, where $T(n)$ is the time complexity of a single comparison; using Orlin's serial algorithm for the MCNF problem $T(n) = O(n \log n(m + n \log n))$. Therefore, the parametric MCNF problem can be solved in $O(n^4 \log^2 n + n^2 m \log^4 n)$ time.

We conclude this discussion with the following theorem.

THEOREM 3.1. *The parametric shortest path problem can be solved in* $O(n^3 \log n +$

$(\log^2 n)T(n))$ *time where* $T(n)$ *is the time complexity of a single comparison. The parametric MCNF problem can be solved in* $O(n^4 \log^2 n + n^2 m \log^4 n)$ *time.*

4. Extensions on the algorithm to solve the general linear objective function of (Circular). The algorithm of Bartholdi, Orlin, and Ratliff is based on treating the transformed circular problem, as explained in section 2, as a parametric MCNF problem. The algorithm of [BOR80] consists of a binary search for the optimal value of $\lambda = y_n$ where in each call a MCNF problem is solved for a specific value of $\lambda = y_n$. That algorithm is applicable to (Circular) with a general linear objective function, $\min \sum_{j=1}^{n} c_j x_j$.

The algorithm in [BOR80] is given for the pure covering problem. We show in the appendix how to extend it to the mixed packing and covering constraints. A second modification we propose is a strongly polynomial time algorithm based on the parametric network flow algorithm in Theorem 3.1.

With these modifications we establish the following theorem (proved in the appendix).

THEOREM 4.1. *There is an* $O(n^4 \log^2 n + n^2 m \log^4 n)$*-time algorithm that solves problem (Circular) with a general linear cost function.*

In the remainder of this paper we consider the unweighted objective function case $c_j = 1\ \forall j$, and present faster algorithms for this problem and its special cases.

5. Covering consecutive 1's constraints. For the pure covering problem with $A = A_{cover}$, only a minimization objective is meaningful since the maximization problem $\max \sum_i x_i$ is trivially unbounded.

Consider the minimum *longest path problem* in an acyclic graph. This is an optimization problem in which the objective is to find the smallest bound within which we can traverse every path in a network where each arc (i, j) has a cost, or distance, b_{ij}. The formulation of the longest path problem is precisely the transformed formulation of the problem (Consec) on pure covering constraints. In the transformed problem variable y_i corresponds to node i and b_{ij} represents the *distance* between nodes i and j. The objective function of the minimum *longest path problem* is to minimize y_n which is equivalent to the objective function $\sum_{j=1}^{n} x_j$ in the formulation of (Consec).

Construct a graph $G = (V, A)$ corresponding to the formulation with a node $i \in V$ for each variable y_i. For every constraint of the type $y_j - y_i \geq b_{ij}$ there is a directed arc $(i, j) \in A$ with weight b_{ij}. Arcs $(i-1, i)$ correspond to the variable $x_i = y_i - y_{i-1}$ and can have length 0 for every nonnegativity constraint, or other lower bound constraint. The graph is illustrated in Figure 1. Since for every arc (i, j), $i < j$ the graph G is necessarily acyclic, or directed acyclic graph (DAG).

To demonstrate that our problem is indeed the longest path problem on the DAG G, let P be any path from 0 to n in G. Consider the inequality which is the sum of the constraints that correspond to the arcs of P. This inequality has a left-hand side $y_n - y_0$, and its right-hand side equals the length of P. Since $y_0 = 0$, we conclude that y_n is at least as large as the total length of P. Since P is an arbitrary path from 0 to n, y_n is at least the length of the longest path from 0 to n. Because our objective is to minimize y_n, the optimal value of y_n equals the length of the longest path from 0 to n.

The longest path problem is solvable in polynomial time on a DAG using dynamic programming (DP). Let the distance labels $\underline{y}_j^*$ be the length of the longest path from 0 to j. We compute lower bounds $\underline{y}_j^*$ on the partial sum variables y_j.

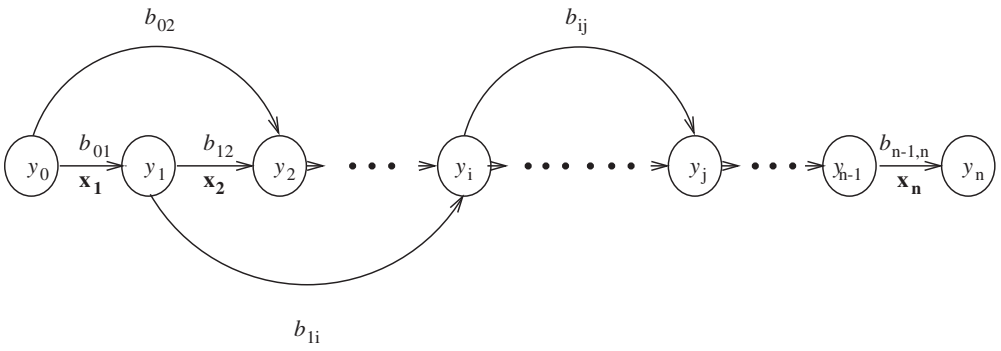

FIG. 1. *Directed Acyclic Graph* (DAG).

Let $\underline{y}_0^* = 0$. Then, once $\underline{y}_1^*, \underline{y}_2^*, \ldots, \underline{y}_{j-1}^*$ has been computed, we evaluate $\underline{y}_j^*$ using the following forward recursion:

Forward recursion	$\underline{y}_j^* = \max_{(i,j)\in A}\{\underline{y}_i^* + b_{ij}\}$

Every feasible solution with partial sums vector $\mathbf{y}$ obviously must satisfy $y_j \geq \underline{y}_j^*$ for $j = 1, \ldots, n$. Since the solution $x_j = \underline{y}_j^* - \underline{y}_{j-1}^*$ is feasible with objective value $\underline{y}_n^*$, it is an optimal solution. The validity of this DP recursion implies the following theorem.

THEOREM 5.1. *Problem (Consec) with pure covering constraints is solved in* $O(m+n)$ *time.*

6. Packing consecutive 1's constraints. For the pure packing problem $A = A_{pack}$, only a maximization objective is meaningful as the minimization problem $\min \sum_j x_j$ is trivially solved by $x_j = 0\ \forall j$.

For the transformed problem there is a corresponding graph $G = (V, A)$ with one node i corresponding to each variable y_i and an arc (i, j) of weight b_{ij} corresponding to each constraint $y_j - y_i \leq b_{ij}$. A nonnegativity constraint $x_j \geq 0$ is transformed into $y_j - y_{j-1} \geq 0$, and is represented by a backward zero arc directed from j to $j-1$.

The graph G contains cycles but the lengths of arcs are all nonnegative.

Our problem is the shortest path problem on G from 0 to n. To see this let P be any path from 0 to n in G. Consider the inequality which is the sum of the constraints that correspond to the arcs of P. This inequality has a left-hand side $y_n - y_0$, and its right-hand side equals the length of P. Since $y_0 = 0$, we conclude that y_n is at most as large as the total length of P. Since P is an arbitrary path from 0 to n, y_n is at most the length of the shortest path from 0 to n. Because our objective is to maximize y_n, the optimal value of y_n equals the length of the shortest path from 0 to n.

Since the lengths are nonnegative we can apply Dijkstra's algorithm [Dij59] to find the shortest path from 0 to n in G:

THEOREM 6.1. *Problem (Consec) with pure packing constraints is solved in* $O(m + n \log n)$ *time.*

7. The relation between the pure packing problem and the pure covering problem. In this section we consider problems (Consec) and (Circular) with pure covering constraints or pure packing constraints. We note that for the pure packing problem the meaningful objective function is $\max \sum_{j=1}^{n} x_j$ as a minimization

problem is trivially solved by the zero vector, and for the pure covering problem the meaningful objective function is $\min \sum_{j=1}^{n} x_j$ as a maximization problem is trivially unbounded.

Given a "pure" problem we let $M \geq \sum_{i=1}^{m} b_i$, and consider the transformation of the variables $(x_1, \ldots, x_n)$ to $(x'_1, \ldots, x'_n)$ defined by $x'_j = M - x_j$ for all j.

A covering constraint $\sum_{j \in S} x_j \geq b$ is transformed to $\sum_{j \in S}(M - x'_j) \geq b$ which is equivalent to the packing constraint $\sum_{j \in S} x'_j \leq M|S| - b$. Similarly, a packing constraint $\sum_{j \in S} x_j \leq b$ is transformed to the covering constraint $\sum_{j \in S} x'_j \geq M|S| - b$.

This transformation maps a consecutive (circular) constraint to a consecutive (circular) constraint. The objective function $\max \sum_{j=1}^{n} x_j$ is mapped to $nM + \max \sum_{j=1}^{n} (-x'_j)$ which is equivalent to $\min \sum_{j=1}^{n} x'_j$. Similarly, the objective function $\min \sum_{j=1}^{n} x_j$ is mapped to $nM + \min \sum_{j=1}^{n}(-x'_j)$ which is equivalent to $\max \sum_{j=1}^{n} x'_j$.

This transformation maps a pure covering problem into a pure packing problem. However, a pure packing problem is mapped into a pure covering problem with additional upper bounds constraints. These upper bounds result from the nonnegativity constraints in the pure packing formulation. This also explains the different time complexities for solving the pure covering (Consec) problem and the pure packing (Consec) problem.

This simple transformation proves the following theorem.

THEOREM 7.1. *Let $T(n, m)$ be a function that grows at least at a linear rate, $T(n, m) = \Omega(n)$. Then,*

1. *If there is an algorithm of complexity $T(n, m)$ that solves the pure packing (Circular) problem, then there is an algorithm of complexity $T(n, m)$ that solves the pure covering (Circular) problem.*
2. *There is an algorithm of complexity $T(n, m)$ that solves the mixed (Consec) problem with a maximization objective if and only if there is an algorithm of complexity $T(n, m)$ that solves the mixed (Consec) problem with a minimization objective.*
3. *There is an algorithm of complexity $T(n, m)$ that solves the mixed (Circular) problem with a maximization objective if and only if there is an algorithm of complexity $T(n, m)$ that solves the mixed (Circular) problem with a minimization objective.*

8. The mixed (Consec) problem. In this section we present an $O(mn)$ time algorithm for problem (Consec) with both covering and packing constraints.

We begin by applying Veinott and Wagner's [VW62] transformation, getting a transformed constraint of the type $y_q - y_p \leq b_{pq}$ for each packing constraint $(p, q) \in A_{pack}$, and $y_q - y_p \geq b_{pq}$ for each covering constraint $(p, q) \in A_{cover}$ (or nonnegativity constraint). By multiplying each covering constraint by -1, $y_p - y_q \leq -b_{pq}$, all constraints become uniformly of packing type, albeit no longer with positive right-hand sides.

We claim that the sum of variables at the optimum is the length of the *shortest path* from node 0 to n in the corresponding network, which is possibly cyclic and contains negative arc lengths. The network $G = (V, A)$ is composed of a node set $V = \{0, 1, \ldots, n\}$. The set of arcs A consists of three types of arcs: For every packing constraint $(p, q) \in A_{pack}$ there is an arc (p, q) of length b_{pq}; for every covering constraint $(p, q) \in A_{cover}$ there is an arc (q, p) of length $-b_{pq}$ (note that such an arc is in the reverse direction and has a negative length), and for every nonnegativity constraint $y_j - y_{j-1} \geq 0$ there is an arc $(j, j-1)$ of zero length.

To see that our problem is the shortest path from 0 to n in the resulting network

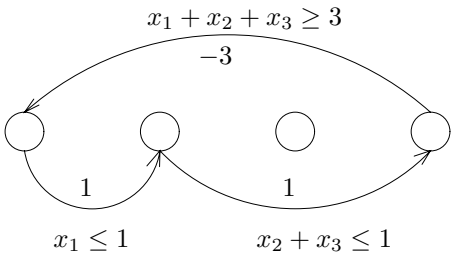

FIG. 2. *The graph G with a negative length cycle that corresponds to the set of constraints $x_1 \leq 1$, $x_2 + x_3 \leq 1$, and $x_1 + x_2 + x_3 \geq 3$.*

we use an argument similar to the one in section 5. Let $P = [j_o, j_1, j_2, \ldots, j_{k-1}, j_k]$, where $j_0 = 0$ and $j_k = n$ be an arbitrary path from 0 to n in G. Consider the inequality which is the sum of the constraints that correspond to the arcs of P,

$$(y_{j_1} - y_0) + (y_{j_2} - y_{j_1}) + \cdots + (y_n - y_{j_{k-1}}) \leq \sum_{\ell=1}^{n} b_{j_{\ell-1} j_\ell} = B_P.$$

This constraint has a left-hand side $y_n - y_0$, and its right-hand side equals the length of P, B_P. Since $y_0 = 0$, we conclude that y_n is at most as large as the total length of P. Since P is an arbitrary path from 0 to n, y_n is at most the length of a shortest path from 0 to n, $y_n \leq \min_P B_P$. Because our objective is to maximize y_n, the optimal value of y_n equals the length of a shortest path from 0 to n.

We now argue that the existence of a negative length cycle C in G implies that the original (Consec) problem is infeasible (as illustrated in an example in Figure 2). Summing up the constraints that correspond to the arcs of C we get 0 on the left-hand side, and the length of C on the right-hand side. That is, the aggregate constraint is $0 \leq$ a negative number. Therefore, the original problem is infeasible.

To solve problem (Consec) we can therefore use the Bellman–Ford algorithm for computing the shortest path from 0 to n in G. If there is a negative length cycle, then (Consec) is provably infeasible. Otherwise, the shortest path distance from node 0 to i is the value of the variable y_i in the optimal solution. All these distances are computed by the Bellman–Ford's algorithm in $O(mn)$ time.

THEOREM 8.1. *There is an $O(mn)$-time algorithm that solves mixed (Consec) problem.*

Remark 8.1. Under a restriction about the relative values of the coefficients of the objective function, the algorithm above can also solve (Consec) with nonuniform coefficients. The transformed constraints of (Consec) are monotone as in each row of the constraint matrix there is at most one positive coefficient and at most one negative coefficient. It is well known [HN94] that the feasible integral solution set on monotone constraints forms a lattice. In this lattice there is a least element and a largest element. The least element solves the problem of minimizing $\sum_j \bar{c}_j y_j$ for all nonnegative $\bar{c}$. The largest element of the lattice solves the problem of maximizing $\sum_j \bar{c}_j y_j$ for all nonnegative $\bar{c}$. The transformed problem (Consec) has nonnegative cost coefficients if the original cost coefficients are monotone nondecreasing. In this case we now show that our solution for problem (Consec) finds the least or largest element of the lattice. For the pure covering (Consec) problem our algorithm finds the least element of the lattice. To see this note that for each i y_i is the length of the longest path in G from 0 to i. Therefore, it is the optimal solution cost of $\min y_i$ subject to

the same transformed constraint matrix. This shows that the solution returned by the algorithm is the least element of the lattice. For pure packing (Consec) and mixed (Consec) our algorithms find the largest element of the lattice. To see this note that in both cases y_i is set to the length of a shortest path from 0 to i in G (or $\tilde{G}$). Therefore, it is the optimal solution value of $\max y_i$ subject to the same transformed constraint matrix. This shows that the solution returned by the algorithm is the largest element of the lattice.

If the cost coefficients are monotone nonincreasing we can reverse the order of the variables x_j (i.e., let $x'_j = x_{n+1-j}\ \forall j$), and then use the result in the previous paragraph.

9. Pure packing and pure covering (Circular). In this section we consider the pure cases of (Circular) with either all packing constraints or all consecutive constraints. We present an $O(n^3 \log n + mn \log^2 n)$ time algorithm for the pure packing problem, and show how to improve it to an $O(mn + n^2 \log n)$-time algorithm. For the pure covering problem the same algorithms are derived analogously.

Applying Veinott and Wagner's [VW62] transformation we get a problem where the objective function is $\max y_n$, and there are three types of constraints:

1. $y_j - y_k \leq b_{kj}$ $(n \geq j > k)$ for each consecutive ones constraint.
2. $y_k - y_j + y_n \leq b_{kj}$ $(n > j > k)$ for each circular ones constraint. Here we move y_n to the right-hand side to get a constraint $y_k - y_j \leq b_{kj} - y_n$ $(n > j > k)$.
3. $y_j - y_{j-1} \geq 0$ for each nonnegativity constraint. Multiplying by -1 the constraint is $y_{j-1} - y_j \leq 0$.

The resulting formulation is of the shortest path from 0 to n in a graph $\tilde{G} = (V, A)$, with nodes corresponding to the n variables and one additional node corresponding to $y_0 = 0$, and the set of arcs has all the consecutive constraints represented by *forward* arcs, (i, j) for $i < j$, each of cost b_{ij} (the circular constraints are represented by *backward* arcs (p, q) for $p > q$ of cost $b_{qp} - y_n$ and the nonnegativity constraints, are represented by zero cost *backward* arcs $(j, j-1)$). A graph of this type is displayed in Figure 3. Thus $\tilde{G}$ contains cycles, and parameterized arc costs with $\lambda = y_n$ the parameter. For values of y_n that are large enough there could be negative cost arcs.

Consider applying Cole's algorithm for computing the parametric shortest path from 0 to n in a parametric network in order to compute the optimal value of the parameter y_n^* for which the shortest path is maximum (see section 3). To apply this algorithm, we need a serial algorithm that resolves, for a given parameter value λ, whether y_n^* is greater than λ, equal to λ, or smaller than λ.

The selected serial algorithm is the Bellman–Ford algorithm computing a shortest path from 0 to n for the parameter value λ in $T(n) = O(mn)$ time. Note that decreasing λ increases all the arc lengths, and the length of the shortest path can thus only increase. Respectively, increasing λ only decreases the arc lengths, and the length of the shortest path can only decrease. Therefore, when applying a parametric shortest path algorithm in the network $\tilde{G}$ for a parameter λ, only the following outcomes are possible.

LEMMA 9.1. *Either $y_n^* \leq \lambda$ if there is a negative cycle or the shortest path is at most λ; or $y_n^* > \lambda$ if the shortest path is longer than λ.*

Using Theorem 3.1 with $T(n) = O(mn)$ we conclude that the resulting algorithm for computing y_n^* has a total time complexity of $O(n^3 \log n + \log^2 n(mn))$.

THEOREM 9.1. *Problem (Circular) where all constraints are packing constraints can be solved in $O(n^3 \log n + mn \log^2 n)$ time.*

COROLLARY 9.1. *Problem (Circular) where all constraints are covering con-*

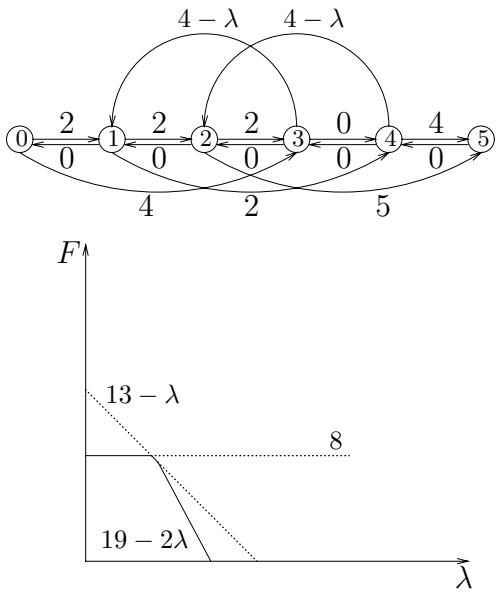

FIG. 3. *A graph $\tilde{G}$ with the corresponding function $F(\lambda) = \min\{8, 13 - \lambda, 19 - 2\lambda\}$.*

straints can be solved in $O(n^3 \log n + mn \log^2 n)$ time.

Proof. By Theorems 7.1 and 9.1. □

If there were a faster single-source shortest path algorithm that can run in poly-log parallel time, we could have gotten a faster algorithm for this case. However, we are not aware of such an algorithm.

An alternative algorithm with better run time to solve the parametric shortest path from 0 to n in $\tilde{G}$ is shown next.

We observe that the length of any path P in $\tilde{G}$ from 0 to n is a linear function of y_n with a slope $-k$ where k is the number of circular arcs in P. The key idea of the improved algorithm is to compute the *entire* lower envelope of the 0 to n shortest path length as a function of the parameter $\lambda = y_n$. For that we apply the algorithm of Young, Tarjan, and Orlin [YTO91], (YTO-algorithm) which computes the entire lower envelope $F(\lambda)$ of the 0 to n shortest path length when each arc has length that is a linear function of a common parameter λ with slope that is either 0 or -1. The time complexity of YTO-algorithm is $O(mn + n^2 \log n)$.

The lower envelope $F(\lambda)$ is a list of $O(n)$ linear functions of λ each representing the length of a shortest path from 0 to n in $\tilde{G}$ using k circular arcs (for some $k \in \{0, 1, 2, \ldots, n-1\}$). In Figure 3 we present a graph $\tilde{G}$ and the corresponding $F(\lambda)$. In this example the shortest path from 0 to 5 that uses only consecutive arcs is 8, with one circular arc is $13 - \lambda$, and two circular arcs is $19 - 2\lambda$.

By Lemma 9.1 and since $F(\lambda)$ is continuous monotone nonincreasing, then if a fixed point solution to the equation $y_n^* = F(y_n^*)$ exists, it is the correct optimal fractional solution to (Circular). Therefore, in order to find an optimal fractional solution, we seek the value y_n^* such that $y_n^* = F(y_n^*)$. It remains to consider the case in which there is no fixed point solution.

A *feasible value* of λ is a value for which the network $\tilde{G}$ does not contain a negative length cycle. Suppose that a fixed point solution y_n^* does not exist. For $\lambda = 0$, $F(0) \geq 0$ since for $\lambda = 0$ the network does not contain a negative length

arc. Since there is no fixed point solution, for all feasible values of λ, $F(\lambda) > \lambda$. Then, by Lemma 9.1, we can resolve comparisons, and therefore conclude that the optimal fractional solution is the maximum value for which the resulting network has no negative cycle. We denote this value by y_n^* as well.

The value of y_n^* can be deduced from the lower envelope in $O(n)$ time as follows: We traverse the list of intervals forming the linear sections of the lower envelope, seeking whether each intersects with the linear function λ. If such intersection exists, then this is the value y_n^*. Otherwise, y_n^* does not belong to this interval. For each interval we spend $O(1)$ time, and since there are $O(n)$ intervals, the total time complexity of this procedure is $O(n)$. If we traverse the entire lower envelope $F(\lambda)$ without reaching to a fixed point solution, then such a fixed point does not exist and we can compute the maximum value for which the resulting network has no negative cycle.

We next use the value of y_n^* to compute for each u, the shortest length of a path from 0 to u in $\tilde{G}$ where the length of the arcs are set using the parameter value $\lambda = y_n^*$. This can be done by using a single application of the Bellman–Ford algorithm on the graph where the values of λ are substituted by y_n^*, in $O(mn)$ time. Denote the resulting distance vector by $\mathbf{y}^* = (y_1^*, y_2^*, \ldots, y_n^*)$.

If y_n^* is an integer, then $\mathbf{y}^*$ is an optimal integral solution. To see this note that when we substitute $\lambda = y_n^*$ we obtain a right-hand side that is an integral vector and the constraint matrix is totally unimodular, and therefore the resulting solution is integral. This solution is obtained by the Bellman–Ford algorithm, and therefore it equals $\mathbf{y}^*$. This solution has a value y_n^* that is the optimal value.

Otherwise, $\mathbf{y}^*$ is an optimal fractional solution which is an optimal solution for the linear programming relaxation of the problem. Reference [BOR80] proved for the unweighted case (as we have) and pure covering problem, that an optimal integral solution is obtained from an optimal fractional solution by rounding-up all the elements of the solution vector $\mathbf{y}$. Using the relation between pure covering problems and pure packing problems, the optimal solution for our problem is obtained by rounding-down $\mathbf{y}^*$; i.e., the optimal solution is $(\lfloor y_1^* \rfloor, \lfloor y_2^* \rfloor, \ldots, \lfloor y_n^* \rfloor)$. The total time complexity of the algorithm is therefore dominated by the complexity of finding $F(\lambda)$, $O(mn + n^2 \log n)$.

THEOREM 9.2. *Problem (Circular) where all constraints are packing constraints that can be solved in $O(mn + n^2 \log n)$ time.*

COROLLARY 9.2. *Problem (Circular) where all constraints are covering constraints that can be solved in $O(mn + n^2 \log n)$ time.*

Proof. By Theorems 7.1 and 9.2. □

10. An O(n min{mn, n² log n + m log² n}) time algorithm for the mixed (Circular) problem. In this section we show an $O(n \min\{mn, n^2 \log n + m \log^2 n\})$-time algorithm that solves problem mixed (Circular). We first present an $O(n^3 \log n + mn \log^2 n)$-time algorithm based on the parametric method, and then an alternative $O(mn^2)$-time algorithm. Together these yield the stated running time.

10.1. An O(n³ log n + mn log² n) time algorithm for mixed (Circular). Consider a covering constraint with circular 1's $\sum_{j=1}^{q'} x_j + \sum_{j=p'+1}^{n} x_j \geq b_{q'p'}$. Let y_n^* be the value of $\sum_{j=1}^{n} x_j$ in an optimal solution. Suppose we knew what y_n^* is, then this constraint can be written as

$$\sum_{j=q'+1}^{p'} x_j \leq y_n^* - b_{q'p'}.$$

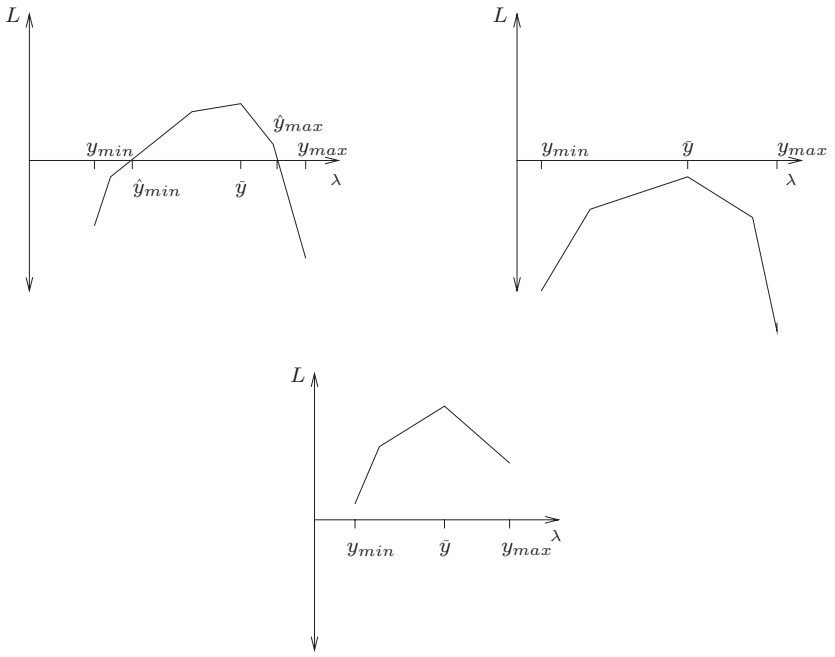

FIG. 4. *Examples of* $L(\lambda)$.

Similarly, a packing constraint with circular 1's $\sum_{j=1}^{q'} x_j + \sum_{j=p'+1}^{n} x_j \leq b_{q'p'}$ can be written as

$$\sum_{j=q'+1}^{p'} x_j \geq y_n^* - b_{q'p'}.$$

Thus the problem becomes a parameterized instance of (Consec) with mixed packing and covering constraints.

Let the right-hand side of a circular constraint (either covering or packing) be denoted by $\bar{b}_{q'p'} = y_n^* - b_{q'p'}$ and for a consecutive constraint $\bar{b}_{q'p'} = b_{q'p'}$. The right-hand sides in this formulation are linear functions of y_n^* with slope 1 or 0. We now convert the covering constraints (and the nonnegativity constraints) into packing constraints, as in section 8, by multiplying these constraints by -1. This result in a formulation of the shortest path from 0 to n where the arcs' lengths are linear functions of the parameter $\lambda = y_n^*$ with slopes -1 or 0 or 1. Note that the YTO-algorithm [YTO91] cannot be applied to solve this parametric shortest path problem as their algorithm is suitable only to the cases where the slopes of λ are either 0 or -1 (by changing the definition of λ it can work also for cases where the slopes are either 0 or $+1$ but not for networks where arcs' lengths are linear functions of the parameter with slopes in $\{-1, 0, +1\}$).

Let the length of a shortest path from 0 to n as a function of $\lambda = y_n$ be as before, $F(\lambda)$. This function is piecewise linear with integer slopes in the range $[-n+1, n-1]$. Since it is a lower envelope of the shortest paths functions of λ, $F(\lambda)$ is a concave function. $F(\lambda)$ is defined for an interval $I = [y_{min}, y_{max}]$, where for $\lambda \in I$ the network does not contain a negative length cycle. In I we define the function $L(\lambda) = F(\lambda) - \lambda$

which is also a piecewise linear concave function with integer slopes in the range $[-n, n-2]$; Figure 4 shows typical cases of $L(\lambda)$.

THEOREM 10.1. *For any $\lambda \in I$, $L(\lambda) \geq 0$ if and only if there is a feasible (fractional) solution vector $\mathbf{y}(\lambda)$ to problem (Circular) whose objective value is λ.*

Proof. Let G_λ be the network where the arcs lengths are set to the parameter value λ. The constraints in (Circular) for $\lambda \in I$ are equivalent to requiring for each arc (u, v) in G_λ that $y_v - y_u$ is at most the length of (u, v).

Assume first that $L(\lambda) \geq 0$. We add a constraint of the form $y_n \leq \lambda$, and find a feasible solution to this augmented set of constraints. Let G'_λ be the corresponding network resulting from adding to G_λ an arc from 0 to n whose length is λ.

Let $\mathbf{y}(\lambda)$ be the shortest paths vector in G'_λ. Then, $y(\lambda)_n \leq \lambda$ because the new arc is a possible path from 0 to n. However, since $L(\lambda) \geq 0$, the length of the shortest path from 0 to n in G_λ is at least λ. Therefore, the length of the shortest path from 0 to n in G'_λ is exactly λ, and $y(\lambda)_n = \lambda$. Thus $\mathbf{y}(\lambda)$ is a feasible solution to problem (Circular) whose cost is exactly λ.

Now suppose that there is a feasible solution $\mathbf{y}(\lambda)$ to problem (Circular) whose cost is exactly λ, so $y(\lambda)_n = \lambda$. Therefore, the shortest path in the network G_λ from 0 to n is of length at least λ, and $F(\lambda) \geq \lambda$. Thus $L(\lambda) \geq 0$. ∎

As a concave function, $L(\lambda)$ satisfies the following lemma.

LEMMA 10.1. *$L()$ has a single maximizer $\tilde{y} \in I$ and at most two zeros $z_1 \leq z_2$. Also, $L(\lambda)$ is increasing for $\lambda \in [y_{min}, \tilde{y})$, and $L(\lambda)$ is decreasing for $\lambda \in (\tilde{y}, y_{max}]$.*

If $L(\tilde{y}) \geq 0$, we let $\hat{y}_{min} = z_1$. We let $\hat{y}_{max}$ be the maximum value in I for which $L(\lambda) \geq 0$, $\hat{y}_{max} = \max\{\lambda \in I | L(\lambda) \geq 0\}$.

If $L(\tilde{y}) < 0$, then by Theorem 10.1, problem (Circular) is infeasible. In this case we do not define $\hat{y}_{min}$ and $\hat{y}_{max}$.

If $L(\lambda) > 0$ for all $\lambda \in I$ such that $\lambda \geq \tilde{y}$, then we set $\hat{y}_{max} = y_{max}$. It follows then from Theorem 10.1 that $\hat{y}_{max}$ is well-defined for all feasible instances of (Circular).

Since our objective is $\max y_n$, an optimal solution is $\hat{y}_{max} = \max\{\lambda \in I | L(\lambda) \geq 0\}$. This is derived by first finding a fractional value $\hat{y}_{max}$ that is an optimal fractional solution value of the linear programming relaxation of (Circular), and then generating from it an optimal integral solution.

We now show how to use Cole's method for computing the parametric shortest path from 0 to n in order to find $\hat{y}_{max}$, which is the solution of the linear programming relaxation of (Circular). The use of this algorithm requires the resolution of $O(\log^2 n)$ questions of the type, "is $y^*_n \leq \lambda_c$?". In order to resolve such a comparison we apply the Bellman–Ford algorithm to find the 0 to n shortest path where the arcs lengths are evaluated for $\lambda = \lambda_c$. The time complexity of this algorithm is $O(mn)$. The result obtained from the Bellman–Ford algorithm is either a negative length cycle C in the network or a shortest path P from 0 to n if a negative length cycle does not exist.

We now show how to resolve the comparison using the output of the Bellman–Ford algorithm.

1. If the Bellman–Ford algorithm finds a negative length cycle C, then we compute the linear function $f_C(\lambda)$ that defines its length. Since this is a negative cycle, we know that $f_C(\lambda_c) < 0$. We compute the slope (derivative) of $f_C(\lambda)$ at λ_c, $f'_C(\lambda_c)$.
   - If $f'_C(\lambda_c) \geq 0$, then for every $\lambda \leq \lambda_c$ the length of C remains negative, and therefore if (Circular) is feasible, then $y^*_n > \lambda_c$.
   - If $f'_C(\lambda_c) < 0$, then for every $\lambda \geq \lambda_c$ the length of C remains negative, and therefore if (Circular) is feasible, then $y^*_n < \lambda_c$.

- If $f'_C(\lambda_c) = 0$, then for all λ the length of C remains negative and therefore (Circular) is infeasible (because the maximum of $F(\lambda)$ is attained at λ_c).

2. If the Bellman–Ford algorithm finds a shortest path P from 0 to n, then there are no negative cycles and $\lambda_c \in I$. We compute the linear function $f_P(\lambda)$ for the length of P. Since P is a shortest path for $\lambda = \lambda_c$, there is a sufficiently small interval that contains λ_c such that P is the shortest path for λ in that interval, and $f_P(\lambda) - \lambda$ and $L(\lambda)$ coincide in that interval. The slope of $L(\lambda)$ in this interval is $L'(\lambda) = f'_P(\lambda) - 1$.
   - If $f'_P(\lambda_c) - 1 > 0$, then L is increasing in λ_c, and therefore by Lemma 10.1, $\lambda_c \in [y_{min}, \tilde{y})$. Therefore, if (Circular) is feasible, then $y^*_n \geq \tilde{y}$, and thus $y^*_n > \lambda_c$.
     If (Circular) is infeasible, then $I \neq \emptyset$ as for λ_c the network does not contain negative length cycles so $\lambda_c \in I$. Hence, from Theorem 10.1, $L(\lambda) < 0\ \forall \lambda \in I$. In this case it is correct to resolve the comparison in an arbitrary way as all possibilities will be infeasible. Therefore, it is correct to resolve the comparison with $y^*_n > \lambda_c$. Therefore, if the slope of $f_P(\lambda) - \lambda = L(\lambda)$ is positive at $\lambda = \lambda_c$ we conclude that $y^*_n > \lambda_c$.
   - If $f'_P(\lambda_c) - 1 \leq 0$, then $L(\lambda)$ is nonincreasing at λ_c.
     - If $f_P(\lambda_c) > \lambda_c$, then $L(\lambda_c) > 0$, and therefore $\lambda_c \in [\tilde{y}, \hat{y}_{max})$. Hence $y^*_n > \lambda_c$.
     - If $f_P(\lambda_c) = \lambda_c$, then $L(\lambda_c) = 0$, and therefore $y^*_n = \lambda_c$.
     - If $f_P(\lambda_c) < \lambda_c$, then $L(\lambda_c) < 0$. Hence $\lambda_c \in (\hat{y}_{max}, y_{max}]$, and therefore if (Circular) is feasible, then $y^*_n < \lambda_c$. Even if (Circular) is infeasible we may resolve the comparison as $y^*_n < \lambda_c$ (because in this case we can resolve any comparison in an arbitrary way).

We thus showed a $T(n) = O(mn)$-time algorithm that resolves a single comparison. By Theorem 3.1 it then follows that $\hat{y}_{max}$ is found in $O(n^3 \log n + mn \log^2 n)$ time. This value may be fractional as it is an optimal solution to the linear programming relaxation.

Using the optimal solution $\hat{y}_{max}$, if fractional, we get an optimal integer solution by rounding down the solution cost to $\lfloor \hat{y}_{max} \rfloor$. This is the optimal value of an integral solution, but we still need to find a corresponding integral solution. We substitute the value of $y^*_n = \lfloor \hat{y}_{max} \rfloor$ in the circular constraints: $\sum_{j=q'+1}^{p'} x_j \leq y^*_n - b_{q'p'}$ and $\sum_{j=q'+1}^{p'} x_j \geq y^*_n - b_{q'p'}$. The resulting constraints are exactly the constraints of mixed (Consec) which we solve with the algorithm of section 8. This computation is done in $O(mn)$ time and results in an integer solution. Therefore, we have the following theorem.

THEOREM 10.2. *There is an $O(n^3 \log n + mn \log^2 n)$-time algorithm that solves problem (Circular) with both covering and packing constraints.*

10.2. An $O(mn^2)$ time algorithm for mixed (Circular). We use the following facts obtained in the previous subsection.

- If the value of y^*_n is given, then an optimal solution can be found in $O(mn)$ time using the Bellman–Ford algorithm in a network where the arc lengths depend on y^*_n.
- For a given value of $\lambda = y_n$, one can check in $O(mn)$ time if (Circular) is feasible for this parameter value, and if so obtain a feasible solution of this value.

We next show how to implement the algorithm of the previous subsection for all values of y_n simultaneously in $O(mn^2)$ time. The idea is to construct the entire lower envelope of the shortest path lengths as a function of the parameter value λ. This is similar to the idea used by Young, Tarjan, and Orlin [YTO91] except that their algorithm constructs solutions for a sequence of different values of the parameter one after the other, whereas our algorithm constructs the entire lower envelope simultaneously. Our algorithm is based on implementing the Bellman–Ford algorithm for all values of λ simultaneously with an increase of run time compared to the nonparametric case of factor $O(n)$. We first present the nonparametric Bellman–Ford algorithm for arc costs c_{ij}, and then its adjustment to the parametric case.

Bellman–Ford algorithm:
Input: A graph $G = (\{0, 1, 2, \ldots, n\}, E)$ with arc lengths c_{ij}.
Output: Either a certificate of a negative length cycle, or for each i, the length of a shortest path from 0 to i in G.

Initialization: $u_0^1 = 0$, $u_i^1 = c_{0i}$ $\forall i$.
For $m = 2$ **to** $n + 1$ **do**
For $i = 0$ **to** n **do**
$u_i^m = \min\{u_i^{m-1}, \min_{j \neq i}\{u_j^{m-1} + c_{ji}\}\}$.

Negative cycle detector: If there is i such that $u_i^{n+1} < u_i^n$, then **return** G has a negative length cycle.
Otherwise, **return** $(u_i^n)_{i=1}^n$.

For the parametric problem each arc cost is of the form $\bar{b}_{i,j} = b_{i,j} + c\lambda$ for $c \in \{-1, 0, 1\}$. The length of the shortest path from 0 to i is therefore a concave piecewise linear lower envelope with up to $2n + 1$ linear functions with integer slopes in $[-n, n]$. We retain these functions as an *array* $\mathbf{u}$ of $2n + 1$ entries. Each entry $j \in [-n, n]$ has a linear function $a + j\lambda$ with the least constant value a among all functions of the same slope j, as only the one with the least constant can be on the lower envelope. Note that the lower envelope does not necessarily contain all the functions in the array, but possibly only a strict subset of them. The adjustments made in the parametric version of the Bellman–Ford algorithm are:

- *Initialization* $\mathbf{u}_0^1 = 0$, $\mathbf{u}_i^1 = \bar{b}_{0,i}$ $\forall i$*:* This is implemented in the same time complexity as the initialization step in the Bellman–Ford algorithm.
- *Computing* $\mathbf{u}_j^{m-1} + \bar{b}_{j,i}$*:* This requires computing the piecewise linear function array obtained from another function array by adding a linear function $c\lambda + d$ with $c \in \{-1, 0, 1\}$ and $d = \bar{b}_{j,i}$. This is done by adding d to all the constants of the linear functions of the array and then shift the array functions by one position to the right if $c = 1$, or to the left if $c = -1$, in $O(n)$ time. A faster way to implement this step is by using dynamic trees data structure in $O(\log n)$. This, however, is not going to affect the overall complexity, and thus is not discussed in detail.
- *Minimum of a pair of piecewise linear functions:* This operation is used in the line $\mathbf{u}_i^m = \min\{\mathbf{u}_i^{m-1}, \min_{j \neq i}\{\mathbf{u}_j^{m-1} + \bar{b}_{j,i}\}\}$ of the Bellman–Ford algorithm. For the parametric version this is done by comparing two entries of the same slope in the two arrays and take the one with the lower constant term. If only one of the arrays has a linear function, then that function becomes the one corresponding entry of the minimum array. This operation is implemented in $O(n)$ time.

So the main part of the parametric algorithm has complexity $O(mn^2)$. We now need to address the negative cycle detection. A negative cycle is identified, when the piecewise linear concave lower envelope U_i^{n+1} is strictly below U_i^n for some i.

To find the representation of the lower envelope of the linear functions as a sequence of $O(n)$ breakpoints and the slopes of the lines between them, we scan the array progressing from the largest slope linear function to lower slope functions. Having evaluated the jth lower envelope including the functions with slopes from n to j, we find the intersection of the jth lower envelope with the next linear function of slope $j-1$ or less. If the breakpoint of the intersection of the linear function of slope $j-1$ with the rightmost linear function in the envelope is left of the previously evaluated rightmost breakpoint br, then br and the slope of the line adjacent to br's right are omitted from the jth lower envelope and the intersection step of the rightmost linear function with the linear function of slope $j-1$ or less is repeated. If the intersection is to the right of all previously evaluated breakpoints it is added with the new linear function to the $j-1$st lower envelope. Each step involves finding the intersection of two linear functions in $O(1)$ and is associated either with proceeding to the next iteration, or else in the elimination of a breakpoint previously evaluated. Since there are at most $O(n)$ breakpoints, the total number of operations is $O(n)$.

We thus find the lower envelopes of U_i^n and U_i^{n+1} in $O(n^2)$ operations for all i. Note that $U_i^{n+1}() \leq U_i^n()$. For values of λ such that $U_i^{n+1}(\lambda) < U_i^n(\lambda)$, there is a negative length cycle that contains i. If (Circular) is feasible, then there is an interval $[y_{min}^i, y_{max}^i]$ such that for $y_n \in [y_{min}^i, y_{max}^i]$, the network does not contain a negative length cycle that contains i. If there exists i such that $U_i^{n+1}(\lambda) < U_i^n(\lambda)$ for all λ, then (Circular) is infeasible and we can identify such cases in $O(n)$ time (for each i) by computing the (empty) intersection of U_i^n and U_i^{n+1}. Therefore, the two functions U_i^n and U_i^{n+1} intersect in at most two points $y_{min}^i < y_{max}^i$, and we can compute these points in $O(n)$ time for each i.

Let $[y_{min}, y_{max}] = \bigcap_i [y_{min}^i, y_{max}^i]$. To find this interval of parameter values for which the network does not contain a negative cycle, we initialize the interval $[y_{min}, y_{max}]$ to $[0, \infty)$ and intersect it for each i with the interval $[y_{min}^i, y_{max}^i]$. This requires additional run time not exceeding $O(n^2)$.

Therefore, the total complexity of this procedure is $O(mn^2)$. At termination we have an interval $[y_{min}, y_{max}]$, such that for each integer value in this interval there is a feasible solution to (Circular) with this cost. We set the value of y_n to be $\lfloor y_{max} \rfloor$, and then apply the algorithm for mixed (Consec) problem in $O(mn)$-time complexity using Theorem 8.1. This algorithm outputs the solution with cost $\lfloor y_{max} \rfloor$.

THEOREM 10.3. *There is an $O(mn^2)$-time algorithm that solves problem (Circular) with both covering and packing constraints.*

11. Conclusions. We address here covering and packing problems on circular 1's constraints. We show how to solve such problems efficiently and in strongly polynomial time, thereby improving on the method of solving these problems as a parametric dual of minimum cost network flow.

Appendix: Extensions of Bartholdi, Orlin, and Ratliff.

Extension to mixed problems. In applying the transformation of Veinott and Wagner to the constraint matrix of the problem, let $\left[\begin{array}{c|c} \overline{A_{cover}} & \overline{A_{\cdot,n_{cover}}} \\ \hline \overline{A_{pack}} & \overline{A_{\cdot,n_{pack}}} \end{array}\right]$ be the resulting transformed constraint matrix where $\left[\begin{array}{c} \overline{A_{\cdot,n_{cover}}} \\ \hline \overline{A_{\cdot,n_{pack}}} \end{array}\right]$ is the transformed column that

corresponds to y_n. Let $\begin{bmatrix} b_{cover} \\ b_{pack} \end{bmatrix}$ denote the right-hand side vector. For $\overline{c_i} = \sum_{j=1}^{i} c_j$, $[\overline{c}, \overline{c_n}]$ is the transformed cost coefficient vector where $\overline{c_n}$ is the coefficient of y_n. Let $\overline{y} = [y_1, y_2, \ldots, y_{n-1}]$, then, the transformed problem is

$$\begin{aligned} \min \quad & \overline{cy} + \overline{c_n} y_n \\ \text{subject to:} & \\ \overline{A_{cover}}\overline{y} + \overline{A_{\cdot,n_{cover}}} y_n &\geq b_{cover} \\ \overline{A_{pack}}\overline{y} + \overline{A_{\cdot,n_{pack}}} y_n &\leq b_{pack} \\ \overline{y}, y_n \quad & \text{unrestricted integer.} \end{aligned}$$

For a specified integer value of y_n we get the problem

$$\begin{aligned} P(y_n) &= \overline{c_n} y_n + \min \overline{cy} \\ \text{subject to:} & \\ \overline{A_{cover}}\overline{y} &\geq b_{cover} - \overline{A_{\cdot,n_{cover}}} y_n \\ \overline{A_{pack}}\overline{y} &\leq b_{pack} - \overline{A_{\cdot,n_{pack}}} y_n \\ \overline{y} \quad & \text{unrestricted.} \end{aligned}$$

Although the integrality constraints for $\overline{y}$ are dropped here, it is shown in what follows that it does not affect the algorithm.

Multiplying the packing constraints by -1 we get

$$\begin{aligned} P(y_n) &= \overline{c_n} y_n + \min \overline{cy} \\ \text{subject to:} & \\ \overline{A_{cover}}\overline{y} &\geq b_{cover} - \overline{A_{\cdot,n_{cover}}} y_n \\ (-\overline{A_{pack}})\overline{y} &\geq \overline{A_{\cdot,n_{pack}}} y_n - b_{pack} \\ \overline{y} \quad & \text{unrestricted.} \end{aligned}$$

The dual of this problem is

$$\begin{aligned} D(y_n) = \overline{c_n} y_n &+ \max \lambda_{cover}(b_{cover} - \overline{A_{\cdot,n_{cover}}} y_n) \\ &+ \lambda_{pack}(\overline{A_{\cdot,n_{pack}}} y_n - b_{pack}) \\ \text{subject to:} & \\ \lambda_{cover}\overline{A_{cover}} - \lambda_{pack}\overline{A_{pack}} &= \overline{c} \\ \lambda_{cover}, \lambda_{pack} &\geq 0. \end{aligned}$$

$D(y_n)$ is a MCNF problem, where the arcs' cost are parameterized by a common parameter y_n. Then, as in Lemmas 1.1 and 1.2 in [BOR80], the optimal solution cost is a convex function of y_n and the optimal solution satisfies $y_n^* \leq \sum_i b_i$. One can thus apply binary search using $O(log \sum_i b_i)$ applications of a MCNF algorithm. The total complexity of the resulting algorithm when we use Orlin's [Orl93] algorithm for the MCNF is $O(\log(\sum_i b_i)[n \log n(m + n \log n)])$.

It remains to show that when we find the optimal integer value y_n^*, we can find a feasible integral solution $\overline{y}$ with this cost. We use Orlin's algorithm for solving $D(y_n^*)$. Orlin's algorithm produces both primal solution $(\lambda_{cover}, \lambda_{pack})$ (i.e., a solution to $D(y_n^*)$) and a dual solution $\overline{y}$ (i.e., a solution to $P(y_n^*)$). For an integer value of y_n^*, both the right-hand side and the objective function of $D(y_n^*)$ are integral. Therefore,

Orlin's algorithm produces an integer solution for both $P(y_n^*)$ and $D(y_n^*)$, and the above algorithm produces an integer optimal solution.

A modified strongly polynomial time algorithm. From the previous subsection it follows that problem (Circular) can be solved by solving a parametric MCNF problem where the costs are parameterized by the single common parameter $\lambda = y_n^*$. The use of the parametric method described in section 3 results in an $O(n^4 \log^2 n + n^2 m \log^4 n)$-time algorithm. Thus we show the following theorem.

Theorem. There is an $O(n^4 \log^2 n + n^2 m \log^4 n)$-time algorithm that solves problem (Circular) with a general linear cost function.

APPROXIMATION ALGORITHM FOR THE MIXED FRACTIONAL PACKING AND COVERING PROBLEM*

KLAUS JANSEN†

Abstract. We propose an approximation algorithm based on the Lagrangian or price-directive decomposition method to compute an ϵ-approximate solution of the mixed fractional packing and covering problem: find $x \in B$ such that $f(x) \leq (1+\epsilon)a$, $g(x) \geq (1-\epsilon)b$, where $f(x), g(x)$ are vectors with M nonnegative convex and concave functions, a and b are M-dimensional nonnegative vectors, and B is a convex set that can be queried by an optimization oracle. We propose an algorithm that needs only $O(M\epsilon^{-2}\ln(M\epsilon^{-1}))$ iterations or calls to the oracle. The main contribution is that the algorithm solves the general mixed fractional packing and covering problem (in contrast to pure fractional packing and covering problems and to the special mixed packing and covering problem with $B = \mathbb{R}^N_+$) and runs in time independent of the so-called width of the problem.

1. Introduction.

We study mixed fractional packing and covering problems (MPC_ϵ) of the following form: Given a vector $f : B \to \mathbb{R}^M_+$ of M nonnegative continuous convex functions and a vector $g : B \to \mathbb{R}^M_+$ of M nonnegative continuous concave functions, two M-dimensional nonnegative vectors a, b, a nonempty convex compact set B, and a relative tolerance $\epsilon \in (0, 1)$, find an approximately feasible vector $x \in B$ such that $f(x) \leq (1+\epsilon)a$ and $g(x) \geq (1-\epsilon)b$ or find a proof that no vector is feasible (that satisfies $x \in B$, $f(x) \leq a$, and $g(x) \geq b$). Without loss of generality we may assume that a and b are equal to the vector e of all ones.

The fractional packing problem with convex constraints, i.e., to find $x \in B$ such that $f(x) \leq (1+\epsilon)a$, is solved in [3, 4, 7] by the Lagrangian decomposition method in $O(M(\epsilon^{-2} + \ln M))$ iterations where each iteration requires a call to an approximate block solver $ABS(p, t)$ of the form: find $\hat{x} \in B$ such that $p^T f(\hat{x}) \leq (1+t)\Lambda(p)$ where $\Lambda(p) = \min_{x \in B} p^T f(x)$. Furthermore, Grigoriadis et al. [5] also proposed an approximation algorithm for the fractional covering problem with concave constraints, i.e., to find $x \in B$ such that $g(x) \geq (1-\epsilon)b$, within $O(M(\epsilon^{-2}+\ln M))$ iterations where each iteration requires here a call to an approximate block solver $ABS(q, t)$ of the form: find $\hat{x} \in B$ such that $q^T g(\hat{x}) \geq (1-t)\Lambda(q)$, where $\Lambda(q) = \max_{x \in B} q^T g(x)$. Both algorithms also solve the corresponding min-max and max-min optimization variants within the same number of iterations. Furthermore, the algorithms can be generalized to the case where the block solver has arbitrary approximation ratio [6, 7, 8].

Part of this work was done while the author was visiting the Department of Computer Science at ETH Zürich.

Further interesting algorithms for the fractional packing and fractional covering problem with linear constraints were developed by Plotkin, Shmoys, and Tardos [10] and Young [11]. These algorithms have a running time that depends linearly on the width—an unbounded function of the input instance. Several relatively complicated techniques were proposed to reduce this dependence. Garg and Könemann [2] and Könemann [9] described a nice algorithm for the fractional packing problem with linear constraints that needs only $O(M\epsilon^{-2}\ln M)$ iterations. On the other hand, the algorithm by Grigoriadis et al. [5] is the only known algorithm that solves the fractional covering problem with a number of iterations independently of the width.

For the mixed packing and covering problem (with linear constraints), Plotkin, Shmoys, and Tardos [10] also proposed approximation algorithms where the running time depends on the width. Young [12] described an approximation algorithm for a special mixed packing and covering problem with linear constraints and special convex set $B = \mathbb{R}^N_+$. The algorithm has a running time of $O(M^2\epsilon^{-2}\ln M)$. Recently, Fleischer [1] gave an approximation scheme for the optimization variant (minimizing $c^T x$ such that $Cx \geq b$, $Px \leq a$, and $x \geq 0$ where a, b, and c are nonnegative integer vectors and P and C are nonnegative integer matrices). Young [12] posed the following interesting open problem: find an efficient width-independent Lagrangian-relaxation algorithm for the abstract mixed packing and covering problem, find $x \in B$ such that $Px \leq (1+\epsilon)a$, $Cx \geq (1-\epsilon)b$, where P, C are nonnegative matrices, a, b are nonnegative vectors, and B is a polytope that can be queried by an optimization oracle (given a vector c, return $x \in B$ minimizing $c^T x$) or some other suitable oracle.

New result. Our contribution here is to present an efficient width-independent Lagrangian-relaxation algorithm for the mixed packing and covering problem that uses a suitable optimization oracle of the form: given two vectors c, d, return $x \in B$, $c^T x \geq 1$, minimizing $d^T x$. Interestingly, it is also sufficient to use a feasibility oracle of the form: given two vectors c, d, return $x \in B$ such that $c^T x \geq 1$ and $d^T x \leq 1$. This solves the open problem by Young [12]. Interestingly, our algorithm also works for a more general problem with a convex set B and nonnegative convex packing and concave covering constraints.

The algorithm uses a variant of the Lagrangian or price-directive decomposition method. This is an iterative strategy that solves (MPC_ϵ) by computing a sequence of triples (p, q, x) as follows. A coordinator uses the current vector $x \in B$ to compute two price vectors $p = p(x) \in \mathbb{R}^M_+$ and $q = q(x) \in \mathbb{R}^M_+$ with $\sum_{m=1}^M p_m + q_m = 1$. Then the coordinator calls an optimization oracle to compute a solution $\hat{x} \in B$ of the block problem (BP)

$$\Lambda(p,q) = \min\left\{ p^T f(y) | y \in B, q^T g(y) \geq \sum_{m=1}^M q_m \right\},$$

and makes a move from x to $(1-\tau)x + \tau\hat{x}$ with an appropriate step length $\tau \in (0,1)$. Such an iteration is called a coordination step. For our algorithm, we require only an approximate block solver (ABS) that solves the underlying block problem to a given relative tolerance $t \in (0,1)$:

$$\begin{aligned} ABS(p,q,t): \qquad \text{compute} \qquad & \hat{x} = \hat{x}(p,q) \in B \text{ such that} \\ & p^T f(\hat{x}) \leq (1+t)\Lambda(p,q), \\ & q^T g(\hat{x}) \geq \tfrac{1}{1+t} \sum_{m=1}^M q_m. \end{aligned}$$

Our main result is the following theorem.

THEOREM 1.1. *There is an approximation algorithm that for any given accuracy* $\epsilon \in (0,1)$ *solves the mixed fractional packing and covering problem* (MPC_ϵ) *within*

$$N = O(M\epsilon^{-2}\ln(M\epsilon^{-1}))$$

iterations or coordination steps, each of which requires a call to $ABS(p,q,\Theta(\epsilon))$ *and a coordination overhead of* $O(M\ln(M\epsilon^{-1}))$ *arithmetic operations.*

Alternatively, instead of using the approximate block solver, an approximate feasibility oracle of the form compute $\hat{x} \in B$ such that $p^T f(\hat{x}) \le (1+t)\sum_{m=1}^M p_m$ and $q^T g(\hat{x}) \ge \frac{1}{1+t}\sum_{m=1}^M q_m$ is also sufficient.

Main ideas. If the mixed packing and covering problem has a solution, then there is a vector $y \in B$ with $f(y) \le e$ and $g(y) \ge e$. This vector satisfies $q^T g(y) = \sum_{m=1}^M q_m g_m(y) \ge \sum_{m=1}^M q_m$ and $p^T f(y) = \sum_{m=1}^M p_m f_m(y) \le \sum_{m=1}^M p_m$. This implies that the block problem has a solution of value at most $\sum_{m=1}^M p_m$. Furthermore if there is a feasible solution, then the objective value $\Lambda(p,q) \le \sum_{m=1}^M p_m$ and $p^T f(\hat{x}) \le (1+t)\sum_{m=1}^M p_m$. In other words, if $p^T f(\hat{x}) > (1+t)\sum_{m=1}^M p_m$, then we can conclude that there is no solution of the mixed packing and covering problem.

Suppose now that there is a feasible solution of our mixed packing and covering problem. For a given vector $x \in B$, the objective value can be defined by

$$\lambda(x) = \max\{f_1(x), \ldots, f_M(x), 1/g_1(x), \ldots, 1/g_M(x)\}.$$

If $g_m(x) = 0$ for one component $m \in \{1,\ldots,M\}$, then we define $\lambda(x) = \infty$.

One of the main ideas is to combine two different potential functions that were proposed for pure fractional packing and covering problems [4, 5]. We associate here with the packing and covering constraints $f(x) \le \lambda e$ and $g(x) \ge (1/\lambda)e$ the following potential function:

$$\begin{aligned}\Phi'_t(\theta,x) &= (2+t)\ln\theta - \tfrac{t}{M}\sum_{m=1}^M \ln(\theta - f_m(x)) - \tfrac{t}{M}\sum_{m=1}^M \ln(g_m(x)\theta - 1)\\ &= 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^M \ln(\theta - f_m(x)) - \tfrac{t}{M}\sum_{m=1}^M \ln(g_m(x) - \tfrac{1}{\theta}),\end{aligned}$$

where $\theta \in \mathbb{R}_+$ and $t > 0$ is a tolerance that depends on ϵ and is used in the approximate block solver. The function Φ' can be extremely small, since there is no upper bound on the function values $g_m(x)$. Let A be a nonempty subset of $\mathcal{M} = \{1,\ldots,M\}$. To control the values of the covering functions $g_m(x)$ and to have a lower bound for the potential function, we eliminate functions g_m (and the corresponding index in A) when the function value $g_m(x)$ is larger than a prespecified threshold value T and modify the potential function. Let $A(x)$ denote the index set corresponding to a given vector $x \in B$. Then the modified potential function has the form

$$\begin{aligned}\Phi_t(\theta,x,A(x)) &= 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^M \ln(\theta - f_m(x)) - \tfrac{t}{M}\sum_{m\in A(x)} \ln(g_m(x) - \tfrac{1}{\theta})\\ &\quad - \tfrac{t}{M}\sum_{m\notin A(x)} \ln(T).\end{aligned}$$

The potential function Φ_t has a unique minimum $\theta_{A(x)}(x)$ that approximates the objective value $\lambda_{A(x)}(x) = \max(\max_{m\in\mathcal{M}} f_m(x), \max_{m\in A(x)} 1/g_m(x))$. This potential

function Φ_t and the minimizer $\theta_{A(x)}(x)$ are used to define the price vectors $p = p(x)$ and $q = q(x)$ for the current vector $x \in B$ and to optimize in the correct direction. Another important parameter for the convergence of the algorithm is the reduced potential value $\phi_t(x, A(x)) = \Phi_t(\theta_{A(x)}(x), x, A(x))$ for $x \in B$ and $A(x) \subset \{1, \ldots, M\}$ (see the discussion below). Since we cannot control the values of eliminated functions g_m for $m \notin A(x)$ (after the elimination), at the end of each phase s we take a convex combination over different computed vectors.

The step length τ is defined carefully in dependence on the minimizer $\theta_{A(x)}(x)$ of the potential function. In the general case, the coordinator moves from solution x to $(1-\tau)x + \tau\hat{x}$ and sets the index set $A(x') = \{m \in A(x) | g_m(x') < T\}$. In the case where $\max_{m \in A} g_m(x)(1-\tau) + g_m(\hat{x})\tau > T$, we reduce the step length from τ to $\bar{\tau}$ and use as next vector $x' = (1-\bar{\tau})x + \bar{\tau}\hat{x}$. This is important for the convergence analysis.

Our algorithm computes solutions within different phases. Starting with an initial solution $x^{(0)}$ with objective value $\lambda(x^{(0)}) = O(M)$, we compute in phase s a solution $x^{(s)}$ with objective value $\lambda(x^{(s)}) \leq 1/(1-\epsilon_s)$, where $\epsilon_1 = 1/2$ and $\epsilon_s = \epsilon_{s-1}/2$ for $s \geq 2$. In the potential function, the parameters t and T are replaced by parameters t_s and $T(s)$ (that depend on phase s), respectively. We stepwise decrease the objective values until $\epsilon_s \leq \epsilon/2$. The solution $x^{(s)}$ in the last phase satisfies $f_m(x^{(s)}) \leq 1/(1-\epsilon/2) \leq 1+\epsilon$ and $1/g_m(x^{(s)}) \leq 1/(1-\epsilon/2)$ or, equivalently, $g_m(x^{(s)}) \geq 1-\epsilon/2 > 1-\epsilon$.

The main argument in the proof of the convergence is to show that the reduced potential values $\phi_t(x, A(x))$ (that approximate the objective values $\lambda_{A(x)}(x)$) are monotone decreasing. If we do not eliminate a covering function g_m (i.e., $A(x) = A(x')$), then the difference

$$\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq t^3/(4M).$$

In the case where we eliminate a covering function g_m (i.e., $A(x) \neq A(x')$), the difference

$$\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq 0.$$

To show this inequality, we use the fact that the step length τ is reduced to $\bar{\tau}$ when $\max_{m \in A} g_m(x)(1-\tau) + g_m(\hat{x})\tau > T$. This enables us to prove that

$$\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y})) \geq \Theta(t^3/M)(N_s - M - 1),$$

where N_s is the number of iterations, y is the initial solution, and $\bar{y}$ is the solution after $N_s - 1$ iterations in phase s. Using the modification of the potential function and the implied lower bound for $\phi_t(\bar{y}, A(\bar{y}))$, the difference $\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y}))$ is at most $O(t \ln(M/t))$ (where $t = t_s = \Theta(\epsilon_s)$ depends on phase s). This gives us an upper bound for the number N_s of iterations in phase s and the total number N of iterations.

The paper is organized as follows. In section 2 we show some properties of the used potential function and define the price vectors $p(x)$ and $q(x)$. In section 3 we describe our approximation algorithm. After giving the algorithm we describe the main techniques in detail. We show how to compute an initial solution in subsection 3.1. In subsection 3.2 we describe the stopping rules and prove some properties. In subsections 3.3 and 3.4 we define the step lengths depending on the cases described above, and we prove that the decrease in the reduced potential is sufficiently large. After that in subsection 3.5 we show how to get a good solution for all constraints using the convex combination. Finally in section 4 we determine the total number of iterations and show how to approximate the minimizer of the potential function.

2. Potential function and price vectors. Let A be a nonempty subset of $\mathcal{M} = \{1, \ldots, M\}$. During a phase, we eliminate a concave function g_m (and the corresponding index in A) when the function value $g_m(x) \geq T$. Let $A(x)$ denote the index set corresponding to a given vector $x \in B$.

2.1. Potential function. The used potential function has the form

$$\begin{aligned}\Phi_t(\theta, x, A(x)) \;=\; & 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^{M}\ln(\theta - f_m(x)) - \tfrac{t}{M}\sum_{m\in A(x)}\ln(g_m(x) - \tfrac{1}{\theta}) \\ & -\tfrac{t}{M}\sum_{m\notin A(x)}\ln(T).\end{aligned}$$

For simplicity we use $A = A(x)$ (if the dependence is clear). The potential function Φ_t is well defined for $\lambda_A(x) < \theta < \infty$, where

$$\lambda_A(x) = \max\left(\max_{1\leq m\leq M} f_m(x), \max_{m\in A}\frac{1}{g_m(x)}\right).$$

If $g_m(x) = 0$ for at least one index $m \in A$, then we define $\lambda_A(x) = \infty$. Furthermore, Φ_t has the barrier property (i.e., $\Phi_t(\theta, x, A) \to \infty$ for $\theta \to \infty$ and for $\theta \to \lambda_A(x)$). We define the reduced potential function $\phi_t(x, A)$ as the minimum value $\Phi_t(\theta, x, A)$ over $\theta \in (\lambda_A(x), \infty)$ for a given $x \in B$. The minimizer $\theta_A(x)$ can be determined from the first-order optimality condition:

$$\frac{t\theta}{M}\sum_{m=1}^{M}\frac{1}{\theta - f_m(x)} + \frac{t}{M\theta}\sum_{m\in A}\frac{1}{g_m(x) - 1/\theta} = 2. \tag{2.1}$$

Consider the function $h(\theta) = \frac{t}{M}(\sum_{m=1}^{M}\frac{\theta}{\theta - f_m(x)} + \frac{1}{\theta}\sum_{m\in A}\frac{1}{g_m(x)-1/\theta})$. Notice that $h(\theta) \to \infty$ for $\theta \to \lambda_A(x)$ and $h(\theta) \to t < 1$ for $\theta \to \infty$. Since $\frac{\theta}{\theta - f_m(x)}$ and $\frac{1}{g_m(x)\theta - 1}$ are decreasing in θ, the function $h(\theta)$ is also decreasing for $\theta \in (\lambda_A(x), \infty)$. Therefore, we have a unique minimum $\theta_A(x)$. The implicit function $\theta_A(x)$ approximates $\lambda_A(x)$. This is important for the further analysis.

LEMMA 2.1.

$$\frac{\theta_A(x)}{(1 + t/(2M))} \geq \lambda_A(x) \geq \theta_A(x)\left(1 - \frac{t}{2} - \frac{t|A|}{2M}\right) \geq \theta_A(x)(1 - t).$$

Proof. First, we consider a function value $f_m(x)$. Since $f_m(x) \leq \lambda_A(x)$, we have $\theta_A(x) - f_m(x) \geq \theta_A(x) - \lambda_A(x)$. This implies

$$\frac{\theta_A(x)}{\theta_A(x) - f_m(x)} \leq \frac{\theta_A(x)}{\theta_A(x) - \lambda_A(x)}.$$

Furthermore, $g_m(x) \geq 1/\lambda_A(x)$ for each $m \in A$. This gives

$$g_m(x) - \frac{1}{\theta_A(x)} \geq \frac{\theta_A(x) - \lambda_A(x)}{\lambda_A(x)\theta_A(x)}$$

or, equivalently,

$$\frac{\frac{1}{\theta_A(x)}}{g_m(x) - \frac{1}{\theta_A(x)}} \leq \frac{\lambda_A(x)}{\theta_A(x) - \lambda_A(x)} < \frac{\theta_A(x)}{\theta_A(x) - \lambda_A(x)}.$$

Combining both inequalities we obtain

$$\begin{aligned} 1 &= \tfrac{t}{2M}\sum_{m=1}^{M}\tfrac{\theta_A(x)}{\theta_A(x)-f_m(x)} + \tfrac{t}{2M}\sum_{m\in A}\tfrac{1/\theta_A(x)}{g_m(x)-1/\theta_A(x)} \\ &\leq \tfrac{t}{2M}(M+|A|)\tfrac{\theta_A(x)}{\theta_A(x)-\lambda_A(x)}. \end{aligned}$$

This implies now

$$\theta_A(x) - \lambda_A(x) \leq \frac{t(M+|A|)}{2M}\theta_A(x)$$

or

$$\lambda_A(x) \geq \theta_A(x)\left(1 - \frac{t}{2} - \frac{t|A|}{2M}\right) \geq \theta_A(x)(1-t).$$

On the other hand, (using the definition of $\lambda_A(x)$), there is an index $m \in \{1,\ldots,M\}$ with $\lambda_A(x) = f_m(x)$ or an index $m \in A$ with $\lambda_A(x) = 1/g_m(x)$.

Case 1. $\lambda_A(x) = f_m(x)$. In this case $\frac{t\theta_A(x)}{2M(\theta_A(x)-\lambda_A(x))} \leq 1$, which is equivalent to

$$\lambda_A(x) \leq \theta_A(x)\left(1 - \frac{t}{2M}\right).$$

Case 2. $\lambda_A(x) = 1/g_m(x)$. Here we have $\frac{t/\theta_A(x)}{2M(1/\lambda_A(x)-1/\theta_A(x))} \leq 1$. This implies

$$\lambda_A(x) \leq \theta_A(x)/(1+\tfrac{t}{2M}).$$

Notice that $(1-t/(2M)) \leq 1/(1+t/(2M))$ for any $t \geq 0$. Therefore, $\lambda_A(x)$ can be bounded in both cases by $\leq \theta_A(x)/(1+t/(2M))$. □

Lemma 2.1 shows that the value $\theta_A(x)$ approximates the objective value $\lambda_A(x)$ for small t. Interestingly, the reduced potential function $\phi_t(x,A)$ also can be bounded in terms of $\theta_A(x)$.

LEMMA 2.2. *If $g_m(x) \leq T$ for each $m \in A$, then*

$$\phi_t(x,A) \geq (2-t)\ln\theta_A(x) - t\ln T.$$

Furthermore, if $T > 1/\lambda_A(x)$, then

$$\phi_t(x,A) \leq 2\ln\theta_A(x) + 2t\ln\left(\frac{2M}{t}\right) + t\ln\left(1+\frac{t}{2M}\right).$$

Proof.

$$\begin{aligned} 2\ln\theta_A(x) &= \phi_t(x,A) + \tfrac{t}{M}\sum_{m=1}^{M}\ln(\theta_A(x)-f_m(x)) + \tfrac{t}{M}\sum_{m\in A}\ln(g_m(x)-1/\theta_A(x)) \\ &\quad + \tfrac{t}{M}\sum_{m\notin A}\ln(T) \\ &\leq \phi_t(x,A) + \tfrac{t}{M}\sum_{m=1}^{M}\ln\theta_A(x) + \tfrac{t}{M}\sum_{m=1}^{M}\ln(T) \\ &= \phi_t(x,A) + t\ln\theta_A(x) + t\ln(T). \end{aligned}$$

This implies the lower bound. On the other hand, $f_m(x) \le \lambda_A(x)$ for each $m \in \{1,\dots,M\}$ and $g_m(x) \ge 1/\lambda_A(x)$ for each $m \in A$. This gives $2\ln\theta_A(x) \ge \phi_t(x,A) + \frac{t}{M}\sum_{m=1}^{M}\ln(\theta_A(x)-\lambda_A(x)) + \frac{t}{M}\sum_{m\in A}\ln(1/\lambda_A(x)-1/\theta_A(x)) + \frac{t}{M}\sum_{m\notin A}\ln(T)$. For $T > 1/\lambda_A(x)$, this sum is at least $\phi_t(x,A)+2t\ln(\theta_A(x)-\lambda_A(x))+t\ln(1/(\lambda_A(x)\theta_A(x)))$.

Now we use the upper bound $\lambda_A(x) \le \theta_A(x)/(1+t/(2M))$ or, equivalently, $\theta_A(x)-\lambda_A(x) \ge \theta_A(x)(1-1/(1+t/(2M))) = \frac{t/(2M)\theta_A(x)}{1+t/(2M)}$. In addition $1/(\lambda_A(x)\theta_A(x)) \ge (1+t/(2M))/\theta_A(x)^2$. As a consequence we get

$$2\ln\theta_A(x) \ge \phi_t(x,A) + 2t\ln\left(\frac{t}{2M}\cdot\frac{\theta_A(x)}{1+t/(2M)}\right) + t\ln\left(\frac{1+t/(2M)}{\theta_A(x)^2}\right).$$

Using $\ln(\frac{1+t/(2M)}{\theta_A(x)^2}) = \ln(1+t/(2M)) - 2\ln\theta_A(x)$,

$$\begin{aligned} 2\ln\theta_A(x) &\ge \phi_t(x,A) + 2t\ln\left(\tfrac{t}{2M}\cdot\tfrac{1}{1+t/(2M)}\right) + t\ln\left(1+\tfrac{t}{2M}\right) \\ &= \phi_t(x,A) + 2t\ln\left(\tfrac{t}{2M}\right) - t\ln\left(1+\tfrac{t}{2M}\right). \end{aligned}$$

This gives the desired upper bound

$$\phi_t(A,x) \le 2\ln\theta_A(x) + 2t\ln\left(\frac{2M}{t}\right) + t\ln\left(1+\frac{t}{2M}\right). \qquad \square$$

2.2. Price vectors. Given an $x \in B$ and a subset $A \subset \{1,\dots,M\}$, the price vector $p(x,A)$ is defined by

$$p_m(x,A) = \frac{t}{2M}\frac{\theta_A(x)}{\theta_A(x)-f_m(x)} \tag{2.2}$$

and the price vector $q(x,A)$ is given by

$$q_m(x,A) = \begin{cases} \frac{t}{2M}\frac{1}{g_m(x)\theta_A(x)-1}, & m \in A, \\ 0 & \text{otherwise.} \end{cases} \tag{2.3}$$

Using the first-order condition, $\sum_{m=1}^{M} p_m(x,A) + \sum_{m=1}^{M} q_m(x,A) = 1$ and each component $p_m(x,A), q_m(x,A)$ is nonnegative.

LEMMA 2.3.

(a) $p(x,A)^T f(x) = \theta_A(x)(\sum_{m=1}^{M} p_m(x,A) - t/2) \le \theta_A(x)(1-t/2)$,

(b) $q(x,A)^T g(x) = (\sum_{m\in A} q_m(x,A) + t|A|/(2M))/\theta_A(x) \le (\sum_{m\in A} q_m(x,A) + t/2)/\theta_A(x) \le (1+t/2)/\theta_A(x)$.

Proof. The (in-)equalities corresponding to $p(x,A)^T f(x)$ follow from

$$\begin{aligned} p(x,A)^T f(x) &= \tfrac{t\theta_A(x)}{2M}\sum_{m=1}^{M}\tfrac{f_m(x)}{\theta_A(x)-f_m(x)} \\ &= \tfrac{t\theta_A(x)}{2M}\sum_{m=1}^{M}\left(-1+\tfrac{\theta_A(x)}{\theta_A(x)-f_m(x)}\right) \\ &= -\tfrac{t\theta_A(x)}{2} + \theta_A(x)\sum_{m=1}^{M} p_m(x,A) \\ &= \theta_A(x)\left(\sum_{m=1}^{M} p_m(x,A) - \tfrac{t}{2}\right) \\ &\le \theta_A(x)\left(1-\tfrac{t}{2}\right). \end{aligned}$$

For $q(x,A)^T g(x)$ we argue as follows:

$$\begin{aligned}
q(x,A)^T g(x) &= \tfrac{t}{2M} \sum_{m\in A} \tfrac{g_m(x)/\theta_A(x)}{g_m(x)-1/\theta_A(x)} \\
&= \tfrac{t}{2M\theta_A(x)} \sum_{m\in A} \left(1 + \tfrac{1/\theta_A(x)}{g_m(x)-1/\theta_A(x)}\right) \\
&= \tfrac{t|A|}{2M\theta_A(x)} + \tfrac{t}{2M\theta_A(x)} \sum_{m\in A} \tfrac{1/\theta_A(x)}{g_m(x)-1/\theta_A(x)} \\
&= \left(\sum_{m\in A} q_m(x,A) + \tfrac{t|A|}{2M}\right)/\theta_A(x) \\
&\le \left(\sum_{m\in A} q_m(x,A) + t/2\right)/\theta_A(x) \\
&\le (1+t/2)/\theta_A(x). \qquad \square
\end{aligned}$$

Notice that Lemma 2.3(a) implies that $\sum_{m=1}^{M} p_m(x,A) \ge t/2$ (using $p(x,A)^T f(x) \ge 0$). Let $\bar{p}(x) = \sum_{m=1}^{M} p_m(x,A)$ and use $\bar{p} = \bar{p}(x)$ if the dependence on x is clear.

3. Our approximation algorithm. In this section we describe the approximation algorithm for the mixed fractional packing and covering problem. First we suppose that there exists a feasible solution $x \in B$ with $f(x) \le e$ and $g(x) \ge e$. Then the approximation algorithm works as follows:

(1) compute initial solution $x^{(0)}$, $s := 0$, $\epsilon_0 := 1$;
(2) **repeat** {scaling phase}
  (2.1) $s := s+1$; $\epsilon_s := \epsilon_{s-1}/2$; $x := x^{(s-1)}$; $T(s) := 2112(M^3\epsilon_s^{-2})/\lambda_{\mathcal{M}}(x)$;
    $A := \{m \in \{1,\dots,M\} | g_m(x) < T(s)\}$; $finished := false$; $k := 0$;
  (2.2) **if** $A \neq \{1,\dots,M\}$ **then begin** $k := k+1$; $x_k := x$ **end**;
  (2.3) **if** stopping rule 1 is satisfied for x **then** $finished := true$; $y := x$ **end**;
  (2.4) **while** $not(finished)$ **do begin**
    (2.4.1) compute $\theta_A(x)$, $p(x,A)$ and $q(x,A)$;
    (2.4.2) $\hat{x} := ABS(p(x,A), q(x,A), \epsilon_s/32)$;
    (2.4.3) **if** one of the stopping rules is satisfied
      then begin $finished := true$; $y := x$ **end**
      else begin
      (2.4.3.1) compute step length τ and $x' := (1-\tau)x + \tau\hat{x}$;
      (2.4.3.2) **if** $\max_{m\in A} g_m(x)(1-\tau) + g_m(\hat{x})\tau > T(s)$ **then** reduce
        τ to $\bar{\tau}$ and $x' := (1-\bar{\tau})x + \bar{\tau}\hat{x}$;
      (2.4.3.3) $A' := A \setminus \{m | g_m(x') \ge T(s)\}$; $x := x'$;
      (2.4.3.4) **if** $A \neq A'$ **then begin** $k := k+1$; $x_k = x'$;
        $A := A'$ **end**
    end
  end;
  (2.5) compute convex combination of $x_1,\dots,x_k,y$ to get $x^{(s)}$;
  (2.6) **until** $\epsilon_s \le \epsilon/2$ or $\lambda(x^{(s)}) \le 1+\epsilon$;
(3) return$(x^{(s)})$.

The details of the algorithm are described later in this section (how to compute an initial solution, the stopping rules, the choice of the step length, and the reduction of the step length).

For the case where the set of feasible solutions $\{x \in B | f(x) \leq e, g(x) \geq e\}$ is empty, we have to modify the program above. If an inequality $p(x,A)^T f(\hat{x}) > (1+t)\sum p_m(x,A)$ holds for a block solution $\hat{x}$, then we can conclude that there is no feasible solution.

3.1. Initial solution. For each $m \in \{1,\dots,M\}$, we consider the block problem (B_m) with price vectors $p = (1/M,\dots,1/M)$ and $q = e_m$, where e_m is the unit vector with all zero coordinates except for its mth component which is 1:

$$(B_m) \qquad \begin{aligned} \min \quad & \tfrac{1}{M}\sum_{\ell=1}^{M} f_\ell(x), \\ & g_m(x) \geq 1, \\ & x \in B. \end{aligned}$$

If there is a solution $\bar{x} \in B$ with $f(\bar{x}) \leq e$ and $g(\bar{x}) \geq e$, then this solution satisfies $(1/M)\sum_{\ell=1}^{M} f_\ell(\bar{x}) \leq 1$ and $g_m(\bar{x}) \geq 1$. Let $\hat{x}^{[m]} \in B$ be an approximate solution of the block problem (B_m) with tolerance $t = 1/2$, and let $x^{(0)} = (1/M)\sum_{m=1}^{M} \hat{x}^{[m]}$. Using the convexity of B, $x^{(0)} \in B$. If the approximate solution satisfies $(1/M)\sum_{\ell=1}^{M} f_\ell(\hat{x}^{[m]}) > 1+t$, then we can conclude that the solution set of the mixed problem is empty.

LEMMA 3.1. *If there exists a feasible solution of the mixed packing and covering problem, then* $\lambda(x^{(0)}) \leq 3M/2$.

Proof. If there is a feasible solution, then $(1/M)\sum_{\ell=1}^{M} f_\ell(\hat{x}^{[m]}) \leq (1+t) = 3/2$ and $g_m(x^{[m]}) \geq 1/(1+t) = 2/3$ (using the approximate block solver $ABS(p,q,1/2)$ above). Then using the concavity and nonnegativity of g_m,

$$g_m(x^{(0)}) = g_m\left(\frac{1}{M}\sum_{\ell=1}^{M}\hat{x}^{[\ell]}\right) \geq \frac{1}{M}\sum_{\ell=1}^{M} g_m(\hat{x}^{[\ell]}) \geq \frac{1}{M} g_m(\hat{x}^{[m]}) \geq \frac{2}{3M}.$$

Using the convexity and nonnegativity of f_m,

$$f_m(x^{(0)}) = f_m\left(\frac{1}{M}\sum_{\ell=1}^{M}\hat{x}^{[\ell]}\right) \leq \frac{1}{M}\sum_{\ell=1}^{M} f_m(\hat{x}^{[\ell]}) \leq \frac{1}{M}\sum_{m=1}^{M}\sum_{\ell=1}^{M} f_m(\hat{x}^{[\ell]}) \leq \frac{3M}{2}.$$

Combining both inequalities, $\lambda(x^{(0)}) \leq 3M/2$. ∎

3.2. Stopping rules. In the algorithm we stepwise decrease the objective value λ from $3M/2$ to $1/(1-\epsilon/2)$. In the first phase we decrease $3M/2$ to $\epsilon_1 = 1/2$. After that we set $\epsilon_s = \epsilon_{s-1}/2$. The goal in phase s is to obtain a solution $x^{(s)}$ with $\lambda(x^{(s)}) \leq 1/(1-\epsilon_s)$. In order to get such a solution we need at the end of phase s a solution y with $\lambda_A(y) \leq 1/(1-\epsilon_s/4)$.

To obtain the solution and to show the convergence we use three stopping rules. For the first rule we simply test whether

$$\lambda_A(x) \leq 1 + \epsilon_s/4 \tag{3.1}$$

for the current solution x. For this rule we immediately get the following lemma.

LEMMA 3.2. *If $\lambda_A(x) \leq 1+\epsilon_s/4$, then $f_m(x) \leq 1+\epsilon_s/4 \leq 1/(1-\epsilon_s/4)$ for each $m \in \{1,\ldots,M\}$, and $g_m(x) \geq 1/(1+\epsilon_s/4) \geq 1-\epsilon_s/4$ for each $m \in A$.*

For the second rule we define a parameter ν that depends on the current iterate x and the approximate block solution $\hat{x}$ as follows:

$$\nu = \nu(x,\hat{x}) = \frac{(p^T f(x) - p^T f(\hat{x}))/\theta + \theta(q^T g(\hat{x}) - q^T g(x))}{(p^T f(x) + p^T f(\hat{x}))/\theta + \theta(q^T g(\hat{x}) + q^T g(x))}, \tag{3.2}$$

where $p = p(x,A)$, $q = q(x,A)$, and $\theta = \theta_A(x)$. Clearly, $\nu(x,\hat{x}) \leq 1$. The lemma below states that x is an approximate solution of the phase s corresponding to subset A, when ν is bounded by $t_s = \Theta(\epsilon_s)$. Therefore, for the second rule we test whether

$$\nu(x,\hat{x}) \leq t \tag{3.3}$$

for the current solution x and the block solution $\hat{x}$.

LEMMA 3.3. *Suppose $\epsilon_s \in (0,4)$ and $t_s = \epsilon_s/32$. For a given $x \in B$, let p,q be computed by (2.2), (2.3) and $\hat{x}$ computed by $ABS(p,q,t_s)$. If $\nu(x,\hat{x}) \leq t_s$, then $f_m(x) \leq 1+\epsilon_s/4 \leq 1/(1-\epsilon_s/4)$ for each $m \in \{1,\ldots,M\}$ and $g_m(x) \geq 1/(1+\epsilon_s/4) \geq (1-\epsilon_s/4)$ for each $m \in A$.*

Proof. Use (3.2) to rewrite $\nu(x,\hat{x}) \leq t = t_s$ as follows:

$$(p^T f(x) - p^T f(\hat{x}))/\theta + \theta(q^T g(\hat{x}) - q^T g(x)) \leq t[(p^T f(x) + p^T f(\hat{x}))/\theta + \theta(q^T g(\hat{x}) + q^T g(x))].$$

Since $p^T f(x) = \theta(\bar{p} - t/2)$, $q^T g(x) = (1 - \bar{p} + t|A|/(2M))/\theta \leq (1 - \bar{p} + t/2)/\theta$, $p^T f(\hat{x}) \leq (1+t)\bar{p}$, and $q^T g(\hat{x}) \geq (1-\bar{p})/(1+t)$, we obtain $\theta\frac{(1-\bar{p})(1-t)}{(1+t)} \leq (1-\bar{p})(1+t) + t + \bar{p}(t + t/\theta) + \bar{p}(1/\theta - 1) + t\bar{p}/\theta(1+t)$.

In the case $\theta \leq 1+8t$ we can prove the lemma directly as follows. Using $\lambda_A(x) < \theta$ and $t = t_s$, we obtain

$$\lambda_A(x) < (1+8t_s) = (1+\epsilon_s/4)$$

for $t_s = \epsilon_s/32$. This implies $f_m(x) \leq 1+\epsilon_s/4 \leq 1/(1-\epsilon_s/4)$ for each $m \in \{1,\ldots,M\}$ and $g_m(x) \geq 1/(1+\epsilon_s/4) \geq (1-\epsilon_s/4)$ for each $m \in A$.

Now suppose that $\theta > 1+8t \geq 1$. Then using the inequality above we obtain

$$\theta\frac{(1-\bar{p})(1-t)}{(1+t)} \leq (1-\bar{p})(1+t) + t + 3\bar{p}t - \bar{p}\frac{8t}{1+8t}.$$

Now we get (using $t < 1/8$) $3\bar{p}t - \frac{8t}{1+8t}\bar{p} = \bar{p}t\frac{-5+24t}{1+8t} < -\bar{p}t$. This implies

$$\theta\frac{(1-\bar{p})(1-t)}{(1+t)} < (1-\bar{p})(1+t) + t - t\bar{p}.$$

If $\bar{p} = 1$, we obtain with $0 < 0$ a contradiction. If $\bar{p} \neq 1$, then we get

$$\theta \leq \frac{(1+t)^2}{(1-t)} + \frac{(t - t\bar{p})(1+t)}{(1-\bar{p})(1-t)} = \frac{(1+2t)(1+t)}{(1-t)}.$$

The right-hand side can be bounded by $(1+2t)(1+3t) \leq (1+6t)$ for $t \leq 1/6$. But again this is a contradiction. ∎

The third stopping rule is used to control the number of iterations during one phase. Here we use a parameter ω_s that depends on the phase s:

$$\omega_s = \begin{cases} \frac{2}{3M(1-\epsilon_1/4)}, & s = 1, \\ \frac{1-\epsilon_{s-1}}{1-\epsilon_s/4}, & s > 1. \end{cases}$$

Then the third rule is defined by

$$\lambda_A(x) \le \omega_s \lambda_{\mathcal{M}}(x^{(s-1)}), \tag{3.4}$$

where $x^{(s-1)}$ is the solution of phase $s-1$ that satisfies $\lambda(x^{(s-1)}) \le 1/(1-\epsilon_{s-1})$.

LEMMA 3.4. *Let $x^{(s-1)}$ be the initial solution and x be a vector in phase $s \ge 1$ with $\lambda_A(x) \le \omega_s \lambda(x^{(s-1)})$ for $A \subset \mathcal{M}$. If*

$$\lambda_A(x^{(s-1)}) \le \begin{cases} 3M/2 & \text{for } s = 1, \\ 1/(1-\epsilon_{s-1}) & \text{for } s \ge 2, \end{cases}$$

then we get

$$\lambda_A(x) \le 1/(1-\epsilon_s/4).$$

Proof. For $s = 1$ we obtain

$$\lambda_A(x) \le \frac{2}{3M(1-\epsilon_1/4)} \cdot \lambda(x^{(0)}) \le \frac{2}{3M(1-\epsilon_1/4)} \cdot \frac{3M}{2} = \frac{1}{(1-\epsilon_1/4)}$$

and for $s \ge 2$ we get

$$\lambda_A(x) \le \omega_s \lambda(x^{(s-1)}) \le \frac{1-\epsilon_{s-1}}{1-\epsilon_s/4} \cdot \frac{1}{1-\epsilon_{s-1}} = \frac{1}{1-\epsilon_s/4}. \qquad \square$$

Notice that in both cases of the proof ($s = 1$ and $s \ge 2$), $f_m(x) \le 1/(1-\epsilon_s/4)$ for each $m \in \mathcal{M}$, and $g_m(x) \ge (1-\epsilon_s/4)$ for each $m \in A$.

3.3. Choice of the step length. In this subsection we describe the choice of the step length τ. We suppose that we have computed a vector x and an approximate block solution $\hat{x}$ in a phase s such that $\nu(x,\hat{x}) > t$, $p^T f(\hat{x}) \le (1+t)\sum_{m=1}^{M} p_m$, and $q^T g(\hat{x}) \ge \frac{1}{1+t}\sum_{m=1}^{M} q_m$ (where $t = t_s$, $p = p(x, A(x))$, and $q = q(x, A(x))$). Let $x' = (1-\tau)x + \tau\hat{x}$. First we focus on the case where $g_m(x') < T = T(s)$ for each $m \in A(x)$. In this case we do not eliminate a component (i.e., $A(x') = A(x)$). The other case will be discussed later (in some cases we also have to reduce the step length).

For simplification we use $\theta = \theta_{A(x)}(x)$.

Since each function f_m is convex, we get independently of the choice of τ the following inequality:

$$\begin{aligned} \theta - f_m(x') &\ge \theta - (1-\tau)f_m(x) - \tau f_m(\hat{x}) \\ &= (\theta - f_m(x))\left(1 + \tau\tfrac{f_m(x) - f_m(\hat{x})}{\theta - f_m(x)}\right) \\ &= (\theta - f_m(x))\left(1 + \tfrac{2\tau M}{t\theta} p_m (f_m(x) - f_m(\hat{x}))\right) \end{aligned}$$

for each $m \in \mathcal{M}$. Since each function g_m is concave, we obtain

$$\begin{aligned} g_m(x') - \tfrac{1}{\theta} &\ge (1-\tau)g_m(x) + \tau g_m(\hat{x}) - \tfrac{1}{\theta} \\ &= \left(g_m(x) - \tfrac{1}{\theta}\right)\left(1 + \tau\tfrac{g_m(\hat{x}) - g_m(x)}{g_m(x) - 1/\theta}\right) \\ &= \left(g_m(x) - \tfrac{1}{\theta}\right)\left(1 + \tfrac{2\tau M\theta}{t} q_m (g_m(\hat{x}) - g_m(x))\right) \end{aligned}$$

for each $m \in A$. We call a step length τ *feasible* if $\tau \in (0,1)$ and if the following bound is satisfied:

(3.5)
$$\max\left(\max_{m\in\mathcal{M}}\left|\frac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right|,\max_{m\in A(x)}\left|\frac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right|\right)\le 1/2.$$

Suppose from now on that τ is a feasible step length. Later we will specify a step length τ with $\tau \in (0,1)$ to obtain the bound (3.5). Then using $\theta - f_m(x) > 0$ and $g_m(x) - 1/\theta > 0$ we obtain $\theta - f_m(x') > 0$ and $g_m(x') - 1/\theta > 0$ for the next computed vector $x' \in B$. This implies that the objective value $\lambda_{A(x')}(x')$ for the next vector x' is at most $\theta_{A(x)}(x)$, where here $A(x') = A(x)$.

LEMMA 3.5. *For any two consecutive iterations in a phase with computed vectors x, x' and $A(x') = A(x)$ and any feasible step length τ, the difference $\phi_t(x, A(x)) - \phi_t(x', A(x'))$ is at least*

$$\begin{aligned}&+2\tau[(p^Tf(x)-p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})-q^Tg(x))\theta]\\&-\tfrac{4M\tau^2}{t}[(p^Tf(x)+p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})+q^Tg(x))\theta]^2,\end{aligned}$$

where $\theta = \theta_{A(x)}(x)$, $p = p(x, A(x))$, and $q = q(x, A(x))$.

Proof. Using the definition of the reduced potential function and $\lambda_{A(x')}(x') \le \theta_{A(x)}(x)$, we get $\phi_t(x', A(x')) = \min_{\lambda_{A(x')}(x')\le\xi} \Phi_t(\xi, x', A(x')) \le \Phi_t(\theta, x', A(x))$. The inequality above implies the following upper bound for $\phi_t(x', A(x'))$:

$$\begin{aligned}&\phi_t(x',A(x'))\le\Phi_t(\theta,x',A(x))\\&=2\ln\theta-\tfrac{t}{M}\sum_{m=1}^{M}\ln(\theta-f_m(x'))-\tfrac{t}{M}\sum_{m\in A(x)}\ln\left(g_m(x')-\tfrac{1}{\theta}\right)-\tfrac{t}{M}\sum_{m\notin A(x)}\ln(T)\\&\le 2\ln\theta-\tfrac{t}{M}\sum_{m=1}^{M}\ln(\theta-f_m(x))-\tfrac{t}{M}\sum_{m=1}^{M}\ln\left(1+\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right)\\&\quad-\tfrac{t}{M}\sum_{m\in A(x)}\ln\left(g_m(x)-\tfrac{1}{\theta}\right)-\tfrac{t}{M}\sum_{m\in A(x)}\ln\left(1+\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right)\\&\quad-\tfrac{t}{M}\sum_{m\notin A(x)}\ln(T)\\&=\phi_t(x,A(x))-\tfrac{t}{M}\sum_{m=1}^{M}\ln\left(1+\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right)\\&\quad-\tfrac{t}{M}\sum_{m\in A(x)}\ln\left(1+\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right).\end{aligned}$$

Above we have used the lower bounds for $\theta - f_m(x')$ and $g_m(x') - 1/\theta$. The

calculation above shows that the difference $\phi_t(x, A(x)) - \phi_t(x', A(x'))$ is at least

$$\begin{aligned}&\tfrac{t}{M}\sum_{m=1}^{M}\ln\left(1+\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right)\\&\quad+\tfrac{t}{M}\sum_{m\in A(x)}\ln\left(1+\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right).\end{aligned}$$

Now we can use the inequality $\ln(1+z) \geq z - z^2$ for $z \geq -1/2$:

$$\ln\left(1+\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right) \geq \tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))-\left(\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right)^2$$

and

$$\ln(1+\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))) \geq \tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))-(\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x)))^2.$$

Using both inequalities above and $q_m = 0$ for $m \notin A(x)$, the difference $\phi_t(x, A(x)) - \phi_t(x', A(x'))$ is at least

$$\begin{aligned}\geq\;&+\tfrac{2\tau}{\theta}(p^Tf(x)-p^Tf(\hat{x}))+2\tau\theta(q^Tg(\hat{x})-q^Tg(x))\\&-\tfrac{4M\tau^2}{t\theta^2}(p^Tf(x)+p^Tf(\hat{x}))^2+\tfrac{4M\tau^2\theta^2}{t}(q^Tg(\hat{x})+q^Tg(x))^2\\=\;&+2\tau[(p^Tf(x)-p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})-q^Tg(x))\theta]\\&-\tfrac{4M\tau^2}{t}[(p^Tf(x)+p^Tf(\hat{x}))^2/\theta^2+(q^Tg(\hat{x})+q^Tg(x))^2\theta^2]\\\geq\;&+2\tau[(p^Tf(x)-p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})-q^Tg(x))\theta]\\&-\tfrac{4M\tau^2}{t}[(p^Tf(x)+p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})+q^Tg(x))\theta]^2.\qquad\square\end{aligned}$$

In our algorithm we use the following feasible step length.

LEMMA 3.6. *The following step length is feasible for any $t < 1$:*

$$\tau \;=\; \frac{t^2}{4M[(p^Tf(x)+p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})+q^Tg(x))\theta]}$$

where $\theta = \theta_A(x)$ and $\nu = \nu(x, \hat{x})$.

Proof. Since $p^Tf(x)/\theta+\theta q^Tg(x) = 1-t/2+t|A|/(2M) > 1-t/2 \geq 1/2$, the step length τ is at most $t^2/(2M) < 1$. Furthermore,

$$\begin{aligned}\left|\tfrac{2\tau M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))\right| &\leq \tfrac{2\tau M}{t\theta}(p^Tf(x)+p^Tf(\hat{x}))\\&= \tfrac{2M}{t}\tfrac{t^2}{4M}\frac{(p^Tf(x)+p^Tf(\hat{x}))/\theta}{[(p^Tf(x)+p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})+q^Tg(x))\theta]}\\&\leq \tfrac{t}{2} < \tfrac{1}{2}\end{aligned}$$

and

$$\begin{aligned}\left|\tfrac{2\tau M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right| &\leq \tfrac{2\tau M\theta}{t}(q^Tg(\hat{x})+q^Tg(x))\\&= \tfrac{2M}{t}\tfrac{t^2}{4M}\frac{(q^Tg(\hat{x})+q^Tg(x))\theta}{[(p^Tf(x)+p^Tf(\hat{x}))/\theta+(q^Tg(\hat{x})+q^Tg(x))\theta]}\\&\leq \tfrac{t}{2} < \tfrac{1}{2}.\qquad\square\end{aligned}$$

The main goal now is to prove the following result.

THEOREM 3.7. *For any two consecutive iterations in a phase with computed vectors x, x' and $A(x) = A(x')$ we obtain*

$$\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq \frac{t^3}{4M}.$$

Proof. Since the second stopping rule is not satisfied we have $\nu(x, \hat{x}) > t$. This implies the following inequality:

$$\begin{aligned}(3.6)\qquad &[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\ &\quad \geq t[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta].\end{aligned}$$

Then we obtain for the difference $\phi_t(x, A(x)) - \phi_t(x', A(x'))$ of the potential values the following lower bound:

$$\begin{aligned}&2\tau[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\ &\quad - \tfrac{4M\tau^2}{t}[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta]^2 \\ &\qquad \geq 2\tau t[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta] \\ &\qquad\quad - \tau t[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta] \\ &\qquad = \tau t[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta] \\ &\qquad = \tfrac{t^3}{4M}.\end{aligned}$$

We used above the inequality (3.6) and inserted the step length τ. ∎

3.4. Reducing the step length. Let $x' = (1-\tau)x + \tau\hat{x}$, where x is the current vector, $\hat{x}$ is the block solution, and τ is the step length as used in the previous subsection. Consider a phase s with threshold value $T(s)$. For simplicity we use $T = T(s)$. If $g_m(x') \leq T$ for each $m \in A(x)$, then we use x' as the next iterate and set $A(x') = \{m \in A(x) | g_m(x') < T\}$. In this case some components may be eliminated, but we use the original step length. Now we consider the case that $g_m(x') > T$ for at least one coordinate $m \in A(x)$. Let

$$\gamma(\tilde{\tau}) = \max_{m \in A(x)} g_m(x)(1 - \tilde{\tau}) + g_m(\hat{x})\tilde{\tau}$$

for $0 \leq \tilde{\tau} \leq 1$. If $\gamma(\tau) > T$, then we reduce the step length τ. In this case we compute $\bar{\tau} < \tau$ such that $\gamma(\bar{\tau}) = T$. Using $g_m(x) < T$ for each $m \in A(x)$ and $\gamma(\tau) > T$, there is at least one component $m \in A(x)$ such that $g_m(\hat{x}) > T$. In addition, the value $\bar{\tau}$ is unique and can be computed in $O(M)$ time. We use here $x' = x(1 - \bar{\tau}) + \hat{x}\bar{\tau}$ as next iterate and set $A(x') = \{m \in A(x) | g_m(x') < T\}$. If $\gamma(\tau) \leq T$, then we do not have to reduce the step length τ and use again $x' = x(1 - \tau) + \hat{x}\tau$. But we eliminate as above all components $m \in A(x)$ with $g_m(x') \geq T$. Notice that the case with $g_m(x') > T > g_m(x)(1-\tau) + g_m(\hat{x})\tau$ is possible (since the functions g_m are concave).

For each $m \in A(x')$ we have $g_m(x') < T$. If we use a reduced step length $\bar{\tau} < \tau$, then $A(x) \neq A(x')$. But $A(x) \neq A(x')$ also can happen when $\gamma(\tau) < T$ or $g_m(x') \leq T$ for each $m \in A(x)$. The new potential value for x' and $A(x')$ is

$$\begin{aligned}\phi_t(x', A(x')) = 2\ln\theta' &- \frac{t}{M}\sum_{m=1}^{M} \ln(\theta' - f_m(x')) \\ &- \frac{t}{M}\sum_{m \in A(x')} \ln(g_m(x') - 1/\theta') - \frac{t}{M}\sum_{m \notin A(x')} \ln(T),\end{aligned}$$

where $\theta' = \theta_{A(x')}(x')$.

Now we consider two cases depending on whether we use the original step length τ or the reduced step length $\bar{\tau}$.

THEOREM 3.8. *For any two consecutive iterations with computed vectors x, x', index sets $A(x) \neq A(x')$, and $\max_{m\in A(x)} g_m(x)(1-\tau) + g_m(\hat{x})\tau \leq T$, we have*

$$\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq \frac{t^3}{4M}.$$

Proof. If $g_m(x)(1-\tau) + g_m(\hat{x})\tau \leq T$ for each $m \in A(x)$, then $-\ln(T) \leq -\ln(g_m(x)(1-\tau)+g_m(\hat{x})\tau - 1/\theta)$, where $\theta = \theta_{A(x)}(x)$. Furthermore, for each feasible choice for τ, we have $\theta - f_m(x') > 0$ for each $m \in \{1, \ldots, M\}$ and $g_m(x') - 1/\theta > 0$ for each $m \in A(x)$. This implies $\lambda_{A(x')}(x') \leq \lambda_{A(x)}(x') < \theta_{A(x)}(x)$. Then using the definition of the potential function and $g_m(x') - 1/\theta \geq g_m(x)(1-\tau) + g_m(\hat{x})\tau - 1/\theta$ (concavity of functions g_m),

$$\begin{aligned}
\phi_t(x', A(x')) &= \min_{\lambda_{A(x')}(x') \leq \xi} \Phi_t(\xi, x', A(x')) \leq \Phi_t(\theta, x', A(x')) \\
&= 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^{M} \ln(\theta - f_m(x')) - \tfrac{t}{M}\sum_{m\in A(x')} \ln(g_m(x') - \tfrac{1}{\theta}) \\
&\quad - \tfrac{t}{M}\sum_{m\notin A(x')} \ln(T) \\
&\leq 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^{M} \ln(\theta - f_m(x')) \\
&\quad - \tfrac{t}{M}\sum_{m\in A(x)} \ln(g_m(x)(1-\tau) + g_m(\hat{x})\tau - \tfrac{1}{\theta}) \\
&\quad - \tfrac{t}{M}\sum_{m\notin A(x)} \ln(T) \\
&\leq 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^{M} \ln\left((\theta - f_m(x))\left(1 + \tau\tfrac{f_m(x) - f_m(\hat{x})}{\theta - f_m(x)}\right)\right) \\
&\quad - \tfrac{t}{M}\sum_{m\in A(x)} \ln\left(\left(g_m(x) - \tfrac{1}{\theta}\right)\left(1 + \tau\tfrac{g_m(\hat{x}) - g_m(x)}{g_m(x) - 1/\theta}\right)\right) \\
&\quad - \tfrac{t}{M}\sum_{m\notin A(x)} \ln(T).
\end{aligned}$$

Using the same arguments as in Lemma 3.5, the difference of the potential values $\phi_t(x, A(x)) - \phi_t(x', A(x'))$ is at least

$$\begin{aligned}
&2\tau[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\
&-\tfrac{4M\tau^2}{t}[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta]^2.
\end{aligned}$$

The remaining analysis goes in the same way as for $A(x) = A(x')$. ∎

THEOREM 3.9. *For any two consecutive iterations with computed vectors x, x', index sets $A(x) \neq A(x')$, and $\max_{m\in A(x)} g_m(x)(1-\tau) + g_m(\hat{x})\tau > T$, we have*

$$\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq 0.$$

Proof. If $\max_{m\in A(x)} g_m(x)(1-\tau)+g_m(\hat{x})\tau > T$, then we use the reduced step length $\bar{\tau}$. In this case $g_m(x)(1-\bar{\tau})+g_m(\hat{x})\bar{\tau}$ is also bounded by T for each $m \in A(x)$. This implies $-\ln(T) \leq -\ln(g_m(x)(1-\bar{\tau})+g_m(\hat{x})\bar{\tau}-1/\theta_A(x))$. Since $\bar{\tau}$ is also a feasible choice, $\lambda_{A(x')}(x') < \theta_A(x)$. Using the definition of the potential function and an analysis similar to the one above, we get with $\theta = \theta_A(x)$ the following:

$$\begin{aligned}
\phi_t(x', A(x')) \;\leq\; & 2\ln\theta - \tfrac{t}{M}\sum_{m=1}^{M} \ln\left((\theta - f_m(x))\left(1+\bar{\tau}\tfrac{f_m(x)-f_m(\hat{x})}{\theta-f_m(x)}\right)\right) \\
& -\tfrac{t}{M}\sum_{m\in A(x)} \ln\left(\left(g_m(x)-\tfrac{1}{\theta}\right)\left(1+\bar{\tau}\tfrac{g_m(\hat{x})-g_m(x)}{g_m(x)-1/\theta}\right)\right) \\
& -\tfrac{t}{M}\sum_{m\notin A(x)} \ln(T) \\
\leq\; & \phi_t(x, A(x)) - \tfrac{t}{M}\sum_{m=1}^{M} \ln(1+\tfrac{2\bar{\tau}M}{t\theta}p_m(f_m(x)-f_m(\hat{x}))) \\
& -\tfrac{t}{M}\sum_{m\in A(x)} \ln\left(1+\tfrac{2\bar{\tau}M\theta}{t}q_m(g_m(\hat{x})-g_m(x))\right).
\end{aligned}$$

Again, since $\bar{\tau} < \tau$ is a feasible choice,

$$\begin{aligned}
\phi_t(x, A(x)) - \phi_t(x', A(x')) \;\geq\; & 2\bar{\tau}[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\
& -\tfrac{4M\bar{\tau}^2}{t}[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta]^2 \\
\geq\; & 2\bar{\tau}[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\
& -\tfrac{4M\bar{\tau}\tau}{t}[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta]^2 \\
=\; & 2\bar{\tau}[[(p^T f(x) - p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) - q^T g(x))\theta] \\
& -\tfrac{2M\tau}{t}[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta]^2].
\end{aligned}$$

Now we use the inequality (3.6), insert step length τ, and get $\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq \bar{\tau}t[(p^T f(x) + p^T f(\hat{x}))/\theta + (q^T g(\hat{x}) + q^T g(x))\theta] \geq 0$. ∎

3.5. Convex combination of different vectors. First we prove an upper bound for the packing constraints.

LEMMA 3.10. *For any iteration of the phase s with computed vector x, $\lambda_f(x) = \max_{1\leq m\leq M} f_m(x)$ is bounded by $4M/t_s$.*

Proof. For the initial solution, $f_m(x^{(0)}) \leq 3M/2$ for $m = 1, \ldots, M$. This implies $\lambda_f(x^{(0)}) \leq 3M/2 \leq 3M/(2t_s)$ (for any $t_s \in (0,1)$). Note that $t_s < t_{s-1}$ and $t_1 < 1$. For each block solution $\hat{x}$ in phase s we have

$$p(x, A)^T f(\hat{x}) \leq (1+t_s)\sum_{m=1}^{M} p_m(x, A) < 2\sum_{m=1}^{M} p_m(x, A(x)) \leq 2,$$

where $A = A(x)$. Suppose that $\lambda_f(\hat{x}) > 4M/t_s$. Then, there is an index $m \in \{1, \ldots, M\}$ such that $f_m(\hat{x}) = \lambda_f(\hat{x})$. We note that

$$p_m(x, A) = \frac{t_s}{2M}\frac{\theta_A(x)}{\theta_A(x) - f_m(x)} > \frac{t_s}{2M}.$$

Then we obtain a contradiction using

$$2 = \frac{t_s}{2M}\frac{4M}{t_s} < p_m(x,A)f_m(\hat{x}) \le p(x,A)^T f(\hat{x}) \le 2.$$

In other words $f_m(\hat{x}) \le 4M/t_s$ for each $m \in \{1,\dots,M\}$. Since each vector x' computed by the algorithm is the linear combination of the previous vector x and a block solution $\hat{x}$, and using the convexity of function f_m,

$$f_m(x') = f_m((1-\tau)x + \tau\hat{x}) \le (1-\tau)f_m(x) + \tau f_m(\hat{x}) \le \max\{f_m(x), f_m(\hat{x})\}.$$

Then, the lemma follows by induction on the number of iterations. ∎

Lemma 3.10 shows that the values $f_m(x)$ are not arbitrarily large in the algorithm. Notice that this is independent from the chosen step length $\tau \in (0,1)$. We use this bound for the convex combination below. Notice that, in addition, the components $p_m(x,A(x))$ of the price vector $p(x,A(x))$ are not arbitrarily small (i.e., $p_m(x,A(x)) > t_s/(2M)$).

At the end of phase s we have computed a vector $y \in B$ with $\lambda_{A(y)}(y) \le 1/(1-\epsilon_s/4)$. This implies $f_m(y) \le 1/(1-\epsilon_s/4)$ for each $m \in \{1,\dots,M\}$, and $g_m(y) \ge 1-\epsilon_s/4$ for each $m \in A(y)$. The goal is now to compute a vector $x^{(s)} \in B$ with $\lambda_{\mathcal{M}}(x^{(s)}) \le 1/(1-\epsilon_s)$. The key idea is to use a convex combination over several vectors computed during the phase. Let $x_1,\dots,x_k$ be the vectors in phase s where at least one function g_m is eliminated (i.e., where $g_m(x_i) \ge T(s)$). Clearly, $k \le M$. We have $x_1 = x^{(s-1)}$ if $g_m(x^{(s-1)}) \ge T(s)$ for at least one $m \in \mathcal{M}$ (here $x^{(s-1)}$ is the solution of the previous phase).

Take the following convex combination:

$$x^{(s)} \;=\; \sum_{i=1}^{k} \tfrac{\epsilon_s^2}{264M^2}\, x_i + \left(1 - \tfrac{k\epsilon_s^2}{264M^2}\right) y.$$

Since the set B is convex and $x_1,\dots,x_k,y \in B$, we obtain $x^{(s)} \in B$. Since the functions g_m are concave and the functions f_m are convex,

$$g_m(x^{(s)}) \;\ge\; \tfrac{\epsilon_s^2}{264M^2}\sum_{i=1}^{k} g_m(x_i) + \left(1 - \tfrac{k\epsilon_s^2}{264M^2}\right) g_m(y),$$

$$f_m(x^{(s)}) \;\le\; \tfrac{\epsilon_s^2}{264M^2}\sum_{i=1}^{k} f_m(x_i) + \left(1 - \tfrac{k\epsilon_s^2}{264M^2}\right) f_m(y).$$

Our threshold value $T(s)$ is given by

$$T(s) = 2112\left(\frac{M^3}{\epsilon_s^2}\right)\cdot\frac{1}{\lambda_{\mathcal{M}}(x^{(s-1)})}.$$

Notice that $T(s) \le 2112M^3/\epsilon_s^2$, since $\lambda_{\mathcal{M}}(x^{(s-1)}) \ge 1$ (otherwise we are done).

LEMMA 3.11. *The computed solution $x^{(s)}$ satisfies $\lambda_{\mathcal{M}}(x^{(s)}) \le 1/(1-\epsilon_s)$.*

Proof. First we consider the concave functions g_m. For each eliminated function g_m we have

$$g_m(x^{(s)}) \ge \frac{\epsilon_s^2}{264M^2} g_m(x_i) \ge \frac{\epsilon_s^2}{264M^2} T(s) = \frac{8M}{\lambda_{\mathcal{M}}(x^{(s-1)})},$$

since all other functions are nonnegative. This implies for $s > 1$ that

$$g_m(x^{(s)}) \geq 8(1-\epsilon_{s-1}) = 8(1-2\epsilon_s) \geq 1-\epsilon_s$$

for $8 - 16\epsilon_s \geq 1 - \epsilon_s$ or, equivalently, $\epsilon_s \leq 7/15 < 1/2$. In addition we get for $s = 1$ that

$$g_m(x^{(1)}) \geq 4M/(3M) \geq 1-\epsilon_s.$$

For each remaining component $m \in A(y)$ we have

$$g_m(x^{(s)}) \geq \left(1 - \frac{k\epsilon_s^2}{264M^2}\right) g_m(y) \geq \left(1 - \frac{\epsilon_s^2}{264M}\right)\left(1 - \frac{\epsilon_s}{4}\right) > 1-\epsilon_s.$$

The last inequality holds for each $\epsilon_s \leq 1$.

Next we consider the convex functions f_m. Here we use Lemma 3.10. For each iterate x we have $\lambda_f(x) \leq 4M/t_s$. This implies the following upper bound:

$$f_m(x^{(s)}) \leq \frac{\epsilon_s^2}{264M^2} \cdot \frac{4kM}{t_s} + \left(1 - \frac{k\epsilon_s^2}{264M^2}\right) f_m(y).$$

Since $t_s = \epsilon_s/32$, $k \leq M$, and $f_m(y) \leq 1/(1-\epsilon_s/4)$, we get

$$f_m(x^{(s)}) \leq \frac{32\epsilon_s}{66} + \left(1 - \frac{k\epsilon_s^2}{264M^2}\right) \frac{1}{1-\epsilon_s/4}.$$

The first term is at most $\epsilon_s/2$, and the second term can be bounded by $1 + \epsilon_s/2$ (for $\epsilon_s \leq 2$). This gives $f_m(x^{(s)}) \leq 1 + \epsilon_s$. All three cases together imply that $\lambda_{\mathcal{M}}(x^{(s)}) \leq \max\{1+\epsilon_s, 1/(1-\epsilon_s)\} = 1/(1-\epsilon_s)$. □

4. Analysis of the approximation algorithm.

4.1. Number of iterations. In this subsection we determine the total number of iterations of our algorithm. To do this we first calculate the number of iterations N_s in a single phase s. Let $y, \tilde{y}$ denote the initial and final iterate of phase s. Furthermore, let $\bar{y}$ be the solution after $\bar{N}_s = N_s - 1$ iterations. For consecutive iterations with computed vectors x, x' in a phase and $A(x) = A(x')$, the difference in the potential values $\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq \frac{ct^3}{M}$, where c is a positive constant and $t = t_s = \epsilon_s/32$. In addition, there are at most M iterations with consecutive vectors x, x' and different subsets $A(x) \neq A(x')$ (i.e., in these iterations at least one component is eliminated). In these cases, we have $\phi_t(x, A(x)) - \phi_t(x', A(x')) \geq 0$. Therefore,

$$\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y})) \geq \frac{ct^3}{M}(\bar{N}_s - M).$$

Next we determine an upper bound for the difference $\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y}))$. Using Lemma 2.2,

$$\begin{aligned}
\phi_t(y, A(y)) &\leq 2\ln\theta_{A(y)}(y) + 2t\ln(2M/t) + t\ln(1 + t/(2M)), \\
\phi_t(\bar{y}, A(\bar{y})) &\geq (2-t)\ln\theta_{A(\bar{y})}(\bar{y}) - t\ln(T),
\end{aligned}$$

where $T = T(s)$.

This gives

$$\begin{aligned}\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y})) \;\le\; & (2-t)\ln\tfrac{\theta_{A(y)}(y)}{\theta_{A(\bar{y})}(\bar{y})} + t\ln\theta_{A(y)}(y) + t\ln(T) \\ & + 2t\ln\left(\tfrac{2M}{t}\right) + t\ln\left(1+\tfrac{t}{2M}\right).\end{aligned}$$

Notice that $\theta_{A(y)}(y) \le \lambda_{A(y)}(y)/(1-t) \le O(M)$ for the initial solution y of each phase. This together with the definition of $T = T(s)$ and $t = t_s$ implies that $t\ln\theta_{A(y)}(y) + 2t\ln(2M/t) + t\ln(T) + t\ln(1+t/(2M))$ is bounded by $O(t_s\ln(M/t_s))$.

Now we need a bound for $\ln(\theta_{A(y)}(y)/\theta_{A(\bar{y})}(\bar{y}))$. Using $\theta_{A(y)}(y) < \lambda_{A(y)}(y)/(1-t)$ and $\theta_{A(\bar{y})}(\bar{y}) > \lambda_{A(\bar{y})}(\bar{y})(1+t/(2M)) > \lambda_{A(\bar{y})}(\bar{y})$, we get

$$\ln\frac{\theta_{A(y)}(y)}{\theta_{A(\bar{y})}(\bar{y})} < \ln\frac{\lambda_{A(y)}(y)}{\lambda_{A(\bar{y})}(\bar{y})} + \ln\frac{1}{1-t} \le \ln\frac{\lambda_{A(y)}(y)}{\lambda_{A(\bar{y})}(\bar{y})} + \ln(1+2t).$$

Notice that $\lambda_{A(\bar{y})}(\bar{y}) > \omega_s\lambda_{\mathcal{M}}(y) \ge \omega_s\lambda_{A(y)}(y)$, since $\bar{y}$ does not satisfy the second stopping rule. Therefore,

$$\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y})) \le (2-t)\ln\left(\frac{1}{\omega_s}\right) + O\left(t_s\ln\left(\frac{M}{t_s}\right)\right).$$

The term $\ln(\frac{1}{\omega_s})$ depends on the scaling phase s. For $s = 1$, $\ln(\frac{1}{\omega_s}) = O(\ln M)$. For the other phases, $\ln(\frac{1}{\omega_s}) \le \ln(1+4\epsilon_s) \le O(\epsilon_s)$ (using $\epsilon_s \le 1/4$). This implies that the difference in the potential function is at most $O(\ln M)$ for $s = 1$ and at most $O(\epsilon_s\ln(M/\epsilon_s))$ for $s \ge 2$. The lower and upper bounds for $\phi_t(y, A(y)) - \phi_t(\bar{y}, A(\bar{y}))$ imply

$$\bar{N}_s \le O(M\epsilon_s^{-2}\ln(M\epsilon_s^{-1})).$$

Summing over all phases, the total number of iterations (calls to the block solver) is

$$O\left(M\ln(M\epsilon^{-1})\sum_{k=0}^{\lceil\log(1/\epsilon)\rceil}(2^k)^2\right).$$

Since $\sum_{k=0}^{\lceil\log(1/\epsilon)\rceil}(2^k)^2 \le O(\epsilon^{-2})$, the total number of iterations is

$$O(M\epsilon^{-2}\ln(M\epsilon^{-1})).$$

4.2. How to compute the minimizer $\boldsymbol{\theta_A(x)}$. We assumed in the sections above that the price vectors $p = p(x, A)$ and $q = q(x, A)$ are computed exactly from (2.2), (2.3) in each iteration. But this is impractical since (2.2), (2.3) requires the root $\theta_A(x)$ of (2.1). However, an approximation of the price vectors is sufficient. Suppose that $\tilde{p}, \tilde{q}$ is an approximation of the exact vectors p, q with relative accuracy $\delta \in (0, 1/2)$, i.e.,

$$(1-\delta)p \;\le\; \tilde{p} \;\le\; (1+\delta)p,$$

$$(1-\delta)q \;\le\; \tilde{q} \;\le\; (1+\delta)q.$$

Let $\hat{x} \in B$ be computed by $ABS(\tilde{p}, \tilde{q}, t)$ with $\tilde{p}^T f(\hat{x}) \leq (1+t) \sum_{m=1}^{M} \tilde{p}_m$ and $\tilde{q}^T g(\hat{x}) \geq \frac{1}{(1+t)} \sum_{m=1}^{M} \tilde{q}_m$. This implies for the original price vectors that

$$p^T f(\hat{x}) \leq \tfrac{(1+t)(1+\delta)}{(1-\delta)} \sum_{m=1}^{M} p_m \leq (1+t+4\delta) \sum_{m=1}^{M} p_m,$$

$$q^T g(\hat{x}) \geq \tfrac{(1-\delta)}{(1+\delta)(1+t)} \sum_{m=1}^{M} q_m \geq \tfrac{1}{1+t+4\delta} \sum_{m=1}^{M} q_m$$

for $t, \delta \leq 1/3$. Using $\delta = t/4 = \Theta(\epsilon)$, we obtain a relative accuracy of $2t$. This shows that (2.2), (2.3) need only the price components p_m, q_m up to a relative accuracy of $\delta = \Theta(\epsilon)$.

Notice that the minimizer $\theta_A(x)[f, g]$ (that also depends on the functions f and g) satisfies the condition $\theta_A(x)[f \cdot s, g/s] = s\, \theta_A(x)[f, g]$ where s is a positive scalar. In addition the price components are independent of a positive scalar s; i.e., $p_m(x, A)[f \cdot s] = p_m(x, A)[f]$ and $q_m(x, A)[g/s] = q_m(x, A)[g]$. This helps to prescale locally the f and g vectors such that $\lambda_A(x)[f, g] = 1$. Suppose that $\lambda_A(x)[f, g] \neq 1$. Then define $\bar{f}_m(x) = f_m(x)/\lambda_A(x)[f, g]$ and $\bar{g}_m(x) = g_m(x)\lambda_A(x)[f, g]$. This gives $\lambda_A(x)[\bar{f}, \bar{g}] = \max(\max_{m \in \mathcal{M}} \bar{f}_m(x), \max_{m \in A} 1/\bar{g}_m(x)) = 1$, and the price vectors for $(\bar{f}, \bar{g})$ are the same. Using this prescaling, we can suppose that the minimizer $\theta = \theta_A(x)$ lies in the interval $[1 + t/(2M), 1 + 2t]$.

Now we estimate the influence of a small absolute error in θ for the price vectors p, q. Suppose that $\tilde{\theta}$ is an approximation of the correct minimizer θ, i.e., $|\tilde{\theta} - \theta| \leq \Delta$. The modified price vectors $\tilde{p}, \tilde{q}$ are given by

$$\begin{aligned} \tilde{p}_m &= \tfrac{t}{2M} \tfrac{\tilde{\theta}}{\tilde{\theta} - f_m(x)}, \\ \tilde{q}_m &= \tfrac{t}{2M} \tfrac{1/\tilde{\theta}}{g_m(x) - 1/\tilde{\theta}}. \end{aligned}$$

These price vectors have to satisfy the following inequalities in order to obtain a relative accuracy of δ:

$$\begin{aligned} |\tfrac{\tilde{p}_m - p_m}{p_m}| &\leq \delta, \\ |\tfrac{\tilde{q}_m - q_m}{q_m}| &\leq \delta. \end{aligned}$$

These are equivalent to

$$\begin{aligned} \left| \frac{\tilde{\theta}}{\theta} \frac{\theta - f_m(x)}{\tilde{\theta} - f_m(x)} - 1 \right| &\leq \delta, \\ \left| \frac{g_m(x)\theta - 1}{g_m(x)\tilde{\theta} - 1} - 1 \right| &\leq \delta. \end{aligned}$$

These inequalities hold if we can prove the following stronger inequalities:

$$\begin{aligned}
\frac{(\theta+\Delta)(\theta-f_m(x))}{\theta(\theta-\Delta-f_m(x))}-1 &\leq \delta,\\
1-\frac{(\theta-\Delta)(\theta-f_m(x))}{\theta(\theta+\Delta-f_m(x))} &\leq \delta,\\
\frac{g_m(x)\theta-1}{g_m(x)(\theta-\Delta)-1}-1 &\leq \delta,\\
1-\frac{g_m(x)\theta-1}{g_m(x)(\theta+\Delta)-1} &\leq \delta.
\end{aligned}$$

The first type of inequality is equivalent to

$$\Delta \leq \frac{\delta\theta(\theta-f_m(x))}{2\theta-f_m(x)+\delta\theta}.$$

Since $\theta \geq 1$, $f_m(x) \leq \lambda_A(x) = 1$, $\theta \leq 1+2t$, and $t, \delta < 1/6$, we have $\delta\theta(\theta-f_m(x)) \geq \delta(\theta-f_m(x)) \geq \delta(\theta-1)$ and $2\theta-f_m(x)+\delta\theta \leq (2+\delta)(1+2t) \leq 3$. Using $\theta \geq 1+t/(2M)$, this gives

$$\frac{\delta\theta(\theta-f_m(x))}{2\theta-f_m(x)+\delta\theta} \geq \frac{\delta}{3}(\theta-1) \geq \frac{\delta t}{6M}.$$

In other words, $\Delta \leq \frac{\delta}{6M}$ is a sufficient condition that the first type of inequality is satisfied. The same holds for the inequalities of the second type. Since δ and t are of order $\Theta(\epsilon)$, the absolute error Δ should be $\Theta(\frac{\epsilon^2}{M})$.

The third type of inequality is equivalent to

$$\Delta \leq \frac{\delta}{1+\delta}\frac{g_m(x)\theta-1}{g_m(x)} = \frac{\delta}{1+\delta}\left(\theta-\frac{1}{g_m(x)}\right).$$

Since $1/g_m(x) \leq \lambda_A(x) = 1$, $\delta \leq 1$, and $\theta \geq 1+t/(2M)$, the right-hand side is at least $\frac{\delta}{1+\delta}(\theta-1) \geq \frac{\delta t}{4M}$. This implies that $\Delta \leq \frac{\delta t}{4M}$ is a sufficient condition that the third type of inequality is satisfied. The same holds for the inequalities of the fourth type. This analysis shows that an absolute error $\Delta = \Theta(\frac{\epsilon^2}{M})$ in the computation of $\theta_A(x)[f,g]$ results in a relative error of $\delta = \Theta(\epsilon)$ in the value of each p_m and q_m.

To compute the value $\theta_A(x)(f,g) \in [1+t/(2M), 1+2t]$ approximately with an absolute error of Δ, we can use binary search. Since the length of the interval is $\Theta(\epsilon)$, there are at most $O(\ln(M/\epsilon))$ steps necessary. In each step, we have to compute the sum

$$\frac{t\theta}{M}\sum_{m=1}^{M}\frac{1}{\theta-f_m(x)} + \frac{t}{M\theta}\sum_{m\in A(x)}\frac{1}{g_m(x)-1/\theta}$$

for a candidate $\theta \in [1+t/(2M), 1+2t]$. Therefore, at most $O(M\ln(M\epsilon^{-1}))$ arithmetic operations per iteration are necessary. Using Newton's method this probably can be improved to $O(M\ln\ln(M\epsilon^{-1}))$ (see the analysis in [4, 5]).

Acknowledgment. The author thanks Florian Diedrich for many helpful discussions.

CALMNESS AND ERROR BOUNDS FOR CONVEX CONSTRAINT SYSTEMS*

WEN SONG†

Abstract. In the paper, we first compare the concepts of calmness, local error bound, and locally linear regularity. Second, we present some dual sufficient conditions for local error bound and local linear regularity. By using a characterization of the locally linear regularity for a collection of finite nonempty closed and convex subsets, we prove that the sufficient conditions provided in [R. Henrion and J. Outrata, *J. Math. Anal. Appl.*, 258 (2001), pp. 110–130; R. Henrion and A. Jourani, *SIAM J. Optim.*, 13 (2002), pp. 520–534; R. Henrion, A. Jourani, and J. Outrata, *SIAM J. Optim.*, 13 (2002), pp. 603–618] imply not only the calmness but also the existence of local error bounds for the convex constraint system in an infinite-dimensional setting.

Key words. calmness, error bounds, convex systems, local linear regularity, set-valued mapping

DOI. 10.1137/S1052623403430361

1. Introduction.

The concept of calmness or error bound plays an important role in various branches of the theory of constrained optimization such as nondegenerate multiplier rules (e.g., [7, 14, 28]), exactly penalty functions, and stability of constraint systems (e.g., [13, 27, 21, 5, 19]).

We recall (see [1, 28]) that a set-valued mapping $M\colon Y \rightrightarrows X$ between metric spaces Y, X is called pseudo-Lipschitz (or has Aubin property) at some point $(\bar{y}, \bar{x})$ of its graph if there exist neighborhoods $\mathcal{V}$,$\mathcal{U}$ of $\bar{y}, \bar{x}$, respectively, and some $\gamma > 0$ such that

$$d(x, M(y')) \leq \gamma d(y, y') \ \ \forall y, y' \in \mathcal{V}\ , \forall x \in M(y) \cap \mathcal{U},$$

or equivalently,

$$M(y) \cap \mathcal{U} \subset M(y') + \gamma d(y, y') B_X \ \forall y, y' \in \mathcal{V},$$

where B_X denotes the closed unit ball of X. When fixing $y' = \bar{y}$ in the above definition, M is called calm at $(\bar{y}, \bar{x})$ (see [28, 9]), i.e., there exist neighborhoods $\mathcal{V}$,$\mathcal{U}$ of $\bar{y}, \bar{x}$, respectively, and some $\gamma > 0$ such that

$$d(x, M(\bar{y})) \leq \gamma d(y, \bar{y}) \ \ \forall x \in M(y) \cap \mathcal{U}, \forall y \in \mathcal{V},$$

or equivalently,

$$M(y) \cap \mathcal{U} \subset M(\bar{y}) + \gamma d(y, \bar{y}) B_X \ \ \forall y \in \mathcal{V}.$$

When $\mathcal{U} = X$, the calmness reduces to the upper Lipschitz property of set-valued mapping introduced by Robinson [27]. Obviously, either the pseudo-Lipschitz property or the upper Lipschitz property implies calmness, but the converse is not true in

general (see [19, 11]). The pseudo-Lipschitz property and the upper Lipschitz property for a set-valued mapping have been extensively studied in the literature (see [1, 14, 23, 24, 15, 17, 19, 8]).

Sufficient conditions for calmness in a finite-dimensional setting have been derived in [9, 11] for set-valued maps of the type

$$M(y) = S(y) \cap C, \tag{1}$$

where $S\colon Y \rightrightarrows X$ is a set-valued map with closed graph and $C \subset X$ is closed. For instance, $S(y)$ may be a solution set of a constraint system

$$S(y) = \{x \in X \mid f(x) \in y - K\}, \tag{2}$$

where a function $f\colon X \to Y$ and a nonempty subset $K \subset Y$ are given. In particular, when $Y = \mathbb{R} \cup \{+\infty\}$ and $K = \mathbb{R}_+$

$$S(y) = \{x \in X \mid f(x) \leq y\}. \tag{2'}$$

In the convex case, a subdifferential condition for calmness of the constraint system (1) and (2′) has been given by Henrion and Jourani [10] in infinite-dimensional spaces.

We say that M has a local error bound at $(\bar{y}, \bar{x})$ if there exist $\delta, \gamma > 0$ such that

$$d(x, M(\bar{y})) \leq \gamma \max\{d(x, C), d(\bar{y}, S^{-1}(x))\} \ \ \forall x \in B(\bar{x}, \delta).$$

Clearly, when S is given by (2) or (2′), M has a local error bound $(\bar{y}, \bar{x})$ if and only if there exist positive scalars γ and δ such that

$$d(x, M(\bar{y})) \leq \gamma \max\{d(x, C), d(f(x), \bar{y} - K)\} \ \ \forall x \in B(\bar{x}, \delta) \tag{3}$$

or

$$d(x, M(\bar{y})) \leq \gamma \max\{d(x, C), (f(x) - \bar{y})^+\} \ \ \forall x \in B(\bar{x}, \delta), \tag{3'}$$

where $r^+ = \max\{r, 0\}$ for $r \in \mathbb{R}$.

Existence of error bounds for constraint systems has been extensively studied by many authors (see [13, 27, 20, 21, 26]).

The collection of closed convex sets $\{C_1, \ldots, C_n\}$ is called locally linearly regular around $\bar{x} \in C = \cap_{i=1}^n C_i$ if there exist $\delta, \gamma > 0$ such that

$$d(x, C) \leq \gamma \max\{d(x, C_1), \ldots, d(x, C_n)\} \ \ \forall x \in B(\bar{x}, \delta).$$

This notion is a special case of so-called bounded linear regularity introduced in [2]. It is known that bounded linear regularity is very useful in various branches of convex optimization, such as convex feasibility problem, constrained approximation, Fenchel duality, systems of convex inequalities and associated with error bounds, and subdifferential calculus (see [2, 3, 10, 13, 29, 15]).

In this paper, we first compare the concepts of calmness, local error bound, and local linear regularity. Second, we present some dual sufficient conditions for local error bound and local linear regularity. By using a characterization of the local linear regularity, we prove that the sufficient conditions provided in [9, 10, 11] imply not only the calmness but also the existence of local error bounds for the convex constraint system in an infinite-dimensional setting.

2. Notation and basic results. Let X be a normed space with topological dual space X^*. Denote by B_X and B_{X^*} the closed unit ball of X and X^*, respectively. We write $B(x,\delta)$ for $x+\delta B_X$, where $x\in X$ and $\delta>0$. Let A be a nonempty subset of X. Denote by $\bar{A}$ and $\mathrm{int}A$, respectively, the closure and the interior of A. The cone generated by A is $\mathrm{cone}(A)=\cup_{\lambda\geq 0}\lambda A$. For a nonempty closed convex subset C of X and $\bar{x}\in C$, define the tangent cone to C at $\bar{x}$ by $T_C(\bar{x})=\overline{\mathrm{cone}}(C-\bar{x})$ and the normal cone to C at $\bar{x}$ by

$$N_C(\bar{x})=(T_C(\bar{x}))^0=\{x^*\in X^*\mid \langle x^*,x-\bar{x}\rangle\leq 0\ \ \forall x\in C\}.$$

Let $f\colon X\to\mathbb{R}\cup\{+\infty\}$ be a lower semicontinuous proper convex function. By $\mathrm{epi}f$, $\partial f(\bar{x})$, and $\partial^\infty f(\bar{x})$ we denote the epigraph, the usual, and the singular subdifferentials of f, respectively, in the sense of convex analysis. It is well known that

$$\partial f(\bar{x})=\{x^*\in X^*\mid (x^*,-1)\in N_{\mathrm{epi}f}(\bar{x},f(\bar{x}))\},$$

$$\partial^\infty f(\bar{x})=\{x^*\in X^*\mid (x^*,0)\in N_{\mathrm{epi}f}(\bar{x},f(\bar{x}))\}.$$

Let $I_C(\cdot)$ be the indicator function of C, i.e.,

$$I_C(x)=\begin{cases}0 & \text{if } x\in C,\\ +\infty & \text{if } x\notin C.\end{cases}$$

It is obvious that $N_C(x)=\partial I_C(x)$.

Let us recall some notation and basic results on linear regularity of sets in X (see [3, 29]).

