We next show that the entire sequence of iterates converges to the origin. This happens because this instance of GPS never generates any trial points in the cone where f is negative. It either jumps over the cone, which results in an unsuccessful iteration, or takes a small step which falls short of reaching the cone. For example,

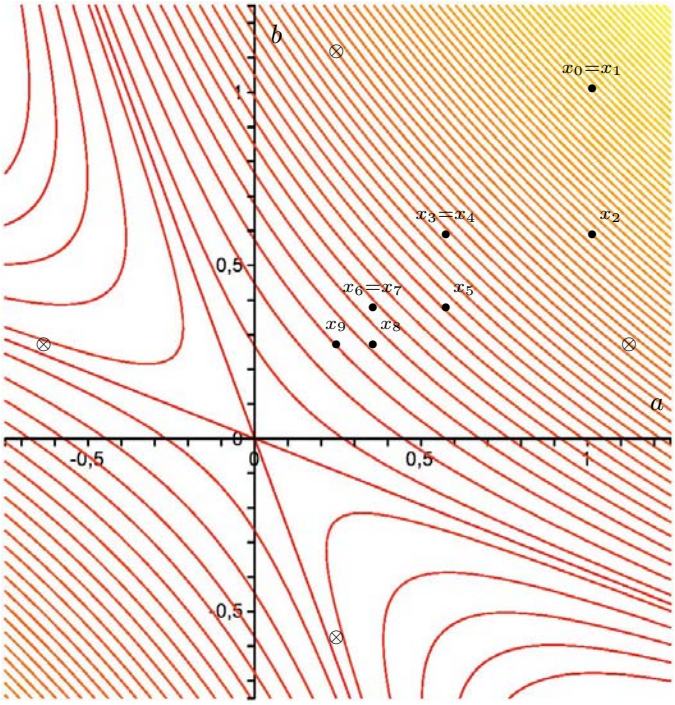

FIG. 5.1. *Initial GPS iterates.*

TABLE 5.1
Iterations $k = 3\ell$ to $k = 3(\ell+1)$.

k	x_k	Δ_k	Trial poll points at $x_k = (a_k, b_k)$
3ℓ	$(2^{-\ell}, 2^{-\ell})$	$2^{3-\ell}$	$f(a_k+\Delta_k, b_k) = f(9\times 2^{-\ell}, 2^{-\ell}) = 109\times 4^{-\ell}$
			$= f(2^{-\ell}, 9\times 2^{-\ell}) = f(a_k, b_k+\Delta_k)$
			$f(a_k-\Delta_k, b_k) = f(-7\times 2^{-\ell}, 2^{-\ell}) = 29\times 4^{-\ell}$
			$= f(2^{-\ell}, -7\times 2^{-\ell}) = f(a_k, b_k+\Delta_k)$
$3\ell+1$	$(2^{-\ell}, 2^{-\ell})$	$2^{-\ell-1}$	$f(a_k, b_k-\Delta_k) = f(2^{-\ell}, 2^{-\ell-1}) = 11\times 4^{-\ell-1}$
$3\ell+2$	$(2^{-\ell}, 2^{-\ell-1})$	$2^{-\ell-1}$	$f(a_k-\Delta_k, b_k) = f(2^{-\ell-1}, 2^{-\ell-1}) = 5\times 4^{-\ell-1}$
$3(\ell+1)$	$(2^{-\ell-1}, 2^{-\ell-1})$	$2^{2-\ell}$	...

at iteration $k = 9$, the trial poll points are $(\frac{9}{8}, 1), (1, \frac{9}{8}), (-\frac{7}{8}, 1)$, and $(1, -\frac{7}{8})$. These four trial points are represented by the symbol $\otimes$ in the figure.

PROPOSITION 5.1. *For any integer $\ell \geq 0$, the GPS iterates are such that $x_{3\ell} = x_{3\ell+1} = \left(2^{-\ell}, 2^{-\ell}\right)$, $x_{3\ell+2} = \left(2^{-\ell}, 2^{-\ell-1}\right)$, and $\Delta_{3\ell} = 2^{3-\ell}$, $\Delta_{3\ell+1} = \Delta_{3\ell+2} = 2^{-\ell-1}$.*

Proof. The proof is done by induction. The result is true for the initial iteration $k = 0$. Suppose that iteration $k = 3\ell$ is initiated with $\Delta_k = 2^{3-\ell}$ and $x_k = \left(2^{-\ell}, 2^{-\ell}\right)$. The current objective function value is $f(x_k) = 5\times 4^{-\ell}$. Table 5.1 details the objective function values at the poll points for iterations $k = 3\ell, 3\ell+1$, and $3\ell+2$. Trial points that improve the incumbent appear in shaded boxes. This table shows that the iterate for $k = 3(\ell+1)$ is $(2^{-\ell-1}, 2^{-\ell-1})$ and that the corresponding mesh size parameter is $2^{2-\ell}$. This concludes the proof. ∎

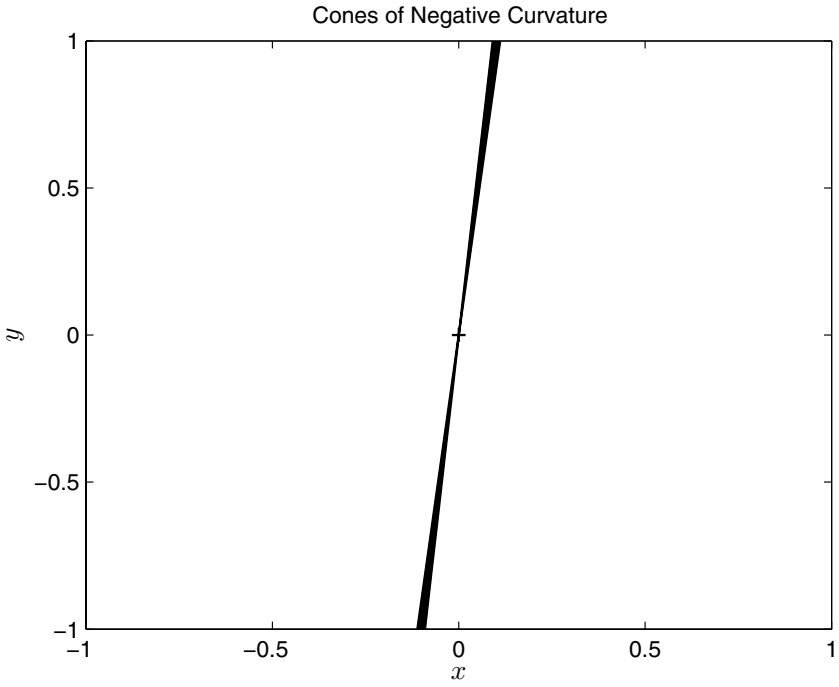

FIG. 5.2. *For $f(a,b) = (9a - b)(11a - b)$, the cones of descent at the saddle point (0,0) are shown in the shaded area between the lines $b = 9a$ and $b = 11a$.*

The previous proposition shows that the entire sequence of iterates generated by GPS converges to the saddle point $(0, 0)$, which is not a local minimizer. Theorem 4.8 ensures that any MADS instance with an asymptotically dense set of refining directions will not converge to that saddle point, since the necessary optimality condition is not satisfied: $v^T = (-1, 1)$ is a feasible direction for which $v^T \nabla f(0, 0) = 0$, but

$$v^T \nabla^2 f(0,0) v \;=\; v^T \begin{bmatrix} 2 & 3 \\ 3 & 2 \end{bmatrix} v^T \;=\; -2$$

is negative.

5.2. An example where GPS reaches and stalls at a saddle point. Consider the bound constrained problem

$$\min_{-2 \le a,b \le 2} \; f(a,b) \;=\; 99a^2 - 20ab + b^2 \;=\; (9a - b)(11a - b).$$

At the saddle point $(0, 0)$, directions of descent lie only in the narrow cone formed by the lines $b = 9a$ and $b = 11a$. Thus to avoid stalling at the saddle point, GPS or MADS would have to generate a feasible iterate that lies inside this cone (see Figure 5.2). In this example, the SEARCH step is empty and the initial point is chosen to be $(1.01,\ 0.93)$. This starting point is chosen to be nonintegral to make it more difficult for GPS to reach the integral point $(0, 0)$. Both GPS and MADS were run using the NOMAD software package [13] with primarily default settings: $G = I$, $Z = D = [I;\ -I]$, $\tau = 2$, $w^- = -1$, $w^+ = 0$, and standard $2n$ coordinate directions as poll directions.

GPS reaches the saddle point at the 358th function evaluation with a poll size parameter of 10^{-17}. This implies that, regardless of the termination tolerance chosen, it stalls there because none of the poll directions are directions of descent. On the other hand, NOMAD's implementation of LTMADS successfully moved off of the saddle point to reach a local minimizer in 100 of 100 runs. This is again consistent with Theorem 4.8, since $v^T = (1, 10)$ is a feasible direction for which $v^T \nabla f(0,0) = 0$ but

$$v^T \nabla^2 f(0,0) v \;=\; v^T \begin{bmatrix} 198 & -20 \\ -20 & 2 \end{bmatrix} v^T \;=\; -2$$

is negative.

6. Concluding remarks. The theoretical results presented here establish strong convergence results for MADS. In spite of MADS being a derivative-free method, we have shown convergence of a subsequence of MADS iterates to a second-order stationary point under conditions weaker than standard Newton assumptions, namely, that f is continuously differentiable with Lipschitz derivatives near the limit point. Moreover, if Ω is locally convex and f is twice strictly differentiable near the limit point, then the limit point is a local minimizer for (1.1).

In section 5, we provided examples to illustrate the superior convergence properties of MADS over GPS. However, since our implementation involves random selection of positive spanning directions, the convergence properties established in section 4.3 are achieved, in practice, with probability one. We envision a future area of research being the clever enumeration of these directions so that the stronger type of convergence is retained by an implementable instance of the algorithm. Specifically, we would like to deterministically generate an asymptotically dense set of directions in such a way that, after any finite number of iterations, the directions used by the algorithm are uniformly spaced (or as close to it as possible).

ON THE MINIMUM VOLUME COVERING ELLIPSOID OF ELLIPSOIDS*

E. ALPER YILDIRIM†

Abstract. Let $\mathcal{S}$ denote the convex hull of m full-dimensional ellipsoids in $\mathbb{R}^n$. Given $\epsilon > 0$ and $\delta > 0$, we study the problems of computing a $(1+\epsilon)$-approximation to the minimum volume covering ellipsoid of $\mathcal{S}$ and a $(1+\delta)n$-rounding of $\mathcal{S}$. We extend the first-order algorithm of Kumar and Yıldırım [*J. Optim. Theory Appl.*, 126 (2005), pp. 1–21] that computes an approximation to the minimum volume covering ellipsoid of a finite set of points in $\mathbb{R}^n$, which, in turn, is a modification of Khachiyan's algorithm [L. G. Khachiyan, *Math. Oper. Res.*, 21 (1996), pp. 307–320]. Our algorithm can also compute a $(1+\delta)n$-rounding of $\mathcal{S}$. For fixed $\epsilon > 0$ and $\delta > 0$, we establish polynomial-time complexity results for the respective problems, each of which is linear in the number of ellipsoids m. In particular, our algorithm can approximate the minimum volume covering ellipsoid of $\mathcal{S}$ in asymptotically the same number of iterations as that required by the algorithm of Kumar and Yıldırım to approximate the minimum volume covering ellipsoid of a set of m points. The main ingredient in our analysis is the extension of polynomial-time complexity of certain subroutines in the algorithm from a set of points to a set of ellipsoids. As a byproduct, our algorithm returns a finite "core" set $\mathcal{X} \subseteq \mathcal{S}$ with the property that the minimum volume covering ellipsoid of $\mathcal{X}$ provides a good approximation to the minimum volume covering ellipsoid of $\mathcal{S}$. Furthermore, the size of the core set depends only on the dimension n and the approximation parameter ϵ, but not on the number of ellipsoids m. We also discuss the extent to which our algorithm can be used to compute an approximate minimum volume covering ellipsoid and an approximate n-rounding of the convex hull of other sets in $\mathbb{R}^n$. We adopt the real number model of computation in our analysis.

Key words. minimum volume covering ellipsoids, Löwner ellipsoids, core sets, rounding of convex sets, approximation algorithms

DOI. 10.1137/050622560

1. Introduction.

Given m full-dimensional ellipsoids $\mathcal{E}_1, \ldots, \mathcal{E}_m$ in $\mathbb{R}^n$, let $\mathcal{S}$ denote their convex hull. In this paper, we are concerned with the problems of approximating the minimum volume covering ellipsoid (MVCE) of $\mathcal{S}$, denoted by MVCE($\mathcal{S}$), also known as the Löwner ellipsoid of $\mathcal{S}$, and computing an approximate n-rounding of $\mathcal{S}$.

Ellipsoidal approximations of a compact convex set $\mathcal{S} \subset \mathbb{R}^n$ with a nonempty interior play an important role in several applications. By the Löwner–John theorem (see Theorem 2.1), MVCE($\mathcal{S}$) provides a good rounding of the set $\mathcal{S}$, which implies that certain characteristics of $\mathcal{S}$ can be approximated using an ellipsoidal rounding as long as MVCE($\mathcal{S}$) can be computed efficiently. For instance, an ellipsoidal rounding of $\mathcal{S}$ can be used to efficiently compute lower and upper bounds for a quadratic optimization problem over $\mathcal{S}$ (see Proposition 2.6).

The idea of approximating complicated objects using simpler ones is widely used in computational geometry and computer graphics. A common approach is to replace a complicated but more realistic model of a complex object with a simpler model of a less complex object covering the original object such as a minimum volume box

or a sphere. More recently, ellipsoidal models have been proposed in the literature as they usually provide better approximations than bounding boxes or spheres (see, e.g., [25, 26, 14, 10]). The key idea is to construct a so-called bounding volume hierarchy [11], which is simply a tree of bounding volumes. The bounding volume at a given node encloses the bounding volumes of its children. The bounding volume of a leaf encloses a primitive. Such a data structure can be used for detection collision or ray tracing. For instance, if a ray misses the bounding volume of a particular node, then the ray will miss all of its children, and the children can be skipped. The ray tracing algorithm traverses this hierarchy, usually in depth-first order, and determines if the ray intersects an object. Therefore, if an ellipsoidal approximation is used, the construction of a bounding volume hierarchy requires the computation of the MVCE of a union of ellipsoids at every node.

There is an extensive body of research on MVCEs of a finite set of points. We refer the reader to [15, 29, 18] and the references therein for a detailed account of numerous applications and several algorithms. In contrast, we are not aware of any specialized algorithms for the MVCE of ellipsoids in the literature. It is known that the problem can be formulated as an instance of a convex determinant optimization problem with linear matrix inequalities [5, 2, 6], which is amenable to theoretically efficient algorithms proposed in [32, 31]. Our main objective in this paper is to establish that the problem of MVCE of ellipsoids admits a sufficiently rich structure that enables us to extend the first-order algorithm of Kumar and Yıldırım [18], which, in turn, is a modification of Khachiyan's algorithm [15], that computes an approximate MVCE of a finite set of points in an almost verbatim fashion to a set of ellipsoids. The main ingredient in our analysis is the extension of polynomial-time complexity of certain subroutines in the algorithm of [18] from a set of points to a set of ellipsoids. We mainly rely on the complexity results of Porkolab and Khachiyan [21] on semidefinite optimization with a fixed number of constraints, which leads to the polynomial-time complexity of quadratic optimization over an ellipsoid—one of the subroutines in our algorithm (see Proposition 2.6). Throughout this paper, we adopt the real number model of computation [4]; i.e., arithmetic operations with real numbers and comparisons can be done with unit cost.

Given $\epsilon > 0$ and a compact convex set $\mathcal{S} \subset \mathbb{R}^n$, an ellipsoid $\mathcal{E}$ is said to be a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$) if

$$\mathcal{E} \supseteq \mathcal{S}, \quad \text{vol } \mathcal{E} \leq (1+\epsilon) \text{ vol MVCE}(\mathcal{S}), \tag{1}$$

where vol $\mathcal{E}$ denotes the volume of $\mathcal{E}$. Given $\delta > 0$ and a compact convex set $\mathcal{S} \subset \mathbb{R}^n$, an ellipsoid $\tilde{\mathcal{E}}$ is said to be a $(1+\delta)n$-rounding of $\mathcal{S}$ if

$$\frac{1}{(1+\delta)n}\,\tilde{\mathcal{E}} \subseteq \mathcal{S} \subseteq \tilde{\mathcal{E}}, \tag{2}$$

where the ellipsoid on the left-hand side of (2) is obtained by scaling $\tilde{\mathcal{E}}$ around its center by a factor of $1/((1+\delta)n)$. If $\mathcal{S}$ is centrally symmetric (i.e., $\mathcal{S} = -\mathcal{S}$), then we replace the factor on the left-hand side by $1/\sqrt{(1+\delta)n}$. In this paper, we extend the first-order algorithm of [18] to compute a $(1+\epsilon)$-approximation to the MVCE of ellipsoids for $\epsilon > 0$. In particular, we establish that our extension has precisely the same iteration complexity as that of the algorithm of [18] (see Theorem 4.7). Furthermore, the overall complexity result is given by $O(mn^{O(1)}(\log n + [(1+\epsilon)^{2/n} - 1]^{-1}))$, which depends only linearly on the number of ellipsoids m (see Theorem 4.8). In addition, our algorithm can also compute a $(1+\delta)n$-rounding of the convex hull of a finite

number of ellipsoids for $\delta > 0$ in $O(mn^{O(1)}(\log n + \delta^{-1}))$ arithmetic operations (see Corollary 5.1). In both complexity results, $O(1)$ denotes a universal constant greater than four that does not depend on the particular instance. Therefore, our algorithm has polynomial-time complexity for fixed $\epsilon > 0$ and for fixed $\delta > 0$ and is especially well-suited for instances with $m \gg n$ and moderately small values of ϵ or δ.

As a byproduct, our algorithm computes a finite set $\mathcal{X} \subset \cup_{i=1,\ldots,m}\mathcal{E}_i$ with the property that the convex hull of $\mathcal{X}$, denoted by $\mathrm{conv}(\mathcal{X})$, provides a good approximation of $\mathcal{S} = \mathrm{conv}\,(\cup_{i=1,\ldots,m}\mathcal{E}_i)$. Moreover, the size of $\mathcal{X}$ depends only on the dimension n and the parameter ϵ but is independent of the number of ellipsoids m. In particular, $\mathcal{X}$ satisfies

$$\mathrm{vol\ MVCE}(\mathcal{X}) \leq \mathrm{vol\ MVCE}(\mathcal{S}) \leq \mathrm{vol}\ \mathcal{E} \leq (1+\epsilon)\mathrm{vol\ MVCE}(\mathcal{X}) \leq (1+\epsilon)\mathrm{vol\ MVCE}(\mathcal{S}),$$

where $\mathcal{E}$ denotes the $(1+\epsilon)$-approximation to the MVCE of $\mathcal{S}$ computed by our algorithm, which implies that $\mathcal{E}$ is simultaneously a $(1+\epsilon)$-approximation to $\mathrm{MVCE}(\mathcal{X})$ and to $\mathrm{MVCE}(\mathcal{S})$ (see Proposition 4.9).

Following the literature, we refer to $\mathcal{X}$ as an "ϵ-core set" (or a "core set") [8, 7, 17, 18] since $\mathrm{conv}(\mathcal{X})$ provides a compact approximation to the input set $\mathcal{S}$. Recently, core sets have received significant attention, and small core set results have been established for several geometric optimization problems such as the minimum enclosing ball problem and related clustering problems [17, 8, 7, 9, 1, 18]. Small core set results form a basis for developing practical algorithms for large-scale problems since many geometric optimization problems can be solved efficiently for small input sets.

The paper is organized as follows. We define our notation in the remainder of this section. In section 2, we present some preliminary results and discuss the complexity of semidefinite feasibility and optimization. We then establish that the ellipsoid containment problem can be cast as a linear matrix inequality and can therefore be checked in polynomial time. Section 3 is devoted to a deterministic volume approximation algorithm that will serve as an initialization stage for our algorithm. In section 4, we present and analyze a first-order algorithm for the MVCE problem. Section 5 establishes that our algorithm can also be used to compute an approximate n-rounding. We discuss how to extend our algorithm to other input sets in section 6. Section 7 concludes the paper with future research directions.

1.1. Notation. Vectors will be denoted by lowercase roman letters. For a vector u, u_i denotes its ith component. Inequalities on vectors will apply to each component. e will be reserved for the vector of ones in the appropriate dimension, which will be clear from the context. e^j is the jth unit vector. Uppercase roman letters will be reserved for matrices. $\mathcal{S}^n$ denotes the space of $n \times n$ real symmetric matrices. The inner product in $\mathcal{S}^n$ is given by $U \bullet V := \mathrm{trace}(UV) = \sum_{i,j} U_{ij}V_{ij}$ for any $U, V \in \mathcal{S}^n$. Note that $u^T Au = A \bullet uu^T$ for any $A \in \mathcal{S}^n$ and $u \in \mathbb{R}^n$. For $A \in \mathcal{S}^n$, $A \succ 0$ ($A \succeq 0$) indicates that A is positive definite (semidefinite) (i.e., the eigenvalues of A are strictly positive (nonnegative)). $\det(A)$ and $\mathrm{rank}(A)$ denote the determinant and the rank of a square matrix A, respectively. The identity matrix will be denoted by I. For a finite set of vectors $\mathcal{V}$, $\mathrm{span}(\mathcal{V})$ denotes the linear subspace spanned by the vectors in $\mathcal{V}$. The convex hull of a set $\mathcal{T} \in \mathbb{R}^n$ is referred to as $\mathrm{conv}(\mathcal{T})$. For a function $f : \mathbb{R}^n \to \mathbb{R}$, we use $x^* = \arg\max\ f(x)$ and $x_* = \arg\min\ f(x)$ to denote a global maximizer and a global minimizer of f, respectively. Superscripts will be used to refer to members of a sequence of vectors or matrices. Lowercase Greek letters will represent scalars. i, j, and k will be reserved for indexing purposes, and m and n will refer to the problem

data. Uppercase calligraphic letters will be used for all other objects such as sets, operators, and ellipsoids.

2. Preliminaries. A full-dimensional ellipsoid $\mathcal{E}$ in $\mathbb{R}^n$ admits a representation that is specified by an $n \times n$ symmetric positive definite matrix Q and a center $c \in \mathbb{R}^n$ and is defined as

$$\mathcal{E} = \{x \in \mathbb{R}^n : (x-c)^T Q(x-c) \leq 1\}. \tag{3}$$

The matrix Q determines the shape and the orientation of $\mathcal{E}$. In particular, the axes of $\mathcal{E}$ are the eigenvectors $d^1, \ldots, d^n \in \mathbb{R}^n$ of Q, and the length of each axis is given by $1/\sqrt{\lambda_1}, \ldots, 1/\sqrt{\lambda_n}$, where $\lambda_1, \ldots, \lambda_n$ are the corresponding eigenvalues of Q. Therefore, the volume of $\mathcal{E}$, denoted by vol $\mathcal{E}$, is given by

$$\text{vol } \mathcal{E} = \eta \det Q^{-\frac{1}{2}} = \eta \left(1/\sqrt{\Pi_{i=1}^n \lambda_i}\right), \tag{4}$$

where η is the volume of the unit ball in $\mathbb{R}^n$ [12]. Note that an ellipsoid $\mathcal{E}$ induces a norm on $\mathbb{R}^n$ via $\|x\|_{\mathcal{E}} := (x^T Q x)^{1/2}$. Therefore, every ellipsoid can be viewed as a translation of the unit ball in terms of the ellipsoidal norm induced by it.

Throughout this paper, we will assume that each of the input ellipsoids $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$ is full-dimensional. Note that this assumption is without loss of generality since any lower-dimensional ellipsoid can easily be approximated by a "thin" full-dimensional one. We remark that this assumption is merely for technical convenience, which allows us to have a uniform representation of each of the ellipsoids in the form given by (3). In addition, this assumption guarantees that $\text{conv}(\cup_{i=1}^m \mathcal{E}_i)$ is full-dimensional and leads to a simpler characterization of the ellipsoid containment problem (see Proposition 2.7). In particular, the full-dimensionality assumption on each of the ellipsoids can be relaxed by the weaker assumption that $\text{conv}(\cup_{i=1}^m \mathcal{E}_i)$ is full-dimensional and our analysis would still carry over to this slightly more general setting (see the discussion after Proposition 2.6). We refer the reader to [2] for further discussions on extremal ellipsoids.

We start with a classical result on the quality of the approximation of MVCE($\mathcal{S}$) of a convex set $\mathcal{S} \subset \mathbb{R}^n$.

THEOREM 2.1 (Löwner–John [13]). *Let $\mathcal{S} \subset \mathbb{R}^n$ be a compact, convex set with a nonempty interior. Then, MVCE($\mathcal{S}$) exists and is unique and satisfies*

$$\frac{1}{n} MVCE(\mathcal{S}) \subseteq \mathcal{S} \subseteq MVCE(\mathcal{S}), \tag{5}$$

where the ellipsoid on the left-hand side is obtained by scaling MVCE($\mathcal{S}$) around its center by a factor of $1/n$. Furthermore, if $\mathcal{S}$ is symmetric around the origin, then the factor on the left-hand side of (5) can be improved to $1/\sqrt{n}$.

We next state a well-known lemma that will be useful for our analysis.

LEMMA 2.2 (Schur complement). *Let*

$$A = \begin{bmatrix} B & C \\ C^T & D \end{bmatrix}$$

be a symmetric matrix with $B \in \mathcal{S}^\alpha$ and $D \in \mathcal{S}^\beta$. Assume that $D \succ 0$. Then, $A \succeq 0$ if and only if $B - CD^{-1}C^T \succeq 0$.

2.1. Complexity of semidefinite feasibility and optimization. Consider the following feasibility problems:

1. **(PF)** Given $A_1, A_2, \ldots, A_\kappa \in \mathcal{S}^n$ and $\beta_1, \ldots, \beta_\kappa \in \mathbb{R}$, determine whether there exists a matrix $X \in \mathcal{S}^n$ such that
$$A_i \bullet X \leq \beta_i, \quad i = 1, \ldots, \kappa, \quad X \succeq 0.$$
2. **(DF)** Given $B_0, B_1, \ldots, B_\kappa \in \mathcal{S}^n$, determine whether there exist real numbers $y_1, \ldots, y_\kappa$ such that
$$B_0 + y_1 B_1 + y_2 B_2 + \cdots + y_\kappa B_\kappa \succeq 0.$$

The complexity of the problems **(PF)** and **(DF)** is still a fundamental open problem. In the real number model of computation, both problems are in NP since one can check in polynomial time whether a given symmetric matrix is positive semidefinite using Cholesky factorization. Ramana [22] proved that both problems belong to NP $\cap$ co-NP. Porkolab and Khachiyan [21] established the following complexity results, which, in turn, are mainly based on the first-order theory of the reals developed by Renegar [24].

THEOREM 2.3. *Problems* **(PF)** *and* **(DF)** *can be solved in* $\kappa n^{O(\min\{\kappa, n^2\})}$ *and* $O(\kappa n^4) + n^{O(\min\{\kappa, n^2\})}$ *operations over the reals, respectively.*

In addition, let us consider the following optimization versions:

1. **(PO)** Given $D, A_1, A_2, \ldots, A_\kappa \in \mathcal{S}^n$ and $\beta_1, \ldots, \beta_\kappa \in \mathbb{R}$, solve
$$\alpha^* := \inf_{X \in \mathcal{S}^n} \{D \bullet X : A_i \bullet X \leq \beta_i, \quad i = 1, \ldots, \kappa, \quad X \succeq 0\}.$$
2. **(DO)** Given $B_0, B_1, \ldots, B_\kappa \in \mathcal{S}^n$ and $d \in \mathbb{R}^\kappa$, solve
$$\beta^* := \sup_{y_1, \ldots, y_\kappa \in \mathbb{R}} \left\{ \sum_{i=1}^{\kappa} d_i y_i : B_0 + y_1 B_1 + y_2 B_2 + \cdots + y_\kappa B_\kappa \succeq 0 \right\}.$$

The complexity results of Theorem 2.3 also extend to the optimization versions **(PO)** and **(DO)** [21].

THEOREM 2.4. *For problems* **(PO)** *and* **(DO)**, *each of the following can be solved in* $\kappa n^{O(\min\{\kappa, n^2\})}$ *and* $O(\kappa n^4) + n^{O(\min\{\kappa, n^2\})}$ *operations over the reals, respectively:* (i) *feasibility,* (ii) *boundedness,* (iii) *attainment of the optimal value, and* (iv) *computation of a least norm optimal solution.*

One important consequence of Theorems 2.3 and 2.4 is that semidefinite feasibility and semidefinite optimization can be solved in polynomial time if κ is fixed. We state this as a separate corollary.

COROLLARY 2.5. *Each of the four problems* **(PF)**, **(DF)**, **(PO)**, *and* **(DO)** *can be solved in polynomial time for fixed* κ.

This result will play a key role in our algorithm as the semidefinite feasibility and semidefinite optimization problems we will encounter will always satisfy the condition of the corollary.

2.2. Ellipsoid containment. In this section, we study the problem of deciding whether a given full-dimensional ellipsoid $\mathcal{E}$ is contained in another full-dimensional ellipsoid $\mathcal{E}^*$. Furthermore, we establish how to efficiently compute a point in $\mathcal{E}$ that is furthest from the center of $\mathcal{E}^*$ in terms of the ellipsoidal norm induced by $\mathcal{E}^*$.

We start with the following well-known result about polynomiality of quadratic optimization over an ellipsoid (see, e.g., [34]). We remark that this result can be found elsewhere in the literature (see, e.g., [27, 23, 28, 36, 6]). We mainly include it here for the sake of completeness. Our treatment can be considered as a special case of the more general proof of [28] and relies on the fact that the possibly nonconvex optimization problem admits a tight semidefinite programming (SDP) relaxation, whose optimal solution can be used to recover an optimal solution for the original problem.

PROPOSITION 2.6. *Any quadratic function $f : \mathbb{R}^n \to \mathbb{R}$ can be maximized over a full-dimensional ellipsoid in $O(n^{O(1)})$ operations, where $O(1)$ is a universal constant greater than three.*

Proof. Let $f(x) := x^T Ax + 2b^T x + \gamma$, where $A \in \mathcal{S}^n$, $b \in \mathbb{R}^n$, and $\gamma \in \mathbb{R}$, and let $\mathcal{E} \subset \mathbb{R}^n$ denote a full-dimensional ellipsoid, which admits a representation given by $\mathcal{E} := \{x \in \mathbb{R}^n : (x-c)^T Q(x-c) \leq 1\}$, where $Q \in \mathcal{S}^n$ is positive definite and $c \in \mathbb{R}^n$. We wish to solve

$$\text{(P)} \quad \max_{x \in \mathbb{R}^n} \{f(x) : x \in \mathcal{E}\}.$$

We consider the following SDP relaxation:

$$\text{(SP)} \quad \max_{X \in \mathcal{S}^{n+1}} \{F \bullet X : G \bullet X \leq 0,\, E_{n+1} \bullet X = 1,\, X \succeq 0\},$$

where

$$F := \begin{bmatrix} A & b \\ b^T & \gamma \end{bmatrix}, \quad G := \begin{bmatrix} Q & -Qc \\ -c^T Q & c^T Qc - 1 \end{bmatrix}, \quad E_{n+1} = e^{n+1}(e^{n+1})^T.$$

Note that (SP) is a relaxation of (P) since for any feasible solution $x \in \mathbb{R}^n$ of (P),

$$\begin{bmatrix} x \\ 1 \end{bmatrix} [x^T \quad 1] = \begin{bmatrix} xx^T & x \\ x^T & 1 \end{bmatrix} \succeq 0$$

is a feasible solution of (SP) with the same objective function value. We claim that the relaxation is exact in the sense that the optimal values of (P) and (SP) coincide and an optimal solution of (SP) can be converted into an optimal solution of (P).

Consider the following Lagrangian dual of (SP):

$$\text{(SD)} \quad \min_{\lambda, \beta} \{\beta :\ \lambda G + \beta E_{n+1} \succeq F,\, \lambda \geq 0\}.$$

We now make several observations about (SP) and (SD). Note that (SP) satisfies the Slater condition since the solution given by

$$\tilde{X} := \begin{bmatrix} cc^T + \alpha I & c \\ c^T & 1 \end{bmatrix}$$

satisfies $E_{n+1} \bullet \tilde{X} = 1$, $G \bullet \tilde{X} = -1 + \alpha\, Q \bullet I < 0$, for sufficiently small $\alpha > 0$, and $\tilde{X} \succ 0$, which implies that $\tilde{X}$ is a strictly feasible solution of (SP). Therefore, strong duality holds between (SP) and (SD), and the optimal value is attained in (SD). Furthermore, the feasible set of (SP) is bounded because the only solution to the system

$$G \bullet Y \leq 0, \quad E_{n+1} \bullet Y = 0, \quad Y \succeq 0, \quad Y \in \mathcal{S}^{n+1}$$

is $Y = 0$ since $Q \succ 0$. Therefore, the optimal value is also attained in (SP).

By Corollary 2.5, we can solve (SP) in $O(n^{O(1)})$ time (one can replace the equality constraint with two inequality constraints). Let X^* and (λ^*, β^*) denote optimal solutions of (SP) and (SD), respectively. It follows from optimality conditions that

$$X^* \bullet (\lambda^* G + \beta^* E_{n+1} - F) = 0, \quad \lambda^*(G \bullet X^*) = 0. \tag{6}$$

Since $G \bullet X^* \leq 0$, we can compute a rank-one decomposition of $X^* := \sum_{i=1}^{\rho} p^i (p^i)^T$, where $\rho := \text{rank}(X^*) \geq 1$ and $p^i \in \mathbb{R}^{n+1}$, $p^i \neq 0$, $i = 1, \ldots, \rho$, in $O(n^3)$ operations such that $(p^i)^T G p^i \leq 0$, $i = 1, \ldots, \rho$ [28, Proposition 3]. We now construct a rank-one optimal solution of (SP) using this decomposition.

By (6), $\sum_{i=1}^{\rho} (p^i)^T (\lambda^* G + \beta^* E_{n+1} - F) p^i = 0$, which implies that

$$(p^i)^T (\lambda^* G + \beta^* E_{n+1} - F) p^i = 0, \quad i = 1, \ldots, \rho, \tag{7}$$

by dual feasibility. Similarly, $\lambda^*(G \bullet X^*) = \lambda^* \sum_{i=1}^{\rho} (p^i)^T G p^i = 0$, which implies that

$$\lambda^* (p^i)^T G p^i = 0, \quad i = 1, \ldots, \rho, \tag{8}$$

since $(p^i)^T G p^i \leq 0$, $i = 1, \ldots, \rho$, and $\lambda^* \geq 0$.

Let j be any index in $\{1, 2, \ldots, \rho\}$ and let us define

$$p^j = \begin{bmatrix} x^j \\ \alpha^j \end{bmatrix},$$

where $x^j \in \mathbb{R}^n$ and $\alpha^j \in \mathbb{R}$. We claim that $\alpha^j \neq 0$. Otherwise, $0 \geq (p^j)^T G p^j = (x^j)^T Q x^j$, which implies that $x^j = 0$ since $Q \succ 0$, contradicting the fact that $p^j \neq 0$. We now let $x_*^j := (1/\alpha^j) p^j$. Since $G \bullet x_*^j (x_*^j)^T \leq 0$ and $E_{n+1} \bullet x_*^j (x_*^j)^T = 1$, it follows from (7) and (8) that $x_*^j (x_*^j)^T$ is a rank-one optimal solution of (SP), which implies that $(1/\alpha^j) x^j$ is an optimal solution of (P). (We remark that each of the indices in $\{1, 2, \ldots, \rho\}$ can be used to compute a different optimal solution of (P).) ∎

In fact, Proposition 2.6 holds true even if the ellipsoid defining the feasible region of the optimization problem is lower-dimensional. In this case, one can restrict the quadratic function f to the smallest affine subspace containing the ellipsoid and invoke the same analysis in the proof. We now use Proposition 2.6 to give a simple proof of the well-known characterization of the ellipsoid containment problem.

PROPOSITION 2.7. *Let $\mathcal{E} \subset \mathbb{R}^n$ and $\mathcal{E}^* \subset \mathbb{R}^n$ denote two full-dimensional ellipsoids with representations given by $\mathcal{E} := \{x \in \mathbb{R}^n : (x - c)^T Q (x - c) \leq 1\}$ and $\mathcal{E}^* := \{x \in \mathbb{R}^n : (x - c^*)^T Q^* (x - c^*) \leq 1\}$, where $Q \in \mathcal{S}^n$ and $Q^* \in \mathcal{S}^n$ are positive definite and $c \in \mathbb{R}^n$ and $c^* \in \mathbb{R}^n$. Then, $\mathcal{E} \subseteq \mathcal{E}^*$ if and only if there exists $\tau > 0$ such that*

$$\tau \begin{bmatrix} Q & -Qc \\ -c^T Q & c^T Q c - 1 \end{bmatrix} \succeq \begin{bmatrix} Q^* & -Q^* c^* \\ -c^{*T} Q^* & c^{*T} Q^* c^* - 1 \end{bmatrix}. \tag{9}$$

Proof. The statement follows directly from the $\mathcal{S}$-lemma [33] (see also [20] for a comprehensive treatment). However, we give a simple proof using standard duality arguments.

If (9) is satisfied, then we must have $\tau > 0$ since $Q \succ 0$ and $Q^* \succ 0$. Consider

$$\text{(P)} \quad \max_{x \in \mathbb{R}^n} \{(x - c^*)^T Q^* (x - c^*) - 1 : \ (x - c)^T Q (x - c) - 1 \leq 0\}.$$

By an argument similar to that in the proof of Proposition 2.6, it follows that

$$\text{(SP)} \quad \max_{X \in \mathcal{S}^{n+1}} \{F \bullet X : \ G \bullet X \leq 0, \, E_{n+1} \bullet X = 1, \, X \succeq 0\}$$

is a tight SDP relaxation of (P), where $F \in \mathcal{S}^{n+1}$ and $G \in \mathcal{S}^{n+1}$ are respectively given by

$$F = \begin{bmatrix} Q^* & -Q^*c^* \\ -c^{*T}Q^* & c^{*T}Q^*c^* - 1 \end{bmatrix}, \quad G = \begin{bmatrix} Q & -Qc \\ -c^TQ & c^TQc - 1 \end{bmatrix}.$$

The dual of (SP) is

$$\text{(SD)} \quad \min_{\lambda, \beta} \{\beta : \ \lambda G + \beta E_{n+1} \succeq F, \, \lambda \geq 0\}.$$

Let $v(P), v(SP)$, and $v(SD)$ denote the optimal values of (P), (SP), and (SD), respectively. It follows from the proof of Proposition 2.6 that

$$v(P) = v(SP) = v(SD). \tag{10}$$

Obviously, $\mathcal{E} \subseteq \mathcal{E}^*$ if and only if $v(P) \leq 0$. If (9) is feasible, then $(\lambda, \beta) = (\tau, 0)$ is a feasible solution of (SD), which implies that $v(P) = v(SD) \leq 0$. Conversely, if $v(P) \leq 0$, then let (λ^*, β^*) be an optimal solution of (SD) with optimal value $v(SD) = v(P) = \beta^* \leq 0$. Then

$$\lambda^* G \succeq \lambda^* G + \beta^* E_{n+1} \succeq F,$$

since $E_{n+1} \succeq 0$ and $\beta^* \leq 0$, which implies that λ^* is a feasible solution of (9). This completes the proof. □

We close this subsection by giving an equivalent characterization of (9).

LEMMA 2.8. *Condition* (9) *is equivalent to*

$$\tau \begin{bmatrix} Q & -Qc & 0 \\ -c^TQ & c^TQc - 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \succeq \begin{bmatrix} Q^* & -Q^*c^* & 0 \\ -c^{*T}Q^* & -1 & c^{*T}Q^* \\ 0 & Q^*c^* & -Q^* \end{bmatrix}. \tag{11}$$

Proof. We use the notation of Lemma 2.2. After rewriting (11) as a constraint of the form $A \succeq 0$, we let B denote the top left 2×2 block and define C and D accordingly. The equivalence now simply follows from the Schur complement lemma since $D := Q^* \succ 0$. □

We remark that condition (9) (or, equivalently, condition (11)) is a semidefinite constraint in a single variable. Therefore, it follows from Corollary 2.5 that ellipsoid containment can be checked in polynomial time.

It follows from (11) that the problem of computing the MVCE of a set of m full-dimensional ellipsoids can be formulated as a convex determinant maximization problem (see, e.g., [5, 6, 2]) with m linear matrix inequalities of size $(2n+1) \times (2n+1)$, m nonnegative variables $\tau_1, \ldots, \tau_m$, an $n \times n$ positive definite matrix variable Q^* that determines the shape and the orientation of the optimal ellipsoid, and an n-dimensional vector variable $z^* := Q^*c^*$, from which the center of the optimal ellipsoid can be recovered. As the dimension of the problem grows, the computational cost of interior-point algorithms [32, 31] quickly becomes prohibitive. This is one of our motivations to develop a specialized algorithm for the MVCE problem.

3. Initial volume approximation. Let $\mathcal{E}_1, \ldots, \mathcal{E}_m$ denote m full-dimensional ellipsoids, which admit representations given by

$$\mathcal{E}_i := \{x \in \mathbb{R}^n : (x - c^i)^T Q^i (x - c^i) \leq 1\},\ i = 1, \ldots, m, \tag{12}$$

where $Q^i \in \mathcal{S}^n$ is positive definite and $c^i \in \mathbb{R}^n,\ i = 1, \ldots, m$. We define $\mathcal{S} := \operatorname{conv}(\cup_{i=1}^m \mathcal{E}_i)$. In this section, we present a simple deterministic algorithm that identifies a finite subset $\mathcal{X}_0 \subset \cup_{i=1}^m \mathcal{E}_i$ of size $2n$ such that vol MVCE($\mathcal{X}_0$) is a provable approximation to vol MVCE($\mathcal{S}$).

ALGORITHM 3.1 (volume approximation algorithm).

Require: Input set $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$

1: $\Psi \leftarrow \{0\}$, $\mathcal{X}_0 \leftarrow \emptyset$, $k \leftarrow 0$.
2: While $\mathbb{R}^n \setminus \Psi \neq \emptyset$ do
3: **loop**
4: $k \leftarrow k+1$. Pick an arbitrary unit vector $b^k \in \mathbb{R}^n$ in the orthogonal complement of Ψ.
5: $x^{2k-1} \leftarrow \arg\max_{i=1,\ldots,m}\{(b^k)^T x : x \in \mathcal{E}_i\}$, $\mathcal{X}_0 \leftarrow \mathcal{X}_0 \cup \{x^{2k-1}\}$.
6: $x^{2k} \leftarrow \arg\min_{i=1,\ldots,m}\{(b^k)^T x : x \in \mathcal{E}_i\}$, $\mathcal{X}_0 \leftarrow \mathcal{X}_0 \cup \{x^{2k}\}$.
7: $\Psi \leftarrow \operatorname{span}(\Psi, \{x^{2k-1} - x^{2k}\})$.
8: **end loop**
9: **Output:** $\mathcal{X}_0$

LEMMA 3.1. *Algorithm* 3.1 *terminates after* $O(mn^3)$ *arithmetic operations and returns a subset* $\mathcal{X}_0 \subset \cup_{i=1}^m \mathcal{E}_i$ *with* $|\mathcal{X}_0| = 2n$ *such that*

$$\text{vol MVCE}(\mathcal{S}) \leq n^{2n} \text{vol MVCE}(\mathcal{X}_0). \tag{13}$$

Proof. We first establish the running time of Algorithm 3.1. At step k, Ψ is given by the span of k linearly independent vectors since $\mathcal{S}$ is full-dimensional. Hence, upon termination, $\Psi = \mathbb{R}^n$. It follows that $|\mathcal{X}_0| = 2n$. At each step, we optimize a linear function over each of the m ellipsoids $\mathcal{E}_i$. Let $Q^i = (U^i)^T U^i,\ i = 1, \ldots, m$, denote the Cholesky factorization of $Q^i,\ i = 1, \ldots, m$, which can be computed in $O(mn^3)$ operations. Note that $\mathcal{E}_i = \{x \in \mathbb{R}^n : x = (U^i)^{-1}u + c^i,\ \|u\| \leq 1\},\ i = 1, \ldots, m$. Therefore, at step k, each optimization problem has a closed form solution given by $\tilde{x}^{i,k}_{\max,\min} := c^i \pm (1/\|(U^i)^{-T} b^k\|)(U^i)^{-1}(U^i)^{-T} b^k$ with an optimal value of $(b^k)^T c^i \pm (1/\|(U^i)^{-T} b^k\|)(b^k)^T (U^i)^{-1}(U^i)^{-T} b^k$. For each ellipsoid $\mathcal{E}_i$, $\tilde{x}^{i,k}_{\max,\min}$ can be computed in $O(n^2)$ operations since U^i is upper triangular, which yields an overall computational cost of $O(mn^3)$ operations after n steps. Therefore, Algorithm 3.1 terminates after $O(mn^3)$ arithmetic operations.

We now prove (13). It follows from the results of Betke and Henk [3] that vol $\mathcal{S} \leq n!$ vol conv($\mathcal{X}_0$). Combining this inequality with Theorem 2.1, we obtain

$$\frac{1}{n^n} \text{ vol MVCE}(\mathcal{S}) \leq \text{vol } \mathcal{S} \leq n! \text{ vol conv}(\mathcal{X}_0) \leq n! \text{ vol MVCE}(\mathcal{X}_0),$$

which implies that vol MVCE($\mathcal{S}$) $\leq n! n^n$ vol MVCE($\mathcal{X}_0$) $\leq n^{2n}$ vol MVCE($\mathcal{X}_0$). ∎

4. A first-order algorithm. In this section, we present a first-order algorithm to compute a $(1 + \epsilon)$-approximation to the MVCE of the union of a set of full-dimensional ellipsoids $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$ for $\epsilon > 0$. Our algorithm is a generalization of the first-order algorithm presented in [18] to compute the MVCE of a finite set of m points, which, in turn, is obtained from a modification of Khachiyan's algorithm [15].

Our treatment closely follows the interpretation of Khachiyan's algorithm presented in [18].

As a by-product, we establish the existence of a finite core set $\mathcal{X} \subset \cup_{i=1,\ldots,m} \mathcal{E}_i$ whose size depends on only the dimension n and the parameter ϵ, but is independent of the number of ellipsoids m.

ALGORITHM 4.1 (a first-order algorithm that computes a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$)).

Require: Input set of ellipsoids $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$ given by (12) and $\epsilon > 0$.

1: Run Algorithm 3.1 on $\mathcal{E}_1, \ldots, \mathcal{E}_m$ to obtain output $\mathcal{X}_0 := \{x^1, \ldots, x^{2n}\}$.
2: $u^0 \leftarrow (1/2n)e \in \mathbb{R}^{2n}$.
3: $w^0 \leftarrow \sum_{j=1}^{2n} x^j u_j^0$.
4: $(M^0)^{-1} \leftarrow n \sum_{j=1}^{2n} u_j^0 (x^j - w^0)(x^j - w^0)^T$.
5: $\mathcal{F}_0 \leftarrow \{x \in \mathbb{R}^n : (x - w^0)^T M^0 (x - w^0) \leq 1\}$.
6: $x^{2n+1} \leftarrow \arg\max_{i=1,\ldots,m} \{(x - w^0)^T M^0 (x - w^0) : x \in \mathcal{E}_i\}$.
7: $\epsilon_0 \leftarrow (x^{2n+1} - w^0)^T M^0 (x^{2n+1} - w^0) - 1$.
8: $k \leftarrow 0$.
9: While $\epsilon_k > (1+\epsilon)^{2/n} - 1$ do
10: **loop**
11: $\beta_k \leftarrow \frac{\epsilon_k}{(n+1)(1+\epsilon_k)}$.
12: $k \leftarrow k + 1$.
13: $u^k \leftarrow \begin{bmatrix} (1-\beta_{k-1})u^{k-1} \\ \beta_{k-1} \end{bmatrix}$.
14: $w^k \leftarrow \sum_{j=1}^{2n+k} x^j u_j^k$.
15: $(M^k)^{-1} \leftarrow n \sum_{j=1}^{2n+k} u_j^k (x^j - w^k)(x^j - w^k)^T$.
16: $\mathcal{F}_k \leftarrow \{x \in \mathbb{R}^n : (x - w^k)^T M^k (x - w^k) \leq 1\}$.
17: $\mathcal{X}_k \leftarrow \mathcal{X}_{k-1} \cup \{x^{2n+k}\}$.
18: $x^{2n+k+1} \leftarrow \arg\max_{i=1,\ldots,m} \{(x - w^k)^T M^k (x - w^k) : x \in \mathcal{E}_i\}$.
19: $\epsilon_k \leftarrow (x^{2n+k+1} - w^k)^T M^k (x^{2n+k+1} - w^k) - 1$.
20: **end loop**
21: **Output:** $\sqrt{1+\epsilon_k}\,\mathcal{F}_k$, $\mathcal{X}_k$

We now describe Algorithm 4.1. Given m full-dimensional ellipsoids $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$ with representations given by (12), the algorithm calls Algorithm 3.1 and computes a finite set $\mathcal{X}_0 \subset \cup_{i=1}^m \mathcal{E}_i$ with $|\mathcal{X}_0| = 2n$. Next, a "trial ellipsoid" $\mathcal{F}_0$ is defined. Note that the center w^0 of $\mathcal{F}_0$ is simply the sample mean of $\mathcal{X}_0$ and M^0 is the inverse of the (scaled) sample covariance matrix of $\mathcal{X}_0$. ϵ_k measures the extent to which $\mathcal{F}_k$ should be enlarged around its center in order to cover $\mathcal{S} := \text{conv}(\cup_{i=1}^m \mathcal{E}_i)$. u^k can be viewed as a nonnegative weight vector whose components sum up to one. Note that the dimension of u^k increases by one at each iteration and is equal to $|\mathcal{X}_k|$. Unless the termination criterion is satisfied, the algorithm proceeds in an iterative manner as follows: At Step 13, u^k gets updated and is used to define w^k and M^k for the next trial ellipsoid $\mathcal{F}_k$. Observe that x^{2n+k} is precisely the farthest point in $\mathcal{S}$ from the center of the trial ellipsoid $\mathcal{F}_{k-1}$ in terms of its ellipsoidal norm. It is straightforward to verify that

$$w^k = (1-\beta_{k-1})w^{k-1} + \beta_{k-1}x^{2n+k}, \quad k = 1, 2, \ldots, \tag{14}$$

and

$$(M^k)^{-1} = (1-\beta_{k-1})(M^{k-1})^{-1} + n(1-\beta_{k-1})\beta_{k-1} d^k (d^k)^T \tag{15}$$

for $k = 1, 2, \ldots$, where $d^k := x^{2n+k} - w^{k-1}$. It follows that the next trial ellipsoid $\mathcal{F}_k$ is obtained by shifting the center of $\mathcal{F}_{k-1}$ towards x^{2n+k}, and its shape is determined by a nonnegative combination of $(M^{k-1})^{-1}$ and a rank-one update. This update can be viewed as "enriching the eigenspace of $(M^{k-1})^{-1}$ in the direction $d^k := x^{2n+k} - w^{k-1}$." We refer the reader to [18, section 4.3] for a related discussion. The parameter $\beta_{k-1} \in [0, 1)$ solves the following line search problem as observed by Khachiyan [15]:

$$(\mathrm{LS}(k)) \qquad \max_{\beta \in [0,1]} \log\det\left[(1-\beta)(M^{k-1})^{-1} + n(1-\beta)\beta d^k (d^k)^T\right]$$

for $k = 1, 2, \ldots$, where $d^k := x^{2n+k} - w^{k-1}$. Algorithm 4.1 terminates when the desired accuracy is achieved.

Algorithm 4.1 is an extension of the one proposed in [18] that computes a $(1+\epsilon)$-approximation to the MVCE of a finite set of *m points* in $\mathbb{R}^n$, which, in turn, is a modification of Khachiyan's algorithm [15]. The algorithm in [15] can be viewed as a sequential linear programming algorithm (or, equivalently, as a Frank–Wolfe algorithm [29]) for the nonlinear optimization problem arising from the dual formulation of the MVCE problem (cf. $(\mathbf{D}(\mathcal{X}_\mathbf{0}))$ in the proof of Theorem 4.1) for a finite set of points (see, e.g., the discussion in [18, section 4.1]). Algorithm 4.1 is motivated by the simple observation that the union of a set of ellipsoids in $\mathbb{R}^n$ can be viewed as an infinite set of points. Despite the fact that the finite-dimensional optimization formulation on which Khachiyan's algorithm is based no longer carries over to this more general setting, our main goal in this paper is to establish that essentially the same framework can be used with proper modifications to approximate the MVCE of the union of a finite number of ellipsoids. Since the algorithm is driven by linearizing the nonlinear objective function of the dual optimization formulation, we continue to refer to Algorithm 4.1 as a first-order algorithm. We remark that the interior-point algorithms of [32, 31] also rely on the second-order information arising from the Hessian of the objective function.

We next analyze the complexity of Algorithm 4.1. Our analysis resembles those of Khachiyan [15] and Kumar and Yıldırım [18]. The key ingredient in the complexity analysis is to demonstrate that Algorithm 4.1 produces a sequence $\{\mathcal{F}_k\}$ of trial ellipsoids with strictly increasing volumes. We utilize Lemma 3.1 to show that vol $\mathcal{F}_0$ is already a provable approximation to vol MVCE($\mathcal{S}$). The analysis will then be complete by establishing that each step of Algorithm 4.1 can be executed efficiently.

We start by proving that vol $\mathcal{F}_0$ is a provable approximation to vol MVCE($\mathcal{S}$).

THEOREM 4.1. *The ellipsoid $\mathcal{F}_0 \subset \mathbb{R}^n$ defined in Algorithm 4.1 satisfies*

$$\log \mathrm{vol}\ \mathcal{F}_0 \le \log \mathrm{vol}\ \mathrm{MVCE}(\mathcal{S}) \le \log \mathrm{vol}\ \mathcal{F}_0 + 2n \log n + \frac{n}{2} \log 2. \tag{16}$$

Proof. We first establish that

$$\log \mathrm{vol}\ \mathcal{F}_0 \le \log \mathrm{vol}\ \mathrm{MVCE}(\mathcal{X}_0), \tag{17}$$

where $\mathcal{X}_0 = \{x^1, \ldots, x^{2n}\}$ denotes the set of $2n$ points returned by Algorithm 3.1. Consider the following dual formulation to compute MVCE($\mathcal{X}_0$) (see, e.g., [15] or [29]):

$$(\mathbf{D}(\mathcal{X}_\mathbf{0})) \quad \begin{array}{ll} \max_u & \log\det \Pi_0(u) \\ \text{s.t.} & e^T u = 1, \\ & u \ge 0, \end{array}$$

where $u \in \mathbb{R}^{2n}$ is the decision variable and $\Pi_0 : \mathbb{R}^{2n} \to \mathcal{S}^{n+1}$ is a linear operator given by

$$\Pi_0(u) := \sum_{j=1}^{2n} u_j \begin{bmatrix} x^j(x^j)^T & x^j \\ (x^j)^T & 1 \end{bmatrix}.$$

MVCE($\mathcal{X}_0$) can be recovered from an optimal solution u^* of ($\mathbf{D}(\mathcal{X}_\mathbf{0})$) [18, Lemma 2.1]. Furthermore, the optimal value of ($\mathbf{D}(\mathcal{X}_\mathbf{0})$) satisfies

$$\log \text{vol MVCE}(\mathcal{X}_0) = \log \eta + \frac{n}{2} \log n + \frac{1}{2} \log \det \Pi_0(u^*), \tag{19}$$

where η is the volume of the unit ball in $\mathbb{R}^n$.

Let us consider the feasible solution $u^0 := (1/2n)e \in \mathbb{R}^{2n}$ of ($\mathbf{D}(\mathcal{X}_\mathbf{0})$). We have

$$\begin{aligned} \Pi_0(u^0) &= \begin{bmatrix} (1/2n)\sum_{j=1}^{2n} x^j(x^j)^T & w^0 \\ (w^0)^T & 1 \end{bmatrix}, \\ &= \begin{bmatrix} I & w^0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} (1/n)(M^0)^{-1} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} I & 0 \\ (w^0)^T & 1 \end{bmatrix}, \end{aligned} \tag{20}$$

which implies that

$$\log \det \Pi_0(u^0) = -n \log n + \log \det (M^0)^{-1} = -n \log n + 2 \log \det (M^0)^{-1/2}. \tag{21}$$

However, $\log \text{vol } \mathcal{F}_0 = \log \eta + \log \det (M^0)^{-1/2}$. Combining this equality with (21), we obtain

$$\log \text{vol } \mathcal{F}_0 = \log \eta + \frac{n}{2} \log n + \frac{1}{2} \log \det \Pi_0(u^0).$$

Since u^0 is a feasible solution for the maximization problem ($\mathbf{D}(\mathcal{X}_\mathbf{0})$), it follows from (19) that $\log \text{vol } \mathcal{F}_0 \leq \log \text{vol MVCE}(\mathcal{X}_0)$.

Since $\mathcal{X}_0 \subset \mathcal{S}$, we clearly have $\log \text{vol MVCE}(\mathcal{X}_0) \leq \log \text{vol MVCE}(\mathcal{S})$, which proves the first inequality in (16). To prove the second inequality, let

$$B := [x^1, \ldots, x^{2n}] \in \mathbb{R}^{n \times 2n}.$$

Then, $w^0 = (1/2n)Be$ and it is easy to verify that $(M^0)^{-1} = (1/2)BPB^T$, where $P := I - (1/2n)ee^T$ is an orthogonal projection matrix onto the orthogonal complement of the vector e. Note that $Pe^j = e^j - (1/2n)e$, $j = 1, \ldots, 2n$. Therefore, for any $j = 1, \ldots, 2n$, we have

$$\begin{aligned} (x^j - w^0)^T M^0 (x^j - w^0) &= 2(e^j - (1/2n)e)^T B^T (BPB^T)^{-1} B(e^j - (1/2n)e), \\ &= 2(Pe^j)^T PB^T (BP^2B^T)^{-1} BP(Pe^j), \\ &\leq 2\|Pe^j\|^2, \\ &= \frac{2n-1}{n}, \\ &< 2, \end{aligned}$$

where we used $P = P^2$ on the second line and the fact that $PB^T(BP^2B^T)^{-1}BP$ is an orthogonal projection matrix to derive the first inequality. Consequently, the

ellipsoid $\mathcal{G} := \{x \in \mathbb{R}^n : (x - w^0)^T (1/2) M^0 (x - w^0) \le 1\}$ covers $\mathcal{X}_0$. Therefore,

$$\begin{aligned}\log \text{vol MVCE}(\mathcal{X}_0) &\le \log \text{vol } \mathcal{G},\\ &= \log \eta + \frac{n}{2}\log 2 + \log \det (M^0)^{-1/2},\\ &= \frac{n}{2}\log 2 + \log \text{vol } \mathcal{F}_0,\end{aligned}$$

which implies that $\log \text{vol } \mathcal{F}_0 \ge \log \text{vol MVCE}(\mathcal{X}_0) - (n/2)\log 2$. By Lemma 3.1, we have $\log \text{vol MVCE}(\mathcal{X}_0) \ge \log \text{vol MVCE}(\mathcal{S}) - 2n \log n$. Combining these two inequalities, we obtain $\log \text{vol } \mathcal{F}_0 + 2n \log n + (n/2)\log 2 \ge \log \text{vol MVCE}(\mathcal{S})$ as desired. ∎

The next lemma relates $\log \text{vol } \mathcal{F}_k$ to $\log \text{vol MVCE}(\mathcal{S})$.

LEMMA 4.2. *For any $k = 0, 1, 2, \ldots$, we have*

$$\log \text{vol } \mathcal{F}_k \le \log \text{vol MVCE}(\mathcal{S}) \le \log \text{vol } \mathcal{F}_k + \frac{n}{2}\log(1 + \epsilon_k). \tag{22}$$

Proof. By definition of ϵ_k, $\sqrt{1+\epsilon_k}\,\mathcal{F}_k \supseteq \mathcal{S}$, where $\sqrt{1+\epsilon_k}\,\mathcal{F}_k$ is given by expanding $\mathcal{F}_k$ around its center w^k by a factor of $\sqrt{1+\epsilon_k}$. Therefore, $\log \text{vol MVCE}(\mathcal{S}) \le \log \text{vol } \mathcal{F}_k + (n/2)\log(1+\epsilon_k)$, which proves the second inequality in (22).

We follow an argument similar to that in the proof of Theorem 4.1 to establish the first inequality (cf. (20), (21), and (19)). At step k of Algorithm 4.1, $u^k \in \mathbb{R}^{2n+k}$ is a feasible solution of the optimization problem $(\mathbf{D}(\mathcal{X}_\mathbf{k}))$. Therefore,

$$\begin{aligned}\log \text{vol } \mathcal{F}_k &= \log \eta + \frac{n}{2}\log n + \frac{1}{2}\log \det \Pi_k(u^k),\\ &\le \log \eta + \frac{n}{2}\log n + \frac{1}{2}\log \det \Pi_k(u^k_*),\\ &= \log \text{vol MVCE}(\mathcal{X}_k),\end{aligned}$$

where u^k_* denotes the optimal solution of $(\mathbf{D}(\mathcal{X}_\mathbf{k}))$ and $\Pi_k : \mathbb{R}^{2n+k} \to \mathcal{S}^{n+1}$ is a linear operator given by

$$\Pi_k(u) := \sum_{j=1}^{2n+k} u_j \begin{bmatrix} x^j (x^j)^T & x^j \\ (x^j)^T & 1 \end{bmatrix}. \tag{23}$$

Since $\mathcal{X}_k \subset \mathcal{S}$, the first inequality follows. ∎

The following corollary immediately follows from Lemma 4.2.

COROLLARY 4.3. *For any $k = 0, 1, 2, \ldots$, $\epsilon_k \ge 0$. Furthermore, if Algorithm 4.1 does not terminate at step k, then $\epsilon_k > (1+\epsilon)^{2/n} - 1$.*

So far, we have established the following results: (i) vol $\mathcal{F}_0$ is a provable approximation to vol MVCE($\mathcal{S}$) and (ii) the sequence of ellipsoids $\mathcal{F}_k$ generated by Algorithm 4.1 yields a sequence of lower bounds on vol MVCE($\mathcal{S}$). Our next goal is to demonstrate that $\{\text{vol } \mathcal{F}_k\}, k = 0, 1, \ldots$, is a strictly increasing sequence, which implies that Algorithm 4.1 produces increasingly sharper lower bounds to vol MVCE($\mathcal{S}$). At this stage, it is worth noticing that the line search problem LS(k) precisely computes the next trial ellipsoid which yields the largest increase in the volume for the particular updating scheme of Algorithm 4.1.

PROPOSITION 4.4. *For any $k = 0, 1, 2, \ldots$,*

$$\log \text{vol } \mathcal{F}_{k+1} \ge \log \text{vol } \mathcal{F}_k + \begin{cases} \frac{1}{2}\log 2 - \frac{1}{4} > 0 & \text{if } \epsilon_k \ge \frac{n+1}{n}, \\ \frac{1}{16}\epsilon_k^2 & \text{if } \epsilon_k < \frac{n+1}{n}. \end{cases} \tag{24}$$

Proof. Our proof mimics Khachiyan's argument [15]. By the definition of ϵ_k, we have $1+\epsilon_k = (x^{2n+k+1}-w^k)^T M^k (x^{2n+k+1}-w^k)$. Let $z^k := x^{2n+k+1}-w^k$. It follows from (15) that

$$\begin{aligned}
\log\det(M^{k+1})^{-1} &= \log\det\left\{(1-\beta_k)\left[(M^k)^{-1}+n\beta_k z^k(z^k)^T\right]\right\},\\
&= n\log(1-\beta_k)+\log\det\left[(M^k)^{-1}\left(I+n\beta_k M^k z^k(z^k)^T\right)\right],\\
&= \log\det(M^k)^{-1}+n\log(1-\beta_k)+\log\left[1+n\beta_k(1+\epsilon_k)\right],\\
&= \log\det(M^k)^{-1}-n\log\left(1+\frac{\beta_k}{1-\beta_k}\right)+\log\left(1+\left(\frac{n}{n+1}\right)\epsilon_k\right),\\
&= \log\det(M^k)^{-1}-n\log\left(1+\frac{\epsilon_k}{(n+1)(1+\epsilon_k)-\epsilon_k}\right)\\
&\qquad +\log\left(1+\left(\frac{n}{n+1}\right)\epsilon_k\right),\\
&\geq \log\det(M^k)^{-1}-\frac{\left(\frac{n}{n+1}\right)\epsilon_k}{1+\left(\frac{n}{n+1}\right)\epsilon_k}+\log\left(1+\left(\frac{n}{n+1}\right)\epsilon_k\right),
\end{aligned}$$

where we used the definition of β_k in the last two equalities and the inequality $\log(1+\zeta)\leq\zeta$ for $\zeta>-1$. Since $\log\text{vol}\,\mathcal{F}_k = \log\eta+\log\det(M^k)^{-1/2} = \log\eta+(1/2)\log\det(M^k)^{-1}$, it follows that

$$\log\text{vol}\,\mathcal{F}_{k+1}\geq\log\text{vol}\,\mathcal{F}_k+\frac{1}{2}\log\left(1+\left(\frac{n}{n+1}\right)\epsilon_k\right)-\frac{\left(\frac{n}{n+1}\right)\epsilon_k}{2\left(1+\left(\frac{n}{n+1}\right)\epsilon_k\right)}.$$

The assertion follows from the observation that $f(\nu) := (1/2)\log(1+\nu)-\nu/[2(1+\nu)]$ is a strictly increasing function for $\nu\geq 0$ and $f(\nu)\geq\nu^2/16$ for $\nu\in[0,1]$. ∎

We are now ready to analyze the iteration complexity of Algorithm 4.1. To this end, we define the following parameters:

$$\tau_\rho := \min\left\{k:\left(\frac{n}{n+1}\right)\epsilon_k\leq 1/2^\rho\right\},\quad \rho=0,1,2,\ldots. \tag{25}$$

The next lemma establishes certain properties of τ_ρ.

LEMMA 4.5. *τ_ρ satisfies the following relationships:*

$$\tau_0 = O(n\log n), \tag{26}$$

$$\tau_\rho-\tau_{\rho-1}\leq n2^{\rho+5},\quad \rho=1,2,\ldots. \tag{27}$$

Proof. By Theorem 4.1, $\log\text{vol}\,\mathcal{F}_0\leq\log\text{vol MVCE}(\mathcal{S})\leq\log\text{vol}\,\mathcal{F}_0+2n\log n+(n/2)\log 2$. At every iteration k with $\epsilon_k>(n+1)/n$, we have $\log\text{vol}\,\mathcal{F}_{k+1}-\log\text{vol}\,\mathcal{F}_k\geq(1/2)\log 2-1/4>0$ by Proposition 4.4. Therefore, $\tau_0=O(n\log n)$.

Let us now consider $\tau_\rho-\tau_{\rho-1}$, $\rho\geq 1$. For simplicity, let $\gamma := \tau_{\rho-1}$. By definition of $\tau_{\rho-1}$, it follows from Lemma 4.2 that $\log\text{vol}\,\mathcal{F}_\gamma\leq\log\text{vol MVCE}\,(\mathcal{S})\leq\log\text{vol}\,\mathcal{F}_\gamma+(n/2)\log(1+[(n+1)/n]2^{-(\rho-1)})\leq\log\text{vol}\,\mathcal{F}_\gamma+(n+1)2^{-\rho}$. By Proposition 4.4, $\log\text{vol}\,\mathcal{F}_{k+1}-\log\text{vol}\,\mathcal{F}_k\geq[(n+1)/n]^2 2^{-(2\rho+4)}\geq 2^{-(2\rho+4)}$ at every iteration k with $\epsilon_k>[(n+1)/n]2^{-\rho}$. Therefore, $\tau_\rho-\tau_{\rho-1}\leq[(n+1)2^{-\rho}]/2^{-(2\rho+4)}=(n+1)2^{\rho+4}\leq n2^{\rho+5}$, which completes the proof. ∎

Lemma 4.5 enables us to establish the following result.

LEMMA 4.6. *Let $\mu \in (0,1)$. Algorithm* 4.1 *computes an iterate with $\epsilon_k \leq \mu$ in $O(n(\log n + \mu^{-1}))$ iterations.*

Proof. Let σ be a positive integer such that $[(n+1)/n]2^{-\sigma} \leq \mu \leq [(n+1)/n]2^{1-\sigma}$. Therefore, after $k = \tau_\sigma$ iterations, we already have $\epsilon_k \leq [(n+1)/n]2^{-\sigma} \leq \mu$. However,

$$\tau_\sigma = \tau_0 + \sum_{\rho=1}^{\sigma}(\tau_\rho - \tau_{\rho-1}) \leq \tau_0 + 64n\sum_{\rho=1}^{\sigma} 2^{\rho-1} \leq \tau_0 + 64n2^\sigma \leq O\left(n\log n + \frac{n}{\mu}\right),$$

where we used Lemma 4.5 and the inequality $2^\sigma \leq 4/\mu$. ∎

We are now in a position to establish the iteration complexity of Algorithm 4.1.

THEOREM 4.7. *Let $\epsilon > 0$. Algorithm* 4.1 *computes a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$) after at most $O(n(\log n + [(1+\epsilon)^{2/n} - 1]^{-1}))$ iterations.*

Proof. We first establish that Algorithm 4.1 returns a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$) upon termination. Let κ denote the index of the final iterate. We have $\epsilon_\kappa \leq (1+\epsilon)^{2/n} - 1$. The trial ellipsoid $\mathcal{F}_\kappa$ satisfies $\mathcal{S} \subseteq \sqrt{1+\epsilon_\kappa}\,\mathcal{F}_\kappa$, which together with Lemma 4.2 implies that

$$\text{vol } \mathcal{F}_\kappa \leq \text{vol MVCE}(\mathcal{S}) \leq \text{vol}\sqrt{1+\epsilon_\kappa}\mathcal{F}_\kappa = (1+\epsilon_\kappa)^{n/2}\text{vol } \mathcal{F}_\kappa \leq (1+\epsilon)\text{vol } \mathcal{F}_\kappa.$$

Therefore, $\sqrt{1+\epsilon_\kappa}\,\mathcal{F}_\kappa$ is indeed a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$).

We now prove the iteration complexity. If $\epsilon \geq [2+(1/n)]^{n/2} - 1$, then $(1+\epsilon)^{2/n} - 1 \geq (n+1)/n$, which implies that at most $\tau_0 = O(n\log n)$ iterations already suffice. Otherwise, the result follows from Lemma 4.6. ∎

Remark 1. The iteration complexity of Algorithm 4.1 is asymptotically identical to that of the algorithm of Kumar and Yıldırım [18] that computes a $(1+\epsilon)$-approximation to the MVCE of a finite set of m points.

We now establish the overall complexity of Algorithm 4.1.

THEOREM 4.8. *Algorithm* 4.1 *computes a $(1+\epsilon)$-approximation to MVCE($\mathcal{S}$) in*

$$O\left(mn^{O(1)}(\log n + [(1+\epsilon)^{2/n} - 1]^{-1})\right)$$

operations, where $O(1)$ denotes a universal constant greater than four.

Proof. We already have the iteration complexity from Theorem 4.7. We need only analyze the computational cost of each iteration.

Let us start with the initialization stage. By Lemma 3.1, Algorithm 3.1 runs in $O(mn^3)$ operations. w^0 and $(M^0)^{-1}$ can be computed in $O(n^2)$ and $O(n^3)$ operations, respectively. The furthest point x^{2n+1} from the center of $\mathcal{F}_0$ can be determined by solving m separate quadratic optimization problems with a single ellipsoidal constraint. By Proposition 2.6, each optimization problem can be solved in $O(n^{O(1)}+n^3)$ operations. Finally, it takes $O(n^2)$ operations to compute ϵ_0. Therefore, the overall complexity of the initialization step is $O(m(n^{O(1)} + n^3))$ operations. Similarly, at iteration k, the major work is the computation of the furthest point x^{2n+k+1}, which can be performed in $O(m(n^{O(1)}+n^3))$ operations. Therefore, the overall running time of Algorithm 4.1 is given by $O(mn^{O(1)}(\log n + [(1+\epsilon)^{2/n} - 1]^{-1}))$ operations. ∎

Remark 2. The overall complexity of Algorithm 4.1 is linear in m, the number of ellipsoids. This suggests that, in theory, Algorithm 4.1 is especially well-suited for instances of the MVCE problem that satisfy $m \gg n$ and for moderate values of ϵ. In addition, if $\epsilon \in (0,1)$, we have $(1+\epsilon)^{2/n} - 1 = \Theta(\epsilon/n)$, in which case the running time of Algorithm 4.1 can be simplified to $O((1/\epsilon)mn^{O(1)})$ operations, where $O(1)$ is now

a universal constant greater than five. Note that the running time of Algorithm 4.1 is polynomial for fixed ϵ.

We close this section by establishing that the convex hull of the finite set of points collected by Algorithm 4.1 serves as a reasonably good approximation to $\mathcal{S}$ in the sense that their respective MVCEs are closely related.

PROPOSITION 4.9. *Let κ denote the index of the final iterate of Algorithm* 4.1. *Then, $\mathcal{X}_\kappa$ satisfies*

$$\text{vol } MVCE(\mathcal{X}_\kappa) \leq \text{vol } MVCE(\mathcal{S}) \leq (1+\epsilon)\text{vol } MVCE(\mathcal{X}_\kappa). \tag{28}$$

In addition,

$$|\mathcal{X}_\kappa| = O\left(n(\log n + [(1+\epsilon)^{2/n} - 1]^{-1})\right). \tag{29}$$

Proof. We first prove (28). Note that the first inequality is obvious since $\mathcal{X}_\kappa \subset \mathcal{S}$. The second inequality follows from the relationships vol $\mathcal{F}_\kappa \leq$ vol MVCE$(\mathcal{X}_\kappa) \leq$ vol MVCE$(\mathcal{S})$ (see the proof of Lemma 4.2) and vol MVCE$(\mathcal{S}) \leq (1+\epsilon)$vol $\mathcal{F}_\kappa$ (see the proof of Theorem 4.7).

Since $|\mathcal{X}_\kappa| = 2n + \kappa$, (29) simply follows from Theorem 4.7. ∎

Remark 3. Proposition 4.9 establishes that Algorithm 4.1 computes a finite set of points $\mathcal{X}_\kappa \subset \mathcal{S}$ whose MVCE is related to MVCE$(\mathcal{S})$ via (28). In addition, $|\mathcal{X}_\kappa|$ depends only on the dimension n and the approximation factor ϵ but is independent of the number of ellipsoids m. Furthermore, for $\epsilon \in (0,1)$, we have $|\mathcal{X}_\kappa| = O(n^2/\epsilon)$. Therefore, $\mathcal{X}_\kappa$ serves as a finite core set for $\mathcal{S}$. Viewed from this perspective, Proposition 4.9 is an addition to the previous core set results for other geometric optimization problems [17, 8, 7, 9, 1, 18].

Remark 4. In [18], a similar core set result has been established for the MVCE problem for a finite set of m points in $\mathbb{R}^n$. It is remarkable that asymptotically the same result holds regardless of the difference in the underlying geometric structures of the two input sets. In particular, the main ingredient in [18] that leads to the improved complexity result over Khachiyan's algorithm [15] as well as the core set result is the initial volume approximation. In a similar manner, the counterpart of this initialization stage (cf. Algorithm 3.1) enables us to extend the algorithm of Kumar and Yıldırım to a set of ellipsoids. Khachiyan's algorithm cannot be extended to a set of ellipsoids as it relies on the finiteness property of the input set at the initialization stage.

5. Rounding. In this section, we establish that Algorithm 4.1 can also be used to compute a $(1+\delta)n$-rounding of $\mathcal{S} := \text{conv}(\cup_{i=1}^m \mathcal{E}_i)$, where $\mathcal{E}_1, \ldots, \mathcal{E}_m \subset \mathbb{R}^n$ are full-dimensional ellipsoids and $\delta > 0$. We assume that $\mathcal{S}$ is not symmetric around the origin.

Our analysis closely follows Khachiyan's treatment for an input set of a finite number of points in $\mathbb{R}^n$ [15]. At iteration k of Algorithm 4.1, let $q^j := [(x^j)^T, 1]^T \in \mathbb{R}^{n+1}$, $j = 1, \ldots, 2n+k$, and let $\mathcal{Q}_k := \text{conv}(\{\pm q^1, \ldots, \pm q^{2n+k}\})$, which is a centrally symmetric polytope in $\mathbb{R}^{n+1}$ (i.e., $\mathcal{Q}_k = -\mathcal{Q}_k$).

Let $u^k \in \mathbb{R}^{2n+k}$ denote the iterate at iteration k of Algorithm 4.1. Let us define a full-dimensional ellipsoid $\mathcal{G}_k \subset \mathbb{R}^{n+1}$ given by

$$\mathcal{G}_k := \{y \in \mathbb{R}^{n+1} : y^T \Pi_k (u^k)^{-1} y \leq 1\}, \tag{30}$$

where $\Pi_k : \mathbb{R}^{2n+k} \to \mathcal{S}^{n+1}$ is a linear operator defined by (23). Since u^k is a feasible solution of $(\mathbf{D}(\mathcal{X}_\mathbf{k}))$, it follows from [15, Lemma 2] that $\mathcal{G}_k \subseteq \mathcal{Q}_k$. Furthermore, for any $q^j,\ j = 1, \ldots, 2n+k$, we have

$$\begin{aligned}(q^j)^T \Pi_k (u^k)^{-1} q^j &= [(x^j)^T \quad 1] \begin{bmatrix} I & 0 \\ -(w^k)^T & 1 \end{bmatrix} \begin{bmatrix} nM_k & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} I & -w^k \\ 0 & 1 \end{bmatrix} \begin{bmatrix} x^j \\ 1 \end{bmatrix}, \\ &= n(x^j - w^k)^T M_k (x^j - w^k) + 1, \\ &\leq n(1+\epsilon_k) + 1,\end{aligned}$$

which, together with the previous inclusion, implies that

$$\mathcal{G}_k \subseteq \mathcal{Q}_k \subseteq \sqrt{1 + n(1+\epsilon_k)}\, \mathcal{G}_k; \tag{31}$$

i.e., $\sqrt{1+n(1+\epsilon_k)}\,\mathcal{G}_k$ is a $\sqrt{(1+\tilde{\delta})(n+1)}$-rounding of $\mathcal{Q}_k$, where $\tilde{\delta} := (n\epsilon_k)/(n+1)$.

Let $\mathcal{H}_k := \{x \in \mathbb{R}^n : [x^T \quad 1]^T \in \sqrt{1+n(1+\epsilon_k)}\,\mathcal{G}_k \cap \Lambda\}$, where

$$\Lambda := \{y \in \mathbb{R}^{n+1} : y_{n+1} = 1\}. \tag{32}$$

Note that $\mathcal{H}_k \subset \mathbb{R}^n$ is a full-dimensional ellipsoid. By [15, Lemma 5],

$$\frac{1}{(1+\epsilon_k)n}\, \mathcal{H}_k \subseteq \operatorname{conv}(\mathcal{X}_k) \subseteq \mathcal{H}_k; \tag{33}$$

i.e., $\mathcal{H}_k \subset \mathbb{R}^n$ is a $(1+\epsilon_k)n$-rounding of $\operatorname{conv}(\mathcal{X}_k)$. However, it is straightforward to verify that $x \in \mathcal{H}_k$ if and only if $(x - w^k)^T M^k (x - w^k) \leq 1 + \epsilon_k$, which implies that $\mathcal{H}_k = \sqrt{1+\epsilon_k}\,\mathcal{F}_k$. Since $\operatorname{conv}(\mathcal{X}_k) \subseteq \mathcal{S} \subseteq \sqrt{1+\epsilon_k}\,\mathcal{F}_k$, it follows from (33) that

$$\frac{1}{(1+\epsilon_k)n}\, \mathcal{H}_k \subseteq \operatorname{conv}(\mathcal{X}_k) \subseteq \mathcal{S} \subseteq \mathcal{H}_k; \tag{34}$$

i.e., $\mathcal{H}_k$ is simultaneously a $(1+\epsilon_k)n$-rounding of $\operatorname{conv}(\mathcal{X}_k)$ and of $\mathcal{S}$. Therefore, in order to obtain a $(1+\delta)n$-rounding of $\mathcal{S}$, it suffices to run Algorithm 4.1 until $\epsilon_k \leq \delta$. We summarize this result in the following corollary, whose proof follows directly from Lemma 4.6.

COROLLARY 5.1. *Given $\delta > 0$, Algorithm* 4.1 *computes a $(1+\delta)n$-rounding of $\mathcal{S}$ in*

$$O(mn^{O(1)}(\log n + \delta^{-1}))$$

arithmetic operations, where $O(1)$ is a universal constant greater than four. In addition, upon termination of Algorithm 4.1*, the ellipsoid computed by Algorithm* 4.1 *is also a $(1+\delta)n$-rounding of the convex hull of a finite subset $\mathcal{X}_k \subset \mathcal{S}$ with the property that*

$$|\mathcal{X}_k| = O\left(n(\log n + \delta^{-1})\right). \tag{35}$$

Remark 5. Upon termination of Algorithm 4.1 with a $(1+\delta)n$-rounding of $\mathcal{S}$, Corollary 5.1 establishes that $\mathcal{X}_k$ is an $\tilde{\epsilon}$-core set for $\mathcal{S}$, where $\tilde{\epsilon} := (1+\delta)^{n/2} - 1$. In fact, Khachiyan's algorithm [15] is motivated by first computing a $(1+\delta)n$-rounding of $\mathcal{S}$ and then choosing δ in such a way that the ellipsoid computed by the algorithm is a $(1+\epsilon)$-approximation to the MVCE.

We close this section by noting that Corollary 5.1 can be improved if $\mathcal{S}$ is centrally symmetric. In this case, we no longer need to "lift" the vectors in $\mathcal{X}_k$ to $\mathbb{R}^{n+1}$. A similar argument can be invoked to establish that $\mathcal{H}_k := \sqrt{1+\epsilon_k}\,\mathcal{F}_k$ satisfies

$$\frac{1}{\sqrt{(1+\epsilon_k)n}}\, \mathcal{H}_k \subseteq \operatorname{conv}(\{\pm x^1, \ldots, \pm x^{2n+k}\}) \subseteq \mathcal{S} \subseteq \mathcal{H}_k.$$

6. Extensions to other sets. In this section, we discuss the extent to which Algorithm 4.1 can be used to compute an approximate MVCE and an approximate n-rounding of other input sets. Let $\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_m$ denote m objects in $\mathbb{R}^n$ and let $\mathcal{T} := \cup_{i=1}^m \mathcal{T}_i$. In order to extend Algorithm 4.1, we identify the following two subroutines that need to be implemented efficiently:

1. *Subroutine* 1: Optimizing a linear function over $\mathcal{T}$.
2. *Subroutine* 2: Maximizing a quadratic function over $\mathcal{T}$.

Note that Subroutine 1 is required by Algorithm 3.1. Similarly, the computation of the furthest point from the center of a trial ellipsoid (in its ellipsoidal norm) is equivalent to Subroutine 2. All of the other operations of Algorithm 4.1 can be performed efficiently for any input set $\mathcal{T}$.

Let us now consider specific examples of input sets. Clearly, a finite set of points and a finite set of balls would be special cases of a finite set of ellipsoids. Therefore, Algorithm 4.1 would be trivially applicable in these cases. We just remark that certain subroutines can be implemented more efficiently for these input sets. For a finite set of points, Subroutines 1 and 2 can be performed in $O(mn)$ and $O(mn^2)$ operations, respectively. We then recover the algorithm of Kumar and Yıldırım [18]. For a finite set of balls, while Subroutine 1 can still be implemented in $O(mn)$ operations, Subroutine 2 would require the same computational cost as that required by a set of ellipsoids. Therefore, the running time of Algorithm 4.1 would asymptotically remain the same for a finite set of balls. A similar argument also holds for an input set of ellipsoids, each of which is defined by the same matrix $Q = Q^i,\ i = 1, \ldots, m$, since such an input set can be a priori transformed into a set of balls.

6.1. Set of half ellipsoids. Let $\mathcal{T}_i := \{x \in \mathbb{R}^n : (x - c^i)^T Q^i (x - c^i) \leq 1, (f^i)^T x \leq \alpha^i\}$, where $c^i \in \mathbb{R}^n$ and $Q^i \in \mathcal{S}^n$ are positive definite, $f^i \in \mathbb{R}^n$ with $f^i \neq 0$, and $\alpha^i \in \mathbb{R},\ i = 1, \ldots, m$. $\mathcal{T}_i$ is simply given by the intersection of a full-dimensional ellipsoid and a half-space. We will refer to each $\mathcal{T}_i$ as a half-ellipsoid. To avoid trivialities, we assume that each $\mathcal{T}_i$ has a nonempty interior. It follows from the results of Sturm and Zhang [28] that the problem of optimizing any quadratic (hence linear) objective function over $\mathcal{T}_i$ can be cast as an equivalent SDP problem with a fixed number of constraints using a technique similar to that used in the proof of Proposition 2.6. Since both Subroutines 1 and 2 naturally decompose into a linear and quadratic optimization problem over each $\mathcal{T}_i$, respectively, it follows from Corollary 2.5 that both of them can be implemented in polynomial time. Therefore, Algorithm 4.1 can compute an approximate MVCE and an approximate n-rounding of a set of half-ellipsoids in polynomial time.

6.2. Set of intersections of a pair of ellipsoids. Let $\mathcal{T}_i := \{x \in \mathbb{R}^n : (x - c^i)^T Q^i (x - c^i) \leq 1, (x - h^i)^T Q^i (x - h^i) \leq 1\}$, where $c^i \in \mathbb{R}^n$, $h^i \in \mathbb{R}^n$, and $Q^i \in \mathcal{S}^n$ are positive definite, $i = 1, \ldots, m$. Note that each $\mathcal{T}_i$ is given by the intersection of two ellipsoids defined by the same matrix Q^i with different centers. Similarly to the previous case, Sturm and Zhang [28] establish that the problem of optimizing any quadratic (hence linear) objective function over $\mathcal{T}_i$ can be decomposed into two quadratic (linear) optimization problems over a half-ellipsoid, each of which can be solved in polynomial time. Therefore, Algorithm 4.1 can compute an approximate MVCE and an approximate n-rounding of a set of intersections of a pair of ellipsoids in polynomial time. We remark that the complexity of solving a general quadratic optimization problem over the intersection of two arbitrary ellipsoids is still an open problem.

6.3. Other sets and limitations. Based on the previous examples, it is clear that Algorithm 4.1 can be applied to any input set as long as Subroutines 1 and 2 admit efficient implementations. While Subroutine 1 can be performed efficiently for a rather large class of input sets (e.g., classes of convex sets that admit efficiently computable barrier functions [19]), Subroutine 2 can be efficiently implemented only in very special cases, some of which have been outlined in this section.

For instance, if $\mathcal{T}$ is given by the union of polytopes $\mathcal{T}_i := \{x \in \mathbb{R}^n : A^i x \leq b^i\}$, where $A^i \in \mathbb{R}^{m \times n}$ and $b^i \in \mathbb{R}^m$, $i = 1, \ldots, m$, then Subroutine 1 reduces to linear programming, which can be solved efficiently using interior-point methods combined with a finite termination strategy [35]. However, maximizing a convex quadratic function over a polytope is in general an NP-hard problem. Therefore, even in the case of a single polytope defined by linear inequalities, the problem of computing an approximate MVCE is computationally intractable. We remark that the maximum volume inscribed ellipsoid in a polytope defined by linear inequalities can be efficiently approximated (see, e.g., [16]).

In summary, the extent to which Algorithm 4.1 can be applied to other input sets is largely determined by whether Subroutine 2 can be implemented efficiently. Since quadratic optimization over various feasible regions is an active area of research [28, 36], further progress in establishing polynomial complexity may widen the domain of input sets to which Algorithm 4.1 can be applied.

7. Concluding remarks. In this paper, we established that the first-order algorithm of Kumar and Yıldırım [18] that computes an approximate MVCE of a finite set of points can be extended to compute the MVCE of the union of finitely many full-dimensional ellipsoids without compromising the polynomial-time complexity for a fixed approximation parameter $\epsilon > 0$. Moreover, the iteration complexity of our extension and the core set size remain asymptotically identical. In addition, we establish that our algorithm can also compute an appproximate n-rounding of the convex hull of a finite number of ellipsoids. We discuss how the framework of our algorithm can be extended to compute an approximate MVCE and an approximate n-rounding of other input sets in polynomial time and present certain limitations. Our core set result is an addition to the recent sequence of works on core sets for several geometric optimization problems [17, 8, 7, 9, 1, 18].

While our algorithm has a polynomial-time complexity in theory, it would be especially well suited for instances of the MVCE problem with $m \gg n$ and moderately small values of ϵ. In particular, our algorithm would be applicable to the problem of constructing a bounding volume hierarchy as the objects lie in three-dimensional space (i.e., $n = 3$) and a fixed parameter ϵ usually suffices for practical applications. To the best of our knowledge, this is the first result in the literature towards approximating the convex hull of a union of ellipsoids by that of a finite subset whose size depends on only the dimension n and the parameter ϵ.

On the other hand, our algorithm would probably not be practical if a higher accuracy (i.e., a smaller ϵ) were required or if the dimension n were large. In addition, it is well known that first-order algorithms in general suffer from slow convergence in practice, especially for smaller values of ϵ. Our preliminary computational results indicate that both of the first-order algorithms of [15, 18] for an input set of points tend to take an excessive number of iterations as ϵ is decreased, which suggests that the practical performance of these algorithms is indeed closely related to the worst-case theoretical complexity bounds. Motivated by the core set result established in this paper and the encouraging computational results based on a similar core set

result for the minimum enclosing ball problem [17], we intend to work on a column generation algorithm for the MVCE problem with an emphasis on establishing an upper bound on the number of subproblems solved to obtain a desired accuracy.

Very recently, Todd and Yıldırım [30] proposed a modification of the algorithm of Kumar and Yıldırım [18] that computes an approximate MVCE and an approximate n-rounding of a finite set of points. Their modification allows "dropping" points from a working core set throughout the algorithm and maintains the same complexity bound as that of the algorithm of [18]. As such, it has the potential of computing smaller core sets in practice. We remark that the same idea can easily be incorporated into our algorithm for a set of ellipsoids without any increase in the asymptotic complexity bound.

Acknowledgments. I am grateful to Piyush Kumar for several inspiring discussions that led to the fruition of this work and for bringing to my attention the initial volume approximation result, which provides the backbone of our algorithm. I would like to thank Mike Todd and two anonymous referees for their careful, helpful, and perceptive comments and suggestions, which led to a significant improvement in the exposition. In particular, I would like to acknowledge an anonymous referee who pointed out a flaw in an earlier draft, suggested several improvements in section 4, and made comments that prompted the addition of section 5.

FINDING OPTIMAL ALGORITHMIC PARAMETERS USING DERIVATIVE-FREE OPTIMIZATION*

CHARLES AUDET† AND DOMINIQUE ORBAN†

Abstract. The objectives of this paper are twofold. We devise a general framework for identifying locally optimal algorithmic parameters. Algorithmic parameters are treated as decision variables in a problem for which no derivative knowledge or existence is assumed. A derivative-free method for optimization seeks to minimize some measure of performance of the algorithm being fine-tuned. This measure is treated as a black-box and may be chosen by the user. Examples are given in the text. The second objective is to illustrate this framework by specializing it to the identification of locally optimal trust-region parameters in unconstrained optimization. The derivative-free method chosen to guide the process is the mesh adaptive direct search, a generalization of pattern search methods. We illustrate the flexibility of the latter and in particular make provision for surrogate objectives. Locally, optimal parameters with respect to overall computational time on a set of test problems are identified. Each function call may take several hours and may not always return a predictable result. A tailored surrogate function is used to guide the search towards a local solution. The parameters thus identified differ from traditionally used values, and allow one to solve a problem that remained otherwise unsolved in a reasonable time using traditional values.

Key words. derivative-free optimization, black-box optimization, parameter estimation, surrogate functions, mesh adaptive direct search, trust-region methods

1. Introduction.

Most algorithms, be it in optimization or any other field, depend more or less critically on a number of parameters. Some parameters may be real numbers, such as an initial trust-region radius, or a scalar that dictates the precision at which a subproblem needs to be solved. These parameters may be required to remain between two, possibly infinite bounds, or may be constrained in a more complex way. They may also be discrete, such as the maximal number of iterations or the number of banned directions in a taboo search heuristic, or even categorical, such as a Boolean indicating whether exact or inexact Hessian is used, or which preconditioner to use. The overall behavior of the algorithm is influenced by the values of these parameters. Unfortunately, for most practical cases, it remains unclear how a user should proceed to determine *good*, let alone optimal, values for those parameters. We devise a framework for fine-tuning such parameters which is general enough to encompass most numerical algorithms from engineering, numerical analysis and optimization. The design of the framework relies on the observation that measures of *performance* can be derived from the dependency of the algorithm on its parameters. These measures are context- and problem-dependent and for this reason, we wish to

treat them as black-boxes in the remainder of this paper. We shall, however, give examples in the context of a particular application.

An optimization problem is formulated where such a measure of performance is minimized as a function of the parameters, over a domain of acceptable values. We use a class of nonsmooth optimization algorithms to solve this problem which makes provision for an optional *surrogate* function to guide the search strategy. A surrogate function is a simplification of the real objective function that possesses similar behavior, but is believed to be less costly to evaluate, or easier to manipulate, in some sense. Surrogate functions range from simplified physical models to approximation surfaces, such as Kriging models. The reader is invited to consult [6] for a general framework for the use of surrogates in an optimization context.

As an illustration of how to use this framework, we address the study of standard parameters present in trust-region algorithms for unconstrained optimization and try to identify some locally optimal values. The quality of a set of parameters is measured by the overall computational time required by a trust-region algorithm to solve a significant number of test problems to a prescribed precision. Other possibilities of performance measures include the overall number of function calls, the number of failures, the total number of iterations or the agreement of the algorithm with some prescribed behavior. In the numerical tests presented, the test problems originate from the CUTEr [19] collection. We formulate an optimization problem, where each evaluation of the objective function requires solving a collection of test problems. This objective function is time-consuming to evaluate, is highly nonlinear and no derivative is available or even proved to exist. Moreover, evaluating the objective twice with the same arguments may lead to slightly different function values since the computational time is influenced by the current machine load and fluctuates with network activity. We opted for the mesh adaptive direct search (MADS) [4] as derivative-free method for reasons which we explain below. In our context, a surrogate function is obtained by applying the same trust-region algorithm to a set of easier problems. The trust-region parameters obtained by MADS allow the solution of a problem which remained otherwise unsolved in reasonable time by the trust-region method.

Related work on locally optimal parameter identification in a similar trust-region framework is presented in [17], where the parameter space is discretized and a thorough search is carried out. However, even for a modest number of discretized values, devising a mechanism able to compare so many variants of an algorithm becomes an issue. In recent years, performance profiles [13] have been extensively used to compare algorithms, but it remains unclear how to use them to efficiently compare more than five or six. We circumvent this issue in the present paper by delegating the task to another optimization algorithm.

In recent years, pattern-search methods have proved to perform decently on molecular geometry and conformation problems [1, 28]. The paper [23] provides a review of direct search methods.

The paper is structured as follows. In section 2, we describe a derivative-free framework, then outline a specific implementation of the MADS class of algorithms, and highlight the main convergence results. We also describe how a surrogate function can be used within this algorithm. Section 3 describes a standard trust-region algorithm, and discusses the four algorithmic parameters to be fine-tuned. In section 4, we present a methodology specializing our framework to identify locally optimal trust-region parameters using a MADS algorithm. Results are presented in secton 5, and we give concluding remarks in section 7.

2. A framework for nondifferentiable problems. A general optimization problem may be stated as

$$\min_{p\in\Omega} \quad \psi(p), \tag{2.1}$$

with $\psi : \Omega \subseteq \mathbb{R}^\ell \to \mathbb{R} \cup \{+\infty\}$. The nature and structure of the function ψ and the domain Ω limit the type of algorithms that may be used to attempt to solve this problem. Global optimization is often only possible when the problem structure is sufficiently rich and exploitable, and when the problem size is reasonable, but frequently out of reach in acceptable time. Under appropriate smoothness assumptions, we are thus often content with first-order critical solutions. For example, when ψ is continuously differentiable over Ω, an appropriate variant of Newton's method combined with a globalizing scheme yields a critical point under reasonable assumptions. When ψ is nondifferentiable, discontinuous or fails to evaluate for some values of its argument $p \in \Omega$, problem (2.1) cannot be satisfactorily approached by such a method. This is often the case when evaluating the objective entices running a computer code. In order to evaluate, the code may, for instance, have to solve a coupled system of differential equations, and may, for some internal reasons, fail to return a meaningful value. In this case, the function value is simply considered to be infinite. In a helicopter rotor blade design application [5], the objective function failed to return a value two times out of three. Randomness may also be present in the evaluation of a function, as in [29], where two evaluations of ψ at the same point p return slightly different values. In this less optimistic case, the best optimality condition which can be hoped for is to find a *refined point*. We shed light on this concept in section 2.3.

2.1. A general overview of pattern search type methods with surrogate. In the special case where Ω is defined by finitely many linear inequalities, algorithms from the broad class of generalized pattern search (GPS) methods [3] are natural candidates to perform the minimization. They have the advantage of being relatively simple and easy to implement.

Algorithms of the pattern search type attempt to locate a minimizer of the function ψ over Ω by means of the *barrier* function

$$\psi_\Omega(p) = \begin{cases} +\infty & \text{if } p \notin \Omega \\ \psi(p) & \text{otherwise.} \end{cases} \tag{2.2}$$

We will refer to ψ as being the *truth function* or, sometimes, simply the truth.

As is frequent in nonlinear programming, a second function, $\sigma : \Omega \to \mathbb{R} \cup \{+\infty\}$, playing the role of a *model* for ψ, may be used to steer the iterates towards promising regions. In the context of nondifferentiable optimization and pattern search methods, a model is often referred to as a *surrogate*. The surrogate may be an approximation to the truth, or it may be a simplified function whose behavior is similar to that of the truth. An important feature of the surrogate is that it should be *cheaper* than the truth, in some sense—less costly in terms of time or other. The previous sentences are left intentionally vague, since the formal convergence analysis is independent of the quality of the approximation of ψ by σ. However, in practice, appropriate surrogates may improve the convergence speed. A *barrier* surrogate σ_Ω is defined similarly to (2.2).

Pattern search type methods are iterative procedures where each iteration essentially consists of two steps. First, a global exploration of the space of variables

is conducted in hopes of improving the best feasible solution so far, or *incumbent*, $p_k \in \Omega$. This flexible exploration stage, called the SEARCH step, returns a set of candidates, but the truth function need not be evaluated at all of them. To decide at which of these the truth ψ_Ω will be evaluated, they are ordered in increasing surrogate function values. After ordering, the set of candidates $\mathcal{L} = \{q^1, q^2, \ldots, q^m\}$ satisfies $\sigma_\Omega(q^1) \leq \sigma_\Omega(q^2) \leq \cdots \leq \sigma_\Omega(q^m)$. A candidate $q^j \in \mathcal{L}$ will be considered promising if $\sigma_\Omega(q^j) \leq \sigma_\Omega(p_k) + v|\sigma_\Omega(p_k)|$, where $v \in \mathbb{R}_+ \cup \{+\infty\}$ is a threshold supplied by the user. Candidates which are not promising are eliminated from the SEARCH list.

The truth function is then evaluated at the promising candidates in $\mathcal{L}$ with increasing values of i, and terminating the process as soon as $\psi_\Omega(q^i) < \psi_\Omega(p_k)$. In this case, an improved incumbent is found and we set $p_{k+1} = q^i$.

In the event where the SEARCH fails to identify an improved iterate, a local exploration about p_k is performed. This is called the POLL step. Again, the surrogate function is used to order the trial points. The convergence analysis relies only on this step and it must obey stricter rules. In particular, it prohibits the pruning of candidates.

A inconvenience about GPS algorithm is that they require some prior knowledge on the structure of Ω to decide on a set of appropriate search directions. Lack of such knowledge may prevent progress towards a minimizer [26]. So as to make a provision for more general Ω and bypass such a prior knowledge requirement, we opted for an extension of GPS named the mesh adaptive direct search (MADS) [4], which is also based on the above principles. MADS allows a more general exploration of the space of variables ensuring stronger convergence results than GPS. Indeed, GPS confines the POLL at each iteration to a fixed finite set of directions, while the set of directions for the MADS POLL may vary at each iteration, and in the limit the union of these poll directions over all iterations is dense in the whole space.

2.2. An iteration of a MADS algorithm. We now present a lower-level description of MADS. The reader is invited to refer to [4] for a complete algorithmic description, a detailed convergence analysis and numerical comparisons with GPS. The version presented here is specialized to our purposes and some algorithmic choices were made.

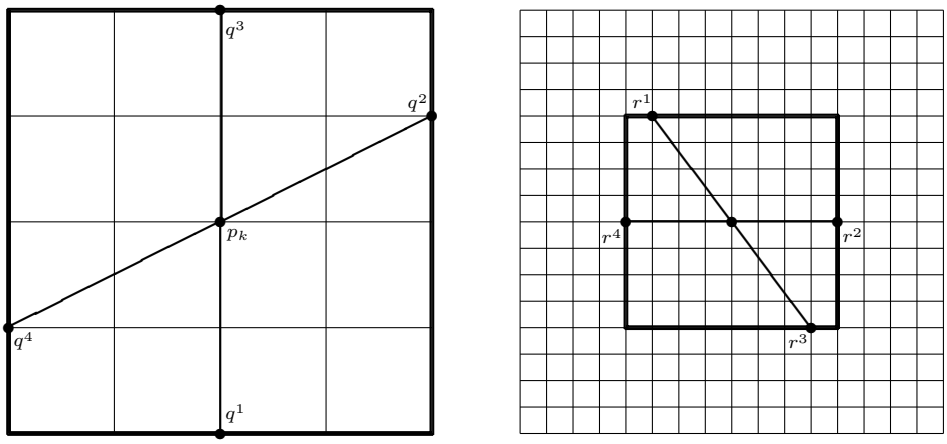
Let $S_0 \subset \Omega$ denote a finite set of initial guesses, provided by the user (a strategy exploiting the surrogate to determine S_0 is presented in section 4.4). Set p_0 to be the best initial guess in S_0. A MADS algorithm is constructed in such a way that any trial point generated by the SEARCH or POLL step is required to lie on the *current mesh*, the coarseness of which is governed by a *mesh size parameter* $\Delta_k \in \mathbb{R}_+$. The mesh is formally defined in Definition 2.1.

DEFINITION 2.1. *At iteration k, the current mesh is defined to be the union*

$$M_k = \bigcup_{p \in S_k} \left\{ p + \Delta_k z : z \in \mathbb{Z}^\ell \right\},$$

where S_k is the set of points where the objective function ψ has been evaluated by the start of iteration k and $\mathbb{Z}$ denotes the set of integers.

The goal of the iteration is to find a trial mesh point with a lower objective function value than the current incumbent value $\psi_\Omega(p_k)$. Such a trial point is called an *improved mesh point*, and the iteration is called a *successful* iteration. There are no sufficient decrease requirements: any improvement in ψ_Ω leads to a successful iteration. The iteration is said to be *unsuccessful* if no improved point is found.



Iteration k (unsuccessful) Iteration $k+1$ with $p_{k+1} = p_k$

FIG. 1. *Two consecutive frames F_k, F_{k+1} in $\mathbb{R}^2$ with $\Delta_k = \frac{1}{2}$, $\Delta_{k+1} = \frac{1}{8}$.*

The POLL step evaluates ψ_Ω at 2ℓ trial points surrounding the current incumbent. These neighboring points are called the *frame*, and are denoted by

$$F_k = \{p_k \pm \Delta_k d : d \in D_k\}, \tag{2.3}$$

where $D_k = \{d^1, d^2, \ldots, d^\ell\}$ is a basis in $\mathbb{Z}^\ell$. To ensure convergence, the radii $(\max\{\|\Delta_k d\|_\infty : d \in D_k\})$ of successive frames must converge to zero at a slower rate than the mesh size parameter. The construction of the basis D_k proposed in [4] ensures that

$$\|\Delta_k d\|_\infty = O(\sqrt{\Delta_k}) \quad \text{for all} \quad d \in D_k. \tag{2.4}$$

Figure 1 shows an example of two consecutive frames in $\mathbb{R}^2$. The figure on the left represents iteration k. The mesh M_k is represented by the intersection of all lines. Suppose that $\Delta_k = \frac{1}{2}$. The thick lines delimit the frame, i.e., the region in which all four POLL points must lie. In this example, the frame points q_1 and q_3 are obtained by the randomly generated direction $d_1 = (0, -2)$, and q_2 and q_4 are obtained by $d_2 = (2, 1)$. The figure on the right displays a possible frame if iteration k is unsuccessful. The mesh is finer at iteration $k+1$ than it was at iteration k, and there are more possibilities in choosing a frame. More precisely, $\Delta_{k+1} = \frac{\Delta_k}{4} = \frac{1}{8}$ and, as in (2.4), the distance from the boundary of the frame to the incumbent is reduced by a factor of 2; $\|r^i - p_{k+1}\|_\infty = \sqrt{\frac{1}{4}}\|q^j - p_k\|_\infty$ for all i, j. The direction used to construct the frame points r_1 and r_3 are $d_1 = (-3, 4)$, and the direction for r_2 and r_4 are $d_2 = (4, 0)$. In the event that iteration $k+1$ is successful at the mesh POLL point r_3, iteration $k+2$ would be initiated at the new incumbent $p_{k+2} = r_3$ with a larger mesh size parameter $\Delta_{k+2} = 4\Delta_{k+1} = \frac{1}{2}$.

When the POLL step fails to generate an improved mesh point then the frame is called a *minimal frame*, and the frame center p_k is said to be a *minimal frame center*. At iteration k, the rule for updating the mesh size parameter is

$$\Delta_{k+1} = \begin{cases} \Delta_k/4 & \text{if } p_k \text{ is a minimal frame center,} \\ 4\Delta_k & \text{if an improved mesh point is found, and } \Delta_k \le \frac{1}{4}, \\ \Delta_k & \text{otherwise.} \end{cases} \tag{2.5}$$

ALGORITHM 2.1. [A MADS ALGORITHM]

Step 0 [Initialization] Let S_0 be given, $p_0 \in \arg\min\{\psi(p) : p \in S_0\}$, $\Delta_0 > 0$, and $v \in \mathbb{R}_+ \cup \{+\infty\}$. Set the iteration counter $k = 0$, and go to Step 1.

Step 1 [SEARCH step] Let $\mathcal{L} = \{q^1, q^2, \ldots, q^m\} \subset M_k$ be a finite (possibly empty) set of mesh points such that $\sigma_\Omega(q^i) \le \sigma_\Omega(q^j) \le \sigma_\Omega(p_k) + v|\sigma_\Omega(p_k)|$ when $1 \le i < j \le m$.
Let i_0 be the smallest $i \in \{1, \ldots, m\}$ such that $\psi_\Omega(q^i) < \psi_\Omega(p_k)$.
If no such index i_0 exists, go to Step 2.
Otherwise, declare k successful, set $p_{k+1} = q^{i_0}$ and go to Step 3.

Step 2 [POLL step] Construct the frame $F_k = \{q^1, q^2, \ldots, q^{2\ell}\}$ as in (2.3) and order the points so that $\sigma_\Omega(q^i) \le \sigma_\Omega(q^j)$ when $1 \le i < j \le 2\ell$.
Let i_0 be the smallest $i \in \{1, \ldots, 2\ell\}$ such that $\psi_\Omega(q^i) < \psi_\Omega(p_k)$.
If no such index i_0 exists, declare k unsuccessful and go to Step 3.
Otherwise, declare k successful, set $p_{k+1} = q^{i_0}$ and go to Step 3.

Step 3 [Parameter update] If iteration k was declared unsuccessful, then p_k is a minimal frame center and p_{k+1} is set to p_k. Otherwise p_{k+1} is an improved mesh point.
Update Δ_{k+1} according to (2.5). Increase $k \leftarrow k + 1$ and go back to Step 1.

The previous description is summarized in Algorithm 2.1.

Given the functions ψ and σ, the only steps that are not completely defined in Algorithm 2.1 are the selection of the set of initial guesses S_0 and the SEARCH strategy. Particular choices in the framework of an application are discussed in section 4.4.

2.3. Convergence properties of MADS. We restrict ourselves to the case where Ω is convex and full dimensional, i.e., with nonempty interior. This encompasses the case where Ω is defined by (possibly strict) linear inequalities. It seems reasonable to assume that in practice, most algorithms depend on parameters satisfying this assumption. Moreover, the MADS convergence analysis greatly simplifies. This section presents the specialized results. The proofs of these results are special cases of the proofs in [4].

Let $\mathrm{cl}(A)$ denote the closure of a set A. Under our conditions, the tangent cone to Ω at some $\hat{p} \in \mathrm{cl}(\Omega)$, denoted by $T_\Omega(\hat{p})$, becomes the closure of the set $\{\mu(v - \hat{p}) : \mu \in \mathbb{R}_+,\ v \in \Omega\}$. The normal cone to Ω at $\hat{p} \in \mathrm{cl}(\Omega)$ is the polar of the tangent cone $N_\Omega(\hat{p}) = T_\Omega(\hat{p})^\circ = \{w \in \mathbb{R}^\ell \mid w^T v \le 0\ \forall v \in T_\Omega(\hat{p})\}$. If the gradient $\nabla\psi(\hat{p})$ exists at $\hat{p} \in \mathrm{cl}(\Omega)$, we say that $\hat{p}$ is *first-order critical* for (2.1) if $-\nabla\psi(\hat{p}) \in N_\Omega(\hat{p})$. For nonconvex domains, more general definitions of tangency from nonsmooth analysis are used in [4].

The analysis relies on Assumption 2.1.

ASSUMPTION 2.1. *At least one initial guess $p_0 \in S_0 \subseteq \Omega$ has finite $\psi(p_0)$ value and all iterates $\{p_k\}$ produced by Algorithm* 2.1 *lie in a compact set.*

The mechanism of Algorithm 2.1 ensures the following property.

LEMMA 2.2. *The sequence of mesh size parameters satisfies* $\liminf_{k\to\infty} \Delta_k = 0$. *Moreover, since Δ_k shrinks only at minimal frames, it follows that there are infinitely many minimal frame centers.*

Definition 2.3 specifies important subsequences of iterates and limiting directions.

DEFINITION 2.3. *A subsequence of the* MADS *iterates consisting of minimal frame centers, $\{p_k\}_{k\in K}$ for some subset of indices K, is said to be a* refining subsequence

if $\{\Delta_k\}_{k\in K}$ *converges to zero. Any accumulation point of* $\{p_k\}_{k\in K}$ *will be called a refined point.*

Let $\{p_k\}_{k\in K}$ *be a convergent refining subsequence, with refined point* $\hat{p}$*, and let* v *be any accumulation point of the set* $\{\frac{d_k}{\|d_k\|} : p_k + \Delta_k d_k \in \Omega,\ k \in K\} \subset \mathbb{R}^\ell$*. Then* v *is said to be a refining direction for* $\hat{p}$*.*

Along a refining subsequence, we thus always have $\psi(p_{k+1}) \leq \psi(p_k)$. Note that under Assumption 2.1, there always exists at least one convergent refining subsequence, one refining point and a positive spanning set of refining directions.

Recall that the Clarke generalized directional derivative [7, 22] of ψ at $\hat{p}$ in the direction $v \neq 0$ is defined as

$$\psi^\circ(\hat{p}; v) \equiv \limsup_{\substack{y \to \hat{p},\ y \in \Omega, \\ t \downarrow 0,\ y + tv \in \Omega}} \frac{\psi(y + tv) - \psi(y)}{t}.$$

The following result presents a hierarchy of optimality conditions satisfied at a refining point. The weakest conclusion is a direct consequence of Definition 2.3. The next conclusions result from increasingly strong assumptions on ψ. The main result is that the Clarke derivatives of ψ at a refined point $\hat{p}$ are nonnegative for all directions in the tangent cone.

THEOREM 2.4. *Let* $\hat{p} \in cl(\Omega)$ *be a refined point of a refining subsequence* $\{p_k\}_{k\in K}$*, and assume that the set of refining directions for* $\hat{p}$ *is dense in* $T_\Omega(\hat{p})$*.*

- $\hat{p}$ *is the limit of minimal frame center on frames that become infinitely fine,*
- *if* ψ *is lower semicontinuous at* $\hat{p}$*, then* $\psi(\hat{p}) \leq \lim_{k\in K} \psi(p_k)$*,*
- *if* ψ *is Lipschitz near* $\hat{p}$*, then* $\psi^\circ(\hat{p}, v) \geq 0$ *for every* $v \in T_\Omega(\hat{p})$*,*
- *if* ψ *is Lipschitz near* $\hat{p} \in int(\Omega)$*, then* $0 \in \partial\psi(\hat{p}) \equiv \{s \in \mathbb{R}^\ell : \psi^\circ(\hat{x}; v) \geq v^T s,\ \forall v \in \mathbb{R}^\ell\}$*,*
- *if* ψ *is strictly differentiable* [24] *at* $\hat{p} \in \Omega$*, then* $\hat{p}$ *is first-order critical for* (2.1) *and is a KKT point of* (2.1)*.*

Note that the above convergence results rely only on the POLL step, and are independent of the surrogate function and of the SEARCH step. Furthermore, even though Algorithm 2.1 is applied to ψ_Ω instead of ψ, the convergence results are linked to the local smoothness of ψ and not ψ_Ω, which is obviously discontinuous on the boundary of Ω.

Practical implementations of MADS ensure that the density assumption of Theorem 2.4 is satisfied [4].

3. Trust-region methods. In this section, we briefly cover a globally convergent framework for unconstrained programming. This framework depends on a number of parameters which influence the impact of the main convergence result.

To successfully tackle a smooth nonlinear nonconvex programming problem from a remote starting guess, the iteration must often be embedded into a *globalization* scheme, the most popular of which are the linesearch, the trust region [10], and the more recent filters [14, 20]. The first two are probably the most well known and their philosophies may be seen as dual; a linesearch strategy computes a step length along a predetermined direction, while a trust-region strategy considers all acceptable directions but limits the maximal step length.

3.1. A basic trust-region algorithm. Trust-region methods appear to date back to a 1944 paper in which they were used to solve nonlinear least-squares problems [25]. After updating rules were introduced in 1966 [15] for the size of the region,

global convergence of a particular algorithm was proved in 1970 [30]. Trust-region methods now form one of the most popular globalization schemes and are often praised for their robustness and flexibility. They are used throughout optimization, from regularization problems to derivative-free and interior-point methods. For lists of references, historical notes, and thorough theoretical developments across the whole optimization spectrum we refer the interested reader to [10].

For simplicity, assume we wish to solve the unconstrained programming problem

$$\min_{x \in \mathbb{R}^n} \quad f(x), \tag{3.1}$$

where $f : \mathbb{R}^n \to \mathbb{R}$ is a twice-continuously differentiable function which might be highly nonlinear and/or costly to evaluate. For problem (3.1) to be well defined, we will assume that f is bounded below. At iteration k, instead of manipulating f directly, f is replaced by a suitable local model m_k which is easier and cheaper to evaluate. A region $\mathcal{B}_k \subset \mathbb{R}^n$, referred to as the *trust region*, is defined around x_k to represent the extent to which m_k is believed to reasonably model f. The trust region is defined as the ball

$$\mathcal{B}_k \equiv \{x_k + s \in \mathbb{R}^n \ : \ \|s\| \leq \delta_k\},$$

where $\delta_k > 0$ is the current trust-region radius and $\|\cdot\|$ represents any norm on $\mathbb{R}^n$. To simplify the exposition, we choose the Euclidean norm but other choices are acceptable [10]. The model m_k is approximately minimized within $\mathcal{B}_k$. If the decrease thus achieved is sufficient, and if the agreement between f and m_k at the trial point is satisfactory, the step is accepted and the radius δ_k is possibly increased. Otherwise, the step is rejected and the radius is decreased. This last option indicates that m_k might have been trusted in too large a neighborhood of x_k.

Global convergence of trust-region schemes is ensured by mild assumptions on m_k and on the decrease that should be achieved at each iteration. In practice, one of the most popular models is the quadratic model

$$m_k(x_k + s) = f(x_k) + \nabla f(x_k)^T s + \frac{1}{2} s^T \nabla^2 f(x_k) s. \tag{3.2}$$

Sufficient decrease in the model at a trial point $x_k + s$ is achieved if the decrease in m_k is at least a fraction of that obtained at the *Cauchy point* x_k^{C}—the minimizer of m_k along the steepest descent direction $d = -\nabla m_k(x_k)$ within $\mathcal{B}_k$—i.e.,

$$m_k(x_k) - m_k(x_k + s) \geq \theta \left[m_k(x_k) - m_k(x_k^{\mathrm{C}}) \right], \tag{3.3}$$

where $0 < \theta < 1$ is independent of k.

A typical trust-region framework for problem (3.1) may be stated as Algorithm 3.1.

The updating rule (3.4) at Step 3 of Algorithm 3.1 is not the only one used in practice, but most likely the most common one. Other rules involve polynomial interpolation of $\rho_k = \rho(s_k)$ as a function of the step s_k [12], while others devise more sophisticated functions to obtain the new radius [21, 38].

The lengthy subject of how to solve the subproblems at Step 1 of Algorithm 3.1 while ensuring (3.3) is out of the scope of this paper. We shall simply argue in section 4 that the method used in our implementation ensures this.

3.2. Convergence properties of the basic algorithm. We recall in this section the important global convergence properties of Algorithm 3.1 without proof. The proofs may be found in [10].

ALGORITHM 3.1. [BASIC TRUST-REGION ALGORITHM]

Step 0 [Initialization] An initial point $x_0 \in \mathbb{R}^n$ and an initial trust-region radius $\delta_0 > 0$ are given, as well as parameters

$$0 \leq \eta_1 < \eta_2 < 1 \quad \text{and} \quad 0 < \alpha_1 < 1 < \alpha_2.$$

Compute $f(x_0)$ and set $k = 0$.

Step 1 [Step calculation] Define the model (3.2) of $f(x_k + s)$ in $\mathcal{B}_k$ and compute a step $s_k \in \mathcal{B}_k$ which satisfies (3.3).

Step 2 [Acceptance of the trial point] Compute $f(x_k + s_k)$ and

$$\rho_k = \frac{f(x_k) - f(x_k + s_k)}{m_k(x_k) - m_k(x_k + s_k)}.$$

If $\eta_1 \leq \rho_k$, then set $x_{k+1} = x_k + s_k$; otherwise, set $x_{k+1} = x_k$.

Step 3 [Trust-region radius update] Set

$$\delta_{k+1} = \begin{cases} \alpha_1 \|s_k\| & \text{if} \quad \rho_k < \eta_1 \\ \delta_k & \text{if} \quad \eta_1 \leq \rho_k < \eta_2 \\ \max[\alpha_2 \|s_k\|, \delta_k] & \text{if} \quad \eta_2 \leq \rho_k. \end{cases} \tag{3.4}$$

Increment k by one, and go to Step 1.

Step 2 of Algorithm 3.1 is often referred to as the computation of achieved versus predicted reduction. Achieved reduction is the actual reduction in the objective f, defined by $\text{ared}_k = f(x_k) - f(x_k + s_k)$. Predicted reduction is the reduction suggested by the model, $\text{pred}_k = m_k(x_k) - m_k(x_k + s_k)$. A step s_k is thus accepted whenever $\text{ared}_k \geq \eta_1 \text{pred}_k$, an iteration we refer to as *successful*.

Requirements on the function f and each model m_k are gathered in Assumption 3.1.

ASSUMPTION 3.1. *The function f is bounded below and its Hessian matrix remains bounded over a set containing all iterates x_k.*

The first stage in the global convergence analysis of Algorithm 3.1 is usually summarized by Theorem 3.1.

THEOREM 3.1. *Suppose that Assumption* 3.1 *is satisfied. Then*

$$\liminf_{k \to \infty} \|\nabla f(x_k)\| = 0.$$

Theorem 3.1 was first proved in [30] in a framework where $\eta_1 = 0$, i.e., where all trial points are accepted as soon as they produce a decrease in the objective. This result proves that if $\{x_k\}$ has limit points, at least one of them is critical. In fact, this is as good a convergence result as we can obtain when $\eta_1 = 0$ [39]. Algorithm 3.1 is more demanding on the trial point—*sufficient* reduction must be achieved. This sheds some light on the importance of the value of η_1 in the framework, for as the next result shows, a much stronger conclusion holds in this case.

THEOREM 3.2. *Suppose Assumption* 3.1 *is satisfied, and that $\eta_1 > 0$. Then*

$$\lim_{k \to \infty} \|\nabla f(x_k)\| = 0.$$

In other words, Theorem 3.2 shows that *all* limit points are first-order critical for (3.1). The distinction between Theorem 3.1 and Theorem 3.2 was reinforced by the

careful example of [39], where it is shown that an algorithm with $\eta_1 = 0$ may very well produce limit points which are not critical.

The importance of the parameters η_1 and η_2, but also α_1 and α_2 of Algorithm 3.1 will be of interest to us in the remainder of this paper. In particular, we shall come back to the issue of reduction versus sufficient reduction.

4. Methodology. An objective of the paper is to address a long-standing question of identifying four optimal parameters found in a trust-region update (3.4), namely η_1, η_2, α_1, and α_2. In this section, we present a general methodology to address this issue.

4.1. A black-box approach to parameter estimation. Suppose that Algorithm $\mathcal{A}$ depends on a set of continuous parameters p restricted to lie in $\Omega \subset \mathbb{R}^\ell$, where ℓ is typically small. Let $\mathcal{P}_\mathcal{O} = \{\mathcal{P}_i \mid i \in \mathcal{O}\}$ be a set of $n_\mathcal{O} \geq 1$ problem instances believed to be representative of the class of problems for which Algorithm $\mathcal{A}$ was designed, or to be of particular interest in the context of Algorithm $\mathcal{A}$. Define a function $\psi : \Omega \to \mathbb{R}$ so that for any $p \in \Omega$, $\psi(p)$ is some measure of the performance of Algorithm $\mathcal{A}$ in solving the set of problems $\mathcal{P}_i \in \mathcal{P}_\mathcal{O}$ and such that, the smaller the value of $\psi(p)$, the better the performance of the algorithm, in a context-dependent sense.

In an optimization context, examples of a function ψ would include the total CPU time required to solve the complete test set, the number of problems unsuccessfully solved or the cumulative number of iterations or of function evaluations. In other contexts, any appropriate measure may be used.

The above description qualifies as a black-box optimization problem in the sense that a computer program must in general be run in order to evaluate $\psi(\cdot)$ at a given parameter value $p \in \Omega$. For all allowed values of the parameters p, we seek to minimize a global measure of the performance of Algorithm $\mathcal{A}$. In other words, we wish to solve problem (2.1).

Problem (2.1) is usually a small-dimensional nondifferentiable optimization problem with expensive black-box function evaluation. As an additional difficulty, evaluating the objective function of (2.1) twice at the same value of p might produce two sligthly different results.[1] It therefore seems natural to use the MADS algorithm to approach it.

In the present context, there is a natural way to define a less expensive surrogate function that would have an overall behavior similar to that of ψ. Let $\mathcal{P}_\mathcal{S} = \{\mathcal{P}_j \mid j \in \mathcal{S}\}$ be a set of $n_\mathcal{S} \geq 1$ *easy* problems and for any $p \in \Omega$, define $\sigma(p)$ to be the same measure (as with ψ) of performance of Algorithm $\mathcal{A}$ in solving the set $\mathcal{P}_\mathcal{S}$ of problems. The quality of an approximation of the behavior of ψ by the surrogate function σ depends on $n_\mathcal{S}$ and on the features of the problems in $\mathcal{P}_\mathcal{S}$. The more problems, the better the approximation, but the cost of surrogate evaluations will increase. There is therefore a trade-off between the quality and the cost of a surrogate function. It would thus make sense to include in $\mathcal{P}_\mathcal{S}$ problems that are less expensive to solve and possibly, but not necessarily, we may choose $\mathcal{S} \subseteq \mathcal{O}$.

Another interesting possibility for a surrogate would be to solve the problems in $\mathcal{P}_\mathcal{S}$ to a looser accuracy.

Note that this framework is sufficiently general to encompass algorithmic parameter estimation in almost any branch of applied mathematics or engineering.

[1] And thus technically, ψ is not a function in the mathematical sense.

4.2. An implementation of the basic trust-region Algorithm 3.1. Our implementation of the trust-region method is relatively conventional and relies on the building blocks of the GALAHAD library for optimization [18]. Trust-region subproblems are solved by means of the Generalized Lanczos method for Trust Regions GLTR [16, 18]. This method is attractive for its ability to naturally handle negative curvature and to stop at the Steihaug–Toint point, i.e., the intersection of the trust-region boundary with a direction of sufficiently negative curvature [35, 37]. It ensures satisfaction of (3.3).

We now discuss the termination criteria of applying the trust-region Algorithm 3.1 to the unconstrained problem

$$(\mathcal{P}_i) \;\equiv\; \min_{x\in\mathbb{R}^{n_i}} \quad f_i(x),$$

where $f_i : \mathbb{R}^{n_i} \to \mathbb{R}$, for $i \in \mathcal{O} \cup \mathcal{S}$. The trust-region algorithm stops as soon as an iterate x_k satisfies

$$\|\nabla f_i(x_k)\|_2 \leq 10^{-5}.$$

The algorithm is also terminated when this criterion was not met in the first 1000 iterations. We elected against scaling the problem or the stopping test, as this introduced a new parameter in the procedure. Following the Steihaug–Toint procedure, the subproblem in $s \in \mathbb{R}^{n_i}$

$$\begin{array}{ll} \min & \nabla f_i(x_k)^T s + \frac{1}{2} s^T \nabla^2 f_i(x_k) s \\ \text{s.t.} & \|s\|_2 \leq \delta_k \end{array}$$

is successfully solved as soon as

$$\|\nabla f_i(x_k + s)\|_2 \;\leq\; \min\left[\frac{1}{10}, \|\nabla f_i(x_k)\|_2^{1/2}\right] \quad \text{or} \quad \|s\|_2 = \delta_k.$$

The initial trust-region radius was chosen according to

$$\delta_0 \;=\; \max\left(\frac{1}{10}\|\nabla f_i(x_0)\|_2,\; 1\right). \tag{4.1}$$

4.3. Measures of performance. In our experiments below, a single function $\psi(\cdot)$ is considered, the evaluation of which involves running a computer program which has a given trust-region algorithm for unconstrained optimization solve a series of problems with given values of the parameters. The parameters are $p = (\eta_1, \eta_2, \alpha_1, \alpha_2)$ from Step 3 of Algorithm 3.1, $\ell = 4$, and

$$\Omega = \left\{p \in \mathbb{R}^4 \mid 0 \leq \eta_1 < \eta_2 < 1 \text{ and } 0 < \alpha_1 < 1 < \alpha_2 \leq 10\right\}. \tag{4.2}$$

A strategy to fine-tune the parameter δ_0 appears in [32]. We have chosen to exclude this parameter from Ω, as the problem-dependent value (4.1) seems more sensible both conceptually and in our tests. This also makes comparisons with the results of [17] more manageable.

Note that Assumption 2.1 is satisfied since the domain Ω is a full-dimensional bounded convex set. The upper bound on α_2 was introduced on the one hand to

satisfy Assumption 2.1, and on the other hand because it does not appear intuitive, or useful, to enlarge the trust-region by an arbitrarily large factor on very successful iterations. The domain Ω is handled by MADS through the barrier approach, i.e., if a parameter value violates any linear constraint, the resulting value of the objective is set to infinity.

To ensure that a change in Δ in Algorithm 2.1 is comparable for all four parameters, the latter are scaled using

$$\begin{bmatrix} \tilde{\eta}_1 \\ \tilde{\eta}_2 \\ \tilde{\alpha}_1 \\ \tilde{\alpha}_2 \end{bmatrix} = \begin{bmatrix} 1000 & & & \\ & 100 & & \\ & & 100 & \\ & & & 10 \end{bmatrix} \begin{bmatrix} \eta_1 \\ \eta_2 \\ \alpha_1 \\ \alpha_2 \end{bmatrix}. \tag{4.3}$$

MADS then works with the variables $(\tilde{\eta}_1, \tilde{\eta}_2, \tilde{\alpha}_1, \tilde{\alpha}_2)$.

Suppose a set of $n_{\mathcal{O}}$ unconstrained problems from the CUTEr [19] collection is chosen. An evaluation of the black-box function $\psi(\cdot)$ is defined by the solution of these problems using Algorithm 3.1 and the current parameter values $p \in \Omega$. The outcome of this evaluation is either a real number—our measure of performance—or an infinite value, resulting from a computer or algorithmic failure in one or more problems. Failures may occur because the maximum number of iterations has been exceeded, because of memory or system-dependent errors or perhaps because of a floating-point exception.

Noticeably, in the context of Algorithm 3.1, the same parameter values

$$p^{\mathrm{C}} = (\eta_1, \eta_2, \alpha_1, \alpha_2) = \left(\frac{1}{4}, \frac{3}{4}, \frac{1}{2}, 2\right) \tag{4.4}$$

are often recommended in the literature [8, 9, 11, 31, 33, 34]. We shall refer to those as the *classical* parameter values. Our contention is to show that the values (4.4) are arbitrary and that much better options are available. We use Algorithm MADS to identify them. In our tests, the initial trial point considered by MADS is p^{C}.

If evaluating the objective function is relatively cheap compared to the algorithm's internal work, which might be the case when the dimension of the problem is large and the linear algebra therefore more expensive, then the overall CPU time is an obvious choice for measuring performance. Since this turned out to be the case for several problems in our objective list, it is the measure of performance which we chose. If we denote by $\tau_i(p)$ the CPU time which was necessary to solve problem $\mathcal{P}_i$ with the parameters p, we may define

$$\psi^{\mathrm{cpu}}(p) = \sum_{i \in \mathcal{O}} \tau_i(p). \tag{4.5}$$

Obviously, similar performance functions may be defined to minimize the overall number of function evaluations—a measure justified in the frequent case where objective function evaluations are computationally costly and dominate the other internal work of the algorithm.

From the MADS point of view, each objective function evaluation requires the computation of $n_{\mathcal{O}}$ values: $\tau_i(\cdot)$ for $i \in \mathcal{O}$.

4.4. The role and choice of surrogate function σ. A surrogate function plays three important roles in the present context. First, it is used as if it were the

real objective function, for the sole purpose of obtaining a better starting point than p^{C} before restarting the procedure with the objective function defined by the objective list. Its purpose is thus to postpone the long computations until a basin containing a local minimizer is reached. No surrogate approximation of the surrogate σ was used. Starting from p^{C} given by (4.4), MADS terminates with some solution p^{S}. After having obtained these parameters, we can now apply MADS on the truth function ψ and use the surrogate function σ to guide the algorithm. The set of initial guesses was chosen as $S_0 = \{p^{\mathrm{C}}, p^{\mathrm{S}}\}$.

Second, the surrogate is used to order trial points generated by the MADS POLL or SEARCH steps, as described in section 2.1. If the surrogate is appropriate, the ordering should produce a successful iterate for the real objective function before all directions have been explored.

Finally, the third role of the surrogate is to eliminate from consideration the trial SEARCH points at which the surrogate function value exceeds the user threshold value v (introduced in section 2.1), which is in our case set to 0.1.

In the present application, the SEARCH strategy differs from one iteration to another, and goes as follows. When $k = 0$, the SEARCH consists of a 64 point Latin hypercube sampling of Ω in hopes of identifying promising basins [27, 36]. At iteration $k \geq 1$, the SEARCH consists of evaluating the surrogate barrier function at 8 randomly generated mesh points and at the point produced by the *dynamic search* described in [4] (when applicable). This dynamic search is only called after a successful iteration, and essentially consists of evaluating ψ at the next mesh point in a previously successful direction.

In the present context, a function evaluation consists in solving a list of problems with the trust-region Algorithm 3.1 and combining the results on each problem into a unique real number. The objective function was defined by a list of relatively hard problems of significant dimension. A surrogate function σ, as described in section 4.1, was defined by a set of smaller problems which could be expected to be solved in overall reasonable time. The surrogate function is simply

$$\sigma^{\mathrm{cpu}}(p) = \sum_{j \in \mathcal{S}} \tau_j(p). \tag{4.6}$$

The problems were chosen as follows.

The trust-region algorithm described in section 4.2 with the classical parameter values p^{C} was run on the 163 unconstrained regular problems from the CUTEr collection, using the default dimensions. From those, some problems failed to be solved for memory reasons and some reached the maximum number of iterations of 1000. Two test lists were extracted from the results. The *surrogate* list $\mathcal{S}$ consists of those problems for which $n_i < 1000$ and $0.01 \leq \tau_i(p^{\mathrm{C}}) \leq 30$ (measured in seconds). The surrogate list contains 54 problems of small to moderate dimension, $2 \leq n_i \leq 500$ and such that $\sum_{i \in \mathcal{S}} \tau_i(p^{\mathrm{C}}) = 68.20$ seconds. We may thus expect that running through the surrogate list, i.e., evaluating the surrogate, should not take much longer than two minutes. Problems in this list and their dimension are summarized in Table 5. The *objective* list $\mathcal{O}$ consists in those problems for which $n_i \geq 1000$ and $\tau_i(p^{\mathrm{C}}) \leq 3600$. This yields a list of 55 problems with $1000 \leq n_i \leq 20000$ and such that $\sum_{i \in \mathcal{O}} \tau_i(p^{\mathrm{C}}) = 13461$ seconds, which amounts to approximately 3 hours and 45 minutes. The latter is the time that *one* objective function evaluation may be expected to take. Problems in this list and their dimension are summarized in Table 4.

5. Numerical results. All tests were run on a 500 MHz Sun Blade 100 running SunOS 5.8. The implementation of MADS is a C++ package called NOMAD.[2]

5.1. Improving the initial solution with a surrogate function. The first run consisted of applying MADS to the surrogate function (4.6) from the classical parameters p^{C}. Results are reported in Table 1. The first column contains the number of MADS function evaluations required to improve the measure to the value in the second column. The other columns contain the corresponding parameter values.

MADS stopped after 310 function evaluations as the mesh size parameter Δ_k dropped below the stopping tolerance of 10^{-6}. The best set of parameters

$$p^{\text{S}} = (0.221625, 0.90207031, 0.38996094, 2.2792969)$$

was identified at the 289th evaluation. This strategy allowed the improvement of the truth initial value from $\psi^{\text{cpu}}(p^{\text{C}}) = 13461$ to $\psi^{\text{cpu}}(p^{\text{S}}) = 11498$ seconds, i.e., an improvement of approximately 33 minutes or 14.58%.

Note that the value of the surrogate at p^{C} had to be evaluated again during the first iteration and that its differred by approximately 1% from the one we had first obtained section 4.4 before building the surrogate. This is an illustration of the nondeterministic aspect of such objective functions.

5.2. Performance profiles. Comparison between the initial and final values of the objective function, i.e., the benchmarking of the trust-region method on a set of nonlinear unconstrained programs for the initial and final values of the parameters, will be presented using performance profiles. Originally introduced in [13], we briefly recall here how to read them.

Suppose that a given algorithm $\mathcal{A}_i$ from a competing set $\mathcal{A}$ reports a statistic $u_{ij} \geq 0$ when run on problem j from a test set $\mathcal{S}$, and that the smaller this statistic the better the algorithm is considered. Let the function

$$\omega(u, u^*, \alpha) = \begin{cases} 1 & \text{if } u \leq \alpha u^* \\ 0 & \text{otherwise} \end{cases}$$

be defined for all u, u^* and all $\alpha \geq 1$. The *performance profile* of algorithm $\mathcal{A}_i$ is the function

$$\pi_i(\alpha) = \frac{\sum_{j \in \mathcal{S}} \omega(u_{ij}, u_j^*, \alpha)}{|\mathcal{S}|} \quad \text{with} \quad \alpha \geq 1,$$

[2]May be downloaded from www.gerad.ca/NOMAD.

TABLE 2

Minimization of the objective function from improved starting point. The measure $\psi^{cpu}(p)$ is in seconds.

98	10195.39	221.25	94.457031	37.933594	23.042969
115	10195.39	221.25	94.457031	37.933594	23.042969
116	10193.14	221.25	94.457031	37.933594	23.042969
142	10193.14	221.25	94.457031	37.933594	23.042969

where $u_j^* = \min_{i \in \mathcal{A}} u_{ij}$. Thus, $\pi_i(1)$ gives the fraction of the number of problems for which algorithm $\mathcal{A}_i$ was the most effective, according to the statistics u_{ij}, $\pi_i(2)$ gives the fraction for which algorithm $\mathcal{A}_i$ is within a factor of 2 of the best, and $\lim_{\alpha \to \infty} \pi_i(\alpha)$ gives the fraction of examples for which the algorithm succeeded.

5.3. Minimizing the total computing time. Algorithm 2.1 was restarted using the objective function $\psi^{\text{cpu}}(\cdot)$. The starting point was the parameter values suggested by the surrogate function in Table 1. The stopping condition this time was to perform a maximum of 150 truth evaluations. Based on the estimate of roughly 3 hours and 45 minutes per function evaluation, this amounts to an expected total running time of just about three weeks. Fragments of the evolution of $\psi^{\text{cpu}}(\cdot)$ are given in Table 2.

The final iterate

$$p^* = (0.22125, 0.94457031, 0.37933594, 2.3042969) \tag{5.1}$$

produced by MADS gives a value $\psi^{\text{cpu}}(p^*) = 10193.14$, and reduces the total computing time to just under 2 hours and 50 minutes; a reduction of more than 11% of the computing time when compared to p^{S} and of almost 25% when compared to p^{C}. This p^* is clearly in favor of a sufficient decrease condition rather than of $\eta_1 \approx 0$.

The values $\psi^{\text{cpu}}(p^{\text{C}})$ and $\psi^{\text{cpu}}(p^*)$ can be visualized in the profile of Figure 2 which compares the cpu-time profiles of Algorithm 3.1 applied to the objective list for the initial and final parameter values. The profile of Figure 3 presents a similar comparison, using the number of function evaluations.

5.4. Interpretation of the results. The above results must be interpreted in light of the objective function used in the minimization procedure. Figures 2 and 3 result from a minimization of $\psi^{\text{cpu}}(\cdot)$. A minimization of the total number of trust-region function evaluations $\psi^{\text{fval}}(\cdot)$ would likely have produced a different set of parameters. Moreover, the simplicity of $\psi^{\text{fval}}(\cdot)$ and $\psi^{\text{cpu}}(\cdot)$ is counterbalanced by their disadvantage of computing *global* measures. More sophisticated objectives in the present application could penalize the fact that a particular problem took a long time to fail for some parameter values while for others, failure was quickly detected.

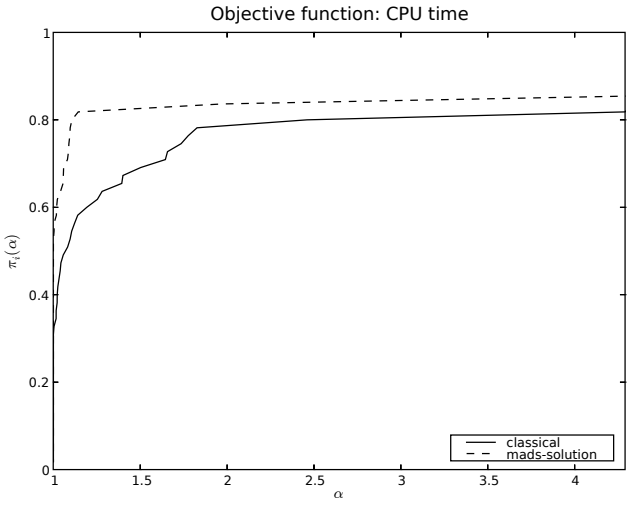

FIG. 2. *Profile comparing the CPU time required for one evaluation of the* MADS *objective for the initial and final parameter values.*

Similarly, they do not treat differently problems which are uniformly solved in a fraction of a second for nearly all parameter values and problems whose running time varies with great amplitude. Such effects might, and do, cause MADS to elect against exploring certain regions.

To illustrate this point, we note that the parameter values recommended by MADS differ significantly from those recommended in [17]. In a separate preliminary series

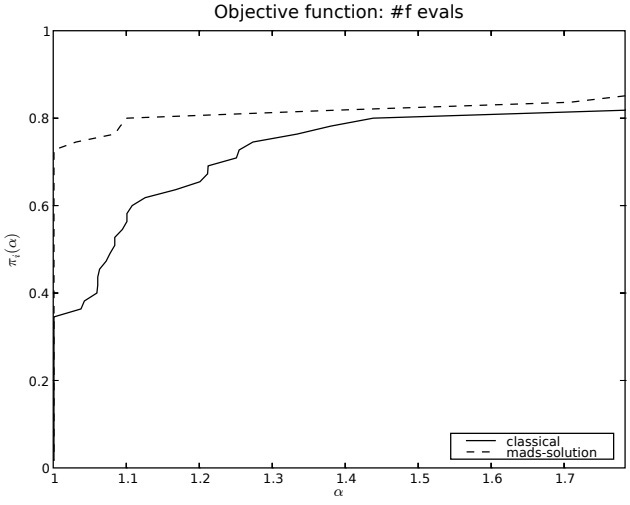

FIG. 3. *Profile comparing the number of function evaluations required for one evaluation of the* MADS *objective for the initial and final parameter values. The scale of the* α *axis has been extended.*

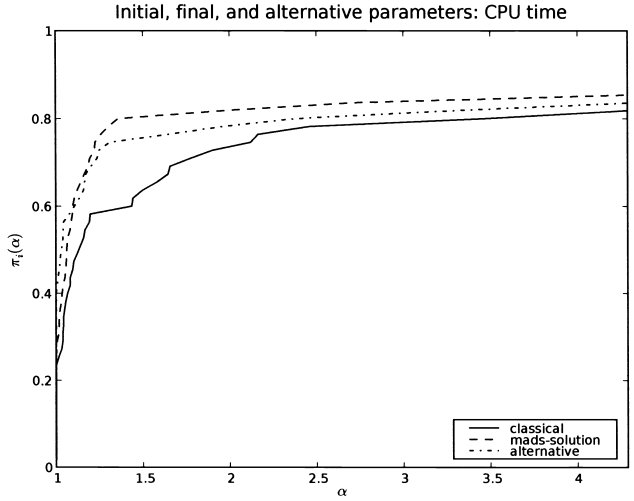

FIG. 4. *Profile comparing the CPU time required for one evaluation of the* MADS *objective for the initial, final, and alternative parameter values.*

of tests, the surrogate function $\sigma^{\text{cpu}}(\cdot)$ was minimized over Ω (4.2) without using the scaling (4.3). The final, *alternative*, set of parameters thus produced

$$p^{\text{A}} = (0.000008, 0.9906, 0.3032, 3.4021), \tag{5.2}$$

is rather close to the recommendations of [17] and seems to indicate that enforcing sufficient descent is not particularly beneficial in practice. The value $\psi^{\text{cpu}}(p^{\text{A}}) = 13707$ is surprisingly higher than $\psi^{\text{cpu}}(p^{\text{C}}) = 13461$. However, the corresponding profile appears significantly better than the reference algorithm using p^{C} as illustrated by Figures 4 and 5. Problems with long solution times are gathered in Table 3. The first three of those do not appear to influence the behavior of MADS by much, as their solution time varies little. Some problems failed to be solved for any values of the parameter. Among those, `GENHUMPS` is particularly detrimental to the value $\psi^{\text{cpu}}(p^{\text{A}})$ as the failure takes 10 times longer to be detected than at p^*. Likely, the value p^{A} would produce much better results if `GENHUMPS` were not present. We see nonetheless in the present case that MADS performed its task as it should have and that, perhaps, it is the objective function $\psi^{\text{cpu}}(\cdot)$ which should take such outliers into account, since the presence of problems like `GENHUMPS` cannot be anticipated.

TABLE 3

Problems with relatively high and varying solution times. A "F" indicates a failure. CPU times are in seconds.

Problem $\mathcal{P}_i$	$\tau_i(p^{\text{C}})$	$\tau_i(p^*)$	$\tau_i(p^{\text{A}})$
`DIXON3DQ`	2728.24	1572.75	1286.14
`EIGENALS`	1768.25	1177.19	1119.76
`NCB20B`	1444.47	1152.80	964.25
`CHAINWOO`	1224.25 F	1224.10 F	1392.78 F
`GENHUMPS`	615.29 F	444.96 F	4028.99 F

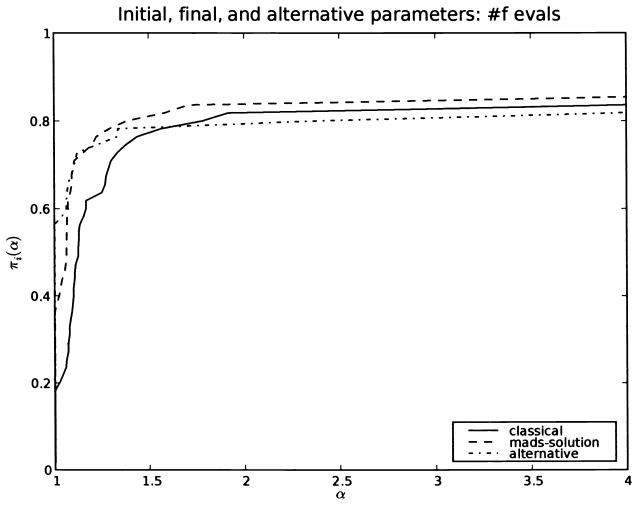

FIG. 5. *Profile comparing the number of function evaluations required for one evaluation of the* MADS *objective for the initial, final, and alternative parameter values.*

A phenomenon of a much more optimistic kind is revealed by problem `CRAGGLVY` which could not be solved in less than 1000 iterations using p^{C}, which took 83.3 seconds, but was solved in 20 iterations and 6.59 seconds using p^*.

6. Discussion. As mentioned earlier, the determination of useful parameter values for the management of the trust region was examined in the past in [17], where, on a much smaller list of 24 problems and after discretizing Ω into 3960 values for the parameters, the final value p^{A} (5.2) was identified. In order to supplement Figures 4 and 5 and to validate the final parameter value p^* (5.1) produced by MADS, we performed an additional series of tests.

We restarted MADS with the initial value p^{A} to determine whether or not it would identify p^{A} as a local minimum, or escape and move to a different region. To make the task more difficult for MADS, it was initialized with a small initial mesh size $\Delta_0 = 4^{-4} = 0.00390625$. The initial search was disabled to force the algorithm to explore only nearby regions. As before, the surrogate was used and all other algorithmic parameters were left unaltered. To limit the effort, we imposed a maximum of 100 truth function evaluations.

After almost 16 days of computation and 100 evaluations of the truth function, MADS moved away from p^* and exited with final parameter values

$$\overline{p} = (0.0023205, 0.999233, 0.356989, 3.39077)$$

and objective value $\psi^{\mathrm{cpu}}(\overline{p}) = 11144$. Most noticeably, the values of the first and third parameters changed the most, causing an improvement of 42 minutes. From the output of the algorithm, it is likely that it would have kept moving away towards larger values of η_1. We believe this is due to the diverse nature of the problems in $\mathcal{O}$ and in particular, `GENHUMPS`, cf. Table 3. This indicates that, in the present case, p^{A} is not a local minimizer.

To simply compare the computational burden involved in the tests with MADS and those of [17], notice that one function evaluation in [17] takes between 8.76 and 63.9 seconds, which is comparable to the cost of our surrogate. According to Table 1, it only took 289 evaluations of the surrogate to identify p^{S} which is already rather close to p^*. Even if $\psi^{\mathrm{cpu}}(p^{\mathrm{S}})$ is not as good as $\psi^{\mathrm{cpu}}(p^*)$, it is much lower than $\psi^{\mathrm{cpu}}(p^{\mathrm{A}})$. The overall cost of the tests of section 5.1 on the surrogate function is about 4 hours—only marginally more than an expected evaluation of ψ^{cpu}. We could therefore estimate that the total cost of identifying p^* is the 142 evaluations reported in Table 2 plus the evaluation of section 5.1, or 143 evaluations. This is 27.7 times less than the 3960 evaluations required by the exhaustive exploration.

With an expected 3 hours and 45 minutes per function evluation, discretizing as in [17] and evaluating ψ^{cpu} at the 3960 different parameter values might have taken us as much as 3960×3.75 hours ≈ 619 days. Pessimistically speaking, this almost represents 2 years of computation. While this might be perceived as the price to pay for global information, there still is no guarantee that a global minimizer has been found. We prefer to think in terms of regions instead of precise parameter values.

7. Conclusion. We presented a framework for the optimization of algorithmic parameters, which is general enough to be applied to many branches of engineering and computational science. Using the algorithm presented in [2], this framework may also be extended to the case where some parameters are categorical. The framework is illustrated on an example which at the same time addresses the long-standing question of determining locally optimal trust-region parameters in unconstrained minimization. The MADS algorithm for nonsmooth optimization of expensive functions [4] is at the core of the framework.

The very notion of optimality for such problems is not well defined. Hence, our aim in designing this framework was to suggest values for the parameters which seem to perform *better*, in a sense specified by the user, on a set of problems which are context-dependent and can also be specified by the user. In real applications, we believe this black-box approach is beneficial since it allows users to take full advantage of their knowledge of the context to design appropriate test sets and performance measures. As our numerical experience indicates, the choice of objective to be optimized will likely influence the results.

We reserve the exploration of more elaborate objective functions, making provision for outliers, and the study of scaling strategies for MADS for future work. We also wish to explore modifications of the algorithm to accept more general constraints.

Appendix. Tables. Tables 4 and 5 report numerical results on the objective and surrogate lists. In these tables, n is the number of variables, $\#f$ eval is the number of function evaluations, $\tau_i(\cdot)$ is the CPU time in seconds, and $\varphi_i(\cdot)$ is the number of trust-region function evaluations. These statistics are reported at the three sets of parameters p^{C}, p^*, and p^{A}.

Acknowledgments. We wish to thank Gilles Couture for developing NOMAD, the C++ implementation of MADS. We also wish to acknowledge the constructive comments of two anonymous referees which helped improve an earlier version of this paper.

BEND MINIMIZATION IN PLANAR ORTHOGONAL DRAWINGS USING INTEGER PROGRAMMING*

PETRA MUTZEL† AND RENÉ WEISKIRCHER‡

Abstract. We consider the problem of minimizing the number of bends in a planar orthogonal graph drawing. While the problem can be solved via network flow for a given planar embedding of a graph, it is NP-hard if we consider all planar embeddings. Our approach for biconnected graphs combines a new integer linear programming (ILP) formulation for the set of all embeddings of a planar graph with the network flow formulation of the bend minimization problem for fixed embeddings. We report on extensive computational experiments with two benchmark sets containing a total of more than 12,000 graphs where we compared the performance of our ILP-based algorithm with a heuristic and a previously published branch & bound algorithm for solving the same problem. Our new algorithm is significantly faster than the previously published approach for the larger graphs of the benchmark graphs derived from industrial applications and almost twice as fast for the benchmark graphs from the artificially generated set of hard instances.

1. Introduction.

Drawing graphs is important in many scientific and economic areas. Applications include the drawing of UML diagrams in software engineering, business process modeling as well as the design and visualization of databases. A popular way of drawing graphs is representing the vertices as boxes and the edges as sequences of horizontal and vertical line segments connecting the boxes. This drawing style is called *orthogonal* drawing. A point where two segments of an edge meet is called a *bend*. Figure 1 shows an orthogonal drawing of a graph.

A well-known approach for computing orthogonal drawings of general graphs is the topology-shape-metrics method (see, for example, [7]). In the first step, the topology of the drawing is computed. The objective in this phase is to minimize the number of edge crossings. In the second step, the shape of the drawing is defined in terms of bends along the edges and angles around the vertices. The objective is to minimize the number of bends for the given topology. Finally, the metrics of the drawing is computed. Commonly adopted optimization requirements in this step are short edge lengths and small area for the given shape. In this paper, we focus on the bend minimization step (the second step). Given a planar graph, the task is to compute an orthogonal representation with the minimum number of bends.

The infinite set of different planar drawings of a graph can be partitioned into a finite set of equivalence classes called *embeddings* of a graph. An embedding defines

the topology of a planar drawing without assigning lengths or shapes to the edges or fixing the shapes and positions of vertices.

A *combinatorial embedding* fixes the sequence of incident edges around each vertex in clockwise order. This also fixes the list of *faces* of a drawing. The faces are the connected regions of the plane defined by a planar drawing. A *planar embedding* additionally defines the outer (unbounded) face of a planar drawing. *Orthogonal representations* are equivalence classes of orthogonal drawings that fix the planar embedding and the bends and angles in an orthogonal drawing.

There are some results in the literature on the topic of optimizing certain functions over the set of all embeddings of a graph. Bienstock and Monma studied the complexity of covering vertices by faces [3] and minimizing certain distance measures on the faces of a graph with respect to the outer face [4, 5]. Tamassia presented the first algorithm for minimizing the number of bends in a planar orthogonal drawing for the case where the embedding is fixed [21]. Garg and Tamassia showed that optimizing the number of bends in an orthogonal drawing over the set of all embeddings of a planar graph is NP-hard [14]. In [9], Di Battista, Liotta, and Vargiu show that the problem is polynomially solvable for series-parallel graphs and 3-planar graphs.

If we consider only orthogonal drawings where the bends of the edges are placed on the same grid as the vertices and all vertices occupy only one grid point, we can only represent graphs with a maximum degree of four (so called *four-graphs*). In [11], Didimo and Liotta present an algorithm that produces planar orthogonal drawings of four-graphs with the minimum number of bends. The running time is exponential only in the number of vertices with degree four.

Bertolazzi, Di Battista, and Didimo [2] used the SPQR-tree data structure to devise a branch & bound algorithm for solving the bend minimization problem over

the set of all embeddings of a planar graph in a more general orthogonal model where a vertex can have degree greater than four. In this paper, we attack the same problem using integer linear programming. To do this, we have developed a new integer linear program describing the set of all combinatorial embeddings of a planar biconnected graph. To our knowledge, this is the first practicable description of the set of all combinatorial embeddings of a planar graph as an integer linear program. We achieve a manageable size of the program by computing the set of variables and constraints recursively using the SPQR-tree data structure. By combining our new integer linear program with a linear program that describes the set of all orthogonal representations of a planar graph with a fixed embedding, we obtain a mixed integer linear program that represents the set of all orthogonal representations for a planar biconnected graph over the set of all embeddings.

We use this new mixed integer linear program to minimize the number of bends in an orthogonal drawing over the set of all embeddings of a planar graph. Like the approach in [2], our new method can only guarantee optimality for biconnected graphs because we also use the SPQR-tree data structure, which is only defined for graphs that have this property. Our algorithm first computes the mixed integer linear program and then uses a commercial solver (CPLEX) to find an optimal solution. This solution is then transformed into an orthogonal representation of the graph.

We tested our approach on two different benchmark sets of graphs. The first consists of graphs derived from industrial applications and the second of graphs computed by a graph generator. The latter set was also used in [2] to measure the performance of the branch & bound algorithm. Our new approach is faster for the larger graphs in the first benchmark set than the branch & bound approach of Bertolazzi, Di Battista, and Didimo [2] and about twice as fast on the graphs in the seconds benchmark set, as our computational results show.

Preliminary descriptions of the computation of the integer linear program that describes all embeddings of a planar biconnected graph can be found in [18] and [19]. A preliminary description of the combination with the integer linear program that describes all orthogonal representations for a fixed embedding and first computational results can be found in [20].

In section 2, we give a short overview of SPQR-trees. We present the four different types of nodes in the tree and the properties of the tree that are important for our approach. Section 3 summarizes the recursive construction of the new integer linear program that describes the combinatorial embeddings of a graph and contains the proof of correctness.

The linear program describing the orthogonal representations of a graph for a fixed embedding is the topic of section 4. This is basically the formulation of a minimum cost flow problem in a special network constructed from the graph and the embedding as a linear program. In section 5, we present the mixed integer linear program that is the result of merging the new integer linear program describing the embeddings of a graph with the linear program that describes the orthogonal representations for a graph where the embedding is fixed.

The topic of section 6 is the algorithm that we use to compute an orthogonal representation of a graph with the minimum number of bends over the set of all embeddings. The computational results we obtained by applying the algorithm to two sets containing a total of more than 12,000 benchmark graphs are given in section 7. We compare the algorithm with a heuristic and with the branch & bound algorithm of Bertolazzi, Di Battista, and Didimo. The conclusion (section 8) summarizes the

main results and contains possible starting points for future work.

2. SPQR-trees. In this section, we give a brief overview of the SPQR-tree data structure for biconnected graphs. A graph is biconnected if it is connected and cannot be disconnected by deleting a single vertex. SPQR-trees have been developed by Di Battista and Tamassia [10]. They represent a decomposition of a biconnected graph into its triconnected components. A connected graph is triconnected if there is no pair of vertices in the graph whose removal splits the graph into two or more components. Such a pair of vertices is called a *split pair*.

An SPQR-tree has four types of nodes and with each node we associate a biconnected graph which is called the *skeleton* of that node. This graph can be seen as a simplified version of the original graph where certain subgraphs are replaced by edges. The vertices in a skeleton are vertices of the original graph. The edges in a skeleton either correspond to edges in the original graph or represent subgraphs. Thus, each node of the SPQR-tree defines a decomposition of the graph. The node types and their skeletons are as follows:

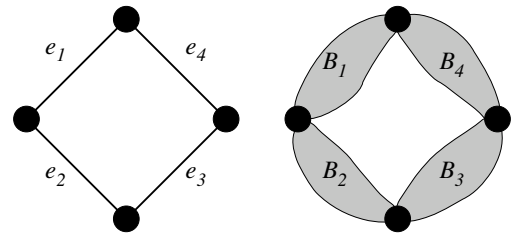
1. Q**-node:** The skeleton consists of two vertices connected by two edges. There is one Q-node for each edge in the graph.
2. S**-node:** The skeleton is a simple cycle with at least three vertices.
3. P**-node:** The skeleton consists of two vertices connected by at least three edges.
4. R**-node:** The skeleton is a triconnected graph with at least four vertices.

All leaves of the SPQR-tree are Q-nodes and all inner nodes S-, P- or R-nodes. When we see the SPQR-tree as an unrooted tree, then it is unique for every biconnected graph. Another important property of these trees is that their size (including the skeletons) is linear in the size of the original graph and that they can be constructed in linear time [17, 15]. See Figure 2 for examples of the skeletons of inner nodes of an SPQR-tree and the decomposition of the graph they define.

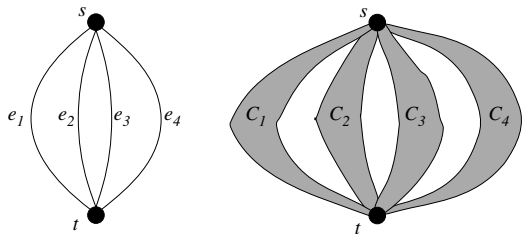
As described in [10], SPQR-trees can be used to represent the set of all combinatorial embeddings of a biconnected planar graph. Every combinatorial embedding of the original graph defines a unique combinatorial embedding for the skeleton of each node in the SPQR-tree. Conversely, when we define an embedding for the skeleton of each node in the SPQR-tree, we define a unique embedding for the original graph. The skeletons of S- and Q-nodes are simple cycles, so they have only one embedding. But the skeletons of the R- and P-nodes have at least two different combinatorial embeddings. This is the reason why they determine the embedding of the graph and we call these nodes the *decision nodes* of the SPQR-tree.

3. The ILP-formulation describing the set of all embeddings. Our new integer linear program (ILP) describing the set of all combinatorial embeddings of a planar graph is constructed recursively using the SPQR-tree data structure. Because SPQR-trees are only defined for biconnected graphs, the same is true for the ILP. We construct the program recursively by splitting the SPQR-tree into smaller SPQR-trees, constructing ILPs for the corresponding smaller graphs, and then merging them into an ILP for the original graph. The basis of the recursive construction are graphs whose SPQR-trees have only one inner node (S-, P- or R-node).

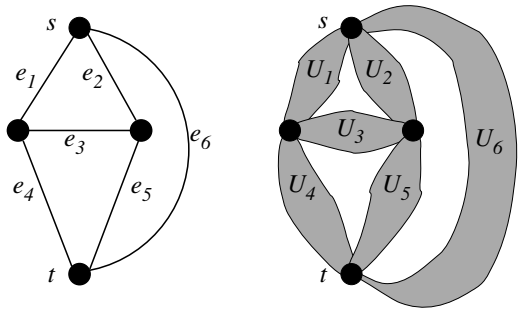
3.1. The ILP for graphs where the SPQR-tree has only one inner node. If the SPQR-tree for a graph G has exactly one inner node μ, then G is isomorphic to the skeleton S_μ of μ. It follows that the graph is either a simple cycle (μ is an S-node), a triconnected graph (μ is an R-node) or consists of two vertices connected



(a) S-node



(b) P-node



(c) R-node

FIG. 2. *The skeletons of the inner nodes of an SPQR-tree together with the decomposition of the graph they define. The grey shapes on the right depict the subgraphs represented by the edges with the same number on the left.*

by at least three edges (μ is a P-node).

In all three cases, the set of combinatorial embeddings is easy to describe. If the graph is a cycle, it has only one combinatorial embedding. If it is a triconnected graph, it has two embeddings that are mirror images of each other. If it consists of two vertices and at least three edges, the embeddings are determined by the different circular permutations of the edges connecting the two vertices.

The variables of the ILP correspond to the set of directed cycles of the graph, that are *face cycles* in at least one embedding. A directed cycle is a face cycle in an embedding, if the area of the plane on the right side of the cycle is empty in every planar drawing that realizes the embedding. First we describe the three possible

cases for graphs whose SPQR-tree has only one inner node together with the ILPs that describe their embeddings. We distinguish the three cases by the type of the only inner node of the SPQR-tree.

3.1.1. The ILP for graphs whose only inner node in the SPQR-tree is an *S*-node. In this case, G is a simple cycle. Therefore, G contains exactly two directed cycles and both are face cycles in the only combinatorial embedding of G. It follows that the corresponding ILP has two variables that are both equal to one in the only solution. So the ILP that describes all embeddings of a graph whose only inner node in its SPQR-tree is an S-node is simply $x_1 = x_2 = 1$.

3.1.2. The ILP for graphs whose only inner node in the SPQR-tree is an *R*-node. In this case the graph G is triconnected. A triconnected graph has two combinatorial embeddings that are mirror images of each other. This means that for any directed cycle c that is a face cycle in the first embedding, the directed cycle $\bar{c}$ passing the same edges as c in the opposite direction is a face cycle of the other embedding.

To find all potential face cycles of the graph, we first compute an arbitrary embedding of G, using for example the linear time planarity test of Hopcroft and Tarjan [16]. The face cycles in this embedding together with their reversal cycles form the set of all cycles in G that are face cycles in at least one embedding.

Let l be the number of faces in an embedding of G (note that $l = m - n + 2$ if m is the number of edges in G and n the number of vertices). Then there are $2l$ directed cycles in G that are face cycles in an embedding. If we write down the two embeddings of G as two vectors $\vec{s_1}, \vec{s_2} \in \{0,1\}^{2l}$, then each of the vectors contain l ones. Any entry with value one in $\vec{s_1}$ has value zero in $\vec{s_2}$ and vice versa. Therefore it is straightforward to describe the embeddings of G as an ILP.

If we order the variables for the face cycles such that the variables with odd numbers represent the face cycles of the first embedding and the variables with even numbers represent the second embedding, the ILP has a very simple structure. Let the variables of the problem be x_1 to x_{2l}. Then the ILP describing the embeddings is the following:

$$\begin{aligned} x_{2i-1} + x_{2l} &= 1 \text{ for } 1 \le i \le l, \\ x_{2i} - x_{2l} &= 0 \text{ for } 1 \le i \le l-1, \\ x_i &\ge 0 \text{ for } 1 \le i \le 2l, \\ x_i &\le 1 \text{ for } 1 \le i \le 2l. \end{aligned}$$

Note that this is a complete description of the polytope that describes the combinatorial embeddings of a triconnected graph. So if we want to optimize a linear function over the set of all embeddings, there is no need to demand that the solutions are integral.

3.1.3. The ILP for graphs whose only inner node in the SPQR-tree is a *P*-node. In this case, the graph G consists of two vertices connected by k edges with $k \ge 3$. Since combinatorial embeddings can be defined by the circular sequence of the edges around each vertex, G has $(k-1)!$ different embeddings. Each pair of edges in G corresponds to two directed cycles and all cycles are face cycles in at least one of the embeddings. Therefore, there are $d = k^2 - k$ variables in the ILP.

We realized that in this case the set of embeddings of G can be interpreted as the set of Hamiltonian tours in a complete directed graph H. The graph H has one

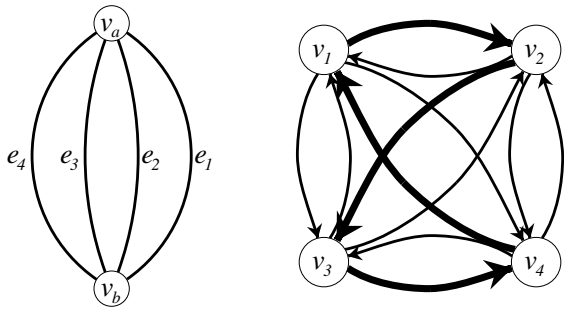


FIG. 3. *A graph where the only inner node in its SPQR-tree is a P-node and the corresponding graph H.*

vertex for every edge of G and one edge for each directed cycle. The edge in H that corresponds to the directed cycle c in G connects the vertices of H that correspond to the two edges in G that form the cycle c.

Figure 3 shows this correspondence. The edges of the graph on the left correspond to the vertices in the complete directed graph H on the right. Edge (v_i, v_j) in H corresponds to the cycle in G that passes edge e_i from v_a to v_b and edge e_j from v_b to v_a. The cycles that are face cycles in the embedding of G on the left correspond to the thick edges in the graph H on the right. Thus, the embedding of G shown on the left corresponds to the tour in H consisting of the thick edges. Note that the sequence of the edges in clockwise order around vertex v_a corresponds to the sequence of the vertices defined by the tour.

Because of the correspondence between the Hamiltonian tours in H and the embeddings of G, we can use the ILP-formulation for the asymmetric traveling salesman problem (ATSP) to describe the set of embeddings of G. We use the formulation of [6], which consists of a linear number of *degree constraints* and an exponential number of *subtour elimination constraints.* In our case, the degree constraints say that each edge in G is contained in exactly two face cycles of each embedding, once for each direction. The subtour elimination constraints say that for each proper subset E' of the edges of G, there must be at least one face cycle that consists of an edge in E' and of an edge in $E \setminus E'$.

Because the number of subtour elimination constraints grows exponentially with the number of edges in G (there is one constraint for each proper subset of the edges of G), we define the ILP for a graph whose SPQR-tree has a P-node as the only inner node just as the set of degree constraints. To cope with the subtour elimination constraints, we use the same approach that is used for the ATSP-problem: We separate the subtour elimination constraints during the optimization process.

So we first compute a solution vector $\vec{s} \in \{0,1\}^d$ for the problem without the subtour elimination constraints and then check if $\vec{s}$ violates any of the subtour elimination constraints. If this is not the case, we have found a valid solution representing a combinatorial embedding of G. Otherwise, we add the violated subtour elimination constraint to the set of constraints and reoptimize. To check if there is a violated subtour elimination constraint, we find a minimum cut in the graph H where the weight of each edge is defined by the corresponding component of the vector $\vec{s}$.

3.2. The ILP for graphs whose SPQR-tree has more than one inner node. If the SPQR-tree of G has more than one inner node, we split the tree at an

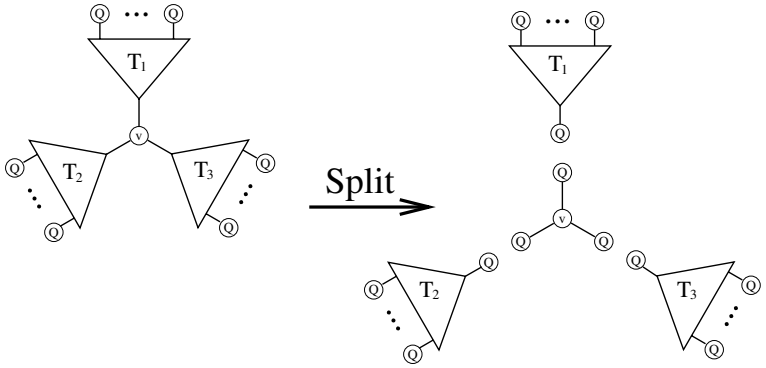

FIG. 4. *Splitting an SPQR-tree at an inner node.*

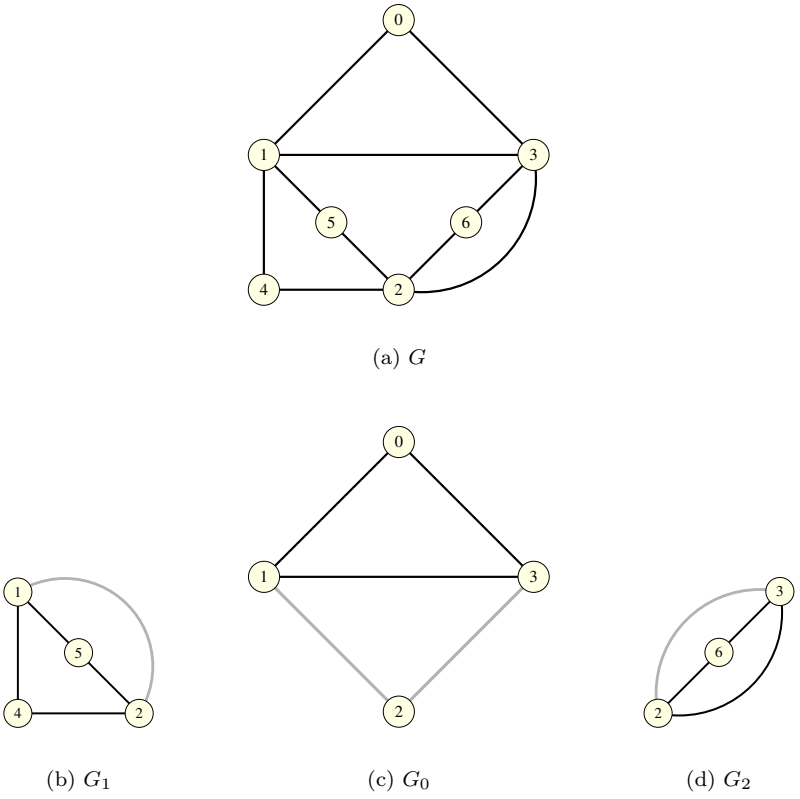
arbitrary decision node (R- or P-node). This is done as shown in Figure 4. In this figure, the split node is v. We split all the edges that connect v to the rest of the tree by inserting two new Q-nodes per edge. This is necessary to ensure that all leaves of the resulting trees are Q-nodes. In this way, we obtain smaller SPQR-trees, the *split trees*.

The graph represented by a split tree is called *split graph*. Each split graph can be obtained from G by replacing subgraphs connected to the rest of G only via a pair of vertices by an edge. These new edges, the *virtual edges*, correspond to the Q-nodes we add in the splitting process. Figure 5 shows a graph together with the split graphs resulting from splitting its SPQR-tree at its R-node. The grey edges are the virtual edges of the split graphs.

One of the resulting split trees contains v as the only inner node and so the ILP for the corresponding split graph has already been defined in the last section. We call this split graph the *center split graph*. In Figure 5, the center split graph is G_0. All other split trees contain at least one decision node less than the original tree, because they do not contain v. We continue the recursive splitting process until we have only SPQR-trees with just one inner node. This is always possible because any SPQR-tree with more than one inner node contains at least one decision node (two S-nodes can never be adjacent).

After recursively computing the ILPs for the split graphs, we merge them into an ILP for the original graph G. To achieve this, we need to lift the constraints computed for the split graphs, since G contains more potential face cycles than the split graphs. Therefore, the ILP describing its embeddings has more variables and thus a higher dimension. The number of variables and thus the number of potential face cycles in the original graph depend to a large degree on v. If it is a P-node, the number of potential face cycles in the original graph is roughly a multiple of the number of face cycles in the split graph where the multiplication factor is the number of face cycles in the skeleton of v. In all other cases, the number of face cycles and thus of variables in the ILP will be about the same as the sum of the number of variables in all split graphs.

The crucial idea in the computation of the merged ILP is to find for each cycle c in a split graph the set L_c of cycles of G that are *represented* by c. We say a cycle c' in G is represented by cycle c in the split graph G_i if the set of edges in c' that are also edges in G_i is identical to the set of nonvirtual edges in c and these edges are passed in the same direction in both cycles.



(a) G

(b) G_1 (c) G_0 (d) G_2

FIG. 5. *A graph G and its split graphs G_0, G_1, and G_2. Grey edges are virtual.*

Let $G_0, \ldots, G_k$ be the split graphs of G and G_0 the center split graph. Let C_i for $0 \leq i \leq k$ be the set of cycles in G_i that are represented by a variable in the corresponding ILP and $C = \bigcup_{i=0}^{k} C_i$. We can split C into two sets: The set C_L of cycles that do not include a virtual edge of a split graph (called *local cycles*, because they contain only nonvirtual edges of one of the G_i) and the set C_M of cycles that contain a virtual edge (called *component cycles*).

The local cycles in C_L are also represented by variables in the ILP for G. We use the component cycles in C_M to construct cycles in G. Every cycle c in $C_i \cap C_M$ with $1 \leq i \leq k$ contains exactly one virtual edge. If we remove this edge, we get a path p in G_i connecting the two vertices of G_i that it shares with G_0. If we take a cycle c of $C_0 \cap C_M$ and replace each virtual edge by a path p in the corresponding split graph obtained from a cycle in C_M, we get a cycle $c' \in L_c$ in G.

Consider, for example, Figure 5. We construct cycles in G by taking a cycle c_0 in the center split graph G_0 and combining it with a cycle c_1 in G_1 and a cycle c_2 in G_2 that both contain the virtual edge (all split graphs except the center split graph contain exactly one virtual edge). This is done by replacing the virtual edges in c_0 by the paths in the split graphs obtained from the cycles in G_1 and G_2 by deleting the virtual edge. We choose the component cycle c_0 given by the vertex sequence $(0, 1, 2, 3)$. We combine c_0 with the component cycle $c_1 = (1, 4, 2)$ in G_1 and the component cycle $c_1 = (2, 6, 3)$ in G_2. The result is the cycle $c_3 = (0, 1, 4, 2, 6, 3)$ in G.

The set L_{c_0} consists of the four different cycles that we can obtain by combining the two possible paths through G_1 and G_2.

The variables in the ILP for G correspond to the cycles in C_L and to the cycles in G that we can construct by combining cycles in C_M. The latter are called *global cycles* because they contain edges from more than one of the split graphs. In general, a component cycle in C_M is used to construct several global cycles in G. We store for each component cycle c the set L_c of global cycles in G constructed by combining c with other cycles. For each cycle in C_L, we define L_c as the cycle itself.

By constructing the variables set in this way, we make sure that the set of variables corresponds exactly to the set of directed cycles that are face cycles in at least one embedding of the graph. This can be shown in a similar way as in the proof of the correctness of the ILP in section 3.3. So we have all the variables necessary to represent all embeddings but significantly less variables than if we introduced a variable for each directed cycle in the graph. The computational results in section 7 show that the number of variables grows only linearly with the size of the benchmark graphs.

Let c be a cycle in a split graph that is represented by variable x_c in the corresponding ILP. The set L_c defines a set L_{x_c} of variables in the ILP for the original graph. We use these sets L_{x_c} to lift the constraints of the ILPs of the split graphs. We simply replace each variable x_c in each constraint computed for a split graph by the sum of the variables in L_{x_c}. We call the constraints generated in this way the *lifted constraints*.

Remember that we have not explicitly computed the subtour elimination constraints for graphs whose only inner node in the SPQR-tree is a P-node. Instead, there is a complete directed graph H for each P-node where we can find violated subtour elimination constraints by computing a minimum cut. When we compute the ILP for G from the ILPs of the split graphs, we have to update the set of cycles that are represented by each edge of H.

If the only inner node of an SPQR-tree is a P-node, every edge e in H represents exactly one directed cycle c of the graph. The weight of e is the value of the corresponding cycle variable x_c in the current solution vector. When we compute the ILP of the original graph from the ILPs of the split graphs, we assume that every edge in H represents a *set* of cycles.

Let us now assume that H is the complete directed graph computed for the separation of subtour elimination constraints in a split graph and e an edge in H representing the set C_e of cycles. After we have computed the global cycles of the original graph, we replace each cycle c in C_e by the set L_c of global cycles generated using c. Thus, the new set of cycles represented by e consists of the set of all the global cycles in G constructed from cycles in C_e.

So each edge e in the complete bidirected graph H corresponds to a set $C(e)$ of cycles in G. To separate the subtour elimination constraints, we define the weight $w(e)$ of each edge e in H as $\sum_{c \in C(e)} x_c$, where x_c is the binary variable of the ILP associated with the cycle c. If there is a proper subset V' of the vertices of H such that the sum of the weights of the edges connecting vertices of V' is greater than $|V' - 1|$, we have found a violated constraint. We call these constraints the *lifted subtour elimination constraints.*

After we have computed the new variables, lifted the constraints of the split graphs, and updated the complete directed graphs computed for each P-node skeleton, we add two types of additional constraints. The first type of constraints says that

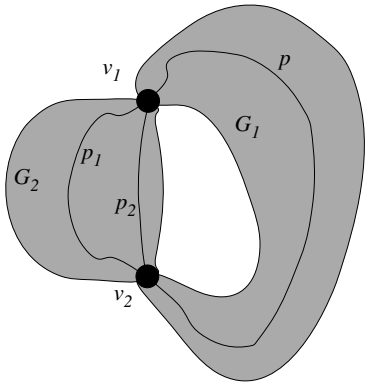


FIG. 6. *Two cycles that pass a split component in the same direction cannot both be face cycles in the same embedding.*

out of all global cycles created using the same component cycle, at most one can be a face cycle in any embedding of the original graph. This is true because there is a split component of a split pair of the graph that all these cycles pass in the same direction. We call this type of constraints the *choice constraints*. If c is a cycle in a split graph, than the corresponding choice constraint is:

$$\sum_{c' \in L_c} x_{c'} \leq 1.$$

To get an intuition why two such cycles can never be face cycles in the same embedding consider Figure 6. We assume that v_1 and v_2 are a split pair of the graph with the split components G_1 and G_2. We also assume that the two directed cycles c_1 and c_2 use the same path p in G_1 but different paths (p_1 and p_2) in G_2. If we assume that both c_1 and c_2 are face cycles in the same embedding Π of G, then we have a contradiction: Since c_1 is a face cycle, the area right of c_1 must be empty in Π and so the edges of p_2 must be left of p_1. But since c_2 is also a face cycle, the area to the right of c_2 must be empty and the path p_1 must be left of p_2.

The second type of constraints fixes the number of global cycles that are face cycles in each embedding. This number must be equal to the number of face cycles in an embedding of the center split graph that contain virtual edges. This constraint is called the *center graph constraint*.

3.3. Correctness of the ILP.

THEOREM 3.1. *Every feasible solution of the ILP corresponds to a combinatorial embedding of the given biconnected planar graph G and vice versa: every combinatorial embedding of G corresponds to a feasible solution for the generated ILP.*

The proof is split into three lemmas. They rely on the fact that by fixing the combinatorial embedding of each decision node in the SPQR-tree of a graph G, we define a unique combinatorial embedding of G. On the other hand, a combinatorial embedding of G defines a unique combinatorial embedding for the skeleton of each decision node in the SPQR-tree of G. From this fact, we can easily derive the following lemma:

LEMMA 3.2. *Let G be a biconnected planar graph and let T be its SPQR-tree. Let μ be a decision node in T, $T_0, \ldots, T_d$ be the split trees of μ (T_0 is the center split tree) and $G_0, \ldots, G_d$ the associated split graphs. Every combinatorial embedding Γ of G*

defines a unique embedding for each G_i. On the other hand, if we fix a combinatorial embedding Γ_i for each G_i, we have defined a unique embedding for G.

To prove the main theorem, we first define the *incidence vector* of a combinatorial embedding. Let C be the set of all directed cycles in the graph that are face cycles in at least one combinatorial embedding of the graph. Then the incidence vector of an embedding Γ is given as a vector in $\{0,1\}^{|C|}$, where the components representing the face cycles in Γ have value one and all other components have value zero.

LEMMA 3.3. *Let Γ be a combinatorial embedding of the biconnected planar graph G. Then the incidence vector χ^Γ satisfies all constraints of the ILP we defined.*

Proof. We prove the lemma using induction over the number n of decision nodes in the SPQR-tree T of G. The value $\chi(x_c)$ is the value of the component in χ associated with the variable for cycle c. We do not consider the case $n = 0$, because G is a simple cycle in this case and has only one combinatorial embedding.

1. $n = 1$:
   No splitting of the SPQR-tree is necessary, the ILP is defined directly by G. The variables are defined as the set of all directed cycles that are face cycles in at least one combinatorial embedding of G. If the decision node in T is an R-node, the constraints we have defined form a complete description of the polytope of all embeddings of G and thus the claim is true.
   Otherwise, the decision node is a P-node and the claim follows from the fact that the embeddings of G correspond to the tours in an ATSP problem and thus satisfy the degree constraints and subtour elimination constraints.
2. $n > 1$:
   From the previous lemma we know that Γ uniquely defines embeddings Γ_i with incidence vectors χ_i for the split graphs G_i. We will use the induction basis to show that χ^Γ satisfies all lifted constraints. We know that the choice constraints are satisfied by χ^Γ because in any embedding there can be only one cycle passing a certain split pair in the same direction (see section 3.2 where we defined the choice constraints).
   Let u be a constraint computed for a split graph G_i and c be a component cycle of G_i that is represented by the variable x_c in u. When we lift u, we replace x_c by the sum $\sum_{c' \in L_c} x_{c'}$, where L_c is the set of global cycles in G generated using c. Since the choice constraints are satisfied, this sum is either 0 or 1. Using the fact that the choice constraints are satisfied and by construction of the χ_i from χ^Γ, we can show that

$$\sum_{c' \in L_c} \chi(x_{c'}) = \chi_i(x_c).$$

   Therefore, all lifted constraints are satisfied. This is also true for the lifted subtour elimination constraints.
   To see that the center graph constraint is satisfied, we observe that we can construct any embedding of G from an embedding Γ_0 of G_0 by replacing edges by the embeddings of subgraphs. The global face cycles in Γ are represented by face cycles in Γ_0 and each local face cycle in G_0 is also a face cycle in Γ_0. Therefore the center graph constraint is satisfied.

It follows that every embedding of G satisfies the constraints of the ILP. □

LEMMA 3.4. *Let G be a biconnected planar graph and $\chi \in \{0,1\}^{|C|}$ a vector satisfying all constraints of the ILP including the lifted subtour elimination constraints. Then χ is the incidence vector of a combinatorial embedding Γ of G.*

Proof. Again, we use induction on the number n of decision nodes in the SPQR-tree T of G and we disregard the case $n = 0$.

1. $n = 1$:
   Like in the previous lemma, our claim holds by definition of the ILP.
2. $n > 1$:
   The proof works in two stages: First we construct vectors χ_i for each split graph from χ and prove that these vectors satisfy the ILPs for the G_i, and are therefore incidence vectors of embeddings Γ_i of the G_i by induction basis. In the second stage, we use the Γ_i to construct an embedding Γ for G and show that χ is the incidence vector of Γ.
   The construction of the χ_i works as follows: When x_c is a variable in the ILP of G_i and the corresponding cycle c is a local cycle, then x_c in the ILP of G_i is defined as the value of x_c in χ. Otherwise, if c is a component cycle, we define the value of x_c as the sum of the values of all variables in χ representing global cycles constructed using c,

$$\chi_i(x_c) := \sum_{c' \in L_c} \chi(x_{c'}) \; .$$

   This value is either 0 or 1 because χ satisfies the choice constraints.
   Because χ satisfies the lifted constraints, each χ_i constructed in this way must satisfy the constraints of the ILP for G_i and by induction basis we know that each χ_i represents an embedding Γ_i of G_i. By combining the embeddings χ_i for the split graphs, we construct an embedding Γ for G.
   To show that χ is the incidence vector of Γ, we define χ^Γ as the incidence vector of Γ and show that χ and χ^Γ are identical. By construction of Γ and χ^Γ, the components in χ^Γ and χ corresponding to local cycles must be equal. The number of global cycles whose variable in χ has value 1 must be equal to the number of faces in Γ consisting of such cycles. This is guaranteed by the center graph constraint. Using the fact that for all face cycles in Γ_0 that contain a virtual edge (the embedding of the center split graph) there must be a represented global cycle in G whose component in χ and in χ^Γ is 1 we can show that both vectors also agree on the values of the variables of the global cycles, and thus must be identical.

It follows that a vector that satisfies all constraints of the ILP is the incidence vector of a combinatorial embedding. □

A more detailed version of the proof for Theorem 3.1 can be found in [22].

4. The linear program describing orthogonal representations for a fixed embedding. Orthogonal representations not only fix the planar embedding of a graph but also the number, type, and sequence of the bends on each edge and the angles between edges incident to the same vertex in an orthogonal drawing. However, they do not fix the lengths of the edge segments in the drawing. The first efficient algorithm for computing an orthogonal representation of a graph with the minimum number of bends for a fixed planar embedding was presented by Tamassia [21]. This algorithm constructs a flow network using the planar embedding and then computes a minimum cost flow in this network. This flow can be translated into an orthogonal representation of the graph with the minimum number of bends for the fixed embedding.

The drawback of the original method of Tamassia is that it cannot deal with vertices of degree greater than four. Some modifications of the algorithm have been

published that overcome this constraint. The approach we use implements the *podevsnef* drawing convention (planar orthogonal drawings with equal vertex size and nonempty faces) defined in [13]. According to this convention, the vertices are drawn as squares of equal size and the edges are positioned on a finer grid than the vertices. Because of this modification, more than one edge can be incident to each of the four sides of a vertex (see Figure 1 on page 666 for an example of a podevsnef drawing).

Bertolazzi, Di Battista, and Didimo describe a minimum cost flow network N that can be used to compute an orthogonal representation in a simplified podevsnef model with the minimum number of bends for a fixed embedding [2]. The model is simplified, because whenever edges run parallel, the first bend of the rightmost edge in the bundle is a bend to the right. Another property of the simplified model is that a vertex with degree at least four always has at least one edge attached to each side. This is the case in Figure 1 on page 666. We have chosen this model for our approach because it is the only podevsnef model we are aware of that can be modeled as a standard min-cost-flow problem.

The network N for G contains one node for every vertex of G (called *v-nodes*) and one node for every face cycle of the given embedding (called *f-nodes*). The basic idea of the network is that the flow on its arcs corresponds to bends on edges and to the angles between neighboring edges incident to the same vertex. One unit of flow corresponds to an angle of 90 degrees. The supply of flow assigned to each node and the capacity of the edges guarantee that a feasible flow corresponds to an orthogonal representation of the graph. The costs of the arcs are defined such that the cost of a flow is equal to the number of bends in the corresponding orthogonal representation.

We used this network and transformed it into a linear program. There is one variable f_e for each arc e in the network that represents the amount of flow routed via e. One constraint for each vertex in the network makes sure that the outgoing amount of flow minus the incoming amount is equal to the supply of the node. Some nodes in the network have negative supply, and thus consume flow. We have one constraint for each arc that says that the flow on the arc must be nonnegative and we also introduce upper bounds on the flow on arcs that start or end in a v-node. The objective function minimizes the sum of the amount of flow over each arc multiplied by the cost of the arc. An optimal solution represents a minimum cost flow in N and thus an orthogonal representation with the minimum number of bends.

LP 1 shows the corresponding linear program (LP). The set E_N is the set of arcs in the network, V the set of vertices in G and F the set of faces in the embedding. The face f_o is the outer face of the embedding. The degree of a face is defined as the number of edges that form the boundary of the face. The variable f_e denotes the flow on arc e. The constraints guarantee that the solution corresponds to an orthogonal representation of G.

LP 1

$$\min \quad \sum_{e \in E_N} cost(e) \cdot f_e$$

subject to

$$\sum_{e=(v,w)\in E_N} f_e - \sum_{e=(w,v)\in E_N} f_e = 4 - deg(b^{-1}(v)) \; \forall \text{ nodes } v \text{ with } b^{-1}(v) \neq f_o$$

$$\sum_{e=(b(f_o),w)\in E_N} f_e - \sum_{e=(w,b(f_o))\in E_N} f_e = \; -4 - deg(f_o)$$

$$
\begin{aligned}
f_e &\leq 4 - deg(b^{-1}(v)) \quad \forall\, e = (v, w) \in E_{vf} \\
f_e &\leq 1 \quad \forall\, e \in E_{fv} \\
f_e &\geq 0 \quad \forall\, e \in E_N
\end{aligned}
$$

Since this linear program is a straightforward formulation of the flow network introduced in [2], the correctness follows directly from the correctness of the flow network.

5. The mixed integer linear program describing the set of all orthogonal representations of a graph. The flow network N of the last section describing the set of orthogonal representations of a graph for a fixed embedding contains one f-node for every face of the embedding. When we want to optimize over the set of all embeddings of a graph, we do not know at the beginning which cycles will be face cycles in an optimal solution. Therefore, we construct a new network N', where we have one c-node for every directed cycle in the graph, that is a face cycle in at least one embedding. These nodes play a similar role to the f-nodes in the linear program for a fixed embedding we presented in the previous section. The set of cycles that are face cycles in at least one embedding of the graph corresponds to the set of variables in our ILP from section 3 that describes the set of all embeddings of a graph.

In a solution of the embedding ILP, the variable corresponding to a cycle has value one if this cycle is a face cycle in the embedding represented by the solution and zero otherwise. The capacities of the arcs in the network N' depend on the values of the cycle variables. If the cycle-variables represent an embedding Γ of the graph, then the set of feasible flows in N' corresponds to the set of feasible flows in the network N constructed for embedding Γ. Let A be the set of arcs incident to the c-node for cycle c in N' and the variable for c in the embedding ILP be zero. Then all arcs in A must have capacity zero. This has the same effect on the flow as removing the c-node from the network.

We first compute the capacities of the arcs and the demand of each c-node analogously to the corresponding values for the f-nodes in the network N. Then we multiply the amount of flow produced or consumed by a c-node with the value of the corresponding variable in the ILP. This ensures that vertices in N' that correspond to cycles in G that are not face cycles do not produce or consume flow.

Any arc that starts or ends at a c-node has capacity zero if the c-node corresponds to a cycle whose ILP-value is zero. If the capacity of the arc is limited even if the corresponding cycle is a face cycle, we can just multiply this limit with the ILP-value of the cycle to achieve this behavior. But the arcs in the network N that connect two f-nodes have unlimited capacity. However, we can easily compute an upper bound f_{max} for the flow produced in the whole network N, by computing the sum of all positive supplies in the network. The resulting value can be used as the upper bound on the flow on any arc. For each arc a in N' connecting two c-nodes v_1 and v_2, we set the capacity to the minimum of $f_{max}x_1$ and $f_{max}x_2$, where x_i for $i \in \{1, 2\}$ is the binary variable in the embedding ILP for the cycle corresponding to node v_i. This guarantees that the flow on a is zero if at least one of the cycles represented by the nodes v_i is not a face cycle in the represented embedding.

In this way, the capacities of the arcs and the amount of flow produced and consumed by the vertices in N' depend on the values of the cycle variables in the ILP. We transform N' into a linear program and merge it with the ILP that represents the embeddings of the graph. To correctly set the supply and demand of the c-nodes,

we need to know the cycle chosen as the outer face cycle. Therefore, we introduce an outer face variable for each cycle and add constraints that guarantee that exactly one of the cycles chosen as face cycles is chosen as the outer face cycle. The result is a mixed integer linear program, where an optimal solution corresponds to an orthogonal representation with the minimum number of bends over the set of *all* embeddings of the input graph.

MILP 1 is the resulting mixed integer linear program (MILP). We omitted the constraints that define the embedding because they are defined recursively. Again, variable f_e denotes the flow on arc e. The set C is the set of cycles in G that are face cycles in at least one embedding. For each of these cycles c, the variable x_c is one if c is a face cycle and variable o_c is one if c is the outer face cycle. The set E_{cc} is the set of arcs that connect two c-nodes. Arcs in E_{vc} start in a v-node and end in a c-node while the arcs in E_{cv} start in a c-node and end in a v-node. The expression $len(c)$ denotes the number of edges in cycle c. The function b is the bijection from the vertices of G to the v-nodes in N' and from the directed cycles in C to the c-nodes of the network.

MILP 1

$$\min \quad \sum_{e \in E_N} cost(e) \cdot f_e$$

subject to

$$\sum_{c \in C} o_c = 1 \tag{5.1}$$

$$x_c - o_c \geq 0 \qquad \forall\, c \in C \tag{5.2}$$

$$\sum_{e=(v,w) \in E_N} f_e - \sum_{e=(w,v) \in E_N} f_e = 4 - deg(v) \qquad \forall\, v \in V \tag{5.3}$$

$$\sum_{e=(c,w) \in E_N} f_e - \sum_{e=(w,c) \in E_N} f_e = x_c(4 - len(c)) - 8o_c \forall\, c \in C \tag{5.4}$$

$$f_e \leq x_c(4 - deg(v)) \qquad \forall\, e = (v,c) \in E_{vc} \tag{5.5}$$

$$f_e \leq x_c \qquad \forall\, e = (c,v) \in E_{cv} \tag{5.6}$$

$$f_e \leq x_{c_1} f_{max} \qquad \forall\, e = (c_1,c_2) \in E_{cc} \tag{5.7}$$

$$f_e \leq x_{c_2} f_{max} \qquad \forall\, e = (c_1,c_2) \in E_{cc} \tag{5.8}$$

$$f_e \geq 0 \qquad \forall\, e \in E_N \tag{5.9}$$

$$x_c, o_c \in \{0,1\} \qquad \forall\, c \in C \tag{5.10}$$

Constraint 5.1 says that there is exactly one cycle chosen as the outer face cycle and the constraints of type 5.2 guarantee that this cycle is also chosen as a face cycle. Constraint 5.3 is the same as in the LP of the previous section because the supply of the nodes representing vertices of G is independent of the chosen embedding. A node in N' corresponding to a cycle that is not chosen as a face cycle does not consume or supply any flow since its cycle variable and its outer face variable are both zero. This is guaranteed by constraint 5.4. If the outer face variable of a cycle is one, the constraint sets its supply to $-4 - len(c)$ and if the cycle variable is one but the outer face variable is zero to $4 - len(c)$.

The constraints of type 5.5, 5.6, 5.7, and 5.8 make sure that the arcs incident to c-vertices where the corresponding cycle is not a face cycle in the chosen embedding have capacity zero. If a cycle is chosen as face cycle, the arcs incident to the corresponding c-node in N' have either the same capacities as in the network N of the previous section or if the capacity in N is unbounded (for the arcs in E_{cc}), the capacity is now set to an upper bound for the flow in the network.

6. The algorithm for minimizing the number of bends. The algorithm first computes the recursive ILP describing the set of all combinatorial embeddings of the graph. This is done by recursively splitting the SPQR-tree into smaller trees and computing the ILPs for the corresponding split-graphs. Then we compute the set of cycle-variables for the original graph by combining the cycles that are represented as variables in the ILPs for the split graph. This also gives us for each cycle variable in the ILPs of the split graphs the list of corresponding cycle variables in the original graph. Using this information, we can lift the constraints of the ILPs, compute the choice constraints, the center graph constraint, and update the complete directed graphs computed for the P-nodes used for the separation of the subtour elimination constraints.

After this step, we use the set of cycle variables computed for the original graph to compute the network N' and the corresponding MILP. We use CPLEX (version 6.5) to compute an integer solution and then check if there are any violated subtour elimination constraints by computing a minimum cut in the complete directed graphs computed for each P-node skeleton. If we find a violated constraint, we add it to the MILP and reoptimize. When we have found a feasible solution, we transform it into an orthogonal representation of the graph.

To improve the performance of the algorithm, we modified the MILP slightly. We realized that we only need outer face variables for half of the cycles. The reason is that for every cycle c represented by a variable in the embedding ILP, the cycle $\bar{c}$ passing the same edges in the opposite direction is also represented by a variable. The orthogonal representations we exclude by introducing outer face variables only for one direction of each undirected cycle are mirror images of other orthogonal representations that can still be represented. Of course, every orthogonal representation has the same number of bends as its mirror image and therefore we do not exclude all optimal solutions.

The second modification is that we hard-coded a complete description of the set of embeddings for P-node skeletons with less than five vertices into our program to reduce the need for separating subtour elimination constraints.

7. Computational results. To test our approach, we used two sets of benchmark graphs. The first was introduced in [8] and consists of 11,529 graphs that either come from industrial applications or were derived from such graphs by introducing small changes. We call this set the *real world set*. The second set consists of randomly generated graphs that were used in [2] to test the performance of the branch & bound approach for minimizing the number of bends. We call this set the *artificial set*.

The graphs in the artificial set are already biconnected and planar, so we can directly apply our new algorithm for minimizing the number of bends and compare it with the branch & bound algorithm from [2]. The majority of the graphs in the real world set are not planar and biconnected. Therefore, we used a standard approach to transform them into planar biconnected graphs whose drawing can be easily transformed back into a drawing of the original graph.

This is done as follows: We first determine the topology of the graph using the standard planarization method implemented in the AGD-library [1]. This method

computes an embedding of a planar subgraph of the original graph and then inserts the missing edges one by one into the current embedding. The crossings produced by inserting an edge are replaced by artificial vertices with degree four. If the resulting graph is not biconnected, we introduce new edges while maintaining planarity using the heuristic presented in [12] that is also implemented in the AGD-library. Note that these operations can increase the number of vertices and edges of a graph considerably.

If we have computed a drawing for the modified graph, it is straightforward to transform it into a drawing for the original graph. We remove all edges from the drawing that were introduced to make the graph biconnected and replace the drawings of the artificial vertices by crossings. Note that this always works because the simple podevsnef standard guarantees that a vertex with degree four has one incident edge on each side of the vertex. Therefore, we can easily replace the drawing of an artificial vertex with an orthogonal crossing. The result is a drawing of the original graph. Note that because of the artificial vertices and edges introduced before the optimization step, this drawing does not necessarily have the minimum number of bends over all embeddings of the original graph.

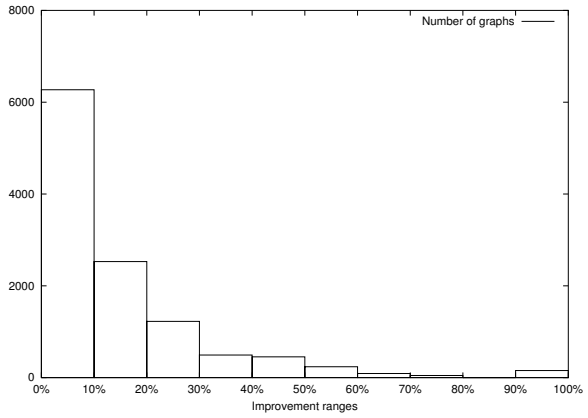
We compared the results produced by our algorithm for minimizing the number of bends over all embeddings to the results computed by the following heuristic: We use the linear planarity test of Hopcroft and Tarjan [16] to compute an embedding for the graph and then compute a minimum cost flow in the network given in section 4. The flow defines an orthogonal representation of the graph with the minimum number of bends for the chosen embedding.

Let h be the number of bends in the orthogonal representation computed by the heuristic and o the number of bends in an orthogonal representation with the minimum number of bends over all embeddings. For each graph in the benchmark sets, we computed the value $\frac{h-o}{h}100\%$. This is the percentage of the improvement we get using an optimal algorithm.

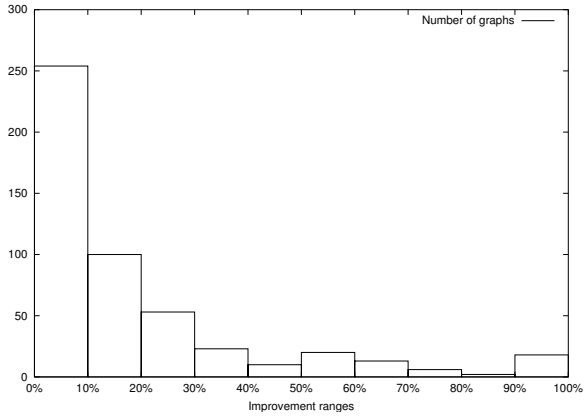
We broke the set of all graphs of each benchmark set into ten subsets. The first subset contained the graphs where the improvement was smaller than ten percent, the second subset contained the graphs where the improvement was at least ten and smaller than 20 percent and so on. The last subset contained the graphs where the improvement was at least 90 percent. Note that the improvement is 100 percent if the heuristic solutions contains bends while the optimum solution contains no bends.

The x-axes in Figure 7 show the improvement ranges while the height of the boxes corresponds to the number of graphs that fall into that range. Figure 7(a) shows the data for the real world graphs while Figure 7(b) shows the data for the artificial graphs. Both diagrams are remarkably similar. For about half of all graphs, optimizing over all embeddings results in a significant reduction of the number of bends (at least 10 percent).

We compared the average running times for graphs with the same number of vertices of our new algorithm (MIX) and the branch & bound algorithm (B&B) from [2]. Both algorithms are written in C++ and were compiled with the flag `-O` using gcc version 2.95.1. The algorithms ran on a Sun Enterprise 450 Model 4400 with four Sun UltraSPARC-II 400 MHz CPUs and 4 GB of memory. Figure 8 shows the corresponding diagrams for the real world graphs (Figure 8(a)) and for the artificial graphs (Figure 8(b)). The x-axes show the number of vertices while the y-axes give the average time in seconds needed for a problem instance. Note that the times given for MIX include the time needed for constructing the recursive ILP, the flow network, and solving the MILP.



(a)



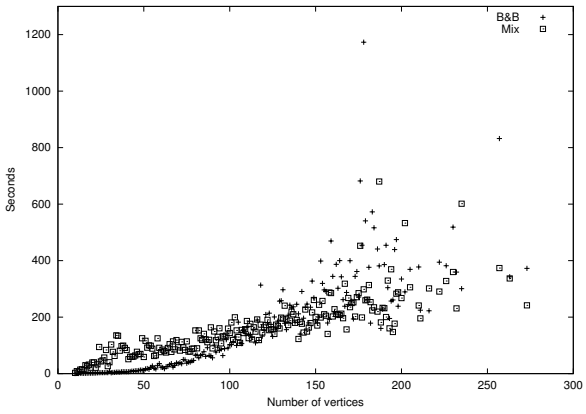
(b)

FIG. 7. *Improvement ranges of our algorithm compared to the heuristic for the real world benchmark set* (a) *and the artificial benchmark set* (b).

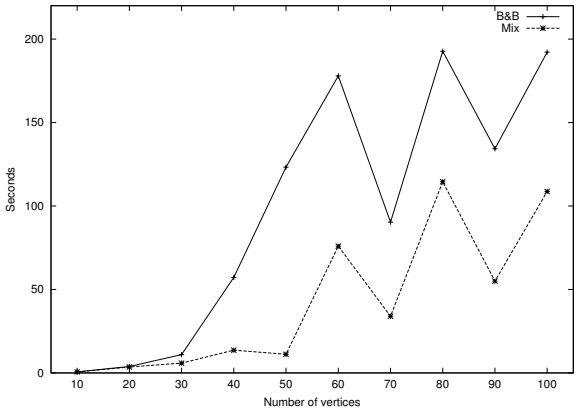
Figure 8(a) shows that B&B is faster for graphs with up to 120 vertices, but for larger graphs our new algorithm is faster. For example, for one graph with 130 vertices and 205 edges, B&B needed 5244 seconds while MIX found an optimal solution in only 108 seconds. The corresponding drawing is shown in Figure 1 on page 666.

There were 197 graphs in the real world benchmark set that B&B could not solve in one hour computation time. Our algorithm could not solve 25 graphs within the same time limit. Another interesting fact is that we only had to add subtour elimination constraints and reoptimize for six graphs out of 11,529. This shows the effect of hard-coding the complete ILP-description for P-nodes with up to four edges. We never had to add more than one subtour elimination constraint.

As Figure 8(b) shows, the speed advantage of our new algorithm is very pronounced for the artificial graphs. The B&B needs on average almost twice as long to



(a)



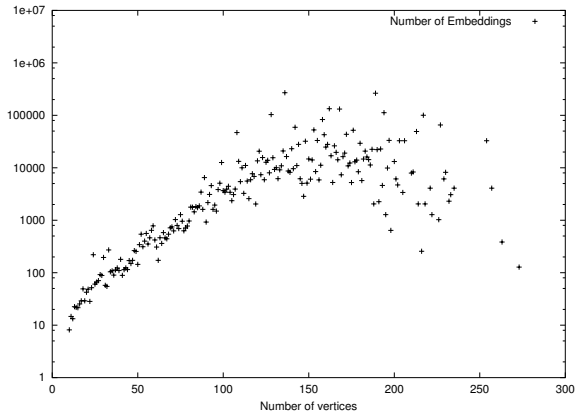
(b)

FIG. 8. *Runtime comparison of our new algorithm with the branch & bound algorithm for the real world benchmark set* (a) *and the artificial benchmark set* (b).

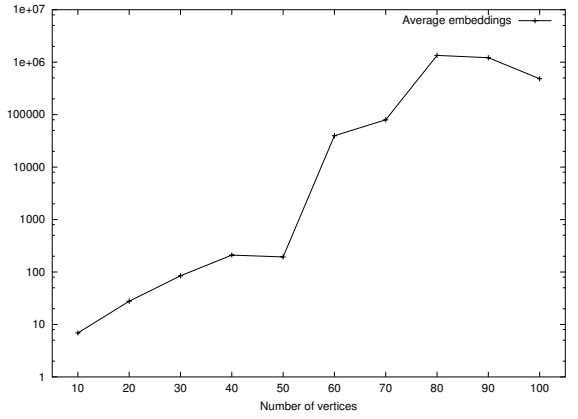
compute an optimal solution compared to our new method.

Figure 9 shows the average number of embeddings for graphs with the same number of vertices for the real world benchmark set and the artificial benchmark set. Again, the x-axes show the number of vertices. The y-axes have a logarithmic scale and show the average number of embeddings for the graphs.

Figure 9(a) shows the number of embeddings of the real world graphs. Until about 150 vertices, the average number of embeddings grows exponentially with the size of the graphs (remember that the y-axis is logarithmic). The reason for the drop in the number of embeddings for larger graphs is the planarization method. Graphs where many edges have to be deleted to obtain a planar graph tend to have large triconnected components after the planarization method is applied because this method replaces crossings with vertices of degree four.



(a)



(b)

FIG. 9. *The average number of embeddings for graphs in the real world benchmarks set (Figure* 9(a)*) and the artificial benchmark set (Figure* 9(b)*).*

The growth of the average number of embeddings for the artificial graphs is also roughly exponential until about 80 vertices, as Figure 9(b) shows. The number of embeddings varies widely for graphs with the same number of vertices because the set was generated using five different settings for the parameters of the generation algorithm that influence the number of embeddings. The details of the generation algorithm and the parameter settings can be found in [2].

Figure 10 shows the average number of constraints and embeddings in the MILP computed by our algorithm for the real world graphs (Figure 10(a)) and for the artificial graphs (Figure 10(b)). For both benchmarks sets, the number of variables and constraints grows roughly linear with the size of the graphs. This benign growth behavior is in sharp contrast to the exponential growth of the number of embeddings. The spike at 35 vertices in Figure 10(a) mirrors the smaller spike in the number of

embeddings for the real world graphs.

8. Conclusion. Using methods of integer linear programming to minimize the number of bends in an orthogonal drawing seems to be a promising approach. The main drawback is that at the moment, the algorithm can only guarantee optimality for biconnected graphs. The reason is that SPQR-trees are only defined for biconnected graphs. One possible approach to overcome this limitation is to work with the block-cut-tree of biconnected components of the graph. If it can be used to describe the set of all embeddings of a connected graph as an ILP, our approach can be easily extended to deal with any planar graph.

Acknowledgment. We thank Walter Didimo for providing the code of the branch & bound algorithm and the real world benchmark set.

A UNIFIED APPROACH AND OPTIMALITY CONDITIONS FOR APPROXIMATE SOLUTIONS OF VECTOR OPTIMIZATION PROBLEMS*

CÉSAR GUTIÉRREZ†, BIENVENIDO JIMÉNEZ‡, AND VICENTE NOVO‡

Abstract. This paper deals with approximate (ε-efficient) solutions of vector optimization problems. We introduce a new ε-efficiency concept which extends and unifies different approximate solution notions introduced in the literature. We obtain necessary and sufficient conditions via nonlinear scalarization, which allow us to study this new class of approximate solutions in a general framework, since any convexity hypothesis is required. Several examples are proposed to show the concepts introduced and the results attained.

Key words. vector optimization, approximate solutions, ε-efficiency, scalarization, gauge functional

DOI. 10.1137/05062648X

1. Introduction.

Approximate solutions are a usual kind of solution used to solve optimization problems. There are two reasons for this statement. First, optimization models are simplified representations of real problems. Second, these models are solved frequently using iterative algorithms or heuristic methods, and these procedures give approximations to the theoretical solution.

In vector optimization, the notion of approximate solution has been defined in several ways. The first and most popular concept was introduced by Kutateladze [12]. This notion has been used to obtain vector variational principles, approximate Kuhn–Tucker type conditions, approximate duality theorems, solution methods, etc. (see [2, 5, 6, 7, 10, 11, 14, 15, 17, 18, 19, 23, 26, 30, 32]).

However, the ε-efficiency set obtained according to Kutateladze's definition is sometimes too large. Thus, several authors have proposed other ε-efficiency concepts (see, for example, [8, 21, 28, 29, 31]). In this paper, all these notions are analyzed through a new concept that allows us to study them simultaneously.

We characterize this new ε-efficiency notion via nonlinear scalarization, i.e., by means of approximate solutions of related nonlinear scalar optimization problems. Necessary conditions are obtained via Minkowski-type functionals, and sufficient conditions are deduced using a new class of monotone functionals.

Our results are general because we do not assume any convexity hypothesis. We consider a nonconvex constrained vector optimization problem and a preference relation to solve it which is not necessarily a preorder relation. This type of preference is usual in economics (see, for example, [20] and references therein).

The work is structured as follows. In section 2, the vector optimization problem and the preference relation are fixed. Moreover, we describe some notations used in what follows. In section 3, we propose a new ε-efficiency concept and prove some properties of this notion when ε tends to zero. In section 4, we recall several well-known ε-efficiency concepts to show as our concept extends and unifies different notions introduced previously in the literature by Helbig [8], Kutateladze [12], Németh [21], Tanaka [28], and White [31]. In this sense, Helbig's concept is seen as a particular case of a more general notion, which shows the standard nature of our definition. In section 5, we characterize the ε-efficiency set through approximate solutions of scalar optimization problems. The scalarization process is based on the postcomposition of the objective map with a suitable nonlinear scalar functional from the final space. In section 6, the results attained in the previous section are applied to study the finite dimensional case. In particular, several types of ε-efficient solutions are characterized taking into account this special structure. Finally, in section 7, we present some conclusions that summarize this work.

2. Preliminaries. In this work, we consider two topological real linear spaces X and Y. We denote by $\operatorname{int}(C)$, $\operatorname{cl}(C)$, $\operatorname{bd}(C)$, C^c, and $\operatorname{conv}(C)$ the interior, the closure, the boundary, the complement, and the convex hull of a set $C \subset Y$, respectively. The cone generated by a set C is defined as

$$\operatorname{cone}(C) := \bigcup_{\alpha>0} \alpha C,$$

and it is said that $D \subset Y$ is a cone if $\operatorname{cone}(D) = D$. Let us observe that $0 \in \operatorname{cone}(C)$ if and only if $0 \in C$ and thus it is possible that $0 \in D$ or $0 \notin D$ when D is a cone. We say that a set C is solid if $\operatorname{int}(C) \neq \emptyset$, is proper if $\emptyset \neq C \neq Y$, and is pointed if $C \cap (-C) \subset \{0\}$, i.e., if $C \cap (-C) = \{0\}$ when $0 \in C$ and if $C \cap (-C) = \emptyset$ when $0 \notin C$. We denote the nonnegative orthant in $\mathbb{R}^p$ by $\mathbb{R}^p_+$.

The topological dual space of Y is denoted by Y^*. For a cone $D \subset Y$, its positive polar cone (resp., strict positive polar cone) is denoted by D^+ (resp., D^{s+}).

In this paper, we study the vector optimization problem

$$\operatorname{Min}\{f(x) : x \in S\}, \tag{2.1}$$

where $f : X \to Y$ and $S \subset X$, $S \neq \emptyset$. As usual, to solve (2.1) the preference relation $\leq$ defined in Y by a nonempty set $D \subset Y$ is used, which models the preferences stated by the decision-maker:

$$y, z \in Y,\ y \leq z \iff y - z \in -D.$$

We assume that D is a pointed cone. Notice that the relation $\leq$ is not a preorder, since D is not necessarily a convex set.

We recall that $x_0 \in S$ is an efficient solution of (2.1) with respect to D (or an efficient solution for short) if $(f(x_0) - D) \cap f(S) \subset \{f(x_0)\}$. We denote the set of efficient solutions of (2.1) with respect to D by $\operatorname{E}(f, D)$ and with respect to $\operatorname{int}(D)$ by $\operatorname{WE}(f, D)$ (in this case it is assumed that D is solid and these efficient solutions of (2.1) are called weakly efficient solutions).

3. A new concept of approximate efficiency in vector optimization. Next, we introduce a new approximate solution concept for vector optimization problems. This notion is motivated in the following idea: An approximate solution of (2.1)

is every feasible point $x_0 \in S$ such that for every feasible point $x \in S$ whose image $f(x)$ is better than $f(x_0)$, the improvement $f(x_0) - f(x)$ is near zero.

To define this concept, we use a proper pointed co-radiant set $C \subset Y$, i.e., a proper pointed set C such that $\alpha d \in C \; \forall\, d \in C$, $\forall\, \alpha > 1$. Moreover, we assume that C is a solid set and we denote $C(\varepsilon) := \varepsilon C \; \forall\, \varepsilon > 0$ and

$$C(0) := \bigcup_{\varepsilon > 0} C(\varepsilon)\,. \tag{3.1}$$

Let us observe that a pointed cone is a pointed co-radiant set. However, the class of pointed co-radiant sets is wider. For example, given any convex set $A \subset Y$ such that $0 \in A$, the complement A^c is a co-radiant set, and for each continuous linear functional $g \in Y^*$ and $\alpha > 0$, the set $A^c \cap \{y \in Y : g(y) \geq \alpha\}$ is a co-radiant pointed set, which is not a cone. It is easy to check that if C is a nonempty pointed co-radiant set such that $0 \notin \mathrm{cl}(C)$, then $C(\varepsilon) \neq C(0) \; \forall\; \varepsilon > 0$, and $C(0)$ is proper.

LEMMA 3.1.

(i) *$C(\varepsilon)$ is a solid pointed co-radiant set $\forall\, \varepsilon > 0$.*

(ii) *$C(\varepsilon_2) \subset C(\varepsilon_1)$ $\forall\, \varepsilon_1, \varepsilon_2 > 0$, $\varepsilon_1 < \varepsilon_2$.*

(iii) *$C(0)$ is a solid pointed cone.*

Proof. Part (i). As $C(\varepsilon) = \varepsilon C \; \forall\, \varepsilon > 0$, and C is a solid pointed co-radiant set, then $C(\varepsilon)$ is also a solid pointed co-radiant set $\forall\, \varepsilon > 0$.

Part (ii). Let $\varepsilon_1, \varepsilon_2 > 0$, $\varepsilon_1 < \varepsilon_2$, and $y \in C(\varepsilon_2)$. There exists $d \in C$ such that $y = \varepsilon_2 d$. For

$$\alpha := 1 + (\varepsilon_2 - \varepsilon_1)/\varepsilon_1$$

we have that $y = \alpha(\varepsilon_1 d) \in C(\varepsilon_1)$, since $\alpha > 1$ and $C(\varepsilon_1)$ is a co-radiant set. Then, $C(\varepsilon_2) \subset C(\varepsilon_1)$.

Part (iii). It is clear that $C(0) = \mathrm{cone}(C)$, and thus $C(0)$ is a solid cone.

If $y \in C(0) \cap (-C(0))$, then there exist $\delta, \nu > 0$ such that $y \in C(\delta) \cap (-C(\nu))$. Consider $\beta = \min\{\delta, \nu\} > 0$. By parts (i)–(ii) we see that $y \in C(\beta) \cap (-C(\beta)) \subset \{0\}$, and therefore, $C(0)$ is a pointed set. ∎

DEFINITION 3.2. *Let $\varepsilon \geq 0$. We say that a feasible point $x_0 \in S$ is an ε-efficient solution of* (2.1) *with respect to C (or an ε-efficient solution for short) if*

$$(f(x_0) - C(\varepsilon)) \cap f(S) \subset \{f(x_0)\}.$$

We denote by $\mathrm{AE}(f, C, \varepsilon)$ the set of ε-efficient solutions of (2.1) with respect to C.

As C is a solid set, it follows that $\mathrm{int}(C)$ is a nonempty pointed co-radiant set and we can also consider the set of all ε-efficient solutions of (2.1) with respect to $\mathrm{int}(C)$ (or weakly ε-efficient solutions for short):

$$\mathrm{WAE}(f, C, \varepsilon) := \mathrm{AE}(f, \mathrm{int}(C)\,, \varepsilon) = \{x \in S : (f(x) - \mathrm{int}(C)\,(\varepsilon)) \cap f(S) = \emptyset\}.$$

Notice that

$$\mathrm{int}(C)\,(0) := \bigcup_{\varepsilon > 0} \varepsilon\, \mathrm{int}(C) = \bigcup_{\varepsilon > 0} \mathrm{int}(C(\varepsilon)) \tag{3.2}$$

is an open cone, and as C is a proper co-radiant set, it follows that $0 \notin \mathrm{int}(C)\,(\varepsilon)$ $\forall\, \varepsilon \geq 0$.

Remark 3.3. Let us observe that when $\varepsilon = 0$ we have $\mathrm{AE}(f, C, 0) = \mathrm{E}(f, C(0))$ and $\mathrm{WAE}(f, C, 0) = \mathrm{E}(f, \mathrm{int}(C)\,(0))$, since the sets $C(0)$ and $\mathrm{int}(C)\,(0)$ are cones. In

what follows the notations $\mathrm{AE}(f,C,0)$ and $\mathrm{WAE}(f,C,0)$ are used in order to stress that efficient solutions with respect to the preference relations induced in Y by $C(0)$ and $\mathrm{int}(C)\,(0)$ are ε-efficient and weakly ε-efficient solutions of (2.1) with respect to C and precision $\varepsilon = 0$, respectively.

For each $\varepsilon > 0$ it follows that $\mathrm{AE}(f,C,\varepsilon) \subset \mathrm{WAE}(f,C,\varepsilon)$. Moreover, as $\mathrm{int}(C)\,(0) \subset \mathrm{int}(C(0)) \subset C(0)$, we have that

$$\mathrm{AE}(f,C,0) \subset \mathrm{WE}(f,C(0)) \subset \mathrm{WAE}(f,C,0)\,.$$

Theorem 3.4 shows several properties of the family $\{\mathrm{AE}(f,C,\varepsilon)\}_{\varepsilon\geq 0}$. As usual, for a set $K \subset Y$ we denote $f^{-1}(K) = \{x \in X : f(x) \in K\}$.

THEOREM 3.4.

(i) $\mathrm{AE}(f,C,0) \subset \mathrm{AE}(f,C,\varepsilon)\ \forall\,\varepsilon > 0$.

(ii) $\mathrm{AE}(f,C,\varepsilon_1) \subset \mathrm{AE}(f,C,\varepsilon_2)\ \forall\,\varepsilon_1,\varepsilon_2 > 0$, $\varepsilon_1 < \varepsilon_2$.

(iii) $\bigcap_{\varepsilon>0} \mathrm{AE}(f,C,\varepsilon) = \mathrm{AE}(f,C,0)$.

(iv) *Let* $(x_n) \subset S$, $(\varepsilon_n) \subset \mathbb{R}_+$, *and* $y \in Y$ *such that* $x_n \in \mathrm{AE}(f,C,\varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and* $f(x_n) \to y$. *Then* $f^{-1}(y) \cap S \subset \mathrm{WAE}(f,C,0)$.

(v) *Let* $(x_n) \subset S$ *and* $(\varepsilon_n) \subset \mathbb{R}_+$ *such that* $x_n \in \mathrm{AE}(f,C,\varepsilon_n)$ *and* $\varepsilon_n \downarrow 0$. *Consider*

$$K := \bigcap_n (f(x_n) - C(\varepsilon_n)).$$

Then $f^{-1}(K) \cap S \subset \mathrm{AE}(f,C,0)$.

Proof. Part (i). Let $\varepsilon > 0$ and $x \in \mathrm{AE}(f,C,0)$. It follows that

$$(f(x) - C(\varepsilon)) \cap f(S) \subset \left(f(x) - \bigcup_{\delta>0} C(\delta)\right) \cap f(S) = (f(x) - C(0)) \cap f(S) \subset \{f(x)\}$$

and thus $x \in \mathrm{AE}(f,C,\varepsilon)$.

Part (ii). Let $\varepsilon_1,\varepsilon_2 > 0$, $\varepsilon_1 < \varepsilon_2$, and $x \in \mathrm{AE}(f,C,\varepsilon_1)$. By Lemma 3.1(ii) we have that $C(\varepsilon_2) \subset C(\varepsilon_1)$ and we deduce that

$$(f(x) - C(\varepsilon_2)) \cap f(S) \subset (f(x) - C(\varepsilon_1)) \cap f(S) \subset \{f(x)\}.$$

Then $x \in \mathrm{AE}(f,C,\varepsilon_2)$.

Part (iii). From part (i) it follows that

$$\mathrm{AE}(f,C,0) \subset \bigcap_{\varepsilon>0} \mathrm{AE}(f,C,\varepsilon)\,.$$

Conversely, let $x \in \bigcap_{\varepsilon>0} \mathrm{AE}(f,C,\varepsilon)$. Then, for each $\varepsilon > 0$ we have

$$(f(x) - C(\varepsilon)) \cap f(S) \subset \{f(x)\}$$

and

$$(f(x) - C(0)) \cap f(S) = \bigcup_{\varepsilon>0} ((f(x) - C(\varepsilon)) \cap f(S)) \subset \{f(x)\}.$$

Therefore, $x \in \mathrm{AE}(f,C,0)$.

Part (iv). Let $x \in f^{-1}(y) \cap S$ and suppose that there exists $z \in S$ such that $f(z) \in f(x) - \operatorname{int}(C)\,(0)$. From (3.2) it follows that there exists $\varepsilon > 0$ verifying $f(z) \in f(x) - \operatorname{int}(C(\varepsilon))$. As $f(x_n) \to y$ we deduce that there exists $n_0 \in \mathbb{N}$ such that

$$f(z) + y - f(x_n) \in f(x) - \operatorname{int}(C(\varepsilon)) \quad \forall\, n \geq n_0.$$

As $\varepsilon_n \downarrow 0$, it follows from Lemma 3.1(ii) that there exists $n_1 \geq n_0$ such that

$$f(z) \in f(x_n) - \operatorname{int}(C(\varepsilon_n)) \quad \forall\, n \geq n_1,$$

and this relation contradicts the weak ε_n-efficiency of x_n, taking into account that $\mathrm{AE}(f, C, \varepsilon_n) \subset \mathrm{WAE}(f, C, \varepsilon_n)$. This finishes the proof of Part (iv).

Part (v). Consider $x \in f^{-1}(K) \cap S$. As $f(x) \in K$ and $x_n \in \mathrm{AE}(f, C, \varepsilon_n)$, we have that

$$f(x) \in (f(x_n) - C(\varepsilon_n)) \cap f(S) \subset \{f(x_n)\} \quad \forall\, n$$

and we deduce that $f(x) = f(x_n)\ \forall\, n$. Therefore,

$$(f(x) - C(\varepsilon_n)) \cap f(S) = (f(x_n) - C(\varepsilon_n)) \cap f(S) \subset \{f(x_n)\} = \{f(x)\} \quad \forall\, n.$$

Thus, by (3.1) we see that

$$(f(x) - C(0)) \cap f(S) \subset \{f(x)\}$$

and we conclude that $x \in \mathrm{AE}(f, C, 0)$. □

Remark 3.5. From Theorem 3.4(iv) it is clear that, if f is a continuous map at $x_0 \in S$ and there exist $(x_n) \subset S$ and $(\varepsilon_n) \subset \mathbb{R}_+$ such that $x_n \in \mathrm{AE}(f, C, \varepsilon_n)$, $x_n \to x_0$, and $\varepsilon_n \downarrow 0$, then $x_0 \in \mathrm{WAE}(f, C, 0)$.

Remark 3.6. As $\operatorname{int}(C)$ is also a solid pointed co-radiant set, we see that Theorem 3.4 holds if we change C by $\operatorname{int}(C)$ and $\mathrm{AE}(f, C, \varepsilon)$ by $\mathrm{WAE}(f, C, \varepsilon)$. In this case, let us observe that the conclusion in Part (iv) is $f^{-1}(y) \cap S \subset \mathrm{WAE}(f, \operatorname{int}(C)\,, 0) = \mathrm{WAE}(f, C, 0)$ since $\operatorname{int}(\operatorname{int}(C)) = \operatorname{int}(C)$.

4. Relations with other ε-efficiency concepts. In this section, we obtain various well-known ε-efficiency concepts by considering suitable (not necessarily convex) sets C in Definition 3.2. Let us observe that in subsection 4.3 we give a new ε-efficiency concept in the sense of Helbig.

4.1. ε-efficiency in the senses of Kutateladze and Németh. Let $D \subset Y$ be a solid pointed convex cone. Suppose that $0 \in D$ and consider $C := H + D$, where $H \subset D \backslash \{0\}$. C is a pointed set, since $C \subset D$ and D is a pointed cone. For each $q \in H$ it is clear that $q + D$ is a solid co-radiant set, since $\operatorname{int}(q + D) = q + \operatorname{int}(D)$ and

$$\alpha(q + D) = q + ((\alpha - 1)q + \alpha D) \subset q + D \quad \forall\, \alpha > 1.$$

Then, writing the set C as

$$C = \bigcup_{q \in H} (q + D),$$

we see that C is a solid co-radiant set and

$$C(\varepsilon) = \bigcup_{q \in H} \varepsilon(q + D) = \bigcup_{q \in H} (\varepsilon q + D) = \varepsilon H + D \quad \forall\, \varepsilon > 0. \tag{4.1}$$

Thus, from Definition 3.2 an ε-efficiency notion can be deduced by taking $C = H + D$. With this notion, for each $\varepsilon > 0$ the following ε-efficiency set is obtained:

$$x \in \mathrm{AE}(f, C, \varepsilon) \iff x \in S, \quad (f(x) - \varepsilon H - D) \cap f(S) \subset \{f(x)\}. \tag{4.2}$$

As $0 \notin C$, for each $\varepsilon > 0$ statement (4.2) becomes

$$x \in \mathrm{AE}(f, C, \varepsilon) \iff x \in S, \quad (f(x) - \varepsilon H - D) \cap f(S) = \emptyset. \tag{4.3}$$

This notion was introduced by Németh [21]. For each $\varepsilon \geq 0$, the set of all ε-efficient (resp., weakly ε-efficient) solutions in this sense, i.e., with respect to $C = H + D$ (resp., $C = \mathrm{int}(H + D)$), is denoted by $\mathrm{AE}(f, C_N, \varepsilon)$ (resp., $\mathrm{WAE}(f, C_N, \varepsilon)$).

If $H = \{q\}$, $\varepsilon > 0$, and $q \in D\backslash\{0\}$, then from (4.3) we obtain the following ε-efficiency notion:

$$x \in \mathrm{AE}(f, C, \varepsilon) \iff x \in S, \quad (f(x) - \varepsilon q - D) \cap f(S) = \emptyset.$$

This concept was introduced by Kutateladze [12], and it is the most popular notion of ε-efficiency (see [31, 25, 9, 35] for more details about it). We denote the set of ε-efficient (resp., weakly ε-efficient) solutions of (2.1) in this sense by $\mathrm{AE}(f, C_K, \varepsilon)$ (resp., $\mathrm{WAE}(f, C_K, \varepsilon)$).

Some properties of Németh's approximate solutions are collected in Proposition 4.2. The following lemma is necessary.

LEMMA 4.1.

(i) $H \subset \mathrm{int}(D) \iff C(0) = \mathrm{int}(D)$.

(ii) $\mathrm{bd}(D) \cap (D\backslash\{0\}) \subset \mathrm{cone}(H) \Rightarrow C(0) = D\backslash\{0\}$.

(iii) $\mathrm{int}(C)\,(0) = \mathrm{int}(D)$.

Proof. Part (i). Suppose that $H \subset \mathrm{int}(D)$. As D is a solid convex cone, from (4.1) we have

$$C(\varepsilon) = \varepsilon H + D \subset \varepsilon\,\mathrm{int}(D) + D \subset \mathrm{int}(D) \quad \forall\, \varepsilon > 0,$$

and $C(0) \subset \mathrm{int}(D)$. Reciprocally, let $d \in \mathrm{int}(D)$ and consider $q \in H$. Then, there exists $\varepsilon > 0$ such that $d - \varepsilon\, q \in D$. It follows that $d \in \varepsilon q + D \subset \varepsilon H + D$ and

$$\mathrm{int}(D) \subset \bigcup_{\varepsilon > 0} C(\varepsilon) = C(0)\,.$$

Next, consider $C(0) = \mathrm{int}(D)$. Then, taking $\varepsilon = 1$ in (4.1) we deduce that $H \subset H + D \subset C(0) = \mathrm{int}(D)$.

Part (ii). If $\mathrm{bd}(D) \cap (D\backslash\{0\}) = \emptyset$, then $D\backslash\{0\}$ is an open set and $H \subset \mathrm{int}(D)$. Thus, by part (i), we have that $C(0) = \mathrm{int}(D) = D\backslash\{0\}$.

Suppose that $\mathrm{bd}(D) \cap (D\backslash\{0\}) \neq \emptyset$. From (4.1) we see that $C(0) = \bigcup_{\varepsilon > 0} C(\varepsilon) \subset D\backslash\{0\}$, since D is a pointed convex cone.

Reciprocally, by the hypothesis,

$$\mathrm{bd}(D) \cap (D\backslash\{0\}) \subset \mathrm{cone}(H) = \bigcup_{\alpha > 0} \alpha\, H \subset C(0)\,. \tag{4.4}$$

Let $d \in \mathrm{int}(D)$ and take a point $d_1 \in \mathrm{bd}(D) \cap (D\backslash\{0\})$. There exist $d_2 \in D$ and $\lambda \in (0, 1)$ such that $d = \lambda d_1 + (1 - \lambda) d_2$. From (4.4) we deduce that there exist $q \in H$ and $\alpha > 0$ such that $d_1 = \alpha q$ and thus

$$d = \lambda(\alpha q) + (1 - \lambda) d_2 \in \lambda \alpha H + D \subset C(0)\,.$$

Thus, $\operatorname{int}(D) \subset C(0)$. From this inclusion and (4.4) it follows that $D\backslash\{0\} \subset C(0)$.

Part (iii). As $H \subset D$ and D is a solid convex cone,

$$\operatorname{int}(C)(0) = \bigcup_{\varepsilon>0} \varepsilon \operatorname{int}(H + D) \subset \operatorname{int}(D).$$

Let $d \in \operatorname{int}(D)$. Taking a point $q \in H$, there exists $\varepsilon > 0$ such that $d - \varepsilon q \in \operatorname{int}(D)$. Therefore, $d \in \operatorname{int}(\varepsilon q + D) \subset \varepsilon \operatorname{int}(H + D)$, and we conclude that $\operatorname{int}(D) \subset \operatorname{int}(C)(0)$. □

PROPOSITION 4.2.

(i) *If* $H \subset \operatorname{int}(D)$, *then*

$$\bigcap_{\varepsilon>0} \mathrm{AE}(f, C_N, \varepsilon) = \mathrm{WE}(f, D),$$

and if $\operatorname{bd}(D) \cap (D\backslash\{0\}) \subset \operatorname{cone}(H)$, *then*

$$\bigcap_{\varepsilon>0} \mathrm{AE}(f, C_N, \varepsilon) = \mathrm{E}(f, D).$$

(ii) *Let* $(x_n) \subset S$, $(\varepsilon_n) \subset \mathbb{R}_+$, *and* $y \in Y$ *such that* $x_n \in \mathrm{AE}(f, C_N, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and* $f(x_n) \to y$. *Then* $f^{-1}(y) \cap S \subset \mathrm{WE}(f, D)$.

(iii) *Let* $(x_n) \subset S$ *and* $(\varepsilon_n) \subset \mathbb{R}_+$ *such that* $x_n \in \mathrm{AE}(f, C_N, \varepsilon_n)$ *and* $\varepsilon_n \downarrow 0$. *Consider*

$$K := \bigcap_n (f(x_n) - \varepsilon_n H - D).$$

If $H \subset \operatorname{int}(D)$, *then* $f^{-1}(K) \cap S \subset \mathrm{WE}(f, D)$ *and if* $\operatorname{bd}(D) \cap (D\backslash\{0\}) \subset \operatorname{cone}(H)$, *then* $f^{-1}(K) \cap S \subset \mathrm{E}(f, D)$.

Proof. If $H \subset \operatorname{int}(D)$, then $C(0) = \operatorname{int}(D)$ by Lemma 4.1(i), and so $\mathrm{AE}(f, C_N, 0) = \mathrm{WE}(f, D)$. Moreover, from Lemma 4.1(iii), it follows that $\operatorname{int}(C)(0) = \operatorname{int}(D)$, and we have $\mathrm{WAE}(f, C_N, 0) = \mathrm{WE}(f, D)$. If $\operatorname{bd}(D) \cap (D\backslash\{0\}) \subset \operatorname{cone}(H)$, we deduce from Lemma 4.1(ii) that $C(0) = D\backslash\{0\}$ and $\mathrm{AE}(f, C_N, 0) = \mathrm{E}(f, D)$. Then properties (i)–(iii) hold by Theorem 3.4(iii)–(v). □

In Proposition 4.2 we have extended several properties proved in the literature for the ε-efficiency set in the sense of Kutateladze (see, for example, [9, Lemma 3.3 and Theorem 3.4]) to the approximate solutions in the sense of Németh. We can deduce these properties by considering $H = \{q\}$ in Proposition 4.2.

4.2. ε-efficiency in the sense of White. Let D be a proper solid convex cone such that $0 \in D$. Assume that $\operatorname{cl}(D)$ is a pointed set, consider $q \in \operatorname{int}(D)$, and define

$$C := D \cap (q - D)^c.$$

LEMMA 4.3.

(i) C *is a solid pointed co-radiant set.*

(ii) $C(\varepsilon) = D \cap (\varepsilon q - D)^c \ \forall\, \varepsilon > 0$.

(iii) $C(0) = D\backslash\{0\}$ *and* $\operatorname{int}(C)(0) = \operatorname{int}(D)$.

Proof. Part (i). Suppose that $\operatorname{int}(C) = \emptyset$. Then $\operatorname{int}(D) \cap \operatorname{int}((q - D)^c) = \emptyset$; hence, $\operatorname{int}(D) \subset [\operatorname{int}((q - D)^c)]^c = q - \operatorname{cl}(D)$ and $\operatorname{int}(D) \subset \operatorname{int}(q - \operatorname{cl}(D)) = q - \operatorname{int}(D)$, since D is a solid convex cone. Thus, $0 \in \operatorname{int}(D)$, and it follows that $D = Y$, which is a contradiction.

C is pointed since $C \subset \mathrm{cl}(D)$ and $\mathrm{cl}(D)$ is a pointed set.

Let $d \in C$ and $\alpha > 1$. It is clear that $\alpha\, d \in D$. Moreover, if $\alpha\, d \in q - D$, then there exists $v \in D$ such that $\alpha\, d = q - v$ and

$$d = q - (v + (\alpha - 1)d).$$

As D is a convex cone and $\alpha > 1$, we have $d \in q - D$, which is a contradiction. Then $\alpha\, d \notin q - D$ and therefore $\alpha\, d \in C$.

Part (ii). Let $\varepsilon > 0$ and $z \in D \cap (\varepsilon q - D)^c$. As D is a cone, we have that $(1/\varepsilon)z \in D$. Moreover, $(1/\varepsilon)z \in (q - D)^c$. Indeed, if $(1/\varepsilon)z \in q - D$, then $z \in \varepsilon q - D$, which is absurd. Thus, $(1/\varepsilon)z \in D \cap (q - D)^c$, and it follows that

$$D \cap (\varepsilon q - D)^c \subset \varepsilon(D \cap (q - D)^c) = \varepsilon C = C(\varepsilon)\,.$$

From here we deduce that

$$\varepsilon(D \cap (q - D)^c) = \varepsilon(D \cap ((1/\varepsilon)(\varepsilon q) - D)^c) \subset D \cap (\varepsilon q - D)^c,$$

and we conclude that $C(\varepsilon) = D \cap (\varepsilon q - D)^c$.

Part (iii). First, let us see that

$$\bigcap_{\varepsilon > 0} (\varepsilon q - D) = -\mathrm{cl}(D)\,. \tag{4.5}$$

As $\mathrm{cl}(-D) + \mathrm{int}(-D) \subset \mathrm{int}(-D)$, it follows that $\mathrm{cl}(-D) - \varepsilon q \subset \mathrm{int}(-D)\ \forall \varepsilon > 0$. Hence,

$$-\mathrm{cl}(D) \subset \varepsilon q + \mathrm{int}(-D) \subset \varepsilon q - D \quad \forall\, \varepsilon > 0.$$

Therefore, $-\mathrm{cl}(D) \subset \bigcap_{\varepsilon > 0}(\varepsilon q - D)$. Now, we prove the reciprocal inclusion. If $y \in \bigcap_{\varepsilon > 0}(\varepsilon q - D)$, then $\forall\, \varepsilon > 0$ there exists $d_\varepsilon \in D$ such that $y = \varepsilon q - d_\varepsilon$. Hence,

$$\lim_{\varepsilon \downarrow 0}(-d_\varepsilon) = \lim_{\varepsilon \downarrow 0}(y - \varepsilon q) = y \in -\mathrm{cl}(D)\,,$$

and we have (4.5).

As $\mathrm{cl}(D)$ is a pointed cone, it follows that $D \backslash \{0\} \subset (-\mathrm{cl}(D))^c$ and, taking into account (4.5),

$$C(0) = \bigcup_{\varepsilon > 0} D \cap (\varepsilon q - D)^c = D \cap \left(\bigcap_{\varepsilon > 0} (\varepsilon q - D) \right)^c = D \cap (-\mathrm{cl}(D))^c = D \backslash \{0\}.$$

Analogously, we have

$$\mathrm{int}(C)\,(0) = \bigcup_{\varepsilon > 0} \mathrm{int}(D \cap (\varepsilon q - D)^c) = \mathrm{int}(D) \cap \left(\bigcup_{\varepsilon > 0} \mathrm{int}((\varepsilon q - D)^c) \right)$$

$$= \mathrm{int}(D) \cap \left(\bigcup_{\varepsilon > 0} (\varepsilon q - \mathrm{cl}(D))^c \right) = \mathrm{int}(D) \cap (-\mathrm{cl}(D))^c = \mathrm{int}(D)\,. \qquad \square$$

By Definition 3.2, for each $\varepsilon \geq 0$, the following ε-efficiency concept is obtained:

$$x \in \mathrm{AE}(f, C, \varepsilon) \iff x \in S,\ (f(x) - (D \cap (\varepsilon q - D)^c)) \cap f(S) = \emptyset$$

$$\iff x \in S,\ f(z) \in f(x) - \varepsilon q + D \qquad \forall\, z \in S \text{ such that } f(z) \in f(x) - D.$$

This notion was introduced by White [31]. We denote the set of all ε-efficient (resp., weakly ε-efficient) solutions in this sense by $\mathrm{AE}(f, C_W, \varepsilon)$ (resp., $\mathrm{WAE}(f, C_W, \varepsilon)$). Its elements satisfy the following properties.

PROPOSITION 4.4.

(i) $\bigcap_{\varepsilon>0} \mathrm{AE}(f, C_W, \varepsilon) = \mathrm{E}(f, D)$.

(ii) *Let* $(x_n) \subset S$, $(\varepsilon_n) \subset \mathbb{R}_+$, *and* $y \in Y$ *such that* $x_n \in \mathrm{AE}(f, C_W, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and* $f(x_n) \to y$. *Then* $f^{-1}(y) \cap S \subset \mathrm{WE}(f, D)$.

(iii) *Let* $(x_n) \subset S$ *and* $(\varepsilon_n) \subset \mathbb{R}_+$ *such that* $x_n \in \mathrm{AE}(f, C_W, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and*

$$K := \bigcap_n (f(x_n) - (D \cap (\varepsilon_n q - D)^c)).$$

Then $f^{-1}(K) \cap S \subset \mathrm{E}(f, D)$.

Proof. By Lemma 4.3(iii) we deduce that $\mathrm{WAE}(f, C_W, 0) = \mathrm{WE}(f, D)$ and $\mathrm{AE}(f, C_W, 0) = \mathrm{E}(f, D)$. Then, the proposition is a consequence of Theorem 3.4(iii)–(v). □

In [35, Propositions 2.6(2) and 2.8], Yokoyama proved parts (i) and (iii) of Proposition 4.4 by considering approximate elements of a set. In Proposition 4.4, we have extended these results to vector optimization problems and we have given an additional property.

4.3. A new ε-efficiency in the sense of Helbig. Suppose that D is a solid pointed cone not necessarily convex such that $0 \in D$. Let $g_i \in D^+\backslash\{0\}$, $i = 1, 2, \ldots, m$, and

$$g(y) := \max_{1 \le i \le m} \{g_i(y)\}. \tag{4.6}$$

Let $\mathcal{M}^{s+} = \{h : Y \to \mathbb{R} : h(d) > 0 \ \forall\, d \in D\backslash\{0\}\}$. It is clear that $g \in \mathcal{M}^{s+}$ if $g_i \in D^{s+}$ for some i. However, it is possible that $g \in \mathcal{M}^{s+}$ and $g_i \notin D^{s+} \ \forall\, i$. For example, if $Y = \mathbb{R}^2$, $D = \mathbb{R}^2_+$, $m = 2$, $g_1(y_1, y_2) = y_1$, and $g_2(y_1, y_2) = y_2$, it is obvious that $g_i \notin D^{s+}$, $i = 1, 2$, and $g \in \mathcal{M}^{s+}$.

For each $\alpha \in \mathbb{R}$ we denote

$$[g > \alpha] = \{y \in Y : g(y) > \alpha\}.$$

Consider the set $C := D \cap [g > 1]$.

LEMMA 4.5.

(i) C *is a solid pointed co-radiant set.*

(ii) $C(\varepsilon) = D \cap [g > \varepsilon] \ \forall\, \varepsilon \ge 0$.

(iii) $\mathrm{int}(D) = \mathrm{int}(C)\,(0) \subset C(0) \subset D\backslash\{0\}$.

(iv) *If* $g \in \mathcal{M}^{s+}$, *then* $C(0) = D\backslash\{0\}$.

Proof. Part (i). It is obvious that C is a pointed co-radiant set, and we prove just that C is solid. Indeed, as D is a proper solid cone, there exist $d \in \mathrm{int}(D)$ and $\alpha := g(d) > 0$, since $g_i \in D^+\backslash\{0\}$, and thus $g_i(d) > 0 \ \forall\, i = 1, 2, \ldots, m$. Then $(2/\alpha)d \in \mathrm{int}(D) \cap [g > 1] = \mathrm{int}(C)$, and C is solid.

Part (ii). For $\varepsilon > 0$ it follows easily since D is a cone and g is a positively homogeneous functional. For $\varepsilon = 0$ it is clear.

Part (iii). Let $d \in \mathrm{int}(D)$. As $g_i \in D^+\backslash\{0\}$, we see that $g(d) > 0$. Then, there exists $\varepsilon > 0$ such that $d \in [g > \varepsilon]$ and we deduce that $d \in \mathrm{int}(C)\,(\varepsilon)$. Thus, it follows that $\mathrm{int}(D) \subset \mathrm{int}(C)\,(0)$.

By part (ii) it is obvious that $C(0) \subset D\backslash\{0\}$. Moreover, we deduce that $\operatorname{int}(D) = \operatorname{int}(C)(0)$, since $\operatorname{int}(C)(0)$ is open.

Part (iv). If $g \in \mathcal{M}^{s+}$, then $g(d) > 0\ \forall\, d \in D\backslash\{0\}$ and we see that $D\backslash\{0\} \subset C(0)$. By part (iii) we have the reciprocal inclusion and, therefore, $C(0) = D\backslash\{0\}$. □

By Definition 3.2, for each $\varepsilon \geq 0$ we obtain the following ε-efficiency set:

$$\begin{aligned} x \in \mathrm{AE}(f, C, \varepsilon) &\iff x \in S,\ (f(x) - (D \cap [g > \varepsilon])) \cap f(S) = \emptyset \\ &\iff x \in S,\ (f(x) - f(S)) \cap (D \cap [g > \varepsilon]) = \emptyset \\ \iff [x \in S,\ z \in S,\ f(z) \in f(x) - D &\Rightarrow g_i(f(x)) - \varepsilon \leq g_i(f(z)) \forall\, i = 1, 2, \ldots, m]. \end{aligned}$$

If we consider the particular case $m = 1$, then we obtain the ε-efficiency notion introduced by Helbig [8]. By using this generalization, the decision-maker can take several criteria g_i into account in order to solve (2.1). We denote the set of ε-efficient (resp., weakly ε-efficient) solutions in this sense by $\mathrm{AE}(f, C_H, \varepsilon)$ (resp., $\mathrm{WAE}(f, C_H, \varepsilon)$). Its elements satisfy the following properties.

Proposition 4.6.

(i) $\mathrm{E}(f, D) \subset \bigcap_{\varepsilon > 0} \mathrm{AE}(f, C_H, \varepsilon) \subset \mathrm{WE}(f, D)$, *and if* $g \in \mathcal{M}^{s+}$, *then*

$$\bigcap_{\varepsilon > 0} \mathrm{AE}(f, C_H, \varepsilon) = \mathrm{E}(f, D)\,.$$

(ii) *Let* $(x_n) \subset S$, $(\varepsilon_n) \subset \mathbb{R}_+$, *and* $y \in Y$ *such that* $x_n \in \mathrm{AE}(f, C_H, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and* $f(x_n) \to y$. *Then* $f^{-1}(y) \cap S \subset \mathrm{WE}(f, D)$.

(iii) *Let* $(x_n) \subset S$ *and* $(\varepsilon_n) \subset \mathbb{R}_+$ *such that* $x_n \in \mathrm{AE}(f, C_H, \varepsilon_n)$ *and* $\varepsilon_n \downarrow 0$. *Consider*

$$K := \bigcap_n (f(x_n) - (D \cap [g > \varepsilon_n])).$$

Then $f^{-1}(K) \cap S \subset \mathrm{WE}(f, D)$ *and if* $g \in \mathcal{M}^{s+}$, *then* $f^{-1}(K) \cap S \subset \mathrm{E}(f, D)$.

Proof. From Lemma 4.5(iii) we deduce that

$$\mathrm{E}(f, D) \subset \mathrm{AE}(f, C_H, 0) \subset \mathrm{WE}(f, D)\,.$$

Moreover, by Lemma 4.5(iii)–(iv), we have that $\mathrm{WAE}(f, C_H, 0) = \mathrm{WE}(f, D)$ and for each $g \in \mathcal{M}^{s+}$ we see that $\mathrm{AE}(f, C_H, 0) = \mathrm{E}(f, D)$. Then, parts (i)–(iii) follow easily from Theorem 3.4(iii)–(v). □

4.4. ε-efficiency in the sense of Tanaka. In this subsection we assume that the final space Y is normed and we consider a solid pointed (not necessarily convex) cone D such that $0 \in D$ and the following set:

$$C := D \cap \mathrm{cl}(\mathrm{B})^c\,,$$

where B denotes the open ball of center 0 and radius 1.

Lemma 4.7.

(i) C *is a solid pointed co-radiant set.*

(ii) $C(\varepsilon) = D \cap \mathrm{cl}(\varepsilon \mathrm{B})^c\ \forall\, \varepsilon > 0$.

(iii) $C(0) = D\backslash\{0\}$ *and* $\operatorname{int}(C)(0) = \operatorname{int}(D)$.

Proof. Part (i). First, we prove that C is a solid set. Indeed, there exists a point $q \in \operatorname{int}(D)$, $q \neq 0$, since D is a solid cone. Then, $(2/\|q\|)q \in \operatorname{int}(D) \cap \mathrm{cl}(\mathrm{B})^c = \operatorname{int}(C)$, and C is a solid set.

Moreover, C is a pointed set, since $C \subset D$ and D is a pointed cone. Let $y \in C$ and $\alpha > 1$. As D is a cone, we have that $\alpha y \in D$. Moreover, $\|\alpha y\| = \alpha\|y\| > 1$ since $\alpha > 1$ and $y \notin \mathrm{cl}(\mathrm{B})$. Then $\alpha y \in C$, and it follows that C is a co-radiant set.

Part (ii). Let $y \in C$ and $\varepsilon > 0$. It is clear that $\varepsilon y \in D$ and $\|\varepsilon y\| = \varepsilon\|y\| > \varepsilon$ since $y \in \mathrm{cl}(\mathrm{B})^c$. It follows that $\varepsilon y \in D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c$ and $C(\varepsilon) \subset D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c$. Similarly, if $y \in D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c$, then $(1/\varepsilon)y \in D \cap \mathrm{cl}(\mathrm{B})^c = C$. Thus, $y \in \varepsilon C$ and $C(\varepsilon) = D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c$.

Part (iii). By part (ii) it is clear that

$$C(0) = \bigcup_{\varepsilon>0} D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c = D \cap \left(\bigcap_{\varepsilon>0} \mathrm{cl}(\varepsilon\mathrm{B})\right)^c = D\backslash\{0\}.$$

Analogously,

$$\mathrm{int}(C)\,(0) = \bigcup_{\varepsilon>0} \mathrm{int}(D) \cap \mathrm{cl}(\varepsilon\mathrm{B})^c = \mathrm{int}(D) \cap \left(\bigcap_{\varepsilon>0} \mathrm{cl}(\varepsilon\mathrm{B})\right)^c = \mathrm{int}(D)\,. \qquad \square$$

We denote by $\mathrm{AE}(f, C_T, \varepsilon)$ (resp., $\mathrm{WAE}(f, C_T, \varepsilon)$) the ε-efficiency (resp., weak ε-efficiency) set with respect to this set C. For each $\varepsilon \geq 0$ it follows that

$$\begin{aligned} x \in \mathrm{AE}(f, C_T, \varepsilon) &\iff x \in S,\ (f(x) - (D \cap \mathrm{cl}(\varepsilon\mathrm{B})^c)) \cap f(S) = \emptyset \\ &\iff x \in S,\ (f(x) - D) \cap f(S) \subset f(x) + \mathrm{cl}(\varepsilon\mathrm{B})\,. \end{aligned}$$

This concept of ε-efficiency was introduced by Tanaka [28]. Next, we give some properties of this notion, which extend a previous property proved by Tanaka in [28, Proposition 3.3]. The proof is omitted since it is similar to the proof of Proposition 4.4.

Proposition 4.8.

(i) $\bigcap_{\varepsilon>0} \mathrm{AE}(f, C_T, \varepsilon) = \mathrm{E}(f, D)$.

(ii) *Let* $(x_n) \subset S$, $(\varepsilon_n) \subset \mathbb{R}_+$, *and* $y \in Y$ *such that* $x_n \in \mathrm{AE}(f, C_T, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and* $f(x_n) \to y$. *Then* $f^{-1}(y) \cap S \subset \mathrm{WE}(f, D)$.

(iii) *Let* $(x_n) \subset S$ *and* $(\varepsilon_n) \subset \mathbb{R}_+$ *such that* $x_n \in \mathrm{AE}(f, C_T, \varepsilon_n)$, $\varepsilon_n \downarrow 0$, *and*

$$K := \bigcap_n (f(x_n) - (D \cap \mathrm{cl}(\varepsilon_n\mathrm{B})^c)).$$

Then $f^{-1}(K) \cap S \subset \mathrm{E}(f, D)$.

5. A general scalarization for ε-efficient solutions. In the literature, approximate solutions of (2.1) are usually studied in convex problems via Kutateladze's definition and using scalarization methods which characterize this kind of solutions by means of solutions of related scalar optimization problems (see, for example, [1, Theorem 2.1], [2, Theorem 2.1], [16, Theorems 1 and 2], [17, Lemma 2.1], and [31, Lemma 3.2]). However, scalarization methods for ε-efficiency in nonconvex vector optimization problems or using ε-efficiency notions different from Kutateladze's definition are very limited (see [6, Lemma 3.1], [13], [18, Propositions 3.1 and 3.2], and [34, Lemmas 4.1 and 4.2]).

In this section we deduce several scalarizations for ε-efficient solutions obtained by Definition 3.2 and different solid pointed star-shaped co-radiant sets C. We recall that a set C is star-shaped if there exists $q \in C$ such that

$$\alpha q + (1-\alpha)y \in C \quad \forall\, y \in C, \qquad \forall\, \alpha \in (0,1). \tag{5.1}$$

We denote by $\operatorname{kern}(C)$ the set of all points $q \in C$ such that (5.1) holds. It is easy to prove that if C is a co-radiant set, then $\operatorname{kern}(C)$ is also a co-radiant set.

First, we obtain a necessary condition for ε-efficient solutions through a scalarization process based on the following nonconvex separation theorem due to Göpfert et al. [4, Theorem 2.3.1]. We denote $\mathbb{R}q = \{sq : s \in \mathbb{R}\}$.

THEOREM 5.1. *Let $G \subset Y$ be a proper closed solid set and $q \in Y$ be such that*

$$\begin{aligned} G + (0,\infty)q &\subset \operatorname{int}(G)\,, \\ Y &= \mathbb{R}q - G, \\ \forall\, y \in Y,\ \exists\, s \in \mathbb{R} &\text{ such that } y + sq \notin G. \end{aligned}$$

Then, the functional $\varphi_{q,G} : Y \to \mathbb{R}$ defined by

$$\varphi_{q,G}(y) = \inf\{s \in \mathbb{R} : y \in sq - G\} \tag{5.2}$$

is a continuous functional such that

$$\begin{aligned} \{y \in Y : \varphi_{q,G}(y) < c\} &= cq - \operatorname{int}(G) \quad \forall\, c \in \mathbb{R}, \\ \{y \in Y : \varphi_{q,G}(y) = c\} &= cq - \operatorname{bd}(G) \quad \forall\, c \in \mathbb{R}, \\ \varphi_{q,G}(-G) \le 0, &\qquad \varphi_{q,G}(-\operatorname{bd}(G)) = 0. \end{aligned}$$

We denote by $\operatorname{AMin}(g,\varepsilon)$ the set of ε-approximate solutions of the scalar optimization problem

$$\operatorname{Min}\{g(x) : x \in F\},$$

i.e.,

$$\operatorname{AMin}(g,\varepsilon) = \{x \in F : g(x) - \varepsilon \le g(z)\, \forall\, z \in F\},$$

where $g : X \to \mathbb{R}$, $F \subset X$, $F \neq \emptyset$, and $\varepsilon \ge 0$.

LEMMA 5.2. *Let C be a proper star-shaped co-radiant set such that* $\operatorname{kern}(C)$ *is solid. Then the following hold:*

(i) $d + \lambda q \in C\ \forall\, d \in C,\ \forall\, q \in \operatorname{kern}(C),\ \forall\, \lambda > 0$.
(ii) $d + \lambda q \in C(\varepsilon)\ \forall\, \varepsilon > 0,\ \forall\, d \in C(\varepsilon),\ \forall\, q \in \operatorname{kern}(C),\ \forall\, \lambda > 0$.
(iii) $\operatorname{cl}(C(\varepsilon)) + (0,\infty)q \subset \operatorname{int}(C(\varepsilon))\ \forall\, \varepsilon > 0,\ \forall\, q \in \operatorname{int}(\operatorname{kern}(C))$.
(iv) $Y = \mathbb{R}q - C(\varepsilon)\ \forall\, q \in \operatorname{int}(C),\ \forall\, \varepsilon > 0$.
(v) $Y = \mathbb{R}q + \varepsilon \operatorname{int}(\operatorname{kern}(C))\ \forall\, q \in \operatorname{int}(\operatorname{kern}(C)),\ \forall\, \varepsilon > 0$.
(vi) $\forall\, q \in \operatorname{int}(\operatorname{kern}(C)),\ \forall\, \varepsilon > 0,\ \forall\, y \in Y,\ \exists\, s \in \mathbb{R}$ *such that* $y + sq \notin \operatorname{cl}(C(\varepsilon))$.
(vii) $\operatorname{int}(\operatorname{cl}(C(\varepsilon))) = \operatorname{int}(C(\varepsilon))\ \forall\, \varepsilon > 0$.

Proof. Part (i). Let $d \in C$, $q \in \operatorname{kern}(C)$, and $\lambda > 0$. As C is a star-shaped co-radiant set and $q \in \operatorname{kern}(C)$, it follows that

$$d + \lambda q = (\lambda + 1)\left(\frac{1}{\lambda + 1} d + \left(1 - \frac{1}{\lambda + 1}\right) q\right) \in C.$$

Part (ii). Let $d \in C(\varepsilon)$, $q \in \operatorname{kern}(C)$, and $\lambda > 0$. As $(1/\varepsilon)d \in C$, by part (i) it follows that $(1/\varepsilon)d + (\lambda/\varepsilon)q \in C$. Thus, $d + \lambda q \in \varepsilon C = C(\varepsilon)$.

Part (iii). Let $q \in \operatorname{int}(\operatorname{kern}(C))$ and $\varepsilon > 0$. First, we prove that

$$C(\varepsilon) + (0,\infty)q \subset \operatorname{int}(C(\varepsilon))\,. \tag{5.3}$$

Indeed, consider $d \in C(\varepsilon)$ and $\lambda > 0$. There exists a neighborhood U of 0 such that $q + U \subset \ker(C)$, and by Part (ii) we deduce that $d + \lambda(q + U) \subset C(\varepsilon)$. Thus, it follows that $d + \lambda q \in \operatorname{int}(C(\varepsilon))$.

Next, we prove that $\operatorname{cl}(C(\varepsilon)) + (0,\infty)q \subset \operatorname{int}(C(\varepsilon))$. Let $d \in \operatorname{cl}(C(\varepsilon))$ and $\lambda > 0$. There exists $v \in C(\varepsilon)$ such that $q + (1/\lambda)(d - v) \in \operatorname{int}(\ker(C))$. Then, by (5.3) we see that $d + \lambda q = v + \lambda(q + (1/\lambda)(d - v)) \in \operatorname{int}(C(\varepsilon))$ and Part (iii) holds.

Part (iv). Let $q \in \operatorname{int}(C)$, $\varepsilon > 0$, and $y \in Y$. There exists $\delta \in (0,1)$ such that $q - (\delta/\varepsilon)y \in C$. As $\delta < 1$ and $C(\varepsilon)$ is a co-radiant set by Lemma 3.1(i), it follows that

$$y \in (\varepsilon/\delta)q - (1/\delta)(\varepsilon C) \subset \mathbb{R}q - C(\varepsilon)\,.$$

Part (v). Let $q \in \operatorname{int}(\ker(C))$, $\varepsilon > 0$, and $y \in Y$. As in the proof of Part (iv) we see that there exists $\delta \in (0,1)$ such that $y \in (\varepsilon/\delta)q - \varepsilon((1/\delta)\operatorname{int}(\ker(C)))$, and it follows that $y \in \mathbb{R}q - \varepsilon\operatorname{int}(\ker(C))$, since $\operatorname{int}(\ker(C))$ is a co-radiant set. Therefore, we have that $Y \subset \mathbb{R}q - \varepsilon\operatorname{int}(\ker(C))$, which implies that $Y = \mathbb{R}q + \varepsilon\operatorname{int}(\ker(C))$.

Part (vi). Suppose that there exist $q \in \operatorname{int}(\ker(C))$, $\varepsilon > 0$, and $y \in Y$ such that $y + \mathbb{R}q \subset \operatorname{cl}(C(\varepsilon))$. Then, by Part (v) we deduce that

$$Y = (y + \mathbb{R}q) + \varepsilon\operatorname{int}(\ker(C)) - y \subset \operatorname{cl}(C(\varepsilon)) + \varepsilon\operatorname{int}(\ker(C)) - y.$$

From Part (iii) it follows that $\operatorname{cl}(C(\varepsilon)) + \varepsilon\operatorname{int}(\ker(C)) \subset \operatorname{int}(C(\varepsilon))$. Therefore, $Y \subset \varepsilon\operatorname{int}(C) - y$, which is a contradiction, since C is a proper set.

Part (vii). It is clear that $\operatorname{int}(C(\varepsilon)) \subset \operatorname{int}(\operatorname{cl}(C(\varepsilon)))$. Reciprocally, let $d \in \operatorname{int}(\operatorname{cl}(C(\varepsilon)))$ and $q \in \operatorname{int}(\ker(C))$. There exists $\delta > 0$ such that $d - \delta q \in \operatorname{cl}(C(\varepsilon))$. Then, by Part (iii) we deduce that

$$d \in \operatorname{cl}(C(\varepsilon)) + \delta q \subset \operatorname{int}(C(\varepsilon))\,,$$

and therefore $\operatorname{int}(\operatorname{cl}(C(\varepsilon))) \subset \operatorname{int}(C(\varepsilon))$. □

THEOREM 5.3. *Let C be a proper star-shaped co-radiant set such that $\ker(C)$ is solid, $q \in \operatorname{int}(\ker(C))$, and $\varepsilon > 0$. Then the following holds:*

$$x_0 \in \operatorname{WAE}(f, C, \varepsilon) \Rightarrow x_0 \in \operatorname{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big),$$

where $\varphi_{q,C(\varepsilon),f(x_0)}(y) := \varphi_{q,\operatorname{cl}(C(\varepsilon))}(y - f(x_0))\ \forall\, y \in Y$.

Proof. Let $\varepsilon > 0$ and consider $G := \operatorname{cl}(C(\varepsilon))$. By parts (iii), (iv), and (vi) of Lemma 5.2, we deduce that G satisfies the hypotheses of Theorem 5.1. Then, from this theorem we deduce that

$$\{y \in Y : \varphi_{q,\operatorname{cl}(C(\varepsilon))}(y) < 0\} = -\operatorname{int}(\operatorname{cl}(C(\varepsilon)))\,. \tag{5.4}$$

For each $x_0 \in \operatorname{WAE}(f, C, \varepsilon)$ we have that

$$(f(S) - f(x_0)) \cap -\operatorname{int}(C(\varepsilon)) = \emptyset.$$

Then, by (5.4) and Lemma 5.2(vii) we see that

$$(\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x) = \varphi_{q,\operatorname{cl}(C(\varepsilon))}(f(x) - f(x_0)) \geq 0 \quad \forall\, x \in S.$$

Moreover, by (5.2) it is clear that

$$(\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x_0) = \varphi_{q,\operatorname{cl}(C(\varepsilon))}(0) = \inf\{s \in \mathbb{R} : sq \in \operatorname{cl}(C(\varepsilon))\} \leq \varepsilon.$$

Thus, $(\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x_0) - \varepsilon \leq (\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x)\ \forall\, x \in S$, and we conclude that $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$. ∎

Gerth and Weidner [3, section 3] and Rubinov and Gasimov [22, Theorem 7.2] have obtained necessary conditions for weakly efficient solutions using Minkowski-type functionals similar to $\varphi_{q,C(\varepsilon),f(x_0)}$. In Theorem 5.3 we have extended these necessary conditions to the weak ε-efficiency set.

Necessary conditions for the ε-efficiency set in the sense of Kutateladze have been proved via Minkowski-type functionals by Göpfert et al. [4, section 3.1.1] and Tammer [27, Theorem 1]. In Theorem 5.3 we have extended these results to other ε-efficiency concepts since, in the theorem, we have obtained necessary conditions for the general ε-efficiency notion introduced in Definition 3.2 based on the Minkowski-type functional $\varphi_{q,C(\varepsilon),f(x_0)}$.

Next, we extend Theorem 5.3 for some vectors $q \in \mathrm{cl}(\mathrm{int}(\mathrm{kern}(C)))$.

LEMMA 5.4. *Let $G \subset Y$ and let $(\alpha_n) \subset \mathbb{R}$ be such that $\alpha_n \downarrow 0$. Consider $q \in Y$ and the sequence (q_n), where $q_n := (1+\alpha_n)q\ \forall\, n$. Then, $\varphi_{q_n,G}(y) \to \varphi_{q,G}(y)\ \forall\, y \in Y$, where $\varphi_{q_n,G}$ and $\varphi_{q,G}$ are given by* (5.2).

Proof. Let $y \in Y$. For each $s \in \mathbb{R}$ such that $y \in sq - G$, it follows that $y \in (s/(1+\alpha_n))q_n - G$. Then, $\varphi_{q_n,G}(y) \leq s/(1+\alpha_n)$ and we deduce that

$$(1+\alpha_n)\varphi_{q_n,G}(y) \leq \varphi_{q,G}(y). \tag{5.5}$$

Analogously, for each $s \in \mathbb{R}$ such that $y \in sq_n - G$, it follows that $y \in s(1+\alpha_n)q - G$, and we have that

$$\varphi_{q,G}(y) \leq \varphi_{q_n,G}(y)(1+\alpha_n). \tag{5.6}$$

Combining (5.5) and (5.6) we see that

$$\varphi_{q,G}(y) \leq \varphi_{q_n,G}(y)(1+\alpha_n) \leq \varphi_{q,G}(y)$$

and taking the limit when $n \to \infty$ we conclude that $\varphi_{q_n,G}(y) \to \varphi_{q,G}(y)\ \forall\, y \in Y$. ∎

PROPOSITION 5.5. *Let C be a proper star-shaped co-radiant set such that* $\mathrm{kern}(C)$ *is solid. Consider $\varepsilon > 0$, $q \in Y$, $\alpha_n \downarrow 0$, and a sequence (q_n), where $q_n = (1+\alpha_n)q$ and $q_n \in \mathrm{int}(\mathrm{kern}(C))\ \forall\, n$. If $x_0 \in \mathrm{WAE}(f, C, \varepsilon)$, then $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$.*

Proof. Let $x_0 \in \mathrm{WAE}(f, C, \varepsilon)$. From Theorem 5.3 we have that

$$(\varphi_{q_n,C(\varepsilon),f(x_0)} \circ f)(x_0) - \varepsilon \leq (\varphi_{q_n,C(\varepsilon),f(x_0)} \circ f)(x) \quad \forall\, x \in S, \qquad \forall\, n$$

and taking the limit when $n \to \infty$ we deduce from Lemma 5.4 that

$$(\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x_0) - \varepsilon \leq (\varphi_{q,C(\varepsilon),f(x_0)} \circ f)(x) \quad \forall\, x \in S. \qquad ∎$$

Remark 5.6. Let us observe that Theorem 5.3 and Proposition 5.5 give necessary conditions for ε-efficient solutions since $\mathrm{AE}(f, C, \varepsilon) \subset \mathrm{WAE}(f, C, \varepsilon)$.

In Proposition 5.7 we use the recession cone 0^+C of a star-shaped set C to obtain a simple sufficient condition to have $\mathrm{int}(\mathrm{kern}(C)) \neq \emptyset$.

PROPOSITION 5.7. *Let C be a star-shaped set and $q \in \mathrm{kern}(C)$. Then $q + 0^+C \subset \mathrm{kern}(C)$, and* $\mathrm{kern}(C)$ *is a solid set when 0^+C is a solid cone.*

Proof. Consider $d \in 0^+C$, $y \in C$, and $\alpha \in (0,1)$. It is clear that

$$\alpha(q+d) + (1-\alpha)y = \alpha q + (1-\alpha)y + \alpha d \in C + \alpha 0^+C \subset C$$

and $q + 0^+C \subset \operatorname{kern}(C)$. Moreover, $\operatorname{kern}(C)$ is a solid set when 0^+C is a solid cone since $q + \operatorname{int}(0^+C) \subset \operatorname{int}(\operatorname{kern}(C))$. □

Usually, sufficient conditions for efficient solutions are obtained via scalarization methods based on monotone functionals (see, for example, [33, Theorem 9]). Next, we obtain sufficient conditions for ε-efficient solutions through a scalarization process whose functional verifies the following new monotonicity concept. In the rest of this section we assume that Y is a normed space.

DEFINITION 5.8. *Let $K \subset Y$ be a cone. We say that a functional $g : Y \to \mathbb{R}$ is strictly local K-monotone at $y_0 \in Y$ if there exist $\sigma > 0$ and $\rho > 0$ such that*

$$z \in y_0 - (K \cap \rho \mathrm{B}), \quad y \in z - K \Rightarrow g(y) \leq g(z), \tag{5.7}$$

$$y \in y_0 - (K \cap \rho \mathrm{B}) \Rightarrow g(y) + \sigma \|y - y_0\| \leq g(y_0). \tag{5.8}$$

We will say that g is strictly local K-monotone at y_0 with constants σ and ρ. Condition (5.7) tells us that g is a monotone functional with respect to the preference relation defined by the cone K at points near to y_0 (we will say that g is local K-monotone at y_0). These functionals are frequently used to obtain sufficient conditions for the efficient solutions of vector optimization problems. Let us observe that (5.7) is a "local" condition. For example, consider $Y = \mathbb{R}$, $K = \mathbb{R}_+$, and

$$g(y) = \begin{cases} \cos y & \text{if} \quad y \leq 0, \\ 1 & \text{if} \quad y > 0. \end{cases}$$

For each $y_0 > 0$ it is clear that g verifies (5.7) taking $0 < \rho \leq y_0$. However, g does not verify (5.7) at $y_0 > 0 \; \forall \, \rho > 0$.

Property (5.8) says that y_0 is a strict (or sharp) local maximum of order 1 for the scalar optimization problem $\operatorname{Max}\{g(y) : y \in y_0 - K\}$. Below simple examples of strictly local K-monotone functionals are given. Parts (i)–(iii) are obvious, and their proofs are omitted. In Lemmas 6.2 and 6.3 other examples are provided.

Example 5.9. Let g_1, g_2 be two functionals from Y into $\mathbb{R}$ and assume that $0 \in K$.

(i) If g_1 and g_2 are strictly local K-monotone at y_0, then $\max\{g_1, g_2\}$ and $\min\{g_1, g_2\}$ are strictly local K-monotone at y_0.

(ii) If g_1 is strictly local K-monotone at y_0 and g_2 is local K-monotone at y_0, then $g_1 + g_2$ is strictly local K-monotone at y_0.

(iii) If $g \in K^+$, then for each $y_0 \in Y$ and $\rho > 0$, g is local K-monotone at y_0.

(iv) If $g \in K^{s+}$, K is closed, and Y is finite dimensional, then for each $y_0 \in Y$ and $\rho > 0$, g is strictly local K-monotone at y_0 with constants σ and ρ, where

$$\sigma := \min\{g(d) : d \in K, \|d\| = 1\}.$$

Indeed, as the set $A := \{d \in K : \|d\| = 1\}$ is compact and $g(d) > 0 \; \forall \, d \in A$, by the Weierstrass theorem it follows that $\sigma > 0$. Then $\forall \, y \in y_0 - (K \cap \rho \mathrm{B})$, $y \neq y_0$, as $(y_0 - y)/\|y_0 - y\| \in A$ we have that $\sigma \leq g((y_0 - y)/\|y_0 - y\|)$. By linearity we obtain that statement (5.8) is satisfied. Condition (5.7) holds by part (iii).

THEOREM 5.10. *Let $C \subset Y$ be a nonempty pointed co-radiant set. Consider $x_0 \in S$ and let $g : Y \to \mathbb{R}$ be a strictly local $C(0)$-monotone functional at $f(x_0)$ with constants σ and ρ.*

(i) *If $0 \notin \operatorname{cl}(C)$, $x_0 \in \operatorname{AMin}(g \circ f, \delta)$, and $0 < \delta < \sigma\rho$, then $x_0 \in \operatorname{AE}(f, C, \delta/(\sigma\beta))$ $\forall \, \beta > 0$ such that $\operatorname{cl}(\beta \mathrm{B}) \cap C = \emptyset$.*

(ii) *If $x_0 \in \operatorname{AMin}(g \circ f, 0)$, then $x_0 \in \operatorname{AE}(f, C, 0)$.*

Proof. Part (i). To obtain a contradiction, suppose that there exists $\beta > 0$ such that $\mathrm{cl}(\beta \mathrm{B}) \cap C = \emptyset$ and $x_0 \notin \mathrm{AE}(f, C, \delta/(\sigma\beta))$. Then

$$(f(x_0) - C(\delta/(\sigma\beta))) \cap f(S) \not\subset \{f(x_0)\}$$

and there exist $x \in S$ and $d \in C(\delta/(\sigma\beta))$ such that $f(x_0) - d = f(x)$. As $\mathrm{cl}(\beta \mathrm{B}) \cap C = \emptyset$ and $C(\delta/(\sigma\beta)) = (\delta/(\sigma\beta))C$, it follows that $\|(\sigma\beta/\delta)d\| > \beta$, and so $\|d\| > \delta/\sigma$. Thus, there exists $\nu > 0$ such that

$$\frac{\delta + \nu}{\sigma\|d\|} < 1, \quad \delta + \nu < \sigma\rho. \tag{5.9}$$

As $x_0 \in \mathrm{AMin}(g \circ f, \delta)$ and $x \in S$, it follows that

$$g(f(x_0)) - \delta \leq g(f(x)). \tag{5.10}$$

Choosing the point

$$z := f(x_0) + \frac{\delta + \nu}{\sigma\|d\|}(-d),$$

we see that $z \in f(x_0) - C(0)$ and taking into account (5.9),

$$\|z - f(x_0)\| = \frac{\delta + \nu}{\sigma} < \rho.$$

Thus $z \in f(x_0) - (C(0) \cap \rho \mathrm{B})$. As g satisfies (5.7) with $y_0 = f(x_0)$ and $K = C(0)$, and

$$z = f(x_0) + \frac{\delta + \nu}{\sigma\|d\|}(f(x) - f(x_0)) = f(x) + \left(1 - \frac{\delta + \nu}{\sigma\|d\|}\right) d \in f(x) + C(0)\,,$$

we have that

$$g(f(x)) \leq g(z). \tag{5.11}$$

Then, by (5.10) and (5.11) we deduce that

$$g(f(x_0)) - \delta \leq g(z). \tag{5.12}$$

As $z \in f(x_0) - (C(0) \cap \rho \mathrm{B})$ and g is a strictly local $C(0)$-monotone functional at $f(x_0)$ we deduce from (5.8) that

$$g(f(x_0)) \geq g(z) + \sigma\|z - f(x_0)\| = g(z) + \delta + \nu > g(z) + \delta,$$

contrary to (5.12).