DEFINITION 2.1. *Suppose that $C_1,\dots,C_n$ are subsets of a normed space X with $C=\cap_{i=1}^n C_i\neq\emptyset$.*

(i) *The collection $\{C_1,\dots,C_n\}$ is linearly regular if there exists $k>0$ such that $d(x,C)\leq k\max\{d(x,C_1),\dots,d(x,C_n)\}$ for every $x\in X$.*

(ii) *The collection $\{C_1,\dots,C_n\}$ is boundedly linearly regular if for every bounded set S, there exists $k_S>0$ such that*

$$d(x,C)\leq k_S\max\{d(x,C_1),\dots,d(x,C_n)\}\ \ \forall x\in S.$$

(iii) *The collection $\{C_1,\dots,C_n\}$ is locally linearly regular around some point $\bar{x}\in C$ if there exist $\delta,\gamma>0$ such that $d(x,C)\leq\gamma\max\{d(x,C_1),\dots,d(x,C_n)\}$ for every $x\in B(\bar{x},\delta)$.*

It is trivial that linear regularity implies bounded linear regularity, which, in turn, implies locally linear regularity around every point of C.

In the following we assume that X is a Banach space. We recall the following result, which can be proved by Lemma 1.1 and Proposition 1.3 in [26]; for completeness we give its proof here.

LEMMA 2.1. *Let S be a closed convex subset of X and $\bar{x}\in S$. Then for every $\delta>0$, $0<\sigma<1$ and every $x\in B(\bar{x},\delta/3)$, there exists $z\in \mathrm{bd}S\cap B(\bar{x},\delta)$ such that*

$$\sigma d(x,S)\leq d(x-z,T_S(z)).$$

Proof. Let $x\in B(\bar{x},\delta/3)\setminus S$, let $d=d(x,S)$, and take $\epsilon>0$ such that $\sigma\leq\frac{d-\sqrt{\epsilon}(d+\epsilon+\sqrt{\epsilon})}{(1+\sqrt{\epsilon})(d+\epsilon+\sqrt{\epsilon})}$ and $\epsilon+\sqrt{\epsilon}\leq\delta/3$. By the separation theorem, there exists $x_0^*\in X^*$ with $\|x_0^*\|=1$ such that

$$\sup_{u\in S}\langle x_0^*,u\rangle=\inf_{u\in B_X}\langle x_0^*,x+du\rangle=\langle x_0^*,x\rangle-d.$$

Take $x_0 \in S$ such that $\|x - x_0\| \le d + \epsilon$. Then

$$\sup_{u\in S}\langle x_0^*, u\rangle = \langle x_0^*, x\rangle - d \le \|x_0^*\|\|x - x_0\| + \langle x_0^*, x_0\rangle - d \le \epsilon + \langle x_0^*, x_0\rangle.$$

By Phelps, Brøndsted, and Rockafellar's lemma (see [12]), there exist $z \in \mathrm{bd}S$, $x^* \in X^*$ such that

$$\sup_{u\in S}\langle x^*, u\rangle = \langle x^*, z\rangle \text{ (equivalently, } x^* \in N_S(z))$$

and

$$\|z - x_0\| \le \sqrt{\epsilon}, \ \ \|x^* - x_0^*\| \le \sqrt{\epsilon}.$$

This implies that

$$\|x^*\| \le 1 + \sqrt{\epsilon}, \ \ \|z - x\| \le d + \epsilon + \sqrt{\epsilon}$$

and

$$\langle x^*, z - x\rangle = \langle x^* - x_0^*, z - x\rangle + \langle x_0^*, z - x\rangle \le \sqrt{\epsilon}(d + \epsilon + \sqrt{\epsilon}) - d.$$

It follows that

$$\langle x^*, x - z\rangle \ge d - \sqrt{\epsilon}(d + \epsilon + \sqrt{\epsilon}) \ge \frac{d - \sqrt{\epsilon}(d + \epsilon + \sqrt{\epsilon})}{(1 + \sqrt{\epsilon})(d + \epsilon + \sqrt{\epsilon})}\|x^*\|\|z - x\| \ge \sigma\|x^*\|d(x, S).$$

Note that $T_S(z) \subset \{u \in X \mid \langle x^*, u\rangle \le 0\} =: D$. Hence, we can deduce that

$$\sigma d(x, S) \le \frac{\langle x^*, x - z\rangle}{\|x^*\|} = d(x - z, D) \le d(x - z, T_S(z)).$$

It is clear that

$$\|z - \bar{x}\| \le \|z - x\| + \|x - \bar{x}\| < d + \epsilon + \sqrt{\epsilon} + \frac{\delta}{3} < \delta,$$

i.e., $z \in B(\bar{x}, \delta)$. □

THEOREM 2.1. *Let $C_1, \ldots, C_n$ be closed convex subsets of X with $C = \cap_i C_i \ne \emptyset$ and let $\bar{x} \in C$. The following statements are equivalent:*

(i) *There exist $\delta, \gamma > 0$ such that for every $u \in C \cap B(\bar{x}, \delta)$*

$$N_C(u) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

(ii) *There exist $\delta, \gamma > 0$ such that*

$$d(h, T_C(u)) \le \gamma \max\{d(h, T_{C_1}(u)), \ldots, d(h, T_{C_n}(u))\} \ \ \forall h \in X, u \in B(\bar{x}, \delta) \cap C.$$

(iii) *There exist $\hat{\delta}, \hat{\gamma} > 0$ such that*

$$d(x, C) \le \hat{\gamma} \max\{d(x, C_1), \ldots, d(x, C_n)\} \ \ \forall x \in B(\bar{x}, \hat{\delta}).$$

Proof. (i) $\Rightarrow$ (ii) For every $u \in C \cap B(\bar{x}, \delta)$, since $N_C(u) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*})$, we have that $N_C(u) \subset \sum_i N_{C_i}(u)$. The converse inclusion is obvious. Hence $N_C(u) = \sum_i N_{C_i}(u)$ and hence $\sum_i N_{C_i}(u)$ is weakly star closed. By Jameson's Theorem 2.1 in [16] (see also Proposition 6 in [3]), we have

$$d(h, T_C(u)) \leq \gamma \max\{d(h, T_{C_i}(u)), \ldots, d(h, T_{C_n}(u))\} \ \ \forall h \in X.$$

(ii) $\Rightarrow$ (i) Condition (ii) implies that for every $u \in C \cap B(\bar{x}, \delta)$, $T_C(u) = \cap_{i=1}^n T_{C_i}(u))$. By the bipolar theorem, we have $N_C(u) = \mathrm{cl}^*(\sum_i N_{C_i}(u))$. Again, by Jameson's Theorem 2.1 in [16] (see also Proposition 6 in [3]), we see that $\sum_i N_{C_i}(u)$ is weakly star closed and $N_C(u) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*})$. Hence, we obtain (i).

(ii) $\Rightarrow$ (iii) If $x \in C$, then the assertion is obvious. Suppose that $x \in B(\bar{x}, \hat{\delta}) \setminus C$, where $\hat{\delta} = \frac{\delta}{3}$. From Corollary 2 in [6], i.e., for every closed convex subset D in X and $u \in D$, $d^{'}(\cdot, D)(u, h) = d(h, T_D(u))$ for all $h \in X$, one has $d^{'}(\cdot, C_i)(u, h) = d(h, T_{C_i}(u)$ for all $h \in X$, $i = 1, \ldots, n$. By the convexity of the distance function, we have

$$d'(\cdot, C_i)(u, x - u) \leq d(x, C_i) - d(u, C_i) = d(x, C_i) \ \ \forall u \in C.$$

Consequently,

$$d(x - u, T_{C_i}(u)) \leq d(x, C_i) \ \ \forall u \in C. \tag{4}$$

For $0 < \sigma < 1$, by Lemma 2.1, there exists $u \in \mathrm{bd}C \cap B(\bar{x}, \delta)$ such that

$$\sigma d(x, C) \leq d(x - u, T_C(u)). \tag{5}$$

It follows from (4), (5), and (ii) that

$$\sigma d(x, C) \leq \gamma \max\{d(x, C_1), \ldots, d(x, C_n)\}.$$

Let σ tend to 1. We have

$$d(x, C) \leq \gamma \max\{d(x, C_1), \ldots, d(x, C_n)\}.$$

(iii) $\Rightarrow$ (ii) Let $\delta = \hat{\delta}/2, \gamma = \hat{\gamma}$, and let $u \in \mathrm{bd}C \cap B(\bar{x}, \delta)$ and $h \notin T_C(u)$ with $\|h\| = 1$. Then $u + th \notin C$ for all $t > 0$. Since, $\|u + th - \bar{x}\| \leq \|u - \bar{x}\| + t\|h\| \leq \hat{\delta}$ for all $t \in (0, \delta)$, we have

$$d(u + th, C) \leq \gamma \max\{d(u + th, C_1), \ldots, d(u + th, C_n)\}.$$

Noticing that $u \in C = \cap_{i=1}^n C_i$, it follows from taking the limit that

$$d'(\cdot, C)(u, h) \leq \gamma \max\{d'(\cdot, C_1)(u, h), \ldots, d^{'}(\cdot, C_n)(u, h)\}.$$

That is

$$d(h, T_C(u)) \leq \gamma \max\{d(h, T_{C_1}(u)), \ldots, d(h, T_{C_n}(u))\}.$$

For the other case, the conclusion is obviously true. □

Remark 1. Condition (i) is equivalent to each of the following conditions:

(i$^{'}$) There exist $\delta, \gamma > 0$ such that for every $u \in C \cap B(\bar{x}, \delta)$

$$N_C(u) = \sum_i N_{C_i}(u), \ \ \left(\sum_i N_{C_i}(u)\right) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

(i$''$) There exist $\delta, \gamma > 0$ such that for every $u \in C \cap B(\bar{x}, \delta)$

$$T_C(u) = \cap_i T_{C_i}(u), \quad \left(\sum_i N_{C_i}(u)\right) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

Indeed, (i) implies that $N_C(u) \subset \sum_i N_{C_i}(u)$, and the converse inclusion is obviously true. Hence (i$'$) is true. It clear that (i$'$) implies (i$''$). By the bipolar theorem, $T_C(u) = \cap_i T_{C_i}(u)$ implies that $N_C(u) = \mathrm{cl}^*(\sum_i N_{C_i}(u))$. By Proposition 5 in [16], $(\sum_i N_{C_i}(u)) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*})$ implies that $\sum_i N_{C_i}(u)$ is weakly star closed. Hence $N_C(u) = \sum_i N_{C_i}(u)$ and (i) is true.

The equivalence of (i$''$), (ii), and (iii) has been proved in [29]. From the proof of Theorem 2.1, we can see that the following result concerning the linear regularity is also true.

COROLLARY 2.1. *Let $C_1, \ldots, C_n$ be closed convex subsets of X with $C = \cap_i C_i \neq \emptyset$. The following statements are equivalent:*

(i) *There exist $\gamma > 0$ such that for every $u \in C$*

$$N_C(u) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

(i$'$) *There exists $\gamma > 0$ such that for every $u \in C$*

$$N_C(u) = \sum_i N_{C_i}(u), \quad \left(\sum_i N_{C_i}(u)\right) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

(i$''$) *There exists $\gamma > 0$ such that for every $u \in C$*

$$T_C(u) = \cap_i T_{C_i}(u), \quad \left(\sum_i N_{C_i}(u)\right) \cap B_{X^*} \subset \gamma \sum_i (N_{C_i}(u) \cap B_{X^*}).$$

(ii) *There exists $\gamma > 0$ such that*

$$d(h, T_C(u)) \leq \gamma \max\{d(h, T_{C_1}(u)), \ldots, d(h, T_{C_n}(u))\} \ \ \forall h \in X, u \in C.$$

(iii) *There exists $\hat{\gamma} > 0$ such that*

$$d(x, C) \leq \hat{\gamma} \max\{d(x, C_1), \ldots, d(x, C_n)\} \ \ \forall x \in X.$$

The equivalence of (i$'$), (ii), and (iii) has been proved in Theorem 2.6 in [26].

3. Calmness and error bounds. In the following we assume that X and Y are Banach spaces. Consider now a set-valued mapping $M\colon Y \rightrightarrows X$ defined as the intersection $M(y) = S(y) \cap C$, where $S\colon Y \rightrightarrows X$ is a set-valued mapping and C is a subset of X.

THEOREM 3.1. *Let the set-valued mapping M defined as above and let $(\bar{y}, \bar{x}) \in \mathrm{gr}M$. Consider the following conditions:*

(i) *The set-valued mapping M is calm at $(\bar{y}, \bar{x})$.*

(ii) *There exist $\delta, \gamma > 0$ such that*

$$d(x, M(\bar{y})) \leq \gamma d(\bar{y}, S^{-1}(x)) \ \ \forall x \in C \cap B(\bar{x}, \delta).$$

(iii) *There exist* $\delta, \gamma > 0$ *such that*

$$d(x, M(\bar{y})) \le \gamma \max\{d(x, C), d(\bar{y}, S^{-1}(x))\} \ \ \forall x \in B(\bar{x}, \delta).$$

(iv) *There exist* $\delta, \gamma > 0$ *such that*

$$d(x, M(\bar{y})) \le \gamma \max\{d((x, \bar{y}), C \times \{\bar{y}\}), d((x, \bar{y}), \mathrm{gr}S^{-1})\} \ \ \forall x \in B(\bar{x}, \delta).$$

Then

$$\text{(iv)} \Longrightarrow \text{(iii)} \Longrightarrow \text{(ii)} \Longleftrightarrow \text{(i)}.$$

When $C = X$*, all the conditions are equivalent.*

Proof. It is obvious that

$$\text{(iv)} \Longrightarrow \text{(iii)} \Longrightarrow \text{(ii)} \Longrightarrow \text{(i)}.$$

(i) $\Rightarrow$ (ii) By the calmness of M at $(\bar{y}, \bar{x})$, fix some positive numbers $\delta, \hat{\gamma}$ $(\hat{\gamma} \ge 1)$ such that

$$d(x, M(\bar{y})) \le \hat{\gamma}\|\bar{y} - y\| \ \ \forall y \in B(\bar{y}, \delta), \ x \in S(y) \cap C \cap B(\bar{x}, \delta).$$

Let $x \in B(\bar{x}, \delta) \cap C$, $y \in S^{-1}(x)$. If $y \in B(\bar{y}, \delta)$ as well, then $d(x, M(\bar{y})) \le \hat{\gamma}\|\bar{y} - y\|$. Otherwise we get the desired estimate that

$$d(x, M(\bar{y})) \le \|x - \bar{x}\| \le \delta \le \hat{\gamma}\|\bar{y} - y\|.$$

Consequently, we have

$$d(x, M(\bar{y})) \le \hat{\gamma} d(\bar{y}, S^{-1}(x)) \ \ \forall x \in B(\bar{x}, \delta) \cap C.$$

Suppose $C = X$. It is trivial that (iii) $\Longleftrightarrow$ (ii). For the proof of (iii) $\Longrightarrow$ (iv), see Proposition 4 in [15]. For the completeness, we include the proof. Fix $x \in B(\bar{x}, \delta)$ and consider any $(y', x') \in \mathrm{gr}S$ with $y' \in B(\bar{y}, \delta)$, $x' \in B(\bar{x}, \delta)$. Then

$$\begin{aligned} d(x, M(\bar{y})) &\le \|x - x'\| + d(x', M(\bar{y})) \\ &\le \|x - x'\| + \gamma\|\bar{y} - y'\| \\ &\le \max\{1, \gamma\}(\|x - x'\| + \|\bar{y} - y'\|). \end{aligned}$$

So, putting $\hat{\gamma} = \max\{1, \gamma\}$ we obtain

$$d(x, M(\bar{y})) \le \hat{\gamma} \inf\{\|x - x'\| + \|\bar{y} - y'\| \mid (x', y') \in (\mathrm{gr}S^{-1}) \cap B(\bar{x}, \delta) \times B(\bar{y}, \delta)\}.$$

Since for any $(x', y') \in X \times Y$ with $\|x' - \bar{x}\| \ge \delta$ and $\|y' - \bar{y}\| \ge \delta$ we have

$$\|x - x'\| + \|\bar{y} - y'\| \ge \|x' - \bar{x}\| - \|x - \bar{x}\| + \|y' - \bar{y}\| \ge 2\delta - \delta \ge d((x, \bar{y}), \mathrm{gr}S^{-1}).$$

Hence

$$d(x, M(\bar{y})) \le \hat{\gamma} d((x, \bar{y}), \mathrm{gr}S^{-1}) \ \ \forall x \in B(\bar{x}, \delta). \qquad \square$$

Remark 2. (a) The equivalence between (i) and (ii) shows that there is no need at all to restrict y to a neighborhood V of $\bar{y}$ in the description of calmness (this equivalence was also proved in [8] under some additional condition). Moreover, the

equivalence between (i) and (ii) also shows that the calmness of M at $(\bar{y},\bar{x})$ amounts to the existence of a local error bound of M at the same point whenever $C = X$.

(b) Condition (ii) implies (iii) whenever S^{-1} is pseudo-Lipschitz at $(\bar{x},\bar{y})$.

Indeed, if $S^{-1}(x)$ is pseudo-Lipschitz at $(\bar{x},\bar{y})$, then the function $\rho(x) := d(\bar{y}, S^{-1}(x))$ is locally Lipschitz at $\bar{x}$. Without loss of generality, we may assume that

$$|\rho(x_1) - \rho(x_2)| \le L\|x_1 - x_2\| \ \ \forall x_1, x_2 \in B(\bar{x},\delta)$$

for some $\delta > 0$ and $L > 0$. By the nonexpansivity of distance function and (ii), for every $x_1 \in C \cap B(\bar{x},\delta)$, $x \in B(\bar{x},\delta)$, we have

$$0 \le \gamma d(\bar{y}, S^{-1}(x_1)) - d(x_1, M(\bar{y})) \le \gamma d(\bar{y}, S^{-1}(x)) - d(x, M(\bar{y})) + (\gamma L + 1)\|x - x_1\|.$$

This implies that

$$d(x, M(\bar{y})) \le \gamma d(\bar{y}, S^{-1}(x)) + (\gamma L + 1) d(x, C \cap B(\bar{x},\delta)).$$

Hence,

$$d(x, M(\bar{y})) \le \hat{\gamma} \max\{d(\bar{y}, S^{-1}(x)), d(x, C)\} \ \ \forall x \in B(\bar{x},\delta/3),$$

where $\hat{\gamma} = \max\{\gamma L + 1, \gamma\}$.

(c) When $C = X$, the equivalence between (i) and (iv) implies that if S is calm at $(\bar{y},\bar{x})$ and $\bar{x}$ is a locally minimizer of a locally Lipschitz function $f\colon X \to \mathbb{R}$ on $S(\bar{y})$, then $\bar{x}$ is a free local minimizer of $p(x) := f(x) + \alpha p_S(x)$ whenever α is sufficiently large, where $p_S(x) = d((x,\bar{y}), \mathrm{gr}S^{-1}) = d((\bar{y},x), \mathrm{gr}S)$. This result has been proved by Klatte and Kummer in [19] by constructing a locally upper Lipschitz submapping.

PROPOSITION 3.1. *The condition* (iv) *in Theorem* 3.1 *holds if and only if* $\{C \times \{\bar{y}\}, \mathrm{gr}S^{-1}\}$ *is locally linear regular around* $(\bar{x},\bar{y})$.

Proof. The implication "$\Leftarrow$" is trivial. Suppose (iv) holds, i.e., there exist $\delta, \gamma > 0$ such that

$$d(x, M(\bar{y})) \le \gamma \max\{d((x,\bar{y}), C \times \{\bar{y}\}), d((x,\bar{y}), \mathrm{gr}S^{-1})\} \ \ \forall x \in B(\bar{x},\delta).$$

This implies that

$$d((x,y), (C \times \{\bar{y}\}) \cap \mathrm{gr}S^{-1}) \le \gamma d((x,y), \mathrm{gr}S^{-1}) \ \ \forall (x,y) \in (C \times \{\bar{y}\}) \cap B((\bar{x},\bar{y}),\delta).$$

By the nonexpansivity of the distance function, we can deduce that for all $(x,y) \in B((\bar{x},\bar{y}),\delta/3)$

$$d((x,y), (C \times \{\bar{y}\}) \cap \mathrm{gr}S^{-1}) \le (2\gamma + 1) \max\{d((x,y), C \times \{\bar{y}\}), d((x,y), \mathrm{gr}S^{-1})\}$$

(see Proposition 6 in [29] and also Proposition 2.43 in [7]). Hence $\{C \times \{\bar{y}\}, \mathrm{gr}S^{-1}\}$ is locally linear regular around $(\bar{x},\bar{y})$. □

We recall the following notions of normal cones (see [23, 24]). Let $\Omega \subset X$ and $\epsilon \ge 0$. Given $x \in \mathrm{cl}\Omega$, the nonempty set

$$\hat{N}_\epsilon(x,\Omega) := \left\{ x^* \in X^* \ \middle|\ \limsup_{u \xrightarrow{\Omega} x} \frac{\langle x^*, u - x\rangle}{\|u - x\|} \le \epsilon \right\}$$

is called the set of (Fréchet) ϵ-normal cones to Ω at x. When $\epsilon = 0$, the set $\hat{N}_0(x,\Omega)$ is called the Fréchet normal cone to Ω at x and is denoted by $\hat{N}(x,\Omega)$. If $x \notin \mathrm{cl}\Omega$, we set $\hat{N}_\epsilon(x,\Omega) = \emptyset$ for all $\epsilon \ge 0$.

The nonempty cone

$$N(x,\Omega) := \limsup_{x\to\bar{x},\epsilon\searrow 0} \hat{N}_\epsilon(x,\Omega)$$

is called the normal cone to Ω at x, where

$$\limsup_{x\to\bar{x},\epsilon\searrow 0} \hat{N}_\epsilon(x,\Omega) = \{x^* \in X^* \mid \exists \text{ sequences } x_k \to \bar{x}, \epsilon_k \searrow 0$$
$$\text{and } x_k^* \overset{w^*}{\to} x^* \text{ with } x_k^* \in \hat{N}_{\epsilon_k}(x_k,\Omega)\}.$$

We set $N(x,\Omega) = \emptyset$ for $\bar{x} \notin \mathrm{cl}\Omega$.

It is well known that for a convex set Ω, both the Fréchet normal cone $\hat{N}(x,\Omega)$ and normal cone $N(x,\Omega)$ coincide with the normal cone $N_\Omega(x)$ in the sense of convex analysis, i.e.,

$$N_\Omega(x) = \{x^* \in X^* \mid \langle x^*, u-x\rangle \le 0 \ \ \forall u \in \Omega\}.$$

A closed set Ω in X is called normally compact around $\bar{x} \in \Omega$ (see [22, 23]) if there exist positive numbers γ, σ and a compact subset K of X such that

$$\hat{N}(x,\Omega) \subset \left\{x^* \in X^* \mid \sigma\|x^*\| \le \max_{z\in K} |\langle x^*, z\rangle|\right\} \ \ \forall x \in B_\gamma(\bar{x}) \cap \Omega.$$

It is clear that if Ω is convex and normally compact around $\bar{x} \in \Omega$, then for any net

$$x_i^* \in N_\Omega(x_i) \text{ with } x_i \to \bar{x} \text{ and } x_i^* \overset{w^*}{\to} 0$$

one has $x_i^* \to 0$ in the norm topology of X^* (see [22, 25]).

Observe that each closed set Ω in a finite-dimensional space is normally compact around every point $\bar{x} \in \Omega$. Loewen [22] shows that Ω is normally compact around $\bar{x} \in \Omega$ if Ω is compactly epi-Lipschitzian at $\bar{x} \in \Omega$ in the sense of Borwein and Strojwas [4]. The latter means that there exist a neighborhood N_x of x, a neighborhood U of the origin, a positive number ϵ, and a compact set K such that

$$C \cap N_x + \lambda U \subset C + \lambda K \ \ \forall 0 < \lambda < \epsilon.$$

For a set-valued map $S\colon X \to Y$ and some point $(x,y) \in \mathrm{gr}S$, the coderivative $D^*S(x,y)\colon Y^* \to X^*$ is defined by

$$D^*S(x,y)(u^*) := \{v^* \in X^* \mid (v^*, -u^*) \in N((x,y), \mathrm{gr}S\}.$$

If S is single-valued, we simply write $D^*S(x)$ instead of $D^*S(x, S(x))$.

A set-valued mapping $S\colon X \to Y$ is said to be partially ∂-coderivatively compact at $(\bar{x},\bar{y}) \in \mathrm{gr}S$ (see [18]) if for every net $\{(x_i,y_i)\} \subset \mathrm{gr}S$ converging to $(\bar{x},\bar{y})$ and every net $\{(x_i^*, y_i^*)\}$ satisfying $x_i^* \in D^*S(x_i,y_i)(y_i^*)$, $\|x_i^*\| \to 0$, and $y_i^* \overset{w^*}{\to} 0$ we have $\|y_i^*\| \to 0$.

Observe that the above property always holds when Y is finite-dimensional. It has been proved that $S\colon X \to Y$ is partially ∂-coderivatively compact at $(\bar{x},\bar{y})$ if the graph of S is closed and convex and $\bar{y} \in \mathrm{int}S(X)$ (see [18]) or if S is partially compactly epi-Lipschitz at $(\bar{x},\bar{y})$ in the sense of Jourani and Thibault (see [18]) or if the graph of S is closed and S partially normally compact with respect to y around $(\bar{x},\bar{y})$ in the sense of Mordukhovich and Shao (see [25]).

LEMMA 3.1. *Let $S\colon X \to Y$ be a set-valued mapping with closed and convex graph, let C be a closed convex subset of X, let D be a closed convex subset of Y, and let $(\bar{x},\bar{y}) \in \mathrm{gr}S \cap (C \times D)$. Suppose that one of the following conditions holds:*

(i) *Either* $C \times D$ *or* $\mathrm{gr}S$ *is normally compact around* $(\bar{x}, \bar{y})$.
(ii) C *is normally compact around* $\bar{x}$ *and* S *is partially* ∂*-coderivatively compact at* $(\bar{x}, \bar{y})$.

Then $N_{\mathrm{gr}S}((\bar{x}, \bar{y})) \cap (-N_{C\times D}((\bar{x}, \bar{y}))) = \{(0, 0)\}$ *if and only if* $(0, 0) \in \mathrm{int}[\mathrm{gr}S - (C \times D)]$, *which implies that there exist* $\delta, \gamma > 0$ *such that*

$$d((x, y), (C \times D) \cap \mathrm{gr}S) \leq \gamma \max\{d((x, y), C \times D), d((x, y), \mathrm{gr}S\} \ \ \forall (x, y) \in B((\bar{x}, \bar{y}), \delta).$$

Proof. "$\Longrightarrow$" Denote by E the product space $X \times Y$ with the norm $\|u\| = \|x\| + \|y\|$ for every $u = (x, y) \in E$. Assume that $(0, 0) \notin \mathrm{int}[\mathrm{gr}S - (C \times D)]$. For an arbitrary positive sequence $\epsilon_k \to 0$ as $k \to \infty$, we can find sequence $\{\bar{u}_k\} = \{(\bar{x}_k, \bar{y}_k)\} \in E$ with $\|\bar{u}_k\| \leq \epsilon_k^2$ such that $\bar{u}_k \notin \mathrm{gr}S - (C \times D)$. Set $A = \mathrm{gr}S - \bar{u}_k$, $B = C \times D$, and $\bar{u} = (\bar{x}, \bar{y})$, and equip E with the norm $\|(u, v)\| = \|u\| + \|v\|$ for every $u, v \in E$. Applying Ekeland's variational principle to the function $f(u, v) := \|u - v\|$ on the complete metric space $A \times B$, since

$$f(\bar{u} - \bar{u}_k, \bar{u}) = \|\bar{u}_k\| \leq \inf\{f(u, v) \mid (u, v) \in A \times B\} + \epsilon_k^2,$$

there exists $(u_k, v_k) \in A \times B$ such that

$$\|u_k - \bar{u} + \bar{u}_k\| + \|v_k - \bar{u}\| \leq \epsilon_k \tag{6}$$

and

$$f(u_k, v_k) \leq f(u, v) + \epsilon_k(\|u - u_k\| + \|v - v_k\|) \ \ \forall (u, v) \in A \times B.$$

This implies that

$$(0, 0) \in \partial f(u_k, v_k) + \epsilon_k B_{E^*} \times B_{E^*} + N_A(u_k) \times N_B(v_k).$$

Hence there exist $w_k^* \in E^*$ with $\|w_k^*\| = 1$ and $\langle w_k^*, u_k - v_k\rangle = \|u_k - v_k\|$ such that

$$(0, 0) \in (w_k^*, -w_k^*) + \epsilon_k B_{E^*} \times B_{E^*} + N_A(u_k) \times N_B(v_k).$$

It follows that there exist $\{w_{ik}^*\} \subset E^*$, $i = 1, 2$, with $w_{1k}^* \in N_A(u_k)$, $w_{2k}^* \in N_B(v_k)$ such that

$$1 - \epsilon_k \leq \|w_{ik}^*\| \leq 1 + \epsilon_k, \ i = 1, 2, \qquad \text{and} \qquad \|w_{1k}^* + w_{2k}^*\| \leq 2\epsilon_k. \tag{7}$$

Let $\{(x_{1k}, y_{1k})\} \subset \mathrm{gr}S$, $\{(x_{2k}, y_{2k})\} \subset C$ be such that $u_k = (x_{1k}, y_{1k}) - \bar{u}_k$, $v_k = (x_{2k}, y_{2k})$ and let $\{(x_{ik}^*, y_{ik}^*)\} \subset E^*$ be such that $w_{ik}^* = (x_{ik}^*, y_{ik}^*)$, $i = 1, 2$. Then $(x_{1k}^*, y_{1k}^*) \in N_A(u_k) = N_{\mathrm{gr}S}((x_{1k}, y_{1k}))$ and $(x_{2k}^*, y_{2k}^*) \in N_C((x_{2k}, y_{2k}))$, and by (6) and (7), we get that

$$(x_{ik}, y_{ik}) \to (\bar{x}, \bar{y}) \ (i = 1, 2) \qquad \text{and} \qquad (x_{1k}^* + x_{2k}^*, y_{1k}^* + y_{2k}^*) \to (0, 0) \text{ as } k \to \infty. \tag{8}$$

Since $\|(x_{ik}^*, y_{ik}^*)\| \to 1$ as $k \to \infty$, $i = 1, 2$, and by taking into account that the closed unit ball B_{E^*} is weak-star compact, without of loss of generality we may assume that

$$(x_{ik}^*, y_{ik}^*) \xrightarrow{w^*} (x_i^*, y_i^*) \ \text{ as } k \to \infty, \quad i = 1, 2.$$

Thus

$$(x_1^*, y_1^*) \in N_{\mathrm{gr}S}((\bar{x}, \bar{y})), \ (x_2^*, y_2^*) \in N_{C\times D}((\bar{x}, \bar{y})), \text{ and } (x_1^* + x_2^*, y_1^* + y_2^*) = (0, 0).$$

Let us denote $(x^*, y^*) = (x_1^*, y_1^*) = -(x_2^*, y_2^*)$. To finish the proof it remains to show that $(x^*, y^*) \neq (0, 0)$. It is clear that this is true if (i) holds since $\|(x_{ik}^*, y_{ik}^*)\| \to 1$ as $k \to \infty$, $i = 1, 2$. Suppose that (ii) holds. If $\|x_{2k}^*\| \not\to 0$, then by the normal compactness of C around $\bar{x}$, we have $x^* = -x_2^* \neq 0$; if $\|x_{2k}^*\| \to 0$, noticing that $\|(x_{2k}^*, y_{2k}^*)\| \to 1$, then $\|y_{2k}^*\| \to 1$. It follows from (8) that $\|x_{1k}^*\| \to 0$ and $\|y_{1k}^*\| \to 1$. Since S is partially ∂-coderivatively compact at $(\bar{x}, \bar{y})$, we obtain $y^* = y_1^* \neq 0$.

"$\Longleftarrow$" Choose arbitrary $(x^*, y^*) \in N_{\mathrm{gr}S}(\bar{x}, \bar{y}) \cap (-N_{C\times D}(\bar{x}, \bar{y}))$. Then

$$\langle (x^*, y^*), (x_1 - \bar{x}, y_1 - \bar{y})\rangle \leq 0 \ \ \forall (x_1, y_1) \in \mathrm{gr}S,$$

$$\langle (x^*, y^*), (x_2 - \bar{x}, y_2 - \bar{y})\rangle \geq 0 \ \ \forall (x_2, y_2) \in C \times D.$$

In other words,

$$\langle (x^*, y^*), (x_1 - x_2, y_1 - y_2)\rangle \leq 0 \ \ \forall (x_1, y_1) \in \mathrm{gr}S, (x_2, y_2) \in C \times D.$$

However, by assumption $(0, 0) \in \mathrm{int}[\mathrm{gr}S - (C \times D)]$, one has that $(x^*, y^*) = (0, 0)$.

The last implication is well known. For instance, see Theorem 4.1 in [10] or Theorem 1 in [29]. □

The conclusion of Lemma 3.1 was proved by Henrion and Jourani [10] under the assumption that either $C \times D$ or $\mathrm{gr}S$ is compactly epi-Lipschitzian at $(\bar{x}, \bar{y})$.

THEOREM 3.2. *Consider the set-valued mapping $M\colon Y \rightrightarrows X$ defined as $M(y) = S(y) \cap C$, where $S\colon Y \rightrightarrows X$ is a set-valued mapping with closed convex graph and C is a closed convex set of X. Let $(\bar{y}, \bar{x}) \in \mathrm{gr}M$. Then the following statements hold:*

(i) *If there exist positive numbers γ, δ such that*

$$B_{X^*} \cap N_{M(\bar{y})}(u) \subset \gamma[B_{X^*} \cap N_C(u) + B_{X^*} \cap D^*S^{-1}(u, \bar{y})(B_{Y^*})] \tag{9}$$

for all $u \in B(\bar{x}, \delta) \cap M(\bar{y})$, then M has a local error bound at $(\bar{y}, \bar{x})$.

(ii) *If either C is normally compact around $\bar{x}$ and S^{-1} is partially ∂-coderivatively compact at $(\bar{x}, \bar{y})$ or $\mathrm{gr}S^{-1}$ is normally compact around $(\bar{x}, \bar{y})$, and if*

$$D^*S^{-1}(\bar{x}, \bar{y})(y^*) \cap (-\mathrm{bd}N_C(\bar{x})) = \begin{cases} \emptyset & \text{or} \\ \{0\} & \text{if } y^* = 0, \end{cases} \tag{10}$$

then $\{C \times \{\bar{y}\}, \mathrm{gr}S^{-1}\}$ is locally linearly regular around $(\bar{x}, \bar{y})$.

Proof. (i) Suppose (9) holds. Let $x \in B(\bar{x}, \frac{\delta}{3}) \setminus M(\bar{y})$ and $\sigma \in (0, 1)$. From the proof of Lemma 2.1, one sees that there exist $z \in \mathrm{bd}M(\bar{y}) \cap B(\bar{x}, \delta)$ and $x^* \in N_{M(\bar{y})}(z)$ with $\|x^*\| = 1$ such that

$$\sigma\|x - z\| \leq \langle x^*, x - z\rangle.$$

According to (9), there exist $u^* \in B_{X^*} \cap N_C(z)$, $y^* \in B_{Y^*}$, $v^* \in B_{X^*} \cap D^*S^{-1}(z, \bar{y})(y^*)$ such that $x^* = \gamma(u^* + v^*)$. It follows that

$$\sigma\|x - z\| \leq \gamma(\langle u^*, x - z\rangle + \langle v^*, x - z\rangle).$$

Noticing that $u^* \in \partial d(\cdot, C)(z)$ and $(v^*, -y^*) \in N_{\mathrm{gr}S^{-1}}(z, \bar{y})$, one has that

$$\langle u^*, x - z\rangle \leq d(x, C)$$

and

$$\langle v^*, x - z\rangle \le \langle y^*, y - \bar{y}\rangle \le \|y - \bar{y}\| \ \ \forall y \in S^{-1}(x).$$

Hence, we get that

$$\sigma d(x, M(\bar{y})) \le 2\gamma \max\{d(x, C), d(\bar{y}, S^{-1}(x))\}.$$

Letting $\sigma \to 1$, we obtain the desired result.

(ii) If $0 \notin -\mathrm{bd}N_C(\bar{x}))$, then $N_C(\bar{x}) = X^*$, which implies that $C = \{\bar{x}\}$. In this case, the conclusion is obvious. We assume that $0 \in -\mathrm{bd}N_C(\bar{x}))$. This, together with (10), implies that $D^*S^{-1}(\bar{x}, \bar{y})(0) \cap (-\mathrm{bd}N_C(\bar{x})) = \{0\}$ and that

$$N_{\mathrm{gr}S^{-1}}((\bar{x}, \bar{y})) \cap (-\mathrm{bd}N_{C\times\{\bar{y}\}}((\bar{x}, \bar{y}))) = \{(0, 0)\}.$$

If

$$N_{\mathrm{gr}S^{-1}}((\bar{x}, \bar{y})) \cap -\mathrm{int}(N_{C\times\{\bar{y}\}}((\bar{x}, \bar{y}))) \ne \emptyset, \tag{11}$$

then there exists $(x^*, y^*) \in N_{\mathrm{gr}S^{-1}}((\bar{x}, \bar{y}))$ such that $-B((x^*, y^*), \delta) \subset N_{C\times\{\bar{y}\}}((\bar{x}, \bar{y}))$ for some $\delta > 0$. In other words,

$$\langle -x^*, x - \bar{x}\rangle + \delta\|x - \bar{x}\| \le 0 \ \ \forall x \in C,$$

$$\langle x^*, x - \bar{x}\rangle + \langle y^*, y - \bar{y}\rangle \le 0 \ \ \forall (x, y) \in \mathrm{gr}S^{-1}.$$

Hence for any $x \in M(\bar{y})$, i.e., $(x, \bar{y}) \in \mathrm{gr}S^{-1} \cap C \times \{\bar{y}\}$, we have

$$\delta\|x - \bar{x}\| \le \langle -x^*, x - \bar{x}\rangle + \delta\|x - \bar{x}\| \le 0,$$

and hence $x = \bar{x}$. This shows that $M(\bar{y}) = \{\bar{x}\}$. Hence

$$N_{M(\bar{y})\times\{\bar{y}\}}((\bar{x}, \bar{y})) = X^* \times Y^*.$$

On the other hand, formula (11) implies

$$N_{\mathrm{gr}S^{-1}}((\bar{x}, \bar{y})) + N_{C\times\{\bar{y}\}}((\bar{x}, \bar{y})) = X^* \times Y^*.$$

Hence,

$$N_{\mathrm{gr}S^{-1}}((u, v)) + N_{C\times\{\bar{y}\}}((u, v)) = X^* \times Y^* = N_{M(\bar{y})\times\{\bar{y}\}}((u, v)) \tag{12}$$

for all $(u, v) \in (M(\bar{y}) \times \{\bar{y}\}) \cap B((\bar{x}, \bar{y}), \delta) = \{(\bar{x}, \bar{y})\}$, where δ is an arbitrary positive number.

By Proposition 4 in [16], (12) implies that there exists some $\gamma > 0$ such that

$$N_{M(\bar{y})\times\{\bar{y}\}}((u, v)) \cap B_{X^*\times Y^*} \subset \gamma(N_{C\times\{\bar{y}\}}((u, v)) \cap B_{X^*\times Y^*} + N_{\mathrm{gr}S^{-1}}((u, v)) \cap B_{X^*\times Y^*})$$

for all $(u, v) \in (M(\bar{y}) \times \{\bar{y}\}) \cap B((\bar{x}, \bar{y}), \delta)$. It follows from Theorem 2.1 that there exists some $\hat{\delta} > 0$ such that

$$d(x, M(\bar{y}) \le \gamma \max\{d((x, \bar{y}), C \times \{\bar{y}\}), d((x, \bar{y}), \mathrm{gr}S^{-1})\} \ \ \forall x \in B(\bar{x}, \hat{\delta}).$$

Hence, the conclusion follows from Proposition 3.1.

Otherwise, we have

$$N_{\mathrm{gr}S^{-1}}((\bar{x},\bar{y}))\cap -N_{C\times\{\bar{y}\}}((\bar{x},\bar{y}))=\{(0,0)\}.$$

Then the conclusion follows from Lemma 3.1. □

Remark 3. From the proof, it is easy to see that the hypotheses of (ii) imply (9). The second part of Theorem 3.2 generalizes Theorem 3.2 in [11] to the infinite-dimensional space in the case when the set C and the graph of the set-valued map S are convex.

When $C=X$, obviously, C is normally compact around $\bar{x}$ and condition (10) reduces to

$$\ker D^*S^{-1}(\bar{x},\bar{y})=\{0\},$$

or equivalently,

$$D^*S(\bar{y},\bar{x})(0)=\{0\}. \tag{13}$$

It has been proved that (see [18]) S is pseudo-Lipschitz at $(\bar{y},\bar{x})$ under the assumption of (ii) with $C=X$, which, in turn, implies the conclusion of (ii); when X and Y are finite-dimensional spaces, condition (13) is equivalent to the pseudo-Lipschitz property of S at $(\bar{y},\bar{x})$. The above-mentioned results are valid even in the nonconvex case.

Let $K\subset Y$ be a closed convex cone. A single-valued map $f\colon X\to Y$ is said to be K-convex if its epigraph

$$\mathrm{epi}_K f=\{(x,y)\mid f(x)\in y-K\}$$

is a convex set in $X\times Y$.

COROLLARY 3.1. *Let X, Y be Asplund spaces, let C be a closed convex subset of X, and let K be a closed convex cone of Y. Consider the set-valued maps $S,M\colon Y\rightrightarrows X$ defined as*

$$S(y)=\{x\in X\mid f(x)\in y-K\}$$

and $M(y)=C\cap S(y)$, where $f\colon X\to Y$ is a continuous K-convex map. Suppose that $(0,\bar{x})\in \mathrm{gr}M$ and that K is normally compact around $-f(\bar{x})$ (especially $\mathrm{int}K\neq\emptyset$). Then the following statements hold:

(i) *If there exist positive numbers γ,δ such that*

$$B_{X^*}\cap N_{M(0)}(u)\subset\gamma[B_{X^*}\cap N_C(u)+B_{X^*}\cap D^*(f+K)(u,0)(B_{Y^*})]$$

for all $u\in B(\bar{x},\delta)\cap M(0)$, then M has a local error bound at $(0,\bar{x})$.

(ii) *If either C is normally compact around $\bar{x}$ and $0\in\mathrm{int}(f(X)+K)$ or $\mathrm{epi}f$ is normally compact around $(\bar{x},f(\bar{x}))$, and if for every $y^*\in N_{-K}(f(\bar{x}))$,*

$$D^*f(\bar{x})(y^*)\cap(-\mathrm{bd}N_C(\bar{x}))=\begin{cases}\emptyset & \text{or}\\ \{0\} & \text{if } y^*=0,\end{cases}$$

then $\{C\times\{0\},\mathrm{gr}S^{-1}\}$ is locally linearly regular around $(\bar{x},0)$ (where the coderivative $D^*f(\bar{x})(y^*)$ is defined in the sense of limit Fréchet).

Proof. It is easy to see that $S^{-1}(x) = f(x) + K$ is a set-valued map with closed convex graph. (i) follows from Theorem 3.2 directly.

(ii) The case in which $0 \notin \mathrm{bd}N_C(\bar{x})$ is trivial, so assume that $0 \in \mathrm{bd}N_C(\bar{x})$. Define a mapping $g\colon X \times Y \to Y$ by

$$g(x, y) = f(x) - y.$$

Then $\mathrm{gr}S^{-1} = g^{-1}(-K)$. Applying the coderivative sum rule (see Theorem 3.5 in [24]), we get

$$D^*g(\bar{x}, 0)(y^*) = \{(x^*, -y^*) \mid x^* \in D^*f(\bar{x})(y^*)\}$$

(where the coderivative is defined in the sense of limit Fréchet). It is clear that

$$N_{-K}(g(\bar{x}, 0)) = N_{-K}(f(\bar{x})), \quad \ker D^*g(\bar{x}, 0) = \{0\}$$

and so that $N_{-K}(g(\bar{x}, 0)) \cap \ker D^*g(\bar{x}, 0) = \{0\}$. By Corollary 6.9 of [23], under the hypotheses of Corollary 3.1, we have

$$\begin{aligned} N_{\mathrm{gr}S^{-1}}(\bar{x}, 0) &\subset \bigcup \big\{D^*g(\bar{x}, 0))(y^*) \mid y^* \in N_{-K}(g(\bar{x}, 0)\big\} \\ &= \bigcup \big\{\{(x^*, -y^*) \mid x^* \in D^*f(\bar{x})(y^*)\} \mid y^* \in N_{-K}(f(\bar{x})\big\}. \end{aligned}$$

It follows that

$$D^*S^{-1}(\bar{x}, 0)(y^*) \subset \begin{cases} D^*f(\bar{x})(y^*) & \text{if } y^* \in N_{-K}(f(\bar{x})), \\ \emptyset & \text{otherwise.} \end{cases}$$

Thus, the conclusion follows from Theorem 3.2. □

COROLLARY 3.2. *Let X, Y be Banach spaces, let C be a closed convex subset of X, and let K be a closed convex cone of Y. Consider the set-valued maps $S, M\colon Y \rightrightarrows X$ defined as*

$$S(y) = \{x \in X \mid T(x) \in y - K\}$$

and $M(y) = C \cap S(y)$, where $T\colon X \to Y$ is a continuous linear operator. Let $(0, \bar{x}) \in \mathrm{gr}M$. Then the following statements hold:

(i) *M has a local error bound at $(0, \bar{x})$ if and only if there exist positive numbers γ, δ such that*

$$B_{X^*} \cap N_{M(0)}(u) \subset \gamma[B_{X^*} \cap N_C(u) + T^*(B_{Y^*} \cap N_{-K}(T(\bar{x})))] \tag{14}$$

for all $u \in B(\bar{x}, \delta) \cap M(0)$.

(ii) *If C is normally compact around $\bar{x}$ and $0 \in \mathrm{int}(T(X) + K)$, and if*

$$\left.\begin{array}{c} T^*(y^*) \in -\mathrm{bd}N_C(\bar{x}) \\ y^* \in N_{-K}(f(\bar{x})) \end{array}\right\} \Longrightarrow y^* = 0,$$

then $\{C \times \{\bar{y}\}, \mathrm{gr}S^{-1}\}$ is locally linearly regular around $(\bar{x}, 0)$.

Proof. (i) Noticing that $S^{-1}(x) = T(x) + K$, we have that $\mathrm{gr}S^{-1} = \mathrm{gr}T + \{0\} \times K$. It is easy to verify that

$$N_{\mathrm{gr}S^{-1}}(u, 0) = \bigcup \big\{(-T^*(y^*), y^*) \mid y^* \in N_K(-T(u))\big\} \ \ \forall u \in S^{-1}(0).$$

It follows that

$$D^*S^{-1}(u,0)(y^*) = \begin{cases} T^*(y^*) & \text{if } y^* \in N_{-K}(T(u)), \\ \emptyset & \text{otherwise.} \end{cases}$$

If condition (14) is satisfied, then

$$B_{X^*} \cap N_{M(0)}(u) \subset \tau(\|T^*\|+1)[B_{X^*} \cap N_C(u) + B_{X^*} \cap D^*S^{-1}(u,0)(B_{Y^*})]$$

for all $u \in B(\bar{x},\delta) \cap M(0)$. By Theorem 3.2, M has a local error bound at $(0,\bar{x})$. Conversely, suppose that M has a local error bound at $(0,\bar{x})$. Then there exist positive scalars γ and δ_1 such that

$$d(x, M(0)) \le \gamma(d(x,C) + d(T(x), -K)) \ \ \forall x \in B(\bar{x},\delta_1).$$

Hence

$$d(x, M(0)) \le \gamma(d(x,C) + d(T(x), -K)) + I_{\text{int}B(\bar{x},\delta_1)}(x) \ \ \forall x \in X.$$

As both functions on the two sides of the above inequality are 0 at each $u \in M(0) \cap \text{int}B(\bar{x},\delta_1)$, we obtain that

$$\begin{aligned} N_{M(0)}(u) \cap B_{X^*} &= \partial d(\cdot, M(0))(u) \subset \partial[\gamma(d(\cdot,C) + d(T(\cdot),-K)) + I_{\text{int}B(\bar{x},\delta_1)}(\cdot)](u) \\ &= \gamma[\partial d(\cdot,C)(u) + \partial d(T(\cdot),-K)(u)] + \partial I_{\text{int}B(\bar{x},\delta_1)}(u) \\ &= \gamma[B_{X^*} \cap N_C(u) + T^*(B_{Y^*} \cap N_{-K}(T(\bar{x})))]. \end{aligned}$$

By taking $\delta > 0$ such that $B(\bar{x},\delta) \subset \text{int}B(\bar{x},\delta_1)$, we get (14).

The assertion of (ii) follows directly from Theorem 3.2 and the calculation of $D^*S^{-1}(u,0)(y^*)$. □

Consider the set-valued map S defined by a convex inequality system, i.e.,

$$S(y) := \{x \in X \mid f(x) \le y\},$$

where $f\colon X \to \mathbb{R} \cup \{+\infty\}$ is a lower semicontinuous proper convex function. Let $\bar{x} \in M(0) = C \cap S(0)$. If $f(\bar{x}) < 0$, then it is easy to show that M is calm at $(0,\bar{x})$ by the Robinson–Ursescu theorem (see [27, 10]). In this special case, the conditions of Theorem 3.2 can be refined.

THEOREM 3.3. *Consider the set-valued maps $S, M\colon Y \rightrightarrows X$ defined as*

$$S(y) = \{x \in X \mid f(x) \le y\}$$

and $M(y) = C \cap S(y)$, where C is a closed convex subset of X and $f\colon X \to \mathbb{R} \cup \{+\infty\}$ is a lower semicontinuous proper convex function. Let $\bar{x} \in C$ be a given point such that $f(\bar{x}) = 0$. Consider the following conditions:

(a) *M has a local error bound at $(0,\bar{x})$.*

(b) *$\{C \times \{0\}, \text{epi}f\}$ is locally linearly regular around $(\bar{x},0)$.*

(c) *There exist $\delta,\gamma > 0$ such that for all $h \in X$, $u \in B(\bar{x},\delta) \cap M(0)$,*

$$d(h, T_{M(0)}(u)) \le \gamma \max\{d(h, T_C(u)), d((h,0), T_{\text{epi}f}((u,0)))\}.$$

(d) *There exist $\delta,\gamma > 0$ such that for all $u \in M(0) \cap B(\bar{x},\delta)$,*

$$(N_{M(0)}(u) \cap B_{X^*}) \times B_{\mathbb{R}} \subset \gamma[(N_C(u) \cap B_{X^*}) \times B_{\mathbb{R}} + N_{\text{epi}f}((u,0)) \cap B_{X^* \times \mathbb{R}}].$$

(e) *Either* (i) *or* (ii) *holds:*
(i) $\mathrm{bd}\partial f(\bar{x}) \cap -\mathrm{bd}N_C(\bar{x}) \neq \partial f(\bar{x}) \cap -N_C(\bar{x})$*;*
(ii) $\mathrm{bd}\partial f(\bar{x}) \cap (-\mathrm{bd}N_C(\bar{x})) = \emptyset$*,* $\partial^\infty f(\bar{x}) \cap -N_C(\bar{x}) = \{0\}$ *and either* C *is normally compact around* $\bar{x}$ *or* $\mathrm{epi}f$ *is normally compact around* $(\bar{x}, 0)$.

Then (e) $\Longrightarrow$ (d) $\Longleftrightarrow$ (c) $\Longleftrightarrow$ (b) $\Longrightarrow$ (a).

Proof. It is clear that conditions (c) and (d) can be rewritten as

$$\begin{aligned} d(h, T_{M(0)}(u)) &= d((h,0), T_{(C\times\{0\})\cap \mathrm{epi}f}((u,0))) \\ &\leq \gamma \max\{d((h,0), T_{C\times\{0\}}((u,0))), d((h,0), T_{\mathrm{epi}f}((u,0)))\} \end{aligned} \tag{15}$$

and

$$N_{M(0)\times\{0\}}((u,0)) \cap B_{X^*\times\mathbb{R}} \subset \gamma(N_{C\times\{0\}}((u,0)) \cap B_{X^*\times\mathbb{R}} + N_{\mathrm{epi}f}((u,0)) \cap B_{X^*\times\mathbb{R}}). \tag{16}$$

We can see from Theorem 2.1 that conditions (15) and (16) are equivalent to the condition that there exist $\delta, \gamma > 0$ such that

$$d((x,0), C\times\{0\} \cap \mathrm{epi}f) \leq \gamma \max\{d(x,C), d((x,0), \mathrm{epi}f)\} \ \ \forall x \in B(\bar{x}, \delta),$$

which is equivalent to (b) and implies (a) by Proposition 3.1 and Theorem 3.1.

In the following we shall prove that (e) implies (d). Suppose that (i) of (e) is satisfied. Then, since both $\partial f(\bar{x})$ and $N_C(\bar{x})$ are strongly closed in X^*, it follows that

$$\mathrm{int}\partial f(\bar{x}) \cap -N_C(\bar{x}) \neq \emptyset \ \text{ or } \partial f(\bar{x}) \cap -\mathrm{int}N_C(\bar{x}) \neq \emptyset. \tag{17}$$

We now show that $M(0) = \{\bar{x}\}$, i.e., $C\times\{0\} \cap \mathrm{epi}f = \{(\bar{x}, 0)\}$. Indeed, if the first condition of (17) holds, then there exist $x^* \in \mathrm{int}\partial f(\bar{x}) \cap -N_C(\bar{x})$ and $\delta > 0$ such that $B(x^*, \delta) \subset \partial f(\bar{x})$. In other words,

$$\begin{gathered} \delta\|x - \bar{x}\| + \langle x^*, x - \bar{x}\rangle \leq f(x) - f(\bar{x}) \ \ \forall x \in X, \\ \langle x^*, x - \bar{x}\rangle \geq 0 \ \ \forall x \in C. \end{gathered}$$

Hence for any x with $(x,0) \in C\times\{0\} \cap \mathrm{epi}f$, we have

$$\delta\|x - \bar{x}\| \leq \delta\|x - \bar{x}\| + \langle x^*, x - \bar{x}\rangle \leq f(x) - f(\bar{x}) \leq 0,$$

and hence $x = \bar{x}$. This shows our claim. If the second condition of (17) holds, we can prove our claim similarly. Therefore, $M(0) \cap B(\bar{x}, \delta) = \{\bar{x}\}$. On the other hand, the condition (17) yields that

$$0 \in \mathrm{int}(\partial f(\bar{x}) + N_C(\bar{x})).$$

Hence, there exists $\varepsilon > 0$ such that for any $x^* \in \varepsilon B_{X^*}$ there exist $x_1^* \in \partial f(\bar{x})$, $x_2^* \in N_C(\bar{x})$ such that $x^* = x_1^* + x_2^*$, and hence for every $r \in \mathbb{R}$ with $|r| \leq \varepsilon$,

$$(x^*, r) = (x_1^*, -1) + (x_2^*, r+1) \in N_{\mathrm{epi}f}(\bar{x}, 0) + N_{C\times\{0\}}(\bar{x}, 0).$$

This implies that

$$N_{\mathrm{epi}f}(\bar{x}, 0) + N_{C\times\{0\}}(\bar{x}, 0) = X^*\times\mathbb{R}.$$

Therefore, for every $u \in M(0) \cap B(\bar{x}, \delta)$, we have

$$N_{\mathrm{epi}f}(u, 0) + N_C(u)\times\mathbb{R} = X^*\times\mathbb{R} = N_{M(0)}(u)\times\mathbb{R}. \tag{18}$$

By Proposition 4 in [16], (18) implies that there exists some $\gamma > 0$ such that

$$(N_{M(0)}(u) \cap B_{X^*}) \times B_{\mathbb{R}} \subset \gamma((N_C(u) \cap B_{X^*}) \times B_{\mathbb{R}} + N_{\mathrm{epi}f}((u,0)) \cap B_{X^* \times \mathbb{R}}).$$

Finally, assume that (ii) of (e) holds. If $0 \in \mathrm{int}\partial f(\bar{x})$, then $0 \in \mathrm{int}\partial f(\bar{x}) \cap -N_C(\bar{x})$. This means that the first case of (17) is satisfied and that the conclusion follows. Suppose that $0 \in \mathrm{bd}\partial f(\bar{x})$. If $0 \in -\mathrm{int}N_C(\bar{x})$, the case reduces to the second case of (17); if $0 \in -\mathrm{bd}N_C(\bar{x})$, then it leads to a contradiction. It remains to check the case of $0 \notin \partial f(\bar{x})$. Then one has

$$\partial f(\bar{x}) \cap -N_C(\bar{x}) = \emptyset \ \text{ or } \partial f(\bar{x}) \subset -\mathrm{int}N_C(\bar{x}). \tag{19}$$

Suppose that the second case of (19) holds. If $\partial f(\bar{x}) = \emptyset$, then we are back to the first case of (19). Hence, assume that $\partial f(\bar{x}) \neq \emptyset$. Then the second case of (19), along with (ii), yields (i).

We now consider the first case of (19). We claim, in this case, that

$$N_{\mathrm{epi}f}((\bar{x},0)) \cap (-N_{C\times\{0\}}((\bar{x},0))) = \{(0,0)\}. \tag{20}$$

Indeed, $\partial^\infty f(\bar{x}) \cap (-N_C(\bar{x})) = \{0\}$ is equivalent to $N_{\mathrm{epi}f}(\bar{x},0) \cap (-N_C(\bar{x}) \times \{0\}) = \{(0,0)\}$; $\partial f(\bar{x}) \cap (-N_C(\bar{x})) = \emptyset$ is equivalent to $N_{\mathrm{epi}f}(\bar{x},0) \cap -(N_C(\bar{x}) \times (0,+\infty)) = \emptyset$. Let $(x^*, r) \in N_{\mathrm{epi}f}(\bar{x},0) \cap (-N_{C\times\{0\}}(\bar{x},0))$. Then $x^* \in -N_C(\bar{x})$ and $r \geq 0$, and then

$$\langle x^*, x - \bar{x}\rangle + r(f(x) + \varepsilon) \leq 0 \ \ \forall x \in \mathrm{dom}f, \varepsilon > 0.$$

Taking $x = \bar{x}$ in the above inequality, one deduces that $r = 0$. This, together with $\partial^\infty f(\bar{x}) \cap -N_C(\bar{x}) = \{0\}$, implies that $x^* = 0$. Hence, our claim is proved and hence (d) is true by Lemma 3.1. □

It has been proved by Henrion and Jourani [10, Theorem 3.3] that M is calm at $(0, \bar{x})$ if condition (e) is satisfied.

The following example in [10] will show that (d) does not imply (e), in general.

Example. Let $X = C = \mathbb{R}$, $\bar{x} = 0$, and $f(x) = \max\{x, 0\}$. Then

$$M(y) = \begin{cases} \emptyset & \text{if } y < 0, \\ (-\infty, y] & \text{if } y \geq 0. \end{cases}$$

Hence $\bar{x} \in M(0) = -\mathbb{R}_+$. It is obvious that

$$N_{M(0)}(\bar{x}) = \mathbb{R}_+, \quad N_C(\bar{x}) = \{0\}, \quad \text{and} \quad N_{\mathrm{epi}f}((\bar{x},0)) = \{(r_1, r_2) \mid r_2 \leq -r_1, r_1 \geq 0\}.$$

It is easy to verify that

$$N_{M(0)}(\bar{x}) \times \mathbb{R} = N_C(\bar{x}) \times \mathbb{R} + N_{\mathrm{epi}f}((\bar{x},0)) = \mathbb{R}_+ \times \mathbb{R}$$

and

$$(N_{M(0)}(\bar{x}) \cap [-1,1]) \times [-1,1] \subset 2((N_C(\bar{x}) \cap [-1,1]) \times [-1,1] + N_{\mathrm{epi}f}((\bar{x},0)) \cap ([-1,1] \times [-1,1])).$$

Let δ be an arbitrary positive number. For every $u \in M(0) \cap B(\bar{x}, \delta)$ with $u \neq \bar{x}$, we have

$$N_{M(0)}(u) = \{0\}, \quad N_C(u) = \{0\}, \quad \text{and} \quad N_{\mathrm{epi}f}((u,0)) = \{(0, r_2) \mid r_2 \leq 0\}.$$

Hence

$$N_{M(0)}(u) \times \mathbb{R} = N_C(u) \times \mathbb{R} + N_{\mathrm{epi}f}((u,0)) = \{0\} \times \mathbb{R}$$

and

$$(N_{M(0)}(u) \cap [-1,1]) \times [-1,1] \subset ((N_C(u) \cap [-1,1]) \times [-1,1] + N_{\mathrm{epi}f}((u,0)) \cap ([-1,1] \times [-1,1])).$$

Therefore condition (d) in Theorem 3.3 holds true. On the other hand, since $\partial f(\bar{x}) = [0,1]$ and $N_C(\bar{x}) = \{0\}$, we have $\mathrm{bd}\partial f(\bar{x}) \cap -\mathrm{bd}N_C(\bar{x}) = \partial f(\bar{x}) \cap -N_C(\bar{x}) = \{0\}$. This shows that conditions (i) and (ii) of (e) do not hold.

CONVERGENT LAGRANGIAN AND CONTOUR CUT METHOD FOR NONLINEAR INTEGER PROGRAMMING WITH A QUADRATIC OBJECTIVE FUNCTION*

D. LI†, X. L. SUN‡, AND F. L. WANG‡

Abstract. In this paper we present an efficient exact solution method for solving nonlinear separable integer programming problems with a quadratic objective function. The proposed method combines the Lagrangian dual method with a duality reduction scheme using contour cut. At each iteration of the algorithm, lower and upper bounds of the problem are determined by the Lagrangian dual search. To eliminate the duality gap, a novel cut-and-partition scheme is derived by exploring the special structure of the quadratic contour. The method finds an exact solution of the problem in a finite number of iterations. Computational results are reported for problems with up to 2000 integer variables. Comparison results with other methods are also presented.

Key words. nonlinear integer programming, quadratic integer programming, Lagrangian relaxation, duality theory, objective contour cut

1. Introduction.

Consider the following nonlinear integer programming problem with a quadratic objective function:

$$
\begin{aligned}
(P) \qquad \min\ & q(x) = \sum_{j=1}^{n} \left(\frac{1}{2} c_j x_j^2 + d_j x_j \right) \\
\text{s.t.}\ & g_i(x) = \sum_{j=1}^{n} g_{ij}(x_j) \le b_i,\ i = 1, \ldots, m, \\
& x \in X = \{ x \mid l_j \le x_j \le u_j,\ x_j \text{ integer},\ j = 1, \ldots, n \},
\end{aligned}
$$

where g_{ij}'s are continuous functions and l_j and u_j are integer lower and upper bounds of x_j for $j = 1, \ldots, n$. Two cases of quadratic objective functions are considered first in this paper: (a) $q(x)$ is a convex function, i.e., $c_j > 0$ for $j = 1, \ldots, n$, and (b) $q(x)$ is a concave function, i.e., $c_j < 0$ for $j = 1, \ldots, n$. Problems with an indefinite quadratic objective function will be considered later in the paper as an extension.

Integer programming models with a convex quadratic objective function have various applications, including capital budgeting [27], [36], capacity planning [9], and optimization problems from graph theory [2], [26]. An important class of applications of problem (P) arises in portfolio selection models with discrete features (see [1], [6], [23], [31]). It was shown in [41], [42] that the Markowitz mean-variance model [33] can be simplified to a separable problem formulation of (P) by using market indices

together with some additional variables and constraints. A method for reformulating general nonlinear programs to separable forms is discussed in [37].

Concave quadratic cost functions are often encountered in real-world integer programming models involving economies of scale (see [19], [39]), which corresponds to the economic phenomenon of "decreasing marginal cost." The continuous version of problem (P) with $q(x)$ being concave and $g_i(x)$ linear or convex quadratic has been extensively studied (see, e.g., [7], [14], [39], [24], [43], [48]) and has been considered the standard test problem in concave minimization. Its methods exploit the special structures of quadratic functions and the extreme point property of concave programming in which the minimum of a concave function over a polyhedron is always achieved at one of its extreme points. There are, however, few methods in the literature for concave integer programming. Branch-and-bound methods based on continuous relaxation and convex underestimating were proposed in [4], [5], [8], [9], [11] for solving concave integer problems over a polyhedron.

Existing methods in the literature for nonlinear separable integer programming problems are mainly dynamic programming–based methods and continuous relaxation–based branch-and-bound methods. When an integer programming problem is separable, dynamic programming can be used to find its optimal solution (see [12], [13], [25]). Dynamic programming, however, suffers from the curse of dimensionality when m is large. Marsten and Morin [34] proposed a method that uses a dynamic programming technique to generate efficient feasible solutions and prunes nonpromising incomplete feasible solutions by a branch-and-bound strategy. Various branch-and-bound methods and their combination with dynamic programming were proposed for nonlinear knapsack-type problems (see [9], [10], [22], [35], [46])—in particular, convex quadratic knapsack problems [15], [36]. To guarantee the global optimality, the continuous relaxation–based branch-and-bound methods often require the convexity of all q and g_i's.

The Lagrangian dual method has been a powerful method in dealing with discrete optimization problems. The separability of the primal problem, when it exists, allows one to solve the Lagrangian relaxation by decomposition, thus searching efficiently for the dual optimal solution. The optimal dual value provides a lower bound for the optimal value of the objective function of the primal problem. The Lagrangian dual method, however, does not provide an optimal solution or even a feasible solution to the primal problem, in most situations, due to the existence of a duality gap (see [3], [17], [18], [20], [40]). Nonlinear Lagrangian formulations and convexification methods were proposed as attempts to eliminate the duality gap [29], [32], [44], [45]. In spite of a theoretical advantage of achieving a zero duality gap, certain computational issues in the implementation of the nonlinear Lagrangian dual methods remain unsolved due to the destruction of the separability in the primal problem when adopting a nonlinear Lagrangian formulation.

In this paper we develop a new exact method for problem (P). The framework of the proposed algorithm is a combination of the Lagrangian dual method and an objective contour cut-and-partition approach. The key motivation behind our method is an observation that cutting certain integer boxes inside and outside the ellipsoids formed by the objective contours still retains the optimal solution to (P) in the revised domain. This in turn leads to successive reductions of the duality gap of the primal problem. At each iteration, the algorithm first finds a lower bound of the problem using the Lagrangian dual search. To reduce the duality gap, a novel contour cut method is used to remove certain integer boxes that do not contain any feasible solution better than the incumbent. The revised integer domain is then partitioned

into a union of integer subboxes to facilitate the dual search on the revised integer domain in the next iteration. Numerical results show that the proposed algorithm is efficient and robust in solving large-scale instances of (P) with up to 2000 integer variables.

The paper is organized as follows. In section 2, we first introduce some preliminary results in Lagrangian duality theory for general singly constrained integer programming. New solution properties of the Lagrangian relaxation problem are presented. An exact dual search procedure is also described in section 2. In section 3, the quadratic contour cuts and the partition scheme are derived. We motivate the algorithm in section 4 by a small numerical example. The algorithm for singly constrained problem (P) is then formally described. Extensions to problems with multiple constraints and problems with an indefinite quadratic objective function are discussed in sections 5 and 6, respectively. Computational results are reported in section 7 for problems with different types of objective functions and constraint functions. Comparison results with other existing methods are also presented in section 7. Finally, a short concluding remark is given in section 8.

2. Lagrangian duality and dual search. In this section, we present some basic properties of the Lagrangian dual for general singly constrained integer programming. The relationship between the perturbation function and the Lagrangian dual is established. Solution properties of the Lagrangian relaxation problem are also derived. Furthermore, we will describe an exact dual search scheme specifically for singly constrained integer programming.

2.1. Lagrangian dual. Consider the following singly constrained integer program:

$$(P_1) \quad \min_{x\in X} \{f(x) \mid g(x) \le b\}, \tag{2.1}$$

where f and g are continuous functions on $\mathbb{R}^n$ and X is an arbitrary finite integer set. The Lagrangian relaxation of (P_1) is

$$(L_\lambda) \quad d(\lambda) = \min_{x\in X} L(x,\lambda), \tag{2.2}$$

where

$$L(x,\lambda) = f(x) + \lambda(g(x) - b)), \quad \lambda \ge 0. \tag{2.3}$$

Let

$$S = \{x \in X \mid g(x) \le b\},$$
$$f^* = \min_{x\in S} f(x).$$

The following weak duality holds:

$$d(\lambda) \le f(x) \quad \forall x \in S, \quad \lambda \ge 0. \tag{2.4}$$

Therefore $d(\lambda)$ always provides a lower bound for f^*. The Lagrangian dual problem of (P_1) is

$$(D) \quad \max_{\lambda\ge 0} d(\lambda). \tag{2.5}$$

Let λ^* be the optimal solution to (D). The nonnegative constant $f^* - d(\lambda^*)$ is called the *duality gap* of the problem and $f(x) - d(\lambda^*)$ is called a *duality bound* for any $x \in S$.

We assume in the following that $S \neq \emptyset$. Define the perturbation function of (P_1) as

$$w(y) = \min_{x \in X} \{f(x) \mid g(x) \leq y\}, \quad y \in \mathbb{R}. \tag{2.6}$$

The domain of w is $Y = [\tau, +\infty)$, where $\tau = \min_{x \in X} g(x)$. It is easy to see that w is a nonincreasing function on Y and it is continuous from the right. Since X is finite, there exists a finite number of points $a_i \in [\tau, +\infty)$ $(i = 1, \ldots, K)$ such that w can be expressed as

$$w(y) = f_i \quad \text{for } a_i \leq y < a_{i+1}, \quad i = 1, \ldots, K, \tag{2.7}$$

where $\tau = a_1 < a_2 < \cdots < a_K < a_{K+1} = +\infty$, and $f_1 > f_2 > \cdots > f_K$. By the assumption that $S \neq \emptyset$, we have $a_1 \leq b$. If we further assume that $X \setminus S \neq \emptyset$ and $\min_{x \in X} f(x) < f^*$, we then have $b < a_K$. Let

$$\Phi = \{(a_i, f_i) \mid i = 1, \ldots, K\}.$$

A point in Φ is called a *corner point* of $w(y)$.

Define the convex envelope function of w to be the maximum convex function underestimating w:

$$\psi(y) = \max\{h(y) \mid h \text{ is convex on } Y,\ h(\tilde{y}) \leq w(\tilde{y}) \quad \forall \tilde{y} \in Y\}. \tag{2.8}$$

It is easy to see that ψ is a nonincreasing piecewise linear functions on Y. We have

$$\psi(y) = \max_{\lambda, r \in \mathbb{R}} \{\lambda y + r \mid \lambda \tilde{y} + r \leq w(\tilde{y}) \quad \forall \tilde{y} \in Y\},$$

or equivalently,

$$\begin{aligned} \psi(y) = \max_{\lambda \in \mathbb{R}_-, r \in \mathbb{R}} & (\lambda y + r) \\ \text{s.t. } & \lambda a_i + r \leq f_i,\ i = 1, \ldots, K. \end{aligned} \tag{2.9}$$

For any fixed $y \in Y$, a dual variable $\mu_i \geq 0$ is introduced for each constraint $\lambda a_i + r \leq f_i,\ i = 1, \ldots, K$. Dualizing the linear program (2.9) yields

$$\psi(y) = \min \left\{ \sum_{i=1}^{K} \mu_i f_i \,\middle|\, \sum_{i=1}^{K} \mu_i a_i \leq y,\ \sum_{i=1}^{K} \mu_i = 1,\ \mu_i \geq 0,\ i = 1, \ldots, K \right\}. \tag{2.10}$$

The perturbation function characterizes the duality by the following theorem.

THEOREM 1. *Let $(-\lambda^*, r^*)$ and μ^* be optimal solutions to* (2.9) *and* (2.10) *with $y = b$, respectively. Then*

(i) *λ^* is an optimal solution to the dual problem (D) and*

$$\psi(b) = \max_{\lambda \geq 0} d(\lambda) = d(\lambda^*). \tag{2.11}$$

(ii) *for each i with $\mu_i^* > 0$, any $\bar{x} \in X$ satisfying $(g(\bar{x}), f(\bar{x})) = (a_i, f_i)$ is an optimal solution to the Lagrangian problem (L_{λ^*}).*

Proof. See [28], [32], and [30]. □

The following results investigate the primal feasibility and infeasibility of the solutions to the Lagrangian relaxation.

THEOREM 2. *Assume that $S \neq \emptyset$ and $X \setminus S \neq \emptyset$.*

(i) *Let λ^* be an optimal solution to (D). Then, there exists an $\tilde{x} \in S$ that solves (L_{λ^*}). Moreover, if $d(\lambda^*) < f^*$, then there exists a $\tilde{y} \in X \setminus S$ that solves (L_{λ^*}).*

(ii) *If for some $\lambda^* \geq 0$ there exist an $\tilde{x} \in S$ and a $\tilde{y} \in X \setminus S$ that both solve (L_{λ^*}), then λ^* must be an optimal solution to the dual problem (D).*

Proof. (i) By (2.10), there exist $\mu_i^* \geq 0$, $i = 1, \ldots, K$, that solve the following problem:

$$\begin{aligned} \psi(b) = \min & \sum_{i=1}^{K} \mu_i f_i, \\ \text{s.t.} & \sum_{i=1}^{K} \mu_i a_i \leq b, \\ & \sum_{i=1}^{K} \mu_i = 1, \quad \mu_i \geq 0, \quad i = 1, \ldots, K. \end{aligned} \tag{2.12}$$

Let $I = \{i \mid \mu_i^* > 0\}$. It follows from (2.12) that

$$\sum_{i \in I} \mu_i^* (a_i - b) \leq 0. \tag{2.13}$$

This implies that there exists at least one $i \in I$ such that $a_i \leq b$. Let $\tilde{x}$ be such that $(g(\tilde{x}), f(\tilde{x})) = (a_i, f_i)$. Then $\tilde{x} \in S$, and by Theorem 1(ii), $\tilde{x}$ solves (L_{λ^*}).

Suppose that $a_i \leq b_i$ for all $i \in I$. If $\sum_{i=1}^{K} \mu_i^* a_i = b$, then $a_i = b$ for all $i \in I$. Hence I is a singleton and $\mu_i^* = 1$, $i \in I$. By Theorem 1(i) and (2.12), we have

$$d(\lambda^*) = \psi(b) = f_i = w(a_i) = w(b) = f^*, \quad i \in I,$$

which contradicts the assumption of $d(\lambda^*) < f^*$. If $\sum_{i=1}^{K} \mu_i^* a_i < b$, then we claim that there do not exist $k, l \in I$ such that $f_k \neq f_l$. Otherwise, suppose that $f_k > f_l$, $k \neq l$. Define $\tilde{\mu} = (\tilde{\mu}_1, \ldots, \tilde{\mu}_K)$ as follows: $\tilde{\mu}_i = \mu_i^*$ if $i \neq k$ and $i \neq l$; $\tilde{\mu}_k = \mu_k^* - \epsilon$, $\tilde{\mu}_l = \mu_l^* + \epsilon$, where $\epsilon > 0$. We can always choose a sufficiently small $\epsilon > 0$ such that $\tilde{\mu}_k > 0$ and $\sum_{i \in I} \tilde{\mu}_i a_i < b$. Thus $\tilde{\mu}$ is feasible for problem (2.12). However, we have

$$\sum_{i \in I} \tilde{\mu}_i f_i = \sum_{i \in I} \mu_i^* f_i + \epsilon(f_l - f_k) < \sum_{i \in I} \mu_i^* f_i,$$

which contradicts that μ^* is an optimal solution to (2.12). Therefore, $f_k = f_l$ for any $k, l \in I$. It then follows that $\psi(b) = f_i$ for any $i \in I$. Also, since $a_i \leq b$ for $i \in I$, $w(a_i) \geq w(b)$. Thus, by Theorem 1(i), we have

$$d(\lambda^*) = \psi(b) = f_i = w(a_i) \geq w(b) = f^*, \quad i \in I,$$

which contradicts the assumption of nonzero duality gap.

The above arguments conclude that there exists an $i \in I$ such that $a_i > b$. Let $\tilde{y}$ be such that $(g(\tilde{y}), f(\tilde{y})) = (a_i, f_i)$. Then $\tilde{y}$ is infeasible, and by Theorem 1(ii), $\tilde{y}$ solves (L_{λ^*}).

(ii) For any $\lambda \geq 0$, if $\lambda^* > \lambda$, then

$$d(\lambda) \leq L(\tilde{y}, \lambda) = f(\tilde{y}) + \lambda(g(\tilde{y}) - b) < f(\tilde{y}) + \lambda^*(g(\tilde{y}) - b) = L(\tilde{y}, \lambda^*) = d(\lambda^*).$$

If $\lambda^* < \lambda$, then

$$d(\lambda) \leq L(\tilde{x}, \lambda) = f(\tilde{x}) + \lambda(g(\tilde{x}) - b) \leq f(\tilde{x}) + \lambda^*(g(\tilde{x}) - b) = L(\tilde{x}, \lambda^*) = d(\lambda^*).$$

Thus λ^* is an optimal solution to (D). □

THEOREM 3. *If the dual optimal solution $\lambda^* = 0$, then any feasible solution to (L_{λ^*}) is an optimal solution to (P_1) and $f^* = d(\lambda^*)$. Conversely, if there is a feasible solution x^* in the optimal solution set of (L_λ) with $\lambda = 0$, then $\lambda = 0$ is an optimal solution to (D) and x^* is an optimal solution to (P_1) with $f(x^*) = d(\lambda^*)$.*

Proof. Let x^* be a feasible solution to (L_{λ^*}) with $\lambda^* = 0$. Since

$$f(x^*) = \min_{x \in X} L(x, 0) = \min_{x \in X} f(x) \leq \min_{x \in S} f(x) = f^*, \tag{2.14}$$

we imply that x^* is optimal to (P_1) and $f(x^*) = f^* = d(\lambda^*)$. Conversely, if x^* solves (L_λ) with $\lambda = 0$ and is feasible for (P_1), then x^* must be optimal to (P_1). Moreover, by weak duality, we have $d(\lambda) \leq f(x^*) = d(0)$ for all $\lambda \geq 0$. Thus $\lambda = 0$ is the dual optimal solution. □

2.2. Dual search scheme. Motivated by the relationship between the convex envelope of the perturbation function and the optimal dual value, we can derive an exact dual search solution procedure for (D). Geometrically, the procedure visits the corner points of the perturbation function $w(y)$ at each iteration and eventually determines the optimal Lagrangian multiplier λ^*, where $-\lambda^*$ is exactly the slope of the line segment in the graph of $\psi(y)$ that intersects line $y = b$. The procedure starts by finding the corner point (a_1, f_1) and the corner point (a_K, f_K) in Φ. At each iteration, the Lagrangian relaxation (L_λ) is solved, where $-\lambda$ is the slope of the line connecting two corner points that correspond to the feasible incumbent solution and an infeasible solution with the least violation of the constraint up to the current stage, respectively. The distance between the feasible incumbent solution and the infeasible solution with the least constraint violation reduces monotonically in the iteration process. The algorithm terminates when a feasible optimal solution and an infeasible optimal solution to (L_λ) are found simultaneously or when $\lambda = 0$. By Theorems 2 and 3, an optimal dual solution is achieved when the algorithm terminates.

PROCEDURE 1 (dual search procedure).

Step 1. Calculate

$$x^0 = \arg\min_{x \in X} \ g(x), \ y^0 = \arg\min_{x \in X} \ f(x).$$

(i) If $g(x^0) > b$, stop. Problem (P_1) has no feasible solution.
(ii) If $g(y^0) \leq b$, stop. We conclude that y^0 is an optimal solution to (P_1) and $\lambda^* = 0$ is the optimal solution to (D).
(iii) Let $f_0^- = f(x^0)$, $g_0^- = g(x^0)$, $f_0^+ = f(y^0)$, $g_0^+ = g(y^0)$. Set $k = 0$.

Step 2. Compute

$$\lambda_k = -\frac{f_k^+ - f_k^-}{g_k^+ - g_k^-}.$$

Step 3. Solve (L_{λ_k}). Let x^k and y^k be the optimal solutions to (L_{λ_k}) with a minimum value of g and a maximum value of g, respectively.

(i) If $g(x^k) \le b < g(y^k)$, set $\tilde{x} = x^k$ and $\tilde{y} = y^k$, stop. $\lambda^* = \lambda^k$ is the optimal solution to the dual problem (D).

(ii) If $g(y^k) \le b$, then set

$$f_{k+1}^- = f(y^k),\ f_{k+1}^+ = f_k^+,$$
$$g_{k+1}^- = g(y^k),\ g_{k+1}^+ = g_k^+.$$

(iii) If $g(x^k) > b$, then set

$$f_{k+1}^- = f_k^-,\ f_{k+1}^+ = f(x^k),$$
$$g_{k+1}^- = g_k^-,\ g_{k+1}^+ = g(x^k).$$

Set $k := k + 1$. Return to Step 2.

THEOREM 4. *Procedure* 1 *stops at an optimal solution to* (D) *within a finite number of iterations.*

Proof. The proof of the finite termination of the procedure is similar to the one in [29]. The optimality of λ^* in Step 1(ii) and Step 3(i) follows from Theorems 2 and 3. □

It is clear that if Procedure 1 does not stop at Step 1, then the procedure stops at Step 3(i) and generates a lower bound $d(\lambda^*)$ to (P_1), a feasible solution $\tilde{x}$, and an infeasible solution $\tilde{y}$, where both $\tilde{x}$ and $\tilde{y}$ solve (L_{λ^*}).

The efficiency of the dual search procedure depends on whether or not the Lagrangian relaxation problem (L_λ) can be easily solved. Let $q_j(x_j) = (1/2)c_j x_j^2 + d_j x_j$ for $j = 1, \ldots, n$. Consider the singly constrained case of (P):

$$(P_s) \qquad \min\ q(x) = \sum_{j=1}^{n} q_j(x_j)$$
$$\text{s.t.}\ \ g(x) = \sum_{j=1}^{n} g_j(x_j) \le b,$$
$$x \in X.$$

A subproblem (SP) of (P_s) is formed by replacing X with a subset $\widetilde{X} \subseteq X$. The Lagrangian relaxation problem of (SP) can be written as

$$d(\lambda) = \min_{x \in \widetilde{X}} L(x, \lambda) = -\lambda b + \sum_{j=1}^{n} \min_{x_j \in \widetilde{X}_j} L_j(x_j, \lambda), \tag{2.15}$$

where $L_j(x_j, \lambda) = q_j(x_j) + \lambda g_j(x_j)$, $\widetilde{X}_j = \{x_j \mid \tilde{l}_j \le x_j \le \tilde{u}_j,\ x_j \text{ integer}\}$. The complexity of a total enumeration of evaluating $d(\lambda)$ is $O(\sum_{j=1}^{n}(\tilde{u}_j - \tilde{l}_j + 1))$. For problems with convex $q(x)$ and linear constraints, it is possible to derive a more efficient procedure for computing $d(\lambda)$ by exploiting the convex hull of q_j on $\widetilde{X}_j$ (see [16]). For nonlinear constraints, consider the following two cases: (a) $q_j(x_j)$ and $g_j(x_j)$ are convex; (b) $q_j(x_j)$ and $g_j(x_j)$ are concave. For case (a), the optimal solution of the one-dimensional integer problem in (2.15) can be obtained by comparing the values of L_j on two neighboring integer points of the continuous optimal solution of L_j on $[\tilde{l}_j, \tilde{u}_j]$. For case (b), since L_j is a concave function of x_j, the integer minimum of L_j over $[\tilde{l}_j, \tilde{u}_j]$ is either $\tilde{l}_j$ or $\tilde{u}_j$.

Therefore, the Lagrangian relaxation problems of the subproblems (SP) can be solved efficiently by decomposition. Moreover, the solutions x^k and y^k in Step 3 of Procedure 1 can also be easily obtained by computing the minimum and maximum values of g_j, respectively, when solving the one-dimensional problem in (2.15).

3. Quadratic contour cut. In this section, we will establish a cut-and-partition scheme by exploiting the geometry of the quadratic contour of the objective function $q(x)$. The cut-and-partition technique will be used later on to develop an exact solution method for solving (P).

Let $\alpha, \beta \in \mathbb{Z}^n$, where $\mathbb{Z}^n$ denotes the set of integer points in $\mathbb{R}^n$. Denote by $[\alpha, \beta]$ the box (hyperrectangle) formed by α and β, $[\alpha, \beta] = \{x \mid \alpha_j \le x_j \le \beta_j, j = 1, \ldots, n\}$. Let $\langle \alpha, \beta \rangle$ denote the set of integer points in $[\alpha, \beta]$,

$$\langle \alpha, \beta \rangle = \Pi_{j=1}^n \langle \alpha_j, \beta_j \rangle = \langle \alpha_1, \beta_1 \rangle \times \langle \alpha_2, \beta_2 \rangle \times \cdots \times \langle \alpha_n, \beta_n \rangle.$$

The set $\langle \alpha, \beta \rangle$ is called an *integer box*. For convenience, we define $[\alpha, \beta] = \langle \alpha, \beta \rangle = \emptyset$ if $\alpha \not\le \beta$.

3.1. Ellipse of quadratic contour. Let $q(x)$ be the quadratic function defined in (P). Let $\tau = -\sum_{j=1}^n d_j^2/(2c_j)$. Consider the ellipse contour of $q(x)$,

$$\sum_{j=1}^{n} [(1/2)c_j x_j^2 + d_j x_j] = v, \tag{3.1}$$

where $v \ge \tau$ when $c_j > 0$ $(j = 1, \ldots, n)$ and $v \le \tau$ when $c_j < 0$ $(j = 1, \ldots, n)$. The center of ellipse (3.1) is

$$o = (-d_1/c_1, \ldots, -d_n/c_n)^T. \tag{3.2}$$

The length of the jth axis of ellipse (3.1) is

$$2r_j = 2\sqrt{|2(v - \tau)/c_j|}. \tag{3.3}$$

Let $E(v)$ denote the ellipsoid formed by the contour (3.1). Then

$$E(v) = \begin{cases} \{x \in \mathbb{R}^n \mid q(x) \le v\} & \text{if } q(x) \text{ is convex,} \\ \{x \in \mathbb{R}^n \mid q(x) \ge v\} & \text{if } q(x) \text{ is concave.} \end{cases} \tag{3.4}$$

The minimum rectangle that encloses the ellipsoid $E(v)$ is $[a, b]$ with

$$a = (o_1 - r_1, \ldots, o_n - r_n)^T,$$
$$b = (o_1 + r_1, \ldots, o_n + r_n)^T,$$

where o is defined in (3.2) and r_j is defined in (3.3). Let $\lfloor t \rfloor$ denote the maximum integer less than or equal to t and $\lceil t \rceil$ the minimum integer greater than or equal to t. Then the minimum integer box containing all the integer points in the ellipsoid $E(v)$ can be expressed as $M(v) = \langle \alpha, \beta \rangle$, where

$$\alpha = (\lceil o_1 - r_1 \rceil, \ldots, \lceil o_n - r_n \rceil)^T, \tag{3.5}$$
$$\beta = (\lfloor o_1 + r_1 \rfloor, \ldots, \lfloor o_n + r_n \rfloor)^T. \tag{3.6}$$

Let $\tilde{x}$ be an integer point inside the ellipsoid $E(v)$. Let $N(\tilde{x})$ denote the integer subbox inside $E(v)$ with $\tilde{x}$ being one of its corner point. By the symmetry of $E(v)$, we have $N(\tilde{x}) = \langle \gamma, \delta \rangle$, where

$$\gamma = (\lceil o_1 - |\tilde{x}_1 - o_1| \rceil, \ldots, \lceil o_n - |\tilde{x}_n - o_n| \rceil)^T, \tag{3.7}$$

$$\delta = (\lfloor o_1 + |\tilde{x}_1 - o_1| \rfloor, \ldots, \lfloor o_n + |\tilde{x}_n - o_n| \rfloor)^T. \tag{3.8}$$

Notice that if $q(\tilde{x}) = v$, then $\langle \gamma, \delta \rangle$ is the maximum integer box inside $E(v)$ that passes through $\tilde{x}$.

3.2. Contour cuts of quadratic function. Consider the subproblem (SP) of the singly constrained problem (P_s) in subsection 2.2. Assume that $\widetilde{X} \cap S \neq \emptyset$ and $\widetilde{X} \setminus S \neq \emptyset$, where S is the feasible region of (P_s). Let q_s denote the optimal value of (SP). Let $\lambda^* > 0$ be the dual optimal solution to (SP). Suppose that the duality gap of (SP) is nonzero, i.e., $d(\lambda^*) < q_s$. By Theorem 2, the dual search procedure described in subsection 2.2 can find two optimal solutions, $\tilde{x} \in S$ and $\tilde{y} \in \widetilde{X} \setminus S$, to the Lagrangian relaxation problem (L_{λ^*}). The following always holds:

$$q(\tilde{y}) < d(\lambda^*) < q_s \leq q(\tilde{x}). \tag{3.9}$$

In the following we will show that cutting certain integer boxes from $\widetilde{X}$ will not remove any optimal solution of (SP) after recording $\tilde{x}$. We consider the contour cut for the two cases, where $q(x)$ is either convex or concave.

Case (a). $q(x)$ is convex, i.e., $c_j > 0$, $j = 1, \ldots, n$. Let $v_1 = q(\tilde{x})$ and $v_2 = d(\lambda^*)$. By (3.9) and the convexity of q, either $\tilde{x}$ is the optimal solution of (SP) or the optimal solution still lies in the set

$$\Omega = (\widetilde{X} \cap E(v_1)) \setminus E(v_2), \tag{3.10}$$

where $E(v_1)$ and $E(v_2)$ are defined by (3.4). In other words, removing sets $\widetilde{X} \setminus E(v_1)$ and $E(v_2)$ from $\widetilde{X}$ will not miss any optimal solution to (SP) after we record $\tilde{x}$. Since both $E(v_1)$ and $E(v_2)$ are ellipsoids, it is difficult to calculate Ω in (3.10). We instead outerapproximate Ω using integer boxes. More specifically, we consider a union of boxes of which Ω is a subset. Note that set Ω is a finite set containing only integer points. It is true that

$$\widetilde{X} \cap M(v_1) \supset \widetilde{X} \cap E(v_1), \tag{3.11}$$

where $M(v_1)$ is the minimum integer box enclosing all the integer points in $E(v_1)$. Let $B(v_1) = \widetilde{X} \cap M(v_1)$. Then $B(v_1) = \langle \bar{\alpha}, \bar{\beta} \rangle$, where

$$\bar{\alpha} = (\max(\tilde{l}_1, \alpha_1), \ldots, \max(\tilde{l}_n, \alpha_n))^T, \tag{3.12}$$

$$\bar{\beta} = (\min(\tilde{u}_1, \beta_1), \ldots, \min(\tilde{u}_n, \beta_n))^T, \tag{3.13}$$

with α and β defined in (3.5) and (3.6), respectively.

By (3.9), the infeasible point $\tilde{y}$ is contained in the ellipsoid $E(v_2)$. Thus, the integer box $N(\tilde{y}) = \langle \gamma, \delta \rangle$ is also contained in $E(v_2)$, where γ and δ can be found by using (3.7)–(3.8). This, combined with (3.11), implies that

$$B(v_1) \setminus N(\tilde{y}) \supset \Omega. \tag{3.14}$$

We further would like to cut $\tilde{x}$ from $\widetilde{X}$ if $\tilde{x} \in B(v_1)$ after recording $\tilde{x}$. Let $T(\tilde{x}) = \langle \tilde{\alpha}, \tilde{\beta} \rangle$ be the integer box with (i) $\tilde{x}$ being one of its corner points and (ii) all edges starting

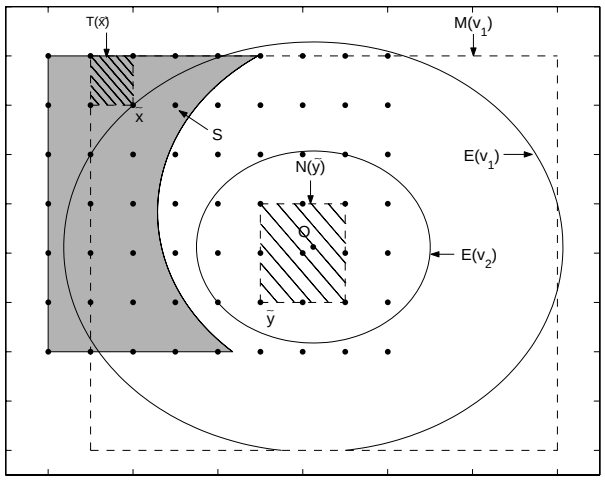

FIG. 3.1. *Contour cuts for Case* (a).

from $\tilde{x}$ leaving the ellipsoid $E(v_1)$ and moving towards the boundaries of $B(v_1)$. Specifically, $T(\tilde{x})$ can be determined by

$$\tilde{\alpha}_j = \begin{cases} \min(\tilde{x}_j, \bar{\alpha}_j), & \tilde{x}_j \le o_j, \\ \min(\tilde{x}_j, \bar{\beta}_j), & \tilde{x}_j > o_j, \end{cases} \tag{3.15}$$

$$\tilde{\beta}_j = \begin{cases} \max(\tilde{x}_j, \bar{\alpha}_j), & \tilde{x}_j \le o_j, \\ \max(\tilde{x}_j, \bar{\beta}_j), & \tilde{x}_j > o_j, \end{cases} \tag{3.16}$$

where o is defined in (3.2) and $\bar{\alpha}$ and $\bar{\beta}$ are defined in (3.12) and (3.13), respectively. Since $\tilde{x}$ is on the boundary of $E(v_1)$, we can cut $T(\tilde{x})$ from $B(v_1)$. We have

$$\tilde{\Omega} = [B(v_1) \setminus N(\tilde{y})] \setminus T(\tilde{x}) \supset \Omega \setminus \{\tilde{x}\}. \tag{3.17}$$

Figure 3.1 illustrates the contour cut process for Case (a).

Case (b). $q(x)$ is concave, i.e., $c_j < 0$, $j = 1, \ldots, n$. Let $v_1 = d(\lambda^*)$ and $v_2 = q(\tilde{x})$. Then, by (3.9) and the concavity of q, the optimal solution of (SP) must lie in the set Ω defined in (3.10). Similar to Case (a), we have

$$B(v_1) \setminus N(\tilde{x}) \supset \Omega. \tag{3.18}$$

Since $q(\tilde{y}) < d(\lambda^*) = v_1$, $\tilde{y}$ is outside the ellipsoid $E(v_1)$. If $\tilde{y}$ is contained in $B(v_1)$, then we can cut $T(\tilde{y})$ from $B(v_1)$, where $T(\tilde{y}) = \langle \tilde{\alpha}, \tilde{\beta} \rangle$; $\tilde{\alpha}$ and $\tilde{\beta}$ are defined in (3.15)–(3.16), with $\tilde{x}$ replaced by $\tilde{y}$. Therefore, we have

$$\tilde{\Omega} = [B(v_1) \setminus N(\tilde{x})] \setminus T(\tilde{y}) \supset \Omega. \tag{3.19}$$

Figure 3.2 illustrates the contour cut process for Case (b).

One clear conclusion is that after recording the feasible solution $\tilde{x}$, we can reduce the domain of (SP) from $\widetilde{X}$ to $\tilde{\Omega}$ without missing any optimal solution to (SP). This domain reduction process will improve the quality of the dual search, as witnessed in the following sections.

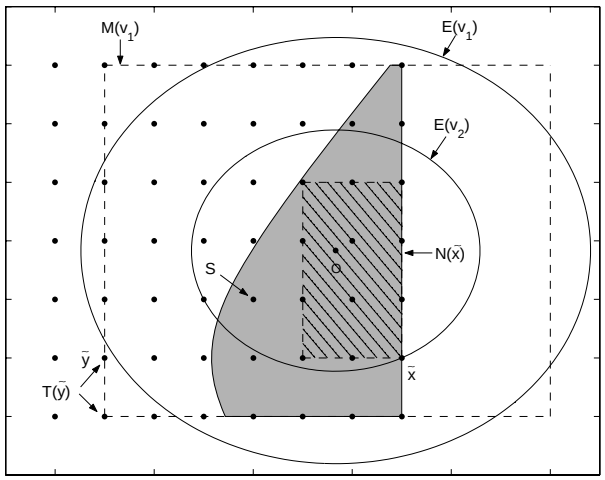

FIG. 3.2. *Contour cuts for Case* (b).

4. Convergent Lagrangian and contour cut method for singly constrained problems. In this section, we develop a convergent Lagrangian and contour cut method for the singly constrained problem (P_s). The method will be extended in section 5 to handle multiple constraints. We first motivate the method by an example and then describe the method formally.

4.1. Motivation. To motivate the method, let us consider a two-dimensional example with a concave quadratic objective function.

Example 1.

$$\begin{aligned} \min\ & q(x) = -1.5x_1^2 + 2x_1 - 2x_2^2 + 8x_2 \\ \text{s.t.}\ & g(x) = 3x_1^2 - 2x_1 + 2x_2^2 - 6x_2 \le 35, \\ & x \in X = \{x \mid -1 \le x_1 \le 5,\ 0 \le x_2 \le 6 \text{ integer},\ j = 1, 2\}. \end{aligned}$$

The optimal solution of this problem is $x^* = (-1, 5)^T$ with $q(x^*) = -13.5$. The perturbation function of the example is illustrated in Figure 4.1. It can be observed from Figure 4.1 that the point C that corresponds to the optimal solution x^* is "hidden" above the convex envelope of the perturbation function, and thus the traditional Lagrangian dual method will fail to find the optimal solution x^*.

Solving the dual problem of the example, we obtain the optimal multiplier $\lambda^0 = 0.6667$ with $d(\lambda^0) = -23.5$. The optimal solutions to (L_{λ^0}) are $x^0 = (-1, 0)^T$ and $y^0 = (-1, 6)^T$. The current duality bound is $q(x^0) - d(\lambda^0) = -3.5 + 23.5 = 20$.

Now, let $v_1^0 = -23.5$, $v_2^0 = -3.5$. Applying the contour cut scheme in section 3 to the example by using (3.19), we obtain a revised domain

$$X^1 = [B(v_1^0) \setminus N(x^0)] \setminus T(y^0),$$

where

$$B(v_1^0) = X \cap M(v_1^0) = \langle (-1, 0)^T, (5, 6)^T \rangle \cap \langle (-3, -2)^T, (5, 6)^T \rangle = \langle (-1, 0)^T, (5, 6)^T \rangle,$$
$$N(x^0) = \langle (-1, 0)^T, (2, 4)^T \rangle,\ T(y^0) = \{(-1, 6)^T\}.$$

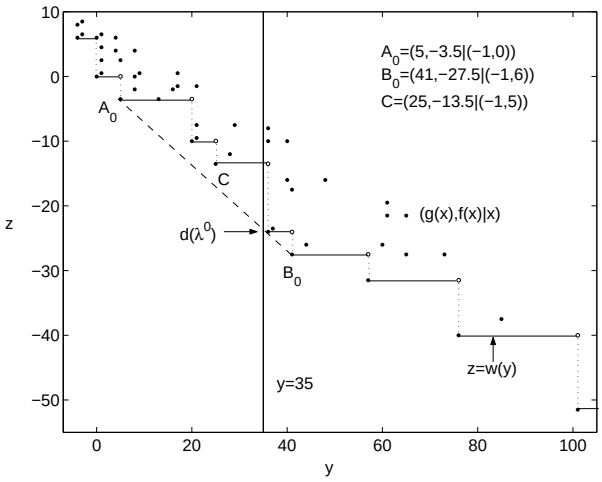

FIG. 4.1. *Perturbation function of Example* 1.

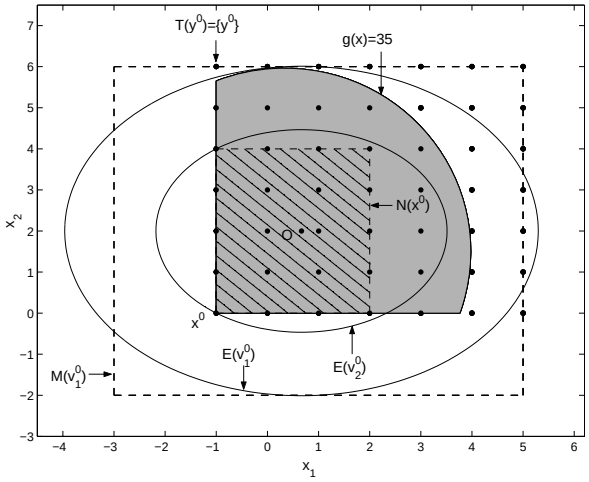

FIG. 4.2. *Domain X and the objective contour cuts.*

The ellipsoids $E(v_1^0)$, $E(v_2^0)$ and the integer boxes $M(v_1^0)$, $N(x^0)$, and $T(y^0)$ are illustrated in Figure 4.2. It can be seen from Figures 4.1 and 4.2 that cutting sets $N(x^0)$ and $T(y^0)$ from the domain X will remove the corner points A_0 and B_0 in the plot of the perturbation function, and thus will raise the dual value. The revised domain X^1 and the corresponding perturbation function are shown in Figures 4.3 and 4.4, respectively. The optimal dual value of the revised problem is $d(\lambda^1) = -23.125$ and the feasible and infeasible solutions of (L_{λ^1}) are $x^1 = (0,5)^T$, $y^1 = (0,6)^T$. The dual bound is reduced to $q(x^1) - d(\lambda^1) = -10 + 23.125 = 13.125$. Let $v_1^1 = -23.125$ and $v_2^1 = -10$. The ellipsoids $E(v_1^1)$, $E(v_2^1)$ and the integer boxes $M(v_1^1)$, $N(x^1)$, and $T(y^1)$ are illustrated in Figure 4.3.

The above discussion reveals that the contour cut scheme described in section 3 will reduce the duality bound, and thus the duality gap, and will eventually expose

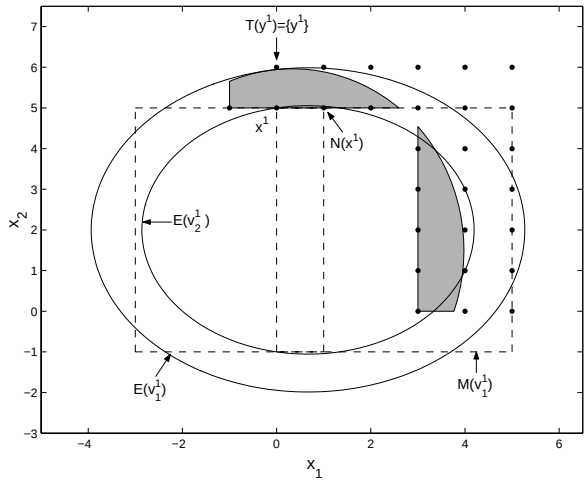

FIG. 4.3. *The revised domain* X^1.

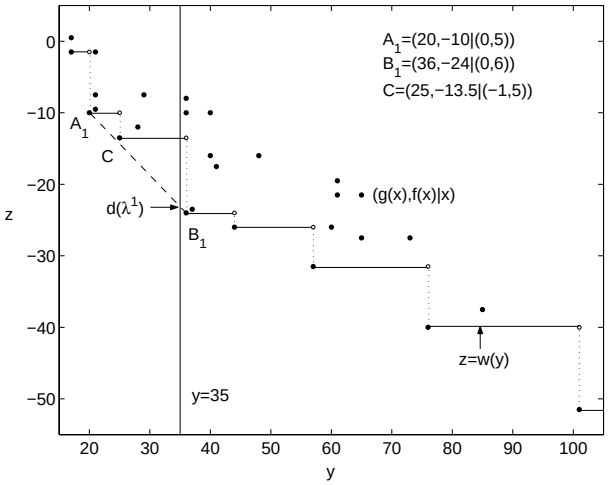

FIG. 4.4. *Perturbation function of the revised problem on* X^1.

the "hidden" optimal point to the convex envelope of the perturbation function. In fact, as we can foresee from Figure 4.4, one more contour cut will make the point C lie on the convex envelope of the revised perturbation function, thus enabling the dual search to find the optimal solution x^*.

4.2. Partition of a nonrectangular integer set. A key issue in the proposed Lagrangian dual and contour cut method is how to partition the sets in the right-hand sides of (3.17) and (3.19) into a union of integer boxes so that Lagrangian relaxation and dual search can still be applied to the revised problems after a cutting process. We have the following result.

LEMMA 1. *Let $A = \langle \alpha, \beta \rangle$ and $B = \langle \gamma, \delta \rangle$, where α, β, γ, $\delta \in \mathbb{Z}^n$, and $\alpha \le \gamma \le \delta \le \beta$. Then $A \setminus B$ can be partitioned into at most $2n$ integer boxes:*

$$A \setminus B = \big\{ \cup_{j=1}^{n} \big(\Pi_{i=1}^{j-1} \langle \alpha_i, \delta_i \rangle \times \langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle \big) \big\} \cup \big\{ \cup_{j=1}^{n} \big(\Pi_{i=1}^{j-1} \langle \gamma_i, \delta_i \rangle \times \langle \alpha_j, \gamma_j - 1 \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \delta_i \rangle \big) \big\}. \tag{4.1}$$

Proof. As illustrated in Figure 4.5, $A \setminus B$ can be expressed as

$$A \setminus B = \langle \alpha, \beta \rangle \setminus \langle \gamma, \delta \rangle = (\langle \alpha, \beta \rangle \setminus \langle \alpha, \delta \rangle) \cup (\langle \alpha, \delta \rangle \setminus \langle \gamma, \delta \rangle). \tag{4.2}$$

Let $C = \langle \alpha, \delta \rangle$. Then, by (4.2), we have

$$A \setminus B = (A \setminus C) \cup (C \setminus B). \tag{4.3}$$

For $j = 0, 1, \ldots, n-1$, define

$$A_j = \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle,$$
$$C_j = \Pi_{i=j+1}^{n} \langle \alpha_i, \delta_i \rangle.$$

Then

$$\begin{aligned}
&A_{j-1} \setminus C_{j-1} \\
&= \Pi_{i=j}^{n} \langle \alpha_i, \beta_i \rangle \setminus \Pi_{i=j}^{n} \langle \alpha_i, \delta_i \rangle \\
&= \big\{ (\langle \alpha_j, \delta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle) \cup (\langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle) \big\} \setminus \Pi_{i=j}^{n} \langle \alpha_i, \delta_i \rangle \\
&= \big\{ (\langle \alpha_j, \delta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle) \setminus \Pi_{i=j}^{n} \langle \alpha_i, \delta_i \rangle \big\} \cup (\langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle) \\
&= \big\{ \langle \alpha_j, \delta_j \rangle \times (\Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle \setminus \Pi_{i=j+1}^{n} \langle \alpha_i, \delta_i \rangle) \big\} \cup (\langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle) \\
&= \{ \langle \alpha_j, \delta_j \rangle \times (A_j \setminus C_j) \} \cup (\langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle).
\end{aligned} \tag{4.4}$$

Using the partition formulation (4.4) recursively for $j = 1, \ldots, n-1$, and noting that $A = A_0$, $C = C_0$, $A_{n-1} \setminus C_{n-1} = \langle \alpha_n, \beta_n \rangle \setminus \langle \alpha_n, \delta_n \rangle = \langle \delta_n + 1, \beta_n \rangle$, we get

$$A \setminus C = \cup_{j=1}^{n} \big(\Pi_{i=1}^{j-1} \langle \alpha_i, \delta_i \rangle \times \langle \delta_j + 1, \beta_j \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \beta_i \rangle \big). \tag{4.5}$$

Similarly, we have

$$C \setminus B = \cup_{j=1}^{n} \big(\Pi_{i=1}^{j-1} \langle \gamma_i, \delta_i \rangle \times \langle \alpha_j, \gamma_j - 1 \rangle \times \Pi_{i=j+1}^{n} \langle \alpha_i, \delta_i \rangle \big). \tag{4.6}$$

Combining (4.3) with (4.5) and (4.6), we obtain (4.1). ∎

As an example, let us consider the X^1 in Figure 4.3. By using Lemma 1, X^1 can be partitioned into three integer boxes:

$$\begin{aligned}
X^1 &= [\langle (-1, 0), (5, 6)^T \rangle \setminus \langle (-1, 0)^T, (2, 4)^T \rangle] \setminus \langle (-1, 6)^T, (-1, 6)^T \rangle \\
&= [\langle (3, 0)^T, (5, 6)^T \rangle \cup \langle (-1, 5)^T, (2, 6)^T \rangle] \setminus \langle (-1, 6)^T, (-1, 6)^T \rangle \\
&= \langle (3, 0)^T, (5, 6)^T \rangle \cup \langle (0, 5)^T, (2, 6)^T \rangle \cup \langle (-1, 5)^T, (-1, 5)^T \rangle.
\end{aligned}$$

Lemma 1 shows that the revised domain $\tilde{\Omega}$ in (3.17) or (3.19) can be partitioned into a union of integer subboxes. The Lagrangian relaxation problem on the revised domain (e.g., X^1 in Example 1) can be easily solved by using decomposition. We will refer to the cutting process in (3.17) or (3.19) and the partition of the complement set

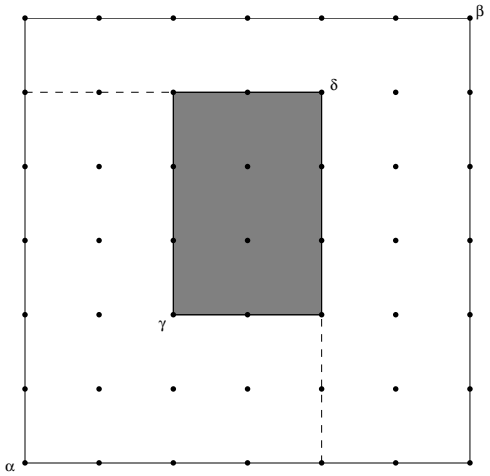

FIG. 4.5. *Partition of* $A \setminus B$.

by formula (4.1) as the *cut-and-partition* scheme. It is easy to see that the number of the new integer subboxes generated by partitioning set $\tilde{\Omega}$ is at most $3n-1$.

In implementation, instead of performing dual search on the revised domain as a whole, we apply the dual search procedure separately on each new integer subbox. This will yield a better lower bound of the revised problem as proved in the following lemma.

LEMMA 2. *Let*

$$\begin{aligned}
\hat{X} &= \cup_{i=1}^{t} \hat{X}_i, \\
\hat{S} &= \{x \in \hat{X} \mid g(x) \le b\}, \\
\hat{S}_i &= \{x \in \hat{X}_i \mid g(x) \le b\},\ i = 1, \ldots, t, \\
\hat{d}(\lambda) &= \min_{x \in \hat{X}} L(x, \lambda), \\
\hat{d}_i(\lambda) &= \min_{x \in \hat{X}_i} L(x, \lambda),\ i = 1, \ldots, t.
\end{aligned}$$

Further let $\hat{\lambda}^*$ *be the optimal solution of* $\max_{\lambda \ge 0} \hat{d}(\lambda)$ *and* $\hat{\lambda}_i^*$ *be the optimal solution of* $\max_{\lambda \ge 0} \hat{d}_i(\lambda)$, $i = 1, \ldots, t$. *Then,*

$$\hat{d}(\hat{\lambda}^*) \le \min_{1 \le i \le t} \hat{d}_i(\hat{\lambda}_i^*) \le \min_{x \in \hat{S}} f(x). \tag{4.7}$$

Proof. Since $\hat{X}_i \subseteq \hat{X}$, $\hat{d}(\lambda) \le \hat{d}_i(\lambda)$ for all $\lambda \ge 0$ and $i = 1, \ldots, t$. We thus have $\hat{d}(\hat{\lambda}^*) \le \hat{d}_i(\hat{\lambda}_i^*)$ for $i = 1, \ldots, t$. This further leads to the first inequality in (4.7). On the other hand, from the weak duality, we have $\hat{d}_i(\hat{\lambda}_i^*) \le \min_{x \in \hat{S}_i} f(x)$. This further yields $\min_{1 \le i \le t} \hat{d}_i(\hat{\lambda}_i^*) \le \min_{1 \le i \le t} \min_{x \in \hat{S}_i} f(x) = \min_{x \in \hat{S}} f(x)$, which is the second inequality in (4.7). □

It is clear from the above lemma that the minimum from among the dual values of all integer subboxes provides a Lagrangian lower bound higher than the dual value of the entire revised domain.

4.3. The main algorithm. Based on the above discussion, a convergent Lagrangian and contour cut algorithm can be developed by combining the Lagrangian relaxation with the cut-and-partition scheme. Let $X^0 = \{X\}$. Initially, a dual search procedure is applied to (P_s) to produce an optimal dual value $d(\lambda^0)$ together with a feasible optimal solution x^0 and an infeasible optimal solution y^0 to (L_{λ^0}). The optimal dual value $d(\lambda^0)$ gives a lower bound of the problem and x^0 is set to be the incumbent. At the kth iteration, the integer subbox with the minimum dual value is selected from X^k. The cut-and-partition scheme is then applied to that integer subbox. For each newly generated integer subbox, Procedure 1 is applied to determine its dual value together with a feasible solution and an infeasible solution. The current best feasible solution is recorded as the incumbent solution and all integer subboxes whose dual value is greater than or equal to the objective function value of the incumbent are removed. The process repeats until there is no integer subbox in X^k and the incumbent solution is the optimal solution to (P_s) when the algorithm terminates.

We now formally present the algorithm.

ALGORITHM 1 (convergent Lagrangian and contour cut algorithm for (P_s)).

Step 0 (initialization). Apply the dual search procedure to (P_s) and obtain the dual value $d(\lambda^0)$, a feasible solution x^0, and an infeasible solution y^0. Set $LB = d(\lambda^0)$ as the lower bound, $x_{opt} = x^0$, $f_{opt} = q(x_{opt})$, $X^0 = X$, $k = 0$.

Step 1. Select the integer subbox $\langle \alpha^k, \beta^k \rangle$ from X^k that yields the minimum lower bound LB. Let $x^k,\ y^k \in \langle \alpha^k, \beta^k \rangle$ be the feasible and infeasible solutions generated by Procedure 1, respectively.

Step 2 (contour cut and partition).

Case (a). q is a convex function. Set $v_1 = q(x^k)$, $v_2 = LB$; calculate integer boxes $B(v_1)$, $N(y^k)$, and $T(x^k)$. Use (4.1) to partition the set

$$Y^{k+1} = [B(v_1) \setminus N(y^k)] \setminus T(x^k). \tag{4.8}$$

Case (b). q is a concave function. Set $v_1 = LB$, $v_2 = q(x^k)$; calculate integer boxes $B(v_1)$, $N(x^k)$, and $T(y^k)$. Use (4.1) to partition the set

$$Y^{k+1} = [B(v_1) \setminus N(x^k)] \setminus T(y^k). \tag{4.9}$$

Step 3 (dual search).

(i) Apply Procedure 1 to each integer subbox $\langle \alpha, \beta \rangle \in Y^{k+1}$ with X replaced by $\langle \alpha, \beta \rangle$. Let

$$\tilde{x}^0 \in \arg \min_{x \in \langle \alpha, \beta \rangle} g(x),\ \tilde{y}^0 \in \arg \min_{x \in \langle \alpha, \beta \rangle} q(x).$$

One of the following three cases happens: (a) If $g(\tilde{x}^0) > b$, then remove $\langle \alpha, \beta \rangle$ from Y^{k+1}; (b) if $g(\tilde{y}^0) \le b$, then set $x_{opt} = \tilde{y}^0$ and $f_{opt} = q(\tilde{y}^0)$ if $f(\tilde{y}^0) < f_{opt}$, and remove $\langle \alpha, \beta \rangle$ from Y^{k+1}; (c) if $g(\tilde{x}^0) \le b$ and $g(\tilde{y}^0) > b$, then Procedure 1 generates a dual value on the integer box, a feasible solution, and an infeasible solution. If the dual value is greater than or equal to f_{opt}, then remove $\langle \alpha, \beta \rangle$ from Y^{k+1}. Compute the objective function value of the feasible solution and update x_{opt} and f_{opt} if necessary.

(ii) Set $X^{k+1} = Y^{k+1} \cup (X^k \setminus \{\langle \alpha^k, \beta^k \rangle\})$.

Step 4 (termination). If X^{k+1} is empty, stop. x_{opt} is an optimal solution to (P_s). Otherwise, set $k := k + 1$, goto Step 1.

THEOREM 5. *Algorithm* 1 *stops within a finite number of iterations with either an optimal solution to* (P_s) *being found or an infeasibility of* (P_s) *being reported.*

Proof. The finite convergence is obvious by noting that X is a finite integer set, and at each iteration, x^k and y^k are cut from X^k in Step 2 and are not included in X^{k+1}. From the discussion in section 3, no feasible solution better than x^k will be cut from X^k in Step 2. Also, by weak duality, no feasible solution better than x^k will be cut from X^k in Step 3. Thus, at each iteration, either x_{opt} is already the optimal solution or there is an optimal solution in X^k. Therefore, x_{opt} must be an optimal solution to the original problem when the algorithm stops at Step 4. □

5. Extension to problems with multiple constraints. The algorithm developed in section 4 can be extended to deal with multiply constrained cases of (P). Consider a subproblem (SP) of (P) with X replaced by an integer subbox $\widetilde{X} \subseteq X$. The Lagrangian dual of (SP) is

$$\max_{\lambda \in \mathbb{R}^m_+} d(\lambda), \tag{5.1}$$

where

$$d(\lambda) := \min_{x \in \widetilde{X}} \left[q(x) + \sum_{i=1}^{m} \lambda_i (g_i(x) - b_i) \right]. \tag{5.2}$$

From the weak duality, $d(\lambda) \le q(x)$ for any feasible solution $x \in \widetilde{X}$. Therefore, $d(\lambda)$ provides a lower bound of the optimal value of (SP). Let λ^* be an optimal solution to (5.1). Then, $LB = d(\lambda^*)$ is the best lower bound generated by the Lagrangian relaxation (5.2).

Since $d(\lambda)$ is a concave piecewise linear function, the subgradient method is an efficient method for computing an approximate solution to (5.1). Alternatively, we can use the outer Lagrangian linearization method (see [38]) to compute an exact solution to (5.1) when an initial feasible solution to (P) is available.

Consider the following surrogate constraint problem:

$$\begin{aligned} \min \ & q(x) = \sum_{j=1}^{n} \left(\frac{1}{2} c_j x_j^2 + d_j x_j \right) \\ \text{s.t.} \ & g_{\lambda^*}(x) = \sum_{i=1}^{m} \lambda_i^* g_i(x) \le \sum_{i=1}^{m} \lambda_i^* b_i, \\ & x \in \tilde{X}. \end{aligned} \tag{5.3}$$

Let $b_{\lambda^*} = \sum_{i=1}^{m} \lambda_i^* b_i$. Denote by $\underline{g}_{\lambda^*}$ and $\overline{g}_{\lambda^*}$ the minimum value and maximum value of $g_{\lambda^*}(x)$ over $\widetilde{X}$, respectively. Without loss of generality, we can assume that

$$\underline{g}_{\lambda^*} \le b_{\lambda^*} < \overline{g}_{\lambda^*}. \tag{5.4}$$

Suppose that λ^* is an exact solution to (5.1). It is easy to see that (5.3) and (SP) have the same dual value and that the optimal solution to the dual problem of problem (5.3) is 1. Moreover, by Theorem 2, there exist a feasible solution $\tilde{x}$ and an infeasible $\tilde{y}$ to problem (5.3) that solve the Lagrangian relaxation (5.2) with $\lambda = \lambda^*$.

If $\tilde{\lambda}$ is an approximate solution to (5.1), then we can apply Procedure 1 to search for an exact dual solution μ^* to problem (5.3) with λ^* replaced by $\tilde{\lambda}$. Set $\lambda^* = \mu^* \tilde{\lambda}$. Again, by Theorem 2, there exist a feasible solution $\tilde{x}$ and an infeasible $\tilde{y}$ to problem (5.3) that solve the Lagrangian relaxation (5.2) with $\lambda = \lambda^*$.

Now we are ready to extend Algorithm 1 to the multiply constrained case of (P). It is noticed that

$$q(\tilde{y}) < d(\lambda^*) \leq q(\tilde{x}). \tag{5.5}$$

Moreover, $\tilde{y}$ is infeasible to (P) while $\tilde{x}$ is not necessarily feasible to (P). Therefore, the contour cutting process in Step 2 of Algorithm 1 has to be modified for situations in which $\tilde{x}$ is infeasible to (P). More specifically, we need the following modifications in Algorithm 1.

Step $2'$. Case (a). q is a convex function. If $\tilde{x}$ is feasible to (P), set $v_1 = q(\tilde{x})$ and compute Y^{k+1} by

$$Y^{k+1} = [B(v_1) \setminus T(\tilde{x})] \setminus N(\tilde{y}).$$

Otherwise, if $\tilde{x}$ is infeasible to (P), then compute Y^{k+1} by

$$Y^{k+1} = [\langle \tilde{l}, \tilde{u} \rangle \setminus \{\tilde{x}\}] \setminus N(\tilde{y}).$$

Case (b). q is a concave function. Set $v_1 = LB$. If $\tilde{x}$ is feasible to (P), then compute Y^{k+1} by

$$Y^{k+1} = [B(v_1) \setminus N(\tilde{x})] \setminus T(\tilde{y}).$$

Otherwise, if $\tilde{x}$ is infeasible to (P), compute Y^{k+1} by

$$Y^{k+1} = [B(v_1) \setminus \{\tilde{x}\}] \setminus T(\tilde{y}).$$

We also need to replace the dual search procedure used in Step 0 and Step 3(i) of Algorithm 1 with an exact dual search method or an approximate method for (5.1). When the dual problems (5.1) in Step 0 and Step 3(i) are solved approximately, Procedure 1 is applied to the surrogate problem (5.3) to search for the lower bound, together with a feasible solution and infeasible solution for (5.3). Finally, two special cases have to be considered in the algorithm when (5.4) does not hold. If $\underline{g}_{\lambda^*} > b_{\lambda^*}$, then there is no feasible solution in $\widetilde{X}$, and $\widetilde{X}$ can be removed from further consideration. If $\overline{g}_{\lambda^*} \leq b_{\lambda^*}$, then solving (5.3) using the dual search will yield a zero dual solution and an optimal solution $\tilde{x}$ which is feasible for (5.3). If $\tilde{x}$ is also feasible for (P), discard $\tilde{X}$ from further consideration after updating x_{opt} and f_{opt} if $q(\tilde{x}) < f_{opt}$. Otherwise, remove $\tilde{x}$ from $\tilde{X}$.

The finite convergence of the extended algorithm for multiply constrained problems and the optimality of x_{opt} when the algorithm stops can be proved similarly as in Theorem 5.

An important observation from Step $2'$ is that in multiply constrained situations, we are not always able to find a feasible solution to the primal problem during the dual search procedure, which constitutes a major difference between multiply constrained problems and singly constrained problems. The unavailability of feasible solutions to the primal problem affects the efficiency of the contour cut algorithm for multiply constrained problems, as witnessed from our computational experiences. Specifically, a guaranteed two-direction cutting process (cutting the outside of a bigger ellipse and the inside of a smaller ellipse) in singly constrained situations often becomes a one-direction cutting process in multiply constrained situations when a feasible solution is not available. Nevertheless, in some situations, certain heuristics can be used to

search for a feasible solution which does not necessarily solve problem (5.2). This may improve the efficiency of the contour cutting process. For example, if the constraint functions are nondecreasing, as is the case in nonlinear knapsack problems, then the lower bound point $\tilde{l}$ of $\widetilde{X}$ is always feasible for (SP) in nontrivial cases.

We now illustrate the extended algorithm for multiply constrained problems by a two-dimensional example with a concave quadratic objective function, a convex constraint, and a nonconvex constraint.

Example 2.

$$\begin{aligned} \min\ & q(x) = -1.5x_1^2 + 2x_1 - 2x_2^2 + 8x_2 \\ \text{s.t.}\ & g_1(x) = 3x_1^2 - 2x_1 + 2x_2^2 - 6x_2 \le 66, \\ & g_2(x) = -x_1^2 - x_1 + x_2^2 - 2x_2 \le -3.5, \\ & x \in X = \{x \mid -1 \le x_1 \le 5,\ 0 \le x_2 \le 6,\ x_i \text{ integer}\}. \end{aligned}$$

The optimal solution is $x^* = (5,0)^T$ with $q(x^*) = -27.5$.

For this example, we use the subgradient method to solve the dual problem (5.1). The iterative process is described as follows.

Iteration 0.

Step 0. Solving (5.1) with $\widetilde{X} = X$, we get $\lambda^* = (0.5145, 0.2284)^T$. Applying Procedure 1 to the surrogate constraint problem (5.3), we obtain the dual value $LB = -34.0771$ and two optimal solutions $x^0 = (-1,6)^T$ and $y^0 = (5,6)^T$. An initial feasible solution $(5,0)^T$ is also obtained during the dual search. Set $x_{opt} = (5,0)^T$ and $f_{opt} = q(x_{opt}) = -27.5$. Notice that both x^0 and y^0 are infeasible for (P). Set $X^0 = X$ and $k = 0$.

Iteration 1.

Step 1. Select X to generate new integer boxes.

Step 2. Set $v_1 = LB = -34.0771$. We have

$$B(v_1) = M(v_1) \cap X = \langle (-4,-2)^T, (6,6)^T \rangle \cap X = X$$

and

$$Z^1 = B(v_1) \setminus \{x^0\} = \langle (0,0)^T, (5,6)^T \rangle \cup \langle (-1,0)^T, (-1,5)^T \rangle = Z_1^1 \cup Z_2^1.$$

Since the dual value on Z_2^1 is $-13.5 > -27.5 = f_{opt}$, we can remove Z_2^1 from Z^1. We have $T(y^0) = \langle (5,6)^T, (5,6)^T \rangle$. Thus,

$$Y^1 = Z^1 \setminus T(y^0) = \langle (0,0)^T, (4,6)^T \rangle \cup \langle (5,0)^T, (5,5)^T \rangle = Y_1^1 \cup Y_2^1.$$

For Y_1^1, the dual value is -33.1476 with two solutions $(0,6)^T$ and $(4,6)^T$; for Y_2^1, the dual value is -32.2875 with two solutions $(5,0)^T$ and $(5,5)^T$.

Step 3. Set $X^1 = Y^1$, $k = 1$.

Iteration 2.

Step 1. Select Y_1^1 from X^1 to generate new integer boxes. Set $x^1 = (0,6)^T$ and $y^1 = (4,6)^T$. Notice that x^1 is infeasible to (P).

Step 2. Set $v_1 = -33.1476$. Calculate $B(v_1) = M(v_1) \cap Y_1^1 = \langle (-4,-2)^T, (5,6)^T \rangle \cap Y_1^1 = Y_1^1$. We have

$$Z^2 = B(v_1) \setminus \{x^1\} = \langle (1,0)^T, (4,6)^T \rangle \cup \langle (0,0)^T, (0,5)^T \rangle = Z_1^2 \cup Z_2^2.$$

Since the dual value on Z_2^2 is $-1.5966 > -27.5 = f_{opt}$, we can remove Z_2^2 from Z^2. We have $T(y^1) = \langle (4,6)^T, (4,6)^T \rangle$. Thus

$$Y^2 = Z^2 \setminus T(y^1) = \langle (1,0)^T, (3,6)^T \rangle \cup \langle (4,0)^T, (4,5)^T \rangle = Y_1^2 \cup Y_2^2.$$

The dual value on Y_1^2 is -20.7748 and the dual value on Y_2^2 is -26.0. Since both of them are greater than f_{opt}, we can remove Y_1^2 and Y_2^2 from Y^2.

Step 3. Set $X^2 = \{Y_2^1\}$, $k = 2$.

Iteration 3.

Step 1. Select Y_2^1 to generate the new integer subboxes. Set $x^2 = (5,0)^T$ and $y^2 = (5,5)^T$. Note that x^2 is feasible to (P).

Step 2. Set $v_1 = -32.2875$. Calculate $B(v_1) = M(v_1) \cap Y_2^1 = \langle (-4,-2)^T, (5,6)^T \rangle \cap Y_2^1 = Y_2^1$ and $N(x^2) = \langle (5,0)^T, (5,4)^T \rangle$. We have

$$Z^2 = B(v_1) \setminus N(x^2) = \{(5,5)^T\}.$$

Thus

$$Y^2 = Z^2 \setminus \{y^2\} = \emptyset.$$

Step 3. $X^3 = \emptyset$.

Step 4. Stop. $x_{opt} = (5,0)^T$ is an optimal solution to the example.

6. Extension to problems with indefinite q. The contour cut method developed in the previous sections can be extended to handle problems with an indefinite quadratic objective function. We describe the main idea of this extension in this section. Let's first consider the singly constrained problem (P_s), where some c_j coefficients are positive and some others are negative.

We can always express $q(x)$ as the sum of a convex quadratic function and a concave quadratic function: $q(x) = q_1(x) + q_2(x)$ with $q_1(x) = \sum_{j=1}^n (\frac{1}{2} c_j^1 x_j^2 + d_j x_j)$ and $q_2(x) = -\sum_{j=1}^n \frac{1}{2} c_j^2 x_j^2$, where all c_j^1 and c_j^2, $j = 1, 2, \ldots, n$, are positive. Note that the expression of $q(x)$ is not unique. The subproblem (SP) of problem (P_s) can be expressed as

$$\begin{aligned} \min\ & q(x) = q_1(x) + q_2(x) \\ \text{s.t.}\ & g(x) = \sum_{j=1}^n g_j(x_j) \le b, \\ & x \in \widetilde{X} = \{x \mid \tilde{l}_j \le x_j \le \tilde{u}_j,\ x_j \text{ integer},\ j = 1, \ldots, n\}, \end{aligned}$$

where $\widetilde{X} \subseteq X$. Consider the following two problems associated with (SP):

$$\begin{aligned} (SP^1) \qquad \min\ & q_1(x) = \sum_{j=1}^n \left(\frac{1}{2} c_j^1 x_j^2 + d_j x_j \right) \\ \text{s.t.}\ & g(x) = \sum_{j=1}^n g_j(x_j) \le b, \\ & x \in \widetilde{X} = \{x \mid \tilde{l}_j \le x_j \le \tilde{u}_j,\ x_j \text{ integer},\ j = 1, \ldots, n\} \end{aligned}$$

and

$$(SP^2) \quad \min\ q_2(x) = -\sum_{j=1}^{n} \frac{1}{2} c_j^2 x_j^2$$
$$\text{s.t.}\ \ g(x) = \sum_{j=1}^{n} g_j(x_j) \le b,$$
$$x \in \widetilde{X} = \{x \mid \tilde{l}_j \le x_j \le \tilde{u}_j,\ x_j \text{ integer},\ j = 1, \ldots, n\}.$$

Obviously, (SP^1) and (SP^2) are nonlinear integer programming problems with a convex quadratic objective function and a concave quadratic objective function, respectively. Let $f_i^* = \min_{x \in S \cap \widetilde{X}} q_i(x)$, $i = 1, 2$, where S is the feasible region of (P_s). Further define the following Lagrangian relaxation for (SP^1) and (SP^2), respectively, for $\lambda \ge 0$:

$$(L_\lambda^i) \quad d_i(\lambda) = \min_{x \in \widetilde{X}} q_i(x) + \lambda(g(x) - b)), \qquad i = 1, 2.$$

Let λ_i^* be the optimal solutions to the dual problems of $\max_{\lambda \ge 0} d_i(\lambda)$ for $i = 1, 2$, respectively. Let $\tilde{x} \in S \cap \widetilde{X}$. By the weak duality, we have

$$d_1(\lambda_1^*) + d_2(\lambda_2^*) \le f_1^* + f_2^* \le f^* \le q_1(\tilde{x}) + q_2(\tilde{x}). \tag{6.1}$$

Let

$$C_1 = \{x \in \widetilde{X} \mid q_i(x) < d_i(\lambda_i^*), \quad i = 1, 2\},$$
$$C_2(\tilde{x}) = \{x \in \widetilde{X} \mid q_i(x) \ge q_i(\tilde{x}), \quad i = 1, 2\}.$$

It is easy to see from (6.1) and the weak duality that sets C_1 and $C_2(\tilde{x})$ can be cut off from $\widetilde{X}$ without removing the optimal solution after recording $\tilde{x}$. Let $\tilde{x}_i$ and $\tilde{y}_i$ be the feasible and infeasible optimal solutions to $(L_{\lambda_i^*}^i)$ $(i = 1, 2)$, respectively. Notice that $q_i(\tilde{y}_i) \le d_i(\lambda_i^*)$, $i = 1, 2$. Let $v_i = q_1(\tilde{x}_i)$, $i = 1, 2$, and $w = d_2(\lambda_2^*)$. Similar to section 3, we define sets $B_i(\cdot)$ and $N_i(\cdot)$ for functions q_i, $i = 1, 2$, respectively. Then we have

$$Q_1 = N_1(\tilde{y}_1) \cap [\widetilde{X} \setminus B_2(w)] \subseteq C_1 \cap \widetilde{X},$$
$$Q_2(\tilde{x}_i) = [\widetilde{X} \setminus B_1(v_i)] \cap N_2(\tilde{x}_i) \subseteq C_2(\tilde{x}_i) \cap \widetilde{X}, \qquad i = 1, 2.$$

Thus, cutting both Q_1 and $Q_2(\tilde{x}_i)$ $(i = 1, 2)$ from $\widetilde{X}$ will not remove any optimal solution to the primal problem after recording the current best feasible solution as the incumbent. Note Q_1 and/or $Q_2(\tilde{x}_i)$ could be empty in certain circumstances. In the cutting process, points $\tilde{x}_i$, $i = 1, 2$, will be removed from $\widetilde{X}$ after updating the incumbent.

Replacing Step 2 of Algorithm 1 with the above contour cutting process, we can then deal with (P_s) with an indefinite quadratic objective function. Similar to section 5, we can further extend the algorithm to solve the multiply constrained case of (P) with an indefinite objective function.

Now, let's demonstrate the above solution idea by an illustrative example.

Example 3.

$$\min\ q(x) = -1.75x_1^2 - 1.75x_1 + x_2^2 - 12x_2$$
$$\text{s.t.}\ \ g(x) = 4(x_1 - 1)^2 + 9(x_2 - 2.5)^2 \le 10,$$
$$x \in X = \{x \mid 0 \le x_i \le 4,\ x_i \text{ integer},\ i = 1, 2\}.$$

The optimal solution of the example is $x^* = (2, 3)^T$ with $q(x^*) = -37.5$.

Decompose the above example into the following two associated problems, of which the first has a convex quadratic objective function and the second has a concave quadratic objective function:

$$\begin{aligned} \min\ & q_1(x) = 0.25x_1^2 - 1.75x_1 + 3x_2^2 - 12x_2 \\ \text{s.t.}\ & g(x) = 4(x_1-1)^2 + 9(x_2-2.5)^2 \le 10, \\ & x \in X = \{x \mid 0 \le x_i \le 4,\ x_i \text{ integer},\ i = 1,2\} \end{aligned} \tag{6.2}$$

and

$$\begin{aligned} \min\ & q_2(x) = -2x_1^2 - 2x_2^2 \\ \text{s.t.}\ & g(x) = 4(x_1-1)^2 + 9(x_2-2.5)^2 \le 10, \\ & x \in X = \{x \mid 0 \le x_i \le 4,\ x_i \text{ integer},\ i = 1,2\}. \end{aligned} \tag{6.3}$$

Iteration 0.

Step 0. Solving the dual problem of (6.2) yields a dual value, $d_1 = -14.6563$, and two solutions, $\tilde{x}_1 = (2,2)^T$ and $\tilde{y}_1 = (3,2)^T$. Solving the dual problem of (6.3) yields a dual value, $d_2 = -29.1250$, and two solutions, $\tilde{x}_2 = (2,3)^T$ and $\tilde{y}_2 = (3,3)^T$. Thus, the lower bound is $LB = d_1 + d_2 = -14.6563 - 29.1250 = -43.7813$ and the incumbent is $x_{opt} = (2,3)^T$ with $f_{opt} = q((2,3)^T) = -37.5$. Set $X^0 = \{\langle (0,0)^T, (4,4)^T \rangle\}$ and $k = 0$.

Iteration 1.

Step 1. Select the unique integer subbox in X^0.

Steps 2 *and* 3. Since $N_1(\tilde{y}_1) = \langle (3,2)^T, (4,2)^T \rangle$ and $B_2(d_2) = \langle (0,0)^T, (3,3)^T \rangle$, we have $Q_1 = N_1(\tilde{y}_1) \cap [X \setminus B_2(d_2)] = \{(4,2)^T\}$. Thus

$$Z^1 = X \setminus Q_1 = \langle (0,3)^T, (4,4)^T \rangle \cup \langle (0,0)^T, (3,2)^T \rangle \cup \langle (4,0)^T, (4,1)^T \rangle = Z_1^1 \cup Z_2^1 \cup Z_3^1.$$

For Z_1^1, we have $d_1 + d_2 = -11.6563 - 29.1250 = -40.7813 < -37.5 = f_{opt}$. For Z_2^1, we have $d_1 + d_2 = -14.6563 - 19.1250 = -33.7813 > -37.5 = f_{opt}$. Thus Z_2^1 is removed from Z^1. Since there is no feasible solution in Z_3^1, Z_3^1 is also removed from Z^1. Set $Y^1 = \{Z_1^1\}$. Figure 6.1 illustrates the set $Z^1 = X \setminus Q_1$.

Let $v_1 = q_1(\tilde{x}_1) = -14.5$. Since $N_2(\tilde{x}_1) = \langle (0,0)^T, (2,2)^T \rangle$ and $B_1(v_1) = \langle (2,2)^T, (4,2)^T \rangle$, we have

$$Q_2(\tilde{x}_1) = [X \setminus B_1(v_1)] \cap N_2(\tilde{x}_1) = N_2(\tilde{x}_1) \setminus \{(2,2)^T\} = \langle (0,0)^T, (2,2)^T \rangle \setminus \{(2,2)^T\}.$$

Notice $Q_2(\tilde{x}_2)$ is an empty set. Since $Q_2(\tilde{x}_1) \cap Y^1 = \emptyset$, a revised domain X^1 is generated from cutting $\tilde{x}_2$ from Y^1 (see Figure 6.2). Decompose X^1 as

$$X^1 = \langle (3,3)^T, (4,4)^T \rangle \cup \langle (0,4)^T, (2,4)^T \rangle \cup \langle (0,3)^T, (1,3)^T \rangle = X_1^1 \cup X_2^1 \cup X_3^1.$$

Since there is no feasible solution in X_1^1 and X_2^1, they can be removed from X^1. For X_3^1, we have $d_1 + d_2 = -10.5 - 20.0 = -30.5 > f_{opt}$, and thus X_3^1 is also removed. Therefore, $X^2 = \emptyset$.

Step 4. Stop. $x_{opt} = (2,3)^T$ is an optimal solution.

In computational implementation with an indefinite q, we can also solve the dual problem of (SP) directly to obtain a dual value $d(\lambda^*)$ and use $\max\{d(\lambda^*), d_1(\lambda_1^*) + d_2(\lambda_2^*)\}$ as the lower bound to identify unpromising subboxes to be fathomed. Let $\tilde{x}$ and $\tilde{y}$ be the feasible and infeasible optimal solutions to the Lagrangian relaxation problem of (SP) with λ set at λ^*, respectively. Instead of cutting $Q_2(\tilde{x}_i)$, $i = 1, 2$, we cut $Q_2(\tilde{x})$ in the algorithm.

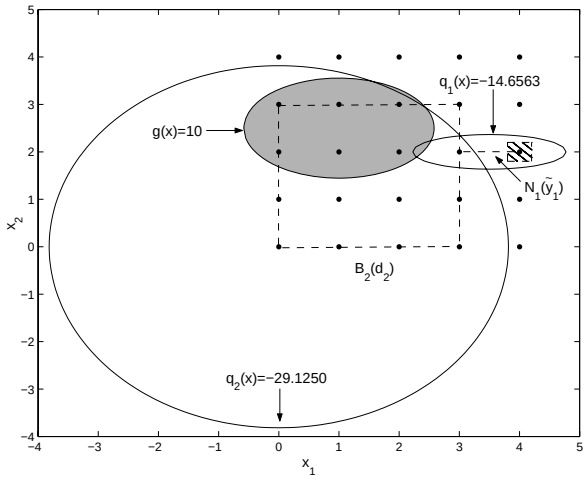

FIG. 6.1. *Set* $Z^1 = X \setminus Q_1$.

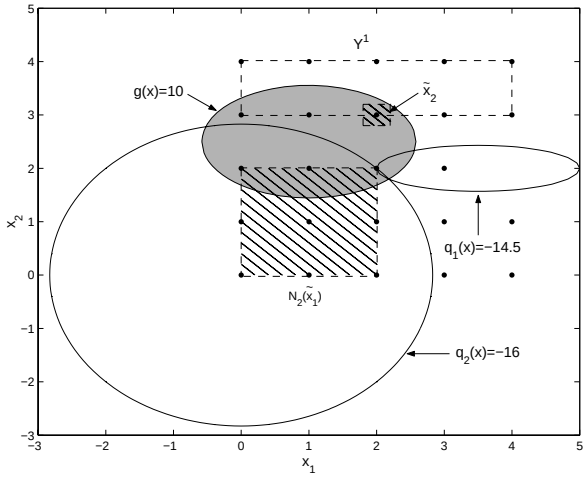

FIG. 6.2. *Sets* $X^1 = Y^1 \setminus \{\tilde{x}_2\}$ *and* $Q_2(\tilde{x}_1)$.

7. Computational experiment. In this section, we will present computational results of Algorithm 1 developed in section 4 and its extensions in sections 5 and 6. The algorithms were programmed in FORTRAN 90 and run on a SUN Workstation (Blade 2000). Comparison results with other methods in the literature will also be reported.

7.1. Test problems. Two sets of test problems are considered in our computational experiments. The first set of test problems consists of 12 problems with different types of objective functions and constraint functions. The second set of test problems is a class of convex quadratic integer programming problems arising in portfolio optimization. All the coefficients in the test problems are randomly generated from uniform distributions.

TABLE 7.1
Coefficients in the test problems.

Type	Single constraint			Multiple constraints		
	α_{1j}	β_{1j}	γ_{1j}	α_{ij}	β_{ij}	γ_{ij}
1	$[-10, 40]$	0	0	$[1, 40]$	0	0
2	$[-10, 30]$	$[1, 20]$	0	$[10, 50]$	$[1, 10]$	0
3	$[100, 200]$	$[-20, -1]$	0	$[-10\beta_{ij}, -10\beta_{ij} + 5]$	$[-15, -5]$	0
4	$[-10, 20]$	$[5, 25]$	$[-2, 8]$	$[10, 50]$	$[1, 10]$	$[1, 5]$

In the first set of test problems, three types of objective functions in the form of $q(x) = \sum_{j=1}^{n}(\frac{1}{2}c_j x_j^2 + d_j x_j)$ are generated using the following data:

- $q(x)$ is convex quadratic with $c_j \in [2, 20]$ and $d_j \in [-100, -50]$;
- $q(x)$ is concave quadratic with $c_j \in [-20, -2]$ and $d_j \in [-10, 40]$;
- $q(x)$ is indefinite quadratic with $c_j \in [-10, 10]$ and $d_j \in [-40, 10]$.

The constraint functions in the test problems are in the following form:

$$g_i(x) = \sum_{j=1}^{n}(\alpha_{ij}x_j + \beta_{ij}x_j^2 + \gamma_{ij}x_j^3), \quad i = 1, \ldots, m.$$

Table 7.1 describes the ranges of coefficients in g_i's for singly constrained test problems and multiply constrained test problems, where Type 1 denotes the linear constraints, Type 2 the convex quadratic constraints, Type 3 the concave quadratic constraints and Type 4 the third polynomial constraints.

In the first set of test problems, we take $l_j = 1$ and $u_j = 5$, $j = 1, \ldots, n$, and the right-hand side of b is taken as $b = g_{min} + r \cdot (g_{max} - g_{min})$, where g_{min} and g_{max} are the minimum and maximum values of $g(x)$ over X, respectively, and $r \in (0, 1)$.

The second set of problems arises from portfolio optimization. It has been shown in [41], [42] that the Markowitz mean-variance portfolio selection model can be reformulated as a simplified model which is a separable convex quadratic programming problem with linear constraints. The discrete version of the simplified portfolio selection problem [47] can be expressed as

$$\begin{aligned}(SMV) \qquad \min\ & q(x) = \sum_{j=1}^{n}\left(\frac{1}{2}c_j x_j^2 + d_j x_j\right) \\ \text{s.t.}\ & Ax \le b, \\ & x \in X = \{x \mid l_j \le x_j \le u_j,\ x_j \text{ integer},\ j = 1, \ldots, n\},\end{aligned}$$

where $c_j > 0$ for all j and $A = (a_{ij})$ is an $m \times n$ matrix. Obviously, problem (SMV) is a special case of (P). In our testing, the data in (SMV) are taken as the same as in [47], where additional dependency relationships are considered. The ranges of coefficients in (SMV) are $c_j \in [10, 50]$, $d_j \in [-3000, -1000]$, $a_{ij} \in [1, 5]$, $l_j \in [0, 40]$, and $u_j = l_j + 5$. The right-hand side b is taken as $b = A \cdot [l + r \cdot (u - l)]$, where $l = (l_1, \ldots, l_n)^T$, $u = (u_1, \ldots, u_n)^T$ and $r \in (0, 1)$.

7.2. Computational results. The computational results of our proposed solution algorithms for the first set of test problems are summarized in Tables 7.2–7.4. The following notations are used in the numerical results:

- n = number of variables;
- m = number of constraints;
- N_{iter} = average number of iterations of the algorithm for 20 test problems;

TABLE 7.2

- N_{box} = average number of the total integer boxes examined during the algorithm for 20 test problems;
- T_{cpu} = average CPU seconds measured on a SUN Workstation (Blade 2000) for 20 test problems.

In our implementation of the algorithm for multiply constrained problems, the outer Lagrangian linearization method is used to solve the dual problem (5.1). The results in Tables 7.2–7.4 show that the proposed algorithm is efficient and robust for solving large-scale quadratic integer problems with convex, concave, and indefinite objective functions and different types of constraint functions. Comparing results in Table 7.2–Table 7.4, we can see that the algorithm is more efficient for problems with a concave objective function. We can also see that the efficiency of the algorithm is not sensitive to the convexity of the constraint functions. This is partially due to the fact that the cut-and-partition scheme does not depend on the property of the constraints.

The computational results for portfolio selection problems (SMV) are presented in Table 7.5, where N_{iter}, N_{box}, and T_{cpu} are obtained by running the code for 10 test problems. We see from Table 7.5 that the problem becomes more difficult as the ratio of right-hand side, r, decreases.

7.3. Comparison with other methods. To compare our algorithm with other existing methods in the literature, we implemented two exact methods in the literature which are applicable to (P):

- branch-and-bound method of Bretthauer and Shetty (see [9]).
- hybrid method of Marsten and Morin (see [34]).

Classical branch-and-bound methods using continuous relaxation can solve (P) when both $q(x)$ and $g(x)$ are convex functions. Gupta and Ravindran [21] reported computational results of the branch-and-bound method for general convex integer programming, where the generalized reduced gradient method was used as a solver for the continuous subproblems. Bretthauer and Shetty [9] proposed a special branch-and-bound method for singly constrained convex nonlinear separable integer programming problems (see also [10]). This method is based on solving the continuous relaxation subproblems by manipulating the KKT conditions of the subproblems and uses the standard branch rule to generate nodes in the search tree.

The hybrid method proposed in [34] is applicable to general separable integer programming problems, including (P). The method is a combination of the dynamic programming approach and the branch-and-bound method. The basic idea of the method is to recursively generate the efficient feasible solutions of the problem and to remove the inefficient feasible solutions by dominance rules. The branch-and-bound strategy is employed to remove unpromising incomplete solutions during the recursion.

TABLE 7.6
Comparison results for convex problems.

n	Our method	Branch-and-bound method	Hybrid method
	T_{cpu}	T_{cpu}	T_{cpu}
50	0.10	0.32	8.0
100	0.88	16.5	152.1
150	2.0	485.1	833.6

TABLE 7.7
Comparison results for nonconvex problems.

n	Our method	Hybrid method
	T_{cpu}	T_{cpu}
100	0.4	26.6
150	2.0	131.0
200	1.6	397.0

We have implemented the above two methods by FORTRAN 90 and tested for two sets of test problems for comparison. The first set of test problems is a convex instance of (P) with a single linear constraint. Both the branch-and-bound method and hybrid method are applicable to this set of test problems. The ranges of the parameters of $q(x)$ are $c_j \in [1, 10]$ and $d_j \in [-100, -300]$. The linear constraint is $g(x) = \sum_{j=1}^{n} \alpha_j x_j$ with $\alpha_j \in [1, 50]$. The ratio of the right-hand side b is taken as $r = 0.7$, and $l_j = 1$, $u_j = 5$, $j = 1, \ldots, n$. Table 7.6 summarizes the average CPU time of our proposed method, the branch-and-bound method, and the hybrid method for 20 randomly generated test problems in the first set.

The second set of test problems for comparison is a concave instance of (P) with a single linear constraint. Note that only the hybrid method in the literature is applicable to this kind of nonconvex problem. The ranges of the parameters of $q(x)$ are $c_j \in [-10, -1]$ and $d_j \in [-50, -1]$. The ranges of the coefficients in the linear constraint are $\alpha_j \in [1, 50]$. The ratio of the right-hand side b is taken as $r = 0.7$, and $l_j = 1$, $u_j = 5$, $j = 1, \ldots, n$. The comparison results for test problems with different n are reported in Table 7.7, where the average CPU time is obtained by running the algorithms for 20 randomly generated test problems.

The average CPU time in Tables 7.6 and 7.7 indicates that our algorithm is much more efficient than the branch-and-bound method and the hybrid method for both convex and nonconvex problems. Part of the theoretical reason for the outperformance of the proposed method over the continuous relaxation-based branch-and-bound method is that the Lagrangian bound of a convex integer programming problem is at least as good as the continuous bound. Moreover, cutting certain integer boxes from the domain at each iteration in the cut-and-partition scheme of our algorithm speeds up the convergence of the algorithm significantly. We also notice that it is difficult for dynamic programming in the hybrid method to exploit the special structure of the problems in generating efficient feasible solutions and it is thus not efficient to find an exact solution of the original problem.

8. Concluding remarks. We have presented in this paper an efficient exact algorithm for solving nonlinear separable integer programming problems with convex, concave, and indefinite quadratic objective functions and general constraints. The algorithm exploits the special structure of the ellipsoid contour in order to eliminate the duality bound, and thus the duality gap. A prominent feature of the proposed

algorithm is that at each iteration, the algorithm cuts certain unpromising integer subboxes by using quadratic contour cuts. This greatly speeds up the convergence of the Lagrangian dual algorithm. The computational results for large-scale test problems are promising.

Acknowledgment. The authors would like to thank Dr. Jun Wang for his help during this research.

A FEASIBLE ACTIVE SET QP-FREE METHOD FOR NONLINEAR PROGRAMMING*

LIFENG CHEN†, YONGLI WANG‡, AND GUOPING HE§

Abstract. We propose a monotone descent active set QP-free method for inequality constrained optimization that ensures the feasibility of all iterates and allows for iterates on the boundary of the feasible set. The study is motivated by the Facchinei–Fischer–Kanzow active set identification technique for nonlinear programming and variational inequalities [F. Facchinei, A. Fischer, and C. Kanzow, *SIAM J. Optim.*, 9 (1999), pp. 14–32]. Distinguishing features of the proposed method compared with existing QP-free methods include lower subproblem costs and a fast convergence rate under milder assumptions. Specifically, four reduced linear systems with a common coefficient matrix involving only constraints in a working set are solved at each iteration. To determine the working set, the method makes use of multipliers from the last iteration, eliminating the need to compute a new estimate, and no additional linear systems are solved to select linearly independent constraint gradients. A new technique is presented to avoid possible ill-conditioned Newton systems caused by dual degeneracy. It is shown that the method converges globally to KKT points under the linear independence constraint qualification (LICQ), and the asymptotic rate of convergence is Q-superlinear under an additional strong second-order sufficient condition (SSOSC) without strict complementarity.

Key words. constrained optimization, nonlinear programming, QP-free methods, global convergence, superlinear convergence, strict complementarity

1. Introduction.

This paper is concerned with finding a solution of the inequality constrained optimization problem

$$\text{(P)} \qquad \begin{aligned} &\min\ f(x) \\ &\text{s.t. } x \in \mathcal{F} = \{x \in \Re^n | c_i(x) \le 0,\ i = 1, \dots, m\}, \end{aligned}$$

where $f : \Re^n \to \Re$ and $c : \Re^n \to \Re^m$ are assumed to be real valued and twice continuously differentiable on $\mathcal{F}$. A pair $(x, \lambda) \in \Re^{n+m}$ with $x \in \mathcal{F}$ is called a stationary point of problem (P) if it satisfies

$$\begin{aligned} &\nabla_x \mathcal{L}(x, \lambda) = 0, \\ &\lambda_i c_i(x) = 0,\ i = 1, \dots, m, \end{aligned} \tag{1.1}$$

where $\mathcal{L}(x,\lambda) = f(x) + \sum_{i=1}^{m} \lambda_i c_i(x)$ is the Lagrange function of (P). If furthermore $\lambda \geq 0$, (x,λ) is called a KKT point. We also call $x \in \mathcal{F}$ a stationary point or a KKT point of (P) if there exists $\lambda \in \Re^m$ such that (x,λ) is a stationary point or a KKT point of (P).

QP-free methods, which at each iteration require only the solution of a few linear systems usually with common coefficient matrices, were developed to address some computational issues in traditional sequential quadratic programming methods (SQPs). For example, the QP subproblems may be infeasible and the cost for finding their exact solutions can become prohibitive in the absence of a QP truncating scheme. A number of numerical results (see, e.g., [7, 9, 19, 28]) have shown the promise of QP-free methods as an alternative to SQPs for a class of primal nondegenerate problems, such as bound constrained optimization. Under certain regularity assumptions, QP-free methods enjoy global convergence as well as local superlinear/quadratic convergence. For the advantages of QP-free methods, see Facchinei and Lucidi [8].

QP-free methods can be classified into type-1 methods (see, e.g., [18, 13, 19]), which are based on applying Newton's method to the KKT systems (1.1), and type-2 methods (see, e.g., [7, 9, 20, 28]), which are derived from the alternative formulation of the first-order necessary optimality conditions

$$\begin{aligned} &\nabla f(x) + \sum_{i \in I(x)} \lambda_i \nabla c_i(x) = 0, \\ &c_i(x) = 0,\ \lambda_i \geq 0,\ i \in I(x);\ \lambda_i = 0,\ i \in I \backslash I(x), \end{aligned} \tag{1.2}$$

where $I = \{1, \ldots, m\}$ and, for $x \in \mathcal{F}$, $I(x)$ denotes the active set, i.e.,

$$I(x) = \{i | c_i(x) = 0, \quad i \in I\}.$$

1.1. Related work. Panier, Tit, and Herskovits [18] proposed a feasible QP-free method for problem (P) which forms the basic framework of type-1 QP-free methods. Their method directly applies the Newton method to (1.1) and at each iteration first calculates a descent direction $d^{k,0}$ by solving the following Newton equations:

$$\begin{bmatrix} H_k & \nabla c(x^k) \\ \operatorname{diag}(\mu^k)\nabla c(x^k)^\top & \operatorname{diag}(c(x^k)) \end{bmatrix} \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ 0 \end{bmatrix}, \tag{1.3}$$

where $H_k \in \Re^{n \times n}$ is an estimate of the Lagrangian Hessian, (x^k, μ^k) is an approximation to a KKT point, and, for a vector $\mu \in \Re^m$, $\operatorname{diag}(\mu)$ denotes the diagonal matrix whose ith diagonal element is μ_i. In order to maintain the feasibility of the next iterate, the method calculates a second direction $d^{k,1}$ pointing toward the feasible region by solving a perturbed system of (1.3),

$$\begin{bmatrix} H_k & \nabla c(x^k) \\ \operatorname{diag}(\mu^k)\nabla c(x^k)^\top & \operatorname{diag}(c(x^k)) \end{bmatrix} \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ -\|d^{k,0}\|^\nu \operatorname{diag}(\mu^k) e \end{bmatrix}, \tag{1.4}$$

where $\nu > 2$ and e is the vector of all ones of an appropriate dimension (here $e \in \Re^m$). Globally, the search direction is a convex combination of these two directions, namely,

$$d^k = (1 - \rho_k) d^{k,0} + \rho_k d^{k,1},$$

where ρ_k is calculated explicitly. To avoid the Maratos effect, locally the search direction is slightly bent by a relatively small amount using an arc search, which is

obtained through a second-order correction. It is shown that any accumulation point of the iterates generated by the algorithm is a stationary point of problem (P). Under the assumption that any stationary point is isolated, this point is shown to be a KKT point. The algorithm was later improved by Gao, He, and Wu [13] in the sense that every accumulation point of the iterates is a KKT point. To achieve this, they solve an extra linear system obtained from (1.3) by slightly perturbing the right-hand side of (1.3). As pointed out in [18, 19], the Panier–Tits–Herskovits framework is very sensitive to the parameters chosen due to dual degeneracy. Specifically, in spite of the presence of the linear independence constraint qualification (LICQ), the linear systems (1.3) and (1.4) may become very ill-conditioned when some multiplier μ_i corresponding to a nearly active constraint c_i becomes very small. This may occur when strict complementarity does not hold at the solution of problem (P). In this case the multiplier approximation sequence can diverge, and thus global convergence fails.

To avoid the ill-conditioning, Qi and Qi [19] presented a new type-1 QP-free method for problem (P), based on a nonsmooth equation reformulation of the KKT system (1.1), by using the Fischer–Burmeister function that is often used in nonlinear complementarity problems (see, e.g., [5, 16]). The coefficient matrix of their Newton equations has the form

$$V_k = \begin{bmatrix} H_k & \nabla c(x^k) \\ \operatorname{diag}(\xi^k)\nabla c(x^k)^\top & \Theta_k \end{bmatrix}, \tag{1.5}$$

where

$$\xi_i^k = \frac{c_i(x^k)}{\sqrt{c_i^2(x^k) + (\mu_i^k)^2}} + 1, \quad \Theta_k = -\sqrt{2}\operatorname{diag}(\theta^k), \quad \theta_i^k = \left(1 - \frac{\mu_i^k}{\sqrt{c_i^2(x^k) + (\mu_i^k)^2}}\right)^{1/2}.$$

It is shown that under the LICQ, (1.5) is uniformly nonsingular and well conditioned even if strict complementarity does not hold at accumulation points. We note that the methods in [18, 13, 19] require the sequence of Hessian estimates $\{H_k\}$ to be uniformly positive definite. This may interfere with the fast local convergence of their methods since for a general nonlinear programming problem, the Lagrangian Hessian at a second-order stationary point is usually only positive definite on the null space of the active constraint gradients. This issue has been recently circumvented in [1, 22] in the context of primal-dual interior-point methods.

From both a practical and a theoretical point of view, there are still some shortcomings of type-1 QP-free methods. For example, the methods in [18, 13, 19] need all inequality constraints to be involved in each subproblem computation. However, since QP-free methods do not follow the spirit of interior-point methods, whose iterates are forced to be away from the boundary of the feasible region, intuitively some active set strategies should be incorporated into these methods to ignore redundant constraints and save subproblem costs. Moreover, to guarantee global convergence, the methods in [18, 13, 19, 1, 22] must bound the multiplier approximation sequence $\{\mu^k\}$ by a preselected threshold value $\bar{\mu}$. However, to achieve fast local convergence, they have to assume that this truncation does not affect the convergence of the approximate multipliers, i.e., all multipliers are less than or equal to $\bar{\mu}$. Finally, all type-1 QP-free methods need strict complementarity for proving superlinear convergence.

Type-2 QP-free methods were first studied as locally convergent Newton methods for the KKT system (1.2) (see, e.g., [2, 8]). If the active set at a solution is available,

(1.2) reduces to a nonlinear system of equations involving only active constraints, which can be handled by standard Newton methods. Unfortunately, knowledge of the active set becomes available only when the iterates are close to the solution. In order to ensure global convergence, when the iterates are far from the solution, type-2 QP-free methods try to guess a so-called working set A_k for approximating the active set. Consequently, the Newton equations for these methods usually have the following coefficient matrices:

$$V_k = \begin{bmatrix} H_k & \nabla c_{A_k}(x^k) \\ \nabla c_{A_k}(x^k)^\top & 0 \end{bmatrix}, \tag{1.6}$$

where H_k is an estimate of the Lagrangian Hessian and $\nabla c_{A_k}(x^k)^\top$ is the Jacobian corresponding to the constraints in A_k. It is easy to see from (1.6) that V_k is nonsingular if and only if the constraint gradients in A_k are linearly independent, provided H_k is positive definite on the null space of $\nabla c_{A_k}(x^k)^\top$. The convergence properties of type-2 QP-free methods are very similar to that of type-1 QP-free methods as they eventually generate almost identical search directions. However, in practice, their behavior can be rather different in that type-2 QP-free methods, as active set methods, can be relatively sensitive to changes in the working set, while they do not suffer the pitfall triggered by dual degeneracy, as do some type-1 QP-free methods.

A careful examination of existing type-2 QP-free methods, however, reveals two shortcomings. The first one concerns the computation of multiplier estimates. Since the performance of type-2 QP-free methods largely depends on how well the active set can be identified, these methods require that the working set be able to approximate the active set quickly and accurately. To this end, methods in [7, 20, 28] resort to the following continuous multiplier function to obtain an ideal estimate of the multipliers:

$$\lambda(x) = -W(x)^{-1}\nabla c(x)^\top \nabla f(x),$$

where

$$W(x) = \nabla c(x)^\top \nabla c(x) + C(x)^2$$

and $C(x) = \mathrm{diag}(c(x))$. This involves solving a product form linear system of size $m \times m$, which is very likely to be fully dense. Second, type-2 QP-free methods require an expensive procedure to select linearly independent constraint gradients. In [20, 28] this is done iteratively by (i) checking the rank of the constraint gradients in an ε-working set; (ii) if they are rank deficient, reducing ε until they have full rank. Some do this by iteratively computing matrix determinant, which provides a criterion for singularity. Generally, these operations require computing factorizations for a sequence of down-dated matrices. An exception is [7], which relies on a restrictive assumption that, for a fixed ε, the constraint gradients in the ε-working set are linearly independent.

QP-free methods have many desirable local convergence properties. In [2, 8] some classes of local QP-free methods were shown to be superlinearly convergent without strict complementarity. This feature was extended to SC^1 problems in [6]. Moreover, local convergence properties of Newton or quasi-Newton methods have been widely studied under the Mangasarian–Fromovitz constraint qualification (MFCQ) or even without constraint qualifications (see, e.g., [10, 11, 15, 25, 26, 27]). Unfortunately, these nice local properties were rarely achieved in a globally convergent framework.

1.2. Basic results and notation. In this paper we propose a new feasible descent active set QP-free method for solving problem (P) that combines the best of type-1 and type-2 QP-free methods while overcoming several problematic aspects of them. The method, compared with existing QP-free methods, enjoys some theoretical advantages in saving computational cost and achieving fast local convergence. Specifically, two ε-working sets are maintained throughout the algorithm. One aims at identifying the final active set, while the other tries to identify the final strong active set. Our working set strategy is based on the Facchinei–Fischer–Kanzow active set identification technique [4], which can be accurate even without the LICQ or strict complementarity. To determine the working sets, we use multiplier information from the previous iteration, eliminating the need to compute a new estimate. Moreover, to avoid the expensive procedure of selecting linearly independent constraint gradients, we use as our Newton system (see (2.3)) a modified version of (1.3). At each iteration four reduced linear systems with a common coefficient matrix involving only constraints in the working set identifying the active set are computed. It is shown that under the LICQ, our method converges globally to KKT points of problem (P). To achieve fast local convergence, our method always employs the exact Lagrangian Hessian to compute the step if it is positive definite on the null space of some (nearly) active constraint gradients. This is particularly so when a KKT point satisfying the strong second-order sufficient condition (SSOSC) is approached. A new technique is introduced to avoid the ill-conditioning caused by dual degeneracy in some type-1 QP-free methods. In particular, since some active multipliers may vanish when strict complementarity fails, we control the multiplier estimates μ^k in a way that the active ones converge to the true multipliers plus a positive parameter δ_*, namely, δ_*-drifted multipliers. It will be shown that this technique does not affect the global and local convergence analysis. Furthermore, in order to guarantee the uniform nonsingularity of our Newton systems, we do not simply bound μ^k by a preselected parameter as in [1, 13, 18, 19, 22]. Instead, we adaptively increase the bound estimate χ of μ^k and decrease the active set parameter ε until a better estimate of the active set is obtained. It will be shown that under the LICQ, χ and ε are updated at most finitely many times.

Another contribution of this paper is that our method achieves fast local convergence without assuming strict complementarity. This property benefits a lot from the identification of the strong active set and a new system of inequalities introduced in the paper, through which better choices of search directions become possible. At each iteration, a "fast" direction, which can generate superlinear convergence when a solution is approached, is always computed first and is accepted as the search direction if the system of inequalities is met. However, if the system is violated, a steeper descent direction is computed to ensure global convergence. A key observation for our local analysis is that the "fast" direction enjoys both descent and feasible features in the vicinity of a solution and can be eventually accepted in spite of dual degeneracy.

The paper is organized as follows. In section 2 we present our algorithm and show that it is well defined. The global convergence of the method is established in section 3. Local superlinear convergence is proved in section 4. Concluding remarks are given in section 5.

A few words concerning the notation: The Euclidean vector norm or its associated matrix norm is denoted by $\|\cdot\|$. Given $h : \Re^n \to \Re^m$ and a subset A of I, we denote by $h_A(x)$ the subvector of $h(x)$ with components $h_i(x),\ i \in A$, and by $\nabla h_A(x)^\top$ the transposed Jacobian of $h_A(x)$. For a positive integer p, $e \in \Re^p$ is the vector of all ones and $E \in \Re^{p\times p}$ is the identity matrix. Given two vectors x and y of the same

dimension l, we say $x \geq (>)\ y$ if and only if $x_i \geq (>)\ y_i$ for all $i = 1, \ldots, l$, and $\min(x, y)$ is a vector whose ith element is $\min(x_i, y_i)$. For two symmetric matrices $\mathcal{A}$ and $\mathcal{B}$ of the same dimension, $\mathcal{A} \succ \mathcal{B}$ means $\mathcal{A} - \mathcal{B}$ is positive definite. We denote by $\emptyset$ the empty set.

2. Algorithm. In the remainder of the paper, we let (x^*, λ^*) denote a KKT point of problem (P). Our algorithm makes use of the following identification function $\varphi : \Re^{n+m} \to \Re$ proposed in [4]:

$$\varphi(x, \lambda) = \sqrt{\|\Phi(x, \lambda)\|}, \tag{2.1}$$

where the operator $\Phi : \Re^{n+m} \to \Re^{n+m}$ is defined by

$$\Phi(x, \lambda) = \begin{pmatrix} \nabla_x \mathcal{L}(x, \lambda) \\ \min\{-c(x), \lambda\} \end{pmatrix}. \tag{2.2}$$

It follows from [4, Theorem 3.15] that φ is nonnegative and continuous with $\varphi(x, \lambda) = 0$ if and only if (x, λ) is a KKT point of problem (P). The identification function $\varphi(x, \lambda)$ plays two roles in our algorithm. First, it is used to determine an ε-working set at each iteration,

$$A_{\varepsilon, \varphi_{\max}}(x, \lambda) = \{i \in I | c_i(x) \geq -\varepsilon \min\{\varphi(x, \lambda), \varphi_{\max}\}\},$$

which is an estimate of the final active set $I(x^*)$. When (x, λ) is sufficiently close to (x^*, λ^*), the estimate is accurate, provided both the MFCQ and the SSOSC hold at (x^*, λ^*); see [4, Theorem 2.3]. Second, in the algorithm we also need to "guess" the strong active set, i.e., the set of active constraints with positive multipliers,

$$I^+(x^*) = \{i \in I(x^*) | \lambda_i^* > 0\}.$$

To do so, we again employ function $\varphi(x, \lambda)$ to measure the multiplier estimate. Specifically, we set

$$\Lambda_{\varepsilon, \varphi_{\max}}(x, \lambda) = \{i \in A_{\varepsilon, \varphi_{\max}} | \lambda_i \geq \varepsilon \min\{\varphi(x, \lambda), \varphi_{\max}\}\}.$$

If a strict MFCQ[1] and the SSOSC hold at (x^*, λ^*), $\Lambda_{\varepsilon, \varphi_{\max}}(x, \lambda)$ eventually identifies the strong active set $I^+(x^*)$; see [4, Theorem 2.4]. Note that the strict MFCQ is implied by the LICQ. To simplify the presentation, for the kth iteration ($k = 1, 2, \ldots$) we let

$$I_k = A_{\varepsilon_k, \varphi_{\max}}(x^k, \lambda^{k-1,0}) \quad \text{and} \quad L_k = \Lambda_{\varepsilon_k, \varphi_{\max}}(x^k, \lambda^{k-1,0}),$$

where $\lambda^{k-1,0}$ and ε_k will be specified in the algorithm.

In order to avoid computing linearly independent constraint gradients, the coefficient matrices of our Newton equations follow the form of (1.3) but involving only constraints in the working set I_k,

$$M_k = \begin{bmatrix} H_k & \nabla c_{I_k}(x^k) \\ U_k \nabla c_{I_k}(x^k)^\top & C_{I_k}(x^k) \end{bmatrix}, \tag{2.3}$$

where $U_k = \operatorname{diag}(\mu_{I_k}^k)$ and $C_{I_k}(x^k) = \operatorname{diag}(c_{I_k}(x^k))$. Note that M_k is slightly different from the coefficient matrix of (1.3) in that μ^k in (2.3) are controlled to be componentwise bounded below over zero under the LICQ and the SSOSC. In particular, it

[1] This nomenclature is from [4].

will be shown that μ^k actually converges to some δ_*-drifted ($\delta_* > 0$) multipliers with respect to the active set, i.e.,

$$\mu_i^k \to \delta_* + \lambda_i^* \quad \text{for} \quad i \in I(x^*).$$

This ensures that M_k are uniformly well conditioned even if λ^* is degenerate or nearly degenerate.

We are now ready to state the algorithm.

ALGORITHM 2.1.

Step 0 (INITIALIZATION).

Parameters: $\beta \in (0,1)$, $\sigma \in (0,1/2)$, $\eta \in (2,3)$, $\tau \in (0,1)$, $\nu \in (2,3)$, $\theta \in (0,1)$, $\gamma > 2$, $\delta > 0$, $\varphi_{\max} > 0$, $\vartheta \in (0,1)$.

Data: $x^1 \in \mathcal{F}$, $\lambda^{0,0} \geq 0$. If $L_1 \neq \emptyset$ and $\varphi(x^1, \lambda^{0,0}) > 0$, $\delta_1 = \vartheta \min\{\lambda_i^{0,0}, i \in L_1\}$; otherwise, $\delta_1 = \delta$. $\mu^1 = \lambda^{0,0} + \delta_1 e$, $\varepsilon_1 > 0$, $\chi_1 \gg \varphi_{\max}$, $H_1 = \nabla^2_{xx}\mathcal{L}(x^1, \lambda^{0,0})$.

Set $k = 1$.

Step 1 (COMPUTATION OF SEARCH DIRECTION).

(i) Modify H_k, if necessary, so that

$$d^\top \hat{H}_k d > 0 \ \forall d \in \mathcal{T}(x^k)\backslash\{0\}, \tag{2.4}$$

where $\mathcal{T}(x) = \{y \in \Re^n | \nabla c_i(x)^\top y = 0, \ i \in I(x)\}$ for $x \in \mathcal{F}$ and

$$\hat{H}_k = H_k - \sum_{i \in I_k \backslash I(x^k)} \frac{\mu_i^k}{c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top. \tag{2.5}$$

Compute $(d^{k,0}, \lambda_{I_k}^{k,0})$ by solving the following linear system in (d, λ):

$$M_k \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ 0 \end{bmatrix}. \tag{2.6}$$

If $d^{k,0} = 0$ and $\lambda_{I_k}^{k,0} \geq 0$, stop.

(ii) Compute $(d^{k,1}, \lambda_{I_k}^{k,1})$ by solving the following linear system in (d, λ):

$$M_k \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ -\delta_k c_{I_k}(x^k) \end{bmatrix}. \tag{2.7}$$

If $(d^{k,1}, \lambda_{I_k}^{k,1})$ satisfies

$$\begin{cases} \nabla f(x^k)^\top d^{k,1} \leq -\|d^{k,1}\|^\gamma, \\ |\lambda_{-,i}^{k,1}| \leq \|d^{k,1}\| \ \ \forall i \in I_k, \end{cases} \tag{2.8}$$

set FAST = TRUE; else set FAST = FALSE, where $\lambda_{-,i}^{k,1} = \min\{\lambda_i^{k,1}, \ 0\}$, $i \in I_k$.

(iii) Compute $(d^{k,2}, \lambda_{I_k}^{k,2})$ by solving the following linear system in (d, λ):

$$M_k \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ v^k \end{bmatrix}, \tag{2.9}$$

where if FAST = TRUE, then

$$v_i^k = -\delta_k c_i(x^k) - \mu_i^k \rho_k, \ i \in I_k, \tag{2.10}$$

with

$$\rho_k = \frac{(\theta-1)\nabla f(x^k)^\top d^{k,1}}{1+\sum_{i\in I_k}|\lambda_i^{k,0}|\|d^{k,1}\|^\eta}\|d^{k,1}\|^\eta; \tag{2.11}$$

else

$$v_i^k = \lambda_{-,i}^{k,0} = \min\{\lambda_i^{k,0}, 0\}, \quad i \in I_k. \tag{2.12}$$

(iv) Compute $(d^{k,3}, \lambda_{I_k}^{k,3})$ by solving the following linear system in (d, λ):

$$M_k \begin{bmatrix} d \\ \lambda \end{bmatrix} = \begin{bmatrix} -\nabla f(x^k) \\ \varpi^k \end{bmatrix}, \tag{2.13}$$

where if FAST = TRUE, then

$$\varpi_i^k = v_i^k - \mu_i^k c_i(x^k + d^{k,2}) - \pi_k, \quad i \in I_k, \tag{2.14}$$

with

$$\pi_k = \max\left\{\|d^{k,2}\|^\nu, \max_{i\in I_k}\left\{\left|1 - \frac{\mu_i^k}{\max\{\frac{\delta_k}{2}, \delta_k + \lambda_i^{k,2}\}}\right|^\tau \|d^{k,2}\|^2\right\}\right\}; \tag{2.15}$$

else

$$\varpi_i^k = v_i^k - \mu_i^k \rho_k, \quad i \in I_k, \tag{2.16}$$

with

$$\rho_k = \frac{(\theta-1)\nabla f(x^k)^\top d^{k,2}}{1+\sum_{i\in I_k}|\lambda_i^{k,0}|\|d^{k,2}\|^2}\|d^{k,2}\|^2. \tag{2.17}$$

Step 2 (Arc search).

Set $\lambda_{I\setminus I_k}^{k,j} = 0$ $(j = 0, 1, 2, 3)$. If FAST = TRUE, then set $(d^k, \lambda^k) = (d^{k,2}, \lambda^{k,2})$ and

$$(\hat{d}^k, \hat{\lambda}^k) = \begin{cases} (d^{k,3}, \lambda^{k,3}) & \text{if } \|d^{k,3} - d^{k,2}\| \le \|d^{k,2}\|, \\ (d^{k,2}, \lambda^{k,2}) & \text{else.} \end{cases}$$

If FAST = FALSE, then set $(d^k, \lambda^k) = (\hat{d}^k, \hat{\lambda}^k) = (d^{k,3}, \lambda^{k,3})$.

Compute t_k, the first number t of the sequence $\{1, \beta, \beta^2, \dots\}$ satisfying

$$\begin{cases} f(x^k + td^k + t^2(\hat{d}^k - d^k)) - f(x^k) \le \sigma t \nabla f(x^k)^\top d^k, \\ c_i(x^k + td^k + t^2(\hat{d}^k - d^k)) \le 0, \ i \in I. \end{cases} \tag{2.18}$$

Step 3 (Update).

Set $x^{k+1} = x^k + t_k d^k + t_k^2(\hat{d}^k - d^k)$. If $\|\lambda^{k,0}\|_\infty > \chi_k$, set $\varepsilon_{k+1} = \frac{1}{2}\varepsilon_k$ and $\chi_{k+1} = 2\chi_k$; else set $(\varepsilon_{k+1}, \chi_{k+1}) = (\varepsilon_k, \chi_k)$. If $L_{k+1} \neq \emptyset$ and $\varphi(x^{k+1}, \lambda^{k,0}) > 0$, set $\delta_{k+1} = \vartheta \min\{\lambda_i^{k,0}, i \in L_{k+1}\}$; otherwise, set $\delta_{k+1} = \delta$. Set

$$\mu_i^{k+1} = \begin{cases} \delta_{k+1} + \max\{\lambda_i^{k,0}, 0\} & \text{if } i \in I_k, \\ \delta_{k+1} & \text{if } i \in I\setminus I_k. \end{cases} \tag{2.19}$$

Set $H_{k+1} = \nabla^2_{xx}\mathcal{L}(x^{k+1}, \mu^{k+1} - \delta_{k+1}e)$. Set $k = k + 1$ and go to Step 1.

Remark 2.1. Clearly, $\mu^k > 0$ at each iteration. Hence, by Lemma 6.1 in the appendix, condition (2.4) and the LICQ can guarantee the nonsingularity of M_k. To motivate fast local convergence, in Algorithm 2.1 the exact Lagrangian Hessian is used to compute the step if it satisfies (2.4). This is the case for iterates in a neighborhood of a KKT point of problem (P) satisfying the SSOSC; see section 4. However, outside such a neighborhood, it may be necessary to modify H_k so that (2.4) holds. There are two often used ways to do so. One way is to repeatedly add multiples of the identity to H_k until (2.4) holds; e.g., see [23, 24]. The other way is based on the inertia-controlling factorization of the matrix obtained by symmetrizing M_k that determines a positive quantity and those diagonal elements of H_k to which the positive quantity should be added so that the resulting $\hat{H}_k$ satisfies (2.4); e.g., see [12].

Remark 2.2. The role of linear equations (2.6) is to provide a descent direction $d^{k,0}$ of f and an approximate multiplier vector $\lambda^{k,0}$, which is used to compute the perturbation value ρ_k in (2.11) and (2.17). A system of inequalities (2.8) is introduced in the algorithm through which we can determine whether direction $d^{k,1}$, a "fast" local direction, is acceptable as an ideal search direction. The first inequality of (2.8) checks whether $d^{k,1}$ can provide a sufficient reduction in f, while the second inequality measures the convergence progress of $\lambda^{k,1}$ toward the optimal multipliers. If (2.8) holds (i.e., FAST = TRUE), another linear equation (2.9), a slight perturbation of (2.7), is solved to keep the feasibility of the next iterate. To avoid the Maratos effect, second-order correction is carried out by solving (2.13), a slight perturbation of (2.9). If (2.8) is violated, a steeper descent direction is gotten by (2.9) and feasibility of the next iterate is ensured by solving (2.13). Consequently, linear equations (2.9) and (2.13) may serve for different purposes depending on the value of "FAST." Note that the inequality system (2.8) actually provides an efficient framework for balancing well the global and local behavior of our algorithm. We believe that without much modification, this framework can be readily extended to other active set–based algorithms for solving problem (P).

The following assumptions guarantee that our algorithm is well defined.

ASSUMPTION A1. *$\mathcal{F}$ is nonempty.*

ASSUMPTION A2. *The LICQ holds on $\mathcal{F}$, i.e., vectors $\{\nabla c_i(x),\ i \in I(x)\}$ are linearly independent for any $x \in \mathcal{F}$.*

Assumption A1 ensures the existence of a feasible starting point x^1. Assumption A2 is a common assumption for both type-1 and type-2 QP-free methods. The rest of the section is devoted to showing that Algorithm 2.1 is well defined. It has been analyzed in Remark 2.1 that under Assumption A2, M_k is nonsingular for every k. Hence, $(d^{k,j}, \lambda^{k,j})$ $(j = 0, 1, 2, 3)$ are all well defined. In the following we continue to show that if the algorithm terminates at Step 1(i), the current iterate is a KKT point of problem (P); otherwise, the arc search in Step 2 is executable and the algorithm generates the next iterate.

LEMMA 2.1. *Under Assumptions A1 and A2, Algorithm* 2.1 *terminates at Step* 1(i), *i.e., $d^{k,0} = 0$ and $\lambda^{k,0} \geq 0$, if and only if x^k is a KKT point of problem* (P).

Proof. Suppose $d^{k,0} = 0$ and $\lambda^{k,0} \geq 0$ at the kth iteration. Then it follows from linear equations (2.6) that

$$\nabla f(x^k) + \sum_{i \in I_k} \lambda_i^{k,0} \nabla c_i(x^k) = 0, \quad \lambda_i^{k,0} c_i(x^k) = 0, \quad i \in I_k.$$

This implies that $(x^k, \lambda^{k,0})$ is a KKT point of problem (P) as $\lambda^{k,0}_{I \setminus I_k} = 0$.

Suppose x^k is a KKT point of problem (P) and $\bar{\lambda}$ is the corresponding Lagrangian multiplier vector. By Assumption A2 and the nonsingularity of M_k, we know that $(0, \bar{\lambda}_{I_k})$ is the unique solution of linear equations (2.6). Hence, we conclude that $d^{k,0} = 0$ and $\lambda^{k,0} = \bar{\lambda}$. □

In the remainder of the paper, we assume that Algorithm 2.1 generates an infinite sequence of iterates, i.e., it does not stop at Step 1(i) with a KKT point of problem (P). Before proceeding further, we need some basic relations that are useful for our analysis. To simplify the presentation, in the following algebra we omit superscript k, subscript k, and function variables. For example, C, ∇c, and ∇f will denote $C_{I_k}(x^k)$, $\nabla c_{I_k}(x^k)$, and $\nabla f(x^k)$, respectively. Consider the following linear equations:

$$\begin{cases} Hd + \nabla c\lambda = -\nabla f, \\ U\nabla c^\top d + C\lambda = w. \end{cases} \tag{2.20}$$

It follows from Lemma 6.1 that (2.20) is nonsingular and has a unique solution. Letting $a = I_k \backslash I(x^k)$ and $b = I(x^k)$, we have

$$\lambda_a = -C_a^{-1}U_a\nabla c_a^\top d + C_a^{-1}w_a, \tag{2.21}$$

$$\kappa\nabla c_b U_b \nabla c_b^\top d = \kappa\nabla c_b w_b, \tag{2.22}$$

where κ is a positive scalar. Substituting (2.21) into the first block of equations in (2.20) and adding both sides of (2.22) to the first block of equations in (2.20) gives

$$\bar{H}d = -\nabla f - \nabla c_a C_a^{-1} w_a + \kappa\nabla c_b w_b - \nabla c_b \lambda_b,$$

where

$$\bar{H} = H - \nabla c_a C_a^{-1} U_a \nabla c_a^\top + \kappa\nabla c_b U_b \nabla c_b^\top.$$

Since (2.4) holds and $U \succ 0$ in view of Step 3 of Algorithm 2.1, by Lemma 6.2 in the appendix, we can pick κ large enough so that $\bar{H} \succ 0$. Thus,

$$d = -\bar{H}^{-1}\nabla f - \bar{H}^{-1}\nabla c_a C_a^{-1} w_a + \kappa\bar{H}^{-1}\nabla c_b w_b - \bar{H}^{-1}\nabla c_b \lambda_b. \tag{2.23}$$

Substitute (2.23) into the second block of equations in (2.20) and we get

$$\lambda_b = -D^{-1}\nabla c_b^\top \bar{H}^{-1}\nabla f - D^{-1}\nabla c_b^\top \bar{H}^{-1}\nabla c_a C_a^{-1} w_a + \kappa w_b - D^{-1}U_b^{-1} w_b, \tag{2.24}$$

where $D = \nabla c_b^\top \bar{H}^{-1}\nabla c_b$. Note that Assumption A2 ensures the nonsingularity of D. Let (d^0, λ^0) be the solution of (2.20) when $w = 0$, i.e., the solution of (2.6). We have

$$\lambda_a^0 = (C_a^{-1}U_a\nabla c_a^\top \bar{H}^{-1} - C_a^{-1}U_a\nabla c_a^\top \bar{H}^{-1}\nabla c_b D^{-1}\nabla c_b^\top \bar{H}^{-1})\nabla f, \tag{2.25}$$

$$\lambda_b^0 = -D^{-1}\nabla c_b^\top \bar{H}^{-1}\nabla f, \tag{2.26}$$

and

$$\begin{aligned} d = d^0 &+ (\bar{H}^{-1}\nabla c_b D^{-1}\nabla c_b^\top \bar{H}^{-1}\nabla c_a C_a^{-1} - \bar{H}^{-1}\nabla c_a C_a^{-1}) w_a \\ &+ \bar{H}^{-1}\nabla c_b D^{-1} U_b^{-1} w_b. \end{aligned} \tag{2.27}$$

Consequently, we obtain from (2.25), (2.26), and (2.27) that

$$\nabla f^\top d = \nabla f^\top d^0 - (\lambda_a^0)^\top U_a^{-1} w_a - (\lambda_b^0)^\top U_b^{-1} w_b = \nabla f^\top d^0 - (\lambda^0)^\top U^{-1} w. \tag{2.28}$$

In the following lemmas, (2.28) is used to show the descent and feasible properties of search direction d^k. To this end, we first show that $d^{k,0}$ is a descent direction of f. Since $I(x^k) \subseteq I_k$, it follows from (2.6) that

$$\mu_i^k \nabla c_i(x^k)^\top d^{k,0} = -c_i(x^k)\lambda_i^{k,0} = 0 \qquad \forall i \in I(x^k). \tag{2.29}$$

Hence, $d^{k,0} \in \mathcal{T}(x^k)$ as $\mu^k > 0$ by Step 3 of Algorithm 2.1. Hence, from (2.6), (2.4), and (2.5), we have

$$\begin{aligned} &\nabla f(x^k)^\top d^{k,0} \\ &= -(d^{k,0})^\top \left(H_k - \sum_{i \in I_k \setminus I(x^k)} \frac{\mu_i^k}{c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top \right) d^{k,0} \\ &\quad - \sum_{i \in I(x^k)} \lambda_i^{k,0} \nabla c_i(x^k)^\top d^{k,0} \\ &= -(d^{k,0})^\top \hat{H}_k d^{k,0} \le 0. \end{aligned} \tag{2.30}$$

LEMMA 2.2. *Suppose Assumptions A1 and A2 hold and* FAST = TRUE *at the kth iteration. Then* $\nabla f(x^k)^\top d^{k,1} \neq 0$.

Proof. Suppose $\nabla f(x^k)^\top d^{k,1} = 0$. Since FAST = TRUE, it follows from (2.8) that $d^{k,1} = 0$ and $\lambda_{I_k}^{k,1} \ge 0$. Hence, from linear equations (2.7) we obtain that

$$\begin{aligned} &\nabla f(x^k) + \sum_{i \in I_k} \lambda_i^{k,1} \nabla c_i(x^k) = 0, \\ &0 \le -\delta_k c_i(x^k) = \lambda_i^{k,1} c_i(x^k) \le 0, \quad i \in I_k. \end{aligned}$$

Since $I(x^k) \subseteq I_k$ and $\lambda_{I \setminus I_k}^{k,1} = 0$, we conclude that $(x^k, \lambda^{k,1})$ is a KKT point of problem (P). Hence, Lemma 2.1 implies that Algorithm 2.1 should have terminated at Step 1(i), a contradiction. □

LEMMA 2.3. *Under Assumptions A1 and A2, if* FAST = TRUE *at the kth iteration, then*

(i) $\nabla f(x^k)^\top d^k \le \theta \nabla f(x^k)^\top d^{k,1} < 0$;

(ii) $\nabla c_i(x^k)^\top d^k = -\rho_k < 0$ *for all* $i \in I(x^k)$.

Proof. Since FAST = TRUE, we know that (2.8) holds, $d^k = d^{k,2}$, and ρ_k is defined by (2.11). Since we have assumed that Algorithm 2.1 generates an infinite iterate sequence, it follows from Lemma 2.1 that x^k is not a KKT point of (P). Thus, it follows from Lemma 2.2 and (2.8) that $\nabla f(x^k)^\top d^{k,1} < 0$. Hence, from (2.10), (2.11), and (2.28), we obtain that

$$\begin{aligned} &\nabla f(x^k)^\top d^k \\ &= \nabla f(x^k)^\top d^{k,1} + (\lambda_{I_k}^{k,0})^\top U_k^{-1} U_k(\rho_k e) \\ &= \nabla f(x^k)^\top d^{k,1} + \frac{(\theta - 1)\nabla f(x^k)^\top d^{k,1}}{1 + \sum_{i \in I_k} |\lambda_i^{k,0}| \|d^{k,1}\|^\eta} \|d^{k,1}\|^\eta \sum_{i \in I_k} \lambda_i^{k,0} \\ &\le \theta \nabla f(x^k)^\top d^{k,1} < 0. \end{aligned} \tag{2.31}$$

Notice that $I(x^k) \subseteq I_k$. By (2.9) and (2.10), we have that $\nabla c_i(x^k)^\top d^k = -\rho_k < 0$ for $i \in I(x^k)$. □

LEMMA 2.4. *Under Assumptions A1 and A2, if* FAST = FALSE *at the kth iteration, then*

(i) $\nabla f(x^k)^\top d^{k,2} = \nabla f(x^k)^\top d^{k,0} - \sum_{i\in I_k}(\lambda^{k,0}_{-,i})^2/\mu^k_i < 0$;
(ii) $\nabla f(x^k)^\top d^k \le \theta \nabla f(x^k)^\top d^{k,2}$;
(iii) $\nabla c_i(x^k)^\top d^k \le -\rho_k < 0$ *for* $i \in I(x^k)$.

Proof. Since FAST = FALSE, we have that $d^k = d^{k,3}$ and v^k and ρ_k are computed by (2.12) and (2.17), respectively. It follows from (2.28) and (2.30) that

$$\begin{aligned} &\nabla f(x^k)^\top d^{k,2} \\ &= \nabla f(x^k)^\top d^{k,0} - (\lambda^{k,0}_{I_k})^\top U_k^{-1} v^k \\ &= \nabla f(x^k)^\top d^{k,0} - \sum_{i\in I_k}(\lambda^{k,0}_{-,i})^2/\mu^k_i \\ &= -(d^{k,0})^\top \hat{H}_k d^{k,0} - \sum_{i\in I_k}(\lambda^{k,0}_{-,i})^2/\mu^k_i. \end{aligned} \tag{2.32}$$

Since Algorithm 2.1 generates an infinite iterate sequence, x^k is not a KKT point of (P), i.e., either $d^{k,0} = 0$ or $\lambda^{k,0}_{I_k} \ge 0$ is violated in view of Lemma 2.1. Moreover, since $I(x^k) \subseteq I_k$, we have from (2.6) that (2.29) holds. Hence, $d^{k,0} \in \mathcal{T}(x^k)$ as $\mu^k > 0$. Consequently, we know from (2.4) and (2.32) that $\nabla f(x^k)^\top d^{k,2} < 0$. This establishes (i). From (2.16), (2.17), (2.28), and (2.13), we obtain that

$$\begin{aligned} &\nabla f(x^k)^\top d^k \\ &= \nabla f(x^k)^\top d^{k,2} + (\lambda^{k,0}_{I_k})^\top U_k^{-1} U_k(\rho_k e) \\ &= \nabla f(x^k)^\top d^{k,2} + \frac{(\theta-1)\nabla f(x^k)^\top d^{k,2}}{1+\sum_{i\in I_k}|\lambda^{k,0}_i|\|d^{k,2}\|^2}\|d^{k,2}\|^2 \sum_{i\in I_k}\lambda^{k,0}_i \\ &\le \theta \nabla f(x^k)^\top d^{k,2}. \end{aligned} \tag{2.33}$$

This establishes (ii). Moreover, it follows from (2.12), (2.16), and (2.13) that for $i \in I(x^k)$, $\nabla c_i(x^k)^\top d^k \le -\rho_k < 0$. ∎

PROPOSITION 2.5. *Under Assumptions A1 and A2, Algorithm 2.1 is well defined.*

Proof. Assumption A1 ensures that Algorithm 2.1 can start properly. At each iteration, $\mu^k > 0$ by Step 3 of Algorithm 2.1, and it is always possible to modify H_k, if necessary, so that (2.4) holds (e.g., it suffices to add a sufficiently large multiple of the identity to H_k). Since (2.4) and Assumption A2 guarantee the nonsingularity of M_k by Lemma 6.1, every linear system involved in Algorithm 2.1 has a unique solution. By Lemma 2.1, if Algorithm 2.1 terminates at an iteration k, x^k is a KKT point of problem (P). To finish our analysis, we only need to show that the arc search in Step 2 of Algorithm 2.1 is well defined.

Suppose Algorithm 2.1 does not terminate at x^k. Then by Lemmas 2.3 and 2.4, $\nabla f(x^k)^\top d^k < 0$ and $\nabla c_i(x^k)^\top d^k < 0$ for all $i \in I(x^k)$. Let $\tilde{d}^k = \hat{d}^k - d^k$. Since f and c are twice continuously differentiable, we have

$$\begin{aligned} &f(x^k + td^k + t^2\tilde{d}^k) = f(x^k) + t\nabla f(x^k)^\top d^k + O(t^2), \\ &c_i(x^k + td^k + t^2\tilde{d}^k) = c_i(x^k) + t\nabla c_i(x^k)^\top d^k + O(t^2),\ i \in I. \end{aligned}$$

Hence, it follows that for all sufficiently small t ($t \in (0,1)$),

$$f(x^k + td^k + t^2\tilde{d}^k) - f(x^k) \le \sigma t \nabla f(x^k)^\top d^k$$

as $\sigma \in (0, 1/2)$ and

$$c_i(x^k + td^k + t^2\tilde{d}^k) \le c_i(x^k) = 0 \quad \forall i \in I(x^k).$$

Moreover, since $c_i(x^k) < 0$ for $i \in I \backslash I(x^k)$, it follows that for such i and all sufficiently small t, $c_i(x^k + td^k + t^2\tilde{d}^k) < 0$. Therefore, we conclude that Step 2 of Algorithm 2.1 is well defined. Thus, Algorithm 2.1 can proceed to the next iterate. ∎

3. Global convergence. In this section we show that Algorithm 2.1 is globally convergent to KKT points of problem (P). To this end, we further assume the following.

ASSUMPTION A3. *There exist $\varrho_1, \varrho_2 > 0$ such that for all k,*

$$d^\top \hat{H}_k d \geq \varrho_1 \|d\|^2 \quad \forall d \in \mathcal{T}(x^k),$$

where $\hat{H}_k$ is defined by (2.5)*, and $\|H_k\| \leq \varrho_2$.*

ASSUMPTION A4. *The set $\mathcal{F} \cap \{x | f(x) \leq f(x^1)\}$ is compact.*

Assumption A3 is weaker than the uniform positive definiteness assumption on H_k made in [13, 18, 19, 28]. It holds with the exact Hessian in the neighborhood of any solution of problem (P) at which the SSOSC holds. Assumption A4 ensures that our descent algorithm generates accumulated iterates.

LEMMA 3.1. *Under Assumptions A1–A4, sequences $\{\chi_k\}$ and $\{\varepsilon_k\}$ are changed at most finitely many times.*

Proof. The proof is by contradiction. Suppose that $\{\chi_k\}$ and $\{\varepsilon_k\}$ are changed infinitely many times, i.e., there exists an infinite index set $\mathcal{K}$ such that $\chi_{k+1} = 2\chi_k$ and $\varepsilon_{k+1} = \frac{1}{2}\varepsilon_k$ for all $k \in \mathcal{K}$. Then we have $\{\chi_k\} \to +\infty$ and $\varepsilon_k \to 0^+$ as $k \to \infty$. Due to the finiteness of set I, we can assume without loss of generality that I_k are identical for all $k \in \mathcal{K}$ and let $I_{\mathcal{K}} = I_k$. Moreover, by Assumption A4 we can assume $x^k \to \bar{x}$ as $k \in \mathcal{K} \to \infty$. We get from the definition of I_k that $I_{\mathcal{K}} \subseteq I(\bar{x})$ since $\{\varepsilon_k \min\{\varphi(x^k, \lambda^{k-1,0}), \varphi_{\max}\}\} \to 0$ as $k \to \infty$.

In addition, the criteria that trigger updating of $\{\chi_k\}$ and $\{\varepsilon_k\}$ must be satisfied for all $k \in \mathcal{K}$, i.e., $\|\lambda^{k,0}\|_\infty > \chi_k$. This implies that $\|\lambda^{k,0}\|_\infty \to \infty$. Consequently, the sequence $\{\alpha_k\}$, with

$$\alpha_k = \max\{\|d^{k,0}\|,\ \|\lambda^{k,0}_{I_{\mathcal{K}}}\|_\infty,\ 1\},$$

tends to infinity on $\mathcal{K}$. Define

$$\bar{d}^k = \alpha_k^{-1} d^{k,0} \quad \text{and} \quad \bar{\lambda}^k_{I_{\mathcal{K}}} = \alpha_k^{-1} \lambda^{k,0}_{I_{\mathcal{K}}}$$

for $k \in \mathcal{K}$. By construction we have $\max\{\|\bar{d}^k\|, \|\bar{\lambda}^k_{I_{\mathcal{K}}}\|_\infty\} = 1$ for all $k \in \mathcal{K}$ large enough. Hence, there exists an infinite index set $\mathcal{K}_1 \subseteq \mathcal{K}$ and nonzero vector $(\bar{d}, \bar{\lambda}_{I_{\mathcal{K}}})$ such that $\bar{d}^k \to \bar{d}$ and $\bar{\lambda}^k_{I_{\mathcal{K}}} \to \bar{\lambda}_{I_{\mathcal{K}}}$ as $k \in \mathcal{K}_1 \to \infty$. From (2.30) and Assumption A3, we have

$$\nabla f(x^k)^\top d^{k,0} \leq -\varrho_1 \|d^{k,0}\|^2. \tag{3.1}$$

Dividing both sides of (3.1) by α_k^2 and letting $k \in \mathcal{K}_1 \to \infty$ yields $\bar{d} = 0$. Thus, $\bar{\lambda}_{I_{\mathcal{K}}}$ is nonzero. Besides, it follows from (2.6) that for $k \in \mathcal{K}$,

$$H_k d^{k,0} + \nabla c_{I_{\mathcal{K}}}(x^k) \lambda^{k,0}_{I_{\mathcal{K}}} = -\nabla f(x^k). \tag{3.2}$$

Dividing both sides of (3.2) by α_k and letting $k \in \mathcal{K}_1 \to \infty$ gives us

$$\nabla c_{I_{\mathcal{K}}}(\bar{x}) \bar{\lambda}_{I_{\mathcal{K}}} = 0.$$

This contradicts Assumption A2, as we have proved that $I_{\mathcal{K}} \subseteq I(\bar{x})$. ∎

LEMMA 3.2. *Under Assumptions A1–A4, sequences* $\{\lambda^{k,0}\}$, $\{\delta_k\}$, *and* $\{\mu^k\}$ *are bounded.*

Proof. Lemma 3.1 gives that $\{\chi_k\}$ has an upper bound, and thus $\{\lambda^{k,0}\}$ is bounded by Step 3 of Algorithm 2.1. The boundedness of $\{\delta_k\}$ and $\{\mu^k\}$ follows directly from their definitions and the boundedness of $\{\lambda^{k,0}\}$. ∎

LEMMA 3.3. *Under Assumptions A1–A4, if* $\{\delta_k\}_{\mathcal{K}} \to 0$, *then any accumulation point of* $\{(x^k, \lambda^{k-1,0})\}_{\mathcal{K}}$ *is a KKT point of problem* (P), *where* $\mathcal{K}$ *is an infinite index set.*

Proof. First note that $\{(x^k, \lambda^{k-1,0})\}_{\mathcal{K}}$ is bounded by Assumption A4 and Lemma 3.2. Since $\{\delta_k\}_{\mathcal{K}} \to 0$, the definitions of δ_k and L_k indicate that $\{\varphi(x^k, \lambda^{k-1,0})\}_{\mathcal{K}} \to 0$. Since $\varphi(x, \lambda) = 0$ if and only if (x, λ) is a KKT point of problem (P), the result follows from continuity. ∎

LEMMA 3.4. *Suppose Assumptions A1–A4 hold. If* $\{\delta_k\}_{\mathcal{K}}$ *is bounded below over zero, sequence* $\{\|M_k^{-1}\|\}_{\mathcal{K}}$ *is uniformly bounded, where* $\mathcal{K}$ *is an infinite index set.*

Proof. Since $\mu^k > 0$ by Algorithm 2.1, we know from Lemma 6.1 that (2.4) and Assumption A2 guarantee the nonsingularity of M_k for each k. Now assume to the contrary that there exists an infinite index set $\mathcal{K}' \subseteq \mathcal{K}$ such that $\|M_k^{-1}\| \to \infty$ as $k \in \mathcal{K}' \to \infty$. Due to Lemma 3.2 and Assumptions A3 and A4, we can assume that $\delta_k \to \bar{\delta} > 0$, $\mu^k \to \bar{\mu} > 0$, $x^k \to \bar{x} \in \mathcal{F}$, and $H_k \to H_*$ as $k \in \mathcal{K}' \to \infty$. Moreover, since set I is finite, we can further assume that I_k, L_k, and $I(x^k)$ are, respectively, identical for all $k \in \mathcal{K}'$ and let $I_{\mathcal{K}'} = I_k$, $L_{\mathcal{K}'} = L_k$, and $\bar{I}_{\mathcal{K}'} = I(x^k)$. Putting all the limits together, we have

$$\{M_k\}_{\mathcal{K}'} \to \bar{M} = \begin{bmatrix} H_* & \nabla c_{I_{\mathcal{K}'}}(\bar{x}) \\ \operatorname{diag}(\bar{\mu}_{I_{\mathcal{K}'}})\nabla c_{I_{\mathcal{K}'}}(\bar{x})^\top & \operatorname{diag}(c_{I_{\mathcal{K}'}}(\bar{x})) \end{bmatrix}.$$

Pick any $y \in \mathcal{T}(\bar{x})\backslash\{0\}$. Assumption A2 ensures that $\nabla c_{I(\bar{x})}(x^k)^\top$ has full row rank for all $k \in \mathcal{K}'$ large enough. So we can let

$$y^k = (E - \nabla c_{I(\bar{x})}(x^k)(\nabla c_{I(\bar{x})}(x^k)^\top \nabla c_{I(\bar{x})}(x^k))^{-1}\nabla c_{I(\bar{x})}(x^k)^\top)y$$

for sufficiently large $k \in \mathcal{K}'$. Obviously, we have $\nabla c_{I(\bar{x})}(x^k)^\top y^k = 0$ for all large $k \in \mathcal{K}'$ and $y^k \to y$ as $k \in \mathcal{K}' \to \infty$. This implies that $y^k \in \mathcal{T}(x^k)$ since $\bar{I}_{\mathcal{K}'} \subseteq I(\bar{x})$ when x^k is close to $\bar{x}$. Therefore, we obtain by Assumption A3 that for $k \in \mathcal{K}'$ large enough

$$\begin{aligned} &(y^k)^\top \left(H_k - \sum_{I_{\mathcal{K}'}\backslash I(\bar{x})} \frac{\mu_i^k}{c_i(x^k)} \nabla c_i(x^k)\nabla c_i(x^k)^\top \right) y^k \\ &= (y^k)^\top \left(H_k - \sum_{I_{\mathcal{K}'}\backslash \bar{I}_{\mathcal{K}'}} \frac{\mu_i^k}{c_i(x^k)} \nabla c_i(x^k)\nabla c_i(x^k)^\top \right) y^k \\ &= (y^k)^\top \hat{H}_k y^k \geq \varrho_1 \|y^k\|^2. \end{aligned}$$

Thus, letting $k \in \mathcal{K}' \to \infty$ yields that

$$y^\top \left(H_* - \sum_{I_{\mathcal{K}'}\backslash I(\bar{x})} \frac{\bar{\mu}_i}{c_i(\bar{x})} \nabla c_i(\bar{x})\nabla c_i(\bar{x})^\top \right) y > 0.$$

Now we can use Lemma 6.1 to show that $\bar{M}$ is nonsingular, a contradiction. ∎

The following corollary is a direct consequence of Lemmas 3.2 and 3.4.

COROLLARY 3.5. *Suppose Assumptions A1–A4 hold. If $\{\delta_k\}_{\mathcal{K}}$ is bounded below over zero, sequences $\{d^{k,0}\}$, $\{d^{k,j}, \lambda^{k,j}\}$ $(j = 1, 2, 3)$ are all bounded, where $\mathcal{K}$ is an infinite index set.*

Proof. Since the matrix sequence $\{M_k^{-1}\}_{\mathcal{K}}$ is uniformly bounded by Lemma 3.4 and $\{x^k\}$ is bounded due to Assumption A4, we obtain the boundedness of $\{d^{k,0}\}$ and $\{(d^{k,1}, \lambda^{k,1})\}_{\mathcal{K}}$ from (2.6) and (2.7), respectively. This together with Lemma 3.2 implies the boundedness of $\{v^k\}_{\mathcal{K}}$ in view of (2.10), (2.11), and (2.12). Hence, $\{(d^{k,2}, \lambda^{k,2})\}_{\mathcal{K}}$ is bounded, and this further implies the boundedness of $\{\varpi^k\}_{\mathcal{K}}$ in view of (2.14)–(2.17). Hence, $\{(d^{k,3}, \lambda^{k,3})\}_{\mathcal{K}}$ is also bounded. ∎

LEMMA 3.6. *Suppose Assumptions A1–A4 hold. If $\{\delta_k\}_{\mathcal{K}}$ is bounded below over zero and there exists a constant $\alpha > 0$ such that $\nabla f(x^k)^\top d^k \le -\alpha$ for all $k \in \mathcal{K}$, where $\mathcal{K}$ is an infinite index set, then there exists a constant $\bar{\alpha} > 0$ such that $\rho_k \ge \bar{\alpha}$ for all $k \in \mathcal{K}$ large enough.*

Proof. Assume to the contrary that there exists an infinite subset $\mathcal{K}' \subseteq \mathcal{K}$ such that $\{\rho_k\} \to 0$ as $k \in \mathcal{K}' \to \infty$. There are two cases.

Case 1. There exists an infinite subset $\mathcal{K}_1 \subseteq \mathcal{K}'$ such that FAST = TRUE for all $k \in \mathcal{K}_1$. In this case, $d^k = d^{k,2}$ and ρ_k is defined by (2.11). Since ρ_k tends to zero as $k \in \mathcal{K}' \to \infty$, it follows from (2.11) that $\{\nabla f(x^k)^\top d^{k,1}\}_{\mathcal{K}_1} \to 0$. Considering the finiteness of I, we can assume that I_k are identical for all $k \in \mathcal{K}_1$ and let $I_{\mathcal{K}_1} = I_k$. Moreover, due to boundedness we can further assume that $\{\delta_k\} \to \bar{\delta} > 0$, $\{M_k\} \to \bar{M}$, $\{(d^{k,1}, \lambda^{k,1})\} \to (\bar{d}, \bar{\lambda})$, and $\{(d^k, \lambda^k)\} \to (\bar{d}', \bar{\lambda}')$ as $k \in \mathcal{K}_1 \to \infty$. Now letting $k \in \mathcal{K}_1 \to \infty$ in linear systems (2.7), (2.9), and (2.10) yields that

$$\bar{M} \begin{bmatrix} \bar{d} \\ \bar{\lambda}_{I_{\mathcal{K}_1}} \end{bmatrix} = \bar{M} \begin{bmatrix} \bar{d}' \\ \bar{\lambda}'_{I_{\mathcal{K}_1}} \end{bmatrix} = \begin{bmatrix} -\nabla f(\bar{x}) \\ -\bar{\delta} c_{I_{\mathcal{K}_1}}(\bar{x}) \end{bmatrix}.$$

This implies that $(\bar{d}, \bar{\lambda}) = (\bar{d}', \bar{\lambda}')$ as $\bar{M}$ is nonsingular by Lemma 3.4. Hence, we have

$$\{\nabla f(x^k)^\top d^k\}_{\mathcal{K}_1} \to \nabla f(\bar{x})^\top \bar{d}' = \nabla f(\bar{x})^\top \bar{d} = 0.$$

This contradicts the condition that $\nabla f(x^k)^\top d^k \le -\alpha$ for all $k \in \mathcal{K}$.

Case 2. There exists an infinite subset $\mathcal{K}_2 \subseteq \mathcal{K}'$ such that FAST = FALSE for all $k \in \mathcal{K}_2$. In this case, $d^k = d^{k,3}$ and ρ_k is defined by (2.17). Since $\{\rho_k\} \to 0$ as $k \in \mathcal{K}' \to \infty$, (2.17) gives that $\{\nabla f(x^k)^\top d^{k,2}\}_{\mathcal{K}_2} \to 0$. Without loss of generality, assume that $\{d^{k,2}\}_{\mathcal{K}_2} \to \hat{d}$ and $\{d^k\}_{\mathcal{K}_2} \to \hat{d}'$. By following a similar argument to that of Case 1, we can show that $\hat{d} = \hat{d}'$ and thus $\{\nabla f(x^k)^\top d^k\}_{\mathcal{K}_2} \to 0$, a contradiction.

Since either Case 1 or Case 2 happens, the result follows immediately. ∎

LEMMA 3.7. *Suppose Assumptions A1–A4 hold, $\{x^k\}_{\mathcal{K}} \to \bar{x}$, and $\{\delta_k\}_{\mathcal{K}}$ is bounded below over zero, where $\mathcal{K}$ is an infinite index set. If $I(\bar{x}) \subseteq I_k$ for all $k \in \mathcal{K}$ large enough, then $\{\nabla f(x^k)^\top d^k\} \to 0$ as $k \in \mathcal{K} \to \infty$.*

Proof. Assume to the contrary that there exist an infinite index set $\mathcal{K}' \subseteq \mathcal{K}$ and a constant $\alpha > 0$ such that

$$\nabla f(x^k)^\top d^k \le -\alpha \quad \forall k \in \mathcal{K}'. \tag{3.3}$$

Then it follows from Lemma 3.6 that there exists a constant $\bar{\alpha} > 0$ such that $\rho_k \ge \bar{\alpha}$ for all $k \in \mathcal{K}'$. Since I is finite, we can assume that I_k are identical for all $k \in \mathcal{K}'$ and let $I_{\mathcal{K}'} = I_k$. Due to the boundedness of $\{d^k\}$, we can also assume that $\{d^k\} \to \bar{d} \ne 0$ as $k \in \mathcal{K}' \to \infty$. It follows from linear equations (2.9) and (2.13) that for each $i \in I_{\mathcal{K}'}$,

$$\mu_i^k \nabla c_i(x^k)^\top d^k + \lambda_i^k c_i(x^k) = \begin{cases} -\delta_k c_i(x^k) - \mu_i^k \rho_k & \text{if FAST = TRUE;} \\ \lambda_{-,i}^{k,0} - \mu_i^k \rho_k & \text{if FAST = FALSE.} \end{cases} \tag{3.4}$$

Since $I(\bar{x}) \subseteq I_{\mathcal{K}'}$, dividing both sides of (3.4) by μ_i^k and letting $k \in \mathcal{K}' \to \infty$ yields

$$\nabla c_i(\bar{x})^\top \bar{d} \leq -\inf_{k\in\mathcal{K}'}\{\rho_k\} \leq -\bar{\alpha} \quad \forall i \in I(\bar{x}).$$

This implies that for all $k \in \mathcal{K}'$ large enough,

$$\nabla c_i(x^k)^\top d^k \leq -\frac{1}{2}\bar{\alpha} \quad \forall i \in I(\bar{x}). \tag{3.5}$$

From (3.3) and the proof of [18, Lemma 3.9], we have the following basic relations (because of the differentiability of the functions) for the functions f, c and $k \in \mathcal{K}'$ large enough:

$$\begin{aligned} & f(x^k + td^k + t^2(\hat{d}^k - d^k)) - f(x^k) - \sigma t \nabla f(x^k)^\top d^k \\ \leq\ & t\Big\{ \sup_{\xi\in[0,1]} \|\nabla f(x^k + t\xi d^k + t^2\xi^2(\hat{d}^k - d^k)) - \nabla f(x^k)\|\|d^k\| \\ & +2t\ \sup_{\xi\in[0,1]} \|\nabla f(x^k + t\xi d^k + t^2\xi^2(\hat{d}^k - d^k))\|\|\hat{d}^k - d^k\| \\ & -(1-\sigma)\alpha\Big\}, \end{aligned} \tag{3.6}$$

$$\begin{aligned} & c_i(x^k + td^k + t^2(\hat{d}^k - d^k)) - c_i(x^k) \\ \leq\ & t\Big\{ \sup_{\xi\in[0,1]} \|\nabla c_i(x^k + t\xi d^k + t^2\xi^2(\hat{d}^k - d^k)) - \nabla c_i(x^k)\|\|d^k\| \\ & +2t\ \sup_{\xi\in[0,1]} \|\nabla c_i(x^k + t\xi d^k + t^2\xi^2(\hat{d}^k - d^k))\|\|\hat{d}^k - d^k\| \\ & +\nabla c_i(x^k)^\top d^k\Big\}, \quad i \in I. \end{aligned} \tag{3.7}$$

Note that $\{\hat{d}^k - d^k\}$ is also bounded in view of the relation $\|\hat{d}^k - d^k\| \leq \|d^k\|$. Hence, (3.6) implies that there exists $t_f > 0$, independent of k, such that, for all $k \in \mathcal{K}'$ large enough,

$$f(x^k + td^k + t^2(\hat{d}^k - d^k)) - f(x^k) - \sigma t \nabla f(x^k)^\top d^k \leq 0 \quad \forall t \in (0, t_f]. \tag{3.8}$$

Moreover, (3.5) and (3.7) imply that there exists $t_c > 0$, independent of k, such that for $t \in (0, t_c]$ and $k \in \mathcal{K}'$ large enough,

$$c_i(x^k + td^k + t^2(\hat{d}^k - d^k)) < 0 \quad \forall i \in I(\bar{x}).$$

For all $i \in I\backslash I(\bar{x})$, there exists $\hat{\alpha} > 0$ such that $c_i(x^k) \leq -\hat{\alpha}$ for all $k \in \mathcal{K}'$ large enough. Since d^k and $\hat{d}^k$ are bounded, there exists $\bar{t}_c > 0$, independent of k, such that

$$c_i(x^k + td^k + t^2(\hat{d}^k - d^k)) < 0 \quad \forall i \in I\backslash I(\bar{x})$$

for all $t \in (0, \bar{t}_c]$ and $k \in \mathcal{K}'$ large enough.

Let $\bar{t} = \min\{t_f, \bar{t}_c, t_c\}$. By the arc search step of Algorithm 2.1, we have $t_k \geq \beta\bar{t}$ for all $k \in \mathcal{K}'$ large enough. Thus, it follows from (3.3) and (3.8) that

$$f(x^k + t_k d^k + t_k^2(\hat{d}^k - d^k)) - f(x^k) \leq -\sigma\beta\bar{t}\alpha,$$

which implies $f(x^k) \to -\infty$, a contradiction to Assumption A4 and the assumption that f is real valued and continuously differentiable on $\mathcal{F}$. ∎

LEMMA 3.8. *Suppose Assumptions A1–A4 hold,* $\{x^k, \lambda^{k,0}\}_{\mathcal{K}} \to (\bar{x}, \bar{\lambda})$, *and* $\{\delta_k\}_{\mathcal{K}}$ *is bounded below over zero, where* $\mathcal{K}$ *is an infinite index set. If* $\{\nabla f(x^k)^\top d^k\}_{\mathcal{K}} \to 0$, *then* $(\bar{x}, \bar{\lambda})$ *is a KKT point of problem* (P).

Proof. It is obvious that $\bar{x} \in \mathcal{F}$. There are two cases.

Case 1. There exists an infinite subset $\mathcal{K}_1 \subseteq \mathcal{K}$ such that FAST = TRUE for all $k \in \mathcal{K}_1$. In this case, $d^k = d^{k,2}$ and $(d^{k,1}, \lambda^{k,1}_{I_k})$ satisfies system (2.8). Since I is finite, we can assume that I_k are identical for all $k \in \mathcal{K}_1$ and let $I_{\mathcal{K}_1} = I_k$. Since $\nabla f(x^k)^\top d^k \le \theta \nabla f(x^k)^\top d^{k,1}$ by Lemma 2.3(i), it follows that $\{\nabla f(x^k)^\top d^{k,1}\} \to 0$ as $k \in \mathcal{K}_1 \to \infty$. Without loss of generality, suppose $\{\delta_k\}_{\mathcal{K}_1} \to \bar{\delta} > 0$ and $\{\lambda^{k,1}\}_{\mathcal{K}_1} \to \lambda'$. Letting $k \in \mathcal{K}_1 \to \infty$ in (2.8) yields that $\{d^{k,1}\}_{\mathcal{K}_1} \to 0$ and $\lambda'_{I_{\mathcal{K}_1}} \ge 0$. Moreover, we obtain from linear equations (2.7) that

$$\nabla f(\bar{x}) + \sum_{i \in I_{\mathcal{K}_1}} \lambda'_i \nabla c_i(\bar{x}) = 0 \quad \text{and} \quad c_i(\bar{x}) = 0 \quad \forall i \in I_{\mathcal{K}_1}.$$

Since $\lambda'_{I \setminus I_{\mathcal{K}_1}} = 0$, we conclude that $(\bar{x}, \lambda')$ is a KKT point of problem (P). Furthermore, since $\{d^{k,0}\}$ and all elements of M_k are bounded, we can assume that $\{d^{k,0}\} \to \bar{d}$ and $\{M_k\} \to \bar{M}$ as $k \in \mathcal{K}_1 \to \infty$. Due to the nonsingularity of $\bar{M}$, letting $k \in \mathcal{K}_1 \to \infty$ in linear equations (2.6) and (2.7) yields that $\bar{d} = 0$ and $\bar{\lambda}_{I_{\mathcal{K}_1}} = \lambda'_{I_{\mathcal{K}_1}}$. Hence, $(\bar{x}, \bar{\lambda})$ is a KKT point of problem (P).

Case 2. There exists an infinite subset $\mathcal{K}_2 \subseteq \mathcal{K}$ such that FAST = FALSE for all $k \in \mathcal{K}_2$. In this case, $d^k = d^{k,3}$. Similarly to Case 1, we assume that I_k are identical for all $k \in \mathcal{K}_2$ and let $I_{\mathcal{K}_2} = I_k$. Since $\nabla f(x^k)^\top d^k \le \theta \nabla f(x^k)^\top d^{k,2}$ by Lemma 2.4(ii), it follows that $\{\nabla f(x^k)^\top d^{k,2}\} \to 0$ as $k \in \mathcal{K}_2 \to \infty$. Notice that $\{\mu^k\}_{\mathcal{K}_2}$ is bounded and componentwise bounded below over zero. Therefore, we obtain from (2.30) and Lemma 2.4(i) that $\{d^{k,0}\}_{\mathcal{K}_2} \to 0$ and $\bar{\lambda}_{I_{\mathcal{K}_2}} \ge 0$. Furthermore, letting $k \in \mathcal{K}_2 \to \infty$ in linear equations (2.6) yields that

$$\nabla f(\bar{x}) + \sum_{i \in I_{\mathcal{K}_2}} \bar{\lambda}_i \nabla c_i(\bar{x}) = 0 \quad \text{and} \quad \bar{\lambda}_i c_i(\bar{x}) = 0 \quad \forall i \in I_{\mathcal{K}_2}.$$

Since $\bar{\lambda}_{I \setminus I_{\mathcal{K}_2}} = 0$, we conclude that $(\bar{x}, \bar{\lambda})$ is a KKT point of problem (P).

Since either Case 1 or Case 2 happens, the result follows immediately. ∎

Now we are in a position to establish the global convergence of Algorithm 2.1. By Lemma 2.1 we have known that if Algorithm 2.1 terminates in a finite number of iterations, a KKT point of problem (P) is found. The following theorem deals only with the case of infinite iterations.

THEOREM 3.9. *Suppose Assumptions A1–A4 hold. Let* $(\bar{x}, \hat{\lambda}, \bar{\lambda})$ *be an accumulation point of sequence* $\{x^k, \lambda^{k-1,0}, \lambda^{k,0}\}$ *generated by Algorithm* 2.1, *and let* $\mathcal{K}$ *be the corresponding index set such that* $\{x^k, \lambda^{k-1,0}, \lambda^{k,0}\}_{\mathcal{K}} \to (\bar{x}, \hat{\lambda}, \bar{\lambda})$. *Then either* $(\bar{x}, \hat{\lambda})$ *or* $(\bar{x}, \bar{\lambda})$ *is a KKT point of problem* (P).

Proof. First note that Lemma 3.2 and Assumption A4 ensure the existence of an accumulation point of $\{x^k, \lambda^{k-1,0}, \lambda^{k,0}\}$. Lemma 3.3 states that if there exists an infinite subset $\mathcal{K}' \subseteq \mathcal{K}$ such that $\{\delta_k\}_{\mathcal{K}'} \to 0$, then $(\bar{x}, \hat{\lambda})$ is a KKT point of problem (P). Therefore, we only need to consider the case that $\{\delta_k\}_{\mathcal{K}}$ is bounded below over zero. Assume to the contrary that neither $(\bar{x}, \hat{\lambda})$ nor $(\bar{x}, \bar{\lambda})$ is a KKT point of problem (P). Then there exists a constant $\alpha > 0$ such that $\varphi(x^k, \lambda^{k-1,0}) \ge \alpha$ for all $k \in \mathcal{K}$ large enough. Moreover, Lemma 3.1 shows that the sequence $\{\varepsilon_k\}$ has a lower bound $\bar{\varepsilon} > 0$. Therefore, the definition of working set indicates that $I(\bar{x}) \subseteq I_k$ for all $k \in \mathcal{K}$ large enough. Then by Lemma 3.7 we have that $\{\nabla f(x^k)^\top d^k\} \to 0$ as $k \in \mathcal{K} \to \infty$.

Thus, it follows from Lemma 3.8 that $(\bar{x}, \bar{\lambda})$ is a KKT point of problem (P). This contradicts the assumption that $(\bar{x}, \bar{\lambda})$ is not a KKT point. ∎

4. Fast local convergence. Suppose $(x^*, \hat{\lambda}, \bar{\lambda})$ is an accumulation point of the sequence $\{(x^k, \lambda^{k-1,0}, \lambda^{k,0})\}$ generated by Algorithm 2.1. It follows from Theorem 3.9 that either $(x^*, \hat{\lambda})$ or $(x^*, \bar{\lambda})$ is a KKT point of problem (P). Since by Assumption A2 there exists a unique multiplier vector corresponding to x^*, we have either $\hat{\lambda} = \lambda^*$ or $\bar{\lambda} = \lambda^*$. To begin our analysis, we further assume that $f,\ c_i,\ i \in I$, are twice continuously differentiable and $\nabla^2 f,\ \nabla^2 c_i,\ i \in I$, are locally Lipschitz continuous in a neighborhood of x^*. The following assumption is used to guarantee that x^* is an isolated accumulation point of $\{x^k\}$.

ASSUMPTION A5. *The SSOSC holds at (x^*, λ^*), i.e., the Lagrangian Hessian $\nabla^2_{xx}\mathcal{L}(x^*, \lambda^*)$ is positive definite on the null space*

$$\{y \in \Re^n | \nabla c_i(x^*)^\top y = 0 \quad \forall i \in I^+(x^*)\}.$$

From Lemma 3.2 we know that ε_k are changed at most finitely many times. Therefore, we can assume $\varepsilon_k = \bar{\varepsilon}$ for all k large enough. The following lemma follows directly from [4, Theorems 2.3, 2.4, and 3.7].

LEMMA 4.1. *Under Assumptions A2 and A5, there exists a neighborhood of (x^*, λ^*) such that, for each (x, λ) in this neighborhood, $A_{\bar{\varepsilon},\varphi_{\max}}(x, \lambda) = I(x^*)$ and $\Lambda_{\bar{\varepsilon},\varphi_{\max}}(x, \lambda) = I^+(x^*)$.*

LEMMA 4.2. *Suppose Assumptions A1–A5 hold and that $\{(x^k, \lambda^{k-1,0}, \lambda^{k,0})\}_{\mathcal{K}} \to (x^*, \hat{\lambda}, \bar{\lambda})$. Then $I(x^*) \subseteq I_k$ for all $k \in \mathcal{K}$ large enough and $\bar{\lambda} = \lambda^*$.*

Proof. If $\hat{\lambda} = \lambda^*$, it follows from Theorem 3.9 and Lemma 4.1 that for all $k \in \mathcal{K}$ large enough, $I_k = I(x^*)$. If $\hat{\lambda} \neq \lambda^*$, then $(x^*, \hat{\lambda})$ is not a KKT point of problem (P). The properties of φ imply that there exists $\alpha > 0$ such that $\varphi(x^k, \lambda^{k-1,0}) \geq \alpha$ for all $k \in \mathcal{K}$ large enough. Hence, $I(x^*) \subseteq I_k$ for all $k \in \mathcal{K}$ large enough. Now we show that $\bar{\lambda} = \lambda^*$. Since $I(x^*) \subseteq I_k$ for all sufficiently large $k \in \mathcal{K}$, it follows from Lemma 3.7 that $\{\nabla f(x^k)^\top d^k\} \to 0$ as $k \in \mathcal{K} \to \infty$. Hence, we know from Lemma 3.8 that $(x^*, \bar{\lambda})$ is a KKT point of problem (P). Thus, by Assumption A2, we have $\bar{\lambda} = \lambda^*$. ∎

LEMMA 4.3. *Suppose Assumptions A1–A5 hold and that $\{(x^k, \lambda^{k-1,0}, \lambda^{k,0})\}_{\mathcal{K}} \to (x^*, \hat{\lambda}, \bar{\lambda})$. Then $\{d^k\}_{\mathcal{K}} \to 0$.*

Proof. Consider any subsequence $\{\lambda^{k-1,0}\}_{\bar{\mathcal{K}}}$ with $\bar{\mathcal{K}} \subseteq \mathcal{K}$. If it converges to λ^*, by Lemma 4.1, we have $L_k = I^+(x^*)$ for $k \in \bar{\mathcal{K}}$ large enough. Hence, if $I^+(x^*) \neq \emptyset$, then $\delta_k > \frac{1}{2}\min\{\lambda_i^*,\ i \in I^+(x^*)\}$ for large $k \in \bar{\mathcal{K}}$; otherwise, $\delta_k = \delta > 0$ due to Step 3 of Algorithm 2.1. If $\{\lambda^{k-1,0}\}_{\bar{\mathcal{K}}}$ does not converge to λ^*, then $\{\varphi(x^k, \lambda^{k-1,0})\}_{\bar{\mathcal{K}}}$ is bounded below over zero and so is $\{\delta_k\}_{\bar{\mathcal{K}}}$ by the definition of δ_k. Hence, we conclude that $\{\delta_k\}_{\mathcal{K}}$ is uniformly bounded below over zero and then by Lemma 3.4 that $\{\|M_k^{-1}\|\}_{\mathcal{K}}$ is uniformly bounded.

From Lemma 4.2 we know that $I(x^*) \subseteq I_k$ for all $k \in \mathcal{K}$ large enough. Hence it follows from Lemma 3.7 that $\{\nabla f(x^k)^\top d^k\} \to 0$ as $k \in \mathcal{K} \to \infty$. Now consider any infinite index set $\mathcal{K}' \subseteq \mathcal{K}$ in which $\{d^k\} \to \bar{d}$. There are two cases.

Case 1. There exists an infinite subset $\mathcal{K}_1 \subseteq \mathcal{K}'$ such that FAST = TRUE for all $k \in \mathcal{K}_1$. In this case, $d^k = d^{k,2}$ and ρ_k is defined by (2.11). Without loss of generality, we can assume that $\{\lambda^{k,1}\}_{\mathcal{K}_1} \to \tilde{\lambda}$, $\{\lambda^{k,2}\}_{\mathcal{K}_1} \to \breve{\lambda}$ and $\{\delta_k\}_{\mathcal{K}_1} \to \delta_* > 0$. Moreover, since I is finite, we can assume that I_k are identical for all $k \in \mathcal{K}_1$ and let $I_{\mathcal{K}_1} = I_k$. Since all elements of M_k are bounded, we can further assume that $\{M_k\}_{\mathcal{K}_1} \to \bar{M}$. By Lemma 2.3(i) we have that $\{\nabla f(x^k)^\top d^{k,1}\}_{\mathcal{K}_1} \to 0$ as $\{\nabla f(x^k)^\top d^k\}_{\mathcal{K}_1} \to 0$. Thus, (2.8) and (2.11) imply that $\{d^{k,1}\}_{\mathcal{K}_1} \to 0$ and $\{\rho_k\}_{\mathcal{K}_1} \to 0$. Letting $k \in \mathcal{K}_1 \to \infty$ in

linear equations (2.7) and (2.9) yields that

$$\bar{M}\begin{bmatrix} 0 \\ \tilde{\lambda}_{I_{\mathcal{K}_1}} \end{bmatrix} = \bar{M}\begin{bmatrix} \bar{d} \\ \breve{\lambda}_{I_{\mathcal{K}_1}} \end{bmatrix} = \begin{bmatrix} -\nabla f(x^*) \\ -\delta_* c_{I_{\mathcal{K}_1}}(x^*) \end{bmatrix}.$$

Since we have proved that $\{\|M_k^{-1}\|\}_{\mathcal{K}_1}$ is bounded, i.e., $\bar{M}$ is nonsingular, we get that $\bar{d} = 0$.

Case 2. There exists an infinite subset $\mathcal{K}_2 \subseteq \mathcal{K}'$ such that FAST = FALSE for all $k \in \mathcal{K}_2$. In this case, $d^k = d^{k,3}$, and v^k, ϖ^k, and ρ_k are defined by (2.12), (2.16), and (2.17), respectively. Similarly to the analysis in Case 1, we can assume, without loss of generality, that $\{\lambda^{k,3}\}_{\mathcal{K}_2} \to \lambda'$, $\{M_k\}_{\mathcal{K}_2} \to \hat{M}$ and that I_k are identical for all $k \in \mathcal{K}_2$ and let $I_{\mathcal{K}_2} = I_k$. Lemma 2.4(ii) implies that $\{\nabla f(x^k)^\top d^{k,2}\}_{\mathcal{K}_2} \to 0$ as $\{\nabla f(x^k)^\top d^k\}_{\mathcal{K}} \to 0$. Thus, we know from (2.17), Lemma 2.4(i), (2.30), and Assumption A3 that $\{\rho_k\}_{\mathcal{K}_2} \to 0$ and $\{d^{k,0}\}_{\mathcal{K}_2} \to 0$. Hence, it follows from (2.12) and (2.16) that $\{\varpi^k\}_{\mathcal{K}_2} \to 0$. Letting $k \in \mathcal{K}_2 \to \infty$ in linear equations (2.6) and (2.13) yields that

$$\hat{M}\begin{bmatrix} 0 \\ \bar{\lambda}_{I_{\mathcal{K}_2}} \end{bmatrix} = \hat{M}\begin{bmatrix} \bar{d} \\ \lambda'_{I_{\mathcal{K}_2}} \end{bmatrix} = \begin{bmatrix} -\nabla f(x^*) \\ 0 \end{bmatrix}.$$

Again, the nonsingularity of $\hat{M}$ implies that $\bar{d} = 0$.

Since either Case 1 or Case 2 happens, the result follows immediately. ∎

The original version of the next result is due to Moré and Sorensen [17]; here we cite a slightly different version of the result from [16, Proposition 5.4].

PROPOSITION 4.4. *Assume that $\omega^* \in \Re^t$ is an isolated accumulation point of a sequence $\{\omega^k\} \subset \Re^t$ such that for every subsequence $\{\omega^k\}_{\mathcal{K}}$ converging to ω^*, there is an infinite subset $\bar{\mathcal{K}} \subseteq \mathcal{K}$ such that $\{\|\omega^{k+1} - \omega^k\|\}_{\bar{\mathcal{K}}} \to 0$. Then the whole sequence $\{\omega^k\}$ converges to ω^*.*

LEMMA 4.5. *Under Assumptions A1–A5, the whole sequence $\{(x^k, \lambda^{k,0})\}$ converges to (x^*, λ^*).*

Proof. The SSOSC and the LICQ guarantee that x^* is an isolated accumulation point of $\{x^k\}$; see [21]. Let $\{x^k\}_{\mathcal{K}}$ be a subsequence of iterates converging to x^*. It follows from Lemma 4.3 that there exists a subsequence $\mathcal{K}' \subseteq \mathcal{K}$ such that $\{d^k\}_{\mathcal{K}'} \to 0$. Since

$$\|x^{k+1} - x^k\| \le \|d^k\| + \|\hat{d}^k\| \le 2\|d^k\|,$$

we have that $\{\|x^{k+1} - x^k\|\}_{\mathcal{K}'} \to 0$. Hence, by Proposition 4.4 we conclude that the whole sequence $\{x^k\}$ converges to x^*. Furthermore, Lemma 4.2 implies that the whole sequence $\{\lambda^{k,0}\}$ converges to λ^*. ∎

COROLLARY 4.6. *Under Assumptions A1–A5, $I_k = I(x^*)$, $L_k = I^+(x^*)$ for all k large enough, and the sequences generated by Algorithm* 2.1 *satisfy*

(i) *$\delta_k \to \delta_* > 0$ and $\{\|M_k^{-1}\|\}$ is bounded, where*

$$\delta_* = \begin{cases} \vartheta \min\{\lambda_i^*,\ i \in I^+(x^*)\} & \text{if } I^+(x^*) \neq \emptyset, \\ \delta & \text{if } I^+(x^*) = \emptyset; \end{cases}$$

(ii) *$\mu_i^k \to \mu_i^* = \delta_* + \lambda_i^*$ for all $i \in I(x^*)$;*
(iii) *$d^k \to 0$, $d^{k,0} \to 0$, $d^{k,1} \to 0$;*
(iv) *$\lambda^{k,1} \to \lambda^*$, $\lambda^k \to \lambda^*$.*

Proof. Since Lemma 4.5 gives that the whole sequence $\{(x^k, \lambda^{k,0})\}$ converges to (x^*, λ^*), we have from Lemma 4.1 that $I_k = I(x^*)$ and $L_k = I^+(x^*)$ for all k large enough. Hence, result (i) is a direct consequence of the definition of δ_k and Lemma 3.4. Moreover, (2.19) implies result (ii). Lemma 4.3 gives that $d^k \to 0$. Letting $k \to \infty$ in linear equations (2.6) and (2.7) yields that $d^{k,0} \to 0$, $d^{k,1} \to 0$, $\lambda^{k,1} \to \lambda^*$. This further implies that $\rho_k \to 0$, $v^k \to 0$, and $\varpi^k \to 0$. Finally, letting $k \to \infty$ in linear equations (2.9) and (2.13) yields that $\lambda^k \to \lambda^*$. □

The next result shows that under the SSOSC, the exact Lagrangian Hessian is eventually accepted by Algorithm 2.1 without any modification, and Assumption A3 holds correctly.

LEMMA 4.7. *Suppose $\{(x^k, \lambda^{k,0})\} \to (x^*, \lambda^*)$ and Assumptions A2 and A5 hold. Then there exists $\bar{\varrho} > 0$ such that for all k large enough and any $d \in \mathcal{T}(x^k)$,*

$$d^\top \left(\nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e) - \sum_{i \in L_k \setminus I(x^k)} \frac{\mu_i^k}{2c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top \right) d \geq \bar{\varrho}\|d\|^2, \tag{4.1}$$

and $H_k = \nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e)$ eventually.

Proof. Since the SSOSC holds, Lemma 6.2 implies that for each $\bar{I} \subseteq I^+(x^*)$, there exist $\kappa(\bar{I}) > 0$ and $\varrho(\bar{I}) > 0$ such that

$$d^\top \left(\nabla^2_{xx}\mathcal{L}(x^*, \lambda^*) + \sum_{i \in I^+(x^*) \setminus \bar{I}} \kappa(\bar{I}) \nabla c_i(x^*) \nabla c_i(x^*)^\top \right) d \geq \varrho(\bar{I})\|d\|^2 \tag{4.2}$$

for any $d \in \{y \in \Re^n | \nabla c_i(x^*)^\top y = 0, i \in \bar{I}\}$. Let $\tilde{\kappa} = \max\{\kappa(\bar{I}), \bar{I} \subseteq I^+(x^*)\}$ and $\tilde{\varrho} = \min\{\varrho(\bar{I}), \bar{I} \subseteq I^+(x^*)\}$.

Suppose (4.1) is not true for $\bar{\varrho} = \frac{1}{2}\tilde{\varrho}$. Then there exists an infinite sequence $\{y^k\}_{\mathcal{K}}$, $y^k \in \{y \in \mathcal{T}(x^k) | \|y\| = 1\}$, such that

$$(y^k)^\top \left(\nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e) - \sum_{i \in L_k \setminus I(x^k)} \frac{\mu_i^k}{2c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top \right) y^k < \frac{1}{2}\tilde{\varrho}\|y^k\|^2.$$

Since $\{y^k\}_{\mathcal{K}}$ is bounded, we can assume $\{y^k\}_{\mathcal{K}} \to \bar{y}$ with $\|\bar{y}\| = 1$. Since I is finite, we can assume that $I(x^k)$ are identical for all $k \in \mathcal{K}$ and let $\bar{I}_{\mathcal{K}} = I(x^k)$. It is obvious that $\bar{y} \in \{y \in \Re^n | \nabla c_i(x^*)^\top y = 0, i \in I^+(x^*) \cap \bar{I}_{\mathcal{K}}\}$. Since $L_k = I^+(x^*)$ and $-\mu_i^k / c_i(x^k) \to \infty$ for $i \in I^+(x^*) \setminus \bar{I}_{\mathcal{K}}$, we obtain by continuity that for sufficiently large $k \in \mathcal{K}$,

$$\begin{aligned}
&\bar{y}^\top \left(\nabla^2_{xx}\mathcal{L}(x^*, \lambda^*) + \sum_{i \in I^+(x^*) \setminus \bar{I}_{\mathcal{K}}} \tilde{\kappa} \nabla c_i(x^*) \nabla c_i(x^*)^\top \right) \bar{y} \\
&\leq \frac{3}{2}(y^k)^\top \left(\nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e) - \sum_{i \in L_k \setminus I(x^k)} \frac{\mu_i^k}{2c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top \right) y^k \\
&< \frac{3}{4}\tilde{\varrho}\|y^k\|^2 \leq \frac{7}{8}\varrho(I^+(x^*) \cap \bar{I}_{\mathcal{K}})\|\bar{y}\|^2.
\end{aligned}$$

This contradicts (4.2). Hence (4.1) holds, which implies that for all k large enough

$$d^\top \left(\nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e) - \sum_{i \in I_k \setminus I(x^k)} \frac{\mu_i^k}{c_i(x^k)} \nabla c_i(x^k) \nabla c_i(x^k)^\top \right) d > 0 \tag{4.3}$$

for any $d \in \mathcal{T}(x^k)\backslash\{0\}$. Therefore, we know from Step 1(i) and Step 3 of Algorithm 2.1 that $H_k = \nabla^2_{xx}\mathcal{L}(x^k, \mu^k - \delta_k e)$ eventually. ∎

LEMMA 4.8. *Under Assumptions A1–A5, the sequences generated by Algorithm 2.1 satisfy*

(i) $\|x^k + d^{k,1} - x^*\| = o(\|x^k - x^*\|)$;

(ii) $|\lambda_i^{k,1} - \lambda_i^*| = o(\|d^{k,1}\|)$ *for all* $i \in I(x^*)$.

Proof. It follows from linear equations (2.7) and Corollary 4.6 that for each $i \in I(x^*)$,

$$\begin{aligned} c_i(x^k) &= -\frac{\mu_i^k}{\delta_k + \lambda_i^{k,1}} \nabla c_i(x^k)^\top d^{k,1} \\ &= -\nabla c_i(x^k)^\top d^{k,1} + \left(1 - \frac{\mu_i^k}{\delta_k + \lambda_i^{k,1}}\right) \nabla c_i(x^k)^\top d^{k,1} \\ &= -\nabla c_i(x^k)^\top d^{k,1} + o(\|d^{k,1}\|). \end{aligned} \tag{4.4}$$

Hence, for all k large enough, we can rewrite (2.7) as follows:

$$\begin{bmatrix} H_k & \nabla c_{I(x^*)}(x^k) \\ \nabla c_{I(x^*)}(x^k)^\top & 0 \end{bmatrix} \begin{bmatrix} d^{k,1} \\ \lambda^{k,1}_{I(x^*)} \end{bmatrix} = - \begin{bmatrix} \nabla f(x^k) \\ c_{I(x^*)}(x^k) + o(\|d^{k,1}\|) \end{bmatrix}. \tag{4.5}$$

Thus, we obtain that

$$\begin{bmatrix} H_k & \nabla c_{I(x^*)}(x^k) \\ \nabla c_{I(x^*)}(x^k)^\top & 0 \end{bmatrix} \begin{bmatrix} x^k + d^{k,1} - x^* \\ \lambda^{k,1}_{I(x^*)} - \lambda^*_{I(x^*)} \end{bmatrix} = \mathcal{W}_{\lambda^*}(x^k), \tag{4.6}$$

where

$$\mathcal{W}_{\lambda^*}(x^k) = \begin{bmatrix} -\nabla f(x^k) - \nabla c_{I(x^*)}(x^k)\lambda^*_{I(x^*)} + H_k(x^k - x^*) \\ -c_{I(x^*)}(x^k) + \nabla c_{I(x^*)}(x^k)^\top (x^k - x^*) + o(\|d^{k,1}\|) \end{bmatrix}. \tag{4.7}$$

By the medium value theorem, we have

$$\begin{aligned} \nabla f(x^*) &= \nabla f(x^k) - \nabla^2 f(x^k)(x^k - x^*) \\ &\quad - \int_0^1 [\nabla^2 f(x^k + t(x^* - x^k)) - \nabla^2 f(x^k)](x^k - x^*)dt, \\ \nabla c_i(x^*) &= \nabla c_i(x^k) - \nabla^2 c_i(x^k)(x^k - x^*) \\ &\quad - \int_0^1 [\nabla^2 c_i(x^k + t(x^* - x^k)) - \nabla^2 c_i(x^k)](x^k - x^*)dt,\ i \in I. \end{aligned}$$

Since $\nabla^2 f$ and $\nabla^2 c_i$ $(i \in I)$ are locally Lipschitz continuous in a neighborhood of

x^*, we can assume that L_f and L_i $(i \in I)$ are their Lipschitz constants, respectively. Thus, it follows that for all k large enough,

$$\begin{aligned} &\|\nabla f(x^*) - \nabla f(x^k) - \nabla^2 f(x^k)(x^* - x^k)\| \le \frac{L_f}{2}\|x^k - x^*\|^2, \\ &\|\nabla c_i(x^*) - \nabla c_i(x^k) - \nabla^2 c_i(x^k)(x^* - x^k)\| \le \frac{L_i}{2}\|x^k - x^*\|^2,\ i \in I. \end{aligned} \tag{4.8}$$

Moreover, we have from Corollary 4.6 and Lemma 4.7 that

$$\|[H_k - \nabla^2_{xx}\mathcal{L}(x^*, \lambda^*)](x^k - x^*)\| = o(\|x^k - x^*\|). \tag{4.9}$$

By (4.8) and (4.9), we further obtain that

$$\begin{aligned} &- \nabla f(x^k) - \nabla c_{I(x^*)}(x^k)\lambda^*_{I(x^*)} + H_k(x^k - x^*) \\ &= [\nabla f(x^*) - \nabla f(x^k) - \nabla^2 f(x^k)(x^* - x^k)] \\ &\quad + \sum_{i \in I(x^*)} \lambda_i^*[\nabla c_i(x^*) - \nabla c_i(x^k) - \nabla^2 c_i(x^k)(x^* - x^k)] \\ &\quad + [H_k - \nabla^2_{xx}\mathcal{L}(x^*, \lambda^*)](x^k - x^*) \\ &\quad + \left[\nabla^2 f(x^*) - \nabla^2 f(x^k) + \sum_{i \in I(x^*)} \lambda_i^*(\nabla^2 c_i(x^*) - \nabla^2 c_i(x^k))\right](x^k - x^*) \\ &= o(\|x^k - x^*\|), \end{aligned}$$

$$\begin{aligned} &- c_{I(x^*)}(x^k) + \nabla c_{I(x^*)}(x^k)^\top (x^k - x^*) \\ &= c_{I(x^*)}(x^*) - c_{I(x^*)}(x^k) + \nabla c_{I(x^*)}(x^k)^\top (x^k - x^*) \\ &= O(\|x^k - x^*\|^2). \end{aligned}$$

This together with (4.7) implies that $\mathcal{W}_{\lambda^*}(x^k) = o(\|x^k - x^*\|) + o(\|d^{k,1}\|)$. By following an identical proof to that of [8, Proposition 3.1], we know that under Assumptions A2 and A5, the coefficient matrices of (4.6) are uniformly nonsingular for all k large enough. Hence, we know from (4.6) that $\|x^k + d^{k,1} - x^*\| = o(\|x^k - x^*\|) + o(\|d^{k,1}\|)$, which implies that $\|x^k - x^*\| = O(\|d^{k,1}\|)$. Thus, results (i) and (ii) again follow from (4.6). ∎

LEMMA 4.9. *Under Assumptions A1–A5, we eventually have* FAST = TRUE *in Step* 1(ii) *of Algorithm* 2.1*, i.e.,* (2.8) *holds for all k large enough.*

Proof. Since $\lambda^{k,1} \to \lambda^*$, it follows from Lemma 4.8 that for all sufficiently large k,

$$\begin{aligned} &\lambda_i^{k,1} > 0 && \forall i \in I^+(x^*); \\ &\lambda_i^{k,1} = \lambda_i^{k,1} - \lambda_i^* = o(\|d^{k,1}\|) && \forall i \in I(x^*) \backslash I^+(x^*). \end{aligned} \tag{4.10}$$

From the fact that $I(x^k) \subseteq I_k$ and (2.7), we have

$$\mu_i^k \nabla c_i(x^k)^\top d^{k,1} = (-\delta_k - \lambda_i^{k,1}) c_i(x^k) = 0 \quad \forall i \in I(x^k),$$

which implies that $d^{k,1} \in \mathcal{T}(x^k)$ since $\mu^k > 0$. Moreover, by Corollary 4.6 we have $\delta_k < \lambda_i^{k,1}$ for all $i \in I^+(x^*)$ and large enough k. Hence, we can obtain from (2.7),

Corollary 4.6, Lemma 4.7, and (4.10) that for all k large enough,

$$
\begin{aligned}
&\nabla f(x^k)^\top d^{k,1}\\
&= -(d^{k,1})^\top H_k d^{k,1} - \sum_{i\in I(x^*)} \lambda_i^{k,1}\nabla c_i(x^k)^\top d^{k,1}\\
&= -(d^{k,1})^\top H_k d^{k,1} + \sum_{i\in I^+(x^*)\setminus I(x^k)} \frac{\mu_i^k}{2c_i(x^k)}(d^{k,1})^\top \nabla c_i(x^k)\nabla c_i(x^k)^\top d^{k,1}\\
&\quad + \sum_{i\in I^+(x^*)\setminus I(x^k)} \left(\frac{\mu_i^k}{2c_i(x^k)}\nabla c_i(x^k)^\top d^{k,1} + \delta_k\right)\nabla c_i(x^k)^\top d^{k,1}\\
&\quad - \sum_{i\in I(x^*)\setminus I^+(x^*)} \lambda_i^{k,1}\nabla c_i(x^k)^\top d^{k,1}\\
&= -(d^{k,1})^\top \left(H_k - \sum_{i\in I^+(x^*)\setminus I(x^k)} \frac{\mu_i^k}{2c_i(x^k)}\nabla c_i(x^k)\nabla c_i(x^k)^\top\right) d^{k,1}\\
&\quad + \sum_{i\in I^+(x^*)\setminus I(x^k)} \frac{c_i(x^k)}{2\mu_i^k}((\lambda_i^{k,1})^2 - \delta_k^2) + o(\|d^{k,1}\|^2)\\
&\le -\bar{\varrho}\|d^{k,1}\|^2 + o(\|d^{k,1}\|^2) \le -\|d^{k,1}\|^\gamma
\end{aligned}
\tag{4.11}
$$

as $\gamma > 2$, where $\bar{\varrho} > 0$ is defined in Lemma 4.7. Formulas (4.10) and (4.11) imply that (2.8) eventually holds. □

LEMMA 4.10. *Under Assumptions A1–A5, the sequences generated by Algorithm 2.1 eventually satisfy*

(i) $\|d^k - d^{k,1}\| = o(\|d^{k,1}\|^2)$, $\|\lambda^k - \lambda^{k,1}\| = o(\|d^{k,1}\|^2)$;

(ii) $(\hat{d}^k, \hat{\lambda}^k) = (d^{k,3}, \lambda^{k,3})$ *and*

$$
\|\hat{d}^k - d^k\| = O\left(\max\left\{\|d^k\|^2, \max_{i\in I(x^*)}\left\{\left|1 - \frac{\mu_i^k}{\delta_k + \lambda_i^k}\right| \|d^k\|\right\}\right\}\right) = o(\|d^k\|),
$$

$$
\|\hat{\lambda}^k - \lambda^k\| = O\left(\max\left\{\|d^k\|^2, \max_{i\in I(x^*)}\left\{\left|1 - \frac{\mu_i^k}{\delta_k + \lambda_i^k}\right| \|d^k\|\right\}\right\}\right) = o(\|d^k\|).
$$

Proof. From (2.11) we have $\rho_k = o(\|d^{k,1}\|^2)$. Subtracting both sides of (2.7) by the corresponding sides of (2.9) yields that

$$
\begin{aligned}
&\|d^k - d^{k,1}\| = O(\rho_k) = o(\|d^{k,1}\|^2);\\
&|\lambda_i^k - \lambda_i^{k,1}| = O(\rho_k) = o(\|d^{k,1}\|^2) \quad \forall i \in I(x^*).
\end{aligned}
\tag{4.12}
$$

Since $\lambda_i^{k,1} = \lambda_i^k = 0$ for $i \in I\setminus I(x^*)$, result (i) follows from (4.12). Now subtracting both sides of (2.13) by the corresponding sides of (2.9) yields that

$$
M_k \begin{bmatrix} d^{k,3} - d^k \\ \lambda^{k,3}_{I(x^*)} - \lambda^k_{I(x^*)} \end{bmatrix} = \begin{bmatrix} 0 \\ \varpi^k - v^k \end{bmatrix}. \tag{4.13}
$$

From (2.15) we have $\pi_k = o(\|d^k\|^2)$. Hence, it follows from (2.14), (4.4), and (4.12)

that

$$
\begin{aligned}
&\max_{i\in I(x^*)}\{|\varpi_i^k - v_i^k|\}\\
&= \max_{i\in I(x^*)}\{|-\mu_i^k c_i(x^k+d^k)-\pi_k|\}\\
&= \max_{i\in I(x^*)}\{|-\mu_i^k(c_i(x^k)+\nabla c_i(x^k)^\top d^{k,1})\\
&\quad -\mu_i^k\nabla c_i(x^k)^\top(d^k-d^{k,1})-\pi_k+O(\|d^k\|^2)|\}\\
&= \max_{i\in I(x^*)}\left\{\left|-\mu_i^k\left(1-\frac{\mu_i^k}{\delta_k+\lambda_i^{k,1}}\right)\nabla c_i(x^k)^\top d^{k,1}+O(\|d^k\|^2)\right|\right\}\\
&= \max_{i\in I(x^*)}\left\{O\left(\left|1-\frac{\mu_i^k}{\delta_k+\lambda_i^{k,1}}\right|\|d^{k,1}\|\right)+O(\|d^k\|^2)\right\}\\
&= O\left(\max\left\{\|d^k\|^2,\max_{i\in I(x^*)}\left\{\left|1-\frac{\mu_i^k}{\delta_k+\lambda_i^k}\right|\|d^k\|\right\}\right\}\right),
\end{aligned}
\tag{4.14}
$$

where $\lambda_i^{k,1}$ and $d^{k,1}$ are directly replaced by λ_i^k and d^k due to (4.12). Since $\{\|M_k^{-1}\|\}$ is bounded by Corollary 4.6 and $\lambda_i^{k,3}=\lambda_i^k=0$ for $i\in I\backslash I(x^*)$, it follows that for all sufficiently large k, $\|d^{k,3}-d^k\|<\|d^k\|$, which indicates $(\hat{d}^k,\hat{\lambda}^k)=(d^{k,3},\lambda^{k,3})$. Thus, (ii) follows immediately from (4.13) and (4.14). □

LEMMA 4.11. *Under Assumptions A1–A5, the arc search in Step 2 of Algorithm 2.1 eventually accepts a full step of one, i.e., $t_k=1$ for all k large enough.*

Proof. First, we show that for all k large enough,

$$
c_i(x^k+\hat{d}^k)\le 0 \quad \forall i\in I. \tag{4.15}
$$

Lemma 4.10 implies that $\hat{d}^k\to 0$. Hence for all k large enough, $c_i(x^k+\hat{d}^k)<0$ for all $i\in I\backslash I(x^*)$. For $i\in I(x^*)$, by using Taylor expansion we can obtain that for all sufficiently large k,

$$
\begin{aligned}
&\mu_i^k c_i(x^k+\hat{d}^k)\\
&=\mu_i^k c_i(x^k+d^k+\hat{d}^k-d^k)\\
&=\mu_i^k\{c_i(x^k+d^k)+\nabla c_i(x^k+d^k)^\top(\hat{d}^k-d^k)+O(\|\hat{d}^k-d^k\|^2)\}\\
&=\mu_i^k\{c_i(x^k+d^k)+\nabla c_i(x^k)^\top(\hat{d}^k-d^k)+O(\|d^k\|\cdot\|\hat{d}^k-d^k\|)\}\\
&=-(\hat{\lambda}_i^k-\lambda_i^k)c_i(x^k)-\pi_k+O(\|d^k\|\cdot\|\hat{d}^k-d^k\|)\\
&=\frac{\mu_i^k}{\delta_k+\lambda_i^{k,1}}(\hat{\lambda}_i^k-\lambda_i^k)\nabla c_i(x^k)^\top d^{k,1}-\pi_k+O(\|d^k\|\cdot\|\hat{d}^k-d^k\|)\\
&=-\pi_k+O(\|d^k\|\cdot|\hat{\lambda}_i^k-\lambda_i^k|)+O(\|d^k\|\cdot\|\hat{d}^k-d^k\|)\\
&=-\pi_k+O\left(\max\left\{\|d^k\|^3,\max_{i\in I(x^*)}\left\{\left|1-\frac{\mu_i^k}{\delta_k+\lambda_i^k}\right|\|d^k\|^2\right\}\right\}\right)\\
&<-\frac{1}{2}\pi_k<0,
\end{aligned}
\tag{4.16}
$$

where the fourth equality follows from (2.13) and (2.14), the fifth equality follows from (4.4), the last equality is given by Lemma 4.10(ii), and the last line of inequalities

follows from (2.15) since $\nu \in (2,3)$ and $\tau \in (0,1)$. Consequently, it follows from (2.15) and (4.16) that for each $i \in I(x^*)$

$$|c_i(x^k + \hat{d}^k)| = O(\pi_k) = o(\|d^k\|^2). \tag{4.17}$$

Now we show that $t_k = 1$ provides a sufficient reduction in f, i.e.,

$$f(x^k + \hat{d}^k) \le f(x^k) + \sigma \nabla f(x^k)^\top d^k. \tag{4.18}$$

By using Taylor expansion, we get from Lemma 4.10(ii) that for each $i \in I(x^*)$

$$\begin{aligned}
&c_i(x^k + \hat{d}^k)\\
&= c_i(x^k) + \nabla c_i(x^k)^\top \hat{d}^k + \frac{1}{2}(\hat{d}^k)^\top \nabla^2 c_i(x^k)\hat{d}^k + o(\|\hat{d}^k\|^2)\\
&= c_i(x^k) + \nabla c_i(x^k)^\top d^k + \nabla c_i(x^k)^\top (\hat{d}^k - d^k) + \frac{1}{2}(d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2).
\end{aligned}$$

Thus, by (4.4), (4.17), and Lemma 4.10 we can obtain that

$$\begin{aligned}
&-\frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^k - \lambda_i^k \nabla c_i(x^k)^\top (\hat{d}^k - d^k)\\
&= \lambda_i^k c_i(x^k) + \frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^k + \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2)\\
&= \lambda_i^k c_i(x^k) + \frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^{k,1} + \frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top (d^k - d^{k,1})\\
&\quad + \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2)\\
&= \lambda_i^k c_i(x^k) - \lambda_i^k \left(\frac{\delta_k + \lambda_i^{k,1}}{2\mu_i^k}\right) c_i(x^k) + \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2)\\
&= \left(1 - \frac{\delta_k + \lambda_i^{k,1}}{2\mu_i^k}\right) \lambda_i^k c_i(x^k) + \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2).
\end{aligned} \tag{4.19}$$

Since $\frac{\delta_k + \lambda_i^{k,1}}{\mu_i^k} \to 1$ by Corollary 4.6, it follows that for all sufficiently large k, $1 - \frac{\delta_k + \lambda_i^{k,1}}{2\mu_i^k} > 0$. Hence, we get from (4.19) that for $i \in I^+(x^*)$ and large enough k,

$$\begin{aligned}
&-\frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^k - \lambda_i^k \nabla c_i(x^k)^\top (\hat{d}^k - d^k)\\
&\le \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2).
\end{aligned} \tag{4.20}$$

On the other hand, it follows from (4.4), (4.19), and Lemmas 4.8(ii) and 4.10(i) that for $i \in I(x^*) \backslash I^+(x^*)$,

$$\begin{aligned}
&-\frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^k - \lambda_i^k \nabla c_i(x^k)^\top (\hat{d}^k - d^k)\\
&= (\lambda_i^k - \lambda_i^*)\left(1 - \frac{\delta_k + \lambda_i^{k,1}}{2\mu_i^k}\right)(-\nabla c_i(x^k)^\top d^{k,1} + o(\|d^{k,1}\|))\\
&\quad + \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2)\\
&= \frac{1}{2}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k) d^k + o(\|d^k\|^2).
\end{aligned} \tag{4.21}$$

Now we are prepared to derive the following key relation, which also uses Taylor expansion:

$$
\begin{aligned}
& f(x^k+\hat{d}^k) \\
&= f(x^k)+\nabla f(x^k)^\top \hat{d}^k+\frac{1}{2}(\hat{d}^k)^\top \nabla^2 f(x^k)\hat{d}^k+o(\|\hat{d}^k\|^2) \\
&= f(x^k)+\nabla f(x^k)^\top d^k+\nabla f(x^k)^\top(\hat{d}^k-d^k) \\
&\quad +\frac{1}{2}(d^k)^\top \nabla^2 f(x^k)d^k+o(\|d^k\|^2) \\
&= f(x^k)+\frac{1}{2}\nabla f(x^k)^\top d^k-\frac{1}{2}(d^k)^\top H_k d^k-\frac{1}{2}\sum_{i\in I(x^*)}\lambda_i^k \nabla c_i(x^k)^\top d^k \\
&\quad -(\hat{d}^k-d^k)^\top H_k d^k-\sum_{i\in I(x^*)}\lambda_i^k \nabla c_i(x^k)^\top(\hat{d}^k-d^k) \\
&\quad +\frac{1}{2}(d^k)^\top \nabla^2 f(x^k)d^k+o(\|d^k\|^2) \\
&= f(x^k)+\frac{1}{2}\nabla f(x^k)^\top d^k+\frac{1}{2}(d^k)^\top(\nabla^2 f(x^k)-H_k)d^k \\
&\quad -\sum_{i\in I(x^*)}\left(\frac{1}{2}\lambda_i^k \nabla c_i(x^k)^\top d^k+\lambda_i^k \nabla c_i(x^k)^\top(\hat{d}^k-d^k)\right)+o(\|d^k\|^2) \\
&\le f(x^k)+\frac{1}{2}\nabla f(x^k)^\top d^k+\frac{1}{2}(d^k)^\top(\nabla^2 f(x^k)-H_k)d^k \\
&\quad +\frac{1}{2}\sum_{i\in I(x^*)}\lambda_i^k (d^k)^\top \nabla^2 c_i(x^k)d^k+o(\|d^k\|^2) \\
&= f(x^k)+\frac{1}{2}\nabla f(x^k)^\top d^k+\frac{1}{2}(d^k)^\top(\nabla^2_{xx}\mathcal{L}(x^k,\lambda^k)-H_k)d^k+o(\|d^k\|^2) \\
&= f(x^k)+\sigma\nabla f(x^k)^\top d^k+\left(\frac{1}{2}-\sigma\right)\nabla f(x^k)^\top d^k+o(\|d^k\|^2) \\
&\le f(x^k)+\sigma\nabla f(x^k)^\top d^k-\bar{\varrho}\theta\left(\frac{1}{2}-\sigma\right)\|d^k\|^2+o(\|d^k\|^2) \\
&\le f(x^k)+\sigma\nabla f(x^k)^\top d^k,
\end{aligned}
$$

where the second equality is implied by Lemma 4.10, the third equality follows from (2.9), the first inequality is obtained by combining (4.20) and (4.21), the last equality follows from Lemma 4.7, and the second inequality follows from Lemma 2.3(i), (4.11) with $\bar{\varrho}$ defined in Lemma 4.7, Lemma 4.10(i), and the fact that $\sigma<\frac{1}{2}$.

Consequently, we conclude that both (4.15) and (4.18) hold for all sufficiently large k, and thus the unit step size is eventually accepted. □

Putting the results of Lemmas 4.8, 4.9, 4.10, and 4.11 together, we directly obtain the Q-superlinear convergence of Algorithm 2.1.

THEOREM 4.12. *Under Assumptions A1–A5, the sequence* $\{x^k\}$ *generated by Algorithm* 2.1 *converges Q-superlinearly, i.e.,*

$$\|x^{k+1}-x^*\|=o(\|x^k-x^*\|).$$

5. Concluding remarks. In this paper we have presented a new feasible active set QP-free method for inequality constrained optimization. Under very general assumptions (the existence of a feasible initial point, smoothness of the objective

and constraint functions, LICQ and SSOSC, etc.), we have proved that our QP-free method is globally convergent and locally superlinearly convergent to a KKT point of the problem. Noticeably, the superlinear convergence is achieved without assuming that strict complementarity holds or that all optimal multipliers are less than a preselected parameter. Moreover, our method avoids several computational issues in existing active set QP-free methods. For example, our method does not have to compute a new multiplier estimate and select linearly independent constraint gradients to determine a working set at each iteration. A new technique based on so-called δ_*-drifted multipliers is introduced in the method to avoid the possible ill-conditioning of the Newton system caused by dual degeneracy.

Although the main interest of this paper is theoretical, we are also interested in testing the practical efficiency of our method. By implementing it on some small problems from [14], we found that it worked well even for problems failing strict complementarity. However, we feel that it is premature to report numerical results at this stage because of two facts that largely limit the test set for which our method is applicable. First, the current method only tackles problems with inequality constraints. Second, a feasible starting point is required. To deal with equality constraints, we plan to incorporate the ℓ_2-penalty technique introduced in [3] in our QP-free method. Our strategy for the second issue is to transform some inequality constraints to equality constraints by adding slack variables and again, make use of the ℓ_2-penalty technique. We will report on the effectiveness of our approach in due course.

6. Appendix.

LEMMA 6.1. *Suppose Assumption A2 holds,* $H \in \Re^{n\times n}$, $x \in \mathcal{F}$, $I(x) \subseteq \tilde{I} \subseteq I$, *and* $\mu_i > 0$ *for all* $i \in \tilde{I}$. *If*

$$y^\top \left(H - \sum_{i\in \tilde{I}\setminus I(x)} \frac{\mu_i}{c_i(x)} \nabla c_i(x) \nabla c_i(x)^\top \right) y > 0 \tag{6.1}$$

for all $y \in \mathcal{T}(x)\setminus\{0\}$, *then the following matrix is nonsingular:*

$$M = \begin{bmatrix} H & \nabla c_{\tilde{I}}(x) \\ U\nabla c_{\tilde{I}}(x)^\top & C_{\tilde{I}}(x) \end{bmatrix},$$

where $U = \operatorname{diag}(\mu_{\tilde{I}})$ *and* $C_{\tilde{I}}(x) = \operatorname{diag}(c_{\tilde{I}}(x))$.

Proof. Suppose (d, λ) is a solution of the following linear equations:

$$M \begin{bmatrix} d \\ \lambda \end{bmatrix} = 0. \tag{6.2}$$

It follows that

$$\lambda_i = -\frac{\mu_i}{c_i(x)} \nabla c_i(x)^\top d,\ i \in \tilde{I}\setminus I(x), \quad \text{and} \quad \nabla c_i(x)^\top d = 0,\ i \in I(x).$$

Substituting this into (6.2) yields that

$$d^\top \left(H - \sum_{\tilde{I}\setminus I(x)} \frac{\mu_i}{c_i(x)} \nabla c_i(x) \nabla c_i(x)^\top \right) d = 0,$$

which implies that $d = 0$. Moreover, it follows from (6.2) that $\nabla c_{\tilde{I}}(x)\lambda = 0$ and $C_{\tilde{I}}(x)\lambda = 0$. Hence, $\nabla c_{I(x)}\lambda_{I(x)} = 0$ and $\lambda_{\tilde{I}\setminus I(x)} = 0$. Since Assumption A2 implies $\lambda_{I(x)} = 0$, zero is the unique solution of (6.2), i.e., M is nonsingular. ∎

LEMMA 6.2. *Suppose $H \in \Re^{n\times n}$, $J \in \Re^{n\times q}$, and $J = [J_1|J_2]$. If H is positive definite on $S(J)$, where $S(J) = \{y \in \Re^n | J^\top y = 0\}$, then there exists $\bar{r} > 0$ such that for any $r \geq \bar{r}$, $H + rJ_1J_1^\top$ is positive definite on $S(J_2)$, where $S(J_2) = \{y \in \Re^n | J_2^\top y = 0\}$ and in case that $J = J_1$, $S(J_2) = \Re^n$.*

Proof. It suffices to show that there exists $\bar{r} > 0$ such that for any $r \geq \bar{r}$,

$$d^\top (H + rJ_1J_1^\top)d > 0$$

for all $d \in B = \{y \in S(J_2) | \|y\| = 1\}$. Let $N = B \cap \{y \in \Re^n | y^\top Hy \leq 0\}$. Obviously, B and N are both closed and compact. Hence, there exist r_1 and r_2 such that

$$r_1 = \min_{d\in B} d^\top Hd \quad \text{and} \quad r_2 = \min_{d\in N} d^\top J_1J_1^\top d.$$

Since $J_1^\top d \neq 0$ for any $d \in N$, we have $r_2 > 0$. Set $\bar{r} = \max\{-\frac{r_1}{r_2} + 1, 1\}$ and consider any $r \geq \bar{r}$. For any $d \in B$, if $d \in N$, then

$$d^\top (H + rJ_1J_1^\top)d \geq r_1 + rr_2 \geq r_2 > 0;$$

otherwise, $d \in B\backslash N$ and

$$d^\top (H + rJ_1J_1^\top)d \geq d^\top Hd > 0.$$

Hence, we conclude that $H + rJ_1J_1^\top$ is positive definite on B, and hence on $S(J_2)$. ∎

Acknowledgments. We thank Profs. André L. Tits, Andreas Fischer, and Christian Kanzow for their valuable suggestions and comments on a early version of this paper. We are grateful to Prof. Donald Goldfarb for carefully reading the manuscript and improving its clarity and to Drs. Wanmo Kang and Wotao Yin for many helpful discussions. We also wish to thank two anonymous referees and the associate editor Prof. Shuzhong Zhang for their insightful comments, which helped to improve the paper considerably.

RAPID SOURCE INVERSION FOR CHEMICAL/BIOLOGICAL ATTACKS, PART 1: THE STEADY-STATE CASE*

PAUL T. BOGGS†, KEVIN R. LONG†, STEPHEN B. MARGOLIS†, AND PATRICIA A. HOWARD‡

Abstract. A critical first step in responding to an airborne chemical or biological attack is determining the location of the source of the toxin. We have formulated the mathematical description of source location as an inverse problem constrained by the partial differential equation (PDE) that describes the toxin's transport. This transport is advection-dominated, but takes place in a flow field that in realistic settings will be turbulent, thereby inducing an effective diffusivity tensor in the transport model. We model the turbulent flow using a Reynolds-averaged Navier–Stokes (RANS) approach, which can be solved offline for an arbitrary building of interest. The inversion problem then consists of finding the (regularized) source distribution that best reproduces a set of sensor measurements, subject to the transport model constraint relating the source to the concentration at the sensor positions. Though individual toxin sources are likely to be point sources, we cannot make any assumptions about the number of such sources. Hence, because multiple sources are a possibility, we assume a spatially continuous source distribution, thus eliminiating any need to impose assumptions about the number and nature of the sources. The operational context for this problem implies certain practical requirements. In particular, it is critical to reduce the time for inversion and the number of sensors required for an accurate determination of the source field. A particular focus of this paper is the exploration of the degree to which we can economize on computational effort through adaptive mesh coarsening tailored to preserve the essential features of the flow field. We have found that location of multiple sources is well accommodated by this method, and have shown that it is possible to reduce significantly the computational time through flow-tailored mesh adaptation without adverse impact on the accuracy of the source location. Finally, we have done a preliminary study of the number of sensors required for useful inversion. These conclusions will be of considerable use in developing sensor deployment strategies.

1. Introduction.

The key to responding to a chemical or biological attack in a building, e.g., an airport, is speed. In an attack using an airborne toxin, emergency officials need to know as soon as possible what the toxin is and where its source is located. This will allow them to take appropriate action to minimize the impact of the attack, including moving people to safety, confining or venting the release, and possibly even determining who is responsible for the attack.