Part (ii). Suppose that $x_0 \notin \mathrm{AE}(f, C, 0)$; then there exist $x \in S$ and $d \in C(0)$, $d \neq 0$, such that $f(x_0) - d = f(x)$. Let us select $\nu > 0$ such that

$$\frac{\nu}{\sigma\|d\|} < 1, \quad \nu < \sigma\rho.$$

Now, we proceed exactly as in the proof of Part (i), after equation (5.9), taking into account that $\delta = 0$. □

Remark 5.11. Let us observe that if $0 \notin \mathrm{cl}(C)$, then parts (i) and (ii) of Theorem 5.10 can be rewritten jointly by the following statement: If $x_0 \in \mathrm{AMin}(g \circ f, \delta)$ and $0 \leq \delta < \sigma\rho$, then $x_0 \in \mathrm{AE}(f, C, \delta/(\sigma\beta))\ \forall\, \beta > 0$ such that $\mathrm{cl}(\beta \mathrm{B}) \cap C = \emptyset$.

In [4, section 3.1.1], [13, section 5], and [27, Theorem 2] the reader can find sufficient conditions for ε-efficient solutions in the sense of Kutateladze. Theorem 5.10 extends these results to the general ε-efficiency notion introduced in Definition 3.2.

6. Scalarizations for approximate solutions in Pareto multiobjective optimization problems. In this section we consider that (2.1) is a nonconvex Pareto multiobjective optimization problem ($Y = \mathbb{R}^p$ and $D = \mathbb{R}^p_+$) and we obtain necessary and sufficient conditions for the ε-efficient solutions of (2.1) in the senses of Kutateladze, Németh, Helbig, White, and Tanaka via Proposition 5.5 and Theorem 5.10. For Helbig's notion we take $m = 1$, and thus, the functional (4.6) is denoted by $\langle g, \cdot \rangle$ with $g \in \mathbb{R}^p_+ \backslash \{0\}$.

We denote $f = (f_1, f_2, \ldots, f_p)$ and the components of a vector $y \in \mathbb{R}^p$ by y_i, $i = 1, 2, \ldots, p$. For each $C \subset \mathbb{R}^p$ and $y \in \mathbb{R}^p$ we denote $d(y, C) = \inf\{\|y - z\| : z \in C\}$.

In what follows, we assume the supremum norm $\| \|_\infty$ and the Euclidean norm $\| \|_2$ in $\mathbb{R}^p$ when we consider Németh's and Helbig's ε-efficiency notions, respectively. Moreover, for White's and Tanaka's definitions, we consider a norm of the family $\{\| \|^\mu_\infty : \mu \in \operatorname{int}(\mathbb{R}^p_+)\}$, where $\|y\|^\mu_\infty = \|(\mu_1 y_1, \mu_2 y_2, \ldots, \mu_p y_p)\|_\infty \ \forall\, y \in \mathbb{R}^p$ (see [24, section 3.4.2] for more detail).

THEOREM 6.1. *Let $x_0 \in S$, $q \in \operatorname{int}(\mathbb{R}^p_+)$, and $\varepsilon > 0$.*

(i) *Consider*

$$k_{f(x_0)}(y) := \max_{1 \le i \le p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\}.$$

If $x_0 \in \operatorname{WAE}(f, C_K, \varepsilon)$, then $x_0 \in \operatorname{AMin}(k_{f(x_0)} \circ f, \varepsilon)$.

(ii) *Let $L = \{e_1, e_2, \ldots, e_p\}$ be the standard basis of $\mathbb{R}^p$ and let $H = \operatorname{conv}(L)$. Suppose that $q \in H$ and consider*

$$n_{f(x_0)}(y) := \max \left\{ \max_{1 \le i \le p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\}, \sum_{i=1}^{p} (y_i - f_i(x_0)) + \varepsilon \right\}.$$

If $x_0 \in \operatorname{WAE}(f, C_N, \varepsilon)$, then $x_0 \in \operatorname{AMin}(n_{f(x_0)} \circ f, \varepsilon)$.

(iii) *Let $g \in \mathbb{R}^p_+ \backslash \{0\}$ and suppose that $\langle g, q \rangle \ge 1$. Consider*

$$h_{f(x_0)}(y) := \max \left\{ \max_{1 \le i \le p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\}, \frac{\langle g, y \rangle - \langle g, f(x_0) \rangle + \varepsilon}{\langle g, q \rangle} \right\}.$$

If $x_0 \in \operatorname{WAE}(f, C_H, \varepsilon)$, then $x_0 \in \operatorname{AMin}(h_{f(x_0)} \circ f, \varepsilon)$.

(iv) *Let*

$$t_{f(x_0)}(y) := \max \left\{ \max_{1 \le i \le p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\}, \min_{1 \le i \le p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\} + \varepsilon \right\}.$$

If $\mu = (1/q_1, 1/q_2, \ldots, 1/q_p)$ and $x_0 \in \operatorname{WAE}(f, C_T, \varepsilon)$ when the norm $\| \|^\mu_\infty$ is considered, then it follows that $x_0 \in \operatorname{AMin}(t_{f(x_0)} \circ f, \varepsilon)$. Moreover, it follows that $\operatorname{AE}(f, C_T, \varepsilon) = \operatorname{AE}(f, C_W, \varepsilon)$ and $\operatorname{WAE}(f, C_T, \varepsilon) = \operatorname{WAE}(f, C_W, \varepsilon)$.

Proof. Part (i). The elements included in $\operatorname{WAE}(f, C_K, \varepsilon)$ are the weakly ε-efficient solutions of (2.1) with respect to the set $C = q + \mathbb{R}^p_+$. It is clear that C is a proper solid convex co-radiant set. As C is a convex set and $\operatorname{int}(C) = q + \operatorname{int}(\mathbb{R}^p_+)$, it follows that $\operatorname{int}(\operatorname{kern}(C)) = q + \operatorname{int}(\mathbb{R}^p_+)$ and $q_n := (1 + 1/n)q \in \operatorname{int}(\operatorname{kern}(C))$ $\forall\, n$. Therefore, from Proposition 5.5 we deduce that if $x_0 \in \operatorname{WAE}(f, C_K, \varepsilon)$, then $x_0 \in \operatorname{AMin}(\varphi_{q, C(\varepsilon), f(x_0)} \circ f, \varepsilon)$, where $\varphi_{q, C(\varepsilon), f(x_0)}(y) = \varphi_{q, C(\varepsilon)}(y - f(x_0)) \ \forall\, y \in \mathbb{R}^p$ and $C(\varepsilon) = \varepsilon q + \mathbb{R}^p_+$.

From (5.2) we have that

$$\varphi_{q, C(\varepsilon)}(y - f(x_0)) = \inf\{s \in \mathbb{R} : y - f(x_0) \in sq - \varepsilon q - \mathbb{R}^p_+\}.$$

Moreover,

$$y - f(x_0) \in sq - \varepsilon q - \mathbb{R}^p_+ \iff s \geq \frac{y_i - f_i(x_0) + \varepsilon q_i}{q_i} \quad \forall\, i = 1, 2, \ldots, p$$

and

$$\varphi_{q,C(\varepsilon),f(x_0)}(y) = \max_{1 \leq i \leq p} \left\{ \frac{y_i - f_i(x_0)}{q_i} \right\} + \varepsilon = k_{f(x_0)}(y) + \varepsilon.$$

As $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$, we have that

$$k_{f(x_0)}(f(x_0)) \leq k_{f(x_0)}(f(x)) + \varepsilon \quad \forall\, x \in S$$

and $x_0 \in \mathrm{AMin}\big(k_{f(x_0)} \circ f, \varepsilon\big)$.

Part (ii). $\mathrm{WAE}(f, C_N, \varepsilon)$ contains all weakly ε-efficient solutions of (2.1) with respect to $C = H + \mathbb{R}^p_+$, which is a proper solid convex co-radiant set, and $\mathrm{int}(C) = H + \mathrm{int}\big(\mathbb{R}^p_+\big)$. As $q \in H \cap \mathrm{int}\big(\mathbb{R}^p_+\big)$, it follows that $q_n := (1 + 1/n)q \in H + \mathrm{int}\big(\mathbb{R}^p_+\big)$. Then, by Proposition 5.5 we deduce that if $x_0 \in \mathrm{WAE}(f, C_N, \varepsilon)$, then $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$, where $C(\varepsilon) = \varepsilon H + \mathbb{R}^p_+$ is closed. From (5.2) we see that

$$\varphi_{q,C(\varepsilon)}(y - f(x_0)) = \inf\{s \in \mathbb{R} : y - f(x_0) \in sq - \varepsilon H - \mathbb{R}^p_+\}.$$

As

$$-\varepsilon H - \mathbb{R}^p_+ = \left\{ y \in -\mathbb{R}^p_+ : \sum_{i=1}^p y_i \leq -\varepsilon \right\},$$

it follows that

$$y - f(x_0) \in sq - \varepsilon H - \mathbb{R}^p_+ \iff \begin{cases} y - f(x_0) - sq \in -\mathbb{R}^p_+, \\ \displaystyle\sum_{i=1}^p (y_i - f_i(x_0) - sq_i) \leq -\varepsilon \end{cases}$$

$$\iff \begin{cases} s \geq \dfrac{y_i - f_i(x_0)}{q_i} & \forall\, i = 1, 2, \ldots, p, \\ s \geq \displaystyle\sum_{i=1}^p (y_i - f_i(x_0)) + \varepsilon \end{cases}$$

since $q \in H$ implies $\sum_{i=1}^p q_i = 1$. Thus, $\varphi_{q,C(\varepsilon)}(y - f(x_0)) = n_{f(x_0)}(y)\ \forall\, y \in \mathbb{R}^p$, and we conclude that $x_0 \in \mathrm{AMin}\big(n_{f(x_0)} \circ f, \varepsilon\big)$.

Part (iii). The elements of $\mathrm{WAE}(f, C_H, \varepsilon)$ are weakly ε-efficient solutions of (2.1) with respect to the proper solid convex co-radiant set $C = \mathbb{R}^p_+ \cap [\langle g, \cdot \rangle > 1]$. As C is convex, we have that $\mathrm{kern}(C) = \mathbb{R}^p_+ \cap [\langle g, \cdot \rangle > 1]$ and $(1 + 1/n)q \in \mathrm{int}(\mathrm{kern}(C))$ $\forall\, n$. Thus, by Proposition 5.5 we deduce that if $x_0 \in \mathrm{WAE}(f, C_H, \varepsilon)$, then $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$. From (5.2) with $G = \mathrm{cl}(C(\varepsilon)) = \mathbb{R}^p_+ \cap [\langle g, \cdot \rangle \geq \varepsilon]$ we see that

$$\varphi_{q,\mathrm{cl}(C(\varepsilon))}(y - f(x_0)) = \inf\{s \in \mathbb{R} : y - f(x_0) \in sq - (\mathbb{R}^p_+ \cap [\langle g, \cdot \rangle \geq \varepsilon])\}$$

and

$$y - f(x_0) \in sq - (\mathbb{R}^p_+ \cap [\langle g, \cdot\rangle \geq \varepsilon]) \iff \begin{cases} s \geq \dfrac{y_i - f_i(x_0)}{q_i} & \forall\, i = 1, 2, \ldots, p, \\ s \geq \dfrac{\langle g, y\rangle - \langle g, f(x_0)\rangle + \varepsilon}{\langle g, q\rangle}. \end{cases}$$

Therefore, $\varphi_{q,\mathrm{cl}(C(\varepsilon))}(y - f(x_0)) = h_{f(x_0)}(y)\ \forall\, y \in \mathbb{R}^p$, and it follows that $x_0 \in \mathrm{AMin}\big(h_{f(x_0)} \circ f, \varepsilon\big)$.

Part (iv). $\mathrm{WAE}(f, C_T, \varepsilon)$ is the weak ε-efficiency set of (2.1) with respect to $C = \mathbb{R}^p_+ \cap \mathrm{cl}(\mathrm{B})^c$, where the open unit ball B is defined by the norm $\|\ \|^\mu_\infty$. It is clear that C is a proper solid nonconvex co-radiant set. Moreover, C is a star-shaped set since, for example, $(1 + 1/n)q \in \mathrm{kern}(C)\ \forall\, n$. Indeed, $\forall\, y \in C$ it follows that there exists a component $y_i > q_i$ and

$$\alpha(1 + 1/n)q + (1 - \alpha)y \in \mathbb{R}^p_+ \cap \mathrm{cl}(\mathrm{B})^c \quad \forall\, \alpha \in (0, 1), \quad \forall\, n,$$

because $C \subset \mathbb{R}^p_+$ and $\alpha(1 + 1/n)q_i + (1 - \alpha)y_i > q_i$.

We have that $\mathbb{R}^p_+ \subset 0^+C$, since $\forall\, y \in C$, $\forall\, \alpha > 0$, and $\forall\, d \in \mathbb{R}^p_+$ we have that $y + \alpha d \in \mathbb{R}^p_+ + \mathbb{R}^p_+ = \mathbb{R}^p_+$ and

$$\|y + \alpha d\|^\mu_\infty = \max_{1 \leq i \leq p} \left\{ \frac{y_i + \alpha d_i}{q_i} \right\} \geq \max_{1 \leq i \leq p} \left\{ \frac{y_i}{q_i} \right\} = \|y\|^\mu_\infty > 1.$$

Therefore, by Proposition 5.7 we deduce that $(1 + 1/n)q + \mathbb{R}^p_+ \subset \mathrm{kern}(C)\ \forall\, n$, and so $(1 + 1/n)q \in \mathrm{int}(\mathrm{kern}(C))\ \forall\, n$, and by Proposition 5.5 we have that if $x_0 \in \mathrm{WAE}(f, C_T, \varepsilon)$, then $x_0 \in \mathrm{AMin}\big(\varphi_{q,C(\varepsilon),f(x_0)} \circ f, \varepsilon\big)$. From (5.2) we see that

$$\varphi_{q,\mathrm{cl}(C(\varepsilon))}(y - f(x_0)) = \inf\{s \in \mathbb{R} : y - f(x_0) \in sq - (\mathbb{R}^p_+ \cap (\varepsilon \mathrm{B})^c)\}$$

since $\mathrm{cl}(C(\varepsilon)) = \mathbb{R}^p_+ \cap (\varepsilon \mathrm{B})^c$. It follows that

$$y - f(x_0) \in sq - (\mathbb{R}^p_+ \cap (\varepsilon \mathrm{B})^c) \iff \begin{cases} s \geq \dfrac{y_i - f_i(x_0)}{q_i} & \forall\, i = 1, 2, \ldots, p, \\ s \geq \min\limits_{1 \leq i \leq p} \left\{ \dfrac{y_i - f_i(x_0)}{q_i} \right\} + \varepsilon. \end{cases}$$

Thus, $\varphi_{q,\mathrm{cl}(C(\varepsilon))}(y - f(x_0)) = t_{f(x_0)}(y)\ \forall\, y \in \mathbb{R}^p$ and $x_0 \in \mathrm{AMin}\big(t_{f(x_0)} \circ f, \varepsilon\big)$.

Finally, $\mathrm{AE}(f, C_W, \varepsilon)$ is the ε-efficiency set with respect to $\mathbb{R}^p_+ \cap (q - \mathbb{R}^p_+)^c$. As $\mathbb{R}^p_+ \cap (q - \mathbb{R}^p_+)^c = \mathbb{R}^p_+ \cap \mathrm{cl}(\mathrm{B})^c = C$, we conclude that

$$\mathrm{AE}(f, C_T, \varepsilon) = \mathrm{AE}(f, C_W, \varepsilon) \tag{6.1}$$

and

$$\mathrm{WAE}(f, C_T, \varepsilon) = \mathrm{WAE}(f, C_W, \varepsilon)\,. \qquad \square$$

In [34, Proposition 3.2], Yokoyama proved relation (6.1) for $q = (1, 1, \ldots, 1)$. We extend this result to each $q \in \mathrm{int}\big(\mathbb{R}^p_+\big)$.

Next, we deduce sufficient conditions for approximate solutions of Pareto multiobjective optimization problems. The following monotonicity properties of the functions $n_{f(x_0)}$, $h_{f(x_0)}$, and $t_{f(x_0)}$ are necessary, in order to apply Theorem 5.10.

LEMMA 6.2. *The functions $n_{f(x_0)}$ and $t_{f(x_0)}$ are strictly local $\mathbb{R}^p_+$-monotone at $f(x_0)$ by taking $\|\ \|_\infty$, $\sigma = 1$, $\rho = \varepsilon/p$ and $\|\ \|^\mu_\infty$, $\sigma = 1$, $\rho = \varepsilon$ in (5.7)–(5.8), respectively.*

Proof. It is clear that if $y, z \in \mathbb{R}^p$ and $y \in z - \mathbb{R}^p_+$, then $n_{f(x_0)}(y) \le n_{f(x_0)}(z)$ and $t_{f(x_0)}(y) \le t_{f(x_0)}(z)$. Therefore, the functions $n_{f(x_0)}$ and $t_{f(x_0)}$ satisfy condition (5.7) $\forall \rho > 0$ and $y_0 = f(x_0)$.

Let us consider $\mathbb{R}^p$ with the norm $\|\ \|_\infty$ and $y \in f(x_0) - (\mathbb{R}^p_+ \cap (\varepsilon/p)\mathrm{B})$. Then

$$\frac{\varepsilon}{p} > \|y - f(x_0)\|_\infty \ge |y_i - f_i(x_0)| = f_i(x_0) - y_i \quad \forall\, i = 1, 2, \dots, p,$$

and so $\sum_{i=1}^{p}(y_i - f_i(x_0)) + \varepsilon > 0$. As $y - f(x_0) \in -\mathbb{R}^p_+$, it follows that

$$n_{f(x_0)}(y) = \sum_{i=1}^{p}(y_i - f_i(x_0)) + \varepsilon$$

and we see that

$$n_{f(x_0)}(f(x_0)) - n_{f(x_0)}(y) = \varepsilon - \sum_{i=1}^{p}(y_i - f_i(x_0)) - \varepsilon$$

$$= -\sum_{i=1}^{p}(y_i - f_i(x_0)) = \sum_{i=1}^{p}|y_i - f_i(x_0)| \ge \|y - f(x_0)\|_\infty.$$

Therefore, $n_{f(x_0)}$ is a strictly local $\mathbb{R}^p_+$-monotone function at $f(x_0)$ by taking the norm $\|\ \|_\infty$ in $\mathbb{R}^p$ and constants $\sigma = 1$ and $\rho = \varepsilon/p$.

Next, let us consider $\mathbb{R}^p$ with the norm $\|\ \|^\mu_\infty$, $\mu = (1/q_1, 1/q_2, \dots, 1/q_p)$, and $y \in f(x_0) - (\mathbb{R}^p_+ \cap \varepsilon\mathrm{B})$. Then

$$\min_{1\le i\le p}\left\{\frac{y_i - f_i(x_0)}{q_i}\right\} + \varepsilon = -\max_{1\le i\le p}\left\{-\frac{y_i - f_i(x_0)}{q_i}\right\} + \varepsilon = -\|y - f(x_0)\|^\mu_\infty + \varepsilon > 0,$$

and we have that

$$t_{f(x_0)}(f(x_0)) - t_{f(x_0)}(y) = \varepsilon + \|y - f(x_0)\|^\mu_\infty - \varepsilon = \|y - f(x_0)\|^\mu_\infty.$$

Therefore, $t_{f(x_0)}$ is a strictly local $\mathbb{R}^p_+$-monotone function at $f(x_0)$ by taking the norm $\|\ \|^\mu_\infty$ in $\mathbb{R}^p$ and constants $\sigma = 1$ and $\rho = \varepsilon$. □

For each $g \in \operatorname{int}\big(\mathbb{R}^p_+\big)$ we denote

$$m_g = \min\{\langle g, y\rangle : y \in \mathbb{R}^p_+,\ \|y\|_2 = 1\},$$

where $\|\ \|_2$ is the Euclidean norm. Let us observe that $m_g > 0$.

LEMMA 6.3. *Let us consider $\varepsilon > 0$, $g \in \operatorname{int}\big(\mathbb{R}^p_+\big)$, and the Euclidean norm in $\mathbb{R}^p$. Then, the function $h_{f(x_0)}$ is strictly local $\mathbb{R}^p_+$-monotone at $f(x_0)$ satisfying (5.7)–(5.8) with constants $\sigma = m_g/\langle g, q\rangle$ and $\rho = \varepsilon/\|g\|_2$.*

Proof. It is clear that $h_{f(x_0)}$ satisfies (5.7) $\forall\, \rho > 0$ and $y_0 = f(x_0)$. To prove (5.8) consider the Euclidean norm in $\mathbb{R}^p$, $\sigma = m_g/\langle g, q\rangle$, $\rho = \varepsilon/\|g\|_2$, and $y \in f(x_0) - (\mathbb{R}^p_+ \cap \rho\mathrm{B})$. We have that

$$h_{f(x_0)}(y) = \frac{\langle g, y\rangle - \langle g, f(x_0)\rangle + \varepsilon}{\langle g, q\rangle},$$

since $y_i - f_i(x_0) \leq 0 \; \forall\, i = 1, 2, \ldots, p$ and

$$-\langle g, y - f(x_0)\rangle = |\langle g, y - f(x_0)\rangle| \leq \|g\|_2 \, \|y - f(x_0)\|_2 < \|g\|_2 \rho = \varepsilon.$$

Therefore,

$$h_{f(x_0)}(f(x_0)) - h_{f(x_0)}(y) = \frac{\langle g, f(x_0) - y\rangle}{\langle g, q\rangle} \geq \frac{m_g \|f(x_0) - y\|_2}{\langle g, q\rangle} = \sigma \|f(x_0) - y\|_2$$

and so the lemma holds. □

THEOREM 6.4. *Let $L = \{e_1, e_2, \ldots, e_p\}$ be the standard basis of $\mathbb{R}^p$, $H = \operatorname{conv}(L)$, and $0 \leq \delta < \varepsilon/p$ and suppose that $x_0 \in \operatorname{AMin}\big(n_{f(x_0)} \circ f, \delta\big)$. Then $x_0 \in \operatorname{AE}(f, C_N, \delta/\beta) \; \forall\, \beta > 0$ such that $\beta < 1/p$.*

Proof. Consider $C = H + \mathbb{R}^p_+$. As H is the unit simplex, we have that $\operatorname{cone}(H) = \mathbb{R}^p_+ \backslash \{0\}$, and it follows that $\operatorname{bd}\big(\mathbb{R}^p_+\big) \cap (\mathbb{R}^p_+ \backslash \{0\}) \subset \operatorname{cone}(H)$. Then, by Lemma 4.1(ii) we see that $C(0) = \mathbb{R}^p_+ \backslash \{0\}$.

Moreover, $0 \notin \operatorname{cl}(C)$ and as B is defined by the norm $\|\ \|_\infty$, we see that $\operatorname{cl}(\beta \mathrm{B}) \cap C = \emptyset \; \forall\, \beta < 1/p$, since

$$d(0, C) = d(0, H) = 1/p.$$

By Lemma 6.2, we have that $n_{f(x_0)}$ is a strictly local $\mathbb{R}^p_+$-monotone function at $f(x_0)$ with constants $\sigma = 1$ and $\rho = \varepsilon/p$. Therefore, as $x_0 \in \operatorname{AMin}\big(n_{f(x_0)} \circ f, \delta\big)$ and $0 \leq \delta < \varepsilon/p$, by Theorem 5.10 and Remark 5.11 the conclusion follows. □

THEOREM 6.5. *Let $g \in \operatorname{int}\big(\mathbb{R}^p_+\big)$, $\varepsilon > 0$, and $0 \leq \delta < m_g \varepsilon/(\langle g, q\rangle \|g\|_2)$. If a point $x_0 \in \operatorname{AMin}\big(h_{f(x_0)} \circ f, \delta\big)$, then $x_0 \in \operatorname{AE}(f, C_H, \delta \langle g, q\rangle \|g\|_2/m_g)$.*

Proof. From Lemma 6.3 we have that $h_{f(x_0)}$ is a strictly local $\mathbb{R}^p_+$-monotone function at $f(x_0)$ with constants $\sigma = m_g/\langle g, q\rangle$ and $\rho = \varepsilon/\|g\|_2$. By Lemma 4.5(i) and (iv) we see that $C = \mathbb{R}^p_+ \cap [\langle g, \cdot\rangle > 1]$ is a pointed co-radiant set such that $C(0) = \mathbb{R}^p_+ \backslash \{0\}$, since $g \in \operatorname{int}\big(\mathbb{R}^p_+\big)$. Moreover, $0 \notin \operatorname{cl}(C)$ and if $\beta = 1/\|g\|_2$, then

$$\langle g, d\rangle \leq \|g\|_2 \|d\|_2 \leq \|g\|_2 \beta = 1 \quad \forall\, d \in \operatorname{cl}(\beta \mathrm{B})$$

and $\operatorname{cl}(\beta \mathrm{B}) \cap C = \emptyset$. Thus, by Theorem 5.10 and Remark 5.11 it follows that if $x_0 \in \operatorname{AMin}\big(h_{f(x_0)} \circ f, \delta\big)$ and $0 \leq \delta < m_g \varepsilon/(\langle g, q\rangle \|g\|_2)$, then

$$x_0 \in \operatorname{AE}(f, C_H, \delta \langle g, q\rangle \|g\|_2/m_g)\,,$$

which completes the proof. □

THEOREM 6.6. *Consider $0 \leq \delta < \varepsilon$ and suppose that $x_0 \in \operatorname{AMin}\big(t_{f(x_0)} \circ f, \delta\big)$. Then $x_0 \in \operatorname{AE}(f, C_T, \delta)$, where $\mu = (1/q_1, 1/q_2, \ldots, 1/q_p)$.*

Proof. Let $C = \mathbb{R}^p_+ \cap \operatorname{cl}(\mathrm{B})^c$ with B defined by the norm $\|\ \|^\mu_\infty$ and $\mu = (1/q_1, 1/q_2, \ldots, 1/q_p)$. It is clear that $0 \notin \operatorname{cl}(C)$ and $\operatorname{cl}(\beta \mathrm{B}) \cap C = \emptyset \; \forall\, \beta \in (0, 1]$. By Lemma 4.7(iii) we have that $C(0) = \mathbb{R}^p_+ \backslash \{0\}$, and from Lemma 6.2 it follows that $t_{f(x_0)}$ is a strictly local $\mathbb{R}^p_+$-monotone function at $f(x_0)$ by taking the norm $\|\ \|^\mu_\infty$ in $\mathbb{R}^p$ and constants $\sigma = 1$ and $\rho = \varepsilon$. Then, by Theorem 5.10 and Remark 5.11 we deduce that $x_0 \in \operatorname{AE}(f, C_T, \delta/\beta) \; \forall\, \beta \in (0, 1]$. Therefore $x_0 \in \operatorname{AE}(f, C_T, \delta)$. □

7. Conclusions. In this paper we have introduced a new ε-efficiency concept for vector optimization problems, which extends and unifies several different ε-efficiency notions previously defined in the literature.

We prove several properties of this new concept and characterize it via approximate solutions of related scalar optimization problems. These results have been

obtained in a general framework since we do not assume any convexity hypothesis. Thus, our results can be applied in nonconvex vector optimization problems and with preference structures which are not necessarily preorder relations.

As a final conclusion, we think that several results of this work can be useful in order to develop new methods to solve vector optimization problems. In this line, to obtain approximate Kuhn–Tucker conditions, approximate duality assertions and approximate Lagrange multiplier rules for the new ε-efficiency concept could be interesting.

Acknowledgment. The authors are grateful to the anonymous referees for their helpful comments and suggestions.

SOLVING SECOND ORDER CONE PROGRAMMING VIA A REDUCED AUGMENTED SYSTEM APPROACH*

ZHI CAI† AND KIM-CHUAN TOH‡

To the memory of Jos Sturm

Abstract. The standard Schur complement equation-based implementation of interior-point methods for second order cone programming may encounter stability problems in the computation of search directions, and as a consequence, accurate approximate optimal solutions are sometimes not attainable. Based on the eigenvalue decomposition of the $(1,1)$ block of the augmented equation, a reduced augmented equation approach is proposed to ameliorate the stability problems. Numerical experiments show that the new approach can achieve more accurate approximate optimal solutions than the Schur complement equation-based approach.

Key words. second order cone programming, augmented equation, Nesterov–Todd direction, stability

1. Introduction.

A second order cone programming (SOCP) problem is a linear optimization problem over a cross product of second order convex cones. A wide range of problems can be formulated as SOCP problems; they include linear programming (LP) problems, convex quadratically constrained quadratic programming problems, filter design problems [5, 20], and problems arising from limit analysis of collapses of solid bodies [6]. An extensive list of application problems that can be formulated as SOCP problems can be found in [14]. For a comprehensive introduction to SOCP, we refer the reader to the paper by Alizadeh and Goldfarb [1].

SOCP itself is a subclass of semidefinite programming (SDP). In theory, SOCP problems can be solved as SDP problems. However, it is far more efficient computationally to solve SOCP problems directly. A few interior-point methods (IPMs) have been developed to solve SOCP problems directly [3, 21, 25]. But these IPMs sometimes fail to deliver solutions with satisfactory accuracy. The main objective of this paper is to propose a method that can solve an SOCP to high accuracy but with comparable or moderately higher cost than the standard IPMs employing the Schur complement equation (SCE) approach. We note that global polynomial convergence results for IPMs for SOCP can be found in [15] and the references therein.

Given a column vector x_i, we will write it as $x_i = [x_i^0\,;\,\bar{x}_i]$ with x_i^0 being the first component and $\bar{x}_i$ consisting of the remaining components. Given square matrices P, Q, the notation $[P\,;\,Q]$ means that Q is appended to the last row of P, and $\mathrm{diag}(P,Q)$ denotes the block diagonal matrix with P, Q as its diagonal blocks. Throughout this paper, $\|\cdot\|$ denotes the matrix 2-norm or vector 2-norm, unless otherwise specified. For a given matrix M, we let $\lambda_{\max}(M)$ and $\lambda_{\min}(M)$ be the

largest and smallest eigenvalues of M in magnitude, respectively. The condition number of a matrix M (not necessarily square) is the number $\kappa(M) = \sigma_{\max}(M)/\sigma_{\min}(M)$, where $\sigma_{\max}(M)$ and $\sigma_{\min}(M)$ are the largest and smallest singular values of M, respectively. For a matrix M^μ which depends on a positive parameter μ, the notation $\|M^\mu\| = O(\mu)$ ($\|M^\mu\| = \Omega(\mu)$) means that there is a positive constant c such that $\|M^\mu\| \le c\mu$ ($\|M^\mu\| \ge c\mu$) as $\mu \downarrow 0$, and $\|M^\mu\| = \Theta(\mu)$ means that there are positive constants c_1, c_2 such that $c_1\mu \le \|M^\mu\| \le c_2\mu$ as $\mu \downarrow 0$. More generally, for a function K^μ depending on a positive parameter μ, the notation $\|M^\mu\| = \Theta(1)K^\mu$ means that there are positive constants c_1, c_2 such that $c_1K^\mu \le \|M^\mu\| \le c_2K^\mu$ for all μ sufficiently small.

Consider the following standard primal and dual SOCP problems:

$$(1)\qquad \begin{aligned} &\text{(P)} \quad \min\left\{\sum_{i=1}^N c_i^T x_i \,:\, \sum_{i=1}^N A_i x_i \,=\, b,\ x_i \succeq 0,\ i=1,\dots,N\right\},\\ &\text{(D)} \quad \max\{b^T y \,:\, A_i^T y + z_i \,=\, c_i,\ z_i \succeq 0,\ i=1,\dots,N\}, \end{aligned}$$

where $A_i \in \mathbb{R}^{m\times n_i}$, $c_i, x_i, z_i \in \mathbb{R}^{n_i}$, $i = 1,\dots,N$, and $y \in \mathbb{R}^m$. The constraint $x_i \succeq 0$ is a second order cone constraint defined by $x_i^0 \ge \|\bar{x}_i\|$. In particular, if the cone dimension n_i is 1, then the constraint is simply the standard nonnegativity constraint $x_i \ge 0$, and such a variable is called a linear variable. For convenience, we define

$$A \,=\, [A_1 \ A_2 \ \cdots \ A_N], \quad c \,=\, [c_1 \,;\, c_2 \,;\, \cdots \,;\, c_N],$$

$$x \,=\, [x_1 \,;\, x_2 \,;\, \cdots \,;\, x_N], \quad z \,=\, [z_1 \,;\, z_2 \,;\, \cdots \,;\, z_N], \quad n \,=\, \sum_{i=1}^N n_i.$$

The notation $x \succeq 0$ ($x \succ 0$) means that each x_i is in (the interior of) the ith second order cone.

In this paper, we will assume that A has full row rank, and that (P) and (D) in (1) are strictly feasible. Under these assumptions, the solutions to the perturbed KKT conditions of (1) form a path (known as the central path) in the interior of the primal-dual feasible region. At each iteration of an IPM, the Newton equation associated with the perturbed KKT conditions needs to be solved. By performing block eliminations, one can solve either a system of linear equations of size $m + n$ or one of size m. These linear systems are known as the augmented equation and the Schur complement equation (SCE), respectively. The SCE has the obvious advantage of being smaller in size as well as being symmetric positive definite. Currently, most implementations of IPMs [3, 21, 24, 25] are based on solving the SCE. However, as we shall see in section 3, the SCE can be severely ill-conditioned when the barrier parameter is close to 0. This typically causes numerical difficulties and imposes a limit on how accurately one can solve an SOCP problem.

In the case of LP, the ill-conditioning of the augmented equation was analyzed by Wright [28, 29]. Under certain assumptions including nondegeneracy, the computed search direction from the augmented equation is shown to be sufficiently accurate for the IPM to converge to high accuracy. The structure of the ill-conditioning of the SCE arising from LP was analyzed in [13]. A stabilization method based on performing Gaussian elimination with a certain pivoting order was also proposed to transform the SCE into a better-conditioned linear system of equations.

In nonlinear conic programming, however, the ill-conditioning of the augmented equation and the SCE is much more complicated than that in LP. The potential

numerical difficulties posed by the ill-conditioned SCE in SOCP were recognized by developers of solvers for SOCP (see, e.g., [3, 4, 23, 25]). It was also recognized by Goldfarb and Scheinberg [9], and that motivated them to propose and analyze a product-form Cholesky factorization for the Schur complement matrix. Subsequently, Sturm [23] implemented the product-form Cholesky factorization [9] in his very popular code SeDuMi to solve the SCE arising at each iteration of a homogeneous self-dual (HSD) IPM. SeDuMi also employed sophisticated techniques to minimize numerical cancellations when computing the SCE and its factorization [23]. These sophisticated techniques typically greatly improve the stability of the SCE approach. However, for certain extreme cases, they do not entirely ameliorate the numerical difficulties caused by the inherently ill-conditioned SCE; see section 4.

The IPM code SeDuMi differs from standard infeasible interior-point methods in that it solves the HSD embedding model. A natural question to ask is whether SeDuMi's unusually good performance arises from the inherent structure of the HSD model itself or from the sophisticated numerical techniques it uses in solving the SCE (or both). For a certain class of SOCP problems with no strictly feasible primal/dual points, we show numerically in section 4 that SeDuMi's superior performance can be explained by the structure of the HSD model itself. For some SOCP problems with strictly feasible points, we shall also see in section 4 that the sophisticated numerical techniques sometimes may offer only limited improvement in the attainable accuracy when compared to simpler techniques used to solve the SCE.

Herein we propose a method to compute the search directions based on a reduced augmented equation (RAE). This RAE is derived by applying block row operations to the augmented equation, together with appropriate partitioning of the eigenspace of its (1,1) block. The RAE is generally much smaller in size compared to the original augmented equation. By their construction, RAE-based IPMs are computationally more expensive than SCE-based IPMs. Fortunately, numerical experiments show that if sparsity in the SOCP data is properly preserved when forming the RAE, it can generally be solved rather efficiently by a judicious choice of a symmetric indefinite system solver.

The RAE-based IPMs are superior to SCE-based IPMs in that the former can usually deliver approximate optimal solutions that are much more accurate than the latter before numerical difficulties are encountered. For example, for the `schedxxx` SOCP problems selected from the DIMACS library [17], our RAE-based IPMs are able to obtain accuracies of 10^{-9} or better, while the SCE-based IPMs (SDPT3 version 3.1 and SeDuMi) can only obtain accuracies of 10^{-3} or 10^{-4} in some cases.

The paper is organized as follows. In section 2, we introduce the augmented and Schur complement equations. In section 3, we analyze the conditioning and the growth in the norm of the Schur complement matrix. We also discuss how the latter affects the primal infeasibility as the interior-point iterates approach optimality. In section 4, we present numerical results obtained from two different SCE-based primal-dual IPMs. In section 5, we derive the RAE. The conditioning of the reduced augmented matrix is analyzed in section 6. In section 7, we discuss major computational issues for efficiently solving the RAE. Numerical results for an RAE-based IPM are presented in section 8. We conclude the paper in section 9.

2. The augmented and Schur complement equations. In this section, we present the linear systems that need to be solved to compute the search direction at each IPM iteration.

For x_i in a second order cone, we define

$$\boldsymbol{aw}(x_i) \;=\; \begin{bmatrix} x_i^0 & \bar{x}_i^T \\ \bar{x}_i & x_i^0 I \end{bmatrix}, \qquad \gamma(x_i) \;=\; \sqrt{(x_i^0)^2 - \|\bar{x}_i\|^2}. \tag{2}$$

For a given barrier parameter ν, the perturbed KKT conditions of (1) in matrix form are

$$Ax \;=\; b, \quad A^T y + z \;=\; c, \quad \boldsymbol{aw}(x)\,\boldsymbol{aw}(z)e^0 \;=\; \nu e^0, \tag{3}$$

where $e^0 = [e_1\,;\, e_2\,;\, \cdots\,;\, e_N]$, with e_i being the first unit vector in $\mathbb{R}^{n_i}$. The matrix $\boldsymbol{aw}(x) \;=\; \mathrm{diag}(\boldsymbol{aw}(x_1), \ldots, \boldsymbol{aw}(x_N))$ is a block diagonal matrix with $\boldsymbol{aw}(x_1), \ldots, \boldsymbol{aw}(x_N)$ as its diagonal blocks. The matrix $\boldsymbol{aw}(z)$ is defined similarly.

For reasons of computational efficiency that we will explain later, in most IPM implementations for SOCP, a block diagonal scaling matrix is usually applied to the last equation in (3). Here, we apply the Nesterov–Todd (NT) scaling matrix [25] to produce the following equation:

$$\boldsymbol{aw}(Fx)\,\boldsymbol{aw}(F^{-1}z)e^0 = \nu e^0, \tag{4}$$

where $F = \mathrm{diag}(F_1, \ldots, F_N)$ is chosen such that $Fx \;=\; F^{-1}z \;=:\; v$. For details on the conditions that F must satisfy and on other scaling matrices, we refer the reader to [15]. Let

$$f_i \;=\; \begin{bmatrix} f_i^0 \\ \bar{f}_i \end{bmatrix} \;:=\; \frac{1}{\sqrt{2\Big(\gamma(x_i)\gamma(z_i) + x_i^T z_i\Big)}} \begin{bmatrix} \dfrac{1}{\omega_i} z_i^0 + \omega_i x_i^0 \\ \dfrac{1}{\omega_i}\bar{z}_i - \omega_i \bar{x}_i \end{bmatrix},$$

where $\omega_i = \sqrt{\gamma(z_i)/\gamma(x_i)}$. (Note that $\gamma(f_i) = 1$.) The precise form of F_i is given by

$$F_i \;=\; \omega_i \begin{bmatrix} f_i^0 & \bar{f}_i^T \\ \bar{f}_i & I + \frac{\bar{f}_i \bar{f}_i^T}{1+f_i^0} \end{bmatrix}. \tag{5}$$

Let $\mu = x^T z/N$ be the normalized complementarity gap. The Newton equation associated with the perturbed KKT conditions (3) with NT scaling is given by

$$A\Delta x \;=\; r_p, \quad A^T\Delta y + \Delta z \;=\; r_d, \quad VF\Delta x + VF^{-1}\Delta z \;=\; r_c, \tag{6}$$

where $V = \boldsymbol{aw}(v)$, $r_p = b - Ax$, $r_d = c - z - A^T y$, $r_c = \sigma\mu e^0 - Vv$. Note that we have chosen ν to be $\nu = \sigma\mu$ for some parameter $\sigma \in (0, 1)$.

The solution $(\Delta x, \Delta y, \Delta z)$ of the Newton equation (6) is referred to as the search direction. At each IPM iteration, solving (6) for the search direction is computationally the most expensive step. Observe that by eliminating Δz, the Newton equation (6) reduces to the so-called augmented equation

$$\begin{bmatrix} -F^2 & A^T \\ A & 0 \end{bmatrix} \begin{bmatrix} \Delta x \\ \Delta y \end{bmatrix} \;=\; \begin{bmatrix} r_x \\ r_p \end{bmatrix}, \tag{7}$$

where $r_x = r_d - FV^{-1}r_c$. The augmented equation can further be reduced in size by eliminating Δx in (7) to produce the SCE

$$\underbrace{AF^{-2}A^T}_{M}\Delta y \;=\; r_y \;:=\; r_p + AF^{-2}r_x \;=\; r_p + AF^{-2}r_d - AF^{-1}V^{-1}r_c. \tag{8}$$

The coefficient matrix M in (8) is known as the Schur complement matrix. It is symmetric positive definite if $x, z \succ 0$. The search direction corresponding to (6) always exists as long as $x, z \succ 0$. Note that if the scaling matrix F is not applied to the last equation in (3), the corresponding Schur complement matrix would be $A\,\boldsymbol{aw}(z)^{-1}\boldsymbol{aw}(x)\,A^T$, which is a nonsymmetric matrix. This nonsymmetric coefficient matrix is not guaranteed to be nonsingular even when $x, z \succ 0$. Moreover, computing its sparse LU factorization is usually much more expensive than computing the sparse Cholesky factorization of M.

In their simplest form, most current implementations of IPMs compute the search direction $(\Delta x, \Delta y, \Delta z)$ based on the SCE (8) via the following procedure.

Simplified SCE approach:

(i) Compute the Schur complement matrix M and the vector r_y;
(ii) Compute the Cholesky or sparse Cholesky factor of M;
(iii) Compute Δy by solving two triangular linear systems involving the Cholesky factor;
(iv) Compute Δz via $\Delta z = r_d - A^T\Delta y$, and Δx via $\Delta x = F^{-2}(A^T\Delta y - r_x)$.

We should note that various heuristics to improve the numerical stability of the simplified SCE approach are usually incorporated in the actual implementations. We will describe in section 4 variants of the above approach implemented in two publicly available SOCP solvers, SDPT3, version 3.1 [26], and SeDuMi, version 1.05 [22].

The SCE is preferred because it is usually a much smaller system compared to the augmented or Newton equations. Furthermore, the Schur complement matrix has the highly desirable property of being symmetric positive definite. (In contrast, the coefficient matrix in (7) is symmetric indefinite while that of (6) is nonsymmetric.) Consequently, the SCE can be solved very efficiently via Cholesky or sparse Cholesky factorization of M. We should mention that there are highly efficient and machine optimized sparse Cholesky codes readily available in the public domain, the prime example being the sparse Cholesky codes of Ng and Peyton [16]. Comparatively, the state-of-the-art LDL^T factorization codes (an example being the MA47 codes of Duff and Reid [18]) for a sparse symmetric indefinite matrix available in the public domain are less advanced.

3. Conditioning of M and the deterioration of primal infeasibility. Despite the advantages of the SCE approach described in the last section, the SCE is, however, generally severely ill-conditioned when the iterates (x, y, z) approach optimality, and this typically causes numerical difficulties. The most common numerical difficulty one may encounter in practice is that the Schur complement matrix M is numerically indefinite, although in exact arithmetic M is positive definite. Furthermore, the computed solution Δy from (8) may also be very inaccurate in that the residual norm $\|r_y - M\Delta y\|$ is much larger than the machine epsilon, and this typically causes the IPM to stall.

In this section, we will analyze the relationship between the norm $\|M\|$, the residual norm $\|r_y - M\Delta y\|$ of the computed solution Δy, and the primal infeasibility $\|r_p\|$ as the interior-point iterates approach optimality.

3.1. Eigenvalue decomposition of F^2. To analyze the norm $\|M\|$ and the conditioning of M, we need to know the eigenvalue decomposition of F^2. Recall that $F = \mathrm{diag}(F_1, \ldots, F_N)$. Thus it suffices to find the eigenvalue decomposition of F_i^2, where F_i is given in (5). By noting that for cones of dimensions $n_i \geq 2$, F_i^2 can be written as $F_i^2 = \omega_i^2(I + 2(f_i f_i^T - e_i e_i^T))$, the eigenvalue decomposition of F_i^2 can readily be found. (The case where $n_i = 1$ is easy, and $F_i^2 = z_i/x_i$.) Without going

through the algebraic details, the eigenvalue decomposition of F_i^2 is given by

$$F_i^2 = Q_i \Lambda_i Q_i^T, \qquad Q_i = \begin{bmatrix} -\frac{1}{\sqrt{2}} & +\frac{1}{\sqrt{2}} & 0 & \cdots & 0 \\ \frac{1}{\sqrt{2}}\, g_i & \frac{1}{\sqrt{2}}\, g_i & q_i^3 & \cdots & q_i^{n_i} \end{bmatrix}, \tag{9}$$

with $\Lambda_i = \omega_i^2 \operatorname{diag}\big((f_i^0 - \|\bar{f}_i\|)^2,\, (f_i^0 + \|\bar{f}_i\|)^2,\, 1, \ldots, 1\big)$, and

$$g_i := [g_i^0\,;\, \bar{g}_i] = \bar{f}_i / \|\bar{f}_i\| \in \mathbb{R}^{n_i - 1}. \tag{10}$$

Notice that since $\gamma(f_i) = 1$, the first eigenvalue is the smallest, and the second is the largest. The set $\{q_i^3, \ldots, q_i^{n_i}\}$ is an orthonormal basis of the subspace $\{u \in \mathbb{R}^{n_i - 1} : u^T g_i = 0\}$. To construct such an orthonormal basis, one may first construct the $(n_i - 1) \times (n_i - 1)$ Householder matrix H_i [10] associated with the vector g_i; then the last $n_i - 2$ columns of H_i is such an orthonormal basis. The precise form of H_i will be given later in section 6.

3.2. Analysis of $\|M\|$ and the conditioning of M. Recall that M is dependent on the normalized complementarity gap μ. Here we analyze how fast the norm $\|M\|$ and the condition number of M will grow when $\mu \downarrow 0$, i.e., when the interior-point iterates approach an optimal solution (x^*, y^*, z^*). To simplify the analysis, we will assume that strict complementarity holds at the optimal solution. Unless otherwise stated, we assume that $n_i \geq 2$ in this subsection.

Strict complementarity [2] implies that for each pair of the optimal primal and dual solutions, x_i^* and z_i^*, we have $\gamma(x_i^*) + \|z_i^*\|$ and $\gamma(z_i^*) + \|x_i^*\|$ both positive. In other words, (a) either $\gamma(x_i^*) = 0$ or $z_i^* = 0$, but not both; and (b) either $\gamma(z_i^*) = 0$ or $x_i^* = 0$, but not both. Under the strict complementarity assumption, we have the following three types of eigenvalue structures (following the classification in [9]) for F_i^2 when $\boldsymbol{aw}(x_i)\boldsymbol{aw}(z_i)e_i = \mu e_i$ and μ is small. Note that $x_i^T z_i = \mu$.

- Type 1 solution: $x_i^* \succ 0$, $z_i^* = 0$. In this case, $\gamma(x_i) = \Theta(1)$, $\gamma(z_i) = \Theta(\mu)$, and $\omega_i = \Theta(\sqrt{\mu})$. Also, $f_i^0, \|\bar{f}_i\| = \Theta(1)$, implying that all the eigenvalues of F_i^2 are $\Theta(\mu)$.
- Type 2 solution: $x_i^* = 0$, $z_i^* \succ 0$. In this case, $\gamma(x_i) = \Theta(\mu)$, $\gamma(z_i) = \Theta(1)$, and $\omega_i = \Theta(1/\sqrt{\mu})$. Also, $f_i^0, \|\bar{f}_i\| = \Theta(1)$, implying that all the eigenvalues of F_i^2 are $\Theta(1/\mu)$.
- Type 3 solution: $\gamma(x_i^*) = 0$, $\gamma(z_i^*) = 0$, $x_i^*, z_i^* \neq 0$. In this case, $\gamma(x_i), \gamma(z_i) = \Theta(\sqrt{\mu})$, and $\omega_i = \Theta(1)$. This implies that $f_i^0, \|\bar{f}_i\| = \Theta(1/\sqrt{\mu})$. Thus the largest eigenvalue of F_i^2 is $\Theta(1/\mu)$, and by the fact that $\gamma(f_i) = 1$, the smallest eigenvalue of F_i^2 is $\Theta(\mu)$. The rest of the eigenvalues are $\Theta(1)$.

Let D be the diagonal matrix consisting of the eigenvalues of F^2 sorted in ascending order. Then we have $F^2 = QDQ^T$, where the columns of Q are the sorted eigenvectors of F^2. Let D be partitioned into $D = \operatorname{diag}(D_1, D_{2a}, D_{2b})$ such that $\operatorname{diag}(D_1)$ consists of all the small eigenvalues of F^2 of order $\Theta(\mu)$, and $\operatorname{diag}(D_{2a})$ and $\operatorname{diag}(D_{2b})$ consist of the remaining eigenvalues of order $\Theta(1)$ and $\Theta(1/\mu)$, respectively. Note that the three groups of eigenvalues need not all be present. We also partition the matrix Q as $Q = [Q^{(1)}\ ,\ Q^{(2a)}\ ,\ Q^{(2b)}]$. Then $\widetilde{A} := AQ$ is partitioned as $\widetilde{A} = [\widetilde{A}_1\ ,\ \widetilde{A}_{2a}\ ,\ \widetilde{A}_{2b}] = [AQ^{(1)}\ ,\ AQ^{(2a)}\ ,\ AQ^{(2b)}]$. With the above partitions, we can express M as

$$M = \underbrace{\widetilde{A}_1 D_1^{-1} \widetilde{A}_1^T}_{M_1} + \underbrace{\widetilde{A}_{2a} D_{2a}^{-1} \widetilde{A}_{2a}^T}_{M_{2a}} + \underbrace{\widetilde{A}_{2b} D_{2b}^{-1} \widetilde{A}_{2b}^T}_{M_{2b}}. \tag{11}$$

LEMMA 3.1. (a) *For the matrices M_1, M_{2a}, and M_{2b} in* (11), *we have*

$$\|M_1\| = \Theta(1/\mu)\|\widetilde{A}_1\|^2, \quad \|M_{2a}\| = \Theta(\|\widetilde{A}_{2a}\|^2), \quad \|M_{2b}\| = \Theta(\mu)\|\widetilde{A}_{2b}\|^2.$$

(b) *Suppose there are Type* 1 *or Type* 3 *solutions so that $\widetilde{A}_1$ is not a null matrix. Then the following statements hold:* (i) $\|M\| = \Theta(1/\mu)\|\widetilde{A}_1\|^2$. (ii) *If $\widetilde{A}_1$ does not have full row rank, then* $\|M^{-1}\| = (O(1)\|\widetilde{A}_{2a}\|^2 + O(\mu)\|\widetilde{A}_{2b}\|^2)^{-1} = \Omega(1)(\|\widetilde{A}_{2a}\|^2 + \|\widetilde{A}_{2b}\|^2)^{-1}$.

Proof. (a) We shall prove only the first result since the other two can be proved similarly. By the definition of D_1, there are positive constants c_1, c_2 such that $(c_1/\mu)I \preceq D_1^{-1} \preceq (c_2/\mu)I$. Thus $(c_1/\mu)\widetilde{A}_1\widetilde{A}_1^T \preceq M_1 \preceq (c_2/\mu)\widetilde{A}_1\widetilde{A}_1^T$. This implies that $(c_1/\mu)\|\widetilde{A}_1\widetilde{A}_1^T\| \le \|M_1\| \le (c_2/\mu)\|\widetilde{A}_1\widetilde{A}_1^T\|$, and the required result follows by noting that $\|\widetilde{A}_1\widetilde{A}_1^T\| = \|\widetilde{A}_1\|^2$.

(b)(i) From (11), it is clear that $\|M\| = \Theta(1/\mu)\|\widetilde{A}_1\|^2$. (b)(ii) If $\widetilde{A}_1$ does not have full row rank, then the null space $\mathcal{N}(\widetilde{A}_1^T)$ is nontrivial. Let U be a matrix whose columns form an orthonormal basis of $\mathcal{N}(\widetilde{A}_1^T)$ and $W := U^T(M_{2a} + M_{2b})U$. Since $\widetilde{A}_1^T U = 0$, we have $U^T M U = U^T(M_{2a} + M_{2b})U = W$. By the Courant–Fischer theorem, it is clear that $\lambda_{\min}(M) \le \lambda_{\min}(W)$. Thus $\|M^{-1}\| = 1/\lambda_{\min}(M) \ge 1/\lambda_{\min}(W) = \|W^{-1}\| \ge 1/\|W\|$. Since $\|W\| \le \|M_{2a}\| + \|M_{2b}\| = O(1)\|\widetilde{A}_{2a}\|^2 + O(\mu)\|\widetilde{A}_{2b}\|^2 = O(1)(\|\widetilde{A}_{2a}\|^2 + \|\widetilde{A}_{2b}\|^2)$, the required result follows. ∎

Remark 3.1. (a) Lemma 3.1 implies that the growth in $\|M\|$ is caused by F^2 having small eigenvalues of order $\Theta(\mu)$.

(b) If $\widetilde{A}_1$ is present and does not have full row rank, then $\kappa(M) = \Omega(1/\mu)\|\widetilde{A}_1\|^2 (\|\widetilde{A}_{2a}\|^2 + \|\widetilde{A}_{2b}\|^2)^{-1}$. On the other hand, if $\widetilde{A}_1$ has full row rank (which implies that the number of eigenvalues of F^2 of order $\Theta(\mu)$ is at least m), then $\kappa(M) = \Theta(1)\kappa(\widetilde{A}_1)^2$.

(c) If there are only Type 2 solutions (thus $x^* = 0$ and $z \succ 0$), then $M = AQDQ^TA^T$ with $D = \Theta(\mu)$. In this case, we have $\kappa(M) = \Theta(1)\kappa(A)^2$.

Based on the results in [2], we have the following theorem concerning the rank of $\widetilde{A}_1$ and $\widetilde{A}_{2a}$. We refer the reader to [2] for the definitions of primal and dual degeneracies.

THEOREM 3.1. *Suppose that (x^*, y^*, z^*) satisfies strict complementarity. If the primal optimal solution x^* is primal nondegenerate, then $[\widetilde{A}_1\ ,\ \widetilde{A}_{2a}]$ has full row rank when μ is small. If the dual optimal solution (y^*, z^*) is dual nondegenerate, then $\widetilde{A}_1$ has full column rank when μ is small.*

Proof. The result follows from Theorems 20 and 21 in [1]. ∎

Remark 3.2. We should emphasize that while Theorem 3.1 says that $[\widetilde{A}_1,\ \widetilde{A}_{2a}]$ has full row rank when the optimal solution is strictly complementary and primal and dual nondegenerate, the matrix $\widetilde{A}_1$, however, does not necessarily have full row rank under the same condition. In the event that $\widetilde{A}_1$ is present and does not have full row rank, Remark 3.1(b) says that M is ill-conditioned with $\kappa(M) = \Omega(1/\mu)$. Thus even if the optimal solution is strict complementary and primal and dual nondegenerate, M does not necessarily have bounded condition number when $\mu \downarrow 0$. In contrast, for an LP problem (for which all the cones have dimensions $n_i = 1$ and $\widetilde{A}_{2a}$ is absent), primal and dual nondegeneracy ensure that $\widetilde{A}_1$ has full column and row rank, and as a result, M has bounded condition number when $\mu \downarrow 0$.

3.3. Analysis of the deterioration of primal infeasibility. Although Cholesky factorization is stable for any symmetric positive definite matrix, the conditioning

of the matrix may still affect the accuracy of the computed solution of the SCE. It is a common phenomenon that for SOCP, the accuracy of the computed search direction deteriorates as μ decreases due to an increasingly ill-conditioned M. As a result of this loss of accuracy in the computed solution, the primal infeasibility $\|r_p\|$ typically increases or stagnates when the IPM iterates approach optimality.

With the analysis of $\|M\|$ given in the last subsection, we will now analyze why the primal infeasibility may deteriorate or stagnate as interior-point iterations progress.

LEMMA 3.2. *Suppose at the kth iteration, the residual vector in solving the SCE* (8) *is* $\xi = r_y - M\Delta y$. *Assuming that* Δx *is computed exactly via the equation* $\Delta x = F^{-2}(A^T\Delta y - r_x)$, *then the primal infeasibility for the next iterate* $x^+ = x + \alpha\Delta x$, $\alpha \in [0,1]$, *is given by*

$$r_p^+ := b - Ax^+ \;=\; (1-\alpha)r_p \,+\, \alpha\xi.$$

Proof. We have $r_p^+ = (1-\alpha)r_p + \alpha(r_p - A\Delta x)$. Now $A\Delta x = AF^{-2}(A^T\Delta y - r_x) = M\Delta y - r_y + r_p$; thus $r_p - A\Delta x = r_y - M\Delta y = \xi$, and the lemma is proved. ∎

Remark 3.3. (a) In Lemma 3.2, we assume for simplicity that the component direction Δx is computed exactly. In finite precision arithmetic, errors will be introduced in the computation of Δx and that will also worsen the primal infeasibility r_p^+ of the next iterate other than $\|\xi\|$.

(b) Observe that if the SCE is solved exactly, i.e., $\xi = 0$, then $\|r_p^+\| = (1-\alpha)\|r_p\|$, and the primal infeasibility should decrease monotonically.

Lemma 3.2 implies that if the SCE is not solved to sufficient accuracy, then the inaccurate residual vector ξ may worsen the primal infeasibility of the next iterate. By standard perturbation error analysis, the worst-case residual norm of $\|\xi\|$ can be shown to be proportional to $\|M\|\|\Delta y\|$ times the machine epsilon u. The precise statement is given in the next lemma.

LEMMA 3.3. *Let* u *be the machine epsilon. Given a symmetric positive definite matrix* $B \in \mathbb{R}^{n\times n}$ *with* $(n+1)^2u \le 1/3$, *if Cholesky factorization is applied to* B *to solve the linear system* $Bx = b$ *to produce a computed solution* $\widehat{x}$, *then* $(B+\Delta B)\widehat{x} = b$, *for some* ΔB *with* $\|\Delta B\|$ *satisfying the following inequality:* $\|\Delta B\widehat{x}\| \le 3(n+1)^2u\|B\|\|\widehat{x}\|$. *Thus*

$$\|b - B\widehat{x}\| \;=\; \|\Delta B\widehat{x}\| \;=\; O(n^2)u\|B\|\|\widehat{x}\|.$$

Proof. The lemma follows straightforwardly from Theorems 10.3 and 10.4 and their extensions in [12]. ∎

Remark 3.4. Lemma 3.3 implies that if $\|B\|\|\hat{x}\|$ is large, then in the worst-case scenario, the residual norm $\|b - B\widehat{x}\|$ is expected to be proportionately large.

By Lemma 3.2 and the application of Lemma 3.3 to the SCE, we expect in the worst case the primal infeasibility $\|r_p\|$ to grow to some extent that is proportional to $\|M\|\|\Delta y\|u$. We end this section by presenting a numerical example to illustrate the relation between $\|r_p\|$ and $\|M\|\|\Delta y\|u$ in the last few iterations of an SCE-based IPM when solving the SOCP problems `rand200_800_1` and `sched_50_50_orig` (described in section 4).

The IPM we use is the primal-dual path-following method with Mehrotra predictor-corrector implemented in the MATLAB software SDPT3, version 3.1 [26]. But we should mention that to be consistent with the analysis presented in this section, the search directions are computed based on the simplified SCE approach presented in section 2, not the more sophisticated variant implemented in SDPT3.

TABLE 1

Table 1 shows the norms $\|M\|$, $\|M^{-1}\|$, $\|r_y - M\Delta y\|$ when solving the SCE (8). For this problem, $\|M\|$ and (hence $\kappa(M)$) grows like $\Theta(1/\mu)$ because its optimal solutions x_i^*, z_i^* are all of Type 3. The fifth and sixth columns in the table show that the residual norm in solving the SCE and $\|r_p\|$ deteriorate as $\|M\|$ increases. This is consistent with the conclusions of Lemmas 3.2 and 3.3. The last column further shows that $\|r_p\|$ increases proportionately to $\|M\|\|\Delta y\|u$, where the machine epsilon u is approximately 2.2×10^{-16}.

Figure 1 illustrates the phenomenon graphically for the SOCP problems `rand200_800_1` and `sched_50_50_orig`. The curves plotted correspond to the relative duality gap (`relgap`), and the relative primal and dual infeasibility (`p-inf` and `d-inf`), defined by

$$\texttt{relgap} = \frac{|c^T x - b^T y|}{1 + (|c^T x| + |b^T y|)/2}, \quad \texttt{p-inf} = \frac{\|r_p\|}{1 + \|b\|}, \quad \texttt{d-inf} = \frac{\|r_d\|}{1 + \|c\|}. \tag{12}$$

4. Computational results of two SCE-based IPMs on solving some SOCP problems. Here we present numerical results for the SCE-based IPMs implemented in the public domain solvers, SDPT3, version 3.1 [26], and SeDuMi, version 1.05 [22]. In this paper, all the numerical results are obtained in MATLAB 6.5 from a Pentium IV 2.4GHz PC with 1G RAM running a Linux operating system.

Before we analyze the performance of the SCE-based IPMs implemented in SDPT3 and SeDuMi, we must describe the methods employed to solve the SCE in both solvers. The IPM in SDPT3 is an infeasible path-following method that attempts to solve the central path equation based on (3), even if this path does not exist. It solves the resulting SCE at each IPM iteration as follows. First it computes the Cholesky or sparse Cholesky factor of the Schur complement matrix M. Then the computed Cholesky factor is used to construct a preconditioner within a preconditioned symmetric quasi-minimal residual Krylov subspace iterative solver employed to solve the SCE for Δy. The computations of Δz and Δx are the same as in the simplified SCE approach presented in section 2.

SeDuMi is a very well implemented SCE-based public domain solver for both SOCP and SDP. The IPM in SeDuMi is based not on the central path for the original

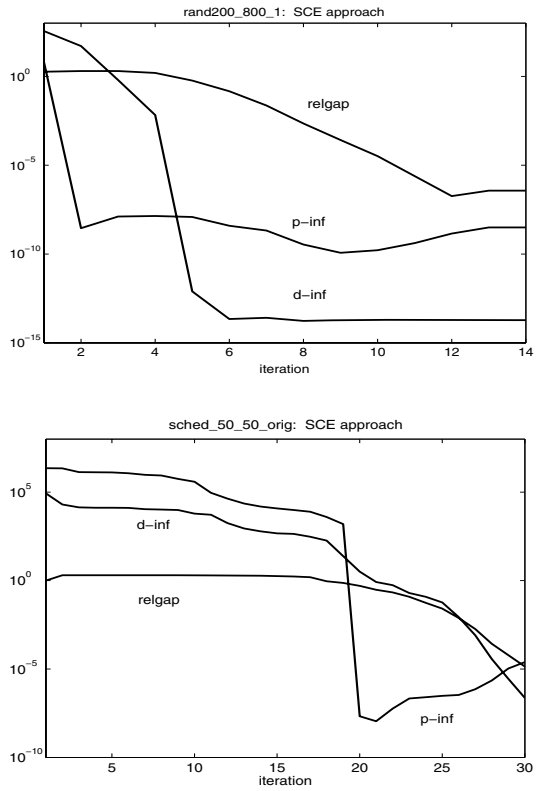

FIG. 1. *Convergence history of the SOCP problems* `rand200_800_1` *and* `sched_50_50_orig` *when solved by the SCE-based IPM in SDPT*3*, version* 3.1. *Notice that the relative primal infeasibility* `p-inf` *deteriorates as interior-point iterates approach optimality, while* `relgap` *may stagnate.*

primal and dual problems (1), but on that of the HSD model of Ye, Todd, and Mizuno [30]. The HSD model has the nice theoretical property that a strictly feasible primal and dual point always exists even if the original problems do not have one, and as a result the central path for the HSD model always exists, which is not necessarily true for the original problems in (1). As a consequence of this nice property, its solution set is always bounded. The same cannot be said for the original problems. For a problem that models an unrestricted variable by the difference of two nonnegative variables, the solution set for the original primal SOCP (P) is unbounded, and the feasible region of (D) has an empty interior, implying that the primal-dual central path does not exist. The HSD model, on the other hand, does not suffer from these defects. Thus the IPM in SeDuMi will not feel the effect of the unbounded solution set and nonexistence of the central path in the original problems in (1), but the effect of the unboundedness of the solution set on the infeasible path-following IPM in SDPT3 can be substantial and often causes serious numerical difficulties.

The computation of the search direction in SeDuMi is based on the SCE associated with the HSD model. But it employs sophisticated numerical techniques to minimize numerical cancellations in its implementation of the SCE approach [23]. It computes the Schur complement matrix in the scaled space (called the v-space) framework and transforms back and forth between quantities in the scaled and original spaces. It employs the sparse Cholesky codes adapted from Ng and Peyton [16] to compute the

factorization. It also employs the product-form Cholesky factorization [9] to handle dense columns. If the computed Cholesky factor is deemed sufficiently stable, SeDuMi will proceed to compute Δy by solving two triangular linear systems involving the Cholesky factor; otherwise, it will solve the SCE by using the preconditioned conjugate gradient iterative method with a preconditioner constructed from the Cholesky factor. Note that the Cholesky factorization has been shown in [9] to produce stable triangular factors for the Schur complement matrix if the iterates are sufficiently close to the central path and strict complementarity holds at optimality. It is important to note, however, that using a stable method to solve the SCE does not necessarily imply that the computed direction $(\Delta x, \Delta y, \Delta z)$ based on the SCE approach will produce a small residual norm with respect to the original linear system (6); see Theorem 3.2 of [11] for the case of SDP.

We tested the SCE-based IPMs in SDPT3 and SeDuMi on the following set of SOCP problems. The statistics for the test problems are shown in Table 2.

(a) The first set consists of 18 SOCP problems in the DIMACS library collected by Pataki and Schmieta [17], available at http://dimacs.rutgers.edu/Challenges/Seventh/Instances/.

(b) The second set consists of 10 SOCP problems from the FIR Filter Optimization Toolbox of Scholnik and Coleman [20], available at http://www.csee.umbc.edu/∼dschol2/opt.html.

(c) The last set consists of 10 randomly generated SOCP problems. These random problems `randxxx` are generated to be feasible and are dominated by Type 3 solutions. For each problem, the constraint matrix A has the form $V_1 \Sigma V_2^T$, where V_1, V_2 are matrices whose columns are orthonormal, and Σ is a diagonal matrix with random diagonal elements drawn from the standard normal distribution, but a few of the diagonal elements are set to 10^5 to make A moderately ill-conditioned.

In our experiments, we stop the IPM iteration in SDPT3 when any of the following situations are encountered: (1) $\max(\texttt{relgap}, \texttt{p-inf}, \texttt{d-inf}) \leq 10^{-10}$; (2) incurable numerical difficulties (such as the Schur complement matrix being numerically indefinite) occur; (3) `p-inf` has deteriorated to the extent that `p-inf` > `relgap`. SeDuMi also has a set of stopping conditions that are similar but based on the variables of the HSD model. In SeDuMi, the dual conic constraints are not strictly enforced; thus the measure `d-inf` for SeDuMi is defined to be $\texttt{d-inf} = \max(\|r_d\|, \|z^-\|)$, where $\|z^-\|$ measures how much the dual conic constraints are violated. We define

$$\phi := \log_{10}(\max\{\texttt{relgap}, \texttt{p-inf}, \texttt{d-inf}\}). \tag{13}$$

Table 2 shows the numerical results for SDPT3 and SeDuMi on 36 SOCP problems. Observe that the accuracy exponents (ϕ) for many of the problems fall short of the target of -10. For the `sched-xxx` problems, the accuracy exponents attained are especially poor, only -3 or -4 in some cases. We should mention that the results shown in Table 2 are not isolated to just the IPMs implemented in SDPT3 or SeDuMi; similar results were also reported in the SCE-based IPM implemented by Andersen, Roos, and Terlaky [3]. For example, for the problem `sched_50_50_orig`, the IPM in [3] reported the values 0.9 and 0.002 for the maximum violation of certain primal bound constraints and the dual constraints, respectively.

From Table 2, we have thus seen the performance of SCE-based IPMs for two rather different implementations in SDPT3 and SeDuMi. It is worthwhile to analyze the performance of these implementations to isolate the factor contributing to the

TABLE 2

Accuracy attained by 2 SCE-based IPMs for solving SOCP problems. The timings reported are in seconds. A number of the form "1.7-4" means 1.7×10^{-4}. An entry of the form "793 × 3" in the "SOC" column means that there are 793 three-dimensional second order cones. The numbers under the "LIN" column are the numbers of linear variables.

good performance in one implementation but not the other. On the first 10 SOCP problems, `nbxxx`, `nqlxxx`, and `qsspxxx` in the DIMACS library, SeDuMi performs much better than the IPM in SDPT3 in terms of accuracy. We hypothesize that SeDuMi is able to obtain accurate approximate optimal solutions for these test problems primarily because of nice theoretical properties (existence of a strictly feasible point, and boundedness of solution set) of the HSD model. These problems contain linear variables that are the results of modeling unrestricted variables as the difference of two nonnegative vectors. Consequently, the resulting primal SOCP problems have unbounded solution sets, and the feasible regions of the dual SOCP problems have empty interior. It should come as no surprise that the IPM in SDPT3 has trouble solving such a problem to high accuracy since the ill-conditioning in the Schur complement matrix is made worse by the growing norm of the primal linear variables as the iterates approach optimality. On the other hand, for the IPM in SeDuMi, the ill-conditioning of the Schur complement matrix is not amplified since the norm of the primal variables in the HSD model stays bounded.

To verify the above hypothesis, we solve the `nbxxx`, `nqlxxx`, and `qsspxxx` problems again in SDPT3, but at each IPM iteration, we trim the growth in the primal linear variables, x^u_+, x^u_-, arising from unrestricted variables x_u using the following heuristic [26]:

$$x^u_+ \;:=\; x^u_+ - 0.8\min(x^u_+, x^u_-), \qquad x^u_- \;:=\; x^u_- - 0.8\min(x^u_+, x^u_-). \tag{14}$$

This modification does not change the original variable x^u, but it slows down the growth of x^u_+, x^u_-. After these modified vectors have been obtained, we also modify the associated dual linear variables z^u_+, z^u_- as follows if $\mu \le 10^{-4}$:

$$(z^u_+)_i \;:=\; \frac{0.5\mu}{\max(1,(x^u_+)_i)}, \qquad (z^u_-)_i \;:=\; \frac{0.5\mu}{\max(1,(x^u_-)_i)}. \tag{15}$$

Such a modification in z^u_+, z^u_- ensures that they approach 0 at the same rate as μ, and thus prevents the dual problem from attaining the equality constraints in (D) prematurely.

The results shown in Table 3 support our hypothesis. Observe that with the heuristic in (14) and (15) to control the growth of $(x^u_+)_i/(z^u_+)_i$ and $(x^u_-)_i/(z^u_-)_i$, the

TABLE 3

Performance of the SCE-based IPM in SDPT3 in solving SOCP problems with linear variables coming from unrestricted variables. The heuristics in (14) *and* (15) *are applied at each IPM iteration.*

IPM in SDPT3 can also achieve accurate approximate solutions, just as the IPM based on the HSD model in SeDuMi is able to achieve. It is surprising that such a simple heuristic to control the growth can result in such a dramatic improvement on the achievable accuracy, even though the problems (P) and (D) in (1) do not have a strictly feasible point and the corresponding central path does not exist.

On other problems such as `schedxxx`, `firxxx`, and `randxxx`, the performances of SDPT3 and SeDuMi are quite comparable in terms of accuracy attained, although SeDuMi is generally more accurate on the `schedxxx` problems, while SDPT3 performs somewhat better on the `randxxx` problems. On the `firxxx` problems, SDPT3 seems to be more robust, whereas SeDuMi runs into numerical difficulties quite early when solving `firL1Linfalph` and `firL2L1alph`.

The empirical evidence of Table 2 shows that even though sophisticated numerical techniques used to solve the SCE in SeDuMi can help to achieve better accuracy, sometimes these techniques give limited improvement over simpler techniques employed in SDPT3. On SOCP problems where the two solvers have vastly different performance in terms of accuracy, the difference can be attributed to the inherent IPM models used in the solvers rather than the numerical techniques employed to solve the SCE. The conclusion we may draw here is that the SCE is generally inherently ill-conditioned, and if our wish is to compute the search direction of (6) to higher accuracy, a new approach other than the SCE is necessary.

5. Reduced augmented equation. In this section, we present a new approach to compute the search direction via a potentially better-conditioned linear system of equations. Based on the new approach, the accuracy of the computed search direction is expected to be better than that computed from the SCE when μ is small. In this new approach, we assume that the iterate (x, y, z) is sufficiently close to the central path so that the eigenvalues of F^2 separate into three distinct groups as described in section 3.2.

In this approach, we start with the augmented equation in (7). By using the eigenvalue decomposition $F^2 = QDQ^T$ presented in section 3.1, where $Q = \mathrm{diag}(Q_1, \ldots, Q_N)$ and $D = \mathrm{diag}(\Lambda_1, \ldots, \Lambda_N)$, we can diagonalize the (1,1) block and rewrite the augmented equation (7) as follows:

$$\begin{bmatrix} -D & \widetilde{A}^T \\ \widetilde{A} & 0 \end{bmatrix} \begin{bmatrix} \Delta\widetilde{x} \\ \Delta y \end{bmatrix} = \begin{bmatrix} \widetilde{r} \\ r_p \end{bmatrix}, \tag{16}$$

where

$$\widetilde{A} = AQ, \quad \Delta\widetilde{x} = Q^T\Delta x, \quad \widetilde{r} = Q^T r_x. \tag{17}$$

The augmented equation (16) has dimension $m+n$, which is usually much larger than m, the dimension of the SCE. We can try to reduce its size while overcoming some of the undesirable features of the SCE such as the growth of $\|M\|$ when $\mu \downarrow 0$.

Let the diagonal matrix D be partitioned into two parts as $D = \mathrm{diag}(D_1, D_2)$ with $\mathrm{diag}(D_1)$ consisting of the small eigenvalues of F^2 of order $\Theta(\mu)$ and $\mathrm{diag}(D_2)$ consisting of the remaining eigenvalues of order $\Theta(1)$ or $\Theta(1/\mu)$. We partition the eigenvector matrix Q accordingly as $Q = [Q^{(1)}\ ,\ Q^{(2)}]$. Then $\widetilde{A}$ is partitioned as $\widetilde{A} = [\widetilde{A}_1\ ,\ \widetilde{A}_2] = [AQ^{(1)}\ ,\ AQ^{(2)}]$ and $\widetilde{r} = [\widetilde{r}_1\,;\,\widetilde{r}_2] = [(Q^{(1)})^T r_x\,;\,(Q^{(2)})^T r_x]$. Similarly, $\Delta\widetilde{x}$ is partitioned as $\Delta\widetilde{x} = [\Delta\widetilde{x}_1\,;\,\Delta\widetilde{x}_2] = [(Q^{(1)})^T\Delta x\,;\,(Q^{(2)})^T\Delta x]$.

By substituting the above partitions into (16), and eliminating $\Delta\widetilde{x}_2$, it is easy to show that solving the system (16) is equivalent to solving the following:

$$\begin{bmatrix} \widetilde{A}_2 D_2^{-1} \widetilde{A}_2^T & \widetilde{A}_1 \\ \widetilde{A}_1^T & -D_1 \end{bmatrix} \begin{bmatrix} \Delta y \\ \Delta\widetilde{x}_1 \end{bmatrix} = \begin{bmatrix} r_p + \widetilde{A}_2 D_2^{-1} \widetilde{r}_2 \\ \widetilde{r}_1 \end{bmatrix}, \tag{18}$$

$$\Delta\widetilde{x}_2 \;=\; D_2^{-1}(\widetilde{A}_2^T \Delta y - \widetilde{r}_2) \;=\; D_2^{-1}(Q^{(2)})^T(A^T\Delta y - r_x). \tag{19}$$

By its construction, the coefficient matrix in (18) does not have large elements when $\mu \downarrow 0$. But its (1,1) block is generally singular or nearly singular, especially when μ is close to 0. Since a singular (1,1) block is not conducive for symmetric indefinite factorization of the matrix or the construction of preconditioners for the matrix, we will construct an equivalent system with a (1,1) block that is less likely to be singular. Let E_1 be a given positive definite diagonal matrix with the same dimension as D_1. Throughout this paper, we take $E_1 = I$. Let $S_1 = E_1 + D_1$. By adding $\widetilde{A}_1 S_1^{-1}$ times the second block equation in (18) to the first block equation, we get $\widetilde{A}\,\mathrm{diag}(S^{-1}, D_2^{-1})\widetilde{A}^T\Delta y + \widetilde{A}_1 S_1^{-1} E_1 \Delta\widetilde{x}_1 \;=\; r_p + \widetilde{A}\,\mathrm{diag}(S^{-1}, D_2^{-1})\widetilde{r}$. This, together with the second block equation in (18) but scaled by $S_1^{-1/2}$, we get the following equivalent system:

$$\underbrace{\begin{bmatrix} \widetilde{M} & \widetilde{A}_1 S_1^{-1/2} \\ S_1^{-1/2}\widetilde{A}_1^T & -D_1 E_1^{-1} \end{bmatrix}}_{\mathcal{B}} \begin{bmatrix} \Delta y \\ S_1^{-1/2} E_1 \Delta\widetilde{x}_1 \end{bmatrix} = \begin{bmatrix} q \\ S_1^{-1/2}\widetilde{r}_1 \end{bmatrix}, \tag{20}$$

where

$$\widetilde{M} \;=\; \widetilde{A}\,\mathrm{diag}(S_1^{-1}, D_2^{-1})\widetilde{A}^T, \quad q \;=\; r_p + \widetilde{A}\,\mathrm{diag}(S_1^{-1}, D_2^{-1})\widetilde{r}. \tag{21}$$

We call the system in (20) the *reduced augmented equation* (RAE).

Note that once Δy and $\Delta\widetilde{x}_1$ are computed from (20) and $\Delta\widetilde{x}_2$ is computed from (19), Δx can be recovered through the equation $\Delta x = Q[\Delta\widetilde{x}_1\,;\,\Delta\widetilde{x}_2]$.

Remark 5.1. (a) If the matrix D_1 is null, then the RAE (20) is reduced to the SCE (8).

(b) $\mathcal{B}$ is a quasi-definite matrix [8, 27]. Such a matrix has the nice property that any symmetric reordering $\Pi\mathcal{B}\Pi^T$ has a "Cholesky factorization" $L\Lambda L^T$, where Λ is diagonal with both positive and negative diagonal elements.

Observe that the $(1,1)$ block, $\widetilde{M}$, in (20) has the same structure as the Schur complement matrix $M = \widetilde{A}\,\mathrm{diag}(D_1^{-1}, D_2^{-1})\widetilde{A}^T$. But for $\widetilde{M}$, $\|\mathrm{diag}(S_1^{-1}, D_2^{-1})\| = O(1)$, whereas for M, $\|\mathrm{diag}(D_1^{-1}, D_2^{-1})\| = O(1/\mu)$. Because of this difference, the reduced augmented matrix $\mathcal{B}$ has bounded norm as $\mu \downarrow 0$, but $\|M\|$ is generally unbounded. Under certain conditions, $\mathcal{B}$ can be shown to have a condition number that is bounded independent of the normalized complementarity gap μ. The precise statements are given in the following theorems.

THEOREM 5.1. *Suppose in* (20) *we use a partition such that* $\mathrm{diag}(D_1)$ *consists of all the eigenvalues of* F^2 *of order* $\Theta(\mu)$. *If the optimal solution of* (1) *satisfies strict complementarity, then* $\|\mathcal{B}\|$ *satisfies the inequality* $\|\mathcal{B}\| \;=\; O(1)\,\|A\|^2$. *Thus* $\|\mathcal{B}\|$ *is bounded independent of* μ *(as* $\mu \downarrow 0$*).*

Proof. It is easy to see that

$$\|\mathcal{B}\| \le \sqrt{2}\,\max(\|\widetilde{M}\| + \|\widetilde{A}_1 S_1^{-1/2}\|,\, \|S_1^{-1/2}\widetilde{A}_1^T\| + \|D_1 E_1^{-1}\|).$$

Under the assumption that the optimal solution of (1) satisfies strict complementarity, then as $\mu \downarrow 0$, $\|D_1\| \downarrow 0$, and $\|D_2^{-1}\| = O(1)$, it is possible to find a constant (independent of μ) $\tau \ge 1$ such that $\max(\|S_1^{-1}\|, \|D_2^{-1}\|, \|D_1 E_1^{-1}\|) \le \tau$. Now $\|\widetilde{M}\| \le \|\widetilde{A}\|\max(\|S_1^{-1}\|, \|D_2^{-1}\|)\|\widetilde{A}\| \le \tau\|\widetilde{A}\|^2$ and $\|S_1^{-1/2}\widetilde{A}_1^T\| = \|\widetilde{A}_1 S_1^{-1/2}\| \le \tau\|\widetilde{A}_1\|$; thus we have

$$\|\mathcal{B}\| \;\le\; \tau\sqrt{2}\max(\|\widetilde{A}\|^2 + \|\widetilde{A}_1\|,\, \|\widetilde{A}_1\| + 1) \;\le\; \tau\sqrt{2}(\|A\| + 1)^2.$$

From here, the required result follows. ∎

LEMMA 5.1. *The reduced augmented matrix* $\mathcal{B}$ *in* (20) *satisfies the following inequality:*

$$\|\mathcal{B}^{-1}\| \;\le\; 2\sqrt{2}\max(\|\widetilde{M}^{-1}\|\,,\, \|W^{-1}\|),$$

where $W = B_1^T\widetilde{M}^{-1}B_1 + D_1E_1^{-1}$ *with* $B_1 = \widetilde{A}_1 S_1^{-1/2}$.

Proof. From [19, p. 389], it can be deduced that

$$\mathcal{B}^{-1} \;=\; \begin{bmatrix} \widetilde{M}^{-1/2}(I-P)\widetilde{M}^{-1/2} & \widetilde{M}^{-1}B_1W^{-1} \\ W^{-1}B_1^T\widetilde{M}^{-1} & -W^{-1} \end{bmatrix},$$

where $P = \widetilde{M}^{-1/2}B_1W^{-1}B_1^T\widetilde{M}^{-1/2}$. Note that P satisfies the condition $0 \preceq P \preceq I$; i.e., P and $I - P$ are positive semidefinite. By the definition of W, we have $0 \preceq W^{-1/2}B_1^T\widetilde{M}^{-1}B_1W^{-1/2} \preceq I$, and thus $\|\widetilde{M}^{-1/2}B_1W^{-1/2}\| \le 1$. This implies that

$$\|\widetilde{M}^{-1}B_1W^{-1}\| \le \|\widetilde{M}^{-1/2}\|\,\|\widetilde{M}^{-1/2}B_1W^{-1/2}\|\,\|W^{-1/2}\| \;\le\; \max(\|\widetilde{M}^{-1}\|\,,\, \|W^{-1}\|).$$

It is easy to see that

$$\|\mathcal{B}^{-1}\| \le \sqrt{2}\max(\|\widetilde{M}^{-1/2}(I-P)\widetilde{M}^{-1/2}\| + \|\widetilde{M}^{-1}B_1W^{-1}\|\,,\, \|W^{-1}B_1^T\widetilde{M}^{-1}\| + \|W^{-1}\|).$$

From here, the required result follows. ∎

THEOREM 5.2. *Suppose in* (20) *we use a partition such that* $\mathrm{diag}(D_1)$ *consists of all the eigenvalues of* F^2 *of order* $\Theta(\mu)$. *If the optimal solution of* (1) *satisfies strict complementarity and the primal and dual nondegeneracy conditions defined in* [2], *then the condition number of the coefficient matrix in* (20) *is bounded independent of* μ *(as* $\mu \downarrow 0$*).*

Proof. Let D_2 be further partitioned into $D_2 = \mathrm{diag}(D_{2a}, D_{2b})$, where $\mathrm{diag}(D_{2a})$ and $\mathrm{diag}(D_{2b})$ consist of eigenvalues of F^2 of order $\Theta(1)$ and $\Theta(1/\mu)$, respectively. Let $Q^{(2)}$ and $\widetilde{A}_2$ be partitioned accordingly as $Q^{(2)} = [Q^{(2a)},\ Q^{(2b)}]$ and $\widetilde{A}_2 = [AQ^{(2a)},\ AQ^{(2b)}] =: [\widetilde{A}_{2a},\ \widetilde{A}_{2b}]$. By Theorems 20 and 21 in [1], dual nondegeneracy implies that $\widetilde{A}_1 = AQ^{(1)}$ has full column rank and primal nondegeneracy implies that $[\widetilde{A}_1,\ \widetilde{A}_{2a}]$ has full row rank. Since $\|\widetilde{M} - [\widetilde{A}_1,\ \widetilde{A}_{2a}]\mathrm{diag}(S_1^{-1},\ D_{2a}^{-1})[\widetilde{A}_1\,,\ \widetilde{A}_{2a}]^T\| = O(\mu)$, thus $\sigma_{\min}(\widetilde{M})$ is bounded away from 0 even when $\mu \downarrow 0$. This, together with the fact that $\widetilde{A}_1 S_1^{-1/2}$ has full column rank, implies that the matrix $W := S_1^{-1/2}\widetilde{A}_1^T\widetilde{M}^{-1}\widetilde{A}_1S_1^{-1/2} + D_1E_1^{-1}$ has $\sigma_{\min}(W)$ bounded away from 0 even when $\mu \downarrow 0$. By Lemma 5.1, $\|\mathcal{B}^{-1}\|$ is bounded independent of μ. By Theorem 5.1, $\|\mathcal{B}\|$ is also bounded independent of μ, and the required result follows. ∎

6. Reduced augmented equation and primal infeasibility. Let $[\xi\,;\,\eta]$ be the residual vector for the computed solution of (20).

LEMMA 6.1. *Let u be the machine epsilon and let l be the dimension of $\Delta\widetilde{x}_1$. Suppose $(l+m)u \le 1/2$ and we use Gaussian elimination with partial pivoting (GEPP) to solve* (20) *to get the computed solution $(\Delta y\,;\,\Delta\widetilde{x}_1)$; then the residual vector $[\xi\,;\,\eta]$ for the computed solution satisfies the following inequality:*

$$\|(\xi\,;\,\eta)\|_\infty \le 4(l+m)^3 u\rho\,\|\mathcal{B}\|_\infty \|(\Delta y\,;\,\Delta\widetilde{x}_1)\|_\infty,$$

where ρ is the growth factor associated with GEPP.

Proof. This lemma follows from Theorem 9.5 in [12]. □

Remark 6.1. Theorem 5.1 stated that if strict complementarity holds at the optimal solution, then $\|\mathcal{B}\|_\infty$ will not grow as $\mu \downarrow 0$ in contrast to $\|M\|$, which usually grows proportionately to $\Theta(1/\mu)$. Now because the growth factor ρ for GEPP is usually $O(1)$, Lemma 6.1 implies that the residual norm $\|(\xi\,;\,\eta)\|_\infty$ will be maintained at some level proportional to $u\|A\|^2$ even when $\mu \downarrow 0$.

Now we establish the relationship between the residual norm in solving (20) and the primal infeasibility associated with the search direction computed from the RAE approach. Suppose that in computing $\Delta\widetilde{x}_2$ from (19), a residual vector δ is introduced, i.e.,

$$\Delta\widetilde{x}_2 = D_2^{-1}(Q^{(2)})^T(A^T\Delta y - r) - \delta.$$

Then we have the following lemma for the primal infeasibility of the next iterate.

LEMMA 6.2. *Suppose Δx is computed from the RAE approach. Then the primal infeasibility $\|r_p^+\|$ for the next iterate $x^+ = x + \alpha\Delta x$, $\alpha \in [0,1]$, satisfies the following inequality:*

$$\|r_p^+\| \;\le\; (1-\alpha)\|r_p\| + \alpha\|\xi + \widetilde{A}_2\delta - \widetilde{A}_1 S_1^{-1/2}\eta\|.$$

Proof. The proof is quite routine and we omit it.

Remark 6.2. From Lemma 6.2, we see that if the RAE returns a small residual norm, then the primal infeasibility of the next iterate would not be seriously worsened by the residual norm. From Theorem 5.1 and Lemma 6.1, we expect the residual norm $\|[\xi;\eta]\|$ to be small since the upper bound on $\|\mathcal{B}\|$ is independent of μ. Also, since by its construction, D_2^{-1} does not have large elements, $\|\delta\|$ is expected to be small as well.

Figure 2 shows the convergence behavior of the IPM in SDPT3, but with search directions computed from the RAE (20) for problems `ran200_800_1` and `sched_50_50_orig`. As can be seen from the relative primal infeasibility curves, the RAE approach is more stable than the SCE approach. It is worth noting that under the new approach, the solver is able to deliver 10 digits of accuracy; i.e., $\phi \le -10$. This is significantly better than the accuracy $\phi \approx -6$ attained by the SCE approach. Note that we use a partition such that eigenvalues of F^2 that are smaller than 10^{-3} are put in D_1.

In Table 4, we show the norms $\|\mathcal{B}\|$, $\|\mathcal{B}^{-1}\|$ and the residual norm in solving the RAE (20) for the last few IPM iterations when solving the problems `rand200_800_1` and `sched_50_50_orig`. Observe that $\|\mathcal{B}\|$ and $\kappa(\mathcal{B})$ do not grow when $\mu \downarrow 0$, in contrast to $\|M\|$ and $\kappa(M)$ in Table 1. The residual norm for the computed solution of (20) remains small throughout, and in accordance with Lemma 6.1, the residual norm is approximately equal to $u\|\mathcal{B}\|$ times the norm of the computed solution. By Lemma 6.2, the small residual norm in solving the RAE explains why the primal infeasibility computed from the RAE approach does not deteriorate as in the SCE approach.

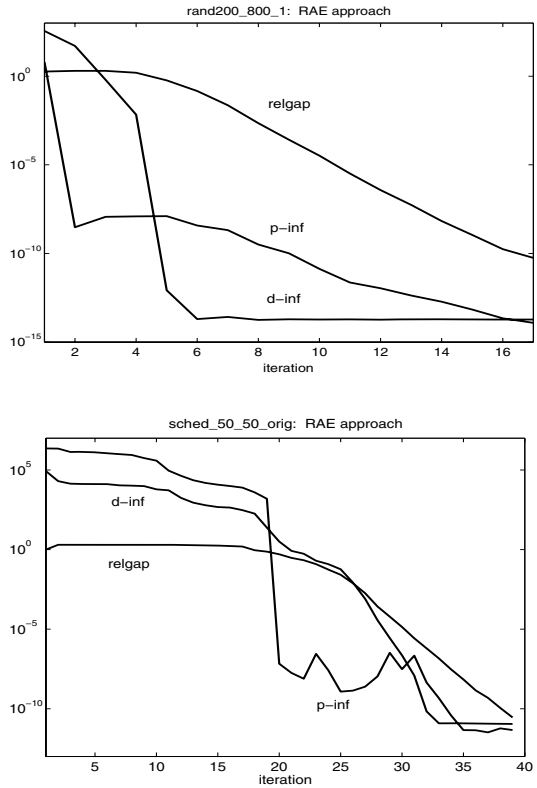

FIG. 2. *Same as Figure* 1 *except for the RAE approach in computing the search directions for the problems* `rand200_800_1` *and* `sched_50_50_orig`*. Notice that the primal infeasibility does not deteriorate when the iterates approach optimality. Both problems are primal and dual nondegenerate, and strict complementarity holds at optimality.*

7. Computational issues. The theoretical analysis in the last section indicates that the RAE approach is potentially more stable than the standard SCE approach, but the trade-off is that the former needs to solve a larger indefinite linear system. Thus, how to efficiently solve (20) is one of our major concerns in the implementation.

In forming the reduced augmented matrix $\mathcal{B}$, those operations involving Q (the eigenvector matrix of F^2) must be handled carefully by exploiting the structure of Q to avoid incurring significant storage and computational cost. Also, the sparsity of AA^T must be properly preserved when computing $\widetilde{M}$.

7.1. Computations involving Q. The operations involving Q in assembling the RAE (20) are as follows:

- Computation of the (1,1) block $\widetilde{M} = AQ\,\mathrm{diag}(S_1^{-1}, D_2^{-1})Q^TA^T$;
- Computation of the (1,2) block $\widetilde{A}_1 = AQ^{(1)}$ and the right-hand side vector $\widetilde{r} = Q^Tr_x$.

To carry out the above operations efficiently, we need to derive an explicit formula for Q to facilitate such calculations. Recall the eigenvector matrix Q_i (9) associated with the ith second order cone.

To get an explicit description of Q_i, we need to construct the Householder matrix H_i explicitly. Without going into the algebraic details, the precise form of H_i is given as follows:

(22)
$$H_i \;=\; I - h_ih_i^T, \quad h_i := \begin{bmatrix} h_i^0 \\ \bar{h}_i \end{bmatrix} = \frac{1}{\tau_i}\begin{bmatrix} \tau_i^2\,\mathrm{sign}(g_i^0) \\ \bar{g}_i \end{bmatrix} \;\in\; \mathbb{R}^{n_i-1}, \quad \tau_i := \sqrt{1+|g_i^0|}.$$

With some algebraic manipulations, the eigenvector Q_i can be rewritten in the form given in the next lemma.

LEMMA 7.1. *Let $\beta_i = -\mathrm{sign}(h_i^0)/\sqrt{2}$. We have $Q_i = \mathrm{diag}(K_i, I) - u_iv_i^T$, where*

$$K_i \;=\; \begin{bmatrix} -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} \\ \beta_i & \beta_i \end{bmatrix}, \quad u_i \;=\; \begin{bmatrix} 0 \\ h_i \end{bmatrix}, \quad v_i \;=\; \begin{bmatrix} \beta_ih_i^0 \\ \beta_ih_i^0 \\ \bar{h}_i \end{bmatrix}. \tag{23}$$

Proof. Note that by construction, the first column of H_i is given by $-\mathrm{sign}(g_i^0)g_i$. Let $\alpha = \frac{1}{\sqrt{2}} + \mathrm{sign}(g_i^0)$. From (9), we have

$$\begin{aligned} Q_i \;&=\; \begin{bmatrix} -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0 & \cdots & 0 \\ \frac{1}{\sqrt{2}}g_i & \alpha g_i & 0 & \cdots & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & I - h_ih_i^T \end{bmatrix} \\ &=\; \begin{bmatrix} -\frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & 0 & \ldots & 0 \\ -\frac{\mathrm{sign}(g_i^0)}{\sqrt{2}} & -\frac{\mathrm{sign}(g_i^0)}{\sqrt{2}} - 1 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & & \vdots \\ 0 & 0 & 0 & \ldots & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ 0 & I \end{bmatrix} - \begin{bmatrix} 0 \\ h_i \end{bmatrix}\begin{bmatrix} -\frac{\tau_i}{\sqrt{2}} \\ h_i^0 - \alpha\tau_i \\ \bar{h}_i \end{bmatrix}^T. \end{aligned}$$

It is readily shown that $h_i^0 - \alpha\tau_i = -\tau_i/\sqrt{2} = \beta_ih_i^0$. Now it is easy to see that the required results hold. ∎

Observe that each Q_i is a rank-one perturbation of a highly sparse block diagonal matrix. Based on the above lemma, those operations listed at the beginning of this subsection, except the first one, can be computed straightforwardly. To compute the matrix $\widetilde{M}$, we have to further analyze the structure of the matrix $Q_i \,\mathrm{diag}(S_{1i}^{-1}, D_{2i}^{-1}) Q_i^T$.

Let $G_i = \mathrm{diag}(S_{1i}^{-1}, D_{2i}^{-1})$ and $\Sigma_i = \mathrm{diag}(K_i, I)$; then $Q_i = \Sigma_i - u_i v_i^T$ and $Q_i\, G_i\, Q_i^T = \Sigma_i\, G_i\, \Sigma_i^T - \Sigma_i G_i v_i u_i^T - u_i v_i^T G_i \Sigma_i^T + u_i v_i^T\, G_i\, v_i u_i^T$. By setting $\rho_i = v_i^T G_i v_i$ and $\widetilde{v}_i = \Sigma_i G_i v_i / \sqrt{\rho_i}$, we have $Q_i\, G_i\, Q_i^T = \Sigma_i G_i \Sigma_i^T + l_i l_i^T - \widetilde{v}_i \widetilde{v}_i^T$, where $l_i = \widetilde{v}_i - \sqrt{\rho_i} u_i$. Thus each component matrix $\widetilde{M}_i$ in $\widetilde{M} = \sum_{i=1}^N \widetilde{M}_i$ can be expressed as

$$\widetilde{M}_i \;=\; A_i Q_i G_i Q_i^T A_i^T \;=\; A_i \left(\Sigma_i G_i \Sigma_i^T\right) A_i^T + (A_i l_i)(A_i l_i)^T - (A_i \widetilde{v}_i)(A_i \widetilde{v}_i)^T. \tag{24}$$

Since $\Sigma_i G_i \Sigma_i^T$ is a highly sparse block diagonal matrix, $\widetilde{M}_i$ is a symmetric rank-two perturbation to a sparse matrix if $A_i A_i^T$ is sparse. Hence, the computational complexity of $\widetilde{M}$ is only slightly more expensive than that for the Schur complement matrix M.

7.2. Handling dense columns. Let $\Sigma = \mathrm{diag}(\Sigma_1, \ldots, \Sigma_N)$, and

$$A_l \;=\; [A_1 l_1, \ldots, A_N l_N]\,, \quad A_v \;=\; [A_1 \widetilde{v}_1, \ldots, A_N \widetilde{v}_N]\,.$$

Then it is readily shown that

$$\widetilde{M} \;=\; A\,\Sigma\,\mathrm{diag}(S_1^{-1}, D_2^{-1})\Sigma^T\, A^T + A_l A_l^T - A_v A_v^T. \tag{25}$$

If AA^T is sparse, then the first matrix in (25) is sparse as well. For an SOCP problem where all the cones are low-dimensional, typically the matrices A_l and A_v are also sparse. In that case, the RAE (20) may be solved directly. However, if high-dimensional cones exist, then A_l and A_v invariably contain dense columns. Moreover, when A is sparse but has dense columns, AA^T will also be dense. In order to preserve the sparsity in $\widetilde{M}$, it is necessary to handle the dense columns separately when they exist.

Let P_1 be the dense columns in $A\Sigma\,\mathrm{diag}(S_1^{-1/2}, D_2^{-1/2})$ and A_l, and let P_2 be the dense columns in A_v. Let $\widetilde{M}_s = \widetilde{M} - P_1 P_1^T + P_2 P_2^T$ be the "sparse part" of $\widetilde{M}$. It is well known that by introducing the following auxiliary variables, $t_1 = P_1^T \Delta y$, $t_2 = -P_2^T \Delta y$, the dense columns can be removed from $\widetilde{M}$; see [4]. The precise form of the RAE (20) with dense column handling is as follows:

$$\begin{bmatrix} \widetilde{M}_s & U \\ U^T & -C \end{bmatrix} \begin{bmatrix} \Delta y\,;\, S_1^{-1/2} E_1 \Delta \widetilde{x}_1\,;\, t_1\,;\, t_2 \end{bmatrix} \;=\; \begin{bmatrix} q\,;\, S_1^{-1/2} \widetilde{r}_1\,;\, 0\,;\, 0 \end{bmatrix}, \tag{26}$$

where q is defined in (21) and $U = \left[\widetilde{A}_1 S_1^{-1/2},\ \ P_1,\ \ P_2\right]$, $C = \mathrm{diag}(D_1 E_1^{-1}, I_1, -I_2)$. Here I_1, I_2 are identity matrices.

7.3. Direct solvers for symmetric indefinite systems. Solving the sparse symmetric indefinite system (26) is one of the most expensive steps at each IPM iteration. Thus, it is critical that the solver used must be as efficient as possible.

We consider two methods for solving (26). The first is the Schur complement method, which is also equivalent to the Sherman–Morrison–Woodbury formula. The

second is the LDL^T factorization implemented in MA47 [18]. Each of these methods has its own advantages under different circumstances.

Schur complement method. This method is widely used for dense column handling in IPM implementations; see [4] and the references therein. It uses the sparse matrix $\widetilde{M}_s$ as the pivoting matrix to perform block eliminations in (26). It is readily shown that solving (26) is equivalent to solving the following systems:

$$\left(U^T\widetilde{M}_s^{-1}U+C\right)\left[\begin{array}{c} S_1^{-1/2}E_1\Delta\widetilde{x}_1\,;\,t_1\,;\,t_2 \end{array}\right] = U^T\widetilde{M}_s^{-1}q-\left[\begin{array}{c} S_1^{-1/2}\widetilde{r}_1\,;\,0\,;\,0 \end{array}\right], \tag{27}$$

$$\Delta y = \widetilde{M}_s^{-1}q-\widetilde{M}_s^{-1}U\left[\begin{array}{c} S_1^{-1/2}E_1\Delta\widetilde{x}_1\,;\,t_1\,;\,t_2 \end{array}\right].$$

Note that since $\widetilde{M}$ is symmetric positive definite, its "sparse part," $\widetilde{M}_s$, is typically also positive definite if the number of dense columns removed from $\widetilde{M}$ is small. If $\widetilde{M}_s$ is indeed positive definite, then (27) can be solved by Cholesky or sparse Cholesky factorization. As mentioned before, highly efficient and optimized Cholesky solvers are readily available in the public domain. Another advantage of the Schur complement method is that the symbolic factorization of $\widetilde{M}_s$ and the pivoting order of the Cholesky factorization need only be computed once or twice during the initial phase of the IPM iteration and they can be reused for subsequent IPM iterations even when the partition in D changes.

But the Schur complement method does have a major disadvantage in that the matrix $U^T\widetilde{M}_s^{-1}U+C$ is typically dense. This can lead to a huge computational burden when U has a large number of columns, say, more than a few hundred. Furthermore, the Schur complement method is numerically less stable than a method that solves (26) directly.

Roughly speaking, the Schur complement method is best suited for problems with U having a small number of columns. When U has a large number of columns or when $\widetilde{M}_s$ is not positive definite, we have to solve (26) directly by the second method described below.

MA47. MA47 is a direct solver developed by Reid and Duff [18] for sparse symmetric indefinite systems. This is perhaps the only publicly available state-of-the-art direct solver for sparse symmetric indefinite systems. It does not appear to be as efficient as the sparse Cholesky codes of Ng and Peyton [16].

The MA47 solver implements the multifrontal sparse Gaussian elimination described in [7]. In the algorithm, the pivots used are not limited to only 1×1 diagonal pivots but also include 2×2 block diagonal pivots. The solver performs a prefactorization phase (called symbolic factorization) on the coefficient matrix to determine a pivoting order so as to minimize fill-ins. In the actual factorization process, this pivoting order may be modified to obtain better numerical stability. Note that in sparse Cholesky factorization, the pivoting order is not modified after the symbolic factorization phase. Because significant overhead may be incurred when the pivoting order is modified in the factorization process, running MA47 is sometimes much more expensive than the sparse Cholesky routine of Ng and Peyton on matrices with the same dimensions and sparsity patterns.

The advantage of using MA47 to solve (26) is that it does not introduce a fully dense matrix in the solution process. Thus it is more suitable for SOCP problems with U having a relatively large number of columns.

However, the MA47 method does have a disadvantage in that the symbolic factorization of the reduced augmented matrix needs to be recomputed whenever the partition in D changes.

7.4. Partitioning strategy. As shown in section 6, the RAE approach for computing the search directions has the potential to overcome certain numerical instabilities encountered in the SCE approach. The RAE was derived from the augmented equation (7) by modifying the part of the coefficient matrix involving the small eigenvalues of F^2. Here we will describe the partition we use in $D = \mathrm{diag}(D_1, D_2)$.

The choice of D_1 is dictated by the need to strike a balance between our desire to compute more accurate search directions and to minimize the size of the RAE to be solved. For computational efficiency, it is better to have as few columns in the matrix U (26) as possible, thus suggesting that the threshold for labelling an eigenvalue as "small" should be low. But to obtain better accuracy, it is beneficial to partition eigenvalues that are smaller than, say 10^{-3}, into D_1 to improve the conditioning of the reduced augmented matrix.

With due consideration in balancing the two issues just mentioned, we adopt a hybrid strategy in computing the search direction at each IPM iteration. If $\kappa(F^2) \geq 10^6$, put the eigenvalues of F^2 that are smaller than 10^{-3} in D_1, and the rest in D_2; otherwise, put all the eigenvalues of F^2 in D_2.

Some of our test problems also contain linear blocks (i.e., cones with dimensions $n_i = 1$). In this case, $F_i^2 = z_i/x_i$ is a scalar, and we put F_i^2 in D_1 if it is smaller than 10^{-3}; otherwise, we put it in D_2.

As noted in Remark 3.1, when $\widetilde{A}_1$ has full row rank (for which a necessary condition is that the number of small eigenvalues put into D_1 is at least m), the Schur complement matrix M is not highly ill-conditioned, and it is not necessary to use the RAE approach to compute the search directions. When such a situation occurs, we use the SCE approach.

8. Numerical experiments. The RAE (20) or (26) is more expensive to solve than the SCE (8) because it is larger in size. As we have discussed in the last section, we can try to minimize the additional computational cost by a judicious choice of the solver used. If the number of columns in U is small, then using the Schur complement method to solve (26) should not be much more expensive than solving the SCE. We adopt the following heuristic rule to select the solver used to solve (26). If the number of columns in U is less than 200, we use the Schur complement method; otherwise, we use the MA47 method.

The RAE approach is implemented in MATLAB based on the IPM in SDPT3, version 3.1; see [25]. But the search direction at each iteration is computed based on the RAE (26). We use the same stopping criteria mentioned in section 4. Again, the numerical results are obtained from a Pentium IV 2.4GHz PC with 1G RAM.

We consider the same SOCP problems in section 4. But in order to focus on the comparison between the SCE and RAE approaches without the complication of unbounded primal solution sets, we exclude the `nbxxx`, `nqlxxx`, and `qsspxxx` problems from the numerical experiments in this section. Our major concerns in the experiments are efficiency and accuracy. We measure efficiency by the total CPU time taken, while accuracy is again measured by the accuracy exponent defined in (13).

The numerical results for the RAE-based IPM are presented in Table 5. In the table, T_{iter} denotes the average CPU time taken per iteration. For the RAE-based IPM, the number of IPM iterations taken for each problem is given under the column "iter." The number in each bracket gives the number of iterations using the RAE approach. The total CPU time taken to solve each problem is given under the column "Time." The number in each bracket gives the CPU time taken by the iterations using the RAE approach.

TABLE 5

A comparison between 2 SCE-based IPMs and the RAE-based IPM for solving SOCP problems. The last column in the table gives the maximum number of columns in the matrix U in (26)*. The numbers in round brackets are those taken by the iterations using the RAE approach.*

The numerical results in Table 2 show that the SCE-based IPMs may not deliver approximate optimal solutions with small primal infeasibilities. In Table 5, we see that the RAE-based IPM can drive the primal infeasibilities of all the problems to a level of 10^{-9} or smaller. For the `schedxxx` and `randxxx` problem sets, both the SCE-based IPMs in SDPT3 and SeDuMi cannot deliver accurate approximate solutions where the accuracies attained a range from $\phi = -2.5$ to $\phi = -8.9$ for the `schedxxx` set and from $\phi = -4.5$ to $\phi = -7.6$ for the `randxxx` set. The RAE-based IPM, however, can achieve solutions with accuracy $\phi \leq -9.1$ for all the problems in these two sets. The improvement in the attainable accuracy is more than five orders of magnitude in some cases. For the `firxxx` problems, the SCE approach can already produce accurate approximate solutions, and the RAE approach produces comparable accuracies.

The good performance in terms of accuracy of the RAE-based IPM on the `schedxxx` and `randxxx` problem sets is consistent with the theoretical results established in section 6. The SOCP problems in the `schedxxx` set are primal and dual nondegenerate, and strict complementarity holds at optimality. For the `randxxx` set, all the problems are primal nondegenerate, but four of the problems are dual degenerate. It is interesting to note that dual degeneracy does not seem to affect the performance of RAE on these degenerate problems. This fact is consistent with the observation we made in Remark 6.2.

By Theorem 5.2, the condition number of the reduced augmented matrix for the problems in the `schedxxx` set is bounded when $\mu \downarrow 0$. But as noted in Remark 3.2, strict complementarity and primal and dual nondegeneracy in an SOCP do not necessarily imply that the associated Schur complement matrix has bounded condition numbers when $\mu \downarrow 0$. The numerical results produced by the `schedxxx` problems concretely show the difference in numerical stability between the SCE and RAE approaches.

From the average CPU time taken per IPM iteration for the RAE and SCE approaches in Table 5, we see that the RAE approach is reasonably efficient in that the ratio (compared with SDPT3) is at most 6.0 for all the test problems, and 78% of them have ratios between 1.0 and 2.0.

The objective values obtained by the RAE-based IPM are given in Table 6.

rand200_300_2	1	0 (62/65)	1				

As we are able to compute rather accurate approximate solutions for (1), it is worthwhile to gather information such as primal and dual degeneracy and strict complementarity for some of the smaller SOCP problems we have considered in this paper. Such information is given in Table 7. We note that the degeneracies of the problems are determined by computing the numerical row and column rank (via the MATLAB command `rank`) of the matrices in Theorems 20 and 21 in [1], respectively.

9. Conclusion. We analyzed the accuracy of the search direction computed from the SCE approach, and how the residual norm in the computed solution affects the primal infeasibility and hence the achievable accuracy in the approximate optimal solution.

We also discussed the factors contributing to the good numerical performance of the very well implemented SCE-based IPM in the software SeDuMi.

A reduced augmented equation is proposed to compute the search direction at each IPM iteration when the SCE cannot be solved to sufficient accuracy. The proposed RAE approach can improve the robustness of IPM solvers for SOCP. It can be implemented efficiently by carefully preserving the sparsity structure in the problem data. Numerical results show that the new approach can produce more accurate approximate optimal solutions compared to the SCE approach.

Acknowledgments. The authors are grateful to Professor Robert Freund for valuable suggestions on the manuscript. The authors also thank the associate editor, Professor M. J. Todd, and the referees for many helpful comments and suggestions on improving the paper.

MODELING COMPENSATION FOR OPTICAL FIBER COMMUNICATION SYSTEMS*

JOHN ZWECK† AND SUSAN E. MINKOFF†

Abstract. Today the vast majority of telecommunication and Internet messages are sent along fiber optic cables buried underground. Binary data (encoded as a sequence of pulses of light) may travel thousands of kilometers to reach its final destination. The fibers that are used for this data transfer necessarily contain manufacturing impurities that lead to fast and slow polarization states for the propagating signal. This imperfection in the fiber results in a random distortion effect known as polarization-mode dispersion (PMD). As binary data travels along these fibers, the pulses spread, causing the ones to decrease in value and the zeros to increase. Thus, the received message may contain errors. To decrease the likelihood of errors in the received signal, a device known as a compensator can be placed at the receiver. Determining an optimal setting for the compensator involves rotating the fiber in the compensator to best align its slow axis with the fast axis of the transmission fiber. Such a rotation should cancel out some of the effects of PMD. Modeling this system numerically requires that one generate fiber realizations with large amounts of PMD. To measure rotation angle goodness of fit between compensation and transmission fiber requires that one choose a feedback signal for the compensator. We compare the eye opening, spectral line, and degree of polarization ellipsoid feedback signals. While the eye opening feedback mechanism is the most accurate measure, it is difficult to optimize numerically. The degree of polarization and spectral line feedback signals act as smooth surrogates for the eye.

1. Introduction.

The vast majority of long-distance telecommunications and Internet traffic is carried by optical fiber communication systems [31]. In an optical communication system binary data is encoded onto a sequence of pulses of light which are then transmitted over long distances through optical fiber. A material property of optical fiber called birefringence causes the pulses to spread and distort as they propagate. This distortion of the optical signal is called polarization-mode dispersion (PMD) and is governed by the linear-PMD equation, which is a special case of the Manakov-PMD equation. The Manakov-PMD equation models the propagation of light through dispersive, nonlinear, birefringent optical fiber and is derived from Maxwell's equations [25], [43]. In the 1980s scientists realized that PMD in optical fibers would have a significant impact on the performance of high-data rate systems [18], [30]. By the time the signal reaches its destination it may not be possible to correctly decode the transmitted binary message; i.e., bit errors may occur. The engineering goal is to ensure that the bit-error ratio, which is the probability that a bit error occurs, is as small as possible (typically 10^{-9}–10^{-15}). A major difficulty in achieving this goal is that the birefringence of optical fiber, and hence the bit-error ratio, varies randomly over time. To reduce the probability of a large bit-error ratio, engineers have proposed using devices called optical PMD compensators.

In birefringent fiber, the speed of the light depends on its polarization state. To first approximation, a given optical fiber has two special principal states of polarization: fast and slow. The delay in the arrival times between light traveling in these two states is called the differential group delay (DGD). If the DGD is too large, bit errors will occur. A PMD compensator is a device that is placed after the transmission fiber just prior to the receiver. It is designed to reduce the deleterious effect that PMD has on the performance of a communication system. A *simple PMD compensator* consists of a device called a polarization controller that is used to change the polarization state of the light, followed by a piece of compensating fiber with a fixed DGD. The polarization controller rotates the fast polarization state of the transmission fiber onto the slow polarization state of the compensation fiber, thereby reducing the total DGD. In this paper, we study the problem of how best to optimize the performance of a simple PMD compensator. For each random realization of the birefringence of the transmission fiber, the goal is to find the rotation of the polarization controller that will minimize the bit-error ratio.

The physical and statistical properties of PMD, the equations that govern the propagation of light through birefringent optical fiber, and Monte Carlo-based models for the random variation in the birefringence of optical fiber have been widely studied over the last 25 years, and several excellent review articles have recently appeared [24], [31], [43].

Because the random fiber realizations that produce unacceptably large PMD are extremely rare, it is very difficult to observe them experimentally. It is also not practical to simulate them using a standard Monte Carlo search of the state space of all possible fiber realizations. However, it is precisely these rare, large-PMD fiber realizations that are most important to consider when assessing the effectiveness of a PMD compensator. Recently, Biondini and Kath [2], [3], [4] developed a multiple importance sampling algorithm that uses biased Monte Carlo simulations to efficiently generate realizations of the fiber which have large amounts of PMD. This advance made it possible to perform simulation studies that more accurately assess the performance of PMD compensators [35], [36], [38], [39], [64].

In recent years several different approaches have been proposed for reducing bit errors due to PMD. Comprehensive reviews of these ideas can be found in [7], [26], [52]. One approach is to install newly designed low-PMD fiber [45]. However, replacing fiber is prohibitively expensive for existing systems. Another approach is to design the shape of the transmitted light pulses to make the signal more resilient to PMD [52]. In addition to these passive methods, active PMD compensation methods have also been proposed. Active compensation techniques can be applied to the optical signal either just before it enters the receiver (optical compensation) or after the optical signal has been converted back into an electrical signal in the receiver (electrical compensation) [39].

We focus in this paper on optical PMD compensation only. Optical PMD compensation is complicated by the fact that the DGD and principal states depend on the frequency of the light. If the PMD in the transmission fiber were actually frequency-independent, then a simple optical PMD compensator like that described above could completely eliminate the effects of PMD. In the realistic case of frequency-dependent PMD it is still theoretically possible (but not experimentally viable) to completely eliminate the effects of PMD via solution of an inverse problem [52]. Compensators that account for at least some frequency-dependent PMD have a relatively large number of degrees of freedom; i.e., their objective functions are defined on a high-dimensional space. However, such devices are costly to build and operate. Since low

cost is desirable, we chose to study the simple optical PMD compensator described above, which has only two degrees of freedom.

An obvious choice for the feedback mechanism to use for compensation is the bit-error ratio. However, it is not actually possible to compute the bit-error ratio in a real system. Instead, for a simple compensator, the most common feedback signals are the power in a spectral line [27] and the degree of polarization (DOP) [33]. The goal is to maximize these feedback signals since small values of the DGD usually result in large values of the monitored signal. In addition, it has been shown that the performance of a compensator can be improved by scrambling the polarization state of the input signal [47]. Therefore, the monitor signals we chose to study for this paper are the spectral line and polarization-scrambled DOP. We compare these two feedback mechanisms to a third—the eye opening [8]—which is highly correlated to the bit-error ratio. Unfortunately, the eye opening monitor is not very practical since it is difficult to build and operate (requiring complex fast electronic circuitry).

Several simulation studies have compared the performance of different PMD compensators. Sunnerud et al. [52], [53] and Buchali and Bülow [7] compared compensators with a few (2–5) degrees of freedom. Their results show that compensators with three or more degrees of freedom are somewhat more effective than the simple compensator. Although they used the spectral line and DOP monitors (without polarization scrambling) they did not study the properties of these objective functions or compare them to the eye opening monitor. Moreover, because they used standard Monte Carlo simulations they were not able to access the rare large-PMD fibers that are of real interest when quantifying the performance of a compensator. I. Lima et al. [39] used multiple importance sampling to study the performance of a simple compensator with a fixed DGD. They showed that the optimal value for the fixed DGD in the compensator is about 2–3 times larger than the mean DGD of the transmission line, averaged over fiber realizations. However, they only used the eye opening objective function in their work. In addition, none of the papers just cited carefully studies how the performance of a compensator depends on the choice of algorithm used to optimize the objective function.

We compare the spectral line, polarization-scrambled DOP, and eye opening objective functions, both for a particular fiber realization and statistically over many fiber realizations. In the special case that the PMD is frequency-independent, we derive analytical formulae for the spectral line and polarization-scrambled DOP objective functions. Each objective function can be regarded as a doubly periodic function on a two-dimensional plane that parametrizes a certain set of rotations of three-dimensional space. Our formulae show that the polarization-scrambled DOP has a single maximum, while the spectral line can have at least two maxima. However, there may be more local maxima in the general case of frequency-dependent PMD.

We also systematically study the combined effect that the choice of feedback signal and optimization algorithm have on the performance of a simple PMD compensator. By using importance sampling with a large number of fiber realizations, we are able to assess performance for the very rare large-PMD realizations of the fiber that are most important to consider when studying PMD compensators. Because the eye opening is so highly correlated to the bit-error ratio, it is very reasonable to assume that the best performance is obtained when the rotation of the polarization controller is given by the global maximum of the eye opening objective function. However, it is difficult to locate the global maximum of the eye opening. On the other hand, we will show that it is much easier to locate the global maxima for the spectral line and polarization-scrambled DOP, which indicates that these two objective functions are

smoother than the eye opening.

The main conclusion of our study is that the spectral line and polarization-scrambled DOP act as smooth surrogates for the eye opening (or bit-error ratio) objective function. This result is obtained by comparing the performance of the compensators with different local and global optimization algorithms, and by statistical studies that compare the location of local and global maxima of the three different objective functions. We show that the best trade-off between computational cost and performance is obtained using the polarization-scrambled DOP objective function with a multilevel optimization algorithm. This algorithm uses a global genetic algorithm followed by a local conjugate gradient algorithm. Preliminary work [64] compared the performance of the simple compensator with the three objective functions but used only local optimization algorithms and did not compare the structure of the objective functions.

In section 2, we review the basic mathematical models for optical fiber communications systems with PMD. In section 3, we describe the PMD compensator we study in this work, and in section 4 we derive formulae for the polarization-scrambled DOP and spectral line objective functions in the special case of only first-order PMD. In section 5 we review the importance sampling algorithm and in section 6 we describe the optimization algorithms we used. Finally, in section 7 we present the results of our optimization case study.

2. Mathematical models for optical communication systems. In this section, we review the linear-PMD equation and the coarse-step algorithm that is used to generate random realizations of the fiber. We also explain how to calculate and measure the performance of an optical communication system.

2.1. The governing equations. In this subsection, we review the Manakov-PMD equation that describes the propagation of an optical signal through birefringent optical fiber. The birefringence of optical fiber, which is the physical cause of PMD in the signal, varies randomly along the fiber and over the course of time due to temperature variations and mechanical vibrations.

Light in an optical fiber propagates in two eigenmodes which are distinguished from each other by their polarization states. To model the propagation of light in an optical fiber, we choose coordinates, (x, y, z), so that the positive z-axis is the propagation direction along the fiber and the (x, y)-plane is orthogonal to the fiber. The electric field of light propagating at a carrier frequency, ω_0, is the real part of the complex-valued vector field, $\mathbf{E}$, which we express as [43]

$$\mathbf{E}(x, y, z, \tau) = \kappa \left[U_1(z, \tau)\mathbf{R}_1 + U_2(z, \tau)\mathbf{R}_2\right] \exp[i\beta(\omega_0, z)z - i\omega_0\tau]. \tag{2.1}$$

Here τ denotes physical time, and the dispersion relation of the fiber is determined by the frequency-dependence of the wavenumber, $\beta(\omega_0, z)$. The vector fields $\mathbf{R}_1$ and $\mathbf{R}_2$ are two eigenfunctions that describe the (x, y)-dependence of the electric field, $\mathbf{E}$. These vector fields are orthogonal to the propagation direction z, and to each other. The functions U_1 and U_2 describe the slow variation of the envelope of the electric field about the rapidly varying carrier wave given by the exponential factor in (2.1). The column vector $\mathbf{U}(z, t) = (U_1(z, t), U_2(z, t))^T$, which is called the *Jones vector* of the light, models the *polarization state* of the light at (z, t). Here we have transformed from physical time, τ, to retarded time, $t = \tau - \frac{\partial\beta}{\partial\omega}(\omega_0, z)z$, which defines a coordinate system that is moving with the group velocity $[\frac{\partial\beta}{\partial\omega}(\omega_0, z)]^{-1}$. The normalization constant κ is chosen so that $|\mathbf{U}|^2 = |U_1|^2 + |U_2|^2$ corresponds to the *optical power* of the

signal. The data is encoded onto the signal by allocating a time slot to each bit and varying the power of the signal so that the power is large in the time slots allocated to the ones and small in the time slots allocated to the zeros.

If the refractive index is perfectly axially symmetric, then the two eigenmodes are equal and the signal is not affected by PMD. However, in real fiber this degeneracy is broken due to imperfections in the fiber. Consequently, real optical fiber has a small *birefringence*: Light propagating in the two different eigenmodes travels at slightly different group velocities. Therefore, if the power of an optical pulse is split between the two polarization eigenmodes, $\mathbf{R}_1$ and $\mathbf{R}_2$, then as it propagates through the fiber, the power will spread in the time domain and can become severely distorted. This phenomenon is called *polarization-mode dispersion* (PMD). As a result, optical power will be transferred between the time slots allocated to the different bits, potentially resulting in bit errors at the receiver. PMD is particularly difficult to combat because it is inherently stochastic in nature. As the distance, z, along the fiber increases, the eigenfunctions $\mathbf{R}_1$ and $\mathbf{R}_2$ rotate rapidly and randomly in the (x, y)-plane but are otherwise unchanged. At each fixed distance, they also rotate randomly over time on a scale of minutes to hours due to temperature variations and mechanical vibrations. Consequently, a PMD compensator must be continually optimized to correct for PMD-induced distortions in the received optical signal.

The equation governing the z-evolution of $\mathbf{U}$ is the *coupled nonlinear Schrödinger equation* (CNLS). The CNLS is derived from Maxwell's equations by averaging over the rapid variations of the carrier wave, $\exp[i\beta(\omega_0, z)z - i\omega_0\tau]$, and over the eigenfunctions, $\mathbf{R}_1$ and $\mathbf{R}_2$ [43]. The CNLS states that

$$\frac{\partial \mathbf{U}}{\partial z} = g\mathbf{U} + i\Delta\mathsf{B}\mathbf{U} - \Delta\mathsf{B}'\frac{\partial \mathbf{U}}{\partial t} - \frac{i}{2}\beta''\frac{\partial^2 \mathbf{U}}{\partial t^2} + i\gamma\left[|\mathbf{U}|^2\mathbf{U} - \frac{1}{3}(\mathbf{U}^\dagger\sigma_2\mathbf{U})\sigma_2\mathbf{U}\right]. \tag{2.2}$$

Here, the scalar coefficient g is the loss coefficient of the fiber. The factor $\Delta\mathsf{B} = \Delta\mathsf{B}(\omega_0, z)$ is the *birefringence matrix*, which is a 2×2 Hermitian matrix that models the anisotropy and asymmetry of the linear dielectric response tensor of the fiber, averaged with respect to the eigenfunctions $\mathbf{R}_1$ and $\mathbf{R}_2$. The matrix $\Delta\mathsf{B}'$ is defined by $\Delta\mathsf{B}' = \frac{\partial \Delta\mathsf{B}}{\partial \omega}(\omega_0, z)$, and the scalar $\beta'' = \frac{\partial^2 \beta}{\partial \omega^2}(\omega_0, z)$ is the chromatic (frequency-dependent) dispersion. The scalar coefficient γ measures the strength of the Kerr nonlinearity in the fiber. The Kerr nonlinearity arises from the fact that the refractive index of optical fiber has a small dependence on the optical power $|\mathbf{U}|^2$ of the light. Finally, $\dagger$ denotes conjugate transpose, and σ_2 is the second of the three Pauli spin matrices

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \qquad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{2.3}$$

Because of the polarization properties of glass [48], optical fiber is *linearly birefringent*, which means that

$$\Delta\mathsf{B} \;=\; \Delta\beta(\cos\theta\sigma_3 + \sin\theta\sigma_1), \tag{2.4}$$

where $\Delta\beta$ is the magnitude of birefringence and θ is an orientation angle whose significance will be explained later. Since θ is a very weak function of frequency, we assume that $\Delta\mathsf{B}' = \Delta\beta'(\cos\theta\sigma_3 + \sin\theta\sigma_1)$. Wai and Menyuk [58] proposed a model for the random variation of the birefringence along the fiber in which $\Delta\beta'\cos\theta$ and $\Delta\beta'\sin\theta$ are independent Gaussian random processes with mean zero and the same

standard deviation [58]. Recently, Galtarossa et al. [19], [20] experimentally validated this model.

The random variations in the fiber birefringence occur on a length scale of 1–100 m and result in very rapid changes in the polarization state of the light as it propagates. However, since optical communication systems are at least several hundred kilometers long, it is not computationally feasible to simulate propagation through birefringent fiber by using a numerical method that takes small enough steps along the fiber to track these rapid changes in the polarization state of the light. This problem can be overcome by transforming the rapid changes in the polarization state of the light at the carrier frequency out of the CNLS to obtain the *Manakov-PMD equation* [42], [43]:

$$\frac{\partial \mathbf{W}}{\partial z} = g\mathbf{W} - \Delta\beta'\bar{\sigma}_3\frac{\partial \mathbf{W}}{\partial t} - \frac{i}{2}\beta''\frac{\partial^2 \mathbf{W}}{\partial t^2} + i\gamma|\mathbf{W}|^2\mathbf{W}. \tag{2.5}$$

Here $\mathbf{W}(z,t) = \mathsf{Q}(z)\mathbf{U}(z,t)$, where $\mathsf{Q}(z)$ is a unitary transformation and $\bar{\sigma}_3 = \mathsf{T}(z)^{-1}\sigma_3\mathsf{T}(z)$ for a matrix $\mathsf{T}(z)$ that is determined by the birefringence parameters $\Delta\beta$ and θ. To explain the rationale for making a transformation of the form $\mathsf{Q}(z)$, we first note that the Fourier conjugate of the retarded time, t, is frequency, ω, measured relative to the carrier frequency, ω_0, of the optical signal. Even though the Fourier transform, $\widehat{\mathbf{U}}(z,\omega)$, of $\mathbf{U}(z,t)$ varies rapidly with the propagation distance z, it only has a very weak dependence on frequency, ω. Therefore, it makes sense to transform $\mathbf{U}$ so that the new coordinates exactly follow the rapid changes of the polarization state of the signal at the center frequency, ω_0, i.e., so that $\widehat{\mathbf{W}}(z,0)$ is constant in z. In this new coordinate system, the Fourier transform, $\widehat{\mathbf{W}}(z,\omega)$, of the solution of the Manakov-PMD equation measures the slow variation of the polarization state of the light at each frequency, ω, with respect to the polarization state of the light at the carrier frequency, ω_0.

2.2. The linear PMD equation. In this subsection we review the linear PMD equation which is a special case of the Manakov-PMD equation. The linear PMD equation is appropriate for studying the statistical behavior of PMD and PMD compensators. We will use this equation to explain how PMD results in the spreading and distortion of optical pulses.

The linear PMD equation is obtained by omitting all but the second term on the right-hand side of (2.5). Another widely studied special case of the Manakov-PMD equation is the scalar nonlinear Schrödinger equation, which is the equation obtained when there is no birefringence ($\Delta\beta' = 0$) and the optical signal at the transmitter is polarized [25], [43]. In many systems, the primary source of bit errors is not the nonlinear effects that are modeled by the scalar nonlinear Schrödinger equation but rather the effects of PMD that are modeled by the linear PMD equation. Moreover, because PMD is a stochastic effect, and because bit errors are so rare, PMD must be studied statistically using a large number of randomly chosen realizations of the birefringence of the optical fiber. Simulations that do not include the Kerr nonlinearity are computationally several orders of magnitude faster than those that do.

We now explain how PMD gives rise to the spreading and distortion of optical pulses, and introduce the concept of differential group delay. The linear PMD equation is most readily analyzed in the frequency domain, where

$$\frac{\partial \widehat{\mathbf{W}}}{\partial z} \;=\; i\Delta\beta'\,\bar{\sigma}_3(z)\,\omega\,\widehat{\mathbf{W}}. \tag{2.6}$$

The solution to this equation can be expressed in the form $\widehat{\mathbf{W}}(z,\omega) = \widehat{f}(\omega)\,\widehat{\mathbf{A}}(z,\omega)$, where $\widehat{f}$ is a real scalar-valued function, and $|\widehat{\mathbf{A}}(z,\omega)|^2 = 1$. As a function of time, the power of the optical signal is given by $|f|^2$, where f is the inverse Fourier transform of $\widehat{f}$. The vector $\widehat{\mathbf{A}}$ is the polarization state of the signal. Suppose that $\mathsf{F} = \mathsf{F}(z,\omega)$ is a matrix such that

$$\frac{\partial \widehat{\mathbf{A}}}{\partial \omega} \;=\; i\mathsf{F}\widehat{\mathbf{A}}. \tag{2.7}$$

It can be shown that F is a Hermitian matrix that is determined by the quantities $\Delta\beta'$ and $\bar{\sigma}_3$ that characterize the birefringence of the optical fiber [43]. The absolute difference of the two real eigenvalues of F is called the *differential group delay* (DGD), and the eigenvectors of F are called the *principal states of polarization*. The DGD and the principal states of polarization depend on both the propagation distance, z, and the frequency, ω.

To see how the DGD is related to pulse spreading, suppose for simplicity that the matrix F is ω-independent, at least over the frequency bandwidth of the signal, $\widehat{\mathbf{W}}$. In this case, we say that the fiber birefringence generates only *first-order PMD*. Diagonalizing F, we see that

$$\widehat{\mathbf{A}}(z,\omega) \;=\; \mathsf{P}e^{i\omega\mathsf{D}(z)}\mathsf{P}^\dagger\widehat{\mathbf{A}}(z,0), \tag{2.8}$$

where $\mathsf{P} = (\mathbf{v}_1, \mathbf{v}_2)$ is unitary, and $\mathsf{D}(z) = \operatorname{diag}\left(-\frac{\tau(z)}{2}, \frac{\tau(z)}{2}\right)$. Here $\tau(z)$ is the DGD. (By ignoring a common phase, we can assume that $\operatorname{trace}(\mathsf{F}) = 0$.) Therefore, the optical signal is given by

$$\mathbf{W}(z,t) \;=\; c_1 f\left(t + \tfrac{\tau(z)}{2}\right)\mathbf{v}_1 \;+\; c_2 f\left(t - \tfrac{\tau(z)}{2}\right)\mathbf{v}_2, \tag{2.9}$$

where c_1 and c_2 are complex constants with $|c_1|^2 + |c_2|^2 = 1$. The DGD is therefore the time delay between light that is launched in the two different principal states of polarization. If the power of an optical pulse is split between the two principal states (i.e., $c_k \neq 0$ for $k = 1, 2$) and the DGD is large, then the power of the pulse is spread out and distorted as a function of time and bit errors are more likely to occur at the receiver.

2.3. The Stokes representation. In our discussion so far, we have modeled the polarization state of light using the Jones representation. In this subsection, we review an alternate approach based on the Stokes representation [5], [24], [43], [44]. Using the Stokes representation, we can regard the propagation of the polarization state of light through birefringent optical fiber as a random walk on a two-dimensional sphere.

With the Jones representation, polarization states are represented as unit vectors $\mathbf{U} \in \mathbf{C}^2$, i.e., as points on the sphere $S^3 \subset \mathbf{C}^2$, while with the Stokes representation they are represented using unit Stokes vectors, $\mathbf{S} = (S_1, S_2, S_3) \in S^2 \subset \mathbf{R}^3$. The sphere of unit Stokes vectors is called the *Poincaré sphere*. The mapping $\psi : S^3 \to S^2$ from Jones space to Stokes space is defined by $\mathbf{S} = \psi(\mathbf{U}) = \mathbf{U}^\dagger\overrightarrow{\sigma}\mathbf{U}$, where $\overrightarrow{\sigma} = (\sigma_3, \sigma_1, -\sigma_2)$ is the Pauli spin vector. For each $\mathbf{S}$, the inverse image $\psi^{-1}(\mathbf{S})$ is the circle in S^3 that consists of all Jones vectors of the form $\mathbf{U}_\varphi = e^{i\varphi}\mathbf{U}$, where $\varphi \in S^1$ and $\psi(\mathbf{U}) = \mathbf{S}$. The angle φ is an overall phase that plays no role in the theory of PMD. Since the matrix acting on the right-hand side of (2.6) is an element of

the Lie algebra $\mathfrak{su}(2)$ of trace-free skew-Hermitian matrices, the solution of the linear-PMD equation is of the form $\widehat{\mathbf{W}}(z,\omega) = \mathsf{T}(z,\omega)\widehat{\mathbf{W}}(0,\omega)$, where the PMD-transmission matrix, T, is an element of the Lie group SU(2) of unitary matrices with determinant 1. The action of an element T of SU(2) on $S^3 \subset \mathbf{C}^2$ is equivalent to the action of an element $\mathtt{R}$ of the special orthogonal group, SO(3), on S^3, where T is mapped to $\mathtt{R}$ by the 2-1 and onto map $\Psi : \mathrm{SU}(2) \to \mathrm{SO}(3)$ that is determined by $\mathtt{R}\overrightarrow{\sigma} = \mathsf{T}^\dagger \overrightarrow{\sigma}\mathsf{T}$. In particular, if $\mathtt{R}$ is a rotation by an angle θ about an axis $\hat{r} \in S^2 \subset \mathbf{R}^3$, then $\mathsf{T} = \pm[\cos(\theta/2)\mathrm{I} - i\sin(\theta/2)\hat{r}\cdot\overrightarrow{\sigma}]$. The Lie algebra $\mathfrak{so}(3)$ of $SO(3)$ consists of all antisymmetric matrices. The induced map between Lie algebras, $\Psi_* : \mathfrak{su}(2) \to \mathfrak{so}(3)$, is defined by $\Psi_*(i\overrightarrow{\beta}\cdot\overrightarrow{\sigma}) = \beta\times$. Here $\overrightarrow{\beta} = (\beta_1,\beta_2,\beta_3) \in \mathbf{R}^3$ and

$$\beta\times = \begin{pmatrix} 0 & -\beta_3 & \beta_2 \\ \beta_3 & 0 & -\beta_1 \\ -\beta_2 & -\beta_1 & 0 \end{pmatrix} \tag{2.10}$$

determines an isomorphism between $\mathfrak{so}(3)$ and $\mathbf{R}^3$. Therefore, if $\widehat{\mathbf{S}}$ is the Stokes vector that is equivalent to the Jones vector $\widehat{\mathbf{A}}$ defined below (2.6), then in Stokes space, the linear PMD (2.6) is given by

$$\frac{\partial\widehat{\mathbf{S}}}{\partial z} \;=\; \overrightarrow{\beta}\times\widehat{\mathbf{S}}, \tag{2.11}$$

where $\overrightarrow{\beta} = \overrightarrow{\beta}(\omega,z)$ is the *local birefringence vector* of the fiber. If the local birefringence vector is constant, then the polarization state $\widehat{\mathbf{S}}$ at a single frequency traces a circle on the Poincaré sphere centered at $\overrightarrow{\beta}$. However, in real linearly birefringent fibers, the local birefringence vector, $\overrightarrow{\beta}$, moves randomly on the equator of the sphere.[1] Therefore, the polarization state of the light, $\widehat{\mathbf{S}}$, moves randomly over the entire sphere. More specifically, given a length of birefringent fiber and an optical signal with a given input polarization state, consider the probability distribution of output polarization states, $\widehat{\mathbf{S}}$, on the Poincaré sphere, where the samples are generated from different realizations of the fiber birefringence. The length scale required for the probability distribution of $\widehat{\mathbf{S}}$ to become uniform on the sphere is on the order of a kilometer, which is short compared to the total length of a communication system. These observations provide the primary motivation for the coarse-step method for modeling PMD, which we will discuss in section 2.4 below.

To explain how the DGD evolves as a function of distance along the fiber, we introduce the *polarization dispersion vector*, $\overrightarrow{\Omega} = \overrightarrow{\Omega}(\omega,z) = (\Omega_1,\Omega_2,\Omega_3)$, which is defined in terms of the Hermitian matrix F in (2.7) by $\mathsf{F} = \mathrm{trace}(\mathsf{F})\mathrm{I} + \frac{1}{2}\overrightarrow{\Omega}\cdot\overrightarrow{\sigma}$. Then the Stokes formulation of (2.7) is

$$\frac{\partial\widehat{\mathbf{S}}}{\partial\omega} \;=\; \overrightarrow{\Omega}\times\widehat{\mathbf{S}}. \tag{2.12}$$

Consequently, the unit vectors $\pm\overrightarrow{\Omega}/|\overrightarrow{\Omega}|$ represent the two principal states of polarization of the fiber on the Poincaré sphere, and the magnitude, $|\overrightarrow{\Omega}|$, is the DGD. Finally, the *dynamical PMD equation*, which describes the evolution of the polarization dispersion vector, is given by [46]

$$\frac{\partial\overrightarrow{\Omega}}{\partial z} \;=\; \frac{\partial\overrightarrow{\beta}}{\partial\omega} \;+\; \overrightarrow{\beta}\times\overrightarrow{\Omega}. \tag{2.13}$$

[1] The angle θ in (2.4) is half the angle between $\overrightarrow{\beta}$ and the positive X-axis.

This equation can be derived by differentiating (2.11) with respect to ω and (2.12) with respect to z.

2.4. The probability space of fiber realizations. Each choice of a set of random local birefringence vectors along the fiber is called a *fiber realization*. In this subsection, we describe the coarse-step method that is used to generate different fiber realizations.

When a PMD compensator is used, each time the fiber realization changes, the compensator needs to be reset via optimization. In reality, the fiber realization can both drift gradually over time due to temperature fluctuations and change abruptly to an unrelated realization in response to large disturbances such as a truck passing overhead [6], [32], [52], [57]. We assume that when the fiber realization changes, there is no correlation between the old and new realizations. Statistically we model PMD by defining an appropriate space of fiber realizations, imposing a probability distribution on this space, and devising a method for randomly sampling the space of fiber realizations. To do so, it is commonly assumed that optical fiber is homogeneous. In other words, the statistical properties of the local birefringence vector $\overrightarrow{\beta}$ do not depend on distance, z, along the fiber. We will consider a space of fiber realizations consisting of fibers of a given length with a prescribed average DGD. In reality, such a space of fiber realizations could correspond either to fibers that are fabricated using the same manufacturing process, or to realizations of a single fiber whose birefringence is randomly varying over time.

The most commonly used method for generating fiber realizations with a given average DGD is the *coarse-step method* [13], [59] which we now describe using the Stokes representation [44]. The coarse-step method can be regarded as a computationally efficient, statistically correct, numerical method for solving the linear-PMD (or Manakov-PMD) equation. In the coarse-step method, the action of a birefringent fiber on the Stokes vector, $\widehat{\boldsymbol{S}}$, of the light is modeled as the concatenation of the action of N segments of fixed-birefringence fiber, each of which is preceded by a random rotation of $\widehat{\boldsymbol{S}}$ on the Poincaré sphere. If $\widehat{\boldsymbol{S}}^{(n)}(\omega)$ denotes the Stokes vector of light at frequency ω after the nth fiber segment, then

$$\widehat{\boldsymbol{S}}^{(n)}(\omega) \;=\; \mathtt{R}(\omega)\,\mathtt{Q}_n\widehat{\boldsymbol{S}}^{(n-1)}(\omega). \tag{2.14}$$

Here, the matrix $\mathtt{R}(\omega)$ is the element of SO(3) that is the rotation about the X-axis through an angle $\Delta\beta'\omega\Delta z$. This rotation models the propagation of light through each of the fixed-birefringence fiber segments. The quantity $\Delta\beta'$ is the magnitude of the frequency derivative of the local birefringence vector of each of the N fiber segments, and is related to the average DGD by $\Delta\beta' = (3\pi N/8)^{1/2}\,\overline{\mathrm{DGD}}/L$, where L is the length of the fiber [42]. The matrix $\mathtt{Q}_n$ is a frequency-independent, random rotation that is chosen using the canonical uniform probability distribution on SO(3). Specifically, $\mathtt{Q}_n$ can be expressed as an Euler-angle rotation matrix [23] of the form $\mathtt{Q}_n = \mathtt{R}_X(\psi_n)\,\mathtt{R}_Y(\theta_n)\,\mathtt{R}_X(\phi_n)$. Here, $\mathtt{R}_X(\psi)$ is a rotation about the X-axis through an angle ψ. The angles ψ_n and ϕ_n are uniformly distributed in $[0, 2\pi]$, and $\cos\theta_n$ is uniformly distributed in $[-1, 1]$. In the special case that $N = 1$, the coarse-step method generates only first-order PMD. For a large enough number of fiber segments, the coarse-step method produces the same statistical properties as are obtained using Wai and Menyuk's model for the randomly varying birefringence [42]. Moreover, the coarse-step method is much more computationally efficient, since it takes steps on the order of a kilometer rather than the meter-long steps required to track the rapid

variations in the birefringence.

The dynamical PMD equation (2.13) can also be solved using a coarse-step approach. If $\overrightarrow{\Omega}^{(n)} = \overrightarrow{\Omega}^{(n)}(z,\omega)$ is the polarization dispersion vector after the nth fiber segment, then

$$\overrightarrow{\Omega}^{(n)} \;=\; \mathtt{R}(\omega)\left[\mathtt{Q}_n\,\overrightarrow{\Omega}^{(n-1)} \;+\; \Delta\overrightarrow{\Omega}_n\right], \tag{2.15}$$

where $\Delta\overrightarrow{\Omega}_n = \Delta\beta'\Delta z\,\overrightarrow{e}_X$ is the polarization dispersion vector of the nth segment. Here $\overrightarrow{e}_X = (1,0,0)^T$, and we regard $\overrightarrow{\Omega}$ as a column vector. In section 3 below, we will use (2.15) to explain the basic idea behind PMD compensation.

There is a large literature on the statistical properties of PMD. The most important result is that in the limit as $N \to \infty$, the DGD is Maxwellian distributed with distribution $f_{\mathrm{DGD}}(x) = \frac{2\pi x^2}{\alpha^3}\exp(-x^2/2\alpha^2)$, where $\alpha = (\pi/8)^{1/2}\,\overline{\mathrm{DGD}}$ [46]. In particular, there is an extremely small probability that the DGD of a fiber realization is significantly larger than the average DGD.

2.5. The receiver and performance evaluation metrics. To evaluate the degree to which a PMD compensator reduces the probability of errors due to PMD, we also need a model of the receiver. The purpose of the receiver is to convert the transmitted optical signal into an electrical current, to determine a *clock time* that is used to set the beginning and ending points of the time intervals for each of the bits being transmitted [55], and finally to make a decision as to whether the voltage of the received electrical current in each of these bit slots is to be received as a one or a zero. This decision is based on a choice of *decision voltage*. If the received voltage is larger than the decision voltage, the bit is declared to be a one. Otherwise a zero is received.

A receiver model should include an algorithm to evaluate the performance of the communication system. There are several ways to measure performance—the most fundamental means is via the *bit-error ratio*, which is given by $\mathrm{BER} = \frac{1}{2}(p_{1|0} + p_{0|1})$. Here $p_{1|0}$ is the probability of receiving a one given that a zero was transmitted, and $p_{0|1}$ is the probability of receiving a zero given that a one was transmitted. In a real system bit errors occur due to the combined effect of PMD and noise from optical amplifiers. Since we did not include noise in our simulations, we measured the performance using a quantity called the *eye opening* [62] rather than the BER. The eye opening of a noise-free signal at the receiver is defined to be the difference between the smallest electrical voltage of a one and the largest electrical voltage of a zero at the clock time.[2] There is a strong correlation between the BER and the eye opening [41], [49], [63]. To study the degree to which PMD degrades the performance of the system, we define the *eye opening penalty* for a particular fiber realization to be the ratio between the eye opening for a version of the system that has just a transmitter and receiver (i.e., no fiber and hence no PMD) and the eye opening for the system with a transmitter, PMD due to the given fiber realization, and a receiver. The more the PMD reduces the eye opening, the larger the eye opening penalty for that fiber realization. System designers typically specify that a *system outage* occurs if the eye opening penalty exceeds a specified threshold, such as 2 dB [52].[3] They require that

[2]The term "eye opening" is used here because in Figure 3.2 the image of each signal under the mapping $t \mapsto t \bmod T$ looks like an eye, where T is the bit period.

[3]A linear factor of x corresponds to $10\log_{10} x$ decibels (dB). So, if the eye opening penalty for a particular fiber realization is 2 dB, then the eye opening is 63% of the value one would see in a system without PMD.

the *outage probability*, which is the probability that such an outage occurs, be on the order of 10^{-3} to 10^{-6}, corresponding to a few minutes to hours of outage per year. A major goal of this paper is to present a numerical model that can be used to assess the degree to which a PMD compensator can reduce the outage probability due to PMD.

3. Polarization-mode dispersion compensation. In this section, we discuss the optical PMD compensator whose performance we study in this paper. As discussed in section 2, imperfections in optical fibers result in two principal states of polarization for the light. Light traveling in the fast principal state arrives at the receiver ahead of the light traveling in the slow state. In practice the power in the optical signal is split between these two principal states, so that the optical pulses used to encode the binary data become spread out and distorted. Consequently, over long distances, the message being transmitted will be corrupted by errors. To compensate for this spread of information, physical devices called optical PMD compensators can be used.

A variety of designs have been proposed for optical PMD compensators [52], [53]. We chose to study a simple compensator that is easy to build and operate. To motivate the design of this compensator, we consider the important special case that the transmission fiber has only first-order PMD, i.e., that the polarization dispersion vector, $\overrightarrow{\Omega}_T$, of the transmission line is frequency independent. Recall from (2.9) that if the polarization state of the signal is not closely aligned with either of the principal states of the transmission fiber, then the larger the DGD, $|\overrightarrow{\Omega}_T|$, the more the signal will be distorted due to PMD, and the greater the probability of a bit error. The simple PMD compensator we study is a device that can at least partially cancel out the DGD of the transmission fiber. The idea is to insert a segment of *compensation fiber* between the transmission fiber and the receiver, and to rotate the polarization state of the signal between the transmission and compensation fibers so as to align the fast principal state $\overrightarrow{\Omega}_T$ of the transmission fiber with the slow principal state $-\overrightarrow{\Omega}_C$ of the compensation fiber. Then by (2.15), the total polarization dispersion vector, $\overrightarrow{\Omega}_R$, at the receiver is given by

$$\overrightarrow{\Omega}_R \;=\; \mathtt{Q}\,\overrightarrow{\Omega}_T \;+\; \overrightarrow{\Omega}_C, \tag{3.1}$$

where $\mathtt{Q}$ is the rotation between the transmission and compensation fibers. Consequently, if the DGD of the compensation fiber were equal to that of the transmission fiber, then the total DGD at the receiver would be zero; i.e., $|\overrightarrow{\Omega}_R| = 0$.

Simple compensators based on this principle have been built, and a diagram of one is shown in Figure 3.1. The optical signal generated in the transmitter propagates through the transmission fiber. The compensator itself is located immediately prior to the receiver and consists of a polarization controller that can be adjusted to transform the polarization state of the fiber by any desired rotation, followed by a short segment of compensation fiber. The compensation fiber is designed to be polarization maintaining in that its principal states of polarization and its DGD are fixed. Notice that since the transmission DGD, $|\overrightarrow{\Omega}_T|$, of a fiber realization may not equal the fixed DGD, $|\overrightarrow{\Omega}_C|$, of the compensator, the total DGD, $|\overrightarrow{\Omega}_R|$, in (3.1) may not be zero. In addition, since this compensator consists of only one polarization controller and one segment of polarization maintaining fiber, it can compensate only for the DGD at the carrier frequency, and not for PMD distortions at all frequencies in the signal.

After passing through the compensation fiber, the optical signal is monitored and a feedback loop is used to adjust the rotation performed by the polarization controller. Given a realization of the birefringence in the transmission fiber, the feedback loop

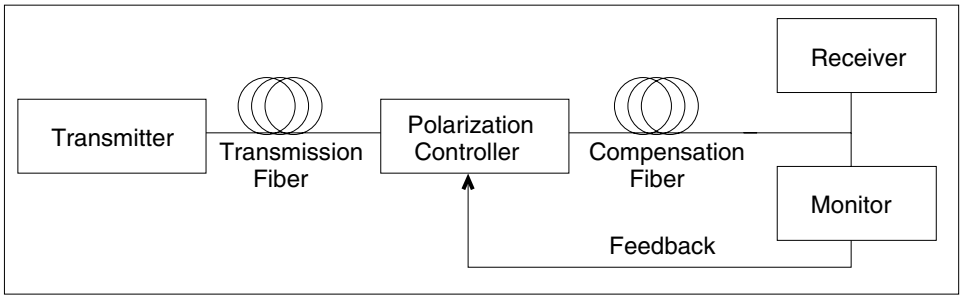

FIG. 3.1. *An optical communication system with a simple PMD compensator.*

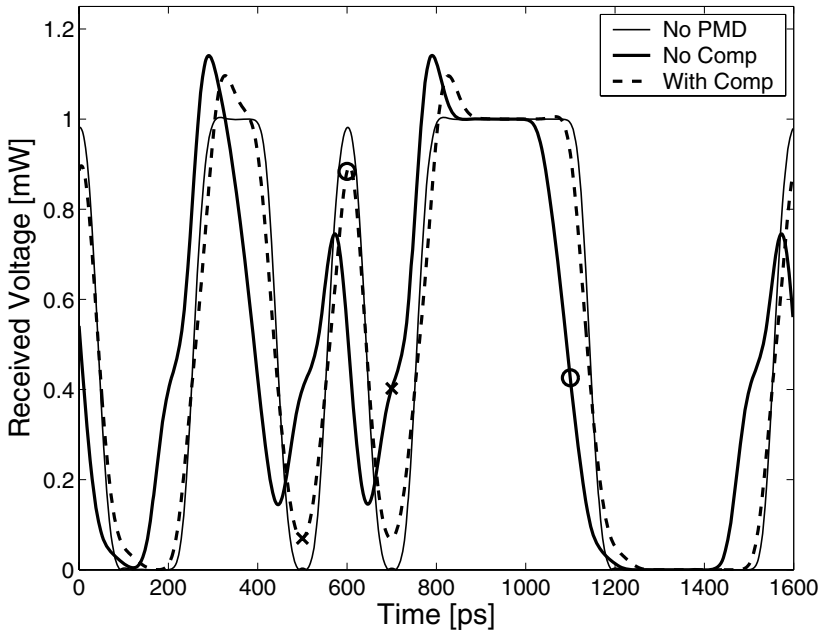

FIG. 3.2. *Compensated versus uncompensated signals.*

can be modeled by optimizing the function from the state space SO(3) of all possible rotations of the polarization controller to **R**, which is given by the monitor.

In Figure 3.2, we show the effect that PMD can have on a signal and how a PMD compensator can decrease the signal distortion due to PMD. The results we show are for a particular fiber realization. Different fiber realizations could have quite different effects on the signal. We plot the received electrical current as a function of time in three cases. The thin solid curve shows the case where there is no PMD in the transmission line and hence no pulse distortion. (This signal is called the *back-to-back* signal as the transmitter and receiver abut each other.) The data pattern 1001101011110000 can be easily recognized in the signal. Notice that the voltage in the signal does not return to zero between two consecutive ones. Signals like this are called *non–return-to-zero* and are commonly used in communication systems. The thick solid curve shows the same signal after it has traveled through the transmission fiber with PMD. The DGD was 75 ps at the carrier frequency, and there was a strong frequency-dependence to the polarization dispersion vector. The signal has clearly

been distorted due to PMD. The circle at 1100 ps shows the minimum-voltage one, and the cross at 700 ps shows the maximum-voltage zero. The eye opening, which is the difference between the height of the circle and the cross, is 0.02 mV. Therefore the eye opening after the transmission fiber is very small compared to the back-to-back eye opening, which is 0.98 mV. Finally, the thick dashed curve shows this same signal after compensation. The circle at 600 ps shows the minimum-voltage one, and the cross at 500 ps shows the maximum-voltage zero. The compensator has increased the eye opening to 0.81 mV, which is a marked improvement over the uncompensated case.

In this paper, we study the performance of this PMD compensator for three choices of monitor. Different monitors and different random realizations of the birefringence in the transmission fiber correspond to different choices of the objective function to be optimized. Since our ultimate goal is to minimize the bit-error ratio, the monitor should be chosen so that the monitored value is strongly correlated (or anticorrelated) to the bit-error ratio, i.e., to the eye opening. The most obvious choice of monitor is the bit-error ratio itself, or the eye opening. However, it is not possible to measure the bit-error ratio in a real system, and it is often not feasible to measure the eye opening in real time.

We will now briefly describe each of the monitors used in our numerical experiments—the eye opening, spectral line, and the DOP ellipsoid. The *eye opening monitor* measures the eye opening of the signal after propagation through the system, relative to the eye opening of the back-to-back signal. Optical signals typically have carrier frequencies of about 200 THz (or about 2×10^{12} Hz) and a bandwidth of about 20 GHz (or 2×10^{10} Hz). The optical signal is sent through a photodetector to convert it from an optical to an electrical signal. The electric signal has a shifted frequency spectrum (shifted relative to the optical signal) in the range $[0, 10]$ GHz. The *spectral line* monitoring technique requires that an electric filter be used to monitor the power in a particular frequency (or tone). In our work we have used a filter to monitor the power in the 5 GHz tone using a window of width 0.5 GHz. The spectral line feedback mechanism attempts to maximize the power in this tone relative to the reference back-to-back signal, which has gone straight from transmitter to receiver without encountering the optical fiber (hence without being affected by PMD).

In the case of only first-order PMD, we will show in (4.17) that the power in the 5 GHz spectral line decreases monotonically with increasing DGD between DGD values of 0 and 100 ps (the width of each bit slot; see also Figure 1 in [51]). Thus it would be hoped that for moderate amounts of DGD, an optimization algorithm which maximizes the power in this spectral line (or frequency) will compensate for the DGD present in the fiber. As has been discussed earlier, the eye opening is correlated to the DGD, and we see now that for first-order PMD, the amount of DGD is correlated to the power in the spectral line. Thus this feedback measure achieves our aim of providing a real-valued function correlated to the eye opening. In the case of higher-order PMD, this correlation becomes more complicated.

We now explain why the functions to be optimized can be regarded as being defined on the 2-sphere, S^2, rather than on the three-dimensional manifold, SO(3). As in our discussion of the coarse-step method in section 2.4, the rotation $\mathtt{Q}$ in (3.1) can be expressed in the form $\mathtt{Q} = \mathtt{R}_X(\psi)\,\mathtt{R}_Y(\theta)\,\mathtt{R}_X(\phi)$, where $\psi, \theta, \phi \in [0, 2\pi]$, and $\mathtt{R}_X(\phi)$ is a rotation by an angle ϕ about the X-axis. We assume that the polarization dispersion vector, $\overrightarrow{\Omega}_C$, of the compensator is parallel to the X-axis. Consequently, $\overrightarrow{\Omega}_R = \mathtt{R}_X(\psi)\left[\mathtt{R}_Y(\theta)\,\mathtt{R}_X(\phi)\,\overrightarrow{\Omega}_T + \overrightarrow{\Omega}_C\right]$. Since the final rotation, $\mathtt{R}_X(\psi)$, does not affect the values of any of the objective functions, we can ignore it and regard $\mathtt{Q} = \mathtt{Q}(\phi, \theta)$

as a function of (ϕ, θ) alone; i.e.,

$$\overrightarrow{\Omega}_R(\phi,\theta) \;=\; \mathtt{R}_Y(\theta)\,\mathtt{R}_X(\phi)\,\overrightarrow{\Omega}_T \;+\; \overrightarrow{\Omega}_C. \tag{3.2}$$

Since $\mathtt{R}_X(\pi) = \mathrm{diag}(1,-1,-1)$, $\mathtt{R}_Y(-\theta)\mathtt{R}_X(\pi) = \mathtt{R}_X(\pi)\mathtt{R}_Y(\theta)$. Therefore, the rotation $\mathtt{Q}(\phi+\pi,-\theta)$ has the same effect as the rotation $Q(\phi,\theta)$. Consequently, we can regard the objective functions as being defined on the rectangle $R = \{(\phi,\theta) \in [-\pi,\pi]\times[0,\pi]\}$. Moreover, ignoring a final rotation about the X-axis, $\mathtt{Q}(\phi,0) = I$ and $\mathtt{Q}(\phi,\pi) = \mathtt{R}_Y(\pi)$ are constants, independent of ϕ. Therefore, the space of rotations performed by the polarization controller is actually diffeomorphic to the sphere, S^2: The rotation $Q(\phi,\theta)$ corresponds to the point on the sphere with spherical coordinates (ϕ,θ), where $\phi = \phi_0$ is a circle of longitude and $\theta = \theta_0$ is a circle of latitude. Consequently, the objective functions are actually defined on S^2.

Next, we examine the structure of the objective function for the eye opening and spectral line monitors. In Figure 3.3, we show a contour plot of the eye opening objective function for a particular fiber realization. In this figure, we have parametrized the sphere in the space of rotations using spherical coordinates (ϕ,θ) so that the horizontal lines $\theta = -\pi$ and $\theta = \pi$ map to the south and north poles, respectively, and the vertical lines $\phi = \pm\pi$ both map to the same great semicircle of longitude. The eye opening objective function in Figure 3.3 has two local maxima located close to $(\phi,\theta) = (-\pi,\pi/2)$ and $(\phi,\theta) = (0,\pi/2)$. The spectral line objective function in Figure 3.4 has a similar structure, although it is smoother than the eye opening objective function. In particular we note that the steep ridge located between $\phi = 0$ and $\phi = -\pi/2$ for the eye objective function has been considerably smoothed out in the spectral line objective function diagram. Thus local optimization techniques would be more effective at finding optima for the spectral line than for the eye in this case.

To motivate the degree of polarization ellipsoid monitor, we observe that when a signal propagates through fiber with PMD there are two basic reasons why the eye opening at the receiver can be large: Either the total DGD is small or the input state of polarization of the signal is aligned with one of the principal states of the fiber [47]. In Figure 3.3, the eye opening is large near $(-\pi,\pi/2)$ because the total DGD is small there, and it is large near $(0,\pi/2)$ because the rotation of the polarization controller is such that the principal state of the entire length of fiber, $\overrightarrow{\Omega}_R$, is parallel to the input state of polarization of the signal. In a real system, the input polarization state can drift over time. Consequently, it is better to operate a PMD compensator near where the DGD is minimized rather than near where the input polarization state of the signal is aligned with a principal state of the fiber [52]. The DOP ellipsoid is one such monitor.

The *DOP ellipsoid* monitor is obtained by polarization scrambling the DOP of the signal. The DOP is used to monitor PMD because polarized signals become depolarized when they propagate through fiber with PMD. The degree to which the signal is depolarized depends on the DGD and on the input state of polarization. Any optical signal can be decomposed as the sum of polarized and unpolarized components [5]. The DOP is the ratio of the power in the polarized component to the total power. If $\mathbf{U}(t) = f(t)\mathbf{U}_0$ denotes the Jones vector of an input polarized signal, then the total power is $S_0 = \int_{-\infty}^{\infty} |\widehat{f}(\omega)|^2\,d\omega$, where $\widehat{f}$ is the Fourier transform of f. The power in the polarized component of the signal is given by the length of the average Stokes vector,

$$\mathbf{S} \;=\; \int_{-\infty}^{\infty} \widehat{\mathbf{S}}(\omega)\,|\widehat{f}(\omega)|^2\,d\omega, \tag{3.3}$$

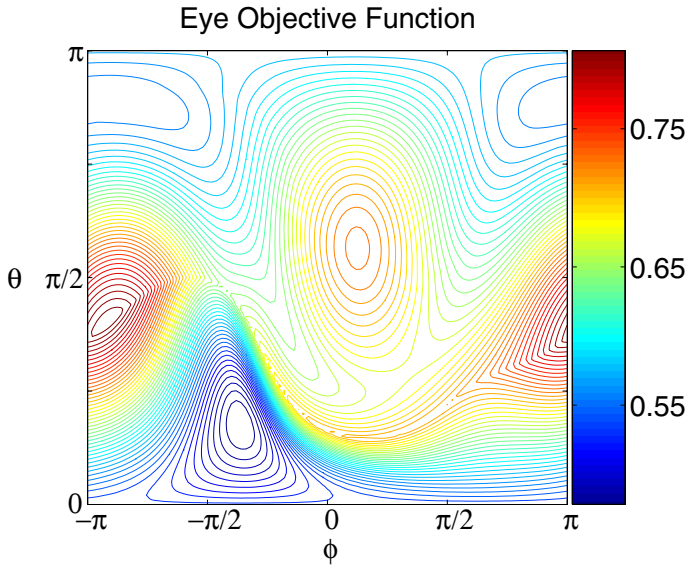

FIG. 3.3. *Eye opening objective function for a typical fiber realization.*

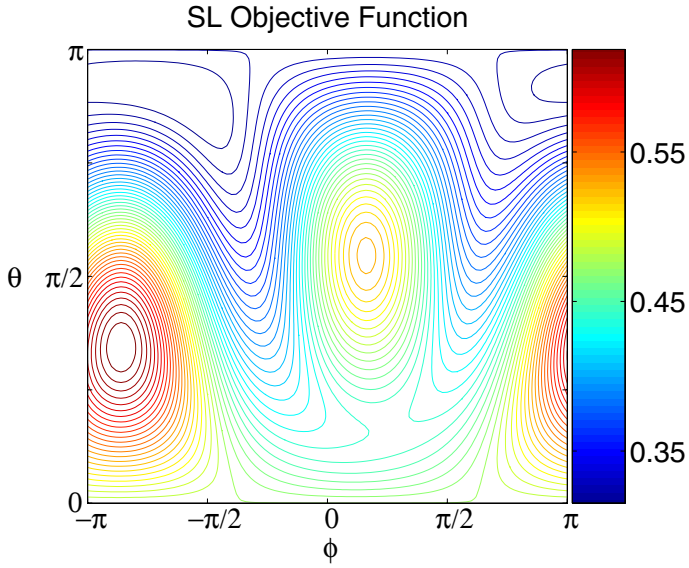

FIG. 3.4. *Spectral line objective function for a typical fiber realization. (Same fiber as is shown in Figure* 3.3*.)*

where $\widehat{\mathbf{S}}(\omega)$ is the Stokes vector at frequency ω defined in section 2.3. The DOP is given by $\text{DOP} = |\mathbf{S}|/S_0$.

To explain why a large DGD results in a low DOP, consider a fiber with only first-order PMD for which the polarization dispersion vector is fixed at the north pole. Then, as a function of frequency, ω, the Stokes vector $\widehat{\mathbf{S}}(\omega)$ traces out an arc of a circle of latitude on the sphere. By (2.12), the larger the DGD, $|\overrightarrow{\Omega}|$, the longer the arc. Suppose, for example, that the input polarization state is such that the circle of

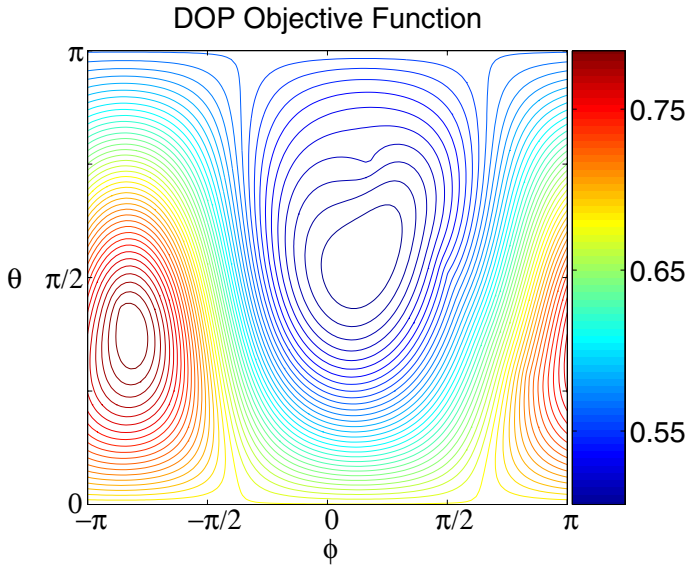

FIG. 3.5. *DOP ellipsoid objective function for a typical fiber realization. (Same fiber as is shown in Figure* 3.3.*)*

latitude is the equator, and the DGD is large enough so that $\widehat{\mathbf{S}}(\omega)$ traces out the entire equatorial circle as ω varies over the bandwidth of the signal. Then, by symmetry, the integral in (3.3) is close to zero and so the DOP is small. More generally, since (3.3) is a weighted average of vectors, the larger the DGD, the smaller the DOP.

The DOP ellipsoid is defined [9], [14], [15], [50], [54] so that for each unit vector $\mathbf{S}_{\text{in}}$, polarized light with Stokes vector $\mathbf{S}_{\text{in}}$ is sent in to a fiber with PMD, and the average output Stokes vector, $\mathbf{S}_{\text{out}}$, is measured. The set of all such vectors $\mathbf{S}_{\text{out}}$ forms the DOP ellipsoid. The length of the shortest principal axis of the DOP ellipsoid is approximately given by [14]

$$\lambda_{\min} \approx 1 - \tfrac{1}{2}\,\overline{\Delta\omega^2}\,|\,\overrightarrow{\Omega}\,|^2. \tag{3.4}$$

Here $\overline{\Delta\omega^2} = (1/S_0)\int_{-\infty}^{\infty} \omega^2 |\widehat{f}(\omega)|^2\, d\omega$ is a measure of the square of the bandwidth of the signal, and $|\,\overrightarrow{\Omega}\,|$ is the DGD at the carrier frequency. Therefore, with the DOP ellipsoid feedback mechanism, we aim to maximize $\lambda_{\min}$ and therefore to minimize the DGD. To fit the ellipsoid we used a Euclidean invariant linear least-squares algorithm that minimized the algebraic distance to 36 output Stokes vectors $\mathbf{S}_{\text{out}}$ [21]. In Figure 3.5, we show a plot of the DOP ellipsoid objective function for the same fiber realization as in Figures 3.3 and 3.4. This objective function has a single maximum that is located near the maximum of the eye opening objective function (and which corresponds to minimizing the DGD). However, unlike the case of the eye opening and spectral line objective functions, it does not have a second local maximum corresponding to the case that the input state of polarization is aligned with one of the principal states of the fiber. The shortest axis of the ellipsoid corresponds to the worst possible choice of input polarization state. The worst state is the one for which the power in the signal is evenly split between the two principal states of polarization of the fiber, rather than being aligned with one of them. Therefore the DOP ellipsoid objective function depends on the DGD but not on the input polarization state of the signal.

4. Analysis of the objective functions for first-order PMD. In section 3 we saw that for a particular fiber realization the eye opening and spectral line objective functions had two local maxima, whereas the DOP ellipsoid objective function had only one local maximum which corresponded to minimizing the DGD. In this section we show that this behavior is typical by deriving formulae for the DOP ellipsoid and spectral line objective functions in the special case of first-order PMD, i.e., in the case that the PMD vector $\overrightarrow{\Omega}_T$ of the transmission fiber is frequency independent. In section 7 we will use numerical simulation to quantify the performance of a PMD compensator, and we will use the analysis in this section to help explain those results. In section 7 we also provide statistical evidence that for an arbitrary fiber realization, we can regard the objective function as being a perturbation of an objective function for a fiber with only first-order PMD. This statistical result is to be expected since for many fiber realizations $\overrightarrow{\Omega}_T$ has only a weak dependence on frequency across the bandwidth of the signal.

As we explained in section 3, the domain for the two-dimensional optimization problem we wish to solve is the unit sphere, $S^2 \subset \mathbf{R}^3$. In other words, we want to solve the problem

$$\max_{p \in S^2} J(p), \tag{4.1}$$

where $J : S^2 \to \mathbf{R}$ is an objective function defined by one of the three feedback mechanisms discussed earlier. In section 7, we will in fact solve an unconstrained optimization problem of the form

$$\max_{(\phi,\theta) \in \mathbf{R}^2} J(\phi, \theta), \tag{4.2}$$

where (ϕ, θ) are spherical coordinates and J is now regarded as a doubly periodic function on $\mathbf{R}^2$. This unconstrained form of the problem is easier to solve computationally.

For our analysis of the DOP ellipsoid, we assume that the polarization dispersion vector $\overrightarrow{\Omega}_R$ of the entire system from transmitter to receiver, including the compensation fiber, is frequency independent. Let τ_T and τ_C be the DGD of the transmission and compensation fibers, respectively. We can assume that $\overrightarrow{\Omega}_C = \tau_C \overrightarrow{e}_X$. If we let Ψ be the angle between $\overrightarrow{\Omega}_T$ and $\overrightarrow{\Omega}_C$, then in spherical coordinates, $\overrightarrow{\Omega}_T = \tau_T(\cos\Psi, \cos\beta \sin\Psi, \sin\beta \sin\Psi)^T$ for some angle β. Substituting (3.2) into (3.4), we find that the DOP ellipsoid objective function is given by

$$J(\phi, \theta) = 1 - \tfrac{1}{2} \overline{\Delta\omega^2} \left[\tau_C^2 + \tau_T^2 + 2\tau_C \tau_T H(\phi, \theta)\right], \tag{4.3}$$

where

$$H(\phi, \theta) = \cos\Psi \cos\theta + \sin\Psi \sin\theta \sin(\phi - \beta). \tag{4.4}$$

If $\Psi \neq 0, \pi$, then the optimization problem (4.2) has six critical points (ϕ, θ) in $[-\pi, \pi] \times [0, \pi]$. The global maximum of H has value 1 and is located at $(\phi, \theta) = (\beta + \pi/2, \Psi)$, and the global minimum is -1 at $(\phi, \theta) = (\beta - \pi/2,\ \pi - \Psi)$. There are saddle points at $(\beta, 0)$, $(\beta + \pi, 0)$, (β, π), and $(\beta + \pi, \pi)$. These saddle points lie on the singularity set $\{\theta = 0\} \cup \{\theta = \pi\}$ of the spherical coordinate mapping from $[-\pi, \pi] \times [0, \pi]$ to S^2, and are mapped to $(0, 0, \pm 1) \in S^2$. However, they do not correspond to critical points for the optimization problem (4.1) on S^2, since $(0, 0, \pm 1)$

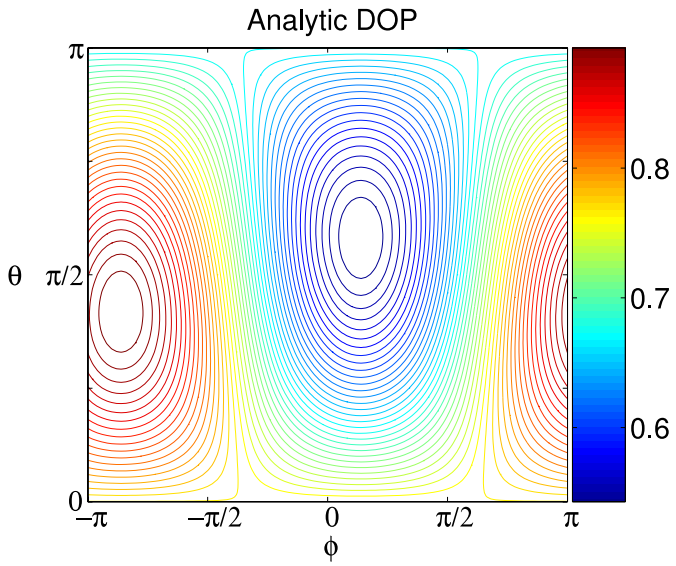

FIG. 4.1. *DOP ellipsoid objective function obtained using* (4.3) *for the first-order PMD approximation of the fiber in Figure* 3.5.

are not critical points of

$$\max_{(x,y,z)\in\mathbf{R}^3} H(x,y,z) = \cos(\Psi)z + \sin(\Psi)y \qquad \text{subject to} \quad x^2+y^2+z^2 = 1. \tag{4.5}$$

If $\Psi = 0$ or π, then $H(\phi,\theta) = \pm\cos\theta$ has global optima at $\theta = 0, \pi$, and these critical points are also global optima for the problem (4.1) on the sphere. To summarize, in the case of only first-order PMD, the DOP ellipsoid objective function on S^2 has one maximum and one minimum which is antipodal to the maximum.

Our analysis agrees well with the numerically computed objective function in Figure 3.5. Given a fiber realization, we can obtain an associated fiber realization with only first-order PMD by computing the polarization dispersion vector, $\overrightarrow{\Omega}_T$, at the carrier frequency of the signal. For the fiber realization in Figure 3.5, the parameters in the formula for $\overrightarrow{\Omega}_T$ are $\tau_C = 30$ ps, $\tau_T = 2.68\,\tau_C$, $\Psi = 105°$, and $\beta = -65°$. We chose $\sqrt{\Delta\omega^2} = 8.75 \times 10^9$ Hz, so as to fit the result in Figure 3.5, as was done in [14]. In Figure 4.1, we show the DOP ellipsoid objective function given by (4.3) with these parameters. The close agreement between the analytical and numerical results is noteworthy since the PMD of the fiber realization used for Figure 3.5 depends strongly on frequency. (In fact, the second-order PMD, $|\overrightarrow{\Omega}_\omega|$, which is the length of the frequency derivative of the polarization dispersion vector, is 3.1 times its mean value.)

For the analysis of the spectral line objective function, we work in Jones space with matrices in SU(2) acting on $\mathbf{C}^2$, rather than in Stokes space. Suppose that the input optical signal at the transmitter is of the form $f(t)\mathbf{u}_0$, where f is a real-valued scalar function, and $\mathbf{u}_0 \in \mathbf{C}^2$ is constant. Let R be the element of SU(2) that corresponds to the product $\prod_n \mathsf{Q}_n$ of the random rotations used in the coarse-step method to model a realization of the transmission fiber. If we approximate the transmission fiber by a fiber with only first-order PMD, then by (2.8) the output optical signal v after the PMD compensator is the $\mathbf{C}^2$-valued function whose Fourier transform is given by

$$\widehat{v}(\omega;\phi,\theta) = \widehat{f}(\omega)\mathsf{B}_C(\omega)\mathsf{Q}(\phi,\theta)\mathsf{P}e^{i\omega\mathsf{D}}\mathsf{P}^\dagger\mathsf{R}\mathbf{u}_0, \tag{4.6}$$

where $\mathsf{P} = (\mathbf{v}_1, \mathbf{v}_2) \in \mathrm{SU}(2)$ is the matrix of principal states of the transmission fiber and $\mathsf{D} = \mathrm{diag}(-\tau_T/2, \tau_T/2)$. In addition,

$$\mathsf{Q}(\phi,\theta) = \begin{pmatrix} e^{-i\phi/2}\cos\theta/2 & -ie^{i\phi/2}\sin\theta/2 \\ -ie^{-i\phi/2}\sin\theta/2 & e^{i\phi/2}\cos\theta/2 \end{pmatrix} \tag{4.7}$$

is the element of SU(2) that models the action of the polarization controller, and

$$\mathsf{B}_C(\omega) = \begin{pmatrix} e^{-i\omega\tau_C/2} & 0 \\ 0 & e^{i\omega\tau_C/2} \end{pmatrix} \tag{4.8}$$

models the DGD in the compensation fiber. Let $\sigma = \frac{\tau_T+\tau_C}{2}$ and $\eta = \frac{\tau_T-\tau_C}{2}$. Then

$$v(t;\phi,\theta) \;=\; \begin{pmatrix} \mathsf{A}_{11}f(t+\sigma) + \mathsf{A}_{12}f(t-\eta) \\ \mathsf{A}_{21}f(t+\eta) + \mathsf{A}_{22}f(t-\sigma) \end{pmatrix}, \tag{4.9}$$

where $\mathsf{A} = \mathsf{Q}(\phi,\theta)(c_1\mathbf{v}_1, c_2\mathbf{v}_2)$. Here $c_k = \mathbf{v}_k^*\mathsf{R}\mathbf{u}_0 \in \mathbf{C}$ is the projection onto the principal state $\mathbf{v}_k$ of the Jones vector of the signal at the central frequency after the transmission fiber.

If we ignore the optical filter and model the electrical filter as a Dirac function centered at frequency ω_{SL}, then the spectral line objective function is given by

$$J(\phi,\theta) = \left|\widehat{P}(\omega_{\mathrm{SL}};\phi,\theta)\right|^2, \qquad \text{where} \quad P(t;\phi,\theta) = |v(t;\phi,\omega)|^2 \tag{4.10}$$

is the received optical power.

To calculate an explicit formula for J we first express quadratic functions of A in terms of the generalized Stokes vectors

$$\mathbf{S}_{jk} \;=\; \mathbf{v}_j^\dagger\overrightarrow{\sigma}\mathbf{v}_k, \qquad j,k \in \{1,2\}, \tag{4.11}$$

where $\overrightarrow{\sigma}$ is the Pauli spin 3-vector defined in section 2.3 whose components are elements of SU(2). Notice that $\mathbf{S}_{11}$ and $\mathbf{S}_{22} = -\mathbf{S}_{11} \in \mathbf{R}^3$ are the standard Stokes vectors of $\mathbf{v}_1$ and $\mathbf{v}_2$, and that $\overline{\mathbf{S}}_{21} = -\mathbf{S}_{12} \in \mathbf{C}^3$. If Q_k denotes the kth row of $\mathsf{Q}(\phi,\theta)$, then $\mathsf{Q}_k^\dagger\mathsf{Q}_k = \frac{1}{2}(\mathrm{I} + (-1)^{k-1}\mathbf{r}(\phi,\theta)\cdot\overrightarrow{\sigma})$ in SU(2), where

$$\mathbf{r}(\phi,\theta) \;=\; (\cos\theta, \sin\phi\sin\theta, -\cos\phi\sin\theta) \tag{4.12}$$

parametrizes a sphere. Then,

$$|\mathsf{A}_{22}|^2 \;=\; \tfrac{1}{2}|c_{22}|^2(1-\mathbf{r}\cdot\mathbf{S}_{22}) \qquad \text{and} \qquad \Re(\mathsf{A}_{22}\overline{\mathsf{A}}_{21}) \;=\; -\tfrac{1}{2}\mathbf{r}\cdot\Re(c_1\bar{c}_2\mathbf{S}_{21}), \tag{4.13}$$

where $\Re$ denotes the real part, with similar formulae for other quadratic functions of A. Finally, let

$$g_{a,b}(t) := f(t+a)f(t+b) \qquad \text{and} \qquad G_{a,b} := \widehat{g}_{a,b}(\omega_{\mathrm{SL}}) \in \mathbf{C}. \tag{4.14}$$

Combining (4.6)–(4.14), the objective function for the optimization problem (4.2) on the plane is of the form

$$J(\phi,\theta) \;=\; \tfrac{1}{4}|\alpha + \mathbf{r}(\phi,\theta)\cdot\mathbf{s}|^2, \tag{4.15}$$

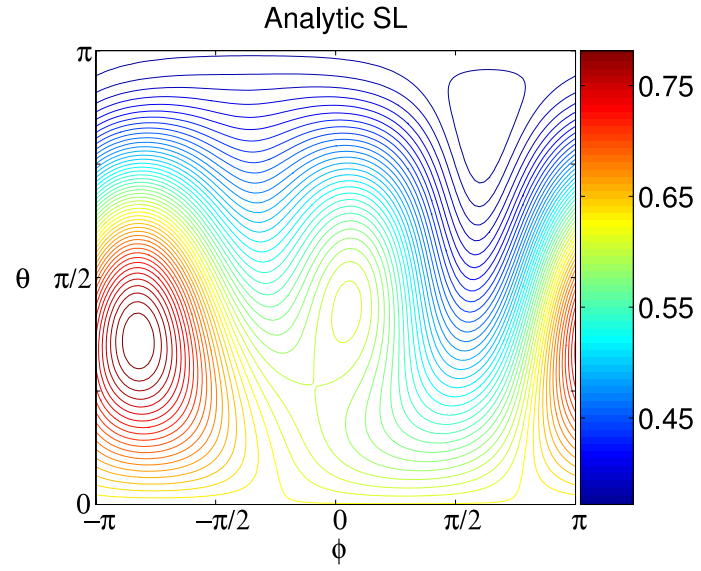

FIG. 4.2. *Spectral line objective function obtained using* (4.15) *for the first-order PMD approximation of the fiber in Figure* 3.4.

where $\alpha \in \mathbf{C}$ and $\mathbf{s} \in \mathbf{C}^3$ are defined by

$$\begin{aligned} \alpha &= |c_1|^2(G_{\sigma,\sigma} + G_{\eta,\eta}) \;+\; |c_2|^2(G_{-\sigma,-\sigma} + G_{-\eta,-\eta}), \\ \mathbf{s} &= \left\{|c_1|^2(G_{\sigma,\sigma} - G_{\eta,\eta}) + |c_2|^2(G_{-\sigma,-\sigma} - G_{-\eta,-\eta})\right\}\mathbf{S}_{11} \\ &\quad + \; 2(G_{\sigma,-\eta} - G_{-\sigma,\eta})\Re(c_1\bar{c}_2\mathbf{S}_{21}). \end{aligned} \tag{4.16}$$

In the special case that there is no compensation ($\tau_C = 0$, $(\phi, \theta) = (0, 0)$), we obtain the well-known formula for the electrical power P_{SL} in frequency ω_{SL} as a function of the DGD τ [28]:

$$P_{\mathrm{SL}}(\tau) = \left[1 - 4\gamma(1-\gamma)\sin^2\left(\tfrac{\omega_{\mathrm{SL}}\tau}{2}\right)\right] P_{\mathrm{SL}}(0), \tag{4.17}$$

where $\gamma = |c_1|^2$ is the power splitting factor and

$$P_{\mathrm{SL}}(0) = \left| \int |f(t)|^2 e^{i\omega_{\mathrm{SL}}t} dt \right|^2. \tag{4.18}$$

Notice the correlation between the power P_{SL} and the DGD τ: For the 5 GHz spectral line with $\gamma = \frac{1}{2}$, $P_{\mathrm{SL}}(\tau)/P_{\mathrm{SL}}(0)$ decreases from 1 to 0 as τ increases from 0 to 100 ps.

If we reformulate the optimization problem to be of the form (4.1) and make an orthogonal change of coordinates, we obtain

$$\max_{\mathbf{x}\in\mathbf{R}^3} J(\mathbf{x}) \;=\; (\mathbf{x} - \mathbf{x}_0)^T \Lambda (\mathbf{x} - \mathbf{x}_0) \qquad \text{subject to} \;\; \|\mathbf{x}\| = 1, \tag{4.19}$$

where $\mathbf{x}_0 \in \mathbf{R}^3$ and Λ is a real diagonal matrix. Using the method of Lagrange multipliers, we find that in the nondegenerate case there are no more than six critical points on S^2, including a global maximum and global minimum. However, it is not possible to obtain explicit formulae for the critical points since they are the zeros of a degree six polynomial.

In Figure 4.2 we plot the analytical objective function given by formula (4.15).

This plot corresponds to an approximation of the fiber when only first-order PMD is present, and it should be compared to the objective function shown in Figure 3.4. The difference between the two objective functions is due to the large amount of second-order PMD present in the fiber realization used for Figure 3.4. Note, however, that the global maximum is in approximately the same location in both figures. There are four critical points of the objective function on S^2: two maxima, one minimum, and a saddle point. As in the case of the DOP ellipsoid, the saddle points on $\{\theta = 0\} \cup \{\theta = \pi\}$ are not critical points of (4.19). Notice that the eye opening objective function in Figure 3.3 has five critical points on S^2.

5. Importance sampling for PMD. In this subsection, we review the importance sampling algorithm we used to accurately compute outage probabilities due to PMD. Importance sampling increases the computational efficiency of Monte Carlo sampling from the space of fiber realizations.

The problem of evaluating the performance of a PMD compensator is quite challenging because system designers require compensators to maintain a high degree of integrity: The system should lose accuracy for no more than a few minutes per year. It is too time consuming to gather enough samples to accurately measure such low probabilities in a laboratory experiment. It is also not feasible to accurately evaluate the performance of a PMD compensator using numerical simulations based on standard Monte Carlo sampling.

PMD-induced outages occur when the eye opening is small. In a system without a PMD compensator, small eye openings are correlated to large DGD values, which occur very rarely since large DGD values correspond to sampling from the tail of a Maxwellian distribution. As we discussed in section 3, in systems with PMD compensators, the DGD in the transmission line can be at least partially canceled out by the DGD of the compensator at the carrier frequency. Therefore, after the compensator, large DGD values *at that frequency* are exceedingly rare. In general, however, the polarization dispersion vector, and hence the DGD, depends on frequency. It is useful to quantify the strength of this dependence using *second-order PMD* (SOPMD), which is defined to be the length, $|\overrightarrow{\Omega}_\omega|$, of the partial derivative of the polarization dispersion vector with respect to frequency. After the signal has traversed the compensation fiber, the DGD may be small at the carrier frequency, but the SOPMD may still be large enough that the eye opening will be small. To summarize, outages tend to occur only in the very rare case that either the DGD or the SOPMD is large relative to its average value. Recently, variance reduction techniques have been developed to greatly increase the computational efficiency of Monte Carlo simulations of PMD. Variance reduction techniques, which have been successfully applied in many contexts [16], [29], [34], simulate low probability events of interest by concentrating Monte Carlo simulations in those regions of the probability state space that are most likely to give rise to these events. More specifically, in the context of PMD [4], let $\boldsymbol{\theta}$ denote a particular fiber realization in the space Θ of all possible fiber realizations, and let p_θ be the probability density function (pdf) on Θ. Let $X : \Theta \to \mathbf{R}^K$ be a random variable on Θ, such as the eye opening or the two-dimensional quantity, $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$. Let $I : \mathbf{R}^K \to \{0, 1\}$ be the indicator function for a prescribed range of values $R \subset \mathbf{R}^K$, i.e., $I(x) = 1$ if $x \in R$ and $I(x) = 0$ otherwise. In practice, R could be a bin in the histogram of X. Our goal is compute the probability, P, that $X(\boldsymbol{\theta})$ lies in R,

$$P = \int_\Theta I(X(\boldsymbol{\theta}))\, p_\theta(\boldsymbol{\theta})\, d\boldsymbol{\theta}. \tag{5.1}$$

Using a standard Monte Carlo simulation, an estimator, $\hat{P}$, for P is given by

$$\hat{P} = \frac{1}{M}\sum_{m=1}^{M} I(X(\boldsymbol{\theta}_m)), \tag{5.2}$$

where we have drawn M samples $\boldsymbol{\theta}_m$ according to p_θ. If the events that lie in the region R are very rare, i.e., $P \ll 1$, then the relative variance of the Monte Carlo estimator $\hat{P}$ is $\sigma_{\hat{P}}/\hat{P} \sim (MP)^{-1/2}$. So, for example, if $P = 10^{-6}$, as is typically the case for an outage probability, then about $M = 10^8$ samples are required to ensure that the relative variance of $\hat{P}$ is on the order of 10%.

If a variance reduction technique is used, instead of drawing samples according to p_θ, we draw them according to a *biasing distribution*, p^*_θ, chosen so that $p^*_\theta(\boldsymbol{\theta})$ is relatively large when $X(\boldsymbol{\theta}) \in R$. Then the probability P can be expressed in the form

$$P = \int_\Theta I(X(\boldsymbol{\theta}))\, L(\boldsymbol{\theta})\, p^*_\theta(\boldsymbol{\theta})\, d\boldsymbol{\theta}, \tag{5.3}$$

where $L = p_\theta/p^*_\theta$ is called the *likelihood ratio*. If we now use a Monte Carlo simulation to draw samples $\boldsymbol{\theta}^*_m$ from Θ according to the biasing distribution p^*_θ, then an estimator $\hat{P}^*$ for P is given by

$$\hat{P}^* = \frac{1}{M}\sum_{m=1}^{M} I(X(\boldsymbol{\theta}^*_m))L(\boldsymbol{\theta}^*_m). \tag{5.4}$$

If the biasing distribution p^*_θ is chosen appropriately, many more of the samples $\boldsymbol{\theta}_m$ will fall into the region R and contribute to the sum in (5.4). To ensure that $\hat{P}^*$ is computed correctly, each sample is weighted by its likelihood ratio, which is small where p^*_θ is large relative to p_θ. If the biasing distribution is chosen appropriately, then the relative variance of P can be much smaller than for an unbiased Monte Carlo simulation.

One important question to address is how the biasing distribution should be determined. When using importance sampling, the researcher must use a combination of physical intuition and mathematical analysis to determine appropriate biasing distributions. Recently, two different variance reduction techniques—an importance sampling algorithm and a multicanonical Monte Carlo method—have been developed for simulations of PMD. These two methods take different approaches to solving the problem of finding an appropriate biasing distribution. The multicanonical Monte Carlo method of Berg and Neuhaus [1] is an iterative method that was adapted for simulations of PMD by Yevick [60], [61] and later by A. Lima [37]. At the nth iteration of the method, samples are drawn from a biasing distribution $p^{*,n}_\theta$, and at the end of each iteration, $p^{*,n}_\theta$ is updated in such a way that as n increases there is approximately an equal number of hits in each bin of the histogram of the eye opening for that iteration. Consequently, after sufficiently many iterations, the relative variance between the bins of the eye opening histogram will be small (even for the low-probability, small eye opening bins).

The second technique (importance sampling) was developed by Biondini and Kath [2], [3], [4], [17] to generate large values of first- and second-order PMD. Building on the work of I. Lima [38], [39] and A. Lima [35], we used this algorithm to generate the results in this paper. To accurately compute outage probabilities for a PMD compensator, it is necessary to sample a large region in the $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$-plane. Since

this cannot be done efficiently using a single choice of biasing distribution [39], several biasing distributions, p_j^*, are used, each of which targets a different region of the $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$-plane. To compute the probability P in (5.3), we associate a weight function $w_j : \Theta \to \mathbf{R}$ to the distribution p_j^* and define a multiple importance sampling Monte Carlo estimator, $\hat{P}$, for P by

$$\hat{P} \;=\; \sum_{j=1}^{J} \frac{1}{M_j} \sum_{m=1}^{M_j} w_j(\boldsymbol{\theta}_{j,m})\, I(X(\boldsymbol{\theta}_{j,m}))\, L(\boldsymbol{\theta}_{j,m}), \tag{5.5}$$

where M_j samples are drawn using the jth distribution, and $\boldsymbol{\theta}_{j,m}$ is the mth such sample. A formula for the relative variance of $\hat{P}$ which was used for the results in this paper is given in [4].

The choices of the biasing distributions and the weights can have a large effect on the relative variance of the estimator $\hat{P}$ in (5.5). For this paper, we used the simple and efficient choice of weights that is given by the *balance heuristic* [56]. With this heuristic,

$$w_j(\boldsymbol{\theta}) \;=\; \frac{M_j p_j^*(\boldsymbol{\theta})}{\sum_{j'=1}^{J} M_{j'} p_{j'}^*(\boldsymbol{\theta})}; \tag{5.6}$$

i.e., the weight $w_j(\boldsymbol{\theta})$ is the probability of realizing the sample $\boldsymbol{\theta}$ using p_j^*, relative to the probability of realizing this sample using all J biasing distributions. Therefore, the distribution p_j^* is weighted most heavily in those regions of the sample space Θ where it is largest.

To define a biasing distribution that targets a region of the $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$-plane, Fogal, Biondini, and Kath [17] first determined fiber realizations that maximize a specified linear combination of $|\overrightarrow{\Omega}|$ and $|\overrightarrow{\Omega}_\omega|$. Consider, for example, the simplest case of maximizing the DGD. From (2.15) we see that to maximize the DGD, the rotation matrices $\mathtt{Q}_n$ should be chosen so that the vector $\mathtt{Q}_n \overrightarrow{\Omega}^{(n-1)}$ is aligned with $\Delta\overrightarrow{\Omega}_n$. This set of rotations, $\{\mathtt{Q}_n\}_{n=1}^N$, defines a particular fiber realization. Once this fiber realization has been determined, a biasing distribution is chosen that preferentially selects nearby fiber realizations. In this way, a family of biasing distributions can be chosen, each of which targets a different region of the $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$-plane. For the results in this paper, we used the ten biasing distributions described in [39]. This multiple importance sampling algorithm has been successfully used to simulate low-probability regions in the $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$-plane. For example, the joint pdf of $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$ has been calculated down to probability levels of 10^{-8} or less with a relative variance of less than 10% using a total of only 6×10^5 samples [39].

To evaluate the performance of a PMD compensator, we actually need to generate fiber realizations that produce low-probability, small values of the eye opening. Although the importance sampling algorithm is not explicitly designed to generate small eye opening values, A. Lima [36] demonstrated that there is a strong correlation between small eye openings and large values of $(|\overrightarrow{\Omega}|, |\overrightarrow{\Omega}_\omega|)$. She reached this conclusion in a study of PMD compensators by comparing results obtained using importance sampling with those obtained using the multicanonical Monte Carlo algorithm. The multiple importance sampling algorithm has several advantages over the multicanonical Monte Carlo algorithm, at least for simulations of PMD: The relative variance is easier to calculate, the algorithm is more computationally efficient, and it can be

easily parallelized by using different processors to draw samples from the different biasing distributions.

6. Optimization. The original optimization studies we performed were carried out using an object-oriented package that performed local optimization only. The Hilbert Class Library (HCL) code was developed at Rice University [22], and preliminary results obtained using this optimization software are discussed in [64]. As described in that paper, we used HCL's limited-memory BFGS (LMBFGS) [40] algorithm with line search [10] to determine an appropriate rotation for the polarization controller. While these early results were intriguing and allowed us to compare the performance of the optimization algorithm with the spectral line and DOP ellipsoid feedback mechanisms, the engineering problem is to find the "best" rotation for the polarization controller, i.e., to find the global optimum. While LMBFGS is a fast (Newton-based) technique that has been "globalized" to accommodate arbitrary initial guesses via the line search feature of HCL, the technique is not guaranteed to find the global optimum. Therefore, after completing the previous study, we decided to incorporate into our optics simulator an object-oriented optimization package that contains a variety of optimization tools (including some global techniques). The Design Analysis Kit for Optimization and Terascale Applications (DAKOTA) is the optimization package we used to obtain the results presented in this paper. The package was developed at Sandia National Labs to allow users to optimize their (generally PDE-based) simulation models for purposes of engineering design.

Our optimization problem is an unconstrained problem of the form (4.2) (although simple bound constraints may be placed on the rotation angles from periodicity), and our goal is to find the global optimum given reasonable computer time limitations. The design variables are continuous, and no analytic gradient information is available.

The experiments described in this paper fall into three categories of optimization jobs—local optimization, multistart jobs which use local optimization repeatedly on the same problem, and global hybrid optimization runs. The local optimization was performed using DAKOTA's *OPT++* library [11]. The *OPT++* library contains mostly gradient-based nonlinear programming algorithms for constrained or unconstrained optimization. In this paper we chose *OPT++*'s conjugate gradient (CG) method, which is appropriate for unconstrained optimization. The optimization in all these experiments is performed over two rotation angles (ϕ and θ). Numerical (finite difference) gradients are used in the CG algorithm with a relative finite difference step size of 0.0001. The gradient stopping tolerance is also set to the default value of 10^{-4}.

The second set of numerical experiments invokes DAKOTA's multistart capabilities. In each multistart job, a series of local optimization runs are completed, each using a different starting point. The multistart jobs also use *OPT++*'s CG routine. Numerical finite difference gradients are used with the same tolerances as in the single starting point local optimization experiments. These multistart jobs were run using either two, four, or nine equally spaced starting points. Since the ϕ values range over the interval $[-\pi, \pi]$, and θ takes values over the interval from $[0, \pi]$, the nine starting points were chosen to be the equally spaced points $(\phi, \theta) = \{(-\pi, 0), (-\pi/3, 0), (\pi/3, 0), (-\pi, \pi/3), (-\pi/3, \pi/3), (\pi/3, \pi/3), (-\pi, 2\pi/3), (-\pi/3, 2\pi/3), (\pi/3, 2\pi/3)\}$. Note that periodicity implies that these equally spaced points cover the (ϕ, θ)-domain uniformly. (The edges of the domain wrap.) For the four-point runs, the initial guesses are $(\phi, \theta) = \{(-\pi, 0), (-\pi, \pi/2), (0, 0), (0, \pi/2)\}$. Finally, the two-point runs use $\{(-\pi, 0), (0, \pi/2)\}$ as starting guesses.

The third type of optimization jobs are hybrid multilevel optimization schemes

which use a global optimization method initially and then switch to a local Newton-based scheme once the optimization is close enough to the solution to ensure fast convergence to the optimum. In our case we chose a genetic algorithm (GA) for the global method. GAs are based on Darwin's theory of survival of the fittest [12]. The GA starts with a random selection of points called a "population." The values of the parameters being optimized over form a string of mathematical "DNA" (a conglomeration of values for the parameters being optimized) which then is adapted to a best fit (or optimal configuration) by a process of natural selection, breeding, and mutation [12]. GAs are convenient when there are multiple local optima or when gradients cannot be computed easily. In those cases, GAs can be used to determine regions of the solution space where the global optimum may be located [12]. Global methods such as GAs, however, are slow to complete convergence to a minimizer and are best used in conjunction with a fast local method. Typical GA behavior shows a rapid decrease in the objective function initially, but then a steady slowing of progress towards the minimum. Often only a few initial GA iterations suffice to move the focus of the optimization to the region of interest.

In our GA runs, we chose a population size of five points (representing five (ϕ, θ) pairs) and ran the GA for a maximum of 25 function evaluations. The stopping tolerance for convergence was chosen to be (a loose) 5×10^{-2}. Once the GA run is finished, control is passed to a local method (in our case we chose the Fletcher–Reeves conjugate gradient algorithm from the *CONMIN* package in DAKOTA). The CONMIN package contains both constrained and unconstrained minimization algorithms similar to *OPT++*. The same default stopping tolerances were used for the local optimization part of the multilevel jobs as for the purely local *OPT++* jobs.

7. Numerical results. We now describe a suite of numerical experiments that we ran to investigate the relative performance of the three compensation feedback mechanisms (DOP ellipsoid, spectral line, and eye opening). The experiments used the local and global optimization routines from DAKOTA discussed in section 6. Specifically, for each of the three feedback mechanisms we ran five optimization jobs involving 200,000 fiber realizations (or Monte Carlo simulations) each. For each feedback mechanism we optimized the compensator using local optimization (conjugate gradients), multilevel global optimization, and a multistart global routine involving varying numbers of starting guesses. The aim in all cases was to compensate for the transmission fiber DGD. As discussed in section 6, the multilevel strategy starts with a small number of GA iterations. After narrowing the optimization search area via the GA, the algorithm passes control to a fast local gradient-based optimization routine (CG in our case) to find the (hopefully) global optima. For the multistart runs, local optimization is "globalized" by running the local optimization to completion from a few different starting points. We ran three sets of multistart jobs for each feedback mechanism. In the first multistart job we used two initial points. In the second we used four starting guesses, and in the last simulation we used nine points. The multistart algorithm is an ad hoc globalization of local methods but suffers from the fact that the starting points are chosen at random. No prior (or current) knowledge of the objective function surface is used.

The goal is to drive the outage probability down to a small acceptable level. System designers typically require a probability of no more than 10^{-3}–10^{-6} that the eye is 40% closed relative to its original back-to-back value (i.e., 2 dB down from the ideal case of no PMD). Note that an eye corresponding to a 1 dB decrease from the back-to-back signal is 79% open. An eye that is 2 dB down is 63% open, and 3 dB

down corresponds to an eye that is only 50% open. Values of 1–2 dB reduction are of greatest interest. A value of 3 dB down corresponds to an eye that is so closed as to indicate system failure.

Parameters in the optical communications simulator which were fixed in these simulations include specifications about the transmitted signal, transmission fiber, and receiver. We modeled the transmitted signal by allocating a time interval of duration 100 ps to each binary digit (corresponding to a data rate of 10 Gb/s). We used the 16-bit data pattern 1001101011110000, and we encoded the binary data onto the amplitude of the signal by setting $\mathbf{U}(0,t) = (\chi_1(t), 0)^T$. Here $\chi_1(t) = 1$ when t is in the time interval of a one, and $\chi_1(t) = 0$ when t is in the time interval of a zero. The signal was polarized since $U_2(0,t) = 0$. We then applied a Gaussian filter to $\mathbf{U}$ to produce a smooth signal. The width of the filter was chosen so that the time required for the signal power to increase from 10% to 90% of its maximum value of 1 milliWatt was 30 ps. The transmission fiber was modeled using the coarse-step method (described in section 2.4) with 80 fiber segments. The average DGD of the transmission fiber was set at 30 ps, and the DGD of the compensation fiber was fixed at 30 ps. We modeled the receiver using a 60 GHz Gaussian-shaped optical filter, a photodetector that converts the optical power to electrical voltage, and a fifth-order electrical Bessel filter with half-width of 8 GHz.

Our first conclusion from these numerical experiments is that the shape of the objective function depends strongly on the feedback mechanism. The eye opening feedback signal is highly correlated to the bit-error ratio, which ultimately is the quantity to optimize. Unfortunately the eye feedback mechanism results in a fairly rough objective function. On the other hand, both the spectral line and DOP feedback mechanisms are smoother than the eye and so are easier to optimize. Figures 3.3, 3.4, and 3.5 are plots of the objective functions for the eye, spectral line, and DOP feedback mechanisms for a typical fiber realization. We see that for this example, the eye objective function has a steep ridge. Features such as this can hinder the progress of local methods towards the maximum. The DOP and spectral line objective functions are considerably smoother.

In Figure 7.1 we show results for the eye opening feedback mechanism. We plot outage probability as a function of the eye opening penalty (in dB down from the back-to-back signal) for six cases: (1) uncompensated signal, (2) compensated case using local optimization, (3) compensated using the global multilevel strategy, and (4–6) compensated using the global multistart strategy with varying numbers of initial guesses. We note that for the majority of fiber realizations, the eye diagram is mostly open and so the eye opening penalty is small. In other words, there is a large probability of a small eye opening penalty. In Figure 7.1, the outage probability is the probability that the eye opening penalty exceeds the value on the horizontal axis. The eye opening penalty will exceed 0 dB, whenever the eye is more closed with PMD than without it, which occurs almost all the time. Consequently, in Figure 7.1 the outage probability is approximately 1.0 when the eye opening penalty is 0 dB. It is only for the very rare fiber realizations with large DGD that the eye opening penalty is large, i.e., that the eye is mostly closed. Therefore, there is a very small outage probability that the eye opening penalty exceeds 2 dB. Clearly, if the typical case resulted in a partially or fully closed eye, the state of optical communications would be considerably more dire. The need for importance sampling to bias the Monte Carlo simulations towards the "bad cases" reflects that in most cases, the DGD of the fiber is small. As expected, the local CG method does compensate for the DGD by reducing the outage probability from 10^{-2} to about 5×10^{-4} at an eye opening penalty

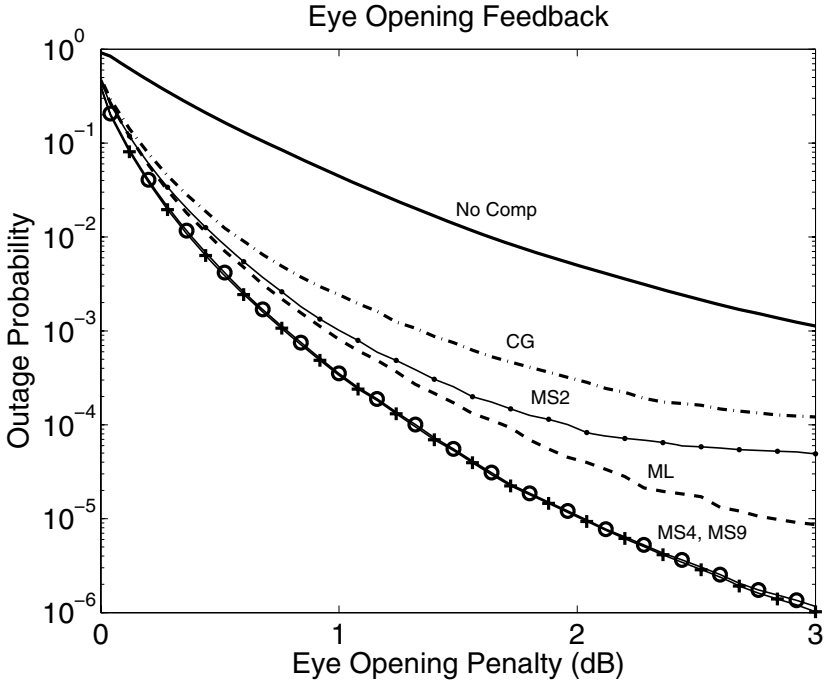

FIG. 7.1. *Outage probability as a function of eye opening penalty for different optimization algorithms applied to the eye opening feedback mechanism. The curves shown include the no compensation case (thick solid line), local (CG) optimization (dot-dash line), the multilevel hybrid optimization scheme (thick dashed line), and three curves for the multistart method (thin dotted line for multistart with two starting guesses; thin line with circles for multistart with four initial guesses; and thin line with crosses for multistart with nine starting points for the local optimization runs). Note that there is no difference in optimization results for the multistart scheme using four and nine starting points in the case of the eye opening feedback mechanism.*

Eye	52	68	99	194	459

of 2 dB. However, the best global method in this case (multistart with four points) further decreases the outage probability to about 10^{-5}. We believe that multistart with four points is finding the global optimum for the eye feedback signal since the multistart algorithm with nine points is unable to reduce the outage probability further. Consequently, this result represents the best possible performance for this fixed DGD compensator.

As Table 7.1 indicates, the cost of the multistart jobs is high. Multistart four- and nine-point schemes require 3–7 times as many function evaluations as the multilevel technique (200 or 450 iterations, respectively, versus about 65). In the case of the eye feedback mechanism, multilevel optimization reduces the outage probability to about 4×10^{-5} at 2 dB. In general the number of function evaluations required (for

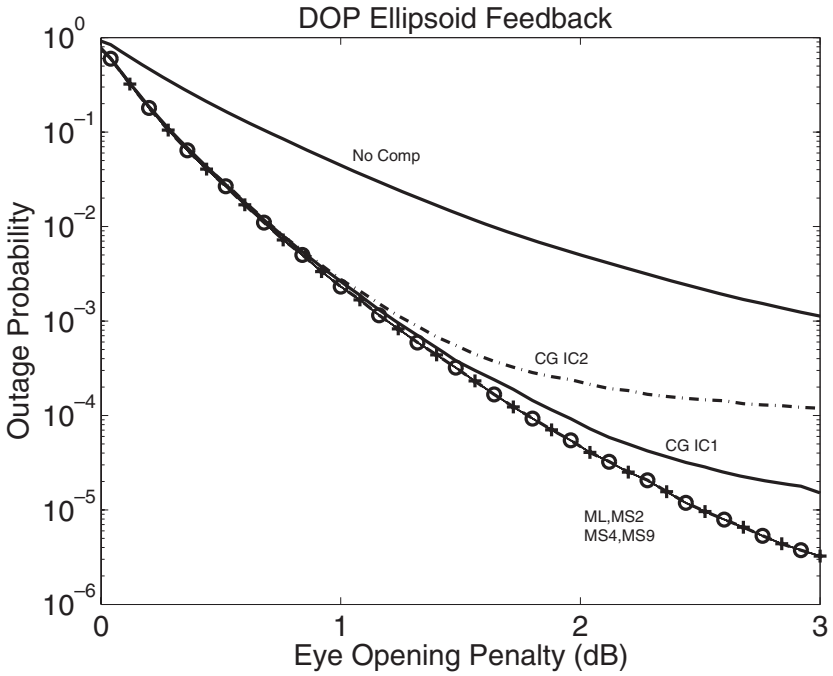

FIG. 7.2. *Outage probability as a function of eye opening penalty for different optimization algorithms applied to the DOP feedback mechanism. The curves shown include the no compensation case (thick solid line), local (CG) optimization (also a thick solid line) starting from the initial guess* $(\phi, \theta) = (0, \pi/2)$*, and local optimization (CG) (dot-dashed line) starting from the initial guess* $(\phi, \theta) = (0, 0)$*. The curves for the multilevel hybrid optimization scheme (thick dashed line), multistart method with two starting guesses (thin dotted line), multistart with four initial guesses (thin line with circles), and multistart with nine initial guesses (thin line with crosses) lie on top of each other.*

all feedback mechanisms and all levels of DGD) increases from least expensive to most costly in the following order: local conjugate gradient method, the multilevel technique, and, finally, multistart. The multistart job cost increases approximately linearly with the number of starting points used. Table 7.1 shows the number of function evaluations for all the algorithms and feedback mechanisms at a fixed eye opening penalty (2 dB).

In Figures 7.2 and 7.3 we show the outage probability versus eye opening penalty for the local and global optimization methods and the DOP and spectral line feedback mechanisms, respectively. These figures include curves for two different CG simulations. The first run (CG IC1) used a starting point of $(\phi, \theta) = (0, \frac{\pi}{2})$, and the second (CG IC2) started from $(0, 0)$. For the DOP ellipsoid, the local CG algorithm (CG IC1) took an average of 50 function evaluations and resulted in an outage probability of 7×10^{-5} at 2 dB. The multilevel scheme took 65 function evaluations to arrive at an outage probability of 3×10^{-5}. Multistart takes considerably more function evaluations to arrive at the same outage probability value (see Table 7.1). The lack of model-based knowledge built into the multistart scheme is clearly to blame for this dramatic increase in the number of function evaluations without a corresponding outage probability reduction.

In sections 3 and 4 we saw that the DOP ellipsoid is very smooth and usually has

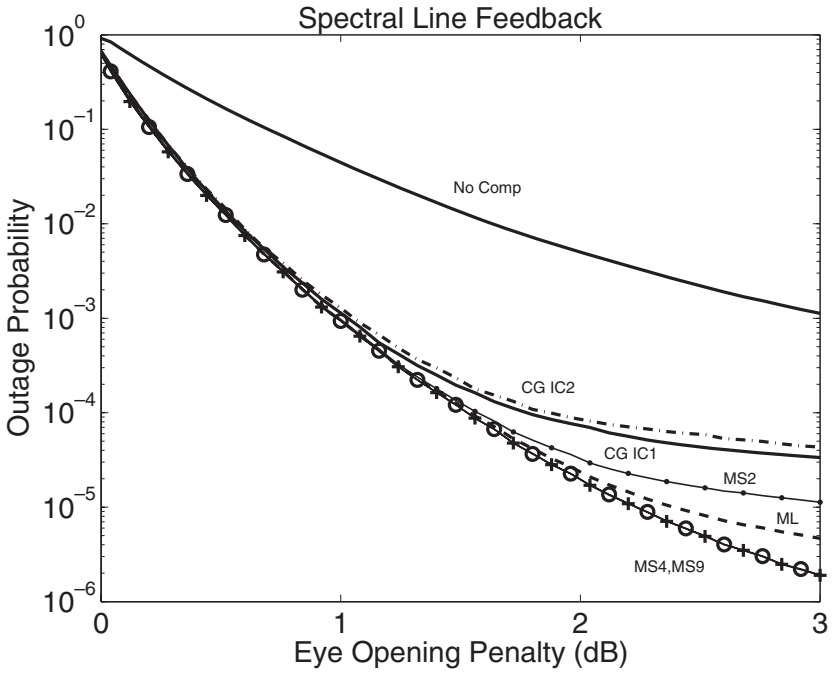

FIG. 7.3. *Outage probability as a function of eye opening penalty for different optimization algorithms applied to the spectral line feedback mechanism. The curves shown include the no compensation case (thick solid line), local (CG) optimization (also a thick solid line) starting from the initial guess* $(\phi, \theta) = (0, \pi/2)$*, and local optimization (CG) (dot-dashed line) starting from the initial guess* $(\phi, \theta) = (0, 0)$*. The curve for the multilevel hybrid optimization scheme is denoted by a thick dashed line, and the multistart method with two starting guesses is indicated by a thin dotted line. The multistart method with four initial guesses (thin line with circles) and multistart with nine initial guesses (thin line with crosses) coincide for this feedback mechanism.*

only one maximum whereas the spectral line can have at least two maxima. Starting from the south pole (IC2), there is a small probability that the CG algorithm will stall near a saddle point since the objective function can be very flat due to distortions inherent in the spherical coordinate mapping. For the DOP ellipsoid, starting from the equator (IC1), the CG algorithm will usually head straight to the top of the only hill. Since this maximum is between the equator and the saddle points at the south pole, there is very little chance that the algorithm will go via these saddle points and hence very little chance that it will get stuck there. Therefore, the outage probability is lower with IC1 than with IC2. Different initial conditions lead to outage probability curves which lie between the curves for IC1 and IC2.

Figure 7.4 compares the best local and best global schemes for the three feedback mechanisms. For each of the pdfs used to determine the curves in this figure, importance sampling produces a relative variation in each bin of the histogram of less than 10%. One can surmise the relative smoothness of the objective functions for the three feedback mechanisms by noting the distance between the local and global curves in the figure. For the eye feedback signal, the local method is least effective at reducing outage probability. Yet the global scheme is more effective for this objective function than it is for either DOP or spectral line. In other words, for the eye feedback mechanism, the outage probability for the best global optimization algorithm is over

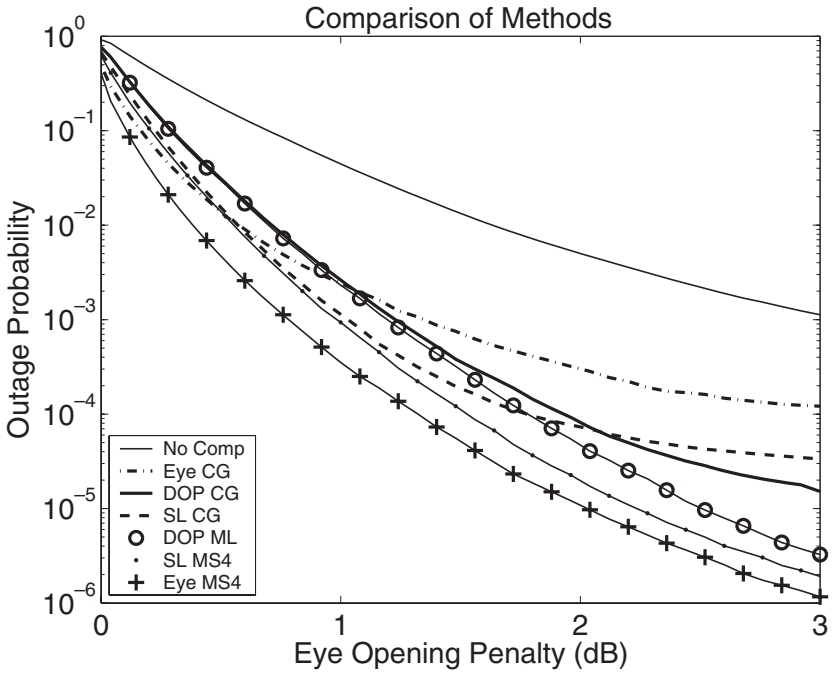

FIG. 7.4. *A comparison of the local and best global optimization results for the three feedback mechanisms. For local optimization of the spectral line and DOP ellipsoid we show the results for the starting point IC*1 $(\phi, \theta) = (0, \pi/2)$.

an order of magnitude smaller than for local optimization. A much smaller decrease occurs for the spectral line feedback signal. (All these comparisons were made at the 2 dB point in the plots.)

The DOP and spectral line feedback signals act as smooth surrogate approximations to the more realistic but bumpier eye signal. The DAKOTA reference manual [11] describes surrogate-based optimization as an iterative process that periodically recalibrates an approximate model via data from a true model. The DOP and spectral line functions are not true surrogates, as in this work we fix the objective functions used throughout a particular optimization run. No updates to the shape of objective function occur during the course of the optimization. Finally, we note (Table 7.1) that for the spectral line, the multilevel scheme does a better job of reducing the objective function than the two-point multistart scheme, but at 50% less cost. Our conclusions are that the simpler smooth DOP and spectral line feedback mechanisms do a good job of approximating the realistic (but bumpy) eye. Moreover, multilevel appears to do the best job of minimizing the number of function evaluations while still reducing the outage probability.

In Figure 7.5 we assess the statistical effect that higher-order PMD has on the performance of the spectral line and DOP ellipsoid feedback mechanisms. For each fiber realization we chose the setting of the polarization controller by optimizing the analytical objective functions given by (4.3) and (4.15) that we obtained using the first-order PMD approximation of the fiber. Given the solution to this surrogate optimization problem, we then computed the performance of the compensator using the original all-order PMD fiber realization. For the DOP ellipsoid we calculated

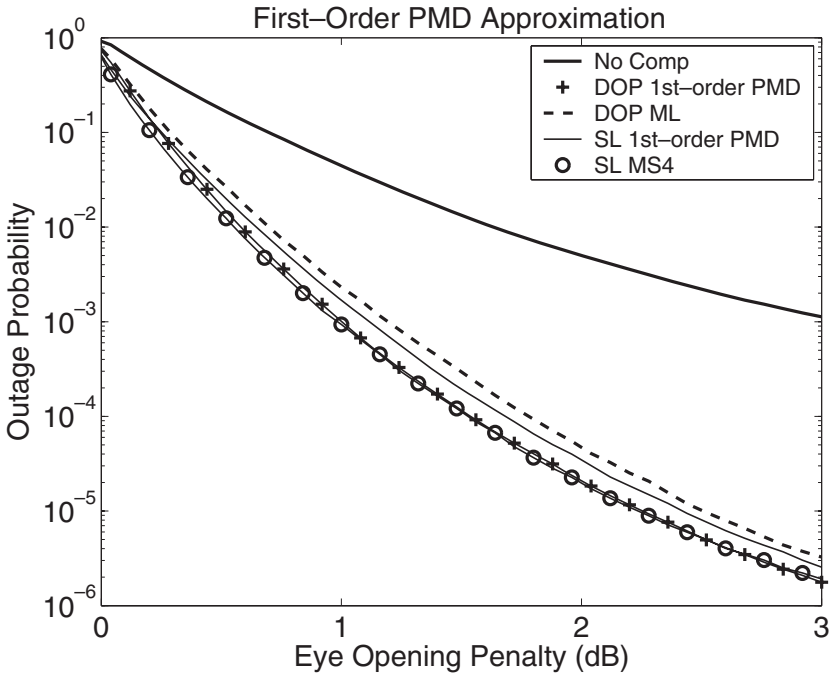

FIG. 7.5. *A comparison of outage probability for the first-order PMD approximation of the objective functions coming from the DOP ellipsoid (thin line with pluses) and the spectral line (thin line) versus the all-order PMD objective functions for the DOP ellipsoid (thick dashed line) and the spectral line (thin line with circles). These results were obtained using global optimization. The result without compensation is shown as a thick line.*

the global maximum analytically using the formula given above (4.5), while for the spectral line we optimized the analytical objective function numerically using the multistart strategy with four starting points. In Figure 7.5, for the DOP ellipsoid, we compare the "analytical" outage probability curve (thin line with pluses) to the one we obtained numerically using the all-order PMD objective functions (thick dashed line). We also compare the analytic and numerical outage probability curves for the spectral line, which we show with a thin line and a thin line with circles, respectively. For both the DOP ellipsoid and the spectral line, the fairly close agreement between the analytic and numerical curves confirms that we can regard the all-order PMD objective functions as being perturbations of objective functions for fibers with only first-order PMD.

Next, we explain the relative performance of the different methods in Figure 7.4 by comparing the relative location of the local and global maxima of the different objective functions. This discussion will also quantify the degree to which the spectral line and DOP ellipsoid objective functions act as smooth surrogates of the eye opening. We begin by discussing the three feedback mechanisms optimized via global methods. First, we observe that across the entire range of eye opening penalty values in Figure 7.4, the outage probability is always larger for the DOP ellipsoid than for the spectral line, and that the eye opening feedback mechanism has the lowest outage probability. The primary reason for the poorer performance with the DOP ellipsoid is that the distance between the global maxima of the DOP ellipsoid and eye objective

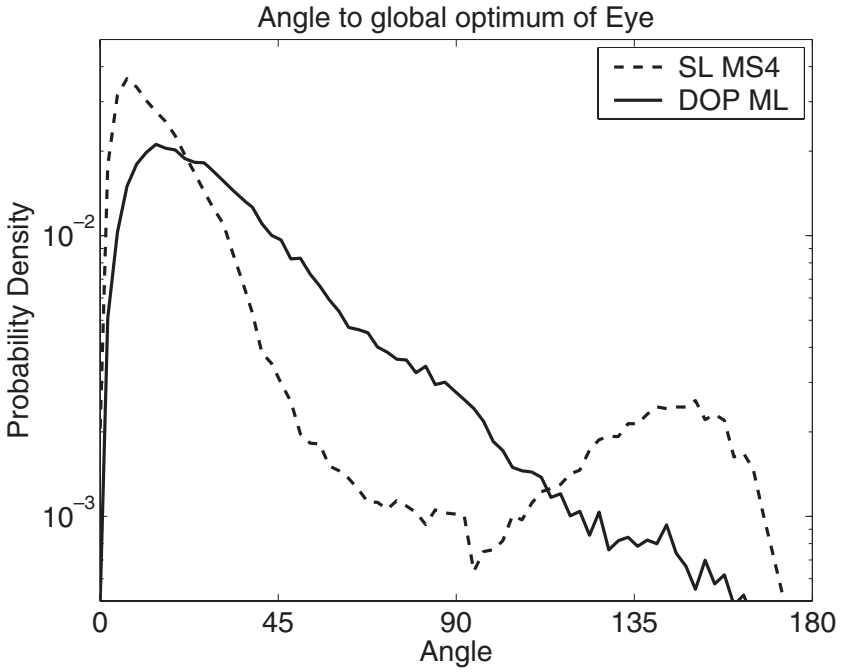

FIG. 7.6. *The pdf of the angle between the global maximum of the eye objective function and the maximum obtained for the spectral line using multistart with four starting points (thick dashed curve) and for the DOP ellipsoid using the multilevel algorithm (thick solid curve).*

functions tends to be larger than between the global maxima of the spectral line and eye objective functions.

To verify this observation, we gathered statistics of the distances between the global maxima for the different feedback mechanisms. To define a physically meaningful notion of distance between two rotations of the polarization controller in a compensator, we begin by recalling that any rotation of S^2 can be expressed as a rotation $R_{\overrightarrow{r}}(\Psi)$ by an angle $\Psi \in [0, \pi]$ about an axis $\overrightarrow{r} \in S^2$. Given two rotations R_1 and R_2, consider the rotation E_0 such that $R_2 = E_0 R_1$, and let Ψ_0 be the angle such that $E_0 = R_{\overrightarrow{r}_0}(\Psi_0)$. In our compensator model the rotations R_1 and $R_X(\pi)R_1$ have the same effect on the signal. Therefore, we also consider the rotation E_π defined by $R_2 = E_\pi R_X(\pi) R_1$ and let Ψ_π be the angle such that $E_\pi = E_0 R_X(\pi) = R_{\overrightarrow{r}_\pi}(\Psi_\pi)$. Finally, we define an angle $\Psi \in [0, \pi]$ by $\Psi = \min\{\Psi_0, \Psi_\pi\}$. The angle Ψ is our measure of distance between two rotations R_1 and R_2 performed by the polarization controller. (Note though that the distance function given by Ψ does not satisfy the triangle inequality.) In the case of only first-order PMD, the angle between global maximum and global minimum of the DOP ellipsoid objective function given by (4.3) is 180°.

In Figure 7.6 we plot the pdf of the angle between the numerically computed global maxima of the spectral line and the eye opening (thick dashed curve) and between the global maxima of the DOP ellipsoid and eye opening (thick solid curve). The most likely angle is 7° for the spectral line and 14° for the DOP ellipsoid. We observe that the probability that the angle is between 30° and 90° degrees is significantly greater for the DOP ellipsoid than for the spectral line. Therefore the global maximum

of the spectral line objective function is usually closer to that of the eye opening than is the global maximum of the DOP ellipsoid. Consequently, the eye opening tends to be somewhat larger for the spectral line than for the DOP ellipsoid. This observation explains why the outage probability is smaller for the spectral line than for the DOP ellipsoid when global optimization is used. One of the physical reasons for this performance difference is that the DOP ellipsoid objective function is defined by minimizing the output DOP over all possible input polarization states. However, when we computed the eye opening penalties for the outage probability curves, we chose the input polarization state to be $(S_1, S_2, S_3) = (1, 0, 0)$ rather than choosing it to be the state which resulted in the smallest DOP at the receiver. If we maximize the DOP for the input polarization state with the smallest output DOP, we do not obtain the same global maximum as we would if we maximized the DOP (or spectral line) when the input polarization state is $(1, 0, 0)$.

We also observe in Figure 7.6 that the probability that the angle is between 130° and 170° is much larger for the spectral line than for the DOP ellipsoid. The physical reason for this feature can be explained using the formulae for the objective functions we derived in section 4: In the case of only first-order PMD the DOP ellipsoid has only one maximum, whereas the spectral line objective function can have at least two maxima. Therefore, in a small proportion of cases the global maximum of the spectral line can be far from that of the eye opening. For example, suppose as in Figures 3.3 and 3.4 that the eye opening has local maxima at (ϕ_1, θ_1) and (ϕ_2, θ_2), and that the spectral line also has local maxima located near these two points. It could happen that the global maximum for the eye opening is at (ϕ_1, θ_1) whereas the global maximum for the spectral line is located near (ϕ_2, θ_2).

We also found that if we gather statistics over only those fiber realizations for which the second-order PMD is large relative to the DGD, then the most likely angle between the global maxima of the DOP ellipsoid and the eye opening feedback increases markedly. In contrast, the most likely angle between the global maxima of the spectral line and the eye opening is unchanged. (We do not show these results.) These results suggest that when higher-order PMD is introduced, the global maxima of the DOP ellipsoid and the eye opening tend to move apart from each other, whereas the global maximum of the spectral line remains closer to that of the eye opening. This difference in behavior with higher-order PMD provides a second explanation for why the outage probability is smaller for the spectral line than for the DOP ellipsoid when global optimization is used.

To summarize, when global optimization is used, it is important to choose an objective function with the property that the global maximum is close to that of the eye opening. Therefore, with global optimization, the spectral line is a better surrogate for the eye opening than is the DOP ellipsoid.

Finally, we explain the relative performance with the three feedback signals when local optimization is used. Looking again at Figure 7.4, when the eye opening penalty is larger than 2 dB, the eye opening feedback does not perform as well as the spectral line with local optimization. The performance with the DOP ellipsoid is comparable to that with the spectral line, but as we saw in Figure 7.2, it can depend significantly on the choice of starting point for the local optimization. To explain the poorer performance with the eye opening feedback, for each feedback mechanism we plot the pdf of the angle, Ψ, between the local maxima reached with conjugate gradients and the global maximum (see Figure 7.7). First, we observe that the DOP ellipsoid and the spectral line have slightly higher probabilities of a very small angle ($\Psi \approx 0$) between the local and global maxima than is the case for the eye opening feedback

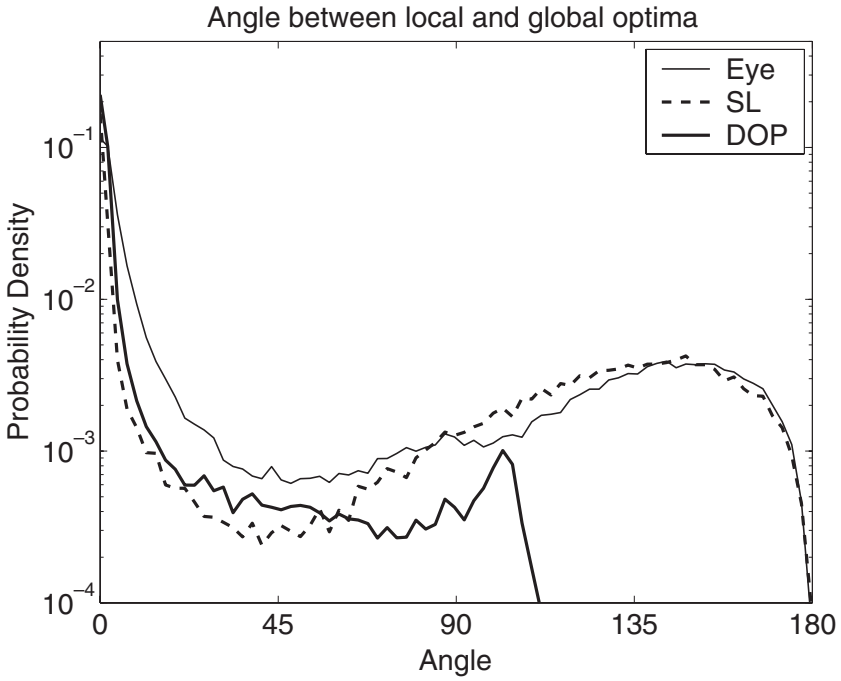

FIG. 7.7. *The pdf of the angle between the local and global maxima for the eye opening (thin solid curve), spectral line (dashed curve), and DOP ellipsoid (thick solid curve). The local and global optimization algorithms are the ones shown in Figure* 7.4.

mechanism. However, there is a significantly higher probability that the angle is between 10° and 50° for the eye opening. This high probability is not seen for the DOP or spectral line objective functions. These observations provide further evidence of the roughness of the eye opening objective function and help to explain why the eye objective function is the worst feedback mechanism for local optimization when the eye opening penalties are large. The other significant feature in Figure 7.7 is that the probability that the angle exceeds 100° is extremely small for the DOP ellipsoid, but it is relatively large for the other two objective functions. This feature is also present in the pdfs if we gather statistics over only those rare fiber realizations for which the eye opening penalty for the DOP ellipsoid (or spectral line) is larger than 1 dB.

We found that the curves in Figure 7.7 have approximately the same shape when we gather statistics over fibers with large second-order PMD. Consequently, even with higher-order PMD, the DOP ellipsoid objective function tends to be very smooth and to have only one maximum, just as the analysis in section 4 showed for fibers with only first-order PMD. Why then for the DOP ellipsoid is the outage probability at 3 dB smaller with global than with local optimization in Figure 7.4? One possible reason is that for some fiber realizations we observed that the DOP ellipsoid objective function has suboptimal, wide flat regions. Also, when second-order PMD is large enough, there can be small bumps in the bottom of the valleys which may present a problem for a local algorithm.

8. Conclusions. In an optical fiber communication system, binary data is transmitted through optical fiber using a sequence of pulses of light. The birefringence of the fiber causes the pulses to spread and distort as they propagate and increases the

probability that bit errors will occur. A simple optical PMD compensator can be used to reduce these distortions and errors. Since the birefringence varies randomly over time, the compensator must be continually optimized with the aid of a feedback signal. To evaluate the performance of a compensator, an optimization problem must be solved for a large number of random realizations of the birefringence. In each case, the goal is to locate the operating point at which the bit-error ratio is smallest. Since it is not possible to measure the bit-error ratio in a real system, we studied three commonly used feedback signals: the eye opening, spectral line, and DOP ellipsoid. To adequately sample the very rare fiber realizations that result in a large uncompensated bit-error ratio, we performed Monte Carlo simulations with multiple importance sampling. We quantified the degree to which the performance of a compensator depends on the choice of feedback signal and optimization algorithm by computing the probability that the eye opening penalty exceeds a given threshold, i.e., that the bit-error ratio is large.

Although the eye opening is highly correlated to the bit-error ratio, its objective function is quite rough and is therefore hard to optimize. Our results show that the spectral line and DOP objective functions act as smooth surrogate approximations to the rougher eye opening. In the special case of first-order PMD, we proved that the spectral line objective function can have as many as six critical points on the sphere, whereas the DOP ellipsoid has only one maximum and one minimum. We verified that these conclusions also hold statistically over a wide range of fiber realizations with higher order PMD. Since the spectral line objective function is similar to the eye opening, the performance is somewhat better with the spectral line than with the DOP ellipsoid when global optimization is used. However, the DOP ellipsoid objective function is smoother and easier to optimize than the spectral line. In conclusion, since it is most desirable to have a low outage probability for large eye opening penalties, we suggest that multilevel optimization with the DOP ellipsoid feedback gives a good trade-off between the requirements of high performance, computational cost, and complexity of the feedback mechanism.

SUFFICIENT SECOND-ORDER OPTIMALITY CONDITIONS FOR AN ELLIPTIC OPTIMAL CONTROL PROBLEM WITH POINTWISE CONTROL-STATE CONSTRAINTS*

A. RÖSCH† AND F. TRÖLTZSCH‡

Abstract. An optimal control problem for a semilinear elliptic equation is investigated, where pointwise constraints are given on control and state. The state constraints are of mixed (bottleneck) type, where associated Lagrange multipliers can be chosen as bounded and measurable functions. Based on this property, a second-order sufficient optimality condition is established that takes into account strongly active constraints.

Key words. optimal control, elliptic differential equation, sufficient second-order optimality condition, pointwise mixed control-state constraints

1. Introduction.

In this paper we consider the optimal control problem to minimize

$$F(y,u) = \int_\Omega f(x,y(x))\,dx + \int_\Gamma g(x,y(x),u(x))\,ds(x) \tag{1.1}$$

subject to the state equations

$$\begin{aligned} Ay + y &= 0 && \text{in } \Omega, \\ \partial_{n_A} y &= b(x,y,u) && \text{on } \Gamma, \end{aligned} \tag{1.2}$$

the control constraints

$$0 \le u(x) \quad \text{for } x \in \Gamma, \tag{1.3}$$

and to the mixed control-state constraints

$$c(x) \le u(x) + \gamma(x)y(x) \quad \text{for } x \in \Gamma. \tag{1.4}$$

The main task of our paper is to establish second-order sufficient optimality conditions that are close to the associated necessary ones. For control-constrained problems, this issue was discussed quite completely in literature for semilinear elliptic and parabolic equations. Specifically, we mention Bonnans [4], Casas, Tröltzsch, and Unger [9], Goldberg and Tröltzsch [12], and Heinkenschloss and Tröltzsch [13].

The main difficulty in our problem is the presence of the pointwise control-state constraint $c(x) \le u(x) + \gamma(x)y(x)$ in (1.4). If pointwise state constraints are given, then the theory of sufficient second-order conditions is faced with specific difficulties

that are still far from being solved. In particular, these problems arise for pointwise state constraints of the type $c(x) \le y(x)$. Here, the Lagrange multipliers associated with the state constraints are Borel measures so that the associated adjoint state exhibits low regularity; cf. Casas [5], [6] or Alibert and Raymond [1]. This fact causes specific difficulties in the discussion for second-order sufficient optimality conditions. We refer to Casas, Tröltzsch, and Unger [10] and Raymond and Tröltzsch [15] or to Casas and Mateos [7], who consider the case of finitely many state constraints.

In our problem (1.1)–(1.4), the situation is slightly simpler, since the constraint (1.4) is a *mixed* control-state constraint of bottleneck type. In the associated parabolic case, the Lagrange multipliers are more regular. They can be assumed to be bounded and measurable functions; see Bergounioux and Tröltzsch [3] and Arada and Raymond [2]. The existence of bounded and measurable Lagrange multipliers for linear-quadratic elliptic optimal control problems is proved in Tröltzsch [21]. The semilinear elliptic case is investigated in Rösch and Tröltzsch [16].

Higher regularity of the multipliers is the main advantage enabling us to establish second-order conditions. The second-order conditions should require minimal assumptions, i.e., they should be as close as possible to associated necessary conditions. Usually, this task is accomplished by considering strongly active sets (see [11] for control-constrained optimal control of ordinary differential equations). Here, we apply this technique to our case of mixed constraints. The analysis shows that this is not an easy task. It indicates that pointwise state constraints of more general type will give rise to even more difficult techniques.

Our paper extends the results of [17], [18], where second-order conditions are derived for a weakly singular integral state equation and for parabolic equations, respectively. Let us shortly sketch the main difference between these papers and our new discussion: In [17], [18] the proof of sufficiency is based on the nonnegativity of some inverse operators related to the Fréchet derivative of the control-to-state mapping. It is this nonnegativity that cannot, in general, be expected for elliptic problems. Therefore, here we abstain from such an assumption. We only require a solvability property of an auxiliary elliptic problem. Based on similarly weak assumptions, also the regularity of Lagrange multipliers has been shown in [16], [21].

Moreover, in our paper the definition of strongly active sets associated with the mixed constraints is a more natural way than the one in [17], [18].

Let us remark that the inequality constraints in our problem differ from the inequality constraints considered in [17], [18], where $u \le c + \gamma y$ is investigated instead of (1.4). It would be easy to adapt our theory to the inequality constraints in [17], [18]. However, even for parabolic problems, the methods in [17], [18] cannot be applied to the inequality constraints (1.3) and (1.4) since certain inverse operators do not preserve the nonnegativity.

The paper is organized as follows: In section 2 we formulate first- and second-order optimality conditions and state the main result. Section 3 contains auxiliary results. The proof that our second-order conditions are sufficient for local optimality is presented in section 4.

In the paper, we use the following notations: By $b'(x,y,u)$ and $b''(x,y,u)$ we denote the gradient and the Hessian matrix of b with respect to (y,u):

$$b'(x,y,u) = \begin{pmatrix} b_y(x,y,u) \\ b_u(x,y,u) \end{pmatrix}, \quad b''(x,y,u) = \begin{pmatrix} b_{yy}(x,y,u) & b_{yu}(x,y,u) \\ b_{yy}(x,y,u) & b_{uu}(x,y,u) \end{pmatrix}.$$

Here, the notations $b_y(x,y,u) = D_y b(x,y,u)$, $b_{yy}(x,y,u) = D_{yy} b(x,y,u)$, etc. are

used for the partial derivatives. The norms $|b'|$, $|b''|$ are defined by adding the absolute values of all entries of b' and b'', respectively. By ∂_{n_A} we denote the conormal derivative.

We adapt the following assumptions from [9]:

(A1) For each $x \in \Omega$ or Γ, respectively, the functions $f = f(x,y)$, $g = g(x,y,u)$, and $b = b(x,y,u)$ are of class C^2 with respect to (y,u). For fixed (y,u) they are Lebesgue measurable with respect to $x \in \Omega$ or $x \in \Gamma$, respectively.

(A2) In this assumption, $p > N-1$, s, and r denote fixed parameters that depend on the dimension N of the domain Ω. The constants s and r express the regularities $y|_\Gamma \in L^s(\Gamma)$ and $y \in L^r(\Omega)$ in the linearized system associated to (1.2). As usual, r' and s' denote mutually conjugate numbers. For instance, s' is defined by $1/s' + 1/s = 1$.
For all $M > 0$, there are constants $C_M > 0$, functions $\psi_f^M \in L^{(r/2)'}(\Omega)$, $\psi_f^{M,1} \in L^{(s/2)'}(\Gamma)$, $\psi_f^{M,2} \in L^{(s/2)'}(\Gamma)$, $\psi_f^{M,3} \in L^\infty(\Gamma)$, and a continuous, monotone increasing function $\eta \in C(\mathbb{R}^+ \cup \{0\})$ with $\eta(0) = 0$ such that

(i) $b(.,0,0) \in L^p(\Gamma)$, for some $p > N-1$,

$$b_y(x,y,u) \le 0 \qquad \text{for a.e. } x \in \Gamma \quad \text{and} \quad \forall (y,u) \in \mathbb{R}^2, \tag{1.5}$$

$$|b'(x,y,u)| + |b''(x,y,u)| \le C_M,$$
$$|b''(x,y_1,u_1) - b''(x,y_2,u_2)| \le C_M \eta(|y_1 - y_2| + |u_1 - u_2|)$$

for almost all $x \in \Gamma$ and all $|y|, |u|, |y_i|, |u_i| \le M$, $i = 1,2$.

(ii) $f(.,0) \in L^1(\Omega)$, $f_y(.,0) \in L^{r'}(\Omega)$, $f_{yy}(.,0) \in L^{(r/2)'}(\Omega)$, and

$$|f_{yy}(x,y_1) - f_{yy}(x,y_2)| \le \psi_f^M(x)\eta(|y_1 - y_2|)$$

for almost all $x \in \Omega$ and all $|y_i| \le M$, $i = 1,2$.

(iii) $g(.,0,0) \in L^1(\Gamma)$, $g_y(.,0,0) \in L^{s'}(\Gamma)$, $g_u \in L^2(\Gamma)$, $g_{yy}(.,0,0) \in L^{(s/2)'}(\Gamma)$, $g_{yu}(.,0,0) \in L^{2(s/2)'}(\Gamma)$, $g_{uu}(.,0,0) \in L^\infty(\Gamma)$, and

$$|g_{yy}(x,u_1,y_1) - g_{yy}(x,u_2,y_2)| \le \psi_f^{M,1}(x)\eta(|y_1 - y_2| + |u_1 - u_2|)$$
$$|g_{yu}(x,u_1,y_1) - g_{yu}(x,u_2,y_2)| \le \psi_f^{M,2}(x)\eta(|y_1 - y_2| + |u_1 - u_2|)$$
$$|g_{yu}(x,u_1,y_1) - g_{yu}(x,u_2,y_2)| \le \psi_f^{M,3}(x)\eta(|y_1 - y_2| + |u_1 - u_2|)$$

for almost all $x \in \Omega$ and all $|y_i| \le M$, $|u_i| \le M$, $i = 1,2$.

Other estimates of b, f, g and their first derivatives can be derived from (A1), (A2) by the mean value theorem.

(A3) We assume that $c, \gamma \in C(\Gamma)$, and $\gamma(x) \ge 0 \quad \forall x \in \Gamma$.

(A4) The domain $\Omega \subset \mathbb{R}^N$ is bounded and has a Lipschitz boundary Γ. The Lebesgue surface measure induced on Γ is denoted by $ds(x)$. The elliptic operator A is defined by

$$Ay(x) = -\sum_{i,j=1}^m D_i(a_{ij}(x)D_j y(x)),$$

where $a_{ij} \in L^\infty(\Omega)$ satisfy, for some positive m_0, the condition of uniform ellipticity

$$\sum_{i,j=1}^m a_{ij}(x)\xi_i\xi_j \ge m_0|\xi|^2.$$

2. First- and second-order optimality conditions. We are looking for a control in the space $U = L^\infty(\Gamma)$, while the state is defined as a weak solution of (1.2) in the state space $Y = C(\bar\Omega) \cap H^1(\Omega)$ by

$$\int_\Omega \Big(\sum_{i,j=1}^m a_{ij} D_j y D_i v + yv \Big)\, dx = \int_\Gamma b(.,y,u)v \; ds(x) \qquad \forall v \in H^1(\Omega). \tag{2.1}$$

We endow Y with the norm $\|y\|_Y = \|y\|_{C(\bar\Omega)} + \|y\|_{H^1(\Omega)}$. It can be shown that, for each $u \in L^\infty(\Gamma)$, the elliptic equation (1.2) admits a unique weak solution $y = y(u) \in Y$, see [8]. Moreover, Casas and Tröltzsch [8] have proved that the solution mapping $G:\ u \mapsto y$ from $L^\infty(\Gamma)$ into Y is of class C^2.

In this paper, we discuss sufficient conditions for a local minimum. Therefore, we investigate a candidate $\bar u$ for the local optimum and an ε-neighborhood of $\bar u$:

$$B_\varepsilon(\bar u) = \{u \in L^\infty(\Gamma) :\ \|u - \bar u\|_{L^\infty(\Gamma)} < \varepsilon\}.$$

For any fixed $\varepsilon > 0$ and arbitrary $\bar u \in U$, there exists a constant $M = M(\varepsilon)$ such that

$$\|y(u)\|_Y \le M \qquad \forall y \in B_\varepsilon(\bar u).$$

The boundary values of y are of particular importance for us. Thus we define the mapping $S : L^\infty(\Gamma) \to C(\bar\Gamma)$ with $S = \tau G$ that assigns to u the boundary values of y. Here, τ denotes the trace operator. Clearly, the Fréchet differentiability of the operator G implies the differentiability of S. The application of $S'(\bar u)$ to an element $h \in U$ is given by the boundary values of the solution z of the elliptic problem

$$\begin{aligned} Az + z &= 0 && \text{in } \Omega, \\ \partial_{n_A} z - \bar b_y z &= \bar b_u h && \text{on } \Gamma, \end{aligned} \tag{2.2}$$

i.e., $S'(\bar u)h = z|_\Gamma$. Here we have used the abbreviations $\bar b_y = b_y(x, \bar y(x), \bar u(x))$ and $\bar b_u = b_u(x, \bar y(x), \bar u(x))$. The operator $S'(\bar u)$ is extended to a linear continuous operator in $\mathcal{L}(L^2(\Gamma))$. From now on, $S'(\bar u)$ will be understood in this way. For the remainder term in the first-order Taylor expansion of $y(\bar u + h)$, we obtain the property

$$\frac{\|y(\bar u + h) - y(\bar u) - z(\bar u, h)\|_{L^2(\Gamma)}}{\|h\|_{L^2(\Gamma)}} \to 0 \quad \text{as } \|h\|_{L^\infty(\Gamma)} \to 0$$

using a known result of Maurer [14].

Next, we introduce the L^2-adjoint operator $S'(\bar u)^* \in \mathcal{L}(L^2(\Gamma))$. This operator is given by $S'(\bar u)^* \mu = \varphi|_\Gamma$, where φ is the solution of the elliptic problem

$$\begin{aligned} A^*\varphi + \varphi &= 0 && \text{in } \Omega, \\ \partial_{n_{A^*}} \varphi - \bar b_y\ \varphi &= \bar b_u\ \mu && \text{on } \Gamma, \end{aligned} \tag{2.3}$$

and A^* is the formal adjoint operator to A. In all that follows, let $(\bar y, \bar u)$ be a candidate for a local solution of (1.1)–(1.4). Let us set up the associated first-order necessary optimality conditions in form of a Karush–Kuhn–Tucker type theorem. To this aim, we introduce the Lagrange functional $L : Y \times L^\infty(\Gamma) \times Y \times L^\infty(\Gamma)^2 \to \mathbb{R}$,

$$\begin{aligned} L(y,u,p,\mu_1,\mu_2) = F(y,u) &+ \int_\Omega \Big(\sum_{i,j=1}^m a_{ij} D_j y D_i p + yp \Big)\, dx - \int_\Gamma b\, p \; ds(x) \\ &- \int_\Gamma \mu_1 u \; ds(x) - \int_\Gamma (u + \gamma y - c)\mu_2 \; ds(x). \end{aligned}$$

Let us comment on this choice for L. The elliptic equation (1.2) is considered in Y, while the inequality constraints (1.3) are posed in $L^\infty(\Gamma)$. Knowing the general Karush–Kuhn–Tucker theory in Banach spaces, one expects associated Lagrange multipliers $p \in Y^*$ and $\mu_i \in (L^\infty(\Gamma))^*$, together with a related quite complicated Lagrange functional. However, special techniques for optimal control problems of bottleneck type allow to show that, under natural assumptions, the Lagrange multipliers can be expressed by regular functions, i.e., $p \in Y$ and $\mu_i \in L^\infty(\Gamma)$; we refer to Tröltzsch [21] and Rösch and Tröltzsch [16]. This well-known advantage of bottleneck type problems is our key idea to establish special second-order sufficient optimality conditions, which can hardly be expected for $\mu_i \in (L^\infty(\Gamma))^*$. The existence of such regular multipliers can be shown under a Slater type condition and the assumption $\gamma(x) \geq 0$. Here, the nonnegativity of γ plays a crucial role.

Therefore, we are justified to *assume* that an adjoint state $\bar{p} \in Y$ and Lagrange multipliers $\bar{\mu}_i \in L^\infty(\Gamma)$ exist such that $(\bar{y}, \bar{u}, \bar{p}, \bar{\mu}_1, \bar{\mu}_2)$ satisfies the following first-order necessary optimality system (FON):

$$(FON)\quad \begin{cases} D_y L(\bar{y}, \bar{u}, \bar{p}, \bar{\mu}_1, \bar{\mu}_2) &= 0 \\ D_u L(\bar{y}, \bar{u}, \bar{p}, \bar{\mu}_1, \bar{\mu}_2) &= 0 \\ \text{and for almost all } x \in \Gamma & \\ \bar{\mu}_1(x) &\geq 0 \\ \bar{\mu}_2(x) &\geq 0 \\ \bar{u}(x)\bar{\mu}_1(x) &= 0 \\ (\bar{u}(x) + \gamma(x)\bar{y}(x) - c(x))\bar{\mu}_2(x) &= 0. \end{cases}$$

Note that the Lagrange multipliers may not be unique. The last two conditions of (FON) are the well-known *complementary slackness conditions*. They imply $\bar{\mu}_1(x) > 0 \;\Rightarrow \bar{u}(x) = 0$ and $\bar{\mu}_2(x) > 0 \;\Rightarrow c(x) = \bar{u}(x) + \gamma(x)\bar{y}(x)$. Let us express these optimality conditions also in terms of the partial differential equation. As it is well known, the first equation of (FON) is equivalent to the adjoint equation

$$\begin{aligned} A^*\bar{p} + \bar{p} &= f_y(x, \bar{y}) && \text{in } \Omega, \\ \partial_{n_{A^*}}\bar{p} - b_y(x, \bar{y}, \bar{u})\bar{p} &= g_y(x, \bar{y}, \bar{u}) - \gamma\bar{\mu}_2 && \text{on } \Gamma. \end{aligned} \tag{2.4}$$

The second equation of (FON) is equivalent to

$$g_u(x, \bar{y}, \bar{u}) + b_u(x, \bar{y}, \bar{u})\bar{p} - \bar{\mu}_1 - \bar{\mu}_2 = 0. \tag{2.5}$$

Next, we discuss a sufficient second-order optimality condition (SSC). For this purpose, following Dontchev et al. [11], we define *strongly active sets* and the associated *critical subspace*. Assume that $(\bar{y}, \bar{u}, \bar{p}, \bar{\mu}_1, \bar{\mu}_2)$ fulfils (FON).

DEFINITION 2.1. *Let $\delta_1, \delta_2 > 0$ be real numbers and $\bar{\mu}_1, \bar{\mu}_2 \in L^\infty(\Gamma)$ be Lagrange multipliers introduced in (FON). The sets*

$$A_1(\delta_1) := \{x \in \Gamma : \bar{\mu}_1(x) \geq \delta_1\}, \tag{2.6}$$

$$A_2(\delta_2) := \{x \in \Gamma \setminus A_1(\delta_1) : \bar{\mu}_2(x) \geq \delta_2\} \tag{2.7}$$

are called strongly active sets.

All further arguments hold true for an arbitrary choice of δ_1 and δ_2. Later, these numbers will be chosen such that a second-order sufficient optimality condition is

satisfied. To shorten the notation, we will drop the dependence of the active sets on these parameters in the proofs, but we will use the detailed notation for the statements of the main results.

DEFINITION 2.2. *We say that* $(y,u) \in C(\bar\Omega) \times L^\infty(\Gamma)$ *belongs to the critical subspace, if*

$$u = 0 \qquad \text{on } A_1(\delta_1), \tag{2.8}$$

$$u + \gamma y|_\Gamma = 0 \qquad \text{on } A_2(\delta_2), \tag{2.9}$$

and

$$\begin{aligned} Ay + y &= 0 && \text{in } \Omega, \\ \partial_{n_A} y - \bar b_y\ y &= \bar b_u\ u && \text{on } \Gamma. \end{aligned} \tag{2.10}$$

Notice that (2.10) implies $y|_\Gamma = S'(\bar u)u$. This critical subspace is larger than really needed. A smaller critical convex cone is discussed at the end of the paper.

Before we formulate the second-order sufficient optimality condition, let us find the explicit expression of $L''_{(u,y)}(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)[h_y,h_u]^2$:

$$\begin{aligned} L''_{(u,y)}(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)[h_y,h_u]^2 &= \int_\Omega f_{yy}h_y^2\,dx + \int_\Gamma (g_{yy}h_y^2 + 2g_{yu}h_yh_u + g_{uu}h_u^2)\,ds(x) \\ &\quad + \int_\Gamma (\bar b_{yy}h_y^2 + 2\bar b_{yu}h_yh_u + \bar b_{uu}h_u^2)\bar p\,ds(x). \end{aligned} \tag{2.11}$$

Here, $h_y \in C(\bar\Omega)$, $h_u \in L^\infty(\Gamma)$ denote arbitrary increments of y and u, respectively. Now we state the second-order sufficient optimality condition.

(SSC): There exist positive numbers δ, δ_1, δ_2 such that the definiteness condition

$$L''_{(u,y)}(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)[h_y,h_u]^2 \ge \delta\|h_u\|^2_{L^2(\Gamma)} \tag{2.12}$$

holds true for all (h_y,h_u) belonging to the critical subspace defined upon δ_1, δ_2.

In our further analysis, the boundary value problem

$$\begin{aligned} Av + v &= 0 && \text{in } \Omega, \\ \partial_{n_A} v + (-\bar b_y + \chi_{A_2(\delta_2)}\bar b_u\gamma)v &= \phi && \text{on } \Gamma \end{aligned} \tag{2.13}$$

plays a basic role. We require the following regularity assumption:

(R) *For* $\phi = 0$*, the problem* (2.13) *has only the trivial solution* $v = 0$.

For instance, this assumption is fulfilled if

$$-\bar b_y + \gamma\chi_{A_2(\delta_2)}\bar b_u \ge 0 \qquad \text{a.e. on } \Gamma. \tag{2.14}$$

Here χ_{A_2} denotes the characteristic function of the set $A_2(\delta_2)$. Thanks to (1.5) and (A3), this condition is fulfilled if $\bar b_u \ge 0$ holds. Now, we state the main result of the paper.

THEOREM 2.3 (second-order sufficiency). *Assume that* $(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)$ *fulfils the first-order optimality system (FON) and the regularity condition (R) holds. If the second-order condition (SSC) is satisfied, then there exist* $\delta_s > 0$ *and* $\varepsilon > 0$ *such that the quadratic growth condition*

$$F(y,u) - F(\bar y,\bar u) \ge \delta_s\|u-\bar u\|^2_{L^2(\Gamma)} \tag{2.15}$$

holds for all admissible pairs (y,u) *with* $\|u-\bar u\|_{L^\infty(\Gamma)} < \varepsilon$*. Therefore,* $\bar u$ *is a locally optimal control in the norm of* $L^\infty(\Gamma)$.

The proof is carried out in section 4.

3. Auxiliary results.

LEMMA 3.1. *Let $\beta \in L^\infty(\Gamma)$ be a fixed function that is almost everywhere nonnegative. Then for all $\phi \in L^p(\Gamma)$ with $p > N-1$, the weak solution $v \in H^1(\Omega)$ of*

$$\begin{aligned} Av + v &= 0 && \text{in } \Omega, \\ \partial_{n_A} v + \beta(\cdot)\, v &= \phi && \text{on } \Gamma \end{aligned} \tag{3.1}$$

belongs to $C(\bar\Omega)$ and satisfies the estimate

$$\|v\|_{C(\bar\Omega)} \le c_p \, \|\phi\|_{L^p(\Gamma)} \tag{3.2}$$

with a positive constant c_p that does not depend on ϕ.

For this classical result, we refer to [6] and the arguments in [1] concerning the case of Lipschitz domains.

For $N = 2$ the trace of $v \in H^1(\Omega)$ belongs to $L^r(\Gamma)$, with any $r < \infty$. For $N > 2$, $v|_\Gamma$ belongs to $L^{\frac{2(N-1)}{N-2}}(\Gamma)$. It implies that $v|_\Gamma \in L^{2+s}(\Gamma)$ with $s = 2/(N-2) > 0$ (arbitrary $s > 0$ for $N = 2$) so that the mapping $\phi \mapsto v|_\Gamma$ is continuous from $L^2(\Gamma)$ to $L^{2+s}(\Gamma)$ and from $L^p(\Gamma)$ to $L^\infty(\Gamma)$, in particular also to $L^{p+s}(\Gamma)$. By classical interpolation, cf. Triebel [20, 1.18.7, Thm. 1], there exists a positive constant δ (independent of s), such that the mapping $\phi \mapsto v|_\Gamma$ satisfies

$$\|v\|_{L^{s+\delta}(\Gamma)} \le c_s \, \|\phi\|_{L^s(\Gamma)} \qquad \forall\, s \ge 2. \tag{3.3}$$

provided that $\beta(\cdot) \ge 0$. Here and in what follows, we write $\|v\|_{L^2(\Gamma)}$ rather than $\|v|_\Gamma\|_{L^2(\Gamma)}$. We can dispense with this sign condition on β, if a regularity condition is fulfilled. To show that, we consider (3.1) for an arbitrary $\beta \in L^\infty(\Gamma)$ and assume that the associated homogeneous equation (3.1) has only the trivial solution. Then the mapping $S_\beta : L^2(\Gamma) \to L^2(\Gamma)$ that assigns to ϕ the trace of the solution v of (3.1) is well defined and continuous.

To verify this, we consider also the shifted equation

$$\begin{aligned} Av + v &= 0 && \text{in } \Omega, \\ \partial_{n_A} v + (\|\beta\|_{L^\infty(\Gamma)} + \beta(\cdot))\, v &= \phi && \text{on } \Gamma. \end{aligned} \tag{3.4}$$

Clearly, the associated mapping $\tilde S_\beta : L^2(\Gamma) \to L^2(\Gamma)$, $\tilde S_\beta : \phi \mapsto v|_\Gamma$, is well defined and compact. By the Fredholm theory, it has only countably many eigenvalues. A number $\lambda \in \mathbb{R}$ is an eigenvalue of $\tilde S_\beta$, if $\tilde S_\beta v = \lambda v$ holds with a nontrivial v. This means that λv solves (3.4) with boundary data $\phi = v$, i.e., after dividing by λ, if the boundary condition

$$\partial_{n_A} v + (\|\beta\|_{L^\infty(\Gamma)} + \beta(\cdot))\, v = \lambda^{-1} v \tag{3.5}$$

is satisfied with some nontrivial v. Obviously, we have a one-to-one correspondence between the eigenvalues of $\tilde S_\beta$ and those of S_β. The boundary condition (3.5) holds for nontrivial v iff the condition $\partial_{n_A} v + \beta(\cdot)\, v = (\lambda^{-1} - \|\beta\|_{L^\infty(\Gamma)})\, v$ is fulfilled so that $1/(\lambda^{-1} - \|\beta\|_{L^\infty(\Gamma)})$ is an eigenvalue of S_β.

In view of this, the assumption on the homogeneous equation (3.1) implies that (3.1) is uniquely solvable for all $\phi \in L^2(\Gamma)$ and that S_β is continuous in $L^2(\Gamma)$.

LEMMA 3.2. *Assume that the homogeneous equation* (3.1) *has only the trivial solution and that $\phi \in L^\infty(\Gamma)$ is given arbitrarily. Let $v \in H^1(\Omega)$ be the solution of*

(3.1). *Then there exists a constant c_β not depending on ϕ such that the following estimates hold true:*

$$\begin{array}{rcll} \|v\|_{L^2(\Gamma)} & \le & c_\beta \|\phi\|_{L^2(\Gamma)}, & \\ \|v\|_{C(\Gamma)} & \le & c_\beta \|\phi\|_{L^p(\Gamma)} & \forall\, p > N-1, \\ \|v\|_{L^1(\Gamma)} & \le & c_\beta \|\phi\|_{L^1(\Gamma)}. & \end{array} \tag{3.6}$$

Proof. (i) The first estimate is a simple consequence of the continuity of S_β in $L^2(\Gamma)$. It is only stated for convenience.

(ii) The second inequality follows by bootstrapping: The solution v solves $Av+v = 0$ subject to the boundary condition

$$\partial_{n_A} v = \phi - \beta(\cdot)\, v.$$

By (3.3) and the first estimate, we find with some $s > 0$ and some generic constant c that

$$\begin{array}{rcl} \|v\|_{L^{2+s}(\Gamma)} & \le & c\,(\|\phi\|_{L^2(\Gamma)} + \|\beta\|_{L^\infty(\Gamma)} \|v\|_{L^2(\Gamma)}) \\ & \le & c\,\|\phi\|_{L^2(\Gamma)} \le c\,\|\phi\|_{L^{2+s}(\Gamma)}. \end{array}$$

Repeating this estimate, we get from the one in $L^{2+s}(\Gamma)$ that

$$\begin{array}{rcl} \|v\|_{L^{2+2\,s}(\Gamma)} & \le & c\,(\|\phi\|_{L^{2+s}(\Gamma)} + \|\beta\|_{L^\infty(\Gamma)} \|v\|_{L^{2+s}(\Gamma)}) \\ & \le & c\,\|\phi\|_{L^{2+\,s}(\Gamma)} \le c\,\|\phi\|_{L^{2+2\,s}(\Gamma)}. \end{array}$$

After finitely many steps, the estimate

$$\|v\|_{L^p(\Gamma)} \le c\,\|\phi\|_{L^p(\Gamma)} \tag{3.7}$$

can be derived for some $p > N-1$. In view of (3.2), boundary data from $L^p(\Gamma)$ are transformed to continuous solutions for $p > N-1$. Therefore, by (3.3), it follows that

$$\begin{array}{rcl} \|v\|_{C(\Gamma)} & \le & c_p\,(\|\phi\|_{L^p(\Gamma)} + \|\beta\|_{L^\infty(\Gamma)} \|v\|_{L^p(\Gamma)}) \\ & \le & c_p\,(\|\phi\|_{L^p(\Gamma)} + \|\beta\|_{L^\infty(\Gamma)} c_p\,\|\phi\|_{L^p(\Gamma)}) \le c\,\|\phi\|_{L^p(\Gamma)}. \end{array}$$

(iii) To show the last estimate, we proceed by duality. The operator S_β is self-adjoint. Moreover, roughly speaking, we have by (ii) that its restriction $S_{\beta,p}$ to $L^p(\Gamma)$ is continuous from $L^p(\Gamma)$ to $C(\Gamma)$. We can assume $p \ge 2$. The adjoint operator $S^*_{\beta,p}$ is continuous from $C(\Gamma)^*$ to $L^{p'}(\Gamma)$, where p' is conjugate to p. Therefore, it is in particular continuous in $L^1(\Gamma)$. Finally, it can be shown that $S^*_{\beta,p}\,\phi = S^*_\beta\,\phi = S_\beta\,\phi$ for all $\phi \in L^2(\Gamma)$. This shows that S_β is continuous in $L^1(\Gamma)$ so that the third estimate is true. These facts are explained more precise and slightly more detailed in [16]. ∎

We should remark that the third estimate is not surprising. If $\beta \ge 0$, the estimate follows from the results by Casas [5] and Alibert and Raymond [1]. They have shown in this case that the boundary value problem (3.1) with given regular Borel measure ϕ admits a unique solution $v \in W^{1,\sigma}(\Omega)$ for all $\sigma < N/(N-1)$. Clearly, this implies the L^1-estimate. More or less, the result for arbitrary β is a natural extension. We have presented these details for the convenience of the reader.

As a corollary of the preceding lemma, we obtain for $\beta := -\bar b_y + \gamma \chi_{A_2} \bar b_u$ the following result.

LEMMA 3.3. *Suppose that the regularity condition (R) is satisfied. Then, for all $\phi \in L^2(\Gamma)$, the boundary value problem*

$$\begin{array}{rll} Av + v = 0 & & \text{in } \Omega, \\ \partial_{n_A} v + (-\bar b_y + \chi_{A_2} \bar b_u \gamma) v = \phi & & \text{in } \Gamma \end{array} \tag{3.8}$$

has a unique solution $v \in H^1(\Omega)$. Moreover, the estimate

$$\|v\|_{L^1(\Gamma)} \le c_1 \|\phi\|_{L^1(\Gamma)} \tag{3.9}$$

is fulfilled with some constant c_1 that does not depend on ϕ.

To perform our analysis, we repeatedly need controls u defined as follows:

$$u(x) = \begin{cases} \phi(x) & \text{on } \Gamma \setminus A_2, \\ \phi(x) - \gamma(x)(S'(\bar u)u)(x) & \text{on } A_2. \end{cases} \tag{3.10}$$

The next lemma shows that this setting is correct.

LEMMA 3.4. *Assume that the regularity condition (R) is fulfilled. Then, there is exactly one function $u \in L^\infty(\Gamma)$ that satisfies condition* (3.10)*. Moreover, the estimates*

$$\|u\|_{L^1(\Gamma)} \le c_1 \|\phi\|_{L^1(\Gamma)}, \tag{3.11}$$

$$\|u\|_{L^2(\Gamma)} \le c_2 \|\phi\|_{L^2(\Gamma)}, \tag{3.12}$$

$$\|u\|_{L^\infty(\Gamma)} \le c_\infty \|\phi\|_{L^\infty(\Gamma)} \tag{3.13}$$

hold with certain constants c_1, c_2, c_∞ that do not depend on ϕ.

Proof. Suppose that $u \in L^\infty(\Gamma)$ satisfies (3.10). Put $v := G'(\bar u)u$. Then v satisfies the elliptic problem with the boundary condition

$$\partial_{n_A} v - \bar b_y v = \begin{cases} \bar b_u \phi & \text{on } \Gamma \setminus A_2, \\ \bar b_u(\phi - \gamma v) & \text{on } A_2, \end{cases} \tag{3.14}$$

that is

$$\partial_{n_A} v + (-\bar b_y + \chi_{A_2} \bar b_u \gamma) v = \bar b_u \phi \quad \text{on } \Gamma. \tag{3.15}$$

This is exactly the boundary condition of (3.8). Consequently, the solution v is unique. Therefore, if u satisfies (3.10), then $v = G'(\bar u)u$ is unique, hence u is unique, because of

$$u = \begin{cases} \phi & \text{on } \Gamma \setminus A_2, \\ \phi - \gamma v|_\Gamma & \text{on } A_2. \end{cases} \tag{3.16}$$

On the other hand, starting from ϕ, the solution v of the elliptic equation with the boundary condition (3.15) is well defined, and the function u given by (3.16) satisfies (3.10), since, by definition of v, $u = S'(\bar u)v|_\Gamma$.

The estimate (3.11) is obtained by Lemma 3.3. Estimate (3.12) follows by standard arguments. The Stampacchia method [19] delivers estimate (3.13). ∎

To prove the main result, we later have to compare the reference pair $(\bar y, \bar u)$ with another admissible pair (y,u), where $y = G(u)$. In this case, we estimate the difference

$$y|_\Gamma - \bar y|_\Gamma = S(u) - S(\bar u) = S'(\bar u)(u - \bar u) + r_1(\bar u, u - \bar u), \tag{3.17}$$

where r_1 stands for the associated first-order remainder term of S. In the following, if there is no risk of notational confusion, we denote for short the remainder $r_1(\bar u, u - \bar u)$ and the derivative $S'(\bar u)$ by r_1 and S', respectively.

Before continuing our analysis of second-order sufficiency, let us discuss the main difficulties and our main ideas to resolve them. We start without the pointwise control-state constraints. On A_1, we have $\bar{u}(x) \equiv 0$, hence $u - \bar{u} \geq 0$ on A_1. The associated term in the Lagrange functional can be estimated as

$$\int_{A_1} \bar{\mu}_1(u - \bar{u})\, ds(x) \geq \int_{A_1} \delta_1(u - \bar{u})\, ds(x) = \delta_1 \|u - \bar{u}\|_{L^1(A_1)}. \tag{3.18}$$

In the proof of the sufficiency theorem, the L^1-norms on the right-hand side will compensate for the lack of coercivity, since (2.12) does not contribute to definiteness on $A_1 \cup A_2$.

However, we cannot expect such a property for the mixed control-state constraints. It can happen that $\int_{A_2} \bar{\mu}_2(u+y-\bar{u}-\bar{y})\, ds(x) = 0$ although $\|u-\bar{u}\|_{L^1(A_2)} > 0$ holds simultaneously.

To overcome this difficulty, we represent u in the form $u = u_1 + u_2$, where the component u_1 is chosen in such a way that an estimate similar to (3.18) holds. The u_2-part stands for the additional margin of freedom that is caused by subtracting the values of u and $\bar{u}$ outside of A_2. This splitting is performed by

$$\begin{array}{llll} u_1 = \bar{u}, & & u_2 = u - \bar{u} & \text{on } \Gamma \setminus A_2, \\ u_2 = -\gamma(S'u_2 + r_1), & & u_1 = u - u_2 & \text{on } A_2. \end{array} \tag{3.19}$$

The functions u_1 and u_2 are well defined. To see this, we write u_2 in the form

$$u_2 = \begin{cases} \phi & \text{on } \Gamma \setminus A_2, \\ \phi - \gamma S'u_2 & \text{on } A_2, \end{cases}$$

where $\phi = u - \bar{u}$ on $\Gamma \setminus A_2$, $\phi = \gamma r_1$ on A_2. Then u_2 is well defined by Lemma 3.4. Note that $S'(\bar{u})u_2 = S'(\bar{u})(\chi_{\Gamma\setminus A_2}(u - \bar{u}) + \chi_{A_2}u_2)$. From (3.13) and (3.19) we easily get

$$\|u_2\|_{L^\infty(\Gamma)} \leq c_3(\|u - \bar{u}\|_{L^\infty(\Gamma)} + \|r_1\|_{L^\infty(\Gamma)}).$$

The Fréchet differentiability of S in $L^\infty(\Gamma)$ implies

$$\|r_1\|_{L^\infty(\Gamma)} \leq \|u - \bar{u}\|_{L^\infty(\Gamma)}$$

for sufficiently small $\|u - \bar{u}\|_{L^\infty(\Gamma)}$.

Therefore, it holds by $u_1 = u - u_2$ that

$$\begin{aligned} \|u_1 - \bar{u}\|_{L^\infty(A_2)} &\leq \|u - \bar{u}\|_{L^\infty(A_2)} + \|u_2\|_{L^\infty(A_2)} \\ &\leq c_4\|u - \bar{u}\|_{L^\infty(\Gamma)}. \end{aligned} \tag{3.20}$$

LEMMA 3.5. *Assume that $(\bar{y}, \bar{u}, \bar{p}, \bar{\mu}_1, \bar{\mu}_2)$ fulfills the first-order optimality system (FON) and the regularity condition (R) holds. Then there exists a positive constant c_A such that, for all $\varepsilon > 0$ the estimates*

$$\int_\Gamma (u - \bar{u})\bar{\mu}_1\, ds(x) \geq \frac{\delta_1}{\varepsilon}\|u - \bar{u}\|^2_{L^2(A_1(\delta_1))}, \tag{3.21}$$

$$\int_\Gamma (u - \bar{u} + \gamma(y - \bar{y}))\bar{\mu}_2\, ds(x) \geq c_A \cdot \frac{\delta_2}{\varepsilon}\|u_1 - \bar{u}\|^2_{L^2(A_2(\delta_2))} \tag{3.22}$$

are valid for all admissible pairs (u, y) satisfying $\|u - \bar{u}\|_{L^\infty(\Gamma)} < \varepsilon$.

Proof. (i) Because of (FON), $\bar\mu_1(x) > 0$ can only hold where $\bar u(x) = 0$. If $\bar u(x) > 0$, then $\bar\mu_1(x) = 0$. Moreover, u is admissible, hence $u \ge 0$ and we have almost everywhere

$$(u - \bar u)\bar\mu_1 \ge 0.$$

Therefore we get by (2.6)

$$\int_\Gamma (u - \bar u)\bar\mu_1 \, ds(x) \ge \int_{A_1} (u - \bar u)\bar\mu_1 \, ds(x) \ge \delta_1 \|u - \bar u\|_{L^1(A_1)}.$$

By our assumption, we have $\|u - \bar u\|_{L^\infty(\Gamma)} < \varepsilon$. In particular, this inequality implies $\|u - \bar u\|_{L^\infty(A_1)} < \varepsilon$. Consequently,

$$\int_\Gamma (u - \bar u)\bar\mu_1 \, ds(x) \ge \delta_1 \|u - \bar u\|_{L^1(A_1)} \frac{\|u - \bar u\|_{L^\infty(A_1)}}{\varepsilon} \ge \frac{\delta_1}{\varepsilon} \|u - \bar u\|^2_{L^2(A_1)},$$

and (3.21) is proven.