Two things are needed to determine the type and source of a biological attack: First, one needs sensors that can reliably determine the nature of the toxin and its local concentration; and second, one needs to have a mathematical model of the

toxin dispersion in the air flow in the building that can be inverted to provide the location of the source. Here we assume that appropriate sensors have been placed in the building. Such sensors are being actively developed in several laboratories, including Sandia National Laboratories (see, e.g., [13]); in section 6 we comment on some related work designed to improve these sensors. The location of the sensors within the building is clearly an important issue in reconstructing the source field. We do not consider the optimal location of the sensors in this paper, but, again, in section 6 we discuss the issues involved. In this paper we concentrate on providing an optimization model that simultaneously predicts both the number of sources in the attack and the location of each, given the concentration data from the sensors and the air flow field. We refer to this problem as the *source-inversion problem.*

Source inversion in this context is an example of optimization problems that are constrained by partial differential equations (PDE). Due to the dramatic increase in computational power afforded by massively parallel computers, the substantial gains in our optimization technology, and the major improvements in our understanding and ability to precondition the linear systems that arise in these problems, PDE-constrained optimization has emerged as an important research area. (See [26] for an introduction and the papers in [2] for more extensive coverage.) Source inversion has been considered by [1] and excellent work in preconditioning is given in [4].

The source-inversion problem that we have briefly described above has important features that have motivated our work. In particular, speed of solution is much more important than accuracy. Indeed, if we can correctly predict the number of sources and their locations to within a few meters, emergency personnel can easily find the release devices. As stated above, we need to know the flow field in the building to determine the locations quickly. The air flow in a modern building is determined by the heating, ventilating, and air-conditioning (HVAC) system. It is our understanding that the flows in such a building do not change much over the course of a day. Thus we can assume that a small number of flow fields can be computed in advance and the appropriate one can be selected based on the time of the attack. We can also assume that there will be moderate computing capability in the building. Indeed, given the expense of security in general, the purchase of a small cluster of processors seems quite reasonable.

Since one of our main motivations is speed, we also investigate some strategies for decreasing the time for the calculations. In particular, we will require a relatively fine mesh to solve for the flow field within a given building. The question arises, however, of whether the estimation of the source, or sources, can be done on a coarser mesh. We show that, in fact, a much coarser mesh will suffice and that using such a coarse mesh reduces the computing time by factors of 40–100. This rather surprising result indicates that a practical system using these strategies may be possible. Thus, novel contributions in this paper include the model that allows for the simultaneous determination of both the number and the locations of the source(s) and the fact that very coarse meshes can be used to accelerate the inversion algorithms significantly.

Finally, the problem is clearly time-dependent, but we think that much can be learned initially from considering the simpler steady-state case. We demonstrate in this paper that consideration of a two-dimensional, steady-state model can provide much insight that will guide our efforts in the general three-dimensional, time-dependent case. We do not claim that we have answered all of the questions for this case, but we can do the additional development and experiments in the context of the more general case that will be considered in part 2 of this work. In addition, the

steady-state case is of interest in its own right; one can use the techniques developed here to find, for example, a persistent leak in a complex facility.

In conducting such a project, it was crucial to have a powerful software environment in which to develop and test ideas rapidly. This work would have been far more difficult without the tools that have been developed at Sandia National Laboratories by many people. Most important for this work is Sundance, a code that takes a symbolic description of PDEs and then efficiently creates finite element (mass) matrices and associated right-hand side vectors. The details of how we formulate the flow-field problems and the optimization problems are dictated by our use of Sundance. An optimization code, Split/O3D, has been built to work directly with Sundance operators.

The paper is organized as follows. Given the importance of the software environment, and its impact on some of our analyses and decisions, we describe it first in section 2. We next describe (in section 3) the flow problem that we formulate and solve. In creating the flow field, we tried to specify realistic models that take into account the fact that the air flow in a building such as an airport is subject to many perturbations, including the opening and closing of doors and the movement of people, luggage, and equipment. We then provide (in section 4) the appropriate source dispersion model and the resulting optimization problems that we consider for locating the sources. In section 5, we give a simple two-dimensional example of a building and the resulting flow field. We then give the results of our numerical tests based on the optimization approaches in section 4. We also develop our coarse mesh approximations and show the results using these. In section 6 we provide some discussion about the work that needs to be done to extend this approach to the time-dependent case and to the question of optimal sensor location.

2. Software environment. In this section we briefly describe the software environment that was used for all of the computations in this paper. We emphasize that the development of and experimentation with the models and approaches described here were greatly aided by this powerful set of software tools. We also point out that most of the tools described here are publically available.

The most important tool for our work with PDE-constrained optimization models is Sundance (see [18]). Sundance is a system for specifying, building, and applying finite element approximations to general PDEs. Sundance consists of user-callable components written in C++ that allow the user to specify the PDE and associated boundary conditions in weak form using operator overloading on a family of symbolic objects. The Sundance symbolic objects and operators can be used to assemble virtually any PDE. Each test or unknown function in a Sundance problem is constructed with a specifier of its finite element basis, and any integral can be given a specifier for the type and order of quadrature rule to be used. Stabilization terms can be added at the symbolic level; typically, these involve the mesh size h, so a special symbolic object, `CellDiameterExpr`, has been created which, when evaluated, refers to the mesh to obtain a numerical value of h on each element. The ability to specify basis, quadrature, and optional stabilization terms gives the Sundance user fine control over the discretization process.

Since it is easy to change the equation and/or the boundary conditions, it is easy to experiment with different models by making a small number of changes to a code that uses Sundance. This ability to modify models and solution procedures at a high level of abstraction was key to rapidly creating the flow-field models to be described in section 3. In fact, the code for the Reynolds-averaged Navier–Stokes (RANS) equations were created and solved in fewer than 200 lines of Sundance code. The

symbolic problem setup capability of Sundance is useful not only for rapid development of forward simulators such as our flow model, but even more important, for making possible the concurrent specification of gradient and/or adjoint equations, greatly facilitating the application of gradient-based optimization methods.

Sundance does the work of assembling matrices and vectors from a problem specification; computations on those mathematical objects are then done using the Trilinos family of solver components (see [17]). Trilinos includes a high-performance, low-level matrix/vector library (EPetra), incomplete factorization preconditioners (Ifpack), algebraic multilevel solvers and preconditioners (ML), Krylov solvers (belos), and nonlinear solvers (nox). Trilinos also provides a set of abstract interfaces allowing interoperability with other solver libraries.

Finally, we use a particular optimization method that was also built using Trilinos components and is therefore directly compatible with Sundance. This method, called O3D (see [5]), is an interior-point quadratic programming solver. It has been used as the basis for a sequential quadratic programming (SQP) algorithm that has been successfully applied to a number of problems. (See [7] and [6].) O3D requires the solution of linear systems that may conveniently be expressed mathematically as block matrices. Trilinos allows such linear operators to be created and manipulated easily. It also allowed us to experiment with different formulations and solution strategies quickly.

3. Flow-field computation. As noted above, there are only a few flow fields that need to be calculated to solve the source-inversion problem. Since all of these can be computed in advance, there is no need to be overly concerned with efficiency at this stage. We first describe and justify the turbulent flow model that we have adopted. We next show the manipulations necessary to create the appropriate weak form required by Sundance. This leads naturally to the means of handling the boundary conditions. We then discuss the use of the eikonal equation to calculate a distance variable that appears in our turbulence model. We conclude this section with a discussion of a pressure-stabilization technique that was useful in formulating a stable and well-posed computational algorithm.

3.1. The turbulence model. The time-dependent continuity and momentum (Navier–Stokes) equations for an incompressible fluid are given, in the absence of body forces, by

$$\frac{\partial u_i}{\partial x_i} = 0\,, \tag{3.1}$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_j \partial x_j}\,, \tag{3.2}$$

where repeated unhatted indices denote summation. Here, the dependent variables u_i and p are, respectively, the ith component of the fluid velocity and pressure, the independent variables x (with components x_i in a domain Ω) and t are the spatial and temporal coordinates, and ρ and ν are the density and kinematic viscosity, both of which are assumed constant.

For air flow in large rooms, typical values of the dimensionless Reynolds number $Re = UL/\nu$, where U is a characteristic flow velocity ($\sim 1\,m/s$) and L is a characteristic length scale ($\sim 10m$), are quite large. In particular, the kinematic viscosity of air at standard temperature and pressure is $\nu \sim 10^{-6}\,m^2/s$, which gives a value for the Reynolds number of $Re \sim 10^7$. In this regime, the flow is inherently unstable and

thus certain to exhibit turbulent behavior in the vicinity of walls and other obstacles. Hence, (3.1) and (3.2), short of direct numerical simulation, must be supplemented by an appropriate turbulence model.

Our approach to the problem follows the classical methodology of first decomposing the dependent variables into steady and fluctuating quantities, where the latter are not necessarily small. In particular, we define time-averaged (mean) and fluctuating quantities as $u_i = U_i + u_i'$ and $p = P + p'$, where $U_i = \overline{u}_i \equiv \lim_{\tau\to\infty} \int_{t_0}^{t_0+\tau} u_i\, dt/\tau$ and similarly for P. Substituting the definitions for u_i and p into (3.1) and (3.2) and performing the above time-averaging operation yields the well-known RANS equations given by

$$\frac{\partial U_i}{\partial x_i} = 0\,, \tag{3.3}$$

$$U_j \frac{\partial U_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial P}{\partial x_i} + \nu \frac{\partial^2 U_i}{\partial x_j \partial x_j} + \frac{1}{\rho}\frac{\partial \tau_{ij}}{\partial x_j}\,. \tag{3.4}$$

Here, the components τ_{ij} of the Reynolds stress tensor, which arise from the nonlinear terms in (3.2), are given by $\tau_{ij} = -\rho\,\overline{u_i' u_j'}$ (cf. [23]).

The closure of (3.3)–(3.4) for the mean quantities U_i and P require that additional relations be specified for the quadratic averages τ_{ij}. Although equations can be developed for these quantities, such equations generally introduce higher-order correlations (e.g., triple averages), thus giving rise to the well-known closure difficulty associated with turbulent flow modeling (cf. [23], [11], [27]). Alternatively, physically motivated assumptions regarding the relationship of τ_{ij} to the mean-flow variables can be introduced, and it is a variant of this approach that we use here. In particular, algebraic relationships (so-called zero-equation turbulence models) are introduced for the dominant components of the turbulent stress tensor based on the classical eddy-viscosity/mixing-length concept for turbulent shear- and boundary-layer flows.

For an essentially two-dimensional parallel mean flow [e.g., $U_2 \sim 0$, $U_1 \sim U_1(x_2)$], the standard analogy with laminar flow, originally postulated by Boussinesq [10], is to assume that $\tau_{12} = \tau_{21}$ can be expressed as

$$\tau_{12} = \tau_{21} = \rho\nu_t \frac{\partial U_1}{\partial x_2}\,, \tag{3.5}$$

where ν_t is the kinematic eddy viscosity. In contrast to the kinematic laminar viscosity ν, however, it is generally an unacceptably poor approximation to simply regard ν_t as a constant parameter (cf. [21]). For example, it is clear by definition that τ_{12} should approach zero at a no-slip and/or no-penetration boundary, but this is necessarily true only if ν_t vanishes there. Hence, it is customary to appeal to a mixing-length argument originally put forth by Prandtl [22] and to further express ν_t in terms of a mixing length ℓ as

$$\nu_t = \ell^2 \left|\frac{\partial U_1}{\partial x_2}\right|\,, \tag{3.6}$$

where ℓ is also a function of position that must approach zero near a wall.

For boundary-layer flows, an analysis of the turbulent boundary layer indicates that its structure consists of an inner viscous sublayer in which laminar viscous effects are important and the Reynolds stress is negligible, an outer defect layer in which the effects of ν are small but those due to ν_t are significant, and an intermediate overlap,

or matching, region in which both kinematic viscosities ν_t and ν are nonnegligible. It is in the latter regime that the mean-flow velocity varies logarithmically with distance x_2 from the wall, giving rise to the well-known "law of the wall." One modern-day uniformly valid expression for ℓ is given by

$$\frac{\ell}{\delta} = \lambda \left[1 - \exp\left(-\frac{x_2}{A}\right)\right] \tanh\left(\frac{\kappa}{\lambda} \cdot \frac{x_2}{\delta}\right) \tag{3.7}$$

(see [20]), where δ is the local turbulent boundary-layer thickness, A is a damping constant, and κ and λ are fitted constants which, for smooth walls and no mass transfer, are found to have the approximate values $\kappa = 0.41$, $\lambda = 0.085$, and $A = 26\nu/u_\tau$, where $u_\tau = (\tau_w/\rho)^{1/2}$ is the friction velocity expressed in terms of a specified wall stress τ_w. It is observed that ℓ/δ approaches zero in either a linear or quadratic fashion (depending on whether or not the damping factor is present) as $x_2 \to 0$, and approaches a constant value as x_2 exceeds the boundary-layer thickness.

In the present work, we propose an extension of (3.7), applicable to multidimensional wall-bounded flows, as follows. However, we first remark that since the boundaries in the present problem are not necessarily smooth (due to carpeting, acoustic tiles, structural protrusions, chairs, desks, counters, people, etc.), neither the laminar viscosity ν nor the above quoted turbulence parameters are regarded as given. Rather, they should ideally be fitted to actual data. Second, while the functional form given by (3.7) is retained to describe the turbulent boundary layers, an appropriate generalization must be given to account for multiple boundaries (e.g., both a floor and a ceiling) and the fact that the local mean flow is not necessarily parallel.

In generalizing the classical mixing-length model to the present two-dimensional problem, we assume that the dominant effects of turbulence are felt in the effective turbulent boundary layers in the vicinity of walls, floors, and ceilings. Consequently, it is assumed that the shear components of the Reynolds stress tensor, τ_{ij}, $i \neq j$, dominate the normal components $\tau_{\hat{i}\hat{i}}$. Hence, we define the shear components of the stress tensor $\tau^s_{ij} = \tau_{ij}(1 - \delta_{\hat{i}\hat{j}})$, where δ_{ij} is the Kronecker delta and hatted indices imply no summation, and approximate τ_{ij} with τ^s_{ij} in (3.4). Restricting further consideration to two dimensions, we then generalize (3.5) and (3.6) by representing the only shear component $\tau_{12} = \tau_{21} = -\rho\overline{u_1{}'u_2{}'}$ as

$$\frac{1}{\rho}\tau_{12} = \nu^t_{12}\frac{\partial U_1}{\partial x_2} + \nu^t_{21}\frac{\partial U_2}{\partial x_1} = \nu^t_{ij}\frac{\partial U_i}{\partial x_j}(1 - \delta_{ij})\,, \tag{3.8}$$

where

$$\nu^t_{ij} = \ell^2_{\hat{j}}\left|\frac{\partial U_i}{\partial x_j}\right|, \quad i \neq j\,, \tag{3.9}$$

with the mixing length $\ell_{\hat{j}} = \ell_{\hat{j}}(x_j)$ defined in a manner consistent with (3.7). In particular, we adopt the functional form of (3.7) for each $\ell_{\hat{j}}$, replacing the coordinate x_2 with a distance variable ℓ^* that represents the distance from the nearest *wall* boundary. The latter is calculated by first solving the eikonal equation, as described in section 3.3. For simplicity, we take the turbulence parameters δ, λ, κ, and A as constants independent of $\hat{j}$, so that in fact

$$\ell_1 = \ell_2 \equiv \ell = \delta\lambda\left[1 - \exp(-\ell^*/A)\right]\tanh\left[(\kappa/\delta\lambda)\ell^*\right]\,. \tag{3.10}$$

We note that other multidimensional generalizations are possible (cf. [14], [27]); however, the present flow-decomposition approach is appealing in that it facilitates direct use of generally accepted functional forms for parallel flows, such as (3.7).

3.2. Implementation of the flow-field model in Sundance. The use of the symbolic PDE package Sundance requires a weak form of the problem, which is then solved iteratively from an appropriately defined linearized form to determine the solution of the nonlinear flow field. While Sundance can generate such a scheme internally, we choose instead to specify this aspect of the solution procedure explicitly. We thus first derive the exact weak form of the nonlinear problem, and then prescribe an efficient functional iteration scheme for solving, via Sundance, a convergent sequence of appropriately linearized approximations.

The weak formulation of the flow-field problem is derived as follows. We first rewrite (3.3) and (3.4) in vector form as

$$\overrightarrow{\nabla} \cdot \overrightarrow{U} = 0\,, \tag{3.11}$$

$$\big(\overrightarrow{U} \cdot \overrightarrow{\nabla}\big)\overrightarrow{U} + \frac{1}{\rho}\overrightarrow{\nabla} P - \nu\nabla^2\overrightarrow{U} - \frac{1}{\rho}\big(\underline{\underline{\tau}} \cdot \overleftarrow{\nabla}\big) = 0\,, \tag{3.12}$$

where a double underlined quantity denotes a tensor (e.g., the Reynolds stress tensor $\underline{\underline{\tau}}$) and the arrow over the gradient operator denotes the location (left or right) of the object on which the corresponding operation is to be applied. Introducing test functions q and $\overrightarrow{v}$, we multiply (3.11) by q, (3.12) by $\overrightarrow{v}$, and integrate over the space Ω to obtain the weak forms

$$\int_\Omega q\overrightarrow{\nabla} \cdot \overrightarrow{U}\, d\Omega = 0\,, \tag{3.13}$$

$$\int_\Omega \overrightarrow{v} \cdot \Big[\big(\overrightarrow{U} \cdot \overrightarrow{\nabla}\big)\overrightarrow{U} + \rho^{-1}\overrightarrow{\nabla} P - \nu\nabla^2\overrightarrow{U} - \rho^{-1}\big(\underline{\underline{\tau}} \cdot \overleftarrow{\nabla}\big)\Big]\, d\Omega = 0\,. \tag{3.14}$$

Equation (3.13) is satisfactory in its present state, but in order to eliminate second derivatives (Sundance requires at most first derivatives of the variables and test functions in the integrands) and to otherwise simplify (using boundary conditions) the weak form (3.14), we manipulate the various terms in (3.14) as follows. First, though not essential, we write

$$\begin{aligned}\int_\Omega \big(\overrightarrow{v} \cdot \overrightarrow{\nabla}\big) P\, d\Omega &= \int_\Omega \Big[\overrightarrow{\nabla} \cdot \big(\overrightarrow{v} P\big) - P\big(\overrightarrow{\nabla} \cdot \overrightarrow{v}\big)\Big]\, d\Omega \\ &= \int_{\partial\Omega} P\big(\overrightarrow{v} \cdot \overrightarrow{n}\big)\, d(\partial\Omega) - \int_\Omega P\big(\overrightarrow{\nabla} \cdot \overrightarrow{v}\big)\, d\Omega,\end{aligned} \tag{3.15}$$

where $\overrightarrow{n}$ is the unit normal and the last term introduces a symmetry with respect to (3.11). Second, we remove explicit second derivatives according to

$$\begin{aligned}\int_\Omega \overrightarrow{v} \cdot \big(\nabla^2\overrightarrow{U}\big)\, d\Omega &= \int_\Omega v_i\partial_j\partial_j U_i\, d\Omega \\ &= \int_\Omega \big[\partial_j(v_i\partial_j U_i) - (\partial_j v_i)(\partial_j U_i)\big]\, d\Omega \\ &= \int_{\partial\Omega} v_i\big(\overrightarrow{\nabla} U_i\big) \cdot \overrightarrow{n}\, d(\partial\Omega) - \int_\Omega \big(\overrightarrow{\nabla} v_i\big) \cdot \big(\overrightarrow{\nabla} U_i\big)\, d\Omega \\ &= \int_{\partial\Omega} \overrightarrow{v} \cdot \big(\overrightarrow{U}\overleftarrow{\nabla}\big) \cdot \overrightarrow{n}\, d(\partial\Omega) - \int_\Omega \big(\overrightarrow{v}\overleftarrow{\nabla}\big) : \big(\overrightarrow{U}\overleftarrow{\nabla}\big)\, d\Omega,\end{aligned} \tag{3.16}$$

where repeated indices imply summation, $\partial_j \equiv \partial/\partial x_j$, and the tensor contraction operator is defined by $\underline{\underline{a}} : \underline{\underline{b}} = a_{ij}b_{ij}$. Finally, since the Reynolds stress $\underline{\underline{\tau}}$ involves first

derivatives of the flow variables, which would thus lead to the appearance of second derivatives in (3.14), we rewrite the last term in (3.14) as

$$\begin{aligned}\int_\Omega \overrightarrow{v}\cdot\left(\underline{\underline{\tau}}\cdot\overleftarrow{\nabla}\right)d\Omega &= \int_\Omega v_i\partial_j\tau_{ij}\,d\Omega \\ &= \int_\Omega \left[\partial_j(v_i\tau_{ij}) - \tau_{ij}(\partial_j v_i)\right]d\Omega \\ &= \int_{\partial\Omega}\overrightarrow{v}\cdot\underline{\underline{\tau}}\cdot\overrightarrow{n}\,d(\partial\Omega) - \int_\Omega \underline{\underline{\tau}} : \left(\overrightarrow{v}\overleftarrow{\nabla}\right)d\Omega.\end{aligned} \tag{3.17}$$

Substituting (3.15)–(3.17) into (3.14), the weak form of momentum conservation thus becomes

$$\begin{aligned}\int_\Omega \Big[\overrightarrow{v}\cdot\left(\overrightarrow{U}\cdot\overleftarrow{\nabla}\right)\overrightarrow{U} - \rho^{-1}P\left(\overleftarrow{\nabla}\cdot\overrightarrow{v}\right) + \nu\left(\overrightarrow{v}\overleftarrow{\nabla}\right) : \left(\overrightarrow{U}\overleftarrow{\nabla}\right) + \rho^{-1}\,\underline{\underline{\tau}} : \left(\overrightarrow{v}\overleftarrow{\nabla}\right)\Big]\,d\Omega \\ + \int_{\partial\Omega}\left[\rho^{-1}P\left(\overrightarrow{v}\cdot\overrightarrow{n}\right) - \nu\,\overrightarrow{v}\cdot\left(\overrightarrow{U}\overleftarrow{\nabla}\right)\cdot\overrightarrow{n} - \rho^{-1}\,\overrightarrow{v}\cdot\underline{\underline{\tau}}\cdot\overrightarrow{n}\right]d(\partial\Omega) = 0.\end{aligned} \tag{3.18}$$

The boundary integral in (3.18) can be simplified further by considering the boundary conditions (at inlet(s), outlet(s), and walls (including floor and ceilings)) for the problem of interest. At outlets, denoted by $\partial\Omega_o$, we assume no forcing, which is expressed as

$$\left[\rho^{-1}P\overrightarrow{n} - \left(\overrightarrow{U}\overleftarrow{\nabla}\right)\cdot\overrightarrow{n} - \rho^{-1}\,\underline{\underline{\tau}}\cdot\overrightarrow{n}\right]_{\partial\Omega_o} = 0\,. \tag{3.19}$$

Consequently, condition (3.19) implies that the boundary integral in (3.18) vanishes on an outlet boundary $\partial\Omega_o$. At an inlet, denoted by $\partial\Omega_I$, or at walls, denoted by $\partial\Omega_w$, the boundary conditions for the present problem are given by $\overrightarrow{U} = \overrightarrow{U}_I$ and $\overrightarrow{U} = \overrightarrow{U}_w = 0$, respectively, where the latter corresponds to a no-slip, no-penetration condition at $\partial\Omega_w$. (It is also true, by definition, that the Reynolds stress tensor $\underline{\underline{\tau}} = 0$ on $\partial\Omega_w$.) However, since (3.19) involves only gradients of $\overrightarrow{U}$, we approximate these conditions as

$$-\left(\overrightarrow{U}\overleftarrow{\nabla}\right)\cdot\overrightarrow{n}\Big|_{\partial\Omega_{I,w}} = \epsilon^{-1}\left(\overrightarrow{U} - \overrightarrow{U}_{I,w}\right)_{\partial\Omega_{I,w}}, \quad \epsilon \ll 1\,, \tag{3.20}$$

which implies $\left|\left|\overrightarrow{U} - \overrightarrow{U}_{I,w}\right|\right| \to 0$ on $\partial\Omega_{I,w}$ as $\epsilon \to 0$. Substituting (3.19) and (3.20) into (3.18) and taking the limit $\epsilon \to 0$ thus allows us, after invoking the assumption that the discrete basis functions used to represent the variables are nodal [19], to replace the boundary integral in the latter with a simple penalty term according to

$$\begin{aligned}\int_{\partial\Omega}\left[\rho^{-1}P\left(\overrightarrow{v}\cdot\overrightarrow{n}\right) - \nu\,\overrightarrow{v}\cdot\left(\overrightarrow{U}\overleftarrow{\nabla}\right)\cdot\overrightarrow{n} - \rho^{-1}\,\overrightarrow{v}\cdot\underline{\underline{\tau}}\cdot\overrightarrow{n}\right]d(\partial\Omega) \\ \sim \int_{\partial\Omega}\overrightarrow{v}\cdot\left(\overrightarrow{U} - \overrightarrow{U}_{I,w}\right)d(\partial\Omega).\end{aligned} \tag{3.21}$$

Hence, the final weak form of momentum conservation to be used in the present study is given by

$$\begin{aligned}\int_\Omega \Big[\overrightarrow{v}\cdot\left(\overrightarrow{U}\cdot\overleftarrow{\nabla}\right)\overrightarrow{U} - \rho^{-1}P\left(\overleftarrow{\nabla}\cdot\overrightarrow{v}\right) + \nu\left(\overrightarrow{v}\overleftarrow{\nabla}\right) : \left(\overrightarrow{U}\overleftarrow{\nabla}\right) + \rho^{-1}\,\underline{\underline{\tau}} : \left(\overrightarrow{v}\overleftarrow{\nabla}\right)\Big]\,d\Omega \\ + \int_{\partial\Omega_{I,w}}\overrightarrow{v}\cdot\left(\overrightarrow{U} - \overrightarrow{U}_{I,w}\right)d(\partial\Omega) = 0,\end{aligned} \tag{3.22}$$

where the (shear) components of $\underline{\underline{\tau}} \approx \underline{\underline{\tau}}^s$ are given by (3.8)–(3.10).

We observe that (3.22) is nonlinear with respect to $\overrightarrow{U}$ through the appearance of the factors $\big(\overrightarrow{U}\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}$ and the Reynolds stress tensor $\underline{\underline{\tau}}$, where, from (3.8) and (3.9), the latter consists of the shear components $\tau_{12}=\tau_{21}=\rho\ell_1^2\big|\partial U_2/\partial x_1\big|(\partial U_2/\partial x_1)+\rho\ell_2^2|\partial U_1/\partial x_2|(\partial U_1/\partial x_2)$. Consequently, since we ultimately require a weak form that is linear with respect to the dependent variables (as well as the test functions), we solve the coupled system (3.13) and (3.22) by an iterative approach. In particular, the nonlinear terms are formally linearized and functional iteration on the resultant linear problem is employed to obtain the solution to the original nonlinear problem. Thus, if the solution to the kth iterate $\overrightarrow{U}_k$ is known, the next iterate $\overrightarrow{U}_{k+1}$ is determined by solving a linear problem obtained from the original nonlinear equations by linearizing nonlinear terms about $\overrightarrow{U}_k$. In particular, making the a priori assumption that $|\overrightarrow{U}_{k+1}-\overrightarrow{U}_k|$ is sufficiently small, we have

$$
\begin{aligned}
(3.23)\qquad \big(\overrightarrow{U}_{k+1}\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_{k+1} &= \Big\{\big[\overrightarrow{U}_k+\big(\overrightarrow{U}_{k+1}-\overrightarrow{U}_k\big)\big]\cdot\overrightarrow{\nabla}\Big\}\big[\overrightarrow{U}_k+\big(\overrightarrow{U}_{k+1}-\overrightarrow{U}_k\big)\big]\\
&\approx \big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_k+\Big[\big(\overrightarrow{U}_{k+1}-\overrightarrow{U}_k\big)\cdot\overrightarrow{\nabla}\Big]\overrightarrow{U}_k\\
&\quad+\big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\big(\overrightarrow{U}_{k+1}-\overrightarrow{U}_k\big)\\
&= \big(\overrightarrow{U}_{k+1}\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_k+\big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_{k+1}-\big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_k
\end{aligned}
$$

and, denoting $\partial U_i/\partial x_j$ by $U_{i,j}$,

$$
\begin{aligned}
(3.24)\ \big|U_{i,j}^{(k+1)}\big|\,U_{i,j}^{(k+1)} &= \Big[U_{i,j}^{(k+1)}U_{i,j}^{(k+1)}\Big]^{1/2}U_{i,j}^{(k+1)}\\
&= \Big\{\big[U_{i,j}^{(k)}+\big(U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big)\big]\big[U_{i,j}^{(k)}+\big(U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big)\big]\Big\}^{1/2}\\
&\qquad\times\big[U_{i,j}^{(k)}+\big(U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big)\big]\\
&= \Big\{U_{i,j}^{(k)}U_{i,j}^{(k)}+2\big(U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big)U_{i,j}^{(k)}+\big[U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big]^2\Big\}^{1/2}\\
&\qquad\times\big[U_{i,j}^{(k)}+\big(U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big)\big]\\
&\approx \Big[U_{i,j}^{(k)}U_{i,j}^{(k)}\Big]^{1/2}\Big\{1+\big[U_{i,j}^{(k)}\big]^{-1}\big[U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big]\Big\}\\
&\qquad\times\Big\{U_{i,j}^{(k)}+\big[U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\big]\Big\}\\
&\approx \Big[U_{i,j}^{(k)}U_{i,j}^{(k)}\Big]^{1/2}\Big[2U_{i,j}^{(k+1)}-U_{i,j}^{(k)}\Big].
\end{aligned}
$$

Using these linearized representations in (3.22), we thus arrive at a functional iteration scheme that computes the successive approximations $\overrightarrow{U}_{k+1}$ and P_{k+1} in terms of initial guesses $\overrightarrow{U}_k$ and P_k according to

$$
(3.25)\qquad \int_\Omega q\,\overrightarrow{\nabla}\cdot\overrightarrow{U}_{k+1}\,d\Omega=0\,,
$$

$$
\begin{aligned}
(3.26)\qquad \int_\Omega\Big\{\overrightarrow{v}\cdot\big[\big(\overrightarrow{U}_{k+1}\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_k+\big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_{k+1}-\big(\overrightarrow{U}_k\cdot\overrightarrow{\nabla}\big)\overrightarrow{U}_k\big]\\
-\rho^{-1}P_{k+1}\big(\overrightarrow{\nabla}\cdot\overrightarrow{v}\big)+\nu\big(\overrightarrow{v}\overleftarrow{\nabla}\big):\big(\overrightarrow{U}_{k+1}\overleftarrow{\nabla}\big)+\rho^{-1}\,\underline{\underline{\tau}}^{\,l}:\big(\overrightarrow{v}\overleftarrow{\nabla}\big)\Big\}\,d\Omega\\
+\int_{\partial\Omega_{I,w}}\overrightarrow{v}\cdot\big(\overrightarrow{U}-\overrightarrow{U}_{I,w}\big)\,d(\partial\Omega)\;=\;0,
\end{aligned}
$$

where $\underline{\underline{\tau}}^l$, whose components are given by $\tau^l_{ij} = \rho\big[U^{(k)}_{i,j}U^{(k)}_{i,j}\big]^{1/2}\big[2U^{(k+1)}_{i,j} - U^{(k)}_{i,j}\big](1 - \delta_{\hat{i}\hat{j}})$, is the linearized form of $\underline{\underline{\tau}}$ based on (3.24). Equation (3.26) is linear with respect to the unknown function $\overrightarrow{U}_{k+1}$ and can be handled directly by Sundance.

The above sequence of approximations is expected to be convergent, provided the kth iterate is a sufficiently good approximation to the actual solution of the nonlinear problem. In practice, this generally requires that the iteration scheme defined by (3.25) and (3.26) be embedded in an outer iterative loop with respect to increasing values of a suitably defined Reynolds number U^*L^*/ν, where L^* and U^* are appropriately defined length and time scales. Indeed, for a sufficiently small initial value of the Reynolds number, the linear terms dominate and convergence is therefore more likely to be achieved in that case. The resulting converged solution for such a given Reynolds number then provides a good starting guess for the next sequence of iterations at a modestly larger value of that parameter, and so forth. It is also found, consistent with the need to resolve boundary layers and other finer aspects of the flow field, that the ability to achieve convergence at a given Reynolds number depends on the discretization (mesh). In particular, larger Reynolds numbers are generally found to require finer discretizations, especially in the vicinity of boundaries, independent of the goodness of the previous iterate with respect to the true solution.

3.3. The eikonal equation and its regularization. The turbulence model described in section 3.1 requires knowing the wall distance ℓ^* introduced in the expression (3.10) for the mixing length ℓ. The wall distance function can, in principle, be computed exactly given knowledge of the geometry of the walls; however, this computation is tedious and must be repeated for each new geometry considered. To simplify and automate the computation of ℓ^*, we use the eikonal equation of geometrical optics (e.g., [9]) which, with appropriate boundary conditions, has the wall distance ℓ^* as a solution. We can thus bypass tedious computational geometry and obtain the wall function as the solution of a PDE. This additional PDE, with regularization for numerical stability, is easily incorporated into our numerical algorithm and is described in detail in the appendix.

3.4. Pressure stabilization. It is well known that representing velocity and pressure with basis functions of the same order tends to be unstable (cf. [15]). Consequently, various stabilization schemes have been proposed to allow these variables to be represented with the same set of basis functions. One popular approach is to augment the continuity equation with a (small) term proportional to the Laplacian of pressure according to

$$\overrightarrow{\nabla} \cdot \overrightarrow{U} = \beta h^2 \nabla^2 P\,, \tag{3.27}$$

where h is the linear dimension (diameter) of the finite element discretization and β is an optimally chosen small parameter (cf. [15]). Aside from allowing equal-order interpolants, the added term has the positive effect of removing the indefiniteness of the discretized linear system and smoothing out numerical oscillations in the pressure variable.

Multiplication of (3.27) by the test function q followed by an integration over the domain Ω then leads to the weak form

$$\int_\Omega \Big[q\overrightarrow{\nabla}\cdot\overrightarrow{U} + \beta h^2(\overrightarrow{\nabla}q)\cdot(\overrightarrow{\nabla}P)\Big]\,d\Omega - \int_{\partial\Omega}\beta h^2(q\overrightarrow{\nabla}P)\cdot\overrightarrow{n}\;d(\partial\Omega) = 0\,, \tag{3.28}$$

where we have used the identity $q\nabla^2 P = \overrightarrow{\nabla}\cdot(q\overrightarrow{\nabla}P) - (\overrightarrow{\nabla}q)\cdot(\overrightarrow{\nabla}P)$ and applied the divergence theorem to obtain the form (3.28). Dropping the boundary term, which

implies that we are actually only regularizing the weak form (3.28) rather than (3.27), thus leads to

$$\int_\Omega \left[q\overrightarrow{\nabla}\cdot\overrightarrow{U} + \beta h^2 (\overrightarrow{\nabla} q)\cdot(\overrightarrow{\nabla} P)\right] d\Omega = 0 \tag{3.29}$$

and

$$\int_\Omega \left[q\overrightarrow{\nabla}\cdot\overrightarrow{U}_{k+1} + \beta h^2 (\overrightarrow{\nabla} q)\cdot(\overrightarrow{\nabla} P_{k+1})\right] d\Omega = 0 \tag{3.30}$$

in place of (3.13) and (3.25), respectively.

4. The optimization problem. In this section we consider the steady-state transport of the toxin in the flow field developed in the preceding section. We thus make the implicit assumption that the toxin concentration is insufficient to affect the flow field itself, but that the transport influences of the flow clearly play a key role in determining the distribution of the toxin. After first formulating the toxin-transport model, the optimization problem is then constructed so as to recover the source location(s) from specific concentration data, where the latter consist of readings obtained from sensors placed strategically throughout the building. Prior to that phase of the calculation, we consider several possible optimization formulations before settling on the one used in our numerical experiments.

4.1. The toxin-transport model. Given the time-averaged flow field U calculated in section 3, we can write the corresponding time-averaged continuity equation describing the transport of the toxin as

$$k\nabla^2 c - \big(U\cdot\overrightarrow{\nabla}\big)c + \overrightarrow{\nabla}\cdot\overrightarrow{\mathcal{J}} + s = 0\,, \tag{4.1}$$

where $c(\overrightarrow{x})$ and $s(\overrightarrow{x})$ are, respectively, the (time-averaged) concentration and source fields at a point $\overrightarrow{x}\in\Omega$, k is the binary mass diffusivity (assumed constant) of the toxin with respect to the mixture, and $\overrightarrow{\mathcal{J}}$ is the turbulent mass-flux vector whose components are defined as $\mathcal{J}_i = -\overline{u_i' c'}$. The derivation of an expression for $\mathcal{J}$ in terms of time-averaged quantities follows in an analogous fashion the derivation of the expression for the Reynolds stress tensor in section 3.1. In particular, by analogy with Fick's law of diffusion, it is logical to write, at least for nearly parallel flows $\overrightarrow{U}\sim\big(U_1(x_2),0\big)$,

$$\overrightarrow{\mathcal{J}}\sim(0,\mathcal{J}_2)\,,\quad \mathcal{J}_2 = k^t\frac{\partial c}{\partial x_2}\,,\quad k^t = \ell^2\left|\frac{\partial U_1}{\partial x_2}\right|\,, \tag{4.2}$$

where k^t is the turbulent, or eddy, diffusivity and ℓ is the same mixing length that was defined by (3.6) and (3.7) (cf. [3]). This expression may be extended to multi-dimensional flows using reasoning somewhat similar to that which led to (3.8) and (3.9). Hence, we define

$$\mathcal{J}_j = k^t_{\hat{j}}\frac{\partial c}{\partial x_j}\,,\quad k^t_{\hat{j}} = \ell^2_{\hat{j}}\left|\frac{\partial U_i}{\partial x_j}\right|\,,\quad i\neq j\,, \tag{4.3}$$

where the $\ell_{\hat{j}}$ are the same as those introduced in (3.9) and, for our present purposes, given by the single expression for $\ell_{\hat{j}}\equiv\ell$ in (3.10).

As in the flow-field problem, a corresponding reduction of the weak form of the toxin continuity equation (4.1) is obtained by first multiplying that equation by a scalar test function r and integrating. This gives

$$\int_\Omega r\left[(\overrightarrow{U}\cdot\overrightarrow{\nabla})c - k\nabla^2 c - \overrightarrow{\nabla}\cdot\overrightarrow{\mathcal{J}} - s\right]\,d\Omega = 0\,, \tag{4.4}$$

where the components $\mathcal{J}_j$ of $\overrightarrow{\mathcal{J}}$ are given in terms of $\partial c/\partial x_j$ according to (4.3). As in the case of the Navier–Stokes equations, we manipulate the individual terms appearing in (4.4) so as to eliminate second derivatives. In particular, by analogy with (3.16), we have

$$\begin{aligned}\int_\Omega r\nabla^2 c\,d\Omega &= \int_\Omega r\partial_j\partial_j c\,d\Omega\\ &= \int_\Omega \left[\partial_j(r\partial_j c) - (\partial_j r)(\partial_j c)\right]\,d\Omega\\ &= \int_{\partial\Omega} r\left(\overrightarrow{\nabla}c\right)\cdot\overrightarrow{n}\;d(\partial\Omega) - \int_\Omega \left(\overrightarrow{\nabla}r\right)\cdot\left(\overrightarrow{\nabla}c\right)d\Omega\,,\end{aligned} \tag{4.5}$$

and, since $\overrightarrow{\mathcal{J}}^i$ depends on derivatives of c, we also write, analogous to (3.17),

$$\begin{aligned}\int_\Omega r\overrightarrow{\nabla}\cdot\overrightarrow{\mathcal{J}}\,d\Omega &= \int_\Omega \left[\overrightarrow{\nabla}\cdot\left(r\overrightarrow{\mathcal{J}}\right) - \overrightarrow{\mathcal{J}}\cdot\left(\overrightarrow{\nabla}r\right)\right]\,d\Omega\\ &= \int_{\partial\Omega} r\overrightarrow{\mathcal{J}}\cdot\overrightarrow{n}\;d(\partial\Omega) - \int_\Omega \overrightarrow{\mathcal{J}}\cdot\left(\overrightarrow{\nabla}r\right)d\Omega.\end{aligned} \tag{4.6}$$

Finally, since $\overrightarrow{\nabla}\cdot\overrightarrow{U} = 0$,

$$\begin{aligned}\int_\Omega r\left(\overrightarrow{U}\cdot\overrightarrow{\nabla}\right)c\,d\Omega &= \int_\Omega r\overrightarrow{\nabla}\cdot\left(c\overrightarrow{U}\right)d\Omega\\ &= \int_\Omega \left[\overrightarrow{\nabla}\cdot\left(rc\overrightarrow{U}\right) - c\overrightarrow{U}\cdot\left(\overrightarrow{\nabla}r\right)\right]\,d\Omega\\ &= \int_{\partial\Omega}\left(rc\overrightarrow{U}\right)\cdot\overrightarrow{n}\;d(\partial\Omega) - \int_\Omega c\overrightarrow{U}\cdot\left(\overrightarrow{\nabla}r\right)d\Omega.\end{aligned} \tag{4.7}$$

Thus, in place of (4.4), the weak form of toxin mass conservation may be written as

$$\begin{aligned}&\int_\Omega \left\{\left(\overrightarrow{\nabla}r\right)\cdot\left[k\overrightarrow{\nabla}c - c\overrightarrow{U} + \overrightarrow{\mathcal{J}}\right] - rs\right\}\,d\Omega\\ &\qquad - \int_{\partial\Omega} r\left(k\overrightarrow{\nabla}c - c\overrightarrow{U} + \overrightarrow{\mathcal{J}}\right)\cdot\overrightarrow{n}\;d(\partial\Omega) = 0.\end{aligned} \tag{4.8}$$

As before, the boundary integral in (4.8) can be simplified by applying the boundary conditions. In particular, the assumption of no mass transport across the walls implies that the integrand in the boundary integral vanishes on $\partial\Omega_w$ since the mixing lengths ℓ_j, and hence $\overrightarrow{\mathcal{J}}$, also vanish there. At the inlet and outlet boundaries $\partial\Omega_I$ and $\partial\Omega_o$, we neglect the contribution of $\overrightarrow{\mathcal{J}}$ because the mixing length ℓ is likely to be small along most of such boundaries. In addition, at the inlet, we specify the incoming flux fraction (or concentration) of toxin α, which implies the set of conditions

$$\left[\left(c\overrightarrow{U}_I - k\overrightarrow{\nabla}c\right)\cdot\overrightarrow{n}\right]_{\partial\Omega_I} = -\alpha\overrightarrow{U}_I\cdot\overrightarrow{n}\,, \tag{4.9}$$

where $\overrightarrow{n}$ always denotes the outward-facing normal at the boundary. At the outflow boundary, we represent the boundary condition in the general form

$$\left[\left(\overrightarrow{\nabla} c\right) \cdot \overrightarrow{n} + \beta c\right]_{\partial\Omega_o} = 0\,, \tag{4.10}$$

where $\beta > 0$ is a loss coefficient; the choice $\beta = 0$ would correspond to a finite-boundary approximation if the actual outlet were at infinity. Applying these conditions to (4.8) then yields the final weak form of species mass conservation as

$$\begin{aligned}\int_\Omega \left\{\left(\overrightarrow{\nabla} r\right) \cdot \left[k\overrightarrow{\nabla} c - c\overrightarrow{U} + \overrightarrow{\mathcal{J}}\right] - rs\right\} d\Omega - \int_{\partial\Omega_I} r\alpha_i \overrightarrow{U}_I \cdot \overrightarrow{n}\; d(\partial\Omega) \\ + \int_{\partial\Omega_o} rc\left(\overrightarrow{U} \cdot \overrightarrow{n} + k\beta\right) d(\partial\Omega) = 0.\end{aligned} \tag{4.11}$$

We note that in the event that there is no incoming flux of toxin, $\alpha = 0$ and the first boundary integral in (4.11) vanishes.

4.2. The source-inversion optimization problem. We can now form the preliminary version of the optimization problem. Suppose we have data c_i^* that is the concentration reading from sensor i. Then we seek the source $s(x)$ that creates a calculated concentration field that best matches this data. That is, we define

$$f_p(s, c) = \frac{1}{2}\sum_{i=1}^{N_s} (c(x_i) - c_i^*)^2,$$

where N_s is the number of sources. This is the L_2 measure of the discrepancy. We then write the first version of the optimization problem as

$$\begin{aligned} &\underset{c,\,s}{\text{minimize}} \quad f_p(c, s) \\ &\text{subject to (4.11).}\end{aligned} \tag{4.12}$$

There are several points that need to be addressed before we have a problem that we can attempt to solve.

First, there are several ways to handle the source term in (4.11). One way is to assume a model for the sources. For example, we could assume a Gaussian model for source i, i.e.,

$$s_i(x) = \alpha_i e^{\beta_i (x - x_i)^2},$$

where α_i and β_i are constants and $x_i \in \Omega$ is the location. Then the source field is

$$s(x) = \sum_{i=1}^{S} s_i(x),$$

where S is the number of sources. Alternatively, we could consider source i to be a δ-function with a specified strength. In both of these cases, the number of sources is not known in advance and must be determined as part of the source inversion problem. Also, it is clear that some of the parameters enter the source term nonlinearly. The advantage of these models, however, is that there is a small number of parameters to estimate.

Another way to proceed is to leave $s(x)$ as simply a function over all of Ω to be determined. The two major advantages of this approach are that the function s enters (4.11) linearly and there is no need to know in advance the number of sources. The disadvantage is that the number of parameters to be estimated is the number of nodes, a potentially large number. We believe, however, that the advantages of this approach outweigh the disadvantages and we thus choose this form for the source term.

Second, given the form of the source term, there is a need to regularize the problem. As posed, the problem is underdetermined; there are many source functions that will make $f_p = 0$, but they will be excessively oscillatory. We therefore need to smooth the solution since we expect s to be essentially zero except where real sources exist. Thus we use standard Tikhonov regularization, i.e., we modify the objective function f_p to be of the form

$$f(c, s) = f_p + \frac{1}{2}\sigma \int_\Omega (\nabla s)^2.$$

Our modified form of the optimization problem becomes

$$\begin{aligned} &\underset{c,\, s}{\text{minimize}} \quad f(c, s) \\ &\text{subject to (4.11).} \end{aligned} \tag{4.13}$$

As posed, problem (4.13) is an equality-constrained quadratic programming problem. It is well known that, when discretized, such quadratic programs (QPs) can be solved by solving the linear system that arises from writing the first order necessary, or KKT, conditions. We point out that Sundance allows for the creation of discrete functions defined on the mesh. Thus we can easily define the objective function $f(c, s)$ and then create the Lagrangian

$$L(c, s, \lambda) = f(c, s) + \int_\Omega \lambda h(c, s),$$

where λ is the Lagrange multiplier and $h(c, s)$ is the left hand side of (4.11). In Sundance we can define an expression that is the variation of $L(c, s, \lambda)$ with respect to its arguments, i.e., the first order conditions. We can then create a Sundance problem, specify a solver (and a preconditioner), and solve the system. This procedure takes fewer than 20 lines of code.

We need to consider, however, the possibility of adding additional constraints to problem (4.13). In particular, we know that both the source field and the concentration field must be nonnegative. In the case of (4.11), it is easy to see that if $s \geq 0$, then it follows that $c \geq 0$. Thus, the final form of the optimization problem that we consider is

$$\begin{aligned} &\underset{c,\, s}{\text{minimize}} \quad f(c, s) \\ &\text{subject to} \quad \begin{aligned} &(4.11) \\ &s \geq 0. \end{aligned} \end{aligned} \tag{4.14}$$

Sundance can also be used to create this problem. Let

$$a^{\mathrm{t}} x + \frac{1}{2} x^{\mathrm{t}} Q x \tag{4.15}$$

be the general form of a quadratic objective function, where $a \in \mathcal{R}^n$ and Q is an $(n \times n)$ symmetric matrix. We create a Sundance problem for the function given by $f(c, s)$. Then by getting the linear operator for this problem, we have the matrix Q, and by getting the right-hand side we have a. Similarly, we can then get the matrix and right-hand side associated with the Sundance problem corresponding to (4.11), thus obtaining the discretized linear equality constraints. It is then trivial in Trilinos to create the identity matrix (never actually formed) and vector of zeros corresponding to the constraints $s \geq 0$. These matrices and vectors can be passed to any appropriate QP solver.

We now make the following remarks about problem (4.14) that motivate our choice of QP solver:

1. Recall that we are not interested in high accuracy solutions.
2. With this formulation, there will be many near-active constraints, i.e., many points with very small, but positive, function values; such problems often create severe computational difficulties.
3. We expect that our formulation, which uses the Tikhonov regularization term, will tend to smear the constraints. Thus, we are not concerned with getting the correct active set.
4. Given that we do not care about getting the correct active set, we are certainly not interested in getting the Lagrange multipliers.
5. Since the equality constraint given by (4.11) will be a discretized PDE in the QP, we do not need to worry about satisfying these constraints to high accuracy.

The above observations lead us to consider the use of O3D to solve the inequality-constrained problem (4.14). O3D is a primal, interior-point method that can be controlled so that estimates of the multipliers are not computed. It operates on a QP with the objective function given by (4.15) and with only inequality constraints of the form

$$Ax + b \leq 0.$$

In essence, O3D, which stands for optimizing over three-dimensional subspaces, is an iterative method that at each iteration creates a three-dimensional subspace, solves the QP restricted to that subspace, and moves 99% of the distance to the boundary in the direction implied by the solution. The three directions, p_i, all satisfy a linear system of the form

$$\left(A^{\mathsf{t}} D^2 A + Q/\gamma\right) p_i = t_i, \qquad i = 1, 2, 3,$$

where

$$D = \operatorname{diag} 1/\left(Ax + b\right)_i,$$

γ is a scalar computed at each iteration, and t_i is an appropriate right-hand side. There are, of course, many other details; see [5] for a more complete description.

In the tests reported in the next section, we tried several formulations of the problem in an attempt to find an efficient strategy. The original strategy for handling equality constraints in O3D is to convert them into a pair of inequality constraints and then to form a "big M phase 1 problem." This problem has an artificial variable that is forced to zero as the solution draws near. In the limit, this forces the two inequalities corresponding to an equality constraint to become equal, thus satisfying

the equality constraint. Although this has often worked well in practice, it was not efficient enough for our purposes here; we thus looked for a more efficient formulation. Although not often recommended, the best formulation that we found was to create a penalty form of (4.14) so that we have a problem with only inequality constraints. This formulation allows us to control the tolerance to which the equality constraints will be satisfied. As noted above, it does not make sense to require satisfaction of the equality constraint to high accuracy since it is a finite element approximation to (4.11). The penalty form that we consider is given by

$$\begin{aligned} &\underset{c,\,s}{\text{minimize}} \quad f(c,s) + \frac{1}{2}\rho \left\| h(c,s) \right\|^2 \\ &\text{subject to } s \geq 0. \end{aligned} \tag{4.16}$$

We choose an increasing sequence ρ_i and solve (4.16) for $\rho_i,\ i = 1, \ldots,$ for a relaxed set of convergence criteria. After each solution, we check the value of $\|h(c,s)\|$. If the value is less than ϵ, where ϵ is a given tolerance, then we fix ρ at the current value and solve (4.16) to a tighter set of convergence criteria. We note that in this form it is easy to get a good interior starting approximation by solving problem (4.13) for s (by solving one linear system) and then modifying any value of $s \leq 0$ to be some small positive value. As reported in the next section, this allowed convergence to acceptable accuracy in a very small number of iterations.

5. Numerical results. To conduct our numerical tests, it was first necessary to solve the flow model developed in section 3. We therefore first describe a simple two-dimensional room with one inlet and one outlet and display the resulting flow field. After commenting on some of the realistic features of this field, we then show the source-inversion results that were obtained when sources and sensors were placed in the room.

5.1. Sample two-dimensional problem geometry and flow field. As indicated above, a simple two-dimensional room was constructed with an inlet and an outlet, as shown by the domain in Figure 1. The main part of the room is 15×20 units, with two small (2×2) inlet/outlet sections on the left and right, respectively. Various triangular meshes for this geometry were created with Shewchuk's mesh-generating package, Triangle [24], [25], with two layers of additional nodes specified along the boundaries to better resolve the (turbulent) boundary-layer structure in the vicinity of the walls. In all, the flow field used in the numerical calculations described below was generated by Sundance on a roughly 15,000-node mesh with approximately 31,000 triangles. This degree of mesh resolution enabled us to calculate, using the iterative procedure described in section 3, a flow field corresponding to fairly high Reynolds numbers (the source-inversion calculations described below corresponded to $Re = 10{,}000$). Generally speaking, the ability to iterate to increasingly large Reynolds numbers required increasingly finer meshes.

As suggested in section 3.2, the specific procedure we successfully employed, given a sufficiently fine mesh, was to start with zero initial data for the velocity and pressure fields and iterate to a converged solution for $Re = 100$. That solution was then used as initial data for the $Re = 200$ problem, and so forth, in increments of 100 in the Reynolds number. Since (3.24) represents a formal linearization of the flow-field model based on Taylor expansions of the nonlinear terms, roughly quadratic convergence was achieved at each step in the Reynolds-number loop. Typically, only four or five iterations were required to meet our fairly stringent convergence criteria, although

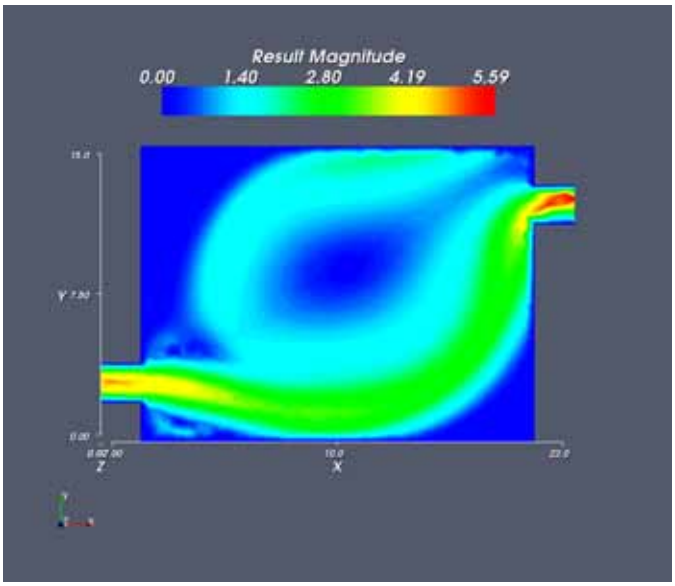

FIG. 1. *Calculated vector flow field for* $Re = 10{,}000$.

somewhat more (about 10) were usually needed on the first $Re = 100$ step due to our starting the iteration from zero initial data. A convergence failure at a particular Reynolds number generally implied an insufficiently fine mesh and could be remedied by recalculating on a finer mesh.

The inlet velocity profile was specified to be a Poiseuille flow with the peak inlet flow velocity at the center of the profile taken to be 4. The resulting vector flow field for $Re = 10{,}000$ is shown in Figure 1. It is readily observed that the main flow direction is from the inlet to the outlet. A more careful look, however, reveals several recirculation zones and other structures that are indicative of a realistic flow field.

5.2. Source-inversion tests. To test our source-inversion procedure we first generate some data on the two-dimensional example above. We do this by assuming a Gaussian source as described in section 4 and solving the forward problem, i.e., we solve (4.11). In particular, we take our sources to be

$$s(x) = \alpha_i e^{\beta_i (x - x_i)^2},$$

where $\alpha_i = 20$ and $\beta_i = 2$ for all i. We then specify the location for a set of sensors in the room, get the concentration c at each sensor location, and modify it by a random value of $\pm 5\%$. (The value of 5% was chosen in consultation with one of our Sandia National Laboratory colleagues who is working on the design of the sensors [12].) We investigated two patterns of the locations for the sensors. The first was a regular pattern of 9 sensor locations; the second was a hand-selected pattern of 30 locations, shown in Figure 2. This second pattern will be discussed further later.

The results for the 9-sensor source-inversion problems are as follows. First, it was sometimes possible to achieve reasonable predictions, even without using the inequality constraints, but it was very easy to pick source locations for which the prediction of both the number and location of the sources was poor. Without using inequality constraints, we often observed negative values of the source field, but even

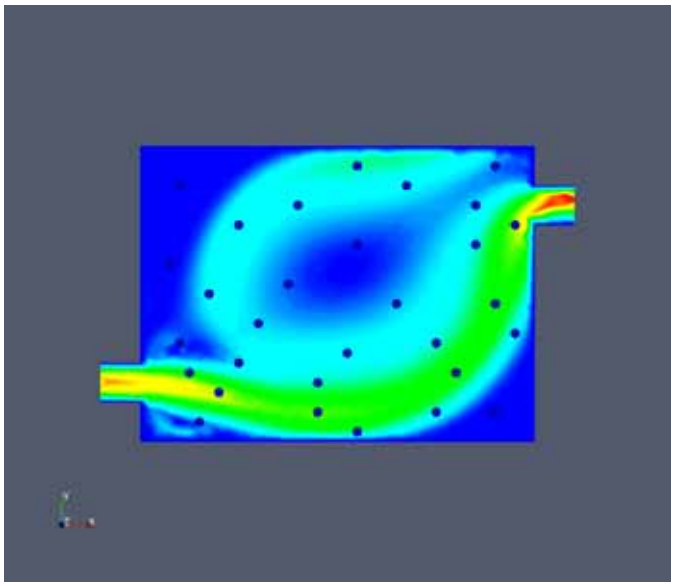

FIG. 2. *Flow field with* 30 *irregularly spaced sensors.*

when we used the inequality constraints, the results were still poor. We conclude from this that 9 sensors on a regular grid are not sufficient to reconstruct the sources for many source locations.

To determine an effective sensor arrangement, it is necessary to consider how the toxin is transported throughout the building and how this information is represented by the sensor readings. Here, we will look at two different cases. First, suppose a source is located in a region of the building in which the air flow is minimal, e.g., a corner. Over time the toxin will accumulate and any sensor in that region will exhibit a high concentration reading while all other sensors return comparatively low readings, assuming only one source exists. Thus, given at least one sensor in this region, any solution would exhibit a source in the proper area of the building. Since any sensor in this location will eventually have a comparatively high concentration reading, we require only one sensor to adequately determine sources in these types of regions. For the second case, suppose we have a source in the main stream of the flow. Instead of accumulating around the source location, the toxin will be distributed throughout the building as dictated by the flow field. Thus, if the main stream of the flow contains too few sensors, as in the 9-sensor arrangement, many different source locations could result in the same set of concentration readings. Therefore, in the main stream of the flow it is necessary to place sensors based on both the direction and the magnitude of the flow.

Using this knowledge, we picked sensor locations by hand by conducting many experiments. We make no claims, however, that these are the optimal sensor locations, a topic to which we return in section 6. With these locations, we were able to locate any pair of sources with acceptable accuracy.

We can draw several conclusions from these results:

1. Thirty sensors usually get acceptable accuracy.
2. Adding inequality constraints sometimes helps significantly by reducing nonphysical oscillations of the source field and is not computationally too

expensive. In fact, it generally took fewer than 10 iterations of O3D to solve the problem to acceptable accuracy.
3. Experience and knowledge of the flow field helps to predict locations of the sources.
4. As expected, because of our use of the Tikhonov regularization, the sources are smeared, especially for sources placed in the main stream of the flow. Nevertheless, the peaks in the computed source field correspond reasonably well with the true source locations.
5. We could do better with more sensors, but we want to restrict the number due to practical considerations: In a real three-dimensional building, we will not be able to have a high concentration of sensors with complete freedom of placement. On the other hand, the sources cannot be placed arbitrarily either.
6. The reconstructed concentration field is much better than the source field; this implies that we have an ill-conditioned problem.
7. We also ran these problems with 10% and 15% error with progressively worse, but not horrible, results.

5.3. Coarse meshes. In the results reported above, we showed that we were, indeed, able to reconstruct the source or sources with acceptable accuracy. In this section, we consider the issue of doing this rapidly. In particular, we discuss the possibility of using a coarser mesh to reconstruct the source field than was necessary to compute the flow field. Obviously, if a coarser meshes suffices, the time to solve the required linear systems will decrease.

Two possibilities present themselves for creating a coarser mesh. As noted above, we solved for the flow field on a fine, uniform mesh that was necessary to achieve convergence for the Reynolds number we desired. Thus, the first way to generate a coarser mesh is simply to regenerate the mesh with a larger value of the parameter that controls the size of the elements. Having done this, we can then interpolate the flow field from the solution on the fine mesh onto this coarser mesh and proceed with the source inversion. The second way to proceed is to try to generate a coarser mesh that is adapted to the flow field itself so that larger elements will appear in regions where the flow field is not changing rapidly and smaller elements where the flow field is rapidly varying. Fortunately, the meshing tool that we are using allows us to do this relatively easily. A few words about this tool are in order.

We have installed and used the bidirectional anisotropic mesh generator (BAMG) that is being developed at INRIA (see [16]). This code allows the generation of meshes over a two-dimensional domain by specifying a number of parameters. These parameters control properties such as maximum and minimun edge length, the maximum number of triangles, etc., to generate uniform meshes. More interestingly, it also allows the specification of a "metric" field and will attempt to adapt the mesh to that field. Thus, if we compute the flow field on a fine mesh and use this as the metric field, BAMG will produce a mesh that is adapted to this field. The other parameters are also used so that by specifying the minimum and maximum edge lengths along with this metric file, BAMG will produce a coarser mesh that is adapted to the flow field. BAMG will then compute a Lagrangian interpolation of the fine flow-field values onto the coarse meshes. BAMG is currently being extended to three-dimensions.

Using BAMG we were easily able to generate both the uniform and adapted coarse meshes necessary to run our source-inversion method on these problems. We were (pleasantly) surprised by the amount of coarsening that was possible without noticing

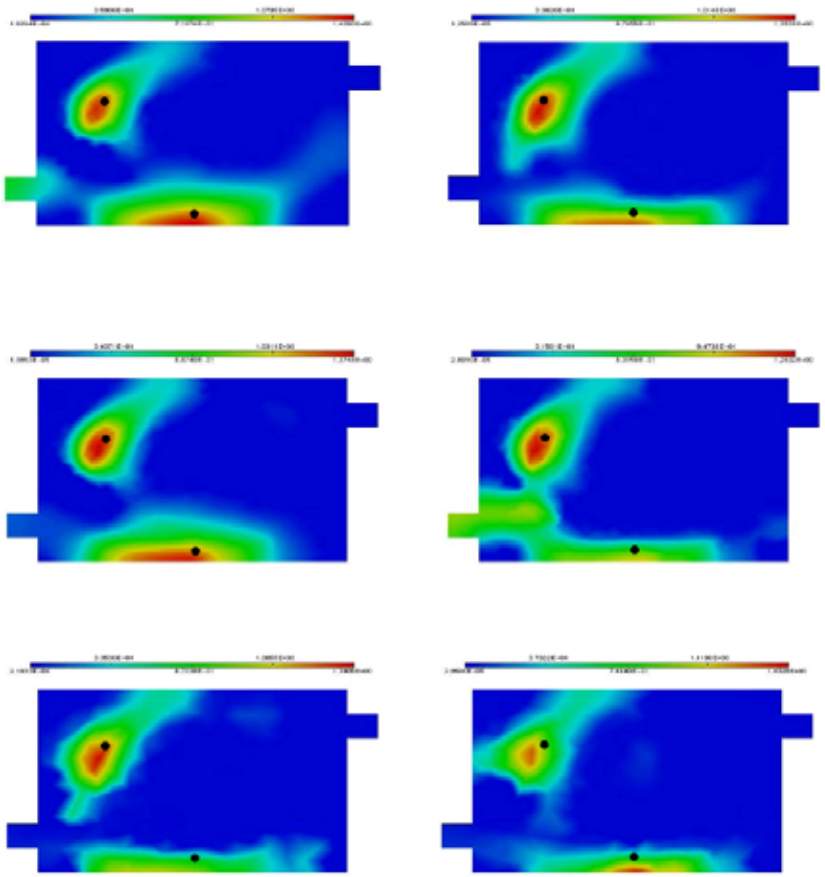

FIG. 3. *Source inversion with adaptive (left) and uniform (right) meshes. Top row,* 1471 *and* 1488 *triangles; middle row,* 1172 *and* 1196 *triangles; bottom row,* 474 *and* 476 *triangles. The true source locations are the points* $(10.0, 1.0)$ *and* $(4.5, 10.0)$.

any degradation in the accuracy of the reconstructed sources. Indeed, we could not see any difference in the predicted source locations by reducing the number of triangles from the original 31,000 to approximately 1500, a factor of over 20! Recall that a grid of 1500 triangles would not be nearly fine enough to compute the flow field. Some representative results are shown in Figures 3–7.

These figures show the results of using ≈ 1500 triangles, ≈ 1200 triangles, and ≈ 500 triangles for both adaptive and uniform meshes. The cases pictured generally show situations where there were some problems. In many of the cases not pictured here, we were able to obtain acceptable results to the lowest number of triangles. Overall, our experience suggests that the adaptive meshes yield better results for the coarsest meshes. There were certainly cases in which the adaptive meshes did not perform better. For example, Figure 5 shows that the adaptive mesh predicts two sources at the coarsest level, whereas the uniform mesh correctly predicts only one.

For some source configurations, it was not possible to get acceptable predictions at the coarsest levels for either mesh strategy; see, e.g., Figure 7. In this figure, we note that the adaptive mesh was able to achieve acceptable results using approximately

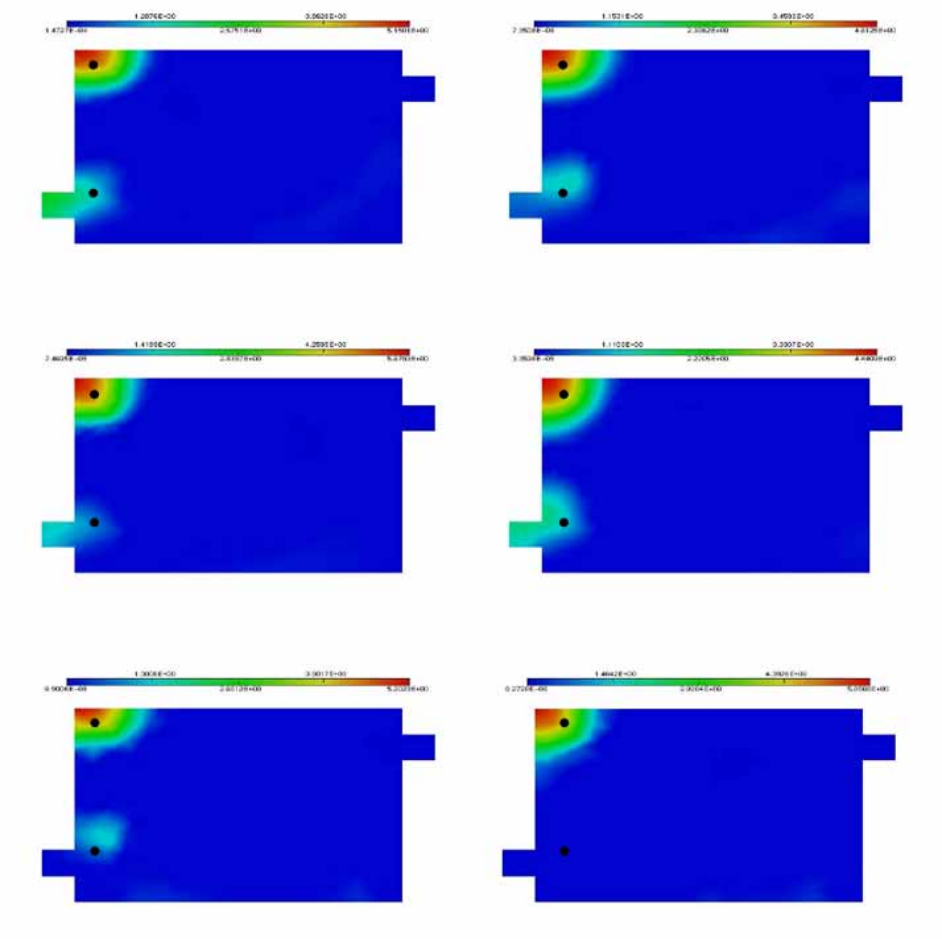

FIG. 4. *Source inversion with adaptive (left) and uniform (right) meshes. Top row,* 1471 *and* 1488 *triangles; middle row,* 1172 *and* 1196 *triangles; bottom row,* 474 *and* 476 *triangles. The true source locations are the points* $(1.0, 14.0)$ *and* $(1.0, 4.0)$.

1200 triangles, whereas the uniform mesh incorrectly predicts three sources. In Figure 6 we also see that the adaptive mesh performs better at the coarser levels.

We observe that sources placed in the main flow are much harder to locate due to the rapid dispersal of the agent in this region of the flow field. It is also true that the predicted strength in these regions is also much less than the true value. Again, we think that that the use of the Tikhonov regularization accounts for some of this.

Finally, we point out that the times required for doing the inversion are, as expected, substantially reduced by using these coarser meshes. Table 1 gives the the number of O3D iterations necessary to achieve the required accuracy and the number of seconds it took to run. Clearly the reduction of run-times by a factor between 40 and 100 will be significant.

6. Discussion and conclusions. In this paper we have developed a formulation for the source-inversion problem that we have shown to be effective for locating sources in a steady-state environment. Although we have not stressed computational efficiency in our numerical experiments, we have been able to solve these problems relatively

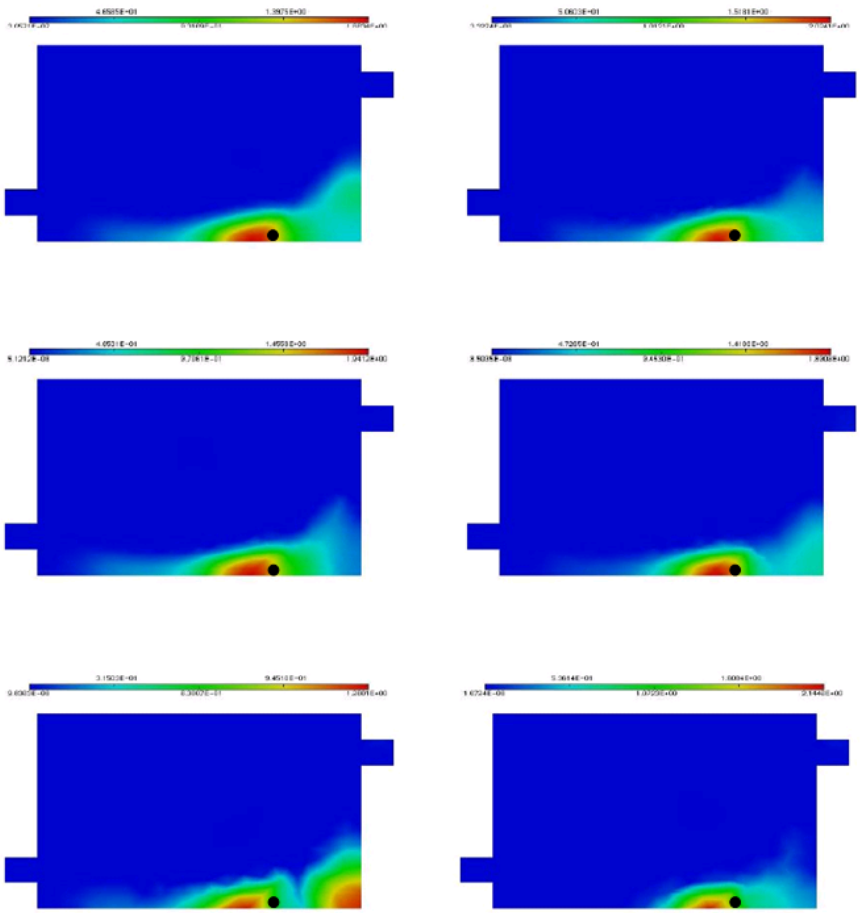

FIG. 5. *Source inversion with adaptive (left) and uniform (right) meshes. Top row,* 1471 *and* 1488 *triangles; middle row,* 1172 *and* 1196 *triangles; bottom row,* 474 *and* 476 *triangles. The true source location is the point* $(14.5, 0.5)$.

quickly, in terms of the number of iterations of O3D. Much work remains, however, to improve the efficiency of the linear solvers, the main source of computational costs in our runs. We have also shown that Sundance and Trilinos are powerful tools for the rapid prototyping and testing of various ideas and strategies.

In addition to continuing to work on the linear solver strategies, both in serial and in parallel, we need to investigate several other topics as follows:

1. As noted above, problem (4.14) uses a standard Tikhonov regularization scheme. Our computational results indicate that this tends to smear the source. Other possible regularizations can be considered, as in [1].
2. The problem of the optimal location of sensors is difficult. It is not at all clear what the objective should be. Our understanding is that different toxins dictate different attack strategies. Thus, we must take that into account when determining the location of the sensors. We are pursuing ideas related to hierarchical control (see, e.g., [8]); this will be the subject of a future paper. We are also considering ideas related to the mesh strategies noted

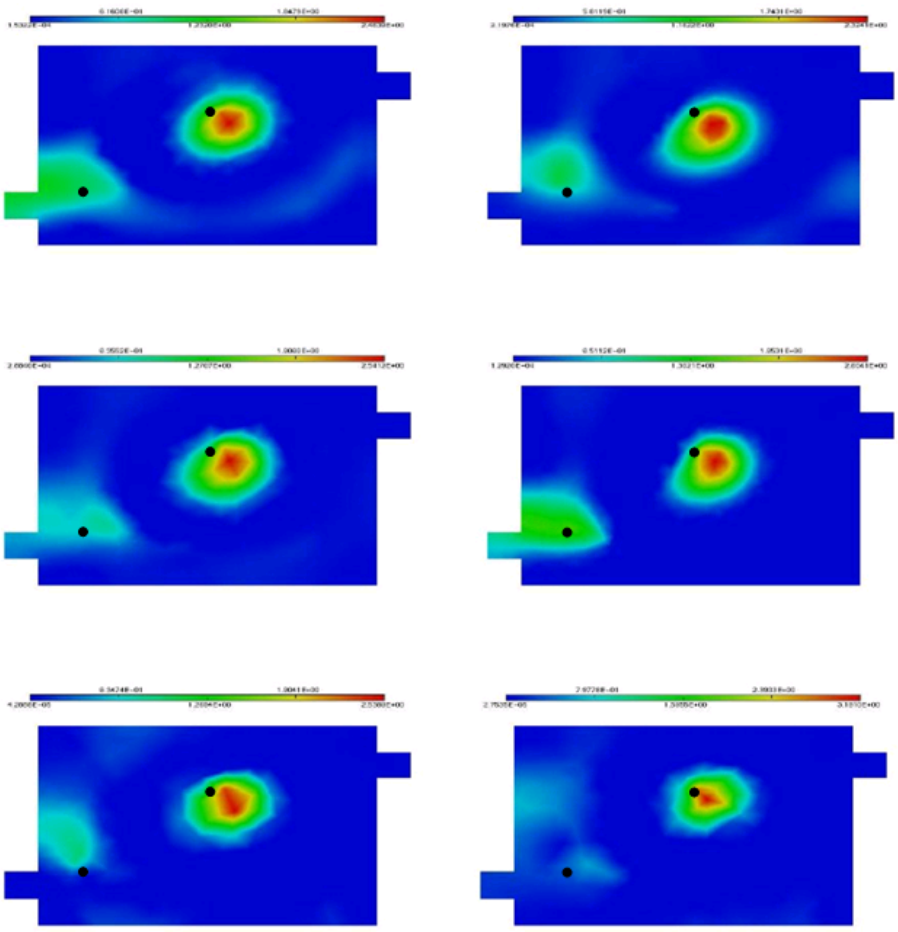

FIG. 6. *Source inversion with adaptive (left) and uniform (right) meshes. Top row,* 1471 *and* 1488 *triangles; middle row,* 1172 *and* 1196 *triangles; bottom row,* 474 *and* 476 *triangles. The true source locations are the points* $(3.0, 4.0)$ *and* $(10.0, 8.0)$.

above, where sensors could be located in regions of rapid change in the flow field.

We note in closing that PDE-constrained optimization problems arise in the context of improving the sensors themselves. We have been studying the problem of improving the shape and the topology of the channels in a microfluidic sensor. Here we want to improve certain aspects of the movement of the contaminant within the sensor subject to the flow within the channels.

In part 2 of this paper we will consider the time-dependent source-inversion problem. Although the problem will be much larger, we will also have more information. That is, we will have the time history of the transport, or, put another way, each sensor will provide much more that one measurement. In our preliminary analysis of the time-dependent problem, we have observed that the linear systems that we will have to solve will have a structure that can be exploited by a direct solver. In addition, we will consider many of the ideas enumerated above concerning the mesh and the regularization strategy in the time-dependent case.

1200	6.88	7.13	5.84	6.58
500	7.78	3.00	8.09	3.05

Appendix. The regularized eikonal equation. We motivate and derive the weak form of the regularized eikonal equation used in the main body of the paper as follows. First, we illustrate ideas by considering a couple of (essentially) one-dimensional analytical examples; then, a weak form of the fully multidimensional problem is derived; finally, an iterative procedure is specified and illustrated using the flow geometry prescribed in section 5.

We begin by considering the one-dimensional eikonal equation

$$\left(\frac{d\ell^*}{dx}\right)^2 = 1\,, \tag{A.1}$$

subject to $\ell^* = 0$ at the boundaries $x = 0$ and $x = 1$. Solutions to (A.1) are given by $\ell^* = \pm x$, which cannot solve the boundary conditions without introducing discontinuities in either ℓ^* or its derivative at $x = 1/2$. For example, the generalized function

$$\ell^* = \begin{cases} x, & 0 \le x \le 1/2, \\ 1-x, & 1/2 \le x \le 1, \end{cases} \tag{A.2}$$

which clearly satisfies (A.1) except at $x = 1/2$, measures the distance from the nearest boundary point ($x = 0$ or $1/2$). For stable solution by finite elements in an enclosed region, the eikonal equation must be regularized. If we add a regularization term $-\epsilon d^2\ell^*/dx^2$, where ϵ is a small positive quantity, to the left-hand side of (A.1), the problem becomes

$$\left(\frac{d\ell^*}{dx}\right)^2 - \epsilon\frac{d^2\ell^*}{dx^2} = 1\,, \quad \ell^*(0) = \ell^*(1) = 0\,. \tag{A.3}$$

The general solution of the differential equation for ℓ^* is obtained by first solving the first order equation for $d\ell^*/dx$ and then performing a second integration to give $\ell^* = d - \epsilon \ln\cosh[(x-c)/\epsilon]$, where c and d are constants of integration. Applying the boundary conditions then determines ℓ^* uniquely as

$$\ell^*(x) = \epsilon \ln\left\{\frac{\cosh\left[-1/(2\epsilon)\right]}{\cosh\left[(2x-1)/(2\epsilon)\right]}\right\} = -\epsilon\ln\left[\frac{e^{(2x-1)/(2\epsilon)} + e^{-(2x-1)/(2\epsilon)}}{e^{-1/(2\epsilon)} + e^{1/(2\epsilon)}}\right]. \tag{A.4}$$

It is readily deduced that for $0 < \epsilon \ll 1$, ℓ^* has the asymptotic behavior $\ell^* \sim x$ for $0 \le x < 1/2$ and $\ell^* \sim 1-x$ for $1/2 < x \le 1$. In the neighborhood of $x = 1/2$, we define the stretched coordinate $\eta = \epsilon^{-1}(x - 1/2)$, in terms of which $\ell^* \sim 1/2 - \epsilon\ln[2\cosh\eta]$. In the asymptotic context, a composite approximation spanning both the outer regions ($0 \le x < 1/2$ and $1/2 < x \le 1$) and the inner zone $|x - 1/2| \sim \mathrm{O}(\epsilon)$ is in fact given by the inner approximation written in terms of x. Hence, an asymptotic approximation for (A.4), valid in the limit of small ϵ, is given by

$$\ell^*(x) \sim \frac{1}{2} - \epsilon\ln\left[2\cosh\left(\frac{2x-1}{2\epsilon}\right)\right] = \frac{1}{2} - \epsilon\ln\left[e^{(2x-1)/(2\epsilon)} + e^{-(2x-1)/(2\epsilon)}\right]. \tag{A.5}$$

We note that the maximum deviation in ℓ^* from $\sup\{x, 1-x\}$ occurs at $x = 1/2$, where $\ell^*(1/2) \sim 1/2 - \epsilon\ln 2$. The exact solution (A.4) and its approximation (A.5) are illustrated in Figure 8.

The straightforward multidimensional generalization of (A.3) used in the present work is given, on a domain Ω, by

$$\left(\overrightarrow{\nabla}\ell^*\right)\cdot\left(\overrightarrow{\nabla}\ell^*\right) - \epsilon\nabla^2\ell^* = 1\,, \quad \ell^* = 0 \text{ on } \partial\Omega_w\,, \quad \overrightarrow{\nabla}\ell^* = 0 \text{ on } \partial\Omega_{I,o}\,. \tag{A.6}$$

The solution of this problem yields a tent-like structure, with the aforementioned distance-representation property for ℓ^*, over the domain Ω. For example, if the domain is the rectangle $0 \le x \le 1$, $0 \le y \le L$, with $\ell^* = 0$ on $x = 0$ and $x = 1$, and

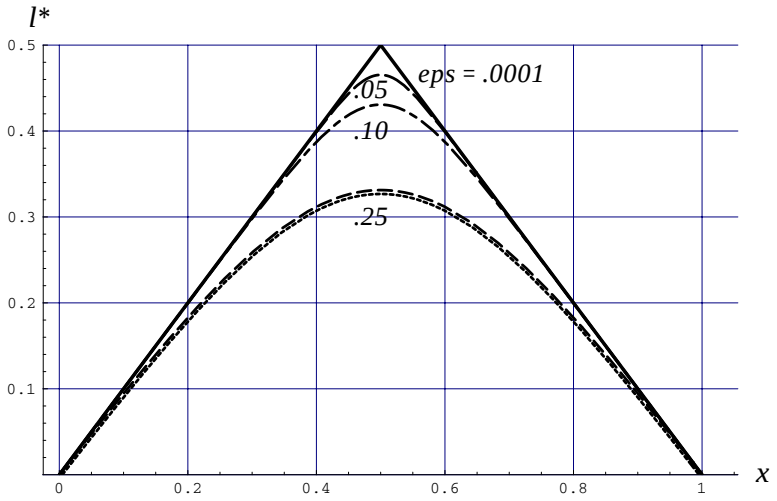

FIG. 8. *Solution of* (A.3) *for several values of* ϵ *("eps"). The two curves (dashed and dotted) for* $\epsilon = .25$ *correspond to the exact solution* (A.4) *and its asymptotic representation* (A.5)*, respectively; the two expressions are virtually indistinguishable for smaller values of* ϵ*.*

$\partial \ell^*/\partial y = 0$ on $y = 0$ and $y = L$, the solution is simply (A.4), independent of y. A more nontrivial example is the solution of (A.6) in polar coordinates (r, ϑ) when $\partial\Omega_w$ is the ring $0 < r_i \le r \le r_0$ and the boundary conditions are $\ell^*(r_i) = \ell^*(r_0) = 0$. Due to angular symmetry, (A.6) reduces to solving $(d\ell^*/dr)^2 - \epsilon r^{-1}(d/dr)(r\, d\ell^*/dr) = 1$, ultimately giving the final result

$$\ell^* = \epsilon \ln \left\{ \frac{I_0(r_i/\epsilon)K_0(r_0/\epsilon) - I_0(r_0/\epsilon)K_0(r_i/\epsilon)}{I_0(r/\epsilon)\big[K_0(r_0/\epsilon) - K_0(r_i/\epsilon)\big] - K_0(r/\epsilon)\big[I_0(r_0/\epsilon) - I_0(r_i/\epsilon)\big]} \right\}, \tag{A.7}$$

where I_0 and K_0 are the zero order modified Bessel functions. This solution is illustrated in Figure 9; its physical appearance in three dimensions is obtained by rotating the profiles about the ℓ^*-axis to yield the upper part of a torus-like structure.

As with the Navier–Stokes equations, the use of Sundance requires a weak form of the eikonal problem (A.6). We begin by writing

$$\int_\Omega r \left[\big(\overrightarrow{\nabla}\ell^*\big) \cdot \big(\overrightarrow{\nabla}\ell^*\big) - \epsilon \nabla^2 \ell^* - 1 \right] d\Omega = 0\,, \tag{A.8}$$

where r is the test function. Use of the identity $r\nabla^2\ell^* = \overrightarrow{\nabla} \cdot \big(r\overrightarrow{\nabla}\ell^*\big) - \big(\overrightarrow{\nabla} r\big) \cdot \big(\overrightarrow{\nabla}\ell^*\big)$ and application of the divergence theorem allows (A.8) to be expressed in terms of first derivatives as

$$\begin{aligned} \int_\Omega \Big\{ r \Big[\big(\overrightarrow{\nabla}\ell^*\big) \cdot \big(\overrightarrow{\nabla}\ell^*\big) - 1 \Big] + \epsilon \big(\overrightarrow{\nabla} r\big) \cdot \big(\overrightarrow{\nabla}\ell^*\big) \Big\}\, d\Omega \\ - \epsilon \int_{\partial\Omega} r \big(\overrightarrow{\nabla}\ell^*\big) \cdot \overrightarrow{n}\, d(\partial\Omega) = 0\,, \end{aligned} \tag{A.9}$$

where $\overrightarrow{n}$ is the unit normal to $\partial\Omega$.

FIG. 9. *Solution of* (A.7) *for* $r_i = 1/2$, $r_0 = 1$, *and several values of* ϵ (*"eps"*).

Based on the boundary conditions expressed in (A.6), the surface integral vanishes on the inlet and outlet portions of $\partial\Omega$. Approximating the wall boundary condition by

$$-\big(\overrightarrow{\nabla}\ell^*\big)\cdot\overrightarrow{n}\Big|_{\partial\Omega_w} = \hat{\epsilon}^{-1}\ell^*\,, \quad \hat{\epsilon}\ll 1\,, \tag{A.10}$$

and taking the limit $\hat{\epsilon}\to 0$ (independent of the ϵ in (A.9)), we obtain, by the same argument advanced in section 3.2, a replacement for the surface term according to

$$\int_\Omega \Big\{ r\Big[\big(\overrightarrow{\nabla}\ell^*\big)\cdot\big(\overrightarrow{\nabla}\ell^*\big)-1\Big] + \epsilon\big(\overrightarrow{\nabla}r\big)\cdot\big(\overrightarrow{\nabla}\ell^*\big)\Big\}\, d\Omega + \epsilon\int_{\partial\Omega_w} r\ell^*\, d(\partial\Omega) = 0\,. \tag{A.11}$$

Equation (A.11) is thus the final weak form of problem (A.6). We note that (A.11) is decoupled from the larger problem, although the reverse is obviously not true since ℓ^* enters into (3.22) through the mixing length $\ell_{\hat{j}}$ that appears in the expression for the turbulent stress tensor $\underline{\underline{\tau}}$.

In order to actually solve (A.11), which is nonlinear in the unknown function ℓ^*, it is necessary to adopt an iterative approach as discussed in section 3.2. In particular, since we ultimately require a weak form that is linear with respect to the unknown function ℓ^* (as well as the test function r), we formally linearize the nonlinear term $\big(\overrightarrow{\nabla}\ell^*\big)\cdot\big(\overrightarrow{\nabla}\ell^*\big)$ about an initial guess ℓ_0^* by writing $\ell^* = \ell_0^* + \ell_1^*$, where the correction ℓ_1^* is presumed to be small. Consequently,

$$\begin{aligned}
\big(\overrightarrow{\nabla}\ell^*\big)\cdot\big(\overrightarrow{\nabla}\ell^*\big) &= \big(\overrightarrow{\nabla}\ell_0^*\big)\cdot\big(\overrightarrow{\nabla}\ell_0^*\big) + 2\big(\overrightarrow{\nabla}\ell_1^*\big)\cdot\big(\overrightarrow{\nabla}\ell_0^*\big) + \big(\overrightarrow{\nabla}\ell_1^*\big)\cdot\big(\overrightarrow{\nabla}\ell_1^*\big)\\
&\approx \big(\overrightarrow{\nabla}\ell_0^*\big)\cdot\big(\overrightarrow{\nabla}\ell_0^*\big) + 2\big(\overrightarrow{\nabla}\ell_1^*\big)\cdot\big(\overrightarrow{\nabla}\ell_0^*\big)\\
&= \big(\overrightarrow{\nabla}\ell_0^*\big)\cdot\big(\overrightarrow{\nabla}\ell_0^*\big) + 2\big[\overrightarrow{\nabla}(\ell^*-\ell_0^*)\big]\cdot\big(\overrightarrow{\nabla}\ell_0^*\big)\\
&= \big(\overrightarrow{\nabla}\ell_0^*\big)\cdot\big(2\overrightarrow{\nabla}\ell^* - \overrightarrow{\nabla}\ell_0^*\big).
\end{aligned} \tag{A.12}$$

Using this linearized representation for $\big(\overrightarrow{\nabla}\ell^*\big)\cdot\big(\overrightarrow{\nabla}\ell^*\big)$ in (A.11), we thus arrive at a functional iteration scheme that computes the successive approximation ℓ_{i+1}^* in terms

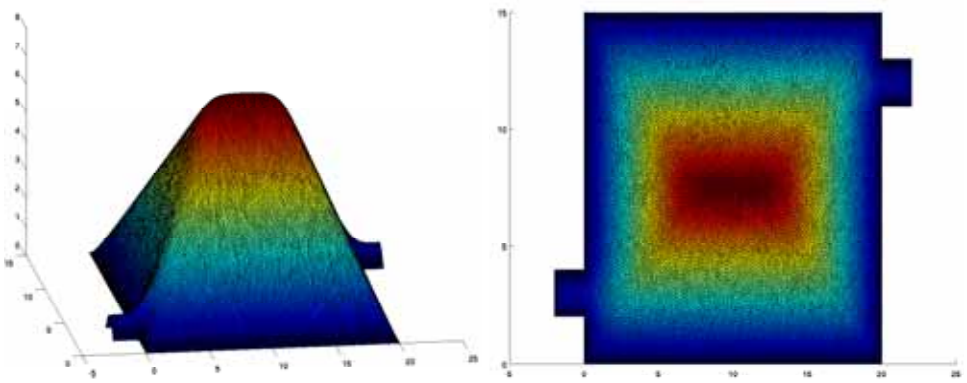

FIG. 10. *Angle and top views of the converged iterative solution of* (A.13) *for* $\epsilon = .05$ *on a sample domain* Ω *with inlet (lower left) and outlet (upper right) boundaries.*

of an initial guess ℓ_i^* according to

$$\int_\Omega \left\{ r\left[\left(\vec{\nabla}\ell_i^*\right)\cdot\left(2\vec{\nabla}\ell_{i+1}^* - \vec{\nabla}\ell_i^*\right) - 1\right] + \epsilon\left(\vec{\nabla}r\right)\cdot\left(\vec{\nabla}\ell_{i+1}^*\right)\right\} d\Omega + \epsilon\int_{\partial\Omega} r\ell_{i+1}^*\, d(\partial\Omega) = 0\,. \tag{A.13}$$

Equation (A.13) is linear with respect to the unknown function ℓ_{i+1}^* and can be handled directly by Sundance. The sequence of approximations is expected to be convergent given even a crude starting guess ℓ_0^* for sufficiently large ϵ, since in that limit the original nonlinearity becomes a perturbation of an otherwise linear problem. An outer iteration scheme can then be used to generate sufficiently good starting guesses ℓ_0^* for the recursive algorithm (A.13) with successively smaller values of ϵ. An example of such a calculation is illustrated in Figure 10.

AN ACTIVE SET METHOD FOR SINGLE-CONE SECOND-ORDER CONE PROGRAMS*

E. ERDOĞAN† AND G. IYENGAR†

Abstract. We develop an active set method for solving second-order cone programs that may have an arbitrary number of linear constraints but are restricted to having only one second-order cone constraint. Problems of this form arise in the context of robust optimization and trust region methods. The proposed active set method exploits the fact that a second-order cone program with only one second-order cone constraint and no inequality constraints can be solved in closed form.

Key words. second-order cone programs, single-cone, active set method, robust optimization, uncertain linear program, duality

DOI. 10.1137/040612592

1. Introduction.

In this paper we are concerned with the following special case of a second-order cone program (SOCP):

$$\begin{array}{rl} \min & \mathbf{f}^T\mathbf{x} \\ \text{subject to} & \mathbf{H}\mathbf{x} = \mathbf{g}, \\ & \mathbf{E}\mathbf{x} \geq \mathbf{0}, \\ & \mathbf{D}\mathbf{x} \succeq \mathbf{0}, \end{array} \tag{1.1}$$

where $\mathbf{x} \in \mathbf{R}^n$, $\mathbf{f} \in \mathbf{R}^n$, $\mathbf{H} \in \mathbf{R}^{m\times n}$, $\mathbf{g} \in \mathbf{R}^m$, $\mathbf{E} \in \mathbf{R}^{l\times n}$, $\mathbf{D} \in \mathbf{R}^{p\times n}$, and $\succeq$ denotes the partial order with respect to the standard conic quadratic cone $\mathcal{Q} = \{(z_0, \bar{\mathbf{z}})^T \in \mathbf{R}^p : z_0 \geq \sqrt{\bar{\mathbf{z}}^T\bar{\mathbf{z}}}\} \subset \mathbf{R}^p$. We shall call the optimization problem (1.1) a single-cone SOCP since it is restricted to having only *one* second-order cone constraint.

Our interest in single-cone SOCPs stems from the fact that they arise as the robust counterpart of uncertain linear programs (LPs). Many decision problems in engineering and operations research can be formulated as LPs of the form

$$\begin{array}{rl} \min & \mathbf{c}^T\mathbf{x} \\ \text{subject to} & \mathbf{A}\mathbf{x} = \mathbf{b}, \\ & \mathbf{x} \geq \mathbf{0}. \end{array}$$

Solution techniques for LPs compute a solution assuming that the parameters $(\mathbf{A}, \mathbf{b}, \mathbf{c})$ are known exactly. However, in practice, these parameters are typically the result of some measurement or estimation process and are therefore never certain. LPs whose parameters are not known exactly are called *uncertain* LPs. Several strategies have been proposed to address parameter uncertainty in optimization problems. One approach is to solve the LP for a nominal set of parameters $(\mathbf{A}_0, \mathbf{b}_0, \mathbf{c}_0)$ and then analyze the quality of the solution using a postoptimization tool such as sensitivity

analysis [5]. This approach is particularly attractive when the uncertainty is "small" in an appropriate sense. In the stochastic programming approach, the uncertainty is assumed to be random with a known distribution, and samples from this known distribution are used to compute good solutions [16]. However, identifying appropriate distributions for the parameters is not straightforward. Also, as the dimension of the problem grows, the complexity of the stochastic program quickly becomes prohibitive. Recently Ben-Tal and Nemirovski [2, 3, 4] proposed *robust* optimization as another approach to address data uncertainty. In this approach, the uncertain parameters $(\mathbf{A}, \mathbf{b}, \mathbf{c})$ are assumed to belong to a bounded uncertainty set $\mathcal{U}$ and the goal of the *robust* counterpart is to compute a minimax optimal solution. The results in [2, 3, 4] establish that when $\mathcal{U}$ satisfies some regularity properties, the robust counterpart can be reformulated as an SOCP and therefore can be solved efficiently both in theory [14] and in practice [17].

The robust counterpart of an uncertain LP where the parameters $(\mathbf{A}, \mathbf{b})$ are completely known and the uncertain cost vector $\mathbf{c}$ belongs to an ellipsoidal uncertainty set can be reformulated as a single-cone SOCP [3] (see also section 5). In many engineering applications the constraints in the LP are given by design considerations and are therefore fixed and certain. For example, in routing problems arising in the context of road or air traffic control and communication networks, the capacities are determined at the network design stage; therefore, the constraints in the problem, namely, the flow balance equations and capacity constraints, are completely known when the routing problem is to be solved. However, the "cost" of an arc is typically a nonlinear function of the capacity and flows in the network, and measuring this cost is often difficult and expensive [8]. The "cost" of a feasible flow can often be modeled as an uncertain linear function with an ellipsoidal uncertainty set by using the so-called delta method [12]. Production planning is another natural example where the constraints are fixed and only the costs are uncertain. Here the vector $\mathbf{c}$ denotes the vector of future expected market prices for the various raw materials and is, typically, estimated from historical prices via linear regression. Since the confidence regions associated with linear regression are ellipsoidal [10, 12], the resulting robust counterpart is a single-cone SOCP.

From the equivalence

$$\|\mathbf{Pu}\| \leq 1 \quad \Leftrightarrow \quad u_0 = 1, \ \begin{bmatrix} u_0 \\ \mathbf{Pu} \end{bmatrix} \succeq \mathbf{0},$$

it follows that the trust region problem is a special case of a single-cone SOCP. This provides another motivation for developing active set methods for single-cone SOCPs. Note that formulating the trust region problem as a single-cone SOCP allows one to consider hyperbolic and parabolic trust regions.

Alizadeh and Goldfarb [1] showed that under appropriate regularity conditions, the optimal solution of a single-cone SOCP with no inequality constraints can be computed in closed form. We use this result to explicitly compute the value of the Lagrangian obtained by dualizing the nonnegativity constraints $\mathbf{Ex} \geq \mathbf{0}$. We compute the optimal dual multipliers using an active set method, and then recover an optimal primal solution using the results in [1]. The formulation of the appropriate dual problem is discussed in section 2, the active set method is detailed in section 3, and section 4 details how to recover an optimal solution of (1.1).

Clearly, any algorithm for solving general SOCPs can be used to solve a single-cone SOCP. All the known codes for solving general SOCPs, e.g., SeDuMi [17] and

MOSEK, are based on interior point methods. Our efforts in developing an active set method for the single-cone SOCP were motivated, in part, by the observation that active set methods are known to solve convex quadratic programs efficiently. Our goal was to investigate whether a simple active set algorithm outperforms general purpose SOCP codes at least for certain problem classes. We report the results of our computational experiments in section 5.

Finally, Muramatsu [13] proposed a simplex-type algorithm for solving a special case of the single-cone SOCP (1.1). His algorithm is a generalization of the simplex method used for solving LPs [7], which is different than our approach.

2. Formulation of the Lagrangian dual. In this section we formulate a Lagrangian dual for the single-cone SOCP (1.1). We assume that $\mathbf{H} \in \mathbf{R}^{m\times n}$ has full row rank and the following constraint qualification holds.

ASSUMPTION 2.1. *There exists* $\bar{\mathbf{x}} \in \mathbf{R}^n$ *such that* $\mathbf{H}\bar{\mathbf{x}} = \mathbf{g}$, $\mathbf{E}\bar{\mathbf{x}} \succeq \mathbf{0}$, *and* $\mathbf{D}\bar{\mathbf{x}} \succ \mathbf{0}$.

The active set algorithm proposed in this paper exploits the following result from [1].

LEMMA 2.2. *Suppose the pair of primal-dual SOCPs*

$$\begin{array}{rlrl} \min & \mathbf{c}^T\mathbf{x} & \max & \mathbf{b}^T\mathbf{y} \\ \textit{subject to} & \mathbf{A}\mathbf{x} = \mathbf{b}, & \textit{subject to} & \mathbf{A}^T\mathbf{y} + \mathbf{z} = \mathbf{c}, \\ & \mathbf{x} \succeq \mathbf{0}, & & \mathbf{z} \succeq \mathbf{0} \end{array} \tag{2.1}$$

are both *strictly feasible. Then the optimal solution of the primal SOCP is given by*

$$\mathbf{x}^* = \left(\sqrt{\frac{-\mathbf{b}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{b}}{\mathbf{c}^T\mathbf{P}_R\mathbf{c}}} \right) \mathbf{P}_R\mathbf{c} + \mathbf{R}\mathbf{A}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{b}, \tag{2.2}$$

where

$$\mathbf{R} = \begin{bmatrix} 1 & \mathbf{0}^T \\ \mathbf{0} & -\mathbf{I} \end{bmatrix}, \quad \mathbf{P}_R = \mathbf{R} - \mathbf{R}\mathbf{A}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{A}\mathbf{R},$$

and $\mathbf{I}$ *denotes an identity matrix.*

REMARK 2.3. *In Lemma* 2.2 *we have implicitly assumed that* $\mathbf{A}\mathbf{R}\mathbf{A}^T$ *is nonsingular. A similar result holds when* $\mathbf{A}\mathbf{R}\mathbf{A}^T$ *is singular. See* [1] *for details.*

In order to reformulate (1.1) into a form similar to the primal SOCP in (2.1), we dualize the nonnegativity constraints to obtain the Lagrangian

$$\begin{array}{rlrl} q(\boldsymbol{\lambda}) \equiv & & \min & (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{x} \\ & & \text{subject to} & \mathbf{H}\mathbf{x} = \mathbf{g}, \\ & & & \mathbf{D}\mathbf{x} \succeq \mathbf{0}, \end{array} \tag{2.3}$$

where $\boldsymbol{\lambda} \in \mathbf{R}^l_+$ denotes the Lagrange multipliers for the inequality constraints. Note that the result in [1] applies only when the primal and the dual SOCPs are *both* strictly feasible. For SOCPs, feasibility is a subtle issue; e.g., the fact that the primal is bounded does not imply that the dual is feasible [4]; therefore, one has to be careful in applying the results in [1]. Elementary properties of convex duality [6] implies the following claim.

CLAIM 2.4. *Let* $q(\boldsymbol{\lambda})$ *denote the Lagrangian defined in* (2.3). *Let* $\mathbf{x}^*$ *and* v^* *denote, respectively, any optimal solution and the optimum value of* (1.1). *Then*

(a) $v^* = \max\{q(\boldsymbol{\lambda}) : \boldsymbol{\lambda} \geq \mathbf{0},\ \boldsymbol{\lambda} \in \mathcal{D}_q\}$, *where* $\mathcal{D}_q = \{\boldsymbol{\lambda} : q(\boldsymbol{\lambda}) > -\infty\}$,
(b) $\mathbf{x}^* \in \operatorname{argmin}\{(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}^*)^T\mathbf{x} : \mathbf{H}\mathbf{x} = \mathbf{g},\ \mathbf{D}\mathbf{x} \succeq \mathbf{0}\}$, *where* $\boldsymbol{\lambda}^* \in \operatorname{argmax}\{q(\boldsymbol{\lambda}) : \boldsymbol{\lambda} \geq 0,\ \boldsymbol{\lambda} \in \mathcal{D}_q\}$.

Thus, an optimal solution to (1.1) can be obtained by first computing an optimal multiplier $\boldsymbol{\lambda}^* \in \operatorname{argmax}\{q(\boldsymbol{\lambda}) : \boldsymbol{\lambda} \geq \mathbf{0},\ \boldsymbol{\lambda} \in \mathcal{D}_q\}$ and then computing an optimal $\mathbf{x}^*$ by solving $q(\boldsymbol{\lambda}^*)$. In section 2.1 we show how to compute the value of the Lagrange dual function $q(\boldsymbol{\lambda})$ for a fixed value of $\boldsymbol{\lambda} \in \mathcal{D}_q$, in section 3 we describe an active set algorithm to solve for the optimal dual multipliers $\boldsymbol{\lambda}^*$, and in section 4 we show how to recover the optimal primal solution $\mathbf{x}^*$.

2.1. Computing the Lagrangian $q(\boldsymbol{\lambda})$. Claim 2.4 allows us to restrict ourselves to $\boldsymbol{\lambda} \geq \mathbf{0}$ such that $q(\boldsymbol{\lambda}) > -\infty$, i.e., $\boldsymbol{\lambda} \in \mathcal{D}_q \cap \mathbf{R}^l_+$, without any loss of generality. Fix $\mathbf{y} \succeq \mathbf{0}$ and consider the optimization problem in $\mathbf{x}$:

$$q(\boldsymbol{\lambda}, \mathbf{y}) \equiv \begin{array}{rl} \min & (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{x} \\ \text{subject to} & \mathbf{H}\mathbf{x} = \mathbf{g}, \\ & \mathbf{D}\mathbf{x} = \mathbf{y}. \end{array} \tag{2.4}$$

Note that $q(\boldsymbol{\lambda}) > -\infty$ if and only if $q(\boldsymbol{\lambda}, \mathbf{y}) > -\infty$ for all $\mathbf{y} \succeq \mathbf{0}$. Since $\mathbf{H}$ has full row rank, $\mathbf{H}\mathbf{x} = \mathbf{g}$ if and only if $\mathbf{x} = \mathbf{x}_0 + \mathbf{B}\mathbf{z}$, where $\mathbf{x}_0 = \mathbf{H}^T(\mathbf{H}\mathbf{H}^T)^{-1}\mathbf{g} \in \mathbf{R}^n$, $\mathbf{B} \in \mathbf{R}^{n\times(n-m)}$ is any orthonormal basis for the nullspace $\mathcal{N}(\mathbf{H})$ of $\mathbf{H}$, and $\mathbf{z} \in \mathbf{R}^{n-m}$. Thus, we have that

$$q(\boldsymbol{\lambda}, \mathbf{y}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{x}_0 + \begin{array}{rl} \min & (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{B}\mathbf{z} \\ \text{subject to} & \mathbf{D}\mathbf{B}\mathbf{z} = \mathbf{y} - \mathbf{D}\mathbf{x}_0. \end{array} \tag{2.5}$$

Since $\mathbf{DB} \in \mathbf{R}^{p\times(n-m)}$ the following three cases exhaust all possibilities:

(i) $\mathbf{rank}(\mathbf{DB}) = r < \min\{p, n-m\}$. In this case, a singular value decomposition (SVD) of $\mathbf{DB}$ has the form

$$\mathbf{DB} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = \begin{bmatrix}\mathbf{U}_0 & \mathbf{U}_1\end{bmatrix}\begin{bmatrix}\boldsymbol{\Sigma}_0 & \mathbf{0} \\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{V}_0^T \\ \mathbf{V}_1^T\end{bmatrix} = \mathbf{U}_0\boldsymbol{\Sigma}_0\mathbf{V}_0^T,$$

where $\mathbf{U}_0 \in \mathbf{R}^{p\times r}$, $\mathbf{U}_1 \in \mathbf{R}^{p\times(p-r)}$, $\mathbf{V}_0 \in \mathbf{R}^{(n-m)\times r}$, $\mathbf{V}_1 \in \mathbf{R}^{(n-m)\times(n-m-r)}$, and $\boldsymbol{\Sigma}_0 \in \mathbf{R}^{r\times r}$ is a diagonal matrix. Consequently, $\mathbf{U}_1^T(\mathbf{y} - \mathbf{D}\mathbf{x}_0) = \mathbf{0}$, and $\mathbf{z} = \mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T(\mathbf{y} - \mathbf{D}\mathbf{x}_0) + \mathbf{V}_1\mathbf{t}$, where $\mathbf{t} \in \mathbf{R}^{n-m-r}$. Thus,

$$q(\boldsymbol{\lambda}, \mathbf{y}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \boldsymbol{\xi}^T\mathbf{y} + \min_{\mathbf{t}}\left\{(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{B}\mathbf{V}_1\mathbf{t}\right\}, \tag{2.6}$$

where $\mathbf{z}_0 = (\mathbf{I} - \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{D})\mathbf{x}_0$ and $\boldsymbol{\xi} = \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})$. From (2.6), we have

$$\mathbf{q}(\boldsymbol{\lambda}, \mathbf{y}) > -\infty \quad \Leftrightarrow \quad \mathbf{V}_1^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}) = \mathbf{0}, \tag{2.7}$$

and in that case

$$q(\boldsymbol{\lambda}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \bar{q}(\boldsymbol{\xi}), \tag{2.8}$$

where

$$\bar{q}(\boldsymbol{\xi}) = \begin{array}{rl} \min & \boldsymbol{\xi}^T\mathbf{y} \\ \text{subject to} & \mathbf{A}\mathbf{y} = \mathbf{b}, \\ & \mathbf{y} \succeq \mathbf{0} \end{array} \tag{2.9}$$

and

$$\begin{aligned} \mathbf{z}_0 &= (\mathbf{I} - \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{D})\mathbf{H}^T(\mathbf{H}\mathbf{H}^T)^{-1}\mathbf{g}, \\ \boldsymbol{\xi} &= \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}), \\ \mathbf{b} &= \mathbf{U}_1^T\mathbf{D}\mathbf{H}^T(\mathbf{H}\mathbf{H}^T)^{-1}\mathbf{g}, \\ \mathbf{A} &= \mathbf{U}_1^T. \end{aligned} \tag{2.10}$$

(ii) $\mathbf{rank}(\mathbf{DB}) = n - m < p$. In this case, we have

$$\mathbf{DB} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = \begin{bmatrix}\mathbf{U}_0 & \mathbf{U}_1\end{bmatrix}\begin{bmatrix}\boldsymbol{\Sigma}_0 \\ \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{V}_0^T\end{bmatrix} = \mathbf{U}_0\boldsymbol{\Sigma}_0\mathbf{V}_0^T,$$

where $\mathbf{U}_0 \in \mathbf{R}^{p\times(n-m)}$, $\mathbf{U}_1 \in \mathbf{R}^{p\times(p-n+m)}$, $\mathbf{V}_0 \in \mathbf{R}^{(n-m)\times(n-m)}$, and $\boldsymbol{\Sigma}_0 \in \mathbf{R}^{(n-m)\times(n-m)}$ is a diagonal matrix. Thus, (2.5) is feasible if and only if

$$\mathbf{U}_1^T(\mathbf{y} - \mathbf{D}\mathbf{x}_0) = \mathbf{0}. \tag{2.11}$$

Since $\mathbf{V}_0$ has full rank, it follows that when equation (2.11) holds we have $\mathbf{z} = \mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T(\mathbf{y} - \mathbf{D}\mathbf{x}_0)$. Consequently,

$$q(\boldsymbol{\lambda}, \mathbf{y}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \boldsymbol{\xi}^T\mathbf{y}, \tag{2.12}$$

where $\mathbf{z}_0 = (\mathbf{I} - \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{D})\mathbf{x}_0$ and $\boldsymbol{\xi} = \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})$. Thus, (2.8), (2.9), and (2.10) remain valid in this case.

(iii) $\mathbf{rank}(\mathbf{DB}) = p < n - m$. An SVD of $\mathbf{DB}$ is given by

$$\mathbf{DB} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = \begin{bmatrix}\mathbf{U}_0\end{bmatrix}\begin{bmatrix}\boldsymbol{\Sigma}_0 & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{V}_0^T \\ \mathbf{V}_1^T\end{bmatrix} = \mathbf{U}_0\boldsymbol{\Sigma}_0\mathbf{V}_0^T,$$

where $\mathbf{U}_0 \in \mathbf{R}^{p\times p}$, $\mathbf{V}_0 \in \mathbf{R}^{(n-m)\times p}$, $\mathbf{V}_1 \in \mathbf{R}^{(n-m)\times(n-m-p)}$, and $\boldsymbol{\Sigma}_0 \in \mathbf{R}^{p\times p}$ is a diagonal matrix. Since $\mathbf{U}_0$ has full rank, (2.5) is always feasible. Thus, $\mathbf{z} = \mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T(\mathbf{y} - \mathbf{D}\mathbf{x}_0) + \mathbf{V}_1\mathbf{t}$, where $\mathbf{t} \in \mathbf{R}^{n-m-p}$. Consequently,

$$q(\boldsymbol{\lambda}, \mathbf{y}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \boldsymbol{\xi}^T\mathbf{y} + \min_{\mathbf{t}}\left\{(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{B}\mathbf{V}_1\mathbf{t}\right\}, \tag{2.13}$$

where $\mathbf{z}_0 = (\mathbf{I} - \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{D})\mathbf{x}_0$ and $\boldsymbol{\xi} = \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})$. From (2.13) we have

$$\mathbf{q}(\boldsymbol{\lambda}, \mathbf{y}) > -\infty \quad \Leftrightarrow \quad \mathbf{V}_1^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}) = \mathbf{0}. \tag{2.14}$$

Thus,

$$q(\boldsymbol{\lambda}) = (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \hat{q}(\boldsymbol{\xi}), \tag{2.15}$$

where

$$\begin{aligned} \hat{q}(\boldsymbol{\xi}) \;=\; & \min \quad \boldsymbol{\xi}^T\mathbf{y} \\ & \text{subject to} \quad \mathbf{y} \succeq \mathbf{0} \end{aligned} \tag{2.16}$$

and

$$\begin{aligned} \mathbf{z}_0 &= (\mathbf{I} - \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{D})\mathbf{H}^T(\mathbf{H}\mathbf{H}^T)^{-1}\mathbf{g}, \\ \boldsymbol{\xi} &= \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}). \end{aligned} \tag{2.17}$$

Since the structures of the optimization problems (2.9) and (2.16), although similar, are not identical, the corresponding active set methods are also similar but not identical. In the paper we focus on developing an active set method for optimizing the Lagrangian defined in (2.8). The active set method for optimizing the Lagrangian defined in (2.15) is in Appendix B.

LEMMA 2.5. *Let $\bar{q} : \mathbf{R}^p \mapsto \mathbf{R}$ denote the function defined in* (2.9). *Then the domain $\mathcal{D}_{\bar{q}} = \{\boldsymbol{\xi} : \bar{q}(\boldsymbol{\xi}) > -\infty\}$ is given by*

$$\mathcal{D}_{\bar{q}} = \begin{cases} \mathbf{R}^p, & \gamma < 0, \\ \left\{\boldsymbol{\xi} : \mathbf{e}^T\mathbf{P}\boldsymbol{\xi} \geq 0, (\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2 \geq 0\right\}, & \gamma \geq 0, \end{cases} \tag{2.18}$$

where $\mathbf{e} = (1, \mathbf{0}^T)^T$, $\mathbf{P} = \mathbf{I} - \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{A}$, $\mathbf{a} = \mathbf{A}\mathbf{e}$, *and* $\gamma = \frac{1}{2} - \mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}$. *For all* $\boldsymbol{\xi} \in \mathcal{D}_{\bar{q}}$,

$$\bar{q}(\boldsymbol{\xi}) = \mathbf{v}^T\boldsymbol{\xi} + f(\mathbf{P}\boldsymbol{\xi}),$$

where

$$\mathbf{v} = \begin{cases} \mathbf{R}\mathbf{A}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{b}, & \gamma \neq 0, \\ \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{b}, & \gamma = 0, \end{cases} \tag{2.19}$$

$$f(\mathbf{u}) = \begin{cases} \frac{\sqrt{-\gamma(\mathbf{b}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{b})}}{\gamma}\sqrt{(\mathbf{e}^T\mathbf{u})^2 - \gamma\|\mathbf{u}\|^2}, & \gamma \neq 0, \\ \left(\frac{\|\mathbf{y}_0\|^2 - 2(\mathbf{e}^T\mathbf{y}_0)^2}{2\mathbf{e}^T\mathbf{y}_0}\right)\mathbf{e}^T\mathbf{u} - \mathbf{e}^T\mathbf{y}_0\left(\frac{\|\mathbf{u}\|^2 - 2(\mathbf{e}^T\mathbf{u})^2}{2\mathbf{e}^T\mathbf{u}}\right), & \gamma = 0, \end{cases} \tag{2.20}$$

and $\mathbf{y}_0 = \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{b}$.

The proof of this result is fairly straightforward and is therefore relegated to Appendix A.

3. Active set algorithm for the Lagrangian dual problem. Note that from (2.10) we have that $\mathbf{A}\boldsymbol{\xi} = \mathbf{U}_1^T\mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}) = \mathbf{0}$, i.e., $\boldsymbol{\xi} = \mathbf{P}\boldsymbol{\xi}$. Thus, (2.7), (2.8), (2.9), (2.10), and Lemma 2.5 imply that the Lagrangian dual problem is given by

$$\begin{aligned} \max \quad & (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 + \mathbf{v}^T\boldsymbol{\xi} + f(\boldsymbol{\xi}) \\ \text{subject to} \quad & \mathbf{L}\boldsymbol{\lambda} + \boldsymbol{\xi} = \mathbf{h}, \\ & \mathbf{M}\boldsymbol{\lambda} \quad = \mathbf{p}, \\ & \boldsymbol{\lambda} \quad \geq \mathbf{0}, \\ & \boldsymbol{\xi} \in \mathcal{K}, \end{aligned} \tag{3.1}$$

where

$$\begin{aligned} \mathbf{L} &= \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T\mathbf{E}^T, \\ \mathbf{h} &= \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T\mathbf{f}, \\ \mathbf{M} &= \mathbf{V}_1^T\mathbf{B}^T\mathbf{E}^T, \\ \mathbf{p} &= \mathbf{V}_1^T\mathbf{B}^T\mathbf{f}, \end{aligned}$$

and

The LagrangeDual algorithm.

end
return $\boldsymbol{\mu}$

FIG. 3.1. *Lagrangian dual algorithm.*

$$\mathcal{K} = \begin{cases} \mathbf{R}^p, & \gamma < 0, \\ \left\{\mathbf{z} : \mathbf{e}^T\mathbf{z} \geq 0, (\mathbf{e}^T\mathbf{z})^2 - \gamma\|\mathbf{z}\|^2 \geq 0\right\}, & \gamma \geq 0, \end{cases}$$

where $\mathbf{v}$ and $f(\cdot)$ are as defined in (2.19) and (2.20), respectively. In the rest of the paper we denote the system of linear equalities in (3.1) by $\mathcal{A}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}] = \mathbf{0}$.

When $\gamma \leq 0$, the constraints in (3.1) are linear, and hence (3.1) can be solved using any standard active set method for optimizing a concave function over a polytope. Moreover, γ is strictly positive for all single-cone SOCPs arising in the context of robust optimization. Therefore, in this paper we focus on constructing an active set algorithm for the case when γ is strictly positive. In the rest of this section we prove that the LagrangeDual algorithm displayed in Figure 3.1 computes an optimal solution of (3.1). We adopt the convention that a solution algorithm returns the empty set as a solution if and only if the problem is infeasible.