(ii) Next, we discuss the integral in (3.22). Because of (FON), $\bar\mu_2(x) > 0$ can hold only if $\bar u(x) + \gamma(x)\bar y(x) = c(x)$. In addition, (y, u) is admissible, hence in particular $c(x) \le u(x) + \gamma(x)y(x)$. Therefore, we obtain almost everywhere

$$(u - \bar u + \gamma(y - \bar y))\bar\mu_2 \ge 0$$

and

$$\begin{aligned} \int_\Gamma (u - \bar u + \gamma(y - \bar y))\bar\mu_2 \, ds(x) &\ge \int_{A_2} (u - \bar u + \gamma(y - \bar y))\bar\mu_2 \, ds(x) \\ &\ge \delta_2 \|u - \bar u + \gamma(y - \bar y)\|_{L^1(A_2)} \end{aligned} \tag{3.23}$$

by definition (2.7). Let us discuss this integral more detailed. Expressing $y - \bar y$ in terms of the controls by (3.17),

$$u - \bar u + \gamma(y - \bar y) = u - \bar u + \gamma(S'(\bar u)(u - \bar u) + r_1) \tag{3.24}$$

is found. Since $u = u_1 + u_2$ and $u_2 + \gamma S' u_2 + \gamma r_1 = 0$ on A_2 hold by Definition (3.19), we find

$$u + \gamma(S'u + r_1) = u_1 + u_2 + \gamma S'u_1 + \gamma S'u_2 + \gamma r_1 = u_1 + \gamma S'u_1 \quad \text{on } A_2. \tag{3.25}$$

Consequently, (3.23) and (3.24) yield

$$\begin{aligned} \int_\Gamma (u - \bar u + \gamma(y - \bar y))\bar\mu_2 \, ds(x) &\ge \delta_2 \|u_1 - \bar u + \gamma S'(\bar u)(u_1 - \bar u)\|_{L^1(A_2)} \\ &= \delta_2 \|w + \gamma S' w\|_{L^1(A_2)} \end{aligned} \tag{3.26}$$

with $w := u_1 - \bar u$. Notice, that $w = 0$ on $\Gamma \setminus A_2$. Moreover, we set $v = G'w$ and

$$z = \begin{cases} 0 & \text{on } \Gamma \setminus A_2, \\ w + \gamma v|_\Gamma & \text{on } A_2. \end{cases}$$

By this definition, we have

$$\|w + \gamma S' w\|_{L^1(A_2)} = \|z\|_{L^1(A_2)}$$

and therefore

$$\int_\Gamma (u-\bar u+\gamma(y-\bar y))\bar\mu_2\, ds(x) \ge \delta_2\|z\|_{L^1(A_2)}. \tag{3.27}$$

Then we find

$$\begin{aligned} Av+v &= 0 && \text{in } \Omega,\\ \partial_{n_A} v-\bar b_y v &= \bar b_u w && \text{on } \Gamma. \end{aligned} \tag{3.28}$$

On A_2 we have

$$\bar b_u w = \bar b_u(z-\gamma v|_\Gamma) = \bar b_u z - \chi_{A_2}\bar b_u \gamma v|_\Gamma.$$

Because of $z=w=0$ on $\Gamma\backslash A_2$, this equation is also correct on $\Gamma\backslash A_2$ and consequently it holds that

$$\begin{aligned} Av+v &= 0 && \text{in } \Omega,\\ \partial_{n_A} v+(-\bar b_y+\chi_{A_2}\bar b_u\gamma)v &= \bar b_u z && \text{on } \Gamma. \end{aligned} \tag{3.29}$$

Applying Lemma 3.3, we obtain

$$\|v\|_{L^1(\Gamma)} \le c\|z\|_{L^1(\Gamma)} = c\|z\|_{L^1(A_2)}. \tag{3.30}$$

Setting $\bar\gamma = \|\gamma\|_{C(\Gamma)}$, we get

$$\begin{aligned} \|w\|_{L^1(A_2)} &= \|z-\gamma v\|_{L^1(A_2)}\\ &\le \|z\|_{L^1(A_2)} + \bar\gamma\|v\|_{L^1(A_2)}\\ &\le \|z\|_{L^1(A_2)} + \bar\gamma c\|z\|_{L^1(A_2)} \end{aligned}$$

or

$$\|z\|_{L^1(A_2)} \ge \frac{1}{1+\bar\gamma c}\|w\|_{L^1(A_2)}. \tag{3.31}$$

Combining (3.27) and (3.31), we find

$$\int_\Gamma (u-\bar u+\gamma(y-\bar y))\bar\mu_2\, ds(x) \ge \frac{\delta_2}{1+\bar\gamma c}\|w\|_{L^1(A_2)} = \frac{\delta_2}{1+\bar\gamma c}\|u_1-\bar u\|_{L^1(A_2)}. \tag{3.32}$$

Invoking again $\|u-\bar u\|_{L^\infty(\Gamma)} < \varepsilon$ and (3.32), we obtain

$$\begin{aligned} \int_{A_2} (u-\bar u+\gamma(y-\bar y))\bar\mu_2\, ds(x) &\ge \frac{\delta_2}{1+\bar\gamma c}\|u_1-\bar u\|_{L^1(A_2)}\cdot\frac{\|u-\bar u\|_{L^\infty(A_2)}}{\varepsilon}\\ &\ge \frac{\delta_2}{c_4\varepsilon(1+\bar\gamma c)}\|u_1-\bar u\|^2_{L^2(A_2)}, \end{aligned}$$

implying inequality (3.22) with $c_A = \frac{1}{c_4(1+\bar\gamma c)}$. □

If $A_1\cup A_2=\Gamma$, then the critical subspace contains only the function $(y,u)=(0,0)$. Then the assumptions of Theorem 2.3 are trivially fulfilled. In this case, (3.21) and (3.22) imply the so-called *first-order sufficient optimality conditions*.

4. Second-order sufficient optimality condition. Here, we outline the proof of the sufficiency Theorem 2.3. This part is very similar to the discussion in [18]. Nevertheless, for the convenience of the reader, we present the main steps of the proof.

We select an arbitrary admissible control u in a sufficiently small L^∞-neighborhood of $\bar u$ and have to show that $F(y,u) \ge F(\bar y,\bar u)$. Let us introduce the increments $\delta u := u - \bar u$ and $\delta y := G'(\bar u)\delta u$. We split $\delta u = u_0 + u_+$, where

$$\begin{array}{lll} u_0 = 0, & u_+ = \delta u & \text{on } A_1, \\ u_0 = \delta u, & u_+ = 0 & \text{on } \Gamma \setminus (A_1 \cup A_2), \\ u_0 = -\gamma S'(\bar u)u_0, & u_+ = \delta u - u_0 & \text{on } A_2. \end{array} \tag{4.1}$$

Notice that $u_0 + \gamma S'(\bar u)u_0 = 0$ on A_2. This setting is justified again by Lemma 3.4: It holds

$$u_0 = \begin{cases} \phi & \text{on } \Gamma \setminus A_2, \\ \phi - \gamma S' u_0 & \text{on } A_2, \end{cases}$$

where ϕ is defined by

$$\phi = \begin{cases} 0 & \text{on } A_1 \cup A_2, \\ \delta u & \text{on } \Gamma \setminus (A_2 \cup A_1). \end{cases}$$

The part u_0 belongs to the critical subspace, while u_+ is the part of δu that accounts for the effects of first-order sufficiency. Furthermore, we define $y_0 := G'u_0$ and $y_+ := G'u_+$. By the linearity of G', we have $\delta y = y_0 + y_+$.

Below, we estimate the difference $L(y,u,\bar p,\bar\mu_1,\bar\mu_2) - L(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)$. Let us write for short $L(y,u) - L(\bar y,\bar u)$, since $(\bar p,\bar\mu_1,\bar\mu_2)$ remains fixed in all the following considerations. We also do not explicitly indicate the point $(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)$, where all derivatives are taken, i.e., we write $L_u u$ instead of $D_u L(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)u$.

LEMMA 4.1. *Under the assumptions of Theorem* 2.3,

$$L(y,u) - L(\bar y,\bar u) \ge \frac{\delta}{4}\|u_0\|^2_{L^2(\Gamma)} - \frac{c_s}{2}\|u_+\|^2_{L^2(\Gamma)} + r_2 + \tilde r_2 \tag{4.2}$$

holds, where r_2, $\tilde r_2$ are second-order remainder terms with

$$\frac{|r_i|}{\|u-\bar u\|^2_{L^2(\Gamma)}} \to 0 \quad \textit{as } \|u-\bar u\|_{L^\infty(\Gamma)} \to 0.$$

Proof. Using Taylor's expansion, in view of (FON) we get

$$\begin{aligned} L(y,u) - L(\bar y,\bar u) &= L_u[u-\bar u] + L_y[y-\bar y] + \frac{1}{2}(L_{uu}[u-\bar u]^2 \\ &\quad + 2L_{uy}[u-\bar u, y-\bar y] + L_{yy}[y-\bar y]^2) + r_2 \\ &= \frac{1}{2}(L_{uu}[u-\bar u]^2 + 2L_{uy}[u-\bar u, y-\bar y] + L_{yy}[y-\bar y]^2) + r_2. \end{aligned} \tag{4.3}$$

The following property of the remainder is known:

$$\frac{|r_2(\bar u,h)|}{\|h\|^2_{L^2(\Gamma)}} \to 0 \quad \text{as } \|h\|_{L^\infty(\Gamma)} \to 0.$$

For the proof we refer to [22]. According to the notation of Lemma 3.4, we get $y-\bar{y}=\delta y+r_1$. Replacing $y-\bar{y}$ by δy in (4.3), another second-order remainder term is needed

$$\begin{aligned}\tilde{r}_2 := &\frac{1}{2}(L_{uu}[u-\bar{u}]^2+2L_{uy}[u-\bar{u},y-\bar{y}]+L_{yy}[y-\bar{y}]^2)\\ &-\frac{1}{2}(L_{uu}[\delta u]^2+2L_{uy}[\delta u,\delta y]+L_{yy}[\delta y]^2).\end{aligned}$$

It is easy to show that

$$\frac{|\tilde{r}_2|}{\|u-\bar{u}\|^2_{L^2(\Gamma)}}\to 0 \quad \text{as } \|u-\bar{u}\|_{L^\infty(\Gamma)}\to 0.$$

With these notations, (4.3) admits the form

$$L(y,u)-L(\bar{y},\bar{u})=\frac{1}{2}(L_{uu}[\delta u]^2+2L_{uy}[\delta u,\delta y]+L_{yy}[\delta y]^2)+r_2+\tilde{r}_2. \tag{4.4}$$

We continue by splitting the Lagrange functional in terms of u_0 and u_+,

$$\begin{aligned}L_{uu}[\delta u]^2+2L_{uy}[\delta u,\delta y]+L_{yy}[\delta y]^2 = &L_{uu}[u_0]^2+2L_{uy}[u_0,y_0]+L_{yy}[y_0]^2\\ &+L_{uu}[u_+]^2+2L_{uy}[u_+,y_+]+L_{yy}[y_+]^2\\ &+2L_{uu}[u_0,u_+]+2L_{uy}[u_0,y_+]\\ &+2L_{uy}[u_+,y_0]+2L_{yy}[y_0,y_+].\end{aligned}$$

As u_0 belongs to the critical subspace, the SSC yields

$$L''[u_0,y_0]^2=L_{uu}[u_0]^2+2L_{uy}[u_0,y_0]+L_{yy}[y_0]^2\ge\delta\|u_0\|^2_{L^2(\Gamma)}.$$

The other terms are easily estimated by $\|y_0\|^2_{L^2(\Gamma)}\le\|S'\|^2\|u_0\|^2_{L^2(\Gamma)}$, $\|y_+\|^2_{L^2(\Gamma)}\le\|S'\|^2\|u_+\|^2_{L^2(\Gamma)}$, and by means of Young's inequality,

$$\begin{aligned}|&L_{uu}[u_+]^2+2L_{uy}[u_+,y_+]+L_{yy}[y_+]^2\\ &+2L_{uu}[u_0,u_+]+2L_{uy}[u_0,y_+]\\ &+2L_{uy}[u_+,y_0]+2L_{yy}[y_0,y_+]|\le\frac{\delta}{2}\|u_0\|^2_{L^2(\Gamma)}+c_s\|u_+\|^2_{L^2(\Gamma)}.\end{aligned}$$

In this setting, c_s is a certain (large) constant. Combining the last two results, we arrive at

$$L_{uu}[\delta u]^2+2L_{uy}[\delta u,\delta y]+L_{yy}[\delta y]^2\ge\frac{\delta}{2}\|u_0\|^2_{L^2(\Gamma)}-c_s\|u_+\|^2_{L^2(\Gamma)}.$$

Returning to (4.4), we end up with

$$L(y,u)-L(\bar{y},\bar{u})\ge\frac{\delta}{4}\|u_0\|^2_{L^2(\Gamma)}-\frac{c_s}{2}\|u_+\|^2_{L^2(\Gamma)}+r_2+\tilde{r}_2,$$

which is exactly the assertion. □

In the next lemma, the term $\|u_+\|^2_{L^2(\Gamma)}$ in (4.2) is estimated.

LEMMA 4.2. *Under the assumptions of Theorem* 2.3,

$$\left(\frac{c_s}{2}+\frac{\delta}{4}\right)\|u_+\|^2_{L^2(\Gamma)}\le c_5\|u_1-\bar{u}\|^2_{L^2(A_2)}+c_6\|r_1\|^2_{L^2(\Gamma)}+c_7\|u-\bar{u}\|^2_{L^2(A_1)} \tag{4.5}$$

holds with certain positive constants c_5, c_6, and c_7.

Proof. First, we get on A_1

$$\|u_+\|_{L^2(A_1)} = \|\delta u\|_{L^2(A_1)} = \|u - \bar{u}\|_{L^2(A_1)}.$$

On the whole set Γ we have

$$u_+ + u_0 = \delta u = u - \bar{u}.$$

We apply the operator $I + \gamma S'$ to this equation and consider the image only on the set A_2. Using $u_0 = -\gamma S' u_0$ on A_2, we find

$$u_+ + \gamma S' u_+ = u + \gamma S' u - (\bar{u} + \gamma S' \bar{u}) \text{ on } A_2. \tag{4.6}$$

Now, u is again replaced by $u_1 + u_2$; see (3.19) to obtain on A_2,

$$u_+ + \gamma S' u_+ = u_1 + \gamma S' u_1 + u_2 + \gamma S' u_2 - (\bar{u} - \gamma S' \bar{u}).$$

By definition (3.19), the equation $u_2 + \gamma S' u_2 = -r_1$ is satisfied on A_2. Therefore, here we are able to continue by

$$u_+ + \gamma S' u_+ = u_1 - \bar{u} + (\gamma S'(\bar{u})(u_1 - \bar{u})) - r_1 \text{ on } A_2. \tag{4.7}$$

Due to (4.1), $u_+ = \delta u = u - \bar{u}$ holds on A_1. In addition, u_+ vanishes on $\Gamma \setminus (A_1 \cup A_2)$. Therefore, we find by (4.1) and (4.7),

$$u_+ = \begin{cases} u_1 - \bar{u} - \gamma S'(\bar{u})(u_+ - u_1 + \bar{u}) - r_1 & \text{on } A_2, \\ u - \bar{u} & \text{on } A_1, \\ 0 & \text{on } \Gamma \setminus (A_1 \cup A_2). \end{cases}$$

Again we have a construction that was investigated in Lemma 3.4. Applying (3.12), we get the inequality

$$\|u_+\|_{L^2(\Gamma)} \le c_2 \|\phi\|_{L^2(\Gamma)},$$

where ϕ is defined by

$$\phi = \begin{cases} -r_1 + (u_1 - \bar{u}) + \gamma S'(\bar{u})(u_1 - \bar{u}) & \text{on } A_2, \\ u - \bar{u} & \text{on } A_1, \\ 0 & \text{on } \Gamma \setminus (A_1 \cup A_2). \end{cases}$$

Therefore, we obtain

$$\|u_+\|_{L^2(\Gamma)} \le c_2(\|u - \bar{u}\|_{L^2(A_1)} + c_8 \|u_1 - \bar{u}\|_{L^2(\Gamma)} + \|r_1\|_{L^2(A_2)}),$$

where the positive constant c_8 depends on $\|S'\|$. In view of (3.19), it holds that $\|u_1 - \bar{u}\|_{L^2(\Gamma)} = \|u_1 - \bar{u}\|_{L^2(A_2)}$, and hence we get

$$\|u_+\|_{L^2(\Gamma)} \le c_9 \|u_1 - \bar{u}\|_{L^2(A_2)} + c_2 \|r_1\|_{L^2(A_2)} + c_2 \|u - \bar{u}\|_{L^2(A_1)}.$$

Young's inequality yields

$$\|u_+\|^2_{L^2(\Gamma)} \le 3c_9 \|u_1 - \bar{u}\|^2_{L^2(A_2)} + 3c_2 \|r_1\|^2_{L^2(\Gamma)} + 3c_2 \|u - \bar{u}\|^2_{L^2(A_1)}.$$

A multiplication by $(\frac{c_s}{2} + \frac{\delta}{4})$,

$$\left(\frac{c_s}{2} + \frac{\delta}{4}\right) \|u_+\|^2_{L^2(\Gamma)} \le c_5 \|u_1 - \bar{u}\|^2_{L^2(A_2)} + c_6 \|r_1\|^2_{L^2(\Gamma)} + c_7 \|u - \bar{u}\|^2_{L^2(A_1)},$$

concludes the proof of the lemma. ∎

Now we are able to prove our main result Theorem 2.3.

Proof of Theorem 2.3. Inserting (4.5) in (4.2),

$$\begin{aligned} L(y,u) - L(\bar{y},\bar{u}) \ge \frac{\delta}{4}(\|u_0\|^2_{L^2(\Gamma)} + \|u_+\|^2_{L^2(\Gamma)}) + r_2 + \tilde{r}_2 \\ -c_7 \|u - \bar{u}\|^2_{L^2(A_1)} - c_5 \|u_1 - \bar{u}\|^2_{L^2(A_2)} - c_6 \|r_1\|^2_{L^2(\Gamma)} \end{aligned}$$

is obtained. Next, we return to the objective F,

$$\begin{aligned} L(y,u) - L(\bar{y},\bar{u}) = F(y,u) - F(\bar{y},\bar{u}) - \int_\Gamma \bar{\mu}_1 (u - \bar{u})\, ds(x) - \int_\Gamma (u - \bar{u} \\ + \gamma(y - \bar{y}))\bar{\mu}_2\, ds(x). \end{aligned}$$

Using Lemma 3.5 we find

$$\begin{aligned} F(y,u) - F(\bar{y},\bar{u}) \ge \frac{\delta}{4}(\|u_0\|^2_{L^2(\Gamma)} + \|u_+\|^2_{L^2(\Gamma)}) + r_2 + \tilde{r}_2 \\ + \left(\frac{\delta_1}{\varepsilon} - c_7\right) \|u - \bar{u}\|^2_{L^2(A_1)} + \left(c_A \frac{\delta_2}{\varepsilon} - c_5\right) \|u_1 - \bar{u}\|^2_{L^2(A_2)} \\ -c_6 \|r_1\|^2_{L^2(\Gamma)}. \end{aligned} \tag{4.8}$$

Next, $\|\delta u\|_{L^2(\Gamma)} = \|u_0 + u_+\|^2_{L^2(\Gamma)} \le 2\|u_0\|^2_{L^2(\Gamma)} + 2\|u_+\|^2_{L^2(\Gamma)}$ is applied to continue by

$$\begin{aligned} F(y,u) - F(\bar{y},\bar{u}) \ge \frac{\delta}{8} \|\delta u\|^2_{L^2(\Gamma)} + r_2 + \tilde{r}_2 \\ + \left(\frac{\delta_1}{\varepsilon} - c_7\right) \|u - \bar{u}\|^2_{L^2(A_1)} + \left(c_A \frac{\delta_2}{\varepsilon} - c_5\right) \|u_1 - \bar{u}\|^2_{L^2(A_2)} \\ -c_6 \|r_1\|^2_{L^2(\Gamma)}. \end{aligned} \tag{4.9}$$

Now take ε sufficiently small, such that

$$\frac{\delta_1}{\varepsilon} - c_7 \ge 0 \quad \text{and} \quad c_A \frac{\delta_2}{\varepsilon} - c_5 \ge 0.$$

Then we can omit the associated terms in (4.9),

$$F(y,u) - F(\bar{y},\bar{u}) \ge \frac{\delta}{8} \|\delta u\|^2_{L^2(\Gamma)} + r_2 + \tilde{r}_2 - c_6 \|r_1\|^2_{L^2(\Gamma)}. \tag{4.10}$$

Due to the discussions during the proof, all terms on the right-hand side (except the first one) are small with respect to $\|u - \bar{u}\|^2_{L^2(\Gamma)}$. Therefore

$$F(y,u) - F(\bar{y},\bar{u}) \ge \frac{\delta}{16} \|u - \bar{u}\|^2_{L^2(\Gamma)} \tag{4.11}$$

holds if $\|u - \bar{u}\|_{L^\infty(\Gamma)} < \varepsilon$ and ε is sufficiently small. The quadratic growth condition is proven. We can now choose $\delta_s = \delta/16$. ∎

5. Generalizations. In this section, we discuss weaker assumptions and possible generalizations. The second-order sufficient optimality condition can be weakened. Let us define the weakly active control constraints

$$A_1^{weak} := \{x \in \Gamma \setminus (A_1 \cup A_2) : \ \bar\mu_1(x) > 0\}.$$

On A_1^{weak} we have almost everywhere $\bar u(x) = 0$. The control constraints imply $u(x) - \bar u(x) \geq 0$ a.e. on A_1^{weak} for all admissible controls u. Therefore, it is enough to consider only those elements of the critical subspace, which satisfy the condition

$$u(x) \geq 0 \qquad \forall x \in A_1^{weak}.$$

COROLLARY 5.1. *Suppose that the following weakened second-order sufficient optimality condition is satisfied: The condition (SSC) is required to be fulfilled only for those elements (y, u) belonging to the critical subspace (defined in Definition* 2.2*) which satisfy the condition*

$$u \geq 0 \quad \text{on } A_1^{weak}.$$

This weaker assumption ensures the result of Theorem 2.3*, too.*

The presented techniques can be extended to derive sufficient second-order optimality conditions for other types of optimal control problems. For instance, it applies to distributed elliptic control problems with mixed control constraints considered in Ω. Moreover, it works for two-sided constraints on the control, where we minimize (1.1) subject to (1.2),

$$u_a \leq u(x) \leq u_b \quad \text{for } x \in \Gamma, \tag{5.1}$$

together mixed control-state constraints

$$c(x) \leq u(x) + \gamma(x)y(x) \quad \text{for } x \in \Gamma. \tag{5.2}$$

In this case, the Lagrange functional is

$$\begin{aligned} L(y,u,p,\mu_1,\mu_2,\mu_3) = F(y,u) &+ \int_\Omega \Big(\sum_{i,j=1}^m a_{ij} D_j y D_i p + yp \Big)\, dx - \int_\Gamma b\, p\, ds(x) \\ &- \int_\Gamma \mu_1(u - u_a)\, ds(x) + \int_\Gamma \mu_3(u - u_b)\, ds(x) \\ &- \int_\Gamma (u + \gamma y - c)\mu_2\, ds(x). \end{aligned}$$

In this definition, we tacitly assume that the Lagrange multiplier μ_2 for the constraint (5.2) is a bounded and measurable function. In contrast to the former sections, we have not been able to show this. Then, the necessary first-order optimality conditions

are

$$(FONBOX)\quad\begin{cases} D_y L(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2,\bar\mu_3) &= 0\\ D_u L(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2,\bar\mu_3) &= 0\\ \text{and for almost all } x\in\Gamma & \\ \bar\mu_1(x) &\geq 0\\ \bar\mu_3(x) &\geq 0\\ \bar\mu_2(x) &\geq 0\\ (\bar u(x)-u_a)\bar\mu_1(x) &= 0\\ (\bar u(x)-u_b)\bar\mu_3(x) &= 0\\ (\bar u(x)+\gamma(x)\bar y(x)-c(x))\bar\mu_2(x) &= 0. \end{cases}$$

DEFINITION 5.2. *The strongly active sets for problem* (1.1), (1.2), (5.1), (5.2) *are*

$$A_1(\delta_1) := \{x\in\Gamma : \bar\mu_1(x)\geq\delta_1\}, \tag{5.3}$$

$$A_3(\delta_3) := \{x\in\Gamma : \bar\mu_3(x)\geq\delta_3\}, \tag{5.4}$$

$$A_2(\delta_2) := \{x\in\Gamma\setminus(A_1(\delta_1)\cup A_3(\delta_3)) : \bar\mu_2(x)\geq\delta_2\}. \tag{5.5}$$

A pair $(y,u)\in C(\bar\Omega)\times L^\infty(\Gamma)$ *belongs to the critical subspace, if*

$$u = 0 \qquad \text{on } A_1(\delta_1)\cup A_3(\delta_3), \tag{5.6}$$

$$u+\gamma y|_\Gamma = 0 \qquad \text{on } A_2(\delta_2), \tag{5.7}$$

and

$$\begin{aligned} Ay + y &= 0 && \text{in } \Omega,\\ \partial_{n_A} y - \bar b_y\ y &= \bar b_u\ u && \text{in } \Gamma. \end{aligned} \tag{5.8}$$

Again, (5.8) implies $y|_\Gamma = S'(\bar u)u$.

(SSCBOX): There exist positive numbers δ, δ_1, δ_2, δ_3 such that the definiteness condition

$$L''_{(u,y)}(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2)[h_y,h_u]^2 \geq \delta\|h_u\|^2_{L^2(\Gamma)} \tag{5.9}$$

holds true for all (h_y,h_u) belonging to the critical subspace defined upon δ_1, δ_2, δ_3.

THEOREM 5.3 (second-order sufficiency for box constraints and mixed constraints). *Assume that* $(\bar y,\bar u,\bar p,\bar\mu_1,\bar\mu_2,\bar\mu_3)$ *fulfills the first-order optimality system (FONBOX) and the regularity condition (R) is satisfied. If the second-order condition (SSCBOX) is satisfied, then there exist* $\delta_s>0$ *and* $\varepsilon>0$ *such that the quadratic growth condition*

$$F(y,u)-F(\bar y,\bar u)\geq\delta_s\|u-\bar u\|^2_{L^2(\Gamma)} \tag{5.10}$$

holds for all admissible pairs (y,u) *with* $\|u-\bar u\|_{L^\infty(\Gamma)}<\varepsilon$. *Therefore,* $\bar u$ *is a locally optimal control in the norm of* $L^\infty(\Gamma)$.

This result can be shown along the lines of the sections 3 and 4—with minor modifications. For the upper control constraint, we find another estimate of the type (3.21). In section 4, A_1 has to be replaced by $A_1\cup A_3$ and δ_1 by $\min(\delta_1,\delta_3)$.

SECOND-ORDER SUFFICIENT CONDITIONS FOR ERROR BOUNDS IN BANACH SPACES*

YIRAN HE† AND JIE SUN‡

Abstract. Recently, Huang and Ng presented second-order sufficient conditions for error bounds of continuous and Gâteaux differentiable functions in Banach spaces. Wu and Ye dropped the assumption of Huang and Ng on Gâteaux differentiability but required the space to be a Hilbert space. We carry on this research in two directions. First we extend Wu and Ye's result to some non-Hilbert spaces; second, same as Huang and Ng, we work on Banach spaces but provide different second-order sufficient conditions that may allow the function to be non-Gâteaux differentiable.

Key words. error bound, Hölder smooth subdifferential, proximal subdifferential, nonsmooth analysis

1. Introduction. We consider error bounds for lower semicontinuous functions in Banach spaces. Let f be a proper lower semicontinuous function on a Banach space X. Our goal is to study conditions that guarantee the existence of positive constants γ and m such that

$$\operatorname{dist}^m(x, S) \le \gamma f(x)_+ \quad \text{for all } x \in X, \tag{1.1}$$

where $S := f^{-1}(-\infty, 0]$ and $f(x)_+ := \max\{f(x), 0\}$. We call (1.1) an error bound of order m. If (1.1) holds for $m = 1$, then the error bound is of Lipschitz type, which has been much discussed in the literature; see [7, 10, 11, 12, 13, 14, 15] and the book [5]. If the function f is convex, then there exist many equivalent characterizations for error bounds in terms of the first-order directional derivative or first-order subdifferential of function f. However, if the function is not convex, one usually gives only sufficient conditions in terms of various first-order generalized subdifferentials or first-order generalized directional derivatives [7, 8, 12, 14].

The first-order conditions used in the nonconvex case require that the generalized subdifferentials of f for all $x \notin S$ are bounded away from zero. Specifically, let ∂ be a certain generalized subdifferential of f and let

$$P(\alpha) := \{x \in X : x \notin S, \partial f(x) \cap B(0, \alpha) \neq \emptyset\},$$

where $B(x, \alpha)$ denotes a closed ball centered at x with radius α. In order to establish error bounds for nonconvex functions, it is usually assumed that $P(\alpha)$ is empty for some $\alpha > 0$; in other words, there exists a positive scalar α such that $\|\xi\| \ge \alpha$ for

all $\xi \in \partial f(X \setminus S)$. This assumption is quite restrictive. One naturally asks whether there are certain conditions for error bound to hold, provided that

$$P(\alpha) \neq \emptyset \quad \text{for every } \alpha > 0. \tag{1.2}$$

If f is sufficiently smooth such that $\partial f(x)$ is a singleton and equals the derivative $f'(x)$ of f for every $x \notin S$, then (1.2) is equivalent to the existence of a sequence $\{x_n\}$ in $X \setminus S$ satisfying that $\lim_{n\to\infty} f'(x_n) = 0$.

Recently, some researchers have considered second-order sufficient conditions for error bounds of lower semicontinuous functions. Huang and Ng [7] proved that if f is Gâteaux differentiable and continuous in a Banach space, then an error bound of Lipschitz type holds under an assumption on certain second-order directional derivatives. Wu and Ye [15] removed this assumption and established a similar result. However, their result requires the space to be a Hilbert space. In this paper we present results that extend Wu and Ye's result to non-Hilbert spaces and results that extend Huang and Ng's work to possibly non-Gâteaux differentiable functions in Banach spaces.

2. Smoothness and subdifferentials. Let X be a Banach space. $B(x, r)$ and $B_r(x)$ denote the closed and the open ball centered at x with radius $r > 0$, respectively.

DEFINITION 2.1 (see [9]). *The modulus of smoothness $\rho_X(\tau)$, $\tau > 0$, of X is defined as*

$$\rho_X(\tau) := \sup\{(\|x + y\| + \|x - y\|)/2 - 1 : x, y \in X, \|x\| = 1, \|y\| = \tau\}.$$

X is said to be uniformly smooth if $\lim_{\tau\to 0+} \rho_X(\tau)/\tau = 0$. A uniformly smooth Banach space is said to have modulus of smoothness of power p *if for some $s > 0$,*

$$\rho_X(\tau) \leq s\tau^p \quad \textit{for all } \tau \geq 0. \tag{2.1}$$

Consider the example of $X = L_p$ $(p > 1)$. For $\tau \geq 0$,

$$\rho_{L_p}(\tau) \leq \begin{cases} \tau^p/p, & p \in (1, 2), \\ (p-1)\tau^2/2, & p \in [2, \infty). \end{cases}$$

Thus, L_p is uniformly smooth for $p > 1$ and has modulus of smoothness of power p for $p \in (1, 2)$ and of power 2 for $p \geq 2$. Let

$$J_p(x) := \{\xi \in X^* : \langle \xi, x\rangle = \|\xi\| \|x\|, \|\xi\| = \|x\|^{p-1}\}.$$

It is known that every uniformly smooth Banach space is reflexive, and if X is a reflexive Banach space, then $J_p(x)$ is the subdifferential of the convex function $x \mapsto \|x\|^p / p$. That is, $\xi \in J_p(x)$ if and only if

$$\|y\|^p / p - \|x\|^p / p \geq \langle \xi, y - x\rangle \quad \text{for all } y \in X.$$

In general, $J_p(x)$ is not necessarily a singleton; however, X is uniformly smooth if and only if $J_p(x)$ is single valued and uniformly continuous on bounded sets [4].

LEMMA 2.2. *Let X be a uniformly smooth Banach space, $x, y \in X$, and $m > 1$. Then*

$$\|y\|^m - \|x\|^m \geq m \langle J_m(x), y - x\rangle .$$

Proof. This is obvious from the definition of subdifferential inequality of convex functions. □

LEMMA 2.3. *Let X be a uniformly smooth Banach space and $x, y \in X$. If X has modulus of smoothness of power m for some $m > 1$, then there exists a constant $L > 0$ such that*

$$\langle J_m(x) - J_m(y), x - y\rangle \le L \|x - y\|^m \quad \text{for all } x, y \in X. \tag{2.2}$$

Proof. See Theorem 2 and Remarks 4 and 5 in [16]. □

Let $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function with

$$\operatorname{dom} f := \{x \in X : f(x) < \infty\} \neq \emptyset.$$

Let us recall several well-known subdifferentials. Let $x \in \operatorname{dom} f$.

- The *Hölder-smooth subdifferential* of order $p > 1$ of f at x is defined as (see [2])

$$\partial_p^{HS} f(x) := \left\{\xi \in X^* : \liminf_{\|v\|\to 0} \frac{f(x+v) - f(x) - \langle \xi, v\rangle}{\|v\|^p} > -\infty\right\}.$$

  When $p = 2$, $\partial_p^{HS} f(x)$ is just the *Lipschitz-smooth subdifferential* $\partial^{LS} f(x)$ of f at x [1]:

$$\partial^{LS} f(x) := \left\{\xi \in X^* : \liminf_{\|v\|\to 0} \frac{f(x+v) - f(x) - \langle \xi, v\rangle}{\|v\|^2} > -\infty\right\}. \tag{2.3}$$

  When X is a Hilbert space and $p = 2$, $\partial_p^{HS} f(x)$ coincides with the proximal subdifferential $\partial^P f(x)$ [3]. Note that $\xi \in \partial^P f(x)$ if and only if there exist $\eta > 0$ and $\sigma > 0$ such that

$$f(x+v) - f(x) \ge \langle \xi, v\rangle - \sigma \|v\|^2 \quad \text{for all } v \in B(0, \eta).$$

- The *Fréchet subdifferential* of f at x is the set

$$\partial^F f(x) := \left\{\xi \in X^* : \liminf_{\|v\|\to 0} \frac{f(x+v) - f(x) - \langle \xi, v\rangle}{\|v\|} \ge 0\right\}.$$

- The *Clarke–Rockafellar subdifferential* of f at x is the set

$$\partial^{CR} f(x) := \left\{\xi \in X^* : \langle \xi, v\rangle \le \sup_{\varepsilon>0} \limsup_{y \to^f x\, t\downarrow 0} \inf_{u \in B_\varepsilon(v)} \frac{f(y+tu) - f(y)}{t},\ \forall v \in X\right\},$$

  where $y \to^f x$ means $y \to x$ and $f(y) \to f(x)$; when f is locally Lipschitz at x, the Clarke–Rockafellar subdifferential coincides with the *Clarke subdifferential*

$$\partial^C f(x) := \left\{\xi \in X^* : \langle \xi, v\rangle \le \limsup_{(y,t)\to(x,0^+)} \frac{f(y+tv) - f(y)}{t}, \forall v \in X\right\}.$$

- The *Hadamard subdifferential* of f at x is the set

$$\partial^H f(x) := \left\{\xi \in X^* : \langle \xi, v\rangle \le \liminf_{(u,t)\to(v,0^+)} \frac{f(x+tu) - f(x)}{t}, \forall v \in X\right\}.$$

  When f is locally Lipschitz at x, the Hadamard subdifferential coincides with the *Gâteaux subdifferential*

$$\partial^G f(x) := \left\{\xi \in X^* : \langle \xi, v\rangle \le \liminf_{t\to 0^+} \frac{f(x+tv) - f(x)}{t}, \forall v \in X\right\}.$$

It is straightforward to verify that for $p > 1$,

$$\partial_p^{HS} f(x) \subset \partial^F f(x) \subset \partial^H f(x) \subset \partial^{CR} f(x). \tag{2.4}$$

PROPOSITION 2.4. *Let g be a continuous function on a Banach space X. Suppose that $\partial_p^{HS} g(x)$ and $\partial_p^{HS}(-g)(x)$ are both nonempty. Then $\partial_p^{HS} g(x)$ is equal to $-\partial_p^{HS}(-g)(x)$ and $\partial_p^{HS} g(x)$ is a singleton.*

Proof. Let $\xi \in \partial_p^{HS} g(x)$ and $x^* \in \partial_p^{HS}(-g)(x)$. From the definition of the Hölder-smooth subdifferential, there exist $\sigma > 0$ and $\eta > 0$ such that for all $v \in B(0, \eta)$,

$$\begin{aligned} g(x+v) - g(x) &\geq \langle \xi, v \rangle - (\sigma/2) \|v\|^p, \\ -g(x+v) + g(x) &\geq \langle x^*, v \rangle - (\sigma/2) \|v\|^p. \end{aligned}$$

Adding these two expressions together, we have

$$\langle \xi + x^*, v \rangle \leq \sigma \|v\|^p \quad \text{for all } v \in B(0, \eta),$$

which implies that $\xi + x^* = 0$ as $p > 1$. Since $\xi \in \partial_p^{HS} g(x)$ and $x^* \in \partial_p^{HS}(-g)(x)$ are arbitrary, $\partial_p^{HS} g(x)$ is equal to $-\partial_p^{HS}(-g)(x)$ and is a singleton. ∎

PROPOSITION 2.5. *The subdifferential ∂_p^{HS} has the following properties:*

(P1) *$\partial_p^{HS} f(x)$ coincides with the subdifferential in the sense of convex analysis whenever f is convex;*

(P2) *$0 \in \partial_p^{HS} f(x)$ whenever $x \in \operatorname{dom} f$ is a local minimum of f;*

(P3) *$\partial_p^{HS}(f+g)(x) \subset \partial_p^{HS} f(x) + \partial_p^{HS} g(x)$ whenever g is a continuous function with the property that $\partial_p^{HS} g(x)$ and $\partial_p^{HS}(-g)(x)$ are both nonempty.*

Proof. (P1) Let g be a convex function and $x \in \operatorname{dom} g$. Just observe that for a convex function the Clarke–Rockafellar subdifferential and the usual (Fenchel) subdifferential in convex analysis coincide for lower semicontinuous functions and that the Fenchel subdifferential is obviously contained in $\partial_p^{HS} g(x)$. The conclusion follows immediately from (2.4).

(P2) It is obvious from the definition of ∂_p^{HS}.

(P3) Note that

$$\partial_p^{HS} f(x) = \partial_p^{HS}(f+g-g)(x) \supset \partial_p^{HS}(f+g)(x) + \partial_p^{HS}(-g)(x), \tag{2.5}$$

where the inclusion relation is from the definition of the Hölder-smooth subdifferential. Since g is continuous and $\partial_p^{HS} g(x)$ and $\partial_p^{HS}(-g)(x)$ are both nonempty, by virtue of Proposition 2.4, $\partial_p^{HS}(-g)(x)$ is a singleton and $\partial_p^{HS}(-g)(x) = -\partial_p^{HS} g(x)$. This together with (2.5) yield the conclusion. ∎

PROPOSITION 2.6. *If X is a uniformly smooth Banach space which has modulus of smoothness of power p for some $p > 1$ and $x \neq 0$, then the Hölder-smooth subdifferential of order p of the functions $\|x\|^p / p$ and $-\|x\|^p / p$ are nonempty and $\partial_p^{HS}(-\|\cdot\|^p / p)(x) = -J_p(x)$.*

Proof. Since X is uniformly smooth, the function $\|\cdot\|$ and hence the convex function $\|\cdot\|^p / p$ are Fréchet differentiable at x. Therefore $\partial_p^{HS}(\|\cdot\|)(x)$ is nonempty by Proposition 2.5. Now we prove that $\partial_p^{HS}(-\|\cdot\|^p / p)(x)$ is nonempty. Since $J_p(x)$ is the subdifferential of $\|x\|^p / p$ in the sense of convex analysis, for $v \neq 0$,

$$\frac{-\|x+v\|^p / p + \|x\|^p / p - \langle -J_p(x), v \rangle}{\|v\|^p} \geq \frac{\langle J_p(x) - J_p(x+v), v \rangle}{\|v\|^p} \geq -L,$$

where the last inequality follows from Lemma 2.3 and L is the constant that appeared in Lemma 2.3. This proves that $-J_p(x)$ belongs to $\partial_p^{HS}(-\|\cdot\|^p / p)(x)$ by the definition of the Hölder-smooth subdifferential. ∎

3. Error bounds in smooth Banach spaces. The following result generalizes the second-order sufficient condition for error bounds established in [15] from the Hilbert space to smooth Banach spaces.

THEOREM 3.1. *Let X be a uniformly smooth Banach space which has modulus of smoothness of power m for some $m > 1$, and let $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function. Suppose that there exists $\delta > 0$ such that for all $x \in f^{-1}(0, \infty)$,*

$$\liminf_{\|u\| \to 1, t \downarrow 0} \frac{f(x+tu) - f(x) - t\langle \xi, u\rangle}{t^m} < -\delta \quad \text{for each } \xi \in \partial_m^{HS} f(x). \tag{3.1}$$

Then

$$\operatorname{dist}^m(x, S) \le (mL/\delta)\, f(x)_+ \quad \text{for all } x \in X, \tag{3.2}$$

where L is the constant that appeared in (2.2).

Proof. Write γ for mL/δ. Suppose that the conclusion does not hold: there exists some u with $f(u) > 0$ such that

$$\operatorname{dist}^m(u, S) > \gamma\, f(u).$$

Then we can find $t > 1$ such that $\operatorname{dist}^m(u, S) > t\gamma\, f(u)$, and hence

$$f(u) = f(u)_+ < \inf_{x \in X} f(x)_+ + \gamma^{-1} c, \tag{3.3}$$

where $c := t\gamma\, f(u)$. Applying the Borwein–Preiss smooth variational principle [2], we obtain the existence of some $v \in X$ such that

$$\|u - v\| < \sqrt[m]{c} \quad \text{and} \tag{3.4}$$

$$f(v)_+ + \gamma^{-1}\Delta_m(v) \le f(x)_+ + \gamma^{-1}\Delta_m(x) \quad \text{for all } x \in X, \tag{3.5}$$

where $\Delta_m(x) := \sum_{k=1}^{\infty} \mu_k \|x - v_k\|^m$ for some sequence $\{v_k\}$ converging to v and some sequence $\{\mu_k\}$ satisfying $\mu_k > 0$ and $\sum_{k=1}^{\infty} \mu_k = 1$.

It follows from (3.4) and the choice of u that $v \notin S$. Hence v is a global minimizer of the function $f(x) + \gamma^{-1}\Delta_m(x)$ and hence a global minimizer of the function $\gamma m^{-1} f(x) + m^{-1}\Delta_m(x)$ over the open set $X \setminus S$. In view of the definition of Hölder-smooth subdifferential ∂_m^{HS}, it follows that

$$0 \in \partial_m^{HS}(\gamma m^{-1} f + m^{-1}\Delta_m)(v). \tag{3.6}$$

Clearly $m^{-1}\Delta_m(x)$ is a real valued continuous convex function. Hence $\partial_m^{HS}(m^{-1}\Delta_m)(v)$ coincides with the subdifferential in the sense of convex analysis by Proposition 2.5 and so is nonempty. Since the space X is uniformly smooth, it follows that for every x, $J_m(x - v_k)$ is a singleton for each k and the sequence $\{J_m(x - v_k)\}_{k=1}^{\infty}$ is bounded. Thus, $m^{-1}\Delta_m(x)$ is Fréchet differentiable with its Fréchet derivative $(m^{-1}\Delta_m)'(x) = \sum_{k=1}^{\infty} \mu_k J_m(x - v_k)$. Since $\partial_m^{HS}(m^{-1}\Delta_m)(v)$ is nonempty, it follows that

$$\partial_m^{HS}(m^{-1}\Delta_m)(v) = \left\{(m^{-1}\Delta_m)'(v)\right\}. \tag{3.7}$$

We claim that $\partial_m^{HS}(-m^{-1}\Delta_m)(v)$ contains $-(m^{-1}\Delta_m)'(v)$ and hence is nonempty. This together with (3.6), Propositions 2.4 and 2.5, and (3.7) yields that

$$\xi := -m\gamma^{-1} \sum_{k=1}^{\infty} \mu_k J_m(v - v_k) \in \partial_m^{HS} f(v). \tag{3.8}$$

Indeed,

$$\begin{aligned}
&\liminf_{h\to 0} \frac{(-m^{-1}\Delta_m)(v+h)-(-m^{-1}\Delta_m)(v)-\left\langle(-m^{-1}\Delta_m)'(v),h\right\rangle}{\|h\|^m}\\
&=\liminf_{h\to 0} \frac{\left\langle(-m^{-1}\Delta_m)'(v+\theta(h)h),h\right\rangle-\left\langle(-m^{-1}\Delta_m)'(v),h\right\rangle}{\|h\|^m} \quad (0<\theta(h)<1)\\
&=\liminf_{h\to 0} \frac{\sum_{k=1}^{\infty}\mu_k\left\langle J_m(v-v_k)-J_m(v+\theta(h)h-v_k),h\right\rangle}{\|h\|^m}\\
&\geq \liminf_{h\to 0} -L\theta(h)^{m-1}\geq -L>-\infty,
\end{aligned}$$

where the first equality is from the mean value theorem and the first inequality follows from Lemma 2.3 and the facts of $\mu_k>0$ and $\sum_{k=1}^{\infty}\mu_k=1$. In view of the definition of Hölder-smooth subdifferential ∂_m^{HS}, it follows that $-(m^{-1}\Delta_m)'(v)\in\partial_m^{HS}(-m^{-1}\Delta_m)(v)$.

By (3.8) and the assumption (3.1), there exist sequences $t_n\to 0+$ and $\|u_n\|\to 1$ such that

$$\lim_{n\to\infty}\frac{f(v+t_nu_n)-f(v)-t_n\left\langle\xi,u_n\right\rangle}{t_n^m}<-\delta=-mL\gamma^{-1}. \tag{3.9}$$

Since $X\setminus S$ is an open set as f is lower semicontinuous, we have $f(v+t_nu_n)>0$ for sufficiently large n. It follows from (3.5) that

$$\begin{aligned}
&\frac{f(v+t_nu_n)-f(v)-t_n\left\langle\xi,u_n\right\rangle}{t_n^m}\\
&=\frac{f(v+t_nu_n)-f(v)+m\gamma^{-1}t_n\sum_{k=1}^{\infty}\mu_k\left\langle J_m(v-v_k),u_n\right\rangle}{t_n^m}\\
&\geq\frac{\sum_{k=1}^{\infty}\mu_k\left\{\|v-v_k\|^m-\|v+t_nu_n-v_k\|^m\right\}+m\sum_{k=1}^{\infty}\mu_k\left\langle J_m(v-v_k),t_nu_n\right\rangle}{\gamma t_n^m}\\
&\geq m\gamma^{-1}t_n^{-m}\sum_{k=1}^{\infty}\mu_k\left\langle J_m(v-v_k)-J_m(v+t_nu_n-v_k),t_nu_n\right\rangle\\
&\geq -mL\gamma^{-1}\|u_n\|^m\to -mL\gamma^{-1}=-\delta\ (\text{ as } n\to\infty),
\end{aligned}$$

where the second inequality follows from Lemma 2.2 and the third inequality follows from Lemma 2.3. This contradicts (3.9). ∎

In view of the assumption (3.1), it is straightforward to see that if the $\partial_p^{HS}f(x)$ is replaced by a larger set such as $\partial^F f(x)$, $\partial^H f(x)$, or $\partial^{CR}f(x)$ (see (2.4)), then the condition becomes more stringent. In other words, our requirement on the subdifferential is fairly weak.

COROLLARY 3.2. *Let X be a uniformly smooth Banach space which has modulus of smoothness of power 2, and let $f:X\to\mathbb{R}\cup\{\infty\}$ be a proper lower semicontinuous function. If there exists $\delta>0$ such that for all $x\in f^{-1}(0,\infty)$ and all $\xi\in\partial^{LS}f(x)$,*

$$\liminf_{\|u\|\to 1,t\downarrow 0}\frac{f(x+tu)-f(x)-t\left\langle\xi,u\right\rangle}{t^2}<-\delta,$$

then

$$\operatorname{dist}^2(x,S)\leq(2L/\delta)\,f(x)_+\quad \textit{for all } x\in X.$$

Proof. Since $p = 2$, the Hölder subdifferential ∂_p^{HS} coincides with the Lipschitz-smooth subdifferential ∂^{LS}. The conclusion thus follows immediately from Theorem 3.1. ∎

Remark 3.1. Since all Hilbert spaces are uniformly smooth with modulus of smoothness of power 2 (see [9]) and since when X is a Hilbert space $\partial^{LS} f(x)$ coincides with the proximal subdifferential $\partial^P f(x)$, Corollary 3.2 generalizes Theorem 3.1 in [15] for its $\varepsilon = \infty$. Moreover, there exist Banach spaces, say $L^p(\mu)$ for $p \geq 2$, which are uniformly smooth with modulus of smoothness of power 2 but are not Hilbert spaces [9]. Therefore Corollary 3.2 is applicable to a broader class of spaces than [15, Theorem 3.1]. The same as what was done in [15], our results can also be verified for general $\varepsilon > 0$. We omit the details for brevity.

From the argument of Theorem 3.1, it can be seen that one can replace the Hölder smooth subdifferential ∂_m^{HS} of f by some other classes of subdifferentials. Let us define an abstract subdifferential in the following.

DEFINITION 3.3 (see [1]). *An abstract subdifferential, denoted by ∂, is any operator that associates a subset $\partial f(x) \subset X^*$ to a lower semicontinuous function $f : X \to \mathbb{R} \cup \{\infty\}$ and a point $x \in X$, satisfying the following properties:*

(P1) *$\partial f(x)$ coincides with the subdifferential in the sense of convex analysis whenever f is convex;*

(P2) *$0 \in \partial f(x)$ whenever $x \in \operatorname{dom} f$ is a local minimum of f;*

(P3) *$\partial(f + g)(x) \subset \partial f(x) + \partial g(x)$ whenever g is a real valued convex continuous function which satisfies $\partial g(x)$ and $\partial(-g)(x)$ are both nonempty.*

Paper [1] provides various classes of subdifferentials satisfying the above properties (P1)–(P3)—for example, the Hadamard subdifferential, the Gâteaux subdifferential, the Fréchet subdifferential, and the Clarke–Rockafellar subdifferential.

For $p > 1$, we denote by Γ_p all the functions of the form

$$\Gamma(x) := \frac{1}{p} \sum_{k=1}^{\infty} \mu_k \|x - u_k\|^p \quad \text{for all } x \in X, \tag{3.10}$$

where $\{u_k\}$ is any convergent sequence in X and $\{\mu_k\}$ is any sequence of nonnegative scalars satisfying $\sum_{k=1}^{\infty} \mu_k = 1$. Clearly, each function in Γ_p is a real valued continuous convex function.

THEOREM 3.4. *Let X be a uniformly smooth Banach space which has modulus of smoothness of power $m > 1$ and let $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function. Let ∂ be an abstract subdifferential satisfying properties* (P1)–(P3) *in Definition* 3.3 *and an additional property:*

(P4) *$\partial(-\Gamma)(x)$ is nonempty for each $\Gamma \in \Gamma_m$.*

If there exists $\delta > 0$ such that for all $x \in f^{-1}(0, \infty)$ and all $\xi \in \partial f(x)$,

$$\liminf_{\|u\| \to 1, t \downarrow 0} \frac{f(x + tu) - f(x) - t \langle \xi, u \rangle}{t^m} < -\delta,$$

then

$$\operatorname{dist}^m(x, S) \leq (mL/\delta)\, f(x)_+ \quad \text{for all } x \in X.$$

Proof. After checking the proof of Theorem 3.1, we know the key role played by the subdifferential is the part from (3.6) to (3.8). Since each $\Gamma(x)$ is a continuous real valued convex function, $\partial\Gamma(x)$ is nonempty. In view of the property (P4) and (P3),

one can establish (3.8) in a similar way. The remaining proof is similar to the proof of Theorem 3.1. □

The above theorems establish m-order error bounds for lower semicontinuous functions in certain classes of Banach spaces. As a corollary of Theorem 3.1, we give an error bound of order one whose proof is similar to that of Theorem 3.3 in [15]. Recall that S is the set $f^{-1}(-\infty, 0]$, and define

$$P(\alpha) := \{x \in X \setminus S : \partial_m^{HS} f(x) \cap B(0, \alpha) \neq \emptyset\} \quad \text{for } \alpha > 0. \tag{3.11}$$

THEOREM 3.5. *Let X be a uniformly smooth Banach space which has modulus of smoothness of power m for some $m > 1$ and let $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function. Suppose that the following two conditions hold.*

(i) *$P(\alpha) \subset f^{-1}(\beta, \infty)$ for some $\alpha > 0$ and some $\beta > 0$.*

(ii) *There exists $\delta > 0$ such that for all $x \in f^{-1}(\beta, \infty)$ and all $\xi \in \partial_m^{HS} f(x)$,*

$$\liminf_{\|u\| \to 1, t \downarrow 0} \frac{f(x + tu) - f(x) - t \langle \xi, u \rangle}{t^m} < -\delta.$$

Then there exists $c > 0$ such that

$$\operatorname{dist}(x, S) \leq c\, f(x)_+ \quad \text{for all } x \in X.$$

4. Error bounds in general Banach spaces. In the last section, we have established second-order sufficient conditions for error bounds of lower semicontinuous functions in smooth Banach spaces. In what follows we will provide different second-order sufficient conditions for error bounds in general Banach spaces. The result of this section generalizes that in [7], which gives second-order sufficient conditions for error bounds in general Banach spaces but requires the function to be Gâteaux differentiable. Our results show that the assumption of Gâteaux differentiability can be removed. Before that, we need to define second-order directional derivative. Let X be a Banach space and $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function. For $x, u, v \in X$, we define respectively Hadamard directional derivative and a second-order directional derivative:

$$f'_-(x; u) := \liminf_{v \to u,\, t \downarrow 0} \frac{f(x + tv) - f(x)}{t};$$

$$d^2_- f(x; u, v) := \liminf_{t \to 0+} \frac{f(x + tu + t^2 v) - f(x) - t f'(x) u}{t^2}$$

whenever f is Gâteaux differentiable.

It can be seen that if f is Gâteaux differentiable at x with $f'(x)$ being the Gâteaux derivative, then $f'_-(x; u) \leq f'(x)u$ for every u; the equality holds if in addition f is locally Lipschitz at x. If f is twice continuously differentiable, then

$$d^2_- f(x; u, 0) = (1/2)\nabla^2 f(x)(u, u),$$

where $\nabla^2 f(x)$ denotes the second-order derivative of f at x.

For $\varepsilon > 0$, we define a set

$$D(\varepsilon) := \left\{x \in X : x \notin S \text{ and } \inf_{\|u\|=1} f'_-(x; u) \geq -\varepsilon\right\}.$$

If f is Gâteaux differentiable on X, then

$$D(\varepsilon) \subset \{x \in X : x \notin S \text{ and } \|f'(x)\| \leq \varepsilon\} =: \mathfrak{D}(\varepsilon),$$

where the set $\mathfrak{D}(\varepsilon)$ is introduced and used in [7] for studying second-order sufficient conditions for continuous and Gâteaux differentiable functions to have error bounds.

The following lemma [12, Lemma 2.3] is a straightforward consequence of Theorem 2(ii) in [6].

LEMMA 4.1. *Let X be a Banach space and $f : X \to \mathbb{R} \cup \{\infty\}$ be a proper lower semicontinuous function. If there exists $\gamma > 0$ such that for every $x \in f^{-1}(0, \infty)$ there is $y \in f^{-1}[0, \infty)$ such that*

$$f(x) - f(y) \geq \gamma \|x - y\| > 0,$$

then $\operatorname{dist}(x, S) \leq \gamma^{-1} f(x)_+$ *for all* $x \in X$.

THEOREM 4.2. *Let $f : X \to \mathbb{R}$ be a continuous function. Suppose that there exist positive scalars r, ρ, and δ such that the following conditions hold:*

(i) $D(\rho) \subset f^{-1}(r, \infty)$;

(ii) $\limsup_{t \to 0+} \sup_{x \in D(\rho)} \inf_{\|u\|=1} \frac{f(x+tu) - f(x) + t f'_-(x; -u)}{t^2} < -\delta$.

Then there exists $\gamma > 0$ such that $\operatorname{dist}(x, S) \leq \gamma^{-1} f(x)_+$ *for all* $x \in X$.

Proof. We need to consider only those points x not in S. In view of the assumption (ii), there exists $\beta \in (0, 1/2]$ such that for every $t \in (0, \beta)$ and every $x \in D(\rho)$, a unit vector u (dependent on t and x) exists and satisfies that

$$\frac{f(x + tu) - f(x) + t f'_-(x; -u)}{t^2} < -\delta. \tag{4.1}$$

Take $\varepsilon = \min\{\rho, \beta\delta/4\}$ and $\gamma = \min\{r, \varepsilon/2\}$.

Let $x \in D(\varepsilon)$ be such that $\operatorname{dist}(x, S) \geq 1$. Put $\lambda = \beta/2$. It follows that $x + \lambda u \notin S$ for any unit vector u. Since $\varepsilon \leq \rho$, $x \in D(\varepsilon) \subset D(\rho)$, it follows from (4.1) that there exists a unit vector u_λ such that

$$f(x + \lambda u_\lambda) - f(x) + \lambda f'_-(x; -u_\lambda) < -\lambda^2 \delta.$$

In view of the definition of $D(\varepsilon)$, $x \in D(\varepsilon)$ implies that $f'_-(x; -u_\lambda) \geq -\varepsilon$. Therefore,

$$f(x) - f(x + \lambda u_\lambda) \geq \lambda^2 \delta - \lambda\varepsilon \geq \gamma\lambda = \gamma \|x - (x + \lambda u_\lambda)\|.$$

For $x \in D(\varepsilon)$ and $\operatorname{dist}(x, S) < 1$, there exists $y \in S$ such that $\|x - y\| < 1$. Since f is continuous, y can be chosen to satisfy $f(y) = 0$. Since $x \in D(\varepsilon)$ and $D(\varepsilon) \subset f^{-1}(r, \infty)$, one has $f(x) > r$. It follows that

$$f(x) - f(y) \geq r > r \|x - y\| \geq \gamma \|x - y\| > 0.$$

For $x \notin D(\varepsilon)$, we have $f'_-(x; u) < -\varepsilon$ for some unit vector u. It follows that there exist a sequence of positive scalars $\{t_n\}$ converging to zero and a sequence $\{u_n\}$ converging to u such that for sufficiently large n,

$$f(x + t_n u_n) - f(x) < -\varepsilon t_n.$$

Since $\gamma < \varepsilon$ and $\|u_n\| \to 1$, $\gamma \|u_n\| < \varepsilon$ for large enough n. This implies that

$$f(x) - f(x + t_n u_n) > \varepsilon t_n \geq \gamma t_n \|u_n\| = \gamma \|x - (x + t_n u_n)\|$$

for sufficiently large n.

Thus, we have shown that for each $x \notin S$, there exists $y \in f^{-1}[0,\infty)$ such that $f(x) - f(y) \geq \gamma \|x - y\|$. Then, by applying Lemma 4.1, we obtain the desired conclusion. □

Huang and Ng [7] considered error bounds in general Banach spaces for a function which is Gâteaux differentiable and continuous. Besides the assumption (i) of Theorem 4.2, [7] requires another condition: There exist $\beta > 0$ and $\delta > 0$ such that for all $x \in \mathfrak{D}(\rho)$,

$$\inf_{\|u\|=1} \sup_{t\in[0,\beta)} d^2_- f(x + tu; u, 0) < -\delta. \tag{4.2}$$

Because f is Gâteaux differentiable and continuous, $f'_-(x; -u) \leq -f'(x)u$. It follows from [7, Theorem 3.1] that the condition (4.2) implies the existence of $\beta > 0$ and $\delta > 0$ such that for all $x \in \mathfrak{D}(\rho)$,

$$\inf_{\|u\|=1} \sup_{t\in(0,\beta)} \frac{f(x + tu) - f(x) + tf'_-(x; -u)}{t^2} < -\delta. \tag{4.3}$$

Note that our assumption (ii) in Theorem 4.2 is that there exist $\beta > 0$ and $\delta > 0$ such that for all $x \in D(\rho)$,

$$\sup_{t\in(0,\beta)} \inf_{\|u\|=1} \frac{f(x + tu) - f(x) + tf'_-(x; -u)}{t^2} < -\delta. \tag{4.4}$$

Since $D(\rho) \subset \mathfrak{D}(\rho)$, it is straightforward that (4.3) and hence (4.2) imply (4.4). The latter is a restatement of our assumption (ii), which is therefore less restrictive than the assumption (4.2) as our assumption (ii) also allows f to be non-Gâteaux differentiable.

ALL LINEAR AND INTEGER PROGRAMS ARE SLIM 3-WAY TRANSPORTATION PROGRAMS*

JESÚS A. DE LOERA† AND SHMUEL ONN‡

Abstract. We show that any rational convex polytope is polynomial-time representable as a 3-way line-sum transportation polytope of "slim" $(r, c, 3)$ format. This universality theorem has important consequences for linear and integer programming and for confidential statistical data disclosure. We provide a polynomial-time embedding of arbitrary linear programs and integer programs in such slim transportation programs and in bitransportation programs. Our construction resolves several standing problems on 3-way transportation polytopes. For example, it demonstrates that, unlike the case of 2-way contingency tables, the range of values an entry can attain in any slim 3-way contingency table with specified 2-margins can contain arbitrary gaps. Our smallest such example has format $(6, 4, 3)$. Our construction provides a powerful automatic tool for studying concrete questions about transportation polytopes and contingency tables. For example, it automatically provides new proofs for some classical results, including a well-known "real-feasible but integer-infeasible" $(6, 4, 3)$-transportation polytope of M. Vlach, and bitransportation programs where any feasible bitransportation must have an arbitrarily large prescribed denominator.

Key words. integer programming, linear programming, combinatorial optimization, convex polytopes, transportation problems, multicommodity flows, strongly polynomial time, contingency tables, multiway table, statistical table, data security, privacy, approximation algorithms, Markov basis, toric ideal, cofinetiality, disclosure

1. Introduction.

Transportation polytopes, their integer points (called contingency tables by statisticians), and their projections have been used and studied extensively in the operations research and mathematical programming literature (see, e.g., [1, 2, 5, 17, 20, 23, 24, 29, 30] and references therein) and in the context of secure statistical data management by agencies such as the U.S. Census Bureau [28] (see, e.g., [3, 4, 9, 10, 13, 18, 22] and references therein).

We start right away with the statement of the main theorem of this article. Its proof will be the subject of section 3. Some of the many implications of the main theorem for linear and integer programming, combinatorial optimization, and confidential statistical data disclosure will be discussed in section 2. The consequences include the solution of several long-standing open questions stated by Vlach in 1986 [29]. Following a common convention we denote by $\mathbb{R}_{\geq 0}$ the nonnegative reals. In what follows, a 3-way transportation polytope is *slim* if one of its dimensions has depth three.

THEOREM 1.1. *Any rational polytope* $P = \{y \in \mathbb{R}^n_{\geq 0} : Ay = b\}$ *is polynomial-time representable as a slim* 3*-way transportation polytope:*

$$T = \left\{ x \in \mathbb{R}^{r\times c\times 3}_{\geq 0} \ : \ \sum_i x_{i,j,k} = w_{j,k}\,,\ \sum_j x_{i,j,k} = v_{i,k}\,,\ \sum_k x_{i,j,k} = u_{i,j} \right\}.$$

By saying that a polytope $P \subset \mathbb{R}^p$ is *representable* as a polytope $Q \subset \mathbb{R}^q$ we mean in the strong sense that there is an injection $\sigma : \{1,\ldots,p\} \longrightarrow \{1,\ldots,q\}$ such that the coordinate-erasing projection

$$\pi : \mathbb{R}^q \longrightarrow \mathbb{R}^p \ : \ x = (x_1,\ldots,x_q) \mapsto \pi(x) = (x_{\sigma(1)},\ldots,x_{\sigma(p)})$$

provides a bijection between Q and P and between the sets of integer points $Q\cap\mathbb{Z}^q$ and $P\cap\mathbb{Z}^p$. In particular, if P is representable as Q, then P and Q are isomorphic in any reasonable sense: They are linearly equivalent, and hence all linear programming related problems over the two are polynomial-time equivalent; they are combinatorially equivalent and hence have the same facial structure; and they are integer equivalent, and therefore all integer programming and integer counting related problems over the two are polynomial-time equivalent as well. The polytope T in the theorem is a 3-way transportation polytope with specified *line-sums* $(u_{i,j}), (v_{i,k}), (w_{j,k})$ (2*-margins* in the statistical context to be elaborated upon below). The arrays in T are of size $(r, c, 3)$; that is, they have r rows, c columns, and "slim" depth 3, which is the best possible: 3-way line-sum transportation polytopes of depth ≤ 2 are equivalent to ordinary 2-way transportation polytopes which are not universal.

An appealing feature of Theorem 1.1 is that the defining system of T has only $\{0,1\}$-valued coefficients and depends only on r and c. Thus, every rational polytope has a representation by one such system, where all information enters through the right-hand side $(u_{i,j}), (v_{i,k}), (w_{j,k})$.

We have also proved a second universality theorem about the following *bitransportation problems*: Given *supply* vectors $s^1, s^2 \in \mathbb{R}^r_{\geq 0}$, *demand* vectors $d^1, d^2 \in \mathbb{R}^c_{\geq 0}$, and *capacity* matrix $u \in \mathbb{R}^{r\times c}_{\geq 0}$, find a pair of nonnegative "transportations" $x^1, x^2 \in \mathbb{R}^{r\times c}_{\geq 0}$ satisfying supply and demand requirements $\sum_j x^k_{i,j} = s^k_i$, $\sum_i x^k_{i,j} = d^k_j$, $k = 1, 2$, and capacity constraints $x^1_{i,j} + x^2_{i,j} \leq u_{i,j}$. In other words, find $x^1, x^2 \geq 0$ such that x^k has row-sum s^k and column-sum d^k for $k = 1, 2$, and $x^1 + x^2 \leq u$.

THEOREM 1.2. *Any rational polytope* $P = \{y \in \mathbb{R}^n_{\geq 0} : Ay = b\}$ *is polynomial-time representable as a bitransportation polytope*

$$F = \left\{ (x^1, x^2) \in \mathbb{R}^{r\times c}_{\geq 0} \oplus \mathbb{R}^{r\times c}_{\geq 0} \ : \ x^1_{i,j} + x^2_{i,j} \leq u_{i,j}\,, \right.$$

$$\left. \sum_j x^k_{i,j} = s^k_i\,,\ \sum_i x^k_{i,j} = d^k_j\,,\quad k = 1,2 \right\}.$$

The proof is an easy adjustment of part of the proof of Theorem 1.1 (i.e., Theorem 3.3) and is presented in section 3.5. The theorem remains valid if we take all supplies to have the same value $s^k_i = U$, $i = 1,\ldots,r$, $k = 1, 2$; further, all capacities $u_{i,j}$ can be taken to be $\{0, U\}$-valued, giving a stronger statement.

The bitransportation problem gives at once a very simple two-commodity flow network as follows: start with the directed bipartite graph with vertex set $I \uplus J$,

$|I| = r$, $|J| = c$, and arc set $I \times J$ with capacities $u_{i,j}$, and augment it with two sources a_1, a_2 and two sinks b_1, b_2 and with arcs (a_k, i), $i \in I$, (j, b_k), $j \in J$, $k = 1, 2$ with capacities $u(a_k, i) := s_i^k$, $u(j, b_k) := d_j^k$. The feasible bitransportations are then precisely the two-commodity flows of maximal total value. This implies a result first obtained by A. Itai [19]: every linear program is polynomially equivalent to a two-commodity flow problem. It is worth noting that our transformation is in fact much simpler than Itai's. In particular, the above network is exceedingly special: every dipath has length three and is of the form (a_k, i, j, b_k) for some $k \in \{1, 2\}$, $i \in I$, and $j \in J$ and involves only one "interesting" arc ij. Further, each such arc ij carries flow of each commodity on precisely one path.

To demonstrate the concrete nature of our transformations, the procedures that convert any given data A, b to data to the representations of Theorems 1.1 and 1.2 have been implemented in a computer program which is available on-line (see [27]).

2. The consequences of the main results. We now discuss some consequences of Theorems 1.1 and 1.2. A few of them were first presented in [7].

2.1. Universality of transportation polytopes: Solution of Vlach's problems. As mentioned above, there is a large body of literature on the structure of various transportation polytopes. In particular, in the comprehensive paper [29], M. Vlach surveys some ten families of necessary conditions published over the years by several authors (including Schell, Haley, Smith, Morávek, and Vlach) on the line-sums $(u_{i,j}), (v_{i,j}), (w_{i,j})$ for a transportation polytope to be nonempty, and raises several concrete problems regarding these polytopes. Specifically, [29, Problems 4, 7, 9, 10] ask about the sufficiency of some of these conditions. Our results say that transportation polytopes (in fact already of slim, $(r, c, 3)$, arrays) are universal and include all polytopes. This indicated that the answer to each of Problems 4, 7, 9, and 10 has to be negative. Indeed we have already verified this.

Example 2.1 (Smith II conditions are not sufficient). Using our encoding, in particular, applying the algorithm of Theorem 3.2 to the infeasible polyhedron $P = \{(x, y) : x + y = 1, x + y = 2,\ x, y \geq 0\}$, with 2 as an upper bound on its entry values, we obtained concrete 2-margins (below). These 2-margins satisfy conditions (8.1)–(8.3) on page 72 of [29] while giving an infeasible system; thus the example solves open problem 7 in [29]. Note for reference that for the given matrices the top-left corners are the margin values $u_{1,1}, v_{1,1}, w_{1,1}$.

$$\begin{pmatrix} 2 & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 2 & 0 & 2 & 0 & 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 & 0 & 2 & 0 & 2 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 2 & 0 & 2 & 0 & 0 & 0 & 0 & 2 \\ 0 & 2 & 0 & 0 & 0 & 0 & 2 & 2 & 0 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 & 2 & 0 & 0 & 2 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 2 \end{pmatrix}, \quad \begin{pmatrix} 2 & 2 & 2 \\ 2 & 0 & 2 \\ 2 & 2 & 2 \\ 2 & 0 & 2 \\ 2 & 0 & 2 \\ 2 & 2 & 2 \\ 2 & 0 & 2 \\ 2 & 2 & 2 \\ 2 & 2 & 2 \\ 2 & 2 & 2 \\ 2 & 2 & 2 \end{pmatrix}, \quad \begin{pmatrix} 2 & 2 & 0 \\ 2 & 2 & 0 \\ 2 & 2 & 0 \\ 2 & 2 & 0 \\ 7 & 0 & 1 \\ 6 & 0 & 2 \\ 3 & 0 & 5 \\ 0 & 2 & 4 \\ 0 & 2 & 4 \\ 0 & 2 & 4 \\ 0 & 2 & 4 \end{pmatrix}.$$

Similarly, Problem 12 on page 76 of [29] asks whether all dimensions can occur as that of a suitable transportation polytope: the affirmative answer, given very recently in

[15], follows also at once from our universality result. Our construction also provides a powerful tool for studying concrete questions about transportation polytopes and their integer points, by allowing us to write down simple systems of equations that encode desired situations and lifting them up. Here is an example to this effect.

Example 2.2 (Vlach's rational-nonempty integer-empty transportation). Using our construction, we automatically recover the smallest known example, first discovered by Vlach [29], of a rational-nonempty integer-empty transportation polytope, as follows. We start with the polytope $P = \{y \geq 0 : 2y = 1\}$ in one variable, containing a (single) rational point but no integer point. Our construction represents it as a transportation polytope T of $(6, 4, 3)$-arrays with line-sums given by the three matrices below; by Theorem 1.1, T is integer equivalent to P and hence also contains a (single) rational point but no integer point.

$$\begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix}.$$

Returning to the Vlach problems, [29, Problem 13] asks for a characterization of those line-sums margins that guarantee an integer point in a 3-way transportation polytope T. In [18], Irving and Jerrum showed that deciding whether $T \cap \mathbb{Z}^{r \times c \times h} \neq \emptyset$ is NP-complete, and hence an efficient such characterization cannot exist unless $NP = coNP$. An immediate corollary of Theorem 1.1 strengthens this result to hold for slim arrays:

COROLLARY 2.3. *Deciding if a slim,* $(r, c, 3)$*, transportation polytope has an integer point is NP-complete.*

A comprehensive complexity classification of this decision problem under various assumptions on the array size and on the input, as well as of the related lattice point counting problem and other variants, appeared in [6].

The last Vlach problem [29, Problem 14] asks whether there is a *strongly polynomial-time* algorithm for deciding the (real) feasibility $T \neq \emptyset$ of a transportation polytope. Since the system defining T is $\{0, 1\}$-valued, the results of Tardos [26] provide an affirmative answer. However, the existence of a strongly polynomial-time algorithm for linear programming in general is open and of central importance; our construction embeds any linear program in an $(r, c, 3)$ transportation program in polynomial-time, but unfortunately this process is *not* strongly polynomial. Nonetheless, our construction may shed some light on the problem and may turn out useful in sharpening the boundary (if any) between strongly and weakly polynomial-time solvable linear programs.

2.2. Universality for approximations. The representation manifested by Theorem 1.1 allows us to represent an arbitrary integer programming problem $\min\{cy : y \in \mathbb{N}^n, Ay = b\}$ as a problem of finding minimum cost integer transportation,

$$\min \left\{ \sum_{i,j,k} p_{i,j,k} x_{i,j,k} \ : \ x \in \mathbb{N}^{r \times c \times 3}, \ \sum_i x_{i,j,k} = w_{j,k}, \right.$$

$$\left. \sum_j x_{i,j,k} = v_{i,k}, \ \sum_k x_{i,j,k} = u_{i,j} \right\},$$

by simply extending the cost vector c by zeros to a cost array p. In particular, the feasible (integer) solutions y to the original problem are in *cost-preserving* bijection with the feasible (integer) transportations x (that is, $cy = px$ for any corresponding pair). This shows that the representation preserves *approximations*, and that minimum cost transportation problems of slim format $(r, c, 3)$ are universal for approximation as well. In particular, any nonapproximability result—say, for the maximum clique problem [14]—lifts at once to the slim minimum cost transportation problem: just start with an integer programming formulation of the maximum clique problem with $\{0, 1\}$-valued right-hand-side vector b, and lift it up. We get the following hardness-of-approximation result.

COROLLARY 2.4. *Under the assumption $P \neq NP$, there is an $\epsilon > 0$ such that there is no polynomial-time $(rc)^{\epsilon}$-approximation algorithm for the minimum cost slim $(r, c, 3)$ line-sum transportation problem.*

We do not attempt here to provide the largest possible ϵ. Note, of course, that in particular, unless $P = NP$, there is no constant ratio approximation for the 3-way transportation problem (the problem is not in the class APX).

2.3. Confidential statistical data disclosure: Entry-range. Next, we briefly discuss some of the applications to statistical model theory: a comprehensive treatment can be found in [8]. A central goal of statistical data management by agencies such as the U.S. Census Bureau is to allow public access to information on their data base while protecting confidentiality of individuals whose data is in the base. A common practice [10], taken in particular by the Bureau [28], is to allow the release of some margins of tables in the base but not the individual entries themselves. The security of an entry is closely related to the range of values it can attain in any table with the fixed released collection of margins: if the range is "simple," then the entry may be exposed, whereas if it is "complex" the entry may be assumed secure.

In this subsection only, we use the following notation, which is common in statistical applications. A *d-table of size $n = (n_1, \ldots, n_d)$* is an array of nonnegative integers $x = (x_{i_1,\ldots,i_d})$, $1 \leq i_j \leq n_j$. For any $0 \leq k \leq d$ and any k-subset $J \subseteq \{1, \ldots, d\}$, the *$k$-margin* of x corresponding to J is the k-table $x^J := (x^J_{i_j : j \in J}) := (\sum_{i_j : j \notin J} x_{i_1,\ldots,i_d})$ obtained by summing the entries over all indices *not in* J. For instance, the 2-margins of a 3-table $x = (x_{i_1,i_2,i_3})$ are its *line-sums* x^{12}, x^{13}, x^{23} such as $x^{13} = (x^{13}_{i_1,i_3}) = (\sum_{i_2} x_{i_1,i_2,i_3})$, and its 1-margins are its *plane-sums* x^1, x^2, x^3 such as $x^2 = (x^2_{i_2}) = (\sum_{i_1,i_3} x_{i_1,i_2,i_3})$.

A *statistical model* is a triple $\mathcal{M} = (d, \mathcal{J}, n)$, where $\mathcal{J}$ is a set of subsets of $\{1, \ldots, d\}$ none containing the other and $n = (n_1, \ldots, n_d)$ is a tuple of positive integers. The model dictates the collection of margins for d-tables of size n to be specified. Our results concern the models $(3, \{12, 13, 23\}, (r, c, 3))$, that is, slim, $(r, c, 3)$-tables, with all three of their 2-margins specified.

For any model $\mathcal{M} = (d, \mathcal{J}, n)$ and any specified collection of margins $u = (u^J : J \in \mathcal{J})$ under the model $\mathcal{M}$, the corresponding set of *contingency tables* with collection of margins u is

$$C(\mathcal{M}; u) := \{\, x \in \mathbb{N}^{n_1 \times \cdots \times n_d} \;:\; x^J = u^J \,,\; J \in \mathcal{J} \,\} \,.$$

Clearly, this set is precisely the set of integer points in the corresponding transportation polyhedron.

Finally, we define entry-ranges. Permuting coordinates, we may always consider the first entry $x_{\mathbf{1}}$, where $\mathbf{1} := (1, \ldots, 1)$. The *entry-range* of a collection of margins

u under a model $\mathcal{M}$ is the set $R(\mathcal{M};u) := \{x_{\mathbf{1}} : x \in C(\mathcal{M};u)\} \subset \mathbb{N}$ of values $x_{\mathbf{1}}$ can attain in any table with these margins.

Often, the entry-range is an interval and hence "simple" and vulnerable, that is, for some $a, b \in \mathbb{N}$, $R(\mathcal{M};u) = \{r \in \mathbb{N} : a \le r \le b\}$. For instance, as shown in [8], this indeed is the case for any 1-margin model $\mathcal{M} = (d, \{1,2,\dots,d\}, (n_1,\dots,n_d))$ and any collection of margins $u = (u^1,\dots,u^d)$ under $\mathcal{M}$.

In striking contrast with this situation and with recent attempts by statisticians to better understand entry behavior of slim 3-tables (cf. [3, 4, 10]), we have the following surprising consequence of Theorem 1.1, implying that entry-ranges of 2-margined slim 3-table models consist of all finite sets of nonnegative integers and hence are "complex" and presumably secure. For the proof, see [8].

COROLLARY 2.5 (universality of entry-range). *For any finite set $D \subset \mathbb{N}$ of nonnegative integers, there are $r, c,$ and 2-margins for $(r, c, 3)$-tables such that the set of values occurring in a fixed entry in all possible tables with these margins is precisely D.*

Example 2.6 (Gap in entry-range of 2-margined 3-tables). Applying our automatic universal generator [27] to the polytope $P = \{y \ge 0 : y_0 - 2y_1 = 0,\ y_1 + y_2 = 1\}$ in three variables, we obtain the following 2-margins for $(16, 11, 3)$-tables giving entry-range $D = \{0, 2\}$,

$$\begin{pmatrix}
2&0&0&0&0&0&2&0&0&2&0&0&0&0&0&0\\
0&0&0&0&0&2&0&0&0&0&0&0&0&0&0&2\\
2&0&0&0&0&0&0&0&0&0&2&0&0&0&0&2\\
2&2&2&2&0&0&0&0&0&0&0&0&0&0&0&0\\
0&0&0&0&2&2&2&2&0&0&0&0&0&0&0&0\\
0&0&0&0&0&0&0&0&2&2&2&2&0&0&0&0\\
0&0&0&0&0&0&0&0&0&0&0&0&2&2&2&2\\
2&0&0&0&2&0&0&0&2&0&0&0&2&0&0&0\\
0&2&0&0&0&2&0&0&0&2&0&0&0&2&0&0\\
0&0&2&0&0&0&2&0&0&0&2&0&0&0&2&0\\
0&0&0&2&0&0&0&2&0&0&0&2&0&0&0&2
\end{pmatrix},$$

$$\begin{pmatrix}
2&2&2&2&2&2&2&2&2&2&2&2&2&2&2&2\\
4&0&0&0&0&2&2&0&0&2&2&0&0&0&0&4\\
2&2&2&2&2&2&2&2&2&2&2&2&2&2&2&2
\end{pmatrix},$$

$$\begin{pmatrix}
4&1&3&6&6&6&6&0&0&0&0\\
2&3&3&0&0&0&0&2&2&2&2\\
0&0&0&2&2&2&2&6&6&6&6
\end{pmatrix};$$

with a suitable "human" short cut it is possible to get it down to the following (possibly smallest) collection of margins for $(6, 4, 3)$-tables, giving again the entry-range $D = \{0, 2\}$ with a gap,

$$\begin{pmatrix}
2&1&2&0&2&0\\
1&0&2&0&0&2\\
1&0&0&2&2&0\\
0&1&0&2&0&2
\end{pmatrix},\quad
\begin{pmatrix}
2&1&2&3&0&0\\
2&1&0&0&2&1\\
0&0&2&1&2&3
\end{pmatrix},\quad
\begin{pmatrix}
2&3&2\\
2&1&2\\
2&1&2\\
2&1&2
\end{pmatrix}.$$

Further applications of Theorem 1.1 to statistical model theory are discussed in [8]; these include important consequences for *Markov bases* of 2-margined slim 3-way models. (Recall that a Markov basis is a set of moves that connects any pair of tables in the model that have the same set of margins, and is needed for the design of a random walk on the space of tables with fixed margins to address the problems of *sampling* and *estimating* various statistics on this space; see [8] for more details.)

2.4. Universality of the bitransportation problem. Our construction for Theorem 1.2 allows automatic generation of bitransportation programs with integer supplies, demands and capacities, where any feasible bitransportation must have an arbitrarily large prescribed denominator, in contrast with Hu's celebrated half-integrality theorem for the undirected case [16].

Example 2.7 (Bitransportations with arbitrarily large denominator). Fix any positive integer q. Start with the polytope $P = \{y \geq 0 : qy = 1\}$ in one variable containing the single point $y = \frac{1}{q}$. Our construction represents it as a bitransportation polytope F with integer supplies, demands and capacities, where y is embedded as the transportation $x^1_{1,1}$ of the first commodity from supply vertex $1 \in I$ to demand vertex $j \in J$. By Theorem 1.2, F contains a single bitransportation with $x^1_{1,1} = y = \frac{1}{q}$. For instance, for $q = 3$ we get the bitransportation problem with the data

$$u = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \end{pmatrix}, \quad s^1 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, \quad s^2 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix},$$

$$d^1 = (1 \;\; 1 \;\; 1 \;\; 1 \;\; 1 \;\; 1 \;\; 0 \;\; 0), \quad d^2 = (0 \;\; 0 \;\; 0 \;\; 1 \;\; 1 \;\; 1 \;\; 2 \;\; 1),$$

which has the following unique, $\{0, \frac{1}{3}, \frac{2}{3}\}$-valued, bitransportation solution:

$$x^1 = \frac{1}{3}\begin{pmatrix} 1 & 0 & 0 & 2 & 0 & 0 & 0 & 0 \\ 0 & 2 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 2 & 0 & 0 \\ 2 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{pmatrix}, \quad x^2 = \frac{1}{3}\begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 & 0 & 1 \end{pmatrix}.$$

By Theorem 1.2, any (say, feasibility) linear programming problem can be encoded as such a bitransportation problem (unbounded programs can also be treated by adding to the original system a single equality $\sum_{j=0}^{n} y_j = U$ with y_0 a new "slack" variable and U derived from the Cramer's rule bound of Theorem 10.3 [25]). Thus, any (hopefully combinatorial) algorithm for the bitransportation problem will give an algorithm for general linear programming. There has been much interest lately (A. Levin [21]) in combinatorial approximation algorithms for (fractional) multiflows, e.g., [11, 12]; these yield, via Theorem 1.2, approximation algorithms for general linear programming, which might prove a useful and fast solution strategy in practice. Details of this will appear elsewhere.

3. The three-stage construction. Our construction consists of three stages which are independent of each other as reflected in Lemma 3.1 and Theorems 3.2

and 3.3 below. Stage one, in section 3.1, is a simple preprocessing based on standard scaling ideas, in which a given polytope is represented as another whose defining system involves only small, $\{-1,0,1,2\}$-valued coefficients, at the expense of increasing the number of variables. This enables us to make the entire construction run in time polynomial in the size of the input. However, for systems with small coefficients, such as in the examples above, this may result in unnecessary blow-up and can be skipped. Stage two, in section 3.2, represents any rational polytope as a 3-way transportation polytope with specified *plane-sums* and *forbidden-entries*. In the last stage, in section 3.3, any plane-sum transportation polytope with upper-bounds on the entries is represented as a slim 3-way line-sum transportation polytope. In section 3.4 these three stages are integrated to give Theorem 1.1, and a complexity estimate is provided to close the presentation. Theorem 1.2 is a result of an easy modification of Theorem 3.2, and it is the content of section 3.5.

3.1. Preprocessing: Coefficient reduction. Let $P = \{y \geq 0 : Ay = b\}$ where $A = (a_{i,j})$ is an integer matrix and b is an integer vector. We represent it as a polytope $Q = \{x \geq 0 : Cx = d\}$, in polynomial-time, with a $\{-1,0,1,2\}$-valued matrix $C = (c_{i,j})$ of coefficients, as follows. Consider any variable y_j and let $k_j := \max\{\lfloor \log_2 |a_{i,j}| \rfloor : i = 1,\ldots,m\}$ be the maximum number of bits in the binary representation of the absolute value of any $a_{i,j}$. We introduce variables $x_{j,0},\ldots,x_{j,k_j}$, and relate them by the equations $2x_{j,s} - x_{j,s+1} = 0$. The representing injection σ is defined by $\sigma(j) := (j,0)$, embedding y_j as $x_{j,0}$. Consider any term $a_{i,j}\,y_j$ of the original system. Using the binary expansion $|a_{i,j}| = \sum_{s=0}^{k_j} t_s 2^s$ with all $t_s \in \{0,1\}$, we rewrite this term as $\pm \sum_{s=0}^{k_j} t_s x_{j,s}$. To illustrate, consider a system consisting of the single equation $3y_1 - 5y_2 + 2y_3 = 7$. Then the new system is

$$
\begin{array}{rrrrrrrrr}
2x_{1,0} & -x_{1,1} & & & & & & = & 0,\\
 & & 2x_{2,0} & -x_{2,1} & & & & = & 0,\\
 & & & 2x_{2,1} & -x_{2,2} & & & = & 0,\\
 & & & & & 2x_{3,0} & -x_{3,1} & = & 0,\\
x_{1,0} & +x_{1,1} & -x_{2,0} & & -x_{2,2} & & +x_{3,1} & = & 7.
\end{array}
$$

It is easy to see that this procedure provides the sought representation, and we get the following.

LEMMA 3.1. *Any rational polytope $P = \{y \geq 0 : Ay = b\}$ is polynomial-time representable as a polytope $Q = \{x \geq 0 : Cx = d\}$ with $\{-1,0,1,2\}$-valued defining matrix C.*

3.2. Representing polytopes as plane-sum entry-forbidden transportation polytopes. The next stage of construction we are about to explain will normally be applied to the output $Q = \{x \geq 0 : Cx = d\}$ of stage one, but we present the construction for a general polyhedron P since the construction holds in that generality. Let $P = \{y \geq 0 : Ay = b\}$, where $A = (a_{i,j})$ is an $m \times n$ integer matrix and b is an integer vector: we assume that P is bounded and hence a (possibly empty) polytope, with an integer upper bound U on the value of any coordinate y_j of any $y \in P$ (U can be derived efficiently from Cramer's rule as explained in Theorem 10.3 of [25]).

For each variable y_j, let r_j be the maximum of the sum of the positive coefficients of y_j over all equations and the sum of absolute values of the negative coefficients of y_j over all equations:

$$r_j := \max\left(\sum_k \{a_{k,j} : a_{k,j} > 0\}\,,\ \sum_k \{|a_{k,j}| : a_{k,j} < 0\}\right)\ .$$

Let $r := \sum_{j=1}^n r_j$, $R := \{1,\ldots,r\}$, $h := m+1$, and $H := \{1,\ldots,h\}$. We now describe how to construct vectors $u, v \in \mathbb{Z}^r, w \in \mathbb{Z}^h$, and a set $E \subset R \times R \times H$ of triples—the "enabled," non-"forbidden" entries—such that the polytope P is represented as the corresponding transportation polytope of $r \times r \times h$ arrays with plane-sums u, v, w and only entries indexed by E enabled:

$$T = \left\{ x \in \mathbb{R}_{\geq 0}^{r\times r\times h} \ :\ x_{i,j,k} = 0 \ \text{ for all } \ (i,j,k) \notin E\,, \ \text{ and } \right.$$

$$\left. \sum_{i,j} x_{i,j,k} = w_k\,,\ \sum_{i,k} x_{i,j,k} = v_j\,,\ \sum_{j,k} x_{i,j,k} = u_i \right\}\ .$$

We also indicate the injection $\sigma : \{1,\ldots,n\} \longrightarrow R \times R \times H$ giving the desired embedding of the coordinates y_j as the coordinates $x_{i,j,k}$ and the representation of P as T (see paragraph following Theorem 1.1).

Basically, each equation $k = 1,\ldots,m$ will be encoded in a "horizontal plane" $R \times R \times \{k\}$ (the last plane $R \times R \times \{h\}$ is included for consistency and its entries can be regarded as "slacks"); and each variable y_j, $j = 1,\ldots,n$, will be encoded in a "vertical box" $R_j \times R_j \times H$, where $R = \biguplus_{j=1}^n R_j$ is the natural partition of R with $|R_j| = r_j$, namely with $R_j := \{1 + \sum_{l<j} r_l, \ldots, \sum_{l\leq j} r_l\}$.

Now, all "vertical" plane-sums are set to the same value U, that is, $u_j := v_j := U$ for $j = 1,\ldots,r$. All entries not in the union $\biguplus_{j=1}^n R_j \times R_j \times H$ of the variable boxes will be forbidden. We now describe the enabled entries in the boxes; for simplicity we discuss the box $R_1 \times R_1 \times H$, the others being similar. We distinguish between the two cases $r_1 = 1$ and $r_1 \geq 2$. In the first case, $R_1 = \{1\}$; the box, which is just the single line $\{1\}\times\{1\}\times H$, will have exactly two enabled entries $(1,1,k^+), (1,1,k^-)$ for suitable k^+, k^- to be defined later. We set $\sigma(1) := (1,1,k^+)$, namely embed $y_1 = x_{1,1,k^+}$. We define the *complement* of the variable y_1 to be $\bar{y}_1 := U - y_1$ (and likewise for the other variables). The vertical sums u, v then force $\bar{y}_1 = U - y_1 = U - x_{1,1,k^+} = x_{1,1,k^-}$, so the complement of y_1 is also embedded. Next, consider the case $r_1 \geq 2$. For each $s = 1,\ldots,r_1$, the line $\{s\} \times \{s\} \times H$ (respectively, $\{s\} \times \{1 + (s \bmod r_1)\} \times H$) will contain one enabled entry $(s, s, k^+(s))$ (respectively, $(s, 1 + (s \bmod r_1), k^-(s))$. All other entries of $R_1 \times R_1 \times H$ will be forbidden. Again, we set $\sigma(1) := (1,1,k^+(1))$, namely embed $y_1 = x_{1,1,k^+(1)}$; it is then not hard to see that, again, the vertical sums u, v force $x_{s,s,k^+(s)} = x_{1,1,k^+(1)} = y_1$ and $x_{s,1+(s \bmod r_1),k^-(s)} = U - x_{1,1,k^+(1)} = \bar{y}_1$ for each $s = 1,\ldots,r_1$. Therefore, both y_1 and $\bar{y}_1$ are each embedded in r_1 distinct entries.

To clarify the above description it is helpful to visualize the $R \times R$ matrix $(x_{i,j,+})$ whose entries are the vertical line-sums $x_{i,j,+} := \sum_{k=1}^h x_{i,j,k}$. For instance, if we have three variables with $r_1 = 3, r_2 = 1, r_3 = 2$ then $R_1 = \{1,2,3\}, R_2 = \{4\}, R_3 = \{5,6\}$,

and the line-sums matrix $x = (x_{i,j,+})$ is

$$\begin{pmatrix} x_{1,1,+} & x_{1,2,+} & 0 & 0 & 0 & 0 \\ 0 & x_{2,2,+} & x_{2,3+} & 0 & 0 & 0 \\ x_{3,1,+} & 0 & x_{3,3,+} & 0 & 0 & 0 \\ 0 & 0 & 0 & x_{4,4,+} & 0 & 0 \\ 0 & 0 & 0 & 0 & x_{5,5,+} & x_{5,6,+} \\ 0 & 0 & 0 & 0 & x_{6,5,+} & x_{6,6,+} \end{pmatrix} = \begin{pmatrix} y_1 & \bar{y}_1 & 0 & 0 & 0 & 0 \\ 0 & y_1 & \bar{y}_1 & 0 & 0 & 0 \\ \bar{y}_1 & 0 & y_1 & 0 & 0 & 0 \\ 0 & 0 & 0 & U & 0 & 0 \\ 0 & 0 & 0 & 0 & y_3 & \bar{y}_3 \\ 0 & 0 & 0 & 0 & \bar{y}_3 & y_3 \end{pmatrix}.$$

We now encode the equations by defining the horizontal plane-sums w and the indices $k^+(s), k^-(s)$ mentioned above as follows. For $k = 1, \ldots, m$, consider the kth equation $\sum_j a_{k,j} y_j = b_k$. Define the index sets $J^+ := \{j : a_{k,j} > 0\}$ and $J^- := \{j : a_{k,j} < 0\}$, and set $w_k := b_k + U \cdot \sum_{j \in J^-} |a_{k,j}|$. The last coordinate of w is set for consistency with u, v to be $w_h = w_{m+1} := r \cdot U - \sum_{k=1}^{m} w_k$. Now, with $\bar{y}_j := U - y_j$ the complement of variable y_j as above, the kth equation can be rewritten as

$$\sum_{j \in J^+} a_{k,j} y_j + \sum_{j \in J^-} |a_{k,j}| \bar{y}_j = \sum_{j=1}^{n} a_{k,j} y_j + U \cdot \sum_{j \in J^-} |a_{k,j}| = b_k + U \cdot \sum_{j \in J^-} |a_{k,j}| = w_k.$$

We encode this equation by setting, for each $j \in J_+$, $k^+(s) = k$ for $|a_{k,j}|$ many different values of s (respectively, for each $j \in J_-$ we set $k^-(s) = k$ for enough values of s). By suitably setting $k^+(s) := k$ or $k^-(s) := k$, this has the effect of pulling enough copies of the variables y_j or $\bar{y}_j$ to the corresponding kth horizontal plane. Of course, once a variable is used at a certain horizontal level it cannot be used in others. By the choice of r_j there are sufficiently many copies of variables y_j $\bar{y}_j$, possibly with a few redundant copies which are absorbed in the last hyperplane by setting $k^+(s) := m + 1$ or $k^-(s) := m + 1$. For instance, if $m = 8$, the first variable y_1 has $r_1 = 3$ as above, its coefficient $a_{4,1} = 3$ in the fourth equation is positive, its coefficient $a_{7,1} = -2$ in the seventh equation is negative, and $a_{k,1} = 0$ for $k \neq 4, 7$, then we set $k^+(1) = k^+(2) = k^+(3) := 4$ (so $\sigma(1) := (1, 1, 4)$ embedding y_1 as $x_{1,1,4}$), $k^-(1) = k^-(2) := 7$, and $k^-(3) := h = 9$. This way, all equations are suitably encoded, and we obtain the following theorem.

THEOREM 3.2. *Any rational polytope $P = \{y \in \mathbb{R}^n_{\geq 0} : Ay = b\}$ is polynomial-time representable as a plane-sum entry-forbidden* 3*-way transportation polytope*

$$T = \left\{ x \in \mathbb{R}^{r \times r \times h}_{\geq 0} \ : \ x_{i,j,k} = 0 \ \textit{for all} \ (i,j,k) \notin E\,, \quad \textit{and} \right.$$

$$\left. \sum_{i,j} x_{i,j,k} = w_k\,,\ \sum_{i,k} x_{i,j,k} = v_j\,,\ \sum_{j,k} x_{i,j,k} = u_i \right\}\,.$$

Here E denotes the set of enabled, nonforbidden entries.

Proof. The proof follows from the construction outlined above and Lemma 3.1. □

3.3. Representing plane-sum entry-bounded as slim line-sum entry-free. Here we start with a transportation polytope of plane-sums and *upper-bounds*

$e_{i,j,k}$ on the entries,

$$P = \left\{ y \in \mathbb{R}^{l\times m\times n}_{\geq 0} : \sum_{i,j} y_{i,j,k} = c_k \, , \sum_{i,k} y_{i,j,k} = b_j \, , \sum_{j,k} y_{i,j,k} = a_i \, , \; y_{i,j,k} \leq e_{i,j,k} \right\} .$$

Clearly, this is a more general form than that of T appearing in Theorem 3.2 above; the forbidden entries can be encoded by setting a "forbidding" upper-bound $e_{i,j,k} := 0$ on all forbidden entries $(i,j,k) \notin E$ and an "enabling" upper-bound $e_{i,j,k} := U$ on all enabled entries $(i,j,k) \in E$. Thus, by Theorem 3.2, any rational polytope is representable also as such a plane-sum entry-bounded transportation polytope P. We now describe how to represent, in turn, such a P as a slim line-sum (unrestricted-entry) transportation polytope of the form of Theorem 1.1,

$$T \; = \; \left\{ x \in \mathbb{R}^{r\times c\times 3}_{\geq 0} \; : \; \sum_{I} x_{I,J,K} = w_{J,K} \, , \; \sum_{J} x_{I,J,K} = v_{I,K} \, , \; \sum_{K} x_{I,J,K} = u_{I,J} \right\} .$$

This stage of our construction was first presented in [6] while studying the complexity of deciding if T has an integer point; we include the details for completeness of the presentation. We give explicit formulas for $u_{I,J}, v_{I,K}, w_{J,K}$ in terms of a_i, b_j, c_k, and $e_{i,j,k}$ as follows. Put $r := l \cdot m$ and $c := n + l + m$. The first index I of each entry $x_{I,J,K}$ will be a pair $I = (i,j)$ in the r-set

$$\{(1,1), \ldots, (1,m), (2,1), \ldots, (2,m), \ldots, (l,1), \ldots, (l,m)\} \, .$$

The second index J of each entry $x_{I,J,K}$ will be a pair $J = (s,t)$ in the c-set

$$\{(1,1), \ldots, (1,n), (2,1), \ldots, (2,l), (3,1), \ldots, (3,m)\} \, .$$

The last index K will simply range in the 3-set $\{1,2,3\}$. We represent P as T via the injection σ given explicitly by $\sigma(i,j,k) := ((i,j),(1,k),1)$, embedding each variable $y_{i,j,k}$ as the entry $x_{(i,j),(1,k),1}$. Let U now denote the minimum between the two values $\max\{a_1, \ldots, a_l\}$ and $\max\{b_1, \ldots, b_m\}$. The 2-margins entries will be

$$u_{(i,j),(1,t)} = e_{i,j,t}, \quad u_{(i,j),(2,t)} = \begin{cases} U & \text{if } t = i, \\ 0 & \text{otherwise,} \end{cases} \quad u_{(i,j),(3,t)} = \begin{cases} U & \text{if } t = j, \\ 0 & \text{otherwise,} \end{cases}$$

$$v_{(i,j),t} = \begin{cases} U & \text{if } t = 1, \\ e_{i,j,+} & \text{if } t = 2, \\ U & \text{if } t = 3, \end{cases}$$

$$w_{(i,j),1} = \begin{cases} c_j & \text{if } i = 1, \\ m \cdot U - a_j & \text{if } i = 2, \\ 0 & \text{if } i = 3. \end{cases} \qquad w_{(i,j),2} = \begin{cases} e_{+,+,j} - c_j & \text{if } i = 1, \\ 0 & \text{if } i = 2, \\ b_j & \text{if } i = 3. \end{cases}$$

$$w_{(i,j),3} = \begin{cases} 0 & \text{if } i = 1, \\ a_j & \text{if } i = 2, \\ l \cdot U - b_j & \text{if } i = 3. \end{cases}$$

THEOREM 3.3. *Any rational plane-sum entry-bounded* 3*-way transportation polytope*

$$P = \left\{ y \in \mathbb{R}^{l\times m\times n}_{\geq 0} : \sum_{i,j} y_{i,j,k} = c_k \,, \sum_{i,k} y_{i,j,k} = b_j \,, \sum_{j,k} y_{i,j,k} = a_i \,,\ y_{i,j,k} \leq e_{i,j,k} \right\}$$

is strongly-polynomial-time representable as a line-sum slim transportation polytope

$$T = \left\{ x \in \mathbb{R}^{r\times c\times 3}_{\geq 0} \ :\ \sum_{I} x_{I,J,K} = w_{J,K} \,,\ \sum_{J} x_{I,J,K} = v_{I,K} \,,\ \sum_{K} x_{I,J,K} = u_{I,J} \right\}.$$

Proof. We outline the proof; complete details appeared in [6]. First, consider any $y = (y_{i,j,k}) \in P$; we claim the embedding via σ of $y_{i,j,k}$ in $x_{(i,j),(1,k),1}$ can be extended uniquely to $x = (x_{I,J,K}) \in T$. First, the entries $x_{I,(3,t),1}$, $x_{I,(2,t),2}$ and $x_{I,(1,t),3}$ for all $I = (i,j)$ and t are zero since so are the line-sums $w_{(3,t),1}$, $w_{(2,t),2}$ and $w_{(1,t),3}$. Next, consider the entries $x_{I,(2,t),1}$: since all entries $x_{I,(3,t),1}$ are zero, examining the line-sums $u_{I,(2,t)}$ and $v_{I,1} = U$, we find $x_{(i,j),(2,i),1} = U - \sum_{t=1}^{n} x_{(i,j),(1,t),1} = U - y_{i,j,+} \geq 0$ whereas for $t \neq i$ we get $x_{(i,j),(2,t),1} = 0$. This also gives the entries $x_{I,(2,t),3}$: we have $x_{(i,j),(2,i),3} = U - x_{(i,j),(2,i),1} = y_{i,j,+} \geq 0$ whereas for $t \neq i$ we have $x_{(i,j),(2,t),3} = 0$. Next, consider the entries $x_{I,(1,t),2}$: since all entries $x_{I,(1,t),3}$ are zero, examining the line-sums $u_{(i,j),(1,k)} = e_{i,j,k}$ we find $x_{(i,j),(1,k),2} = e_{i,j,k} - y_{i,j,k} \geq 0$ for all i,j,k. Next consider the entries $x_{I,(3,t),2}$: since all entries $x_{I,(2,t),2}$ are zero, examining the line-sums $u_{(i,j),(3,t)}$ and $v_{(i,j),2} = e_{i,j,+}$, we find $x_{(i,j),(3,j),2} = e_{i,j,+} - \sum_{k=1}^{l} x_{(i,j),(1,k),2} = y_{i,j,+} \geq 0$ whereas for $t \neq j$ we get $x_{(i,j),(3,t),2} = 0$. This also gives the entries $x_{I,(3,t),3}$: we have $x_{(i,j),(3,j),3} = U - x_{(i,j),(3,j),2} = U - y_{i,j,+} \geq 0$ whereas for $t \neq j$ we get $x_{(i,j),(3,t),3} = 0$. Using the relations established above, one can easily check that all line-sums are correct.

Conversely, given any $x = (x_{I,J,K}) \in T$, let $y = (y_{i,j,k})$ with $y_{i,j,k} := x_{(i,j),(1,k),1}$. Since x is nonnegative, so is y. Further, $e_{i,j,k} - y_{i,j,k} = x_{(i,j),(1,k),2} \geq 0$ for all i,j,k and hence y obeys the entry upper-bounds. Finally, using the relations established above $x_{(i,j),(3,t),2} = 0$ for $t \neq j$, $x_{(i,j),(2,t),3} = 0$ for $t \neq i$, and $x_{(i,j),(3,j),2} = x_{(i,j),(2,i),3} = y_{i,j,+}$, we obtain

$$\sum_{i,j} y_{i,j,k} \ = \ \sum_{i,j} x_{(i,j),(1,k),1} \ = \ w_{(1,k),1} \ = \ c_k \,, \qquad 1 \leq k \leq n \ ;$$

$$\sum_{i,k} y_{i,j,k} \ = \ \sum_{i} x_{(i,j),(3,j),2} \ = \ w_{(3,j),2} \ = \ b_j \,, \qquad 1 \leq j \leq m \ ;$$

$$\sum_{j,k} y_{i,j,k} \ = \ \sum_{j} x_{(i,j),(2,i),3} \ = \ w_{(2,i),3} \ = \ a_i \,, \qquad 1 \leq i \leq l \ .$$

This shows that y satisfies the plane-sums as well and hence is in P. Since integrality is also preserved in both directions, this completes the proof. □

3.4. The main theorem and a complexity estimate. Call a class $\mathcal{P}$ of rational polytopes *polynomial-time representable* in a class $\mathcal{Q}$ if there is a polynomial-time

algorithm that represents any given $P \in \mathcal{P}$ as some $Q \in \mathcal{Q}$. The resulting binary relation on classes of rational polytopes is clearly transitive. Thus, the composition of Theorem 3.2 (which incorporates Lemma 3.1) and Theorem 3.3 gives at once Theorem 1.1 stated in the introduction. Working out the details of our three-stage construction, we can give the following estimate on the number of rows r and columns c in the resulting representing transportation polytope, in terms of the input. The computational complexity of the construction is also determined by this bound, but we do not dwell on the details here.

THEOREM 1.1 (with complexity estimate). *Any polytope* $P=\{y \in \mathbb{R}^n_{\geq 0} : Ay = b\}$ *with integer* $m \times n$ *matrix* $A = (a_{i,j})$ *and integer* b *is polynomial-time representable as a slim transportation polytope*

$$T = \left\{ x \in \mathbb{R}^{r\times c\times 3}_{\geq 0} \ : \ \sum_i x_{i,j,k} = w_{j,k}\,,\ \sum_j x_{i,j,k} = v_{i,k}\,,\ \sum_k x_{i,j,k} = u_{i,j} \right\}\,,$$

with $r = O(m^2(n+L)^2)$ *rows and* $c = O(m(n+L))$ *columns, where*

$$L := \sum_{j=1}^{n} \max_{i=1}^{m} \lfloor \log_2 |a_{i,j}| \rfloor .$$

3.5. Proof of the universality of the bitransportation problem. We conclude with the modification of the proof of Theorem 3.3 that establishes Theorem 1.2.

THEOREM 1.2. *Any rational polytope* $P = \{y \in \mathbb{R}^n_{\geq 0} : Ay = b\}$ *is polynomial-time representable as a bipartite bitransportation polytope*

$$F = \left\{ (x^1, x^2) \in \mathbb{R}^{r\times c}_{\geq 0} \oplus \mathbb{R}^{r\times c}_{\geq 0} \ : \ x^1_{i,j} + x^2_{i,j} \leq u_{i,j}\,, \right.$$

$$\left. \sum_j x^k_{i,j} = s^k_i\,,\ \sum_i x^k_{i,j} = d^k_j\,, \quad k = 1,2 \right\}\,.$$

Here r, c are the same values as presented in Theorem 1.1 above. Moreover, the statement remains valid with all supplies s^k_i having the same value U and all capacities $u_{i,j}$ being 0 or U for some suitable nonnegative integer U.

Proof. We do an easy adjustment of the proof of Theorem 3.3 above: We essentially need to describe the capacities, demands and supplies (for each of two commodities) for a bipartite network with $l \cdot m$ nodes for the first part and $n + l + m$ nodes in the second part, with $l \cdot m \cdot (n + l + m)$ arcs. Take the capacities of the arcs to be $u_{i,j}$ as defined in section 3.3; take the supplies to be $s^1_i := v_{i,1} = U$ and $s^2_i := v_{i,3} = U$ for all i, and take the demands to be $d^1_j := w_{j,1}$ and $d^2_j := w_{j,3}$ for all j. Note that by taking s^2_i and d^2_j to be $v_{i,3}$ and $w_{j,3}$ instead of $v_{i,2}$ and $w_{j,2}$ we can guarantee that all supplies have the same value U. Moreover, since the proof follows by the composition of Theorem 3.2 and Theorem 3.3, and the former makes use of forbidden entries only, rather than upper bounds, it is easy to see that we can take all upper bounds $e_{i,j,k}$ in the latter (and hence all $u_{i,j}$) to be either 0 or U, proving the stronger statement. More visually, the data can also be described in matrix form as follows:

$$u = \begin{pmatrix}
e_{1,1,1} & e_{1,1,2} & \cdots & e_{1,1,n} & U & 0 & \cdots & 0 & U & 0 & \cdots & 0 \\
e_{1,2,1} & e_{1,2,2} & \cdots & e_{1,2,n} & U & 0 & \cdots & 0 & 0 & U & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
e_{1,m,1} & e_{1,m,2} & \cdots & e_{1,m,n} & U & 0 & \cdots & 0 & 0 & 0 & \cdots & U \\
\\
e_{2,1,1} & e_{2,1,2} & \cdots & e_{2,1,n} & 0 & U & \cdots & 0 & U & 0 & \cdots & 0 \\
e_{2,2,1} & e_{2,2,2} & \cdots & e_{2,2,n} & 0 & U & \cdots & 0 & 0 & U & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
e_{2,m,1} & e_{2,m,2} & \cdots & e_{2,m,n} & 0 & U & \cdots & 0 & 0 & 0 & \cdots & U \\
\\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
\\
e_{l,1,1} & e_{l,1,2} & \cdots & e_{l,1,n} & 0 & 0 & \cdots & U & U & 0 & \cdots & 0 \\
e_{l,2,1} & e_{l,2,2} & \cdots & e_{l,2,n} & 0 & 0 & \cdots & U & 0 & U & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
e_{l,m,1} & e_{l,m,2} & \cdots & e_{l,m,n} & 0 & 0 & \cdots & U & 0 & 0 & \cdots & U
\end{pmatrix},$$

$$s^1 = s^2 = \begin{pmatrix}
U \\ U \\ \vdots \\ U \\ \\ U \\ U \\ \vdots \\ U \\ \\ \vdots \\ \\ U \\ U \\ \vdots \\ U
\end{pmatrix},$$

$$d^1 = (\, c_1, \quad c_2, \quad \ldots, \quad c_n, \quad m \cdot U - a_1, \quad m \cdot U - a_2, \ldots, \quad m \cdot U - a_l, \quad 0, \quad 0, \quad \ldots, \quad 0\,),$$
$$d^2 = (\, 0, \quad 0, \quad \ldots, \quad 0, \quad a_1, \quad a_2, \quad \ldots, a_l, \quad l \cdot U - b_1, \quad l\cdot, U - b_2, \ldots, \quad l \cdot U - b_m\,). \qquad \square$$

CONVERGENT SDP-RELAXATIONS IN POLYNOMIAL OPTIMIZATION WITH SPARSITY*

JEAN B. LASSERRE†

Abstract. We consider a polynomial programming problem $\mathbf{P}$ on a compact basic semialgebraic set $\mathbf{K} \subset \mathbb{R}^n$, described by m polynomial inequalities $g_j(X) \geq 0$, and with criterion $f \in \mathbb{R}[X]$. We propose a hierarchy of semidefinite relaxations in the spirit of those of Waki et al. [*SIAM J. Optim.*, 17 (2006), pp. 218–242]. In particular, the SDP-relaxation of order r has the following two features: (a) The number of variables is $O(\kappa^{2r})$, where $\kappa = \max[\kappa_1, \kappa_2]$ with κ_1 (resp., κ_2) being the maximum number of variables appearing in the monomials of f (resp., appearing in a single constraint $g_j(X) \geq 0$). (b) The largest size of the linear matrix inequalities (LMIs) is $O(\kappa^r)$. This is to compare with the respective number of variables $O(n^{2r})$ and LMI size $O(n^r)$ in the original SDP-relaxations defined in [J. B. Lasserre, *SIAM J. Optim.*, 11 (2001), pp. 796–817]. Therefore, great computational savings are expected in case of sparsity in the data $\{g_j, f\}$, i.e., when κ is small, a frequent case in practical applications of interest. The novelty with respect to [H. Waki, S. Kim, M. Kojima, and M. Maramatsu, *SIAM J. Optim.*, 17 (2006), pp. 218–242] is that we prove convergence to the global optimum of $\mathbf{P}$ when the sparsity pattern satisfies a condition often encountered in large size problems of practical applications, and known as the *running intersection property* in graph theory. In such cases, and as a by-product, we also obtain a new representation result for polynomials positive on a compact basic semialgebraic set, a *sparse* version of Putinar's Positivstellensatz [M. Putinar, *Indiana Univ. Math. J.*, 42 (1993), pp. 969–984].

1. Introduction.

In this paper we consider the polynomial programming problem

$$\mathbf{P}: \quad \inf_{x \in \mathbb{R}^n} \{ f(x) \mid \quad x \in \mathbf{K} \}, \tag{1.1}$$

where $f \in \mathbb{R}[X]$, and $\mathbf{K} \subset \mathbb{R}^n$ is the basic closed semialgebraic set defined by

$$\mathbf{K} := \{ x \in \mathbb{R}^n \mid \quad g_j(x) \geq 0, \quad j = 1, \ldots, m \}, \tag{1.2}$$

for some polynomials $\{g_j\}_{j=1}^m \subset \mathbb{R}[X]$.

The hierarchy of semidefinite programming (SDP) relaxations introduced in [11] provides a sequence of SDPs of increasing size, whose associated sequence of optimal values converges to the global minimum of $\mathbf{P}$. Moreover, as proved by Schweighofer in [17], convergence to a global minimizer of $\mathbf{P}$ (if unique) also holds. For more details, the reader is referred to [5, 11, 17] and the many references therein. In addition, practice reveals that convergence is usually fast, and often *finite* (up to machine precision); see, e.g., Henrion and Lasserre [5].

However, despite these nice features, the size of the SDP-relaxations grows rapidly with the size of the original problem. Typically, the kth SDP-relaxation has to handle

*Received by editors November 12, 2005; accepted for publication (in revised form) April 13, 2006; published electronically October 16, 2006. This research was sponsored by the French National Research Agency (ANR) under grant NT-05-3-41612.

at least one linear matrix inequality (LMI) of size $\binom{n+k}{n}$ and $\binom{n+2k}{n}$ variables, which clearly limits the applicability of the methodology to problems with small to medium size only. Therefore, validation of the above methodology for larger size problems (and even more, for large scale problems) is a real challenge of practical importance.

One way to extend the applicability of the methodology to problems of larger size is to take into account *sparsity* in the original data, frequently encountered in practical cases. Indeed, as is typical in many applications of interest, f as well as the polynomials $\{g_j\}$ that describe $\mathbf{K}$ are sparse, i.e., each monomial of f and each polynomial g_j are only concerned with a small subset of variables. This is the approach taken in Waki et al. [9] (extending Kim, Kojima, and Waki [7] and Kojima, Kim, and Waki [8]), where the authors have built up a hierarchy of SDP-relaxations in the spirit of those in [11], but where sparsity is taken into account. Sometimes, a sparsity pattern can be "read" from the data of $\mathbf{P}$ but not always, and in [9] the authors have proposed a systematic procedure to detect and structure sparsity in $\mathbf{P}$, via the so-called *chordal extension* of the *correlation sparsity pattern graph* (csp graph); the csp graph has as many nodes as variables, and a link between two nodes (i.e., variables) means that these two variables both appear in a monomial of the objective function or in some inequality constraint $g_j \geq 0$ of $\mathbf{P}$. Once a sparsity pattern has been detected, they define a simplified "sparse" version of the SDP-relaxations of [11]; briefly, in the dual, the sum of squares (s.o.s.) multiplier associated with a constraint is now a polynomial in only those variables appearing in that constraint. In doing so, they have obtained impressive gains in the size of the resulting SDP-relaxations, as well as in the computational time needed for obtaining an optimal solution. As a matter of fact, they were even able to solve problems that could not be handled with the original SDP-relaxations. However, and despite good approximations are obtained in most problems in their sample of experiments, convergence to the global minimum is *not* guaranteed.

Contribution. Our contribution is twofold: We first propose a hierarchy of SDP-relaxations $\{\mathbf{Q}_r\}$ in the spirit of the original SDP-relaxations [11] and close to those defined in [9]. They are valid for arbitrary polynomial programming problems, and have the following three appealing features:

(a) In the SDP-relaxation $\mathbf{Q}_r$ of order r, the number of variables is $O(\kappa^{2r})$, where $\kappa = \max[\kappa_1, \kappa_2]$ with κ_1 (resp., κ_2) being the maximum number of variables appearing in each monomial of f (resp., in a single constraint $g_j(X) \geq 0$).

(b) The largest size of the LMIs is $O(\kappa^r)$.

This is to compare with the respective number of variables $O(n^{2r})$ and LMI size $O(n^r)$ in the original SDP-relaxations defined in [11].

(c) Under a certain condition on the sparsity pattern, the resulting sequence of their optimal value *converges* to the global minimum of $\mathbf{P}$.

So in view of (a) and (b), and when κ is small ($\kappa \ll n$), i.e., when sparsity is present, dramatic computational savings can be expected. In other words, these new SDP-relaxations are inherently exploiting sparsity in the data $\{f, g_j\}$ when present. Moreover, the size of the SDP-relaxation $\mathbf{Q}_r$ is in a sense *minimal*, at least when considering such types of SDP-relaxations, because one should at least handle moments involving κ variables, whenever some monomial of κ variables appears in the data $\{f, g_j\}$.

The condition under which such SDP-relaxations converge to the global minimum of $\mathbf{P}$ is easy to describe, and reflects a sparsity pattern frequently encountered in large scale problems. Namely, let $\{1, \ldots, n\}$ be the union $\bigcup_{k=1}^{p} I_k$ of subsets $I_k \subset \{1, \ldots, n\}$.

Every polynomial g_j in the definition (1.2) of $\mathbf{K}$ is only concerned with variables $\{X_i \,|\, i \in I_k\}$ for some k. Next, $f \in \mathbb{R}[X]$ can be written $f = f_1 + \cdots + f_p$, where each f_k uses only variables $\{X_i \,|\, i \in I_k\}$. In cases where the subsets $\{I_k\}$ are not so easy to detect, one may use the procedure of Waki et al. [9] via the chordal extension of the csp graph.

Finally, the collection $\{I_1, \ldots, I_p\}$ should obey the following condition: For every $k = 1, \ldots, p-1$,

$$I_{k+1} \cap \bigcup_{j=1}^{k} I_j \subseteq I_s \quad \text{for some } s \leq k. \tag{1.3}$$

Notice that (1.3) is always satisfied when $p = 2$. Property (1.3) depends on the ordering and so can be satisfied possibly after some relabelling of the I_k's. Moreover, if not satisfied, one may enforce (1.3) but at the price of enlarging some of the sets I_k. If $I_1, \ldots, I_p$ are the maximal cliques of a chordal graph, then (1.3) is satisfied possibly after some reordering of the cliques, and is known as the *running intersection property*; for more details on chordal graphs, the reader is referred to Fukuda et al. [4] and Nakata et al. [15].

In particular, (1.3) is naturally satisfied in a number of applications, in particular, in what we call *strong* and *weak* coupling. In the former, we have $I_k \cap I_{k+j} = \emptyset$ whenever $j > 1$, so that (1.3) holds. In the latter, there is a set of *coupling variables* with index set $I_0' \subset \{1, \ldots, n\}$, and a partition of $\{1, \ldots, n\} \setminus I_0'$ into p disjoint subsets of *independent variables* I_k', $k = 1, \ldots, p$. In this case one has $I_k := I_0' \cup I_k'$, $k = 1, \ldots, p$, and so $I_k \cap I_j = I_0'$ for all $j \neq k$, which in turn implies that (1.3) holds.

At last, and as a by-product of the property (1.3) of the sparsity pattern, we also obtain a new *sparse representation* result for polynomials, nonnegative on a basic closed semialgebraic set, a *sparse* version of Putinar's Positivstellensatz [16].

Link with related literature. As already mentioned, our work is closely related to the recent work of Kojima, Kim, and Waki [8] and Waki et al. [9], in which they were the first to exploit sparsity of data and modify (or simplify) in an appropriate way the original SDP-relaxations defined in [11]. Our SDP-relaxations are very close to those defined in [9], but handle p additional quadratic constraints. These p additional constraints, together with condition (1.3), are crucial to prove our convergence result. To summarize, our result implies that by a slight modification of the SDP-relaxations defined in [9], convergence is now guaranteed when the sparsity pattern satisfies (1.3).

The paper is organized as follows. After introducing notation and definitions, our main result is presented in section 3, and for clarity of exposition, some proofs are postponed to section 4, whereas auxiliary results needed in some proofs are postponed to an appendix section.

2. Notation and definitions. As common in algebra, variables of polynomials are denoted with capitals (e.g., X) whereas points in $\mathbb{R}^n$ are denoted with small letters (e.g., x). For a real symmetric matrix $A \in \mathbb{R}^{n \times n}$, the notation $A \succeq 0$ (resp., $A \succ 0$) stands for A is positive definite (resp., semidefinite), and for a vector x, let x' denote its transpose.

Let $\mathbb{R}[X]$ denote the ring of real polynomials in the variables $X_1, \ldots, X_n$. In the usual canonical basis $v_\infty(X) = \{X^\alpha \,|\, \alpha \in \mathbb{N}^n\}$ of monomials, a polynomial $g \in \mathbb{R}[X]$ is written

$$g(X) = \sum_{\alpha \in \mathbb{N}^n} g_\alpha X^\alpha, \tag{2.1}$$

for some real vector $\mathbf{g} = \{g_\alpha\}$ with finitely many nonzero coefficients.

With $\alpha \in \mathbb{N}^n$, let $|\alpha| := \sum_i \alpha_i$, and let $\mathbb{R}_r[X] \subset \mathbb{R}[X]$ be the $\mathbb{R}$-vector space of polynomials of degree at most r, with usual canonical basis of monomials $v_r(X) = \{X^\alpha \,|\, \alpha \in \mathbb{N}^n;\, |\alpha| \le r\}$.

Let $I_0 := \{1, \ldots, n\}$ be the union $\cup_{k=1}^p I_k$ of p subsets I_k, $k = 1, \ldots, p$, with cardinal denoted n_k. Let $\mathbb{R}[X(I_k)]$ denote the ring of polynomials in the n_k variables $X(I_k) = \{X_i \,|\, i \in I_k\}$, and so $\mathbb{R}[X(I_0)] = \mathbb{R}[X]$.

For each $k = 0, 1, \ldots, p$, let $\mathcal{I}_k$ be the set of all subsets of I_k. Next, for every $\alpha \in \mathbb{N}^n$, let $\mathrm{supp}\,(\alpha) \in \mathcal{I}_0$ be the support of α, i.e.,

$$\mathrm{supp}\,(\alpha) := \{\, i \in \{1, \ldots, n\} \,:\quad \alpha_i \neq 0 \,\}, \qquad \alpha \in \mathbb{N}^n.$$

For instance, with $n = 6$ and $\alpha := (004020)$, $\mathrm{supp}\,(\alpha) = \{3, 5\}$. Next, define

$$S_k := \{\, \alpha \in \mathbb{N}^n \,:\quad \mathrm{supp}\,(\alpha) \,\in\, \mathcal{I}_k \,\}, \qquad k = 1, \ldots, p. \tag{2.2}$$

A polynomial $h \in \mathbb{R}[X(I_k)]$ can be viewed as a member of $\mathbb{R}[X]$, and is written

$$h(X) \,=\, h(X(I_k)) \,=\, \sum_{\alpha \in S_k} h_\alpha\, X^\alpha \tag{2.3}$$

for some real vector $\mathbf{h} = \{h_\alpha\}$ with finitely many nonzero coefficients.

2.1. Moment matrix. Let $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$ (i.e., a sequence indexed in the canonical basis $v_\infty(X)$), and define the linear functional $L_y : \mathbb{R}[X] \to \mathbb{R}$ to be

$$g \mapsto L_y(g) \,:=\, \sum_{\alpha \in \mathbb{N}^n} g_\alpha\, y_\alpha, \tag{2.4}$$

whenever g is as in (2.1).

As already presented in [11], given a sequence $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$, the *moment* matrix $M_r(y)$ associated with y, is the matrix with rows and columns indexed in $v_r(X)$, and such that

$$M_r(y)(\alpha, \beta) \,:=\, L_y(X^\alpha X^\beta) \,=\, y_{\alpha+\beta} \quad \forall\, \alpha, \beta \in \mathbb{N}^n \text{ with } |\alpha|, |\beta| \le r.$$

A sequence y is said to have a representing measure μ on $\mathbb{R}^n$ if

$$y_\alpha \,=\, \int_{\mathbb{R}^n} X^\alpha\, \mu(dX) \qquad \forall\, \alpha \in \mathbb{N}^n.$$

Let $s(r) := \binom{n+r}{r}$ be the dimension of vector space $\mathbb{R}_r[X]$. For a vector $\mathbf{u} \in \mathbb{R}^{s(r)}$, let $u \in \mathbb{R}[X]$ be the polynomial $u(X) = \langle \mathbf{u}, v_r(X) \rangle$. Then, one has

$$\langle \mathbf{u}, M_r(y)\mathbf{u} \rangle \,=\, L_y(u^2) \qquad \forall\, \mathbf{u} \in \mathbb{R}^{s(r)}.$$

Therefore, if y has a representing measure μ, then

$$\langle \mathbf{u}, M_r(y)\mathbf{u} \rangle \,=\, L_y(u^2) \,=\, \int_{\mathbb{R}^n} u(X)^2\, \mu(dX) \,\ge\, 0,$$

which implies $M_r(y) \succeq 0$ (as $\mathbf{u} \in \mathbb{R}^{s(r)}$ was arbitrary).

Of course, in general, not every sequence y such that $M_r(y) \succeq 0$ for all $r \in \mathbb{N}$ has a representing measure. The $\mathbf{K}$-moment problem is precisely concerned with finding conditions on the sequence y, to ensure it is the moment sequence of some measure μ, with support contained in $\mathbf{K} \subset \mathbb{R}^n$.

2.2. Localizing matrix. Let $h \in \mathbb{R}[X]$ be a given polynomial

$$h(X) \,=\, \sum_{\gamma \in \mathbb{N}^n} h_\gamma \, X^\gamma,$$

and let $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$ be given. The *localizing* matrix $M_r(h\,y)$ associated with h and y is the matrix with rows and columns indexed in $v_r(X)$, obtained from the moment matrix $M_r(y)$ by

$$M_r(h\,y)(\alpha,\beta) \,:=\, L_y(h(X)\,X^\alpha X^\beta) \,=\, \sum_{\gamma \in \mathbb{N}^n} h_\gamma \, y_{\gamma+\alpha+\beta}$$

for all $\alpha, \beta \in \mathbb{N}^n$, with $|\alpha|, |\beta| \le r$.

As before, let $\mathbf{u} \in \mathbb{R}^{s(r)}$, and let $u := \langle \mathbf{u}, v_r(X)\rangle \in \mathbb{R}_r[X]$. Then

$$\langle \mathbf{u}, M_r(h\,y)\mathbf{u}\rangle \,=\, L_y(h\,u^2) \qquad \forall\, \mathbf{u} \in \mathbb{R}^{s(r)},$$

and if y has a representing measure μ with support contained in the set $\{x \in \mathbb{R}^n \,:\, h(x) \ge 0\}$, then

$$\langle \mathbf{u}, M_r(h\,y)\mathbf{u}\rangle \,=\, L_y(h\,u^2) \,=\, \int_{\mathbb{R}^n} h(X)\,u(X)^2\,\mu(dX) \,\ge 0,$$

which implies $M_r(h\,y) \succeq 0$ (as $\mathbf{u} \in \mathbb{R}^{s(r)}$ was arbitrary).

Next, with $k \in \{1,\ldots,p\}$ fixed, and $h \in \mathbb{R}[X(I_k)]$, let $M_r(y, I_k)$ (resp., $M_r(h\,y, I_k)$) be the moment (resp., localizing) submatrix obtained from $M_r(y)$ (resp., $M_r(h\,y)$) by retaining only those rows (and columns) $\alpha \in \mathbb{N}^n$ of $M_r(y)$ (resp., $M_r(h\,y)$) with $\mathrm{supp}\,(\alpha) \in \mathcal{I}_k$.

In doing so, $M_r(y, I_k)$ and $M_r(h\,y, I_k)$ can be viewed as moment and localizing matrices with rows and columns indexed in the canonical basis $v_r(X(I_k))$ of $\mathbb{R}_r[X(I_k)]$. Indeed, $M_r(y, I_k)$ contain only variables y_α with $\mathrm{supp}\,(\alpha) \in \mathcal{I}_k$, and so does $M_r(h\,y, I_k)$ because $h \in \mathbb{R}[X(I_k)]$. And for every polynomial $u \in \mathbb{R}_r[X(I_k)]$, with coefficient vector $\mathbf{u}$ in the basis $v_r(X(I_k))$, we also have

$$\begin{aligned}
\langle \mathbf{u}, M_r(y, I_k)\mathbf{u}\rangle &= L_y(u^2) \qquad \forall\, u \in \mathbb{R}_r[X(I_k)],\\
\langle \mathbf{u}, M_r(h\,y, I_k)\mathbf{u}\rangle &= L_y(h\,u^2) \qquad \forall\, u \in \mathbb{R}_r[X(I_k)],
\end{aligned}$$

and therefore,

$$M_r(y, I_k) \,\succeq\, 0 \Leftrightarrow L_y(u^2) \ge 0 \qquad \forall\, u \in \mathbb{R}_r[X(I_k)], \tag{2.5}$$

$$M_r(h\,y, I_k) \,\succeq\, 0 \Leftrightarrow L_y(h\,u^2) \ge 0 \qquad \forall\, u \in \mathbb{R}_r[X(I_k)]. \tag{2.6}$$

3. Main result. Consider problem **P** as defined in (1.1), and recall that $I_0 = \{1,\ldots,n\} = \bigcup_{k=1}^p I_k$ for some subsets $I_k \subset \{1,\ldots,n\}$, $k = 1,\ldots,p$. The subsets $\{I_k\}$ may be read directly from the data or may have been obtained by some procedure, e.g., the one described in Waki et al. [9].

With $\|x\|_\infty$ (resp., $\|x\|$) denoting the usual sup-norm (resp., Euclidean norm) of a vector $x \in \mathbb{R}^n$, we make the following assumption.

Assumption 1. *Let* $\mathbf{K} \subset \mathbb{R}^n$ *be as in* (1.2). *Then, there is* $M > 0$ *such that* $\|x\|_\infty < M$ *for all* $x \in \mathbf{K}$.

In view of Assumption 1, one has $\|X(I_k)\|^2 \leq n_k M^2$, $k = 1, \ldots, p$, and therefore, in the definition (1.2) of $\mathbf{K}$, we add the p redundant quadratic constraints

$$g_{m+k}(X) := n_k M^2 - \|X(I_k)\|^2 \geq 0, \quad k = 1, \ldots, p, \tag{3.1}$$

and set $m' = m + p$, so that $\mathbf{K}$ is now defined by

$$\mathbf{K} := \{x \in \mathbb{R}^n \mid \quad g_j(x) \geq 0, \quad j = 1, \ldots, m'\}. \tag{3.2}$$

Notice that $g_{m+k} \in \mathbb{R}[X(I_k)]$, for every all $k = 1, \ldots, p$.

Assumption 2. Let $\mathbf{K} \subset \mathbb{R}^n$ be as in (3.2). The index set $J = \{1, \ldots, m'\}$ is partitioned into p disjoint sets J_k, $k = 1, \ldots, p$, and the collections $\{I_k\}$ and $\{J_k\}$ satisfy the following:

(i) For every $j \in J_k$, $g_j \in \mathbb{R}[X(I_k)]$, that is, for every $j \in J_k$, the constraint $g_j(X) \geq 0$ is only concerned with the variables $X(I_k) = \{X_i \mid i \in I_k\}$. Equivalently, viewing g_j as a polynomial in $\mathbb{R}[X]$, $g_{j\alpha} \neq 0 \Rightarrow \mathrm{supp}\,(\alpha) \in \mathcal{I}_k$.

(ii) The objective function $f \in \mathbb{R}[X]$ can be written

$$f = \sum_{k=1}^{p} f_k, \quad \text{with } f_k \in \mathbb{R}[X(I_k)], \quad k = 1, \ldots, p. \tag{3.3}$$

Equivalently, $f_\alpha \neq 0 \Rightarrow \mathrm{supp}\,(\alpha) \in \cup_{k=1}^{p} \mathcal{I}_k$.

(iii) Property (1.3) holds.

As already mentioned, (1.3) always holds when $p \leq 2$.

Example 3.1. When $n = 6$ and $m = 6$, let

$$g_1(X) = X_1X_2 - 1; \quad g_2(X) = X_1^2 + X_2X_3 - 1; \quad g_3(X) = X_2 + X_3^2X_4,$$

and

$$g_4(X) = X_3 + X_5; \quad g_5(X) = X_3X_6; \quad g_6(X) = X_2X_3.$$

Then one may choose $p = 4$ with

$$I_1 = \{1, 2, 3\};\ I_2 = \{2, 3, 4\};\ I_3 = \{3, 5\};\ I_4 = \{3, 6\},$$

and $J_1 = \{1, 2, 6\}, J_2 = \{3\}, J_3 = \{4\}, J_4 = \{4\}$. So in Example 3.1, the objective function $f \in \mathbb{R}[X]$ should be a sum of polynomials in $\mathbb{R}[X_1, X_2, X_3]$, $\mathbb{R}[X_2, X_3, X_4]$, $\mathbb{R}[X_3, X_5]$, and $\mathbb{R}[X_3, X_6]$ (also considered as polynomials in $\mathbb{R}[X_1, \ldots, X_6]$).

Remark 3.1. For every $k = 1, \ldots, p$, let

$$\mathbf{K}_k := \{x \in \mathbb{R}^{n_k} : g_j(x) \geq 0 \quad \forall\, j \in J_k\}. \tag{3.4}$$

For every $k = 1, \ldots, p$, the set $\mathbf{K}_k \subset \mathbb{R}^{n_k}$ satisfies Putinar's condition, that is, there exists $u \in \mathbb{R}[X(I_k)]$ which can be written $u = u_0 + \sum_{l \in J_k} u_l\, g_l$ for some s.o.s. polynomials $\{u_0, u_l\} \subset \mathbb{R}[X(I_k)]$, and such that the level set $\{x \in \mathbb{R}^{n_k} : u \geq 0\}$ is compact. (Take $u = g_{m+k}$.) When satisfied, Putinar's condition has the important consequences stated in Theorem 4.1.

3.1. Convergent SDP-relaxations. For each $j = 1, \ldots, m'$, and depending on its parity, write $\deg g_j = 2r_j - 1$ or $2r_j$. Next, with $2r \geq 2r_0 := \max[\deg f, \max_j 2r_j]$, consider the following SDP:

$$\mathbf{Q}_r : \quad \left\{ \begin{array}{lrl} \inf\limits_{y} & L_y(f) & \\ \text{s.t.} & M_r(y, I_k) \succeq 0, & k = 1, \ldots, p \\ & M_{r-r_j}(g_j\, y, I_k) \succeq 0, & j \in J_k; \quad k = 1, \ldots, p \\ & y_0 = 1, & \end{array} \right. \tag{3.5}$$

where the moment and localizing matrices $M_r(y, I_k)$, $M_r(g_j\, y, I_k)$ have been defined at the end of section 2.2. Denote the optimal value of $\mathbf{Q}_r$ by $\inf \mathbf{Q}_r$, and $\min \mathbf{Q}_r$ if the infimum is attained.

Notice that $\mathbf{Q}_r$ is well defined under Assumption 2(i)–(ii). Assumption 2(iii) is only useful to show convergence in Theorem 3.1 below.

The SDP $\mathbf{Q}_r$ is a relaxation of $\mathbf{P}$. Indeed, with $x \in \mathbb{R}^n$ being a feasible solution of $\mathbf{P}$, the moment vector $y = \{y_\alpha\}$ of the Dirac measure $\mu = \delta_x$ at x is feasible for $\mathbf{Q}_r$, with value $L_y(f) = \int f d\mu = f(x)$.

Under Assumption 2, and from the definition of $M_r(y, k)$ and $M_r(g_j\, y, k)$ in section 2.2, the SDP-relaxation $\mathbf{Q}_r$ contains only variables y_α with α in the set

$$\Gamma_r := \left\{ \alpha \in \mathbb{N}^n : \quad \text{supp}\,(\alpha) \in \bigcup_{k=1}^{p} \mathcal{I}_k\,; \quad |\alpha| \leq 2r \right\}. \tag{3.6}$$

Remark 3.2. (i) Maximality of the I_k''s is not required, i.e., one may have $I_j \subset I_k$ for some pair (j, k). In this case, the LMI constraint $M_r(y, I_j) \succeq 0$ is redundant. However, if nondesirable in theory, in practice it may be more convenient to allow for nonmaximality.

(ii) Comparing with the SDP-relaxations of Waki et al. [9]. When the sets $\{I_k\}$ are just the *cliques* $\{C_k\}$ obtained from the chordal extension of the csp graph as defined in [9], then the SDP-relaxations (3.5) are basically the same as those defined in (32) in [9]. The only difference is in the definition of the feasible set $\mathbf{K}$ of $\mathbf{P}$, where we have now included the p redundant quadratic constraints (3.1). In this case, the SDP-relaxations (3.5) are thus stronger than (32) in [9], because they are more constrained.

In view of the definition of the moment matrix $M_r(y, I_k)$, write

$$M_r(y, I_k) \;=\; \sum_{\alpha \in \mathbb{N}^n} y_\alpha B_\alpha^k, \qquad k = 1, \ldots, p,$$

for appropriate symmetric matrices $\{B_\alpha^k\}$, and notice that for every $k = 1, \ldots, p$, one has $B_\alpha^k = 0$ whenever $\text{supp}\,(\alpha) \notin \mathcal{I}_k$. Similarly, for every $k = 1, \ldots, p$, and $j \in J_k$, write

$$M_{r-r_j}(g_j\, y, I_k) \;=\; \sum_{\alpha \in \mathbb{N}^n} y_\alpha C_\alpha^{jk},$$

for appropriate symmetric matrices $\{C_\alpha^{jk}\}$, and notice that $C_\alpha^{jk} = 0$ whenever $\text{supp}\,(\alpha) \notin \mathcal{I}_k$.

The dual SDP $\mathbf{Q}_r^*$ of $\mathbf{Q}_r$, reads

$$\left\{\begin{array}{ll} \sup\limits_{\Omega_k, Z_{jk}, \lambda} & \lambda \\ \text{s.t.} & \sum\limits_{k:\,\mathrm{supp}\,(\alpha)\in\mathcal{I}_k}\left[\langle\Omega_k, B_\alpha^k\rangle + \sum\limits_{j\in J_k}\langle Z_{jk}, C_\alpha^{jk}\rangle\right] + \lambda\,\delta_{\alpha 0} \;=\; f_\alpha \\ & \forall \alpha \in \Gamma_r \\ & \Omega_k, Z_{jk} \succeq 0, \qquad j \in J_k, \quad k = 1,\ldots,p, \end{array}\right. \tag{3.7}$$

where Γ_r is defined in (3.6) and $\delta_{\alpha 0}$ is the usual Kronecker symbol. From an arbitrary feasible solution $(\lambda, \Omega_k, Z_{jk})$ of $\mathbf{Q}_r^*$, multiplying each side of the constraint in (3.7) with X^α for all $\alpha \in \Gamma_r$, and summing up yields

$$\sum_{\alpha\in\Gamma_r}\left[\sum_{k:\,\mathrm{supp}\,(\alpha)\in\mathcal{I}_k}\left(\langle\Omega_k, B_\alpha^k X^\alpha\rangle + \sum_{j\in J_k}\langle Z_{jk}, C_\alpha^{jk} X^\alpha\rangle\right)\right] \;=\; f(X) - \lambda,$$

which, denoting $\Gamma_{kr} := \{\alpha \in \mathbb{N}^n : \mathrm{supp}\,(\alpha) \in \mathcal{I}_k;\ |\alpha| \le 2r\}$, can be rewritten

$$\sum_{k=1}^{p}\left[\left\langle \Omega_k, \sum_{\alpha\in\Gamma_{kr}} B_\alpha^k X^\alpha\right\rangle + \sum_{j\in J_k}\left\langle Z_{jk}, \sum_{\alpha\in\Gamma_{kr}} C_\alpha^{jk} X^\alpha\right\rangle\right] \;=\; f(X) - \lambda. \tag{3.8}$$

Proceeding as in Lasserre [11], and using the spectral decomposition of matrices $\Omega_k, Z_{jk} \succeq 0$, write

$$\Omega_k = \sum_l \mathbf{q}_{kl}\mathbf{q}_{kl}', \quad Z_{jk} = \sum_t \mathbf{q}_{jkt}\mathbf{q}_{jkt}', \quad j \in J_k, \quad k = 1,\ldots,p,$$

for some vectors $\{\mathbf{q}_{kl}, \mathbf{q}_{jkt}\}$. Next, notice that

$$\sum_{\alpha\in\Gamma_{kr}} B_\alpha^k X^\alpha \;=\; v_r(X(I_k))\, v_r(X(I_k))', \qquad k = 1,\ldots,p \tag{3.9}$$

(recall that $v_r(X(I_k))$ is the canonical basis of $\mathbb{R}_r[X(I_k)]$). Similarly, for every $k = 1,\ldots,p$, and $j \in J_k$,

$$\sum_{\alpha\in\Gamma_{kr}} C_\alpha^{jk} X^\alpha \;=\; g_j(X)\, v_{r-r_j}(X(I_k))\, v_{r-r_j}(X(I_k))'. \tag{3.10}$$

In view of the dimension of the matrix Ω_k (resp., Z_{jk}), one may identify $\mathbf{q}_{kl}$ (resp., $\mathbf{q}_{jkt}$) with the vector of coefficients of a polynomial $q_{kl} \in \mathbb{R}_r[X(I_k)]$ (resp., $q_{jkt} \in \mathbb{R}_{r-r_j}[X(I_k)]$), and so for every l, t

$$\langle v_r(X(I_k)), \mathbf{q}_{kl}\rangle \;=\; q_{kl}(X), \quad k = 1,\ldots,p,$$

$$\langle v_{r-r_j}(X(I_k)), \mathbf{q}_{jkt}\rangle \;=\; q_{jkt}(X), \quad j \in J_k, \quad k = 1,\ldots,p.$$

Combining the latter with (3.8)–(3.10), one may rewrite (3.8) as

$$\sum_{k=1}^{p}\left[\sum_l q_{kl}(X)^2 + \sum_{j\in J_k} g_j(X)\sum_t q_{jkt}(X)^2\right] \;=\; f(X) - \lambda.$$

In other words,

$$f-\lambda \;=\; \sum_{k=1}^{p}\left(\,q_k+\sum_{j\in J_k} q_{jk}\,g_j\,\right), \tag{3.11}$$

for some s.o.s. polynomials $q_k, q_{jk}\in\mathbb{R}[X(I_k)]$, $k=1,\ldots,p$, a *sparse* version of Putinar's representation [16] for the polynomial $f-\lambda$, nonnegative on $\mathbf{K}$.

Finally, in view of what precedes, the dual $\mathbf{Q}_r^*$ also reads

$$\left\{\begin{array}{lll} \sup\limits_{q_k,q_{jk},\lambda} & \lambda & \\ \text{s.t.} & f-\lambda \;=\; \sum\limits_{k=1}^{p}\left(\,q_k+\sum\limits_{j\in J_k} q_{jk}\,g_j\,\right) & \\ & q_k,\,q_{jk}\in\mathbb{R}[X(I_k)] \text{ and s.o.s.}, & j\in J_k,\quad k=1,\ldots,p \\ & \deg q_k,\,\deg q_{jk}g_j\le 2r, & j\in J_k,\quad k=1,\ldots,p. \end{array}\right. \tag{3.12}$$

THEOREM 3.1. *Let* $\mathbf{P}$ *be as defined in* (1.1)*, with global minimum denoted* $\min\mathbf{P}$*, and let Assumptions* 1 *and* 2 *hold. Let* $\{\mathbf{Q}_r\}$ *be the hierarchy of SDP-relaxations defined in* (3.5)*. Then the following hold:*

(a) $\inf\mathbf{Q}_r\uparrow\min\mathbf{P}$ *as* $r\to\infty$.

(b) *If* $\mathbf{K}$ *has a nonempty interior, then there is no duality gap between* $\mathbf{Q}_r$ *and its dual* $\mathbf{Q}_r^*$*, and* $\mathbf{Q}_r^*$ *is solvable for sufficiently large* r*, i.e.,* $\inf\mathbf{Q}_r=\max\mathbf{Q}_r^*$.

(c) *Let* y^r *be a nearly optimal solution of* $\mathbf{Q}_r$*, with, e.g.,*

$$L_{y^r}(f)\;\le\;\inf\mathbf{Q}_r+\frac{1}{r}\qquad\forall\, r\ge r_0,$$

and let $\widehat{y}^r:=\{y^r_\alpha:\;|\alpha|=1\}$*. If* $\mathbf{P}$ *has a unique global minimizer* $x^*\in\mathbf{K}$*, then*

$$\widehat{y}^r\;\to\;x^*\qquad\text{as } r\to\infty. \tag{3.13}$$

For a proof, see section 4.1. Theorem 3.1 establishes convergence of the hierarchy of SDP-relaxations to the global minimum $\min\mathbf{P}$, as well as convergence to a global minimizer $x^*\in\mathbf{K}$ (if unique).

3.2. Computational complexity. The number of variables for the SDP-relaxation $\mathbf{Q}_r$ defined in (3.5) is bounded by $\sum_{k=1}^{p}\binom{n_k+2r}{2r}$, and so, if all n_k's are *close* to each other, say $n_k\approx n/p$ for all k, then one has at most $O(p(\frac{n}{p})^{2r})$ variables, a big saving when compared with $O(n^{2r})$ in the original SDP-relaxations defined in [11] and implemented in [5].

In addition, one also has p LMI constraints of size $O((\frac{n}{p})^r)$ and $m+p$ LMI constraints of size $O((\frac{n}{p})^{r-r'})$ (where $2r'$ is the largest degree of the polynomials g_j's), to be compared with a single LMI constraint of size $O(n^r)$ and m LMI constraints of size $O(n^{r-r'})$ in [5, 11]. So, for instance, when using an interior point method, it is definitely better to handle p LMIs, each of size $(n/p)^r$, rather than a single LMI of size n^r.

For illustration purposes, consider the following elementary example. Let $n = 4$, and consider the optimization problem

$$\mathbf{P}: \quad \begin{cases} \inf\limits_{x} & x_1x_2 + x_1x_3 + x_1x_4 \\ \text{s.t.} & x_1^2 + x_2^2 \le a_{12} \\ & x_1^2 + x_3^2 \le a_{13} \\ & x_1^2 + x_4^2 \le a_{14}. \end{cases}$$

Hence, $I_1 = \{1,2\}$, $I_2 = \{1,3\}$, $I_3 = \{1,4\}$. The first SDP-relaxation $\mathbf{Q}_1$ in the hierarchy is obtained with $r = 1$ and reads

$$\inf_y \; y_{1100} + y_{1010} + y_{1001}$$

$$\begin{bmatrix} 1 & y_{1000} & y_{0100} \\ y_{1000} & y_{2000} & y_{1100} \\ y_{0100} & y_{1100} & y_{0200} \end{bmatrix}, \begin{bmatrix} 1 & y_{1000} & y_{0010} \\ y_{1000} & y_{2000} & y_{1010} \\ y_{0010} & y_{1010} & y_{0020} \end{bmatrix}, \begin{bmatrix} 1 & y_{1000} & y_{0001} \\ y_{1000} & y_{2000} & y_{1001} \\ y_{0001} & y_{1001} & y_{0002} \end{bmatrix} \succeq 0$$

$$a_{12} - y_{2000} - y_{0200} \ge 0;\; a_{13} - y_{2000} - y_{0020} \ge 0;\; a_{14} - y_{2000} - y_{0002} \ge 0.$$

3.3. Extraction of solutions. As for the standard SDP-relaxations of [11], one may also detect global optimality, i.e., when $\min \mathbf{Q}_{s_0} = \min \mathbf{P}$ for some s_0, in which case *finite* convergence occurs, and the SDP-relaxation $\mathbf{Q}_{s_0}$ is said to be *exact*. Recall that for the standard SDP-relaxations [11], one has defined a rank-test to detect finite convergence (see, e.g., Lasserre [12]), as well as an *extraction procedure* (applied to the moment matrix of an exact SDP-relaxation) to obtain one or several global minimizers $x^* \in \mathbb{R}^n$ of $\mathbf{P}$; for more details, see Henrion and Lasserre [5, 6].

For all j,k with $I_{jk} := I_j \cap I_k \neq \emptyset$, denote by $\mathcal{I}_{jk}$ the set of subsets of I_{jk}. Let $M_r(y, I_{jk})$ be the submatrix obtained from $M_r(y, I_j)$ or $M_r(y, I_k)$, by selecting only those rows and columns $\alpha \in \mathbb{N}^n$, with $\operatorname{supp}(\alpha) \in \mathcal{I}_{jk}$ and $|\alpha| \le r$.

THEOREM 3.2. *Let Assumption* 2(i)–(ii) *hold, and let* $\{\mathbf{Q}_r\}$ *be the hierarchy of SDP-relaxations defined in* (3.5). *Let* $a_k := \max_{j \in J_k}[r_j]$, *for all* $k = 1, \ldots, p$, *and assume that* y *is an optimal solution of* $\mathbf{Q}_{s_0}$ *for some* s_0.

The SDP-relaxation $\mathbf{Q}_{s_0}$ *is exact, i.e.,* $\min \mathbf{Q}_{s_0} = \min \mathbf{P}$, *if*

$$\operatorname{rank} M_{s_0}(y, I_k) \;=\; \operatorname{rank} M_{s_0 - a_k}(y, I_k), \qquad k = 1, \ldots, p, \tag{3.14}$$

and if $\operatorname{rank} M_{s_0}(y, I_{jk}) = 1$ *for all pairs* (j,k) *with* $I_j \cap I_k \neq \emptyset$.

Moreover, let $\Delta_k := \{x^*(k)\} \subset \mathbb{R}^{n_k}$ *be a set of solutions obtained from the extraction procedure applied to each moment matrix* $M_{s_0}(y, I_k)$, $k = 1, \ldots, p$. *Then every* $x^* \in \mathbb{R}^n$ *obtained by* $(x_i^*)_{i \in I_k} = x^*(k)$ *for some* $x^*(k) \in \Delta_k$ *is an optimal solution of* $\mathbf{P}$.

For a proof, see section 4.2.

Remark 3.3. In Theorem 3.2, Assumption 2(iii) is not needed. In addition, it also holds even if the SDP-relaxations are defined with the original set $\mathbf{K}$ defined in (1.2) instead of (3.2), i.e., without the additional quadratic constraints (3.1). And so, Theorem 3.2 is also valid for noncompact sets $\mathbf{K}$, provided Assumption 2(i)–(ii) holds true.

3.4. A sparse representation result. As a by-product of Theorem 3.1, we obtain the following representation result.[1]

[1] In a recent note [10], Kojima and Maramatsu have improved Corollary 3.3 and show the same result without assuming that $\mathbf{K}$ has a nonempty interior.

COROLLARY 3.3. *Let* $\mathbf{K}$ *be as in* (3.2) *with the additional quadratic constraints* (3.1)*, and with nonempty interior. Let Assumption* 2 *hold. If* $f \in \mathbb{R}[X]$ *is strictly positive on* $\mathbf{K}$*, then*

$$f = \sum_{k=1}^{p} \left(q_k + \sum_{j \in J_k} q_{jk}\, g_j \right), \tag{3.15}$$

for some s.o.s. polynomials $q_k, q_{jk} \in \mathbb{R}[X(I_k)]$*,* $k = 1, \ldots, p$*.*

Proof. Let $f \in \mathbb{R}[X]$ be strictly positive on $\mathbf{K}$, and let $f^* > 0$ be its global minimum on $\mathbf{K}$. From Theorem 3.1(a)–(b), we have $\inf \mathbf{Q}_r = \max \mathbf{Q}_r^* \uparrow f^*$, as $r \to \infty$. Therefore, let $r \in \mathbb{N}$ be such that $\max \mathbf{Q}_r^* \geq f^*/2 > 0$, and as $\mathbf{Q}_r^*$ is solvable, let (q_k, q_{jk}, λ) be an arbitrary optimal solution, so that $\max \mathbf{Q}_r^* = \lambda > 0$. From that solution, one obtains (3.11), i.e.,

$$f - \lambda = \sum_{k=1}^{p} \left(q_k + \sum_{j \in J_k} q_{jk}\, g_j \right),$$

for some s.o.s. polynomials $q_k, q_{jk} \in \mathbb{R}[X(I_k)]$, $k = 1, \ldots, p$ (associated with the optimal solution (q_k, q_{jk}, λ) of $\mathbf{Q}_r^*$. But then,

$$f = \lambda + \sum_{k=1}^{p} \left(q_k + \sum_{j \in J_k} q_{jk}\, g_j \right)$$

becomes the desired result (by adding $\lambda > 0$ to one of the s.o.s. polynomials q_k). □

Observe that (3.15) is a sparse version of Putinar's representation for polynomials strictly positive on $\mathbf{K}$; see Theorem 4.1. Indeed, (3.15) is a certificate of nonnegativity of f on $\mathbf{K}$. Finally, Corollary 3.3 also holds if $\mathbf{K}$ is such that for every $k = 1, \ldots, p$, $\mathbf{K}_k$ satisfies Putinar's condition (so that there is no need of the quadratic constraints (3.1)).

3.5. Examples. We provide here some examples considered in Waki et al. [9].

Example 3.2. The chained singular function. With n a multiple of 4,

$$I_k = \{k, k+1, k+2, k+3\}, \quad k = 1, \ldots, n-3,$$

and the sparsity pattern satisfies (1.3). One has $\kappa = 4$.

Example 3.3. The Broyden banded function. In this case,

$$I_k = \{k, k+1, \ldots, \min[k+6, n]\}, \quad k = 1, \ldots, n,$$

and the sparsity pattern also satisfies (1.3). One has $\kappa = 7$.

Example 3.4. The Broyden tridiagonal function. In this case

$$I_k = \{k, k+1, \min[n, k+2]\}, \quad k = 1, \ldots, n,$$

and the sparsity pattern also satisfies (1.3). One has $\kappa = 3$.

Example 3.5. The chained Wood function. In this case, with n a multiple of 4,

$$I_k = \{k, k+1, k+2, k+3\}, \quad k = 1, \ldots, n-3,$$

and the sparsity pattern also satisfies (1.3). One has $\kappa = 4$.

Example 3.6. The generalized Rosenbrock function. In this case,

$$I_k = \{k, k-1\}, \quad k = 2, \ldots, n,$$

and the sparsity pattern also satisfies (1.3).

Example 3.7. The optimal control problem (38) considered in [9]. In this case,

$$I_k = \{\{y_{k,j}\}_{j=1}^{n_y}, \{x_{k,l}\}_{l=1}^{n_x}\}, \quad k = 1, \ldots, M-1,$$

$I_M = \{\{y_{M,j}\}_{j=1}^{n_y}\}$, and the sparsity pattern also satisfies (1.3). One has $\kappa = n_x \times n_y$. Example 3.7 is typical of what we call *strong coupling*, always the case in discrete-time optimal control problems. Indeed, the *control* variables at each period are *independent*, whereas the coupling of periods is done through the *state* equations (i.e., the dynamics) and via the *state* variables.

In view of Remark 3.2, the SDP-relaxations (3.5) are stronger than (32) in [9], when the sets $\{I_k\}$ are the same as the cliques $\{C_k\}$ in [9], which is the case in all the previous examples, for which Waki et al. [9] report excellent numerical results; in particular, problems of large size that could not be handled via the standard SDP-relaxations of [11] have been solved relatively easily.

Indeed, for instance, in Examples 3.4, 3.5, and 3.6, they have solved problems with up to $n = 500$ variables, a remarkable result! For the interested reader, more details and numerical results can be found in [9].

4. Proofs. We first restate Putinar's theorem, which is crucial in the proof of Theorem 3.1 below.

THEOREM 4.1 (see Putinar [16]). *Let $\mathbf{K} \subset \mathbb{R}^n$ be a compact basic semialgebraic set as defined in* (1.2)*, and let $y = (y_\alpha)_{\alpha \in \mathbb{N}^n}$ be given. Let $M_r(y)$ and $M_r(g_j\, y)$ be the moment and localizing matrices defined in section* 2*. Assume that there exists $u \in \mathbb{R}[X]$ such that $u = u_0 + \sum_{j=1}^m u_j\, g_j$ for some s.o.s. polynomials $\{u_j\}_{j=0}^m \subset \Sigma^2$, and such that the level set $\{x : u(x) \geq 0\}$ is compact.*

(a) *If $h \in \mathbb{R}[X]$ is strictly positive on $\mathbf{K}$, then $h = h_0 + \sum_{j=1}^m h_j\, g_j$ for some s.o.s. polynomials $\{h_j\}_{j=0}^m \subset \Sigma^2$.*

(b) *If $M_r(y) \succeq 0$ and $M_r(g_j\, y) \succeq 0$ for all $j = 1, \ldots, m$, and all $r = 0, 1, \ldots$, then y has a representing measure μ with support contained in $\mathbf{K}$.*

4.1. Proof of Theorem 3.1. (a) We first prove that $\mathbf{Q}_r$ has a feasible solution. Recall the definitions

$$\begin{aligned}
\Gamma_{kr} &:= \{\, \alpha \in \mathbb{N}^n \,:\, \mathrm{supp}\,(\alpha) \in \mathcal{I}_k; \quad |\alpha| \leq 2r \,\}, \quad k = 1, \ldots, p,\\
\Gamma_r &:= \bigcup_{k=1}^p \Gamma_{kr} \,=\, \left\{ \alpha \in \mathbb{N}^n \,:\, \mathrm{supp}\,(\alpha) \in \bigcup_{k=1}^p \mathcal{I}_k; \quad |\alpha| \leq 2r \right\},\\
\Gamma &:= \bigcup_{r \in \mathbb{N}} \Gamma_r \,=\, \left\{ \alpha \in \mathbb{N}^n \,:\, \mathrm{supp}\,(\alpha) \in \bigcup_{k=1}^p \mathcal{I}_k \right\}.
\end{aligned}$$

Let $\nu := \delta_x$ be the Dirac measure at a feasible solution $x \in \mathbf{K}$ of $\mathbf{P}$, and let

$$y_\alpha = \int X^\alpha\, d\nu \qquad \forall\, \alpha \in \Gamma_r.$$

Recalling the definition of $M_r(y, I_k)$ and $M_{r-r_j}(g_j\, y, I_k)$ in section 2.2, one has $M_r(y, I_k) \succeq 0$ and $M_{r-r_j}(g_j\, y, I_k) \succeq 0$; therefore, y is an obvious feasible solution of $\mathbf{Q}_r$. Next we prove that $\inf \mathbf{Q}_r > -\infty$ for all sufficiently large r.

Recall that $2r_0 \geq \max[\deg f, \max_j \deg r_j]$. In view of Assumption 1 and from the definition of the set $\mathbf{K}_k$ in (3.4), there exists N such that $N \pm X^\alpha > 0$ on $\mathbf{K}_k$ for all $\alpha \in \Gamma_{kr_0}$, and all $k = 1, \ldots, p$. Therefore, for every $k = 1, \ldots, p$ and $\alpha \in \Gamma_{kr_0}$, the polynomial $N \pm X^\alpha$ belongs to the quadratic module $Q_k \subset \mathbb{R}[X(I_k)]$ generated by $\{g_j\}_{j \in J_k} \subset \mathbb{R}[X(I_k)]$, i.e.,

$$Q_k := \left\{ \sigma_0 + \sum_{j \in J_k} \sigma_j \, g_j \; : \quad \sigma_j \text{ s.o.s. in } \in \mathbb{R}[X(I_k)] \quad \forall \, j \in \{0\} \cup J_k \right\}.$$

But there is even some $l(r_0)$ such that $N \pm X^\alpha \in Q_k(l(r_0))$ for all $\alpha \in \Gamma_{kr_0}$ and $k = 1, \ldots, p$, where $Q_k(t) \subset Q_k$ is the set of elements of Q_k which have a representation $\sigma_0 + \sum_{j \in J_k} \sigma_j \, g_j$ for some s.o.s. $\{\sigma_j\} \subset \mathbb{R}[X(I_k)]$ with $\deg \sigma_0 \leq 2t$ and $\deg \sigma_j g_j \leq 2t$ for all $j \in J_k$. Of course we also have $N \pm X^\alpha \in Q_k(l)$ for all $\alpha \in \Gamma_{kr_0}$, whenever $l \geq l(r_0)$. Therefore, let us take $l(r_0) \geq r_0$.

For every feasible solution y of $\mathbf{Q}_{l(r_0)}$ one has

$$| \, L_y(X^\alpha) \, | \leq N, \qquad \alpha \in \Gamma_{kr_0}; \quad k = 1, \ldots, p.$$

This follows from $y_0 = 1$, $M_{l(r_0)}(y, I_k) \succeq 0$ and $M_{l(r_0)-r_j}(g_j \, y, I_k) \succeq 0$, which implies

$$L_y(N \pm X^\alpha) \; = \; L_y(\sigma_0) + \sum_{j \in J_k} L_y(\sigma_j \, g_j) \geq 0$$

because the σ_j's are s.o.s. (see (2.5) and (2.6)).

As $2r_0 \geq \deg f$, it follows that $L_y(f) \geq -N \sum_\alpha |f_\alpha|$. This is because by Assumption 2(ii), $f_\alpha \neq 0 \Rightarrow \alpha \in \Gamma_{r_0}$. Hence $\inf \mathbf{Q}_{l(r_0)} > -\infty$.

So from what precedes, and with $s \in \mathbb{N}$ arbitrary, let $l(s) \geq s$ be such that

$$N_s \pm X^\alpha \in Q_k(l(s)) \qquad \forall \, \alpha \in \Gamma_{ks}; \quad k = 1, \ldots, p, \tag{4.1}$$

for some N_s. Next, let $r \geq l(r_0)$ (so that $\inf \mathbf{Q}_r > -\infty$), and let y^r be a nearly optimal solution of $\mathbf{Q}_r$ with value

$$\inf \mathbf{Q}_r \; \leq \; L_{y^r}(f) \; \leq \; \inf \mathbf{Q}_r + \frac{1}{r} \quad \left(\leq \min \mathbf{P} + \frac{1}{r} \right). \tag{4.2}$$

Fix $s \in \mathbb{N}$. Notice that from (4.1), for all $r \geq l(s)$, one has

$$| \, L_{y^r}(X^\alpha) \, | \; \leq \; N_s \qquad \forall \, \alpha \in \Gamma_s.$$

Therefore, for all $r \geq r_0$,

$$|y^r_\alpha| \; = \; | \, L_{y^r}(X^\alpha) \, | \; \leq \; N'_s \quad \forall \, \alpha \in \Gamma_s, \tag{4.3}$$

where $N'_s = \max[N_s, V_s]$, with

$$V_s := \max \{ |y^r_\alpha| \; : \quad \alpha \in \Gamma_s; \; r_0 \leq r \, < \, l(s) \}.$$

Complete each y^r with zeros to make it an infinite vector in l_∞, indexed in the canonical basis $v_\infty(X)$ of $\mathbb{R}[X]$. Notice that $y^r_\alpha \neq 0$ only if $\alpha \in \Gamma$.

In view of (4.3), one has

$$|y^r_\alpha| \leq N'_s \qquad \forall \, \alpha \in \Gamma; \quad 2s - 1 \leq |\alpha| \leq 2s \tag{4.4}$$

for all $s = 1, 2, \ldots$.

Hence, define the new sequence $\widehat{y}^r \in l_\infty$ defined by $\widehat{y}_0 := 1$, and

$$\widehat{y}^r_\alpha := \frac{y^r_\alpha}{N'_s} \qquad \forall\, \alpha \in \Gamma, \quad 2s-1 \le |\alpha| \le 2s$$

for all $s = 1, 2, \ldots$, and in l_∞, consider the sequence $\{\widehat{y}^r\}$ as $r \to \infty$.

Obviously, the sequence $\{\widehat{y}^r\}$ is in the unit ball B_1 of l_∞, and so, by the Banach–Alaoglu theorem (see, e.g., Ash [1, Thm. 3.5.16]), there exists $\widehat{y} \in B_1$ and a subsequence $\{r_i\}$, such that $\widehat{y}^{r_i} \to \widehat{y}$ as $i \to \infty$ for the weak $\star$ topology $\sigma(l_\infty, l_1)$ of l_∞. In particular, pointwise convergence holds, that is,

$$\lim_{i\to\infty} \widehat{y}^{r_i}_\alpha \to \widehat{y}_\alpha, \qquad \alpha \in \mathbb{N}^n.$$

Notice that $\widehat{y}_\alpha \neq 0$ only if $\alpha \in \Gamma$. Next, define $y_0 := 1$ and

$$y_\alpha := \widehat{y}_\alpha \times N'_s, \quad 2s-1 \le |\alpha| \le 2s, \quad s = 1, 2, \ldots .$$

The pointwise convergence $\widehat{y}^{r_i} \to \widehat{y}$ implies the pointwise convergence $y^{r_i} \to y$, i.e.,

$$\lim_{i\to\infty} y^{r_i}_\alpha \to y_\alpha \qquad \forall\, \alpha \in \Gamma. \tag{4.5}$$

Let $s \in \mathbb{N}$ be fixed. From the pointwise convergence (4.5), we deduce that

$$\lim_{i\to\infty} M_s(y^{r_i}, I_k) \,=\, M_s(y, I_k) \succeq 0, \qquad k = 1, \ldots, p.$$

Similarly

$$\lim_{i\to\infty} M_s(g_j\, y^{r_i}, I_k) \,=\, M_s(g_j\, y, I_k) \succeq 0, \quad j \in J_k, \qquad k = 1, \ldots, p.$$

As s was arbitrary, we obtain that for all $k = 1, \ldots, p$,

$$M_r(y, I_k) \succeq 0; \quad M_r(g_j\, y, I_k) \succeq 0, \quad j \in J_k; \quad r = 0, 1, 2, \ldots . \tag{4.6}$$

Introduce the subsequence y^k obtained from y by

$$y^k := \{\, y_\alpha \,:\, \mathrm{supp}\,(\alpha) \,\in\, \mathcal{I}_k \,\} \qquad \forall\, k = 1, \ldots, p. \tag{4.7}$$

Recall that $M_r(y, I_k)$ (resp., $M_r(g_j\, y, I_k)$) is also the moment matrix $M_r(y^k)$ (resp., the localizing matrix $M_r(g_j\, y^k)$) for the sequence y^k indexed in the canonical basis $v_\infty(X(I_k))$ of $\mathbb{R}[X(I_k)]$; see section 2.2.

Therefore, by Remark 3.1, (4.6) implies that y^k has a representing measure ν_k with support contained in $\mathbf{K}_k$, $k = 1, \ldots, p$; see Theorem 4.1. As $y^k_0 = 1$, ν_k is a probability measure on $\mathbf{K}_k$ for all $k = 1, \ldots, p$.

Next, let j, k be such that $I_{jk} := I_j \cap I_k \neq \emptyset$, and recall that $\mathcal{I}_{jk}$ is the set of all subsets of I_{jk}. Let $m_{jk} := \mathrm{card}\,(I_j \cup I_k)$ and let $n_{jk} := \mathrm{card}\,(I_j \cap I_k)$. Define $\pi_j : \mathbb{R}^{m_{jk}} \to \mathbb{R}^{n_j}$, $\pi_k : \mathbb{R}^{m_{jk}} \to \mathbb{R}^{n_k}$, and $\pi_{jk} : \mathbb{R}^{m_{jk}} \to \mathbb{R}^{n_{jk}}$, the natural projections with respect to the variables $\{X_i \,|\, i \in I_j\}$, $\{X_i \,|\, i \in I_k\}$, and $\{X_i \,|\, i \in I_j \cap I_k\}$, respectively. Let $\mathbf{K}_{j\vee k} \subset \mathbb{R}^{m_{jk}}$ and $\mathbf{K}_{j\wedge k} \subset \mathbf{K}_{j\vee k}$ be the compact sets

$$\mathbf{K}_{j\vee k} := \{\, x \in \mathbb{R}^{m_{jk}} \,:\, \pi_j(x) \,\in\, \mathbf{K}_j; \quad \pi_k(x) \,\in\, \mathbf{K}_k \,\}; \quad \mathbf{K}_{j\wedge k} := \pi_{jk}(\mathbf{K}_{j\vee k}).$$

The probability measures ν_j and ν_k can be understood as probability measures on $\mathbf{K}_{j\vee k}$, supported on $\mathbf{K}_j = \pi_j(\mathbf{K}_{j\vee k})$ and $\mathbf{K}_k = \pi_k(\mathbf{K}_{j\vee k})$, respectively.

Observe that from the definition (4.7) of y^j and y^k, one has

$$y^j_\alpha \,=\, y^k_\alpha \qquad \forall\, \alpha \text{ with } \mathrm{supp}\,(\alpha) \in \mathcal{I}_{jk},$$

and as measures on compact sets are moment determinate, it follows that the marginal probability measures of ν_j and ν_k on $\mathbf{K}_{j\wedge k}$ (i.e., with respect to the variables $X = \{X_i \,|\, i \in I_{jk}\}$) are the *same* probability measure, denoted ν_{jk}. That is,

$$y^k_\alpha \,=\, y^j_\alpha \,=\, \int X^\alpha \, d\nu_{jk} \qquad \forall\, \alpha \text{ with } \mathrm{supp}\,(\alpha) \in \mathcal{I}_{jk}.$$

From Lemma 6.4, there exists a probability measure μ on $\mathbf{K}$, constructed from the ν_k's, and with marginal ν_k on $\mathbf{K}_k$ for all $k = 1, \ldots, p$. In particular, this implies

$$y_\alpha \,=\, \int X^\alpha \, d\mu \qquad \forall\, \alpha \in \Gamma. \tag{4.8}$$

Recall that by Assumption 2, $f_\alpha \neq 0 \Rightarrow \alpha \in \Gamma$, and so $L_y(f) = \int f\, d\mu$. On the other hand, from (4.2) and the pointwise convergence (4.5),

$$\min \mathbf{P} \,\geq\, \lim_{i\to\infty} \inf \mathbf{Q}_{r_i} \,=\, \lim_{i\to\infty} L_{y^{r_i}}(f) \,=\, L_y(f) \,=\, \int f\, d\mu.$$

But as μ is supported on $\mathbf{K}$, we necessarily have $\int f\, d\mu \,\geq\, f^* \,=\, \min \mathbf{P}$, and so $\min \mathbf{P} \,=\, \int f\, d\mu$. Therefore, we have proved that $\lim_{i\to\infty} \inf \mathbf{Q}_{r_i} \,=\, \min \mathbf{P}$, and so $\inf \mathbf{Q}_r \,\uparrow\, \min \mathbf{P}$ follows because the sequence $\{\inf \mathbf{Q}_r\}$ is monotone nondecreasing. This completes the proof of (a).

(b) In the feasible solution ν that we have constructed at the beginning of the proof of (a), choose now ν to be *uniform* on $\mathbf{K}$, and let $y = \{y_\alpha\}_{\alpha\in\mathbb{N}^n}$ be the vector of all its moments, well defined because $\mathbf{K}$ is compact. As $\mathbf{K}$ has a nonempty interior, the probability measure ν satisfies $M_r(y) \succ 0$ and $M_r(g_j y) \succ 0$, for all $j = 1, \ldots, m$, and all $r = 0, 1, \ldots$.

Then, obviously, $M_r(y, I_k) \succ 0$ (resp., $M_r(g_j\, y, I_k) \succ 0$, $j \in J_k$) as a submatrix of $M_r(y) \succ 0$ (resp., $M_r(g_j\, y) \succ 0$), for all $k = 1, \ldots, p$.

Hence, the feasible solution y is now strictly feasible, i.e., Slater's condition holds for $\mathbf{Q}_r$. This implies the absence of a duality gap between $\mathbf{Q}_r$ and its dual $\mathbf{Q}^*_r$, and as $\inf \mathbf{Q}_r > -\infty$ for sufficiently large r, $\mathbf{Q}^*_r$ is solvable, i.e., $\inf \mathbf{Q}_r = \sup \mathbf{Q}^*_r = \max \mathbf{Q}^*_r$. This completes the proof of (b).

(c) Finally, let $x^* \in \mathbf{K}$ be the unique global minimizer of $\mathbf{P}$, and let y^r be as in Theorem 3.1(c). From (a) there exists a subsequence y^{r_i} for which we have the pointwise convergence $y^{r_i} \,\to\, y$ (see (4.5)), where y is the moment sequence of a probability measure μ on $\mathbf{K}$. In particular, (4.8) holds and $\min \mathbf{P} = \int f\, d\mu$. From uniqueness of the global minimizer $x^* \in \mathbf{K}$, it follows that $\mu = \delta_{x^*}$ (the Dirac measure at $x^* \in \mathbf{K}$). But then (4.8) yields

$$\lim_{i\to\infty} y^{r_i}_\alpha \,=\, y_\alpha \,=\, \int X^\alpha \, d\mu \,=\, (x^*)^\alpha \qquad \forall \alpha \in \Gamma.$$

Taking $\alpha \in \Gamma$ with $|\alpha| = 1$ yields $\widehat{y}^{r_i} \,\to\, x^*$, and as the converging subsequence was arbitrary, it follows that the whole sequence $\widehat{y}^r$ converges to $x^* \in \mathbf{K}$, the desired result. □

4.2. Proof of Theorem 3.2. Let $\gamma_k := \operatorname{rank} M_{s_0}(y, I_k)$, $k = 1, \ldots, p$. From (3.14) the vector $y^k = \{y^k_\alpha\}$ defined in (4.7) (with $|\alpha| \le 2s_0$) is the vector of moments (up to order $2s_0$) of a γ_k-atomic probability measure ν_k supported on $\mathbf{K}_k \subset \mathbb{R}^{n_k}$, with $\mathbf{K}_k$ being defined in (3.4), $k = 1, \ldots, p$. This follows from a result of Curto and Fialkow [3, Thm. 1.6] already used in Lasserre [12] to prove finite convergence of SDP-relaxations for 0-1 programs; see also Laurent [14] for a shorter proof of [3, Thm. 1.6], and related comments.

Therefore, when applying the extraction procedure defined in [6] to the moment matrix $M_{s_0}(y^k) = M_{s_0}(y, I_k)$, $k = 1, \ldots, p$, one obtains sets of vectors $\Delta_k := \{x^l(k)\}_{l=1}^{\gamma_k} \subset \mathbf{K}_k$ for all $k = 1, \ldots, p$.

With $\delta_\bullet$ denoting the Dirac measure at $\bullet$, one may thus write

$$\nu_k \;=\; \sum_{l=1}^{\gamma_k} p_{kl}\, \delta_{x^l(k)}, \qquad \text{for some} \qquad p_{kl} > 0 \quad \forall\, l; \quad \sum_{l=1}^{\gamma_k} p_{kl} = 1$$

for all $k = 1, \ldots, p$.

But then, pick *any* solution $x^{l_k}(k) \in \Delta_k$, for some l_k, $k = 1, \ldots, p$, and define $x^* \in \mathbb{R}^n$ to be the vector such that

$$x^*(k) := \{x^*_i\}_{i \in I_k} \;=\; x^{l_k}(k); \quad k = 1, \ldots, p. \tag{4.9}$$

There is no ambiguity for x^*_i when $i \in I_j \cap I_k \neq \emptyset$ for some $j, k \in \{1, \ldots, p\}$, because in this case, from $\operatorname{rank} M_{s_0}(y, I_{jk}) = 1$, we deduce that $y^{jk} = \{y_\alpha\}$ with $\operatorname{supp}(\alpha) \in \mathcal{I}_j \cap \mathcal{I}_k$, is the vector of moments (up to order $2s_0$) of some Dirac measure ν_{jk}. As in the proof of (a), ν_{jk} is the marginal of ν_k and ν_j on $\mathbf{K}_{j \wedge k}$ (i.e., with respect to the variables $\{X_i : i \in I_j \cap I_k\}$), and so the Dirac measure at some point denoted $x(j \wedge k) \in \mathbf{K}_{j \wedge k}$.

Hence, for any two choices $x^{l_j}(j) \in \Delta_j$ and $x^{l_k}(k) \in \Delta_k$, the point $x^* \in \mathbb{R}^n$ defined in (4.9) is in $\mathbf{K}$. We can thus construct $s := \prod_{k=1}^p \gamma_k$ solutions $\{x^\omega\}_{\omega=1}^s \subset \mathbf{K}$, each associated with the probability $p_\omega := \prod_{k=1}^p p_{kl_k}$ if $x^\omega(k) = x^{l_k}(k) \in \Delta_k$, for some $l_k \in \{1, \ldots, \gamma_k\}$, $k = 1, \ldots, p$. But then, by construction, the probability measure μ on $\mathbb{R}^n$, defined by

$$\mu := \sum_{\omega=1}^{s} p_\omega \delta_{x^\omega},$$

is supported on $\mathbf{K}$, and its marginal probability measure on $\mathbf{K}_k$ is ν_k for all $k = 1, \ldots, p$. Therefore,

$$\min \mathbf{P} \;\ge\; \min \mathbf{Q}_{s_0} \;=\; L_y(f) \;=\; \int f\, d\mu \;=\; \sum_{\omega=1}^{s} p_\omega f(x^\omega),$$

which implies that $f(x^\omega) = \min \mathbf{P}$ for all $\omega = 1, \ldots, s$, because $x^\omega \in \mathbf{K}$ for all $\omega = 1, \ldots, s$. Therefore, we have proved that $\min \mathbf{P} = \min \mathbf{Q}_{s_0}$. In addition, each $x^\omega \in \mathbf{K}$ is an optimal solution of $\mathbf{P}$. □

5. Conclusion. We have provided a hierarchy of SDP-relaxations when the polynomial optimization problem $\mathbf{P}$ has some structured sparsity (which can be detected as in Waki et al. [9]). This hierarchy is of the same flavor (in fact a minor modification) as that in Waki et al. [9], for which excellent numerical results have been reported. Our contribution was to prove convergence of the optimal values to

the global minimum of **P** when the sparsity pattern satisfies the condition (1.3), called the *running intersection property* in graph theory, and frequently encountered in practice. Therefore, this result together with [9] opens the door for the applicability of the general approach of SDP-relaxations to medium (and even large) scale polynomial optimization problems, at least when a certain sparsity pattern is present.

6. Appendix. We state some auxiliary results needed in the proof of Theorem 3.1 in section 4.1.

For a topological space Y let $\mathcal{B}(Y)$ denote the usual Borel σ-algebra associated with Y, and let $P(Y)$ denote the space of probability measures on Y. A Borel space is a Borel subset of a complete separable metric space. Let Y, Z be two Borel spaces. A stochastic kernel $q(dy\,|\,z)$ on Y given Z is defined by

- $q(dy\,|\,z) \in P(Y)$ for all $z \in Z$,
- the function $z \mapsto q(B\,|\,z)$ is $\mathcal{B}(Z)$-measurable for all $B \in \mathcal{B}(Y)$.

6.1. Disintegration of a Borel probability measure. The following result states that one may decompose or *disintegrate* a probability measure on a product of Borel spaces into a marginal and a stochastic kernel (also called *conditional probability* when dealing with distributions of random variables).

PROPOSITION 6.1. *Let Y, Z be two Borel spaces, and let μ be a probability measure on $Y \times Z$. Then there exists a probability measure $\nu \in P(Z)$ and a stochastic kernel $q(dy\,|\,z)$ on Y given Z, such that*

$$\mu(A \times B) \;=\; \int_B q(A\,|\,z)\,\nu(dz) \qquad \forall\, A \in \mathcal{B}(Y),\; B \in \mathcal{B}(Z). \tag{6.1}$$

(Proposition 6.1 can be extended to the Cartesian product of an arbitrary number of Borel spaces.) The probability measure ν is called the *marginal* of μ on Z. One also has the converse.

PROPOSITION 6.2. *Let Y, Z be two Borel spaces, and let ν be a probability measure on Z, and $q(dy\,|\,z)$ a stochastic kernel on Y given Z. Then there exists a unique probability measure μ on $Y \times Z$ such that*

$$\mu(A \times B) \;=\; \int_B q(A\,|\,z)\,\nu(dz) \qquad \forall\, A \in \mathcal{B}(Y),\; B \in \mathcal{B}(Z). \tag{6.2}$$

(See, e.g., Ash [1, sect. 6] and Bertsekas and Schreve [2, pp. 139–141].)

Let μ (resp., ν) be a finite Borel probability measure on $\mathbb{R}^n \times \mathbb{R}^m$ (resp., $\mathbb{R}^m \times \mathbb{R}^p$) with all moments $y = (y_{\alpha\beta})_{\alpha\in\mathbb{N}^n,\beta\in\mathbb{N}^m}$ (resp., $z = (z_{\beta\gamma})_{\beta\in\mathbb{N}^m,\gamma\in\mathbb{N}^p}$) finite. Let μ_1 and ν_1 be the respective marginals of μ and ν on $\mathbb{R}^m$, hence with moments

$$\int X^\beta\, d\mu_1(X) \;=\; \int Y^0 X^\beta\, d\mu(Y,X) \;=\; y_{0\beta} \qquad \forall \beta \in \mathbb{N}^m,$$

$$\int X^\beta\, d\nu_1(X) \;=\; \int X^\beta Z^0\, d\mu(X,Z) \;=\; z_{\beta 0} \qquad \forall \beta \in \mathbb{N}^m.$$

If both μ and ν have compact support and $y_{0\beta} = z_{\beta 0}$ for all $\beta \in \mathbb{N}^m$, then $\mu_1 = \nu_1$. This is because measures with compact support are *moment determinate*, i.e., if two measures on a compact subset of $\mathbb{R}^m$ have all same moments, they must coincide.

6.2. Probability measures with given marginals. Case $p = 2$. Let $I_0 := \{1, \ldots, n\}$, and let $I_0 = I_1 \cup I_2$ with $I_1 \cap I_2 \neq \emptyset$. Let $n_k = \operatorname{card} I_k$, for $k = 1, 2$, and $n_{12} = \operatorname{card} I_1 \cap I_2$. For $k = 1, 2$, let $\pi_k : \mathbb{R}^n \to \mathbb{R}^{n_k}$ be the natural projection with respect to I_k, that is,

$$x \mapsto \pi_k(x) = \{x_i \,:\, i \in I_k\}, \qquad x \in \mathbb{R}^n,$$

and let $\pi_{12} : \mathbb{R}^{n_1} \to \mathbb{R}^{n_{12}}$, $\pi_{21} : \mathbb{R}^{n_2} \to \mathbb{R}^{n_{12}}$ be the projections with respect to $I_1 \cap I_2$, that is,

$$\begin{aligned} x &\mapsto \pi_{12}(x) = \{x_i \,:\, i \in I_1 \cap I_2\}, \qquad x \in \mathbb{R}^{n_1}, \\ x &\mapsto \pi_{21}(x) = \{x_i \,:\, i \in I_1 \cap I_2\}, \qquad x \in \mathbb{R}^{n_2}, \end{aligned}$$

and one also extends π_{12} and π_{21} to $\mathbb{R}^n$ in the obvious way.

Next, for $k = 1, 2$, let $\mathbf{K}_k \in \mathcal{B}(\mathbb{R}^{n_k})$ be given, and let $\nu_k \in P(\mathbf{K}_k)$. Denote by ν_{12} and ν_{21} the respective marginals of ν_1 and ν_2 on $\mathbb{R}^{n_{12}}$ (i.e., with respect to the variables $\{X_i,\, i \in I_1 \cap I_2\}$). That is, letting $Z := \mathbb{R}^{n_{12}}$,

$$\begin{aligned} \nu_{12}(B) &= \nu_1(\pi_{12}^{-1}(B) \cap \mathbf{K}_1) \qquad \forall\, B \in \mathcal{B}(Z), \\ \nu_{21}(B) &= \nu_2(\pi_{21}^{-1}(B) \cap \mathbf{K}_2) \qquad \forall\, B \in \mathcal{B}(Z), \end{aligned}$$

and we have

$$\nu_{12}(\pi_{12}(\mathbf{K}_1)) = \nu_{21}(\pi_{21}(\mathbf{K}_2)) = 1. \tag{6.3}$$

Let $\mathbf{K} \subset \mathbb{R}^n$ be the set

$$\mathbf{K} := \{x \in \mathbb{R}^n : \quad \pi_k(x) \in \mathbf{K}_k, \qquad k = 1, 2\}, \tag{6.4}$$

and view the sets $\mathbf{K}_k$, $k = 1, 2$ as naturally embedded in $\mathbb{R}^n$, with $\mathbf{K}_k = \pi_k(\mathbf{K})$, for every $k = 1, 2$.

LEMMA 6.3. *For $k = 1, 2$, let $\mathbf{K}_k \in \mathcal{B}(\mathbb{R}^{n_k})$ be given, and let $\nu_k \in P(\mathbf{K}_k)$ be such that $\nu_{12} = \nu_{21} =: \nu$. Then there exists a probability measure μ on $\mathbf{K}$ with marginals ν_k on $\mathbf{K}_k = \pi_k(\mathbf{K})$, $k = 1, 2$, and marginal ν on $\pi_{12}(\mathbf{K})$.*

Proof. For $k = 1, 2$, let π'_k be the natural projection with respect to $I_k \setminus I_1 \cap I_2$, i.e.,

$$x \mapsto \pi'_k(x) = \{x_i \,:\, i \in I_k \setminus I_1 \cap I_2\}, \quad x \in \mathbb{R}^{n_k},\ k = 1, 2,$$

and define $Y_k \in \mathcal{B}(\mathbb{R}^{n_k - n_{12}})$ to be the Borel set $\{\pi'_k(x) \,:\, x \in \mathbf{K}_k\}$, $k = 1, 2$.

Then, for $k = 1, 2$, one may view ν_k as a probability measure on the Cartesian product $Y_k \times Z$. By Proposition 6.1, and from $\nu_{12} = \nu_{21} =: \nu$, for $k = 1, 2$, one may disintegrate ν_k as

$$\nu_k(A \times B) = \int_B q_k(A \,|\, z)\, \nu(dz) \qquad \forall\, A \in \mathcal{B}(Y_k),\ B \in \mathcal{B}(Z),$$

for some stochastic kernels q_k, $k = 1, 2$. Next, let μ be the measure on $Y_1 \times Z \times Y_2$, defined by

$$\mu(A \times B \times C) = \int_B q_1(A \,|\, z)\, q_2(C \,|\, z)\, \nu(dz),$$

for every Borel rectangle

$$A \times B \times C \in \mathcal{B}(Y_1) \times \mathcal{B}(Z) \times \mathcal{B}(Y_2).$$

Taking $A = Y_1$ yields $q_1(A \,|\, z) = 1$, ν-a.e. and so

$$\mu(Y_1 \times B \times C) = \int_B q_2(C \,|\, z)\, \nu_{12}(dz) = \nu_2(B \times C).$$

Therefore, ν_2 is the marginal of μ on $Z \times Y_2$ (and so on $\mathbf{K}_2$). With similar argument, ν_1 is the marginal of μ on $Y_1 \times Z$ (and so on $\mathbf{K}_1$). Finally, taking $A = Y_1$, $C = Y_2$ and using $q_k(Y_k \,|\, z) = 1$, ν-a.e., yields

$$\mu(Y_1 \times B \times Y_2) = \int_B \nu(dz) = \nu(B),$$

which shows that ν is the marginal of μ on Z, i.e., with respect to the variables X_i, $i \in I_1 \cap I_2$. It remains to prove that $\mu(\mathbf{K}) = 1$. But notice that from the definitions of $\mathbf{K}_1, \mathbf{K}_2$, and ν,

$$q_1(\{\, y \,:\, (y,z) \in \mathbf{K}_1\} \,|\, z) = q_2(\{\, y' \,:\, (z,y') \in \mathbf{K}_2\} \,|\, z) = 1, \qquad \nu\text{-a.e.}$$

So, writing (6.4) as

$$\mathbf{K} = \{(y,z,y') \in \mathbb{R}^n \,:\quad (y,z) \in \mathbf{K}_1\,;\, (z,y') \in \mathbf{K}_2\,\}$$

yields

$$\mu(\mathbf{K}) = \int_Z q_1(\{y \,:\, (y,z) \in \mathbf{K}_1\} \,|\, z)\, q_2(\{y' \,:\, (z,y') \in \mathbf{K}_2\} \,|\, z)\, \nu(dz) = 1.$$

Therefore, ν_k is the marginal of μ on $\mathbf{K}_k = \pi_k(\mathbf{K})$ for $k = 1, 2$, and ν is the marginal of μ on $\pi_{12}(\mathbf{K})$. □

6.3. Probability measures with given marginals. General case. Let I_k, J_k, $k = 1, \ldots, p$, be as in section 2, and let $\mathbf{K} \subset \mathbb{R}^n$ be as defined in (1.2), with $\mathbf{K}_k \subset \mathbb{R}^{n_k}$ as in (3.4), $k = 1, \ldots, p$. Let ν_k be a given probability measure on $\mathbf{K}_k$, $k = 1, \ldots, p$.

Given a set $I \subset I_k$ denote by $X(I)$ the vector of variables $\{X_i\}_{i \in I} \in \mathbb{R}^{|I|}$, and denote by ν_{kI} the marginal of ν_k on $\mathbb{R}^{|I|}$ (i.e., with respect to the variables X_i, $i \in I$), so that ν_k can be disintegrated into $q_k(. \,|\, z) d\nu_{kI}(dz)$ for a stochastic kernel q on $\mathbb{R}^{n_k - |I|}$ given $\mathbb{R}^{|I|}$ (see Proposition 6.1).

We say that the family of probability measures $\{\nu_k\}_{k=1}^p$ is *consistent* with respect to marginals, if whenever $l, k \in \{1, \ldots, p\}$ and $I_k \cap I_l \neq \emptyset$,

$$I \subseteq I_k \cap I_l \Rightarrow \nu_{kI} = \nu_{lI}.$$

Equivalently, when ν_k and ν_l have compact support,

$$\int X^\alpha \, d\nu_k = \int X^\alpha \, d\nu_l \qquad \forall\, \alpha \,:\, \sup(\alpha) \subseteq I_k \cap I_l.$$

For every $k = 1, \ldots, p$, let $W_k := \bigcup_{l=1}^k I_l$, $s_k := |W_k|$, and

$$\Omega_k := \left\{ x \in \mathbb{R}^{s_k} \,|\quad g_j(x) \geq 0, \quad j \in \bigcup_{l=1}^k J_l \right\}. \tag{6.5}$$

Notice that $\Omega_n \equiv \mathbf{K} \subset \mathbb{R}^n$.

LEMMA 6.4. *Let ν_k be a probability measure on $\mathbf{K}_k \subset \mathbb{R}^{n_k}$, $k = 1, \ldots, p$, and assume that the family $\{\nu_k\}_{k=1}^p$ is consistent with respect to marginals. If (1.3) holds, then there is the following:*

(a) *There exists a probability measure μ on $\mathbb{R}^n$ such that ν_k is the marginal of μ with respect to I_k for all $k = 1, \ldots, p$.*

(b) *μ is supported on $\mathbf{K} \subset \mathbb{R}^n$.*

Proof. The proof is by induction on p. With $p = 1$ it is trivial. Let $p = 2$. Observe that the condition (1.3) is automatically satisfied. If $I_1 \cap I_2 = \emptyset$, just let $\mu := \nu_1 \otimes \nu_2$, the product measure on $\mathbf{K}_1 \times \mathbf{K}_2$, i.e.,

$$\mu(A \times B) \,=:\, \nu_1(A)\,\nu_2(B) \qquad \forall\,(A, B) \in \mathcal{B}(\mathbf{K}_1) \times \mathcal{B}(\mathbf{K}_1).$$

If $I_1 \cap I_2 \neq \emptyset$, then the result follows from Lemma 6.3.

Next, suppose that the results holds for $1 \leq m < p$. That is, let Ω_m be as in (6.5), and let ν_k be given probability measures on $\mathbf{K}_k$, $k = 1, \ldots, m$, consistent with marginals, i.e., whenever $l, k \in \{1, \ldots, m\}$, and $I_l \cap I_k \neq \emptyset$,

$$I \subseteq I_k \cap I_l \Rightarrow \nu_{lI} \,=\, \nu_{kI}.$$

Then there exists a probability measure μ_m on Ω_m, such that ν_k is the marginal of μ_m on $\mathbf{K}_k$ (i.e., with respect to the variables X_i, $i \in I_k$), for every $k = 1, \ldots, m$. We next show that it holds true for $m + 1$.

Set $\Delta := I_{m+1} \cap W_m$. If $\Delta = \emptyset$, then just take $\mu_{m+1} := \mu_m \otimes \nu_{m+1}$, the product measure on $\Omega_m \times \mathbf{K}_{m+1}$, and the induction is trivially satisfied for $m+1$. (As $\Delta = \emptyset$, one has $\Omega_{m+1} = \Omega_m \times \mathbf{K}_{m+1}$.)

Consider the case $\Delta \neq \emptyset$, and let $\delta := |\Delta|$, $s_{m+1} := |W_{m+1}|$. Let $\pi_\Delta : \Omega_m \to \mathbb{R}^\delta$, and $\pi'_\Delta : \mathbf{K}_{m+1} \to \mathbb{R}^\delta$ be the natural projection with respect to the variables X_i, $i \in \Delta$. Similarly, let $\pi_{\Delta^c} : \Omega_m \to \mathbb{R}^{s_m - \delta}$, and $\pi'_{\Delta^c} : \mathbf{K}_{m+1} \to \mathbb{R}^{n_{m+1} - \delta}$ be the natural projections with respect to the variables X_i, $i \in W_m \setminus \Delta$, and X_i, $i \in I_{m+1} \setminus \Delta$, respectively. So consider μ_m and ν_{m+1} as probability measures on the Borel spaces

$$Y \times Z \,:=\, \pi_{\Delta^c}(\Omega_m) \times \pi_\Delta(\Omega_m), \quad \text{and} \quad Z' \times Y' \,:=\, \pi'_\Delta(\mathbf{K}_{m+1}) \times \pi'_{\Delta^c}(\mathbf{K}_{m+1}),$$

respectively. Next, consider the marginals $\mu_{m\Delta}$ and $\nu_{(m+1)\Delta}$ of μ_m and ν_{m+1} on Z and Z', respectively, and the corresponding disintegrations,

$$\mu_m \,=\, q_m(.\,|\,z)\,\mu_{m\Delta}(dz)\,; \quad \nu_{m+1} \,=\, q'_m(.\,|\,z)\,\nu_{(m+1)\Delta}(dz).$$

From (1.3), $\Delta \subseteq I_s$ for some $s \in \{1, \ldots, m\}$. Therefore, $\nu_{(m+1)\Delta} = \nu_{s\Delta}$ because $\{\nu_k\}_{k=1}^{m+1}$ are consistent with marginals, and $\mu_{m\Delta} = \nu_{s\Delta} =: \nu$ by the induction hypothesis. Hence, one may take $Z = Z'$, and notice that

$$q_m(Y\,|\,z) \,=\, q'_m(Y'\,|\,z) \,=\, 1, \quad \nu\text{-a.e.} \tag{6.6}$$

Then define the probability measure μ_{m+1} on $Y \times Z \times Y' \subset \mathbb{R}^{s_{m+1}}$ by

$$\mu_{m+1}(A \times B \times C) \,:=\, \int_B q_m(A\,|z)\,q'_m(C\,|z)\,\nu(dz), \tag{6.7}$$

for all Borel rectangles $A \times B \times C \in \mathcal{B}(Y) \times \mathcal{B}(Z) \times \mathcal{B}(Y')$.

We claim that μ_{m+1} has the required properties of the induction hypothesis. First consider the marginal $\mu_{(m+1)I_{m+1}}$ of μ_{m+1} on $Z \times Y'$. It is obtained from (6.7) with $A = Y$. But from (6.6),

$$\begin{aligned}\mu_{(m+1)I_{m+1}}(B \times C) \;=\; \mu_{m+1}(Y \times B \times C) &= \int_B q'_m(C\,|z)\,\nu(dz)\\ &= \int_B q'_m(C\,|z)\,\nu_{(m+1)\Delta}(dz)\\ &= \nu_{m+1}(B \times C)\end{aligned}$$

for all $B \times C$ in $\mathcal{B}(Z) \times \mathcal{B}(Y')$, which proves that $\mu_{(m+1)I_{m+1}} = \nu_{m+1}$, the desired result. Next, consider the marginal $\mu_{(m+1)W_m}$ of μ_{m+1} with respect to the variables X_i, $i \in W_m$. It is obtained from (6.7) with $C = Y'$. So, using (6.6) again,

$$\begin{aligned}\mu_{(m+1)W_m}(A \times B) \;=\; \mu_{m+1}(A \times B \times Y') &= \int_B q_m(A\,|z)\,\nu(dz)\\ &= \int_B q_m(A\,|z)\,\mu_{m\Delta}(dz)\\ &= \mu_m(A \times B)\end{aligned}$$

for all $A \times B$ in $\mathcal{B}(Y) \times \mathcal{B}(Z)$, which proves that $\mu_{(m+1)W_m} = \mu_m$. But then, $\mu_{(m+1)I_k} = \mu_{mI_k}$ for all $k \le m$, and so, by the induction hypothesis, $\mu_{(m+1)I_k} = \mu_{mI_k} = \nu_k$ for all $k \le m$.

Hence, we have constructed a probability measure μ_{m+1} on $Y \times Z \times Y'$, such that for all $k = 1, \ldots, m+1$, ν_k is the marginal of $\mu_{(m+1)I_k}$ with respect to the variables X_i, $i \in I_k$. It remains to show that $\mu_{m+1}(\Omega_{m+1}) = 1$.

But from the definition of $\mathbf{K}_{m+1}$, Y', ν, and $\nu_{m+1}(\mathbf{K}_{m+1}) = 1$,

$$q'_m(B(z)\,|\,z) = 1 \quad \nu\text{-a.e. with } B(z) := \{y \,:\, g_j(z,y) \ge 0\;\forall\, j \in J_{m+1}\}.$$

Similarly, from the definitions of Ω_m, Y, ν, and $\mu_m(\Omega_m) = 1$,

$$q_m(A(z)\,|\,z) = 1 \quad \nu\text{-a.e. with } A(z) := \{y \,:\, g_j(y,z) \ge 0\;\forall\, j \in \cup_{k=1}^m J_k\}.$$

Therefore, (6.7), together with the definition (6.5) of Ω_{m+1}, yields

$$\mu_{m+1}(\Omega_{m+1}) \;=\; \int_Z q_m(A(z)\,|\,z)\,q'_m(B(z)\,|\,z) \times \nu(dz) \;=\; 1.$$

Therefore, the induction hypothesis is also true for $m+1$.

(b) From $\mu(\Omega_n) = 1$, and $\Omega_n = \mathbf{K}$, we obtain $\mu(\mathbf{K}) = 1$, the desired result. □

Acknowledgments. The author is indebted to Professor M. Kojima for very interesting and helpful discussions on the topic of sparse SDP-relaxations. He also wishes to thank T. Netzer and M. Schweighofer from Konstanz University (Germany), who indicated a way to simplify the original SDP-relations of the author in an earlier version, so as to yield the SDP-relaxations of this paper. Finally, the author wishes to thank anonymous referees for helpful remarks and suggestions to improve the initial version of the paper.

STRONG DUALITY IN NONCONVEX QUADRATIC OPTIMIZATION WITH TWO QUADRATIC CONSTRAINTS*

AMIR BECK† AND YONINA C. ELDAR‡

Abstract. We consider the problem of minimizing an indefinite quadratic function subject to two quadratic inequality constraints. When the problem is defined over the complex plane we show that strong duality holds and obtain necessary and sufficient optimality conditions. We then develop a connection between the image of the real and complex spaces under a quadratic mapping, which together with the results in the complex case lead to a condition that ensures strong duality in the *real* setting. Preliminary numerical simulations suggest that for random instances of the extended trust region subproblem, the sufficient condition is satisfied with a high probability. Furthermore, we show that the sufficient condition is always satisfied in two classes of nonconvex quadratic problems. Finally, we discuss an application of our results to robust least squares problems.

Key words. quadratic programming, nonconvex optimization, strong duality, quadratic mappings

1. Introduction.

In this paper we consider quadratic minimization problems with two quadratic constraints both in the real and the complex domain:

$$(QP_{\mathbb{C}}) \quad \min_{\boldsymbol{z}\in\mathbb{C}^n} \{f_0(\boldsymbol{z}) : f_1(\boldsymbol{z}) \geq 0, f_2(\boldsymbol{z}) \geq 0\}, \tag{1}$$

$$(QP_{\mathbb{R}}) \quad \min_{\boldsymbol{x}\in\mathbb{R}^n} \{f_0(\boldsymbol{x}) : f_1(\boldsymbol{x}) \geq 0, f_2(\boldsymbol{x}) \geq 0\}. \tag{2}$$

In the real case each function $f_j : \mathbb{R}^n \to \mathbb{R}$ is defined by $f_j(\boldsymbol{x}) = \boldsymbol{x}^T\boldsymbol{A}_j\boldsymbol{x} + 2\boldsymbol{b}_j^T\boldsymbol{x} + c_j$ with $\boldsymbol{A}_j = \boldsymbol{A}_j^T \in \mathbb{R}^{n\times n}, \boldsymbol{b}_j \in \mathbb{R}^n$, and $c_j \in \mathbb{R}$. In the complex setting, $f_j : \mathbb{C}^n \to \mathbb{R}$ is given by $f_j(\boldsymbol{z}) = \boldsymbol{z}^*\boldsymbol{A}_j\boldsymbol{z} + 2\Re(\boldsymbol{b}_j^*\boldsymbol{z}) + c_j$, where $\boldsymbol{A}_j = \boldsymbol{A}_j^*$ are Hermitian matrices, $\boldsymbol{b}_j \in \mathbb{C}^n$, and $c_j \in \mathbb{R}$. The problem $(QP_{\mathbb{R}})$ appears as a subproblem in some trust region algorithms for constrained optimization [6, 10, 26] where the original problem is to minimize a general nonlinear function subject to equality constraints. The subproblem, often referred to as the *two trust region problem* [1] or the *extended trust region problem* [35], has the form

$$(TTRS) \quad \min_{\boldsymbol{x}\in\mathbb{R}^n} \left\{\boldsymbol{x}^T\boldsymbol{B}\boldsymbol{x} + 2\boldsymbol{g}^T\boldsymbol{x} : \|\boldsymbol{x}\| \leq \Delta, \|\boldsymbol{A}^T\boldsymbol{x} + \boldsymbol{c}\| \leq \xi\right\}. \tag{3}$$

More details on trust region algorithms can be found in [8, 23, 36, 37, 10]. A simpler (nonconvex) quadratic problem than (TTRS) is the *trust region subproblem*, which appears in trust region algorithms for *unconstrained* optimization:

$$(TR) \quad \min_{\boldsymbol{x}\in\mathbb{R}^n} \{\boldsymbol{x}^T\boldsymbol{B}\boldsymbol{x} + 2\boldsymbol{g}^T\boldsymbol{x} : \|\boldsymbol{x}\|^2 \leq \delta\}. \tag{4}$$

‡Department of Electrical Engineering, Technion—Israel Institute of Technology, Haifa 32000, Israel (yonina@ee.technion.ac.il).

Problem (TR) has been studied extensively in the literature; see, e.g., [5, 12, 20, 21, 22, 30, 31] and references therein; it enjoys many useful and attractive properties. In particular, it is known that (TR) admits no duality gap and that the semidefinite relaxation (SDR) of (TR) is tight. Moreover, the solution of (TR) can be extracted from the dual solution. A necessary and sufficient condition for $\bar{\boldsymbol{x}}$ to be optimal for (TR) is that there exists $\bar{\alpha} \geq 0$ such that [15, 30]

$$(\boldsymbol{B} + \bar{\alpha}\boldsymbol{I})\bar{\boldsymbol{x}} + \boldsymbol{g} = \boldsymbol{0}, \tag{5}$$

$$\|\bar{\boldsymbol{x}}\|^2 \leq \delta, \tag{6}$$

$$\bar{\alpha}(\|\bar{\boldsymbol{x}}\|^2 - \delta) = 0, \tag{7}$$

$$\boldsymbol{B} + \bar{\alpha}\boldsymbol{I} \succeq \boldsymbol{0}. \tag{8}$$

Unfortunately, in general these results cannot be extended to the (TTRS) problem, or to ($QP_{\mathbb{R}}$). Indeed, it is known that the SDR of ($QP_{\mathbb{R}}$) is not necessarily tight [35, 36]. An exception is when the functions f_0, f_1, f_2 are homogeneous quadratic functions and there exists a positive definite linear combination of the matrices $\boldsymbol{A}_j$ [35]. Another interesting result obtained in [35], based on the dual cone representation approach [33], is that if f_1 is concave and f_2 is linear, then, although the SDR is *not necessarily tight*, ($QP_{\mathbb{R}}$) can be solved efficiently.

If the original nonlinear constrained problem has complex variables, then instead of ($QP_{\mathbb{R}}$) one should consider the complex variant ($QP_{\mathbb{C}}$). Optimization problems with complex variables appear naturally in many engineering applications. For example, if the estimation problem is posed in the Fourier domain, then typically the parameters to be estimated will be complex [24, 28]. In the context of digital communications, many signal constellations are modelled as complex valued. Another area where complex variables naturally arise is narrowband array processing [9].

Of course, every complex quadratic problem of dimension n can be written as a *real* quadratic problem of dimension $2n$ by decomposing the complex vector $\boldsymbol{z}$ as $\boldsymbol{z} = \boldsymbol{x} + i\boldsymbol{y}$, where $\boldsymbol{x} = \Re(\boldsymbol{z})$ and $\boldsymbol{y} = \Im(\boldsymbol{z})$ are real. Then $f_j(\boldsymbol{z})$ can be written as $f_j(\boldsymbol{z}) = \boldsymbol{w}^T\mathbf{Q}_j\boldsymbol{w} + 2\boldsymbol{d}_j^T\boldsymbol{w} + c_j$, with

$$\boldsymbol{w} = \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{y} \end{pmatrix} \in \mathbb{R}^{2n}, \mathbf{Q}_j = \begin{pmatrix} \Re(\boldsymbol{A}_j) & -\Im(\boldsymbol{A}_j) \\ \Im(\boldsymbol{A}_j) & \Re(\boldsymbol{A}_j) \end{pmatrix}, \boldsymbol{d} = \begin{pmatrix} \Re(\boldsymbol{b}_j) \\ \Im(\boldsymbol{b}_j) \end{pmatrix}.$$

However, the opposite claim is false: not every real quadratic problem of dimension $2n$ can be formulated as an n-dimensional complex quadratic problem. Evidently, the family of complex quadratic problems is a special case of real quadratic problems. *Why then consider the complex setting separately?* The answer to this question is that, as we shall see, there are stronger results for complex problems than for their real counterparts (cf. section 2).

In this paper we discuss both the complex and real settings. Our interest in the complex case is two-fold: First, as noted above, in certain applications we naturally deal with complex variables. Second, our derivations in the complex setting will serve as a basis for the results in the real case. In section 2, we use an extended version of the S-lemma [13] to show that under some mild conditions strong duality holds for the complex valued problem ($QP_{\mathbb{C}}$) and that the SDR is tight. We then develop optimality conditions similar to those known for the TR problem (4), and present a method for calculating the optimal solution of ($QP_{\mathbb{C}}$) from the dual solution. Thus, all the results known for (TR) can essentially be extended to ($QP_{\mathbb{C}}$). Section 3 treats the real setting. After a discussion of the complex relaxation of ($QP_{\mathbb{R}}$), which is an

alternative lifting procedure to the popular SDP relaxation, we present a sufficient condition that ensures zero duality gap (and tightness of the SDR) for $(QP_{\mathbb{R}})$. Our result is based on the connection between the image of the real and complex spaces under a quadratic mapping. The advantage of our condition is that it is expressed via the dual optimal solution and therefore can be validated in polynomial-time. Furthermore, this condition can be used to establish strong duality in some general classes of problems. As we show, an example where a problem of this form arises naturally is in robust least squares design where the uncertainty set is described by two norm constraints. In addition, preliminary numerical experiments suggest that for random instances of the TTRS problem (3), our condition is often satisfied.

Throughout the paper, the following notation is used: For simplicity, instead of inf/sup we use min/max; however, this does not mean that we assume that the optimum is attained and/or finite. Vectors are denoted by boldface lowercase letters; e.g., $\boldsymbol{y}$, and matrices by boldface uppercase letters; e.g., $\boldsymbol{A}$. For two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$, $\boldsymbol{A} \succ \boldsymbol{B}$ ($\boldsymbol{A} \succeq \boldsymbol{B}$) means that $\boldsymbol{A} - \boldsymbol{B}$ is positive definite (semidefinite). $\mathcal{S}_+^n = \{\boldsymbol{A} \in \mathbb{R}^{n\times n} : \boldsymbol{A} \succeq \boldsymbol{0}\}$ is the set all real valued $n \times n$ symmetric positive semidefinite matrices and $\mathcal{H}_n^+ = \{\boldsymbol{A} \in \mathbb{C}^{n\times n} : \boldsymbol{A} \succeq \boldsymbol{0}\}$ is the set of all complex valued $n \times n$ Hermitian positive semidefinite matrices. $\boldsymbol{I}_n$ is the identity matrix of order n. The real and imaginary part of scalars, vectors, or matrices are denoted by $\Re(\cdot)$ and $\Im(\cdot)$. The value of the optimal objective function of an optimization problem

$$(\mathrm{P}) : \min / \max\{f(\boldsymbol{x}) : \boldsymbol{x} \in C\}$$

is denoted by val(P). We use some standard abbreviations such as SDP (semidefinite programming), SDR (semidefinite relaxation), and LMI (linear matrix inequalities).

2. The complex case. We begin by treating the complex valued problem $(QP_{\mathbb{C}})$. Using an extended version of the S-lemma we prove a strong duality result, and then develop necessary and sufficient optimality conditions, similar to those known for the TR problem (4) (conditions (5)–(8)). Finally, we discuss how to extract a solution for $(QP_{\mathbb{C}})$, given a dual optimal point.

2.1. Strong duality for $(QP_{\mathbb{C}})$. The fact that strong duality in (nonconvex) quadratic optimization problems is equivalent in some sense to the existence of a corresponding S-lemma has already been exhibited by several authors [13, 25]. For example, strong duality for quadratic problems with a single constraint can be shown to follow from the nonhomogeneous S-lemma [13], which states that if there exists $\bar{\boldsymbol{x}} \in \mathbb{R}^n$ such that $\bar{\boldsymbol{x}}^T\boldsymbol{A}_2\bar{\boldsymbol{x}} + 2\boldsymbol{b}_2^T\bar{\boldsymbol{x}} + c_2 > 0$, then the following two conditions are equivalent:

1. $\boldsymbol{x}^T\boldsymbol{A}_1\boldsymbol{x} + 2\boldsymbol{b}_1^T\boldsymbol{x} + c_1 \geq 0$ for every $\boldsymbol{x} \in \mathbb{R}^n$ such that $\boldsymbol{x}^T\boldsymbol{A}_2\boldsymbol{x} + 2\boldsymbol{b}_2^T\boldsymbol{x} + c_2 \geq 0$.
2. There exists $\lambda \geq 0$ such that

$$\begin{pmatrix} \boldsymbol{A}_1 & \boldsymbol{b}_1 \\ \boldsymbol{b}_1^T & c_1 \end{pmatrix} \succeq \lambda \begin{pmatrix} \boldsymbol{A}_2 & \boldsymbol{b}_2 \\ \boldsymbol{b}_2^T & c_2 \end{pmatrix}.$$

Generalizations of the S-lemma in the real case are in general not true. For example, the natural extension to the case of two quadratic inequalities that imply a third quadratic inequality does not hold in general (see the example in [4]). However, the following theorem of Fradkov and Yakubovich [13, Theorem 2.2] extends the S-lemma to the complex case. This result will be the key ingredient in proving strong duality.

THEOREM 2.1 (extended S-lemma [13]). *Let*

$$f_j(\boldsymbol{z}) = \boldsymbol{z}^*\boldsymbol{A}_j\boldsymbol{z} + 2\Re(\boldsymbol{b}_j^*\boldsymbol{z}) + c_j, \quad \boldsymbol{z} \in \mathbb{C}^n, j = 0, 1, 2,$$

where $\boldsymbol{A}_j$ *are* $n \times n$ *Hermitian matrices,* $\boldsymbol{b}_j \in \mathbb{C}^n$*, and* $c_j \in \mathbb{R}$*. Suppose that there exists* $\tilde{\boldsymbol{z}} \in \mathbb{C}^n$ *such that* $f_1(\tilde{\boldsymbol{z}}) > 0, f_2(\tilde{\boldsymbol{z}}) > 0$*. Then the following two claims are equivalent:*

1. $f_0(\boldsymbol{z}) \geq 0$ *for every* $\boldsymbol{z} \in \mathbb{C}^n$ *such that* $f_1(\boldsymbol{z}) \geq 0$ *and* $f_2(\boldsymbol{z}) \geq 0$*.*
2. *There exists* $\alpha, \beta \geq 0$ *such that*

$$\begin{pmatrix} \boldsymbol{A}_0 & \boldsymbol{b}_0 \\ \boldsymbol{b}_0^* & c_0 \end{pmatrix} \succeq \alpha \begin{pmatrix} \boldsymbol{A}_1 & \boldsymbol{b}_1 \\ \boldsymbol{b}_1^* & c_1 \end{pmatrix} + \beta \begin{pmatrix} \boldsymbol{A}_2 & \boldsymbol{b}_2 \\ \boldsymbol{b}_2^* & c_2 \end{pmatrix}.$$

The Lagrangian dual of $(QP_{\mathbb{C}})$ can be shown to have the following form:[1]

$$(D_{\mathbb{C}}) \quad \max_{\alpha \geq 0, \beta \geq 0, \lambda} \left\{ \lambda \;\middle|\; \begin{pmatrix} \boldsymbol{A}_0 & \boldsymbol{b}_0 \\ \boldsymbol{b}_0^* & c_0 - \lambda \end{pmatrix} \succeq \alpha \begin{pmatrix} \boldsymbol{A}_1 & \boldsymbol{b}_1 \\ \boldsymbol{b}_1^* & c_1 \end{pmatrix} + \beta \begin{pmatrix} \boldsymbol{A}_2 & \boldsymbol{b}_2 \\ \boldsymbol{b}_2^* & c_2 \end{pmatrix} \right\}. \tag{9}$$

Problem $(D_{\mathbb{C}})$ is sometimes called Shor's relaxation [29]. Theorem 2.2 states that if problem $(QP_{\mathbb{C}})$ is finite and strictly feasible, then $\mathrm{val}(QP_{\mathbb{C}}) = \mathrm{val}(D_{\mathbb{C}})$.

THEOREM 2.2 (strong duality for complex valued quadratic problems). *Suppose that problem* $(QP_{\mathbb{C}})$ *is strictly feasible, i.e., there exists* $\tilde{\boldsymbol{z}} \in \mathbb{C}^n$ *such that* $f_1(\tilde{\boldsymbol{z}}) > 0, f_2(\tilde{\boldsymbol{z}}) > 0$*. If val*$(QP_{\mathbb{C}})$ *is finite, then the maximum of problem* $(D_{\mathbb{C}})$ *is attained and val*$(QP_{\mathbb{C}}) =$ *val*$(D_{\mathbb{C}})$*.*

Proof. Since $\mathrm{val}(QP_{\mathbb{C}})$ is finite then clearly

$$\mathrm{val}(QP_{\mathbb{C}}) = \max_{\lambda} \{\lambda : \mathrm{val}(QP_{\mathbb{C}}) \geq \lambda\}. \tag{10}$$

Now, the statement $\mathrm{val}(QP_{\mathbb{C}}) \geq \lambda$ holds true if and only if the implication

$$f_1(\boldsymbol{z}) \geq 0, f_2(\boldsymbol{z}) \geq 0 \Rightarrow f_0(\boldsymbol{z}) \geq \lambda$$

is valid. By Theorem 2.1 this is equivalent to

$$\exists \alpha, \beta \geq 0 \quad \begin{pmatrix} \boldsymbol{A}_0 & \boldsymbol{b}_0 \\ \boldsymbol{b}_0^* & c_0 - \lambda \end{pmatrix} \succeq \alpha \begin{pmatrix} \boldsymbol{A}_1 & \boldsymbol{b}_1 \\ \boldsymbol{b}_1^* & c_1 \end{pmatrix} + \beta \begin{pmatrix} \boldsymbol{A}_2 & \boldsymbol{b}_2 \\ \boldsymbol{b}_2^* & c_2 \end{pmatrix}. \tag{11}$$

Therefore, by replacing the constraint in (10) with the LMI (11), we obtain that $\mathrm{val}(QP_{\mathbb{C}}) = \mathrm{val}(D_{\mathbb{C}})$. The maximum of $(D_{\mathbb{C}})$ is attained at $(\bar{\lambda}, \bar{\alpha}, \bar{\beta})$, where $\bar{\lambda}$ is the (finite) value $\mathrm{val}(QP_{\mathbb{C}})$ and $\bar{\alpha}, \bar{\beta}$ are the corresponding nonnegative constants that satisfy the LMI (11) for $\lambda = \bar{\lambda}$. ∎

One referee pointed us to a recent related paper [18] from June 2005, which was posted to a web site after we submitted our paper. In [18], the strong duality result of Theorem 2.2 is derived by using an interesting new rank-one decomposition, while our proof is a direct consequence of the classical extended S-lemma of Fradkov and Yakubovich.

It is interesting to note that the dual problem to $(D_{\mathbb{C}})$ is the so-called SDR of $(QP_{\mathbb{C}})$:

$$(SDR_{\mathbb{C}}) \quad \min_{\boldsymbol{Z}} \{\mathrm{Tr}(\boldsymbol{Z}\boldsymbol{M}_0) : \mathrm{Tr}(\boldsymbol{Z}\boldsymbol{M}_1) \geq 0, \mathrm{Tr}(\boldsymbol{Z}\boldsymbol{M}_2) \geq 0, Z_{n+1,n+1} = 1, \boldsymbol{Z} \in \mathcal{H}_{n+1}^+\}, \tag{12}$$

where

$$\boldsymbol{M}_j = \begin{pmatrix} \boldsymbol{A}_j & \boldsymbol{b}_j \\ \boldsymbol{b}_j^* & c_j \end{pmatrix}.$$

[1] This formulation can be found in [34].

By the conic duality theorem (see, e.g., [4]), it follows that if both problems $(QP_{\mathbb{C}})$ and $(D_{\mathbb{C}})$ are strictly feasible, then they attain their solutions and $\mathrm{val}(QP_{\mathbb{C}}) = \mathrm{val}(D_{\mathbb{C}}) = \mathrm{val}(SDR_{\mathbb{C}})$. Finally, we note that strict feasibility of the dual problem $(D_{\mathbb{C}})$ is equivalent to saying that there exist $\tilde{\alpha} \geq 0, \tilde{\beta} \geq 0$ such that $\boldsymbol{A}_0 \succ \tilde{\alpha}\boldsymbol{A}_1 + \tilde{\beta}\boldsymbol{A}_2$. This condition is automatically satisfied when at least one of the constraints or the objective function is strictly convex (see also [35, Proposition 2.1]), an assumption that is true in many practical scenarios, for example in the TTRS problem (3).

2.2. Optimality conditions. Theorem 2.3 will be very useful in section 2.3, where a method for extracting the optimal solution of $(QP_{\mathbb{C}})$ from the optimal dual solution of $(D_{\mathbb{C}})$ will be described.

THEOREM 2.3. *Suppose that both problems $(QP_{\mathbb{C}})$ and $(D_{\mathbb{C}})$ are strictly feasible, and let $(\bar{\alpha}, \bar{\beta}, \bar{\lambda})$ be an optimal solution of $(D_{\mathbb{C}})$. Then $\bar{\boldsymbol{z}}$ is an optimal solution of $(QP_{\mathbb{C}})$ if and only if*

$$(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)\bar{\boldsymbol{z}} + \boldsymbol{b}_0 - \bar{\alpha}\boldsymbol{b}_1 - \bar{\beta}\boldsymbol{b}_2 = \boldsymbol{0}, \tag{13}$$

$$f_1(\bar{\boldsymbol{z}}), f_2(\bar{\boldsymbol{z}}) \geq 0, \tag{14}$$

$$\bar{\alpha} f_1(\bar{\boldsymbol{z}}) = \bar{\beta} f_2(\bar{\boldsymbol{z}}) = 0. \tag{15}$$

Proof. The proof follows from the strong duality result (Theorem 2.2) and from saddle point optimality conditions (see, e.g., [2, Theorem 6.2.5]). ∎

Note that a direct consequence of Theorem 2.3 is that the linear system (13) is consistent.

We now develop necessary and sufficient optimality conditions for $(QP_{\mathbb{C}})$ assuming strict feasibility, which are a natural generalization of the optimality conditions (5)–(8) for the trust region subproblem. Notice that for the complex version of the (TTRS), strict feasibility of $(D_{\mathbb{C}})$ is always satisfied since the norm constraint is strictly convex.

THEOREM 2.4. *Suppose that both problems $(QP_{\mathbb{C}})$ and $(D_{\mathbb{C}})$ are strictly feasible. Then $\bar{\boldsymbol{z}}$ is an optimal solution of $(QP_{\mathbb{C}})$ if and only if there exist $\alpha, \beta \geq 0$ such that*

(i) $(\boldsymbol{A}_0 - \alpha\boldsymbol{A}_1 - \beta\boldsymbol{A}_2)\bar{\boldsymbol{z}} + \boldsymbol{b}_0 - \alpha\boldsymbol{b}_1 - \beta\boldsymbol{b}_2 = 0$;

(ii) $f_1(\bar{\boldsymbol{z}}), f_2(\bar{\boldsymbol{z}}) \geq 0$;

(iii) $\alpha f_1(\bar{\boldsymbol{z}}) = \beta f_2(\bar{\boldsymbol{z}}) = 0$;

(iv) $\boldsymbol{A}_0 - \alpha\boldsymbol{A}_1 - \beta\boldsymbol{A}_2 \succeq 0$.

Proof. The necessary part is trivial since $\bar{\boldsymbol{z}}$, $\bar{\alpha}$, and $\bar{\beta}$ of Theorem 2.3 satisfy conditions (i)–(iv). Suppose now that conditions (i)–(iv) are satisfied. Then by (ii), $\bar{\boldsymbol{z}}$ is feasible and therefore $f_0(\bar{\boldsymbol{z}}) \geq \mathrm{val}(QP_{\mathbb{C}})$. To prove the reverse inequality ($f_0(\bar{\boldsymbol{z}}) \leq \mathrm{val}(QP_{\mathbb{C}})$), consider the unconstrained minimization problem:

$$\min_{\boldsymbol{z} \in \mathbb{C}^n} \{f_0(\boldsymbol{z}) - \bar{\alpha} f_1(\boldsymbol{z}) - \bar{\beta} f_2(\boldsymbol{z})\}. \tag{16}$$

We have

$$\begin{aligned} \mathrm{val}((16)) &\leq \min_{\boldsymbol{z} \in \mathbb{C}^n} \{f_0(\boldsymbol{z}) - \bar{\alpha} f_1(\boldsymbol{z}) - \bar{\beta} f_2(\boldsymbol{z}) : f_1(\boldsymbol{z}) \geq 0, f_2(\boldsymbol{z}) \geq 0\} \\ &\leq \min_{\boldsymbol{z} \in \mathbb{C}^n} \{f_0(\boldsymbol{z}) : f_1(\boldsymbol{z}) \geq 0, f_2(\boldsymbol{z}) \geq 0\} = \mathrm{val}(QP_{\mathbb{C}}). \end{aligned} \tag{17}$$

Conditions (i) and (iv) imply that $\bar{\boldsymbol{z}}$ is an optimal solution of (16) so that

$$f_0(\bar{\boldsymbol{z}}) - \bar{\alpha} f_1(\bar{\boldsymbol{z}}) - \bar{\beta} f_2(\bar{\boldsymbol{z}}) = \mathrm{val}((16)) \leq \mathrm{val}(QP_{\mathbb{C}}), \tag{18}$$

where the latter inequality follows from (17). By condition (iii) we have that $f_0(\bar{\boldsymbol{z}}) = f_0(\bar{\boldsymbol{z}}) - \bar{\alpha} f_1(\bar{\boldsymbol{z}}) - \bar{\beta} f_2(\bar{\boldsymbol{z}})$. Combining this with (18) we conclude that $f_0(\bar{\boldsymbol{z}}) \leq \mathrm{val}(QP_{\mathbb{C}})$. ∎

2.3. Finding an explicit solution of ($QP_{\mathbb{C}}$). Theorem 2.3 can be used to find an explicit solution to ($QP_{\mathbb{C}}$) from the solution of the dual ($D_{\mathbb{C}}$). Specifically, in section 2.3.1 we show that given the optimal dual solution, ($QP_{\mathbb{C}}$) reduces to a quadratic feasibility problem, whose solution is described in section 2.3.2.

2.3.1. Reduction to a quadratic feasibility problem. Suppose that both ($QP_{\mathbb{C}}$) and ($D_{\mathbb{C}}$) are strictly feasible. From Theorem 2.3, $\bar{\boldsymbol{z}}$ is an optimal solution if it satisfies (13), (14), and (15). If $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2 \succ \boldsymbol{0}$, then the (unique) solution to the primal problem ($QP_{\mathbb{C}}$) is given by

$$\bar{\boldsymbol{z}} = -(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)^{-1}(\boldsymbol{b}_0 - \bar{\alpha}\boldsymbol{b}_1 - \bar{\beta}\boldsymbol{b}_2).$$

Next, suppose that $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$ is positive semidefinite but not positive definite. In this case (13) can be written as $\boldsymbol{z} = \boldsymbol{B}\boldsymbol{w} + \boldsymbol{a}$, where the columns of $\boldsymbol{B}$ form a basis for the null space of $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$ and $\boldsymbol{a} = -(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)^{\dagger}(\boldsymbol{b}_0 - \bar{\alpha}\boldsymbol{b}_1 - \bar{\beta}\boldsymbol{b}_2)$ is a solution of (13). It follows that $\bar{\boldsymbol{z}} = \boldsymbol{B}\bar{\boldsymbol{w}} + \boldsymbol{a}$ is an optimal solution to ($QP_{\mathbb{C}}$) if and only if conditions (14) and (15) of Theorem 2.3 are satisfied, i.e.,

$$g_1(\bar{\boldsymbol{w}}) \geq 0, g_2(\bar{\boldsymbol{w}}) \geq 0, \bar{\alpha}g_1(\bar{\boldsymbol{w}}) = 0, \bar{\beta}g_2(\bar{\boldsymbol{w}}) = 0, \quad (g_j(\boldsymbol{w}) \equiv f_j(\boldsymbol{B}\boldsymbol{w} + \boldsymbol{a})). \tag{19}$$

We are left with the problem of finding a vector which is a solution of a system of two quadratic equalities or inequalities as described in Table 1. This problem will be called the *quadratic feasibility problem.*

TABLE 1
Cases of the quadratic feasibility problem.

No.	Case	Feasibility problem
I	$\bar{\alpha} = 0, \bar{\beta} = 0$	$g_1(\boldsymbol{w}) \geq 0$ and $g_2(\boldsymbol{w}) \geq 0$
II	$\bar{\alpha} > 0, \bar{\beta} = 0$	$g_1(\boldsymbol{w}) = 0$ and $g_2(\boldsymbol{w}) \geq 0$
III	$\bar{\alpha} = 0, \bar{\beta} > 0$	$g_1(\boldsymbol{w}) \geq 0$ and $g_2(\boldsymbol{w}) = 0$
IV	$\bar{\alpha} > 0, \bar{\beta} > 0$	$g_1(\boldsymbol{w}) = 0$ and $g_2(\boldsymbol{w}) = 0$

Note that since $(\bar{\lambda}, \bar{\alpha}, \bar{\beta})$ is an optimal solution of the dual problem ($D_{\mathbb{C}}$), we must have $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2 \succeq \boldsymbol{0}$. Thus, the first case is possible only when $\boldsymbol{A}_0 \succeq \boldsymbol{0}$.

We summarize the above discussion in the following theorem.

THEOREM 2.5. *Suppose that both problems ($QP_{\mathbb{C}}$) and ($D_{\mathbb{C}}$) are strictly feasible and let $(\bar{\alpha}, \bar{\beta}, \bar{\lambda})$ be an optimal solution of problem ($D_{\mathbb{C}}$). Then*

1. *if $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2 \succ \boldsymbol{0}$, then the (unique) optimal solution of ($QP_{\mathbb{C}}$) is given by*

$$\bar{\boldsymbol{z}} = -(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)^{-1}(\boldsymbol{b}_0 - \bar{\alpha}\boldsymbol{b}_1 - \bar{\beta}\boldsymbol{b}_2),$$

2. *if $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2 \succeq \boldsymbol{0}$ but not positive definite, then the solutions of ($QP_{\mathbb{C}}$) are $\boldsymbol{z} = \boldsymbol{B}\boldsymbol{w} + \boldsymbol{a}$, where the columns of $\boldsymbol{B} \in \mathbb{C}^{n\times d}$ form a basis for $\mathcal{N}(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)$, $\boldsymbol{a}$ is a solution of (13), and $\boldsymbol{w} \in \mathbb{C}^d$ ($d = \dim\big(\mathcal{N}(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)\big)$) is any solution of (19).*

2.3.2. Solving the quadratic feasibility problem. We now develop a method for solving all cases of the quadratic feasibility problem described in Table 1, under the condition that f_1 is strictly concave, i.e., $\boldsymbol{A}_1 \prec \boldsymbol{0}$ (so that the corresponding constraint is strictly convex).[2] The strict concavity of $g_1(\boldsymbol{w}) = f_1(\boldsymbol{B}\boldsymbol{w} + \boldsymbol{a})$ follows

[2]Note that this assumption readily implies that problem ($D_{\mathbb{C}}$) is strictly feasible.

immediately. By applying an appropriate linear transformation on g_1, we can assume without loss of generality that $g_1(\boldsymbol{w}) = \gamma - \|\boldsymbol{w}\|^2$ ($\gamma \geq 0$). Our approach will be to use solutions of at most two (TR) problems.

We split our analysis according to the different cases.

Case I+II. A solution to the feasibility problem in Case I (II) is any solution to the problem $\max\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 \leq \gamma\}$ ($\max\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 = \gamma\}$)

Case III. We first calculate $\boldsymbol{w}^0, \boldsymbol{w}^1$ given by

$$\boldsymbol{w}^0 \in \operatorname{argmin}\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 \leq \gamma\}, \quad \boldsymbol{w}^1 \in \operatorname{argmax}\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 \leq \gamma\}.$$

A solution to the feasibility problem is then given by $\bar{\boldsymbol{w}} = \boldsymbol{w}^0 + \eta(\boldsymbol{w}^1 - \boldsymbol{w}^0)$, where η is a solution to the scalar quadratic problem $g_2(\boldsymbol{w}^0 + \eta(\boldsymbol{w}^1 - \boldsymbol{w}^0)) = 0$ with $\eta \in [0, 1]$.

Case IV. Let $\boldsymbol{w}^0$ and $\boldsymbol{w}^1$ be defined by

$$\boldsymbol{w}^0 \in \operatorname{argmin}\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 = \gamma\}, \quad \boldsymbol{w}^1 \in \operatorname{argmax}\{g_2(\boldsymbol{w}) : \|\boldsymbol{w}\|^2 = \gamma\}.$$

The case in which $\boldsymbol{w}^0$ and $\boldsymbol{w}^1$ are linearly dependent can be analyzed in the same way as Case III. If $\boldsymbol{w}^0$ and $\boldsymbol{w}^1$ are linearly independent we can define

$$\boldsymbol{u}(\eta) = \boldsymbol{w}^0 + \eta(\boldsymbol{w}^1 - \boldsymbol{w}^0), \quad \boldsymbol{w}(\eta) = \sqrt{\gamma}\frac{\boldsymbol{u}(\eta)}{\|\boldsymbol{u}(\eta)\|}, \quad \eta \in [0, 1].$$

A solution to the feasibility problem is given by $w(\eta)$, where η is any root of the scalar equation $g_2(\boldsymbol{w}(\eta)) = 0,\ \eta \in [0, 1]$. The latter equation can be written (after some elementary algebraic manipulation) as the following *quartic* scalar equation:

$$\left(\gamma \boldsymbol{u}(\eta)^* \boldsymbol{A}_2 \boldsymbol{u}(\eta) + c_2 \|\boldsymbol{u}(\eta)\|^2\right)^2 = 4\gamma \|\boldsymbol{u}(\eta)\|^2 (\Re(\boldsymbol{b}_2^* \boldsymbol{u}(\eta)))^2. \tag{20}$$

Notice that (20) has at most four solutions, which have explicit algebraic expressions.

An alternative procedure for finding an explicit solution of $(QP_{\mathbb{C}})$ is described in [18]. The dominant computational effort in both methods is the solution of the SDP $(SDR_{\mathbb{C}})$ or its dual $(D_{\mathbb{C}})$, which can be solved by a primal dual interior point method that requires $O(n^{3.5})$ operations per accuracy digit (see, e.g., [4, section 6.6.1]).

3. The real case. We now treat the problem $(QP_{\mathbb{R}})$ in which the data and variables are assumed to be real valued. The dual problem to $(QP_{\mathbb{R}})$ is

$$(D_{\mathbb{R}}) \quad \max_{\alpha \geq 0, \beta \geq 0, \lambda} \left\{ \lambda \;\middle|\; \begin{pmatrix} \boldsymbol{A}_0 & \boldsymbol{b}_0 \\ \boldsymbol{b}_0^T & c_0 - \lambda \end{pmatrix} \succeq \alpha \begin{pmatrix} \boldsymbol{A}_1 & \boldsymbol{b}_1 \\ \boldsymbol{b}_1^T & c_1 \end{pmatrix} + \beta \begin{pmatrix} \boldsymbol{A}_2 & \boldsymbol{b}_2 \\ \boldsymbol{b}_2^T & c_2 \end{pmatrix} \right\}. \tag{21}$$

Note that this is *exactly the same* as problem $(D_{\mathbb{C}})$ (problem (9)), where here we use the fact that the data is real and therefore $\boldsymbol{b}_j^* = \boldsymbol{b}_j^T$. The SDR in this case is given by

$$(SDR_{\mathbb{R}}) \quad \min_{\boldsymbol{X}} \{\operatorname{Tr}(\boldsymbol{X}\boldsymbol{M}_0) : \operatorname{Tr}(\boldsymbol{X}\boldsymbol{M}_1) \geq 0, \operatorname{Tr}(\boldsymbol{X}\boldsymbol{M}_2) \geq 0, X_{n+1,n+1} = 1, \boldsymbol{X} \in \mathcal{S}_+^{n+1}\}. \tag{22}$$

In contrast to the complex case, strong duality is generally not true for $(QP_{\mathbb{R}})$. Nonetheless, in this section we use the results obtained for $(QP_{\mathbb{C}})$ in order to establish several results on $(QP_{\mathbb{R}})$. In section 3.1 we show that if the constraints of $(QP_{\mathbb{R}})$ are convex, then $(QP_{\mathbb{C}})$, considered as a relaxation of $(QP_{\mathbb{R}})$, can produce an approximate solution. In section 3.2 we relate the image of the real and complex space under a

quadratic mapping, which will enable us to bridge between the real and complex case. Using the latter result, a sufficient condition for zero duality gap is proved in section 3.3. The condition is expressed via the optimal dual variables and thus can be verified in polynomial time. Preliminary numerical results suggest that for the TTRS problem (3) this condition is often satisfied. Moreover, we identify two general classes of problems with zero duality gap, based on this condition. As we show in section 3.4, these results can be applied to the robust least-squares problem in order to obtain a polynomial time algorithm in the presence of uncertainty sets described by two norm constraints.

3.1. The complex relaxation. As already mentioned, val($QP_{\mathbb{R}}$) is not necessarily equal to val($D_{\mathbb{R}}$). However, the *complex counterpart* ($QP_{\mathbb{C}}$) does satisfy val($QP_{\mathbb{C}}$) = val($D_{\mathbb{R}}$) and we can always find a *complex valued* solution to ($QP_{\mathbb{C}}$) that attains the bound val($D_{\mathbb{R}}$). Therefore, we can consider ($QP_{\mathbb{C}}$) as a tractable relaxation (*the complex relaxation*) of the real valued problem ($QP_{\mathbb{R}}$). The following example, whose data is taken from Yuan [36, p. 59], illustrates this fact.

Example. Consider the following real valued quadratic optimization problem:

$$\min_{x_1,x_2\in\mathbb{R}} \{-2x_1^2 + 2x_2^2 + 4x_1 : x_1^2 + x_2^2 - 4 \le 0, x_1^2 + x_2^2 - 4x_1 + 3 \le 0\}, \tag{23}$$

which is a special case of ($QP_{\mathbb{R}}$) with

$$\boldsymbol{A}_0 = \begin{pmatrix} -2 & 0 \\ 0 & 2 \end{pmatrix}, \boldsymbol{A}_1 = \boldsymbol{A}_2 = -\boldsymbol{I}, \boldsymbol{b}_0(2;0), \boldsymbol{b}_1 = \boldsymbol{0}, \boldsymbol{b}_2 = (2;0), c_0 = 0, c_1 = 4, c_2 = -3.$$

The solution to the dual problem is given by $\bar{\alpha} = 1, \bar{\beta} = 1$, and $\bar{\lambda} = -1$. It is easy to see that the optimal solution to ($QP_{\mathbb{R}}$) is given by $x_1 = 2, x_2 = 0$ and its corresponding optimal solution is 0. The duality gap is thus 1. By the strong duality result of Theorem 2.2, we can find a complex valued solution to the complex counterpart

$$\min_{z_1,z_2\in\mathbb{C}} \{-2|z_1|^2 + 2|z_2|^2 + 4\Re(z_1) : |z_1|^2 + |z_2|^2 - 4 \le 0, |z_1|^2 + |z_2|^2 - 4\Re(z_1) + 3 \le 0\}. \tag{24}$$

with value equal to that of the dual problem (that is, equal to -1). Using the techniques described in section 2.3 we obtain that the solution of problem (24) is $z_1 = 7/4 + \sqrt{15/16}i, z_2 = 0$ with function value -1.

The following theorem states that if the constraints of ($QP_{\mathbb{C}}$) are convex (as in the two trust region problem), then we can extract an *approximate real solution* that is feasible from the optimal complex solution $\bar{\boldsymbol{z}}$ by taking $\bar{\boldsymbol{x}} = \Re(\bar{\boldsymbol{z}})$.

THEOREM 3.1. *Suppose that both* ($QP_{\mathbb{R}}$) *and* ($D_{\mathbb{R}}$) *are strictly feasible. Let* $\boldsymbol{A}_1, \boldsymbol{A}_2 \in \mathbb{R}^{n\times n}$ *be negative definite matrices,* $\boldsymbol{A}_0 = \boldsymbol{A}_0^T \in \mathbb{R}^{n\times n}$, $\boldsymbol{b}_j \in \mathbb{R}^n$, *and* $c_j \in \mathbb{R}$. *Let* $\bar{\boldsymbol{z}}$ *be an optimal complex valued solution of* ($QP_{\mathbb{C}}$) *and let* $\bar{\boldsymbol{x}} = \Re(\bar{\boldsymbol{z}})$. *Then* $\bar{\boldsymbol{x}}$ *is a feasible solution of* ($QP_{\mathbb{R}}$) *and*

$$f_0(\bar{\boldsymbol{x}}) - val(QP_{\mathbb{R}}) \le -\Im(\bar{\boldsymbol{z}})^T \boldsymbol{A}_0 \Im(\bar{\boldsymbol{z}}).$$

Proof. To show that $\bar{\boldsymbol{x}}$ is a feasible solution of ($QP_{\mathbb{R}}$) note that for $\boldsymbol{z} \in \mathbb{C}^n, j = 1, 2$ one has

$$\begin{aligned} 0 \le f_j(\boldsymbol{z}) &= \boldsymbol{z}^* \boldsymbol{A}_j \boldsymbol{z} + 2\Re(\boldsymbol{b}_j^* \boldsymbol{z}) + c_j \\ &= \Re(\boldsymbol{z})^T \boldsymbol{A}_j \Re(\boldsymbol{z}) + \Im(\boldsymbol{z})^T \boldsymbol{A}_j \Im(\boldsymbol{z}) + 2\boldsymbol{b}_j^T \Re(\boldsymbol{z}) + c_j \\ &\le \Re(\boldsymbol{z})^T \boldsymbol{A}_j \Re(\boldsymbol{z}) + 2\boldsymbol{b}_j^T \Re(\boldsymbol{z}) + c_j = f_j(\Re(\boldsymbol{z})), \end{aligned}$$

where the last inequality follows from $\boldsymbol{A}_j \prec \boldsymbol{0}$. Thus, since $\bar{\boldsymbol{z}}$ is feasible, so is $\Re(\bar{\boldsymbol{z}})$. Finally,

$$f_0(\Re(\bar{\boldsymbol{z}}))-\mathrm{val}(QP_{\mathbb{R}}) \leq f_0(\Re(\bar{\boldsymbol{z}}))-\mathrm{val}(QP_{\mathbb{C}}) = f_0(\Re(\bar{\boldsymbol{z}}))-f_0(\bar{\boldsymbol{z}}) = -\Im(\bar{\boldsymbol{z}})^T\boldsymbol{A}_0\Im(\bar{\boldsymbol{z}}). \qquad \square$$

In our example the approximate solution is $(7/4, 0)$ and its function value is equal to 0.875.

The extension from real to complex variables can be considered as *lifting*. A very popular lifting procedure is the SDR in which a nonconvex quadratic optimization problem defined over $\mathbb{R}^n$ is lifted to the corresponding SDR, which is defined over the space of $n \times n$ positive semidefinite matrices $\mathcal{S}_+^n$. This approach has been studied in various contexts such as approximation of combinatorial optimization problems (see [4] and references therein), polynomial inequalities [19], and more. The lifting procedure we suggest is relevant only in the context of quadratic optimization problems with *two* quadratic constraints. Our method is based on extending the real number field $\mathbb{R}$ into the complex number field $\mathbb{C}$. The *value* of the convex relaxation $\mathrm{val}(QP_{\mathbb{C}})$ is equal to the value of the SDR $\mathrm{val}(SDR_{\mathbb{R}})$. The main difference between the two strategies is in the "projection" stage onto $\mathbb{R}^n$. In our strategy, the projection is simple and natural: we take the real part of the vector. If the constraints are convex, then we have obtained a feasible point. In contrast, the choice of projection of the SDR solution, which is an $n \times n$ matrix, is not obvious. There are well established methods for specific instances (such as Max-Cut problems), but it is not clear how to extract a "good" approximate and feasible solution for general convex quadratic constraints. Another advantage to our method is that the procedure for finding a solution to $(QP_{\mathbb{C}})$ defined in section 2.3 can be manipulated so that it will output a real valued optimal solution in the case where strong duality indeed holds. In contrast, projection of the SDR solution may no longer be optimal, even in the case of strong duality.

3.2. The image of the complex and real space under a quadratic mapping. One of the key ingredients in proving the sufficient condition in section 3.3 is a result (Theorem 3.3) on the image of the spaces $\mathbb{C}^n$ and $\mathbb{R}^n$ under a quadratic mapping, composed from two nonhomogeneous quadratic functions. Results on the image of quadratic mappings play an important role in nonconvex quadratic optimization (see, e.g., [17, 25, 27] and references therein). We begin with the following theorem due to Polyak [25, Theorem 2.2], which is very relevant to our analysis.

THEOREM 3.2 (see [25]). *Let $\boldsymbol{A}_1, \boldsymbol{A}_2 \in \mathbb{R}^{n\times n}, (n \geq 2)$ be symmetric matrices for which the following condition is satisfied:*

$$\exists \alpha, \beta \in \mathbb{R} \text{ such that } \alpha\boldsymbol{A}_1 + \beta\boldsymbol{A}_2 \succ \boldsymbol{0}. \tag{25}$$

Let $\boldsymbol{b}_1, \boldsymbol{b}_2 \in \mathbb{R}^n$ and $c_1, c_2 \in \mathbb{R}$, and define $f_j(\boldsymbol{x}) = \boldsymbol{x}^T\boldsymbol{A}_j\boldsymbol{x} + 2\boldsymbol{b}_j^T\boldsymbol{x} + c_j$. Then the set

$$W = \{(f_1(\boldsymbol{x}), f_2(\boldsymbol{x})) : \boldsymbol{x} \in \mathbb{R}^n\}$$

is closed and convex.

The following theorem states that the images of $\mathbb{C}^n$ and $\mathbb{R}^n$ under the quadratic mapping defined in Theorem 3.2 are the same.

THEOREM 3.3. *Consider the setup of Theorem 3.2, and let $f_j(\boldsymbol{z}) = \boldsymbol{z}^*\boldsymbol{A}_j\boldsymbol{z} + 2\Re(\boldsymbol{b}_j^*\boldsymbol{z}) + c_j$. Then the sets*

$$F = \{(f_1(\boldsymbol{z}), f_2(\boldsymbol{z})) : \boldsymbol{z} \in \mathbb{C}^n\}, \quad W = \{(f_1(\boldsymbol{x}), f_2(\boldsymbol{x})) : \boldsymbol{x} \in \mathbb{R}^n\}$$

are equal. The proof of Theorem 3.3 relies on the following lemma.

LEMMA 3.4. *Let* $\boldsymbol{A}$ *be a real* $n \times n$ *symmetric matrix,* $\boldsymbol{b} \in \mathbb{R}^n, c \in \mathbb{R}$, *and* $\beta \geq 0$. *Then*

(26)
$$\min_{\boldsymbol{x}\in\mathbb{R}^n} \{\boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x} + 2\boldsymbol{b}^T\boldsymbol{x} + c : \|\boldsymbol{x}\|^2 = \beta\} = \min_{\boldsymbol{z}\in\mathbb{C}^n} \{\boldsymbol{z}^*\boldsymbol{A}\boldsymbol{z} + 2\Re(\boldsymbol{b}^*\boldsymbol{z}) + c : \|\boldsymbol{z}\|^2 = \beta\}.$$

Proof. First note that (26) is obvious for $\beta = 0$. Suppose that $\beta > 0$. The value of the first problem in (26) is equal to

$$\max_{\mu}\{\mu : \boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x} + 2\boldsymbol{b}^T\boldsymbol{x} + c \geq \mu \text{ for every } \boldsymbol{x} \in \mathbb{R}^n \text{ such that } \|\boldsymbol{x}\|^2 = \beta\}. \tag{27}$$

Similarly, the value of the second problem is equal to

$$\max_{\mu}\{\mu : \boldsymbol{z}^*\boldsymbol{A}\boldsymbol{z} + 2\Re(\boldsymbol{b}^*\boldsymbol{z}) + c \geq \mu \text{ for every } \boldsymbol{z} \in \mathbb{C}^n \text{ such that } \|\boldsymbol{z}\|^2 = \beta\}. \tag{28}$$

By Theorem A.2 (note that condition (45) is satisfied for $f_1(\boldsymbol{x}) \equiv \|\boldsymbol{x}\|^2 - \beta$ with $\beta > 0$), the value of both problems is equal to the value of

$$\begin{array}{ll} \max_{\mu,\lambda} & \mu \\ \text{s.t.} & \begin{pmatrix} \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{b}^T & c-\mu \end{pmatrix} \succeq \lambda \begin{pmatrix} \boldsymbol{I} & \boldsymbol{0} \\ \boldsymbol{0} & -\beta \end{pmatrix}, \end{array}$$

and therefore these values are the same. ∎

We are now ready to prove Theorem 3.3.

Proof of Theorem 3.3. By Theorem 3.2 both W and F are convex. Obviously $W \subseteq F$. To prove the opposite, we first assume without loss of generality that $f_1(\boldsymbol{x}) = \|\boldsymbol{x}\|^2$. The latter assumption is possible since (25) is satisfied. Suppose that $(a, b) \in F$, i.e., $a = \|\boldsymbol{z}\|^2, b = f_2(\boldsymbol{z})$ for some $\boldsymbol{z} \in \mathbb{C}^n$, and let

$$b_{min} = \min\{f_2(\boldsymbol{z}) : \|\boldsymbol{z}\|^2 = a\} \text{ and } b_{max} = \max\{f_2(\boldsymbol{z}) : \|\boldsymbol{z}\|^2 = a\}.$$

By Lemma 3.4, there must be two *real* vectors $\boldsymbol{x}^0, \boldsymbol{x}^1 \in \mathbb{R}^n$ such that $\|\boldsymbol{x}^0\|^2 = \|\boldsymbol{x}^1\|^2 = a$ and $f_2(\boldsymbol{x}^0) = b_{min} \leq b \leq b_{max} = f_2(\boldsymbol{x}^1)$. Therefore, $(a, b_{min}), (a, b_{max}) \in W$. Since W is convex we conclude that (a, b), being a convex combination of (a, b_{min}) and (a, b_{max}), also belongs to W. ∎

3.3. A sufficient condition for zero duality gap of $(QP_{\mathbb{R}})$.

3.3.1. The condition. We now use the results on the complex valued problem $(QP_{\mathbb{C}})$ in order to find a sufficient condition for zero duality gap and tightness of the SDR of the real valued problem $(QP_{\mathbb{R}})$. Our derivation is based on the fact that if an optimal solution of $(QP_{\mathbb{C}})$ is *real valued*, then $(QP_{\mathbb{R}})$ admits no gap with its dual problem $(D_{\mathbb{R}})$.

THEOREM 3.5. *Suppose that both problems* $(QP_{\mathbb{R}})$ *and* $(D_{\mathbb{R}})$ *are strictly feasible and that*

$$\exists \hat{\alpha}, \hat{\beta} \in \mathbb{R} \text{ such that } \hat{\alpha}\boldsymbol{A}_1 + \hat{\beta}\boldsymbol{A}_2 \succ \boldsymbol{0}. \tag{29}$$

Let $(\bar{\lambda}, \bar{\alpha}, \bar{\beta})$ *be an optimal solution of the dual problem* $(D_{\mathbb{R}})$. *If*

$$d = \dim\left(\mathcal{N}(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)\right) \neq 1, \tag{30}$$

then val($QP_{\mathbb{R}}$) = val($D_{\mathbb{R}}$) = val($SDR_{\mathbb{R}}$) and there exists a real valued solution to ($QP_{\mathbb{C}}$).

Proof. Since both ($SDR_{\mathbb{R}}$) and ($D_{\mathbb{R}}$) are strictly feasible, $\mathrm{val}(D_{\mathbb{R}}) = \mathrm{val}(SDR_{\mathbb{R}})$. Now, suppose that $d = 0$. Then by (13), a solution to ($QP_{\mathbb{C}}$) is given by the real valued vector

$$\bar{\boldsymbol{x}} = -(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)^{-1}(\boldsymbol{b}_0 - \bar{\alpha}\boldsymbol{b}_1 - \bar{\beta}\boldsymbol{b}_2).$$

Since ($QP_{\mathbb{C}}$) has a real valued solution it follows that $\mathrm{val}(QP_{\mathbb{R}}) = \mathrm{val}(QP_{\mathbb{C}}) = \mathrm{val}(D_{\mathbb{R}})$, where the last equality follows from Theorem 2.2.

Next, suppose that $d \geq 2$. By Theorem 2.5, any optimal solution $\bar{\boldsymbol{z}}$ of ($QP_{\mathbb{C}}$) has the form $\bar{\boldsymbol{z}} = \boldsymbol{B}\bar{\boldsymbol{w}} + \boldsymbol{a}$, where $\bar{\boldsymbol{w}} \in \mathbb{C}^d$ is a solution of

$$g_1(\boldsymbol{w}) \geq 0, g_2(\boldsymbol{w}) \geq 0, \bar{\alpha}g_1(\boldsymbol{w}) = 0, \bar{\beta}g_2(\boldsymbol{w}) = 0, \quad (g_j(\boldsymbol{w}) \equiv f_j(\boldsymbol{B}\boldsymbol{w} + \boldsymbol{a})). \tag{31}$$

Both the matrix $\boldsymbol{B}$ and the vector $\boldsymbol{a}$ are chosen to be real valued; such a choice is possible since the columns of $\boldsymbol{B}$ form a basis for the null space of the *real valued* matrix $\boldsymbol{A}_1 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$ and $\boldsymbol{a}$ is an arbitrary solution of a real valued linear system. Now, obviously $(g_1(\bar{\boldsymbol{w}}), g_2(\bar{\boldsymbol{w}})) \in S_1$, where $S_1 = \{(g_1(\boldsymbol{w}), g_2(\boldsymbol{w})) : \boldsymbol{w} \in \mathbb{C}^d\}$. Since $\boldsymbol{B}$ has full column rank, if (29) is satisfied, then

$$\hat{\alpha}\boldsymbol{B}^T\boldsymbol{A}_1\boldsymbol{B} + \hat{\beta}\boldsymbol{B}^T\boldsymbol{A}_2\boldsymbol{B} \succ \boldsymbol{0}. \tag{32}$$

The LMI (32) together with the fact that $d \geq 2$ imply that the conditions of Theorem 3.3 are satisfied and thus $S_1 = S_2$, where $S_2 = \{(g_1(\boldsymbol{x}), g_2(\boldsymbol{x})) : \boldsymbol{x} \in \mathbb{R}^d\}$. Therefore, there exists $\bar{\boldsymbol{x}} \in \mathbb{R}^d$ such that $g_j(\bar{\boldsymbol{w}}) = g_j(\bar{\boldsymbol{x}})$ and as a result, (31) has a real valued solution. To conclude, $\bar{\boldsymbol{z}} = \boldsymbol{B}\bar{\boldsymbol{x}} + \boldsymbol{a} \in \mathbb{R}^n$ is a real valued vector which is an optimal solution to ($QP_{\mathbb{C}}$). ∎

A more restrictive sufficient condition than (30) is

$$\dim(\mathcal{N}(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)) = 0.$$

This condition, as opposed to condition (30), can be directly derived from complementarity conditions of ($SDR_{\mathbb{R}}$) and its dual ($D_{\mathbb{R}}$).

We note that although a direct verification of the sufficient condition (30) requires the solution of the dual problem ($D_{\mathbb{R}}$), we will show that it is possible to use this condition in order to prove strong duality is *always* satisfied for certain classes of structured nonconvex quadratic problems (see section 3.3.3).

3.3.2. Numerical experiments. To demonstrate the fact that for the TTRS problem (3), the sufficient condition of Theorem 3.5 often holds for random problems, we considered different values of m and n (the number of constraints and the number of variables in the original nonlinear problem) and randomly generated 1000 instances of $\boldsymbol{B}, \boldsymbol{g}, \boldsymbol{A}$, and $\boldsymbol{c}$. We chose $\Delta = 0.1$ and $\xi = \|\boldsymbol{A}^T(-\alpha\boldsymbol{A}\boldsymbol{c}) + \boldsymbol{c}\|$, with

$$\alpha = \min\left\{\frac{\Delta}{\|\boldsymbol{A}\boldsymbol{c}\|}, \frac{\boldsymbol{c}^T(\boldsymbol{A}^T\boldsymbol{A})\boldsymbol{c}}{\boldsymbol{c}^T(\boldsymbol{A}^T\boldsymbol{A})^2\boldsymbol{c}}\right\},$$

as suggested in the trust region algorithm of [6]. The SDP problems were solved by SeDuMi [32]. The results are given in Table 2.

In the table, *distribution* is the distribution from which the coefficients of $\boldsymbol{B}, \boldsymbol{g}, \boldsymbol{A}$, and $\boldsymbol{c}$ are generated. There are two possibilities: uniform distribution ($U[0, 1]$) or

TABLE 2
Results for TTRS.

n	m	distribution	N_{suf}	mean	sd
10	1	Normal	997	5.50	2.34
10	1	Uniform	1000	1.61	0.62
10	10	Normal	1000	5.04	2.31
10	10	Uniform	1000	1.60	0.61
100	1	Normal	1000	13.15	2.65
100	1	Uniform	1000	3.75	0.64
100	100	Normal	1000	12.54	2.31
100	100	Uniform	1000	3.71	0.65

standard normal distribution ($N(0,1)$). N_{suf} is the number of problems satisfying the sufficient condition (30) out of 1000. *mean* and *sd* are the mean and standard deviation of the minimal eigenvalue of the matrix $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$. Numerically, the dimension of the null space in condition (30) was determined by the number of eigenvalues of the matrix $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$ whose absolute value was less than 10^{-8}. It is interesting to note that *almost all* the instances satisfied condition (30) except for 3 cases when $n = 10, m = 1$ with data generated from the normal distribution. Of course, these experiments reflect the situation in random problems and the results might be different (for better or for worse) if the data is generated differently.

3.3.3. Two classes of problems with zero duality gap. We will now present two classes of nonconvex quadratic problems for which the sufficient condition of Theorem 3.5 is always satisfied.

First class. Consider the problem of minimizing an indefinite quadratic function subject to a norm constraint and a linear inequality constraint:

$$\min_{\boldsymbol{x}\in\mathbb{R}^n} \{\boldsymbol{x}^T\mathbf{Q}\boldsymbol{x} + 2\boldsymbol{b}^T\boldsymbol{x} : \|\boldsymbol{x}\|^2 \le \delta, \boldsymbol{a}^T\boldsymbol{x} \le \xi\}. \tag{33}$$

This problem was treated in [33, 35], where it was shown that the SDR is not always tight, although a polynomial-time algorithm for solving this problem was presented. We will find a condition on the data $(\mathbf{Q}, \boldsymbol{a}, \boldsymbol{b})$ that will be sufficient for zero duality gap.

THEOREM 3.6. *Suppose that problem* (33) *is strictly feasible and* $n \ge 2$. *If the dimension of* $\mathcal{N}(\mathbf{Q} - \lambda_{min}(\mathbf{Q})\boldsymbol{I}_n)$ *is at least* 2, *then strong duality holds for problem* (33).

Proof. Let $(\bar{\lambda}, \bar{\alpha}, \bar{\beta})$ be an optimal solution of the dual problem to (33). From the feasibility of the dual problem it follows that $\mathbf{Q}+\bar{\alpha}\boldsymbol{I}_n \succeq \mathbf{0}$. Now, either $\bar{\alpha} > -\lambda_{min}(\mathbf{Q})$ and in that case $\mathbf{Q} + \bar{\alpha}\boldsymbol{I}_n$ is nonsingular and thus the dimension of $\mathcal{N}(\mathbf{Q} + \bar{\alpha}\boldsymbol{I}_n)$ is 0 or $\bar{\alpha} = -\lambda_{min}(\mathbf{Q})$ and in this case $\mathcal{N}(\mathbf{Q} + \bar{\alpha}\boldsymbol{I}_n)$ is of dimension at least 2 by the assumptions. The result follows now from Theorem 3.5. ∎

Second class. Consider problem $(QP_{\mathbb{R}})$ with matrices $\boldsymbol{A}_i$ of the following form:

$$\boldsymbol{A}_i = \boldsymbol{I}_r \otimes \mathbf{Q}_i, \quad i = 0, 1, 2, \tag{34}$$

where $\mathbf{Q}_i = \mathbf{Q}_i^T \in \mathbb{R}^{m\times m}, r > 1$, and $n = rm$. Here $\otimes$ denotes the Kronecker product. In section 3.4 we will show that this class of problems naturally arises in unstructured robust least squares problems. The following theorem, which is a direct consequence of the sufficient condition (30), states that under some mild conditions (such as strict feasibility), strong duality holds.

THEOREM 3.7. *Suppose that both problems* $(QP_{\mathbb{R}})$ *and* $(D_{\mathbb{R}})$ *are strictly feasible and that* $\boldsymbol{A}_i$ *is given by* (34). *Moreover, suppose that there exist* $\hat{\alpha}$ *and* $\hat{\beta}$ *such that*

$$\hat{\alpha}\mathbf{Q}_1 + \hat{\beta}\mathbf{Q}_2 \succ \mathbf{0}. \tag{35}$$

Then strong duality holds for $(QP_{\mathbb{R}})$.

Proof. The validity of condition (35) readily implies that (29) holds true. Moreover, by the premise of the theorem, both problems $(QP_{\mathbb{R}})$ and $(D_{\mathbb{R}})$ are strictly feasible. We are thus left with the task of proving that condition (30) is satisfied. Indeed, let $(\bar{\lambda}, \bar{\alpha}, \bar{\beta})$ be an optimal solution of the dual problem $(D_{\mathbb{R}})$. Then the matrix $\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2$ is equal to $\boldsymbol{I}_r \otimes (\mathbf{Q}_0 - \bar{\alpha}\mathbf{Q}_1 - \bar{\beta}\mathbf{Q}_2)$. Using properties of eigenvalues of Kronecker products [14], we conclude that the multiplicities of the eigenvalues of the latter matrix must be multiplicities of r, i.e., $r, 2r, \ldots$. The dimension of $\mathcal{N}(\boldsymbol{A}_0 - \bar{\alpha}\boldsymbol{A}_1 - \bar{\beta}\boldsymbol{A}_2)$ is the multiplicity of the eigenvalue 0, which by the fact that $r > 1$, cannot be equal to 1. Hence, by Theorem 3.5, strong duality holds. ∎

3.4. Application to unstructured robust least squares. The *robust least squares* (RLS) problem was introduced and studied in [16, 7]. Consider a linear system $\boldsymbol{A}\boldsymbol{x} \approx \boldsymbol{b}$ where $\boldsymbol{A} \in \mathbb{R}^{r\times n}, \boldsymbol{b} \in \mathbb{R}^r$, and $\boldsymbol{x} \in \mathbb{R}^n$. Assume that the matrix and right-hand side vector $(\boldsymbol{A}, \boldsymbol{b})$ are not fixed but rather given by a family of matrices[3] $(\boldsymbol{A}, \boldsymbol{b}) + \boldsymbol{\Delta}^T$, where $(\boldsymbol{A}, \boldsymbol{b})$ is a known nominal value and $\boldsymbol{\Delta} \in \mathbb{R}^{(n+1)\times r}$ is an unknown perturbation matrix known to reside in a compact uncertainty set $\mathcal{U}$. The RLS approach to this problem is to seek a vector $\boldsymbol{x} \in \mathbb{R}^n$ that minimizes the worst case data error with respect to all possible values of $\boldsymbol{\Delta} \in \mathcal{U}$:

$$\min_{\boldsymbol{x}} \max_{\boldsymbol{\Delta}\in\mathcal{U}} \left\| \boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} + \boldsymbol{\Delta}^T \begin{pmatrix} \boldsymbol{x} \\ -1 \end{pmatrix} \right\|^2. \tag{36}$$

In [16] the uncertainty set $\mathcal{U}$ in the unstructured case was chosen to contain all matrices $\boldsymbol{\Delta}$ satisfying a simple Frobenius norm constraint, i.e.,

$$\mathrm{Tr}(\boldsymbol{\Delta}^T\boldsymbol{\Delta}) \le \rho. \tag{37}$$

The RLS problem is considered difficult in the case when the uncertainty set $\mathcal{U}$ is given by an *intersection* of ellipsoids; see the related problem[4] of finding a robust counterpart of a conic quadratic problem [3]. Nonetheless, we will now show that a byproduct of our results is that as long as $r > 1$, the RLS problem with uncertainty set given by an intersection of two ellipsoids is tractable. Specifically, we consider an uncertainty set $\mathcal{U}$ given by two norm constraints:

$$\mathcal{U} = \{\boldsymbol{\Delta} \in \mathbb{R}^{(n+1)\times r} : \mathrm{Tr}(\boldsymbol{\Delta}^T\boldsymbol{B}_i\boldsymbol{\Delta}) \le \rho_i, i = 1, 2\}, \tag{38}$$

where $\boldsymbol{B}_i = \boldsymbol{B}_i^T \in \mathbb{R}^{(n+1)\times(n+1)}$ and $\rho_i > 0$. We also assume that

$$\exists \gamma_1 \ge 0, \gamma_2 \ge 0 \text{ such that } \gamma_1\boldsymbol{B}_1 + \gamma_2\boldsymbol{B}_2 \succ \mathbf{0}. \tag{39}$$

The above condition will ensure strict feasibility of the dual problem to the inner maximization problem of (36).

[3] The perturbation matrix appears in a transpose form for the sake of simplicity of notation.

[4] Note that finding a tractable formulation to the RLS problem is the key ingredient in deriving a robust counterpart of a conic quadratic constraint of the form $\|\boldsymbol{A}\boldsymbol{x} + \boldsymbol{b}\| \le \boldsymbol{c}^T\boldsymbol{x} + d$.

The form of the uncertainty set (38) is more general than the standard single-constraint form (37) and it can thus be used to describe more complicated scenarios of uncertainties. Using some simple algebraic manipulations the objective function in (36) can be written as

$$\|\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}+\boldsymbol{\Delta}^T\tilde{\boldsymbol{x}}\|^2=\mathrm{Tr}(\boldsymbol{\Delta}^T\tilde{\boldsymbol{x}}\tilde{\boldsymbol{x}}^T\boldsymbol{\Delta})+2\mathrm{Tr}((\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})\tilde{\boldsymbol{x}}^T\boldsymbol{\Delta})+\mathrm{Tr}((\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T),$$

where we denoted

$$\tilde{\boldsymbol{x}}=\begin{pmatrix}\boldsymbol{x}\\-1\end{pmatrix}. \tag{40}$$

Relying on the identities

$$\mathrm{Tr}(\boldsymbol{A}^T\boldsymbol{B}\boldsymbol{A})=\mathrm{vec}(\boldsymbol{A})^T(\boldsymbol{I}_r\otimes\boldsymbol{B})\,\mathrm{vec}(\boldsymbol{A}),\quad \mathrm{Tr}(\boldsymbol{A}^T\mathbf{C})=\mathrm{vec}(\boldsymbol{A})^T\,\mathrm{vec}(\mathbf{C}) \tag{41}$$

for every $\boldsymbol{A},\mathbf{C}\in\mathbb{R}^{p\times r}\boldsymbol{B}\in\mathbb{R}^{p\times p}$, where for a matrix $\boldsymbol{M}$, $\mathrm{vec}(\boldsymbol{M})$ denotes the vector obtained by stacking the columns of $\boldsymbol{M}$, the inner maximization problem in (36) takes the following form:

$$\max\{\mathrm{vec}(\boldsymbol{\Delta})^T\mathbf{Q}\,\mathrm{vec}(\boldsymbol{\Delta})+2\boldsymbol{f}^T\,\mathrm{vec}(\boldsymbol{\Delta})+c:\boldsymbol{\Delta}\in\mathcal{U}\}, \tag{42}$$

where $\mathbf{Q}=\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}}\tilde{\boldsymbol{x}}^T$, $\boldsymbol{f}=\mathrm{vec}(\tilde{\boldsymbol{x}}(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T)$, and $c=\|\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}\|^2$. By the first identity of (41) it follows that $\mathcal{U}$ can be written as

$$\mathcal{U}=\{\boldsymbol{\Delta}\in\mathbb{R}^{(n+1)\times r}:\mathrm{vec}(\boldsymbol{\Delta})^T(\boldsymbol{I}_r\otimes\boldsymbol{B}_i)\,\mathrm{vec}(\boldsymbol{\Delta})\le\rho_i,i=1,2\}.$$

Therefore, all the matrices in the inner maximization problem (42) are of the form $\boldsymbol{I}_r\otimes G$. Noting that all the other conditions of Theorem 3.7 are satisfied (strict feasibility of the primal and dual problems and (35)), we conclude that strong duality holds for (42) and its value is thus equal to the value of the dual problem given by

$$\min_{\alpha\ge0,\beta\ge0,\lambda}\left\{-\lambda\left|\begin{pmatrix}-\mathbf{Q}+\boldsymbol{I}_r\otimes(\alpha\boldsymbol{B}_1+\beta\boldsymbol{B}_2) & -\boldsymbol{f}\\ -\boldsymbol{f}^T & -c-\lambda-\alpha\rho_1-\beta\rho_2\end{pmatrix}\succeq\mathbf{0}\right.\right\}.$$

Now, using the following identities (see [14]):

$$\begin{aligned}\mathbf{Q}&=\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}}\tilde{\boldsymbol{x}}^T=(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})^T,\\ \boldsymbol{f}&=\mathrm{vec}(\tilde{\boldsymbol{x}}(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T)=(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})\end{aligned}$$

the dual problem is transformed to

$$\min_{\alpha\ge0,\beta\ge0,\lambda}\left\{-\lambda\left|\begin{pmatrix}-(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}}^T)+\boldsymbol{I}_r\otimes(\alpha\boldsymbol{B}_1+\beta\boldsymbol{B}_2) & -(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})\\ -(\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T(\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})^T & -\|\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}\|^2-\lambda-\alpha\rho_1-\beta\rho_2\end{pmatrix}\succeq\mathbf{0}\right.\right\},$$

which, by Schur complement, can be written as

$$\min_{\alpha\ge0,\beta\ge0,\lambda}\left\{-\lambda\left|\begin{pmatrix}\boldsymbol{I}_r & (\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})^T & \boldsymbol{A}\boldsymbol{x}-\boldsymbol{b}\\ \boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}} & \boldsymbol{I}_r\otimes(\alpha\boldsymbol{B}_1+\beta\boldsymbol{B}_2) & \mathbf{0}\\ (\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T & \mathbf{0} & -\lambda-\alpha\rho_1-\beta\rho_2\end{pmatrix}\succeq\mathbf{0}\right.\right\}.$$

Finally, we arrive at the following SDP formulation of the RLS problem (36):

(43)
$$\min_{\alpha\geq 0,\beta\geq 0,\lambda,x}\left\{-\lambda \left| \begin{pmatrix} \boldsymbol{I}_r & (\boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}})^T & \boldsymbol{A}\boldsymbol{x}-\boldsymbol{b} \\ \boldsymbol{I}_r\otimes\tilde{\boldsymbol{x}} & \boldsymbol{I}_r\otimes(\alpha\boldsymbol{B}_1+\beta\boldsymbol{B}_2) & \boldsymbol{0} \\ (\boldsymbol{A}\boldsymbol{x}-\boldsymbol{b})^T & \boldsymbol{0} & -\lambda-\alpha\rho_1-\beta\rho_2 \end{pmatrix}\succeq \boldsymbol{0}\right.\right\}.$$

We summarize the discussion in this section in the following theorem.

THEOREM 3.8. *Consider the RLS problem* (36)*, where the uncertainty set* $\mathcal{U}$ *is given by* (38)*,* $r>1$*, and* $\boldsymbol{B}_1,\boldsymbol{B}_2$ *satisfy condition* (39)*. Let* $(\alpha,\beta,\lambda,\boldsymbol{x})$ *be a solution to the SDP problem* (43)*, where* $\tilde{\boldsymbol{x}}$ *is given in* (40)*. Then* $\boldsymbol{x}$ *is the optimal solution of the RLS problem* (36)*.*

Appendix. Extended Finsler's theorem.

THEOREM A.1 (Finsler's theorem [11, 21]). *Let* $\mathbb{F}$ *be one of the fields* $\mathbb{R}$ *or* $\mathbb{C}$ *and let* $\boldsymbol{A},\boldsymbol{B}\in\mathbb{R}^{n\times n}$ *be symmetric matrices. Suppose that there exist* $\boldsymbol{x}_1,\boldsymbol{x}_2\in\mathbb{F}^n$ *such that* $\boldsymbol{x}_1^*\boldsymbol{A}\boldsymbol{x}_1>0$ *and* $\boldsymbol{x}_2^*\boldsymbol{A}\boldsymbol{x}_2<0$*. Then*

$$\boldsymbol{z}^*\boldsymbol{B}\boldsymbol{z}\geq 0 \text{ for every } \boldsymbol{z}\in\mathbb{F}^n \text{ such that } \boldsymbol{z}^*\boldsymbol{A}\boldsymbol{z}=0$$

if and only if there exists $\alpha\in\mathbb{R}$ *such that* $\boldsymbol{B}-\alpha\boldsymbol{A}\succeq\boldsymbol{0}$*.*

We note that the complex case can be reduced to the real case by using

$$\boldsymbol{z}^*\boldsymbol{A}\boldsymbol{z}=(\boldsymbol{x}^T\boldsymbol{y}^T)\begin{pmatrix}\boldsymbol{A} & \boldsymbol{0}\\ \boldsymbol{0} & \boldsymbol{A}\end{pmatrix}\begin{pmatrix}\boldsymbol{x}\\ \boldsymbol{y}\end{pmatrix}$$

for all $\boldsymbol{z}=\boldsymbol{z}+i\boldsymbol{y},\boldsymbol{x},\boldsymbol{y}\in\mathbb{R}^n$, where $\boldsymbol{A}\in\mathbb{R}^{n\times n}$ is symmetric.

While Finsler's theorem deals with *homogeneous* quadratic forms, the extended version considers *nonhomogeneous* quadratic functions.

THEOREM A.2 (extended Finsler's theorem). *Let* $\mathbb{F}$ *be one of the fields* $\mathbb{R}$ *or* $\mathbb{C}$ *and let* $\boldsymbol{A}_1,\boldsymbol{A}_2\in\mathbb{R}^{n\times n}$ *be symmetric matrices such that*

$$\boldsymbol{A}_2\succeq\eta\boldsymbol{A}_1 \text{ for some } \eta\in\mathbb{R}. \tag{44}$$

Let $f_j:\mathbb{F}^n\to\mathbb{R}, f_j(\boldsymbol{x})=\boldsymbol{x}^*\boldsymbol{A}_j\boldsymbol{x}+2\Re(\boldsymbol{b}_j^T\boldsymbol{x})+c_j$*, where* $\boldsymbol{b}_j\in\mathbb{R}^n$ *and* c_j *is a real scalar.*[5] *Suppose that*

$$\exists\boldsymbol{x}_1,\boldsymbol{x}_2\in\mathbb{F}^n \text{ such that } f_1(\boldsymbol{x}_1)>0, f_1(\boldsymbol{x}_2)<0. \tag{45}$$

Then the following two statements are equivalent:

(i) $f_2(\boldsymbol{x})\geq 0$ *for every* $\boldsymbol{x}\in\mathbb{F}^n$ *such that* $f_1(\boldsymbol{x})=0$*.*

(ii) *There exists* $\lambda\in\mathbb{R}$ *such that*

$$\begin{pmatrix}\boldsymbol{A}_2 & \boldsymbol{b}_2\\ \boldsymbol{b}_2^T & c_2\end{pmatrix}\succeq\lambda\begin{pmatrix}\boldsymbol{A}_1 & \boldsymbol{b}_1\\ \boldsymbol{b}_1^T & c_1\end{pmatrix}.$$

Proof. (ii) $\Rightarrow$ (i) is a trivial implication. Now, suppose that (i) is satisfied. Making the change of variables $\boldsymbol{x}=(1/t)\boldsymbol{y}$ $(\boldsymbol{y}\in\mathbb{F}^n,t\neq 0)$ and multiplying f_1 and f_2 by $|t|^2$, (i) becomes

$$g_2(\boldsymbol{y},t)\geq 0 \text{ for every } \boldsymbol{y}\in\mathbb{F}^n,t\neq 0 \text{ such that } g_1(\boldsymbol{y},t)=0, \tag{46}$$

[5] In the case $\mathbb{F}=\mathbb{R}$, f_j can be written as $f_j(\boldsymbol{x})=\boldsymbol{x}^T\boldsymbol{A}_j\boldsymbol{x}+2\boldsymbol{b}_j^T\boldsymbol{x}+c_j$.

where $g_j(\boldsymbol{y}, t) = \boldsymbol{y}^* \boldsymbol{A}_j \boldsymbol{y} + 2\Re(\boldsymbol{b}_j^T \boldsymbol{y} t) + c_j |t|^2$. Notice that if t would not be restricted to be nonzero, then by Theorem A.1, statement (ii) is true (g_1 and g_2 are homogeneous quadratic functions). Thus, all is left to prove is that (46) is true for $t = 0$. However, by replacing $t \neq 0$ with $t = 0$, (46) reduces to

$$\boldsymbol{y}^* \boldsymbol{A}_2 \boldsymbol{y} \geq 0 \text{ for every } \boldsymbol{y} \in \mathbb{F}^n \text{ such that } \boldsymbol{y}^* \boldsymbol{A}_1 \boldsymbol{y} = 0,$$

which, by Theorem A.1, is equivalent to condition (44). □

The condition in Theorem A.2 holds true, for instance, if $\boldsymbol{A}_2$ is positive definite or if $\boldsymbol{A}_1$ is definite. The case in which $\boldsymbol{A}_1$ is definite was already proven for the real case in [33, Corollary 6].