Let $\mathcal{C} = \left\{\boldsymbol{\xi} : \exists\boldsymbol{\lambda} \geq \mathbf{0} \text{ s.t. } \mathcal{A}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}] = \mathbf{0}\right\}$. Then $\mathcal{C} \cap \mathcal{K} = \{\mathbf{h} - \mathbf{L}\boldsymbol{\lambda} : \mathbf{M}\boldsymbol{\lambda} = \mathbf{p}, \mathbf{h} - \mathbf{L}\boldsymbol{\lambda} \in \mathcal{K},\ \boldsymbol{\lambda} \geq \mathbf{0}\}$. We construct the active set algorithm by considering the following three mutually exclusive cases: $\mathcal{C} \cap \mathcal{K} = \emptyset$, $\mathcal{C} \cap \mathcal{K} \subset \partial\mathcal{K}$, and $\mathcal{C} \cap \mathbf{int}(\mathcal{K}) \neq \emptyset$. In order to distinguish between these three cases we "homogenize" the set $\mathcal{C} \cap \mathcal{K}$ and solve the following least squares problem:

$$\begin{aligned} \min \quad & \|\alpha\mathbf{h} - \mathbf{L}\boldsymbol{\lambda}\|^2 \\ \text{subject to} \quad & \alpha\mathbf{e}^T\mathbf{h} - \mathbf{e}^T\mathbf{L}\boldsymbol{\lambda} = 1, \\ & \alpha\mathbf{p} - \mathbf{M}\boldsymbol{\lambda} = \mathbf{0}, \\ & \alpha \geq 0, \\ & \boldsymbol{\lambda} \geq \mathbf{0}. \end{aligned} \tag{3.2}$$

Let $(\alpha^{(0)}, \boldsymbol{\mu}^{(0)})$ denote the optimal solution of (3.2). Then one of the following three mutually exclusive conditions holds:

```
The ActiveSet algorithm.
Input: Optimization problem (3.1), μ^(1), and μ^(2).
Output: Optimal solution of (3.1).
 quit ← 0    k ← 0
 if (μ^(1) ≠ ∅)
                (d_ξ, d_λ) ← FindDirection(∅)
                if (v^T d_ξ − z_0^T E^T d_λ + f(d_ξ) ≤ 0) return (0, μ^(1))
                else (ξ^(0), λ^(0)) ← FindStep((0, μ^(1)), (d_ξ, d_λ), ∞)
 else

FIG. 3.2. *Active set algorithm.*

(i) Either (3.2) is infeasible or $\|\alpha^{(0)}\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(0)}\|^2 > \frac{1}{\gamma}$. Since (3.2) was constructed by "homogenizing" $\mathcal{C}\cap\mathcal{K}$, it follows that either $\mathcal{C}\cap\mathcal{K}=\emptyset$ or $\mathcal{C}\cap\mathcal{K}=\{\mathbf{0}\}$. The latter can be checked by solving an LP.

(ii) $\|\alpha^{(0)}\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(0)}\|^2 < \frac{1}{\gamma}$. We have the following two possibilities:
   (a) $\alpha^{(0)} > 0$: $\boldsymbol{\mu}^{(2)} = \frac{1}{\alpha^{(0)}}\boldsymbol{\mu}^{(0)}$ satisfies $\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)} \in \mathcal{C}\cap\mathbf{int}(\mathcal{K})$.
   (b) $\alpha^{(0)} = 0$: It is easy to check that $\boldsymbol{\mu}^{(0)}$ is a recession direction of the polytope $\mathcal{P} = \{\boldsymbol{\lambda} : \mathbf{M}\boldsymbol{\lambda}=\mathbf{p},\ \boldsymbol{\lambda}\geq\mathbf{0}\}$ and $-\mathbf{e}^T\mathbf{L}\boldsymbol{\mu}^{(0)} = 1$. Let $\hat{\boldsymbol{\lambda}}\in\mathcal{P}$. Then, by definition, $\boldsymbol{\lambda}_\omega = \hat{\boldsymbol{\lambda}} + \omega\boldsymbol{\mu}^{(0)} \in \mathcal{P}$ for all $\omega\geq 0$. Since $\mathbf{e}^T(\mathbf{h}-\mathbf{L}\boldsymbol{\lambda}_\omega) > 0$ for all large enough ω, and $\lim_{\omega\to\infty}\{\|\mathbf{h}-\mathbf{L}\boldsymbol{\lambda}_\omega\|/(\mathbf{e}^T(\mathbf{h}-\mathbf{L}\boldsymbol{\lambda}_\omega))\} < \frac{1}{\sqrt{\gamma}}$, it follows that there exists $\omega > 0$ such that $\boldsymbol{\mu}^{(2)} = \boldsymbol{\lambda}_\omega$ satisfies $\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)} \in \mathcal{C}\cap\mathbf{int}(\mathcal{K})$.

   In this case, LagrangeDual completes the optimization by calling the ActiveSet algorithm displayed in Figure 3.2.

(iii) $\|\alpha^{(0)}\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(0)}\|^2 = \frac{1}{\gamma}$. In this case $\mathcal{C}\cap\mathbf{int}(\mathcal{K}) = \emptyset$ and one has to consider the following two possibilities.
   (a) $\alpha^{(0)} > 0$: $\boldsymbol{\mu}^{(2)} = \frac{1}{\alpha^{(0)}}\boldsymbol{\mu}^{(0)}$ satisfies $\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)} \in \mathcal{C}\cap\partial\mathcal{K}$. Since the optimal value of (3.2) is $\frac{1}{\gamma}$ and the Euclidean norm is a strictly convex function, it follows that $\mathcal{C}\cap\mathcal{K} = \{\omega(\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)}) : \mathbf{h}-\mathbf{L}\boldsymbol{\lambda} = \omega(\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)}),\ \mathbf{M}\boldsymbol{\lambda}=\mathbf{p},\ \boldsymbol{\lambda}\geq\mathbf{0},\ \omega\geq 0\}$. Since $f(\xi) = 0$ for all $\xi\in\mathcal{C}\cap\mathcal{K}$ (see (2.20)), it follows

that the optimization problem (3.1) reduces to the LP

$$\begin{array}{rl} \max & (\mathbf{f}-\mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0+\mathbf{v}^T(\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)})\omega \\ \text{subject to} & \mathbf{L}\boldsymbol{\lambda}+(\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)})\omega=\mathbf{h}, \\ & \mathbf{M}\boldsymbol{\lambda} = \mathbf{p}, \\ & \boldsymbol{\lambda} \geq \mathbf{0}, \\ & \omega \geq 0. \end{array} \tag{3.3}$$

(b) $\alpha^{(0)}=0$: The recession direction $\boldsymbol{\mu}^{(0)}$ satisfies $-\mathbf{L}\boldsymbol{\mu}^{(0)}\in\partial\mathcal{K}$. An argument similar to the one in part (a) implies that (3.1) reduces to the LP

$$\begin{array}{rl} \max & (\mathbf{f}-\mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0-\mathbf{v}^T(\mathbf{L}\boldsymbol{\mu}^{(0)})\omega \\ \text{subject to} & \mathbf{L}\boldsymbol{\lambda}-(\mathbf{L}\boldsymbol{\mu}^{(0)})\omega=\mathbf{h}, \\ & \mathbf{M}\boldsymbol{\lambda} = \mathbf{p}, \\ & \boldsymbol{\lambda} \geq \mathbf{0}, \\ & \omega \geq 0. \end{array} \tag{3.4}$$

Next, we establish the correctness of the procedure ActiveSet displayed in Figure 3.2. We begin by showing that for any optimal solution $(\boldsymbol{\xi}^*,\boldsymbol{\lambda}^*)$ of (3.1), either $\boldsymbol{\xi}^*=\mathbf{0}$ or $\boldsymbol{\xi}^*\in\mathcal{C}\cap\mathbf{int}(\mathcal{K})$, i.e., $\boldsymbol{\xi}^*\notin\mathcal{C}\cap\big(\partial\mathcal{K}\backslash\{\mathbf{0}\}\big)$.

Lemma 3.1. *Suppose* $\mathcal{C}\cap\mathbf{int}(\mathcal{K})\neq\emptyset$ *and let* $(\boldsymbol{\xi}^*,\boldsymbol{\lambda}^*)$ *denote any optimal solution of* (3.1). *Then* $\boldsymbol{\xi}^*\notin\mathcal{C}\cap\big(\partial\mathcal{K}\backslash\{\mathbf{0}\}\big)$.

Proof. Assume otherwise, i.e., $\boldsymbol{\xi}^*\in\mathcal{C}\cap\big(\partial\mathcal{K}\backslash\{\mathbf{0}\}\big)$ for some optimal solution $(\boldsymbol{\xi}^*,\boldsymbol{\lambda}^*)$. Let $(\boldsymbol{\xi}_0,\boldsymbol{\lambda}_0)$ denote any feasible solution of (3.1) with $\boldsymbol{\xi}_0\in\mathcal{C}\cap\mathbf{int}(\mathcal{K})$. For $\beta\in[0,1]$, let $(\boldsymbol{\xi}_\beta,\boldsymbol{\lambda}_\beta)$ denote the convex combination $(\boldsymbol{\xi}_\beta,\boldsymbol{\lambda}_\beta)=\beta(\boldsymbol{\xi}_0,\boldsymbol{\lambda}_0)+(1-\beta)(\boldsymbol{\xi}^*,\boldsymbol{\lambda}^*)$ and let $r(\beta)$ denote the objective value of (3.1) evaluated at $(\boldsymbol{\xi}_\beta,\boldsymbol{\lambda}_\beta)$. Then

$$\begin{aligned} r(\beta) &= \mathbf{v}^T\boldsymbol{\xi}_\beta+\mathbf{f}^T\mathbf{z}_0-\mathbf{z}_0^T\mathbf{E}^T\boldsymbol{\lambda}_\beta+f(\boldsymbol{\xi}_\beta) \\ &= \mathbf{v}^T\boldsymbol{\xi}_\beta+\mathbf{f}^T\mathbf{z}_0-\mathbf{z}_0^T\mathbf{E}^T\boldsymbol{\lambda}_\beta+\theta\sqrt{(\mathbf{e}^T\boldsymbol{\xi}_\beta)^2-\gamma\|\boldsymbol{\xi}_\beta\|^2} \\ &\geq \underbrace{\big(\mathbf{v}^T\boldsymbol{\xi}^*+\mathbf{f}^T\mathbf{z}_0-\mathbf{z}_0^T\mathbf{E}^T\boldsymbol{\lambda}^*\big)}_{=r(0)}+\beta\underbrace{\big(\mathbf{v}^T(\boldsymbol{\xi}_0-\boldsymbol{\xi}^*)-\mathbf{z}_0^T\mathbf{E}^T(\boldsymbol{\lambda}_0-\boldsymbol{\lambda}^*)\big)}_{\triangleq\delta} \\ &\quad+\theta\sqrt{\beta^2\left((\mathbf{e}^T\boldsymbol{\xi}_0)^2-\gamma\|\boldsymbol{\xi}_0\|^2\right)+2\beta(1-\beta)\left((\mathbf{e}^T\boldsymbol{\xi}_0)(\mathbf{e}^T\boldsymbol{\xi}^*)-\gamma\|\boldsymbol{\xi}_0\|\|\boldsymbol{\xi}^*\|\right)}, \end{aligned} \tag{3.5}$$

where $\theta=\frac{\sqrt{-\gamma\mathbf{b}^T(\mathbf{A}\mathbf{R}\mathbf{A}^T)^{-1}\mathbf{b}}}{\gamma}$ and the last inequality follows from the fact that $(\mathbf{e}^T\boldsymbol{\xi}^*)^2-\gamma\|\boldsymbol{\xi}^*\|^2=0$. Since $\boldsymbol{\xi}_0\in\mathcal{C}\cap\mathbf{int}(\mathcal{K})$ we have

$$\epsilon=\min\left\{(\mathbf{e}^T\boldsymbol{\xi}_0)^2-\gamma\|\boldsymbol{\xi}_0\|^2,(\mathbf{e}^T\boldsymbol{\xi}_0)(\mathbf{e}^T\boldsymbol{\xi}^*)-\gamma\|\boldsymbol{\xi}_0\|\|\boldsymbol{\xi}^*\|\right\}>0.$$

From (3.5) we have that $r(\beta)-r(0)\geq\theta\sqrt{\epsilon}\sqrt{2\beta-\beta^2}+\beta\delta$. Choose β_0 as follows:

$$\beta_0=\begin{cases}1, & \delta\geq 0,\\ 1+\frac{\delta}{\sqrt{\theta^2\epsilon+\delta^2}}, & \delta<0.\end{cases}$$

Then it follows that $\beta_0>0$ and $r(\beta_0)-r(0)>0$, a contradiction. ∎

The ActiveSet algorithm receives as input

(i) $\boldsymbol{\mu}^{(1)}=\text{argmax}\{-\mathbf{z}_0^T\mathbf{E}^T\boldsymbol{\lambda}:\mathcal{A}[\boldsymbol{\lambda},\mathbf{0},\mathbf{h},\mathbf{p}],\ \boldsymbol{\lambda}\geq\mathbf{0}\}$, and

(ii) a vector $\boldsymbol{\mu}^{(2)}$ such that $\mathbf{h}-\mathbf{L}\boldsymbol{\mu}^{(2)}\in\mathcal{C}\cap\mathbf{int}(\mathcal{K})$.

When $\boldsymbol{\mu}^{(1)} \neq \emptyset$, the algorithm calls the procedure FindDirection that returns an ascent direction at $(\boldsymbol{\xi}, \boldsymbol{\lambda}) = (\mathbf{0}, \boldsymbol{\mu}^{(1)})$, if it exists; otherwise it returns $(\mathbf{0}, \mathbf{0})$. If FindDirection returns $(\mathbf{0}, \mathbf{0})$, it follows that $(\mathbf{0}, \boldsymbol{\mu}^{(1)})$ is optimal and the algorithm terminates; otherwise ActiveSet calls the procedure FindStep$((\boldsymbol{\xi}, \boldsymbol{\lambda}), (\mathbf{d}_\xi, \mathbf{d}_\lambda), \alpha_q)$ that computes the iterate $(\boldsymbol{\xi}^{(0)}, \boldsymbol{\lambda}^{(0)})$ as follows:

$$(\boldsymbol{\xi}^{(0)}, \boldsymbol{\lambda}^{(0)}) = (\boldsymbol{\xi}, \boldsymbol{\lambda}) + \alpha_{\min}(\mathbf{d}_\xi, \mathbf{d}_\lambda), \quad \alpha_{\min} = \min\{\max\{\alpha : \boldsymbol{\lambda} + \alpha \mathbf{d}_\lambda \geq \mathbf{0}\}, \alpha_q\}.$$

Since $\alpha \mathbf{d}_\xi \in \mathcal{K}$ for all $\alpha \geq 0$, $\alpha_{\min}$ is only limited by the nonnegativity constraints on $\boldsymbol{\lambda}$. Note that the iterate $(\boldsymbol{\xi}^{(0)}, \boldsymbol{\lambda}^{(0)})$ satisfies $\boldsymbol{\xi}^{(0)} \in \mathbf{int}(\mathcal{K})$; therefore, the optimum solution $(\boldsymbol{\xi}^*, \boldsymbol{\lambda}^*)$ also satisfies $\boldsymbol{\xi}^* \in \mathbf{int}(\mathcal{K})$ by Lemma 3.1.

Next, we show that the procedure FindDirection can be implemented efficiently. The pair $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is an ascent direction at $(\mathbf{0}, \boldsymbol{\mu}^{(1)})$ if and only if $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is a recession direction for the set

$$\begin{aligned} -\mathbf{z}_0^T \mathbf{E}^T \mathbf{d}_\lambda + \mathbf{v}^T \mathbf{d}_\xi + \theta \sqrt{(\mathbf{e}^T \mathbf{d}_\xi)^2 - \gamma \|\mathbf{d}_\xi\|^2} > 0, \\ \mathcal{A}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ \mathbf{d}_\xi \in \mathcal{K}, \end{aligned} \tag{3.6}$$

Lemma 3.2. *Let* $\mathcal{A}_{\mathbf{W}}[\mathbf{u}, \mathbf{v}, \boldsymbol{\gamma}, \boldsymbol{\nu}] = \mathbf{0}$ *denote the system of linear equalities*

$$\begin{bmatrix} \mathbf{L} & \mathbf{I} \\ \mathbf{M} & \mathbf{0} \\ \mathbf{W} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} = \begin{bmatrix} \boldsymbol{\gamma} \\ \boldsymbol{\nu} \\ \mathbf{0} \end{bmatrix},$$

where $(\mathbf{u}, \mathbf{v})$ *are variables, and* $(\boldsymbol{\gamma}, \boldsymbol{\nu}, \mathbf{W})$ *are parameters. Then a recession direction* $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ *for the set*

$$\begin{aligned} -\mathbf{z}_0^T \mathbf{E}^T \mathbf{d}_\lambda + \mathbf{v}^T \mathbf{d}_\xi + \theta \sqrt{(\mathbf{e}^T \mathbf{d}_\xi)^2 - \gamma \|\mathbf{d}_\xi\|^2} > 0, \\ \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ \mathbf{d}_\xi \in \mathcal{K}, \end{aligned} \tag{3.7}$$

if it exists, can be computed by solving two systems of linear equalities.

Remark 3.3. *Although* FindDirection *computes an ascent direction of the set* (3.7) *for the special case* $\mathbf{W} = \mathbf{0}$*, we prove the result for general* $\mathbf{W}$ *since we need such a result at a later stage.*

Proof. The set in (3.7) has a recession direction if and only if the optimization problem

$$\begin{aligned} \max \quad & -\mathbf{z}_0^T \mathbf{E}^T \mathbf{d}_\lambda + \mathbf{v}^T \mathbf{d}_\xi + \theta \sqrt{(\mathbf{e}^T \mathbf{d}_\xi)^2 - \gamma \|\mathbf{d}_\xi\|^2} \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{d}_\xi \in \mathcal{K} \end{aligned} \tag{3.8}$$

is unbounded.

An argument similar to the one employed in the proof of Lemma 3.1 establishes that one can restrict one's attention to $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ satisfying $\mathbf{d}_\xi \in \mathbf{int}(\mathcal{K}) \cup \{\mathbf{0}\}$. The direction $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ can be computed by considering the following three cases:

(a) First consider positive recession directions of the form $(\mathbf{0}, \mathbf{d}_\lambda)$. It is easy to see that all such directions, modulo a positive multiple, are solutions of the following set of linear equalities:

$$\begin{aligned} -\mathbf{z}_0^T \mathbf{E}^T \mathbf{d}_\lambda = 1, \\ \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{0}, \mathbf{0}, \mathbf{0}] = \mathbf{0}. \end{aligned} \tag{3.9}$$

(b) Next, suppose (3.9) is infeasible; there still exists, however, a positive recession direction for (3.8). Set $\mathbf{e}^T\mathbf{d}_\xi = 1$ in (3.8) to obtain

$$\begin{aligned} \max \quad & -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + \mathbf{v}^T\mathbf{d}_\xi + \theta\sqrt{1-\gamma\|\mathbf{d}_\xi\|^2} \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{d}_\xi = 1, \\ & \gamma\|\mathbf{d}_\xi\|^2 \le 1. \end{aligned} \tag{3.10}$$

Since (3.9) is assumed to be infeasible, (3.10) is bounded. Setting $\mathbf{d}_\xi = -\mathbf{L}\mathbf{d}_\lambda$, we get

$$\begin{aligned} \max \quad & -\left(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v}\right)^T\mathbf{d}_\lambda + \theta\sqrt{1-\gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2} \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, -\mathbf{L}\mathbf{d}_\lambda, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda = -1, \\ & \gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2 \le 1. \end{aligned} \tag{3.11}$$

Since the optimal $\mathbf{d}_\xi^* \in \mathbf{int}(\mathcal{K})$, we have $\gamma\|\mathbf{L}\mathbf{d}_\lambda^*\|^2 < 1$, and therefore the optimal Lagrange multiplier corresponding to this constraint is zero. Thus, the Lagrangian $\mathcal{L}$ of (3.11) reduces to

$$\begin{aligned} \mathcal{L} = & -(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v})^T\mathbf{d}_\lambda + \theta\sqrt{1-\gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2} \\ & - \boldsymbol{\tau}^T\mathbf{M}\mathbf{d}_\lambda - \boldsymbol{\rho}^T\mathbf{W}\mathbf{d}_\lambda - \eta(\mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda + 1) \end{aligned}$$

and the first-order optimality conditions are given by

$$\begin{aligned} & \tfrac{\theta\gamma}{\beta}\mathbf{L}^T\mathbf{L}\mathbf{d}_\lambda + \mathbf{M}^T\boldsymbol{\tau} + \mathbf{W}^T\boldsymbol{\rho} + \mathbf{L}^T\mathbf{e}\eta = -(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v}), \\ & \mathbf{M}\mathbf{d}_\lambda = \mathbf{0}, \\ & \mathbf{W}\mathbf{d}_\lambda = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda = -1, \end{aligned} \tag{3.12}$$

where $\beta = \sqrt{1-\gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2}$. Since we are looking for solutions $\mathbf{d}_\xi = -\mathbf{L}\mathbf{d}_\lambda \in \mathbf{int}(\mathcal{K})$, we are interested only in the solutions to (3.12) that satisfy $\beta > 0$. By setting $\bar{\boldsymbol{\rho}} = \beta\boldsymbol{\rho}$, $\bar{\boldsymbol{\tau}} = \beta\boldsymbol{\tau}$, and $\bar{\eta} = \beta\eta$, we see that (3.12) is equivalent to

$$\underbrace{\begin{bmatrix} \theta\gamma\mathbf{L}^T\mathbf{L} & \mathbf{M}^T & \mathbf{W}^T & \mathbf{L}^T\mathbf{e} \\ \mathbf{M} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{W} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{e}^T\mathbf{L} & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}}_{\triangleq \mathbf{K}} \begin{bmatrix} \mathbf{d}_\lambda \\ \bar{\boldsymbol{\tau}} \\ \bar{\boldsymbol{\rho}} \\ \bar{\eta} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ -1 \end{bmatrix} - \beta \begin{bmatrix} \mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v} \\ \mathbf{0} \\ \mathbf{0} \\ 0 \end{bmatrix}. \tag{3.13}$$

Suppose $\mathbf{K}$ is nonsingular. Let $\mathbf{w} = (\bar{\boldsymbol{\tau}}^T, \bar{\boldsymbol{\rho}}^T, \bar{\eta})^T$, $\mathbf{b}_1 = (\mathbf{0}^T, \mathbf{0}^T, -1)^T$, and $\mathbf{b}_2 = \mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v}$. Partition $\mathbf{K}^{-1}$ into submatrices

$$\mathbf{K}^{-1} = \begin{bmatrix} \mathbf{K}_{11}^{-1} & \mathbf{K}_{12}^{-1} \\ \mathbf{K}_{12}^{-T} & \mathbf{K}_{22}^{-1} \end{bmatrix}$$

such that

$$\begin{bmatrix} \mathbf{d}_\lambda \\ \mathbf{w} \end{bmatrix} = \mathbf{K}^{-1}\begin{bmatrix} \mathbf{0} \\ \mathbf{b}_1 \end{bmatrix} - \beta\mathbf{K}^{-1}\begin{bmatrix} \mathbf{b}_2 \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{K}_{12}^{-1}\mathbf{b}_1 - \beta\mathbf{K}_{11}^{-1}\mathbf{b}_2 \\ \mathbf{K}_{22}^{-1}\mathbf{b}_1 - \beta\mathbf{K}_{12}^{-T}\mathbf{b}_2 \end{bmatrix}.$$

This partition implies that $\mathbf{K}_{12}^{-T}\mathbf{L}^T\mathbf{L}\mathbf{K}_{11}^{-1} = \mathbf{0}$. Therefore,

$$\begin{aligned}\beta^2 + \gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2 - 1 &= \beta^2(1+\gamma\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2) - 2\beta\gamma(\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1)^T\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2 \\ &\quad + \gamma\|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 - 1 \\ &= \beta^2(1+\gamma\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2) + \gamma\|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 - 1.\end{aligned}$$

Consequently, the unique positive solution of the quadratic equation $\beta^2 = 1 - \gamma\|\mathbf{L}\mathbf{d}_\lambda\|^2$ is

$$\beta = \sqrt{\frac{1-\gamma\|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2}{1+\gamma\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2}}.$$

Thus, (3.12) has a solution if and only if $1 - \gamma\|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 > 0$.

The case where $\mathbf{K}$ is singular can be handled by taking the SVD of $\mathbf{K}$ and working in the appropriate range spaces.

(c) In case one is not able to produce a solution in either (a) or (b), it follows that the optimal solution of (3.8) is 0, and $(\mathbf{d}_\xi, \mathbf{d}_\lambda) = (\mathbf{0}, \mathbf{0})$ achieves this value. ∎

When the ActiveSet algorithm enters the `while` loop, we are guaranteed that $\boldsymbol{\xi}^* \in \mathbf{int}(\mathcal{K})$. Within the loop, one has to compute the optimal value of

$$\begin{aligned} &\max && -\mathbf{z}_0^T\mathbf{E}^T\boldsymbol{\lambda} + \mathbf{v}^T\boldsymbol{\xi} + f(\boldsymbol{\xi}) \\ &\text{subject to} && \mathcal{A}_{\mathbf{W}}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}] = \mathbf{0}, \\ &&& \boldsymbol{\xi} \in \mathcal{K}\backslash\{\mathbf{0}\}, \end{aligned} \tag{3.14}$$

where $\mathbf{W}$ denotes the current inactive set, i.e., $\mathbf{W} = \sum_{i:\lambda_i=0}\mathbf{e}_i\mathbf{e}_i^T$. At this stage we have already determined that $\boldsymbol{\xi} = \mathbf{0}$ is *not* optimal for (3.1); therefore, by Lemma 3.1 it follows that we can restrict ourselves to $\boldsymbol{\xi} \in \mathbf{int}(\mathcal{K})$. The procedure $(\mathbf{d}_\xi, \mathbf{d}_\lambda, \alpha_q) =$ FindOpt$(\boldsymbol{\xi}, \boldsymbol{\lambda}, \mathbf{W})$ takes as input the current iterate and the current $\mathbf{W}$, and returns an output $(\mathbf{d}_\xi, \mathbf{d}_\lambda, \alpha_q)$ that satisfies the following:

(i) When (3.14) is bounded, $(\mathbf{d}_\xi, \mathbf{d}_\lambda) = (\boldsymbol{\xi}^*, \boldsymbol{\lambda}^*) - (\boldsymbol{\xi}, \boldsymbol{\lambda})$, where $(\boldsymbol{\xi}^*, \boldsymbol{\lambda}^*)$ is the optimal solution of (3.14), and $\alpha_q = 1$.

(ii) When (3.14) is unbounded, $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is any recession direction of the feasible set of (3.14) satisfying $-\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + \mathbf{v}^T\mathbf{d}_\xi + f(\mathbf{d}_\xi) > 0$ and $\alpha_q = \infty$.

When $(\mathbf{d}_\xi, \mathbf{d}_\lambda) = (\mathbf{0}, \mathbf{0})$, the ActiveSet algorithm checks the Lagrange multipliers $\boldsymbol{\rho}$ corresponding to the constraints $\mathbf{W}\boldsymbol{\lambda} = \mathbf{0}$ by calling the procedure FindMultipliers that computes the solution of

$$\begin{bmatrix}\mathbf{W}^T & \mathbf{M}^T\end{bmatrix}\begin{bmatrix}\boldsymbol{\rho} \\ \boldsymbol{\tau}\end{bmatrix} = -\left[\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v} + \mathbf{L}^T\nabla f(\boldsymbol{\xi}^*)\right]. \tag{3.15}$$

If the signs of all the Lagrange multipliers are consistent with the KKT conditions, i.e., $\max_i\{\rho_i\} \le 0$, the algorithm terminates; otherwise, it drops one of the constraints with the incorrect sign. Lemma 3.5 establishes that ActiveSet terminates finitely. Thus, all that remains to be shown is that FindOpt can be implemented efficiently.

Lemma 3.4. *Suppose there exists a feasible* $(\bar{\boldsymbol{\xi}}, \bar{\boldsymbol{\lambda}})$ *for* (3.14) *such that* $\bar{\boldsymbol{\xi}} \in \mathbf{int}(\mathcal{K})$. *Then* (3.14) *can be solved in closed form by solving at most three systems of linear equations.*

Proof. Let $\mathbf{d}_\xi = \boldsymbol{\xi} - \bar{\boldsymbol{\xi}}$ and $\mathbf{d}_\lambda = \boldsymbol{\lambda} - \bar{\boldsymbol{\lambda}}$. Then (3.14) is equivalent to

$$\begin{aligned} &\max && -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + \mathbf{v}^T\mathbf{d}_\xi + \theta\sqrt{(\mathbf{e}^T(\bar{\boldsymbol{\xi}} + \mathbf{d}_\xi))^2 - \gamma\|\bar{\boldsymbol{\xi}} + \mathbf{d}_\xi\|^2} \\ &\text{subject to} && \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ &&& \bar{\boldsymbol{\xi}} + \mathbf{d}_\xi \in \mathcal{K}\backslash\{\mathbf{0}\}. \end{aligned} \tag{3.16}$$

First, suppose (3.16) is unbounded, i.e., there exists $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ such that

$$\begin{aligned}&\lim_{t\to\infty}\left\{-t\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + t\mathbf{v}^T\mathbf{d}_\xi + \theta\sqrt{(\mathbf{e}^T(\bar{\boldsymbol{\xi}}+t\mathbf{d}_\xi))^2 - \gamma\|\bar{\boldsymbol{\xi}}+t\mathbf{d}_\xi\|^2}\right\}\\ &= \lim_{t\to\infty}\left\{-t\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + t\mathbf{v}^T\mathbf{d}_\xi + t\theta\sqrt{(\mathbf{e}^T(\bar{\boldsymbol{\xi}}/t+\mathbf{d}_\xi))^2 - \gamma\|\bar{\boldsymbol{\xi}}/t+\mathbf{d}_\xi\|^2}\right\} = +\infty.\end{aligned}$$

Since $\bar{\boldsymbol{\xi}}/t \to 0$, it follows that (3.16) is unbounded if and only if $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is a recession direction for

$$\begin{aligned}&-\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda + \mathbf{v}^T\mathbf{d}_\xi + \theta\sqrt{(\mathbf{e}^T\mathbf{d}_\xi)^2 - \gamma\|\mathbf{d}_\xi\|^2} > 0,\\ &\mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0},\\ &\mathbf{d}_\xi \in \mathcal{K}.\end{aligned} \tag{3.17}$$

Since (3.17) is the same as (3.7), it follows that a positive recession direction for (3.16), if it exists, can be computed by solving at most two systems of linear equations.

Next, suppose (3.16) is bounded. By introducing a scaling parameter α, (3.16) can be reformulated as

$$\begin{aligned}\max\quad & -(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v})^T\mathbf{d}_\lambda + \theta\sqrt{1-\gamma\|\alpha\bar{\boldsymbol{\xi}} - \mathbf{L}\mathbf{d}_\lambda\|^2}\\ \text{subject to}\quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, -\mathbf{L}\mathbf{d}_\lambda, \mathbf{0}, \mathbf{0}] = \mathbf{0},\\ & \alpha \ge 0,\\ & -\mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda + \mathbf{e}^T\bar{\boldsymbol{\xi}}\alpha = 1,\\ & \gamma\|\alpha\bar{\boldsymbol{\xi}} - \mathbf{L}\mathbf{d}_\lambda\|^2 \le 1.\end{aligned}$$

Since (3.16) is bounded, i.e., it does not have any positive recession direction, we have that $\alpha^* > 0$. Also, by Lemma 3.1 it follows that $\alpha^*\bar{\boldsymbol{\xi}} + \mathbf{d}_\xi^* \in \mathbf{int}(K)$, i.e., $\gamma\|\alpha^*\bar{\boldsymbol{\xi}} - \mathbf{L}\mathbf{d}_\lambda^*\|^2 < 1$; therefore the optimal Lagrange multiplier corresponding to this constraint is zero. Consequently, the Lagrangian $\mathcal{L}$ reduces to

$$\begin{aligned}\mathcal{L} = &-(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v})^T\mathbf{d}_\lambda + \theta\sqrt{1-\gamma\|\alpha\bar{\boldsymbol{\xi}} - \mathbf{L}\mathbf{d}_\lambda\|^2} - \boldsymbol{\tau}^T\mathbf{M}\mathbf{d}_\lambda - \boldsymbol{\rho}^T\mathbf{W}\mathbf{d}_\lambda\\ &- \eta(\mathbf{e}^T\alpha\bar{\boldsymbol{\xi}} - \mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda - 1).\end{aligned}$$

The first-order optimality conditions are given by

$$\begin{aligned}\tfrac{\theta\gamma}{\beta}\mathbf{L}^T\mathbf{L}\mathbf{d}_\lambda - \tfrac{\theta\gamma}{\beta}\mathbf{L}^T\bar{\boldsymbol{\xi}}\alpha - \mathbf{L}^T\mathbf{e}\eta + \mathbf{M}^T\boldsymbol{\tau} + \mathbf{W}^T\boldsymbol{\rho} &= -(\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v}),\\ -\tfrac{\theta\gamma}{\beta}\bar{\boldsymbol{\xi}}^T\mathbf{L}\mathbf{d}_\lambda + \tfrac{\theta\gamma}{\beta}\|\bar{\boldsymbol{\xi}}\|^2\alpha + \mathbf{e}^T\bar{\boldsymbol{\xi}}\eta &= 0,\\ -\mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda + \mathbf{e}^T\bar{\boldsymbol{\xi}}\alpha &= 1,\\ \mathbf{M}\mathbf{d}_\lambda &= \mathbf{0},\\ \mathbf{W}\mathbf{d}_\lambda &= \mathbf{0},\end{aligned} \tag{3.18}$$

where $\beta = \sqrt{1-\gamma\|\alpha\bar{\boldsymbol{\xi}} - \mathbf{L}\mathbf{d}_\lambda\|^2}$. Set $\bar{\boldsymbol{\rho}} = \beta\boldsymbol{\rho}$, $\bar{\boldsymbol{\tau}} = \beta\boldsymbol{\tau}$, and $\bar{\eta} = \beta\eta$. Then (3.18) is equivalent to

$$\underbrace{\begin{bmatrix}\theta\gamma\mathbf{L}^T\mathbf{L} & -\theta\gamma\mathbf{L}^T\bar{\boldsymbol{\xi}} & -\mathbf{L}^T\mathbf{e} & \mathbf{M}^T & \mathbf{W}^T\\ -\theta\gamma\bar{\boldsymbol{\xi}}^T\mathbf{L} & \theta\gamma\|\bar{\boldsymbol{\xi}}\|^2 & \mathbf{e}^T\bar{\boldsymbol{\xi}} & \mathbf{0} & \mathbf{0}\\ -\mathbf{e}^T\mathbf{L} & \mathbf{e}^T\bar{\boldsymbol{\xi}} & \mathbf{0} & \mathbf{0} & \mathbf{0}\\ \mathbf{M} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0}\\ \mathbf{W} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0}\end{bmatrix}}_{\triangleq\mathbf{K}}\begin{bmatrix}\mathbf{d}_\lambda\\ \alpha\\ \bar{\eta}\\ \bar{\boldsymbol{\tau}}\\ \bar{\boldsymbol{\rho}}\end{bmatrix} = \begin{bmatrix}\mathbf{0}\\ 0\\ 1\\ \mathbf{0}\\ \mathbf{0}\end{bmatrix} - \beta\begin{bmatrix}\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v}\\ 0\\ 0\\ \mathbf{0}\\ \mathbf{0}\end{bmatrix}. \tag{3.19}$$

Suppose $\mathbf{K}$ is nonsingular. Let $\hat{\mathbf{d}} = (\mathbf{d}_\lambda^T, \alpha)^T$, $\mathbf{w} = (\bar{\eta}, \bar{\boldsymbol{\tau}}^T, \bar{\boldsymbol{\rho}}^T)^T$, $\mathbf{b}_1 = (1, \mathbf{0}^T, \mathbf{0}^T)^T$, and $\mathbf{b}_2 = ((\mathbf{E}\mathbf{z}_0 + \mathbf{L}^T\mathbf{v})^T, \mathbf{0}^T)^T$. Partition $\mathbf{K}^{-1}$ such that

$$\begin{bmatrix} \hat{\mathbf{d}} \\ \mathbf{w} \end{bmatrix} = \mathbf{K}^{-1} \begin{bmatrix} \mathbf{0} \\ \mathbf{b}_1 \end{bmatrix} - \beta \mathbf{K}^{-1} \begin{bmatrix} \mathbf{b}_2 \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{K}_{12}^{-1}\mathbf{b}_1 - \beta \mathbf{K}_{11}^{-1}\mathbf{b}_2 \\ \mathbf{K}_{22}^{-1}\mathbf{b}_1 - \beta \mathbf{K}_{12}^{-T}\mathbf{b}_2 \end{bmatrix}.$$

This partition implies that $\mathbf{K}_{12}^{-T}[-\mathbf{L}, \bar{\boldsymbol{\xi}}]^T[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{11}^{-1} = \mathbf{0}$. Therefore,

$$\begin{aligned} \beta^2 + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\hat{\mathbf{d}}\|^2 - 1 &= \beta^2(1 + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2) - 2\beta\gamma([-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{12}^{-1}\mathbf{b}_1)^T \\ &\qquad [-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{11}^{-1}\mathbf{b}_2 + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 - 1 \\ &= \beta^2(1 + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2) + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 - 1. \end{aligned}$$

Consequently, the unique positive solution of the quadratic equation $\beta^2 = 1 - \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\hat{\mathbf{d}}\|^2$ is

$$\beta = \sqrt{\frac{1 - \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2}{1 + \gamma\|[-\mathbf{L}, \bar{\boldsymbol{\xi}}]\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2}}.$$

The case where $\mathbf{K}$ is singular can be handled by taking the SVD of $\mathbf{K}$ and working in the appropriate range spaces. ∎

In our numerical experiments we found that solving (3.19) as a least squares problem was much faster than computing the inverse or the SVD of $\mathbf{K}$.

Lemma 3.4 implies that at each iteration of the ActiveSet algorithm, we have to solve at most three systems of linear equations, namely, (3.9), (3.13), and (3.19). Next we show that the special structures of these systems of linear equalities can be leveraged to solve them more efficiently. We will demonstrate our technique on the linear system (3.13). Extensions to (3.9) and (3.19) are straightforward.

The matrix $\mathbf{K}$ in (3.13) is an $(l + n - m - r + 1 + w)$-dimensional square matrix, where $r = \mathbf{rank}\,(\mathbf{DB})$ and w is the cardinality of the current inactive set, i.e., number of rows of $\mathbf{W}$. Only the matrix $\mathbf{W}$ changes from one iteration to the next—all the other elements of $\mathbf{K}$ remain fixed. This fact can be leveraged as follows:

1. The equality $\mathbf{W}\mathbf{d}_\lambda = \mathbf{0}$ sets the components of $\mathbf{d}_\lambda$ corresponding to the current inactive set to zero. Removing these variables and dropping the corresponding rows of $\mathbf{K}$ reduces the dimension of $\mathbf{K}$ to $l+n-m-r+1$. Thus, this simple operation ensures that the size of the linear equations remains independent of the cardinality of the inactive set.
2. Let

   (3.20)
   $$\tilde{\mathbf{d}} = \begin{bmatrix} \mathbf{d}_\lambda \\ \bar{\boldsymbol{\tau}} \\ \bar{\eta} \end{bmatrix}, \quad \tilde{\mathbf{K}} = \begin{bmatrix} \theta\gamma\mathbf{L}^T\mathbf{L} & \mathbf{M}^T & \mathbf{L}^T\mathbf{e} \\ \mathbf{M} & \mathbf{0} & \mathbf{0} \\ \mathbf{e}^T\mathbf{L} & \mathbf{0} & \mathbf{0} \end{bmatrix} \in \mathbf{R}^{(l+n-m-r+1)\times(l+n-m-r+1)},$$

   let $\mathbf{B}_1$ be any orthonormal basis for row space of $\tilde{\mathbf{K}}$, and let $\mathbf{B}_2$ be any orthonormal basis for the nullspace $\mathcal{N}(\tilde{\mathbf{K}})$. Then $\tilde{\mathbf{d}} = \mathbf{B}_1\boldsymbol{\mu} + \mathbf{B}_2\boldsymbol{\zeta}$, where $\boldsymbol{\mu} \in \mathbf{R}^{r_K}$, $\boldsymbol{\zeta} \in \mathbf{R}^{l+n-m-r+1-r_K}$, and $r_K = \mathbf{rank}(\tilde{\mathbf{K}})$. An SVD-based argument similar to the one in section 2.1 (detailed in Appendix C) shows that the dimension of $\mathbf{K}$ can be reduced to $l + n - m - r + 1 - r_K + w$.

These observations suggest that one can speed up FindOpt as follows: If $(l + n - m - r + 1) < (l + n - m - r + 1 - r_K + w)$, i.e., if $w > r_K$, solve (3.13) using the first dimension reduction technique; otherwise, use the second dimension reduction.

In each iteration either new rows are added to $\mathbf{W}$ or some of the rows of $\mathbf{W}$ are dropped. Since every row of $\mathbf{W}$ is a row of an identity matrix, one can suitably adapt the revised simplex method [5] to efficiently update the iterates. For example, adding a new row to $\mathbf{W}$ forces an entry of $\mathbf{d}_\lambda$ to be equal to zero, i.e., a variable leaves the basis, and introduces a new variable through $\bar{\boldsymbol{\rho}}$, i.e., a variable enters the basis. This process, although requiring a careful bookkeeping of variables and bases, is fairly straightforward.

We conclude this section with the following finite convergence result.

LEMMA 3.5. *The* ACTIVESET *algorithm terminates after a finite number of iterations.*

Proof. Let $\mathcal{A}_j$, $j \geq 1$, denote the active set on the jth call to the procedure FINDMULTIPLIERS. Since every iteration of ACTIVESET that does not call FINDMULTIPLIERS strictly improves the objective value of (3.1), it follows that $\mathcal{A}_{j_1} \neq \mathcal{A}_{j_2}$ for all $j_1 \neq j_2$. Since the size of the active set can only increase between successive calls to FINDMULTIPLIERS, it follows that ACTIVESET terminates after, at most, $l2^l$ iterations, where l is number of inequality constraints in the single-cone SOCP (1.1). ∎

4. Recovering an optimal solution. Let $\boldsymbol{\lambda}^*$ denote the solution returned by LAGRANGEDUAL, i.e., $\boldsymbol{\lambda}^*$ is optimal for (3.1). Set $\boldsymbol{\xi}^* = \mathbf{U}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{V}_0^T\mathbf{B}^T(\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda}^*)$, and using Lemma (2.5) obtain the closed form optimal solution $\mathbf{y}^*$ to $\bar{q}(\xi^*)$ defined in (2.9). Then all $\mathbf{x}^*$ satisfying

$$\mathbf{x}^* = \mathbf{x}_0 + \mathbf{B}\mathbf{z}^* = \mathbf{x}_0 + \mathbf{B}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T(\mathbf{y}^* - \mathbf{D}\mathbf{x}_0) + \mathbf{B}\mathbf{V}_1\mathbf{t},$$

where $\mathbf{x}_0 = \mathbf{H}^T(\mathbf{H}\mathbf{H}^T)^{-1}\mathbf{g}$, $\mathbf{t} \in \mathbf{R}^{n-m-r}$, and $r = \mathbf{rank}(\mathbf{DB})$, are optimal for (1.1). Thus, if $\mathbf{V}_1 \neq \emptyset$, i.e., $\mathbf{rank}(\mathbf{DB}) \neq n - m$, the optimal solution is not unique; in fact, an entire affine space is optimal.

5. Computational experiments. In this section we discuss the computational performance of the LAGRANGEDUAL algorithm on special classes of single-cone SOCPs that arise in the context of robust optimization.

Consider the LP

$$\begin{aligned} &\min && \mathbf{c}^T\mathbf{z} \\ &\text{subject to} && \mathbf{A}\mathbf{z} = \mathbf{b}, \\ &&& \mathbf{z} \geq \mathbf{0}, \end{aligned} \tag{5.1}$$

where $\mathbf{c}, \mathbf{z} \in \mathbf{R}^{\bar{n}}$, $\mathbf{A} \in \mathbf{R}^{\bar{m}\times\bar{n}}$, and $\mathbf{b} \in \mathbf{R}^{\bar{m}}$. Suppose the constraint matrix $(\mathbf{A}, \mathbf{b})$ is known exactly; the cost vector $\mathbf{c}$, however, is uncertain and is only known to lie within an ellipsoidal uncertainty set $\mathcal{S}$ given by

$$\mathcal{S} = \{\mathbf{c} = \mathbf{c}_0 + \mathbf{P}^T\boldsymbol{\alpha} : \boldsymbol{\alpha} \in \mathbf{R}^s, \boldsymbol{\alpha}^T\boldsymbol{\alpha} \leq 1\}.$$

We will call (5.1) an LP with uncertain cost. Such an LP is a special case of a more general class of uncertain LPs where the constraints are also uncertain [2, 3].

Let $f(\mathbf{z}) = \max_{\mathbf{c}\in\mathcal{S}}\{\mathbf{c}^T\mathbf{z}\}$ denote the worst-case cost of the decision $\mathbf{z}$. Then we have that

$$f(\mathbf{z}) = \mathbf{c}_0^T\mathbf{z} + \max_{\{\boldsymbol{\alpha}:\boldsymbol{\alpha}^T\boldsymbol{\alpha}\leq 1\}}\left\{\boldsymbol{\alpha}^T\mathbf{P}\mathbf{z}\right\} = \mathbf{c}_0^T\mathbf{z} + \|\mathbf{P}\mathbf{z}\|.$$

The robust counterpart of the uncertain LP is defined as follows [2, 3]:

$$\begin{array}{rl} \min & \mathbf{c}_0^T\mathbf{z} + \|\mathbf{P}\mathbf{z}\| \\ \text{subject to} & \mathbf{A}\mathbf{z} = \mathbf{b}, \\ & \mathbf{z} \geq \mathbf{0}. \end{array} \tag{5.2}$$

By defining,

$$\mathbf{x} = \begin{bmatrix} \mathbf{z} \\ y_0 \\ \mathbf{y} \end{bmatrix}, \quad \mathbf{H} = \begin{bmatrix} \mathbf{A} & 0 & \mathbf{0} \\ \mathbf{P} & 0 & -\mathbf{I} \end{bmatrix}, \quad \mathbf{E} = \begin{bmatrix} \mathbf{I} & 0 & \mathbf{0} \end{bmatrix},$$
$$\mathbf{D} = \begin{bmatrix} \mathbf{0} & 1 & \mathbf{0} \\ \mathbf{0} & 0 & \mathbf{I} \end{bmatrix}, \quad \mathbf{g} = \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} \mathbf{c}_0 \\ 1 \\ \mathbf{0} \end{bmatrix},$$

it is easy to see that (5.2) can be reformulated as a single-cone SOCP. The constant γ for problems of the form (5.2) is given by $\gamma = 0.5$. Thus, we are in a position to use the LagrangeDual algorithm.

All the systems of linear equations encountered during the course of the LagrangeDual algorithm were solved using the MATLAB function `mldivide` and all the computations were carried out using MATLAB R13 on a PC with a Pentium M (1.50GHz) processor and 512 MB of RAM. For moderate values of $(\bar{n}, \bar{m})$ the LP that defines $\boldsymbol{\mu}^{(1)}$ (see Figure 3.1) was solved using SeDuMi 1.05 R5. For large $(\bar{n}, \bar{m})$, $\boldsymbol{\mu}^{(1)}$ was computed using the simplex algorithm.

In the first set of experiments, the LP instances were randomly generated. In particular, the entries of matrix $\mathbf{A}$ and the cost vector $\mathbf{c}_0$ were drawn independently at random according to the uniform distribution on the unit $[0, 1]$ interval. To ensure feasibility of (5.1), the vector $\mathbf{b}$ was set to $\mathbf{b} = \mathbf{A}\mathbf{w}$, where each component of the vector $\mathbf{w}$ was generated independently at random from the uniform distribution on $[0, 1]$. The matrix $\mathbf{P}$ defining the uncertainty set $\mathcal{S}$ was set equal to the $\bar{n}$-dimensional identity matrix, and for each $(\bar{n}, \bar{m})$ pair, we generated 50 random instances.

Table 5.1 compares the running times of LagrangeDual to those of SeDuMi 1.05 R5 on the randomly generated instances. Column 3 lists the average of the ratio of running time t_{sed} of SeDuMi 1.05 R5 to running time t_{alg} of LagrangeDual, and column 4 lists the average of the ratio of t_{sed} to the running time t_{act} of ActiveSet. Note that the running time of ActiveSet is equal to the difference between the running time of LagrangeDual and the time t_{init} required to compute the initial Lagrange multipliers $(\boldsymbol{\mu}^{(1)}, \boldsymbol{\mu}^{(2)})$. The time t_{init} is listed in column 6. Columns 5 and 7 list, respectively, the average running time t_{alg} of LagrangeDual and the average number of iterations of the `while` loop in ActiveSet.

From the results displayed in Table 5.1, it is clear that the performance of the LagrangeDual algorithm (including the time spent to obtain the initial Lagrange multipliers) is superior to the SeDuMi 1.05 R5 when either

(i) the number of variables $\bar{n}$ is small, and/or
(ii) the ratio of the number of constraints to the number of variables $\bar{m}/\bar{n} \leq 0.1$ or $\bar{m}/\bar{n} \geq 0.5$.

The data in column 4 of Table 5.1 implies that the performance of LagrangeDual algorithm is superior to that of SeDuMi 1.05 R5 when the time spent to obtain the initial Lagrange multipliers is excluded. This observation suggests that the performance of LagrangeDual is likely to improve if it is initialized using a more efficient LP-solver.

Since network flow problems are a natural class of LPs where the number of variables is large but the number of constraints is reasonably small, next we tested LagrangeDual on random instances of the uncertain min-cost flow problems. The

random networks were generated using the network generator developed by Goldberg [9]. Results are averaged over 10 runs for each pair $(\bar{n}, \bar{m})$.

Table 5.2 displays the results for the randomly generated network matrices. In order to be consistent with the previous set of results, we continue to denote the number of variables by $\bar{n}$ and the number of constraints by $\bar{m}$. Thus, $\bar{n}$ and $\bar{m}$ denote, respectively, the number of *arcs* and the number of *nodes* in the network. As before, column 3 lists the average of the ratio of running time t_{sed} of SeDuMi 1.05 R5 to running time t_{alg} of LAGRANGEDUAL. Columns 4 and 5 list, respectively, the average

running time of LagrangeDual and the average number of iterations of the `while` loop in ActiveSet. Since the version of LagrangeDual that we implemented did not take advantage of sparsity, in this set of experiments we did not allow SeDuMi 1.05 R5 to leverage sparsity. From the results of our computational experiments it appears that LagrangeDual is faster than SeDuMi 1.05 R5 on relatively dense networks. Also, for large networks, $\bar{n} \approx 5000$, SeDuMi 1.05 R5 failed to solve the problem but LagrangeDual did not have any trouble converging.

We also compared the performance of LagrangeDual with that of SeDuMi 1.05 R5 on some of the small problems from the NETLIB LP [15] library. All the LP instances were converted to canonical form LPs (5.1). To define the uncertainty set $\mathcal{S}$, we took the nominal cost vector $\mathbf{c}_0$ as given by the NETLIB LP library, assumed that only the nonzero elements of $\mathbf{c}_0$ are uncertain, and then defined the matrix $\mathbf{P}$ accordingly. In these experiments the performance of SeDuMi 1.05 R5 was superior to that of LagrangeDual. This is not surprising given that for most of these small problems the ratio $\bar{m}/\bar{n}$ (after the problem was converted to the canonical form) was between 0.1 and 0.6. Note that in this set of experiments we are allowing SeDuMi to exploit sparsity.

Before concluding, we would like to mention that these experiments are biased in favor of SeDuMi. As mentioned in [17] (the version updated for SeDuMi 1.05) SeDuMi "takes full advantage of sparsity," which increases its speed considerably, and it uses a dense column factorization proposed in [11]. In addition, most of the subroutines of SeDuMi are written in C code. On the other hand, the LagrangeDual algorithm was implemented using only MATLAB functions, without any special treatment of sparsity and dense columns. Indeed, since the SVD steps will destroy any sparsity in the input matrices $\mathbf{H}$ and $\mathbf{D}$, it is not clear how one could exploit sparsity to improve the run time of the LagrangeDual algorithm. Recall that when comparing the performance of LagrangeDual on robust min-cost flow problems with that of SeDuMi we had not allowed SeDuMi to exploit sparsity. When SeDuMi is allowed to take advantage of sparsity, it outperforms LagrangeDual.

Appendix A. Proofs.

A.1. Structural results for single-cone SOCPs.

Lemma A.1. *Suppose* $\mathbf{A} \in \mathbf{R}^{m\times n}$ *has full row rank and there exists* $\mathbf{d} \succeq \mathbf{0}$, $\mathbf{d} \neq \mathbf{0}$ *such that* $\mathbf{Ad} = \mathbf{0}$. *Let* $\mathbf{a}$ *denote the first column of the matrix* $\mathbf{A}$. *Then*

(a) $\gamma = \frac{1}{2} - \mathbf{a}^T(\mathbf{AA}^T)^{-1}\mathbf{a} \in [0, 0.5]$;

(b) *for all* $\mathbf{d}$ *such that* $\mathbf{Ad} = \mathbf{0}$, *we have* $\|\mathbf{d}\|^2 \geq \frac{2}{1+2\gamma}(\mathbf{e}^T\mathbf{d})^2$;

(c) $\gamma > 0 \Leftrightarrow \exists \mathbf{d} \succ \mathbf{0} : \mathbf{Ad} = \mathbf{0}$;

(d) $\gamma = 0 \Leftrightarrow \{\mathbf{d} : \mathbf{Ad} = \mathbf{0}, \mathbf{d} \succeq \mathbf{0}\} = \{\beta(\mathbf{e} - \mathbf{A}^T(\mathbf{AA}^T)^{-1}\mathbf{a}) : \beta \geq 0\}$.

Proof. Partition the matrix $\mathbf{A}$ as $\mathbf{A} = [\mathbf{a}, \bar{\mathbf{A}}]$. By scaling, we can assume that $\mathbf{d} = (1; \bar{\mathbf{d}}) \succeq \mathbf{0}$. Since $\mathbf{d} \succeq \mathbf{0}$, $\|\bar{\mathbf{d}}\| \leq 1$. Then

$$\begin{aligned}
\mathbf{AA}^T - 2\mathbf{aa}^T &= \mathbf{aa}^T + \bar{\mathbf{A}}\bar{\mathbf{A}}^T - 2\mathbf{aa}^T \\
&= \bar{\mathbf{A}}\bar{\mathbf{A}}^T - \mathbf{aa}^T \\
&= \bar{\mathbf{A}}\bar{\mathbf{A}}^T - \bar{\mathbf{A}}\bar{\mathbf{d}}\bar{\mathbf{d}}^T\bar{\mathbf{A}}^T \qquad \text{(A.1)} \\
&= \bar{\mathbf{A}}(\mathbf{I} - \bar{\mathbf{d}}\bar{\mathbf{d}}^T)\bar{\mathbf{A}}^T \succeq \mathbf{0}, \qquad \text{(A.2)}
\end{aligned}$$

where (A.1) follows from the fact that $\mathbf{Ad} = \mathbf{a} + \bar{\mathbf{A}}\bar{\mathbf{d}} = \mathbf{0}$, and (A.2) follows from the fact that $\|\bar{\mathbf{d}}\| \leq 1$. Define

$$\mathbf{M} = \begin{bmatrix} \frac{1}{2} & \mathbf{a}^T \\ \mathbf{a} & \mathbf{AA}^T \end{bmatrix}.$$

Since $\frac{1}{2} > 0$ and the Schur complement of $\frac{1}{2}$ in $\mathbf{M}$ is $\mathbf{A}\mathbf{A}^T - 2\mathbf{a}\mathbf{a}^T \succeq \mathbf{0}$, it follows that $\mathbf{M} \succeq \mathbf{0}$. Since $\mathbf{A}$ has full row rank, it follows that $\mathbf{A}\mathbf{A}^T \succ \mathbf{0}$, and the matrix $\mathbf{M} \succeq \mathbf{0}$ if and only if the Schur complement of $\mathbf{A}\mathbf{A}^T$

$$\gamma = \frac{1}{2} - \mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a} \geq 0.$$

Since $(\mathbf{A}\mathbf{A}^T)^{-1} \succ \mathbf{0}$, it follows that $\gamma = \frac{1}{2} - \mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a} \leq \frac{1}{2}$. This establishes part (a).

To establish the other results, consider the minimum norm problem

$$\begin{array}{rl} \min & \|\mathbf{d}\|^2 \\ \text{subject to} & \mathbf{A}\mathbf{d} = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{d} = 1. \end{array} \tag{A.3}$$

The optimal solution $\mathbf{d}^*$ and the optimal value v^* of (A.3) can be obtained easily via the Lagrange multipliers technique, and is given by

$$\mathbf{d}^* = \frac{2}{1+2\gamma}\Big(\mathbf{e} - \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}\Big), \quad v^* = \frac{2}{1+2\gamma}.$$

Thus, it follows that for all $\mathbf{d}$ such that $\mathbf{A}\mathbf{d} = \mathbf{0}$, we have $\|\mathbf{d}\|^2 \geq \frac{2}{1+2\gamma}(\mathbf{e}^T\mathbf{d})^2$.

Since there exists $\mathbf{d} = (1; \bar{\mathbf{d}}) \succeq \mathbf{0}$ with $\mathbf{A}\mathbf{d} = \mathbf{0}$, there exists a $\mathbf{d} \succ \mathbf{0}$ with $\mathbf{A}\mathbf{d} = \mathbf{0}$ if and only if $v^* < 2$, i.e., $\gamma > 0$. Moreover when $\gamma = 0$, $\big\{\mathbf{d} : \mathbf{A}\mathbf{d} = \mathbf{0}, \mathbf{d} \succeq \mathbf{0}\big\} = \{\beta\mathbf{d}^* : \beta \geq 0\}$. □

LEMMA A.2. *Suppose* $\mathbf{A} \in \mathbf{R}^{m\times n}$ *has full row rank and consider the SOCP*

$$\begin{array}{rl} \min & \boldsymbol{\xi}^T\mathbf{y} \\ \textit{subject to} & \mathbf{A}\mathbf{y} = \mathbf{b}, \\ & \mathbf{y} \succeq \mathbf{0}. \end{array} \tag{A.4}$$

Let $\mathbf{a}$ *denote the first column of the matrix* $\mathbf{A}$*, and let* $\gamma = \frac{1}{2} - \mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a} \neq 0$*. Then we have the following:*

(i) *The dual of* (A.4) *is strictly feasible for all* $\gamma < 0$*.*

(ii) *When* $\gamma > 0$*, the dual of* (A.4) *is strictly feasible if and only if* $\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} > 0$ *and* $(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2 > 0$*, where* $\mathbf{P} = \mathbf{I} - \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{A}$ *denotes the orthogonal projector operator onto* $\mathcal{N}(\mathbf{A})$*.*

Proof. The dual of (A.4) is given by

$$\begin{array}{rl} \max & \mathbf{b}^T\boldsymbol{\mu} \\ \text{subject to} & \boldsymbol{\xi} - \mathbf{A}^T\boldsymbol{\mu} \succeq \mathbf{0}. \end{array}$$

Since $\mathbf{A}$ has full row rank, $\boldsymbol{\xi}$ can be written as $\boldsymbol{\xi} = \mathbf{P}\boldsymbol{\xi} + \mathbf{A}^T\mathbf{w}$ for some $\mathbf{w} \in \mathbf{R}^m$. Thus, it follows that there exists a $\boldsymbol{\mu}$ such that $\boldsymbol{\xi} - \mathbf{A}^T\boldsymbol{\mu} \succ \mathbf{0}$ if and only if there exists a $\boldsymbol{\mu}$ such that $\mathbf{P}\boldsymbol{\xi} + \mathbf{A}^T\boldsymbol{\mu} \succ \mathbf{0}$.

From the definition of the Lorentz cone, it follows that there exists a $\boldsymbol{\mu}$ such that $\mathbf{P}\boldsymbol{\xi} + \mathbf{A}^T\boldsymbol{\mu} \succ \mathbf{0}$ if and only if the optimal value of

$$\begin{array}{rl} \min & \|\alpha\mathbf{P}\boldsymbol{\xi} + \mathbf{A}^T\boldsymbol{\mu}\|^2 \\ \text{subject to} & \alpha\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} + \mathbf{a}^T\boldsymbol{\mu} = 1, \\ & \alpha \geq 0 \end{array} \tag{A.5}$$

is less than 2.

First consider the case $\gamma < 0$. Note that the solution $\alpha = 0$, $\boldsymbol{\mu} = \frac{(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}}{\mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}}$ is feasible to (A.5) with the objective function value $\frac{1}{\mathbf{a}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}} = \frac{2}{1-2\gamma} < 2$.

If $\gamma > 0$, then the first part of Lemma 2.5 shows that $\boldsymbol{\xi}$ has to satisfy $\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} \geq 0$ and $(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2 \geq 0$. Otherwise, (A.4) becomes unbounded and therefore, by the weak duality lemma for SOCPs [1], its dual is infeasible.

The rest of the analysis is very similar to the one used in the proof of Lemma A.1 and is left to the reader. □

A.2. Proof of Lemma 2.5. By definition, $\boldsymbol{\xi} \in \mathcal{D}_{\bar{q}}$ if and only if (2.9) is bounded, or, equivalently, the optimal value of the homogeneous problem

$$\begin{array}{rl} \min & \boldsymbol{\xi}^T\mathbf{d} \\ \text{subject to} & \mathbf{A}\mathbf{d} = \mathbf{0}, \\ & \mathbf{d} \succeq \mathbf{0} \end{array} \tag{A.6}$$

is nonnegative. Without loss of generality, we assume that $\boldsymbol{\xi} \in \mathcal{N}(\mathbf{A})$. Otherwise, $\boldsymbol{\xi}$ can be decomposed as $\boldsymbol{\xi} = \mathbf{P}\boldsymbol{\xi} + \boldsymbol{\xi}_1$ where $\mathbf{P}\boldsymbol{\xi} \in \mathcal{N}(\mathbf{A})$ and $\boldsymbol{\xi}_1$ belongs to the row space of $\mathbf{A}$ (the space orthogonal to $\mathcal{N}(\mathbf{A})$). Since $\mathbf{A}\mathbf{d} = \mathbf{0}$ implies $\boldsymbol{\xi}_1^T\mathbf{d} = 0$, we can drop $\boldsymbol{\xi}_1$ from the objective.

Lemma A.1(b) in Appendix A.1 establishes that $\|\mathbf{d}\|^2 \geq \frac{2}{1+2\gamma}(\mathbf{e}^T\mathbf{d})^2$ for all $\mathbf{d}$ such that $\mathbf{A}\mathbf{d} = \mathbf{0}$. Since $\mathbf{d} \succeq \mathbf{0}$ implies that $2(\mathbf{e}^T\mathbf{d})^2 \geq \|\mathbf{d}\|^2$, it follows that $\mathbf{d} = \mathbf{0}$ is the only feasible solution to (A.6) when $\gamma < 0$. Hence, $\mathcal{D}_{\bar{q}} = \mathbf{R}^p$.

Next, suppose $\gamma \geq 0$. Then (A.6) is bounded if and only if

$$\begin{array}{rl} \min & \boldsymbol{\xi}^T\mathbf{d} \\ \text{subject to} & \mathbf{A}\mathbf{d} = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{d} = 1, \\ & \mathbf{d}^T\mathbf{d} \leq 2 \end{array} \tag{A.7}$$

has a nonnegative optimal value.

The Lagrangian of (A.7) is given by

$$\mathcal{L} = \boldsymbol{\xi}^T\mathbf{d} - \hat{\boldsymbol{\tau}}^T\mathbf{A}\mathbf{d} - \hat{\delta}(\mathbf{e}^T\mathbf{d} - 1) + \hat{\beta}(\mathbf{d}^T\mathbf{d} - 2),$$

where $\hat{\beta} \geq 0$. Setting the derivative $\nabla\mathcal{L} = 0$ we get

$$\mathbf{d} = -\beta\boldsymbol{\xi} + \mathbf{A}^T\boldsymbol{\tau} + \delta\mathbf{e},$$

where β, $\boldsymbol{\tau}$, and δ are rescaled values of $\hat{\beta}$, $\hat{\boldsymbol{\tau}}$, and $\hat{\delta}$; however, $\beta \geq 0$ still holds. Since $\mathbf{A}\boldsymbol{\xi} = \mathbf{0}$, the constraint $\mathbf{A}\mathbf{d} = \mathbf{0}$ yields

$$\boldsymbol{\tau} = -\delta(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{A}\mathbf{e} = -\delta(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}.$$

Next, the constraint $\mathbf{e}^T\mathbf{d} = 1$ implies that

$$\begin{aligned} 1 &= -\beta\mathbf{e}^T\boldsymbol{\xi} + \delta\mathbf{e}^T(\mathbf{e} - \mathbf{A}^T(\mathbf{A}\mathbf{A})^{-1}\mathbf{a}) = -\beta\mathbf{e}^T\boldsymbol{\xi} + \delta(1 - \mathbf{a}^T(\mathbf{A}\mathbf{A})^{-1}\mathbf{a}) \\ &= -\beta\mathbf{e}^T\boldsymbol{\xi} + \delta\left(\frac{1+2\gamma}{2}\right). \end{aligned}$$

Thus,

$$\mathbf{d} = -\beta\boldsymbol{\xi} + \left(\frac{2}{1+2\gamma}\right)(1 + \beta\mathbf{e}^T\boldsymbol{\xi})\Big(\mathbf{e} - \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{a}\Big).$$

From Lemma A.1(a) we have $\gamma \in [0, 0.5]$, and therefore $\mathbf{d}$ is well-defined.

Since (A.7) has a linear objective and its feasible set is the intersection of an affine set with a Euclidean ball, there exists an optimal solution to (A.7) that satisfies $\mathbf{d}^T\mathbf{d} = 2$. It is easy to see this when the matrix $[\mathbf{A}; \mathbf{e}^T]$ does not have full column rank. When $[\mathbf{A}; \mathbf{e}^T]$ has full column rank, the system $\mathbf{Ad} = \mathbf{0}$, $\mathbf{e}^T\mathbf{d} = 1$ admits the unique solution $\tilde{\mathbf{d}} = \frac{2}{1+2\gamma}(\mathbf{e} - \mathbf{A}^T(\mathbf{AA}^T)^{-1}\mathbf{a})$, which implies $\{\mathbf{d} : \mathbf{Ad} = 0,\ \mathbf{d} \succeq \mathbf{0}\} = \{t\big(\mathbf{e} - \mathbf{A}^T(\mathbf{AA}^T)^{-1}\mathbf{a}\big) : t \geq 0\}$. Then, by Lemma A.1(d) in Appendix A.1, we have $\gamma = 0$. Therefore, $\tilde{\mathbf{d}}^T\tilde{\mathbf{d}} = \frac{2}{1+2\gamma} = 2$. Simplifying the constraint $\mathbf{d}^T\mathbf{d} = 2$, we get

$$\beta^2 \left(\|\boldsymbol{\xi}\|^2 - \frac{2}{1+2\gamma}(\mathbf{e}^T\boldsymbol{\xi})^2 \right) = \frac{4\gamma}{1+2\gamma}.$$

Since $\mathbf{A}\boldsymbol{\xi} = \mathbf{0}$, Lemma A.1(b) implies that $\|\boldsymbol{\xi}\|^2 \geq \frac{2}{1+2\gamma}(\mathbf{e}^T\boldsymbol{\xi})^2$. Therefore, we only have to consider the following two cases:

(i) $(\mathbf{e}^T\boldsymbol{\xi})^2 = \frac{1+2\gamma}{2}\|\boldsymbol{\xi}\|^2$.
Suppose that $\mathbf{e}^T\boldsymbol{\xi} = \sqrt{\frac{1+2\gamma}{2}}\|\boldsymbol{\xi}\|$. Then $\boldsymbol{\xi} \succeq \mathbf{0}$, and the optimal value of (A.7) is nonnegative, or, equivalently, that (A.6) is bounded. Next, suppose $\mathbf{e}^T\boldsymbol{\xi} = -\sqrt{\frac{1+2\gamma}{2}}\|\boldsymbol{\xi}\|$. Then $\mathbf{d} = -\boldsymbol{\xi} \succeq \mathbf{0}$, and $\mathbf{d}^T\boldsymbol{\xi} = -\|\boldsymbol{\xi}\|^2 < 0$. Therefore, (A.6) is unbounded.

(ii) $(\mathbf{e}^T\boldsymbol{\xi})^2 < \frac{1+2\gamma}{2}\|\boldsymbol{\xi}\|^2$.
In this case $\beta = \sqrt{\frac{4\gamma}{(1+2\gamma)\|\boldsymbol{\xi}\|^2 - 2(\mathbf{e}^T\boldsymbol{\xi})^2}}$, and (A.7) has a nonnegative optimal value if and only if

$$\begin{aligned} 0 &\leq \boldsymbol{\xi}^T\mathbf{d} \\ &= -\beta\|\boldsymbol{\xi}\|^2 + \left(\frac{2}{1+2\gamma}\right)(1 + \beta\mathbf{e}^T\boldsymbol{\xi})(\mathbf{e}^T\boldsymbol{\xi}) \\ &= -\frac{\beta}{1+2\gamma}\Big((1+2\gamma)\|\boldsymbol{\xi}\|^2 - 2(\mathbf{e}^T\boldsymbol{\xi})^2\Big) + \frac{2(\mathbf{e}^T\boldsymbol{\xi})}{1+2\gamma}. \end{aligned}$$

Substituting the value of β and simplifying we get

$$\mathbf{e}^T\boldsymbol{\xi} \geq 0, \quad (\mathbf{e}^T\boldsymbol{\xi})^2 \geq \gamma\|\boldsymbol{\xi}\|^2.$$

Since, as we discussed above, assuming $\boldsymbol{\xi} \in \mathcal{N}(\mathbf{A})$ is equivalent to replacing $\boldsymbol{\xi}$ by $\mathbf{P}\boldsymbol{\xi}$, the result follows.

For the second part of Lemma 2.5, first consider the case $\gamma \neq 0$, or, equivalently, $\mathbf{ARA}^T$ is nonsingular [1]. Using the results of the first part of this lemma, one can prove (see Lemma A.2 in Appendix A.1) that if $\gamma < 0$, then the dual of (A.6) is strictly feasible for any $\boldsymbol{\xi} \in \mathbf{R}^p$, and when $\gamma > 0$ the dual of (A.6) is strictly feasible if and only if $\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} \geq 0$ and $(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2 > 0$; and from [1, section 5] it follows that when the dual is strictly feasible,

$$\bar{q}(\boldsymbol{\xi}) = \frac{\sqrt{-\gamma(\mathbf{b}^T(\mathbf{ARA}^T)^{-1}\mathbf{b})}}{\gamma}\sqrt{(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2} + \boldsymbol{\xi}^T\mathbf{RA}^T(\mathbf{ARA}^T)^{-1}\mathbf{b}.$$

When the dual is not strictly feasible, i.e., $(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2 = \gamma\|\mathbf{P}\boldsymbol{\xi}\|^2$, choose $\hat{\boldsymbol{\xi}} \in \mathcal{D}_{\bar{q}}$ such that the dual corresponding to $\hat{\boldsymbol{\xi}}$ is strictly feasible. For $0 < \epsilon \leq 1$, let $\boldsymbol{\xi}_\epsilon = (1-\epsilon)\boldsymbol{\xi} + \epsilon\hat{\boldsymbol{\xi}}$. Then we have two cases:

(i) $\mathbf{P}\boldsymbol{\xi} = \mathbf{0}$. In this case, $(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi}_\epsilon)^2 - \gamma\|\mathbf{P}\boldsymbol{\xi}_\epsilon\|^2 = \epsilon^2\big((\mathbf{e}^T\mathbf{P}\hat{\boldsymbol{\xi}})^2 - \gamma\|\mathbf{P}\hat{\boldsymbol{\xi}}\|^2\big) > 0$.

(ii) $\mathbf{P}\boldsymbol{\xi} \neq \mathbf{0}$. In this case, $\gamma > 0$. Since $\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} - \sqrt{\gamma}\|\mathbf{P}\boldsymbol{\xi}\|$ is a concave function of $\boldsymbol{\xi}$, it follows that

$$\begin{aligned}\mathbf{e}^T\mathbf{P}\boldsymbol{\xi}_\epsilon - \sqrt{\gamma}\|\mathbf{P}\boldsymbol{\xi}_\epsilon\| &\geq \epsilon\big(\mathbf{e}^T\mathbf{P}\hat{\boldsymbol{\xi}} - \sqrt{\gamma}\|\mathbf{P}\hat{\boldsymbol{\xi}}\|\big) + (1-\epsilon)\big(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} - \sqrt{\gamma}\|\mathbf{P}\boldsymbol{\xi}\|\big)\\ &= \epsilon\big(\mathbf{e}^T\mathbf{P}\hat{\boldsymbol{\xi}} - \sqrt{\gamma}\|\mathbf{P}\hat{\boldsymbol{\xi}}\|\big) > 0.\end{aligned}$$

Thus, the dual corresponding to $\boldsymbol{\xi}_\epsilon$ is always strictly feasible and

$$\bar{q}(\boldsymbol{\xi}_\epsilon) = f(\mathbf{P}\boldsymbol{\xi}_\epsilon) + \mathbf{v}^T\boldsymbol{\xi}_\epsilon.$$

Taking the limit as $\epsilon \downarrow 0$ establishes the result.

Next, consider the case $\gamma = 0$, or, equivalently, $\mathbf{A}\mathbf{R}\mathbf{A}^T$ is singular. Note that

$$\bar{q}(\boldsymbol{\xi}) = \boldsymbol{\xi}^T\mathbf{y}_0 + \hat{q}(\mathbf{P}\boldsymbol{\xi}),$$

where $\mathbf{y}_0 = \mathbf{A}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{b}$, and

$$\hat{q}(\mathbf{P}\boldsymbol{\xi}) = \begin{array}{rl}\min & (\mathbf{P}\boldsymbol{\xi})^T\mathbf{w}\\ \text{subject to} & \mathbf{A}\mathbf{w} = \mathbf{0},\\ & \mathbf{y}_0 + \mathbf{w} \succeq \mathbf{0}.\end{array} \tag{A.8}$$

The following are easy to check linear algebra facts:

(i) $\gamma = 0 \Rightarrow 2(\mathbf{e}^T\mathbf{y}_0)^2 \leq \|\mathbf{y}_0\|^2$.

(ii) $\gamma = 0 \Rightarrow 2(\mathbf{e}^T\mathbf{w})^2 \leq \|\mathbf{w}\|^2$ for all $\mathbf{w} \in \mathcal{N}(\mathbf{A})$. In particular, $\|\mathbf{P}\boldsymbol{\xi}\|^2 \geq 2(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2$.

We solve (A.8) by first scaling it to reduce it to a minimum norm problem and then optimizing over the scaling factor. Let $\mathbf{w}^*$ denote the optimal solution of (A.8) and let $\alpha^* = \mathbf{e}^T(\mathbf{y}_0 + \mathbf{w}^*)$. Then

$$\|\mathbf{w}^* + \mathbf{y}_0\|^2 = \|\mathbf{w}^*\|^2 + \|\mathbf{y}_0\|^2 \leq 2(\alpha^*)^2,$$

where the equality follows from the fact that $\mathbf{y}_0^T\mathbf{w}^* = \mathbf{b}^T(\mathbf{A}\mathbf{A}^T)^{-1}\mathbf{A}\mathbf{w}^* = 0$. It follows that $\mathbf{w}^*$ is the optimal solution of

$$\begin{array}{rl}\min & (\mathbf{P}\boldsymbol{\xi})^T\mathbf{w}\\ \text{subject to} & \mathbf{A}\mathbf{w} = 0,\\ & \mathbf{e}^T\mathbf{w} = \alpha - \mathbf{e}^T\mathbf{y}_0,\\ & \|\mathbf{w}\|^2 \leq 2\alpha^2 - \|\mathbf{y}_0\|^2,\end{array} \tag{A.9}$$

with α set equal to α^*. Using Lagrange multipliers, the optimal value of (A.9) is given by

$$\begin{aligned}(\mathbf{P}\boldsymbol{\xi})^T\mathbf{w}_\alpha = &-\sqrt{\|\mathbf{P}\boldsymbol{\xi}\|^2 - 2(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2}\sqrt{4\alpha(\mathbf{e}^T\mathbf{y}_0) - \|\mathbf{y}_0\|^2 - 2(\mathbf{e}^T\mathbf{y}_0)^2}\\ &+ 2(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})(\alpha - \mathbf{e}^T\mathbf{y}_0).\end{aligned} \tag{A.10}$$

Differentiating this expression with respect to α we get

$$4\alpha^*(\mathbf{e}^T\mathbf{y}_0) - \|\mathbf{y}_0\|^2 - 2(\mathbf{e}^T\mathbf{y}_0)^2 = \left(\frac{\mathbf{e}^T\mathbf{y}_0}{\mathbf{e}^T\mathbf{P}\boldsymbol{\xi}}\right)^2\left(\|\mathbf{P}\boldsymbol{\xi}\|^2 - 2(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2\right).$$

It is easy to check that $2(\alpha^*)^2 \geq \|\mathbf{y}_0\|^2$. Substituting α^* into (A.10) and simplifying we get

$$\begin{aligned}\bar{q}(\boldsymbol{\xi}) &= \boldsymbol{\xi}^T\mathbf{y}_0 + (\mathbf{P}\boldsymbol{\xi})^T\mathbf{w}_{\alpha^*}\\ &= \boldsymbol{\xi}^T\mathbf{y}_0 + \left(\frac{\|\mathbf{y}_0\|^2 - 2(\mathbf{e}^T\mathbf{y}_0)^2}{2\mathbf{e}^T\mathbf{y}_0}\right)\mathbf{e}^T\mathbf{P}\boldsymbol{\xi} - \mathbf{e}^T\mathbf{y}_0\left(\frac{\|\mathbf{P}\boldsymbol{\xi}\|^2 - 2(\mathbf{e}^T\mathbf{P}\boldsymbol{\xi})^2}{2\mathbf{e}^T\mathbf{P}\boldsymbol{\xi}}\right).\end{aligned}$$

Appendix B. Analysis for the case rank(DB) = $p < n - m$. Note that in this case $\mathbf{A} = \mathbf{U}_1^T = \emptyset$, so $\gamma = \frac{1}{2}$ and $\mathbf{P} = \mathbf{I}$. The following lemma is easy to prove.

LEMMA B.1. *Let $\hat{q} : \mathbf{R}^p \mapsto \mathbf{R}$ denote the function defined in* (2.16). *Then the domain $\mathcal{D}_{\hat{q}} = \{\boldsymbol{\xi} : \hat{q}(\boldsymbol{\xi}) > -\infty\}$ is given by*

$$\mathcal{D}_{\hat{q}} = \Big\{\boldsymbol{\xi} : \mathbf{e}^T\boldsymbol{\xi} \geq 0, 2(\mathbf{e}^T\boldsymbol{\xi})^2 - \|\boldsymbol{\xi}\|^2 \geq 0\Big\}, \tag{B.1}$$

where $\mathbf{e} = (1, \mathbf{0}^T)^T$. For all $\boldsymbol{\xi} \in \mathcal{D}_{\hat{q}}$, we have $\hat{q}(\boldsymbol{\xi}) = 0$.

Then (2.14), (2.15), (2.16), (2.17), and Lemma B.1 imply that the Lagrangian dual problem is given by

$$\begin{aligned} \max \quad & (\mathbf{f} - \mathbf{E}^T\boldsymbol{\lambda})^T\mathbf{z}_0 \\ \text{subject to} \quad & \mathcal{A}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}] = \mathbf{0}, \\ & \boldsymbol{\lambda} \geq \mathbf{0}, \\ & \boldsymbol{\xi} \in \mathcal{K}, \end{aligned} \tag{B.2}$$

where $\mathcal{A}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}]$ denotes the set of linear equalities in (3.1) and $\mathcal{K} = \{\mathbf{z} : \mathbf{e}^T\mathbf{z} \geq 0, 2(\mathbf{e}^T\mathbf{z})^2 - \|\mathbf{z}\|^2 \geq 0\}$.

As in the case discussed in the paper, first set $\boldsymbol{\xi} = \mathbf{0}$ and solve (B.2). Let $\boldsymbol{\mu}^{(1)}$ be its optimal solution. A direction $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is an ascent direction at $(\mathbf{0}, \boldsymbol{\mu}^{(1)})$ if and only if $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ is a recession direction of the set

$$\begin{aligned} -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda > 0, \\ \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ \mathbf{d}_\xi \in \mathcal{K}, \end{aligned} \tag{B.3}$$

with the matrix $\mathbf{W} = \mathbf{0}$.

LEMMA B.2. *A recession direction $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ of* (B.3)*, if it exists, can be computed by solving two systems of linear equations.*

Proof. We will find a recession direction of (B.3) by solving the following problem:

$$\begin{aligned} \max \quad & -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{d}_\xi \in \mathcal{K}. \end{aligned} \tag{B.4}$$

If the optimal value of this problem is positive, then (B.3) has a recession direction. The direction $(\mathbf{d}_\xi, \mathbf{d}_\lambda)$ can be computed by considering the following three cases:

(a) Suppose $\mathbf{d}_\xi = \mathbf{0}$. Then $(\mathbf{0}, \mathbf{d}_\lambda)$ is a recession direction for (B.3) if and only if $\mathbf{d}_\lambda$ solves

$$\begin{aligned} -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda = 1, \\ \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{0}, \mathbf{0}, \mathbf{0}] = \mathbf{0}. \end{aligned} \tag{B.5}$$

(b) Next, suppose (B.5) is infeasible; however, there exists a positive recession direction for (B.4). Set $\mathbf{e}^T\mathbf{d}_\xi = 1$ in (B.4) to obtain

$$\begin{aligned} \max \quad & -\mathbf{z}_0^T\mathbf{E}^T\mathbf{d}_\lambda \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, \mathbf{d}_\xi, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{d}_\xi = 1, \\ & \|\mathbf{d}_\xi\|^2 \leq 2. \end{aligned} \tag{B.6}$$

Since (B.5) is assumed to be infeasible, (B.6) is bounded. Setting $\mathbf{d}_\xi = -\mathbf{L}\mathbf{d}_\lambda$, we get

$$\begin{aligned} \max \quad & -\big(\mathbf{E}\mathbf{z}_0\big)^T \mathbf{d}_\lambda \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\mathbf{d}_\lambda, -\mathbf{L}\mathbf{d}_\lambda, \mathbf{0}, \mathbf{0}] = \mathbf{0}, \\ & \mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda = -1, \\ & \|\mathbf{L}\mathbf{d}_\lambda\|^2 \le 2. \end{aligned}$$

Since the objective function of this problem is linear, the optimal $\mathbf{d}_\lambda^*$ satisfies $\|\mathbf{L}\mathbf{d}_\lambda^*\|^2 = 2$ and the Lagrangian function $\mathcal{L}$ is given by

$$\mathcal{L} = -(\mathbf{E}\mathbf{z}_0)^T\mathbf{d}_\lambda - \boldsymbol{\tau}^T\mathbf{M}\mathbf{d}_\lambda - \boldsymbol{\rho}^T\mathbf{W}\mathbf{d}_\lambda - \eta(\mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda + 1) - \beta(\|\mathbf{L}\mathbf{d}_\lambda\|^2 - 2),$$

where $\beta \ge 0$ and the first-order optimality conditions are given by

$$\begin{aligned} 2\beta\mathbf{L}^T\mathbf{L}\mathbf{d}_\lambda + \mathbf{M}^T\boldsymbol{\tau} + \mathbf{W}^T\boldsymbol{\rho} + \mathbf{L}^T\mathbf{e}\eta &= -\mathbf{E}\mathbf{z}_0, \\ \mathbf{M}\mathbf{d}_\lambda &= \mathbf{0}, \\ \mathbf{W}\mathbf{d}_\lambda &= \mathbf{0}, \\ \mathbf{e}^T\mathbf{L}\mathbf{d}_\lambda &= -1, \end{aligned} \tag{B.7}$$

and $\beta(\|\mathbf{L}\mathbf{d}_\lambda\|^2 - 2) = 0$. If $\beta = 0$, then (B.7) can be solved easily. Suppose $\beta > 0$. Then by setting $\bar{\boldsymbol{\rho}} = \frac{1}{\beta}\boldsymbol{\rho}$, $\bar{\boldsymbol{\tau}} = \frac{1}{\beta}\boldsymbol{\tau}$, and $\bar{\eta} = \frac{1}{\beta}\eta$, we see that (B.7) is equivalent to

$$\underbrace{\begin{bmatrix} 2\mathbf{L}^T\mathbf{L} & \mathbf{M}^T & \mathbf{W}^T & \mathbf{L}^T\mathbf{e} \\ \mathbf{M} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{W} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{e}^T\mathbf{L} & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}}_{\triangleq \mathbf{K}} \begin{bmatrix} \mathbf{d}_\lambda \\ \bar{\boldsymbol{\tau}} \\ \bar{\boldsymbol{\rho}} \\ \bar{\eta} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ -1 \end{bmatrix} - \frac{1}{\beta}\begin{bmatrix} \mathbf{E}\mathbf{z}_0 \\ \mathbf{0} \\ \mathbf{0} \\ 0 \end{bmatrix}.$$

Suppose $\mathbf{K}$ is nonsingular. Let $\mathbf{w} = (\bar{\boldsymbol{\tau}}^T, \bar{\boldsymbol{\rho}}^T, \bar{\eta})^T$, $\mathbf{b}_1 = (\mathbf{0}^T, \mathbf{0}^T, -1)^T$, and $\mathbf{b}_2 = \mathbf{E}\mathbf{z}_0$. Partition $\mathbf{K}^{-1}$ into submatrices

$$\mathbf{K}^{-1} = \begin{bmatrix} \mathbf{K}_{11}^{-1} & \mathbf{K}_{12}^{-1} \\ \mathbf{K}_{12}^{-T} & \mathbf{K}_{22}^{-1} \end{bmatrix}$$

such that

$$\begin{bmatrix} \mathbf{d}_\lambda \\ \mathbf{w} \end{bmatrix} = \mathbf{K}^{-1}\begin{bmatrix} \mathbf{0} \\ \mathbf{b}_1 \end{bmatrix} - \frac{1}{\beta}\mathbf{K}^{-1}\begin{bmatrix} \mathbf{b}_2 \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \mathbf{K}_{12}^{-1}\mathbf{b}_1 - \frac{1}{\beta}\mathbf{K}_{11}^{-1}\mathbf{b}_2 \\ \mathbf{K}_{22}^{-1}\mathbf{b}_1 - \frac{1}{\beta}\mathbf{K}_{12}^{-T}\mathbf{b}_2 \end{bmatrix}.$$

This partition implies that $\mathbf{K}_{12}^{-T}\mathbf{L}^T\mathbf{L}\mathbf{K}_{11}^{-1}$. Therefore, β is the unique positive root of

$$\begin{aligned} 2 &= \|\mathbf{L}\mathbf{d}_\lambda\|^2 \\ &= \|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 - 2\frac{1}{\beta}(\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1)^T\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2 + \frac{1}{\beta^2}\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2 \\ &= \|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 + \frac{1}{\beta^2}\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2. \end{aligned}$$

Consequently,

$$\beta = \sqrt{\frac{\|\mathbf{L}\mathbf{K}_{11}^{-1}\mathbf{b}_2\|^2}{2 - \|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2}}.$$

Thus, (B.7) has a solution if and only if $2 - \|\mathbf{L}\mathbf{K}_{12}^{-1}\mathbf{b}_1\|^2 > 0$.
The case where $\mathbf{K}$ is singular can be handled by taking an SVD of $\mathbf{K}$ and working in the appropriate range spaces.

(c) In case one is not able to produce a solution in either (a) or (b), it follows that the optimal solution of (B.4) is 0, and $(\mathbf{d}_\xi, \mathbf{d}_\lambda) = (\mathbf{0}, \mathbf{0})$ achieves this value. □

In a typical step of the ActiveSet when $\mathbf{rank}(\mathbf{DB}) = p$, we have to solve the following problem:

$$\begin{aligned} \max \quad & -\mathbf{z}_0^T \mathbf{E}^T \boldsymbol{\lambda} \\ \text{subject to} \quad & \mathcal{A}_{\mathbf{W}}[\boldsymbol{\lambda}, \boldsymbol{\xi}, \mathbf{h}, \mathbf{p}] = \mathbf{0}, \\ & \boldsymbol{\xi} \in \mathcal{K}, \end{aligned} \tag{B.8}$$

where $\mathbf{W}$ denotes the current inactive set, i.e., $\mathbf{W} = \sum_{i:\lambda_i=0} \mathbf{e}_i \mathbf{e}_i^T$.

Lemma B.3. *Suppose there exists a feasible* $(\bar{\boldsymbol{\xi}}, \bar{\boldsymbol{\lambda}})$ *for* (B.8) *such that* $\bar{\boldsymbol{\xi}} \in \mathbf{int}(\mathcal{K})$. *Then* (B.8) *can be solved in closed form by solving at most three systems of linear equations.*

This result can be established using a combination of the techniques used to establish Lemmas B.2 and 3.4.

Appendix C. Decreasing dimensions of K. Consider the system of linear equalities

$$\begin{aligned} \tilde{\mathbf{K}}\tilde{\mathbf{d}} + \tilde{\mathbf{W}}^T \bar{\boldsymbol{\rho}} &= \mathbf{b}, \\ \tilde{\mathbf{W}}\tilde{\mathbf{d}} &= \mathbf{0}, \end{aligned} \tag{C.1}$$

where $\tilde{\mathbf{K}}$ and $\tilde{\mathbf{d}}$ are given in (3.20) and $\tilde{\mathbf{W}} = [\mathbf{W}, \mathbf{0}, \mathbf{0}]$. Let an SVD of $\tilde{\mathbf{K}}$ be given by

$$\tilde{\mathbf{K}} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = \mathbf{U} \begin{bmatrix} \boldsymbol{\Sigma}_0 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{V}_0^T \\ \mathbf{V}_1^T \end{bmatrix},$$

where $\boldsymbol{\Sigma}_0 \in \mathbf{R}^{r_K \times r_K}$ is a diagonal matrix and $r_K = \mathbf{rank}(\tilde{\mathbf{K}})$. Decompose $\tilde{\mathbf{d}} = \mathbf{V}_0\boldsymbol{\mu} + \mathbf{V}_1\boldsymbol{\zeta}$. Then (C.1) is equivalent to

$$\begin{aligned} \mathbf{U} \begin{bmatrix} \boldsymbol{\Sigma}_0\boldsymbol{\mu} \\ \mathbf{0} \end{bmatrix} + \tilde{\mathbf{W}}^T \bar{\boldsymbol{\rho}} &= \mathbf{b}, \\ \tilde{\mathbf{W}}(\mathbf{V}_0\boldsymbol{\mu} + \mathbf{V}_1\boldsymbol{\zeta}) &= \mathbf{0}, \end{aligned}$$

which is equivalent to

$$\begin{aligned} \begin{bmatrix} \boldsymbol{\Sigma}_0\boldsymbol{\mu} \\ \mathbf{0} \end{bmatrix} + \mathbf{U}^T\tilde{\mathbf{W}}^T \bar{\boldsymbol{\rho}} &= \mathbf{U}^T\mathbf{b}, \\ \tilde{\mathbf{W}}(\mathbf{V}_0\boldsymbol{\mu} + \mathbf{V}_1\boldsymbol{\zeta}) &= \mathbf{0}. \end{aligned} \tag{C.2}$$

Let

$$\mathbf{U}^T = \begin{bmatrix} \mathbf{U}_0^T \\ \mathbf{U}_1^T \end{bmatrix}.$$

Then (C.2) is equivalent to

$$\begin{aligned} \boldsymbol{\Sigma}_0\boldsymbol{\mu} + \mathbf{U}_0^T\tilde{\mathbf{W}}^T \bar{\boldsymbol{\rho}} &= \mathbf{U}_0^T\mathbf{b}, \\ \mathbf{U}_1^T\tilde{\mathbf{W}}^T \bar{\boldsymbol{\rho}} &= \mathbf{U}_1^T\mathbf{b}, \\ \tilde{\mathbf{W}}\mathbf{V}_0\boldsymbol{\mu} + \tilde{\mathbf{W}}\mathbf{V}_1\boldsymbol{\zeta} &= \mathbf{0}. \end{aligned}$$

Setting $\boldsymbol{\mu} = \boldsymbol{\Sigma}_0^{-1}(\mathbf{U}_0^T\mathbf{b} - \mathbf{U}_0^T\tilde{\mathbf{W}}^T\bar{\boldsymbol{\rho}})$, we obtain the following system which has a smaller number of variables:

$$\mathbf{U}_1^T\tilde{\mathbf{W}}^T\bar{\boldsymbol{\rho}} = \mathbf{U}_1^T\mathbf{b},$$
$$\tilde{\mathbf{W}}\mathbf{V}_1\boldsymbol{\zeta} - \tilde{\mathbf{W}}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\tilde{\mathbf{W}}^T\bar{\boldsymbol{\rho}} = -\tilde{\mathbf{W}}\mathbf{V}_0\boldsymbol{\Sigma}_0^{-1}\mathbf{U}_0^T\mathbf{b}.$$

Acknowledgments. The authors would like to thank the anonymous referees and the associate editor, Michael J. Todd, for constructive comments and suggestions.

ON SOLUTIONS TO THE MASS TRANSFER PROBLEM*

JUAN GONZÁLEZ-HERNÁNDEZ†, J. RIGOBERTO GABRIEL‡, AND ONÉSIMO HERNÁNDEZ-LERMA§

Abstract. This paper studies the Monge–Kantorovich mass transfer (MT) problem on metric spaces, with possibly unbounded "cost" function. Conditions are given under which the MT problem is solvable and, furthermore, an optimal solution can be obtained as the weak limit of a sequence of optimal solutions to suitably approximating MT problems.

Key words. mass transfer problem, Monge–Kantorovich problem, approximation of optimization problems

DOI. 10.1137/050623991

1. Introduction.

In this paper we study the Monge–Kantorovich mass transfer (MT) problem (introduced in section 2; see (2.1), (2.2)) on metric spaces X and Y, and with a possibly unbounded real-valued "cost" function c on $X \times Y$. We propose *two* new approaches to show that MT is solvable. First in section 4 we show that MT is *equivalent* to a problem MTK on a set of randomized strategies, also known as stochastic kernels or Young measures [5, 13, 14]. Then in section 5 we prove that MTK is solvable and, therefore, so is MT. Moreover, in section 6, we introduce an *approximating approach* to MT by means of mass transfer problems MTi with marginals (see ν_1, ν_2 in (2.2)) concentrated on *finite sets*. We show that the sequence of optimal solutions to MTi and the sequence of the corresponding optimal values converge to an optimal solution to MT and to the optimal value, respectively.

The MT problem is among the oldest and most well-known problems in probability theory and its applications. It was originally introduced by Monge in 1781 [19], but it was posed as a mathematical programming problem by Kantorovich in 1942 [17]. Kantorovich considered the case of compact metric spaces $X = Y$ and cost $c(x, y) := d(x, y)$, the distance function on X. He proved that the problem is solvable in this case. In the 1970s, Levin and Milyutin (see [21, 22, 23] for earlier references) proved solvability for compact metric spaces and some classes of discontinuous cost functions. In fact, several authors have studied the MT problem with a *lower semicontinuous* (l.s.c.) cost function. In particular, Jiménez–Guerra and Rodríguez–Salinas [16] dealt with Hausdorff topological spaces X and Y, Radon measures, and an l.s.c. cost function. Hernández–Lerma and Gabriel [15] proved solvability of the MT problem in general metric spaces, and an *inf-compact* cost function, which means that the lower level set $\{(x, y) \in X \times Y \mid c(x, y) \le r\}$ is compact for each $r \in \mathbb{R}$. Other

solvability results when X and Y are compact spaces and $c(x, y)$ is l.s.c. are discussed in [23, Chapter 4] and [2, Chapter 5].

In addition to solvability, several other aspects of the MT problem have been studied by many authors using different approaches. For instance, Wu [26] studied the structure of extreme points for the MT problem with X and Y compact Hausdorff spaces. Cuesta-Albertos and Tuero-Díaz [10] characterized the solution of the MT problem in terms of a so-called optimal coupling in the case that ν_2 has *finite* support and ν_1 verifies a continuity condition. A similar approach was used by Abdellaoui [1]. Cambanis, Simons, and Stout [7] and also McCann [18] found some explicit solutions to the MT problem on the real line, i.e., $X = Y = \mathbb{R}$. Ruzankin [25] also studied the form of optimal solutions on the real line. In [11], Gangbo used randomized strategies to formulate the MT problem as a variational one on $\mathbb{R}^d \times \mathbb{R}^d$.

In this paper we also use randomized strategies, but in general metric spaces. The idea is to introduce a suitable topology on the space of those strategies, and then use the Bauer extremum principle [8] to prove that MT (actually, the equivalent problem MTK) is solvable. Our approximation approach in section 6 is partly inspired by [3], although our setting and proof techniques are quite different.

Summarizing, in this paper we present *two* new, different, approaches to obtaining the solvability of MT. The first one is to give conditions for the *equivalent* problem MTK to be solvable. The second is an approximation approach by means of MT problems with marginals concentrated on finite sets.

After some technical preliminaries in sections 2 and 3, the plan for the remainder of the paper (sections 4, 5, and 6) is as sketched in the first paragraph of the introduction.

2. The MT problem. In the MT problem with which we are concerned, we are given the following data: (i) two metric spaces X and Y endowed with the corresponding Borel σ-algebras $\mathbb{B}(X)$ and $\mathbb{B}(Y)$; (ii) a nonnegative measurable function $c : X \times Y \to \mathbb{R}$; and (iii) a probability measure (p.m.) ν_1 on X, and a p.m. ν_2 on Y. Moreover, let $M(X \times Y)$ be the linear space of finite signed measures on $X \times Y$, endowed with the topology of weak convergence, and let $M^+(X \times Y)$ be the convex cone of nonnegative measures in $M(X \times Y)$. If μ is in $M(X \times Y)$, we denote by $\Pi_1\mu$ and $\Pi_2\mu$ the marginals (or projections) of μ on X and Y, respectively; that is, for all $A \in \mathbb{B}(X)$ and $B \in \mathbb{B}(Y)$

$$\Pi_1\mu(A) := \mu(A \times Y) \quad \text{and} \quad \Pi_2\mu(B) := \mu(X \times B).$$

Then, with $\langle \mu, c\rangle := \int c \, d\mu$, the MT problem can be stated as follows:

$$\textbf{MT} \qquad \text{Minimize} \quad \langle \mu, c\rangle \tag{2.1}$$

$$\text{subject to} \quad \Pi_1\mu = \nu_1, \quad \Pi_2\mu = \nu_2, \quad \mu \in M^+(X \times Y). \tag{2.2}$$

A measure $\mu \in M(X \times Y)$ is said to be a *feasible solution* for the MT problem if it satisfies (2.2) and $\int c \, d\mu$ is finite. The MT problem is called *consistent* if the set of feasible solutions is nonempty, in which case its (optimum) *value* is defined as

$$\inf(\text{MT}) := \inf\{\langle \mu, \text{c}\rangle | \mu \text{ is feasible for MT}\}.$$

It is said that the MT problem is *solvable* if there is a feasible solution μ^* that attains the optimum value. In this case, μ^* is called an *optimal solution* for the MT problem, and the value $\inf(\text{MT})$ is written as $\min(\text{MT}) = \langle \mu^*, c\rangle$.

Remark 2.1.

(a) Since ν_1 and ν_2 are p.m.'s, a feasible solution for the MT problem is necessarily a p.m.

(b) If c is a *bounded* function, then the product measure $\mu := \nu_1 \times \nu_2$ is feasible. This fact is not necessarily true if c is *unbounded*; see Example 1.2 in [12]. Even for unbounded c, however, mild assumptions ensure that the MT problem is consistent [12].

(c) If X and Y are compact metric spaces and c is l.s.c., then the set of feasible solutions is compact and, therefore, the MT problem is solvable. (See Theorem 2.2 and Remark 2.5 in [15].)

Now we will introduce an optimization problem on a family of stochastic kernels, which in section 4 is shown to be equivalent to the MT problem, when ν_2 has finite support.

Let $\mathbb{F}$ be the set of all (Borel) measurable functions from X to Y. Following the usage in control and game theory [6, 13, 14], a function in $\mathbb{F}$ will be referred to as a *deterministic strategy*. We also need the following more general concept of strategy.

DEFINITION 2.2. *A* randomized strategy (*also known as a* stochastic kernel) φ *from X to Y is a real-valued mapping $(x, B) \mapsto \varphi(B|x)$ on $X \times \mathbb{B}(Y)$ such that*

(a) *$\varphi(\cdot|x)$ is a p.m. on $\mathbb{B}(Y)$ for every fixed $x \in X$, and*

(b) *$\varphi(B|\cdot)$ is a measurable function on X for every fixed $B \in \mathbb{B}(Y)$.*

If (a) *is replaced with*

(a′) *$\varphi(\cdot|x)$ is a finite signed measure on $\mathbb{B}(Y)$ for every fixed $x \in X$,*

then φ is called a signed kernel *from X to Y. We shall denote by Φ the set* (*actually linear space*) *of all such kernels, and by Φ_1 the convex subset of randomized strategies.*

Given a deterministic strategy $f \in \mathbb{F}$, we may identify each $f(x) \in Y$ with the Dirac measure (or unit mass) $\varphi(\cdot|x) := \delta_{f(x)}(\cdot)$ concentrated at $f(x)$ for each $x \in X$. This of course defines a randomized strategy. With this identification we may write

$$\mathbb{F} \subset \Phi_1. \tag{2.3}$$

Let ν be a p.m. on X, and consider the following optimization problem:

$$\mathbb{P} \qquad \text{Minimize} \quad \int_X \int_Y c(x,y)\varphi(dy|x)\nu(dx), \tag{2.4}$$

$$\text{subject to} \quad \int_X \int_Y c_i(x,y)\varphi(dy|x)\nu(dx) \le b_i \quad \forall i = 1, \dots, n, \quad \varphi \in \Phi_1, \tag{2.5}$$

where $c_1, \dots, c_n$ are given measurable functions on $X \times Y$ and $b_1, \dots, b_n$ are given real numbers. This problem is a "randomized version" of the typical allocation problem in economics; see [4, 13, 27]. In section 6 below, we use a particular case of the MT problem that is of the form (2.4)–(2.5), and we will need to describe the extreme points $\varphi \in \Phi_1$ that satisfy (2.5). We describe these extreme points in Theorem 3.2.

Remark 2.3. An important variant of MT is the mass transshipment problem defined as [9, 23, 24]:

$$\text{Minimize} \quad \langle \mu, c \rangle$$

$$\text{subject to} \quad \Pi_1\mu - \Pi_2\mu = \nu_1 - \nu_2, \quad \mu \in M^+(X \times X), \tag{2.6}$$

where $c : X \times X \to \mathbb{R}$ is a given cost function and ν_1 and ν_2 are p.m.'s on X, a metric space. The so-called balance condition in (2.6) is equivalent to the following: there

exists $\Delta \in M(X)$ such that

$$\Pi_1\mu = \nu_1 + \Delta \quad \text{and} \quad \Pi_2\mu = \nu_2 - \Delta.$$

Hence, for any feasible measure μ for the mass transshipment problem we have

$$\mu(X \times X) = \Pi_1\mu(X) = \nu_1(X) + \Delta(X) = 1 + \Delta(X),$$

$$\mu(X \times X) = \Pi_2\mu(X) = \nu_2(X) - \Delta(X) = 1 - \Delta(X).$$

It follows that $\Delta(X) = 0$, and, therefore, μ is a p.m. Summarizing, if μ is feasible for the MT problem with $X = Y$ (see (2.2)), then μ is feasible for the mass transshipment problem. Moreover, the results for MT introduced in the following sections can be extended, with appropriate changes, to the mass transshipment problem. Research on this matter is in progress.

3. Convex sets of randomized strategies. In this section we introduce a result from [13] that characterizes the extreme points of feasible solutions to the problem $\mathbb{P}$ in (2.4)–(2.5). This result is applied to the MT problem in section 6. First, we need a definition. (Recall (2.3).)

DEFINITION 3.1. *A randomized strategy $\varphi \in \Phi_1$ is said to be a* randomization of at most $n+1$ *deterministic strategies, or simply an* $(n+1)$-randomization, *if there exist a positive integer $m \leq n+1$, functions $f_1, \ldots, f_m$ in $\mathbb{F}$, and nonnegative numbers $\alpha_1, \ldots, \alpha_m$ with $\alpha_1 + \cdots + \alpha_m = 1$ such that*

$$\varphi(B|x) = \sum_{j=1}^{m} \alpha_j \delta_{f_j(x)}(B) \quad \forall B \in \mathbb{B}(Y),\ x \in X. \tag{3.1}$$

In this case we write $\varphi \in \mathcal{R}_{n+1}(f_1, \ldots, f_m; \alpha_1, \ldots, \alpha_m)$.

The following result, which uses the notation in (2.5), is applied to the MT problem in section 6.

THEOREM 3.2. *Let X be a metric space, and Y a separable metric space. Fix an arbitrary p.m. ν on $\mathbb{B}(X)$, real-valued measurable functions $c_1, \ldots, c_n$ on $X \times Y$, and real numbers $b_1, \ldots, b_n$. Consider the set $\Delta \subset \Phi_1$ consisting of all the randomized strategies φ in Φ_1 for which, for all $i = 1, \ldots, n$,*

$$\int_X \int_Y |c_i(x,y)| \varphi(dy|x)\nu(dx) < \infty \tag{3.2}$$

and

$$\int_X \int_Y c_i(x,y) \varphi(dy|x)\nu(dx) \leq b_i. \tag{3.3}$$

Let $ex(\Delta)$ be the set of extreme points of Δ. Then

(a) *Δ is convex and*

$$ex(\Delta) \subset \mathcal{R}^0_{n+1}, \tag{3.4}$$

where $\mathcal{R}^0_{n+1}$ is the set of all the $(n+1)$-randomizations $\varphi \in \mathcal{R}_{n+1}(f_1, \ldots, f_m; \alpha_1, \ldots, \alpha_m)$ for which the vectors

$$\left(\int c_1(x, f_j(x))\nu(dx), \ldots, \int c_n(x, f_j(x))\nu(dx), 1 \right) \in \mathbb{R}^{n+1} \tag{3.5}$$

for $j = 1, \ldots, m$ are linearly independent.

(b) *If equality holds in* (3.3), *then the sets in* (3.4) *are equal.*

Proof. See [13]. □

4. An equivalent problem to MT. In this section we show that the MT problem is equivalent to the following optimization problem on the set Φ_1 of randomized strategies.

Let c, ν_1, and ν_2 be as in the MT problem (2.1)–(2.2). Consider

$$\textbf{MTK} \qquad \text{Minimize} \quad \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dx), \tag{4.1}$$

$$\text{subject to} \quad \int_X \varphi(\cdot|x)\nu_1(dx) = \nu_2(\cdot),\ \varphi \in \Phi_1. \tag{4.2}$$

A randomized strategy $\varphi \in \Phi_1$ is said to be a *feasible solution* for MTK if it satisfies (4.2) and the integral in (4.1) is finite. The problem MTK is called *consistent* if the set of feasible solutions is nonempty, in which case its *value* is defined as the infimum, over the set of feasible solutions, of the integrals in (4.1). If the infimum is attained at some feasible solution, say φ^*, then MTK is said to be *solvable* and φ^* is called an *optimal solution* for MTK.

THEOREM 4.1. *MT and MTK are equivalent; that is, for each φ in Φ_1 that satisfies* (4.2) (*a feasible solution for MTK*), *there is a p.m. μ on $X \times Y$ that satisfies* (2.2) (*a feasible solution for MT*) *such that*

$$\langle \mu, c\rangle := \int_{X\times Y} c\ d\mu = \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dx) =: \langle \varphi, c\rangle. \tag{4.3}$$

Conversely, for each feasible solution μ for MT, there exists a feasible solution φ for MTK such that φ and μ satisfy (4.3).

Proof. Let μ be a feasible solution for MT. Then, by a well-known result on the disintegration of product measures (see, e.g., [14, Proposition D.8, p. 184]), there is a stochastic kernel $\varphi \in \Phi_1$ such that

$$\mu(A \times B) = \int_A \varphi(B|x)\nu_1(dx) \quad \forall A \in \mathbb{B}(X), \quad B \in \mathbb{B}(Y). \tag{4.4}$$

Hence

$$\begin{aligned} \nu_2(B) = \Pi_2\mu(B) &= \mu(X \times B) \\ &= \int_X \varphi(B|x)\nu_1(dx), \end{aligned}$$

and thus φ is a feasible solution for MTK by (4.2). Moreover, by (4.4),

$$\int_{X\times Y} c\ d\mu = \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dx),$$

and (4.3) follows.

Now, let φ be a feasible solution for MTK. Then there is unique p.m. μ on $X \times Y$ given by

$$\mu(A \times B) := \int_A \varphi(B|x)\nu_1(dx) \quad \forall A \in \mathbb{B}(X), \quad B \in \mathbb{B}(Y), \tag{4.5}$$

and for which

$$\int_{X\times Y} c\, d\mu = \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dx).$$

Furthermore,

$$\Pi_1\mu(A) = \mu(A \times Y) = \int_A \varphi(Y|x)\nu_1(dx) = \nu_1(A),$$

and since φ is a feasible solution for MTK, (4.2) gives

$$\Pi_2\mu(B) = \mu(X \times B) = \int_X \varphi(B|x)\nu_1(dx) = \nu_2(B).$$

Therefore, μ satisfies (2.2) and thus it is a feasible solution for MT. □

A measure defined as in (4.5) will be denoted by $\mu := \varphi \cdot \nu_1$.

Part (c) in the following corollary uses (2.3).

COROLLARY 4.2.

(a) *MT is consistent if and only if MTK is consistent.*

(b) *MT is solvable if and only if MTK is solvable.*

(c) *If MTK has an optimal solution $\varphi \in \Phi_1$ which is a deterministic strategy, say $\varphi(\cdot|x) = \delta_{f(x)}(\cdot)$ for some $f \in \mathbb{F}$, then f is a so-called* optimal coupling *for MT (which means that the measure $\mu(A \times B) = \int_A \delta_{f(x)}(B)\nu_1(dx)$ is concentrated along $(x, f(x))$) and is an optimal solution for MT* [1, 18, 21, 22].

Let $\mathcal{F}_{MT}$ be the class of feasible solutions to MT and let $\mathcal{F}_{MTK}$ be the class of feasible solutions to MTK. In view of Corollary 4.2(b), in the following section we study the solvability of MTK. In fact, we show that MTK has an optimal solution which is an extreme point of $\mathcal{F}_{MTK}$.

5. Solvability of MTK. To show that MTK is solvable, first we introduce some concepts that will be used to define suitable topologies on sets of stochastic kernels. The following definitions can also be found in [5, 6], for instance. (Recall Definition 2.2 on Φ and Φ_1.)

DEFINITION 5.1. *A* uniformly finite kernel *from X to Y is a signed kernel $\varphi \in \Phi$ such that*

$$\sup_{x \in X} |\varphi(Y|x)| < \infty,$$

where, for each $x \in X$, $|\varphi(Y|x)|$ denotes the total variation of $\varphi(\cdot|x)$.

The set of all uniformly finite kernels is denoted by Φ_0. It is evident that Φ_0 is a linear space with the usual addition and scalar multiplication of signed kernels, and that, moreover, $\Phi_1 \subset \Phi_0 \subset \Phi$.

DEFINITION 5.2. *A* normal integrand bounded from below *on $X \times Y$ is a function $g : X \times Y \to (-\infty, \infty]$ such that*

(i) *$g(x, \cdot)$ is l.s.c. on Y for every $x \in X$,*

(ii) *g is $\mathbb{B}(X) \times \mathbb{B}(Y)$-measurable, and*

(iii) *there is a function $f \in L_1(\nu_1) := L_1(X, \mathbb{B}(X), \nu_1)$ such that $g(x, y) \geq f(x)$ for all $x \in X, y \in Y$.*

The set of all normal integrands bounded from below is denoted by $\mathcal{C}^{bb}$. We next introduce a suitable subset of $\mathcal{C}^{bb}$.

DEFINITION 5.3. *A* Carathéodory integrand *on $X \times Y$ is a function $g : X \times Y \to \mathbb{R}$ such that*

(i) *$g(x, \cdot)$ is continuous on Y for every $x \in X$,*

(ii) *g is $\mathbb{B}(X) \times \mathbb{B}(Y)$-measurable on $X \times Y$, and*

(iii) *$|g| \leq f$ on $X \times Y$ for some $f \in L_1(\nu_1)$.*

The set of all Carathéodory integrands on $X \times Y$ is denoted by $\mathcal{C}^c$. Observe that $\mathcal{C}^c$ contains the space $C_b(X \times Y)$ of continuous bounded functions on $X \times Y$. On the other hand, for each $g \in \mathcal{C}^c$ we define a functional $I_g : \Phi_0 \to \mathbb{R}$ by

$$I_g(\varphi) := \int_X \int_Y g(x,y)\varphi(dy|x)\nu_1(dx). \tag{5.1}$$

The *weak topology* on Φ_0 is defined as the coarsest topology for which all the functionals $I_g : \Phi_0 \to \mathbb{R}$, for $g \in \mathcal{C}^c$, are continuous. Similarly, the *weak topology* on Φ_1 is defined as the coarsest topology for which all the functionals $I_g : \Phi_1 \to \mathbb{R}$, for $g \in \mathcal{C}^c$, are continuous. It can be proved that Φ_0 is a Hausdorff topological vector space which is locally convex [5].

ASSUMPTION 5.4.

(a) *Y is a complete and separable metric space.*

(b) *The "cost" function $c(x,y)$ is nonnegative and $c(x,\cdot)$ is l.s.c. on Y for every $x \in X$. (Hence c is in $\mathcal{C}^{bb}$.)*

(c) *MT is consistent.*

Concerning the consistency in Assumption 5.4(c), see Remark 2.1.

We have the following result.

THEOREM 5.5. *Under Assumption* 5.4*, there exists a stochastic kernel $\varphi \in \Phi_1$ such that φ is an optimal solution to MTK and, moreover, φ is an extreme point of $\mathcal{F}_{MTK}$.*

Proof. First we will show that $\mathcal{F}_{MTK}$ is weakly closed. Let $(N, \leq)$ be a directed set and suppose that $\{\varphi_n, n \in N\}$ converges weakly to φ in Φ_1. Then, by Theorem 2.2(b) in [6], we have

$$\int_X \int_Y g(x,y)\varphi_n(dy|x)\nu_1(dx) \to \int_X \int_Y g(x,y)\varphi(dy|x)\nu_1(dx) \tag{5.2}$$

for all g in $\mathcal{C}^c$.

For φ and each φ_n, let μ and μ_n be the corresponding p.m.'s on $X \times Y$ defined by (4.5). By Theorem 4.1, $\{\mu_n, n \in N\}$ is a net in $\mathcal{F}_{MT}$. Moreover, by (4.5) again, for each f in $\mathcal{C}^c$ we have

$$\int_{X\times Y} f d\mu_n = \int_X \int_Y f(x,y)\varphi_n(dy|x)\nu_1(dx) \tag{5.3}$$

and

$$\int_{X\times Y} f d\mu = \int_X \int_Y f(x,y)\varphi(dy|x)\nu_1(dx). \tag{5.4}$$

In particular, if $f \in C_b(X \times Y)$, then by (5.2)–(5.4), we have

$$\begin{aligned} \int_{X\times Y} f d\mu_n &= \int_X \int_Y f(x,y)\varphi_n(dy|x)\nu_1(dx) \\ &\to \int_X \int_Y f(x,y)\varphi(dy|x)\nu_1(dx) \\ &= \int_{X\times Y} f d\mu. \end{aligned}$$

This implies that $\{\mu_n\}$ converges weakly to μ. In turn, the latter yields, by Lemma 2.7 in [15], that μ is a feasible solution to MT. Therefore, by Theorem 4.1, φ is in $\mathcal{F}_{MTK}$ and we conclude that $\mathcal{F}_{MTK}$ is weakly closed.

As Φ_1 is weakly compact (see Theorem 2.3(a) in [6]) and $\mathcal{F}_{MTK}$ is weakly closed, it follows that $\mathcal{F}_{MTK}$ is weakly compact. This fact, together with Assumption 5.6(b) and Theorem 2.3(b) in [6], gives that the functional

$$I_c(\varphi) := \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dx) \tag{5.5}$$

is weakly inf-compact. Thus, I_c is a weakly l.s.c. functional and thus, by the Bauer extremum principle (see, for instance, Theorem 25.9 in [8]), it follows that there is an extreme point φ of $\mathcal{F}_{MTK}$ where I_c attains its minimum value. Finally comparing (5.5) and (4.1) we obtain the desired conclusion. □

6. An approximation approach to the MT problem. In this section we study the MT problem by means of an approximation procedure consisting of three steps. First, we assume that the marginal ν_2 has finite support, and we characterize an optimal solution for this problem (see Theorem 6.1). Second, we construct a sequence {MTi} of MT problems with the characteristic that the marginals ν_1^i and ν_2^i both have finite support. Then for each i, we find an optimal solution μ_i of MTi and show that $\{\mu_i\}$ is relatively compact. Therefore, there exist a measure μ^* and a subsequence $\{\mu_m\}$ such that $\{\mu_m\}$ converges weakly to μ^*. Finally, in the third step we prove that μ^* is an optimal solution to MT and, furthermore, $\lim_{m\to\infty}\langle \mu_m, c\rangle = \langle \mu^*, c\rangle$.

Step 1. Let us assume that ν_2 has finite support. Then there is a finite subset $\{y_1, y_2, \ldots, y_n\}$ of Y such that $\nu_2(\{y_i\}) := b_i \neq 0$ for all $i = 1, \ldots, n$, and $\nu_2(\{y_1, y_2, \ldots, y_n\}) = 1$.

We observe that the constraints (4.2) in this case are equivalent to

$$\int_X \varphi(\{y_i\}|x)\nu_1(dx) = \nu_2(\{y_i\}) = b_i \quad \forall i = 1, \ldots, n, \quad \varphi \in \Phi_1. \tag{6.1}$$

Consider $c_i(x,y) := I_{\{y_i\}}(y)$, where I_B is the indicator function of $B \in \mathbb{B}(X)$; that is, $I_B(x) := 1$ if $x \in B$ and $I_B(x) := 0$ if $x \notin B$. Then (6.1) can be expressed as

$$\int_X \int_Y I_{\{y_i\}}(y)\varphi(dy|x)\nu_1(dx) = b_i \quad \forall i = 1, \ldots, n, \quad \varphi \in \Phi_1$$

or, equivalently,

$$\int_X \int_Y c_i(x,y)\varphi(dy|x)\nu_1(dx) = b_i \quad \forall i = 1, \ldots, n, \quad \varphi \in \Phi_1.$$

Therefore, we have the following optimization problem, which is of the form (2.4)–(2.5):

$$\textbf{MTKn} \qquad \text{Minimize} \quad \int_X \int_Y c(x,y)\varphi(dy|x)\nu_1(dy) \tag{6.2}$$

$$\text{subject to} \quad \int_X \int_Y c_i(x,y)\varphi(dy|x)\nu_1(dx) = b_i \quad \forall i = 1, \ldots, n, \varphi \in \Phi_1. \tag{6.3}$$

Now, by Theorem 5.5, the MTKn problem achieves its minimum value at an extreme point φ_n^*. Moreover, by Theorem 3.2, φ_n^* is an $(n+1)$-randomization; that

is, there exist a positive integer $m \le n+1$, functions $f_1, \dots, f_m$ in $\mathbb{F}$, and nonnegative numbers $\alpha_1, \dots, \alpha_m$ such that $\alpha_1 + \cdots + \alpha_m = 1$ and

$$\varphi_n^*(B|x) = \sum_{j=1}^{m} \alpha_j \delta_{f_j(x)}(B) \quad \forall B \in \mathbb{B}(X), \quad x \in X. \tag{6.4}$$

In addition, by Corollary 4.2, the MT problem associated to MTKn is solvable.

Combining the latter facts we obtain the following theorem.

THEOREM 6.1. *If Assumption* 5.4 *holds and the marginal* ν_2 *has finite support, then there are a stochastic kernel* φ^* *of the form* (6.4) *and a probability measure* $\mu^* := \varphi^* \cdot \nu_1$ *on* $X \times Y$ *as in* (4.5)*; i.e.,*

$$\mu^*(A \times B) = \int_A \varphi^*(B|x)\nu_1(dx)$$

such that μ^* *is an optimal solution for the MT problem.*

Step 2. We need the following assumption.

ASSUMPTION 6.2.

(a) *The "cost" function* $c(x, y)$ *is nonnegative and continuous.*

(b) X *and* Y *are separable metric spaces.*

(c) *There exists a sequence* $\{H_n\}$ *of compact subsets of* $X \times Y$ *such that* $H_n \uparrow X \times Y$*; i.e., the* H_n *form a nondecreasing sequence that converges to* $\bigcup_n H_n = X \times Y$*.*

We observe that the Assumption 6.2(c) holds, for instance, if X and Y are both σ-compact metric spaces or if c is an inf-compact function.

The next proposition is a variant of a well-known result on the denseness of finitely supported measures in spaces of probability measures (see Theorem 4 in [20, p. 237]). Here for our approximation approach we need a more explicit result.

PROPOSITION 6.3. *If the Assumption* 6.2 *holds, then there exist two sequences of probability measures* $\{\nu_1^i\}$ *on* $\mathbb{B}(X)$ *and* $\{\nu_2^i\}$ *on* $\mathbb{B}(Y)$*, both with finite supports and such that* $\{\nu_1^i\}$ *converges weakly to* ν_1 *and* $\{\nu_2^i\}$ *converges weakly to* ν_2*.*

Proof. By Assumption 6.2(c), there are two sequences of compact sets F_t and G_t in X and Y, respectively, such that $F_t \times G_t \uparrow X \times Y$.

Let

$$E_i = \{(x, y) | c(x, y) \le i\}$$

for $i = 1, 2, \dots$. Let $\Pi_1(E_i)$ and $\Pi_2(E_i)$ be the projections of E_i on X and Y, respectively. Then there is a positive integer t_i such that

$$\nu_1(F_{t_i} \cap \Pi_1(E_i)) \ge \nu_1(\Pi_1(E_i)) - 1/4i^2 \tag{6.5}$$

and

$$\nu_2(G_{t_i} \cap \Pi_2(E_i)) \ge \nu_2(\Pi_2(E_i)) - 1/4i^2. \tag{6.6}$$

Since c is a continuous function and $F_{t_i} \times G_{t_i} \cap E_i$ is a compact set, there exists $\gamma_i > 0$ such that

$$\text{if } d_1(x, x') < \gamma_i \quad \text{and} \quad d_2(y, y') < \gamma_i, \quad \text{then } |c(x, y) - c(x', y')| < 1/i,$$

for $(x, y), (x', y') \in F_i \times G_i \cap E_i$. Let $\varepsilon_i = \min\{\gamma_i, 1/i\}$.

Let $B_r(z)$ be the open neighborhood with center in z and radius r. By the compactness of $F_{t_i} \times G_{t_i} \cap E_i$, there are positive integers M_i, N_i and finite sets $\{x_1^i, x_2^i, \ldots, x_{M_i}^i\}$ and $\{y_1^i, y_2^i, \ldots, y_{N_i}^i\}$ such that $F_{t_i} \cap \Pi_1(E_i) \subset \bigcup_{k=1}^{M_i} B_{\varepsilon_i}(x_k^i)$ and $G_i \cap \Pi_2(E_i) \subset \bigcup_{j=1}^{N_i} B_{\varepsilon_i}(y_j^i)$.

We define the disjoint sets

$$A_k^i = \left(B_{\varepsilon_i}(x_k^i) \Big\backslash \bigcup_{s=1}^{k-1} B_{\varepsilon_i}(x_s^i) \right) \cap F_{t_i} \cap \Pi_1(E_i) \quad \text{for } k = 1, 2, \ldots, M_i,$$

$$D_j^i = \left(B_{\varepsilon_i}(y_j^i) \Big\backslash \bigcup_{s=1}^{j-1} B_{\varepsilon_i}(y_s^i) \right) \cap G_{t_i} \cap \Pi_2(E_i) \quad \text{for } j = 1, 2, \ldots, N_i,$$

$$A_{M_i+1}^i = (F_{t_i} \cap \Pi_1(E_i))^c \quad \text{and} \quad D_{N_i+1}^i = (G_{t_i} \cap \Pi_2(E_i))^c.$$

We take $(x_{M_i+1}^i, y_{N_i+1}^i)$ in $(F_{t_i} \times G_{t_i}) \cap E_i$.

Now, we introduce measures ν_1^i and ν_2^i with finite supports

$$\{x_1^i, \ldots, x_{M_i+1}^i\} \subset F_{t_i} \cap \Pi_1(E_i)$$

and

$$\{y_1^i, \ldots, y_{N_i+1}^i\} \subset G_{t_i} \cap \Pi_2(E_i),$$

respectively, and defined as

$$\nu_1^i(A) := \sum_{k=1}^{M_i+1} \nu_1(A_k^i) \delta_{\{x_k^i\}}(A) \quad \text{for } A \in \mathbb{B}(X)$$

and

$$\nu_2^i(D) := \sum_{j=1}^{N_i+1} \nu_2(D_j^i) \delta_{\{y_j^i\}}(D) \quad \text{for } D \in \mathbb{B}(Y).$$

We claim that ν_1^i converges weakly to ν_1, and ν_2^i converges weakly to ν_2. The proofs of the last two facts are quite similar, and so we will prove only the latter, ν_2^i converges weakly to ν_2, i.e.,

$$\lim_{i \to \infty} \int f d\nu_2^i = \int f d\nu_2$$

for every bounded real-valued uniformly continuous function f (see, for instance, [20, Theorem 6.1(b), p. 40]).

Let $f : Y \to \mathbb{R}$ be a bounded uniformly continuous function. Let $M > 0$ be such that

$$|f(y)| \leq M \quad \forall y \in Y. \tag{6.7}$$

Pick an arbitrary $\varepsilon > 0$. As f is uniformly continuous, there exists $\gamma > 0$ such that

$$\text{if } d_2(y, y') < \gamma, \quad \text{then } |f(y) - f(y')| < \varepsilon/3. \tag{6.8}$$

Now let i_1 and i_2 be positive integers such that $1/i_1 < \gamma$ and $1/(i_2)^2 < \varepsilon/6M$. Moreover, as $\Pi_2(E_i) \uparrow Y$, there is an integer i_3 such that $\nu_2(E_{i_3}^c) < \varepsilon/6M$.

Let $i_0 = \max\{i_1, i_2, i_3\}$. Then, by (6.6), (6.7), (6.8), and the construction of ν_2^i, we have that for all $i \geq i_0$

$$\begin{aligned}
&\left| \int_Y f(y)\nu_2(dy) - \int_Y f(y)\nu_2^i(dy) \right| \\
&\quad \leq \sum_{j=1}^{N_i} \int_{D_j^i} |f(y) - f(y_j^i)|\nu_2(dy) + \int_{D_{N_i+1}} |f(y) - f(y_{N_i+1}^i)|\nu_2(dy) \\
&\quad \leq \frac{\varepsilon}{3} \sum_{j=1}^{N_i} \nu_2(D_j^i) + 2M\nu_2(\Pi_2(E_i) - G_{t_i}) + 2M\nu_2(\Pi_2(E_i)^c) \\
&\quad < \varepsilon. \qquad \square
\end{aligned}$$

In the following theorem $\{\nu_1^i\}$ and $\{\nu_2^i\}$ are the sequences given by Proposition 6.3, and

$$c_i := \min\{c, i\}.$$

THEOREM 6.4. *If the Assumption* 6.2 *holds and if μ is a feasible solution to the MT problem, then there exists a sequence of p.m.'s $\{\mu_i\}$ on $\mathbb{B}(X \times Y)$ with marginals $\Pi_1\mu_i = \nu_1^i$ and $\Pi_2\mu_i = \nu_2^i$, and such that μ_i converges weakly to μ. Moreover,*

$$\lim_{i\to\infty} \langle \mu_i, c_i \rangle = \langle \mu, c \rangle.$$

Proof. Let A_k^i, D_j^i, F_{t_i}, G_{t_i}, E_i, M_i, N_i, $\{x_1^i, \ldots, x_{M_i+1}^i\}$, and $\{y_1^i, \ldots, y_{N_i+1}^i\}$ be as in the proof of Proposition 6.3.

Now, let μ be a probability measure on $\mathbb{B}(X \times Y)$ such that $\Pi_1\mu = \nu_1$ and $\Pi_2\mu = \nu_2$. We define measures μ_i by

$$\mu_i(E) = \sum_{k=1}^{M_i+1} \sum_{j=1}^{N_i+1} \mu(A_k^i \times D_j^i)\delta_{(x_k^i, y_j^i)}(E)$$

for all E in $\mathbb{B}(X \times Y)$.

Observe that μ_i has a finite support contained in $(F_{t_i} \times G_{t_i}) \cap E_i$. We will now see that $\Pi_1\mu_i = \nu_1^i$.

Choose an arbitrary set A in $\mathbb{B}(X)$. Then the definition and properties of Dirac measures give

$$\begin{aligned}
\Pi_1\mu_i(A) &= \mu_i(A \times Y) \\
&= \sum_{k=1}^{M_i+1} \left(\sum_{j=1}^{N_i+1} \mu(D_k^i \times C_j^i) \right) \delta_{x_k^i}(A) \\
&= \sum_{k=1}^{M_i+1} \mu(D_k^i \times Y)\delta_{x_k^i}(A) \\
&= \sum_{k=1}^{M_i+1} \nu_1(D_k^i)\delta_{x_k^i}(A) \\
&= \nu_1^i(A);
\end{aligned}$$

that is, $\Pi_1\mu_i = \nu_1^i$. Similarly $\Pi_2\mu_i = \nu_2^i$.

We observe that, as in the proof of Proposition 6.3, $\{\mu_i\}$ converges weakly to μ. Finally we show that

$$\lim_{i\to\infty}\langle\mu_i, c_i\rangle = \langle\mu, c\rangle.$$

As $E_i \uparrow X\times Y$ and c is μ-integrable, given $\varepsilon>0$ there exists an integer i_1 such that, for all $i\geq i_1$, we have

$$\int_{E_i^c} c\,d\mu < \varepsilon/6. \tag{6.9}$$

Moreover, there exists i_2 such that, for all $i\geq i_2$, we have

$$1/i < \varepsilon/6. \tag{6.10}$$

Now, let $i_0=\min\{i_1,i_2\}$. By (6.5), (6.6), (6.9), and (6.10) we have that for all $i\geq i_0$

$$\begin{aligned}
\left|\int_{X\times Y} c\,d\mu - \int_{X\times Y} c_i d\mu_i\right| &= \left|\int_{E_i} c\,d\mu + \int_{E_i^c} c\,d\mu - \int_{E_i} c_i d\mu_i - \int_{E_i^c} c_i d\mu_i\right| \\
&= \left|\int_{E_i} c\,d\mu + \int_{E_i^c} c\,d\mu - \sum_{k=1}^{M_i+1}\sum_{j=1}^{N_i+1} c_i(x_k^i,y_j^i)\mu((A_k^i\times D_j^i)\cap E_i)\right. \\
&\quad \left. - \sum_{k=1}^{M_i+1}\sum_{j=1}^{N_i+1} c_i(x_k^i,y_j^i)\mu((A_k^i\times D_j^i)\cap E_i^c)\right| \\
&\leq 2\int_{E_i^c} c\,d\mu + \sum_{k=1}^{M_i}\sum_{j=1}^{N_i}\int_{(A_k^i\times D_j^i)\cap E_i} |c(x,y)-c_i(x_k^i,y_j^i)|d\mu \\
&\quad + \sum_{k=1}^{M_i}\int_{(A_k^i\times D_{N_i+1}^i)\cap E_i} c\,d\mu + \sum_{k=1}^{M_i+1} c_i(x_k^i,y_{N_i+1}^i)\mu((A_k^i\times D_{N_i+1}^i)\cap E_i) \\
&\quad + \sum_{j=1}^{N_i}\int_{(A_{M_i+1}^i\times D_j^i)\cap E_i} c\,d\mu + \sum_{j=1}^{N_i+1} c_i(x_{M_i+1}^i,y_j^i)\mu((A_{M_i+1}^i\times D_j^i)\cap E_i) \\
&\leq \varepsilon/3 + (1/i)\sum_{k=1}^{M_i}\sum_{j=1}^{N_i}\mu((A_k^i\times D_j^i)\cap E_i) \\
&\quad + 2i\{\mu((X\times D_{N_i+1}^i)\cap E_i) + \mu(((A_{M_i+1}^i)\times Y)\cap E_i)\} \\
&< \varepsilon/6 + 2i\{\mu(X\times(D_{N_i+1}^i\cap\Pi_2(E_i))) + \mu((A_{M_i+1}^i\cap\Pi_1(E_i))\times Y)\} \\
&= \varepsilon/6 + 2i\{\nu_2(D_{N_i+1}^i\cap\Pi_2(E_i)) + \nu_1(A_{M_i+1}^i\cap\Pi_1(E_i))\} \\
&\leq \varepsilon/6+\varepsilon/3<\varepsilon. \qquad \square
\end{aligned}$$

Step 3. We now complete the approximation procedure. We will need either one of the following assumptions.

ASSUMPTION 6.5.

(a) *X is a separable metric space.*

(b) *Y is a complete and separable metric space.*

(c) *The "cost" function $c(x,y)$ is nonnegative, inf-compact, and continuous.*

ASSUMPTION 6.6.
(a) *X is a σ-compact metric space.*
(b) *Y is a complete and σ-compact metric space.*
(c) *The "cost" function $c(x, y)$ is nonnegative and continuous.*

Finally, we state our main result, in which N_m is as in the proof of Proposition 6.3.

THEOREM 6.7. *If either Assumption* 6.5 *or Assumption* 6.6 *holds, then there exists a sequence $\{\mu_m^*\}$ of probability measures of the form*

$$\mu_m^* = \varphi_m^* \cdot \nu_1,$$

where φ_m^* is a randomization of at most N_m+1 deterministic strategies, and, moreover
(a) *μ_m^* converges weakly to a probability measure μ^*,*
(b) *μ^* is an optimal solution to MT, and*
(c) *$\lim_{m\to\infty}\langle c_m, \mu_m^*\rangle = \langle c, \mu^*\rangle = \min(MT)$, with $c_m = \min\{c, m\}$.*

Proof. Let $\{\nu_1^i\}$ and $\{\nu_2^i\}$ be sequences of p.m.'s as in Proposition 6.3. Consider the following MT problems:

$$\textbf{MTi} \qquad \text{Minimize} \quad \langle \mu, c_i\rangle$$
$$\text{subject to} \quad \Pi_1\mu = \nu_1^i, \quad \Pi_2\mu = \nu_2^i, \quad \mu \geq 0.$$

Now, by Theorem 6.1, for each i there exists a randomization of at most $N_i + 1$ deterministic strategies φ_{N_i+1} of the form (6.4) and such that $\mu_i = \varphi_{N_i+1} \cdot \nu_1^i$ is an optimal solution for MTi.

The hypothesis (Assumption 6.5 or 6.6) implies that the sequence $\{\mu_i\}$ is tight; see Lemma 2.4 and Remark 2.5 in [15]. Hence, by Prohorov's theorem there are a subsequence $\{\mu_m^*\}$ of $\{\mu_i\}$ and a p.m. μ^* on $\mathbb{B}(X \times Y)$ such that $\{\mu_m^*\}$ converges weakly to μ^*.

In addition, by Lemma 2.7 in [15], the marginals $\Pi_k\mu_m^*$ converge weakly to the marginal $\Pi_k\mu^*$ for $k = 1, 2$, which implies that $\Pi_1\mu^* = \nu_1$ and $\Pi_2\mu^* = \nu_2$; that is, μ^* is a feasible solution for MT.

Suppose now that μ is an optimal solution for MT. Then by Theorem 6.4 there is a sequence $\{\mu_m\}$ of p.m.'s on $\mathbb{B}(X \times Y)$ such that $\{\mu_m\}$ converges weakly to μ, and μ_m is a feasible solution for MTm. Since μ is an optimal solution for MT and μ^* is feasible for MT, we have

$$\langle \mu, c\rangle \leq \langle \mu^*, c\rangle. \tag{6.11}$$

On the other hand, for each m, we have that

$$\langle \mu_m, c_m\rangle \geq \langle \mu_m^*, c_m\rangle,$$

whereas by Theorem 6.4

$$\langle \mu, c\rangle = \lim_{m\to\infty}\langle \mu_m, c_m\rangle \geq \limsup_{m\to\infty}\langle \mu_m^*, c_m\rangle \geq 0. \tag{6.12}$$

Now, pick an arbitrary $\epsilon > 0$. Since $c_n \uparrow c$, there exists an integer n such that

$$\langle \mu^*, c\rangle \geq \langle \mu^*, c_n\rangle \geq \langle \mu^*, c\rangle - \varepsilon. \tag{6.13}$$

For each $m \geq n$ we have

$$0 \leq \langle \mu_m^*, c_n\rangle \leq \langle \mu_m^*, c_m\rangle,$$

and as $\mu_m^* \to \mu^*$ we obtain

$$\langle \mu^*, c_n \rangle = \lim_{m\to\infty} \langle \mu_m, c_n \rangle \le \limsup_{m\to\infty} \langle \mu_m^*, c_m \rangle.$$

Therefore, by (6.13), it follows that

$$\langle \mu^*, c \rangle \le \limsup_{m\to\infty} \langle \mu_m^*, c_m \rangle + \varepsilon.$$

Consequently, as ε was arbitrary,

$$\langle \mu^*, c \rangle \le \limsup_{m\to\infty} \langle \mu_m^*, c_m \rangle,$$

which together with (6.12) gives

$$\langle \mu^*, c \rangle \le \langle \mu, c \rangle. \tag{6.14}$$

Thus, from (6.11) and (6.14) we obtain $\langle \mu, c \rangle = \langle \mu^*, c \rangle$; that is, μ^* is an optimal solution for MT. □

Remark 6.8. Since the measures ν_1^i and ν_2^i have finite support, MTi is a classical transportation problem [23, 24].

7. Concluding remarks. In the previous sections we presented two new approaches to obtain the solvability of the MT problem in metric spaces. In the first one, we transform MT into an equivalent optimization problem, MTK, using randomized strategies. In the second approach we obtain the solution of MT, and the corresponding optimal value, as the limit of a sequence of MT problems with marginals supported on finite sets.

The second approach requires the cost function $c(x, y)$ to be continuous, but this condition can be weakened. For instance, if c is l.s.c. and bounded below, say, nonnegative, then it is the limit of a nondecreasing sequence of continuous bounded functions $c_n \ge 0$. In this case, we might solve the MT problem for c_n and then try to show that, as $n \to \infty$, in the limit we obtain the solution of the original MT problem. Another case is the following.

Suppose that the Assumption 5.4 holds and that Y is a σ-compact space. Let $\{X_l\}$ be a countable partition of X such that each X_l is a σ-compact subspace of X and the cost function c restricted to each $X_l \times Y$ is continuous. Without loss of generality we may take $\alpha_l := \nu_1(X_l) > 0$ for all $l = 1, 2, \ldots$. Let us define

$$\nu_1^l(B) := (1/\alpha_l)\nu_1(B \cap X_l) \quad \forall B \in \mathbb{B}(X), \quad l = 1, 2, \ldots.$$

Consider the following problem:

MTl Minimize $\langle \mu, c \rangle$

subject to $\Pi_1 \mu = \nu_1^l, \quad \Pi_2 \mu = \nu_2, \quad \mu \ge 0.$

Now, for each feasible measure μ to the MT problem, we obtain the decomposition $\mu = \sum_l \alpha_l \mu_l$, where $\mu_l(E) := \mu(E \cap (X_l \times Y))/\alpha_l$ for E in $\mathbb{B}(X \times X)$ and $l = 1, 2, \ldots$, and, moreover, μ_l is feasible for MTl.

In fact, μ is an optimal solution to MT if and only if μ_l is optimal to MTl for all $l \ge 1$. Hence we may apply the approximation scheme for each $X_l \times Y$.

OPTIMALITY CONDITIONS FOR QUASICONVEX PROGRAMS*

NGUYEN THI HONG LINH† AND JEAN-PAUL PENOT‡

Abstract. We present necessary and sufficient optimality conditions for a problem with a convex set constraint and a quasiconvex objective function. We apply the obtained results to a mathematical programming problem involving quasiconvex functions.

Key words. convex programming, normal cone, optimality conditions, quasiconvex function, quasiconvex programming, subdifferential

AMS subject classifications. 90C26, 26B25, 52A41

DOI. 10.1137/040621843

1. Introduction. It is the purpose of this paper to present some optimality conditions for constrained optimization problems under generalized convexity assumptions. We essentially deal with quasiconvex functions, i.e., functions whose sublevel sets are convex. Such functions form the main class of generalized convex functions and are widely used in mathematical economics. We do not assume that the data of the problem are smooth. Thus, we replace the derivatives appearing in the classical results by subdifferentials. We only use the adapted subdifferentials of quasiconvex analysis, namely the Plastria subdifferential [35] and the infradifferential or Gutiérrez subdifferential [10]. Because these subdifferentials are useful for algorithmic purposes [20], [35] and have links with duality [17, Prop. 6.1], [29], [30], [31], their use in problems in which quasiconvexity properties occur seems to be sensible, although their calculus rules are not as rich as in the case of convex analysis [24], [33]. In [17, Prop. 6.1] Martínez-Legaz presented a result of the Kuhn–Tucker type using these subdifferentials; in [18, Thm. 4.1] and [19, Prop. 6.3] variants of these subdifferentials are used. In each of these results, a Slater condition and a semistrict quasiconvexity assumption (called strict quasiconvexity in [15]) are imposed. Here we essentially assume the functions are quasiconvex and we deduce the results from optimality conditions for problems with set constraints. We also point out the link with the differentiable case dealt with in the pioneer paper [1]. We do not make a comparison with results using the all-purpose subdifferentials of nonsmooth analysis (see [3], [22]). The reason is that these subdifferentials are local, whereas the ones we use are of global character; intermediate notions are presented in [4], [21], and [25]. On the other hand, our necessary conditions refine conditions using normal cones or subdifferentials related to normal cones to sublevels sets as the Greenberg–Pierskalla subdifferential [9] as in [26]. Numerous papers deal with optimality conditions for constrained problems under generalized convexity conditions (see [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [26], [27], [28], [29], [30], [31], [34], [36] for example). A link with the case we are dealing with here, which is essentially the quasiconvex case, could be found by assuming that the Gutiérrez or Plastria

subdifferentials are nonempty at each point. However, we do not wish to impose such a restrictive condition.

2. Preliminaries: Gutiérrez and Plastria functions. In what follows X is a normed vector space (n.v.s.) with closed unit ball B_X. We denote by $N(C,x)$ the *normal cone* at $x \in X$ to a convex subset C of X given by

$$N(C,x) := \{x^* \in X^* : \forall u \in C,\ \langle x^*, u-x\rangle \le 0\}.$$

When $x \in C$, it is the polar cone of the *tangent cone* $T(C,x)$ which is the closure of $\mathbb{R}_+(C-x)$.

A function $f : X \to \mathbb{R}_\infty := \mathbb{R} \cup \{+\infty\}$ is said to be *quasiconvex* if for each $\overline{x} \in X$ its sublevel set

$$S_f(\overline{x}) := \{x \in X : f(x) \le f(\overline{x})\}$$

is convex, or, equivalently, if for each $r \in \mathbb{R}$ the strict sublevel set $S_f^<(r) := \{x \in X : f(x) < r\}$ is convex.

Recall that the *lower subdifferential*, or *Plastria subdifferential* of a function $f : X \to \overline{\mathbb{R}}$ on a Banach space X at some point $\overline{x}$ of its domain $\operatorname{dom} f := \{x \in X : f(x) \in \mathbb{R}\}$ is the set

$$\partial^< f(\overline{x}) := \{\overline{x}^* \in X^* : \forall x \in S_f^<(\overline{x}),\ f(x) - f(\overline{x}) \ge \langle \overline{x}^*, x-\overline{x}\rangle\},$$

where $S_f^<(\overline{x}) := S_f^<(f(\overline{x}))$ is the strict sublevel set of f at $\overline{x}$. We will also use the following variant, called the *infradifferential* [10] or *Gutiérrez subdifferential*:

$$\partial^\le f(\overline{x}) := \{\overline{x}^* \in X^* : \forall x \in S_f(\overline{x}),\ f(x) - f(\overline{x}) \ge \langle \overline{x}^*, x-\overline{x}\rangle\}.$$

If no point of the level set $L_f(\overline{x}) := f^{-1}(f(\overline{x}))$ is a local minimizer of f, we have $\partial^< f(\overline{x}) = \partial^\le f(\overline{x})$. If $f(\overline{x}) > \inf f(X)$, this equality also holds when f is radially continuous (i.e., continuous along lines) and *semistrictly quasiconvex* in the sense that when $f(x) < f(y)$ one has $f((1-t)x+ty) < f(y)$ for any $t \in (0,1)$; in particular, this equality holds for convex continuous functions. In spite of the fact that the preceding constructions have a close similarity with the Fenchel subdifferential, they differ by significant features. In particular $\partial^< f(\overline{x})$ and $\partial^\le f(\overline{x})$ are unbounded or empty: it is easy to check that they are shady in the sense that they are closed, convex, and stable by homotheties with rate t greater than 1 since for $\overline{x}^* \in \partial^< f(\overline{x})$ and $x \in S_f^<(\overline{x})$ we have $\langle t\overline{x}^*, x-\overline{x}\rangle \le \langle \overline{x}^*, x-\overline{x}\rangle \le 0$ and a similar observation when $\overline{x}^* \in \partial^\le f(\overline{x})$ and $x \in S_f(\overline{x})$.

We say that f is a *Plastria function* at $\overline{x}$ if its strict sublevel set $S_f^<(\overline{x})$ is convex and such that

$$N(S_f^<(\overline{x}), \overline{x}) = \mathbb{R}_+ \partial^< f(\overline{x}). \tag{1}$$

We say that f is a *Gutiérrez function* at $\overline{x}$ if its sublevel set $S_f(\overline{x})$ is convex and such that

$$N(S_f(\overline{x}), \overline{x}) = \mathbb{R}_+ \partial^\le f(\overline{x}). \tag{2}$$

Since $\partial^< f(\overline{x})$ and $\partial^\le f(\overline{x})$ are shady in the sense that they are stable under multiplication by any $t \in [1,\infty)$, relations (1) and (2) are equivalent to $N(S_f^<(\overline{x}), \overline{x}) =$

$[0,1]\partial^< f(\overline{x})$ and $N(S_f(\overline{x}),\overline{x}) = [0,1]\partial^{\leq} f(\overline{x})$, respectively. These conditions being rather stringent, it may be useful to replace f by its extension by $+\infty$ outside some ball (see [20] for the case of nonconvex quadratic functions). However, we provide three criteria. The first one deals with convex transformable functions, an important class of quasiconvex functions.

PROPOSITION 1. *Let f be a proper convex function and let $\overline{x} \in \operatorname{dom} f := f^{-1}(\mathbb{R})$ be such that $f(\overline{x}) > \inf f(X)$ and $\mathbb{R}_+(\operatorname{dom} f - \overline{x}) = X$. Then f is a Gutiérrez function and a Plastria function at $\overline{x}$:*

$$N(S_f(\overline{x}),\overline{x}) = \mathbb{R}_+\partial^{\leq} f(\overline{x}) = \mathbb{R}_+\partial f(\overline{x}) = \mathbb{R}_+\partial^< f(\overline{x}) = N(S_f^<(\overline{x}),\overline{x}).$$

More generally, if $f := h \circ g$, where $g : \mathbb{R} \to \mathbb{R}_\infty$ is a convex function and $h : T \to \mathbb{R}_\infty$ is a strictly increasing function on some interval T of $\mathbb{R}_\infty$ containing $g(X)$, with $h(+\infty) = +\infty$, then f is a Gutiérrez function and a Plastria function at $\overline{x}$ provided $f(\overline{x}) > \inf f(X)$ and $\mathbb{R}_+(\operatorname{dom} f - \overline{x}) = X$. Moreover, $\mathbb{R}_+\partial^< f(\overline{x}) = \mathbb{R}_+\partial^< g(\overline{x}) = \mathbb{R}_+\partial^{\leq} g(\overline{x}) = \mathbb{R}_+\partial^{\leq} f(\overline{x})$.

Proof. By [32, Prop. 5.4] one has $N(S_f(\overline{x}),\overline{x}) = \mathbb{R}_+\partial f(\overline{x})$; here we use the fact that under the assumption $\mathbb{R}_+(\operatorname{dom} f - \overline{x}) = X$, we have $N(\operatorname{dom} f,\overline{x}) = \{0\}$. Since $\mathbb{R}_+\partial f(\overline{x}) \subset \mathbb{R}_+\partial^{\leq} f(\overline{x}) \subset N(S_f(\overline{x}),\overline{x})$, we get equality. Moreover, if $\overline{x}^* \in \partial^< f(\overline{x})$ and $x \in S_f(\overline{x})$, taking $z \in X$ such that $f(z) < f(\overline{x})$ and $t \in (0,1)$ we have $x_t := (1-t)x + tz \in S_f^<(\overline{x})$, hence

$$(1-t)f(x) + tf(z) \geq f(x_t) \geq f(\overline{x}) + \langle \overline{x}^*, x - \overline{x}\rangle,$$

and taking the limit as $t \to 0$, we get $f(x) \geq f(\overline{x}) + \langle \overline{x}^*, x - \overline{x}\rangle$, hence $\overline{x}^* \in \partial^{\leq} f(\overline{x})$. Moreover, the preceding argument shows that $S_f(\overline{x})$ is contained in the closure of $S_f^<(\overline{x})$, so that $N(S_f(\overline{x}),\overline{x}) = N(S_f^<(\overline{x}),\overline{x})$.

Now let $f := h \circ g$ be as in the second part of the statement. Since h is (strictly) increasing, we have $S_f(\overline{x}) = S_g(\overline{x})$, $S_f^<(\overline{x}) = S_g^<(\overline{x})$. Setting $\overline{r} := g(\overline{x})$, since $\partial^< h(\overline{r}) \subset (0,+\infty)$, using [33, Prop. 3.5], we have

$$N(S_f^<(\overline{x}),\overline{x}) = N(S_g^<(\overline{x}),\overline{x}) = \mathbb{R}_+\partial^< g(\overline{x}) = \mathbb{R}_+\partial^< h(\overline{r})\partial^< g(\overline{x}) \subset \mathbb{R}_+\partial^< f(\overline{x}),$$

hence equality, the reverse inclusion being obvious. The proof that f is a Gutiérrez function at $\overline{x}$ is similar. □

The second one is a slight improvement of previous results in [35], [17], [24]. It uses the now classical notion of calmness: $f : X \to \overline{\mathbb{R}}$ is said to be *calm* with rate c at $w \in X$ if $f(w)$ is finite and if

$$\forall x \in X \qquad\qquad f(x) - f(w) \geq -c\,\|x - w\|\,.$$

Such a condition is obviously satisfied if f is Lipschitzian with rate c or if f is Stepanovian (or stable) with rate c at w in the sense that $|f(x) - f(w)| \leq c\,\|x - w\|$ for any $x \in X$.

PROPOSITION 2. *Assume that f is radially continuous on X and calm with rate $c \in \mathbb{R}_+$ at each point of the level set $L_f(\overline{x}) := f^{-1}(f(\overline{x}))$ and that $S_f(\overline{x})$ and $S_f^<(\overline{x})$ are convex. Then*

$$N(S_f^<(\overline{x}),\overline{x})\backslash cB_X = \partial^< f(\overline{x})\backslash cB_X,$$
$$N(S_f(\overline{x}),\overline{x})\backslash cB_X = \partial^{\leq} f(\overline{x})\backslash cB_X.$$

If, moreover, $N(S_f^<(\overline{x}),\overline{x}) \neq \{0\}$*, then the function* f *is a Plastria function at* $\overline{x}$*, while if* $N(S_f(\overline{x}),\overline{x}) \neq \{0\}$*, then* f *is also a Gutiérrez function at* $\overline{x}$*.*

The condition $N(S_f(\overline{x}),\overline{x}) \neq \{0\}$ (or $N(S_f^<(\overline{x}),\overline{x}) \neq \{0\}$) is a rather mild condition when X is finite dimensional. However, when X is infinite dimensional, it may occur that a closed convex set $C \neq X$ is such that $N(C,\overline{x}) = \{0\}$ for some $\overline{x} \in C \backslash \mathrm{int} C$.

Proof. Let us first prove that whenever $\overline{x}^* \in N'_f(\overline{x}) := N(S_f^<(\overline{x}),\overline{x})$ satisfies $\|\overline{x}^*\| := \lambda c$ for some $\lambda > 1$, then $\overline{x}^* \in \partial^< f(\overline{x})$. Since $N'_f(\overline{x})$ is a cone and $\partial^< f(\overline{x})$ is w*-closed, this will show that $N'_f(\overline{x}) \backslash cB_X \subset \partial^< f(\overline{x}) \backslash cB_X$ and that equality holds. Let $\overline{y}^* := c^{-1}\lambda^{-1}\overline{x}^*$. Given $x \in [f < f(\overline{x})]$ we have by assumption $t := \langle \overline{y}^*, x - \overline{x}\rangle < 0$. Let us choose $v \in X$ such that $\|v\| \leq \lambda$ and $\langle \overline{y}^*, v\rangle = 1$ and set $w = x - \overline{x} - tv$. Then $\langle \overline{y}^*, w\rangle = 0$. Let us show that $f(\overline{x}+w) \geq f(\overline{x})$. In order to do so, we pick $z \in X$ such that $\langle \overline{y}^*, z\rangle > 0$; then for any $s > 0$, we have $\langle \overline{y}^*, w+sz\rangle > 0$, thus $f(\overline{x}+w+sz) \geq f(\overline{x})$. By radial continuity, $f(\overline{x}+w) \geq f(\overline{x})$.

Since $f\,|_{[x,\overline{x}+w]}$ is continuous and $f(x) < f(\overline{x}) \leq f(\overline{x}+w)$, there exists $x' \in [x, \overline{x}+w]$ such that $f(x') = f(\overline{x})$ and $f(x'') < f(\overline{x})$ for all $x'' \in [x, x')$. Then, since $\lambda > 1$, $\|\overline{y}^*\| = 1$ and $t = \langle \overline{y}^*, x - \overline{x}\rangle$, we have

$$\begin{aligned} f(x) - f(\overline{x}) = f(x) - f(x') &\geq -c\,\|x - x'\| \geq -c\,\|x - (\overline{x}+w)\| \\ &= -c\,\|tv\| = ct\,\|v\| \geq \lambda c\,\langle \overline{y}^*, x - \overline{x}\rangle = \langle \overline{x}^*, x - \overline{x}\rangle\,. \end{aligned}$$

Thus $f(x) - f(\overline{x}) \geq \langle \overline{x}^*, x - \overline{x}\rangle$ holds for all $x \in [f < f(\overline{x})]$ and $\overline{x}^* \in \partial^< f(\overline{x})$.

Assume now that $\overline{x}^* \in N(S_f(\overline{x}),\overline{x})$ is such that $\|\overline{x}^*\| \geq c$; then $\overline{x}^* \in N(S_f^<(\overline{x}),\overline{x})$, hence $\overline{x}^*$ is such that $f(x) - f(\overline{x}) \geq \langle \overline{x}^*, x - \overline{x}\rangle$ for each $x \in S_f^<(\overline{x})$, while if $f(x) = f(\overline{x})$, then

$$f(x) - f(\overline{x}) = 0 \geq \langle \overline{x}^*, x - \overline{x}\rangle\,.$$

This proves that $\overline{x}^* \in \partial^\leq f(\overline{x})$.

Now, given $\overline{x}^* \in N(S_f^<(\overline{x}),\overline{x})$, $\overline{x}^* \neq 0$, we can find $r > 0$ such that $\overline{x}^* = r\overline{w}^*$ for some $\overline{w}^* \in N(S_f^<(\overline{x}),\overline{x})$ satisfying $\|\overline{w}^*\| \geq c$. Thus $\overline{x}^* \in \mathbb{R}_+ \partial^< f(\overline{x})$. Since $\partial^< f(\overline{x})$ is nonempty by what precedes, we also have $0 \in \mathbb{R}_+ \partial^< f(\overline{x})$, hence $N(S_f^<(\overline{x}),\overline{x}) \subset \mathbb{R}_+ \partial^< f(\overline{x})$. The reverse inclusion being obvious, we get $N(S_f^<(\overline{x}),\overline{x}) = \mathbb{R}_+ \partial^< f(\overline{x})$. The equality $N(S_f(\overline{x}),\overline{x}) = \mathbb{R}_+ \partial^\leq f(\overline{x})$ is obtained similarly. □

The third criterion uses a differentiability assumption and brings some supplement to [23, Prop. 15].

Proposition 3. *Let* f *be quasiconvex, differentiable at* $\overline{x}$ *with a nonzero derivative. If* $\partial^< f(\overline{x})$ *is nonempty, then* f *is a Plastria function at* $\overline{x}$ *and there exists some* $\overline{r} \geq 1$ *such that* $\partial^< f(\overline{x}) = [\overline{r}, \infty) f'(\overline{x})$*. If* $\partial^\leq f(\overline{x})$ *is nonempty, then* f *is a Gutiérrez function at* $\overline{x}$ *and there exists some* $\overline{s} \geq 1$ *such that* $\partial^\leq f(\overline{x}) = [\overline{s}, \infty) f'(\overline{x})$*.*

Proof. Let us first prove that if f is quasiconvex, differentiable at $\overline{x}$ with a nonzero derivative one has $N(S_f^<(\overline{x}),\overline{x}) = \mathbb{R}_+ f'(\overline{x})$. We first observe that

$$f'(\overline{x})^{-1}((-\infty,0)) \subset T(S_f^<(\overline{x}),\overline{x}) \subset T(S_f(\overline{x}),\overline{x}) \subset f'(\overline{x})^{-1}((-\infty,0]).$$

Since $f'(\overline{x}) \neq 0$, we can find some $w \in X$ with $f'(\overline{x})w < 0$. Then, for any $v \in f'(\overline{x})^{-1}((-\infty,0])$ and any sequence $(r_n) \to 0_+$ we have

$$v_n := v + r_n w \in f'(\overline{x})^{-1}((-\infty,0)) \subset T(S_f^<(\overline{x}),\overline{x}),$$

and since $(v_n) \to v$ and $T(S_f^<(\overline{x}),\overline{x})$ is closed, we get $v \in T(S_f^<(\overline{x}),\overline{x})$. Thus $T(S_f^<(\overline{x}),\overline{x}) = T(S_f(\overline{x}),\overline{x}) = f'(\overline{x})^{-1}((-\infty,0])$. Then, the Farkas lemma ensures

that

$$N(S_f^<(\overline{x}),\overline{x}) = N(S_f(\overline{x}),\overline{x}) = \mathbb{R}_+ f'(\overline{x}).$$

Let us now assume that $0 \notin \partial^< f(\overline{x}) \neq \varnothing$ and let us pick some $\overline{x}^* \in \partial^< f(\overline{x})$. By what precedes, for any $v \in X$ such that $f'(\overline{x})v \leq 0$ we can find sequences $(t_n) \to 0_+$, $(v_n) \to v$ such that $f(\overline{x} + t_n v_n) < f(\overline{x})$ for each n. Then we get

$$\langle \overline{x}^*, v\rangle \leq \lim_n \frac{1}{t_n}\left(f(\overline{x} + t_n v_n) - f(\overline{x})\right) = f'(\overline{x})v \leq 0,$$

so that, by the Farkas lemma again, there exists some $r \in \mathbb{R}_+$ such that $\overline{x}^* = rf'(\overline{x})$. In fact, the preceding inequalities (taken with some v such that $f'(\overline{x})v < 0$) show that $r \geq 1$. Let $\overline{r} := \inf\{r \in \mathbb{R} : \exists \overline{x}^* \in \partial^< f(\overline{x}),\ \overline{x}^* = rf'(\overline{x})\}$. We have $\overline{r} \geq 1$ by what precedes, and, by closedness of $\partial^< f(\overline{x})$, $\overline{x}^* = \overline{r}f'(\overline{x})$ for some $\overline{x}^* \in \partial^< f(\overline{x})$. Thus, $\partial^< f(\overline{x}) \subset [\overline{r},\infty)f'(\overline{x})$ and since $\overline{r}f'(\overline{x}) = \overline{x}^* \in \partial^< f(\overline{x})$ and $[1,\infty)\partial^< f(\overline{x}) \subset \partial^< f(\overline{x})$, we get $\partial^< f(\overline{x}) = [\overline{r},\infty)f'(\overline{x})$. It follows that $\mathbb{R}_+\partial^< f(\overline{x}) = \mathbb{R}_+ f'(\overline{x})$.

The proof for $\partial^\leq f(\overline{x})$ is similar. □

The following example shows that one may have $\overline{r} > 1$.

Example 1. Let $X = \mathbb{R}$ and for $c < 0$ let f be given by $f(x) = c^3/3$ for $x \in (-\infty, c)$, $f(x) = x^3/3$ for $x \geq c$. Then, for $\overline{x} = 1$, we have $\partial^< f(\overline{x}) = \partial^\leq f(\overline{x}) = [\overline{r},\infty)$ with $\overline{r} = \max(1, (1 + c + c^2)/3)$.

A localization of the preceding concepts may enlarge the range of the optimality conditions which follow. Let us define the local normal cone to C at $\overline{x}$ as

$$N_{loc}(C,\overline{x}) := \bigcup_{r>0} N(C \cap B(\overline{x},r),\overline{x}),$$

where $B(\overline{x},r)$ denotes the open ball with center $\overline{x}$ and radius r. When C is convex, we have $N_{loc}(C,\overline{x}) = N(C,\overline{x})$. We also define the *local Gutiérrez subdifferential* and the *local Plastria subdifferential* of f at $\overline{x}$ by

$$\partial^\leq_{loc} f(\overline{x}) := \{\overline{x}^* \in X^* : \exists r > 0, \forall x \in S_f(\overline{x}) \cap B(\overline{x},r),\ f(x) - f(\overline{x}) \geq \langle \overline{x}^*, x - \overline{x}\rangle\},$$
$$\partial^<_{loc} f(\overline{x}) := \{\overline{x}^* \in X^* : \exists r > 0, \forall x \in S_f^<(\overline{x}) \cap B(\overline{x},r),\ f(x) - f(\overline{x}) \geq \langle \overline{x}^*, x - \overline{x}\rangle\},$$

respectively. We say that f is *locally a Plastria function at* $\overline{x}$ if there exists some $r > 0$ such that $S_f^<(\overline{x}) \cap B(\overline{x},r)$ is convex and if

$$N_{loc}(S_f^<(\overline{x}),\overline{x}) = \mathbb{R}_+ \partial^<_{loc} f(\overline{x}).$$

Locally Gutiérrez functions can be defined similarly.

3. Optimality conditions for constrained problems. In the present section we consider the minimization problem

$$(\mathcal{C}) \quad \text{minimize } f(x) \text{ subject to } x \in C,$$

where $f : X \to \overline{\mathbb{R}}$ is a function on the n.v.s. X and C is a convex subset of X.

Proposition 4. *Let f be an u.s.c. Plastria function at some solution $\overline{x}$ to $(\mathcal{C})$ which is not a local minimizer of f. Then one has*

$$0 \in \partial^< f(\overline{x}) + N(C,\overline{x}). \tag{3}$$

Proof. Since f is quasiconvex and u.s.c., the strict sublevel set $S_f^<(\overline{x})$ is open and convex; it is nonempty since $\overline{x}$ is not a minimizer of f. Since $\overline{x}$ is a solution to $(\mathcal{C})$, this sublevel set is disjoint from C. Thus, the Hahn–Banach separation theorem yields some $c \in \mathbb{R}$ and u^* in the unit sphere of X^* such that

$$\langle u^*, x - \overline{x}\rangle \geq c \geq \langle u^*, w - \overline{x}\rangle \qquad \forall w \in S_f^<(\overline{x}), \forall x \in C. \tag{4}$$

Taking $x = \overline{x}$, we see that $c \leq 0$. Moreover, since $\overline{x}$ is not a local minimizer of f, there exists a sequence $(w_n) \to \overline{x}$ such that $w_n \in S_f^<(\overline{x})$ for each n. Therefore $c = 0$. Then we have $u^* \in N(S_f^<(\overline{x}), \overline{x}) = \mathbb{R}_+ \partial^< f(x)$ and since $u^* \neq 0$, we can find $\overline{x}^* \in \partial^< f(\overline{x})$ and $r \in \mathbb{R}_+$ such that $\overline{x}^* = ru^*$. On the other hand, the first inequality of (4) means that $-u^* \in N(C, \overline{x})$. Thus, $\overline{x}^* + r(-u^*) = 0$ and (3) is satisfied. □

Example 2. The example (taken from [26]) of the function $f : \mathbb{R} \to \mathbb{R}$ given by $f(x) = x$ for $x \in (-\infty, 0)$, $f(x) = 0$ for $x \in [0, 1]$, $f(x) = x - 1$ for $x \in (1, +\infty)$ and $C := \mathbb{R}_+$, $\overline{x} = 1$ shows that the assumption that $\overline{x}$ is not a local minimizer cannot be dispensed within the preceding statement.

Now let us give a sufficient condition. Observe that no assumption is required on f besides finiteness at $\overline{x}$.

PROPOSITION 5. *Let $f : X \to \mathbb{R} \cup \{\infty\}$ be an arbitrary function finite at $\overline{x}$ satisfying relation* (3). *Then $\overline{x}$ is a solution to $(\mathcal{C})$.*

Proof. Let $\overline{x}^* \in \partial^< f(\overline{x})$ be such that $-\overline{x}^* \in N(C, \overline{x})$. Assume that $\overline{x}$ is not a solution to $(\mathcal{C})$: there exists some $x \in C$ such that $f(x) < f(\overline{x})$. Then one has, by the definitions of $\partial^< f(\overline{x})$ and $N(C, \overline{x})$,

$$0 > f(x) - f(\overline{x}) \geq \langle \overline{x}^*, x - \overline{x}\rangle,$$
$$\langle \overline{x}^*, x - \overline{x}\rangle \geq 0,$$

a contradiction. □

Let us observe that the preceding sufficient condition can also be derived from the one in [26, Prop. 2.1] which uses the Greenberg–Pierskalla subdifferential

$$\partial^* f(\overline{x}) := \{\overline{x}^* \in X^* : \forall x \in S_f^<(\overline{x})\ \langle \overline{x}^*, x - \overline{x}\rangle < 0\}$$

since $\partial^< f(\overline{x}) \subset \partial^* f(\overline{x})$. On the other hand, the necessary condition in Proposition 4 is more precise than the necessary condition in [26, Prop. 2.2].

A slight supplement to the preceding results can be given. It deals with *strict solutions* to $(\mathcal{C})$, i.e., points $\overline{x} \in C$ such that $f(\overline{x}) < f(x)$ for each $x \in C \backslash \{\overline{x}\}$. For the sufficient condition we assume that C is *strictly convex at* $\overline{x}$ in the sense that $\langle \overline{x}^*, x - \overline{x}\rangle < 0$ for every $x \in C \backslash \{\overline{x}\}$ and $\overline{x}^* \in N(C, \overline{x}) \backslash \{0\}$. Observe that if $N(C, \overline{x}) \backslash \{0\}$ is nonempty (in particular if C is a convex subset of a finite dimensional space) and if C is strictly convex at $\overline{x}$, then $\overline{x}$ is an extremal point of C (i.e., $C \backslash \{\overline{x}\}$ is convex).

PROPOSITION 6. *Given a function $f : X \to \mathbb{R} \cup \{\infty\}$ finite at $\overline{x}$ and a subset C of X which is strictly convex at $\overline{x}$, the following relation implies that $\overline{x}$ is a strict solution to $(\mathcal{C})$ or a global minimizer of f on X:*

$$0 \in \partial^{\leq} f(\overline{x}) + N(C, \overline{x}). \tag{5}$$

Conversely, when X is finite dimensional, C is a convex subset of X not reduced to $\{\overline{x}\}$, $\overline{x}$ is an extremal point of C, and f is a Gutiérrez function at $\overline{x}$; relation (5) *is necessary in order that $\overline{x}$ be a strict solution to $(\mathcal{C})$ or a global minimizer of f on X.*

Proof. Assume relation (5) holds and C is strictly convex at $\overline{x}$. If $\overline{x}$ is not a global minimizer of f on X there exists some $\overline{x}^* \in \partial^{\leq} f(\overline{x})$ such that $-\overline{x}^* \in N(C,\overline{x})$ and $\overline{x}^* \neq 0$. Then, if $x \in C\backslash\{\overline{x}\}$ is such that $f(x) \leq f(\overline{x})$ we have $\langle \overline{x}^*, x-\overline{x}\rangle \leq f(x) - f(\overline{x}) \leq 0$ since $\overline{x}^* \in \partial^{\leq} f(\overline{x})$ and $\langle -\overline{x}^*, x-\overline{x}\rangle < 0$ since $-\overline{x}^* \in N(C,\overline{x})\backslash\{0\}$, a contradiction. Thus $\overline{x}$ is a strict solution to $(\mathcal{C})$.

When $\overline{x}$ is a strict solution to $(\mathcal{C})$, the sets $C\backslash\{\overline{x}\}$ and $S_f(\overline{x})$ are disjoint. If, moreover, f is a Gutiérrez function at $\overline{x}$ and $\overline{x}$ is an extremal point of C but is not a global minimizer of f on X, and $C \neq \{\overline{x}\}$, then these sets are convex and nonempty. Thus, when X is finite dimensional, a separation theorem yields some $c \in \mathbb{R}$ and u^* in the unit sphere of X^* such that

$$\langle u^*, x-\overline{x}\rangle \geq c \geq \langle u^*, w-\overline{x}\rangle \qquad \forall w \in S_f(\overline{x}), \forall x \in C\backslash\{\overline{x}\}. \tag{6}$$

Since x can be arbitrarily close to $\overline{x}$, we have $c \leq 0$. On the other hand, since we can take $w = \overline{x}$, we have $c \geq 0$, hence $c = 0$. Thus $-u^* \in N(C,\overline{x})$ and $u^* \in N(S_f(\overline{x}),\overline{x}) = \mathbb{R}_+ \partial^{\leq} f(\overline{x})$ since f is a Gutiérrez function at $\overline{x}$. Since $u^* \neq 0$, one can find $r > 0$ and $\overline{x}^* \in \partial^{\leq} f(\overline{x})$ such that $u^* = r\overline{x}^*$ and $-\overline{x}^* \in N(C,\overline{x})$, so that relation (5) holds. When $\overline{x}$ is a global minimizer of f on X, we have $0 \in \partial^{\leq} f(\overline{x}) \cap (-N(C,\overline{x}))$. ∎

Now, let us give conditions for local minimization.

PROPOSITION 7. *Let f be an u.s.c. locally Plastria function at some local solution $\overline{x}$ to $(\mathcal{C})$ which is not a local minimizer of f. Then one has*

$$0 \in \partial^{<}_{loc} f(\overline{x}) + N(C,\overline{x}). \tag{7}$$

Conversely, for any function f finite at $\overline{x}$ which satisfies relation (7), $\overline{x}$ is a solution to $(\mathcal{C})$.

Proof. By assumption, we can find $r > 0$ such that $\overline{x}$ is a minimizer of f on $C \cap V$, where $V := B(\overline{x}, r)$. Taking a smaller r if necessary and setting $f_V(x) = f(x)$ if $x \in V$, $f_V(x) = +\infty$ if $x \in X\backslash V$, we may assume that f_V is a Plastria function at $\overline{x}$. Then relation (7) follows from Proposition 4.

The converse assertion follows from the sufficient condition and from the observation that if $\overline{x}^* \in \partial^{<}_{loc} f(\overline{x})$, then there is some neighborhood V of $\overline{x}$ such that $\overline{x}^* \in \partial^{<} f_V(\overline{x})$. ∎

4. Necessary condition for the mathematical programming problem. Let us consider now the case in which the constraint set C is defined by a finite family of inequalities, so that problem $(\mathcal{C})$ turns into the mathematical programming problem

$$(\mathcal{M}) \qquad \text{minimize } f(x) \text{ subject to } x \in C := \{x \in X : \ g_1(x) \leq 0, \ldots, g_n(x) \leq 0\}.$$

Let us first consider the case of a single constraint.

LEMMA 8. *Let $\overline{x}$ be a solution to $(\mathcal{M})$ in which $g_1 = \cdots = g_n = g$ and $\overline{x}$ is not a local minimizer of f. Assume that f is a Plastria function at $\overline{x}$ and that g is u.s.c. at $\overline{x}$ and a Gutiérrez function at $\overline{x}$. Then $g(\overline{x}) = 0$ and there exists some $y \in \mathbb{R}_+$ such that*

$$0 \in \partial^{<} f(\overline{x}) + y\partial^{\leq} g(\overline{x}).$$

Proof. By Proposition 4, there exists $\overline{x}^* \in \partial^{<} f(\overline{x})$ such that $-\overline{x}^* \in N(C,\overline{x})$. If $g(\overline{x}) < 0$, since g is u.s.c. at $\overline{x}$, $\overline{x}$ belongs to the interior of C, hence $\overline{x}$ is a local minimizer of f, and our assumption discards that case. Thus $g(\overline{x}) = 0$, and since g is

a Gutiérrez function at $\overline{x}$, we have $N(C,\overline{x}) = \mathbb{R}_+\partial^{\leq} g(\overline{x})$. Thus there exists $y \in \mathbb{R}_+$ such that $-\overline{x}^* \in y\partial^{\leq} g(\overline{x})$. □

Now let us turn to the general case. We will use the following lemma.

LEMMA 9. *Let $(g_i)_{i\in I}$ be a finite family of quasiconvex Gutiérrez functions at some $\overline{x} \in X$. For $i \in I$, let $C_i := g_i^{-1}((-\infty, 0])$. Assume g_i is u.s.c. at $\overline{x}$, $g_i(\overline{x}) = 0$ for each $i \in I$ and either*

(a) *there exist some $k \in I$ and some $z \in C_k$ such that $g_i(z) < 0$ for each $i \in I\backslash\{k\}$ (Slater condition), or*

(b) *C_i is closed for each $i \in I$ and $\mathbb{R}_+ \left(\Delta - \prod_{i\in I} C_i\right) = X^I$, where $\Delta := \{(x_i)_{i\in I} : \forall j, k \in I,\ x_j = x_k\}$ is the diagonal of X^I.*

Then, $h := \max_{i\in I} g_i$ is a Gutiérrez function at $\overline{x}$ and one has

$$\mathbb{R}_+\partial^{\leq} h(\overline{x}) = \sum_{i\in I} \mathbb{R}_+\partial^{\leq} g_i(\overline{x}). \tag{8}$$

Proof. In case (a) we have $C_k \cap \left(\bigcap_{i\in I\backslash\{k\}} \operatorname{int} C_i\right) \neq \varnothing$; hence, for $C := \bigcap_{i\in I} C_i$, we get

$$N(C,\overline{x}) = \overline{\operatorname{co}}\left(\bigcup_{i\in I} N(C_i,\overline{x})\right) = \sum_{i\in I} N(C_i,\overline{x}).$$

In case (b), this relation also holds by the Attouch–Brézis qualification condition [2]. Thus, since $\partial^{\leq} g_i(\overline{x}) \subset \partial^{\leq} h(\overline{x})$ and $\partial^{\leq} h(\overline{x})$ is convex,

$$\mathbb{R}_+\partial^{\leq} h(\overline{x}) \subset N(C,\overline{x}) = \sum_{i\in I} N(C_i,\overline{x}) = \sum_{i\in I} \mathbb{R}_+\partial^{\leq} g_i(\overline{x}) \subset \mathbb{R}_+\partial^{\leq} h(\overline{x}),$$

so that h is a Gutiérrez function at $\overline{x}$ and relation (8) holds. □

THEOREM 10. *Let $\overline{x}$ be a solution to $(\mathcal{M})$ which is not a local minimizer of f. Let $I := \{i \in \{1,\dots,n\} : g_i(\overline{x}) = 0\}$. Assume that one of the assumptions* (a) *or* (b) *of Lemma 9 is satisfied. Assume that f is a Plastria function at $\overline{x}$, $g_1,\dots,g_n$ are u.s.c. at $\overline{x}$ and that for every $i \in I$, g_i is a Gutiérrez functions at $\overline{x}$. Then, there exist some $y_1,\dots,y_n \in \mathbb{R}_+$ such that*

$$\begin{aligned} 0 &\in \partial^{<} f(\overline{x}) + y_1\partial^{\leq} g_1(\overline{x}) + \cdots + y_n\partial^{\leq} g_n(\overline{x}), \\ y_i g_i(\overline{x}) &= 0 \qquad\qquad \text{for } i = 1,\dots,n. \end{aligned}$$

Proof. Let $g := \max_{1\leq i\leq n} g_i$, $h := \max_{i\in I} g_i$, and let $D := h^{-1}((-\infty, 0])$. Then, for $i \in \{1,\dots,n\}\backslash I$, the point $\overline{x}$ belongs to the interior of $C_i := g_i^{-1}((-\infty, 0])$, so that for any $x \in C := g^{-1}((-\infty, 0])$ and any $t > 0$ small enough we have $\overline{x} + t(x - \overline{x}) \in D$. It follows that $N(D,\overline{x}) = N(C,\overline{x})$. By Proposition 4 there exists some $\overline{x}^* \in \partial^{<} f(\overline{x})$ such that $-\overline{x}^* \in N(D,\overline{x}) = N(C,\overline{x})$. Now h is u.s.c. at $\overline{x}$ and is a Gutiérrez function at $\overline{x}$ by Lemma 9. Then, by relation (8), there exist $y_i \in \mathbb{R}_+$, $\overline{y}_i^* \in \partial^{\leq} g_i(\overline{x})$ such that $-\overline{x}^* = y_1\overline{y}_1^* + \cdots + y_n\overline{y}_n^*$ and the result is proven. □

Proposition 1 shows that the preceding statement encompasses the classical result for convex mathematical programming. The next example illustrates the theorem; note that since the function f is not semistrictly quasiconvex [17, Prop. 6.1] and [19, Prop. 6.3] cannot be applied.

Example 3. Let f be as in Example 2 with $X := \mathbb{R}$ and let g_1 be given by $g_1(x) := -x$. Then f and g_1 are Gutiérrez and Plastria functions at $\overline{x} = 0$ and $\overline{x}$

is not a local minimizer of f. Moreover, the Slater condition is satisfied at $\overline{x}$. We can take $y_1 = 1$ as a multiplier since $\partial^< f(\overline{x}) = [1, +\infty)$ and $\partial^{\leq} g_1(\overline{x}) = (-\infty, -1]$, $g_1(\overline{x}) = 0$.

A link with the classical Karush, Kuhn, and Tucker theorem is delineated in the next statement.

COROLLARY 11. *Assume the hypothesis of the preceding proposition are satisfied and that $f, g_1, \ldots, g_n$ are differentiable at $\overline{x}$ with nonzero derivatives. Then there exist some $\lambda_1, \ldots, \lambda_n \in \mathbb{R}_+$ such that*

$$\begin{aligned} f'(\overline{x}) + \lambda_1 g_1'(\overline{x}) + \cdots + \lambda_n g_n'(\overline{x}) &= 0, \\ \lambda_i g_i(\overline{x}) &= 0 \qquad \text{for } i = 1, \ldots, n. \end{aligned}$$

Proof. By Proposition 3 and the preceding result, there exist some $r \geq 1, y_i \in \mathbb{R}_+$ and some $\overline{y}_i^* \in \partial^{\leq} g_i(\overline{x})$ for $i = 1, \ldots, n$ such that

$$r f'(\overline{x}) + y_1 \overline{y}_1^* + \cdots + y_n \overline{y}_n^* = 0;$$

also $\overline{y}_i^* = s_i g_i'(\overline{x})$ for some $s_i \geq 1$. Setting $\lambda_i = r^{-1} s_i y_i$, we get the result. □

Let us give a simple sufficient condition for the mathematical programming problem $(\mathcal{M})$.

THEOREM 12. *If $\overline{x} \in C$ is such that there exist $y_i \in \mathbb{R}_+$ for $i = 1, \ldots, n$ such that the following conditions are satisfied, then $\overline{x}$ is a solution to problem $(\mathcal{M})$:*

$$\begin{aligned} 0 &\in \partial^< f(\overline{x}) + y_1 \partial^{\leq} g_1(\overline{x}) + \cdots + y_n \partial^{\leq} g_n(\overline{x}), \\ g_1(\overline{x}) &\leq 0, \ldots, g_n(\overline{x}) \leq 0, \\ y_1 g_1(\overline{x}) &= 0, \ldots, y_n g_n(\overline{x}) = 0. \end{aligned}$$

Proof. Suppose to the contrary that there exists some $x \in C$ such that $f(x) < f(\overline{x})$. Let $I(\overline{x}) := \{i \in \{1, \ldots, n\} : g_i(\overline{x}) = 0\}$. Let $\overline{x}^* \in \partial^< f(\overline{x})$, $\overline{x}_i^* \in \partial^{\leq} g_i(\overline{x})$ for $i = 1, \ldots, n$ be such that

$$0 = \overline{x}^* + y_1 \overline{x}_1^* + \cdots + y_n \overline{x}_n^* = \overline{x}^* + \sum_{i \in I(\overline{x})} y_i \overline{x}_i^*.$$

Since $f(x) < f(\overline{x})$, $g_i(x) \leq 0 = g_i(\overline{x})$ for $i \in I(\overline{x})$, by the definitions of $\partial^< f(\overline{x})$, $\partial^{\leq} g_i(\overline{x})$ we have

$$\begin{aligned} \langle \overline{x}^*, x - \overline{x} \rangle &\leq f(x) - f(\overline{x}), \\ \langle \overline{x}_i^*, x - \overline{x} \rangle &\leq g_i(x) - g_i(\overline{x}), \qquad i \in I(\overline{x}). \end{aligned}$$

Multiplying each side of the last inequality by y_i and adding the obtained sides to the ones of the preceding relation, we get

$$\begin{aligned} 0 &= \langle \overline{x}^*, x - \overline{x} \rangle + \sum_{i \in I(\overline{x})} y_i \langle \overline{x}_i^*, x - \overline{x} \rangle \\ &\leq f(x) - f(\overline{x}) + \sum_{i \in I(\overline{x})} y_i \left(g_i(x) - g_i(\overline{x}) \right) \leq f(x) - f(\overline{x}), \end{aligned}$$

a contradiction. □

Example 4. Let X, $\overline{x}$, f, and g_1 be as in Example 3. Then, since $y_1 := 1$ is a multiplier we get that $\overline{x}$ is a solution to problem $(\mathcal{M})$.

STABILITY OF MULTISTAGE STOCHASTIC PROGRAMS*

H. HEITSCH†, W. RÖMISCH†, AND C. STRUGAREK‡

Abstract. Quantitative stability of linear multistage stochastic programs is studied. It is shown that the infima of such programs behave (locally) Lipschitz continuous with respect to the sum of an L_r-distance and of a distance measure for the filtrations of the original and approximate stochastic (input) processes. Various issues of the result are discussed and an illustrative example is given. Consequences for the reduction of scenario trees are also discussed.

Key words. stochastic programming, multistage, nonanticipativity, stability, filtration, probability metrics

1. Introduction. We consider a finite horizon sequential decision process under uncertainty, in which a decision made at t is based only on information available at t ($1 \le t \le T$). We assume that the information is given by a discrete time multivariate stochastic process $\{\xi_t\}_{t=1}^T$ defined on some probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and with ξ_t taking values in $\mathbb{R}^d$. The information available at t consists of the random vector $\xi^t := (\xi_1, \dots, \xi_t)$, and the stochastic decision x_t at t varying in $\mathbb{R}^{m_t}$ is assumed to depend only on ξ^t. The latter property is called *nonanticipativity* and is equivalent to the measurability of x_t with respect to the σ-field $\mathcal{F}_t \subseteq \mathcal{F}$, which is generated by ξ^t. Hence, we have $\mathcal{F}_t \subseteq \mathcal{F}_{t+1}$ for $t = 1, \dots, T-1$ and we assume that $\mathcal{F}_1 = \{\emptyset, \Omega\}$, i.e., ξ_1 and x_1 are deterministic and, with no loss of generality, that $\mathcal{F}_T = \mathcal{F}$.
More precisely, we consider the following *linear multistage stochastic program*:

$$\min \left\{ \mathbb{E}\left[\sum_{t=1}^{T} \langle b_t(\xi_t), x_t \rangle\right] \;\middle|\; \begin{array}{l} x_t \in X_t, \\ x_t \text{ is } \mathcal{F}_t\text{-measurable}, t = 1, \dots, T, \\ A_{t,0}x_t + A_{t,1}(\xi_t)x_{t-1} = h_t(\xi_t), t = 2, \dots, T \end{array} \right\}, \tag{1.1}$$

where the subsets X_t of $\mathbb{R}^{m_t}$ are nonempty, closed, and polyhedral; the cost coefficients $b_t(\xi_t)$ belong to $\mathbb{R}^{m_t}$; the right-hand sides $h_t(\xi_t)$ are in $\mathbb{R}^{n_t}$; $A_{t,0}$ are fixed (n_t, m_t)-matrices; and $A_{t,1}(\xi_t)$ are (n_t, m_{t-1})-matrices, respectively. We assume that $b_t(\cdot)$, $h_t(\cdot)$, and $A_{t,1}(\cdot)$ depend affinely linearly on ξ_t covering the situation that some of the components of b_t and h_t, and of the elements of $A_{t,1}$ are random.

The challenge of multistage models consists in the presence of two groups of entirely different constraints, namely of measurability and of pointwise constraints for the decisions x_t. This fact does not lead to consequences in the two-stage situation ($T = 2$). In general, however, it is the origin of both the theoretical and computa-

tional challenges of multistage models. In the present paper, it produces the essential difference of quantitative stability estimates compared to the two-stage case.

When solving multistage models computationally, the first step consists of approximating the stochastic process $\xi = \{\xi_t\}_{t=1}^T$ by a process having finitely many scenarios that exhibit tree structure and have its root at the fixed element ξ_1 of $\mathbb{R}^d$ (see the survey [4] for further information). In this way, both the random vectors ξ^t and the σ-fields $\mathcal{F}_t$ are approximated at each t. This process finally leads to linear programming models that are very large scale in most cases and may be solved by decomposition methods that exploit specific structures of the model (see [31] for additional background). In order to reduce the model dimension, it might be desirable to reduce the originally designed tree. The approaches to scenario reduction in [5, 11] and to scenario tree generation in [21, 14, 10] make use of probability metrics, i.e., of metric distances on spaces of probability measures, where the metrics are selected such that the optimal values of original and approximate stochastic program are close if the distance of the original probability distribution $P = \mathcal{L}(\xi)$ of ξ and its approximation Q is small.

Such quantitative stability results are well developed for two-stage models (cf. the survey [28]). It turned out that distances of probability measures are relevant which are given by certain Monge–Kantorovich mass transportation problems. Such problems are of the form

$$\inf\Big\{\int_{\Xi\times\Xi} c(\xi,\tilde{\xi})\eta(d\xi,d\tilde{\xi}) : \eta\in\mathcal{P}(\Xi\times\Xi),\ \pi_1\eta = P,\ \pi_2\eta = Q\Big\}, \tag{1.2}$$

where Ξ is a closed subset of some Euclidean space, π_1 and π_2 denote the projections onto the first and second components, respectively, c is a nonnegative, symmetric, and continuous cost function and P and Q belong to a set $\mathcal{P}_c(\Xi)$ of probability measures on Ξ, where all integrals are finite. Two types of cost functions have been used in stability analysis of stochastic programs [5, 29], namely,

$$c(\xi,\tilde{\xi}) := \|\xi-\tilde{\xi}\|^r \quad (\xi,\tilde{\xi}\in\Xi) \tag{1.3}$$

and

$$c(\xi,\tilde{\xi}) := \max\{1, \|\xi-\xi_0\|^{r-1}, \|\tilde{\xi}-\xi_0\|^{r-1}\}\|\xi-\tilde{\xi}\| \quad (\xi,\tilde{\xi}\in\Xi) \tag{1.4}$$

for some $r\geq 1$ and $\xi_0\in\Xi$. In both cases, the set $\mathcal{P}_c(\Xi)$ may be chosen as the set $\mathcal{P}_r(\Xi)$ of all probability measures on Ξ having absolute moments of order r. The cost (1.3) leads to *L_r-minimal metrics* ℓ_r [25], which are defined by

$$\ell_r(P,Q) := \inf\left\{\int_{\Xi\times\Xi}\|\xi-\tilde{\xi}\|^r\eta(d\xi,d\tilde{\xi})\,|\eta\in\mathcal{P}(\Xi\times\Xi),\ \pi_1\eta = P,\ \pi_2\eta = Q\right\}^{\frac{1}{r}} \tag{1.5}$$

and sometimes also called Wasserstein metrics of order r [9]. The mass transportation problem (1.2) with cost (1.4) defines the Monge–Kantorovich functionals $\hat{\mu}_r$ [22, 24]. A variant of the functional $\hat{\mu}_r$ appears if, in its definition by (1.2), the conditions $\eta\in\mathcal{P}(\Xi\times\Xi), \pi_1\eta = P,\ \pi_2\eta = Q$ are replaced by η being a finite measure on $\Xi\times\Xi$ such that $\pi_1\eta - \pi_2\eta = P - Q$. The corresponding functionals $\mathring{\mu}_r$ are smaller than $\hat{\mu}_r$ and turn out to be metrics on $\mathcal{P}_r(\Xi)$. They are called Fortet–Mourier metrics of order r [8, 22]. The convergence of sequences of probability measures, with respect to both metrics ℓ_r and $\mathring{\mu}_r$, is equivalent to their weak convergence and the convergence