DISCONTINUOUS BUT WELL-POSED OPTIMIZATION PROBLEMS*

JACQUELINE MORGAN† AND VINCENZO SCALZO‡

Abstract. Using classes of *sequentially pseudocontinuous* functions, recently introduced by the authors, the aim of the paper is to investigate Tikhonov and parametric well-posedness for optimization problems when the objective functions are not necessarily sequentially lower semicontinuous. Sequential pseudocontinuity is a property more general than sequential semicontinuity and finds motivations in choice theory, since the continuity of preference relations on first countable topological spaces is characterized by the sequential pseudocontinuity of any utility function. Examples show that it is not possible to improve the results with other well-known classes of discontinuous functions.

Key words. Tikhonov well-posedness, parametric well-posedness, minimum problems, parametric minimum problems, sequentially pseudocontinuous functions

DOI. 10.1137/050636358

1. Introduction.

The problem of minimizing an extended real valued function f is declared *well-posed* if any minimizing sequence clusters to a minimizer. That is, if $f(y_n) \longrightarrow \inf f$ and f has only one minimum point, then $(y_n)_n$ converges to the minimum point, while if f has more than one minimum point, then some subsequence $(y_{n_k})_k$ converges to a minimizer. This crucial property—most informative when the minimum point is unique and also interesting from a numerical point of view—was introduced by Tikhonov in [12], and it was the objective of numerous studies: see, for example, [3], [13], and [6]. It is commonly assumed there that f is at least sequentially lower semicontinuous. There are, however, some important instances in which even less than sequentially lower semicontinuity prevails. To wit, in the framework of choice theory when an abstract preference relation $\succeq$ is represented by a utility function, to assume $\succeq$ *continuous* on a first countable topological space (see [4] and [2]) amounts to requiring that every utility function representing $\succeq$ be *sequentially pseudocontinuous* (Proposition 1 in [9]). A sequentially pseudocontinuous function is not necessarily sequentially lower semicontinuous; see [7]. Broadly, sequential pseudocontinuity requires that strict inequalities be preserved along approximating sequences (see Proposition 2.3). Moreover, if $\succeq$ is a *weakly continuous* preference relation [1] represented by utility functions, then any such utility satisfies a property introduced in [8] which is called *sequential weak pseudocontinuity* in the following. The sequential weak pseudocontinuity generalizes the sequential pseudocontinuity; see [8]. The sequential (weak) pseudocontinuity allows us to extend several well-known results already obtained for functions at least sequentially lower semicontinuous: the Weierstrass theorem, convergence results for minimum points and for social Nash equilibria, existence results for MinSup and MinInf problems; see [7] and [8]. Finally, the sequential (weak) pseudocontinuity is related to monotone functions: any strictly monotone function is a sequentially pseudocontinuous function and any monotone function is a

sequentially weakly pseudocontinuous function; see [7] and [8] for finite dimensional spaces.

The aim of the paper is to generalize the results already obtained for Tikhonov well-posedness and parametric well-posedness using just the sequentially pseudocontinuous or the sequentially weakly pseudocontinuous functions. The paper is organized as follows. In section 2 we present some properties and a useful characterization for these classes of functions. In section 3 we obtain new sufficient conditions for Tikhonov well-posedness of unconstrained optimization problems. In section 4 we consider the case of constrained and parametric problems and compare our results with the previous ones (see [6]). Finally, examples show that it is not possible to further improve our results.

2. Pseudocontinuous functions. This section recalls some well-known concepts and introduces a few classes of functions.

For simplicity let all spaces be metric. However, we point out that all the results of the paper could be proved, using the same arguments, in the more general framework of *sequential convergence spaces* (see Kuratowski [5]).

Let f be an extended real valued function defined on a metric space Z. The function f is *sequentially lower semicontinuous* at $z \in Z$ if

$$f(z) \leq \liminf_{n\to\infty} f(z_n) \ \forall\ z_n \longrightarrow z \text{ in } Z,$$

and f is *sequentially upper semicontinuous* at z if $-f$ is sequentially lower semicontinuous at z.

Let $(A_n)_n$ be a sequence of subsets of Z; then

- $z \in \operatorname{Liminf} A_n$ (see [5], *inner limit* of $(A_n)_n$ in [10]) if and only if there exists a sequence $(z_n)_n$ converging in Z to z and such that $z_n \in A_n$ for n sufficiently large ($n \in \mathbb{N}$);
- $z \in \operatorname{Limsup} A_n$ (see [5], *outer limit* of $(A_n)_n$ in [10]) if and only if there exists a subsequence (A_{n_k}) of $(A_n)_n$ and a sequence $(z_k)_k$ converging to z in Z such that $z_k \in A_{n_k}$ for each $k \in \mathbb{N}$.

Let K be a set-valued function from X to Y, two metric spaces.

- K is *sequentially lower semicontinuous* at a point $x \in X$ if $K(x) \subseteq \operatorname{Liminf} K(x_n)$ for all $x_n \longrightarrow x$.
- K is *sequentially closed* at a point $x \in X$ if $\operatorname{Limsup} K(x_n) \subseteq K(x)$ for all $x_n \longrightarrow x$.

Let us remind the reader about some definitions introduced in [7] and [8].

Definition 2.1 (Definition 2.4 in [7]). *Let f be an extended real valued function defined on Z and $z \in Z$.*

- *f is said to be* sequentially lower pseudocontinuous at z *if*

$$f(y) < f(z) \Rightarrow \begin{cases} f(y) < \liminf\limits_{n\to\infty} f(z_n) \\ \forall\ z_n \longrightarrow z. \end{cases}$$

- *f is said to be* sequentially upper pseudocontinuous at z *if $-f$ is sequentially lower pseudocontinuous at z.*
- *f is said to be* sequentially pseudocontinuous at z *if it is both sequentially lower and upper pseudocontinuous at z.*

Definition 2.2 (Definition 3.1 in [8]). *Let f be an extended real valued function defined on Z and $z \in Z$.*

• *f is said to be* sequentially lower weakly pseudocontinuous at z *(sequentially lower quasi-continuous in* [8]*) if*

$$f(y) < f(z) \Rightarrow \begin{cases} f(y) \leq \liminf\limits_{n\to\infty} f(z_n) \\ \forall\ z_n \longrightarrow z. \end{cases}$$

• *f is said to be* sequentially upper weakly pseudocontinuous at z *(sequentially upper quasi-continuous in* [8]*) if $-f$ is sequentially lower weakly pseudocontinuous at z.*

• *f is said to be* sequentially weakly pseudocontinuous at z *(sequentially quasi-continuous in* [8]*) if it is both sequentially lower and upper weakly pseudocontinuous at z.*

Trivially a sequentially lower pseudocontinuous function is also sequentially lower weakly pseudocontinuous. Conversely, however, the well-known Dirichlet function (which is equal to 0 on all rational numbers and equal to 1 on all irrational numbers) is sequentially lower weakly pseudocontinuous, but it is not sequentially lower pseudocontinuous. Moreover, the class of sequentially lower pseudocontinuous functions strictly includes the class of sequentially lower semicontinuous function (see [7, Example 2.1]). Characterizations of the sequential lower pseudocontinuity are presented in [7]. For simplicity, from now on, we omit the term *sequentially*.

Finally, we prove a new characterization of pseudocontinuous functions, useful in the following.

PROPOSITION 2.3. *Let f be an extended real valued function defined on a metric space Z. Then f is pseudocontinuous on Z if and only if the following holds:*

$$\left.\begin{array}{c} f(x) < f(y) \\ x_n \longrightarrow x \\ y_n \longrightarrow y \end{array}\right\} \Longrightarrow \limsup_{n\to\infty} f(x_n) < \liminf_{n\to\infty} f(y_n). \tag{2.1}$$

Proof. First, assume that f is pseudocontinuous on Z. Let $f(x) < f(y)$, $x_n \longrightarrow x$, and $y_n \longrightarrow y$. We set $\mathrm{Im}(f) = \{f(z) \,/\, z \in Z\}$.

If there exists a value $f(z) \in]f(x), f(y)[$, then one has

$$\limsup_{n\to\infty} f(x_n) < f(z) < \liminf_{n\to\infty} f(y_n).$$

Otherwise, let $]f(x), f(y)[\cap \mathrm{Im}(f) = \emptyset$. Since f is upper pseudocontinuous at x, one has

$$\limsup_{n\to\infty} f(x_n) < f(y).$$

Now, if $f(x) < \limsup_{n\to\infty} f(x_n)$, then $]f(x), f(y)[\cap \mathrm{Im}(f) \neq \emptyset$, which is in conflict with our assumption. So, $\limsup_{n\to\infty} f(x_n) \leq f(x) < f(y)$. Similarly, f being lower pseudocontinuous at y, one gets $f(y) \leq \liminf_{n\to\infty} f(y_n)$ and then

$$\limsup_{n\to\infty} f(x_n) \leq f(x) < f(y) \leq \liminf_{n\to\infty} f(y_n),$$

that is, the property (2.1).

Finally, assume that the property (2.1) is satisfied. Let $f(x) < f(y)$, $x_n \longrightarrow x$, and $(y_n)_n$ such that $y_n = y$ for all n. Then

$$\limsup_{n\to\infty} f(x_n) < f(y);$$

that is, f is upper pseudocontinuous at x. Similarly, one can prove that property (2.1) implies the lower pseudocontinuity of f at y. □

Moreover, pseudocontinuity is connected with monotonicity. In fact, the following result extends the results given in [7] and [8] for finite dimensional spaces.

PROPOSITION 2.4. *Let f be an extended real valued function defined on a normed space V, and let $\mathcal{C}$ be a convex and pointed cone in V with its apex at the origin and nonempty interior. If f is strictly monotone (resp., monotone) with respect to $\mathcal{C}$, that is, strictly increasing (resp., increasing),*

$$y \in x + \operatorname{int}\mathcal{C} \Longleftrightarrow f(x) < f(y) \ \ (\textit{resp.}, \ \ f(x) \leq f(y)),$$

or strictly decreasing (resp., decreasing),

$$y \in x + \operatorname{int}\mathcal{C} \Longleftrightarrow f(x) > f(y) \ \ (\textit{resp.}, \ \ f(x) \geq f(y)),$$

then f is pseudocontinuous (resp., weakly pseudocontinuous) on V.

Proof. Suppose that f is strictly decreasing with respect to $\mathcal{C}$.

We first prove that f is lower pseudocontinuous. Let z and y be such that $f(y) < f(z)$, and let $z_n \longrightarrow z$. Then we have $y \in z + \operatorname{int}\mathcal{C}$. So, there exists an element $y' \in y - \operatorname{int}\mathcal{C}$ and an open neighborhood $\mathcal{A}$ of z such that $y' \in u + \operatorname{int}\mathcal{C}$ for all $u \in \mathcal{A}$. Since $z_n \longrightarrow z$, we have that $y' \in z_n + \operatorname{int}\mathcal{C}$ for n sufficiently large. Then

$$f(y) < f(y') \leq \liminf_{n\to\infty} f(z_n).$$

Now we prove that f is upper pseudocontinuous. Let z and y be such that $f(z) < f(y)$, and let $z_n \longrightarrow z$. Then $z \in y + \operatorname{int}\mathcal{C}$. Moreover, there exists $y' \in z - \operatorname{int}\mathcal{C}$ and an open neighborhood $\mathcal{B}$ of z such that $u \in y' + \operatorname{int}\mathcal{C}$ for all $u \in \mathcal{B}$. Consequently, $f(z_n) < f(y')$ for n sufficiently large. So,

$$\limsup_{n\to\infty} f(z_n) \leq f(y') < f(y).$$

Analogously, we obtain that f is pseudocontinuous if it is strictly increasing.

With similar arguments, one can prove that any monotone function is weakly pseudocontinuous. □

3. Well-posed unconstrained unparametric optimization. Let Y be a metric space and f be a proper function defined on Y with values in $]-\infty, +\infty]$. We recall that the minimum problem

$$\mathcal{M}: \ \min_{y\in Y} f(y)$$

is *Tikhonov well-posed* (see [12], [3]) if $-\infty < \inf f$ and there exists a unique global minimum point $\hat{y}$ and any sequence $(y_n)_n$ such that

$$f(y_n) - \min_{y\in Y} f(y) \longrightarrow 0$$

(called a *minimizing sequence*) is converging to $\hat{y}$. Moreover, $\mathcal{M}$ is said to be *Tikhonov well-posed in the generalized sense* (see [12], [3]) if $-\infty < \inf f$, $\operatorname{argmin}(Y, f) = \{y' \in Y \,/\, f(y') \leq f(y) \text{ for all } y \in Y\}$ is nonempty, and any minimizing sequence has at least a subsequence converging to a global minimum point.

In the following, for simplicity, we refer to well-posed and well-posed in the generalized sense problems.

Sufficient conditions for well-posedness and well-posedness in the generalized sense of the problem $\mathcal{M}$ have been obtained for lower semicontinuous functions (see Chapter 1 in [3]).

In this section, we generalize the previous results using *lower weakly pseudocontinuous* and *lower pseudocontinuous* functions. In fact, we have the following theorem.

THEOREM 3.1. *Let Y be a compact metric space, and let $f : Y \longrightarrow]-\infty, +\infty]$ be a proper function. If* $\operatorname{argmin}(Y, f) = \{\hat{y}\}$ *and f is lower weakly pseudocontinuous on Y, then $\mathcal{M}$ is well-posed.*

Proof. Let $(y_n)_n$ be a minimizing sequence of $\mathcal{M}$ which does not converge to $\hat{y}$. Since Y is compact, there exists a subsequence $(y_{n_k})_k$ converging to a point $\bar{y} \neq \hat{y}$. Hence, $\lim_{k\to\infty} f(y_{n_k}) = f(\hat{y}) < f(\bar{y})$, and we have $f(y_{n_k}) \in [f(\hat{y}), f(\bar{y})[$ for k sufficiently large. If $f(y_{n_k}) = f(\hat{y})$ for k sufficiently large, then $y_{n_k} = \hat{y}$, which is impossible since $y_{n_k} \longrightarrow \bar{y}$. So, there exists $y' \in Y$ such that $f(y') \in]f(\hat{y}), f(\bar{y})[$. Since f is lower weakly pseudocontinuous at $\bar{y}$, we have $f(y') \leq \liminf_{k\to\infty} f(y_{n_k}) = f(\hat{y})$, and we get a contradiction. □

About well-posedness in the generalized sense, sufficient conditions are obtained using lower pseudocontinuous functions.

THEOREM 3.2. *Let Y be a compact metric space, and let $f : Y \longrightarrow]-\infty, +\infty]$ be a proper function. If f is lower pseudocontinuous on Y, then $\mathcal{M}$ is well-posed in the generalized sense.*

Proof. First, in light of [8, Corollary 3.1], we have that $\operatorname{argmin}(Y, f)$ is nonempty. Assume a minimizing sequence $(y_n)_n$ has a subsequence $(y_{n_k})_k$ that converges to $\bar{y} \notin \operatorname{argmin}(Y, f)$. So, there exists $y \in Y$ such that $f(y) < f(\bar{y})$. Since f is lower pseudocontinuous at $\bar{y}$, we have $f(y) < \liminf_{k\to\infty} f(y_{n_k}) = \min_{z\in Y} f(z)$, and we get a contradiction. □

In order to obtain sufficient conditions for well-posedness, lower weak pseudocontinuity (used in Theorem 3.1) cannot be weakened using the minimal conditions for the existence of minimum points in a sequential setting (see [8] for general sequential convergence spaces and [11] for topological spaces). In fact, in Example 3.1, a *transfer lower continuous* function (see [11]) on a compact space determines a minimum problem which is not well-posed.

Example 3.1. Let $Y = [0, 2]$ and $f : Y \longrightarrow \mathbb{R}$ be such that

$$f(y) = \begin{cases} (y-1)^2 & \text{if } y \in [0, 1[, \\ 2 - y & \text{if } y \in [1, 2]. \end{cases}$$

The function f is not lower weakly pseudocontinuous at $y = 1$, but it is transfer lower continuous on $[0, 2]$. Now, if $y_n \longrightarrow 1^-$, we have $f(y_n) \longrightarrow 0 = \min f$, but $(y_n)_n$ does not converge to the unique minimum point $\hat{y} = 2$. So, the associate minimum problem is not well-posed.

As shown by Example 3.2, lower pseudocontinuity (used in Theorem 3.2) cannot be substituted by lower weak pseudocontinuity in order to obtain a minimum problem well-posed in the generalized sense.

Example 3.2. Let $Y = [0, 2]$ and $f : Y \longrightarrow \mathbb{R}$ be such that

$$f(y) = \begin{cases} 0 & \text{if } y \in [0, 2]\backslash\{1\}, \\ 1 & \text{if } y = 1. \end{cases}$$

The function f is not lower pseudocontinuous at $y = 1$, but it is lower weakly pseudocontinuous on $[0, 2]$. If $y_n \longrightarrow 1^-$, we have $f(y_n) \longrightarrow 0 = \min f$, but 1 is not a

minimum point. So, the associate minimum problem is not well-posed in the generalized sense.

In order to obtain well-posedness, compactness of Y can be replaced by completeness of Y and a suitable diameter assumption (already considered in [3]). For any $\varepsilon > 0$, let

$$M(\varepsilon) = \left\{ y \in Y \,/\, f(y) - \inf_{z \in Y} f(z) < \varepsilon \right\},$$

and let $diam[M(\varepsilon)]$ be the diameter of $M(\varepsilon)$.

THEOREM 3.3. *Let $f : Y \longrightarrow]-\infty, +\infty]$ be a proper function. If $\mathcal{M}$ is well-posed, then*

$$\lim_{\varepsilon \downarrow 0} diam[M(\varepsilon)] = 0. \tag{3.1}$$

Moreover, if Y is complete, f is lower pseudocontinuous and bounded from below on Y, and (3.1) *is satisfied, then $\mathcal{M}$ is well-posed.*

Proof. The first part of the thesis is given in [3, Theorem 11]. Here we prove that (3.1) is a sufficient condition for well-posedness.

Let $(y_n)_n$ be a minimizing sequence of $\mathcal{M}$. In light of (3.1), $(y_n)_n$ is a Cauchy sequence. Y being complete, $(y_n)_n$ converges to a point $\hat{y} \in Y$. If $\hat{y} \notin \operatorname{argmin}(Y, f)$, there exists $y \in Y$ such that $f(y) < f(\hat{y})$. Since f is lower pseudocontinuous at $\hat{y}$, we get the following contradiction:

$$f(y) < \liminf_{n \to \infty} f(y_n) = \inf_{z \in Y} f(z).$$

So, $\hat{y} \in \operatorname{argmin}(Y, f)$. Again from (3.1), it follows that $\operatorname{argmin}(Y, f) = \{\hat{y}\}$, and the proof is concluded. ∎

4. Well-posed constrained parametric optimization. Given X, Y, two metric spaces, let $f : X \times Y \longrightarrow]-\infty, +\infty]$ be a proper function and K be a set-valued function defined on X with nonempty values in Y. For any $x \in X$, we consider the following parametric minimum problem:

$$\mathcal{M}(x) : \quad \min_{y \in K(x)} f(x, y).$$

Let $\boldsymbol{M} = \{\mathcal{M}(x) \,/\, x \in X\}$. Following [13], the family $\boldsymbol{M}$ is said to be *parametrically well-posed at $x \in X$* if

(i) $-\infty < \inf\{f(x, y) \,/\, y \in K(x)\}$ and there exists a unique global solution to $\mathcal{M}(x)$;

(ii) if $x_n \longrightarrow x$, any sequence $(y_n)_n \subseteq Y$, with $y_n \in K(x_n)$ for n sufficiently large and such that

$$f(x_n, y_n) - \inf_{z \in K(x_n)} f(x_n, z) \longrightarrow 0,$$

is converging to the unique global solution to $\mathcal{M}(x)$.

If $x_n \longrightarrow x$, a sequence $(y_n)_n \subseteq Y$ which satisfies the above condition (ii) is said to be an *approximating sequence* of $\mathcal{M}(x)$ (with respect to $(x_n)_n$).

Moreover, if $\operatorname{argmin}(K(x), f(x, \cdot))$ is nonempty, $\boldsymbol{M}$ is said to be *parametrically well-posed in the generalized sense at $x \in X$* if, for every sequence $x_n \longrightarrow x$, any

approximating sequence (with respect to $(x_n)_n$) has some subsequence converging to a point of $\operatorname{argmin}(K(x), f(x,\cdot))$.

The following theorem gives sufficient conditions for the parametric well-posedness of the family $\boldsymbol{M}$, explicit on any data and weaker than continuity of the objective function. Let ν be the marginal function defined on X by $\nu(x) = \inf_{y\in K(x)} f(x,y)$.

THEOREM 4.1. *Let $x \in X$. If Y is compact and*

(i) *the function f is pseudocontinuous at (x,y), for any $y \in K(x)$, and*

(ii) *the set-valued function K is closed and lower semicontinuous at x,*

then the family $\boldsymbol{M}$ is parametrically well-posed in the generalized sense at x. Moreover, if $\mathcal{M}(x)$ has only one solution, then $\boldsymbol{M}$ is parametrically well-posed at x.

Proof. Since $K(x)$ is compact and f is lower pseudocontinuous at (x,y) for all $y \in K(x)$, in light of [8, Corollary 3.1], $\operatorname{argmin}(K(x), f(x,\cdot))$ is nonempty. Now we prove that $\boldsymbol{M}$ is parametrically well-posed in the generalized sense at x. Let $x_n \longrightarrow x$ and $(y_n)_n$ be an approximating sequence (with respect to $(x_n)_n$) such that any converging subsequence does not converge to an element of $\operatorname{argmin}(K(x), f(x,\cdot))$. Let $(y_{n_k})_k$ converge to a point y which is not a global minimum point of $f(x,\cdot)$ over $K(x)$. Since K is closed at x, we have that $y \in K(x)$ and there exists $z \in K(x)$ such that $f(x,z) < f(x,y)$. K being lower semicontinuous at x, there exists a sequence $z_k \longrightarrow z$ such that $z_k \in K(x_{n_k})$ for k sufficiently large. From Proposition 2.3, one has

$$\limsup_{k\to\infty} \nu(x_{n_k}) \le \limsup_{k\to\infty} f(x_{n_k}, z_k) < \liminf_{k\to\infty} f(x_{n_k}, y_{n_k}). \tag{4.1}$$

Let α be a real number such that

$$\limsup_{k\to\infty} \nu(x_{n_k}) < \alpha < \liminf_{k\to\infty} f(x_{n_k}, y_{n_k}). \tag{4.2}$$

Therefore, there exists $k_o \in \mathbb{N}$ such that

$$\nu(x_{n_k}) - f(x_{n_k}, y_{n_k}) < \alpha - f(x_{n_k}, y_{n_k}) \tag{4.3}$$

for all $k \ge k_o$. So, we obtain

$$0 = \lim_{k\to\infty} [\nu(x_{n_k}) - f(x_{n_k}, y_{n_k})] \le \alpha - \liminf_{k\to\infty} f(x_{n_k}, y_{n_k}) < 0,$$

and we get a contradiction.

Assume now that $\operatorname{argmin}(K(x), f(x,\cdot)) = \{\hat{y}\}$. Let $(y_n)_n$ be an approximating sequence (with respect to $(x_n)_n$) which does not converge to $\hat{y}$. By compactness of Y, there exists a subsequence $(y_{n_k})_k$ of $(y_n)_n$ converging to a point $y \in Y\backslash\{\hat{y}\}$. Now the thesis follows using the same arguments as in the previous case. ∎

Sufficient conditions, weaker than continuity of f, for the parametric well-posedness of $\boldsymbol{M}$ at a point x are given in [6]. More precisely, a lower semicontinuous function f, whose marginal function ν is assumed to be upper semicontinuous, is considered. Obviously, the assumptions of Theorem 4.1 are not connected with the assumptions used in [6]. Moreover, we note that the result obtained in [6] can be improved replaying the lower semicontinuity of f with the lower pseudocontinuity. In fact, we have the following theorem.

THEOREM 4.2. *Let $x \in X$. If Y is compact and*

(i) *the function f is lower pseudocontinuous at (x,y), for any $y \in K(x)$,*

(ii) *the function ν is upper semicontinuous at x, and*

(iii) *the set-valued function K is closed at x,*

then the family $\boldsymbol{M}$ is parametrically well-posed in the generalized sense at x. Moreover, if $\mathcal{M}(x)$ has only one solution, then $\boldsymbol{M}$ is parametrically well-posed at x.

Proof. Let $x_n \longrightarrow x$. Assume an approximating sequence and $(y_n)_n$ (with respect to $(x_n)_n$) have a subsequence $(y_{n_k})_k$ that converges to $y \notin \operatorname{argmin}(K(x), f(x,\cdot))$ (nonempty in light of [8, Corollary 3.1]). So, one has $f(x,z) < f(x,y)$ for some $z \in K(x)$, and f being lower pseudocontinuous at (x,y), one gets

$$\nu(x) \leq f(x,z) < \liminf_{k\to\infty} f(x_{n_k}, y_{n_k}).$$

Since ν is upper semicontinuous at x, one obtains (4.2) for some real number α. So, as in the proof of Theorem 4.1, it follows that $\boldsymbol{M}$ is parametrically well-posed in the generalized sense at x.

If $\mathcal{M}(x)$ has only one solution, similarly one can obtain that $\boldsymbol{M}$ is parametrically well-posed at x. □

Note that the assumptions on the function f in Theorem 4.1 are not connected with those in Theorem 4.2, as shown by Examples 4.1 and 4.2.

Example 4.1. Let $f : [0,1] \times [0,1] \longrightarrow \mathbb{R}$ be defined by

$$f(x,y) = \begin{cases} 2(1-x) & \text{if } (x,y) \in [0,1[\times [0,1/2], \\ 2y(1-x) & \text{if } (x,y) \in [0,1[\times]1/2,1], \\ -1 & \text{if } (x,y) \in \{1\} \times [0,1] \end{cases}$$

and $K(x) = [0,1]$ for any $x \in [0,1]$.

The function f is pseudocontinuous at $(1,y)$ for all $y \in [0,1]$, but the marginal function ν is not upper semicontinuous at $x = 1$.

Example 4.2. Let $f : [0,1] \times [0,1] \longrightarrow \mathbb{R}$ be defined by

$$f(x,y) = \begin{cases} x(y-1) & \text{if } (x,y) \in]0,1] \times [0,1[, \\ -1 & \text{if } (x,y) \in [0,1] \times \{1\}, \\ 0 & \text{if } (x,y) \in \{0\} \times [0,1[\end{cases}$$

and $K(x) = [0,1]$ for any $x \in [0,1]$.

All assumptions of Theorem 4.2 are satisfied at $x = 0$, but f is not upper pseudocontinuous at $(0,1)$.

Moreover, the assumption of pseudocontinuity used in Theorem 4.1 cannot be weakened with weak pseudocontinuity. In fact, Example 4.3 shows a parametric minimum problem with a weakly pseudocontinuous objective function which is not parametrically well-posed in the generalized sense.

Example 4.3. Let $f : [0,1] \times [0,3] \longrightarrow \mathbb{R}$ be the function defined as below:

- if $x \in [0,1[$,

$$f(x,y) = \begin{cases} 1-y & \text{if } y \in [0,1[, \\ 0 & \text{if } y \in [1,2], \\ (x-1)y - 1 & \text{if } y \in]2,3]. \end{cases}$$

- if $x = 1$,

$$f(x,y) = \begin{cases} 1-y & \text{if } y \in [0,1], \\ -1 & \text{if } y \in]1,3], \end{cases}$$

and let K be the set-valued function from $[0,1]$ to $[0,3]$ defined by $K(x) = [0,2x]$. The function f is weakly pseudocontinuous at $(1,y)$ for all $y \in [0,3]$, but it is not

pseudocontinuous at $(1,2)$, and K satisfies assumption (ii) of Theorem 4.1. If we consider the sequences $(x_n)_n = (1-1/n)_n$ and $(y_n)_n = (1-1/n)_n$, then $(y_n)_n$ is an approximating sequence of $\mathcal{M}(1)$ (with respect to $(x_n)_n$), and it converges to $1 \notin \operatorname{argmin}(K(1), f(1,\cdot)) =]1,2]$. Hence, $\boldsymbol{M}$ is not parametrically well-posed in the generalized sense at $x = 1$.

In order to obtain parametric well-posedness, the compactness of Y can be replaced by completeness and a diameter assumption. Let

$$M(x,\varepsilon) = \big\{y \in K(x) \;/\; f(x,y) - \nu(x) < \varepsilon\big\}.$$

The assumptions of Theorem 4.1 (or Theorem 4.2) are sufficient conditions for parametric well-posedness together with the following condition (already considered in [6]):

$$\lim_{\varepsilon \downarrow 0} diam[\cup_{u \in B(x,\varepsilon)} M(u,\varepsilon)] = 0, \tag{4.4}$$

where $B(x,\varepsilon)$ is the open ball with center x and ray ε. In fact, we have the following result.

THEOREM 4.3. *If $\boldsymbol{M}$ is parametrically well-posed at x, then* (4.4) *holds. Moreover, if Y is complete, f is bounded from below, and* (i) *and* (ii) *of Theorem* 4.1 *(or* (i), (ii), *and* (iii) *of Theorem* 4.2*) are satisfied, then* (4.4) *implies that $\boldsymbol{M}$ is parametrically well-posed at x.*

Proof. Assume that $\boldsymbol{M}$ is parametrically well-posed at x and $(\varepsilon_n)_n$ is a decreasing sequence of positive real numbers converging to 0. Let $A(\varepsilon) = \cup_{u \in B(x,\varepsilon)} M(u,\varepsilon)$. If (4.4) is not true, there exists a positive number ℓ and $n_o \in \mathbb{N}$ such that

$$\ell < diam[A(\varepsilon_n)] \quad \forall\, n \geq n_o.$$

So, for any $n \geq n_o$, there exist $y_n, z_n \in A(\varepsilon_n)$ such that $\ell < d(y_n, z_n)$. Consequently, for any $n \geq n_o$, there exist x_n^1 and x_n^2 belonging to $B(x,\varepsilon_n)$ such that

$$y_n \in M(x_n^1, \varepsilon_n) \quad \text{and} \quad z_n \in M(x_n^2, \varepsilon_n).$$

Now the sequences $(x_n^1)_n$ and $(x_n^2)_n$ converge to x, and the sequences $(y_n)_n$ and $(z_n)_n$ are approximating sequences of $\mathcal{M}(x)$ (with respect to $(x_n^1)_n$ and $(x_n^2)_n$, respectively). Since $\boldsymbol{M}$ is parametrically well-posed at x, the sequences $(y_n)_n$ and $(z_n)_n$ converge to the same point (that is the unique solution to $\mathcal{M}(x)$), and we get the following contradiction:

$$0 < \ell \leq \lim_{n \to \infty} d(y_n, z_n) = 0.$$

Assume now that $x_n \longrightarrow x$ and $(y_n)_n$ is an approximating sequence (with respect to $(x_n)_n$). From (4.4), it follows that $(y_n)_n$ is a Cauchy sequence, so it converges to a point $\hat{y}$. Since K is closed at x, one has $\hat{y} \in K(x)$. If $\hat{y}$ is not a solution to $\mathcal{M}(x)$, using the same arguments of the proof of Theorem 4.1, we get a contradiction. Hence $\hat{y}$ is a solution to $\mathcal{M}(x)$. Again from (4.4), $\operatorname{argmin}(K(x), f(x,\cdot)) = \{\hat{y}\}$, and the proof is concluded. ∎

CORRECTOR-PREDICTOR METHODS FOR SUFFICIENT LINEAR COMPLEMENTARITY PROBLEMS IN A WIDE NEIGHBORHOOD OF THE CENTRAL PATH*

XING LIU† AND FLORIAN A. POTRA†

Abstract. A higher order corrector-predictor interior-point method is proposed for solving sufficient linear complementarity problems. The algorithm produces a sequence of iterates in the $\mathcal{N}_\infty^-$ neighborhood of the central path. The algorithm does not depend on the handicap κ of the problem. It has $O((1+\kappa)\sqrt{n}L)$ iteration complexity and is superlinearly convergent even for degenerate problems.

Key words. linear complementarity, interior-point, path-following, corrector-predictor, wide neighborhood

1. Introduction.

The Mizuno–Todd–Ye (MTY) predictor-corrector algorithm proposed by Mizuno, Todd, and Ye [9] is a typical representative of a large class of MTY-type predictor-corrector methods, which play a very important role among primal-dual interior-point methods. It was the first algorithm for linear programming that had both polynomial complexity and superlinear convergence. This result was extended to monotone linear complementarity problems that are nondegenerate, in the sense that they have a strictly complementarity solution [6, 23]. It turned out that the nondegeneracy assumption is not restrictive, since according to [10] a large class of interior-point methods, which contains MTY, can have only linear convergence if this assumption is violated. However, it is possible to obtain arbitrarily high order of convergence for degenerate problems by using higher order information of the central path [19, 21].

The existence of a central path is crucial for interior-point methods. An important result of the 1991 monograph of Kojima et al. [7] shows that the central path exists for any P_* linear complementarity problem, provided that the relative interior of its feasible set is nonempty. We recall that every P_* linear complementarity problem is a $P_*(\kappa)$ problem for some $\kappa \geq 0$, i.e.,

$$P_* = \bigcup_{\kappa \geq 0} P_*(\kappa).$$

The class of sufficient matrices was introduced by Cottle, Pang, and Stone [3] in connection with the linear complementarity problems. A matrix $M \in R^{n\times n}$ is said to be column sufficient if

$$z_i(Mz)_i \leq 0 \quad \forall i \quad \text{implies} \quad z_i(Mz)_i = 0 \quad \forall i.$$

The matrix M is called row sufficient if its transpose is column sufficient. The matrix M is sufficient if it is both column and row sufficient. It is proved in the same book

that the class of sufficient matrices is closely related to the existence of the solution of the linear complementarity problems and the convexity of the solution set. A surprising result given by Väliaho [22] showed that the class of P_* matrices coincides with the class of sufficient matrices. Therefore, every P_* linear complementarity problem is a sufficient linear complementarity problem, and vice versa. The class of sufficient linear complementarity problems is a very general framework for studying interior-point methods. In 1995 Miao [8] extended the MTY predictor-corrector algorithm for $P_*(\kappa)$ linear complementarity problems. His algorithm has $O((1+\kappa)\sqrt{n}L)$ iteration complexity and is quadratically convergent for nondegenerate problems. However, the constant κ is explicitly used in the construction of the algorithm, which implies that the algorithm cannot be used for sufficient linear complementarity problems. Potra and Sheng [17] extended the MTY predictor-corrector algorithm further for sufficient complementarity problems. While the algorithms of [17] do not depend on the constant κ, their computational complexity does: if the problem is a $P_*(\kappa)$ linear complementarity problem, they terminate in at most $O((1+\kappa)\sqrt{n}L)$ iterations. Moreover, the algorithms may attain arbitrarily high orders of convergence on nondegenerate problems. Predictor-corrector algorithms with arbitrarily high order of convergence for degenerate sufficient linear complementarity problems were given in [19]. The algorithms, as shown in [18], have $O((1+\kappa)\sqrt{n}L)$ iteration complexity for $P_*(\kappa)$ linear complementarity problems.

All the above algorithms operate in l_2 neighborhoods, also known as the small neighborhoods, of the central path. It is well known, however, that primal-dual interior-point methods have better practical performances in wide neighborhoods of the central path. Unfortunately, the iteration complexity of the predictor-corrector methods that use wide neighborhoods is worse than the complexity of the corresponding methods for small neighborhoods. Moreover, as shown in [2, 4], it is more difficult to develop and analyze predictor-corrector methods in wide neighborhoods. The best iteration complexity achieved by any known interior-point method for monotone linear complementarity problems in the wide neighborhoods using first order information is $O(nL)$. By using a large neighborhood defined by a suitable self-regular proximity measure, Peng, Terlaky, and Zhao [12] have obtained a predictor-corrector method with $O(\log n\sqrt{n}L)$ iteration complexity which is superlinearly convergent on nondegenerate problems. It turns out that the complexity result can be improved by using higher order information. The algorithms described in [11, 5, 24] have $O(\sqrt{n}L)$ iteration complexity. However, these algorithms are not of a predictor-corrector type, and they are not superlinearly convergent. The algorithm described in [20] operates in the δ_∞^- neighborhood and is superlinear convergent for sufficient linear complementarity problems, but no complexity results have been proved for this algorithm. A predictor-corrector method for monotone linear complementarity problems using wide neighborhoods of the central path was proposed in [14]. The algorithm has $O(\sqrt{n}L)$ iteration complexity by using a higher order predictor, and it is superlinear convergent even for degenerate problems. In a recent paper, Potra and Liu [16] extended the algorithm in [14] to sufficient linear complementarity problems. Two algorithms are analyzed in [16]. Both algorithms are of predictor-corrector type acting in between two wide neighborhoods of the central path. The radii of those neighborhoods have to satisfy an inequality that depends on the handicap κ of the problems. The first algorithm in [16] depends also on κ, while the second does not. The second algorithm uses the first algorithm by assigning $\kappa = 1$ and then doubles κ until a certain criterion is satisfied. Both algorithms have

$O((1+\kappa)^{1+1/m}\sqrt{n}L)$ iteration complexity and are superlinearly convergent even for degenerate problems.

The traditional predictor-corrector algorithms operate between two neighborhoods of the central path. The predictor step aims to decrease the duality gap while keeping the point in the outer neighborhood. It is followed by a corrector step, which brings the point back into the inner neighborhood so that the next predictor-corrector iteration can be performed. As analyzed in a recent paper [15], the centering direction is not as efficient in the wide neighborhoods as in the small neighborhoods, so that a line search on the centering direction is always needed in the corrector step using wide neighborhoods. Moreover, since the pure centering direction is anyhow inefficient in the wide neighborhoods, a corrector-predictor method was proposed in [15], where the corrector is used to improve both optimality and centrality. In the present paper, we generalize this algorithm to sufficient linear complementarity problems. By using higher order information, the algorithm has $O((1+\kappa)\sqrt{n}L)$ iteration complexity, which matches the best iteration complexity obtained in the small neighborhoods. Moreover, our algorithm is superlinearly convergent even for degenerate problems. More precisely, by using a predictor with order $m_p > 1$, we show that the duality gap converges to zero with Q-order $m_p + 1$ in the nondegenerate case and with Q-order $(m_p + 1)/2$ in the degenerate case. Our algorithm improves considerably the results of [16]. First, the algorithm is a corrector-predictor interior-point method so that it uses only one wide neighborhood of the central path, whose radius can be any number between 0 and 1, and therefore does not depend on κ. Second, its iteration complexity is improved ($O((1+\kappa)\sqrt{n}L)$ versus $O((1+\kappa)^{1+1/m}\sqrt{n}L)$). Finally, by contrast with the algorithms of [16] the present algorithm reduces the duality gap both in the corrector and the predictor steps, and therefore it is more efficient. In the present paper we work on horizontal linear complementarity problems (HLCP), which is a slight generalization of the standard linear complementarity problem. Equivalence results of different variants of linear complementarity problems can be found in [1]. We choose to work on HLCP because of its symmetry.

Conventions. We denote by $\mathbb{N}$ the set of all nonnegative integers. $\mathbb{R}$, $\mathbb{R}_+$, and $\mathbb{R}_{++}$ denote the set of real, nonnegative real, and positive real numbers, respectively. For any real number κ, $\lceil\, \kappa \,\rceil$ denotes the smallest integer greater than or equal to κ. Given a vector x, the corresponding uppercase symbol denotes, as usual, the diagonal matrix X defined by the vector. The symbol e represents the vector of all ones, with dimension given by the context.

We denote componentwise operations on vectors by the usual notations for real numbers. Thus, given two vectors u, v of the same dimension, uv, u/v, etc. will denote the vectors with components $u_i v_i$, u_i/v_i, etc. This notation is consistent as long as componentwise operations always have precedence in relation to matrix operations. Note that $uv \equiv Uv$ and if A is a matrix, then $Auv \equiv AUv$, but in general $Auv \neq (Au)v$. Also if f is a scalar function and v is a vector, then $f(v)$ denotes the vector with components $f(v_i)$. For example if $v \in \mathbb{R}^n_+$, then $\sqrt{v}$ denotes the vector with components $\sqrt{v_i}$, and $1 - v$ denotes the vector with components $1 - v_i$. Traditionally the vector $1 - v$ is written as $e - v$, where e is the vector of all ones. Inequalities are to be understood in a similar fashion. For example if $v \in \mathbb{R}^n$, then $v \geq 3$ means that $v_i \geq 3$, $i = 1, \ldots, n$. Traditionally this is written as $v \geq 3\, e$. If $\|\,.\,\|$ is a vector norm on $\mathbb{R}^n$ and A is a matrix, then the operator norm induced by $\|\,.\,\|$ is defined by $\|\,A\,\| = \max\{\|\,Ax\,\| \;;\; \|\,x\,\| = 1\}$. As a particular case we note that if U is the diagonal matrix defined by the vector u, then $\|\,U\,\|_2 = \|\,u\,\|_\infty$.

We use the notations $O(\cdot)$, $\Omega(\cdot)$, $\Theta(\cdot)$, and $o(\cdot)$ in the standard way to express asymptotic relationships between functions. The most common usage will be associated with a sequence $\{x^k\}$ of vectors and a sequence $\{\tau_k\}$ of positive real numbers. In this case $x^k = O(\tau_k)$ means that there is a constant K (dependent on problem data) such that for every $k \in \mathbb{N}$, $\left\| x^k \right\| \leq K\tau_k$. Similarly, if $x^k > 0$, $x^k = \Omega(\tau_k)$ means that $(x^k)^{-1} = O(1/\tau_k)$. If we have both $x^k = O(\tau_k)$ and $x^k = \Omega(\tau_k)$, we write $x^k = \Theta(\tau_k)$.

If $x, s \in \mathbb{R}^n$, then the vector $z \in \mathbb{R}^{2n}$ obtained by concatenating x and s will be denoted by $\lceil\, x,\, s \,\rfloor$, i.e.,

$$z = \lceil\, x,\, s \,\rfloor = \begin{bmatrix} x \\ s \end{bmatrix} = \left[\, x^T,\, s^T \,\right]^T. \tag{1.1}$$

Throughout this paper the mean value of xs will be denoted by

$$\mu(z) = \frac{x^T s}{n}. \tag{1.2}$$

2. The $P_*(\kappa)$ horizontal linear complementarity problem. Given two matrices $Q, R \in \mathbb{R}^{n\times n}$ and a vector $b \in \mathbb{R}^n$, the horizontal linear complementarity problem (HLCP) consists in finding a pair of vectors $z = \lceil\, x,\, s \,\rfloor$ such that

$$\begin{aligned} xs &= 0, \\ Qx + Rs &= b, \\ x, s &\geq 0. \end{aligned} \tag{2.1}$$

The standard (monotone) linear complementarity problem (SLCP or simply LCP) is obtained by taking $R = -I$, and Q positive semidefinite. Let $\kappa \geq 0$ be a given constant. We say that (2.1) is a $P_*(\kappa)$ HLCP if

$$Qu + Rv = 0 \text{ implies } (1+4\kappa)\sum_{i\in\mathcal{I}^+} u_i v_i + \sum_{i\in\mathcal{I}^-} u_i v_i \geq 0 \quad \text{for any } u, v \in \mathbb{R}^n,$$

where $\mathcal{I}^+ = \{i : u_i v_i > 0\}$ and $\mathcal{I}^- = \{i : u_i v_i < 0\}$. If the above condition is satisfied, we say that (Q, R) is a $P_*(\kappa)$ pair and write $(Q, R) \in P_*(\kappa)$. In case $R = -I$, $(Q, -I)$ is a $P_*(\kappa)$ pair if and only if Q is a $P_*(\kappa)$ matrix in the sense that

$$(1+4\kappa)\sum_{i\in\hat{\mathcal{I}}^+} x_i[Qx]_i + \sum_{i\in\hat{\mathcal{I}}^-} x_i[Qx]_i \geq 0 \quad \forall x \in \mathbb{R}^n,$$

where $\hat{\mathcal{I}}^+ = \{i : x_i[Qx]_i > 0\}$ and $\hat{\mathcal{I}}^- = \{i : x_i[Qx]_i < 0\}$. Problem (2.1) is then called a $P_*(\kappa)$ LCP and is extensively discussed in [7]. If (Q, R) belongs to the class

$$P_* = \bigcup_{\kappa\geq 0} P_*(\kappa),$$

then we say that (Q, R) is a P_* pair and (2.1) is a P_* HLCP.

The class of sufficient matrices was defined by Cottle, Pang, and Stone [3]. The appropriate generalization to sufficient pair [18, 19] is in terms of the null space of the matrix $[Q\ R] \in \mathbb{R}^{n\times 2n}$

$$\Phi := \mathcal{N}([Q\ R]) = \{\lceil\, u,\, v \,\rfloor | Qu + Rv = 0\} \tag{2.2}$$

and its orthogonal space

$$\Phi^{\perp} = \left\{ \lceil\, u,\, v \,\rfloor | u = Q^T x,\, v = R^T x \ \text{ for some } x \in \mathbb{R}^n \right\}. \tag{2.3}$$

(Q, R) is called column sufficient if

$$\lceil\, u,\, v \,\rfloor \in \Phi, \quad uv \leq 0 \text{ implies } uv = 0,$$

and row sufficient if

$$\lceil\, u,\, v \,\rfloor \in \Phi^{\perp}, \quad uv \geq 0 \text{ implies } uv = 0.$$

(Q, R) is a sufficient pair if it is both column and row sufficient. The corresponding results of row and column sufficient matrices in [3] can be extended to row and column sufficient pairs (see, for example, [20]): (Q, R) is a sufficient pair if and only if for any b, the HLCP (2.1) has a convex (perhaps empty) solution set and every KKT point of

$$\begin{array}{cc} \min_{x,s}, & x^T s \\ \text{s.t.} & Qx + Rs = b, \\ & x, s \geq 0, \end{array}$$

is a solution of (2.1).

Väliaho's result [22] states that a matrix is sufficient if and only if it is a $P_*(\kappa)$ matrix for some $\kappa \geq 0$. The result can be extended to sufficient pairs by using the equivalence results from [1] (see also [20]): (Q, R) is a sufficient pair if and only if there is a finite $\kappa \geq 0$ so that (Q, R) is a $P_*(\kappa)$ pair. By extension, a P_* HLCP will be called a sufficient HLCP and a P_* pair will be called a sufficient pair.

Let us note that if (Q, R) is a sufficient pair, then the matrix $[Q\ R]$ is full rank. In fact, we have the following slightly stronger result.

THEOREM 2.1. *Given two matrices $Q, R \in \mathbb{R}^{n\times n}$, if the pair (Q, R) is column sufficient, the matrix $[Q\ R]$ is full rank.*

Proof. Let r be the rank of Q, and the LU factorization of Q can be written as

$$PQ = L \begin{bmatrix} F_1 & F_2 \\ 0 & 0 \end{bmatrix},$$

where P is a permutation matrix, $L \in \mathbb{R}^{n\times n}$ is an invertible lower triangular matrix, $F_1 \in \mathbb{R}^{n-r\times n-r}$ is an invertible upper triangular matrix, and F_2 and the zeros are matrices with the correct dimensions.

Let us denote by G

$$G = L^{-1}PR = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix},$$

where $G_{11} \in \mathbb{R}^{n-r\times n-r}$, and G_{12}, G_{21}, and G_{22} are with the correct dimensions.

Since permutation matrices are invertible, and L is invertible, we have

$$\operatorname{rank}([Q\ R]) = \operatorname{rank}(L^{-1}P[Q\ R]) = \operatorname{rank}\left(\begin{bmatrix} F_1 & F_2 & G_{11} & G_{12} \\ 0 & 0 & G_{21} & G_{22} \end{bmatrix} \right).$$

We denote by u_1 and u_2 the components of u in the first r and last $n - r$ indices, respectively, and similarly for v. Therefore, $\lceil\, u,\, v \,\rfloor \in \Phi$ is equivalent to

$$\begin{cases} F_1 u_1 + F_2 u_2 + G_{11} v_1 + G_{12} v_2 = 0, \\ \qquad\qquad\qquad\quad G_{21} v_1 + G_{22} v_2 = 0. \end{cases}$$

For any $v_2 \in \mathrm{Ker}(G_{22})$, we construct a pair of vectors u and v such that

$$v_1 = 0, \quad u_2 = -v_2, \quad u_1 = -F_1^{-1}(F_2 u_2 + G_{12} v_2).$$

Clearly, we have $\lceil\, u,\, v \,\rfloor \in \Phi$. Moreover, we also obtain

$$u_1 v_1 \le 0 \quad \text{and} \quad u_2 v_2 = -v_2^2 \le 0.$$

Because (Q, R) is column sufficient, we have

$$u_1 v_1 = 0 \quad \text{and} \quad u_2 v_2 = 0.$$

We thus have that $v_2 \in \mathrm{Ker}(G_{22})$ implies $v_2 = 0$. Therefore G_{22} is invertible, and

$$\mathrm{rank}([Q\ R]) = \mathrm{rank}\left(\begin{bmatrix} F_1 & F_2 & G_{11} & G_{12} \\ 0 & 0 & G_{21} & G_{22} \end{bmatrix}\right) = n. \qquad \square$$

It is interesting to remark that row sufficiency alone does not imply the full rank property. For example, take

$$Q = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad R = \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix};$$

it is easily seen that (Q, R) is row sufficient, but $\mathrm{rank}([Q\ R]) = 1$. We also note that in [19, 18, 20], the full rank property was given as an assumption, which in fact always hold because of the above theorem.

We denote the set of all feasible points of HLCP by

$$\mathcal{F} = \{z = \lceil\, x,\, s \,\rfloor \in \mathbb{R}^{2n}_{+} \ : \quad Qx + Rs = b\}$$

and its solution set by

$$\mathcal{F}^* = \{z^* = \lceil\, x^*,\, s^* \,\rfloor \in \mathcal{F} \ : \quad x^* s^* = 0\}.$$

The relative interior of $\mathcal{F}$, which is also known as the set of strictly feasible points or the set of interior points, is given by

$$\mathcal{F}^0 = \mathcal{F} \bigcap \mathbb{R}^{2n}_{++}.$$

It is known (see, for example, [7]) that if $\mathcal{F}^0$ is nonempty, then the nonlinear system

$$\begin{aligned} xs &= \tau e, \\ Qx + Rs &= b \end{aligned}$$

has a unique positive solution for any $\tau > 0$. The set of all such solutions defines the central path $\mathcal{C}$ of the HLCP, that is,

$$\mathcal{C} = \{z \in \mathbb{R}^{2n}_{++} \ : \ F_\tau(z) = 0,\, \tau > 0\},$$

where

$$F_\tau(z) = \begin{bmatrix} xs - \tau e \\ Qx + Rs - b \end{bmatrix}.$$

If $F_\tau(z) = 0$, then it is easy to see that $\tau = \mu(z)$, where $\mu(z)$ is given by (1.2). The wide neighborhood $\mathcal{N}_\infty^-(\alpha)$ is defined as

$$\mathcal{N}_\infty^-(\alpha) = \{z \in \mathcal{F}^0 \ : \ \delta_\infty^-(z) \le \alpha\},$$

where $0 < \alpha < 1$ is a given parameter and

$$\delta_\infty^-(z) := \left\| \left[\frac{xs}{\mu(z)} - e \right]^- \right\|_\infty$$

is a proximity measure of z to the central path. Alternatively, if we denote

$$\mathcal{D}(\beta) = \{z \in \mathcal{F}^0 : xs \ge \beta\mu(z)\},$$

then the neighborhood $\mathcal{N}_\infty^-(\alpha)$ can also be written as

$$\mathcal{N}_\infty^-(\alpha) = \mathcal{D}(1-\alpha).$$

It is well known (see, for example, the proof in [15]) that

$$\lim_{\alpha \downarrow 0} \mathcal{N}_\infty^-(\alpha) = \lim_{\beta \uparrow 1} \mathcal{D}(\beta) = \mathcal{C}, \quad \lim_{\alpha \uparrow 1} \mathcal{N}_\infty^-(\alpha) = \lim_{\beta \downarrow 0} \mathcal{D}(\beta) = \mathcal{F}.$$

3. A higher order corrector-predictor algorithm. The higher order corrector and predictor use higher derivatives of the central path. Given a point $z = \lceil x, s \rfloor \in \mathcal{D}(\beta)$, we consider the curve given by an mth order vector valued polynomial of the form

$$z(\theta) = z + \sum_{i=1}^{m} w^i \theta^i, \tag{3.1}$$

where the vectors $w^i = \lceil u^i, v^i \rfloor$ are obtained as solutions of the following linear systems:

$$\begin{aligned}
&\begin{cases} su^1 + xv^1 = \gamma\mu e - (1+\epsilon)xs, \\ Qu^1 + Rv^1 = 0, \end{cases} \\
&\begin{cases} su^2 + xv^2 = \epsilon xs - u^1 v^1, \\ Qu^2 + Rv^2 = 0, \end{cases} \\
&\begin{cases} su^i + xv^i = -\sum_{j=1}^{i-1} u^j v^{i-j}, \\ Qu^i + Rv^i = 0, \end{cases} \qquad i = 3, \ldots, m.
\end{aligned} \tag{3.2}$$

In a corrector step we choose $\epsilon = 0$ and $\gamma \in [\underline{\gamma}, \overline{\gamma}]$, where $0 < \underline{\gamma} < \overline{\gamma} < 1$ are given parameters, while in a predictor step we take

$$\gamma = 0 \quad \text{and} \quad \epsilon = \begin{cases} 0 & \text{if HLCP is nondegenerate,} \\ 1 & \text{if HLCP is degenerate.} \end{cases} \tag{3.3}$$

We note that in the corrector step, where we have $\epsilon = 0$, w^1 is the affine scaling direction if $\gamma = 0$ and the classical centering direction if $\gamma = 1$. In system (3.2), w^1 is a convex combination of the affine scaling and the centering directions. The directions w^i are related to the higher derivatives of the central path [19]. We note that the central path passing through z is analytic in μ when HLCP is nondegenerate and in $\sqrt{\mu}$ when HLCP is degenerate.

As the m linear systems in (3.2) have the same left-hand matrix, only one matrix factorization and m backsolves are needed. Therefore it involves $O(n^3) + O(m\,n^2)$ arithmetic operations. We take $m = m_c$ in the corrector step, and $m = m_p$ in the predictor step. From (3.1) and (3.2) it follows that

$$x(\theta)s(\theta) = (1-\theta)^{1+\epsilon}xs + \gamma\theta\mu e + \sum_{i=m+1}^{2m} \theta^i h^i,$$

$$\mu(\theta) = (1-\theta)^{1+\epsilon}\mu + \gamma\theta\mu + \sum_{i=m+1}^{2m} \theta^i (e^T h^i/n),$$

$$\text{where } h^i = \sum_{j=i-m}^{m} u^j v^{i-j}. \tag{3.4}$$

In the development of our algorithm, we want to preserve positivity of each iterated point. We thus give an upper bound θ_0 for the step-length taken both in the predictor and the corrector step:

$$\theta_0 = \sup\{\hat{\theta}_0 \ :\ x(\theta) > 0,\ s(\theta) > 0 \quad \forall \theta \in [0\,, \hat{\theta}_0]\}. \tag{3.5}$$

We introduce the following notation, which will be used in describing both the corrector and predictor steps:

$$p(\theta) = \frac{x(\theta)s(\theta)}{\mu(\theta)}, \quad f(\theta) = \min_{i=1,\ldots,n} p_i(\theta). \tag{3.6}$$

The corrector. The corrector step is obtained by taking $\epsilon = 0$, and $0 < \gamma < 1$ in (3.1)–(3.2). The main purpose of the corrector step is to increase proximity to the central path. However, we also improve the normalized complementarity gap $\mu(\theta)$ at the same time. We choose $\sigma \in [\underline{\sigma}, \overline{\sigma}]$, where $0 < \underline{\sigma} < \overline{\sigma} < 1$ are given parameters, and define

$$\theta_1 = \sup\{\hat{\theta}_1 \ :\ 0 \le \hat{\theta}_1 \le \theta_0,\ \mu(\theta) \le (1 - \sigma(1-\gamma)\theta)\mu \quad \forall \theta \in [0, \hat{\theta}_1]\}. \tag{3.7}$$

The step-length of the corrector is obtained as

$$\theta_c = \operatorname{argmax}\{f(\theta) \ :\ \theta \in [\,0, \theta_1]\,\}. \tag{3.8}$$

As a result of the corrector step we obtain the point

$$\overline{z} = \lceil\, \overline{x}\,,\, \overline{s}\,\rfloor := z(\theta_c). \tag{3.9}$$

We have clearly $\overline{z} \in \mathcal{D}(\beta_c)$ with $\beta_c > \beta$. While the parameter β is fixed during the algorithm, the positive quantity β_c varies from iteration to iteration. However, we will prove that there is a constant $\beta_c^* > \beta$, such that $\beta_c > \beta_c^*$ in all iterations.

The predictor. The predictor is obtained by taking $z = \overline{z}$, where $\overline{z}$ is the result of the corrector step, and $\gamma = 0$ in (3.1)–(3.2). The aim of the predictor step is to decrease the normalized complementarity gap as much as possible while keeping the iterate in $\mathcal{D}(\beta)$. We define the predictor step-length as

$$\theta_p = \operatorname{argmin}\{\mu(\theta) \ :\ \theta \in [\,0, \theta_2\,]\,\}, \tag{3.10}$$

where

$$\theta_2 = \max\{\hat{\theta}_2 \ : \ z(\theta) \in \mathcal{D}(\beta) \quad \forall \theta \in [0, \hat{\theta}_2]\}. \tag{3.11}$$

A standard continuity argument can be used to show that $z(\theta) > 0 \ \forall \theta \in [0, \theta_2]$. As a result of the predictor step, we obtain a point

$$z^+ = \lceil x^+, s^+ \rfloor := z(\theta_p). \tag{3.12}$$

By construction we have $z^+ \in \mathcal{D}(\beta)$, so that a new corrector step can be applied. Summing up we can formulate the following iterative procedure.

ALGORITHM 1.

Given real parameters $0 < \beta < 1$, $0 < \underline{\gamma} < \overline{\gamma} < 1$, $0 < \underline{\sigma} < \overline{\sigma} < 1$, integers m_c, $m_p \geq 1$, and a vector $z^0 \in \mathcal{D}(\beta)$:

Set $k \leftarrow 0$;
repeat
(corrector step)
Set $z \leftarrow z^k$;
Choose $\gamma \in [\underline{\gamma}, \overline{\gamma}]$ and set $m = m_c$;
Compute directions $w^i = \lceil u^i, v^i \rfloor$, $i = 1, \ldots, m$, by solving (3.2);
Compute θ_0 from (3.5)
If HLCP is skew-symmetric, set $\sigma = 1$ and $\theta_1 = \theta_0$;
Else, choose $\sigma \in [\underline{\sigma}, \overline{\sigma}]$, and compute θ_1 from (3.7);
Compute corrector step-length θ_c from (3.8);
Compute $\overline{z}$ from (3.9);
Set $\overline{z}^k \leftarrow \overline{z}$, $\overline{\mu}_k \leftarrow \overline{\mu} = \mu(\overline{z})$.
(predictor step)
Set $z \leftarrow \overline{z}^k$, $\gamma = 0$, and $m = m_p$;
Compute directions $w^i = \lceil u^i, v^i \rfloor$, $i = 1, \ldots, m$, by solving (3.2);
Compute θ_p from (3.10);
Compute z^+ from (3.12);
Set $z^{k+1} \leftarrow z^+$, $\mu_{k+1} \leftarrow \mu^+ = \mu(z^+)$, $k \leftarrow k + 1$.
continue

The computation of the exact values of θ_c and θ_p is quite involved, so that in practice good estimates of θ_c and θ_p are obtained by appropriate line search procedures. In particular, by adopting the line search procedure from [15] we can preserve both the computational complexity and the superlinear convergence of the theoretical algorithm. In fact the convergence properties can be proved by using the explicit lower bounds in the next section.

4. Polynomial complexity. We analyze in this section the computational complexity of Algorithm 1. In the proof of the complexity results, we will use the following lemmas, which were proved in [16].

LEMMA 4.1. *Assume that HLCP* (2.1) *is* $P_*(\kappa)$, *let* $w = \lceil u, v \rfloor$ *be the solution of the linear system*

$$\begin{aligned} su + xv &= a, \\ Qu + Rv &= 0, \end{aligned}$$

where $z = \lceil x, s \rfloor \in \mathbb{R}^{2n}_{++}$ *and* $a \in \mathbb{R}^n$ *are given vectors, and consider the index sets:*

$$\mathcal{I}^+ = \{i : u_i v_i > 0\}, \quad \mathcal{I}^- = \{i : u_i v_i < 0\}.$$

Then the following inequalities are satisfied:

$$\frac{1}{1+4\kappa}\,\|\,u\,v\,\|_\infty \le \sum_{i\in\mathcal{I}_+} u_i v_i \le \frac{1}{4}\left\|\,(xs)^{-1/2}\,a\,\right\|_2^2.$$

LEMMA 4.2. *Assume that HLCP* (2.1) *is* $P_*(\kappa)$*, and let* $w = \lceil\, u,\, v \,\rfloor$ *be the solution of the linear system*

$$\begin{aligned} su + xv &= a,\\ Qu + Rv &= 0, \end{aligned}$$

where $z = \lceil\, x,\, s\,\rfloor \in \mathbb{R}^{2n}_{++}$ *and* $a \in \mathbb{R}^n$ *are given vectors. Then the following inequality holds:*

$$u^T v \ge -\kappa \left\|\,(xs)^{-1/2}\,a\,\right\|_2^2. \tag{4.1}$$

Let us denote

$$\eta_i = \left\|\,Du^i + D^{-1}v^i\,\right\|_2, \text{ where } D = X^{-1/2}S^{1/2}. \tag{4.2}$$

The following lemma is a slight improvement over the corresponding results in [16] and a generalization to sufficient HLCP of the corresponding results in [15].

LEMMA 4.3. *If HLCP* (2.1) *is sufficient and* $z = \lceil\, x,\, s\,\rfloor \in \mathcal{D}(\beta)$*, then for* $n \ge 8$*, the solution of* (3.2) *satisfies*

$$\frac{1}{\sqrt{1+2\kappa}}\sqrt{\|\,Du^i\,\|_2^2 + \|\,D^{-1}v^i\,\|_2^2} \le \eta_i \le \frac{2}{1+2\kappa}\alpha_i\sqrt{\beta\mu}\left(\frac{(1+2\kappa)\tau}{4}\sqrt{n}\right)^i, \tag{4.3}$$

where

$$\tau = \frac{2\sqrt{\beta(1+\epsilon-\gamma)^2 + (1-\beta)\gamma^2}}{\beta}, \tag{4.4}$$

and the sequence

$$\alpha_i = \frac{1}{i}\binom{2i-2}{i-1} \le \frac{1}{i}4^i$$

is the solution of the following recurrence scheme:

$$\alpha_1 = 1, \quad \alpha_i = \sum_{j=1}^{i-1}\alpha_j\,\alpha_{i-j}.$$

Proof. The first part of the inequality follows immediately, since by using (3.2) and Lemma 4.2 we have

$$\left\|\,Du^i + D^{-1}v^i\,\right\|_2^2 = \left\|\,Du^i\,\right\|_2^2 + 2u^{i\,T}v^i + \left\|\,D^{-1}v^i\,\right\|_2^2$$

$$\ge \left\|\,Du^i\,\right\|_2^2 + \left\|\,D^{-1}v^i\,\right\|_2^2 - 2\kappa\left\|\,Du^i + D^{-1}v^i\,\right\|_2^2.$$

By multiplying the first equations of (3.2) with $(xs)^{-1/2}$ we obtain

$$\begin{aligned} Du^1 + D^{-1}v^1 &= -\big((1+\epsilon)(xs)^{1/2} - \gamma\mu(xs)^{-1/2}\big), \\ Du^2 + D^{-1}v^2 &= -\big(\epsilon(xs)^{1/2} - (xs)^{-1/2}u^1v^1\big), \\ Du^i + D^{-1}v^i &= -(xs)^{-1/2}\sum_{j=1}^{i-1} Du^j D^{-1}v^{i-j}, \quad 3 \le i \le m. \end{aligned}$$

Because $z \in \mathcal{D}(\beta)$ we have $(xs)^{-1/2} \le (1/\sqrt{\beta\mu})e$, and we deduce that

$$\eta_1 = \|(1+\epsilon)(xs)^{1/2} - \gamma\mu(xs)^{-1/2}\|, \quad \eta_2 = \|\epsilon(xs)^{1/2} - (xs)^{-1/2}u^1v^1\|,$$

and

$$\eta_i \le \frac{1}{\sqrt{\beta\mu}}\sum_{j=1}^{i-1} \| Du^j \|_2 \, \| D^{-1}v^{i-j} \|_2, \quad 3 \le i \le m. \tag{4.5}$$

We have

$$\begin{aligned} \eta_1^2 = \|(1+\epsilon)(xs)^{1/2} - \gamma\mu(xs)^{-1/2}\|^2 &= \sum_{j=1}^{n}\left((1+\epsilon)^2 x_j s_j - 2(1+\epsilon)\gamma\mu + \frac{\gamma^2\mu^2}{x_j s_j}\right) \\ &= ((1+\epsilon)^2 - 2(1+\epsilon)\gamma)\mu n + \gamma^2\mu^2\sum_{j=1}^{n}\frac{1}{x_j s_j} \\ &\le \mu n\left((1+\epsilon)^2 - 2(1+\epsilon)\gamma + \frac{\gamma^2}{\beta}\right) = \frac{\beta\mu n\tau^2}{4}, \end{aligned}$$

which shows that the second inequality in (4.3) is satisfied for $i = 1$. We next show that the inequality also holds for $i = 2$; i.e., we want to prove that

$$\eta_2^2 \le \left(\frac{1+2\kappa}{8}\right)^2 \beta\mu n^2\tau^4 \; = \frac{1}{128}\beta\mu n^2\tau^4(2 + 8\kappa + 8\kappa^2).$$

Using Lemma 4.2, Corollary 2.3 of [13], and the fact $z \in \mathcal{D}(\beta)$, we have

$$\begin{aligned} \eta_2^2 = \|\epsilon(xs)^{1/2} - (xs)^{-1/2}u^1v^1\|^2 &= \sum_{j=1}^{n}\left(\epsilon^2 x_j s_j - 2\epsilon u_i^1 v_i^1 + \frac{(u_i^1 v_i^1)^2}{x_j s_j}\right) \\ \le \epsilon^2 n\mu + 2\epsilon\kappa\eta_1^2 + \frac{\eta_1^4}{8\beta\mu}(1 + 4\kappa + 8\kappa^2) &\le \epsilon^2 n\mu + \frac{\epsilon\kappa\beta\mu n\tau^2}{2} + \frac{\beta\mu n^2\tau^4}{128}(1 + 4\kappa + 8\kappa^2). \end{aligned}$$

Therefore, it remains to show that

$$\epsilon^2 n\mu + \frac{\epsilon\kappa\beta\mu n\tau^2}{2} \le \frac{\beta\mu n^2\tau^4}{128}(1 + 4\kappa),$$

which holds trivially for $\epsilon = 0$. The inequality holds for $\epsilon = 1$, provided

$$\beta n\tau^4 \ge 128, \quad n\tau^2 \ge 16.$$

Using the definition of τ (4.4), this reduces to

$$\frac{n(\beta(2-\gamma)^2 + (1-\beta)\gamma^2)^2}{\beta^3} \ge 8, \quad \frac{n(\beta(2-\gamma)^2 + (1-\beta)\gamma^2)}{\beta^2} \ge 4.$$

Since the minimum over $0 \le \beta, \gamma \le 1$ of both left-hand side functions is attained at $\beta = \gamma = 1$, we conclude that the second inequality in (4.3) is satisfied for $i = 2$ whenever $n \ge 8$. For $i \ge 3$ and $1 \le j < i$ we use the first inequality in (4.2) to obtain

$$\begin{aligned}
&\| Du^j \|_2 \, \| D^{-1}v^{i-j} \|_2 + \| Du^{i-j} \|_2 \, \| D^{-1}v^j \|_2 \\
&\quad \le \left(\| Du^j \|_2^2 + \| D^{-1}v^j \|_2^2 \right)^{1/2} \left(\| Du^{i-j} \|_2^2 + \| D^{-1}v^{i-j} \|_2^2 \right)^{1/2} \\
&\quad \le (1+2\kappa)\eta_j \, \eta_{i-j}.
\end{aligned}$$

From (4.5) it follows that

$$\eta_i \le \frac{1+2\kappa}{2\sqrt{\beta\mu}} \sum_{j=1}^{i-1} \eta_j \, \eta_{i-j}, \quad i = 2, \ldots, m.$$

The required inequalities are then easily proved by mathematical induction. ∎

By virtue of Lemma 4.3 we obtain the following bound for $\|h^i\|$.

LEMMA 4.4. *If HLCP* (2.1) *is sufficient and* $z = \lceil x, s \rfloor \in \mathcal{D}(\beta)$, *then for* $n \ge 8$, *the directions computed in* (3.4) *satisfy*

$$\zeta_i := \|h^i\| \le \frac{2\beta\mu}{(1+2\kappa)i} ((1+2\kappa)\tau\sqrt{n}\,)^i, \quad i = m+1, \ldots, 2m. \tag{4.6}$$

Proof. For any $m+1 \le i \le 2m$, we have

$$\begin{aligned}
\| h^i \|_2 &\le \sum_{j=i-m}^{m} \| Du^j \|_2 \, \| D^{-1}v^{i-j} \|_2 \le \sum_{j=1}^{i-1} \| Du^j \|_2 \, \| D^{-1}v^{i-j} \|_2 \\
&= \frac{1}{2} \sum_{j=1}^{i-1} \left(\| Du^j \|_2 \, \| D^{-1}v^{i-j} \|_2 + \| Du^{i-j} \|_2 \, \| D^{-1}v^j \|_2 \right) \\
&\le \frac{1}{2} \sum_{j=1}^{i-1} \sqrt{\| Du^j \|_2^2 + \| D^{-1}v^j \|_2^2} \sqrt{\| Du^{i-j} \|_2^2 + \| D^{-1}v^{i-j} \|_2^2} \\
&\le \frac{1+2\kappa}{2} \sum_{j=1}^{i-1} \eta_j \, \eta_{i-j} \le \frac{2\beta\mu}{1+2\kappa} \left(\frac{(1+2\kappa)\tau\sqrt{n}}{4} \right)^i \sum_{j=1}^{i-1} \alpha_j \, \alpha_{i-j} \\
&= \frac{2\beta\mu}{1+2\kappa} \left(\frac{(1+2\kappa)\tau\sqrt{n}}{4} \right)^i \alpha_i \le \frac{2\beta\mu}{(1+2\kappa)i} \left((1+2\kappa)\tau\sqrt{n} \right)^i,
\end{aligned}$$

where the last inequality follows from the fact that $\alpha_i \le \frac{1}{i} 4^i$. ∎

From the above lemmas we obtain the following result.

COROLLARY 4.5. *If HLCP* (2.1) *is sufficient and* $z = \lceil x, s \rfloor \in \mathcal{D}(\beta)$, *then the following relations hold for any* $\alpha > 0$, $\kappa \ge 0$, *and* $n \ge 8$*:*

$$\frac{\alpha}{\mu} \sum_{i=m+1}^{2m} \theta^i \| h^i \|_2 < 1 \quad \forall\, 0 \le \theta \le \frac{1}{(1+2\kappa)\tau\sqrt{n}} \min \left\{ 1, \left(\frac{1.4\,\alpha\beta}{1+2\kappa} \right)^{\frac{-1}{m+1}} \right\}, \tag{4.7}$$

$$\frac{\alpha}{\mu\sqrt{n}} \sum_{i=m+1}^{2m} \theta^i \| h^i \|_2 < \theta \quad \forall\, 0 \le \theta \le \frac{1}{(1+2\kappa)\tau\sqrt{n}} \min \left\{ 1, \left(1.4\,\alpha\beta\tau \right)^{\frac{-1}{m}} \right\}. \tag{4.8}$$

Proof. For any $t \in (0,1]$, we have

$$\sum_{i=m+1}^{2m} \frac{t^i}{i} \le t^{m+1} \sum_{i=m+1}^{2m} \frac{1}{i} < t^{m+1} \int_m^{2m} \frac{du}{u} = t^{m+1} \log 2 < .7\, t^{m+1}.$$

Using Lemma 4.4 and the above inequality, we obtain

$$\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 < \frac{1.4\beta\mu}{1+2\kappa}((1+2\kappa)\tau\sqrt{n}\theta)^{m+1} \quad \forall\, \theta \in \left(0,\ \frac{1}{(1+2\kappa)\tau\sqrt{n}}\right]. \tag{4.9}$$

Therefore,

$$\frac{\alpha}{\mu} \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 < \frac{1.4\alpha\beta}{1+2\kappa}((1+2\kappa)\tau\sqrt{n}\theta)^{m+1} \le 1$$
$$\forall\, \theta \in \left(0,\ \frac{1}{(1+2\kappa)\tau\sqrt{n}} \min\left\{1\,,\ \left(\frac{1.4\,\alpha\beta}{1+2\kappa}\right)^{\frac{-1}{m+1}}\right\}\right].$$

Equation (4.9) also implies that

$$\frac{\alpha}{\mu\sqrt{n}} \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 < \frac{1.4\alpha\beta}{(1+2\kappa)\sqrt{n}}((1+2\kappa)\tau\sqrt{n}\theta)^{m+1}$$
$$= 1.4\alpha\beta\tau\theta\ ((1+2\kappa)\tau\sqrt{n}\theta)^m \le \theta$$
$$\forall\, \theta \in \left(0,\ \frac{1}{(1+2\kappa)\tau\sqrt{n}} \min\left\{1\,,\ (1.4\,\alpha\beta\tau)^{\frac{-1}{m}}\right\}\right]. \qquad \square$$

From the definition of τ (4.4) it follows that

$$\frac{2(1+\epsilon)\sqrt{1-\beta}}{\sqrt{\beta}} \le \tau \le 2\max\left\{\frac{1+\epsilon}{\sqrt{\beta}}\,,\ \frac{\sqrt{1-\beta+\beta\epsilon^2}}{\beta}\right\} < \frac{2(1+\epsilon)}{\beta}. \tag{4.10}$$

In the corrector step we take $\epsilon = 0$; therefore we will use the bound $\tau < 2/\beta$ in the analysis below.

THEOREM 4.6. *If HCLP* (2.1) *is sufficient, then Algorithm* 1 *is well defined and the following relations hold for any* $\kappa \ge 0$ *and* $n \ge 8$*:*

$$\overline{z}^{\,k}, z^k \in \mathcal{D}(\beta),$$

$$\mu_{k+1} \le \left(1 - \frac{\chi}{(1+2\kappa)n^{\frac{1}{2}+\frac{m_c+1}{2m_c(m_p+1)}}}\right)\overline{\mu}_{\,k}, \quad k = 0, 1, \ldots,$$

$$\overline{\mu}_{\,k+1} \le \left(1 - \frac{\overline{\chi}}{(1+2\kappa)n^{\frac{1}{2}+\upsilon}}\right)\overline{\mu}_{\,k}, \quad k = 0, 1, \ldots,$$

where χ, $\overline{\chi}$ *are constants depending only on* $\beta, \underline{\gamma}, \overline{\gamma}\,, \underline{\sigma}, \overline{\sigma}\,$, *and*

$$\upsilon := \min\left\{\frac{1}{2m_c},\ \frac{m_c+1}{2m_c(m_p+1)}\right\}. \tag{4.11}$$

Proof.

Analysis of the corrector. On the corrector we have $m = m_c$, $\epsilon = 0$, $0 < \underline{\gamma} < \gamma < \overline{\gamma} < 1$, $0 < \underline{\sigma} < \gamma < \overline{\sigma} < 1$, and $\tau < 2/\beta$.

First, we prove that if $z \in \mathcal{D}(\beta)$, then the quantities θ_0 defined in (3.5) satisfy

$$\theta_0 \geq \theta_3 := \frac{\beta}{2(1+2\kappa)\sqrt{n}} \left(\frac{2.8}{1+2\kappa} \right)^{-\frac{1}{m_c+1}}. \tag{4.12}$$

This can be shown by using (4.7) with $\alpha = 2/\beta$ and the fact that $\theta_3 < 1/2$,

$$\frac{x(\theta)s(\theta)}{\mu} > (1-\theta)\frac{xs}{\mu} + \frac{1}{\mu}\sum_{i=m+1}^{2m} \theta^i h^i \geq \frac{\beta}{2}e - \frac{1}{\mu}\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 e > 0 \quad \forall \theta \in [0,\, \theta_3].$$

Since $x(0) > 0, s(0) > 0$, we can use a standard continuity argument to show that $x(\theta) > 0, s(\theta) > 0 \ \forall\, \theta \in [0, \theta_3]$, which proves that $\theta_0 \geq \theta_3$.

Next, we show that the quantities θ_1 defined in (3.7) satisfy

$$\theta_1 \geq \theta_4 := \frac{\beta}{2(1+2\kappa)\sqrt{n}} \left(\frac{(1-\overline{\sigma}\,)(1-\overline{\gamma}\,)}{2.8} \right)^{\frac{1}{m_c}}. \tag{4.13}$$

By using (4.8) with $\alpha = 1/\left((1-\overline{\sigma}\,)(1-\overline{\gamma}\,)\right)$, we deduce that the following inequalities hold for any $\theta \in [0,\, \theta_4]$:

$$\begin{aligned} \frac{\mu(\theta) - (1-\sigma(1-\gamma)\theta)\mu}{\mu} &= -(1-\sigma)(1-\gamma)\theta + \frac{1}{\mu\, n}\sum_{i=m+1}^{2m} \theta^i e^T h^i \\ &\leq -(1-\overline{\sigma}\,)(1-\overline{\gamma}\,)\theta + \frac{1}{\mu\sqrt{n}}\sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 \leq 0, \end{aligned}$$

which shows that $\theta_1 \geq \theta_4$.

At last, we show that if $z \in \mathcal{D}(\beta)$, then

$$f(\theta) \geq \beta + \frac{1}{2}(1-\beta)\gamma\,\theta \geq \beta + \frac{1}{2}(1-\beta)\underline{\gamma}\,\theta \quad \forall\, \theta \in [0, \theta_5]\,, \tag{4.14}$$

where

$$\theta_5 := \min\left\{ \theta_4,\ \frac{\beta}{2(1+2\kappa)\, n^{\frac{1}{2}+\frac{1}{2m_c}}} \left(\frac{(1-\beta)\underline{\gamma}}{5.6} \right)^{\frac{1}{m_c}} \right\} \geq \frac{\chi_5}{(1+2\kappa)n^{\frac{1}{2}+\frac{1}{2m_c}}}, \tag{4.15}$$

$$\chi_5 := \frac{\beta}{2}\min\left\{ \frac{(1-\overline{\sigma}\,)(1-\overline{\gamma}\,)}{2.8}\,,\ \frac{(1-\beta)\underline{\gamma}}{5.6} \right\}. \tag{4.16}$$

It is easily seen that

$$\begin{aligned} p(\theta) = \frac{x(\theta)s(\theta)}{\mu(\theta)} &= \frac{(1-\theta)xs + \gamma\theta\mu e + \sum_{i=m+1}^{2m} \theta^i h^i}{(1-\theta)\mu + \gamma\theta\mu + \sum_{i=m+1}^{2m} \theta^i e^T h^i/n} \\ &\geq \frac{(1-\theta)\beta\mu e + \gamma\theta\mu e + \sum_{i=m+1}^{2m} \theta^i h^i}{(1-\theta)\mu + \gamma\theta\mu + \sum_{i=m+1}^{2m} \theta^i e^T h^i/n} \end{aligned} \tag{4.17}$$

$$= \beta e \frac{(1-\beta)\gamma\theta\mu e + \beta\sum_{i=m+1}^{2m}\theta^i(h^i - (e^Th^i/n)e) + (1-\beta)\sum_{i=m+1}^{2m}\theta^i h^i}{(1-\theta)\mu + \gamma\theta\mu + \sum_{i=m+1}^{2m}\theta^i e^T h^i/n}$$

$$\geq \beta e + \frac{(1-\beta)\gamma\theta\mu - \sum_{i=m+1}^{2m}\theta^i \left\| h^i \right\|_2}{\mu(\theta)}\, e$$

$$\geq \beta e + (1-\beta)\gamma\theta - \frac{1}{\mu}\sum_{i=m+1}^{2m}\theta^i \left\| h^i \right\|_2 e \quad \forall\, \theta \in [0,1].$$

The last inequality follows from the fact that

$$\mu(\theta) \leq (1-\sigma(1-\gamma)\theta)\mu \leq \mu \quad \forall\, \theta \in [0,\, \theta_4].$$

According to (4.8), with α replaced by $2\sqrt{n}/((1-\beta)\gamma)$ and τ replaced by $2/\beta$, we have

$$\frac{1}{\mu}\sum_{i=m+1}^{2m}\theta^i \left\| h^i \right\|_2 < \frac{1}{2}(1-\beta)\gamma\,\theta \quad \forall\theta \leq \frac{\beta}{2(1+2\kappa)\sqrt{n}}\left(\frac{(1-\beta)\gamma}{5.6\sqrt{n}}\right)^{\frac{1}{m}},$$

and (4.14) follows from the above inequality and (4.17).

Relation (4.14) shows that if $z \in \mathcal{D}(\beta)$, then the point $\overline{z}$ obtained in the corrector step of Algorithm 1 belongs to $\mathcal{D}(\beta+\delta)$, where

$$\delta = \frac{1}{2}(1-\beta)\gamma\,\theta_5. \tag{4.18}$$

As we mentioned before, the main purpose of the corrector is to increase proximity to the central path. However, it turns out that if the corrector step-length θ_c is large enough, then we also obtain a significant reduction of the duality gap during the corrector step. In what follows we find a lower bound for θ_c in case the point $z \in \mathcal{D}(\beta)$ is not very well centered. More precisely we show that

$$\exists j \quad \text{such that } p_j := \frac{x_j s_j}{\mu} \leq \beta + .44\,\delta \Rightarrow \theta_c > .2\,\theta_5\,. \tag{4.19}$$

Let us denote

$$\lambda = .44\,\delta = .22(1-\beta)\gamma\,\theta_5,\ q^i = \frac{h^i}{\mu}, \quad i = m+1, \ldots, 2m.$$

For any $\theta \in [0,\, 1]$, we have

$$p_j(\theta) = \frac{x_j(\theta)s_j(\theta)}{\mu(\theta)} = \frac{(1-\theta)p_j + \gamma\theta + \sum_{i=m+1}^{2m}\theta^i q_j^i}{(1-\theta) + \gamma\theta + \sum_{i=m+1}^{2m}\theta^i e^T q^i/n}$$

$$< \frac{(1-\theta)(\beta+\lambda) + \gamma\theta + \sum_{i=m+1}^{2m}\theta^i q_j^i}{(1-\theta) + \gamma\theta + \sum_{i=m+1}^{2m}\theta^i e^T q^i/n}$$

$$= \beta + \lambda + \frac{\gamma(1-\beta-\lambda)\theta - (\beta+\lambda)\sum_{i=m+1}^{2m}\theta^i e^T q^i/n + \sum_{i=m+1}^{2m}\theta^i q_j^i}{1-(1-\gamma)\theta + \sum_{i=m+1}^{2m}\theta^i e^T q^i/n}$$

$$\leq \beta + \lambda + \frac{\gamma(1-\beta-\lambda)\theta + (1+\frac{\beta+\lambda}{\sqrt{n}})\sum_{i=m+1}^{2m}\theta^i \left\| q^i \right\|_2}{1-(1-\gamma)\theta - \frac{1}{\sqrt{n}}\sum_{i=m+1}^{2m}\theta^i \left\| q^i \right\|_2}$$

$$\leq \beta + \lambda + \frac{\gamma(1-\beta)\theta + 2\sum_{i=m+1}^{2m}\theta^i \left\| q^i \right\|_2}{1-(1-\gamma)\theta - \sum_{i=m+1}^{2m}\theta^i \left\| q^i \right\|_2}.$$

Assume now that $\theta \in [0, .2\,\theta_5]$ and set $\theta = .2\phi$. Since $\phi \in [0,\, \theta_5]$, by virtue of (4.8), we can write

$$\sum_{i=m+1}^{2m} \theta^i \left\| q^i \right\|_2 = \sum_{i=m+1}^{2m} .2^i \phi^i \left\| q^i \right\|_2 \leq .2^{m+1} \sum_{i=m+1}^{2m} \phi^i \left\| q^i \right\|_2$$
$$< \frac{.2^{m+1}}{2} \gamma(1-\beta)\phi = \frac{.2^m}{2} \gamma(1-\beta)\theta \leq .1\gamma(1-\beta)\theta.$$

Using the fact that $\theta_5 < .5\ \forall\, n \geq 1$, we obtain

$$p_j(\theta) < \beta + \lambda + \frac{1.2\gamma(1-\beta)\theta}{1-(1-\gamma+.1\,\gamma(1-\beta))\,\theta} \leq \beta + \lambda + \frac{1.2\gamma(1-\beta)\theta}{1-\theta}$$
$$< \beta + \lambda + 1.4\gamma(1-\beta)\theta \leq\ \beta + \lambda + .28\gamma(1-\beta)\theta_5 = \beta + \delta \quad \forall\, \theta \in [0, .2\,\theta_5].$$

It follows that $f(\theta_c) \geq \beta + \delta > \max_{0 \leq \theta \leq .2\,\theta_5} f(\theta)$, wherefrom we deduce that $\theta_c > .2\,\theta_5$.

Analysis of the predictor. In the predictor step we have $\gamma = 0$ and $m = m_p$. From (4.4) it follows that $\tau = 2(1+\epsilon)/\sqrt{\beta} \leq 4/\sqrt{\beta}$. Since the predictor step follows a corrector step, we have $z \in \mathcal{D}(\beta + \delta) \subset \mathcal{D}(\beta)$.

First, we study the behavior of the normalized duality gap in the predictor step. We start by proving that

$$(1 - 2.5\,\theta)\mu \leq \mu(\theta) \leq (1 - .5\,\theta)\mu \tag{4.20}$$
$$\forall\, 0 \leq \theta \leq \theta_6 := \frac{\sqrt{\beta}}{4(1+2\kappa)\sqrt{n}} \min\left\{1\,,\ \left(11.2\sqrt{\beta}\right)^{\frac{-1}{m_p}}\right\}.$$

Due to the obvious fact that

$$(1-2\theta) \leq (1-\theta)^2 \leq (1-\theta) \quad \forall\, \theta \in [0,1],$$

we have

$$(1-2\theta)\mu + \sum_{i=m+1}^{2m} \theta^i (e^T h^i/n) \leq \mu(\theta) \leq (1-\theta)\mu + \sum_{i=m+1}^{2m} \theta^i (e^T h^i/n).$$

Using (4.8), with $\alpha = 2$ and $\tau = 4/\sqrt{\beta}$, we obtain

$$\left| \sum_{i=m+1}^{2m} \theta^i \left(\frac{e^T h^i}{n} \right) \right| \leq \frac{1}{\sqrt{n}} \sum_{i=m+1}^{2m} \theta^i \left\| h^i \right\|_2 < .5\,\theta\mu$$

$\forall\, \theta \in [0,\, \theta_6]$. Using Lemma 4.4 and the sum of a geometric series with ratio .1, we deduce that for any $\theta \in [0,\, \frac{\sqrt{\beta}}{40(1+2\kappa)\sqrt{n}}]$ it holds that

$$\mu'(\theta) = -(1+\epsilon-2\epsilon\theta)\mu + \sum_{i=m+1}^{2m} i\theta^{i-1} \left(\frac{e^T h^i}{n} \right) \leq -\mu + \frac{1}{\sqrt{n}} \sum_{i=m+1}^{2m} i\theta^{i-1} \left\| h^i \right\|_2$$
$$\leq -\mu + 8\mu\sqrt{\beta} \sum_{i=m}^{2m-1} \left(\frac{4(1+2\kappa)\theta\sqrt{n}}{\sqrt{\beta}} \right)^i < -\mu + 8\mu\sqrt{\beta} \frac{.1^m}{1-.1}$$
$$< -\mu + 8\mu \frac{.1^m}{.9} < 0.$$

Since $\theta_6 > \frac{\sqrt{\beta}}{44.8(1+2\kappa)\sqrt{n}} > \frac{\sqrt{\beta}}{50(1+2\kappa)\sqrt{n}}$, we conclude that

$$(1-2.5\,\theta)\mu \le \mu(\theta) \le (1-.5\,\theta)\mu \quad \text{and} \quad \mu'(\theta) < 0 \tag{4.21}$$

$$\forall \theta \in \left[0,\ \frac{\sqrt{\beta}}{50(1+2\kappa)\sqrt{n}}\right]. \tag{4.22}$$

Next, we claim that the quantity θ_2 from (3.11) used in the computation of the predictor step-length satisfies

$$\begin{aligned}\theta_2 \ge \theta_7 &:= \frac{\sqrt{\beta}}{4(1+2\kappa)\sqrt{n}} \min\left\{1\,,\left(11.2\sqrt{\beta}\right)^{\frac{-1}{m_p}}\,,\left(\frac{(1+2\kappa)\delta}{2\beta}\right)^{\frac{1}{m_p+1}}\right\}\\ &\ge \frac{\chi_7}{(1+2\kappa)n^{\frac{1}{2}+\frac{m_c+1}{2m_c(m_p+1)}}}\,, \qquad (4.23)\end{aligned}$$

$$\chi_7 := \frac{1}{4}\min\left\{\frac{1}{11.2},\left(\frac{(1-\beta)\underline{\gamma}\chi_5}{4}\right)^{\frac{1}{2}}\right\}. \tag{4.24}$$

Using (4.20) with $n \ge 8$ we obtain

$$\mu(\theta) \ge (1-2.5\theta_6)\mu \ge \left(1-\frac{2.5}{8\sqrt{2}}\right)\mu \ge .7\mu \quad \forall\,\theta \in [0,\,\theta_6].$$

By taking $\gamma = 0$, and $\beta+\delta$ instead of β, in (4.17), using (4.7) with $\alpha = 1/(.7\delta)$, we deduce that

$$f(\theta) \ge \beta+\delta - \frac{\sum_{i=m+1}^{2m}\theta^i \left\| h^i \right\|_2}{\mu(\theta)} \ge \beta+\delta - \frac{1}{.7\mu}\sum_{i=m+1}^{2m}\theta^i \left\| h^i \right\|_2 \ge \beta \quad \forall\,\theta \in [0,\,\theta_7],$$

which proves that $\theta_2 \ge \theta_7$. From the definition of θ_7 it follows that

$$\begin{aligned}\theta_7 &\ge \frac{\sqrt{\beta}}{4(1+2\kappa)\sqrt{n}}\min\left\{\frac{1}{11.2\sqrt{\beta}},\frac{1}{\sqrt{\beta}}\left(\frac{(1+2\kappa)\delta}{2}\right)^{\frac{1}{m_p+1}}\right\}\\ &\ge \frac{1}{4(1+2\kappa)\sqrt{n}}\min\left\{\frac{1}{11.2},\left(\frac{(1-\beta)\underline{\gamma}\theta_5}{4}\right)^{\frac{1}{m_p+1}}\right\}\\ &\ge \frac{\sqrt{\beta}}{4(1+2\kappa)\sqrt{n}}\min\left\{\frac{1}{11.2},\left(\frac{(1-\beta)\underline{\gamma}\chi_5}{4n^{\frac{m_c+1}{2m_c}}}\right)^{\frac{1}{m_p+1}}\right\}\\ &\ge \frac{\chi_7}{(1+2\kappa)n^{\frac{1}{2}+\frac{m_c+1}{2m_c(m_p+1)}}}.\end{aligned}$$

Bounding the decrease of the duality gap. Due to the fact that the duality gap decreases both in the predictor step and the corrector step, a complete analysis of the decreases of the duality gap has to be done by studying a succession of corrector-predictor-corrector steps. Assume that we are at iteration k and have a point $z^k \in \mathcal{D}(\beta)$ with normalized duality gap μ_k. We follow the notations of Algorithm 1. The corrector step produces a point $\overline{z}^{\,k} \in \mathcal{D}(\beta+\delta)$, with δ given by (4.18). The corresponding normalized duality gap clearly satisfies $\overline{\mu}_k \le \mu_k$, but a bound on the decrease of the duality gap cannot be given at this stage. The corrector is followed by a predictor that produces a point $z^{k+1} = z(\theta_p) \in \mathcal{D}(\beta)$ with duality gap

$\mu_{k+1} = \mu(\theta_p) = \min_{0\le\theta\le\theta_2} \mu(\theta)$. We have $\theta_7 \le \theta_2$ and $\theta_7 \le \theta_6$, so that according to (4.20)

$$\mu_{k+1} \le \mu(\theta_7) \le (1 - .5\,\theta_7)\,\overline{\mu}_k \le \left(1 - \frac{\chi_7}{2\,n^{\frac{1}{2}+\frac{m_c+1}{2m_c(m_p+1)}}}\right)\overline{\mu}_k, \quad \overline{\mu}_k \le \mu_k. \tag{4.25}$$

The above relation is sufficient for proving polynomial complexity, but it does not take into account the contribution of the corrector step. A finer analysis is needed in order to account for that. We distinguish two cases:

(a) $\theta_2 \ge \frac{\sqrt{\beta}}{50(1+2\kappa)\sqrt{n}}$. According to (4.21), in this case we have

$$\mu_{k+1} = \min_{0\le\theta\le\theta_2} \mu(\theta) \le \left(1 - \frac{\sqrt{\beta}}{100(1+2\kappa)\sqrt{n}}\right)\overline{\mu}_k\,;$$

(b) $\theta_2 < \frac{\sqrt{\beta}}{50(1+2\kappa)\sqrt{n}}$. In this case $\mu(\theta)$ is decreasing on the interval $[0,\,\theta_2]$, by virtue of (4.21), and by using (4.23) we deduce that $\theta_p = \theta_2, f(\theta_p) = \beta$. The latter equality must be true, since if $f(\theta_p) > \beta$, then, by a continuity argument, it follows that $\theta_2 > \theta_p$, which is a contradiction (see the definition of θ_2 (3.11)). But if $f(\theta_p) = \beta$, then, according to (3.8), in the next corrector step we have $\theta_c > .2\,\theta_5$, so that

$$\overline{\mu}_{k+1} < (1 - .2\,\underline{\sigma}(1-\overline{\gamma})\theta_5)\,\mu_{k+1} \le \left(1 - \frac{\underline{\sigma}(1-\overline{\gamma})\chi_5}{5(1+2\kappa)\,n^{\frac{1}{2}+\frac{1}{2m_c}}}\right)\mu_{k+1}.$$

In conclusion, for any $k \ge 0$ we have

$$\overline{\mu}_{k+1} \le \mu_{k+1} \le \left(1 - \frac{\sqrt{\beta}}{100(1+2\kappa)\sqrt{n}}\right)\overline{\mu}_k$$

or

$$\overline{\mu}_{k+1} < \left(1 - \frac{\underline{\sigma}(1-\overline{\gamma})\chi_5}{5(1+2\kappa)\,n^{\frac{1}{2}+\frac{1}{2m_c}}}\right)\left(1 - \frac{\chi_7}{2(1+2\kappa)\,n^{\frac{1}{2}+\frac{m_c+1}{2m_c(m_p+1)}}}\right)\overline{\mu}_k.$$

By taking

$$\overline{\chi} := \min\left\{\frac{\sqrt{\beta}}{100},\ \frac{\underline{\sigma}(1-\overline{\gamma})\chi_5}{5}\,,\ \frac{\chi_7}{2}\right\},$$

we deduce that

$$\overline{\mu}_{k+1} \le \left(1 - \frac{\overline{\chi}}{(1+2\kappa)n^{\frac{1}{2}+\upsilon}}\right)\overline{\mu}_k, \quad k = 0, 1, \ldots,$$

where υ is given by (4.11). The proof is complete. □

As an immediate consequence of the above theorem we obtain the following complexity result.

COROLLARY 4.7. *Algorithm* 1 *produces a point* $z = \lceil\, x,\, s \,\rfloor \in \mathcal{D}(\beta)$ *with* $x^T s \le \varepsilon$, *in at most* $O((1+\kappa)n^{1/2+\upsilon}\log(x^{0\,T}s^0/\varepsilon))$ *iterations, where* υ *is given by* (4.11).

It follows that if the order of either the corrector or the predictor is larger than a multiple of $\log n$, then Algorithm 1 has $O\left((1+\kappa)\sqrt{n}L\right)$-iteration complexity.

TABLE 4.1

n	10^4	10^5	10^6	10^7	10^8	10^9	10^{10}
$\lceil n^{.1} \rceil$	3	4	4	6	7	8	11

COROLLARY 4.8. *If* $\max\{m_c, m_p\} = \Omega(\log n)$, *then Algorithm* 1 *produces a point* $z = \lceil x, s \rfloor \in \mathcal{D}(\beta)$ *with* $x^T s \leq \varepsilon$, *in at most* $O((1+\kappa)\sqrt{n}\log(x^{0\,T}s^0/\varepsilon))$.

Proof. Under the hypothesis of the corollary there is a constant ϑ, such that $\upsilon \leq \vartheta/\log n$. Hence $n^{1/2+\upsilon} \leq n^{\frac{\vartheta}{\log n}}\sqrt{n} = e^{\vartheta}\sqrt{n}$. □

Due to the fact that $\lim_{n\to\infty} n^{1/n^{\omega}} = 1$ for any $\omega \in (0,1)$, in applications we can choose $m_p = \lceil n^{\omega} \rceil$ for some value of $\omega \in (0,1)$. This choice was initially suggested by Roos (private communication) and subsequently used in [24] and [16]. A correspondence between n and $\lceil n^{\omega} \rceil$ with $\omega = 0.1$ is shown in Table 4.1.

5. Superlinear convergence. In this section we show that the duality gap of the sequence produced by Algorithm 1 is superlinearly convergent. The result is based on the following lemma, which is a consequence of the results about the analyticity of the central path from [19].

LEMMA 5.1. *If HLCP* (2.1) *is sufficient, then the solution of* (3.2) *with* $\gamma = 0$ *satisfies*

$$u^i = O(\mu^i), \quad v^i = O(\mu^i), \quad i = 1, \ldots, m, \text{ if } \text{HLCP } (2.1) \text{ is nondegenerate}$$

and

$$u^i = O(\mu^{i/2}), \quad v^i = O(\mu^{i/2}), \quad i = 1, \ldots, m, \text{ if } \text{HLCP } (2.1) \text{ is degenerate.}$$

By using the above lemma we obtain the following superlinear convergence result, which is a trivial extension of the corresponding result in [15] to sufficient linear complementarity problems.

THEOREM 5.2. *The sequence* μ_k *produced by Algorithm* 1 *satisfies*

$$\mu_{k+1} = O(\mu_k^{m_p+1}) \text{ if } \text{HLCP } (2.1) \text{ is nondegenerate}$$

and

$$\mu_{k+1} = O(\mu_k^{(m_p+1)/2}) \text{ if } \text{HLCP } (2.1) \text{ is degenerate.}$$

6. Conclusions. We have presented a corrector-predictor interior-point algorithm for sufficient HLCP acting in a wide neighborhood of the central path.

The corrector of order m_c is used to improve both the centrality and the complementarity gap. The predictor of order m_p follows each corrector step to further decrease the complementarity gap. If $\max\{m_c, m_p\} = \Omega(\log n)$, then the iteration complexity of the algorithms is $O((1+\kappa)\sqrt{n}L)$. Although the complexity of our algorithm depends on κ, the algorithm itself does not, so that the algorithm works for the class of sufficient HLCP. Our algorithm has the best known iteration complexity for sufficient linear complementarity problems and is superlinearly convergent even for degenerate problems. The cost of implementing one iteration of our algorithm is $O(n^3)$ arithmetic operations.

A REGULARIZED SAMPLE AVERAGE APPROXIMATION METHOD FOR STOCHASTIC MATHEMATICAL PROGRAMS WITH NONSMOOTH EQUALITY CONSTRAINTS*

FANWEN MENG† AND HUIFU XU‡

Abstract. We investigate a class of two stage stochastic programs where the second stage problem is subject to nonsmooth equality constraints parameterized by the first stage variant and a random vector. We consider the case when the parametric equality constraints have more than one solution. A regularization method is proposed to deal with the multiple solution problem, and a sample average approximation method is proposed to solve the regularized problem. We then investigate the convergence of stationary points of the regularized sample average approximation programs as the sample size increases. The established results are applied to stochastic mathematical programs with P_0-variational inequality constraints. Preliminary numerical results are reported.

Key words. sample average approximation, Karush–Kuhn–Tucker conditions, regularization methods, P_0-variational inequality, convergence of stationary points

1. Introduction.

In this paper, we study the following stochastic mathematical program:

$$\begin{array}{ll} \min & \mathbb{E}\left[f(x, y(x, \xi(\omega)), \xi(\omega))\right] \\ \text{s.t.} & x \in \mathcal{X}, \end{array} \tag{1}$$

where $\mathcal{X}$ is a nonempty compact subset of $\mathbb{R}^m$, $f : \mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}$ is continuously differentiable, $\xi : \Omega \to \Xi \subset \mathbb{R}^k$ is a vector of random variables defined on probability space $(\Omega, \mathcal{F}, P)$, $\mathbb{E}$ denotes the mathematical expectation, and $y(x, \xi(\omega))$ is *some measurable selection* (which will be reviewed in section 2.2) from the set of solutions of the following system of equations:

$$H(x, y, \xi(\omega)) = 0, \tag{2}$$

where $H : \mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}^n$ is a piecewise smooth vector-valued function. Piecewise smooth function is a large class of locally Lipschitz continuous functions which cover most practical problems [29]. For the simplicity of notation, we will write $\xi(\omega)$ as ξ, and this should be distinguished from where ξ is a deterministic vector of Ξ in a context. Throughout this paper, we assume that the probability measure P of our considered space $(\Omega, \mathcal{F}, P)$ is nonatomic.

The model is slightly different from the standard two stage stochastic programming model where the second stage decision variate y is chosen to either minimize or maximize $f(x, y, \xi)$ for given x and every realization of $\xi(\omega)$. See an excellent survey

by Ruszczyński and Shapiro [27, Chapters 1 and 2] for the latter. In some practical instances, finding an optimal solution for the second stage problem may be very difficult and/or expensive. For example, in a two stage stochastic Stackelberg–Nash–Cournot model [32], x is the leader's decision variable and y is the followers' Nash–Cournot equilibrium vector with each component representing a follower's decision variable. The followers' equilibrium problem can be reformulated as a system of nonsmooth equations like (2) which depends on the leader's decision variable x and realization of uncertainty ξ in market demand. In the case when the followers have multiple equilibria, the "selection" of an optimal $y(x,\xi)$ at the second stage can be interpreted as the leader's attitude towards the followers' multiple equilibria: an optimistic attitude leads to a selection in favor of his utility, whereas a pessimistic attitude goes to an opposite selection. See [32, section 2] for details. Alternatively such an optimal selection can be interpreted as that the leader puts in some resources so that the followers reach an equilibrium in his favor. In either interpretation, finding such an optimal $y(x,\xi)$ implies additional cost to the leader.

Our argument here is that the leader may not necessarily select an extreme equilibrium (which minimizes/maximizes $f(x,y,\xi)$); instead, he may select one of the feasible equilibria $y(x,\xi)$ under the following circumstances: (a) minimizing/maximizing $f(x,y,\xi)$ with respect to y may be difficult or even impossible numerically; for instance, one can obtain only a local optimal solution or a stationary point; (b) in the case when an optimal solution is obtainable, the cost for obtaining such a solution in the second stage overweighs the overall benefit; for instance, the leader is a dominant player, while the followers are small players and the range of possible followers' equilibria is very narrow; (c) the chance of followers reaching one equilibrium or another is equal, and the leader is unaware of which particular equilibrium may be actually reached in the future and has no intention of putting in any additional resources to influence it.

Of course, such a selection must be consistent for all x and ξ; in other words, $y(x,\xi)$ must be a single-valued function with some measurability or even continuity. Note that there may exist many such selections, and the leader considers only one of them. This means that the leader takes a neutral attitude towards the follower's every possible equilibrium. Note also that in this paper, the selection is not arbitrary and is guided by a regularization method to be discussed shortly.

The argument can be extended to two stage stochastic mathematical programs with equilibrium constraints (SMPECs)

$$\begin{array}{ll} \min & \mathbb{E}[f(x,y(x,\xi),\xi)] \\ \text{s.t.} & x \in \mathcal{X}, \end{array} \tag{3}$$

where $y(x,\xi)$ solves

$$\begin{array}{ll} \min\limits_{y} & f(x,y,\xi) \\ \text{s.t.} & F(x,y,\xi)^T(v-y) \geq 0 \quad \forall v \in \mathcal{C}(x,\xi), \end{array} \tag{4}$$

f and F are continuously differentiable function, ξ is a random variable, and $\mathcal{C}(x,\xi)$ is a random convex set. SMPECs were initially studied by Patriksson and Wynter [18]. Like deterministic MPECs, SMPECs have various potential applications in engineering and economics, etc. [9, 34]. Over the past few years, SMPECs have received increasing investigation from perspectives of both stochastic programming and MPEC; see [17, 30, 35, 36] and the references therein. Observe that the second stage problem

(4) is a deterministic parametric MPEC that is intrinsically nonconvex. Finding an optimal solution for MPECs is often difficult if not impossible. Consequently it may be a realistic approach to take *some* feasible measurable solution at the second stage (which is a solution of the variational inequality problem in the constraint) rather than trying to find an optimal one. Note that MPECs can be easily reformulated as a nonsmooth system of equations, and this is the very reason why we consider general nonsmooth equality constraints (2). We will discuss these in detail in section 5.

Having motivated our model, we next explain how to find the unspecified $y(x,\xi)$ in (1). Our idea can be outlined as follows. We approximate function H with some function R parameterized by a small positive number μ and then solve the following equation:

$$R(x,y,\xi,\mu)=0. \tag{5}$$

Of course, R cannot be any function, and it must be constructed according to the structure of H. First, it must coincide with H when $\mu=0$; second, it must have some nice topological properties such as Lipschitz continuity and directional differentiability. Finally and perhaps most importantly, (5) must have a unique solution for every $x\in\mathcal{X}$, $\xi\in\Xi$, and nonzero μ. We specify these needed properties in a definition of R (Definition 2.1) and regard R as a *regularization* in consistency with the terminology in the literature [19, 11]. Using the regularization method, we expect that an implicit function $\tilde{y}(x,\xi,\mu)$ defined by (5) approximates a measurable feasible solution $y(x,\xi)$ of (2), and consequently we can utilize the program

$$\begin{array}{ll}\min & \mathbb{E}\left[f(x,\tilde{y}(x,\xi,\mu),\xi)\right]\\ \text{s.t.} & x\in\mathcal{X}\end{array} \tag{6}$$

to approximate the true problem (1), where $y(x,\xi)$ is the limit of $\tilde{y}(x,\xi,\mu)$ as $\mu\to 0$.

We then propose a sample average approximation (SAA) method to solve (6). The SAA method and its variants, known under various names such as "stochastic counterpart method," "sample-path method," "simulated likelihood method," etc., were discussed in the stochastic programming and statistics literature over the years. See, for instance, [22, 25, 3, 31] for general stochastic problems and [17, 4, 30, 32, 36] for SMPECs.

We investigate the convergence of the SAA problem of (6) as $\mu\to 0$ and sample size tends to infinity. Since the underlying functions are piecewise smooth and nonconvex in general, our analysis focuses on stationary points rather than local or global optimal solutions. For this purpose, we study the optimality conditions for both the true and the regularized problems. We introduce a kind of generalized Karush–Kuhn–Tucker (KKT) condition for characterizing both true and regularized problems in terms of Clarke generalized Jacobians (subdifferentials). Rockafellar and Wets [23] investigated KKT conditions for a class of two stage convex stochastic programs and derived some "basic Kuhn–Tucker conditions" in terms of convex subdifferentials. More recent discussions on the optimality conditions can also be found in books by Birge and Louveaux [5] and Ruszczyński and Shapiro [27]. These conditions rely on the convexity of underlying functions and hence cannot be applied to our problems, which are nonconvex.

The main contributions of this paper can be summarized as follows: we show that under some conditions, the solution of (5) approximates a measurable solution of (2); we then show that with probability 1 (w.p.1 for short) an accumulation point of a sequence of generalized stationary points of the regularized problem is a generalized

stationary point of the true problem. We propose an SAA method to solve the regularized problem (6) and show that w.p.1 an accumulation point of the sequence of the stationary points of the regularized SAA problem is a generalized stationary point of the true problem as sample size tends to infinity and parameter μ tends to zero. Finally, we apply the established results to a class of SMPECs where the underlying function is a P_0-function.

The rest of the paper is organized as follows. In section 2, we discuss the regularization scheme. In section 3, we investigate the generalized stationary points of both the regularized problem and the true problem. In section 4, we study the convergence of the SAA program of the regularized problem. We then apply the established results to a class of stochastic MPEC problems in section 5. Some preliminary numerical results are reported in section 6.

2. Preliminaries and a regularization scheme. In this section, we characterize the function R in (5) and investigate the approximation of (6) to (1) as $\mu \to 0$.

Throughout this paper, we use the following notation. We use $\|\cdot\|$ to denote the Euclidean norm of a vector, a matrix, and a compact set of matrices. Specifically, if $\mathcal{M}$ is a compact set of matrices, then $\|\mathcal{M}\| := \max_{M\in\mathcal{M}} \|M\|$. We use $\operatorname{dist}(x, \mathcal{D}) := \inf_{x'\in\mathcal{D}} \|x - x'\|$ to denote the distance between point x and set $\mathcal{D}$. Here $\mathcal{D}$ may be a subset of $\mathbb{R}^n$ or a subset of matrix space $\mathbb{R}^{n\times n}$. Given two compact sets $\mathcal{C}$ and $\mathcal{D}$, we use $\mathbb{D}(\mathcal{C}, \mathcal{D}) := \sup_{x\in\mathcal{C}} \operatorname{dist}(x, \mathcal{D})$ to denote the distance from set $\mathcal{C}$ to set $\mathcal{D}$. For two sets $\mathcal{C}$ and $\mathcal{D}$ in a metric space, $\mathcal{C} + \mathcal{D}$ denotes the usual Minkowski addition, and $\mathcal{C}\mathcal{D} := \{CD \mid \text{ for all } C \in \mathcal{C}, \text{ for all } D \in \mathcal{D}\}$ represents the multiplication. We use $\mathcal{B}(x, \delta)$ to denote the closed ball in $\mathbb{R}^n$ with radius δ and center x, that is, $\mathcal{B}(x, \delta) := \{x' \in \mathbb{R}^m : \|x' - x\| \le \delta\}$. For a vector-valued function $g : \mathbb{R}^m \to \mathbb{R}^l$, we use $\nabla g(x)$ to denote the classical Jacobian of g when it exists. In the case when $l = 1$, that is, g is a real-valued function, $\nabla g(x)$ denotes the gradient of g which is a row vector. We use $\overline{\lim}$ to denote the outer limit of a sequence of vectors and a set-valued mapping. We let $\mathbb{R}_{++} := \{x \mid x > 0, x \in \mathbb{R}\}$ and $\mathbb{R}^2_{++} := \{(x, y) \mid x > 0, y > 0, x, y \in \mathbb{R}\}$. For a set-valued mapping $\mathcal{A}(u, v) : \mathbb{R}^n \times \mathbb{R}^m \to 2^{\mathbb{R}^{n\times m}}$, $\pi_u\mathcal{A}(u, v)$ denotes the set of all $n \times n$ matrices M such that, for some $n \times m$ matrix N, the $n \times (n+m)$ matrix $[M\ N]$ belongs to $\mathcal{A}(u, v)$.

2.1. Preliminaries. We first present some preliminaries about the Clarke generalized Jacobian of random functions which will be used throughout the paper.

Let $G : \mathbb{R}^j \to \mathbb{R}^l$ be a locally Lipschitz continuous vector-valued function. Recall that the Clarke generalized Jacobian [10] of G at $x \in \mathbb{R}^j$ is defined as

$$\partial G(x) := \operatorname{conv}\left\{\lim_{y\to x, y\in D_G} \nabla G(y)\right\},$$

where D_G denotes the set of points at which G is Fréchet differentiable, $\nabla G(y)$ denotes the usual Jacobian of G, and "conv" denotes the convex hull of a set. It is well known that the Clarke generalized Jacobian $\partial G(x)$ is a convex compact set [10]. In the case that $j = l$, $\partial G(x)$ consists of square matrices. We say $\partial G(x)$ is nonsingular if every matrix in set $\partial G(x)$ is nonsingular, and in this case we use $\partial G(x)^{-1}$ to denote the set of all inverse matrices of $\partial G(x)$.

In later discussions, particularly sections 2–4, we will have to deal with mathematical expectation of the Clarke generalized Jacobians of locally Lipschitz random functions. For this purpose, we recall some basics about measurability of a random set-valued mapping.

Let $V \subset \mathbb{R}^n$ be a compact set of $\mathbb{R}^n$ and $\xi : \Omega \to \Xi \subset \mathbb{R}^k$ be a random vector defined on the probability space $(\Omega, \mathcal{F}, P)$ (note that we use the same notation ξ and Ξ as in (1), although we do not have to in this general discussion). A random set-valued mapping $\mathcal{A}(\cdot, \xi) : V \to 2^{\mathbb{R}^{n\times m}}$ is said to be *closed-valued* if for every $v \in V$ and $\xi \in \Xi$ (a realization of $\xi(\omega)$), $\mathcal{A}(v, \xi)$ is a closed set. Let $\mathfrak{B}$ denote the space of nonempty, closed subsets of $\mathbb{R}^{n\times m}$ equipped with Hausdorff distance. Then $\mathcal{A}(v, \xi(\cdot))$ can also be viewed as a single-valued mapping from Ω to $\mathfrak{B}$. For a fixed $v \in V$, $\mathcal{A}(v, \xi(\cdot)) : \Omega \to 2^{\mathbb{R}^{n\times m}}$ is said to be *measurable* if for every closed set $B \subset \mathbb{R}^{n\times m}$, $\{\omega : \mathcal{A}(v, \xi(\omega)) \bigcap B \neq \emptyset\}$ belongs to the σ-algebra $\mathcal{F}$. Alternatively, by viewing $\mathcal{A}(v, \xi(\cdot))$ as a single-valued mapping, we can say that $\mathcal{A}(v, \xi(\cdot))$ is measurable if and only if for every $B \in \mathfrak{B}$, $\mathcal{A}(v, \xi(\cdot))^{-1}B$ is $\mathcal{F}$-measurable. See Theorem 14.4 of [24].

We now define the expectation of $\mathcal{A}(v, \xi(\omega))$. A *selection* of a random set $\mathcal{A}(v, \xi(\omega))$ is a random matrix $A(v, \xi) \in \mathcal{A}(v, \xi)$ (which means $A(v, \xi(\omega))$ is measurable). Selections exist. The *expectation of* $\mathcal{A}(v, \xi(\omega))$, denoted by $\mathbb{E}[\mathcal{A}(v, \xi(\omega))]$, is defined as the collection of $\mathbb{E}[A(v, \xi(\omega))]$, where $A(v, \xi(\omega))$ is a selection. For a detailed discussion in this regard, see [1, 2] and the references therein.

Finally, we need the following definitions concerning matrices and functions. A matrix $M \in \mathbb{R}^{l\times l}$ is called a P_0-matrix if for any $x \neq 0$, there exists $i \in \{1, \ldots, l\}$ such that $x_i(Mx)_i \geq 0$ and $x_i \neq 0$. It is evident that a positive semidefinite matrix is a P_0-matrix. A function $G : \mathcal{D} \subset \mathbb{R}^l \to \mathbb{R}^l$ is said to be (over set $\mathcal{D}$) a P_0-function if for all $u, v \in \delta$ with $u \neq v$,

$$\max_{\substack{i\in\{1,\ldots,l\}\\ u_i\neq v_i}} (u_i - v_i)[G_i(u) - G_i(v)] \geq 0.$$

For a continuously differentiable function G, if $\nabla G(x)$ is a P_0-matrix for all $x \in \mathcal{D}$, then $G(x)$ is a P_0-function on $\mathcal{D}$. For a comprehensive discussion of the properties of the above matrices and functions, we refer readers to the book [11].

2.2. A regularization scheme. We specify the regularized approximation outlined in section 1 and investigate the limiting behavior of the implicit function defined by the regularized approximation problem (6) as $\mu \to 0$.

Throughout this paper $\partial H(x, y, \xi)$ denotes the Clarke generalized Jacobian of H at (x, y, ξ), and $\partial R(x, y, \xi, \mu)$ denotes the Clarke generalized Jacobian of H at (x, y, ξ, μ).

DEFINITION 2.1. *Let $\mu \in [0, \mu_0]$, where μ_0 is a positive number. A continuous function $R : \mathcal{X} \times \mathbb{R}^n \times \Xi \times [0, \mu_0] \to \mathbb{R}^n$ is said to be a* regularization *of H if the following hold:*

(i) *for every $x \in \mathcal{X}$, $y \in \mathbb{R}^n$, $\xi \in \Xi$, $R(x, y, \xi, 0) = H(x, y, \xi)$;*

(ii) *$R(x, y, \xi, \mu)$ is locally Lipschitz continuous and piecewise smooth on $\mathcal{X} \times \mathbb{R}^n \times \Xi \times [0, \mu_0]$;*

(iii) *for every $x \in \mathcal{X}$, $y \in \mathbb{R}^n$, and $\xi \in \Xi$,*

$$\overline{\lim_{\mu\downarrow 0}}\, \pi_x \partial R(x, y, \xi, \mu) \subset \pi_x \partial H(x, y, \xi), \quad \overline{\lim_{\mu\downarrow 0}}\, \pi_y \partial R(x, y, \xi, \mu) \subset \pi_y \partial H(x, y, \xi);$$

(iv) *equation $R(x, y, \xi, \mu) = 0$ defines a unique locally Lipschitz continuous function $\tilde{y} : \mathcal{X} \times \Xi \times (0, \mu_0) \to \mathbb{R}^n$ such that $R(x, \tilde{y}(x, \xi, \mu), \xi, \mu) = 0$ for every $x \in \mathcal{X}, \mu \in (0, \mu_0), \ \xi \in \Xi$.*

We call μ a regularization parameter (or variable).

The definition contains three elements. First, a regularization is a parameterized continuous approximation and is locally Lipschitz continuous with respect to the

regularization parameter when it is viewed as an additional variable. Second, the regularization (part (iii)) satisfies some kind of Jacobian consistency [8] that was widely used in smoothing methods when R is a smoothing of H; see [21] and the references therein. A sufficient condition for this is that R is strictly differentiable at $\mu = 0$ (when μ is treated as a variable). Third, the regularization scheme defines a unique function $\tilde{y}$ that approximates a measurable solution $y(x, \xi)$ of (2). We shall investigate the existence of such $\tilde{y}$ in Proposition 2.3.

Remark 2.2. Part (iv) of Definition 2.1 is implied by the following *uniform nonsingularity condition*: for every $(x, \xi, \mu) \in \mathcal{X} \times \Xi \times (0, \mu_0)$, there exists y such that $R(x, y, \xi, \mu) = 0$; $\pi_y \partial R(x, y, \xi, \mu)$ is uniformly nonsingular; i.e., there exists a positive constant $C > 0$ such that for every $x \in \mathcal{X}, y \in \mathbb{R}^n, \xi \in \Xi, \mu \in (0, \mu_0)$, $\|[\pi_y \partial R(x, y, \xi, \mu)]^{-1}\| \leq C$. The uniform nonsingularity implies that the outer limit of $\pi_y \partial R(x, y, \xi, \mu)$ as $\mu \to 0$ is a strict subset of $\pi_y \partial H(x, y, \xi)$, which does not include singular matrices.

PROPOSITION 2.3. *Let R be a function satisfying conditions* (i)–(iii) *of Definition* 2.1 *and the uniform nonsingularity condition hold. Then R is a regularization of H.*

Proof. It suffices to verify (iv) in Definition 2.1; that is, (5) defines a unique locally Lipschitz continuous implicit function $\tilde{y} : \mathcal{X} \times \Xi \times (0, \mu_0) \to \mathbb{R}^n$ such that $R(x, \tilde{y}(x, \xi, \mu), \xi, \mu) = 0$ for all $x \in \mathcal{X}, \xi \in \Xi, \mu \in (0, \mu_0)$. With the uniform nonsingularity of $\pi_y \partial R$, the existence of such an implicit function on $\mathcal{X} \times \mathbb{R}^n \times (0, \mu_0)$ comes straightforwardly from [36, Lemma 2.3]. ∎

In the analysis of sections 3 and 4, we will not assume the uniform nonsingularity. Instead we will assume a regularization R with nonsingularity of $\pi_y \partial R$ and other conditions which are weaker than the uniform nonsingularity. Note that not every function has a regularized approximation. Our definition here is motivated by the functions reformulated from equilibrium constraints. See section 5, particularly Example 5.5, for a detailed explanation. In what follows we investigate the properties of $\tilde{y}(x, \xi, \mu)$, in particular, its limit as the regularization parameter μ tends to zero.

THEOREM 2.4. *Let R be a regularization of H and $\tilde{y}(x, \xi, \mu)$ be the implicit function defined as in Definition* 2.1. *Assume that $\lim_{\mu \downarrow 0} \tilde{y}(x, \xi, \mu)$ exists for every $x \in \mathcal{X}$ and $\xi \in \Xi$, that is,*

$$y(x, \xi) := \lim_{\mu \downarrow 0} \tilde{y}(x, \xi, \mu), \quad x \in \mathcal{X}, \xi \in \Xi. \tag{7}$$

Suppose that there exists a positive measurable function $\kappa_1(\xi) > 0$ such that $\|\tilde{y}(x, \xi, \mu)\| \leq \kappa_1(\xi)$ for all $(x, \mu) \in \mathcal{X} \times (0, \mu_0)$ and that $\mathbb{E}[\kappa_1(\xi)] < \infty$. Then the following statements hold:

(i) *$y(x, \xi)$ is a solution function of* (2) *on $\mathcal{X} \times \Xi$, and $y(x, \xi(\cdot)) : \Omega \to \mathbb{R}^n$ is measurable for every $x \in \mathcal{X}$;*

(ii) *if, in addition, there exists a measurable positive function $L(\xi) > 0$ such that*

$$\|\tilde{y}(x'', \xi, \mu) - \tilde{y}(x', \xi, \mu)\| \leq L(\xi)\|x'' - x'\| \quad \forall x', x'' \in \mathcal{X}, \tag{8}$$

then $y(\cdot, \xi)$ is Lipschitz continuous on $\mathcal{X}$ for every $\xi \in \Xi$.

Proof. Part (i). By Definition 2.1, we have $R(x, \tilde{y}(x, \xi, \mu), \xi, \mu) = 0$ for $x \in \mathcal{X}, \xi \in \Xi, \mu \in (0, \mu_0)$. By Definition 2.1 and the continuity of R in y, it follows that

$$\lim_{\mu \downarrow 0} R(x, \tilde{y}(x, \xi, \mu), \xi, \mu) = R(x, y(x, \xi), \xi, 0) = H(x, y(x, \xi), \xi),$$

which indicates that $y(x, \xi)$ is a solution of (2) for $(x, \xi) \in \mathcal{X} \times \Xi$.

To show the measurability of $y(x,\xi(\omega))$, observe that since $\tilde{y}(x,\xi,\mu)$ is continuous in ξ, then $\tilde{y}(x,\xi(\cdot),\mu):\Omega\to\mathbb{R}^n$ is measurable. Moreover, since $\tilde{y}(x,\xi,\mu)$ is bounded by $\kappa_1(\xi)$ and $\mathbb{E}[\kappa_1(\xi)]<\infty$, by the Lebesgue dominated convergence theorem, $y(x,\xi(\cdot))$ is measurable.

Part (ii). For $x',x''\in\mathcal{X}$, by (8), $\|\tilde{y}(x'',\xi,\mu)-\tilde{y}(x',\xi,\mu)\|$ is dominated by $L(\xi)\|x''-x'\|$. The latter is integrable. By the Lebesgue dominated convergence theorem, we have from (8)

$$\begin{aligned}\|y(x'',\xi)-y(x',\xi)\| &= \|\lim_{\mu\downarrow 0}(\tilde{y}(x'',\xi,\mu)-\tilde{y}(x',\xi,\mu))\|\\ &= \lim_{\mu\downarrow 0}\|\tilde{y}(x'',\xi,\mu)-\tilde{y}(x',\xi,\mu)\|\le L(\xi)\|x''-x'\| \quad \forall x',x''\in\mathcal{X}.\end{aligned}$$

This completes the proof. □

The theorem above shows that we may obtain a measurable solution of (2) through the process of regularization. Note that our assumption on the existence of limit (7) may be relaxed. Indeed if the sequence of functions $\tilde{y}(\cdot,\cdot,\mu)$ has multiple accumulation points, each of which is Lipschitz continuous, then $y(x,\xi)$ can be taken from any of them. Our assumption is to simplify the consequent discussion, and also we expect this to be satisfied in practical instances; see Example 5.5. The boundedness condition for $\tilde{y}(x,\xi,\mu)$ holds under the uniform nonsingularity condition (Remark 2.2). Throughout the rest of this paper, the $y(x,\xi)$ in the true problem (1) refers to the limit of $\tilde{y}(x,\xi,\mu)$ as $\mu\to 0$.

3. Generalized Karush–Kuhn–Tucker (GKKT) conditions. In this section, we investigate the KKT conditions of both true problem (1) and regularized program (6). Our purpose is to show that w.p.1 the stationary points of the regularized problem converge to a stationary point of the true problem (1) as the regularization parameter is driven to zero; therefore the regularized problem (6) is a reasonable approximation of the true problem.

3.1. GKKT conditions of the true problem. Let R be a regularization of H and $\tilde{y}(x,\xi,\mu)$ the solution of (5), let

$$y(x,\xi)=\lim_{\mu\downarrow 0}\tilde{y}(x,\xi,\mu) \quad \text{for } x\in\mathcal{X},\xi\in\Xi,$$

and let $y(\cdot,\xi)$ be Lipschitz continuous. In this subsection, we investigate the true problem (1) associated with $y(x,\xi)$. We first define a set which resembles the set of Lagrange multipliers in nonlinear programming.

DEFINITION 3.1. *For $(x,\xi)\in\mathcal{X}\times\Xi$, let*

$$\begin{aligned}\Lambda(x,\xi) :=& \operatorname{conv}\{\lambda(x,\xi)\in\mathbb{R}^n \mid 0\in\nabla_y f(x,y(x,\xi),\xi)\\ &+\lambda(x,\xi)\pi_y\partial H(x,y(x,\xi),\xi)\}.\end{aligned} \tag{9}$$

Note that $\lambda(x,\xi)$ is a row vector. Note also that when $y(x,\xi)$ is an optimal solution of

$$\begin{aligned}\min_y \quad & f(x,y,\xi)\\ \text{s.t.} \quad & H(x,y,\xi)=0,\end{aligned} \tag{10}$$

$\Lambda(x,\xi)$ contains the Lagrange multipliers of (10) in that the first-order necessary condition of (10) can be written as $0\in\nabla_y f(x,y(x,\xi),\xi)+\lambda(x,\xi)\partial_y H(x,y(x,\xi),\xi)$, and

by [10, Proposition 2.3.16], $\partial_y H(x, y(x,\xi),\xi) \subset \pi_y \partial H(x, y(x,\xi),\xi)$. Note further that $\Lambda(x,\xi)$ is nonempty if and only if the set $\{\lambda(x,\xi) \in \mathbb{R}^n \mid 0 \in \nabla_y f(x, y(x,\xi),\xi) + \lambda(x,\xi)\ \pi_y \partial H(x, y(x,\xi),\xi)\}$ is nonempty. For every $\lambda(x,\xi)$ of the latter set, there exists a matrix $M \in \pi_y \partial H(x, y(x,\xi),\xi)$ such that $0 = \nabla_y f(x, y(x,\xi),\xi) + \lambda(x,\xi)M$. A necessary and sufficient condition for $\Lambda(x,\xi)$ to be nonempty is that there exists $M \in \pi_y \partial H(x, y(x,\xi),\xi)$ such that $\operatorname{rank}([\nabla_y f^T, M^T]) = \operatorname{rank}(M^T)$. Moreover, the set Λ is bounded if and only if M is of full row rank. The following remark discusses the particular case when $\pi_y \partial H$ is nonsingular.

Remark 3.2. If $\pi_y \partial H(x, y(x,\xi),\xi)$ is nonsingular for $x \in \mathbb{R}^m$ and $\xi \in \Xi$, then we have

$$\Lambda(x,\xi) := -\nabla_y f(x, y(x,\xi),\xi)\operatorname{conv}([\pi_y \partial H(x, y(x,\xi),\xi)]^{-1}).$$

The set contains the Lagrange multipliers of the standard second stage minimization problem (10), since the nonsingularity of the Jacobian guarantees $y(x,\xi)$ to be the only feasible solution and hence trivially the optimal solution! If H is continuously differentiable in x, y, and ξ, then $\pi_y \partial H(x,y,\xi)$ reduces to $\nabla_y H(x,y,\xi)$, and $\Lambda(x,\xi)$ reduces to a singleton,

$$\Lambda(x,\xi) = -\nabla_y f(x, y(x,\xi),\xi)\nabla_y H(x, y(x,\xi),\xi)^{-1}.$$

This corresponds to the classical Lagrange multiplier of a standard second stage minimization problem (10).

In this paper, we consider the case when (2) has multiple solutions; therefore $\pi_y \partial H(x,y,\xi)$ cannot be nonsingular. For the simplicity of discussion, we make a blanket assumption that $\Lambda(x,\xi)$ is nonempty for $x \in \mathcal{X}$ and $\xi \in \Xi$, which implies that there exists at least one matrix $M \in \pi_y \partial H(x, y(x,\xi),\xi)$ such that $\operatorname{rank}([\nabla_y f^T, M^T]) = \operatorname{rank}(M^T)$. Using the notion of Λ, we can define the following optimality conditions for the true problem associated with $y(x,\xi)$.

Definition 3.3. *Let $\Lambda(x,\xi)$ be defined as in Definition* 3.1. *A point $x \in \mathbb{R}^m$ is called a* generalized stationary point *of the true problem* (1) *if*

$$0 \in \mathbb{E}[\nabla_x f(x, y(x,\xi),\xi) + \Lambda(x,\xi)\pi_x \partial H(x, y(x,\xi),\xi)] + \mathcal{N}_{\mathcal{X}}(x), \tag{11}$$

where the expectation is taken over the integrable elements of the set-valued integrand, and $\mathcal{N}_{\mathcal{X}}(x)$ denotes the normal cone of $\mathcal{X}$ at $x \in \mathbb{R}^m$ [6]; *that is,*

$$\mathcal{N}_{\mathcal{X}}(x) := [T_{\mathcal{X}}(x)]^- = \{\varsigma \in \mathbb{R}^m \mid \langle \varsigma, d\rangle \le 0 \quad \forall d \in T_{\mathcal{X}}(x)\},$$

where $T_{\mathcal{X}}(x) := \limsup_{t \downarrow 0}(\mathcal{X} - x)/t$. We call (11) *a GKKT condition of the true problem* (1).

For the set of generalized stationary points to be well defined, it must contain all local minimizers of the true problem. In what follows we discuss this and the relationship between the GKKT conditions with other possible KKT conditions. For this purpose, we need to state the following implicit function theorem for piecewise smooth functions.

Lemma 3.4. *Consider an underdetermined system of nonsmooth equations $P(y,z) = 0$, where $P : \mathbb{R}^m \times \mathbb{R}^n \to \mathbb{R}^m$ is piecewise smooth. Let $(\bar{y},\bar{z}) \in \mathbb{R}^m \times \mathbb{R}^n$ be such that $P(\bar{y},\bar{z}) = 0$. Suppose that $\pi_y \partial P(\bar{y},\bar{z})$ is nonsingular. Then*

(i) *there exist neighborhoods Z of $\bar{z}$ and Y of $\bar{y}$ and a piecewise smooth function $y : Z \to Y$ such that $y(\bar{z}) = \bar{y}$ and, for every $z \in Z$, $y = y(z)$ is the unique solution of the problem $P(y,z) = 0$, $y \in Y$;*

(ii) *for* $z \in Z$,

$$\partial y(z) \subset \operatorname{conv}\{-V^{-1}U : [V,U] \in \partial P(y(z),z),\ V \in \mathbb{R}^{m\times m},\ U \in \mathbb{R}^{m\times n}\}. \tag{12}$$

Proof. The existence of an implicit function comes essentially from the Clarke implicit function theorem [10]. The piecewise smoothness and the differential inclusion (12) follow from [21, Proposition 4.8] straightforwardly. ∎

Note that the purpose of (12) is to give an estimate of the Clarke generalized Jacobian of the implicit function using the Clarke generalized Jacobian of P, which is relatively easier to obtain. The estimate may be improved under some index consistency conditions; see [21] for details. With Lemma 3.4, we are ready to discuss our GKKT condition. The proposition below establishes a relation between (local) minimizers of the true problem and the generalized stationary points defined in Definition 3.3 under some circumstances.

PROPOSITION 3.5. *Let x^* be a local minimizer of the true problem (associated with the limit function $y(x,\xi)$) and $[\pi_y \partial H(x^*, y(x^*,\xi),\xi)]^{-1}$ be nonsingular. Let $\nabla f(x, y(x,\xi),\xi)$, $[\pi_y \partial H(x, y(x,\xi),\xi)]^{-1}$, and $\pi_x \partial H(x, y(x,\xi),\xi)$ be bounded by a positive integrable function for all x in a neighborhood of x^*. Then x^* is a generalized stationary point of the true problem.*

Proof. By Lemma 3.4,

$$\partial y(x,\xi) \subset \operatorname{conv}([-\pi_y \partial H(x, y(x,\xi),\xi)]^{-1})\pi_x \partial H(x, y(x,\xi),\xi)$$

for x close to x^*. Let $v(x,\xi) := f(x, y(x,\xi),\xi)$. Under the boundedness conditions of $\nabla f(x, y(x,\xi),\xi)$, $[\pi_y \partial H(x, y(x,\xi),\xi)]^{-1}$, and $\pi_x \partial H(x, y(x,\xi),\xi)$, we have

$$\begin{aligned}
0 &\in \partial \mathbb{E}[v(x^*,\xi)] + \mathcal{N}_{\mathcal{X}}(x^*) \subset \mathbb{E}[\partial_x v(x^*,\xi)] + \mathcal{N}_{\mathcal{X}}(x^*) \\
&= \mathbb{E}[\nabla_x f(x^*, y(x^*,\xi),\xi) + \nabla_y f(x^*, y(x^*,\xi),\xi)\partial y(x^*,\xi)] + \mathcal{N}_{\mathcal{X}}(x^*) \\
&\subset \mathbb{E}[\nabla_x f(x^*, y(x^*,\xi),\xi) - \nabla_y f(x^*, y(x^*,\xi),\xi)\operatorname{conv}([\pi_y \partial H(x^*, y(x^*,\xi),\xi)]^{-1}) \\
&\quad \times \pi_x \partial H(x^*, y(x^*,\xi),\xi)] + \mathcal{N}_{\mathcal{X}}(x^*) \\
&= \mathbb{E}[\nabla_x f(x^*, y(x^*,\xi),\xi) + \Lambda(x^*,\xi)\pi_x \partial H(x^*, y(x^*,\xi),\xi)] + \mathcal{N}_{\mathcal{X}}(x^*). \qquad (13)
\end{aligned}$$

The inclusion $\partial \mathbb{E}[v(x^*,\xi)] \subset \mathbb{E}[\partial_x v(x^*,\xi)]$ is deduced from the fact that the Clarke generalized directional derivative of $\mathbb{E}[v(x,\xi)]$ is bounded by the expected value of the Clarke generalized directional derivative of $v(x,\xi)$. See [33, Proposition 2.12]. The conclusion follows. ∎

Remark 3.6. In the case when ∂H is singular, if

$$\nabla_y f(x^*, y(x^*,\xi),\xi)\partial y(x^*,\xi) \subset \Lambda(x^*,\xi)\pi_x \partial H(x^*, y(x^*,\xi),\xi), \tag{14}$$

then we can draw a similar conclusion.

Note that if $v(x,\xi)$ is regular at x^* in the sense of Clarke [10, Definition 2.3.4] and $\|\partial_x v(x,\xi)\|$ is bounded by some integrable function $\eta(\xi)$, then by [15, Proposition 5.1], $\partial \mathbb{E}[v(x^*,\xi)] = \mathbb{E}[\partial_x v(x^*,\xi)]$; consequently, equality holds in the first inclusion of (13). This implies that the set of stationary points satisfying $0 \in \partial \mathbb{E}[v(x^*,\xi)] + \mathcal{N}_{\mathcal{X}}(x^*)$ coincides with the set of stationary points satisfying $0 \in \mathbb{E}[\partial_x v(x^*,\xi)] + \mathcal{N}_{\mathcal{X}}(x^*)$. Our discussions above show that all these stationary points are contained in the set of the generalized stationary points satisfying (11) under some appropriate conditions, which means the latter gives a bound or an estimate of the former. To see how precise the estimate is, we need to look at the second inclusion in (13) or the inclusion in (14). The former relies on the index consistency of the piecewise smooth function H

in y at the considered point [21]. The latter depends on the structure of Λ and $\pi_x\partial H$. In general the inclusions are strict but perhaps not very loose. See [21, section 5] for the comparisons of various GKKT conditions for deterministic nonsmooth equality constrained minimization problems.

3.2. GKKT conditions of the regularized problem. We now consider the GKKT conditions of the regularized program (6). Throughout this subsection and section 4, we make the following assumption.

Assumption 3.7. Let R be a regularization of H. $\pi_y\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$ is nonsingular for $x\in\mathcal{X}$, $\xi\in\Xi$, $\mu\in(0,\mu_0)$.

This assumption is rather moderate and is satisfied by many regularizations. See section 5 for a detailed discussion. Let us define the mapping of multipliers of the regularized problem.

DEFINITION 3.8. *For $(x,\xi,\mu)\in\mathcal{X}\times\Xi\times(0,\mu_0)$, let*

$$\begin{aligned}\Lambda^{\mathrm{reg}}(x,\xi,\mu) :=&\mathrm{conv}\{\lambda(x,\xi)\in\mathbb{R}^n \mid 0\in\nabla_y f(x,\tilde{y}(x,\xi,\mu),\xi)\\ &+\lambda(x,\xi)\pi_y\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)\}.\end{aligned}\tag{15}$$

Since $\pi_y\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$ is nonsingular, then Λ^{reg} can be rewritten as

$$\Lambda^{\mathrm{reg}}(x,\xi,\mu) = -\nabla_y f(x,\tilde{y}(x,\xi,\mu),\xi)\mathrm{conv}([\pi_y\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)]^{-1}).\tag{16}$$

Obviously, Λ^{reg} contains the set of Lagrange multipliers of the trivial second stage regularized problem:

$$\min_y f(x,y,\xi)\ \text{ s.t. }\ R(x,y,\xi,\mu)=0,$$

since $\tilde{y}(x,\xi,\mu)$ is the unique feasible solution. Using the notion of Λ^{reg}, we define the stationary point of the regularized problem.

DEFINITION 3.9. *Let $\Lambda^{\mathrm{reg}}(x,\xi,\mu)$ be defined as in Definition* 3.8. *A point $x\in\mathbb{R}^m$ is called a* generalized stationary point *of the regularized problem* (6) *if*

$$0\in\mathbb{E}[\nabla_x f(x,\tilde{y}(x,\xi,\mu),\xi)+\Lambda^{\mathrm{reg}}(x,\xi,\mu)\pi_x\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)]+\mathcal{N}_{\mathcal{X}}(x).\tag{17}$$

We call condition (17) *a GKKT condition for the regularized problem* (6). *Note that this definition depends on the function $\tilde{y}(x,\xi,\mu)$.*

Let $\tilde{v}(x,\xi,\mu) := f(x,\tilde{y}(x,\xi,\mu),\xi)$. Obviously, $\tilde{v}(\cdot,\xi,\mu)$ is locally Lipschitz continuous, since $\tilde{y}(\cdot,\xi,\mu)$ is locally Lipschitz continuous by assumption. Note that by Lemma 3.4

$$\partial\tilde{y}(x,\xi,\mu)\subset -\mathrm{conv}([\pi_y\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)]^{-1})\pi_x\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu).$$

If $x^*\in\mathcal{X}$ be a local minimizer of the regularized problem, then under some appropriate measurable conditions (of $\partial_x\tilde{v}$, etc.) we have

$$\begin{aligned}0&\in\partial\mathbb{E}[\tilde{v}(x^*,\xi,\mu)]+\mathcal{N}_{\mathcal{X}}(x^*)\subset\mathbb{E}[\partial_x\tilde{v}(x^*,\xi,\mu)]+\mathcal{N}_{\mathcal{X}}(x^*)\\ &=\mathbb{E}[\nabla_x f(x^*,\tilde{y}(x^*,\xi,\mu),\xi)+\nabla_y f(x^*,\tilde{y}(x^*,\xi,\mu),\xi)\partial_x\tilde{y}(x^*,\xi,\mu)]+\mathcal{N}_{\mathcal{X}}(x^*)\\ &\subset\mathbb{E}[\nabla_x f(x^*,\tilde{y}(x^*,\xi,\mu),\xi)-\nabla_y f(x^*,\tilde{y}(x^*,\xi,\mu),\xi)\\ &\quad\times\mathrm{conv}([\pi_y\partial R(x^*,\tilde{y}(x^*,\xi,\mu),\xi,\mu)]^{-1})\pi_x\partial R(x^*,\tilde{y}(x^*,\xi,\mu),\xi,\mu)]+\mathcal{N}_{\mathcal{X}}(x^*)\\ &=\mathbb{E}[\nabla_x f(x^*,\tilde{y}(x^*,\xi,\mu),\xi)+\Lambda^{\mathrm{reg}}(x^*,\xi)\pi_x\partial R(x^*,\tilde{y}(x^*,\xi,\mu),\xi,\mu)]\\ &\quad+\mathcal{N}_{\mathcal{X}}(x^*),\end{aligned}\tag{18}$$

which implies that an optimal solution of the regularized problem (6) is a generalized stationary point.

3.3. Convergence analysis of the regularized problem. In this subsection, we investigate the convergence of the stationary points of regularized problem as $\mu \to 0$. We first state the following intermediate result.

LEMMA 3.10. *Let R be a regularization of H and $\Lambda^{\rm reg}$ be defined as in Definition* 3.8. *Suppose that there exists a function $\nu_1(\xi) > 0$ such that*

$$\|\Lambda^{\rm reg}(x,\xi,\mu)\| \le \nu_1(\xi) \quad \forall (x,\mu) \in \mathcal{X} \times (0,\mu_0) \tag{19}$$

and that $\mathbb{E}[\nu_1(\xi)] < \infty$. Then $\Lambda^{\rm reg}(\cdot,\xi,\cdot)$ is upper semicontinuous on $\mathcal{X} \times (0,\mu_0)$, and

$$\overline{\lim_{\mu \downarrow 0}} \Lambda^{\rm reg}(x,\xi,\mu) \subset \Lambda(x,\xi), \quad x \in \mathcal{X}. \tag{20}$$

Proof. The upper semicontinuity of $\Lambda^{\rm reg}$ on $\mathcal{X} \times (0,\mu_0)$ follows from (16), the upper semicontinuity of $\pi_y \partial R(x,y,\xi,\mu)$, and $\nabla_y f(x,y,\xi)$ with respect to x,y,μ. In what follows we show (20). By the definition of $\Lambda^{\rm reg}$,

$$-\nabla_y f(x,\tilde{y}(x,\xi,\mu),\xi) \in \Lambda^{\rm reg}(x,\xi,\mu)\pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu). \tag{21}$$

By Definition 2.1(iii),

$$\overline{\lim_{\mu \downarrow 0}} \pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu) \subset \pi_y \partial H(x,y(x,\xi),\xi).$$

Therefore $\pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$ is bounded for μ close to 0. This and condition (19) allow us to take an outer limit on both sides of (21)

$$\begin{aligned} -\nabla_y f(x,y(x,\xi),\xi) &\in \overline{\lim_{\mu \downarrow 0}} [\Lambda^{\rm reg}(x,\xi,\mu)\pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)] \\ &\subset \overline{\lim_{\mu \downarrow 0}} \Lambda^{\rm reg}(x,\xi,\mu) \overline{\lim_{\mu \downarrow 0}} \pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu). \end{aligned}$$

Then we arrive at

$$-\nabla_y f(x,y(x,\xi),\xi) \in \left[\overline{\lim_{\mu \downarrow 0}} \Lambda^{\rm reg}(x,\xi,\mu)\right] \pi_y \partial H(x,y(x,\xi),\xi)).$$

The conclusion follows immediately from the definition of Λ. □

Note that the boundedness condition (19) is satisfied if $[\pi_y \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)]^{-1}$ is uniformly bounded (see Remark 2.2) and f is uniformly Lipschitz continuous in y. We are now ready to present the main result of this section concerning the convergence of the stationary points of the regularized problem.

THEOREM 3.11. *Suppose that assumptions in Theorem* 2.4 *are satisfied. Suppose also that there exists a function $\kappa_2(\xi)$, where $\mathbb{E}[\kappa_2(\xi)] < \infty$, such that for all $(x,\xi,\mu) \in \mathcal{X} \times \Xi \times (0,\mu_0)$,*

$$\max\{\|\nabla_x f(x,\tilde{y}(x,\xi,\mu),\xi)\|, \|\pi_x \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)\|\} \le \kappa_2(\xi). \tag{22}$$

Let $\{x(\mu)\}$ be a sequence of generalized stationary points of the regularized problem (6). *Assume that x^* is an accumulation point of the sequence as $\mu \to 0$. Suppose that condition* (19) *holds and that $\mathbb{E}[\kappa_2(\xi)(1+\nu_1(\xi))] < \infty$. Then w.p.*1 *$x^*$ is a generalized stationary point of the true problem* (1), *that is,*

$$0 \in \mathbb{E}[\nabla_x f(x^*,y(x^*,\xi),\xi) + \Lambda(x^*,\xi)\pi_x \partial H(x^*,y(x^*,\xi),\xi)] + \mathcal{N}_{\mathcal{X}}(x^*).$$

Proof. We use the Lebesgue dominated convergence theorem to prove the result. Let

$$\mathcal{K}(x,\xi,\mu) := \nabla_x f(x,\tilde{y}(x,\xi,\mu),\xi) + \Lambda^{\rm reg}(x,\xi,\mu)\pi_x \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu).$$

First note that $x(\mu)$ is a generalized stationary point of (6), that is,

$$0 \in \mathbb{E}[\mathcal{K}(x(\mu),\xi,\mu)] + \mathcal{N}_{\mathcal{X}}(x(\mu)). \tag{23}$$

Note that, by Lemma 3.10, $\overline{\lim}_{\mu\downarrow 0}\Lambda^{\rm reg}(x,\xi,\mu) \subset \Lambda(x,\xi)$. By (19), $\Lambda^{\rm reg}(x,\xi,\mu)$ is uniformly dominated by $\nu_1(\xi)$ for μ sufficiently small and x close to x^*. On the other hand, by (22), $\nabla_x f(x,y,\xi)$ and $\pi_x\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$ are uniformly dominated by $\kappa_2(\xi)$ for μ sufficiently small. Hence, $\mathcal{K}(x,\xi,\mu)$ is uniformly dominated by $\kappa_2(\xi)(1+\nu_1(\xi))$ for μ small enough and x sufficiently close to x^*. Note that $\mathbb{E}[\kappa_2(\xi)(1+\nu_1(\xi))] < \infty$; by the Lebesgue dominated convergence theorem, we then have

$$\begin{aligned}
&\overline{\lim_{\mu\downarrow 0}}\,\mathbb{E}[\mathcal{K}(x(\mu),\xi,\mu)] = \mathbb{E}\left[\overline{\lim_{\mu\downarrow 0}}\,\mathcal{K}(x(\mu),\xi,\mu)\right]\\
&= \mathbb{E}\left[\overline{\lim_{\mu\downarrow 0}}\,[\nabla_x f(x(\mu),\tilde{y}(x(\mu),\xi,\mu),\xi) + \Lambda^{\rm reg}(x(\mu),\xi,\mu)\pi_x\partial R(x(\mu),\tilde{y}(x(\mu),\xi,\mu),\xi,\mu)]\right].
\end{aligned}$$

By Theorem 2.4 and Definition 2.1, we have by taking a subsequence if necessary on $\{x(\mu)\}$

$$\overline{\lim_{\mu\downarrow 0}}\,\nabla_x f(x(\mu),\tilde{y}(x(\mu),\xi,\mu),\xi) = \nabla_x f(x^*,y(x^*,\xi),\xi)$$

and

$$\overline{\lim_{\mu\downarrow 0}}\,\pi_x\partial R(x(\mu),\tilde{y}(x(\mu),\xi,\mu),\xi,\mu) \subset \pi_x\partial H(x^*,y(x^*,\xi),\xi).$$

In addition, notice that $\overline{\lim}_{\mu\downarrow 0}\Lambda^{\rm reg}(x(\mu),\xi,\mu) \subset \Lambda(x^*,\xi)$. Thus, with (23), it yields that

$$0 \in \mathbb{E}[\nabla_x f(x^*,y(x^*,\xi),\xi) + \Lambda(x^*,\xi)\pi_x\partial H(x^*,y(x^*,\xi),\xi)] + \mathcal{N}_{\mathcal{X}}(x^*).$$

This completes the proof. ∎

Note that when $f(x,y,\xi)$ and $H(x,y,\xi)$ are uniformly Lipschitz in x, condition (22) is satisfied, since $\pi_x\partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$ approximates $\pi_x\partial H(x,y(x,\xi),\xi)$ following Definition 2.1(iii).

4. Sample average approximations. In this section, we propose a sample average approximation (SAA) method for solving the regularized program (6). SAA methods have been extensively investigated in SMPECs recently. See, for instance, [17, 30, 32, 35, 36]. Our convergence analysis is similar to that in [36]. However, there are two main differences: (a) $\tilde{y}(x,\xi,\mu)$ is a solution of a regularized equation (2), which may be nonsmooth, while in [36] $\tilde{y}(x,\xi,\mu)$ is an implicit smoothing of $y(x,\xi)$ and is smooth in x; (b) $y(x,\xi)$ is the limit of $\{\tilde{y}(x,\xi,\mu)\}_{\mu\to 0}$ which satisfies (2) but it not necessarily a unique implicit function of (2).

Let $\xi^1,\ldots,\xi^N$ be an independent, identically distributed sample of ξ. We consider the following SAA program:

$$\begin{aligned}
\min_{x\in\mathcal{X},y^1,\ldots,y^N} \quad & f_N(x,y^1,\ldots,y^N) := \frac{1}{N}\sum_{i=1}^N f(x,y^i,\xi^i)\\
\text{s.t.} \quad & R(x,y^i,\xi^i,\mu) = 0, \quad i=1,\ldots,N.
\end{aligned} \tag{24}$$

Here $\mu > 0$ is a small positive number which may depend on sample size N in practical computation. Problem (24) is essentially a deterministic continuous minimization problem with variables x and $y^1, \ldots, y^N$. It can also be regarded as a two stage stochastic program with finite discrete distribution. Choosing which numerical method for solving (24) depends on the structure and size of the problem. If the problem is of relatively small size, and R is smooth, then many existing nonlinear programming methods may be readily applied to solving the problem. When R is not continuously differentiable, we need to employ those which can deal with nonsmoothness. Bundle methods and aggregate subgradient methods are effective ones.

In the case when the problem size is large, decomposition methods which are popular in dealing with large scale stochastic programs seem to be the choice. Of course, choosing which particular decomposition method also depends on the structure of the problem such as linearity, convexity, separability, and sparsity of the underlying functions. Higle and Sen [13] and Ruszczyński [26] presented a comprehensive discussion and review of various decomposition methods for solving two stage stochastic programs. We refer readers to them and the references therein for the methods.

Note that our model (1) is motivated by SMPECs; hence it might be helpful to explain how (24) is possibly solved when applied to SMPECs. For many practical SMPEC problems such as the stochastic leader-followers problem and capital expansion problem, f is convex in y, whereas $f(x, y(x, \xi), \xi)$ is usually nonconvex in x. Moreover, the feasible set of variable y is governed by a complementarity constraint and is often nonconvex. This means that the feasible set of variable y^i defined by an equality constraint in (24) is nonconvex when $\mu = 0$. However, since we assume $\pi_y R$ is nonsingular for $\mu > 0$, the equation has a unique solution y^i for given x and ξ^i; that is, the feasible set of y^i is a singleton. This implies the minimization with respect to variable y^i is trivial theoretically, albeit not numerically, and this can be achieved by solving an N system of equations simultaneously. Based on these observations, if we can solve (24), then we are likely to obtain a point $(x_N(\mu), y_N^1(\mu), \ldots, y_N^N(\mu))$ with $x_N(\mu)$ being a stationary point, while $y_N^i(\mu)$ is the unique global minimizer which depends on $x_N(\mu)$. Alternatively, we can say that $x_N(\mu)$ is a stationary point of (6).

In what follows, we focus on the Clarke stationary points of (24) given the nonsmooth and nonconvex nature of the problem. Following Hiriart-Urruty [14], we can write down the GKKT conditions of (24) as follows:

$$
\left\{
\begin{array}{l}
0 \in \dfrac{1}{N} \displaystyle\sum_{i=1}^{N} \nabla_x f(x, y^i, \xi^i) + \sum_{i=1}^{N} \lambda^i \partial_x R(x, y^i, \xi^i, \mu) + \mathcal{N}_{\mathcal{X}}(x), \\[2ex]
0 \in \dfrac{1}{N} \begin{pmatrix} \nabla_y f(x, y^1, \xi^1) \\ \vdots \\ \nabla_y f(x, y^N, \xi^N) \end{pmatrix} + \begin{pmatrix} \lambda^1 \partial_y R(x, y^1, \xi^1, \mu) \\ \vdots \\ \lambda^N \partial_y R(x, y^N, \xi^N, \mu) \end{pmatrix}, \\[2ex]
0 = R(x, y^i, \xi^i, \mu), \quad i = 1, \ldots, N.
\end{array}
\right. \tag{25}
$$

Since by assumption for every $(x, \xi) \in \mathcal{X} \times \Xi$, equation $R(x, y, \xi, \mu) = 0$ has a unique solution $\tilde{y}(x, \xi, \mu)$, then y^i in (25) can be expressed as $\tilde{y}(x, \xi^i, \mu)$, $i = 1, \ldots, N$.

Consequently, the above GKKT conditions can be rewritten as

(26)
$$\begin{cases} 0 \in \dfrac{1}{N}\displaystyle\sum_{i=1}^{N} \nabla_x f(x, \tilde{y}(x,\xi^i,\mu),\xi^i) + \sum_{i=1}^{N} \lambda^i \partial_x R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu) + \mathcal{N}_{\mathcal{X}}(x), \\ 0 \in \dfrac{1}{N}\begin{pmatrix} \nabla_y f(x,\tilde{y}(x,\xi^1,\mu),\xi^1) \\ \vdots \\ \nabla_y f(x,\tilde{y}(x,\xi^N,\mu),\xi^N) \end{pmatrix} + \begin{pmatrix} \lambda^1 \partial_y R(x,\tilde{y}(x,\xi^1,\mu),\xi^1,\mu) \\ \vdots \\ \lambda^N \partial_y R(x,\tilde{y}(x,\xi^N,\mu),\xi^N,\mu) \end{pmatrix}. \end{cases}$$

Note that by [10, Proposition 2.3.16],

$$\partial_x R(x,y,\xi,\mu) \subset \pi_x \partial R(x,y,\xi,\mu) \quad \text{and} \quad \partial_y R(x,y,\xi,\mu) \subset \pi_y \partial R(x,y,\xi,\mu).$$

In addition, under Assumption 3.7, $\pi_y \partial R(x,y^i,\xi^i,\mu)$ is nonsingular; then we replace λ^i, $i=1,\dots,N$, in (25) with

$$-\frac{1}{N}\nabla_y f(x,y^i,\xi^i)\mathrm{conv}([\pi_y \partial R(x,y^i,\xi^i,\mu)]^{-1}), \quad i=1,\dots,N.$$

By writing y^i as $\tilde{y}(x,\xi^i,\mu)$, we may consider a weaker GKKT condition than (26) as

$$\begin{aligned} 0 \in \frac{1}{N}\sum_{i=1}^{N} & [\nabla_x f(x,\tilde{y}(x,\xi^i,\mu),\xi^i) \\ & - \nabla_y f(x,\tilde{y}(x,\xi^i,\mu),\xi^i)\mathrm{conv}([\pi_y \partial R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu)]^{-1})\pi_x \partial R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu)] \\ & + \mathcal{N}_{\mathcal{X}}(x). \end{aligned}$$

The "weaker" is in the sense that a point x satisfying (26) must satisfy the above equation but not vice versa. Let $\Lambda^{\mathrm{reg}}(x,\xi,\mu)$ be defined as in (16). Then the above equation can be written as

$$\begin{aligned} 0 \in \frac{1}{N}\sum_{i=1}^{N} & \left[\nabla_x f(x,\tilde{y}(x,\xi^i,\mu),\xi^i) + \Lambda^{\mathrm{reg}}(x,\xi^i,\mu)\pi_x \partial R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu)\right] \\ & + \mathcal{N}_{\mathcal{X}}(x). \end{aligned} \tag{27}$$

We say that a point $x \in \mathcal{X}$ is a *generalized stationary point* of the reduced regularized SAA problem (24) if it satisfies (27). In what follows, we investigate the convergence of the generalized stationary points as the sample size tends to infinity. We consider two cases: (a) μ is set small and fixed, and the sample size N tends to infinity; (b) μ depends on the sample size and is reduced to zero as N increases to infinity.

We establish the following theorem, which states the convergence results of generalized stationary points.

THEOREM 4.1. *Let assumptions in Theorem* 3.11 *hold,* $\kappa_3(\xi) := \max(\nu_1(\xi), \kappa_2(\xi))$, *and* $\mathbb{E}[\kappa_3(\xi)(1+\kappa_3(\xi))] < \infty$. *Then the following statements hold:*

(i) *Let* $\mu > 0$ *be fixed. If* $\{x_N(\mu)\}$ *is a sequence of generalized stationary points which satisfy* (27), *then w.p.*1 *an accumulation point of the sequence is a generalized stationary point of the regularized problem* (6); *that is,*

$$0 \in \mathbb{E}\left[\mathcal{G}(x,\xi,\mu)\right] + \mathcal{N}_{\mathcal{X}}(x),$$

where $\mathcal{G}(x,\xi,\mu) := \nabla_x f(x,\tilde{y}(x,\xi,\mu),\xi) + \Lambda^{\mathrm{reg}}(x,\xi,\mu)\pi_x \partial R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)$.

(ii) *Let $\mu = \mu_N$, where $\mu_N \to 0$ as $N \to \infty$, and $\{x(\mu_N)\}$ be a sequence of generalized stationary points which satisfy* (27). *Suppose that $\|\pi_x \partial H(x, y(x,\xi),\xi)\|$ is also bounded by $\kappa_2(\xi)$ in* (22). *If x^* is an accumulation point of $\{x(\mu_N)\}$, then w.p.*1 *x^* is a generalized stationary point of the true problem* (1); *that is, x^* satisfies*

$$0 \in \mathbb{E}[\mathcal{L}(x,\xi)] + \mathcal{N}_{\mathcal{X}}(x), \tag{28}$$

where $\mathcal{L}(x,\xi) := \nabla_x f(x, y(x,\xi),\xi) + \Lambda(x,\xi)\pi_x \partial H(x, y(x,\xi),\xi)$, Λ, and $y(x,\xi)$ are as given in section 3.

Proof. Part (i). By assumption, there exists a unique $\tilde{y}(x,\xi,\mu)$ such that

$$R(x, \tilde{y}(x,\xi,\mu),\xi,\mu) = 0$$

for every $(x,\xi,\mu) \in \mathcal{X} \times \Xi \times (0,\mu_0)$. Since $\partial R(\cdot, \tilde{y}(\cdot,\xi,\mu),\xi,\mu)$ is an upper semicontinuous, compact set-valued mapping, then $\mathcal{G}(\cdot,\cdot,\mu)$ is also an upper semicontinuous and compact set-valued mapping on $\mathcal{X}$ for every $\xi \in \Xi$. It follows from (19) and (22) that $\mathcal{G}(x,\xi,\mu)$ is uniformly dominated by $\kappa_3(\xi)(1+\kappa_3(\xi))$, which is integrable by assumption. Assume without loss of generality that $\{x_N(\mu)\} \to \{x^*\}$. Since $x_N(\mu)$ is a generalized stationary point of problem (24), we have by definition

$$0 \in \frac{1}{N}\sum_{i=1}^{N} \mathcal{G}(x_N(\mu),\xi^i,\mu) + \mathcal{N}_{\mathcal{X}}(x_N(\mu)). \tag{29}$$

For any sufficiently small $\delta > 0, \gamma > 0$, we estimate

$$\mathbb{D}\left(\frac{1}{N}\sum_{i=1}^{N} \mathcal{G}(x_N(\mu),\xi^i,\mu), \quad \mathbb{E}[\mathcal{G}_\delta(x^*,\xi,\mu)] + \gamma\mathcal{B}\right),$$

where $\mathcal{G}_\delta(x^*,\xi,\mu) := \bigcup_{x\in\mathcal{B}(x^*,\delta)} \mathcal{G}(x,\xi,\mu)$ and $\mathbb{E}[\mathcal{G}_\delta(x^*,\xi,\mu)] = \bigcup_{G\in\mathcal{G}_\delta(x^*,\xi,\mu)} \mathbb{E}[G]$. Note that

$$\begin{aligned}
&\mathbb{D}\left(\frac{1}{N}\sum_{i=1}^{N} \mathcal{G}(x_N(\mu),\xi^i,\mu), \quad \mathbb{E}[\mathcal{G}_\delta(x^*,\xi,\mu)] + \gamma\mathcal{B}\right) \\
&\le \mathbb{D}\left(\frac{1}{N}\sum_{i=1}^{N} \mathcal{G}(x_N(\mu),\xi^i,\mu), \quad \frac{1}{N}\sum_{i=1}^{N} \mathcal{G}_{\delta/2}(x^*,\xi^i,\mu) + \gamma/2\mathcal{B}\right) \\
&+ \mathbb{D}\left(\frac{1}{N}\sum_{i=1}^{N} \mathcal{G}_{\delta/2}(x^*,\xi^i,\mu) + \gamma/2\mathcal{B}, \quad \mathbb{E}[\mathcal{G}_\delta(x^*,\xi,\mu)] + \gamma\mathcal{B}\right).
\end{aligned}$$

By Lemma 3.2 of [36], the second term on the right-hand side of the equation tends to zero w.p.1 as $N \to \infty$. On the other hand, for N large enough such that $x_N(\mu) \in \mathcal{B}(x^*,\delta)$, by definition $\mathcal{G}(x_N(\mu),\xi^i,\mu) \subset \mathcal{G}_\delta(x^*,\xi^i,\mu)$, which leads to

$$\mathbb{D}\left(\frac{1}{N}\sum_{i=1}^{N} \mathcal{G}(x_N(\mu),\xi^i,\mu), \quad \frac{1}{N}\sum_{i=1}^{N} \mathcal{G}_\delta(x^*,\xi^i,\mu) + \gamma\mathcal{B}\right) = 0$$

for N sufficiently large. Hence, by (29), it follows that

$$0 \in \mathbb{E}[\mathcal{G}_\delta(x^*,\xi,\mu)] + \mathcal{N}_{\mathcal{X}}(x^*) + \gamma\mathcal{B} \text{ w.p.1.}$$

By the Lebesgue dominated convergence theorem and noticing the arbitrariness of δ and γ, we get the desired conclusion.

Part (ii). We now treat μ in $\mathcal{G}(x,\xi,\mu)$ as a variable and define

$$\hat{\mathcal{G}}(x,\xi,\mu) := \begin{cases} \mathcal{G}(x,\xi,\mu), & \mu > 0, \\ \mathcal{A}(x,\xi), & \mu = 0, \end{cases}$$

where $\mathcal{A}(x,\xi) := \nabla_x f(x,y(x,\xi),\xi) + \overline{\lim}_{\mu\downarrow 0} \Lambda^{\rm reg}(x,\xi,\mu)\pi_x \partial H(x,y(x,\xi),\xi)$. By assumption, it follows that $\hat{\mathcal{G}}(\cdot,\xi,\cdot) : \mathcal{X}\times[0,\mu_0) \to 2^{\mathbb{R}^n}$ is an upper semicontinuous and compact set-valued mapping for every $\xi\in\Xi$. Conditions (19) and (22) and the bound $\kappa_2(\xi)$ on $\pi_x\partial H(x,y(x,\xi),\xi)$ imply that $\hat{\mathcal{G}}(x,\xi,\mu)$ is bounded by $\kappa_3(\xi)(1+\kappa_3(\xi))$, which is integrable by assumption. Since $x(\mu_N)$ is a generalized stationary point of problem (24) with $\mu=\mu_N$, it follows that

$$0 \in \frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}(x(\mu_N),\xi^i,\mu_N) + \mathcal{N}_{\mathcal{X}}(x(\mu_N)). \tag{30}$$

Assume without loss of generality that $x(\mu_N)\to x^*$ as $N\to\infty$. For any small $\delta>0$ and $\gamma>0$, we will show that

$$\mathbb{D}\left(\frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}(x(\mu_N),\xi^i,\mu_N), \quad \mathbb{E}\left[\mathcal{L}_\delta(x^*,\xi)\right] + \gamma\mathcal{B}\right) \to 0, \quad \text{w.p.1 as } N\to\infty,$$

where $\mathcal{L}_\delta(x^*,\xi) = \hat{\mathcal{G}}_\delta(x^*,\xi,0), \hat{\mathcal{G}}_\delta(x,\xi,\mu) = \bigcup_{(x',\mu')\in\mathcal{B}(x,\delta)\times[0,\delta]} \mathcal{G}(x',\xi,\mu')$. Note that

$$\begin{aligned}
&\mathbb{D}\left(\frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}(x(\mu_N),\xi^i,\mu_N), \quad \mathbb{E}\left[\mathcal{L}_\delta(x^*,\xi)\right] + \gamma\mathcal{B}\right) \\
&\le \mathbb{D}\left(\frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}(x(\mu_N),\xi^i,\mu_N), \quad \frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}_{\delta/2}(x^*,\xi^i,0) + \gamma/2\mathcal{B}\right) \\
&+ \mathbb{D}\left(\frac{1}{N}\sum_{i=1}^N \hat{\mathcal{G}}_{\delta/2}(x^*,\xi^i,0) + \gamma/2\mathcal{B}, \quad \mathbb{E}\left[\mathcal{L}_\delta(x^*,\xi)\right] + \gamma\mathcal{B}\right).
\end{aligned}$$

By Lemma 3.2 of [36], the second term on the right-hand side of the equation above tends to zero as $N\to\infty$. On the other hand, since $\hat{\mathcal{G}}(x(\mu_N),\xi^i,\mu_N) \subset \hat{\mathcal{G}}_\delta(x^*,\xi^i,0)$ for any $(x(\mu_N),\mu_N)\in\mathcal{B}(x^*,\delta)\times[0,\delta]$, hence the first term on the right-hand side equals zero for N sufficiently large. Since γ and δ are arbitrarily small, thereby, the conclusion follows immediately by virtue of the Lebesgue dominated convergence theorem and (30). The proof is completed. □

Theorem 4.1 states that if μ is fixed, then w.p.1. an accumulation point of a sequence of the generalized stationary points of the regularized SAA problem (24) is a generalized stationary point of the regularized problem (6). In the case that μ depends on sample size N and is reduced to zero as $N\to\infty$, then w.p.1. an accumulation point of a sequence of the generalized stationary points of the regularized SAA problem (24) is a generalized stationary point of the true problem.

5. Applications to SMPECs.

5.1. Stochastic program with variational constraints. In this section, we apply the results established in the preceding sections to the following stochastic mathematical programs with boxed constrained variational inequality (BVI) constraints:

$$\min_{x\in\mathcal{X}} \quad \mathbb{E}\left[f(x, y(x,\xi),\xi)\right], \tag{31}$$

where $y(x,\xi)$ is a measurable solution to the VI problem

$$F(x,y,\xi)^T(z-y)\geq 0 \quad \forall z\in\Upsilon, \tag{32}$$

where $\mathcal{X}$ is a nonempty compact subset of $\mathbb{R}^m$, $f:\mathbb{R}^m\times\mathbb{R}^n\times\mathbb{R}^k\to\mathbb{R}$ is continuously differentiable, $\xi:\Omega\to\Xi\subset\mathbb{R}^k$ is a vector of random variables defined on probability space $(\Omega,\mathcal{F},P)$ with nonatomic P, $F:\mathbb{R}^m\times\mathbb{R}^n\times\mathbb{R}^k\to\mathbb{R}^n$ is continuously differentiable, $F(x,\cdot,\xi)$ is a P_0-function for every $(x,\xi)\in\mathcal{X}\times\Xi$, $\Upsilon:=\{y\in\mathbb{R}^n \mid a\leq y\leq b\}$, $a\in\{\mathbb{R}\cup\{-\infty\}\}^n$, $b\in\{\mathbb{R}\cup\{\infty\}\}^n$, and $a<b$ (componentwise). Here we assume that Ξ is a compact set. Notice that if we set $a=0$ and $b=\infty$, then problem (31) is reduced to the stochastic mathematical programs with complementarity constraints. For simplicity in analysis, we assume all components in a or b are finite or infinite simultaneously. In other words, we will focus on the following cases: (i) $a\in\mathbb{R}^n$ and $b\in\mathbb{R}^n$; (ii) $a\in\mathbb{R}^n$, $b=\infty$; (iii) $a=-\infty$, $b\in\mathbb{R}^n$; (iv) $a=-\infty$, $b=\infty$.

For every $(x,\xi)\in\mathcal{X}\times\Xi$, the constraint of the second stage problem (32) is actually a parametric BVI problem. Throughout this section, we assume that the BVI has at least one solution for every $(x,\xi)\in\mathcal{X}\times\Xi$.

Let $\Pi_\Upsilon(y)$ be the Euclidean projection of y onto Υ. Then the parametric BVI can be reformulated as a parameterized normal equation

$$H(x,y,\xi):=F(x,\Pi_\Upsilon(y),\xi)+y-\Pi_\Upsilon(y)=0, \quad (x,\xi)\in\mathcal{X}\times\Xi, \tag{33}$$

in the sense that if $y(x,\xi)$ is a solution of (33), then $\bar{y}(x,\xi):=\Pi_\Upsilon(y(x,\xi))$ is a solution of the BVI problem, and conversely, if $\bar{y}(x,\xi)$ is a solution of the BVI, then $y(x,\xi):=\bar{y}(x,\xi)-F(x,\bar{y}(x,\xi),\xi)$ is a solution of (33). Consequently, we can reformulate (31) as

$$\min_{x\in\mathcal{X}} \quad \mathbb{E}\left[f(x,\Pi_\Upsilon(y(x,\xi)),\xi)\right], \tag{34}$$

where $y(x,\xi)$ is a measurable solution to the following equation:

$$H(x,y,\xi)=0. \tag{35}$$

Obviously, H defined in (33) is locally Lipschitz continuous and piecewise smooth with respect to x,y,ξ as Υ is a box. The nonsmoothness of Π_Υ may result in the ill-posedness of (33). Note also that since F is a P_0-function, the parametric BVI may have multiple solutions, and consequently (33) may have multiple solutions for every x and ξ. In what follows, we use a smoothed regularization method to deal with (33). First, we will use the Gabriel–Moré smoothing function to smooth Π_Υ [12], and consequently we get a smooth approximation of (33)

$$\hat{R}(x,v,y,\xi):=F(x,p(v,y),\xi)+y-p(v,y)=0, \quad (x,\xi)\in\mathcal{X}\times\Xi. \tag{36}$$

Here $p:\mathbb{R}^n\times\mathbb{R}^n\to\mathbb{R}^n$ is continuously differentiable, except at the point $(v,y)\in\mathbb{R}^n\times\mathbb{R}^n$, such that $v_i=0$ for some $i\in\{1,2,\ldots,n\}$, and for any $(v,y)\in\mathbb{R}^n\times\mathbb{R}^n$, $p(v,y)\in\Upsilon$. We set $v_i=\mu$ and apply the well-known *Tikhonov* regularization to $\hat{R}$

$$R(x,y,\xi,\mu):=\hat{R}(x,\mu e,y,\xi)+\mu y=F(x,p(\mu e,y),\xi)+y-p(\mu e,y)+\mu y, \tag{37}$$

where $e = (1, 1, \ldots, 1) \in \mathbb{R}^n$ and μ is a positive parameter.

In the following analysis, we use the well-known Chen–Harker–Kanzow–Smale (CHKS) smoothing function [7, 16] to smooth the components of $\Pi_\Upsilon(y)$:

$$\phi(\alpha, c, d, \beta) = (c + \sqrt{(c-\beta)^2 + 4\alpha^2})/2 + (d - \sqrt{(d-\beta)^2 + 4\alpha^2})/2,$$

where $(\alpha, \beta) \in \mathbb{R}_{++} \times \mathbb{R}$ and $(c, d) \in \mathbb{R} \times \mathbb{R}$. Then

$$\begin{aligned} p_i(\mu e, y) &:= \phi(\mu, a_i, b_i, y_i) \\ &= (a_i + \sqrt{(a_i - y_i)^2 + 4\mu^2})/2 + (b_i - \sqrt{(b_i - y_i)^2 + 4\mu^2})/2, \quad i = 1, \ldots, n. \end{aligned}$$

For any $\mu \in \mathbb{R}_{++}$ and $(x, \xi) \in \mathcal{X} \times \Xi$, since $p(\mu e, y)$ is continuously differentiable with respect to y, it follows that $R(x, y, \xi, \mu)$ is continuously differentiable with respect to x, y for almost every ξ. In what follows, we will verify that R defined in (37) satisfies Definition 2.1 for regularization functions. We first state the following result.

LEMMA 5.1. *Given $(x, \xi) \in \mathcal{X} \times \Xi$ and $\mu > 0$, let R be defined as in* (37). *Then the Jacobian $\nabla_y R(x, y, \xi, \mu)$ is nonsingular.*

Proof. First, we have

$$\nabla_y R(x, y, \xi, \mu) = \nabla_y F(x, p(\mu e, y), \xi) D(\mu, y) + \mu I + I - D(\mu, y),$$

where $D(\mu, y) = \operatorname{diag}(d_1(\mu, y), \ldots, d_n(\mu, y))$ and $d_i(\mu, y) = \partial p_i(\mu e, y)/\partial y_i \in [0, 1]$ for every $i \in \{1, \ldots, n\}$. Since $F(x, y, \xi)$ is a P_0-function with respect to y and $p(\mu e, y) \in \Upsilon$, then $\nabla_y F(x, p(\mu e, y), \xi)$ is a P_0-matrix. For $u \in \mathbb{R}^n$, let

$$[\nabla_y F(x, p(\mu e, y), \xi) D(\mu, y) + \mu I + I - D(\mu, y)]u = 0.$$

We claim that $D(\mu, y)u = 0$. Assume that $[D(\mu, y)u]_i \neq 0$ for any i; we then have

$$\begin{aligned} [D(\mu, y)u]_i [\nabla_y F(x, p(\mu e, y), \xi) D(\mu, y)u]_i &= -[D(\mu, y)u]_i [(\mu + 1)u - D(\mu, y)u]_i \\ &= -(\mu + 1) d_i(\mu, y) u_i^2 + d_i^2(\mu, y) u_i^2 < 0, \end{aligned}$$

which contradicts the definition of P_0-matrix of $\nabla_y F(x, p(\mu e, y), \xi)$. So, $D(\mu, y)u = 0$. Hence, $(\mu + 1)u = 0$, which derives $u = 0$. Thus, $\nabla_y R(x, y, \xi, \mu)$ is nonsingular. ∎

LEMMA 5.2. *Let $\{x^k\}$, $\{y^k\}$, $\{\xi^k\}$ be sequences in $\mathcal{X}$, $\mathbb{R}^n$, Ξ and let $\{\mu^k\}$ be a sequence in any closed subset of $(0, \mu_0)$ with $\{\|y^k\|\} \to \infty$ as $k \to \infty$, where μ_0 is a small positive number. Then $\|R(x^k, y^k, \xi^k, \mu^k)\| \to \infty$ as $k \to \infty$.*

See a detailed proof in the appendix.

By Lemmas 5.1 and 5.2, we are ready to show that function R constructed in (37) is a regularization of H.

PROPOSITION 5.3. *Let μ_0 be a small positive number. Function R defined in* (37) *is a regularization of H as defined in Definition* 2.1. *Moreover, $\tilde{y}$ is continuously differentiable on $\mathcal{X} \times \Xi \times (0, \mu_0)$.*

The proof is long. We move it to the appendix.

Based on the above discussions, we can convert the true problem (31) (or equivalently, (34)) to the following regularized program:

$$\min_{x \in \mathcal{X}} \quad \mathbb{E}\left[f(x, \Pi_\Upsilon(\tilde{y}(x, \xi, \mu)), \xi)\right], \tag{38}$$

where $\tilde{y}(x, \xi, \mu)$ uniquely solves $R(x, y, \xi, \mu) = 0$, $(x, \xi, \mu) \in \mathcal{X} \times \Xi \times (0, \mu_0)$.

In the next subsection, we will investigate a numerical method for solving (38) by using its SAA.

5.2. SAA program. In this subsection, we consider the SAA program of (38)

$$\begin{aligned} \min_{x\in\mathcal{X},\ y^1,\dots,y^N} \quad & \frac{1}{N}\sum_{i=1}^{N} f(x,\Pi_\Upsilon(y^i),\xi^i) \\ \text{s.t.} \quad & R(x,y^i,\xi^i,\mu)=0, \quad i=1,\dots,N, \end{aligned} \tag{39}$$

where μ is a small positive number. Analogous to the discussion in section 4, we can write down the GKKT conditions of (39) as follows:

$$\begin{cases} 0 \in \dfrac{1}{N}\displaystyle\sum_{i=1}^{N} \nabla_x f(x,\Pi_\Upsilon(y^i),\xi^i) + \sum_{i=1}^{N} \lambda^i \nabla_x R(x,y^i,\xi^i,\mu) + \mathcal{N}_{\mathcal{X}}(x), \\ 0 \in \dfrac{1}{N}\begin{pmatrix} \nabla_y f(x,\Pi_\Upsilon(y^1),\xi^1)\partial\Pi_\Upsilon(y^1) \\ \vdots \\ \nabla_y f(x,\Pi_\Upsilon(y^N),\xi^N)\partial\Pi_\Upsilon(y^N) \end{pmatrix} + \begin{pmatrix} \lambda^1\nabla_y R(x,y^1,\xi^1,\mu) \\ \vdots \\ \lambda^N\nabla_y R(x,y^N,\xi^N,\mu) \end{pmatrix}, \\ 0 = R(x,y^i,\xi^i,\mu), \quad i=1,\dots,N. \end{cases} \tag{40}$$

Following similar arguments as in section 4, we derive

$$\begin{aligned} 0 \in & \frac{1}{N}\sum_{i=1}^{N} \left[\nabla_x f(x,\Pi_\Upsilon(\tilde{y}(x,\xi^i,\mu)),\xi^i) + \Lambda^{\mathrm{reg}}(x,\xi^i,\mu)\nabla_x R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu)\right] \\ & + \mathcal{N}_{\mathcal{X}}(x), \end{aligned} \tag{41}$$

where

$$\Lambda^{\mathrm{reg}}(x,\xi^i,\mu) = -\nabla_y f(x,\Pi_\Upsilon(\tilde{y}(x,\xi^i,\mu)),\xi^i)\partial\Pi_\Upsilon(\tilde{y}(x,\xi^i,\mu))\nabla_y R(x,\tilde{y}(x,\xi^i,\mu),\xi^i,\mu)^{-1}.$$

Note that for any $(x,y,\xi)\in\mathcal{X}\times\mathbb{R}^n\times\Xi$ and $\mu>0$,

$$\nabla_x H(x,y,\xi) = \nabla_x R(x,y,\xi,\mu) = \nabla_x F(x,\Pi_\Upsilon(y),\xi)$$

and

$$\partial\Pi_\Upsilon(y) \subset \{M\in\mathbb{R}^{n\times n} \mid M=\mathrm{diag}(d_1,\dots,d_n),\ \ d_i\in[0,1]\}.$$

Obviously, $\partial\Pi_\Upsilon(y)$ is bounded for any $y\in\mathbb{R}^n$. Assume that $\lim_{\mu\downarrow 0}\tilde{y}(x,\xi,\mu)$ exists. Let $y(x,\xi)=\lim_{\mu\downarrow 0}\tilde{y}(x,\xi,\mu)$ on $\mathcal{X}\times\Xi$, and for $(x,\xi)\in\mathcal{X}\times\Xi$

$$\begin{aligned} \Lambda(x,\xi) := \mathrm{conv}\{\lambda(x,\xi)\in\mathbb{R}^n \mid & 0\in\nabla_y f(x,\Pi_\Upsilon(y(x,\xi)),\xi)\partial\Pi_\Upsilon(y(x,\xi)) \\ & + \lambda(x,\xi)\pi_y\partial H(x,y(x,\xi),\xi)\}. \end{aligned}$$

Following a similar argument as in Theorem 4.1, we derive convergence results for (39) below.

THEOREM 5.4. *Suppose that there exist a function $\kappa_4(\xi)$ and a constant $\mu_0>0$ such that for all $(x,\xi,\mu)\in\mathcal{X}\times\Xi\times(0,\mu_0)$*

$$\begin{aligned} & \max\{\|\nabla_x f(x,\Pi_\Upsilon(\tilde{y}(x,\xi,\mu),\xi))\|, \|\nabla_x F(x,\Pi_\Upsilon(\tilde{y}(x,\xi,\mu)),\xi)\|, \|\Lambda^{\mathrm{reg}}(x,\xi,\mu)\|\} \\ & \le \kappa_4(\xi) \end{aligned} \tag{42}$$

with $\mathbb{E}[\kappa_4(\xi)]<\infty$. Suppose that $\mathbb{E}[\kappa_4(\xi)(1+\kappa_4(\xi))]<\infty$. Then

(i) *for fixed $\mu > 0$, w.p.*1 *an accumulation point of the sequence of the generalized stationary points $\{x_N(\mu)\}$ of* (39) *satisfies*

$$0 \in \mathbb{E}\left[\hbar(x,\xi,\mu)\right] + \mathcal{N}_{\mathcal{X}}(x),$$

where

$$\hbar(x,\xi,\mu) := \nabla_x f(x, \Pi_{\Upsilon}(\tilde{y}(x,\xi,\mu)),\xi) + \Lambda^{\mathrm{reg}}(x,\xi,\mu)\nabla_x F(x,\Pi_{\Upsilon}(\tilde{y}(x,\xi,\mu)),\xi);$$

(ii) *if $\mu = \mu_N$, where $\mu_N \to 0$ as $N \to \infty$, and $\{x(\mu_N)\}$ is a sequence of generalized stationary points of* (39), *then w.p.*1 *an accumulation point of $\{x(\mu_N)\}$ satisfies*

$$0 \in \mathbb{E}[\mathcal{M}(x,\xi)] + \mathcal{N}_{\mathcal{X}}(x), \tag{43}$$

where

$$\mathcal{M}(x,\xi) := \nabla_x f(x, \Pi_{\Upsilon}(y(x,\xi)),\xi) + \Lambda(x,\xi)\nabla_x F(x,\Pi_{\Upsilon}(y(x,\xi)),\xi).$$

Note that the boundedness condition in (42) on $\|\nabla_x f(x,\Pi_{\Upsilon}(\tilde{y}(x,\xi,\mu)),\xi)\|$ and $\|\nabla_x F(x,\Pi_{\Upsilon}(\tilde{y}(x,\xi,\mu)),\xi)\|$ is satisfied if f and F are uniformly globally Lipschitz with respect to x. The boundedness condition on $\Lambda^{\mathrm{reg}}(x,\xi,\mu)$ is satisfied if $f(x,y,\xi)$ is uniformly globally Lipschitz with respect to y and $\pi_y \partial H(x,y(x,\xi),\xi)$ is uniformly nonsingular. In particular, if $H(x,y,\xi)$ is regular in the sense of [20] in y at $y(x,\xi)$, then $\pi_y \partial H(x,y(x,\xi),\xi)$ is nonsingular. See [20] for a detailed discussion in this regard.

Example 5.5. Consider the following stochastic mathematical program:

$$\min_{x\in\mathcal{X}} \quad \mathbb{E}\left[f(x,y(x,\xi),\xi)\right]. \tag{44}$$

Here $f : \mathbb{R}\times\mathbb{R}^2\times\mathbb{R}\to\mathbb{R}$ is given as

$$f(x,y,\xi) = 2(y_1 - \arctan y_1) + 4y_1^4 y_2/(1+y_1^2)^2 + 1 + x + \xi,$$

and $y(x,\xi)$ is any measurable solution of the following BVI problem:

$$F(x,y(x,\xi),\xi)^T(z - y(x,\xi)) \geq 0 \quad \forall z \in \Upsilon, \tag{45}$$

where $\Upsilon = \mathbb{R}^2_+$, $\mathcal{X} = [0,1]$, ξ can be any random variable that can take values on the interval $\Xi := [-1,-1/4]$, and $F(x,y,\xi) = (0, y_1 + y_2 + x + \xi - 1)^T$. Evidently, F is continuously differentiable and $F(x,\cdot,\xi)$ is a P_0-function for every $(x,\xi)\in\mathcal{X}\times\Xi$ and

$$\nabla_x F(x,y,\xi) = (0,1)^T. \tag{46}$$

Note that f is continuously differentiable on $\mathbb{R}\times\mathbb{R}^2\times\mathbb{R}$, $f'_x(x,y,\xi) = f'_\xi(x,y,\xi) = 1$, and

$$\nabla_y f(x,y,\xi) = \left(2y_1^2/(1+y_1^2) + 16y_1^3y_2/(1+y_1^2)^3,\quad 4y_1^4/(1+y_1^2)^2\right). \tag{47}$$

In this example, we have $H(x,y,\xi) = (y_1 - \max\{0,y_1\},\ \max\{0,y_1\} + y_2 + x + \xi - 1)$. It is not hard to obtain the solution set of the VI problem (45) as follows: for $(x,\xi)\in\mathcal{X}\times\Xi$,

$$\mathcal{Y}(x,\xi) := \{y\in\mathbb{R}^2_+ : y_1 \geq 1 - x - \xi,\ y_2 = 0\} \cup \{y\in\mathbb{R}^2_+ : y_1 + y_2 - 1 + x + \xi = 0\}.$$

Obviously, $\mathcal{Y}$ is a set-valued mapping on $\mathcal{X} \times \Xi$.

We now consider the regularization of the VI problem (45), in which given a regularization parameter, we expect to derive a unique solution function on $\mathcal{X} \times \Xi$. Note here that $\Upsilon = \mathbb{R}^2_+$, we have $a_i = 0$, and $b_i = \infty$, $i = 1, 2$. Then we get the ith component of the smoothing function $p_i(\mu e, y) = \phi(\mu, 0, \infty, y_i)$, $i = 1, 2$, $\mu > 0$, where ϕ is the reduced CHKS smoothing NCP function: $\phi(\alpha, 0, \infty, \beta) = (\sqrt{\beta^2 + 4\alpha^2} + \beta)/2, (\alpha, \beta) \in \mathbb{R}_{++} \times \mathbb{R}$. By definition, we have $p_i(\mu e, y) = (\sqrt{y_i^2 + 4\mu^2} + y_i)/2$, $i = 1, 2, \mu > 0$. And

$$R(x, y, \xi, \mu) = \begin{pmatrix} -(\sqrt{y_1^2 + 4\mu^2} + y_1)/2 + (1 + \mu)y_1 \\ (\sqrt{y_1^2 + 4\mu^2} + y_1)/2 + (1 + \mu)y_2 + x + \xi - 1 \end{pmatrix}.$$

Evidently, R is continuously differentiable on $\mathcal{X} \times \mathbb{R}^2 \times \Xi \times (0, \infty)$.

After some basic manipulations, we derive the unique solution of $R(x, y, \xi, \mu) = 0$ for any $\mu > 0$, $(x, \xi) \in \mathcal{X} \times \Xi$ as follows:

$$\tilde{y}(x, \xi, \mu) = \left(\sqrt{\mu/(\mu + 1)}, \quad (1 - x - \xi)/(1 + \mu) - \sqrt{\mu/(\mu + 1)} \right)^T.$$

Moreover, for any $x \in \mathcal{X}$ and $\mu > 0$, $\|\tilde{y}(x, \xi, \mu)\| \le \kappa_1(\xi)$ with $\mathbb{E}[\kappa_1(\xi)] < \infty$, where $\kappa_1(\xi) = 7 - \xi$, and

$$\|\tilde{y}(x'', \xi, \mu) - \tilde{y}(x', \xi, \mu)\| \le L(\xi)\|x'' - x'\| \qquad \text{for any } x'', x' \in \mathcal{X},$$

where $L(\xi)$ can be taken as any measurable positive function satisfying $1 \le \mathbb{E}[L(\xi)] < \infty$, say, $L(\xi) = 1 - \xi$. Also, $\lim_{\mu \downarrow 0} \tilde{y}(x, \xi, \mu) = y(x, \xi) = (0, 1 - x - \xi) \in \mathcal{Y}(x, \xi)$, $(x, \xi) \in \mathcal{X} \times \Xi$. Thereby, all conditions in Theorem 2.4 are satisfied. Obviously, $y(x, \xi)$ is measurable for every $x \in \mathcal{X}$ and Lipschitz continuous in x.

In addition, by Proposition 5.3, the regularization R defined above satisfies parts (i)–(iv) of Definition 2.1, where μ_0 can be chosen any small positive number.

Next, we investigate the boundedness condition (42). After some simple calculations, we can see that $\tilde{y}(x, \xi, \mu) \in \mathbb{R}^2_{++}$ for any $(x, \xi, \mu) \in \mathcal{X} \times \Xi \times (0, \hat{\mu})$, where $\hat{\mu} = (\sqrt{5} - 2)/4$. So, $\Pi_\Upsilon(\tilde{y}(x, \xi, \mu)) = \tilde{y}(x, \xi, \mu)$ and

$$\partial \Pi_\Upsilon(\tilde{y}(x, \xi, \mu)) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

On the other hand, we have

$$\nabla_y R(x, y, \xi, \mu)^{-1} = \varpi(y, \mu)^{-1} \begin{pmatrix} 1 + \mu & 0 \\ -\frac{1}{2}\left(1 + \frac{y_1}{\sqrt{y_1^2 + 4\mu^2}}\right) & -\frac{1}{2}\left(1 + \frac{y_1}{\sqrt{y_1^2 + 4\mu^2}}\right) + \mu \end{pmatrix},$$

where $\varpi(y, \mu) = (1 + \mu)[\frac{1}{2}(1 - y_1/\sqrt{y_1^2 + 4\mu^2}) + \mu]$. Then it follows that

$$\nabla_y R(x, \tilde{y}(x, \xi, \mu), \xi, \mu)^{-1} = \frac{1 + 2\mu}{2\mu(1 + \mu)^2} \begin{pmatrix} 1 + \mu & 0 \\ -\dfrac{1 + \mu}{1 + 2\mu} & \dfrac{2\mu^2 - 1}{1 + 2\mu} \end{pmatrix}.$$

In addition, we have

$$\begin{aligned}&\nabla_y f(x,\tilde{y}(x,\xi,\mu),\xi)\\&=\frac{2\mu}{2\mu+1}\left((1+8\sqrt{\mu(\mu+1)})\left(\frac{1-x-\xi-\sqrt{\mu(\mu+1)}}{(2\mu+1)^2}\right),\quad \frac{2\mu}{2\mu+1}\right).\end{aligned}$$

Then, for $\mu\in(0,\hat{\mu})$ and $(x,\xi)\in\mathcal{X}\times\Xi$, it follows that

$$\begin{aligned}\Lambda^{\rm reg}(x,\xi,\mu)&=-\nabla_y f(x,\Pi_\Upsilon(\tilde{y}(x,\xi,\mu)),\xi)\partial\Pi_\Upsilon(\tilde{y}(x,\xi,\mu))\nabla_y R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)^{-1}\\&=-\left(\frac{8\sqrt{\mu}(1-x-\xi)}{\sqrt{1+\mu}(1+2\mu)^2}+\frac{1-6\mu-4\mu^2}{(1+\mu)(1+2\mu)^2},\quad \frac{2\mu(2\mu^2-1)}{(1+\mu)^2(1+2\mu)^2}\right).\end{aligned}$$

By applying some basic operations, we have $\|\Lambda^{\rm reg}(x,\xi,\mu)\|<\varrho(\xi)$ for any $(x,\mu)\in\mathcal{X}\times(0,\mu_0)$, where $\varrho(\xi):=\sqrt{2}+8\sqrt{2\hat{\mu}}(1-\xi)$. Assume that ξ follows a uniform distribution with parameters -1 and $-1/4$, i.e., $\xi\sim U(-1,-1/4)$. Then $\mathbb{E}[\varrho(\xi)]=\sqrt{2}+13\sqrt{2\hat{\mu}}<\infty$ and $\mathbb{E}[\varrho(\xi)(1+\varrho(\xi))]<\infty$. Hence, we can choose $\kappa_4(\xi)=\varrho(\xi)$ in Theorem 5.4. This, together with (46) and (47), shows that the boundedness condition (42) holds in this example. □

Note that in this example, one may ask why the objective function f is not chosen in a simpler form, say, a linear function of y rather than in a complex form as it stands. The answer is that we use this example not only to illustrate how regularization works for this particular SMPEC problem but also to demonstrate how the boundedness conditions (19) in Lemma 3.10 and (42) of Theorem 5.4 can be satisfied. In this particular example, if f is made linear in y, then we are not able to guarantee the boundedness of the set $\Lambda^{\rm reg}$, although this does not mean the method will not work.

6. Preliminary numerical results. We have carried out numerical tests on the regularized SAA scheme for stochastic problems with VI constraints. In this section, we report some preliminary numerical results. Such stochastic problems are artificially made by ourselves, since there are few test problems on SMPECs in the literature. The tests are carried out by implementing mathematical programming codes in MATLAB 6.5 installed in a PC with Windows XP operating system. We use the MATLAB built-in solver *fmincon* for solving the regularized SAA problems.

6.1. Estimating the optimal value of the regularized problem. The following methodology of constructing statistical lower and upper bounds was suggested in [28]. Given $\mu>0$, let $v(\mu)$ denote the optimal value of the regularized problem (38) and $\tilde{v}_N(\mu)$ the optimal value of (39). It is known [28] that $\mathbb{E}[\tilde{v}_N(\mu)]\le v(\mu)$. To estimate the expected value $\mathbb{E}[\tilde{v}_N(\mu)]$, we generate M independent samples of ξ, $\{\xi_j^1,\dots,\xi_j^N\}$, $j=1,\dots,M$, each of size N. For each sample j, solve the corresponding SAA problem (39), which can be written as

$$\begin{aligned}\min_{x\in\mathcal{X}\ y^1,\dots,y^N}\quad&\frac{1}{N}\sum_{i=1}^N f(x,\Pi_\Upsilon(y^i),\xi_j^i)\\\text{s.t.}\quad&R(x,y^i,\xi_j^i,\mu)=0,\quad i=1,\dots,N.\end{aligned}\tag{48}$$

Let $\tilde{v}_N^j(\mu)$, $j=1,\dots,M$, denote the corresponding optimal value of problem (48). Compute

$$L_{N,M}(\mu):=\frac{1}{M}\sum_{j=1}^M\tilde{v}_N^j(\mu),$$

which is an unbiased estimate of $\mathbb{E}[\tilde{v}_N(\mu)]$. Then $L_{N,M}(\mu)$ provides a statistical lower bound for $v(\mu)$. An estimate of variance of the estimator $L_{N,M}(\mu)$ can be computed as

$$s_L^2(M;\mu) := \frac{1}{M(M-1)} \sum_{j=1}^{M} \left(\tilde{v}_N^j(\mu) - L_{N,M}(\mu) \right)^2.$$

Let $v(x,\xi,\mu) = f(x, \Pi_\Upsilon(\tilde{y}(x,\xi,\mu)),\xi)$ and $\tilde{\vartheta}(x,\mu) = \mathbb{E}[v(x,\xi,\mu)]$. Then an upper bound for the optimal value $v(\mu)$ can be obtained by the fact that $\tilde{\vartheta}(\bar{x},\mu) \geq v(\mu)$ for any $\bar{x} \in \mathcal{X}$. Hence, by choosing $\bar{x}$ to be a near-optimal solution, for example, by solving one SAA problem and using an unbiased estimator of $\tilde{\vartheta}(\bar{x},\mu)$, we can obtain an estimate of an upper bound for $v(\mu)$. To do so, generate M' independent batches of samples: $\{\xi_j^1,\ldots,\xi_j^{N'}\}$, $j = 1,\ldots,M'$, each of size N'. For $x \in \mathcal{X}$, let $\tilde{v}_{N'}^j(x,\mu) := \frac{1}{N'} \sum_{i=1}^{N'} v(x,\xi_j^i,\mu)$. Then $\mathbb{E}[\tilde{v}_{N'}^j(x,\mu)] = \tilde{\vartheta}(x,\mu)$. Compute

$$U_{N',M'}(\bar{x};\mu) := \frac{1}{M'} \sum_{j=1}^{M'} \tilde{v}_{N'}^j(\bar{x},\mu),$$

which is an unbiased estimate of $\tilde{\vartheta}(\bar{x},\mu)$. So, $U_{N',M'}(\bar{x};\mu)$ is an estimate of an upper bound on $v(\mu)$. An estimate of variance of the estimator $U_{N',M'}(\bar{x},\mu)$ can be computed as

$$s_U^2(\bar{x},M';\mu) := \frac{1}{M'(M'-1)} \sum_{j=1}^{M'} \left(\tilde{v}_{N'}^j(\bar{x},\mu) - U_{N',M'}(\bar{x},\mu) \right)^2.$$

Note that in this part, for each $j = 1,\ldots,M'$ and $i = 1,\ldots,N'$, we need to solve the following repeated subproblems:

$$\begin{array}{ll} \min & f(\bar{x}, \Pi_\Upsilon(y), \xi_j^i) \\ \text{s.t.} & R(\bar{x}, y, \xi_j^i, \mu) = 0; \end{array}$$

then the corresponding optimal value is $v(\bar{x},\xi_j^i,\mu)$. Hence, we can obtain $\tilde{v}_{N'}^j(\bar{x},\mu)$, $U_{N',M'}(\bar{x};\mu)$, and $s_U^2(\bar{x},M';\mu)$. Note that, in practice, we may choose $\bar{x}$ to be any of the solutions of the M regularized SAA problems (48) by generating independent samples $\{\xi_j^1,\ldots,\xi_j^N\}$, $j = 1,\ldots,M$. In fact, we will use $\bar{x}_N^j$, the *best* optimal solution which estimates the smallest optimal value $v(\mu)$, to compute the upper bound estimates, and the optimality gap.

Using the lower bound estimate and the objective function value estimate of the optimal value, $v(\mu)$, of the first stage regularized problem as discussed above, we compute an estimate of the optimality gap of the solution $\bar{x}$ and the corresponding estimated variance as follows:

$$Gap_{N,M,N',M'}(\bar{x}) := U_{N',M'}(\bar{x};\mu) - L_{N,M}(\mu), \quad S_{\text{Gap}}^2 := s_L^2(M;\mu) + s_U^2(\bar{x},M';\mu).$$

6.2. Preliminary computational results. In the following test problem, we choose different values for the regularization parameter μ and sample sizes N, M, N', and M'. We report the lower and upper bounds, $L_{N,M}$ and $U_{N',M'}$, of $v(\mu)$, the sample variances, s_L, s_U, and the estimate of the optimality gap, *Gap*, of the solution candidate $\bar{x}_N^j$, the variance of the gap estimator S_{Gap}.

TABLE 1
Summary of lower and upper bounds on $v(\mu)$, the optimality gap.

Example 6.1. Consider the following problem:

$$\begin{array}{ll} \min & \mathbb{E}[x^2 + y_2(x,\xi)^2] \\ \text{s.t.} & 0 \le x \le 1, \end{array} \tag{49}$$

where $y(x,\xi)$ is a solution of the following complementarity problem, which is a special case of VI problems:

$$0 \le F(x,y,\xi) \perp y \ge 0, \qquad F(x,y,\xi) = (0, y_1 + y_2 + x + \xi - 1)^T,$$

where ξ is a random variable with truncated standard normal distribution on $[-1, 1]$. Using the regularization scheme, we can convert the above problem into the following problem:

$$\begin{array}{ll} \min\limits_{x,y} & \mathbb{E}[x^2 + (\max(0, y_2))^2] \\ \text{s.t.} & R(x,y,\xi,\mu) = 0, \quad 0 \le x \le 1, \end{array}$$

where μ is a small positive parameter tending to 0 and $R(x,y,\xi,\mu)$ is given in Example 5.5. Note that the limit of the corresponding unique solution function $\tilde{y}(x,\xi,\mu)$ of $R(x,y,\xi,\mu) = 0$ equals $y(x,\xi) := (0, 1 - x - \xi)$. After basic operations, we can derive the optimal solution of problem (49) associated with $y(x,\xi)$ as $x^* = 0.5$, and the optimal value is $f^* = 0.77454$ (obtained from Maple). The test results are displayed in Table 1.

The results show that both optimal solutions and values of the regularized SAA problems approximate those of the true problem very well as sample size increases and the regularization parameter is driven to zero. More numerical tests are needed to evaluate the performance of the proposed method, but this is beyond the scope of this paper.

Appendix. *Proof of Lemma* 5.2. We first define an index set $\mathcal{I}_0^\infty := \{i \mid \{y_i^k\}$ is unbounded, $i = 1, \ldots, n\}$. By assumption, $\mathcal{I}_0^\infty$ is nonempty, and for all $i \in \mathcal{I}_0^\infty$, $|y_i^k| \to \infty$ as $k \to \infty$. In the following analysis, we will consider the following cases: (i) $a = -\infty$, $b = \infty$; (ii) $a \in \mathbb{R}^n$, $b = \infty$; (iii) $a = \infty$, $b \in \mathbb{R}^n$; and (iv) $a, b \in \mathbb{R}^n$.

Case (i). Since $a = -\infty$, $b = \infty$, we have $p(\mu e, y) = y$. Then $R(x,y,\xi,\mu) = F(x,y,\xi) + \mu y$. We now construct a bounded sequence $\{w^k\}$ by letting $w_i^k = 0$ if $i \in \mathcal{I}_0^\infty$ and $w_i^k = y_i^k$ otherwise. Since F is a P_0-function in y, hence for any k,

$$\begin{aligned} 0 &\le \max_{1 \le i \le n} (y_i^k - w_i^k)[F_i(x^k, y^k, \xi^k) - F_i(x^k, w^k, \xi^k)] \\ &= \max_{i \in \mathcal{I}_0^\infty} y_i^k [F_i(x^k, y^k, \xi^k) - F_i(x^k, w^k, \xi^k)] \\ &= y_{i_0}^k [F_{i_0}(x^k, y^k, \xi^k) - F_{i_0}(x^k, w^k, \xi^k)]. \end{aligned} \tag{50}$$

Here i_0 denotes an index in $\mathcal{I}_0^\infty$ at which the maximum value is attained. Without loss of generality, we may assume that the above index i_0 is independent of k. Since $\mathcal{X}$ and Ξ are compact, and $\{w^k\}$ is bounded, hence $\{F_{i_0}(x^k, w^k, \xi^k)\}$ is bounded by virtue of the continuity of F_{i_0}. We now consider two cases: $y_{i_0}^k \to \infty$; $y_{i_0}^k \to -\infty$. In the former case, it follows from (50) that $\{F_{i_0}(x^k, y^k, \xi^k)\}$ does not tend to $-\infty$. Since $\{\mu^k\}$ is contained in a closed interval of $(0, \mu_0)$, hence $F_{i_0}(x^k, y^k, \xi^k) + \mu^k y_{i_0}^k \to \infty$, which implies that $\|F(x^k, y^k, \xi^k) + \mu^k y^k\| \to \infty$. Similarly, in the latter case, we have that $\{F_{i_0}(x^k, y^k, \xi^k)\}$ does not tend to ∞ by (50). Thereby, $F_{i_0}(x^k, y^k, \xi^k) + \mu^k y_{i_0}^k \to -\infty$. Thus, in both cases, we have $\|R(x^k, y^k, \xi^k, \mu^k)\| \to \infty$.

Case (ii). Note that in this case

$$p_i(\mu e, y) = (a_i + \sqrt{(a_i - y_i)^2 + 4\mu^2} + y_i)/2, \quad i = 1, \ldots, n.$$

Then it is not hard to show that for each i, and any sequences $\{y_i^l\}$ and $\{\mu^l\}$ satisfying $y_i^l \to \infty$ and μ^l being in a closed subset of $(0, \mu_0)$ for all l, we have

$$\lim_{l\to\infty} [y_i^l - p_i(\mu^l e, y^l)] = 0. \tag{51}$$

Let

$$\mathcal{I}_+^\infty := \{i \in \mathcal{I}_0^\infty \mid \{y_i^k\} \to \infty\} \quad \text{and} \quad \mathcal{I}_-^\infty := \{i \in \mathcal{I}_0^\infty \mid \{y_i^k\} \to -\infty\}.$$

We now consider two cases: $\mathcal{I}_+^\infty = \emptyset$; $\mathcal{I}_+^\infty \neq \emptyset$. In Case (i), we have $\{y_i^k\} \to -\infty$ for all $i \in \mathcal{I}_0^\infty$. Then it is easy to show that $\lim_{k\to\infty} p_i(\mu^k e, y^k) = a_i$ for all $i \in \mathcal{I}_0^\infty$. Thus, $\{p(\mu^k e, y^k)\}$ is bounded. Noticing the boundedness of $\{x^k\}$ and $\{\xi^k\}$ and by virtue of the continuity of F_i, $i \in \mathcal{I}_0^\infty$, it follows that

$$\left|\big(R(x^k, y^k, \xi^k, \mu^k)\big)_i\right| = \left|F_i(x^k, p(\mu^k e, y^k), \xi^k) - p_i(\mu^k e, y^k) + y_i^k + \mu^k y_i^k\right| \to \infty.$$

In Case (ii), evidently, $\lim_{k\to\infty} p_i(\mu^k e, y^k) = \infty$ or a_i for $i \in \mathcal{I}_+^\infty$ or $\mathcal{I}_-^\infty$. We now define a sequence $\{v^k\}$ with $v_i^k := 0$ if $i \in \mathcal{I}_+^\infty$; $v_i^k := p_i(\mu^k e, y^k)$ if $i \in \mathcal{I}_-^\infty$; $v_i^k := p_i(\mu^k e, y^k)$ if $i \notin \mathcal{I}_0^\infty$. Based on the above arguments, evidently, $\{v^k\}$ is bounded. By the notion of P_0-function, we have

$$\begin{aligned} 0 &\le \max_{1\le i\le n} (p_i(\mu^k e, y^k) - v_i^k)[F_i(x^k, p(\mu^k e, y^k), \xi^k) - F_i(x^k, v^k, \xi^k)] \\ &= \max_{i\in\mathcal{I}_+^\infty} p_i(\mu^k e, y^k)[F_i(x^k, p(\mu^k e, y^k), \xi^k) - F_i(x^k, v^k, \xi^k)] \\ &= p_j(\mu^k e, y^k)[F_j(x^k, p(\mu^k e, y^k), \xi^k) - F_j(x^k, v^k, \xi^k)], \end{aligned} \tag{52}$$

where $j \in \mathcal{I}_+^\infty$ such that the maximum value is attained at j, without loss of generality, which is assumed to be independent of k. By assumption, F_j is continuous, and note that $\{x^k\}$, $\{\xi^k\}$, $\{v^k\}$ are bounded; hence $\{F_j(x^k, v^k, \xi^k)\}$ is bounded as well. In addition, since $p_j(\mu^k e, y^k) \to \infty$, thus by (52), $\{F_j(x^k, p(\mu^k e, y^k), \xi^k)\}$ does not tend to $-\infty$. Thereby, $F_j(x^k, p(\mu^k e, y^k), \xi^k) + \mu^k y_j^k \to \infty$. On the other hand, note that

$$\begin{aligned} \big(R(x^k, y^k, \xi^k, \mu^k)\big)_j &= F_j(x^k, p(\mu^k e, y^k), \xi^k) + y_j^k - p_j(\mu^k e, y^k) + \mu^k y_j^k \\ &= F_j(x^k, p(\mu^k e, y^k), \xi^k) + \mu^k y_j^k + y_j^k - p_j(\mu^k e, y^k). \end{aligned}$$

By (51), $y_j^k - p_j(\mu^k e, y^k) \to 0$. So, $\big(R(x^k, y^k, \xi^k, \mu^k)\big)_j \to \infty$. Therefore,

$$\|R(x^k, y^k, \xi^k, \mu^k)\| \to \infty.$$

Case (iii). In this case, the arguments are similar to Case (ii). Here we omit them for brevity.

Case (iv). Note that for any $i \in \mathcal{I}_0^\infty$, $\lim_{k\to\infty} p_i(\mu^k e, y^k) = \lim_{k\to\infty} \phi(\mu^k, a_i, b_i, y_i^k)$ equals b_i if $y_i^k \to \infty$ or a_i if $y_i^k \to -\infty$. Then $\{p(\mu^k e, y^k)\}$ is bounded; thereby, $\{F_i(x^k, p(\mu^k e, y^k), \xi^k)\}$ is bounded as well for $i \in \mathcal{I}_0^\infty$. Hence,

$$\left|\left(R(x^k, y^k, \xi^k, \mu^k)\right)_i\right| = \left|F_i(x, p(\mu^k e, y^k), \xi^k) + y_i^k - p_i(\mu^k e, y^k) + \mu^k y_i^k\right| \to \infty.$$

Thereby, $\|R(x^k, y^k, \xi^k, \mu^k)\| \to \infty$. □

Proof of Proposition 5.3. Note that R is continuous on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times[0,\mu_0]$. We now check parts (i)–(iv) in Definition 2.1. Obviously, part (i) holds, since $p(0, y) = \Pi_\Upsilon(y)$ for any $y \in \mathbb{R}^n$. By [20, Theorem 3.1], $p(\mu e, y)$ is continuously differentiable at any $(\mu, y) \in \mathbb{R}_{++} \times \mathbb{R}^n$. Then R is continuously differentiable on $\mathcal{X} \times \mathbb{R}^n \times \Xi \times (0, \mu_0]$. Note also that $H(x, y, \xi)$ is piecewise smooth; hence R is piecewise smooth on $\mathcal{X} \times \mathbb{R}^n \times \Xi \times [0, \mu_0]$. Thereby, part (ii) holds.

We now consider part (iii). Note that

$$\pi_x\partial R(x, y, \xi, \mu) = \partial_x R(x, y, \xi, \mu) = \nabla_x F(x, p(\mu e, y), \xi),$$

$$\pi_x\partial H(x, y, \xi) = \partial_x H(x, y, \xi) = \nabla_x F(x, \Pi_\Upsilon(y), \xi)$$

and $\lim_{\mu\downarrow 0} p(\mu e, y) = \Pi_\Upsilon(y)$. Then we have

$$\lim_{\mu\downarrow 0} \partial_x R(x, y, \xi, \mu) = \lim_{\mu\downarrow 0} \nabla_x F(x, p(\mu e, y), \xi) = \nabla_x F(x, \Pi_\Upsilon(y), \xi) = \partial_x H(x, y, \xi)$$

for any $(x, y, \xi) \in \mathcal{X} \times \mathbb{R}^n \times \Xi$. On the other hand, noticing that $\pi_y\partial H(x, y, \xi) = \partial_y H(x, y, \xi) = (\nabla_y F(x, \Pi_\Upsilon(y), \xi) - I)\partial\Pi_\Upsilon(y) + I$, and by Lemma 5.1, $\pi_y\partial R(x, y, \xi, \mu) = \partial_y R(x, y, \xi, \mu) = \nabla_y R(x, y, \xi, \mu) = (\nabla_y F(x, p(\mu e, y), \xi) - I)D(\mu, y) + \mu I + I$. Hence, to show $\lim_{\mu\downarrow 0} \pi_y\partial R(x, y, \xi, \mu) \subset \pi_y\partial H(x, y, \xi)$, it suffices to prove $\lim_{\mu\downarrow 0} D(\mu, y) \subset \partial\Pi_\Upsilon(y)$. Note that for any $y \in \mathbb{R}^n$,

$$\partial\Pi_\Upsilon(y) = \begin{bmatrix} \partial\Pi_{[a_1,b_1]}(y_1) & \cdots & 0 \\ \vdots & \vdots & \vdots \\ 0 & \cdots & \partial\Pi_{[a_n,b_n]}(y_n) \end{bmatrix},$$

where $\partial\Pi_{[a_i,b_i]}(y_i)$ equals 0 if $y_i \in (-\infty, a_i) \cup (b_i, \infty)$; 1 if $y_i \in (a_i, b_i)$; $[0, 1]$ if $y_i = a_i$ or b_i. Then, after some basic manipulations, $\lim_{\mu\downarrow 0} d_i(\mu, y) = \lim_{\mu\downarrow 0} \partial p_i(\mu e, y)/\partial y_i$ equals 0 if $y_i \in (-\infty, a_i) \cup (b_i, \infty)$; 1 if $y_i \in (a_i, b_i)$; 1/2 if $y_i = a_i$ or b_i. Hence, $\lim_{\mu\downarrow 0} d_i(\mu, y) \subset \partial\Pi_{[a_i,b_i]}(y_i)$ for each i; thereby, $\lim_{\mu\downarrow 0} D(\mu, y) \subset \partial\Pi_{[a,b]}(y) (= \partial\Pi_\Upsilon(y))$. Thus, $\lim_{\mu\downarrow 0} \nabla_y R(x, y, \xi, \mu) \subset \partial_y H(x, y, \xi)$ for any $(x, y, \xi) \in \mathcal{X} \times \mathbb{R}^n \times \Xi$. So, part (iii) holds.

Finally, we prove part (iv). Define a mapping $G : \mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}^k \times \mathbb{R} \to \mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}^k \times \mathbb{R}$ by $G(x, y, \xi, \mu) := (x, R(x, y, \xi, \mu), \xi, \mu)$. Then G is continuously differentiable on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0, \mu_0)$. We first show that G is a diffeomorphism on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0, \mu_0)$; that is, G has a differentiable inverse function on $\mathcal{X} \times \mathbb{R}^n \times \Xi \times (0, \mu_0)$. It is well known that a necessary and sufficient condition for function G to be a diffeomorphism is the nonsingularity of the Jacobian ∇G at every point (x, y, ξ, μ) and the closedness of G; that is, the image $G(S)$ of any closed set $S \subset \mathcal{X} \times \mathbb{R}^n \times \Xi \times (0, \mu_0)$ is closed.

We now prove the closedness of G. Let S be a closed subset of $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$. Assume for the sake of a contradiction that $G(S)$ is not closed. Then there exists a convergent sequence $\{w^k\}\subset G(S)$ such that $\lim_{k\to\infty} w^k = w^0$, but $w^0\notin G(S)$. By definition, there exists a sequence $\{z^k\}$ with $z^k=(x^k,y^k,\xi^k,\mu^k)\in S$ such that $w^k = G(z^k)$. We consider two cases: (i) $\{z^k\}$ is bounded; (ii) $\{z^k\}$ is unbounded. In case (i), obviously, there exists a convergent subsequence, $\{z^{k_l}\}$, of $\{z^k\}$ with $\{z^{k_l}\}$ tending to z^0. Hence, $z^0\in S$ given the closeness of S. Thus, $\lim_{l\to\infty} w^{k_l} = \lim_{l\to\infty} G(z^{k_l}) = G(z^0)$. Clearly, $G(z^0)\in G(S)$. Since $w^{k_l}\to w^0$, then $w^0 = G(z^0)\in G(S)$, which leads to a contradiction as desired. In case (ii), without loss of generality, we assume that $\|z^k\|\to\infty$ as $k\to\infty$. With the help of the compactness of $\mathcal{X}$ and Ξ, there exists a subsequence $\{z^{k_l}\}$ of $\{z^k\}$ such that $\{x^{k_l}\}$, $\{\xi^{k_l}\}$, and $\{\mu^{k_l}\}$ are bounded, while $\|y^{k_l}\|\to\infty$ as $l\to\infty$. Then, by Lemma 5.2, $\lim_{l\to\infty}\|R(x^{k_l},y^{k_l},\xi^{k_l},\mu^{k_l})\| = \infty$. Thus,

$$\lim_{l\to\infty}\|w^{k_l}\| = \lim_{l\to\infty}\|G(z^{k_l})\| = \infty$$

by noticing $w^{k_l} = G(z^{k_l}) = \left(x^{k_l}, R(x^{k_l},y^{k_l},\xi,\mu^{k_l}),\xi^{k_l},\mu^{k_l}\right)$. This contradicts the fact that $\lim_{l\to\infty} w^{k_l} = w^0$. Therefore, G is closed on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$.

Next, we prove the nonsingularity of ∇G. By Lemma 5.1, we can easily see that $\nabla G(x,y,\mu,\xi)$ is nonsingular at any point $(x,y,\xi,\mu)\in\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$. Hence, G is a diffeomorphism on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$. Let G^{-1} denote its inverse function. For any $(x,y,\xi,\mu)\in\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$, we then have $(G^{-1}(x,y,\xi,\mu))_x = x$, $(G^{-1}(x,y,\xi,\mu))_\xi = \xi$, and $(G^{-1}(x,y,\xi,\mu))_\mu = \mu$. Furthermore, for any $(p,t,q)\in\mathcal{X}\times\Xi\times(0,\mu_0)$, equation $G(x,y,\xi,\mu) = (p,0,t,q)$ has a unique solution $(x,y,\xi,\mu) = G^{-1}(p,0,t,q)$. Clearly, $x=p$, $\xi=t$, and $\mu=q$. Let $y=\tilde{y}(p,t,q) := \left(G^{-1}(p\ 0\ t\ q)\right)_y$. By virtue of the arbitrariness of p, t, and q, we obtain the unique solution of $\tilde{y}$ defined on $\mathcal{X}\times\Xi\times(0,\mu_0)$, which satisfies $R(x,\tilde{y}(x,\xi,\mu),\xi,\mu)=0$ for $(x,\xi,\mu)\in\mathcal{X}\times\Xi\times(0,\mu_0)$. Thereby, part (iv) is satisfied. In addition, note that G is continuously differentiable on $\mathcal{X}\times\mathbb{R}^n\times\Xi\times(0,\mu_0)$ by assumption. This leads to the continuous differentiability of $\tilde{y}$ immediately.

In conclusion, based on the above arguments, function R defined in (37) satisfies Definition 2.1. This completes the proof. ∎

Acknowledgments. The authors would like to thank Alexander Shapiro for his constructive comments on an earlier version of this paper. They would also like to thank two anonymous referees for insightful comments which led to a significant improvement of the paper and the associate editor, Andrzej Ruszczyński, for organizing a quick and quality review.

GLOBAL OPTIMIZATION OF POLYNOMIALS USING GRADIENT TENTACLES AND SUMS OF SQUARES*

MARKUS SCHWEIGHOFER†

Abstract. We consider the problem of computing the global infimum of a real polynomial f on $\mathbb{R}^n$. Every global minimizer of f lies on its gradient variety, i.e., the algebraic subset of $\mathbb{R}^n$ where the gradient of f vanishes. If f attains a minimum on $\mathbb{R}^n$, it is therefore equivalent to look for the greatest lower bound of f on its gradient variety. Nie, Demmel, and Sturmfels proved recently a theorem about the existence of sums of squares certificates for such lower bounds. Based on these certificates, they find arbitrarily tight relaxations of the original problem that can be formulated as semidefinite programs and thus be solved efficiently. We deal here with the more general case when f is bounded from below but does not necessarily attain a minimum. In this case, the method of Nie, Demmel, and Sturmfels might yield completely wrong results. In order to overcome this problem, we replace the gradient variety by larger semialgebraic subsets of $\mathbb{R}^n$ which we call gradient tentacles. It now gets substantially harder to prove the existence of the necessary sums of squares certificates.

Key words. global optimization, polynomial, preorder, sum of squares, semidefinite programming

1. Introduction.

Throughout this article, $\mathbb{N} := \{1, 2, \dots\}$, $\mathbb{R}$, and $\mathbb{C}$ denote the sets of natural, real, and complex numbers, respectively. We fix $n \in \mathbb{N}$ and consider real polynomials in n variables $\bar{X} := (X_1, \dots, X_n)$. These polynomials form a commutative ring

$$\mathbb{R}[\bar{X}] := \mathbb{R}[X_1, \dots, X_n].$$

1.1. The problem.

We consider the problem of computing good approximations for the global infimum

$$f^* := \inf\{f(x) \mid x \in \mathbb{R}^n\} \in \mathbb{R} \cup \{-\infty\}$$

of a polynomial $f \in \mathbb{R}[\bar{X}]$. Since f^* is the greatest lower bound of f, it is equivalent to compute

$$f^* = \sup\{a \in \mathbb{R} \mid f - a \geq 0 \text{ on } \mathbb{R}^n\} \in \mathbb{R} \cup \{-\infty\}. \tag{1}$$

To solve this hard problem, it has become a standard approach to approximate f^* by exchanging in (1) the nonnegativity constraint

$$f - a \geq 0 \quad \text{on } \mathbb{R}^n \tag{2}$$

by a computationally more feasible condition and analyze the error caused by this substitution. Typically, the choice of this replacement is related to the interplay between (globally) nonnegative polynomials, sums of squares of polynomials, and semidefinite optimization (also called semidefinite programming).

1.2. Method based on the fact that every sum of squares of polynomials is nonnegative (Shor [Sho], Shor and Stetsyuk [SS], Parrilo and Sturmfels [PS], et al.). We start with the most basic ideas concerning these connections which can be found in greater detail in the references just cited. A first try is to replace condition (2) by the constraint

$$f - a \text{ is a sum of squares in the polynomial ring } \mathbb{R}[\bar{X}], \tag{3}$$

since every sum of squares in $\mathbb{R}[\bar{X}]$ is obviously nonnegative on $\mathbb{R}^n$.

The advantage of (3) over (2) is that sums of squares of polynomials can be nicely parametrized. Fix a column vector v whose entries are a basis of the vector space $\mathbb{R}[\bar{X}]_d$ of all real polynomials of degree $\leq d$ in n variables ($d \in \mathbb{N}_0 := \{0\} \cup \mathbb{N}$). This vector has a certain length $k = \dim \mathbb{R}[\bar{X}]_d$. It is easy to see that the map from the vector space $S\mathbb{R}^{k\times k}$ of symmetric $k \times k$-matrices to $\mathbb{R}[\bar{X}]_{2d}$ defined by $M \mapsto v^T M v$ is surjective. Using the spectral theorem for symmetric matrices, it is not hard to prove that a polynomial $f \in \mathbb{R}[\bar{X}]_{2d}$ is a sum of squares in $\mathbb{R}[\bar{X}]$ if and only if $f = v^T M v$ for some positive semidefinite matrix $M \in S\mathbb{R}^{k\times k}$. Use the following remark, which is an easy exercise (write the polynomials as sums of their homogeneous parts).

Remark 1. In any representation $f = \sum_i g_i^2$ of a polynomial $f \in \mathbb{R}[\bar{X}]_{2d}$ as a sum of squares $g_i \in \mathbb{R}[\bar{X}]$, we have necessarily $\deg g_i \leq d$.

The described parametrization shows that the modified problem (where we exchange (2) by (3)), i.e., the problem to compute

$$f^{\text{sos}} := \sup\{a \in \mathbb{R} \mid f - a \text{ is a sum of squares in } \mathbb{R}[\bar{X}]\} \in \mathbb{R} \cup \{-\infty\}, \tag{4}$$

can be written as a *semidefinite optimization problem* (also called semidefinite program or SDP for short), i.e., as the problem of minimizing (or maximizing) an affine linear function on the intersection of the cone of positive semidefinite matrices with an affine subspace in $S\mathbb{R}^{k\times k}$. For solving SDPs, there exist very good numerical algorithms, perhaps almost as good as for linear optimization problems. Linear optimization can be seen as the restriction of semidefinite optimization to diagonal matrices, i.e., a method to minimize an affine linear function on the intersection of the cone $\mathbb{R}^k_{\geq 0}$ with an affine subspace of $\mathbb{R}^k$. Speaking very vaguely, most concepts from linear optimization carry over to semidefinite optimization because every symmetric matrix can be diagonalized. We refer readers, for example, to [Tod] for an introduction to semidefinite programming.

Whereas computing f^* as defined in (1) is a very hard problem, it is relatively easy to compute (numerically to a given precision) f^{sos} defined in (4). Of course, the question of how f^* and f^{sos} are related arises. Since (3) implies (2), it is clear that $f^{\text{sos}} \leq f^*$. The converse implication (and thus $f^{\text{sos}} = f^*$) holds in some cases: A globally nonnegative polynomial

- in one variable or
- of degree at most two or
- in two variables of degree at most four

is a sum of squares of polynomials. We refer readers to [Rez] for an overview of these and related old facts. However, recently Blekherman has shown in [Ble] that for fixed degree $d \geq 4$ and high number of variables n only a very small portion (in some reasonable sense) of the globally nonnegative polynomials of degree at most d in n variables are sums of squares. In particular, f^{sos} will often differ from f^*. For example, the *Motzkin polynomial*

$$M := X^2Y^2(X^2 + Y^2 - 3Z^2) + Z^6 \in \mathbb{R}[X, Y, Z] \tag{5}$$

is nonnegative but not a sum of squares (see [Rez, PS]). We have $M^* = 0$ but $M^{\mathrm{sos}} = -\infty$. The latter follows from the fact that M is homogeneous and not a sum of squares by the following remark applied to $f := M - a$ for $a \in \mathbb{R}$ (which can again be proved easily by considering homogeneous parts).

Remark 2. If f is a sum of squares in $\mathbb{R}[\bar{X}]$, then so is the highest homogeneous part (the leading form) of f.

We see that the basic problem with this method (computing f^{sos} by solving an SDP and hoping that f^{sos} is close to f^*) is that polynomials positive on $\mathbb{R}^n$ in general do not have a representation as a sum of squares, a fact that Hilbert already knew.

1.3. The Positivstellensatz. In the 17th of his famous of 23 problems, Hilbert asked whether every (globally) nonnegative (real) polynomial (in several variables) was a sum of squares of *rational functions*. Artin answered this question affirmatively in 1926, and today there exist numerous refinements of his solution. One of them is the *Positivstellensatz* (in analogy to Hilbert's Nullstellensatz). It is often attributed to Stengle [Ste], who clearly deserves credit for finding it independently and making it widely known. However, Prestel [PD, section 4.7] recently discovered that Krivine [Kri] knew the result about 10 years earlier in 1964. Here we state only the following special case of the Positivstellensatz.

THEOREM 3 (Krivine). *For every $f \in \mathbb{R}[\bar{X}]$, the following are equivalent:*

(i) *$f > 0$ on $\mathbb{R}^n$.*

(ii) *There are sums of squares s and t in $\mathbb{R}[\bar{X}]$ such that $sf = 1 + t$.*

By this theorem, we have, of course, that f^* is the supremum over all $a \in \mathbb{R}$ such that there are sums of squares $s, t \in \mathbb{R}[\bar{X}]$ with $s(f - a) = 1 + t$. When one tries to write this as an SDP, there are two obstacles.

First, each SDP involves matrices of a fixed (finite) size. But with matrices of a fixed size, we can parametrize sums of squares only up to a certain degree. We need therefore to impose a degree restriction on s and t. There are no (at least up to now) *practically relevant* degree bounds that could guarantee that such a restriction would not affect the result. We refer readers to the tremendous work [Scd] of Schmid on degree bounds. This first obstacle, namely the question of degrees of the sums of squares, will accompany us throughout the article. The answer will always be to model the problem not as a single SDP but as a whole *sequence* of SDPs, each SDP corresponding to a certain degree restriction. As one solves one SDP after the other, the degree restriction gets less restrictive, and one hopes for fast convergence of the optimal values of the SDPs to f^*. For newcomers in the field, it seems at first glance unsatisfactory having to deal with a whole sequence of SDPs rather than a single SDP. But, after all, it is only natural that a very hard problem cannot be modeled by an SDP of a reasonable size so that one has to look for good *relaxations* of the problem which can be dealt with more easily and to which the techniques of mathematical optimization can be applied.

The second obstacle is much more severe. It is the fact that the unknown polynomial $s \in \mathbb{R}[\bar{X}]$ is multiplied with the unknown $a \in \mathbb{R}$ on the left-hand side of the constraint $s(f - a) = 1 + t$. This makes the formulation as an SDP (even after having imposed a restriction on the degree of s and t) impossible (or at least highly nonobvious). Of course, if one *fixes* $a \in \mathbb{R}$ and a degree bound $2d$ for s and t, then the question of whether there exist sums of squares s and t of degree at most $2d$ such that $s(f - a) = 1 + t$ is equivalent to the feasibility of an SDP. But this plays (at least currently) only a role as a criterion that *might help to decide* whether a certain fixed (or guessed) $a \in \mathbb{R}$ is a strict lower bound of f. We refer readers to [PS] for

more details. What one needs are representation theorems for positive polynomials that are better suited for optimization than the Positivstellensatz (even if they are sometimes less aesthetic).

1.4. "Big ball" method proposed by Lasserre [L1]. In the last 15 years, a lot of progress has been made in proving existence of sums of squares certificates which can be exploited for optimization (although most of the new results were obtained without having in mind the application in optimization which has been established more recently). The first breakthrough was perhaps Schmüdgen's theorem [Sch, Corollary 3], all of whose proofs use the Positivstellensatz. In this article, we will prove a generalization of Schmüdgen's theorem, namely Theorem 9. In [L1], Lasserre uses the following special case of Schmüdgen's theorem which has already been proved by Cassier [Cas, Théorème 4] and which can even be derived easily from [Kri, Théorème 12].

THEOREM 4 (Cassier). *For $f \in \mathbb{R}[\bar{X}]$ and $R \geq 0$, the following are equivalent:*

(i) *$f \geq 0$ on the closed ball centered at the origin of radius R.*

(ii) *For all $\varepsilon > 0$, there are sums of squares s and t in $\mathbb{R}[\bar{X}]$ such that*

$$f + \varepsilon = s + t(R^2 - \|\bar{X}\|^2).$$

Here and in the following, we use the notation

$$\|\bar{X}\|^2 := X_1^2 + \cdots + X_n^2 \in \mathbb{R}[\bar{X}].$$

Similar to section 1.2, it can be seen that for any fixed $d \in \mathbb{N}_0$, computing the supremum over all $a \in \mathbb{R}$ such that $f - a = s + t(R^2 - \|\bar{X}\|^2)$ for some sums of squares $s, t \in \mathbb{R}[\bar{X}]$ of degree at most $2d$ amounts to solving an SDP. Therefore one gets a sequence of SDPs parametrized by $d \in \mathbb{N}_0$. Theorem 4 can now be interpreted as a convergence result; namely, the sequence of optimal values of these SDPs converges to the minimum of f on the closed ball around the origin with radius R. If one has a polynomial $f \in \mathbb{R}[\bar{X}]$ attaining a minimum on $\mathbb{R}^n$ and for which one knows, moreover, a big ball on which this minimum is attained, this method is good for computing f^*. Of course, if one does not know such a big ball in advance, one might choose larger and larger R. But at the same time one might have to choose a bigger and bigger degree restriction $d \in \mathbb{N}_0$, and it is not really clear how to get a sequence of SDPs that converges to f^*.

1.5. Lasserre's high order perturbation method [L2]. Recently, Lasserre used in [L2] a theorem of Nussbaum from operator theory to prove the following result that can be exploited in a similar way for global optimization of polynomials.

THEOREM 5 (Lasserre). *For every $f \in \mathbb{R}[\bar{X}]$, the following are equivalent:*

(i) *$f \geq 0$ on $\mathbb{R}^n$.*

(ii) *For all $\varepsilon > 0$, there is $r \in \mathbb{N}_0$ such that*

$$f + \varepsilon \sum_{i=1}^{n} \sum_{k=0}^{r} \frac{X_i^{2k}}{k!} \text{ is a sum of squares in } \mathbb{R}[\bar{X}].$$

Note that (ii) implies that $f(x) + \varepsilon \sum_{i=1}^{n} \exp(x_i) \geq 0$, for all $x \in \mathbb{R}^n$ and $\varepsilon > 0$, which in turn implies (i). In condition (ii), r depends on ε and f. Using real algebra and model theory, Netzer showed that in fact r depends only on ε, n, the degree of f, and a bound on the size of the coefficients of f [Net, LN].

1.6. "Gradient perturbation" method proposed by Jibetean and Laurent [JL]. The most standard idea for finding the minimum of a function everybody knows from calculus is to compute critical points, i.e., the points where the gradient vanishes. It is a natural question whether the power of classical differential calculus can be combined with the relatively new ideas using sums of squares. Fortunately, it can and the rest of the article will be about how to merge both concepts, sums of squares and differential calculus.

If a polynomial $f \in \mathbb{R}[\bar{X}]$ attains a minimum in $x \in \mathbb{R}^n$, i.e., $f(x) \leq f(y)$ for all $y \in \mathbb{R}^n$, then the gradient ∇f of f vanishes at x, i.e., $\nabla f(x) = 0$. However, there are polynomials that are bounded from below on $\mathbb{R}^n$ and yet do not attain a minimum on $\mathbb{R}^n$. The simplest example is perhaps

$$f := (1 - XY)^2 + Y^2 \in \mathbb{R}[X, Y] \tag{6}$$

for which we have $f > 0$ on $\mathbb{R}^n$ but $f^* = 0$, since $\lim_{x\to\infty} f(x, \frac{1}{x}) = 0$. In the following,

$$(\nabla f) := \left(\frac{\partial f}{\partial X_1}, \ldots, \frac{\partial f}{\partial X_n}\right) \subseteq \mathbb{R}[\bar{X}]$$

denotes the ideal generated by the partial derivatives of f in $\mathbb{R}[\bar{X}]$. We call this ideal the *gradient ideal* of f.

Without going into details, the basic idea of Jibetean and Laurent in [JL] is again to apply a perturbation to f. Instead of adding a truncated exponential like Lasserre, they just add $\varepsilon \sum_{i=1}^n X_i^{2(d+1)}$ for small $\varepsilon > 0$ when $\deg f = 2d$. If $f > 0$ on $\mathbb{R}^n$, then the perturbed polynomial $f_\varepsilon := f + \varepsilon \|\bar{X}\|^{2(d+1)}$ is again a sum of squares but this time only modulo its gradient ideal (∇f_ε). In this case, this is quite easy to prove, since it turns out that this ideal will be zero-dimensional; i.e., $\mathbb{R}[\bar{X}]/(\nabla f_\varepsilon)$ is a finite-dimensional real algebra. We will later see in Theorems 6 and 46 that this finite dimensionality is not needed for the sums of squares representation. But the work of Jibetean and Laurent exploits the finite dimensionality in many ways. We refer readers to [JL] for details.

1.7. "Gradient variety" method by Nie, Demmel, and Sturmfels [NDS]. The two perturbation methods just sketched rely on introducing very small coefficients in a polynomial. These small coefficients might lead to SDPs which are hard to solve because of numerical instability. It is therefore natural to think of another method which avoids perturbation entirely. Nie, Demmels, and Sturmfels considered, for a polynomial $f \in \mathbb{R}[\bar{X}]$, its *gradient variety*

$$V(\nabla f) := \{x \in \mathbb{C}^n \mid \nabla f(x) = 0\}.$$

This is the algebraic variety corresponding to the radical of the gradient ideal (∇f). It can be shown that a polynomial $f \in \mathbb{R}[\bar{X}]$ is constant on each irreducible component of the gradient variety (see [NDS] or use an unpublished algebraic argument of Scheiderer based on Kähler differentials). This is the key to show that a polynomial $f \in \mathbb{R}[\bar{X}]$ nonnegative on its gradient variety is a sum of squares modulo its gradient ideal in the case where the ideal is radical. In the general case where the gradient ideal is not necessarily radical, the same thing still holds for polynomials *positive* on their gradient variety. The following is essentially [NDS, Theorem 9] (confer also the recent work [M2]). We will later prove a generalization of this theorem as a by-product. See Corollary 47.

THEOREM 6 (Nie, Demmel, and Sturmfels). *For every $f \in \mathbb{R}[\bar{X}]$ attaining a minimum on $\mathbb{R}^n$, the following are equivalent:*

(i) $f \geq 0$ *on* $\mathbb{R}^n$.
(ii) $f \geq 0$ *on* $V(\nabla f) \cap \mathbb{R}^n$.
(iii) *For all* $\varepsilon > 0$, *there exists a sum of squares* s *in* $\mathbb{R}[\bar{X}]$ *such that*

$$f + \varepsilon \in s + (\nabla f).$$

Moreover, (ii) *and* (iii) *are equivalent for all* $f \in \mathbb{R}[\bar{X}]$.

For each degree restriction $d \in \mathbb{N}_0$, the problem of computing the supremum over all $a \in \mathbb{R}$ such that

$$f - a = s + p_1 \frac{\partial f}{\partial X_1} + \cdots + p_n \frac{\partial f}{\partial X_n}$$

for some sum of squares s in $\mathbb{R}[\bar{X}]$ and polynomials $p_1, \ldots, p_n$ of degree at most d can be expressed as an SDP. Theorem 6 shows that the optimal values of the corresponding sequence of SDPs (indexed by d) tend to f^*, provided that f attains a minimum on $\mathbb{R}^n$. However, if f does not attain a minimum on $\mathbb{R}^n$, the computed sequence still tends to the infimum of f on its gradient variety, which might, however, now be very different from f^*. Take, for example, the polynomial f from (6). It is easy to see that $V(\nabla f) = \{0\}$, and therefore the method computes $f(0) = 1$ instead of $f^* = 0$. In [NDS, section 7], the authors write:

> "This paper proposes a method for minimizing a multivariate polynomial $f(x)$ over its gradient variety. We assume that the infimum f^* is attained. This assumption is nontrivial, and we do not address the (important and difficult) question of how to verify that a given polynomial $f(x)$ has this property."

1.8. Our "gradient tentacle" method. The reason why the method just described might fail is that the global infimum of a polynomial $f \in \mathbb{R}[\bar{X}]$ is not always a *critical value* of f, i.e., a value that f takes on at least on one of its critical points in $\mathbb{R}^n$. Now there is a well-established notion of *generalized critical values* which includes also the *asymptotic critical values* (a kind of critical value at infinity we will introduce in Definition 12).

In this article, we will replace the real part $V(\nabla f) \cap \mathbb{R}^n$ of the gradient variety by several larger semialgebraic sets on which the partial derivatives do not necessarily vanish but get very small far away from the origin. These semialgebraic sets often look like tentacles, and that is what we will call them. All tentacles we will consider are defined by a single polynomial inequality that depends only on the polynomial

$$\|\nabla f\|^2 := \left(\frac{\partial f}{\partial X_1}\right)^2 + \cdots + \left(\frac{\partial f}{\partial X_n}\right)^2$$

and expresses that this polynomial gets very small. Given a polynomial f for which one wants to compute f^*, the game will consist in finding a tentacle such that two things will hold at the same time:

- There exist suitable sums of squares certificates for nonnegativity on the tentacle.
- The infimum of f on $\mathbb{R}^n$ and on the tentacle coincide.

One can imagine that these two properties are hardly compatible. Taking $\mathbb{R}^n$ as a tentacle would, of course, ensure the second condition, but we have discussed in section 1.2 that the first one would be badly violated. The other extreme would be to take the empty set as a tentacle. Then the first condition would trivially be

satisfied, whereas the second would fail badly. How we will roughly be able to find the balancing act between the two requirements is as follows: The second condition will be satisfied by known nontrivial theorems about asymptotic behavior of polynomials at infinity. The existence of suitable sums of squares certificates will be based on the author's (real) algebraic work [Sr1] on iterated rings of bounded elements (also called real holomorphy rings).

1.9. Contents of the article. The article is organized as follows. In section 2, we prove a general sums of squares representation theorem which generalizes Schmüdgen's theorem, mentioned in section 1.4. This representation theorem is interesting in itself and will be used in the subsequent sections. In section 3, we introduce a gradient tentacle (see Definition 17) which is defined by the polynomial inequality

$$\|\nabla f\|^2 \|\bar{X}\|^2 \leq 1.$$

We call this gradient tentacle *principal*, since we can prove that it does the job in a large number of cases (see Theorem 25), and there is hope that it works in fact for all polynomials $f \in \mathbb{R}[\bar{X}]$ bounded from below. Indeed, we have not found any counterexamples (see Open Problem 33). In case this hope were disappointed, we present in section 4 a collection of other gradient tentacles (see Definition 41) defined by the polynomial inequalities

$$\|\nabla f\|^{2N}(1+\|\bar{X}\|^2)^{N+1} \leq 1 \qquad (N \in \mathbb{N}).$$

Their advantage is that if $f \in \mathbb{R}[\bar{X}]$ is bounded from below and N is large enough for this particular f, then we can prove that the corresponding tentacle does the job (see Theorems 46 and 50). We call these tentacles higher gradient tentacles, since the degree of the defining inequality gets unfortunately high when N gets big, which certainly has negative consequences for the complexity of solving the SDPs arising from these tentacles. However, if f attains a minimum on $\mathbb{R}^n$, then any choice of $N \in \mathbb{N}$ will be good. Conclusions are drawn in section 5.

2. The sums of squares representation. In this section, we prove the important sums of squares representation theorem we will need in the following sections. It is a generalization of Schmüdgen's Positivstellensatz (see [PD, Sch]), which is also of independent interest. Schmüdgen's result is not to be confused with the (classical) Positivstellensatz we described in the introduction. The connection between the two is that all known proofs of Schmüdgen's result use the classical Positivstellensatz. Our result, Theorem 9, is much harder to prove than Schmüdgen's result. Its proof relies on the theory of iterated *rings of bounded elements* (also called real holomorphy rings) described in [Sr1].

DEFINITION 7. *For any polynomial $f \in \mathbb{R}[\bar{X}]$ and subset $S \subseteq \mathbb{R}^n$, the set $R_\infty(f,S)$ of* asymptotic values *of f on S consists of all $y \in \mathbb{R}$ for which there exists a sequence $(x_k)_{k\in\mathbb{N}}$ of points $x_k \in S$ such that*

$$\lim_{k\to\infty} \|x_k\| = \infty \qquad \text{and} \qquad \lim_{k\to\infty} f(x_k) = y. \tag{7}$$

We now recall the important notion of a preordering of a commutative ring. Except in the proof of Theorem 9, we need this concept only for the ring $\mathbb{R}[\bar{X}]$.

DEFINITION 8. *Let A be a commutative ring (with 1). A subset $T \subseteq A$ is called a* preordering *if it contains all squares f^2 of elements $f \in A$ and is closed under*

addition and multiplication. The preordering generated *by* $g_1, \dots, g_m \in A$

$$T(g_1, \dots, g_m) = \left\{ \sum_{\delta \in \{0,1\}^m} s_\delta g_1^{\delta_1} \dots g_m^{\delta_m} \mid s_\delta \text{ is a sum of squares in } A \right\} \tag{8}$$

is by definition the smallest preordering containing $g_1, \dots, g_m$.

If $g_1, \dots, g_m \in \mathbb{R}[\bar{X}]$ are polynomials, then the elements of $T(g_1, \dots, g_m)$ have obviously the geometric property that they are nonnegative on the (basic closed semi-algebraic) set S they define by (9). The next theorem is a partial converse. Namely, if a polynomial satisfies on S some stronger geometric condition, then it lies necessarily in $T(g_1, \dots, g_m)$. In case that S is compact, the conditions (a) and (b) below are empty and the theorem is Schmüdgen's Positivstellensatz (see [PD, Sch]). The more general version we need here is quite hard to prove.

THEOREM 9. *Let* $f, g_1, \dots, g_m \in \mathbb{R}[\bar{X}]$ *and set*

$$S := \{x \in \mathbb{R}^n \mid g_1(x) \geq 0, \dots, g_m(x) \geq 0\}. \tag{9}$$

Suppose that

(a) f *is bounded on* S,

(b) f *has only finitely many asymptotic values on* S *and all of these are positive, i.e.,* $R_\infty(f, S)$ *is a finite subset of* $\mathbb{R}_{>0}$, *and*

(c) $f > 0$ *on* S.

Then $f \in T(g_1, \dots, g_m)$.

Proof. Write $R_\infty(f, S) = \{y_1, \dots, y_s\} \subseteq \mathbb{R}_{>0}$ and consider the polynomial

$$h := \prod_{i=1}^{s} (f - y_i).$$

This polynomial is "on S small at infinity" by which we mean that for every $\varepsilon > 0$ there exists $k \in \mathbb{N}$ such that for all $x \in S$ with $\|x\| \geq k$, we have $|h(x)| < \varepsilon$.

To show this, assume the contrary. Then there exists $\varepsilon > 0$ and a sequence $(x_k)_{k \in \mathbb{N}}$ of points $x_k \in S$ with $\lim_{k \to \infty} \|x_k\| = \infty$ and

$$|h(x_k)| \geq \varepsilon \qquad \text{for all } k \in \mathbb{N}. \tag{10}$$

Because the sequence $(f(x_k))_{k \in \mathbb{N}}$ is bounded by hypothesis (a), we find an infinite subset $I \subseteq \mathbb{N}$ such that the subsequence $(f(x_k))_{k \in I}$ converges. The limit must be one of the asymptotic values of f on S, i.e., $\lim_{k \in I, k \to \infty} f(x_k) = y_i$ for some $i \in \{1, \dots, s\}$. Using (a), it follows that $\lim_{k \in I, k \to \infty} h(x_k) = 0$, contradicting (10).

Let $A := (\mathbb{R}[\bar{X}], T)$, where $T := T(g_1, \dots, g_m)$. The set

$$H'(A) := \{p \in \mathbb{R}[\bar{X}] \mid N \pm p \in T \text{ for some } N \in \mathbb{N}\}$$

is a subring of A (see, e.g, [Sr1, Definition 1.2]). We endow $H'(A)$ with the preordering $T' := T \cap H'(A)$ and consider it also as a preordered ring. By [Sr1, Corollary 3.7], the smallness of h at infinity proved above is equivalent to $h \in S_\infty(A)$ in the notation of [Sr1]. By [Sr1, Corollary 4.17], we have $S_\infty(A) \subseteq H'(A)$ and consequently $h \in H'(A)$. The advantage of $H'(A)$ over A is that its preordering is Archimedean, i.e., $T' + \mathbb{Z} = H'(A)$. According to an old criterion, for an element to be contained in an Archimedean preordering (see, for example, [PD, Proposition 5.2.3 and Lemma 5.2.7]

or [Sr1, Theorem 1.3]), our claim $f \in T'$ follows if we can show that $\varphi(f) > 0$ for all ring homomorphisms $\varphi : H'(A) \to \mathbb{R}$ with $\varphi(T') \subseteq \mathbb{R}_{\geq 0}$. For all such homomorphisms possessing an extension $\bar{\varphi} : A \to \mathbb{R}$ with $\bar{\varphi}(T) \subseteq \mathbb{R}_{\geq 0}$, this follows from hypothesis (c) because it is easy to see that such an extension $\bar{\varphi}$ must be evaluation $p \mapsto p(x)$ in the point $x := (\bar{\varphi}(X_1), \ldots, \bar{\varphi}(X_n)) \in S$. Using the theory in [Sr1], we will see that the only possibility for such a φ not to have such an extension $\bar{\varphi}$ is that $\varphi(h) = 0$. Then we will be done, since $\varphi(h) = 0$ implies $\varphi(f) = y_i > 0$ for some i. We have used here that $f \in H'(A)$, which follows from $h \in H'(A)$, since $H'(A)$ is integrally closed in A (see [Sr1, Theorem 5.3]).

So let us now use [Sr1]. By [Sr1, Corollary 3.7 and Theorem 4.18], the smallness of h at infinity means that

$$A_h = H'(A)_h,$$

where we deal on both sides of this equation with the localization of a preordered ring by the element h (see [Sr1, pages 24 and 25]). If $\varphi : H'(A) \to \mathbb{R}$ is a ring homomorphism with $\varphi(T') \subseteq \mathbb{R}_{\geq 0}$ and $\varphi(h) \neq 0$, then φ extends to a ring homomorphism $\tilde{\varphi} : A_h = H'(A)_h \to \mathbb{R}$ with $\tilde{\varphi}(T_h) = \tilde{\varphi}(T'_h) \subseteq \mathbb{R}_{\geq 0}$. Then $\bar{\varphi} := \tilde{\varphi}|_A$ is the desired extension of φ. □

Example 10. Consider the polynomials

$$h_N := 1 - Y^N (1+X)^{N+1} \in \mathbb{R}[X,Y] \qquad (N \in \mathbb{N}) \tag{11}$$

in two variables. We fix $N \in \mathbb{N}$ and apply Theorem 9 with $f = h_{N+1}$, $m = 3$, $g_1 = X$, $g_2 = Y$, and $g_3 = h_N$. The set S defined by the g_i as in (9) is a subset of the first quadrant which is bounded in the Y-direction but unbounded in the X-direction. Of course, we have $0 \leq h_N \leq 1$ and

$$0 \leq Y(1+X) \leq \frac{1}{\sqrt[N]{1+X}} \qquad \text{on } S$$

showing that 0 is the only asymptotic value of

$$1 - h_{N+1} = (1 - h_N) Y (1+X)$$

on S and therefore $R_\infty(h_{N+1}, S) = \{1\}$. It follows also that $0 \leq h_{N+1} \leq 1$ on S. By Theorem 9, we obtain

$$h_{N+1} + \varepsilon \in T(X, Y, h_N) \tag{12}$$

for all $\varepsilon > 0$.

The following lemma shows that (12) holds even for $\varepsilon = 0$, a fact that does not follow from Theorem 9. This lemma will be interesting later to compare the quality of certain SDP relaxations (see Proposition 49). In its proof, we will explicitly construct a representation of h_{N+1} as an element of $T(X, Y, h_N)$. Only part of this explicit representation will be needed in the following, namely an explicit polynomial $g \in T(X,Y)$ such that $h_{N+1} \in T(X,Y) + g h_N \subseteq T(X, Y, h_N)$. This explains the formulation of the statement. Theorem 9 will not be used in the proof but gave us good hope before we had the proof. The role of Theorem 9 in this article is above all to prove Theorems 25 and 46.

LEMMA 11. *For the polynomials h_N defined by* (11)*, we have*

$$h_{N+1} - \left(1 + \frac{1}{N}\right) Y(1+X) h_N \in T(X,Y).$$

Proof. For a new variable Z,

$$\begin{aligned}(Z-1)^2\sum_{k=0}^{N-1}(N-k)Z^k &= (Z-1)^2\left(N\sum_{k=0}^{N-1}Z^k - Z\sum_{k=1}^{N-1}kZ^{k-1}\right)\\ &= (Z-1)^2\left(N\frac{Z^N-1}{Z-1} - Z\frac{\partial}{\partial Z}\left(\frac{Z^N-1}{Z-1}\right)\right)\\ &= N(Z-1)(Z^N-1) - Z((Z-1)NZ^{N-1} - (Z^N-1))\\ &= Z^{N+1} - (N+1)Z + N.\end{aligned}$$

Specializing Z to $z := Y(1+X)$, we have therefore

$$\begin{aligned}Nh_{N+1} - (N+1)zh_N &= N(1 - z^{N+1}(1+X)) - (N+1)z(1 - z^N(1+X))\\ &= z^{N+1}X + (z^{N+1} - (N+1)z + N)\\ &= z^{N+1}X + (z-1)^2\sum_{k=0}^{N-1}(N-k)z^k \in T(X,Y).\end{aligned}$$

Dividing by $N = (\sqrt{N})^2$ yields our claim. □

3. The principal gradient tentacle. In this section, we associate with every polynomial $f \in \mathbb{R}[\bar{X}]$ a gradient tentacle which is a subset of $\mathbb{R}^n$ containing the real part of the gradient variety of f and defined by a single polynomial inequality whose degree is not more than twice the degree of f. The infimum of any polynomial $f \in \mathbb{R}[\bar{X}]$ bounded from below on $\mathbb{R}^n$ will coincide with the infimum on its principal gradient tentacle (see Theorem 19). Under some technical assumption (see Definition 20) which is not known to be necessary (see Open Problem 33), we prove a sums of squares certificate for nonnegativity of f on its principal gradient tentacle which is suitable for optimization purposes. This representation theorem (Theorem 25) is of independent interest, and its proof is mainly based on the nontrivial representation theorem from the previous section and a result of Parusiński on the behavior of polynomials at infinity [P1, Theorem 1.4]. In section 3.2, we outline how to get a sequence of SDPs growing in size whose optimal values tend to f^* for any f satisfying the conditions of Theorem 25 (or perhaps for any f with $f^* > -\infty$ if the answer to Open Problem 33 is yes). In sections 3.3 and 3.4, we give a MATLAB code for the sums of squares optimization toolboxes YALMIP [Löf] and SOSTOOLS [PPS] that produces and solves these SDP relaxations. This short and simple code is meant for readers who have little experience with such toolboxes and want nevertheless to try our proposed method on their own. In section 3.5, we provide simple examples which have been calculated using the YALMIP code from section 3.3.

We start by recalling the concept of asymptotic critical values developed by Rabier in his 1997 milestone paper [Rab]. For simplicity, we stay in the setting of real polynomials right from the beginning (though part of this theory make sense in a much broader context).

DEFINITION 12. *Suppose $f \in \mathbb{R}[\bar{X}]$. The set $K_0(f)$ of* critical values *of f consists of all $y \in \mathbb{R}$ for which there exists $x \in \mathbb{R}^n$ such that $\nabla f(x) = 0$ and $f(x) = y$. The set $K(f)$ of* generalized critical values *of f consists of all $y \in \mathbb{R}$ for which there exists a sequence $(x_k)_{k\in\mathbb{N}}$ in $\mathbb{R}^n$ such that*

$$\lim_{k\to\infty}\|\nabla f(x_k)\|(1+\|x_k\|) = 0 \qquad \text{and} \qquad \lim_{k\to\infty} f(x_k) = y. \tag{13}$$

The set $K_\infty(f)$ *of* asymptotic critical values *consists of all* $y \in \mathbb{R}$ *for which there exists a sequence* $(x_k)_{k\in\mathbb{N}}$ *in* $\mathbb{R}^n$ *such that* $\lim_{k\to\infty} \|x_k\| = \infty$ *and* (13) *hold.*

The following proposition is easy.

PROPOSITION 13. *The set of generalized critical values of a polynomial* $f \in \mathbb{R}[\bar{X}]$ *is the union of its set of critical and asymptotic critical values, i.e.,*

$$K(f) = K_0(f) \cup K_\infty(f).$$

The following notions go back to Thom [Tho].

DEFINITION 14. *Suppose* $f \in \mathbb{R}[\bar{X}]$. *We say that* $y \in \mathbb{R}$ *is a* typical value *of* f *if there is neighborhood* U *of* y *in* $\mathbb{R}$ *and a smooth (i.e.,* C^∞*) manifold* F *such that* $f|_{f^{-1}(U)} : f^{-1}(U) \to U$ *is a (not necessarily surjective) trivial smooth fiber bundle; i.e., there exist a smooth manifold* F *and a* C^∞ *diffeomorphism* $\Phi : f^{-1}(U) \to F \times U$ *such that* $f|_{f^{-1}(U)} = \pi_2 \circ \Phi$, *where* $\pi_2 : F \times U \to U$ *is the canonical projection. We call* $y \in \mathbb{R}$ *an* atypical value *of* f *if it is not a typical value of* f. *The set of all atypical values of* f *is denoted by* $B(f)$ *and called the* bifurcation set *of* f.

Note that a Φ as in the above definition induces a C^∞ diffeomorphism $f^{-1}(y) \to F \times \{y\} \cong F$ for every $y \in U$. In this context, the preimages $f^{-1}(y)$ are called fibers and F is called *the* fiber. We do not require that the fiber bundle $f|_{f^{-1}(U)} : f^{-1}(U) \to U$ is surjective (if it is not, then the image is necessarily empty). Hence the fiber F may be empty, and a *typical value* is not necessarily a value taken on by f. We make use of the following well-known theorem (see, e.g., [KOS, Theorem 3.1]).

THEOREM 15. *Suppose* $f \in \mathbb{R}[\bar{X}]$. *Then* $B(f) \subseteq K(f)$ *and* $K(f)$ *is finite.*

The advantage of $K(f)$ over $K_0(f)$ is that $f^* \in K(f)$ even if f does not attain a minimum on $\mathbb{R}^n$. This is an easy consequence of Theorem 15. See Theorem 19.

Example 16. Consider again the polynomial $f = (1-XY)^2+Y^2 \in R[X,Y]$ from (6) that does not attain its infimum $f^* = 0$ on $\mathbb{R}^2$. Calculating the partial derivatives, it is easy to see that the origin is the only critical point of f. Because f takes the value 1 at the origin, we have $K_0(f) = \{1\}$ and therefore $f^* = 0 \notin K_0(f)$. Clearly, we have $0 \in B(f)$, since $f^{-1}(-y) = \emptyset \neq f^{-1}(y)$ for small $y \in \mathbb{R}_{>0}$. By Theorem 15, we have therefore $0 \in K_\infty(f) \subseteq K(f)$. To show this directly, a first guess would be that $\|\nabla f(x, \frac{1}{x})\|(1 + \|(x, \frac{1}{x})\|)$ tends to zero when $x \to \infty$ because $\lim_{x\to\infty} f(x, \frac{1}{x}) = 0$. But in fact, this expressions tends to 2 when $x \to \infty$. However, a calculation shows that $\lim_{x\to\infty} \|\nabla f(x, \frac{1}{x})\|(1 + \|(x, \frac{1}{x} - \frac{1}{x^3})\|) = 0$.

DEFINITION 17. *For a polynomial* $f \in \mathbb{R}[\bar{X}]$, *we call*

$$S(\nabla f) := \{x \in \mathbb{R}^n \mid \|\nabla f(x)\|\|x\| \leq 1\}$$

the principal gradient tentacle *of* f.

Remark 18. In the definition of $S(\nabla f)$, the inequality $\|\nabla f(x)\|\|x\| \leq 1$ could be exchanged by $\|\nabla f(x)\|\|x\| \leq R$ for some constant $R > 0$. Then all subsequent results will still hold with obvious modifications. Using an R different from 1 might have in certain cases a practical advantage (see section 3.6). However, we decided to stay with this definition in order to not get too technical and to keep the paper readable.

As expressed by the notation $S(\nabla f)$, polynomials f with the same gradient ∇f have the same gradient tentacle; in other words,

$$S(\nabla(f + a)) = S(\nabla f) \qquad \text{for all } a \in \mathbb{R}.$$

The first important property of $S(\nabla f)$ is stated in the following immediate consequence of Theorem 15.

THEOREM 19. *Suppose $f \in \mathbb{R}[\bar{X}]$ is bounded from below. Then $f^* \in K(f)$ and therefore $f^* = \inf\{f(x) \mid x \in S(\nabla f)\}$.*

Proof. By Theorem 15, it suffices to show that $f^* \in B(f)$. Assume that $f^* \notin B(f)$; i.e., f^* is a typical value of f. Then for all y in a neighborhood of f^*, the fibers $f^{-1}(y)$ are smoothly diffeomorphic to each other. But this is absurd, since $f^{-1}(y)$ is empty for $y < f^*$ but certainly not empty in a neighborhood of f^*. □

Let $\mathbb{P}^{n-1}(\mathbb{C})$ denote the $(n-1)$-dimensional complex projective space over $\mathbb{C}$. For a homogeneous polynomial f and a point $z \in \mathbb{P}^{n-1}(\mathbb{C})$, we simply say $f(z) = 0$ to express that f vanishes on (a nonzero point of) the straight line $z \subseteq \mathbb{C}^n$. Following [P1], we give the following definition.

DEFINITION 20. *We say that a polynomial $f \in \mathbb{C}[\bar{X}]$ has only isolated singularities at infinity if $f \in \mathbb{C}$ (i.e., f is constant) or $d := \deg f \geq 1$ and there are only finitely many $z \in \mathbb{P}^{n-1}(\mathbb{C})$ such that*

$$\frac{\partial f_d}{\partial X_1}(z) = \cdots = \frac{\partial f_d}{\partial X_n}(z) = f_{d-1}(z) = 0, \tag{14}$$

where $f = \sum_i f_i$ and each $f_i \in \mathbb{C}[\bar{X}]$ is zero or homogeneous of degree i.

As shown in [P1, section 1.1], the geometric interpretation of the above definition is that the projective closure of a generic fiber of f has only isolated singularities.

Remark 21. A generic complex polynomial has only isolated singularities at infinity. In fact, much more is true: A generic polynomial $f \in \mathbb{C}[\bar{X}]$ of degree $d \geq 1$ has *no* isolated singularities at infinity in the sense that there is no $z \in \mathbb{P}^{n-1}(\mathbb{C})$ such that (14) holds. In more precise words, to every $d \geq 2$, there exists a complex polynomial relation that is valid for all coefficient tuples of polynomials $f \in \mathbb{C}[\bar{X}]$ of degree d for which (14) has an infinite number of solutions. This follows from the fact that for a generic homogeneous polynomial $g \in \mathbb{C}[\bar{X}]$ of degree $d \geq 1$, there are only finitely many points $z \in \mathbb{P}^{n-1}(\mathbb{C})$ such that $\frac{\partial f}{\partial X_i}(z) = 0$ for all i. See [Kus, Théorème II] or [Shu, Proposition 1.1.1].

Remark 22. In the two variable case $n = 2$, every polynomial $f \in \mathbb{C}[\bar{X}]$ has only isolated singularities at infinity. This is clear, since (14) defines an algebraic subvariety of $\mathbb{P}^1(\mathbb{C})$.

The following theorem follows easily from [P1, Theorem 1.4].

THEOREM 23. *Suppose $f \in \mathbb{R}[\bar{X}]$ has only isolated singularities at infinity. Then*

$$R_\infty(f, S(\nabla f)) \subseteq K(f).$$

In particular, $R_\infty(f, S(\nabla f))$ is finite; i.e., f has only finitely many asymptotic values on its principal gradient tentacle.

Proof. Let $(x_k)_{k\in\mathbb{N}}$ be a sequence of points $x_k \in S(\nabla f)$ and $y \in \mathbb{R}$ such that $\lim_{k\to\infty} ||x_k|| = \infty$ and $\lim_{k\to\infty} f(x_k) = y \notin K_0(f)$. We show that $y \in K_\infty(f)$ using implication (i) $\Longrightarrow$ (ii) in [P1, Theorem 1.4]. Because of our sequence $(x_k)_{k\in\mathbb{N}}$, it is impossible that there exist $N \geq 1$ and $\delta > 0$ such that for all $x \in \mathbb{R}^n$ with $\|x\|$ sufficiently large and $f(x)$ sufficiently close to y, we have

$$\|x\|\|\nabla f(x)\| \geq \delta \sqrt[n]{\|x\|}.$$

This means that condition (ii) in [P1, Theorem 1.4] is violated. The implication (i) $\Longrightarrow$ (ii) in [P1, Theorem 1.4] yields that $y \in B(f)$ (here we use that $y \notin K_0(f)$). But $B(f) \subseteq K(f)$ by Theorem 15. This shows $y \in K(f) \setminus K_0(f) \subseteq K_\infty(f)$ by Proposition 13. □

LEMMA 24. *Every $f \in \mathbb{R}[\bar{X}]$ is bounded on $S(\nabla f)$.*

Proof. By the Łojasiewicz inequality at infinity [Spo, Theorem 1], there exist $c_1, c_2 \in \mathbb{N}$ such that for all $x \in \mathbb{C}^n$,

$$|f(x)| \geq c_1 \implies |f(x)| \leq c_2 \|\nabla f(x)\| \|x\|.$$

Then $|f| \leq \max\{c_1, c_2\}$ on $S(\nabla f)$. ∎

3.1. The principal gradient tentacle and sums of squares. Here comes one of the main results of this article which is interesting on its own but can later be read as a convergence result for a sequence of optimal values of SDPs (Theorem 30).

THEOREM 25. *Let $f \in \mathbb{R}[\bar{X}]$ be bounded from below. Furthermore, suppose that f has only isolated singularities at infinity (which is always true in the two variable case $n = 2$) or the principal gradient tentacle $S(\nabla f)$ is compact. Then the following are equivalent:*

(i) *$f \geq 0$ on $\mathbb{R}^n$.*
(ii) *$f \geq 0$ on $S(\nabla f)$.*
(iii) *For every $\varepsilon > 0$, there are sums of squares of polynomials s and t in $\mathbb{R}[\bar{X}]$ such that*

$$f + \varepsilon = s + t(1 - \|\nabla f\|^2 \|\bar{X}\|^2). \tag{15}$$

Proof. First of all, the polynomial $g := 1 - \|\nabla f\|^2 \|\bar{X}\|^2$ is a polynomial describing the principal gradient tentacle

$$S := \{x \in \mathbb{R}^n \mid g(x) \geq 0\} = S(\nabla f).$$

Because sums of squares of polynomials are globally nonnegative on $\mathbb{R}^n$, identity (15) can be viewed as a certificate for $f \geq -\varepsilon$ on S. Hence it is clear that (iii) implies (ii). For the reverse implication, we apply Theorem 9 (with $m = 1$ and $g_1 := g$) to $f + \varepsilon$ instead of f. We have to check only the hypotheses. Condition (a) is clear from Lemma 24. By Theorem 23, we have that $R_\infty(f, S)$ is a finite set if f has only isolated singularities at infinity. If $S(\nabla f)$ is compact, the set $R_\infty(f, S)$ is even empty. Since $f \geq 0$ on S by hypothesis, this set contains clearly only nonnegative numbers. This shows condition (b); i.e., $R_\infty(f + \varepsilon, S) = \varepsilon + R_\infty(f, S)$ is a finite subset of $\mathbb{R}_{>0}$. Finally, the hypothesis $f \geq 0$ on S gives $f + \varepsilon > 0$ on S, which is condition (c). Therefore (ii) and (iii) are proved to be equivalent. The equivalence of (i) and (ii) is an immediate consequence of Theorem 19. ∎

Remark 26. Let $f \in \mathbb{R}[\bar{X}]$ be bounded from below and $S(\nabla f)$ be compact. Then f attains its infimum f^*. To see this, observe that the equivalence of (i) and (ii) in the preceding theorem implies

$$\begin{aligned} f^* &= \sup\{a \in \mathbb{R} \mid f - a \geq 0 \text{ on } \mathbb{R}^n\} \\ &= \sup\{a \in \mathbb{R} \mid f - a \geq 0 \text{ on } S(\nabla f)\} \\ &= \min\{f(x) \mid x \in S(\nabla f)\}. \end{aligned}$$

The following observation is proved in the same way as Remark 2.

Remark 27. If f is a sum of squares in the ring $\mathbb{R}[[\bar{X}]]$ of formal power series, then its lowest (nonvanishing) homogeneous part must be a sum of squares in $\mathbb{R}[\bar{X}]$.

Remark 28. There are polynomials $f \in \mathbb{R}[\bar{X}]$ such that $f \geq 0$ on $\mathbb{R}^n$, but there is no representation (15) for $\varepsilon = 0$. To see this, take a polynomial $f \in \mathbb{R}[\bar{X}]$ such that

$f \geq 0$ on $\mathbb{R}^n$, but f is not a sum of squares in the ring $\mathbb{R}[[\bar{X}]]$ of formal power series (the Motzkin polynomial from (5) is such an example by the preceding remark). Then a representation (15) with $\varepsilon = 0$ is impossible, since the polynomial $1 - \|\nabla f\|^2 \|\bar{X}\|^2$ has a positive constant term and is therefore a square in $\mathbb{R}[[\bar{X}]]$.

3.2. Optimization using the gradient tentacle and sums of squares. Theorem 25 shows that under certain conditions, computation of f^* amounts to computing the supremum over all a such that $f - a = s + t(1 - \|\nabla f\|^2 \|\bar{X}\|^2)$ for some sums of squares s and t in $\mathbb{R}[\bar{X}]$. As sketched in the introduction, sums of squares *of bounded degree* can be nicely parametrized by positive semidefinite matrices. This motivates the following definition.

DEFINITION 29. *For all polynomials $f \in \mathbb{R}[\bar{X}]$ and all $k \in \mathbb{N}_0$, we define $f_k^* \in \mathbb{R} \cup \{\pm\infty\}$ as the supremum over all $a \in \mathbb{R}$ such that $f - a$ can be written as a sum*

$$f - a = s + t(1 - \|\nabla f\|^2 \|\bar{X}\|^2), \tag{16}$$

where s and t are sums of squares of polynomials with $\deg t \leq 2k$.

Here and in the following, we use the convention that the degree of the zero polynomial is $-\infty$ so that $t = 0$ is allowed in the above definition. Note that when the degree of t in (16) is restricted, then automatically also the degree of s.

Therefore the problem of computing f_k^* can be written as an SDP. How to do this is already suggested in our introduction. It goes exactly as in the well-known method of Lasserre for optimization of polynomials on compact basic closed semialgebraic sets. We refer readers to [L1, M1, Sr2] for the details. There are, anyway, several toolboxes for MATLAB (a software for numerical computation) which can be used to create and solve the corresponding SDPs without knowing these details. The toolboxes we know are YALMIP [Löf] (which is very flexible and good for much more than sums of squares things), SOSTOOLS [PPS] (which has a very flexible and nice syntax), GloptiPoly [HL] (very easy to use for simple problems), and SparsePOP [KKW] (specialized for sparse polynomials). Besides MATLAB and such a toolbox one needs also an SDP solver for which the toolbox provides an interface.

A side remark that we want to make here is that to each SDP there is a dual SDP, and it is desirable from the theoretical and practical point of view that *strong duality* holds; i.e., the optimal value of the primal and dual SDP coincide. For the SDPs arising from Definition 29, strong duality holds. This follows from the fact that principal gradient tentacles (unlike gradient varieties) always have nonempty interior (they always contain a small neighborhood of the origin). For a proof confer [L1, Theorem 4.2], [M1, Corollary 3.2], or [Sr2, Corollary 21]. Here we will neither define the dual SDP nor discuss its interpretation in terms of the so-called moment problem.

Recalling the definition of f^{sos} in (4), we have obviously

$$f^{\text{sos}} \leq f_0^* \leq f_1^* \leq f_2^* \leq \dots, \tag{17}$$

and if f is bounded from below, then all f_k^* are lower bounds (perhaps $-\infty$) of f^* by Theorem 19. Note that the technique from Jibetean and Laurent (see section 1.6) gives upper bounds for f^* so that it complements nicely our method. It is easy to see that Theorem 25 can be expressed in terms of the sequence $f_0^*, f_1^*, f_2^*, \dots$ as follows.

THEOREM 30. *Let $f \in \mathbb{R}[\bar{X}]$ be bounded from below. Suppose that f has only isolated singularities at infinity (e.g., $n = 2$) or the principle gradient tentacle $S(\nabla f)$ is compact. Then the sequence $(f_k^*)_{k \in \mathbb{N}}$ converges monotonically increasing to f^*.*

The following example shows that it is, unfortunately, in general not true that $f_k^* = f^*$ for big $k \in \mathbb{N}$.

Example 31. Let f be the Motzkin polynomial from (5). By Theorem 30, we have $\lim_{k\to\infty} f_k = 0$. But it is not true that $f_k = 0$ for some $k \in \mathbb{N}$. By Definition 29, this would imply that for all $\varepsilon > 0$, there is an identity (15) with sums of squares s and t such that $\deg s \leq k$. Because $S(\nabla f)$ has nonempty interior (note that $\nabla f(1,1,1) = 0$, since $f(1,1,1) = 0$), we can use [PS, Proposition 2.6(b)] (see [Sr2, Theorem 4.5] for a more elementary exposition) to see that such an identity would then also have to exist for $\varepsilon = 0$. But this is impossible, as we have seen in Remark 28.

Unfortunately, the assumption that f is bounded from below is necessary in Theorem 30, as shown by the following trivial example.

Example 32. Consider $f := X \in \mathbb{R}[X]$ (i.e., let $n = 1$ and write X instead of X_1). Then $K(f) = \emptyset$, $S(\nabla f) = [-1, 1]$, and $(f_k^*)_{k\in\mathbb{N}}$ converges monotonically increasing to $\inf\{f(x) \mid -1 \leq x \leq 1\} = -1 \neq -\infty = f^*$.

Open Problem 33. *Do Theorems* 25 *and* 30 *hold without the hypothesis that f has only isolated singularities at infinity or $S(\nabla f)$ is compact?*

By the above arguments, it is easy to see that this question could be answered in the affirmative if $R_\infty(f, S(\nabla f))$ were finite for all polynomials $f \in \mathbb{R}[\bar{X}]$ bounded from below on $\mathbb{R}^n$. But this is not true, as the following counterexample shows. We are grateful to Zbigniew Jelonek for pointing out to us this adaption of an example of Parusiński [P2, Example 1.11].

Example 34. Consider the polynomial $h := X + X^2Y + X^4YZ \in \mathbb{R}[X, Y, Z]$, set $f := h^2$, and define for fixed $a > 0$ the curve

$$\gamma : \mathbb{R}_{>0} \to \mathbb{R}^3 : s \mapsto \left(s, \frac{2a}{s^2}, -\frac{\left(1 + \frac{s}{4a}\right)}{2s^2} \right).$$

Observe that

$$h(\gamma(s)) = \frac{3}{4}s + a \qquad \text{and} \qquad \frac{\partial h}{\partial X}(\gamma(s)) = 0,$$

and therefore $f(\gamma(s)) = (\frac{3}{4}s + a)^2$ and

$$\|\nabla f\|^2(\gamma(s)) = 4f\|\nabla h\|^2(\gamma(s)) = 4s^4 \left(\frac{3}{4}s + a\right)^2 \left(\left(\frac{1}{2} - \frac{s}{8a}\right)^2 + (2a)^2 \right).$$

It follows that $\|\nabla f\|^2(\gamma(s))\|\gamma(s)\|^2$ equals

$$\left(4s^6 + 16a^2 + \left(1 + \frac{s}{4a}\right)^2\right) \left(\frac{3}{4}s + a\right)^2 \left(\left(\frac{1}{2} - \frac{s}{8a}\right)^2 + (2a)^2 \right),$$

which tends to $(16a^2 + 1)a^2(1/4 + 4a^2)$ for $s \to 0$. We now see that for $s \to 0$, $\|\gamma(s)\|$ tends to infinity, $f(\gamma(s))$ tends to a^2, and, when a is a sufficiently small positive number, $\|\nabla f\|^2(\gamma(s))\|\gamma(s)\|^2$ tends to a real number smaller than 1. This shows that $a^2 \in R_\infty(f, S(\nabla f))$ for every sufficiently small positive number a. Hence f is an example of a polynomial bounded from below such that $R_\infty(f, S(\nabla f))$ is infinite.