of their rth order absolute moments. For $r = 1$ we have the identity $\mathring{\mu}_1 = \hat{\mu}_1 = \ell_1$ and the corresponding metric is also called Kantorovich distance. Two-stage models are known to behave stable with respect to Fortet–Mourier metrics [23].

Much less is known, however, of the multistage case. The present paper may be regarded as an extension of the quantitative analysis in [7], which considers a less general probabilistic setup and assumes implicitly that the filtrations of the original and approximate stochastic processes coincide. The paper [19] and the recent work [20] provide (qualitative) convergence results of approximations and [16, 32] deal with empirical estimates in multistage models. In the recent paper [34] the role of probability metrics for studying stability of multistage models is questioned critically. An example is given showing that closeness of original and approximate probability distributions in terms of some probability metric is not sufficient for the infima to be close in general. The recent thesis [1] focuses precisely on the question of information in stochastic programs. The conclusions of this work do not address stability, but only discretization of multistage stochastic programs. They illuminate the role which should be played by σ-field distances in order to obtain a consistent discretization of such programs.

The main result of the present paper (Theorem 2.1) provides stability of infima of the multistage model (1.1) with respect to a sum of the L_r-norm and of a distance of the information structures, i.e., the filtrations of σ-fields, of the original and approximate stochastic (input) processes. Hence, it enlightens the corresponding arguments in [34]. Several comments are given on the stability result, its assumptions, the filtration distance, and on the choice of the underlying probability space if the original and approximate (input) probability distributions are given in practical models. Furthermore, we provide an illustrative example which shows that the filtration distance is indispensable for stability (Example 2.6). Finally, some consequences for designing scenario reduction schemes in multistage models are discussed.

2. Stability of multistage models. Under weak hypotheses, the program (1.1) can be equivalently reformulated as a minimization problem for the deterministic first stage decision x_1 (see [31, Chapter 1] or [6, 26] for example). It is of the form

$$\min\Big\{\mathbb{E}[f(x_1,\xi)] = \int_{\Xi} f(x_1,\xi)P(d\xi) : x_1 \in X_1\Big\}, \tag{2.1}$$

where Ξ is a closed subset of $\mathbb{R}^{Td}$ containing the support of the probability distribution P of ξ, and f is an integrand on $\mathbb{R}^{m_1}\times\Xi$ given by the dynamic programming recursion

$$\begin{aligned} f(x_1,\xi) &:= \Phi_1(x_1,\xi^1) = \langle b_1(\xi_1), x_1\rangle + \Phi_2(x_1,\xi^2), \qquad (2.2)\\ \Phi_t(x_1,\dots,x_{t-1},\xi^t) &:= \inf\Big\{\langle b_t(\xi_t), x_t\rangle + \mathbb{E}\left[\Phi_{t+1}(x_1,\dots,x_t,\xi^{t+1})|\mathcal{F}_t\right] : x_t \in X_t,\\ &\qquad\qquad x_t \text{ is } \mathcal{F}_t\text{-measurable}, A_{t,0}x_t + A_{t,1}(\xi_t)x_{t-1} = h_t(\xi_t)\Big\}\\ &\qquad (t = 2,\dots,T),\\ \Phi_{T+1}(x_1,\dots,x_T,\xi^{T+1}) &:= 0. \end{aligned}$$

Using the representation (2.2) of the integrand f for $T = 2$ quantitative stability results are proved in [23, 28] with respect to Fortet–Mourier metrics of probability distributions and earlier in [29] with respect to L_r-minimal metrics. For $T > 2$, however, the integrand f depends on conditional expectations with respect to the σ-fields $\mathcal{F}_t$ and, hence, on the underlying probability measure $\mathbb{P}$ in a nonlinear way. Consequently, the methodology for studying quantitative stability properties of stochastic

programs of the form (2.1) developed in [23, 28] does not apply to multistage models in general.

An alternative for studying stability of multistage models consists in considering them as optimization problems in functional spaces (see also [18, 26]), where the Banach spaces $L_{r'}(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^m)$ with $m = \sum_{t=1}^T m_t$ and endowed with the norm

$$\|x\|_{r'} := \left(\sum_{t=1}^T \mathbb{E}[\|x_t\|^{r'}] \right)^{\frac{1}{r'}} \quad \text{for } r' \geq 1 \text{ and } \quad \|x\|_\infty := \max_{t=1,\dots,T} \operatorname{ess\,sup} \|x_t\|$$

are appropriate. Here, the stochastic input process ξ belongs to $L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ for some $r \geq 1$ and $s := Td$, and r' is defined by

$$r' := \begin{cases} \frac{r}{r-1} & \text{if only costs are random,} \\ r & \text{if only right-hand sides are random,} \\ r = 2 & \text{if only costs and right-hand sides are random,} \\ \infty & \text{if all technology matrices are random and } r = T. \end{cases}$$

The number r corresponds to the order of (absolute) moments of ξ that are required to exist. The definition of the numbers r' implies that the objective function is well defined and finite. In the third case it may alternatively be required that the costs $b_t(\xi_t)$ have finite moments of order $\hat{r} \geq 1$. Then we choose $r' := \frac{\hat{r}}{\hat{r}-1}$ and require that $h_t(\xi_t)$ belongs to $L_{r'}$.

Let us introduce some notations. Let F denote the objective function defined on $L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s) \times L_{r'}(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^m) \to \mathbb{R}$ by $F(\xi, x) := \mathbb{E}[\sum_{t=1}^T \langle b_t(\xi_t), x_t \rangle]$, let

$$\mathcal{X}_t(x_{t-1}; \xi_t) := \{x_t \in X_t | A_{t,0} x_t + A_{t,1}(\xi_t) x_{t-1} = h_t(\xi_t)\}$$

denote the tth feasibility set for every $t = 2, \dots, T$, and

$$\mathcal{X}(\xi) := \{x \in \times_{t=1}^T L_{r'}(\Omega, \mathcal{F}_t, \mathbb{P}; \mathbb{R}^{m_t}) | x_1 \in X_1, x_t \in \mathcal{X}_t(x_{t-1}; \xi_t), t = 2, \dots, T\}$$

denote the set of feasible elements of the stochastic program (1.1) with input ξ. Then the stochastic program (1.1) may be rewritten in the form

$$\min\{F(\xi, x) : x \in \mathcal{X}(\xi)\}. \tag{2.3}$$

Let $v(\xi)$ denote the optimal value of (2.3) and let, for any $\alpha \geq 0$,

$$l_\alpha(F(\xi, \cdot)) := \{x \in \mathcal{X}(\xi) : F(\xi, x) \leq v(\xi) + \alpha\}$$

denote its *α-level set*. The following conditions are imposed on (2.3).

(A1) There exists a $\delta > 0$ such that for any $\tilde{\xi} \in L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ with $\|\tilde{\xi} - \xi\|_r \leq \delta$, any $t = 2, \dots, T$ and any $x_1 \in X_1$, $x_\tau \in L_{r'}(\Omega, \mathcal{F}_t, \mathbb{P}; \mathbb{R}^{m_\tau})$ with $x_\tau \in \mathcal{X}_\tau(x_{\tau-1}; \tilde{\xi}_\tau)$, $\tau = 2, \dots, t-1$, the tth feasibility set $\mathcal{X}_t(x_{t-1}; \tilde{\xi}_t)$ is nonempty (*relatively complete recourse locally around ξ*).

(A2) The optimal values $v(\tilde{\xi})$ of (2.3) with input $\tilde{\xi}$ are finite for all $\tilde{\xi}$ in a neighborhood of ξ and the objective function F is *level-bounded locally uniformly at ξ*, i.e., for some $\alpha > 0$ there exists a $\delta > 0$ and a bounded subset B of $L_{r'}(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^m)$ such that $l_\alpha(F(\tilde{\xi}, \cdot))$ is nonempty and contained in B for all $\tilde{\xi} \in L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ with $\|\tilde{\xi} - \xi\|_r \leq \delta$.

(A3) $\xi \in L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ for some $r \geq 1$.

To state our main result we introduce the distance $D_{\mathrm{f}}(\xi, \tilde{\xi})$ of the filtrations of ξ and its approximation (or perturbation) $\tilde{\xi}$, respectively. It is defined by

$$D_{\mathrm{f}}(\xi, \tilde{\xi}) := \sup_{\varepsilon \in (0,\alpha]} D_{\mathrm{f},\varepsilon}(\xi, \tilde{\xi}) \tag{2.4}$$

and $D_{\mathrm{f},\varepsilon}(\xi, \tilde{\xi})$ denotes the ε-filtration distance given by

$$D_{\mathrm{f},\varepsilon}(\xi, \tilde{\xi}) := \inf \sum_{t=2}^{T-1} \max\{\|x_t - \mathbb{E}[x_t|\tilde{\mathcal{F}}_t]\|_{r'}, \|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\mathcal{F}_t]\|_{r'}\}, \tag{2.5}$$

where the infimum is taken with respect to all $x \in l_\varepsilon(F(\xi, \cdot))$ and $\tilde{x} \in l_\varepsilon(F(\tilde{\xi}, \cdot))$, respectively, i.e., with respect to all feasible decisions belonging to the ε-level sets of the original and perturbed programs. Furthermore, $\mathcal{F}_t$ and $\tilde{\mathcal{F}}_t$, $t = 1, \ldots, T$, denote the filtrations of ξ and $\tilde{\xi}$, respectively.

Now, we are ready to state our main stability result for multistage stochastic programs.

THEOREM 2.1. *Let* (A1), (A2), *and* (A3) *be satisfied and* X_1 *be bounded. Then there exists positive constants* L, α, *and* δ *such that the estimate*

$$|v(\xi) - v(\tilde{\xi})| \le L(\|\xi - \tilde{\xi}\|_r + D_{\mathrm{f}}(\xi, \tilde{\xi})) \tag{2.6}$$

holds for all random elements $\tilde{\xi} \in L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ *with* $\|\tilde{\xi} - \xi\|_r \le \delta$.

Proof. Let M_t denote the set-valued mappings $u \mapsto \{x \in \mathbb{R}^{m_t} | A_{t,0}x = u,\ x \in X_t\}$ from $\mathbb{R}^{n_t}$ to $\mathbb{R}^{m_t}$ for $t = 2, \ldots, T$. The mappings have polyhedral graph and, hence, are Lipschitz continuous with respect to the Hausdorff distance on their domain $\operatorname{dom} M_t \subseteq \mathbb{R}^{n_t}$ [27, Example 9.35]. Hence, there exist positive constants l_t such that we have

$$\sup_{x \in M_t(\bar{u})} d(x, M_t(\tilde{u})) \le l_t \|\bar{u} - \tilde{u}\| \tag{2.7}$$

for all $\bar{u}, \tilde{u} \in \operatorname{dom} M_t$, where $d(x, C)$ denotes the distance of x to a nonempty set C in $\mathbb{R}^{m_t}$.

Now, let $\alpha > 0$ and $\delta > 0$ be selected as in (A1) and (A2). Let $\varepsilon \in (0, \alpha]$, $\tilde{\xi} \in L_r(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^s)$ be such that $\|\tilde{\xi} - \xi\|_r < \delta$ and $v(\tilde{\xi}) \in \mathbb{R}$, and let $\bar{x} \in l_\varepsilon(F(\xi, \cdot))$. By $\tilde{\mathcal{F}}_t$ we denote the σ-field generated by $\tilde{\xi}^t := (\tilde{\xi}_1, \ldots, \tilde{\xi}_t)$ for $t = 1, \ldots, T$. Now, we show recursively the existence of constants $\hat{L}_t > 0$ and of elements $\tilde{x}_t$ belonging to the appropriate spaces $L_{r'}(\Omega, \tilde{\mathcal{F}}_t, \mathbb{P}; \mathbb{R}^{m_t})$ for each $t = 1, \ldots, T$ such that $\tilde{x}_t \in X_t$, $t = 1, \ldots, T$, $A_{t,0}\tilde{x}_t + A_{t,1}(\tilde{\xi}_t)\tilde{x}_{t-1} = h_t(\tilde{\xi}_t)$, $t = 2, \ldots, T$, and that

$$\|\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t] - \tilde{x}_t\|$$

can be estimated recursively with respect to t. Let $t = 1$, we then set $\tilde{x}_1 := \bar{x}_1$ and $\hat{L}_1 := 1$. For $t > 1$, we assume that $\hat{L}_{t-1}$ and $\tilde{x}_{t-1}$ have already been constructed, set $\bar{u}_t := h_t(\xi_t) - A_{t,1}(\xi_t)\bar{x}_{t-1}$, $\tilde{u}_t := h_t(\tilde{\xi}_t) - A_{t,1}(\tilde{\xi}_t)\tilde{x}_{t-1}$ and consider the following set-valued mappings from Ω to $\mathbb{R}^{m_t}$ given by

$$\omega \to M_t(\tilde{u}_t(\omega)) \qquad \text{and} \qquad \omega \to \arg\min_{x \in M_t(\tilde{u}_t(\omega))} \|\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t](\omega) - x\|.$$

Both are measurable with respect to the σ-field $\tilde{\mathcal{F}}_t$ due to the measurability of $\tilde{x}_{t-1}$ with respect to $\tilde{\mathcal{F}}_{t-1}$ and well-known measurability results for set-valued mappings

(e.g., [27, Theorem 14.36]). In addition, the set-valued mapping $\omega \to M_t(\tilde{u}_t(\omega))$ is nonempty-valued due to (A1). Hence, by appealing to [27, Theorem 14.37] there exists a $\tilde{\mathcal{F}}_t$-measurable selection $\tilde{x}_t$ of the second mapping. Since $\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]$ belongs to $M_t(\mathbb{E}[\bar{u}_t|\tilde{\mathcal{F}}_t])$, (2.7) provides the estimate

$$\begin{aligned}
\|\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t] - \tilde{x}_t\| &\le l_t\|\mathbb{E}[\bar{u}_t|\tilde{\mathcal{F}}_t] - \tilde{u}_t\| \\
&\le l_t(\|\mathbb{E}[h_t(\xi_t)|\tilde{\mathcal{F}}_t] - h_t(\tilde{\xi}_t)\| + \|\mathbb{E}[A_{t,1}(\xi_t)\bar{x}_{t-1}|\tilde{\mathcal{F}}_t] - A_{t,1}(\tilde{\xi}_t)\tilde{x}_{t-1}\|) \\
&\le l_t(K_t\|\mathbb{E}[\xi_t|\tilde{\mathcal{F}}_t] - \tilde{\xi}_t\| + \|\mathbb{E}[A_{t,1}(\xi_t)\bar{x}_{t-1} - A_{t,1}(\tilde{\xi}_t)\bar{x}_{t-1}|\tilde{\mathcal{F}}_t]\| \\
&\qquad + \|A_{t,1}(\tilde{\xi}_t)\|\|\mathbb{E}[\bar{x}_{t-1}|\tilde{\mathcal{F}}_t] - \tilde{x}_{t-1}\|) \\
&\le l_t\bar{K}_t(\|\mathbb{E}[\xi_t - \tilde{\xi}_t|\tilde{\mathcal{F}}_t]\| + \mathbb{E}[\|\xi_t - \tilde{\xi}_t\|\|\bar{x}_{t-1}\||\tilde{\mathcal{F}}_t] \\
&\qquad + \max\{1, \|\tilde{\xi}_t\|\}(\|\mathbb{E}[\bar{x}_{t-1} - \mathbb{E}[\bar{x}_{t-1}|\tilde{\mathcal{F}}_{t-1}]|\tilde{\mathcal{F}}_t]\| \\
&\qquad + \|\mathbb{E}[\bar{x}_{t-1}|\tilde{\mathcal{F}}_{t-1}] - \tilde{x}_{t-1}\|)),
\end{aligned}$$

where K_t and $\bar{K}_t$ are certain positive constants, the affine linearity of $h_t(\cdot)$ and $A_{t,1}(\cdot)$ and Jensen's inequality is used for the second summand. Clearly, we have $\|\tilde{\xi}_\tau\| \le C\|\tilde{\xi}^t\|$ with some constant C for all $\tau = 2, \dots, t$, $t = 2, \dots, T$, and the corresponding norms in $\mathbb{R}^d$ and $\mathbb{R}^{td}$. Using Jensen's inequality also in the first and third summand of the latter estimate we obtain recursively

$$\begin{aligned}
\|\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t] - \tilde{x}_t\| \le \hat{L}_t\Big(&\sum_{\tau=2}^{t} \max\{1, \|\tilde{\xi}^t\|^{t-\tau}\}\mathbb{E}[(1 + \|\bar{x}_{\tau-1}\|)\|\xi_\tau - \tilde{\xi}_\tau\|\,|\tilde{\mathcal{F}}_\tau] \\
&+ \sum_{\tau=2}^{t-1} \max\{1, \|\tilde{\xi}^t\|^{t-\tau}\}\mathbb{E}[\|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|\,|\tilde{\mathcal{F}}_{\tau+1}]\Big)
\end{aligned} \tag{2.8}$$

with some positive constant $\hat{L}_t$ for $t = 2, \dots, T$. Note that the sum on the right-hand side of (2.8) disappears if only costs are random. The max-terms in (2.8) and the norms $\|x_{\tau-1}\|$ in (2.8) vanish if the technology matrices are not random. Inserting $\bar{x}$ and $\tilde{x}$ into the objective function we obtain

$$v(\tilde{\xi}) - v(\xi) \le F(\tilde{\xi}, \tilde{x}) - F(\xi, \bar{x}) + \varepsilon. \tag{2.9}$$

In case of only right-hand sides being random we continue (2.9) using (2.8) and obtain

$$\begin{aligned}
v(\tilde{\xi}) - v(\xi) &\le \sum_{t=2}^{T} \mathbb{E}[\langle b_t, \mathbb{E}[\tilde{x}_t - \bar{x}_t|\tilde{\mathcal{F}}_t]\rangle] + \varepsilon \le \sum_{t=2}^{T} \|b_t\|\mathbb{E}[\|\tilde{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|] + \varepsilon \\
&\le \hat{L}\sum_{t=2}^{T} \mathbb{E}\Big[\sum_{\tau=2}^{t} \mathbb{E}[\|\xi_\tau - \tilde{\xi}_\tau\||\tilde{\mathcal{F}}_\tau] + \sum_{\tau=2}^{t-1} \mathbb{E}[\|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|\,|\tilde{\mathcal{F}}_{\tau+1}]\Big] + \varepsilon \\
&\le \hat{L}T\mathbb{E}\Big[\sum_{t=2}^{T} \|\xi_t - \tilde{\xi}_t\| + \sum_{\tau=2}^{T-1} \|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|\Big] + \varepsilon \\
&\le \hat{L}T\Big(\|\xi - \tilde{\xi}\|_r + \sum_{\tau=2}^{T-1} \|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|_r\Big) + \varepsilon,
\end{aligned}$$

where $\hat{L} := \max_{t=1,\dots,T} \hat{L}_t\|b_t\|$. If costs are random, we obtain the estimate

$$v(\tilde{\xi}) - v(\xi) \le F(\tilde{\xi}, \tilde{x}) - F(\tilde{\xi}, \bar{x}) + F(\tilde{\xi}, \bar{x}) - F(\xi, \bar{x}) + \varepsilon$$

$$\leq \mathbb{E}\Big[\sum_{t=2}^{T}\langle b_t(\tilde{\xi}_t), \mathbb{E}[\tilde{x}_t - \bar{x}_t|\tilde{\mathcal{F}}_t]\rangle\Big] + \mathbb{E}\Big[\sum_{t=1}^{T}\langle b_t(\tilde{\xi}_t) - b_t(\xi_t), \bar{x}_t\rangle\Big] + \varepsilon$$

$$\leq \hat{K}\mathbb{E}\Big[\sum_{t=2}^{T}\max\{1, \|\tilde{\xi}_t\|\}\|\tilde{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\| + \sum_{t=1}^{T}\|\tilde{\xi}_t - \xi_t\|\|\bar{x}_t\|\Big] + \varepsilon \tag{2.10}$$

with some positive constant $\hat{K}$. In case of only costs being random, i.e., $r' = \frac{r}{r-1}$, we continue with

$$v(\tilde{\xi}) - v(\xi) \leq \hat{K}\mathbb{E}\Big[\sum_{t=2}^{T}\max\{1, \|\tilde{\xi}_t\|\}\|\tilde{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|\Big] + \hat{K}\|\tilde{\xi} - \xi\|_r\|\bar{x}\|_{r'} + \varepsilon$$

$$\leq \hat{K}\mathbb{E}\Big[\sum_{t=2}^{T}\max\{1, \|\tilde{\xi}_t\|\}\|\tilde{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|\Big] + K\|\tilde{\xi} - \xi\|_r + \varepsilon,$$

where Hölder's inequality and the boundedness of $\|\bar{x}\|_{r'}$ according to (A2) were used leading to some constant $K > 0$. Using the estimate (2.8), we conclude that

$$v(\tilde{\xi}) - v(\xi) \leq L\Big(\|\tilde{\xi} - \xi\|_r + \sum_{t=2}^{T-1}\|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_{r'}\Big) + \varepsilon,$$

where Hölder's inequality and the fact that $\tilde{\xi}$ varies in a bounded set in L_r were used leading to some constant $L > 0$ (depending on ξ).

Next, we consider the case $r = r' = 2$. Starting from (2.10) we use the Cauchy–Schwarz inequality and obtain

$$v(\tilde{\xi}) - v(\xi) \leq \hat{K}\Big[\Big(\sum_{t=2}^{T}\mathbb{E}[\max\{1, \|\tilde{\xi}_t\|^2\}]\Big)^{\frac{1}{2}}\Big(\sum_{t=2}^{T}\mathbb{E}[\|\tilde{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|^2]\Big)^{\frac{1}{2}} + \|\tilde{\xi} - \xi\|_2\|\bar{x}\|_2\Big] + \varepsilon$$

$$\leq \Big(\|\tilde{\xi} - \xi\|_2 + \sum_{t=2}^{T-1}\|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_2\Big) + \varepsilon$$

with some constant $L > 0$ (depending on ξ) due to (2.8), (A2), and the fact that $\tilde{\xi}$ varies in some bounded set in L_2.

Finally, we consider the situation that costs, right-hand sides, and technology matrices are random, i.e., $r = T$ and $r' = \infty$. In this case, the estimate (2.8) attains the form

$$\|\mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t] - \tilde{x}_t\| \leq \hat{L}_t\Big(\sum_{\tau=2}^{t}\max\{1, \|\tilde{\xi}^t\|^{t-\tau}\}\mathbb{E}[\|\xi_\tau - \tilde{\xi}_\tau\|\,|\tilde{\mathcal{F}}_\tau] + \sum_{\tau=2}^{t-1}\max\{1, \|\tilde{\xi}^t\|^{t-\tau}\}\|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|_\infty\Big).$$

Now, we start again from (2.10) and use the latter estimate and obtain

$$v(\tilde{\xi}) - v(\xi) \leq \hat{L}\mathbb{E}\Big[\sum_{t=2}^{T}\Big(\sum_{\tau=2}^{t}\max\{1, \|\tilde{\xi}^t\|^{t+1-\tau}\}\mathbb{E}[\|\xi_\tau - \tilde{\xi}_\tau\|\,|\tilde{\mathcal{F}}_\tau]$$

$$
\begin{aligned}
&\quad + \sum_{\tau=2}^{t-1} \max\{1, \|\tilde{\xi}^t\|^{t+1-\tau}\} \|\bar{x}_\tau - \mathbb{E}[\bar{x}_\tau|\tilde{\mathcal{F}}_\tau]\|_\infty \Big) + \sum_{t=1}^{T} \|\tilde{\xi}_t - \xi_t\| \Big] + \varepsilon \\
&\leq \tilde{L}\mathbb{E}\Big[\sum_{t=2}^{T} \max\{1, \|\tilde{\xi}^t\|^{t-1}\} \mathbb{E}[\|\xi_t - \tilde{\xi}_t\| \, |\tilde{\mathcal{F}}_t] \Big] \\
&\quad + \sum_{t=2}^{T-1} \mathbb{E}[\max\{1, \|\tilde{\xi}^t\|^{t-1}\}] \|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_\infty + \|\tilde{\xi} - \xi\|_1 + \varepsilon \\
&\leq \bar{L}\mathbb{E}[\max\{1, \|\tilde{\xi}\|^T\}] \Big(\|\xi - \tilde{\xi}\|_T + \sum_{t=2}^{T-1} \|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_\infty \Big) + \varepsilon,
\end{aligned} \tag{2.11}
$$

where $\hat{L}, \tilde{L}, \bar{L}$ are certain positive constants and Hölder's inequality was used. Since $\tilde{\xi}$ varies in a bounded subset of L_T, there exists a constant $L > 0$ (depending on ξ) such that

$$
v(\tilde{\xi}) - v(\xi) \leq L\Big(\|\xi - \tilde{\xi}\|_r + \sum_{t=2}^{T-1} \|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_{r'} \Big) + \varepsilon, \tag{2.12}
$$

where $r = T$ and $r' = \infty$. Hence, an estimate of the form (2.12) is obtained in all cases. Changing the role of ξ and $\tilde{\xi}$ leads to an estimate of the form

$$
v(\xi) - v(\tilde{\xi}) \leq L\Big(\|\xi - \tilde{\xi}\|_r + \sum_{t=2}^{T-1} \|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\mathcal{F}_t]\|_{r'} \Big) + \varepsilon. \tag{2.13}
$$

We note that the second summands in the estimates (2.12) and (2.13) are bounded by

$$
\sum_{t=2}^{T-1} \max\{\|\bar{x}_t - \mathbb{E}[\bar{x}_t|\tilde{\mathcal{F}}_t]\|_{r'}, \|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\mathcal{F}_t]\|_{r'}\}. \tag{2.14}
$$

Since the estimates (2.12) and (2.13) are valid for all $\bar{x} \in l_\varepsilon(F(\xi, \cdot))$ and $\tilde{x} \in l_\varepsilon(F(\tilde{\xi}, \cdot))$, we arrive at the estimate

$$
|v(\xi) - v(\tilde{\xi})| \leq L\Big(\|\xi - \tilde{\xi}\|_r + D_{\mathrm{f},\varepsilon}(\xi, \tilde{\xi}) \Big) + \varepsilon \leq L\Big(\|\xi - \tilde{\xi}\|_r + \sup_{\varepsilon \in (0,\alpha]} D_{\mathrm{f},\varepsilon}(\xi, \tilde{\xi}) \Big) + \varepsilon.
$$

Finally, it remains to take the infimum of the right-hand side with respect to $\varepsilon > 0$ and the proof is complete. □

Remark 2.2. A sufficient condition for (A1) to hold is the *complete fixed recourse* condition on all matrices $A_{t,0}$, i.e., the sets X_t are polyhedral cones and $A_{t,0}X_t = \mathbb{R}^{n_t}$ holds for $t = 2, \ldots, T$. Assumption (A2) on the locally uniform level-boundedness of the objective function F is quite standard in perturbation results for optimization problems (see, e.g., [27, Theorem 1.17]). The finiteness condition for the optimal values is needed because it is not implied by the level-boundedness of F for all relevant pairs (r, r'). In the case that Ω is finite or $1 < r' < \infty$, the existence of solutions of (2.3) (and, thus, the finiteness of $v(\xi)$) is a simple consequence of the compactness or the weak sequential compactness of $l_\alpha(F(\xi, \cdot))$ in the reflexive Banach space $L_{r'}(\Omega, \mathcal{F}, \mathbb{P}; \mathbb{R}^m)$ and of the linearity of the objective. Then the filtration distance is of the form

$$
D_{\mathrm{f}}(\xi, \tilde{\xi}) = \inf\Big\{ \sum_{t=2}^{T-1} D_t(\xi, \tilde{\xi}) : x \in l_0(F(\xi, \cdot)), \tilde{x} \in l_0(F(\tilde{\xi}, \cdot)) \Big\}, \tag{2.15}
$$

where $D_t(\xi, \tilde{\xi})$ is defined by

$$D_t(\xi,\tilde{\xi}) := \max\{\|x_t - \mathbb{E}[x_t|\tilde{\mathcal{F}}_t]\|_{r'}, \|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\mathcal{F}_t]\|_{r'}\} = \max\{\|x_t - \mathbb{E}[x_t|\tilde{\xi}_1,\dots,\tilde{\xi}_t]\|_{r'}, \|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\xi_1,\dots,\xi_t]\|_{r'}\}. \tag{2.16}$$

Remark 2.3. In practical situations, the available knowledge on the stochastic input consists in (partial or complete) information on its probability distribution. Which probability space should be selected? A natural answer certainly is: Take a probability space where the L_r-distance $\|\xi-\tilde{\xi}\|_r$ and the $L_{r'}$-distances $\|x_t-\mathbb{E}[x_t|\tilde{\xi}_1,\dots,\tilde{\xi}_t]\|_{r'}$ and $\|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\xi_1,\dots,\xi_t]\|_{r'}$, $t = 2,\dots,T-1$, are minimal. Let us explain this minimality condition in case of the L_r-distance $\|\xi-\tilde{\xi}\|_r$. Let P and Q in $\mathcal{P}_r(\Xi)$ be the probability distributions of ξ and $\tilde{\xi}$. Then there exists an optimal solution $\eta^* \in \mathcal{P}(\Xi\times\Xi)$ of the mass transportation problem (1.5) [22, Theorem 8.1.1], i.e.,

$$\ell_r^r(P,Q) = \int_{\Xi\times\Xi} \|\xi-\tilde{\xi}\|^r \eta^*(d\xi, d\tilde{\xi}),$$

where $\pi_1\eta^* = P$ and $\pi_2\eta^* = Q$. Furthermore, there exists a probability space $(\Omega',\mathcal{F}',\mathbb{P}')$ and an optimal coupling, i.e., a pair $(\xi'(\cdot),\tilde{\xi}'(\cdot))$ of Ξ-valued random elements defined on it, such that the probability distribution of $(\xi'(\cdot),\tilde{\xi}'(\cdot))$ is just η^* [22, Theorem 2.5.1]. In particular, we have that the distance in $L_r(\Omega',\mathcal{F}',\mathbb{P}';\mathbb{R}^s)$ is just the L_r-minimal distance of the probability distributions, i.e.,

$$\ell_r(P,Q) = \|\xi'(\cdot) - \tilde{\xi}'(\cdot)\|_r.$$

In the same way, the relevant minimal $L_{r'}$-distances $\|x_t - \mathbb{E}[x_t|\tilde{\xi}_1,\dots,\tilde{\xi}_t]\|_{r'}$ and $\|\tilde{x}_t - \mathbb{E}[\tilde{x}_t|\xi_1,\dots,\xi_t]\|_{r'}$ correspond to the $\ell_{r'}$-distance of the probability distributions of $x(t)$ and $\mathbb{E}[x_t|\tilde{\xi}_1,\dots,\tilde{\xi}_t]$, and of $\tilde{x}(t)$ and $\mathbb{E}[\tilde{x}_t|\xi_1,\dots,\xi_t]$, respectively.

Remark 2.4 (stability of first-stage solutions). Using the same technique as for proving [28, Theorem 9], the continuity property of infima in Theorem 2.1 can be supplemented by a quantitative stability property of the solution set $S(\xi)$ of (2.1), i.e., of the set of first stage solutions. Namely, there exists a constant $\hat{L} > 0$ such that

$$\sup_{x\in S(\tilde{\xi})} d(x, S(\xi)) \le \Psi_\xi^{-1}(\hat{L}(\|\xi-\tilde{\xi}\|_r + D_{\mathrm{f}}(\xi,\tilde{\xi}))), \tag{2.17}$$

where $\Psi_\xi(\tau) := \inf\left\{\mathbb{E}[f(x_1,\xi)] - v(\xi) : d(x_1, S(\xi)) \ge \tau,\, x_1 \in X_1\right\}$ with $\Psi_\xi^{-1}(\alpha) := \sup\{\tau \in \mathbb{R}_+ : \Psi_\xi(\tau) \le \alpha\}$ $(\alpha \in \mathbb{R}_+)$ is the growth function of the original problem (2.1) near its solution set $S(\xi)$. The boundedness condition for X_1 in Theorem 2.1 can be relaxed to the assumption that the set $S(\xi)$ is bounded. In the latter case a version of (2.6) is derived that contains localized optimal values. Then the estimate (2.6) is valid whenever its right-hand side is sufficiently small.

Remark 2.5 (convergence of filtrations). This remark aims at precising the link between the filtration distance (2.4) and previous work on *convergence of information*. A distance between σ-fields was introduced in [2]. It metrizes a topology called uniform topology on the set of σ-fields. Due to the work of [30] and [17], this distance reads, for all $\mathcal{B},\mathcal{B}'$ sub-σ-fields of $\mathcal{F}$

$$d_B(\mathcal{B},\mathcal{B}') := \sup_{f\in\Phi} \|\mathbb{E}[f|\mathcal{B}] - \mathbb{E}[f|\mathcal{B}']\|_1, \tag{2.18}$$

with Φ the set of all $\mathcal{F}$-measurable functions f such that for all $\omega \in \Omega$, $\|f(\omega)\| \le 1$. Thanks to [15], a filtration can be said to converge to another one if and only if

each σ-field at each time step converges according to the distance d_B. Hence, a distance between filtrations can be introduced, based on the sum of the distances between σ-fields. The second summand in our stability result can be seen as such a distance between the filtrations generated by the two stochastic processes ξ and $\tilde{\xi}$. This summand is not exactly the same as the sum of distances d_B, but it has the same sense: If the feasible set of the stochastic program is bounded, the filtration distance (2.4) is bounded by a sum of distances d_B. Other distances between filtrations and σ-fields have been introduced (see, e.g., [3]) to fit with stochastic optimization problems. The thesis [1] provides a good survey and a few new results on the application of such information distances.

The following example shows that filtration distances are indispensable for the stability of multistage models.

Example 2.6. We consider a multistage stochastic program that models the optimal purchase over time under cost uncertainty. Its decisions x_t correspond to the amounts to be purchased at each time period. The uncertain prices are ξ_t, $t = 1, \dots, T$, and the objective consists in minimizing the expected costs such that a prescribed amount $a > 0$ is achieved at the end of a given time horizon. The problem is of the form

$$\min \left\{ \mathbb{E}\left[\sum_{t=1}^{T} \xi_t x_t\right] \;\middle|\; \begin{array}{l} (x_t, s_t) \in X_t = \mathbb{R}^2_+, \\ (x_t, s_t) \text{ is } \mathcal{F}_t\text{-measurable}, \\ s_t - s_{t-1} = x_t,\ t = 2, \dots, T, \\ s_1 = 0, \quad s_T = a \end{array} \right\},$$

where the state variable s_t corresponds to the amount at time t and $\mathcal{F}_t := \sigma\{\xi_1, \dots, \xi_t\}$. Let $T := 3$ and P_ε denote the probability distribution of the stochastic price process. P_ε is given by the two scenarios $\xi^1_\varepsilon = (3, 2+\varepsilon, 3)$ ($\varepsilon \in [0, 1)$) and $\xi^2_\varepsilon = (3, 2, 1)$ each endowed with probability $\frac{1}{2}$. Let $Q := P_0$ denote the approximation of P_ε given by the two scenarios $\tilde{\xi}^1 = (3, 2, 3)$ and $\tilde{\xi}^2 = (3, 2, 1)$ with the same probabilities $\frac{1}{2}$. We assume that the scenario trees of the processes ξ_ε and $\tilde{\xi}$ are of the form displayed in Figure 2.1, i.e., the filtrations of σ-fields generated by ξ_ε and $\tilde{\xi}$ do not coincide.

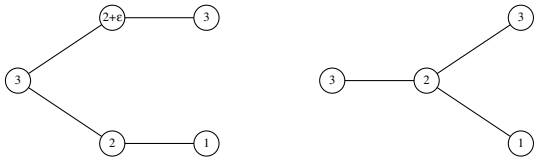

FIG. 2.1. *Scenario trees for P_ε (left) and Q.*

We obtain

$$v(\xi_\varepsilon) = \frac{3+\varepsilon}{2} a \quad \text{and} \quad v(\tilde{\xi}) = 2a\,, \text{ but } \quad \ell_1(P_\varepsilon, Q) = \|\xi_\varepsilon - \tilde{\xi}\|_1 = \frac{\varepsilon}{2}.$$

Hence, the multistage stochastic purchasing model is *not stable* with respect to the L_1-distance $\|\cdot\|_1$. However, the estimate for $|v(\xi) - v(\tilde{\xi})|$ in Theorem 2.1 is valid with $L = 1$ since $D_{\mathrm{f}}(\xi, \tilde{\xi}) = \frac{a}{2}$ holds for the filtration distance (with $r' = \infty$).

Finally, let us consider the case of discrete probability measures P and Q. Let P have scenarios ξ^i with probabilities $p_i > 0$, $i = 1, \dots, N$, and Q scenarios $\tilde{\xi}^j$ and probabilities $q_j > 0$, $j = 1, \dots, M$. Clearly, $\sum_{i=1}^N p_i = 1$ and $\sum_{j=1}^M q_j = 1$. Then $\ell_r^r(P, Q)$ is the optimal value of a finite-dimensional linear transportation problem

(e.g., [24]) and there exist optimal weights $\eta_{ij} \geq 0$ of the scenario pair $(\xi^i, \tilde{\xi}^j)$, $i = 1, \ldots, N$, $j = 1, \ldots, M$. Hence, there exists a pair $(\xi, \tilde{\xi})$ of random vectors on the probability space $(\Omega, \mathcal{F}, \mathbb{P})$, where $\Omega = \{\omega_{ij} : i = 1, \ldots, N, j = 1, \ldots, M\}$ and $\mathbb{P}(\omega_{ij}) = \eta_{ij}$, $i = 1, \ldots, N$, $j = 1, \ldots, M$. We define $\xi(\omega_{ij}) = \xi^i$ for every $j = 1, \ldots, M$ and $\tilde{\xi}(\omega_{ij}) = \tilde{\xi}^j$ for every $i = 1, \ldots, N$.

Now, our aim is to study the second term in the stability estimate in Theorem 2.1, namely, the distance of filtrations. Let $\mathcal{F}_t$ and $\tilde{\mathcal{F}}_t$ denote the σ-fields generated by $(\xi_1, \ldots, \xi_t)$ and $(\tilde{\xi}_1, \ldots, \tilde{\xi}_t)$, respectively. Let I_t and $\tilde{I}_t$ denote the index set of realizations of ξ_t and $\tilde{\xi}_t$, respectively. Furthermore, let $\mathcal{E}_t$ and $\tilde{\mathcal{E}}_t$ denote families of nonempty elements of $\mathcal{F}_t$ and $\tilde{\mathcal{F}}_t$, respectively, that form partitions of Ω and generate the corresponding σ-fields. We set $E_{ts} := \{\omega \in \Omega : (\xi_1(\omega), \ldots, \xi_t(\omega)) = (\xi_1^s, \ldots, \xi_t^s)\}$, $s \in I_t$, and $\tilde{E}_{ts} := \{\omega \in \Omega : (\tilde{\xi}_1(\omega), \ldots, \tilde{\xi}_t(\omega)) = (\tilde{\xi}_1^s, \ldots, \tilde{\xi}_t^s)\}$, $s \in \tilde{I}_t$.

We set $r = r' = 1$ and require conditions (A1) and (A2) to hold. Since (2.3) is finite-dimensional in this case, optimal solutions x and $\tilde{x}$ exist and we obtain according to Remark 2.2 that

$$
\begin{aligned}
D_t(\xi, \tilde{\xi}) &= \max\Big\{ \sum_{i,j} \eta_{ij} \|x_t(\omega_{ij}) - \mathbb{E}[x_t|\tilde{\mathcal{F}}_t](\omega_{ij})\|, \\
&\qquad \sum_{i,j} \eta_{ij} \|\tilde{x}_t(\omega_{ij}) - \mathbb{E}[\tilde{x}_t|\mathcal{F}_t](\omega_{ij})\| \Big\} \\
&= \max\Big\{ \sum_{s \in \tilde{I}_t} \sum_{\omega_{ij} \in \tilde{E}_{ts}} \eta_{ij} \Big\| x_t(\omega_{ij}) - \frac{\sum_{\omega_{kl} \in \tilde{E}_{ts}} \eta_{kl} x_t(\omega_{kl})}{\sum_{\omega_{kl} \in \tilde{E}_{ts}} \eta_{kl}} \Big\|, \\
&\qquad \sum_{s \in I_t} \sum_{\omega_{ij} \in E_{ts}} \eta_{ij} \Big\| \tilde{x}_t(\omega_{ij}) - \frac{\sum_{\omega_{kl} \in E_{ts}} \eta_{kl} \tilde{x}_t(\omega_{kl})}{\sum_{\omega_{kl} \in E_{ts}} \eta_{kl}} \Big\| \Big\}.
\end{aligned} \tag{2.19}
$$

The latter representation of D_t has potential to be further estimated in specific cases. In particular, it simplifies considerably for the situation of scenario reduction.

Example 2.7 (scenario reduction). Let us consider the case of deleting scenario $l \in \{1, \ldots, N\}$ of ξ according to the methodology in [5, 11] for the distance ℓ_1 and $r = r' = 1$. Then $\tilde{\xi}$ has the scenarios $\xi^1, \ldots, \xi^{l-1}, \xi^{l+1}, \ldots, \xi^N$ and the probabilities of ξ^j are $q_j = p_j$ for every $j \notin \{j(l), l\}$ and $q_{j(l)} = p_{j(l)} + p_l$, where $j(l) \in \arg\min_{j \neq l} \|\xi^j - \xi^l\|$ (see [5, Theorem 2]). This corresponds to $\tilde{\xi}(\omega_{ij}) = \xi^j$ for every $i = 1, \ldots, N$, $j = 1, \ldots, N$, $j \neq l$. We also infer from [5, Theorem 2] that the optimal weights of the transportation problem defining $\ell_1(P, Q)$ are

$$
\eta_{ij} = \begin{cases} p_l, & i = l,\ j = j(l), \\ p_j, & i = j \neq l, \\ 0 & \text{otherwise.} \end{cases}
$$

We set $\hat{\omega}_j := \omega_{jj}$ for every $j = 1, \ldots, N$, $j \neq l$, $\hat{\omega}_l = \omega_{lj(l)}$ and introduce the notation E_{ts_j} and $\tilde{E}_{ts_j}$ for the sets in $\mathcal{E}_t$ and $\tilde{\mathcal{E}}_t$, respectively, that contain $\hat{\omega}_j$. From (2.19) we conclude the following representations of D_t:

$$
D_t(\xi, \tilde{\xi}) = \max\left\{ \sum_{s \in \tilde{I}_t} \sum_{\hat{\omega}_j \in \tilde{E}_{ts}} p_j \Big\| x_t(\hat{\omega}_j) - \frac{\sum_{\hat{\omega}_k \in \tilde{E}_{ts}} p_k x_t(\hat{\omega}_k)}{\sum_{\hat{\omega}_k \in \tilde{E}_{ts}} p_k} \Big\|, \right.
$$

$$\left. \sum_{s\in I_t} \sum_{\hat\omega_j\in E_{ts}} p_j \Big\| \tilde x_t(\hat\omega_j) - \frac{\sum_{\omega_k\in E_{ts}} p_k \tilde x_t(\hat\omega_k)}{\sum_{\hat\omega_k\in E_{ts}} p_k} \Big\| \right\}$$

$$= \max \left\{ \sum_{s\in \tilde I_t} \frac{1}{\sum_{\hat\omega_k\in \tilde E_{ts}} p_k} \sum_{\hat\omega_j\in \tilde E_{ts}} \Big\| \sum_{\hat\omega_k\in \tilde E_{ts}} p_k p_j [x_t(\hat\omega_j) - x_t(\hat\omega_k)] \Big\|, \right.$$

$$\left. \sum_{s\in I_t} \frac{1}{\sum_{\hat\omega_k\in E_{ts}} p_k} \sum_{\hat\omega_j\in E_{ts}} \Big\| \sum_{\hat\omega_k\in E_{ts}} p_k p_j [\tilde x_t(\hat\omega_j) - \tilde x_t(\hat\omega_k)] \Big\| \right\}$$

$$= \max \left\{ \sum_{s\in \tilde I_t} \frac{1}{\sum_{\hat\omega_k\in \tilde E_{ts}} p_k} \sum_{\hat\omega_j\in \tilde E_{ts}} \Big\| \sum_{\hat\omega_k\in \tilde E_{ts}\setminus E_{ts_j}} p_k p_j [x_t(\hat\omega_j) - x_t(\hat\omega_k)] \Big\|, \right.$$

$$\left. \sum_{s\in I_t} \frac{1}{\sum_{\hat\omega_k\in E_{ts}} p_k} \sum_{\hat\omega_j\in E_{ts}} \Big\| \sum_{\hat\omega_k\in E_{ts}\setminus \tilde E_{ts_j}} p_k p_j [\tilde x_t(\hat\omega_j) - \tilde x_t(\hat\omega_k)] \Big\| \right\},$$

where the final equality is a consequence of the corresponding measurability properties of x_t, which imply $x_t(\hat\omega_j) = x_t(\hat\omega_k)$ if $\hat\omega_k \in E_{ts}\cap \tilde E_{ts_j}$ and $\hat\omega_k \in \tilde E_{ts}\cap E_{ts_j}$, respectively. Since $E_{ts_j} = \tilde E_{ts_j}$ for $j \notin \{l, j(l)\}$ and $\tilde E_{ts_l} = E_{tj(l)} \cup \{\hat\omega_l\}$, we may continue with

$$D_t(\xi,\tilde\xi) = \max \left\{ \frac{1}{\sum_{\hat\omega_k\in \tilde E_{ts_l}} p_k} \sum_{\hat\omega_j\in \tilde E_{ts_l}} \Big\| \sum_{\hat\omega_k\in \tilde E_{ts_l}\setminus E_{ts_j}} p_k p_j [x_t(\hat\omega_j) - x_t(\hat\omega_k)] \Big\|, \right.$$

$$\left. \frac{1}{\sum_{\hat\omega_k\in E_{ts_l}} p_k} \sum_{\hat\omega_j\in E_{ts_l}} \Big\| \sum_{\hat\omega_k\in E_{ts_l}\setminus \tilde E_{ts_j}} p_k p_j [\tilde x_t(\hat\omega_j) - \tilde x_t(\hat\omega_k)] \Big\| \right\}$$

$$= \max \left\{ \frac{1}{\sum_{\hat\omega_k\in \tilde E_{ts_l}} p_k} \left\{ \sum_{\hat\omega_k\in E_{ts_{j(l)}}} \Big\| p_l p_k [x_t(\hat\omega_k) - x_t(\hat\omega_l)] \Big\| \right.\right.$$

$$\left. + \Big\| \sum_{\hat\omega_k\in E_{ts_{j(l)}}} p_k p_l [\tilde x_t(\hat\omega_l) - \tilde x_t(\hat\omega_k)] \Big\| \right\},$$

$$\frac{1}{\sum_{\hat\omega_k\in E_{ts_l}} p_k} \left\{ \sum_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} \Big\| p_l p_k [x_t(\hat\omega_k) - x_t(\hat\omega_l)] \Big\| \right.$$

$$\left.\left. + \Big\| \sum_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} p_k p_l [\tilde x_t(\hat\omega_l) - \tilde x_t(\hat\omega_k)] \Big\| \right\} \right\}$$

$$\le \max \left\{ \frac{\sum_{\hat\omega_k\in E_{ts_{j(l)}}} 2p_l p_k \|x_t(\hat\omega_k) - x_t(\hat\omega_l)\|}{p_l + \sum_{\hat\omega_k\in E_{ts_{j(l)}}} p_k}, \frac{\sum_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} 2p_l p_k \|\tilde x_t(\hat\omega_k) - \tilde x_t(\hat\omega_l)\|}{p_l + \sum_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} p_k} \right\}$$

$$\le 2p_l \max \Big\{ \|x_t(\hat\omega_{j(l)}) - x_t(\hat\omega_l)\|, \min_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} \|\tilde x_t(\hat\omega_k) - \tilde x_t(\hat\omega_l)\| \Big\}, \tag{2.20}$$

where the convention is used that $\min_{\hat\omega_k\in E_{ts_l}\setminus\{\hat\omega_l\}} = 0$ if $E_{ts_l} \setminus \{\hat\omega_l\} = \emptyset$. The final

estimate makes use of the fact that all $x_t(\hat{\omega}_k)$ with $\hat{\omega}_k \in E_{ts_{j(l)}}$ and $\hat{\omega}_k \in E_{ts_l} \setminus \{\hat{\omega}_l\}$, respectively, coincide.

In the following two cases, the above estimate simplifies to

$$D_t(\xi, \tilde{\xi}) \leq \begin{cases} 0 & \text{if } \hat{\omega}_l \in E_{ts_{j(l)}}, \\ 2p_l \|x_t(\hat{\omega}_{j(l)}) - x_t(\hat{\omega}_l)\| & \text{if } E_{ts_l} = \{\hat{\omega}_l\}. \end{cases}$$

As the sets $l_0(F(\xi, \cdot))$ and $l_0(F(\tilde{\xi}, \cdot))$ of solutions of the original and perturbed multistage models are bounded in $L_{r'}$ due to (A2), there exists a constant $K > 0$ such that

$$D_{\mathrm{f}}(\xi, \tilde{\xi}) \leq K p_l.$$

Hence, if the probability p_l of the deleted scenario is small, the filtration distance is also small. Then there is no need to modify the deletion procedure based on best approximations with respect to the metric ℓ_1. This is mostly the case if the tree is bushy, i.e., contains many scenarios.

A more reliable estimate for the filtration distance may be obtained by solving the stochastic program for an approximation $\hat{\xi}$ of ξ (on $\{\hat{\omega}_1, \ldots, \hat{\omega}_N\}$), which contains much less scenarios than ξ. Then an estimate for the filtration distance may be obtained by computing

$$2p_l \sum_{t=2}^{T-1} \max \Big\{ \|\hat{x}_t(\hat{\omega}_{j(l)}) - \hat{x}_t(\hat{\omega}_l)\|, \min_{\hat{\omega}_k \in E_{ts_l} \setminus \{\hat{\omega}_l\}} \|\hat{x}_t(\hat{\omega}_k) - \hat{x}_t(\hat{\omega}_l)\| \Big\},$$

where $\hat{x} \in l_0(F(\hat{\xi}, \cdot))$ is the corresponding solution. Altogether, some scenario deletion suggested by the strategy in [5, 11] can either be carried out if the bound (2.20) on the filtration distance remains small or is rejected.

3. Conclusions. While quantitative stability results for two-stage stochastic programs have to take into account only a suitable distance of probability distributions, this is no longer the case for multistage models, where the filtration distance enters stability estimates. This fact demonstrates the importance of the conditional structure of multistage stochastic programs. This is in line with the observations and results of [32]. In a sense, it also seems to illustrate the complexity results obtained in the recent paper [33]. It is shown there that multistage stochastic programs have higher complexity than two-stage models. Techniques for generating and reducing *scenario trees* in multistage stochastic programs, which are based on stability arguments, have to respect *both* probability *and* filtration distances as both contribute to changes of optimal values. Example 2.7 provides upper bounds for the filtration distance if some scenario is deleted. Bounding the filtration distance is also possible for the forward and backward scenario tree generation algorithms developed in [10] and [12]. Such bounds are derived and discussed in the companion paper [13].

Acknowledgments. The first two authors wish to thank the members of the OSIRIS Division at R&D of EDF for several stimulating discussions on scenario trees and stability. We extend our gratitude to René Henrion (WIAS Berlin) for his comments on an earlier version of this paper and to two anonymous referees for their insightful comments.

A NEW ACTIVE SET ALGORITHM FOR BOX CONSTRAINED OPTIMIZATION*

WILLIAM W. HAGER† AND HONGCHAO ZHANG†

Abstract. An active set algorithm (ASA) for box constrained optimization is developed. The algorithm consists of a nonmonotone gradient projection step, an unconstrained optimization step, and a set of rules for branching between the two steps. Global convergence to a stationary point is established. For a nondegenerate stationary point, the algorithm eventually reduces to unconstrained optimization without restarts. Similarly, for a degenerate stationary point, where the strong second-order sufficient optimality condition holds, the algorithm eventually reduces to unconstrained optimization without restarts. A specific implementation of the ASA is given which exploits the recently developed cyclic Barzilai–Borwein (CBB) algorithm for the gradient projection step and the recently developed conjugate gradient algorithm CG_DESCENT for unconstrained optimization. Numerical experiments are presented using box constrained problems in the CUTEr and MINPACK-2 test problem libraries.

Key words. nonmonotone gradient projection, box constrained optimization, active set algorithm, ASA, cyclic BB method, CBB, conjugate gradient method, CG_DESCENT, degenerate optimization

1. Introduction.

We develop an active set method for the box constrained optimization problem

$$\min \{f(\mathbf{x}) : \mathbf{x} \in \mathcal{B}\}, \tag{1.1}$$

where f is a real-valued, continuously differentiable function defined on the set

$$\mathcal{B} = \{\mathbf{x} \in \mathbb{R}^n : \mathbf{l} \le \mathbf{x} \le \mathbf{u}\}. \tag{1.2}$$

Here $\mathbf{l} < \mathbf{u}$, and possibly $l_i = -\infty$ or $u_i = \infty$.

The box constrained optimization problem appears in a wide range of applications, including the obstacle problem [67], the elastic-plastic torsion problem [47], optimal design problems [7], journal bearing lubrication [20], inversion problems in elastic wave propagation [6], and molecular conformation analysis [48]. Problem (1.1) is often a subproblem of augmented Lagrangian or penalty schemes for general constrained optimization (see [24, 25, 37, 38, 43, 46, 52, 53, 65]). Thus the development of numerical algorithms to efficiently solve (1.1), especially when the dimension is large, is important in both theory and applications.

We begin with an overview of the development of active set methods. A seminal paper is Polyak's 1969 paper [68] which considers a convex, quadratic cost function. The conjugate gradient method is used to explore a face of the feasible set, and the negative gradient is used to leave a face. Since Polyak's algorithm added or dropped

†Department of Mathematics, University of Florida, P.O. Box 118105, Gainesville, FL 32611-8105 (hager@math.ufl.edu, http://www.math.ufl.edu/∼hager; hzhang@math.ufl.edu, http://www.math.ufl.edu/∼hzhang).

only one constraint in each iteration, Dembo and Tulowitzki proposed [32] the conjugate gradient projection (CGP) algorithm which could add and drop many constraints in an iteration. Later, Yang and Tolle [79] further developed this algorithm to obtain finite termination, even when the problem was degenerate at a local minimizer $\mathbf{x}^*$. That is, for some i, $x_i^* = l_i$ or $x_i^* = u_i$ and $\nabla f(\mathbf{x}^*)_i = 0$. Another variation of the CGP algorithm, for which there is a rigorous convergence theory, is developed by Wright [77]. Moré and Toraldo [67] point out that when the CGP scheme starts far from the solution, many iterations may be required to identify a suitable working face. Hence, they propose using the gradient projection method to identify a working face, followed by the conjugate gradient method to explore the face. Their algorithm, called GPCG, has finite termination for nondegenerate quadratic problems. Recently, adaptive conjugate gradient algorithms have been developed by Dostál [35, 36] and Dostál, Friedlander, and Santos [38] which have finite termination for a strictly convex quadratic cost function, even when the problem is degenerate.

For general nonlinear functions, some of the earlier research [3, 19, 49, 61, 66, 71] focused on gradient projection methods. To accelerate the convergence, more recent research has developed Newton and trust region methods (see [26] for an in-depth analysis). In [4, 17, 24, 42] superlinear and quadratic convergence is established for nondegenerate problems, while [44, 46, 60, 63] establish analogous convergence results, even for degenerate problems. Although computing a Newton step can be computationally expensive, approximation techniques, such as a sparse, incomplete Cholesky factorization [62], could be used to reduce the computational expense. Nonetheless, for large-dimensional problems or for problems in which the initial guess is far from the solution, the Newton/trust region approach can be inefficient. In cases when the Newton step is unacceptable, a gradient projection step is preferred.

The affine-scaling interior-point method of Coleman and Li [21, 22, 23] (also see Branch, Coleman, and Li [14]) is a different approach to (1.1), related to the trust region algorithm. More recent research on this strategy includes [33, 58, 59, 76, 83]. These methods are based on a reformulation of the necessary optimality conditions obtained by multiplication with a scaling matrix. The resulting system is often solved by Newton-type methods. Without assuming strict complementarity (i.e., for degenerate problems), the affine-scaling interior-point method converges superlinearly or quadratically, for a suitable choice of the scaling matrix, when the strong second-order sufficient optimality condition [70] holds. When the dimension is large, forming and solving the system of equations at each iteration can be time consuming, unless the problem has special structure. Recently, Zhang [83] proposed an interior-point gradient approach for solving the system at each iteration. Convergence results for other interior-point methods applied to more general constrained optimization appear in [39, 40, 78].

The method developed in this paper is an active set algorithm (ASA) which consists of a nonmonotone gradient projection step, an unconstrained optimization step, and a set of rules for branching between the steps. Global convergence to a stationary point is established. For a nondegenerate stationary point, the ASA eventually reduces to unconstrained optimization without restarts. Similarly, for a degenerate stationary point, where the strong second-order sufficient optimality condition holds, the ASA eventually reduces to unconstrained optimization without restarts. If strict complementarity holds and all the constraints are active at a stationary point, then convergence occurs in a finite number of iterations. In general, our analysis does not show that the strictly active constraints are identified in a finite number of iterations;

instead, when the strong second-order sufficient optimality condition holds, we show that the ASA eventually branches to the unconstrained optimization step, and henceforth, the active set does not change. Thus in the limit, the ASA reduces to unconstrained optimization without restarts. Furthermore, if the ith constraint in (1.1) is strictly active at a stationary point $\mathbf{x}^*$ (i.e., $\nabla f(\mathbf{x}^*)_i \neq 0$) and the iterates $\mathbf{x}_k$ converge to $\mathbf{x}^*$, then the distance between the ith component of $\mathbf{x}_k$ and the associated limit, either l_i or u_i, is on the order of the square of the distance between $\mathbf{x}_k$ and $\mathbf{x}^*$.

A specific implementation of the ASA is given, which utilizes our recently developed cyclic Barzilai–Borwein (CBB) algorithm [30] for the gradient projection step and our recently developed conjugate gradient algorithm CG_DESCENT [54, 55, 56, 57] for the unconstrained optimization step. Recent numerical results [27, 45, 50, 51, 74, 81] indicate that in some cases, a nonmonotone line search is superior to a monotone line search. Moreover, gradient methods based on a Barzilai–Borwein (BB) step [2] have exhibited impressive performance in a variety of applications [7, 10, 28, 29, 48, 64, 72]. The BB methods developed in [8, 9, 10, 11, 12, 69] are all based on a Grippo–Lampariello–Lucidi (GLL) type of line search [50]. We have obtained better performance using an adaptive, nonmonotone line search which originates from [31, 75]. Using the adaptive nonmonotone line search, more constraints can be added or dropped in a single iteration. In addition, the cyclic implementation of the BB step [30], in which the same BB stepsize is reused for several iterations, performs better than the original BB step. Hence, in the gradient projection phase of the ASA, we use the CBB scheme of [30] and an adaptive nonmonotone line search.

After detecting a suitable working face, the ASA branches to the unconstrained optimization algorithm, which operates in a lower-dimensional space since some components of $\mathbf{x}$ are fixed. For the numerical experiments, we implement this step using our conjugate gradient algorithm CG_DESCENT. An attractive feature of this algorithm is that the search directions are always sufficient descent directions; furthermore, when the cost function is a strongly convex quadratic, the ASA converges in a finite number of iterations, even when strict complementary slackness does not hold.

Our paper is organized as follows. In section 2 we present the nonmonotone gradient projection algorithm (NGPA) and analyze its global convergence properties. Section 3 presents the ASA and specifies the requirements of the unconstrained optimization algorithm. Section 4 establishes global convergence results for the ASA, while section 5 analyzes local convergence. Section 6 presents numerical comparisons using box constrained problems in the CUTEr [13] and MINPACK-2 [1] test problem libraries. Finally, the appendix gives a specific implementation of the nonmonotone gradient projection method based on our CBB method.

Throughout this paper, we use the following notation. For any set $\mathcal{S}$, $|\mathcal{S}|$ stands for the number of elements (cardinality) of $\mathcal{S}$, while $\mathcal{S}^c$ is the complement of $\mathcal{S}$. $\|\cdot\|$ is the Euclidean norm of a vector. The subscript k is often used to denote the iteration number in an algorithm, while x_{ki} stands for the ith component of the iterate $\mathbf{x}_k$. The gradient $\nabla f(\mathbf{x})$ is a row vector, while $\mathbf{g}(\mathbf{x}) = \nabla f(\mathbf{x})^\mathsf{T}$ is a column vector; here $^\mathsf{T}$ denotes transpose. The gradient at the iterate $\mathbf{x}_k$ is $\mathbf{g}_k = \mathbf{g}(\mathbf{x}_k)$. We let $\nabla^2 f(\mathbf{x})$ denote the Hessian of f at $\mathbf{x}$. The ball with center $\mathbf{x}$ and radius ρ is denoted $B_\rho(\mathbf{x})$.

2. Nonmonotone gradient projection algorithm. In this section, we consider a generalization of (1.1) in which the box $\mathcal{B}$ is replaced with a nonempty, closed convex set Ω:

$$\min \{f(\mathbf{x}) : \mathbf{x} \in \Omega\}. \tag{2.1}$$

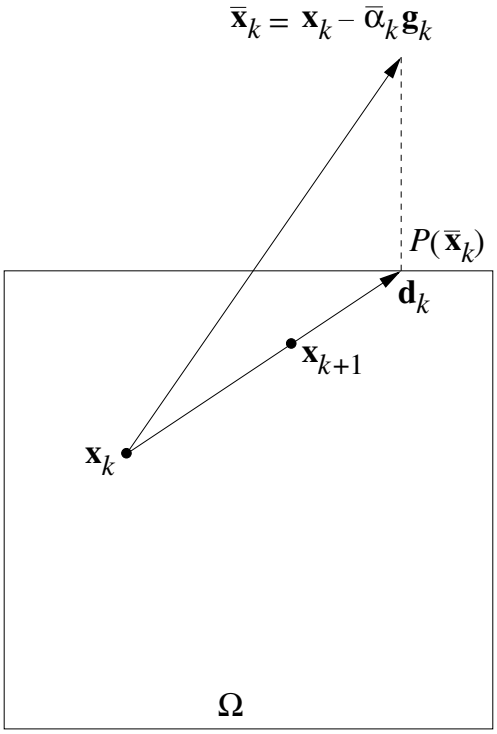

FIG. 2.1. *The gradient projection step.*

We begin with an overview of our gradient projection algorithm. Step k in our algorithm is depicted in Figure 2.1. Here P denotes the projection onto Ω:

$$P(\mathbf{x}) = \arg \min_{\mathbf{y} \in \Omega} \|\mathbf{x} - \mathbf{y}\|. \tag{2.2}$$

Starting at the current iterate $\mathbf{x}_k$, we compute an initial iterate $\bar{\mathbf{x}}_k = \mathbf{x}_k - \bar{\alpha}_k \mathbf{g}_k$. The only constraint on the initial steplength $\bar{\alpha}_k$ is that $\bar{\alpha}_k \in [\alpha_{\min}, \alpha_{\max}]$, where $\alpha_{\min}$ and $\alpha_{\max}$ are fixed, positive constants, independent of k. Since the nominal iterate may lie outside Ω, we compute its projection $P(\bar{\mathbf{x}}_k)$ onto Ω. The search direction is $\mathbf{d}_k = P(\bar{\mathbf{x}}_k) - \mathbf{x}_k$, similar to the choice made in SPG2 [11]. Using a nonmonotone line search along the line segment connecting $\mathbf{x}_k$ and $P(\bar{\mathbf{x}}_k)$, we arrive at the new iterate $\mathbf{x}_{k+1}$.

In the statement of the NGPA given below, f_k^r denotes the "reference" function value. A monotone line search corresponds to the choice $f_k^r = f(\mathbf{x}_k)$. The nonmonotone GLL scheme takes $f_k^r = f_k^{\max}$, where

$$f_k^{\max} = \max\{f(\mathbf{x}_{k-i}) : 0 \le i \le \min(k, M-1)\}. \tag{2.3}$$

Here $M > 0$ is a fixed integer, the memory. In the appendix, we give a procedure for choosing the reference function value based on our CBB scheme.

NGPA PARAMETERS.

- $\epsilon \in [0, \infty)$, error tolerance
- $\delta \in (0, 1)$, descent parameter used in Armijo line search

- $\eta \in (0,1)$, decay factor for stepsize in Armijo line search
- $[\alpha_{\min}, \alpha_{\max}] \subset (0,\infty)$, interval containing initial stepsize

NONMONOTONE GRADIENT PROJECTION ALGORITHM (NGPA).

Initialize $k = 0$, $\mathbf{x}_0$ = starting guess, and $f_{-1}^r = f(\mathbf{x}_0)$.

While $\|P(\mathbf{x}_k - \mathbf{g}_k) - \mathbf{x}_k\| > \epsilon$

1. Choose $\overline{\alpha}_k \in [\alpha_{\min}, \alpha_{\max}]$ and set $\mathbf{d}_k = P(\mathbf{x}_k - \overline{\alpha}_k \mathbf{g}_k) - \mathbf{x}_k$.
2. Choose f_k^r so that $f(\mathbf{x}_k) \le f_k^r \le \max\{f_{k-1}^r, f_k^{\max}\}$ and $f_k^r \le f_k^{\max}$ infinitely often.
3. Let f_R be either f_k^r or $\min\{f_k^{\max}, f_k^r\}$. If $f(\mathbf{x}_k + \mathbf{d}_k) \le f_R + \delta \mathbf{g}_k^{\mathsf{T}} \mathbf{d}_k$, then $\alpha_k = 1$.
4. If $f(\mathbf{x}_k + \mathbf{d}_k) > f_R + \delta \mathbf{g}_k^{\mathsf{T}} \mathbf{d}_k$, then $\alpha_k = \eta^j$, where $j > 0$ is the smallest integer such that
$$f(\mathbf{x}_k + \eta^j \mathbf{d}_k) \le f_R + \eta^j \delta \mathbf{g}_k^{\mathsf{T}} \mathbf{d}_k. \tag{2.4}$$
5. Set $\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{d}_k$ and $k = k + 1$.

End

The condition $f(\mathbf{x}_k) \le f_k^r$ guarantees that the Armijo line search in step 4 can be satisfied. The requirement that "$f_k^r \le f_k^{\max}$ infinitely often" in step 2 is needed for the global convergence result, Theorem 2.2. This is a rather weak requirement which can be satisfied by many strategies. For example, at every L iteration, we could simply set $f_k^r = f_k^{\max}$. Another strategy, closer in spirit to the one used in the numerical experiments, is to choose a decrease parameter $\Delta > 0$ and an integer $L > 0$ and set $f_k^r = f_k^{\max}$ if $f(\mathbf{x}_{k-L}) - f(\mathbf{x}_k) \le \Delta$.

To begin the convergence analysis, recall that $\mathbf{x}^*$ is a stationary point for (2.1) if the first-order optimality condition holds:

$$\nabla f(\mathbf{x}^*)(\mathbf{x} - \mathbf{x}^*) \ge 0 \quad \text{for all } \mathbf{x} \in \Omega. \tag{2.5}$$

Let $\mathbf{d}^\alpha(\mathbf{x})$, $\alpha \in \mathbb{R}$, be defined in terms of the gradient $\mathbf{g}(\mathbf{x}) = \nabla f(\mathbf{x})^{\mathsf{T}}$ as follows:

$$\mathbf{d}^\alpha(\mathbf{x}) = P(\mathbf{x} - \alpha \mathbf{g}(\mathbf{x})) - \mathbf{x}.$$

In the NGPA, the search direction is $\mathbf{d}_k = \mathbf{d}^{\overline{\alpha}_k}(\mathbf{x}_k)$. For unconstrained optimization, $\mathbf{d}^\alpha(\mathbf{x})$ points along the negative gradient at $\mathbf{x}$ when $\alpha > 0$. Some properties of P and $\mathbf{d}^\alpha$ are summarized below.

PROPOSITION 2.1 (Properties of P and $\mathbf{d}^\alpha$).

P1. $(P(\mathbf{x}) - \mathbf{x})^{\mathsf{T}}(\mathbf{y} - P(\mathbf{x})) \ge 0$ *for all* $\mathbf{x} \in \mathbb{R}^n$ *and* $\mathbf{y} \in \Omega$.

P2. $(P(\mathbf{x}) - P(\mathbf{y}))^{\mathsf{T}}(\mathbf{x} - \mathbf{y}) \ge \|P(\mathbf{x}) - P(\mathbf{y})\|^2$ *for all* $\mathbf{x}$ *and* $\mathbf{y} \in \mathbb{R}^n$.

P3. $\|P(\mathbf{x}) - P(\mathbf{y})\| \le \|\mathbf{x} - \mathbf{y}\|$ *for all* $\mathbf{x}$ *and* $\mathbf{y} \in \mathbb{R}^n$.

P4. $\|\mathbf{d}^\alpha(\mathbf{x})\|$ *is nondecreasing in* $\alpha > 0$ *for any* $\mathbf{x} \in \Omega$.

P5. $\|\mathbf{d}^\alpha(\mathbf{x})\|/\alpha$ *is nonincreasing in* $\alpha > 0$ *for any* $\mathbf{x} \in \Omega$.

P6. $\mathbf{g}(\mathbf{x})^{\mathsf{T}} \mathbf{d}^\alpha(\mathbf{x}) \le -\|\mathbf{d}^\alpha(\mathbf{x})\|^2/\alpha$ *for any* $\mathbf{x} \in \Omega$ *and* $\alpha > 0$.

P7. *For any* $\mathbf{x} \in \Omega$ *and* $\alpha > 0$, $\mathbf{d}^\alpha(\mathbf{x}) = \mathbf{0}$ *if and only if* $\mathbf{x}$ *is a stationary point for* (2.1).

P8. *Suppose* $\mathbf{x}^*$ *is a stationary point for* (2.1). *If for some* $\mathbf{x} \in \mathbb{R}^n$ *there exist positive scalars* λ *and* γ *such that*
$$(\mathbf{g}(\mathbf{x}) - \mathbf{g}(\mathbf{x}^*))^{\mathsf{T}}(\mathbf{x} - \mathbf{x}^*) \ge \gamma \|\mathbf{x} - \mathbf{x}^*\|^2 \tag{2.6}$$
and
$$\|\mathbf{g}(\mathbf{x}) - \mathbf{g}(\mathbf{x}^*)\| \le \lambda \|\mathbf{x} - \mathbf{x}^*\|, \tag{2.7}$$

then we have

$$\|\mathbf{x}-\mathbf{x}^*\| \le \left(\frac{1+\lambda}{\gamma}\right)\|\mathbf{d}^1(\mathbf{x})\|.$$

Proof. P1 is the first-order optimality condition associated with the solution of (2.2). Replacing $\mathbf{y}$ with $P(\mathbf{y})$ in P1 gives

$$(P(\mathbf{x})-\mathbf{x})^{\mathsf{T}}(P(\mathbf{y})-P(\mathbf{x})) \ge 0.$$

Adding this to the corresponding inequality obtained by interchanging $\mathbf{x}$ and $\mathbf{y}$ yields P2 (see [80]). P3 is the nonexpansive property of a projection (for example, see [5, Prop. 2.1.3]). P4 is given in [73]. For P5, see [5, Lem. 2.3.1]. P6 is obtained from P1 by replacing $\mathbf{x}$ with $\mathbf{x}-\alpha\mathbf{g}(\mathbf{x})$ and replacing $\mathbf{y}$ with $\mathbf{x}$. If $\mathbf{x}^*$ is a stationary point satisfying (2.5), then P6 with $\mathbf{x}$ replaced by $\mathbf{x}^*$ yields $\mathbf{d}^\alpha(\mathbf{x}^*)=\mathbf{0}$. Conversely, if $\mathbf{d}^\alpha(\mathbf{x}^*)=\mathbf{0}$, then by P1 with $\mathbf{x}$ replaced by $\mathbf{x}^*-\alpha\mathbf{g}(\mathbf{x}^*)$, we obtain

$$0 \le \alpha\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{y}-P(\mathbf{x}^*-\alpha\mathbf{g}(\mathbf{x}^*)) = \alpha\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{y}-\mathbf{x}^*),$$

which implies that $\mathbf{x}^*$ is a stationary point (see [5, Fig. 2.3.2]).

Finally, let us consider P8. Replacing $\mathbf{x}$ with $\mathbf{x}-\mathbf{g}(\mathbf{x})$ and replacing $\mathbf{y}$ with $\mathbf{x}^*$ in P1 gives

$$[P(\mathbf{x}-\mathbf{g}(\mathbf{x}))-\mathbf{x}+\mathbf{g}(\mathbf{x})]^{\mathsf{T}}[\mathbf{x}^*-P(\mathbf{x}-\mathbf{g}(\mathbf{x}))] \ge 0. \tag{2.8}$$

By the definition of $\mathbf{d}^\alpha(\mathbf{x})$, (2.8) is equivalent to

$$[\mathbf{d}^1(\mathbf{x})+\mathbf{g}(\mathbf{x})]^{\mathsf{T}}[\mathbf{x}^*-\mathbf{x}-\mathbf{d}^1(\mathbf{x})] \ge 0.$$

Rearranging this and utilizing (2.6) gives

$$\begin{aligned}\mathbf{d}^1(\mathbf{x})^{\mathsf{T}}(\mathbf{x}^*-\mathbf{x})-\mathbf{g}(\mathbf{x})^{\mathsf{T}}\mathbf{d}^1(\mathbf{x})-\|\mathbf{d}^1(\mathbf{x})\|^2 &\ge \mathbf{g}(\mathbf{x})^{\mathsf{T}}(\mathbf{x}-\mathbf{x}^*)\\ &\ge \gamma\|\mathbf{x}-\mathbf{x}^*\|^2+\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{x}-\mathbf{x}^*).\end{aligned} \tag{2.9}$$

Focusing on the terms involving $\mathbf{g}$ and utilizing (2.7), we have

$$\begin{aligned}\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{x}^*-\mathbf{x})-\mathbf{g}(\mathbf{x})^{\mathsf{T}}\mathbf{d}^1(\mathbf{x}) &\le \lambda\|\mathbf{x}-\mathbf{x}^*\|\,\|\mathbf{d}^1(\mathbf{x})\|+\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}(\mathbf{x}^*-\mathbf{x}-\mathbf{d}^1(\mathbf{x}))\\ &= \lambda\|\mathbf{x}-\mathbf{x}^*\|\,\|\mathbf{d}^1(\mathbf{x})\|+\mathbf{g}(\mathbf{x}^*)^{\mathsf{T}}[\mathbf{x}^*-P(\mathbf{x}-\mathbf{g}(\mathbf{x}))]\\ &\le \lambda\|\mathbf{x}-\mathbf{x}^*\|\,\|\mathbf{d}^1(\mathbf{x})\|\end{aligned} \tag{2.10}$$

by (2.5), since $P(\mathbf{x}-\mathbf{g}(\mathbf{x})) \in \Omega$. Combining (2.9) and (2.10), the proof is complete. ∎

Next, we establish a convergence result for the NGPA.

THEOREM 2.2. *Let $\mathcal{L}$ be the level set defined by*

$$\mathcal{L}=\{\mathbf{x}\in\Omega : f(\mathbf{x}) \le f(\mathbf{x}_0)\}. \tag{2.11}$$

We assume the following conditions hold:

G1. *f is bounded from below on $\mathcal{L}$ and $d_{\max}=\sup_k\|\mathbf{d}_k\|<\infty$.*

G2. *If $\bar{\mathcal{L}}$ is the collection of $\mathbf{x}\in\Omega$ whose distance to $\mathcal{L}$ is at most $d_{\max}$, then ∇f is Lipschitz continuous on $\bar{\mathcal{L}}$.*

Then either the NGPA with $\epsilon = 0$ terminates in a finite number of iterations at a stationary point, or we have

$$\liminf_{k\to\infty} \|\mathbf{d}^1(\mathbf{x}_k)\| = 0.$$

Proof. By P6, the search direction $\mathbf{d}_k$ generated in step 1 of the NGPA is a descent direction. Since $f_k^r \geq f(\mathbf{x}_k)$ and $\delta < 1$, the Armijo line search condition (2.4) is satisfied for j sufficiently large. We now show that $\mathbf{x}_k \in \mathcal{L}$ for each k. Since $f_0^{\max} = f_{-1}^r = f(\mathbf{x}_0)$, step 2 of the NGPA implies that $f_0^r \leq f(\mathbf{x}_0)$. Proceeding by induction, suppose that for some $k \geq 0$, we have

$$f_j^r \leq f(\mathbf{x}_0) \quad \text{and} \quad f_j^{\max} \leq f(\mathbf{x}_0) \tag{2.12}$$

for all $j \in [0, k]$. Again, since the search direction $\mathbf{d}_k$ generated in step 1 of the NGPA is a descent direction, it follows from steps 3 and 4 of the NGPA and the induction hypothesis that

$$f(\mathbf{x}_{k+1}) \leq f_k^r \leq f(\mathbf{x}_0). \tag{2.13}$$

Hence, $f_{k+1}^{\max} \leq f(\mathbf{x}_0)$ and $f_{k+1}^r \leq \max\{f_k^r, f_{k+1}^{\max}\} \leq f(\mathbf{x}_0)$. This completes the induction. Thus (2.12) holds for all j. Consequently, we have $f_R \leq f(\mathbf{x}_0)$ in steps 3 and 4 of the NGPA. Again, since the search direction $\mathbf{d}_k$ generated in step 1 of the NGPA is a descent direction, it follows from steps 3 and 4 that $f(\mathbf{x}_k) \leq f(\mathbf{x}_0)$, which implies that $\mathbf{x}_k \in \mathcal{L}$ for each k.

Let λ be the Lipschitz constant for ∇f on $\bar{\mathcal{L}}$. As in [81, Lem. 2.1], we have

$$\alpha_k \geq \min\left\{1, \left(\frac{2\eta(1-\delta)}{\lambda}\right)\frac{|\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k|}{\|\mathbf{d}_k\|^2}\right\} \tag{2.14}$$

for all k. By P6,

$$|\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k| \geq \frac{\|\mathbf{d}_k\|^2}{\overline{\alpha}_k} \geq \frac{\|\mathbf{d}_k\|^2}{\alpha_{\max}}.$$

It follows from (2.14) that

$$\alpha_k \geq \min\left\{1, \left(\frac{2\eta(1-\delta)}{\lambda\alpha_{\max}}\right)\right\} := c. \tag{2.15}$$

By steps 3 and 4 of the NGPA and P6, we conclude that

$$f(\mathbf{x}_{k+1}) \leq f_k^r + \delta c\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k \leq f_k^r - \delta c\|\mathbf{d}_k\|^2/\overline{\alpha}_k \leq f_k^r - \delta c\|\mathbf{d}_k\|^2/\alpha_{\max}. \tag{2.16}$$

We now prove that $\liminf_{k\to\infty} \|\mathbf{d}_k\| = 0$. Suppose, to the contrary, that there exists a constant $\gamma > 0$ such that $\|\mathbf{d}_k\| \geq \gamma$ for all k. By (2.16), we have

$$f(\mathbf{x}_{k+1}) \leq f_k^r - \tau, \quad \text{where } \tau = \delta c\gamma^2/\alpha_{\max}. \tag{2.17}$$

Let k_i, $i = 0, 1, \ldots$, denote an increasing sequence of integers with the property that $f_j^r \leq f_j^{\max}$ for $j = k_i$ and $f_j^r \leq f_{j-1}^r$ when $k_i < j < k_{i+1}$. Such a sequence exists by the requirement on f_k^r given in step 2 of the NGPA. Hence, we have

$$f_j^r \leq f_{k_i}^r \leq f_{k_i}^{\max} \quad \text{when } k_i \leq j < k_{i+1}. \tag{2.18}$$

By (2.17) it follows that

$$f(\mathbf{x}_j) \le f_{j-1}^r - \tau \le f_{k_i}^{\max} - \tau \quad \text{when } k_i < j \le k_{i+1}. \tag{2.19}$$

It follows that

$$f_{k_{i+1}}^r \le f_{k_{i+1}}^{\max} \le f_{k_i}^{\max}. \tag{2.20}$$

Hence, if $a = k_{i_1}$ and $b = k_{i_2}$, where $i_1 > i_2$ and $a - b > M$, then by (2.18)–(2.20) we have

$$f_a^{\max} = \max_{0 \le j < M} f(\mathbf{x}_{a-j}) \le \max_{1 \le j \le M} f_{a-j}^r - \tau \le f_b^{\max} - \tau.$$

Since the sequence k_i, $i = 0, 1, \ldots$, is infinite, this contradicts the fact that f is bounded from below. Consequently, $\liminf_{k\to\infty} \|\mathbf{d}_k\| = 0$. By P4 and P5, it follows that

$$\|\mathbf{d}_k\| \ge \min\{\alpha_{\min}, 1\} \|\mathbf{d}^1(\mathbf{x}_k)\|.$$

Thus $\liminf_{k\to\infty} \|\mathbf{d}^1(\mathbf{x}_k)\| = 0$. □

Recall that f is strongly convex on Ω if there exists a scalar $\gamma > 0$ such that

$$f(\mathbf{x}) \ge f(\mathbf{y}) + \nabla f(\mathbf{y})(\mathbf{x} - \mathbf{y}) + \frac{\gamma}{2}\|\mathbf{x} - \mathbf{y}\|^2 \tag{2.21}$$

for all $\mathbf{x}$ and $\mathbf{y} \in \Omega$. Interchanging $\mathbf{x}$ and $\mathbf{y}$ in (2.21) and adding, we obtain the (usual) monotonicity condition

$$(\nabla f(\mathbf{y}) - \nabla f(\mathbf{x}))(\mathbf{y} - \mathbf{x}) \ge \gamma \|\mathbf{y} - \mathbf{x}\|^2. \tag{2.22}$$

For a strongly convex function, (2.1) has a unique minimizer $\mathbf{x}^*$, and the conclusion of Theorem 2.2 can be strengthened as follows.

COROLLARY 2.3. *Suppose f is strongly convex and twice continuously differentiable on Ω, and there is a positive integer L with the property that for each k, there exists $j \in [k, k + L)$ such that $f_j^r \le f_j^{\max}$. Then the iterates $\mathbf{x}_k$ of the NGPA with $\epsilon = 0$ converge to the global minimizer $\mathbf{x}^*$.*

Proof. As shown at the start of the proof of Theorem 2.2, $f(\mathbf{x}_k) \le f(\mathbf{x}_0)$ for each k. Hence, $\mathbf{x}_k$ lies in the level set $\mathcal{L}$ defined in (2.11). Since f is strongly convex, $\mathcal{L}$ is a bounded set; since f is twice continuously differentiable, $\|\nabla f(\mathbf{x}_k)\|$ is bounded uniformly in k. For any $\mathbf{x} \in \Omega$, we have $P(\mathbf{x}) = \mathbf{x}$. By P3, it follows that

$$\|\mathbf{d}^\alpha\| = \|P(\mathbf{x} - \alpha \mathbf{g}(\mathbf{x})) - \mathbf{x}\| = \|P(\mathbf{x} - \alpha \mathbf{g}(\mathbf{x})) - P(\mathbf{x})\| \le \alpha \|\mathbf{g}(\mathbf{x})\|.$$

Since $\bar{\alpha}_k \in [\alpha_{\min}, \alpha_{\max}]$, $d_{\max} = \sup_k \|\mathbf{d}_k\| < \infty$. Consequently, the set $\bar{\mathcal{L}}$ defined in G2 is bounded. Again, since f is twice continuously differentiable, ∇f is Lipschitz continuous on $\bar{\mathcal{L}}$. By assumption, $f_k^r \le f_k^{\max}$ infinitely often. Consequently, the hypotheses of Theorem 2.2 are satisfied, and either the NGPA with $\epsilon = 0$ terminates in a finite number of iterations at a stationary point, or we have

$$\liminf_{k\to\infty} \|\mathbf{d}^1(\mathbf{x}_k)\| = 0. \tag{2.23}$$

Since f is strongly convex on Ω, $\mathbf{x}^*$ is the unique stationary point for (2.1). Hence, when the iterates converge in a finite number of steps, they converge to $\mathbf{x}^*$. Otherwise,

(2.23) holds, in which case there exists an infinite sequence $l_1 < l_2 < \cdots$ such that $\|\mathbf{d}^1(\mathbf{x}_{l_j})\|$ approaches zero as j tends to ∞. Since (2.22) holds, it follows from P8 that $\mathbf{x}_{l_j}$ approaches $\mathbf{x}^*$ as j tends to ∞. By P4 and P5, we have

$$\|\mathbf{d}^\alpha(\mathbf{x})\| \le \max\{1, \alpha\}\|\mathbf{d}^1(\mathbf{x})\|.$$

Since $\bar{\alpha}_k \in [\alpha_{\min}, \alpha_{\max}]$, it follows that

$$\|\mathbf{d}_k\| \le \max\{1, \alpha_{\max}\}\|\mathbf{d}^1(\mathbf{x}_k)\|.$$

Since the stepsize $\alpha_k \in (0, 1]$, we deduce that

$$\|\mathbf{x}_{k+1} - \mathbf{x}_k\| = \alpha_k\|\mathbf{d}_k\| \le \|\mathbf{d}_k\| \le \max\{1, \alpha_{\max}\}\|\mathbf{d}^1(\mathbf{x}_k)\|. \tag{2.24}$$

By P3, P is continuous; consequently, $\mathbf{d}^\alpha(\mathbf{x})$ is a continuous function of $\mathbf{x}$. The continuity of $\mathbf{d}^\alpha(\cdot)$ and $f(\cdot)$ combined with (2.24) and the fact that $\mathbf{x}_{l_j}$ converges to $\mathbf{x}^*$ implies that for any $\delta > 0$ and for j sufficiently large, we have

$$f(\mathbf{x}_k) \le f(\mathbf{x}^*) + \delta \quad \text{for all } k \in [l_j, l_j + M + L].$$

By the definition of $f_k^{\max}$,

$$f_k^{\max} \le f(\mathbf{x}^*) + \delta \quad \text{for all } k \in [l_j + M, l_j + M + L]. \tag{2.25}$$

As in the proof of Theorem 2.2, let k_i, $i = 0, 1, \ldots$, denote an increasing sequence of integers with the property that $f_j^r \le f_j^{\max}$ for $j = k_i$ and $f_j^r \le f_{j-1}^r$ when $k_i < j < k_{i+1}$. As shown in (2.20),

$$f_{k_{i+1}}^{\max} \le f_{k_i}^{\max} \tag{2.26}$$

for each i. The assumption that for each k, there exists $j \in [k, k + L)$ such that $f_j^r \le f_j^{\max}$, implies that

$$k_{i+1} - k_i \le L. \tag{2.27}$$

Combining (2.25) and (2.27), for each l_j, there exists some $k_i \in [l_j + M, l_j + M + L]$ and

$$f_{k_i}^{\max} \le f(\mathbf{x}^*) + \delta. \tag{2.28}$$

Since δ was arbitrary, it follows from (2.26) and (2.28) that

$$\lim_{i\to\infty} f_{k_i}^{\max} = f(\mathbf{x}^*); \tag{2.29}$$

the convergence is monotone by (2.26). By the choice of k_i and by the inequality $f(\mathbf{x}_k) \le f_k^r$ in step 2, we have

$$f(\mathbf{x}_k) \le f_k^r \le f_{k_i}^{\max} \quad \text{for all } k \ge k_i. \tag{2.30}$$

Combining (2.29) and (2.30),

$$\lim_{k\to\infty} f(\mathbf{x}_k) = f(\mathbf{x}^*). \tag{2.31}$$

Together, (2.5) and (2.21) yield

$$f(\mathbf{x}_k) \ge f(\mathbf{x}^*) + \frac{\gamma}{2}\|\mathbf{x}_k - \mathbf{x}^*\|^2. \tag{2.32}$$

Combining this with (2.31), the proof is complete. ∎

3. The active set algorithm. Starting with this section, we focus on the box constrained problem (1.1). To simplify the exposition, we consider the special case when $\mathbf{l} = \mathbf{0}$ and $\mathbf{u} = \boldsymbol{\infty}$:

$$\min \{f(\mathbf{x}) : \mathbf{x} \geq \mathbf{0}\}.$$

We emphasize that the analysis and algorithm apply to the general box constrained problem (1.1) with both upper and lower bounds.

Although the gradient projection scheme of the NGPA has an attractive global convergence theory, the convergence rate can be slow in a neighborhood of a local minimizer. In contrast, for unconstrained optimization, the conjugate gradient algorithm often exhibits superlinear convergence in a neighborhood of a local minimizer. We develop an ASA which uses the NGPA to identify active constraints, and which uses an unconstrained optimization algorithm, such as the CG_DESCENT scheme in [54, 55, 57, 56], to optimize f over a face identified by the NGPA.

We begin with some notation. For any $\mathbf{x} \in \Omega$, let $\mathcal{A}(\mathbf{x})$ and $\mathcal{I}(\mathbf{x})$ denote the active and inactive indices, respectively:

$$\mathcal{A}(\mathbf{x}) = \{i \in [1, n] : x_i = 0\},$$
$$\mathcal{I}(\mathbf{x}) = \{i \in [1, n] : x_i > 0\}.$$

The active indices are further subdivided into those indices satisfying strict complementarity and the degenerate indices:

$$\mathcal{A}_+(\mathbf{x}) = \{i \in \mathcal{A}(\mathbf{x}) : g_i(\mathbf{x}) > 0\},$$
$$\mathcal{A}_0(\mathbf{x}) = \{i \in \mathcal{A}(\mathbf{x}) : g_i(\mathbf{x}) = 0\}.$$

We let $\mathbf{g}_I(\mathbf{x})$ denote the vector whose components associated with the set $\mathcal{I}(\mathbf{x})$ are identical to those of $\mathbf{g}(\mathbf{x})$, while the components associated with $\mathcal{A}(\mathbf{x})$ are zero:

$$g_{Ii}(\mathbf{x}) = \begin{cases} 0 & \text{if } x_i = 0, \\ g_i(\mathbf{x}) & \text{if } x_i > 0. \end{cases}$$

An important feature of our algorithm is that we try to distinguish between active constraints satisfying strict complementarity and active constraints that are degenerate using an identification strategy, which is related to the idea of an identification function introduced in [41]. Given fixed parameters $\alpha \in (0, 1)$ and $\beta \in (1, 2)$, we define the (undecided index) set $\mathcal{U}$ at $\mathbf{x} \in \mathcal{B}$ as follows:

$$\mathcal{U}(\mathbf{x}) = \{i \in [1, n] : |g_i(\mathbf{x})| \geq \|\mathbf{d}^1(\mathbf{x})\|^\alpha \text{ and } x_i \geq \|\mathbf{d}^1(\mathbf{x})\|^\beta\}.$$

In the numerical experiments, we take $\alpha = 1/2$ and $\beta = 3/2$. In practice, $\mathcal{U}$ is almost always empty when we reach a neighborhood of a minimizer, and the specific choice of α and β does not have a significant effect on convergence. The introduction of the $\mathcal{U}$ set leads to a strong local convergence theory developed in section 5.

The indices in $\mathcal{U}$ correspond to components of $\mathbf{x}$ for which the associated gradient component $g_i(\mathbf{x})$ is relatively large, while x_i is not close to 0 (in the sense that $x_i \geq \|\mathbf{d}^1(\mathbf{x})\|^\beta$). When the set $\mathcal{U}$ of uncertain indices is empty, we feel that the indices with large associated gradient components are almost identified. In this case we prefer the unconstrained optimization algorithm.

Although our numerical experiments are based on the conjugate gradient code CG_DESCENT, a broad class of unconstrained optimization algorithms (UAs) can

be applied. The following requirements for the UA are sufficient for establishing the convergence results that follow. Conditions U1–U3 are sufficient for global convergence, while U1–U4 are sufficient for the local convergence analysis. Condition U4 could be replaced with another descent condition for the initial line search; however, the analysis of section 5 has been carried out under U4.

Unconstrained algorithm (UA) requirements.

U1. $\mathbf{x}_k \geq \mathbf{0}$ and $f(\mathbf{x}_{k+1}) \leq f(\mathbf{x}_k)$ for each k.

U2. $\mathcal{A}(\mathbf{x}_k) \subset \mathcal{A}(\mathbf{x}_{k+1})$ for each k.

U3. If $\mathcal{A}(\mathbf{x}_{j+1}) = \mathcal{A}(\mathbf{x}_j)$ for $j \geq k$, then $\liminf_{j\to\infty} \|\mathbf{g}_I(\mathbf{x}_j)\| = 0$.

U4. Whenever the UA is started, $\mathbf{x}_{k+1} = P(\mathbf{x}_k - \alpha_k \mathbf{g}_I(\mathbf{x}_k))$, where α_k is obtained from a Wolfe line search. That is, α_k is chosen to satisfy

$$\phi(\alpha_k) \leq \phi(0) + \delta\alpha_k\phi'(0) \quad \text{and} \quad \phi'(\alpha_k) \geq \sigma\phi'(0), \tag{3.1}$$

where

$$\phi(\alpha) = f(P(\mathbf{x}_k - \alpha\mathbf{g}_I(\mathbf{x}_k))), \quad 0 < \delta < \sigma < 1. \tag{3.2}$$

Condition U1 implies that the UA is a monotone algorithm, so that the cost function can only decrease in each iteration. Condition U2 concerns how the algorithm behaves when an infeasible iterate is generated. Condition U3 describes the global convergence of the UA when the active set does not change. In U4, $\phi'(\alpha)$ is the derivative from the right side of α; α_k exists since ϕ is piecewise smooth with a finite number of discontinuities in its derivative, and $\phi'(\alpha)$ is continuous at $\alpha = 0$.

Our ASA is presented in Figure 3.1. In the first step of the algorithm, we execute the NGPA until we feel that the active constraints satisfying strict complementarity have been identified. In step 2, we execute the UA until a subproblem has been solved (step 2a). When new constraints become active in step 2b, we may decide to restart either the NGPA or the UA. By restarting the NGPA, we mean that $\mathbf{x}_0$ in the NGPA is identified with the current iterate $\mathbf{x}_k$. By restarting the UA, we mean that iterates are generated by the UA using the current iterate as the starting point.

4. Global convergence. We begin with a global convergence result for the ASA.

Theorem 4.1. *Let $\mathcal{L}$ be the level set defined by*

$$\mathcal{L} = \{\mathbf{x} \in \mathcal{B} : f(\mathbf{x}) \leq f(\mathbf{x}_0)\}.$$

Assume the following conditions hold:

A1. *f is bounded from below on $\mathcal{L}$ and $d_{\max} = \sup_k \|\mathbf{d}_k\| < \infty$.*

A2. *If $\bar{\mathcal{L}}$ is the collection of $\mathbf{x} \in \mathcal{B}$ whose distance to $\mathcal{L}$ is at most $d_{\max}$, then ∇f is Lipschitz continuous on $\bar{\mathcal{L}}$.*

A3. *The UA satisfies* U1–U3.

Then either the ASA with $\epsilon = 0$ terminates in a finite number of iterations at a stationary point, or we have

$$\liminf_{k\to\infty} \|\mathbf{d}^1(\mathbf{x}_k)\| = 0. \tag{4.1}$$

Proof. If only the NGPA is performed for large k, then (4.1) follows from Theorem 2.2. If only the UA is performed for large k, then by U2, the active sets $\mathcal{A}(\mathbf{x}_k)$ must approach a limit. Since μ does not change in the UA, it follows from U3 and the condition $\|\mathbf{g}_I(\mathbf{x}_k)\| \geq \mu\|\mathbf{d}^1(\mathbf{x}_k)\|$ that (4.1) holds. Finally, suppose that the NGPA

ASA PARAMETERS.

- $\epsilon \in [0, \infty)$, error tolerance, stop when $\|\mathbf{d}^1(\mathbf{x}_k)\| \leq \epsilon$
- $\mu \in (0, 1)$, $\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu \|\mathbf{d}^1(\mathbf{x}_k)\|$ implies subproblem solved
- $\rho \in (0, 1)$, decay factor for μ tolerance
- $n_1 \in [1, n)$, number of repeated $\mathcal{A}(\mathbf{x}_k)$ before switch from the NGPA to the UA
- $n_2 \in [1, n)$, used in switch from the UA to the NGPA

ACTIVE SET ALGORITHM (ASA).

1. While $\|\mathbf{d}^1(\mathbf{x}_k)\| > \epsilon$ execute the NGPA and check the following:
   a. If $\mathcal{U}(\mathbf{x}_k) = \emptyset$, then
      If $\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu \|\mathbf{d}^1(\mathbf{x}_k)\|$, then $\mu = \rho\mu$.
      Otherwise, goto step 2.
   b. Else if $\mathcal{A}(\mathbf{x}_k) = \mathcal{A}(\mathbf{x}_{k-1}) = \cdots = \mathcal{A}(\mathbf{x}_{k-n_1})$, then
      If $\|\mathbf{g}_I(\mathbf{x}_k)\| \geq \mu \|\mathbf{d}^1(\mathbf{x}_k)\|$, then goto step 2.

   End

2. While $\|\mathbf{d}^1(\mathbf{x}_k)\| > \epsilon$ execute the UA and check the following:
   a. If $\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu \|\mathbf{d}^1(\mathbf{x}_k)\|$, then restart the NGPA (step 1).
   b. If $|\mathcal{A}(\mathbf{x}_{k-1})| < |\mathcal{A}(\mathbf{x}_k)|$, then
      If $\mathcal{U}(\mathbf{x}_k) = \emptyset$ or $|\mathcal{A}(\mathbf{x}_k)| > |\mathcal{A}(\mathbf{x}_{k-1})| + n_2$, restart the UA at $\mathbf{x}_k$.
      Else restart the NGPA.
      End

   End

FIG. 3.1. *Statement of the ASA.*

is restarted an infinite number of times at $k_1 < k_2 < \cdots$ and that it terminates at $k_1 + l_1 < k_2 + l_2 < \cdots$, respectively. Thus $k_i < k_i + l_i \leq k_{i+1}$ for each i. If (4.1) does not hold, then by (2.19) and (2.20), we have

$$f(\mathbf{x}_{k_i + l_i}) \leq f(\mathbf{x}_{k_i}) - \tau. \tag{4.2}$$

By U1,

$$f(\mathbf{x}_{k_{i+1}}) \leq f(\mathbf{x}_{k_i + l_i}). \tag{4.3}$$

Combining (4.2) and (4.3), we have $f(\mathbf{x}_{k_{i+1}}) \leq f(\mathbf{x}_{k_i}) - \tau$, which contradicts the assumption that f is bounded from below. □

When f is strongly convex, the entire sequence of iterates converges to the global minimizer $\mathbf{x}^*$, as stated in the following corollary. Since the proof of this result relies on the local convergence analysis, the proof is delayed until the end of section 5.

COROLLARY 4.2. *If f is strongly convex and twice continuously differentiable on $\mathcal{B}$, and assumption* A3 *of Theorem* 4.1 *is satisfied, then the iterates $\mathbf{x}_k$ of the ASA with $\epsilon = 0$ converge to the global minimizer $\mathbf{x}^*$.*

5. Local convergence. In the next series of lemmas, we analyze local convergence properties of the ASA. We begin by focusing on nondegenerate stationary points; that is, stationary points $\mathbf{x}^*$ with the property that $g_i(\mathbf{x}^*) > 0$ whenever $x_i^* = 0$.

5.1. Nondegenerate problems. In this case, it is relatively easy to show that the ASA eventually performs only the UA without restarts. The analogous result for degenerate problems is established in section 5.2.

THEOREM 5.1. *If f is continuously differentiable, $0 < \mu \le 1$, and the iterates $\mathbf{x}_k$ generated by the ASA with $\epsilon = 0$ converge to a nondegenerate stationary point $\mathbf{x}^*$, then after a finite number of iterations, the ASA performs only the UA without restarts.*

Proof. Since $\mathbf{x}^*$ is a nondegenerate stationary point and f is continuously differentiable, there exists $\rho > 0$ with the property that for all $\mathbf{x} \in \mathcal{B}_\rho(\mathbf{x}^*)$, we have

$$g_i(\mathbf{x}) > 0 \text{ if } i \in \mathcal{A}(\mathbf{x}^*) \quad \text{and} \quad x_i > 0 \text{ if } i \in \mathcal{A}(\mathbf{x}^*)^c. \tag{5.1}$$

Let k_+ be chosen large enough that $\mathbf{x}_k \in \mathcal{B}_\rho(\mathbf{x}^*)$ for all $k \ge k_+$. If $k \ge k_+$ and $x_{ki} = 0$, then $d_{ki} = 0$ in step 1 of the NGPA. Hence, $x_{k+1,i} = 0$ if $\mathbf{x}_{k+1}$ is generated by the NGPA. By U2, the UA cannot free a bound constraint. It follows that if $k \ge k_+$ and $x_{ki} = 0$, then $x_{ji} = 0$ for all $j \ge k$. Consequently, there exists an index $K \ge k_+$ with the property that $\mathcal{A}(\mathbf{x}_k) = \mathcal{A}(\mathbf{x}_j)$ for all $j \ge k \ge K$.

For any index i, $|d_i^1(\mathbf{x})| \le |g_i(\mathbf{x})|$. Suppose $\mathbf{x} \in \mathcal{B}_\rho(\mathbf{x}^*)$; by (5.1), $d_i^1(\mathbf{x}) = 0$ if $x_i = 0$. Hence,

$$\|\mathbf{d}^1(\mathbf{x})\| \le \|\mathbf{g}_I(\mathbf{x})\| \tag{5.2}$$

for all $\mathbf{x} \in \mathcal{B}_\rho(\mathbf{x}^*)$. If $k > K + n_1$, then in step 1b of the ASA, it follows from (5.2) and the assumption $\mu \in (0, 1]$ that the NGPA will branch to step 2 (UA). In step 2, the condition "$\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu\|\mathbf{d}^1(\mathbf{x}_k)\|$" of step 2a is never satisfied by (5.2). Moreover, the condition "$|\mathcal{A}(\mathbf{x}_{k-1})| < |\mathcal{A}(\mathbf{x}_k)|$" of step 2b is never satisfied since $k > K$. Hence, the iterates never branch from the UA to the NPGA and the UA is never restarted. ∎

5.2. Degenerate problems. We now focus on degenerate problems and show that a result analogous to Theorem 5.1 holds under the strong second-order sufficient optimality condition. We begin with a series of preliminary results.

LEMMA 5.2. *If f is twice-continuously differentiable and there exists an infinite sequence of iterates $\mathbf{x}_k$ generated by the ASA with $\epsilon = 0$ converging to a stationary point $\mathbf{x}^*$, $\mathbf{x}_k \ne \mathbf{x}^*$ for each k, then for each $i \in \mathcal{A}_+(\mathbf{x}^*)$ we have*

$$\limsup_{k\to\infty} \frac{x_{ki}}{\|\mathbf{x}_k - \mathbf{x}^*\|^2} < \infty. \tag{5.3}$$

Proof. Assume that $\mathcal{A}_+(\mathbf{x}^*)$ is nonempty; otherwise there is nothing to prove. Let k_+ be chosen large enough that $g_i(\mathbf{x}_k) > 0$ for all $i \in \mathcal{A}_+(\mathbf{x}^*)$ and $k \ge k_+$. Since f is twice-continuously differentiable, ∇f is Lipschitz continuous in a neighborhood of $\mathbf{x}^*$. Choose $\rho > 0$ and let λ be the Lipschitz constant for ∇f in the ball $B_\rho(\mathbf{x}^*)$ with center $\mathbf{x}^*$ and radius ρ. Since $\mathbf{d}^1(\mathbf{x}^*) = \mathbf{0}$, it follows from the continuity of $\mathbf{d}^1(\cdot)$ that $\mathbf{d}_k$ tends to $\mathbf{0}$ (see (2.24)). Choose k_+ large enough that the ball with center $\mathbf{x}_k$ and radius $\|\mathbf{d}_k\|$ is contained in $B_\rho(\mathbf{x}^*)$ for all $k \ge k_+$. If $x_{li} = 0$ for some $i \in \mathcal{A}_+(\mathbf{x}^*)$ and $l \ge k_+$, then by the definition of $\mathbf{d}_k$ in the NGPA, we have $d_{ki} = 0$ for all $k \ge l$. Hence, $x_{ki} = 0$ for each $k \ge l$ in the NGPA. Likewise, in the UA it follows from U2 that $x_{ji} = 0$ for $j \ge k$ when $x_{ki} = 0$; that is, the UA does not free an active constraint. In other words, when an index $i \in \mathcal{A}_+(\mathbf{x}^*)$ becomes active at iterate $\mathbf{x}_k$, $k \ge k_+$, it remains active for all the subsequent iterations. Thus (5.3) holds trivially for any $i \in \mathcal{A}_+(\mathbf{x}^*)$ with the property that $x_{ki} = 0$ for some $k \ge k_+$.

Now, let us focus on the nontrivial indices in $\mathcal{A}_+(\mathbf{x}^*)$. That is, suppose that there exists $l \in \mathcal{A}_+(\mathbf{x}^*)$ and $x_{kl} > 0$ for all $k \geq k_+$. By the analysis given in the previous paragraph, when k_+ is sufficiently large,

$$\text{either } x_{ki} > 0 \quad \text{or} \quad x_{ki} = 0 \tag{5.4}$$

for all $k \geq k_+$ and $i \in \mathcal{A}_+(\mathbf{x}^*)$ (since an index $i \in \mathcal{A}_+(\mathbf{x}^*)$, which becomes active at iterate $\mathbf{x}_k$, remains active for all the subsequent iterations). We consider the following possible cases.

Case 1. For an infinite number of iterations k, $\mathbf{x}_k$ is generated by the UA, and the UA is restarted a finite number of times.

In this case, the ASA eventually performs only the UA, without restarts. By U2 and U3, we have $\liminf_{k\to\infty} \|\mathbf{g}_I(\mathbf{x}_k)\| = 0$. On the other hand, by assumption, $l \in \mathcal{I}(\mathbf{x}_k)$ for $k \geq k_+$ and $g_l(\mathbf{x}^*) > 0$, which is a contradiction since $g_l(\mathbf{x}_k)$ converges to $g_l(\mathbf{x}^*)$.

Case 2. For an infinite number of iterations k, $\mathbf{x}_k$ is generated by the UA, and the UA is restarted an infinite number of times.

In this case, we will show that after a finite number of iterations, $x_{ki} = 0$ for all $i \in \mathcal{A}_+(\mathbf{x}^*)$. Suppose, to the contrary, that there exists an $l \in \mathcal{A}_+(\mathbf{x}^*)$ such that $x_{kl} > 0$ for all $k \geq k_+$. By U4, each time the UA is restarted, we perform a Wolfe line search. By the second half of (3.1), we have

$$\phi'(\alpha_k) - \phi'(0) \geq (\sigma - 1)\phi'(0). \tag{5.5}$$

It follows from the definition (3.2) of $\phi(\alpha)$ that

$$\phi'(0) = -\sum_{i\in\mathcal{I}(x_k)} g_{ki}^2 = -\|\mathbf{g}_I(\mathbf{x}_k)\|^2 \quad \text{and} \tag{5.6}$$

$$\begin{aligned}\phi'(\alpha_k) &= -\sum_{i\in\mathcal{I}(x_{k+1})} g_{ki}g_{k+1,i} \\ &= -\sum_{i\in\mathcal{I}(x_k)} g_{ki}g_{k+1,i} + \sum_{i\in\mathcal{A}(x_{k+1})\setminus\mathcal{A}(x_k)} g_{ki}g_{k+1,i}. \end{aligned} \tag{5.7}$$

By the Lipschitz continuity of ∇f and P3, we have

$$\begin{aligned}\|\mathbf{g}(\mathbf{x}_k) - \mathbf{g}(\mathbf{x}_{k+1})\| &= \|\mathbf{g}(P(\mathbf{x}_k)) - \mathbf{g}(P(\mathbf{x}_k - \alpha_k\mathbf{g}_I(\mathbf{x}_k)))\| \\ &\leq \lambda\alpha_k\|\mathbf{g}_I(\mathbf{x}_k)\|.\end{aligned}$$

Hence, by the Schwarz inequality,

$$\left|\sum_{i\in\mathcal{I}(\mathbf{x}_k)} g_{ki}(g_{ki} - g_{k+1,i})\right| \leq \lambda\alpha_k\|\mathbf{g}_I(\mathbf{x}_k)\|^2. \tag{5.8}$$

Since $\mathcal{A}(\mathbf{x}_{k+1}) \setminus \mathcal{A}(\mathbf{x}_k) \subset \mathcal{I}(\mathbf{x}_k)$, the Schwarz inequality also gives

$$\sum_{i\in\mathcal{A}(x_{k+1})\setminus\mathcal{A}(x_k)} g_{ki}g_{k+1,i} \leq \|\mathbf{g}_I(\mathbf{x}_k)\|\|\mathbf{g}_{k+1}\|_{\mathcal{N}}, \tag{5.9}$$

where

$$\|\mathbf{g}_{k+1}\|_{\mathcal{N}}^2 = \sum_{i\in\mathcal{A}(x_{k+1})\setminus\mathcal{A}(x_k)} g_{k+1,i}^2.$$

Here $\mathcal{N} = \mathcal{A}(\mathbf{x}_{k+1}) \setminus \mathcal{A}(\mathbf{x}_k)$ corresponds to the set of constraints that are newly activated as we move from $\mathbf{x}_k$ to $\mathbf{x}_{k+1}$. Combining (5.5)–(5.9),

$$\alpha_k \geq \frac{1-\sigma}{\lambda} - \frac{\|\mathbf{g}_{k+1}\|_{\mathcal{N}}}{\lambda \|\mathbf{g}_I(\mathbf{x}_k)\|}, \quad \text{where } \|\mathbf{g}_{k+1}\|_{\mathcal{N}}^2 = \sum_{i \in \mathcal{A}(x_{k+1}) \setminus \mathcal{A}(x_k)} g_{k+1,i}^2. \tag{5.10}$$

For k sufficiently large, (5.4) implies that the newly activated constraints $\mathcal{A}(\mathbf{x}_{k+1}) \setminus \mathcal{A}(\mathbf{x}_k)$ exclude all members of $\mathcal{A}_+(\mathbf{x}^*)$. Since the $\mathbf{x}_k$ converge to $\mathbf{x}^*$, $\|\mathbf{g}_{k+1}\|_{\mathcal{N}}$ tends to zero. On the other hand, $\|\mathbf{g}_I(\mathbf{x}_k)\|$ is bounded away from zero since the index l is contained in $\mathcal{I}(\mathbf{x}_k)$. Hence, the last term in (5.10) tends to 0 as k increases, and the lower bound for α_k approaches $(1-\sigma)/\lambda$. Since $x_l^* = 0$, it follows that x_{kl} approaches 0. Since the lower bound for α_k approaches $(1-\sigma)/\lambda$, $g_l(\mathbf{x}^*) > 0$, and $\mathbf{x}_k$ converges to $\mathbf{x}^*$, we conclude that

$$x_{k+1,l} = x_{kl} - \alpha_k g_{kl} < 0$$

for k sufficiently large. This contradicts the initial assumption that constraint l is inactive for k sufficiently large. Hence, in a finite number of iterations, $x_{ki} = 0$ for all $i \in \mathcal{A}_+(\mathbf{x}^*)$.

Case 3. The UA is executed a finite number of iterations.

In this case, the iterates are generated by the NGPA for k sufficiently large. Suppose that (5.3) is violated for some $l \in \mathcal{A}_+(\mathbf{x}^*)$. We show that this leads to a contradiction. By (5.4), $x_{kl} > 0$ for all $k \geq k_+$. Since $\mathbf{x}_k$ converges to $\mathbf{x}^*$, $\mathbf{x}_l^* = 0$, and $g_l(\mathbf{x}^*) > 0$, it is possible to choose k larger, if necessary, so that

$$x_{kl} - g_{kl}\alpha_{\min} < 0. \tag{5.11}$$

Since (5.3) is violated and $\mathbf{x}_k$ converges to $\mathbf{x}^*$, we can choose k larger, if necessary, so that

$$\frac{x_{kl}}{\|\mathbf{x}_k - \mathbf{x}^*\|^2} \geq \frac{\lambda(2+\lambda)^2 \max\{1, \alpha_{\max}\}^2}{2(1-\delta)g_{kl}}, \tag{5.12}$$

where $0 < \delta < 1$ is the parameter appearing in step 3 of the NGPA, and λ is the Lipschitz constant for ∇f. We will show that for this k, we have

$$f(\mathbf{x}_k + \mathbf{d}_k) \leq f_R + \delta \mathbf{g}_k^{\mathsf{T}} \mathbf{d}_k, \tag{5.13}$$

where f_R is specified in step 3 of the NGPA. According to step 3 of the NGPA, when (5.13) holds, $\alpha_k = 1$, which implies that

$$x_{k+1,l} = x_{kl} + d_{kl}. \tag{5.14}$$

Since (5.11) holds and $\bar{\alpha}_k \geq \alpha_{\min}$, we have

$$d_{kl} = \max\{x_{kl} - \bar{\alpha}_k g_{kl}, 0\} - x_{kl} = -x_{kl}. \tag{5.15}$$

This substitution in (5.14) gives $x_{k+1,l} = 0$, which contradicts the fact that $x_{kl} > 0$ for all $k \geq k_+$.

To complete the proof, we need to show that when (5.12) holds, (5.13) is satisfied. Expanding in a Taylor series around $\mathbf{x}_k$ and utilizing (5.15) gives

$$\begin{aligned} f(\mathbf{x}_k + \mathbf{d}_k) &= f(\mathbf{x}_k) + \int_0^1 f'(\mathbf{x}_k + t\mathbf{d}_k)dt \\ &= f(\mathbf{x}_k) + \mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k + \int_0^1 (\nabla f(\mathbf{x}_k + t\mathbf{d}_k) - \mathbf{g}_k^{\mathsf{T}})\mathbf{d}_k dt \\ &\le f(\mathbf{x}_k) + \mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k + \frac{\lambda}{2}\|\mathbf{d}_k\|^2 \\ &= f(\mathbf{x}_k) + \delta\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k + (1-\delta)\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k + \frac{\lambda}{2}\|\mathbf{d}_k\|^2 \\ &\le f(\mathbf{x}_k) + \delta\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k + (1-\delta)g_{kl}d_{kl} + \frac{\lambda}{2}\|\mathbf{d}_k\|^2 \qquad \text{(5.16a)} \\ &= f(\mathbf{x}_k) + \delta\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k - (1-\delta)g_{kl}x_{kl} + \frac{\lambda}{2}\|\mathbf{d}_k\|^2. \qquad \text{(5.16b)} \end{aligned}$$

The inequality (5.16a) is due to the fact that $g_{ki}d_{ki} \le 0$ for each i. By P3, P4, P5, and P7, and by the Lipschitz continuity of ∇f, we have

$$\begin{aligned} \|\mathbf{d}_k\| &\le \max\{1, \alpha_{\max}\}\|\mathbf{d}^1(\mathbf{x}_k)\| \\ &= \max\{1, \alpha_{\max}\}\|\mathbf{d}^1(\mathbf{x}_k) - \mathbf{d}^1(\mathbf{x}^*)\| \\ &= \max\{1, \alpha_{\max}\}\|P(\mathbf{x}_k - \mathbf{g}_k) - \mathbf{x}_k - P(\mathbf{x}^* - \mathbf{g}(\mathbf{x}^*)) + \mathbf{x}^*\| \\ &\le \max\{1, \alpha_{\max}\}(\|\mathbf{x}_k - \mathbf{x}^*\| + \|P(\mathbf{x}_k - \mathbf{g}_k) - P(\mathbf{x}^* - \mathbf{g}(\mathbf{x}^*))\|) \\ &\le \max\{1, \alpha_{\max}\}(\|\mathbf{x}_k - \mathbf{x}^*\| + \|\mathbf{x}_k - \mathbf{g}_k - (\mathbf{x}^* - \mathbf{g}(\mathbf{x}^*))\|) \\ &\le \max\{1, \alpha_{\max}\}(2\|\mathbf{x}_k - \mathbf{x}^*\| + \|\mathbf{g}_k - \mathbf{g}(\mathbf{x}^*)\|) \\ &\le \max\{1, \alpha_{\max}\}(2 + \lambda)\|\mathbf{x}_k - \mathbf{x}^*\|. \end{aligned}$$

Combining this upper bound for $\|\mathbf{d}_k\|$ with the lower bound (5.12) for x_{kl}, we conclude that

$$\begin{aligned} \frac{\lambda}{2}\|\mathbf{d}_k\|^2 &\le \frac{\lambda}{2}\max\{1, \alpha_{\max}\}^2(2+\lambda)^2\|\mathbf{x}_k - \mathbf{x}^*\|^2 \\ &\le \frac{1}{2}\left(\frac{2(1-\delta)x_{kl}g_{kl}}{\|\mathbf{x}_k - \mathbf{x}^*\|^2}\right)\|\mathbf{x}_k - \mathbf{x}^*\|^2 \\ &= (1-\delta)x_{kl}g_{kl}. \end{aligned}$$

Hence, by (5.16b) and by the choice for f_R specified in step 3 of the NGPA, we have

$$f(\mathbf{x}_k + \mathbf{d}_k) \le f(\mathbf{x}_k) + \delta\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k \le f_R + \delta\mathbf{g}_k^{\mathsf{T}}\mathbf{d}_k. \qquad \text{(5.17)}$$

This completes the proof of (5.13). □

There is a fundamental difference between the gradient projection algorithm presented in this paper and algorithms based on a "piecewise projected gradient" [15, 16, 17]. For our gradient projection algorithm, we perform a single projection, and then we backtrack towards the starting point. Thus we are unable to show that the active constraints are identified in a finite number of iterations; in contrast, with the piecewise project gradient approach, where a series of projections may be performed, the active constraints can be identified in a finite number of iterations. In Lemma 5.2 we show that even though we do not identify the active constraints, the

components of $\mathbf{x}_k$ corresponding to the strictly active constraints are on the order of the error in $\mathbf{x}_k$ squared.

If all the constraints are active at a stationary point $\mathbf{x}^*$ and strict complementarity holds, then convergence is achieved in a finite number of iterations.

COROLLARY 5.3. *If f is twice-continuously differentiable, the iterates $\mathbf{x}_k$ generated by the ASA with $\epsilon = 0$ converge to a stationary point $\mathbf{x}^*$, and $|\mathcal{A}_+(\mathbf{x}^*)| = n$, then $\mathbf{x}_k = \mathbf{x}^*$ after a finite number of iterations.*

Proof. Let $\mathbf{x}_{k,\max}$ denote the largest component of $\mathbf{x}_k$. Since $\|\mathbf{x}_k\|^2 \le n\mathbf{x}_{k,\max}^2$, we have

$$\frac{\mathbf{x}_{k,\max}}{\|\mathbf{x}_k\|^2} \ge \frac{1}{n\mathbf{x}_{k,\max}}. \tag{5.18}$$

Since all the constraints are active at $\mathbf{x}^*$, $\mathbf{x}_{k,\max}$ tends to zero. By (5.18) the conclusion (5.3) of Lemma 5.2 does not hold. Hence, after a finite number of iterations, $\mathbf{x}_k = \mathbf{x}^*$. ∎

Recall [70] that for any stationary point $\mathbf{x}^*$ of (1.1), the strong second-order sufficient optimality condition holds if there exists $\gamma > 0$ such that

$$\mathbf{d}^{\mathsf{T}}\nabla^2 f(\mathbf{x}^*)\mathbf{d} \ge \gamma\|\mathbf{d}\|^2 \quad \text{whenever} \quad d_i = 0 \text{ for all } i \in \mathcal{A}_+(\mathbf{x}^*). \tag{5.19}$$

Using P8, we establish the following.

LEMMA 5.4. *If f is twice-continuously differentiable near a stationary point $\mathbf{x}^*$ of (1.1) satisfying the strong second-order sufficient optimality condition, then there exists $\rho > 0$ with the following property:*

$$\|\mathbf{x} - \mathbf{x}^*\| \le \sqrt{1 + \left(\frac{(1+\lambda)^2}{.5\gamma}\right)^2}\,\|\mathbf{d}^1(\mathbf{x})\| \tag{5.20}$$

for all $\mathbf{x} \in B_\rho(\mathbf{x}^*)$, where λ is any Lipschitz constant for ∇f over $B_\rho(\mathbf{x}^*)$.

Proof. By the continuity of the second derivative of f, it follows from (5.19) that for $\rho > 0$ sufficiently small,

$$(\mathbf{g}(\mathbf{x}) - \mathbf{g}(\mathbf{x}^*))^{\mathsf{T}}(\mathbf{x} - \mathbf{x}^*) \ge .5\gamma\|\mathbf{x} - \mathbf{x}^*\|^2 \tag{5.21}$$

for all $\mathbf{x} \in B_\rho(\mathbf{x}^*)$ with $x_i = 0$ for all $i \in \mathcal{A}_+(\mathbf{x}^*)$. Choose ρ smaller if necessary so that

$$x_i - g_i(\mathbf{x}) \le 0 \text{ for all } i \in \mathcal{A}_+(\mathbf{x}^*) \text{ and } \mathbf{x} \in B_\rho(\mathbf{x}^*). \tag{5.22}$$

Let $\bar{\mathbf{x}}$ be defined as follows:

$$\bar{x}_i = \begin{cases} 0 \text{ if } i \in \mathcal{A}_+(\mathbf{x}^*), \\ x_i \text{ otherwise.} \end{cases} \tag{5.23}$$

Since (5.22) holds, it follows that

$$\|\mathbf{x} - \bar{\mathbf{x}}\| \le \|\mathbf{d}^1(\mathbf{x})\| \tag{5.24}$$

for all $\mathbf{x} \in B_\rho(\mathbf{x}^*)$. Also, by (5.22), we have

$$[P(\bar{\mathbf{x}} - \mathbf{g}(\mathbf{x})) - \bar{\mathbf{x}}]_i = 0 \quad \text{and} \quad \mathbf{d}^1(\mathbf{x})_i = [P(\mathbf{x} - \mathbf{g}(\mathbf{x})) - \mathbf{x}]_i = -x_i$$

for all $i \in \mathcal{A}_+(\mathbf{x}^*)$, while

$$[P(\bar{\mathbf{x}} - \mathbf{g}(\mathbf{x})) - \bar{\mathbf{x}}]_i = \mathbf{d}^1(\mathbf{x})_i = [P(\mathbf{x} - \mathbf{g}(\mathbf{x})) - \mathbf{x}]_i$$

for $i \notin \mathcal{A}_+(\mathbf{x}^*)$. Hence, we have

$$\|P(\bar{\mathbf{x}} - \mathbf{g}(\mathbf{x})) - \bar{\mathbf{x}}\| \leq \|\mathbf{d}^1(\mathbf{x})\| \tag{5.25}$$

for all $\mathbf{x} \in B_\rho(\mathbf{x}^*)$. By the Lipschitz continuity of $\mathbf{g}$, (5.24), (5.25), and P3, it follows that

$$\begin{aligned} \|\mathbf{d}^1(\bar{\mathbf{x}})\| &= \|P(\bar{\mathbf{x}} - \mathbf{g}(\bar{\mathbf{x}})) - P(\bar{\mathbf{x}} - \mathbf{g}(\mathbf{x})) + P(\bar{\mathbf{x}} - \mathbf{g}(\mathbf{x})) - \bar{\mathbf{x}}\| \\ &\leq \lambda\|\bar{\mathbf{x}} - \mathbf{x}\| + \|\mathbf{d}^1(\mathbf{x})\| \\ &\leq (1+\lambda)\|\mathbf{d}^1(\mathbf{x})\| \end{aligned} \tag{5.26}$$

for all $\mathbf{x} \in B_\rho(\mathbf{x}^*)$. By P8, (5.21), and (5.26), we have

$$\|\bar{\mathbf{x}} - \mathbf{x}^*\| \leq \left(\frac{1+\lambda}{.5\gamma}\right)\|\mathbf{d}^1(\bar{\mathbf{x}})\| \leq \left(\frac{(1+\lambda)^2}{.5\gamma}\right)\|\mathbf{d}^1(\mathbf{x})\|. \tag{5.27}$$

Since $\|\mathbf{x} - \bar{\mathbf{x}}\|^2 + \|\bar{\mathbf{x}} - \mathbf{x}^*\|^2 = \|\mathbf{x} - \mathbf{x}^*\|^2$, the proof is completed by squaring and adding (5.27) and (5.24). □

We now show that the undecided index set $\mathcal{U}$ becomes empty as the iterates approach a stationary point, where the strong second-order sufficient optimality condition holds.

LEMMA 5.5. *Suppose f is twice-continuously differentiable, $\mathbf{x}^*$ is a stationary point of* (1.1) *satisfying the strong second-order sufficient optimality condition, and $\mathbf{x}_k$, $k = 0, 1, \ldots$, is an infinite sequence of feasible iterates for* (1.1) *converging to $\mathbf{x}^*$, $\mathbf{x}_k \neq \mathbf{x}^*$ for each k. If there exists a constant ξ such that*

$$\limsup_{k\to\infty} \frac{x_{ki}}{\|\mathbf{x}_k - \mathbf{x}^*\|^2} \leq \xi < \infty \tag{5.28}$$

for all $i \in \mathcal{A}_+(\mathbf{x}^*)$, then $\mathcal{U}(\mathbf{x}_k)$ is empty for k sufficiently large.

Proof. To prove that $\mathcal{U}(\mathbf{x})$ is empty, we must show that for each $i \in [1, n]$, one of the following inequalities is violated:

$$|g_i(\mathbf{x})| \geq \|\mathbf{d}^1(\mathbf{x})\|^\alpha \text{ or} \tag{5.29}$$

$$x_i \geq \|\mathbf{d}^1(\mathbf{x})\|^\beta. \tag{5.30}$$

By Lemma 5.4, there exists a constant c such that $\|\mathbf{x} - \mathbf{x}^*\| \leq c\|\mathbf{d}^1(\mathbf{x})\|$ for all $\mathbf{x}$ near $\mathbf{x}^*$. If $i \in \mathcal{A}_+(\mathbf{x}^*)$, then by (5.28), we have

$$\limsup_{k\to\infty} \frac{x_{ki}}{\|\mathbf{d}^1(\mathbf{x}_k)\|^\beta} \leq \limsup_{k\to\infty} \frac{\xi\|\mathbf{x}_k - \mathbf{x}^*\|^2}{\|\mathbf{d}^1(\mathbf{x}_k)\|^\beta} \leq \limsup_{k\to\infty} \xi c^2 \|\mathbf{d}^1(\mathbf{x}_k)\|^{2-\beta} = 0$$

since $\beta \in (1, 2)$. Hence, for each $i \in \mathcal{A}_+(\mathbf{x}^*)$, (5.30) is violated for k sufficiently large.

If $i \notin \mathcal{A}_+(\mathbf{x}^*)$, then $g_i(\mathbf{x}^*) = 0$. By Lemma 5.4, we have

$$\begin{aligned} \limsup_{k\to\infty} \frac{|g_i(\mathbf{x}_k)|}{\|\mathbf{d}^1(\mathbf{x}_k)\|^\alpha} &= \limsup_{k\to\infty} \frac{|g_i(\mathbf{x}_k) - g_i(\mathbf{x}^*)|}{\|\mathbf{d}^1(\mathbf{x}_k)\|^\alpha} \\ &\leq \limsup_{k\to\infty} \frac{\lambda\|\mathbf{x}_k - \mathbf{x}^*\|}{\|\mathbf{d}^1(\mathbf{x}_k)\|^\alpha} \\ &\leq \limsup_{k\to\infty} \lambda c \|\mathbf{d}^1(\mathbf{x}_k)\|^{1-\alpha} = 0, \end{aligned}$$

since $\alpha \in (0,1)$. Here, λ is a Lipschitz constant for $\mathbf{g}$ in a neighborhood of $\mathbf{x}^*$. Hence, (5.29) is violated if $i \notin \mathcal{A}_+(\mathbf{x}^*)$. ∎

Remark. If $i \in \mathcal{A}_+(\mathbf{x}^*)$ and the iterates $\mathbf{x}_k$ converge to a stationary point $\mathbf{x}^*$, then $g_i(\mathbf{x}_k)$ is bounded away from 0 for k sufficiently large. Since $\mathbf{d}^1(\mathbf{x}_k)$ tends to zero, the inequality $|g_i(\mathbf{x}_k)| \geq \|\mathbf{d}^1(\mathbf{x}_k)\|^\alpha$ is satisfied for k sufficiently large. Hence, if $\mathcal{U}(\mathbf{x}_k)$ is empty and $i \in \mathcal{A}_+(\mathbf{x}^*)$, then $x_{ki} < \|\mathbf{d}^1(\mathbf{x}_k)\|^\beta$ where $\beta \in (1,2)$. In other words, when $\mathcal{U}(\mathbf{x}_k)$ is empty, the components of $\mathbf{x}_k$ associated with strictly active indices $\mathcal{A}_+(\mathbf{x}^*)$ are going to zero faster than the error $\|\mathbf{d}^1(\mathbf{x}_k)\|$.

LEMMA 5.6. *Suppose f is twice-continuously differentiable, $\mathbf{x}^*$ is a stationary point of* (1.1) *satisfying the strong second-order sufficient optimality condition, and $\mathbf{x}_k$, $k = 0, 1, \ldots$, is an infinite sequence of feasible iterates for* (1.1) *converging to $\mathbf{x}^*$, $\mathbf{x}_k \neq \mathbf{x}^*$ for each k. If there exists a constant ξ such that*

$$\limsup_{k\to\infty} \frac{x_{ki}}{\|\mathbf{x}_k - \mathbf{x}^*\|^2} \leq \xi < \infty \tag{5.31}$$

for all $i \in \mathcal{A}_+(\mathbf{x}^*)$, then there exist $\mu^* > 0$ such that

$$\|\mathbf{g}_I(\mathbf{x}_k)\| \geq \mu^* \|\mathbf{d}^1(\mathbf{x}_k)\| \tag{5.32}$$

for k sufficiently large.

Proof. Choose $\rho > 0$, and let λ be the Lipschitz constant for ∇f in $B_\rho(\mathbf{x}^*)$. As in (5.23), let $\bar{\mathbf{x}}$ be defined by $\bar{x}_i = 0$ if $i \in \mathcal{A}_+(\mathbf{x}^*)$ and $\bar{x}_i = x_i$ otherwise. If $\mathbf{x}_k \in B_\rho(\mathbf{x}^*)$, we have

$$\begin{aligned} \|\mathbf{d}^1(\mathbf{x}_k)\| &\leq \|\mathbf{d}^1(\mathbf{x}_k) - \mathbf{d}^1(\mathbf{x}^*)\| \\ &\leq \|\mathbf{d}^1(\mathbf{x}_k) - \mathbf{d}^1(\bar{\mathbf{x}}_k)\| + \|\mathbf{d}^1(\bar{\mathbf{x}}_k) - \mathbf{d}^1(\mathbf{x}^*)\| \\ &\leq (2+\lambda)(\|\mathbf{x}_k - \bar{\mathbf{x}}_k\| + \|\bar{\mathbf{x}}_k - \mathbf{x}^*\|). \end{aligned} \tag{5.33}$$

Utilizing (5.31) gives

$$\begin{aligned} \|\bar{\mathbf{x}}_k - \mathbf{x}_k\| &\leq \sum_{i=1}^n |\bar{x}_{ki} - x_{ki}| \\ &= \sum_{i \in \mathcal{A}_+(\mathbf{x}^*)} x_{ki} \leq n\xi \|\mathbf{x}_k - \mathbf{x}^*\|^2 \\ &\leq n\xi \|\mathbf{x}_k - \mathbf{x}^*\|(\|\mathbf{x}_k - \bar{\mathbf{x}}_k\| + \|\bar{\mathbf{x}}_k - \mathbf{x}^*\|). \end{aligned}$$

Since $\mathbf{x}_k$ converges to $\mathbf{x}^*$, it follows that for any $\epsilon > 0$,

$$\|\bar{\mathbf{x}}_k - \mathbf{x}_k\| \leq \epsilon \|\bar{\mathbf{x}}_k - \mathbf{x}^*\| \tag{5.34}$$

when k is sufficiently large. Combining (5.33) and (5.34), there exists a constant $c > 0$ such that

$$\|\mathbf{d}^1(\mathbf{x}_k)\| \leq c \|\bar{\mathbf{x}}_k - \mathbf{x}^*\| \tag{5.35}$$

for k sufficiently large.

Let k be chosen large enough that

$$\|\mathbf{x}_k - \mathbf{x}^*\| < \min\{x_i^* : i \in \mathcal{I}(\mathbf{x}^*)\}. \tag{5.36}$$

Suppose, in this case, that $i \in \mathcal{A}(\mathbf{x}_k)$. If $x_i^* > 0$, then $\|\mathbf{x}_k - \mathbf{x}^*\| \geq x_i^*$, which contradicts (5.36). Hence, $\bar{x}_{ki} = x_i^* = 0$. Moreover, if $i \in \mathcal{A}_+(\mathbf{x}^*)$, then by the definition (5.23), $\bar{x}_{ki} = x_i^* = 0$. In summary,

$$\begin{cases} \bar{x}_{ki} = x_i^* = 0 & \text{for each } i \in \mathcal{A}(\mathbf{x}_k) \cup \mathcal{A}_+(\mathbf{x}^*), \\ g_i(\mathbf{x}^*) = 0 & \text{for each } i \in \mathcal{A}_+(\mathbf{x}^*)^c, \end{cases} \tag{5.37}$$

where $\mathcal{A}_+(\mathbf{x}^*)^c$ is the complement of $\mathcal{A}_+(\mathbf{x}^*)$. Define $\mathcal{Z} = \mathcal{A}(\mathbf{x}_k)^c \cap \mathbf{A}_+(\mathbf{x}^*)^c$.

By the strong second-order sufficient optimality condition and for $\mathbf{x}$ near $\mathbf{x}^*$, we have

$$\begin{aligned} \frac{\gamma}{2}\|\bar{\mathbf{x}} - \mathbf{x}^*\|^2 &\leq [\bar{\mathbf{x}} - \mathbf{x}^*]^\mathsf{T} \int_0^1 \nabla^2 f(\mathbf{x}^* + t(\bar{\mathbf{x}} - \mathbf{x}^*))dt \;\; [\bar{\mathbf{x}} - \mathbf{x}^*] \\ &= (\bar{\mathbf{x}} - \mathbf{x}^*)^\mathsf{T}(\mathbf{g}(\bar{\mathbf{x}}) - \mathbf{g}(\mathbf{x}^*)). \end{aligned} \tag{5.38}$$

We substitute $\mathbf{x} = \mathbf{x}_k$ in (5.38) and utilize (5.37) to obtain

$$\begin{aligned} (\bar{\mathbf{x}}_k - \mathbf{x}^*)^\mathsf{T}(\mathbf{g}(\bar{\mathbf{x}}_k) - \mathbf{g}(\mathbf{x}^*)) &= \sum_{i=1}^n (\bar{x}_{ki} - x_i^*)(g_i(\bar{\mathbf{x}}_k) - g_i(\mathbf{x}^*)) \\ &= \sum_{i \in \mathcal{Z}} (\bar{x}_{ki} - x_i^*) g_i(\bar{\mathbf{x}}_k) \\ &\leq \|\bar{\mathbf{x}}_k - \mathbf{x}^*\| \left(\sum_{i \in \mathcal{I}(\mathbf{x}_k)} g_i(\bar{\mathbf{x}}_k)^2 \right)^{1/2}, \end{aligned} \tag{5.39}$$

since $\mathcal{Z} \subset \mathcal{A}(\mathbf{x}_k)^c = \mathcal{I}(\mathbf{x}_k)$. Exploiting the Lipschitz continuity of ∇f, (5.39) gives

$$(\bar{\mathbf{x}}_k - \mathbf{x}^*)^\mathsf{T}(\mathbf{g}(\bar{\mathbf{x}}_k) - \mathbf{g}(\mathbf{x}^*)) \leq \|\bar{\mathbf{x}}_k - \mathbf{x}^*\|(\|\mathbf{g}_I(\mathbf{x}_k)\| + \lambda\|\bar{\mathbf{x}}_k - \mathbf{x}_k\|). \tag{5.40}$$

Combining (5.34), (5.38), and (5.40), we conclude that for k sufficiently large,

$$\frac{\gamma}{4}\|\bar{\mathbf{x}}_k - \mathbf{x}^*\| \leq \|\mathbf{g}_I(\mathbf{x}_k)\|. \tag{5.41}$$

Combining (5.35) and (5.41), the proof is complete. ∎

Remark. If $\mathbf{x}_k$ is a sequence converging to a nondegenerate stationary point $\mathbf{x}^*$, then (5.32) holds with $\mu^* = 1$, without assuming either the strong second-order sufficient optimality condition or (5.31)—see Theorem 5.1. In Lemma 5.6, the optimization problem could be degenerate.

We now show that after a finite number of iterations, the ASA will perform only the UA with a fixed active constraint set.

THEOREM 5.7. *If f is twice-continuously differentiable and the iterates $\mathbf{x}_k$ generated by the ASA with $\epsilon = 0$ converge to a stationary point $\mathbf{x}^*$ satisfying the strong second-order sufficient optimality condition, then after a finite number of iterations, the ASA performs only the UA without restarts.*

Proof. By Lemma 5.2, the hypotheses (5.28) and (5.31) of Lemmas 5.5 and 5.6 are satisfied. Hence, for k sufficiently large, the undecided set $\mathcal{U}(\mathbf{x}_k)$ is empty and the lower bound (5.32) holds. In step 1a, if $\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu\|\mathbf{d}^1(\mathbf{x}_k)\|$, then μ is multiplied by the factor $\rho < 1$. When $\mu < \mu^*$, Lemma 5.6 implies that $\|\mathbf{g}_I(\mathbf{x}_k)\| \geq \mu\|\mathbf{d}^1(\mathbf{x}_k)\|$. Hence, step 1a of the ASA branches to step 2, while step 2 cannot branch to step 1 since the condition $\|\mathbf{g}_I(\mathbf{x}_k)\| < \mu\|\mathbf{d}^1(\mathbf{x}_k)\|$ is never satisfied in step 2a and $\mathcal{U}(\mathbf{x}_k)$

is empty in step 2b for k sufficiently large. Since the UA only adds constraints, we conclude that after a finite number of iterations, the active set does not change. ∎

Remark. If f is a strongly convex quadratic function, then by Corollary 4.2, the iterates $\mathbf{x}_k$ converge to the global minimizer $\mathbf{x}^*$. If the UA is based on the conjugate gradient method for which there is finite convergence when applied to a convex quadratic, it follows from Theorem 5.7 that the ASA converges in a finite number of iterations.

We now give the proof of Corollary 4.2; that is, when f is strongly convex and twice-continuously differentiable on $\mathcal{B}$, and assumption A3 of Theorem 4.1 is satisfied, then the entire sequence of iterates generated by the ASA converges to the global minimizer $\mathbf{x}^*$. Note that the assumptions of Corollary 4.2 are weaker than those of Corollary 2.3 (global convergence of the NGPA) since Corollary 4.2 requires only that $f_k^r \le f_k^{\max}$ infinitely often in the NGPA.

Proof. For a strongly convex function, A1 and A2 always hold. Since all the assumptions of Theorem 4.1 are satisfied, there exists a subsequence $\mathbf{x}_{k_j}$, $j = 1, 2, \ldots$, of the iterates such that

$$\lim_{j\to\infty} \|\mathbf{d}^1(\mathbf{x}_{k_j})\| = 0.$$

Since the UA is monotone and since the NGPA satisfies (2.12) and (2.13), it follows from the strong convexity of f that the $\mathbf{x}_{k_j}$ are contained in a bounded set. Since $\mathbf{d}^1(\cdot)$ is continuous, there exists a subsequence, also denoted $\mathbf{x}_{k_j}$, converging to a limit $\mathbf{x}^*$ with $\mathbf{d}^1(\mathbf{x}^*) = \mathbf{0}$. Since the unique stationary point of a strongly convex function is its global minimizer, $\mathbf{x}^*$ is the global solution of (1.1).

Case A. There exists an infinite subsequence, also denoted $\{\mathbf{x}_{k_j}\}$, with the property that $\mathbf{x}_{k_j+1}$ is generated by the UA.

In this case, we are done since the UA is monotone and the inequality

$$f(\mathbf{x}_k) \le f(\mathbf{x}_{k_j}) \tag{5.42}$$

holds for all $k \ge k_j$ (see (2.12) and (2.13)). Since $\mathbf{x}_{k_j}$ converges to $\mathbf{x}^*$, it follows that $f(\mathbf{x}_{k_j})$ converges to $f(\mathbf{x}^*)$, and hence, by (5.42) and (2.32), the entire sequence converges to $\mathbf{x}^*$.

Case B. There exists an infinite subsequence, also denoted $\{\mathbf{x}_{k_j}\}$, with the property that $\mathbf{x}_{k_j+1}$ is generated by the NGPA.

Either

$$\limsup_{j\to\infty} \frac{(\mathbf{x}_{k_j})_i}{\|\mathbf{x}_{k_j} - \mathbf{x}^*\|^2} < \infty \quad \text{for all } i \in \mathcal{A}_+(\mathbf{x}^*) \tag{5.43}$$

holds or (5.43) is violated. By the analysis given in Case 3 of the proof of Lemma 5.2, when (5.43) is violated, (5.13) holds, from which it follows that for j sufficiently large,

$$\mathbf{x}_{k_j+1,i} = 0 \quad \text{for all } i \in \mathcal{A}_+(\mathbf{x}^*). \tag{5.44}$$

Hence, either the sequence $\mathbf{x}_{k_j}$ satisfies (5.43) or the sequence $\mathbf{x}_{k_j+1}$ satisfies (5.44). In this latter case, it follows from (5.17) that

$$f(\mathbf{x}_{k_j+1}) \le f(\mathbf{x}_{k_j}).$$

Since $f(\mathbf{x}_{k_j})$ converges to $f(\mathbf{x}^*)$, we conclude that $f(\mathbf{x}_{k_j+1})$ converges to $f(\mathbf{x}^*)$, and $\mathbf{x}_{k_j+1}$ converges to $\mathbf{x}^*$.

In either case (5.43) or (5.44), there exists a sequence K_j (either $K_j = k_j$ or $K_j = k_j + 1$) with the property that $\mathbf{x}_{K_j}$ converges to $\mathbf{x}^*$ and

$$\limsup_{j\to\infty} \frac{(\mathbf{x}_{K_j})_i}{\|\mathbf{x}_{K_j} - \mathbf{x}^*\|^2} < \infty \quad \text{for all } i \in \mathcal{A}_+(\mathbf{x}^*).$$

By Lemma 5.5, $\mathcal{U}(\mathbf{x}_{K_j})$ is empty for j sufficiently large. By Lemma 5.6, there exists $\mu^* > 0$ such that

$$\|\mathbf{g}_I(\mathbf{x}_{K_j})\| \geq \mu^* \|\mathbf{d}^1(\mathbf{x}_{K_j})\|$$

for j sufficiently large. As in the proof of Theorem 5.7, at iteration K_j for j sufficiently large, the ASA jumps from step 1 to the UA in step 2. Hence, for j sufficiently large, $\mathbf{x}_{K_j+1}$ is generated by the UA, which implies that Case A holds. □

6. Numerical experiments. This section compares the CPU time performance of the ASA, implemented using the nonlinear conjugate gradient code CG_DESCENT for the UA and the CBB method (see the appendix) for the NGPA, to the performance of the following codes:

- L-BFGS-B [18, 84]: The limited memory quasi-Newton method of Zhu, Byrd, and Nocedal (ACM algorithm 778).
- SPG2 version 2.1 [10, 11]: The nonmonotone spectral projected gradient method of Birgin, Martínez, and Raydan (ACM algorithm 813).
- GENCAN [9]: The monotone active set method with spectral projected gradients developed by Birgin and Martínez.
- TRON version 1.2 [63]: A Newton trust region method with incomplete Cholesky preconditioning developed by Lin and Moré.

A detailed description of our implementation of the ASA is given in the appendix.

L-BFGS-B was downloaded from Jorge Nocedal's Web page (http://www.ece.northwestern.edu/∼nocedal/lbfgsb.html); TRON was downloaded from Jorge Moré's Web page (http://www-unix.mcs.anl.gov/∼more/tron/); and SPG2 and GENCAN were downloaded on June 28, 2005, from the TANGO Web page maintained by Ernesto Birgin (http://www.ime.usp.br/∼egbirgin/tango/downloads.php). All codes are written in Fortran and compiled with f77 (default compiler settings) on a Sun workstation. The stopping condition was

$$\|P(\mathbf{x} - \mathbf{g}(\mathbf{x})) - \mathbf{x}\|_\infty \leq 10^{-6},$$

where $\|\cdot\|_\infty$ denotes the sup-norm of a vector. In running any of these codes, default values were used for all parameters. In the NGPA, we chose the following parameter values:

$$\alpha_{\min} = 10^{-20}, \quad \alpha_{\max} = 10^{+20}, \quad \eta = .5, \quad \delta = 10^{-4}, \quad M = 8.$$

Here M is the memory used to evaluate $f_k^{\max}$ (see (2.3)). In the ASA the parameter values were as follows:

$$\mu = .1, \quad \rho = .5, \quad n_1 = 2, \quad n_2 = 1.$$

In the CBB method (see the appendix), the parameter values were the following:

$$\theta = .975, \quad L = 3, \quad A = 40, \quad m = 4, \quad \gamma_1 = M/L, \quad \gamma_2 = A/M.$$

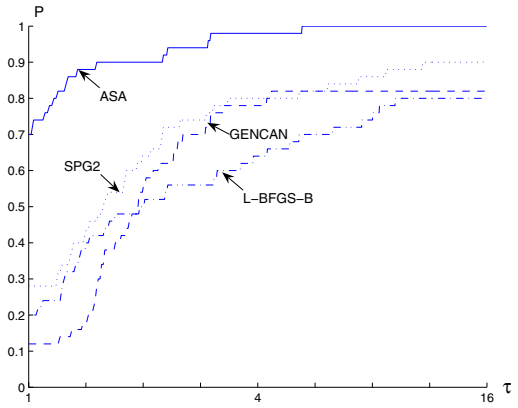

FIG. 6.1. *Performance profiles, CPU time metric, 50 CUTEr test problems, gradient-based methods.*

The separation parameter Δ in condition R4 of the appendix was the natural separation between floating point numbers. That is, R4 was satisfied when the floating point version of f_{k+1} was strictly less than the floating point version of $f_k^{\min}$.

The test set consisted of all 50 box constrained problems in the CUTEr library [13] with dimensions between 50 and 15,625, and all 23 box constrained problems in the MINPACK-2 library [1] with dimension 2500. TRON is somewhat different from the other codes since it employs Hessian information and an incomplete Cholesky preconditioner, while the codes ASA, L-BFGS-B, SPG2, and GENCAN utilize only gradient information. When we compare our code to TRON, we use the same Lin–Moré preconditioner [62] used by TRON for our unconstrained algorithm. The preconditioned ASA code is called P-ASA. Since TRON is targeted to large-sparse problems, we compare our code to TRON using the 23 MINPACK-2 problems and the 42 sparsest CUTEr problems (the number of nonzeros in the Hessian was at most 1/5 the total number of entries). The codes L-BFGS-B, SPG2, and GENCAN were implemented for the CUTEr test problems, while ASA and TRON were implemented for both test sets CUTEr and MINPACK-2.

The CPU time in seconds and the number of iterations, function evaluations, gradient evaluations, and Hessian evaluations for each of the methods are posted at the following Web site: http://www.math.ufl.edu/∼hager/papers/CG. In running the numerical experiments, we checked whether different codes converged to different local minimizers; when comparing the codes, we restricted ourselves to test problems in which all codes converged to the same local minimizer, and where the running time of the fastest code exceeded .01 seconds. The numerical results are now analyzed.

The performance of the algorithms, relative to CPU time, was evaluated using the performance profiles of Dolan and Moré [34]. That is, for each method, we plot the fraction P of problems for which the method is within a factor τ of the best time. In Figure 6.1, we compare the performance of the four codes ASA, L-BFGS-B, SPG2, and GENCAN using the 50 CUTEr test problems. The left side of the figure gives the percentage of the test problems for which a method is the fastest; the right side gives the percentage of the test problems that were successfully solved by each of the methods. The top curve is the method that solved the most problems in a time that was within a factor τ of the best time. Since the top curve in Figure 6.1 corresponds

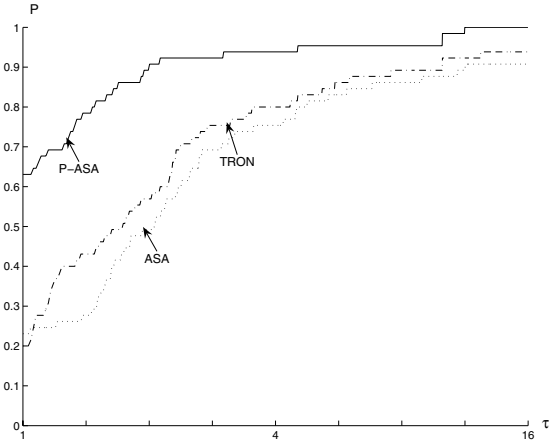

FIG. 6.2. *Performance profiles, CPU time metric,* 42 *sparsest CUTEr problems,* 23 *MINPACK-2 problems,* $\epsilon = 10^{-6}$.

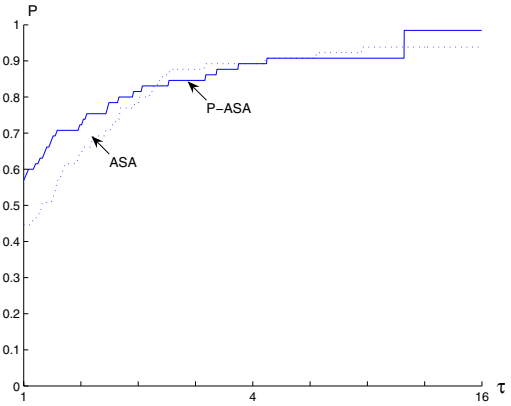

FIG. 6.3. *Performance profiles, CPU time metric,* $\epsilon = 10^{-2}\|\mathbf{d}^1(\mathbf{x}_0)\|_\infty$.

to the ASA, this algorithm is clearly fastest for this set of 50 test problems with dimensions ranging from 50 to 15,625. The relative difference in performance between the ASA and the competing methods seen in Figure 6.1 is greater than the relative difference in performance between CG_DESCENT and the competing methods, as seen in the figures given in [55, 57]. Hence, both the gradient projection algorithm and the conjugate gradient algorithm are contributing to the better performance of the ASA.

In Figure 6.2 we compare the performance of TRON to P-ASA and ASA for the 42 sparsest CUTEr test problems and the 23 MINPACK-2 problems. Observe that P-ASA has the top performance, and that ASA, which utilizes only the gradient, performs almost as well as the Hessian-based code TRON. The number of conjugate gradient iterations performed by the P-ASA code is much less than the number of conjugate gradient iterations performed by the ASA code. Finally, in Figure 6.3 we

compare the performance of P-ASA to ASA for the relaxed convergence tolerance $\epsilon = 10^{-2}\|\mathbf{d}^1(\mathbf{x}_0)\|_\infty$. Based on Figures 6.2 and 6.3, the preconditioned ASA scheme is more efficient than unconditioned ASA for the more stringent stopping criterion, while the unconditioned and preconditioned schemes are equally effective for a more relaxed stopping criterion. Although the performance profile for ASA is beneath 1 in Figure 6.2, it reaches 1 as τ increases—there are some problems in which P-ASA is more than 16 times faster than ASA. Due to these difficult problems, the ASA profile is still beneath 1 for $\tau = 16$.

When we solve an optimization problem, the solution time consists of two parts, as follows:

T1. The time associated with the evaluation of the function or its gradient or its Hessian.

T2. The remaining time, which is often dominated by the time used in the linear algebra.

The CPU time performance profile measures a mixture of T1 and T2 for a set of test problems. In some applications, T1 (the evaluation time) may dominate. In order to assess how the algorithms may perform in the limit, when T2 is negligible compared to T1, we could ignore T2 and compare the algorithms based on T1. In the next set of experiments, we explore how the algorithms perform in the limit, as T1 becomes infinitely large relative to T2.

Typically, the time to evaluate the gradient of a function is greater than the time to evaluate the function itself. Also, the time to evaluate the Hessian is greater than the time to evaluate the gradient. If the time to evaluate the function is 1, then the average time to evaluate the gradient and Hessian for the CUTEr bound constrained test set is as follows:

$$\text{function } = 1, \quad \text{gradient } = 2.6, \quad \text{Hessian } = 21.0.$$

Similarly, for the MINPACK-2 test set, the relative evaluation times are

$$\text{function } = 1, \quad \text{gradient } = 2.0, \quad \text{Hessian } = 40.5$$

on average.

For each method and for each test problem, we compute an "evaluation time" where the time for a function evaluation is 1, the time for a gradient evaluation is either 2.6 (CUTEr) or 2.0 (MINPACK-2), and the time for a Hessian evaluation is either 21.0 (CUTEr) or 40.5 (MINPACK-2). In Figure 6.4 we compare the performance of gradient-based methods, and in Figure 6.5 we compare the performance of the gradient-based ASA and the method which exploits the Hessian (P-ASA or TRON).

In Figure 6.4 we see that for the evaluation metric and τ near 1, L-BFGS-B performs better than ASA, but as τ increases, ASA dominates L-BFGS-B. In other words, in the evaluation metric, there are more problems in which L-BFGS-B is faster than the other methods; however, ASA is not much slower than L-BFGS-B. When τ reaches 1.5, ASA starts to dominate L-BFGS-B.

In Figure 6.5 we see that P-ASA dominates TRON in the evaluation metric. Hence, even though TRON uses far fewer function evaluations, it uses many more Hessian evaluations. Since the time to evaluate the Hessian is much greater than the time to evaluate the function, P-ASA has better performance. In summary, by neglecting the time associated with the linear algebra, the relative gap between P-ASA and TRON decreases, while the relative gap between TRON and ASA increases, as seen in Figure 6.5. Nonetheless, in the evaluation metric, the performance profile for P-ASA is still above the profile for TRON.

7. Conclusions. We have presented a new ASA for solving box constrained optimization problems. The algorithm consists of a nonmonotone gradient projection phase and an unconstrained optimization phase. Rules are given for deciding when to branch from one phase to the other. The branching criteria are based on whether the set of undecided indices is empty or the active set subproblem is solved with sufficient accuracy. We show that for a nondegenerate stationary point, the algorithm eventually reduces to unconstrained optimization without restarts. The analogous result for a degenerate stationary point is established under the strong second-order sufficient optimality condition.

For an implementation of the ASA which uses the CBB method [30] for the nonmonotone gradient projection and which uses CG_DESCENT [54, 55, 56, 57] for unconstrained optimization, we obtained higher CPU time performance profiles than

those of L-BFGS-B, SPG2, GENCAN, and TRON for a test set consisting of all 50 CUTEr [13] box constrained problems with dimension greater than 50, and all 23 MINPACK-2 [1] box constrained problems.

Appendix. An implementation of the ASA. For the numerical results in section 6, our choice for the UA is the conjugate gradient algorithm CG_DESCENT [54, 55, 57, 56]. When an iterate lands outside the feasible set, we may increase the size of the active set using an approach similar to that in [9]. Roughly, we perform an approximate line search for the function

$$\phi(\alpha) = f(P(\mathbf{x}_k + \alpha \mathbf{d}_k))$$

along the current search direction $\mathbf{d}_k$, and any components of $\mathbf{x}_{k+1} = P(\mathbf{x}_k + \alpha_k \mathbf{d}_k)$ which reach the boundary are added to the current active set.

The initial stepsize $\bar{\alpha}_k$ in the NGPA is generated using the CBB method [30]. In the remainder of this section, we explain in detail the initial stepsize computation and choice for the reference function value f_k^r in the NGPA (see [82] for preliminary numerical results based on a closely related initial stepsize and reference function value). We show that these choices satisfy the hypotheses of Theorem 2.2.

The BB stepsize [2] is given by

$$\overline{\alpha}_{k+1}^{BB} = \frac{\mathbf{s}_k^{\mathsf{T}} \mathbf{s}_k}{\mathbf{s}_k^{\mathsf{T}} \mathbf{y}_k}, \tag{A.1}$$

where $\mathbf{s}_k = \mathbf{x}_{k+1} - \mathbf{x}_k$ and $\mathbf{y}_k = \mathbf{g}_{k+1} - \mathbf{g}_k$. An attractive feature of the BB stepsize is that for unconstrained optimization and without a line search, linear convergence is achieved [30] for a starting guess in a neighborhood of the local minimizer with a positive definite Hessian. Moreover, if the same BB stepsize is repeated for several iterations, then even faster convergence is often achieved (see [30]). We refer to schemes that employ the same BB stepsize for several iterations as cyclic BB (CBB) schemes. From an asymptotic perspective, either BB or CBB schemes are inferior to conjugate gradient schemes, for which the convergence rate can be superlinear. On the other hand, for a bound constrained optimization problem, where the active constraints at an optimal solution are unknown, the asymptotic convergence rate is irrelevant until the active constraints are identified. A nonmonotone BB or CBB iteration yields an efficient strategy for identifying active constraints.

When possible, the initial stepsize $\overline{\alpha}_k$ is given by the CBB formula

$$\overline{\alpha}_{k+j} = \overline{\alpha}_k^{BB} \quad \text{for } j = 0, \ldots, m-1,$$

where the BB step appears in (A.1) and m is the number of times the BB step is reused. When $\overline{\alpha}_k^{BB} \notin [\alpha_{\min}, \alpha_{\max}]$, we project it on the interval $[\alpha_{\min}, \alpha_{\max}]$.

We now provide a more detailed statement of our algorithm for computing the initial stepsize. The integer j counts the number of times the current BB step has been reused, while the parameter m is the CBB memory (the maximum number of times the BB step will be reused).

Initial stepsize.

I0. If $k = 0$, choose $\overline{\alpha}_0 \in [\alpha_{\min}, \alpha_{\max}]$ and a parameter $\theta < 1$ near 1; set $j = 0$ and $flag = 1$. If $k > 0$, set $flag = 0$.
I1. If $0 < |d_{ki}| < \bar{\alpha}_k |g_{ki}|$ for some i, then set $flag = 1$.
I2. If $\alpha_k = 1$ in the NGPA, then set $j = j + 1$.
I3. If $\alpha_k < 1$ in the NGPA, then set $flag = 1$.

I4. If $j \geq m$ or $flag = 1$ or $\mathbf{s}_k^T\mathbf{y}_k/(\|\mathbf{s}_k\|\|\mathbf{y}_k\|) \geq \theta$, then
  a. If $\mathbf{s}_k^T\mathbf{y}_k \leq 0$, then
    1. If $j \geq 1.5m$, then set $t = \min\{\|\mathbf{x}_k\|_\infty, 1\}/\|\mathbf{d}^1(\mathbf{x}_k)\|_\infty$, $\overline{\alpha}_{k+1} = \min\{\alpha_{\max}, \max[t, \alpha_k]\}$, and $j = 0$.
    2. Else set $\overline{\alpha}_{k+1} = \overline{\alpha}_k$.
  b. Else set $\overline{\alpha}_{k+1} = \min\{\alpha_{\max}, \max[\alpha_{\min}, \mathbf{s}_k^T\mathbf{s}_k/\mathbf{s}_k^T\mathbf{y}_k]\}$ and $j = 0$.

Since this procedure always generates an initial stepsize $\overline{\alpha}_k \in [\alpha_{\min}, \alpha_{\max}]$, it complies with the requirement in step 1 of the NGPA. If the original BB step is truncated (see I1), or an Armijo line search is performed (see I3), or the cycle number j reaches m (see I4), or $\mathbf{s}_k^T\mathbf{y}_k/(\|\mathbf{s}_k\|\|\mathbf{y}_k\|)$ is close to 1 (see I4), then we try to compute a new BB step. The BB stepsize computation appears in step I4b. One motivation for computing a new BB step when $\mathbf{s}_k^T\mathbf{y}_k/(\|\mathbf{s}_k\|\|\mathbf{y}_k\|)$ is close to 1 is given in [30]; when f is a quadratic, this condition is satisfied when the step $\mathbf{s}_k$ is close to an eigenvector of the Hessian. When $\mathbf{s}_k^T\mathbf{y}_k \leq 0$ (see I4a), the function is not convex on the line segment connecting $\mathbf{x}_k$ and $\mathbf{x}_{k+1}$, and a relatively large stepsize is used in the next iteration. A rationale for the step taken in this case appears in [57].

Now consider the reference function value f_k^r. Let f_k denote $f(\mathbf{x}_k)$. In the algorithm which follows, the integer a counts the number of consecutive iterations that $\alpha_k = 1$ in the NGPA (and the Armijo line search in step 4 is skipped). The integer l counts the number of iterations since the function value is strictly decreased by an amount $\Delta > 0$.

Reference function value.

R0. If $k = 0$, choose parameters $A > L > 0$, $\gamma_1 > 1$, $\gamma_2 > 1$, and $\Delta > 0$; initialize $a = l = 0$ and $f_0^{\min} = f_0^{\max\min} = f_0^r = f_{-1}^r = f_0$.

R1. Update f_k^r as follows:
  a. If $l = L$, then set $l = 0$ and
$$f_k^r = \begin{cases} f_k^{\max\min} & \text{if } \frac{f_k^{\max} - f_k^{\min}}{f_k^{\max\min} - f_k^{\min}} \geq \gamma_1, \\ f_k^{\max} & \text{otherwise.} \end{cases}$$
  b. Else if $a > A$, then set
$$f_k^r = \begin{cases} f_k^{\max} & \text{if } f_k^{\max} > f_k \text{ and } \frac{f_{k-1}^r - f_k}{f_k^{\max} - f_k} \geq \gamma_2, \\ f_{k-1}^r & \text{otherwise.} \end{cases}$$
  c. Otherwise, $f_k^r = f_{k-1}^r$.

R2. Set f_R as follows in step 3 of the NGPA:
  a. If $j = 0$ (first iterate in a CBB cycle), then $f_R = f_k^r$.
  b. If $j > 0$, then $f_R = \min\{f_k^{\max}, f_k^r\}$.

  If $\alpha_k < 1$ in the NGPA, then set $a = 0$.

R3. If $\alpha_k = 1$ in the NGPA, then set $a = a + 1$.

R4. If $f_{k+1} \leq f_k^{\min} - \Delta$, then set $f_{k+1}^{\max\min} = f_{k+1}^{\min} = f_{k+1}$ and $l = 0$; otherwise, put $l = l + 1$, $f_{k+1}^{\min} = f_k^{\min}$, and $f_{k+1}^{\max\min} = \max\{f_k^{\max\min}, f_{k+1}\}$.

The variable $f_k^{\max}$, defined in (2.3), stores the maximum of recent function values. The variable $f_k^{\min}$ stores the minimum function value to within the tolerance Δ. The variable $f_k^{\max\min}$ stores the maximum function value since the last new minimum was recorded in $f_k^{\min}$. More explanations concerning the choice of the reference function value are given in [30, 31]. Now, let us check that the choice for f_k^r given above satisfies the requirements in step 2 of the NGPA.

Proof that $f_k \leq f_k^r$. In R1, we set

(i) $f_k^r = f_k^{\max\min}$ or
(ii) $f_k^r = f_k^{\max}$ or
(iii) $f_k^r = f_{k-1}^r$.

By R4, $f_k^{\max\min} \geq f_k$. In case (ii), $f_k^{\max} \geq f_k$ by the definition of $f_k^{\max}$. In steps 3 and 4 of the NGPA, we have $f_k \leq f_R \leq f_{k-1}^r$. Hence, in each of the cases (i)–(iii), we have $f_k \leq f_k^r$. □

Proof that $f_k^r \leq \max\{f_{k-1}^r, f_k^{\max}\}$. In R1a, f_k^r is equal to either $f_k^{\max}$ or $f_k^{\max\min}$. Since $\gamma_1 > 1$, we set only $f_k^r = f_k^{\max\min}$ when $f_k^{\max\min} \leq f_k^{\max}$. Hence, in R1a, $f_k^r \leq f_k^{\max}$. In R1b, f_k^r is equal to either $f_k^{\max}$ or f_{k-1}^r. Since $\gamma_2 > 1$, we set only $f_k^r = f_{k-1}^r$ when $f_{k-1}^r \geq f_k^{\max}$. Hence, in R1b, $f_k^r \leq f_k^{\max}$. In R1c, we set $f_k^r = f_{k-1}^r$. Combining these observations, $f_k^r \leq \max\{f_{k-1}^r, f_k^{\max}\}$ in R1a–R1c. □

Proof that $f_k^r \leq f_k^{\max}$ *infinitely often.* The condition $f_{k+1} \leq f_k^{\min} - \Delta$ in R4 is satisfied only a finite number of times when f is bounded from below. Thus for k sufficiently large, f_k^r is updated in R1a every L iterations. In this case, since $\gamma_1 > 1$, $f_k^r = f_k^{\max\min}$ only when $f_k^{\max\min} \leq f_k^{\max}$, which implies that $f_k^r \leq f_k^{\max}$. Hence, for large k, $f_k^r \leq f_k^{\max}$ every L iterations. □

Acknowledgments. Constructive comments by the referees are gratefully acknowledged. In particular, the idea of splitting the local convergence analysis into the nondegenerate case (where there is no need to assume the strong second-order sufficient optimality condition), followed by the degenerate case, was suggested by one of the referees.

JORDAN-ALGEBRAIC APPROACH TO CONVEXITY THEOREMS FOR QUADRATIC MAPPINGS*

L. FAYBUSOVICH†

Abstract. We describe a Jordan-algebraic version of results related to convexity of images of quadratic mappings as well as related results on exactness of symmetric relaxations of certain classes of nonconvex optimization problems. The exactness of relaxations is proved based on rank estimates. Our approach provides a unifying viewpoint on a large number of classical results related to cones of Hermitian matrices over real and complex numbers. We describe (apparently new) results related to cones of Hermitian matrices with quaternion entries and to the exceptional 27-dimensional Euclidean Jordan algebra.

Key words. Jordan-algebraic technique, symmetric relaxations, convexity theorems

AMS subject classifications. 90C26, 52A41

DOI. 10.1137/050635560

1. Introduction. Starting with [F1, F2], the Jordan-algebraic technique proved to be useful as a unifying tool for the description and analysis of interior-point algorithms. In the present paper we use this technique for similar goals, but with the difference being that we use it to study the convexity images of quadratic mappings between finite-dimensional vector spaces. This circle of problems has numerous connections with optimization theory (see, e.g., [Pol] and the references therein for a discussion of various connections of this type). In particular, questions such as under what assumptions are semidefinite relaxations of quadratically constrained quadratic programming problems exact (see, e.g., [YZ] and the references therein) or when can one omit rank constraints in semidefinite programming problems (see [BM] and the references therein) are important for modern optimization theory. Another very interesting connection is with the famous S-lemma (see [BN, pp. 300–314]). Our approach is modeled on the work of Barvinok [B2, B3, B1] but is developed within a more general framework of Jordan algebras. The paper is organized as follows. In section 2 we briefly describe Jordan-algebraic concepts related to our discussion. In section 3 we give a complete description of the facial structure of a symmetric cone in the form somewhat different from one in [FK]. Section 4 is of central importance and provides estimates on the rank of a feasible point in the intersection of an affine subspace and a symmetric cone. Our results are a direct (but not an immediate!) generalization of the results of Barvinok, who considered the cones of Hermitian matrices over $\mathbf{R}$ and $\mathbf{C}$. In section 5 we derive from rank estimates some convexity results and results about exact convex relaxations of generally nonconvex optimization problems. It is done within the general Jordan-algebraic context. The central object here is the manifold of primitive idempotents in a simple Euclidean Jordan algebra (or its conic hull). A very general Jordan-algebraic version of the well-known S-lemma is given. In section 6 we interpret the results of section 5 for concrete symmetric cones. The

cases of symmetric cones corresponding to algebras of Hermitian matrices over **H** and exceptional 27-dimensional algebra seem to lead to new results.

Another type of convexity result (a Jordan-algebraic version of the Horn–Schur theorem) was obtained in [LKF].

2. Jordan-algebraic concepts. We stick to the notation of an excellent book [FK]. We do not attempt to describe the Jordan-algebraic language here but instead provide detailed references to [FK]. Throughout this paper, we use the following notation:

- V is a simple Euclidean Jordan algebra;
- $\mathrm{rank}(V)$ stands for the rank of V;
- $x \circ y$ is the Jordan algebraic multiplication for $x, y \in V$;
- $\langle x, y\rangle = \mathrm{tr}(x \circ y)$ is the canonical scalar product in V; here tr is the trace operator on V;
- Ω is the cone of invertible squares in V;
- $\bar{\Omega}$ is the closure of Ω in V;
- an element $f \in V$ such that $f^2 = f$ and $\mathrm{tr}(f) = 1$ is called a primitive idempotent in V;
- the set $\mathcal{T}(V)$ of primitive idempotents is a smooth compact connected submanifold in V;
- given $x \in V$, we denote by $L(x)$ the corresponding multiplication operator on V, i.e.,

$$L(x)y = x \circ y, \quad y \in V;$$

- given $x \in V$, we denote by $P(x)$ the so-called quadratic representation of x, i.e.,

$$P(x) = 2L(x)^2 - L(x^2).$$

Given $x \in V$, there exist idempotents $f_1, \dots, f_k$ in V such that $f_i \circ f_j = 0$ for $i \neq j$ and such that $f_1 + f_2 + \cdots + f_k = e$, and distinct real numbers $\lambda_1, \dots, \lambda_k$ with the following property:

$$x = \sum_{i=1}^{k} \lambda_i f_i. \tag{1}$$

The numbers λ_i and idempotents f_i are uniquely defined by x (see Theorem III.1.1 in [FK]).

The representation (1) is called the spectral decomposition of x. Within the context of this paper the notion of the rank of x is very important. By definition,

$$\mathrm{rank}(x) = \sum_{i:\lambda_i \neq 0} \mathrm{tr}(f_i). \tag{2}$$

Given $x \in V$, the operator $L(x)$ is symmetric with respect to the canonical scalar product. If f is an idempotent in V, it turns out that the spectrum of $L(f)$ belongs to $\{0, \frac{1}{2}, 1\}$. Following [FK], we denote by $V(1, f), V(\frac{1}{2}, f), V(0, f)$ corresponding eigenspaces.

It is clear that

$$V = V(0, f) \oplus V(1, f) \oplus V\left(\frac{1}{2}, f\right) \tag{3}$$

and the eigenspaces are pairwise orthogonal with respect to the scalar product $\langle , \rangle$. This is the so-called Peirce decomposition of V with respect to an idempotent f. However, eigenspaces have more structure (see [FK, Proposition IV.1.1]). In particular, $V(0,f), V(1,f)$ are subalgebras in V. Let f_1, f_2 be two primitive orthogonal idempotents. It turns out that

$$\dim V\left(\frac{1}{2}, f_1\right) \cap V\left(\frac{1}{2}, f_2\right)$$

does not depend on the choice of the pair f_1, f_2 (see Corollary IV.2.6, p. 71 in [FK]). It is called the degree of V (notation $\mathrm{d}(V)$).

If V is a simple Euclidean Jordan algebra, then

$$\dim V = \operatorname{rank}(V) + \frac{\mathrm{d}(V)}{2} \operatorname{rank}(V)(\operatorname{rank}(V) - 1).$$

Note that two simple Euclidean Jordan algebras are isomorphic if and only if their ranks and degrees coincide.

The next proposition will be frequently used in what follows.

PROPOSITION 1. *Let $x, y \in \bar{\Omega}$. Then $\langle x, y\rangle \geq 0$; $\langle x, y\rangle = 0$ if and only if $x \circ y = 0$.*

For a proof see, e.g., [F2].

We summarize some of the properties of algebras $V(1,f)$.

PROPOSITION 2. *Let f be an idempotent in a simple Euclidean Jordan algebra V. Then $V(1,f)$ is a simple Euclidean Jordan algebra with identity element f. Moreover,*

$$\operatorname{rank}(V(1,f)) = \operatorname{rank}(f),$$
$$\mathrm{d}(V(1,f)) = \mathrm{d}(V).$$

The trace operator on $V(1,f)$ coincides with the restriction of the trace operator on V. If $\tilde{\Omega}$ is the cone of invertible squares in $V(1,f)$, then $\bar{\tilde{\Omega}} = \bar{\Omega} \cap V(1,f)$.

Proposition 2 easily follows from the properties of Peirce decomposition on V (see section IV.2 in [FK]). Notice that if c is a primitive idempotent in $V(1,f)$, then c is primitive idempotent in V, i.e., $\mathcal{T}(V(1,f)) = \mathcal{T}(V) \cap V(1,f)$.

Indeed, let $c = c_1 + c_2$ where $c_1, c_2 \in V$ and $c_1^2 = c_1, c_2^2 = c_2$. Since $c \in V(1,f), c \circ (e-f) = 0$, i.e., $(e-f) \circ c_1 + (e-f) \circ c_2 = 0$.

Hence, $\langle e-f, c_1\rangle + \langle e-f, c_2\rangle = 0$. But $e-f, c_1, c_2 \in \bar{\Omega}$. Hence, $\langle e-f, c_1\rangle \geq 0, \langle e-f, c_2\rangle \geq 0$. We conclude that $\langle e-f, c_1\rangle = \langle e-f, c_2\rangle = 0$. By Proposition 1 $(e-f) \circ c_1 = (e-f) \circ c_2 = 0$, i.e., $c_1, c_2 \in V(1,f)$. But c is primitive in $V(1,f)$. Hence $c_1 = 0$ or $c_2 = 0$, which proves that c is primitive in V.

Let $f_1, \ldots, f_r$, where $r = \operatorname{rank}(V)$, be a system of primitive idempotents such that $f_i \circ f_j = 0$ for $i \neq j$ and $f_1 + \cdots + f_r = e$. Such a system is called a Jordan frame. Given $x \in V$, there exists a Jordan frame $f_1, \ldots, f_r$ and real numbers $\lambda_1, \ldots, \lambda_r$ such that

$$x = \sum_{i=1}^{r} \lambda_i f_i.$$

The numbers λ_i (with their multiplicities) are uniquely determined by x (see Theorem III.1.2 in [FK]).

It is clear that

$$\operatorname{tr}(x) = \sum_{i=1}^{r} \lambda_i, \quad \operatorname{rank}(x) = \operatorname{card}\{i \in [1,r] : \lambda_i \neq 0\}.$$

Since primitive idempotents in $V(1,f)$ remain primitive in V, it easily follows that the rank of $x \in V(1,f)$ is the same as its rank in V.

3. Facial structure of the cone of squares. Throughout this paper we will use notation B_ϵ for an open ball in V with the center at 0 and of radius ϵ (with respect to the norm induced by the canonical Euclidean product). Given a subset $S \subset V$, we denote by $\mathrm{Aff}(S)$ the smallest affine subspace in V containing S (affine hull of S). The notation $\mathrm{ri}(S)$ is used for the relative interior of S:

$$\mathrm{ri}(S) = \{x \in S : \exists \epsilon > 0, (x + B_\epsilon) \cap \mathrm{Aff}(S) \subset S\}.$$

Let S be a convex subset of V. A face of S is a convex subset T of S such that whenever $\lambda x + \mu y \in T$, where $x, y \in S, \lambda, \mu > 0, \lambda + \mu = 1$, then $x, y \in T$. Recall the following theorem (Theorem 2.6.10 in [W]).

THEOREM 1. *Let a be a point of convex set S in V. Let $\mathcal{F}_a$ be the intersection of all faces of S containing a. Then $\mathcal{F}_a$ is a face of S. Moreover, $a \in \mathrm{ri}(\mathcal{F}_a)$ and the relative interiors of the faces of S form a partition of S.*

In this section we describe the facial structure of the cone of squares $\bar{\Omega}$ in V in a form somewhat different from the one given in Proposition IV.3.1 of [FK].

THEOREM 2. *Let $x \in \partial\Omega = \bar{\Omega} \backslash \Omega$ and*

$$x = \sum_{i=1}^{k+1} \lambda_i(x) f_i(x)$$

be the spectral decomposition of x, where $\lambda_i(x) > 0$, $i = 1, 2, \ldots, k$, $\lambda_{k+1}(x) = 0$ are pairwise distinct eigenvalues of x. Let

$$\mathcal{F}_x = \{z \in \bar{\Omega} : \langle f_{k+1}(x), z\rangle = 0\}.$$

Then $\mathcal{F}_x$ is a face of $\bar{\Omega}$. Moreover, $x \in \mathrm{ri}(\mathcal{F}_x), \mathrm{Aff}(\mathcal{F}_x) = V(0, f_{k+1}(x)) = V(1, f_1(x) + \cdots + f_k(x)); \mathrm{ri}(\mathcal{F}_x) = \tilde{\Omega}$, where $\tilde{\Omega}$ is the cone of invertible squares in $V(0, f_{k+1}(x))$, $\bar{\tilde{\Omega}} = \bar{\Omega} \cap V(0, f_{k+1}(x))$.

COROLLARY 1. *In particular,*

$$\dim \mathcal{F}_x = \dim V(1, f_1(x) + \cdots + f_k(x)) = \varphi_d(\mathrm{rank}(x)),$$
$$\varphi_d(x) = x + \frac{dx(x-1)}{2}.$$

Here $d = d(V)$ is the degree of V.

Proof of Theorem 2. Since $x \in \partial\Omega, f_{k+1}(x) \neq 0$. Let $H_x = \{z \in V; \langle z, f_{k+1}(x)\rangle = 0\}$. If $z \in \bar{\Omega}$, then $\langle z, f_{k+1}(x)\rangle \geq 0$ ($f_{k+1}^2(x) = f_{k+1}(x)$; hence, $f_{k+1}(x) \in \bar{\Omega}$). This implies that H_x is a supporting hyperplane to $\bar{\Omega}$ ($x \in H_x$). Thus, $\mathcal{F} = H_x \cap \bar{\Omega}$ is a face of $\bar{\Omega}$ and, moreover, $x \in \mathcal{F}$. Furthermore, $y \in \mathcal{F}$ is equivalent to $y \in \bar{\Omega}$ and $\langle y, f_{k+1}(x)\rangle = 0$. But then, by Proposition 1, $y \circ f_{k+1}(x) = 0$ and consequently $y \in V(0, f_{k+1}(x)) = V(1, e - f_{k+1}(x))$. Thus, $\mathcal{F} \subset V(0, f_{k+1}(x))$, which implies $\mathrm{Aff}(\mathcal{F}) \subset V(0, f_{k+1}(x))$. It is clear that $x \in \tilde{\Omega}$ (with inverse $\sum_{i=1}^k (1/\lambda_i) f_i(x)$ in $V(0, f_{k+1}(x))$).

Thus $\mathrm{rank} V(0, f_{k+1}(x)) = \mathrm{rank}(x)$. Since $\bar{\tilde{\Omega}} = \bar{\Omega} \cap V(0, f_{k+1}(x))$ by Proposition 2 we conclude that $\tilde{\Omega} \subset \mathcal{F}$, which implies that $V(0, f_{k+1}(x)) = \mathrm{Aff}(\tilde{\Omega}) \subset \mathrm{Aff}(\mathcal{F})$. Thus

$$V(0, f_{k+1}(x)) = \mathrm{Aff}(\mathcal{F}).$$

Since $\tilde{\Omega}$ is relatively open in $V(0, f_{k+1}(x))$, we see that $\tilde{\Omega} \subset \mathrm{ri}(\mathcal{F})$. On the other hand, $\mathcal{F} = \mathcal{F} \cap \mathrm{Aff}(\mathcal{F}) = \bar{\Omega} \cap V(0, f_{k+1}(x)) = \bar{\tilde{\Omega}}$. Hence, $\mathrm{ri}(\mathcal{F}) = \mathrm{ri}(\bar{\tilde{\Omega}}) = \tilde{\Omega}$.

4. Rank estimates. We are now in a position to generalize the main results of [B2, B3] to arbitrary symmetric cones.

THEOREM 3. *Let $\mathcal{A}$ be an affine subspace in V such that*

$$S = \bar{\Omega} \cap \mathcal{A} \neq \emptyset.$$

Then there exists $x \in S$ such that

$$\varphi_d(\text{rank}(x)) \leq \text{codim}_V \mathcal{A}.$$

Here d is the degree of V.

Proof. Since S is closed, nonempty, and does not contain straight lines, it contains an extreme point x (see, e.g., [B1, p. 53], [B2, B3]). Let $\text{rank}(x) = m$. There exists a unique face $\mathcal{F}_x$ of $\bar{\Omega}$ such that $x \in \text{ri}(\mathcal{F}_x)$. By Theorem 2, $\dim\mathcal{F}_x = \varphi_d(m)$. It is clear that $\mathcal{F}_x \cap \mathcal{A}$ is a face of S and, moreover, $x \in \text{ri}(\mathcal{F}_x \cap \mathcal{A})$. Indeed, $x \in \text{ri}(\mathcal{F}_x)$ implies that $\exists \epsilon > 0$ such that $(x + B_\epsilon) \cap \text{Aff}(\mathcal{F}_x) \subset \mathcal{F}_x$. But then $(x + B_\epsilon) \cap \text{Aff}(\mathcal{F}_x) \cap \mathcal{A} \subset \mathcal{F}_x \cap \mathcal{A}$. Since $\text{Aff}(\mathcal{F}_x \cap \mathcal{A}) \subset \text{Aff}(\mathcal{F}_x) \cap \mathcal{A}$ we have $x \in \text{ri}(\mathcal{F}_x \cap A)$. Since x is an extreme point of S, $x \in \text{ri}(\mathcal{F}_x \cap \mathcal{A})$, and $\mathcal{F}_x \cap \mathcal{A}$ is a face of S, we conclude that $\mathcal{F}_x \cap \mathcal{A} = \{x\}$ (by Theorem 1, there exists a unique face $\mathcal{F}$ of S such that $x \in \text{ri}(\mathcal{F})$).

Let $\text{Aff}(\mathcal{F}_x) = x + X, \mathcal{A} = x + Y$, where X, Y is a vector subspace of V. We are going to show that $X \cap Y = 0$. We know that there exists $\epsilon > 0$ such that $(x + B_\epsilon) \cap (x + X) \subset \mathcal{F}_x$. Hence, $(x + B_\epsilon) \cap (x + X) \cap (x + Y) = x + (B_\epsilon \cap X \cap Y) \subset \mathcal{F}_x \cap \mathcal{A} = \{x\}$. If $X \cap Y \neq 0$, we would arrive at a contradiction. Now, $X \cap Y = 0$ implies that $\dim(X + Y) = \dim X + \dim Y$. On the other hand, $\dim(X + Y) \leq \dim V$. Hence, $\dim\mathcal{F}_x = \dim X \leq \dim V - \dim Y = \text{codim}_V \mathcal{A}$. We noticed before that $\dim\mathcal{F}_x = \varphi_d(\text{rank}(x))$. The result follows. □

Remark. Let $a_1, \ldots, a_k \in V, b_1, \ldots, b_k \in \mathbf{R}$, and

$$\mathcal{A} = \{z \in V : \langle a_i, z\rangle = b_i, i = 1, \ldots, k\}.$$

It is clear that $\text{codim}_V \mathcal{A} \leq k$, provided $\mathcal{A} \neq \emptyset$. In this case Theorem 3 implies that $\varphi_d(\text{rank}(x)) \leq k$.

Remark. In the case where V is the Jordan algebra of real symmetric matrices, Theorem 3 coincides with the result on p. 194 of [B2]. See also [Pat]. In this case $\text{d}(V) = 1$.

THEOREM 4. *Let $\mathcal{A}$ be an affine subspace in V such that*

$$S = \bar{\Omega} \cap \mathcal{A}$$

is nonempty and bounded. Suppose that there exists an integer $r \geq 1$ such that $\text{codim}_V(\mathcal{A}) \leq \varphi_d(r + 1)$, $\text{rank}(V) \geq r + 2$. Then there exists $x \in S$ such that $\text{rank}(x) \leq r$. Here $d = d(V)$ is the degree of V.

Proof. We need to consider several cases.

(i) Let $\mathcal{A} \cap \Omega = \emptyset$. But $\mathcal{A} \cap \partial\Omega \neq \emptyset$. Let $y \in \mathcal{A} \cap \partial\Omega$. Since $\mathcal{A} \cap \Omega = \emptyset$, there exists a hyperplane H in V separating $\mathcal{A}$ and Ω. Since $\mathcal{A} \cap \partial\Omega \neq \emptyset$ we should have that H is a supporting hyperplane to $\bar{\Omega}$ and A (as an affine subspace) is a subset in H. Then $\mathcal{F} = H \cap \bar{\Omega}$ is a proper face of $\bar{\Omega}$. By Theorem 2 $H \cap \bar{\Omega}$ is the face of the form $\bar{\Omega}_0$ where $\bar{\Omega}_0$ is the cone of squares in the algebra $V(0, f)$ and f is a nonzero idempotent in V. Since $\mathcal{A} \subset H$, we have $S = \mathcal{A} \cap \bar{\Omega} \subset H \cap \bar{\Omega} = \bar{\Omega}_0$. Thus $S \subset \bar{\Omega}_0 \cap (V(0, f) \cap \mathcal{A})$. Since $\bar{\Omega}_0 = \bar{\Omega} \cap V(0, f) \subset \bar{\Omega}$, we have $\bar{\Omega}_0 \cap (V(0, f) \cap \mathcal{A}) \subset \bar{\Omega} \cap \mathcal{A}$. Thus

$$S = \bar{\Omega}_0 \cap (V(0, f) \cap \mathcal{A}).$$

Let us estimate $\mathrm{codim}_{V(0,f)}\mathcal{A}\cap V(0,f)$.

Let $\mathcal{A}=y+Y$, where $y\in S, Y$ is a vector subspace in V. Denote $V(0,f)$ by W. We have $\dim(Y\cap W)=\dim(W)+\dim Y-\dim(W+Y)$. Now $W+Y=(y+Y)+W\subset H$. Hence, $\dim(W+Y)\le \dim H=\dim V-1$. Consequently, $\dim W-\dim(Y\cap W)=\dim(W+Y)-\dim Y\le \dim V-\dim Y-1=\mathrm{codim}_V\mathcal{A}-1$. Thus $\mathrm{codim}_W(Y\cap W)\le \mathrm{codim}_V\mathcal{A}-1\le \varphi_d(r+1)-1$.

The last inequality is due to the assumptions of the theorem. We can apply Theorem 3 to $S=(\mathcal{A}\cap W)\cap\bar\Omega_0\subset W$ to conclude that there is $x\in S$ such that $\varphi_d(\mathrm{rank}(x))\le\varphi_d(r+1)-1$. Since φ_d is an increasing function on $[0,+\infty)$ (notice that $d\ge 1$), we conclude that $\mathrm{rank}(x)\le r$.

Suppose now that $\mathcal{A}\cap\Omega\neq\emptyset$.

(ii) Consider first the case $\mathrm{rank}(V)=r+2, r\ge 1, \mathcal{A}\subset V$, and $\mathrm{codim}_V(\mathcal{A})=\varphi_d(r+1)$. Since $\mathcal{A}\cap\Omega\neq\emptyset$, we have $\mathrm{ri}(S)=\mathcal{A}\cap\Omega$, $\mathrm{Aff}(S)=\mathcal{A}$. Hence, $\dim S=\dim\mathcal{A}=\dim V-\mathrm{codim}_V\mathcal{A}=\varphi_d(r+2)-\varphi_d(r+1)=1+d(r+1)$. It is also clear that $\partial_1 S=\mathrm{rebd}S=\mathcal{A}\cap\partial\Omega$. If there exists $x\in\partial_1 S$ such that $\mathrm{rank}(x)\le r$, there is nothing to prove. For $x\in\mathrm{ri}(S)$, $\mathrm{rank}(x)=\mathrm{rank}(V)=r+2$. Otherwise, notice that for $x\in\partial_1 S$ $\mathrm{rank}(x)<\mathrm{rank}(V)=r+2$. Thus we should have $\mathrm{rank}(x)=r+1$ for all $x\in\partial_1 S$. Take $y\in\mathcal{A}\cap\Omega$. There exists $\epsilon>0$ such that $(y+B_\epsilon)\cap\mathcal{A}\subset S$. Let $\mathcal{A}=y+Y, Y$ be a vector subspace in V. Consider $\mathbf{S}_\epsilon=\partial_1(B_\epsilon\cap Y)=\partial B_\epsilon\cap Y$. It is clear that $\mathbf{S}_\epsilon$ is homeomorphic to the $d(r+1)$-dimensional sphere. Given $z\in\mathbf{S}_\epsilon$, there exists a unique positive $t(z)$ such that $y+t(z)z\in\partial_1 S=\mathcal{A}\cap\partial\Omega$ (recall that S is a convex compact set). The map $\psi:\mathbf{S}_\epsilon\to V, \psi(z)=y+t(z)z$ is clearly continuous. Since $\psi(\mathbf{S}_\epsilon)\subset\partial_1 S$, we have $\mathrm{rank}\psi(z)=r+1$ for any $z\in\mathbf{S}_\epsilon$.

We need the following lemma.

LEMMA 1. *Let V be a simple Euclidean Jordan algebra,* $\mathrm{rank}(V)=l$. *Suppose that* $0<s<l$ *and*

$$\bar\Omega_s=\{x\in\bar\Omega:\mathrm{rank}(x)=s\}.$$

For $x\in\bar\Omega_s$ consider the spectral decomposition

$$x=\sum_{j=1}^{k+1}\lambda_j(x)f_j(x),$$

where $\lambda_{k+1}=0$. The map $\gamma_s=\bar\Omega_s\to V, \gamma_s(x)=f_{k+1}(x)$ is continuous.

We postpone the proof of the lemma and continue with the proof of the theorem.

Consider $\tilde\psi:\mathbf{S}_\epsilon\to V, \tilde\psi(z)=\gamma_{r+1}(\psi(z))$. Since $\psi(\mathbf{S}_\epsilon)\subset\bar\Omega_{r+1}$, the map $\tilde\psi$ is continuous. Notice that $\tilde\psi(\mathbf{S}_\epsilon)\subset\mathcal{T}(V)$ (the manifold of primitive idempotents in V). Indeed, let $\psi(z)=\sum_{j=1}^{k+1}\lambda_j f_j$ be spectral decomposition and $\lambda_{k+1}=0$. Since $\mathrm{rank}(\psi(z))=r+1$, we have $\sum_{j=1}^{k}\mathrm{tr}(f_j)=r+1$.

But $\sum_{j=1}^{k+1}f_j=e$. Hence, $\sum_{j=1}^{k+1}\mathrm{tr}(f_j)=\mathrm{tr}(e)=\mathrm{rank}(V)=r+2$.

Thus, $\mathrm{tr}f_{k+1}=1$, i.e., $f_{k+1}\in\mathcal{T}(V)$. Notice that $\dim\mathcal{T}(V)=\mathrm{d}(r+1)$ (see exercise 4a, p. 78 in [FK]). Hence $\tilde\psi:\mathbf{S}_\epsilon\to\mathcal{T}(V)$ is a continuous map between two compact connected manifolds of the same dimension. But then $\tilde\psi$ cannot be injective. Indeed, if $\tilde\psi$ is injective, then $\tilde\psi$ should be a homeomorphism of $\mathbf{S}_\epsilon$ onto $\mathcal{T}(V)$ (see, e.g., Corollary 28.4, p. 172 in [Ha]). However, under our assumptions $\mathcal{T}(V)$ is not homeomorphic to a sphere. Indeed, we assume that $r\ge 1$ and $\mathrm{rank}(V)=r+2$, i.e., $\mathrm{rank}(V)\ge 3$. (Notice that if $\mathrm{rank}(V)=2$, then $\mathcal{T}(V)$ is homeomorphic to a sphere.) We need to consider two separate cases.

If $d = 1$, then $\mathcal{T}(V)$ is homeomorphic to $\mathbf{P}_{r+1}(\mathbf{R})$ (see exercise 5, p. 99 in [FK]), which is not homeomorphic to sphere for $r \geq 1$.