3.3. Implementation in YALMIP. We show here how to encode computation of f_k^* (as well as of $f_{-1}^* := f^{\text{sos}}$) for any $k \in \mathbb{N}$ with YALMIP. First, declare the variables appearing in the polynomial f (here x and y) as well as the variable a to maximize.

```
sdpvar x y a
```

Now specify the polynomial f and the degree bound k (-1 for computing f^{sos}). Here we take the dehomogenization $f := M(X, Y, 1)$, where M is the Motzkin polynomial introduced in (5).

```
f = x^4 * y^2 + x^2 * y^4 - 3 * x^2 * y^2 + 1, k = 0
```

Now compute the partial derivatives with respect to the variables (here x and y) and specify the polynomial g defining the gradient tentacle.

```
df = jacobian(f, [x y]), g = 1 - (df(1)^2 + df(2)^2) * (x^2 + y^2)
```

Define a polynomial variable t of degree $\leq 2k$ and impose the constraints that t and $f - a - tg$ are sums of squares (for some reason the current version of YALMIP does here not accept a degree zero polynomial t so that this has to be modeled as a scalar variable).

```
if k > 0
 v = monolist([x; y], 2*k), coeffVec = sdpvar(length(v), 1)
 t = coeffVec' * v
 constraints = set(sos(f - a - t * g)) + set(sos(t))
elseif k == 0
 coeffVec = sdpvar(1, 1), t = coeffVec
 constraints = set(sos(f - a - t * g)) + set(t > 0)
else
 coeffVec = []
 constraints = set(sos(f - a))
end
```

Now solve the SDP and output the result for a.

```
solvesos(constraints, -a, [], [a; coeffVec]), double(a)
```

3.4. Implementation in SOSTOOLS. Below we give an SOSTOOLS code which is even slightly easier to read but essentially analogous to the YALMIP code. In contrast to the YALMIP code above, the Symbolic Math Toolbox is required to execute the code below.

```
syms x y a t
f = x^4 * y^2 + x^2 * y^4 - 3 * x^2 * y^2 + 1, k = 0
df = jacobian(f, [x y]), g = 1 - (df(1)^2 + df(2)^2) * (x^2 + y^2)
prog = sosprogram([x; y], a)

if k > 0
 v = monomials([x; y], [0 : k]), [prog, t] = sossosvar(prog, v)
 prog = sosineq(prog, f - a - t * g)
elseif k == 0
 prog = sosdecvar(prog, t), prog = sosineq(prog, t)
 prog = sosineq(prog, f - a - t * g)
else
 prog = sosineq(prog, f - a)
end

prog = sossetobj(prog, -a), prog = sossolve(prog)
sosgetsol(prog, a)
```

3.5. Numerical results. The following examples have been computed on an ordinary PC with MATLAB 7, YALMIP 3, and the SDP solver SeDuMi 1.1. Most of the computations took a few seconds, some of them a few minutes. The first example

corresponds exactly to the code in section 3.3. To compute the others, the variables, the polynomial f, and the degree bound k have to be changed in that code.

Example 35. Let $f := M(X,Y,1)$ be the dehomogenization of the Motzkin polynomial M from (5), i.e., $f := M(X,Y,1) = X^4Y^2 + X^2Y^4 - 3X^2Y^2 + 1 \in \mathbb{R}[X,Y]$. We have $f^* = 0$ but $f^{\text{sos}} = -\infty$ (the latter is an easy exercise). If we execute the program from section 3.3 with $k = -1$ instead of $k = 0$, the computer answers that the SDP is infeasible, which means indeed that $f^{\text{sos}} = -\infty$. Executing the same program for $k = 0, 1, 2$ yields $f_0^* \approx -0.0017$, $f_1^* \approx -0.0013$, and $f_2^* \approx 0.000066$, which is already very close to $f^* = 0$. By Theorem 30, the sequence $f_0, f_1, f_2, \ldots$ converges monotonically to $f^* = 0$. But the computed value $f_2^* \approx 0.000066$ is positive so that there are obviously numerical problems. Confer [PS, Example 2].

Example 36. Define $f := M(X,1,Z) \in \mathbb{R}[X,Z]$, where M is the Motzkin polynomial from (5), i.e., $f = X^4 + X^2 + Z^6 - 3X^2Z^2 \in \mathbb{R}[X,Z]$. Computation yields $f^{\text{sos}} \approx -0.1780$, $f_0^* \approx -5.1749 \cdot 10^{-5}$, $f_1^* \approx -1.2520 \cdot 10^{-7}$, and $f_2^* = 8.7662 \cdot 10^{-10}$, which "equals numerically" $f^* = 0$. This is in accordance with Theorem 25, which guarantees convergence to f^*, since we are in the two variable case. Confer [PS, Example 3].

Example 37. Consider the Berg polynomial $f := X^2Y^2(X^2 + Y^2 - 1) \in \mathbb{R}[X,Y]$ with global minimum $f^* = -1/27$ attained in $(\pm 1/\sqrt{3}, \pm 1/\sqrt{3})$. We have $f^{\text{sos}} = -\infty$, and running the corresponding program gives indeed an output saying that the corresponding SDP is infeasible. The computed optimal values of the first principal tentacle relaxations are $f_0^* \approx -0.0564$, $f_1^* \approx -0.0555$, $f_2^* \approx -0.0371$, and $f_3^* \approx -0.0370 \approx -1/27 = f^*$. Confer [L1, Example 3], [NDS, Example 3], and [JL, Example 4].

Example 38. Being a polynomial in two variables of degree at most four, we have that for $f := (X^2+1)^2 + (Y^2+1)^2 - 2(X+Y+1)^2 \in \mathbb{R}[X,Y]$, $f - f^*$ must be a sum of squares (see introduction) whence $f^* = f^{\text{sos}}$. By computation, we obtain for all values $f^{\text{sos}}, f_0^*, f_1^*, f_2^*$ approximately -11.4581. That all these computed values are the same can be expected by $f^* = f^{\text{sos}}$ and the monotonicity (17). Confer [L1, Example 2] and [JL, Example 3].

Example 39. In [LL], it is shown that

$$f := \sum_{i=1}^{5} \prod_{j \neq i} (X_i - X_j) \in \mathbb{R}[X_1, X_2, X_3, X_4, X_5]$$

is nonnegative on $\mathbb{R}^5$ but not a sum of squares of polynomials. Therefore $f^{\text{sos}} = -\infty$ by Remark 2, since f is homogeneous. The SDP solver detects indeed infeasibility of the corresponding SDP. We have computed $f_0^* \approx -0.2367$, $f_1^* \approx -0.0999$, and $f_2^* \approx -0.0224$. Solving the SDP relaxation computing f_2^* already took the time of a coffee break. As in [JL, Example 6], we observe therefore that minimizing f is after the change of variables $X_i \mapsto X_1 - Y_i$ $(i = 2, 3, 4, 5)$ equivalent to minimizing

$$h := Y_2Y_3Y_4Y_5 + \sum_{i=2}^{5} (-Y_i) \prod_{j \neq i} (Y_j - Y_i) \in \mathbb{R}[Y_2, Y_3, Y_4, Y_5].$$

Computing h^{sos} results in infeasibility. The numerical results using the principle gradient tentacle are $h_0^* \approx -0.2380$, $h_1^* \approx -0.0351$, $h_2^* \approx -0.0072$, $h_3^* \approx -0.0019$, and $h_4^* \approx -0.00086285$, which is already very close to $h^* = 0$. The condition in Theorem 30 is satisfied neither for f nor for h, and yet it seems that we have convergence to

h^*. This is a typical observation that might give hope that Open Problem 33 has a positive answer.

Example 40. Consider once more the polynomial $f = (1 - XY)^2 + Y^2$ from (6) and Example 16 that does not attain its infimum $f^* = 0$ on $\mathbb{R}^2$. Since this polynomial is by definition a sum of squares, we have $f^{\text{sos}} = 0 = f^*$ and therefore $f_k^* = 0$ for all $k \in \mathbb{N}$ by (17). By computation, we get $f^{\text{sos}} \approx 1.5142 \cdot 10^{-12}$, which is almost zero but also $f_0^* \approx 0.0016$, $f_1^* \approx 0.0727$, and $f_2^* \approx 0.1317$, which shows that there are big numerical problems. We have verified that the corresponding SDPs have nevertheless been solved quite accurately. The problem is that small numerical errors in the coefficients of a polynomial can perturb its infimum quite a lot whenever the infimum is not attained (or attained very far from the origin). It should be subject to further research how to fight this problem. Anyway, the gradient tentacle method still performs in this example much better than the gradient variety method, which yields the wrong answer 1 (as described in section 1.7). The method of Jibetean and Laurent gives the best results in this case [JL, Example 5].

3.6. Numerical stability. If the coefficients of f and $\|\nabla f\|\|\bar{X}\|$ have an order of magnitude very different from 1, then the defining polynomial $g = 1 - \|\nabla f\|^2\|\bar{X}\|^2$ for the gradient tentacle should be better exchanged by $R - \|\nabla f\|^2\|\bar{X}\|^2$, where R is a real number of that order of magnitude. This is justified by Remark 18.

Example 40 and other experiments that we did with polynomials bounded from below that do not attain a minimum are a bit disappointing and show that for this "hard" class of polynomials (exactly the class we were attacking), a lot of work remains to be done, at least on the numerical side. The corresponding SDPs tend to be numerically unstable.

For polynomials attaining their minimum, the method in [NDS] is often much more efficient, e.g., for Example 39.

4. Higher gradient tentacles. In this section, we associate with every polynomial $f \in \mathbb{R}[\bar{X}]$ a *sequence* of gradient tentacles. Each of these is defined by a polynomial inequality just as the principal tentacle from section 3 was. But the degree of this polynomial inequality for the Nth tentacle in this sequence will be roughly $2N$ times the degree of f. This has the disadvantage that the corresponding SDP relaxations get very big for large N. Also, we have to deal for *each* N with a sequence of SDPs. All in all, we have therefore a double sequence of SDPs. The advantage is, however, that we can prove a sums of squares representation theorem (Theorem 46) applicable for *all* $f \in \mathbb{R}[\bar{X}]$ bounded from below independently of the answer to Open Problem 33. Again, we think that this theorem is also of theoretical interest. Implementation of the higher gradient tentacle method is analogous to sections 3.3 and 3.4. This time we do not give numerical examples because of Open Problem 33, Remark 21, and numerical problems for big N.

Definition 41. *For $f \in \mathbb{R}[\bar{X}]$ and $N \in \mathbb{N}$, we call*

$$S(\nabla f, N) := \{x \in \mathbb{R}^n \mid \|\nabla f(x)\|^{2N}(1 + \|x\|^2)^{N+1} \leq 1\}$$

the Nth gradient tentacle *of f.*

A trivial fact that one should keep in mind is that $\|\nabla f(x)\|^2(1 + \|x\|^2) \leq 1$ and in particular $\|\nabla f(x)\|\|x\| \leq 1$ for all $x \in S(\nabla f, N)$. This shows that

$$V(\nabla f) \cap \mathbb{R}^n \subseteq S(\nabla f, 1) \subseteq S(\nabla f, 2) \subseteq S(\nabla f, 3) \subseteq \cdots \subseteq S(\nabla f).$$

The definition of $S(\nabla f, N)$ is motivated by the following definition, which is taken from [KOS, page 79].

DEFINITION 42. *Suppose $f \in \mathbb{R}[\bar{X}]$ and $N \in \mathbb{N}$. The set $K_\infty^N(f)$ consists of all $y \in \mathbb{R}$ for which there exists a sequence $(x_k)_{k\in\mathbb{N}}$ in $\mathbb{R}^n$ such that*

$$\lim_{k\to\infty} ||x_k|| = \infty, \qquad \lim_{k\to\infty} \|\nabla f(x_k)\|\|x_k\|^{1+\frac{1}{N}} = 0, \quad \text{and} \qquad \lim_{k\to\infty} f(x_k) = y. \tag{18}$$

Clearly, we have

$$K_\infty^1(f) \subseteq K_\infty^2(f) \subseteq K_\infty^3(f) \subseteq \cdots \subseteq K_\infty(f).$$

The next lemma says that this chain actually gets stationary and reaches $K_\infty(f)$. For the proof, we refer readers to [KOS, Lemma 3.1].

LEMMA 43 (Kurdyka, Orro, and Simon). *For all $f \in \mathbb{R}[\bar{X}]$, there exists $N \in \mathbb{N}$ such that*

$$K_\infty(f) = K_\infty^N(f).$$

Now we prove for sufficiently large gradient tentacles what Theorem 19 was for the principal gradient tentacle (which contains all higher gradient tentacles).

THEOREM 44. *Suppose $f \in \mathbb{R}[\bar{X}]$ is bounded from below. Then $f^* \in K(f)$ and there is $N_0 \in \mathbb{N}$ such that for all $N \geq N_0$,*

$$f^* = \inf\{f(x) \mid x \in S(\nabla f, N)\}. \tag{19}$$

Proof. We know already from Theorem 19 that $f^* \in K(f)$. By Proposition 13, at least one of the following two cases therefore must occur. The first case is that $f^* \in K_0(f)$. Then f^* is attained by f on its gradient variety and therefore on the Nth gradient tentacle for actually all $N \in \mathbb{N}$. Hence we can set $N_0 := 1$. In the second case, $f^* \in K_\infty(f)$, we can choose some $N_0 \in \mathbb{N}$ such that $f^* \in K_\infty^N(f)$ by the previous lemma. Then $f^* \in K_\infty^N(f)$ for any $N \geq N_0$. This means that there exists a sequence $(x_k)_{k\in\mathbb{N}}$ satisfying (18). Therefore $\|\nabla f(x)\|\|x_k\|^{1+1/N} \leq \frac{1}{2}$ and consequently

$$\|\nabla f(x_k)\|^{2N}(1 + \|x_k\|^2)^{N+1} \leq \|\nabla f(x_k)\|^{2N}(2\|x_k\|^2)^{N+1} \leq 1$$

for all large k, since $\|x_k\| \geq 1$ and $2^{N+1} \leq 2^{2N}$. This shows that $x_k \in S(\nabla f, N)$ for all large k, which implies our claim. ∎

The great advantage of the higher gradient tentacles over the principal one is that they are *always* small enough to admit only finitely many asymptotic values; i.e., there is no counterpart to Example 34.

THEOREM 45. *For every $f \in \mathbb{R}[\bar{X}]$, $R_\infty(f, S(\nabla f)) \subseteq K_\infty(f)$. In particular, every $f \in \mathbb{R}[\bar{X}]$ has only finitely many asymptotic values on each of its higher gradient tentacles; i.e., the set $R_\infty(f, S(\nabla f, N))$ is finite for all $N \in \mathbb{N}$.*

Proof. Let $y \in \mathbb{R}$ be such that (7) holds for some sequence $(x_k)_{k\in\mathbb{N}}$ of points $x_k \in S(\nabla f, N)$. By Definition 41,

$$\|\nabla f(x_k)\|^N \|x_k\|^N \leq \frac{1}{\|x_k\|} \to 0 \qquad \text{for } k \to \infty,$$

implying (13). This shows that $y \in K_\infty(f)$. ∎

4.1. Higher gradient tentacles and sums of squares. We are now able to prove the third important sums of squares representation theorem of this article besides Theorems 9 and 25.

THEOREM 46. *For all $f \in \mathbb{R}[\bar{X}]$ bounded from below, there is $N_0 \in \mathbb{N}$ such that for all $N \geq N_0$, the following are equivalent:*

(i) *$f \geq 0$ on $\mathbb{R}^n$.*
(ii) *$f \geq 0$ on $S(\nabla f, N)$.*
(iii) *For every $\varepsilon > 0$, there are sums of squares of polynomials s and t in $\mathbb{R}[\bar{X}]$ such that*

$$f + \varepsilon = s + t(1 - \|\nabla f\|^{2N}(1 + \|\bar{X}\|^2)^{N+1}). \tag{20}$$

Moreover, these conditions are equivalent for all f attaining a minimum on $\mathbb{R}^n$ and all $N \in \mathbb{N}$. Finally, (ii) *and* (iii) *are equivalent for all $f \in \mathbb{R}[\bar{X}]$ and $N \in \mathbb{N}$.*

Proof. We first show that (ii) and (iii) are always equivalent. To see this, observe that $g_1 := 1 - \|\nabla f\|^{2N}\|\bar{X}\|^{2N+2}$ is a polynomial that defines the set $S := \{x \in \mathbb{R}^n \mid g_1 \geq 0\} = S(\nabla f, N)$. Because sums of squares of polynomials are globally nonnegative on $\mathbb{R}^n$, identity (20) can be viewed as a certificate for $f \geq -\varepsilon$ on S. Hence it is clear that (iii) implies (ii). For the reverse implication, we apply Theorem 9 to $f + \varepsilon$ instead of f. We have to check only the hypotheses. Condition (a) is clear from Lemma 24. By Theorem 45, we have that $R_\infty(f, S)$ is a finite set. Since $f \geq 0$ on S by hypothesis, this set contains clearly only nonnegative numbers. This shows condition (b); i.e., $R_\infty(f + \varepsilon, S) = \varepsilon + R_\infty(f, S)$ is a finite subset of $\mathbb{R}_{>0}$. Finally, the hypothesis $f \geq 0$ on S gives $f + \varepsilon > 0$ on S, which is condition (c).

Now suppose that $f \in \mathbb{R}[\bar{X}]$ attains a minimum $f(x^*) = f^*$ in a point $x^* \in \mathbb{R}^n$. Then $\nabla f(x^*) = 0$ and therefore $x^* \in S(\nabla f, N)$ for all $N \in \mathbb{N}$. This shows that (i) and (ii) are in this case equivalent for *all* $N \in \mathbb{N}$.

By what has already been proved, it remains only to show that (i) and (ii) are equivalent for large $N \in \mathbb{N}$ when $f \in \mathbb{R}[\bar{X}]$ is bounded from below but does not attain a minimum. But in this case, (19) holds by Theorem 44 yielding the equivalence of the first two conditions. □

Without needing it for our application, we draw the following immediate corollary. Taking $N = 1$ in the second part of this corollary yields Theorem 6 of Nie, Demmel, and Sturmfels.

COROLLARY 47. *Suppose $f \in \mathbb{R}[\bar{X}]$ and $f \geq 0$ on $V(\nabla f) \cap \mathbb{R}^n$. Then $f + \varepsilon$ is for all $\varepsilon > 0$ a sum of squares modulo any principal ideal generated by a power of the polynomial $\|\nabla f\|^2(1 + \|\bar{X}\|^2)$; i.e., for every $\varepsilon > 0$ and $N \in \mathbb{N}$, there is a sum of squares s in $\mathbb{R}[\bar{X}]$ and a polynomial $p \in \mathbb{R}[\bar{X}]$ such that*

$$f = s + p(\|\nabla f\|^2(1 + \|\bar{X}\|^2))^N.$$

In particular, $f + \varepsilon$ is for all $\varepsilon > 0$ a sum of squares modulo each power of its gradient ideal; i.e., for every $\varepsilon > 0$ and $N \in \mathbb{N}$, there is a sum of squares s in $\mathbb{R}[\bar{X}]$ such that

$$f \in s + (\nabla f)^N.$$

Proof. The second claim follows from the first one. The first claim follows immediately from implication (i) $\Longrightarrow$ (iii) in Theorem 46, which always holds for all $N \in \mathbb{N}$. □

4.2. Optimization using higher gradient tentacles and sums of squares. The following definition can be motivated in the same way as Definition 29 in section 3.

DEFINITION 48. *For all polynomials $f \in \mathbb{R}[\bar{X}]$, all $N \in \mathbb{N}$, and all $k \in \mathbb{N}_0$, we define $f^*_{N,k} \in \mathbb{R} \cup \{\pm\infty\}$ as the supremum over all $a \in \mathbb{R}$ such that $f - a$ can be written as a sum*

$$f - a = s + t(1 - \|\nabla f\|^{2N}(1 + \|\bar{X}\|^2)^{N+1}), \tag{21}$$

where s and t are sums of squares of polynomials with $\deg t \leq 2k$.

Again, as outlined in section 3, computation of $f_{N,k}$ amounts to solving an SDP for each fixed $N \in \mathbb{N}$ and $k \in \mathbb{N}_0$. Recalling the definition of f^{sos} in (4), we have for each fixed $N \in \mathbb{N}$,

$$f^{\text{sos}} \leq f^*_{N,0} \leq f^*_{N,1} \leq f^*_{N,2} \leq \cdots,$$

and if f is bounded from below, then all $f^*_{N,k}$ are lower bounds of f^* by Theorem 44. It would be desirable to also have information on how the $f_{N,k}$ are related to each other when not only k but also N varies. All we know about that is the following proposition.

PROPOSITION 49. *For all $f \in \mathbb{R}[\bar{X}]$, $N \in \mathbb{N}$, and $k \in \mathbb{N}_0$,*

$$f^*_{N+1,k} \leq f^*_{N,k+d}.$$

Proof. Let us define the polynomials h_N as in (11) and substitute into the identity proved in Lemma 11 the polynomials $\|\nabla f\|^2$ for Y and $\|\bar{X}\|^2$ for $\bar{X}$. Then we get

$$1 - \|\nabla f\|^{2(N+1)}(1 + \|\bar{X}\|^2)^{N+2} = p + q(1 - \|\nabla f\|^{2N}(1 + \|\bar{X}\|^2)^{N+1}), \tag{22}$$

where p and

$$q := \left(1 + \frac{1}{N}\right)\|\nabla f\|^2(1 + \|\bar{X}\|^2)$$

are sums of squares of polynomials. The degree of q is no higher than $2(d-1)+2 = 2d$. Now if for $a \in \mathbb{R}$ we have an identity

$$f - a = s + t(1 - \|\nabla f\|^{2(N+1)}(1 + \|\bar{X}\|^2)^{N+2})$$

for sums of squares s and t with $\deg t \leq 2k$, then for the same a

$$f - a = (s + tp) + tq(1 - \|\nabla f\|^{2N}(1 + \|\bar{X}\|^2)^{N+1})$$

and $\deg(tq) \leq 2(k + d)$. ∎

We conclude by interpreting Theorem 46 as a convergence result concerning the optimal values $f^*_{N,k}$ of the proposed relaxations. This is the counterpart to Theorem 30 from section 2.

THEOREM 50. *For all $f \in \mathbb{R}[\bar{X}]$ bounded from below, $(f^*_{N,k})_{k\in\mathbb{N}}$ converges monotonically increasing to f^*, provided that $N \in \mathbb{N}$ is sufficiently large (depending on f). If f attains a minimum on $\mathbb{R}^n$, $(f^*_{N,k})_{k\in\mathbb{N}}$ converges monotonically increasing to f^* no matter what $N \in \mathbb{N}$ is.*

5. Conclusions. We have proposed a method for computing numerically the infimum of a real polynomial in n variables which is bounded from below on $\mathbb{R}^n$. As in [JL] and [NDS], the approach is to find semidefinite relaxations relying on sums of squares certificates and critical point theory. As one could expect, polynomials that do not attain a minimum on $\mathbb{R}^n$ (that are either unbounded from below or have a finite infimum that is not attained) are particularly hard to handle. In [JL], this problem (among others) was solved by perturbing the coefficients of the polynomial to guarantee a minimum (in particular, boundedness from below). Though the results in [JL] are quite good, we are convinced that one should also look for other methods that avoid perturbations and the danger of numerical ill-conditioning coming along with them. Proving sums of squares representations for polynomials positive on their gradient variety, it was shown by Nie, Demmel, and Sturmfels [NDS] that an approach without perturbation is possible. The computational performance of their method is extremely good. However, for polynomials that do not attain a minimum, their method yields wrong answers. Combining considerable machinery from differential geometry and real algebraic geometry, we have shown that part of this limitation can be removed. By using our gradient tentacles instead of the gradient variety, polynomials that do not attain a minimum but are bounded from below can also be handled. Our method has three major problems. First, we do not address the important question of how to check efficiently if a polynomial is bounded from below. For such polynomials, our method still gives a wrong answer (see Example 32). Second, it turns out that solving SDPs that arise from a polynomial that does not attain a minimum takes sometimes a surprisingly long time. And third, small numerical inaccuracies might lead to big changes in the infimum of a polynomial if the infimum is not attained. All three problems should be subject to further research. Polynomials not attaining a minimum remain hard to handle in practice. On the theoretical side, we have combined the theory of generalized critical values with the theory of real holomorphy rings and have obtained new interesting characterizations of nonnegative polynomials.

Acknowledgments. We are most grateful to Zbigniew Jelonek for the discussions in Passau, where he showed us Example 34 and Parusinski's theorem, Theorem 23. Our thanks go also to Mohab Safey El Din for shifting our attention to Theorem 19, to Richard Leroy for helping to prove Lemma 11, and to Krzysztof Kurdyka for interesting discussions in Paris.

STATIONARITY RESULTS FOR GENERATING SET SEARCH FOR LINEARLY CONSTRAINED OPTIMIZATION*

TAMARA G. KOLDA†, ROBERT MICHAEL LEWIS‡, AND VIRGINIA TORCZON§

Abstract. We present a new generating set search (GSS) approach for minimizing functions subject to linear constraints. GSS is a class of direct search optimization methods that includes generalized pattern search. One of our main contributions in this paper is a new condition to define the set of conforming search directions that admits several computational advantages. For continuously differentiable functions we also derive a bound relating a measure of stationarity, which is equivalent to the norm of the gradient of the objective in the unconstrained case, and a parameter used by GSS algorithms to control the lengths of the steps. With the additional assumption that the derivative is Lipschitz, we obtain a big-O bound. As a consequence of this relationship, we obtain subsequence convergence to a KKT point, even though GSS algorithms lack explicit gradient information. Numerical results indicate that the bound provides a reasonable estimate of stationarity.

Key words. constrained optimization, linear constraints, global convergence analysis, direct search, generating set search, generalized pattern search, derivative-free methods, stopping criteria

DOI. 10.1137/S1052623403433638

1. Introduction.

We consider a class of direct search methods called *generating set search* (GSS) [15] which encompasses methods such as generalized pattern search [33, 18, 19] and certain classes of derivative-free optimization methods [21, 22, 23, 24]. The problem of interest is the linearly constrained minimization problem:

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && Ax \le b. \end{aligned} \tag{1.1}$$

Here $f : \mathbb{R}^n \to \mathbb{R}$, A is an $m \times n$ matrix, and b is a vector in $\mathbb{R}^m$. Both A and b are assumed to be explicitly available. No assumption of nondegeneracy of the constraints is made. Let Ω denote the feasible region

$$\Omega = \{\, x \;\mid\; Ax \le b \,\}.$$

We assume that the objective f is continuously differentiable on Ω but that the gradient is not computationally available because no procedure exists for computing the gradient and it cannot be approximated accurately.

FIG. 1.1. *Coordinate search with exact penalization applied to the modified Broyden tridiagonal function with bound constraints.*

1.1. An illustrative example. We illustrate an instance of a GSS method in Figure 1.1. We consider coordinate search applied to the two-dimensional modified Broyden tridiagonal function [4, 26], a standard test problem, with the addition of bounds on the variables. Level curves of the function are shown in the background, and the feasible region is the box labeled Ω. The current iterate x_k is indicated by a circle; this is the point with the lowest value of f found so far, also known as the *best point*. If there are no constraints, a coordinate search method evaluates the function at the $2n$ *trial points* defined by taking a step of a specified length from x_k along the positive and negative coordinate directions, i.e., the *search directions*. The iterates must remain feasible with respect to the bound constraints present in this problem, which means that infeasible trial points are not considered. Terminal crosses show infeasible trial points; solid squares indicate feasible trial points. The lighter versions given in (b)–(f) indicate the search directions and trial points from the previous iteration.

To establish notation and give context for the discussion that follows, we give an outline of a GSS method. Details are developed throughout the paper; complete statements of the algorithms can be found in section 5.

Let $x_0 \in \Omega$ be the initial iterate, and let Δ_0 be the initial choice for the *step-length control parameter* with $\Delta_0 > \Delta_{\text{tol}} > 0$, where Δ_{tol} serves as a measure for termination. The search proceeds for iterations $k = 0, 1, 2, \ldots$ until $\Delta_k < \Delta_{\text{tol}}$.

The first step in each iteration is to select a set of search directions. The number

of search directions is denoted by p_k and the set of search directions by

$$\mathcal{D}_k = \{d_k^{(1)}, \ldots, d_k^{(p_k)}\}.$$

The second step in each iteration is to construct feasible trial points of the form

$$x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)}, \quad i \in \{1, \ldots, p_k\},$$

with $\tilde{\Delta}_k^{(i)} \in [0, \Delta_k]$ chosen to ensure feasibility. These trial points are where the objective function may be evaluated in the search for a new best point to replace x_k.

The third step is to determine whether the iteration is successful or unsuccessful and correspondingly update x and Δ. If one of the trial points reduces the objective function value by an acceptable amount, then that trial point becomes the new iterate x_{k+1}. The step-length control parameter may either be increased or, more usually, left unchanged so that $\Delta_{k+1} = \Delta_k$. In this case the iteration is deemed *successful* and k is assigned to the set of successful iterates denoted by $\mathcal{S}$. Otherwise, none of the trial points improves the value of the objective function, so the step Δ_k is reduced, e.g., $\Delta_{k+1} = \frac{1}{2}\Delta_k$, and the next iterate is unchanged, i.e., $x_{k+1} = x_k$. In this case the iteration is deemed *unsuccessful* and k is assigned to the set of unsuccessful iterates denoted by $\mathcal{U}$.

1.2. Goals of this paper. A primary contribution of this paper is a new condition on the set of search directions $\mathcal{D}_k$ that is flexible but also sufficient to ensure desirable convergence properties of the algorithm. Key to our new results is the way in which the classification of constraints as being nearly binding is tied to Δ_k, the step-length control parameter.

The following measure of stationarity, introduced in [5], is central to our analysis: for $x \in \Omega$,

$$\chi(x) \equiv \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} -\nabla f(x)^T w.$$

As discussed in [6], $\chi(x)$ is a continuous function on Ω. Furthermore, $\chi(x) = 0$ for $x \in \Omega$ if and only if x is a Karush–Kuhn–Tucker (KKT) point of the linearly constrained problem.

In Theorem 6.4, under certain assumptions, we show that at unsuccessful iterations there is a big-O relationship between the step-length control parameter and the measure of stationarity:

$$\chi(x_k) = O(\Delta_k) \quad \text{for } k \in \mathcal{U}. \tag{1.2}$$

This means that as Δ_k is reduced, the upper bound on the value of the measure of stationarity is also reduced. Relationship (1.2) is analogous to the unconstrained minimization result (see [8, section 3] or [15, section 3.6]):

$$\| \nabla f(x_k) \| = O(\Delta_k) \quad \text{for } k \in \mathcal{U}. \tag{1.3}$$

Results (1.2) and (1.3) support using the magnitude of Δ_k as a test for termination. In section 7 we give numerical illustrations of relationship (1.2).

Another consequence of (1.2) is that it leads directly to a global convergence result (Theorem 6.5) showing that a subsequence of the iterates converges to a KKT point:

$$\liminf_{k \to \infty} \chi(x_k) = 0. \tag{1.4}$$

The latter follows immediately from (1.2) once the result $\liminf_{k \to \infty} \Delta_k = 0$ from [33] is invoked, thus further simplifying prior global convergence analyses.

1.3. Related work. The GSS methods we propose for solving linearly constrained problems are *feasible-point* methods; i.e., they require all iterates to be feasible. They also share many features with classical feasible directions methods that rely on derivatives [2, 35, 36], especially in the way in which they handle the proximity of the current iterate to the boundary of the feasible region.

Most prior related work has used similar mechanisms for identifying the set of nearly binding linear constraints [25, 34, 19, 1, 30] and [24, Algorithm 2]. Constraints were identified as being nearly binding by considering either the Euclidean distance from the current iterate to the constraint faces [25, 19, 24, 1] or the magnitude of the constraint residual $|\, a_i^T x - b_i \,|$ at the current iterate [34, 30]. A constraint was treated as binding if one of the preceding measures fell below some fixed threshold.

The convergence properties of GSS algorithms rely on the presence at each iteration of a theoretically necessary set of search directions, which we call *core directions*. In the work just cited ([25, 34, 19, 1, 30] and [24, Algorithm 2]), the core directions are all the generators for a *set* of cones. There are situations where the resulting number of search directions is quite large. Since Δ_k can be reduced only at the conclusion of an unsuccessful iteration, and each unsuccessful iteration requires the evaluation of the function at the trial points defined by core directions, there is incentive to try and keep the cardinality of the set of core directions small when the cost of computing f at a feasible point is appreciable.

Algorithm 1 of [24] addresses this concern. Its core directions are the generators of a single cone. However, the *only* allowable search directions are the core directions—the set of search directions cannot be augmented.

The approach we advocate here is a compromise. Our set of core directions is smaller than in [25, 34, 19, 1, 30] and [24, Algorithm 2], but the choice of search directions is more flexible than Algorithm 1 of [24]. The core set need only contain generators for a single cone, but accommodates additional search directions. As reported in [17], the computational advantages of this compromise are appreciable in terms of reducing the number of search directions per iteration, reducing the total number of iterations, and reducing the total number of function evaluations.

Another focus of the work reported here is on establishing (1.2) and a related result regarding the projection of the direction of steepest descent onto the polar of the cone defined by the working set of constraints. Proposition 7.1 in [19] also established a relationship between Δ_k and a different measure of stationarity. The quantity

$$q(x) \equiv P_\Omega\left(x - \nabla f(x)\right) - x, \tag{1.5}$$

where P_Ω denotes the projection onto Ω, is a continuous function of x with the property that $q(x) = 0$ for $x \in \Omega$ if and only if x is a KKT point. In [19, Proposition 7.1] it is shown that

$$\| \, q(x_k) \, \| = O(\sqrt{\Delta_k}) \quad \text{for } k \in \mathcal{U}, \tag{1.6}$$

a result that is neither as satisfying nor as useful as that in (1.2).

Continuing along the lines we began in [15], here we incorporate the sufficient decrease step acceptance criterion from [23, 22, 24], while also preserving a version of the algorithm that requires only simple decrease, as in the work in [19, 1, 30]. The sufficient decrease condition simplifies the analysis. More importantly, the sufficient decrease condition gives us greater flexibility in how we maintain feasibility in the

presence of linear constraints. In particular, using a sufficient decrease acceptance criterion makes steps onto the boundary straightforward.

As mentioned in section 1.2, given (1.2) it is straightforward to prove convergence of a subsequence to a KKT point. The approach to convergence analysis in [1, 30] takes a different tack by focusing on the directional derivatives along the search directions and considering whether limit points of the sequence of iterates are KKT points. This allows a relaxation of the smoothness assumptions on f. If f is not assumed to be continuously differentiable, but is only assumed to be strictly differentiable at limit points of the sequence of iterates, the results in [1, 30] show that those limit points are KKT points. However, subsequence convergence to KKT points in the nonsmooth case is not guaranteed by the results in [1, 30] and, in fact, may not be realized [15].

1.4. Organization. The paper is organized as follows. In section 2, we describe the conditions on the set of core directions for GSS methods applied to problems with linear constraints. As we saw in Figure 1.1, GSS algorithms may generate trial points that are infeasible, so in section 3 we describe how feasibility is maintained. In section 4 we discuss the globalization strategies. Formal statements of GSS algorithms for solving linearly constrained problems are given in section 5. We present two general algorithms. The first (Algorithm 5.1) uses a sufficient decrease condition as in [22, 24]. The second (Algorithm 5.2) uses a simple decrease condition as in [18, 19]. Results showing the stationarity properties of these algorithms are derived in section 6. In section 7 we discuss what the analysis reveals about using Δ_k to test for stationarity and demonstrate its effectiveness on two test problems. In section 8, we summarize the results and their importance. Appendix A contains a discussion of $\chi(x)$ and its use as a measure of stationarity. Appendix B contains geometric results on cones and polyhedra.

2. Search directions. GSS methods for linearly constrained optimization need to choose $\mathcal{D}_k$, the set of search directions, at each iteration. In this section, we describe the conditions we place on $\mathcal{D}_k$ to guarantee (1.2), and thus (1.4). Since GSS methods do not use gradient information, they cannot directly identify descent directions. Instead, the set $\mathcal{D}_k$ must include enough search directions to guarantee that at least one of them is a descent direction and, moreover, allows a sufficiently long step within the feasible region if x_k is not a KKT point. To describe the conditions on the sets of search directions, we start in section 2.1 by reviewing some standard concepts regarding finitely generated cones. Then, in section 2.2, we show how to use the constraints $Ax \leq b$ to define cones that mirror the geometry of the boundary of the polyhedron Ω near the current iterate x_k. Finally, in section 2.3, we detail the conditions placed on the set $\mathcal{D}_k$ to ensure that, for every iteration of any GSS algorithm, there exists at least one direction along which it is possible to take a step of sufficient length while remaining inside Ω.

2.1. Cones and generators. A *cone* K is a set that is closed under nonnegative scalar multiplication, i.e., K is a cone if $x \in K$ implies $\alpha x \in K$ for all $\alpha \geq 0$. The *polar* of a cone K, denoted K°, is defined by

$$K^\circ = \{\ v \ \mid\ w^T v \leq 0 \text{ for all } w \in K\ \}$$

and is itself a cone. Given a convex cone K and any vector v, there is a unique closest point of K to v, the *projection* of v onto K, which we denote by v_K. Given a vector v and a convex cone K, any vector v can be written as $v = v_K + v_{K^\circ}$ and $v_K^T v_{K^\circ} = 0$ [27, 12].

A set of vectors $\mathcal{G}$ *generates* a cone K if K is the set of all nonnegative linear combinations of elements of $\mathcal{G}$. A cone K is *finitely generated* if it can be generated by a finite set of vectors. For any finite set of vectors $\mathcal{G}$, we define

$$\kappa(\mathcal{G}) = \inf_{\substack{v \in \mathbb{R}^n \\ v_K \neq 0}} \max_{d \in \mathcal{G}} \frac{v^T d}{\| v_K \| \, \| d \|}, \quad \text{where } K \text{ is the cone generated by } \mathcal{G}. \tag{2.1}$$

This is a generalization of the quantity given in [15, (3.10)], where $\mathcal{G}$ generates $\mathbb{R}^n$. Note that the value $\kappa(\mathcal{G})$ is a property of the set $\mathcal{G}$—not of the cone K. See Proposition 10.3 in [19] for a proof of the following result.

PROPOSITION 2.1. *If* $\mathcal{G} \neq \{\mathbf{0}\}$, *then* $\kappa(\mathcal{G}) > 0$.

A special case occurs if $\mathcal{G}$ generates $\mathbb{R}^n$. In this case, a set of generators is a *positive spanning set* [7]. Thus a positive spanning set is like a linear spanning set but with the additional requirement that all the coefficients be nonnegative. One particular choice of generating set for $\mathbb{R}^n$ is the set of the positive and negative unit coordinate vectors

$$\{e_1, e_2, \ldots, e_n, -e_1, -e_2, \ldots, -e_n\},$$

which is the set of search directions used for the illustration of coordinate search in Figure 1.1.

2.2. Tangent and normal cones. Let a_i^T be the ith row of the constraint matrix A and let

$$\mathcal{C}_i = \{\ y \ \mid \ a_i^T y = b_i \ \}$$

denote the set where the ith constraint is binding. The set of indices for the binding constraints at x is $I(x) = \{\ i \ \mid \ x \in \mathcal{C}_i \ \}$. The *normal cone* at a point x, denoted by $N(x)$, is the cone generated by the binding constraints, i.e., the cone generated by the set $\{\ a_i \ \mid \ i \in I(x) \ \} \cup \{\mathbf{0}\}$. The presence of $\{\mathbf{0}\}$ means that $N(x) = \{\mathbf{0}\}$ if there are no binding constraints. The *tangent cone*, denoted by $T(x)$, is the polar of the normal cone. Further discussion of the tangent and polar cones in the context of optimization can be found, for instance, in [31, 12, 13, 29].

In our case, we are not only interested in the binding constraints, but also in the nearby constraints. Given $x \in \Omega$, the indices of the *ε-binding constraints* are given by

$$I(x, \varepsilon) = \{\ i \ \mid \ \operatorname{dist}(x, \mathcal{C}_i) \leq \varepsilon \ \}. \tag{2.2}$$

The vectors a_i for $i \in I(x, \varepsilon)$ are the outward-pointing normals to the faces of the boundary of Ω within distance ε of x. The idea of using ε-binding constraints is identical to one sometimes used in gradient-based feasible directions methods, e.g., [2, section 2.5].

Given $x \in \Omega$, we define the *ε-normal cone* $N(x, \varepsilon)$ to be the cone generated by the set $\{\ a_i \ \mid \ i \in I(x, \varepsilon) \ \} \cup \{\mathbf{0}\}$. The presence of $\{\mathbf{0}\}$ means that $N(x, \varepsilon) = \{\mathbf{0}\}$ if $I(x, \varepsilon) = \emptyset$. The corresponding polar cone is the *ε-tangent cone* $T(x, \varepsilon)$. Observe that if $\varepsilon = 0$, then these are just the standard normal and tangent cones; that is, $N(x, 0) = N(x)$ and $T(x, 0) = T(x)$.

Examples of ε-normal and ε-tangent cones are illustrated in Figure 2.1. The set $x + T(x, \varepsilon)$ approximates the feasible region near x, where "near" is with respect to the value of ε. Note that if $I(x, \varepsilon) = \emptyset$, so that $N(x, \varepsilon) = \{\mathbf{0}\}$, then $T(x, \varepsilon) = \mathbb{R}^n$; in other words, if the boundary is more than distance ε away, then the problem looks

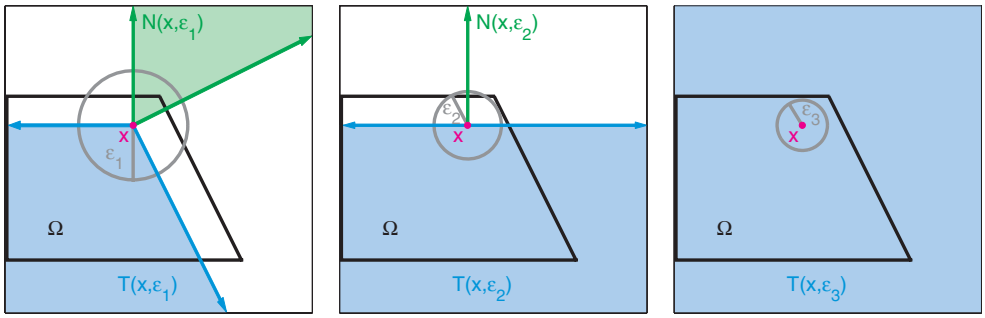

FIG. 2.1. *The cones $N(x,\varepsilon)$ and $T(x,\varepsilon)$ for the values ε_1, ε_2, and ε_3. Note that for this example, as ε varies from ε_1 to 0, there are only the three distinct pairs of cones illustrated ($N(x,\varepsilon_3) = \{\mathbf{0}\}$).*

unconstrained in the ε-neighborhood of x, as can be seen in the third example in Figure 2.1. Observe that one can proceed from x along any direction in $T(x,\varepsilon)$ for a distance of at least ε, and remain inside the feasible region; this is formalized in Proposition 2.2. Overall, the number of *distinct* ε-normal cones (and consequently the number of distinct ε-polar cones) is finite; see Proposition 2.3.

PROPOSITION 2.2. *If $x \in \Omega$, and $v \in T(x,\varepsilon)$ satisfies $\|v\| \leq \varepsilon$, then $x + v \in \Omega$.*

Proof. Let $x \in \Omega$, and $v \in T(x,\varepsilon)$ with $\|v\| \leq \varepsilon$. Since $v \in T(x,\varepsilon) = (N(x,\varepsilon))^\circ$, $a_i^T v \leq 0$ for all $i \in I(x,\varepsilon)$. Thus, $x+v$ satisfies all constraints with $i \in I(x,\varepsilon)$ because

$$a_i^T(x+v) = a_i^T x + a_i^T v \leq b + 0 = b.$$

Meanwhile, if $i \notin I(x,\varepsilon)$, the face $\mathcal{C}_i$ where the ith constraint is binding is more than distance ε away from x. Thus, $x + v \in \Omega$. ∎

PROPOSITION 2.3. *For all $x \in \Omega$ and $\varepsilon > 0$, there are at most 2^m distinct sets $I(x,\varepsilon)$. Consequently, there are at most 2^m distinct cones $N(x,\varepsilon)$ and at most 2^m distinct cones $T(x,\varepsilon)$.*

Proof. Each $I(x_k,\varepsilon_k)$ is a subset of $\{1,\ldots,m\}$, of which there are exactly 2^m possible subsets, including the empty set. The remainder of the proof follows directly from the definitions of $N(x,\varepsilon)$ and $T(x,\varepsilon)$. ∎

2.3. Conditions on the search directions. We now state the conditions on the sets of search directions for GSS for linearly constrained optimization.

At each iteration, a linearly constrained GSS method assembles $\mathcal{D}_k$, the set of search directions. We partition $\mathcal{D}_k$ into two subsets that play different roles in the analysis:

$$\mathcal{D}_k = \mathcal{G}_k \cup \mathcal{H}_k.$$

The set $\mathcal{G}_k$ is required to generate $T(x_k,\varepsilon_k)$ and is called the set of *core directions*. The requirement that the set of search directions contain a set of generators for $T(x_k,\varepsilon_k)$ (which is always $\mathbb{R}^n$ in the unconstrained case) is what led to the name *generating set search* [15].

The (possibly empty) set $\mathcal{H}_k$ accommodates any remaining directions in $\mathcal{D}_k$, the presence of which may prove instrumental in efforts to accelerate the overall progress of the search. For instance, using $\mathcal{H}_k = \{a_i : i \in I(x_k,\varepsilon_k)\}$ can be advantageous computationally [17].

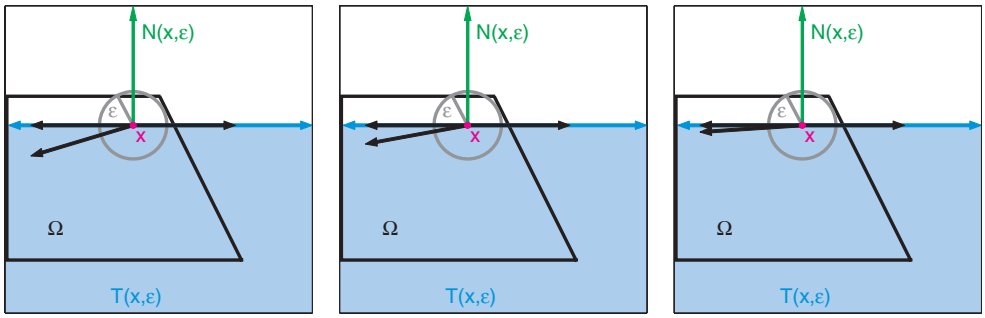

FIG. 2.2. *Condition* 1 *is needed to avoid a sequence of* $\mathcal{G}_k$*'s for which* $\kappa(\mathcal{G}_k) \to 0$.

Our focus here is on the conditions on $\mathcal{G}_k$. The set $\mathcal{H}_k$ accommodates additional directions suggested by heuristics to improve the progress of the search, but has little effect on the analysis. The generating set for $T(x_k, \varepsilon_k)$ contained in $\mathcal{G}_k$ is crucial.

CONDITION 1. There exists a constant $\kappa_{\min} > 0$, independent of k, such that for every k for which $T(x_k, \varepsilon_k) \neq \{\mathbf{0}\}$, the set $\mathcal{G}_k$ generates $T(x_k, \varepsilon_k)$ and satisfies $\kappa(\mathcal{G}_k) \geq \kappa_{\min}$.

Even though there are only finitely many ε-tangent cones $T(x, \varepsilon)$, the set of possible generators for each cone is not necessarily unique, as seen in Figure 2.2. The lower bound $\kappa_{\min}$ from Condition 1 precludes a sequence of $\mathcal{G}_k$'s for which $\kappa(\mathcal{G}_k) \to 0$. Such a situation is depicted in Figure 2.2 for

$$\mathcal{G} = \left\{ \begin{pmatrix} -1 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ -\eta \end{pmatrix} \right\}$$

with three choices of $\eta > 0$. If $-\nabla f(x) = (0, \ -1)^T$, neither of the first two elements of $\mathcal{G}$ are descent directions. Furthermore, since

$$\kappa(\mathcal{G}) \leq \max_{d \in \mathcal{G}} \frac{-\nabla f(x)^T d}{\| \nabla f(x) \| \, \| d \|} = \frac{\eta}{\sqrt{1+\eta^2}} < \eta,$$

the remaining element in $\mathcal{G}$ will be an increasingly poor descent direction if $\eta \to 0$. A nonzero lower bound on $\kappa(\mathcal{G})$, as in Condition 1, will keep the angle between v and at least one generator bounded away from 90°; see [15, sections 2.2 and 3.4.1] for further discussion.

A simple technique to ensure Condition 1 is satisfied is as follows. Let $k_2 > k_1$. If $I(x_{k_2}, \varepsilon_{k_2}) = I(x_{k_1}, \varepsilon_{k_1})$, use the same generators for $T(x_{k_2}, \varepsilon_{k_2})$ as were used for $T(x_{k_1}, \varepsilon_{k_1})$. Recall from Proposition 2.3 that there at most 2^m distinct index sets $I(x, \varepsilon)$ and their corresponding ε-tangent cones $T(x, \varepsilon)$. It then follows that there are at most 2^m distinct sets $\mathcal{G}$ if the same set of generators is always used to generate a particular ε-tangent cone. Since by Proposition 2.1 each $\mathcal{G} \neq \{\mathbf{0}\}$ has a strictly positive value for $\kappa(\mathcal{G})$, and since this technique ensures there are only finitely many $\mathcal{G}_k$'s, we can set $\kappa_{\min} = \min\{\kappa(\mathcal{G}_k) : T(x_k, \varepsilon_k) \neq \{\mathbf{0}\}\}$. Thus, Condition 1 is satisfied.

We have not yet indicated how to compute the generators for a given $T(x_k, \varepsilon_k)$ so as to assemble $\mathcal{G}_k$. If the working set $\{ a_i \mid i \in I(x_k, \varepsilon_k) \}$ is linearly independent, then it is straightforward to calculate the generators of $T(x_k, \varepsilon_k)$ as described in

[25, 19, 17]. If the set $\{ a_i \mid i \in I(x_k, \varepsilon_k) \}$ is linearly dependent (e.g., in the degenerate case), then it is also possible to calculate the generators as described in [17]. In the latter case, the experience reported in [17] suggests that the worst-case computational complexity bounds do not indicate expected performance. For example, for one problem illustrated in [17], the worst-case estimate indicates that more than 4×10^{17} vectors need to be considered when, in fact, only one vector was needed and this one vector was easily identified in less than one-seventh of a second on a conventional workstation using Fukuda's `cddlib` package [9].

Finally, all the core directions must be uniformly bounded; see Condition 2.

CONDITION 2. There exist $\beta_{\max} \geq \beta_{\min} > 0$, independent of k, such that for every k for which $T(x_k, \varepsilon_k) \neq \{\mathbf{0}\}$, the following holds:

$$\beta_{\min} \leq \|d\| \leq \beta_{\max} \qquad \text{for all } d \in \mathcal{G}_k.$$

Condition 2 is easy to satisfy, say, by normalizing all search directions so that $\beta_{\min} = \beta_{\max} = 1$. However, there may be situations where it makes sense to allow the directions in $\mathcal{G}_k$ to accommodate scaling information. This poses no difficulties for the analysis, so long as there are lower and upper bounds, independent of k, on the norm of each $d \in \mathcal{G}_k$.

3. Choosing the step lengths. Given a set of search directions, the length of the step along each direction is dictated by the step-length control parameter Δ_k. In the unconstrained case, the set of trial points at iteration k would be

$$\left\{ x_k + \Delta_k d_k^{(i)} \mid i = 1, \ldots, p_k \right\},$$

where

$$\mathcal{D}_k = \left\{ d_k^{(1)}, d_k^{(2)}, \ldots, d_k^{(p_k)} \right\}.$$

In the constrained case, however, some of those trial points may be infeasible. Thus, the trial points are instead defined by

$$\left\{ x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \mid i = 1, \ldots, p_k \right\},$$

where

$$\tilde{\Delta}_k^{(i)} \in [0, \Delta_k]$$

is chosen so that $x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \in \Omega$. The main requirement on choosing $\tilde{\Delta}_k^{(i)}$ is that a full step is used if possible, as formally stated in the following condition.

CONDITION 3. If $x_k + \Delta_k d_k^{(i)} \in \Omega$, then $\tilde{\Delta}_k^{(i)} = \Delta_k$.

The simplest formula for choosing $\tilde{\Delta}_k^{(i)} \in [0, \Delta_k]$ that satisfies Condition 3 is

$$\tilde{\Delta}_k^{(i)} = \begin{cases} \Delta_k & \text{if } x_k + \Delta_k d_k^{(i)} \in \Omega, \\ 0 & \text{otherwise.} \end{cases} \tag{3.1}$$

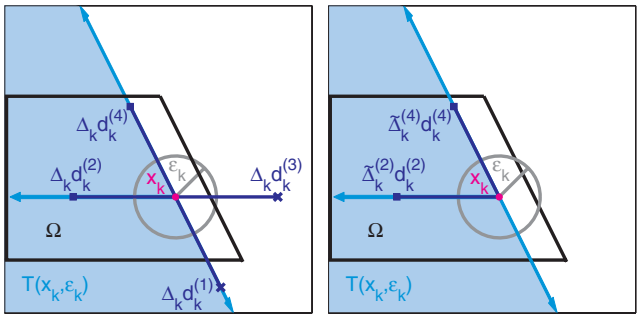

FIG. 3.1. *The step-length control parameter Δ_k may lead to infeasible trial points. The effect of using* (3.1) *is that infeasible points simply are not considered as candidates to replace x_k.*

This corresponds to a form of exact penalization (see [15, section 8.1]) since the effect of (3.1) is to reject (by setting $\tilde{\Delta}_k^{(i)} = 0$) any step $\Delta_k d_k^{(i)}$ that would generate an infeasible trial point. Since the constraints are assumed to be explicit (i.e., A and b are known), verifying the feasibility of a trial point is straightforward. This strategy is illustrated in Figure 3.1.

More sophisticated strategies can be employed for choosing $\tilde{\Delta}_k^{(i)}$ when $x_k + \Delta_k d_k^{(i)}$ is infeasible. Since alternatives for choosing $\tilde{\Delta}_k^{(i)}$ depend on the globalization strategy, we defer the discussion of further examples to section 4.

4. Globalization. Globalization of GSS refers to the conditions that are enforced to ensure that

$$\liminf_{k\to\infty} \Delta_k = 0. \tag{4.1}$$

These conditions affect the decision of whether or not to accept a trial point as the next iterate and how to update Δ_k. Globalization strategies for GSS are discussed in detail in [15, section 3.7]. Here we review those features that are relevant to our analysis of algorithms for the linearly constrained case.

In any GSS algorithm, x_k is always the best feasible point discovered thus far; i.e., $f(x_k) \le f(x_j)$ for all $j \le k$. However, different conditions are imposed on *how much better* a trial point must be to be accepted as the next iterate.

In general, for an iteration to be considered successful we require that

$$\begin{aligned} &x_k + \tilde{\Delta}_k d_k \in \Omega \quad \text{and} \quad f(x_k + \tilde{\Delta}_k d_k) < f(x_k) - \rho(\Delta_k) \\ &\text{for some } d_k \in \mathcal{D}_k \quad \text{and} \quad \tilde{\Delta}_k \in [0, \Delta_k]. \end{aligned} \tag{4.2}$$

The function $\rho(\cdot)$ is called the *forcing function* and must satisfy Condition 4.

CONDITION 4 (general requirements on the forcing function).
1. The function $\rho(\cdot)$ is a nonnegative continuous function on $[0, +\infty)$.
2. The function $\rho(\cdot)$ is $o(t)$ as $t \downarrow 0$; i.e., $\lim_{t\downarrow 0} \rho(t)/t = 0$.
3. The function $\rho(\cdot)$ is nondecreasing; i.e., $\rho(t_1) \le \rho(t_2)$ if $t_1 \le t_2$.

Both $\rho(\Delta) \equiv 0$ and $\rho(\Delta) = \alpha\Delta^p$, where $\alpha > 0$ and $p > 1$, satisfy Condition 4. The first choice also requires globalization via a rational lattice, which is discussed in

section 4.2. The second choice can be used with globalization via a sufficient decrease condition, which is discussed in section 4.1.

In the case of a successful iteration (i.e., one that satisfies (4.2)), the next iterate is defined by

$$x_{k+1} = x_k + \tilde{\Delta}_k d_k \quad \text{for } k \in \mathcal{S}.$$

(Recall from section 1.1 that the set of indices of all successful iterations is denoted by $\mathcal{S}$.) In addition, Δ_k is updated according to

$$\Delta_{k+1} = \phi_k \Delta_k, \ \phi_k \geq 1 \quad \text{for } k \in \mathcal{S}.$$

The parameter ϕ_k is called the *expansion parameter*.

For the kth iteration to be unsuccessful, it must be the case that

$$x_k + \Delta_k d \notin \Omega \ \text{ or } \ f(x_k + \Delta_k d) \geq f(x_k) - \rho(\Delta_k) \text{ for every } d \in \mathcal{G}_k. \tag{4.3}$$

When the iteration is unsuccessful, the best point is unchanged:

$$x_{k+1} = x_k \quad \text{for } k \in \mathcal{U}.$$

(Recall from section 1.1 that the set of indices of all unsuccessful iterations is denoted by $\mathcal{U}$.) In addition, the step-length control parameter is reduced:

$$\Delta_{k+1} = \theta_k \Delta_k, \ \theta_k \in (0, 1) \quad \text{for } k \in \mathcal{U}.$$

The parameter θ_k is called the *contraction parameter*.

There are intimate connections between choosing the ϕ_k or θ_k in the update for Δ_k and guaranteeing that (4.1) holds. Further requirements depend on the particular choice of globalization strategy, and so are given in sections 4.1 and 4.2.

4.1. Globalization via a sufficient decrease condition. In the context of gradient-based nonlinear programming algorithms, the enforcement of a sufficient decrease condition on the step is well established (e.g., [10, 28, 29], or see the discussion in [15, section 2.2]). In the context of gradient-based methods, enforcing a sufficient decrease condition ties the choice of the step-length control parameter to the expected decrease, as estimated by the initial rate of decrease $-\nabla f(x_k)^T d_k$. In the context of GSS methods, the underlying assumption is that the value of $\nabla f(x_k)$ is unavailable—which means that the types of sufficient decrease conditions often used with gradient-based methods cannot be enforced. However, in [11] an alternative that uses the step-length control parameter, rather than $\nabla f(x_k)$, was introduced and analyzed in the context of linesearch methods for unconstrained minimization. In [21, 22, 23, 24], this basic concept was then extended to both unconstrained and constrained versions of what we here refer to as GSS methods. We now review the essential features of this approach.

Within the context of GSS methods for linearly constrained optimization, a sufficient decrease globalization strategy requires the following of the forcing function $\rho(\cdot)$ and the choice of the contraction parameter θ_k.

> CONDITION 5 (the forcing function for sufficient decrease).
> The forcing function $\rho(\cdot)$ is such that $\rho(t) > 0$ for $t > 0$.

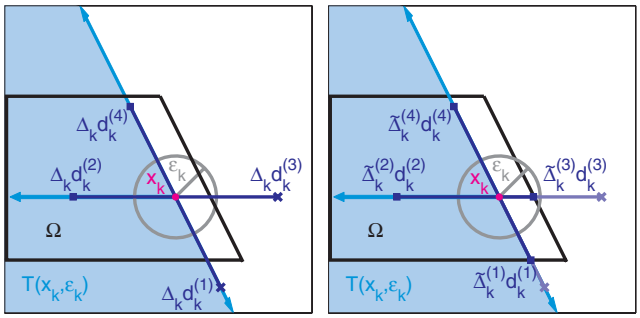

FIG. 4.1. *Observe in the second illustration that globalization via a sufficient decrease condition makes it possible to avoid infeasible trial points by simply stopping at the boundary of* Ω.

CONDITION 6 (contracting Δ_k for sufficient decrease).
A constant $\theta_{\max} < 1$ exists such that $\theta_k \leq \theta_{\max}$ for all k.

Full details are discussed in [15, section 3.7.1], but we include a few salient observations here. The requirements of Condition 5 are easily satisfied by choosing, say, $\rho(\Delta) = 10^{-4}\Delta^2$, while the requirements of Condition 6 are easily satisfied by choosing, say, $\theta_k = \frac{1}{2}$ for all k. The upper bound on the contraction factor θ_k ensures a predictable fraction of reduction on Δ_k at the conclusion of an unsuccessful iteration.

If a sufficient decrease condition is being employed, then we can use an alternative to the exact penalization strategy, given in (3.1), for choosing $\tilde{\Delta}_k^{(i)}$ when $x_k + \Delta_k d_k^{(i)} \notin \Omega$: simply find the step to the nearest constraint from x_k along $d_k^{(i)}$. This is a well-known technique in nonlinear programming (see, for instance, [10, section 5.2] or [28, section 15.4]). In other words, compute $\tilde{\Delta}_k^{(i)}$ as the maximum nonnegative feasible step along $d_k^{(i)}$. This option is illustrated in Figure 4.1.

4.2. Globalization via a rational lattice. Traditionally, direct search methods have relied on simple, as opposed to sufficient, decrease when accepting a step [33]. In other words, it is enough for the step $\tilde{\Delta}_k^{(i)} d_k^{(i)}$ to satisfy $f(x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)}) < f(x_k)$. The trade-off is that when the condition for accepting a step is relaxed to admit simple decrease, further restrictions are required on the types of steps that are allowed. These restrictions are detailed in Conditions 7, 8, and 9.

CONDITION 7 (choosing the directions for the rational lattice).
Let $\mathbf{G} = \cup_{k=0}^{\infty} \mathcal{G}_k$.
1. The set $\mathbf{G}$ is finite and so can be written as $\mathbf{G} = \{g^{(1)}, \ldots, g^{(p)}\}$.
2. Every vector $g \in \mathbf{G}$ is of the form $g \in \mathbb{Z}^n$, where $\mathbb{Z}$ is the set of integers.
3. Every vector $h \in \mathcal{H}_k$ is of the form $h \in \mathbb{Z}^n$.

CONDITION 8 (expanding or contracting Δ_k for the rational lattice).
1. The scalar τ is a fixed rational number strictly greater than 1.
2. For all $k \in \mathcal{S}$, ϕ_k is of the form $\phi_k = \tau^{\ell_k}$, where $\ell_k \in \{0, \dots, L\}$, $L \geq 0$.
3. For all $k \in \mathcal{U}$, θ_k is of the form $\theta_k = \tau^{m_k}$, where $m_k \in \{M, \dots, -1\}$, $M \leq -1$.

CONDITION 9 (choosing the steps for the rational lattice).
$\tilde{\Delta}_k^{(i)}$ satisfies either $\tilde{\Delta}_k^{(i)} = 0$ or $\tilde{\Delta}_k^{(i)} = \tau^{\tilde{m}_k^{(i)}} \Delta_k$, where $\tilde{m}_k^{(i)} \in \{\tilde{M}, \dots, 0\}$, $\tilde{M} \leq 0$.

While the list of requirements in Conditions 7, 8, and 9 looks onerous, they can be satisfied in a straightforward fashion. A discussion of the reasons for these conditions can be found in [19, sections 3.4, 4, and 5]. (A detailed discussion of the rational lattice globalization strategy for the unconstrained case can be found in [15, section 3.7.2].) Here we make only a few pertinent observations.

First, a critical consequence of Conditions 7 and 8 is that when these two conditions are enforced, along with the exact penalization strategy in (3.1), Theorem 5.1 in [19] ensures that all iterates lie on a rational lattice. This fact plays a crucial role in guaranteeing (4.1) when only simple decrease is enforced. Condition 9 is a straightforward extension that preserves the fact that all the iterates lie on a rational lattice while relaxing the exact penalization strategy in (3.1) (an example is shown in Figure 4.2).

Obtaining a finite $\mathbf{G}$ to satisfy part 1 of Condition 7 can be done by following the procedure outlined in section 2.3 (i.e., if $I(x_{k_2}, \varepsilon_{k_2}) = I(x_{k_1}, \varepsilon_{k_1})$ for $k_2 > k_1$, then use the same generators for $T(x_{k_2}, \varepsilon_{k_2})$ as were used for $T(x_{k_1}, \varepsilon_{k_1})$). To satisfy part 2, a standard assumption in the context of simple decrease is that the linear constraints are rational, i.e., $A \in \mathbb{Q}^{m \times n}$, where $\mathbb{Q}$ denotes the set of rational numbers. By clearing denominators, it is then possible—with some care—to obtain a set of integral vectors to generate all possible ε-tangent cones; see [19, section 8] for further discussion. Part 3 is enforced directly.

In Condition 8, the usual choice of τ is 2. The parameter ϕ_k typically is chosen to be 1 so that $\ell_k = 0$ for all k, satisfying the requirement placed on ϕ_k in Condition 8. Usually θ_k is chosen to be $\frac{1}{2}$ so that $m_k = -1$ for all k, satisfying the requirement placed on θ_k in Condition 8. The fact that τ^{-1} is the largest possible choice of θ_k obviates the need to explicitly bound θ_k from above, as was required in Condition 6 for sufficient decrease.

Condition 9 says that it is possible to choose a partial step along a given direction so long as the trial point remains on a rational lattice. One strategy is illustrated in Figure 4.2. Starting with the situation illustrated on the left, along direction $d^{(1)}$, $\tilde{\Delta}_k^{(1)} = 0.5\Delta_k$ yields the feasible trial step $\tilde{\Delta}_k^{(1)} d^{(1)}$ while along direction $d^{(3)}$, $\tilde{\Delta}_k^{(3)} = 0.25\Delta_k$ yields the feasible trial step $\tilde{\Delta}_k^{(3)} d^{(3)}$, as illustrated on the right. These choices for $\tilde{\Delta}_k^{(1)}$ and $\tilde{\Delta}_k^{(3)}$ correspond to choosing $m_k^{(1)} = -1$ and $m_k^{(3)} = -2$, with $\tau = 2$ and $\tilde{M} = -2$.

The general strategy is to find the largest $\tilde{\Delta}_k^{(i)}$ (by finding the largest $m_k^{(i)}$) such that $x_k + \tilde{\Delta}_k^{(i)} d_k^{(i)} \in \Omega$ while satisfying Condition 9. To do so, either reduce Δ_k by a

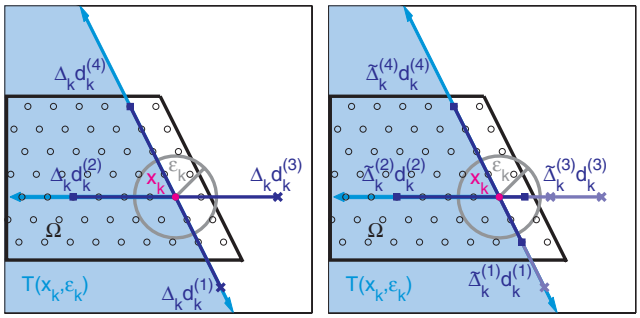

FIG. 4.2. *Globalization via a rational lattice means that the trial points lie on the rational lattice that exists as a consequence of Conditions 7–9. For this example note that while the two reduced steps are near the boundary, the requirement that they remain on the rational lattice means that they may not be on the boundary.*

factor of $1/\tau$ until

$$x_k + \tau^{m_k^{(i)}} \Delta_k d_k^{(i)} \in \Omega \quad \text{with } m_k^{(i)} \geq \tilde{M} \tag{4.4}$$

or set $\tilde{\Delta}_k^{(i)} = 0$ if it is not possible to satisfy (4.4) (for instance, when x_k is on the boundary of the feasible region then *any* step along $d_k^{(i)}$ would be infeasible).

5. GSS algorithms for linearly constrained problems. We now formally state two GSS algorithms for solving linearly constrained optimization problems. The fundamental requirement for both algorithms is that at every iteration k, the set of search directions $\mathcal{D}_k$ must include a set of generators $\mathcal{G}_k$ for the ε-normal cone $T(x_k, \varepsilon_k)$—hence the name *generating set search* methods. The primary requirements on the GSS methods presented here are that they satisfy Conditions 1, 2, 3, and 4. The differences in the two versions given depend on the type of globalization that is used: sufficient decrease in Algorithm 5.1 versus simple decrease in Algorithm 5.2. Sufficient decrease requires Conditions 5 and 6. Simple decrease admits the choice $\rho(\cdot) \equiv 0$, but requires Conditions 7, 8, and 9 in lieu of Conditions 5 and 6.

New in the statements of Algorithms 5.1 and 5.2, and to the analysis that follows, is the way in which ε_k is defined, which has bearing on the construction of the critical set $\mathcal{G}_k \subseteq \mathcal{D}_k$. Here we set $\varepsilon_k = \min\{\varepsilon_{\max}, \beta_{\max}\Delta_k\}$. This selection of ε_k differs from that used in either [19] or [24]. Specifically, in [19] and Algorithm 2 of [24]—as well as earlier in [25], in a slightly restricted form—$\mathcal{G}_k$ is required to contain generators for $T(x_k, \varepsilon)$ for all ε in the interval $[0, \varepsilon_{\max}]$, with $\varepsilon_{\max} > 0$. This means that $\mathcal{G}_k$ may need to contain generators for multiple cones rather than a single cone. Since Δ_k can be reduced only at the conclusion of an unsuccessful iteration, and an unsuccessful iteration requires the verification of (4.3), there is practical incentive to try and keep the cardinality of $\mathcal{G}_k$ manageable when the cost of computing $f(x)$ for $x \in \Omega$ is appreciable. Thus, Algorithm 1 in [24] first introduced the potential for a smaller set of search directions: the set of search directions must exactly generate $T(x_k, \varepsilon_k)$—and *only* $T(x_k, \varepsilon_k)$. Using our notation, this means that $\mathcal{H}_k = \emptyset$ for all k. Furthermore, for Algorithm 1 in [24], ε_k is simply a parameter decreased at unsuccessful iterations as opposed to the particular choice of ε_k given here.

Our requirement that the search directions include generators for $T(x_k, \varepsilon_k)$, with $\varepsilon_k = \min\{\varepsilon_{\max}, \beta_{\max}\Delta_k\}$, is a compromise. On the one hand, it may significantly

ALGORITHM 5.1. LINEARLY CONSTRAINED GSS USING A SUFFICIENT DECREASE GLOBALIZATION STRATEGY

INITIALIZATION.

Let $x_0 \in \Omega$ be the initial guess.

Let $\Delta_{\text{tol}} > 0$ be the tolerance used to test for convergence.

Let $\Delta_0 > \Delta_{\text{tol}}$ be the initial value of the step-length control parameter.

Let $\varepsilon_{\max} > \beta_{\max}\Delta_{\text{tol}}$ be the maximum distance used to identify nearby constraints ($\varepsilon_{\max} = +\infty$ is permissible).

Let $\rho(\cdot)$ be a forcing function satisfying Conditions 4 and 5.

ALGORITHM. For each iteration $k = 0, 1, 2, \ldots$

STEP 1. Let $\varepsilon_k = \min\{\varepsilon_{\max}, \beta_{\max}\Delta_k\}$. Choose a set of search directions $\mathcal{D}_k = \mathcal{G}_k \cup \mathcal{H}_k$ satisfying Conditions 1 and 2.

STEP 2. If there exists $d_k \in \mathcal{D}_k$ and a corresponding $\tilde{\Delta}_k \in [0, \Delta_k]$ satisfying Condition 3 such that $x_k + \tilde{\Delta}_k d_k \in \Omega$ and

$$f(x_k + \tilde{\Delta}_k d_k) < f(x_k) - \rho(\Delta_k),$$

then:

- Set $x_{k+1} = x_k + \tilde{\Delta}_k d_k$.
- Set $\Delta_{k+1} = \phi_k \Delta_k$ for any choice of $\phi_k \geq 1$.

STEP 3. Otherwise, for every $d \in \mathcal{G}_k$, either $x_k + \Delta_k d \notin \Omega$ or

$$f(x_k + \Delta_k d) \geq f(x_k) - \rho(\Delta_k).$$

In this case:

- Set $x_{k+1} = x_k$ (no change).
- Set $\Delta_{k+1} = \theta_k \Delta_k$ for some choice $\theta_k \in (0, 1)$ satisfying Condition 6.

If $\Delta_{k+1} < \Delta_{\text{tol}}$, then terminate.

FIG. 5.1. *Linearly constrained GSS using a sufficient decrease globalization strategy.*

decrease the number of directions in $\mathcal{G}_k$ over that needed when $\mathcal{G}_k$ is required to contain generators for $T(x_k, \varepsilon)$ for all ε in the interval $[0, \varepsilon_{\max}]$. On the other hand, it allows $\mathcal{H}_k \neq \emptyset$—the set of search directions can be augmented in an effort to accelerate the search—without adversely affecting the convergence guarantees for the algorithm.

Yoking the value of ε_k to the value of Δ_k has geometrical motivations. Once Δ_k is small enough, so that $\varepsilon_k = \beta_{\max}\Delta_k$, full steps along directions in $\mathcal{G}_k$ will be feasible, as Figure 2.1 demonstrates.

There is an intuitive practical appeal to allowing—while not requiring—$\mathcal{D}_k$ to

ALGORITHM 5.2. LINEARLY CONSTRAINED GSS USING A RATIONAL LATTICE GLOBALIZATION STRATEGY

INITIALIZATION.

Let $x_0 \in \Omega$ be the initial guess.

Let $\Delta_{\text{tol}} > 0$ be the tolerance used to test for convergence.

Let $\Delta_0 > \Delta_{\text{tol}}$ be the initial value of the step-length control parameter.

Let $\varepsilon_{\max} > \beta_{\max}\Delta_{\text{tol}}$ be the maximum distance used to identify nearby constraints ($\varepsilon_{\max} = +\infty$ is permissible).

Let $\rho(\cdot)$ be a forcing function satisfying Condition 4, e.g., $\rho(\cdot) \equiv 0$ is typical.

ALGORITHM. For each iteration $k = 0, 1, 2, \ldots$

STEP 1. Let $\varepsilon_k = \min\{\varepsilon_{\max}, \beta_{\max}\Delta_k\}$. Choose a set of search directions $\mathcal{D}_k = \mathcal{G}_k \cup \mathcal{H}_k$ satisfying Conditions 1, 2, and 7.

STEP 2. If there exists $d_k \in \mathcal{D}_k$ and a corresponding $\tilde{\Delta}_k \in [0, \Delta_k]$ satisfying Conditions 3 and 9 such that $x_k + \tilde{\Delta}_k d_k \in \Omega$ and

$$f(x_k + \tilde{\Delta}_k d_k) < f(x_k) - \rho(\Delta_k),$$

then:

- Set $x_{k+1} = x_k + \tilde{\Delta}_k d_k$.
- Set $\Delta_{k+1} = \phi_k \Delta_k$ for a choice of $\phi_k \geq 1$ satisfying Condition 8.

STEP 3. Otherwise, for every $d \in \mathcal{G}_k$, either $x_k + \Delta_k d \notin \Omega$ or

$$f(x_k + \Delta_k d) \geq f(x_k) - \rho(\Delta_k).$$

In this case:

- Set $x_{k+1} = x_k$ (no change).
- Set $\Delta_{k+1} = \theta_k \Delta_k$ for some choice $\theta_k \in (0, 1)$ satisfying Condition 8.

If $\Delta_{k+1} < \Delta_{\text{tol}}$, then terminate.

FIG. 5.2. *Linearly constrained GSS using a rational lattice globalization strategy.*

include more search directions. Note that if $T(x_k, \varepsilon_k) \neq \{\mathbf{0}\}$, then the directions in $\mathcal{G}_k$ will move the search along directions that are in some sense "parallel" (the situation is more complicated for $n > 2$) to the faces of the polyhedron that have been identified by the working set. This is best seen in the illustration on the left in Figure 2.1. Intuitively, it makes sense to also allow the search to move *toward* the faces of the polyhedron that have been identified by the working set—particularly

when the solution lies on the boundary of the feasible region. Such intuition is borne out by the numerical results reported in [17].

Before proceeding, we note a technical difference between the presentation of the algorithms in Algorithms 5.1 and 5.2 and what is assumed for the analysis in section 6. In practice, GSS algorithms terminate when the step-length control parameter Δ_k falls below a given threshold $\Delta_{\text{tol}} > 0$. Because this is important to any implementation, we have included it in the statement of the algorithm. In Theorems 6.3, 6.4, and 6.5, however, we assume that the iterations continue ad infinitum (i.e., in the context of the analysis, the reader should assume $\Delta_{\text{tol}} = 0$).

5.1. GSS using a sufficient decrease condition. A linearly constrained GSS algorithm based on a sufficient decrease globalization strategy is presented in Algorithm 5.1. Using a sufficient decrease globalization strategy, as outlined in section 4.1, requires that we enforce two particular conditions. Condition 5 ensures that $\rho(\Delta_k) = 0$ only when $\Delta_k = 0$. Condition 6 ensures that there is sufficient reduction on Δ_k at unsuccessful iterations.

The only assumption on f necessary to show that some subsequence of $\{\Delta_k\}$ converges to zero is that f be bounded below in the feasible region.

THEOREM 5.1 (see Theorem 3.4 of [15]). *Suppose f is bounded below on Ω. Then for a linearly constrained GSS method using a sufficient decrease globalization strategy satisfying Conditions* 4, 5, *and* 6 (*as outlined in Algorithm* 5.1), $\liminf_{k\to\infty} \Delta_k = 0$.

5.2. GSS using a rational lattice. A linearly constrained GSS algorithm based on a rational lattice globalization strategy is presented in Algorithm 5.2. The choice $\rho(\cdot) \equiv 0$ is standard for the rational lattice globalization strategy, which means only simple decrease, i.e., $f(x_k + \tilde{\Delta}_k d_k) < f(x_k)$, is required. We note, however, that a sufficient decrease condition may be employed in conjunction with a rational lattice globalization strategy; see [15, section 3.7.2]. The choice $\rho(\cdot) \equiv 0$ also means that Condition 4 is satisfied automatically. The trade-off for using simple decrease is that additional conditions must be imposed on the choice of admissible $\mathcal{D}_k$ (Condition 7), ϕ_k and θ_k (Condition 8), and $\tilde{\Delta}_k$ (Condition 9).

Using a rational lattice globalization strategy, to show that some subsequence of the step-length control parameters goes to zero, the only assumption placed on f is that the set $\mathcal{F} = \{\, x \in \Omega \mid f(x) \le f(x_0) \,\}$ be bounded. This is a stronger condition on f than is needed when using a sufficient decrease globalization strategy, where all that is required is that f be bounded below. The analysis for the rational lattice globalization strategy requires the sequence $\{x_k\}$ to remain in a bounded set so as to ensure that there is a finite number of lattice points to consider. We could adopt this weaker assumption, though it is not clear how it would be enforced in practice. Instead, assuming that $\mathcal{F}$ is bounded guarantees this requirement.

THEOREM 5.2 (see Theorem 6.5 of [19]). *Assume that $\mathcal{F} = \{x \in \Omega \mid f(x) \le f(x_0)\}$ is bounded and that $A \in \mathbb{Q}^{m\times n}$, where $\mathbb{Q}$ denotes the set of rational numbers. Then for a linearly constrained GSS method using a rational lattice globalization strategy satisfying Conditions* 4, 7, 8, *and* 9 (*as outlined in Algorithm* 5.2), $\liminf_{k\to\infty} \Delta_k = 0$.

6. Stationarity results. At *unsuccessful* iterations of the linearly constrained GSS methods outlined in Algorithms 5.1 and 5.2, we can bound the measure of stationarity $\chi(x_k)$ in terms of Δ_k. To do so, we make the following assumptions.

ASSUMPTION 6.1. *The set* $\mathcal{F} = \{ x \in \Omega \mid f(x) \leq f(x_0) \}$ *is bounded.*

ASSUMPTION 6.2. *The gradient of* f *is Lipschitz continuous with constant* M *on* Ω.

If Assumptions 6.1 and 6.2 hold, then there exists $\gamma > 0$ such that for all $x \in \mathcal{F}$,

$$\| \nabla f(x) \| < \gamma. \tag{6.1}$$

We then have the following results for the algorithms in Algorithms 5.1 and 5.2. Recall from section 2.1 that given a convex cone K and any vector v, we denote the projection of v onto K by v_K.

THEOREM 6.3. *Suppose that Assumption* 6.2 *holds. Consider the linearly constrained GSS algorithms given in Algorithms* 5.1 *and* 5.2*, both of which satisfy Conditions* 1*,* 2*, and* 3*. If* $k \in \mathcal{U}$ *and* ε_k *satisfies* $\varepsilon_k = \beta_{\max}\Delta_k$*, then*

$$\| [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \| \leq \frac{1}{\kappa_{\min}} \left(M\Delta_k\beta_{\max} + \frac{\rho(\Delta_k)}{\Delta_k\beta_{\min}} \right). \tag{6.2}$$

Here, $\kappa_{\min}$ *is from Condition* 1*,* M *is from Assumption* 6.2*, and* $\beta_{\max}$ *and* $\beta_{\min}$ *are from Condition* 2*.*

Proof. Clearly, we need only consider the case when $[-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \neq 0$. Condition 1 guarantees a set $\mathcal{G}_k$ that generates $T(x_k, \varepsilon_k)$. By (2.1) (with $K = T(x_k, \varepsilon_k)$ and $v = -\nabla f(x_k)$) there exists some $\hat{d} \in \mathcal{G}_k$ such that

$$\kappa(\mathcal{G}_k) \, \| [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \| \, \| \hat{d} \| \leq -\nabla f(x_k)^T \hat{d}. \tag{6.3}$$

Condition 3 and the fact that iteration k is unsuccessful tell us that

$$f(x_k + \Delta_k d) \geq f(x_k) - \rho(\Delta_k) \quad \text{for all } d \in \mathcal{G}_k \quad \text{for which } x_k + \Delta_k d \in \Omega.$$

Condition 2 ensures that for all $d \in \mathcal{G}_k$, $\| \Delta_k d \| \leq \Delta_k \beta_{\max}$ and, by assumption, $\Delta_k\beta_{\max} = \varepsilon_k$, so we have $\| \Delta_k d \| \leq \varepsilon_k$ for all $d \in \mathcal{G}_k$. Proposition 2.2 then assures us that $x_k + \Delta_k d \in \Omega$ for all $d \in \mathcal{G}_k$. Thus,

$$f(x_k + \Delta_k d) - f(x_k) + \rho(\Delta_k) \geq 0 \quad \text{for all } d \in \mathcal{G}_k. \tag{6.4}$$

Meanwhile, since the gradient of f is assumed to be continuous (Assumption 6.2), we can apply the mean value theorem to obtain, for some $\alpha_k \in (0, 1)$,

$$f(x_k + \Delta_k d) - f(x_k) = \Delta_k \nabla f(x_k + \alpha_k \Delta_k d)^T d \quad \text{for all } d \in \mathcal{G}_k.$$

Putting this together with (6.4),

$$0 \leq \Delta_k \nabla f(x_k + \alpha_k \Delta_k d)^T d + \rho(\Delta_k) \quad \text{for all } d \in \mathcal{G}_k.$$

Dividing through by Δ_k and subtracting $\nabla f(x_k)^T d$ from both sides yields

$$-\nabla f(x_k)^T d \leq \left(\nabla f(x_k + \alpha_k \Delta_k d) - \nabla f(x_k)\right)^T d + \rho(\Delta_k)/\Delta_k \quad \text{for all } d \in \mathcal{G}_k.$$

Since $\nabla f(x)$ is Lipschitz continuous (Assumption 6.2) and $0 < \alpha_k < 1$, we obtain

$$-\nabla f(x_k)^T d \le M\Delta_k \| d \|^2 + \rho(\Delta_k)/\Delta_k \quad \text{for all } d \in \mathcal{G}_k. \tag{6.5}$$

Since (6.5) holds for all $d \in \mathcal{G}_k$, (6.3) tells us that for some $\hat{d} \in \mathcal{G}_k$,

$$\kappa(\mathcal{G}_k) \, \| \, [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \, \| \le M\Delta_k \| \, \hat{d} \, \| + \frac{\rho(\Delta_k)}{\Delta_k \, \| \, \hat{d} \, \|}.$$

Using the bounds on $\| \, \hat{d} \, \|$ in Condition 2,

$$\| \, [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \, \| \le \frac{1}{\kappa(\mathcal{G}_k)} \left(M\Delta_k \beta_{\max} + \frac{\rho(\Delta_k)}{\Delta_k \beta_{\min}} \right).$$

The theorem then follows from the fact that $\kappa(\mathcal{G}_k) \ge \kappa_{\min}$ (Condition 1). ∎

Theorem 6.4 relates the measure of stationarity $\chi(x_k)$ to the step-length control parameter Δ_k. Before we proceed, we define the following constant (recall that $\kappa(\cdot)$ is defined in (2.1)):

$$\nu_{\min} = \min \left\{ \kappa(\mathcal{A}) : \mathcal{A} = \cup_{i \in I(x,\varepsilon)} \{a_i\}, \; x \in \Omega, \; \varepsilon \ge 0, \; I(x,\varepsilon) \ne \emptyset \right\} > 0. \tag{6.6}$$

We know that $\nu_{\min} > 0$ because there are no more than 2^m possibilities for $\mathcal{A}$.

THEOREM 6.4. *Suppose that Assumptions* 6.1 *and* 6.2 *hold. Consider the linearly constrained GSS algorithms given in Algorithms* 5.1 *and* 5.2*, both of which satisfy Conditions* 1*,* 2*, and* 3*. If $k \in \mathcal{U}$ and $\varepsilon_k = \beta_{\max}\Delta_k$, then*

$$\chi(x_k) \le \left(\frac{M}{\kappa_{\min}} + \frac{\gamma}{\nu_{\min}} \right) \Delta_k \, \beta_{\max} + \frac{1}{\kappa_{\min} \, \beta_{\min}} \frac{\rho(\Delta_k)}{\Delta_k}. \tag{6.7}$$

Here, $\kappa_{\min}$ is from Condition 1*, $\nu_{\min}$ is from* (6.6)*, M is from Assumption* 6.2*, γ is from* (6.1)*, and $\beta_{\max}$ and $\beta_{\min}$ are from Condition* 2*.*

Proof. Since $\varepsilon_k = \Delta_k \beta_{\max}$, Proposition B.2 tells us that

$$\chi(x_k) \le \| \, [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \, \| + \frac{\Delta_k \beta_{\max}}{\nu_{\min}} \, \| \, [-\nabla f(x_k)]_{N(x_k,\varepsilon_k)} \, \|.$$

Furthermore, the bound on $\| \, [-\nabla f(x_k)]_{T(x_k,\varepsilon_k)} \, \|$ from Theorem 6.3 holds. The projection onto convex sets is contractive, so $\| \, [-\nabla f(x_k)]_{N(x_k,\varepsilon_k)} \, \| \le \| \, \nabla f(x_k) \, \|$. Under Assumptions 6.1 and 6.2, (6.1) holds, so $\| \, [-\nabla f(x_k)]_{N(x_k,\varepsilon_k)} \, \| \le \gamma$. The result follows. ∎

If we choose either $\rho(\Delta) \equiv 0$ or $\rho(\Delta) = \alpha\Delta^p$ with $\alpha > 0$ and $p \ge 2$, then we obtain an estimate of the form $\chi(x_k) = O(\Delta_k)$.

The constants M, γ, and $\nu_{\min}$ in (6.7) are properties of the linearly constrained optimization problem. The remaining quantities—the bounds on the lengths of the search directions $\beta_{\min}$ and $\beta_{\max}$, as well as $\kappa_{\min}$—are under the control of the algorithm.

Before continuing, we observe that the Lipschitz assumption (Assumption 6.2) can be relaxed. A similar bound can be obtained assuming only continuous differentiability of f. Let ω denote the following modulus of continuity of $\nabla f(x)$: given $x \in \Omega$ and $r > 0$,

$$\omega(x,r) = \max \{ \| \, \nabla f(y) - \nabla f(x) \, \| \;\mid\; y \in \Omega, \; \| \, y - x \, \| \le r \}.$$

Then the proof of Theorem 6.4 yields the bound

$$\chi(x_k) \leq \frac{1}{\kappa_{\min}} \omega(x_k, \Delta_k \beta_{\max}) + \frac{\gamma}{\nu_{\min}} \Delta_k \beta_{\max} + \frac{1}{\kappa_{\min} \beta_{\min}} \frac{\rho(\Delta_k)}{\Delta_k}.$$

Returning to Theorem 6.4, if we recall from Theorems 5.1 and 5.2 that the step-length control parameter Δ_k is manipulated explicitly by GSS methods in a way that ensures $\liminf_{k\to\infty} \Delta_k = 0$, then an immediate corollary is the following first-order convergence result.

THEOREM 6.5. *Suppose that Assumptions* 6.1 *and* 6.2 *hold. Consider either*

(i) *the linearly constrained GSS algorithm in Algorithm* 5.1*, which satisfies Conditions* 1*,* 2*,* 3*,* 4*,* 5*, and* 6*, or*

(ii) *the linearly constrained GSS algorithm in Algorithm* 5.2*, which satisfies Conditions* 1*,* 2*,* 3*,* 4*,* 7*,* 8*, and* 9*, with the additional assumption that A is rational.*

For both algorithms we have $\liminf_{k\to+\infty} \chi(x_k) = 0$.

7. Using Δ_k to terminate GSS methods after unsuccessful iterations. We now present some numerical illustrations of the practical implications of Theorem 6.4. We show that Δ_k can be used as a reasonable measure of stationarity when implementing GSS methods to solve linearly constrained minimization problems. The results in section 6 serve as a justification for terminating the search when $\Delta_k < \Delta_{\text{tol}}$.

To demonstrate that Δ_k is a reasonable measure of stationarity, we show the following results from experiments using an implementation of a GSS method for solving linearly constrained optimization problems (a thorough discussion of the implementation, as well as further numerical results, can be found in [17]).

The first test problem is the following quadratic program (QP) for $n = 8$:

$$\begin{array}{ll} \text{minimize} & f(x) = \sum_{j=1}^{n} j^2 x_j^2 \\ \text{subject to} & 0 \leq x \leq 1, \\ & \sum_{j=1}^{n} x_j \geq 1, \end{array} \tag{7.1}$$

where x_j is the jth component of the vector x. The last constraint is binding at the solution. The second test problem is posed on a pyramid in $\mathbb{R}^3$:

$$\begin{array}{ll} \text{minimize} & f(x) = \sum_{j=1}^{3} [(4-j)^2 (x_j - c_j)^2 - x_j] \\ \text{subject to} & x_3 \geq 0, \\ & x_1 + x_2 + x_3 \leq 1, \\ & x_1 - x_2 + x_3 \leq 1, \\ & -x_1 + x_2 + x_3 \leq 1, \\ & -x_1 - x_2 + x_3 \leq 1, \end{array} \tag{7.2}$$

with $c = (0.01, 0.01, 0.98)^T$. Again, x_j and c_j are the jth components of the vectors x and j, respectively. The solution is at c, which is near the apex of the pyramid. The algorithm actually visits the apex, which is a degenerate vertex insofar as there are four constraints in three variables that meet there.

These two problems were solved using the implementation of Algorithm 5.1 reported in [17]. The forcing function was $\rho(\Delta) = 10^{-4}\Delta^2$. The set of search directions $\mathcal{D}_k$ contained both the set $\mathcal{G}_k$, the generators for the ε-tangent cone $T(x_k, \varepsilon_k)$, as well as the set $\mathcal{H}_k$, which contained the nonzero generators for the ε-normal cone $N(x_k, \varepsilon_k)$.

All search directions were normalized, so $\beta_{\min} = \beta_{\max} = 1$. For these choices, Theorem 6.4 says that $\chi(x_k) = O(\Delta_k)$ at unsuccessful iterations when $\Delta_k \leq \varepsilon_{\max}$.

We used $\theta_k = \frac{1}{2}$ and $\phi_k = 1$ for all k. After any unsuccessful iteration, we recorded the value of Δ_k and computed the value of $\chi(x_k)$. These values are reported in Table 7.1 for unsuccessful iterations with $\varepsilon_k = \Delta_k \beta_{\max}$.

(b) The QP in (7.2).

The point of the results reported in Table 7.1 is not to demand close scrutiny of each entry but rather to demonstrate the trend in the quantities measured. We clearly see the linear relationship between Δ_k and $\chi(x_k)$ that Theorem 6.4 tells us to expect. These results are consistent with findings for the unconstrained case [8] as well as with a long-standing recommendation for using Δ_k as a stopping criterion for direct search methods (see [14, 3, 32]).

One practical benefit of using Δ_k as a measure of stationarity is that it is already present in GSS algorithms; no additional computation is required.

We close with the observation that the effectiveness of Δ_k as a measure of stationarity clearly depends on the value of the constants in the bound in (6.7). For instance, if f is highly nonlinear, so that the Lipschitz constant M is large, then using Δ_k to estimate $\chi(x_k)$ might be misleading. While GSS methods cannot control M, γ, or $\nu_{\min}$, which depend on the linearly constrained optimization problem, a careful implementation of GSS methods for solving linearly constrained optimization problems can control the remaining constants in (6.7). Thus a careful implementation can ensure that Δ_k is a useful measure of stationarity except when f is highly nonlinear (i.e., M

is large with respect to $\| \nabla f \|$) or A is ill-conditioned.

8. Conclusions. The results we have presented are useful in several ways. First, we present a new prescription for how the search directions should conform to the boundary near an iterate x_k. Theorems 6.3 and 6.4 bring out many of the elements common to the approaches described in [18, 19] and [23, 24]. Although the globalization approaches that ensure $\liminf_{k\to\infty} \Delta_k = 0$ differ, the same analysis shows that for both classes of algorithms,

$$\chi(x_k) = O(\Delta_k).$$

This result does not depend on the method of globalization.

Second, the results presented here give theoretical support for terminating GSS methods for linearly constrained optimization when Δ_k falls below some tolerance. Under the assumptions of Theorem 6.4, at the subsequence of unsuccessful iterations ($k \in \mathcal{U}$) we have $\chi(x_k) = O(\Delta_k)$ as $\Delta_k \to 0$. At the same time, Theorem 6.4 also suggests that this stopping criterion may be unsuitable if the objective is highly nonlinear, making clear the need for direct search methods, like all optimization algorithms, to account for scaling.

Theorem 6.3 underlies the use of linearly constrained GSS methods in the augmented Lagrangian framework given in [5]. The latter proceeds by successive approximate minimization of an augmented Lagrangian. The stopping criterion in the subproblems involves the norm of the projection onto $T(x_k, \omega_k)$ of the negative gradient of the augmented Lagrangian, for a parameter $\omega_k \downarrow 0$. In the direct search setting the gradient is unavailable. However, Theorem 6.3 enables us to use Δ_k as an alternative measure of stationarity in the subproblems. Details appear in [16].

Appendix A. Criticality measure for first-order constrained stationarity. Here we discuss $\chi(x)$ and $\| q(x) \|$ in more detail. Because these measures are not novel, we have relegated their discussion to an appendix.

For $x \in \Omega$, progress toward a KKT point of (1.1) is measured by

$$\chi(x) \equiv \max_{\substack{x+w\in\Omega \\ \| w \| \le 1}} -\nabla f(x)^T w. \tag{A.1}$$

This measure was originally proposed in [5] and is discussed at length in section 12.1.4 of [6], where the following properties are noted:

1. $\chi(x)$ is continuous,
2. $\chi(x) \ge 0$, and
3. $\chi(x) = 0$ if and only if x is a KKT point for (1.1).

Showing that $\chi(x_k) \to 0$ as $k \to \infty$ for a subsequence of iterates k constitutes a global first-order stationarity result.

To help better understand this measure, the w's that define $\chi(x)$ in (A.1) are illustrated in Figure A.1 for several choices of $-\nabla f(x)$. Conn, Gould, and Toint [6] observe that $\chi(x)$ can be interpreted as the progress that can be made on a first-order model at x in a ball of radius unity with the constraint of preserving feasibility. They go on to observe that $\chi(x)$ is a direct generalization of $\| \nabla f(x) \|$; in fact, $\chi(x) = \| \nabla f(x) \|$ whenever $\Omega = \mathbb{R}^n$ or $x - \nabla f(x) \in \Omega$.

The work in [19, 20] used the measure $q(x)$ defined in (1.5) (this quantity appears in [6] as equation (12.1.19)), but the resulting stationarity result is unsatisfying in the case of general linear constraints. The quantity $\chi(x)$ turns out to be easier to work with than $q(x)$. The latter involves a projection onto the feasible polyhedron, and if

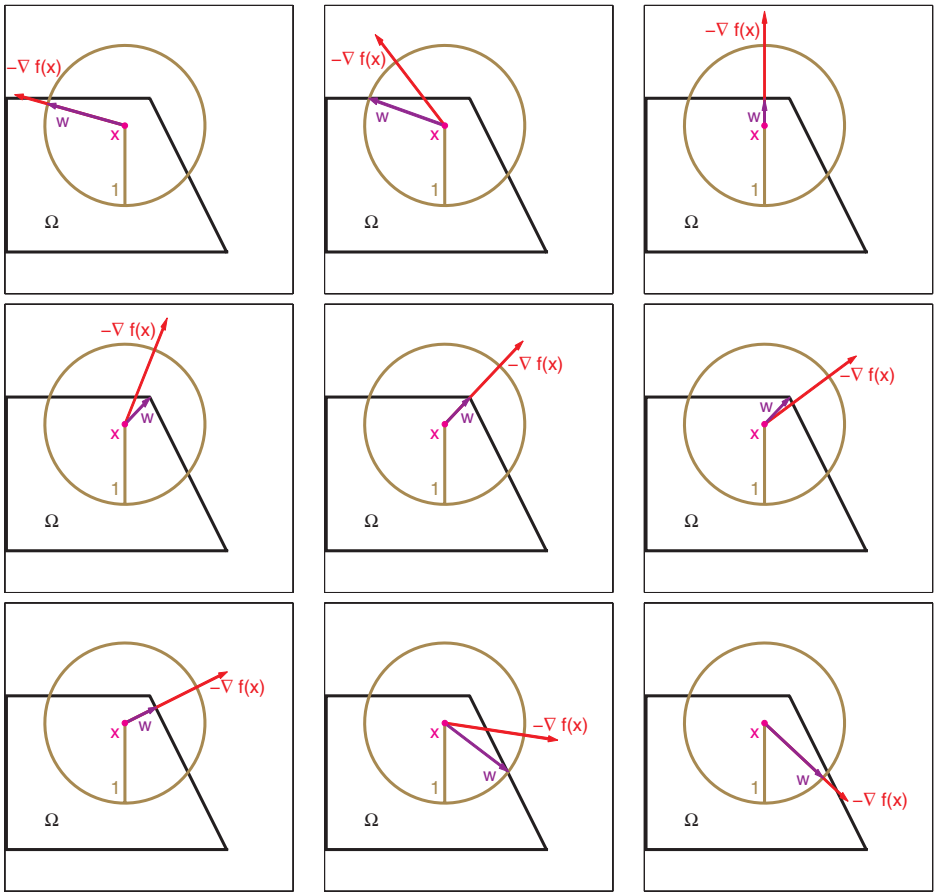

FIG. A.1. *How the* w *in* (A.1) *varies with* $-\nabla f(x)$ *when* $x - \nabla f(x) \notin \Omega$.

the constraints binding at the projection do not correspond to the constraints near x, technical difficulties ensue in relating $q(x)$ to the geometry of the feasible region near x. This is not the case with $\chi(x)$.

Appendix B. Geometric results on cones and polyhedra. Here we present geometrical results having to do with our use of $\chi(\cdot)$ as a measure of stationarity.

The first proposition says that if one can move from x to $x+v$ and remain feasible, then v cannot be too outward-pointing with respect to the constraints near x. Recall from section 2.1 that given a convex cone K and any vector v, there is a unique closest point of K to v, the *projection* of v onto K, which we denote by v_K. Thus $v_{N(x,\varepsilon)}$ is the projection of v onto the ε-normal cone $N(x,\varepsilon)$ while $v_{T(x,\varepsilon)}$ is the projection of v onto the ε-tangent cone $T(x,\varepsilon)$.

PROPOSITION B.1. *If* $x \in \Omega$ *and* $x + v \in \Omega$, *then for any* $\varepsilon \geq 0$, $\| v_{N(x,\varepsilon)} \| \leq \varepsilon/\nu_{\min}$, *where* $\nu_{\min}$ *is the constant from* (6.6).

Proof. Let $N = N(x,\varepsilon)$. The result is immediate if $v_N = 0$, so we need only consider the case when $v_N \neq 0$. Recall that N is generated by the outward-pointing normals to the binding constraints within distance ε of x; thus, the set $\mathcal{A} = \{\, a_i \mid i \in I(x,\varepsilon) \,\}$ generates N. A simple calculation shows that the distance

from x to $\{\ y\ \mid\ a_i^T y = b_i\ \}$ is $(b_i - a_i^T x)/\| a_i \|$, so it follows that

$$\frac{b_i - a_i^T x}{\| a_i \|} \leq \varepsilon \quad \text{for all } i \in I(x, \varepsilon).$$

Meanwhile, since $x + v \in \Omega$, we have

$$a_i^T x + a_i^T v \leq b_i \quad \text{for all } i.$$

The preceding two relations then lead to

$$a_i^T v \leq b_i - a_i^T x \leq \varepsilon \| a_i \| \quad \text{for all } i \in I(x, \varepsilon).$$

Since N is generated by $\mathcal{A} \subseteq \mathbf{A} = \{a_1, \ldots, a_m\}$ and $v_N \neq 0$, by (2.1) and (6.6),

$$\nu_{\min} \| v_N \| \leq \max_{i \in I(x,\varepsilon)} \frac{v^T a_i}{\| a_i \|} \leq \max_{i \in I(x,\varepsilon)} \frac{\varepsilon \| a_i \|}{\| a_i \|} = \varepsilon. \qquad \square$$

For $x \in \Omega$ and $v \in \mathbb{R}^n$, define

$$\hat{\chi}(x; v) = \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v. \tag{B.1}$$

Note from (A.1) that $\chi(x) = \hat{\chi}(x; -\nabla f(x))$. We use v in (B.1) to emphasize that the following results are purely geometric facts about cones and polyhedra.

The following proposition relates $\hat{\chi}(x; v)$ to the projection of v onto the cones $T(x, \varepsilon)$ and $N(x, \varepsilon)$. Roughly speaking, it says that if $\varepsilon > 0$ is small, so that we are only looking at a portion of the boundary very near x, then the projection of v onto $T(x, \varepsilon)$ (i.e., the portion of v pointing into the interior of the feasible region) cannot be small unless $\hat{\chi}(x; v)$ is also small.

PROPOSITION B.2. *If $x \in \Omega$, then for all $\varepsilon \geq 0$,*

$$\hat{\chi}(x; v) \leq \| v_{T(x,\varepsilon)} \| + \frac{\varepsilon}{\nu_{\min}} \| v_{N(x,\varepsilon)} \|,$$

where $\nu_{\min}$ is the constant from (6.6).

Proof. Let $N = N(x, \varepsilon)$ and $T = T(x, \varepsilon)$. Writing v in terms of its polar decomposition, $v = v_N + v_T$, we obtain

$$\hat{\chi}(x; v) = \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v \leq \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v_T + \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v_N.$$

For the first term on the right-hand side we have

$$\max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v_T \leq \| v_T \|.$$

Meanwhile, for any w we have

$$w^T v_N = (w_T + w_N)^T v_N \leq w_N^T v_N$$

since $w_T^T v_N \leq 0$. Thus,

$$\max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} w^T v_N \leq \max_{\substack{x+w \in \Omega \\ \| w \| \leq 1}} \| w_N \| \ \| v_N \|.$$

However, since $x + w \in \Omega$, Proposition B.1 tells us that

$$\| w_N \| \leq \frac{\varepsilon}{\nu_{\min}}.$$

Therefore,

$$\hat{\chi}(x; v) \leq \| v_T \| + \frac{\varepsilon}{\nu_{\min}} \| v_N \|. \qquad \square$$

Acknowledgments. We thank Margaret Wright, the associate editor who handled this paper, along with two anonymous referees, for the many useful comments that led to a significant improvement in this presentation.

CONVEX APPROXIMATIONS OF CHANCE CONSTRAINED PROGRAMS*

ARKADI NEMIROVSKI† AND ALEXANDER SHAPIRO†

Abstract. We consider a chance constrained problem, where one seeks to minimize a convex objective over solutions satisfying, with a given close to one probability, a system of randomly perturbed convex constraints. This problem may happen to be computationally intractable; our goal is to build its computationally tractable approximation, i.e., an efficiently solvable deterministic optimization program with the feasible set contained in the chance constrained problem. We construct a general class of such convex conservative approximations of the corresponding chance constrained problem. Moreover, under the assumptions that the constraints are affine in the perturbations and the entries in the perturbation vector are independent-of-each-other random variables, we build a large deviation-type approximation, referred to as "Bernstein approximation," of the chance constrained problem. This approximation is convex and efficiently solvable. We propose a simulation-based scheme for bounding the optimal value in the chance constrained problem and report numerical experiments aimed at comparing the Bernstein and well-known scenario approximation approaches. Finally, we extend our construction to the case of ambiguous chance constrained problems, where the random perturbations are independent with the collection of distributions known to belong to a given convex compact set rather than to be known exactly, while the chance constraint should be satisfied for every distribution given by this set.

Key words. stochastic programming, chance constraints, convex programming, Monte Carlo sampling, scenario generation, large deviation bounds, ambiguous chance constrained programming

1. Introduction.

Let us consider the following optimization problem:

$$\operatorname*{Min}_{x\in X} f(x) \quad \text{subject to} \quad \operatorname{Prob}\big\{F(x,\xi)\le 0\big\}\ge 1-\alpha. \tag{1.1}$$

Here ξ is a random vector with probability distribution P supported on a set $\Xi\subset\mathbb{R}^d$, $X\subset\mathbb{R}^n$ is a nonempty convex set, $\alpha\in(0,1)$, $f:\mathbb{R}^n\to\mathbb{R}$ is a real valued convex function, $F=(f_1,\dots,f_m):\mathbb{R}^n\times\Xi\to\mathbb{R}^m$, and $\operatorname{Prob}(A)$ denotes probability of an event A. Probability constraints of the form appearing in (1.1) arise naturally in various applications and are called *chance* (or probabilistic) constraints. Such constraints can be viewed as a compromise with the requirement of enforcing the constraints $F(x,\xi)\le 0$ for *all* values $\xi\in\Xi$ of the uncertain data vector, which could be too costly or even impossible. Chance constrained optimization problems were introduced in Charnes, Cooper, and Symonds [8], Miller and Wagner [17], and Prékopa [21].

Aside from potential modelling problems with formulation (1.1) (e.g., the necessity to know the probability distribution of the random vector ξ, which in practice is not always easy), there could be serious problems with numerical processing of chance constraints. First, it may happen that the only way to check whether or not a given chance constraint is satisfied at a given point x is to use Monte Carlo simulation, and

†Georgia Institute of Technology, Atlanta, GA 30332 (nemirovs@isye.gatech.edu, ashapiro@isye.gatech.edu). The first author's research was partly supported by the Binational Science Foundation grant 2002038. The second author's research was partly supported by the NSF grant DMS-0510324.

this becomes too costly when α is small. The second potential difficulty is that even with nice, say affine in x and in ξ, functions $F(x,\xi)$, the feasible set of a chance constraint may happen to be nonconvex, which makes optimization under this constraint highly problematic. It should be mentioned that there are generic situations where the latter difficulty does not occur. First, there exists a wide family of *logarithmically concave distributions* extensively studied by Prékopa [22]; he shows, in particular, that whenever the distribution of a random vector ξ is logarithmically concave, the feasible set of a chance constraint $\mathrm{Prob}\{\xi : Ax \geq \xi\} \geq 1-\epsilon$ (A is a deterministic matrix) or, more generally, the feasible set of a chance constraint $\mathrm{Prob}\{\xi : (x,\xi) \in X\} \geq 1-\epsilon$ (X is a deterministic convex set) is convex. There is also a recent result, due to Lagoa, Li, and Sznaier [16], which states that the feasible set of a scalar chance constraint

$$\mathrm{Prob}\left\{a^T x \leq b\right\} \geq 1-\epsilon \tag{1.2}$$

is convex, provided that the vector $(a^T, b)^T$ of the coefficients has symmetric logarithmically concave density and $\epsilon < 1/2$. Note, however, that in order to process a chance constraint efficiently, we need both efficient computability of the probability in question *and* the convexity of the corresponding feasible set. This combination seems to be a "rare commodity."[1] As far as chance constraint (1.2) is concerned, the only case known to us when both these requirements are satisfied is the one where the random vector $(a^T, b)^T$ is the image, under deterministic affine transformation, of a random vector with rotationally invariant distribution; cf. [16]. The simplest case of this situation is the one when $(a^T, b)^T$ is a normally distributed random vector. There are also other cases (see, e.g., [23, 11]) where a chance constraint can be processed efficiently, but in general the problem still persists; there are numerous situations where the chance constrained version of a randomly perturbed constraint $F(x,\xi) \leq 0$, even as simple-looking a one as the bilinear constraint (1.2), is "severely computationally intractable." Whenever this is the case, a natural course of action is to look for *tractable approximations* of the chance constraint, i.e., for efficiently verifiable *sufficient conditions* for its validity. In addition to being sufficient, such a condition should define a convex and "computationally tractable" set in the x-space, e.g., should be represented by a system of convex inequalities $G(x,u) \leq 0$ in x and, perhaps, in additional variables $u \in \mathbb{R}^s$, with efficiently computable $G(x,u)$. Whenever this is the case, the problem

$$\min_{x \in X,\, u \in \mathbb{R}^s} f(x) \quad \text{subject to} \quad G(x,u) \leq 0 \tag{1.3}$$

is a convex programming problem with efficiently computable objective and constraints and as such it is efficiently solvable.[2] This problem provides a *conservative approximation* of the chance constrained problem of interest, meaning that the projection of the feasible set of (1.3) onto the space of x-variables is contained in the feasible set of the chance constrained problem (1.1), so that an optimal solution to (1.3) is *feasible suboptimal* solution to (1.1).

A general way to build computationally tractable approximations (not necessarily conservative) of chance constrained problems is offered by the *scenario approach* based

[1] For example, let b in (1.2) be deterministic and a be uniformly distributed in the unit box. In this case, the feasible set of (1.2) is convex, provided that $\epsilon < 1/2$, but the left-hand side in (1.2) is difficult to compute: it is known (see Khachiyan [15]) that it cannot be computed within accuracy ϵ in time polynomial in $\dim a$ and $\ln(1/\epsilon)$, unless P=NP.

[2] For a detailed description of tractability issues in continuous optimization and their relation to convexity, see, e.g., [4, Chapter 5].

on Monte Carlo sampling techniques. That is, one generates a sample $\xi^1, \ldots, \xi^N$ of N (independent) realizations of the random vector ξ and approximates (1.1) with the problem

$$(P^N) \qquad \min_{x \in X} f(x) \quad \text{subject to} \quad F(x, \xi^\nu) \leq 0,\ \nu = 1, \ldots, N.$$

The main advantage of this approach is its generality: it imposes no restrictions on the distribution of ξ and on how the data enters the constraints. In order to build (P^N) there is no need even to know what the distribution of ξ is; all we need is to be able to sample from this distribution. Last, but not least, is the "tractability status" of the approximation. The approximation (P^N) is efficiently solvable, provided that the function $F(x, \xi)$ is componentwise convex in x and is efficiently computable, and the sample size N is not too large.

An important theoretical question related to the scenario approximation is the following. The approximation itself is random and its solution may not satisfy the chance constraints. The question is, How large should the sample size N be in order to ensure, with probability of at least $1 - \delta$, that the optimal solution to (P^N) is feasible for the problem of interest (1.1)? To some extent this question was resolved in recent papers of Calafiore and Campi [6, 7] and de Farias and Van Roy [10]. Their results were then extended in [14] to a more complicated case of *ambiguous* chance constraints (that is, the case when the "true" distribution of ξ is assumed to belong to a given family of distributions rather than to be known exactly, while the samples are drawn from a specified reference distribution). The answer to the outlined question, as given in [7], is that if $F(x, \xi)$ is componentwise convex in x, then, under mild additional conditions, with the sample size N satisfying

$$N \geq N^* := \text{Ceil}\left[2n\alpha^{-1}\log(12/\alpha) + 2\alpha^{-1}\log(2/\delta) + 2n\right], \tag{1.4}$$

the optimal solution to (P^N) is, with a probability of at least $1 - \delta$, feasible for the chance constrained problem (1.1). A remarkable feature of this result is that, similar to the scenario approximation itself it, is completely distribution-free.

Aside from the conservativeness (which is a common drawback of all approximations), an intrinsic drawback of the scenario approximation based on (1.4) is that, as is easily seen, the sample size N should be at least inverse proportional to the risk α and thus could be impractically large when the risk is small. Moreover, the sample size as given by (1.4) (and by all other known results of this type) grows linearly with n, which makes it difficult to apply the approach already to medium-size problems (with $\alpha = 0.01$ and $n = 200$, $\delta = 0.01$, the estimate (1.4) results in $N^* = 285,063$). Note that for a properly modified scenario approximation, "bad" dependence of N on α given by (1.4) can be replaced with

$$N = O(1)\left[\log(1/\delta) + dm^2\log(d\log(1/\alpha))\right], \tag{1.5}$$

provided that $F(x, \xi)$ is affine in ξ and ξ has a "nice" distribution, e.g., uniform in a box, or on the vertices of a box, or normal [19].

An alternative to the scenario approximation is an approximation based on "analytical" upper bounding of the probability for the randomly perturbed constraint $F(x, \xi) \leq 0$ to be violated. The simplest approximation scheme of this type was proposed in [2] for the case of a single affine in ξ inequality

$$f_0(x) + \sum_j \xi_j f_j(x) \leq 0 \tag{1.6}$$

(cf., (1.2)). Assuming that ξ_j are independent-of-each-other random variables with zero means varying in segments $[-\sigma_i, \sigma_i]$, it is easy to see that if x satisfies the constraint

$$f_0(x) + \Omega\left(\sum_{j=1}^{d} \sigma_j^2 f_j^2(x)\right)^{1/2} \leq 0, \tag{1.7}$$

where $\Omega > 0$ is a "safety" parameter, then x violates the randomly perturbed constraint (1.6) with probability of at most $\exp\{-\kappa\Omega^2\}$, where $\kappa > 0$ is an absolute constant (as we shall see in section 6, one can take $\kappa = 1/2$). It follows that if all components $f_i(x, \xi)$ are of the form

$$f_i(x, \xi) = f_{i0}(x) + \sum_{j=1}^{d} \xi_j f_{ij}(x), \tag{1.8}$$

then the optimization program

$$\min_{x \in X} f(x) \quad \text{subject to} \quad f_{i0}(x) + \Omega\left(\sum_{j=1}^{d} \sigma_j^2 f_{ij}^2(x)\right)^{1/2} \leq 0,\ i = 1, \ldots, m, \tag{1.9}$$

with $\Omega := \sqrt{2\log(m\alpha^{-1})}$, is an approximation of the chance constrained problem (1.1). This approximation is convex, provided that all $f_{ij}(x)$ are convex and every one of the functions $f_{ij}(x)$ with $j \geq 1$ is either affine or nonnegative. Another, slightly more convenient computationally, analytical approximation of randomly perturbed constraint (1.6) was proposed in [5]. Analytical approximations of more complicated chance constraints, notably a randomly perturbed conic quadratic inequality, are presented in [18]. An advantage of the "analytical" approach as compared to the scenario one is that the resulting approximations are deterministic convex problems with sizes independent of the required value of risk (reliability) α, so that these approximations remain practical also in the case of very small values of α. On the negative side, building an analytical approximation requires structural assumptions on $F(x, \xi)$ and on the stochastic nature of ξ (in all known constructions of this type, ξ_j should be independent of each other and possess "nice" distributions).

In this paper, we develop a new class of analytical approximations of chance constraints, referred to as *Bernstein* approximations.[3] Our major assumptions are that the components of $F(x, \xi)$ are of the form (1.8) with convex $f_{ij}(x)$, and ξ_j are independent of each other and possess distributions with efficiently computable moment generating functions. Besides this, we assume that for every $j \geq 1$ for which not all of the functions $f_{ij}(x)$, $i = 1, \ldots, m$, are affine, the corresponding random variable ξ_j is nonnegative. Under these assumptions, the approximation we propose is an explicit convex program.

After the initial version of this paper was released, we became aware of the paper of Pinter [20] proposing (although not in full generality) Bernstein approximation, even in its advanced "ambiguous" form (see section 6 below). The only (but, we believe, quite important) step ahead in what follows as compared to Pinter's paper is

[3] The construction is based on the ideas used by S. N. Bernstein when deriving his famous inequalities for probabilities of large deviations of sums of independent random variables.

that with our approach the natural scale parameter of Bernstein approximation ("h" in Pinter's paper) becomes a variable rather than an ad hoc chosen constant (as is the case in [20]). Specifically, we manage to represent Bernstein bound in a form which is jointly convex in the original decision variables *and* the scale parameter, which allows one to deal, staying all the time within the convex programming framework, with the bound which is pointwise optimized in the scale parameter.

The rest of the paper is organized as follows. In section 2 we introduce a class of convex conservative approximations of (1.1). Bernstein approximation of (1.1) is derived and discussed in section 3. In section 4, we propose a simple simulation-based scheme for bounding the true optimal value in (1.1), which allows one to evaluate numerically the quality (that is, the conservatism) of various approximations. In section 5, we report some preliminary numerical experiments with Bernstein approximation. Our numerical results demonstrate that this approximation compares favorably with the scenario one. In concluding section 6, we extend Bernstein approximation to the case of *ambiguous uncertainty model*, where the tuple of distributions of (mutually independent) components ξ_j of ξ is assumed to belong to a given convex compact set rather than to be known exactly (cf., [14], where similar extensions of the scenario approach are considered).

2. Convex approximations of chance constrained problems. In this section we discuss convex approximations of chance constrained problems of the form (1.1). As was mentioned in the introduction, chance constrained problems, even simple-looking ones, are often computationally intractable. A natural way to overcome, to some extent, this difficulty is to replace chance constraint problem (1.1) with a *tractable approximation*. That is, with an efficiently solvable problem of the form (1.3). To this end we require the function $G(x,u)$ to be *convex* in (x,u) and efficiently computable. We also would like the constraints $G(x,u) \le 0$ to be *conservative*, in the sense that if for $x \in X$ and u it holds that $G(x,u) \le 0$, then $\mathrm{Prob}\big\{F(x,\xi) \le 0\big\} \ge 1-\alpha$. Thus, feasible solutions to (1.3) induce feasible solutions to (1.1), so that the optimal solution of the approximation is a feasible suboptimal solution of the problem of interest. If these two conditions hold, we refer to (1.3) as a *convex conservative* approximation of the true problem (1.1). Our goal in this section is to construct a special class of convex conservative approximations.

Let us consider first the scalar case of $m = 1$, i.e., $F : \mathbb{R}^n \times \Xi \to \mathbb{R}$. Then the probabilistic (chance) constraint of problem (1.1) is equivalent to the constraint

$$p(x) := \mathrm{Prob}\big\{F(x,\xi) > 0\big\} \le \alpha. \tag{2.1}$$

By $\mathbb{1}_A$ we denote the indicator function of a set A, i.e., $\mathbb{1}_A(z) = 1$ if $z \in A$ and $\mathbb{1}_A(z) = 0$ if $z \notin A$.

Let $\psi : \mathbb{R} \to \mathbb{R}$ be a *nonnegative valued, nondecreasing, convex* function satisfying the following property:

$(*)$ $\psi(z) > \psi(0) = 1$ for any $z > 0$.

We refer to function $\psi(z)$ satisfying the above properties as a (one-dimensional) *generating function*. It follows from $(*)$ that for $t > 0$ and random variable Z,

$$\mathbb{E}[\psi(tZ)] \ge \mathbb{E}\left[\mathbb{1}_{[0,+\infty)}(tZ)\right] = \mathrm{Prob}\{tZ \ge 0\} = \mathrm{Prob}\{Z \ge 0\}.$$

By taking $Z = F(x,\xi)$ and changing t to t^{-1}, we obtain that

$$p(x) \le \mathbb{E}\left[\psi\left(t^{-1}F(x,\xi)\right)\right] \tag{2.2}$$

holds for all x and $t > 0$. Denote that

$$\Psi(x,t) := t\,\mathbb{E}\left[\psi\left(t^{-1}F(x,\xi)\right)\right]. \tag{2.3}$$

We obtain that if there exists $t > 0$ such that $\Psi(x,t) \le t\alpha$, then $p(x) \le \alpha$. In fact this observation can be strengthened to

$$\inf_{t>0}\left[\Psi(x,t) - t\alpha\right] \le 0 \quad \text{implies} \quad p(x) \le \alpha. \tag{2.4}$$

Indeed, let us fix x and set $\phi(t) := \Psi(x,t) - t\alpha$, $Z := F(x,\xi)$. It may happen (case (A)) that $\mathrm{Prob}\{Z > 0\} > 0$. Then there exist $a, b > 0$ such that $\mathrm{Prob}\{Z \ge a\} \ge b$, whence

$$\Psi(x,t) = t\,\mathbb{E}\left[\psi(t^{-1}F(x,\xi))\right] \ge tb\psi(t^{-1}a) \ge tb\left[\psi(0) + (\psi(a) - \psi(0))/t\right]$$

provided that $0 < t < 1$ (we have taken into account that $\psi(\cdot)$ is convex). Since $\psi(a) > \psi(0)$, we conclude that

$$\Psi(x,t) \ge \gamma := b(\psi(a) - \psi(0)) > 0 \quad \text{for } 0 < t < 1,$$

and hence $\liminf_{t\to+0}\phi(t) > 0$. Further, we have

$$\liminf_{t\to\infty}\mathbb{E}\left[\psi(t^{-1}Z)\right] \ge \psi(0) \ge 1,$$

and hence $\liminf_{t\to\infty}\phi(t) = \infty$ due to $\alpha \in (0,1)$. Finally, $\phi(t)$ is clearly lower semicontinuous in $t > 0$. We conclude that if (A) is the case, then $\inf_{t>0}\phi(t) \le 0$ iff there exists $t > 0$ such that $\phi(t) \le 0$, and in this case, as we already know, $p(x)$ indeed is $\le \alpha$. And if (A) is not the case, then the conclusion in (2.4) is trivially true, so that (2.4) is true.

We see that the inequality

$$\inf_{t>0}\left[\Psi(x,t) - t\alpha\right] \le 0 \tag{2.5}$$

is a conservative approximation of (2.1)—whenever (2.5) is true, so is (2.1). Moreover, assume that for every $\xi \in \Xi$ the function $F(\cdot,\xi)$ is convex. Then $G(x,t) := \Psi(x,t) - t\alpha$ is convex. Indeed, since $\psi(\cdot)$ is nondecreasing and convex and $F(\cdot,\xi)$ is convex, it follows that $(x,t) \mapsto t\psi(t^{-1}F(x,t))$ is convex[4]. This, in turn, implies convexity of the expected value function $\Psi(x,t)$, and hence convexity of $G(x,t)$.

We obtain, under the assumption that X, $f(\cdot)$ and $F(\cdot,\xi)$ are convex, that

$$\min_{x\in X,\, t>0} f(x) \quad \text{subject to} \quad \inf_{t>0}\left[\Psi(x,t) - t\alpha\right] \le 0 \tag{2.6}$$

gives a *convex* conservative approximation of the chance constrained problem (1.1).

Clearly the above construction depends on a choice of the generating function $\psi(z)$. This raises the question of what would be a "best" choice of $\psi(z)$. If we consider this question from the point of view of a better (tighter) approximation of the corresponding chance constraints, then the smaller is $\psi(\cdot)$, the better is bound

[4]We have used the well-known fact that if $f(x)$ is convex, so is the function $g(x,t) = tf(t^{-1}x)$, $t > 0$. Indeed, given x', x'', $\lambda \in (0,1)$, and $t', t'' > 0$, and setting $t = \lambda t' + (1-\lambda)t''$, $x = \lambda x' + (1-\lambda)x''$, we have $\lambda t' f(x'/t') + (1-\lambda)t'' f(x''/t'') = t\left[\lambda t' t^{-1} f(x'/t') + (1-\lambda)t'' t^{-1} f(x''/t'')\right] \ge tf\left(t'\lambda t^{-1}(x'/t') + (1-\lambda)t''t^{-1}(x''/t'')\right) = tf(x/t)$.

(2.2). If the right derivative $\psi'_+(0)$ is zero, then $\psi(z) \geq \psi(0) = 1$ for all $z \in \mathbb{R}$, and the above construction produces trivial bounds. Therefore we may assume that $a := \psi'_+(0) > 0$. Since $\psi(0) = 1$ and $\psi(\cdot)$ is convex and nonnegative, we conclude that $\psi(z) \geq \max\{1 + az, 0\}$ for all z, so that the upper bounds (2.2) can be only improved when replacing $\psi(z)$ with the function $\hat{\psi}(z) := \max\{1 + az, 0\}$, which also is a generating function. But the bounds produced by the latter function are, up to scaling $z \leftarrow z/a$, the same as those produced by the function

$$\psi^*(z) := [1 + z]_+, \tag{2.7}$$

where $[a]_+ := \max\{a, 0\}$. That is, from the point of view of the most accurate approximation, the best choice of the generating function ψ is the piecewise linear function ψ^* defined in (2.7).

For the generating function ψ^* defined in (2.7) the approximate constraint (2.5) takes the form

$$\inf_{t>0} \left[\mathbb{E}\big[\big[F(x,\xi) + t\big]_+\big] - t\alpha\right] \leq 0. \tag{2.8}$$

Replacing in the left-hand side $\inf_{t>0}$ with $\inf_t$, we clearly do not affect the validity of the relation; thus, we can rewrite (2.8) equivalently as

$$\inf_{t\in\mathbb{R}} \big[-t\alpha + \mathbb{E}\big[[F(x,\xi) + t]_+\big]\big] \leq 0. \tag{2.9}$$

In that form the constraint is related to the concept of conditional value at risk (CVaR) going back to [13, 21]. Recall that CVaR of a random variable Z is

$$\mathrm{CVaR}_{1-\alpha}(Z) := \inf_{\tau\in\mathbb{R}} \left[\tau + \frac{1}{\alpha}\mathbb{E}[Z - \tau]_+\right]. \tag{2.10}$$

It is easily seen that $\mathrm{CVaR}_{1-\alpha}(Z)$ is a convex and monotone functional on the space of random variables with finite first moment, and that the $(1-\alpha)$-quantile ("value at risk")

$$\mathrm{VaR}_{1-\alpha}(Z) := \inf\left[t : \mathrm{Prob}(Z \leq t) \geq 1 - \alpha\right]$$

of the distribution of Z is a minimizer of the right-hand side in (2.10), so that it always holds that $\mathrm{CVaR}_{1-\alpha}(Z) \geq \mathrm{VaR}_{1-\alpha}(Z)$. Since the chance constraint in (1.1) is nothing but $\mathrm{VaR}_{1-\alpha}[F(x,\xi)] \leq 0$, the constraint

$$\mathrm{CVaR}_{1-\alpha}[F(x,\xi)] \leq 0 \tag{2.11}$$

defines a convex conservative approximation of the chance constraint. The idea of using CVaR as a convex approximation of VaR is due to Rockafellar and Uryasev [24]. Recalling the definition of CVaR, we see that the constraints (2.9) and (2.11) are equivalent to each other.

One of the possible drawbacks of using the "optimal" generating function ψ^* (as compared with the exponential $\psi(z) := e^z$, which we will discuss in the next section) in the above approximation scheme is that it is unclear how to compute efficiently the corresponding function $\Psi(x,t)$ even in the simple case $F(x,\xi) := g_0(x) + \sum_{j=1}^d \xi_j g_j(x)$ of affine in ξ function $F(x,\xi)$ and independent-of-each-other random variables ξ_j with known and simple distributions.

There are several ways how the above construction can be extended for $m > 1$. One simple way is to replace the constraints $f_i(x,\xi) \le 0$, $i = 1,\dots,m$, with one constraint $f(x,\xi) \le 0$, say by taking $f(x,\xi) := \max\{f_1(x,\xi),\dots,f_m(x,\xi)\}$. Note, however, that this may destroy a simple, e.g., affine in ξ, structure of the constraint mapping $F(x,\xi)$. An alternative approach is the following.

Consider a closed convex cone $K \subseteq \mathbb{R}^m_+$ and the corresponding partial order $\succeq_K$, i.e., $z \succeq_K y$ iff $z - y \in K$. Of course, for the nonnegative orthant cone $K := \mathbb{R}^m_+$ the constraint $F(x,\xi) \le 0$ means that $F(x,\xi) \preceq_K 0$. We can also consider some other convex closed cones and define constraints in that form. The corresponding chance constraint can be written in the form

$$p(x) := \mathrm{Prob}\big\{F(x,\xi) \notin -K\big\} < \alpha. \tag{2.12}$$

Let $\psi : \mathbb{R}^m \to \mathbb{R}$ be a nonnegative valued, convex function such that the following hold:

$(\star)$ ψ is K-monotone; i.e., if $z \succeq_K y$, then $\psi(z) \ge \psi(y)$.

$\binom{\star}{\star}$ $\psi(z) > \psi(0) = 1$ for every $z \in \mathbb{R}^m \setminus (-K)$.

We refer to function $\psi(z)$ satisfying these properties as a K-generating function.

By $\binom{\star}{\star}$ we have that $\mathbb{E}[\psi(F(x,\xi))]$ provides an upper bound for $p(x)$, and the corresponding inequality of the form (2.2) holds. Suppose, further, that for every $\xi \in \Xi$ the mapping $F(\cdot,\xi)$ is K-convex; i.e., for any $t \in [0,1]$ and $x, y \in \mathbb{R}^n$,

$$tF(x,\xi) + (1-t)F(y,\xi) \succeq_K F(tx + (1-t)y, \xi).$$

(Note that for $K = \mathbb{R}^m_+$, K-convexity means that $F(\cdot,\xi)$ is componentwise convex.) Then for $\Psi(x,t) := t\,\mathbb{E}[\psi(t^{-1}F(x,\xi))]$, the problem of the form (2.6) gives a convex conservative approximation of the chance constrained problem (1.1).

In such construction for $m > 1$, there is no "best" choice of the K-generating function $\psi(z)$. A natural choice in the case of $K = \mathbb{R}^m_+$ could be

$$\hat{\psi}(z) := \max_{1\le i\le m} [1 + a_i z_i]_+, \tag{2.13}$$

where $a_i > 0$ are "scale parameters."

Yet there is another possible extension of the above approximation scheme for $m > 1$. Let $\alpha_1,\dots,\alpha_m$ be positive numbers such that $\alpha_1 + \cdots + \alpha_m \le \alpha$. The chance constraint of (1.1) is equivalent to $\mathrm{Prob}\,\{\bigcup_{i=1}^m \{\xi : f_i(x,\xi) > 0\}\} < \alpha$. Since

$$\mathrm{Prob}\left\{\bigcup_{i=1}^m \{f_i(x,\xi) > 0\}\right\} \le \sum_{i=1}^m \mathrm{Prob}\big\{f_i(x,\xi) > 0\},$$

it follows that the system of constraints

$$\mathrm{Prob}\big\{f_i(x,\xi) > 0\} \le \alpha_i, \quad i = 1,\dots,m, \tag{2.14}$$

is more conservative then the original chance constraint. We can now apply the one-dimensional construction to each individual constraint of (2.14) to obtain the following convex conservative approximation of the chance constrained problem (1.1):

$$\min_{x\in X} f(x) \quad \text{subject to} \quad \inf_{t>0} [\Psi_i(x,t) - t\alpha_i] \le 0,\ i = 1,\dots,m, \tag{2.15}$$

where $\Psi_i(x,t) := t\mathbb{E}\left[\psi_i(t^{-1}f_i(x,\xi))\right]$, and each $\psi_i(\cdot)$, $i = 1,\dots,m$, is a one-dimensional generating function.

Remark 2.1. An open question related to the approximation (2.15) is how to choose α_i. It would be very attractive to treat these quantities in (2.15) as design variables (subject to the constraints $\alpha_i > 0$ and $\sum_i \alpha_i \leq \alpha$) rather than as parameters. Unfortunately, such an attempt destroys the convexity of (2.15) and thus makes the approximation seemingly intractable. The simplest way to resolve the issue in question is to set

$$\alpha_i := \alpha/m,\ i = 1, \ldots, m. \tag{2.16}$$

3. Bernstein approximation. One of the drawbacks of using the piecewise linear generating functions of the form (2.7) (or (2.13)) is that the corresponding constraint function may be difficult to compute even for relatively simple functions $F(x, \xi)$. In this section we consider the (one-dimensional) generating function $\psi(z) := e^z$. For such a choice of the generating function, constructions of the previous section are closely related to the classical large deviations theory (cf., [9]).

We assume in this section that the following hold:

A1. The components ξ_j, $j = 1, \ldots, d$, of the random vector ξ are independent of other random variables.

We denote by P_j the probability distribution of ξ_j, supported on $\Xi_j \subset \mathbb{R}$ (so that the support of the distribution P of ξ is $\Xi = \Xi_1 \times \cdots \times \Xi_d$), by

$$M_j(t) := \mathbb{E}\left[e^{t\xi_j}\right] = \int \exp(tz) dP_j(z),$$

the moment generating function, and by $\Lambda_j(t) := \log M_j(t)$, the logarithmic moment generating function of ξ_j.

A2. The moment generating functions $M_j(t)$, $j = 1, \ldots, d$, are finite valued for all $t \in \mathbb{R}$ and are efficiently computable.

In fact, we could allow for the moment generating functions to be finite valued just in a neighborhood of $t = 0$. We make the stronger assumption of requiring the moment generating functions to be finite valued for all t in order to simplify the presentation.

A3. The components $f_i(x, \xi)$ in the constraint mapping $F(x, \xi)$ are affine in ξ:

$$f_i(x, \xi) = f_{i0}(x) + \sum_{j=1}^{d} \xi_j f_{ij}(x), \quad i = 1, \ldots, m, \tag{3.1}$$

and the functions $f_{ij}(x)$, $j = 0, 1, \ldots, d$, are well defined and convex on X. Besides this, for every $j \geq 1$ such that $\Xi_j \not\subset \mathbb{R}_+$, all functions $f_{ij}(x)$, $i = 1, \ldots, m$, are affine. In addition, the objective $f(x)$ in (1.1) is well defined and convex on X.

In what follows, we refer to problem (1.1) satisfying the assumptions A1–A3 as *an affinely perturbed convex* chance constrained problem.

Let $z = (z_0, z_1, \ldots, z_d) \in \mathbb{R}^{d+1}$. By A1 and A2, the function

$$\Phi(z) := \log\left(\mathbb{E}\left[\exp\left\{z_0 + \sum_{j=1}^{d} \xi_j z_j\right\}\right]\right) = z_0 + \sum_{j=1}^{d} \Lambda_j(z_j)$$

is well defined and continuous in z. Besides this, it is convex (since, as is well known, the logarithmic moment generating functions are so). Moreover, $\Phi(z)$ is monotone in

z_0 and in every z_j with $j \in J := \{j \geq 1 : \Xi_j \subset \mathbb{R}_+\}$. Finally, one clearly has for $t > 0$ and $p(z) := \text{Prob}\{z_0 + \sum_{j=1}^d \xi_j z_j > 0\}$ that

$$\Phi(t^{-1}z) \geq \log p(z).$$

Consequently, for every $\beta \in (0,1)$,

$$\exists t > 0 : t\Phi(t^{-1}z) - t\log\beta \leq 0 \quad \text{implies} \quad p(z) \leq \beta.$$

Similar to the reasoning which led us to (2.4), the latter implication can be strengthened to

$$\inf_{t>0}\left[t\Phi(t^{-1}z) - t\log\beta\right] \leq 0 \quad \text{implies} \quad p(z) \leq \beta. \tag{3.2}$$

Now consider an affine chance constrained problem with real-valued constraint mapping

$$F(x,\xi) = g_0(x) + \sum_{j=1}^d \xi_j g_j(x).$$

By (3.2), the problem

$$\min_{x\in X} f(x) \quad \text{subject to} \quad \inf_{t>0}\left[g_0(x) + \sum_{j=1}^d t\Lambda_j(t^{-1}g_j(x)) - t\log\alpha\right] \leq 0 \tag{3.3}$$

is a conservative approximation of the chance constrained problem (1.1). In fact this approximation is convex. Indeed, the function

$$G(z,t) := t\Phi(t^{-1}z) - t\log\beta$$

is convex in $(z, t > 0)$ (since $\Phi(z)$ is convex) and is monotone in z_0 and every z_j with $j \in J$, while, by A3, all $g_j(x)$, $j = 0, 1, \ldots, d$, are convex in $x \in X$, and all $g_j(x)$ with $j \geq 1$ such that $j \notin J$ are affine. It follows that the function $G(g_0(x), \ldots, g_d(x), t)$ is convex in $(x \in X, t > 0)$, whence the constraint in (3.3) is convex; the objective is convex by A3, and X was once forever assumed to be convex when formulating (1.1). Thus, (3.3) is a *convex conservative* approximation of an affinely perturbed chance constrained problem with $m = 1$, as claimed.

We can extend the outlined construction to the case of $m > 1$ in a way similar to the construction of problem (2.15). That is, given an affinely perturbed chance constrained problem (1.1), (3.1), we choose $\alpha_i > 0$, $\sum_i \alpha_i \leq \alpha$, and build the optimization problem

$$\begin{array}{ll} \min\limits_{x\in X} & f(x) \\ \text{subject to} & \inf\limits_{t>0}\left[f_{i0}(x) + \sum\limits_{j=1}^d t\Lambda_j(t^{-1}f_{ij}(x)) - t\log\alpha_i\right] \leq 0,\ i = 1,\ldots,m. \end{array} \tag{3.4}$$

Similar to the case of $m = 1$, this problem is a convex conservative approximation of (1.1). We refer to (3.4) as the *Bernstein* approximation of (1.1).

An advantage of the Bernstein approximation over the one discussed in the previous section is that under assumptions A1–A3, Bernstein approximation is an explicit

convex program with efficiently computable constraints and as such is efficiently solvable.

Remark 3.1. A somehow less accurate version of Bernstein approximation was in fact proposed in [2] for the situation where the random variables ξ_j are independent with zero mean and supported on segments $[-\sigma_i, \sigma_i]$. We have cited this result in the introduction; see (1.9). The justification of (1.9) is based on a straightforward bounding from above (going back to Bernstein) of the associated logarithmic moment generating function and demonstrating that if x satisfies (1.7), then the resulting (conservative) version of the corresponding probability bound, as applied to $z = (f_{i0}(x), f_{i1}(x), \ldots, f_{id}(x))$, implies that

$$\text{Prob}\left\{ f_{i0}(x) + \sum_{j=1}^{d} \xi_j f_{ij}(x) > 0 \right\} \le \exp\{-\kappa\Omega^2\}.$$

Clearly, Bernstein approximation as presented here is less conservative than (1.9), since it is based on the corresponding "true" function rather than on its upper bound given solely by the expected values and the sizes of supports of ξ_j.

4. Upper and lower bounds. In general, the approximation-based approach to processing chance constrained problems requires mechanisms for (i) measuring the actual risk (reliability) associated with the resulting solution, and (ii) bounding from below the true optimal value Opt^* of the chance constraint problem (1.1). Task (i) corresponds to the case when the approximation is not necessarily conservative, as it is the case, e.g., with the scenario approximation. With the latter, even applied with the theoretically justified sample size (1.4), there is still a chance $1 - \delta$ that the resulting solution $\bar{x}$ does not satisfy the chance constraint, and we would like to check whether the solution indeed is feasible for (1.1). Task (ii) is relevant to basically all approximations, since they usually are conservative ("for sure," as Bernstein approximation, or "with probability close to 1," as the scenario approximation with sample size (1.4)), and a lower bound on Opt^* allows one to quantify this conservatism.

A straightforward way to measure the actual risk of a given candidate solution $\bar{x} \in X$ is to use Monte Carlo sampling. That is, a sample $\xi^1, \ldots, \xi^{N'}$ of N' realizations of random vector ξ is generated and the probability $p(\bar{x}) := \text{Prob}\big\{F(\bar{x}, \xi) \not\le 0\big\}$ is estimated as Δ/N', where Δ is the number of times the constraint $F(\bar{x}, \xi^\nu) \le 0$, $\nu = 1, \ldots, N'$, is violated. A more reliable upper bound on $p(\bar{x})$ is the random quantity

$$\widehat{\alpha} := \max_{\gamma \in [0,1]} \left\{ \gamma : \sum_{r=0}^{\Delta} \binom{N'}{r} \gamma^r (1-\gamma)^{N'-r} \ge \delta \right\},$$

where $1 - \delta$ is the required confidence level. The quantity $\widehat{\alpha}$ is, with probability of at least $1 - \delta$, an upper bound on $p(\bar{x})$, so that if our experiment results in $\widehat{\alpha} \le \alpha$, we may be sure, "up to probability of bad sampling $\le \delta$," that $\bar{x}$ is feasible for (1.1) and $f(\bar{x})$ is an upper bound on Opt^*. Since the outlined procedure involves only the calculation of quantities $F(\bar{x}, \xi^\nu)$, it can be performed with a large sample size N', and hence feasibility of $\bar{x}$ can be evaluated with a high reliability, provided that α is not too small (otherwise the procedure would require an unrealistically large sample size).

It is more tricky to bound Opt^* from below. Here we propose a bounding scheme as follows. Let us choose three positive integers M, N, L, with $L \le M$, and let

us generate M independent samples $\xi^{1,\mu},\dots,\xi^{N,\mu}$, $\mu=1,\dots,M$, each of size N, of random vector ξ. For each sample we solve the associated optimization problem

$$\min_{x\in X} f(x) \quad \text{subject to} \quad F(x,\xi^{\nu,\mu})\le 0,\ \nu=1,\dots,N, \tag{4.1}$$

and hence calculate its optimal value Opt_μ.

We compute the quantities Opt_μ, $\mu=1,\dots,M$, by treating the infeasibility and unboundedness according to the standard optimization conventions: the optimal value of an infeasible optimization problem is $+\infty$, while for a feasible and unbounded problem from below it is $-\infty$. We then rearrange the resulting quantities $\{\mathrm{Opt}_\mu\}_{\mu=1,\dots,M}$ in nondescending order: $\mathrm{Opt}_{(1)}\le\cdots\le\mathrm{Opt}_{(M)}$ (in the statistics literature these are called the order statistics of the sample $\{\mathrm{Opt}_\mu\}_{\mu=1,\dots,M}$). By definition, the lower bound on the true optimal value is the random quantity $\mathrm{Opt}_{(L)}$.

Let us analyze the resulting bounding procedure. Let x be a feasible point of the true problem (1.1). Then x is feasible for problem (4.1) with probability of at least $\theta_N=(1-\alpha)^N$. When x is feasible for (4.1), we of course have $\mathrm{Opt}_\mu\le f(x)$. Thus, for every $\mu\in\{1,\dots,M\}$ and for every $\varepsilon>0$ we have

$$\theta := \mathrm{Prob}\{\mathrm{Opt}_\mu\le \mathrm{Opt}^*+\varepsilon\}\ge\theta_N.$$

Now, in the case of $\mathrm{Opt}_{(L)}>\mathrm{Opt}^*+\varepsilon$, the corresponding realization of the random sequence $\mathrm{Opt}_1,\dots,\mathrm{Opt}_M$ contains less than L elements which are less than or equal to $\mathrm{Opt}^*+\varepsilon$. Since the elements of the sequence are independent, the probability $\rho(\theta,M,L)$ of the latter event is

$$\rho(\theta,M,L)=\sum_{r=0}^{L-1}\binom{M}{r}\theta^r(1-\theta)^{M-r}.$$

Since $\theta\ge\theta_N$, we have that $\rho(\theta,M,L)\le\rho(\theta_N,M,L)$.

Thus,

$$\mathrm{Prob}\left\{\mathrm{Opt}_{(L)}>\mathrm{Opt}^*+\varepsilon\right\}\le\rho(\theta_N,M,L).$$

Since the resulting inequality is valid for all $\varepsilon>0$, we arrive at the bound

$$\mathrm{Prob}\left\{\mathrm{Opt}_{(L)}>\mathrm{Opt}^*\right\}\le\sum_{r=0}^{L-1}\binom{M}{r}(1-\alpha)^{Nr}\left[1-(1-\alpha)^N\right]^{M-r}. \tag{4.2}$$

We now arrive at the following simple result.

PROPOSITION 4.1. *Given $\delta\in(0,1)$, let us choose positive integers M,N,L in such a way that*

$$\sum_{r=0}^{L-1}\binom{M}{r}(1-\alpha)^{Nr}\left[1-(1-\alpha)^N\right]^{M-r}\le\delta. \tag{4.3}$$

Then with probability of at least $1-\delta$, the random quantity $\mathrm{Opt}_{(L)}$ gives a lower bound for the true optimal value Opt^*.

The question arising in connection with the outlined bounding scheme is how to choose M, N, L. Given a desired reliability $1-\delta$ of the bound *and* M and N, it is easy to specify L: this should be just the largest $L>0$ satisfying condition (4.3). (If no

$L > 0$ satisfying (4.3) exists, the lower bound, by definition, is $-\infty$.) We end up with a question of how to choose M and N. For N given, the larger M is, the better. For given N, the "ideal" bound yielded by our scheme as M tends to infinity is the lower θ_N-quantile of the true distribution of the random variable Opt_1. The larger M, the better we can estimate this quantile from a sample of M independent realizations of this random variable. In reality, however, M is bounded by the computational effort required to solve M problems (4.1). Note that the larger the effort per problem, the larger the sample size N. We have no definite idea how to choose N. As N grows, the distribution of Opt_1 "goes up" in the sense that $\mathrm{Prob}\{\mathrm{Opt}_1 > a\}$ increases for every a. As a result, every lower θ-quantile of this distribution also increases. If our bound were the lower θ-quantile of the distribution of Opt_1, it would grow (that is, improve) with N. Unfortunately, our bound is the (empirical estimate of) the lower θ_N-quantile of the distribution in question, with θ_N decreasing as N grows, and this decrease shifts the bound down. For the time being, we do not know how to balance these two opposite trends, except for a trivial way to test several values of N and to choose the best (the largest) of the resulting bounds. To keep reliability δ by testing k different values of N, would require one to strengthen reliability of every one of the tests, e.g., in accordance with the Bonferroni inequality, by replacing δ in the right-hand side of (4.3) with δ/k.

5. Numerical illustration. We are about to present the results of an illustrative experiment. While the model below is described in financial terms, we do not pretend this toy model is of actual applied value; our only goal here is to compare Bernstein approximations with the scenario approach (see the introduction).

Test problem: optimizing value at risk. The toy test problem we are about to consider is the following. There are $n+1$ assets $0, 1, \ldots, n$ with random returns. The problem is to distribute \$1 between the assets in order to maximize the upper $(1-\alpha)$th quantile of the total profit (that is, the total return of the resulting portfolio minus the initial capital of \$1). The corresponding model is the chance constrained linear programming problem

$$(P_\alpha) \qquad \max_{x\geq 0,\, t\in\mathbb{R}} t - 1 \quad \text{subject to} \quad \mathrm{Prob}\left\{t > \sum_{j=0}^{n} r_j x_j\right\} \leq \alpha,\ \sum_{j=0}^{n} x_j \leq 1,$$

where x_j is the capital invested in asset j, and r_j is the return of this asset.

The data we used in our experiment are as follows:

- There are $n+1 = 65$ assets; asset #0 ("money") has deterministic return $r_0 \equiv 1$, while the returns r_i of the remaining 64 "true" assets are random variables with expectations $\mathbb{E}[r_i] = 1+\rho_i$, with the nominal profits ρ_i varying in $[0, 0.1]$ and growing with i.
- The random variables r_i, $1 \leq i \leq 64$, are of the form

$$r_i = \eta_i + \sum_{\ell=1}^{8} \gamma_{i\ell}\zeta_\ell, \tag{5.1}$$

where $\eta_i \sim \mathcal{LN}(\mu_i, \sigma_i^2)$ (that is, $\log \eta_i \sim \mathcal{N}(\mu_i, \sigma_i^2)$) is the individual noise in ith return, $\zeta_\ell \sim \mathcal{LN}(\nu_\ell, \theta_\ell^2)$ are "common factors" affecting all returns, and $\gamma_{i\ell} \geq 0$ are deterministic "influence coefficients." All "primitive" random variables (64 of η_i's and 8 of ζ_ℓ's) are independent of each other.

We used $\nu_\ell = 0$, $\theta_\ell = 0.1$, $\mu_i = \sigma_i$ (that is, the more promising an asset at average, the more risky it is). The influence coefficients $\gamma_{i\ell}$ and the parameters μ_i were chosen in such a way that $\mathbb{E}\big[\sum_{\ell=1}^{8} \gamma_{i\ell}\zeta_\ell\big] = \rho_i/2$ and $\mathbb{E}[\eta_i] = 1 + \rho_i/2$ for all i.

Processing log-normal distributions. The random returns r_i are linear combinations of independent random variables $\eta_1, \ldots, \eta_{64}$, $\zeta_1, \ldots, \zeta_8$, so that the structure of (P_α) allows for applying Bernstein approximation. The difficulty, however, is that the random variables in question are log-normal and thus the corresponding moment-generating functions are $+\infty$ outside of the origin. This difficulty can be easily circumvented, specifically, as follows. Given a log-normal random variable $\xi \sim \mathcal{LN}(\mu, \sigma^2)$, and positive "threshold probability" $\epsilon > 0$ and "resolution" $\Delta > 0$, we associate with these data a discrete random variable $\widehat{\xi}$ as follows. Let $\pi(s)$ be the $\mathcal{N}(0,1)$-Gaussian density and R be such that $\int_R^\infty \pi(s)ds = \epsilon/2$; we split the segment $[-R, R]$ into bins $[a_k, a_{k+1}]$, $1 \le k < n$, of length $\sigma^{-1}\Delta$ (the last bin can be shorter) and assign the points $b_0 = 0$, $b_k = \exp\{\sigma a_k + \mu\}$, $k = 1, \ldots, n$, probability masses $\nu_k = \int_{a_k}^{a_{k+1}} \pi(s)ds$, where $a_0 = -\infty$ and $a_{n+1} = \infty$. The variable $\widehat{\xi}$ takes the values b_k, $k = 0, \ldots, n$, with probabilities ν_k. Note that this random variable can be thought of as a "rounding" of $\xi \sim \mathcal{LN}(\mu, \sigma^2)$: given a realization a of ξ, we look to which one of the $n+1$ sets $[0, b_1)$, $[b_1, b_2)$,..., $[b_{n-1}, b_n)$, $[b_n, \infty)$ a belongs, and replace a with the left endpoint of this set, thus obtaining a realization $\widehat{a}$ of $\widehat{\xi}$. Note that with our choice of a_i, we always have $\widehat{a}/a \le 1$, and $\widehat{a}/a \ge \exp\{-\Delta\}$ unless $a < b_1$ or $a > b_n$; the latter can happen with probability of at most ϵ. Thus, $\widehat{\xi}$ can be thought of as a lower bound on ξ which with probability of $\ge 1 - \epsilon$ is tight within factor $\exp\{\Delta\}$. Now let us replace in (P_α) underlying log-normal random variables $\eta_1, \ldots, \zeta_8$ with their roundings $\widehat{\eta}_1, \ldots, \widehat{\zeta}_8$. Since we "round down" and all $\gamma_{i\ell}$ are nonnegative, every feasible solution to the resulting chance constrained problem will be feasible for (P_α) as well. At the same time, the new problem is an affinely perturbed chance constrained problem with *discrete* random variables, and building its Bernstein approximation causes no problems at all. This is the scheme we used in our experiments, the parameters being $\epsilon = 10^{-6}$ and $\Delta = 0.0025$. Even with that high (in fact, redundant) quality of discretization, there was no difficulty with handling the resulting discrete random variables—the average, over all 71 discrete random variables in question, number of different values taken by a variable was just ≈ 138, which made computing Bernstein bound a pretty easy task.

Tuning the approximations. Both approximations we are dealing with in our experiments—the scenario and Bernstein one—are conservative in the sense that a solution yielded by an approximation violates the randomly perturbed constraint in question with probability $\alpha_{\rm f}$, which is less than the required risk α (this claim is completely true for Bernstein approximation and is "true with high probability" for the scenario one). Experiments show that the ratio $\alpha/\alpha_{\rm f}$ could be pretty large (see Table 1), which makes it natural to look for ways to reduce the resulting conservatism. To some extent, this can indeed be done via a simple tuning, provided that α is not too small, so that the probabilities of order of α can be measured reliably by Monte Carlo simulations with samples of reasonable size. When tuning Bernstein approximation, we replace the required risk α by a larger quantity α_+, solve the approximation as if the required risk were α_+, and then run Monte Carlo simulation in order to check with a desired reliability whether the actual risk $\alpha_{\rm f}$ of the resulting solution is $\le \alpha$. We then choose the (nearly) largest possible α_+ which meets the outlined requirement and treat the associated solution as the result of our tuning. Of course, tuning can

TABLE 1
Results of experiments with the value-at-risk model.

Quantity	Value	Empirical risk[a]	Inferred risk[a]
Nominal optimal value[b]	0.0950	—	—
Upper bound[c]	0.0799	—	—
Bernstein optimal value (tuned)[d_b]	0.0689	0.043	0.050
Bernstein optimal value[d_a]	0.0586	0.002	0.004
Scenario optimal value (tuned)[e_b]	0.0674	0.040	0.047
Scenario optimal value[e_a] ($N = 14,684$)	0.0557	0.001	0.003
Robust optimal value[f]	0.0000	—	—

be used in the case of scenario approximation as well, with the number of scenarios in the role of tuning parameter.

The experiments. The experiments were conducted for the value of risk $\alpha = 0.05$. The reliability $1 - \delta$ for the scenario approximation (see (1.4)) was set to 0.999. Similarly, the reliability of all other simulation-based inferences (like those on actual risks of various solutions, bound on the true optimal value in the chance constrained problem, etc.) was set to 0.999. The results are presented in Table 1; the reader should be aware that we work with a maximization problem, so that the larger the value of the objective yielded by a method, the better. Therefore, what was before a lower bound on the optimal value in the chance constrained problem becomes an upper bound, etc.

Explanations to Table 1. [a]Empirical risk makes sense only with respect to the optimal values yielded by various methods and is the empirical frequency estimate, taken over 10,000 simulations, of the probability p of violating the randomly perturbed constraint in $(P_{0.05})$ at the solution yielded by the method. Inferred risk is the 0.999-reliable upper bound on p, as inferred from the same 10,000 simulations.

[b]Optimal value in the nominal problem—the one where all randomly perturbed coefficients are set to their expected values.

[c]See section 4. Since $(P_{0.05})$ is a maximization problem, the corresponding construction yields an upper bound on the optimal value in $(P_{0.05})$. The reliability of the bound is 0.999.

[d_a]Optimal value in Bernstein approximation (3.4) of $(P_{0.05})$.

[d_b]Optimal value in tuned Bernstein approximation. In our experiment, the best tuning corresponded to replacing the true value 0.05 of risk with the value 0.3.

[e_a]Optimal value in the scenario approximation (P^N) of $(P_{0.05})$, the sample size N being chosen according to (1.4) (where $n = 66$, $\alpha = 0.05$, and $\delta = 0.001$).

[e_b]Optimal value in tuned scenario approximation. In our experiment, the best tuning corresponded to reducing the number of scenarios with its theoretical value 14,684 to 550.

[f]Optimal value given by robust optimization; under mild regularity assumptions, which hold true in the case of (P), this is the same as the optimal value in (P_α) in the case of $\alpha = 0$. In our case, the robust optimal value is 0, meaning that there is no way to make guaranteed profit, so that the best, in the worst-case setting, policy is to not to invest into "nonmoney" assets at all.

Discussion. A. As far as the objective value is concerned, Bernstein approximation outperforms the (nontuned) scenario approximation; the same is true for the tuned versions of the procedures (this is consistent with all other numerical exper-

iments we have run, including those for test problems of different structure). The differences, although not large, are not negligible (2.2% for tuned approximations).

B. Additional good news about Bernstein approximation is that even with tuning, this still is an implementable routine: the solution and the optimal value in (3.4), (2.16) are well-defined functions of α, and the resulting value of the objective is better, the larger α is. Consequently, tuning becomes an easy-to-implement routine, a kind of bisection: we solve (3.4), (2.16) for a certain value of α and check the actual risk of the resulting solution; if it is worse then necessary, we decrease α in (3.4), otherwise increase it. In contrast to this, the optimal value and the optimal solution of scenario approximation with a given sample size are random. For not too large sample sizes, the variability of these random entities is high, which makes tuning difficult.

C. It should be added that Bernstein approximation in its nontuned form remains practical in the case of very small risks α and/or high design dimension, that is, in situations where the scenario approximation requires samples of unrealistic sizes. To get an impression of the numbers, assume that we want α as small as 0.5% or even 0.1%, while the reliability $1-\delta$ of our conclusions (which in previous experiments was set to 0.999) is now increased to 0.9999. In this case the scenario approximation becomes completely impractical. Indeed, the theoretically valid sample size given by (1.4) becomes 209,571 for $\alpha = 0.5\%$ and 1,259,771 for $\alpha = 0.1\%$, which is a bit too much. Using smaller sample sizes plus tuning also is problematic, since it becomes too complicated to test the risk of candidate solutions by simulation. For example, with $\alpha = 0.005$ and $\alpha = 0.001$, it takes over 100,000 simulations to conclude, with reliability 0.9999, that a given candidate solution which in fact is feasible for $(P_{0.9\alpha})$ is feasible for (P_α).

• At the same time, Bernstein approximation with no tuning is 100% reliable, remains of the same complexity independently of how small is α, and at the uncertainty level 0.5 results in the profits 0.0500 for $\alpha = 0.5\%$ and 0.0445 for $\alpha = 0.1\%$. This is not that bad, given that the robust optimal value in our situation is 0.

The bottom line, as suggested by the experiments (and as such, not conclusive yet) is as follows: The scenario approximation has no advantages whatsoever as compared to the Bernstein one, *provided the latter is applicable* (that is, that we are in the case of a affinely perturbed convex chance constrained problem with known and simple enough distributions of ξ_j).

6. The case of ambiguous chance constraints. As was mentioned in the introduction, one of the basic problems with the formulation of chance constrained problem (1.1) is that it assumes an exact knowledge of the underlying probability distribution P of ξ. Therefore it appears natural to consider "robust" or minimax versions of the chance constrained problems; for results in this direction, see [12, 27, 25, 26, 14] and references therein. When applying the minimax approach to chance constrained problems, one assumes that the distribution P of random vector ξ in (1.1) belongs to a given in advance family $\mathfrak{P}$ of probability distributions supported on a (closed) set $\Xi \subset \mathbb{R}^d$ and replaces the chance constraint in (1.1) with its worst-case, over $P \in \mathfrak{P}$, version, thus arriving at the *ambiguous chance constrained* problem

$$\min_{x\in X} f(x) \quad \text{subject to} \quad \mathrm{Prob}_P\big\{F(x,\xi)\le 0\big\} \ge 1-\alpha \ \ \forall P \in \mathfrak{P}, \tag{6.1}$$

where Prob_P is the P-probability of the corresponding event.

Of course, we can replace the probability constraints in (6.1) with one constraint by taking the minimum of $\mathrm{Prob}_P\big\{F(x,\xi)\le 0\big\}$ with respect to $P \in \mathfrak{P}$. That is,

problem (6.1) is constrained with respect to a "worst" distribution of the considered family $\mathfrak{P}$. We can also write the probability constraints of (6.1) in the following form:

$$\sup_{P\in\mathfrak{P}} \mathbb{E}_P\left[\mathbb{1}_{A_x}\right] \leq \alpha, \tag{6.2}$$

where $A_x := \{\xi \in \Xi : F(x,\xi) \not\leq 0\}$. The "worst-case-distribution" (or minimax) stochastic programming problems were considered in a number of publications (e.g., [12, 27]). When applied to chance constraints, such worst-case-distribution problems are called *ambiguous* chance constrained problems (see [14] and references therein).

For some families of distributions the maximum in the left-hand side of (6.2) can be calculated explicitly. With every family $\mathfrak{P}$ of probability distributions is associated the function

$$\rho(Z) := \sup_{P\in\mathfrak{P}} \mathbb{E}_P\left[Z\right] \tag{6.3}$$

defined on a space of real-valued random variables Z. Formula (6.3) describes a dual representation of so-called *coherent risk measures* introduced by Artzner et al [1]. Consider now the following family:

$$\mathfrak{P} := \big\{P : \gamma_1 P^* \preceq P \preceq \gamma_2 P^*,\ P(\Xi) = 1\big\}. \tag{6.4}$$

Here γ_1 and γ_2 are constants such that $0 \leq \gamma_1 \leq 1 \leq \gamma_2$, P^* is a (reference) probability distribution on Ξ and the notation $P_1 \preceq P_2$ means that for two (not necessarily probability) Borel measures P_1 and P_2 on Ξ it holds that $P_1(A) \leq P_2(A)$ for any Borel set $A \subset \Xi$. The constraint $P(\Xi) = 1$ in (6.3) is written to ensure that P is a probability measure. This family $\mathfrak{P}$ defines a coherent risk measure, which can be written in the following equivalent form:

$$\rho(Z) = \mathbb{E}[Z] + \inf_{\tau\in\mathbb{R}} \mathbb{E}\left[(1-\gamma_1)[\tau - Z]_+ + (\gamma_2 - 1)[Z-\tau]_+\right], \tag{6.5}$$

where all expectations are taken with respect to the reference distribution P^*. In particular, for $\gamma_1 = 0$ and $\kappa := (\gamma_2 - 1)/\gamma_2$,

$$\rho(Z) = \mathrm{CVaR}_\kappa[Z]$$

(cf., [25, 26]).

By the definition (6.4) of $\mathfrak{P}$ we have that $\mathbb{E}_P\left[\mathbb{1}_{A_x}\right] \leq \gamma_2 P^*(A_x)$ for any $P \in \mathfrak{P}$, with the equality holding if $P(A_x) = \gamma_2 P^*(A_x)$. Since $P(\Xi) = 1$, this can be achieved iff $\gamma_2 P^*(A_x) + \gamma_1(1 - P^*(A_x)) \leq 1$, i.e., iff $P^*(A_x) \leq \frac{1-\gamma_1}{\gamma_2-\gamma_1}$. We obtain the following.

> If $\alpha \leq (1-\gamma_1)/(\gamma_2-\gamma_1)$, then the ambiguous chance constrained problem (6.1) with $\mathfrak{P}$ given by (6.4) is equivalent to the chance constrained problem (1.1) with respect to the reference distribution P^* and with rescaled risk $\alpha \leftarrow \alpha^* := \alpha/\gamma_2$.

Another popular example of a coherent risk measure is the mean-upper-absolute semideviation

$$\rho(Z) := \mathbb{E}[Z] + c\mathbb{E}\left(\big[Z - \mathbb{E}[Z]\big]_+\right), \tag{6.6}$$

where $c \in [0,1]$ is a constant and the expectations are taken with respect to a reference distribution P^*. It has the dual representation (6.3) with the corresponding family

$$\mathfrak{P} = \big\{\zeta' : \zeta' = 1 + \zeta - \mathbb{E}[\zeta],\ \|\zeta\|_\infty \leq c\big\}, \tag{6.7}$$

where $\zeta' = dP/dP^*$ denotes the density of P with respect to P^* (cf., [26]). By using the definition (6.6) it is straightforward to calculate that

$$\rho(\mathbb{1}_{A_x}) = P^*(A_x) + 2cP^*(A_x)(1 - P^*(A_x)). \tag{6.8}$$

By solving the quadratic inequality $t + 2ct(1-t) \le \alpha$ for $t = P^*(A_x)$, we obtain that $P^*(A_x) \le \varphi(\alpha)$, where

$$\varphi(\alpha) := \frac{1 + 2c - \sqrt{1 + 4c(1-2\alpha) + 4c^2}}{4c}$$

for $c \in (0,1]$, and $\varphi(\alpha) = \alpha$ if $c = 0$. (Note that for $\alpha \in (0,1)$ and $c \in (0,1]$, it always holds that $\varphi(\alpha) \in (0,\alpha)$.) We obtain the following.

> The ambiguous chance constrained problem (6.1) with $\mathfrak{P}$ given by (6.7) is equivalent to the chance constrained problem (1.1) with respect to the reference distribution P^* and with rescaled reliability parameter $\alpha \leftarrow \alpha^* := \varphi(\alpha)$.

Of course, such explicit reduction of the ambiguous chance constrained problem (6.1) to the regular chance constrained problem (1.1) is possible only for some specific families $\mathfrak{P}$. Our current goal is to develop Bernstein-type approximation of the constraint in (6.1). As before, we restrict ourselves with problems where the "bodies" of the constraints are affine in ξ:

$$\begin{array}{l} \min\limits_{x\in X} f(x) \quad \text{subject to} \\ \inf\limits_{P\in\mathfrak{P}} \mathrm{Prob}_P\left\{\xi : f_{i0}(x) + \sum\limits_{j=1}^{d} \xi_j f_{ij}(x) \le 0,\ i = 1,\dots,m\right\} \ge 1-\alpha. \end{array} \tag{6.9}$$

6.1. Assumptions and construction.

Assumptions. From now on, we make the following assumptions about the "data" of (6.9):

B1. The family $\mathfrak{P}$ of possible distributions of ξ is as follows. Let D_j, $j = 1,\dots,d$, be nonempty compact subsets of the axis, and $\mathcal{M}$ be a nonempty set of tuples $\{P_j\}_{j=1}^d$, where P_j are Borel probability measures on D_j. We assume that

- whenever $\{P_j\}_{j=1}^d$, $\{P'_j\}_{j=1}^d$ are two elements from $\mathcal{M}$, so is $\{\lambda P_j + (1-\lambda)P'_j\}_{j=1}^d$, $\lambda \in [0,1]$ (convexity), and
- whenever a sequence $\{P_j^t\}_{j=1}^d$, $t = 1,2,\dots$, of elements of $\mathcal{M}$ weakly converges to $\{P_j\}_{j=1}^d$ (meaning that $\int f(s)dP_j^t(s) \to \int f(s)dP_j(s)$ as $t \to \infty$ for every j and every continuous and bounded on the axis function f), then $\{P_j\}_{j=1}^d \in \mathcal{M}$ (weak closedness).

We assume that $\mathfrak{P}$ is comprised of all product distributions $P = P_1 \times \cdots \times P_d$ on $\mathbb{R}^d$ with the tuple of marginals $\{P_j\}_{j=1}^d$ running through a given set $\mathcal{M}$ with the outlined properties.

From now on, we equip the set $\mathcal{M}$ underlying, via the outlined construction, the set $\mathfrak{P}$ in question with the weak topology. It is well known that under the above assumptions this topology is yielded by an appropriate metric on $\mathcal{M}$, and that with this metric $\mathcal{M}$ is a compact metric space.

> The simplest example of a set $\mathfrak{P}$ of the outlined structure is as follows. Let D_j be finite subsets of $\mathbb{R}$, let $\Delta := \bigcup_{j=1}^d D_j = \{s_1,\dots,s_K\}$, and let $\mathcal{M}$ be a closed and convex set of matrices $P = [p_{kj}]_{\substack{1\le k\le K\\ 1\le j\le d}}$

with nonnegative entries such that $\sum_k p_{kj} = 1$ for all j and $p_{kj} = 0$ whenever $s_k \notin D_j$. For every $P \in \mathcal{M}$, the jth column P_j of P can be naturally identified with a probability distribution on D_j; the set $\mathfrak{P}$ generated by $\mathcal{M}$ is comprised of all product distributions $P_1 \times \cdots \times P_d$ coming from matrices $P \in \mathcal{M}$.

From now on, we denote a generic element of $\mathcal{M}$ by $Q = \{Q_j\}_{j=1}^d$.

B2. The objective $f(x)$ and all functions $f_{ij}(x)$, $i = 1, \ldots, m$, $j = 0, 1, \ldots, d$, are convex and well defined on X. Moreover, let

$$J := \{j : 1 \le j \le d, \text{ not all functions } f_{ij},\ i = 1, \ldots, m, \text{ are affine}\}.$$

We assume that whenever $j \in J$, the quantities ξ_j and η_j "are always nonnegative," that is, for every $j \in J$

• jth marginal distribution of every $P \in \mathfrak{P}$ is supported on the nonnegative ray, and

• all points $\eta \in \mathcal{U}$ satisfy $\eta_j \ge 0$

(compare with assumption A3 in section 3).

Building Bernstein approximation. For $P = P_1 \times \cdots \times P_d$, let $\widehat{P}$ be the tuple $\{P_j\}_{j=1}^d$, so that when P runs trough $\mathcal{P}$, $\widehat{P}$ runs through $\mathcal{M}$.

Let

$$\begin{aligned} \Phi(z, Q) &:= \log\left(\mathbb{E}_{Q_1 \times \cdots \times Q_d}\left[\exp\left\{z_0 + \sum_{j=1}^d \xi_j z_j\right\}\right]\right) \\ &= z_0 + \sum_{j=1}^d \log\left(\int \exp\{z_j s\} dQ_j(s)\right), \ Q = \{Q_j\}_{j=1}^d \in \mathcal{M}, \\ \widehat{\Phi}(z) &:= \max_{Q \in \mathcal{M}} \Phi(z, Q). \end{aligned} \tag{6.10}$$

By B1, $\Phi(z, Q)$ is a well-defined and continuous function of $(z, Q) \in \mathbb{R}^{d+1} \times \mathcal{M}$ (recall that $\mathcal{M}$ is equipped with w^*-topology). From (6.10) it is also evident that $\Phi(z, Q)$ is convex in $z \in \mathbb{R}^{d+1}$ and concave in $Q \in \mathcal{M}$. From these observations and the compactness of $\mathcal{M}$ it follows that $\widehat{\Phi}(z)$ is well defined everywhere and is convex. Finally, from B2 it follows that $\Phi(z, Q)$ (and therefore $\widehat{\Phi}(z)$) is nondecreasing in z_0 and in every z_j with $j \in J$.

Now let

$$\Theta_Q(z, t) := t\Phi_Q(t^{-1}z), \ \widehat{\Theta}(z, t) := t\widehat{\Phi}(t^{-1}z),$$

so that $\Theta_Q(z, t)$ and $\widehat{\Theta}(z, t)$ are well-defined convex functions in the domain $t > 0$. Same as in section 3, for every $\beta \in (0, 1)$ and every $z \in \mathbb{R}^{d+1}$ we have

$$\inf_{t>0}\left[\Theta_{\widehat{P}}(z, t) - t\log\beta\right] \le 0 \quad \text{implies} \quad \text{Prob}_P\left\{z_0 + \sum_{j=1}^d \xi_j z_j > 0\right\} \le \beta,$$

and we arrive at the following implication:

$$
\begin{aligned}
&P(\beta): && \left\{\forall Q\in\mathcal{M}: \inf_{t>0}\left[\Theta_Q(z,t)-t\log\beta\right]\le 0\right\}\\
&&&\text{implies that}\\
&Q(\beta): && \sup_{P\in\mathfrak{P}}\mathrm{Prob}_P\left\{z_0+\sum_{j=1}^d\xi_j z_j>0\right\}\le\beta.
\end{aligned}
\tag{6.11}
$$

We are about to replace (6.11) with an equivalent and more convenient computationally implication:

$$
\begin{aligned}
&\widehat{P}(\beta): && \left\{\inf_{t>0}\left[\widehat{\Theta}(z,t)-t\log\beta\right]\le 0\right\}\\
&&&\text{implies that}\\
&Q(\beta): && \sup_{P\in\mathfrak{P}}\mathrm{Prob}_P\left\{z_0+\sum_{j=1}^d\xi_j z_j>0\right\}\le\beta.
\end{aligned}
\tag{6.12}
$$

The advantage of (6.12) as compared to (6.11) is that the premise in the latter implication is semi-infinite: to verify its validity, we should check certain conditions for every $Q\in\mathcal{M}$. In contrast to this, the premise in (6.12) requires checking validity of a univariate convex inequality, which can be done by bisection, provided that the function $\widehat{\Theta}$ is efficiently computable. The latter condition is equivalent to efficient computability of the function $\widehat{\Phi}(z)$, which indeed is the case when $\mathcal{M}$ is not too complicated (e.g., is finite-dimensional and computationally tractable).

The validity of (6.12) and the equivalence of (6.11) and (6.12) are given by the following lemma.

LEMMA 6.1. *Let $0<\beta<1$. Then the following holds:*

$$
\widehat{P}(\beta)\quad\text{iff}\quad P(\beta).
\tag{6.13}
$$

Proof. Implication $\Rightarrow$ in (6.13) is evident, since $\widehat{\Theta}(z,t)=\max_{Q\in\mathcal{M}}\Theta_Q(z,t)$. Note that this implication combines with (6.11) to imply the validity of (6.12).

Now let us prove the implication $\Leftarrow$ in (6.13). This is a straightforward consequence of the fact that $\Theta_Q(z,t)$ is concave in Q and convex in $t>0$; for the sake of completeness, we present the corresponding standard reasoning.

As we remember, $\Phi(z,Q)$ is continuous and concave in $Q\in\mathcal{M}$; since $\Theta_Q(z,t)=t\Phi(t^{-1}z,Q)$, the function $\Theta_Q(z,t)$ is continuous in $(t>0,Q\in\mathcal{M})$ and concave in Q; the fact that this function is convex in $t>0$ is already known to us. Now let $P(\beta)$ be valid, and let us prove the validity of $\widehat{P}(\beta)$. Let us fix z and set $\theta(t,Q)=\Theta_Q(z,t)-t\log\beta$, and let $\gamma>0$. By $P(\beta)$, for every $Q\in\mathcal{M}$ there exists $t_Q>0$ such that $\theta(t,Q)<\gamma$. Since $\theta(t,Q)$ is continuous in $Q\in\mathcal{M}$, there exists a neighborhood (in $\mathcal{M}$) V_Q of the point Q such that $\theta(t_Q,Q')\le\gamma$ for all $Q'\in V_Q$. Since $\mathcal{M}$ is a compact set, there exist finitely many points $Q^i\in\mathcal{M}$ such that the corresponding neighborhoods V_{Q^i} cover the entire $\mathcal{M}$. In other words, there exist finitely many positive reals $t_1,\dots,t_N$ such that

$$
\min_{1\le i\le N}\theta(t_i,Q)\le\gamma\ \ \forall Q\in\mathcal{M}.
\tag{6.14}
$$

Since θ is concave and continuous in $Q \in \mathcal{M}$ and $\mathcal{M}$ is convex, (6.14) implies that

$$\exists \lambda^* \in \Delta_N := \left\{ \lambda \in \mathbb{R}^N_+ : \sum_i \lambda_i = 1 \right\} : \sum_i \lambda_i^* \theta(t_i, Q) \le \gamma \ \ \forall Q \in \mathcal{M}. \tag{6.15}$$

The latter conclusion is a standard fact of convex analysis. For the sake of a reader uncomfortable with possible infinite dimension of $\mathcal{M}$, here is a derivation of this fact from the standard von Neumann lemma. For $Q \in \mathcal{M}$, let Λ_Q be the set of those $\lambda \in \Delta_N$ for which $\sum_i \lambda_i \theta(t_i, Q) \le \gamma$; the set Λ_Q clearly is a closed subset of the finite-dimensional compact Δ_N. All we need is to prove that all these sets have a point in common (such a point can be taken as λ^*), and to this end it suffices to prove that all sets Λ_Q from a finite family $\Lambda_{Q_1}, \dots, \Lambda_{Q_M}$, $Q_j \in \mathcal{M}$, have a point in common. But the latter is readily given by the von Neumann lemma as applied to the convex hull Q_N of the points Q_j, $j = 1, \dots, M$ (which is a finite-dimensional convex compact set):

$$\gamma \ge \max_{Q \in Q_N} \min_{\lambda \in \Delta_N} \sum_{i=1}^N \lambda_i \theta(t_i, Q) = \min_{\lambda \in \Delta_N} \max_{Q \in Q_N} \sum_{i=1}^N \lambda_i \theta(t_i, Q)$$

(the inequality is given by (6.14), the equality by the von Neumann lemma; the required point in $\bigcap_i \Lambda_{Q_i}$ is $\operatorname{argmin}_{\lambda \in \Delta_N} \max_{Q \in Q_N} \sum_{i=1}^N \lambda_i \theta(t_i, Q)$).

Since θ is convex in $t > 0$, setting $t_\gamma = \sum_i \lambda_i^* t_i$ we get from (6.15) that $\Theta_Q(t_\gamma, z) - t_\gamma \log \beta \equiv \theta(t_\gamma, Q) \le \sum_i \lambda_i^* \theta(t_i, Q) \le \gamma$ for all $Q \in \mathcal{M}$, whence $\widehat{\Theta}(t_\gamma, z) - t_\gamma \log \beta \equiv \max_{Q \in \mathcal{M}} \Theta_Q(t_\gamma, z) - t_\gamma \log \beta \le \gamma$. Since t_γ is positive by construction and $\gamma > 0$ is arbitrary, we conclude that $\inf_{t>0} \left[\widehat{\Theta}(t_\gamma, z) - t_\gamma \log \beta \right] \le 0$, so that $\widehat{P}(\beta)$ is valid. ∎

Putting things together, we arrive at the following result.

THEOREM 6.2. *Assume that the ambiguous chance constrained problem* (6.9) *satisfies Assumptions* B1 and B2*, and let* α_i, $i = 1, \dots, m$, *be positive reals such that* $\sum_i \alpha_i \le \alpha$. *Then the program*

$$\min_{x \in X} f(x) \ \text{ subject to } \ \underbrace{\inf_{t>0} \left[f_{i0}(x) + t \widehat{\Psi}(t^{-1} z^i[x]) - t \log \alpha_i \right]}_{g_i(x,t)} \le 0, \ i = 1, \dots, m, \tag{6.16}$$

$$z^i[x] \ = \ (f_{i1}(x), \dots, f_{id}(x)), \ \ \widehat{\Psi}(z) = \max_{\{Q_j\}_{j=1}^d \in \mathcal{M}} \sum_{j=1}^d \log \left(\int \exp\{z_j s\} dQ_j(s) \right)$$

is a conservative approximation of problem (6.9)*: every feasible solution to the approximation is feasible for the chance constrained problem. This approximation is a convex program and is efficiently solvable, provided that all* f_{ij} *and* $\widehat{\Psi}$ *are efficiently computable, and* X *is computationally tractable.*

Proof. Function $g_i(x,t)$ is obtained from the function $\theta_i(z,t) := \widehat{\Theta}(z,t) - t \log \alpha_i$ by the substitution

$$(z,t) \leftarrow ((f_{i0}(x), f_{i1}(x), \dots, f_{id}(x)), t).$$

The outer function $\theta_i(z,t)$ is convex and nondecreasing in z_0 and every z_j with $j \in J$ (see the remarks following (6.10)). The inner functions $f_{i0}(x)$, $f_{ij}(x)$, $j \ge 1$, are

convex on X, and functions $f_{ij}(x)$ with $0 < j \notin J$ are affine. It follows that $g_i(x,t)$ is convex in $(t > 0, x \in X)$, so that (6.16) is indeed a convex program. Further, if x is feasible for (6.16), then $x \in X$, and for every i the predicate $\widehat{P}(\alpha_i)$ corresponding to $z = (f_{i0}(x), f_{i1}(x), \ldots, f_{id}(x))$ is valid, which, by (6.12), implies that

$$\sup_{P\in\mathfrak{P}} \mathrm{Prob}_P \left\{ f_{i0}(x) + \sum_{j=1}^{d} \xi_j f_{ij}(x) > 0 \right\} \le \alpha_i.$$

Since $\sum_i \alpha_i \le \alpha$, x is feasible for (6.9). □

Remark 6.1. Assumption B1 requires, among other things, from all distributions $P \in \mathfrak{P}$ to be supported on a common *compact* set $D_1 \times \cdots \times D_d$. This requirement can be straightforwardly relaxed to the requirement for all $P \in \mathfrak{P}$ to have "uniformly light tails": there exists a function $\gamma(t)$, $t > 0$, such that $\exp\{\alpha t\}\gamma(t) \to 0$ as $t \to \infty$ for all α, and for every $Q = \{Q_j\} \in \mathcal{M}$, every j and every $t > 0$ one has $Q_j(\{s : |s| \ge t\}) \le \gamma(t)$.

Examples. In order not to care for nonnegativity of ξ_j's associated with nonaffine $f_{ij}(\cdot)$, we assume from now on that all functions f_{ij}, $j = 1, \ldots, d$, in (6.9) are affine.

Example 1 (*range information on* ξ_j). Assume that all we know about the distributions of ξ is that ξ_j take values in given finite segments (and, as always, that $\xi_1, \ldots, \xi_d$ are independent). By shifting and scaling $f_{ij}(x)$, we may assume w.l.o.g. that ξ_j are independent and take values in $[-1, 1]$. This corresponds to the case where $\mathcal{M}$ is the set of all d-element tuples of Borel probability distributions supported on $[-1, 1]$. Denoting by Π the set of all Borel probability measures on $[-1, 1]$, we have

$$\begin{aligned} \widehat{\Phi}(z) &= z_0 + \sum_{j=1}^{d} \max_{P_j\in\Pi} \log\left(\int \exp\{z_j s\} dP_j(s) \right) = z_0 + \sum_{j=1}^{d} |z_j|, \\ \widehat{\Theta}(z,t) &= t\widehat{\Phi}(t^{-1}z) = z_0 + \sum_{j=1}^{d} |z_j|; \end{aligned}$$

consequently, approximation (6.16) becomes

$$\min_{x\in X} f(x) \quad \text{subject to} \quad \inf_{t>0} \left[f_{i0}(x) + \sum_{j=1}^{d} |f_{ij}(x)| - t \log \alpha_i \right] \le 0,\ i = 1, \ldots, m,$$

or, which is the same due to $\alpha_i \le 1$,

$$\min_{x\in X} f(x) \quad \text{subject to} \quad f_{i0}(x) + \sum_{j=1}^{d} |f_{ij}(x)| \le 0,\ i = 1, \ldots, m. \tag{6.17}$$

As it could be expected, in the situation in question, Bernstein approximation recovers the *robust counterpart* (RC) of the original uncertain problem [3], which in our case is the semi-infinite optimization program:

$$\min_{x\in X} f(x) \quad \text{subject to} \quad f_{i0}(x) + \sum_{j=1}^{d} \xi_j f_{ij}(x) \le 0\ \forall i,\ \forall \xi \in \bigcup_{P\in\mathfrak{P}} \mathrm{supp}(P). \tag{RC}$$

It is clear that in the extreme case we are considering the approximation is *exactly equivalent* to the chance constrained problem (6.9). A relatively good fact of Bernstein

approximation (6.17) is that in our example it is no more conservative than (RC). It is immediately seen that this is a general fact: whenever Bernstein approximation (6.16) is well defined, its feasible set contains the feasible set of (RC).

We see that when all our knowledge on uncertainty is the ranges of ξ_j, both the chance constrained problem (6.9) itself and its Bernstein approximation become the completely worst-case oriented (RC). The situation changes dramatically when we add something to the knowledge of ranges, for example, assume that we know the expected values of ξ_j.

Example 2 (*ranges and expectations of ξ_j are known*). Assume that we know that ξ_j are independent, take values in known finite segments, and have known expectations. As in Example 1, we may further assume w.l.o.g. that ξ_j vary in $[-1,1]$ and have known expectations μ_j, $|\mu_j| \le 1$. We are in the situation where $\mathcal{M}$ is the set of all tuples $\{Q_j\}_{j=1}^d$ with Q_j belonging to the family Π_{μ_j} of all Borel probability distributions on $[-1,1]$ with expectation μ_j, $j = 1,\dots,d$, and $\mathfrak{P}$ is the set of all product distributions on $\mathbb{R}^d$ with the collection of marginal distributions belonging to $\mathcal{M}$. It is easy to see that when $|\mu| \le 1$, then

$$\Lambda_\mu(t) := \max_{Q\in\Pi_\mu} \log\left(\int \exp\{ts\}dQ(s)\right) = \log(\cosh(t) + \mu\sinh(t))^5$$

and that $\Lambda_\mu(0) = 0$, $\Lambda'_\mu(0) = \mu$, and $\Lambda''_\mu(t) \le 1$ for all t, whence

$$\Lambda_\mu(s) \le \mu s + s^2/2 \ \forall s.$$

We therefore have

$$\begin{aligned}
\widehat{\Phi}(z) &:= \max_{P\in\mathfrak{P}} \log\left(\mathbb{E}_P\left\{\exp\{z_0 + \sum_{j=1}^d \xi_j z_j\}\right\}\right)\\
&= z_0 + \sum_{j=1}^d \log\left(\cosh(z_j) + \mu_j\sinh(z_j)\right)\\
&\le \widetilde{\Phi}(z) := z_0 + \sum_{j=1}^d \left[\mu_j z_j + z_j^2/2\right], \qquad (6.18)\\
\widehat{\Theta}(z,t) &:= t\widehat{\Phi}(t^{-1}z) = z_0 + \sum_{j=1}^d t\log\left(\cosh(t^{-1}z_j) + \mu_j\sinh(t^{-1}z_j)\right)\\
&\le \widetilde{\Theta}(z,t) := z_0 + \sum_{j=1}^d \mu_j z_j + (2t)^{-1}\sum_{j=1}^d z_j^2.
\end{aligned}$$

To proceed, we were supposed to compute the functions

$$G(z,\beta) := \inf_{t>0}\left[\widehat{\Theta}(z,t) - t\log\beta\right]$$

[5]Here is the verification: let $\lambda = \sinh(t)$ and $g(s) = \exp\{ts\} - \lambda s$. This function is convex and therefore takes its maximum on $[-1,1]$ at an endpoint; it is immediately seen that this maximum is $g(1) = g(-1) = \cosh(t)$. It follows that when $Q \in \Pi_\mu$, one has $\int \exp\{ts\}dQ(s) = \int g(s)dQ(s) + \lambda\mu = \cosh(t) + \mu\sinh(t)$. The resulting upper bound on $\int \exp\{ts\}dQ(s)$ is achieved when Q is a two-point distribution with mass $(1+\mu)/2$ at 1 and mass $(1-\mu)/2$ at -1.

and write down Bernstein approximation (6.16) of the ambiguous chance constrained problem in question as the convex program

$$\begin{array}{l}\min\limits_{x\in X}\left\{f(x) : G(z^i[x],\alpha_i)\le 0,\ i=1,\dots,m\right\},\\ \qquad z^i[x]=(f_{i0}(x),f_{i1}(x),\dots,f_{id}(x))^T,\end{array}\tag{6.19}$$

where $\alpha_i > 0$ are chosen to satisfy $\sum_i \alpha_i \le \alpha$. While computing $G(z,\beta)$ and its derivatives in z_j numerically (which is all we need in order to solve convex program (6.19) numerically) is easy, a closed form analytic expression for this function seems to be impossible. What we can do analytically is to bound G from above,[6] exploiting the simple upper bound on $\widehat{\Theta}$ presented in (6.18). From the concluding inequality in (6.18) it follows that

$$\begin{array}{rcl} G(z,\beta) & := & \inf\limits_{t>0}\left[\widehat{\Theta}(z,t)-t\log\beta\right]\\ & \le & G_*(z,\beta):=\inf\limits_{t>0}\left[z_0+\sum\limits_{j=1}^d\mu_j z_j+(2t)^{-1}\sum\limits_{j=1}^d z_j^2-t\log\beta\right]\\ & = & z_0+\sum\limits_{j=1}^d\mu_j z_j+\sqrt{2\log(1/\beta)}\left(\sum\limits_{j=1}^d z_j^2\right)^{1/2}.\end{array}\tag{6.20}$$

It follows that the convex optimization program

$$\min_{x\in X}\left\{f(x):\begin{array}{c} f_{i0}(x)+\sum_{j=1}^d\mu_j f_{ij}(x)\\ +\sqrt{2\log(1/\alpha_i)}\left(\sum_{j=1}^d f_{ij}^2(x)\right)^{1/2}\le 0,\ i=1,\dots,m\end{array}\right\}\quad[\textstyle\sum_i\alpha_i\le\alpha]$$

is an approximation (more conservative than Bernstein) of the ambiguous chance constrained problem (6.9), where the independent-of-each-other random perturbations ξ_j are known to vary in $[-1,1]$ and possess expected values μ_j. As could be expected, we have recovered (a slightly refined version of) the results of [2] mentioned in the introduction (see (1.9) and Remark 3.1.

Comparing (6.17) and (6.19)–(6.20), we clearly see how valuable the information on expectations of ξ_j could be, provided that ξ_j are independent (this is the only case we are considering). First of all, from the origin of $G(z,\beta)$ it follows that the left-hand sides of constraints in (6.17) are pointwise and $\ge$ their counterparts in (6.19), so that (6.19) is always less conservative than (6.17). To see how large the corresponding "gap" could be, consider the case when all ξ_j have zero means ($\mu_j = 0$ for all j). In this case, the ith constraint in (6.17) requires from the vector $h_i(x) := (f_{i1}(x),\dots,f_{id}(x))^T$ to belong to the centered at the origin $\|\cdot\|_1$-ball of radius $\rho(x) = -f_{i0}(x)$, let this ball be called $V_1(x)$. The ith constraint in (6.19), first, allows for $h_i(x)$ to belong to $V_1(x)$ (recall that (6.19) is less conservative than (6.17)) and, second, allows for this vector to belong to the centered at the origin $\|\cdot\|_2$-ball $V_2(x)$ of the radius $\kappa^{-1}\rho(x)$, where $\kappa=\sqrt{2\log(1/\alpha_i)}$ (see (6.20) and take into account that $\mu_j\equiv 0$);

[6] It should be stressed that this bounding is completely irrelevant as far as the numerical processing of (6.19) is concerned; the only purpose of the exercise to follow is to link our approach with some previously known constructions.

by convexity, it follows that the ith constraint in (6.19) allows for $h_i(x)$ to belong to the set $V_{1,2}(x) = \mathrm{Conv}\{V_1(x) \cup V_2(x)\} \supset V_1(x)$. When d is not small, the set $V_{1,2}(x)$ is not merely larger, it is "much larger" than $V_1(x)$, and, consequently, the ith constraint in (6.19) is "much less restricting" than its counterpart in (6.17). To get an impression of what "much larger" means, note that the distance from the origin to the boundary of $V_2(x)$ along every direction is $\kappa^{-1}\rho(x)$; the distance to the boundary of $V_{1,2}(x)$ can only be larger. At the same time, the distance from the origin to the boundary of $V_1(x)$ along a randomly chosen direction is, with probability approaching 1 as $d \to \infty$, at most $\sqrt{\pi/2}(1+\delta)d^{-1/2}$ for every fixed $\delta > 0$. Thus, the ratio of the distances, taken along a randomly chosen direction, from the origin to the boundaries of $V_{1,2}(x)$ and of $V_1(x)$ is always ≥ 1, and with probability approaching 1 as $d \to \infty$, is at least $(1-\delta)\kappa^{-1}\sqrt{2d/\pi}$ for every $\delta > 0$; in this sense $V_{1,2}$ is "at average" nearly $\kappa^{-1}\sqrt{2d/\pi}$ times larger in linear sizes than $V_1(x)$. Now, for all practical purposes κ is a moderate constant;[7] thus, we can say that as d grows, approximation (6.19) becomes progressively ("by factor $\sqrt{d}$") less conservative than (6.17).

Coming back to our examples, observe that if $\mathcal{M} = \Pi_1 \times \cdots \times \Pi_d$, where Π_j is a given set in the space of Borel probability distributions on the axis, we have

$$\widehat{\Phi}(z) = z_0 + \sum_{j=1}^{d} \max_{Q \in \Pi_j} \log\left(\int \exp\{z_j s\} dQ(s)\right),$$

and therefore computation of $\widehat{\Phi}(z)$ (which is all we need in order to build Bernstein approximation) reduces to computing the functions $\Lambda^{\Pi}(t) \equiv \max_{Q\in\Pi} \log\left(\int \exp\{ts\}dQ(s)\right)$ for $\Pi = \Pi_1, \ldots, \Pi_d$. In Table 2, we present explicit expressions for $\Lambda^{\Pi}(\cdot)$ for a number of interesting sets Π comprised of distributions with support in a given finite segment (which we w.l.o.g. can assume to be $[-1, 1]$). In the table, Mean$[Q]$, Var$[Q]$ stand for the mean $\int s dQ(s)$ and the second moment $\int s^2 dQ(s)$ of distribution Q; to save notation, we present the expressions for $\exp\{\Lambda^{\Pi}(t)\}$ rather than for Λ^{Π} itself.

Example 3 (*"light tail" families*). In previous examples, all distributions from Π were supported on a fixed finite segment. Now consider the case when Π is comprised of Borel probability distributions P on the axis such that $\mathbb{E}_P[\exp\{|x^r|/r\}] \leq \exp\{\sigma^r/r\}$, where $r \in (1, \infty)$ and $\sigma \in (0, \infty)$ are given parameters. In this case, precise computations of $\Lambda^{\Pi}(t)$ seems to be difficult, but we can point out a tight convex upper bound on $\Lambda^{\Pi}(\cdot)$, specifically,

$$\Lambda^{\Pi}(t) \leq \begin{cases} \sigma|t|, & |t| \leq \sigma^{r-1} \\ \sigma^r/r + |t|^{r_*}/r_*, & |t| \geq \sigma^{r-1}, \end{cases} \quad r_* = r/(r-1). \tag{6.21}$$

This bound coincides with $\lambda_{\Pi}(t)$ when $|t| \leq \sigma^{r-1}$ and coincides with $\Lambda^{\Pi}(t)$ within additive constant $-\log(1 - \exp\{-\sigma^r/r\})$ when $|t| \geq \sigma^{r-1}$.

Here is a justification. It suffices to verify (6.21) when $t \geq 0$. Let $P \in \Pi$. We have $|x|^r/r + t^{r_*}/r_* - tx \geq 0$ for all x, whence $\int \exp\{tx\}dP(x) \leq \int \exp\{|x|^r/r + t^{r_*}/r_*\}dP(x) \leq \exp\{\sigma^r/r + t^{r_*}/r_*\}$; thus, (6.21) holds true when $t \geq \sigma^{r-1}$. Now let us prove that (6.21) is true when $0 \leq t \leq \sigma^{r-1}$. In this range, the bound in (6.21) is true when $t = 0$ and is linear in t, while $\Lambda^{\Pi}(t)$ is convex in t, so that it suffices to verify

[7] With $\alpha_i = \alpha/m$, even risk as small as α =1.e-12 and the number of constraints as large as $m = 10,000,000$ result in $\kappa \leq 9.4$.

TABLE 2

$\left\{Q : \begin{array}{c}\mathrm{supp}(Q) \subset [-1,1],\\ \mathrm{Mean}[Q] = \mu, \mathrm{Var}[Q] \le \sigma^2\end{array}\right\}$	$\begin{cases}\frac{(1-\mu)^2\exp\{t\frac{\mu-\sigma^2}{1-\mu}\}+(\sigma^2-\mu^2)\exp\{t\}}{1-2\mu+\sigma^2}, & t \ge 0\\ \frac{(1+\mu)^2\exp\{t\frac{\mu+\sigma^2}{1+\mu}\}+(\sigma^2-\mu^2)\exp\{-t\}}{1+2\mu+\sigma^2}, & t \le 0\end{cases}$

[a] Q is unimodal w.r.t. 0 if Q is the sum of two measures: a mass at 0 and a measure with density $p(s)$ which is nondecreasing when $t \le 0$ and nonincreasing when $t \ge 0$.

the bound's validity when $t = \sigma^{r-1}$. This we already know, since with $t = \sigma^{r-1}$ we have $\sigma^r/r + t^{r_*}/r_* = t\sigma$. Further, when $0 \le t \le \sigma^{r-1}$, our upper bound coincides with $\Lambda^\Pi(t)$—look what happens when P assigns mass 1 to the point $x = \sigma$. Finally, let $t > \sigma^{r-1}$, and let P assign the mass $\mu = \lambda\exp\{(\sigma^r - t^{r_*})/r\}$ to the point t^{r_*-1} and the mass $1-\mu$ to the point 0; here $\lambda = (1-\exp\{-\sigma^r/r\})\,/\,(1-\exp\{-t^{r_*}/r\})$. Since $t \ge \sigma^{r-1}$, we have $t^{r_*} \ge \sigma^r$, so that $\lambda \le 1$ and $\mu \in [0,1]$; thus, P indeed is a probability distribution. An immediate computation shows that $\int \exp\{|x|^r/r\}dP(x) = \exp\{\sigma^r/r\}$, so that $P \in \Pi$. We now have $\int \exp\{tx\}dP(x) \ge \mu\exp\{t^{r_*}\} = \lambda\exp\{\sigma^r/r + t^{r_*}/r_*\}$, so that $\Lambda^\Pi(t) \ge \sigma^r/r + t^{r_*}/r_* - \log\lambda \ge \sigma^r/r + t^{r_*}/r_* - \log(1-\exp\{-\sigma^r/r\})$.

We could proceed in the same fashion, adding more a priori information on the distribution of ξ; until this information becomes too complicated for numerical processing, it can be "digested" by Bernstein approximation. Instead of moving in this direction, we prefer to present an example of another sort, where the assumptions underlying Theorem 6.2 are severely violated, but the Bernstein approximation scheme still works.

Example 4 (*parametric uncertainty*). Assume that we know a priori that some of ξ_j are normal, and the remaining ones are Poisson; however, we do not know exactly the parameters of the distributions. Specifically, let us parameterize a normal distribution by its mean and variance (note: variance, not standard deviation!), and a Poisson distribution by its natural parameter λ (so that the probability for the corresponding random variable to attain value $i = 0, 1, \ldots$ is $\frac{\lambda^i}{i!}\exp\{-\lambda\}$). Let us arrange parameters of the d distributions in question in a vector ω, and assume that our a priori knowledge is that ω belongs to a known-in-advance convex compact set

Ω. We assume also that the latter set is "realizable" in the sense that every point $\omega \in \Omega$ indeed represents a collection of distributions of the outlined type; specifically, the coordinates of $\omega \in \Omega$ which represent variances of normal distributions and the parameters of the Poisson distributions are positive. Note that our a priori knowledge is incompatible with assumption B1: convexity in the space of parameters has little in common with convexity in the space of distributions. For example, when the mean of a normal distribution with unit variance runs through a given segment, the distribution itself moves along a complicated curve. We can, however, try to use the same approach which led us to Theorem 6.2. Observe that when P_j is the Poisson distribution with parameter λ, we have

$$\begin{aligned}\log\left(\int \exp\{rs\}dP_j(s)\right) &= \log\left(\sum_{i=0}^{\infty}\frac{(\lambda e^r)^i}{i!}\exp\{-\lambda\}\right) = \log(\exp\{\lambda e^r - \lambda\}) \\ &= \lambda\exp\{r\} - \lambda;\end{aligned}$$

the resulting function is continuous, convex in r, as is always the case for the logarithmic moment generating function, and is concave in λ, which is pure luck. We are equally lucky with the normal distribution P_j with mean μ and variance ν:

$$\log\left(\int \exp\{rs\}dP_j(s)\right) = \log\left(\frac{1}{\sqrt{2\pi\nu}}\int \exp\left\{rs - \frac{(s-\mu)^2}{2\nu}\right\}ds\right) = r\mu + \frac{r^2\nu}{2},$$

and the result again is continuous, convex in r and concave in (μ, ν). It follows that if P^ω is the joint distribution of the sequence of d normal/Poisson independent random variables ξ_j, the vector of parameters of the marginal distributions being ω, then, for every vector $z \in \mathbb{R}^{d+1}$, the function

$$\Phi_\omega(z) = \log\left(\mathbb{E}_{P^\omega}\left[\exp\left\{z_0 + \sum_{j=1}^{d}\xi_j z_j\right\}\right]\right)$$

is given by a simple explicit expression, is continuous in $(z \in \mathbb{R}^{d+1}, \omega \in \Omega)$, and is convex in z and concave (in fact even affine) in ω. We now can use the reasoning which led us to Theorem 6.2 and (6.16) to conclude that the optimization problem

$$\begin{gathered}\min_{x\in X} f(x) \quad \text{subject to} \quad \inf_{t>0}\left[t\widehat{\Phi}(t^{-1}z^i[x]) - t\log\alpha_i\right] \le 0,\ i = 1,\dots,m, \\ \widehat{\Phi}(z) = \max_{\omega\in\Omega}\Phi_\omega(z),\ z^i[x] = (f_{i0}(x), f_{i1}(x), \dots, f_{id}(x))\end{gathered}$$

is an approximation of the ambiguous chance constrained problem under consideration, provided that $\alpha_i \in (0,1)$ are such that $\sum_i \alpha_i \le \alpha$. This approximation is convex, provided that all functions f_{ij} are convex and well defined on X and the functions f_{ij} with j's corresponding to normally distributed components in ξ are affine. Finally, our approximation is computationally tractable, provided that $\widehat{\Phi}(\cdot)$ is efficiently computable (which indeed is the case when Ω is computationally tractable).

Acknowledgment. We express our gratitude to Yuri Kan who brought to our attention the paper of Pinter [20].

DETERMINANT MAXIMIZATION OF A NONSYMMETRIC MATRIX WITH QUADRATIC CONSTRAINTS*

SERGE DÉGERINE† AND ABDELHAMID ZAÏDI‡

Abstract. This paper presents the problem of maximizing the determinant of a real $K \times K$-matrix B, subject to the constraint that each row b_k of B satisfies $b_k^t \Gamma_k b_k \leq 1$, where $\Gamma_1, \ldots, \Gamma_K$ are K given real symmetric positive definite matrices. This problem comes from a specific blind signal separation approach, but the criterion differs from approximate diagonalization criteria usually encountered in this area. Furthermore our criterion corresponds to the following nice geometrical problem: given K ellipsoids in $\mathbf{R}^K, \varepsilon_k = \{x : x^t \Gamma_k x \leq 1\}, k = 1, \ldots, K$, find K vectors, $b_1 \in \varepsilon_1, \ldots, b_K \in \varepsilon_K$, such that the volume of the parallelepiped defined by these vectors is maximum. Existence and uniqueness of the solution are discussed. An iterative algorithm, based on a relaxation technique, is proposed in order to solve this problem, and its convergence is proved under a simple sufficient condition. Some numerical experiments are performed showing the behavior of the algorithm and its comparison with Newton's methods for nonlinear optimization.

Key words. determinant maximization, relaxation technique, nonconvex optimization

1. Introduction.

We consider the optimization problem

$$\begin{aligned} &\text{maximize} \quad \det B, \quad B = [b_1, \ldots, b_K]^t, \\ &\text{subject to} \quad b_k^t \Gamma_k b_k \leq 1, \quad k = 1, \ldots, K, \end{aligned} \tag{1.1}$$

where $\mathcal{G} = \{\Gamma_1, \ldots, \Gamma_K\}$ is a set of K given real symmetric positive definite matrices.

From a geometrical point of view, this problem is equivalent to the following: Given K ellipsoids in $\mathbf{R}^K, \varepsilon_k = \{x : x^t \Gamma_k x \leq 1\}, k = 1, \ldots, K$, find K vectors, $b_1 \in \varepsilon_1, \ldots, b_K \in \varepsilon_K$, such that the volume of the parallelepiped defined by these vectors is maximum. Note that the dimension K of the problem is equal to the number of ellipsoids. As we will see in section 3, this nice geometrical problem has an explicit solution for $K = 2$ and for some particular classes of jointly diagonalizable matrices. Otherwise, the existence of a solution is easily proved, but the uniqueness is a tricky problem. This last point will be illustrated by several examples with diagonal matrices when $K = 3$.

We will see in section 3.4 below that this max-det problem, with $|\det B|$ instead of $\det B$, is equivalent to maximizing, with respect to B, the following criterion coming from a blind source separation problem:

$$l(B; \mathcal{G}) = \log |\det B| - \frac{1}{2} \sum_{k=1}^{K} b_k^t \Gamma_k b_k. \tag{1.2}$$

This max-det problem becomes a convex optimization problem, as those considered in [14], only when B is restricted to the cone of symmetric positive definite matrices. We propose an algorithm, using a relaxation technique, for this max-det

problem in the set of all square matrices. Numerical experiments in the last section show that this algorithm is very fast in comparison with Newton's methods for large values of K. Each step of our algorithm consists of maximizing $l(B;\mathcal{G})$ with respect to one row b_k when the other rows $b_j, j \neq k$, are fixed; $l(B;\mathcal{G})$ is strictly concave with respect to b_k and the solution $\hat{b}_k$ is explicit. Denoting by $\langle\cdot,\cdot\rangle_{\Gamma_k}$ the inner product in $\mathbf{R}^K$, defined by $\langle x, y\rangle_{\Gamma_k} = x^t\Gamma_k y$, and by $\|\cdot\|_{\Gamma_k}$ the corresponding norm, this solution satisfies $\|\hat{b}_k\|_{\Gamma_k} = 1$ and $\langle\hat{b}_k, b_j\rangle_{\Gamma_k} = 0$ for $j \neq k$. So, $\hat{b}_k$ is the normalized projection error of b_k with respect to $\langle\cdot,\cdot\rangle_{\Gamma_k}$ on the subspace spanned by the rows $b_j, j \neq k$. Notice that the existence of a solution to our max-det problem (Proposition 3.9) proves the following relevant fact: Given K inner products $\langle\cdot,\cdot\rangle_{\Gamma_k}, k = 1,\ldots,K$, in $\mathbf{R}^K$, there exist K vectors $b_1,\ldots,b_K$ such that, for each k, b_k is orthogonal to $b_j, j \neq k$, with respect to $\langle\cdot,\cdot\rangle_{\Gamma_k}$.

The criterion $l(B;\mathcal{G})$ comes from a blind source separation method based on the maximum likelihood principle [8]. In this area, other methods lead to approximate diagonalization criteria of a set of N matrices $C_1,\ldots,C_N$ (see, for example, [1], [3], [11], [15]). Here, the required matrix B is such that, for each k, only the off-diagonal elements of the kth row (and column) of $B\Gamma_k B^t$ are set to zero and $N = K$. Thus $l(B;\mathcal{G})$ is not an approximate diagonalization criterion, except for $K = 2$.

The blind source separation problem is presented in section 2, and the max-det problem is studied in section 3. The last section is devoted to the algorithm.

2. The blind source separation problem. Let $X(t) = AS(t), t = 1,\ldots,T$, be the observations of an instantaneous linear mixture of sources $S(\cdot)$. The mixing matrix A is an unknown $K \times K$ nonsingular matrix. The goal is to extract the sources from the observations, with a minimum knowledge about the sources except that they are statistically independent. Independent components analysis exploits only the space independence between the sources [7]. In this case, each component $S_k(\cdot), k = 1,\ldots,K$, of the source process $S(\cdot)$ can be modeled as a sequence of independent identically distributed variables (white sources), provided that there is not more than one Gaussian source in the mixture [3]. Second-order methods exploit the decorrelation hypothesis but require sources having distinct normalized spectra (colored sources) [1]. The method proposed in [8] is in this last category, but, using the maximum entropy principle, $S_k(\cdot)$ is modeled as an $AR(p_k)$ stationary zero-mean Gaussian process. This model is parametrized by the set $\beta_k = \{\beta_k(j), j = 1,\ldots,p_k\}$ of its partial autocorrelation coefficients, since the innovation variance is fixed equal to 1. The innovation variance is a scale parameter which is integrated in the norm of the columns of A. So, $S_k = [S_k(1),\ldots,S_k(T)]^t$ is a zero-mean Gaussian random vector with a $T \times T$ covariance matrix, denoted by $R_k^T(\beta_k)$, which depends only on β_k. Using the independence of the sources, the probability density function of the bloc $S_T = [S(1),\ldots,S(T)]$ equals

$$[2\pi]^{-KT/2}\prod_{k=1}^{K}[\det R_k^T(\beta_k)]^{-1/2}\exp -\frac{1}{2}\sum_{k=1}^{K}S_k^t[R_k^T(\beta_k)]^{-1}S_k.$$

Thus, the log-likelihood function of the observations $X_T = [X(1),\ldots,X(T)] = AS_T$ is

$$l_T(X_T;B,\beta) = T\log|\det B| - \frac{1}{2}\sum_{k=1}^{K}b_k^t X_T[R_k^T(\beta_k)]^{-1}X_T^t b_k$$
$$-\frac{1}{2}\sum_{k=1}^{K}\log[\det R_k^T(\beta_k)] - \frac{KT}{2}\log(2\pi),$$

where $B = A^{-1}$ is the separating matrix and $\beta = \{\beta_1, \ldots, \beta_K\}$. Notice that B and β are two independent parameters. The maximization of $l_T(X_T; B, \beta)$ is obtained through a relaxation technique. When B is fixed, the maximization with respect to β leads to K independent problems of maximum likelihood estimation of AR models. When β is fixed, we recognize criterion (1.2) with

$$\Gamma_k = \frac{1}{T} X_T [R_k^T(\beta_k)]^{-1} X_T, \quad k = 1, \ldots, K.$$

Related approaches, in this blind source separation area, lead to various problems of approximate diagonalization of some sets of matrices [5], [10], [15]. For instance, the problem in [10] is to maximize, with respect to the separating matrix B, the following criterion:

$$\log|\det B| - \frac{1}{2}\sum_{n=1}^{N} \log\det \operatorname{diag}(BC_nB^t),$$

where $C_1, \ldots, C_N$ is a set of $K \times K$ symmetric positive definite matrices obtained from an estimate of the spectral density of $X(\cdot)$ [11]. This criterion measures the global deviation of the matrices BC_nB^t from diagonality and is invariant with respect to the scale of the rows of B.

3. The max-det problem. We consider the first and second derivatives of the criterion $l(B; \mathcal{G})$. Then, we describe some special cases in which an explicit solution is obtained. Finally, we discuss the existence and the uniqueness of the solution.

3.1. Derivatives of the criterion. Let $\{e_k, k = 1, \ldots, K\}$ be the canonical base of $\mathbf{R}^K$. We also use the notations b_{ij} and a_{ij} to designate the entries of B and $A = B^{-1}$, and δ_{ij} is the Kronecker symbol ($\delta_{ij} = 1$ if $i = j$, else 0).

PROPOSITION 3.1. *The first and second derivatives of the criterion $l(B; \mathcal{G})$ are given by*

$$\frac{\partial l(B; \mathcal{G})}{\partial b_{ij}} = a_{ji} - e_j^t \Gamma_i B^t e_i, \tag{3.1}$$

$$\frac{\partial^2 l(B; \mathcal{G})}{\partial b_{kl} \partial b_{ij}} = -a_{li}a_{jk} - \delta_{ki}\Gamma_i(j, l). \tag{3.2}$$

Proof. Let B_{ij} be the matrix formed by deleting row i and column j from B; then

$$\det B = \sum_k b_{ik}(-1)^{i+k} \det B_{ik}, \qquad a_{ji} = (-1)^{i+j} \det B_{ij} (\det B)^{-1}.$$

Using the derivative $(\log|x|)' = x^{-1}$ for $x \neq 0$, we obtain the gradient of $\log\det|B|$,

$$\frac{\partial \log|\det B|}{\partial b_{ij}} = a_{ji}, \qquad \nabla \log\det|B| = \frac{\partial \log|\det B|}{\partial B} = B^{-t}.$$

The differentiation (see [2])

$$0 = dI = d(B^tB^{-t}) = dB^tB^{-t} + B^t d(B^{-t})$$

gives $d(B^{-t}) = -B^{-t}dB^tB^{-t}$. So the quadratic form associated with the Hessian of $\log|\det B|$ is

$$\langle dB, \nabla^2 \log|\det B|(dB)\rangle = -\operatorname{trace}(dB^tB^{-t}dB^tB^{-t}).$$

The identification of the coefficient of $db_{kl}db_{ij}$ gives

$$\frac{\partial^2 \log\det|B|}{\partial b_{kl}\partial b_{ij}} = -a_{li}a_{jk}.$$

The derivatives of the quadratic part in the criterion are obvious. □

As we will see below (Proposition 3.10), the solution of our problem satisfies the optimality conditions $\nabla l(B;\mathcal{G}) = 0$. Using the first derivatives (3.1) and the notation $A = [a_1, \ldots, a_K]$, we have

$$\frac{\partial l(B;\mathcal{G})}{\partial b_k} = a_k - \Gamma_k B^t e_k = 0 \quad \Longleftrightarrow \quad a_k = \Gamma_k B^t e_k.$$

By applying the matrix B to this equality, we obtain the following result.

COROLLARY 3.2. *The optimality conditions $\nabla l(B;\mathcal{G}) = 0$ are equivalent to the following set of equations:*

$$B\Gamma_k B^t e_k = e_k, \quad k = 1, \ldots, K. \tag{3.3}$$

COROLLARY 3.3. *The Hessian matrix is negative definite, $\nabla^2 l(B;\mathcal{G}) \prec 0$, if and only if*

$$\operatorname{trace}(X^2) + \sum_{k=1}^{K} x_k^t B\Gamma_k B^t x_k > 0 \tag{3.4}$$

for all $K \times K$-matrices $X = [x_1, \ldots, x_K]^t \neq 0$.

Proof. Using the second derivatives (3.2), the Hessian is negative definite if and only if

$$\langle dB, \nabla^2 l(B;\mathcal{G})\rangle = -\operatorname{trace}(dB^t B^{-t} dB^t B^{-t}) - \sum_{k=1}^{K} \operatorname{trace}(e_k e_k^t dB\Gamma_k dB^t) < 0$$

for all $dB \neq 0$. Thus the result is given by taking $dB = BX^t$. □

Notice that $\operatorname{trace}(X^2)$ in (3.4) shows that the Hessian is not always negative definite. This point is the main difficulty in the implementation of the Newton methods. On the other hand, the following property is very useful.

LEMMA 3.4. *For any nonsingular square matrix M, we have*

$$l(BM^{-1};\mathcal{G}_M) = l(B;\mathcal{G}) - \log|\det M|,$$

where $\mathcal{G}_M = \{M\Gamma_1 M^t, \ldots, M\Gamma_K M^t\}$.

In order to maximize the criterion in a neighborhood of a nonsingular matrix B, it is apparently easier to maximize $l(X;\mathcal{G}_B)$ with respect to X, since we have

$$\left.\frac{\partial l(X;\mathcal{G}_B)}{\partial x_k}\right|_{X=I} = e_k - B\Gamma_k b_k, \qquad \left.\frac{\partial^2 l(X;\mathcal{G}_B)}{\partial x_l \partial x_k}\right|_{X=I} = -e_k e_l^t - \delta_{lk} B\Gamma_k B^t. \tag{3.5}$$

Let us denote by ∇_B and ∇_B^2 the gradient vector and the Hessian matrix associated with (3.5); i.e., $\nabla_B = [e_1^t - b_1^t\Gamma_1 B^t, \ldots, e_K^t - b_K^t\Gamma_K B^t]^t$ and $\nabla_B^2 = -[E + \Gamma_B]$ with

$$E = \begin{bmatrix} e_1 e_1^t & \cdots & e_K e_1^t \\ \vdots & \vdots & \vdots \\ e_1 e_K^t & \cdots & e_K e_K^t \end{bmatrix}, \qquad \Gamma_B = \begin{bmatrix} B\Gamma_1 B^t & & \\ & \ddots & \\ & & B\Gamma_K B^t \end{bmatrix}.$$

Notice that ∇_B and ∇_B^2 are gradient and Hessian of $l(X;\mathcal{G}_B)$ as a function of $(x_1^t,\dots,x_K^t)^t$, where $X=[x_1,\dots,x_K]^t$ at $X=I$, and are simply obtained from B without computing $A=B^{-1}$. In the algorithm, the new iterate is given by

$$B(n+1)=[I+\lambda_n dB]B(n), \tag{3.6}$$

where λ_n is a scale factor to be chosen and dB corresponds to the Newton step

$$[db_1^t,\dots,db_K^t]^t=dB,\qquad \nabla^2_{B(n)}d_B=-\nabla_{B(n)}.$$

Here, maximizing $l(X;\mathcal{G}_B)$ instead of $l(B;\mathcal{G})$ leads to the introduction of the relative gradient ∇_B. Generally, this approach simplifies the computation of the Hessian, but its more relevant interest is in the statistical properties of the corresponding methods in blind source separation problems [4].

Let $\mathcal{E}$ be a diagonal matrix whose diagonal elements are equal to ±1, called a sign matrix. Then, if B is a solution of (3.3), so is $\mathcal{E}B$ and $l(\mathcal{E}B;\mathcal{G})=l(B;\mathcal{G})$. In what follows, we will say that a matrix M is essentially unique when it is uniquely defined, up to a left multiplication by a sign matrix. Note that a row-permutation of B, which is a classical invariance property in blind source separation, corresponds here to the same permutation on the order of the matrices $\Gamma_1,\dots,\Gamma_K$ in $\mathcal{G}$.

3.2. The case $K=2$. In this situation, an explicit formula for the solution is obtained. A matrix B satisfying (3.3) realizes a joint diagonalization of Γ_1 and Γ_2. This is related to the eigendecomposition problem [9, p. 467].

LEMMA 3.5. *Let Γ_1 and Γ_2 be two symmetric matrices. Assume that Γ_1 is positive definite. Then there exists a matrix W satisfying*

$$W\Gamma_1W^t=I,\quad W\Gamma_2W^t=\Delta,$$

where $\Delta=\operatorname{diag}(\delta_1,\dots,\delta_K)$ is a diagonal matrix. Moreover, the matrix W is essentially unique if and only if the elements of Δ are distinct and arranged in decreasing (or increasing) order.

The rows of W are the eigenvectors of Γ_2, with respect to the inner product $\langle\cdot,\cdot\rangle_{\Gamma_1}$, associated with the eigenvalues given by Δ, i.e., the roots of the polynomial $\det(\Gamma_2-\delta\Gamma_1)$, since we have $\Gamma_2W^t=\Gamma_1W^t\Delta$.

PROPOSITION 3.6. *Let Γ_1 and Γ_2 be two nonproportional symmetric positive definite matrices of order 2. Then the solution of the max-det problem is essentially unique and given by*

$$B=\begin{pmatrix}1&0\\0&\frac{1}{\sqrt{\delta_2}}\end{pmatrix}W,\qquad \det B=\left(\frac{\delta_1}{\delta_2}\right)^{1/4}(\det\Gamma_1\times\det\Gamma_2)^{-1/4},$$

where δ_1,δ_2, and W are elements of the joint diagonalization

$$W\Gamma_1W^t=\begin{pmatrix}1&0\\0&1\end{pmatrix},\quad W\Gamma_2W^t=\begin{pmatrix}\delta_1&0\\0&\delta_2\end{pmatrix},\quad \delta_1>\delta_2>0.$$

Proof. Using Lemma 3.4 with $M=W$, we have $B=CW$, where C is the solution of the max-det problem in which $\Gamma_1=I$ and $\Gamma_2=\Delta$. Now, the solutions of (3.3) are essentially equal to

$$C=\begin{pmatrix}1&0\\0&\frac{1}{\sqrt{\delta_2}}\end{pmatrix},\qquad \tilde{C}=\begin{pmatrix}0&1\\\frac{1}{\sqrt{\delta_1}}&0\end{pmatrix}.$$

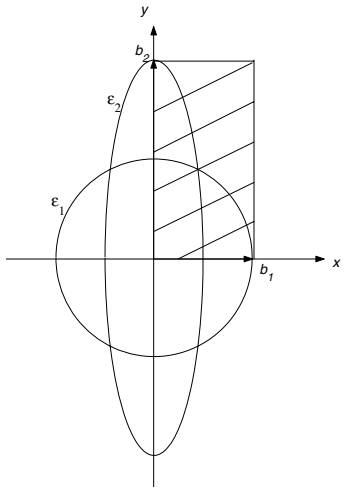

FIG. 3.1. *The max-det problem with $\Gamma_1 = I$ (ellipsoid ϵ_1) and $\Gamma_2 = \Delta$ (ellipsoid ϵ_2): The solution $B = [b_1, b_2]^t$ defines the parallelepiped (hatched) with maximum area when $b_1 \in \epsilon_1$ and $b_2 \in \epsilon_2$.*

Let $\delta = \det C$. The characteristic polynomials of the Hessian matrices are

$$P_C(\lambda) = \delta_2(\delta_2\lambda + 2)(\lambda + 2)(\delta_2^2\lambda^2 + (\delta_1 + 1)\delta_2\lambda + \delta_1 - \delta_2),$$
$$P_{\tilde{C}}(\lambda) = \delta_1(\delta_1\lambda + 2)(\lambda + 2)(\delta_1^2\lambda^2 + (\delta_2 + 1)\delta_1\lambda + \delta_2 - \delta_1).$$

It follows that $P_C(\lambda)$ has four negative roots, whereas $P_{\tilde{C}}(\lambda)$ has one positive and three negative roots. Hence $B = CW$ is the unique matrix, up to a sign factor, that realizes the maximum of (1.2). The equalities

$$\det B = \delta_2^{-1/2} \det W = \delta_2^{-1/2} (\det \Gamma_1)^{-1/2} = \delta_1^{1/2} (\det \Gamma_2)^{-1/2}$$

give the expression of $\det B$. □

Notice that the other solution of (3.3), $\tilde{B} = \tilde{C}W$, corresponds to a saddle point. When the matrices are proportional, $\Gamma_2 = \delta\Gamma_1$, we have $\delta_1 = \delta_2 = \delta$, and the solution is

$$B = \begin{pmatrix} 1 & 0 \\ 0 & \frac{1}{\sqrt{\delta}} \end{pmatrix} \Gamma_1^{-1/2},$$

where $\Gamma_1^{-1/2}$ is the inverse matrix of any square root of Γ_1.

The solution, for $\Gamma_1 = I$ and $\Gamma_2 = \Delta$, is illustrated by Figure 3.1.

3.3. The case of jointly diagonalizable matrices. We suppose here that the set of matrices $\mathcal{G}$ satisfies $\Gamma_k = A\Delta_k A^t, k = 1, \ldots, K$, with $\Delta_k = \mathrm{diag}(\delta_k(1), \ldots, \delta_k(K))$ a (positive definite) diagonal matrix. This situation corresponds to the asymptotic conditions in the blind source separation problem. We have $X_T = AS_T$ and

$$\Gamma_k = A\frac{1}{T} S_T [R_k^T(\beta_k)]^{-1} S_T^t A^t, \quad k = 1, \ldots, K.$$

Thus, as T goes to infinity, the matrix $\frac{1}{T} S_T [R_k^T(\beta_k)]^{-1} S_T^t$ goes to a diagonal matrix Δ_k because the sources are independent. Moreover, Δ_k satisfies $1 = \delta_k(k) < \delta_k(j), j \neq k$ [8]. This leads to the following result.

PROPOSITION 3.7. *Let $\Gamma_k = A\Delta_k A^t, k = 1, \ldots, K$, be a set of $K \times K$ symmetric positive definite matrices which are jointly diagonalizable. Suppose that each diagonal matrix $\Delta_k = \operatorname{diag}(\delta_k(1), \ldots, \delta_k(K))$ satisfies $1 = \delta_k(k) < \delta_k(j), j \neq k$. Then $B = A^{-1}$ is the essentially unique solution of the max-det problem.*

Proof. Using Lemma 3.4 with $M = A^{-1}$, the solution is $B = UA^{-1}$, where $U = [u_1, \ldots, u_K]^t$ is the solution of the max-det problem associated with the diagonal matrices $\Delta_k, k = 1, \ldots, K$. We have

$$|\det U| \leq \prod_{k=1}^{K} \|u_k\|,$$

where $\|u\|^2 = u^t u$ is the usual Euclidean norm, with equality if and only if $u_k^t u_j = 0$ for $j \neq k$. Now, both constraint $u_k^t \Delta_k u_k \leq 1$ and hypothesis $1 = \delta_k(k) < \delta_k(j), j \neq k$, lead to $\|u_k\| \leq 1$ with equality if and only if $u_k = \pm e_k$. Because U is a sign matrix, the solution $B = A^{-1}$ is essentially unique. ∎

This proposition can be extended as follows.

PROPOSITION 3.8. *Let $\Gamma_k = A\Delta_k A^t, k = 1, \ldots, K$, be a set of $K \times K$ symmetric positive definite matrices which are jointly diagonalizable. The solution B of the max-det problem satisfies*

$$|\det B| \leq |\det A|^{-1} \prod_{k=1}^{K} \delta_k^{-1/2},$$

where $\Delta_k = \operatorname{diag}(\delta_k(1), \ldots, \delta_k(K))$ and $\delta_k = \min_j \delta_k(j), k = 1, \ldots, K$. This upper bound is achieved if and only if there exists a permutation $\{j_1, \ldots, j_K\}$ of $\{1, \ldots, K\}$ such that $\delta_k(j_k) = \delta_k, k = 1, \ldots, K$, and the solution is essentially unique if and only if such a permutation is unique.

Proof. By Lemma 3.4 we can restrict ourself to the case of diagonal matrices. Using the notation and the arguments of the proof above, we have

$$|\det U| \leq \prod_{k=1}^{K} \|u_k\| \leq \prod_{k=1}^{K} \delta_k^{-1/2},$$

and the upper bound is achieved if and only if $U = \Delta^{-1/2} V$, with $\Delta = \operatorname{diag}(\delta_1, \ldots, \delta_K)$ and $V = [v_1, \ldots, v_K]^t$, where v_k is an eigenvector of Δ_k associated with the eigenvalue δ_k and $VV^t = I$. If there exists a permutation $\{j_1, \ldots, j_K\}$ of $\{1, \ldots, K\}$ such that $j_k \in J_k = \{j : \delta_k(j) = \delta_k\}, k = 1, \ldots, K$, then the upper bound is realized by $v_k = \pm e_{j_k}, k = 1, \ldots, K$, and V is essentially a permutation matrix. Suppose now that the upper bound is achieved. Then $V^{\cdot 2} = (v_{ij}^2)$, where $v_{ij}^2 = v_{ij}^2$, is doubly stochastic. So there is a permutation matrix $V^* = (v_{ij}^*)$ such that $v_{ij}^* = 0$ whenever $v_{ij}^2 = 0$ [6, Theorem 20.3, p. 329], and the entries of V^* define the desired permutation. Finally, since any doubly stochastic matrix is a convex combination of permutation matrices [6, Theorem 20.4, p. 330], the solution is essentially unique if and only if such a permutation is unique. ∎

In all other cases, no general result has been obtained. We now give some comments and examples, for diagonal matrices, in order to show the difficulties of the problem.

For any permutation $\{j_1, \ldots, j_K\}$ of $\{1, \ldots, K\}$, the matrix

$$U^t = \left[\frac{e_{j_1}}{\sqrt{\delta_1(j_1)}}, \ldots, \frac{e_{j_K}}{\sqrt{\delta_K(j_K)}} \right], \qquad \det U = \left[\prod_{k=1}^{K} \delta_k(j_k) \right]^{-1/2} \tag{3.7}$$

is a solution of the following system coming from (3.3):

$$U\Delta_k U^t e_k = e_k, \quad k = 1, \dots, K. \tag{3.8}$$

Example 4 below shows that other solutions can exist. From Proposition 3.3, a solution of (3.8) corresponds to a maximum if and only if

$$\frac{\delta_k(j_l)}{\delta_l(j_l)} > \frac{\delta_k(j_k)}{\delta_l(j_k)}, \quad k < l = 1, \dots, K,$$

but it is not proved that the solution of the max-det problem is in this set. Notice that the system (3.8) has a continuum of solutions if, for some $k \neq l$, there exists $i \neq j$ such that $\delta_k(i)\delta_l(j) = \delta_l(i)\delta_k(j)$.

Let us consider now some examples illustrating different situations.

1. For $K = 3, \Delta_1 = \mathrm{diag}(1, 2, 1), \Delta_2 = \mathrm{diag}(1, 1, 2)$, and $\Delta_3 = \mathrm{diag}(2, 1, 1)$, the maximum is equal to 1 and given by the matrices essentially equal to I or to
$$\Pi = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$
2. For $K = 3, \Delta_1 = \mathrm{diag}(1, 1, 1), \Delta_2 = \mathrm{diag}(1, 1, 2)$, and $\Delta_3 = \mathrm{diag}(2, 3, 1)$, the maximum is also equal to 1, but is realized by a continuum of solutions given by the matrices essentially equal to
$$U = \begin{pmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad -\frac{\pi}{2} < \theta \leq \frac{\pi}{2}.$$
3. For $K = 3, \Delta_1 = \mathrm{diag}(1, 1, 1), \Delta_2 = \mathrm{diag}(1, 3, 2)$, and $\Delta_3 = \mathrm{diag}(1, 3, 4)$, the maximum is equal to $1/\sqrt{2}$ and given by the matrices essentially equal to
$$U = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1/\sqrt{2} \\ 1 & 0 & 0 \end{pmatrix}.$$
However, saddle points of the criterion are given by the following matrices:
$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/\sqrt{3} & 0 \\ 0 & 0 & 1/2 \end{pmatrix}, \quad \begin{pmatrix} 0 & 0 & 1 \\ \sin\theta & \cos\theta/\sqrt{3} & 0 \\ \cos\theta & -\sin\theta/\sqrt{3} & 0 \end{pmatrix}, \quad -\frac{\pi}{2} < \theta \leq \frac{\pi}{2},$$
and we have observed that our algorithm can converge to such points.
4. For $K = 3, \Delta_1 = \mathrm{diag}(1, 1, 1), \Delta_2 = \mathrm{diag}(3, 9, 11)/12$, and $\Delta_3 = \mathrm{diag}(7, 5, 15)/20$, the maximum is equal to 4 and essentially uniquely realized by
$$U = \begin{pmatrix} 0 & 0 & 1 \\ 2 & 0 & 0 \\ 0 & 2 & 0 \end{pmatrix}.$$
Five solutions of (3.8) are given by
$$U^t = [e_j/\sqrt{\delta_1(j)}, e_k/\sqrt{\delta_2(k)}, e_l/\sqrt{\delta_3(l)}],$$

where $(j,k,l) \neq (3,1,2)$ are the other permutations of $(1,2,3)$. However, in this case, the matrix

$$\begin{pmatrix} 1 & 2 & 1 \\ -1 & 1 & -3 \\ 5 & -1 & -1 \end{pmatrix} \begin{pmatrix} \sqrt{0.1} & 0 & 0 \\ 0 & \sqrt{0.2} & 0 \\ 0 & 0 & \sqrt{0.1} \end{pmatrix}$$

is also a solution of (3.8).

5. For $K = 3, \Delta_1 = \mathrm{diag}(1,2,5), \Delta_2 = \mathrm{diag}(5,1,2)$, and $\Delta_3 = \mathrm{diag}(2,5,1)$, the maximum is equal to 1 and given by the matrices essentially equal to I. The other solutions of (3.8), associated with the permutations of $(1,2,3)$, lead to saddle points except for $(2,3,1)$ for which the matrix

$$\begin{pmatrix} 0 & 1/\sqrt{2} & 0 \\ 0 & 0 & 1/\sqrt{2} \\ 1/\sqrt{2} & 0 & 0 \end{pmatrix}$$

provides a local maximum of the criterion.

3.4. Existence of the solution. The existence of a solution of our max-det problem is obtained by considering the criterion $l(B;\mathcal{G})$ given in (1.2).

PROPOSITION 3.9. *The maximum of $l(B;\mathcal{G})$ is attained by a nonsingular matrix B satisfying the set of equations* (3.3).

Proof. Let λ_k be the smallest eigenvalue of Γ_k. The inequality

$$l(B;\mathcal{G}) \leq \sum_{k=1}^{K} \left[\log \|b_k\| - \frac{\lambda_k}{2} \|b_k\|^2 \right]$$

shows the coercivity of $l(B;\mathcal{G})$. Thus we can restrict ourself to a set of bounded matrices B. Now, in such a set, $l(B;\mathcal{G})$ goes to $-\infty$ when B goes to a singular matrix because $l(B;\mathcal{G}) < \log\det|B|$. Then the maximum is attained by a nonsingular matrix B, and this matrix satisfies (3.3). ∎

Notice that $b_k^t \Gamma_k b_k \leq 1$ leads to $\|b_k\| \leq \lambda_k^{-1}$. So $\prod_{k=1}^{K} \lambda_k^{-1}$ is an upper bound for $\det B$. This upper bound is attained if and only if $B_{ev} = [\lambda_1^{-1/2} v_1, \ldots, \lambda_K^{-1/2} v_K]^t$, where v_k is an eigenvector associated with λ_k, satisfies (3.3). For example, this will be the case for jointly diagonalizable matrices, $\Gamma_k = V \Lambda_k V^t, k = 1, \ldots, K$, with $V = [v_1, \ldots, v_k]^t, V^t V = I$, and λ_k being the smallest element of Λ_k.

From a geometrical point of view, it is natural to maximize $\det B$ in the formulation of our max-det problem. On the other hand, the maximum likelihood principle in the blind source separation problem leads to the presence of $|\det B|$ instead of $\det B$ in the formulation of the criterion $l(B;\mathcal{G})$. In fact, the two optimization problems are equivalent (have the same set of solutions) if we consider either $\det B$ or $|\det B|$ in the two formulations. We have already observed that $l(\mathcal{E}B;\mathcal{G}) = l(B;\mathcal{G})$ for any sign matrix $\mathcal{E}$. Furthermore, $\det \mathcal{E}B = \det \mathcal{E} \times \det B$ with $\det \mathcal{E} = \pm 1$. So the set of matrices that maximize the criterion $l(B;\mathcal{G})$, with $\det B$ instead of $|\det B|$, is the set of matrices that maximize $l(B;\mathcal{G})$ and satisfy $\det B > 0$. This set is also the set of solutions of our max-det problem. More precisely, we have the following result.

PROPOSITION 3.10. *The maximization of $\det B$ subject to the constraint* (1.1) *is equivalent to minimizing the criterion*

$$l^*(B;\mathcal{G}) = -\log\det B + \frac{1}{2} \sum_{k=1}^{K} (b_k^t \Gamma_k b_k - 1).$$

Proof. If B satisfies (1.1), $\mathcal{E}B$ also satisfies (1.1), for any sign matrix $\mathcal{E}$, so we can restrict ourself to the set of matrices B with $\det B > 0$. Then, our max-det problem is equivalent to the minimization of $-\log\det B$ subject to (1.1). Let us consider the Lagrange function associated with

$$L(B,\mu) = -\log\det B + \sum_{k=1}^{K} \mu_k (b_k^t \Gamma_k b_k - 1),$$

where $\mu = (\mu_1, \ldots, \mu_K)^t$ is the vector of Lagrange multipliers. Since $\det B$ is bounded under the constraint (1.1) and $-\log\det B$ goes to $+\infty$ when B tends to a singular matrix, the minimum of $-\log\det B$, subject to (1.1), exists and is attained by a nonsingular matrix B. For such a matrix, we have

$$\frac{\partial b_k^t \Gamma_k b_k}{\partial B} = 2\,[0, \ldots, 0, \Gamma_k b_k, 0, \ldots, 0]^t \neq 0, \quad k = 1, \ldots, K,$$

because $b_k \neq 0$ and Γ_k is positive definite. So, the linear independence constraint qualification holds. Then, there exists μ such that the solution B satisfies the KKT necessary conditions

$$\mu_k \geq 0, \quad \mu_k (b_k^t \Gamma_k b_k - 1) = 0, \quad b_k^t \Gamma_k b_k - 1 \leq 0, \quad k = 1, \ldots, K, \quad \frac{\partial L(B,\mu)}{\partial B} = 0.$$

We have

$$\frac{\partial L(B,\mu)}{\partial B} = 0 \quad \Longleftrightarrow \quad 2\mu_k B \Gamma_k b_k = e_k, \quad k = 1, \ldots, K. \tag{3.9}$$

Setting $\mathcal{S}_B = \{B : \det B > 0, b_k^t \Gamma_k b_k \leq 1, k = 1, \ldots, K\}$ and $\mathcal{S}_\mu = \{\mu : \mu_k \geq 0, k = 1, \ldots, K\}$, the min-max theorem gives

$$\min_{B \in \mathcal{S}_B} \max_{\mu \in \mathcal{S}_\mu} L(B,\mu) \geq \max_{\mu \in \mathcal{S}_\mu} \min_{B \in \mathcal{S}_B} L(B,\mu).$$

From

$$\min_{B \in \mathcal{S}_B} \max_{\mu \in \mathcal{S}_\mu} L(B,\mu) = \min_{B \in \mathcal{S}_B} -\log\det B, \qquad \max_{\mu \in \mathcal{S}_\mu} \min_{B \in \mathcal{S}_B} L(B,\mu) \geq \min_{B \in \mathcal{S}_B} L(B,\mu^*)$$

given by $\mu = 0$ and $\mu^* = (1/2, \ldots, 1/2)^t$, we obtain

$$\min_{B \in \mathcal{S}_B} -\log\det B \geq \min_{B \in \mathcal{S}_B} L(B,\mu^*) = \min_{B \in \mathcal{S}_B} l^*(B;\mathcal{G}) \geq \min_B l^*(B;\mathcal{G}). \tag{3.10}$$

Now, if $\hat{\mathcal{S}}_B$ is the set of matrices B satisfying $\det B > 0$ and (3.3), Proposition 3.9 leads to

$$\min_B l^*(B;\mathcal{G}) = \min_{B \in \hat{\mathcal{S}}_B} l^*(B;\mathcal{G}) = \min_{B \in \hat{\mathcal{S}}_B} -\log\det B \geq \min_{B \in \mathcal{S}_B} -\log\det B, \tag{3.11}$$

because $\hat{\mathcal{S}}_B \subset \mathcal{S}_B$. Relations (3.10) and (3.11) give the equality

$$\min_{B \in \mathcal{S}_B} -\log\det B = \min_B l^*(B;\mathcal{G}) \tag{3.12}$$

and show that

$$\left\{ \hat{B} : l^*(\hat{B};\mathcal{G}) = \min_B l^*(B;\mathcal{G}) \right\} \subseteq \left\{ \hat{B} : -\log\det \hat{B} = \min_{B \in \mathcal{S}_B} -\log\det B \right\}.$$

Conversely, if $\hat{B} \in \mathcal{S}_B$ minimizes $-\log\det B$, it is also a minimum for $l^*(B;\mathcal{G})$ since

$$-\log\det\hat{B} \geq l^*(\hat{B};\mathcal{G}) \geq \min_B l^*(B;\mathcal{G}) = -\log\det\hat{B},$$

and the proof is achieved. Notice that (3.3) corresponds to (3.9) with $\mu = \mu^*$. □

In the proof above, equality (3.12) shows that there is no duality gap and μ^* is a strong duality solution for our max-det problem although this problem is nonconvex.

3.5. The uniqueness problem. We have shown that the solution of our max-det problem is essentially unique for two nonproportional matrices (see Proposition 3.6) and for particular jointly diagonalizable matrices (see Propositions 3.7 and 3.8). Neither a general result for this problem nor a sufficient condition for the solutions of (3.3) to be a set of isolated points has been obtained. Indeed, this last condition guarantees the convergence of our algorithm. In section 3.3 we have seen, for jointly diagonalizable matrices, that the maximum can be reached by two distinct matrices (example 1) or by a continuum set of matrices (example 2). This comes from the particular structure of these matrices, and such nuisance disappears in the blind source separation problem, because $\mathcal{G} = \{\Gamma_k, k = 1,\ldots,K\}$ is a set of estimated matrices. However, the existence of saddle points (example 3) and local maxima (example 5) for the criterion will be probably true more often than not. This comes from the continuity of $l(B,\mathcal{G})$ with respect to $\mathcal{G}$. We suggest computing the upper bound $\prod_{k=1}^K \lambda_k^{-1}$ of $\det B$ and starting the algorithm with the matrix $B_{ev} = [\lambda_1^{-1/2}v_1,\ldots,\lambda_K^{-1/2}v_K]^t$ presented above. These points will be illustrated at the end of the next section.

4. The algorithm. The algorithm and its convergence properties are presented, and some numerical experiments are performed showing its behavior.

We maximize $l(B,\mathcal{G})$ by a relaxation technique on the rows $b_k, k = 1,\ldots,K$, of B. Such an iterative method guarantees that the criterion increases at each step. Then, the convergence of the algorithm can be obtained under reasonable conditions.

4.1. The relaxation technique. The gradient of $l(B,\mathcal{G})$ with respect to b_k vanishes if and only if $e_k = B\Gamma_k b_k$, i.e., $\|b_k\|_{\Gamma_k} = 1$ and $\langle b_k, b_j\rangle_{\Gamma_k} = 0$ for $j \neq k$. The Hessian

$$\nabla^2_{b_k} l(B;\mathcal{G}) = -a_k a_k^t - \Gamma_k, \qquad [a_1,\ldots,a_K] = A = B^{-1}$$

is negative definite. So the maximum of $l(B,\mathcal{G})$, with respect to b_k and when the other rows of B are fixed, has the following explicit solution. Let B be a nonsingular matrix of order K, and let $B_{(k)}$ denote the $(K-1)\times K$-matrix obtained by removing the kth row of B. Hence the orthogonal projector in $\mathbf{R}^K$, according to $\langle\cdot,\cdot\rangle_{\Gamma_k}$, on the subspace spanned by the rows of $B_{(k)}$ is

$$P_k = B_{(k)}^t \left[B_{(k)}\Gamma_k B_{(k)}^t\right]^{-1} B_{(k)}\Gamma_k.$$

Thus the maximum of $l(B,\mathcal{G})$ is realized by $\pm\hat{b}_k$ with

$$\hat{b}_k = \frac{(I-P_k)b_k}{\|(I-P_k)b_k\|_{\Gamma_k}}.$$

Our algorithm proceeds as follows. A nonsingular initial matrix $B(0)$ is chosen. Then the algorithm constructs a sequence $\{B(n), n \geq 0\}$ by modifying successively the rows of the current matrix using the above process. $B(n+1)$ differs from $B(n)$

only by one row; i.e., $b_k(n+1) = \pm\hat{b}_k(n)$ for some k and the sign is chosen in such a way that the first nonzero component of $b_k(n+1)$ is positive. By construction, each matrix $B(n)$ is nonsingular.

4.2. Convergence of the algorithm. We have seen that the criterion $l(B;\mathcal{G})$ is bounded and is strictly concave with respect to b_k. Hence $l(B(n+1);\mathcal{G}) \geq l(B(n);\mathcal{G})$, with equality if and only if $B(n+1) = B(n)$. However, this equality is not sufficient to prove that $B(n)$ satisfies (3.3); this will be true if and only if $B(n+K) = B(n)$. However, we have the following result.

PROPOSITION 4.1. *The sequence* $\{l(B(n);\mathcal{G}), n \geq 0\}$ *is convergent.*

This does not prove the convergence of the sequence $\{B(n), n \geq 0\}$, which requires many intermediate results.

LEMMA 4.2. *The projection* $P_k(n)b_k(n)$*, computed at each step of the algorithm, converges to* 0 *when* n *goes to* $+\infty$*.*

Proof. Assume, without any loss of generality, that the $(n+1)$th step concerns the modification of the first row of $B(n)$. On the one hand, we have, for $n \geq K$,

$$l(B(n+1);\mathcal{G}) - l(B(n);\mathcal{G}) = \log|\det B(n+1)A(n)|,$$

where $A(n) = [a_1(n), \ldots, a_K(n)] = B(n)^{-1}$. On the other hand, we have

$$B(n+1)A(n) = \begin{pmatrix} \langle b_1(n+1), a_1(n)\rangle & \ldots & \ldots & \langle b_1(n+1), a_K(n)\rangle \\ 0 & 1 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \ldots & \ldots & 1 \end{pmatrix}.$$

Proposition 4.1 shows that the difference $l(B(n+1);\mathcal{G}) - l(B(n);\mathcal{G})$ goes to 0; therefore the inner product $\langle b_1(n+1), a_1(n)\rangle$ goes to ± 1. By construction we have

$$b_1(n+1) = \pm\frac{b_1(n) - P_1(n)b_1(n)}{\|b_1(n) - P_1(n)b_1(n)\|_{\Gamma_1}},$$

and then

$$\begin{aligned}\langle b_1(n+1), a_1(n)\rangle &= \pm\frac{\langle b_1(n), a_1(n)\rangle - \langle P_1(n)b_1(n), a_1(n)\rangle}{\|b_1(n) - P_1(n)b_1(n)\|_{\Gamma_1}} \\ &= \pm\frac{1}{\|b_1(n) - P_1(n)b_1(n)\|_{\Gamma_1}}.\end{aligned}$$

Therefore, $\|b_1(n) - P_1(n)b_1(n)\|_{\Gamma_1}$ converges to 1 when n goes to $+\infty$. Since

$$\begin{aligned}\|P_1(n)b_1(n)\|^2_{\Gamma_1} &= \|b_1(n)\|^2_{\Gamma_1} - \|b_1(n) - P_1(n)b_1(n)\|^2_{\Gamma_1} \\ &= 1 - \|b_1(n) - P_1(n)b_1(n)\|^2_{\Gamma_1},\end{aligned}$$

one deduces that $\|P_1(n)b_1(n)\|^2_{\Gamma_1}$ converges to 0 when n goes to $+\infty$. □

Now we show that, asymptotically, $B(n)$ satisfies the optimality condition (3.3).

LEMMA 4.3. *The sequence* $\{B(n), n \geq 0\}$ *satisfies*

$$\lim_{n\to+\infty} B(n)\Gamma_k B(n)^t e_k = e_k, \quad k = 1, \ldots, K.$$

Proof. We have to show that, for all $k, j = 1, \ldots, K$,

$$\lim_{n\to+\infty} \langle b_k(n), b_j(n)\rangle_{\Gamma_k} = \delta_{kj}.$$

Let $b_i(n)$ be the row modified at the $(n+1)$th step,

$$b_i(n+1) = \frac{b_i(n) - P_i(n)b_i(n)}{\|b_i(n) - P_i(n)b_i(n)\|_{\Gamma_i}}.$$

For $k = i$, we have $\langle b_i(n+1), b_j(n+1)\rangle_{\Gamma_i} = \delta_{ij}$ by construction. For the same reason, we have $\langle b_j(n), b_i(n)\rangle_{\Gamma_j} = 0$ for $j \neq i$ because of the $(K-1)$ preceding steps (provided that $n \geq K-1$). Hence one obtains

$$\begin{aligned}\langle b_j(n+1), b_i(n+1)\rangle_{\Gamma_j} &= \langle b_j(n), b_i(n+1)\rangle_{\Gamma_j} \\ &= \frac{\langle b_j(n), b_i(n) - P_i(n)b_i(n)\rangle_{\Gamma_j}}{\|b_i(n) - P_i(n)b_i(n)\|_{\Gamma_j}} = -\frac{\langle b_j(n), P_i(n)b_i(n)\rangle_{\Gamma_j}}{\|b_i(n) - P_i(n)b_i(n)\|_{\Gamma_j}}.\end{aligned}$$

Since $\|b_j(n)\|_{\Gamma_j} = 1$ for $j = 1, \ldots, K$ and $P_i(n)b_i(n)$ goes to 0 (according to the Lemma 4.2), one deduces that $\langle b_j(n+1), b_i(n+1)\rangle_{\Gamma_j}$ converges to 0 when n goes to $+\infty$. When both j and k are not equal to i, $\langle b_j(n+1), b_k(n+1)\rangle_{\Gamma_j} = 0$ if the jth row was modified after the kth one, which corresponds to the following situations: $i < k < j$, $k < j < i$, and $j < i < k$. Otherwise, we use the same argument as above from the following equalities. We have

$$\langle b_j(n+1), b_k(n+1)\rangle_{\Gamma_j} = -\frac{\langle b_j(l), P_k(l)b_k(l)\rangle_{\Gamma_j}}{\|b_k(l) - P_k(l)b_k(l)\|_{\Gamma_k}}, \quad l = n - i + k + 1,$$

for $j < k < i$ or $k < i < j$, and

$$\langle b_j(n+1), b_k(n+1)\rangle_{\Gamma_j} = -\frac{\langle b_j(l), P_k(l)b_k(l)\rangle_{\Gamma_j}}{\|b_k(l) - P_k(l)b_k(l)\|_{\Gamma_k}}, \quad l = n - i + k - K + 1,$$

for $i < j < k$. □

LEMMA 4.4. *The sequence* $\{B^{-1}(n), n \geq 0\}$ *is bounded.*

Proof. We recall the notation $A(n) = [a_1(n), \ldots, a_K(n)] = B^{-1}(n)$ and take the usual norm, $\|A\|^2 = \text{trace}(AA^t)$. Let λ_k (resp., μ_k) be the smallest (resp., the largest) eigenvalue of the matrix Γ_k. Since $n \geq K-1$, we have

$$\|A(n)\|^2 = \sum_{k=1}^{K} \|a_k(n)\|^2 \leq \sum_{k=1}^{K} \frac{\mu_k^2}{\lambda_k}.$$

Indeed, assume that $b_k(n)$ is the row defined at the nth step. By the construction process, $b_k(n)$ is characterized by

$$B(n)\Gamma_k b_k(n) = e_k \quad \Longleftrightarrow \quad a_k(n) = \Gamma_k b_k(n).$$

The second expression yields to the inequality $\|a_k(n)\| \leq \mu_k \|b_k(n)\|$. Moreover, $\|b_k(n)\|_{\Gamma_k}^2 = 1$ implies that $\|b_k(n)\|^2 \leq \frac{1}{\lambda_k}$. □

LEMMA 4.5. *The gradient of* $l(B; \mathcal{G})$*, evaluated at* $B(n)$*, converges to* 0 *when* n *goes to* $+\infty$*, and any accumulation point of the sequence* $\{B(n), n \geq 0\}$ *satisfies the optimality condition* (3.3).

Proof. From Proposition 3.1, we have

$$\nabla_{b_k} l(B(n); \mathcal{G}) = a_k(n) - \Gamma_k B^t(n) e_k = A(n)(e_k - B(n)\Gamma_k B^t(n) e_k), \quad k = 1, \ldots, K.$$

The matrix $A(n)$ is bounded and, according to the Lemma 4.3,

$$\lim_{n \to +\infty} B(n)\Gamma_k B^t(n) e_k = e_k \quad \forall\, k = 1, \ldots, K;$$

TABLE 4.1

Behavior of the algorithm in three situations: random (6 cases), saddle points, and local maxima. Variables are computed, in each row, with $N = 1000$ choices of matrices Γ_k and B_{ev} or $R = 100$ random matrices as starting value. See the text for further explanation.

Matrices Γ_k	η	div ev	div r	swe ev	swe r	nonun	$ev \neq r$
Random		0	0.4	11.3	12.2	3	1
		1	0.9	10.5	11.5	1	0
		2	2.3	10.2	11.1	0	0
		3	2.0	11.1	12.3	1	0
		4	2.1	10.1	11.1	2	0
		5	4.1	10.8	11.8	4	1
Saddle points	10^{-3}	0	133.0	44.5	50.2	999	0
	10^{-2}	0	52.6	45.0	55.4	376	0
	10^{-1}	32	38.7	58.2	63.9	111	23
	1	7	6.7	31.3	33.6	29	6
	10	2	2.4	15.0	16.2	11	1
	100	1	1.0	10.6	11.4	4	1
Local maxima	10^{-3}	0	0.0	6.6	11.4	523	0
	10^{-2}	0	0.4	7.7	11.4	137	0
	10^{-1}	0	0.1	10.2	13.4	11	0
	1	2	3.7	25.6	27.7	23	8
	10	2	2.6	15.5	16.6	6	0
	100	0	0	10.8	11.7	5	1

then the first part of the lemma is achieved. Let B^* be an accumulation point of the sequence $\{B(n), n \geq 0\}$. Then there exists a increasing function φ such that the sequence $\{B(\varphi(n)), n \geq 0\}$ converges to B^*. This subsequence satisfies the limit property of Lemma 4.3, and this, using the continuity of the inner product, achieves the second part of the lemma. □

LEMMA 4.6. $\lim_{n\to+\infty} \|B(n+1) - B(n)\| = 0$.

Proof. Assume that $B(n+1)$ differs from $B(n)$ by its kth row; then we have

$$\|B(n+1) - B(n)\| = \|b_k(n+1) - b_k(n)\|,$$
$$b_k(n+1) - b_k(n) = \frac{b_k(n)(1 - \|b_k(n) - P_k(n)b_k(n)\|_{\Gamma_k}) - P_k(n)b_k(n)}{\|b_k(n) - P_k(n)b_k(n)\|_{\Gamma_k}}.$$

Thus $b_k(n+1) - b_k(n)$ converges to 0 when n goes to $+\infty$ since $P_k(n)b_k(n)$ converges to 0 and $\|b_k(n)\|_{\Gamma_k} = 1$. □

Both the lemma and a theorem in Ostrowski [13, p. 173] lead to the following result.

THEOREM 4.7. *The sequence $\{B(n), n \geq 0\}$ given by the algorithm converges; otherwise, the set of solutions of the optimality condition* (3.3) *is a continuum.*

4.3. Numerical experiments. Two sets of experiments are conducted. The former illustrates the behavior of our algorithm, and the latter compares our approach with Newton's methods for nonlinear optimization.

Table 4.1 summarizes results on the behavior of the algorithm. For $K = 3$, three kinds of situations are considered: random, saddle points and local maxima. In the first, the set $\mathcal{G}$ is random; i.e., the matrices $\Gamma_k, k = 1, 2, 3$, are mutually independent with $\Gamma_k = R_k R_k^t$, where R_k is a random matrix whose elements are independent zero-mean Gaussian variables with variance one. In the two other situations, we use

diagonal matrices with random perturbations

$$\Gamma_k = \Delta_k + \eta R_k R_k^t, \quad k = 1, 2, 3,$$

where R_k is as above and η is a scalar factor. The diagonal matrices Δ_k are those introduced in section 3.3 illustrating saddle points (example 3) and local maxima (example 5). Each row of the table corresponds to $N = 1000$ experiments associated with N independent choices of $\mathcal{G}$. For each experiment, our algorithm is used starting with $B(0)$ equal to the matrix B_{ev} using the eigenvectors (see section 3.5) and also to $R = 100$ random matrices $B_r, r = 1, \ldots, R$ (B_r is distributed like R_k above). The algorithm is stopped when the two following conditions are satisfied:

- $abs(l(B(mK + K); \mathcal{G}) - l(B(mK); \mathcal{G})) < 10^{-8}$,
- $\max_{i,j}\{|B_{ij}(mK + K) - B_{ij}(mK)|\} < 10^{-8}$,

or when the number of sweeps reaches 200 (a sweep corresponds to the change of $B(mK)$ into $B(mK + K)$). We use 10^{-8}, instead of 10^{-4} as below, in order to well separate, in each experiment, the distinct values of $l(\hat{B}; \mathcal{G})$ given by distinct values of $B(0)$, for the computation of "nonun" and "$ev \neq r$." Noting $\hat{B}_{ev}$ and $\hat{B}_r$ as the solutions of the algorithm associated with $B(0) = B_{ev}$ and $B(0) = B_r$, variables "nonun" and "$ev \neq r$" in Table 4.1 give, respectively, for the N experiments, the number of cases where $\max_r(l(\hat{B}_r; \mathcal{G})) - \min_r(l(\hat{B}_r; \mathcal{G})) > 10^{-4}$ and $|\max_r(l(\hat{B}_r; \mathcal{G})) - l(\hat{B}_{ev}; \mathcal{G})| > 10^{-4}$. So "nonun" represents the number of experiments for which the solution given by the algorithm is not unique, since it depends on the starting value $B(0)$; "$ev \neq r$" measures the ability of the algorithm to reach the maximum, when the starting value is B_{ev}. Variable "div ev" is the number of divergences of the algorithm (when the number of sweeps reaches 200) when $B(0) = B_{ev}$, and "div r" is the corresponding mean number using R starting values $B(0) = B_r$. Variables "swe ev" and "swe r" are the mean number of sweeps for convergence of the algorithm starting with $B(0) = B_{ev}$ (N trials) and $B(0) = B_r$ ($N \times R$ trials), respectively, computed only on the convergence cases.

Looking at $ev \neq r$ and div ev, it is clear that the algorithm must be initialized with $B(0) = B_{ev}$. In that way, saddle points or local maxima seem to be avoided. The random cases reported here have been obtained with numerous tries in order to select cases with increasing values of div ev. The corresponding values of div r and the relatively stability of swe ev and swe r lead to the following conclusions. Generally, the algorithm converges quickly, except for some "ill-conditioned" sets $\mathcal{G}$ for which the convergence is very slow, whatever the starting value. "nonun" shows that the uniqueness problem is not so crucial in standard situations. "div r" illustrates Theorem 4.7, since the set of solutions of the optimality condition (3.3) is a continuum in the saddle points situation, while these solutions are isolated points, including saddle points, in the local maxima situation.

We compare now our relaxation method with Newton's methods for nonlinear optimization. First, we use the Newton approach described in (3.6). The scale factor λ_n is provided by the quadratic and cubic line search procedure given in section 9.7 of [12]. Furthermore, when the Hessian $H = \nabla^2_{B(n)}$ is not negative definite, we replace it by $H - (\lambda_{max} + 10^{-4})I$, where λ_{max} is the largest eigenvalue of H, in order to guarantee that the Newton direction dB is an ascent direction. Table 4.2 gives results of a set of variables for $K = 3, 5, 8, 10, 12, 15, 20$, and 25. Each row of the table corresponds to $N = 1000$ experiments associated with N independent choices of $\mathcal{G}$ in the random situation. For each experiment, our algorithm, like the Newton method, is used starting with $B(0)$ equal to the matrix B_{ev} using the eigenvectors.

TABLE 4.2

Comparison between the relaxation method (r) and Newton's method (n), using the line search procedure with modification of the Hessian, for eight dimensions K. Variables are computed, in each row, with $N = 1000$ choices of matrices Γ_k and B_{ev} as starting value.

Dim	div	$r-n$	swe r	swe n	cpu r	cpu n	cpu hes	cpu ls	hes	ls
$K=3$	2 - 0	0 - 1	6.1	5.0	0.0088	0.0095	0.0018	0.0023	241	265
$K=5$	1 - 0	1 - 6	8.7	6.6	0.0169	0.0166	0.0060	0.0030	457	489

$K=10$	0 - 0	9 - 13	13.3	8.8	0.0386	0.1900	0.1543	0.0063	777	808
$K=12$	1 - 0	14 - 15	14.1	9.3	0.0501	0.4848	0.4225	0.0080	836	860
$K=15$	3 - 0	16 - 22	16.9	10.2	0.0847	1.8966	1.7376	0.0114	914	933
$K=20$	1 - 0	25 - 32	20.4	11.0	0.1498	11.1208	10.6141	0.0150	973	979
$K=25$	3 - 0	31 - 29	22.2	11.8	0.2721	53.3996	51.9327	0.0260	986	987

The stopping rule is the same as above, but with 10^{-4} instead of 10^{-8} and $20K$ instead of 200 for the maximum number of sweeps. Variable "div" gives, for the N experiments, the number of divergences of the two methods, in the order $r-n$. Noting by $\hat{B}_r$ and $\hat{B}_n$ the solutions given by our relaxation method and by Newton's method, variable "$r-n$" represents, for the N experiments, the number of cases where $l(\hat{B}_r;\mathcal{G}) > l(\hat{B}_n;\mathcal{G}) + 2\times 10^{-4}$ and $l(\hat{B}_n;\mathcal{G}) > l(\hat{B}_r;\mathcal{G}) + 2\times 10^{-4}$. Variables "swe r" and "swe n" are the means of sweeps of our algorithm and of Newton's method, computed only on the convergence cases. Variables "cpu r," "cpu n," "cpu hes," and "cpu ls" are the means of cpu times in seconds, computed only on the experiments for which the algorithms converge, of the relaxation algorithm, the Newton's method, the modification of the Hessian, and the line search procedure, respectively. Finally, variables "hes" and "ls" give, for Newton's method, the number of cases where the Hessian has positive eigenvalues and those where the line search procedure is necessary (at least one time during the sweeps of an experiment).

Table 4.2 shows that the performances of the two methods are similar (see variable "$r-n$"). However, our relaxation method is faster (cpu time) than Newton's method, although the mean number of sweeps of Newton's method is lower than that of the relaxation method. Notice that the gain in cpu time increases very quickly with K: from 1 at $K = 5$ to 196 for $K = 25$. As it can be seen from variable "hes," the Hessian frequently has positive eigenvalues, but Newton's method always converges, and we have observed than the Hessian is always negative definite at convergence. An important difference between the two methods is that, in the relaxation technique, the successive values $B(n)$ satisfy the constraint $b_k^t \Gamma_k b_k = 1, k = 1,\ldots,K$, while this constraint is approximatively satisfied only by the solution $\hat{B}_n$ given by the Newton's method. This can explain that "swe r" is greater than "swe n," since the search for the solution is confined on this constrained set in the relaxation technique. Variable "cpu hes" shows that the difference in cpu time between the two methods comes essentially from the computation of the eigenvalues of the Hessian. So, we propose to use a negative definite approximation of $\nabla^2_{B(n)} = E + \Gamma_{B(n)}$ by canceling the off-diagonal blocs of E. The corresponding results are reported in Table 4.3. We observe that the performances of the two methods are still similar (variable "$r-n$"). But this decreases the convergence properties of Newton's method (variables "div" and "swe n"), and the relaxation method remains faster (cpu time) than Newton's method. As suggested by one referee, we also compare our method with Newton's method using the trust region approach. For that, we use the FMINUNC procedure of Matlab 7.0.1, with gradient and Hessian coming from Proposition 3.1. Our stopping rule is

TABLE 4.3

Comparison between the relaxation method (r) and Newton's method (n), using the line search procedure with approximation of the Hessian, for eight dimensions K. Variables are computed, in each row, with $N = 1000$ choices of matrices Γ_k and B_{ev} as starting value.

$K = 30$	0	28.3	0.6337
$K = 50$	0	35.6	5.5955
$K = 75$	2	47.9	23.8969
$K = 100$	3	85.7	109.1694

modified in order to agree with that of this procedure. Thus, our algorithm is stopped when either $abs(l(B(mK+K);\mathcal{G}) - l(B(mK);\mathcal{G})) < 10^{-4}$ or $\max_{i,j}\{|B_{ij}(mK+K) - B_{ij}(mK)|\} < 10^{-4}$, or when the number of sweeps reaches $20K$. This corresponds to $TolFun = 10^{-4}, TolX = 10^{-4}$, and $MaxIter = 20K$ in the options of the FMINUNC procedure. As can be seen in Table 4.4, the performances of the two methods remain similar, and the relaxation method is still faster than Newton's method. The gain in cpu time is less important for large values of K: it increases from 4 for $K = 5$ to 20 for $K = 25$ but is equal to 6 for $K = 3$.

In fact, these methods are not adapted for very large values of K, because the convergence begins slow. This can be seen in Table 4.5 for the relaxation method. In blind sources separation area, small values of K are frequently encountered, and some applications are restricted to $K = 2$.

Acknowledgments. The authors would like to thank the two reviewers for very useful comments and suggestions for clarifying the presentation of the paper.

A PROXIMAL-PROJECTION BUNDLE METHOD FOR LAGRANGIAN RELAXATION, INCLUDING SEMIDEFINITE PROGRAMMING*

KRZYSZTOF C. KIWIEL†

Abstract. We give a proximal bundle method for minimizing a convex function f over a convex set C. It requires evaluating f and its subgradients with a fixed but possibly unknown accuracy $\epsilon > 0$. Each iteration involves solving an unconstrained proximal subproblem and projecting a certain point onto C. The method asymptotically finds points that are ϵ-optimal. In Lagrangian relaxation of convex programs, it allows for ϵ-accurate solutions of Lagrangian subproblems and finds ϵ-optimal primal solutions. For semidefinite programming problems, it extends the highly successful spectral bundle method to the case of inexact eigenvalue computations.

1. Introduction.

We consider the convex constrained minimization problem

$$f_* := \inf\{\, f(u) : u \in C \,\}, \tag{1.1}$$

where C is a nonempty closed convex set in the Euclidean space $\mathbb{R}^n$ with inner product $\langle \cdot, \cdot \rangle$ and norm $|\cdot|$, and $f : \mathbb{R}^n \to \mathbb{R}$ is a convex function. We assume that for a fixed *accuracy tolerance* $\epsilon_f \geq 0$, for each $u \in C$ we can find an *approximate value* f_u and an *approximate subgradient* g_u of f that produce the *approximate linearization* of f:

$$\bar{f}_u(\cdot) := f_u + \langle g_u, \cdot - u \rangle \leq f(\cdot) \quad \text{with} \quad \bar{f}_u(u) = f_u \geq f(u) - \epsilon_f. \tag{1.2}$$

Thus $f_u \in [f(u) - \epsilon_f, f(u)]$ estimates $f(u)$, while $g_u \in \partial_{\epsilon_f} f(u)$; i.e., g_u is a member of the ϵ_f-subdifferential $\partial_{\epsilon_f} f(u) := \{g : f(\cdot) \geq f(u) - \epsilon_f + \langle g, \cdot - u \rangle\}$ of f at u.

Our assumption is realistic in many applications. For instance, if f is a max-type function of the form

$$f(u) := \sup\{\, F_z(u) : z \in Z \,\}, \tag{1.3}$$

where each $F_z : \mathbb{R}^n \to \mathbb{R}$ is convex and Z is an infinite set, then it may be impossible to compute $f(u)$. However, if for some fixed (and possibly *unknown*) tolerance ϵ_f we can find an ϵ_f-maximizer of (1.3), i.e., an element $z_u \in Z$ satisfying $F_{z_u}(u) \geq f(u) - \epsilon_f$, then we may set $f_u := F_{z_u}(u)$ and take g_u as any subgradient of F_{z_u} at u to satisfy (1.2). An important special case arises in *Lagrangian relaxation* [HUL93, Chap. XII], [Lem01], where problem (1.1) with $C := \mathbb{R}^n_+$ is the Lagrangian dual of the primal problem

$$\sup\ \psi_0(z) \quad \text{s.t.} \quad \psi_i(z) \geq 0,\ i = 1\colon n,\ z \in Z, \tag{1.4}$$

with $F_z(u) := \psi_0(z) + \langle u, \psi(z)\rangle$ for $\psi := (\psi_1, \ldots, \psi_n)$. Then, for each multiplier $u \geq 0$, we need only find $z_u \in Z$ such that $f_u := F_{z_u}(y) \geq f(u) - \epsilon_f$ in (1.3) to use $g_u := \psi(z_u)$. For instance, if (1.4) is a *semidefinite program* (SDP) with each ψ_i affine and Z the set of symmetric positive semidefinite matrices of order m with a bounded trace, then $f(u)$ is the maximum eigenvalue of a symmetric matrix $M(u)$ depending affinely on u [Tod01, sect. 6.3], and z_u can be found by computing an approximate eigenvector corresponding to the maximum eigenvalue of $M(u)$ via the Lanczos method [HeK02, HeR00, Nay06].

The recent paper [Kiw06b] extended the proximal bundle methods of [Kiw90] and [HUL93, sect. XV.3] to the inexact setting of (1.2) (see [Hin01, Kiw85, Kiw95, Mil01, Sol03] for earlier related developments, and [Kiw05] for numerical tests). Such methods at each iteration find a trial point that minimizes over C a polyhedral model of f built from accumulated linearizations, stabilized by a quadratic *prox* term centered at a point which is usually the best iterate found so far. Solving this subproblem can require much work for large n even when the set C is polyhedral, including the simplest case of $C = \mathbb{R}^n_+$ used in Lagrangian relaxation.

This paper extends the projection-proximal method of [Kiw99] to the case of inexact linearizations. For this method, we may regard (1.1) as an unconstrained problem $f_* = \inf f_C$ with the *essential objective*

$$f_C := f + i_C, \tag{1.5}$$

where i_C is the *indicator* function of C ($i_C(u) = 0$ if $u \in C$, ∞ otherwise). In its simplest form, the method generates the trial point in two steps. The first *proximal* step minimizes a polyhedral model $\check{f}$ of f, augmented with a quadratic proximal term and a linearization of i_C obtained at the previous iteration, to produce a linearization of $\check{f}$. The second *projection* step minimizes over C this linearization augmented with the proximal term; this amounts to projecting a certain point onto C to produce the trial point and the next linearization of i_C. Thus the standard bundle subproblem is replaced by two subproblems, where the first "unconstrained" subproblem is much easier to solve, and the projection is straightforward if the set C is "simple." Our development is related to the *alternating linearization* approach of [KRR99], in which the prox subproblem for the sum of two functions, such as (1.5), is approximated by two subproblems in which the functions are alternately represented by linear models.

Our extension of [Kiw99] is natural and simple: the original method is run as if the objective linearizations were exact until a test on predicted descent discovers their inaccuracy; then the proximity weight is decreased to produce descent or confirm that the current prox center is ϵ_f-optimal. We show that our method asymptotically estimates the optimal value f_* of (1.1) with accuracy ϵ_f and finds ϵ_f-optimal points. In Lagrangian relaxation, under standard convexity and compactness assumptions on problem (1.4) (see section 5), it finds ϵ_f-optimal primal solutions by combining partial Lagrangian solutions, even when Lagrange multipliers don't exist. These features are essentially "inherited" from the inexact framework of [Kiw06b] (although some technical developments are nontrivial). On the other hand, this paper reorganizes and simplifies the convergence framework of [Kiw06b] and sheds light on several important issues not discussed in there (such as the "true" impact of inexact evaluations, the possible use of "more inexact" null steps, primal recovery for Lagrangian relaxation with subgradient aggregation, and Lagrangian relaxation of equality constraints).

For the important special case where the functions ψ_i of the primal problem (1.4) are affine, we show how to employ *nonpolyhedral* models of f. Each model has the

form $\check{f}(\cdot) := \sup_{z\in\check{Z}} F_z(\cdot)$ stemming from (1.3), where $\check{Z}$ is a closed convex subset of Z. Then the proximal step can be implemented by solving a dual subproblem of minimizing a convex quadratic function over $\check{Z}$ (e.g., via interior-point methods when $\check{Z}$ is simple enough), and the projection on $C := \mathbb{R}^n_+$ is trivial. Further, the dual subproblem solutions estimate ϵ_f-optimal primal solutions asymptotically as above. In particular, our framework extends the highly successful methods of [FGRS06, sect. 3.2] and [ReS06, sect. 3] (see Remark 5.6).

Finally, for SDP (see below (1.4)) our general framework yields extensions of several variants of the spectral bundle method [Hel03, Hel04, HeK02, HeR00, Nay99]. This method employs the nonpolyhedral models discussed above, with $\check{Z}$ constructed from accumulated eigenvectors of the dual objective matrix $M(u)$. The original version of [HeR00] could handle only equality-constrained SDPs. Its extension [HeK02] to inequality-constrained SDPs can be seen as a specialization of the method of [Kiw99]; this helps in distinguishing its "driving force" from "implementation details" (although the latter are, of course, crucial for its performance in practice). Hence the primal recovery result of [Hel04, Thm. 3.6] also follows from our more general results (see Theorems 3.7 and 5.2); in fact, we don't need the assumption of [Hel04, Thm. 3.6] that the dual problem has a solution (see Remark 5.7(i)). Our extension to the case of approximate eigenvectors (see below (1.4)) is relevant for both theory and practice. Namely, while the existing version [HeK02] already employs approximate eigenvectors at so-called null steps (and this saves much work in practice [Hel03, HeK02, Nay99, Nay06]), it requires exact eigenvalues at the remaining descent steps. Our theoretical results show what to expect if approximate eigenvectors are used at descent steps as well, thus opening room for more efficient implementations.

The paper is organized as follows. In section 2 we present our method for general objective models. Its convergence is analyzed in section 3. Various modifications and model choices are given in section 4. Applications to Lagrangian relaxation are studied in section 5.

Our notation is fairly standard. $P_C(u) := \arg\min_C |\cdot - u|$ is the *projector* onto C.

2. The proximal-projection bundle method. Our method generates a sequence of *trial points* $\{u^k\}_{k=1}^\infty \subset C$ for evaluating the approximate values $f_u^k := f_{u^k}$, subgradients $g^k := g_{u^k}$, and linearizations $f_k := \bar{f}_{u^k}$ such that

$$f_k(\cdot) = f_u^k + \langle g^k, \cdot - u^k\rangle \le f(\cdot) \quad \text{with} \quad f_k(u^k) = f_u^k \ge f(u^k) - \epsilon_f, \tag{2.1}$$

as stipulated in (1.2). At iteration k, the current *prox* (or *stability*) *center* $\hat{u}^k := u^{k(l)} \in C$ for some $k(l) \le k$ has the value $f_{\hat{u}}^k := f_u^{k(l)}$ (usually $f_{\hat{u}}^k = \min_{j=1}^k f_u^j$); note that, by (2.1),

$$f_{\hat{u}}^k \in [f(\hat{u}^k) - \epsilon_f, f(\hat{u}^k)]. \tag{2.2}$$

For a model $\check{f}_k \le f$, the next point u^{k+1} approximately solves the prox subproblem

$$\min\ \check{f}_k(\cdot) + i_C(\cdot) + \frac{1}{2t_k}|\cdot - \hat{u}^k|^2, \tag{2.3}$$

where $t_k > 0$ is a *stepsize* that controls the size of $|u^{k+1} - \hat{u}^k|$. To this end, two partial linearizations of (2.3) are employed. First, replacing i_C by its past linearization $\bar{i}_C^{k-1} \le i_C$ in (2.3), we find its solution $\check{u}^{k+1}$ and a linearization $\bar{f}_k \le \check{f}_k$ such that

$\check{u}^{k+1}$ solves (2.3) with $\check{f}_k$, i_C replaced by $\bar{f}_k$, $\bar{\imath}_C^{k-1}$. Next, replacing $\check{f}_k$ by $\bar{f}_k$ in (2.3), we find its solution u^{k+1} and a linearization $\bar{\imath}_C^k \le i_C$ such that u^{k+1} solves (2.3) with $\check{f}_k$, i_C replaced by $\bar{f}_k$, $\bar{\imath}_C^k$. Due to evaluation errors, we may have $f_{\hat{u}}^k < \check{f}_k(\hat{u}^k)$, in which case the *predicted descent* $v_k := f_{\hat{u}}^k - \bar{f}_k(u^{k+1})$ may be nonpositive; then t_k is increased and u^{k+1} is recomputed to decrease $\bar{f}_k(u^{k+1})$ until $v_k > 0$. A *descent* step to $\hat{u}^{k+1} := u^{k+1}$ is taken if $f_u^{k+1} \le f_{\hat{u}}^k - \kappa v_k$ for a fixed $\kappa \in (0,1)$. Otherwise, a *null* step $\hat{u}^{k+1} := \hat{u}^k$ occurs; then $\bar{f}_k$ and the new linearization f_{k+1} are used to produce a better model $\check{f}_{k+1} \ge \max\{\bar{f}_k, f_{k+1}\}$ (e.g., $\check{f}_{k+1} = \max\{\bar{f}_k, f_{k+1}\}$).