If $d > 1, r \geq 3$ (the only possible choices are $d = 2, d = 4, d = 8$), then according to [H, p. 351], the following holds. Denote by $b_i(\mathcal{T}(V))$, $i = 0, 1, \ldots, d(r+1)$, the Betti numbers of $\mathcal{T}(V)$. Then

$$b_i(\mathcal{T}(V)) = \begin{cases} 1 & \text{when } i = 0(\text{mod } d), \\ 0 & \text{otherwise,} \end{cases}$$

whereas $b_i(\mathbf{S}_\epsilon) = 1, i = 0, i = d(r+1)$, and $b_i(\mathbf{S}_\epsilon) = 0$ otherwise. It is then clear that, say, $\beta_d(\mathcal{T}(V)) = 1$ but $\beta_d(\mathbf{S}_\epsilon) = 0$ (recall that $r \geq 1$!). Thus under our assumption, there exist $z_1 \neq z_2$ in $\mathbf{S}_\epsilon$ such that $\tilde{\psi}(z_1) = \tilde{\psi}(z_2)$. Since $z_1 \neq z_2$, it is clear that $\psi(z_1) \neq \psi(z_2)$. Let $c = \tilde{\psi}(z_1) = \tilde{\psi}(z_2)$. According to our construction of c, we have that $\psi(z_1), \psi(z_2) \in V(0, c)$ and, moreover, if Ω_0 is the cone of invertible squares in $V(0, c)$, then both $\psi(z_1)$ and $\psi(z_2) \in \Omega_0$ (see Theorem 2). Let L be a line passing through $\psi(z_1)$ and $\psi(z_2)$. It is clear that $L \subset \mathcal{A}$, and since Ω_0 does not contain lines, L hits its relative boundary at some point z_0. Then $\text{rank}(z_0) < \text{rank}(\psi(z_1)) = \text{rank}(\psi(z_2)) = r + 1$. Clearly, $z_0 \in \bar{\Omega}_0 \cap \mathcal{A} \subset S$. Thus, $\text{rank}(z_0) \leq r$.

(iii) Consider now a general case, where $\text{codim}_V \mathcal{A} \leq \varphi_d(r+1)$, $\dim V \geq r+2, r \geq 1$. (We still assume that $\mathcal{A} \cap \Omega \neq \emptyset$.) If $\text{codim}_V \mathcal{A} < \varphi_d(r+1)$, then the result follows from Theorem 3. It suffices to consider the case $\text{codim}_V \mathcal{A} = \varphi_d(r+1)$. By Theorem 3 there exists $y \in S$ such that $\text{rank}(y) \leq r + 1$. If $\text{rank}(y) < r + 1$, we are done. Consider the case $\text{rank}(y) = r + 1$. Let

$$y = \sum_{j+1}^{k+1} \lambda_j f_j(y)$$

be spectral decomposition of y and $\lambda_{k+1} = 0$. Let $f_{k+1}(y) = c_1 + \cdots + c_s$, where $c_1, \ldots, c_s$ are primitive pairwise orthogonal idempotents.

$$\text{rank}(f_{k+1}(y)) = \text{rank}(V) - \text{rank}(y) = \text{rank}(V) - (r+1) \geq 1.$$

Thus $s = \text{rank}(f_{k+1}(y)) \geq 1$. Let $W = V(0, c_1 + c_2 + \cdots + c_{s-1})$. Notice that $\langle y, f_{k+1}(y) \rangle = 0$ implies $\langle y, c_i \rangle = 0$, $i = 1, 2, \ldots, s$. Hence $y \in W$. Further, $\text{rank}(W) = \text{rank}(y) + 1 = r + 2$. Notice that $\text{codim}_W(\mathcal{A} \cap W) \leq \text{codim}_V(\mathcal{A}) = \varphi_d(r+1)$ (as we saw in case (i)).

Let Ω_W be the cone of invertible squares in W. Since $y \in \bar{\Omega}_W \cap (\mathcal{A} \cap W) = S \cap W$, the result follows from Theorem 3 if $\text{codim}_W(\mathcal{A} \cap W) < \text{codim}_V(\mathcal{A})$, or we are in case (ii) if $\text{codim}_W(\mathcal{A} \cap W) = \text{codim}_V \mathcal{A} = \varphi_d(r+2)$. This completes the proof of the theorem. □

Proof of Lemma 1. Since $\bar{\Omega}_s$ is an orbit of connected component of the group of automorphisms of Ω (see Proposition IV.3.1 (iii) in [FK]), it is a smooth connected submanifold in V.

Let $x \in \bar{\Omega}_s$ have a spectral decomposition

$$x = \sum_{j=1}^{k+1} \lambda_j f_j(x),$$

$\lambda_{k+1} = 0$. Using the Peirce decomposition associated with (complete) system of orthogonal idempotents $f_1(x), \ldots, f_{k+1}(x)$ (see section IV.2 in [FK]), one can easily see

that

$$\mathrm{Im}P(x) = V(1, f_1(x) + f_2(x) + \cdots + f_k(x)) = V(0, f_{k+1}(x)).$$

Recall that $P(x)$ is the quadratic representation of x. But $\dim \mathrm{Im}P(x) = \mathrm{rank}(P(x))$ (rank of the $\mathbf{R}$-linear map $P(x) : V \to V$) and $\mathrm{rank}(P(x))$ is constant when x varies over $\bar{\Omega}_s$ (see Proposition IV.3.1 (iv) in [FK]). Since $\bar{\Omega}_s$ is connected and the map $x \to P(x)$ is continuous, we conclude that the map $x \to \mathrm{Im}P(x)$ is continuous (see Proposition 13.6.1, p. 408 in [GLR]). Let $\pi(x) : V \to \mathrm{Im}P(x)$ be an orthogonal projection (with respect to the canonical scalar product $\langle , \rangle$). The continuity of the map $x \to \mathrm{Im}P(x)$ is equivalent to the continuity of the map $x \to \pi(x)$ (see [GLR, Chapter 13]). But $\pi(x) = P(f_1(x) + f_2(x) + \cdots + f_k(x))$ (see [FK, p. 65]). On the other hand, $P(f_1(x) + f_2(x) + \cdots + f_k(x))e = f_1(x) + \cdots + f_k(x) = e - f_{k+1}(x)$, which implies that the map $x \to f_{k+1}(x) = \gamma_s(x)$ is continuous.

Remark. If V is the algebra of symmetric matrices with real entries, Theorem 4 coincides with Theorem 1.2 in [B3].

5. Some applications. The natural question within the Jordan-algebraic approach developed here concerns the convexity of the image of the manifold $\mathcal{T}(V)$ of primitive idempotents (or its conic hull) under linear maps. We will show how to transform it to the setting of quadratic maps in the section 6.

PROPOSITION 3. *Let V be a simple Euclidean Jordan algebra of degree d. Given $a_1, \ldots, a_k \in V$, consider the linear map*

$$N : V \to \mathbf{R}^k,$$

$$N(x) = \begin{bmatrix} \langle a_1, x \rangle \\ \vdots \\ \langle a_k, x \rangle \end{bmatrix}. \tag{4}$$

If $\varphi_d^{-1}(k) < 2$, then

$$N\left(\bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V)\right) = N(\bar{\Omega}).$$

In particular, $N(\bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V))$ is a convex cone.

Proof. Denote $\bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V)$ by K. Since $K \subset \bar{\Omega}$, it is clear that $N(K) \subset N(\bar{\Omega})$. Let $b = (b_1, \ldots, b_k)^T \in N(\bar{\Omega})$. Then there exists $x \in \bar{\Omega}$ such that $N(x) = b$. Consider $S = \{y \in \bar{\Omega} : N(y) = b\}$. It is clear that $x \in S$, i.e., $S \neq \emptyset$. According to Theorem 3, there exists $z \in S$ such that $\varphi_d(\mathrm{rank}(z)) \leq k$ or (using monotonicity of φ_d) $\mathrm{rank}(z) \leq \varphi_d^{-1}(k) < 2$. Hence, $\mathrm{rank}(z) = 1$ or $\mathrm{rank}(z) = 0$. In both cases, it is clear that $z \in K$. Thus $b \in N(K)$. □

PROPOSITION 4. *Let V be a simple Euclidean Jordan algebra, $d(V) = d$, $\mathrm{rank}(V) \geq 3$. Suppose that $k = \varphi_d(2), a_1, \ldots, a_k \in V$ are such that there exist $\tau_1, \ldots, \tau_k \in \mathbf{R}$ with the property*

$$\sum_{i=1}^{k} \tau_i a_i \in \Omega. \tag{5}$$

Then

$$N\left(\bigcup_{\lambda\geq 0}\lambda\mathcal{T}(V))=N(\bar{\Omega}\right) \text{ is a closed convex cone.}$$

Proof. In the notation of the proof of Proposition 3, it is clear that $N(K)\subset N(\bar{\Omega})$. Let $b\in N(\bar{\Omega})$, i.e., there exists $x\in\bar{\Omega}$ such that $N(x)=b$. The set $S=\{y\in\bar{\Omega}: N(y)=b\}$ is nonempty. Moreover, it is bounded. Indeed,

$$S\subset\left\{y\in\bar{\Omega}:\left\langle\sum_{i=1}^{k}\tau_i a_i,y\right\rangle=\sum_{i=1}^{k}\tau_i b_i\right\}=T.$$

Since $\sum_{i=1}^{k}\tau_i a_i\in\Omega$, the set T is bounded (see Corollary I.1.6 in [FK]). Hence, S is bounded. By Theorem 4 (with $r=1$) there exists $z\in\bar{\Omega}$ such that $\operatorname{rank}(z)\leq 1$. Hence, $z\in K$, i.e., $N(K)=N(\bar{\Omega})$. The closeness of $N(\bar{\Omega})$ immediately follows from the fact that $\operatorname{Ker}N\cap\bar{\Omega}=0$, which in turn easily follows from (5). □

PROPOSITION 5. *Let $d(V)=d$, let $\operatorname{rank}(V)\geq 3$, let N be defined as in* (4)*, and let $k=\varphi_d(2)-1$. Then $N(\mathcal{T}(V))$ is convex.*

Proof. Consider $\tilde{N}:V\to\mathbf{R}^{k+1}$,

$$\tilde{N}(x)=\begin{bmatrix}\langle a_1,x\rangle\\ \vdots\\ \langle a_k,x\rangle\\ \operatorname{tr}(x)=\langle e,x\rangle\end{bmatrix}.$$

By Proposition 4 $\tilde{N}(\bigcup_{\lambda\geq 0}\lambda\mathcal{T}(V))=\tilde{N}(\bar{\Omega})$. Indeed, (5) is clearly satisfied if we take $\tau_1=\tau_2=\cdots=\tau_k=0,\tau_{k+1}=1$. Consider $H=\{(b_1,\dots,b_{k+1})^T\in\mathbf{R}^{k+1}:b_{k+1}=1\}$. H is a hyperplane in $\mathbf{R}^{k+1}$ and $H\cap\tilde{N}(\bar{\Omega})$ is convex. Denote by $\tilde{N}_1$ the restriction of $\tilde{N}$ on $(\bigcup_{\lambda\geq 0}\lambda\mathcal{T}(V))$. It is clear that

$$\tilde{N}_1^{-1}(H\cap\tilde{N}(\bar{\Omega}))=\left\{z\in\bigcup_{\lambda\geq 0}\lambda\mathcal{T}(V):\operatorname{tr}(z)=1\right\}=\mathcal{T}(V).$$

This means that

$$N(\mathcal{T}(V))=H\cap\tilde{N}(\bar{\Omega}).\qquad\square$$

PROPOSITION 6. *Let $d(V)=d$, $\operatorname{rank}(V)\geq 3$, $k<\varphi_d(2)$. Let $c,a_i,i=1,2,\dots,k$, in V be such that there exist $\tau,\tau_i,i=1,2,\dots,k$, in $\mathbf{R}$ with the property*

$$\tau c+\sum_{i=1}^{k}\tau_i a_i\in\Omega.$$

Further, let $b_i,i=1,2,\dots,k$, be in $\mathbf{R}$.

Then

$$\inf\left\{\langle c,x\rangle:\langle a_i,x\rangle=b_i,i=1,2,\dots,k,\quad x\in\bigcup_{\lambda\geq 0}\lambda\mathcal{T}(V)\right\}$$
$$=\inf\{\langle c,x\rangle:\langle a_i,x\rangle=b_i,i=1,2,\dots,k,\quad x\in\bar{\Omega}\}.$$

Proof. We assume that the set $S = \{x \in \bar{\Omega} : \langle a_i, x\rangle = b_i, i = 1, 2, \ldots, k\}$ is not empty. Otherwise, there is nothing to prove.

Let $y \in S, \langle c, y\rangle = t$. Consider the map $N : \bar{\Omega} \to \mathbf{R}^{k+1}$,

$$N(x) = \begin{bmatrix} \langle a_1, x\rangle \\ \vdots \\ \langle a_k, x\rangle \\ \langle c, x\rangle \end{bmatrix}.$$

By Proposition 4 $N(\bar{\Omega}) = N(\bigcup_{\lambda\geq 0} \lambda\mathcal{T}(V))$.

Since $(b_1, \ldots, b_k, t)^T \in N(\bar{\Omega})$, we have $(b_1, \ldots, b_k, t)^T \in N(\bigcup_{\lambda\geq 0} \lambda\mathcal{T}(V))$. The result follows. □

PROPOSITION 7. *Let $d(V) = d$, $\operatorname{rank}(V) \geq 3$. Further, let $c, a_i, i = 1, 2, \ldots, k, k < \varphi_d(2) - 1$. Suppose that the set*

$$S = \{x \in \bar{\Omega} : \langle a_i, x\rangle = b_i, i = 1, 2, \ldots, k, \operatorname{tr}(x) = 1\} \text{ is not empty.}$$

Then

$$\begin{aligned} &\min\{\langle c, x\rangle : x \in \mathcal{T}(V), \langle a_i, x\rangle = b_i, i = 1, 2, \ldots, k\} \\ &= \min\{\langle c, x\rangle : \langle a_i, x\rangle = b_i, i = 1, 2, \ldots, k, \operatorname{tr}(x) = 1, x \in \bar{\Omega}\}. \end{aligned}$$

Proof. Let $y \in S, \langle c, y\rangle = t$. Consider the map $N : V \to \mathbf{R}^{k+2}$,

$$N(z) = \begin{bmatrix} \langle a_1, z\rangle \\ \vdots \\ \langle a_k, z\rangle \\ \langle e, z\rangle = \operatorname{tr}(z) \\ \langle c, z\rangle \end{bmatrix}.$$

We have $N(\bar{\Omega}) \cap \{(d_1, \ldots, d_{k+2})^T \in \mathbf{R}^{k+2} : d_{k+1} = 1\} = N(\mathcal{T}(V))$ by Proposition 5 (or more precisely its proof). It is clear that $(b_1, \ldots, b_k, 1, t) \in N(\bar{\Omega}) \cap \{(d_1, \ldots, d_{k+2})^T \in \mathbf{R}^{k+2} : d_{k+1} = 1\}$. The result follows. □

PROPOSITION 8. *Let $d(V) = d$, $r \geq 1$, and $1 \leq k < \varphi_d(r + 1)$ be such that $\operatorname{rank}(V) \geq r + 2$. Let $a_1, \ldots, a_k \in V$. Consider the map N described as in (4). Then every point of convex hull $\operatorname{conv}(N(\mathcal{T}(V)))$ can be represented as a convex combination of r (not necessarily distinct) points of $N(\mathcal{T}(V))$.*

Proof. Let $b = (b_1, \ldots, b_k)^T \in \operatorname{conv}(N(\mathcal{T}(V)))$. Thus

$$b = \sum_{i=1}^{m} \lambda_i N(x_i)$$

for some $m \geq 1$, $x_i \in \mathcal{T}(V)$, $\lambda_i \geq 0$, $\sum_{i=1}^m \lambda_i = 1$. Let $x = \sum_{i=1}^m \lambda_i x_i$. It is clear that $x \in \bar{\Omega}$, $N(x) = b$, $\operatorname{tr}(x) = \sum_{i=1}^m \lambda_i \operatorname{tr}(x_i) = 1$.

It is clear that $S = \{z \in \bar{\Omega} : N(x) = b, \operatorname{tr}(x) = 1\}$ is nonempty and bounded. By Theorem 4 there exist $z \in S$ such that $\operatorname{rank}(z) \leq r$. Let $\mu_1, \ldots, \mu_t, f_1, \ldots, f_t, t = \operatorname{rank}(V)$ be such that $f_1, \ldots, f_t$ is a Jordan frame and

$$z = \sum_{s=1}^{t} \mu_s f_s.$$

We notice earlier that $\operatorname{rank}(z) \leq r$ is equivalent to $\operatorname{card}\{s \in [1,t] : \mu_s > 0\} \leq r$.

Let $J = \{s \in [1,t] : \mu_s > 0\}$. We have

$$z = \sum_{s \in J}^{t} \mu_s f_s.$$

Since $\operatorname{tr}(z) = \sum_{s \in J} \mu_s = 1$, and $f_s \in \mathcal{T}(V)$ for all s, we conclude that

$$N(z) = b, \quad N(z) = \sum_{s \in J} \mu_s N(f_s).$$

The result follows. □

The next proposition can be interpreted as an abstract version of the well-known S-lemma (see, e.g., [BN]).

PROPOSITION 9. *Let $c, a_i, i = 1, 2, \ldots, k$, in V be such that $N(\mathcal{T}(V))$ is a convex set. Here $N : V \to \mathbf{R}^{k+1}$,*

$$N(x) = \begin{bmatrix} \langle a_1, x \rangle \\ \vdots \\ \langle a_k, x \rangle \\ \langle c, x \rangle \end{bmatrix}.$$

Suppose that there exists $x_0 \in \mathcal{T}(V)$ such that $\langle a_i, x_0 \rangle > 0$ for $i = 1, \ldots, k$. Further, let

$$\Gamma = \{x \in \mathcal{T}(V) : \langle a_i, x \rangle \geq 0, i = 1, \ldots, k\}.$$

Then $\langle c, x \rangle \geq 0$, for all $x \in \Gamma$ if and only if there exist nonnegative $\lambda_1, \ldots, \lambda_k$ such that

$$c - \sum_{i=1}^{k} \lambda_i a_i \in \bar{\Omega}.$$

Proof. We prove the (nontrivial) "only if" part. Let

$$Y = N\left(\bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V)\right)$$

and

$$Z = \{z \in \mathbf{R}^{k+1} : z_i \geq 0, i = 1, \ldots, k, z_{k+1} < 0\}.$$

Then by our assumptions $Y \bigcap Z = \emptyset$. Both Y and Z are convex. Hence, by the separation theorem there exist real $\mu_1, \ldots, \mu_k, \lambda$ not all equal to zero, and real a such that

$$\sum_{i=1}^{k} \mu_i y_i + \lambda y_{k+1} \geq a \quad \text{for all } y \in Y,$$

$$\sum_{i=1}^{k} \mu_i z_i + \lambda z_{k+1} \leq a \quad \text{for all } z \in Z.$$

The standard reasoning then shows that $\mu_i \le 0$ for all i, $\lambda \ge 0$, and $a = 0$. Let us show that $\lambda > 0$. If $\lambda = 0$, then

$$\sum_{i=1}^{k} \mu_i y_i \ge 0$$

for all $y \in Y$, i.e.,

$$\left\langle \sum_{i=1}^{k} \mu_i a_i, x \right\rangle \ge 0$$

for any $x \in \mathcal{T}(V)$. This implies

$$\sum_{i=1}^{k} \mu_i a_i \in \bar{\Omega}.$$

By our assumptions there exists $x_0 \in \mathcal{T}(V)$ such that $\langle a_i, x_0 \rangle > 0$ for all i. We arrive at the contradiction, since all μ_i are nonpositive and not equal to zero simultaneously. Hence, $\lambda > 0$. But then

$$c - \sum_{i=1}^{k} \lambda_i a_i \in \bar{\Omega}$$

for $\lambda_i = -\mu_i/\lambda$. □

6. Interpretation in terms of quadratic mappings. To interpret the results of section 5 in terms of quadratic mappings, we need to understand the structure of manifolds $\mathcal{T}(V)$ for various simple Euclidean Jordan algebras. If $\operatorname{rank}(V) \ge 3$, every such algebra is of the type $\operatorname{Herm}(m, A)$, where $A = \mathbf{R}, \mathbf{C}, \mathbf{H}$, or $\mathbf{O}$. Here $\mathbf{R}, \mathbf{C}, \mathbf{H}, \mathbf{O}$ are algebras of real, complex, quaternion, and octonion numbers, respectively, and $\operatorname{Herm}(m, A)$ stands for the Jordan algebra of Hermitian matrices of size $m \times m$ with entries in A. Notice that if $A = \mathbf{O}, m \le 3$. The Jordan-algebraic multiplication in all these cases is the same:

Given $C, D \in \operatorname{Herm}(m, A)$,

$$C \circ D = \frac{CD + DC}{2},$$

where CD is the usual matrix multiplication. The list of corresponding manifolds $\mathcal{T}(V)$ is given on p. 99 of [FK]. We now consider the situation for concrete series $\operatorname{Herm}(m, A)$.

Case 1. Let $A = \mathbf{R}$. In this case the Jordan-algebraic operator tr coincides with the usual operator Tr of the matrix.

Thus

$$\langle C, D \rangle = \operatorname{Tr}(CD), \quad C, D \in \operatorname{Herm}(m, \mathbf{R}),$$

and $\operatorname{Herm}(m, \mathbf{R})$ is the algebra of $m \times m$ symmetric matrices with real entries.

$$\mathcal{T}(V) = \{C \in \operatorname{Herm}(m, \mathbf{R}) : C^2 = C, \operatorname{Tr}(C) = 1\},$$

i.e., $\mathcal{T}(V)$ is a manifold of one-dimensional orthogonal projections. Consider the map $\mu : \mathbf{R}^m \to \mathcal{T}(V)$, $\mu(x) = xx^T$. It is very well known that $\mu(\mathbf{S}^{m-1}) = \mathcal{T}(V)$.

PROPOSITION 10. *Let $q_i(x) = x^T C_i x$, $i = 1, 2$, be two quadratic forms on $\mathbf{R}^m$. Here $C_1, C_2 \in \mathrm{Herm}(m, \mathbf{R})$. Consider the map $\nu : \mathbf{R}^m \to \mathbf{R}^2$, $\nu(x) = (q_1(x), q_2(x))^T$. Then $\nu(\mathbf{R}^m)$ is a convex cone in $\mathbf{R}^2$*

Proof. It is clear that $\mu(\mathbf{R}^n) = \bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V)$. We are going to use Proposition 3. Notice that $d(\mathrm{Herm}(m, \mathbf{R})) = 1$ for any $m \geq 2$. Hence, $\varphi_d(2) = 3$. Thus for $k = 2$ the image $N(\bigcup_{\lambda \geq 0} \lambda \mathcal{T}(V))$ is convex. In our case

$$N \circ \mu(x) = (x^T C_1 x, x^T C_2 x).$$

The result follows. □

Remark. Proposition 10 is a classical theorem of Dines [D]. Similarly to Proposition 4 we obtain the following result.

PROPOSITION 11. *Let $q_i(x) = x^T C_i x$, $i = 1, 2, 3$, be three quadratic forms on $\mathbf{R}^m$. Here $C_1, C_2, C_3 \in \mathrm{Herm}(m, \mathbf{R})$ are such that there exist real τ_1, τ_2, τ_3 with the property that*

$$\tau_1 C_1 + \tau_2 C_2 + \tau_3 C_3 > 0$$

(i.e., the corresponding matrix is positive definite). Then for $m \geq 3$ the image $\nu(\mathbf{R}^m)$ is a convex closed cone.

Remark. Notice that $\mathrm{rank}(\mathrm{Herm}(m, \mathbf{R})) = m$. The result of Proposition 11 is central in [Pol].

Similarly, Proposition 5 yields Brickman's classical theorem [Br].

Case 2. Let $A = \mathbf{C}$. Notice that $\mathrm{rank}(\mathrm{Herm}(m, \mathbf{C})) = m$, $d(\mathrm{Herm}(m, \mathbf{C})) = 2$. In this case $\mathrm{tr}(C) = \mathrm{Tr}(C)$, where Tr is the usual matrix trace. Hence, for the canonical scalar product we obtain

$$\langle C, D \rangle = \mathrm{Tr}(CD), \quad C, D \in \mathrm{Herm}(m, \mathbf{C}).$$

We have

$$\mathcal{T}(\mathrm{Herm}(m, \mathbf{C})) = \{C \in \mathrm{Herm}(m, \mathbf{C}) : C^2 = C, \mathrm{Tr}(C) = 1\}.$$

Once again $\mathcal{T}(V)$ in this case is the manifold of orthogonal projections on (complex) one-dimensional subspaces in $\mathbf{C}^m$. The map $\mu : \mathbf{C}^m \to \mathrm{Herm}(m, \mathbf{C})$, $\mu(x) = xx^*$, where $x^* = \bar{x}^T$ maps the unit sphere $\mathbf{S}^{2m-1}$ onto $\mathcal{T}(\mathrm{Herm}(m, \mathbf{C}))$. Notice that in this case $\varphi_d(2) = 4$ and all propositions from section 5 admit natural interpretation. For example, Proposition 3 leads to the following result.

PROPOSITION 12. *Let $q_i(x) = x^* C_i x$, $x \in \mathbf{C}^m$, $i = 1, 2, 3$, be three Hermitian forms. Consider the map $\nu : \mathbf{C}^m \to \mathbf{R}^3$,*

$$\nu(x) = (q_1(x), q_2(x), q_3(x)).$$

Then $\nu(\mathbf{C}^m)$ is a convex cone.

Remark. This result is also known (see, e.g., [Pol]).

Proposition 5 takes the following form.

PROPOSITION 13. *Under the assumption of Proposition* 12 *let $m \geq 3$. Then*

$$\nu(\mathbf{S}^{2m-1}) \text{ is convex.}$$

Here $\mathbf{S}^{2m-1} = \{x \in \mathbf{C}^m : x^*x = 1\}$.

Remark. This result is in [AP].

Here is an interpretation of Proposition 8.

PROPOSITION 14. *Let* r, m, k *be such that* $r \geq 1$, $m \geq r+2$, *and* $1 \leq k < \varphi_2(r+1) = (r+1)^2$. *Let* $C_1, \ldots, C_k \in \mathrm{Herm}(m, \mathbf{C})$. *Consider the map* $\nu : \mathbf{C}^m \to \mathbf{R}^k$, $\nu(x) = (x^*C_1x, x^*C_2x, \ldots, x^*C_kx)$. *Then every element of* $\mathrm{conv}(\nu(\mathbf{S}^{2m-1}))$ *can be represented as a convex combination of* r *(not necessarily distinct) points of the form* $\nu(x), x \in \mathbf{S}^{2m-1}$.

Remark. This result is essentially in [Poon].

The next proposition immediately follows from Proposition 6.

PROPOSITION 15. *Let* $C_0, \ldots, C_3 \in \mathrm{Herm}(m, \mathbf{C})$ *be such that*

$$\sum_{i=0}^{3} \tau_i C_i > 0$$

for some real τ_i. *Further, let* $m \geq 3$. *Consider the following quadratic optimization problem:*

$$q_0(x) \to \min, \quad q_i(x) = b_i, \quad i = 1, 2, 3, \ x \in \mathbf{C^m}.$$

Here b_i *are some real numbers. Further, consider its semidefinite relaxation:*

$$\mathrm{Tr}(C_0Y) \to \min, \quad \mathrm{Tr}(C_iY) = b_i, \quad i = 1, 2, 3, \quad Y \geq 0, \quad Y \in \mathrm{Herm}(m, \mathbf{C}).$$

Then this semidefinite relaxation is exact.

Case 3. Consider the case $A = \mathbf{H}$.

In principle, the same approach as that in Cases 1 and 2 works here. However, we prefer to work with complex Hermitian matrices. Notice that $d(\mathrm{Herm}(m, \mathbf{H})) = 4$, $\mathrm{rank}(\mathrm{Herm}(m, \mathbf{H})) = m$.

Let $J = \left[\begin{smallmatrix} 0 & I_m \\ -I_m & 0 \end{smallmatrix}\right]$. Consider a subalgebra

$$V = \{C \in \mathrm{Herm}(2m, \mathbf{C}) : JC = \bar{C}J\}.$$

It is shown in [FK] (see, in particular, p. 88 and exercise 1 of Chapter 3) that $\mathrm{Herm}(m, \mathbf{H})$ is isomorphic (as a Jordan algebra) to subalgebra V of $\mathrm{Herm}(2m, \mathbf{C})$.

Let $C = \left[\begin{smallmatrix} C_1 & C_2 \\ C_3 & C_4 \end{smallmatrix}\right]$ be a partition of a $2m \times 2m$ matrix with complex entries into four $m \times m$ blocks. Then $C \in V$ if and only if $C_1^* = C_1, C_4 = \bar{C}_1, C_2^T = -C_2$, and $C_3 = -\bar{C}_2$ (a direct computation). In other words, a typical element from V looks like this:

$$\left[\begin{array}{cc} C_1 & C_2 \\ -\bar{C}_2 & \bar{C}_1 \end{array}\right], \tag{6}$$

where $C_1^* = C_1, C_2^T = -C_2$.

We need to describe $\mathcal{T}(V)$.

LEMMA 2. *Let* $\xi \in \mathbf{C}^{2m}$ *be such that* $\xi^*\xi = 1$. *Consider* $f(\xi) = \xi\xi^* + (J\bar{\xi})(J\bar{\xi})^*$. *Then* $f(\xi) \in V$, $f(\xi)^2 = f(\xi)$.

Proof. The proof is a direct computation. □

LEMMA 3. *Let* $\xi_1, \ldots, \xi_m \in \mathbf{C}^{2m}$ *be such that* $\xi_i^*\xi_i = 1$, $i = 1, \ldots, m$, $\xi_i^*\xi_j = 0$, $\xi_i^*J\bar{\xi}_j = 0$ *for* $i \neq j$. *Then*

$$f(\xi_i) \circ f(\xi_j) = \delta_{ij} f(\xi_i), \qquad i, j = 1, 2, \ldots, m,$$

and

$$f(\xi_1) + \cdots + f(\xi_m) = I_{2m}.$$

Proof. Notice that under our assumptions $\xi_1, \ldots, \xi_m, J\bar{\xi}_1, \ldots, J\bar{xi}_m$ form an orthonormal basis in $\mathbf{C}^{2m}$. The result follows by a direct computation.

Since $\operatorname{rank}(V) = m$, we see that $f(\xi_1), \ldots, f(\xi_m)$ form a Jordan frame in V. In particular, $\operatorname{tr}(f(\xi)) = 1$ if $\xi^*\xi = 1$. Since $\operatorname{Tr}(f(\xi)) = 2$, we conclude that

$$\operatorname{tr}(X) = \frac{1}{2}\operatorname{Tr}(X), \ X \in V,$$

where Tr is the usual matrix trace. □

LEMMA 4.

$$\mathcal{T}(V) = \{f(\xi) : \xi \in \mathbf{S}^{4m-1}\}.$$

Proof. By Lemma 3 we have $f(\xi) \in \mathcal{T}(V)$ if $\xi^*\xi = 1$. The connected component of the identity of the group $O(V)$ of (Jordan-algebra) automorphisms of V acts transitively on $\mathcal{T}(V)$. In our case

$$O(V) = \{C \in \operatorname{Mat}(2m, \mathbf{C}) : C^* = C^{-1}, JC = \bar{C}J\}.$$

See p. 98 in [FK]. Let $C \in O(V)$. Then

$$C \cdot f(\xi) = C\xi\xi^*C^* + C(J\bar{\xi})(J\bar{\xi})^*C^* = (C\xi)(C\xi)^* + (J\overline{C\xi})(J\overline{C\xi})^* = f(C\xi)).$$

Notice that $C\xi \in \mathbf{S}^{4m-1}$. We see that $O(V)$ maps $\{f(\xi) : \xi \in \mathbf{S}^{4m-1}\}$ onto itself. Hence we have the result. □

Let us compute

$$\Delta = \operatorname{tr}(C \circ f(\xi)) = \langle C, f(\xi)\rangle \ \text{ for } C \in V.$$

We have

$$\Delta = \frac{1}{2}\operatorname{Tr}(Cf(\xi)) = \frac{1}{2}\operatorname{Tr}(\xi^*C\xi + (J\bar{\xi})^*C(J\bar{\xi})).$$

Now, $(J\bar{\xi})^*C(J\bar{\xi}) = -\bar{\xi}^*JCJ\bar{\xi} = -\bar{\xi}^*\bar{C}J^2\bar{\xi} = \bar{\xi}^*\bar{C}\bar{\xi} = \overline{\xi^*C\xi}$. But $\xi^*C\xi$ is real, since C is Hermitian. Hence, $\langle C, f(\xi)\rangle = \xi^*C\xi$.

We summarize our results in the following proposition.

PROPOSITION 16. *Consider a realization of* $\operatorname{Herm}(m, \mathbf{H})$ *in the form*

$$V = \{C \in \operatorname{Herm}(2m, \mathbf{C}) : JC = \bar{C}J\}.$$

Then

$$\mathcal{T}(V) = \{f(\xi) = \xi^*\xi + (J\bar{\xi})(J\bar{\xi})^* : \xi \in \mathbf{S}^{2m-1}\}.$$

Given $C \in V, \langle C, f(\xi)\rangle = \xi^*C\xi$.

In particular, we see that $\mu : \mathbf{C}^{2m} \to V$, $\mu(\xi) = \xi\xi^* + (J\bar{\xi})(J\bar{\xi})^*$ is such that $\mu(\mathbf{S}^{2m-1}) = \mathcal{T}(V)$.

We see now that Propositions 3–9 admit a natural interpretation in terms of convexity of images of families of quadratic forms. Notice that $\varphi_4(2) = 6$.

As an example, consider the reformulation of Proposition 5.

PROPOSITION 17. *Let $D_1, \dots, D_5$ be matrices of the form* (6). *Let $q_i(x) = x^* D_i x, x \in \mathbf{C^{2m}}$, $m \geq 3$, with $\mu : \mathbf{C}^{2m} \to \mathbf{R}^5$ defined as*

$$\mu(x) = (q_1(x), \dots, q_5(x))^T.$$

Then $\mu(\mathbf{S}^{4m-1})$ is convex.

Here $\mathbf{S}^{4m-1} = \{x \in \mathbf{C}^{2m} : x^* x = 1\}$.

Let now $D_0, \dots, D_5$ be matrices of the form (6) and such that

$$\sum_{i=0}^{5} \tau_i D_i > 0$$

for some real τ_i. The next two propositions immediately follow from Propositions 6 and 9.

PROPOSITION 18. *Let $m \geq 3$. Consider the following quadratic optimization problem:*

$$q_0(x) \to \min, \quad q_i(x) = b_i, \quad i = 1, \dots, 5, \ x \in \mathbf{C}^{2m}.$$

Here b_i are some real numbers and $q_i(x) = x^* D_i x$. Consider, further, its semidefinite relaxation:

$$\operatorname{Tr}(D_0 Y) \to \min, \quad \operatorname{Tr}(D_i Y) = b_i, \quad i = 1, \dots, 5,$$

$$Y \geq 0, \quad Y \in \operatorname{Herm}(m, \mathbf{H})$$

(*i.e., Y is of the form* (6)). *Then this semidefinite relaxation is exact.*

PROPOSITION 19. *Let $m \geq 3$,*

$$\Gamma = \{x \in \mathbf{C^{2m}} : q_i(x) \geq 0, i = 1, \dots, 5\}.$$

Suppose that there exists $x_0 \in \mathbf{C^{2m}}$ such that $q_i(x) > 0, i = 1, \dots, 5$. Further, let $q_0(x) \geq 0$ for all $x \in \Gamma$. Then there exist real nonnegative $\lambda_1, \dots, \lambda_5$ such that

$$D_0 - \sum_{i=1}^{5} \lambda_i D_i \geq 0.$$

Remark. Notice that all results obtained from Propositions 3–9 for $A = \mathbf{H}$ seem to be new.

Case 4. Consider the last case $A = \mathbf{O}$, $V = \operatorname{Herm}(3, \mathbf{O})$. In this case $\operatorname{rank}(V) = 3, d(V) = 8, \dim V = 27$. Notice that $\varphi_8(2) = 10$.

Let

$$C = \begin{bmatrix} \xi_1 & x_3 & \bar{x_2} \\ \bar{x_3} & \xi_2 & x_1 \\ x_2 & \bar{x_1} & \xi_3 \end{bmatrix}, \quad D = \begin{bmatrix} \eta_1 & y_3 & \bar{y_2} \\ \bar{y_3} & \eta_2 & y_1 \\ y_2 & \bar{y_1} & \eta_3 \end{bmatrix} \in \operatorname{Herm}(3, \mathbf{O}). \tag{7}$$

Here $\xi_i, \eta_i \in \mathbf{R}$, $x_i, y_i \in \mathbf{O}, i = 1, 2, 3$.

Recall (see, e.g., [E]) that octonions can be identified with the pair of quaternions: $z \in \mathbf{O} \Leftrightarrow z = (z_1, z_2), z_1, z_2 \in \mathbf{H}$.

Moreover, if $t = (t_1, t_2) \in \mathbf{O}$, then

$$zt = (z_1 t_1 - \bar{z}_2 t_2, z_2 \bar{t}_1 + t_2 z_1),$$

$\bar{z} = (\bar{z}_1, -z_2)$. The trace operator tr coincides with the matrix Tr (see [FK, p. 88–90]). Hence,

$$\langle C, D \rangle = \mathrm{Tr}\ (C \circ D) = \mathrm{Tr}\ \frac{(CD + DC)}{2}.$$

A short computation with C, D in the form (7) yields

$$\langle C, D \rangle = \sum_{i=1}^{3} \xi_i \eta_i + \mathrm{Re} \left(\sum_{i=1}^{3} \bar{x}_i y_i + x_i \bar{y}_i \right) = \sum_{i=1}^{3} \xi_i \eta_i + 2 \sum_{i=1}^{3} \langle x_i, y_i \rangle_{\mathbf{O}}.$$

Here $\langle x, y \rangle_{\mathbf{O}} = \mathrm{Re}(x\bar{y})$, $x, y \in \mathbf{O}$. Notice that the last equality follows from $\mathrm{Re}(xy) = \mathrm{Re}(yx), x, y \in \mathbf{O}$. See Proposition V.1.2 in [FK].

As usual,

$$\mathcal{T}(V) = \{C \in V : C^2 = C, \mathrm{Tr}(C) = 1\}.$$

A direct computation (see, e.g., [BP]) yields the following.

PROPOSITION 20. *Let C be parameterized as in* (7). *Then* $\mathcal{T}(Herm(3, \mathbf{O})) = \{(x_1, x_2, x_3, \xi_1, \xi_2, \xi_3) \in \mathbf{O}^3 \times \mathbf{R}^3 : \xi_1 + \xi_2 + \xi_3 = 1,\ \xi_1 = \xi_1^2 + \|x_2\|^2 + \|x_3\|^2,\ \xi_2 = \xi_2^2 + \|x_1\|^2 + \|x_3\|^2,\ \xi_3 = \xi_3^2 + \|x_1\|^2 + \|x_2\|^2,\ \xi_1 \bar{x}_1 = x_2 x_3,\ \xi_2 \bar{x}_2 = x_3 x_1,\ \xi_3 \bar{x}_3 = x_1 x_2\}$.

Here $\|x\|^2 = x\bar{x} = \bar{x}x$.

Propositions 3–8 are the statements about the convexity of linear images of the manifold $\mathcal{T}(V)$ or its conic hull. Notice that $\dim \mathcal{T}(V) = d(V)(\mathrm{rank}(V) - 1) = 16$.

It is not so easy, however, to translate these results into ones concerning images of quadratic forms. Acting in analogy with the cases of $A = \mathbf{R}, \mathbf{C}, \mathbf{H}$, we need to consider the map $\mu : \mathbf{O}^3 \to \mathrm{Herm}(3, \mathbf{O})$,

$$\mu(d_1, d_2, d_3) = (d_i \bar{d}_j), \quad i, j = 1, 2, 3.$$

Let $\mathbf{S}^{23} = \{(d_1, d_2, d_3) \in \mathbf{O}^3 : \|d_1\|^2 + \|d_2\|^2 + \|d_3\|^2 = 1\}$.

Unfortunately, $\mu(\mathbf{S}^{23}) \neq \mathcal{T}(\mathrm{Herm}(3, \mathbf{O}))$. More precisely $\mathcal{T}(\mathrm{Herm}(3, \mathbf{O})) \subset \mu(\mathbf{S}^{23})$, but the inclusion is strict. Similar construction for $A = \mathbf{R}, \mathbf{C}, \mathbf{H}$ yields a coincidence of corresponding sets.

The problem is due to the fact that multiplication in $\mathbf{O}$ is not associative (see [BP] for details). Nevertheless, we have the following proposition.

PROPOSITION 21. *Let $\tilde{\mu}$ be the restriction of μ to $\mathbf{O} \times \mathbf{O} \times \mathbf{R}$. Then* $\tilde{\mu}(\mathbf{S}^{16}) = \mathcal{T}(V)$.

Here $\mathbf{S}^{16} = \{(d_1, d_2, \zeta) \in \mathbf{O} \times \mathbf{O} \times \mathbf{R} : \|d_1\|^2 + \|d_2\|^2 + \zeta^2 = 1\},\ \|d\| = \sqrt{d\bar{d}}, d \in \mathbf{O}$.

Proof. Let us show first that $\tilde{\mu}(\mathbf{S}^{16}) \subset \mathcal{T}(V)$. We simply need to check all conditions of Proposition 20.

We have that $\mu(d_1, d_2, \zeta) = (x_1, x_2, x_3, \xi_1, \xi_2, \xi_3)$ is equivalent to $\xi_i = \|d_i\|^2, i = 1, 2, 3,\ x_3 = d_1 \bar{d}_2,\ \bar{x}_2 = \zeta d_1, x_1 = \zeta d_2$. Let us check, for example, that $\xi_1 = \xi_1^2 + \|x_2\|^2 + \|x_3\|^2$. We have $\Delta = \xi_1^2 + \|x_2\|^2 + \|x_3\|^2 = \|d_1\|^4 + \zeta^2 \|d_1\|^2 + \|d_1\|^2 \|d_2\|^2$. Here we used $\|d_1 d_2\| = \|d_1\| \|d_2\|$. Hence, $\Delta = \|d_1\|^2 (\|d_1\|^2 + \zeta^2 + \|d_2\|^2) = \|d_1\|^2 = \xi_1$.

The other conditions are verified similarly. Let us show that $\tilde{\mu}(\mathbf{S}^{16}) \supset \mathcal{T}(V)$. Let $(\xi_1, \xi_2, \xi_3, x_1, x_2, x_3) \in \mathcal{T}(V)$. Consider, first, the case where $\xi_3 > 0$.

Take $d_1 = \frac{\bar{x_2}}{\sqrt{\xi_3}}$, $d_2 = \frac{x_1}{\sqrt{\xi_3}}$, $\zeta = \sqrt{\xi_3}$.

Notice that $\|d_1\|^2+\|d_2\|^2+\zeta^2 = \frac{\|x_2\|^2+\|x_1\|^2+\xi_3^2}{\xi_3} = 1$ because of the one of the defining relations for $\mathcal{T}(V)$. We can easily check that $\mu(d_1, d_2, \zeta) = (\xi_1, \xi_2, \xi_3, x_1, x_2, x_3)$.

Consider now the case $\xi_3 = 0$. Due to the condition $\xi_3 = \xi_3^2 + \|x_1\|^2 + \|x_2\|^2$, we obtain $x_1 = x_2 = 0$. Hence, we have

$$\xi_1 = \xi_1^2 + \|x_3\|^2, \quad \xi_2 = \xi_2^2 + \|x_3\|^2, \quad \xi_1 + \xi_2 = 1.$$

This system has two solutions:

$$\xi_1 = \frac{1}{2} \pm \frac{\sqrt{1 - 4\|x_3\|^2}}{2},$$

$$\xi_2 = \frac{1}{2} \mp \frac{\sqrt{1 - 4\|x_3\|^2}}{2},$$

provided $\|x_3\| \le \frac{1}{2}$. Take $d_1 = \frac{\sqrt{\xi_1}x_3}{\|x_3\|}, d_2 = \sqrt{\xi_2}, \zeta = 0$ if $x_3 \neq 0$. If $x_3 = 0$, then $\xi_1 = 0, \xi_2 = 1$ or $\xi_1 = 1, \xi_2 = 0$. In both cases take $d_1 = \sqrt{\xi_1}, d_2 = \sqrt{\xi_2}, \zeta = 0$. We easily check that $\mu(d_1, d_2, \eta) = (\xi_1, \xi_2, \xi_3, x_1, x_2, x_3)$. □

We identify $\mathbf{O}\times\mathbf{O}\times\mathbf{R}$ with $\mathbf{R}^{17}$. Consider on $\mathbf{R}^{17}$ quadratic forms of the following type:

$$\begin{aligned} f_{y,\eta}(d_1, d_2, \zeta) = {} & \eta_1\|d_1\|^2 + \eta_2\|d_2\|^2 + \eta_3\zeta^2 \\ & + 2\langle y_1, d_2\rangle_{\mathbf{O}}\zeta + 2\langle y_2, \bar{d_1}\rangle_{\mathbf{O}}\zeta + 2\langle y_3, d_1\bar{d_2}\rangle_{\mathbf{O}}\zeta. \end{aligned} \tag{8}$$

Here $y_1, y_2, y_3 \in \mathbf{O}, \eta_1, \eta_2, \eta_3 \in \mathbf{R}$.

Notice that if D is constructed from $(y_1, y_2, y_3, \eta_1, \eta_2, \eta_3)$ as in (7), then

$$f_{y,\eta}(d_1, d_2, \zeta) = \mathrm{Tr}(D \circ \tilde{\mu}(d_1, d_2, \zeta)).$$

We can now easily reformulate Propositions 3–8 in terms of quadratic forms $f_{y,\eta}$ on $\mathbf{R}^{17}$. For example, Proposition 3 leads to the following result. Notice that $\varphi_8(2) = 10$.

PROPOSITION 22. *Let $q_i, i = 1, 2, \ldots, 9$, be nine quadratic forms of type* (8) *on $\mathbf{R}^{17}$ identified with $\mathbf{O} \times \mathbf{O} \times \mathbf{R}$. Consider the map*

$$\nu(d_1, d_2, \zeta) = (q_1(d_1, d_2, \zeta), \ldots, q_9(d_1, d_2, \zeta)).$$

Then $\nu(\mathbf{R}^{17})$ is a convex cone.

7. Concluding remarks. In the present paper we have considered a large number of classical results related to the convexity of image of quadratic mappings in a general context of Euclidean Jordan algebras. The technique used is a generalization of semidefinite relaxation technique which has been used by Barvinok for similar purposes. Our context is more general and allows one to obtain convexity result corresponding to the series $\mathrm{Herm}(m, \mathbf{H})$ of Euclidean Jordan algebra and exceptional 27-dimensional algebra, which seem to be new. The present paper does not exhaust all possibilities offered by the Jordan-algebraic technique for the analysis of this circle of questions. We plan to address the remaining issues elsewhere.

ACTIVE SET IDENTIFICATION IN NONLINEAR PROGRAMMING*

CHRISTINA OBERLIN† AND STEPHEN J. WRIGHT†

Abstract. Techniques that identify the active constraints at a solution of a nonlinear programming problem from a point near the solution can be a useful adjunct to nonlinear programming algorithms. They have the potential to improve the local convergence behavior of these algorithms and in the best case can reduce an inequality constrained problem to an equality constrained problem with the same solution. This paper describes several techniques that do not require good Lagrange multiplier estimates for the constraints to be available a priori, but depend only on function and first derivative information. Computational tests comparing the effectiveness of these techniques on a variety of test problems are described. Many tests involve degenerate cases, in which the constraint gradients are not linearly independent and/or strict complementarity does not hold.

Key words. nonlinear programming, active constraint identification, degeneracy

AMS subject classifications. 90C30, 90C46

DOI. 10.1137/050626776

1. Introduction.

Consider the following nonlinear programming problem:

$$\min f(x) \text{ subject to } h(x) = 0, \quad c(x) \leq 0, \tag{1.1}$$

where $x \in \mathbb{R}^n$ and $f : \mathbb{R}^n \to \mathbb{R}$, $c : \mathbb{R}^n \to \mathbb{R}^m$, and $h : \mathbb{R}^n \to \mathbb{R}^p$ are twice continuously differentiable functions.

In this paper, we examine identification of active inequality constraints—the components of c for which equality holds at a local solution x^*—using information available at a point x near x^*. We focus on identification schemes that do not require good estimates of the Lagrange multipliers to be available a priori. Rather, in some cases, such estimates are computed as an adjunct to the identification technique. In most of our results, we relax the "standard" nondegeneracy assumptions at x^* to allow linearly dependent active constraint gradients and weakly active constraints. We consider three schemes that require solution of linear programs and one that requires solution of a mixed integer program. We analyze the effectiveness of these schemes and discuss computational issues of solving the linear and mixed-integer programs. Finally, we present results obtained on randomly generated problems and on degenerate problems from the CUTEr test set [13].

One area in which identification schemes are useful is in "EQP" approaches to sequential quadratic programming (SQP) algorithms, in which each iteration consists of an estimation of the active set followed by solution of an equality constrained quadratic program that enforces the apparently active constraints and ignores the apparently inactive ones. The "IQP" variant of SQP, in which an inequality constrained subproblem is solved (thereby estimating the active set implicitly), has been more widely studied in the past two decades, but the EQP variant has been revived recently by Byrd et al. [5, 6].

1.1. Assumptions and background. We describe here the notation and assumptions used in the remainder of the paper.

The Lagrangian for (1.1) is

$$\mathcal{L}(x,\mu,\lambda) = f(x) + \mu^T h(x) + \lambda^T c(x), \tag{1.2}$$

where $\mu \in \mathbb{R}^p$ and $\lambda \in \mathbb{R}^m$ are Lagrange multipliers. First-order necessary conditions for x^* to be a solution of (1.1), assuming a constraint qualification, are that there exist multipliers (μ^*, λ^*) such that

$$\nabla_x \mathcal{L}(x^*, \mu^*, \lambda^*) = 0, \tag{1.3a}$$

$$h(x^*) = 0, \tag{1.3b}$$

$$0 \geq c(x^*) \perp \lambda^* \geq 0, \tag{1.3c}$$

where the symbol $\perp$ denotes vector complementarity; that is, $a \perp b$ means $a^T b = 0$. We define the "dual" solution set as follows:

$$\mathcal{S}_D \stackrel{\text{def}}{=} \{(\mu^*, \lambda^*) \text{ satisfying (1.3)}\}, \tag{1.4}$$

while the primal-dual solution set $\mathcal{S}$ is

$$\mathcal{S} \stackrel{\text{def}}{=} \{x^*\} \times \mathcal{S}_D.$$

The set of *active inequality constraints* at x^* is defined as follows:

$$\mathcal{A}^* = \{i = 1, 2, \ldots, m \,|\, c_i(x^*) = 0\}.$$

The *weakly active inequality constraints* $\mathcal{A}_0^*$ are those active constraints i for which $\lambda_i^* = 0$ for all optimal multipliers (μ^*, λ^*); that is,

$$\mathcal{A}_0^* = \{i \in \mathcal{A}^* \,|\, \lambda_i^* = 0 \text{ for all } (\mu^*, \lambda^*) \in \mathcal{S}_D\}. \tag{1.5}$$

The constraints $\mathcal{A}^* \setminus \mathcal{A}_0^*$ are said to be the *strongly active inequalities*.

In this paper, we make use of the following two constraint qualifications at x^*. The linear independence constraint qualification (LICQ) is that

$$\{\nabla h_i(x^*),\ i = 1, 2, \ldots, p\} \cup \{\nabla c_i(x^*),\ i \in \mathcal{A}^*\} \text{ is linearly independent.} \tag{1.6}$$

The Mangasarian–Fromovitz constraint qualification (MFCQ) is that there is a vector $v \in \mathbb{R}^n$ such that

$$\nabla c_i(x^*)^T v < 0,\ \ i \in \mathcal{A}^*; \quad \nabla h_i(x^*)^T v = 0,\ \ i = 1, 2, \ldots, p, \tag{1.7a}$$

$$\{\nabla h_i(x^*),\ i = 1, 2, \ldots, p\} \text{ is linearly independent.} \tag{1.7b}$$

In some places, we use the following second-order sufficient condition: Defining

$$\begin{aligned} \mathcal{C} \stackrel{\text{def}}{=} \{v \,|\, & \nabla c_i(x^*)^T v = 0,\ i \in \mathcal{A}^* \setminus \mathcal{A}_0^*,\ \ \nabla c_i(x^*)^T v \leq 0,\ i \in \mathcal{A}_0^*, \\ & \nabla h_i(x^*)^T v = 0,\ i = 1, 2, \ldots, p\}, \end{aligned} \tag{1.8}$$

we require that

$$v^T \nabla^2_{xx} \mathcal{L}(x^*, \mu^*, \lambda^*) v > 0 \text{ for all } v \in \mathcal{C} \setminus \{0\} \text{ and all } (\mu^*, \lambda^*) \in \mathcal{S}_D. \tag{1.9}$$

The following notation is used for first derivatives of the objective and constraint functions at x:

$$g(x) = \nabla f(x), \quad J(x) = [\nabla h_i(x)^T]_{i=1,2,\ldots,p}, \quad A(x) = [\nabla c_i(x)^T]_{i=1,2,\ldots,m}.$$

We use $A_i(x) = \nabla c_i(x)^T$ to denote the ith row of $A(x)$, while for any index set $\mathcal{T} \subset \{1, 2, \ldots, m\}$, we use $A_{\mathcal{T}}(x)$ to denote the $|\mathcal{T}| \times n$ submatrix corresponding to $\mathcal{T}$. In some subsections, the argument x is omitted from the quantities $c(x)$, $A(x)$, $A_i(x)$, and $A_{\mathcal{T}}(x)$ if the dependence on x is clear from the context. In some instances, we also use ∇c_i^*, g^*, etc., to denote $\nabla c_i(x^*)$, $g(x^*)$, etc., respectively.

Given a matrix $B \in \mathbb{R}^{n\times q}$ we denote

$$\text{range}[B] = \{Bz \,|\, z \in \mathbb{R}^q\}, \quad \text{pos}[B] = \{Bz \,|\, z \in \mathbb{R}^q,\ z \geq 0\}.$$

The norms $\|\cdot\|_1$, $\|\cdot\|_2$, and $\|\cdot\|_\infty$ all appear in the paper. When the subscript is omitted, the Euclidean norm $\|\cdot\|_2$ is intended.

We use the usual definition of the distance function $\text{dist}\,(\cdot,\cdot)$ between sets, that is,

$$\text{dist}\,(\mathcal{S}_1, \mathcal{S}_2) = \inf_{s_1\in\mathcal{S}_1, s_2\in\mathcal{S}_2} \|s_1 - s_2\|. \tag{1.10}$$

(Distance between a point and a set is defined similarly.)

For a vector z, function $\max(z, 0)$ (defined componentwise) is denoted by z_+, while z_- denotes $\max(-z, 0)$. We use the notation e throughout the paper to denote the vector $(1, 1, \ldots, 1)^T$. (The dimension of e is not specified but is clear from the context.)

In assessing the accuracy of an active set estimate, a *false positive* is an index i that is identified as active by our scheme but which actually does not belong to $\mathcal{A}^*$, while a *false negative* is an index $i \in \mathcal{A}^*$ which is wrongly identified as inactive.

1.2. Related work. Some previous works have studied the behavior of nonlinear programming algorithms in identifying active constraint sets, more or less as a by-product of their progress toward a solution. Other papers have described the use of these active set estimates to speed the convergence of the algorithm in its final stages. We mention several works of both types here, in nonlinear programming and in the context of other optimization and complementarity problems.

Bertsekas [1] proposed a two-metric algorithm for minimizing a nonlinear function subject to bound constraints on the components of x. A key aspect of this method is estimation of the active bounds at the solution. (Different second-order scalings are applied to the apparently active components and the free components.) Strongly active constraints are identified for all feasible x in a neighborhood of x^*. The latter result is also proved by Lescrenier [16] for a trust-region algorithm.

Burke and Moré [3, 4] take a geometric approach, assuming the constraints to be expressed in the form $x \in \Omega$ for a convex set Ω. This set can be partitioned into faces, where a face F is defined to be a subset of Ω such that every line segment in Ω whose relative interior meets F is contained in F. In this context, active set identification corresponds to the identification of the face that contains the solution x^*. In [3], it is shown that "quasi-polyhedral" faces are identified for all x close to x^* provided that a geometric nondegeneracy condition akin to strict complementarity is satisfied. (Quasi-polyhedrality is defined in [3, Definition 2.5]; curved faces are not quasi-polyhedral.) Burke [2] takes a partly algebraic viewpoint and shows that the set

of active indices of a linear approximation to the problem at x near x^* are sufficient for the objective gradient to be contained in the cone of active constraint gradients—a result not unlike Theorem 3.2 below.

Wright [21] also uses a hybrid geometric-algebraic viewpoint and considers convex constraint sets Ω with (possibly curved) boundaries defined by (possibly nonlinear) inequalities. The concept of a "class-$\mathcal{C}^p$ identifiable surface" is defined, and it is shown that this surface is identified at all x close to x^* provided that a nondegeneracy condition is satisfied. Hare and Lewis [15] extend these concepts to nonconvex sets, using concepts of prox-regularity and partly smooth functions developed elsewhere by Lewis [17] and others.

Facchinei, Fischer, and Kanzow [10] describe a technique based on the algebraic representation of the constraint set that uses estimates of the Lagrange multipliers (μ, λ) along with the current x to obtain a two-sided estimate of the distance of (x, μ, λ) to the primal-dual solution set. This estimate is used in a threshold test to obtain an estimate of $\mathcal{A}^*$. We discuss this technique further in section 2.

Conn, Gould, and Toint [8, Chapter 12] discuss the case of convex constraints, solved with a trust-region algorithm in which a "generalized Cauchy point" is obtained via gradient projection. They prove that when assumptions akin to strict complementarity and LICQ hold at the solution x^*, their approach identifies the active set once the iterates enter a neighborhood of x^*; see, for example, [8, Theorem 12.3.8].

Active constraint identification has played an important role in finite termination strategies for linear programming (LP). Ye [25] proposed such a strategy, which determined the active set estimate by a simple comparison of the primal variables with the dual slacks. (An equality constrained quadratic program, whose formulation depends crucially on the active set estimate, is solved in an attempt to "jump to" an optimal point.) El-Bakry, Tapia, and Zhang [9] discuss methods based on "indicators" for identifying the active constraints for LP.

Similar active identification and finite termination strategies are available for monotone linear complementarity problems; see, for example, the paper of Monteiro and Wright [18]. For monotone nonlinear complementarity problems, Yamashita, Dan, and Fukushima [24] describe a technique for classifying indices (including degenerate indices) at the limit point of a proximal point algorithm. This threshold is defined similarly to the one in [10], while the classification test is similar to that of [18].

1.3. Organization of the paper. In section 2, we review a technique for identifying the active set using an estimate (x, μ, λ) of the primal-dual optimum. This technique provides the basis for the identification techniques of subsections 3.2 and 3.3. Section 3 describes the main techniques for identifying the active set without assuming that reliable estimates of the Lagrange multipliers (μ, λ) are available. Subsection 3.1 describes a technique used by Byrd et al. [5, 6] along with a dual variant; subsection 3.2 describes a technique based on minimizing the primal-dual measure of section 2, which can be formulated as a mixed integer program; and subsection 3.3 derives an LP approximation to the latter technique. In all cases, we prove results about the effectiveness of these schemes and discuss their relationship to each other. In section 4, we describe our implementation of the identification schemes and present results obtained on randomly generated problems (with controlled degeneracy) and on degenerate problems from the CUTEr test set. Some conclusions appear in section 5.

2. Identification from a primal-dual point. In this section, we suppose that along with an estimate x of the solution x^*, we have estimates of the Lagrange multi-

pliers (μ, λ). We describe a threshold test based on the function ψ defined as follows:

$$\psi(x,\mu,\lambda) = \left\| \begin{bmatrix} \nabla_x \mathcal{L}(x,\mu,\lambda) \\ h(x) \\ \min(\lambda, -c(x)) \end{bmatrix} \right\|_1, \tag{2.1}$$

where the $\min(\cdot,\cdot)$ is taken componentwise. (Other norms could be used in this definition, including weighted norms, but the ℓ_1 norm is convenient for computation in later contexts.) The test based on ψ provides the starting point for the LPEC (linear program with equilibrium constraints) scheme of subsection 3.2, where we fix x and choose (μ, λ) to minimize ψ, rather than assuming that (μ, λ) are given.

The following result shows that for (x, μ, λ) close to $\mathcal{S}$, this function provides a two-sided estimate of the distance to the solution. (See Facchinei, Fischer, and Kanzow [10, Theorem 3.6], Hager and Gowda [14], and Wright [22, Theorem A.1] for proofs of results similar or identical to this one.)

THEOREM 2.1. *Suppose the KKT conditions* (1.3)*, the MFCQ* (1.7)*, and the second-order condition* (1.9) *are satisfied at* x^**. There are constants* $\epsilon \in (0, 1]$ *and* $C > 0$ *such that, for all* (x, μ, λ) *with* $\lambda \geq 0$ *and* $\operatorname{dist}((x,\mu,\lambda), \mathcal{S}) \leq \epsilon$*, we have*

$$C^{-1}\psi(x,\mu,\lambda) \leq \operatorname{dist}((x,\mu,\lambda), \mathcal{S}) \leq C\psi(x,\mu,\lambda). \tag{2.2}$$

(The upper bound of 1 *in the definition of* ϵ *is needed to simplify later arguments.)*

For future reference, we define L to be a Lipschitz constant for the functions g, c, h, A, and J in the neighborhood $\|x - x^*\| \leq \epsilon$, for the ϵ given in Theorem 2.1. In particular, we have

$$\begin{aligned} &\|g(x) - g(x^*)\| \leq L\|x - x^*\|, \quad \|c(x) - c(x^*)\| \leq L\|x - x^*\|, \\ &\|A(x) - A(x^*)\| \leq L\|x - x^*\|, \quad \|h(x) - h(x^*)\| \leq L\|x - x^*\|, \\ &\|J(x) - J(x^*)\| \leq L\|x - x^*\|, \quad \text{for all } x \text{ with } \|x - x^*\| \leq \epsilon. \end{aligned} \tag{2.3}$$

We define a constant K_1 such that the following condition is satisfied:

$$K_1 = \max\left(\|c(x^*)\|_\infty, \max_{(\mu^*,\lambda^*)\in\mathcal{S}_D} \|(\mu^*, \lambda^*)\|_\infty \right) + 1. \tag{2.4}$$

(Note that finiteness of K_1 is assured under MFCQ.)

The active set estimate is a threshold test, defined as follows for a given parameter $\sigma \in (0, 1)$:

$$\mathcal{A}(x,\mu,\lambda) = \{i \mid c_i(x) \geq -\psi(x,\mu,\lambda)^\sigma\}. \tag{2.5}$$

The following result is an immediate consequence of Theorem 2.1. It has been proved in earlier works (see, for example, [10]), but since the proof is short and illustrative, we repeat it here.

THEOREM 2.2. *Suppose that the KKT conditions* (1.3)*, the MFCQ* (1.7)*, and the second-order condition* (1.9) *are satisfied at* x^**. Then there is* $\bar{\epsilon}_1 > 0$ *such that for all* (x, μ, λ) *with* $\lambda \geq 0$ *and* $\operatorname{dist}((x,\mu,\lambda), \mathcal{S}) \leq \bar{\epsilon}_1$*, we have that* $\mathcal{A}(x,\mu,\lambda) = \mathcal{A}^*$*.*

Proof. First set $\bar{\epsilon}_1 = \epsilon$, where ϵ is small enough to satisfy the conditions in Theorem 2.1. Taking any $i \notin \mathcal{A}^*$, we can decrease $\bar{\epsilon}_1$ if necessary to ensure that the following inequalities hold for all (x, μ, λ) with $\operatorname{dist}((x,\mu,\lambda), \mathcal{S}) \leq \bar{\epsilon}_1$:

$$c_i(x) < (1/2)c_i(x^*) \leq -\psi(x,\mu,\lambda)^\sigma,$$

thus ensuring that $i \notin \mathcal{A}(x, \mu, \lambda)$.

We can reduce $\bar{\epsilon}_1$ again if necessary to ensure that the following relation holds for all $i \in \mathcal{A}^*$ and all (x, μ, λ) with $\operatorname{dist}((x, \mu, \lambda), \mathcal{S}) \leq \bar{\epsilon}_1$:

$$|c_i(x)| \leq L\|x - x^*\| \leq L \operatorname{dist}((x, \mu, \lambda), \mathcal{S}) \leq LC\psi(x, \mu, \lambda) \leq \psi(x, \mu, \lambda)^\sigma,$$

where L is the Lipschitz constant defined in (2.3). We conclude that $i \in \mathcal{A}(x, \mu, \lambda)$. □

High-quality estimates of the optimal Lagrange multipliers may be available in primal-dual interior-point algorithms and augmented Lagrangian algorithms. In SQP algorithms, an estimate (μ, λ) may be available from the QP subproblem solved at the previous iteration, or from an approximation procedure based on the current estimate of the active set (which usually also derives from the QP subproblem). However, the use of devices such as trust regions or ℓ_1 penalty terms in the subproblem may interfere with the accuracy of the Lagrange multiplier estimates. Moreover, in many algorithms, there is not a particularly strong motivation for obtaining accurate estimates of (μ, λ). For instance, in SQP algorithms that use exact second derivatives, rapid convergence of the primal iterates to x^* can be obtained even when (μ, λ) do not converge to $\mathcal{S}_D$; see Theorem 12.4.1 of Fletcher [11] and the comments that follow this result. The QP subproblem of the primal-dual algorithms in the `Knitro` software package may return only the primal variables, in which case the multipliers must be approximated using primal information [7].

Even in cases in which an estimate of (μ, λ) is available from the algorithm, it may be desirable to seek alternative values of (μ, λ) that decrease the value of $\psi(x, \mu, \lambda)$, thereby tightening the tolerance in the threshold test (2.5). This approach forms the basis of the techniques described in subsections 3.2 and 3.3, which provide asymptotically accurate estimates of the Lagrange multipliers as well as of the active set $\mathcal{A}^*$.

3. Identification from a primal point. We describe a number of techniques for estimating $\mathcal{A}^*$ for a given x near the solution x^*. We discuss the relationships between these techniques and conditions under which they provide asymptotically accurate estimates of $\mathcal{A}^*$.

3.1. Linear programming techniques. We describe here techniques based on a linearization of the ℓ_1 penalty formulation of (1.1). A linearized trust-region subproblem is solved and an estimate of $\mathcal{A}^*$ is extracted from the solution. One of these techniques is used by Byrd et al. [5, 6] as part of their SQP-EQP approach. (The idea of a linearized trust-region subproblem was proposed initially by Fletcher and Sainz de la Maza [12].)

The following subproblem forms the basis of the techniques in this section:

$$\min_d \; g^T d + \nu\|Jd + h\|_1 + \nu\|(c + Ad)_+\|_1 \quad \text{subject to } \|d\|_\infty \leq \Delta, \tag{3.1}$$

where ν is a penalty parameter, Δ is the trust-region radius, and all functions are assumed to be evaluated at x. This problem can be formulated explicitly as a linear program by introducing auxiliary variables r, s, and t, and writing

$$\min_{(d,r,s,t)} \; g^T d + \nu e^T r + \nu e^T s + \nu e^T t \quad \text{subject to} \tag{3.2a}$$

$$Ad + c \leq r, \;\; Jd + h = t - s, \;\; -\Delta e \leq d \leq \Delta e, \;\; (r, s, t) \geq 0, \tag{3.2b}$$

where, as mentioned in the introduction, we have $e = (1, 1, \ldots, 1)^T$. The dual of this problem is as follows:

$$\min_{(\lambda,\mu,u,v)} \; -c^T\lambda - h^T\mu + \Delta e^T u + \Delta e^T v \quad \text{subject to} \tag{3.3a}$$

$$A^T\lambda + J^T\mu + g = u - v, \;\; 0 \le \lambda \le \nu e, \;\; -\nu e \le \mu \le \nu e, \;\; (u, v) \ge 0. \tag{3.3b}$$

This formulation can be written more compactly as follows:

$$\min_{(\lambda,\mu)} \; -c^T\lambda - h^T\mu + \Delta\|A^T\lambda + J^T\mu + g\|_1 \quad \text{subject to} \tag{3.4a}$$

$$0 \le \lambda \le \nu e, \;\; -\nu e \le \mu \le \nu e. \tag{3.4b}$$

The formulations above are feasible and bounded. Moreover, they admit some invariance to scaling the constraints. Suppose, for some constraint c_i, we have that the λ_i component of the dual solution is strictly less than its upper bound of ν. By duality, we then have $r_i = 0$ at the solution of (3.2). If we scale constraint c_i by some $\sigma_i > 0$ (that is, we set $c_i \leftarrow \sigma_i c_i$ and $A_i \leftarrow \sigma_i A_i$), constraints (3.2b) and (3.3b) continue to be satisfied, while the objectives (3.2a) and (3.3a) remain unchanged (and therefore optimal) if we set $\lambda_i \leftarrow \lambda_i/\sigma_i$, provided that $\lambda_i/\sigma_i \le \nu$. Similar comments apply regarding the components of h.

The active set estimate can be derived from the solution of these linear programs in different ways. We mention the following three possibilities:

$$\mathcal{A}_c(x) = \{i \,|\, A_i d + c_i \ge 0\}, \tag{3.5a}$$

$$\mathcal{A}_\lambda(x) = \{i \,|\, \lambda_i > 0\}, \tag{3.5b}$$

$$\mathcal{A}_B(x) = \{i \,|\, \lambda_i \text{ is in the optimal basis for (3.3)}\}. \tag{3.5c}$$

The first of these activity tests (3.5a) cannot be expected to identify weakly active constraints except when $x = x^*$. The second test (3.5b) will generally not identify weakly active constraints, and will also fail to identify a strongly active constraint i if the particular multiplier estimate used in the test happens to have $\lambda_i = 0$. The third test (3.5c) does not attempt to estimate the full active set, but rather a "sufficient" subset of it that can be used in subsequent calculations requiring a nonsingular basis matrix for the active constraint gradients.

For the remainder of this section, we focus on $\mathcal{A}_c(x)$. The following simple lemma shows that, for x sufficiently near x^* and Δ sufficiently small, this activity test does not contain false positives.

LEMMA 3.1. *There are positive constants $\bar{\epsilon}_2$ and $\bar{\Delta}$ such that when $\|x - x^*\| \le \bar{\epsilon}_2$ and $\Delta \le \bar{\Delta}$, we have $\mathcal{A}_c(x) \subset \mathcal{A}^*$.*

Proof. We first choose $\bar{\epsilon}_2$ small enough such that for any x with $\|x - x^*\| \le \bar{\epsilon}_2$ and any $i \notin \mathcal{A}^*$ we have $c_i(x) \le \frac{1}{2}c_i(x^*) < 0$. By decreasing $\bar{\Delta}$ if necessary, we also have, for any $\|d\|_\infty \le \Delta \le \bar{\Delta}$ with $\|x - x^*\| \le \bar{\epsilon}_2$, that $i \notin \mathcal{A}^* \Rightarrow A_i(x)d + c_i(x) < 0$. The result follows from the definition (3.5a) of $\mathcal{A}_c(x)$. ∎

When the trust-region radius Δ is bounded in terms of $\|x - x^*\|$ and a constraint qualification holds, we can show that the set identified by (3.5a) is at least extensive enough to "cover" the objective gradient g^*.

THEOREM 3.2. *If MFCQ holds at x^*, for any $\zeta \in (0, 1)$, there are positive constants $\bar{\nu}$, $\bar{\epsilon}_2$, and $\bar{\Delta}$ such that whenever the conditions $\nu \ge \bar{\nu}$, $\|x - x^*\| \le \bar{\epsilon}_2$, and $\Delta \in [\|x - x^*\|^\zeta, \bar{\Delta}]$ are satisfied, we have*

$$-g^* \in \text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i \in \mathcal{A}_c(x)}]. \tag{3.6}$$

Proof. We start by defining $\bar{\epsilon}_2$ and $\bar{\Delta}$ as in Lemma 3.1. For these values (and any smaller values) we have immediately that $\mathcal{A}_c(x) \subset \mathcal{A}^*$.

We require $\nu \geq \bar{\nu}$, where

$$\bar{\nu} \stackrel{\text{def}}{=} \max\ (\{\|(\mu^*, \lambda^*)\|_\infty \mid (\mu^*, \lambda^*) \in \mathcal{S}_D\}) + 1. \tag{3.7}$$

Note that $\bar{\nu}$ is well defined because the KKT and MFCQ conditions guarantee the nonemptiness and boundedness of $\mathcal{S}_D$.

For any $(\mu^*, \lambda^*) \in \mathcal{S}_D$, the dual problem (3.3) at x^* with $(\mu, \lambda, u, v) = (\mu^*, \lambda^*, 0, 0)$ has objective value 0 because of the complementarity condition (1.3c). For the problem with $x \neq x^*$, we obtain a feasible point for (3.3) by setting

$$(\mu, \lambda, u, v) = \left(\mu^*, \lambda^*, (A^T\lambda^* + J^T\mu^* + g)_+, (A^T\lambda^* + J^T\mu^* + g)_-\right).$$

The objective at this point is

$$\begin{aligned}
&-c^T\lambda^* - h^T\mu^* + \Delta\|A^T\lambda^* + J^T\mu^* + g\|_1 \\
&= (c(x^*) - c(x))^T\lambda^* + (h(x^*) - h(x))^T\mu^* \\
&\qquad +\Delta\|(A(x^*)^T - A(x)^T)\lambda^* + (J(x^*)^T - J(x)^T)\mu^* + (g(x^*) - g(x))\|_1 \\
&= O(\|x - x^*\|).
\end{aligned} \tag{3.8}$$

The first equality is due to (1.3), while the second is due to the continuous differentiability of f, c, and h and the boundedness of $\mathcal{S}_D$. The optimal point for (3.3) must therefore have an objective value that is bounded above by a positive number of size $O(\|x - x^*\|)$.

Suppose for contradiction that regardless of how small we choose $\bar{\epsilon}_2$, there is an x with $\|x - x^*\| \leq \bar{\epsilon}_2$ such that the active set $\mathcal{A}_c(x)$ has the property that $-g^* \notin \text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i\in\mathcal{A}_c(x)}]$. Since there are only a finite number of possible sets $\mathcal{A}_c(x)$, we pick one of them for which this property holds for x arbitrarily close to x^* and call it $\mathcal{A}_1$. The set $\text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i\in\mathcal{A}_1}]$ is finitely generated and is therefore closed; see Rockafellar [19, Theorem 19.1].

Using the definition for dist $(\cdot, \cdot)$ (1.10), we have that τ defined by

$$\tau \stackrel{\text{def}}{=} (0.5)\text{dist}\ (-g^*, \text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i\in\mathcal{A}_1}]) \tag{3.9}$$

is strictly positive. After a possible reduction of $\bar{\epsilon}_2$, we have that

$$\text{dist}\ (-g(x), \text{range}[\nabla h(x)] + \text{pos}[(\nabla c_i(x))_{i\in\mathcal{A}_1}]) \geq \tau \tag{3.10}$$

for the given $\mathcal{A}_1$ and *all* x with $\|x - x^*\| \leq \bar{\epsilon}_2$. (The proof of the latter claim makes use of standard arguments and appears in Appendix A.)

Given x with $\mathcal{A}_c(x) = \mathcal{A}_1$, let the solutions to the problems (3.2) and (3.3) at x be denoted by (d_x, r_x, s_x, t_x) and $(\mu_x, \lambda_x, u_x, v_x)$, respectively. For all $i \notin \mathcal{A}_1$, we have by (3.5a) and complementarity that $A_i d_x + c_i < 0$, $(r_x)_i = 0$, and

$$(\lambda_x)_i = 0 \ \text{ for all } i \notin \mathcal{A}_1. \tag{3.11}$$

We now consider the objective of the dual problem (3.3) in two parts. We have by using the property (3.11) that

$$\begin{aligned}
\Delta e^T u_x + \Delta e^T v_x &\geq \Delta \min_{\lambda\geq 0, \mu} \left\| g + J^T\mu + \sum_{i\in\mathcal{A}_1} \lambda_i \nabla c_i \right\|_1 \\
&= \Delta\text{dist}\ (-g, \text{range}[\nabla h] + \text{pos}[(\nabla c_i)_{i\in\mathcal{A}_1}]) \\
&\geq \Delta\tau.
\end{aligned}$$

From $\nu \geq \bar{\nu}$ and (3.7), we also have

$$-c^T\lambda_x - h^T\mu_x \geq -\nu\|c_+\|_1 - \nu\|h\|_1.$$

By substituting these relations into the dual objective (3.3), we have

$$-c^T\lambda_x - h^T\mu_x + \Delta e^T u_x + \Delta e^T v_x \geq \Delta\tau - \nu\|c_+\|_1 - \nu\|h\|_1.$$

Finally, we decrease $\bar{\epsilon}_2$ further if necessary so that

$$\Delta\tau - \nu\|c(x)_+\|_1 - \nu\|h(x)\|_1 \geq (\tau/2)\|x - x^*\|^\zeta$$

for $\|x - x^*\| \leq \bar{\epsilon}_2$. We note that such a choice is possible since $\Delta \geq \|x - x^*\|^\zeta$ and $h(x)$ and $(c(x))_+$ are both $O(\|x - x^*\|)$. Hence the optimal objective in (3.3) is bounded below by $(\tau/2)\|x - x^*\|^\zeta$. This bound contradicts our earlier observation in (3.8) that the optimal objective is bounded above by a multiple of $\|x - x^*\|$. We conclude that $\tau = 0$ in (3.9), and thus $-g^* \in \text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i\in\mathcal{A}_c(x)}]$, as claimed. ∎

When the assumptions are made stronger, we obtain the following result.

COROLLARY 3.3. *If LICQ holds at x^*, for any ζ, $\bar{\epsilon}_2$, Δ, ν, and x satisfying the conditions of Theorem* 3.2, $\mathcal{A}^* \setminus \mathcal{A}_0^* \subset \mathcal{A}_c(x) \subset \mathcal{A}^*$. *If strict complementarity also holds at x^*, then $\mathcal{A}_c(x) = \mathcal{A}^*$.*

Proof. When LICQ holds at x^*, the multiplier (μ^*, λ^*) which satisfies equations (1.3) is unique, and $\lambda_i^* > 0$ for all $i \in \mathcal{A}^* \setminus \mathcal{A}_0^*$. For ζ, $\bar{\epsilon}_2$, Δ, and ν defined in Theorem 3.2, we must have $i \in \mathcal{A}_c(x)$ whenever $\lambda_i^* > 0$, since otherwise (3.6) would not hold. Thus, $\mathcal{A}^* \setminus \mathcal{A}_0^* \subset \mathcal{A}_c(x)$. Lemma 3.1 supplies $\mathcal{A}_c(x) \subset \mathcal{A}^*$. The final statement follows trivially from the equivalence of strict complementarity with $\mathcal{A}_0^* = \emptyset$. ∎

The implementation of SQP-EQP known as `Active` [5, 6], which is contained in the `Knitro` package, solves the formulation (3.2) using variants of the simplex method. It is observed (Waltz [20]) that many simplex iterations are spent in resolving the trust-region bounds $-\Delta e \leq d \leq \Delta e$. This effort would seem to be wasted; we are much more interested in the question of which linearized inequality constraints from (1.1) are active at the solution of (3.2) (and, ultimately, of (1.1)) than in the trust-region bounds. The authors of `Active` have tried various techniques to terminate the solution of (3.2) prematurely at an inexact solution, but these appear to increase the number of "outer" iterations of the SQP algorithm.

Because there is no curvature, trust-region bounds in (3.1) may be active, regardless of the size of Δ, even when x is arbitrarily close to x^*. The theorems above highlight the importance of choosing Δ large enough to allow constraints in $\mathcal{A}^*$ to become active in (3.1) but small enough to prevent inactive constraints (those not in $\mathcal{A}^*$) from becoming active in (3.1). Byrd et al. [5, section 3] describe a heuristic for `Active` in which Δ is adjusted from its value at the previous iteration of the outer algorithm according to the success of the QP step, the norms of the QP step, the solution d of (3.1), and whether or not the minimizer of the quadratic model in this direction d lies at the boundary of the trust region.

The performance of these schemes also depends strongly on the value of ν in (3.1) and (3.4). The bound

$$\nu \geq \max\left(\max_j \lambda_j^*, \max_k |\mu_k^*|\right) \tag{3.12}$$

ensures global convergence. However, excessively large estimates of ν can slow convergence. The heuristic used in `Active` [5, section 9] re-solves the LP for increasing values of ν whenever a substantial decrease in infeasibility is possible. In addition, ν is decreased whenever the bound (3.12) (using the current multiplier estimates) is inactive for several consecutive successful, feasible LP iterations.

Theorem 3.2 and Corollary 3.3 suggest that the approaches of this section may give false negatives for constraints that are weakly active, or which may have an optimal Lagrange multiplier of zero. However, it is not obvious that failure to identify such constraints would adversely affect the performance of nonlinear programming algorithms. To first order, they are not critical to satisfying the KKT conditions.

3.2. A technique based on the primal-dual estimate. Here we describe a scheme based on explicit minimization of $\psi(x, \mu, \lambda)$ in (2.1) with respect to (μ, λ) for $\lambda \geq 0$. We show that this minimization problem can be formulated as a linear program with equilibrium constraints (LPEC), one that is related to the linear programs discussed in subsection 3.1. However, in contrast to this earlier approach, we use a threshold test like (2.5) to estimate the active set, rather than active set or Lagrange multiplier information from the subproblem.

The LPEC subproblem is as follows:

$$\omega(x) \stackrel{\text{def}}{=} \min_{\lambda \geq 0, \mu} \sum_{i=1}^{m} |\min(\lambda_i, -c_i)| + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1. \tag{3.13}$$

The activity test $\mathcal{A}_{\text{lpec}}$ is defined as

$$\mathcal{A}_{\text{lpec}}(x) = \{i \,|\, c_i(x) \geq -(\beta\omega(x))^\sigma\}, \tag{3.14}$$

where $\beta > 0$ and $\sigma \in (0, 1)$ are constants.

The problem (3.13) can be formulated as the following LPEC:

$$\omega(x) \stackrel{\text{def}}{=} \min_{(\lambda,\mu,s,u,v)} e^T s + \sum_{c_i \geq 0} c_i + \|h\|_1 + e^T u + e^T v \quad \text{subject to} \tag{3.15a}$$

$$0 \leq (-c)_+ - s \perp \lambda - s \geq 0, \tag{3.15b}$$

$$A^T\lambda + J^T\mu + g = u - v, \qquad (\lambda, s, u, v) \geq 0. \tag{3.15c}$$

By introducing a large constant M and binary variables y_i, $i = 1, 2, \ldots, m$ (which take on the value 0 if the minimum in $\min(-c_i, \lambda_i)$ is achieved by $-c_i$ and 1 if it is achieved by λ_i), we can write (3.15) as the following mixed-integer (binary) program:

$$\omega(x) \stackrel{\text{def}}{=} \min_{(\lambda,\mu,s,y,u,v)} e^T s + \|h\|_1 + e^T u + e^T v \quad \text{subject to} \tag{3.16a}$$

$$-c_i - s_i \leq -c_i y_i, \quad i = 1, 2, \ldots, m, \tag{3.16b}$$

$$\lambda_i - s_i \leq M(1 - y_i), \quad i = 1, 2, \ldots, m, \tag{3.16c}$$

$$A^T\lambda + J^T\mu + g = u - v, \tag{3.16d}$$

$$(\lambda, u, v) \geq 0, \qquad s \geq (c)_+, \qquad y_i \in \{0, 1\}, \quad i = 1, 2, \ldots m. \tag{3.16e}$$

The validity of this formulation for (3.13) is based on the nonnegativity of λ and the minimization of the $e^T s$ term. The large parameter M is necessary for (3.16c) but not for (3.16b), because $-c$ is a parameter while λ is a variable in the program.

There are notable similarities between the formulation (3.13) of the LPEC subproblem and the dual formulation (3.4) of the previous subsection. First, the term

$\|A^T\lambda + J^T\mu + g\|_1$ appears in both objectives, though in (3.4) it is weighted by the trust-region radius Δ. Second, the term $\|h\|_1$ in (3.13) (which is constant in (3.13) and (3.16a)) corresponds to the rather different term $-\mu^T h$ in (3.4). Third, the parameter ν which penalizes constraint violation does not appear in (3.13). Fourth, and perhaps most interestingly, the minimum $|\min(-c_i, \lambda_i)|$ in (3.13) is replaced by the product $(-c_i)\lambda_i$ in (3.4). While the use of the minimum may lead to stronger identification properties (see below), it is responsible for the presence of equilibrium constraints in (3.13) and therefore makes the subproblem much harder to solve. In addition, the attractive scale invariance property possessed by the $-c_i\lambda_i$ term is lost. If we multiply c_i and A_i by some $\sigma_i > 0$ and replace $\lambda_i \leftarrow \lambda_i/\sigma_i$ to maintain constancy of the product $A_i\lambda_i$, the minimum $|\min(-c_i, \lambda_i)|$ will be replaced by $|\min(-\sigma_i c_i, \lambda_i/\sigma_i)|$, which has a different value in general.

We now show that $\omega(x)$ defined in (3.13) provides a two-sided estimate of the distance to the solution and that the identification scheme (3.14) eventually is successful, under appropriate assumptions.

THEOREM 3.4. *Suppose that the KKT conditions* (1.3)*, the MFCQ* (1.7)*, and the second-order condition* (1.9) *are satisfied at* x^**, and let* ϵ *be as defined in Theorem* 2.1*. Then there are positive constants* $\bar{\epsilon} \in (0, \epsilon/2]$ *and* $\bar{C}$ *such that for all* x *with* $\|x - x^*\| \le \bar{\epsilon}$*, we have that*

(i) *the minimum in* (3.13) *is achieved at some* (μ, λ) *with* $\operatorname{dist}((\mu, \lambda), \mathcal{S}_D) \le \epsilon/2$*;*
(ii) $\bar{C}^{-1}\omega(x) \le \|x - x^*\| \le \bar{C}\omega(x)$*; and*
(iii) $\mathcal{A}_{\mathrm{lpec}}(x) = \mathcal{A}^*$.

Proof.

(i) Note first that for any $(\mu^*, \lambda^*) \in \mathcal{S}_D$ and any x with $\|x - x^*\| \le \epsilon$, we have that

$$\begin{aligned}
\omega(x) &\le \psi(x, \mu^*, \lambda^*) \\
&= \sum_{i=1}^{m} |\min(\lambda_i^*, -c_i(x))| + \|h(x)\|_1 + \|A(x)^T\lambda^* + J(x)^T\mu^* + g(x)\|_1 \\
&\le \sum_{i=1}^{m} |c_i(x) - c_i(x^*)| + \|h(x) - h(x^*)\|_1 \\
&\qquad + \|(A(x) - A(x^*))^T\lambda^* + (J(x) - J(x^*))^T\mu^* + (g(x) - g(x^*))\|_1 \\
&\le C_1\|x - x^*\| \qquad (3.17)
\end{aligned}$$

for some constant C_1. (In the second-to-last inequality, we used $\min(\lambda_i^*, -c_i(x^*)) = 0$, which follows from (1.3c).) Hence, if the minimum in (3.13) occurs outside the set $\{(\mu, \lambda) | \lambda \ge 0, \operatorname{dist}((\mu, \lambda), \mathcal{S}_D) \le \epsilon/2\}$ for x arbitrarily close to x^*, we must be able to choose a sequence (x^k, μ^k, λ^k) with $x^k \to x^*$, $\lambda^k \ge 0$, and $\operatorname{dist}((\mu^k, \lambda^k), \mathcal{S}_D) > \epsilon/2$ such that

$$\psi(x^k, \mu^k, \lambda^k) \le \psi(x^k, \mu^*, \lambda^*) \le C_1\|x^k - x^*\| \text{ for all } k.$$

In particular we have $\psi(x^k, \mu^k, \lambda^k) \to 0$. Consider first the case in which (μ^k, λ^k) is unbounded. By taking a subsequence if necessary, we can assume that

$$\|(\mu^k, \lambda^k)\| \to \infty, \quad \frac{(\mu^k, \lambda^k)}{\|(\mu^k, \lambda^k)\|} \to (\mu^*, \lambda^*), \quad \|(\mu^*, \lambda^*)\| = 1, \quad \lambda^* \ge 0.$$

For any $i \notin \mathcal{A}^*$, we have, by taking a further subsequence if necessary, that $c_i(x^k) < (1/2)c_i(x^*) < 0$ for all k. Since $|\min(\lambda_i^k, -c_i(x^k))| \le \psi(x^k, \mu^k, \lambda^k) \to 0$, we have that

$\lambda_i^k \to 0$ and thus $\lambda_i^* = 0$ for all $i \notin \mathcal{A}^*$. We also have that $A(x^k)^T\lambda^k + J(x^k)^T\mu^k + g(x^k) \to 0$; thus when we divide this expression by $\|(\mu^k, \lambda^k)\|$ and take limits, we obtain

$$A(x^*)^T\lambda^* + J(x^*)^T\mu^* = A_{\mathcal{A}^*}(x^*)^T\lambda^*_{\mathcal{A}^*} + J(x^*)^T\mu^* = 0.$$

We can now use the usual argument based on the MFCQ property (1.7) (see Appendix A) to deduce that $\lambda^*_{\mathcal{A}^*} = 0$ and then $\mu^* = 0$, contradicting $\|(\mu^*, \lambda^*)\| = 1$. Hence, the sequence (μ^k, λ^k) must be bounded.

By taking a subsequence if necessary, we can define a vector $(\hat{\mu}, \hat{\lambda})$ such that

$$(\mu^k, \lambda^k) \to (\hat{\mu}, \hat{\lambda}), \quad \hat{\lambda} \geq 0.$$

The limit $\psi(x^k, \mu^k, \lambda^k) \to 0$ thus implies that $\psi(x^*, \hat{\mu}, \hat{\lambda}) = 0$, which in turn implies that $(\hat{\mu}, \hat{\lambda}) \in \mathcal{S}_D$, contradicting $\text{dist}\,((\mu^k, \lambda^k), \mathcal{S}_D) > \epsilon/2$. Thus, there is some $\bar{\epsilon}$ such that for all x with $\|x - x^*\| \leq \bar{\epsilon}$ the minimum occurs in the set $\{(\mu, \lambda) | \lambda \geq 0, \text{dist}\,((\mu, \lambda), \mathcal{S}_D) \leq \epsilon/2\}$. Since this set is compact (boundedness of $\mathcal{S}_D$ follows from the MFCQ (1.7)), we conclude that the minimum in (3.13) is attained by some (μ, λ) in this set.

(ii) The left-hand inequality is already proved by (3.17). We now show that, for the $\bar{\epsilon} \in (0, \epsilon/2]$ determined in part (i), we have

$$\|x - x^*\| \leq C\omega(x) \text{ for all } x \text{ with } \|x - x^*\| \leq \bar{\epsilon} \tag{3.18}$$

for C defined in Theorem 2.1. First note that for any (μ, λ) with $\text{dist}\,((\mu, \lambda), \mathcal{S}_D) \leq \epsilon/2$, we have

$$\text{dist}\,((x, \mu, \lambda), \mathcal{S}) \leq \|x - x^*\| + \text{dist}\,((\mu, \lambda), \mathcal{S}_D) \leq \bar{\epsilon} + \epsilon/2 \leq \epsilon,$$

so that from Theorem 2.1 we have

$$\|x - x^*\| \leq \text{dist}\,((x, \mu, \lambda), \mathcal{S}) \leq C\psi(x, \mu, \lambda) \tag{3.19}$$

for all (μ, λ) with $\text{dist}\,((\mu, \lambda), \mathcal{S}_D) \leq \epsilon/2$ and $\lambda \geq 0$. We showed in part (i) that the minimum of $\psi(x, \mu, \lambda)$ is attained in this set for sufficiently small choice of $\bar{\epsilon}$. Hence, we have

$$\|x - x^*\| \leq C \min_{\lambda \geq 0, \text{dist}\,((\mu,\lambda),\mathcal{S}_D) \leq \epsilon/2} \psi(x, \mu, \lambda) = C\omega(x),$$

as required. The result follows by taking $\bar{C} = \max(C, C_1)$, where C_1 is from (3.17).

(iii) The proof of this final claim follows from an argument like that of Theorem 2.2. ∎

We note that an exact solution of (3.13) (or (3.16)) is not needed to estimate the active set. In fact, any approximate solution whose objective value is within a chosen fixed factor of the optimal objective value will suffice to produce an asymptotically accurate estimate. Computationally speaking, we can terminate the branch-and-bound procedure at the current incumbent once the lower bound is within a fixed factor of the incumbent objective value. Moreover, we can derive an excellent starting point for (3.16) from the solution of the dual subproblem (3.3) of the previous subsection or from the LP subproblem of the next section. (As our experiments of section 4 show, the branch-and-bound procedure often terminates at the root node, without

doing any expansion of the branch-and-bound tree at all. When this occurs, the main computational cost is the cost of solving a single LP relaxation of (3.16).)

The main differences between the schemes of this subsection and the previous one can be summarized as follows:

- When a second-order sufficient condition holds, the scheme of this subsection accurately estimates $\mathcal{A}^*$ (including the weakly active constraints), whereas the schemes of the previous subsection may identify only those active constraints that are instrumental in satisfying the first KKT condition (1.3a).
- Effectiveness of the techniques of the previous subsection depends critically on the choice of trust-region radius Δ, whereas no such parameter is present in this subsection. However, the practical performance of the latter approach may depend on the scaling of the constraints c_i and their multipliers λ_i. Performance may be improved for some problems by changing the relative weightings of the terms $\|h\|_1$ and $\|A^T\lambda + J^T\mu + g\|_1$ in $\omega(x)$. However, it is difficult to determine a choice of weights that works reliably for a range of problems.

3.3. A linear programming approximation to the LPEC. In this section, we describe a technique that has the same identification properties as the scheme of the previous subsection, as described in Theorem 3.4, but requires only the solution of a linear program, rather than an LPEC. The key to the scheme is to obtain a two-sided bound on $\omega(x)$, defined in (3.13), that can be obtained by solving a single linear program.

We start by defining the following functions:

$$\rho(x,\mu,\lambda) \stackrel{\text{def}}{=} \sum_{c_i<0} -c_i\lambda_i + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1, \tag{3.20}$$

$$\bar{\rho}(x,\mu,\lambda) \stackrel{\text{def}}{=} \sum_{c_i<0} (-c_i\lambda_i)^{1/2} + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1. \tag{3.21}$$

These functions are related in the following elementary fashion.

LEMMA 3.5. *For any (μ,λ) with $\lambda \geq 0$, we have*

$$\bar{\rho}(x,\mu,\lambda) \leq \rho(x,\mu,\lambda) + \sqrt{m}\rho(x,\mu,\lambda)^{1/2}.$$

Proof.

$$\begin{aligned}
\bar{\rho}(x,\mu,\lambda) &= \left\| \left[(-c_i\lambda_i)^{1/2} \right]_{c_i<0} \right\|_1 + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1 \\
&\leq \sqrt{m} \left\| \left[(-c_i\lambda_i)^{1/2} \right]_{c_i<0} \right\|_2 + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1 \\
&= \sqrt{m} \left[\sum_{c_i<0} (-c_i\lambda_i) \right]^{1/2} + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1 \\
&\leq \sqrt{m}\rho(x,\mu,\lambda)^{1/2} + \rho(x,\mu,\lambda). \qquad \square
\end{aligned}$$

The next result defines the relationship between ρ, $\bar{\rho}$, and the proximality measure ψ defined in (2.1).

LEMMA 3.6. *Let $K_2 \geq 1$ be given. Then for all (x, μ, λ) with $\lambda \geq 0$ and*

$$\|c\|_\infty \leq K_2, \quad \|\lambda\|_\infty \leq K_2, \tag{3.22}$$

we have that

$$K_2^{-1}\rho(x,\mu,\lambda) \leq \psi(x,\mu,\lambda) \leq \bar{\rho}(x,\mu,\lambda). \tag{3.23}$$

Proof. For $c_i < 0$ and $\lambda_i \geq 0$, we have

$$-c_i\lambda_i = \min(-c_i, \lambda_i)\max(-c_i, \lambda_i) \geq \min(-c_i, \lambda_i)^2 \tag{3.24}$$

and also

$$-c_i\lambda_i \leq K_2 \min(-c_i, \lambda_i). \tag{3.25}$$

From (3.24) we have

$$\begin{aligned}\psi(x,\mu,\lambda) &= \sum_{c_i<0} |\min(-c_i,\lambda_i)| + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|g + A^T\lambda + J^T\mu\|_1 \\ &\leq \sum_{c_i<0} (-c_i\lambda_i)^{1/2} + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|g + A^T\lambda + J^T\mu\|_1 \\ &= \bar{\rho}(x,\mu,\lambda),\end{aligned}$$

thereby proving the right-hand inequality in (3.23).

For the left-hand inequality, we have from (3.25) and $K_2 \geq 1$ that

$$\psi(x,\mu,\lambda) \geq K_2^{-1}\sum_{c_i<0}(-c_i\lambda_i) + \sum_{c_i\geq 0} c_i + \|h\|_1 + \|A^T\lambda + J^T\mu + g\|_1 \geq K_2^{-1}\rho(x,\mu,\lambda),$$

as required. ∎

We are particularly interested in the solution (μ_x, λ_x) to the program

$$\min_{\mu, 0\leq\lambda\leq K_1 e} \rho(x,\mu,\lambda), \tag{3.26}$$

where K_1 is the constant defined in (2.4). The problem of determining (μ_x, λ_x) can also be expressed as the following linear program:

$$\min_{(\lambda,\mu,u,v)} \sum_{c_i<0}(-c_i\lambda_i) + \sum_{c_i\geq 0} c_i + \|h\|_1 + e^Tu + e^Tv \quad \text{subject to} \tag{3.27a}$$

$$A^T\lambda + J^T\mu + g = u - v, \;\; 0 \leq \lambda \leq K_1 e, \;\; (u,v) \geq 0. \tag{3.27b}$$

We define the activity test associated with $\bar{\rho}$ as follows:

$$\mathcal{A}_{\bar{\rho}}(x) = \{i = 1, 2, \ldots, m \,|\, c_i(x) \geq -(\beta\bar{\rho}(x,\mu_x,\lambda_x))^{\bar{\sigma}}\} \tag{3.28}$$

for given constants $\beta > 0$ and $\bar{\sigma} \in (0, 1)$.

We now prove a result similar to Theorem 3.4, showing in particular that under the same assumptions as the earlier result, the identification scheme above is asymptotically successful.

THEOREM 3.7. *Suppose that the KKT conditions* (1.3)*, the MFCQ* (1.7)*, and the second-order condition* (1.9) *are satisfied at x^*, and let ϵ be as defined in Theorem* 2.1*. Then there exists a positive constant $\hat{\epsilon} \in (0, \epsilon/2]$ such that for all x with $\|x - x^*\| \leq \hat{\epsilon}$, we have*

(i) *the minimum in* (3.27) *is attained at some* (μ, λ) *with* $\operatorname{dist}((\mu, \lambda), \mathcal{S}_D) \le \epsilon/2$*;*
(ii) $K_1^{-1}\rho(x, \mu_x, \lambda_x) \le \omega(x) \le \bar{\rho}(x, \mu_x, \lambda_x)$*, where* K_1 *is the constant defined in* (2.4)*; and*
(iii) $\mathcal{A}_{\bar{\rho}}(x) = \mathcal{A}^*$.

Proof.

(i) Note that for any $(\mu^*, \lambda^*) \in \mathcal{S}_D$ and any x with $\|x - x^*\| < \epsilon$, we have

$$\begin{aligned}
&\rho(x, \mu^*, \lambda^*) \\
&= \sum_{c_i<0} -c_i(x)\lambda_i^* + \sum_{c_i\ge 0} c_i(x) + \|h(x)\|_1 + \|A(x)^T\lambda^* + J(x)^T\mu^* + g(x)\|_1 \\
&\le \sum_{c_i<0} (c_i(x^*) - c_i(x))\lambda_i^* + \sum_{c_i\ge 0} (c_i(x) - c_i(x^*)) + \|h(x) - h(x^*)\|_1 \\
&\qquad + \|(A(x) - A(x^*))^T\lambda^* + (J(x) - J(x^*))^T\mu^* + (g(x) - g(x^*))\|_1 \\
&\le C_2\|x - x^*\|
\end{aligned}$$

for some constant C_2. (In the first inequality above, we used the fact $\lambda_i^* c_i^* = 0$ for all i to bound the first summation, and the fact that $c_i^* \le 0$ for all i to bound the second summation.) Note that since $\|(\mu^*, \lambda^*)\|_\infty \le K_1$, we have $0 \le \lambda^* \le K_1 e$, so that (μ^*, λ^*), together with an obvious choice of (u, v), is feasible for (3.27). We note also that any $(\hat{\mu}, \hat{\lambda})$ for which $\rho(x^*, \hat{\mu}, \hat{\lambda}) = 0$ and $\hat{\lambda} \ge 0$ satisfies $(\hat{\mu}, \hat{\lambda}) \in \mathcal{S}_D$. Using these observations, the remainder of the proof closely parallels that of Theorem 3.4(i), so we omit the details.

(ii) Reduce $\hat{\epsilon}$ if necessary to ensure that $\hat{\epsilon} \le \bar{\epsilon} \le \epsilon/2$, where $\bar{\epsilon}$ is defined in Theorem 3.4. Reduce $\hat{\epsilon}$ further if necessary to ensure that $\|c(x)\|_\infty \le K_1$ for all x with $\|x - x^*\| \le \hat{\epsilon}$. Note that by Theorem 3.4(i), the minimizer of (3.13) has $\operatorname{dist}((\mu, \lambda), \mathcal{S}_D) \le \epsilon/2$, and therefore $\|\lambda\|_\infty \le \|\lambda^*\|_\infty + 1 \le K_1$ for any $(\mu^*, \lambda^*) \in \mathcal{S}_D$.

Using the result of Lemma 3.6 (with K_1 replacing K_2), we have that

$$\begin{aligned}
&K_1^{-1}\rho(x, \mu_x, \lambda_x) \\
&= \min_{\mu, 0\le\lambda\le K_1 e} K_1^{-1}\rho(x, \mu, \lambda) \le \min_{\mu, 0\le\lambda\le K_1 e} \psi(x, \mu, \lambda) \le \psi(x, \mu_x, \lambda_x) \le \bar{\rho}(x, \mu_x, \lambda_x).
\end{aligned}$$

However, as we showed in Theorem 3.4(i), the minimizer of $\psi(x, \mu, \lambda)$ over the set of (μ, λ) with $\lambda \ge 0$ is attained at values of (μ, λ) that satisfy the restriction $\|\lambda\|_\infty \le K_1$; thus we can write

$$K_1^{-1}\rho(x, \mu_x, \lambda_x) \le \min_{\mu, 0\le\lambda} \psi(x, \mu, \lambda) \le \bar{\rho}(x, \mu_x, \lambda_x),$$

which yields the result, by (3.13).

(iii) We have from Lemma 3.5, Theorem 3.4(ii), and part (ii) of this theorem that $\bar{\rho}(x, \mu_x, \lambda_x) \to 0$ as $x \to x^*$. Therefore, using continuity of c_i, $i = 1, 2, \ldots, m$, we can decrease $\hat{\epsilon}$ if necessary to ensure that for $\|x - x^*\| \le \hat{\epsilon}$, we have

$$c_i(x) < (1/2)c_i(x^*) \le -(\beta\bar{\rho}(x, \mu_x, \lambda_x))^{\bar{\sigma}} \quad \text{for all } i \notin \mathcal{A}^*.$$

Hence, $i \notin \mathcal{A}_{\bar{\rho}}(x)$ for all such x.

For $i \in \mathcal{A}^*$, we have for the Lipschitz constant L defined in (2.3), and using

Theorem 3.4(ii) and part (ii) of this theorem, that

$$\begin{aligned}|c_i(x)| &\le L\|x-x^*\| \\ &= L\|x-x^*\|^{1-\bar\sigma}\|x-x^*\|^{\bar\sigma} \\ &\le L\|x-x^*\|^{1-\bar\sigma}\bar C^{\bar\sigma}\omega(x)^{\bar\sigma} \\ &\le \left[L\|x-x^*\|^{1-\bar\sigma}\bar C^{\bar\sigma}/\beta^{\bar\sigma}\right](\beta\bar\rho(x,\mu_x,\lambda_x))^{\bar\sigma} \\ &\le (\beta\bar\rho(x,\mu_x,\lambda_x))^{\bar\sigma}\end{aligned}$$

for $\hat\epsilon$ sufficiently small. Hence, we have $i \in \mathcal{A}_{\bar\rho}(x)$ for all x with $\|x-x^*\| \le \hat\epsilon$. □

Near the solution, $\omega(x)$ may be (and often is) much smaller than $\bar\rho(x,\mu_x,\lambda_x)$, because of the looseness of the estimate (3.24). To compensate for this difference, we set $\bar\sigma$ in the definition of $\mathcal{A}_{\bar\rho}$ (3.28) to be larger than σ in the definition of $\mathcal{A}_{\rm lpec}$ (3.14) in the tests described in the next section.

A referee has pointed out that some interesting insights are available from examination of the dual of the subproblem (3.27). Ignoring the upper bound $\lambda \le K_1 e$, we can write the dual as

$$\begin{aligned}\min g^T d \quad & \text{subject to} \\ A_i d + c_i \le 0 \quad & \text{for } i \text{ with } c_i < 0, \\ A_i d \le 0 \quad & \text{for } i \text{ with } c_i \ge 0, \\ Jd = 0, \quad & -e \le d \le e.\end{aligned}$$

It is not difficult to construct examples for which $A_i d + c_i = 0$ for an inactive constraint i, even when x is arbitrarily close to x^*. (The referee gave the example of minimizing a scalar x^2 subject to $-x - 0.5 \le 0$ for x slightly greater than the optimum $x^* = 0$.) Thus, if the active set estimate were obtained from formulae such as (3.5), it may not be asymptotically accurate. Hence, the use of the threshold test (3.28) in place of activity tests (3.5) is key to the effectiveness of the approach of this section. In this vein, it can be shown that if the (μ,λ) components of the solution of the earlier LP problem (3.3) are inserted into the threshold test (3.28) in place of (μ_x,λ_x), an asymptotically accurate estimate is obtained, under certain reasonable assumptions. We omit a formal statement and proof of this claim, as we believe (μ_x,λ_x) to be a better choice of the Lagrange multipliers, because their calculation does not depend on the parameters ν and Δ that appear in (3.3).

4. Computational results. In this section, we apply the techniques of section 3 to a variety of problems in which x is slightly perturbed from its (approximately) known solution x^*. The resulting active set estimate is compared with our best guess of the active set at the solution. We report the false positives and false negatives associated with each technique, along with the runtimes required to execute the tests.

The LP techniques of subsection 3.1 are referred to as LP-P for the primal formulation (3.2) and LP-D for the dual formulation (3.3). For these formulations, we use both activity tests $\mathcal{A}_c$ and $\mathcal{A}_\lambda$ of (3.5), modified slightly with activity thresholds. We also implement the LPEC scheme of subsection 3.2 and the LP approximation scheme of subsection 3.3, which we refer to below as LPEC-A. We implemented all tests in C, using the CPLEX callable library (version 9.0) to solve the linear and mixed-integer programs.

The times required to implement the tests are related to the size and density of the constraint matrix for each formulation. The matrix dimensions for each formulation

TABLE 4.1
Problem dimensions as a function of the number of inequalities (m), variables (n), and equalities (p).

	LP-D	LP-P	LPEC-A	LPEC
Rows	n	$m+p$	n	$5m+n$
Columns	$m+2n+p$	$m+n+2p$	$m+2n+p$	$4m+2n+p$

are given in Table 4.1. Except for problems with many equality constraints, the LPEC formulation has the largest constraint matrix. Further, it is the only formulation with binary variables.

Subsection 4.1 discusses some specifics of the formulations, such as the choice of parameters and tolerances in the identification procedures. In subsection 4.2, we apply the identification techniques to a set of random problems, for which we have control over the dimensions and amount of degeneracy. In subsection 4.3, we consider a subset of constrained problems from the CUTEr test set, a conglomeration of problems arising from theory, modeling, and real applications [13]. While the random problems are well scaled with dense constraint Jacobians, the CUTEr problems may be poorly scaled and typically have sparse constraint Jacobians. Subsection 4.4 contains some remarks about additional testing.

4.1. Implementation specifics.

4.1.1. Choosing parameters and tolerances. The following implementation details are common to both random and CUTEr test sets. We bound the ℓ_∞ norm of the perturbation x from the (approximately) optimal point x^* by a noise parameter `noise`. Denoting by ϕ a random variable drawn from the uniform distribution on $[-1, 1]$, we define the perturbed point x as follows:

$$x_i = x_i^* + \frac{\texttt{noise}}{n}\phi, \quad i = 1, 2, \ldots, n. \tag{4.1}$$

A second parameter `DeltaFac` controls the bound on the trust-region radius for the LP-P and LP-D programs. We set

$$\Delta = \texttt{DeltaFac}\frac{\texttt{noise}}{n},$$

so that when $\texttt{DeltaFac} \geq 1$, the trust region is large enough to contain the true solution x^*. For the results tabulated below, we use $\texttt{DeltaFac} = 4$. This value is particularly felicitous for the LP-P and LP-D schemes, as it yields a Δ large enough to encompass the solution yet small enough to exclude many inactive constraints. The number of false positives therefore tends to be small for LP-P and LP-D in our tables. The relatively small trust region also allows the CPLEX presolver to streamline the LP formulations before calling the simplex code, thus reducing the solve times for the linear programs in LP-P and LP-D. (Specifically, for each inequality constraint that is inactive over the entire trust region, the LP-P subproblem is reduced by one row and column, while the LP-D subproblem is reduced by one column.) It is unlikely that a nonlinear programming algorithm that uses LP-P or LP-D as its identification technique could in practice choose a value of Δ as nice as the one used in these tests.

The activity tests $\mathcal{A}_c$ (3.5a) and $\mathcal{A}_\lambda$ (3.5b) were modified to include a tolerance, as follows:

$$\mathcal{A}_c(x) = \{i \mid A_i d + c_i \geq -\epsilon_0\} \tag{4.2}$$

and

$$\mathcal{A}_\lambda(x) = \{i \,|\, \lambda_i \geq \epsilon_0\}, \tag{4.3}$$

with $\epsilon_0 = 10^{-4}$.

In the tests $\mathcal{A}_{\text{lpec}}(x)$ (3.14) for LPEC and $\mathcal{A}_{\bar{\rho}}$ (3.28) for LPEC-A, we set $\beta = 1/(m+n+p)$. The value 0.75 is used for σ in $\mathcal{A}_{\text{lpec}}$ (3.14), while the larger value 0.90 is used for $\bar{\sigma}$ in $\mathcal{A}_{\bar{\rho}}$ (3.28).

By default, the mixed-integer solver in CPLEX makes use of various cut generation schemes, including flow covers, MIR cuts, implied bound cuts, and Gomory fractional cuts. We disabled these schemes because, given our usually excellent starting point for the LPEC test, the cost of cut generation is excessive compared to the cost of solving the root relaxation. However, for all tests, we allowed both linear and mixed-integer solvers to perform their standard presolving procedures, as they generally improved the performance. For the mixed-integer solver in LPEC, we accept the solution if it is within a factor of 2 of the lower bound.

For both linear and integer programming solvers, we tightened the general feasibility tolerance `eprhs` from 10^{-6} to 10^{-9} because problems in the CUTEr test set (notably BRAINPC0 and BRAINPC3) report infeasibilities after scaling for LPEC-A under the default tolerance. In addition, we observed LP-P objective values that were too negative when using default `eprhs` values. Specifically, for some of the constraints $A_i d + c_i - r_i \leq 0$ in (3.2), the solver would find a d with $A_i d + c_i$ slightly positive, while setting r_i to zero. Thus, the constraint would be satisfied to the specified tolerance, while avoiding the larger value of $g^T d$ that would be incurred if it were satisfied exactly.

4.1.2. Formulation details. For all test problems, the parameter ν of the LP-P and LP-D programs is assigned a value large enough to ensure that the known optimal multipliers (μ^*, λ^*) are feasible for (3.4). The results of this paper, theoretical and computational, are otherwise insensitive to the choice of ν. (However, the choice of ν appears to be important for global convergence of the nonlinear programming algorithm, as discussed in Byrd et al. [6].)

The computational efficiency of the LPEC mixed-integer program (3.16) is sensitive to the magnitude of M. Recall that the formulation (3.16) is identical to the LPEC (3.15) provided that M is sufficiently large, in particular, larger than $\|c+\lambda^*\|_\infty$, where λ^* is an optimal multiplier. However, excessively large M values may result in long runtimes. We observed runtime reductions of as much as 50% when we replaced heuristically chosen values of M with near-minimal values.

We describe some heuristics for setting M and ν in the following subsections.

In solving LPEC, we use a starting point based on the solution for LPEC-A. Specifically, we set λ, μ, u, and v to their optimal values from (3.27); set $y_i = 0$ if $-c_i < \lambda_i$ and $y_i = 1$ otherwise; and set $s_i = |\min(-c_i, \lambda_i)|$. In most cases, this starting point is close to an acceptable solution for LPEC and little extra work is needed beyond solving an LP relaxation of the LPEC at the root node and verifying that the starting point is not far from the lower bound obtained from this relaxation. The solution to LP-D also provides a useful starting point for LPEC in most cases.

For LPEC and LPEC-A, no attempt is made to scale the constraints c_i or the components of the threshold functions $\omega(x)$ and $\bar{\rho}(x, \mu_x, \lambda_x)$. Heuristics to adjust such weightings may improve the performance of LPEC and LPEC-A techniques.

4.2. Random problems. We generate random problems involving dense Jacobians J and A to mimic the behavior of a nonlinear program near a local solution x^*. Besides choosing the dimensions n, m, and p, we influence the amount of degeneracy in the problem by specifying the row rank of J and A and the proportion of weakly active constraints.

4.2.1. Problem setup. Parameters specific to the random problem setup are `fStrong` and `fWeak` (approximate proportion of strongly and weakly active inequality constraints, respectively) and `degenA` and `degenJ` (proportional to the ranks of the null spaces of A and J, respectively). We first fill out the first $(1 - \texttt{degenA})m$ rows of the optimal inequality constraint Jacobian A^* with components 5ϕ (where, as above, ϕ represents a random variable uniformly distributed in $[-1, 1]$). We then set the last $(\texttt{degenA})m$ rows of A^* to be random linear combinations of the first $(1-\texttt{degenA})m$ rows, where the coefficients of the linear combinations are chosen from ϕ. A similar process is used to choose the optimal equality constraint Jacobian J^* using the parameter `degenJ`.

We set the solution to be $x^* = 0$. Recall that x is a perturbation of x^* (4.1). First, we set each component of μ^* to $\frac{1}{2}\phi(\phi + 1)$. Next, we randomly classify each index $i \in \{1, 2, \ldots, m\}$ as "strongly active," "weakly active," or "inactive," such that the proportion in each category is approximately `fStrong`, `fWeak`, and $(1-\texttt{fStrong}-\texttt{fWeak})$, respectively. For the inactive components, we set $c_i^* = -\frac{5}{2}(\phi + 1)^2$, while for the strongly active components, we set $\lambda_i^* = \frac{5}{2}(\phi + 1)^2$. Other components of c^* and λ^* are set to zero. To make the optimality condition (1.3a) consistent, we now set $g^* = -(A^*)^T\lambda^* - (J^*)^T\mu^*$. Naturally, $h^* = 0$.

In accordance with the assumed Lipschitz properties, we set

$$\begin{aligned} g_i &= g_i^* + (\texttt{noise}/n)\phi, \quad i = 1, 2, \ldots, m, \\ A_{ij} &= A_{ij}^* + (\texttt{noise}/n)\phi, \quad i = 1, 2, \ldots, m, \quad j = 1, 2, \ldots, n, \\ J_{ij} &= J_{ij}^* + (\texttt{noise}/n)\phi, \quad i = 1, 2, \ldots, p, \quad j = 1, 2, \ldots, n. \end{aligned}$$

Since $c(x) = c^* + A^*(x - x^*) + O(\|x - x^*\|^2) = c^* + A^*x + O(\|x\|^2)$, we set

$$c_i = c_i^* + A_i^*x + (\texttt{noise}/n)^2\phi, \quad i = 1, 2, \ldots, m.$$

A similar scheme is used to set h.

The data thus generated is consistent to first order, but there is no explicit assurance that the second-order condition holds. (This condition is required for Theorems 3.4 and 3.7 concerning the exact identification properties of the LPEC and LPEC-A schemes.)

By setting ν to the large value 100, we ensure that solutions of LP-P and LP-D have $r = 0$ and $s = t = 0$. For the LPEC problem (3.16), we define $M = 5 \max_j(|c_j|)$. This value is large enough to secure local optimality of the LPEC programs of our test problems.

4.2.2. Nondegenerate problems. Results for a set of random nondegenerate problems are shown in Table 4.2, with runtimes in Table 4.3. Nondegeneracy is assured by setting $\texttt{fWeak} = 0$, $\texttt{degenA} = 0$, and $\texttt{degenJ} = 0$. The number of equality constraints p is $n/5$, and we set $\texttt{noise} = 10^{-3}$. Each entry in Table 4.2 shows the numbers of false positives and false negatives for the problem and test in question. For LP-P and LP-D, we report both active sets $\mathcal{A}_c$ (4.2) and $\mathcal{A}_\lambda$ (4.3). The case $m = 400$, $n = 200$, `fStrong=0.50` does not appear because the expected number of degrees of freedom $(n - p - (\texttt{fStrong} + \texttt{fWeak})m)$ is nonpositive.

The identification techniques are accurate on these problems. Because the LICQ conditions hold (to high probability), even the LP-P and LP-D procedures are guaranteed to be asymptotically correct. Indeed, the LP-P and LP-D schemes generally perform best; the LPEC-A and LPEC schemes show a few false positives on the larger examples. For these problems, it is not necessary for the LPEC to search beyond the root node in the branch-and-bound tree, except in the case $m = 400$, $n = 200$, `fStrong` $= 0.10$, for which one additional node is considered.

In agreement with the theory of section 3, the false positives reported in LPEC-A and LPEC results disappear for smaller noise values. In particular, for `noise` $= 10^{-7}$ the identification results are perfect for the LPEC-A and LPEC methods, while the LP-D and LP-P methods still give some errors.

Runtimes are shown in Table 4.3. The differences between the approaches are not significant, except for two of the $n = 400$ cases, for which LPEC is substantially slower than LPEC-A.

4.2.3. Degenerate problems. Results for a set of random degenerate problems are shown in Table 4.4, with runtimes in Table 4.5. In these tables, we fixed `fStrong` $= 0.2$, `noise` $= 10^{-3}$, `degenJ` $= 0$, and $p = n/5$. The values of `fWeak` and `degenA` were varied, along with the dimensions m and n.

TABLE 4.4

All methods perform well when $m = 50$. The LPEC and LPEC-A approaches rarely make an identification error on these problems, whereas LP-P and LP-D record a few false negatives. For the problems with 400 inequality constraints, the numbers of errors made by LPEC-A and LPEC are lower than those made by LP-P and LP-D. The misidentifications for LP-D and LP-P tend to be false negatives, and their numbers increase with the number of weakly active constraints. This experience is in accordance with the theory of subsection 3.1, which gives no guarantee that the weakly active constraints will be identified. The numbers of false negatives are larger for test $\mathcal{A}_\lambda$ than for $\mathcal{A}_c$—nearly as large as the number of degenerate constraints. (For $m = 400$, `fWeak` $= 0.05$ there are 20 such constraints, while for $m = 400$ and `fWeak` $= 0.20$ there are 80.) This observation indicates that the multiplier (μ, λ) determined by the LP-P and LP-D solution is similar to the optimal multiplier (μ^*, λ^*) for the original problem, for which $\lambda_i^* = 0$ when constraint i is weakly active. The errors for LPEC-A and LPEC contain both false positives and false negatives, indicating that the values of σ and $\bar{\sigma}$ and the factor β that we use in the activity test are appropriate. (For larger values of σ and $\bar{\sigma}$, the numbers of false negatives increase dramatically.)

The methods can usually be ranked in order of speed as LP-P, LP-D, LPEC-A, and LPEC. The differences between LP-P and LP-D are likely due to problem size reductions by the presolver, which are greater for LP-P, and which are significant because the matrix is dense. As expected (see our discussion in subsection 4.1.1), we observed size reductions corresponding to the number of inactive constraints. In contrast, no presolver reductions were observed for LPEC-A.

For the mixed-integer program arising in the LPEC test, an additional node beyond the root node of the branch-and-bound tree is considered only for the case $m = 400$, $n = 200$, `fWeak` $= 0.05$, and `degenA` $= 0.1$. We observed large initial scaled dual infeasibilities and runtimes that are sensitive to the LPEC parameter M. For the case $m = 400$, the relative slowness of the LPEC method may be due to the relatively large size of the matrix generated by the LPEC (see Table 4.1).

4.3. CUTEr problems. We now consider a subset of constrained minimization problems from the CUTEr test set [13]. The subset contains degenerate problems of small or medium size for which the `Interior/Direct` algorithm of `Knitro 4.x` terminates successfully within 3000 iterations (with default parameter values). From the output of this code, we obtain approximations x^* to a solution and (μ^*, λ^*) to the optimal Lagrange multipliers.

The format of the CUTEr test problems differs from that of (1.1) in that bound constraints are treated separately from general constraints and all constraints are two-sided; that is, they have both lower and upper bounds. We implemented alternative formulations for our four tests which treated the bounds explicitly and combined them with the trust-region constraints, thereby reducing the total number of constraints and/or variables. We found that these formulations gave little or no improvement in performance, so we do not report on them further. For the results below, we rewrite the CUTEr test problems in the format (1.1), treating bound constraints in the same way as general inequality constraints.

4.3.1. Determining the "true" active set. In contrast to the random problems of section 4.2, the true active set $\mathcal{A}^*$ is not known but must be estimated from the solution determined by `Interior/Direct`. Inevitably, this solution is approximate; the code terminates when the constraint-multiplier product for each inequality constraint falls below a given tolerance, set by default to 10^{-6} (see Byrd, Hribar, and Nocedal [7]). If one of λ_i or $-c_i$ is much smaller than the other, classification

of the constraint is easy, but in many cases these two quantities are of comparable magnitude. For example, the `Interior/Direct` solutions of problems such as CAR2, BRAINPC*, and READING1 (when formulated as (1.1)) display patterns in which $-c_i$ increases steadily with i while λ_i decreases steadily, or vice versa. It is difficult to tell at which index i the line should be drawn between activity and inactivity.

In our tables below, we define $\mathcal{A}^*$ by applying the LPEC-A test (3.28) with $\bar{\sigma} = .75$ and $\beta = 1/(m+n+p)$ to the solution returned by `Knitro`. (LPEC could be used in place of LPEC-A to estimate $\mathcal{A}^*$ because both schemes are theoretically guaranteed to return the true active set for x close enough to x^*.) We also wish to determine the weakly active inequality set $\mathcal{A}_0^*$, defined by (1.5). Procedure ID0 from [23, section 3], which involves repeated solution of linear programs, could be used to determine this set. However, for purposes of Table 4.6, we populated $\mathcal{A}_0^*$ with those indices in the estimated $\mathcal{A}^*$ that fail the test (4.3) when applied to the multipliers returned by LPEC-A at x^*. Note that this technique produces a superset of $\mathcal{A}_0^*$ in general.

4.3.2. Implementation details. The penalty parameter in the LP-P and LP-D formulations is defined by

$$\nu = 1.5 \max(\max_j(\lambda_j^*), \max_k(|\mu_k^*|), 1),$$

where (μ^*, λ^*) are the approximately optimal multipliers that were reported by the `Interior/Direct` algorithm. This heuristic guarantees that these particular multipliers (μ^*, λ^*) are feasible for the LP-D formulation (3.3) at the `Interior/Direct` approximate solution x^*. For the parameter M in (3.16) we use

$$M = 3 \max(\max_j(\lambda_j^*), \max_j(|c_j(x)|)).$$

Function and gradient evaluations are obtained through the Fortran and C tools contained in the CUTEr distribution and through a driver modeled after the routine `loqoma.c` (an interface for the code LOQO), which is also contained in CUTEr.

4.3.3. Test results and runtimes. Results for `noise` $= 10^{-3}$ are shown in Table 4.6. The numbers of elements in our estimate of the optimal active set $\mathcal{A}^*$ and weakly active set $\mathcal{A}_0^*$ are listed as $|\mathcal{A}^*|$ and $|\mathcal{A}_0^*|$. Each entry in the main part of the table contains the false positive/false negative count for each combination of test problem and identification technique. Table 4.7 shows the dimensions of each problem in the format $m/n/p$, with the main part of the table displaying runtimes in seconds. The LPEC column additionally reports the number of nodes beyond the root needed to solve the LPEC to the required (loose) tolerance. For many of the problems, the root node is within a factor of 2 of the optimal solution, and the reported number is therefore zero. If the LPEC test exceeds our time limit of 180 seconds, we qualify the approximate solution with the symbol "†".

Trends. In Table 4.6, the LP-D and LP-P results are nearly identical, indicating that the two methods usually find the same solution. The errors for both tests are mostly false negatives, which is expected, because the theory of section 3.1 gives no guarantee that weakly active constraints will be identified. Further, false positives are unlikely because the nice value of Δ (set up by the choice of parameter `DeltaFac` $= 4$) excludes most inactive constraints from the trust region. The number of false negatives for the $\mathcal{A}_\lambda$ test is usually higher than for $\mathcal{A}_c$, because weakly active constraints will generally fail the $\mathcal{A}_\lambda$ test (4.3), while they may pass the $\mathcal{A}_c$ test (4.2). This behavior

TABLE 4.6

is highlighted in the results for the problems GMNCASE4 and OET7. Their numbers of false negatives for the $\mathcal{A}_\lambda$ test correspond exactly to $|\mathcal{A}_0^*|$, while the corresponding numbers of false negatives for the $\mathcal{A}_c$ test are much lower.

In contrast to the results for LP-D and LP-P, the results for LPEC-A and LPEC show a mixture of false positives and false negatives. Further, the results for LPEC-A and LPEC are similar for most problems. For several problems, for example, TWIRIMD1 and ZAMB2, the results for LPEC-A agree with those for LPEC but not with those for LP-D and LP-P.

The runtimes given in Table 4.7 are typically much shorter than for the random problems in Tables 4.3 and 4.5 because the constraint Jacobians in the CUTEr problems are usually sparse (OET7 is an exception). The LP-D times are similar to the LP-P times, and LPEC-A times are generally comparable. With few exceptions, LPEC requires more execution time than LPEC-A. In cases for which LPEC requires significantly more time than LPEC-A, the LPEC identification performance is not better in general.

The LPEC method is usually the slowest, despite initialization from a good starting point. (The use of this starting point reduces significantly the solve time and the number of searched nodes for several problems, including HANGING, NGONE, SMMPSF, TRIMLOSS, and TWIRISM1.)

Anomalies. For several problems, the numbers of false negatives for LP-D and LP-P with test $\mathcal{A}_\lambda$ are larger than $|\mathcal{A}_0^*|$; see, for example, SREADIN3. This may happen because the LP-P and LP-D programs find a sparse λ, one that has many more zeros than the λ^* that we used to form our estimate of $\mathcal{A}_0^*$ as described above.

For certain problems, *all* methods return large numbers of false negatives. These problems often contain many bound constraints, for example, C-RELOAD, READING1, SREADIN3, TRIMLOSS, TWIRIMD1, and ZAMB2. We note that these errors still occurred when we reformulated the tests to treat the bound constraints explicitly.

For LPEC-A and LPEC, the BRAINPC* and OET7 problems have many false positives, as a result of many inactive constraints having values of $c_i(x)$ close to zero, below the threshold for determining activity.

For the problem SOSQP1, a quadratic program, only the LPEC method detects any active constraints; in fact, it makes no identification errors. A smaller choice for the parameter $\bar{\sigma}$ in the LPEC-A identification test would produce perfect identification for the LPEC-A technique also.

We remark on a few more of the anomalies in Table 4.7. Runtimes for HANGING are especially large, given its size. The LP solvers performed many perturbations, and the MIP solver for the LPEC test reports trouble identifying an integer solution. For LPEC, an extremely large number of iterations and nodes is reported for C-RELOAD, again due to difficulty in finding feasible integer solutions. Allowing the use of heuristics by the MIP solver yielded a large reduction in the number of considered nodes for this problem, but the runtime did not change significantly.

4.4. Additional remarks. We conclude this section with some general comments on the numerical results and on additional testing not reported above.

In general, the LP-P and LP-D tests give similar identification results, with a tendency to underestimate the active set (that is, false negatives). The primal activity test $\mathcal{A}_c$ is superior to the dual activity test $\mathcal{A}_\lambda$ for these methods. LP-P tended to take less time to solve, probably because of the greater reductions due to presolving.

We tested the effect of using a much larger Δ in the LP-P and LP-D formulations for the random test problems. Runtimes were slightly longer on the largest problems,

and the time advantage that LP-P has for smaller Δ disappears. The $\mathcal{A}_\lambda$ activity test returned the same poor underestimate of the active set as for the smaller Δ, while the $\mathcal{A}_c$ activity test made many more identification errors.

The LPEC-A test obviously is preferable to LPEC, as the results are similar (with the anomalies easily explained) and the runtimes are sometimes much shorter. We note that it might be possible to improve the performance of these methods by better scaling of the constraints.

We used a `noise` value of 10^{-3} in all reported results, but performed additional experiments with other values of this parameter. For smaller values of `noise`, LP-P and LP-D tend to have similar false positive counts, but show higher false negative counts in some cases. LPEC and LPEC-A show an overall improvement; for example, at `noise` $= 10^{-7}$ the BRAINPC* problems' results for LPEC and LPEC-A are nearly perfect. However, more false negatives are reported on some CUTEr problems. These difficult problems are the ones for which our estimate of the true active set $\mathcal{A}^*$ is sensitive to the parameters β, σ, and $\bar{\sigma}$ used in the threshold test (see subsection 4.3.1), and for which the estimate of the true active set changes significantly if we use LPEC in place of LPEC-A. Specifically, on problems LISWET10, OET7, and READING1, the additional false negatives that were reported when `noise` was decreased from 10^{-3} to 10^{-7} disappeared when $\bar{\sigma}$ was changed or when LPEC was used in place of LPEC-A in the determination of $\mathcal{A}^*$.

As expected, the results of the random problems in Tables 4.2 and 4.3 for the LPEC and LPEC-A techniques are nearly perfect for `noise` $= 10^{-7}$. (`noise` must be decreased to an even smaller value to remove a single false positive in some cases; this identification error is caused by a constraint that is only very slightly inactive.)

For values of `noise` larger than 10^{-3}, LP-P and LP-D report more false positives on the random problems and fewer false negatives on the CUTEr problems. The LPEC and LPEC-A tests tend to give more false positives, while the false negative count decreases on the CUTEr problems and increases on the random problems.

Following a suggestion of a referee, and in line with the discussion at the end of section 3, we obtained a new identification technique by inserting the solution of (3.3) in place of (μ_x, λ_x) in the threshold test (3.28). We found that, indeed, this "threshold LP-D" estimate of the active set was more accurate than those obtained from (3.5a) and (3.5b), as is done in the standard LP-D technique. On the random problem set, the results for threshold LP-D for `noise` $= 10^{-7}$ are identical to those for LPEC-A, in accordance with our claim that both techniques are asymptotically exact.

5. Conclusions. We have described several schemes for predicting the active set for a nonlinear program with inequality constraints, given an estimate x of a solution x^*. The effectiveness of some of these schemes in identifying the correct active set for x sufficiently close to x^* is proved, under certain assumptions. In particular, the scheme of subsection 3.3 has reasonable computational requirements and strong identification properties and appears to be novel. Computational tests are reported which show the properties of the various schemes on random problems and on degenerate problems from the CUTEr test set.

Knowledge of the correct active set considerably simplifies algorithms for inequality constrained nonlinear programming, as it removes the "combinatorial" aspect from the problem. However, it remains to determine how the schemes above can be used effectively as an element of a practical algorithm for solving nonlinear programs. It may be that reliable convergence can be obtained in general without complete knowl-

edge of the active set; some "sufficient subset" may suffice. What are the required properties of such a subset, and can we devise inexpensive identification schemes, based on the ones described in this paper, that identify it? We leave these and other issues to future research.

Appendix A. Proof of (3.10).

We prove this statement by contradiction. Suppose that there is a sequence $\{x^k\}$ with $x^k \to x^*$ such that

$$\text{dist } \left(-g(x^k), \text{range}[\nabla h(x^k)] + \text{pos}[(\nabla c_i(x^k))_{i\in\mathcal{A}_1}]\right) < \tau \tag{A.1}$$

for all k. By closedness, there must be vectors z^k and $y^k \geq 0$ such that the

$$\begin{aligned}&\text{dist } \left(-g(x^k), \text{range}[\nabla h(x^k)] + \text{pos}[(\nabla c_i(x^k))_{i\in\mathcal{A}_1}]\right)\\ &= \left\|\nabla h(x^k)z^k + \sum_{i\in\mathcal{A}_1} \nabla c_i(x^k)y_i^k + g(x^k)\right\| \leq \tau\end{aligned}$$

for all k. If $\{(z^k, y^k)\}$ is unbounded, we have by compactness of the unit ball, and by taking a subsequence if necessary, that $\|(z^k, y^k)\| \uparrow \infty$ and $(z^k, y^k)/\|(z^k, y^k)\| \to (z^*, y^*)$ with $\|(z^*, y^*)\| = 1$ and $y^* \geq 0$. Hence, by dividing both sides in the expression above by $\|(z^k, y^k)\|$ and taking limits, we have

$$(\nabla h^*)z^* + \sum_{i\in\mathcal{A}_1} (\nabla c_i^*)y_i^* = 0. \tag{A.2}$$

From Lemma 3.1, we have $\mathcal{A}_1 \subset \mathcal{A}^*$, so that the MFCQ condition (1.7) holds at x^* for $\mathcal{A}_1$ replacing $\mathcal{A}^*$. Hence, for the vector v in this condition, we have that $\nabla h(x^*)$ has full column rank and that $(\nabla h^*)^T v = 0$ and $\nabla(c_i^*)^T v < 0$ for all $i \in \mathcal{A}_1$. By taking inner products of (A.2) with v, we can deduce first that $y^* = 0$ and subsequently that $z^* = 0$, by a standard argument, contradicting $\|(z^*, y^*)\| = 1$. Therefore, the sequence $\{(z^k, y^k)\}$ must be bounded. Since the sequence remains in a ball about the origin (that is, a compact set), it has an accumulation point.

By taking a subsequence again if necessary, suppose that $(z^k, y^k) \to (\hat{z}, \hat{y})$. We then have that

$$\begin{aligned}&\left\|\nabla h(x^k)\hat{z} + \sum_{i\in\mathcal{A}_1} \nabla c_i(x^k)\hat{y}_i + g(x^k)\right\|\\ &\leq \left\|\nabla h(x^k)z^k + \sum_{i\in\mathcal{A}_1} \nabla c_i(x^k)y_i^k + g(x^k)\right\| + \|\nabla h(x^k)\|\|z^k - \hat{z}\|\\ &\qquad\qquad + \sum_{i\in\mathcal{A}_1} \|\nabla c_i(x^k)\|\,|y_i^k - \hat{y}_i|\\ &\leq \tau + o(1)\end{aligned}$$

for all k sufficiently large. By taking limits in this expression, we deduce that

$$\text{dist } (-g^*, \text{range}[\nabla h^*] + \text{pos}[(\nabla c_i^*)_{i\in\mathcal{A}_1}]) \leq \tau,$$

which contradicts the definition of τ, for $\tau > 0$. Hence, a sequence $\{x^k\}$ with the property (A.1) cannot exist, so (3.10) holds for all $\bar{\epsilon}_2$ sufficiently small. ∎

Acknowledgments. We thank Richard Waltz for many discussions during the early part of this project, for supplying us with the `Knitro` results, and for advice about the implementations. We also thank Dominique Orban for providing helpful advice about using CUTEr. Finally, we are most grateful to two anonymous referees for extremely thorough and helpful comments on the first version of this paper.

CONVERGENCE OF MESH ADAPTIVE DIRECT SEARCH TO SECOND-ORDER STATIONARY POINTS*

MARK A. ABRAMSON† AND CHARLES AUDET‡

Abstract. A previous analysis of second-order behavior of generalized pattern search algorithms for unconstrained and linearly constrained minimization is extended to the more general class of mesh adaptive direct search (MADS) algorithms for general constrained optimization. Because of the ability of MADS to generate an asymptotically dense set of search directions, we are able to establish reasonable conditions under which a subsequence of MADS iterates converges to a limit point satisfying second-order necessary or sufficient optimality conditions for general set-constrained optimization problems.

Key words. nonlinear programming, mesh adaptive direct search, derivative-free optimization, convergence analysis, second-order optimality conditions

AMS subject classifications. 90C30, 90C56, 65K05

DOI. 10.1137/050638382

1. Introduction. In this paper, we consider the class of derivative-free mesh adaptive direct search (MADS) algorithms applied to general constrained optimization problems of the form

$$\min_{x\in\Omega} f(x) \tag{1.1}$$

with $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ and $\Omega \subseteq \mathbb{R}^n$.

We treat the constraints by the "barrier" approach of applying the algorithm, not to f, but to the barrier objective function $f_\Omega = f + \psi_\Omega$, where ψ_Ω is the indicator function for Ω; i.e., it is zero on Ω, and infinity elsewhere. If a point x is not in Ω, then we set $f_\Omega(x) = \infty$, and f is not evaluated. This is important in many practical engineering problems in which f is expensive to evaluate.

The class of MADS algorithms was introduced and analyzed in [4], as an extension of generalized pattern search (GPS) algorithms [3, 21] for solving nonlinearly constrained problems. Rather than applying a penalty function [18] or filter [5] approach to handle the nonlinear constraints, MADS defines an additional parameter that enables the algorithm to perform an exploration of the space of variables in an asymptotically dense set of directions. Under mild assumptions, the Clarke [9] calculus together with three types of tangent cones (hypertangent, Clarke tangent, and

contingent cones) is used to prove convergence of a subsequence of iterates to a point satisfying certain first-order conditions for optimality. An implementable instance of MADS is introduced in [4], in which positive spanning directions are chosen in a random fashion and almost sure convergence to a first-order stationary point is obtained. A similar first-order analysis is done in [15] for the DIRECT algorithm.

This paper extends the MADS analysis to show convergence to points satisfying certain second-order stationarity properties, in a manner similar to that of [1] for GPS. An important result of [1] is that the iterates produced by a GPS algorithm on a sufficiently smooth problem cannot converge in an infinite number of steps to a local maximizer. We show here that it may, unfortunately, converge in an infinite number of steps to a saddle point. The analysis in the present paper gives sufficient conditions under which a subsequence of the iterates produced by a MADS algorithm converges to a strict local minimizer. The necessary optimality condition is not based on any of the three tangent cones used in [4] but rather on the cone of feasible directions.

The paper is outlined as follows. The MADS algorithm is briefly described in section 2, with first-order properties restated in section 3. Section 4 introduces the generalized Hessian [16] with some associated properties, followed by second-order necessary and sufficient optimality conditions and convergence results. Section 5 provides some examples to illustrate the strength of these results, and section 6 offers some concluding remarks.

Notation. $\mathbb{R}$, $\mathbb{Z}$, and $\mathbb{N}$ denote the set of real numbers, integers, and nonnegative integers, respectively. For any set S, $\text{int}(S)$ denotes its interior, and $\text{cl}(S)$ its closure. For any matrix A, the notation $a \in A$ means that a is a column of A. For $x \in \mathbb{R}^n$ and $\varepsilon > 0$, we denote by $B_\varepsilon(x)$ the open ball $\{y \in \mathbb{R}^n : \|y - x\| < \epsilon\}$. We say that f is $C^{1,1}$ near x if there exists an open set S containing x such that f is continuously differentiable with Lipschitz derivatives for every point in S. The reader is invited to consult [16] for a discussion and examples of $C^{1,1}$ functions.

2. Mesh adaptive direct search. Like GPS methods, each iteration k of a MADS algorithm is characterized by two steps—an optional SEARCH step and a local POLL step, in which f_Ω is evaluated at specified points that lie on a mesh. The mesh is constructed from a finite fixed set of n_D directions $D \subset \mathbb{R}^n$ scaled by a mesh size parameter $\Delta_k^m > 0$. The directions form a positive spanning set [14] (i.e., nonnegative linear combinations of D must span $\mathbb{R}^n$), and each direction $d \in D$ must be constructed as the product Gz, where $G \in \mathbb{R}^{n\times n}$ is a nonsingular generating matrix and $z \in \mathbb{Z}^n$ is a vector of integers.

The following definition, taken from [4] and [5], precisely defines the current mesh so that all previously visited points lie on the current mesh.

DEFINITION 2.1. *At iteration k, the* current mesh *is defined to be the following union:*

$$M_k = \bigcup_{x \in S_k} \{x + \Delta_k^m D z : z \in \mathbb{N}^{n_D}\},$$

where S_k is the finite set of points where the objective function f has been evaluated by the start of iteration k and S_0 is a finite set of initial feasible points.

In both the SEARCH and POLL steps, the algorithm seeks to find an *improved mesh point*; i.e., a point $y \in M_k$ for which $f_\Omega(y) < f_\Omega(x_k)$, where x_k is the current iterate or incumbent best iterate found thus far.

The SEARCH step allows evaluation of f_Ω at any finite set of mesh points. Any strategy may be used, including none. This is more restrictive than the frame meth-

ods of Coope and Price [12], but it helps to ensure convergence without a sufficient decrease condition or any other assumptions on mesh directions. The SEARCH step adds nothing to the convergence theory, but well-chosen SEARCH strategies can greatly improve algorithm performance (see [2, 6, 7, 19]).

In the POLL step, f_Ω is evaluated at points adjacent to the current iterate in a subset of the mesh directions. Unlike GPS, the class of MADS algorithms has a second mesh parameter Δ_k^p, called the *poll size parameter*, which satisfies $\Delta_k^m \leq \Delta_k^p$ for all k, and also

$$\lim_{k\in K} \Delta_k^m = 0 \Leftrightarrow \lim_{k\in K} \Delta_k^p = 0 \text{ for any infinite subset of indices } K. \tag{2.1}$$

Under this construction, GPS methods now become the specific MADS instance in which $\Delta_k = \Delta_k^p = \Delta_k^m$.

The set of points generated in the POLL step is called a *frame*, with x_k referred to as the *frame center*. These terms are now formally defined as follows.

DEFINITION 2.2. *At iteration k, the* MADS frame *is defined to be the set*

$$P_k = \{x_k + \Delta_k^m d : d \in D_k\} \subset M_k,$$

where D_k is a positive spanning set such that for each $d \in D_k$, the following hold:

- *$d \neq 0$ can be written as a nonnegative integer combination of the directions in D: $d = Du$ for some vector $u \in \mathbb{N}^{n_D}$ that may depend on the iteration number k.*
- *The distance from the frame center x_k to a poll point $x_k + \Delta_k^m d$ is bounded by a constant times the poll size parameter: $\Delta_k^m \|d\| \leq \Delta_k^p \max\{\|d'\| : d' \in D\}$.*
- *Limits (as defined in Coope and Price* [11]*) of the normalized sets D_k are positive spanning sets.*

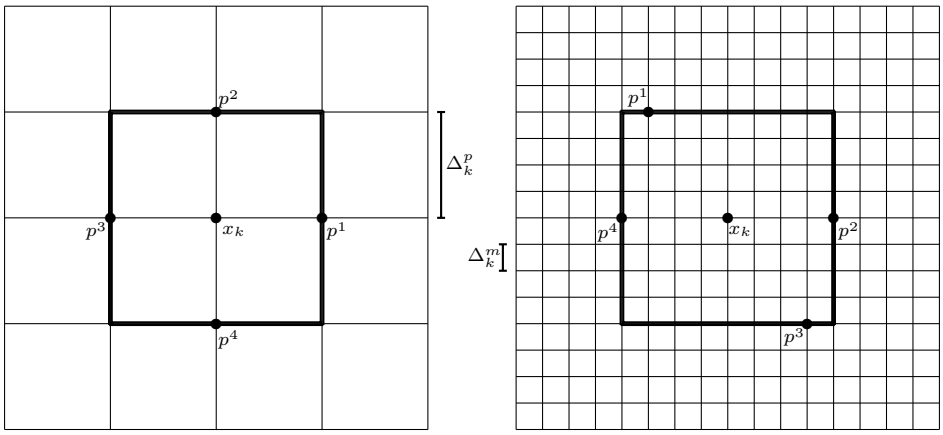
In GPS, the set of directions D_k used to construct the frame is a subset of the finite set D. There is more flexibility in MADS. In [4], an instance of MADS is presented in which the closure of the cone generated by the set $\bigcup_{k=1}^{\infty}\{\frac{d}{\|d\|} : d \in D_k\}$ equals $\mathbb{R}^n$. In this case, we say that the set of poll directions is *asymptotically dense* in $\mathbb{R}^n$.

Figure 2.1 illustrates typical GPS and MADS frames in $\mathbb{R}^2$ using the standard $2n$ coordinate directions. In each case, the mesh M_k is the set of points at the intersections of the horizontal and vertical lines. The thick lines delimit the points that are at a relative distance equal to the poll size parameter Δ_k^p from the frame center x_k. In MADS, the mesh size parameter Δ_k^m is much smaller than the poll size parameter; this allows many more possibilities in the frame construction.

If the POLL step fails to produce an improved mesh point, P_k is said to be a *minimal frame* with *minimal frame center* x_k. If either the SEARCH or POLL step is successful in finding an improved mesh point, the improved mesh point becomes the new current iterate $x_{k+1} \in \Omega$ and the mesh is either retained or coarsened. If neither step is successful, then the minimal frame center is retained as the current iterate (i.e., $x_{k+1} = x_k$) and the mesh is refined.

Rules for refining and coarsening the mesh are as follows. Given a fixed rational number $\tau > 1$ and two integers $w^- \leq -1$ and $w^+ \geq 0$, the mesh size parameter Δ_k^m is updated according to the rule

$$\Delta_{k+1}^m = \tau^{w_k}\Delta_k^m$$
$$\text{for some } w_k \in \begin{cases} \{0, 1, \ldots, w^+\} & \text{if an improved mesh point is found,} \\ \{w^-, w^- + 1, \ldots, -1\} & \text{otherwise.} \end{cases} \tag{2.2}$$



A GPS frame A MADS frame

FIG. 2.1. *GPS and MADS frames* $P_k = \{p^1, p^2, p^3, p^4\}$ *around the frame center* x_k*, with the same poll size parameter* Δ_k^p*.*

The class of MADS algorithms is stated formally as follows:

A GENERAL MADS ALGORITHM

0. INITIALIZATION: Let $x_0 \in \Omega$, set $\Delta_0^p \geq \Delta_0^m > 0$. Set iteration counter to $k = 0$.
1. SEARCH AND POLL STEP: Perform the SEARCH and POLL steps to completion, or until an improved mesh point x_{k+1} is found on the mesh M_k (see Definition 2.1).
   - OPTIONAL SEARCH: Evaluate f_Ω on a finite subset of trial points on the mesh M_k.
   - LOCAL POLL: Evaluate f_Ω on the frame P_k (see Definition 2.2).
2. PARAMETER UPDATE: Update Δ_{k+1}^m according to (2.2), and Δ_{k+1}^p according to (2.1). Increment $k \leftarrow k + 1$ and go to step 1.

3. Existing first-order stationarity results. Before presenting new results, we reproduce known convergence properties of MADS, originally published in [4]. All results are based on the following assumptions:

A1. A feasible initial point x_0 is provided.

A2. The initial objective function value $f(x_0)$ is finite.

A3. All iterates $\{x_k\}$ generated by MADS lie in a compact set.

Under these assumptions, Audet and Dennis [4] proved that

$$\liminf_{k \to +\infty} \Delta_k^p \;=\; \liminf_{k \to +\infty} \Delta_k^m \;=\; 0.$$

This ensures the existence of infinitely many minimal frame centers, since Δ_k^m shrinks only when a minimal frame is found. The following definition, taken from [4], is needed for later results.

DEFINITION 3.1. *A subsequence of the MADS iterates consisting of minimal frame centers,* $\{x_k\}_{k \in K}$ *for some subset of indices* K*, is said to be a* refining subsequence *if* $\{\Delta_k^p\}_{k \in K}$ *converges to zero.*

Let $\hat{x}$ *be the limit of a convergent refining subsequence. If* $\lim_{k \in L} \frac{d_k}{\|d_k\|}$ *exists for some subset* $L \subseteq K$ *with poll direction* $d_k \in D_k$*, and if* $x_k + \Delta_k^m d_k \in \Omega$ *for infinitely many* $k \in L$*, then this limit is said to be a* refining direction *for* $\hat{x}$*.*

Existence of refining subsequences for MADS was proved in [4]. The following four definitions [9, 17, 20] are needed in the main theorems.

DEFINITION 3.2. *A vector $v \in \mathbb{R}^n$ is said to be a* hypertangent vector *to the set $\Omega \subset \mathbb{R}^n$ at the point $x \in \Omega$ if there exists a scalar $\epsilon > 0$ such that*

$$y + tw \in \Omega \qquad \text{for all } y \in \Omega \cap B_\epsilon(x), \quad w \in B_\epsilon(v), \quad \text{and} \quad 0 < t < \epsilon. \tag{3.1}$$

The set of hypertangent vectors to Ω at x is called the hypertangent cone to Ω at x *and is denoted by $T_\Omega^H(x)$.*

DEFINITION 3.3. *A vector $v \in \mathbb{R}^n$ is said to be a* Clarke tangent vector *to the set $\Omega \subset \mathbb{R}^n$ at the point $x \in \mathrm{cl}(\Omega)$ if for every sequence $\{y_k\}$ of elements of Ω that converges to x and for every sequence of positive real numbers $\{t_k\}$ converging to zero, there exists a sequence of vectors $\{w_k\}$ converging to v such that $y_k + t_k w_k \in \Omega$. The set $T_\Omega^{Cl}(x)$ of all Clarke tangent vectors to Ω at x is called the* Clarke tangent cone *to Ω at x.*

DEFINITION 3.4. *A vector $v \in \mathbb{R}^n$ is said to be a* tangent vector *to the set $\Omega \subset \mathbb{R}^n$ at the point $x \in \mathrm{cl}(\Omega)$ if there exists a sequence $\{y_k\}$ of elements of Ω that converges to x and a sequence of positive real numbers $\{\lambda_k\}$ for which $v = \lim_k \lambda_k(y_k - x)$. The set $T_\Omega^{Co}(x)$ of all tangent vectors to Ω at x is called the* contingent cone *(or* sequential Bouligand tangent cone*) to Ω at x.*

DEFINITION 3.5. *The set Ω is said to be* regular *at x if $T_\Omega^{Cl}(x) = T_\Omega^{Co}(x)$.*

In addition to these definitions, we add the following clarifying remarks, due to Clarke [9] unless otherwise noted:

- Any convex set is regular at each of its points.
- Both $T_\Omega^{Co}(x)$ and $T_\Omega^{Cl}(x)$ are closed, and both $T_\Omega^{Cl}(x)$ and $T_\Omega^H(x)$ are convex.
- $T_\Omega^H(x) \subseteq T_\Omega^{Cl}(x) \subseteq T_\Omega^{Co}(x)$.
- Rockafellar [20] showed that if $T_\Omega^H(x)$ is nonempty, $T_\Omega^H(x) = \mathrm{int}(T_\Omega^{Cl}(x))$, and therefore, $T_\Omega^{Cl}(x) = \mathrm{cl}(T_\Omega^H(x))$.

In order to establish the results of this section, we apply a generalization of the Clarke [9] directional derivative, as presented in [17], in which function evaluations are restricted to points in the domain. Specifically, the Clarke generalized directional derivative of the locally Lipschitz function f at $x \in \Omega$ in the direction $v \in \mathbb{R}^n$ is defined by

$$f^\circ(x; v) := \limsup_{\substack{y \to x,\ y \in \Omega \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{f(y + tv) - f(y)}{t}. \tag{3.2}$$

The fundamental result upon which the entire first order convergence analysis [4] of MADS relies is that if f is Lipschitz near the limit point $\hat{x}$ of a refining subsequence, then $f^\circ(\hat{x}; v) \geq 0$ for any refining direction v in the hypertangent cone $T_\Omega^H(\hat{x})$. The next definition, also from [4], provides some nonsmooth terminology for stationarity.

DEFINITION 3.6. *Let f be Lipschitz near $x^* \in \Omega$. Then x^* is said to be a Clarke (resp., contingent) stationary point of f over Ω if $f^\circ(x^*; v) \geq 0$ for every direction v in the Clarke tangent cone (resp., contingent cone) to Ω at x^*.*

In addition, x^* is said to be a Clarke (resp., contingent) KKT stationary point of f over Ω if $-\nabla f(x^*)$ exists and belongs to the polar of the Clarke tangent cone (resp., contingent cone) to Ω at x^*.

If $\Omega = \mathbb{R}^n$ or x^* lies in the interior of Ω, then a stationary point as described by Definition 3.6 meets the condition that $f^\circ(x^*; v) \geq 0$ for all $v \in \mathbb{R}^n$. This is equivalent

to $0 \in \partial f(x^*)$, the generalized gradient of f at x^* [9], which is defined by

$$\partial f(x) := \left\{ s \in \mathbb{R}^n : f^\circ(x; v) \geq v^T s \text{ for all } v \in \mathbb{R}^n \right\}.$$

The function f is said to be *strictly differentiable* at x if the generalized gradient of f at x is a singleton; i.e., $\partial f(x) = \{\nabla f(x)\}$.

The main results of [4] can now be summarized in the next theorem.

THEOREM 3.7. *Let $\hat{x} \in \Omega$ be the limit of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$ and the set of refining directions is dense in $T_\Omega^H(\hat{x})$.*

1. *If f is Lipschitz near $\hat{x}$, then $\hat{x}$ is a Clarke stationary point of f on Ω.*
2. *If f is strictly differentiable at $\hat{x}$, then $\hat{x}$ is a Clarke KKT stationary point of f on Ω.*

Furthermore, if Ω is regular at $\hat{x}$, then the following hold:

1. *If f is Lipschitz near $\hat{x}$, then $\hat{x}$ is a contingent stationary point of f on Ω.*
2. *If f is strictly differentiable at $\hat{x}$, then $\hat{x}$ is a contingent KKT stationary point of f on Ω.*

4. New second-order stationarity results. This section contains second-order convergence theory for MADS. In section 4.1 we recall the definition of the generalized Hessian and identify some useful properties. In section 4.2 we present second-order necessary and sufficient conditions for optimality for set-constrained optimization problems. Finally, in section 4.3, we establish conditions under which convergence of MADS iterates to a point satisfying second-order necessary and sufficient conditions is achieved.

4.1. Generalized second-order derivatives. Before proving convergence to second-order points, we present nonsmooth notions of second derivatives and introduce second-order optimality conditions. Generalized second-order directional derivatives are developed in [10] and [16], consistent with the Clarke [9] calculus for first-order derivatives. In this paper, we follow the Hiriart-Urruty, Strodiot, and Nguyen [16] definition of a generalized Hessian, given as follows.

DEFINITION 4.1. *Let $g : \mathbb{R}^n \to \mathbb{R}$ be $C^{1,1}$ near $x \in \Omega \subseteq \mathbb{R}^n$. The* generalized Hessian *of g at x, denoted by $\partial^2 g(x)$, is the set of matrices defined as the convex hull of the set*

$$\{A \in \mathbb{R}^{n \times n} : \exists\, x_k \to x \text{ with } g \text{ twice differentiable at } x_k \text{ and } \nabla^2 g(x_k) \to A\}.$$

By construction, $\partial^2 g(x)$ is a nonempty, compact, and convex set of symmetric matrices [16]. The function g is said to be *twice strictly differentiable* at x if the generalized Hessian is a singleton; i.e., $\partial^2 g(x) = \{\nabla^2 g(x)\}$. Furthermore, as a set-valued mapping, $x \rightrightarrows \partial^2 g(x)$ has two key properties, also identified in [16], which are necessary to establish optimality conditions in the next section.

- $\partial^2 g(x)$ is a *locally bounded* set-valued mapping:
  Given a matrix norm $\|\cdot\|$, there exist an $\varepsilon > 0$ and $\eta \in \mathbb{R}$ such that
  $$\sup\{\|A\| : A \in \partial^2 g(y), y \in B_\varepsilon(x)\} \ \leq \ \eta;$$
- $\partial^2 g(x)$ is a *closed* set-valued mapping:
  If $x_k \to x$ and $A_k \to A$ with $A_k \in \partial^2 g(x_k)$ for all k, then $A \in \partial^2 g(x)$.

The following second-order Taylor series result also comes from [16].

THEOREM 4.2. *Let $g : \mathbb{R}^n \to \mathbb{R}$ be $C^{1,1}$ in a open set $U \subset \mathbb{R}^n$, and let $[a, b] \subset U$ be a line segment. Then there exist an $x \in]a, b[$ and a matrix $A_x \in \partial^2 f(x)$ such that*

$$g(b) \ = \ g(a) + (b - a)^T \nabla f(a) + \frac{1}{2}(b - a)^T A_x (b - a).$$

In the next section, we apply this result to feasible points that may lie on the boundary of Ω. We are able to do this because our assumptions on the local smoothness of f are independent of Ω.

4.2. Second-order optimality conditions. Second-order necessary and sufficient optimality conditions for constrained problems are traditionally expressed in terms of the Lagrangian function. However, our use of the barrier approach in handling constraints provides no useful information about the constraint gradients, and thus prevents us from proving anything with respect to traditional optimality conditions. Therefore, instead of dealing with the Lagrangian function, we extend optimality conditions for set-constrained problems (see [8] for further discussions).

We now establish Clarke-based second-order necessary and sufficient conditions for set-constrained optimality. The proof for the former is very similar to one found in [16] for unconstrained problems, the only difference being the first-order condition satisfied by the local minimizer. It is expressed in terms of feasible directions, formally given in Definition 4.3.

DEFINITION 4.3. *The direction $v \in \mathbb{R}^n$ is said to be feasible for $\Omega \subset \mathbb{R}^n$ at $x \in \Omega$ if there exists an $\epsilon > 0$ for which $x + tv \in \Omega$ for all $0 \leq t < \epsilon$. The set of feasible directions for Ω at $x \in \Omega$ is a cone and is denoted by $T_\Omega^F(x)$.*

It follows immediately that $T_\Omega^H(x) \subseteq T_\Omega^F(x) \subseteq T_\Omega^{Co}(x)$ for any $x \in \Omega$. Moreover, if $T_\Omega^H(x) \neq \emptyset$ for some $x \in \Omega$, and if Ω is regular at x, then $\mathrm{cl}(T_\Omega^H(x)) = \mathrm{cl}(T_\Omega^F(x)) = T_\Omega^{Cl}(x) = T_\Omega^{Co}(x)$. However, without regularity it is possible that either of the following holds:

- $T_\Omega^{Cl}(x) \subset \mathrm{int}(T_\Omega^F(x))$: e.g., if $\Omega = \{(a,b) \in \mathbb{R}^2 : a \geq 0 \text{ or } b \geq 0\}$, then $T_\Omega^{Cl}(0,0) = \mathbb{R}^2_+$ and $T_\Omega^F(0,0) = \Omega$,
- $\mathrm{cl}(T_\Omega^F(x)) \subset \mathrm{int}(T_\Omega^{Cl}(x))$: e.g., if $\Omega = \mathbb{R}^2 \backslash \{(-\frac{1}{k}, b) \in \mathbb{R}^2 : b \in \mathbb{R}, k = 1, 2, \dots\}$, then $T_\Omega^F(0,0) = \{(a,b) \in \mathbb{R}^2 : a \geq 0\}$ and $T_\Omega^{Cl}(0,0) = \mathbb{R}^2$.

THEOREM 4.4 (second-order necessary condition for set-constrained optimality). *Let $x^* \in \Omega$ be a local solution of (1.1). If f is $C^{1,1}$ near x^*, then any feasible direction $v \in T_\Omega^F(x^*)$ for which $v^T \nabla f(x^*) = 0$ satisfies $v^T A v \geq 0$ for some $A \in \partial^2 f(x^*)$.*

Proof. Let $v \in \mathbb{R}^n$ be a feasible direction that satisfies $v^T \nabla f(x^*) = 0$, and consider the sequence $\{x_k\}$, where $x_k = x^* + \frac{1}{k} v$. It follows that $x_k \in \Omega$ when k is sufficiently large. Then by second-order Taylor series in a neighborhood of the local minimizer x^*, we have for each k sufficiently large

$$0 \;\leq\; f(x_k) - f(x^*) \;=\; \frac{1}{k} \nabla f(x^*)^T v + \frac{1}{2k^2} v^T A_k v \;=\; \frac{1}{2k^2} v^T A_k v, \tag{4.1}$$

where $A_k \in \partial^2 f(\bar{x}_k)$ for some $\bar{x}_k \in]x^*, x_k[$.

Since $\partial^2 f$ is locally bounded and $\bar{x}_k \to x^*$, the sequence $\{A_k\}$ is locally bounded and thus possesses an accumulation point A. Furthermore, since $\partial^2 f$ is a closed set-valued mapping, we have $A \in \partial^2 f(x^*)$. Taking limits in (4.1) leads to $v^T A v \geq 0$. ∎

Theorem 4.4 applies to the set of hypertangent vectors as well as feasible directions since the set of feasible directions contains the hypertangent cone. However, this necessary condition does not necessarily hold for directions in the Clarke tangent or contingent cone, as the following example shows.

Example 4.5. Consider the quadratic optimization problem, in which $f : \mathbb{R}^2 \to \mathbb{R}$ is defined by $f(a,b) = -(a^2 + b^2)$, and $\Omega = \{(a,b) \in \mathbb{R}^2 : a^2 + (b-1)^2 \leq 1\}$. The optimal solution is at $(0,2)$, where

$$T_\Omega^H(0,2) = T_\Omega^F(0,2) = \{(v_1, v_2) : v_2 < 0\},$$

$$T_\Omega^{Cl}(0,2) = T_\Omega^{Co}(0,2) = \{(v_1, v_2) : v_2 \leq 0\}.$$

The direction $v = (1,0)^T \in T_\Omega^{Cl}(0,2) = T_\Omega^{Co}(0,2)$ is not a feasible direction and makes a zero inner product with $\nabla f(0,2) = (0,-4)^T$, but the Hessian matrix is given by

$$\nabla^2 f(0,2) \;=\; \begin{bmatrix} -2 & 0 \\ 0 & -2 \end{bmatrix},$$

which yields $v^T \nabla^2 f(0,2) v = -2 < 0$.

THEOREM 4.6 (second-order sufficient condition for set-constrained optimality). *Let $x^* \in \Omega$ be a contingent stationary point for the optimization problem defined in* (1.1)*, and suppose that $T_\Omega^H(x^*) \neq \emptyset$ and that Ω is convex near x^*. If f is $C^{1,1}$ near x^*, and if $v^T A v > 0$ for all matrices $A \in \partial^2 f(x^*)$ and all nonzero tangent directions $v \in T_\Omega^{Co}(x)$ that satisfy $v^T \nabla f(x^*) = 0$, then x^* is a strict local solution of* (1.1).

Proof. The proof is by contraposition. Suppose that x^* is not a strict local minimizer. Then there exists a sequence $\{y_k\} \subset \Omega$ (with $y_k \neq x^*$) converging to x^* satisfying $f(y_k) \leq f(x^*)$ for all k. By taking subsequences if necessary, we can assume that the sequence $\{w_k\}$ with $w_k = \frac{y_k - x^*}{\|y_k - x^*\|}$ converges to some vector $v \in \mathbb{R}^n$.

Local convexity of Ω near x^* implies that v and w_k are contingent directions for all $k \geq \ell$, for some integer $\ell \geq 0$. Moreover, since x^* is assumed to be a contingent stationary point, and since f is continuously differentiable, then $v^T \nabla f(x^*) \geq 0$ and $w_k^T \nabla f(x^*) \geq 0$ for all $k \geq \ell$. However, since $f(y_k) \leq f(x^*)$ for all k, then $v^T \nabla f(x^*) = 0$.

Theorem 4.2 on Taylor series ensures that for each $k \geq \ell$, there exists some matrix $A_k \in \partial^2 f(\bar{x}_k)$ with $\bar{x}_k \in]x^*, y_k[$ such that

$$\begin{aligned} 0 \;\geq\; f(y_k) - f(x^*) &= (y_k - x^*)^T \nabla f(x^*) + \frac{1}{2}(y_k - x^*)^T A_k (y_k - x^*) \\ &\geq \frac{1}{2}(y_k - x^*)^T A_k (y_k - x^*). \end{aligned} \tag{4.2}$$

Now, since $\bar{x}_k \to x^*$, and since $\partial^2 f(x^*)$ is a closed locally bounded set-valued mapping, there exists an accumulation point $A \in \partial^2 f(x^*)$ of the sequence $\{A_k\}$. Dividing (4.2) by $\|y_k - x^*\|^2$ and taking limits leads to $0 \geq \frac{1}{2} v^T A v$, where $v \neq 0$ belongs to $T_\Omega^{Co}(x^*)$ and satisfies $v^T \nabla f(x^*) = 0$. ∎

The previous theorem requires as an assumption that the set Ω is locally convex. The following example shows that regularity of Ω is not sufficient to guarantee a local minimizer.

Example 4.7. Consider the quadratic optimization problem, in which $f : \mathbb{R}^2 \to \mathbb{R}$ is defined by $f(a,b) = a^2 + 2b$, and $\Omega = \{(a,b) \in \mathbb{R}^2 : 2a^2 + b \geq 0\}$. The solution $x^T = (0,0)$ is a contingent stationary point, and Ω is regular at x since

$$T_\Omega^{Cl}(x) = T_\Omega^{Co}(x) = \{(v_1, v_2) : v_2 \geq 0\}.$$

The vector $v = (1,0)^T \in T_\Omega^{Co}(x)$ satisfies $v^T \nabla f(x) = 0$ and $v^T \nabla^2 f(x) v = 2 > 0$. However, $(\epsilon, -\epsilon^2)$ belongs to the strict interior of Ω for all $\epsilon \neq 0$, and $f(\epsilon, -\epsilon^2) = -\epsilon^2 < 0 = f(x)$.

4.3. Second-order stationarity results for MADS. The next two results are the main contributions of this paper. The first theorem establishes convergence of

a subsequence of MADS iterates to a point satisfying the second-order necessary condition identified in Theorem 4.4, and the second establishes the sufficiency conditions of Theorem 4.6.

THEOREM 4.8. *Let f be $C^{1,1}$ near a limit $\hat{x}$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$ and that Ω is regular near $\hat{x}$. If the set of refining directions is dense in $T_\Omega^H(\hat{x})$, then $\hat{x}$ satisfies the second-order necessary condition for set-constrained optimality.*

Proof. Let $v \in \mathbb{R}^n$ be any nonzero feasible direction that satisfies $v^T \nabla f(\hat{x}) = 0$, and suppose, by way of contradiction, that $v^T \hat{A} v < 0$ for all matrices $\hat{A} \in \partial^2 f(\hat{x})$. Since $\partial^2 f(\hat{x})$ is nonempty and compact, and $\partial^2 f$ is a closed set-valued mapping, there exists some $\varepsilon > 0$ such that $v^T A v < 0$ for all $A \in \partial^2 f(x)$ and for all $x \in B_\varepsilon(\hat{x})$.

Let K denote the set of indices of unsuccessful iterations. Regularity of Ω, together with the assumption that $T_\Omega^H(\hat{x}) \neq \emptyset$, guarantees that $\mathrm{cl}(T_\Omega^H(\hat{x})) = T_\Omega^{Co}(\hat{x}) = \mathrm{cl}(T_\Omega^F(\hat{x}))$. Therefore, the denseness of the set of refining directions in $T_\Omega^H(\hat{x})$ ensures the existence of $\{w_k\}_{k \in K}$ converging to v with $w_k = \frac{d_k}{\|d_k\|}$, $d_k \in D_k$, for each $k \in K$. Applying Taylor series yields

$$f(x_k + \Delta_k^p d_k) - f(x_k) = \Delta_k^p d_k^T \nabla f(x_k) + \frac{1}{2}(\Delta_k^p)^2 d_k^T A_k^+ d_k, \tag{4.3}$$

$$f(x_k - \Delta_k^p d_k) - f(x_k) = -\Delta_k^p d_k^T \nabla f(x_k) + \frac{1}{2}(\Delta_k^p)^2 d_k^T A_k^- d_k, \tag{4.4}$$

where $A_k^+ \in \partial^2 f(x^+)$ for some $x^+ \in]x_k, x_k + \Delta_k^p d_k[$ and $A_k^- \in \partial^2 f(x^-)$ for some $x^- \in]x_k, x_k - \Delta_k^p d_k[$. Since $\Delta_k \to 0^+$ and $x_k \to \hat{x}$, there is a subsequence for which A_k^+ converges to some $A^+ \in \partial^2 f(\hat{x})$, and A_k^- converges to some $A^- \in \partial^2 f(\hat{x})$. Moreover, since $\partial^2 f(\hat{x})$ is a convex set, $A = \frac{1}{2}(A^+ + A^-) \in \partial^2 f(\hat{x})$.

Adding (4.3) and (4.4) and substituting $d_k = \|d_k\| w_k$ yields

$$\frac{1}{\Delta_k^p \|d_k\|} \left[\frac{f(x_k + \Delta_k^p \|d_k\| w_k) - f(x_k)}{\Delta_k^p \|d_k\|} + \frac{f(x_k - \Delta_k^p \|d_k\| w_k) - f(x_k)}{\Delta_k^p \|d_k\|} \right] = w_k^T A_k w_k, \tag{4.5}$$

where $A_k = \frac{1}{2}(A_k^+ + A_k^-)$. Furthermore, since $w_k \to v$ and $v^T A v < 0$, there exists $\gamma < 0$ such that $w_k^T A_k w_k \leq \gamma < 0$ for all sufficiently large $k \in K$, which forces the left-hand side of (4.5) to also be negative and bounded away from zero. But since $d_k \in D_k$ for all sufficiently large $k \in K$, we have that $f(x_k) \leq f(x_k + \Delta_k^p d_k)$, which makes nonnegative the first term of the left-hand side of (4.5) (for all sufficiently large $k \in K$). Thus it must be the case that

$$\frac{f(x_k - \Delta_k^p \|d_k\| w_k) - f(x_k)}{\Delta_k^p \|d_k\|} \leq \gamma < 0 \tag{4.6}$$

for all sufficiently large $k \in K$. Taking the limit of (4.6) as $k \to \infty$ in K yields $\nabla f(\hat{x})^T(-v) < 0$, or $\nabla f(\hat{x})^T v > 0$, which contradicts the assumption that $\nabla f(\hat{x})^T v = 0$. ∎

The following result shows that the sufficient conditions of Theorem 4.6 can be satisfied by a subsequence of MADS iterates, given stronger hypotheses than those of Theorem 4.8.

THEOREM 4.9. *Let f be twice strictly differentiable at a limit $\hat{x}$ of a refining subsequence, and assume that $T_\Omega^H(\hat{x}) \neq \emptyset$, Ω is convex near $\hat{x}$, and $\nabla^2 f(\hat{x})$ is nonsingular. If the set of refining directions is dense in $T_\Omega^H(\hat{x})$, then $\hat{x}$ is a strict local minimizer of f on Ω.*

Proof. Since f is twice strictly differentiable at $\hat{x}$, $\partial^2 f(\hat{x}) = \{\nabla^2 f(\hat{x})\}$. Thus, it follows from Theorem 4.8 that $v^T \nabla^2 f(\hat{x}) v \geq 0$ for all feasible directions $v \in T_\Omega^F(\hat{x})$ satisfying $\nabla f(\hat{x})^T v = 0$. But since $\nabla^2 f(\hat{x})$ is assumed to be nonsingular, this inequality is strict. Furthermore, by Theorem 3.7 and the smoothness of f near $\hat{x}$, $\hat{x}$ is a first-order contingent stationary point. Thus the hypotheses of Theorem 4.6 are satisfied, and the result is proved. ∎

Clearly, these are strong results for a direct search method. However, in practice, achieving denseness of the refining directions in the hypertangent cone (a key assumption) requires increasingly more poll directions per iteration. To overcome this problem, an implementable instance of MADS is introduced in [4], called LTMADS, in which the positive spanning directions used at each iteration are limited in number but are chosen randomly from among the increasing number of possible poll directions. While this is not difficult to implement, the drawback is that denseness of the refining directions is only achieved *almost surely* (i.e., with probability one). Thus, in practice, the convergence results proved both here and in [4] are only attained *almost surely*. This is a weaker measure of convergence, but it works well in practice [4]. We apply LTMADS to one of the numerical examples in the next section.

5. Examples. Second order results for GPS are presented in [1]. They are not as strong as those presented here for MADS. In this section, we illustrate this difference through two quadratic examples in $\mathbb{R}^2$. The first shows how GPS, but not MADS, can converge in an infinite number of iterations to a saddle point with wide cones of descent. This result is actually proved, but doing so requires an uncommon set of parameter choices. The second example [1] uses more realistic parameter choices, and numerical tests show that GPS stalls at a saddle point with narrow cones of descent, but MADS successfully avoids it.

5.1. An example where GPS converges in an infinite number of iterations to a saddle point. Consider the unconstrained quadratic optimization problem in which the polynomial objective function in $\mathbb{R}^2$ is $f(a, b) = a^2 + 3ab + b^2$. The point (0,0) is a saddle point, at which the descent directions lie in the cone generated by $a = \frac{1}{2}b(-3 \pm \sqrt{5})$.

We apply an instance of GPS where $D_k = D = \{e_1, e_2, -e_1, -e_2\}$ is constant throughout all iterations. On iterations that fail to improve the incumbent, the mesh size parameter is divided by 16. On successful iterations that follow an unsuccessful one, the mesh size is kept constant, and on other successful iterations, the mesh size parameter is multiplied by 8. Thus, the GPS parameters are $G = I$ (the identity matrix), $Z = D = [I;\ -I]$, $\tau = 2$, $w^- = -4$, and $w^+ = 3$.

Furthermore, we use an empty SEARCH and an opportunistic POLL, i.e., an iteration terminates as soon as an improved mesh point is generated. Moreover, when the iteration number k modulo 3 is 1, the POLL step first evaluates $x_k - \Delta_k e_2$, and otherwise, the POLL step first evaluates $x_k - \Delta_k e_1$. The order in which the other poll points are explored is irrelevant to this example.

The initial parameters are $x_0^T = (1, 1)$ with $f(x_0) = 5$ and $\Delta_0 = 8$. Figure 5.1 displays the first iterates generated by the algorithm. The figure also displays some level sets of f.