Specific rules of our method will be discussed after its formal statement below.

ALGORITHM 2.1.

Step 0 (initialization). Select $u^1 \in C$, a *descent parameter* $\kappa \in (0,1)$, a *stepsize bound* $t_{\min} > 0$, and a *stepsize* $t_1 \ge t_{\min}$. Set $\bar{f}_0 := f_1$ (cf. (2.1)), $\bar{\imath}_C^0 := \langle p_C^0, \cdot - u^1\rangle$ with $p_C^0 := 0$, $\hat{u}^1 := u^1$, $f_{\hat{u}}^1 := f_u^1 := f_{u^1}$, $g^1 := g_{u^1}$ (cf. (2.1)), $i_t^1 := 0$, $k := k(0) := 1$, $l := 0$ ($k(l) - 1$ will denote the iteration of the lth descent step).

Step 1 (model selection). Choose $\check{f}_k : \mathbb{R}^n \to \mathbb{R}$ closed convex and such that

$$\max\{\bar{f}_{k-1}, f_k\} \le \check{f}_k \le f_C. \tag{2.4}$$

Step 2 (proximal point finding). Set

$$\check{u}^{k+1} := \arg\min\left\{ \phi_f^k(\cdot) := \check{f}_k(\cdot) + \bar{\imath}_C^{k-1}(\cdot) + \frac{1}{2t_k}|\cdot - \hat{u}^k|^2 \right\}, \tag{2.5}$$

$$\bar{f}_k(\cdot) := \check{f}_k(\check{u}^{k+1}) + \langle p_f^k, \cdot - \check{u}^{k+1}\rangle \quad \text{with} \quad p_f^k := \frac{1}{t_k}(\hat{u}^k - \check{u}^{k+1}) - p_C^{k-1}. \tag{2.6}$$

Step 3 (projection). Set

$$u^{k+1} := \arg\min\left\{ \phi_C^k(\cdot) := \bar{f}_k(\cdot) + i_C(\cdot) + \frac{1}{2t_k}|\cdot - \hat{u}^k|^2 \right\} = P_C(\hat{u}^k - t_k p_f^k), \tag{2.7}$$

$$\bar{\imath}_C^k(\cdot) := \langle p_C^k, \cdot - u^{k+1}\rangle \quad \text{with} \quad p_C^k := \frac{1}{t_k}(\hat{u}^k - u^{k+1}) - p_f^k, \tag{2.8}$$

$$v_k := f_{\hat{u}}^k - \bar{f}_k(u^{k+1}), \quad p^k := \frac{1}{t_k}(\hat{u}^k - u^{k+1}), \quad \text{and} \quad \epsilon_k := v_k - t_k|p^k|^2. \tag{2.9}$$

Step 4 (stopping criterion). If $\max\{|p^k|, \epsilon_k\} = 0$, stop ($f_{\hat{u}}^k \le f_*$).

Step 5 (stepsize correction). If $v_k < -\epsilon_k$, set $t_k := 10t_k$, $i_t^k := k$, and go back to Step 2.

Step 6 (descent test). Evaluate f_u^{k+1} and g^{k+1} (cf. (2.1)). If the *descent test* holds,

$$f_u^{k+1} \le f_{\hat{u}}^k - \kappa v_k, \tag{2.10}$$

set $\hat{u}^{k+1} := u^{k+1}$, $f_{\hat{u}}^{k+1} := f_u^{k+1}$, $i_t^{k+1} := 0$, $k(l+1) := k+1$, and increase l by 1 (*descent step*); otherwise, set $\hat{u}^{k+1} := \hat{u}^k$, $f_{\hat{u}}^{k+1} := f_{\hat{u}}^k$, and $i_t^{k+1} := i_t^k$ (*null step*).

Step 7 (stepsize updating). If $k(l) = k+1$ (i.e., after a descent step), select $t_{k+1} \ge t_k$; otherwise, either set $t_{k+1} := t_k$ or choose $t_{k+1} \in [t_{\min}, t_k]$ if $i_t^{k+1} = 0$.

Step 8 (loop). Increase k by 1 and go to Step 1.

Several comments on the method are in order. Step 1 may choose the simplest model $\check{f}_k = \max\{\bar{f}_{k-1}, f_k\}$; more efficient choices are given in section 4.4. For a polyhedral model $\check{f}_k$, subproblem (2.5) can be handled via simple quadratic program-

ming (QP) solvers [Kiw86]; in contrast, the more difficult subproblem (2.3) employed in [Kiw06b] requires more sophisticated solvers even for a polyhedral set C [Kiw94]. The projection of (2.7) is easily found if the set C is "simple" (e.g., the Cartesian product of boxes, simplices, and ellipsoids).

We now use the relations of Steps 2 and 3 to derive an optimality estimate, which involves the *aggregate linearization* $\bar{f}_C^k := \bar{f}_k + \bar{\imath}_C^k$ and the *optimality measure*

$$V_k := \max\bigl\{|p^k|, \epsilon_k + \langle p^k, \hat{u}^k\rangle\bigr\}. \tag{2.11}$$

LEMMA 2.2. (i) *The vectors* p_f^k *and* p_C^k *defined in* (2.6) *and* (2.8) *are in fact subgradients,*

$$p_f^k \in \partial \check{f}_k(\check{u}^{k+1}) \quad \text{and} \quad p_C^k \in \partial i_C(u^{k+1}), \tag{2.12}$$

and the linearizations $\bar{f}_k$ *and* $\bar{\imath}_C^k$ *defined in* (2.6) *and* (2.8) *provide the minorizations*

$$\bar{f}_k \le \check{f}_k, \quad \bar{\imath}_C^k \le i_C, \quad \text{and} \quad \bar{f}_C^k := \bar{f}_k + \bar{\imath}_C^k \le f_C. \tag{2.13}$$

(ii) *The* aggregate subgradient p^k *defined in* (2.9) *and the linearization* $\bar{f}_C^k$ *above satisfy*

$$p^k = p_f^k + p_C^k = \frac{\hat{u}^k - u^{k+1}}{t_k}, \tag{2.14}$$

$$\bar{f}_C^k(\cdot) = \bar{f}_k(u^{k+1}) + \langle p^k, \cdot - u^{k+1}\rangle. \tag{2.15}$$

(iii) *The predicted descent* v_k *and the* aggregate linearization error ϵ_k *of* (2.9) *satisfy*

$$v_k = t_k|p^k|^2 + \epsilon_k \quad \text{and} \quad \epsilon_k = f_{\hat{u}}^k - \bar{f}_C^k(\hat{u}^k). \tag{2.16}$$

(iv) *The aggregate linearization* $\bar{f}_C^k$ *is expressed in terms of* p^k *and* ϵ_k *as follows:*

$$f_{\hat{u}}^k - \epsilon_k + \langle p^k, \cdot - \hat{u}^k\rangle = \bar{f}_C^k(\cdot) \le f_C(\cdot). \tag{2.17}$$

(v) *The optimality measure* V_k *of* (2.11) *satisfies* $V_k \le \max\{|p^k|, \epsilon_k\}(1 + |\hat{u}^k|)$ *and*

$$f_{\hat{u}}^k \le f_C(u) + V_k\bigl(1 + |u|\bigr) \quad \text{for all } u. \tag{2.18}$$

(vi) *We have* $v_k \ge -\epsilon_k \Leftrightarrow t_k|p^k|^2/2 \ge -\epsilon_k \Leftrightarrow v_k \ge t_k|p^k|^2/2$. *Moreover,* $v_k \ge \epsilon_k$, $-\epsilon_k \le \epsilon_f$, *and*

$$v_k \ge \max\left\{\frac{t_k|p^k|^2}{2}, |\epsilon_k|\right\} \qquad \text{if} \quad v_k \ge -\epsilon_k, \tag{2.19}$$

$$V_k \le \max\left\{\left(\frac{2v_k}{t_k}\right)^{1/2}, v_k\right\}\bigl(1 + |\hat{u}^k|\bigr) \quad \text{if} \quad v_k \ge -\epsilon_k, \tag{2.20}$$

$$V_k < \left(\frac{2\epsilon_f}{t_k}\right)^{1/2}\bigl(1 + |\hat{u}^k|\bigr) \qquad \text{if} \quad v_k < -\epsilon_k. \tag{2.21}$$

Proof. (i) By (2.5)–(2.6), the optimality condition (using $\nabla\bar{\imath}_C^{k-1} = p_C^{k-1}$; cf. (2.8))

$$0 \in \partial\phi_f^k(\check{u}^{k+1}) = \partial\check{f}_k(\check{u}^{k+1}) + p_C^{k-1} + \frac{\check{u}^{k+1} - \hat{u}^k}{t_k} = \partial\check{f}_k(\check{u}^{k+1}) - p_f^k$$

and the equality $\bar{f}_k(\check{u}^{k+1}) = \check{f}_k(\check{u}^{k+1})$ yield $p_f^k \in \partial\check{f}_k(\check{u}^{k+1})$ and $\bar{f}_k \le \check{f}_k$. By (2.7)–(2.8),

$$0 \in \partial\phi_C^k(u^{k+1}) = p_f^k + \partial i_C(u^{k+1}) + \frac{u^{k+1} - \hat{u}^k}{t_k} = \partial i_C(u^{k+1}) - p_C^k$$

(using $\nabla\bar{f}_k = p_f^k$) and $\bar{\imath}_C^k(u^{k+1}) = i_C(u^{k+1}) = 0$ give $p_C^k \in \partial i_C(u^{k+1})$ and $\bar{\imath}_C^k \le i_C$. Combining both minorizations, we obtain that $\bar{f}_k + \bar{\imath}_C^k \le \check{f}_k + i_C \le f_C$ by (2.4) and (1.5).

(ii) Use the linearity of $\bar{f}_C^k := \bar{f}_k + \bar{\imath}_C^k$, (2.6), (2.8) with $\bar{\imath}_C^k(u^{k+1}) = 0$, and (2.9).

(iii) Rewrite (2.9), using the fact that $\bar{f}_C^k(\hat{u}^k) = \bar{f}_k(u^{k+1}) + t_k|p^k|^2$, by (ii).

(iv) We have $f_{\hat{u}}^k - \epsilon_k = \bar{f}_C^k(\hat{u}^k)$ by (iii), and $\bar{f}_C^k$ is affine by (ii) and minorizes f_C by (i).

(v) Use the Cauchy–Schwarz inequality in the definition (2.11) and in (iv).

(vi) The equivalences follow from the expression of $v_k = t_k|p^k|^2 + \epsilon_k$ in (iii); in particular, $v_k \ge \epsilon_k$. Next, by (2.16), (2.13), and (2.2) with $f_C(\hat{u}^k) = f(\hat{u}^k)$ ($\hat{u}^k \in C$), we have

$$-\epsilon_k = \bar{f}_C^k(\hat{u}^k) - f_{\hat{u}}^k \le f_C(\hat{u}^k) - f_{\hat{u}}^k = f(\hat{u}^k) - f_{\hat{u}}^k \le \epsilon_f.$$

Finally, to obtain the bounds (2.19)–(2.21), use the equivalences together with the facts that $v_k \ge \epsilon_k$, $-\epsilon_k \le \epsilon_f$ and the bound on V_k from assertion (v). ∎

The optimality estimate (2.18) justifies the stopping criterion of Step 4: $V_k = 0$ yields $f_{\hat{u}}^k \le \inf f_C = f_*$; thus, the point $\hat{u}^k$ is ϵ_f-*optimal*; i.e., $f(\hat{u}^k) \le f_* + \epsilon_f$ by (2.2). In the case of exact evaluations ($\epsilon_f = 0$), we have $v_k \ge \epsilon_k \ge 0$ by Lemma 2.2(vi), Step 5 is redundant, and Algorithm 2.1 becomes essentially that of [Kiw99, Alg. 3.1]. When inexactness is discovered via $v_k < -\epsilon_k$, the stepsize t_k is increased to produce descent or confirm that $\hat{u}^k$ is ϵ_f-optimal. Namely, when $\hat{u}^k$ is bounded in (2.21), increasing t_k drives V_k to 0, so that $f_{\hat{u}}^k \le f_*$ asymptotically. Whenever t_k is increased at Step 5, the *stepsize indicator* $i_t^k \ne 0$ prevents Step 7 from decreasing t_k after null steps until the next descent step occurs (cf. Step 6). Otherwise, decreasing t_k at Step 7 aims at collecting more local information about f at null steps.

We now show that an infinite cycle between Steps 2 and 5 means that $\hat{u}^k$ is ϵ_f-optimal.

LEMMA 2.3. *If an infinite cycle between Steps* 2 *and* 5 *occurs, then* $f_{\hat{u}}^k \le f_*$ *and* $V_k \to 0$.

Proof. At Step 5 during the cycle the facts that $V_k < (2\epsilon_f/t_k)^{1/2}(1 + |\hat{u}^k|)$ by (2.21) and $t_k \uparrow \infty$ as the cycle continues give $V_k \to 0$, so that $f_{\hat{u}}^k \le \inf f_C = f_*$ by (2.18). ∎

3. Convergence. In view of Lemma 2.3, we may suppose that the algorithm neither terminates nor cycles infinitely between Steps 2 and 5 (otherwise $\hat{u}^k$ is ϵ_f-optimal). At Step 6, we have $u^{k+1} \in C$ and $v_k > 0$ (by (2.19), since $\max\{|p^k|, \epsilon_k\} > 0$ at Step 4), so that $\hat{u}^{k+1} \in C$ and $f_{\hat{u}}^{k+1} \le f_{\hat{u}}^k$ for all k. We shall show that the asymptotic value $f_{\hat{u}}^\infty := \lim_k f_{\hat{u}}^k$ satisfies $f_{\hat{u}}^\infty \le f_*$. As in [Kiw99, sect. 4], we assume that the model subgradients $p_f^k \in \partial\check{f}_k(\check{u}^{k+1})$ in (2.12) satisfy

$$\{p_f^k\} \text{ is bounded if } \{u^k\} \text{ is bounded.} \tag{3.1}$$

It will be seen in Remark 4.4 that typical models $\check{f}_k$ satisfy this condition automatically.

We first consider the case where only finitely many descent steps occur. After the last descent step, only null steps occur, and the sequence $\{t_k\}$ eventually becomes monotone, since once Step 5 increases t_k, Step 7 can't decrease t_k; thus the limit $t_\infty := \lim_k t_k$ exists. We deal with the cases of $t_\infty = \infty$ in Lemma 3.1 and $t_\infty < \infty$ in Lemma 3.2 below.

LEMMA 3.1. *Suppose there exists $\bar{k}$ such that only null steps occur for all $k \geq \bar{k}$, and $t_\infty := \lim_k t_k = \infty$. Let $K := \{k \geq \bar{k} : t_{k+1} > t_k\}$. Then $V_k \xrightarrow{K} 0$ at Step 5.*

Proof. At iteration $k \in K$, before Step 5 increases t_k for the last time, we have $V_k < (2\epsilon_f/t_k)^{1/2}(1 + |\hat{u}^{\bar{k}}|)$ by (2.21); consequently, $t_k \to \infty$ gives $V_k \xrightarrow{K} 0$. ∎

LEMMA 3.2. *Suppose there exists $\bar{k}$ such that, for all $k \geq \bar{k}$, only null steps occur and Step 5 doesn't increase t_k. Then $V_k \to 0$.*

Proof. First, using partial linearizations of subproblems (2.5) and (2.7), we show that their optimal values $\phi_f^k(\check{u}^{k+1}) \leq \phi_C^k(u^{k+1})$ are nondecreasing and bounded above.

Fix $k \geq \bar{k}$. By the definitions in (2.5)–(2.6), we have $\bar{f}_k(\check{u}^{k+1}) = \check{f}_k(\check{u}^{k+1})$ and

$$\check{u}^{k+1} = \arg\min \left\{ \bar{\phi}_f^k(\cdot) := \bar{f}_k(\cdot) + \bar{\imath}_C^{k-1}(\cdot) + \tfrac{1}{2t_k}|\cdot - \hat{u}^k|^2 \right\} \tag{3.2}$$

from $\nabla\bar{\phi}_f^k(\check{u}^{k+1}) = 0$. Since $\bar{\phi}_f^k$ is quadratic and $\bar{\phi}_f^k(\check{u}^{k+1}) = \phi_f^k(\check{u}^{k+1})$, by Taylor's expansion

$$\bar{\phi}_f^k(\cdot) = \phi_f^k(\check{u}^{k+1}) + \tfrac{1}{2t_k}|\cdot - \check{u}^{k+1}|^2. \tag{3.3}$$

Similarly, by the definitions in (2.7)–(2.8), we have $\bar{\imath}_C^k(u^{k+1}) = i_C(u^{k+1}) = 0$,

$$u^{k+1} = \arg\min \left\{ \bar{\phi}_C^k(\cdot) := \bar{f}_k(\cdot) + \bar{\imath}_C^k(\cdot) + \tfrac{1}{2t_k}|\cdot - \hat{u}^k|^2 \right\}, \tag{3.4}$$

$$\bar{\phi}_C^k(\cdot) = \phi_C^k(u^{k+1}) + \tfrac{1}{2t_k}|\cdot - u^{k+1}|^2. \tag{3.5}$$

Next, to bound the objective values of the linearized subproblems (3.2) and (3.4) from above, we use the minorizations $\bar{f}_k \leq f_C$ and $\bar{\imath}_C^{k-1}, \bar{\imath}_C^k \leq i_C$ of (2.13) with $\hat{u}^k \in C$:

$$\phi_f^k(\check{u}^{k+1}) + \tfrac{1}{2t_k}|\check{u}^{k+1} - \hat{u}^k|^2 = \bar{\phi}_f^k(\hat{u}^k) \leq f(\hat{u}^k), \tag{3.6a}$$

$$\phi_C^k(u^{k+1}) + \tfrac{1}{2t_k}|u^{k+1} - \hat{u}^k|^2 = \bar{\phi}_C^k(\hat{u}^k) \leq f(\hat{u}^k), \tag{3.6b}$$

where the equalities stem from (3.3) and (3.5). Due to the minorization $\bar{\imath}_C^{k-1} \leq i_C$, the objectives of subproblems (3.2) and (2.7) satisfy $\bar{\phi}_f^k \leq \phi_C^k$. On the other hand, since $\hat{u}^{k+1} = \hat{u}^k$, $t_{k+1} \leq t_k$ (cf. Step 7), and $\bar{f}_k \leq \check{f}_{k+1}$ by (2.4), the objectives of (3.4) and the next subproblem (2.5) satisfy $\bar{\phi}_C^k \leq \phi_f^{k+1}$. Altogether, by (3.3) and (3.5), we see that

$$\phi_f^k(\check{u}^{k+1}) + \tfrac{1}{2t_k}|u^{k+1} - \check{u}^{k+1}|^2 = \bar{\phi}_f^k(u^{k+1}) \leq \phi_C^k(u^{k+1}), \tag{3.7a}$$

$$\phi_C^k(u^{k+1}) + \tfrac{1}{2t_k}|\check{u}^{k+2} - u^{k+1}|^2 = \bar{\phi}_C^k(\check{u}^{k+2}) \leq \phi_f^{k+1}(\check{u}^{k+2}). \tag{3.7b}$$

In particular, the inequalities $\phi_f^k(\check{u}^{k+1}) \leq \phi_C^k(u^{k+1}) \leq \phi_f^{k+1}(\check{u}^{k+2})$ imply that the nondecreasing sequences $\{\phi_f^k(\check{u}^{k+1})\}_{k\geq\bar{k}}$ and $\{\phi_C^k(u^{k+1})\}_{k\geq\bar{k}}$, which are bounded above

by (3.6) with $\hat{u}^k = \hat{u}^{\bar{k}}$ for all $k \geq \bar{k}$, must have a common limit, say $\phi_\infty \leq f(\hat{u}^{\bar{k}})$. Moreover, since the stepsizes satisfy $t_k \leq t_{\bar{k}}$ for all $k \geq \bar{k}$, we deduce from the bounds (3.6)–(3.7) that

$$\phi_f^k(\check{u}^{k+1}),\ \phi_C^k(u^{k+1}) \uparrow \phi_\infty, \qquad \check{u}^{k+2} - u^{k+1} \to 0, \tag{3.8}$$

and the sequences $\{\check{u}^{k+1}\}$ and $\{u^{k+1}\}$ are bounded. Then the sequence $\{p_f^k\}$ is bounded by (3.1), and the sequence $\{g^k\}$ is bounded as well, since $g^k \in \partial_{\epsilon_f} f(u^k)$ by (2.1), whereas the mapping $\partial_{\epsilon_f} f$ is locally bounded [HUL93, sect. XI.4.1].

We now show that the *approximation error* $\check{\epsilon}_k := f_u^{k+1} - \bar{f}_k(u^{k+1})$ vanishes. Using the form (2.1) of f_{k+1}, the minorization $f_{k+1} \leq \check{f}_{k+1}$ of (2.4), the Cauchy–Schwarz inequality, and the optimal values of subproblems (2.5) and (2.7) with $\hat{u}^k = \hat{u}^{\bar{k}}$ for $k \geq \bar{k}$, we estimate

$$\begin{aligned}
\check{\epsilon}_k &:= f_u^{k+1} - \bar{f}_k(u^{k+1}) = f_{k+1}(\check{u}^{k+2}) - \bar{f}_k(u^{k+1}) + \langle g^{k+1}, u^{k+1} - \check{u}^{k+2}\rangle \\
&\leq \check{f}_{k+1}(\check{u}^{k+2}) - \bar{f}_k(u^{k+1}) + |g^{k+1}||u^{k+1} - \check{u}^{k+2}| \\
&= \phi_f^{k+1}(\check{u}^{k+2}) - \phi_C^k(u^{k+1}) + \Delta_k - \bar{\imath}_C^k(\check{u}^{k+2}) + |g^{k+1}||u^{k+1} - \check{u}^{k+2}|, \qquad (3.9)
\end{aligned}$$

where $\Delta_k := |u^{k+1} - \hat{u}^{\bar{k}}|^2/2t_k - |\check{u}^{k+2} - \hat{u}^{\bar{k}}|^2/2t_{k+1}$. To see that $\Delta_k \to 0$, note that

$$|\check{u}^{k+2} - \hat{u}^{\bar{k}}|^2 = |u^{k+1} - \hat{u}^{\bar{k}}|^2 + 2\langle \check{u}^{k+2} - u^{k+1}, u^{k+1} - \hat{u}^{\bar{k}}\rangle + |\check{u}^{k+2} - u^{k+1}|^2,$$

$|u^{k+1} - \hat{u}^{\bar{k}}|^2$ is bounded, $\check{u}^{k+2} - u^{k+1} \to 0$ by (3.8), and $t_{\min} \leq t_{k+1} \leq t_k$ for $k \geq \bar{k}$ by Step 7. These properties also give $\bar{\imath}_C^k(\check{u}^{k+2}) \to 0$, since by (2.8) and the Cauchy–Schwarz inequality, we have

$$|\bar{\imath}_C^k(\check{u}^{k+2})| \leq |p_C^k||\check{u}^{k+2} - u^{k+1}| \quad \text{with} \quad |p_C^k| \leq |u^{k+1} - \hat{u}^{\bar{k}}|/t_k + |p_f^k|,$$

where $\{p_f^k\}$ is bounded. Hence, using (3.8) and the boundedness of $\{g^{k+1}\}$ in (3.9) yields $\overline{\lim}_k \check{\epsilon}_k \leq 0$. On the other hand, for $k \geq \bar{k}$ the null step condition $f_u^{k+1} > f_{\hat{u}}^k - \kappa v_k$ gives

$$\check{\epsilon}_k = \big[f_u^{k+1} - f_{\hat{u}}^k\big] + \big[f_{\hat{u}}^k - \bar{f}_k(u^{k+1})\big] > -\kappa v_k + v_k = (1-\kappa)v_k \geq 0,$$

where $\kappa < 1$ by Step 0; we conclude that $\check{\epsilon}_k \to 0$ and $v_k \to 0$. Finally, since $v_k \to 0$, $t_k \geq t_{\min}$ (cf. Step 7), and $\hat{u}^k = \hat{u}^{\bar{k}}$ for $k \geq \bar{k}$, we have $V_k \to 0$ by (2.20). ∎

We may now finish the case of infinitely many consecutive null steps.

LEMMA 3.3. *Suppose that there exists $\bar{k}$ such that only null steps occur for all $k \geq \bar{k}$. Let $K := \{k \geq \bar{k} : t_{k+1} > t_k\}$ if $t_k \to \infty$, $K := \{k : k \geq \bar{k}\}$ otherwise. Then $V_k \xrightarrow{K} 0$.*

Proof. Steps 5–7 ensure that the sequence $\{t_k\}$ is monotone for large k. We have $V_k \xrightarrow{K} 0$ from either Lemma 3.1 if $t_\infty = \infty$, or Lemma 3.2 if $t_\infty < \infty$. ∎

It remains to analyze the case of infinitely many descent steps.

LEMMA 3.4. *Suppose that infinitely many descent steps occur and $f_{\hat{u}}^\infty := \lim_k f_{\hat{u}}^k > -\infty$. Let $K := \{k : f_{\hat{u}}^{k+1} < f_{\hat{u}}^k\}$. Then $\underline{\lim}_{k\in K} V_k = 0$. Moreover, if $\{\hat{u}^k\}$ is bounded, then $V_k \xrightarrow{K} 0$.*

Proof. We have $0 < \kappa v_k \leq f_{\hat{u}}^k - f_{\hat{u}}^{k+1}$ if $k \in K$, $f_{\hat{u}}^{k+1} = f_{\hat{u}}^k$ otherwise (see Step 6). Thus $\sum_{k\in K} \kappa v_k \leq f_{\hat{u}}^1 - f_{\hat{u}}^\infty < \infty$ gives $v_k \xrightarrow{K} 0$ and hence $\epsilon_k, t_k|p^k|^2 \xrightarrow{K} 0$ by (2.19)

and $|p^k| \xrightarrow{K} 0$, using $t_k \geq t_{\min}$ (cf. Step 7). For $k \in K$, $\hat{u}^{k+1} - \hat{u}^k = -t_k p^k$ by (2.9), so

$$|\hat{u}^{k+1}|^2 - |\hat{u}^k|^2 = t_k\big\{t_k|p^k|^2 - 2\langle p^k, \hat{u}^k\rangle\big\}.$$

Sum up and use the facts that $\hat{u}^{k+1} = \hat{u}^k$ if $k \notin K$, $\sum_{k\in K} t_k \geq \sum_{k\in K} t_{\min} = \infty$ to get

$$\overline{\lim_{k\in K}}\big\{t_k|p^k|^2 - 2\langle p^k, \hat{u}^k\rangle\big\} \geq 0$$

(since otherwise $|\hat{u}^k|^2 \to -\infty$, which is impossible). Combining this with $t_k|p^k|^2 \xrightarrow{K} 0$ gives $\underline{\lim}_{k\in K}\langle p^k, \hat{u}^k\rangle \leq 0$. Since also $\epsilon_k, |p^k| \xrightarrow{K} 0$, we have $\underline{\lim}_{k\in K} V_k = 0$ by (2.11).

If $\{\hat{u}^k\}$ is bounded, using $\epsilon_k, |p^k| \xrightarrow{K} 0$ in Lemma 2.2(v) gives $V_k \xrightarrow{K} 0$. ∎

We may now state and prove our principal result.

THEOREM 3.5. (i) *We have* $f_{\hat{u}}^k \downarrow f_{\hat{u}}^\infty \leq f_*$, *and additionally* $\underline{\lim}_k V_k = 0$ *if* $f_* > -\infty$.

(ii) $f_* \leq \underline{\lim}_k f(\hat{u}^k) \leq \overline{\lim}_k f(\hat{u}^k) \leq f_{\hat{u}}^\infty + \epsilon_f$.

Proof. The inequalities in (ii) stem from the facts that $f_* = \inf_C f$, $\{\hat{u}^k\} \subset C$, and $f(\hat{u}^k) \leq f_{\hat{u}}^k + \epsilon_f$ for all k by (2.2). By (ii), if $f_{\hat{u}}^\infty = -\infty$, then $f_* = -\infty$ in (i). Hence, suppose $f_* > -\infty$. Then $f_{\hat{u}}^\infty \geq f_* - \epsilon_f > -\infty$ by (ii). We have $\underline{\lim}_k V_k = 0$ by Lemma 3.3 in the case of finitely many descent steps, or by Lemma 3.4 otherwise. Finally, using $\underline{\lim}_k V_k = 0$ in the estimate (2.18) gives $f_{\hat{u}}^\infty \leq \inf f_C = f_*$. ∎

It is instructive to examine the assumptions of the preceding results.

Remark 3.6. (i) Inspection of the preceding proofs reveals that Theorem 3.5 requires only convexity and finiteness of f on C, and *local boundedness* of the approximate subgradient mapping $u \mapsto g_u$ of f on C (see below (3.8)). In particular, it suffices to assume that f is finite convex on a neighborhood of C.

(ii) The requirement $\max\{\bar{f}_{k-1}, f_k\} \leq \check{f}_k$ of (2.4) is needed only after null steps in the proof of Lemma 3.2. After a descent step (when $k = k(l)$), Step 1 may take any $\check{f}_k \leq f_C$.

We now show that for exact evaluations ($\epsilon_f = 0$), our algorithm has the usual strong convergence properties of typical bundle methods. Instead of requiring that $\inf_k t_k \geq t_{\min} > 0$, as before, we give more general stepsize conditions in the theorem below.

THEOREM 3.7. *Suppose that* $\epsilon_f = 0$. *Let* $U_* := \operatorname{Arg\,min}_C f$ *denote the* (*possibly empty*) *solution set of problem* (1.1). *Then we have the following statements:*

(i) *If only* $l < \infty$ *descent steps occur and* $t_k \downarrow t_\infty > 0$, *then* $\hat{u}^{k(l)} \in U_*$ *and* $V_k \to 0$.

(ii) *Assuming that infinitely many descent steps occur, suppose that* $\sum_{k\in K} t_k = \infty$ *for* $K := \{k : f(\hat{u}^{k+1}) < f(\hat{u}^k)\}$. *Then* $f(\hat{u}^k) \downarrow f_*$. *Moreover, we have the following.*

(a) Let $\check{\epsilon}_k := f(\hat{u}^{k+1}) - \bar{f}_k(\hat{u}^{k+1})$ for $k \in K$. If $U_* \neq \emptyset$ and $\sum_{k\in K} t_k\check{\epsilon}_k < \infty$ (e.g., $\sup_{k\in K} t_k < \infty$), then $\hat{u}^k \to \hat{u}^\infty \in U_*$, and $V_k \xrightarrow{K} 0$ if $\inf_{k\in K} t_k > 0$.

(b) If $U_* = \emptyset$, then $|\hat{u}^k| \to \infty$.

Proof. Since $\epsilon_f = 0$, Step 5 is inactive, and Algorithm 2.1 fits the framework of [Kiw99, Alg. 3.1]. For $l \not\to \infty$, the conclusion follows from Lemma 3.2 and Theorem 3.5. For $l \to \infty$, combine [Kiw99, Thm. 4.4] and the proof of Lemma 3.4. ∎

4. Modifications.

4.1. Looping between subproblems. To obtain a more accurate solution to the prox subproblem (2.3), we may cycle between subproblems (2.5) and (2.7), updating their data as if null steps occur without changing the model $\check{f}_k$. Specifically, for a given *subproblem accuracy threshold* $\check{\kappa} \in (0,1)$, suppose that the following step is inserted after Step 5.

Step 5′ (subproblem accuracy test). If

$$\check{f}_k(u^{k+1}) > f_{\hat{u}}^k - \check{\kappa} v_k, \tag{4.1}$$

set $\bar{\imath}_C^{k-1}(\cdot) := \bar{\imath}_C^k(\cdot)$, $p_C^{k-1} := p_C^k$ and go back to Step 2.

We now give two motivations for the test (4.1) written as (cf. (2.9))

$$\bar{\epsilon}_k := \check{f}_k(u^{k+1}) - \bar{f}_k(u^{k+1}) > (1-\check{\kappa}) v_k.$$

First, when $\bar{\epsilon}_k$ is small relative to v_k, $\check{f}_k$ is correctly approximated by $\bar{f}_k$, so the loop can be broken. Second, since $\bar{f}_k \le \check{f}_k$ (Lemma 2.2(i)) in (2.7), by standard arguments [Kiw99, p. 145], the distance from u^{k+1} to the prox solution of (2.3) is at most $\sqrt{2t_k\bar{\epsilon}_k}$.

The analysis of this modification is given in the following remarks.

Remark 4.1. (i) For any k, each execution of Steps 2 through 5′ is called a loop. First, suppose that finitely many loops occur for each k. By its proof, Lemma 2.2 holds at Step 4 for the current quantities. This suffices for the proofs of Lemmas 2.3, 3.1, and 3.4, whereas the proofs of Lemma 3.3 and Theorem 3.5 will go through once Lemma 3.2 is established. The proof of Lemma 3.2 is modified as follows. For each $k \ge \bar{k}$, (3.6) and (3.7a) hold at each loop, and (3.7b) holds for the final loop. For any preceding loop, letting $\check{u}_{\rm next}^{k+1}$ and $\phi_{f,{\rm next}}^k$ stand for $\check{u}^{k+1}$ and ϕ_f^k produced by Step 2 on the next loop, use the minorization $\bar{f}_k \le \check{f}_k$ of (2.13) in subproblems (3.4) and (2.7) to get $\bar{\phi}_C^k \le \phi_{f,{\rm next}}^k$ and, by (3.5),

$$\phi_C^k(u^{k+1}) + \tfrac{1}{2t_k}|\check{u}_{\rm next}^{k+1} - u^{k+1}|^2 = \bar{\phi}_C^k(\check{u}_{\rm next}^{k+1}) \le \phi_{f,{\rm next}}^k(\check{u}_{\rm next}^{k+1}). \tag{4.2}$$

Then, replacing (3.7b) by (4.2) for all nonfinal loops, we deduce that the optimal values $\phi_f^k(\check{u}^{k+1}) \le \phi_C^k(u^{k+1})$ can't decrease during the loops or when k grows; hence (3.8) and the boundedness of $\{\check{u}^{k+1}\}$ and $\{u^{k+1}\}$ follow as before. For the rest of the proof, let $\check{u}^{k+2}$ in (3.9) stand for the point produced by Step 2 on the first loop at iteration $k+1$, and argue as before.

(ii) Next, suppose that infinitely many loops occur at iteration $k = \check{k}$, for some $\check{k}$. If Step 5 drives t_k to ∞, $f_{\hat{u}}^{\check{k}} \le f_*$ and $V_k \to 0$ by the proof of Lemma 2.3. Hence we may assume that Step 5 doesn't increase t_k at all. To show that $V_k \to 0$ (in which case $f_{\hat{u}}^{\check{k}} \le f_*$ by (2.18)), we suppose that the subdifferential $\partial\check{f}_k$ is locally bounded, and we use a subgradient mapping $C \ni u \mapsto \check{g}_u \in \partial\check{f}_k(u)$. Consider the following modification of Algorithm 2.1. Starting from the first loop at iteration $k = \check{k}$, omit Step 5′; at Step 6 set $f_u^{k+1} := \check{f}_k(u^{k+1})$, $g^{k+1} := \check{g}_{u^{k+1}}$, and $\kappa := \check{\kappa}$; at Step 7, set $t_{k+1} := t_k$; finally, when Step 1 is reached, set $\check{f}_k := \check{f}_{k-1}$. This modification only translates loops into additional iterations with a constant model $\check{f}_k = \check{f}_{\check{k}}$; in particular, only null steps occur, because the descent test (2.10) can't hold with $f_u^{k+1} := \check{f}_k(u^{k+1})$ and $\kappa := \check{\kappa}$ due to the model test (4.1). Further, the "new" linearization $f_{k+1}(\cdot) := f_u^{k+1} + \langle g^{k+1}, \cdot - u^{k+1}\rangle$ satisfies $f_{k+1} \le \check{f}_{k+1}$. Hence, to get $V_k \to 0$, we may use the proof of Lemma 3.2, obtaining boundedness of $\{p_f^k\}$, $\{g^{k+1}\}$ from the boundedness of $\{\check{u}^{k+1}\}$, $\{u^{k+1}\}$ and the local boundedness of $\partial\check{f}_k$.

Note that having $\bar{\imath}_C^{k-1}$ as a model of i_C in subproblem (2.5) is essential only after null steps or loops due to Step 5′. Otherwise, a better model may be constructed as follows. After Step 5 increases t_k, we can set $\bar{\imath}_C^{k-1}(\cdot) := \bar{\imath}_C^k(\cdot)$, $p_C^{k-1} := p_C^k$, or use the more efficient update $u^k := P_C(\hat{u}^k - t_k p_f^k)$, $p_C^{k-1} := (\hat{u}^k - u^k)/t_k - p_f^k$, and $\bar{\imath}_C^{k-1}(\cdot) := \langle p_C^{k-1}, \cdot - u^k\rangle$, which corresponds to resolving subproblem (2.7) before going back to Step 2. Similarly, if $\hat{u}^{k+1} \neq \hat{u}^k$ after Step 7, we may use $\tilde{u} := P_C(\hat{u}^{k+1} - t_{k+1}p_f^k)$, $p_C^k := (\hat{u}^{k+1} - \tilde{u})/t_{k+1} - p_f^k$, and $\bar{\imath}_C^k(\cdot) := \langle p_C^k, \cdot - \tilde{u}\rangle$, where $\tilde{u}$ plays the rôle of u^{k+1}.

4.2. Evaluation errors and relaxed null-step requirements. We now inspect the impact of inexact evaluations on our preceding results, in order to obtain weaker convergence conditions and to provide some practical recommendations.

Our assumption (1.2) on the error tolerance ϵ_f means $\epsilon_f := \sup_{u\in C}[f(u) - f_u] < \infty$. In fact, we need only the weaker condition that $\epsilon_f := \sup_k \epsilon_f^k < \infty$ for the *evaluation errors* $\epsilon_f^k := f(u^k) - f_u^k$ (cf. (2.1)). Thus, for $\epsilon_f := \sup_k \epsilon_f^k$, Theorem 3.5 says that our method produces solutions that are as good as the supplied linearizations.

In fact, the asymptotic accuracy depends *only* on the errors that occur at descent steps. Indeed, at Step 1 we have $\hat{u}^k = u^{k(l)}$ and $f(\hat{u}^k) = f_{\hat{u}}^k + \epsilon_f^{k(l)}$, where $k(l) - 1$ is the iteration number of the lth (i.e., latest) descent step (see Steps 0 and 6). Hence the tolerance ϵ_f in Theorem 3.5(ii) may be replaced by the *asymptotic error*

$$\epsilon_f^\infty := \begin{cases} \epsilon_f^{k(l)} & \text{if only } l < \infty \text{ descent steps occur,} \\ \overline{\lim}_l\, \epsilon_f^{k(l)} & \text{otherwise.} \end{cases} \tag{4.3}$$

In particular, $\epsilon_f^\infty = 0$ if all descent steps happen to be exact. On the other hand, whenever an inexact descent step occurs, then $\epsilon_f^{k+1} := f(u^{k+1}) - f_u^{k+1}$ may potentially determine ϵ_f^∞ (only if $f_u^{k+1} \le f_*$, since $f_{\hat{u}}^\infty \le f_*$ by Theorem 3.5).

Since the asymptotic error is not influenced by the errors occurring at null steps, let us now discuss the case where infinitely many successive null steps occur. Then, by the proof of Lemma 3.2, instead of the requirement $\sup_k \epsilon_f^k < \infty$ (which may be difficult to check for some oracles), it suffices if the following *relaxed null-step requirements* are met:

(a) the sequence $\{g^k\}$ is bounded whenever the sequence $\{u^k\}$ is bounded;

(b) a null step implies that $f_u^{k+1} > f_{\hat{u}}^k - \bar{\kappa} v_k$ for some fixed parameter $\bar{\kappa} \in [\kappa, 1)$.

Condition (a) holds if the mapping $u \mapsto g_u$ is locally bounded on C (cf. Remark 3.6(i)). Condition (b) means that the new linearization f_{k+1} may have any accuracy, as long as it improves the next model sufficiently at u^{k+1}. For $\bar{\kappa} > \kappa$, the oracle may set an indicator $i_{\bar{\kappa}} := 1$ when $\bar{\kappa}$ should replace κ in the descent test (2.10) to accept a shallower null step; $i_{\bar{\kappa}} := 0$ otherwise (i.e., when (2.10) is not modified). Of course, shallow cuts may slow down convergence, but this may be offset by saving the oracle's work per call. To illustrate these requirements, consider the following generalization of the setting of [HeK02].

Example 4.2. Suppose that the objective f has the form $f(\cdot) := \sup_{z\in Z} F_z(\cdot)$ of (1.3) with $F_z(\cdot)$ convex and $\partial F_z(\cdot)$ locally bounded on C, uniformly w.r.t. $z \in Z$. Suppose for each k that the oracle used for approximate evaluation of $f(u^{k+1})$ generates points $z^{(i)} \in Z$, $i = 1, 2, \ldots$, stopping for some i to deliver $f_u^{k+1} := F_{z^{(i)}}(u^{k+1})$ and some $g^{k+1} \in \partial F_{z^{(i)}}(u^{k+1})$. To meet the relaxed null-step requirements, the oracle may stop when $F_{z^{(i)}}(u^{k+1}) > f_{\hat{u}}^k - \bar{\kappa} v_k$ holds, possibly together with other conditions, setting $i_{\bar{\kappa}} := 1$ to force a null step.

Remark 4.3. For an SDP (cf. section 5.6), Example 4.2 accommodates the "inexact null steps" of [HeK02], which can save much work in eigenvalue computations [Hel03, Nay99, Nay06]. In general, when the relaxed null-step requirements are met and the descent steps are exact, then $\epsilon_f^\infty = 0$ in (4.3) and Theorem 3.7 holds (by its proof). In particular, Theorem 3.7 holds for the method of [HeK02].

Insisting that all descent steps be exact may be unrealistic (e.g., as in [Hel03, HeK02, Nay06], where this issue is ignored) or too expensive (cf. [Kiw05]).

For the oracle of Example 4.2, additional stopping criteria may be employed to make a "too inexact" descent step less likely. The general idea is to make the oracle work harder before a descent step is accepted. We distinguish the following two cases.

Case 1. Suppose that the oracle's underestimates $F_{z^{(i)}}(u^{k+1})$ of $f(u^{k+1})$ improve when i grows. Then for a given iteration limit $i_{\max}$ the oracle may stop when either $F_{z^{(i)}}(u^{k+1}) > f_{\hat{u}}^k - \bar{\kappa} v_k$ and $i \le i_{\max}$ (setting $i_{\bar{\kappa}} := 1$ to force a null step), or $F_{z^{(i)}}(u^{k+1}) \le f_{\hat{u}}^k - \kappa v_k$ and $i = i_{\max}$ (setting $i_{\bar{\kappa}} := 0$ for a descent step).

Case 2. In addition to the assumptions of Case 1, suppose that the oracle generates upper bounds $f_{\rm up}^{(i)} \ge f(u^{k+1})$ such that $\bar{f}_{\rm up}^{(i)} - F_{z^{(i)}}(u^{k+1}) \to 0$ if $i \to \infty$. Then the oracle may also stop as soon as for some $i \le i_{\max}$, $\bar{f}_{\rm up}^{(i)} < f_{\hat{u}}^k$, or $f_{\rm up}^{(i)} - F_{z^{(i)}}(u^{k+1}) \le \epsilon_r |F_{z^{(i)}}(u^{k+1})|$ for a given *relative accuracy tolerance* $\epsilon_r > 0$, setting $i_{\bar{\kappa}} := 0$ to promote a descent step.

We add that Case 2 covers oracles employing branch and bound in Lagrangian relaxation of integer programming problems. Then, for difficult Lagrangian subproblems, it pays to use rather loose accuracy requirements, because tighter criteria (e.g., small ϵ_r) may force the oracle to work too long on some calls (see, e.g., [Kiw05]). Fortunately, a typical branch-and-bound oracle generates a good lower bound $F_{z^{(i)}}(u^{k+1})$ quickly (although improving the upper bound $f_{\rm up}^{(i)}$ may need much time). Then the stopping criterion of Case 2 with a moderate tolerance ϵ_r (or another heuristic criterion) may still ensure that the actual error $\epsilon_f^{k+1} := f(u^{k+1}) - f_u^{k+1}$ is small enough. Thus our framework is especially suitable for applications with oracles that deliver reasonably accurate linearizations most of the time, although explicit control of their accuracy might be too costly. (We add that the preceding remarks apply also to the method of [Kiw06b], and they partly explain the good numerical results of [Kiw05].)

4.3. A weaker descent test. As in [Kiw06b, sect. 4.3], at Steps 5 and 6 we may replace the predicted decrease $v_k = t_k|p^k|^2 + \epsilon_k$ (cf. (2.16)) by the smaller quantity $w_k := t_k|p^k|^2/2 + \epsilon_k$. Then the equivalences in Lemma 2.2(vi) are replaced by the fact that

$$w_k \ge -\epsilon_k \quad \Longleftrightarrow \quad \frac{t_k|p^k|^2}{4} \ge -\epsilon_k \quad \Longleftrightarrow \quad w_k \ge \frac{t_k|p^k|^2}{4}.$$

Hence, $w_k \ge -\epsilon_k$ at Step 6 implies $w_k \le v_k \le 3w_k$ and $v_k \ge -\epsilon_k$ for the bounds (2.19)–(2.20), whereas for Step 5, the bound (2.21) is replaced by the fact that

$$V_k < \left(\frac{4\epsilon_{\max}}{t_k}\right)^{1/2} (1 + |\hat{u}^k|) \quad \text{if} \quad w_k < -\epsilon_k.$$

The preceding results extend easily. (In the proof of Lemma 3.2, $f_u^{k+1} > f_{\hat{u}}^k - \kappa w_k$ implies $f_u^{k+1} > f_{\hat{u}}^k - \kappa v_k$, whereas in the proof of Lemma 3.4, $\sum_{k\in K} v_k \le 3 \sum_{k\in K} w_k < \infty$.)

4.4. Linearization accumulation, selection, and aggregation. There are three basic choices of polyhedral models satisfying relation (2.4) rewritten as

$$\max\{\bar{f}_k, f_{k+1}\} \le \check{f}_{k+1} \le f_C. \tag{4.4}$$

First, *accumulation* takes $\check{f}_{k+1} := \max\{\check{f}_k, f_{k+1}\}$, $\check{f}_1 := f_1$; then we may replace f_C by f in (4.4), using the minorizations $\bar{f}_k \le \check{f}_k$ of (2.13) and $f_{k+1} \le f$ of (2.1). In other words, here $\check{f}_k = \max_{j=1}^k f_j$ is the richest model stemming from all the past linearizations, but its storage requirements and QP work per iteration grow with k, so the other choices discussed below are more attractive in practice.

Second, *selection* retains only selected linearizations for its kth model,

$$\check{f}_k(\cdot) := \max_{j\in J_k} f_j(\cdot) \quad \text{with} \quad k \in J_k \subset \{1,\dots,k\}. \tag{4.5}$$

Then $\check{f}_k \le f$ by (2.1), so, in view of (4.4), we need only show how to choose the set J_{k+1} so that $\bar{f}_k \le \check{f}_{k+1}$. Since $p_f^k \in \partial \check{f}_k(\check{u}^{k+1})$ by (2.12) and each f_j is affine in (4.5), there exist multipliers ν_j^k, $j \in J_k$, also known as *convex weights*, such that (cf. [HUL93, Ex. VI.3.4])

$$(p_f^k, 1) = \sum_{j\in J_k} \nu_j^k (\nabla f_j, 1), \quad \nu_j^k \ge 0, \quad \nu_j^k \big[\check{f}_k(\check{u}^{k+1}) - f_j(\check{u}^{k+1})\big] = 0, \quad j \in J_k. \tag{4.6}$$

Then, using relations (2.6) and (4.6), it is easy to obtain the following expansion:

$$(\bar{f}_k, 1) = \sum_{j\in \hat{J}_k} \nu_j^k (f_j, 1) \quad \text{with} \quad \hat{J}_k := \{j \in J_k : \nu_j^k > 0\}. \tag{4.7}$$

In other words, the aggregate linearization $\bar{f}_k$ is a convex combination of the "ordinary" linearizations f_j selected by the *active* set $\hat{J}_k$. Since $\bar{f}_k \le \max_{j\in\hat{J}_k} f_j$, it suffices to choose

$$J_{k+1} \supset \hat{J}_k \cup \{k+1\}. \tag{4.8}$$

Active-set methods for solving subproblem (2.5) [Kiw86, Kiw94] find multipliers ν_j^k such that $|\hat{J}_k| \le n+1$. Hence we can keep $|J_{k+1}| \le \bar{n}$ for any given upper bound $\bar{n} \ge n+2$.

Third, *aggregation* treats the past aggregate linearizations $\bar{f}_j$ like the "ordinary" linearizations f_j, defining $f_{-j} := \bar{f}_j$ for $j = 0\colon k-1$ to replace (4.5) by the aggregate model

$$\check{f}_k(\cdot) := \max_{j\in J_k} f_j(\cdot) \quad \text{with} \quad k \in J_k \subset \{1-k\colon k\}, \quad f_j := \bar{f}_{-j} \text{ for } j \le 0. \tag{4.9}$$

The weights ν_j^k of (4.6) produce $f_{-k} := \bar{f}_k$ via (4.7), and relation (4.8) is replaced by

$$J_{k+1} \supset \{-k, k+1\}, \tag{4.10}$$

so that only $\bar{n} \ge 2$ linearizations may be kept. Formally, if $f_j \le f$ for all $j \in J_k$, then $f_{-k} := \bar{f}_k \le f$ by (4.7); hence, by induction, (4.9)–(4.10) yield (4.4) for all k. Of course, the selection requirement (4.8) may replace (4.10) whenever $|\hat{J}_k| \le \bar{n} - 1$. After a descent step, we can replace (4.8) and (4.10) by $J_{k+1} \ni k+1$ (cf. Remark 3.6(ii)).

Remark 4.4. In the proof of Lemma 3.2, condition (3.1) holds *automatically* for the models discussed above. Indeed, by (4.6) (and induction for aggregation), we have $p_f^k \in \operatorname{co}\{g^j\}_{j=1}^k$ and hence $|p_f^k| \le \max_{j=1}^k |g^j|$, whereas the sequence $\{g^k\}$ is bounded. Similarly, each model $\check{f}_k$ has a bounded subdifferential, as required in Remark 4.1(ii).

5. Lagrangian relaxation.

5.1. The primal problem. Let $\mathcal{Z}$ be a real inner-product space with a finite dimension $\bar{m}$. (We could, of course, always identify $\mathcal{Z}$ with $\mathbb{R}^{\bar{m}}$, but a less concrete approach helps our future development.) In this section we consider the special case where problem (1.1) with $C := \mathbb{R}^n_+$ is the Lagrangian dual problem of the following *primal* convex optimization problem in $\mathcal{Z}$:

$$\psi_0^{\max} := \max\ \psi_0(z) \quad \text{s.t.} \quad \psi_i(z) \geq 0,\ i = 1\colon n,\ z \in Z, \tag{5.1}$$

where $\emptyset \neq Z \subset \mathcal{Z}$ is compact and convex, and each ψ_i is concave and closed (upper semicontinuous) with $\operatorname{dom}\psi_i \supset Z$. The Lagrangian of (5.1) has the form $\psi_0(z) + \langle u, \psi(z)\rangle$, where $\psi := (\psi_1, \ldots, \psi_n)$ and u is a multiplier. Suppose that, at each $u \in C$, the *dual function*

$$f(u) := \max\{\, \psi_0(z) + \langle u, \psi(z)\rangle : z \in Z \,\} \tag{5.2}$$

can be evaluated with *accuracy* $\epsilon_f \geq 0$ by finding a *partial Lagrangian* ϵ_f*-solution*

$$z(u) \in Z \quad \text{such that} \quad f_u := \psi_0(z(u)) + \langle u, \psi(z(u))\rangle \geq f(u) - \epsilon_f. \tag{5.3}$$

Thus f is finite convex and has an ϵ_f-subgradient mapping $g_u := \psi(z(u))$ for $u \in C$. In view of Remark 3.6(i), we suppose that $\psi(z(\cdot))$ is locally bounded on C. (Note that the whole set $\psi(z(C))$ is bounded if $\inf_Z \min_{i=1}^n \psi_i > -\infty$, or the function ψ is continuous on Z.)

5.2. Primal recovery with selection. We first consider our method with linearization selection (cf. section 4.4).

The partial Lagrangian solutions $z^k := z(u^k)$ (cf. (5.3)) and their constraint values $g^k := \psi(z^k)$ determine the linearizations (2.1) as Lagrangian pieces of f in (5.2):

$$f_k(\cdot) = \psi_0(z^k) + \langle \cdot, \psi(z^k)\rangle. \tag{5.4}$$

Using their weights $\{\nu_j^k\}_{j\in J_k}$ (cf. (4.6)), we may estimate a solution to (5.1) via the *aggregate primal solution*

$$\hat{z}^k := \sum_{j\in J_k} \nu_j^k z^j. \tag{5.5}$$

By (4.7), this convex combination is associated with the aggregate linearization $\bar{f}_k$ via

$$(\bar{f}_k, \hat{z}^k, 1) = \sum_{j\in \hat{J}_k} \nu_j^k (f_j, z^j, 1) \quad \text{with} \quad \hat{J}_k := \{j \in J_k : \nu_j^k > 0\}. \tag{5.6}$$

We now derive useful bounds on $\psi_0(\hat{z}^k)$ and $\psi(\hat{z}^k)$, generalizing [Kiw06b, Lem. 5.1].

LEMMA 5.1. *$\hat{z}^k \in Z$, $\psi_0(\hat{z}^k) \geq f_{\hat{u}}^k - \epsilon_k - \langle p^k, \hat{u}^k\rangle$, and $\psi(\hat{z}^k) \geq p_f^k \geq p^k$.*

Proof. By (5.6), $\hat{z}^k \in \operatorname{co}\{z^j\}_{j\in\hat{J}_k} \subset Z$, $\psi_0(\hat{z}^k) \geq \sum_j \nu_j^k \psi_0(z^j)$, and $\psi(\hat{z}^k) \geq \sum_j \nu_j^k \psi(z^j)$ by convexity of Z and concavity of ψ_0, ψ. Since $p_C^k \in \partial i_{\mathbb{R}^n_+}(u^{k+1})$ by (2.12), we have $p_C^k \leq 0$ and $\langle p_C^k, u^{k+1}\rangle = 0$ [HUL93, Ex. III.5.2.6(b)], so $p_f^k = p^k - p_C^k \geq p^k$ by (2.14). Next, using (5.6) with $p_f^k = \nabla \bar{f}_k$ by (2.6) and $\nabla f_j = \psi(z^j)$ by (5.4), we get $\bar{f}_k(0) = \sum_j \nu_j^k \psi_0(z^j)$ and $p_f^k = \sum_j \nu_j^k \psi(z^j)$. Since $\bar{f}_k(0) = \bar{f}_C^k(0) - \bar{\imath}_C^k(0)$ with

$\bar{\imath}_C^k(0) = -\langle p_C^k, u^{k+1}\rangle = 0$ from (2.8), we have $\bar{f}_k(0) = \bar{f}_C^k(0) = f_{\hat{u}}^k - \epsilon_k - \langle p^k, \hat{u}^k\rangle$ by (2.17). Combining the preceding relations yields the conclusion. ∎

In terms of the optimality measure V_k of (2.11), the bounds of Lemma 5.1 imply

$$\hat{z}^k \in Z \quad \text{with} \quad \psi_0(\hat{z}^k) \geq f_{\hat{u}}^k - V_k, \quad \psi_i(\hat{z}^k) \geq -V_k, \quad i = 1\colon n. \tag{5.7}$$

We now show that $\{\hat{z}^k\}$ has cluster points in the set of *ϵ_f-optimal primal solutions* of (5.1),

$$Z_{\epsilon_f} := \{\, z \in Z : \psi_0(z) \geq \psi_0^{\max} - \epsilon_f, \psi(z) \geq 0 \,\}, \tag{5.8}$$

unless this set is empty, i.e., the primal problem is infeasible.

THEOREM 5.2. *Either $f_* = -\infty$ and $f_{\hat{u}}^k \downarrow -\infty$, in which case the primal problem* (5.1) *is infeasible, or $f_* > -\infty$, $f_{\hat{u}}^k \downarrow f_{\hat{u}}^\infty \in [f_* - \epsilon_f, f_*]$, $\overline{\lim}_k f(\hat{u}^k) \leq f_{\hat{u}}^\infty + \epsilon_f$, and $\underline{\lim}_k V_k = 0$. In the latter case, let $K' \subset \mathbb{N}$ be a subsequence such that $V_k \xrightarrow{K'} 0$. Then we have the following:*

(i) *The sequence $\{\hat{z}^k\}_{k\in K'}$ is bounded, and all its cluster points lie in the set Z.*

(ii) *Let $\hat{z}^\infty$ be a cluster point of the sequence $\{\hat{z}^k\}_{k\in K'}$. Then $\hat{z}^\infty \in Z_{\epsilon_f}$.*

(iii) $d_{Z_{\epsilon_f}}(\hat{z}^k) := \inf_{z\in Z_{\epsilon_f}} |\hat{z}^k - z| \xrightarrow{K'} 0$.

Proof. The first assertion follows from Theorem 3.5 (since $f_* = -\infty$ implies primal infeasibility by weak duality). In the second case, using $f_{\hat{u}}^k \downarrow f_{\hat{u}}^\infty \geq f_* - \epsilon_f$ and $V_k \xrightarrow{K'} 0$ in the bounds of (5.7) yields $\underline{\lim}_{k\in K'} \psi_0(\hat{z}^k) \geq f_* - \epsilon_f$ and $\underline{\lim}_{k\in K'} \min_{i=1}^n \psi_i(\hat{z}^k) \geq 0$.

(i) By (5.7), $\{\hat{z}^k\}$ lies in the set Z, which is compact by our assumption.

(ii) We have $\hat{z}^\infty \in Z$, $\psi_0(\hat{z}^\infty) \geq f_* - \epsilon_f$, and $\psi(\hat{z}^\infty) \geq 0$ by the closedness of ψ_0 and ψ. Since $f_* \geq \psi_0^{\max}$ by weak duality (cf. (1.1), (5.1), (5.2)), we get $\psi_0(\hat{z}^\infty) \geq \psi_0^{\max} - \epsilon_f$. Thus $\hat{z}^\infty \in Z_{\epsilon_f}$ by the definition (5.8).

(iii) This follows from (i), (ii), and the continuity of the distance function $d_{Z_{\epsilon_f}}$. ∎

Remark 5.3. (i) For Theorem 5.2, we can replace ϵ_f in (5.8) by ϵ_f^∞ (cf. (4.3)).

(ii) By the proofs of Lemma 2.3 and Theorem 5.2, if an infinite cycle between Steps 2 and 5 occurs, then $V_k \to 0$ yields $d_{Z_{\epsilon_f}}(\hat{z}^k) \to 0$. Similarly, if Step 4 terminates with $V_k = 0$, then $\hat{z}^k \in Z_{\epsilon_f}$. In both cases, we can replace ϵ_f with ϵ_f^∞ (cf. (4.3)).

(iii) Given a tolerance $\epsilon_{\text{tol}} > 0$, the method may stop if

$$\psi_0(\hat{z}^k) \geq f_{\hat{u}}^k - \epsilon_{\text{tol}} \quad \text{and} \quad \psi_i(\hat{z}^k) \geq -\epsilon_{\text{tol}}, \quad i = 1\colon n.$$

Then $\psi_0(\hat{z}^k) \geq \psi_0^{\max} - \epsilon_f - \epsilon_{\text{tol}}$ from $f_{\hat{u}}^k \geq f_* - \epsilon_f$ (cf. (2.2)) and $f_* \geq \psi_0^{\max}$ (weak duality), so that the point $\hat{z}^k \in Z$ is an approximate primal solution of (5.1). This stopping criterion will be satisfied for some k if $f_* > -\infty$ (cf. (5.7) and Theorem 5.2).

5.3. Primal recovery with aggregation. Let us now consider the variant with aggregation based on (4.9), where each linearization f_j has an associated primal point z^j, with $f_j := \bar{f}_{-j}$ and $z^j := \hat{z}^{-j}$ for $j < 0$. Letting $z^0 := z^1$, suppose for induction that $(f_j, z^j) \in \text{co}\{(f_i, z^i)\}_{i=0}^{|j|}$ for $j \in J_k$. For the convex weights ν_j^k satisfying (4.7), let $z^{-k} := \hat{z}^k$ for the aggregate primal solution $\hat{z}^k$ given by (5.6). Since a convex combination of convex combinations of given points is a convex combination of those points, we deduce the existence of convex weights $\bar{\nu}_j^k$ such that

$$(f_{-k}, z^{-k}, 1) := (\bar{f}_k, \hat{z}^k, 1) = \sum_{0\leq j\leq k} \bar{\nu}_j^k (f_j, z^j, 1) \quad \text{with} \quad \bar{\nu}_j^k \geq 0,\ j = 0\colon k. \tag{5.9}$$

In other words, $(f_{-k}, z^{-k}) \in \mathrm{co}\{(f_i, z^i)\}_{i=0}^k$, as required for induction. Replacing (5.6) by (5.9) for Lemma 5.1, we conclude that the preceding convergence results remain valid.

5.4. Handling primal equality constraints. Consider the primal problem (5.1) with additional equality constraints of the form

$$\psi_0^{\max} := \max\ \psi_0(z) \quad \text{s.t.} \quad \psi_{\mathcal{I}}(z) \ge 0,\ \psi_{\mathcal{E}}(z) = 0,\ z \in Z, \tag{5.10}$$

where $\mathcal{I} \cup \mathcal{E} = \{1\colon n\}$, $\mathcal{I} \cap \mathcal{E} = \emptyset$, and $\psi_{\mathcal{E}}$ is affine. For $C := \mathbb{R}_+^{|\mathcal{I}|} \times \mathbb{R}^{|\mathcal{E}|}$, the final bound in Lemma 5.1 becomes $\psi_{\mathcal{I}}(\hat{z}^k) \ge p_{f,\mathcal{I}}^k \ge p_{\mathcal{I}}^k$, $\psi_{\mathcal{E}}(\hat{z}^k) = p_{f,\mathcal{E}}^k = p_{\mathcal{E}}^k$ (using $p_{C,\mathcal{I}}^k \le 0$, $p_{C,\mathcal{E}}^k = 0$, $\langle p_C^k, u^{k+1}\rangle = 0$ as before); the final inequalities in (5.7) are replaced by $\min_{i\in\mathcal{I}} \psi_i(\hat{z}^k) \ge -V_k$, $\max_{i\in\mathcal{E}} |\psi_i(\hat{z}^k)| \le V_k$, and $\psi(z) \ge 0$ in (5.8) by $\psi_{\mathcal{I}}(z) \ge 0$, $\psi_{\mathcal{E}}(z) = 0$. With these replacements, the proof of Theorem 5.2 extends easily (since $\underline{\lim}_{k\in K'} \max_{i\in\mathcal{E}} |\psi_i(\hat{z}^k)| = 0$ yields $\psi_{\mathcal{E}}(\hat{z}^\infty) = 0$ in (ii)).

Remark 5.4. We add that the ideas of sections 4.2, 5.3, and 5.4 can be translated into additional properties of the method of [Kiw06b]. Further, a simplified variant of the latter method is obtained by modifying relations (2.5)–(2.8) as follows. Letting u^{k+1} solve the prox subproblem (2.3), for the subgradients $p_f^k \in \partial \check{f}_k(u^{k+1})$ and $p_C^k \in \partial i_C(u^{k+1})$ such that $p_f^k + p_C^k = (\hat{u}^k - u^{k+1})/t_k$, define $\bar{f}_k$ by (2.6) with $\check{u}^{k+1} := u^{k+1}$ and $\bar{\imath}_C^k$ by (2.8). Then Lemma 2.2 holds by construction, and the proof of Lemma 3.2 simplifies to that of [Kiw06b, Lem. 3.3]. In effect, except for section 4.1, all the preceding results hold for this variant as well.

5.5. Nonpolyhedral objective models. In addition to the assumptions of section 5.1, suppose ψ is affine: $\psi(z) := b - Az$ for some given $b \in \mathbb{R}^n$ and a linear mapping $A : \mathcal{Z} \to \mathbb{R}^n$. Then the Lagrangian of (5.1) has the form

$$L(z,u) := \psi_0(z) + \langle u, \psi(z)\rangle = \psi_0(z) + \langle u, b - Az\rangle \tag{5.11}$$

and $f(\cdot) := \max_{z\in Z} L(z,\cdot)$. Suppose Step 1 selects the (possibly) *nonpolyhedral* model

$$\check{f}_k(\cdot) := \max_{z\in Z_k} L(z,\cdot) \quad \text{with} \quad z^k \in Z_k \subset Z, \tag{5.12}$$

where the set Z_k is closed convex. Since $f_k(\cdot) = L(z^k,\cdot)$ by (5.4), we have $f_k \le \check{f}_k \le f$. Thus, to meet the requirement of (4.4), we need only show how to choose a set $Z_{k+1} \ni z^{k+1}$ so that $\bar{f}_k \le \check{f}_{k+1}$. First, for solving subproblem (2.5) with the model $\check{f}_k$ given by (5.12), we employ the *Lagrangian* $\bar{L} : \mathbb{R}^n \times Z_k \to \mathbb{R}$ of subproblem (2.5) defined by

$$\bar{L}(u,z) := L(z;u) + \langle p_C^{k-1}, u - u^k\rangle + \frac{1}{2t_k}|u - \hat{u}^k|^2, \tag{5.13}$$

so that

$$\phi_f^k(\cdot) = \max\big\{\bar{L}(\cdot,z) : z \in Z_k\big\}. \tag{5.14}$$

For each primal point $z \in Z_k$, the (unique) *Lagrangian solution*

$$u_z := \arg\min \bar{L}(\cdot,z) = \hat{u}^k - t_k\big[\psi(z) + p_C^{k-1}\big] \tag{5.15}$$

substituted for u in (5.13) gives the value of the *dual function* $q : Z_k \to \mathbb{R}$ defined by

(5.16)
$$q(z) := \min \bar{L}(\cdot, z) = \psi_0(z) + \langle \psi(z), \hat{u}^k \rangle + \langle p_C^{k-1}, \hat{u}^k - u^k \rangle - \frac{t_k}{2} |\psi(z) + p_C^{k-1}|^2.$$

Since q is closed and Z_k is compact, the *dual problem* $\max_{Z_k} q$ has at least one solution:

$$\hat{z}^k \in \operatorname{Arg\,max} \{ q(z) : z \in Z_k \}. \tag{5.17}$$

LEMMA 5.5. *Given a dual solution $\hat{z} := \hat{z}^k$ of (5.17), define the Lagrangian solution $\check{u} := u_{\hat{z}}$ by (5.15). Then we have the following statements:*

(i) *The pair $(\check{u}, \hat{z})$ is a saddle-point of the Lagrangian $\bar{L}$ defined by (5.13):*

$$\bar{L}(\check{u}, z) \le \bar{L}(\check{u}, \hat{z}) \le \bar{L}(u, \hat{z}) \quad \forall u \in \mathbb{R}^n, z \in Z_k. \tag{5.18}$$

(ii) *For $\check{u}^{k+1}$, $\bar{f}_k$, and p_f^k defined by (2.5)–(2.6), we have $\check{u}^{k+1} = \check{u}$, $p_f^k = \psi(\hat{z}^k)$,*

$$\check{u}^{k+1} = \hat{u}^k - t_k \big[\psi(\hat{z}^k) + p_C^{k-1} \big], \tag{5.19}$$

$$\bar{f}_k(\cdot) = \psi_0(\hat{z}^k) + \langle \cdot, \psi(\hat{z}^k) \rangle. \tag{5.20}$$

Proof. (i) $\bar{L}$ is convex-concave on $\mathbb{R}^n \times Z_k$, Z_k is compact, and for each $z \in Z_k$, $\bar{L}(u, z) \to \infty$ when $|u| \to \infty$. Hence $\bar{L}$ has a saddle-point $(\bar{u}, \bar{z})$ [HUL93, Thm. VII.4.3.1]. Since $\hat{z} \in \operatorname{Arg\,max}_{Z_k} \min_u \bar{L}(u, \cdot)$ by (5.16)–(5.17), $(\bar{u}, \hat{z})$ is a saddle-point as well [HUL93, Thm. VII.4.2.5]. Then $\bar{L}(\bar{u}, \hat{z}) \le \bar{L}(u, \hat{z})$ $\forall u$ yields $\bar{u} = u_{\hat{z}} = \check{u}$ by (5.15), so that (5.18) holds.

(ii) By (2.5) and (5.14), (5.18) implies $\check{u}^{k+1} = \check{u}$ [HUL93, Thm. VII.4.2.5]. Then (2.6) and (5.15) with $z = \hat{z}$ yield $p_f^k = \psi(\hat{z}^k)$. The left inequality in (5.18) combined with (5.11)–(5.13) gives $\check{f}_k(\check{u}^{k+1}) = \psi_0(\hat{z}^k) + \langle \check{u}^{k+1}, \psi(\hat{z}^k) \rangle$, and then (2.6) yields (5.20). ∎

In view of (5.12) and (5.20), the requirement of (4.4) is met if the set Z_{k+1} satisfies

$$Z_{k+1} \supset \{ \hat{z}^k, z^{k+1} \}, \tag{5.21}$$

in addition to being a closed convex subset of Z. Further, condition (3.1) holds (with $p_f^k = \psi(\hat{z}^k)$, $\hat{z}^k \in Z_k$, Z_k compact, ψ continuous), and the aggregate representation (5.20) can be seen as a special case of (5.6) (with $\hat{J}_k := \{k\}$ and z^k replaced by $\hat{z}^k$ in (5.4)). In effect, the results of section 5.2 hold for this variant as well.

Remark 5.6. (i) We add that for $p_f^k = \psi(\hat{z}^k)$ (and $C := \mathbb{R}^n_+$), (2.7)–(2.8) simplify to

$$u^{k+1} = \max \{ \hat{u}^k - t_k(b - A\hat{z}^k), 0 \} \quad \text{and} \quad p_C^k = \min \left\{ \frac{1}{t_k} \hat{u}^k - b + A\hat{z}^k, 0 \right\}. \tag{5.22}$$

In general, $\langle p_C^{k-1}, u^k \rangle = 0$ from $p_C^{k-1} \in \partial i_C(u^k)$, so we can omit u^k in (5.13) and (5.16). A dual interpretation of (5.22) follows. Since $i_C(\cdot) = \sup\{-\langle \eta, \cdot \rangle : \eta \in \mathbb{R}^n_+\}$, using a dual variable $\eta \in \mathbb{R}^n_+$ for subproblem (2.3), its Lagrangian $\bar{L}(u, z, \eta)$, relaxed solution $u_{z,\eta}$, and dual function $q(z, \eta)$ are given by (5.13), (5.15), and (5.16) with p_C^{k-1} replaced by $-\eta$. Let $\eta^k := -p_C^{k-1}$. The dual problem $\max_{Z_k \times \mathbb{R}^n_+} q$ is treated in a Gauss–Seidel fashion by finding $\hat{z}^k \in \operatorname{Arg\,max}_{Z_k} q(\cdot, \eta^k)$ (cf. (5.17)) and then $\eta^{k+1} := \arg\max_{\mathbb{R}^n_+} q(\hat{z}^k, \cdot)$, for which $u^{k+1} = u_{\hat{z}^k, \eta^{k+1}}$ and $\eta^{k+1} = -p_C^k$ by (5.22).

Thus alternating linearizations of subproblem (2.3) correspond to coordinatewise maximizations of its dual function.

(ii) Suppose that ψ_0 is linear and $Z_k := \mathrm{co}\{z^j\}_{j=1}^k$. Then $z \in Z_k$ iff $z = \sum_j \nu_j z^j$ for a weight vector ν in $N := \{\nu \in \mathbb{R}^k_+ : \sum_j \nu_j = 1\}$. For $F := [\psi_0(z^1), \ldots, \psi_0(z^k)]$ and $G := [g^1, \ldots, g^k]$, we have $\psi_0(z) = F\nu$ and $\psi(z) = G\nu$. Using these representations in (5.16)–(5.17), we may take $\hat{z}^k = \sum_j \nu^k_j z^j$ for any solution ν^k to the dual QP subproblem

$$\nu^k \in \mathrm{Arg\,max}\left\{F\nu + \nu^T G^T \hat{u}^k - \frac{t_k}{2}|G\nu - p_C^{k-1}|^2 : \nu \in N\right\}. \tag{5.23}$$

In effect, our framework comprises the method of [FGRS06, sect. 3.2], which requires exact evaluations. Note that the similarity of $\hat{z}^k$ above to (5.5) is not accidental: the model (5.12) with $Z_k := \mathrm{co}\{z^j\}_{j=1}^k$ is *equivalent* to the polyhedral model (4.5) with $J_k := \{1\colon k\}$ (cf. (5.11) and (5.4)). Other choices of J_k from section 4.4 correspond to $Z_k := \mathrm{co}\{z^j\}_{j\in J_k}$.

(iii) For problem (5.10) with mixed constraints, formula (5.22) is valid for components indexed by $\mathcal{I}$, whereas $u^{k+1}_{\mathcal{E}} = \hat{u}^k_{\mathcal{E}} - t_k(b - A\hat{z}^k)_{\mathcal{E}}$ and $p^k_{C,\mathcal{E}} = 0$. Then the setting of (ii) above comprises the method of [ReS06, sect. 3] (for exact evaluations).

(iv) By Remark 4.1, the results of section 5.2 hold when Step 5′ is used as well, since each $\check{f}_k$ has bounded subgradients (by (5.11)–(5.12) and the compactness of $Z_k \subset Z$).

5.6. SDP via eigenvalue optimization. To discuss applications in SDP, we need the following notation.

We consider the Euclidean space S^m of $m \times m$ real symmetric matrices with the Frobenius inner product $\langle x, y\rangle = \mathrm{tr}\, xy$ (we use lowercase notation for the elements of S^m for consistency with the rest of the text). S^m_+ is the cone of positive semidefinite matrices. The maximum eigenvalue $\lambda_{\max}(y)$ of a matrix $y \in S^m$ and its positive part $\lambda^+_{\max}(y) := \max\{\lambda_{\max}(y), 0\}$ satisfy (see, e.g., [LeO96, Tod01])

$$\lambda_{\max}(y) = \max\big\{\langle y, x\rangle : x \in \Sigma^m\big\} \quad \text{with} \quad \Sigma^m := \big\{x \in S^m_+ : \mathrm{tr}\, x = 1\big\}, \tag{5.24a}$$

$$\lambda^+_{\max}(y) = \max\big\{\langle y, x\rangle : x \in \Sigma^m_{\leq}\big\} \quad \text{with} \quad \Sigma^m_{\leq} := \big\{x \in S^m_+ : \mathrm{tr}\, x \leq 1\big\}. \tag{5.24b}$$

Let $a > 0$, $b \in \mathbb{R}^n$, $c \in S^m$, and $A : S^m \to \mathbb{R}^n$ be linear. Consider the *SDPs*

$$(P_=): \quad \max \langle c, x\rangle \quad \text{s.t.} \quad Ax \leq b, \quad x \in S^m_+, \quad \mathrm{tr}\, x = a, \tag{5.25}$$

$$(P_{\leq}): \quad \max \langle c, x\rangle \quad \text{s.t.} \quad Ax \leq b, \quad x \in S^m_+, \quad \mathrm{tr}\, x \leq a. \tag{5.26}$$

Any SDP can be formulated as $(P_{\leq})$ without the final trace condition. If we know or simply guess an upper bound a on the trace of some optimal solution, we may use $(P_{\leq})$. (For a wrong guess, our method will produce dual values going to $-\infty$, thus indicating primal infeasibility.) Of course, $(P_{\leq})$ can be formulated as $(P_=)$ by adding a slack variable, but this is not really necessary, since our method can handle both. $(P_=)$ is natural in many combinatorial applications, where the trace of all feasible solutions is known [HeR00]; $(P_{\leq})$ is employed in [Nay06] for equality-constrained SDPs.

We can regard $(P_=)$ as an instance of (5.1) with $\mathcal{Z} := S^m$, $\psi_0(z) := \langle c, z\rangle$, $\psi(z) := b - Az$, and $Z := a\Sigma^m$. Then, by (5.2) and (5.24a), the dual function f satisfies

$$f(u) = a\lambda_{\max}(c - A^*u) + \langle b, u\rangle \quad \forall\, u, \tag{5.27}$$

where A^* is the adjoint of A (defined by $\langle z, A^*u\rangle = \langle Az, u\rangle \ \forall\ z \in S^m,\ u \in \mathbb{R}^n$). For each u, the approximate evaluation condition (5.3) is met by $z(u) := ar(u)r(u)^T$, where $r(u) \in \mathbb{R}^m$ is an (ϵ_f/a)-*eigenvector* of the matrix $s(u) := c - A^*u \in S^m$ satisfying

$$r(u)^T s(u) r(u) \geq \lambda_{\max}(s(u)) - \frac{\epsilon_f}{a}, \qquad r(u)^T r(u) = 1. \tag{5.28}$$

Then the ϵ_f-subgradient mapping $u \to g_u := \psi(z(u)) = b - Az(u)$ is bounded on $\mathbb{R}^n$.

Thus we can use the setting of section 5.5 with models $\check{f}_k$ given by (5.12) for sets Z_k satisfying (5.21). In effect, the results of section 5.2 and Remark 5.6 hold for this variant as well.

Remark 5.7. (i) Our dual problem $f_* := \inf_C f$ is equivalent to the standard dual of $(P_=)$, which is strictly feasible. Hence (cf. [Tod01, Thm. 4.1]) if $(P_=)$ is feasible, then its optimal value is finite and equals f_*, although the dual problem need not have solutions. Thus, even for exact evaluations, Theorem 5.2 improves upon [Hel04, Thm. 3.6], which assumes that $\operatorname{Arg\,min}_C f \neq \emptyset$. We show elsewhere [Kiw06a] how to extend a related result of [Hel04, Thm. 4.8], without assuming that $\operatorname{Arg\,min}_C f$ is nonempty and bounded.

(ii) Condition (5.28) is particularly useful when approximate eigenvectors are found by iterative methods (such as the Lanczos method [Hel03, Nay06]) that employ only matrix-vector multiplications to exploit the structure of the matrix $s(u) := c - A^*u$. This condition has the following meaning in the setting of Example 4.2 with $u = u^{k+1}$, $s^{k+1} := s(u^{k+1})$. Suppose that an iterative method generates approximate eigenvectors $r^{(i)} \in \mathbb{R}^m$, $|r^{(i)}| = 1$, $i = 1, 2, \ldots$, stopping for some i to deliver $z^{k+1} := ar^{(i)}r^{(i)^T}$. To meet the relaxed null-step requirements, the method may stop when $ar^{(i)^T}s^{k+1}r^{(i)} + \langle b, u^{k+1}\rangle > f_{\hat{u}}^k - \bar{\kappa}v_k$. If a descent step occurs, then $\epsilon_f^{k+1} = a\lambda_{\max}(s^{k+1}) - ar^{(i)^T}s^{k+1}r^{(i)}$ may potentially determine the asymptotic error ϵ_f^∞ of (4.3). To ensure that ϵ_f^{k+1} is not "too large," we can employ additional stopping criteria based on upper estimates of $\lambda_{\max}(s^{k+1})$ generated as in [Nay06].

(iii) We may employ the following choice of the set Z_k due to [Nay99, Nay06]:

$$Z_k := \left\{ \sum_{j=1}^{\check{j}} \nu_j \check{z}^j + pvp^T : \nu \in \mathbb{R}^{\check{j}}_+, v \in S^r_+, \sum_{j=1}^{\check{j}} \nu_j + \operatorname{tr} v = a \right\}, \tag{5.29}$$

where each $\check{z}^j \in \Sigma^m$ and p is an $m \times r$ orthonormal matrix. The resulting model

$$\check{f}_k(u) = a \max\Big\{ \max_{j=1:\ \check{j}} \langle c - A^*u, \check{z}^j\rangle, \lambda_{\max}\big(p^T(c - A^*u)p\big) \Big\} + \langle b, u\rangle \tag{5.30}$$

attempts to strike a balance between being easy to handle (the polyhedral part) and accurate enough for fast convergence (the semidefinite part). Then the dual subproblem (5.17) can be cast as a conic optimization problem and handled by specialized solvers. Two efficient updates of Z_k satisfying (5.21) are given in [Nay99, sect. 4.4.2] (although they update AZ_k, they can update Z_k as well). For $\check{j} = 1$, (5.29) reduces to the original choice of [HeR00]; again, (5.17) can be solved efficiently as a quadratic SDP [HeK02], and efficient updates of Z_k are given in [Hel03, HeK02].

(iv) For problem $(P_\leq)$ of (5.26), we can take $Z := a\Sigma^m_\leq$. Then (cf. (5.24)), $\lambda^+_{\max}$ replaces $\lambda_{\max}$ in (5.27), and we can take $r(u) := 0$ if $\lambda_{\max}(s(u)) < 0$, using (5.28) otherwise. We can thus stop an iterative eigenvalue computation whenever an upper bound indicates that $\lambda_{\max}(s(u)) < 0$. Of course, the final "=" in (5.29) is replaced by "$\leq$".

Acknowledgments. I would like to thank the Associate Editor, the two anonymous referees, and Claude Lemaréchal for helpful comments.

TRANSPOSITION THEOREMS AND QUALIFICATION-FREE OPTIMALITY CONDITIONS*

HERMANN SCHICHL† AND ARNOLD NEUMAIER†

Abstract. New theorems of the alternative for polynomial constraints (based on the Positivstellensatz from real algebraic geometry) and for linear constraints (generalizing the transposition theorems of Motzkin and Tucker) are proved. Based on these, two Karush–John optimality conditions—holding without any constraint qualification—are proved for single- or multiobjective constrained optimization problems. The first condition applies to polynomial optimization problems only, and gives for the first time necessary and sufficient global optimality conditions for polynomial problems. The second condition applies to smooth local optimization problems and strengthens known local conditions. If some linear or concave constraints are present, the new version reduces the number of constraints for which a constraint qualification is needed to get the Kuhn–Tucker conditions.

Key words. certificate of global optimality, first order optimality conditions, Fritz John conditions, Karush–John conditions, global optimality condition, global optimization, Kuhn–Tucker conditions, Mangasarian–Fromovitz constraint qualification, necessary and sufficient conditions, Positivstellensatz, second order optimality conditions, theorem of the alternative, transposition theorem

1. Introduction.

In this paper, we present a number of theorems that are useful for the global analysis of optimization problems, i.e., the assessment of their feasibility, and the construction and verification of a global solution. Several of the results are, however, also relevant for local optimization.

In constrained optimization, first and second order optimality conditions play a central role, as they give necessary and/or sufficient conditions for a point to attain a local or global minimum of the problem considered, and thus define the goals that numerical methods should try to satisfy.

The various conditions currently available usually depend on qualitative conditions (concerning smoothness, linearity, convexity, etc.) that delineate the problem class, and on technical conditions, so-called constraint qualifications, that allow one to avoid certain difficulties in proofs or certain known counterexamples.

The proof of the optimality conditions depends crucially on the availability of certain theorems of the alternative, which state that among two alternative existence statements, exactly one can be satisfied. Thus a theorem of the alternative may serve to define certificates whose presence implies the solvability of one alternative and the unsolvability of the other alternative.

Recent advances in global optimization [27, 30] make it possible in many cases to find and verify the global optimality of a solution, or to verify that no feasible point exists. Certificates acquire in this case a special importance, particularly in the context of computer-assisted proofs.

However, in order to apply a necessary optimality condition to rule out candidate solutions, or a sufficient optimality condition to verify the existence of a solution,

*Received by the editors May 11, 2005; accepted for publication (in revised form) May 15, 2006; published electronically December 5, 2006.
http://www.siam.org/journals/siopt/17-4/63129.html
†Fakultät für Mathematik, Universität Wien, Nordbergstr. 15, A-1090 Wien, Austria (Hermann.Schichl@esi.ac.at, Arnold.Neumaier@univie.ac.at; http://www.mat.univie.ac.at/∼neum/).

it is important that these conditions are valid under conditions that can be checked explicitly. Therefore the optimality conditions should not depend on any constraint qualification.

Optimality conditions characterizing the solutions of smooth nonlinear programming problems by first order necessary conditions are often called Fritz John conditions if they apply without constraint qualification, after Fritz John [15], who rediscovered unpublished earlier results of Karush [16]; see Kuhn [18, section 6] for a history. Therefore, we shall refer to such conditions as *Karush–John optimality conditions*.

The importance of the Karush–John conditions stems from the fact that they apply without any hypothesis on the optimization problem (apart from smoothness). For the known (second order) sufficient conditions, a similar result was not known before, sufficiency requiring very strong nondegeneracy conditions. It is therefore remarkable that, *for polynomial optimization problems*, it is possible to formulate necessary and sufficient conditions for (global) optimality, valid without any restriction. These strong results are based on the so-called Positivstellensatz, a polynomial analogue of the transposition theorem for linear systems. The Positivstellensatz is a highly nontrivial tool from real algebraic geometry which has been applied recently also in an algorithmic way for the solution of global polynomial optimization problems. Some of the consequences of the Positivstellensatz are implemented in the packages GloptiPoly (Henrion and Lasserre [12, 13, 14]) and SOSTOOLS (Prajna, Papachristodoulou, and Parrilo [32]).

Related results in this direction are in Lasserre [20]. He proved in his Theorem 4.2 a sufficient condition for global optimality in polynomial optimization problems, which is a special case of our necessary and sufficient conditions. (The unconstrained minimization of the Motzkin polynomial shows that Lasserre's condition is not sufficient.) He shows that his certificates can be interpreted as polynomial multipliers in a fashion analogous to the Kuhn–Tucker optimality conditions. Instead of necessary conditions he obtains under some compactness assumption an infinite sequence of semidefinite relaxations whose optimal values converge to the global optimum.

In this article we derive in section 2 polynomial transposition theorems and deduce from them a global Karush–John condition which is a necessary and sufficient condition for global optimality of *polynomial* programs.

Section 3 then proves a very general transposition theorem for *linear* constraints, establishing a theorem of the alternative from which the transposition theorems of Motzkin [24] and of Tucker [34] (as well as many weaker ones) can be obtained as corollaries. This level of generality is necessary to deduce in section 4 a form of the constraint qualifications for the Kuhn–Tucker optimality conditions for general *smooth nonlinear* programming problems which is stronger (i.e., makes more stringent assertions about the multipliers) than the known Karush–John conditions and also applies for multiple objectives.

Our Karush–John conditions imply derived Kuhn–Tucker conditions with linear independence constraint qualifications for fewer constraints than the conditions found in the literature. In particular, they imply the known result that for concavely (or linearly) constrained problems no constraint qualification is needed.

The new conditions will be incorporated in the COCONUT environment [9] for deterministic global optimization; the local Karush–John conditions from section 4 are already in place.

Notation. In the following, $\mathbb{R}$ is the field of real numbers, and $\mathbb{N}_0$ the set of nonnegative integers. To denote monomials and their degrees, we use the multi-index

notation

$$x^\alpha = x_1^{\alpha_1} \dots x_n^{\alpha_n}, \quad |\alpha| = \alpha_1 + \dots + \alpha_n$$

($x \in \mathbb{R}^n, \alpha \in \mathbb{N}_0^n$). Inequalities ($\leq$, $\geq$) and strict inequalities ($<$, $>$) between vectors and matrices are interpreted componentwise. However, disequality ($\neq$) is the negation of equality ($=$) and hence not interpreted componentwise. The infimum $\inf\{x, y\}$ of two vectors x, y of the same size is taken in the partial order $\leq$, and is equivalent to the componentwise minimum. In particular, the condition $\inf\{x, y\} = 0$ is just the complementarity condition $x \geq 0, y \geq 0, x_i y_i = 0$ for all i. By e we denote a column vector of arbitrary size all of whose entries have the value 1. $[A, B]$ denotes the $m \times (n+p)$-matrix formed by juxtaposition of the $m \times n$-matrix A and the $m \times p$-matrix B. Zero dimensional vectors and matrices (needed to avoid stating many special cases) are handled according to the conventions in de Boor [7]; in addition, any of the relations $=$, $<$, $\leq$ (but not $\neq$) between zero dimensional objects is considered to be valid.

2. Global optimality conditions for polynomials. It is well known that first order (Kuhn–Tucker) optimality conditions for constrained (single-objective) optimization are sufficient for convex problems, but not in general. For nonconvex problems, they must be complemented by second order conditions, which come in two forms—as necessary conditions and as sufficient conditions—and they apply to local optimality only. Moreover, between necessary and sufficient conditions is a theoretical gap, in which various degenerate exceptional situations are possible. It is therefore remarkable that, for polynomial systems, it is possible to bridge this gap and formulate necessary and sufficient conditions for (global) optimality, valid without any restriction.

The following discussion is based on a polynomial analogue of the transposition theorem (Theorem 3.4), the so-called Positivstellensatz, a highly nontrivial result from real algebraic geometry. To present this result, we need some definitions.

$\mathbb{N}_0$ denotes the set of nonnegative integers. $\mathbb{R}[x_{1:n}] := \mathbb{R}[x_1, \dots, x_n]$ denotes the algebra of polynomials in the indeterminates $x_1, \dots, x_n$ with real coefficients. Let $R_i \in \mathbb{R}[x_{1:n}]$ $(i = 1 : k)$ be a finite family of polynomials, combined in the vector $R = (R_1, \dots, R_k)^T$. The *ideal* generated by the R_i is the vector space

$$I\langle R\rangle = I\langle R_1, \dots, R_k\rangle := \left\{ \sum_{i=1}^k a_i R_i \;\middle|\; a_i \in \mathbb{R}[x_{1:n}] \right\}.$$

The *multiplicative monoid* generated by the R_i is the semigroup

$$M\langle R\rangle = M\langle R_1, \dots, R_k\rangle := \left\{ \prod_{i=1}^k R_i^{e_i} \;\middle|\; e_i \in \mathbb{N}_0 \right\}. \tag{1}$$

A *polynomial cone* C is a subset of $\mathbb{R}[x_{1:n}]$ containing all squares a^2 with $a \in \mathbb{R}[x_{1:n}]$, such that $r+s, rs \in C$ whenever $r, s \in C$. The smallest polynomial cone is the set SOS of polynomials which can be represented as sums of squares; we call such polynomials *SOS polynomials*. The *polynomial cone* generated by the R_i is the smallest polynomial cone containing $R_1, \dots, R_k$; it is given by

$$C\langle R\rangle = C\langle R_1, \dots, R_k\rangle = \left\{ y_0 + Y^T R_S \;\middle|\; y_0 \in SOS,\ Y \in SOS^{2^k} \right\}, \tag{2}$$

where R_S denotes the vector containing the 2^k polynomials in the *squarefree part*

$$S\langle R\rangle = S\langle R_1,\ldots,R_k\rangle := \left\{ \prod_{i=1}^{k} R_i^{e_i} \;\middle|\; e_i \in \{0,1\} \right\} \tag{3}$$

of $M\langle R_1,\ldots,R_k\rangle$.

THEOREM 2.1 (polynomial transposition theorem I). *Let P, Q, and R be vectors of polynomials. Then exactly one of the following holds:*

(i) $P(x) \geq 0, \quad Q(x) = 0, \quad R_i(x) \neq 0$ *for* $i = 1,\ldots,k, \quad$ *for some* $x \in \mathbb{R}^n$,

(ii) $f + g + h = 0$ *for some* $f \in C\langle P\rangle$, $g \in I\langle Q\rangle$, *and* $h \in M\langle R_1^2,\ldots,R_k^2\rangle$.

Proof. That conditions (i) and (ii) are mutually inconsistent can easily be seen. Indeed, if (i) holds then for any $f \in C\langle P\rangle$, $g \in I\langle Q\rangle$, and $h \in M\langle R_1^2,\ldots,R_k^2\rangle$, we have $f(x) \geq 0$, $g(x) = 0$, and $h(x) > 0$, whence $f(x) + g(x) + h(x) > 0$, contradicting (ii). That one of the two conditions can always be satisfied is the hard part. It follows from the statement that the inconsistency of (i) implies the solvability of (ii), which is equivalent to the weak Positivstellensatz stated and proved as Theorem 4.4.2 in Bochnak, Coste, and Roy [4]. □

For our application to optimality conditions, we need the following slightly different formulation.

THEOREM 2.2 (polynomial transposition theorem II). *Let P, Q, and R be vectors of polynomials. Then exactly one of the following holds:*

(i) $P(x) \geq 0$, $Q(x) = 0$, *and* $R(x) > 0$ *for some* $x \in \mathbb{R}^n$,

(ii) $f + g + h = 0$ *for some* $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, *and* $h \in M\langle R\rangle$.

Proof. That conditions (i) and (ii) are mutually inconsistent can again easily be seen. Indeed, if (i) holds then for any $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, and $h \in M\langle R\rangle$, we have $f(x) \geq 0$, $g(x) = 0$, and $h(x) > 0$, whence $f(x) + g(x) + h(x) > 0$, contradicting (ii).

If, on the other hand, (i) is inconsistent, this implies that the system $\big(P(x), R(x)\big) \geq 0$, $Q(x) = 0$, and $R(x) \neq 0$ is inconsistent, and by Theorem 2.1, there exist $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, and $h \in M\langle R_1^2,\ldots,R_k^2\rangle$ with $f+g+h = 0$. Since $M\langle R_1^2,\ldots,R_k^2\rangle \subset M\langle R\rangle$, the result follows. □

Both versions have the following common generalization.

THEOREM 2.3 (general polynomial transposition theorem). *Let P, Q, R, and $S_1,\ldots,S_k$ be vectors of polynomials. Then exactly one of the following holds:*

(i) $P(x) \geq 0$, $Q(x) = 0$, $R(x) > 0$, *and* $S_i(x) \neq 0$ *for* $i = 1,\ldots,k$, *for some* $x \in \mathbb{R}^n$,

(ii) $f+g+h = 0$ *for some* $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, *and* $h \in M\langle R, S_1^T S_1,\ldots,S_k^T S_k\rangle$.

Proof. That conditions (i) and (ii) are mutually inconsistent can be proved as before. Given that (i) holds, then for any $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, and $h \in M\langle R, S_1^T S_1,\ldots,$
$S_k^T S_k\rangle$, we have $f(x) \geq 0$, $g(x) = 0$, and $h(x) > 0$, leading to $f(x) + g(x) + h(x) > 0$, contradicting (ii).

The fact that (i) is inconsistent implies that the system of constraints $R(x) \geq 0$, $Q(x) = 0$, and $\big(R(x), S_1(x)^T S_1(x),\ldots,S_k(x)^T S_k(x)\big) > 0$ is inconsistent, and by Theorem 2.2, there exist polynomials $f \in C\langle P, R\rangle$, $g \in I\langle Q\rangle$, and $h \in M\langle R, S_1^T S_1,\ldots,$
$S_k^T S_k\rangle$ with $f + g + h = 0$. □

The equivalence of the three transposition theorems, Theorems 2.1, 2.2, and 2.3, can be seen by taking $R(x) \equiv 1 \in \mathbb{R}$ in Theorem 2.3 and noting that $C\langle P, 1\rangle = C\langle P\rangle$ and $M\langle 1, S_1^T S_1,\ldots,S_k^T S_k\rangle = M\langle S_1^2,\ldots,S_k^2\rangle$ when all S_j are scalars.

The following result gives necessary and sufficient conditions for the global opti-

mality of a feasible point of an optimization problem defined in terms of a polynomial objective function f and polynomial constraints. In most applications, f will be a real-valued function.

However, it is not difficult to state and prove analogous conditions for multiobjective optimization problems, by allowing f to be vector-valued. In this case, optimality is replaced by Pareto optimality, defined as follows. The point $\hat{x}$ is called *weakly Pareto minimal* with respect to the continuous function $f : X \subseteq \mathbb{R}^n \to \mathbb{R}^m$ for f on X if $x \in X$ and there exists a neighborhood of $\hat{x}$ in X which does not contain a point y with $f(y) < f(\hat{x})$.

THEOREM 2.4 (global Karush–John conditions). *Let $\hat{x}$ be a feasible point of the polynomial Pareto optimization problem*

$$\begin{aligned} &\min\ f(x) \\ &s.t.\ \ C(x) \geq 0, \\ &\qquad F(x) = 0, \end{aligned} \tag{4}$$

where $f \in \mathbb{R}[x_{1:n}]^k$ and $C \in \mathbb{R}[x_{1:n}]^m$, $F \in \mathbb{R}[x_{1:n}]^r$ are vectors of polynomials in $x_{1:n}$. Write B for the vector obtained by concatenating C with the vector $G(x) = f(\hat{x}) - f(x)$, so that $B_k = C_k$ for $k \leq m$, and define B_S as indicated by (3). Then the following are equivalent:

(i) *The point $\hat{x}$ is a global weak Pareto minimum of (4).*

(ii) *There are a polynomial $y_0 \in SOS$, polynomial vectors $Y \in SOS^{2^{m+1}}$, and $Z \in \mathbb{R}[x_{1:n}]^r$, and a multi-index $\alpha \in \mathbb{N}_0^k$ with $|\alpha| > 0$ such that*

$$G(x)^\alpha + y_0(x) + Y(x)^T B_S(x) + Z(x)^T F(x) = 0 \tag{5}$$

identically in x.

Moreover, any solution of (5) satisfies

$$y_0(\hat{x}) = 0, \quad \inf\{Y(\hat{x}), B_S(\hat{x})\} = 0, \quad F(\hat{x}) = 0, \tag{6}$$

$$\delta_{|\alpha|\,1} f_i'(\hat{x})^T = B_S{}'(\hat{x})^T Y(\hat{x}) + F'(\hat{x})^T Z(\hat{x}), \tag{7}$$

where $\alpha_i = 1$ and δ_{ik} is the Kronecker symbol.

Proof. $\hat{x}$ is a global weak Pareto minimum of (4) iff the conditions

$$C(x) \geq 0, \quad F(x) = 0, \quad f(x) < f(\hat{x})$$

are inconsistent. Because $f(x) < f(\hat{x})$ iff $G > 0$, the polynomial transposition theorem, Theorem 2.2, applies and shows that this is equivalent to the existence of polynomials $q \in C\langle B\rangle$, $r \in I\langle F\rangle$, and $s \in M\langle G\rangle$ with $q + r + s = 0$. Expressing this more explicitly using (1) and (2) shows this to be equivalent to (ii) without the constraint (6), and α only restricted to being a nonnegative multi-index. The equivalence of (i) and (ii) follows if we show that $|\alpha| \neq 0$.

Since $\hat{x}$ is feasible, we have $B(\hat{x}) \geq 0$, $F(\hat{x}) = 0$, and by construction, $G(\hat{x}) = 0$. Moreover, as a sum of squares, $y_0(\hat{x}) \geq 0$ and $Y(\hat{x}) \geq 0$. Inserting $x = \hat{x}$ into (5) gives, with the Kronecker δ,

$$\delta_{0\,|\alpha|} \leq \delta_{0\,|\alpha|} + y_0(\hat{x}) + Y(\hat{x})^T B_S(\hat{x}) = 0.$$

This indeed forces $|\alpha| > 0$.

We also get $y_0(\hat{x}) = 0$ and $Y(\hat{x})^T B_S(\hat{x}) = 0$. But the latter inner product is a sum of nonnegative terms; hence each product vanishes, giving the complementarity conditions (6). Differentiating the relation (5) and evaluating the result at $\hat{x}$ yield

$$\begin{aligned} 0 = &\sum_{\substack{i=1 \\ \alpha_i>0}}^{k} \alpha_i G^{\alpha-e_i}(\hat{x}) G_i'(\hat{x})^T + y_0'(\hat{x}) + Y'(\hat{x})^T B_S(\hat{x}) + {B_S}'(\hat{x})^T Y(\hat{x}) \\ &+ Z'(\hat{x})^T F(\hat{x}) + F'(\hat{x})^T Z(\hat{x}). \end{aligned} \tag{8}$$

We now note that $y_0'(\hat{x}) = 0$ because $y_0(\hat{x}) = 0$ and y_0 is SOS. Together with the facts that $|\alpha| > 0$, $G(\hat{x}) = 0$, and $F(\hat{x}) = 0$, we can simplify (8) and get

$$0 = \delta_{|\alpha|\,1} G_i'(\hat{x})^T + Y'(\hat{x})^T B_S(\hat{x}) + {B_S}'(\hat{x})^T Y(\hat{x}) + F'(\hat{x})^T Z(\hat{x}) \tag{9}$$

for that i with $\alpha_i = 1$. Finally, whenever $(B_S)_j(\hat{x}) \neq 0$, the complementarity conditions in (6) imply $Y_j(\hat{x}) = 0$ and then $Y_j'(\hat{x})^T = 0$ since Y_j is an SOS. Thus, $Y'(\hat{x})^T B_S(\hat{x}) = 0$, and (9) simplifies further to (7), upon noting that $G_i'(\hat{x}) = -f_i'(\hat{x})$. □

We may interpret the polynomials in (5) as a certificate that $\hat{x}$ is a global optimizer of (4). For applications in practice, one would first try to find $\hat{x}$ by local optimization or a heuristic global search, and then try to prove its globality by solving (5) with the side constraints (6). Note that the conditions are linear, except for the SOS conditions which give semidefinite constraints. Since the degree of the polynomials involved is not known a priori, one would solve a sequence of linear semidefinite feasibility problems on the finite-dimensional spaces of polynomials defined by limiting the total degree of the terms in (5) to $d = 1, 2, 3, \ldots$. Once a certificate is found one can stop.

Our theorem guarantees that this procedure will be finite (though worst case exponential because of the size of Y and B_S) iff $\hat{x}$ is indeed a global minimizer. In contrast, the method of Lasserre [20] yields an infinite sequence of semidefinite relaxations whose optimal values converge (under some compactness assumption) to the global optimum. There is no guarantee that the global optimum is found after finitely many steps. It would be interesting to combine the approaches to a constructive procedure for finding and verifying a global optimizer in finitely many steps.

Of course, an efficient implementation would try to avoid the exponential work in the majority of cases, by using suitable heuristics. For rigorous certification, one would have the additional problem of verifying the existence of an exact certificate close to the computed approximation.

We now relate the global Karush–John conditions to the traditional local conditions.

COROLLARY 2.5 (Kuhn–Tucker conditions). *If $\hat{x}$ is a global optimum of problem* (4) *with $k = 1$ and* (5) *holds with $\alpha = (1)$ then there are vectors $y \geq 0$ and z with*

$$\nabla f(\hat{x}) = C'(\hat{x})^T y + F'(\hat{x})^T z \tag{10}$$

and

$$\inf\{y, C(\hat{x})\} = 0. \tag{11}$$

Proof. We already know by Theorem 2.4 (7) that

$$\nabla f(\hat{x}) = {B_S}'(\hat{x})^T Y(\hat{x}) + F'(\hat{x})^T Z(\hat{x}).$$

We can write that in a slightly expanded way as follows:

$$\nabla f(\hat{x}) = C_S'(\hat{x})^T Y^{(1)}(\hat{x}) + G_1'(\hat{x})^T C_S(\hat{x}) Y^{(2)}(\hat{x}) + F'(\hat{x})^T Z(\hat{x}).$$

Noting that $C_S(\hat{x})Y^{(2)}(\hat{x}) \geq 0$ and $G_1'(\hat{x})^T = -\nabla f(\hat{x})$ and expanding further we see that

$$\gamma \nabla f(\hat{x}) = \sum_{\beta \in \{0,1\}^m} \sum_{\substack{i=1 \\ \beta_i = 1}}^{m} C_i'(\hat{x})^T C^{\beta - e_i}(\hat{x}) Y_\beta^{(1)}(\hat{x}) + F'(\hat{x})^T Z(\hat{x}) = 0,$$

where $\gamma = 1 + C_S(\hat{x})Y^{(2)}(\hat{x}) > 0$. We reorder the sums and get

$$\gamma \nabla f(\hat{x}) = \sum_{i=1}^{m} C_i'(\hat{x})^T \sum_{\substack{\beta \in \{0,1\}^m \\ \beta_i = 1}} C^{\beta - e_i}(\hat{x}) Y_\beta^{(1)}(\hat{x}) + F'(\hat{x})^T Z(\hat{x}) = 0.$$

If we now set

$$y_i = \frac{1}{\gamma} \sum_{\substack{\beta \in \{0,1\}^m \\ \beta_i = 1}} C^{\beta - e_i}(\hat{x}) Y_\beta^{(1)}(\hat{x}), \quad z = \frac{1}{\gamma} Z(\hat{x}), \tag{12}$$

we get the required equality (10). For the complementarity conditions we calculate

$$C_i(\hat{x}) y_i = \frac{1}{\gamma} \sum_{\substack{\beta \in \{0,1\}^m \\ \beta_i = 1}} C^{\beta}(\hat{x}) Y_\beta^{(1)}(\hat{x}) = 0,$$

since by (6) all terms in the sum vanish. ∎

Example 2.6. We consider the simple optimization problem

$$\begin{aligned} &\min \ 2x - x^2 \\ &\text{s.t.} \ \ x \in [-1, 1]. \end{aligned}$$

Clearly, the objective function is concave; hence the global minimum $\hat{f} = -3$ is attained at the bound $\hat{x} = -1$. We can write

$$f(x) - f(\hat{x}) = 2x - x^2 + 3 = (1 + x)(3 - x) = 1(1 + x)(1 - x) + 2(1 + x).$$

Obviously, each term on the right is nonnegative, showing again that $\hat{x}$ is a global minimizer.

From this representation one reads off the certificate ($\alpha = 1$, $y_0 = 0$, $Y^T = (0, 0, 2, 0, 1, 0, 0, 0)$, $Z = (\ )$) satisfying (5), where the components of B_S are arranged in the order $1, 1 + x, 1 - x, x^2 - 2x - 3, 1 - x^2, \ldots$.

While this example is trivial, it shows the essentials. Higher dimensional examples differ only in the complexity of what has to be written. In many other situations, as, e.g., in Example 2.7, the certificate will be very sparse and of low degree, thus simplifying the search for it.

By Theorem 2.4, for every global minimizer *all* terms in (5) have to vanish, i.e., for every global minimizer $\hat{x}$ we have that $G(\hat{x}) = 0$ and (6) and (7) are valid. Using this information frequently allows the identification of all global minimizers of an optimization problem when a certificate is available.

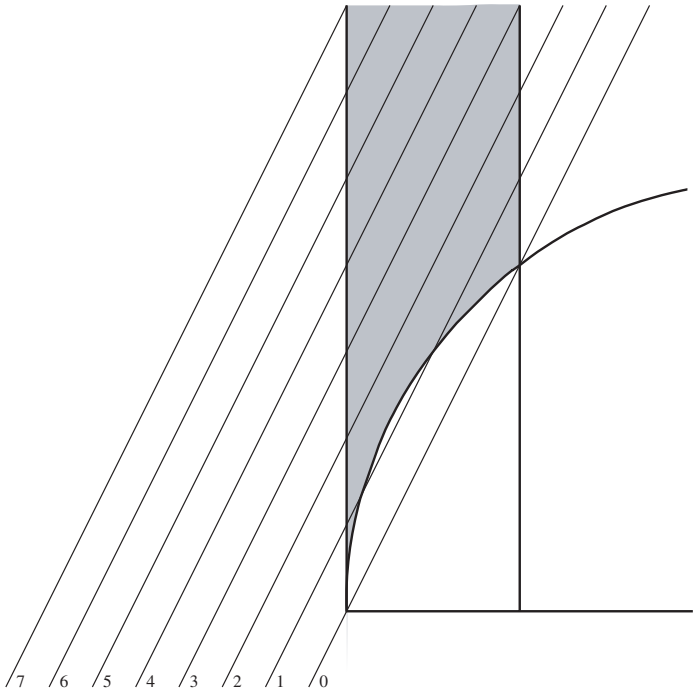

FIG. 1. *Feasible set (grey) and lines of constant value of f for Example* 2.7*, after eliminating z.*

Example 2.7. We consider the optimization problem

$$\begin{aligned} &\min\ z - x \\ &\text{s.t.}\ \ x - y + z = 0, \\ &\qquad x^2 - 10x + y^2 \geq 0, \\ &\qquad x \in [0,2], \quad y \geq 0. \end{aligned} \tag{13}$$

As Figure 1 shows, the point $(0,0,0)$ is a global optimizer with objective function value 0. This can be validated formally by Theorem 2.4, using the following polynomial identity:

$$\begin{aligned} &(x-z) + \tfrac{1}{2}y(2-x) + \tfrac{1}{4}y(x-z) + \tfrac{1}{4}x(2-x) + \tfrac{1}{4}(x^2 - 10x + y^2) \\ &\quad + \tfrac{1}{4}(4+y)(x-y+z) = 0. \end{aligned}$$

By checking when in this identity all terms vanish, we see that for the point $(2,4,2)$ (and no third point), all terms of the certificate vanish as well. Hence (cf. also the figure), this point is another global minimizer of (13), and no other global minimizers exist.

Example 2.8. For the problem

$$\begin{aligned} &\min\ x + y + z \\ &\text{s.t.}\ \ y - y^2 + z \geq 0, \\ &\qquad 2x + y + y^2 + z - 2 \geq 0, \\ &\qquad x \geq 0, \end{aligned}$$

we can find the polynomial identity

$$1-(x+y+z)+\tfrac{1}{2}\cdot(y-y^2+z)+\tfrac{1}{2}\cdot(2x+y+y^2+z-2)=0,$$

which implies that the global minimum value of the objective function is 1. By the complementarity conditions, we find that the two nonlinear inequality constraints must be active at every global minimum, i.e.,

$$\begin{aligned} y-y^2+z&=0,\\ 2x+y+y^2+z-2&=0, \end{aligned}$$

which implies that all

$$\hat{x}\in\left\{\begin{pmatrix}1-s^2\\ s\\ s(s-1)\end{pmatrix}\;\middle|\; s\in[-1,1]\right\}$$

are global optima.

Finally, the following example shows that in (5), the possibility $|\alpha|>1$ may indeed be necessary.

Example 2.9. For every nonnegative integer k the optimization problem

$$\begin{aligned} &\min\ x\\ &\text{s.t.}\ \ x^{2k+1}\geq 0 \end{aligned}$$

admits the unique global optimizer $\hat{x}=0$. The required polynomial identity of smallest degree is

$$(-x)^{\alpha}+1\cdot x^{2k+1}=0,\quad \alpha=2k+1.$$

In the GloptLab package [28], an optimization package currently developed in MATLAB, methods are being implemented and tested, which work along the lines presented in this section. They use the SeDuMi [33] package for the semidefinite programming part and combine the present techniques with branch-and-bound, constraint propagation, interval techniques [25, 26, 27], and linear relaxations. They have produced very promising results. At a later stage, the most successful techniques will be implemented as inference modules for the COCONUT environment [10].

3. Refined linear theorems of the alternative. In the linear case, there is a long tradition of theorems of the alternative, beginning with the lemma of Farkas [11], and culminating in the transposition theorems of Motzkin [24] and Tucker [34]. These transposition theorems are concerned with the solvability of linear constraints of various forms (equations, inequalities, strict inequalities, disequalities); see, e.g., Broyden [6] for some history.

As we shall show, there is a single general transposition theorem, which contains the others as special cases. As for the latter, our starting point is the lemma of Farkas.

LEMMA 3.1 (Farkas). *Let $A\in\mathbb{R}^{m\times n}$ and $g\in\mathbb{R}^n$. Then exactly one of the following conditions can be satisfied.*

(i) $g^Tp<0$, $Ap\geq 0$ *for some* $p\in\mathbb{R}^n$.

(ii) $g=A^Tq$, $q\geq 0$ *for some* $q\in\mathbb{R}^m$.

For the formulation of the transposition theorem and the constraint qualification we define $[\mathbf{1},-u]=:E_u\in\mathbb{R}^{k\times(k+1)}$ with $0<u\in\mathbb{R}^k$ and $\mathbf{1}$ being the identity matrix. We get the following result.

LEMMA 3.2. *For $X \in \mathbb{R}^{n\times k}$ with $\operatorname{rk} X = n$, $0 < u \in \mathbb{R}^k$, $0 < v \in \mathbb{R}^\ell$, and $Y \in \mathbb{R}^{n\times\ell}$ there exists a matrix $0 \le S \in \mathbb{R}^{(k+1)\times(\ell+1)}$ with*

$$XE_uS = YE_v.$$

Proof. Since $\operatorname{rk} X = n$ every $y \in \mathbb{R}^n$ can be written as a linear combination of the columns x_i of X:

$$y = \sum_{i=1}^{k} \lambda_i x_i.$$

Define

$$\mu = \max_{i=1}^{k} \left\{ -\frac{\lambda_i}{u_i}, 0 \right\}.$$

Then

$$y = \sum_{i=1}^{k} (\lambda_i + \mu u_i) x_i + \mu \left(-\sum_{i=1}^{k} u_i x_i \right) = XE_u s,$$

with $0 \ge s_i := \lambda_i + \mu u_i$ and $s_{k+1} := \mu$. Since all columns of $YE_v \in \mathbb{R}^n$, the result follows. ∎

We prove the following general theorem of the alternative, and deduce from it the transposition theorems of Motzkin and Tucker.

THEOREM 3.3 (general linear transposition theorem). *Consider matrices $A \in \mathbb{R}^{m_A\times n}$, $B \in \mathbb{R}^{m_B\times n}$, $C \in \mathbb{R}^{m_C\times n}$, and $D_j \in \mathbb{R}^{m_j\times n}$ with $m_j > 0$ for $j = 1, \dots, N$. Then exactly one of the following holds.*

(i) *$Ax = 0$, $Bx \ge 0$, $Cx > 0$, and $D_j x \ne 0$ for $j = 1, \dots, N$, for some $x \in \mathbb{R}^n$.*

(ii) *We have $m_C > 0$ and there exist $q \in \mathbb{R}^{m_A}$, $r \in \mathbb{R}^{m_B}$, and $s \in \mathbb{R}^{m_C}$ with*

$$A^T q + B^T r + C^T s = 0, \quad r \ge 0, \quad s \ge 0,\ s \ne 0, \tag{14}$$

or for some $j \in \{1, \dots, N\}$ there exist matrices $Q \in \mathbb{R}^{m_A\times(m_j+1)}$ and $R \in \mathbb{R}^{m_B\times(m_j+1)}$ with

$$A^T Q + B^T R = D_j^T E_u, \quad R \ge 0, \tag{15}$$

for some $u > 0$. Moreover, the same alternative holds if in (ii) *a fixed vector $u > 0$ (such as the all-one vector $u = e$) is prescribed.*

Proof. If (i) and (ii) hold simultaneously then multiplying (14) with x^T yields

$$(Bx)^T r + (Cx)^T s = 0.$$

Since $Bx \ge 0$ and $r \ge 0$ we have $(Cx)^T s \le 0$, which is a contradiction to $Cx > 0$ and $s \ge 0$, $s \ne 0$. Multiplying, on the other hand, (15) by x^T we get

$$0 \le (Bx)^T R = [(D_j x)^T, -(D_j x)^T u],$$

whence $D_j x \ge 0$ and $u^T D_j x < 0$ forces $D_j x = 0$, which is a contradiction.

Now assume that (i) cannot be solved. Then, for all $j = 1, \dots, N$ and all $v_j \in \mathbb{R}^{m_j}$, there is no $x \in \mathbb{R}^n$ with

$$Ax = 0, \quad Bx \ge 0, \quad Cx > 0, \quad \text{and} \quad v_j^T D_j x > 0. \tag{16}$$

Writing

$$g := \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad F := \begin{pmatrix} A & 0 \\ -A & 0 \\ B & 0 \\ C & e \\ v_1^T D_1 & 1 \\ \vdots & \vdots \\ v_N^T D_N & 1 \end{pmatrix}, \quad p := \begin{pmatrix} x \\ -\lambda \end{pmatrix},$$

we find that

$$g^T p < 0, \quad Fp \geq 0 \tag{17}$$

is unsolvable for $p \in \mathbb{R}^{n+1}$. By the Lemma of Farkas, Lemma 3.1, we can find $q \in \mathbb{R}^{2m_A + m_B + m_C + N}$ with

$$F^T q = g, \quad q = \begin{pmatrix} \hat{a} \\ \bar{a} \\ b \\ c \\ \mu \end{pmatrix} \geq 0. \tag{18}$$

Writing $a := \hat{a} - \bar{a}$, we find the existence of vectors $a \in \mathbb{R}^{m_A}$, $b \in \mathbb{R}^{m_B}$, $c \in \mathbb{R}^{m_C}$, and $\mu \in \mathbb{R}^N$ (depending on the choice of the v_j) such that

$$A^T a + B^T b + C^T c + \sum_{j=1}^{N} \mu_j D_j^T v_j = 0, \quad e^T \begin{pmatrix} c \\ \mu \end{pmatrix} = 1, \quad b, c, \mu \geq 0. \tag{19}$$

For $M \leq N$, we consider the set S_M consisting of all $(v_1, \ldots, v_{M-1}) \in \mathbb{R}^{m_1} \times \cdots \times \mathbb{R}^{m_{M-1}}$ for which (19) holds with $\mu_j = 0$ for $j \geq M$. Let $S_1 := \emptyset$. Let M be maximal with $S_M \neq \mathbb{R}^{m_1} \times \cdots \times \mathbb{R}^{m_{M-1}}$. If $M = 1$ we get $c \neq 0$, and hence $m_C > 0$, and by setting $q := a$, $r := b$, and $s := c$ we find (14).

Hence we may assume that $M > 1$ and pick $(v_1, \ldots, v_{M-1}) \notin S_M$. Take an arbitrary $v_M \in \mathbb{R}^{m_M}$. We can find vectors a, a', $b \geq 0$, $b' \geq 0$, $c \geq 0$, $c' \geq 0$, $0 \leq \xi, \xi' \in \mathbb{R}^{M-1}$, and numbers $\lambda > 0$ and $\tilde{\lambda} > 0$ with

$$A^T a + B^T b + C^T c + \sum_{j=1}^{M-1} \xi_j D_j^T v_j + \lambda D_M^T v_M = 0, \qquad e^T \begin{pmatrix} c \\ \xi \end{pmatrix} + \lambda = 1, \tag{20}$$

$$A^T a' + B^T b' + C^T c' + \sum_{j=1}^{M-1} \xi'_j D_j^T v_j + \lambda' D_M^T (-v_M) = 0, \quad e^T \begin{pmatrix} c' \\ \xi' \end{pmatrix} + \lambda' = 1. \tag{21}$$

Indeed, assume that we cannot find a, b, c, ξ, and λ with (20). We can get vectors a, b, c, μ satisfying (19). If there are only combinations with $\mu_{M+1:N} \neq 0$, then $(v_1, \ldots, v_M) \notin S_{M+1}$, contradicting the maximality of M. If there is a combination with $\mu_M = 0$, we find $(v_1, \ldots, v_{M-1}) \in S_M$, which is another contradiction. Thus $\mu_M \neq 0$, and we set $\xi := \mu_{1:M-1}$ and $\lambda := \mu_M$. The same argument gives (21).

Combining (20) and (21) leads to

$$A^T\underbrace{\left(\tfrac{1}{\lambda}a+\tfrac{1}{\lambda'}a'\right)}_{:=q}+B^T\underbrace{\left(\tfrac{1}{\lambda}b+\tfrac{1}{\lambda'}b'\right)}_{:=r}+C^T\underbrace{\left(\tfrac{1}{\lambda}c+\tfrac{1}{\lambda'}c'\right)}_{:=s}+\sum_{j=1}^{M-1}\underbrace{\left(\tfrac{\xi_j}{\lambda}+\tfrac{\xi_j'}{\lambda'}\right)}_{:=\nu_j}D_j^Tv_j=0,$$

$$e^T\begin{pmatrix}s\\ \nu\end{pmatrix}=\frac{\lambda+\lambda'}{\lambda\lambda'}-2=:\sigma. \tag{22}$$

If $s\neq 0$ or $\nu\neq 0$ the combination $(\mu_1,\dots,\mu_{M-1}):=\sigma^{-1}\nu\geq 0$, $a:=\sigma^{-1}q$, $b:=\sigma^{-1}r\geq 0$, and $c:=\sigma^{-1}s\geq 0$ proves that $(v_1,\dots,v_{M-1})\in S_M$, which is a contradiction. Thus $s=0$, implying $c=c'=0$, and $\nu=0$, hence $\xi_1=\xi_1'=\cdots=\xi_{N-1}=\xi_{N-1}'=0$, and $\lambda=1$. Since v_M was arbitrary, we have shown that for all $v_M\in\mathbb{R}^{m_M}$ there exist vectors $a\in\mathbb{R}^{m_A}$ and $b\in\mathbb{R}^{m_B}$ with

$$A^Ta+B^Tb+D_M^Tv_M=0. \tag{23}$$

We set $j:=M$ and choose for v_M in turn an arbitrary $u>0$ and the vectors $w_k:=-e_k$ $(k=1,\dots,m_j)$. This gives vectors q' and $r'\geq 0$ with

$$A^Tq'+B^Tr'=-D_j^Tu$$

and vectors q_k and $r_k\geq 0$ $(k=1,\dots,m_j)$ with

$$A^Tq_j+B^Tr_j=-D_j^Tw_j.$$

Forming the matrices $Q:=\left[q_1,\dots,q_{m_j},q'\right]$ and $R:=\left[r_1,\dots,r_{m_j},r'\right]$ finally gives (15). ∎

The well-known theorems of the alternative by Motzkin [24] and Tucker [34] are consequences of this theorem.

THEOREM 3.4 (Motzkin's linear transposition theorem). *Let $B\in\mathbb{R}^{m\times n}$, and let (I,J,K) be a partition of $\{1,\dots,m\}$ with $K\neq\emptyset$. Then exactly one of the following holds:*

(i) $(Bp)_I=0$, $(Bp)_J\geq 0$, $(Bp)_K>0$ *for some* $p\in\mathbb{R}^n$,

(ii) $B^Tq=0$, $q_{J\cup K}\geq 0$, $q_K\neq 0$ *for some* $q\in\mathbb{R}^m$.

Proof. We set $\tilde{A}:=B_{I:}$, $\tilde{B}:=B_{J:}$, $\tilde{C}:=C_{K:}$, $N=0$ and apply Theorem 3.3. ∎

THEOREM 3.5 (Tucker's linear transposition theorem). *Let $B\in\mathbb{R}^{m\times n}$, and let (I,J,K) be a partition of $\{1,\dots,m\}$ with $K\neq\emptyset$. Then exactly one of the following holds:*

(i) $(Bp)_I=0$, $(Bp)_{J\cup K}\geq 0$, $(Bp)_K\neq 0$ *for some* $p\in\mathbb{R}^n$,

(ii) $B^Tq=0$, $q_J\geq 0$, $q_K>0$ *for some* $q\in\mathbb{R}^m$.

Proof. Set $\tilde{A}=-B^T$, define the matrix $\tilde{B}$ whose rows are indexed by $I\cup J\cup K$ and whose columns are indexed by J with $\tilde{B}_{J:}=\mathbf{1}$, $\tilde{B}_{I\cup K,:}=0$, and introduce the matrix $\tilde{C}$ whose rows are indexed by $I\cup J\cup K$ with $\tilde{C}_{K:}=\mathbf{1}$, $\tilde{C}_{I\cup J,:}=0$, and $N=0$. Clearly, case (i) of Theorem 3.3 is equivalent to the solvability of the present (ii). On the other hand, case (ii) of Theorem 3.3 is here equivalent to the existence of vectors q, $r\geq 0$, and $s\geq 0$, $s\neq 0$ with

$$\tilde{A}^Tq+\tilde{B}^Tr+\tilde{C}^Ts=0.$$

Plugging in the definitions of $\tilde{A}$, $\tilde{B}$, and $\tilde{C}$ this becomes

$$-B_{I:}q=0,\quad -B_{J:}q+r=0,\quad -B_{K:}q+s=0,$$

which is clearly equivalent to (i). ∎

For the applications in the next section we need the following corollary of Theorem 3.3.

COROLLARY 3.6. *Let $B \in \mathbb{R}^{m\times n}$, and let (I,J,K) be a partition of $\{1,\dots,m\}$ of $i=|I|$, $j=|J|$, and $k=|K|>0$ elements. Then exactly one of the following holds:*

(i) *If $A = B^T_{K:}E_u$ for any $0 < u \in \mathbb{R}^k$, then* rk $A = k$ *and for some matrix $P \in \mathbb{R}^{n\times(k+1)}$*

$$(B(A+P))_{I:} = 0, \quad (B(A+P))_{J:} \geq 0, \quad \textit{and} \quad (BP)_{K:} = 0.$$

(ii) *$B^Tq = 0$, $q_J \geq 0$, $q_K \neq 0$ for some $q \in \mathbb{R}^m$.*

Proof. We set $\tilde{A} = -B^T$, define $\tilde{B} \in \mathbb{R}^{|I\cup J\cup K|\times|J|}$ with $\tilde{B}_{J:} = \mathbf{1}$, $\tilde{B}_{I\cup K,:} = 0$, construct $\tilde{D} \in \mathbb{R}^{|I\cup J\cup K|\times|K|}$ with $\tilde{D}_{K:} = \mathbf{1}$, $\tilde{D}_{I\cup J,:} = 0$, and set $N = 1$, $m_C = 0$, and $k = |K|$. Clearly, case (i) in Theorem 3.3 is equivalent to the present (ii).

On the other hand, (ii) in Theorem 3.3 is here equivalent to the existence of matrices Q and $R \geq 0$ with

$$B_{I:}Q = 0, \quad B_{J:}Q = R, \quad B_{K:}Q = E_u. \tag{24}$$

This, in turn, is equivalent to (i) by the following argument, for which we introduce the pseudoinverse $B^\dagger_{K:} = B^T_{K:}(B_{K:}B^T_{K:})^{-1}$ of $B_{K:}$.

Let us assume (i). By Lemma 3.2 we can find a matrix $S \geq 0$ with $(B_{K:}B^T_{K:})E_uS = E_u$, and we set $Q := B^\dagger_{K:}E_u + PS$. Then

$$\begin{aligned}
B_{I:}Q &= B_{I:}\big(B^T_{K:}(B_{K:}B^T_{K:})^{-1}E_u + PS\big) = B_{I:}(B^T_{K:}E_u + P)S = 0,\\
B_{J:}Q &= B_{J:}\big(B^T_{K:}(B_{K:}B^T_{K:})^{-1}E_u + PS\big) = B_{J:}(B^T_{K:}E_u + P)S =: R \geq 0,\\
B_{K:}Q &= B_{K:}B^\dagger_{K:}E_u + B_{K:}PS = E_u + 0.
\end{aligned}$$

Now assume (24). The last equation implies $\mathrm{rk}B_{K:} = \mathrm{rk}A = k$, and so the pseudoinverse of $B_{K:}$ exists and Q is of the form $Q = B^\dagger_{K:}E_u + P'$ for some P' with $B_{K:}P' = 0$. By Lemma 3.2 we can find $S \geq 0$ with $(B_{K:}B^T_{K:})^{-1}E_uS = E_u$ and set $P := P'S$. Calculating

$$\begin{aligned}
B_{I:}(A+P) &= B_{I:}(B^T_{K:}E_u + P'S) = B_{I:}(B^\dagger_{K:}E_u + P')S = B_{I:}QS = 0,\\
B_{J:}(A+P) &= B_{J:}(B^T_{K:}E_u + P'S) = B_{J:}(B^\dagger_{K:}E_u + P')S = B_{J:}QS = RS \geq 0,\\
B_{K:}P &= B_{K:}P'S = 0,
\end{aligned}$$

we prove (ii). ∎

4. A refinement of the Karush–John conditions. Karush–John conditions were originally derived—for single-objective optimization with inequality constraints only—by Karush [16], and were rediscovered by John [15]. They were subsequently generalized to mixed equality and inequality constraints, and to multiobjective optimization problems; there is a large literature on the subject, which can be accessed from the references below.

However, the Karush–John conditions in their most general form pose difficulties in applications, because the factor in front of the gradient term may be zero or very small. Therefore, most of the local solvers require a constraint qualification, like that of Mangasarian and Fromovitz [22] (MFCQ), to be able to reduce the Karush–John conditions to the much more convenient Kuhn–Tucker conditions [19]. Thorough discussions of such constraint qualifications can be found for single-objective optimization in Bazaraa, Sherali, and Shetty [3] and Mangasarian [21]. A more recent

account is in Bonnans and Shapiro [5, section 5.2]; there one can also find extensions to conic programming, semi-infinite programming, and infinite-dimensional problems (not considered in the present work). The Karush–John conditions have been investigated in the case of multiobjective optimization in Marusciac [23], though the result implicitly contains a constraint qualification. Further reference can be found in Arrow, Hurwicz, and Uzawa [2], Khanh and Luu [31], and Aghezzaf and Hachimi [1], especially for connections to the constraint qualifications and, e.g., in Cambini [8] for second order conditions.

Deterministic global optimization algorithms cannot take this course, since it is not known beforehand whether the global optimum satisfies an assumed constraint qualification. Therefore, they have to use the Karush–John conditions in their general form (cf., e.g., Kearfott [17]). Unfortunately, the additional constraints needed involve all multipliers and are very inconvenient for the solution process.

In this section we prove a strong version of the Karush–John conditions for nonlinear programming and multiobjective optimization, and a corresponding relaxation of the Mangasarian–Fromovitz constraint qualification (MFCQ). Apart from the inverse function theorem, our main tools are the transposition theorems of the previous section. The treatment is along the lines of the special case of a single objective discussed in our unpublished paper [29].

We consider concave and nonconcave constraints separately, and introduce slack variables to transform all nonconcave constraints into equations. Thus we may write a general nonlinear optimization problem without loss of generality in the form

$$\begin{aligned} &\min\ f(x) \\ &\text{s.t.}\ \ C(x) \geq 0, \quad F(x) = 0. \end{aligned} \tag{25}$$

In many applications, the objective function f will be a real-valued function. However, we allow f to be vector-valued; in this case, optimality is replaced by Pareto optimality.

The form (25), which separates the concave constraints (including bound constraints and general linear constraints) and the remaining nonlinear constraints, is most useful to prove our strong form of the Karush–John conditions. However, in computer implementations, a transformation to this form is not ideal, and the slack variables should be eliminated again from the optimality conditions.

THEOREM 4.1 (general first order optimality conditions). *Let $f : U \to \mathbb{R}^k$, $C : U \to \mathbb{R}^m$, and $F : U \to \mathbb{R}^r$ be functions continuously differentiable on a neighborhood U of $\hat{x} \in \mathbb{R}^n$. If C is convex on U and $\hat{x}$ is a weakly Pareto minimal point of the nonlinear program* (25)*, then there are vectors $\hat{w} \geq 0 \in \mathbb{R}^k$, $\hat{y} \in \mathbb{R}^m$, $\hat{z} \in \mathbb{R}^r$ such that*

$$f'(\hat{x})^T \hat{w} = C'(\hat{x})^T \hat{y} + F'(\hat{x})^T \hat{z}, \tag{26}$$

$$\inf(\hat{y}, C(\hat{x})) = 0, \tag{27}$$

$$F(\hat{x}) = 0, \tag{28}$$

and

$$\hat{w}, \hat{z} \text{ are not both zero.} \tag{29}$$

Proof. We begin by noting that a feasible point $\hat{x}$ of (25) is also a feasible point

for the optimization problem

$$\begin{aligned} &\min\ f(x)\\ &\text{s.t.}\ \ Ax \geq b,\\ &\qquad F(x) = 0, \end{aligned} \tag{30}$$

where J is the set of all components j for which $C(\hat{x})_j = 0$ and

$$A = C'(\hat{x})_{J:}, \quad b = C'(\hat{x})_{J:}\hat{x}.$$

For the indices k corresponding to the set N of inactive constraints, we choose $y_N = 0$ to satisfy condition (27). Since C is convex, we have $C(x) \geq C(\hat{x}) + C'(\hat{x})(x - \hat{x})$. Restricted to the rows J we get $C(x)_J \geq C'(\hat{x})_{J:}(x - \hat{x})$. This fact implies that problem (25) is a relaxation of problem (30) on a neighborhood U of $\hat{x}$. Note that since C is continuous we know that $C(x)_j > 0$ for $k \in N$ in a neighborhood of $\hat{x}$ for all constraints with $C(\hat{x})_j > 0$. Since, by assumption, $\hat{x}$ is weakly Pareto minimal for a relaxation of (30) and a feasible point of (30), it is weakly Pareto minimal for (30) as well. Together with the choice $y_N = 0$ the Karush–John conditions of problem (30) are again conditions (26)–(28). So we have successfully reduced the problem to the case where C is an affine function and all constraints are active at $\hat{x}$.

Thus, in the following, we consider a weakly Pareto minimal point $\hat{x}$ of the optimization problem (30) satisfying

$$A\hat{x} = b. \tag{31}$$

If rk $F'(\hat{x}) < r$ then $z^T F'(\hat{x}) = 0$ has a solution $z \neq 0$, and we can solve (26)–(29) with $\hat{y} = 0$, $\hat{w} = 0$. Hence we may assume that rk $F'(\hat{x}) = r$. This allows us to select a set R of r column indices such that $F'(\hat{x})_{:R}$ is nonsingular. Let B be the $(0,1)$-matrix such that Bs is the vector obtained from $s \in \mathbb{R}^n$ by discarding the entries indexed by R. Then the function $\Phi : C \to \mathbb{R}^n$ defined by

$$\Phi(x) := \begin{pmatrix} F(x) \\ Bx - B\hat{x} \end{pmatrix}$$

has at $x = \hat{x}$ a nonsingular derivative

$$\Phi'(\hat{x}) = \begin{pmatrix} F'(\hat{x}) \\ B \end{pmatrix}.$$

Hence, by the inverse function theorem, Φ defines in a neighborhood of $0 = \Phi(\hat{x})$ a unique continuously differentiable inverse function Φ^{-1} with $\Phi^{-1}(0) = \hat{x}$. Using Φ we can define a curved search path with tangent vector $p \in \mathbb{R}^n$ tangent to the nonlinear constraints satisfying $F'(\hat{x})p = 0$. Indeed, the function defined by

$$s_p(\alpha) := \Phi^{-1}\begin{pmatrix} 0 \\ \alpha Bp \end{pmatrix} - \hat{x}$$

for sufficiently small $\alpha \geq 0$ is continuously differentiable, with

$$s_p(0) = \Phi^{-1}(0) - \hat{x} = 0, \quad \begin{pmatrix} F(\hat{x} + s_p(\alpha)) \\ Bs_p(\alpha) \end{pmatrix} = \Phi\left(\Phi^{-1}\begin{pmatrix} 0 \\ \alpha Bp \end{pmatrix}\right) = \begin{pmatrix} 0 \\ \alpha Bp \end{pmatrix};$$

hence

$$s_p(0) = 0, \quad F(\hat{x} + s_p(\alpha)) = 0, \quad Bs_p(\alpha) = \alpha Bp. \tag{32}$$

Differentiation of (32) at $\alpha = 0$ yields

$$\begin{pmatrix} F'(\hat{x}) \\ B \end{pmatrix} \dot{s}_p(0) = \begin{pmatrix} F'(\hat{x})\dot{s}_p(0) \\ B\dot{s}_p(0) \end{pmatrix} = \begin{pmatrix} 0 \\ Bp \end{pmatrix} = \begin{pmatrix} F'(\hat{x}) \\ B \end{pmatrix} p;$$

hence $\dot{s}_p(0) = p$, i.e., p is indeed a tangent vector to $\hat{x} + s_p(\alpha)$ at $\alpha = 0$.

Since $\hat{x}$ is weakly Pareto minimal, we know that there exists a neighborhood V of $\hat{x}$ in the set of feasible points containing no y with $f(\hat{x}) > f(y)$. Thus, for every $y \in V$ there exists an index j with $f_j(\hat{x}) \le f_j(y)$. Taking an arbitrary curved path γ in the feasible set with $\gamma(0) = \hat{x}$ we conclude that there is an index j with $f_j'(\hat{x})\dot{\gamma}(0) \ge 0$. Hence, there is no direction p along such a curved search path, for which $f'(\hat{x})^T.p < 0$.

Now we consider a direction $p \in \mathbb{R}^n$ such that

$$Ap > 0, \tag{33}$$

$$F'(\hat{x})p = 0. \tag{34}$$

(In contrast to the purely concave case, we need the strict inequality in (33) to take care of curvature terms.) Since $A\hat{x} \ge b$ and (33) imply

$$A(\hat{x} + s_p(\alpha)) = A(\hat{x} + \alpha\dot{s}_p(0) + o(\alpha)) = A\hat{x} + \alpha(Ap + o(1)) \ge b$$

for sufficiently small $\alpha \ge 0$, (32) implies feasibility of the points $\hat{x} + s_p(\alpha)$ for small $\alpha \ge 0$.

Thus, s_p is a curved search path in the feasible set, and we conclude from the discussion above that there is no such p with $f'(\hat{x})^T p < 0$. Thus, (33), (34), and

$$f'(\hat{x})^T p < 0 \tag{35}$$

are inconsistent.

Therefore, the transposition theorem, Theorem 3.4, applies with

$$\begin{pmatrix} -f'(\hat{x}) \\ A \\ F'(\hat{x}) \end{pmatrix}, \quad \begin{pmatrix} w \\ y \\ z \end{pmatrix} \quad \text{in place of } B, q,$$

and shows the solvability of

$$-f'(\hat{x})^T w + A^T y + F'(\hat{x})^T z = 0, \quad w \ge 0, \quad y \ge 0, \quad \begin{pmatrix} w \\ y \end{pmatrix} \ne 0.$$

If we put $\hat{z} = z$, let $\hat{y}$ be the vector with $\hat{y}_J = y$ and zero entries elsewhere, and note that $\hat{x}$ is feasible, we find (26)–(28).

Because of (29), it now suffices to discuss the case where $w = 0$ and $z = 0$, and therefore

$$A^T y = 0, \quad y \ne 0. \tag{36}$$

In this case, $b^T y = (A\hat{x})^T y = \hat{x}^T A^T y = 0$. Therefore any point $x \in U$ satisfies $(Ax - b)^T y = x^T A^T y - b^T y = 0$, and since $y \ge 0$, $Ax - b \ge 0$, we see that the set

$$K := \{i \mid (Ax)_i = b_i \text{ for all } x \in V \text{ with } Ax - b \ge 0\} \tag{37}$$

contains all indices i with $y_i \neq 0$ and hence is nonempty.

Since V is nonempty, the system $A_{K:}x = b_K$ is consistent, and hence equivalent to $A_{L:}x = b_L$, where L is a maximal subset of K such that the rows of A indexed by L are linearly independent. If M denotes the set of indices complementary to K, we can describe the feasible set equivalently by the constraints

$$A_{M:}x \geq b_M, \quad \begin{pmatrix} A_{L:}x - b_L \\ F(x) \end{pmatrix} = 0.$$

This modified description of the feasible set has no equality constraints implicit in the inequality $A_{M:}x \geq b_M$. For a solution $\hat{x}$ of the equivalent optimization problem with these constraints, we find as before vectors $w \geq 0$, $\tilde{y}_M$, and $\binom{\tilde{y}_L}{z}$ such that

$$f'(\hat{x})^T w = A_{M:}^T \tilde{y}_M + \begin{pmatrix} A_{L:} \\ F'(\hat{x}) \end{pmatrix}^T \begin{pmatrix} \tilde{y}_L \\ z \end{pmatrix}, \tag{38}$$

$$\inf(\tilde{y}_M, A_{M:}\hat{x} - b_M) = 0, \tag{39}$$

$$F(x) = 0, \quad A_{K:}\hat{x} - b_K = 0, \tag{40}$$

$$w, \ \begin{pmatrix} \tilde{y}_L \\ z \end{pmatrix} \text{ are not both zero.} \tag{41}$$

Clearly, this yields vectors $\hat{w} = w$, $\hat{y} = \tilde{y}$, and $\hat{z} = z$ satisfying (26) and (27), but now $\tilde{y}_{K \setminus L} = 0$. The exceptional situation $w = 0$, $z = 0$ can no longer occur. Indeed, as before, all indices i with $\tilde{y}_i \neq 0$ lie in K; hence $\tilde{y}_M = 0$ and (38) gives $A_{L:}^T \tilde{y}_L = 0$. Since, by construction, the rows of $A_{L:}$ are linearly independent, this implies $\tilde{y}_L = 0$, contradicting (41). Hence, we have that w and z are not both zero.

It remains to show that we can choose $y \geq 0$ with $A^T y = A_{M:}^T \tilde{y}_M + A_{L:}^T \tilde{y}_L$. From the definition (37) of K we know that the two relations $Ap \geq 0$ and $A_{K:}p \neq 0$ are inconsistent (set $x = \hat{x} + p$). In particular, the relations $Ap \geq 0$ and $\tilde{y}_K^T A_{K:}p < 0$ are inconsistent. By the lemma of Farkas, Lemma 3.1, we conclude the existence of a vector $q \geq 0$ with $A^T q = A_{K:}^T \tilde{y}_K = A_{L:}^T \tilde{y}_L$. Setting $y_M = \tilde{y}_M + q_M$ and $y_K = q_K$ completes the proof. ∎

In contrast to our version of the Karush–John condition, the standard Karush–John condition asserts under our assumptions only that $\hat{w}$, $\hat{y}$, and $\hat{z}$ are not simultaneously zero. Thus the present version gives more information in case that $\hat{w} = 0$. Therefore, weaker constraint qualifications are needed to ensure that $\hat{w} \neq 0$. In that case, the multipliers in (26) can be rescaled so that $\|\hat{w}\| = 1$. However, from a numerical perspective, it may be better to keep the homogeneous formulations, since a tiny w in a well-scaled multiplier vector implies near degeneracy and would give huge multipliers if normalized to $\|\hat{w}\| = 1$.

Note that in view of (27), the condition (29) can be written (after rescaling) in the equivalent form

$$\hat{w} \geq 0, \quad v^T \hat{w} + u^T \hat{y} + \hat{z}^T D \hat{z} = 1, \tag{42}$$

where $v \neq 0$ is an arbitrary nonnegative vector, u is an arbitrary nonnegative vector with $u_J > 0$, $u_N = 0$, and D is an arbitrary diagonal matrix with positive diagonal entries. This form is numerically stable in that all multipliers are bounded and near degeneracies—which would produce huge multipliers in the Kuhn–Tucker conditions—are revealed by a small norm of $\hat{w}$. The lack of a constraint qualification (which

generally cannot be established in finite precision arithmetic anyway) therefore simply appears as the limit $\hat{w} = 0$.

The formulation (42) is particularly useful for the rigorous verification of the existence of a solution of our refined Karush–John conditions in the vicinity of an approximate solution; cf. Kearfott [17, section 5.2.5] for the corresponding use of the standard Karush–John conditions. The advantage of our stronger formulation is that in case there are only a few nonconcave constraints, condition (42) involves only a few variables and hence is a much stronger constraint if constraint propagation techniques [17, 35] are applied to the optimality conditions.

Let $B := F'(\hat{x})^T E_u$ for some $u > 0$. We say that the *constraint qualification (CQ)* is satisfied if $\operatorname{rk} F'(\hat{x}) = r$ and there exists a matrix $Q \in \mathbb{R}^{n\times(r+1)}$ with

$$\begin{aligned} C'(\hat{x})_{J:}(B+Q) &\geq 0, \\ F'(\hat{x})Q &= 0. \end{aligned} \tag{43}$$

COROLLARY 4.2. *If, under the assumptions of Theorem* 4.1*, the constraint qualification* (CQ) *is satisfied then the conclusion of Theorem* 4.1 *holds with* $\hat{w} \neq 0$*.*

Proof. It is obvious that the conclusion of Theorem 4.1 holds with $\hat{w} \neq 0$ if

$$C'(\hat{x})_{J:}^T y_J + F'(\hat{x})^T z = 0,\ y_J \geq 0 \implies z = 0. \tag{44}$$

If (44) is satisfied, we have that $z \neq 0$, $y_J \geq 0$, and $C'(\hat{x})_{J:}^T y_J + F'(\hat{x})^T z = 0$ are inconsistent. By Corollary 3.6 this is equivalent to the constraint qualification. ∎

THEOREM 4.3 (Kuhn–Tucker conditions). *Under the assumption of Theorem* 4.1 *with* f *one-dimensional, if the constraint qualification (CQ) is satisfied, then there are vectors* $\hat{y} \in \mathbb{R}^m, \hat{z} \in \mathbb{R}^r$ *such that*

$$f'(\hat{x})^T = C'(\hat{x})^T \hat{y} + F'(\hat{x})^T \hat{z}, \tag{45}$$

$$\inf(\hat{y}, C(\hat{x})) = 0, \tag{46}$$

$$F(\hat{x}) = 0. \tag{47}$$

Equations (45)–(47) are the *Kuhn–Tucker conditions* for the nonlinear program (25); cf. [19]. The traditional linear independence constraint qualification requires in place of the assumptions in Theorem 4.3 the stronger condition that the rows of $\binom{F'(\hat{x})}{C'(\hat{x})_{J:}}$ are independent. In contrast, our condition allows arbitrary dependence among the rows of $C'(\hat{x})$.

Weaker than the constraint qualification (CQ) is the Mangasarian–Fromowitz constraint qualification (MFCQ), which asserts the existence of a vector q with $C'(\hat{x})_{J:}q > 0$ and $F'(\hat{x})q = 0$. It implies our constraint qualification (CQ), because $Q = q\lambda^T$ satisfies (43) for λ large enough. We now show that (MFCQ) is more restrictive than our new constraint qualification (CQ).

Example 4.4. We reconsider Example 2.7. As we have seen there, the point $\hat{x} = (0,0,0)^T$ is a local (even global) optimum of (13). Figure 1 reveals that there is a degeneracy since the two activities have a common tangent. Thus the constraint qualifications are nontrivial. Clearly, the mapping C defined by transforming the inequality constraints of $C(x) \geq 0$ is convex; hence we can use Theorem 4.1. We have

$$f'(\hat{x}) = \begin{pmatrix} -1 & 0 & 1 \end{pmatrix}, \quad F'(\hat{x}) = \begin{pmatrix} 1 & -1 & 1 \end{pmatrix},$$

$$B = \begin{pmatrix} 1 & -1 \\ -1 & 1 \\ 1 & -1 \end{pmatrix}, \quad C'_{J:}(\hat{x}) = \begin{pmatrix} -10 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix}.$$

We can use the formulas (12) to calculate the multipliers

$$\hat{y} = \frac{1}{4} \begin{pmatrix} 1 \\ 4 \\ 2 \end{pmatrix}, \quad \hat{z} = 1;$$

then (45) reduces to the identity

$$1 \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} = \frac{1}{4} \begin{pmatrix} -10 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 1 \\ 4 \\ 2 \end{pmatrix} + 1 \cdot \begin{pmatrix} 1 \\ -1 \\ 1 \end{pmatrix}.$$

This shows that we can choose $\hat{w} = 1$ in the Karush–John conditions. Indeed, our constraint qualification (CQ) is valid. For

$$Q = \frac{1}{19} \begin{pmatrix} -1 & 1 \\ 1 & -1 \\ 2 & -2 \end{pmatrix}$$

we have

$$C'_{J:}(\hat{x})(B + Q) = 0, \quad F'(\hat{x})Q = 0.$$

However, (MFCQ) is not satisfied since there is no vector q with $C'_{J:}(\hat{x})q > 0$.

5. Conclusions. We presented various theorems of the alternative, and, based on them, derived new optimality conditions that hold without any constraint qualification. These results strengthen known local conditions, but they are also suitable for use in a global optimization context, which was our main motivation for this work.

New and exciting is the fact that, for the first time, it is possible to give necessary and sufficient (global) optimality conditions for polynomial problems. In particular, it is possible to produce (under the idealized assumptions that all semidefinite programs can be solved exactly) certificates for global optimality of a putative solution $\hat{x}$. However, these global results are probably not the best possible.

The failure to find a certificate after all problems up to some maximum degree d have been solved makes it likely that $\hat{x}$ is not a global optimizer of (4). In this case, one would like to have a procedure that guarantees (for sufficiently large but a priori unknown d) to find a feasible point x with a better objective function value than the value at $\hat{x}$. Then a new local optimization could be started from x, resulting in a better candidate for a global optimizer. Work on this is in progress.

Also, at present we have no simple constraint qualification which would guarantee in the single-objective case that the exponent α in the global Karush–John condition of Theorem 2.4 takes the value 1, which is needed to construct from the certificate multipliers satisfying the Kuhn–Tucker conditions. We conjecture that the exponent $e = 1$ is possible iff the Kuhn–Tucker conditions can be satisfied at $\hat{x}$, in particular, under the same (weakened Mangasarian–Fromovitz) constraint qualification as in our Theorem 4.3. This would strengthen the currently weak connections between sections 2 and 3.

LYAPUNOV STABILITY OF COMPLEMENTARITY AND EXTENDED SYSTEMS*

M. KANAT CAMLIBEL†, JONG-SHI PANG‡, AND JINGLAI SHEN§

Abstract. A linear complementarity system (LCS) is a piecewise linear dynamical system consisting of a linear time-invariant ordinary differential equation (ODE) parameterized by an algebraic variable that is required to be a solution to a finite-dimensional linear complementarity problem (LCP), whose constant vector is a linear function of the differential variable. Continuing the authors' recent investigation of the LCS from the combined point of view of system theory and mathematical programming, this paper addresses the important system-theoretic properties of exponential and asymptotic stability for an LCS with a C^1 state trajectory. The novelty of our approach lies in our employment of a quadratic Lyapunov function that involves the auxiliary algebraic variable of the LCS; when expressed in the state variable alone, the Lyapunov function is piecewise quadratic, and thus nonsmooth. The nonsmoothness feature invalidates standard stability analysis that is based on smooth Lyapunov functions. In addition to providing sufficient conditions for exponential stability, we establish a generalization of the well-known LaSalle invariance theorem for the asymptotic stability of a smooth dynamical system to the LCS, which is intrinsically a nonsmooth system. Sufficient matrix-theoretic copositivity conditions are introduced to facilitate the verification of the stability properties. Properly specialized, the latter conditions are satisfied by a passive-like LCS and certain hybrid linear systems having common quadratic Lyapunov functions. We provide numerical examples to illustrate the stability results. We also develop an extended local exponential stability theory for nonlinear complementarity systems and differential variational inequalities, based on a new converse theorem for ODEs with B-differentiable right-hand sides. The latter theorem asserts that the existence of a "B-differentiable Lyapunov function" is a necessary and sufficient condition for the exponential stability of an equilibrium of such a differential system.

Key words. complementarity systems, Lyapunov stability, LaSalle's invariance principle, asymptotic and exponential stability

1. Introduction.

Fundamentally linked to a linear hybrid system, a linear complementarity system (LCS) is a piecewise linear dynamical system defined by a linear time-invariant ordinary differential equation (ODE) parameterized by solutions of a finite-dimensional linear complementarity problem (LCP) linearly coupled with the state of the differential equation. LCSs, and also nonlinear complementarity systems (NCSs), belong to the more general class of differential variational inequalities (DVIs) [38]. In the last few years there has been a rapidly growing interest in complementarity systems and DVIs from the mathematical programming community and the systems

and control community, due to their applications in many areas such as robotics, nonsmooth mechanics, economics, and finance and traffic systems; see the recent review papers [3, 50] and [4, 5, 6, 7, 8, 9, 11, 19, 20, 21, 22, 37, 51, 53, 54] for studies on specific issues pertaining to the LCS.

Stability is a classical issue in dynamical system theory. One of the most widely adopted stability concepts is Lyapunov stability, which plays important roles in system and control theory and in the analysis of engineering systems. In the classical Lyapunov stability theory, we assume that the ODE in consideration has a smooth (at least C^1) right-hand side and the origin is an equilibrium. Furthermore, we assume that there exists a continuously differentiable, positive definite, and coercive function of the system states, which is called a Lyapunov function. If the Lie derivative of such a function along the vector field of the system is nonpositive at all states (in a small neighborhood of the origin), then one can establish stability of the origin in the sense of Lyapunov. On the other hand, if the Lie derivative of such a Lyapunov function along the vector field of the system is negative at all nonzero states (in a small neighborhood of the origin), then the system is asymptotically stable at the origin. In the setting of linear systems, this leads to the well-known Lyapunov equation.

An important extension of the above results is LaSalle's invariance principle [28], which plays a fundamental role in the stability analysis of smooth systems. This theorem says that if the largest invariant set of the zero level of the Lie derivative of the Lyapunov function along the system vector field is a singleton and contains the origin only, then the system is asymptotically stable at the origin. It is known that the singleton condition can be further expressed in terms of certain observability conditions. Thus checking the singleton condition is closely related to the observability analysis of the system.

Extending classical smooth system theory to stability analysis of hybrid and switched systems has received growing attention in recent years. Among the extensive literature on the stability of linear switched systems, we mention a few relevant papers. A multiple-Lyapunov-function approach was proposed in [2]; see also [56] for related discussion. Uniform (asymptotic) stability of switched linear systems is studied in [23] where an extension of LaSalle's invariance principle to certain classes of switched linear systems is addressed. The latter result is further generalized to the stability analysis of switched nonlinear systems [24], where several nonlinear norm-observability notions generalizing classical observability concepts are introduced to obtain sufficient conditions for asymptotic stability using arguments of the LaSalle type. For surveys of recent results, including extensive references, on stability and stabilization of switched linear systems, see [14, 29]. Typically, the mentioned results assume that a Lyapunov-like function exists for each mode's vector field and holds for the entire state space. In many hybrid and switched systems, however, each mode holds only over a subset of the state space, especially for those systems whose switchings are triggered by state evolution, such as the LCS. Hence, the above results are rather restrictive, even for linear switched systems. Due to this concern, the paper [12] had proposed copositive Lyapunov functions for "conewise linear systems" for which the feasible region of each mode is a polyhedral cone. This proposal leads to an interesting study of copositive matrices that satisfy the Lyapunov equation. Similar ideas and relevant results for piecewise linear systems can also be found in [26]. Also employing a copositivity theory, the authors of several recent papers [1, 16, 17, 18] have developed an extensive stability theory for evolutionary variational inequalities (EVIs), including an extension of LaSalle's invariance principle to such systems, nec-

essary conditions for asymptotic stability, application to mechanical systems under frictional contact, and matrix conditions for stability and instability for linear EVIs (LEVIs). The EVIs belong to the class of differential inclusions and are dynamic generalizations of a finite-dimensional variational inequality [15]. In this paper, as an example of a DVI, we briefly discuss the "functional evolutionary variational inequality" (FEVI) as another dynamic generalization of a static finite-dimensional variational inequality (VI); see the system (5.8). In contrast to the EVI, the FEVI always has continuously differentiable solution trajectories, whose stability properties can be established without resorting to the framework of differential inclusions (DIs). Last, we mention [52, section 8.2], which studies the stability of "linear selectionable" DIs. While an LCS is related to such a DI, the two are quite different; consequently, the results from this reference are not applicable to the LCS. See the discussion at the end of subsection 3.3 for details.

It should be emphasized that while complementarity systems, and more generally, differential variational systems via their Karush–Kuhn–Tucker formulations, could be considered as special switched systems, LCSs, NCSs, and DVIs occupy a significant niche in many practical applications and have several distinguished features: inequality constraints on states, state-triggered mode switchings, and an endogenous control variable. These features invalidate much of the known theory of hybrid systems, which often allow arbitrary switchings, and necessitate the employment of the copositivity theory pioneered by such authors as Brogliato, Goeleven, and Schumacher. Another noteworthy point about the switched system theory is that it takes for granted a fundamental "non-Zenoness assumption" (i.e., finite number of switches in finite time) whose satisfaction is the starting point for stability analysis; for complementarity systems, this issue of finite switches is nontrivial and has been rigorously analyzed only very recently [37, 51]; see also [10].

Complementing the aforementioned works, this paper aims at analyzing the asymptotic and exponential stability of classes of nonsmooth differential systems, focusing in particular on the LCSs, NCSs, and DVIs. For an early work on the asymptotic behavior of solutions to the evolutionary nonlinear complementarity problem, see Chapter 3 in the Ph.D. thesis [25]. A key assumption for the class of LCSs treated in our work is that they have C^1 state trajectories for all initial states. Since the right-hand side of such an LCS is a Lipschitz function of state, the results for the LEVIs are not applicable to this class of LCSs; see [16, Remark 10]. Nevertheless, there are LCSs that fall within the framework of the LEVI, and which are therefore amenable to the treatment in the cited reference (see, e.g., Corollary 2 therein) but which cannot be handled by our approach. In contrast to a set-valued approach, our analysis is based to a large extent on the theory of "B-differentiable" functions (see section 2 for a formal definition of such a nonsmooth function). Specifically, unlike many stability results in the literature where the candidate Lyapunov functions are chosen to be continuously differentiable in the state, the nontraditional Lyapunov-like function in our consideration is, in the case of the LCS, quadratic in both the state and the associated algebraic variable; thus it is piecewise quadratic when expressed in the system state only. The nonsmoothness of the resulting Lyapunov function is the novelty of our work, as a result of which mathematical tools that go beyond the scope of the classical Lyapunov stability theory are needed. In this regard, our analysis is in the spirit of [52, Chapter 8]; yet the differential systems considered in our work are of a particular type, whose structure is fully exploited in designing the class of Lyapunov functions. Consequently, we are able to obtain much sharper results than those

derived from the general theory of differential inclusions. In particular, combining LCP theory and stability methods, we obtain asymptotic stability results via an extension of LaSalle's invariance principle; moreover, our stability results for the LCS are expressed in terms of matrix copositivity conditions. Several special cases are highlighted and numerical examples are given. We further extend these results to inhomogeneous LCSs, NCSs, and DVIs, with the latter two classes of systems satisfying the strong regularity condition [43, 15]. The noteworthy point of the latter extension is that it is based on a "converse theorem" of the exponential stability of an equilibrium of an ODE with a "B-differentiable" right-hand side. The latter theorem asserts that the existence of a "B-differentiable Lyapunov function" is a necessary and sufficient condition for the exponential stability of an equilibrium to such a differential system. Incidentally, there is an extensive literature on converse theorems for switched systems, some of which even involve discontinuous Lyapunov functions; see, e.g., [30, 33, 34, 42]. Our main result, Theorem 5.2, differs from the common treatment in switched systems in a major way; namely, our theorem is established for a general ODE with a B-differentiable right-hand side and thus potentially has broader applicability than those restricted to switched systems.

The organization of the rest of the paper is as follows. In the next section, we formally define the LCS, review the notions of stability, asymptotic stability, and exponential stability, and briefly examine some matrix classes related to the LCP [13]. The stability results for the equilibrium $x^e = 0$ of the LCS are presented in section 3, first for the "P-case" which is then extended to a non-P system. Numerical examples illustrating these results and the special case of a single-input-single-output (SISO) system are also given. Sections 4 and 5 address the stability issues of the extended systems; the former section treats the inhomogeneous LCS and the latter the NCS and the DVI, via the above-mentioned converse theorem for a B-differentiable ODE.

2. Linear complementarity systems. An LCS is defined by a tuple of four constant matrices $A \in \Re^{n\times n}$, $B \in \Re^{n\times m}$, $C \in \Re^{m\times n}$, and $D \in \Re^{m\times m}$; it seeks two time-dependent trajectories $x(t) \in \Re^n$ and $u(t) \in \Re^m$ for $t \in [0, T]$ for some $0 < T \leq \infty$ such that

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ 0 \leq u \perp Cx + Du &\geq 0, \\ x(0) &= x^0, \end{aligned} \tag{2.1}$$

where $\dot{x} \equiv dx/dt$ denotes the time derivative of the trajectory $x(t)$, x^0 is the initial condition, and $a \perp b$ means that the two vectors a and b are orthogonal, i.e., $a^T b = 0$. We denote the above LCS by the tuple (A, B, C, D). Obviously, the LCP of finding a vector $u \in \Re^m$ satisfying

$$0 \leq u \perp q + Du \geq 0,$$

which we denote by the pair (q, D) and whose solution set we denote $\mathrm{SOL}(q, D)$, has a lot to do with various properties of the above LCS. We refer the reader to [13] for a comprehensive study of the LCP and also to the two-volume monograph [15] for many advanced solution properties of the LCP that we will freely use throughout this paper. In particular, under the blanket assumption that $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$, an assumption which was introduced in [51] and used subsequently in [39], it follows that the LCS (2.1) is equivalent to the ODE

$$\dot{x} = Ax + B\mathrm{SOL}(Cx, D), \quad x(0) = x^0, \tag{2.2}$$

whose right-hand side $Ax + B\mathrm{SOL}(Cx, D)$ is a (single-valued) piecewise linear, and hence Lipschitz continuous and directionally differentiable (i.e., B(ouligand)-differentiable [35]) function of $x \in \Re^n$. (A word about notation: we identify the single vector in $B\mathrm{SOL}(Cx, D)$ with the set itself; thus we talk about the piecewise linear function $x \mapsto B\mathrm{SOL}(Cx, D)$ directly without referring to the element in $B\mathrm{SOL}(Cx, D)$. The same usage applies to other similar contexts.) The class of B-differentiable functions will play a central role throughout this work. Formally, a function $\Phi : \mathcal{D} \subseteq \Re^n \to \Re^m$ is *B-differentiable* at a point x in the open set $\mathcal{D}$ if Φ is Lipschitz continuous in a neighborhood of x contained in $\mathcal{D}$ and directionally differentiable at x; Φ is B-differentiable in $\mathcal{D}$ if it is B-differentiable at every point therein. We refer the reader to [15, Chapter 3] for basic properties of B-differentiable functions.

It follows from the ODE formulation (2.2) that the LCS (2.1) has a unique solution, which we denote $x(t, x^0)$, for all initial conditions $x^0 \in \Re^n$. If the initial condition x^0 is clear from the context, we will simply write $x(t)$ to de-emphasize the dependence of the solution trajectory on the initial condition. Even in this case where the x-trajectory is unique, there is no guarantee that there is a unique u-trajectory, unless D is a P-matrix [13], which implies that $\mathrm{SOL}(q, D)$ is a singleton for all $q \in \Re^m$, or unless the quadruple (A, B, C, D) satisfies the passifiability by pole shifting property and a rank condition [7]. See Proposition 2.2 for a unification of these uniqueness conditions. For our purpose, we are interested in the LCS (2.1) where the x-trajectory is unique and C^1 in time. It turns out that this condition is equivalent to the single-valuedness of $B\mathrm{SOL}(Cx, D)$ as made precise in the following result.

PROPOSITION 2.1. *Let (A, B, C, D) be given. The following two statements are equivalent.*

(a) *For every $x^0 \in \Re^n$, the LCS* (2.1) *has a unique C^1 trajectory $x(t, x^0)$ defined for all $t \geq 0$.*

(b) *For every $x^0 \in \Re^n$, the set $B\mathrm{SOL}(Cx^0, D)$ is a singleton.*

Proof. It remains to show (a) $\Rightarrow$ (b). This is clear because for any $u^0 \in \mathrm{SOL}(Cx^0, D)$, we have $Bu^0 = \dot{x}(0, x^0) - Ax^0$, where $\dot{x}(0, x^0)$ is the time derivative of the unique trajectory $x(t, x^0)$ evaluated at the initial time $t = 0$. ∎

Throughout the discussion of the LCS (2.1), we assume that condition (b) holds. There are simple instances where this condition holds easily. Statement (a) of the following result identifies one such instance; see [51]. The notation $a \circ b$ denotes the Hadamard product of two vectors; i.e., the ith component of $a \circ b$ is equal to $a_i b_i$.

PROPOSITION 2.2. *Suppose that $\mathrm{SOL}(Cx, D) \neq \emptyset$ for all $x \in \Re^n$. The following two statements hold.*

(a) *If $u \circ Du \leq 0 \Rightarrow Bu = 0$, then $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$.*

(b) *If $[u \circ Du \leq 0,\ Bu = 0] \Rightarrow u = 0$, then $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$ if and only if for every $x^0 \in \Re^n$, there exists a unique pair of trajectories $(x(t, x^0), u(t, x^0))$ defined for all $t \geq 0$ satisfying* (2.1) *such that $x(\cdot, x^0)$ is C^1.*

Proof. For statement (a), it suffices to show that $Bu^1 = Bu^2$ for any two solutions u^1 and u^2 in $\mathrm{SOL}(Cx, D)$. This is easy because any two such solutions must satisfy $u \circ Du \leq 0$ for $u \equiv u^1 - u^2$. For statement (b), it suffices to show the "only if" assertion; in turn it suffices to show the uniqueness of the $u(t, x^0)$ trajectory. But this is also clear in view of the uniqueness of the C^1 trajectory $x(t, x^0)$, which follows from Proposition 2.1. ∎

Remark 2.1. If D is positive semidefinite, then $u \circ Du \leq 0$ implies $(D + D^T)u = 0$. Thus, if the matrix $\begin{bmatrix} D + D^T \\ B \end{bmatrix}$ has full column rank, then the implication $[u \circ Du \leq 0,$

$Bu = 0] \Rightarrow u = 0$ holds. The former rank condition is used in [7] along with the passifiability condition, which implies the positive semidefiniteness of D, to yield the uniqueness of the u-trajectory.

There are many matrix classes in LCP theory; among these, the following are most relevant to this work. A matrix $D \in \Re^{m\times m}$ is a *P-matrix* if $u \circ Du \leq 0 \Rightarrow u = 0$; the matrix D is an *R_0-matrix* if $\mathrm{SOL}(0, D) = \{0\}$; the matrix D is *(strictly) copositive* on a cone $\mathcal{C} \subseteq \Re^m$ if $u^T Du \geq 0$ for all $u \in \mathcal{C}$ ($u^T Du > 0$ for all nonzero $u \in \mathcal{C}$); a copositive matrix D is *copositive plus* on $\mathcal{C}$ if $[u^T Du = 0, u \in \mathcal{C}] \Rightarrow (D + D^T)u = 0$. Properties of these matrices will be used freely in the paper; see [13]. In particular, it is known that a matrix D is P if and only if $\mathrm{SOL}(q, D)$ is a singleton for all $q \in \Re^m$; moreover a constant $c_D > 0$ exists such that $\|u\| \leq c_D\|q\|$ for all $q \in \Re^m$, where u is the unique solution of the LCP (q, D). It is further known that D is an R_0-matrix if and only if $\mathrm{SOL}(q, D)$ is bounded (possibly empty) for all $q \in \Re^m$. Clearly a P-matrix must be R_0. Last, note that if D is copositive on a convex cone $\mathcal{C}$, then

$$[\, u^T Du = 0,\ u \in \mathcal{C}\,] \Rightarrow (D + D^T)u \in \mathcal{C}^*,$$

where $\mathcal{C}^*$ denotes the dual cone of $\mathcal{C}$. Consequently, if D is a symmetric matrix copositive on a convex cone $\mathcal{C}$, then

$$[\, u^T Du = 0,\ u \in \mathcal{C}\,] \Rightarrow [\, \mathcal{C} \ni u \ \perp\ Du \in \mathcal{C}^*\,]. \tag{2.3}$$

We say that $(D, \mathcal{C})$ is an *R_0-pair* if the unique vector satisfying the right-hand complementarity conditions in the above implication is $u = 0$.

The condition that $B\mathrm{SOL}(Cx, D)$ is a singleton is not as restrictive as it seems. Indeed, consider a homogeneous differential affine variational inequality (DAVI)

$$\begin{aligned} \dot{x} &= Ax + Bu, \\ u &\in \mathrm{SOL}(K, Cx, D), \end{aligned} \tag{2.4}$$

where $u \in \mathrm{SOL}(K, Cx, D)$ means that $u \in K$ and

$$(u' - u)^T(Cx + Du) \geq 0 \quad \forall\, u' \in K,$$

with K being the polyhedral cone $\{u \in \Re^m : Eu \leq 0\}$ for some matrix E of appropriate dimension. Introducing a multiplier λ for the constraint in K, we deduce that $u \in \mathrm{SOL}(K, Cx, D)$ if and only if

$$\begin{aligned} 0 &= Cx + Du + E^T\lambda, \\ 0 &\leq -Eu \perp \lambda \geq 0. \end{aligned}$$

If D is positive definite, we can solve for u from the first equation, obtaining $u = -D^{-1}[Cx + E^T\lambda]$, which we can substitute into Eu and Bu. This results in the LCS

$$\begin{aligned} \dot{x} &= [\, A - BD^{-1}C\,]x - BD^{-1}E^T\lambda, \\ 0 &\leq \lambda \perp -ED^{-1}Cx + ED^{-1}E^T\lambda \geq 0. \end{aligned}$$

It is easy to see that the triple of matrices $(B', C', D') \equiv (-BD^{-1}E^T, -ED^{-1}C, ED^{-1}E^T)$ satisfies the property that $B'\mathrm{SOL}(C'x, D')$ is a singleton for all x, due to the positive definiteness of D. More generally, if D is only positive semidefinite (but not necessarily symmetric), it is still possible to convert (2.4) into an LCS (2.1) satisfying the desired singleton property, under suitable conditions; we refer the reader

to [15, Exercise 1.8.10] for a general conversion scheme. In what follows, we illustrate how this conversion can be carried out by assuming that the matrix

$$\begin{bmatrix} D & E^T \\ -E & 0 \end{bmatrix}$$

is nonsingular. Letting $w = -Eu$, we can show that (2.4) is equivalent to

$$\dot{x} = \widehat{A}x + \widehat{B}w,$$
$$0 \leq w \perp \widehat{C}x + \widehat{D}w \geq 0,$$

where

$$\widehat{A} \equiv A - \begin{bmatrix} B & 0 \end{bmatrix} \begin{bmatrix} D & E^T \\ -E & 0 \end{bmatrix}^{-1} \begin{bmatrix} C \\ 0 \end{bmatrix}, \quad \widehat{B} \equiv \begin{bmatrix} B & 0 \end{bmatrix} \begin{bmatrix} D & E^T \\ -E & 0 \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ I \end{bmatrix},$$
$$\widehat{C} \equiv -\begin{bmatrix} 0 & I \end{bmatrix} \begin{bmatrix} D & E^T \\ -E & 0 \end{bmatrix}^{-1} \begin{bmatrix} C \\ 0 \end{bmatrix}, \qquad \widehat{D} \equiv \begin{bmatrix} 0 & I \end{bmatrix} \begin{bmatrix} D & E^T \\ -E & 0 \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ I \end{bmatrix}.$$

It is not difficult to show that if $\mathrm{SOL}(K, Cx, D) \neq \emptyset$ for all $x \in \Re^n$ and if $(D+D^T)u = 0 \Rightarrow Bu = 0$, then the triple $(\widehat{B}, \widehat{C}, \widehat{D})$ is such that $\widehat{B}\mathrm{SOL}(\widehat{C}x, \widehat{D})$ is a singleton for all $x \in \Re^n$.

2.1. Stability concepts. An important goal of this paper is to derive sufficient conditions for the "equilibrium solution" $x = 0$ of the LCS (2.1) to be "exponentially stable" and "asymptotically stable." While these are well-known concepts in systems theory [28], we offer their formal definitions below for completeness. The setting is a time-invariant system on $\Re^n$,

$$\dot{x} = f(x), \quad x(0) = x^0, \tag{2.5}$$

where $f : \Re^n \to \Re^n$ is Lipschitz continuous. Let $x^e \in \Re^n$ be an *equilibrium* of the system (2.5), i.e., $f(x^e) = 0$, and let $x(t, x^0)$ denote the unique trajectory of (2.5).

DEFINITION 2.3. *The equilibrium x^e of (2.5) is*

(a) *stable in the sense of Lyapunov if, for each $\varepsilon > 0$, there is $\delta_\varepsilon > 0$ such that*

$$\| x^0 - x^e \| < \delta_\varepsilon \Rightarrow \| x(t, x^0) - x^e \| < \varepsilon \quad \forall\, t \geq 0;$$

unstable otherwise;

(b) *asymptotically stable if it is stable and $\delta > 0$ exists such that*

$$\| x^0 - x^e \| < \delta \Rightarrow \lim_{t \to \infty} x(t, x^0) = x^e;$$

(c) *exponentially stable if there exist scalars $\delta > 0$, $c > 0$, and $\mu > 0$ such that*

$$\| x^0 - x^e \| < \delta \Rightarrow \| x(t, x^0) - x^e \| \leq c \| x^0 - x^e \| e^{-\mu t} \quad \forall\, t \geq 0.$$

Clearly, exponential stability implies asymptotic stability, which further implies stability, but not vice versa. For a Lipschitz function $f(x)$ that is positively homogeneous in x, i.e., $f(\tau x) = \tau f(x)$ for all $\tau \geq 0$, we will be interested in the particular equilibrium $x^e = 0$. For the system (2.5) with such an f, we have $x(t, \tau x^0) = \tau x(t, x^0)$

for all $\tau \geq 0$ and all pairs $(t, x^0) \in [0, \infty) \times \Re^n$. For such a function f, stability of $x^e = 0$ is equivalent to *linearly bounded stability*, which means the existence of a constant $\eta > 0$ such that $\|x(t, x^0)\| \leq \eta \|x^0\|$ for all $(t, x^0) \in [0, \infty) \times \Re^n$; asymptotic stability is equivalent to *global asymptotic stability*, which means $\lim_{t \to \infty} x(t, x^0) = 0$ for all $x^0 \in \Re^n$; and exponential stability is equivalent to *global exponential stability*, which means the existence of scalars $c > 0$ and $\mu > 0$ such that $\|x(t, x^0)\| \leq c\|x^0\| e^{-\mu t}$ for all $(t, x^0) \in [0, \infty) \times \Re^n$. Throughout the paper, we will omit the adjective "global" when we deal with the equilibrium $x^e = 0$ for an ODE with a positively homogenous right-hand side.

Returning to the LCS (2.1), we note that, under our blanket assumption, the above definition is applicable to the equivalent system (2.2). Furthermore, since $B\mathrm{SOL}(0, D) = \{0\}$, $x^e = 0$ is indeed an equilibrium of (2.2). Due to its piecewise linearity, the right-hand function $f(x) \equiv Ax + B\mathrm{SOL}(Cx, D)$ is in general not Fréchet differentiable (but is indeed positively homogeneous). Although $f(x)$ is (globally) Lipschitz continuous, the nonsmoothness of $f(x)$ invalidates much of the standard analysis of well-known stability results for smooth dynamical systems; see, e.g., the book [28]. Our goal is to undertake a generalized stability analysis of the system (2.2), taking advantage of the special piecewise linear structure of the function $f(x)$. The resulting theory is a significant advance from the classical linear systems theory and involves matrix-theoretic properties that are based on LCP theory.

Before proceeding to derive sufficient conditions for the asymptotic stability of the equilibrium $x = 0$, we state and prove a necessary condition for the said stability.

PROPOSITION 2.4. *Suppose that $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. A necessary condition for $x^e = 0$ to be an asymptotically stable equilibrium for the LCS* (2.1) *is that for all scalars $\lambda \geq 0$, the following implication holds:*

$$\left.\begin{array}{c} \lambda\, x = Ax + Bu \\ 0 \leq u \perp Cx + Du \geq 0 \end{array}\right\} \Rightarrow x = 0. \tag{2.6}$$

If D is an R_0-matrix, then (2.6) *holds if and only if*

$$\left.\begin{array}{c} \lambda\, x = Ax + Bu \\ 0 \leq u \perp Cx + Du \geq 0 \end{array}\right\} \Rightarrow (\, x, u\,) = 0. \tag{2.7}$$

Proof. Indeed, if (x^*, u^*) is a solution of the system at the left-hand side of (2.6) for some $\lambda^* \geq 0$, then defining the trajectory $(x(t, x^*), u(t, x^*)) = (e^{\lambda^* t} x^*, e^{\lambda^* t} u^*)$ for all $t \geq 0$, we deduce that, $\lim_{t \to \infty} x(t, x^*) = 0$ only if $x^* = 0$. This establishes the implication (2.6). Clearly (2.7) implies (2.6). The converse is also clear, provided that D is an R_0-matrix. □

Remark 2.2. By the implication (2.6), which holds for all $\lambda \geq 0$, and by the homotopy invariance of the degree of a continuous mapping [31], it follows that the index of the map $x \mapsto -Ax - B\mathrm{SOL}(Cx, D)$ at the origin is well defined and equal to 1. (The index of a continuous map at an isolated zero is a well-known topological concept; see the reference.) The latter degree-theoretic necessary condition for asymptotic stability is a special case of a more general result due to Mawhin [32]. The implication (2.7) defines the "mixed R_0"-property of the matrix

$$\begin{bmatrix} A - \lambda I & B \\ C & D \end{bmatrix}.$$

If $A - \lambda I$ is nonsingular, then this property is equivalent to the R_0-property of the Schur complement $D - C(A - \lambda I)^{-1}B$. In this regard, the left-hand system of (2.6) is an instance of a homogeneous "mixed LCP," where there is a mixture of linear equations and standard linear complementarity conditions.

3. Stability results for $x^e = 0$. As in the classical analysis, our approach to the stability analysis of the system (2.1) is based on the existence of a Lyapunov function of a special kind. The novelty of our approach lies in the choice of the Lyapunov function: it is a quadratic function in the pair (x, u), which when expressed in the state variable x alone, is piecewise quadratic, and thus not smooth. At this point, we refer to the habilitation thesis of Scholtes [49] for the precise definition and an extensive study of piecewise differentiable functions; see also [15, Chapter 4]. Results from these references will be used freely in our discussion.

We first consider the case where D is a P-matrix. It follows that $\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$, whose unique element we denote $u(x)$. A constant $c'_D > 0$ exists such that

$$\| u(x) \| \leq c'_D \| x \| \quad \forall\, x \in \Re^m. \tag{3.1}$$

Define three fundamental index sets:

$$\begin{aligned}
\alpha(x) &\equiv \{\, i \,:\, u_i(x) > 0 = (\, Cx + Du(x)\,)_i \,\}, \\
\beta(x) &\equiv \{\, i \,:\, u_i(x) = 0 = (\, Cx + Du(x)\,)_i \,\}, \\
\gamma(x) &\equiv \{\, i \,:\, u_i(x) = 0 < (\, Cx + Du(x)\,)_i \,\}.
\end{aligned}$$

In terms of these index sets, we have

$$u_\alpha(x) = -(\, D_{\alpha\alpha}\,)^{-1} C_{\alpha\bullet} x, \quad u_{\bar\alpha}(x) = 0,$$

where $\alpha = \alpha(x)$ and $\bar\alpha = \beta(x) \cup \gamma(x)$. Let $\mathrm{Gr\ SOL}_{CD}$ denote the graph of the solution function $u(x)$; i.e., $\mathrm{Gr\ SOL}_{CD}$, which is a closed (albeit not necessarily convex) cone, consists of all pairs $(x, u(x))$ for all $x \in \Re^n$. This graph can be described as follows. For each subset α of $\{1, \ldots, m\}$ with complement $\bar\alpha$, define

$$\mathcal{C}_\alpha \equiv \left\{ x \in \Re^n \,:\, \begin{bmatrix} -(\, D_{\alpha\alpha}\,)^{-1} C_{\alpha\bullet} \\ C_{\bar\alpha\bullet} - D_{\bar\alpha\alpha}(\, D_{\alpha\alpha}\,)^{-1} C_{\alpha\bullet} \end{bmatrix} x \geq 0 \right\}$$

and the matrix

$$E_\alpha \equiv \begin{bmatrix} I \\ -(\, D_{\alpha\alpha}\,)^{-1} C_{\alpha\bullet} \\ 0 \end{bmatrix} \in \Re^{(n+m)\times n}.$$

We then have

$$\Re^n = \bigcup_\alpha \mathcal{C}_\alpha \quad \text{and} \quad \mathrm{Gr\ SOL}_{CD} = \bigcup_\alpha \{\, E_\alpha x \,:\, x \in \mathcal{C}_\alpha \,\}. \tag{3.2}$$

The solution function $u(x)$ is piecewise linear in x and thus has directional derivatives given as follows: with

$$u'(x; d) \equiv \lim_{\tau \downarrow 0} \frac{u(x + \tau d) - u(x)}{\tau} \tag{3.3}$$

denoting the directional derivative of u at x along the direction d, $u'(x;d)$ is the unique vector v such that

$$\begin{array}{ll} \text{free } v_i & (Cd+Dv)_i = 0, \quad i \in \alpha(x), \\ 0 \le v_i \perp (Cd+Dv)_i \ge 0, & i \in \beta(x), \\ 0 = v_i, & i \in \gamma(x). \end{array}$$

Thus there exists a subset $\beta_d \subseteq \beta(x)$ such that the directional derivative $u'(x;d)$ is given by

$$u'_{\alpha_d}(x;d) = -(D_{\alpha_d\alpha_d})^{-1}C_{\alpha_d\bullet}\, d, \quad u'_{\bar{\alpha}_d}(x;d) = 0,$$

where $\alpha_d = \alpha(x) \cup \beta_d$ and $\bar{\alpha}_d = \{1,\ldots,m\} \setminus \alpha_d$. Note that we also have

$$u_{\alpha_d}(x) = -(D_{\alpha_d\alpha_d})^{-1}C_{\alpha_d\bullet}\, x, \quad u_{\bar{\alpha}_d}(x) = 0.$$

Since there are only finitely many subsets α_d, a constant $\widehat{c}\,' > 0$ exists such that

$$\| u'(x;d) \| \le \widehat{c}\,' \| d \| \quad \forall\, (x,d) \in \Re^{2n}. \tag{3.4}$$

Based on the LCP functions, we define the LCS map $\mathrm{SOL}'_{\mathrm{LCS}} : x \in \Re^n \to \Re^{2m}$ by

$$\mathrm{SOL}'_{\mathrm{LCS}}(x) \equiv \begin{pmatrix} u(x) \\ u'(x;dx) \end{pmatrix}, \quad \text{where } dx \equiv Ax + Bu(x),$$

and let Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ denote its graph. Unlike Gr SOL_{CD}, which has a fairly simple representation in terms of the index subsets of $\{1,\ldots,m\}$ (cf. (3.2)), Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ is somewhat more complicated to describe using index sets; for one thing, the latter graph is not closed because the function $u'(x;d)$ is in general not continuous in x. We denote the closure of Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ by cl Gr $\mathrm{SOL}'_{\mathrm{LCS}}$. Like Gr SOL_{CD}, Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ is a cone, albeit not necessarily convex.

In terms of $u(x)$, the LCS (2.1) becomes the ODE $\dot{x} = Ax + Bu(x)$ with a piecewise linear right-hand side which vanishes at the origin. In order to analyze the stability properties of the latter equilibrium $x^e = 0$, we postulate the existence of a symmetric matrix

$$M \equiv \begin{bmatrix} P & Q \\ Q^T & R \end{bmatrix} \in \Re^{(n+m)\times(n+m)}$$

that is *strictly copositive* on the cone Gr SOL_{CD}; i.e., $y^T My > 0$ for all nonzero $y \in$ Gr SOL_{CD}. Since the latter is a closed cone, the strict copositivity condition is equivalent to the existence of a scalar $c_M > 0$ such that

$$y^T My \ge c_M\, y^T y \quad \forall\, y \in \text{Gr } \mathrm{SOL}_{CD}. \tag{3.5}$$

In fact, one such choice is $c_M \equiv \min\{y^T My : y \in \text{Gr } \mathrm{SOL}_{CD}, \|y\| = 1\}$, which is well defined and positive. Let

$$V(x,u) \equiv \begin{pmatrix} x \\ u \end{pmatrix}^T \begin{bmatrix} P & Q \\ Q^T & R \end{bmatrix} \begin{pmatrix} x \\ u \end{pmatrix}$$

be the quadratic form associated with the matrix M. The composite function

$$\widehat{V}(x) \equiv V(x, u(x)) = x^T P x + 2x^T Q u(x) + u(x)^T R u(x)$$

is locally Lipschitz continuous and directional differentiable with

$$\widehat{V}\,'(x; v) = 2x^T P v + 2v^T Q u(x) + 2x^T Q u'(x; v) + 2u(x)^T R u'(x; v).$$

Associated with the trajectories $(x(t, x^0), u(t, x^0))$ of the LCS (2.1), where $u(t, x^0) \equiv u(x(t, x^0))$, define

$$\varphi_{x^0}(t) \equiv \widehat{V}(x(t, x^0)) \quad \forall\, t \geq 0.$$

By the chain rule of directional differentiation, the one-sided derivative of $\varphi_{x^0}(t)$ is given by

$$\begin{aligned}\varphi'_{x^0}(t+) &= \lim_{\tau \downarrow 0} \frac{\varphi_{x^0}(t+\tau) - \varphi_{x^0}(t)}{\tau} = \widehat{V}\,'(x(t, x^0); \dot{x}(t, x^0)) \\ &= 2x(t, x^0)^T P \dot{x}(t, x^0) + 2\dot{x}(t, x^0)^T Q u(t, x^0) + 2x^T Q u'(x(t, x^0); \dot{x}(t, x^0)) \\ &\quad + 2u(t, x^0)^T R u'(x(t, x^0); \dot{x}(t, x^0)).\end{aligned}$$

Letting $v(t, x^0) \equiv u'(x(t, x^0); \dot{x}(t, x^0))$ and substituting $\dot{x}(t, x^0) = Ax(t, x^0) + Bu(t, x^0)$, we deduce $\varphi'_{x^0}(t+) = v(t, x^0)^T N(t, x^0)$, where

(3.6)
$$N \equiv \begin{bmatrix} A^T P + PA & PB + A^T Q & Q \\ B^T P + Q^T A & Q^T B + B^T Q & R \\ Q^T & R & 0 \end{bmatrix} \text{ and } z(t, x^0) \equiv \begin{pmatrix} x(t, x^0) \\ u(t, x^0) \\ v(t, x^0) \end{pmatrix} \in \text{Gr SOL}'_{\text{LCS}}.$$

Note that, by (3.4),

$$\| v(t, x^0) \| \leq \widehat{c}\,' \| \dot{x}(t, x^0) \| \leq c_v \| (x(t, x^0), u(t, x^0)) \| \quad \forall\, (t, x^0) \in [0, \infty) \times \Re^n, \tag{3.7}$$

for some constant $c_v > 0$. Employing the notation introduced thus far, the following result provides sufficient conditions for the various kinds of stability to hold for the equilibrium $x^e = 0$ of the LCS (2.1) with a P-matrix D.

THEOREM 3.1. *Let D be a P-matrix. Suppose that matrices P, Q, and R, with P and R symmetric, exist such that M is strictly copositive on Gr SOL_{CD}. The following four statements hold for the equilibrium $x^e = 0$ of (2.1).*

(a) *If $-N$ is copositive on Gr SOL'_{LCS}, then x^e is linearly bounded stable.*

(b) *If $-N$ is strictly copositive on cl Gr SOL'_{LCS}, then x^e is exponentially stable.*

(c) *If $-N$ is copositive on Gr SOL'_{LCS} and*

$$[\, z(t, \xi)^T N z(t, \xi) = 0 \quad \forall\, t \geq 0\,] \Rightarrow \xi = 0, \tag{3.8}$$

then x^e is asymptotically stable.

(d) *If $-N$ is copositive-plus on Gr SOL'_{LCS} and*

$$[\, Nz(t, \xi) = 0 \quad \forall\, t \geq 0\,] \Rightarrow \xi = 0, \tag{3.9}$$

then x^e is asymptotically stable.

Proof. Let $x^0 \in \Re^n$ be arbitrary and let $u^0 \equiv u(x^0)$. Since $\varphi_{x^0}(t) \equiv \widehat{V}(x(t,x^0))$ is locally Lipschitz continuous for $t \geq 0$, it is almost everywhere differentiable on $[0,\infty)$, by Radamacher's theorem [48]. Hence for almost all $t \geq 0$, $\varphi'_{x^0}(t)$ exists and is equal to $\varphi'_{x^0}(t+)$, which is nonpositive, by the copositivity of $-N$ on Gr $\mathrm{SOL}'_{\mathrm{LCS}}$. On the one hand, we have, for some constant $\rho_M > 0$ independent of x^0,

$$\varphi_{x^0}(t) = \varphi_{x^0}(0) + \int_0^t \varphi'_{x^0}(s+)\, ds \leq \varphi_{x^0}(0) = V(x^0,u^0) \leq \rho_M \,\|\,(x^0,u^0)\,\|^2.$$

Hence by (3.1), we deduce that, for some constant $\rho'_M > 0$ independent of x^0,

$$\varphi_{x^0}(t) \leq \rho'_M \,\|\,x^0\,\|^2 \quad \forall\, t \geq 0. \tag{3.10}$$

On the other hand, by (3.5),

$$\varphi_{x^0}(t) = V(x(t,x^0),u(t,x^0)) \geq c_M \,\|\,(\,x(t,x^0),u(t,x^0)\,)\,\|^2 \geq c_M \,\|\,x(t,x^0)\,\|^2.$$

Combining the two inequalities, we obtain $\|x(t,x^0)\| \leq \sqrt{\rho'_M/c_M}\|x^0\|$, establishing the desired linearly bounded stability of $x^e = 0$.

The strictly copositivity of $-N$ on cl Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ implies the existence of a scalar $c_N > 0$ such that $z^T N z \leq -c_N z^T z$ for all $z \in \mathrm{GrSOL}'_{\mathrm{LCS}}$. Hence, for all $x^0 \in \Re^n$ and for all $t \geq 0$, $\varphi'_{x^0}(t+) \leq -c_N\|(x(t,x^0),u(t,x^0),v(t,x^0))\|^2$. By (3.7), we deduce the existence of a constant $c'_M > 0$ such that

$$\varphi_{x^0}(t) \geq c'_M \,\|\,(x(t,x^0),u(t,x^0),v(t,x^0))\,\|^2.$$

Therefore, we obtain, for some constant $c > 0$,

$$\|\,z(t,x^0)\,\|^2 \leq c\left[\,\varphi_{x^0}(0) - \int_0^t \|\,z(s,x^0)\,\|^2\, ds\right] \quad \forall\,(\,t,x^0\,) \in [\,0,\infty\,) \times \Re^n,$$

where $z(t,x^0) \equiv (x(t,x^0),u(t,x^0),v(t,x^0))$. By Gronwall's inequality, we therefore deduce

$$\|\,x(t,x^0)\,\|^2 \leq \|\,z(t,x^0)\,\|^2 \leq c\,\varphi_{x^0}(0)\,e^{-ct} \leq c\,\rho'_M \,\|\,x^0\,\|^2\,e^{-ct},$$

where the last inequality is by (3.10). Consequently, $\|x(t,x^0)\| \leq \sqrt{c\rho'_M}\,\|x^0\|\,e^{-ct/2}$. This establishes part (b) of the theorem. We will postpone the proof of part (c) because it requires an auxiliary result that is of independent interest; see Proposition 3.2 below. Since N is symmetric, it follows that if $-N$ is copositive-plus on Gr $\mathrm{SOL}'_{\mathrm{LCS}}$, then (3.8) and (3.9) are equivalent implications. Hence (d) follows from (c). □

Part (c) of Theorem 3.1 is a generalized LaSalle's theorem for the LCS (2.1). The assumed implication (3.8) resembles a "generalized long-time observability condition" on the zero state of the LCS. Subsequently, we will discuss more about this condition; see subsection 3.1. For now, we note that if $-N$ is copositive on Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ and if $(-N,\mathcal{C})$, where $\mathcal{C}$ is the closure of the convex hull of Gr $\mathrm{SOL}'_{\mathrm{LCS}}$, is an R_0-pair, then (3.8) holds. Indeed, in this case, by (2.3), it follows that $z(t,\xi)^T N z(t,\xi) = 0$ implies $z(t,\xi) = 0$. In particular $\xi = x(0,\xi) = 0$; hence (3.8) holds.

To prove part (c) of Theorem 3.1, we define for each fixed $x^0 \in \Re^n$ the *positive limit set*

$$\Omega(x^0) \equiv \Big\{\, x^\infty \in \Re^n \,:\, \exists\,\{\,t_k\,\} \uparrow \infty \text{ such that } x^\infty = \lim_{k\to\infty} x(t_k,x^0)\,\Big\}.$$

If M is strictly copositive on Gr SOL_{CD} and $-N$ is copositive on cl Gr $\mathrm{SOL}'_{\mathrm{LCS}}$, then $\Omega(x^0)$ is nonempty, by part (a) of Theorem 3.1. Additional properties of this set are summarized below.

PROPOSITION 3.2. *Let D be a P-matrix. If M is strictly copositive on* cl Gr $\mathrm{SOL}_{\mathrm{LCS}}$ *and $-N$ is copositive on* cl Gr $\mathrm{SOL}'_{\mathrm{LCS}}$*, then for every $x^0 \in \Re^n$, the following three statements hold:*

(a) *for every $x^\infty \in \Omega(x^0)$, the trajectory $\{x(t, x^\infty)\}_{t\geq 0} \subset \Omega(x^0)$;*
(b) *a constant σ_{x^0} exists such that $V(x^\infty, \mathrm{SOL}(Cx^\infty, D)) = \sigma_{x^0}$ for all $x^\infty \in \Omega(x^0)$;*
(c) *$\varphi'_{x^\infty}(t) = 0$ for all $x^\infty \in \Omega(x^0)$.*

Proof. Suppose $x^\infty = \lim_{k\to\infty} x(t_k, x^0)$ for some sequence $\{t_k\} \uparrow \infty$. For any $t \geq 0$, we have $x(t + t_k, x^0) = x(t, x(t_k, x^0))$; hence taking limits as $k \uparrow \infty$ and using the continuity of $x(t, \cdot)$ in the second argument, we deduce

$$\lim_{k\to\infty} x(t + t_k, x^0) = x(t, x^\infty),$$

which establishes part (a). To prove part (b), note that since $\varphi'_{x^0}(t+) \leq 0$ for all $t \geq 0$, it follows that $\varphi_{x^0}(t)$ is nonincreasing. Since

$$\varphi_{x^0}(t) = V(x(t, x^0), u(t, x^0)) = \begin{pmatrix} x(t, x^0) \\ u(t, x^0) \end{pmatrix} \begin{bmatrix} P & Q \\ Q^T & R \end{bmatrix} \begin{pmatrix} x(t, x^0) \\ u(t, x^0) \end{pmatrix} \geq 0,$$

by the copositivity of M on Gr $\mathcal{G}_{CD}(x(t, x^0))$, it follows that

$$\lim_{t\to\infty} \varphi_{x^0}(t)$$

exists. With σ_{x^0} denoting the above limit, it follows that $V(x^\infty, u(x^\infty)) = \sigma_{x^0}$ for all $x^\infty \in \Omega(x^0)$. Combining (a) and (b), we deduce that for all $x^\infty \in \Omega(x^0)$, we have

$$\varphi_{x^\infty}(t) = V(x(t, x^\infty), u(t, x^\infty)) = \sigma_{x^0} \quad \forall\, t \geq 0.$$

Thus, $\varphi_{x^\infty}(t)$ is a constant function on $[0, \infty)$. Part (c) is therefore trivial. □

Proof of Theorem 3.1(c). It suffices to show that $\Omega(x^0) = \{0\}$ for all $x^0 \in \Re^n$. Let $x^\infty \in \Omega(x^0)$ be given. By part (c) of Proposition 3.2, we have $0 = \varphi'_{x^\infty}(t) = z(t, x^\infty)^T N z(t, x^\infty)$ for all $t \geq 0$. Hence (3.8) implies $x^\infty = 0$ as desired. □

Admittedly, the conditions in Theorem 3.1 are in general not easy to verify. This is inevitable because most matrix properties in LCP theory are already so. Nevertheless, such difficulties have not prevented the fruitful development of the theory and applications of the LCP and its extensions. Thus we fully expect that Theorem 3.1 is of fundamental importance in the stability theory of the LCS. In what follows, we provide evidence for this optimism by deriving various special results and by giving examples to illustrate the broad applicability of this theorem. We begin by considering the case where both Q and R are taken to be zero. Proposition 3.3 below provides succinct matrix-theoretic conditions that ensure the existence of a "common Lyapunov function" for the LCS. (The study of copositivity has recently received renewed interest in the mathematical programming community; see, e.g., the Ph.D. thesis [41] and the paper [55]. It would be of interest to investigate how these works can be used to help check the conditions obtained herein.)

PROPOSITION 3.3. *Let D be a P-matrix and P be a symmetric positive definite matrix.*

(a) *If, for every* $\alpha \subseteq \{1, \ldots, m\}$,

$$\begin{bmatrix} -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \\ C_{\bar{\alpha}\bullet} - D_{\bar{\alpha}\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x \geq 0 \Rightarrow x^T[A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet}]^T Px \leq 0, \tag{3.11}$$

then $x^e = 0$ *is a linearly bounded stable equilibrium of the* LCS (2.1),

(b) *If, for every* $\alpha \subseteq \{1, \ldots, m\}$,

$$\begin{aligned} &\left\{ \begin{bmatrix} -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \\ C_{\bar{\alpha}\bullet} - D_{\bar{\alpha}\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x \geq 0,\ x \neq 0 \right\} \\ &\qquad \Rightarrow x^T[A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet}]^T Px < 0, \end{aligned} \tag{3.12}$$

then $x^e = 0$ *is an exponentially stable equilibrium of the* LCS (2.1).

(c) *If, for every* $\alpha \subseteq \{1, \ldots, m\}$, (3.11) *holds and*

$$\left. \begin{aligned} &\begin{bmatrix} -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \\ C_{\bar{\alpha}\bullet} - D_{\bar{\alpha}\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x \geq 0 \\ &x^T[A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet}]^T Px = 0 \end{aligned} \right\} \Rightarrow\ x = 0, \tag{3.13}$$

then $x^e = 0$ *is an asymptotically stable equilibrium of the LCS* (2.1).

Proof. With $Q = 0$ and $R = 0$, the matrices M and N become

$$M = \begin{bmatrix} P & 0 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad N = \begin{bmatrix} A^TP + PA & PB & 0 \\ B^TP & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

By (3.1) and the positive definiteness of P, it follows that M is strictly copositive on Gr SOL_{CD}. For any triple $z \equiv (x, u(x), v) \in \mathrm{cl\ Gr\ SOL}'_{\mathrm{LCS}}$ with $x \in \mathcal{C}_\alpha$, we have

$$z^T N z = 2x^T[A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet}]^T Px.$$

Hence, the proposition follows easily from Theorem 3.1. ∎

Remark 3.1. It should be noted that the resulting matrix M in the above proposition is not positive definite. This illustrates the fact that the strict copositivity of M on Gr SOL_{CD} is not as restrictive as it seems.

A special case of Proposition 3.3 pertains to a "passive-like" LCS for which there exists a *symmetric positive definite* K such that

$$-\begin{bmatrix} A^TK + KA & KB - C^T \\ B^TK - C & -D - D^T \end{bmatrix} \tag{3.14}$$

is positive semidefinite. This class of LCSs is closely related to the class of passive LCSs defined in [4, 7] and to the class of *positive real transfer functions* via the well-known Kalman–Yakubovich–Popov lemma [28]. In essence, we have bypassed the transfer functions and the "minimality" of the tuple (A, B, C, D) and worked directly with the positive semidefinite matrix (3.14). Note that if (3.14) is positive semidefinite, then the matrix D must be positive semidefinite albeit not necessarily

symmetric. It is possible for such a D to be also P without being positive definite; a trivial example is

$$D \equiv \begin{bmatrix} 1 & -2 \\ 0 & 1 \end{bmatrix}.$$

The next result shows how Proposition 3.3 (b) can be applied to such an LCS. This result complements Theorem 11.2 [7] in providing a sufficient condition for a passive-like LCS to be asymptotically stable.

COROLLARY 3.4. *Suppose that D is a P-matrix and there exists a symmetric positive definite matrix K such that* (3.14) *is positive semidefinite. If for every $\alpha \subseteq \{1, \ldots, m\}$,*

$$\left.\begin{array}{c} \begin{bmatrix} -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \\ C_{\bar{\alpha}\bullet} - D_{\bar{\alpha}\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x \geq 0 \\ \begin{bmatrix} A^TK + KA & KB_{\bullet\alpha} - (C_{\alpha\bullet})^T \\ (B_{\bullet\alpha})^TK - C_{\alpha\bullet} & -D_{\alpha\alpha} - (D_{\alpha\alpha})^T \end{bmatrix} \begin{bmatrix} I \\ -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x = 0 \end{array}\right\} \Rightarrow \ x = 0,$$

then x^e is asymptotically stable.

Proof. It suffices to verify the implication (3.13). Let x satisfy the left-hand condition in the latter implication. Proceeding as before, we deduce

$$\begin{aligned} 0 &= \begin{pmatrix} x \\ u \end{pmatrix}^T \begin{bmatrix} A^TK + KA & KB - C^T \\ B^TK - C & -D - D^T \end{bmatrix} \begin{pmatrix} x \\ u \end{pmatrix} \\ &= x^T \begin{bmatrix} I \\ -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix}^T \begin{bmatrix} A^TK + PA & KB_{\bullet\alpha} - (C_{\alpha\bullet})^T \\ (B_{\bullet\alpha})^TK - C_{\alpha\bullet} & -D_{\alpha\alpha} - (D_{\alpha\alpha})^T \end{bmatrix} \\ &\quad \times \begin{bmatrix} I \\ -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x, \end{aligned}$$

which implies, since (3.14) is symmetric positive semidefinite,

$$\begin{bmatrix} A^TK + PA & KB_{\bullet\alpha} - (C_{\alpha\bullet})^T \\ (B_{\bullet\alpha})^TK - C_{\alpha\bullet} & -D_{\alpha\alpha} - (D_{\alpha\alpha})^T \end{bmatrix} \begin{bmatrix} I \\ -(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} \end{bmatrix} x = 0.$$

The desired implication (3.13) follows easily from the assumption of part (b) herein. ∎

The assumption in Proposition 3.3(b) is significantly weaker than the passivity [4, 7] of the LCS tuple (A, B, C, D). The next two examples illustrate this point. The first example has a matrix A that is not negatively stable and the matrix D is not positive semidefinite.

Example 3.1. Consider the tuple with $n = 1$ and $m = 2$:

$$A = 1, \quad B = \begin{bmatrix} 2 & -2 \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ -1 \end{bmatrix}, \quad \text{and} \quad D = \begin{bmatrix} 1 & 3 \\ 0 & 1 \end{bmatrix}.$$

By an easy calculation, we have

$$A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} = \begin{cases} 1 & \text{if } \alpha = \emptyset, \\ -1 & \text{if } \alpha = \{1\}, \\ -1 & \text{if } \alpha = \{2\}, \\ -9 & \text{if } \alpha = \{1, 2\}, \end{cases} \quad \text{and} \quad \mathcal{C}_\alpha = \begin{cases} \{0\} & \text{if } \alpha = \emptyset, \\ (-\infty, 0] & \text{if } \alpha = \{1\}, \\ [0, \infty) & \text{if } \alpha = \{2\}, \\ \{0\} & \text{if } \alpha = \{1, 2\}. \end{cases}$$

Note that with $P = 1$, the matrix $A - B_{\bullet\emptyset}(D_{\emptyset\emptyset})^{-1}C_{\emptyset\bullet}$ is *not negative definite*; nevertheless, the assumption in Proposition 3.3(b) is satisfied.

The next example has the same matrix D but has $A = -1$ so that A is negatively stable. Yet the LCS (A, B, C, D) is still not passive because D is not positive semidefinite. This example shows that passivity is not a necessary condition for exponential stability, even with a negatively stable matrix A.

Example 3.2. Consider the tuple with $n = 1$ and $m = 2$:

$$A = -1, \quad B = \begin{bmatrix} 0 & 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \quad \text{and} \quad D = \begin{bmatrix} 1 & 3 \\ 0 & 1 \end{bmatrix}.$$

By an easy calculation, we have

$$A - B_{\bullet\alpha}(D_{\alpha\alpha})^{-1}C_{\alpha\bullet} = \begin{cases} -1 & \text{if } \alpha = \emptyset, \\ -1 & \text{if } \alpha = \{1\}, \\ -2 & \text{if } \alpha = \{2\}, \\ -2 & \text{if } \alpha = \{1,2\}, \end{cases} \quad \text{and} \quad \mathcal{C}_\alpha = \begin{cases} [\,0, \infty\,) & \text{if } \alpha = \emptyset, \\ \{0\} & \text{if } \alpha = \{1\}, \\ (\,-\infty, 0\,] & \text{if } \alpha = \{2\}, \\ \{0\} & \text{if } \alpha = \{1,2\}. \end{cases}$$

Again, the assumption in Proposition 3.3(b) is satisfied with $P = 1$.

As noted in the proof of Theorem 3.1(b), the strict copositivity of $-N$ on cl Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ is equivalent to the existence of a constant $\rho_N > 0$ such that

$$-z^T N z \;\geq\; \rho_N \,\|\, z \,\|^2 \quad \forall\, z \;\in\; \mathrm{Gr}\ \mathrm{SOL}'_{\mathrm{LCS}}.$$

Involving only Gr $\mathrm{SOL}'_{\mathrm{LCS}}$, the latter inequality avoids the explicit description of the closure of this graph, which is a nontrivial task. We employ this equivalent condition for the strict copositivity of $-N$ in the example below, for which we establish the asymptotic stability of the equilibrium with the choice of a nonzero pair (Q, R) satisfying part (b) of Theorem 3.1, and to which we cannot apply Proposition 3.3(b). This example combines Example 3.1 and the one in [27, section IV]. As such, the matrix A is not negatively stable.

Example 3.3. Consider the LCS

$$\begin{aligned} \dot{x} \;&=\; \begin{bmatrix} -5 & -4 & 0 \\ -1 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix} x + \begin{bmatrix} -3 & 0 & 0 \\ -21 & 0 & 0 \\ 0 & 2 & -2 \end{bmatrix} u, \\ 0 \;\leq\; u \;&\perp\; \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & -1 \end{bmatrix} x + \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 3 \\ 0 & 0 & 1 \end{bmatrix} u \;\geq\; 0. \end{aligned}$$

We claim that there exists no symmetric positive definite matrix P satisfying the assumptions of Proposition 3.3. Consider the two index sets $\alpha = \emptyset$ and $\alpha = \{1\}$. For these sets, we have

$$\mathcal{C}_\emptyset = \{\, x \in \Re^3 \,:\, x_1 \,\geq\, 0 = x_3 \,\}, \quad \mathcal{C}_{\{1\}} = \{\, x \in \Re^3 \,:\, x_1 \,\leq\, 0 = x_3 \,\}$$

and

$$A - B_{\bullet\emptyset}(D_{\emptyset\emptyset})^{-1}C_{\emptyset\bullet} = \begin{bmatrix} -5 & -4 & 0 \\ -1 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$A - B_{\bullet\{1\}}(D_{\{1\}\{1\}})^{-1}C_{\{1\}\bullet} = \begin{bmatrix} -2 & -4 & 0 \\ 20 & -2 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

By way of contradiction, suppose that there exists a symmetric and positive definite matrix P such that the assumption in Proposition 3.3(b) is satisfied. This would mean that there exists a symmetric positive definite matrix $\bar{P}$ such that

$$\bar{x}^T(\bar{A}_i^T\bar{P} + \bar{P}\bar{A}_i)\bar{x} < 0 \quad \forall\, \bar{x} \in \bar{\mathcal{C}}_i, \tag{3.15}$$

for $i = 1, 2$, where $\bar{\mathcal{C}}_1 \equiv \{\bar{x} \in \Re^2 \mid \bar{x}_1 \geq 0\}$, $\bar{\mathcal{C}}_2 = \{\bar{x} \in \Re^2 \mid \bar{x}_1 \leq 0\}$, and

$$\bar{A}_1 \equiv \begin{bmatrix} -5 & -4 \\ -1 & -2 \end{bmatrix}, \quad \bar{A}_2 \equiv \begin{bmatrix} -2 & -4 \\ 20 & -2 \end{bmatrix}.$$

Since $\bar{\mathcal{C}}_i$ are both half-spaces, the relations (3.15) hold if and only if $\bar{A}_i^T\bar{P} + \bar{P}\bar{A}_i$ are both negative definite for $i = 1, 2$. As shown in [27, section IV], however, this cannot happen. Next, we claim that $x^e = 0$ is an exponentially stable equilibrium of the LCS by verifying that with

$$P \equiv \begin{bmatrix} 1 & 0 & 0 \\ 0 & 3 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad Q \equiv 0, \quad \text{and} \quad R \equiv \begin{bmatrix} 9 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$

the assumptions in Theorem 3.1 are satisfied. The strict copositivity of M on Gr SOL_{CD}, is not difficult to verify. We briefly sketch the proof of the strict copositivity of the matrix

$$-N = \left[\begin{array}{ccc|ccc|ccc} 10 & 7 & 0 & 3 & 0 & 0 & 0 & 0 & 0 \\ 7 & 12 & 0 & 63 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -2 & 0 & -2 & 2 & 0 & 0 & 0 \\ - & - & - & - & - & - & - & - & - \\ 3 & 63 & 0 & 0 & 0 & 0 & 9 & 0 & 0 \\ 0 & 0 & -2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \\ - & - & - & - & - & - & - & - & - \\ 0 & 0 & 0 & 9 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{array}\right]$$

on the closure of Gr $\mathrm{SOL}'_{\mathrm{LCS}}$. We have $u_1(x) = \max(0, -x_1)$, $u_2(x) = \max(0, -x_3)$, and $u_3(x) = \max(0, x_3)$, With the last two rows and columns of N being identically equal to zero, we need not deal with the directional derivatives of u_2 and u_3. Instead, we focus on

$$u_1'(x_1; dx_1) = \begin{cases} 0 & \text{if } x_1 > 0, \\ -dx_1 & \text{if } x_1 < 0, \\ \max(0, -dx_1) & \text{if } x_1 = 0, \end{cases}$$

where $dx_1 = C_{1\bullet}Ax + C_{1\bullet}Bu(x) = -5x_1 - 4x_2 - 3\max(0, -x_1)$. It suffices to show the existence of a constant $\rho_N > 0$ such that

• $x_1 > 0$ implies

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \max(0,-x_3) \\ \max(0,x_3) \end{pmatrix}^T \left[\begin{array}{ccc|cc} 10 & 7 & 0 & 0 & 0 \\ 7 & 12 & 0 & 0 & 0 \\ 0 & 0 & -2 & -2 & 2 \\ \hline 0 & 0 & -2 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 \end{array}\right] \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \max(0,-x_3) \\ \max(0,x_3) \end{pmatrix} \geq \rho_N \| x \|^2,$$

• $x_1 < 0$ implies

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ -x_1 \\ \max(0,-x_3) \\ \max(0,x_3) \\ 2x_1 + 4x_2 \end{pmatrix}^T \left[\begin{array}{ccc|ccc|c} 10 & 7 & 0 & 3 & 0 & 0 & 0 \\ 7 & 12 & 0 & 63 & 0 & 0 & 0 \\ 0 & 0 & -2 & 0 & -2 & 2 & 0 \\ \hline 3 & 63 & 0 & 0 & 0 & 0 & 9 \\ 0 & 0 & -2 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 9 & 0 & 0 & 0 \end{array}\right] \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ -x_1 \\ \max(0,-x_3) \\ \max(0,x_3) \\ 2x_1 + 4x_2 \end{pmatrix}$$
$$\geq \rho_N \|x\|^2,$$

• and ($x_1 = 0$ implies)

$$\begin{pmatrix} x_2 \\ x_3 \\ \max(0,-x_3) \\ \max(0,x_3) \\ \max(0,4x_2) \end{pmatrix}^T \left[\begin{array}{cc|cc|c} 12 & 0 & 0 & 0 & 0 \\ 0 & -2 & -2 & 2 & 0 \\ \hline 0 & -2 & 0 & 0 & 0 \\ 0 & 2 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \end{array}\right] \begin{pmatrix} x_2 \\ x_3 \\ \max(0,-x_3) \\ \max(0,x_3) \\ \max(0,4x_2) \end{pmatrix}$$
$$\geq \rho_N \left\| \begin{pmatrix} x_2 \\ x_3 \end{pmatrix} \right\|^2.$$

We will leave it to the reader to verify that the desired constant ρ_N indeed exists in view of the positive definiteness of certain appropriate matrices.

3.1. Role of observability. The implication (3.8) can be refined by employing an explicit analytic expansion for the vector $z(t,\xi)$ for $t > 0$ sufficiently small. The expansion enables the application of the following known fact about an analytic function expressed in series form.

LEMMA 3.5. *Consider the univariate real-analytic function*

$$\psi(t) \equiv \sum_{j=0}^{\infty} a_j\, t^j, \quad t \geq 0,$$

where $\{a_j\}_{j\geq 0}$ is a given sequence of scalars. The following three statements are valid:

(a) *in order for $\psi(t) > 0$ for all $t > 0$ sufficiently small, it is necessary and sufficient that the sequence of coefficients $\{a_j\}_{j\geq 0}$ be lexicographically positive; i.e., these coefficients are not all zero and the first nonzero coefficient is positive;*

(b) *in order for* $\psi(t) \geq 0$ *for all* $t > 0$ *sufficiently small, it is necessary and sufficient that the sequence of coefficients* $\{a_j\}_{j\geq 0}$ *be lexicographically nonnegative; i.e., either all coefficients are zero or the sequence is lexicographically positive;*

(c) *in order for* $\psi(t) = 0$ *for all* $t > 0$ *sufficiently small, it is necessary and sufficient that* $a_j = 0$ *for all* $j \geq 0$.

If the coefficients a_j *are given by* $e^T G^j \xi$ *for some* n*-vectors* e *and* ξ *and* $n \times n$ *matrix* G*, the above conditions on the infinite sequence* $\{a_j\}_{j\geq 0}$ *can be replaced by the finite sequence* $\{a_j\}_{j=0}^{n-1}$.

For a given pair of matrices $G \in \Re^{k\times k}$ and $H \in \Re^{\ell\times k}$, the unobservable space of (H, G), denoted $\overline{O}(H, G)$, is the set of vectors $\xi \in \Re^k$ such that $HG^j\xi = 0$ for all $j = 0, 1, \ldots, k-1$. In contrast to this linear subspace, the semiunobservable cone of (H, G), denoted $\overline{SO}(H, G)$, is the set of vectors $\xi \in \Re^n$ such that the family of scalars $\{H_{i\bullet}G^j\xi\}_{j=0}^{k-1}$ is lexicographically nonnegative for all $i = 1, \ldots, \ell$. The two sets $\overline{O}(H, G)$ and $\overline{SO}(H, G)$ have played an important role in the observability analysis of the LCS [37]; they have an equally important role here in the asymptotic stability analysis of the LCS. We also define the open subset $SO(H, G)$ of $\overline{SO}(H, G)$ consisting of vectors $\xi \in \Re^n$ such that the family of scalars $\{H_{i\bullet}G^j\xi\}_{j=0}^{k-1}$ is lexicographically positive for all $i = 1, \ldots, \ell$. Note that $0 \notin SO(H, G)$.

The one-sided directional derivative $u'(x(t, x^0); CAx(t, x^0) + CBu(t, x^0))$ is the unique vector $v(t, x^0)$ satisfying

(3.16)

$$\begin{array}{lcll}
\text{free } v_i(t,x^0) & & (\,CAx(t,x^0)+CBu(t,x^0)+Dv(t,x^0)\,)_i = 0, & i \in \alpha(x(t,x^0)),\\
0 \leq v_i(t,x^0) & \perp & (\,CAx(t,x^0)+CBu(t,x^0)+Dv(t,x^0)\,)_i \geq 0, & i \in \beta(x(t,x^0)),\\
0 = v_i(t,x^0), & & (\,CAx(t,x^0)+CBu(t,x^0)+Dv(t,x^0)\,)_i \text{ free}, & i \in \gamma(x(t,x^0)).
\end{array}$$

By a strong non-Zeno result for an LCS with a P-matrix D [37], we deduce the existence of a time $\tau_0 > 0$ and a triple of index sets $(\alpha_{\rm n}, \beta_{\rm n}, \gamma_{\rm n})$, both dependent on the initial condition x^0, such that $(\alpha(x(t, x^0)), \beta(x(t, x^0)), \gamma(x(t, x^0))) = (\alpha_{\rm n}, \beta_{\rm n}, \gamma_{\rm n})$ for all $t \in (0, \tau_0]$. For all such times t, the system (3.16) becomes

$$\begin{array}{lcll}
 & & (\,CAx(t,x^0)+CBu(t,x^0)+Dv(t,x^0)\,)_i = 0, & i \in \alpha_{\rm n},\\
0 \leq v_i(t,x^0) & \perp & (\,CAx(t,x^0)+CBu(t,x^0)+Dv(t,x^0)\,)_i \geq 0, & i \in \beta_{\rm n},\\
0 = v_i(t,x^0), & & & i \in \gamma_{\rm n}.
\end{array}$$

The latter is a mixed LCP of the P-type. As explained in [37], there exist a scalar $\widehat{\tau} \in (0, \tau_0]$ and a subset $\beta_a \subseteq \beta_{\rm n}$ with complement $\bar{\beta}_a \equiv \beta_{\rm n} \setminus \beta_a$ such that for all $t \in (0, \widehat{\tau}\,]$, the unique solution $v(t, x^0)$ of the above mixed LCP satisfies (where $\mathcal{K} \equiv \alpha_{\rm n} \cup \beta_a$)

$$v_{\mathcal{K}}(t, x^0) = -(\,D_{\mathcal{K}\mathcal{K}}\,)^{-1} C_{\mathcal{K}\bullet} \begin{bmatrix} A & B \end{bmatrix} \begin{pmatrix} x(t, x^0) \\ u(t, x^0) \end{pmatrix}.$$

Note that $v_{\beta_a}(t, x^0) \geq 0$, $v_{\bar{\beta}_a}(t, x^0) = 0$, and

$$\left\{\, C_{\bar{\beta}_a\bullet} - D_{\bar{\beta}_a\mathcal{K}}(\,D_{\mathcal{K}\mathcal{K}}\,)^{-1} C_{\mathcal{K}\bullet} \right\} \begin{bmatrix} A & B \end{bmatrix} \begin{pmatrix} x(t, x^0) \\ u(t, x^0) \end{pmatrix} \geq 0.$$

Provided that τ_0 is sufficiently small, we have

$$\text{supp}(u(x^0)) \subseteq \alpha_{\rm n} \subseteq \mathcal{K} \subseteq \alpha_{\rm n} \cup \beta_{\rm n} \subseteq \{\, i : (\,Cx^0 + Du(x^0)\,)_i = 0 \,\}.$$

In terms of the index set $\mathcal{K}$, we have

$$\begin{array}{rl} 0 < \\ 0 = \end{array} \begin{pmatrix} u_{\alpha_{\rm n}}(t,x^0) \\ u_{\beta_a}(t,x^0) \end{pmatrix} = - \begin{bmatrix} D_{\alpha_{\rm n}\alpha_{\rm n}} & D_{\alpha_{\rm n}\beta_a} \\ D_{\beta_a\alpha_{\rm n}} & D_{\beta_a\beta_a} \end{bmatrix}^{-1} \begin{bmatrix} C_{\alpha_{\rm n}\bullet} \\ C_{\beta_a\bullet} \end{bmatrix} x(t,x^0)$$

and

$$\begin{array}{rl} 0 = \\ 0 < \end{array} \left\{ \begin{bmatrix} C_{\bar\beta_a\bullet} \\ C_{\gamma_{\rm n}\bullet} \end{bmatrix} - \begin{bmatrix} D_{\bar\beta_a\alpha_{\rm n}} & D_{\bar\beta_a\beta_t} \\ D_{\gamma_{\rm n}\alpha_{\rm n}} & D_{\gamma_{\rm n}\beta_t} \end{bmatrix} \begin{bmatrix} D_{\alpha_{\rm n}\alpha_{\rm n}} & D_{\alpha_{\rm n}\beta_a} \\ D_{\beta_a\alpha_{\rm n}} & D_{\beta_a\beta_a} \end{bmatrix}^{-1} \begin{bmatrix} C_{\alpha_{\rm n}\bullet} \\ C_{\beta_a\bullet} \end{bmatrix} \right\} x(t,x^0).$$

Substituting the expression for $u_{\mathcal{K}}(t,x^0)$ into the ODE $\dot x = Ax + Bu$ and noting that $u_i(t,x^0) = 0$ for all $i \notin \mathcal{K}$, we deduce

$$x(t,x^0) = \sum_{j=0}^{\infty} \frac{t^j}{j\,!}\, A(\mathcal{K})^j x^0, \quad \overline{C}(\mathcal{K})x(t,x^0) = \sum_{j=0}^{\infty} \frac{t^j}{j\,!}\, \overline{C}(\mathcal{K})A(\mathcal{K})^j x^0,$$

$$\begin{bmatrix} A & B \end{bmatrix} \begin{pmatrix} x(t,x^0) \\ u(t,x^0) \end{pmatrix} = \sum_{j=0}^{\infty} \frac{t^j}{j\,!} \begin{bmatrix} A & B_{\bullet\mathcal{K}} \end{bmatrix} \begin{bmatrix} I \\ \overline{C}_{\mathcal{K}\bullet}(\mathcal{K}) \end{bmatrix} A(\mathcal{K})^j x^0,$$

where $A(\mathcal{K}) \equiv A - B_{\bullet\mathcal{K}}(D_{\mathcal{K}\mathcal{K}})^{-1}C_{\mathcal{K}\bullet}$, and with $\bar{\mathcal{K}} \equiv \{1,\ldots,m\} \setminus \mathcal{K}$,

$$\overline{C}(\mathcal{K}) \equiv \begin{bmatrix} -(\,D_{\mathcal{K}\mathcal{K}}\,)^{-1}C_{\mathcal{K}\bullet} \\ C_{\bar{\mathcal{K}}\bullet} - D_{\bar{\mathcal{K}}\mathcal{K}}(\,D_{\mathcal{K}\mathcal{K}}\,)^{-1}C_{\mathcal{K}\bullet} \end{bmatrix}$$

and

$$\overline{D}(\mathcal{K}) \equiv \overline{C}(\mathcal{K}) \begin{bmatrix} A & B_{\bullet\mathcal{K}} \end{bmatrix} \begin{bmatrix} I \\ \overline{C}_{\mathcal{K}\bullet}(\mathcal{K}) \end{bmatrix}.$$

By Lemma 3.5, in order for $v_{\beta_a}(t,x^0) \geq 0 = u_{\beta_a}(t,x^0)$ to hold for all $t > 0$ sufficiently small, it is necessary and sufficient that $x^0 \in \overline{SO}(\overline{D}_{\beta_a\bullet}(\mathcal{K}), A(\mathcal{K})) \cap \overline{O}(\overline{C}_{\beta_a\bullet}(\mathcal{K}), A(\mathcal{K}))$. Moreover, if $\alpha_{\rm n} \neq \emptyset$, then since $u_{\alpha_{\rm n}}(t,x^0) > 0$ for all $t > 0$ sufficiently small, we must have $x^0 \in SO(\overline{C}_{\alpha_{\rm n}\bullet}(\mathcal{K}), A(\mathcal{K}))$. Similarly, if $\gamma_{\rm n} \neq \emptyset$, we also have $x^0 \in SO(\overline{C}_{\gamma_{\rm n}\bullet}(\mathcal{K}), A(\mathcal{K}))$.

Turning our attention to the implication (3.8), we note that $Nz(t,x^0)$ is equal to

$$\begin{bmatrix} A^TP + PA & PB_{\bullet\mathcal{K}} + A^TQ_{\bullet\mathcal{K}} & Q_{\bullet\mathcal{K}} \\ (B_{\bullet\mathcal{K}})^TP + (Q_{\bullet\mathcal{K}})^TA & (B_{\bullet\mathcal{K}})^TQ_{\bullet\mathcal{K}} + (Q_{\bullet\mathcal{K}})^TB_{\bullet\mathcal{K}} & R_{\mathcal{K}\mathcal{K}} \\ (Q_{\bullet\mathcal{K}})^T & R_{\mathcal{K}\mathcal{K}} & 0 \end{bmatrix} \begin{pmatrix} x(t,x^0) \\ u_{\mathcal{K}}(t,x^0) \\ v_{\mathcal{K}}(t,x^0) \end{pmatrix}$$

$$= \sum_{j=0}^{\infty} \frac{t^j}{j\,!} \begin{bmatrix} A^TP + PA & PB_{\bullet\mathcal{K}} + A^TQ_{\bullet\mathcal{K}} & Q_{\bullet\mathcal{K}} \\ (B_{\bullet\mathcal{K}})^TP + (Q_{\bullet\mathcal{K}})^TA & (B_{\bullet\mathcal{K}})^TQ_{\bullet\mathcal{K}} + (Q_{\bullet\mathcal{K}})^TB_{\bullet\mathcal{K}} & R_{\mathcal{K}\mathcal{K}} \\ (Q_{\bullet\mathcal{K}})^T & R_{\mathcal{K}\mathcal{K}} & 0 \end{bmatrix}$$

$$\times \begin{bmatrix} I \\ \overline{C}_{\mathcal{K}\bullet}(\mathcal{K}) \\ \overline{D}_{\mathcal{K}\bullet}(\mathcal{K}) \end{bmatrix} A(\mathcal{K})^j x^0.$$

Define

$$\overline{N}(\mathcal{K}) \equiv \begin{bmatrix} A^TP + PA & PB_{\bullet\mathcal{K}} + A^TQ_{\bullet\mathcal{K}} & Q_{\bullet\mathcal{K}} \\ (B_{\bullet\mathcal{K}})^TP + (Q_{\bullet\mathcal{K}})^TA & (B_{\bullet\mathcal{K}})^TQ_{\bullet\mathcal{K}} + (Q_{\bullet\mathcal{K}})^TB_{\bullet\mathcal{K}} & R_{\mathcal{K}\mathcal{K}} \\ (Q_{\bullet\mathcal{K}})^T & R_{\mathcal{K}\mathcal{K}} & 0 \end{bmatrix} \begin{bmatrix} I \\ \overline{C}_{\mathcal{K}\bullet}(\mathcal{K}) \\ \overline{D}_{\mathcal{K}\bullet}(\mathcal{K}) \end{bmatrix}.$$

By Lemma 3.5, in order for $Nz(t, x^0) = 0$ for all $t \geq 0$ sufficiently small, it is necessary and sufficient that $x^0 \in \overline{O}(\overline{N}(\mathcal{K}), A(\mathcal{K}))$.

Based on the above discussion, we state and prove the following result which is derived from a refinement of the implication (3.8).

PROPOSITION 3.6. *Let D be a P-matrix. Suppose there exist symmetric matrices P and R and a matrix Q such that M is strictly copositive on* Gr SOL_{CD} *and $-N$ is copositive-plus on* Gr $\mathrm{SOL}'_{\mathrm{LCS}}$. *Assume further that the following two conditions hold for all triples of index sets (α, β, γ) partitioning $\{1, \ldots, m\}$ and for all subsets β_a of β, with $\mathcal{K} \equiv \alpha \cup \beta_a$:*

(a) *for $\alpha = \gamma = \emptyset$,*

$$\overline{SO}(\overline{D}_{\mathcal{K}\bullet}(\mathcal{K}), A(\mathcal{K})) \cap \overline{O}(\overline{C}_{\mathcal{K}\bullet}(\mathcal{K}), A(\mathcal{K})) \cap \overline{O}(\overline{N}(\mathcal{K}), A(\mathcal{K})) = \{0\}, \tag{3.17}$$

(b) *for $\alpha \cup \gamma \neq \emptyset$,*

$$\begin{aligned} &SO(\overline{C}_{\alpha\cup\gamma\bullet}(\mathcal{K}), A(\mathcal{K})) \cap \overline{SO}(\overline{D}_{\beta_a\bullet}(\mathcal{K}), A(\mathcal{K})) \\ &\quad \cap \overline{O}(\overline{C}_{\beta_a\bullet}(\mathcal{K}), A(\mathcal{K})) \cap \overline{O}(\overline{N}(\mathcal{K}), A(\mathcal{K})) = \emptyset; \end{aligned} \tag{3.18}$$

then $x^e = 0$ is an asymptotically stable equilibrium of the LCS (2.1).

Proof. It suffices to show that the implication (3.8) holds. Let ξ satisfy the left-hand side of (3.8). Thus, in particular, $Nz(t, \xi) = 0$ for all $t > 0$ sufficiently small. Following the above argument, we consider the pair of index sets $(\alpha_{\mathrm{n}}, \mathcal{K})$ associated with the trajectories $u(x(t, \xi))$ and $u'(x(t, \xi); dx(t, \xi))$, where $dx(t, \xi) \equiv CAx(t, \xi) + CBu(x(t, \xi))$. The empty intersection (3.18) implies that $\alpha_{\mathrm{n}} = \gamma_{\mathrm{n}} = \emptyset$. Since ξ belongs to the intersection of the three sets in the left-hand side of (3.17), the latter condition then yields $\xi = 0$ as desired. ∎

3.2. A SISO system. We illustrate Proposition 3.6 for a single-input-single-output (SISO) system, which has $m = 1$ and $D = 1$ (the latter is assumed without loss of generality). We write c^T for C and b for B. Thus the SISO LCS is of the form

$$\dot{x} = Ax + b \max(0, -c^Tx). \tag{3.19}$$

In this case, we have $u(x) = \max(0, -c^Tx)$ and

$$\mathrm{SOL}'_{\mathrm{LCS}}(x) = \begin{cases} \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right\} & \text{if } c^Tx > 0, \\ \left\{ \begin{pmatrix} 0 \\ \max(0, -c^TAx) \end{pmatrix} \right\} & \text{if } c^Tx = 0, \\ \left\{ \begin{pmatrix} -c^Tx \\ -c^T(A - bc^T)x \end{pmatrix} \right\} & \text{if } c^Tx < 0. \end{cases}$$

The reader can easily check that Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ is not closed; nevertheless, one can verify that

$$\text{cl Gr SOL}'_{\mathrm{LCS}} = \begin{cases} \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix} \right\} & \text{if } c^T x > 0, \\ \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ -c^T Ax \end{pmatrix} \right\} & \text{if } c^T x = 0, \\ \left\{ \begin{pmatrix} -c^T x \\ -c^T(A - bc^T)x \end{pmatrix} \right\} & \text{if } c^T x < 0. \end{cases}$$

The matrix $M \equiv \left[\begin{smallmatrix} P & q \\ q^T & r \end{smallmatrix} \right]$ is strictly copositive on Gr SOL_{CD} if and only if

$$\left\{ [c^T x \geq 0,\, x \neq 0] \Rightarrow x^T P x > 0 \right\} \text{ and } \left\{ [c^T x < 0] \Rightarrow x^T [P - qc^T - cq^T + rcc^T] x > 0 \right\}.$$

In turn, this holds if and only if P and $P - qc^T - cq^T + rcc^T$ are both positive definite. To see this, suppose that the above two implications hold. If $c^T x < 0$, then $c^T(-x) > 0$; thus $0 < (-x)^T P(-x) = x^T P x$. Hence P must be positive definite. This together with the second implication establishes the positive definiteness of $P - qc^T - cq^T + rcc^T$. The converse is obvious.

The matrix

$$-N \equiv - \begin{bmatrix} A^T P + PA & Pb + A^T q & q \\ b^T P + q^T A & q^T b + b^T q & r \\ q^T & r & 0 \end{bmatrix}$$

is copositive on Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ if and only if

$$c^T x \geq 0 \Rightarrow x^T (A^T P + PA) x \leq 0,$$

$$c^T x \leq 0 \Rightarrow \begin{pmatrix} x \\ -c^T x \\ -c^T(A - bc^T)x \end{pmatrix}^T \begin{bmatrix} A^T P + PA & Pb + A^T q & q \\ b^T P + q^T A & q^T b + b^T q & r \\ q^T & r & 0 \end{bmatrix} \begin{pmatrix} x \\ -c^T x \\ -c^T(A - bc^T)x \end{pmatrix} \leq 0.$$

In turn the above implications hold if and only if $-(A^T P + PA)$ and

(3.20)

$$- \begin{bmatrix} I & -c & -(A^T - cb^T)c \end{bmatrix} \begin{bmatrix} A^T P + PA & Pb + A^T q & q \\ b^T P + q^T A & q^T b + b^T q & r \\ q^T & r & 0 \end{bmatrix} \begin{bmatrix} I \\ -c^T \\ -c^T(A - bc^T) \end{bmatrix}$$

are both positive semidefinite and thus copositive-plus. We examine the two conditions (3.17) and (3.18) in Proposition 3.6. For (3.17) where $\alpha = \gamma = \emptyset$, there are two cases: $\mathcal{K} = \emptyset$ or $\{1\}$. For $\mathcal{K} = \emptyset$, (3.17) stipulates that $\overline{O}(A^T P + PA, A) = \{0\}$. For $\mathcal{K} = \{1\}$, we have

$$\overline{N}(1) = N \begin{bmatrix} I \\ -c^T \\ -c^T(A - bc^T) \end{bmatrix},$$

and the condition (3.17) stipulates that

$$\{0\} = \overline{SO}(-c^T(A-bc^T), A-bc^T) \cap \overline{O}(-c^T, A-bc^T) \cap \overline{O}(\overline{N}(1), A-bc^T)$$
$$= \overline{O}(c^T, A) \cap \overline{O}(\overline{N}(1), A-bc^T) = \overline{O}(c^T, A) \cap \overline{O}(A^TP+PA, A),$$

which is implied by the former case. For (3.18), there are 2 subcases: $\alpha = \{1\}$ or $\gamma = \{1\}$. For $\alpha = \{1\}$, the condition (3.18) stipulates that $SO(-c^T, A-bc^T) \cap \overline{O}(\overline{N}(1), A-bc^T) = \emptyset$. For $\gamma = \{1\}$, the condition (3.18) stipulates that $SO(c^T, A-bc^T) \cap \overline{O}(A^TP+PA, A) = \emptyset$, which is implied by $\overline{O}(A^TP+PA, A) = \{0\}$ because $0 \notin SO(c^T, A-bc^T)$.

Summarizing the above analysis, we present a sufficient condition for $x^e = 0$ to be an asymptotically stable equilibrium of the SISO LCS (3.19).

PROPOSITION 3.7. *If there exist a symmetric positive definite matrix P, a vector q, and a scalar r such that*

(a) $P - qc^T - cq^T + rcc^T$ *is positive definite,*
(b) $-(A^TP+PA)$ *and* (3.20) *are both positive semidefinite,*
(c) $\overline{O}(A^TP+PA, A) = \{0\}$,
(d) $SO(-c^T, A-bc^T) \cap \overline{O}(\overline{N}(1), A-bc^T) = \emptyset$,

then $x^e = 0$ is an asymptotically stable equilibrium of the SISO LCS (3.19). *If the two matrices in* (b) *are positive definite, then $x^e = 0$ is exponentially stable.*

3.3. Extension to non-P systems. In this subsection, we extend Theorem 3.1 to the case where D is not a P-matrix; but we assume the blanket condition that $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. The extension turns out to be technically nontrivial; for one thing, Gr $\mathrm{SOL}'_{\mathrm{LCS}}$ ceases to exist because $\mathrm{SOL}(Cx, D)$ is no longer a single-valued function, and thus we cannot employ its directional derivatives as defined by (3.3). In addition to the main result, Theorem 3.12, we also obtain a stability result for a passive LCS without assuming the P-property of D; see Corollary 3.13.

To carry out the extended analysis, we assume that the matrices Q and R are such that $Q\mathrm{SOL}(Cx, D)$ and $R\mathrm{SOL}(Cx, D)$ are both singletons for all $x \in \Re^n$. Among other things, the single-valuedness of $R\mathrm{SOL}(Cx, D)$ yields the following important property of the quadratic term $\mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D)$.

PROPOSITION 3.8. *Let R be a symmetric matrix. Suppose that $R\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. The function $x \mapsto \mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D)$ is a single-valued piecewise quadratic function on $\Re^n$. In other words, for any four vectors $u^i \in \mathrm{SOL}(Cx, D)$, $i = 1, 2, 3, 4$, it holds that $(u^1)^T Ru^2 = (u^3)^T Ru^4$; moreover, this function is continuous in x and there exist finitely many matrices $\{E^j\}_{j=1}^K \subset \Re^{n\times n}$ for some integer $K > 0$ such that $\mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D) \in \{x^TE^jx\}_{j=1}^K$ for every $x \in \Re^n$.*

Proof. For any $u^i \in \mathrm{SOL}(Cx, D)$, $i = 1, 2, 3, 4$, we have $Ru^1 = Ru^2 = Ru^3 = Ru^4$. Hence by the symmetry of R, we have

$$(u^1)^T Ru^2 = (u^3)^T Ru^2 = (u^3)^T Ru^4.$$

Next, we show that the function $x \mapsto \mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D)$ is continuous. This follows easily from the single-valuedness of this map and the fact that the LCP solution map $q \mapsto \mathrm{SOL}(q, D)$ is *pointwise upper Lipschitz continuous* [13, 15, 44] on $\Re^m$; i.e., for every $q \in \Re^m$, there exist positive scalars c and ε such that

$$\| q' - q \| < \varepsilon \Rightarrow \mathrm{SOL}(q', D) \subseteq \mathrm{SOL}(q, D) + c \| q' - q \| \mathcal{B},$$

where $\mathcal{B}$ is the unit ball in $\Re^m$. Indeed, let $\{x^k\} \subset \Re^n$ be any sequence of vectors converging to some vector $x^\infty \in \Re^n$. Let $\{u^k\} \subset \Re^m$ be such that $u^k \in \mathrm{SOL}(Cx^k, D)$ for every k. By the above continuity property of the LCP solution map, it follows that there exists a corresponding sequence $\{\widehat{u}^k\}$ such that $\widehat{u}^k \in \mathrm{SOL}(Cx^\infty, D)$ for every k and $\lim_{k\to\infty} \| u^k - \widehat{u}^k \| = 0$. By the single-valuedness of $\mathrm{SOL}(Cx^\infty, D)^T R\mathrm{SOL}(Cx^\infty, D)$ and $R\mathrm{SOL}(Cx^\infty, D)$, we can write

$$\begin{aligned}(u^k)^T R u^k &= (\widehat{u}^k)^T R \widehat{u}^k + 2(u^k - \widehat{u}^k)^T R \widehat{u}^k + (u^k - \widehat{u}^k)^T R (u^k - \widehat{u}^k) \\ &= \mathrm{SOL}(Cx^\infty, D)^T R\mathrm{SOL}(Cx^\infty, D) + 2(u^k - \widehat{u}^k)^T R\mathrm{SOL}(Cx^\infty, D) \\ &\quad + (u^k - \widehat{u}^k)^T R (u^k - \widehat{u}^k).\end{aligned}$$

Passing to the limit $k \to \infty$ easily establishes $\lim_{k\to\infty} (u^k)^T R u^k = \mathrm{SOL}(Cx^\infty, D)^T R\mathrm{SOL}\,(Cx^\infty, D)$. Finally, we postpone the identification of the matrices E^j after our description of the structure of $\mathrm{SOL}(Cx, D)$ that immediately follows this proof. □

It is well known that the graph of the set-valued LCP solution map $\mathcal{S}_D : q \mapsto \mathrm{SOL}(q, D)$ is the union of finitely many polyhedra in $\Re^m$; this property is the basis for proving the upper Lipschitz continuity of this map used in the above proof. For the purpose of introducing a closed graph that plays the role of $\mathrm{Gr\ SOL}'_{\mathrm{LCS}}$, which is not available in the non-P case, we first define certain subsets of the polyhedra that compose the graph $\mathrm{Gr\ SOL}_{CD}$. The derivation below is closely related to the development in [39, section 5.1] where we have identified a "linear Newton approximation" for the single-valued map $B\mathrm{SOL}(Cx, D)$.

For every vector $x \in \Re^n$, let $\mathcal{L}(x)$ be the (necessarily nonempty) family of pairs of index subsets α and $\mathcal{J}$ of $\{1, \ldots, m\}$ such that (a) $\alpha \subseteq \mathcal{J}$, (b) the columns of $D_{\mathcal{J}\alpha}$ are linearly independent, and (c) there exists $u \in \mathrm{SOL}(Cx, D)$ such that $\mathrm{supp}(u) \subseteq \alpha$ and $\mathcal{J} \subseteq \{i : (Cx + Du)_i = 0\}$, where $\mathrm{supp}(u) \equiv \{i : u_i > 0\}$ is the *support* of the vector u. Here, we adopt the convention that an empty set of vectors is linearly independent; under this convention, if $0 \in \mathrm{SOL}(Cx, D)$, then $\mathcal{L}(x)$ includes all pairs $(\emptyset, \mathcal{J})$ for all subsets $\mathcal{J} \subseteq \{i : (Cx)_i = 0\}$. For a given pair $(\alpha, \mathcal{J})$ in $\mathcal{L}(x)$, by (b), the solution u in (c) is unique and given by

$$u_\alpha = -\left[\, (D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \,\right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} x, \quad u_{\bar{\alpha}} = 0, \tag{3.21}$$

where $\bar{\alpha}$ is the complement of α in $\{1, \ldots, m\}$. Notice that the converse is not true; namely, for a given solution $u \in \mathrm{SOL}(Cx, D)$, it is possible for multiple pairs $(\alpha, \mathcal{J})$ in $\mathcal{L}(x)$ to give rise to the same u, via (3.21). Define the set-valued map

$$\mathcal{G}_{CD} : x \mapsto \mathcal{G}_{CD}(x) \equiv \left\{ \begin{pmatrix} -\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}\right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} x \\ 0 \end{pmatrix} : (\alpha, \mathcal{J}) \in \mathcal{L}(x) \right\}.$$

Clearly, $\mathrm{Gr}\ \mathcal{G}_{CD} \subseteq \mathrm{Gr\ SOL}_{CD}$. It is easily seen that $\mathrm{Gr}\ \mathcal{G}_{CD}$ is a cone in $\Re^{n+m}$; subsequently, we will show that it is closed. Like the LCP solution graph, $\mathrm{Gr}\ \mathcal{G}_{CD}$ is not necessarily convex. In general, $\mathrm{Gr}\ \mathcal{G}_{CD}$ is a *proper* subset of $\mathrm{Gr\ SOL}_{CD}$; for instance, if D is a singular matrix, then any positive vector that is a solution of the LCP (Cx, D) is not an element of the former graph. Moreover, due to the finite number of index sets, a positive constant $\rho_G > 0$ exists such that

$$\sup\{\, \| u \| \,:\, u \in \mathcal{G}_{CD}(x) \,\} \le \rho_G \| x \| \quad \forall\, x \in \Re^n. \tag{3.22}$$

For any matrix $W \in \Re^{p\times m}$, define the family

$$\mathcal{T}_W(x) \equiv \left\{ -W_{\bullet\alpha} \left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}\right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} : (\alpha, \mathcal{J}) \in \mathcal{L}(x) \right\},$$

where, by convention, we define $W_{\bullet\alpha}[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}]^{-1}(D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet}$ to be the zero matrix if $\alpha = \emptyset$. In general,

$$\{\, Ex \,:\, E \in \mathcal{T}_W(x)\,\} \subseteq W\mathrm{SOL}(Cx, D)$$

with equality holding if $W\mathrm{SOL}(Cx, D)$ is a singleton. Suppose that $W\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. It then follows that the piecewise linear map $h_W(x) \equiv W\mathrm{SOL}(Cx, D)$ is B-differentiable everywhere on $\Re^n$. Thus the directional derivative $h'_W(x; v)$ of h_W at x along the direction v is well defined and, according to standard theory [49], is an element of the set $\{Ev : E \in \mathcal{A}_W(x)\}$, where $\mathcal{A}_W(x) \equiv \{E : Ex = h_W(x)\}$ is the set of *active pieces* of h_W at x. The following result sharpens this representation of $h'_W(x; v)$ by restricting to the pieces in $\mathcal{T}_W(x)$, which is clearly a subfamily of $\mathcal{A}_W(x)$.

PROPOSITION 3.9. *Let $W \in \Re^{p\times m}$ be such that $W\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. For the piecewise linear function $h_W(x) \equiv W\mathrm{SOL}(Cx, D)$, it holds that $h'_W(x; v) \in \{Ev : E \in \mathcal{T}_W(x)\}$ for all x and v in $\Re^n$.*

Proof. For each $\tau > 0$, $h_W(x+\tau v) = E^\tau(x+\tau v)$, where, for any pair of index sets $(\alpha_\tau, \mathcal{J}_\tau)$ in $\mathcal{L}(x+\tau v)$, $E^\tau \equiv -W_{\bullet\alpha_\tau}[(D_{\mathcal{J}_\tau\alpha_\tau})^T D_{\mathcal{J}_\tau\alpha_\tau}]^{-1}(D_{\mathcal{J}_\tau\alpha_\tau})^T C_{\mathcal{J}_\tau\bullet}$. Thus we have (a) $\alpha_\tau \subseteq \mathcal{J}_\tau$, (b) the columns of $D_{\mathcal{J}_\tau\alpha_\tau}$ are linearly independent, and (c) there exists $u^\tau \in \mathrm{SOL}(C(x+\tau v), D)$ such that $\mathrm{supp}(u^\tau) \subseteq \alpha_\tau$ and $\mathcal{J}_\tau \subseteq \{i : [C(x+\tau v)+Du^\tau]_i = 0\}$. In fact, u^τ is given by (3.21),

$$u^\tau_{\alpha_\tau} = -\left[(D_{\mathcal{J}_\tau\alpha_\tau})^T D_{\mathcal{J}_\tau\alpha_\tau}\right]^{-1}(D_{\mathcal{J}_\tau\alpha_\tau})^T C_{\mathcal{J}_\tau\bullet}(x+\tau v), \quad u^\tau_{\bar\alpha_\tau} = 0,$$

where $\bar\alpha_\tau$ is the complement of α_τ in $\{1, \ldots, m\}$. Let $\{\tau_k\}$ be an arbitrary sequence of positive scalars converging to zero for which there exists a pair $(\alpha_\infty, \mathcal{J}_\infty)$ such that $(\alpha_{\tau_k}, \mathcal{J}_{\tau_k}) = (\alpha_\infty, \mathcal{J}_\infty)$ for all k (there must be at least one such sequence for every pair (x, v) because there are only finitely many pairs of index sets). The corresponding sequence of solutions $\{u^{\tau_k}\}$ converges to a vector, say, u^∞, which must be a solution of the LCP (Cx, D), by the continuity of the latter solution with respect to Cx. Moreover, for all k sufficiently large, we have

$$\mathrm{supp}(u^\infty) \subseteq \mathrm{supp}(u^{\tau_k}) \subseteq \alpha_\infty \subseteq \mathcal{J}_\infty \subseteq \{i : (Cx + Du^\infty)_i = 0\}$$

by a simple limiting argument. Thus the pair $(\alpha_\infty, \mathcal{J}_\infty)$ belongs to $\mathcal{L}(x)$ and $E^{\tau_k} \in \mathcal{T}_W(x)$ for all k sufficiently large. Writing $E^\infty \equiv E^{\tau_k}$ for all such k, we have

$$h_W(x + \tau_k v) - h_W(x) = E^{\tau_k}(x + \tau_k v) - E^\infty x = \tau_k\, E^\infty v,$$

from which we obtain $h'_W(x; v) = E^\infty v$, where $E^\infty \in \mathcal{T}_W(x)$, as desired. ∎

Dealing with a symmetric matrix, the next result completes the proof of Proposition 3.8. For a symmetric $m \times m$ matrix R, define the finite family of symmetric matrices $\widehat{\mathcal{T}}_R(x) \subset \Re^{n\times n}$:

$$\left\{ -(C_{\mathcal{J}\bullet})^T D_{\mathcal{J}\alpha}\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}\right]^{-1} R_{\alpha\alpha}\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}\right]^{-1}(D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} : (\alpha, \mathcal{J}) \in \mathcal{L}(x)\right\}.$$

PROPOSITION 3.10. *Let $R \in \Re^{m\times m}$ be symmetric such that $R\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. For the piecewise quadratic function $\widehat{h}_R(x) \equiv \mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D)$, it holds that*

(a) *$\widehat{h}_R(x) = x^T \widehat{E} x$ for all $\widehat{E} \in \widehat{\mathcal{T}}_R(x)$;*

(b) *$\widehat{h}'_R(x; v) \in \{2x^T \widehat{E} v : \widehat{E} \in \widehat{\mathcal{T}}_R(x)\}$ for all x and v in $\Re^n$.*

Proof. It suffices to prove part (b). As a piecewise quadratic function, the directional derivative $\widehat{h}'_R(x;v)$ exists. For each $\tau > 0$, $\widehat{h}_R(x+\tau v) = (x+\tau v)^T \widehat{E}^\tau (x+\tau v)$, where

$$\widehat{E}^\tau \equiv (C_{\mathcal{J}_\tau \bullet})^T D_{\mathcal{J}_\tau \alpha_\tau} \left[(D_{\mathcal{J}_\tau \alpha_\tau})^T D_{\mathcal{J}_\tau \alpha_\tau} \right]^{-1} R_{\alpha_\tau \alpha_\tau} \left[(D_{\mathcal{J}_\tau \alpha_\tau})^T D_{\mathcal{J}_\tau \alpha_\tau} \right]^{-1} (D_{\mathcal{J}_\tau \alpha_\tau})^T C_{\mathcal{J}_\tau \bullet}$$

for any pair of index sets $(\alpha_\tau, \mathcal{J}_\tau) \in \mathcal{L}(x+\tau v)$. As in the proof of Proposition 3.9, we can take a sequence of positive scalars $\{\tau_k\}$ converging to zero and a fixed pair $(\alpha_\infty, \mathcal{J}_\infty)$ such that $(\alpha_{\tau_k}, \mathcal{J}_{\tau_k}) = (\alpha_\infty, \mathcal{J}_\infty)$ for all k. It is now easy to complete the proof. □

We apply the above results to the singled-valued function:

$$\widehat{V}(x) \equiv V(x, \mathrm{SOL}(Cx, D)) = x^T P x + 2x^T Q \mathrm{SOL}(Cx, D) + \mathrm{SOL}(Cx, D)^T R \mathrm{SOL}(Cx, D),$$

assuming that $Q\mathrm{SOL}(Cx, D)$ and $R\mathrm{SOL}(Cx, D)$ are both singletons for all $x \in \Re^n$. Under this assumption, $\widehat{V}(x) = V(x, \mathcal{G}_{CD}(x))$ is piecewise quadratic and

$$\widehat{V}\,'(x;v) = 2x^T P v + 2v^T Q \mathrm{SOL}(Cx, D) + 2x^T E^Q v + 2x^T \widehat{E}^R v,$$

where $E^Q \equiv -Q_{\bullet\alpha} \left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} \in \mathcal{T}_Q(x)$ and

$$\widehat{E}^R \equiv (\, C_{\mathcal{J}\bullet})^T D_{\mathcal{J}\alpha} \left[(\, D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \right]^{-1} R_{\alpha\alpha} \left[(\, D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \right]^{-1} (\, D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} \in \widehat{\mathcal{T}}_R(x)$$

for some pair $(\alpha, \mathcal{J}) \in \mathcal{L}(x)$; note that we can choose the same pair $(\alpha, \mathcal{J})$ for the directional derivatives of $Q\mathrm{SOL}(Cx, D)$ and $\mathrm{SOL}(Cx, D)^T R\mathrm{SOL}(Cx, D)$ because (cf. the proofs of Propositions 3.9 and 3.10) both derivatives were derived from $\mathrm{SOL}(C(x+\tau v), D)$ corresponding to the same v. Since $Q\mathrm{SOL}(Cx, D) = E^Q x$, we have $\widehat{V}\,'(x;v) = 2x^T[P + E^Q + (E^Q)^T + \widehat{E}^R]v$. Note that the matrix $P + E^Q + (E^Q)^T + \widehat{E}^R$ is symmetric. With $\varphi_{x^0}(t) \equiv \widehat{V}(x(t, x^0))$, we have

$$\begin{aligned} \varphi'_{x^0}(t+) &= \widehat{V}\,'(x(t,x^0); \dot{x}(t,x^0)) \\ &= 2\, x(t,x^0)^T \left[P + E^Q_t + (E^Q_t)^T + \widehat{E}^R_t \right] \left(Ax(t,x^0) + B\mathrm{SOL}(Cx(t,x^0), D) \right), \end{aligned}$$

where the equality in the second line is by a simple substitution, and for each $t > 0$,

$$E^Q_t \equiv -Q_{\bullet\alpha_t} (D_{\alpha_t \mathcal{J}_t} D_{\mathcal{J}_t \alpha_t})^{-1} D_{\alpha_t \mathcal{J}_t} C_{\mathcal{J}_t \bullet} \in \mathcal{T}_Q(x(t, x^0)),$$

and

$$\begin{aligned} \widehat{E}^R_t \equiv (C_{\mathcal{J}_t \bullet})^T D_{\mathcal{J}_t \alpha_t} \left[(D_{\mathcal{J}_t \alpha_t})^T D_{\mathcal{J}_t \alpha_t} \right]^{-1} R_{\alpha_t \alpha_t} \left[(D_{\mathcal{J}_t \alpha_t})^T D_{\mathcal{J}_t \alpha_t} \right]^{-1} \\ \times (D_{\mathcal{J}_t \alpha_t})^T C_{\mathcal{J}_t \bullet} \in \widehat{\mathcal{T}}_R(x(t, x^0)) \end{aligned}$$

for some pair $(\alpha_t, \mathcal{J}_t) \in \mathcal{L}(x(t, x^0))$. Corresponding to any such pair of index sets, letting $z(t, x^0) \equiv (x(t, x^0), u(t, x^0), v(t, x^0))$,

$$\begin{pmatrix} u_{\alpha_t}(t, x^0) \\ u_{\bar{\alpha}_t}(t, x^0) \end{pmatrix} \equiv \begin{pmatrix} -\left[(D_{\mathcal{J}_t \alpha_t})^T D_{\mathcal{J}_t \alpha_t} \right]^{-1} (D_{\mathcal{J}_t \alpha_t})^T C_{\mathcal{J}_t \bullet} x(t, x^0) \\ 0 \end{pmatrix} \in \mathrm{Gr}\mathcal{G}_{CD}(x(t, x^0)),$$

$$\begin{pmatrix} v_{\alpha_t}(t, x^0) \\ v_{\bar{\alpha}_t}(t, x^0) \end{pmatrix} \equiv \begin{pmatrix} -\left[(D_{\mathcal{J}_t \alpha_t})^T D_{\mathcal{J}_t \alpha_t} \right]^{-1} (D_{\mathcal{J}_t \alpha_t})^T C_{\mathcal{J}_t \bullet} (Ax(t, x^0) + B\mathrm{SOL}(Cx(t, x^0), D)) \\ 0 \end{pmatrix},$$

where $\bar{\alpha}_t$ is the complement of α_t in $\{1, \dots, m\}$, we obtain

$$\begin{aligned} Qu(t,x^0) = E_t^Q x(t,x^0), \quad Bu(t,x^0) = B\mathrm{SOL}(Cx(t,x^0),D), \\ x(t,x^0)^T \widehat{E}_t^R (Ax(t,x^0) + B\mathrm{SOL}(Cx(t,x^0),D)) = u(t,x^0)^T Rv(t,x^0), \\ x(t,x^0)^T E_t^Q (Ax(t,x^0) + B\mathrm{SOL}(Cx(t,x^0),D)) = x(t,x^0)^T Qv(t,x^0), \end{aligned}$$

and $\varphi'_{x^0}(t+) = z(t,x^0)^T N z(t,x^0)$, where N is the same matrix defined by (3.6). Note that a constant $\rho_{\widehat{G}} > 0$ exists satisfying

$$\| v(t,x^0) \| \le \rho_{\widehat{G}} \| (x(t,x^0), u(t,x^0)) \| \quad \forall (t,x^0) \in [0,\infty) \times \Re^n. \tag{3.23}$$

Augmenting the map $\mathcal{G}_{CD}$, define

$$\widehat{\mathcal{G}}_{\mathrm{LCS}} : x \mapsto \left\{ \begin{pmatrix} -\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} x \\ 0 \\ -\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha} \right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} (Ax + B\mathrm{SOL}(Cx,D)) \\ 0 \end{pmatrix} : (\alpha, \mathcal{J}) \in \mathcal{L}(x) \right\}.$$

Note that the pair $(u(t,x^0), v(t,x^0))$ defined above belongs to $\widehat{\mathcal{G}}_{\mathrm{LCS}}(x(t,x^0)) \subset \Re^{2m}$. In what follows, we let $z(t,x^0)$ denote any triple in Gr $\widehat{\mathcal{G}}_{\mathrm{LCS}}$ such that $\varphi'_{x^0}(t+) = z(t,x^0)^T N z(t,x^0)$. We next show that the two graphs Gr $\mathcal{G}_{CD}$ and Gr $\widehat{\mathcal{G}}_{\mathrm{LCS}}$ are closed.

PROPOSITION 3.11. *Both maps $\mathcal{G}_{CD}$ and $\widehat{\mathcal{G}}_{\mathrm{LCS}}$ have closed graphs.*

Proof. We prove the claim only for $\widehat{\mathcal{G}}_{\mathrm{LCS}}$. Let $\{x^k\}$ be a sequence converging to x^∞. For each k, let $(\alpha_k, \mathcal{J}_k) \in \mathcal{L}(x^k)$ be such that

$$\lim_{k\to\infty} \begin{pmatrix} -\left[(D_{\mathcal{J}_k\alpha_k})^T D_{\mathcal{J}_k\alpha_k} \right]^{-1} (D_{\mathcal{J}_k\alpha_k})^T C_{\mathcal{J}_k\bullet} x^k \\ 0 \\ -\left[(D_{\mathcal{J}_k\alpha_k})^T D_{\mathcal{J}_k\alpha_k} \right]^{-1} (D_{\mathcal{J}_k\alpha_k})^T C_{\mathcal{J}_k\bullet} (Ax^k + B\mathrm{SOL}(Cx^k,D)) \\ 0 \end{pmatrix}$$

exists. As in the proof of Proposition 3.9, there exist an infinite subset κ of $\{1,2,\dots\}$ and a pair $(\alpha_\infty, \mathcal{J}_\infty) \in \mathcal{L}(x^\infty)$ such that $(\alpha_k, \mathcal{J}_k) = (\alpha_\infty, \mathcal{J}_\infty)$ for all $k \in \kappa$. Since $B\mathrm{SOL}(Cx,D)$ is continuous in x, the displayed limit is therefore equal to

$$\begin{pmatrix} -\left[(D_{\mathcal{J}_\infty\alpha_\infty})^T D_{\mathcal{J}_\infty\alpha_\infty} \right]^{-1} (D_{\mathcal{J}_\infty\alpha_\infty})^T C_{\mathcal{J}_\infty\bullet} x^\infty \\ 0 \\ -\left[(D_{\mathcal{J}_\infty\alpha_\infty})^T D_{\mathcal{J}_\infty\alpha_\infty} \right]^{-1} (D_{\mathcal{J}_\infty\alpha_\infty})^T C_{\mathcal{J}_\infty\bullet} (Ax^\infty + B\mathrm{SOL}(Cx^\infty,D)) \\ 0 \end{pmatrix}.$$

The closedness of the graph Gr $\widehat{\mathcal{G}}_{\mathrm{LCS}}$ follows. ∎

The above discussion makes it clear that the LCS (2.1) is related to a "linear selectionable DI"; see Smirnov [52, section 8.2]. Nevertheless, there are significant differences between the two kinds of systems; such differences therefore dismiss the applicability of the stability results in the cited reference to the LCS. If $x(t)$ is a

solution of (2.1), then $\dot{x}(t) \in \mathcal{A}(x(t))$, where the set-valued map $\mathcal{A} : \Re^n \to \Re^n$ is given by

$$\mathcal{A}(x) \equiv \{(A+E)x : E \in \mathcal{T}_B(x)\},$$

with the family $\mathcal{T}_B(x)$ being finite and dependent on the state. In contrast, in order for the DI $\dot{x}(t) \in \widehat{\mathcal{A}}(x(t))$ to be *linear selectionable*, there must exist a constant convex compact set $\mathcal{M}$ of real $n \times n$ matrices such that $\widehat{\mathcal{A}}(x) \equiv \{Mx : M \in \mathcal{M}\}$. Clearly, there are noticeable differences between the two sets $\mathcal{A}(x)$ and $\widehat{\mathcal{A}}(x)$; for instance, the latter is always convex, whereas the former consists of only finitely many vectors. In fact, linear selectionable DIs are like hybrid systems with "state independent switchings" [23], and the LCS is a hybrid system with state-triggered switchings.

The following result extends Theorem 3.1 to a non-P matrix D. The same proof applies.

THEOREM 3.12. *Suppose that* $B\mathrm{SOL}(Cx, D)$ *is a singleton for all* $x \in \Re^n$. *Assume further matrices* P, Q, *and* R, *with* P *and* R *symmetric, exist such that*

(A1) $Q\mathrm{SOL}(Cx, D)$ *and* $R\mathrm{SOL}(Cx, D)$ *are singletons for all* $x \in \Re^n$;

(A2) M *is strictly copositive on* $\mathrm{Gr}\ \mathcal{G}_{CD}$.

Let $z(t, x^0)$ *denote any triple in* $\mathrm{Gr}\ \widehat{\mathcal{G}}_{\mathrm{LCS}}$ *such that* $\varphi'_{x^0}(t+) = z(t, x^0)^T N z(t, x^0)$. *The following four statements hold for the equilibrium* $x^e = 0$ *of* (2.1).

(a) *If* $-N$ *is copositive on* $\mathrm{Gr}\ \widehat{\mathcal{G}}_{\mathrm{LCS}}$, *then* x^e *is linearly bounded stable.*

(b) *If* $-N$ *is strictly copositive on* $cl\ \mathrm{Gr}\ \widehat{\mathcal{G}}_{\mathrm{LCS}}$, *then* x^e *is exponentially stable.*

(c) *If* $-N$ *is copositive on* $\mathrm{Gr}\ \widehat{\mathcal{G}}_{\mathrm{LCS}}$ *and* (3.8) *holds, then* x^e *is asymptotically stable.*

(d) *If* $-N$ *is copositive-plus on* $\mathrm{Gr}\ \widehat{\mathcal{G}}_{\mathrm{LCS}}$ *and* (3.9) *holds, then* x^e *is asymptotically stable.*

Complementing Corollary 3.4, the next result is a specialization of the above theorem to a passive LCS.

COROLLARY 3.13. *Assume that* $\mathrm{SOL}(Cx, D) \neq \emptyset$ *for all* $x \in \Re^n$ *and that* $(D + D^T)u = 0 \Rightarrow Bu = 0$. *If the quadruple* (A, B, C, D) *is passive with a passifying matrix* K *such that the only vector* x *for which*

$$\begin{bmatrix} A^T K + KA & KB_{\bullet\alpha} - (C_{\alpha\bullet})^T \\ (B_{\bullet\alpha})^T K - C_{\alpha\bullet} & -D_{\alpha\alpha} - (D_{\alpha\alpha})^T \end{bmatrix} \begin{bmatrix} I \\ -\left[(D_{\mathcal{J}\alpha})^T D_{\mathcal{J}\alpha}\right]^{-1} (D_{\mathcal{J}\alpha})^T C_{\mathcal{J}\bullet} \end{bmatrix} x = 0$$

for some pair $(\alpha, \mathcal{J}) \in \mathcal{L}(x)$ *is the zero vector, then* $x^e = 0$ *is an asymptotically stable equilibrium of the LCS* (2.1).

Proof. Since D is positive semidefinite, the assumption $(D + D^T)u = 0 \Rightarrow Bu = 0$ implies that $B\mathrm{SOL}(Cx, D)$ is a singleton for all $x \in \Re^n$. The remaining proof is similar to that of part (b) of Corollary 3.4 and is not repeated. □

4. An inhomogeneous extension. The stability results in the last section can be extended to a "generalized LCS" [38], which has exactly the same structure as the LCS except that the nonnegative orthant is replaced by an arbitrary polyhedral cone and its dual. Such an extension is significant because the generalized LCS is a much broader class of nonsmooth dynamical system than the LCS; for instance, it includes the case of a mixed LCP to be satisfied by the algebraic variable and also the case of more general linear constraints on the latter variable than nonnegativity. The generalized LCS also arises from the approximation of inhomogeneous (cf. Corollary 4.6) and nonlinear systems (see section 5). All the piecewise linearity properties that we

have employed for the LCP have known extensions to the generalized LCP defined over a polyhedral cone. Based on these extended LCP results, we can easily generalize the Lyapunov stability theory to the generalized LCS without difficulty. The reason we have chosen to focus on the LCS is because this is a fundamental system in its own right with important applications in diverse fields.

Instead of presenting the details of the extended stability results, which will not involve significantly new ideas, we present below a Lyapunov stability theory for an inhomogeneous differential affine system, via a reduction to an equivalent homogeneous system. At the end of the section, we introduce a general reduction approach that paves the way to the treatment of differential nonlinear systems that is the topic of section 5.

Consider the following inhomogeneous LCS with D being a P-matrix:

$$\begin{aligned} \dot{x} &= p + Ax + Bu, \\ 0 \le u \perp q + Cx + Du &\ge 0, \\ x(0) &= x^0, \end{aligned} \tag{4.1}$$

where $p \in \Re^n$ and $q \in \Re^m$ are constant vectors and the other matrices are defined in the same way as before. To avoid triviality, we assume throughout that $(p, q) \neq 0$. By the P-property of the matrix D, we deduce that the unique solution $u(x)$ to the LCP $(q + Cx, D)$ is globally Lipschitz continuous in x; hence, for any $x^0 \in \Re^n$, there exists a unique continuously differentiable solution $x(t, x^0)$ for all $t \ge 0$ satisfying $\dot{x} = p + Ax + Bu(x)$ and $x(0) = x^0$. Since the right-hand side of the latter ODE is not positively homogeneous in x, the solution $x(t, \cdot)$ is no longer positively homogeneous in the initial condition. Therefore, the local asymptotic/exponential stability of an equilibrium of (4.1) does not imply its global asymptotic/exponential stability. Such an equilibrium is a vector $x^e \in \Re^n$ such that $0 = p + Ax^e + Bu(x^e)$. In order to analyze the stability of such a vector x^e, let

$$\begin{aligned} \alpha_e &\equiv \{\, i \,:\, u_i^e > 0 = (\, q + Cx^e + Du^e \,)_i \,\}, \\ \beta_e &\equiv \{\, i \,:\, u_i^e = 0 = (\, q + Cx^e + Du^e \,)_i \,\}, \\ \gamma_e &\equiv \{\, i \,:\, u_i^e = 0 < (\, q + Cx^e + Du^e \,)_i \,\} \end{aligned}$$

be the three fundamental index sets corresponding to the pair (x^e, u^e), where $u^e \equiv u(x^e)$ and define the matrices

$$\begin{aligned} \widehat{A} &\equiv A - B_{\bullet\alpha_e}(D_{\alpha_e\alpha_e})^{-1}C_{\alpha_e\bullet}, & \widehat{B}_{\bullet\beta_e} &\equiv B_{\bullet\beta_e} - B_{\bullet\alpha_e}(D_{\alpha_e\alpha_e})^{-1}D_{\alpha_e\beta_e}, \\ \widehat{C}_{\beta_e\bullet} &\equiv C_{\beta_e\bullet} - D_{\beta_e\alpha_e}(D_{\alpha_e\alpha_e})^{-1}C_{\alpha_e\bullet}, & \widehat{D}_{\beta_e\beta_e} &\equiv D_{\beta_e\beta_e} - D_{\beta_e\alpha_e}(D_{\alpha_e\alpha_e})^{-1}D_{\alpha_e\beta_e}. \end{aligned}$$

We say that x^e is an *isolated* zero of the equation $0 = p + Ax + Bu(x)$ if a neighborhood of x^e exists within which x^e is the only zero of the equation. A similar definition applies to the "isolatedness" of the pair (x^e, u^e) in part (b) of the proposition below.

PROPOSITION 4.1. *Let D be a P-matrix. The following three statements are equivalent.*

(a) *x^e is an isolated zero of the equation $0 = p + Ax + Bu(x)$;*

(b) *the pair (x^e, u^e) is an isolated solution of the mixed LCP in the variables $(x, u) \in \Re^{n+m}$:*

$$\begin{aligned} 0 &= p + Ax + Bu, \\ 0 \le u \perp q + Cx + Du &\ge 0; \end{aligned}$$

(c) *the following homogeneous mixed LCP has a unique solution* $(z, v) = (0, 0)$*:*

$$\begin{aligned} 0 &= \widehat{A}z + \widehat{B}_{\bullet\beta_e} v, \\ 0 \le v \perp \widehat{C}_{\beta_e \bullet} z &+ \widehat{D}_{\beta_e\beta_e} v \ge 0. \end{aligned}$$

Any one of the above three conditions is necessary for x^e *to be an asymptotically stable equilibrium of* (4.1).

Proof. (a) $\Leftrightarrow$ (b). Clearly (a) implies (b). The converse holds by the P-property of D.

(b) $\Leftrightarrow$ (c). This follows from [15, Corollary 3.3.9] and the fact that $D_{\alpha_e\alpha_e}$ is nonsingular.

To see that any one of the three conditions (a)–(c) is necessary for x^e to be an asymptotically stable equilibrium of (4.1), assume for the sake of contradiction that there exists a sequence $\{x^k\}$ of zeros of the equation $0 = p + Ax + Bu(x)$ such that $x^k \neq x^e$ for all k and $\lim_{k\to\infty} x^k = x^e$. Each such zero x^k, for k sufficiently large, defines a stationary trajectory $x^k(t, x^k) = x^k$ for all $t \ge 0$ that violates the asymptotic stability of x^e. □

Next we show that the stability (resp., asymptotic/exponential stability) of the equilibrium x^e of the inhomogeneous LCS (4.1) is equivalent to the linearly bounded stability (resp., global asymptotic/exponential stability) of the equilibrium $z = 0$ of the homogeneous LCS

$$\begin{aligned} \dot{z} &= \widehat{A}z + \widehat{B}_{\bullet\beta_e} v, \\ 0 \le v \perp \widehat{C}_{\beta_e \bullet} z &+ \widehat{D}_{\beta_e\beta_e} v \ge 0, \end{aligned} \tag{4.2}$$

which has a C^1 solution trajectory $z(t, z^0)$ for every initial condition $z^0 = z(0)$. Via this equivalence, the results in the previous sections can then be applied to yield sufficient conditions for the respective stability properties to hold for the inhomogeneous LCS (4.1).

PROPOSITION 4.2. *Let* D *be a P-matrix. The equilibrium* x^e *of the LCS* (4.1) *is stable (resp., asymptotically/exponentially stable) if and only if* $z^e = 0$ *is a linearly boundedly stable (resp., global asymptotically/exponentially stable) equilibrium of the homogeneous LCS* (4.2).

Proof. Sufficiency. Suppose that $z^e = 0$ is a linearly boundedly stable equilibrium of the homogeneous LCS (4.2). Hence there exists a constant $\eta > 0$ such that for all solution trajectory $z(t, z^0)$ of (4.2) satisfying $z(0, z^0) = z^0$, it holds that $\|z(t, z^0)\| \le \eta\|z^0\|$ for all $(t, z^0) \in [0, \infty) \times \Re^n$. We need to show that for every $\varepsilon > 0$, a constant $\delta_\varepsilon > 0$ exists such that for all $\|x^0 - x^e\| < \delta_\varepsilon \Rightarrow \limsup_{t\ge 0} \|x(t, x^0) - x^e\| < \varepsilon$. The proof lies in showing that for x^0 sufficiently close to x^e, the trajectory $\widehat{z}(t, z^0) \equiv x(t, x^0) - x^e$, which has $\widehat{z}(0, z^0) = x^0 - x^e \equiv z^0$, is a solution of the homogeneous LCS (4.2). Once the latter claim is established, the stability of x^e follows; so do the asymptotic and exponential stability. To prove the claim, let x^0 be given and let $(z(t, z^0), v(t, z^0))$ be the unique solution trajectory of (4.2) satisfying $z(0, z^0) = z^0$; it suffices to show that for all x^0 sufficiently close to x^e, $\widehat{z}(t, z^0) = z(t, z^0)$ for all $t \ge 0$. We do this by producing a suitable trajectory $\widehat{u}(t, x^0)$ such that the pair $(z(t, z^0) + x^e, \widehat{u}(t, x^0))$ satisfies (4.1); by the uniqueness of the solution to the latter LCS, we then deduce $\widehat{z}(t, z^0) = z(t, z^0)$ for all $t \ge 0$ as desired. In turn, to produce

the $\widehat{u}(t,x^0)$ trajectory, let $\widehat{u}_{\beta_e}(t,x^0) \equiv v(t,z^0)$, $\widehat{u}_{\gamma_e}(t,x^0) \equiv 0$, and

$$\begin{aligned}\widehat{u}_{\alpha_e}(t,x^0) &\equiv -(D_{\alpha_e\alpha_e})^{-1}\left[q_{\alpha_e} + C_{\alpha_e\bullet}(z(t,z^0)+x^e) + D_{\alpha_e\beta_e}\widehat{u}_{\beta_e}(t,x^0)\right] \\ &= u^e_{\alpha_e} - (D_{\alpha_e\alpha_e})^{-1}\left[C_{\alpha_e\bullet}z(t,z^0) + D_{\alpha_e\beta_e}v(t,x^0)\right].\end{aligned}$$

We have

$$\begin{aligned}&q_{\beta_e} + C_{\beta_e\bullet}(z(t,z^0)+x^e) + D_{\beta_e\alpha_e}\widehat{u}_{\alpha_e}(t,x^0) + D_{\beta_e\beta_e}\widehat{u}_{\beta_e}(t,x^0) \\ &\quad = \widehat{C}_{\beta_e\bullet}z(t,z^0) + \widehat{D}_{\beta_e\beta_e}v(t,z^0)\end{aligned}$$

and

$$\begin{aligned}&q_{\gamma_e} + C_{\gamma_e\bullet}(z(t,z^0)+x^e) + D_{\gamma_e\alpha_e}\widehat{u}_{\alpha_e}(t,x^0) + D_{\gamma_e\beta_e}\widehat{u}_{\beta_e}(t,x^0) \\ &\quad = q_{\gamma_e} + C_{\gamma_e\bullet}x^e + D_{\gamma_e\alpha_e}u^e_{\alpha_e} + \widehat{C}_{\gamma_e\bullet}z(t,z^0) + \widehat{D}_{\gamma_e\beta_e}v(t,x^0),\end{aligned}$$

where $\widehat{C}_{\gamma_e\bullet} \equiv C_{\gamma_e\bullet} - D_{\gamma_e\alpha_e}(D_{\alpha_e\alpha_e})^{-1}C_{\alpha_e\bullet}$ and $\widehat{D}_{\gamma_e\beta_e} \equiv D_{\gamma_e\beta_e} - (D_{\alpha_e\alpha_e})^{-1}D_{\alpha_e\beta_e}$. Note that both $u^e_{\alpha_e}$ and $q_{\gamma_e} + C_{\gamma_e\bullet}x^e + D_{\gamma_e\alpha_e}u^e_{\alpha_e}$ are positive. Being the Schur complement of a P-matrix, $\widehat{D}_{\beta_e\beta_e}$ is itself a P-matrix. Hence there exists a constant $L_v > 0$ such that

$$\|\, v(t,z^0)\| \le L_v \,\|\, z(t,z^0)\,\| \;\le\; L_v\,\eta\,\|\, z^0\,\| \quad \forall\, t \ge 0,$$

where the second inequality is by the linearly bounded stability of the equilibrium $z^e = 0$ for the homogeneous LCS (4.2). Consequently, provided that x^0 is sufficiently close to x^e, or equivalently, that z^0 is sufficiently close to the origin, $\widehat{u}_{\alpha_e}(t,x^0)$ and $q_{\gamma_e} + C_{\gamma_e\bullet}(z(t,z^0)+x^e) + D_{\gamma_e\alpha_e}\widehat{u}_{\alpha_e}(t,x^0) + D_{\gamma_e\beta_e}\widehat{u}_{\beta_e}(t,x^0)$ remain positive for all $t \ge 0$. Hence for all such x^0, $\widehat{u}(t,x^0) \in \mathrm{SOL}(q + C(z(t,z^0)+x^e), D)$ for all $t \ge 0$.

Since $0 = p + Ax^e + Bu^e = p + Ax^e + B_{\bullet\alpha_e}u^e_{\alpha_e} = p + Ax^e - B_{\bullet\alpha_e}(D_{\alpha_e\alpha_e})^{-1}C_{\alpha_e\bullet}x^e$, we have

$$\begin{aligned}\frac{d(z(t,z^0)+x^e)}{dt} &= \widehat{A}z(t,z^0) + \widehat{B}v(t,z^0) \\ &= [\,A - B_{\bullet\alpha_e}(\,D_{\alpha_e\alpha_e}\,)^{-1}C_{\alpha_e\bullet}\,]z(t,z^0) \\ &\quad + [\,B_{\bullet\beta_e} - B_{\bullet\alpha_e}(\,D_{\alpha_e\alpha_e}\,)^{-1}D_{\alpha_e\beta_e}\,]v(t,z^0) \\ &= p + A(\,z(t,z^0)+x^e) + B\widehat{u}(t,x^0).\end{aligned}$$

We have therefore verified all the required conditions for the pair $(z(t,z^0)+x^e, \widehat{u}(t,x^0))$ to be a solution of (4.1). This establishes the sufficiency part of the proposition.

Necessity. Suppose that x^e is a stable equilibrium of the LCS (4.1). We may choose $\varepsilon > 0$ sufficiently small such that for all x satisfying $\|x - x^e\| < \varepsilon$, we have $u_{\alpha_e}(x) > 0$ and $(q + Cx + Du(x))_{\gamma_e} > 0$. Corresponding to such an ε, let $\delta_\varepsilon > 0$ be such that $\|x^0 - x^e\| < \delta_\varepsilon \Rightarrow \|x(t,x^0) - x^e\| < \varepsilon$ for all $t \ge 0$. Consequently, for any such x^0, we have $[q + Cx(t,x^0) + Du(x(t,x^0))]_{\alpha_e} = 0$ and $u_{\gamma_e}(x(t,x^0)) = 0$. Since $(q + Cx^e + Du^e)_{\alpha_e} = 0$, we deduce

$$C_{\alpha_e\bullet}(\,x(t,x^0) - x^e) + D_{\alpha_e\alpha_e}(\,u(x(t,x^0)) - u^e\,)_{\alpha_e} + D_{\alpha_e\beta_e}u_{\beta_e}(t,x^0) = 0,$$

which yields

$$(u(x(t,x^0)) - u^e)_{\alpha_e} = -(D_{\alpha_e\alpha_e})^{-1}\left[C_{\alpha_e\bullet}(x(t,x^0) - x^e) + D_{\alpha_e\beta_e}u_{\beta_e}(t,x^0)\right]. \tag{4.3}$$

Substituting this and using $(q + Cx^e + Du^e)_{\beta_e} = 0$, we deduce

$$[\, q + Cx(t, x^0) + Du(x(t, x^0))\,]_{\beta_e} = \widehat{C}_{\beta_e \bullet}(\, x(t, x^0) - x^e) \, + \widehat{D}_{\beta_e \beta_e} u_{\beta_e}(t, x^0).$$

Hence $u_{\beta_e}(t, x^0)$ satisfies

$$0 \, \leq \, u_{\beta_e}(t, x^0) \, \perp \, \widehat{C}_{\beta_e \bullet}(\, x(t, x^0) - x^e) \, + \widehat{D}_{\beta_e \beta_e} u_{\beta_e}(t, x^0) \, \geq \, 0$$

for all $t \geq 0$. Furthermore,

$$\begin{aligned} \frac{d(x(t, x^0) - x^e)}{dt} &= p + Ax(t, x^0) + Bu(x(t, x^0)) \\ &= A(x(t, x^0) - x^e) + B_{\bullet \alpha_e}(u(t, x^0) - u^e)_{\alpha_e} + B_{\bullet \beta_e} u_{\beta_e}(t, x^0) \\ &= \widehat{A}(x(t, x^0) - x^e) + \widehat{B}_{\bullet \beta_e} u_{\beta_e}(t, x^0). \end{aligned}$$

Therefore, by the uniqueness of the solution trajectory to (4.2), we deduce that $z(t, z^0) \equiv x(t, x^0) - x^e$ is the unique solution trajectory satisfying (4.2) and $z(0, z^0) = z^0 \equiv x^0 - x^e$, along with the auxiliary algebraic trajectory $v(t, z^0) \equiv u_{\beta_e}(x(t, x^0))$. Consequently, the stability, and thus the linearly bounded stability, of the equilibrium $z^e = 0$ for (4.2) follows readily; so do the global asymptotic and global exponential stability, provided that the equilibrium x^e is, respectively, asymptotically and exponentially stable for (4.1). □

An interesting special case occurs when x^e is *nondegenerate*; i.e., when the index set β_e is empty. In this case, for all x sufficiently close to x^e, the LCP $(q + Cx, D)$ is equivalent to a system of linear equations. As such, intuitively speaking, the stability of x^e can be established via classical system-theoretic results. A formal statement of this assertion is presented below whose proof follows easily from Proposition 4.2.

COROLLARY 4.3. *Let D be a P-matrix. Suppose that the equilibrium x^e of the LCS* (4.1) *is nondegenerate. The following statements are equivalent.*

(a) *x^e is asymptotically stable;*
(b) *x^e is exponentially stable;*
(c) *the matrix $\widehat{A}$ is negatively stable, i.e., there exists a symmetric positive definite matrix K such that $\widehat{A}^T K + K\widehat{A}$ is negative definite.*

Proof. If x^e is nondegenerate, then the system (4.2) becomes the ODE: $\dot{z} = \widehat{A}z$, whose unique solution is given by $z(t, z^0) = e^{t\widehat{A}} z^0$ for all $t \geq 0$. The conclusion of the corollary now follows from classical linear systems theory and Proposition 4.2. □

The proof of Proposition 4.2 can be significantly simplified, and in fact, the proposition itself can be extended considerably, by exploiting an approximation property of a piecewise affine function. In spite of the generalization discussed below, the proof given above is of interest for several reasons: one, it helps us to understand the generalized result; two, it expresses the reduced homogeneous system (4.2) in a form that enables a direct application of the results in section 3, and three, this reduction argument can be extended to a nonlinear complementarity system.

The following lemma is the cornerstone of the generalization of Proposition 4.2. It extends an obvious global property of affine functions to a local property of piecewise affine functions. For a proof of the lemma, see section 2.2.2 (particularly expression (2.2)) in [49] and [15, Exercise 4.8.10].

LEMMA 4.4 (Scholtes). () *Let $f : \Re^n \to \Re^m$ be a piecewise affine function. For every $x \in \Re^n$, there exists a neighborhood $\mathcal{N}_x$ of x such that $f(y) = f(x) + f'(x; y - x)$ for all $y \in \mathcal{N}_x$.*

Notice that the directional derivative $f'(x;\cdot)$ is a piecewise linear function of the second argument; in particular, it is positively homogeneous. In general, a piecewise affine function is not differentiable. Thus the ODE $\dot{x} = f(x)$ has a nonsmooth right-hand side. The following result is the promised generalization of Proposition 4.2; the proof is essentially an abstraction of that of the cited proposition.

PROPOSITION 4.5. *Let $f : \Re^n \to \Re^n$ be a piecewise affine function with $f(x^e) = 0$. The equilibrium x^e is stable (resp., asymptotically/exponentially stable) for the ODE $\dot{x} = f(x)$ if and only if $z^e = 0$ is a linearly boundedly stable (resp., asymptotically/exponentially stable) equilibrium of the ODE $\dot{z} = f'(x^e; z)$.*

Proof. Since f is piecewise affine on $\Re^n$, it is globally Lipschitz continuous there. Hence the initial-value ODE

$$\dot{x} = f(x), \quad x(0) = x^0 \tag{4.4}$$

has a unique solution $x(t, x^0)$ for all $x^0 \in \Re^n$. The same is true of the ODE

$$\dot{z} = f'(x^e; z), \quad z(0) = z^0 \tag{4.5}$$

for all $z^0 \in \Re^n$. Suppose that x^e is a locally stable equilibrium of the ODE $\dot{x} = f(x)$. Let $\varepsilon > 0$ be such that $f(x) = f'(x^e; x - x^e)$ for all x satisfying $\|x - x^e\| < \varepsilon$. Corresponding to this ε, let $\delta_\varepsilon > 0$ be such that $\|x^0 - x^e\| < \delta_\varepsilon \Rightarrow \|x(t, x^0) - x^e\| < \varepsilon$ for all $t \geq 0$. It follows that $z(t, z^0) \equiv x(t, x^0) - x^e$ is the unique solution trajectory of (4.5) satisfying $z(0, z^0) = z^0 \equiv x^0 - x^e$. Hence $z^e = 0$ is a linearly bounded stable equilibrium of (4.5), by the positive homogeneity of $f'(x^e; \cdot)$. The other assertions of the proposition can be proved similarly. □

Instead of showing how Proposition 4.2 is a special instance of Proposition 4.5, we consider the more general inhomogeneous DAVI,

$$\begin{array}{l} \dot{x} = p + Ax + Bu, \\ u \in \mathrm{SOL}(K, q + Cx, D), \end{array} \tag{4.6}$$

where K is a polyhedron in $\Re^m$. We assume that the pair (K, D) is "coherently oriented" [46, 15]. This condition is necessary and sufficient for the AVI $(K, \widehat{q}, D)$ to have a unique solution for all vectors $\widehat{q} \in \Re^m$; moreover, under this condition, such a solution function is necessarily a piecewise affine function of $\widehat{q}$. Hence, letting $u(x)$ be the unique element of $\mathrm{SOL}(K, q + Cx, D)$, the DAVI (4.6) is equivalent to the ODE with a piecewise affine right-hand side: $\dot{x} = p + Ax + Bu(x)$. (Incidentally, this equivalence remains valid if the coherent orientation of the pair (K, D) is weakened to the condition that $B\mathrm{SOL}(K, q + Cx, D)$ is a singleton for all $x \in \Re^n$; nevertheless this weakening necessitates a modification of the following discussion about the directional derivatives, which becomes much more involved. For simplicity, we continue to assume the coherent orientation condition.) If (K, D) is coherently oriented, then the directional derivative $u'(x; dx)$ of the solution function $u(x)$ along a direction $dx \in \Re^n$ is the unique solution v to the generalized LCP

$$\mathcal{C}(x) \ni v \perp Cdx + Dv \in \mathcal{C}(x)^*,$$

where $\mathcal{C}(x)$ is the "critical cone" of the AVI $(K, q + Cx, D)$ at the solution $u(x)$, and $\mathcal{C}(x)^*$ is the dual of $\mathcal{C}(x)$; specifically, $\mathcal{C}(x) \equiv \mathcal{T}(K; u(x)) \cap (q + Cx + Du(x))^\perp$, where $\mathcal{T}(K; u(x))$ denotes the tangent cone of K at $u(x) \in K$ (as in convex analysis [47]) and the superscript denotes the orthogonal complement. It should be pointed out

that both $\mathcal{C}(x)$ and its dual are polyhedral cones. For details of these results, we refer the reader to [15, Volume I, section 4.3].

Applying Proposition 4.5 to the DAVI (4.6), we obtain the following result, which requires no further proof.

COROLLARY 4.6. *Let K be a polyhedron in $\Re^m$. Suppose that the pair (K, D) is coherently oriented. Let x^e satisfy $0 = p + Ax^e + Bu(x^e)$. The equilibrium x^e of* (4.6) *is stable (resp., asymptotically/exponentially stable) if and only if $z^e = 0$ is a linearly boundedly stable (resp., asymptotically/exponentially stable) equilibrium of the differential complementarity system*

$$\begin{aligned} \dot{z} &= Az + Bv, \\ \mathcal{C}(x^e) \ni v \perp Cz + Dv &\in \mathcal{C}(x^e)^*, \end{aligned} \tag{4.7}$$

where $\mathcal{C}(x^e) \equiv \mathcal{T}(K; u(x^e)) \cap (q + Cx^e + u(x^e))^\perp$. □

As mentioned in the beginning of this section, it is possible to extend the Lyapunov stability results for the LCS to the generalized LCS (4.7). Instead of repeating the derivation, we proceed to the other major topic of this paper, to be addressed in the next section. There, we establish a partial generalization of Proposition 4.2 and Corollary 4.6 that deals with the exponential stability of nonlinear systems; see Propositions 5.7 and 5.10.

5. Exponential stability of nonlinear systems via a converse theorem. So far our development has been restricted to systems with linear structures. In this section, we extend our treatment to nonlinear systems via the so-called *Lyapunov indirect method* of "first-order approximation." The results in this section are of the exponential stability type. Due to the nonsmoothness of the solution function to the LCP/AVI, it seems difficult to develop an asymptotic stability theory for nonlinear systems without relying on exponential stability.

The cornerstone of the extended treatment of nonlinear systems is a converse theorem for the exponential stability of an equilibrium to an ODE with a B-differentiable right-hand side that is not F(réchet)-differentiable. In general, if the right-hand side of the ODE is not F-differentiable, the solution map of the ODE is not a differentiable function of the initial condition; nevertheless, the latter map remains B-differentiable, provided that the right-hand function of the ODE is so. This is formally stated in the following result whose proof can be found in the recent paper [39, Theorem 7].

LEMMA 5.1. *Suppose that for a given $\xi \in \Re^n$, f is B-differentiable in a neighborhood of a solution trajectory $x(t, \xi)$ of the ODE* (4.4) *for $t \in [0, T]$. For each $t \in [0, T]$, the solution map $x(t, \cdot)$ of the ODE* (4.4) *is B-differentiable at ξ; the directional derivative*

$$x'_\xi(t, \xi; \eta) \equiv \lim_{\tau \downarrow 0} \frac{x(t, \xi + \tau\eta) - x(t, \xi)}{\tau}$$

of $x(t, \cdot)$ at ξ along the direction η is the unique solution $y(t)$ to the variational equation $\dot{y}(t) = f'(x(t, \xi); y(t))$, $y(0) = \eta$.

The following result gives a necessary and sufficient condition for an equilibrium of the ODE (4.4) to be exponentially stable in terms of the existence of a nonsmooth Lyapunov function satisfying certain conditions. Since the latter function is not necessarily differentiable, the result does not follow from standard system theory; see, e.g., [28, Chapter 3]. Moreover, whereas the proof is inspired by that of Theorem 3.12 in the cited reference, some details are different as the Lyapunov function is not

continuously differentiable. In particular, conditions (b) and (c) are normally stated in terms of the F-derivatives of V; here they are expressed in terms of directional derivatives.

THEOREM 5.2. *Suppose that f is Lipschitz continuous in a neighborhood $\mathcal{N}_0$ of the origin and that $f(0) = 0$. The following two statements hold.*

(I) *If there exist positive constants $c_1 < c_2$, and c_3, a neighborhood $\mathcal{N} \subseteq \mathcal{N}_0$ of $x^e = 0$, and a Lipschitz continuous and directionally differentiable function V in $\mathcal{N}$ such that*
  (a) $c_1\|x^0\|^2 \leq V(x^0) \leq c_2\|x^0\|^2$ *for all* $x^0 \in \mathcal{N}$,
  (b) $V'(x^0; f(x^0)) \leq -c_3\|x^0\|^2$ *for all* $t \geq 0$ *and all* $x^0 \in \mathcal{N}$,
  then $x^e = 0$ is an exponentially stable equilibrium of the ODE (4.4).

(II) *Conversely, if $x^e = 0$ is an exponentially stable equilibrium of the* ODE (4.4) *and if f is additionally directionally differentiable in $\mathcal{N}_0$, then there exist positive constants c_1, c_2, c_3, and c_4, a neighborhood $\mathcal{N} \subseteq \mathcal{N}_0$ of $x^e = 0$, and a Lipschitz continuous and directionally differentiable function V in $\mathcal{N}$ such that (a), (b), and (c) hold, where*
  (c) $|V'(x^0; z) - V'(x^0; z')| \leq c_4\|x^0\|\|z - z'\|$ *for all* $x^0 \in \mathcal{N}$ *and all* z, z' *in* $\Re^n$.

Proof. Without loss of generality, we take $\mathcal{N}$ to be an open ball centered at the origin and with radius $r > 0$. We claim that under the assumption in (I), by defining the neighborhood

$$\mathcal{N}' \equiv \{\, z \in \Re^n \,:\, \|\, z \,\| \,\leq \sqrt{c_1/c_2}\, r/2 \,\},$$

a unique solution trajectory $x(t, x^0)$ exists satisfying the ODE (4.4) for all $t \geq 0$ and all $x^0 \in \mathcal{N}'$; moreover, $\|x(t, x^0)\| < r/2$ for all such pairs (t, x^0). Notice that the existence and uniqueness of such a trajectory do not follow directly from basic ODE theory because f is assumed to be Lipschitz continuous only in $\mathcal{N}_0$ and not everywhere. Let $x^0 \in \mathcal{N}'$; clearly $\|x^0\| < r/2$ because $c_1 < c_2$. Hence there is a time $t_0 > 0$ such that the trajectory $x(t, x^0)$ exists and is unique for all $t \in [0, t_0]$. We claim that $\|x(t, x^0)\| < r/2$ for all t in the domain of definition of the trajectory. Assume for the sake of contradiction that there exists $\widetilde{t} \in (0, t_0]$ such that $\|x(\widetilde{t}, x^0)\| = r/2$ and that $\|x(t, x^0)\| < r/2$ for all $t \in [0, \widetilde{t}\,)$. For all $\varepsilon > 0$ sufficiently small, we can write

$$\begin{aligned} V(x(\widetilde{t}, x^0)) - V(x^0) = &\int_0^{\widetilde{t}-\varepsilon} V'(x(s, x^0); f(x(s, x^0)))\, ds \\ &+ \int_{\widetilde{t}-\varepsilon}^{\widetilde{t}} V'(x(s, x^0); f(x(s, x^0)))\, ds < 0, \end{aligned}$$

where the first summand in the right-hand side is nonpositive by (b) and the second summand is negative because $\|x(s, x^0)\|$ is near $r/2 > 0$ for all $s \in [\widetilde{t} - \varepsilon, \widetilde{t}]$. Hence,

$$c_1 \,\|\, x(\widetilde{t}, x^0) \,\|^2 \,\leq\, V(x(\widetilde{t}, x^0)) < V(x^0) \,\leq\, c_2 \,\|\, x^0 \,\|^2,$$

which implies $\|x(\widetilde{t}, x^0)\|^2 < r^2/4$, which is a contradiction. Thus, $\|x(t, x^0)\| < r/2$ for all $t \in [0, t_0]$. Let

$$\begin{aligned} t_* \,\equiv\, \sup\{\, \bar{t} \,\geq\, t_0 \,:\;& \text{the trajectory } x(t, x^0) \text{ exists, is unique,} \\ & \text{and satisfies } \|x(t, x^0)\| < r/2 \text{ for all } t \in [\,0, \bar{t}\,]\,\}. \end{aligned}$$

It follows that there exists $\varepsilon > 0$ such that for all $\widetilde{t} \in [0, t_*)$, the trajectory $x(t, x^0)$ can be continued beyond time $\widetilde{t}$ for at least ε duration. Since ε is independent of $\widetilde{t}$, we must have $t_* = \infty$. Hence, the trajectory $x(t, x^0)$ exists, is unique, and remains in $\mathcal{N}$ for all $t \geq 0$. By condition (b), the trajectory $x(t, x^0)$ must satisfy $V'(x(t, x^0); f(x(t, x^0))) \leq -c_3 \|x(t, x^0)\|^2$ for all $t \geq 0$ and all $x^0 \in \mathcal{N}'$. From this point on, we can follow the same line of proof as in Theorem 3.1(b) to complete the proof of the exponential stability of x^e. This establishes part (I) of the theorem.

Conversely, to show (II), let $\mathcal{N} \subseteq \mathcal{N}_0$ be a subneighborhood of the equilibrium such that for some positive constants ν and κ, $\|x(t, x^0)\| \leq \kappa e^{-\nu t} \|x^0\|$ for all $t \geq 0$ and all $x^0 \in \mathcal{N}$ and that $x(t, x^0) \in \mathcal{N}_0$ for all such pairs (t, x^0). Define

$$V(z) \equiv \int_0^T x(\tau, z)^T x(\tau, z)\, d\tau, \quad z \in \mathcal{N},$$

where the upper limit $T > 0$ will be determined later. It is clear that V is Lipschitz continuous in $\mathcal{N}$. To show that V is directionally differentiable, we need to show that the limit

$$\lim_{\tau \downarrow 0} \frac{V(z + \tau h) - V(z)}{\tau}$$

exists for all $h \in \Re^n$. We have

$$V(z + \tau h) - V(z) = \int_0^T \left[\left(x(s, z + \tau h) - x(s, z) \right)^T \left(x(s, z + \tau h) + x(s, z) \right) \right] ds.$$

By the Lipschitz property of $x(\tau, \cdot)$ and the exponential bound of $x(\tau, z)$, it follows by the Lebesgue convergence theorem that we can interchange the integral with the limit as $\tau \downarrow 0$ and obtain

$$\lim_{\tau \downarrow 0} \frac{V(z + \tau h) - V(z)}{\tau} = 2 \int_0^T x'_\xi(s, z; h)^T x(s, z)\, ds,$$

where we have used Lemma 5.1 to justify the well-definedness of the directional derivative $x'_\xi(\tau, z; h)$ (this is where the directional differentiability of f is needed). In particular, we have

$$V'(x^0; f(x^0)) = 2 \int_0^T x'_\xi(s, x^0; f(x^0))^T x(s, x^0)\, ds.$$

By Lemma 5.1, $x'_\xi(s, x^0; f(x^0))$ is the unique function $y(s)$ satisfying $\dot{y}(s) = f'(x(s, x^0); y(s))$ and $y(0) = f(x^0)$. It is easy to verify that the function $y(s) \equiv f(x(s, x^0))$ satisfies the latter initial-value ODE because $\dot{x}(s, x^0) = f(x(s, x^0))$. Hence $x'_\xi(s, x^0; f(x^0)) = f(x(s, x^0))$; thus

$$\begin{aligned} V'(x^0; f(x^0)) &= 2 \int_0^T f(x(\tau, x^0))^T x(\tau, x^0)\, d\tau \\ &= 2 \int_0^T \dot{x}(\tau, x^0)^T x(\tau, x^0)\, d\tau = \left[\| x(T, x^0) \|^2 - \| x^0 \|^2 \right] \\ &\leq -(1 - \kappa^2 e^{-2\nu T}) \| x^0 \|^2. \end{aligned}$$

Choosing $T \equiv (\ln(2\kappa^2))/(2\nu)$, we deduce $V'(x^0; f(x^0)) \leq -\|x^0\|^2/2$. Hence (b) holds with $c_3 \equiv 1/2$. To prove (a), note that

$$V(z) \leq \int_0^T \kappa^2 e^{-2\nu\tau} \| z \|^2 d\tau \leq \frac{\kappa^2}{2\nu} \left(1 - e^{-2\nu T}\right) \| z \|^2.$$

Moreover, letting $L > 0$ be a Lipschitz constant of f in $\mathcal{N}$, and by shrinking $\mathcal{N}$ if necessary, we have $\|x(t, x^0)\| \geq e^{-Lt}\|x^0\|$ for all $(t, x^0) \in [0, \infty) \times \mathcal{N}$. Consequently, we can deduce

$$V(z) \geq \frac{1 - e^{-2LT}}{2L} \| z \|^2 \quad \forall\, z \in \mathcal{N}.$$

Hence (a) holds with appropriate positive constants c_1 and c_2. To prove (c), note that

$$V'(x; z) - V'(x; z') = \lim_{\tau \downarrow 0} \frac{V(x + \tau z) - V(x + \tau z')}{\tau}.$$

Substituting the definition of the function V and taking absolute values, we deduce

$$\begin{aligned} &| V'(x^0; z) - V'(x^0; z') | \\ &\quad \leq \int_0^T \lim_{\tau \downarrow 0} \frac{\| x(s, x^0 + \tau z) - x(s, x^0 + \tau z') \| \, \| x(s, x^0 + \tau z) + x(s, x^0 + \tau z') \|}{\tau} \, ds \\ &\quad \leq c_4 \| z - z' \| \, \| x^0 \| \end{aligned}$$

for some constant $c_4 > 0$, where we have used the Lipschitz continuity of the solution map $x(t, \cdot)$ and the finiteness of the time T. □

We call a B-differentiable function V satisfying conditions (a), (b), and (c) in Theorem 5.2 a *B-differentiable Lyapunov function* for the nonsmooth ODE (4.4) at its equilibrium. An important consequence of Theorem 5.2 is the next perturbation result pertaining to the persistence of the exponential stability property. Notice that while the nominal function f is required to be B- (and thus directionally) differentiable, the perturbed function g is required to be only locally Lipschitz continuous. This observation is important as we see in the subsequent Corollary 5.5 that not requiring the perturbed function g to be directionally differentiable has its benefit.

COROLLARY 5.3. *Let f be Lipschitz continuous and directionally differentiable in a neighborhood $\mathcal{N}_0$ of an equilibrium x^e of f. Suppose that x^e is exponentially stable for the* ODE (4.4). *For every function g such that $g(x^e) = 0$, g is Lipschitz continuous in $\mathcal{N}_0$, and*

$$\lim_{x \to x^e} \frac{f(x) - g(x)}{\| x - x^e \|} = 0; \tag{5.1}$$

x^e is an exponentially stable equilibrium of the ODE*: $\dot{x} = g(x)$.*

Proof. Without loss of generality, we may take $x^e = 0$. Let V be a B-differentiable Lyapunov function for the ODE (4.4). According to part (I) of Theorem 5.2 applied to the function g, it suffices to show that a neighborhood $\mathcal{N}' \subseteq \mathcal{N}$ and a constant $c_3' > 0$ exist such that $V'(x^0; g(x^0)) \leq -c_3'\|x^0\|^2$ for all $x^0 \in \mathcal{N}'$. By properties (b) and (c) of V, we have

$$\begin{aligned} V'(x^0; g(x^0)) &= V'(x^0; f(x^0)) + [\, V'(x^0; g(x^0)) - V'(x^0; f(x^0)) \,] \\ &\leq -c_3 \| x^0 \|^2 + c_4 \| x^0 \| \, \| f(x^0) - g(x^0) \| \\ &= -c_3 \| x^0 \|^2 \left(1 - \frac{c_4}{c_3} \frac{\| f(x^0) - g(x^0) \|}{\| x^0 \|} \right). \end{aligned}$$

By (5.1), the existence of $\mathcal{N}'$ and c_3' with the desired property is clear. □

Remark 5.1. The limit condition (5.1) postulates that f and g are "first-order approximations" of each other near x^e. This condition, along with the directional differentiability of f at x^e, implies that the perturbed function g is directionally differentiable at x^e also, but not necessarily at other points.

We present a consequence of Corollary 5.3 that pertains to the ODE where the right-hand side is a "composite nonsmooth" function of a particular kind. Specifically, let $f(x) \equiv \Phi(x, u(x))$, where $\Phi(x, y)$ is a B-differentiable function of two arguments $(x, y) \in \Re^{n+m}$ and $u(x)$ is a B-differentiable function of x. We first state a lemma pertaining to the B-differentiability of such a function f.

LEMMA 5.4. *Let $\Phi : \Re^{n+m} \to \Re^{\ell}$ be Lipschitz continuous in a neighborhood of $(x^0, y^0) \in \Re^{n+m}$. Suppose that $\Phi(\cdot, y^0)$ and $\Phi(x^0, \cdot)$ are directionally (and thus B-) differentiable at x^0 and y^0, respectively. If*

$$\lim_{(x^0,y^0)\neq(x,y)\to(x^0,y^0)} \frac{\Phi(x,y) - \Phi(x^0,y) - (\,\Phi(\cdot,y^0)\,)'(x^0; x-x^0)}{\|\,x-x^0\,\|} = 0, \tag{5.2}$$

then Φ is directionally (and thus B-) differentiable at (x^0, y^0) and

$$\Phi'((x^0,y^0);(dx,dy)) = (\,\Phi(\cdot,y^0)\,)'(x^0;dx) + (\,\Phi(x^0,\cdot)\,)'(y^0;dy). \tag{5.3}$$

Thus, if $u : \Re^n \to \Re^m$ is B-differentiable at x^0, then so is $f(x) \equiv \Phi(x, u(x))$ and

$$f'(x^0;z) = (\,\Phi(\cdot,u(x^0))\,)'(x^0;z) + (\,\Phi(x^0,\cdot))'(u(x^0);u'(x^0;z)).$$

Proof. The B-differentiability of Φ at (x^0, y^0) and the directional derivative formula (5.3) follow from [45]; see also [15, Exercise 3.7.4]. The B-differentiability of the composite function f and the formula for its directional derivative $f'(x^0; z)$ follow from the chain rule of B-differentiation; see [15, Proposition 3.1.6]. □

Remark 5.2. The limit (5.2) is essential for (5.3) to hold; without the former, the latter need not hold. See [15].

The next result formally establishes the above-mentioned consequence of Corollary 5.3.

COROLLARY 5.5. *Let $u : \Re^n \to \Re^m$ be B-differentiable at $x^e \in \Re^n$ and let $\Phi : \Re^{n+m} \to \Re^n$ be Lipschitz continuous in a neighborhood of $(x^e, u^e) \in \Re^{n+m}$, where $u^e \equiv u(x^e)$ and (x^e, u^e) satisfies $\Phi(x^e, u^e) = 0$. Suppose that $\Phi(\cdot, u^e)$ and $\Phi(x^e, \cdot)$ are directionally differentiable at x^e and u^e, respectively, and that*

$$\lim_{(x^e,u^e)\neq(x,u)\to(x^e,u^e)} \frac{\Phi(x,u) - \Phi(x^e,u) - (\,\Phi(\cdot,u^e)\,)'(x^e; x-x^e)}{\|\,x-x^e\,\|} = 0.$$

If the equilibrium x^e is exponentially stable for the ODE (4.4)*, where $f(x) \equiv \Phi(x, u(x))$, then $z^e = 0$ is an exponentially stable equilibrium of the homogeneous* ODE $\dot{z} = (\Phi(\cdot, u^e))'(x^e; z) + (\Phi(x^e, \cdot))'(u^e; u'(x^e; z))$*. The converse is valid if additionally the right-hand side of the latter* ODE *is directionally differentiable in z.*

Proof. We have

$$\begin{aligned} f(x) = f'(x^e; x-x^e) + e(x) = (\Phi(\cdot,u^e))'(x^e;x-x^e) \\ +(\Phi(x^e,\cdot))'(u^e;u'(x^e;x-x^e)) + e(x), \end{aligned}$$

where $\lim_{x\to x^e} e(x)/\|x-x^e\| = 0$. Since x^e is locally exponentially stable for the ODE (4.4) if and only if $\widetilde{x}^e \equiv 0$ is locally exponentially stable for the ODE $\dot{\widetilde{x}} = f(\widetilde{x} + x^e)$,

and since $f(x^e) = \Phi(x^e, u^e) = 0$, we have

$$\lim_{\widetilde{x}\to 0} [\, f(\widetilde{x} + x^e) - (\, \Phi(\cdot, u^e)\,)'(x^e; \widetilde{x}) + (\, \Phi(x^e, \cdot))'(u^e; u'(x^e; \widetilde{x}))\,]/\| \widetilde{x}\, \| = 0,$$

and since the function $z \mapsto (\Phi(\cdot, u^e))'(x^e; z) + (\Phi(x^e, \cdot))'(u^e; u'(x^e; z))$ is positively homogeneous and Lipschitz continuous, the first assertion of the corollary follows from Corollary 5.3. So does the second. □

We further specialize Corollary 5.5 to the case where Φ is F-differentiable and u is piecewise smooth. Specifically, we say that a function $\Psi : \Re^n \to \Re^m$ is PC^1 (piecewise C^1) near a point $x^0 \in \Re^n$ if there exist a neighborhood $\mathcal{N}$ of x^0 and finitely many C^1 functions $\{f^1, \ldots, f^k\}$ near x^0 for some positive integer k such that $\Psi(x) \in \{f^1(x), \ldots, f^k(x)\}$ for all $x \in \mathcal{N}$. Basic properties of the family of PC^1 functions can be found in [49, 15]. In particular, it is known that a PC^1 function must be B-differentiable. Based on this remark, the result below does not require further proof.

Corollary 5.6. *Let $u : \Re^n \to \Re^m$ be PC^1 near $x^e \in \Re^n$ and let $\Phi : \Re^{n+m} \to \Re^n$ be F-differentiable in a neighborhood of $(x^e, u^e) \in \Re^{n+m}$, where $u^e \equiv u(x^e)$ and (x^e, u^e) satisfies $\Phi(x^e, u^e) = 0$. Let $f(x) \equiv \Phi(x, u(x))$. The following statements are equivalent.*

(a) *x^e is an exponentially stable equilibrium of the* ODE (4.4).

(b) *The* ODE (4.4) *has a B-differentiable Lyapunov function at x^e.*

(c) *$z^e = 0$ is an exponentially stable equilibrium of the* ODE

$$\dot{z} = J_x\Phi(x^e, u^e)z + J_y\Phi(x^e, u^e)u'(x^e; z). \tag{5.4}$$

(d) *The* ODE (5.4) *has a B-differentiable Lyapunov function at the origin.*

It is interesting to compare Corollary 5.6 with Proposition 4.5. The corollary pertains only to exponential stability, whereas the proposition deals with asymptotic stability as well. The difference between the two results is that the former proposition concerns a piecewise linear ODE, whereas the corollary concerns an ODE with a PC^1 right-hand side, for which there is no such exact approximation result as Lemma 4.4.

5.1. Strongly regular DVIs. We wish to apply Corollary 5.6 to the following differential variational inequality (DVI) [38]:

$$\begin{aligned} &\dot{x} = F(x, u), \\ &u \in \mathrm{SOL}(K, H(x, \cdot)), \end{aligned} \tag{5.5}$$

where K is a closed convex set in $\Re^m$ and $F : \Re^{n+m} \to \Re^n$ and $H : \Re^{n+m} \to \Re^m$ are continuously differentiable functions in a neighborhood of a given pair $(x^e, u^e) \in \Re^{n+m}$ that satisfies $F(x^e, u^e) = 0$ and $u^e \in \mathrm{SOL}(K, H(x^e, \cdot))$, with the latter notation meaning that u^e is a solution of the variational inequality (VI) defined by the pair $(K, H(x^e, \cdot))$; i.e., $u^e \in K$ and

$$(\, u - u^e\,)^T H(x^e, u^e) \;\geq\; 0 \quad \forall\, u \in K.$$

The key assumption to be made here is that u^e is a "strongly regular" solution of the VI $(K, H(x^e, \cdot))$. The latter is a well-known property in the theory of finite-dimensional VIs/CPs; it was introduced by Robinson [43]; see also [15]. We have employed this property in several recent studies of the DVI [39, 37] and will use it here as the main setting to facilitate the application of the previous results in the

stability analysis of the given equilibrium pair (x^e, u^e). Notice that we avoid assuming the strong monotonicity of the function $H(x, \cdot)$, which is unnecessarily restrictive in general; see nevertheless the discussion about the functional evolutionary variational inequality (5.8).

Under the strong regularity assumption, it follows that there exist neighborhoods $\mathcal{U}$ of u^e and $\mathcal{V}$ of x^e, and a Lipschitz continuous function $u : \mathcal{V} \to \mathcal{U}$ such that for every $x \in \mathcal{V}$, $u(x)$ is the unique solution of the VI $(K, H(x, \cdot))$ belonging to $\mathcal{U}$ and $u(x^e) = u^e$. Without further restricting the set K, the VI solution map $u(x)$ is not necessarily directionally differentiable; nevertheless, for a large class of closed convex sets K (such as a polyhedron), $u(x)$ is a PC^1 [36] (or a "semismooth" [40]) function near x^e. For these special sets, the DVI (5.5) is therefore, locally near the pair (x^e, u^e), equivalent to an ODE with a composite nonsmooth right-hand side, $\dot{x} = F(x, u(x))$, to which Corollary 5.5 is applicable. Before detailing this application, we make an important remark regarding this approach. Namely, corresponding to a given $x^e \in \Re^n$, there may be multiple vectors u^e satisfying the above-mentioned properties, each of which leads to a particular ODE that could be quite distinct from another. More interestingly, x^e may be exponentially stable with respect to one resulting ODE but not to another. (This is illustrated in Example 5.1.) In other words, the "stability" of x^e is linked to the particular solution of the VI $(K, H(x^e, \cdot))$. For future research, it may be of interest to extend this individual ODE-based stability theory for the nonlinear DVI (5.5) to a broader theory analogous to that for the LCS (2.1) or its affine generalization, the DAVI (4.6), where we have relied on the key assumption that $B\mathrm{SOL}(K, q + Cx, D)$ is a singleton for all $x \in \Re^n$. In such affine cases, in spite of the possible multiplicity of solutions to the AVIs $(K, q+Cx, D)$, the singleton assumption, or equivalently, the assumption of a unique C^1 trajectory $x(t, x^0)$, leads to a unique ODE with a piecewise linear (thus Lipschitz) right-hand side to which Definition 2.3 applies. Incidentally, there are multiple C^1 x-trajectories in the example below.

Example 5.1. Consider the following nonlinear complementarity system (NCS):

$$\begin{aligned} \dot{x} &= x(-1 + 2\sin u), \\ 0 \le u &\perp (x+1)(1 - \sin u) \ge 0, \end{aligned} \tag{5.6}$$

where $x \in \Re$ and $u \in \Re$. It is clear that $x^e = 0$ is an equilibrium. For any $x > -1$, the solutions of the associated nonlinear complementarity problem (NCP) $0 \le u \perp (x+1)(1 - \sin u) \ge 0$ are $u = 0$ and $u = (2k + 1/2)\pi$ for $k \ge 0$. Each of these solutions is strongly regular. The unique solution trajectory to (5.6) that is near the pair $(x^e, u^e) = (0, 0)$ initially is $(x(t, x^0), u(t, x^0)) = (x^0 e^{-t}, 0)$ for all $t \ge 0$. The equilibrium $x^e = 0$ is clearly exponentially stable for the resulting ODE, which is $\dot{x} = -x$. In contrast, the unique solution trajectory to (5.6) that is near the pair $(x^e, \widehat{u}^e) = (0, \pi/2)$ initially is $(x(t, x^0), u(t, x^0)) = (x^0 e^t, \pi/2)$ for all $t \ge 0$. The same equilibrium $x^e = 0$ is clearly *unstable* for the resulting ODE, which is $\dot{x} = x$.

Returning to the general discussion, we fix an implicit VI solution function $u(x)$ as defined above. For simplicity, we focus on the case where K is a polyhedron. It follows that $u(x)$ is a PC^1 function of $x \in \mathcal{V}$. Let $\mathcal{C}(x^e) \equiv \mathcal{T}(K; u(x^e)) \cap H(x^e, u^e)^\perp$ be the critical cone of the linearly constrained VI $(K, H(x^e, \cdot))$. It is known that the directional derivative $u'(x^e; z)$ of the VI solution map $u(x)$ along the direction z is the unique solution v of the generalized LCP:

$$\mathcal{C}(x^e) \ni v \perp J_x H(x^e, u^e) z + J_u H(x^e, u^e) v \in \mathcal{C}(x^e)^*.$$

Based on this characterization of the directional derivative, define the following gen-

eralized LCS that extends (4.7) to the nonlinear case:

$$\begin{aligned} \dot{z} &= J_x F(x^e, u^e) z + J_u F(x^e, u^e) v, \\ \mathcal{C}(x^e) \ni v \perp J_x H(x^e, u^e) z + J_u H(x^e, u^e) v &\in \mathcal{C}(x^e)^*. \end{aligned} \tag{5.7}$$

PROPOSITION 5.7. *Let K be polyhedral and let F and H be C^1 in a neighborhood of the pair (x^e, u^e), where $F(x^e, u^e) = 0$ and u^e is a strongly regular solution of the VI $(K, H(x^e, \cdot))$. Let $\mathcal{V} \times \mathcal{U}$ and $u : \mathcal{V} \to \mathcal{U}$ be, respectively, the neighborhood of (x^e, u^e) and the solution map associated with the strong regularity of u^e. The two statements below are equivalent.*

(a) *x^e is an exponentially stable equilibrium of the ODE: $\dot{x} = F(x, u(x))$.*

(b) *$z^e = 0$ is an exponentially stable equilibrium of the generalized LCS* (5.7).

Proof. This follows readily from Corollary 5.6. □

We illustrate Proposition 5.7 with a *functional evolutionary variational inequality* (FEVI) of the following kind:

$$\dot{x} = \Pi_K(x - \Phi(x)) - x, \tag{5.8}$$

where Π_K denotes the Euclidean projection onto the polyhedron K and Φ is a C^1 function defined on $\Re^n$. The equilibria of this DVI are precisely the solutions of the finite-dimensional VI (K, Φ). Incidentally, there are other dynamical systems whose equilibria are solutions of the VI. The above FEVI is different from the kind of evolutionary variational problems studied in the literature of differential inclusions which rely on a "generalized equation" formulation of the VI; see, e.g., [16]. A distinct advantage of the FEVI (5.8) over the latter kind is that the solution trajectories of (5.8) are all C^1 because the right-hand side is a Lipschitz function of x, whereas those based on the differential inclusion formulation need not be so. In addition, when started at a vector in K, a trajectory of (5.8) will remain in K. The last assertion is established in the result below.

PROPOSITION 5.8. *Let K be a closed convex set and Φ be Lipschitz continuous on K. Let $x(t, x^0)$ denote the unique solution trajectory of* (5.8) *initiated at $x(0) = x^0$. If $x^0 \in K$, then $x(t, x^0) \in K$ for all $t \geq 0$.*

Proof. Considering (5.8) as an ODE with an inhomogeneous right-hand side, we have

$$\begin{aligned} x(t, x^0) &= e^{-t} x^0 + \int_0^t e^{-(t-\tau)} \, \Pi_K\big(x(\tau, x^0) - \Phi(x(\tau, x^0))\big) d\tau \\ &= e^{-t} \, x^0 + (\, 1 - e^{-t} \,) \, \frac{\int_0^t e^{\tau} \, \Pi_K\big(x(\tau, x^0) - \Phi(x(\tau, x^0))\big) \, d\tau}{e^t - 1} \\ &= e^{-t} \, x^0 + (\, 1 - e^{-t} \,) \, \frac{\int_0^t e^{\tau} \, \Pi_K\big(x(\tau, x^0) - \Phi(x(\tau, x^0))\big) \, d\tau}{\int_0^t e^{\tau} \, d\tau}. \end{aligned} \tag{5.9}$$

Since $x(t, x^0)$ is well defined for all t, $\Pi_K\big(x(\tau, x^0) - \Phi(x(\tau, x^0))\big)$ is continuous in τ. Hence, we can represent the integrals in (5.9) by Riemann sums:

$$\begin{aligned} I &\equiv \frac{\int_0^t e^{\tau} \, \Pi_K\big(x(\tau, x^0) - \Phi(x(\tau, x^0))\big) \, d\tau}{\int_0^t e^{\tau} \, d\tau} \\ &= \lim_{k \to \infty} \frac{\sum_{i=1}^k e^{s_i} \, \Pi_K\big(x(s_i, x^0) - \Phi(x(s_i, x^0))\big) \, \frac{t}{k}}{\sum_{i=1}^k e^{s_i} \, \frac{t}{k}}, \end{aligned}$$

where s_i is any point in the subinterval $[\frac{(i-1)}{k}\,t, \frac{i}{k}\,t]$. Since K is a convex set, the vector

$$\left(\sum_{i=1}^{k} e^{s_i}\,\frac{t}{k}\right)^{-1}\left[\sum_{i=1}^{k} e^{s_i}\,\Pi_K\big(x(s_i,x^0)-\Phi(x(s_i,x^0))\big)\,\frac{t}{k}\right],$$

which is a convex combination of vectors in K, belongs to K for all positive integers k. By the closedness of K, it follows that the vector I, and thus $x(t,x^0)$, also belongs to K. □

The system (5.8) is a special DVI with $F(x,u)\equiv u-x$ and $H(x,u)\equiv u-x+\Phi(x)$. Since $H(x,\cdot)$ is strongly monotone, the strong regularity condition holds trivially. Moreover, by the chain rule of B-differentiation, we have, letting $u(x)\equiv\Pi_K(x-\Phi(x))$,

$$u'(x;z)=\Pi_{\mathcal{C}}(z-J\Phi(x)z),$$

where $\mathcal{C}\equiv\mathcal{T}(K;u(x))\cap(u(x)-x+\Phi(x))^{\perp}$ is the critical cone of the polyhedron K at the projected vector $u(x)$; see [15, Chapter 4]. Consequently, the first-order LCS (5.7), which becomes $\dot z=\Pi_{\mathcal{C}}(z-J\Phi(x)z)-z$, is a functional evolutionary version of the finite-dimensional generalized LCP $\mathcal{C}\ni z\perp J\Phi(x)z\in\mathcal{C}^*$ of the same kind as (5.8). Notice that if $x\in\mathrm{SOL}(K,\Phi)$ so that $u(x)=x$, then $\mathcal{C}=\mathcal{T}(K,x)\cap\Phi(x)^{\perp}$ coincides with the critical cone of the VI (K,Φ) at the solution x.

Summarizing the above discussion and invoking Proposition 5.7, we obtain the following result for the FEVI (5.8).

COROLLARY 5.9. *Let K be a polyhedron and let $\Phi:\Re^n\to\Re^n$ be C^1. A solution $x^e\in\mathrm{SOL}(K,\Phi)$ is exponentially stable for the* FEVI (5.8) *if and only if the origin is an exponentially stable equilibrium for the linearized* FEVI*: $\dot z=\Pi_{\mathcal{C}}(z-J\Phi(x^e)z)-z$, where $\mathcal{C}\equiv\mathcal{T}(K;x^e)\cap\Phi(x^e)^{\perp}$.* □

Next, we specialize Proposition 5.7 to the NCS

$$\begin{aligned}\dot x(t)&=F(x(t),u(t)),\\ 0\;\le\;u(t)\;&\perp\;H(x(t),u(t))\;\ge\;0,\end{aligned}\tag{5.10}$$

which is a special case of (5.5) with $K=\Re^m_+$. Let (x^e,u^e) be as specified above. The strong regularity of u^e can be characterized by introducing the three fundamental index sets $(\alpha_e,\beta_e,\gamma_e)$ associated with the pair (x^e,u^e) (cf. the LCS with a P-matrix in section 3):

$$\begin{aligned}\alpha_e&=\{\,i\,:\,u^e_i>0=H_i(x^e,u^e)\,\},\\ \beta_e&=\{\,i\,:\,u^e_i=0=H_i(x^e,u^e)\,\},\\ \gamma_e&=\{\,i\,:\,u^e_i=0<H_i(x^e,u^e)\,\}.\end{aligned}$$

According to these sets, we can partition the (partial) Jacobian matrix $J_uH(x^e,u^e)$ as follows:

$$J_uH(x^e,u^e)\;\equiv\;\begin{bmatrix} J_{u_{\alpha_e}}H_{\alpha_e}(x^e,u^e) & J_{u_{\beta_e}}H_{\alpha_e}(x^e,u^e) & J_{u_{\gamma_e}}H_{\alpha_e}(x^e,u^e)\\ J_{u_{\alpha_e}}H_{\beta_e}(x^e,u^e) & J_{u_{\beta_e}}H_{\beta_e}(x^e,u^e) & J_{u_{\gamma_e}}H_{\beta_e}(x^e,u^e)\\ J_{u_{\alpha_e}}H_{\gamma_e}(x^e,u^e) & J_{u_{\beta_e}}H_{\gamma_e}(x^e,u^e) & J_{u_{\gamma_e}}H_{\gamma_e}(x^e,u^e)\end{bmatrix},$$

where $J_{u_\alpha}H_\beta$ denotes the matrix of partial derivatives $[\partial H_j/\partial u_i]_{(i,j)\in\alpha\times\beta}$. It is known that u^e is a strongly regular solution of the NCP

$$0\;\le\;u\;\perp\;H(x^e,u)\;\ge\;0\tag{5.11}$$

if and only if (a) the principal submatrix $J_{u_{\alpha_e}} H_{\alpha_e}(x^e, u^e)$ is nonsingular, and (b) the Schur complement

(5.12)
$$\widehat{D}_{\beta_e\beta_e} \equiv J_{u_{\beta_e}} H_{\beta_e}(x^e, u^e) - J_{u_{\alpha_e}} H_{\beta_e}(x^e, u^e) \left[J_{u_{\alpha_e}} H_{\alpha_e}(x^e, u^e) \right]^{-1} J_{u_{\beta_e}} H_{\alpha_e}(x^e, u^e)$$

is a P-matrix. Moreover, for every $z \in \Re^n$, the directional derivative $u'(x^e; z)$ is the unique vector $\widehat{u}$ satisfying $\widehat{u}_{\gamma_e} = 0$ and

$$\begin{aligned} J_x H_{\alpha_e}(x^e, u^e) z + J_{\alpha_e} H_{\alpha_e}(x^e, u^e) \widehat{u}_{\alpha_e} + J_{\alpha_e} H_{\beta_e}(x^e, u^e) \widehat{u}_{\beta_e} = 0, \\ 0 \le \widehat{u}_{\beta_e} \perp J_x H_{\beta_e}(x^e, u^e) z + J_{\beta_e} H_{\alpha_e}(x^e, u^e) \widehat{u}_{\alpha_e} + J_{\beta_e} H_{\beta_e}(x^e, u^e) \widehat{u}_{\beta_e} \ge 0, \end{aligned}$$

which, by the nonsingularity of $J_{\alpha_e} H_{\alpha_e}(x^e, u^e)$, is equivalent to the standard LCP

$$0 \le \widehat{u}_{\beta_e} \perp \widehat{C}_{\beta_e \bullet} z + \widehat{D}_{\beta_e\beta_e} \widehat{u}_{\beta_e} \ge 0,$$

where $\widehat{C}_{\beta_e \bullet} \equiv J_x H_{\beta_e}(x^e, u^e) - J_{u_{\alpha_e}} H_{\beta_e}(x^e, u^e) [J_{u_{\alpha_e}} H_{\alpha_e}(x^e, u^e)]^{-1} J_x H_{\alpha_e}(x^e, u^e)$. Define the matrices

$$\begin{aligned} \widehat{A} &\equiv J_x F(x^e, u^e) - J_{u_{\alpha_e}} F(x^e, u^e) [J_{u_{\alpha_e}} H_{\alpha_e}(x^e, u^e)]^{-1} J_x H_{\alpha_e}(x^e, u^e), \\ \widehat{B}_{\bullet\beta_e} &\equiv J_{u_{\beta_e}} F(x^e, u^e) - J_{u_{\alpha_e}} F(x^e, u^e) [J_{u_{\alpha_e}} H_{\alpha_e}(x^e, u^e)]^{-1} J_{u_{\beta_e}} H_{\alpha_e}(x^e, u^e); \end{aligned}$$

consider the homogeneous LCS where the algebraic variable involves only the β_e-components:

(5.13)
$$\begin{aligned} \dot{z} &= \widehat{A} z + \widehat{B}_{\bullet\beta_e} \widehat{u}_{\beta_e}, \\ 0 \le \widehat{u}_{\beta_e} &\perp \widehat{C}_{\beta_e \bullet} z + \widehat{D}_{\beta_e\beta_e} \widehat{u}_{\beta_e} \ge 0. \end{aligned}$$

The results in section 3 can surely be applied to (5.13) to yield sufficient conditions for statement (b) of the following proposition to hold, whose proof follows readily from Proposition 5.7.

PROPOSITION 5.10. *Let F and H be C^1 in a neighborhood of the pair (x^e, u^e), where $F(x^e, u^e) = 0$ and u^e is a strongly regular solution of the* NCP (5.11). *Let $\mathcal{V} \times \mathcal{U}$ and $u : \mathcal{V} \to \mathcal{U}$ be, respectively, the neighborhood of (x^e, u^e) and the solution map associated with the strong regularity of u^e. The following two statements are equivalent.*

(a) *x^e is an exponentially stable equilibrium of the* ODE $\dot{x} = F(x, u(x))$.

(b) *$z^e = 0$ is an exponentially stable equilibrium of the homogeneous* LCS (5.13).

6. Concluding remarks. Based on the combined tools of contemporary finite dimensional LCPs and VIs/CPs and classical Lyapunov stability theory for smooth dynamical systems, we have obtained many stability results for the LCS and its nonlinear generalizations. Part of the novelty of our analysis is the employment of a nontraditional Lyapunov function in both the system state and the auxiliary algebraic variable, which leads to a nondifferentiable Lyapunov function of the state alone. We speculate that this approach might be useful in other contexts, such as in the convergence analysis of iterative algorithms for solving finite-dimensional variational and optimization problems.

The results in this paper have left open some questions that are worthy of further investigation. Foremost among these is the question of whether asymptotic stability

would imply exponential stability for an LCS satisfying the P-property. In this vein, we recall [52, Lemma 8.2] which establishes such an implication for a linear selectionable DI. Yet, as we have noted a few times, the DI result is not applicable to the LCS. Nevertheless, the same implication may be valid for the LCS. Another interesting question is the persistence of asymptotic stability of a B-differentiable differential system under small perturbations; related to the latter question is whether there are analogues of the results in subsection 5.1 for asymptotic stability. Finally, the authors in [16] have established a very interesting necessary degree-theoretic condition for the asymptotic stability of an evolutionary variational inequality. We feel that a further degree-theoretic exploration of the LCS and the DVI is warranted.

Acknowledgment. We are grateful to two referees who have offered many constructive comments that have significantly improved the presentation of the paper.

SPASELOC: AN ADAPTIVE SUBPROBLEM ALGORITHM FOR SCALABLE WIRELESS SENSOR NETWORK LOCALIZATION*

MICHAEL W. CARTER†, HOLLY H. JIN‡, MICHAEL A. SAUNDERS§, AND YINYU YE§

Abstract. An adaptive rule-based algorithm, SpaseLoc, is described to solve localization problems for ad hoc wireless sensor networks. A large problem is solved as a sequence of very small subproblems, each of which is solved by semidefinite programming relaxation of a geometric optimization model. The subproblems are generated according to a set of sensor/anchor selection rules. Computational results compared with existing approaches show that the SpaseLoc algorithm scales well and provides excellent localization accuracy.

Key words. sensor localization, semidefinite programming, large-scale optimization

AMS subject classifications. 49M37, 65K05, 90C30

DOI. 10.1137/040621600

1. Introduction.

Ad hoc wireless sensor networks may contain hundreds or even tens of thousands of inexpensive devices (sensors) that can communicate with their neighbors within a limited radio range. By relaying information to each other, they can transmit signals to a command post anywhere within the network. They have many practical uses in areas such as military applications [15], environment or industrial control and monitoring [7, 9], wildlife monitoring [24], and security monitoring [15]. For example, Southern California Edison's Nuclear Generating Station in San Onofre, CA, has deployed wireless mesh networked sensors from Dust Networks, Inc. to obtain real-time trend data [9]. These data are used to predict which motors are about to fail, so they could be preemptively rebuilt or replaced during scheduled maintenance periods. The use of a wireless sensor network saves the station money and avoids potential machine shutdown. Implementation of a sensor localization algorithm would provide a service that eliminates the need to record every sensor's location and its associated ID number in the network.

Wireless sensor networks are potentially important enablers for many other advanced applications. A huge variety of applications lie ahead. By 2008, there could be 100 million wireless sensors in use, up from about 200,000 in 2005, according to the market-research company Harbor Research. The worldwide market for wireless sensors, it says, will grow from $100 million in 2005 to more than $1 billion by 2009 [18]. This is motivating great effort in academia and industry to explore effective ways to build sensor networks with feature-rich services [12].

One of the important inputs these services build upon is the exact locations of all sensors in the network. The need for *sensor localization* arises because accurate

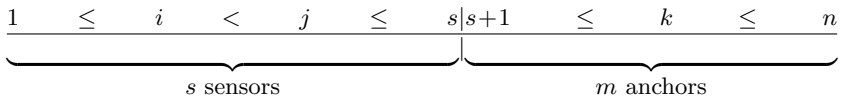

FIG. 1.1. *Indexing of sensors and anchors.*

locations are known for only some of the sensors (which are called *anchors*). If the networks are to achieve their purpose, the locations of the remaining sensors must be determined. One approach to localizing these sensors with unknown locations is to use known anchor locations and distance measurements that neighboring sensors and anchors obtain among themselves. The mathematical problem is to *estimate* all sensors' locations using a sparse data matrix of noisy distance measurements. This leads to a large, nonconvex, constrained optimization problem. Large networks may contain many thousands of sensors, whose locations should be determined accurately and quickly.

1.1. Problem definition. Sensor localization for ad hoc wireless sensor networks aims to find the locations of all sensors in the network, given pairwise distance measurements among some of the sensors and known locations of some of the sensors. The sensors with known locations are called *anchors*. From now on, *sensor* generally means *unlocalized sensor*, excluding anchors. A *node* is any sensor or anchor.

We use a constrained optimization approach to estimate the sensors' locations. The following input, output, and objectives are considered.

Input

Total points: n, the total number of nodes in the network.

Unknown points: s sensors, whose locations $x_i \in \mathcal{R}^2$, $i = 1, \ldots, s$, are to be determined. (We assume the points are on a plane here, but the approach is extended to three dimensions in Jin's thesis [14].)

Known points: m anchors, whose locations $a_k \in \mathcal{R}^2$, $k = s+1, \ldots, n$, are known. (Note that we put anchors at the end of the total points' list without loss of generality, and that $n = s + m$. Index k is specific for indexing anchors. Refer to Figure 1.1 for node indexing.)

Known distance measurements: The nonzero elements of a sparse matrix $\widehat{d}$ containing the readings of certain ranging devices for estimating the distance between two points. $\widehat{d}_{ij}$ is the distance measurement between two sensors x_i and x_j $(i < j \leq s)$, and $\widehat{d}_{ik}$ is the distance measurement between some sensor x_i and anchor a_k $(i \leq s < k)$. The distance measurements are constant data and generally have errors.

Output

Locations: Estimated locations x_i for s sensors.

Objectives

Accuracy: Minimal errors in the estimated sensor locations.

Speed: Fast enough for real-time applications (e.g., networks with moving sensors).

Scalability: Suitable for large-scale deployment (with tens of thousands of nodes).

1.2. Notation. The Euclidean distance between two vectors v and w is defined to be $\|v - w\|$, where $\|\cdot\|$ always means the 2-norm. Nodes are said to be *connected* if the associated measurements $\widehat{d}_{ij}$ or $\widehat{d}_{ik}$ exist. The remaining elements of $\widehat{d}$ are zero.

If a measurement does exist between node i and j but it is zero (i and j are at the same spot), we do not set $\widehat{d}_{ij}$ to zero: we set it to machine precision ϵ instead to distinguish from the case of $\widehat{d}_{ij} = 0$ when two nodes' distance is beyond the sensor device's measuring range.

1.3. Related research work. Sensor localization in ad hoc wireless networks has been a booming research area recently. Hightower and Boriello [12] give an extensive review of the area and available methods. There are many ways to solve the localization problem [6, 8, 10, 13, 17, 19, 20, 21, 22], with two main ones based on triangulation and optimization.

Triangulation methods estimate node locations based on distance measurements between neighboring nodes, and some algorithms use iterative steps to localize all sensors.

Early work using optimization techniques is reported by Doherty, El Ghaoui, and Pister [8]. Ideally the Euclidean distance between neighboring nodes should be fitted in some near-equality sense to the distance measurements:

$$\|x_i - x_j\| \approx \widehat{d}_{ij} \quad \text{and} \quad \|x_i - a_k\| \approx \widehat{d}_{ik}. \tag{1.1}$$

Doherty, El Ghaoui, and Pister formulate a convex optimization model by treating the constraints as $\|x_i - x_j\| \le \widehat{d}_{ij}$ and $\|x_i - a_k\| \le \widehat{d}_{ik}$, and by including certain other convex constraints. This formulation takes advantage of available optimization algorithms, including those for convex optimization. However, the method needs sufficient anchors to be on the boundary of the localization area for it to work effectively.

Biswas and Ye [2] work with the near-equality constraints (1.1), and more importantly introduced a semidefinite programming (SDP) relaxation method in order to retain the benefits of convex optimization. They report that their method yields more accuracy than the approach in [8].

The SDP relaxation approach can solve small problems effectively. The paper [2] reports a few seconds of laptop execution time for a 50-node localization problem. However, the number of constraints in the SDP model is $O(n^2)$, where n is the number of nodes in the network. Even a few-hundred-node problem leads to excessive memory and computation time by available SDP solvers such as DSDP (Benson, Ye, and Zhang [1]) and SeDuMi (Sturm [23]). These solvers are effective for SDP problems with dimension and number of constraints up to a few thousand.

Tseng [25] has presented a second-order cone programming (SOCP) relaxation model that permits solution for problem sizes up to a few thousand using available SOCP solvers. However, the additional relaxation of the original model usually generates larger error rates, and the run-times are high. The author reports CPU times of 330 seconds for 1000 nodes and 3 hours for 2000 nodes using SeDuMi 1.05 [23] and MATLAB 6.1 on a Linux PC.

Biswas and Ye [3] propose a decomposition scheme to overcome the scalability issue with SDP solvers. The anchors in the network are first partitioned into many clusters according to their physical locations, and sensors are assigned to these clusters if they have a direct connection to one of the anchors. Each cluster formulates a subproblem, and the subproblems are solved *independently* on each cluster using the SDP relaxation of [2]. The paper reports results for randomly generated sensor networks of 4000 sensors partitioned into 100 clusters strictly according to their geographic locations. Sensors with distance connections to more than one cluster are included in multiple clusters. The final estimation of their locations is determined

by the cluster that gives the least estimated errors. An execution time of about 4 minutes on a 1.2GHz Pentium laptop is reported for a problem of this size. Thus, the decomposition approach makes large-scale sensor network localization possible on a single processor. The further advantage is that multiple CPUs can be used in a natural way.

1.4. SpaseLoc. A basic tool that we have developed during this research is a rule-based iterative algorithm named SpaseLoc (**s**ub**p**roblem **a**lgorithm for **se**nsor **loc**alization). It is effective for networks involving tens of thousands of sensors and beyond, using a single CPU.

To solve a large localization problem (defined as the *full_problem*), SpaseLoc proceeds iteratively by estimating only a portion of the total sensors' locations at each iteration. Some anchors and sensors are chosen according to a set of rules. They form a sensor localization *subproblem* that can be treated similarly to the basic SDP formulation of Biswas and Ye [2]. The solution from the subproblem is fed back to the *full_problem* and the algorithm iterates again until all sensors are localized.

Computational results show that SpaseLoc can solve small or large problems with excellent accuracy and scalability. It is capable of localizing 4000 nodes with great accuracy in under 20 seconds, and 10000 nodes in under a minute on a 2.4 GHz laptop.

2. The subproblem SDP model. This section reviews the quadratic programming formulation of the sensor localization problem and the SDP relaxation model of Biswas and Ye [2] that the SpaseLoc subproblem is based on. Error analysis is also reviewed here as a reference for later sections.

2.1. Euclidean distance model. Consider a network of sensors and anchors labeled as in Figure 1.1. For any point in the network, there could be three types of distance measurements. Since we generally do not need the distance information between two anchor points, we exclude this type of measurement from now on.

The other types of distance measurements are the two we need for the localization model. First is the distance measurement between two sensors (i and j) with unknown locations; second is the distance measurement between a sensor (i) and an anchor (k) with known location. Corresponding to these two types of distances, we define sets N_1, $\overline{N}_1$, N_2, and $\overline{N}_2$ as follows:

- N_1 includes pairwise sensors (i, j) if $i < j$ and there exists a distance measurement $\widehat{d}_{ij}$:
$$N_1 = \{(i, j) \text{ with known } \widehat{d}_{ij} \text{ and } i < j\}.$$
- $\overline{N}_1$ includes pairwise sensors (i, j) with unknown measurement $\widehat{d}_{ij}$ and $i < j$:
$$\overline{N}_1 = \{(i, j) \text{ with unknown } \widehat{d}_{ij} \text{ and } i < j\}.$$
- N_2 includes pairs of sensor i and anchor k if there exists a measurement $\widehat{d}_{ik}$:
$$N_2 = \{(i, k) \text{ with known } \widehat{d}_{ik}\}.$$
- $\overline{N}_2$ includes pairs of sensor i and anchor k with unknown measurement $\widehat{d}_{ik}$:
$$\overline{N}_2 = \{(i, k) \text{ with unknown } \widehat{d}_{ik}\}.$$

The full set of nodes and pairwise distance measurements form a graph $G = \{V, E\}$, where $V = \{1, 2, \ldots, s, s + 1, \ldots, n\}$ and $E = N_1 \cup N_2$.

Introduce α_{ij} to be the difference between the measured squared distance $(\widehat{d}_{ij})^2$ and the squared Euclidean distance $\|x_i - x_j\|^2$ from sensor i to sensor j. Also, let α_{ik} be the difference between the measured squared distance $(\widehat{d}_{ik})^2$ and the squared Euclidean distance $\|x_i - a_k\|^2$ from sensor i to anchor k. Intuitively, we seek a solution for which the magnitude of these differences is small.

Lower bounds r_{ij} or r_{ik} are imposed if $(i,j) \in \overline{N}_1$ or if $(i,k) \in \overline{N}_2$. Typically each r_{ij} or r_{ik} value is the radio range (also known as *radius*) within which the associated sensors can detect each other.

Biswas and Ye [2] formulate the sensor localization problem as minimizing the ℓ_1-norm of the squared-distance errors α_{ij} and α_{ik} subject to mixed equality and inequality constraints:

$$
\begin{aligned}
\underset{x_i, x_j, \alpha_{ij}, \alpha_{ik}}{\text{minimize}} \quad & \sum_{(i,j)\in N_1} |\alpha_{ij}| \; + \sum_{(i,k)\in N_2} |\alpha_{ik}| \\
\text{subject to} \quad & \|x_i - x_j\|^2 - \alpha_{ij} = (\widehat{d}_{ij})^2 \quad \forall\ (i,j) \in N_1, \\
& \|x_i - a_k\|^2 - \alpha_{ik} = (\widehat{d}_{ik})^2 \quad \forall\ (i,k) \in N_2, \\
& \|x_i - x_j\|^2 \qquad\ \geq r_{ij}^2 \qquad \forall\ (i,j) \in \overline{N}_1, \\
& \|x_i - a_k\|^2 \qquad\ \geq r_{ik}^2 \qquad \forall\ (i,k) \in \overline{N}_2, \\
& x_i,\ x_j \in \mathcal{R}^2, \qquad \alpha_{ij},\ \alpha_{ik} \in \mathcal{R}, \\
& i,j = 1,\ldots,s, \qquad k = s+1,\ldots,n.
\end{aligned}
\tag{2.1}
$$

The above model is a nonconvex constrained optimization problem. As yet there is no effective solution method. In the following subsections, we review Biswas and Ye's [2] relaxation method for solving this problem approximately.

2.2. The Euclidean distance model in matrix form. The distance model (2.1) is reformulated into (2.2) (refer to Biswas and Ye [2]) by introducing matrix variables as follows:

$$
\begin{aligned}
\text{minimize} \quad & \sum_{(i,j)\in N_1} (\alpha_{ij}^+ + \alpha_{ij}^-) \; + \sum_{(i,k)\in N_2} (\alpha_{ik}^+ + \alpha_{ik}^-) \\
\text{subject to} \quad & e_{ij}^T\ Y\ e_{ij} - \alpha_{ij}^+ + \alpha_{ij}^- = (\widehat{d}_{ij})^2 \quad \forall\ (i,j) \in N_1, \\
& \begin{pmatrix} e_i \\ -a_k \end{pmatrix}^T \begin{pmatrix} Y & X^T \\ X & I \end{pmatrix} \begin{pmatrix} e_i \\ -a_k \end{pmatrix} - \alpha_{ik}^+ + \alpha_{ik}^- = (\widehat{d}_{ik})^2 \quad \forall\ (i,k) \in N_2, \\
& e_{ij}^T\ Y\ e_{ij} \geq r_{ij}^2 \qquad \forall\ (i,j) \in \overline{N}_1, \\
& \begin{pmatrix} e_i \\ -a_k \end{pmatrix}^T \begin{pmatrix} Y & X^T \\ X & I \end{pmatrix} \begin{pmatrix} e_i \\ -a_k \end{pmatrix} \geq r_{ik}^2 \qquad \forall\ (i,k) \in \overline{N}_2, \\
& Y = X^T X, \\
& \alpha_{ij}^+,\ \alpha_{ij}^-,\ \alpha_{ik}^+,\ \alpha_{ik}^- \geq 0, \\
& i,j = 1,\ldots,s, \quad k = s+1,\ldots,n,
\end{aligned}
\tag{2.2}
$$

where

- $X = (x_1\ x_2\ \ldots\ x_s)$ is a $2 \times s$ matrix to be determined;
- e_{ij} is a zero column vector except for 1 in location i and -1 in location j, so that

$$\|x_i - x_j\|^2 = e_{ij}^T\ X^T X\ e_{ij};$$

- e_i is a zero column vector except for 1 in position i, so that
$$\|x_i - a_k\|^2 = \begin{pmatrix} e_i \\ -a_k \end{pmatrix}^T \begin{pmatrix} X & I \end{pmatrix}^T \begin{pmatrix} X & I \end{pmatrix} \begin{pmatrix} e_i \\ -a_k \end{pmatrix};$$
- Y is defined to be X^TX;
- The substitutions $\alpha_{ij} = \alpha_{ij}^+ - \alpha_{ij}^-$ and $\alpha_{ik} = \alpha_{ik}^+ - \alpha_{ik}^-$ are made to deal with $|\alpha_{ij}|$ and $|\alpha_{ik}|$ in the normal way.

2.3. The SDP relaxation model. The approach of Biswas and Ye [2] is to relax the constraint $Y = X^TX$ to be $Y \succeq X^TX$, for which an equivalent matrix inequality is (Boyd et al. [5])

$$Z_I \equiv \begin{pmatrix} Y & X^T \\ X & I \end{pmatrix} \succeq 0. \tag{2.3}$$

With the definitions

$$A_I = \begin{pmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} \\ 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}, \qquad b_I = \begin{pmatrix} 1 \\ 1 \\ 2 \end{pmatrix},$$

where $\mathbf{0}$ in A_I is a zero column vector of dimension s, problem (2.2) is relaxed to a linear SDP:

$$\begin{aligned}
\text{minimize} \quad & \sum_{(i,j)\in N_1} (\alpha_{ij}^+ + \alpha_{ij}^-) \ + \sum_{(i,k)\in N_2} (\alpha_{ik}^+ + \alpha_{ik}^-) \\
\text{subject to} \quad & \operatorname{diag}(A_I^T \ Z \ A_I) = b_I, \\
& \begin{pmatrix} e_{ij} \\ \mathbf{0} \end{pmatrix}^T Z \begin{pmatrix} e_{ij} \\ \mathbf{0} \end{pmatrix} - \alpha_{ij}^+ + \alpha_{ij}^- = (\widehat{d}_{ij})^2 \quad \forall\ (i,j) \in N_1, \\
& \begin{pmatrix} e_i \\ -a_k \end{pmatrix}^T Z \begin{pmatrix} e_i \\ -a_k \end{pmatrix} - \alpha_{ik}^+ + \alpha_{ik}^- = (\widehat{d}_{ik})^2 \quad \forall\ (i,k) \in N_2, \\
& \begin{pmatrix} e_{ij} \\ \mathbf{0} \end{pmatrix}^T Z \begin{pmatrix} e_{ij} \\ \mathbf{0} \end{pmatrix} \geq r_{ij}^2 \qquad \forall\ (i,j) \in \overline{N}_1, \\
& \begin{pmatrix} e_i \\ -a_k \end{pmatrix}^T Z \begin{pmatrix} e_i \\ -a_k \end{pmatrix} \geq r_{ik}^2 \qquad \forall\ (i,k) \in \overline{N}_2, \\
& Z \succeq 0, \qquad \alpha_{ij}^+,\ \alpha_{ij}^-,\ \alpha_{ik}^+,\ \alpha_{ik}^- \geq 0, \\
& \qquad\qquad i,j = 1,\dots,s, \quad k = s+1,\dots,n,
\end{aligned} \tag{2.4}$$

where the constraint $\operatorname{diag}(A_I^T Z A_I) = b_I$ ensures that the matrix variable Z's lower right corner is a 2×2 identity matrix I, so that Z takes the form of Z_I in (2.3).

Initially, Biswas and Ye [2, 3] omit the $\geq$ inequalities involving r_{ij} and r_{ik} and solve the resulting problem to obtain an initial solution Z_1. (The inequality constraints increase the problem size dramatically, and Z_1 is likely to satisfy most of them.) They then adopt an "iterative active-constraint generation technique" in which inequalities violated by Z_k are added to the problem and the resulting SDP is solved to give Z_{k+1} ($k = 1, 2, \dots$). The process usually terminates before all constraints are included. Further study of this approach is presented in section 4.1.

2.4. SDP model analysis. Let $\bar{Z} = \begin{pmatrix} \bar{Y} & \bar{X}^T \\ \bar{X} & I \end{pmatrix}$ be a feasible solution of the relaxed SDP (2.4). Assuming the distance measurements are exact (no noise), Biswas and Ye [2] give conditions under which $\bar{X}$ and $\bar{Y}$ solve problem (2.2) exactly as follows:

- $\bar{Z}$ is the unique optimal solution of (2.4), including all inequality constraints.
- In (2.4), there are $2n + n(n+1)/2$ exact pairwise distance measurements.

These conditions ensure that $\bar{Y} = \bar{X}^T\bar{X}$. In practice, distance measurements have noise and we only know that the SDP solution satisfies $\bar{Y} - \bar{X}^T\bar{X} \succeq 0$. This inequality can be used for error analysis of the location estimates provided by the relaxation. For example, $\text{trace}(\bar{Y} - \bar{X}^T\bar{X}) = \sum \tau_i$, where

$$\tau_i \equiv \bar{Y}_{ii} - \|\bar{x}_i\|^2 \geq 0, \tag{2.5}$$

is a measure of deviation of the SDP solution from the desired constraint $Y = X^TX$ (ignoring off-diagonal elements). The individual trace τ_i can be used to evaluate the location estimate $\bar{x}_i$ for sensor i. In particular, we interpret a smaller τ_i to mean higher accuracy in the estimated location x_i. Further explanation is given in [2].

3. SpaseLoc: A scalable localization algorithm. When the number of nodes in (2.4) is large, applying a general SDP solver such as DSDP5.0 [1] or SeDuMi [23] would not scale well. In this section, we present a sequential subproblem approach named SpaseLoc to solve the full localization problem iteratively.

3.1. Adaptive subproblem approach. We call the overall sensor localization problem including all sensors and anchors the *full_problem*. At each iteration, SpaseLoc selects from the *full_problem* a subset of the unlocalized sensors and a subset of the anchors to form a localization *subproblem*. We call the selected sensors in the subproblem *subsensors*, and the selected anchors in the subproblem *subanchors*, These subsensors and subanchors, together with their known distance measurements and known anchors' locations, form a sub-SDP relaxation model to be solved using the same formulation as in (2.4).

In our adaptive approach, the subsensors and subanchors for each subproblem are chosen dynamically according to rule sets. (Rather than using predefined data, every new iteration's subproblem generation is based on the previous iteration's results.) The resulting SDP subproblems are of varying but limited size. Currently they are solved by Benson, Ye, and Zhang's SDP solver DSDP5.0 [1].

SpaseLoc is a *greedy algorithm* in the sense that each subproblem determines the final estimate of the associated sensor locations.

3.2. The SpaseLoc algorithm. The main steps of SpaseLoc are listed below, followed by explanations of the steps and definitions of new terms used therein.

A0. Set *subproblem_size*.
A1. Subproblem creation: Select subsensors and subanchors to be included in the subproblem.
A2. Formulate SDP relaxation model (2.4) based on the chosen subsensors and subanchors, together with the known distances among them and the subanchors' known locations.
A3. Call SDP solver to obtain a solution for the subsensors' locations.
A4. Classify localized subsensors according to their τ_i value.
A5. If all sensors in the network become localized or are determined to be outliers, go to step A6. Otherwise, return to step A1 for the next iteration.
A6. Output all sensor locations and report outliers if any. Stop.

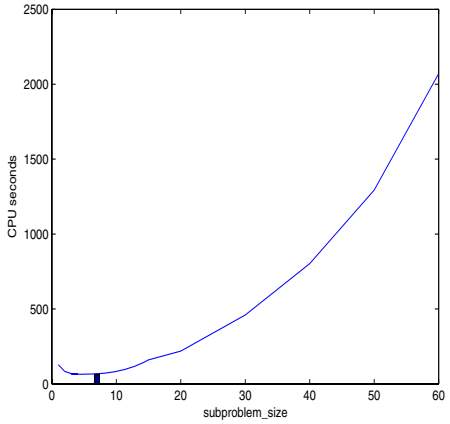

FIG. 3.1. *SpaseLoc execution time as a function of subproblem_size: total nodes* = 10000, *anchors* = 100, *radius* = 0.0226.

In step A0, *subproblem_size* specifies a limit on the number of unlocalized sensors to be included in each subproblem. It can range from 1 to an upper limit value that is potentially solvable by the SDP solver. In our experiments, the upper limit is 150. The most effective *subproblem_size* seems to change with the *full_problem* size, the model parameters such as *radius*, and the SDP solver used. We perform an approximate linesearch to find *subproblem_size* that corresponds to the minimum time because, empirically, the total execution time with all other parameters fixed is essentially a convex function of *subproblem_size*.

For example, when *full_problem* size is 10000 with 100 anchors, *radius* 0.0226, and no noise, *subproblem_size* 7 seems to give the best execution time with the DSDP5.0 solver (refer to Figure 3.1). The search time for *subproblem_size* is not included as part of the SpaseLoc execution time.

Step A1 involves choosing a subset of unlocalized sensors (no more than *subproblem_size*) and an associated subset of nodes with known locations. The latter can include a subset of the original anchors and/or a subset of sensors already localized by a previous subproblem (we define them as *acting anchors*). The rules for choosing subsensors and subanchors in this iteration are discussed in sections 3.4–3.5.

In step A4, the error in sensor i's location is estimated by its individual trace τ_i as discussed in section 2.4. Subsensors whose τ_i value is within a given tolerance τ are labeled as localized and treated as acting anchors for the next iteration, whereas subsensors whose localization error is higher than the tolerance are also labeled as localized but are not used as acting anchors in later iterations. These new acting anchors are labeled with different acting levels as explained in section 3.4. The value of τ has an impact on the localization accuracy. Bigger values allow more localized sensors to be acting anchors, but with possibly greater transitive errors. Smaller values may increase the estimation accuracy for some of the sensors, but could lead to fewer connections to anchors for some unlocalized sensors. A rule of thumb is to use a small τ for networks with high anchor density to achieve potentially more accuracy, and a bigger τ for networks with low anchor density to avoid lacking connections to anchors. In order to avoid the side effect of a bigger τ eliminating too many potential acting anchors, at some later iteration we utilize all localized sensors as acting anchors

(including those whose τ_i value is bigger than the given tolerance τ). This change only starts when the remaining unlocalized sensors are connected to fewer than three anchors. It makes sure that we use acting anchors with higher accuracy first, but if no such acting anchors are available, we use localized points whose locations might be less accurate. In most cases, this is better than using no reference points at all.

In step A5, an unlocalized sensor is called an *outlier* when it does not have any distance information for the algorithm to decide its location. If a sensor has no connection to any anchor, it is classified as an outlier. In addition, if a connected cluster of sensors has no connection to any anchors, then all sensors in the cluster will be outliers.

The next sections explain the subproblem creation procedure used by step A1. Section 3.3 lists steps S1–S8 of the creation procedure itself. Section 3.4 presents rules RS1–RS4 for subsensor selection in step S5. Section 3.5 presents rules RA1–RA3 for subanchor selection in step S7. Section 3.6 illustrates the method for independent subanchor selection used in rules RA2–RA3. Sections 3.7–3.8 discuss the routines used in step S8 to localize sensors that have fewer than 3 connected anchors.

3.3. Subproblem creation procedure. As explained, *subproblem_size* is a predetermined parameter that represents the maximum number of unlocalized sensors that can be selected as subsensors in a subproblem. When there are more than *subproblem_size* unlocalized sensors, we have a choice to make among them.

The subproblem creation procedure makes sure that the choice of subsensors is based first on the number of connected anchors they have, and second on the type of connected anchors such as original anchors and different levels of acting anchors as defined in section 3.4, and that the choice of subanchors is based on a set of rules (section 3.5). The main steps are listed below, followed by explanations of the steps and definitions of new terms used.

S1. Specify *MaxAnchorReq*.

S2. Initialize *AnchorReq* = *MaxAnchorReq*.

S3. Loop through unlocalized sensors, finding all that are connected to at least *AnchorReq* anchors. If *AnchorReq* ≥ 3, determine if there are 3 *independent* subanchors; if not, go to the next sensor.[1] Enter each found sensor into a *candidate subsensor list*, and enter its connected anchors into a corresponding *candidate subanchor list*. Each sensor in the candidate subsensor list has its own candidate subanchor list (so there are as many candidate subanchor lists as the number of sensors in the candidate subsensor list). Let *sub_s_candidate* be the length of the candidate subsensor list.

S4. If $0 <$ *sub_s_candidate* $\leq$ *subproblem_size*, the candidate subsensor list becomes the chosen subsensors list. Go to step S7.

S5. If *sub_s_candidate* $>$ *subproblem_size*, the choice of subsensors is further based on subsensor selection rules RS1–RS4 described in section 3.4. After exactly *subproblem_size* subsensors are selected from the candidate list according these rules, go to step S7.

S6. Now *sub_s_candidate* $= 0$. Reduce *AnchorReq* by 1.
If *AnchorReq* > 0, go to step S3 for another round of subproblem creation.
Otherwise, *AnchorReq* $= 0$ and *sub_s_candidate* $= 0$ indicates that there are still unlocalized sensors left that are not connected to any localized node. We classify them as outliers and exit this procedure to continue at step A6 of

[1] See section 3.6 for dependency definition and independent anchor selection.

section 3.2.

S7. Now that we have a subsensor list and the candidate subanchor lists, choose subanchors using selection rules RA1–RA3 presented in section 3.5.

S8. The subsensors and subanchors are selected and the subproblem creation routine finishes here.
If $AnchorReq \geq 3$, go to step A2 in section 3.2.
If $AnchorReq = 2$, apply the procedure in section 3.7 and go to step A5.
If $AnchorReq = 1$, apply the procedure in section 3.8 and go to step A5.

In step S1, *MaxAnchorReq* determines the initial (maximum) value of *AnchorReq*. It is useful for scalability when connectivity is dense. A smaller *MaxAnchorReq* would generally cause fewer subanchors to be included in the subproblem, thus reducing the number of distance constraints in each SDP subproblem and hence reducing execution time for each iteration. For instance, under ideal conditions (where there is no noise), even if a sensor has 10 distance measurements to 10 anchors, we don't need to include all 10 anchors because we can use 3 to localize that sensor accurately.

In the presence of noise, a bigger *MaxAnchorReq* should reduce the average estimation error. For example, if there is a large distance measurement error from one particular anchor, since *MaxAnchorReq* anchors are all taken into consideration for deciding the sensor's actual location, the large error would be averaged out. Another consideration for setting *MaxAnchorReq* is the trade-off between estimation accuracy and execution speed. If we are in a static environment and would like to have localization as accurate as possible under noise conditions, we might choose a large *MaxAnchorReq*. However, in a real-time environment involving moving sensors, where speed might take priority, we would consider a smaller *MaxAnchorReq*.

In step S2, *AnchorReq* is a dynamic parameter that may decrease in later steps.

In step S4, the subproblem may contain fewer than *subproblem_size* subsensors, which is perfectly acceptable. The alternative is to reduce *AnchorReq* by 1 and find more subsensor candidates that have fewer distance connections. However, this approach might reduce the accuracy of the algorithm, because we do want to localize the subsensors as accurately as possible as the iteration progresses, and the newly localized subsensors could be further used as acting anchors for the next iteration.

In step S6, *AnchorReq* is iteratively reduced by 1 from *MaxAnchorReq* to 0 eventually. This approach allows sensors with at least *AnchorReq* connections to anchors to be localized before sensors with fewer connections to anchors.

As we know, under no-noise conditions, a sensor's location can be uniquely determined by connections to at least 3 independent anchors. If a sensor has connections to only 2 anchors, there are two possible locations; and if there is only 1 connection to an anchor, the sensor can be anywhere on a circle. In step S8, we use heuristic subroutines described in sections 3.7–3.8 to include the sensor's anchors' connected neighboring nodes in the subproblem in order to improve the estimation accuracy.

3.4. Subsensor selection. In step S5, when the number of sensors in the candidate subsensor list is bigger than *subproblem_size*, the choice of subsensors is further based on the types of anchors each sensor is connected to.

First, we introduce the concept of *sensor priority*. We assign a priority to each sensor in the candidate subsensor list. A sensor with a smaller priority value is selected to be localized before one with a bigger priority value. A sensor's priority is based on the types of anchors the sensor is directly connected to. Next, in order to define different types of anchors, we introduce the concept of *anchor acting levels*. All anchors including acting anchors are assigned certain acting levels. Original anchors

TABLE 3.1
An example: priority list when MaxAnchorReq = 3.

Priority value	Level 1 anchor	Level 3 anchor	Level 5 anchor	Level 7 anchor	Level 9 anchor	...	Resulting anchor level
1	≥ 3	any					3
2	$= 2$	≥ 1	any				5
3	$= 1$	≥ 2	any				7
3	$= 2$	$= 0$	≥ 1	any			7
4	$= 1$	$= 1$	≥ 1	any			9
4	$= 2$	$= 0$	$= 0$	≥ 1	any		9
5	$= 1$	$= 1$	$= 0$	≥ 1	any		11
5	$= 2$	$= 0$	$= 0$	$= 0$	≥ 1	any	11
...	$= 0$	total ≥ 3					(11, *bigN*)
bigN	total $= 2$						*bigN*
bigN+1	total $= 1$						*bigN*+1

are always set to acting level 1. Every acting anchor is set to an acting level after it has been localized as a sensor. Essentially, acting anchors are set with acting levels depending on the levels of the anchors that localized them.

The priority rules for selecting subsensors from a candidate subsensor list are as follows:

RS1. When $AnchorReq \geq 3$ and a sensor has at least 3 connected anchors that are independent, the sensor's priority depends on the 3 connected anchors that have the lowest acting levels among all its connected anchors. The sensor's priority value is defined as the summation of these 3 connected anchors' acting levels.

RS2. If the sensor has 3 connected anchors that are dependent, it is ranked with the same priority as when the sensor is connected to only 2 anchors.

RS3. Sensors with 2 anchor connections are ranked with equal priority, independent of the acting levels of the 2 connected anchors. (This can be easily expanded to be more granular according to the connected anchors' acting levels.) Sensors in this category are assigned lower priority than any sensors that have at least 3 independent anchor connections.

RS4. Sensors with 1 anchor connection are ranked with equal priority, independent of the acting level of the connected anchor. (Again, this can be more granular according to the connected anchor's acting level.) Sensors in this category are assigned lower priority than any sensors that have at least 2 anchor connections.

Table 3.1 illustrates the priority list for an example where $MaxAnchorReq = 3$ and the sensor's priority is determined by the 3 anchors that have the lowest acting levels among all the sensor's connected anchors. We can certainly add more granularity by further classifying the acting levels of the sensor's fourth or fifth connected anchors (if any). Although more categorization of the priorities should increase localization accuracy under most noise conditions, more computational effort is required to handle more levels of priorities.

Each item in the table represents the number of anchors with different acting levels that are needed at each priority. The last column represents the resulting acting anchors' acting levels for subsequent iterations. For example, if a sensor has at least three independent connections to anchors, and if 3 of the anchors are original anchors (acting level 1), this sensor belongs to priority 1 as listed in row 1 of the table. Also, when this sensor is localized, it becomes acting anchor level 3 (the summation of the

anchor levels of the three anchors that localized it). Similarly, if a sensor has at least three independent connections to anchors, and if 2 of the anchors are original anchors (acting level 1) and at least 1 of the connected anchors is at acting level 3, then this sensor belongs to priority 2 as listed in row 2 of the table. Also, when this sensor is localized, it becomes acting anchor level 5. The sensors that connect to two anchors belong to the second to last priority, and sensors that connect to only one anchor belong to the last priority. We use a big enough number *bigN* in the implementation to ensure that sensors connected to fewer than 3 anchors are given the lowest priority.

3.5. Subanchor selection. In step S7, for each unlocalized subsensor in the subsensor list, only *AnchorReq* of the connected anchors are allowed to be included in the subproblem. We use the following rules to select subanchors from a candidate subanchor list that contains more than *AnchorReq* anchors.

RA1. Original anchors are selected first, followed by acting anchors with lower acting level.

RA2. The subanchors chosen should be linearly independent.

RA3. Among independent anchors in the candidate subanchor list, we use distance scale-factors to encourage selection of the closest subanchors.

Rules RA2 and RA3 are implemented as in section 3.6. Rule RA3 is based on the assumption that under noise conditions, we trust the shorter distance measurements more than the longer ones.

3.6. Independent subanchors selection. Suppose sensor i is connected to K $(K > 3)$ anchors at locations a_{ik} with corresponding distance measurements $\widehat{d}_{ik}$ $(k = 1, \ldots, K)$. Define the matrices

$$A = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ -a_{i1} & -a_{i2} & \cdots & -a_{iK} \end{pmatrix}, \quad D_1 = \operatorname{diag}(1/\sqrt{1 + \|a_{ik}\|^2}), \quad D_2 = \operatorname{diag}(1/\widehat{d}_{ik}).$$

We select an independent subset by a QR factorization with column interchanges [11]: $B = AD_1D_2$, $BP = QR$, where Q is orthogonal, R is upper-trapezoidal, and P is a permutation chosen to maximize the next diagonal of R at each stage of the factorization. (D_1 normalizes the columns of A, and D_2 biases them in favor of anchors that are closer to sensor i.) If the 3rd diagonal of R is larger than a predefined threshold (10^{-4} is used in our simulation), then the first 3 columns of AP are regarded as independent, and the associated anchors are chosen. Otherwise, all subsets of 3 among the K anchors are regarded as dependent. (In MATLAB, R and P are obtained by a command of the form `[Q,R,P] = qr(B)`.)

3.7. Geometric subroutine (two connected anchors). This section illustrates the heuristic techniques used in step S8 of section 3.3 to localize sensors connected to only two anchors.

When a sensor's connected anchors are also connected to other anchors, this subroutine may improve the accuracy of the sensor's localization, as illustrated by an example in Figure 3.2.

In this example, assume s_1 and s_2 are sensors with unknown locations, and $a_3(1,3)$, $a_4(1,2)$, $a_5(2,2)$, $a_6(4,1)$, $a_7(5,1)$ are anchors with known locations in brackets. Assume that the sensors' radio range is $\sqrt{2}$, and we are also given two distance measurements $\widehat{d}_{13} = 1$ and $\widehat{d}_{14} = \sqrt{2}$ for sensor s_1 and one measurement $\widehat{d}_{27} = 1$ for sensor s_2.

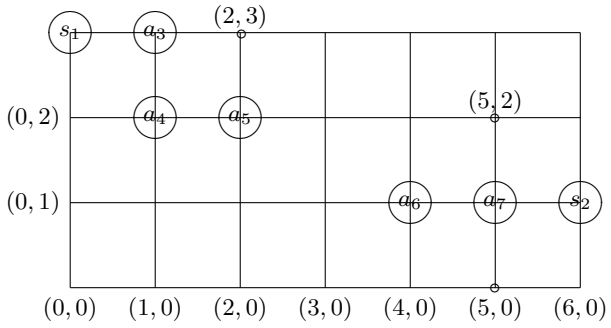

FIG. 3.2. *Sensors with connections to at most two anchors.*

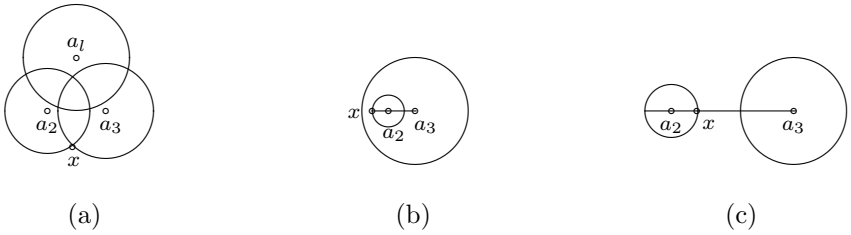

FIG. 3.3. (a) *Sensor with two anchors' circles intersecting.* (b) *Sensor with two anchors, a_2's circle in a_3's.* (c) *Sensor with two anchors' circles disjoint.*

Given two distances $\widehat{d}_{13}$ and $\widehat{d}_{14}$ to two anchors $a_3(1,3)$ and $a_4(1,2)$, we know that s_1 should be at either $(0,3)$ or $(2,3)$. If we only use s_1, $a_3(1,3)$, $a_4(1,2)$ in an SDP subproblem, then SDP relaxation will give a solution near the middle of the two possible points, which would be very close to point $(1,3)$. If there is any anchor (a_5) that is near s_1's connected anchors (a_3 and a_4) with any of the two possible sensor points within their radio range (point $(2,3)$ is within a_5's range), that point $(2,3)$ must not be the real location of s_1, or else s_1 would be connected to this anchor (a_5) as well. Thus we can infer that s_1 must be at the other point $(0,3)$.

Inspired by the above observation, when a sensor has at most 2 connected anchors, we include these anchors' connected anchors in the subproblem (we call them the connected anchors' neighboring anchors) together with the sensor and its directly connected anchors. By including the neighboring anchors, we might hope that the inequality constraints in the SDP relaxation model (2.4) would push the estimation towards the right point. However, because of the relaxation, enforcing inequalities in (2.4) is not equivalent to enforcing them in the distance model (2.2). The added inequality constraints only push the original solution near $(1,3)$ a tiny bit towards s_1's real location $(0,3)$, and the solution essentially stays at around $(1,3)$.

Given the ineffectiveness of the SDP relaxation approach under this condition, we propose instead a geometric approach as illustrated in Figure 3.3. Assume $s_1(x_x, x_y)$ has measurements $\widehat{d}_{12}$ to anchor $a_2(a_{2x}, a_{2y})$ and $\widehat{d}_{13}$ to anchor $a_3(a_{3x}, a_{3y})$. We also assume $\widehat{d}_{12} \le \widehat{d}_{13}$ (we can always swap the two indexes otherwise). Let a_l $(l = 4, \ldots, k)$ be a_2 and/or a_3's neighboring anchors with radio range r_{1l} $(l = 4, \ldots, k)$, and let d_{23} be the known (exact) Euclidean distance between a_2 and a_3.

- If two circles centered at a_2 and a_3 with radii $\widehat{d}_{12}$ and $\widehat{d}_{13}$ intersect each other ($\widehat{d}_{12} + \widehat{d}_{13} \ge d_{23}$ and $\widehat{d}_{13} - \widehat{d}_{12} \le d_{23}$) as in Figure 3.3(a):
  - Two possible locations of s_1 are given by solutions x^* and x^{**} of the

equations

$$\|x - a_2\|^2 = \widehat{d}_{12}^2, \qquad \|x - a_3\|^2 = \widehat{d}_{13}^2.$$

– Sensor s_1's location is selected from x^* and x^{**}, whichever is further away from any neighboring anchor. Thus, for $l = 4$ to k,

if $\|x^* - a_l\|^2 < r_{1l}^2$, then $x = x^{**}$ and stop
else if $\|x^{**} - a_l\|^2 < r_{1l}^2$, then $x = x^*$ and stop.

Otherwise, $x = (x^* + x^{**})/2$ and stop.

- Under noise conditions, the a_2 circle may be inside the a_3 circle ($\widehat{d}_{12} + \widehat{d}_{13} \geq d_{23}$ and $\widehat{d}_{13} - \widehat{d}_{12} > d_{23}$) as in Figure 3.3(b).
  – The solutions x^* and x^{**} of the following equations give two possible points for s_1 on the a_2 circle:

$$(x_x - a_{2x})^2 + (x_y - a_{2y})^2 = \widehat{d}_{12}^2,$$
$$(a_{2x} - a_{3x})(x_y - a_{2y}) = (a_{2y} - a_{3y})(x_x - a_{2x}),$$

  where x is on the line through a_2 and a_3 represented by the second equation.
  – If $\|x^* - a_3\| < \|x^{**} - a_3\|$, then $x = x^{**}$; otherwise $x = x^*$. This guarantees that the point further from a_3 is chosen. Note that we base the sensor's estimation on the closest anchor (a_2 here since $\widehat{d}_{13} \geq \widehat{d}_{12}$), assuming that a shorter measurement is generally more accurate than longer ones, given similar anchor properties.

  The same approach applies when the a_3 circle is inside the a_2 circle ($\widehat{d}_{12} - \widehat{d}_{13} > d_{23}$).
- Under noise conditions, the a_2 and a_3 circles may again have no intersection ($\widehat{d}_{12} + \widehat{d}_{13} < d_{23}$) as in Figure 3.3(c).
  – The solutions x^* and x^{**} of the following equations give two possible points for s_1 on the circle for the anchor with smaller *radius*. Let us assume $\widehat{d}_{12} \leq \widehat{d}_{13}$:

$$(x_x - a_{2x})^2 + (x_y - a_{2y})^2 = \widehat{d}_{12}^2,$$
$$(a_{2x} - a_{3x})(x_y - a_{2y}) = (a_{2y} - a_{3y})(x_x - a_{2x}),$$

  where x is on the line through a_2 and a_3 represented by the second equation.
  – If $\|x^* - a_3\| > \|x^{**} - a_3\|$, then $x = x^{**}$; otherwise $x = x^*$. This guarantees that the point closer to a_3 (in between a_2 and a_3) is chosen.

3.8. Geometric subroutine (one connected anchor). Similar inefficiency occurs in the SDP solution when a sensor connects to only *one* anchor. The SDP solver under this condition gives a solution for the sensor to be in the same location as the sensor's connected anchor. In reality, the sensor could be anywhere on the circle. The SDP gives an average point, at the center of the circle, and that is where the connected anchor is. Even if the anchor's neighboring anchor is included in the SDP subproblem, the inequality constraints are not active most of the time because the SDP solution may not provide optimal solutions all the time.

We propose a heuristic for estimating a sensor's location with only one connecting anchor. The idea is to use one neighboring anchor's radio range information to

FIG. 3.4. (a) *Sensor with one anchor connection a and one neighboring anchor b.* (b) *Sensor with one anchor connection a and two neighboring anchors b, c.*

eliminate the portion of the circle that the sensor would not be on, and then calculate the middle of the other portion of the circle to be the sensor's location. For the example in Figure 3.2, because we know the distance between s_2 and a_7 is 1, we know that s_2 could be anywhere on the circle surrounding a_7 with *radius* 1. Knowing a_7's neighboring anchor node a_6 is not connected to s_2, we know that s_2 would not be in the area surrounding a_6 with *radius* $\sqrt{2}$. Thus, s_2 could be anywhere around the half circle including points $(5,2)$, $(6,1)$, $(5,0)$. The heuristic chooses the middle point between the two circles' intersection points $(5,2)$ and $(5,0)$, which happens to be $(6,1)$ in this example. The heuristic gives better accuracy for the sensor's location than the SDP solution under most conditions. The procedure follows.

- Assume s has one distance measurement $\widehat{d}$ to anchor a, and b is the closest connected neighboring anchor to a with radio range r (refer to Figure 3.4(a)). We assume $a = (a_x, a_y)$, $b = (b_x, b_y)$, $x = (x_x, x_y)$.
- The solutions x^* and x^{**} of the following equations give two possible points s on the circle:

$$(x_x - a_x)^2 + (x_y - a_y)^2 = \widehat{d}^2,$$
$$(a_x - b_x)(x_y - a_y) = (a_y - b_y)(x_x - a_x),$$

  where x is on the line through a and b represented by the second equation.
- If $\|x^* - b\| < r$, then $x = x^{**}$; otherwise $x = x^*$. This guarantees that the point further from b is chosen.

The above heuristic provides a simple way of estimating a sensor's location when the sensor connects to only one anchor. A more complicated approach can be adopted when the connected anchor has more than one neighboring anchor, which can increase the accuracy of the sensor's location. We call it an arc elimination heuristic. The idea is to loop through each of the neighboring anchors and find the portion of the circle that the sensor won't be on, and eliminate that arc as a possible location of the sensor. Eventually, when one or more plausible arcs remain, we choose the middle of the largest arc to be the sensor's location. For example, assume we add one more neighboring anchor c to sensor s's anchor a from the previous example in Figure 3.4(a). The new scenario is shown in Figure 3.4(b). First, we find the intersections (points 1 and 2) of two circles: one at a with *radius* $\widehat{d}$, the other at b with *radius* r. We know that the 1–2 portion of the arc closer to point b won't be the location of s. Second, we find the intersections (points 3 and 4) of two circles: one at a with *radius* $\widehat{d}$, the other at c with *radius* r. We know that the arc 3–4 closer to point c won't be the location of s. Thus we deduce that s must be somewhere on the arc 1–4 further away from b or c. The estimation of s is given in the middle of the arc 1–4. As we see, this method should provide more accuracy than the one-neighboring-anchor approach.

3.9. Subproblem optimality. For the case of one sensor connected to three independent anchors, Biswas and Ye [2] prove when there is no noise that the SDP relaxation (2.4) gives an optimal solution to (2.2). The proof depends on the fact that there are three independent equations and only three variables.

In SpaseLoc, the subproblems are constructed from sensors that have three independent anchors (or acting anchors) where possible. If each of these subsensors (say total s) were included in separate subproblems together with their connected 3 independent anchors, the proof in [2] shows that they would be localized exactly by the SDP approach. If these s subsensors and their connected anchors are treated together in a single subproblem, the larger SDP relaxation contains sets of the same three equations that would arise in the separate SDP relaxations. The equations form a block-diagonal system in the larger SDP. There are $3s$ independent equations and the same number of variables containing only x_i and $y_{ii},\ i = 1, \ldots, s$. The $\widehat{d}_{ik}$ equation in (2.4) reduces under no noise conditions to $y_{ii} = x_i^T x_i$ for all relevant pairs (i, k). The constraint $Y - X^T X \succeq 0$ then guarantees $y_{ij} = x_i^T x_j$ for all $j = 1, \ldots, s$. Hence, the SDP solution for the SpaseLoc subproblem is also rank 2 and gives an exact locations for all subsensors.

4. Computational results. This section explains the simulation method and the setup for experimenting with the SpaseLoc algorithm, then presents results for various parameter settings.

For the simulation, a total number of nodes n (including s sensors and m anchors) is specified in the range 4 to 10000. The locations of these nodes are assigned with a uniform random distribution on a square region of size $r \times r$ where $r = 1$, or put on the grid-points of a regular topology such as a square or an equilateral triangle on the same region. The m anchors are randomly chosen from the given n nodes. We assume all sensors have the same radio range (*radius*) for any given test case. Various radio ranges were tested in the simulation.

Euclidean distances $d_{ij} = \|x_i - x_j\|$ are calculated among all sensor pairs $(i,\ j)$ for $i < j$. We then use $\widehat{d}_{ij}$ to simulate measured distances, where $\widehat{d}_{ij}$ is d_{ij} times a random error simulated by *noise_factor* $\in [0, 1]$. For a given *radius* $\subseteq [0, 1]$ it is defined as follows:

- If $d_{ij} \leq$ *radius*, then $\widehat{d}_{ij} = d_{ij}(1 + \texttt{rn} * \textit{noise\_factor})$, where `rn` is normally distributed with mean zero and variance one. (Any numbers generated outside $(-1, 1)$ are regenerated.)
  In practical networks, depending on the technologies that are being used to obtain the distance measurements, there may be many factors that contribute to the noise level. For example, one way to obtain the distance measurement is to use the received radio signal strength between two sensors. The signal strength could be affected by media or obstacles in between the two sensors. In this study, *noise_factor* is a normally distributed random variable with mean zero and variance one. This model could be replaced by any other noise model in practice.
- If $d_{ij} >$ *radius*, then $\widehat{d}_{ij} = 0$, and the bound $r_{ij} = 1.001 *$ *radius* is used in the SDP model.

In the simulation, we define the average estimation error to be $\frac{1}{s}\sum_{i=1}^{s} \|\bar{x}_i - x_i\|$, where $\bar{x}_i$ is from the SDP solution and x_i is the ith node's true location. In a practical setting, we wouldn't know the node's true location x_i. Instead, we would use the node's trace τ_i (2.5) to gauge the estimation error.

To convey the distribution of estimation errors and trace, we also give the 95%

quartile.

Factors such as noise level, radio range, and anchor densities can directly impact localization accuracy. The sensors' estimated locations are derived directly from the given distance measurements. If the noise level in these measurements is high, the estimation accuracy cannot be high. We also need sufficiently large radio range to achieve accurate localization, because too small a range could cause many sensors to have low connectivity or even be unreachable. Finally, more anchors in the network should help with the estimation accuracy because there are more reference points.

In the following subsections, we present simulation results (most results averaged over 10 runs) to show the accuracy and scalability of the SpaseLoc algorithm. We observe the impact of various radio ranges, anchor densities, and noise levels on the accuracy and performance of the algorithm. Computations were performed on a laptop computer with 2.4 GHz CPU and 1GB system memory, using MATLAB 6.5 [16] for SpaseLoc and a Mex interface to DSDP5.0 (Benson, Ye, and Zhang [1]) for the SDP solutions.

4.1. Effect of inequality constraints in SDP relaxation model. As we discussed in section 3.7, because of the $Y \succeq X^T X$ constraint relaxation, enforcing the r_{ij}^2 and r_{ik}^2 inequality constraints in (2.4) is not equivalent to enforcing them in the distance model (2.2). In order to observe the effectiveness of including these inequality constraints, we conduct simulations with the following three strategies, according to the number of times we check for violated inequality constraints and then include them to obtain a new solution.

- I0. This corresponds to solving the SDP problem with equality constraints only. (No inequality constraints are ever added.) The final solution is optimal for problem (2.4) without the inequality constraints involving r_{ij}^2 and r_{ik}^2.
- I1. This corresponds to solving the SDP problem with all equalities (and no inequalities) first, and then adding violated inequality constraints and resolving it at most once.
- I2. This corresponds to solving the SDP problem with all equalities (and no inequalities) first, and then adding violated inequality constraints and resolving one or more times until all inequalities are satisfied. The final solution is an optimal solution to problem (2.4).

Our experimental results show that the added inequality constraints do not always provide better localization accuracy, but can greatly increase the execution time. In this section, we illustrate the inequality constraints' impact through two simulation examples: one with no noise but low connectivity; the other with full connectivity but with noise.

In our first example, we run simulation results on a network of 100 randomly uniform-distributed sensors with *radius* 0.2275 and 10 randomly selected anchors. One of the sensors happens to be connected to only two other nodes. The sensors are localized with the full SDP and with SpaseLoc, using each of the I0, I1, I2 strategies in turn. In addition, we examine each case with or without our geometric routines for SpaseLoc. The results are shown in Figure 4.1 and Table 4.1.

Figure 4.1 shows there is a sensor connected to only 2 anchors. For full SDP shown in (a), no violated inequalities are ever found, so full SDP with I0, I1, or I2 has only one SDP call and always generates the same results. For SpaseLoc in (b) with I0 and no geometric routine, SDP is called 47 times (with no subsequent check for violated constraints). It produces the similar estimation accuracy as the full SDP approach but with much improved performance. In (c), SpaseLoc with I1 or

Inequality impact on accuracy and speed: 100 *nodes,* 10 *anchors, no noise, radius* 0.2275.

Methods	Error	95% Error	Time	SDP's
Full SDP with I0 or I1 or I2	1.7877e-3	1.7483e-10	11.97	1
SpaseLoc with I0 and no geometric routines	1.7890e-3	1.1684e-7	0.38	47
SpaseLoc with I1 or I2 and no geometric routines	1.7134e-3	1.1684e-7	0.42	48
SpaseLoc with I0 and geometric routines	1.4679e-7	1.1523e-7	0.35	46

I2 produces the same results, which means violated inequalities are found only once. Comparing (b) and (c), we see that including violated inequalities does improve the estimation accuracy a little. Best of all in (d), SpaseLoc with I0 and our geometric routines localizes all sensors with virtually no error.

Table 4.1 shows that adding violated inequalities increases execution time slightly for SpaseLoc.

In our second example, in order to observe the effectiveness of the inequality constraints under noise conditions, we run simulations for a network of 100 nodes whose true locations are at the vertices of an equilateral triangle grid. Ten anchors are placed at the middle grid-point of each row, and the *radius* is 0.25. A *noise_factor*

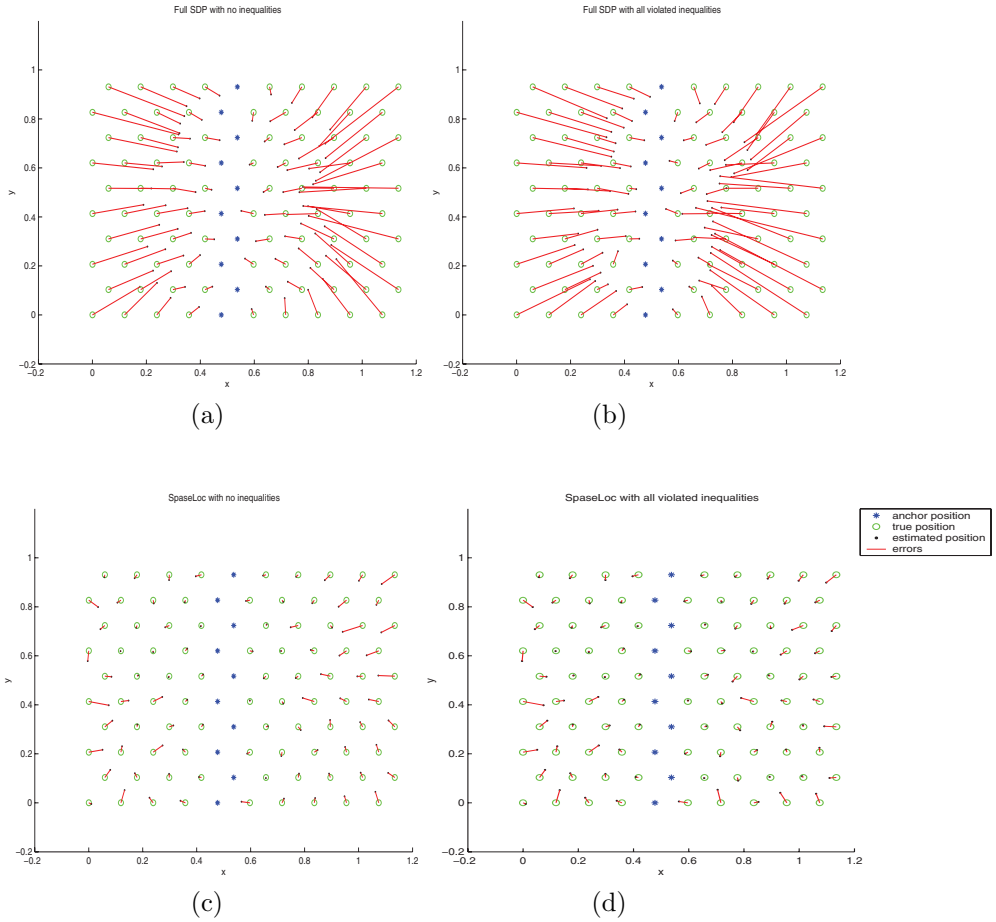

FIG. 4.2. *Inequality impact on accuracy:* 100 *nodes,* 10 *anchors, noise_factor* 0.1*, radius* 0.25.

TABLE 4.2
Inequality impact on accuracy and speed: 100 *nodes,* 10 *anchors, noise_factor* 0.1*, radius* 0.25.

Methods	Error	Time	SDP's
Full SDP with I0	0.1268	13.87	1
Full SDP with I1	0.1292	34.20	2
Full SDP with I2	0.1403	134.50	4
SpaseLoc with I0	0.0231	0.45	54
SpaseLoc with I1 or I2	0.0203	0.51	56

of 0.1 is applied to the distance measurements. The sensors are localized with either full SDP or SpaseLoc using I0, I1, I2 in turn without geometric routines. (Although we do not activate the geometric routines in this experiment, they are not a factor here because the localization error is not caused by low connectivity but by the noisy measurements.) The results are shown in Figure 4.2 and Table 4.2. Figure 4.2(b) and (d) correspond to strategy I1 or I2 for full SDP and SpaseLoc.

As we can see, adding violated inequalities for full SDP not only increases the execution times dramatically, but also increases the localization error. For SpaseLoc, adding violated inequalities improves the estimation accuracy slightly. Note that I1

and I2 produce the same results for SpaseLoc.

In summary, the first experiment shows that when the errors are caused by *low connectivity*, SpaseLoc with geometric routines and no inequality constraints (I0) outperforms SpaseLoc with inequalities (I1 or I2) and all of the full SDP options. Given this observation, from now on we only use SpaseLoc with geometric routines, which means the geometric routines are used instead of SDP to localize sensors connected to less than 3 anchors.

The second experiment indicates that under noise conditions, although adding violated inequalities does not seem to improve the estimation accuracy for full SDP, it does improve accuracy for SpaseLoc.

In the subsequent sections, we continue to examine the inequality constraints' effects on accuracy and speed.

4.2. Accuracy and speed comparison: Full SDP versus SpaseLoc. For very small networks, the SDP approach is both accurate and efficient. (This is vital to SpaseLoc, as many small subproblems must be solved using SDP.) However, the performance of the full SDP approach deteriorates rapidly with network size.

Table 4.3 shows the localization results using full SDP (a) and using SpaseLoc (b) for a range of examples with various numbers of nodes whose true locations in the network are at the vertices of an equilateral triangle grid. Anchors are placed at the middle grid-point of each row. A *noise_factor* of 0.1 is applied to the distance measurements.

Let us first look at the impact of I0, I1, and I2 on estimation accuracy. Table 4.3 (a) shows that for full SDP, 8 errors with I1 are bigger than with I2, and 5 errors with I2 are bigger than with I1. Comparing I0 with I2, we see that for each strategy, 9 errors in I0 are bigger than the errors for the other strategy. It appears that full SDP with added inequalities does not always improve the estimation accuracy. For SpaseLoc, I1 and I2 generate almost equivalent estimation accuracy; I0 has 8 errors that are bigger than with I1, while I1 has 5 errors bigger than with I0. Therefore, the added inequalities provide only marginal accuracy improvement for SpaseLoc.

Now let us compare full SDP with SpaseLoc. Figures 4.3–4.4 plot results for full SDP with I0 and SpaseLoc with I0 for two of these examples: 9 and 49 nodes, including 3 and 7 anchors placed at the grid-point in the middle of each row. As we can see from these two figures and Table 4.3, for localizing 4 and 9 nodes, full SDP and SpaseLoc show comparable performance. Beyond that size, the contrast grows rapidly. For localizing 49 nodes, SpaseLoc is 10 times faster than the full SDP method, with more than four times the accuracy. For 400 nodes, SpaseLoc with strategies I0, I1, and I2 is, respectively, 800, 2500, and 8500 times faster than full SDP with the same strategies, while achieving 10 times greater accuracy. Thus, the full SDP model becomes less effective as problem size increases. In fact, for problem sizes above 49 nodes, the average estimation error using full SDP becomes so large that the computed solution is of little value.

It may seem nonintuitive that SpaseLoc's greedy approach could produce smaller errors than the full SDP method. However, all of the SDP problems and subproblems of the form (2.4) are *relaxations* of Euclidean models of the form (2.2). As we discussed in section 3.9, SpaseLoc always tries to create a subproblem whose subsensors have three independent anchor connections, so that the SDP solution is exact. The same conclusion cannot be drawn under noise conditions, but experimentally the relaxations under noise conditions appear to be *tighter* in SpaseLoc's subproblems than in the single large SDP.

TABLE 4.3
Accuracy and speed comparison between full SDP and SpaseLoc.

In the following sections, we run more simulations only with SpaseLoc.

4.3. Scalability. Table 4.4 shows simulation results for 49 to 10000 randomly uniform-distributed sensors being localized using SpaseLoc with strategies I0, I1, and I2. The node numbers 49, 100, 225, ... are squares k^2, and the *radius* is the minimum value that permits localization on a regular $k \times k$ grid. The number of anchors changes with the number of sensors and is chosen to be k. Noise is not included in this simulation. When the items under I1, I2 are empty, it means that they are equal to the values under I0 in the same row.

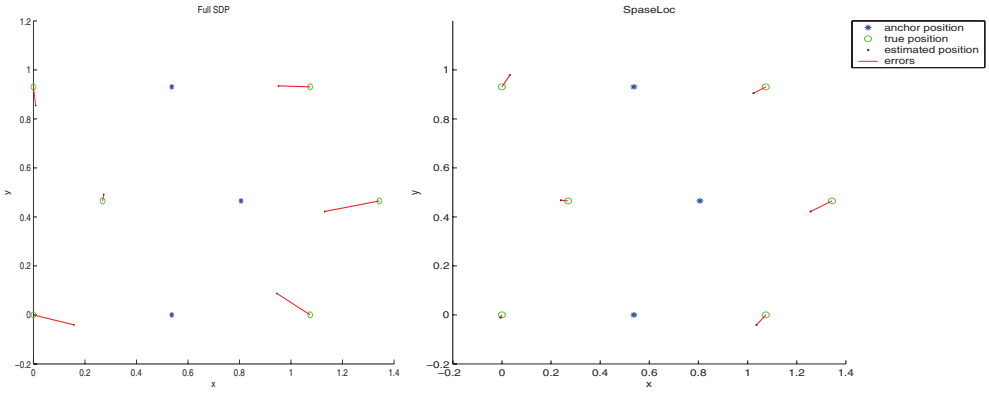

FIG. 4.3. 9 *nodes on equilateral-triangle grids,* 3 *anchors,* 0.1 *noise, radius* 1.12.

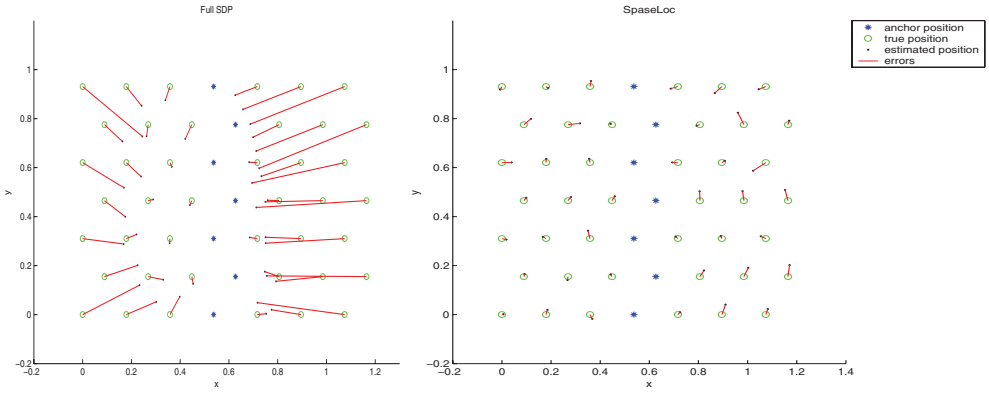

FIG. 4.4. 49 *nodes on equilateral-triangle grids,* 7 *anchors,* 0.1 *noise, radius* 0.40.

We find that strategies I1 and I2 produce the same results, and I0 gives essentially the same. This is because the inaccuracy of the estimation is caused purely by low connectivity, not by noisy distance measurements. Empirically we see that the program scales well: almost linearly in the number of nodes in the network. Indeed, the computational complexity of the SpaseLoc algorithm is of order n, the number of

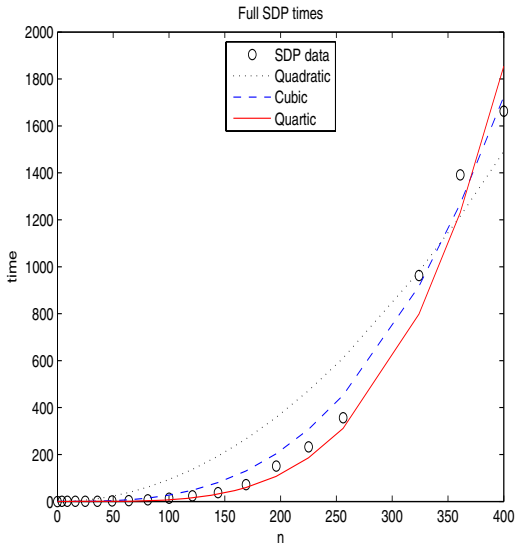

FIG. 4.5. *SDP computational complexity.*

sensors in the network, even though the full SDP approach has much greater complexity, as we now show.

We know that in the full SDP model (2.4), the number of constraints is $O(n^2)$, and in each iteration of its interior-point algorithm the SDP solver needs to solve a *sparse* linear system of equations whose dimension is the number of constraints. Figure 4.5 plots the CPU time for strategy I0 from Table 4.3(a) as well as three curves of the form $time = a_p n^p$ for $p = 2, 3, 4$, where a_p is determined by a least-squares fit. It appears that the SDP complexity with strategy I0 lies somewhere between $O(n^3)$ and $O(n^4)$.

In SpaseLoc, we partition the full problem into p subproblems of size q or less, where $p \times q = n$. We generally set q to be much smaller than n, ranging from 2 to around 10 in most of our simulations. If t represents the execution time taken by the full SDP method for a 10-node network, in the worst case the computation time for SpaseLoc is $t \times O(p)$. Thus, SpaseLoc is really linear in p in theory. Since we can assume q to be a parameter ranging from 2 to 10, with worst case 2, we know that $O(p) = O(n/q) \leq O(n/2) = O(n)$. Now we can see that SpaseLoc's computation time is $O(n)$.

In the remaining subsections we choose the middle network size from Table 4.4 (nodes = 3969) to observe the effect of varying radio range, number of anchors, and noise.

4.4. Radio range impact. With a fixed total number of randomly uniform-distributed nodes (3969, of which 63 are anchors), Table 4.5 shows the direct impact of *radius* in the range 0.0304 to 0.0334 on accuracy and performance.

Strategies I1 and I2 produce essentially the same results, and with slightly better accuracy than I0 for 8 of the 16 *radius* values, while I0 produces slightly better accuracy than I1 or I2 in 4 cases. However, I1 and I2 take more time than I0 because they need more SDP calls.

TABLE 4.5
Radio range impact: nodes = 3969, anchors = 63, no noise, sub_size = 5.

As we see, increasing *radius* leads to increased accuracy and only slightly more computational time. The simulation could assist sensor network designers in selecting a radio range to achieve a desired estimation accuracy with little concern about algorithm speed.

4.5. Number of anchors impact. With constant *radius* (0.0334) and the same randomly distributed nodes (3969), Table 4.6 shows the impact of the number of anchors, ranging from 1% to 10% of the total number of points. (Noise is not included.)

Strategies I1 and I2 produce identical results. Comparing I0 with I1 or I2, we see that added inequalities slightly improve the average error consistently, although the 95% error remains essentially the same. Increasing the number of anchors in the network improves the estimation accuracy in general, with no obvious impact on algorithm speed. However, we don't see accuracy improvement when the number of anchors reaches more than 10% of the total points. This analysis is beneficial for designers to avoid the cost of deploying unnecessary anchors.

4.6. Noise impact. With constant *radius* (0.0334) and the same randomly distributed nodes (3969), Table 4.7 shows the impact of noise conditions on accuracy and performance.

We see that strategies I1 and I2 do not provide consistent improvement over I0 for both average and 95% error, yet they always increase execution time. Also, more noise in the network has a direct impact on estimation accuracy. Simulations of this kind may help designers determine the measurement noise level that will give an acceptable estimation error.

5. Summary and extensions. We have shown that SpaseLoc achieves the aims of accuracy, speed, and scalability with a single processor on very large networks. It takes full advantage of the recent SDP approach of Biswas and Ye [2]. The latter has computational complexity $O(n^p)$, where n is the network size and p is between 3 and 4, but we use it on multiple tiny subproblems to obtain an algorithm with essentially linear complexity. On a 2.4GHz laptop with 1GB memory, SpaseLoc maintains efficiency and provides accurate location estimation for networks with 10000 sensors and beyond.

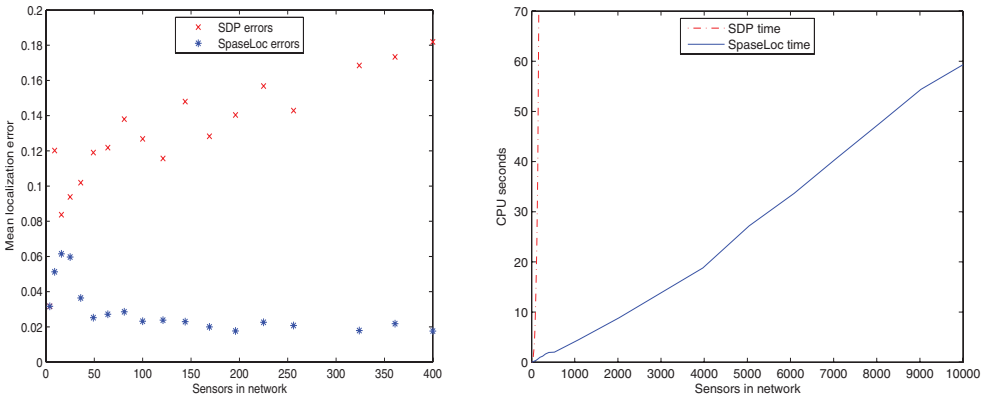

FIG. 5.1. *Accuracy and performance comparison.*

Figure 5.1 compares localization results for our SpaseLoc algorithm and the full SDP approach [2] for various sized networks. The left-hand figure shows a comparison in terms of estimation accuracy for localizing various sizes of networks when sensors are placed at the vertices of an equilateral triangle grid with 0.1 *noise_factor* added to distance measurements (data is taken from Table 4.3). It shows clearly that SpaseLoc provides much improved localization accuracy.

The right-hand graph summarizes results in terms of execution time on various network sizes. Data for the full SDP method is taken from Table 4.3, and data for SpaseLoc is taken from Table 4.4. The figure confirms near-linear complexity for SpaseLoc.

5.1. More general problems. In Jin [14], SpaseLoc is used as a building block for more general localization algorithms. A dynamic version can estimate moving sensors' locations in real time, and a three-dimensional version extends its utility further. For clustered and distributed environments, it is shown how to use SpaseLoc

in parallel (on multiple large subproblems) to obtain essentially linear complexity on clustered networks of unlimited size. Finally, a preprocessor for SpaseLoc has been developed in [14] to localize sensors in anchorless networks.

5.2. A bootstrap procedure. SpaseLoc works effectively when Step A1 (subproblem creation) finds subsensors connected to at least 3 anchors. A difficult situation arises if there are more than 3 anchors in the network but no subsensor is directly connected to 3 anchors. A network with anchors placed at the borders of the region is such an example. SpaseLoc's subproblems will involve sensors connected to only 2 or 1 anchors, leading to a less accurate final solution.

When there is sufficient connection information for sensors to be indirectly connected to at least 3 anchors through other sensors, the full SDP approach can find a solution. We are developing a procedure to choose a subproblem in the above situation. It will include the anchors, certain subsensors, and the sensors on each shortest path from a subsensor to an anchor.

5.3. Alternative subproblem solvers. At present, most of the SpaseLoc subproblems are solved by the SDP approach of Biswas and Ye [2]. This is an approximation method that may produce large errors with noisy data. A recent development by Biswas et al. [4] adds regularization terms to the SDP problem and uses a gradient-descent method to refine the SDP solution. Significant accuracy improvement is reported. An advantage of SpaseLoc is that it can solve each subproblem by any method that is effective on small networks. Our next step is to experiment with such approaches, including that of [4] and various triangulation-based methods.

Acknowledgments. We gratefully acknowledge valuable technical advice from Profs. Henry Wolkowicz, Scott Rogers, and Daniel Frances and two perceptive referees. Thanks also to Dr. Steve Benson for his expert advice on using the DSDP5.0 solver and to Prof. Kenneth Holmström for his help in fine-tuning parts of the MATLAB implementation of SpaseLoc. We are further indebted to Robert Bosch Corporation and the talented Bosch RTC team: Sharmila Ravula, Lakshmi Venkatraman, Bhaskar Srinivasan, Abtin Keshavarzian, Hauke Schmidt, and Karsten Funk; they provided the inspiration and vision for our algorithms to be practical.

INTERIOR POINT TRAJECTORIES AND A HOMOGENEOUS MODEL FOR NONLINEAR COMPLEMENTARITY PROBLEMS OVER SYMMETRIC CONES*

AKIKO YOSHISE†

Abstract. We study the continuous trajectories for solving monotone nonlinear mixed complementarity problems over symmetric cones. While the analysis in [L. Faybusovich, *Positivity*, 1 (1997), pp. 331–357] depends on the optimization theory of convex log-barrier functions, our approach is based on the paper of Monteiro and Pang [*Math. Oper. Res.*, 23 (1998), pp. 39–60], where a vast set of conclusions concerning continuous trajectories is shown for monotone complementarity problems over the cone of symmetric positive semidefinite matrices. As an application of the results, we propose a homogeneous model for standard monotone nonlinear complementarity problems over symmetric cones and discuss its theoretical aspects. Consequently, we show the existence of a path having the following properties: (a) The path is bounded and has a trivial starting point without any regularity assumption concerning the existence of feasible or strictly feasible solutions. (b) Any accumulation point of the path is a solution of the homogeneous model. (c) If the original problem is solvable, then every accumulation point of the path gives us a finite solution. (d) If the original problem is strongly infeasible, then, under the assumption of Lipschitz continuity, any accumulation point of the path gives us a finite certificate proving infeasibility.

Key words. complementarity problem, symmetric cone, homogeneous algorithm, existence of trajectory, interior point method, detecting infeasibility

1. Introduction.

Let $(V, \circ)$ be a Euclidean Jordan algebra with an identity element e. We denote by K the symmetric cone of V which is a self-dual closed convex cone such that for any two elements $x \in \mathrm{int}K$ and $y \in \mathrm{int}K$, there exists an invertible map $\Gamma : V \to V$ satisfying $\Gamma(K) = K$ and $\Gamma(x) = y$. It is known that a cone in V is symmetric if and only if it is the cone of squares of V given by $K = \{x \circ x : \ x \in V\}$.

Faybusovich [6] studied the linear monotone complementarity problem (LCP) over symmetric cones of the form

$$\begin{array}{lll} \text{(LCP)} & \text{find} & (x, y) \in K \times K \\ & \text{s.t.} & (x, y) \in (a, b) + L, \ x \circ y = 0, \end{array} \tag{1.1}$$

where $(a, b) \in V \times V$ and $L \subseteq K \times K$ is a linear subspace with $\dim L = \dim V$ having the monotone property, i.e., $\langle x, y \rangle \geq 0$ if $(x, y) \in L$. The author showed the existence of the central path of the form

$$\{(x, y) \in \mathrm{int}K \times \mathrm{int}K : \ x \circ y = \mu e, \ \mu > 0\}$$

whenever the LCP has an interior feasible solution $(x, y) \in ((a, b)+L) \cap (\mathrm{int}K \times \mathrm{int}K)$, based on primal-dual interior point methods for linear programs [14, 17].

Note that the first extension of primal-dual methods to a more general setting than linear programs was achieved by Nesterov and Todd [21, 22] who developed the powerful theoretical concept of self-scaled barrier functions. It is known that the self-scaled cones associated with the self-scaled barriers are closely related to the symmetric cones [1, 10, 11, 27]. See also [15, 7, 23, 28, 25, 24, 3] for other extensions of primal-dual methods to the positive semidefinite cones, the symmetric cones, the self-scaled cones, or the homogeneous cones.

In most of the papers cited above, the analyses depend on the optimization theory of convex barrier functions. In this paper, apart from the theories of barrier functions, the trajectory of an interior point map is discussed in view of homeomorphisms of continuous maps. There have been studies of various types of central paths using the theory of homeomorphisms for some special cases of symmetric cones, i.e., the non-negative orthant and the cone of symmetric positive semidefinite matrices (see [9, 13, 29, 20]). We extend these results and set out basic properties concerning the existence of central paths for the monotone nonlinear complementarity problems over symmetric cones. Consequently, a first analysis of the trajectory for complementarity problems over the second order cone is provided.

As an application of the results, we give a homogeneous model for solving the problems. The homogeneous model for monotone complementarity problems was first proposed by Andersen and Ye [2] for solving the problems over the n-dimensional positive orthant. Unlike for linear optimization cases, the model is given by a nonlinear system even if the original problems are linear. However, the path associated with the model has some remarkable features as described below:

(a) The path exists, is bounded, and has a trivial starting point without any regularity assumption concerning the existence of feasible or strictly feasible solutions.
(b) Any accumulation point of the path is a solution of the homogeneous model.
(c) If the original problem is solvable, then every accumulation point of the path gives us a finite certificate proving feasibility.
(d) If the original problem is strongly infeasible, then, under the assumption of (scaled) Lipschitz continuity, every accumulation point of the path gives us a finite certificate proving infeasibility.

We show that a path having the above properties also exists for the monotone complementarity problems over symmetric cones.

Consider the following nonlinear and mixed complementarity problem:

$$\begin{array}{lll} \text{(CP)} & \text{Find} & (x, y, z) \in K \times K \times \Re^m \\ & \text{s.t.} & F(x, y, z) = 0,\ x \circ y = 0, \end{array} \tag{1.2}$$

where $F : K \times K \times \Re^m \to V \times \Re^m$ is a continuous map. Many problems can be cast into CPs having the monotone property, e.g., any primal and dual linear optimization problems over symmetric cones, and the robust Nash equilibrium problem introduced by Hayashi, Yamashita, and Fukushima [12].

The map F appearing in our homogeneous model is not necessarily defined on the boundary of the set $K \times K \times \Re^m$. Some *asymptotic* definitions are then introduced as follows:

- The CP is *asymptotically feasible* if and only if there exists a bounded sequence $\{x^{(k)}, y^{(k)}, z^{(k)}\} \subseteq \mathrm{int}K \times \mathrm{int}K \times \Re^m$ such that

$$\lim_{k\to\infty} F(x^{(k)}, y^{(k)}, z^{(k)}) = 0.$$

- The CP is *asymptotically solvable* if and only if there exists a bounded sequence $\{x^{(k)}, y^{(k)}, z^{(k)}\} \subseteq \mathrm{int}K \times \mathrm{int}K \times \Re^m$ such that

$$\lim_{k\to\infty} F(x^{(k)}, y^{(k)}, z^{(k)}) = 0 \text{ and } \lim_{k\to\infty} x^{(k)} \circ y^{(k)} = 0. \tag{1.3}$$

As long as the asymptotic property is discussed, the map F should be defined only on the set $\mathrm{int}K \times \mathrm{int}K \times \Re^m$ rather than on $K \times K \times \Re^m$.

We also introduce the following definitions to discuss the infeasibility of CPs:

- The CP is *infeasible* if and only if there is no feasible point $(x, y, z) \in K \times K \times \Re^m$ satisfying $F(x, y, z) = 0$.
- The CP is *strongly infeasible* if and only if there is no sequence $\{x^{(k)}, y^{(k)}, z^{(k)}\} \subseteq \mathrm{int}K \times \mathrm{int}K \times \Re^m$ such that $\lim_{k\to\infty} F(x^{(k)}, y^{(k)}, z^{(k)}) = 0$.

We impose the following assumption on F.

ASSUMPTION 1.1.

(i) *F is (x, y)-equilevel-monotone on its domain; i.e., if (x, y, z) and (x', y', z') lie in the domain of F and satisfy $F(x, y, z) = F(x', y', z')$, then $\langle x-x', y-y'\rangle \geq 0$ holds.*

(ii) *F is z-bounded on its domain; i.e., for any sequence $\{(x^{(k)}, y^{(k)}, z^{(k)})\}$ in the domain of F, if $\{(x^{(k)}, y^{(k)})\}$ and $\{F(x^{(k)}, y^{(k)}, z^{(k)})\}$ are bounded, then the sequence $\{z^{(k)}\}$ is also bounded.*

(iii) *$F(x, y, z)$ is z-injective on its domain; i.e., if (x, y, z) and (x, y, z') lie in the domain of F and satisfy $F(x, y, z) = F(x, y, z')$, then $z = z'$ holds.*

The above assumption is the same as the one imposed by Monteiro and Pang [19] for the case of the cone of symmetric matrices. Note that, in contrast to the paper [19], the domain of the map F is not given explicitly in the assumption. The domain is set as the set $\mathrm{int}K \times \mathrm{int}K \times \Re^m$ for observing some basic properties required in constructing a homogeneous model (section 3), and as the set $K \times K \times \Re^m$ for discussing the solvability of the CP (section 4).

The paper is organized as follows.

In section 2, some basic results for symmetric cones are summarized.

Section 3 is devoted to deriving a homeomorphism of the map $H : \mathrm{int}K \times \mathrm{int}K \times \Re^m \to V \times V \times \Re^m$ given by

$$H := \begin{pmatrix} x \circ y \\ F(x, y, z) \end{pmatrix}. \tag{1.4}$$

The main result, Theorem 3.10, ensures that if Assumption 1.1 is satisfied with the domain $\mathrm{int}K \times \mathrm{int}K \times \Re^m$, then the system $H(x, y, z) = h$ has a solution $(x, y, z) \in \mathcal{U} \times \Re^m$ for any $h \in \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$, where the set $\mathcal{U}$ is a subset of $\mathrm{int}K \times \mathrm{int}K$ defined by

$$\mathcal{U} := \{(x, y) \in \mathrm{int}K \times \mathrm{int}K : \ x \circ y \in \mathrm{int}K\}.$$

Suppose that there exists a sequence $\{h^{(k)}\} \subseteq \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ satisfying $h^{(k)} \to 0$. Theorem 3.10 implies that there exists a sequence $\{(x^{(k)}, y^{(k)}, z^{(k)})\} \subseteq \mathcal{U} \times \Re^m$ that is the set of solutions of the system $H(x^{(k)}, y^{(k)}, z^{(k)}) = h^{(k)}$ for any k. It is easy to see that the sequence $\{(x^{(k)}, y^{(k)}, z^{(k)})\} \subseteq \mathcal{U} \times \Re^m$ satisfies (1.3). Thus, if $\{(x^{(k)}, y^{(k)}, z^{(k)})\}$ is bounded, then the CP is asymptotically solvable. In section 4, the asymptotic solvability of the CP is discussed under Assumption 1.1 with the domain $K \times K \times \Re^m$. The obtained results are direct extensions of the ones in [19].

In section 5, as an application of the results in section 3, a homogeneous model is provided for a special class of CPs. As we described above, a remarkable feature of the model is that the associated trajectory gives certifications on the feasibility or the (strong) infeasibility of the original problem. We show that the result can be extended for the case of Euclidean Jordan algebras. To the best of our knowledge, this is a first homogeneous model for CPs over the cone of symmetric matrices and/or the second order cone, which are special cases of the symmetric cones. Note that for LCPs over the n-dimensional positive orthant and for linear conic optimization problems, several homogeneous models including the homogeneous self-dual embedding model have been studied [32, 16, 30, 4].

Some concluding remarks are given in section 6.

2. Some key lemmas for the symmetric cone. We give a summary of the theory of Euclidean Jordan algebra. Most of the results can be found in the book of Faraut and Korányi [5] and the papers [6, 7, 8, 28].

Let $(V, \circ)$ be a Euclidean Jordan algebra with the identity element e, where $(x, y) \mapsto x \circ y : V \times V \to V$ is a bilinear map satisfying

(i) $x \circ y = y \circ x$,
(ii) $x \circ (y \circ x^2) = (x \circ y) \circ x^2$, where $x^2 = x \circ x$,
(iii) $x \circ e = e \circ x = x$

for all $x, y, z \in V$. Note that the Jordan algebra $(V, \circ)$ is called Euclidean if there exists a symmetric, positive definite quadratic form $\mathcal{Q}$ on V which is also associative, i.e., $\mathcal{Q}(x \circ y, z) = \mathcal{Q}(x, y \circ z)$ for all $x, y, z \in V$. Since $(x, y) \mapsto x \circ y$ is a bilinear map, for each $x \in V$, the linear transformation $L(x)$ is defined by $L(x)y = x \circ y$. For $x \in V$, the *degree* of x is the smallest integer d such that the set $\{e, x, x^2, \ldots, x^d\}$ is linearly independent. The *rank* r of V is the maximum of the degree of x over all $x \in V$. For any element x in V of rank r, we can define the *characteristic polynomial* of x of the form

$$p_x(\lambda) := \lambda^r - a_1(x)\lambda^{r-1} + \cdots + (-1)^r a_r(x)$$

(cf. section 2 of [28]). We call the roots $\lambda_1, \ldots, \lambda_r$ of $p_x(\lambda)$ the *eigenvalues* of x and define

$$\mathrm{tr}(x) := \sum_{i=1}^{r} \lambda_i = a_1(x), \quad \det(x) := \prod_{i=1}^{r} \lambda_i = a_r(x). \tag{2.1}$$

Since $(x, y) \mapsto x \circ y$ is bilinear and $\mathrm{tr}(x \circ y)$ is a symmetric positive definite quadratic form which is associative, i.e., $\mathrm{tr}\,(x \circ (y \circ z)) = \mathrm{tr}\,((x \circ y) \circ z)$ for all $x, y, z \in V$, we define below the canonical inner product $\langle x, y \rangle$ of $x, y \in V$ and the canonical norm of $x \in V$, which we use throughout the paper:

$$\langle x, y \rangle := \mathrm{tr}(x \circ y), \quad \|x\| := \sqrt{\mathrm{tr}(x \circ x)}. \tag{2.2}$$

Note that $\|e\| = \sqrt{r}$. The property $\mathrm{tr}\,(x \circ (y \circ z)) = \mathrm{tr}\,((x \circ y) \circ z)$ implies that for each $x \in V$, $L(x)$ is self-adjoint with respect to $\langle \cdot, \cdot \rangle$, i.e., $\langle L(x)y, z \rangle = \langle y, L(x)z \rangle$ holds for all $y, z \in V$. We use the notation $L(u) \succ 0$ to mean that $L(u)$ is positive definite.

The set of squares $K := \{x^2 : \ x \in V\}$ is the symmetric cone of V, which is self-dual (i.e., $K = K^* := \{y : \ \langle x, y \rangle \geq 0 \ \text{ for all } x \in K\}$) and has the following properties.

PROPOSITION 2.1.

(i) $\mathrm{int}K = \{u \in V : \ L(u) \succ 0\} = \{x^2 : \ x \in V, \ \det(x) \neq 0\}$.

(ii) *If $y \in \mathrm{int}K$ and $\eta > 0$, then the set $\{x \in K : \langle x, y\rangle \leq \eta\}$ is compact.*

Proof. See Theorem III.2.1 together with its proof and Proposition II.2.4 of [5] for (i) and Corollary I.1.6 of [5] for (ii). □

An *idempotent* c is an element of V such that $c^2 = c$. An idempotent is *primitive* if it is nonzero and not given by the sum of two nonzero idempotents. A complete system of orthogonal idempotents is a set $\{c_1, c_2, \ldots, c_k\}$, where

$$c_j \circ c_j = c_j, \quad c_i \circ c_j = 0 \ (i \neq j), \quad \sum_{j=1}^{k} c_j = e.$$

A complete system of orthogonal primitive idempotents is called a *Jordan frame*.

THEOREM 2.2. *Let r be the rank of V.*

(i) *If $x \in V$, then there exist real numbers $\lambda_1, \ldots, \lambda_r$ and a Jordan frame $c_1, \ldots, c_r$ such that $x = \sum_{j=1}^{r} \lambda_j c_j$. Here the numbers λ_j (with their multiplicities) are uniquely determined by x and λ_j's are the eigenvalues (multiplicities included) of x.*

(ii) *Let c be an idempotent in a Jordan algebra, $c^2 = c$. The only possible eigenvalues of $L(c)$ are 0, $\frac{1}{2}$, and 1.*

Proof. See Theorem III.1.2 of [5] for (i) and Proposition III.1.3 of [5] for (ii). □

The corollary below follows from Proposition 2.1 and the above theorem.

COROLLARY 2.3. *Let $x \in V$ and let $\sum_{j=1}^{r} \lambda_j c_j$ be a decomposition of x given by Theorem 2.2. Then*

(i) *$x \in K$ if and only if $\lambda_j \geq 0$ $(j = 1, 2, \ldots, r)$,*

(ii) *$x \in \mathrm{int}K$ if and only if $\lambda_j > 0$ $(j = 1, 2, \ldots, r)$.*

For each $x, y \in V$, define $P(x) := 2L(x)^2 - L(x^2)$ and

$$P(x, y) := \frac{1}{2}(P(x + y) - P(x) - P(y)) = L(x)L(y) + L(y)L(x) - L(x \circ y). \tag{2.3}$$

$P(x)$ is the *quadratic representation* of x and used in several characterizations of x.

PROPOSITION 2.4.

(i) *If $x, y \in V$, then $P(x)e = x^2$ and $P(P(y)x) = P(y)P(x)P(y)$.*

(ii) *If $x, y \in V$ are invertible, then $P(x)^{-1} = P(x^{-1})$ and $P(x)\mathrm{int}K = \mathrm{int}K$.*

(iii) *If $x \in \mathrm{int}K$, then $P(x)^{-1/2} = P(x^{-1/2})$.*

Proof. See Proposition II.3.1, II.3.3, and III.2.2 of [5] for (i) and (ii). Using (i) and (ii), we obtain (iii) as follows:

$$\begin{aligned}[P(x)^{-1/2}]^2 &= P(x)^{-1} = P(x^{-1}) = P(P(x^{-1/2})e) \\ &= P(x^{-1/2})P(e)P(x^{-1/2}) = [P(x^{-1/2})]^2. \end{aligned}$$ □

The following is a collection of technical facts which are often used in the succeeding sections. Before proceeding, we give a definition of the *star-shaped* set in a vector space.

DEFINITION 2.5. *A subset C of a vector space is said to be* star-shaped *if there exists $c^0 \in C$ such that the line segment connecting c^0 to any other point in C is contained entirely in C.*

LEMMA 2.6.

(i) $x \in K$ *if and only if* $\langle x, y\rangle \geq 0$ *for all* $y \in K$.

(ii) *If* $x \in K$ *and* $y \in K$, *then* $\langle x, y\rangle = 0$ *if and only if* $x \circ y = 0$.

(iii) *If* $x \in \mathrm{int}K$ *and* $y \in K$, *then* $\langle x, y\rangle = 0$ *if and only if* $y = 0$.

(iv) *Define*

$$\mathcal{U} := \{(x, y) \in \mathrm{int}K \times \mathrm{int}K : \ x \circ y \in \mathrm{int}K\}. \tag{2.4}$$

Then $\mathcal{U} = \{(x, y) \in K \times K : \ x \circ y \in \mathrm{int}K\}$.

(v) *If* $(x, y) \in \mathcal{U}$, *then* $L(x)L(y) + L(y)L(x) \succ 0$.

(vi) *If* $(x, y) \in \mathcal{U}$, $(\Delta x, \Delta y) \in V \times V$, *and*

$$\langle \Delta x, \Delta y\rangle \geq 0, \quad x \circ \Delta y + y \circ \Delta x = 0 \tag{2.5}$$

hold, then $\Delta x = \Delta y = 0$.

(vii) $\mathcal{U}$ *is a nonempty and open subset of* $\mathrm{int}K \times \mathrm{int}K$ *which is star-shaped.*

(viii) *If* $x \in \mathrm{int}K$, *then* $(x, x) \in \mathcal{U}$.

(ix) $\mathrm{int}K \times \{\alpha e : \ \alpha \in \Re_{++}\} \subseteq \mathcal{U}$, $\{\alpha e : \ \alpha \in \Re_{++}\} \times \mathrm{int}K \subseteq \mathcal{U}$,
$K \times \{\alpha e : \ \alpha \in \Re_{+}\} \subseteq \mathrm{cl}(\mathcal{U})$, $\{\alpha e : \ \alpha \in \Re_{+}\} \times K \subseteq \mathrm{cl}(\mathcal{U})$,
where $\Re_+ := \{\alpha \in \Re : \ \alpha \geq 0\}$ *and* $\Re_{++} := \{\alpha \in \Re : \ \alpha > 0\}$.

Proof. (i) Since the set K is the symmetric cone, K is self-dual, and we obtain (i).

(ii) See Lemma 2.2 of [7].

(iii) It follows from the fact that K is a self-dual convex cone with nonempty interior. See, for example, Exercise 6.22 of [26].

(iv) Let $\bar{\mathcal{U}} := \{(x, y) \in K \times K : \ x \circ y \in \mathrm{int}K\}$. It is obvious that $\mathcal{U} \subseteq \bar{\mathcal{U}}$. Suppose that $(x, y) \in \bar{\mathcal{U}}$ and $x \in K \setminus \mathrm{int}K$. Let $x = \sum_{i=1}^{r} \lambda_i e_i$ and $y = \sum_{j=1}^{r} \mu_j f_j$ be decompositions of x and y given by (i) of Theorem 2.2. Since $x \in K \setminus \mathrm{int}K$, by (i) and (ii) of Corollary 2.3, there exists an index $\bar{i}$ such that $\lambda_{\bar{i}} = 0$. Define $z := \sum_{k=1}^{r} \nu_k e_k$, where

$$\nu_k = \begin{cases} 1 & \text{if } \lambda_k = 0, \\ 0 & \text{otherwise.} \end{cases}$$

Then $x \circ z^2 = 0$ and $z \neq 0$. Thus, we see that $0 = \langle x \circ z^2, y\rangle = \langle x \circ y, z^2\rangle = \langle z, L(x \circ y)z\rangle$ for $z \neq 0$, which implies that $L(x \circ y)$ is not positive definite; a contradiction to the assumption $(x, y) \in \bar{\mathcal{U}}$. Similarly, we obtain $y \in \mathrm{int}K$.

(v) We first show that $P(x, y)$ defined by (2.3) is positive definite for any $x, y \in \mathrm{int}K$. Suppose that $x, y \in \mathrm{int}K$. Using the results of Proposition 2.4, we see that

$$\begin{aligned} P(x)^{-1/2}P(x + y)P(x)^{-1/2} &= P(x^{-1/2})P(x + y)P(x^{-1/2}) && \text{(by (iii))} \\ &= P(P(x^{-1/2})(x + y)) && \text{(by (i))} \\ &= P(P(x^{-1/2})P(x^{1/2})e + P(x^{-1/2})y) && \text{(by (i))} \\ &= P(e + P(x^{-1/2})y) && \text{(by (iii)).} \end{aligned}$$

Similarly,

$$\begin{aligned} P(x)^{-1/2}P(y)P(x)^{-1/2} &= P(x^{-1/2})P(y)P(x^{-1/2}) && \text{(by (iii))} \\ &= P(P(x^{-1/2})(y)) && \text{(by (i)).} \end{aligned}$$

Therefore, we have

$$P(x+y) - P(x) - P(y) = P(x)^{1/2}[P(e+P(x^{-1/2})y) - P(e) - P(P(x^{-1/2})y)]P(x)^{1/2}.$$

Let $z := P(x^{-1/2})y$. It follows from (2.3) that

$$P(e+z) - P(e) - P(z) = 2[L(e)L(z) + L(z)L(e) - L(e \circ z)] = 2L(z).$$

Note that $z = P(x^{-1/2})y \in \mathrm{int}K$ since $x^{-1/2}$ is invertible and $y \in \mathrm{int}K$ (see (ii) of Proposition 2.4). Thus, $P(x+y) - P(x) - P(y) = 2L(z) \succ 0$. Since $x \circ y \in \mathrm{int}K$ implies that $L(x \circ y)$ is positive definite, using (2.3) again, we can conclude that

$$\begin{aligned} L(x)L(y) + L(y)L(x) &= P(x,y) + L(x \circ y) \\ &= [P(x+y) - P(x) - P(y)] + L(x \circ y) \succ 0. \end{aligned}$$

(vi) Let $(x,y) \in \mathcal{U}$. Since $x \in \mathrm{int}K$, $L(x)$ is invertible by (i) of Proposition 2.1. Suppose that $(\Delta x, \Delta y)$ satisfy (2.5). The equation in (2.5) implies $\Delta y + L(x)^{-1}L(y)\Delta x = 0$ and $\langle \Delta x, \Delta y \rangle + \langle \Delta x, L(x)^{-1}L(y)\Delta x \rangle = 0$. By the inequality in (2.5), we have $\langle \Delta x, L(x)^{-1}L(y)\Delta x \rangle \leq 0$. Define $\Delta \tilde{x} = L(x)^{-1}\Delta x$. Then

$$\begin{aligned} 0 &\geq \langle \Delta x,\ L(x)^{-1}L(y)\Delta x \rangle \\ &= \langle \Delta \tilde{x},\ L(y)L(x)\Delta \tilde{x} \rangle \\ &= \langle \Delta \tilde{x},\ (L(x)L(y) + L(y)L(x))\Delta \tilde{x} \rangle / 2, \end{aligned}$$

which implies that $\Delta \tilde{x} = 0$ by the facts $(x,y) \in \mathcal{U}$ and (v) above. Finally, we see that

$$\Delta x = L(x)\Delta \tilde{x} = 0 \quad \text{and} \quad \Delta y = -L(x)^{-1}L(y)\Delta x = 0.$$

(vii) By the fact that $(e,e) \in \mathcal{U}$ and by the continuity of the operators $x \circ y$ and $L(x)L(y) + L(y)L(x)$, the set $\mathcal{U}$ is a nonempty open subset of $\mathrm{int}K \times \mathrm{int}K$. Let $(x,y) \in \mathcal{U}$. For $\theta \in [0,1]$, define

$$(x(\theta), y(\theta)) := (\theta e + (1-\theta)x, \theta e + (1-\theta)y) = \theta(e,e) - (1-\theta)(x,y).$$

To see that the set $\mathcal{U}$ is star-shaped, it suffices to show that $(x(\theta), y(\theta)) \in \mathcal{U}$ for any $\theta \in [0,1]$. Since the set $\mathrm{int}K \times \mathrm{int}K$ is convex, we have $(x(\theta), y(\theta)) \in \mathrm{int}K \times \mathrm{int}K$ for any $\theta \in [0,1]$. In addition, $x(\theta) \circ y(\theta)$ turns out to be

$$x(\theta) \circ y(\theta) = \theta^2 e + \theta(1-\theta)(x+y) + (1-\theta)^2 x \circ y,$$

where $e \in \mathrm{int}K$, $x + y \in \mathrm{int}K$, and $x \circ y \in \mathrm{int}K$. By the convexity of the cone $\mathrm{int}K$, we see that $x(\theta) \circ y(\theta) \in \mathrm{int}K$ and $(x(\theta), y(\theta)) \in \mathcal{U}$ for any $\theta \in [0,1]$.

(viii) For any $x \in \mathrm{int}K$, (i) of Proposition 2.1 implies $x \circ x \in \mathrm{int}K$ and $(x,x) \in \mathcal{U}$.

(ix) Since $\mathrm{int}K$ is a convex cone, for any $x \in \mathrm{int}K$ and $\alpha \in \Re_{++}$, it must hold that $\alpha e \in \mathrm{int}K$ and $x \circ (\alpha e) = \alpha x \in \mathrm{int}K$. Thus $\mathrm{int}K \times \{\alpha e :\ \alpha \in \Re_{++}\} \subseteq \mathcal{U}$ and $K \times \{\alpha e :\ \alpha \in \Re_{+}\} \subseteq \mathrm{cl}(\mathcal{U})$. By the symmetricity $x \circ y = y \circ x$, we obtain the assertion. □

A Euclidean Jordan algebra is called *simple* if it cannot be represented as the orthogonal direct sum of two Jordan algebras.

PROPOSITION 2.7.

(i) *Any Euclidean Jordan algebra V is, in a unique way, an orthogonal direct sum of simple Euclidean Jordan algebras $V_1, V_2, \ldots, V_m$. That is, any element $x \in V$ is uniquely represented by $x = \sum_{i=1}^{m} x_i$, where $x_i \in V_i$ $(i = 1,2,\ldots,m)$ and $x_i \circ x_j = 0$ $(i \neq j)$.*

(ii) *Let V be a simple Euclidean Jordan algebra. Then, for any $u \in V$,*

$$\mathrm{Tr}(L(u)) = \frac{n}{r}\mathrm{tr}(u).$$

(iii) *Let V be a simple Euclidean Jordan algebra. Then, for any nonzero idempotent c of V,*

$$0 < \sqrt{\frac{r}{2n}} \leq \|c\| = \sqrt{\langle e, c\rangle} \leq \sqrt{r}.$$

(iv) *Let V be a Euclidean Jordan algebra. Then, there exist $\omega_1 > 0$ and $\omega_2 > 0$ for which $0 < \omega_1 \leq \|c\| = \sqrt{\langle e, c\rangle} \leq \omega_2$ holds for any nonzero idempotent c of V.*

Proof. See Propositions III.4.4 and III.4.2 of [5] for (i) and (ii), respectively.

(iii) Since any nonzero idempotent c is an element of K, by (i) of Corollary 2.3, all eigenvalues of c are nonnegative and $\mathrm{tr}(c)$ is positive. The assertion (iii) follows from (ii) of the proposition, (ii) of Theorem 2.2, and

$$0 < \|c\| = \sqrt{\mathrm{tr}(c^2)} = \sqrt{\mathrm{tr}(c)} = \sqrt{\frac{r}{n}\mathrm{Tr}(L(c))}, \quad \langle e, c\rangle = \mathrm{tr}(e \circ c) = \mathrm{tr}(c) = \|c\|^2.$$

(iv) Let V be a Euclidean Jordan algebra. By the assertion (i) above, V is given by an orthogonal direct sum of simple Jordan algebras $V_1, V_2, \ldots, V_m$. For each $i = 1, 2, \ldots, m$, let us denote the dimension and the rank of V_i by n_i and r_i, respectively.

Suppose that c is a nonzero idempotent of V. Then c is given by $c = \sum_{i=1}^m c_i$ for some $c_i \in V_i$ $(i = 1, 2, \ldots, m)$. The orthogonality of V_is and the fact that $c^2 = c$ ensure that $c = c^2 = \sum_{i=1}^m c_i^2$. Therefore, by the uniqueness of the representation, we see that $c_i^2 = c_i$ $(i = 1, 2, \ldots, m)$; i.e., c is given by the sum of c_is which are idempotents of the simple Jordan algebras V_i $(i = 1, 2, \ldots, m)$.

Note that the orthogonality of V_is also ensures that

$$\|c\|^2 = \sum_{i=1}^m \|c_i\|^2 = \sum_{i=1}^m \langle e, c_i\rangle = \langle e, c\rangle.$$

Since $c \neq 0$, there exists $c_i \neq 0$ for some i, and by the assertion (iii) above, we obtain the following inequalities:

$$0 < \min_i \left\{\sqrt{\frac{r_i}{2n_i}}\right\} \leq \|c\| = \sqrt{\langle e, c\rangle} \leq \sqrt{\sum_{i=1}^m r_i}. \qquad \square$$

3. Homeomorphism of an interior point map. In this section, we extend the results in [19] to the case of symmetric cones and show the homeomorphism of an interior point map using the results in section 2.

The arguments used in the section are quite analogous to the ones in [19] and we omit some details in the proofs. Note that we restrict the domain of the map F to $\mathrm{int}K \times \mathrm{int}K \times \Re^m$ and it causes subtle differences in the results.

Here we introduce some notation and definitions. If M and N are two metric spaces, we denote the set of continuous functions from M to N by $C(M, N)$. For given $G \in C(M, N)$, $D \subseteq M$, and $E \subseteq N$, we define

$$G(D) := \{G(u) : \ u \in D\}, \quad G^{-1}(E) := \{u \in M : \ G(u) \in E\}.$$

We also denote "G restricted to the pair (D, E)" by $G|_{(D,E)}$. $G \in C(M, N)$ is called a *homeomorphism* from M onto N if G is bijective from M onto N and G and G^{-1} are continuous on M and N, respectively. We denote the set of homeomorphisms from M onto N by $\mathrm{Hom}(M, N)$. $G : M \to N$ is called a *local homeomorphism* from M onto N if for each $x \in M$, there exist open neighborhoods M_x of x and N_x of $G(x)$ such that $G|_{(M_x,N_x)} \in \mathrm{Hom}(M_x, N_x)$. In addition, for $a, b \in \Re$, $[a, b]$ denotes the line segment $\{x \in \Re : \ a \le x \le b\}$.

DEFINITION 3.1 (section 2 of [18], section 2.2 of [19]).

(i) *A metric space M is* connected *if there exists no partition (V_1, V_2) of M for which V_1 and V_2 are nonempty and open.*

(ii) *A metric space M is* path-connected *if for any two points $u_0, u_1 \in M$, there exists a path, i.e., a continuous function $p : [0, 1] \to M$ such that $p(0) = u_0$ and $p(1) = u_1$.*

(iii) *A metric space M is* simply connected *if it is path-connected and for any path $p : [0, 1] \to M$ with $p(0) = p(1) = u$, there exists a continuous map $\alpha : [0, 1] \times [0, 1] \to M$ such that $\alpha(s, 0) = p(s)$ and $\alpha(s, 1) = u$ for all $s \in [0, 1]$ and $\alpha(0, t) = \alpha(1, t) = u$ for all $t \in [0, 1]$.*

(vi) *The map $G \in C(M, N)$ is said to be* proper *with respect to the set $E \subseteq N$ if the set $G^{-1}(K) \subseteq M$ is compact for any compact set $K \subseteq E$. If G is proper with respect to N, we simply say that G is proper.*

It is easy to see that any star-shaped set (see Definition 2.5) in a normed vector space is simply connected.

The goal of this section is to show that the map H defined by (1.4) gives a homeomorphism between $\mathcal{U} \times \Re^m$ and $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ under Assumption 1.1 (cf. Theorem 3.8 for affine maps and Theorem 3.10 for general maps). The homeomorphism ensures that there exists a unique path $H^{-1}(P) \subset \mathcal{U} \times \Re^m$ for any path $P \subseteq \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$. As we will see in Theorem 3.12, if an additional assumption (Assumption 3.11) holds, then the set $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ is open and convex. Therefore, if $0 \in \mathrm{cl}(\mathrm{int}K \times F(\mathcal{U} \times \Re^m))$ then we may choose the path as $P = \{th : \ t \in (0, 1]\} \subseteq \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ for any $h \in \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$. The set $H^{-1}(P)$ is a so-called *(weighted) interior point trajectory* which is an important element in the development of interior point algorithms (cf. Corollary 4.4 and Theorems 5.4 and 5.5).

PROPOSITION 3.2 (Theorem 1 of [18], Proposition 1 of [19]). *Let M and N be metric spaces such that M is path-connected and N is simply connected. Suppose that $G : M \to N$ is a local homeomorphism. Then G is proper if and only if $G \in \mathrm{Hom}(M, N)$.*

PROPOSITION 3.3 (Corollary 1 of [18], Proposition 2 of [19]). *Let $G \in C(M, N)$, $M_0 \subseteq M$, and $N_0 \subseteq N$.*

(i) *Suppose that G, $M_0 \subseteq M$, and $N_0 \subseteq N$ satisfy the following conditions:*
   (a) *$G|_{(M_0,N)}$ is a local homeomorphism,*
   (b) *$G(M_0) \cap N_0 \neq \emptyset$,*
   (c) *$G(M \setminus M_0) \cap N_0 = \emptyset$, and*
   (d) *G is proper with respect to a subset E such that $N_0 \subseteq E \subseteq N$.*
   Then $G|_{(M_0 \cap G^{-1}(N_0), N_0)}$ is a proper local homeomorphism.

(ii) *Suppose that G, $M_0 \subseteq M$, and $N_0 \subseteq N$ satisfy the conditions* (a)–(d) *in* (i) *above and the additional condition below:*
   (e) *N_0 is connected.*
   Then $G(M_0) \supseteq N_0$ and $G(\mathrm{cl}(M_0)) \supseteq E \cap \mathrm{cl}(N_0)$.

PROPOSITION 3.4 (Corollary 3 of [18], Proposition 3 of [19]). *Let M be a path-connected metric space and let V be an n-dimensional real vector space. Suppose that $G : M \to V$ is a local homeomorphism and that $G^{-1}([y_0, y_1])$ is compact for any pair of points $y_0, y_1 \in G(M)$. Then, $G|_{(M,G(M))} \in \mathrm{Hom}(M, G(M))$ and $G(M)$ is convex.*

The following three lemmas are analogous to Lemmas 2–4 of [19]. See the proofs in [19] for detailed arguments.

LEMMA 3.5 (cf. Lemma 2 of [19]). *Let $F : \mathrm{int}K \times \mathrm{int}K \times \Re^m \to V \times \Re^m$ be a continuous map which satisfies Assumption* 1.1. *Let H be the map defined by* (1.4). *If the map H restricted to $\mathcal{U} \times \Re^m$ is a local homeomorphism, then the map H is proper with respect to $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.*

Proof. Let C be a compact subset of $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$. Then the set $H^{-1}(C)$ is closed since H is continuous. The boundedness of the set $H^{-1}(C)$ can be obtained by using (i) and (ii) of Assumption 1.1 and (ii) of Proposition 2.1, with $\langle x, y\rangle = \mathrm{tr}(x \circ y)$. □

LEMMA 3.6 (cf. Lemma 3 of [19]). *Let $F : V \times V \times \Re^m \to V \times \Re^m$ be an affine map and let F^0 be the linear part of F.*

(i) *F is (x, y)-equilevel-monotone if and only if for any $(\Delta x, \Delta y, \Delta z) \in V \times V \times \Re^m$, $F^0(\Delta x, \Delta y, \Delta z) = 0$ implies that $\langle \Delta x, \Delta y\rangle \geq 0$.*

(ii) *F is z-injective if and only if for any $\Delta z \in \Re^m$, $F^0(0, 0, \Delta z) = 0$ implies that $\Delta z = 0$.*

(iii) *F is z-injective if and only if F is z-bounded.*

Proof. See the proof of Lemma 3 in [19]. □

LEMMA 3.7 (cf. Lemma 4 of [19]). *Let $F : V \times V \times \Re^m$ be an affine map which is (x, y)-equilevel-monotone and z-injective. Then H restricted to $\mathcal{U} \times \Re^m$ is a local homeomorphism.*

Proof. Since $\mathcal{U} \times \Re^m$ is an open set ((vii) of Lemma 2.6), it suffices to show that the derivative map $H'(x, y, z) : V \times V \times \Re^m \to V \times V \times \Re^m$ is an isomorphism for all $(x, y, z) \in \mathcal{U} \times \Re^m$. The isomorphism follows from (i) and (ii) of Lemma 3.6 and (vi) of Lemma 2.6. □

In the following theorem, we consider that F is affine. The theorem leads us to an important technical lemma, Lemma 3.9.

THEOREM 3.8 (cf. Theorem 1 of [19]). *Let $F : V \times V \times \Re^m \to V \times \Re^m$ be an affine map which is (x, y)-equilevel-monotone, z-injective, and z-bounded on $V \times V \times \Re^m$. Then the map H defined by* (1.4) *satisfies*

(i) *H is proper with respect to $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$,*

(ii) *H maps $\mathcal{U} \times \Re^m$ homeomorphically onto $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.*

Proof. Define

$$\begin{aligned} &M := \mathrm{int}K \times \mathrm{int}K \times \Re^m,\ N := V \times V \times \Re^m,\ E := \mathrm{int}K \times F(\mathcal{U} \times \Re^m), \\ &M_0 := \mathcal{U} \times \Re^m,\ N_0 := \mathrm{int}K \times F(\mathcal{U} \times \Re^m),\ G := H|_{(M,N)}. \end{aligned} \tag{3.1}$$

We can easily see that

$$N_0 \subseteq E \subseteq N, \quad M_0 \subseteq H^{-1}(N_0). \tag{3.2}$$

(i) Since F is (x, y)-equilevel-bounded and z-injective, Lemma 3.7 and (iii) of Lemma 3.6 ensure that $H|_{(M_0,N)} = G|_{(M_0,N)}$ is a local homeomorphism and z-bounded. Thus the map F satisfies Assumption 1.1 and by Lemma 3.5, $H|_{(M,E)}$ is proper with respect to $E = \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.

(ii) Note that (i) above ensures that the requirement (d) of Proposition 3.3 is satisfied. In addition, Lemma 3.7 implies that $G|_{(M_0,N)} = H_{(M_0,N)}$ is a local homeomorphism, i.e., the requirement (a) holds. By similar discussions in the proof of Theorem 1 of [19], we can see that other requirements (b) and (c) are also satisfied.

Since (3.2) ensures the relation $M_0 \subseteq M_0 \cap H^{-1}(N_0) = M_0 \cap G^{-1}(N_0)$, we obtain that the map H restricted to

$$(M_0, N_0) = (\mathcal{U} \times \Re^m, \mathrm{int}K \times F(\mathcal{U} \times \Re^m))$$

is a proper local homeomorphism. Next, we show that $H(\mathcal{U}\times\Re^m) = \mathrm{int}K\times F(\mathcal{U}\times\Re^m)$ by using (ii) of Proposition 3.3. It is clear that

$$G(M_0) = H(\mathcal{U} \times \Re^m) \subseteq \mathrm{int}K \times F(\mathcal{U} \times \Re^m) = N_0.$$

To obtain the inverse inclusion, we should mention that the set N_0 is connected. In fact, by (vii) of Lemma 2.6, $\mathcal{U}\times\Re^m$ is star-shaped and hence path-connected. Since F is continuous, the sets $F(\mathcal{U}\times\Re^m)$ and $N_0 = \mathrm{int}K\times F(\mathcal{U}\times\Re^m)$ are also path-connected, and hence connected. Thus, applying (ii) of Proposition 3.3, we obtain

$$H(\mathcal{U} \times \Re^m) = G(M_0) \supseteq N_0 = \mathrm{int}K \times F(\mathcal{U} \times \Re^m).$$

Let us show that $G \in H(M_0, N_0)$. In (vii) of Lemma 2.6, we have seen that the set $\mathcal{U}$ is star-shaped. Since F is affine, both of the sets M_0 and N_0 are star-shaped and hence simply connected. By the local homeomorphism of G, the assertion $G \in H(M_0, N_0)$ follows from Proposition 3.2. □

LEMMA 3.9 (cf. Lemma 5 of [19]). *For any* $(x_0, y_0), (x_1, y_1) \in \mathcal{U}$, *if* $\langle x_0 - x_1, y_0 - y_1\rangle \geq 0$ *and* $x_0 \circ y_0 = x_1 \circ y_1$, *then* $(x_0, y_0) = (x_1, y_1)$.

Proof. See the proof of Lemma 5 of [19]. □

Since the set $\mathcal{U}$ is defined regardless of F, the above lemma is applicable to the case where the map F is nonlinear. The following theorem is our main result.

THEOREM 3.10 (cf. Theorem 2 of [19]). *Suppose that a continuous map* $F : \mathrm{int}K \times \mathrm{int}K \times \Re^m \to V \times \Re^m$ *satisfies Assumption* 1.1. *Then the map* H *defined by* (1.4) *satisfies the following properties:*

(i) H *is proper with respect to* $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.

(ii) H *maps* $\mathcal{U} \times \Re^m$ *homeomorphically onto* $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.

Proof. Define the sets M, N, E, M_0, and N_0 and the map G as in (3.1). Then (3.2) holds even in this case.

(i) To show the local homeomorphism of $H|_{(M_0,N)} = G|_{(M_0,N)}$, we use Lemma 3.9 instead of Lemma 3.7. Since $H|_{(M_0,N)}$ is a continuous map from an open subset of $V \times V \times \Re^m$ into the same space, by the domain invariance theorem, it suffices to show that $H|_{(M_0,N)}$ is one-to-one.

Suppose that $(\hat{x}, \hat{y}, \hat{z}), (\tilde{x}, \tilde{y}, \tilde{z}) \in \mathcal{U} \times \Re^m$ satisfy $H(\hat{x}, \hat{y}, \hat{z}) = H(\tilde{x}, \tilde{y}, \tilde{z})$, i.e.,

$$F(\hat{x}, \hat{y}, \hat{z}) = F(\tilde{x}, \tilde{y}, \tilde{z}), \quad \hat{x} \circ \hat{y} = \tilde{x} \circ \tilde{y}.$$

Since F is (x, y)-equilevel-monotone, we see that

$$\langle \hat{x} - \tilde{x}, \hat{y} - \tilde{y}\rangle \geq 0, \quad \hat{x} \circ \hat{y} = \tilde{x} \circ \tilde{y}.$$

By Lemma 3.9, the above relations imply that $(\hat{x}, \hat{y}) = (\tilde{x}, \tilde{y})$ and by the z-injectivity of F, we have $(\hat{x}, \hat{y}, \hat{z}) = (\tilde{x}, \tilde{y}, \tilde{z})$. Thus, $H|_{(M_0,N)}$ is one-to-one and maps M_0 homeomorphically onto $H(M_0)$. By the local homeomorphism of $H|_{(M_0,N)}$ together with

the equilevel-monotonicity and the z-boundedness of the map F, Lemma 3.5 ensures that H is proper with respect to the set $E = \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$.

(ii) In the proof of (i) above, we have already seen that (a) and (d) of Proposition 3.3 hold. By the same discussions as in the proof of (ii) of Theorem 3.8, we can see that the assumptions (b) and (c) of Proposition 3.3 are also satisfied. Since F is continuous, $F(\mathcal{U} \times \Re^m)$ and $N_0 = \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ are also path-connected. Thus, as in the proof of (ii) of Theorem 3.8 again, we obtain that

$$H(\mathcal{U} \times \Re^m) = G(M_0) = N_0 = \mathrm{int}K \times F(\mathcal{U} \times \Re^m). \qquad \square$$

Next, we discuss the convexity of the set $F(\mathcal{U} \times \Re^m)$, which is a key property in section 5. We impose the additional assumption below on the map F(cf. [19]).

ASSUMPTION 3.11. *F is (x, y)-everywhere-monotone on the domain with respect to the set $V \times \Re^m$, i.e., there exist continuous functions ϕ from the domain of F to the set $V \times \Re^m$ and $c : (V \times \Re^m) \times (V \times \Re^m) \to \Re$ such that $c(r, r) = 0$ for any $r \in V \times \Re^m$ and*

$$\langle x - x', y - y' \rangle \geq \langle r - r', \phi(x, y, z) - \phi(x', y', z') \rangle_{V \times \Re^m} + c(r, r')$$

holds for any (x, y, z) and (x', y', z') in the domain of F satisfying $F(x, y, z) = r$ and $F(x', y', z') = r'$. Here we define

$$\langle (a, b), (a', b') \rangle_{V \times \Re^m} = \langle a, a' \rangle + b^T b'$$

for any $(a, b), (a', b') \in V \times \Re^m$.

It can be easily seen that if F is (x, y)-everywhere-monotone then $r = r'$ implies that $\langle x - x', y - y' \rangle \geq 0$ and F is (x, y)-equilevel-monotone.

THEOREM 3.12 (cf. Theorem 3 of [19]). *Suppose that a continuous map $F : \mathrm{int}K \times \mathrm{int}K \times \Re^m \to V \times \Re^m$ satisfies Assumptions* 1.1 *and* 3.11. *Then the set $F(\mathcal{U} \times \Re^m)$ is an open convex set.*

Proof. It suffices to show that $H(\mathcal{U} \times \Re^m)$ is open and convex since $H(\mathcal{U} \times \Re^m) = \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ holds by (ii) of Theorem 3.10. Since $\mathcal{U} \times \Re^m$ is open ((vii) of Lemma 2.6), (ii) of Theorem 3.10 implies that the set $H(\mathcal{U} \times \Re^m)$ is also open. Define

$$M := \mathcal{U} \times \Re^m, \quad N := V \times V \times \Re^m, \quad G := H|_{(M,N)}.$$

Then the set M is path-connected by (vii) of Lemma 2.6 and G is a local homeomorphism by (ii) of Theorem 3.10. Using (ii) of Proposition 2.1 and (iv) of Lemma 2.6, we can obtain the compactness of the set $G^{-1}([w_0.w_1])$ by similar arguments as in the proof of Theorem 3 of [19]. Therefore, the convexity of the set $H(\mathcal{U} \times \Re^m)$ follows from Proposition 3.4. $\square$

4. Solvability of the CP. In this section, we discuss the solvability of the CP assuming that the map F is defined and continuous on the set $K \times K \times \Re^m$ instead of $\mathrm{int}K \times \mathrm{int}K \times \Re^m$. The following results are direct extensions of the ones in [19] to the case of symmetric cones and obtained similarly as in the previous section. In the proofs below, we give only the differences arising from the expansion of the domain of F.

LEMMA 4.1 (cf. Lemma 2 of [19] and Lemma 3.5). *Let $F : K \times K \times \Re^m \to V \times \Re^m$ be a continuous map which is (x, y)-equilevel-monotone and z-bounded on $K \times K \times \Re^m$. Let H be the map defined by* (1.4). *If the map H restricted to $\mathcal{U} \times \Re^m$ is a local homeomorphism, then the map H is proper with respect to $V \times F(\mathcal{U} \times \Re^m)$.*

Proof. Let C be a compact subset of $V \times F(\mathcal{U} \times \Re^m)$. Since the domain $K \times K \times \Re^m$ of F is closed, by the continuity of H, the set $H^{-1}(C)$ is always closed. The argument to obtain the boundedness of $H^{-1}(C)$ is the same as in the proof of Lemma 3.5. □

THEOREM 4.2 (cf. Theorem 2 of [19] and Theorem 3.10). *Suppose that a continuous map $F : K \times K \times \Re^m \to V \times \Re^m$ satisfies Assumption* 1.1. *Then the map H defined by* (1.4) *satisfies that*

(i) *H is proper with respect to $V \times F(\mathcal{U} \times \Re^m)$,*
(ii) *H maps $\mathcal{U} \times \Re^m$ homeomorphically onto $\mathrm{int}K \times F(\mathcal{U} \times \Re^m)$, and*
(iii) *$H(K \times K \times \Re^m) \supseteq K \times F(\mathcal{U} \times \Re^m)$.*

Proof. Define the sets M, N, M_0, and N_0 and the map G as in (3.1), and the set E by

$$E := V \times F(\mathcal{U} \times \Re^m).$$

(i) The continuity assumption on F is stricter than the one in Theorem 3.10. Thus the local homeomorphism of $H|_{(M_0,N)} = G|_{(M_0,N)}$ is similarly obtained from Lemma 3.9. Using Lemma 4.1 instead of Lemma 3.5, we can see that H is proper with respect to $E = V \times F(\mathcal{U} \times \Re^m)$, i.e., the assertion (i) holds.

(ii) In the above discussion, we have shown that (d) of Proposition 3.3 holds. Since the sets M, N, and N_0 are the same as in Theorem 3.10, we can see that the assumptions (a)–(c) of Proposition 3.3 are also satisfied and that

$$H(\mathcal{U} \times \Re^m) = G(M_0) = N_0 = \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$$

holds.

(iii) Since $\mathcal{U}$ is star-shaped ((vii) of Lemma 2.6), $\mathcal{U} \times \Re^m$ is connected, and N_0 is also connected by the continuity of F. Combining this with the facts

$$K \times K \times \Re^m = \mathrm{cl}(M) \supseteq \mathrm{cl}(M_0) \quad \text{and} \quad E \cap \mathrm{cl}(N_0) = K \times F(\mathcal{U} \times \Re^m),$$

the assertion (iii) follows from (ii) of Proposition 3.3. □

The following corollary is a direct consequence of Theorem 3.12.

COROLLARY 4.3 (cf. Theorem 3 of [19] and Theorem 3.12). *Suppose that a continuous map $F : K \times K \times \Re^m \to V \times \Re^m$ satisfies Assumptions* 1.1 *and* 3.11. *Then the set $F(\mathcal{U} \times \Re^m)$ is an open convex set.*

COROLLARY 4.4 (cf. Corollary 1 of [19]). *Suppose that the map $F : K \times K \times \Re^m \to V \times \Re^m$ is continuous and that $0 \in F(\mathcal{U} \times \Re^m)$, which implies that the CP has an interior feasible point $(\bar{x}, \bar{y}, \bar{z}) \in \mathrm{int}K \times \mathrm{int}K \times \Re^m$ satisfying $\bar{x} \circ \bar{y} \in \mathrm{int}K$ and $F(\bar{x}, \bar{y}, \bar{z}) = 0$. Let $p : [0,1] \to K \times F(\mathcal{U} \cap \Re^m)$ be a path for which $p(0) = 0$ and $p(t) \in \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ hold.*

(i) *If the map F satisfies Assumption* 1.1 *then there exists a unique path $(x, y, z) : (0,1] \to \mathrm{int}K \times \mathrm{int}K \times \Re^m$ such that $H(x(t), y(t), z(t)) = p(t)$ for all $t \in (0,1]$ and $\{(x(t), y(t), z(t)) : t \in (0,1]\}$ is bounded. Thus the CP is asymptotically solvable. In addition, any accumulation point of $\{(x(t), y(t), z(t)) : t \in (0,1]\}$ is a solution of the CP.*
(ii) *If F satisfies Assumptions* 1.1 *and* 3.11 *then for each $h \in \mathrm{int}K \times F(\mathcal{U} \cap \Re^m)$, we can take $p(t) = th$ for all $t \in [0,1]$ as a path $p : [0,1] \to K \times F(\mathcal{U} \cap \Re^m)$ satisfying the requirements above.*

Proof. (i) Note that $\{p(t) : t \in [0,1]\}$ is bounded by (ii) of Definition 3.1 of a path. The assertion follows from Theorem 4.2: (ii) of the theorem implies the unique existence of $(x(t), y(t), z(t))$ for any $t \in (0,1]$, (i) implies the boundedness of

$(x(t), y(t), z(t))$, and (iii) implies that any accumulation point of $\{(x(t), y(t), z(t))\}$ is a solution of the CP.

(ii) Since $(0,0) \in K \times F(\mathcal{U} \times \Re^m)$, Corollary 4.3 ensures that $\{p(t) : p(t) = th,\ t \in [0,1]\} \subseteq K \times F(\mathcal{U} \times \Re^m)$ for any $h \in \mathrm{int}K \times F(\mathcal{U} \cap \Re^m)$. It is obvious that $\{p(t) :\ t \in [0,1]\}$ is bounded, $p(0) = 0$, and $p(t) \in \mathrm{int}K \times F(\mathcal{U} \times \Re^m)$ for all $t \in (0,1]$. □

5. A homogeneous model for the CP. In this section, we give a homogenous model for solving a special class of CPs where the map $F : K \times K \to V$ is of the form

$$F(x,y) = y - \psi(x) \tag{5.1}$$

for a continuous map $\psi : K \to V$.

Our model is a natural extension of the homogeneous model proposed by Andersen and Ye [2] for solving CPs where K is the positive orthant in $\Re^n$. One of the remarkable features of their model is that the associated trajectory gives certifications on the strong feasibility or the strong infeasibility of the original problem. Our results, Theorems 5.4 and 5.5, show that our homogeneous model inherits the property even for the case of symmetric cones.

Throughout this section, we impose the following assumption on ψ.

ASSUMPTION 5.1. *The map $\psi : K \to V$ in (5.1) is monotone on the set K, i.e.,*

$$\langle \psi(x) - \psi(x'), x - x' \rangle \geq 0 \quad \textit{for all } x, x' \in K.$$

PROPOSITION 5.2. *Suppose that $S \subseteq K$ and $\psi : S \to V$ is monotone on the set S. Then the map $F : S \times K \to V$ given by (5.1) is (x,y)-everywhere-monotone on the set $S \times K$ with $m = 0$.*

Proof. Define $\phi : S \times K \to V$ and $c : V \times V \to \Re$ by $\phi(x,y) := x$ and $c := 0$. Let $r := F(x,y)$ and $r' := F(x',y')$, where $(x,y), (x',y') \in S \times K$. Then we see that $\psi(x) - \psi(x') = (y - y') - (r - r')$, and the monotonicity of ψ implies that

$$\begin{aligned} 0 &\leq \langle \psi(x) - \psi(x'), x - x' \rangle \\ &= \langle (y - y') - (r - r'), x - x' \rangle \\ &= \langle y - y', x - x' \rangle - \langle r - r', x - x' \rangle \\ &= \langle y - y', x - x' \rangle - \langle r - r', \phi(x,y) - \phi(x',y') \rangle + c(r, r'). \end{aligned}$$

Thus, by the definition of (x,y)-everywhere-monotonicity in Assumption 3.11, the map F is (x,y)-everywhere-monotone on the set $S \times K$ with $m = 0$. □

Define the sets $\Re_+ := \{\tau \in \Re :\ \tau \geq 0\}$ and $\Re_{++} := \{\tau \in \Re :\ \tau > 0\}$. For a given CP with a map F of the form (5.1), we consider the homogeneous model

$$\begin{array}{lll} \text{(HCP)} & \text{find} & (x, \tau, y, \kappa) \in (K \times \Re_{++}) \times (K \times \Re_+) \\ & \text{s.t.} & F_{\mathrm{H}}(x, \tau, y, \kappa) = 0,\ (x, \tau) \circ_{\mathrm{H}} (y, \kappa) = 0, \end{array} \tag{5.2}$$

where $F_{\mathrm{H}} : (K \times \Re_{++}) \times (K \times \Re_+) \to (V \times \Re)$ and $(x, \tau) \circ_{\mathrm{H}} (y, \kappa)$ are given by

$$F_{\mathrm{H}}(x, \tau, y, \kappa) := \begin{pmatrix} y - \tau\psi(x/\tau) \\ \kappa + \langle \psi(x/\tau), x \rangle \end{pmatrix} \tag{5.3}$$

and

$$(x, \tau) \circ_{\mathrm{H}} (y, \kappa) := \begin{pmatrix} x \circ y \\ \tau\kappa \end{pmatrix}. \tag{5.4}$$

For ease of notation, we use the following symbols:

$$V_{\rm H} := V \times \Re, \quad K_{\rm H} := K \times \Re_+, \quad x_{\rm H} := (x, \tau) \in V_{\rm H}, \quad y_{\rm H} := (y, \kappa) \in V_{\rm H}. \tag{5.5}$$

It should be noted that the set $K_{\rm H}$ is a Cartesian product of two symmetric cones K and $\Re_+$ and is given by

$$K_{\rm H} = \left\{ x_{\rm H}^2 = \begin{pmatrix} x^2 \\ \tau^2 \end{pmatrix} : \ x_{\rm H} \in V_{\rm H} \right\}.$$

Thus the closed convex cone $K_{\rm H}$ is the symmetric cone of $V_{\rm H}$. It can be easily seen that $\mathrm{int}K_{\rm H} = \mathrm{int}K \times \Re_{++}$.

The scalar product $\langle (x, \tau), (y, \kappa) \rangle_{\rm H}$ associated to the bilinear product $\circ_{\rm H}$ is given by

$$\langle (x, \tau), (y, \kappa) \rangle_{\rm H} := \langle x, y \rangle + \tau\kappa. \tag{5.6}$$

For any $x_{\rm H} = (x, \tau) \in V_{\rm H}$, the linear operator

$$L_{\rm H}(x_{\rm H}) := \begin{pmatrix} L(x) & 0 \\ 0^T & \tau \end{pmatrix}$$

is self-adjoint with respect to $\langle \cdot, \cdot \rangle$, i.e., $\langle v_{\rm H}, L_{\rm H}(x_{\rm H}) w_{\rm H} \rangle = \langle L_{\rm H}(x_{\rm H}) v_{\rm H}, w_{\rm H} \rangle$ for any $v_{\rm H}, w_{\rm H} \in V_{\rm H}$.

Let us define the map $\psi_{\rm H}$ by

$$\psi_{\rm H}(x_{\rm H}) = \psi_{\rm H}(x, \tau) := \begin{pmatrix} \tau\psi(x/\tau) \\ -\langle \psi(x/\tau), x \rangle \end{pmatrix} \tag{5.7}$$

for any $x_{\rm H} = (x, \tau) \in K \times \Re_{++}$. Then the map $F_{\rm H}$ is given by

$$F_{\rm H}(x_{\rm H}, y_{\rm H}) = y_{\rm H} - \psi_{\rm H}(x_{\rm H}). \tag{5.8}$$

We also define the set

$$\mathcal{U}_{\rm H} := \{ (x_{\rm H}, y_{\rm H}) \in \mathrm{int}K_{\rm H} \times \mathrm{int}K_{\rm H} : \ x_{\rm H} \circ_{\rm H} y_{\rm H} \in \mathrm{int}K_{\rm H} \}. \tag{5.9}$$

It is clear that the set $\mathcal{U}_{\rm H}$ has the properties described in Lemma 2.6 with $\mathcal{U} = \mathcal{U}_{\rm H}$.

The following proposition shows that a monotonicity of the map $F_{\rm H}$ on the set $\mathrm{int}K_{\rm H} \times \mathrm{int}K_{\rm H}$ can be obtained if the map ψ is monotone on the set K.

PROPOSITION 5.3. *Suppose that $\psi : K \to V$ satisfies Assumption* 5.1. *Then*

(i) *the map $\psi_{\rm H}$ is monotone on* $\mathrm{int}K_{\rm H}$,

(ii) *the map $F_{\rm H}$ is $(x_{\rm H}, y_{\rm H})$-everywhere-monotone on* $\mathrm{int}K_{\rm H} \times \mathrm{int}K_{\rm H}$.

Thus, $F_{\rm H}$ with the domain $\mathrm{int}K_{\rm H} \times \mathrm{int}K_{\rm H}$ *satisfies Assumptions* 1.1 *and* 3.11 *with $m = 0$ whenever ψ is monotone on K.*

Proof. (i) For any $x_{\rm H}, x'_{\rm H} \in \mathrm{int}K_{\rm H}$, it follows from the definition (5.7) that

$$\begin{aligned}
&\langle \psi_{\rm H}(x_{\rm H}) - \psi_{\rm H}(x'_{\rm H}), x_{\rm H} - x'_{\rm H} \rangle_{\rm H} \\
&= \langle \tau\psi(x/\tau) - \tau'\psi(x'/\tau'), x - x' \rangle - (\tau - \tau')[\langle \psi(x/\tau), x \rangle - \langle \psi(x'/\tau'), x' \rangle] \\
&= \langle \tau\psi(x/\tau), x - x' \rangle - \langle \tau'\psi(x'/\tau'), x - x' \rangle - (\tau - \tau')\langle \psi(x/\tau), x \rangle + (\tau - \tau')\langle \psi(x'/\tau'), x' \rangle \\
&= -\tau\langle \psi(x/\tau), x' \rangle - \tau'\langle \psi(x'/\tau'), x \rangle + \tau'\langle \psi(x/\tau), x \rangle + \tau\langle \psi(x'/\tau'), x' \rangle \\
&= -\tau\tau'\langle \psi(x/\tau), x'/\tau' \rangle - \tau\tau'\langle \psi(x'/\tau'), x/\tau \rangle + \tau\tau'\langle \psi(x/\tau), x/\tau \rangle + \tau\tau'\langle \psi(x'/\tau'), x'/\tau' \rangle \\
&= \tau\tau'\langle \psi(x/\tau), (x/\tau) - (x'/\tau') \rangle - \tau\tau'\langle \psi(x'/\tau'), (x/\tau) - (x'/\tau') \rangle \\
&= \tau\tau'\langle \psi(x/\tau) - \psi(x'/\tau'), (x/\tau) - (x'/\tau') \rangle \\
&\geq 0,
\end{aligned}$$

where the last inequality follows from the monotonicity of ψ.

(ii) The assertion follows from (i) above and Proposition 5.2 with $S = \mathrm{int}\, K_{\mathrm{H}}$. □

In the theorem below, the assertions (i)–(iii) follow only from the construction (5.7) of the map ψ_{H}. Note that the assertion (v) in the theorem ensures that if the original CP is strongly infeasible, then, under the assumption of Lipschitz continuity, a finite certificate proving infeasibility is given by an asymptotic solution of the HCP.

THEOREM 5.4 (cf. Theorem 1 of [2]). *Suppose that $\psi : K \to V$ satisfies Assumption* 5.1.

(i) *For any $x_{\mathrm{H}} \in \mathrm{int}K_{\mathrm{H}}$, $\langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}})\rangle_{\mathrm{H}} = 0$.*

(ii) *Any asymptotically feasible solution $(\hat{x}_{\mathrm{H}}, \hat{y}_{\mathrm{H}})$ of the HCP is an asymptotically complementary solution.*

(iii) *The HCP is asymptotically feasible.*

(iv) *The CP has a solution if and only if the HCP has an asymptotic solution $(x^*_{\mathrm{H}}, y^*_{\mathrm{H}}) = (x^*, \tau^*, y^*, \kappa^*)$ with $\tau^* > 0$. In this case, $(x^*/\tau^*, y^*/\tau^*)$ is a solution of the CP.*

(v) *Suppose that ψ satisfies the Lipschitz condition on K; i.e., there exists a constant $\gamma \geq 0$ such that*

$$\|\psi(x+h) - \psi(x)\| \leq \gamma\|h\| \quad \text{for any} \quad x \in K \text{ and } h \in V.$$

If the CP is strongly infeasible then the HCP has an asymptotic solution $(x^*, \tau^*, y^*, \kappa^*)$ with $\kappa^* > 0$. Conversely, if the HCP has an asymptotic solution $(x^*, \tau^*, y^*, \kappa^*)$ with $\kappa^* > 0$ then the CP is infeasible. In the latter case, $(x^*/\kappa^*, y^*/\kappa^*)$ is a certificate to prove infeasibility of the CP.

Proof. (i) By a simple calculation, we have $\langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}})\rangle_{\mathrm{H}} = \langle x, \tau\psi(x/\tau)\rangle - \tau\langle \psi(x/\tau), x\rangle = 0$.

(ii) Suppose that $(\hat{x}_{\mathrm{H}}, \hat{y}_{\mathrm{H}})$ is an asymptotically feasible solution. Then there exists a bounded sequence $(x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}}) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$ such that

$$\lim_{k\to\infty} F_{\mathrm{H}}(x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}}) = \lim_{k\to\infty} (y^{(k)}_{\mathrm{H}} - \psi_{\mathrm{H}}(x^{(k)}_{\mathrm{H}})) = 0.$$

Here (i) above implies that

$$\langle x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}}\rangle_{\mathrm{H}} = \langle x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}}\rangle_{\mathrm{H}} - \langle x^{(k)}_{\mathrm{H}}, \psi_{\mathrm{H}}(x^{(k)}_{\mathrm{H}})\rangle_{\mathrm{H}} = \langle x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}} - \psi_{\mathrm{H}}(x^{(k)}_{\mathrm{H}})\rangle_{\mathrm{H}}$$

holds for all $k \geq 0$. Thus, we see that $\lim_{k\to\infty}\langle x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}}\rangle_{\mathrm{H}} = 0$. By the definition (5.6) of $\langle\cdot,\cdot\rangle_{\mathrm{H}}$ and (ii) of Lemma 2.6, we obtain that $(\hat{x}_{\mathrm{H}}, \hat{y}_{\mathrm{H}})$ is an asymptotically complementary solution.

(iii) For each $k \geq 0$, define

$$x^{(k)} := (1/2)^k e \in \mathrm{int}K,\ \tau_k := (1/2)^k \in \Re_{++},\ y^{(k)} := (1/2)^k e \in \mathrm{int}K,$$
$$\kappa_k := (1/2)^k \in \Re_{++}.$$

Then the sequence $\{(x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}})\} = \{(x^{(k)}, \tau_k, y^{(k)}, \kappa_k)\}$ is bounded and

$$\lim_{k\to\infty} (y^{(k)} - \tau_k\psi(x^{(k)}/\tau_k)) = 0 \quad \text{and} \quad \lim_{k\to\infty} (\kappa_k + \langle\psi(x^{(k)}/\tau_k), x^{(k)}\rangle) = 0.$$

Thus, the bounded sequence $\{(x^{(k)}_{\mathrm{H}}, y^{(k)}_{\mathrm{H}})\} \subseteq \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$ satisfies

$$\lim_{k\to\infty} (y^{(k)}_{\mathrm{H}} - \psi_{\mathrm{H}}(x^{(k)}_{\mathrm{H}})) = \lim_{k\to\infty} F_{\mathrm{H}}(x^{(k)}, y^{(k)}_{\mathrm{H}}) = 0,$$

which implies that the HCP is asymptotically feasible.

(iv) It is easy to see that if $(x^*, \tau^*, y^*, \kappa^*) \in (K \times \Re_+) \times (K \times \Re_+)$ is a solution of the HCP with $\tau^* > 0$, then $y^*/\tau^* - \psi(x^*/\tau^*) = 0$, $x^* \circ y^* = 0$ and $(x^*/\tau^*, y^*/\tau^*) \in K \times K$ is a solution of the CP.

Conversely, let $(\hat{x}, \hat{y}) \in K \times K$ be a solution of the CP. Then $\hat{y} - 1 \cdot \psi(\hat{x}/1) = 0$, $(\hat{x}, 1) \circ_{\mathrm{H}} (\hat{y}, 0) = 0$, and $(\hat{x}, 1, \hat{y}, 0) \in (K \times \Re_{++}) \times (K \times \Re_+)$ is a solution of the HCP.

(v) By Proposition 5.2, the monotonicity of the map ψ on the set K implies that the map F defined by (5.1) satisfies Assumptions 1.1 and 3.11 with the domain $K \times K$ and $m = 0$. Thus the set $F(\mathcal{U})$ is open and convex by Theorem 3.12.

If the CP is strongly infeasible, then we must have $0 \notin \mathrm{cl}(F(\mathcal{U}))$. Since the set $\mathrm{cl}(F(\mathcal{U}))$ is a closed convex set, by the separating hyperplane theorem, there exist $a \in V$ with $\|a\| = 1$ and $\xi \in \Re$ such that

$$\langle a, b \rangle \geq \xi > 0 \quad \text{for all } b \in \mathrm{cl}(F(\mathcal{U})). \tag{5.10}$$

Since F is continuous on the set $\mathrm{cl}(\mathcal{U}) \subseteq K \times K$, we can see that $F(\mathrm{cl}(\mathcal{U})) \subseteq \mathrm{cl}(F(\mathcal{U}))$. In fact, if $b \in F(\mathrm{cl}(\mathcal{U}))$ then there exists a sequence satisfying

$$(x^{(k)}, y^{(k)}) \in \mathcal{U}, \quad \lim_{k \to \infty} (x^{(k)}, y^{(k)}) = (\bar{x}, \bar{y}) \in \mathrm{cl}(\mathcal{U}), \quad F(\bar{x}, \bar{y}) = b,$$

and the continuity of F on the set $\mathrm{cl}(\mathcal{U})$ implies that $\lim_{k \to \infty} F(x^{(k)}, y^{(k)}) = F(\bar{x}, \bar{y}) = b$. Therefore (5.10) implies that

$$\langle a, F(x, y) \rangle = \langle a, y - \psi(x) \rangle = \langle a, y \rangle - \langle a, \psi(x) \rangle \geq \xi > 0 \tag{5.11}$$

for any $(x, y) \in \mathrm{cl}(\mathcal{U})$. Note that (ix) of Lemma 2.6 ensures that the above relation (5.11) holds at $(x, y) = (0, \alpha\bar{y})$ for any fixed $\bar{y} \in K$ and any $\alpha > 0$. Thus, it must be true that $\langle a, \bar{y} \rangle \geq 0$ for all $\bar{y} \in K$, which implies that $a \in K$. Similarly, since $(x, 0) \in \mathrm{cl}(\mathcal{U})$ for all $x \in K$, it follows from (5.11) that

$$-\langle a, \psi(x) \rangle \geq \xi > 0 \tag{5.12}$$

for any $x \in K$. Thus, combining this with the fact that $a \in K$, we see that

$$-\langle a, \psi(\beta a) \rangle \geq \xi > 0 \quad \text{for all } \beta \geq 0. \tag{5.13}$$

From the monotonicity of the map ψ on the set $K \times K$, we also see that for any $x \in K$ and $\beta \geq 0$, $0 \leq \langle \beta x - x, \psi(\beta x) - \psi(x) \rangle = (\beta - 1)\langle x, \psi(\beta x) - \psi(x) \rangle$. Thus, for $\beta \geq 1$,

$$\langle x, \psi(\beta x) - \psi(x) \rangle \geq 0, \tag{5.14}$$

which implies that

$$\liminf_{\beta \to \infty} \langle x, \psi(\beta x) \rangle / \beta \geq 0. \tag{5.15}$$

Let $\{\beta_k\}$ be a sequence such that $\beta_k \to +\infty$, and let

$$\frac{\psi(\beta_k a)}{\beta_k} = \sum_{i=1}^{r} \lambda_i^{(k)} c_i^{(k)} \tag{5.16}$$

be a decomposition given by (i) of Theorem 2.2 for each k. We also define

$$\begin{aligned} &\lambda_k := \min\{\lambda_i^{(k)} \ (i = 1, 2, \ldots, r)\}, \\ &j_k \in \arg\min\{\lambda_i^{(k)} \ (i = 1, 2, \ldots, r)\}, \quad c^{(k)} := c_{j_k}^{(k)}. \end{aligned} \tag{5.17}$$

Note that $\{c^{(k)}\}$ is a sequence of primitive (i.e., nonzero) idempotents of a Euclidean Jordan algebra $(V, \circ)$. Thus, by (iv) of Proposition 2.7, there exist $\omega_1, \omega_2 > 0$ such that

$$0 < \omega_1 \leq \|c^{(k)}\| \leq \omega_2 \quad \text{for all } k. \tag{5.18}$$

We first claim that $\liminf_{k\to\infty} \lambda_k \geq 0$. Suppose that $\liminf_{k\to\infty} \lambda_k < 0$. Then, by taking a subsequence if necessary, we may assume that there exists a $\delta > 0$ satisfying $\lambda_k \leq -\delta$ for sufficiently large k's. Define $x^{(k)} := a + \epsilon c^{(k)}$ for $\epsilon > 0$. We can see that

$$\begin{aligned}
\langle x^{(k)}, \psi(\beta_k x^{(k)})\rangle/\beta_k &= \langle a + \epsilon c^{(k)}, \psi(\beta_k x^{(k)})\rangle/\beta_k \\
&= \langle a, \psi(\beta_k x^{(k)})\rangle/\beta_k + \epsilon\langle c^{(k)}, \psi(\beta_k x^{(k)})\rangle/\beta_k \\
&< \epsilon\langle c^{(k)}, \psi(\beta_k x^{(k)})\rangle/\beta_k \qquad \text{(by (5.12))} \\
&= \epsilon\left(\langle c^{(k)}, \psi(\beta_k x^{(k)}) - \psi(\beta_k a)\rangle/\beta_k + \langle c^{(k)}, \psi(\beta_k a)\rangle/\beta_k\right). \qquad (5.19)
\end{aligned}$$

The definitions (5.16) and (5.17) and the boundedness (5.18) of $\{c^{(k)}\}$ ensure that there exists $\bar{k}$ for which

$$\langle c^{(k)}, \psi(\beta_k a)\rangle/\beta_k = \lambda_k\langle c^{(k)}, c^{(k)}\rangle \leq -\delta\omega_1^2 < 0 \tag{5.20}$$

holds for any $k \geq \bar{k}$. In addition, since we set $x^{(k)} = a + \epsilon c^{(k)}$, by the Lipschitz continuity of ψ and the boundedness of $\{c^{(k)}\}$, there exist $\bar{\gamma} > 0$ and $\bar{\epsilon} > 0$ independent from k, for which

$$\langle c^{(k)}, \psi(\beta_k x^{(k)}) - \psi(\beta_k a)\rangle/\beta_k \leq \bar{\gamma}\epsilon \leq \delta\omega_1^2/2 \tag{5.21}$$

holds for any $\epsilon \leq \bar{\epsilon}$. Thus, by (5.20) and (5.21),

$$\langle c^{(k)}, \psi(\beta_k x^{(k)}) - \psi(\beta_k a)\rangle/\beta_k + \langle c^{(k)}, \psi(\beta_k a)\rangle/\beta_k \leq -\delta\omega_1^2/2 < 0$$

holds for any $k \geq \bar{k}$ and $\epsilon \leq \bar{\epsilon}$. Therefore, by (5.19), we obtain

$$\langle x^{(k)}, \psi(\beta_k x^{(k)})\rangle/\beta_k \leq -\epsilon\delta\omega_1^2/2 < 0$$

for all such k's and ϵ's. Since $x^{(k)} = a + \epsilon c^{(k)} \in K$, by fixing a suitably small $\epsilon \in (0, \bar{\epsilon}]$, the above inequality contradicts (5.15) and we must have

$$\liminf_{k\to\infty} \lambda_k = \liminf_{k\to\infty} \left[\min\{\lambda_i^{(k)}(i = 1, 2, \ldots, r)\}\right] \geq 0. \tag{5.22}$$

Next we claim that $\{\lambda_i^{(k)}\}$ is bounded for any $i = 1, 2, \ldots, r$. By the facts $\beta_k a \in K$ for any k, $e \in K$, and ψ is monotone on K, we see that

$$\begin{aligned}
0 &\leq \langle \beta_k a - e, \psi(\beta_k a) - \psi(e)\rangle/\beta_k \\
&= \langle a, \psi(\beta_k a)\rangle - \langle e, \psi(\beta_k a)/\beta_k\rangle - \langle a, \psi(e)\rangle + \langle e, \psi(e)/\beta_k\rangle \\
&< -\langle e, \psi(\beta_k a)/\beta_k\rangle - \langle a, \psi(e)\rangle + \langle e, \psi(e)/\beta_k\rangle,
\end{aligned}$$

where the last inequality follows from (5.12). This implies the existence of a constant $\sigma > 0$ such that

$$\langle e, \psi(\beta_k a)/\beta_k\rangle \leq \sigma \tag{5.23}$$

holds for sufficiently large k's. By the definition (5.16), the left-hand side of the above inequality is given by

$$\langle e, \psi(\beta_k a)/\beta_k \rangle = \left\langle e, \sum_{i=1}^{r} \lambda_i^{(k)} c_i^{(k)} \right\rangle = \sum_{i=1}^{r} \lambda_i^{(k)} \langle e, c_i^{(k)} \rangle.$$

Combining the above with (5.23), we have

$$\sum_{i=1}^{r} \lambda_i^{(k)} \langle e, c_i^{(k)} \rangle \leq \sigma.$$

Here, (iv) of Proposition 2.7 ensures the existence of $\omega_1, \omega_2 > 0$ such that

$$0 < \omega_1^2 \leq \langle e, c_i^{(k)} \rangle \leq \omega_2^2 \ \text{ for all } i \text{ and } k.$$

Since we have shown the inequality (5.22), the set $\{\lambda_i^{(k)}\}$ must be bounded for any $i = 1, 2, \ldots, r$.

By using (iv) of Proposition 2.7 again, we also see that $\{c_i^{(k)}\}$ is bounded for any $i = 1, 2, \ldots, r$. Thus, $\{\psi(\beta_k a)/\beta_k = \sum_{i=1}^{r} \lambda_i^{(k)} c_i^{(k)}\}$ is bounded, and by (5.22), any accumulation point $\psi^\infty(a)$ of the sequence must satisfy $\psi^\infty(a) \in K$.

Note that $\langle a, \psi(\beta_k a) \rangle \leq -\xi$ from (5.13) and $\langle a, \psi(\beta_k a) \rangle \geq \langle a, \psi(a) \rangle$ from (5.14). Thus $\{\langle a, \psi(\beta_k a) \rangle\}$ is also bounded. To summarize, by taking an appropriate subsequence and setting

$$\begin{aligned}
&\hat{x}^{(k)} := a + (1/\beta_k) e \in \mathrm{int} K, \quad \hat{\tau}_k := 1/\beta_k, \\
&\hat{y}^{(k)} := \sum_{i=1}^{r} (\max\{\lambda_i^{(k)},\ 1/\beta_k\} c_i^{(k)}) \in \mathrm{int} K, \quad \hat{\kappa}_k := -\langle a, \psi(\beta_k a) \rangle \geq \xi > 0,
\end{aligned}$$

then, by (5.18), (5.22), and the boundedness of $\{\lambda_i^{(k)}\}$ and $\{c_i^{(k)}\}$, we have

$$\lim_{k \to \infty} \sum_{i=1}^{r} (\max\{\lambda_i^{(k)},\ 1/\beta_k\} c_i^{(k)}) = \psi^\infty(a) \in K$$

and conclude that $(x^*, \tau^*, y^*, \kappa^*)$ given by

$$\begin{aligned}
&x^* := a = \lim_{k \to \infty} \hat{x}^{(k)} \in K, \quad \tau^* := 0 = \lim_{\beta_k \to \infty} \hat{\tau}_k, \\
&y^* := \psi^\infty(a) = \lim_{k \to \infty} \hat{y}^{(k)} \in K, \quad \kappa^* := \lim_{k \to \infty} \hat{\kappa}_k \geq \xi > 0
\end{aligned}$$

is an asymptotic solution of the HCP with $\kappa^* > 0$.

Conversely, suppose that there exists a bounded sequence $(x^{(k)}, \tau_k, y^{(k)}, \kappa_k) \in (\mathrm{int} K \times \Re_{++}) \times (\mathrm{int} K \times \Re_{++})$ such that

$$\lim_{k \to \infty} y^{(k)} = \lim_{k \to \infty} \tau_k \psi(x^{(k)}/\tau_k) \in K, \quad \lim_{k \to \infty} \kappa_k = \lim_{k \to \infty} -\langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle \geq \xi > 0.$$

Let us show that there is no feasible point $(x, y) \in K \times K$ satisfying $y - \psi(x) = 0$. Suppose that $(x, y) \in K \times K$ and $y - \psi(x) = 0$. Since ψ_{H} is monotone on

$(K \times \Re_{++}) \times (K \times \Re_+)$, by the definition (5.7), we have

$$\begin{aligned}
0 &\le \langle (x^{(k)}, \tau_k) - (x, 1), \psi_{\mathrm{H}}(x^{(k)}, \tau_k) - \psi_{\mathrm{H}}(x, 1) \rangle \\
&= \langle x^{(k)} - x, \tau_k \psi(x^{(k)}/\tau_k) - \psi(x) \rangle + (\tau_k - 1)\big(\langle x, \psi(x) \rangle - \langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle\big) \\
&= \langle x^{(k)}, \tau_k \psi(x^{(k)}/\tau_k) \rangle + \langle x, \psi(x) \rangle \\
&\quad + (\tau_k - 1)\langle x, \psi(x) \rangle - (\tau_k - 1)\langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle \\
&\quad - \langle x^{(k)}, \psi(x) \rangle - \langle x, \tau_k \psi(x^{(k)}/\tau_k) \rangle \\
&= \tau_k \langle x, \psi(x) \rangle + \langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle - \langle x^{(k)}, \psi(x) \rangle - \langle x, \tau_k \psi(x^{(k)}/\tau_k) \rangle
\end{aligned}$$

and hence

$$\begin{aligned}
\langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle &\ge \langle x^{(k)}, \psi(x) \rangle + \langle x, \tau_k \psi(x^{(k)}/\tau_k) \rangle - \tau_k \langle x, \psi(x) \rangle \\
&= \langle x^{(k)}, y \rangle + \langle x, \tau_k \psi(x^{(k)}/\tau_k) \rangle - \tau_k \langle x, y \rangle. \qquad (5.24)
\end{aligned}$$

Here $\lim_{k\to\infty} \tau_k = 0$ since $\lim_{k\to\infty} \kappa_k \ge \xi > 0$. In addition, it follows from the assumption that $\langle x^{(k)}, y \rangle \ge 0$ and that

$$\lim_{k\to\infty} \langle x, y^{(k)} \rangle = \langle x, \lim_{k\to\infty} y^{(k)} \rangle = \langle x, \lim_{k\to\infty} \tau_k \psi(x^{(k)}/\tau_k) \rangle \ge 0.$$

Thus the relation (5.24) ensures that

$$\lim_{k\to\infty} \langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle \ge 0,$$

which contradicts

$$\kappa_k := -\langle x^{(k)}, \psi(x^{(k)}/\tau_k) \rangle \ge \xi > 0.$$

In addition, any limit of $x^{(k)}$ gives a separating hyperplane, i.e., a certificate proving infeasibility. □

Note that the Lipschitz continuity of ψ on K in (v) of the above theorem seems to be indispensable for showing the existence of a uniform bound $\bar{\gamma}$ satisfying (5.21), while only the differentiability (or the scaled Lipschitz continuity) of ψ is assumed in [2]. The differentiability of ψ on K implies the Lipschitz continuity of ψ at $a \in K$. However, the local Lipschitz continuity of ψ might be not enough since the sequence $\{\beta_k a\} \subseteq K$ is never bounded along $\beta_k \to +\infty$.

We are going to show that a central path of the homogeneous model HCP is well defined. As we will see in (iii) of Theorem 5.5, any limit point of the path lets us know if the HCP has an asymptotically complementary solution $(x_{\mathrm{H}}^*, y_{\mathrm{H}}^*) = (x^*, \tau^*, y^*, \kappa^*)$ with $\tau^* > 0$ or if it has such a solution with $\kappa^* > 0$.

Therefore, in view of (iv) and (v) of Theorem 5.4, if we find a limit of the path then we can determine whether the CP is (asymptotically) solvable, strongly infeasible, or of some other type.

Let us consider the map

$$H_{\mathrm{H}}(x_{\mathrm{H}} y_{\mathrm{H}}) := \begin{pmatrix} x_{\mathrm{H}} \circ_{\mathrm{H}} y_{\mathrm{H}} \\ F_{\mathrm{H}}(x_{\mathrm{H}}, y_{\mathrm{H}}) \end{pmatrix} \qquad (5.25)$$

and choose an initial point $(x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)})$ such that $(x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$ and $x_{\mathrm{H}} \circ_{\mathrm{H}} y_{\mathrm{H}} \in \mathrm{int}K_{\mathrm{H}}$. For simplicity, we set $(x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}) = (x^{(0)}, \tau_0, y^{(0)}, \kappa_0) = (e, 1, e, 1) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$. Define

$$h_{\mathrm{H}}^{(0)} := \begin{pmatrix} p_{\mathrm{H}}^{(0)} \\ f_{\mathrm{H}}^{(0)} \end{pmatrix} := \begin{pmatrix} x_{\mathrm{H}}^{(0)} \circ_{\mathrm{H}} y_{\mathrm{H}}^{(0)} \\ F_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}) \end{pmatrix} = \begin{pmatrix} e_{\mathrm{H}} \\ y_{\mathrm{H}}^{(0)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \end{pmatrix}, \qquad (5.26)$$

where $e_{\mathrm{H}} = (e, 1) \in \mathrm{int}K_{\mathrm{H}}$ is the identity element in V_{H}.

THEOREM 5.5 (cf. Theorem 2 of [2]). *Suppose that $\psi : K \to V$ satisfies Assumption* 5.1. *Define $h_{\mathrm{H}}^{(0)}$ by* (5.26).

(i) *For any $t \in (0,1]$, there exists a point $(x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$ such that $H_{\mathrm{H}}(x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)) = th_{\mathrm{H}}^{(0)}$.*

(ii) *The set*

$$P := \{(x_{\mathrm{H}}, y_{\mathrm{H}}) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}} : \ H_{\mathrm{H}}(x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)) = th_{\mathrm{H}}^{(0)}, \ t \in (0,1]\}$$

forms a bounded path in $\mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$. Any accumulation point $(x_{\mathrm{H}}(0), y_{\mathrm{H}}(0))$ is an asymptotically complementary solution of the HCP.

(iii) *If the HCP has an asymptotically complementary solution $(x_{\mathrm{H}}^*, y_{\mathrm{H}}^*) = (x^*, \tau^*, y^*, \kappa^*)$ with $\tau^* > 0$ ($\kappa^* > 0$, respectively), then any accumulation point $(x_{\mathrm{H}}(0), y_{\mathrm{H}}(0)) = (x(0), \tau(0), y(0), \kappa(0))$ of the bounded path P satisfies $\tau(0) > 0$ ($\kappa(0) > 0$, respectively).*

Proof. (i) It follows from Proposition 5.3 that the map F_{H} defined by (5.3) satisfies Assumptions 1.1 and 3.11. Thus, by Theorem 3.12, the set $H_{\mathrm{H}}(\mathcal{U}_{\mathrm{H}})$ with

$$\mathcal{U}_{\mathrm{H}} := \{(x_{\mathrm{H}}, y_{\mathrm{H}}) \in \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}} : \ x_{\mathrm{H}} \circ_{\mathrm{H}} y_{\mathrm{H}} \in \mathrm{int}K_{\mathrm{H}}\}$$

is an open convex subset of $V_{\mathrm{H}} \times V_{\mathrm{H}}$. Here we have already seen that $0 \in \mathrm{cl}(H_{\mathrm{H}}(\mathcal{U}_{\mathrm{H}}))$ in (ii) and (iii) of Theorem 5.4.

Since the set $H_{\mathrm{H}}(\mathcal{U}_{\mathrm{H}})$ is convex, the fact above implies that $th_{\mathrm{H}}^{(0)} \in H_{\mathrm{H}}(\mathcal{U}_{\mathrm{H}})$ for any $t \in (0,1]$. Combining this with the homeomorphism of the map H_{H} in Theorem 3.10, we obtain the assertion (i).

(ii) The homeomorphism of the map H_{H} also ensures that the set P forms a path in $\mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$. It suffices to show that the path P is bounded.

Let $(x_{\mathrm{H}}, y_{\mathrm{H}}) = (x, \tau, y, \kappa) \in P$. Then there exists a $t \in (0,1]$ for which

$$x_{\mathrm{H}} \circ_{\mathrm{H}} y_{\mathrm{H}} = te_{\mathrm{H}} \ \text{ and } \ y_{\mathrm{H}} - \psi_{\mathrm{H}}(x_{\mathrm{H}}) = tf_{\mathrm{H}}^{(0)} \tag{5.27}$$

hold and

$$\begin{aligned}
&\langle x_{\mathrm{H}}, f_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} && \text{(by (5.26))} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}^{(0)}, tf_{\mathrm{H}}^{(0)} + \psi_{\mathrm{H}}(x_{\mathrm{H}}) \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} && \text{(by (5.27))} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - t\langle x_{\mathrm{H}}^{(0)}, f_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}^{(0)}, \psi_{\mathrm{H}}(x_{\mathrm{H}}) \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} \\
&\geq \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - t\langle x_{\mathrm{H}}^{(0)}, f_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}, \psi_{\mathrm{H}}(x_{\mathrm{H}}) \rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}^{(0)}, \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} \\
&\qquad \text{(by the monotonicity of } \psi_{\mathrm{H}}) \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - t\langle x_{\mathrm{H}}^{(0)}, f_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} && \text{(by (i) of Theorem 5.4)} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - t\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(0)}) \rangle_{\mathrm{H}} && \text{(by (5.26))} \\
&= \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} - t\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)} \rangle_{\mathrm{H}} && \text{(by (i) of Theorem 5.4).}
\end{aligned}$$

In addition, for the same $t \in (0,1]$, we have

$$\begin{aligned} t\langle x_{\mathrm{H}}, f_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} &= \langle x_{\mathrm{H}}, tf_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} \\ &= \langle x_{\mathrm{H}}, y_{\mathrm{H}} - \psi_{\mathrm{H}}(x_{\mathrm{H}})\rangle_{\mathrm{H}} \qquad \text{(by (5.27))} \\ &= \langle x_{\mathrm{H}}, y_{\mathrm{H}}\rangle_{\mathrm{H}} \qquad \text{(by (i) of Theorem 5.4)} \\ &= t\langle e_{\mathrm{H}}, e_{\mathrm{H}}\rangle_{\mathrm{H}} \qquad \text{(by (5.27))} \\ &= t\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}}. \end{aligned}$$

Therefore, we obtain that

$$\begin{aligned} \langle x_{\mathrm{H}}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}, x_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} &\le \langle x_{\mathrm{H}}, f_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} + t\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} \\ &= \langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} + t\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} \\ &= (1+t)\langle x_{\mathrm{H}}^{(0)}, y_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} = (1+t)\langle e_{\mathrm{H}}, e_{\mathrm{H}}\rangle_{\mathrm{H}} \le 2\langle e_{\mathrm{H}}, e_{\mathrm{H}}\rangle_{\mathrm{H}}. \end{aligned}$$

Thus, by (ii) of Proposition 2.1, the set P is bounded.

(iii) Let $(x_{\mathrm{H}}^*, y_{\mathrm{H}}^*) = (x^*, \tau^*, y^*, \kappa^*)$ be an asymptotic solution for the HCP. Then there exists a bounded sequence

$$\{(x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)})\} = \{(x^{(k)}, \tau_k, y^{(k)}, \kappa_k)\} \subseteq \mathrm{int}K_{\mathrm{H}} \times \mathrm{int}K_{\mathrm{H}}$$

such that

$$\lim_{k\to\infty}(x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)}) = (x_{\mathrm{H}}^*, y_{\mathrm{H}}^*), \quad \lim_{k\to\infty} y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)}) = 0, \quad \lim_{k\to\infty} x_{\mathrm{H}}^{(k)} \circ_{\mathrm{H}} y_{\mathrm{H}}^{(k)} = 0.$$

Let $(x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)) = (x(t), \tau(t), y(t), \kappa(t))$ be any point on the path P. Then,

$$x_{\mathrm{H}}(t) \circ_{\mathrm{H}} y_{\mathrm{H}}(t) = te_{\mathrm{H}} \ \text{ and } \ y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t)) = tf_{\mathrm{H}}^{(0)}. \tag{5.28}$$

By the boundedness of the set P (see (ii) above), there exists an $\epsilon \in (0,1]$ such that

$$\|x_{\mathrm{H}}(t)\| \le 1/\epsilon \ \text{ and } \ \|y_{\mathrm{H}}(t)\| \le 1/\epsilon \tag{5.29}$$

hold for any $t \in (0,1]$. In addition, for each $t \in (0,1]$, there exists an index $k(t)$ such that for any $k \ge k(t)$, we have

$$\|x_{\mathrm{H}}^{(k)} - x_{\mathrm{H}}^*\| \le \epsilon, \ \ \|y_{\mathrm{H}}^{(k)} - y_{\mathrm{H}}^*\| \le \epsilon, \text{ and } \|y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\| \le t\epsilon. \tag{5.30}$$

Here, by the monotonicity of ψ_{H},

$$\begin{aligned} &\langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\ &\quad = \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, \psi_{\mathrm{H}}(x_{\mathrm{H}}(t)) - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \\ &\qquad + \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \\ &\quad \ge \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \end{aligned}$$

and hence, for any $t \in (0,1]$ and any $k \geq k(t)$,

$$
\begin{aligned}
&\langle x_{\mathrm{H}}(t), y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}(t), x_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\
&\leq \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)\rangle_{\mathrm{H}} + \langle x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\
&\quad - \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} \\
&\quad + \langle x_{\mathrm{H}}(t) - x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \\
&= \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}(t)\rangle_{\mathrm{H}} + \langle x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\
&\quad - \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} - \langle x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \\
&\quad + \langle x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} + \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \\
&= \langle x_{\mathrm{H}}^{(k)}, y_{\mathrm{H}}(t) - \psi_{\mathrm{H}}(x_{\mathrm{H}}(t))\rangle_{\mathrm{H}} + \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \qquad \text{(by (i) of Theorem 5.4)} \\
&= \langle x_{\mathrm{H}}^{(k)}, t f_{\mathrm{H}}^{(0)}\rangle_{\mathrm{H}} + \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\rangle_{\mathrm{H}} \qquad \text{(by (5.28))} \\
&\leq t\|x_{\mathrm{H}}^{(k)}\|\|f_{\mathrm{H}}^{(0)}\| + \|x_{\mathrm{H}}(t)\|\|y_{\mathrm{H}}^{(k)} - \psi_{\mathrm{H}}(x_{\mathrm{H}}^{(k)})\| \\
&\leq t(\|x_{\mathrm{H}}^{*}\| + \epsilon)\|h_{\mathrm{H}}^{(0)}\| + t \qquad \text{(by (5.29) and (5.30))} \\
&\leq t\delta,
\end{aligned}
$$

where $\delta := 1 + (\|x_{\mathrm{H}}^{*}\| + 1)\|h_{\mathrm{H}}^{(0)}\| > 0$. Note that (5.28) implies $x_{\mathrm{H}}(t) = t y_{\mathrm{H}}(t)^{-1}$ and $y_{\mathrm{H}}(t) = t x_{\mathrm{H}}(t)^{-1}$. Combining them, it must hold that for any $t \in (0,1]$ and $k \geq k(t)$,

$$
\begin{aligned}
t\delta &\geq \langle x_{\mathrm{H}}(t), y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} + \langle y_{\mathrm{H}}(t), x_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\
&= \langle t y_{\mathrm{H}}(t)^{-1}, y_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} + \langle t x_{\mathrm{H}}(t)^{-1}, x_{\mathrm{H}}^{(k)}\rangle_{\mathrm{H}} \\
&= t\left\{\langle y(t)^{-1}, y^{(k)}\rangle + \frac{\kappa_k}{\kappa(t)} + \langle x(t)^{-1}, x^{(k)}\rangle + \frac{\tau_k}{\tau(t)}\right\}.
\end{aligned}
$$

Since $\langle y(t)^{-1}, y^{(k)}\rangle > 0$ and $\langle x(t)^{-1}, x^{(k)}\rangle > 0$, we finally obtain that

$$
\frac{\kappa_k}{\kappa(t)} < \delta \quad \text{and} \quad \frac{\tau_k}{\tau(t)} < \delta
$$

for any $t \in (0,1]$ and $k \geq k(t)$. Thus, the assertion (iii) follows from the facts $\kappa_k \to \kappa^*$, $\tau_k \to \tau^*$, and $\delta > 0$. □

6. Concluding remarks. In this paper, we studied the homeomorphism of the interior point map defined by (1.4) for monotone complementarity problems (CPs) over symmetric cones associated with Euclidean Jordan algebras. As an application of our results, we provided a homogeneous model (HCP) for the problems and showed the existence of a trajectory. In Theorem 5.4, we have shown that the following implications hold under the Lipschitz continuity of the map:

[The original CP has a solution.]
$\Longleftrightarrow$ [The HCP has an asymptotic solution $(x^*, \tau^*, y^*, \kappa^*)$ with $\tau^* > 0$.]
[The original CP is strongly infeasible.]
$\Longrightarrow$ [The HCP has an asymptotic solution $(x^*, \tau^*, y^*, \kappa^*)$ with $\kappa^* > 0$.]
$\Longrightarrow$ [The original CP is infeasible (with a finite certification of the infeasibility).]

To our knowledge, no better results have been provided even for the case of $K = \Re^n_{++}$. It is still an open problem to find an exact certification proving strong infeasibility of the original problem.

Other issues to be investigated are the development of numerical algorithms and their complexity analyses and discussing the existence of maximal complementarity solutions for the problems. Concerning the second subject, we have already obtained a partial result in the proof of (iii) of Theorem 5.5. As a related result, we should refer to Chua's work [3] for homogeneous conic programming: The author showed that the paths defined by a class of optimal barriers converge to analytical centers of optimal faces whenever the primal-dual pair of problems has strictly complementarity solutions.

Recently, the concept of P-properties on Euclidean Jordan algebra was introduced by Gowda, Sznajder, and Tao [8] and by Tao and Gowda [31], aiming to provide nonmonotone properties on the algebra. For the case of the n-dimensional positive orthant, a homogeneous model for P_0 complementarity problems has been proposed in [33]. In contrast to our results, however, the lack of the monotonicity of the map prevents us from obtaining the convexity of the image as in Theorem 3.12. The convexity of the set is a key property in obtaining a certificate proving strong infeasibility of the original problem.

Acknowledgments. The author would like to thank Leonid Faybusovich for many helpful comments and valuable suggestions. The author is also grateful to the anonymous referees whose comments helped improve the paper considerably.

THE LAGRANGE MULTIPLIER RULE FOR MULTIFUNCTIONS IN BANACH SPACES*

XI YIN ZHENG† AND KUNG FU NG‡

Abstract. We study general constrained multiobjective optimization problems with objectives being closed multifunctions in Banach spaces. In terms of the coderivatives and normal cones, we provide generalized Lagrange multiplier rules as necessary optimality conditions of the above problems. In an Asplund space setting, sharper results are presented.

Key words. multifunction, normal cone, coderivative, Pareto solution

DOI. 10.1137/060651860

1. Introduction.

Let X be a Banach space and $f_i : X \to R \cup \{+\infty\}$ be proper lower semicontinuous functions $(i = 0, 1, \ldots, m)$. Many authors (see [2, 3, 4, 16, 29, 30]) studied the following optimization problem with inequality and equality constraints:

$$\begin{aligned} &\min f_0(x), \\ &f_i(x) \le 0, \quad i = 1, \ldots, n, \\ &f_i(x) = 0, \quad i = n+1, \ldots, m, \\ &x \in \Omega. \end{aligned} \tag{1.1}$$

Under some restricted conditions (e.g., each f_i is locally Lipschitz), it is well known, as the Lagrange multiplier rule, that if $\bar{x}$ is a local solution of (1.1), then there exists $\lambda_i \in R$ $(0 \le i \le m)$ such that

$$\begin{aligned} &0 \in \sum_{i=0}^{m} \partial(\lambda_i f_i)(\bar{x}) + N(\Omega, \bar{x}), \\ &\sum_{i=0}^{m} |\lambda_i| = 1 \ \text{ and } \ \lambda_i \ge 0, \quad 0 \le i \le n, \end{aligned} \tag{1.2}$$

where $\partial(\lambda_i f_i)$ and $N(\Omega, \bar{x})$ denote the subdifferential and the normal cone (see section 2 for their definitions). Some authors established the so-called fuzzy Lagrange multiplier rule (see [3, 14, 20] and the references therein). The main aim of this paper is to establish the corresponding rules for multifunctions in Banach spaces.

Let X, $Y_0, Y_1, \ldots, Y_m$ be Banach spaces, Ω be a closed subset of X, and $F_i : X \to 2^{Y_i}$ $(i = 0, 1, \ldots, m)$ be closed multifunctions. Let $C_0 \subset Y_0$ be a closed convex cone

such that $C_0 \neq C_0 \cap -C_0$ (i.e, C_0 is not a linear subspace), which specifies a preorder $\leq_{C_0}$ on Y_0 as follows: for $y_1, y_2 \in Y_0$,

$$y_1 \leq_{C_0} y_2 \text{ if and only if } y_2 - y_1 \in C_0.$$

For $i = 1, \ldots, m$, let C_i be a closed convex cone in Y_i. Consider the following constrained multiobjective optimization problem:

$$\begin{aligned} & C_0 - \min F_0(x), \\ & F_i(x) \cap -C_i \neq \emptyset, \quad i = 1, \ldots, m, \\ & x \in \Omega. \end{aligned} \tag{1.3}$$

Recall that $\bar{a} \in A$ is said to be a Pareto efficient point if $\bar{a} \leq_{C_0} a$ whenever $a \in A$ and $a \leq_{C_0} \bar{a}$, that is,

$$A \cap (\bar{a} - C_0) \subset \bar{a} + C_0 \cap -C_0.$$

We use $\mathrm{E}(A, C_0)$ to denote the set of all Pareto efficient points of A. In the case when C_0 is pointed (i.e., $C_0 \cap -C_0 = \{0\}$),

$$\bar{a} \in E(A, C_0) \Longleftrightarrow A \cap (\bar{a} - C_0) = \{\bar{a}\}.$$

For $\bar{x} \in X$ and $\bar{y} \in F_0(\bar{x})$, we say that $(\bar{x}, \bar{y})$ is a local Pareto solution of the multiobjective optimization problem (1.3) if there exists a neighborhood U of $\bar{x}$ such that

$$\bar{y} \in \mathrm{E}\left(F_0\left[U \cap \Omega \cap \left(\bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right)\right], C_0\right).$$

In the case when each F_i is single-valued, many authors have established sufficient or necessary optimality conditions for Pareto solutions and weak Pareto solutions under some restricted conditions; e.g., the ordering cone has a nonempty interior, the spaces are finite dimensional, and $C_i = R_+^n$ (see [1, 5, 7, 9, 10, 11, 12, 13, 22, 23, 24, 26, 27] and the references therein). In the set-valued setting, in terms of cotangent derivatives Götz and Jahn [8] provided the Lagrange multiplier rule for (1.3) under the convexity assumption. Ye and Zhu [25] and Mordukhovich, Treiman, and Zhu [19] gave some necessary optimality conditions for multiobjective optimization problems with respect to an abstract order in a Euclidean space or Asplund space setting. Recently, the authors [28] studied a unconstrained multiobjective problem with the objective being multifunctions in Banach spaces and, as generalizations of the Fermat rule, presented necessary optimization conditions. In this paper, in a general setting we provide the following fuzzy Lagrange multiplier rule for constrained multiobjective optimization problem (1.3).

Let X, Y_i be Banach spaces, Ω be a closed subset of X, and $F_i : X \to 2^{Y_i}$ be a closed multifunction $(i = 0, 1, \ldots, m)$. Suppose that $(\bar{x}, \bar{y}_0)$ is a local Pareto solution of the constrained multiobjective optimization problem (1.3), and let $\bar{y}_i \in F_i(\bar{x}) \cap -C_i$ $(i = 1, \ldots, m)$. Then one of the following two assertions holds.

(i) For any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, and $c_i^* \in C_i^+$ such that

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} D_c^* F_i(x_i, y_i)(c_i^* + \varepsilon B_{Y_i^*}) + N_c(\Omega, w) + \varepsilon B_{X^*},$$

where B_X denotes the closed unit ball of X, $C_i^+ := \{y^* \in Y_i^* : \langle y^*, c\rangle \geq 0\ \forall c \in C_i\}$, $N_c(\cdot,\cdot)$ denotes the Clarke normal cone, and $D_c^*F_i(\cdot,\cdot)$ denotes the Mordukhovich coderivative with respect to the Clarke normal cone.

(ii) For any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, $x_i^* \in D_c^*F_i(x_i, y_i)(\varepsilon B_{Y_i^*})$, and $w^* \in N_c(\Omega, w) + \varepsilon B_{X^*}$ such that

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \ \text{ and } \ w^* + \sum_{i=0}^{m} x_i^* = 0. \tag{1.4}$$

Using this result, we give some exact Lagrange multiplier rules for (1.3). In the case when X, Y_i are Asplund spaces, these results are sharpened; in particular, we prove the following result (see section 2 for terms undefined).

Let $(\bar{x}, \bar{y}_0)$ be a local Pareto solution of (1.3), and let $\bar{y}_i \in F_i(\bar{x}) \cap -C_i$. Suppose that each F_i is pseudo-Lipschitz around $(\bar{x}, \bar{y}_i)$ and that each C_i is dually compact (e.g., C_i has a nonempty interior). Then there exists $c_i^* \in C_i^+$ such that

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \ \text{ and } \ 0 \in \sum_{i=0}^{m} D^*F_i(\bar{x}, \bar{y}_i)(c_i^*) + N(\Omega, \bar{x}), \tag{1.5}$$

where $D^*F_i(\cdot,\cdot)$ denotes the Mordukhovich coderivative with respect to the limiting normal cone (see section 2 for its definition). Under the condition that X, Y_i are finite dimensional, we provide the following necessity optimality condition of constrained multiobjective optimization problem (1.3).

Let each F_i be a closed multifunction and each C_i be a closed convex cone. Suppose that $(\bar{x}, \bar{y}_0)$ is a local Pareto solution of (1.3). Then, for any $\bar{y}_i \in F_i(\bar{x}) \cap -C_i$, one of the following assertions holds.

(a) There exists $c_i^* \in C_i^+$ such that (1.5) holds.

(b) There exist $x_i^* \in D^*F_i(\bar{x}, \bar{y}_i)(0)$ and $w^* \in N(\Omega, \bar{x})$ such that (1.4) holds.

Let $f_0, f_1, \ldots, f_m$ be as in (1.1). In the special case when $Y_i = R$, $C_i = \{0\}$ for $0 \leq i \leq m$, $F_i(x) = [f_i(x),\ +\infty)$ for $0 \leq i \leq n$, and $F_i(x) = f_i(x)$ for $n+1 \leq i \leq m$. The above results can be applied to (1.1). In particular, under the assumption that X is an Asplund space and that $f_0, f_1, \cdot, f_n$ are lower semicontinuous and $f_{n+1}, \ldots, f_m$ are continuous, we prove that if $\bar{x}$ is a local solution of (1.1), then one of the following assertions holds.

(i) For any $\varepsilon > 0$ there exist $\lambda_i \in R \setminus \{0\}$, $w \in (\bar{x} + \varepsilon B_X) \cap \Omega$, and $x_i \in \bar{x} + \varepsilon B_X$ with $|f_i(x_i) - f_i(\bar{x})| < \varepsilon$ such that $\lambda_i \geq 0$ for $0 \leq i \leq n$, $\sum_{i=0}^{m} |\lambda_i| = 1$, and

$$0 \in \sum_{i=0}^{m} \hat{\partial}(\lambda_i f_i)(x_i) \cap MB_{X^*} + \hat{N}(\Omega, w) \cap MB_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

(ii) For any $\varepsilon > 0$ there exist $w \in (\bar{x} + \varepsilon B_X) \cap \Omega$, $x_i \in \bar{x} + \varepsilon B_X$ with $|f_i(x_i) - f_i(\bar{x})| < \varepsilon$, $\varepsilon_i \in (-\varepsilon,\ \varepsilon)$, $w^* \in \hat{N}(\Omega, w) + \varepsilon B_{X^*}$, and $x_i^* \in \hat{\partial}(\varepsilon_i f_i)(x_i)$ such that (1.4) holds and $\varepsilon_i > 0$ for $0 \leq i \leq n$.

2. Preliminaries. Throughout this section, we assume that Y is a Banach space. Let $f : Y \to R \cup \{+\infty\}$ be a proper lower semicontinuous function, and let $\mathrm{epi}(f)$ denote the epigraph of f, that is,

$$\mathrm{epi}(f) := \{(y, t) \in Y \times R :\ f(y) \leq t\}.$$

Let $y \in \mathrm{dom}(f)$, let $h \in Y$, and let $f^\circ(y,h)$ denote the generalized directional derivative given by Rockafellar (see [4]), that is,

$$f^\circ(y,h) := \lim_{\varepsilon \downarrow 0} \limsup_{\substack{f \\ z \to y, t \downarrow 0}} \inf_{w \in h + \varepsilon B_Y} \frac{f(z+tw) - f(z)}{t},$$

where B_Y denotes the closed unit ball of Y, and the expression $z \overset{f}{\to} y$ means $z \to y$ and $f(z) \to f(y)$. It is known that $f^\circ(y,h)$ reduces to Clarke's directional derivative when f is locally Lipschitzian (see [4]). Let

$$\partial_c f(y) := \{y^* \in Y^* : \ \langle y^*, h\rangle \le f^\circ(y,h) \quad \forall h \in Y\}.$$

Let A be a closed subset of Y, and let $N_c(A,a)$ denote Clarke's normal cone of A at a, that is,

$$N_c(A,a) := \begin{cases} \partial_c \delta_A(a), & a \in A, \\ \emptyset, & a \notin A, \end{cases}$$

where δ_A denotes the indicator function of A: $\delta_A(y) = 0$ if $y \in A$ and $\delta_A(y) = +\infty$ otherwise. The following result (see [4, Corollary, p. 52]) presents an important necessity optimality condition in terms of Clarke's subdifferential and normal cone for a nonsmooth constrained optimization problem.

PROPOSITION 2.1. *Let $f : Y \to R$ be a locally Lipschitz function and A be a closed subset of Y. Suppose that f attains its minimum over A at $a \in A$. Then $0 \in \partial_c f(a) + N_c(A,a)$.*

We also need the notion of Fréchet normal cones and that of limiting normal cones. For $\varepsilon \ge 0$, the set of ε-normals to A at a is defined by

$$\hat{N}_\varepsilon(A,a) := \left\{ y^* \in Y^* : \limsup_{y \overset{A}{\to} a} \frac{\langle y^*, y-a\rangle}{\|y-a\|} \le \varepsilon \right\},$$

where $y \overset{A}{\to} a$ means that $y \to a$ with $y \in A$. The set $\hat{N}_0(A,a)$ is simply denoted by $\hat{N}(A,a)$ and is called the Fréchet normal cone to A at a. The limiting Fréchet normal cone to A at a is defined by

$$N(A,a) := \{y^* \in Y^* : \ \exists \varepsilon_n \to 0^+, \ y_n \overset{A}{\to} a, \ y_n^* \overset{w^*}{\to} y^* \text{ with } y_n^* \in \hat{N}_{\varepsilon_n}(A,y_n)\}.$$

In the case when A is convex, it is well known that

$$N_c(A,a) = N(A,a) = \hat{N}(A,a).$$

Recall that the Fréchet subdifferential $\hat{\partial} f(y)$ and the limiting subdifferential $\partial f(y)$ of f at $y \in \mathrm{dom}(f)$ are defined by

$$\hat{\partial} f(y) = \{y^* : \ (y^*, -1) \in \hat{N}(\mathrm{epi}(f), (y, f(y))\}$$

and

$$\partial f(y) := \{y^* \in Y^* : \ (y^*, -1) \in N(\mathrm{epi}(f), (y, f(y)))\},$$

respectively. It is known (see [18]) that

$$\hat{\partial} f(y) := \left\{ y^* \in Y^* : \liminf_{v \to y} \frac{f(v) - f(y) - \langle y^*, v - y \rangle}{\|v - y\|} \geq 0 \right\}.$$

Let $\hat{\partial}^\infty f(y)$ and $\partial^\infty f(y)$ denote, respectively, the singular Fréchet subdifferential and the singular limiting subdifferential of f at y, that is,

$$\hat{\partial}^\infty f(y) = \{ y^* : \ (y^*, 0) \in \hat{N}(\mathrm{epi}(f), (y, f(y))) \}$$

and

$$\partial^\infty f(y) := \{ y^* \in Y^* : \ (y^*, 0) \in N(\mathrm{epi}(f), (y, f(y))) \}.$$

Recall that a Banach space Y is called an Asplund space if every continuous convex function defined on an open convex subset D of Y is Fréchet differentiable at each point of a dense G_δ subset of D. It is well known that Y is an Asplund space if and only if every separable subspace of Y has a separable dual. The class of Asplund spaces is well investigated in geometric theory of Banach spaces; see [21] and the references therein. In the case when Y is an Asplund space, Mordukhovich and Shao [18] proved that $\partial f(y) = \limsup_{v \xrightarrow{f} y} \hat{\partial} f(v)$,

$$N(A, a) := \{ y^* \in Y^* : \ \exists y_n \xrightarrow{A} a, \ y_n^* \xrightarrow{w^*} y^* \text{ with } y_n^* \in \hat{N}(A, y_n) \}, \tag{2.1}$$

and $N_c(A, a)$ is the weak* closed convex hull of $N(A, a)$.

In the Asplund space setting, in terms of the Fréchet subdifferential and Fréchet normal cone one has the following necessity optimality condition similar to Proposition 2.1.

PROPOSITION 2.2. *Let Y be an Asplund space and $f : Y \to R$ a locally Lipschitz function, and let A be a closed subset of Y. Suppose that f attains its minimum over A at $a \in A$. Then for any $\varepsilon > 0$ there exist $a_\varepsilon \in a + \varepsilon B_Y$ and $u_\varepsilon \in A \cap (a + \varepsilon B_Y)$ such that*

$$0 \in \hat{\partial} f(a_\varepsilon) + \hat{N}(A, u_\varepsilon) + \varepsilon B_{Y^*}.$$

Proposition 2.2 is due to Fabian [6] (also see [18] for the details).

For $\Phi : X \to 2^Y$, a multifunction from another Banach space X to Y, let $\mathrm{Gr}(\Phi)$ denote the graph of Φ, that is,

$$\mathrm{Gr}(\Phi) := \{ (x, y) \in X \times Y : \ y \in \Phi(x) \}.$$

We say that Φ is closed if $\mathrm{Gr}(\Phi)$ is a closed subset of $X \times Y$ and that Φ is convex if $\mathrm{Gr}(\Phi)$ is a convex subset of $X \times Y$. Recall (see [15, 17]) that Φ is pseudo-Lipschitz at $(\bar{x}, \bar{y}) \in \mathrm{Gr}(\Phi)$ if there exist a constant $L > 0$, a neighborhood U of $\bar{x}$, and a neighborhood V of $\bar{y}$ such that

$$\Phi(x_1) \cap V \subset \Phi(x_2) + \|x_1 - x_2\| L B_Y \quad \forall x_1, x_2 \in U.$$

For $x \in X$ and $y \in \Phi(x)$, let $\hat{D}^* \Phi(x, y)$, $D^* \Phi(x, y)$ and $D_c^* \Phi(x, y) : Y^* \to 2^{X^*}$ denote the Mordukhovich coderivatives of Φ at (x, y) with respect to the Fréchet, limiting, and Clarke normal cones, respectively, that is,

$$\hat{D}^* \Phi(x, y)(y^*) := \{ x^* \in X^* : \ (x^*, -y^*) \in \hat{N}(\mathrm{Gr}(\Phi), (x, y)) \} \quad \forall y^* \in Y^*, \tag{2.2}$$

$$D^* \Phi(x, y)(y^*) := \{ x^* \in X^* : \ (x^*, -y^*) \in N(\mathrm{Gr}(\Phi), (x, y)) \} \quad \forall y^* \in Y^*, \tag{2.3}$$

and

$$D_c^*\Phi(x,y)(y^*) := \{x^* \in X^* :\ (x^*,-y^*) \in N_c(\mathrm{Gr}(\Phi),(x,y))\} \quad \forall y^* \in Y^*$$

(see [17, 18]). We will need the following known result.

PROPOSITION 2.3. *Let $\Phi : X \to 2^Y$ be a closed multifunction. Suppose that Φ is pseudo-Lipschitz at $(\bar{x},\bar{y}) \in \mathrm{gr}(\Phi)$. Then there exist constants $L,\delta > 0$ such that*

$$\sup\{\|x^*\| :\ x^* \in \hat{D}^*\Phi(x,y)(y^*)\} \le L\|y^*\|$$

for any $(x,y) \in \mathrm{Gr}(\Phi) \cap (B(\bar{x},\delta) \times B(\bar{y},\delta))$ and any $y^* \in Y^*$.

Proposition 2.3 can be found in Mordukhovich [15]. Moreover, readers can find a simpler proof of Proposition 2.3 in Jourani and Thibault [11].

Let $S_i : M_i \to 2^Y$ $(i = 1,\dots,n)$ be multifunctions from metric spaces M_i with metrics d_i. Recall (see [19]) that $\bar{x}$ is called an extremal point of the system $(S_1,\dots,S_n)$ at $(\bar{s}_1,\dots,\bar{s}_n)$, provided that $\bar{x} \in \bigcap_{i=1}^n S_i(\bar{s}_i)$ and there exists $r > 0$ such that for any $\varepsilon > 0$ there exists $(s_1,\dots,s_n) \in M_1 \times \cdots \times M_n$ with

$$d_i(s_i,\bar{s}_i) \le \varepsilon,\ d(\bar{x},S_i(s_i)) \le \varepsilon, \quad i = 1,\dots,n, \text{ and } \bigcap_{i=1}^n S_i(s_i) \cap (\bar{x} + rB_Y) = \emptyset.$$

Mordukhovich, Treiman, and Zhu [19] proved the following extended extremal principle.

Theorem MTZ. Let $S_i : M_i \to 2^Y$ be multifunctions from metric spaces (M_i,d_i) to an Asplund space Y, $i = 1,\dots,n$. Assume that $\bar{x}$ is an extremal point of the system $(S_1,\dots,S_n)$ at $(\bar{s}_1,\dots,\bar{s}_n)$, where each S_i is closed-valued around $\bar{s}_i$. Then for any $\sigma > 0$ there exist $s_i \in M_i$, $x_i \in S_i(s_i)$, and $x_i^* \in Y^*$, $i = 1,\dots,n$, such that

$$d_i(s_i,\bar{s}_i) \le \sigma,\ \|x_i - \bar{x}\| \le \sigma,\ x_i^* \in \hat{N}(S_i(s_i),x_i) + \sigma B_{Y^*},\ \sum_{i=1}^n \|x_i^*\| = 1,\ \text{and}\ \sum_{i=1}^n x_i^* = 0.$$

Next we provide a slight improvement of Theorem MTZ, which will be used in the proofs of the main results.

For a natural number n and subsets $A_1,\dots,A_n$ of Y, we define the nonintersection index $\gamma(A_1,\dots,A_n)$ of $A_1,\dots,A_n$ as

$$\gamma(A_1,\dots,A_n) := \inf\left\{\sum_{i=1}^{n-1} \|a_i - a_n\| :\ (a_1,\dots,a_n) \in A_1 \times \cdots \times A_n\right\}.$$

LEMMA 2.1. *Let Y be an Asplund space and $A_1,\dots,A_n$ be closed subsets of Y with $\bigcap_{i=1}^n A_i = \emptyset$. Let $a_i \in A_i$ $(i = 1,\dots,n)$ and $\varepsilon > 0$ such that*

$$\sum_{i=1}^{n-1} \|a_i - a_n\| < \gamma(A_1,\dots,A_n) + \varepsilon.$$

Then for any $\lambda > 0$ there exist $\tilde{a}_i \in A_i$ and $a_i^* \in Y^*$ such that

$$\sum_{i=1}^n \|a_i - \tilde{a}_i\| < \lambda, \quad a_i^* \in \hat{N}(A_i,\tilde{a}_i) + \frac{\varepsilon}{\lambda}B_{Y^*},$$

$$\sum_{i=1}^n \|a_i^*\| = 1 \ \text{ and } \ \sum_{i=1}^n a_i^* = 0.$$

Proof. Let the product Y^n be equipped with the norm $|||(x_1,\dots,x_n)||| = \sum_{i=1}^n \|x_i\|$ for any $x_i \in Y$ $(i=1,\dots,n)$, and define $f : Y^n \to R \cup \{+\infty\}$ by

$$f(x_1,\dots,x_n) := \sum_{i=1}^{n-1} \|x_i - x_n\| + \delta_{A_1\times\cdots\times A_n}(x_1,\dots,x_n) \quad \forall (x_1,\dots,x_n) \in Y^n.$$

Then

$$\inf\{f(x_1,\dots,x_n) :\ (x_1,\dots,x_n) \in Y^n\} = \gamma(A_1,\dots,A_n),$$

and so, by the assumption,

$$f(a_1,\dots,a_n) < \inf\{f(x_1,\dots,x_n) :\ (x_1,\dots,x_n) \in Y^n\} + \varepsilon.$$

Take $\eta \in (0,\ \varepsilon)$ and $\beta \in (0,\ \lambda)$ such that

$$\frac{\eta}{\beta} < \frac{\varepsilon}{\lambda} \ \text{ and } \ f(a_1,\dots,a_n) < \inf\{f(x_1,\dots,x_n) :\ (x_1,\dots,x_n) \in Y^n\} + \eta.$$

Then, by the Ekeland variational principle, there exists $\tilde{x}_i \in A_i$ such that

$$\sum_{i=1}^n \|a_i - \tilde{x}_i\| \le \beta \tag{2.4}$$

and

$$f(\tilde{x}_1,\dots,\tilde{x}_n) \le f(x_1,\dots,x_n) + \frac{\eta}{\beta}\sum_{i=1}^n \|x_i - \tilde{x}_i\| \quad \forall (x_1,\dots,x_n) \in Y^n. \tag{2.5}$$

This and the definition of f imply that $(\tilde{x}_1,\dots,\tilde{x}_n) \in A_1 \times \cdots \times A_n$. It follows from $\bigcap_{i=1}^n A_i = \emptyset$ that

$$\sum_{i=1}^{n-1} \|\tilde{x}_i - \tilde{x}_n\| > 0. \tag{2.6}$$

We define a continuous convex function ψ by

$$\psi(x_1,\dots,x_n) := \sum_{i=1}^{n-1} \|x_i - x_n\| + \frac{\eta}{\beta}\sum_{i=1}^n \|x_i - \tilde{x}_i\| \quad \forall (x_1,\dots,x_n) \in Y^n.$$

It follows from (2.5) that ψ attains its minimum over $A_1 \times \cdots \times A_n$ at $(\tilde{x}_1,\dots,\tilde{x}_n)$. By (2.6) and Proposition 2.2, there exist $\bar{x}_i \in Y$ and $\tilde{a}_i \in A_i$ $(i=1,\dots,n)$ such that

$$\sum_{i=1}^{n-1} \|\bar{x}_i - \bar{x}_n\| > 0, \quad \sum_{i=1}^n \|\tilde{a}_i - \tilde{x}_i\| < \lambda - \beta$$

and

$$0 \in \partial\psi(\bar{x}_1,\dots,\bar{x}_n) + \hat{N}(A_1 \times \cdots \times A_n, (\tilde{a}_1,\dots,\tilde{a}_n)) + \left(\frac{\varepsilon}{\lambda} - \frac{\eta}{\beta}\right) B^n_{Y^*}. \tag{2.7}$$

It follows from (2.4) that $\sum_{i=1}^n \|\tilde{a}_i - a_i\| \le \sum_{i=1}^n \|\tilde{a}_i - \tilde{x}_i\| + \sum_{i=1}^n \|\tilde{x}_i - a_i\| < \lambda$. Let

$$\phi(x_1, \dots, x_n) := \sum_{i=1}^{n-1} \|x_i - x_n\| \quad \forall (x_1, \dots, x_n) \in Y^n.$$

Then

$$\partial\psi(\bar{x}_1, \dots, \bar{x}_n) \subset \partial\phi(\bar{x}_1, \dots, \bar{x}_n) + \frac{\eta}{\beta} B_{(Y^n)^*}.$$

This and (2.7) imply that

$$0 \in \partial\phi(\bar{x}_1, \dots, \bar{x}_n) + \hat{N}(A_1 \times \cdots \times A_n, (\tilde{a}_1, \dots, \tilde{a}_n)) + \frac{\varepsilon}{\lambda} B_{(Y^n)^*}. \tag{2.8}$$

We claim that

$$\partial\phi(\bar{x}_1, \dots, \bar{x}_n) \subset \left\{ (x_1^*, \dots, x_n^*) \in (Y^*)^n : \sum_{i=1}^n x_i^* = 0 \text{ and } \sum_{i=1}^n \|x_i^*\| \ge 1 \right\}. \tag{2.9}$$

Granting this and noting that

$$\hat{N}(A_1 \times \cdots \times A_n, (\tilde{a}_1, \dots, \tilde{a})) = \hat{N}(A_1, \tilde{a}_1) \times \cdots \times \hat{N}(A_n, \tilde{a}_n)$$

is a cone, it follows from (2.8) that there exists $(a_1^*, \dots, a_n^*) \in (Y^*)^n$ such that

$$a_i^* \in \hat{N}(A_i, \tilde{a}_i) + \frac{\varepsilon}{\lambda} B_{Y^*}, \ \sum_{i=1}^n \|a_i^*\| = 1, \text{ and } \sum_{i=1}^n a_i^* = 0.$$

It remains to show that (2.9) holds. Let $(x_1^*, \dots, x_n^*) \in \partial\phi(\bar{x}_1, \dots, \bar{x}_n)$. It follows from the convexity of ϕ that for any $h \in Y$,

$$\sum_{i=1}^n \langle x_i^*, h\rangle \le \phi(\bar{x}_1 + h, \dots, \bar{x}_n + h) - \phi(\bar{x}_1, \dots, \bar{x}_n) = 0.$$

This means that $\sum_{i=1}^n x_i^* = 0$. On the other hand,

$$-\sum_{i=1}^{n-1} \langle x_i^*, \bar{x}_i - \bar{x}_n\rangle = \sum_{i=1}^n \langle x_i^*, -\bar{x}_i\rangle \le \phi(0, \dots, 0) - \phi(\bar{x}_1, \dots, \bar{x}_n) = -\sum_{i=1}^{n-1} \|\bar{x}_i - \bar{x}_n\|.$$

Since, as in (2.6), $\sum_{i=1}^{n-1} \|\bar{x}_i - \bar{x}_n\| > 0$, it follows that $\sum_{i=1}^n \|x_i^*\| \ge 1$. This completes the proof. □

Remark. Lemma 2.1 recaptures Theorem MTZ. Indeed, by the assumption of Theorem MTZ, there exists $r > 0$ such that for any $\sigma \in (0, \min\{\frac{r}{2}, r^{\frac{1}{2}}\})$ there exists $(s_1, \dots, s_n) \in M_1 \times \cdots \times M_n$ such that each $S_i(s_i)$ is closed,

$$d_i(s_i, \bar{s}_i) < \sigma, \ d(\bar{x}, S_i(s_i)) < \frac{\sigma^2}{2n}, \quad i = 1, \dots, n, \text{ and } \bigcap_{i=1}^n S_i(s_i) \cap (\bar{x} + rB_Y) = \emptyset.$$

Hence, there exists $u_i \in S_i(s_i)$ such that $\|u_i - \bar{x}\| < \frac{\sigma^2}{2n}$. This implies that

$$\sum_{i=1}^{n-1} \|u_i - u_n\| \le \sum_{i=1}^{n-1} (\|u_i - \bar{x}\| + \|\bar{x} - u_n\|) < \sigma^2,$$

and so

$$\sum_{i=1}^{n-1} \|u_i - u_n\| < \gamma(S_1(s_1) \cap (\bar{x} + rB_Y), \ldots, S_n(s_n) \cap (\bar{x} + rB_Y)) + \sigma^2.$$

Now with $A_i = S_i(s_i) \cap (\bar{x} + rB_Y)$, $a_i = u_i$, $\varepsilon = \sigma^2$, and $\lambda = \sigma$, there exist $\tilde{a}_i \in A_i$ and $a_i^* \in Y^*$ satisfying the properties as stated in Lemma 2.1. Note that $\tilde{a}_i$ lies in the interior of $\bar{x} + rB_Y$, and it follows that $a_i^* \in \hat{N}(S_i(s_i), \tilde{a}_i)$. Thus Theorem MTZ is seen to hold.

Similar to the proof of Lemma 2.1 but applying Proposition 2.1 in place of Proposition 2.2, we have the following result applicable to the case when Y is a general Banach space.

LEMMA 2.2. *Let Y be a Banach space and $A_1, \ldots, A_n$ be closed subsets of Y with $\bigcap_{i=1}^n A_i = \emptyset$. Let $a_i \in A_i$ $(i = 1, \ldots, n)$ and $\varepsilon > 0$ such that*

$$\sum_{i=1}^{n-1} \|a_i - a_n\| \le \gamma(A_1, \ldots, A_n) + \varepsilon.$$

Then for any $\lambda > 0$ there exist $\tilde{a}_i \in A_i$ and $a_i^* \in Y^*$ such that

$$\sum_{i=1}^{n} \|a_i - \tilde{a}_i\| < \lambda, \quad a_i^* \in N_c(A_i, \tilde{a}_i) + \frac{\varepsilon}{\lambda} B_{Y^*},$$

$$\sum_{i=1}^{n} \|a_i^*\| = 1 \text{ and } \sum_{i=1}^{n} a_i^* = 0.$$

3. Fuzzy Lagrange multiplier rules. In this section, we always assume that X, Y_i are Banach spaces (unless stated otherwise), that $C_i \subset Y_i$ is a closed convex cone, and that each multifunction $F_i : X \to 2^{Y_i}$ is closed. Further we assume that the ordering cone C_0 in Y_0 is nontrivial (i.e., C_0 is not a linear subspace). For convenience we define the norm on the product $X \times \prod_{i=0}^m Y_i$ by

$$\|(x, y_0, y_1, \ldots, y_m)\| = \|x\| + \sum_{i=0}^{m} \|y_i\|.$$

In this section we present three fuzzy Lagrange multiplier rules. The first one works on general Banach spaces, while the last two work on Asplund spaces dealing, respectively, with the set-valued and the numeral-valued functions.

THEOREM 3.1. *Let $(\bar{x}, \bar{y}_0)$ be a local Pareto solution of the constrained multiobjective optimization problem* (1.3) *and $\bar{y}_i$ be a point in $F_i(\bar{x}) \cap -C_i$ $(i = 1, \ldots, m)$. Then one of the following assertions holds.*

(i) *For any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, and $c_i^* \in C_i^+$ such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} D_c^* F_i(x_i, y_i)(c_i^* + \varepsilon B_{Y_i^*}) \cap M B_{X^*} + N_c(\Omega, w) \cap M B_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

(ii) *For any* $\varepsilon > 0$ *there exist* $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, $x_i^* \in D_c^* F_i(x_i, y_i)(\varepsilon B_{Y_i^*})$, *and* $w^* \in N_c(\Omega, w) + \varepsilon B_{X^*}$ *such that*

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \ \text{ and } \ w^* + \sum_{i=0}^{m} x_i^* = 0.$$

Proof. By the assumption there exists $\delta > 0$ such that

$$\bar{y}_0 \in E\left(F_0\left[(\bar{x} + \delta B_X) \cap \Omega \cap \left(\bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right)\right], C_0\right). \tag{3.1}$$

Since the ordering cone C_0 is not a subspace of Y_0, there exists $c_0 \in C_0$ with $\|c_0\| = 1$ such that

$$c_0 \notin -C_0. \tag{3.2}$$

For any natural number k, let $s_k := \frac{1}{(m+2)k^2}$, and consider the following sets in the product space $X \times \prod_{j=0}^{m} Y_j$:

$$A_i := \left\{(x, y_0, y_1, \ldots, y_m) \in X \times \prod_{j=0}^{m} Y_j : \ (x, y_i) \in \mathrm{Gr}(F_i)\right\}, \quad i = 0, 1, \ldots, m,$$

and

$$A_{m+1} := ((\bar{x} + \delta B_X) \cap \Omega) \times (\bar{y}_0 - s_k c_0 - C_0) \times \prod_{i=1}^{m} (\bar{y}_i - C_i).$$

Then $\bigcap_{i=0}^{m+1} A_i = \emptyset$. Indeed, if this is not the case, then there exist $x' \in X$ and $y_i' \in F_i(x')$ $(i = 0, 1, \ldots, m)$ such that

$$x' \in (\bar{x} + \delta B_X) \cap \Omega, \ y_0' \leq_{C_0} \bar{y}_0 - s_k c_0, \ \text{ and } \ y_i' \in \bar{y}_i - C_i (\subset -C_i), \quad i = 1, \ldots, m.$$

Hence, $x' \in (\bar{x} + \delta B_X) \cap \Omega \cap \left(\bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right)$, and so

$$y_0' \in F_0\left[(\bar{x} + \delta B_X) \cap \Omega \cap \left(\bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right)\right].$$

It follows from (3.1) that $\bar{y}_0 \leq_{C_0} y_0'$, and so $\bar{y}_0 \leq_{C_0} \bar{y}_0 - s_k c_0$. This implies that $c_0 \in -C_0$, contradicting (3.2). Let

$$a_0 = a_1 = \cdots = a_m = (\bar{x}, \bar{y}_0, \bar{y}_1, \ldots, \bar{y}_m) \ \text{ and } \ a_{m+1} = (\bar{x}, \bar{y}_0 - s_k c_0, \bar{y}_1, \ldots, \bar{y}_m).$$

Then

$$\sum_{i=0}^{m} \|a_i - a_{m+1}\| = (m+1)s_k < \frac{1}{k^2} \leq \gamma(A_0, A_1, \ldots, A_{m+1}) + \frac{1}{k^2}.$$

By Lemma 2.2 (applied to the family $\{A_0, A_1, \ldots, A_{m+1}\}$ and the constants $\varepsilon = \frac{1}{k^2}$, $\lambda = \frac{1}{k}$), there exist

$$\tilde{a}_i(k) := (x_i(k), y_{i,0}(k), y_{i,1}(k), \ldots, y_{i,m}(k)) \in X \times \prod_{j=0}^{m} Y_j$$

and

$$(x_i^*(k), y_{i,0}^*(k), y_{i,1}^*(k), \dots, y_{i,m}^*(k)) \in X^* \times \prod_{j=0}^{m} Y_j^*$$

$(i = 0, 1, \dots, m+1)$ such that

$$\sum_{i=0}^{m+1} \|\tilde{a}_i(k) - a_i\| = \sum_{i=0}^{m} \left(\|x_i(k) - \bar{x}\| + \sum_{j=0}^{m} \|y_{i,j}(k) - \bar{y}_j\| \right) \tag{3.3}$$

$$+ \ \|x_{m+1}(k) - \bar{x}\| + \|y_{m+1,0}(k) - (\bar{y}_0 - s_k c_0)\| + \sum_{j=1}^{m} \|y_{m+1,j}(k) - \bar{y}_j\| < \frac{1}{k},$$

$$(x_i^*(k), y_{i,0}^*(k), \dots, y_{i,m}^*(k)) \in N_c(A_i, \tilde{a}_i(k)) + \frac{1}{k} \left(B_{X^*} \times \prod_{j=0}^{m} B_{Y_j^*} \right), \tag{3.4}$$

$$\sum_{i=0}^{m+1} \max\{\|x_i^*(k)\|, \ \max\{\|y_{i,j}^*(k)\| : \ j = 0, 1, \dots, m\}\} = 1, \tag{3.5}$$

and

$$\sum_{i=0}^{m+1} (x_i^*(k), y_{i,0}^*(k), y_{i,1}^*(k), \dots, y_{i,m}^*(k)) = 0. \tag{3.6}$$

By the definitions of A_{m+1} and $\tilde{a}_{m+1}(k)$, we see that $N_c(A_{m+1}, \tilde{a}_{m+1}(k))$ is equal to the following product:

$$N_c((\bar{x}+\delta B_X)\cap\Omega, x_{m+1}(k)) \times N_c(\bar{y}_0 - s_k c_0 - C_0, y_{m+1,0}(k)) \times \prod_{j=1}^{m} N_c(\bar{y}_j - C_j, y_{m+1,j}(k)).$$

By well-known relations

$$N_c(\bar{y}_0 - s_k c_0 - C_0, y_{m+1,0}(k)) \subset C_0^+ \ \text{ and } \ N_c(\bar{y}_j - C_j, y_{m+1,j}(k)) \subset C_j^+ \ (1 \le j \le m),$$

it follows that

$$N_c(A_{m+1}, \tilde{a}_{m+1}(k)) \subset N_c((\bar{x} + \delta B_X) \cap \Omega, x_{m+1}(k)) \times \prod_{j=0}^{m} C_j^+.$$

We do the above for every natural number k, and by (3.3) we assume without loss of generality that $\bar{x} + \delta B_X$ is a neighborhood of $x_{m+1}(k)$, and so $N_c((\bar{x} + \delta B_X) \cap \Omega, x_{m+1}(k)) = N_c(\Omega, x_{m+1}(k))$. Hence,

$$N_c(A_{m+1}, \tilde{a}_{m+1}(k)) \subset N_c(\Omega, x_{m+1}(k)) \times \prod_{j=0}^{m} C_j^+.$$

This and (3.4) imply that there exists $(c_0^*(k), c_1^*(k), \dots, c_m^*(k)) \in \prod_{j=0}^{m} C_j^+$ such that

$$x_{m+1}^*(k) \in N_c(\Omega, x_{m+1}(k)) + \frac{1}{k} B_{X^*} \tag{3.7}$$

and

$$\|y^*_{m+1,j}(k) - c^*_j(k)\| \le \frac{1}{k}, \quad j = 0, 1, \dots, m. \tag{3.8}$$

Moreover, for $0 \le i \le m$, we have by the definition of A_i and $\tilde{a}_i(k)$ that

(3.9)
$$N_c(A_i, \tilde{a}_i(k)) = \{(x^*, y^*_0, \dots, y^*_m) : \ (x^*, y^*_i) \in N_c(\mathrm{Gr}(F_i), (x_i(k), y_{i,i}(k))) \text{ and } y^*_j = 0 \quad \forall j \ne i\}.$$

This and (3.4) imply that for $0 \le i \le m$,

$$x^*_i(k) \in D^*_c F_i(x_i(k), y_{i,i}(k)) \left(-y^*_{i,i}(k) + \frac{1}{k} B_{Y^*_i}\right) + \frac{1}{k} B_{X^*} \tag{3.10}$$

and

$$\|y^*_{i,j}(k)\| \le \frac{1}{k}, \quad 0 \le j \le m \ \text{ and } \ j \ne i. \tag{3.11}$$

By (3.6), (3.8), and (3.11), one has

$$-y^*_{i,i}(k) = y^*_{m+1,i}(k) + \sum_{l=0, l\ne i}^{m} y^*_{l,i}(k) \in c^*_i(k) + \frac{m+1}{k} B_{Y^*_i}, \quad i = 0, 1, \dots, m. \tag{3.12}$$

This and (3.10) imply that for $i = 0, 1, \dots, m$,

$$x^*_i(k) \in D^*_c F_i(x_i(k), y_{i,i}(k)) \left(c^*_i(k) + \frac{m+2}{k} B_{Y^*_i}\right) + \frac{1}{k} B_{X^*}. \tag{3.13}$$

In the case when $\{\sum_{j=0}^m \|c^*_j(k)\|\}$ does not converge to 0, without loss of generality we assume that there exists $r > 0$ such that $\sum_{j=0}^m \|c^*_j(k)\| > r$ for all k (passing to subsequences if necessary). It follows from (3.13), (3.7), and (3.6) that

$$\frac{x^*_i(k)}{\sum\limits_{j=0}^m \|c^*_j(k)\|} \in D^*_c F_i(x_i(k), y_{i,i}(k)) \left(\frac{c^*_i(k)}{\sum\limits_{j=0}^m \|c^*_j(k)\|} + \frac{m+2}{rk} B_{Y^*_i} \right) + \frac{1}{rk} B_{X^*}, \quad 0 \le i \le m,$$

$$\frac{x^*_{m+1}(k)}{\sum\limits_{j=0}^m \|c^*_j(k)\|} \in N_c(\Omega, x_{m+1}(k)) + \frac{1}{rk} B_{X^*} \quad \text{and} \quad \sum_{i=0}^{m+1} \frac{x^*_i(k)}{\sum\limits_{j=0}^m \|c^*_j(k)\|} = 0.$$

By virtue of (3.3) and (3.5) and by considering large enough k, it follows that (i) holds with $M = \frac{m+2}{r}$.

Next we consider the case when $t_k := \sum_{j=0}^m \|c^*_j(k)\| \to 0$. In this case, (3.8) implies that

$$y^*_{m+1,j}(k) \to 0 \ \text{ for } j = 0, 1, \dots, m.$$

It follows from (3.11), (3.12), and (3.5) that $\sum_{i=0}^{m+1} \|x^*_i(k)\| \to 1$. Thus, by (3.13), (3.7), and (3.6), there exist

$$\tilde{x}^*_i(k) \in D^*_c F_i(x_i(k), y_{i,i}(k)) \left(c^*_i(k) + \frac{m+2}{k} B_{Y^*_i}\right) \ \text{ for } i = 0, 1, \dots, m$$

and

$$\tilde{x}^*_{m+1}(k) \in N_c(\Omega, x_{m+1}(k)) + \frac{m+2}{k} B_{X^*}$$

such that

$$r_k := \sum_{i=0}^{m+1} \|\tilde{x}^*_i(k)\| \to 1 \text{ and } \sum_{i=0}^{m+1} \tilde{x}^*_i(k) = 0.$$

Therefore, for all k large enough,

$$\frac{\tilde{x}^*_i(k)}{r_k} \in D^*_c F_i(x_i(k), y_{i,i}(k)) \left(\left(\frac{c^*_i(k)}{r_k} + \frac{m+2}{kr_k} \right) B_{Y_i^*} \right),$$

$$\frac{\tilde{x}^*_{m+1}(k)}{r_k} \in N_c(\Omega, x_{m+1}(k)) + \frac{m+2}{kr_k} B_{X^*},$$

$$\sum_{i=0}^{m+1} \left\| \frac{\tilde{x}^*_i(k)}{r_k} \right\| = 1 \text{ and } \sum_{i=0}^{m+1} \frac{\tilde{x}^*_i(k)}{r_k} = 0.$$

Noting that $r_k \to 1$ and $\|c^*_i(k)\| \le t_k \to 0$, this implies that (ii) holds, and the proof is completed. □

In the special case when $F_i(x) = 0$ for all $x \in X$ and $i = 1, \ldots, m$, (1.3) reduces to the following problem:

$$C_0 - \min F_0(x), \quad x \in \Omega, \tag{3.14}$$

and $D^*_c F_i(x, 0)(y^*_i) = 0$ for all $(x, y^*_i) \in X \times Y_i^*$ and $i = 1, \ldots, m$. Thus, the following corollary is an immediate consequence of Theorem 3.1 and recaptures [28, Theorem 3.1] by putting our $\Omega = X$.

COROLLARY 3.1. *Let $(\bar{x}, \bar{y})$ be a local Pareto solution of the constrained multiobjective optimization problem* (3.14). *Then one of the following two assertions holds.*

(i) *For any $\varepsilon > 0$ there exist $u \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y \in F_0(u) \cap (\bar{y} + \varepsilon B_Y)$, and $c^* \in C^+$ with $\|c^*\| = 1$ such that*

$$0 \in D^*_c F_0(u, y)(c^* + \varepsilon B_{Y^*}) \cap M B_{X^*} + N_c(\Omega, w) \cap M B_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

(ii) *For any $\varepsilon > 0$ there exist $u \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y \in F_0(u) \cap (\bar{y} + \varepsilon B_Y)$, and $x^* \in X^*$ with $\|x^*\| = 1$ such that*

$$x^* \in D^*_c F_0(u, y)(\varepsilon B_{Y^*}) \cap (-N_c(\Omega, w) + \varepsilon B_{X^*}).$$

When X and each Y_i are Asplund spaces, Theorem 3.1 can be strengthened to the following theorem, Theorem 3.2, in which D^*_c and $N_c(\Omega, \cdot)$ are replaced, respectively, by the Fréchet coderivative $\hat{D}^*$ and the Fréchet normal cone $\hat{N}(\Omega, \cdot)$ (recall that $\hat{N}(A, a) \subset N(A, a)$ and $N_c(A, a)$ is the weak*-closed convex hull of $N(A, a)$). The proof is the same as the proof of Theorem 3.1, but use Lemma 2.1 in place of Lemma 2.2.

THEOREM 3.2. *Let $(\bar{x}, \bar{y}_0)$ be a local Pareto solution of the constrained multiobjective optimization problem* (1.3) *and $\bar{y}_i$ be a point in $F_i(\bar{x}) \cap -C_i$ $(i = 1, \ldots, m)$.*

Suppose that X and Y_i $(i = 0, 1, \ldots, m)$ are Asplund spaces. Then one of the following assertions holds.

(i) *For any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, and $c_i^* \in C_i^+$ such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} \hat{D}^* F_i(x_i, y_i)(c_i^* + \varepsilon B_{Y_i^*}) \cap M B_{X^*} + \hat{N}(\Omega, w) \cap M B_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

(ii) *For any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, $x_i^* \in \hat{D}^* F_i(x_i, y_i)(\varepsilon B_{Y_i^*})$, and $w^* \in \hat{N}(\Omega, w) + \varepsilon B_{X^*}$ such that*

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \text{ and } w^* + \sum_{i=0}^{m} x_i^* = 0.$$

Next we prove that (ii) in Theorem 3.2 cannot happen when each F_i is pseudo-Lipschitz at $(\bar{x}, \bar{y}_i)$.

COROLLARY 3.2. *Let $(\bar{x}, \bar{y}_0)$ be a local Pareto solution of the constrained multiobjective optimization problem* (1.3) *and $\bar{y}_i$ be a point in $F_i(\bar{x}) \cap -C_i$ $(i = 1, \ldots, m)$. Suppose that X and Y_i $(i = 0, 1, \ldots, m)$ are Asplund spaces and that each F_i is pseudo-Lipschitz at $(\bar{x}, \bar{y}_i)$. Then for any $\varepsilon > 0$ there exist $x_i \in \bar{x} + \varepsilon B_X$, $w \in \Omega \cap (\bar{x} + \varepsilon B_X)$, $y_i \in F_i(x_i) \cap (\bar{y}_i + \varepsilon B_{Y_i})$, and $c_i^* \in C_i^+$ such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} \hat{D}^* F_i(x_i, y_i)(c_i^* + \varepsilon B_{Y_i^*}) \cap M B_{X^*} + \hat{N}(\Omega, w) \cap M B_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

Proof. Since each F_i is pseudo-Lipschitz at $(\bar{x}, \bar{y}_i)$, Proposition 2.3 implies that there exist constants $L, \delta > 0$ such that for any $(x, y_i) \in \mathrm{Gr}(F_i) \cap (B(\bar{x}, \delta) \times B(\bar{y}_i, \delta))$ and $y_i^* \in Y^*$,

$$\sup\{\|x^*\| : x^* \in \hat{D}^* F_i(x, y_i)(y_i^*)\} \le L\|y_i^*\|. \tag{3.15}$$

We need only show that (i) of Theorem 3.2 holds. If this is not the case, Theorem 3.2 implies that there exist

$$x_i \in B(\bar{x}, \delta),\ w \in \Omega \cap B(\bar{x}, \delta),\ y_i \in F_i(x_i) \cap B(\bar{y}_i, \delta), \tag{3.16}$$

$$x_i^* \in \hat{D}^* F_i(x_i, y_i)\left(\frac{B_{Y_i^*}}{4(m+1)L}\right) \text{ and } w^* \in \hat{N}(\Omega, w) + B_{X^*} \tag{3.17}$$

such that

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \text{ and } w^* + \sum_{i=0}^{m} x_i^* = 0. \tag{3.18}$$

By (3.15), (3.16), and (3.17), one has

$$\left\| \sum_{i=0}^{m} x_i^* \right\| \le \sum_{i=0}^{m} \|x_i^*\| \le \frac{1}{4},$$

contradicting (3.18). This completes the proof. ∎

Let $f : X \to R \cup \{+\infty\}$ be a proper lower semicontinuous function and $F(x) = [f(x), +\infty)$ for all $x \in X$. Then F is closed and $\mathrm{Gr}(F) = \mathrm{epi}(f)$. Recall (see [14, Lemma 2.2]) that if $r \in F(\bar{x})$ and X is an Asplund space, then the following assertions hold.

(α) $\lambda \neq 0$ and $x^* \in \hat{D}^*F(\bar{x}, r)(\lambda) \Longleftrightarrow \lambda > 0$, $r = f(\bar{x})$, and $x^* \in \hat{\partial}(\lambda f)(\bar{x})$.

(β) For any $x^* \in \hat{D}^*F(\bar{x}, r)(0)$ there exist sequences $\{x_k\}$, $\{x_k^*\}$, and $\{\lambda_k\}$ such that

$$x_k^* \in \hat{\partial}(\lambda_k f)(x_k),\ (x_k, f(x_k)) \to (\bar{x}, f(\bar{x})),\ \lambda_k \downarrow 0, \text{ and } \|x_k^* - x^*\| \to 0.$$

Let $g : X \to R$ be a continuous function and $G(x) = \{g(x)\}$ for all $x \in X$. The following assertions are known (see [14, Lemma 2.3]).

(α') $\hat{D}^*G(x, g(x))(\lambda) = \partial(\lambda g)(x)$ for any $\lambda \neq 0$.

(β') $x^* \in \hat{D}^*G(x, g(x))(0)$ if and only if there exist sequences $\{x_k\}$, $\{x_k^*\}$, and $\{t_k\}$ such that

$$x_k^* \in \hat{\partial}(t_k g)(x_k) \cup \hat{\partial}(-t_k g)(x_k),\ (x_k, g(x_k)) \to (\bar{x}, g(\bar{x})),\ t_k \downarrow 0, \text{ and } \|x_k^* - x^*\| \to 0.$$

As an application of Theorem 3.2, now we can establish fuzzy necessary optimality conditions for scalar-objective optimization problem (1.1).

THEOREM 3.3. *Let X be an Asplund space and Ω be a closed subset of X. Let $f_0, f_1, \ldots, f_n : X \to R \cup \{+\infty\}$ be proper lower semicontinuous and $f_{n+1}, \ldots, f_m : X \to R$ be continuous. Suppose that $\bar{x}$ is a local solution of* (1.1). *Then one of the following assertions hold.*

(i) *For any $\varepsilon > 0$ there exist $\lambda_i \in R \setminus \{0\}$, $w \in (\bar{x} + \varepsilon B_X) \cap \Omega$, and $x_i \in \bar{x} + \varepsilon B_X$ with $|f_i(x_i) - f_i(\bar{x})| < \varepsilon$ such that $\lambda_i > 0$ for $0 \le i \le n$, $\sum_{i=0}^m |\lambda_i| = 1$, and*

$$0 \in \sum_{i=0}^m \hat{\partial}(\lambda_i f_i)(x_i) \cap MB_{X^*} + \hat{N}(\Omega, w) \cap MB_{X^*} + \varepsilon B_{X^*},$$

where $M > 0$ is a constant independent of ε.

(ii) *For any $\varepsilon > 0$ there exist $w \in (\bar{x} + \varepsilon B_X) \cap \Omega$, $x_i \in \bar{x} + \varepsilon B_X$ with $|f_i(x_i) - f_i(\bar{x})| < \varepsilon$, $\varepsilon_i \in (-\varepsilon, \varepsilon) \setminus \{0\}$, $w^* \in \hat{N}(\Omega, w) + \varepsilon B_{X^*}$, and $x_i^* \in \hat{\partial}(\varepsilon_i f_i)(x_i)$ such that $\varepsilon_i > 0$ for $0 \le i \le n$,*

$$\|w^*\| + \sum_{i=0}^m \|x_i^*\| = 1 \text{ and } w^* + \sum_{i=0}^m x_i^* = 0.$$

Proof. Let ε be an arbitrary positive number. By the lower semicontinuity assumption, there exists $\delta \in (0, \frac{1}{2})$ such that

$$f_i(\bar{x}) - \varepsilon < f_i(x) \text{ for any } x \in \bar{x} + \delta B_X \text{ and } i = 0, 1, \ldots, n. \tag{3.19}$$

Let $Y_0 = Y_1 = \cdots = Y_m = R$. Let $C_i = R^+$, $F_i(x) = [f_i(x), +\infty)$ for $i = 0, 1, \ldots, n$ and $C_i = \{0\}$, $F_i(x) = \{f_i(x)\}$ for $i = n+1, \ldots, m$. Then, each F_i is closed, $(\bar{x}, \bar{y}_0)$ is a local Pareto solution of (1.3), and $\bar{y}_i := f_i(\bar{x}) \in F_i(\bar{x}) \cap -C_i$ for $i = 1, \ldots, m$. Hence, one of the assertions (i) and (ii) in Theorem 3.2 holds. It suffices to show that (i) in Theorem 3.2$\Longrightarrow$(i) and (ii) in Theorem 3.2$\Longrightarrow$(ii). As the arguments are similar, we shall prove only that the implication (i) in Theorem 3.2$\Longrightarrow$(i). Suppose that (i) in Theorem 3.2 holds. Let $\sigma \in (0, \min\{\frac{\varepsilon}{4}, \delta\})$, and take ($\alpha$) into account. Then there

exist $w \in (\bar{x}+\sigma B_X)\cap\Omega$, $(u_i, r_i) \in (\bar{x}+\sigma B_X)\times(f_i(\bar{x})-\sigma,\ f_i(\bar{x})+\sigma)$, and $s_i \in R$ such that

$$r_i \geq f_i(u_i) \ \text{ for } 0 \leq i \leq n, \quad r_i = f_i(u_i) \ \text{ for } n+1 \leq i \leq m,$$

$$s_i \geq 0 \ \text{ for } i = 0, 1, \ldots, n, \quad \sum_{i=0}^{m} |s_i| \geq 1-\sigma, \tag{3.20}$$

and

$$0 \in \sum_{i=0}^{m} \hat{D}^* F_i(u_i, r_i)(s_i) \cap KB_{X^*} + \hat{N}(\Omega, w) \cap KB_{X^*} + \sigma B_{X^*}, \tag{3.21}$$

where $K > 0$ is a constant. By (3.19), one has

$$f_i(\bar{x}) - \varepsilon < f(u_i) \leq r_i < f_i(\bar{x}) + \sigma < f_i(\bar{x}) + \varepsilon \ \text{ for } i = 0, 1, \ldots, n. \tag{3.22}$$

Take $u_i^* \in \hat{D}F_i(u_i, r_i)(s_i) \cap KB_{X^*}$ (by (3.21)) such that

$$-\sum_{i=0}^{m} u_i^* \in \hat{N}(\Omega, w) \cap KB_{X^*} + \sigma B_{X^*}. \tag{3.23}$$

Let $I_0 := \{0 \leq i \leq m : \ s_i = 0\}$. It follows from (α) and (α') that

$$u_i^* \subset \hat{\partial}(s_i f_i)(u_i) \cap KB_{X^*} \ \text{ for any } i \in \{0, 1, \ldots, m\} \setminus I_0. \tag{3.24}$$

For any $i \in \{0, 1, \ldots, n\} \cap I_0$, (3.22) and (β) imply that there exist $\tilde{u}_i \in u_i + \sigma B_X$ with $|f_i(\tilde{u}_i) - f_i(u_i)| < \varepsilon - |f_i(u_i) - f_i(\bar{x})|$, $t_i > 0$, and $x_i^* \in \hat{\partial}(t_i f_i)(\tilde{u}_i)$ such that $\|x_i^* - u_i^*\| < \frac{\sigma}{m}$. Hence, for any $i \in \{0, 1, \ldots, n\} \cap I_0$,

$$\|\tilde{u}_i - \bar{x}\| \leq \|\tilde{u}_i - u_i\| + \|u_i - \bar{x}\| \leq 2\sigma < \varepsilon, \quad |f_i(\tilde{u}_i) - f_i(\bar{x})| < \varepsilon \tag{3.25}$$

and

$$u_i^* \subset \hat{\partial}(t_i f_i)(\tilde{u}_i) \cap \left(K + \frac{1}{m}\right) B_{X^*} + \frac{\sigma}{m} B_{X^*}. \tag{3.26}$$

Moreover, for any $j \in \{n+1, \ldots, m\} \cap I_0$, (β') implies that there exist $\tilde{u}_j \in u_j + \sigma B_X$ with $|f_j(\tilde{u}_j) - f_j(u_j)| < \sigma$, $t_j \in R \setminus \{0\}$, and $x_j^* \in \hat{\partial}(t_j f_j)(\tilde{u}_j)$ such that $\|x_j^* - u_j^*\| < \frac{\sigma}{m}$. Hence, for any $j \in \{n+1, \ldots, m\} \cap I_0$,

$$\|\tilde{u}_j - \bar{x}\| < 2\sigma < \varepsilon, \quad |f_j(\tilde{u}_j) - f_j(\bar{x})| < 2\sigma < \varepsilon \tag{3.27}$$

and

$$u_j^* \subset \hat{\partial}(t_j f_j)(\tilde{u}_j) \cap \left(K + \frac{1}{m}\right) B_{X^*} + \frac{\sigma}{m} B_{X^*}. \tag{3.28}$$

Let $\eta := \sum_{i=0}^{m} |s_i| + \sum_{i \in I_0} |t_i|$, $\lambda_i := \frac{s_i}{\eta}$ if $i \in \{0, 1, \ldots, m\} \setminus I_0$, and $\lambda_i := \frac{t_i}{\eta}$ if $i \in I_0$, and let $x_i := u_i$ if $i \in \{0, 1, \ldots, m\} \setminus I_0$ and $x_i := \tilde{u}_i$ if $i \in I_0$. Then

$$\eta \geq 1 - \sigma > \frac{1}{2}, \ \lambda_i > 0 \ \text{ for } 0 \leq i \leq n, \ \sum_{i=0}^{m} |\lambda_i| = 1,$$

and dividing (3.23), (3.24), (3.26), and (3.28) by η, it follows that

$$0 \in \sum_{i=0}^{m} \hat{\partial}(\lambda_i f_i)(u_i) \cap \left(2K + \frac{2}{m}\right) B_{X^*} + \hat{N}(\Omega, w) \cap 2KB_{X^*} + \varepsilon B_{X^*}.$$

It follows from (3.25) and (3.27) that (i) holds with $M = 2K + \frac{2}{m}$. The proof is completed. ∎

4. Lagrange multiplier rules. In this section, we provide some exact Lagrange multiplier rules for the constrained multiobjective optimization problem (1.3). We will need the following notions. Recall (see [28]) that a closed convex cone C in X is dually compact if there exists a compact subset K of X such that

$$C^+ \subset \{x^* \in X^* : \ \|x^*\| \leq \max\{\langle x^*, x\rangle : \ x \in K\}\}. \tag{4.1}$$

This condition is trivially satisfied if X is finite dimensional (because one can then take $K = B_X$). Note that if C has a nonempty interior, then there exists $c_0 \in C$ such that

$$C^+ \subset \{x^* \in X^* : \ \|x^*\| \leq \langle x^*, c_0\rangle\}.$$

Thus,

$$\operatorname{int}(C) \neq \emptyset \Longrightarrow C \text{ is dually compact.}$$

It is known that if C is dually compact, then

$$c_n^* \in C^+ \ \text{ and } \ c_n^* \overset{w^*}{\to} 0 \Longrightarrow c_n^* \to 0. \tag{4.2}$$

The concept C being dually compact is closely related to the locally compact concept introduced in Loewen [12] (see [28, Proposition 3.1] for the details).

Following Mordukhovich [15] and Mordukhovich and Shao [17], we say that a multifunction Φ from X to another Banach space Y is partially sequentially normally compact at $(x, y) \in \operatorname{Gr}(\Phi)$ if for any (generalized) sequence $\{(x_n, y_n, x_n^*, y_n^*)\}$ satisfying

$$x_n^* \in \hat{D}^*\Phi(x_n, y_n)(y_n^*), \ \ (x_n, y_n) \to (x, y), \ \|y_n^*\| \to 0, \text{ and } x_n^* \overset{w^*}{\to} 0$$

one has $\|x_n^*\| \to 0$.

Clearly, Φ is automatically partially sequentially normally compact at each point of $\operatorname{Gr}(\Phi)$ if X is finite dimensional. Moreover, Proposition 2.3 implies that Φ is partially sequentially normally compact at $(x, y) \in \operatorname{Gr}(\Phi)$ if Φ is pseudo-Lipschitz at (x, y).

In the remainder of this paper, we make the following blanket assumptions.

Assumption 4.1. Each F_i is a closed multifunction.

Assumption 4.2. $(\bar{x}, \bar{y}_0) \in \operatorname{Gr}(F_0)$ is a local Pareto solution of the constrained multiobjective optimization problem (1.3) and $\bar{y}_i \in F_i(\bar{x}) \cap -C_i$ $(1 \leq i \leq m)$.

We first consider the case when X, Y_i are Asplund spaces (thus, in particular (2.1) is valid in these spaces).

THEOREM 4.1. *Let Assumptions* 4.1 *and* 4.2 *hold and X, Y_i be Asplund spaces. Suppose that each C_i is dually compact and that each F_i is partially sequentially normally compact at $(\bar{x}, \bar{y}_i)$. Then one of the following assertions holds.*

(i) *There exists $c_i^* \in C_i^+$ such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \ \text{ and } \ 0 \in \sum_{i=0}^{m} D^*F_i(\bar{x}, \bar{y}_i)(c_i^*) + N(\Omega, \bar{x}).$$

(ii) *There exist $x_i^* \in D^*F_i(\bar{x}, \bar{y}_i)(0)$ and $w^* \in N(\Omega, \bar{x})$ such that*

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \ \text{ and } \ w^* + \sum_{i=0}^{m} x_i^* = 0.$$

Proof. Since X, Y_i are Asplund spaces, Assumptions 4.1 and 4.2 imply that one of the assertions (i) and (ii) in Theorem 3.2 holds. Suppose that the assertion (i) in Theorem 3.2 holds. Then, for any natural number k there exist

$$(x_i(k), y_i(k)) \in \mathrm{Gr}(F_i) \cap \left(\left(\bar{x} + \frac{1}{k} B_X \right) \times \left(\bar{y}_i + \frac{1}{k} B_{Y_i} \right) \right), \tag{4.3}$$

$$w(k) \in \left(\bar{x} + \frac{1}{k} B_X \right) \cap \Omega \ \text{ and } \ c_i^*(k) \in C_i^+ \tag{4.4}$$

such that

$$\sum_{i=0}^{m} \|c_i^*(k)\| = 1 \tag{4.5}$$

and

$$\begin{aligned} 0 \in \sum_{i=0}^{m} \hat{D}^* F_i(x_i(k), y_i(k)) \left(c_i^*(k) + \frac{1}{k} B_{Y_i^*} \right) \cap M B_{X^*} \\ + \hat{N}(\Omega, w(k)) \cap M B_{X^*} + \frac{1}{k} B_{X^*}, \end{aligned} \tag{4.6}$$

where $M > 0$ is a constant independent of k. Hence there exist bounded sequences $\{x_i^*(k)\}$ and $\{x^*(k)\}$ such that

$$x_i^*(k) \in \hat{D}^* F_i(x_i(k), y_i(k)) \left(c_i^*(k) + \frac{1}{k} B_{Y_i^*} \right),$$

$$x^*(k) \in \hat{N}(\Omega, w(k)) \ \text{ and } \ x^*(k) + \sum_{i=0}^{m} x_i^*(k) \to 0.$$

Since a bounded set in a dual space is relatively weak* compact, without loss of generality we can assume that

$$x_i^*(k) \overset{w^*}{\to} x_i^* \ \text{ and } \ c_i^*(k) \overset{w^*}{\to} c_i^* \ (i = 0, 1, \ldots, m).$$

It follows from (2.1), (4.3), and (4.4) that

$$0 \in \sum_{i=0}^{m} D^* F_i(\bar{x}, \bar{y}_i)(c_i^*) + N(\Omega, \bar{x}).$$

Noting that $\sum_{i=0}^{m} \|c_i^*\| \neq 0$ by (4.2) and (4.5), this implies that (i) is true.

Next suppose that assertion (ii) in Theorem 3.2 holds. Then for any natural number k there exist

(4.7)

$$(x_i(k), y_i(k)) \in \mathrm{Gr}(F_i) \cap \left(\left(\bar{x} + \frac{1}{k} B_X \right) \times \left(\bar{y}_i + \frac{1}{k} B_{Y_i} \right) \right), \ w(k) \in \left(\bar{x} + \frac{1}{k} B_X \right) \cap \Omega,$$

$$x_i^*(k) \in \hat{D}^* F_i(x_i(k), y_i(k)) \left(\frac{1}{k} B_{Y_i^*} \right) \ \text{ and } \ x^*(k) \in \hat{N}(\Omega, w(k)) \tag{4.8}$$

such that

$$\|x^*(k)\| + \sum_{i=0}^{m} \|x_i^*(k)\| \to 1 \ \text{ and } \ x^*(k) + \sum_{i=0}^{m} x_i^*(k) \to 0. \tag{4.9}$$

Without loss of generality we assume that

$$x^*(k) \overset{w^*}{\to} x^* \text{ and } x_i^*(k) \overset{w^*}{\to} x_i^* \ (i = 0, 1, \ldots, m),$$

and hence it follows from (2.1) that

$$x_i^* \in D^*F_i(\bar{x}, \bar{y}_i)(0),\ x^* \in N(\Omega, \bar{x}),\ \text{ and } \ x^* + \sum_{i=0}^{m} x_i^* = 0.$$

Further $\|x^*\| + \sum_{i=0}^{m} \|x_i^*\| \neq 0$ by (4.9) and thanks to the assumption that each F_i is partially sequentially normally compact at $(\bar{x}, \bar{y}_i)$. Thus (ii) holds, and the proof is completed. □

As already noted, every closed multifunction between two finite dimensional spaces is partially sequentially normally compact at each point in its graph, and every closed convex cone in a finite dimensional space is dually compact. Thus, the following corollary is a consequence of Theorem 4.1.

COROLLARY 4.1. *Let Assumptions* 4.1 *and* 4.2 *hold, and suppose that* X, Y_i *are finite dimensional. Then one of* (i) *and* (ii) *in Theorem* 4.1 *holds.*

In the case when each F_i is pseudo-Lipschitz, we have the following sharp Lagrange multiplier rule.

THEOREM 4.2. *Let Assumptions* 4.1 *and* 4.2 *hold and* X, Y_i *be Asplund spaces. Suppose that each* C_i *is dually compact and that each* F_i *is pseudo-Lipschitz at* $(\bar{x}, \bar{y}_i)$. *Then there exists* $c_i^* \in C_i^+$ *such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} D^*F_i(\bar{x}, \bar{y}_i)(c_i^*) + N(\Omega, \bar{x}). \tag{4.10}$$

Proof. By Corollary 3.2, for any natural number k there exist $x_i(k) \in \bar{x} + \frac{1}{k}B_X$, $w(k) \in \Omega \cap (\bar{x} + \frac{1}{k}B_X)$, $y_i(k) \in F_i(x_i) \cap (\bar{y}_i + \frac{1}{k}B_{Y_i})$, and $c_i^*(k) \in C_i^+$ such that

$$\sum_{i=0}^{m} \|c_i^*(k)\| = 1 \tag{4.11}$$

and

$$0 \in \sum_{i=0}^{m} \hat{D}^*F_i(x_i(k), y_i(k)) \left(c_i^*(k) + \frac{1}{k}B_{Y_i^*}\right) \cap MB_{X^*} + \hat{N}(\Omega, w(k)) \cap MB_{X^*} + \frac{1}{k}B_{X^*},$$

where $M > 0$ is a constant independent of k. Hence there exist

$$x_i^*(k) \in \hat{D}^*F_i(x_i(k), y_i(k)) \left(c_i^*(k) + \frac{1}{k}B_{Y_i^*}\right) \text{ and } x^*(k) \in \hat{N}(\Omega, w(k))$$

such that

$$\max\{\|x^*(k)\|,\ \max\{\|x_i^*(k)\| :\ 0 \le i \le m\}\} \le M \text{ and } x^*(k) + \sum_{i=0}^{m} x_i^*(k) \to 0.$$

Without loss of generality, we can assume that

$$x^*(k) \overset{w^*}{\to} x^*,\ x_i^*(k) \overset{w^*}{\to} x_i^*, \text{ and } c_i^*(k) \overset{w^*}{\to} \tilde{c}_i^* \quad \text{for } i = 0, 1, \ldots, m. \tag{4.12}$$

Hence,

$$x^* \in N(\Omega, \bar{x}),\ x_i^* \in D^*F_i(\bar{x}, \bar{y}_i)(\tilde{c}_i^*)\ (i = 0, 1, \ldots, m), \text{ and } x^* + \sum_{i=0}^{m} x_i^* = 0,$$

and so

$$0 \in \sum_{i=0}^{m} D^* F_i(\bar{x}, \bar{y}_i)(\tilde{c}_i^*) + N(\Omega, \bar{x}). \tag{4.13}$$

Since each C_i is dually compact, (4.11), (4.12), and (4.2) imply that $\sum_{i=0}^{m} \|\tilde{c}_i^*\| \neq 0$. It follows from (4.13) that (4.10) holds with $c_i^* = \frac{\tilde{c}_i^*}{\sum_{j=0}^{m} \|\tilde{c}_j^*\|}$. The proof is completed. □

Let $\bar{x}$ be a local solution of single-objective optimization problem (1.1), and suppose that each f_i is locally Lipschitz at $\bar{x}$. Let F_i and C_i be as in the proof of Theorem 3.3. Then $\bar{x}$ is a local Pareto solution of (1.3), and each F_i is pseudo-Lipschitz at $(\bar{x}, f_i(\bar{x}))$. It is routine to verify that

$$D^* F_i(\bar{x}, f_i(\bar{x}))(s) = \partial(sf_i)(\bar{x}) \text{ for } 0 \leq i \leq n, \quad s \geq 0,$$

and

$$D^* F_i(\bar{x}, f_i(\bar{x}))(t) = \partial(tf_i)(\bar{x}) \text{ for } n+1 \leq i \leq m, \quad t \in R.$$

Thus, (4.10) reduces to (1.2).

In the remainder of this section, we consider the case when X, Y_i are general Banach spaces. In this case we need the notion of the normal closedness.

We say that Ω is normally closed at $x \in \Omega$ if for (generalized) sequences

$$x_n \to x,\ x_n^* \in N_c(\Omega, x_n),\ x_n^* \xrightarrow{w^*} x^* \text{ implies } x^* \in N_c(\Omega, x)$$

(see [4, Corollary, p. 58]).

It is known that Ω is normally closed at each point of Ω if Ω is convex. Moreover, if Ω is epi-Lipschitz around $x \in \Omega$, then Ω is normally closed at x. We say that a closed multifunction $\Phi : X \to 2^Y$ is normally closed at $(x, y) \in \mathrm{Gr}(\Phi)$ if $\mathrm{Gr}(\Phi)$ is normally closed at (x, y) (see [28]).

Mimicking a corresponding notion introduced in [17], we say that $\Phi : X \to 2^Y$ is partially sequentially normally compact at $(x, y) \in \mathrm{Gr}(\Phi)$ in the Clarke sense if for any (generalized) sequence $\{(x_n, y_n, x_n^*, y_n^*)\}$ satisfying

$$x_n^* \in D_c^* \Phi(x_n, y_n)(y_n^*),\ \ (x_n, y_n) \to (x, y),\ \|y_n^*\| \to 0, \text{ and } x_n^* \xrightarrow{w^*} 0$$

one has $\|x_n^*\| \to 0$.

The following result can be proved in the same way as for Theorem 4.1 (but apply Theorem 3.2 in place of Theorem 3.1).

THEOREM 4.3. *Let Assumptions* 4.1 *and* 4.2 *hold, and suppose that each C_i is dually compact. Suppose that each F_i is partially sequentially normally compact at $(\bar{x}, \bar{y}_i)$ in the Clarke sense and that Ω and F_i are normally closed at $\bar{x}$ and $(\bar{x}, \bar{y}_i)$, respectively. Then one of the following assertions holds.*

(i) *There exist $c_i^* \in C_i^+$ such that*

$$\sum_{i=0}^{m} \|c_i^*\| = 1 \text{ and } 0 \in \sum_{i=0}^{m} D_c^* F_i(\bar{x}, \bar{y}_i)(c_i^*) + N_c(\Omega, \bar{x}).$$

(ii) *There exist $x_i^* \in D_c^* F_i(\bar{x}, \bar{y}_i)(0)$ and $w^* \in N_c(\Omega, \bar{x})$ such that*

$$\|w^*\| + \sum_{i=0}^{m} \|x_i^*\| = 1 \text{ and } w^* + \sum_{i=0}^{m} x_i^* = 0.$$

As in many classical situations, one can also provide a sufficient condition for $(\bar{x}, \bar{y}_0)$ to be a Pareto solution of (1.3), provided that a suitable convexity assumption is made.

PROPOSITION 4.1. *Let each F_i be a closed convex multifunction and Ω be a closed convex subset of X. Let $\bar{y}_0 \in F_0(\bar{x})$ and $\bar{y}_i \in F_i(\bar{x}) \cap -C_i$ for $i = 1, \ldots, m$. Assume that there exists $c_i^* \in C_i^+$ such that*

$$\langle c_0^*, c\rangle > 0 \quad \forall c \in C_0 \setminus \{0\}, \quad \sum_{i=1}^{m} \langle c_i^*, \bar{y}_i\rangle = 0 \tag{4.14}$$

and

$$0 \in \sum_{i=0}^{m} D^* F_i(\bar{x}, \bar{y}_i)(c_i^*) + N(\Omega, \bar{x}). \tag{4.15}$$

Then $(\bar{x}, \bar{y}_0)$ is a Pareto solution of the constrained multiobjective optimization problem (1.3).

Proof. By (4.15) there exists $x_i^* \in X^*$ such that

$$x_i^* \in D^* F_i(\bar{x}, \bar{y}_i)(c_i^*) \quad \text{and} \quad -\sum_{i=0}^{m} x_i^* \in N(\Omega, \bar{x}).$$

It follows from the convexity of F_i and Ω that

$$\langle x_i^*, x\rangle - \langle c_i^*, y_i\rangle \le \langle x_i^*, \bar{x}\rangle - \langle c_i^*, \bar{y}_i\rangle \quad \forall (x, y_i) \in \mathrm{Gr}(F_i) \ \text{ and } \ i = 0, 1, \ldots, m \tag{4.16}$$

and

$$\left\langle -\sum_{i=0}^{m} x_i^*, x \right\rangle \le \left\langle -\sum_{i=0}^{m} x_i^*, \bar{x} \right\rangle \quad \forall x \in \Omega. \tag{4.17}$$

Summing up (4.16) over all i and making use of (4.17) and (4.14) we have

$$\langle c_0^*, \bar{y}_0\rangle \le \sum_{i=0}^{m} \langle c_i^*, y_i\rangle \ \text{ for any } x \in \Omega, \ y_i \in F_i(x), \text{ and } i = 0, 1, \ldots, m.$$

Since $c_i^* \in C_i^+$, it follows that

$$\langle c_0^*, \bar{y}_0\rangle \le \langle c_0^*, y_0\rangle \quad \forall y_0 \in F_0\left(\Omega \cap \bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right).$$

This and the inequality in (4.14) imply that $\bar{y}_0 \in E\left(F_0\left(\Omega \cap \bigcap_{i=1}^{m} F_i^{-1}(-C_i)\right), C_0\right)$. The proof is completed. ∎

NEW REDUCTION TECHNIQUES FOR THE GROUP STEINER TREE PROBLEM*

CARLOS EDUARDO FERREIRA† AND FERNANDO M. DE OLIVEIRA FILHO†

Abstract. The group Steiner tree problem consists of, given a graph G, a collection $\mathcal{R}$ of subsets of $V(G)$, and a positive cost c_e for each edge e of G, finding a minimum-cost tree in G that contains at least one vertex from each $R \in \mathcal{R}$. We call the sets in $\mathcal{R}$ *groups*. The well-known Steiner tree problem is the special case of the group Steiner tree problem in which each set in $\mathcal{R}$ is unitary. In this paper, we present a general reduction test designed to remove group vertices, that is, vertices belonging to some group. Through the use of these tests we can conclude that a given group vertex can be considered a nonterminal and hence can be removed from its group. We also present some computational results on instances from SteinLib [T. Koch, A. Martin, and S. Voss, *SteinLib*: *An updated library on Steiner tree problems in graphs*, in Steiner Trees in Industry, Kluwer Academic Publishers, Dordrecht, The Netherlands, 2001, pp. 285–325].

1. Introduction.

1.1. The problem and known results.

The Steiner tree problem consists of, given a graph G with costs on its edges and a set of vertices called *terminals*, finding a minimum-cost tree in G that connects all the terminals.

The group Steiner tree problem is a generalization of the Steiner tree problem and was proposed by Reich and Widmayer [12] with applications to VLSI design in mind. It is as follows:

PROBLEM GST $(G, \mathcal{R}, c)$. *Given a graph G, a collection $\mathcal{R}$ of subsets of $V(G)$, and a positive cost c_e for each $e \in E(G)$, find a minimum-cost tree T in G containing at least one vertex of each $R \in \mathcal{R}$.*

The elements of $\mathcal{R}$ are called *groups*. Any vertex belonging to a group is said to be a *group vertex*. All other vertices are *nonterminals* or *Steiner vertices*. We denote by $\hat{\mathcal{R}}$ the set of all group vertices. A tree in G that contains at least one vertex from each group is called a *group Steiner tree*.

We assume that the costs are all positive and that the groups are pairwise disjoint. Such assumptions are reasonable in practice and make our exposition much simpler. So, for a group vertex u, we denote by $\mathrm{gr}(u)$ the group which contains u. Also, we assume that there are at least two groups and that at least one component of G contains at least one vertex from each group (in other words, we assume that the problem is feasible).

Notice that the Steiner tree problem is the special case of the group Steiner tree problem in which every group has only one vertex. Therefore, since the Steiner tree

problem is NP-hard, the group Steiner tree problem is also NP-hard. There are also stronger complexity results related to the group Steiner tree problem. Ihler [8] considered the complexity of several special cases of the problem. From a reduction of set-cover to the GST [6, 8] and from strong results known for set-cover [5], it is known that the group Steiner tree problem, even when G is restricted to a tree, cannot be approximated in polynomial time by a factor better than $(1 + o(1)) \ln |\mathcal{R}|$, where $\mathcal{R}$ is the collection of groups, unless NP $\subseteq$ DTIME$(n^{O(\log \log n)})$. Stronger results on the hardness of approximating the group Steiner tree problem have been obtained by Halperin and Krauthgamer [7], though under a different hypothesis.

Rohe and Zachariasen [13] considered the rectilinear case of the group Steiner tree problem. They developed an exact algorithm for this special case of the problem and presented reduction techniques, some of them based on existing reductions for the Steiner tree problem. Duin, Volgenant, and Voss [4] use a simple reduction to transform an instance of the group Steiner tree problem into an instance of the Steiner tree problem and solve the latter problem. Details on how the group Steiner tree problem arises in VLSI design can be found in the papers of Reich and Widmayer [12] and Rohe and Zachariasen [13].

1.2. Our results. The group Steiner tree problem can be reduced to the Steiner tree problem as follows: given an instance $(G, \mathcal{R}, c)$ of the GST, create a new vertex v_R in G for each $R \in \mathcal{R}$, connecting v_R to all the vertices in R by edges with a conveniently large cost.

Examples can be constructed in which the addition of the artificial edges has a negative impact on the lower bounds provided by formulations for the problem. The performance of primal heuristics may also be poorer on the extended graph.

For that reason, we present in this paper some reduction techniques designed specifically for the group Steiner tree problem. We concentrate on techniques for removing group vertices, that is, methods that can allow us to conclude that a given group vertex can be considered a nonterminal. The quality of many formulations for the group Steiner tree problem depends on the size of the groups in question (cf. [1]), and we have observed in practice that with smaller groups one can really obtain better bounds.

The rest of the paper is structured as follows: in section 2 we present the concept of bottleneck Steiner distances for the GST, which was generalized from the concept of bottleneck distances for the Steiner tree problem by Rohe and Zachariasen [13]. We also present in this section a simple test using the bottleneck distances. In section 3 we present a more powerful test based on expansion techniques. Finally, in section 4 we present some computational results obtained.

2. Bottleneck distances and a simple test.

2.1. Group bottleneck Steiner distances. In this section we present a generalization of the concept of bottleneck distances. The concept of bottleneck Steiner distances was introduced by Duin and Volgenant [3] and still forms the base of the most successful reduction tests for the Steiner tree problem. This concept was then generalized by Rohe and Zachariasen [13] to deal with the GST.

If H is any graph with costs on its edges given by a function l and $u, v \in V(H)$, the *bottleneck* between u and v is given by

$$b(u, v) := \min_{P} \max_{e \in E(P)} l_e,$$

where the minimum is taken over all (u, v)-paths P in H.

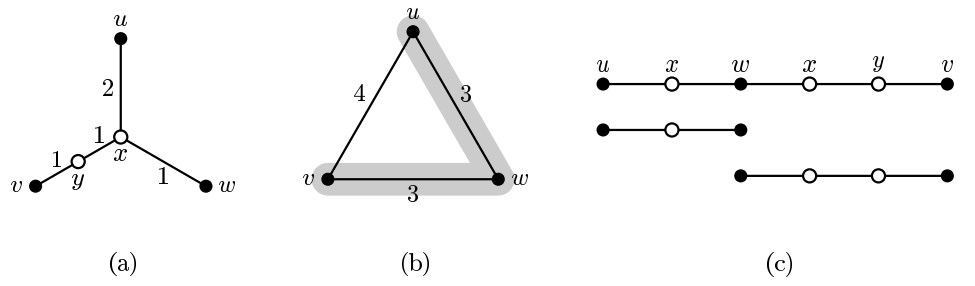

FIG. 1. (a) *A graph G with costs on its edges. The black vertices form the set X.* (b) *The graph $K_G[X]$. On each edge we have the distance, according to the costs in* (a)*, between each pair of vertices of X. In gray we have the path in $K_G[X]$ that gives the bottleneck Steiner distance for X between u and v.* (c) *A bottleneck Steiner walk for X between u and v. Below the walk we have its elementary paths.*

Consider now an instance $(G, \mathcal{R}, c)$ of the GST. We say that a set $X \subseteq V(G)$ is *valid* for $\mathcal{R}$ if X contains exactly one vertex of each group in $\mathcal{R}$. For any collection $\mathcal{R}$ of groups, we denote by $\nu(\mathcal{R})$ the collection of all sets that are valid for $\mathcal{R}$. If we know a valid set $X \in \nu(\mathcal{R})$ contained in some optimal solution of the problem GST $(G, \mathcal{R}, c)$, solving the latter problem is the same as solving the Steiner tree problem in the same graph, with the same costs, with X as the terminal set.

Now, denote by K_G the complete graph with vertex set $V(G)$. Let $d_G(u, v)$ denote the cost of a minimum-cost (u, v)-path in G, with edge costs given by c. We can view $d_G(u, v)$ as being the cost of the edge uv of K_G. In this context, given a valid set X, the *bottleneck Steiner distance* for X between vertices $u, v \in V(G)$ is the bottleneck between u and v in $K_G[X \cup \{u, v\}]$, with edge costs in K_G given by d_G, and is denoted by $s_X(u, v)$. Here, we denote by $K_G[A]$, where $A \subseteq V(G)$, the subgraph of K_G induced by the vertices in A, that is, the graph having A as its vertex set and containing every edge of K_G that has both its endpoints in A.

From each (u, v)-path P in $K_G[X \cup \{u, v\}]$ we can obtain a (u, v)-walk W in G by concatenating minimum-cost paths in G corresponding to the edges of P. Such a walk is divided into paths between u, consecutive vertices of X, and v; such paths are called *elementary*. A (u, v)-walk W obtained from a (u, v)-path P in $K_G[X \cup \{u, v\}]$ such that $s_X(u, v) = \max\{d_G(x, y) \colon xy \in E(P)\}$ is called a *bottleneck Steiner walk* for X. Note that, if W is a bottleneck Steiner walk for X, the cost of the greatest elementary path of W is exactly $s_X(u, v)$. Figure 1 illustrates these definitions.

We are now ready to define the concept of group bottleneck Steiner distance. Given an instance $(G, \mathcal{R}, c)$ of the GST, the *group bottleneck Steiner distance* between vertices $u, v \in V(G)$ is given by

$$s(u, v) := \max_{X \in \nu(\mathcal{R})} s_X(u, v).$$

Given a valid set X and vertices $u, v \in V(G)$, we can compute $s_X(u, v)$ in polynomial time (cf. Duin [2]). Rohe and Zachariasen [13] proved that the problem of computing $s(u, v)$ is NP-hard. In the same work, the authors presented two heuristics for computing upper bounds for $s(u, v)$.

2.2. A simple test. We now illustrate the use of the group bottleneck Steiner distances introduced in the previous section. We first note that many of the reduction methods devised for the Steiner tree problem that use bottleneck Steiner distances

can be easily adapted to be used with the GST. Therefore, we do not concentrate on tests that remove nonterminals or edges, but instead we concentrate on tests that remove group vertices.

Given an instance $(G, \mathcal{R}, c)$ of the GST and a group vertex r, we wish to remove r from its group. Then we may use other reduction methods to try to remove r from the graph. To show that r may be regarded as a nonterminal, we need only show an optimal solution of the problem that contains a vertex from the same group of r different from r. If all the neighbors of r belong to the same group of it, then that is easy: since we assume that there are at least two groups, every optimal solution that uses r also uses some of its neighbors, that is, uses some vertex of $\mathrm{gr}(r) \setminus \{r\}$.

The test we will present in this section generalizes the previous observation. To present it, though, we need some notation. Consider a graph G and a set A of vertices of G. We denote by $N_G(A)$ the set of neighbors of A in G, i.e.,

$$N_G(A) := \{v \in V(G) \setminus A \colon v \text{ is adjacent to some vertex of } A\}.$$

If there is no risk of ambiguity, we drop the graph from the symbol, denoting the set of neighbors simply by $N(A)$. If u is a vertex, we may also write $N(u)$ instead of $N(\{u\})$. Given two disjoint sets of vertices A and B of a graph G, we denote by $\delta_G(A, B)$ the set of edges of G with one endpoint in A and the other in B. Analogously, if there is no risk of ambiguity, we drop the graph from the symbol. Moreover, if u is a vertex we may, for instance, write $\delta(u, B)$ instead of $\delta(\{u\}, B)$.

Consider now an instance $(G, \mathcal{R}, c)$ of the GST. Again, denote by K_G the complete graph with vertex set $V(G)$. Given a set A of vertices of G, we shall denote by $\tau(A)$ the cost of a minimum spanning tree in $K_G[A]$, where the cost of the edge uv of $K_G[A]$ equals $s(u, v)$. Given a group vertex r and a set A of vertices such that $r \notin A$, let

$$\pi(r, A) := \min\{d_G(u, v) \colon u \in A,\ v \in \mathrm{gr}(r) \setminus \{r\}\};$$

that is, $\pi(r, A)$ is the distance from A to the closest vertex of the same group of r distinct from r itself. As is usual, if $A \subseteq E(G)$, we write $c(A) := \sum_{e \in A} c_e$. Finally, we have the following result.

THEOREM 1. *Consider an instance $(G, \mathcal{R}, c)$ of the* GST. *Let $R \in \mathcal{R}$ and $r \in R$. If, for every $U \subseteq N(r) \setminus R$, $|U| \geq 1$, we have $\tau(U) + \pi(r, U) \leq c(\delta(r, U))$, then r may be regarded as a nonterminal.*

To prove Theorem 1, we will need the following lemma, which will also be useful later.

LEMMA 2. *Consider an instance $(G, \mathcal{R}, c)$ of the* GST. *Let F be a forest in G and suppose F contains a valid set X. Let $U \subseteq V(F)$ be a set containing at least one vertex from each component of F. There is a group Steiner tree T in G that contains F, and its cost is at most $c(E(F)) + \tau(U)$.*

Proof. Consider a minimum spanning tree in $K_G[U]$ with cost $\tau(U)$. Let yz be the smallest edge of this tree and consider a (y, z)-bottleneck Steiner walk W for X. Traverse W from y to z. During the traversal, subpaths of W connecting vertices in different components of F may be found. Since F contains a valid set, such subpaths are subpaths of elementary paths of W and have cost at most $s_X(y, z) \leq s(y, z)$. When such a subpath is found, add it to F and continue with the traversal. After doing this, if F is not yet connected, repeat the same procedure, choosing the second smallest edge from the minimum spanning tree, and so on.

After we add at most $|U| - 1$ paths to F it becomes connected and hence contains a spanning tree T containing the original forest F. The total cost of the paths added to

connect F is at most $\tau(U)$, and we have that the cost of T is at most $c(E(F)) + \tau(U)$. Since F contains a valid set, T also contains a valid set and is thus a group Steiner tree. □

With this, we can easily prove Theorem 1.

Proof of Theorem 1. To show that r may be regarded as a nonterminal we show an optimal solution of GST $(G, \mathcal{R}, c)$ that contains some vertex of R other than r.

To this end, let T^* be an optimal solution of GST$(G, \mathcal{R}, c)$ and suppose that r is the only vertex of R that occurs in T^*; otherwise we have nothing to do. Let $U := N_{T^*}(r)$ and $T' := T^* - r$. Let $u \in U$ and $r' \in R \setminus \{r\}$ be such that $d_G(u, r') = \pi(r, U)$. Connect r' to T' using a subpath of a minimum-cost (u, r')-path such that the resulting graph, say F, is a forest.

Note that F has at most $|U|$ components and that each such component contains at least one vertex of U. Notice, moreover, that F contains a valid set. From Lemma 2 we know that there is a group Steiner tree $\hat{T}$ that contains F and whose cost is at most

$$c(E(F)) + \tau(U) \leq c(E(T^*)) + \pi(r, U) - c(\delta(r, U)) + \tau(U) \leq c(E(T^*)),$$

and hence $\hat{T}$ is also an optimal solution. But it contains a vertex in $R \setminus \{r\}$, namely r', and we are done. □

Notice that the test above is indeed a generalization of the observation we made before. Moreover, it is similar to a test introduced by Duin and Volgenant [3] to remove nonterminals in the Steiner tree problem.

3. An expansion approach.

3.1. An outline of the expansion test. In recent years, many reduction tests have been designed for the Steiner tree problem using the idea of expansion [14, 11]. While the classical tests inspect only simple graph structures, like edges or vertices, those tests inspect more general structures, like paths or trees.

Polzin and Daneshmand [11] give a general framework for expansion tests for the Steiner tree problem (also described in the thesis [10]). Their test can be used to eliminate edges and nonterminals, and if we use the group bottleneck Steiner distances defined in section 2, we can use the same tests with the GST after some minor adjustments. In this section we investigate how to use the same idea of expansion presented in [11] in order to remove group vertices. The resulting test is much more powerful than that presented in section 2.

To present our test, we first need to introduce some notation from [11]. Given a tree T, we denote by $L(T)$ the set of leaves of T. Let T' be a subtree of T. The *linking set* between T and T' is the set of vertices v of T' with at least one path from itself to a leaf of T not containing any edge of T'. In other words, the linking set is the set of vertices that connects T' and T. If the linking set between T and T' is $L(T')$, then T' is said to be *peripherally contained* in T. Figure 2 illustrates these definitions.

Let $(G, \mathcal{R}, c)$ be an instance of the GST and consider a group vertex $r \in R$ for some $R \in \mathcal{R}$. Let T be a tree in G. We shall say that the tree T *respects* r if T contains r and every other group vertex that occurs in T is a leaf. Given a leaf u of T, let

$$\mathcal{X}(u, T) := \{uv \in E(G) \colon v \notin V(T)\}.$$

We call any nonempty subset of $\mathcal{X}(u, T)$ an *expansion of* T *through* u.

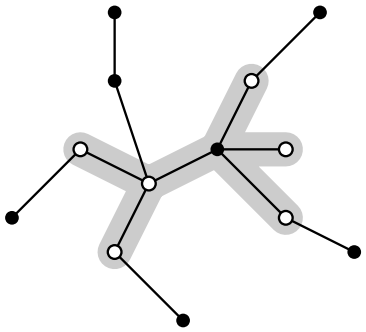

FIG. 2. *The subtree in gray is not peripherally contained in the larger tree. The linking set, which is composed in this case by the white vertices, is not entirely composed of leaves of the gray subtree.*

Our test is comprised of two recursive functions. The first function, EXPANSION-TEST-LEAF, receives a group vertex r and a tree T that respects r and of which r is a leaf. It returns YES if the following assertion is true:

(3.1)
If T is peripherally contained in some optimal solution in which r is a leaf, then there is an optimal solution containing a vertex of $\mathrm{gr}(r)$ *other than r.*

The other function is called EXPANSION-TEST-INT. It receives a group vertex r and a tree T that respects r and returns YES if the following assertion is true:

(3.2)
If T is peripherally contained in some optimal solution in which r is not a leaf, then there is an optimal solution containing a vertex of $\mathrm{gr}(r)$ *other than r.*

The functions described above are very similar; thus we will present only an outline of their code and comment on the differences later. The function TEST-TREE called in line 1 of the code below contains the specific test conditions: the call TEST-TREE (r, T) returns YES if (3.1) (in case of EXPANSION-TEST-LEAF), or (3.2) (in case of EXPANSION-TEST-INT), is satisfied by T. The implementation of such a function will be discussed later.

Function EXPANSION-TEST-OUTLINE (r, T)
1 if TEST-TREE $(r, T) =$ YES
2 then return YES
3 for each leaf u of T that is r or a nonterminal do
4 $S \leftarrow$ YES
5 for each nonempty $U \subseteq \mathcal{X}(u, T)$ do
6 if EXPANSION-TEST-OUTLINE $(r, T + U) =$ NO
7 then $S \leftarrow$ NO
8 if $S =$ YES
9 then return YES
10 return NO

We will delay the proof of correctness of our test until section 3.3. For now, it is

convenient to observe that, throughout execution, the property that T respects r is preserved.

Both functions have almost the same code. The only difference is that, in function Expansion-Test-Leaf, we can only choose to expand through r if it has degree zero in T (i.e., if T is only one vertex, r), as r must be a leaf in $T + U$. Moreover, the expansions considered in this case must all be unitary. In function Expansion-Test-Int, no such care is needed. Another important observation is that in line 5 we may consider only expansions that do not introduce any other vertices of the same group as r, as the test is trivially true for $T + U$ if U contains an edge incident to a vertex in $\mathrm{gr}(r) \setminus \{r\}$.

It is now easy to combine both functions described in a test that determines if a group vertex can be regarded as a nonterminal. Given a group vertex r, we call both functions with r being the initial tree. If both functions return yes, then we know that if r is contained in an optimal solution, there is an optimal solution containing another vertex of $\mathrm{gr}(r)$ distinct from r itself; therefore r can be considered a nonterminal.

As for the running time of our test, it is heavily dependent on the degree of the vertices through which we expand, as well as the maximum depth of the recursion. In practice, we limit the depth of the recursion, truncating the test if necessary, and we also choose not to expand through vertices of higher degree. A more detailed discussion of such issues will be made in section 4.

3.2. Test conditions. In this section we discuss some possible implementations of the function Test-Tree used in the expansion procedure.

From now on, suppose we are given an instance $(G, \mathcal{R}, c)$ of the GST, a group vertex $r \in R$ for some group R, and a tree T that respects r. One of those implementations is based on the following result.

Proposition 3. *If $\tau(L(T)) + \pi(r, L(T) \setminus \{r\}) \leq c(E(T))$, then if T is peripherally contained in some optimal solution, there is an optimal solution containing some vertex of $R \setminus \{r\}$.*

Proof. Suppose T is peripherally contained in some optimal solution T^*. Let I be the set of internal vertices of T and $T' := (T^* - E(T)) - I$. Let $u \in L(T) \setminus \{r\}$ and $r' \in R \setminus \{r\}$ be such that $d_G(u, r') = \pi(r, L(T) \setminus \{r\})$. Connect r' to T' by means of a subpath of a minimum-cost (u, r')-path so that the resulting graph, which we will denote by F, is a forest.

Note that F has at most $|L(T)|$ components and that each such component contains some vertex of $L(T)$ (this is true, since T is peripherally contained in T^*). Moreover, F contains a valid set, since it respects r. Using Lemma 2, it follows that there is a group Steiner tree $\hat{T}$ that contains F and has cost at most

$$c(E(F)) + \tau(L(T)) \leq c(E(T^*)) + \tau(L(T)) + \pi(r, L(T) \setminus \{r\}) - c(E(T)) \leq c(E(T^*)),$$

being, then, an optimal solution to our problem. Since it contains a vertex of $R \setminus \{r\}$, we are done. ∎

If, additionally, r is a leaf in the tree in which T is peripherally contained, we can weaken the hypothesis. In this case, we need not consider r a leaf of T; that is, we may use $\tau(L(T) \setminus \{r\})$ instead of $\tau(L(T))$. This version of the test can be used together with the function Expansion-Test-Leaf.

Another way of proving that assertion (3.1) or (3.2) is true is to show that T is not peripherally contained in any optimal solution. Obviously, this assertion can be modified in accordance with the function being considered. For instance, if we are considering the function Expansion-Test-Leaf, we can show that T is not

peripherally contained in any optimal solution in which r is a leaf. In the case r is a leaf of T, we can use the tests presented in [11] with some minor modifications, including the bound-based tests. For instance, we have the following result.

PROPOSITION 4. *If r is a leaf of T and $\tau(L(T)) < c(E(T))$, then T is not peripherally contained in any optimal solution.*

Proof. Suppose that T is peripherally contained in an optimal solution T^*. Let I be the set of internal vertices of T and $F := (T^* - E(T)) - I$.

Now, since T is peripherally contained in T^*, F is composed of exactly $|L(T)|$ components, each one containing exactly one vertex from $L(T)$. Moreover, since r is a leaf of T and since T respects r, F contains a valid set. It then follows from Lemma 2 that there exists a group Steiner tree $\hat{T}$ containing F, the cost of which is at most

$$c(E(T^*)) + \tau(L(T)) - c(E(T)) < c(E(T^*)),$$

a contradiction. □

Many tests presented in [11] allow one to conclude that there is an optimal solution that does not contain T peripherally. It is important to notice again that Proposition 4 is stronger, allowing one to conclude that T is not peripherally contained in *any* optimal solution. However, several of the tests presented in this same paper can be altered as to allow us to reach the desired conclusion, as is the case of the result just presented.

In the case where r is not a leaf of T we can use a modified version of Proposition 4.

PROPOSITION 5. *Suppose r is not a leaf of T and let p be the cost of a shortest path in G connecting some leaf of T with r. If $\tau(L(T)) + p < c(E(T))$, then T is not peripherally contained in any optimal solution.*

Proof. It is analogous to the proof of Proposition 4. □

It is interesting to observe that we could, instead of using a path of cost p to connect r with a leaf of T, require $\tau(L(T) \cup \{r\}) < c(E(T))$, in which case Lemma 2 could be applied to reconnect the leaves of T and r after we remove T from some optimal solution.

It is also worth pointing out how important it is to assume that T is peripherally contained (instead of only contained) in some optimal solution. This allow us to remove the edges of T and its internal vertices and even then have some information about the structure of the remaining graph. Moreover, since we need only care about reconnecting the leaves of T, we get stronger tests.

Figure 3 contains an example of an instance that can be reduced using the expansion test.

3.3. Correctness of the expansion test. The correctness of the expansion test follows directly from the following proposition.

PROPOSITION 6. *Let T be a tree in G. If the tree T is peripherally contained in some optimal solution T^* of the* GST $(G, \mathcal{R}, c)$*, then for each vertex $u \in L(T)$ which is not a leaf of T^* there exists $U \subseteq \mathcal{X}(u, T)$, $U \neq \emptyset$, such that $T + U$ is peripherally contained in T^*.*

Proof. Let T^* be an optimal solution and assume it peripherally contains T. Choose $u \in L(T)$ such that u is not a leaf of T^* and let $U := \{uv \in E(T^*) \colon v \notin V(T)\}$. Since u is not a leaf in T^*, $U \neq \emptyset$. We claim that $T + U$ is peripherally contained in T^*.

To prove the claim, consider an internal vertex of $T + U$. If this vertex is u, it is immediate that any path from u to a leaf of T^* uses some edge of $T + U$ (since it uses some edge of T or some edge of U). If the internal vertex chosen is not u, then

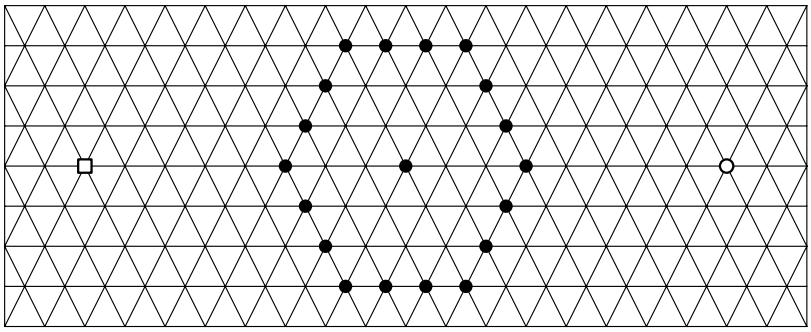

FIG. 3. *In this figure we have an instance of the group Steiner tree problem. The intersections between the segments are vertices and the segments themselves edges of our graph. All costs are unitary. We have tree groups:* •, ∘, *and* □. *The vertex in the center, which belongs to the group* •, *can be removed by the expansion test but not by the simple test of section* 2.2.

it is an internal vertex of T and, since T is peripherally contained in T^*, every path from this vertex to a leaf of T^* uses some edge of T and hence some edge of $T + U$.

Consider now a leaf u of $T + U$. Since $T + U$ is a subtree of T^*, and since T^* is a tree, it is easy to see that there must be a path from u to a leaf of T^* using only edges not in $T + U$. Therefore, $T + U$ is peripherally contained in T^* and the claim is proved. □

Note that the above proposition makes it possible for us to expand through any nonterminal leaf of a tree, since such a vertex cannot be a leaf in any optimal solution. Note also that we do not mention the fact that T respects some group vertex r, although such an assumption is important in the results of the previous section.

3.4. A supporting test. In this section we present a test that follows the same idea of the test presented in Theorem 1. We will then show how to combine this test with the idea of expansion to achieve more reductions. To present the test, we first introduce some notation. Given an instance $(G, \mathcal{R}, c)$ of the GST and disjoint sets A, B of vertices of G, we denote by $\underline{\delta}_G(A, B)$ the set containing for each $u \in B$ a least cost edge from $\delta_G(A, B)$ incident to u, if such an edge exists.

PROPOSITION 7. *Let* $(G, \mathcal{R}, c)$ *be an instance of the* GST, $R \in \mathcal{R}$, *and* $r \in R$. *Let* $C \subseteq V(G)$ *be such that* $C \cap \hat{\mathcal{R}} = \{r\}$. *If for every* $U \subseteq N(C)$ *with* $|U| \geq 1$ *we have* $\tau(U) + \pi(r, U) \leq c(\underline{\delta}(C, U))$, *then there exists an optimal solution containing a vertex of* $R \setminus \{r\}$.

Proof. Let T^* be an optimal solution in which r occurs. Let $C' := C \cap V(T^*)$ and $U := N_{T^*}(C')$. Note that $U \subseteq N_G(C)$, and since $C \cap \hat{\mathcal{R}} = \{r\}$, U is nonempty. Let $T' := T^* - C'$. Choose $u \in U$ and $r' \in R \setminus \{r\}$ such that $d_G(u, r') = \pi(r, U)$. Connect r' to T' by means of a subpath of a minimum-cost (u, r')-path, such that the resulting graph, say F, is a forest.

The graph F has at most $|U|$ components and each such component contains a vertex of U. Moreover, since $C \cap \hat{\mathcal{R}} = \{r\}$, F contains a valid set. Using Lemma 2, we know that there is a group Steiner tree $\hat{T}$ that contains F and that its cost is at most $c(E(F)) + \tau(U)$.

Now, we know that $c(\delta_{T^*}(C')) \geq c(\underline{\delta}_G(C, U))$. Hence, the cost of $\hat{T}$ is at most $c(E(T^*)) + \tau(U) + \pi(r, U) - c(\delta_{T^*}(C')) \leq c(E(T^*))$. Therefore, $\hat{T}$ is also an optimal solution. Now, since it contains a vertex of $R \setminus \{r\}$, we are done. □

We may combine this test with the expansion approach using the following idea. In each call of EXPANSION-TEST-INT we have a tree T and we wish to assert that (3.2)

is true for T. If the tree T is such that $V(T) \cap \hat{\mathcal{R}} = \{r\}$, then we can also check whether $V(T)$ verifies the hypothesis of Proposition 7. If this is the case, then r can be removed and there is no need to continue the expansion or to call the function Expansion-Test-Leaf. In fact, in this case we can end the recursion right away.

4. Computational results. We have implemented all the above methods. We did not implement any of the bound-based tests of [11] mainly because time-efficient heuristics for finding lower bounds were unable to find good lower bounds for the problem.

In our implementation, we observed that the time consumed by the expansion test is highly dependent on the degree of the vertices through which we choose to expand and on the depth of the recursion itself. Therefore, we limit these parameters to a small constant. In our case, we expand only through vertices of degree at most 8 and we limit the depth of the recursion to 8. When using the test of section 3.4, we consider only sets C for which $|N(C)|$ is limited by a small constant (8, in our case).

The test described in section 3.4 is effective in many cases, and reductions can be achieved by using it. We also attempted to use this test alone, together with another mechanism of expansion. In this case the expansion can be carried out in many ways; the only thing needed is to guarantee the necessary properties of the subset of vertices being inspected in each step. For instance, we may run a breadth-first search from r and, in each step of the search, test the set of vertices visited by the search. In all cases, we observed that the combination of this test with the expansion scheme presented earlier is far more effective.

The most important practical issue to consider, however, is the calculation of the group bottleneck Steiner distances. If we have a fixed valid set X, we can compute $s_X(u, v)$ for each pair u, v of vertices in time $O(n^2|X|)$ (cf. Duin [2]), given that we have the distances in G already computed. Since computing the distances takes time $O(n^3)$ (if the original graph is sparse, there are better algorithms), the whole process takes time $O(n^3)$.

Rohe and Zachariasen [13] show that computing $s(u, v)$ is NP-hard. They also propose heuristics to compute upper bounds for $s(u, v)$. We used those heuristics in our implementation and verified that the bounds produced by them are good, especially when the diameter of the groups is small. After removing group vertices, the group bottleneck Steiner distances only decrease. This means that we need not update the distances, though updates could lead to more reductions. In our implementation, we noticed that frequent updates did little to improve the number of reductions, so we try to remove as many group vertices as we can before updating. More specifically, we run our reduction algorithm until we can no longer remove any vertex; then we update the distances and try again.

Our results are summarized in Tables 1 and 2. The instances used are the same as in [13]. We did not have access to the original instances, however, so our reduction algorithm was tested upon instances that had already gone through a reduction process. Therefore, the reductions we achieved are in addition to those already achieved by the tests in [13]. The average number of group vertices removed was 6.5% for the WRP3 collection and 5.98% for the WRP4 collection.

In our tables we do not show time consumption, though it was never above 10 minutes. By changing the parameters of our program, like the maximum depth of the recursion, we observed that the time consumed increases too much, whereas there is no significant increase in the number of reductions achieved. The tests were carried out on a 1.1 GHz AMD Athlon with 512 Mb RAM memory.

TABLE 1

This table shows the results of the reduction procedure for the WRP3 collection. Column "$|\hat{\mathcal{R}}|$" has the number of group vertices of the original instance. Column "Exp." contains the number of group vertices removed by the expansion procedure alone. Column "Supp." contains the number of group vertices removed by the supporting test presented in section 3.4. *The last column, "Total," has the total number of group vertices removed.*

THE IMAGE CONTAINMENT PROBLEM AND SOME CLASSES OF POLYNOMIAL INSTANCES*

RAFFAELE PESENTI† AND FRANCA RINALDI‡

Abstract. The image containment problem (ICP) is a minimum cost design problem concerning the containment of particular polyhedra, called zonotopes, that are images of boxes through linear transformations. The ICP is NP-hard. Here we study a family of nontrivial ICP instances, called worst case demand (WCD) instances. We prove that such instances can be recognized and solved in polynomial time via linear programming. Then we characterize the classes of instances that are WCD independently on the choice of the cost vector (structurally worst case demand classes (SWCD)) and we show that recognizing whether a class of instances is SWCD is a coNP-complete problem. Finally, we describe two families of SWCD classes that are interesting from an applicative point of view: the classes defined by the incidence matrices of particular directed graphs and those defined by pre-Leontief matrices.

Key words. containment of polyhedra, zonotopes, parallelotopes, pre-Leontief matrices, network design

1. Introduction.

The *image containment problem (ICP)* is a design problem concerning the containment of polyhedra and, more specifically, of *zonotopes*.

Given two vectors $d^+ \in \mathbb{Q}_+^q$ and $u^+ \in \mathbb{Q}_+^m$, define the *boxes* $D(d^+) \doteq \{d \in \mathbb{R}^q : 0 \le d \le d^+\}$ and $U(u^+) \doteq \{u \in \mathbb{R}^m : 0 \le u \le u^+\}$.

Image containment problem (ICP). *Let $B \in \mathbb{Q}^{n\times m}$ and $F \in \mathbb{Q}^{n\times q}$ be two matrices and $d^+ \in \mathbb{Q}_+^q$ and $c \in \mathbb{Q}_+^m$ be two vectors with strictly positive components. Find, when it exists, a vector $u^+ \in \mathbb{Q}_+^m$ of minimum cost cu^+ such that*

$$\forall d \in D(d^+) \;\; \exists u \in U(u^+) : \quad Fd = Bu. \tag{1.1}$$

Denoting by $FD(d^+) = \{x \in \mathbb{R}^n : \exists d \in D(d^+) \text{ s.t. } x = Fd\}$ and $BU(u^+) = \{x \in \mathbb{R}^n : \exists u \in U(u^+) \text{ s.t. } x = Bu\}$ the images of $D(d^+)$ and $U(u^+)$ through the linear transformations induced by F and B, respectively, the ICP may be equivalently expressed as

$$\begin{aligned} z_{ICP} &= \min cu^+, \\ FD(d^+) &\subseteq BU(u^+), \\ u^+ &\ge 0. \end{aligned}$$

So, the ICP is the problem of determining the minimum cost box $U(u^+)$ such that its image in $\mathbb{R}^n$ through the linear transformation B contains the image $FD(d^+)$ of the box $D(d^+)$. Note that the assumption $d^+ > 0$ is not restrictive, since one can

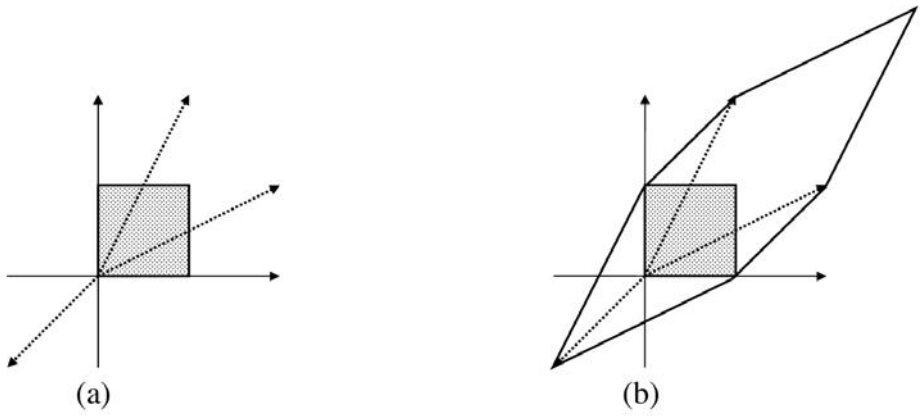

FIG. 1.1. *An ICP instance and its optimal solution.*

always eliminate possible null components of d^+ (and the corresponding columns of F) without modifying the set $FD(d^+)$.

Both sets $BU(u^+)$ and $FD(d^+)$ are zonotopes, i.e., centrally symmetric polytopes that are vector sums (Minkowsky sums) of a finite number of line segments (see [9, 14, 18]). Indeed we may write $BU(u^+) = \sum_{i=1}^{m} [0, u_i^+] B^i$ and $FD(d^+) = \sum_{j=1}^{q} [0, d_j^+] F^j$, where B^i and F^j denote the generic columns of B and F, respectively, and $[0, \alpha]$, $\alpha \in \mathbb{R}_+$, denotes the interval with extremes 0 and α. Therefore, $BU(u^+)$ is a sum of m line segments (called *generators*), where the ith segment has an end in the origin, the direction of the column B^i of B, and length equal to $u_i^+ \|B^i\|$. In this perspective, the cost cu^+ is a weighted sum of the lengths of the generators of $BU(u^+)$. In particular, the sum of the lengths of the generators, $\sum_{i=1}^{m} u_i^+ \|B^i\|$, is called the total length of the zonotope [10]. Figure 1.1 reports an ICP instance (Figure 1.1(a)) and its minimum total length solution (Figure 1.1(b)) where the zonotope $FD = ID$ is represented as a shaded square and the unit directions B^i, $i = 1, 2, 3$, as dotted vectors.

Since in the definition of the ICP the vector d^+ is assigned, in the rest of the paper we also use the notation D instead of $D(d^+)$. In addition, we refer to vectors $d \in D$ as *demands*.

The ICP is a particular case of the *circumbody* containment problem, a relevant subject of *computational convexity* (see [7]). In this setting, the *circumbody* containment problem requires finding, given a class $\mathcal{C}$ of closed convex sets, an element of $\mathcal{C}$ that contains a given convex body K and minimizes an assigned functional $\omega : \mathcal{C} \to \mathbb{R}$, where ω is assumed nonnegative and monotone with respect to inclusion. The ICP corresponds to the case where the elements of $\mathcal{C}$ are zonotopes of the form $BU(u^+)$, $u^+ \in \mathbb{R}_+^m$, the function ω is defined by $\omega(BU(u^+)) = cu^+$, and K is a zonotope of the form $K = FD(d^+)$.

Circumbody containment problems involving zonotopes were studied, for instance, in [10] and [16]. In [10] the authors consider the problem of finding a minimum total length zonotope containing k assigned points of $\mathbb{R}^n$ when the m directions of the generators are given and the center of the zonotope can be chosen arbitrarily. Assuming k greater than m^{n-1}, they show that the problem can be solved via linear programming in $O(km^{n-1} + m^{O(n)})$. In [16] only zonotopes in $\mathbb{R}^2$ centered in the origin are considered and a method to approximate a given zonotope by means of zonotopes

with assigned unit generators is proposed. As stated by the authors, this method converges to an optimal approximation with respect to the Hausdorff/integral metric. Differently from the above cases, in the ICP the center $\frac{Bu^+}{2}$ of the zonotope $BU(u^+)$ depends on the optimal solution u^+ and thus cannot be chosen arbitrarily nor is a priori known.

The ICP may arise in several applicative contexts. It models, for instance, those situations in which a system is subject to two kinds of actions: exogenous inputs and internal decisions. In this context, the vectors $d \in D$ represent exogenous inputs (demands, disturbances, etc.) that are supposed *unknown but bounded*; i.e., they can assume any nonnegative value not exceeding an assigned upper bound d^+. Any input d induces the effect Fd on the system. The vectors $u \in U(u^+)$ represent the internal decisions that have to *counteract* the demand action by producing an effect $Bu = Fd$. So the ICP consists of finding a minimum cost box $U(u^+)$ of decision vectors that can counteract any possible demand. As shown in [4], the condition $FD \subseteq BU(u^+)$ is a necessary and sufficient condition for the existence of feedback stabilizing strategies for the system on an infinite time horizon. That paper also contains an applicative example of the ICP in the context of manufacturing systems.

A particular case of the ICP, where B and F are the incidence matrices of two networks G and H with the same node set, was introduced in [3] and called the *minimum cost network containment problem (MCNCP)*. Given a capacity vector d^+ on the arcs of H, the MCNCP is the problem of determining a minimum cost capacity vector u^+ on the arcs of G with the property that, for any flow $d \in D(d^+)$, there exists a feasible flow $u \in U(u^+)$ in G that counteracts d, i.e., causes the same imbalance $Bu = Fd$ at the nodes. Actually, the MCNCP is coNP-hard [13]. An exact algorithm for the MCNCP was proposed in [15], where the role of this problem in the management of power transmission networks was also outlined.

The ICP may also be interpreted as a minimum cost substitution problem as in the following example. Given a production-distribution system, let F be the incidence matrix of the hypergraph representing the production and/or the distribution lines and d^+ be the vector whose components are the upper capacities of these lines. Then the feasible system outputs y have the form $y = Fd$, $0 \leq d \leq d^+$, where d is a vector of material flows. Suppose that the system has to be renewed and that the new structure of the processes is represented by the matrix B. Then the condition $FD(d^+) \subseteq BU(u^+)$ requires that the capacities u^+ of the new lines allow the production of at least the same set of outputs as the old system.

The ICP extends the MCNCP to the case of general matrices B and F and thus it is coNP-hard as well. In this paper, we deal with a particular subset of ICP instances for which a *worst case demand (WCD)* exists, in the sense stated in the following definition.

DEFINITION 1.1. *An ICP instance is called* worst case demand (WCD) *instance if there exists a vector* $\hat{d} \in D$ *and an optimal solution* $\hat{u}$ *of* $\{\min cu : Bu = F\hat{d}, u \geq 0\}$ *such that* $FD \subseteq BU(\hat{u})$. *In this case the vector* $\hat{d}$ *and the solution* $\hat{u}$ *are called* worst case demand *and* worst case hyperflow*, respectively.*

In other words, for WCD instances, the minimum cost one has to pay to counteract the single demand $\hat{d}$ is the same one has to pay to be able to counteract any demand in D and one can choose $u^+ = \hat{u}$ as the optimal solution of the ICP. In general, an ICP instance is not WCD. For example, Figure 1.2 (a), (b), and (c) report, respectively, the three minimum total length zonotopes that include, separately, each of the three nontrivial vertices $(0, 1)$, $(1, 1)$, and $(1, 0)$ of $FD = ID$ for the instance

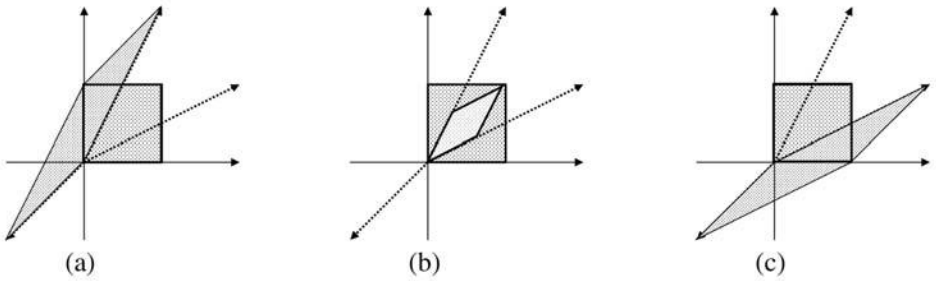

FIG. 1.2. *Optimal zonotopes including, separately, the three vertices of FD for the instance in Figure* 1.1(a).

in Figure 1.1(a). Clearly, FD is not contained in any of these three sets (nor in the minimum total length zonotope that contains any assigned point of FD), and in fact the instance is not WCD.

The main results of the paper are the following. First, we prove that the ICP can be solved in polynomial time on the set of the WCD instances and that the problem of recognizing whether an ICP instance is WCD can be solved in polynomial time as well. In general, for assigned matrices B and F, we show that the WCD property may depend on the choice of the cost vector c while it does not depend on the vector d^+. Then, as a second result, we provide some necessary and sufficient conditions on the structure of the matrices B and F that make the corresponding instances WCD independently of the particular cost vector c. In this case, we say that B and F define a *structurally worst case demand (SWCD)* class of instances. We first use the above conditions to show that any ICP class defined by a matrix B whose columns are linearly independent is SWCD. Then we identify two other families of SWCD classes that have significant interest from an applicative point of view. The first family contains all the MCNCP classes of instances that are SWCD. More precisely, we characterize the structure of the networks G and H that define a class with this property. This result enables us to show, in particular, that the problem of deciding whether a given class of MCNCP instances is SWCD is coNP-complete. Thus, the more general problem of deciding whether an ICP class is SWCD is coNP-complete as well. The second family is defined by matrices B that are pre-Leontief [2] and nonnegative matrices F. This family includes, in particular, the case when B describes either a network system or a system of generalized flows. We also prove that the instances of the two families admit an integral optimal solution whenever d^+ is an integral vector. This property does not in general hold, even for the MCNCP instances [3].

The outline of the paper is the following. In section 2, we present some preliminary results and assumptions concerning the ICP. In section 3, we show how to recognize and solve WCD instances in polynomial time. In section 4, we introduce the SWCD classes of instances and provide some necessary and sufficient conditions on the pairs (B, F) of matrices that define such classes. We also show that these conditions are satisfied when B is a nonsingular matrix. In section 5, we analyze the two families of SWCD classes mentioned above. Finally, in section 6, we discuss the possible extension of the previous results to a particular generalization of the ICP.

Notation. The following notation will be used throughout the paper. Given an $n \times m$ matrix A, we write $A \geq 0$ and $A > 0$ to mean that all the entries of A are

nonnegative and strictly positive, respectively. Given two integers i, k and a set of integers β, we denote by A_{ik}, A^k, and A^β the (i,k)-entry of A, the kth column of A, and the submatrix of A formed by the columns A^k, $k \in \beta$, respectively. Moreover, we denote by $lin\{A\} = \langle A^k : k = 1, \dots, m\rangle$ and $cone\{A\} = cone\{A^k : k = 1, \dots, m\}$ the linear space and the convex cone, respectively, generated by the columns of A. If $m \geq n$, we call any $n \times n$ nonsingular submatrix $\mathcal{B}$ of A a basis submatrix. Given two vectors a and b we write $a \gneq b$ ($a \lneq b$) to mean that, componentwise, $a_k \geq b_k$ ($a_k \leq b_k$) and at least one inequality strictly holds, i.e., $a \neq b$. Given a vector space $\mathbb{R}^q$, we denote by e^j, $j = 1, \dots, q$, the vector defined by $e^j_k = 0$ if $k \neq j$, $e^j_j = 1$ and by e the vector with components $e_k = 1$ for each k. Given a directed hypergraph H with n nodes and m hyperarcs, we call the $n \times m$ matrix A whose kth column corresponds to the hyperarc $h_k = (T, H)$ and has entries $A_{ik} = -1$ if $i \in T$, $A_{jk} = 1$ if $j \in H$, 0 otherwise, the incidence matrix of H.

2. Preliminary results. Denote the generic ICP instance by the quadruple (B, F, c, d^+). The following lemma states a necessary and sufficient condition for the feasibility of the ICP.

LEMMA 2.1. *An ICP instance (B, F, c, d^+) admits a feasible solution if and only if*

$$cone\{F^j : j = 1, \dots, q\} \subseteq cone\{B^i : i = 1, \dots, m\}. \tag{2.1}$$

Proof. If (B, F, c, d^+) is feasible, then for each $j = 1, \dots, q$ there exists $u^j \geq 0$ such that $F(0, \dots, 0, d^+_j, 0, \dots, 0)^T = d^+_j F^j = Bu^j$; thus each F^j is a conic combination of the columns of B. This implies condition (2.1). Conversely, if condition (2.1) holds, then FD is a bounded subset of $cone\{B^i : i = 1, \dots, m\}$ and thus there exists $\bar{u} \geq 0$ such that $FD \subseteq \{Bu : 0 \leq u \leq \bar{u}\}$. Clearly, the vector $\bar{u}$ is a feasible solution of the ICP. ∎

LEMMA 2.2. *Any feasible ICP instance (B, F, c, d^+) with $B \in \mathbb{Q}^{n \times m}$ can be transformed in an equivalent instance (B', F', c, d^+), $B' \in \mathbb{Q}^{k \times m}$, such that* $\operatorname{rank}(B) = \operatorname{rank}(B') = k$.

Proof. Assume $\operatorname{rank}(B) = k < n$ and let $V = \begin{bmatrix} W \\ Z \end{bmatrix}$ be an $n \times n$ matrix where the rows of the $k \times n$ matrix W span $lin\{B\}$, and the rows of the $(n-k) \times n$ matrix Z span the orthogonal space $lin\{B\}^\perp$. Since V is nonsingular, $Bu = Fd$ if and only if $VBu = VFd$. Moreover, $ZBu = 0$ for each $u \in \mathbb{R}^m$ and this implies, by Lemma 2.1, $ZFd = 0$ for each $d \in \mathbb{R}^q_+$. Therefore the condition $FD \subseteq BU(u^+)$ is equivalent to the condition $WFD \subseteq WBU(u^+)$ and the instance (B, F, c, d^+) is equivalent to the instance (WB, WF, c, d^+) where WB is a $k \times m$ matrix of rank k. ∎

Since in general the orthogonal space $lin\{F\}^\perp$ is not contained in $lin\{B\}^\perp$, the argument followed in the proof of Lemma 2.2 cannot be used to assume that F is a full rank matrix. For example, consider the case where B is the 2×2 identity matrix I, $F = [1, 1]^T$, and $d^+ = 1$. For the choice $u^+ = [2, 0]$ the zonotope $BU(u^+) = [0, 2]e^1 + [0, 0]e^2$ does not contain the segment $FD(d^+) = [0, 1]e$ while the projection of $BU(u^+)$ onto the linear space $lin\{F\}$ is equal to (and hence includes) $FD(d^+)$.

By Lemma 2.2 we can always assume that B is an $n \times m$ matrix with $n \leq m$ and full rank. When B is a nonsingular square matrix, the solutions $BU(u^+)$ are parallelotopes, i.e., zonotopes whose generators are linearly independent. If, in particular, the columns of B form an orthogonal basis, these parallelotopes are, possibly not axis parallel, boxes. Then, if B is nonsingular, the ICP is the problem of finding the minimum cost parallelotope with assigned generator directions and a vertex in the origin that encloses the zonotope FD. The following result holds.

THEOREM 2.3. *Any ICP instance* (B, F, c, d^+) *where* B *is a nonsingular square matrix can be solved in polynomial time.*

Proof. For each $u \in \mathbb{R}^m$, we can obtain the representation of the parallelotope $BU(u)$ in terms of a set of $2n$ hyperplanes as $BU(u) = \{x \in \mathbb{R}^n : A_i x \leq b_i, i = 1, \ldots, 2n\}$ in polynomial time [14]. Therefore, the separation problem of finding a vector $d \in D$ such that $Fd \notin BU(u)$, if such a vector exists, can be solved in polynomial time by solving the $2n$ linear programming problems $\max\{A_i F d : d \in D\}$, $i = 1, \ldots, 2n$. Then the thesis follows by a well-known result of Grötschel, Lovász, and Schrijver [8], stating the equivalence between the complexity of an optimization problem and the corresponding separation problem. □

3. WCD instances. In this section, we first reformulate the ICP as a linear programming problem with an exponential number of variables and constraints. Then, we introduce a lower bound and an upper bound for the latter problem and show that an ICP instance is WCD if and only if these two bounds are equal.

Due to the convexity of the sets $BU(u^+)$ and FD, the ICP may be equivalently expressed as a linear programming problem (with an exponential number of variables and constraints) in the following form.

ICP_{LP}:

$$\begin{aligned} & z_{ICP} = \min cu^+, \\ & Bu^r = Fd^r \quad \forall r : d^r \in \text{Ext}\{D\}, \\ & 0 \leq u^r \leq u^+ \quad \forall r : d^r \in \text{Ext}\{D\}, \end{aligned} \tag{3.1}$$

where $\text{Ext}\{D\}$ is the set of the vertices of the set D.

A lower bound on the optimal value z_{ICP} can be found by solving, for any $d \in D$, the following relaxation of (3.1).

Lower bound problem ($\text{LBP}(d)$):

$$\begin{aligned} z_{LBP}(d) &= \min cu, \\ Bu &= Fd, \\ u &\geq 0. \end{aligned} \tag{3.2}$$

According to Definition 1.1, an ICP instance is WCD if there exists a worst case demand $\hat{d} \in D$ such that problems ICP_{LP} and $\text{LBP}(\hat{d})$ have the same optimal value and at least one common optimal solution (the so-called worst case hyperflow) $\hat{u}$. However, as shown in the following example, even in the WCD case, an optimal solution of the problem $\text{LBP}(\hat{d})$ may not be a worst case hyperflow.

Example 3.1. Consider the ICP instance (B, F, c, d^+) where B and F are, respectively, the incidence matrices of the networks $G = (V, E_G)$ and $H = (V, E_H)$ shown in Figure 3.1. The two networks share the node set $V = \{1, 2, 3, 4, 5, 6\}$, while the two arc sets are $E_G = \{(1,2), (1,5), (2,4), (3,2), (3,6), (4,5), (4,6)\}$ and $E_H = \{(1,6), (3,5)\}$. Let $c_{ij} = 1$ for all $(i,j) \in E_G$ except for $c_{15} = c_{36} = 3$ and let D be the box defined by $d^+ = (1,1)$.

Both the settings

$$\hat{u}_{12} = \hat{u}_{32} = \hat{u}_{45} = \hat{u}_{46} = 1, \qquad \hat{u}_{24} = 2, \qquad \hat{u}_{ij} = 0 \ \text{ otherwise} \tag{3.3}$$

and

$$\bar{u}_{15} = \bar{u}_{36} = 1, \qquad \bar{u}_{ij} = 0 \ \text{ otherwise} \tag{3.4}$$

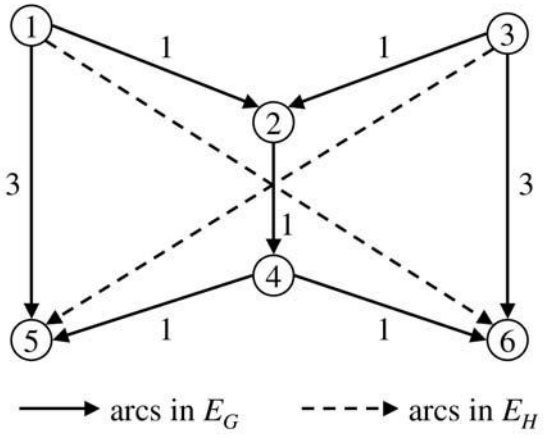

FIG. 3.1. *Networks G and H in Example* 3.1.

define optimal solutions (of cost 6) to problem (3.2) with $\hat{d} = d^+$. Nevertheless, while the solution $\hat{u}$ is feasible for the ICP, the solution $\bar{u}$ is not, since no flow in $U(\bar{u})$ can counteract, for instance, the demand $d = (0, 1)$.

Now consider, for any $d \in D$, the following linear programming problem.

Upper bound problem (UBP(d)):

$$
\begin{aligned}
z_{UBP}(d) &= \min cu, \\
Bu^j &= Fd^j, \quad j = 1, \ldots, q, \\
u &= \sum_{j=1}^{q} u^j, \\
u^j &\geq 0, \quad j = 1, \ldots, q,
\end{aligned}
\tag{3.5}
$$

where d^j, $j = 1, \ldots, q$, denotes the vector of D defined by $d^j_k = 0$ if $k \neq j$ and $d^j_j = d_j$.

It is immediate to verify that, for each $d \in D$, problem UBP(d) can be decomposed in the sum of q independent problems LBP(d^j), $j = 1, \ldots, q$, and that $z_{UBP}(d) = \sum_{j=1}^{q} z_{LBP}(d^j)$. Moreover, the following lemma holds.

LEMMA 3.2. *Given an ICP instance* (B, F, c, d^+), *any feasible solution* $\hat{u} = \sum_{j=1}^{q} \hat{u}^j$ *of UBP*(d^+) *is a feasible solution of the* ICP_{LP}. *Thus,* $z_{ICP} \leq z_{UBP}(d^+)$.

Proof. Any vertex $\bar{d}$ of D may be written as a sum of vertices d^{+j} for j in a suitable set $J \subseteq \{1, \ldots, q\}$. Then the vector $\bar{u} = \sum_{j \in J} \hat{u}^j$ is such that $B\bar{u} = \sum_{j \in J} B\hat{u}^j = \sum_{j \in J} Fd^{+j} = F\bar{d}$ and $0 \leq \bar{u} \leq \hat{u}$. Hence, $F\bar{d} \in BU(\hat{u})$ for each $\bar{d} \in \text{Ext}\{D\}$ and $FD \subseteq BU(\hat{u})$. ∎

A particular consequence of the above lemma is that the existence of a feasible solution u^j of the problem LBP(d^{+j}) for each $j = 1, \ldots, q$ is a necessary and sufficient condition for the existence of a feasible solution of the correspondent ICP problem. It is easy to realize that this condition is an alternative formulation of condition (2.1).

We have proved that for any ICP instance it holds that

$$
z_{LBP}(d^+) \leq z_{ICP} \leq z_{UBP}(d^+). \tag{3.6}
$$

The rest of this section is devoted to characterizing the WCD instances as those instances for which both conditions in (3.6) hold as equalities. To this aim we need the following lemma.

LEMMA 3.3. *If an ICP instance (B, F, c, d^+) is WCD, then $F\hat{d} = Fd^+$ for every worst case demand $\hat{d}$. In particular, d^+ is a worst case demand.*

Proof. Assume that $\hat{d}$ is a worst case demand with $F\hat{d} \neq Fd^+$ and define the vector $\bar{d}$ as $\bar{d} \doteq d^+ - \hat{d}$. Since $\hat{d} \neq d^+$, $\bar{d}$ satisfies the relations $0 \lneq \bar{d} \leq d^+$. If $\hat{u}$ is a worst case hyperflow, there exist two vectors u° and $\bar{u}$, $0 \leq u^\circ, \bar{u} \leq \hat{u}$, such that $Bu^\circ = Fd^+$ and $B\bar{u} = F\bar{d}$. From $F\hat{d} \neq Fd^+$ it follows that $\hat{u} \neq u^\circ$, and, in particular, $\hat{u} \gneq u^\circ$. The latter condition, together with $\bar{u} \geq 0$, implies $\bar{\bar{u}} \doteq \bar{u} + \hat{u} - u^\circ \gneq 0$ and $\bar{\bar{u}}_j = 0$ if $\hat{u}_j = 0$. Moreover, from $B(u^\circ - \hat{u}) = F(d^+ - \hat{d}) = F\bar{d} = B\bar{u}$ we obtain $B\bar{\bar{u}} = 0$. Then, there exists an $\alpha > 0$ such that $\alpha\bar{\bar{u}} \leq \hat{u}$, $\alpha\bar{\bar{u}} \neq 0$, and $B\alpha\bar{\bar{u}} = \alpha B\bar{\bar{u}} = 0$. From $B(\hat{u} - \alpha\bar{\bar{u}}) = B\hat{u} = F\hat{d}$ and $0 \lneq \hat{u} - \alpha\bar{\bar{u}} \lneq \hat{u}$ it follows that $\hat{u} - \alpha\bar{\bar{u}}$ is a feasible solution of problem LBP($\hat{d}$). In addition, since c is a strictly positive vector, we have $c(\hat{u} - \alpha\bar{\bar{u}}) < c\hat{u}$ in contradiction with the optimality of $\hat{u}$ to problem LBP($\hat{d}$). ∎

We now prove the main result of this section.

THEOREM 3.4. *An ICP instance (B, F, c, d^+) is WCD if and only if problems LBP(d^+) and UBP(d^+) have the same optimal value. In this case, any optimal solution u^* of UBP(d^+) is also an optimal solution of ICP_{LP}.*

Proof. Necessity. Let $\hat{u}$ denote a worst case hyperflow. By Lemma 3.3, $B\hat{u} = Fd^+$. In addition, there exist vectors u^j, $j = 1, \ldots, q$, with $0 \leq u^j \leq \hat{u}$ and $Bu^j = Fd^{+j}$. Since $\sum_{j=1}^q u^j$ is a feasible solution of UBP(d^+), it is now sufficient to show that $c\hat{u} = c\sum_{j=1}^q u^j$. Assume, by contradiction, that $c\hat{u} < c\sum_{j=1}^q u^j$, and consider the vector $\bar{u} = \hat{u} - \sum_{j=1}^q u^j$. Then $c\bar{u} < 0$ and $B\bar{u} = F(d^+ - \sum_{j=1}^q d^{+j}) = 0$. Moreover, the inequalities $u^j \leq \hat{u}$, $j = 1, \ldots, q$, imply that, componentwise, $\bar{u}_k < 0$ only if $\hat{u}_k > 0$. Hence, there exists a sufficiently small $\alpha > 0$ such that $\hat{u} + \alpha\bar{u} \geq 0$, $c(\hat{u} + \alpha\bar{u}) < c\hat{u}$, and $B(\hat{u} + \alpha\bar{u}) = Fd^+$, in contradiction with the hypothesis that $\hat{u}$, being a worst case hyperflow, is an optimal solution of problem LBP(d^+).

Sufficiency. The sufficiency follows immediately from Lemma 3.2. ∎

As a consequence of the above theorem, we may state the following complexity result.

COROLLARY 3.5. (i) *The problem of verifying whether an ICP instance (B, F, c, d^+) is WCD can be solved in polynomial time.*

(ii) *The ICP can be solved in polynomial time on the set of the WCD instances.*

Proof. Problems LBP(d^+) and UBP(d^+) are linear programming problems with a polynomial number of variables and constraints; thus they can be solved in polynomial time. Then, statements (i) and (ii) follow from Theorem 3.4. ∎

To conclude this section, we analyze the quality of the upper bound $z_{UBP}(d^+)$ and of the lower bound $z_{LBP}(d^+)$ in the general case.

COROLLARY 3.6. *The optimal value of problem UBP(d^+) is at most q times the optimal value of problem ICP_{LP}.*

Proof. The thesis follows trivially from the inequalities $z_{UBP} \leq q \max_j z_{LBP}(d^{+j})$ and $\max_j z_{LBP}(d^{+j}) \leq z_{ICP}$. ∎

On the other side, as shown in the following example, the worst case ratio $\frac{z_{ICP}}{z_{LBP}(d^+)}$ can be arbitrarily large.

Example 3.7. Consider again the WCD instance in Example 3.1. If the costs c_{15} and c_{36} change from 3 to ε with $0 < \varepsilon < 3$, the instance is not WCD anymore. Indeed, in this case, the only optimal solution of LBP(d^+) is $\bar{u}_{15} = \bar{u}_{36} = 1$, $\bar{u}_{ij} = 0$

otherwise, with $z_{LBP}(d^+) = 2\varepsilon$. On the other hand, the optimal solution of the ICP is still the vector $\hat{u}$ in (3.3) and thus $z_{ICP} = 6$.

4. SWCD classes of instances. In this section, we consider the classes of ICP instances that are WCD independently of the choice of the cost vector c and the demand vector d^+. In particular, we determine some necessary and sufficient conditions that characterize this property.

First note that, as Examples 3.1 and 3.7 show, an ICP instance may or may not be WCD depending on the cost vector c. The next lemma points out that, under the assumption $d^+ > 0$, the WCD property does not depend on the demand d^+.

LEMMA 4.1. *If the ICP instance (B, F, c, d^+), $d^+ > 0$, is WCD, then each instance $(B, F, c, \hat{d})$, $\hat{d} \geq 0$, is WCD.*

Proof. By Theorem 3.4 there exists a common optimal solution u^+ of problems LBP(d^+) and UBP(d^+). Then, by linearity, αu^+, $\alpha > 0$, is a common optimal solution of problems LBP(αd^+) and UBP(αd^+). As a consequence, any instance $(B, F, c, \alpha d^+)$, $\alpha > 0$, is WCD and this observation allows us to assume without loss of generality that $\hat{d} \lneq d^+$. Assume that the instance $(B, F, c, \hat{d})$ is not WCD for some $0 \leq \hat{d} \lneq d^+$ and define $\bar{d} = d^+ - \hat{d} \gneq 0$. Since $(B, F, c, \hat{d})$ is not WCD, the inequalities $z_{LBP}(\bar{d}) \leq z_{UBP}(\bar{d})$ and $z_{LBP}(\hat{d}) < z_{UBP}(\hat{d})$ hold. Moreover, since the sum of any two optimal solutions of problems $LBP(\bar{d})$ and $LBP(\hat{d})$ is feasible for LBP(d^+), we have $z_{LBP}(d^+) \leq z_{LBP}(\bar{d}) + z_{LBP}(\hat{d})$ and, consequently, $z_{LBP}(d^+) < z_{UBP}(\bar{d}) + z_{UBP}(\hat{d})$. On the other hand, for each $d \geq 0$, $z_{UBP}(d) = \sum_{j=1}^{q} z_{LBP}(d^j)$ and, by linearity, $z_{LBP}(d^j) = d_j z_{LBP}(e^j)$ for each $j = 1, \ldots, q$. As a consequence, $z_{UBP}(d^+) = \sum_{j=1}^{q} d_j^+ z_{LBP}(e^j) = \sum_{j=1}^{q} (\bar{d}_j + \hat{d}_j) z_{LBP}(e^j) = \sum_{j=1}^{q} z_{LBP}(\bar{d}^j) + \sum_{j=1}^{q} z_{LBP}(\hat{d}^j) = z_{UBP}(\bar{d}) + z_{UBP}(\hat{d})$. Therefore $z_{LBP}(d^+) < z_{UBP}(d^+)$, in contradiction with the fact that (B, F, c, d^+) is a WCD instance. ∎

Let (B, F) denote the class of all the feasible ICP instances defined by the same pair of matrices B and F and vectors c and d^+ with strictly positive components. By Lemma 2.1, (B, F) either is empty or contains any instance (B, F, c, d^+).

DEFINITION 4.2. *The class (B, F) is a* structurally worst case demand (SWCD) *class if all the instances $(B, F, c, d^+) \in (B, F)$ are WCD.*

As an immediate consequence of Lemma 4.1, a nonempty class (B, F) is SWCD if and only if any instance (B, F, c, e) is WCD.

The next theorem states some necessary and sufficient conditions that characterize the pairs (B, F) of matrices that define SWCD classes.

THEOREM 4.3. *Given a nonempty class (B, F), the following statements are equivalent:*

(i) *(B, F) is SWCD.*

(ii) *Each extreme ray $(\bar{u}, \bar{d})$ of the cone $C = \{(u, d) \in \mathbb{R}^{m+q} : Bu = Fd,\ u \geq 0,\ d \geq 0\}$ is such that $\bar{d}_j > 0$ for at most one j, $j = 1, \ldots, q$.*

(iii) *Each vertex of the polyhedron $P = \{u \in \mathbb{R}^m : Bu = Fe,\ u \geq 0\}$ is determined by a basis submatrix $\mathcal{B}$ of B such that $\mathcal{B}^{-1} F e^j \geq 0$ for each $j = 1, \ldots, q$.*

Proof. The statement holds trivially if $q = 1$, so we can assume $q > 1$. For $d \geq 0$, denote by $\gamma(d)$ the number of nonnull components of d.

(i) ⇒ (ii) We show that, if there exists an extreme ray $(\bar{u}, \bar{d})$ of C with $\gamma(\bar{d}) > 1$, then there exists an instance in (B, F) that is not WCD. Let $(\bar{u}, \bar{d})$ be an extreme ray of C with $\gamma(\bar{d}) > 1$. Then $\bar{u}$ is a vertex of the polyhedron $P(\bar{d}) = \{u \in \mathbb{R}^m : Bu = F\bar{d},\ u \geq 0\}$ and for each vertex $\hat{u}$ of $P(\bar{d})$, $\hat{u} \neq \bar{u}$, we have $\hat{u}_k > 0$ for at least one k such that $\bar{u}_k = 0$. In addition, $r \gneq 0$ for each possible extreme ray r of $P(\bar{d})$. So we can

define a cost vector $c > 0$ such that $c\hat{u} > c\bar{u}$ for each vertex $\hat{u} \neq \bar{u}$ and $cr > 0$ for each extreme ray r by setting $c_k = \varepsilon > 0$ if $\bar{u}_k > 0$, $c_k = 1$ otherwise, and choosing ε sufficiently small. Consider now the ICP instance $(B, F, c, \bar{d})$. By the structure of problem UBP($\bar{d}$), if $\hat{u}$ is an optimal solution of UBP($\bar{d}$) the vector $(\hat{u}, \bar{d})$ is the sum of $\gamma(\bar{d}) > 1$ elements of C. This implies that $(\hat{u}, \bar{d})$ is not an extreme ray of C and $\hat{u} \neq \bar{u}$. Since $\bar{u}$ is the unique optimal solution of problem LBP($\bar{d}$) it follows that $c\bar{u} < c\hat{u}$ and the instance $(B, F, c, \bar{d})$ is not WCD by Theorem 3.4.

(ii) $\Rightarrow$ (iii) We show that the thesis holds for each basis submatrix $\mathcal{B} = B^\beta$ such that $\bar{u}_\beta = \mathcal{B}^{-1}Fe \geq 0$. Given a basis submatrix $\mathcal{B} = B^\beta$, define $\bar{u} = [\bar{u}_\beta, \bar{u}_{\{1,\dots,m\}\setminus\beta}] = [\mathcal{B}^{-1}Fe, 0]$ and $\bar{u}^j = [\bar{u}^j_\beta, \bar{u}^j_{\{1,\dots,m\}\setminus\beta}] = [\mathcal{B}^{-1}Fe^j, 0]$, $j = 1, \dots, q$. We prove the statement by showing that $(\bar{u}, e) \in C$ implies $(\bar{u}^j, e^j) \in C$ for each $j = 1, \dots, q$. Since $\bar{u} \geq 0$, $(\bar{u}, e)$ belongs to C. Moreover, since $\gamma(e) = q > 1$, $(\bar{u}, e)$ is not an extreme ray of C and we can write $(\bar{u}, e) = \sum_{j=1}^q (\hat{u}^j, e^j)$, where each $(\hat{u}^j, e^j)$ is an extreme ray of C. It remains to prove that $\hat{u}^j = \bar{u}^j$, $j = 1, \dots, q$. To this aim, observe that, since $\hat{u}^j \geq 0$ and $\bar{u}_{\{1,\dots,m\}\setminus\beta} = 0$, we have $\hat{u}^j_{\{1,\dots,m\}\setminus\beta} = \bar{u}^j_{\{1,\dots,m\}\setminus\beta} = 0$. In this case, $B\hat{u}^j = \mathcal{B}\hat{u}^j_\beta = Fe^j$ and finally $\hat{u}^j_\beta = \mathcal{B}^{-1}Fe^j = \bar{u}^j_\beta$ for each j.

(iii) $\Rightarrow$ (i) For any $c > 0$, let $\mathcal{B}$ be an optimal basis submatrix of problem LBP(e) as in statement (iii). Then, by hypothesis, $\bar{u} = [\bar{u}_\beta, \bar{u}_{\{1,\dots,m\}\setminus\beta}] = [\mathcal{B}^{-1}Fe, 0] \geq 0$ implies $\bar{u}^j = [\bar{u}^j_\beta, \bar{u}^j_{\{1,\dots,m\}\setminus\beta}] = [\mathcal{B}^{-1}Fe^j, 0] \geq 0$ for $j = 1, \dots, q$, and each $\bar{u}^j$ is a feasible solution of the corresponding problem LBP(e^j). Now, by linearity arguments, $z_{UBP}(e) \leq c\sum_{j=1}^q \bar{u}^j = c\sum_{j=1}^q \mathcal{B}^{-1}Fe^j = c\mathcal{B}^{-1}Fe = z_{LBP}(e)$, which implies $z_{UBP}(e) = z_{LBP}(e)$. Then the instance (B, F, c, e) is WCD by Theorem 3.4. Since the previous argument holds for any $c > 0$, the class (B, F) is SWCD. ∎

From a geometric perspective, Theorem 4.3 in point (iii) states that the class (B, F) is SWCD if and only if for each basis submatrix $\mathcal{B}$ of B the condition $Fe \in cone\{\mathcal{B}\}$ implies $cone\{F\} \subseteq cone\{\mathcal{B}\}$. Moreover, as shown in the proof of part (ii) $\Rightarrow$ (iii), the following property holds.

COROLLARY 4.4. *Let (B, F) be a nonempty SWCD class. Then for every instance $(B, F, c, d^+) \in (B, F)$ any feasible basic solution of problem $LBP(d^+)$ is feasible for the ICP. As a consequence, any instance in (B, F) admits an optimal solution that is a parallelotope.*

For a generic WCD instance, the optimal solution of the ICP obtained by solving problem $UBP(d^+)$ is not in general a parallelotope. Instead, by the above result, if the instance belongs to an SWCD class, an optimal parallelotope solution of the ICP can always be found by solving problem $LBP(d^+)$.

Other consequences of Theorem 4.3 concern the properties of the ICP instances defined by a nonsingular square matrix B. The next corollary strengthens the result in Theorem 2.3; the following one considers the case of more general objective functions.

COROLLARY 4.5. *Let B be a matrix whose columns are linearly independent. Then any nonempty class (B, F) is SWCD.*

Proof. By Lemma 2.2, we can assume that B is a nonsingular square matrix, so B contains itself as a unique basis submatrix. As each problem $LBP(e^j)$, $j = 1, \dots, q$, is feasible by Lemma 2.1, this implies $B^{-1}Fe^j \geq 0$ for each j and the thesis follows by Theorem 4.3 (iii). ∎

COROLLARY 4.6. *Given a nonempty class (B, F), where B is a nonsingular square matrix, let $g(u)$, $g : \mathbb{R}^m \to \mathbb{R}$, be a function not decreasing in any component*

of u. Then $u^+ = B^{-1}Fd^+$ is an optimal solution of the problem

$$\min\{g(u^+) : \ FD(d^+) \subseteq BU(u^+), \ u^+ \geq 0\}. \tag{4.1}$$

Proof. The vector $\bar{u} = B^{-1}Fd^+$ is the unique feasible solution of $LBP(d^+)$ and thus $\bar{u} \leq u^+$ for each feasible solution u^+ of problem (4.1). On the other hand, since $\bar{u}$ is a basic solution, $\bar{u}$ is feasible for (4.1) by Corollary 4.4. Then the thesis follows by the monotonicity of the function g. ∎

A final consequence of Theorem 4.3 (iii) and Lemma 4.1 is that if (B, F) is an SWCD class, then any nonempty class $(\hat{B}, \hat{F})$, where $\hat{B}$ and $\hat{F}$ are obtained from B and F, respectively, by deleting some of their columns, is SWCD as well.

5. Two families of SWCD classes. In this section, we introduce two particular families of SWCD classes. First, we characterize the classes of instances of the minimum cost network containment problem (MCNCP) that enjoy the SWCD property. As a corollary, we prove that the problem of verifying whether a given MCNCP (ICP) class is SWCD is coNP-complete. Next, we prove that pre-Leontief matrices B and nonnegative matrices F define SWCD classes. In both the cases the SWCD property implies the integrality of the optimal basic solutions of the ICP problem.

5.1. The SWCD classes of MCNCP instances. As mentioned in the introduction, the MCNCP instances are particular ICP instances defined by matrices B and F that are the node-arc incidence matrices of two directed graphs with the same set of nodes.

In the following, given a directed graph $G = (V, E)$, a *directed path* in G is a sequence $i_1 a_1 i_2 \dots a_{k-1} i_k$ of nodes and arcs without any repetition of nodes and such that $a_r = (i_r, i_{r+1}) \in E$ for each $1 \leq r \leq k$. A *directed cycle* in G is a directed path together with the arc (i_k, i_1).

DEFINITION 5.1. *Given a class (B, F) of MCNCP instances, let G be the directed graph with incidence matrix $[B| - F]$. We say that the class is* $2F$-cycle free *if each directed cycle of G includes at most one F-arc, i.e., at most one arc corresponding to a column of $-F$.*

THEOREM 5.2. *A class (B, F) of MCNCP instances is SWCD if and only if it is* $2F$-cycle free. *In this case, every instance in (B, F) defined by an integral vector d^+ admits an integral optimal solution.*

Proof. In the case of MCNCP instances, any element of the cone $C = \{(u, d) \in \mathbb{R}^{m+q} : Bu = Fd, \ u \geq 0, \ d \geq 0\}$ corresponds to a circulation in G and, by the flow decomposition theorem [1], it is the sum of cycle flows, that is, flows of the type αx, where x is the incidence vector of a directed cycle of G and $\alpha \in \mathbb{R}_+$. As a consequence, (u, d) is an extreme ray of C if and only if it is a cycle flow. Then, by Theorem 4.3 (ii), (B, F) is SWCD if and only if any cycle in G contains at most one F-arc, that is, G is $2F$-cycle free. The second statement follows by the integrality property of the optimal basic solutions of the min cost flow problem LBP(d^+). ∎

We remark that, as shown in [3], in general an MCNCP instance with integral data may not admit an integral optimal solution.

As a consequence of the above theorem we obtain the following complexity result.

THEOREM 5.3. *Determining whether a given class (B, F) of MCNCP instances is SWCD is a coNP-complete problem.*

Proof. We prove the statement by showing that the problem of deciding whether a class (B, F) of MCNCP instances is not SWCD is an NP-complete problem. We first show that this problem is in NP. By definition, a class (B, F) is not SWCD if

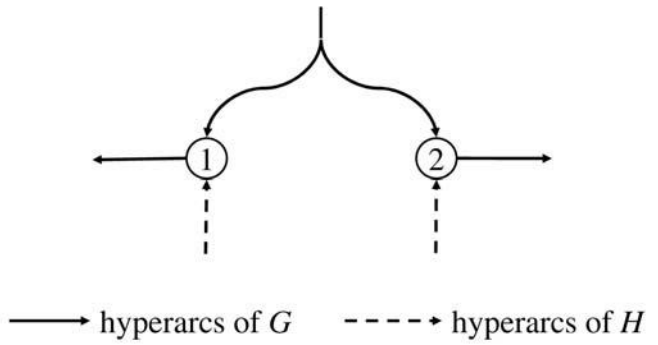

FIG. 5.1. *Hypergraphs G and H in Example* 5.5.

it includes an instance that is not WCD. Then, any non-WCD instance in (B, F) is a certificate that (B, F) is not SWCD which can be checked in polynomial time by Corollary 3.5. In order to prove that the problem is NP-complete, let us consider a polynomial transformation from the 2-disjoint paths problem for directed graphs (2DPP) defined as follows. Given a directed graph $H = (V, E)$ and two assigned pairs of nodes (s_1, t_1) and (s_2, t_2), find if there exist two node-disjoint paths connecting s_1 to t_1 and s_2 to t_2. As shown in [6], 2DPP is NP-complete. Given a 2DPP instance, consider the MCNCP class of instances (B, F) where B is the incidence matrix of the graph H and F is the incidence matrix of the graph having node set V and arc set $\{(s_1, t_2), (s_2, t_1)\}$. By Theorem 5.2, (B, F) is not SWCD if and only if the directed graph G having $[B| - F]$ as incidence matrix contains a directed cycle including both the arcs (t_2, s_1) and (t_1, s_2). It is immediate to verify that this condition is equivalent to the existence of two node-disjoint paths in H connecting s_1 to t_1 and s_2 to t_2. Since the above transformation is polynomial, the thesis follows. □

Since the MCNCP instances are particular ICP instances, the above result trivially generalizes to the ICP problem.

COROLLARY 5.4. *Determining whether a given class (B, F) of ICP instances is SWCD is a coNP-complete problem.*

5.2. The classes of pre-Leontief instances. Let us now consider the case where F is a nonnegative matrix. As the following simple example shows, this condition does not in general imply the SWCD property.

Example 5.5. Consider any instance (B, F, c, d^+) where B is the incidence matrix of the hypergraph G with node set $V = \{1, 2\}$ and hyperarcs $(\emptyset, \{1, 2\}), (1, \emptyset), (2, \emptyset)$, $F = I$ is the incidence matrix of the hypergraph H having hyperarcs $(\emptyset, 1)$ and $(\emptyset, 2)$, $d^+ = (1, 1)$, and $c > 0$ is any cost vector (see Figure 5.1). The solution $(1, 0, 0)$ is the unique feasible solution of problem LBP(d^+). Nevertheless, there exists no u, $0 \leq u \leq (1, 0, 0)$, such that either $Bu = (1, 0)$ or $Bu = (0, 1)$. Indeed, for each cost vector $c > 0$, the optimal solution of the ICP is given by $\hat{u} = (1, 1, 1)$.

Notwithstanding the previous example, Theorem 4.3 implies the following result.

COROLLARY 5.6. *If F is a nonnegative matrix and each vertex of the polyhedron $P = \{u \in \mathbb{R}^m : Bu = Fe, u \geq 0\}$ is determined by a basis submatrix $\mathcal{B}$ that is inverse nonnegative, i.e., $\mathcal{B}^{-1} \geq 0$, then the class (B, F) is SWCD.*

Proof. The thesis follows by Theorem 4.3 (iii), since the vectors $\mathcal{B}^{-1}Fe^j$, $j =$

$1, \ldots, q$, as products of nonnegative matrices, are nonnegative. □

From a geometric point of view, the conditions stated in Corollary 5.6 simply guarantee that the columns of F are contained in $\mathbb{R}^n_+$ and $\mathbb{R}^n_+ \subseteq cone\{\mathcal{B}\}$ for each basis submatrix $\mathcal{B}$ of B that is feasible for problem LBP(e). So $cone\{F\} \subseteq \mathbb{R}^n_+ \subseteq cone\{\mathcal{B}\}$.

Due to the previous corollary, we are interested in matrices B whose basis submatrices are inverse nonnegative. A fundamental class of matrices that enjoy this property is defined by the pre-Leontief matrices [17].

DEFINITION 5.7. *A matrix B is said to be* pre-Leontief *if each column of B contains at most one positive entry (which can be assumed without loss of generality to be equal to 1). Moreover, B is said to be* Leontief *if each column has exactly one positive element and there exists $\bar{u} \geq 0$ such that $B\bar{u} > 0$.*

Pre-Leontief matrices have been extensively studied for their interest in several fields, such as, for instance, operations management, polyhedral combinatorics, logic, and expert systems. An overview on their applications can be found, e.g., in [11, 12]. Any pre-Leontief matrix B can be seen as the incidence matrix of a directed hypergraph whose hyperarcs have at most one head [11]. So this class includes, in particular, the incidence matrices of directed graphs with generalized flows [1] and hyperarborescences.

The algebraic properties of the linear programming problems defined by a pre-Leontief constraint matrix and their algorithmic consequences were thoroughly investigated in [5, 11, 12, 17].

DEFINITION 5.8. *A problem of the form $\{\min cu : Bu = b,\ u \geq 0\}$ where B is a pre-Leontief (Leontief) matrix is called a* pre-Leontief (Leontief) flow problem. *If, in addition, $b \geq 0$, then the problem is called a* pre-Leontief (Leontief) substitution flow problem.

The following lemma reports some results concerning the structure of the vertices of a pre-Leontief substitution flow problem obtained in [17] (and appearing also in [11]).

LEMMA 5.9. (i) *If A is a pre-Leontief matrix, then after permuting the rows and columns appropriately, A can be written as*

$$\begin{pmatrix} A_1 & A_2 \\ 0 & A_3 \end{pmatrix}, \tag{5.1}$$

where A_1 is Leontief and $A_3x = 0$ for each $x \geq 0$ such that $A_3x \geq 0$.

(ii) *If x is a vertex of a pre-Leontief flow problem defined by the constraint matrix A written as in* (5.1) *and right-hand side $b = (b_1, b_2) \geq 0$, then $x = (x_1, x_2)$, where x_1 is a vertex of $\{x_1 \geq 0 : A_1x = b_1\}$ and $x_2 = 0$ (so $b_2 = 0$).*

(iii) *Any vertex x of a Leontief substitution flow problem is determined by a basis submatrix $\mathcal{B}$ that is Leontief.*

(iv) *Any nonsingular square Leontief matrix has a nonnegative inverse.*

(v) *If a pre-Leontief substitution flow problem with integral constraint matrix and integral right-hand side vector has an optimal solution, then it has an integral optimal solution.*

The above properties of pre-Leontief substitution flow problems carry to the following results.

THEOREM 5.10. *Let (B, F) be a class of ICP instances where B is a pre-Leontief matrix and F is a nonnegative matrix. Then (B, F) is an SWCD class. Moreover, every instance in (B, F) defined by integral B, F, and d^+ admits an integral optimal solution.*

Proof. Since B is a pre-Leontief matrix and $F \geq 0$, problems $LBP(e)$ and $LBP(e^j)$, $j = 1, \ldots, q$, are pre-Leontief substitution flow problems. If B is Leontief, then the thesis follows by Lemma 5.9 (iii)–(iv) and Corollary 5.6. In the opposite case, let B be partitioned as in (5.1) and denote by F_1 and F_2 the matrices formed by the rows of F corresponding to the rows of A_1 and A_3, respectively. Since $F \geq 0$ and $e > 0$, if problem LBP(e) is feasible, then $F_2 = 0$ by Lemma 5.9 (ii). In this case, by Lemma 5.9 (ii) and Theorem 4.3 (iii), the class (B, F) is SWCD if and only if the class (A_1, F_1) is SWCD and, A_1 being a Leontief matrix, the thesis follows by the argument above. The second statement is an immediate consequence of Lemma 5.9 (v). ∎

6. Extensions to more general polyhedra. In this section, we discuss which results of sections 3 and 4 can be generalized to the case where the set $U(u^+)$ introduced in (1.1) has the more general form

$$U_A(u^+) = \{u \in \mathbb{R}^m : u \geq 0,\ Au \leq u^+\}, \tag{6.1}$$

where A is a given nonnegative matrix with at least a nonzero entry in each column. Note that, when A is the identity matrix, $U_A(u^+) = U(u^+)$. This generalization was already considered in [15] for the MCNCP. In this context, a set as in (6.1) defines constraints, called *bundle constraints*, which impose upper bounds on the weighted sum of flows on assigned subsets of arcs, and the corresponding upper bounds are called *generalized capacities*.

Denote by (B, F, c, d^+, A) the generic instance of the ICP where a set $U_A(u^+)$ is considered. We redefine the ICP$_{LP}$ problem as

$$\begin{aligned} z^A_{ICP} &= \min cu^+, \\ Bu^r &= Fd^r \quad \forall r : d^r \in \mathrm{Ext}\{D\}, \\ Au^r &\leq u^+ \quad \forall r : d^r \in \mathrm{Ext}\{D\}, \\ u^r &\geq 0 \quad \forall r : d^r \in \mathrm{Ext}\{D\}. \end{aligned} \tag{6.2}$$

Moreover, we say that (B, F, c, d^+, A) is a WCD instance with respect to the matrix A (WCD(A)) if there exists a demand $\bar{d}$ such that the LPB(d) problem

$$\begin{aligned} z^A_{LBP}(d) &= \min c\tilde{u}, \\ Bu &= Fd, \\ Au &\leq \tilde{u}, \\ u &\geq 0 \end{aligned} \tag{6.3}$$

when $d = \bar{d}$ has the same optimal value of (6.2) and at least one common optimal solution $u^+ = \tilde{u}$.

Unfortunately, as the following example shows, one cannot guarantee that, when an instance is WCD(A), d^+ is a worst case demand.

Example 6.1. Consider the ICP instance (B, F, c, e, A), where B and F are, respectively, the incidence matrices of the networks $G = (V, E_G)$ and $H = (V, E_H)$ with node set $V = \{1, 2, 3, 4\}$ and arc sets $E_G = \{(1, 2), (1, 4), (3, 2), (3, 4)\}$ and $E_H = \{(1, 2), (3, 4)\}$. Let A be the matrix

$$A = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix},$$

so that $u^+ \in \mathbb{R}^4$, and consider the cost vector $c = (1,1,1,1)$. First note that the instance is WCD(A) and $\bar{d} = (1,0)$ is a worst case demand. Indeed, the optimal solution of problem (6.3) when $d = \bar{d}$ is $u^* = (1,0,0,0), \tilde{u}^* = (1,1,1,1)$ of cost $z^A_{LBP}(1,0) = 4$. Moreover, $u^+ = \tilde{u}^* = (1,1,1,1)$ is feasible for problem (6.2) and thus $z^A_{ICP} = z^A_{LBP}(1,0) = 4$. Now consider the maximal demand $d^+ = (1,1)$. When $d = d^+$, the optimal solution of problem (6.3) is $u = (0,1,1,0), \tilde{u} = (0,1,1,0)$ of cost $z^A_{LBP}(1,1) = 2 < z^A_{ICP}$, and thus d^+ is not a worst case demand.

Notwithstanding the previous negative result, let us redefine problem UBP(d) as

$$\begin{aligned} z^A_{UBP}(d) &= \min c\tilde{u}, \\ Bu^j &= Fd^j, \quad j = 1,\dots,q, \\ u &= \sum_{j=1}^{q} u^j, \\ Au &\le \tilde{u}, \\ u^j &\ge 0, \quad j = 1,\dots,q. \end{aligned} \tag{6.4}$$

When $d = d^+$, $z^A_{UBP}(d^+)$ is still an upper bound for z^A_{ICP}. As a consequence, if $z^A_{UBP}(d^+) = z^A_{LBP}(d^+)$, then d^+ is a worst case demand and the instance is WCD(A). This observation allows us to show the following result, which links SWCD classes of ICP instances (as defined in section 4) with classes of WCD(A) instances.

THEOREM 6.2. *If a class (B,F) is SWCD, then any instance (B,F,c,d^+,A) where A is a nonnegative matrix without null columns and $c > 0$ is WCD(A). Moreover, d^+ is a worst case demand.*

Proof. Given a nonnegative matrix A without null columns, an SWCD class (B,F), and a cost vector $c > 0$, let $(u^*_{LBP}, \tilde{u}^*_{LBP})$ and $((u^{j*}_{UBP})^q_{j=1}, u^*_{UBP}, \tilde{u}^*_{UBP})$ denote the optimal solutions of problems (6.3) and (6.4), respectively, for the instance (B,F,c,d^+,A). Then, as it is easy to verify, $\tilde{u}^*_{LBP} = Au^*_{LBP}$ and $\tilde{u}^*_{UBP} = Au^*_{UBP}$. This implies that $z^A_{LBP}(d^+)$ and $z^A_{UBP}(d^+)$ are, respectively, equal to the optimal values $z_{LBP}(d^+)$ and $z_{UBP}(d^+)$ of problems LBP(d^+) and UBP(d^+) for the instance (B,F,cA,d^+). Since $cA > 0$, the instance $(B,F,cA,d^+) \in (B,F)$ and thus is WCD. So, by Theorem 3.4, the equality $z^A_{LBP}(d^+) = z_{LBP}(d^+) = z_{UBP}(d^+) = z^A_{UBP}(d^+)$ holds and the instance (B,F,c,d^+,A) is WCD(A). ∎

The above theorem shows that an SWCD class of instances defines a correspondent class of WCD(A) instances. However, the converse does not hold as the following example shows.

Example 6.3. Consider the ICP instance (B,F,c,e,A), where B and F are, respectively, the incidence matrices of the networks $G = (V,E_G)$ and $H = (V,E_H)$ introduced in Example 6.1 and

$$A = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 \end{bmatrix}.$$

Let $c = (c_1,c_2,c_3,c_4) > 0$ be any nonnegative cost vector and $d^+ = e = (1,1)$. Since the optimal value of both problems (6.3) and (6.4) is $z^A_{LBP}(1,1) = z^A_{UBP}(1,1) = c_1 + c_4$ (with optimal solution $u = (1,0,0,1), \tilde{u} = (1,0,0,1)$), the maximal demand e is a WCD and the instance is WCD(A) for any $c > 0$. However, for $c = (2,1,1,2)$, the ICP instance (B,F,c,e) is not WCD since $z_{LBP}(1,1) = 2 < z_{ICP} = 4$.

Acknowledgment. We are grateful to an anonymous referee for useful suggestions concerning the geometrical aspects of this work.

THE ŁOJASIEWICZ INEQUALITY FOR NONSMOOTH SUBANALYTIC FUNCTIONS WITH APPLICATIONS TO SUBGRADIENT DYNAMICAL SYSTEMS*

JÉRÔME BOLTE†, ARIS DANIILIDIS‡, AND ADRIAN LEWIS§

Abstract. Given a real-analytic function $f : \mathbb{R}^n \to \mathbb{R}$ and a critical point $a \in \mathbb{R}^n$, the Łojasiewicz inequality asserts that there exists $\theta \in [\frac{1}{2}, 1)$ such that the function $|f - f(a)|^\theta \, \|\nabla f\|^{-1}$ remains bounded around a. In this paper, we extend the above result to a wide class of nonsmooth functions (that possibly admit the value $+\infty$), by establishing an analogous inequality in which the derivative $\nabla f(x)$ can be replaced by any element x^* of the subdifferential $\partial f(x)$ of f. Like its smooth version, this result provides new insights into the convergence aspects of subgradient-type dynamical systems. Provided that the function f is sufficiently regular (for instance, convex or lower-C^2), the bounded trajectories of the corresponding subgradient dynamical system can be shown to be of finite length. Explicit estimates of the rate of convergence are also derived.

1. Introduction.

Let U be a nonempty open subset of $\mathbb{R}^n$ equipped with its canonical Euclidean norm $||\cdot||$, and let $f : U \to \mathbb{R}$ be a real-analytic function. According to the Łojasiewicz gradient inequality [16, 17, 18], if $a \in U$ is a *critical* point of f, that is, $\nabla f(a) = 0$, then there exists $\theta \in [0, 1)$ such that the function

$$\frac{|f - f(a)|^\theta}{\|\nabla f\|} \tag{1}$$

remains bounded around the point a. (Throughout this work we set $0^0 = 1$, and we interpret $\lambda/0$ as $+\infty$ if $\lambda > 0$ and 0 if $\lambda = 0$.)

Recently, Kurdyka [13, Theorem 1] has extended the above result to C^1 functions whose graphs belong to an o-minimal structure (see [8], for example), and thus in particular to "globally subanalytic" functions. On the other hand, (1) might fail for C^∞ functions with no "adequate" geometric structure. Such functions can either satisfy a weaker condition (i.e., $\theta = 1$) or present wild oscillations around their critical point, preventing any comparison between their value and the norm of their gradient.

The following one-dimensional examples illustrate failures of these two types (around the critical point $a = 0$):

$$f(x) = \begin{cases} \exp(-1/x^2) & \text{if } x \neq 0, \\ 0 & \text{if } x = 0, \end{cases} \quad \text{and} \quad g(x) = \begin{cases} \exp(-1/x^2)\sin(1/x) & \text{if } x \neq 0, \\ 0 & \text{if } x = 0. \end{cases}$$

The aim of this note is to establish a *nonsmooth* version of the Łojasiewicz inequality (1) for lower semicontinuous convex subanalytic functions (Theorem 3.3) and for continuous subanalytic functions (Theorem 3.1). A first and simple illustration is given by the example of the Euclidean norm function $h(x) = \|x\|$, which satisfies (1) for every $\theta \in [0, 1)$ around zero (which is a "generalized" critical point; see Definition 2.11) but is not differentiable at 0. Behavior of this type is hereby shown to hold true for a large class of nonsmooth functions, leading to the conclusion that the Łojasiewicz inequality is more linked to the underlying geometrical structure of f than to its smoothness.

Given an extended-real-valued subanalytic function $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$, our approach to generalizing property (1) relies on a one-sided notion of generalized gradients called subgradients. For both a mathematical and a historical account on this notion, as well as for classical results in nonsmooth analysis, one is referred to the monographs of Clarke et al. [7] and Rockafellar and Wets [20].

Subgradients are obtained according to a two-stage process. First the equality in the definition of the usual gradient is relaxed into an inequality (Definition 2.10(i)): this gives rise to the notion of Fréchet subgradients. Then, by a closure operation, the so-called limiting subdifferential ∂f can be defined (Definition 2.10(ii)). This notion constitutes the basis for the generalization of the Łojasiewicz inequality to nonsmooth functions. Let us also mention that in this formalism Fermat's rule reads as follows: if a is a local minimizer of f, then $\partial f(a) \ni 0$; conversely, if $a \in \mathbb{R}^n$ is such that $\partial f(a) \ni 0$, the point a is called a critical point.

Variational analysis and subdifferential calculus provide a framework for the modeling of unilateral constraints in mechanics and in partial differential equations [11, 6, 9]. Such a calculus is also central in optimization. In particular it provides variational tools to treat constrained and unconstrained minimization problems on an equal theoretical level. This stems from the simple fact that minimizing f over a closed set C amounts to minimizing $f + \delta_C$ over $\mathbb{R}^n$, where δ_C is the indicator function of C; that is

$$\delta_C(x) = \begin{cases} 0 & \text{if } x \in C, \\ +\infty & \text{otherwise.} \end{cases} \tag{2}$$

Those domains have as a common topic the behavior at infinity of dynamical systems governed by subdifferential operators; see [15] for an insight in optimization. An important motivation that drove us to transpose the Łojasiewicz result into a nonsmooth context is precisely its expected consequences in the asymptotic analysis of such subgradient-type dynamical systems. Those are modeled on the following type of differential inclusion:

$$\dot{x}(t) \in -\partial f(x(t)), \quad t \geq 0, \quad x(0) \in \mathbb{R}^n,$$

where for any $x \in \mathbb{R}^n$, $\partial f(x)$ denotes the set of limiting subgradients. The above differential inclusion generalizes the classical gradient dynamical system

$$\dot{x}(t) = -\nabla f(x(t)), \quad t \geq 0, \quad x(0) \in \mathbb{R}^n. \tag{3}$$

In his pioneering work on real-analytic functions [16, 17], Łojasiewicz provided the main ingredient—namely, (1)—that allows us to derive the convergence of all bounded trajectories of (3) to critical points. As can be seen from a counterexample due to Palis and De Melo [19, p. 14], the set of cluster points of a bounded trajectory generated by the gradient of a C^∞ function is, in general, far from being a singleton. Those famous results illustrate the importance of gradient vector fields of functions satisfying the Łojasiewicz inequality. An even more striking feature is that the trajectories converge "in direction" when approaching critical points. This fact had been conjectured by Thom (around 1972; see [22]) for real-analytic functions, and established by Kurdyka, Mostowski, and Parusiński in [14]. The subanalytic generalized Thom conjecture remains open even in the smooth case (see [13, Conjecture F]).

In section 4 we extend Łojasiewicz results to a nonsmooth setting (f is a subanalytic proximal retract), by showing that all bounded trajectories have a finite length (Theorem 4.5). We also provide estimates of the asymptotic convergence rate towards the critical points (Theorem 4.7).

For related results on this topic, see [1] ; for other applications to partial differential equations, see the works of Simon [21] and Haraux [12].

2. Preliminaries. The key ingredients for the nonsmooth extension of the Łojasiewicz inequality are subanalyticity of the function f and notions of generalized differentiation provided by variational analysis.

2.1. Subanalytic sets and stability properties. We recall the following definition.

DEFINITION 2.1 (subanalyticity). (i) *A subset A of $\mathbb{R}^n$ is called* semianalytic *if each point of $\mathbb{R}^n$ admits a neighborhood V for which $A \cap V$ assumes the following form:*

$$\bigcup_{i=1}^{p} \bigcap_{j=1}^{q} \{x \in V : f_{ij}(x) = 0, g_{ij}(x) > 0\},$$

where the functions $f_{ij}, g_{ij} : V \mapsto \mathbb{R}$ are real-analytic for all $1 \le i \le p, 1 \le j \le q$.

(ii) *The set A is called* subanalytic *if each point of $\mathbb{R}^n$ admits a neighborhood V such that*

$$A \cap V = \{x \in \mathbb{R}^n : (x, y) \in B\},$$

where B is a bounded semianalytic subset of $\mathbb{R}^n \times \mathbb{R}^m$ for some $m \ge 1$.

(iii) *Given $m, n \in \mathbb{N}^*$, a function $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ (respectively, a point-to-set operator $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^m$) is called* subanalytic *if its graph is a subanalytic subset of $\mathbb{R}^n \times \mathbb{R}$ (respectively, of $\mathbb{R}^n \times \mathbb{R}^m$).*

Recall that the graphs of f and T, denoted respectively by $\operatorname{Gr} f$ and $\operatorname{Gr} T$, are defined by

$$\operatorname{Gr} f := \{(x, \lambda) \in \mathbb{R}^n \times \mathbb{R} : f(x) = \lambda\}, \qquad \operatorname{Gr} T := \{(x, y) \in \mathbb{R}^n \times \mathbb{R}^m : y \in T(x)\}.$$

Some of the elementary properties of subanalytic sets have been gathered below (see, e.g., [4, 10, 18]):

- Subanalytic sets are closed under locally finite union and intersection. The complement of a subanalytic set is subanalytic (Gabrielov theorem).
- If A is subanalytic, then so are its closure $\operatorname{cl} A$, its interior $\operatorname{int} A$, and its boundary $\operatorname{bd} A$.

- Given a subanalytic set S, the distance $d_S(x) := \inf\{\|x-a\| : a \in S\}$ is a subanalytic function.
- *Path connectedness* (see, e.g., [10, Facts 1.10–1.12]): Any subanalytic set has a locally finite number of connected components. Each component is subanalytic and subanalytically path connected; that is, every two points can be joined by a continuous subanalytic path that lies entirely in the set.
- *Curve selection lemma* (see, e.g., [4, Lemma 6.3]): If A is a subanalytic subset of $\mathbb{R}^n$ and $a \in \operatorname{bd} A$, then there exists an analytic path $z : (-1,1) \to \mathbb{R}^n$ satisfying $z(0) = a$ and $z((0,1)) \subset A$.

The image and the preimage of a subanalytic set are not in general subanalytic sets. This is essentially due to the fact that the image of an unbounded subanalytic set by a linear projection may fail to be subanalytic. Consider, for instance, the set $\{(\frac{1}{n+1}, n) : n \in \mathbb{N}\}$, whose projection onto $\mathbb{R} \times \{0\}$ is not subanalytic at 0.

To remedy to this lack of stability, let us introduce a stronger analytic-like notion called global subanalyticity (see [10] and references therein).

For each $n \in \mathbb{N}$, set $C_n = (-1,1)^n$ and define τ_n by

$$\tau_n(x_1, \dots, x_n) = \left(\frac{x_1}{1+x_1^2}, \dots, \frac{x_n}{1+x_n^2} \right) \in C_n.$$

DEFINITION 2.2 (global subanalyticity; see, e.g., [10, p. 506]). (i) *A subset S of $\mathbb{R}^n$ is called* globally subanalytic *if its image under τ_n is a subanalytic subset of $\mathbb{R}^n$.*

(ii) *An extended-real-valued function (respectively, a multivalued mapping) is called globally subanalytic if its graph is globally subanalytic.*

Globally subanalytic sets are subanalytic, and conversely any *bounded* subanalytic set is globally subanalytic. Typical examples of subanalytic sets which are not globally subanalytic are the set of integers $\mathbb{Z}$, the graph of the sinus function, the spiral $\{(t\cos t, t\sin t) \in \mathbb{R}^2 : t \geq 0\}$, etc. The class of semialgebraic sets (e.g., [3, 8]) provides an important subclass of globally subanalytic sets. Recall that a set $A \subset \mathbb{R}^n$ is called *semialgebraic* if it assumes the following form:

$$A = \bigcup_{i=1}^{p} \bigcap_{j=1}^{q} \{x \in V : f_{ij}(x) = 0, g_{ij}(x) > 0\},$$

where $f_{ij}, g_{ij} : \mathbb{R}^n \mapsto \mathbb{R}$ are polynomial functions for all $1 \leq i \leq p, 1 \leq j \leq q$. (Readers who are unfamiliar with subanalytic geometry might in a first reading replace "subanalytic" and "globally subanalytic" by "semialgebraic" in the statements that follow.)

A major fact concerning the class of globally subanalytic sets is its stability under linear projections.

THEOREM 2.3 (projection theorem; see, e.g., [10, Example 4, p. 505]). *Let $\Pi(x_1, \dots, x_{n+1}) = (x_1, \dots, x_n)$ be the canonical projection from $\mathbb{R}^{n+1}$ onto $\mathbb{R}^n$. If S is a globally subanalytic subset of $\mathbb{R}^{n+1}$, then so is $\Pi(S)$ in $\mathbb{R}^n$.*

Among the numerous consequences of the above result in terms of stability, the following properties are crucial to our main results:

- The image or the preimage of a globally subanalytic set by a globally subanalytic function (respectively, globally subanalytic multivalued operator) is globally subanalytic (see, e.g., [10, p. 504]).
- *Monotonicity lemma* (e.g., [10, Fact 4.1]): Take $\alpha < \beta$ in $\mathbb{R}$. If $\varphi : (\alpha, \beta) \to \mathbb{R}$ is a globally subanalytic function, then there is a partition $t_0 := \alpha < t_1 <$

$\cdots < t_{l+1} := \beta$ of (α, β) such that $\varphi|_{(t_i, t_{i+1})}$ is C^∞ and either constant or strictly monotone, for $i \in \{0, \dots, l\}$. Moreover ([13], e.g.), φ admits a *Puiseux development* at $t = \alpha$; that is, there exists $\delta > 0$, a positive integer k, $l \in \mathbb{Z}$, and $\{a_n\}_{n \geq l} \subset \mathbb{R}$ such that

$$\varphi(t) = \sum_{n \geq l} a_n (t - \alpha)^{n/k} \quad \text{for all } t \in (\alpha, \alpha + \delta).$$

– *Łojasiewicz factorization lemma* (e.g., [4, Theorem 6.4]): Let $K \subset \mathbb{R}^n$ be a compact set and $f, g : K \to \mathbb{R}$ two continuous (globally) subanalytic functions. If $f^{-1}(0) \subset g^{-1}(0)$, then there exist $c > 0$ and a positive integer r such that $|g(x)|^r \leq c\,|f(x)|$ for all $x \in K$.

2.2. Notions from nonsmooth analysis and further stability results. Throughout this paper, we essentially deal with nondifferentiable functions defined on $\mathbb{R}^n$ with values in $\mathbb{R} \cup \{+\infty\}$. We denote by $\operatorname{dom} f$ the domain of the function, that is, the subset of $\mathbb{R}^n$ on which f is finite. In a similar way, the domain of a point-to-set operator $T : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$, denoted by $\operatorname{dom} T$, is defined as the subset of $\mathbb{R}^n$ on which T is nonempty. The epigraph and the strict epigraph of f are respectively defined by

$$\operatorname{epi} f := \{(x, \lambda) \in \mathbb{R}^n \times \mathbb{R} : \lambda \geq f(x)\}, \qquad \operatorname{epi}_s f := \{(x, \lambda) \in \mathbb{R}^n \times \mathbb{R} : \lambda > f(x)\},$$

while the *epigraphical sum* of two extended-real-valued functions $f, g : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ is the function defined by

$$\mathbb{R}^n \ni u \longmapsto h(u) \;=\; \inf\{f(v) + g(v - u) : v \in \mathbb{R}^n\} \in [-\infty, +\infty].$$

The terminology stems from the fact that the strict epigraph of h is the Minkowski sum of the strict epigraphs of f and g.

Even if $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ is subanalytic, its domain and its epigraph may fail to be subanalytic sets.

Example 2.4. Consider the function $f : \mathbb{R} \to \mathbb{R} \cup \{+\infty\}$ whose graph is given by the set $S := \{(\frac{1}{n}, n)\}$. Then the domain of f is not subanalytic, whereas its graph is. If $g : \mathbb{R} \to \mathbb{R} \cup \{+\infty\}$ has $-S := \{(-\frac{1}{n}, -n) : n \in \mathbb{N}\}$ as its graph, both its domain and epigraph are not subanalytic.

Additional geometrical properties like convexity are also not sufficient to obtain regularity on the domain. This is shown in the example below.

Example 2.5. Let $\{q_n\}_{n \geq 1}$ be an enumeration of the rationals $\{q_n\}$, and define $h : \mathbb{R}^2 \to \mathbb{R} \cup \{+\infty\}$ in polar coordinates by

$$h(r, \theta) = \begin{cases} 0 & \text{if } r \in [0, 1), \\ n & \text{if } r = 1 \text{ and } \theta = q_n \pmod{2\pi}, \\ +\infty & \text{otherwise.} \end{cases}$$

Then h is convex and subanalytic, but its domain is not subanalytic.

As expected, such a behavior can be avoided by requiring the function to be globally subanalytic. The following two results are basic consequences of the projection theorem.

PROPOSITION 2.6. *Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a globally subanalytic function. Then the domain, the epigraph, and the strict epigraph of f are globally subanalytic sets.*

PROPOSITION 2.7. *Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a subanalytic function which is relatively bounded on its domain; that is, $\{f(x) : x \in dom\, f \cap B\}$ is bounded for every bounded subset B of $\mathbb{R}^n$. Then the domain, the epigraph, and the strict epigraph of f are subanalytic sets.*

Remark 2.8. Observe that Propositions 2.6 and 2.7 involve distinct assumptions and provide different results. This can be seen by considering, for instance, the subanalytic functions $f(x) = x^{-1}$ with dom $f = (0, +\infty)$ and $g := \delta_{\mathbb{N}}$.

The case for which functions under consideration are convex but not necessarily continuous requires more attention.

PROPOSITION 2.9. *Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous convex and subanalytic function such that $\inf_{\mathbb{R}^n} f \in \mathbb{R}$. Define $h : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ as the epigraphical sum of f and the square function $\frac{1}{2}||\cdot||^2$, that is,*

$$h(x) = \inf\left\{f(u) + \frac{1}{2}||x-u||^2 : u \in \mathbb{R}^n\right\}, \quad x \in \mathbb{R}^n.$$

Then h is a C^1 subanalytic function.

Proof. The proof consists mainly of showing that the epigraphical sum of a convex function with a coercive function is a "graphically local" operation. The fact that h takes finite values and is a C^1 function is a classical result (see [20], for example). Therefore it suffices to prove that $h + \delta_B$ is subanalytic for every bounded subset B of $\mathbb{R}^n$. Let us fix some nonempty bounded set B of $\mathbb{R}^n$, and let us set $M = \sup\{h(x) : x \in B\}$. Thanks to the continuity of h we have $M < +\infty$.

The infimum in the definition of $h(x)$ is always attained at a unique point denoted $J(x)$, and the mapping $J : \mathbb{R}^n \to \mathbb{R}^n$ so defined is a nonexpansive mapping (see [6]). Moreover, the function f is bounded on the bounded set $J(B)$. Indeed, if $u = J(b)$ for some $b \in B$, the definition of J implies that

$$f(u) = f(J(b)) = h(b) - \frac{1}{2}||b - J(b)||^2 < M.$$

Let C be some ball containing the bounded set $J(B)$, and let $f^M : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be the function whose graph is given by Gr $f \cap (C \times [\inf_{\mathbb{R}^n} f, M])$. By definition the function f^M has a bounded subanalytic graph, and it is therefore globally subanalytic. According to the above considerations the values of h on B coincide with those of the function

$$\hat{h}(x) := \inf\left\{f^M(u) + \frac{1}{2}||x-u||^2 : u \in \mathbb{R}^n\right\}, \quad x \in \mathbb{R}^n.$$

The strict epigraph of $\hat{h}$ is the sum of the strict epigraphs of the bounded subanalytic function f^M and the square function $u \mapsto \frac{1}{2}||x-u||^2$ (which is globally subanalytic for it is semialgebraic). This yields that $\hat{h}$ (and consequently $h + \delta_B$) is globally subanalytic; hence h is subanalytic. ∎

The notion of subdifferential—that is, an appropriate multivalued operator playing the role of the usual gradient mapping—is crucial for our considerations. In what follows we denote by $\langle \cdot, \cdot \rangle$ the usual Euclidean product of $\mathbb{R}^n$.

DEFINITION 2.10 (subdifferential; see, e.g., [20, Definition 8.3]). (i) *The* Fréchet subdifferential $\hat{\partial} f(x)$ *of a lower semicontinuous function f at $x \in \mathbb{R}^n$ is given by*

$$\hat{\partial} f(x) = \left\{x^* \in \mathbb{R}^n : \liminf_{y \to x, y \neq x} \frac{f(y) - f(x) - \langle x^*, y - x\rangle}{\|y - x\|} \geq 0\right\}$$

whenever $x \in dom\, f$, and by $\hat{\partial} f(x) = \emptyset$ otherwise.

(ii) *The* limiting subdifferential *at $x \in \mathbb{R}^n$, denoted by $\partial f(x)$, is the set of all cluster points of sequences $\{x_n^*\}_{n\geq 1}$ such that $x_n^* \in \hat{\partial} f(x_n)$ and $(x_n, f(x_n)) \to (x, f(x))$ as $n \to +\infty$.*

If the function f is of class C^1, the above notion coincides with the usual concept of gradient; that is, $\partial f(x) = \hat{\partial} f(x) = \{\nabla f(x)\}$. For a general lower semicontinuous function, the limiting subdifferential $\partial f(x)$ (thus, a fortiori the Fréchet subdifferential $\hat{\partial} f(x)$) can possibly be empty at several points $x \in \operatorname{dom} f$. Nevertheless (see, e.g., [20, Chapter 8]), both the domain of $\hat{\partial} f$ and (a fortiori) the domain of ∂f are dense in the domain of f.

Using the limiting subdifferential ∂f, we define the *nonsmooth slope* of f by

$$m_f(x) := \inf\{\|x^*\| : x^* \in \partial f(x)\}. \tag{4}$$

By definition, $m_f(x) = +\infty$ whenever $\partial f(x) = \emptyset$.

Let us recall that if f is continuous, the operator $\partial f : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ has a closed graph. This is also the case for a lower semicontinuous convex function, where both $\partial f(x)$ and $\hat{\partial} f(x)$ coincide with the classical subdifferential of convex analysis; that is,

$$\partial f(x) = \hat{\partial} f(x) = \{x^* \in \mathbb{R}^n : f(\cdot) - \langle x^*, \cdot\rangle \text{ has a global minimum at } x\}. \tag{5}$$

We are ready to state the notion of generalized critical point (in the sense of variational analysis).

Definition 2.11 (critical point). *A point $a \in \mathbb{R}^n$ is said to be a (generalized)* critical point *of the function $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ if it belongs to the set*

$$\operatorname{crit} f := \{x \in \mathbb{R}^n : 0 \in \partial f(x)\}.$$

Remark 2.12. If f is lower semicontinuous convex or if $\operatorname{dom} f$ is closed and $f\,|_{\operatorname{dom} f}$ is continuous, then the graph of ∂f is closed, which implies that the set $\operatorname{crit} f$ of the critical points of f is closed. In that case, let us also observe that the slope $m_f(x)$ is a lower semicontinuous function, and that

$$\operatorname{crit} f = m_f^{-1}(0).$$

The following result illustrates further the properties of stability of subanalytic sets recalled in subsections 2.1 and 2.2.

Proposition 2.13. *Let f be an extended-real-valued function.*

(i) *If f is globally subanalytic, then the operators $\hat{\partial} f$ and ∂f, the function m_f, and the set* $\operatorname{crit} f$ *are globally subanalytic.*

(ii) *If f is subanalytic and relatively bounded on its domain, then the operators $\hat{\partial} f$ and ∂f, the function m_f, and the set* $\operatorname{crit} f$ *are subanalytic.*

Proof. The local nature of the Fréchet and the limiting subdifferential allows us to restrict our proof to the globally subanalytic function $f_B := f + \delta_B$, where B is some nontrivial ball. It suffices therefore to establish (i).

Thanks to the projection theorem (Theorem 2.3), the proof becomes a routine application of [8, Theorem 1.13], which asserts that if $\Phi(x_1, \ldots, x_n)$ is a first order formula (in the language of the subanalytic structure of $\mathbb{R}^n$), then the set $\{(x_1, \ldots, x_n) \in \mathbb{R}^n : \Phi(x_1, \ldots, x_n)\}$ is definable, or in other words, it belongs to the structure.[1]

[1] Global subanalytic sets form a model-complete first order theory. In fact, whether or not a structure is "model complete" depends only on the theory of the structure, that is, the set of the sentences (i.e., quantifier-free formulas) of its language which are true in this theory. We refer to [23, p. 1052] for more details.

As an illustration of this standard technique, let us prove that the operator $\hat{\partial} f : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ is globally subanalytic. To this end, set $A = \operatorname{epi} f$, $\Gamma = \operatorname{Gr} f$, and $D = \operatorname{dom} f$, which are all globally subanalytic sets. According to Definition 2.10(ii) the graph $\operatorname{Gr} \hat{\partial} f$ of the Fréchet subdifferential $\hat{\partial} f(x)$ is the set of $(x, x^*) \in \mathbb{R}^n \times \mathbb{R}^n$ such that

$$\forall \varepsilon > 0, \exists \delta > 0, \forall (y, \beta) \in (B(x, \delta) \times \mathbb{R}) \cap A \Rightarrow (x, \beta - \langle x^*, y - x \rangle + \varepsilon \|y - x\|) \in A,$$

where $B(x, \delta)$ denotes the open ball of center x and radius $\delta > 0$. Since the above first order formula involves only globally subanalytic sets (namely, the subanalytic sets $B(x, \delta), \mathbb{R}$, and A), it follows that $\operatorname{Gr} \hat{\partial} f$ is subanalytic.

Subanalyticity of the graphs of the operator ∂f and of the function m_f can be proved similarly. Finally, $\operatorname{crit} f$ being the inverse image of (the subanalytic set) $\{0\}$ by m_f, it is a subanalytic set. □

Similarly one obtains the following corollary.

COROLLARY 2.14. *Under the assumptions of Proposition* 2.13(ii), *the restrictions of the multivalued mappings* $\hat{\partial} f$, ∂f, *and of the slope function* m_f *to any bounded subanalytic subset of* $\mathbb{R}^n$ *are globally subanalytic.*

Remark 2.15. The assumptions (and consequently the results) of the statements (i) and (ii) of Proposition 2.13 are of different natures. For example, let us consider the lower semicontinuous convex function $f : \mathbb{R}^2 \to \mathbb{R} \cup \{+\infty\}$, defined by

$$f(x, y) = \begin{cases} x^2/y & \text{if } y > 0, \\ 0 & \text{if } x = y = 0, \\ +\infty & \text{elsewhere.} \end{cases}$$

Then Proposition 2.13(i) applies, but not (ii), since f is not relatively bounded on $\operatorname{dom} f$.

3. Main results.

3.1. The Łojasiewicz inequality for subanalytic continuous functions. Assuming f subanalytic, and having a closed domain relative to which it is continuous, the set $\operatorname{crit} f$ is closed (Remark 2.12) and subanalytic (Proposition 2.13), so it has a locally finite number of connected components (see subsection 2.1). For any a in $\operatorname{crit} f$, let us denote by $(\operatorname{crit} f)_a$ the connected component of $\operatorname{crit} f$ containing a. In [5, Theorem 13] it has been established that

$$f \text{ is constant on } (\operatorname{crit} f)_a . \tag{6}$$

The proof of (6) relies on a fundamental structural result about subanalytic functions (stratification) and on the Pawłucki generalization of the Puiseux lemma; see [5]. Nevertheless, (6) can be easily proved for continuous functions that also satisfy

$$\hat{\partial} f(x) = \partial f(x) \quad \text{for all } x \in \mathbb{R}^n. \tag{7}$$

Indeed, given x and y in some connected component S_i of $\operatorname{crit} f$, we consider the continuous subanalytic path $z : [0, 1] \to S_i$ with $z(0) = x$ and $z(1) = y$, and the subanalytic function $h(t) = (f \circ z)(t)$ (see subsection 2.1). Since $0 \in \hat{\partial} f(z(t))$ for all $t \in [0, 1]$, from the "monotonicity lemma" and the chain rule for the Fréchet subdifferential [20, Theorem 10.6] we get $h'(t) = 0$ for almost all t. It follows that h is constant on $[0, 1]$, whence $f(x) = f(y)$.

Examples of continuous functions that satisfy (7) are C^1 functions (for which $\partial f(x) = \hat{\partial} f(x) = \{\nabla f(x)\}$), proximal retracts (or lower-C^2 functions; see [20, Definition 10.29] and section 4), or more generally subdifferentially regular functions [20, Definition 7.25].

The main result of subsection 3.1 can now be stated as follows.

THEOREM 3.1. *Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a subanalytic function with closed domain, and assume that $f\,|_{\mathrm{dom} f}$ is continuous. Let $a \in \mathbb{R}^n$ be a critical point of f. Then there exists an exponent $\theta \in [0, 1)$ such that the function*

$$\frac{|f - f(a)|^\theta}{m_f} \tag{8}$$

is bounded around a.

Note that we have adopted here the following conventions: $0^0 = 1$ and $\infty/\infty = 0/0 = 0$.

Proof. Let us set $S = \operatorname{crit} f$ and $S_a = (\operatorname{crit} f)_a$. Replacing if necessary f by $g(x) = f(x) - f(a)$, there is no loss of generality to assume $f(a) = 0$, so that (6) implies $S_a \subset f^{-1}(0)$.

We may also assume that f is globally subanalytic and that the set S_a is compact. Indeed, if this is not the case, then we replace the function f by the globally subanalytic function g defined (for some $R > 0$) by $g(x) = f(x) + \delta_{\bar{B}(a,R)}(x)$, where $\delta_{\bar{B}(a,R)}$ denotes the indicator function of the closed ball $\bar{B}(a, R)$. Then g has a closed domain relative to which it is continuous, a is a critical point for g, and $(\operatorname{crit} g)_a \cap B(a, R) = S_a \cap B(a, R)$. Establishing (8) for f is thus the equivalent of doing so for the globally subanalytic function g.

It is also sufficient to establish separately that the function $x \mapsto [m_f(x)]^{-1} |f(x)|^\theta$ is bounded when x varies inside the subanalytic set $f^{-1}((0, +\infty])$, and subsequently to do the same when x varies in $f^{-1}((-\infty, 0])$. Since this latter assertion will follow by reproducing essentially the same arguments, we may assume with no loss of generality that $f \geq 0$.

Let us choose $\Delta > 0$ so that the compact set $U = \{x \in \mathbb{R}^n : d_{S_a}(x) \leq \Delta\} \cap \mathrm{dom}\, f$ separates S_a from the other connected components of S. Note that U is a globally subanalytic set (see subsection 2.1). We claim that for all $\bar{x}$ in the boundary of S_a we have

$$\lim_{\substack{x \to \bar{x} \\ x \in U \setminus S_a}} \frac{f(x)}{m_f(x)} = 0. \tag{9}$$

If the above limit were not zero, there would exist a sequence $\{(x_p, x_p^*)\}$ in $\mathrm{Gr}\, \partial f$ and $r > 0$ with $x_p \to \bar{x}$ as $p \to +\infty$ and such that $f(x_p) > r||x_p^*|| > 0$ for all p. By the definition of the limiting subdifferential there exists a sequence $(y_p, y_p^*) \in \mathrm{Gr}\, \hat{\partial} f$ such that $f(y_p) > r||y_p^*|| > 0$, where y_p converges to $\bar{x}$. This proves that for some $r > 0$ the point $\bar{x}$ belongs to the closure of the set

$$F = \{x \in U \setminus S_a : \exists x^* \in \hat{\partial} f(x), f(x) > r\, ||x^*|| > 0\}.$$

Owing to Proposition 2.13 (i) the latter set is globally subanalytic, so by the "curve selection lemma" (subsection 2.1) there exists an analytic curve $z : (-1, 1) \to \mathbb{R}^n$ with $z(0) = \bar{x}$ and $z((0, 1)) \subset F$. Hence for all small $t > 0$ there exists a nonzero subgradient $z^*(t) \in \hat{\partial} f(z(t))$ satisfying

$$f(z(t)) > r\, \|z^*(t)\| > 0. \tag{10}$$

Thanks to the continuity of $f\,|_{\mathrm{dom} f}$ at $\bar{x} = z(0)$ the subanalytic function

$$[0,1) \ni t \mapsto h(t) = (f \circ z)(t)$$

is continuous at $t = 0$, and (6) implies that $h(0) = f(\bar{x}) = 0$. Applying the "monotonicity lemma" (subsection 2.1) to the globally subanalytic function h and the chain rule calculus for the Fréchet subdifferential [20, Theorem 10.6], we get for t small enough that $|h'(t)| \leq M \|z^*(t)\|$, where $M = \max\{\|\dot{z}(t)\| : t \in (-1/2, 1/2)\}$. Then by applying (10), it follows that

$$\frac{h(t)}{|\,h'(t)\,|} > r\,M^{-1} > 0 \qquad \text{for all small } t > 0. \tag{11}$$

Considering the Puiseux development of h around $t = 0$ (see subsection 2.1), we conclude that for some positive rational q and some $c > 0$ we have $h(t) = ct^q + o(t^q)$ for all small $t > 0$. By differentiating the Puiseux development of h at $t = 0$ and substituting into (11), we obtain a contradiction.

Let us now establish (8). To this end, let us consider the globally subanalytic function

$$\varphi(t) = \inf\{m_f(x) : x \in U \cap f^{-1}(t)\} \quad \text{if } t \in \mathbb{R}_+.$$

Clearly $\varphi(0) = 0$, while from the definition of U, it ensues that $0 < \varphi(t) \leq +\infty$ for all small $t > 0$. If for every $\delta > 0$ the function φ assumes at least one infinite value in the interval $(0, \delta)$, then the subanalyticity of dom φ guarantees that 0 is an isolated point in dom φ. In this case (8) holds trivially. We may thus assume that φ is finite around 0. Evoking again the "monotonicity lemma" (subsection 2.1), we deduce that

$$l = \lim_{t \to 0^+} \varphi \in [0, +\infty].$$

In case $l \neq 0$, equation (8) follows easily (with $\theta = 0$), so we may assume $l = 0$ and φ continuous. In this case, we consider the Puiseux expansion of φ, which has the form

$$\varphi(t) = \sum_{n=0}^{+\infty} a_n t^{\frac{n}{k}} \quad \text{for all small } t > 0,$$

where k is a positive integer. Let $n_0 \in \mathbb{N}^*$ be the first integer such that $a_{n_0} \neq 0$, and let us set $\eta = \frac{n_0}{k}$. Then

$$\varphi(t) = ct^\eta + o(t^\eta), \tag{12}$$

where $c := a_{n_0} > 0$. Unless (8) holds trivially, we may assume by (6) that there exists a sequence $\{x_\nu\}_\nu \subset U \smallsetminus S_a$ such that $x_\nu \to a$, $m_f(x_\nu) \to 0$, and $f(x_\nu) \geq 0$. Let us consider the globally subanalytic set

$$A = \{x \in U \smallsetminus S_a : m_f(x) = \varphi(f(x)),\ f(x) \geq 0\} \neq \emptyset.$$

We claim that

$$\mathrm{cl}\, A \cap S_a \neq \emptyset. \tag{13}$$

Indeed, if (13) were not true, then by a standard compactness argument, there would exist an open neighborhood V around S_a such that $S_a \subset V \cap \mathrm{dom}\, f \subset U$

and $A \cap V = \emptyset$. Setting $t_\nu = f(x_\nu)$ (for the sequence $\{x_\nu\}_\nu$ mentioned above) and considering $y_\nu \in U$ such that $m_f(y_\nu) = \varphi(t_\nu)$ (by Remark 2.12, m_f is lower semicontinuous) and $f(y_\nu) = t_\nu$, we would obtain $\{y_\nu\}_\nu \subset U \setminus V$. By compactness, we could then assume that $y_\nu \to y \in U \setminus V$, which would yield (by continuity of φ) that $m_f(y) = 0$, that is, $y \in S_a$, and a contradiction follows.

Thus (13) holds, and there exists an analytic curve $z : (-1, 1) \to \mathbb{R}^n$ with $z(0) := b \in S_a$ and $z((0, 1)) \subset A$. As $s \searrow 0^+$ we get (by continuity of f and φ) that $f(z(s)) \to 0$ and $m_f(z(s)) = \varphi(f(z(s))) \to 0$. We deduce from (12) that

$$m_f(z(s)) = c(f(z(s)))^\eta + o((f(z(s))^\eta),$$

so (9) implies that $\eta < 1$. Take $\theta \in (\eta, 1)$ and apply (12) to obtain the existence of $t_0 > 0$ such that $\varphi(t) \geq ct^\theta$ for all $t \in [0, t_0)$. By using the continuity of $f \mid_{\operatorname{dom} f}$ at a, it follows that there exists $\mu > 0$ such that $|f(x)| < t_0$ for all $x \in \operatorname{dom} f \cap B(a, \mu)$. Finally, to obtain (8), we simply observe that

$$m_f(x) \geq \varphi(f(x)) \geq cf(x)^\theta \quad \text{for all } x \in B(a, \mu).$$

The proof is complete. □

Remark 3.2. Let us note that (8) still holds around any point $a \in \operatorname{dom} f \setminus \operatorname{crit} f$. Indeed, if $a \notin \operatorname{crit} f$, then $m_f(x)$ is bounded below away from 0 in a neighborhood of a, so (8) follows from the continuity of f. In this case, the assumption of subanalyticity is obviously not needed.

3.2. The Łojasiewicz inequality for subanalytic lower semicontinuous convex functions. In this subsection we are interested in lower semicontinuous convex subanalytic functions $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ which are somewhere finite, that is, convex functions for which $\operatorname{dom} f \neq \emptyset$. In this case, in view of (5), the set of critical points $\operatorname{crit} f$ is closed and convex and coincides with the set of minimizers of f.

Before proceeding let us recall classical facts from convex analysis (e.g., [20]). Let us denote by g the epigraphical sum of f and $\frac{1}{2}\|\cdot\|^2$ (see Proposition 2.9). The function $g : \mathbb{R}^n \to \mathbb{R}$ is finite-valued, and C^1 and enjoys the following properties:

(a) $g \leq f$.

(b) The set of critical points of g is exactly the set of critical points of f.

(c) The infimum values of f and g coincide; i.e., $\inf_{\mathbb{R}^n} f = \inf_{\mathbb{R}^n} g$.

The properties of g are related to the so-called Moreau regularizing process; for more details and further results, see [20].

We are ready to state the main result of this subsection.

THEOREM 3.3. *Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous convex subanalytic function with $\operatorname{crit} f \neq \emptyset$. For any bounded set K there exists an exponent $\theta \in [0, 1)$ such that the function*

$$\frac{|f - \min f|^\theta}{m_f} \tag{14}$$

is bounded on K.

Proof. By Proposition 2.9, the function g defined above is subanalytic and continuous. Applying (b) and the results of the preceding section, we see that $S := \operatorname{crit} f$ is subanalytic. Let us show how g may be used to derive a growth condition for f. For any $x \in K$, the equivalence

$$d_S(x) = 0 \iff |g(x) - \min g| = 0,$$

combined with the Łojasiewicz factorization lemma (subsection 2.1) for the continuous subanalytic functions $|g - \min g|$ and d_S (restricted to the bounded set K), yields the existence of $r > 1$ and $c > 0$ such that

$$c\,[d_S(x)]^r \;\leq\; |g(x) - \min g| \quad \text{for all } x \in K.$$

On the other hand, the properties (a), (b), (c) of g imply that

$$|f(x) - \min f| \geq |g(x) - \min g| \quad \text{for all } x \in \mathbb{R}^n,$$

so that

$$[d_S(x)] \;\leq\; c^{-1/r}\,|f(x) - \min f|^{1/r}. \tag{15}$$

Moreover, since f is convex we get for all a in S and all $(x, x^*) \in \operatorname{Gr} \partial f$

$$f(a) \geq f(x) + \langle x^*, a - x\rangle.$$

Thus for all $(x, x^*) \in \operatorname{Gr} \partial f$ it follows that $|f(x) - f(a)| \;\leq\; \|x^*\|\,\|x - a\|$, and by taking the infimum over all $a \in S$, we obtain

$$|f(x) - \min f| \;\leq\; \|x^*\|\,d_S(x). \tag{16}$$

We therefore deduce from (15) that for all $x \in K$ and all $(x, x^*) \in \operatorname{Gr} \partial f$

$$|f(x) - \min f| \;\leq\; c^{-1/r}\,\|x^*\| \cdot |f(x) - \min f|^{1/r}.$$

By setting $\theta = 1 - r^{-1}$, the latter inequality implies $|f(x) - \min f|^{\theta} \;\leq\; c^{-1/r}\,m_f(x)$ for all $x \in K$, and (14) follows. □

Remark 3.4. The lower semicontinuous convex function f considered in Remark 2.15 provides an example where Theorem 3.3 applies while Theorem 3.1 does not.

Remark 3.5. A careful examination of the proof of Theorem 3.3 shows that the important assumption is not subanalyticity of the function, but rather the growth condition near critical values that subanalyticity implies. Indeed, let K be a compact set and f be any lower semicontinuous convex function f that satisfies

$$|f(x) - \min f| \geq\; c\,d_S(x)^r \qquad \text{for all } x \in K, \tag{17}$$

where $c > 0$, $r \geq 1$ and with $S = \operatorname{crit} f \neq \emptyset$. The argument of Theorem 3.3 may be then slightly modified in order to derive a Łojasiewicz inequality around any critical point a belonging to the interior of K.

Remark 3.6. From relation (16), which is true for all lower semicontinuous convex functions, a weaker version of (14) can be deduced. Indeed, if f is convex (but not necessarily subanalytic), then the function

$$\frac{|f - \min f|}{m_f}$$

is bounded around any critical point of f.

Remark 3.7. By using elementary arguments it can be shown that f satisfies the Łojasiewicz inequality around any point $a \in \operatorname{dom} f$ (cf. Remark 3.2).

4. Applications to dynamical systems. Throughout this section, unless otherwise stated, we make the following assumptions:

($\mathcal{H}1$) f is either lower semicontinuous convex or lower-C^2 with $\operatorname{dom} f = \mathbb{R}^n$.

($\mathcal{H}2$) f is somewhere finite ($\operatorname{dom} f \neq \emptyset$) and bounded from below.

We recall (see [20, Definition 10.29], for example) that a function f is called *lower-C^2* if for every $x_0 \in \operatorname{dom} f$ there exist a neighborhood U of x_0, a compact topological space S, and a jointly continuous function $F : U \times S \to \mathbb{R}$ satisfying $f(x) = \max_{s \in S} F(x, s)$ for all $x \in U$ and such that the (partial) derivatives $\nabla_x F(\cdot, \cdot)$ and $\nabla_x^2 F(\cdot, \cdot)$ exist and are jointly continuous.

A lower-C^2 function f is locally Lipschitz and locally representable as a difference of a convex continuous and a convex quadratic function [20, Theorem 10.33]. In particular, it satisfies

$$\partial f = \hat{\partial} f. \tag{18}$$

Note that (18) is also true for a lower semicontinuous convex function (see relation (5)).

As mentioned in the introduction, an important motivation for establishing the Łojasiewicz inequality for classes of nonsmooth functions is the expected asymptotic properties of the corresponding subgradient dynamical systems. This latter term refers to differential inclusions of the form

$$\dot{x}(t) + \partial f(x(t)) \ni 0,$$

where $\partial f : \mathbb{R}^n \rightrightarrows \mathbb{R}^n$ is the limiting subdifferential of f. A *trajectory* of the above dynamical system is any absolutely continuous curve $x : [0, T) \to \mathbb{R}^n$ that satisfies

$$(\mathcal{G}) \qquad \begin{cases} \dot{x}(t) + \partial f(x(t)) \ni 0 \quad \text{a.e. on } (0, T), \\ \\ \partial f(x(t)) \neq \emptyset \quad \text{for all } t \in [0, T), \end{cases}$$

where the notation "a.e." stands for "almost everywhere" in the sense of the Lebesgue measure of $\mathbb{R}$. Let us also recall that an absolutely continuous function (or curve) $x(t)$ is a.e. differentiable and can be entirely determined, up to a constant, by integration of its classical derivative. A trajectory $x(t)$ is called *maximal* if there is no possible extension of its domain compatible with $(\mathcal{G})$.

The following existence-uniqueness result is known to hold (see [6, Theorem 3.2, p. 57] or [2, Chapter 3.4] for the convex case, and [6, Proposition 3.12, p. 106] for the convex case with Lipschitz perturbation; see also [9] for related work).

Existence of trajectories. Under the assumptions ($\mathcal{H}1$) and ($\mathcal{H}2$), for every $x_0 \in \mathbb{R}^n$ such that $\partial f(x_0) \neq \emptyset$, there exists a unique trajectory $x : [0, T) \to \mathbb{R}^n$ of $(\mathcal{G})$ satisfying

$$(\mathcal{T}) \qquad x(0) = x_0.$$

In addition, the function $h := f \circ x$ is absolutely continuous.

Let us now recall some classical consequences of (18) and of the above existence result. For the sake of completeness, some elementary proofs are provided.

COROLLARY 4.1. *Let $x : [0,T) \to \mathbb{R}^n$ be a trajectory of $(\mathcal{G})$ satisfying $(\mathcal{T})$.*
(i) *For almost all $t \in (0,T)$*

$$\frac{d}{dt}(f \circ x)(t) = \langle \dot{x}(t), x^* \rangle \quad \textit{for all } x^* \in \partial f(x(t)).$$

(ii) *For almost all $t \in (0,T)$, the function $x^* \mapsto \langle \dot{x}(t), x^* \rangle$ is constant on $\partial f(x(t))$.*
(iii) *The trajectory x can be extended to a maximal trajectory $\hat{x} \in W^{1,2}(\mathbb{R}_+ ; \mathbb{R}^n)$.*

Proof. Set $h = f \circ x$ and note that the absolutely continuous functions h and x are simultaneously differentiable on $(0,T) \backslash N$, where N is a set of measure zero. Let $t \in (0,T) \backslash N$. Since $x(t) \in \operatorname{dom} \partial f$ and $\partial f(x(t)) = \hat{\partial} f(x(t))$, one may adapt the ideas of [6, Lemma 3.3, p. 73] (chain rule) to obtain

$$\partial h(t) = \{h'(t)\} = \left\{ \frac{d}{dt}(f \circ x)(t) \right\} = \{ \langle \dot{x}(t),\, x^* \rangle,\ x^* \in \partial f(x(t)) \}.$$

Thus (i) and (ii) follow.

To establish (iii) let us first prove that $x \in W^{1,2}((0,T) ; \mathbb{R}^n)$. Thanks to $(\mathcal{G})$, we deduce from (i) that

$$\frac{d}{dt}(f \circ x)(t) = -\|\dot{x}(t)\|^2 \quad \text{for all } (0,T).$$

Hence f is a Lyapunov function of the dynamical system $(\mathcal{G})$, and

$$\int_0^T \|\dot{x}(t)\|^2 dt = f(x_0) - f(x(T)) < +\infty;$$

that is, $\dot{x} \in L^2((0,T) ; \mathbb{R}^n)$. Note that $\dot{x}(t)$ remains bounded as t converges to T. (For a lower semicontinuous convex function f this is a classical result (see [2, p. 147], for example); if f is lower-C^2, this follows from $(\mathcal{G})$ and the fact that ∂f is locally bounded around T.) Since the graph of ∂f is closed (Remark 2.12) we get $x(T) \in \operatorname{dom} \partial f$. Thus, thanks to the existence result $(\mathcal{T})$, the initial trajectory is in fact extendible to a semiopen interval $[0, T+\delta)$, for some $\delta > 0$, containing $[0,T]$. A standard argument shows that the maximal extension of $x(t)$ is defined in $(0, +\infty)$. □

An interesting hidden property of $(\mathcal{G})$ is the following.

COROLLARY 4.2. *Let x be a maximal trajectory of $(\mathcal{G})$ satisfying $(\mathcal{T})$. Then for almost all $t \in \mathbb{R}_+$*

$$\|\dot{x}(t)\| = m_f(x(t)) \qquad \textit{and} \qquad \frac{d}{dt}(f \circ x)(t) = -\left[m_f(x(t))\right]^2.$$

Proof. From $(\mathcal{G})$, we obtain the existence of a curve $t \mapsto g(t) \in \partial f(x(t))$ such that

$$\dot{x}(t) = -g(t) \quad \text{a.e. on } \mathbb{R}_+.$$

Combining this with Corollary 4.1(ii), we get that for almost all t in $\mathbb{R}_+$

$$\|g(t)\|^2 = \langle g(t),\, x^* \rangle \quad \text{for all } x^* \in \partial f(x(t)),$$

which yields via a standard argument that $\|g(t)\| = m_f(x(t))$. Now evoking Corollary 4.1(i) finishes the proof. □

Remark 4.3. Corollary 4.2 says that the trajectories of $(\mathcal{G})$ (the existence of which is guaranteed under the assumptions $(\mathcal{H}1)$ and $(\mathcal{H}2)$) are necessarily "slow solutions"

(see [2, p. 139]) of the differential inclusion $(\mathcal{G})$. In particular, if the trajectory $x(t)$ meets a critical point of f, that is, if there exists $t_0 > 0$ such that $m_f(x(t_0)) = 0$, then Corollary 4.2 guarantees that the trajectory stops there; that is, $x(t) = x(t_0)$ for all $t \geq t_0$. In this case, the trajectory has a finite length equal to $\int_0^{t_0} \|\dot{x}(s)\| ds$.

Another consequence of Corollary 4.2 is that $(\mathcal{G})$ defines a descent method in the sense that f decreases along any trajectory. Although compactness implies that bounded trajectories have at least one cluster point as $t \to +\infty$, those might not converge towards one of them—and a fortiori, have an infinite length. The next result shows that this cannot happen if f is assumed subanalytic (or more generally, if f satisfies the Łojasiewicz inequality). Indeed, via a "Łojasiewicz-type" argument (e.g., [14]) we establish successively that the tail of the trajectory is trapped inside a convenient ball of its cluster point, that this tail necessarily has a finite length, and finally that the trajectory converges to this cluster point. In the remainder, in addition to $(\mathcal{H}1)$ and $(\mathcal{H}2)$, the following is also assumed:

$(\mathcal{H}3)$ f is a *subanalytic* function.

Let us give some examples of subanalytic functions related with optimization problems.

Example 4.4. - (supremum operations) Let $g : \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}$ be an analytic function, and let K be a compact subanalytic subset of $\mathbb{R}^p$. Then

$$f(x) = \sup_{y \in K} g(x, y)$$

is a lower-C^2 subanalytic function (see [4], for example). If in addition $x \mapsto g(x, y)$ is convex for all y, then f is convex.

- (constraints sets) Let $g_i : \mathbb{R}^n \to \mathbb{R}, i \in \{1, \ldots, m\}$, be a family of analytic functions. The feasible set

$$C := \{x \in \mathbb{R}^n : g_i(x) \leq 0, \forall i \in \{1, \ldots, m\}\}$$

together with its indicator function are subanalytic objects.

- (Barrier and penalty functions) Those can be used to minimize convex functions via parametric versions of $(\mathcal{G})$. Typical examples on $\mathbb{R}$ are the functions $h_1 : x > 0 \mapsto x^{-p} (p \geq 1)$, $h_2 : x \geq 0 \mapsto -x^\nu$, $(\nu \in (0, 1))$, $h_3(x) = x^2$ if $x \leq 0$ and $h_3(x) = 0$ otherwise.

We are now ready to state the following result.

THEOREM 4.5. *Assume that a function f satisfies $(\mathcal{H}1)$–$(\mathcal{H}3)$. Then any bounded maximal trajectory of $(\mathcal{G})$ has a finite length and converges to some critical point of f.*

Proof. Let $\{x(t)\}_{t \geq 0}$ be a bounded maximal trajectory of $(\mathcal{G})$. By Corollary 4.1, the trajectory is defined over all $\mathbb{R}_+$. Using $(\mathcal{H}2)$ and Corollary 4.2(iii), we conclude that there exists $\beta \in \mathbb{R}$ such that $\lim_{t \to +\infty} f(x(t)) = \beta$. Replacing f by $f - \beta$ and using the basic rules of subdifferential calculus, we may assume that $\beta = 0$.

In view of Remark 4.3, we may also assume that $f(x(t)) \neq 0$ for all $t > 0$. Consequently, the function $t \mapsto (f \circ x)(t)$ is positive and strictly decreasing to 0 as $t \to +\infty$. Moreover, by compactness, there exists some cluster point $a \in \mathbb{R}^n$ for the trajectory $x(t)$. So there exists an increasing sequence $(t_n)_{n \geq 1}$ with $t_n \to +\infty$ such that

$$\lim_{t_n \to +\infty} x(t_n) = a. \tag{19}$$

By continuity of $(f \circ x)$ we deduce that $f(a) = 0$. Using $(\mathcal{T})$, (19), and the fact that ∂f has a closed graph (see Remark 2.12), we deduce that $a \in \operatorname{dom} \partial f$. We do not know yet whether a is critical or not, but nevertheless, the Łojasiewicz inequality holds around a. Indeed, if $a \in \operatorname{crit} f$, then use Theorem 3.1 or Theorem 3.3, and if $a \notin \operatorname{crit} f$, then just recall Remarks 3.2 and 3.7. It follows that there exist $c > 0$, $\theta \in [0, 1)$, and $\varepsilon > 0$ (defining an open neighborhood $B(a, \varepsilon)$ of a) such that

$$|f(x)|^\theta \leq c\, m_f(x) \quad \text{for all } x \in B(a, \varepsilon). \tag{20}$$

Let us consider the (positive, absolutely continuous) function $\tilde{h} = (f \circ x)^{1-\theta}$. Since $x(t) \to a$ and since the function $\tilde{h}$ is strictly decreasing and converges to 0 (as $t \to +\infty$), there exists $t_0 > 0$ such that for all $t \geq t_0$

$$\frac{|\tilde{h}(t) - \tilde{h}(t_0)|}{c^{-1}(1-\theta)} \leq \frac{\varepsilon}{3}, \tag{21}$$

with

$$\|x(t_0) - a\| \leq \frac{\varepsilon}{3}. \tag{22}$$

Let us set

$$T_{\text{out}} := \inf \{\, t \geq t_0,\, x(t) \notin B(a, \varepsilon) \,\}. \tag{23}$$

By continuity of the trajectory we have $t_0 < T_{\text{out}} \leq +\infty$.

Claim $T_{\text{out}} = +\infty$ (that is, the tail of the trajectory remains trapped in $B(a, \varepsilon)$).

Proof of the claim. For almost all $t \in [t_0, T_{\text{out}})$ we have

$$\begin{aligned} \frac{d}{dt}\tilde{h}(t) &= (1-\theta)\, f(x(t))^{-\theta}\, \frac{d}{dt}(f \circ x)(t) \\ &\leq -(1-\theta)\, f(x(t))^{-\theta}\, [m_f(x(t))]^2 \\ &\leq -(1-\theta)\, c^{-1}\, m_f(x(t)), \end{aligned}$$

where we have successively used Corollary 4.2 and (20). By integration, we obtain for all $t \in [t_0, T_{\text{out}})$

$$\int_{t_0}^{t} m_f(x(s))ds \leq -\left[\frac{\tilde{h}(t) - \tilde{h}(t_0)}{c^{-1}(1-\theta)}\right], \tag{24}$$

which according to (21) and Corollary 4.2, yields

$$\int_{t_0}^{t} \|\dot{x}(s)\|ds \leq \frac{\varepsilon}{3} \quad \text{for all } t \in [t_0, T_{\text{out}}]. \tag{25}$$

To see that $T_{\text{out}} = +\infty$, we just argue by contradiction. If $T_{\text{out}} < +\infty$, then using (22) and (25), we obtain

$$\|x(T_{\text{out}}) - a\| \leq \left| \left(x(t_0) + \int_{t_0}^{T_{\text{out}}} \|\dot{x}(s)\|ds \right) - a \right| \leq \frac{2\varepsilon}{3}.$$

The latter obviously contradicts (23). Thus $T_{\text{out}} = +\infty$, and the claim is proved.

Resorting to (25) again, we conclude that $\int_{t_0}^{+\infty} \|\dot{x}(s)\| ds \leq \frac{\varepsilon}{3}$, so $x(t)$ has a finite length and hence converges. Thus $\lim_{t\to+\infty} x(t) = a$, and $m_f(x(t))$ admits 0 as a limit point. By using the closedness of $\operatorname{Gr} \partial f$, we conclude that a is a critical point of f. □

Remark 4.6 (generalized gradient conjecture). The "gradient conjecture" of Thom [22] can obviously be reformulated in this nonsmooth setting. For any bounded trajectory $x(\cdot)$ of $(\mathcal{G})$, let us set $x_\infty := \lim_{t\to+\infty} x(t)$. Is it true that

$$t \mapsto \frac{x(t) - x_\infty}{||x(t) - x_\infty||}$$

has a limit as t goes to infinity? For real-analytic functions this conjecture has been proved by Kurdyka, Mostowski, and Parusiński [14].

Before we proceed to an estimate of the rate of convergence, let us introduce some terminology.

- We define

$$\sigma(t) = \int_t^{+\infty} \|\dot{x}(s)\| ds \quad \text{for all } t \in \mathbb{R}_+ \tag{26}$$

  to be the tail length function for the trajectory $x(t)$.
- A *Łojasiewicz exponent* of the function f at a point $a \in \mathbb{R}^n$ of its domain is any number $\theta \in [0, 1)$ for which the Łojasiewicz inequality holds around a.

Let us finally point out some facts arising from the proof of Theorem 4.5. Replacing $\tilde{h}(t)$ by $[f(x(t)]^{1-\theta}$ and $m_f(x(s))$ by $\|\dot{x}(s)\|$ (see Corollary 4.2) in (24) and letting $t \to +\infty$, we deduce

$$\int_{t_0}^{+\infty} \|\dot{x}(s)\| ds \;\leq\; \frac{c}{(1-\theta)}\, f(x(t_0))^{1-\theta}.$$

The above inequality remains true for every $t \geq t_0$ (in view of the Claim). Thus assuming $\theta > 0$ and evoking again (20) and Corollary 4.2, we obtain (for $k = c^{1/\theta}$)

$$\int_t^{+\infty} \|\dot{x}(s)\| ds \;\leq\; \frac{k}{(1-\theta)}\, \|\dot{x}(t)\|^{\frac{1-\theta}{\theta}} \qquad \text{for all } t \geq t_0. \tag{27}$$

We are now ready to state the following result.

THEOREM 4.7. *Under the assumptions* $(\mathcal{H}1)$–$(\mathcal{H}3)$, *let* $x(t)$ *be a bounded maximal trajectory of* $(\mathcal{G})$. *Then* $x(t)$ *converges to some critical point* $a \in \mathbb{R}^n$ *of* f. *Let* $\theta \in [0, 1)$ *be a Łojasiewicz exponent at this point. Then there exist* $k > 0$, $k' > 0$, *and* $t_0 \geq 0$ *such that for all* $t \geq t_0$ *the following estimates hold:*

- *If* $\theta \in (\frac{1}{2}, 1)$, *then* $\|x(t) - a\| \leq k(t+1)^{-(\frac{1-\theta}{2\theta-1})}$.
- *If* $\theta = \frac{1}{2}$, *then* $\|x(t) - a\| \leq k \exp(-k't)$.
- *If* $\theta \in [0, \frac{1}{2})$, *then* $x(t)$ *converges in finite time.*

Proof. We can always assume that $\theta > 0$. (If $\theta = 0$, we replace it by some $\theta' \in (0, 1/2)$, and we proceed as below.)

Let U be a neighborhood of a in which the Łojasiewicz inequality holds. Since $x(t)$ converges to a there exists $t_0 \geq 0$ such that $x(t) \in U$ for every $t \geq t_0$. In particular, (27) holds. Let us now consider the tail length function $\sigma(t)$ defined in (26). Note that

$$\|x(t) - a\| \leq \sigma(t). \tag{28}$$

Since $\dot{\sigma}(t) = -\|\dot{x}(s)\|$ for all $t \geq t_0$, inequality (27) yields

$$\sigma(t) \leq \frac{k}{(1-\theta)} \left[-\dot{\sigma}(t)\right]^{\frac{1-\theta}{\theta}}. \tag{29}$$

Thus $\sigma(t)$ is an absolutely continuous function and satisfies the following differential inequality:

$$\dot{\sigma}(t) \leq -L\left[\sigma(t)\right]^{\frac{\theta}{1-\theta}} \quad \text{for all } t \geq t_0, \tag{30}$$

where L is a positive constant. To obtain the announced estimates it suffices to solve the following differential equation—considering separately the cases $\theta \in (1/2, 1)$, $\theta = 1/2$, and $\theta \in (0, 1/2)$:

$$\begin{cases} \dot{y}(t) = -L\left[y(t)\right]^{\frac{\theta}{1-\theta}} & \text{for all } t \geq t_0, \\ \\ y(t_0) = \sigma(t_0). \end{cases} \tag{31}$$

The announced estimates then follow from (28) and the fact that $\sigma(t) \leq y(t)$ for all $t \geq t_0$. (Indeed, if $\sigma(\bar{t}) = y(\bar{t})$ for some $\bar{t} \geq t_0$, then a comparison of (30) and (31) shows that $\dot{\sigma}(\bar{t}) \leq \dot{y}(\bar{t})$.) The proof is complete. □

Remark 4.8. The results of this section can be generalized to a wider setting as follows. Let $f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\}$ be a lower semicontinuous function complying with the following requirements:

(i) $\operatorname{dom} f \neq \emptyset$ and $\hat{\partial} f = \partial f$.
(ii) either f is convex or $f\,|_{\operatorname{dom} f}$ is continuous.
(iii) f has the Łojasiewicz property; that is, property (8) holds around any critical point.

If we assume in addition that, for all initial conditions $x_0 \in \operatorname{dom} \partial f$, the differential inclusion $(\mathcal{G})$ has a (unique) global solution x such that $f \circ x$ is absolutely continuous, then both Theorems 4.5 and 4.7 can be extended in this wider setting.

Prominent examples of functions meeting the above-mentioned conditions are continuous subanalytic ϕ-convex functions [9], or lower semicontinuous convex functions satisfying some growth condition of the type (17).

QUADRATIC MATRIX PROGRAMMING*

AMIR BECK†

Abstract. We introduce and study a special class of nonconvex quadratic problems in which the objective and constraint functions have the form $f(\boldsymbol{X}) = \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}^T\boldsymbol{X}) + c, \boldsymbol{X} \in \mathbb{R}R^{n\times r}$. The latter formulation is termed *quadratic matrix programming* (QMP) of order r. We construct a specially devised semidefinite relaxation (SDR) and dual for the QMP problem and show that under some mild conditions strong duality holds for QMP problems with at most r constraints. Using a result on the equivalence of two characterizations of the nonnegativity property of quadratic functions of the above form, we are able to compare the constructed SDR and dual problems to other known SDRs and dual formulations of the problem. An application to robust least squares problems is discussed.

Key words. quadratic matrix programming, semidefinite relaxation, strong duality, nonconvex quadratic problems

1. Introduction.

This work is concerned with nonconvex quadratic optimization problems of the form

$$\begin{aligned} &\min \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}_0\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}_0^T\boldsymbol{X}) + c_0 \\ &\text{s.t. } \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}_i\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}_i^T\boldsymbol{X}) + c_i \le \alpha_i, i \in \mathcal{I}, \\ &\quad \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}_j\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}_j^T\boldsymbol{X}) + c_j = \alpha_j, j \in \mathcal{E}, \\ &\quad \boldsymbol{X} \in \mathbb{R}^{n\times r}, \end{aligned} \tag{1}$$

with $\boldsymbol{A}_i = \boldsymbol{A}_i^T \in \mathbb{R}^{n\times n}, \boldsymbol{B}_i \in \mathbb{R}^{n\times r}, \alpha_i, c_i \in \mathbb{R}, i \in \{0\} \cup \mathcal{I} \cup \mathcal{E}$. Problems of the above type arise naturally in several applications such as robust least squares [9], and in problems involving orthogonal constraints such as the orthogonal procrustes problem [17] (see the discussion in section 2).

Problem (1) is called a *quadratic matrix programming* (QMP) problem of order r. Correspondingly, the objective and constraint functions are called *quadratic matrix (QM) functions*. It can be shown that every QM function is in particular a quadratic function with nr variables; see the discussion in section 2.1. Thus, the family of QMP problems is a special case of quadratically constrained quadratic programming (QCQP) problems. However, it is worthwhile to study these problems independently since, as we shall see, they enjoy stronger results than those currently known for the general QCQP problem. For example, we will establish strong duality results for QMP problems with at most r constraints (see section 3.2).

Strong duality is known to hold for only a few classes of nonconvex QCQP. The simplest and best-known example is the trust region problem, which consists of minimizing an indefinite quadratic function over a ball and admits an exact semidefinite relaxation (SDR); see [13, 8]. Extensions of this problem were considered in

[12, 18, 5, 16]. In general these results cannot be extended to QCQP problems involving two constraints [19, 20]. An exception is the case in which all the functions involved (objective plus two constraints) are homogenous quadratic functions. In this case, it was proven in [19] that under mild conditions the semidefinite relaxation is tight. Another interesting tractable class of QCQP problems was considered in [1] in the context of quadratic problems with orthogonal constraints.

In this paper strong duality/tightness of the SDR is shown to hold for the class of QMP problems of order r with at most r constraints. In section 3 we construct an SDR and dual formulations for the QMP problem originating from a homogenization procedure specially devised to QMP problems. Using the SDR formulation combined with known results on the existence of low-rank solutions of semidefinite programs [3, 2, 14, 15], the strong duality result is shown to follow. Moreover, an algorithm for extracting a solution to the QMP problem from its associated SDR is described. In section 4 an alternative SDR and dual construction are discussed. These constructions stem from the standard construction of SDR and dual for QCQP problems. Using a result on the equivalence of two linear matrix inequality (LMI) representations of the claim on nonnegativity of a QM function, we are able to prove that the two SDR and dual formulations are equivalent. Finally, in section 5 we present an application of our results in the field of robust optimization.

Notation. For simplicity, instead of inf/sup we use min/max; however, this does not mean that we assume that the optimum is attained and/or finite. Vectors are denoted by boldface lowercase letters, e.g., $\boldsymbol{y}$, and matrices by boldface uppercase letters, e.g., $\boldsymbol{A}$. For two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$, $\boldsymbol{A} \succ \boldsymbol{B}$ ($\boldsymbol{A} \succeq \boldsymbol{B}$) means that $\boldsymbol{A} - \boldsymbol{B}$ is positive definite (semidefinite). $\mathcal{S}^n = \{\boldsymbol{A} \in \mathbb{R}^{n\times n} : \boldsymbol{A} = \boldsymbol{A}^T\}$ is the set of symmetric $n \times n$ matrices, and $\mathcal{S}^n_+ = \{\boldsymbol{A} \in \mathbb{R}^{n\times n} : \boldsymbol{A} \succeq \boldsymbol{0}\}$ is the set all real $n \times n$ symmetric positive semidefinite matrices. $\boldsymbol{0}_{n\times m}$ is the $n \times m$ matrix of zeros, and $\boldsymbol{I}_r$ is the $r \times r$ identity matrix. For a matrix $\boldsymbol{M}$, $\mathrm{vec}(\boldsymbol{M})$ denotes the vector obtained by stacking the columns of $\boldsymbol{M}$. For a square matrix $\boldsymbol{U}$, $[\boldsymbol{U}]_r$ denotes the southeast $r \times r$ submatrix of $\boldsymbol{U}$; i.e., if $\boldsymbol{U} = (u_{ij})_{i,j=1}^{n+r}$, then $[\boldsymbol{U}]_r = (u_{ij})_{i,j=n+1}^{n+r}$. For two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$, $\boldsymbol{A} \otimes \boldsymbol{B}$ denotes the corresponding Kronecker product. $\boldsymbol{E}^r_{ij}$ is the $r \times r$ matrix with 1 at the ijth component and 0 elsewhere, and δ_{ij} is the Kronecker delta, i.e., $\delta_{ii} = 1$ and $\delta_{ij} = 0$ for $i \neq j$. The value of the optimal objective function of an optimization problem

$$(\mathrm{P}) : \min\{f(\boldsymbol{x}) : \boldsymbol{x} \in C\}$$

is denoted by val(P). The optimization problem (P) is called *bounded below* if the minimum is finite, and termed *solvable* in the case where the minimum is finite and attained (similar definitions for maximum problems). We follow the MATLAB convention and use ";" for adjoining scalars, vectors, or matrices in a column. We also use some standard abbreviations such as SDP (semidefinite programming), LMI (linear matrix inequality), SDR (semidefinite relaxation), and QCQP (quadratically constrained quadratic programming), and some nonstandard abbreviations such as QM (quadratic matrix) and QMP (quadratic matrix programming).

2. Quadratic matrix problems.

2.1. Quadratic matrix functions: Definition and basic properties.

We begin by recalling that a quadratic function $g : \mathbb{R}^n \to \mathbb{R}$ is a function of the form

$$g(\boldsymbol{x}) = \boldsymbol{x}^T \boldsymbol{A} \boldsymbol{x} + 2\boldsymbol{b}^T \boldsymbol{x} + c, \tag{2}$$

where $\boldsymbol{A} \in \mathcal{S}^n, \boldsymbol{b} \in \mathbb{R}^n$, and $c \in \mathbb{R}$. We will also use the term "quadratic vector function" instead of "quadratic function" to distinguish it from the term "quadratic matrix function" defined below.

A *quadratic matrix (QM) function* of order r is a function $f : \mathbb{R}^{n\times r} \to \mathbb{R}$ of the form

$$f(\boldsymbol{X}) = \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}^T\boldsymbol{X}) + c, \quad \boldsymbol{X} \in \mathbb{R}^{n\times r}, \tag{3}$$

where $\boldsymbol{A} \in \mathcal{S}^n$, $\boldsymbol{B} \in \mathbb{R}^{n\times r}$, and $c \in \mathbb{R}$. If $\boldsymbol{B} = \boldsymbol{0}_{n\times r}, c = 0$, then f is called a *homogenous QM function* or a *QM form*. We note that every quadratic vector function is a QM function of order one. The opposite statement is also true: every QM function is in particular a quadratic vector function. Indeed, the function f from (3) can be written as follows:

$$f(\boldsymbol{X}) = f^V(\mathrm{vec}(\boldsymbol{X})), \tag{4}$$

where $f^V : \mathbb{R}^{nr} \to \mathbb{R}$ is defined by

$$f^V(\boldsymbol{z}) = \boldsymbol{z}^T(\boldsymbol{I}_r \otimes \boldsymbol{A})\boldsymbol{z} + 2vec(\boldsymbol{B})^T\boldsymbol{z} + c. \tag{5}$$

The function f^V is called the *vectorized function of* f. From the above relation we can immediately deduce that f is (strictly) convex if and only if $\boldsymbol{A} \succeq \boldsymbol{0}$ ($\boldsymbol{A} \succ \boldsymbol{0}$).[1]

2.2. QM problems. Our main objective is to study *quadratic matrix programming* (QMP) problems in which the goal is to minimize a QM objective function subject to equality and inequality QM constraints:

$$\begin{array}{ll} (\mathrm{QMP}) & \min f_0(\boldsymbol{X}) \\ & \text{s.t. } f_i(\boldsymbol{X}) \le \alpha_i, i \in \mathcal{I}, \\ & \quad f_j(\boldsymbol{X}) = \alpha_j, j \in \mathcal{E}, \\ & \quad \boldsymbol{X} \in \mathbb{R}^{n\times r}, \end{array} \tag{6}$$

where $f_i : \mathbb{R}^{n\times r} \to \mathbb{R}, i \in \mathcal{I} \cup \mathcal{E} \cup \{0\}$, are QM functions of order r given by

$$f_i(\boldsymbol{X}) = \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}_i\boldsymbol{X}) + 2\mathrm{Tr}(\boldsymbol{B}_i^T\boldsymbol{X}) + c_i, \quad \boldsymbol{X} \in \mathbb{R}^{n\times r},$$

with $\boldsymbol{A}_i \in \mathcal{S}^n, \boldsymbol{B}_i \in \mathbb{R}^{n\times r}$, and $c_i \in \mathbb{R}, i \in \{0\} \cup \mathcal{I} \cup \mathcal{E}$. The index sets $\{0\}, \mathcal{I}, \mathcal{E}$ are pairwise disjoint sets of nonnegative integers.

In the case where all the functions $f_i, i \in \mathcal{I} \cup \mathcal{E} \cup \{0\}$, are homogeneous QM functions of order r, the QMP problem (6) is called a *homogenous QMP problem* (of order r). By using the correspondence (4), we can represent the QMP problem as the QCQP problem:

$$\begin{array}{l} \min f_0^V(\boldsymbol{z}) \\ \text{s.t. } f_i^V(\boldsymbol{z}) \le \alpha_i, i \in \mathcal{I}, \\ \quad f_j^V(\boldsymbol{z}) = \alpha_j, j \in \mathcal{E}, \\ \quad \boldsymbol{z} \in \mathbb{R}^{nr}, \end{array} \tag{7}$$

which will be called the *vectorized QMP problem*.

[1] Indeed, $\boldsymbol{I}_r \otimes \boldsymbol{A}$ and $\boldsymbol{A}$ have the same eigenvalues (but with different multiplicities) [10].

The QMP problem appears in several fields of applications. Here we present two examples in which the QMP problem naturally arises.

Example 1. In the *orthogonal procrustes* problem [17] we seek to find a square matrix $\boldsymbol{X}$ which solves the following optimization problem:

$$\begin{aligned} &\min \|\boldsymbol{A}\boldsymbol{X} - \boldsymbol{B}\|_F^2 \\ &\text{s.t. } \boldsymbol{X}^T\boldsymbol{X} = \boldsymbol{I}_r, \\ &\boldsymbol{X} \in \mathbb{R}^{r\times r}, \end{aligned}$$

where $\boldsymbol{A} \in \mathbb{R}^{n\times r}, \boldsymbol{B} \in \mathbb{R}^{n\times r}$. The orthogonal procrustes problem can be rewritten as a QMP problem with r^2 equality constraints:

$$\begin{aligned} &\min \mathrm{Tr}(\boldsymbol{X}^T\boldsymbol{A}^T\boldsymbol{A}\boldsymbol{X}) - 2\mathrm{Tr}(\boldsymbol{B}^T\boldsymbol{A}\boldsymbol{X}) + \|\boldsymbol{B}\|_F^2 \\ &\text{s.t. } \mathrm{Tr}(\boldsymbol{X}^T(\boldsymbol{E}_{ij}^r + \boldsymbol{E}_{ij}^r)\boldsymbol{X}) = 2\delta_{ij}, \quad 1 \le i,j \le r, \\ &\boldsymbol{X} \in \mathbb{R}^{r\times r}. \end{aligned}$$

We note that although the orthogonal procrustes problem can be solved efficiently [17], it is not clear whether the *unbalanced* orthogonal procrustes problem—in which $\boldsymbol{X}$ is not square—is tractable [7].

Example 2. The *robust least squares* (RLS) problem was introduced and studied in [9, 6].[2] Consider a linear system $\boldsymbol{A}\boldsymbol{x} \approx \boldsymbol{b}$, where $\boldsymbol{A} \in \mathbb{R}^{r\times n}, \boldsymbol{b} \in \mathbb{R}^r$, and $\boldsymbol{x} \in \mathbb{R}^n$. Assume that the matrix $\boldsymbol{A}$ is not fixed but rather given by a family of matrices[3] $\boldsymbol{A}+\boldsymbol{\Delta}^T$, where $\boldsymbol{A}$ is a known nominal value and $\boldsymbol{\Delta} \in \mathbb{R}^{n\times r}$ is an unknown perturbation matrix known to reside in a compact uncertainty set $\mathcal{U}$. The RLS approach to this problem is to seek a vector $\boldsymbol{x} \in \mathbb{R}^n$ that minimizes the worst case data error with respect to all possible values of $\boldsymbol{\Delta} \in \mathcal{U}$:

$$\min_{\boldsymbol{x}} \max_{\boldsymbol{\Delta}\in\mathcal{U}} \|\boldsymbol{b} - (\boldsymbol{A} + \boldsymbol{\Delta}^T)\boldsymbol{x}\|^2. \tag{8}$$

Now, by making some simple algebraic manipulation, we can rewrite the objective function in (8) as

$$\|\boldsymbol{b} - (\boldsymbol{A} + \boldsymbol{\Delta}^T)\boldsymbol{x}\|^2 = \mathrm{Tr}(\boldsymbol{\Delta}^T\boldsymbol{x}\boldsymbol{x}^T\boldsymbol{\Delta}) + 2\mathrm{Tr}((\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x})\boldsymbol{x}^T\boldsymbol{\Delta}) + \mathrm{Tr}((\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x})(\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x})^T),$$

so that the inner maximization problem in (8) takes the following form:

$$\max\{\mathrm{Tr}(\boldsymbol{\Delta}^T\mathbf{Q}\boldsymbol{\Delta}) + 2\mathrm{Tr}(\mathbf{F}^T\boldsymbol{\Delta}) + c : \boldsymbol{\Delta} \in \mathcal{U}\}, \tag{9}$$

where $\mathbf{Q}, \mathbf{F}$, and c depend on $\boldsymbol{x}$ and are given by

$$\mathbf{Q} = \boldsymbol{x}\boldsymbol{x}^T \in \mathcal{S}^n, \quad \mathbf{F} = \boldsymbol{x}(\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x})^T \in \mathbb{R}^{n\times r}, \quad c = \|\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x}\|^2 \in \mathbb{R}. \tag{10}$$

In [9] the uncertainty set $\boldsymbol{\Delta}$ was chosen to be a simple Frobenius norm constraint, i.e.,

$$\mathcal{U} = \{\boldsymbol{\Delta} \in \mathbb{R}^{n\times r} : \mathrm{Tr}(\boldsymbol{\Delta}^T\boldsymbol{\Delta}) \le \rho\}.$$

[2]Here we study the unstructured case.

[3]The perturbation matrix appears in a transpose form so that the derived QM function will have the form (3). Furthermore, for the sake of simplicity we do not consider uncertainties in the RHS vector $\boldsymbol{b}$, although such uncertainties can be incorporated into our analysis in a straightforward manner.

The inner maximization problem (9) with the above choice of $\mathcal{U}$ is a QMP problem of order r with a single inequality constraint.

The fact that the uncertainty set $\mathcal{U}$ was given in [9] by a *single* quadratic constraint was a crucial element in establishing the tractability of the RLS problem. In fact, it is well known that in the structured case, the inner maximization problem of the RLS problem becomes NP-hard when the uncertainty set is given by an intersection of ellipsoids. Nonetheless, in section 5, using the results developed in sections 3 and 4, we will show that more complicated choices of $\mathcal{U}$ can be considered. In particular, we will prove in section 5 that the RLS problem remains tractable in the case where $\mathcal{U}$ is given by a set of at most r QM inequality constraints. The latter form of the uncertainty set can model, for example, the situation where each column of the perturbation matrix $\boldsymbol{\Delta}^T$ has a *separate* norm constraint.

3. Semidefinite relaxations of the QMP problem and strong duality results. We begin by constructing an SDR for the QMP problem. A natural approach for constructing such an SDR is to consider the SDR of the vectorized problem (7) (recall that problem (7) is a (QCQP)). However, this approach, which is discussed in detail in section 4, does not seem to offer useful theoretical insights into questions such as strong duality/tightness of SDR. For that reason we construct a *new* scheme, specifically devised to obtain an SDR for QMP problems (see section 3.1). Using the derived SDR, we will show in section 3.2 that, under some mild conditions, strong duality holds for QMP problems of order r with at most r constraints.

3.1. An SDR of the QMP problem. Recall that the homogenized version a quadratic vector function g given by (2) is the quadratic form $g^H : \mathbb{R}^{n+1} \to \mathbb{R}$ defined by

$$g^H(\boldsymbol{x};t) = \boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x} + 2\boldsymbol{b}^T\boldsymbol{x}t + ct^2. \tag{11}$$

The matrix associated with the quadratic form g^H is denoted by

$$\boldsymbol{M}(g) = \begin{pmatrix} \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{b}^T & c \end{pmatrix}. \tag{12}$$

We consider the following generalization of the above homogenization procedure to QM functions of order r: let f be the QM function given by (3); the *homogenized QM function* is denoted by $f^H : \mathbb{R}^{(n+r)\times r} \to \mathbb{R}$ and given by

$$f^H(\mathbf{Y};\boldsymbol{Z}) \equiv \mathrm{Tr}(\mathbf{Y}^T\boldsymbol{A}\mathbf{Y}) + 2\mathrm{Tr}(\boldsymbol{Z}^T\boldsymbol{B}^T\mathbf{Y}) + \frac{c}{r}\mathrm{Tr}(\boldsymbol{Z}^T\boldsymbol{Z}), \quad \mathbf{Y} \in \mathbb{R}^{n\times r}, \boldsymbol{Z} \in \mathbb{R}^{r\times r}, \tag{13}$$

which is a homogenous QM function of order r corresponding to the matrix

$$\boldsymbol{M}(f) \equiv \begin{pmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B}^T & \frac{c}{r}\boldsymbol{I}_r \end{pmatrix}. \tag{14}$$

In the case $r = 1$, definitions (13) and (14) coincide with the definitions of the homogenization of a quadratic function (11) and its associated matrix (12), respectively. The operator $\boldsymbol{M}$ will be used throughout the paper.

The homogenous function f^H satisfies the following easily verifiable properties, which will become useful in what follows:

$$f^H(\mathbf{Y};\boldsymbol{I}_r) = f(\mathbf{Y}) \quad \text{for every } \mathbf{Y} \in \mathbb{R}^{n\times r}, \tag{15}$$

$$f^H(\mathbf{Y};\boldsymbol{Z}) = f(\mathbf{Y}\boldsymbol{Z}^T) \text{ for every } \mathbf{Y} \in \mathbb{R}^{n\times r}, \boldsymbol{Z} \in \mathbb{R}^{r\times r} \text{ such that } \boldsymbol{Z}^T\boldsymbol{Z} = \boldsymbol{I}_r. \tag{16}$$

Using the above homogenization procedure for QM functions, we are able to construct (see Lemma 3.1 below) a homogeneous QMP problem of order r, equivalent to the (nonhomogeneous) QMP problem (6).

LEMMA 3.1. *Consider the following homogenized version of the QMP problem* (6):

$$\begin{aligned} &\min f_0^H(\mathbf{Y};\boldsymbol{Z}) \\ &s.t.\ f_i^H(\mathbf{Y};\boldsymbol{Z}) \le \alpha_i, i \in I, \\ &\quad f_j^H(\mathbf{Y};\boldsymbol{Z}) = \alpha_j, j \in \mathcal{E}, \\ &\quad \psi_{ij}(\mathbf{Y};\boldsymbol{Z}) = 2\delta_{ij}, 1 \le i \le j \le r, \\ &\quad \mathbf{Y} \in \mathbb{R}^{n\times r}, \boldsymbol{Z} \in \mathbb{R}^{r\times r}, \end{aligned} \tag{17}$$

where $\psi_{ij}(\mathbf{Y};\boldsymbol{Z}) = \mathrm{Tr}(\boldsymbol{Z}^T(\boldsymbol{E}_{ij}^r + \boldsymbol{E}_{ji}^r)\boldsymbol{Z})$ *and* δ_{ij} *is the Kronecker delta.*

1. *Suppose that the QMP problem* (6) *is solvable, and let* $\boldsymbol{X}^*$ *be an optimal solution of* (QMP). *Then problem* (17) *is solvable,* $(\boldsymbol{X}^*;\boldsymbol{I}_r)$ *is an optimal solution of* (17), *and* val(QMP) = val(17).
2. *Suppose that problem* (17) *is solvable, and let* $(\mathbf{Y}^*;\boldsymbol{Z}^*)$ *be an optimal solution of* (17). *Then problem* (QMP) *is solvable,* $\boldsymbol{X}^* = \mathbf{Y}^*(\boldsymbol{Z}^*)^T$ *is an optimal solution of* (QMP), *and* val(QMP) = val(17).

Proof. First note that the system of equalities

$$\mathrm{Tr}(\boldsymbol{Z}^T(\boldsymbol{E}_{ij}^r + \boldsymbol{E}_{ji}^r)\boldsymbol{Z}) = 2\delta_{ij}, \quad 1 \le i \le j \le r,$$

can be written as

$$\mathrm{Tr}((\boldsymbol{E}_{ij}^r + \boldsymbol{E}_{ji}^r)\boldsymbol{Z}\boldsymbol{Z}^T) = 2\delta_{ij}, \quad 1 \le i \le j \le r,$$

which, by using the symmetry of the matrix $\boldsymbol{Z}\boldsymbol{Z}^T$, is equivalent to

$$\boldsymbol{Z}^T\boldsymbol{Z} = \boldsymbol{Z}\boldsymbol{Z}^T = \boldsymbol{I}_r.$$

1. Let $\boldsymbol{X}^*$ be an optimal solution of (QMP). For every $(\mathbf{Y};\boldsymbol{Z})$, $(\mathbf{Y} \in \mathbb{R}^{n\times r}, \boldsymbol{Z} \in \mathbb{R}^{r\times r})$ in the feasible set of (17) (and in particular $\boldsymbol{Z}^T\boldsymbol{Z} = \boldsymbol{I}_r$) we have

$$f_0^H(\mathbf{Y},\boldsymbol{Z}) \overset{(16)}{=} f_0(\mathbf{Y}\boldsymbol{Z}^T) \ge f_0(\boldsymbol{X}^*) \overset{(15)}{=} f_0^H(\boldsymbol{X}^*;\boldsymbol{I}_r).$$

Therefore, $(\boldsymbol{X}^*;\boldsymbol{I}_r)$ is an optimal solution of (17) and val(QMP) = val(17).

2. Let $(\mathbf{Y}^*;\boldsymbol{Z}^*)$, $(\mathbf{Y} \in \mathbb{R}^{n\times r}, \boldsymbol{Z} \in \mathbb{R}^{r\times r})$ be an optimal solution of (17), and set $\boldsymbol{X}^* = \mathbf{Y}^*(\boldsymbol{Z}^*)^T$. Then for every $\boldsymbol{X} \in \mathbb{R}^{n\times r}$ which is in the feasible set of (QMP) we have

$$f_0(\boldsymbol{X}) \overset{(15)}{=} f_0^H(\boldsymbol{X};\boldsymbol{I}) \ge f_0^H(\mathbf{Y}^*;\boldsymbol{Z}^*) \overset{(16)}{=} f_0(\mathbf{Y}^*(\boldsymbol{Z}^*)^T) = f_0(\boldsymbol{X}^*),$$

and thus $\boldsymbol{X}^*$ is an optimal solution of (QMP) and val(QMP) = val(17). ∎

COROLLARY 3.2. *The QMP problem* (6) *is solvable if and only if problem* (17) *is solvable, and in that case* val(QMP) = val(17).

We will now exploit the homogenized QMP problem (17) in order to formulate a semidefinite relaxation. By denoting $W = (\mathbf{Y};\boldsymbol{Z}) \in \mathbb{R}^{(n+r)\times r}$, we conclude that

problem (17) can be written as

$$\begin{aligned}
&\min \operatorname{Tr}(\boldsymbol{M}(f_0)\boldsymbol{W}\boldsymbol{W}^T)\\
&\text{s.t. } \operatorname{Tr}(\boldsymbol{M}(f_i)\boldsymbol{W}\boldsymbol{W}^T) \le \alpha_i, i \in I,\\
&\quad \operatorname{Tr}(\boldsymbol{M}(f_j)\boldsymbol{W}\boldsymbol{W}^T) = \alpha_j, j \in \mathcal{E},\\
&\quad \operatorname{Tr}(\boldsymbol{N}_{ij}\boldsymbol{W}\boldsymbol{W}^T) = 2\delta_{ij}, 1 \le i \le j \le r,\\
&\quad \boldsymbol{W} \in \mathbb{R}^{(n+r)\times r},
\end{aligned}$$

where the operator $\boldsymbol{M}$ is defined in (14) and

$$\boldsymbol{N}_{ij} = \begin{pmatrix} \boldsymbol{0}_{n\times n} & \boldsymbol{0}_{n\times r} \\ \boldsymbol{0}_{r\times n} & \boldsymbol{E}_{ij}^r + \boldsymbol{E}_{ji}^r \end{pmatrix}, \quad 1 \le i \le j \le r.$$

Making the change of variables $\boldsymbol{U} = \boldsymbol{W}\boldsymbol{W}^T \in \mathcal{S}_+^{n+r}$, we conclude that problem (17) can be equivalently written as

$$\begin{aligned}
&\min \operatorname{Tr}(\boldsymbol{M}(f_0)\boldsymbol{U})\\
&\text{s.t. } \operatorname{Tr}(\boldsymbol{M}(f_i)\boldsymbol{U}) \le \alpha_i, i \in I,\\
&\quad \operatorname{Tr}(\boldsymbol{M}(f_j)\boldsymbol{U}) = \alpha_j, j \in \mathcal{E},\\
&\quad \operatorname{Tr}(\boldsymbol{N}_{ij}\boldsymbol{U}) = 2\delta_{ij}, 1 \le i \le j \le r,\\
&\quad \boldsymbol{U} \in \mathcal{S}_+^{n+r}, \operatorname{rank}(\boldsymbol{U}) \le r.
\end{aligned}$$

Omitting the "hard" constraint $\operatorname{rank}(\boldsymbol{U}) \le r$, we finally arrive at the following SDR of the QMP problem (6):

$$\begin{aligned}
\text{(SDRM)}\quad &\min \operatorname{Tr}(\boldsymbol{M}(f_0)\boldsymbol{U})\\
&\text{s.t. } \operatorname{Tr}(\boldsymbol{M}(f_i)\boldsymbol{U}) \le \alpha_i, i \in I,\\
&\quad \operatorname{Tr}(\boldsymbol{M}(f_j)\boldsymbol{U}) = \alpha_j, j \in \mathcal{E},\\
&\quad \operatorname{Tr}(\boldsymbol{N}_{ij}\boldsymbol{U}) = 2\delta_{ij}, 1 \le i \le j \le r,\\
&\quad \boldsymbol{U} \in \mathcal{S}_+^{n+r}.
\end{aligned} \tag{18}$$

The dual problem to the SDR problem (SDRM) is given by

$$\begin{aligned}
\text{(DM)}\quad &\max_{\lambda_i, \boldsymbol{\Phi}} -\sum_{i\in\mathcal{I}\cup\mathcal{E}} \lambda_i\alpha_i - \operatorname{Tr}(\boldsymbol{\Phi})\\
&\text{s.t. } \boldsymbol{M}(f_0) + \sum_{i\in\mathcal{I}\cup\mathcal{E}} \lambda_i \boldsymbol{M}(f_i) + \begin{pmatrix} \boldsymbol{0}_{n\times n} & \boldsymbol{0}_{n\times r} \\ \boldsymbol{0}_{r\times n} & \boldsymbol{\Phi} \end{pmatrix} \succeq \boldsymbol{0},\\
&\quad \boldsymbol{\Phi} \in \mathcal{S}^r,\\
&\quad \lambda_i \ge 0, i \in \mathcal{I}.
\end{aligned} \tag{19}$$

The symmetric matrix $\boldsymbol{\Phi} = (\phi_{ij})_{i,j=1}^r$ contains the Lagrange multipliers associated with the equality constraints $\operatorname{Tr}(\boldsymbol{N}_{ij}\boldsymbol{U}) = 2\delta_{ij}$. Specifically, for every $1 \le i \le r$, $\frac{1}{2}\phi_{ii}$ is the multiplier corresponding to the constraint $\operatorname{Tr}(\boldsymbol{N}_{ii}\boldsymbol{U}) = 2$, and $\phi_{ij} (= \phi_{ji})$ is the multiplier associated with $\operatorname{Tr}(\boldsymbol{N}_{ij}\boldsymbol{U}) = 0$ for $1 \le i < j \le r$. By the conic duality theorem [4] it follows that if (DM) is strictly feasible and bounded above, then (SDRM) is solvable and $\operatorname{val}(\text{SDRM}) = \operatorname{val}(\text{DM})$. For that reason we seek to find a simple condition under which (DM) is strictly feasible. The following lemma establishes such a condition.

LEMMA 3.3. *Suppose that the following condition is satisfied:*

$$\exists \gamma_i \in \mathbb{R}, i \in \mathcal{I} \cup \mathcal{E}, \text{ for which } \gamma_i \geq 0, i \in \mathcal{I}, \text{ such that } \boldsymbol{A}_0 + \sum_{i \in \mathcal{I} \cup \mathcal{E}} \gamma_i \boldsymbol{A}_i \succ \boldsymbol{0}. \tag{20}$$

Then problem (DM) *is strictly feasible.*

Proof. Let $\gamma_i \in \mathbb{R}, i \in \mathcal{I} \cup \mathcal{E}$, be numbers satisfying (20), and let $\epsilon > 0$ be a small enough number for which $\boldsymbol{A}_0 + \sum_{i \in \mathcal{I} \cup \mathcal{E}} (\gamma_i + \epsilon) \boldsymbol{A}_i \succ \boldsymbol{0}$. Define $\tilde{\gamma}_i \equiv \gamma_i + \epsilon$. Evidently, $\tilde{\gamma}_i > 0$ for $i \in \mathcal{I}$. Now, for every symmetric $r \times r$ matrix $\boldsymbol{\Phi}$ we have

$$\begin{aligned} \boldsymbol{M}(f_0) + \sum_{i \in \mathcal{I} \cup \mathcal{E}} \tilde{\gamma}_i \boldsymbol{M}(f_i) + \begin{pmatrix} \boldsymbol{0}_{n \times n} & \boldsymbol{0}_{n \times r} \\ \boldsymbol{0}_{r \times n} & \boldsymbol{\Phi} \end{pmatrix} \\ = \begin{pmatrix} \boldsymbol{A}_0 + \sum \tilde{\gamma}_i \boldsymbol{A}_i & \boldsymbol{B}_0 + \sum \tilde{\gamma}_i \boldsymbol{B}_i \\ (\boldsymbol{B}_0 + \sum \tilde{\gamma}_i \boldsymbol{B}_i)^T & \frac{1}{r} (c_0 + \sum \tilde{\gamma}_i c_i) \boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix}, \end{aligned} \tag{21}$$

where all the summations are over $i \in \mathcal{I} \cup \mathcal{E}$. Since $\boldsymbol{A}_0 + \sum \tilde{\gamma}_i \boldsymbol{A}_i \succ \boldsymbol{0}$, then by the Schur complement, the matrix on the RHS of (21) is positive definite if and only if

$$\boldsymbol{\Phi} \succ \left(\boldsymbol{B}_0 + \sum \tilde{\gamma}_i \boldsymbol{B}_i \right)^T \left(\boldsymbol{A}_0 + \sum \tilde{\gamma}_i \boldsymbol{A}_i \right)^{-1} \left(\boldsymbol{B}_0 + \sum \tilde{\gamma}_i \boldsymbol{B}_i \right) - \frac{1}{r} \left(c_0 + \sum \tilde{\gamma}_i c_i \right) \boldsymbol{I}_r.$$

Let $\tilde{\boldsymbol{\Phi}} \in \mathcal{S}^r$ be an arbitrary matrix satisfying the latter LMI. Thus, for $\lambda_i = \tilde{\gamma}_i, i \in \mathcal{I} \cup \mathcal{E}$, and $\boldsymbol{\Phi} = \tilde{\boldsymbol{\Phi}}$ we have that all the inequalities in (19) (regular and generalized) are strictly satisfied. ∎

Remark 3.1. Conditions similar to (20) are very common in the analysis of QCQP problems; see, e.g., [5, 18, 12, 19, 16]. This condition is automatically satisfied when at least one of the constraints or the objective function is strictly convex (see also [19, Proposition 2.1]).

3.2. Tightness of the SDR of the QMP problem. In this section we will show that, under some mild conditions, QMP problems of order r with at most r constraints have a tight SDR, and that strong duality holds. To show this, we need to verify that problem (SDRM) possesses a solution with rank smaller than or equal to r. This prompts us to consider questions concerning the existence of low-rank solutions to SDP problems—a subject extensively studied by Pataki [14, 15] and Barvinok [2, 3]; see also [11] for related results concerning the convexity of the image of several homogenous QMs.

Let us consider a general-form SDP problem:

$$\begin{aligned} &\min \operatorname{Tr}(\boldsymbol{C}_0 \boldsymbol{U}) \\ &\text{s.t. } \operatorname{Tr}(\boldsymbol{C}_i \boldsymbol{U}) \leq \alpha_i, i \in \mathcal{I}_1, \\ &\quad \operatorname{Tr}(\boldsymbol{C}_j \boldsymbol{U}) = \alpha_j, j \in \mathcal{E}_1, \\ &\quad \boldsymbol{U} \in \mathcal{S}^n_+, \end{aligned} \tag{22}$$

where $\mathcal{I}_1$ and $\mathcal{E}_1$ are disjoint index sets, $\boldsymbol{C}_i \in \mathcal{S}^n, i \in \{0\} \cup \mathcal{I}_1 \cup \mathcal{E}_1$, and $\alpha_i \in \mathbb{R}, i \in \mathcal{I}_1 \cup \mathcal{E}_1$. Pataki showed [15] that if the number of constraints is smaller than an upper bound which is a certain quadratic function of r, then there exists a solution with rank no larger than r (see Theorem 3.4 below). The proof of this result is constructive and is based on a simple rank reduction procedure[4] for finding extreme points of convex

[4]The SDP considered in [15] consists only of inequality constraints. However, the same analysis establishes the validity of Theorem 3.4.

sets of the form $\mathcal{S}_+^n \cap \mathcal{A}$, where $\mathcal{A}$ is an affine space. For the sake of completeness, and since the rank reduction procedure is a subroutine of the algorithm for solving the QMP problem, we recall both the claim (Theorem 3.4 below) and the rank reduction procedure (see Algorithm RED in the appendix).

THEOREM 3.4 (see [15]). *Suppose that problem* (22) *is solvable and that* $|\mathcal{I}_1| + |\mathcal{E}_1| \leq \binom{r+2}{2}$*, where* r *is a positive integer. Then problem* (22) *has a solution* $\boldsymbol{X}^*$ *for which* $\mathrm{rank}(\boldsymbol{X}^*) \leq r$.

Proof. Let $\boldsymbol{X}_0^*$ be an optimal solution of problem (22). Apply Algorithm RED (see the appendix) with input $\boldsymbol{X}_0^*$ and obtain an optimal solution $\boldsymbol{X}^*$ with $\mathrm{rank}(\boldsymbol{X}^*) \leq r$. ∎

Equipped with the latter result, we are now able to show that QMP problems of order r with at most r constraints possess a tight SDR under some mild conditions.

THEOREM 3.5 (tight SDR for the QMP problem). *If problem* (SDRM) *is solvable and* $|\mathcal{I}| + |\mathcal{E}| \leq r$*, then problem* (QMP) *is solvable and* $\mathrm{val(SDRM)} = \mathrm{val(QMP)}$.

Proof. It is sufficient to show that problem (SDRM) has a solution with rank smaller than or equal to r. The number of constraints in (SDRM) is equal to $|\mathcal{I}|+|\mathcal{E}|+\binom{r+1}{2}$, where the last term stands for the number of pairs (i,j) for which $1 \leq i \leq j \leq r$. Thus, using $|\mathcal{I}| + |\mathcal{E}| \leq r$, we conclude that the number of constraints in (SDRM) is bounded above by

$$r + \binom{r+1}{2} = \binom{r+2}{2} - 1.$$

Invoking Theorem 3.4, the result follows. ∎

As a conclusion from the conic duality theorem [4] we can now deduce the following corollary that guarantees tightness of the SDR and strong duality under the conditions that the QMP problem (6) is feasible and that condition (20) is valid.

COROLLARY 3.6 (strong duality for QMP problems). *Consider the QMP problem* (6) *with* $|\mathcal{I}| + |\mathcal{E}| \leq r$*, its semidefinite relaxation* (SDRM) *(problem* (18)*) and its dual* (DM) *(problem* (19)*). Suppose that condition* (20) *holds true and that the QMP problem is feasible. Then problems* (QMP) *and* (SDRM) *are solvable and* $\mathrm{val(QMP)} = \mathrm{val(SDRM)} = \mathrm{val(DM)}$.

Proof. By Lemma 3.3, the validity of condition (20) implies that the dual problem (DM) is strictly feasible. Moreover, since the primal SDP problem (SDRM) is feasible, it follows that the dual problem (DM) is bounded above. Thus, by the conic duality theorem [4], we conclude that problem (SDRM) is solvable and that $\mathrm{val(SDRM)} = \mathrm{val(DM)}$. Since problem (SDRM) is solvable we conclude, by Theorem 3.5, that $\mathrm{val(QMP)} = \mathrm{val(SDRM)}$. ∎

Remark 3.2. In the special case $r = 1$, Corollary 3.6 recovers the well-known strong duality/tightness of SDR results for QCQPs with a single quadratic constraint (see, e.g., [12, 5, 18, 16]).

It is interesting to note that we can also describe an algorithm for extracting the solution of a QMP problem (satisfying the condition in Corollary 3.6) from its SDR, which is based on the rank reduction algorithm of [15], as follows.

ALGORITHM SOL-QMP.

Step 1. Solve the SDP problem (SDRM) and obtain an optimal solution $\boldsymbol{U}^* \in \mathcal{S}_+^{n+r}$.

Step 2. Invoke Algorithm RED (see the appendix) with input $\boldsymbol{U}^*$, and produce an optimal solution $\boldsymbol{U}_1^* \in \mathcal{S}_+^{n+r}$ for which $\mathrm{rank}(\boldsymbol{U}_1^*) \leq r$.

Step 3. Calculate a decomposition: $\boldsymbol{U}_1^* = \boldsymbol{W}\boldsymbol{W}^T$, where $\boldsymbol{W} \in \mathbb{R}^{(n+r)\times r}$.

Step 4. Let $\boldsymbol{W} = (\mathbf{Y}; \boldsymbol{Z})$, where $\mathbf{Y} \in \mathbb{R}^{n\times r}$ and $\boldsymbol{Z} \in \mathbb{R}^{r\times r}$. Return an optimal solution $\boldsymbol{X}^* = \mathbf{Y}\boldsymbol{Z}^T$ to the QMP problem.

4. The vectorized semidefinite relaxation and dual of the QMP problem. In the previous section we considered a semidefinite relaxation that was based on a homogenization procedure specifically designed for QM functions. In this section we examine an alternative (and natural) approach in which we begin by transforming the problem into a "standard" QCQP and then use the usual relaxation technique. This approach produces the *vectorized SDR* and *vectorized dual* problems. We will prove that the two constructions are equivalent in some sense. In establishing this result we rely on the tight SDR result of section 3 and a result on two LMI representations of the property of nonnegativity of a QM function over $\mathbb{R}^{n\times r}$.

Our alternative SDR is constructed by following two steps.

Step 1. Transform the QMP problem (6) into the vectorized QMP problem (7).

Step 2. Formulate the corresponding SDR of the homogenized problem (7):

$$
\begin{aligned}
(SDRV)\quad & \min \operatorname{Tr}(\boldsymbol{M}(f_0^V)\boldsymbol{Z}) \\
& \text{s.t. } \operatorname{Tr}(\boldsymbol{M}(f_i^V))\boldsymbol{Z}) \le \alpha_i, i \in \mathcal{I}, \\
& \quad \operatorname{Tr}(\boldsymbol{M}(f_j^V)\boldsymbol{Z}) = \alpha_j, j \in \mathcal{E}, \\
& \quad Z_{nr+1,nr+1} = 1, \\
& \quad \boldsymbol{Z} \in \mathcal{S}_+^{nr+1}
\end{aligned} \tag{23}
$$

(recall that, since f_i^V is a QM function of order one, $\boldsymbol{M}(f_i^V) \equiv \left(\begin{smallmatrix} \boldsymbol{I}_r \otimes \boldsymbol{A}_i & \operatorname{vec}(\boldsymbol{B}_i) \\ \operatorname{vec}(\boldsymbol{B}_i)^T & c_i \end{smallmatrix}\right)$.

Problem (SDRV) is an SDP problem, and its dual is given by

$$
\begin{aligned}
\text{(DV)}\qquad & \max -\sum_{i\in\mathcal{I}\cup\mathcal{E}} \lambda_i\alpha_i - t \\
& \text{s.t. } \boldsymbol{M}(f_0^V) + \sum_{i\in\mathcal{I}\cup E} \lambda_i \boldsymbol{M}(f_i^V) + t\begin{pmatrix} \boldsymbol{0}_{nr,nr} & \boldsymbol{0}_{nr,1} \\ \boldsymbol{0}_{1,nr} & 1 \end{pmatrix} \succeq \boldsymbol{0}, \\
& \quad \lambda_i \ge 0, i \in \mathcal{I}.
\end{aligned} \tag{24}
$$

It can be shown that problem (DV) is in fact a Lagrangian dual of the QMP problem (6), and therefore the SDR (SDRV) can be interpreted as a bidual (i.e., dual of the dual) of the primal QMP problem. Problems (SDRV) and (DV) are called the *vectorized* semidefinite relaxation and dual of the QMP problem (respectively).

The pair of problems (SDRM)/(SDRV) and (DM)/(DV) seem quite different both with respect to the number of variables and the sizes of the related matrices. However, we will show in what follows (cf. Theorem 4.3) that these pairs of problems are equivalent in some sense.

Lemma 4.2 below presents two different LMI characterizations of the nonnegativity of a QM function over the entire space. This lemma is a key ingredient in proving the equivalence between the different dual/SDR problems. The proof of Lemma 4.2 relies on the following well-known result.

LEMMA 4.1 (see [4, p. 163]). *A quadratic inequality with a (symmetric) $n \times n$ matrix $\boldsymbol{A}$,*

$$\boldsymbol{x}^T\boldsymbol{A}\boldsymbol{x} + 2\boldsymbol{b}^T\boldsymbol{x} + c \ge 0,$$

is valid for all $\boldsymbol{x} \in \mathbb{R}^n$ if and only if

$$\begin{pmatrix} \boldsymbol{A} & \boldsymbol{b} \\ \boldsymbol{b}^T & c \end{pmatrix} \succeq \boldsymbol{0}.$$

LEMMA 4.2. *Let f be a QM function given in* (3). *Then the following three statements are equivalent:*

(i) $f(\boldsymbol{X}) \geq 0$ *for every* $\boldsymbol{X} \in \mathbb{R}^{n\times r}$.

(ii) *There exists* $\boldsymbol{\Phi} \in \mathcal{S}^r$ *for which* $Tr(\boldsymbol{\Phi}) \leq 0$ *such that*

$$\begin{pmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B}^T & \frac{c}{r}\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \boldsymbol{0}.$$

(iii)

$$\begin{pmatrix} \boldsymbol{I}_r \otimes \boldsymbol{A} & \mathrm{vec}(\boldsymbol{B}) \\ \mathrm{vec}(\boldsymbol{B})^T & c \end{pmatrix} \succeq \boldsymbol{0}.$$

Proof. (i⇔iii) By (4), the first statement is equivalent to the statement

$$f^V(\boldsymbol{z}) \geq 0 \text{ for every } \boldsymbol{z} \in \mathbb{R}^{nr},$$

which, by Lemma 4.1, is the same as the third statement.

(i⇔ii) We begin by showing the following identity between subsets of $\mathbb{R}$:

$$F = W, \tag{25}$$

where (recall that $[U]_r$ denotes the southeast $r \times r$ submatrix of $\boldsymbol{U}$)

$$\begin{aligned} F &= \{f(\boldsymbol{X}) : \boldsymbol{X} \in \mathbb{R}^{n\times r}\}, \\ W &= \{\mathrm{Tr}(\boldsymbol{M}(f)\boldsymbol{U}) : \boldsymbol{U} \in \mathcal{S}_+^{n+r}, [\boldsymbol{U}]_r = \boldsymbol{I}_r\}. \end{aligned}$$

The inclusion $F \subseteq W$ is clear. We will show that the reverse inclusion ($W \subseteq F$) holds true. Let $\alpha \in W$, and consider the QMP problem

$$\begin{aligned} &\min 0 \\ &\text{s.t. } f(\boldsymbol{X}) = \alpha, \\ &\quad \boldsymbol{X} \in \mathbb{R}^{n\times r}. \end{aligned} \tag{26}$$

Note that this is exactly the QMP problem (6) with $r = 1$, $\mathcal{I} = \emptyset$, $\mathcal{E} = \{1\}$, $\alpha_1 = \alpha, f_0 \equiv 0$, and $f_1 = f$. The corresponding SDR of the QMP problem (26) is given by

$$\begin{aligned} &\min 0 \\ &\text{s.t. } \mathrm{Tr}(\boldsymbol{M}(f)\boldsymbol{U}) = \alpha, \\ &\quad \boldsymbol{U} \in \mathcal{S}_+^{n+r},\ [\boldsymbol{U}]_r = \boldsymbol{I}_r. \end{aligned} \tag{27}$$

Since $\alpha \in W$ it follows that problem (27) is solvable (recall that the objective function is identically zero, and hence "solvability" is the same as "feasibility"). Invoking Theorem 3.5, we conclude that problem (26) is also feasible. Hence, $\alpha \in F$. The identity $F = W$ implies that statement (i) is the same as

$$\min\{\mathrm{Tr}(\boldsymbol{M}(f)\boldsymbol{U}) : \boldsymbol{U} \in \mathcal{S}_+^{n+r}, [\boldsymbol{U}]_r = \boldsymbol{I}_r\} \geq 0. \tag{28}$$

The latter SDP problem is strictly feasible ($\boldsymbol{U} = \boldsymbol{I}_{n+r} \succ \boldsymbol{0}$ is feasible) and bounded below (by zero) and thus, by the conic duality theorem, we conclude that the dual problem, given in this case by

$$\max_{\boldsymbol{\Phi}\in\mathcal{S}^r} \left\{ -\mathrm{Tr}(\boldsymbol{\Phi}) : \begin{pmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B}^T & \frac{c}{r}\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \boldsymbol{0} \right\},$$

is solvable and has value equal to the value of the primal problem. Therefore, statement (28) is equivalent to the existence of a symmetric $r \times r$ matrix $\boldsymbol{\Phi}$ for which

$$\begin{pmatrix} \boldsymbol{A} & \boldsymbol{B} \\ \boldsymbol{B}^T & \frac{c}{r}\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \mathbf{0}$$

and $\mathrm{Tr}(\boldsymbol{\Phi}) \leq 0$. □

We are now ready to prove the main result of this section, namely, that the values of the two dual problems (DM) and (DV) and the two SDR problems (SDRM) and (SDRV) are all equal to each other under some mild conditions.

THEOREM 4.3. *Consider the SDR*s (SDRM) *and* (SDRV) *(problems* (18) *and* (23)*) and the dual problems* (DM) *and* (DV) *(problems* (19) *and* (24)*) of the QMP problem* (6)*. Suppose that condition* (20) *is satisfied and that* (QMP) *is feasible. Then* (SDRM) *and* (SDRV) *are solvable and*

$$\mathrm{val(DM)} = \mathrm{val(DV)} = \mathrm{val(SDRM)} = \mathrm{val(SDRV)}.$$

Furthermore, if $\{\lambda_i\}_{i\in\mathcal{I}\cup\mathcal{E}}$ *and* $\boldsymbol{\Phi}$ *is an optimal solution of* (DM)*, then an optimal solution to* (DV) *is given by* $\{\lambda_i\}_{i\in\mathcal{I}\cup\mathcal{E}}, t$*, where* $t = \mathrm{Tr}(\boldsymbol{\Phi})$.

Proof. Since condition (20) is assumed to hold true then, by Lemma 3.3, the dual problem (DM) is strictly feasible, and an argument similar to the one used in the proof of Lemma 3.3 shows that (DV) is also strictly feasible. Thus, by the conic duality Theorem [4], both problems (SDRM) and (SDRV) are solvable, and we have the equality $\mathrm{val(DM)} = \mathrm{val(SDRM)}$ as well as $\mathrm{val(DV)} = \mathrm{val(SDRV)}$. We are left with the task of proving that $\mathrm{val(DM)} = \mathrm{val(DV)}$. Consider the LMI constraint in problem (DV), which can explicitly be written as follows:

$$\begin{pmatrix} \boldsymbol{I}_r \otimes (\boldsymbol{A}_0 + \sum \lambda_i \boldsymbol{A}_i) & \mathrm{vec}\left(\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i\right) \\ \mathrm{vec}\left(\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i\right)^T & c_0 + \sum \lambda_i c_i + t \end{pmatrix} \succeq \mathbf{0}, \tag{29}$$

where the summations are over $i \in \mathcal{I}\cup\mathcal{E}$. By the equivalence of the second and third part of Lemma 4.2 we have that the above LMI holds true if and only if there exists $\boldsymbol{Z} \in \mathcal{S}^r$ such that

$$\begin{pmatrix} \boldsymbol{A}_0 + \sum \lambda_i \boldsymbol{A}_i & \boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i \\ (\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i)^T & \frac{1}{r}(c_0 + \sum \lambda_i c_i + t)\boldsymbol{I}_r + \boldsymbol{Z} \end{pmatrix} \succeq \mathbf{0},$$

and $\mathrm{Tr}(\boldsymbol{Z}) \leq 0$. Making the change of variables $\boldsymbol{\Phi} = \boldsymbol{Z} + \frac{t}{r}\boldsymbol{I}_r$, we deduce that the LMI (29) is equivalent to the existence of a matrix $\boldsymbol{\Phi} \in \mathcal{S}^r$ such that

$$\begin{pmatrix} \boldsymbol{A}_0 + \sum \lambda_i \boldsymbol{A}_i & \boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i \\ (\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i)^T & \frac{1}{r}(c_0 + \sum \lambda_i c_i)\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \mathbf{0}, \tag{30}$$

and

$$\mathrm{Tr}(\boldsymbol{\Phi}) \leq t. \tag{31}$$

Replacing the LMI in problem (24) with the LMIs (30) and (31), problem (DV) is transformed into

$$\begin{aligned} \max_{\lambda_i, \boldsymbol{\Phi}, t} \; & -\sum_{i\in\mathcal{I}\cup\mathcal{E}} \lambda_i \alpha_i - t \\ \text{s.t.} \; & \begin{pmatrix} \boldsymbol{A}_0 + \sum \lambda_i \boldsymbol{A}_i & \boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i \\ (\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i)^T & \frac{1}{r}(c_0 + \sum \lambda_i c_i)\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \mathbf{0}, \\ & \lambda_i \geq 0, i \in \mathcal{I}, \\ & \mathrm{Tr}(\boldsymbol{\Phi}) \leq t. \end{aligned}$$

It is clear that any optimal solution of the last problem satisfies $t = \mathrm{Tr}(\boldsymbol{\Phi})$, and thus the problem is the same as

$$\begin{array}{l} \max\limits_{\lambda_i,\Phi} -\sum\limits_{i\in\mathcal{I}\cup\mathcal{E}} \lambda_i\alpha_i - \mathrm{Tr}(\boldsymbol{\Phi}) \\ \text{s.t.} \begin{pmatrix} \boldsymbol{A}_0 + \sum \lambda_i \boldsymbol{A}_i & \boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i \\ (\boldsymbol{B}_0 + \sum \lambda_i \boldsymbol{B}_i)^T & \frac{1}{r}(c_0 + \sum \lambda_i c_i)\boldsymbol{I}_r + \boldsymbol{\Phi} \end{pmatrix} \succeq \mathbf{0}, \\ \quad \lambda_i \geq 0, i \in \mathcal{I}, \end{array}$$

which is identical to problem (DM). ∎

Combining the latter result with the strong duality result, Corollary 3.6, the following corollary immediately follows.

COROLLARY 4.4. *Consider the QMP problem* (6) *with* $|\mathcal{I}|+|\mathcal{E}| \leq r$*, its vectorized semidefinite relaxation* (SDRV) *(problem* (23)*), and its vectorized dual* (DV) *(problem* (24)*). Suppose that condition* (20) *holds true and that the QMP problem is feasible. Then problems* (QMP) *and* (SDRV) *are solvable and* $\mathrm{val}(\mathrm{QMP}) = \mathrm{val}(\mathrm{SDRV}) = \mathrm{val}(\mathrm{DV})$.

5. An application to robust least squares. We continue the example from section 2.2. Suppose that the uncertainty set $\mathcal{U}$ associated with the matrix $\boldsymbol{A}$ is given by multiple norm constraints:

$$\mathcal{U} = \{\Delta \in \mathbb{R}^{n\times r} : \|\mathbf{L}_i\boldsymbol{\Delta}\|^2 \leq \rho_i, i = 1,\ldots,m\}, \tag{32}$$

where $\mathbf{L}_i \in \mathbb{R}^{k_i\times n}$ for some positive integers $k_1,\ldots,k_m$ and $\rho_i > 0, i = 1,\ldots,m$. The above form of the uncertainty set is more general then the standard single-constraint form, and it can thus be used to describe more complicated scenarios of uncertainties. For example, by setting $k_i = n, m = n$, and $\mathbf{L}_i = \boldsymbol{E}_{ii}^n$, we model the situation in which the uncertainty associated with each column of the matrix $\boldsymbol{A}$ has a separate norm constraint.

Assume that there exist nonnegative numbers $\gamma_1,\ldots,\gamma_m$ such that

$$\sum_{i=1}^m \gamma_i \mathbf{L}_i^T\mathbf{L}_i \succ \mathbf{0}.$$

If $m \leq r$, then the conditions of Corollary 4.4 are satisfied, and as a consequence the inner maximization problem (9) is equal to the value of the dual problem given by

$$\begin{array}{l} \min\limits_{t,\lambda_i} \sum\limits_{i=1}^m \lambda_i\rho_i + t \\ \text{s.t.} \begin{pmatrix} \boldsymbol{I}_r \otimes (-\mathbf{Q} + \sum_{i=1}^m \lambda_i \mathbf{L}_i^T\mathbf{L}_i) & -\mathrm{vec}(\mathbf{F}) \\ -\mathrm{vec}(\mathbf{F})^T & -c + t \end{pmatrix} \succeq \mathbf{0}, \\ \quad \lambda_i \geq 0, i = 1,2,\ldots,m. \end{array}$$

Here we considered the equivalent vectorized dual because it is not clear how to derive an SDP formulation from the nonvectorized dual. Now, using the identities (see [10])

$$\begin{aligned} \boldsymbol{I}_r \otimes \mathbf{Q} &\overset{(10)}{=} \boldsymbol{I}_r \otimes \boldsymbol{x}\boldsymbol{x}^T = (\boldsymbol{I}_r \otimes \boldsymbol{x})(\boldsymbol{I}_r \otimes \boldsymbol{x})^T, \\ \mathrm{vec}(\mathbf{F}) &\overset{(10)}{=} \mathrm{vec}(\boldsymbol{x}(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})^T) = (\boldsymbol{I}_r \otimes \boldsymbol{x})(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}), \end{aligned}$$

the dual problem is transformed into

$$\begin{aligned}
&\min_{t,\lambda_i} \sum_{i=1}^{m} \lambda_i \rho_i + t \\
&\text{s.t.} \begin{pmatrix} -(\boldsymbol{I}_r \otimes \boldsymbol{x})(\boldsymbol{I}_r \otimes \boldsymbol{x})^T + \sum_{i=1}^{m} \lambda_i (\boldsymbol{I}_r \otimes (\mathbf{L}_i^T \mathbf{L}_i)) & -(\boldsymbol{I}_r \otimes \boldsymbol{x})(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}) \\ -(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})^T (\boldsymbol{I}_r \otimes \boldsymbol{x})^T & -\|\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b}\|^2 + t \end{pmatrix} \succeq \mathbf{0}, \\
&\quad \lambda_i \geq 0, i = 1, 2, \ldots, m,
\end{aligned}$$

which, by the Schur complement can be written as

$$\begin{aligned}
&\min_{t,\lambda_i} \sum_{i=1}^{m} \lambda_i \rho_i + t \\
&\text{s.t.} \begin{pmatrix} \boldsymbol{I}_r & (\boldsymbol{I}_r \otimes \boldsymbol{x})^T & \boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} \\ \boldsymbol{I}_r \otimes \boldsymbol{x} & \sum_{i=1}^{m} \lambda_i (\boldsymbol{I}_r \otimes (\mathbf{L}_i^T \mathbf{L}_i)) & \mathbf{0} \\ (\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})^T & \mathbf{0} & t \end{pmatrix} \succeq \mathbf{0}, \\
&\quad \lambda_i \geq 0, i = 1, 2, \ldots, m.
\end{aligned}$$

Finally, we arrive at the following SDP formulation of the RLS problem (8):

$$\begin{aligned}
&\min_{t,\lambda_i,x} \sum_{i=1}^{m} \lambda_i \rho_i + t \\
&\text{s.t.} \begin{pmatrix} \boldsymbol{I}_r & (\boldsymbol{I}_r \otimes \boldsymbol{x})^T & \boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} \\ \boldsymbol{I}_r \otimes \boldsymbol{x} & \sum_{i=1}^{m} \lambda_i (\boldsymbol{I}_r \otimes (\mathbf{L}_i^T \mathbf{L}_i)) & \mathbf{0} \\ (\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})^T & \mathbf{0} & t \end{pmatrix} \succeq \mathbf{0}, \\
&\quad \lambda_i \geq 0, i = 1, 2, \ldots, m.
\end{aligned}$$

Appendix. A rank reduction algorithm for solvable semidefinite problems. We review here the rank reduction algorithm of [15] for solving SDP problems of the form (22).[5] The underlying assumption that guarantees the validity of the process is that problem (22) is solvable and that $|\mathcal{I}_1| + |\mathcal{E}_1| \leq \binom{r+2}{2} - 1$.

ALGORITHM RED.

Input: $\boldsymbol{X}_0$, an optimal solution to problem (22).

Output: An optimal solution $\boldsymbol{X}^*$ to problem (22) satisfying $\operatorname{rank}(\boldsymbol{X}^*) \leq r$.

1. **If** $\operatorname{rank}(\boldsymbol{X}_0) \leq r$, then go to step 3. **Else** go to step 2.
2. **While** $\operatorname{rank}(\boldsymbol{X}_0) > r$, **repeat** steps (a)–(e):
   (a) **Set** $d \leftarrow \operatorname{rank}(\boldsymbol{X}_0)$.
   (b) Compute a decomposition of $\boldsymbol{X}_0$: $\boldsymbol{X}_0 = \boldsymbol{U}\boldsymbol{U}^T$, where $\boldsymbol{U} \in \mathbb{R}^{n \times d}$.
   (c) Find a nontrivial solution[6] $\boldsymbol{Z}_0$ for the set of homogenous linear equations in the $d \times d$ *symmetric* variables matrix $\boldsymbol{Z}$ ($\boldsymbol{Z} = \boldsymbol{Z}^T$):
   $$\operatorname{Tr}(\boldsymbol{U}^T \boldsymbol{C}_i \boldsymbol{U} \boldsymbol{Z}) = 0, \quad i \in \mathcal{I}_1 \cup \mathcal{E}_1.$$
   (d) **If** $\boldsymbol{Z}_0 \succeq \mathbf{0}$, then **set** $\boldsymbol{W} \leftarrow -\boldsymbol{Z}_0$. **Else set** $\boldsymbol{W} \leftarrow \boldsymbol{Z}_0$.
   (e) **Set** $\boldsymbol{X}_0 \leftarrow \boldsymbol{U}(\boldsymbol{I} + \beta \boldsymbol{W})\boldsymbol{U}^T$, where $\beta = -1/\lambda_{\min}(\boldsymbol{W})$.
3. **Set** $\boldsymbol{X}^* \leftarrow \boldsymbol{X}_0$ and **STOP**.

[5] Note that in [15], the SDP problem contains only inequality constraints. However, it is immediately seen that exactly the same rank reduction algorithm also works here.

[6] Using the relations $|\mathcal{I}_1| + |\mathcal{E}_1| \leq \binom{r+2}{2} - 1, d > r$, it is easy to see that the homogenous system has more variables than equations and, as a result, has a nonzero solution.

Note that the algorithm does not make use of the matrix $\boldsymbol{C}_0$ corresponding to the objective function in (22). Indeed, it can be shown that since the input to the algorithm is an *optimal* solution of the SDP problem (22), then the value $\mathrm{Tr}(\boldsymbol{C}_0\boldsymbol{X}_0)$ remains constant throughout the process.

MAXIMAL MONOTONICITY FOR THE PRECOMPOSITION WITH A LINEAR OPERATOR*

RADU IOAN BOŢ†, SORIN-MIHAI GRAD†, AND GERT WANKA†

Abstract. We give the weakest constraint qualification known to us that ensures the maximal monotonicity of the operator $A^* \circ T \circ A$ when A is a linear continuous mapping between two reflexive Banach spaces and T is a maximal monotone operator. As a special case we get the weakest constraint qualification that guarantees the maximal monotonicity of the sum of two maximal monotone operators on a reflexive Banach space. Then we give a weak constraint qualification assuring the Brézis–Haraux-type approximation of the range of the subdifferential of the precomposition to A of a proper convex lower semicontinuous function in nonreflexive Banach spaces, extending and correcting in a special case an older result due to Riahi.

Key words. maximal monotone operator, Fitzpatrick function, subdifferential, Brézis–Haraux-type approximation

AMS subject classifications. 47H05, 42A50, 90C25

DOI. 10.1137/050641491

1. Introduction.

The literature on maximal monotone operators is quite rich, especially in recent years when their connections to convex analysis, underlined with the help of some functions (see [12], [15], [16], [21], [23], [24]), were more and more intensively studied and used. One of the most interesting problems which involves both maximal monotone operators and convex analysis is the one of finding sufficient conditions that ensure the maximal monotonicity of the operator $A^* \circ T \circ A$ when A is a linear continuous mapping between two reflexive Banach spaces and T is a maximal monotone operator. From the papers dealing with this problem we refer here to [1], [6], [13], [15], and [24], the latter unifying the results concerning this issue from the others and giving four equivalent constraint qualifications, the weakest in the literature known to us. Finding a weaker sufficient condition under which the sum of two maximal monotone operators on reflexive Banach spaces is maximal monotone has been an older challenge for many mathematicians, the problem having existed for more than four decades. From Browder [3] and Rockafellar [20] in the 1960's to the recent papers of Simons and Zălinescu [23], Borwein [1], and Zălinescu [24], the conditions imposed on two maximal monotone operators in order to ensure the maximal monotonicity of their sum became weaker and weaker, the latter paper containing the weakest constraint qualification known to us so far that guarantees the mentioned result. We mention here also Simons' book [21], where many sufficient conditions for the mentioned problem are recalled, compared, and unified. This book and the lecture notes [17] due to Phelps are excellent references for anyone interested in maximal monotone operators. Within this paper we give a constraint qualification that guarantees the maximal monotonicity of $A^* \circ T \circ A$ and is satisfied also by some A and T that violate the other sufficient conditions known to us, already mentioned. This condition uses the so-called Fitzpatrick function and has been developed from the one

†Faculty of Mathematics, Chemnitz University of Technology, D-09107 Chemnitz, Germany (radu.bot@mathematik.tu-chemnitz.de, sorin-mihai.grad@mathematik.tu-chemnitz.de, gert.wanka@mathematik.tu-chemnitz.de).

introduced by two of the authors in [2] for the Fenchel duality. For a special choice of A and T we obtain the weakest sufficient condition known to us that guarantees the maximal monotonicity of the sum of two maximal monotone operators.

Another result in maximal monotonicity for whose fulfillment we give a weaker sufficient condition is the one concerning the so-called Brézis–Haraux-type approximation of the range of $\partial(f \circ A)$, where f is a proper convex lower semicontinuous function defined on the image space of A with extended real values. Here we work in nonreflexive Banach spaces. Something similar has been done by Pennanen in [14] when the image space of A is reflexive. As a special case we recover and correct a result due to Riahi (see [18]) concerning the Brézis–Haraux-type approximation (see [21]) of the range of the sum of the subdifferentials of two lower semicontinuous functions by the sum of the ranges of the two subdifferentials, for which we give a weaker constraint qualification than in the original paper.

The paper is structured as follows. The next section contains necessary preliminaries, notions, and results used later; then we deal with the maximal monotonicity of $A^* \circ T \circ A$ and of the sum of two maximal monotone operators. Section 4 deals with the mentioned Brézis–Haraux-type approximations and is followed by a short summary of the results proved within the paper.

2. Preliminaries. In this section we introduce and recall some notions and results in order to make the paper self-contained. Even if the main results in the paper are given in (reflexive) Banach spaces, some of the preliminaries are valid also for more general spaces, and thus we begin by considering a nontrivial locally convex topological space X and its continuous dual space X^*, endowed with the weak* topology $w(X^*, X)$. By $\langle x^*, x\rangle$ we denote the value of the linear continuous functional $x^* \in X^*$ at $x \in X$. For a subset C of X we have the *indicator* function $\delta_C : X \to \overline{\mathbb{R}} = \mathbb{R} \cup \{\pm\infty\}$, defined by

$$\delta_C(x) = \begin{cases} 0 & \text{if } x \in C, \\ +\infty & \text{otherwise,} \end{cases}$$

and we denote by $\operatorname{int}(C)$ and $\operatorname{cl}(C)$ its *interior*, respectively, its *closure* in the corresponding topology. For C we define also the *linear hull* $\operatorname{lin}(C)$ as the intersection of all the linear subspaces of X containing C and the *affine hull* $\operatorname{aff}(C)$ which is the intersection of all the affine subsets of X containing C. For $C \subseteq X$ convex we denote the *intrinsic relative algebraic interior* of C by ${}^{ic}C$. One has $x \in {}^{ic} C$ if and only if $\cup_{\lambda>0} \lambda(C - x)$ is a closed linear subspace of X. We consider also the *first projection*, i.e., the function $\operatorname{pr}_1 : X \times Y \to X$, for Y some nontrivial locally convex space, defined as follows: $\operatorname{pr}_1(x, y) = x$ for any $(x, y) \in X \times Y$.

Given a function $f : X \to \overline{\mathbb{R}}$, we denote its *domain* by $\operatorname{dom}(f) = \{x \in X : f(x) < +\infty\}$ and its *epigraph* by $\operatorname{epi}(f) = \{(x, r) \in X \times \mathbb{R} : f(x) \le r\}$. For $x \in X$ such that $f(x) \in \mathbb{R}$ we define the *subdifferential* of f at x by $\partial f(x) = \{x^* \in X^* : f(y) - f(x) \ge \langle x^*, y - x\rangle\}$. We call f *proper* if $f(x) > -\infty\ \forall x \in X$ and $\operatorname{dom}(f) \ne \emptyset$. The *conjugate* of the function f is $f^* : X^* \to \overline{\mathbb{R}}$ introduced by

$$f^*(y) = \sup\big\{\langle y, x\rangle - f(x) : x \in X\big\}.$$

Between a function and its conjugate there is *Young's inequality*

$$f^*(y) + f(x) \ge \langle y, x\rangle \quad \forall x \in X\ y \in X^*.$$

Consider also the *identity* function on X defined as follows: $\operatorname{id}_X : X \to X$, $\operatorname{id}_X(x) = x$ $\forall x \in X$. When $f : X \to \overline{\mathbb{R}}$ and $g : Y \to \overline{\mathbb{R}}$, we define the function $f \times g : X \times Y \to \overline{\mathbb{R}} \times \overline{\mathbb{R}}$

through $f \times g(x,y) = (f(x), g(y))$, $(x,y) \in X \times Y$. When $f, g : X \to \overline{\mathbb{R}}$ are proper functions, we have the *infimal convolution* of f and g defined by

$$f \square g : X \to \overline{\mathbb{R}},\ f \square g(a) = \inf\{f(x) + g(a-x) : x \in X\}.$$

Given a linear continuous mapping $A : X \to Y$, we have its *image-set* $\mathrm{Im}(A) = AX = \{Ax : x \in X\} \subseteq Y$ and its *adjoint* $A^* : Y^* \to X^*$ given by $\langle A^*y^*, x\rangle = \langle y^*, Ax\rangle$ for any $(x, y^*) \in X \times Y^*$. For the proper function $f : X \to \overline{\mathbb{R}}$ we define also the *infimal function of f through A* as $Af : Y \to \overline{\mathbb{R}}$, $Af(y) = \inf\left\{f(x) : x \in X,\ Ax = y\right\}$, $y \in Y$. Throughout the present paper when an infimum or a supremum is attained we write min, respectively, max instead of inf and sup.

Further we give some results concerning the composition of a function with a linear continuous operator.

LEMMA 1 (cf. [8, Theorem 2.7]). *Let X and Y be nontrivial locally convex spaces, $A : X \to Y$ a linear continuous mapping, and $f : Y \to \overline{\mathbb{R}}$ a proper, convex, and lower semicontinuous function such that $f \circ A$ is proper on X. Then*

$$\mathrm{epi}((f \circ A)^*) = \mathrm{cl}(\mathrm{epi}(A^* f^*)), \tag{1}$$

where the closure is taken in the product topology of $(X^*, \tau) \times \mathbb{R}$, for every locally convex topology τ on X^* giving X as dual.

Remark 1. Significant choices for τ in the preceding lemma are the weak* topology $w(X^*, X)$ on X^* or the norm topology of X^* in case X is a reflexive Banach space.

LEMMA 2 (cf. [2, Theorem 2.4]). *Let X and Y be nontrivial locally convex spaces, τ a compatible topology on X^*, $A : X \to Y$ a linear continuous mapping, and $f : Y \to \overline{\mathbb{R}}$ a proper function. Then*

$$\mathrm{cl}(\mathrm{epi}(A^* f^*)) = \mathrm{cl}(A^* \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f^*))), \tag{2}$$

where the closure is taken in the product topology of $(X^*, \tau) \times \mathbb{R}$.

Taking into (1) and (2) the closure in the product topology of $(X^*, \tau) \times \mathbb{R}$, with τ any locally convex topology on X^* giving X as dual, we get

$$\mathrm{epi}((f \circ A)^*) = \mathrm{cl}(\mathrm{epi}(A^* f^*)) = \mathrm{cl}(A^* \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f^*))). \tag{3}$$

DEFINITION 1. *A set $M \subseteq X$ is said to be* closed regarding the subspace $Z \subseteq X$ *if $M \cap Z = \mathrm{cl}(M) \cap Z$.*

PROPOSITION 1. *Let X, Y, and U be nontrivial locally convex spaces, $A : X \to Y$ a linear continuous mapping, and $f : Y \to \overline{\mathbb{R}}$ a proper, convex, and lower semicontinuous function such that $f \circ A$ is proper on X. Consider, moreover, a linear mapping $M : U \to X^*$. Let τ be any locally convex topology on X^* giving X as dual. The following statements are equivalent.*

(a) *$A^* \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f^*))$ is closed regarding the subspace $\mathrm{Im}(M) \times \mathbb{R}$ in the product topology of $(X^*, \tau) \times \mathbb{R}$.*

(b) *$(f \circ A)^*(Mu) = \min\left\{f^*(y^*) : A^*y^* = Mu\right\}$ $\forall u \in U$.*

Proof. Because f is proper, convex, and lower semicontinuous, A linear and continuous, and $f \circ A$ proper it follows that $(f \circ A)^*$ is proper, convex, and lower semicontinuous.

(a) $\Rightarrow$ (b) Let $u \in U$. For any $y^* \in Y^*$ fulfilling $A^*y^* = Mu$ we have

$$f^*(y^*) \geq \sup_{x \in X}\{\langle y^*, Ax\rangle - f(Ax)\} = \sup_{x \in X}\{\langle Mu, x\rangle - (f \circ A)(x)\} = (f \circ A)^*(Mu),$$

and so we conclude that

$$\inf\left\{f^*(y^*) : A^*y^* = Mu\right\} \geq (f \circ A)^*(Mu). \tag{4}$$

If $(f \circ A)^*(Mu) = +\infty$, then (4) yields $f^*(y^*) = +\infty = (f \circ A)^*(Mu)$ for any $y^* \in Y^*$ such that $A^*y^* = Mu$. Consider further the case $(f \circ A)^*(Mu) \in \mathbb{R}$. It follows that $(Mu, (f \circ A)^*(Mu)) \in \operatorname{epi}((f \circ A)^*)$, and it is clear that it belongs also to $\operatorname{Im}(M) \times \mathbb{R}$. By (3), (a) gives

$$\begin{aligned}(A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))) \cap (\operatorname{Im}(M) \times \mathbb{R}) &= \operatorname{cl}(A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))) \cap (\operatorname{Im}(M) \times \mathbb{R}) \\ &= \operatorname{epi}((f \circ A)^*) \cap (\operatorname{Im}(M) \times \mathbb{R}),\end{aligned}$$

and so there is some $\bar{y}^* \in Y^*$ such that $A^*\bar{y}^* = Mu$ and $(\bar{y}^*, (f \circ A)^*(Mu)) \in \operatorname{epi}(f^*)$ or, equivalently, $f^*(\bar{y}^*) \leq (f \circ A)^*(Mu)$. Thus by (4) we get

$$\min\left\{f^*(y^*) : A^*y^* = Mu\right\} = (f \circ A)^*(Mu). \tag{5}$$

(b) $\Rightarrow$ (a) From (3) one gets $\operatorname{epi}((f \circ A)^*) \supseteq A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))$, followed by

$$\operatorname{epi}((f \circ A)^*) \cap (\operatorname{Im}(M) \times \mathbb{R}) \supseteq (A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))) \cap (\operatorname{Im}(M) \times \mathbb{R}).$$

For any pair $(x^*, r) \in \operatorname{epi}((f \circ A)^*) \cap (\operatorname{Im}(M) \times \mathbb{R})$ there is some $u \in U$ such that $x^* = Mu$ and we have $(f \circ A)^*(x^*) = (f \circ A)^*(Mu) \leq r$. The hypothesis (b) grants the existence of an $\bar{y}^* \in Y^*$ satisfying both $A^*\bar{y}^* = Mu = x^*$ and $f^*(\bar{y}^*) = (f \circ A)^*(Mu) \leq r$, i.e., $(\bar{y}^*, r) \in \operatorname{epi}(f^*)$. Thus $(x^*, r) = (A^*\bar{y}^*, r) \in A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))$, and as one thus gets

$$\operatorname{epi}((f \circ A)^*) \cap (\operatorname{Im}(M) \times \mathbb{R}) \subseteq (A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))) \cap (\operatorname{Im}(M) \times \mathbb{R}),$$

the conclusion follows by (3). □

COROLLARY 1 (cf. [2, Theorem 3.3]). *Let X and Y be nontrivial locally convex spaces, $A : X \to Y$ a linear continuous mapping, and $f : Y \to \overline{\mathbb{R}}$ a proper, convex, and lower semicontinuous function such that $f \circ A$ is proper. Let τ be any locally convex topology on X^* giving X as dual. Then*

(i) *$A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))$ is closed in the product topology of $(X^*, \tau) \times \mathbb{R}$ if and only if for any $x^* \in X^*$ one has*

$$(f \circ A)^*(x^*) = \min\{f^*(y^*) : A^*y^* = x^*\};$$

(ii) *if $A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))$ is closed in the product topology of $(X^*, \tau) \times \mathbb{R}$, then for any $x \in \operatorname{dom}(f \circ A)$ one has $\partial(f \circ A)(x) = A^*\partial f(Ax)$.*

Proof. (i) follows from Proposition 1 when taking $U = X^*$ and $M = \operatorname{id}_{X^*}$, while for (ii) we refer the reader to [2] and [11]. □

Remark 2. Let τ be any locally convex topology on X^* giving X as dual. We know that $A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*)) \subseteq \operatorname{epi}(A^*f^*) \subseteq \operatorname{epi}((f \circ A)^*)$ (see Lemmas 1 and 2). From (3) it follows that $A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*))$ is closed in the product topology of $(X^*, \tau) \times \mathbb{R}$ if and only if

$$A^* \times \operatorname{id}_{\mathbb{R}}(\operatorname{epi}(f^*)) = \operatorname{epi}(A^*f^*) = \operatorname{epi}((f \circ A)^*).$$

The second part of this section in devoted to monotone operators and some of their properties. Consider further X a Banach space equipped with the norm $\|\cdot\|$, while the norm on X^* is $\|\cdot\|_*$.

DEFINITION 2 (cf. [20]). *A multifunction $T : X \rightrightarrows X^*$ is called a* monotone operator*, provided that for any $x, y \in X$ one has*

$$\langle y^* - x^*, y - x\rangle \geq 0 \quad \textit{whenever } x^* \in T(x) \textit{ and } y^* \in T(y).$$

DEFINITION 3 (cf. [20]). *For any monotone operator $T : X \rightrightarrows X^*$ we have*

- *its* effective domain $D(T) = \{x \in X : T(x) \neq \emptyset\}$,
- *its* range $R(T) = \cup\{T(x) : x \in X\}$,
- *its* graph $G(T) = \{(x, x^*) : x \in X,\ x^* \in T(x)\}$.

DEFINITION 4 (cf. [20]). *A monotone operator $T : X \rightrightarrows X^*$ is called* maximal *when its graph is not properly included in the graph of any other monotone operator $T' : X \rightrightarrows X^*$.*

The subdifferential of a proper convex lower semicontinuous function on X is a typical example of a maximal monotone operator (see [19]). As we shall see in section 4, it belongs to many other classes of operators, too. We introduce also the *duality map* $J : X \rightrightarrows X^*$ defined as follows:

$$J(x) = \frac{1}{2}\partial\|x\|^2 = \left\{x^* \in X^* : \|x\|^2 = \|x^*\|^2 = \langle x^*, x\rangle\right\} \quad \forall x \in X,$$

because it gives the following criterion for the maximal monotonicity of a monotone operator $T : X \rightrightarrows X^*$.

PROPOSITION 2 (cf. [1], [21]). *A monotone operator T on a reflexive Banach space X is maximal if and only if the mapping $T(x + \cdot) + J(\cdot)$ is surjective $\forall x \in X$.*

As underlined by many authors (see [1], [12], [15], [16], [21], [23], [24]), there are strong connections between the maximal monotone operators and convex analysis. They are best noticeable by the *Fitzpatrick function* associated with the monotone operators (see [7]). Rediscovered after some years, it proved to be crucial in treating the problem of maximal monotonicity of the sum of maximal monotone operators within the latest papers on the subject [1], [16], [23], [24]. To a monotone operator $T : X \rightrightarrows X^*$ Fitzpatrick attached the function

$$\varphi_T : X \times X^* \to \overline{\mathbb{R}},\ \varphi_T(x, x^*) = \sup\left\{\langle y^*, x\rangle + \langle x^*, y\rangle - \langle y^*, y\rangle : y^* \in T(y)\right\}.$$

For any monotone operator T it is quite clear that φ_T is a convex lower semicontinuous function as a supremum of a family of continuous affine functions. An important result regarding the Fitzpatrick function and its conjugate in reflexive Banach spaces follows.

PROPOSITION 3 (cf. [5], [7], [15], [23]). *Let T be a maximal monotone operator on a reflexive Banach space X. Then for any pair $(x, x^*) \in X \times X^*$ we have*

$$\varphi_T^*(x^*, x) \geq \varphi_T(x, x^*) \geq \langle x^*, x\rangle.$$

Moreover, $\varphi_T^*(x^*, x) = \varphi_T(x, x^*) = \langle x^*, x\rangle$ if and only if $(x, x^*) \in G(T)$.

3. Maximal monotonicity for the precomposition with a linear operator. Within this section X and Y will be reflexive Banach spaces. Given the maximal monotone operator T on Y and the linear continuous mapping $A : X \to Y$, such that $A^{-1}\big(\mathrm{pr}_1(\mathrm{dom}(\varphi_T))\big) \neq \emptyset$, we introduce the operator $T_A : X \rightrightarrows X^*$ defined by $T_A(x) = A^* \circ T \circ A(x)$, $x \in X$, which is monotone but not always maximal monotone.

3.1. Maximal monotonicity for T_A. Various conditions which ensure the maximal monotonicity of T_A were given in many recent papers, among which we mention [1], [6], [13], [15], and [24]. We prove, using an idea due to Borwein [1], that T_A is maximal monotone, provided that the following constraint qualification is fulfilled:

(CQ) $A^* \times \mathrm{id}_Y \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(\varphi_T^*))$ is closed regarding the subspace $X^* \times \mathrm{Im}(A) \times \mathbb{R}$.

THEOREM 1. *If (CQ) is fulfilled, then T_A is a maximal monotone operator.*

Proof. Let us fix some $z \in X$ and $z^* \in X^*$ and consider $f, g : X \times X^* \to \overline{\mathbb{R}}$, defined by

$$f(x, x^*) = \inf\{\varphi_T(A(x+z), y^*) - \langle y^*, Az\rangle : A^*y^* = x^* + z^*\}$$

and

$$g(x, x^*) = \frac{1}{2}\|x\|^2 + \frac{1}{2}\|x^*\|_*^2 - \langle z^*, x\rangle,\ (x, x^*) \in X \times X^*.$$

As f and g are convex and the latter is continuous we can apply Fenchel's duality theorem (see [25]) that guarantees the existence of some pair $(\bar{x}^*, \bar{x}) \in X^* \times X$ such that

$$\begin{aligned}\inf_{(x,x^*)\in X\times X^*}\{f(x, x^*) + g(x, x^*)\} &= \max_{(x^*,x)\in X^*\times X}\{-f^*(x^*, x) - g^*(-x^*, -x)\}\\ &= -f^*(\bar{x}^*, \bar{x}) - g^*(-\bar{x}^*, -\bar{x}). \qquad (6)\end{aligned}$$

Let us calculate the conjugates of f and g. Before this we introduce the linear continuous operator $B = A \times \mathrm{id}_{Y^*}$. For any $(w^*, w) \in X^* \times X$ we have

$$\begin{aligned}f^*(w^*, w) &= \sup_{\substack{x\in X,\\ x^*\in X^*}}\left\{\langle w^*, x\rangle + \langle x^*, w\rangle - \inf_{A^*y^*=x^*+z^*}\{\varphi_T(A(x+z), y^*) - \langle y^*, Az\rangle\}\right\}\\ &= \sup_{\substack{(x,x^*)\in X\times X^*,\ y^*\in Y^*,\\ A^*y^*=x^*+z^*}}\{\langle w^*, x\rangle + \langle x^*, w\rangle - \varphi_T(A(x+z), y^*) + \langle y^*, Az\rangle\}\\ &= \sup_{\substack{x\in X,\ y^*\in Y^*,\\ u=x+z\in X}}\{\langle w^*, u - z\rangle + \langle A^*y^* - z^*, w\rangle - \varphi_T(A(u), y^*) + \langle A^*y^*, z\rangle\}\\ &= \sup_{\substack{u\in X,\\ y^*\in Y^*}}\{\langle w^*, u\rangle + \langle y^*, A(w+z)\rangle - (\varphi_T \circ B)(u, y^*)\} - \langle w^*, z\rangle - \langle z^*, w\rangle\\ &= (\varphi_T \circ B)^*(w^*, A(w+z)) - \langle w^*, z\rangle - \langle z^*, w\rangle\end{aligned}$$

and

$$\begin{aligned}g^*(w^*, w) &= \sup_{\substack{x\in X,\\ x^*\in X^*}}\left\{\langle w^*, x\rangle + \langle x^*, w\rangle - \frac{1}{2}\|x\|^2 - \frac{1}{2}\|x^*\|_*^2 + \langle z^*, x\rangle\right\}\\ &= \frac{1}{2}\|w^* + z^*\|_*^2 + \frac{1}{2}\|w\|^2.\end{aligned}$$

Proposition 1 ensures that (CQ) is equivalent to the fact that for any $(w^*, w) \in X^* \times X$ one has

$$(\varphi_T \circ B)^*(w^*, Aw) = \min_{(y^*,y)\in Y^*\times Y}\{\varphi_T^*(y^*, y) : B^*(y^*, y) = (w^*, Aw)\}.$$

For any $(x, x^*) \in X \times X^*$ and $y^* \in Y^*$ such that $A^*y^* = x^* + z^*$, by Proposition 3, we have

$$\varphi_T(A(x+z), y^*) - \langle y^*, Az\rangle \geq \langle y^*, Ax + Az\rangle - \langle y^*, Az\rangle = \langle A^*y^*, x\rangle = \langle x^*, x\rangle + \langle z^*, x\rangle,$$

and so $f(x, x^*) \geq \langle x^*, x\rangle + \langle z^*, x\rangle$. Since $g(x, x^*) \geq -\langle x^*, x\rangle - \langle z^*, x\rangle$ we get $f(x, x^*) + g(x, x^*) \geq 0$. Thus $\inf_{(x,x^*)\in X\times X^*}\{f(x, x^*) + g(x, x^*)\} \geq 0$, and taking it into (6) one gets $f^*(\bar{x}^*, \bar{x}) + g^*(-\bar{x}^*, -\bar{x}) \leq 0$, i.e.,

$$(\varphi_T \circ B)^*(\bar{x}^*, A(\bar{x}+z)) - \langle \bar{x}^*, z\rangle - \langle z^*, \bar{x}\rangle + \frac{1}{2}\|-\bar{x}^* + z^*\|_*^2 + \frac{1}{2}\|-\bar{x}\|^2 \leq 0. \tag{7}$$

From Proposition 1 we have

$$(\varphi_T \circ B)^*(\bar{x}^*, A(\bar{x}+z)) = \min_{(y^*,y)\in Y^*\times Y}\{\varphi_T^*(y^*, y) : B^*(y^*, y) = (\bar{x}^*, A(\bar{x}+z))\},$$

with the minimum attained at some $(\bar{y}^*, \bar{y}) \in Y^* \times Y$. As the adjoint operator of B is $B^* : Y^* \times Y \to X^* \times Y$, $B^*(y^*, y) = (A^*y^*, y)$, it follows that $B^*(\bar{y}^*, \bar{y}) = (A^*\bar{y}^*, \bar{y}) = (\bar{x}^*, A(\bar{x}+z))$. Taking the last two relations into (7) we have

$$\begin{aligned}
0 &\geq \varphi_T^*(\bar{y}^*, \bar{y}) - \langle \bar{x}^*, z\rangle - \langle z^*, \bar{x}\rangle + \frac{1}{2}\|\bar{x}^* - z^*\|_*^2 + \frac{1}{2}\|\bar{x}\|^2 \\
&= \varphi_T^*(\bar{y}^*, A(\bar{x}+z)) - \langle \bar{y}^*, Az\rangle - \langle \bar{y}^*, A\bar{x}\rangle + \langle \bar{y}^*, A\bar{x}\rangle - \langle z^*, \bar{x}\rangle + \frac{1}{2}\|\bar{x}\|^2 \\
&\quad + \frac{1}{2}\|A^*\bar{y}^* - z^*\|_*^2 = \big(\varphi_T^*(\bar{y}^*, A(\bar{x}+z)) - \langle \bar{y}^*, A(\bar{x}+z)\rangle\big) \\
&\quad + \left(\langle A^*\bar{y}^* - z^*, \bar{x}\rangle + \frac{1}{2}\|A^*\bar{y}^* - z^*\|_*^2 + \frac{1}{2}\|\bar{x}\|^2\right) \geq 0,
\end{aligned}$$

where the last inequality comes from Proposition 3. Thus the inequalities above must be fulfilled as equalities, and so

$$\varphi_T^*(\bar{y}^*, A(\bar{x}+z)) - \langle \bar{y}^*, A(\bar{x}+z)\rangle = 0;$$

i.e., by Proposition 3, $\bar{y}^* \in T \circ A(\bar{x}+z)$ and

$$\langle A^*\bar{y}^* - z^*, \bar{x}\rangle + \frac{1}{2}\|A^*\bar{y}^* - z^*\|_*^2 + \frac{1}{2}\|\bar{x}\|^2 = 0,$$

i.e., $z^* - A^*\bar{y}^* \in \partial\frac{1}{2}\|\cdot\|^2(\bar{x})$. Further one has $A^*\bar{y}^* \in A^* \circ T \circ A(z+\bar{x}) = T_A(z+\bar{x})$ and $z^* - A^*\bar{y}^* \in J(\bar{x})$, and so $z^* \in T_A(z+\bar{x}) + J(\bar{x})$. As z and z^* have been arbitrarily chosen, Proposition 2 yields the conclusion. □

Remark 3. We compare in the following the constraint qualification (CQ) to some generalized interior-point regularity conditions given in the literature in order to ensure the maximality of the monotone operator T_A. Under the condition in [6] one gets the fulfillment of the ones considered in [1] and [15], which imply the ones in [13] and [24], that are actually equivalent (according to Theorem 7 in [24]) to

$$(CQ_Z) \qquad \bigcup_{\lambda>0} \lambda(D(T) - \mathrm{Im}(A)) \text{ is a closed linear subspace.}$$

By Corollary 3.6 in [16] this is nothing but $0 \in^{ic} (\mathrm{pr}_1(\mathrm{dom}(\varphi_T)) - \mathrm{Im}(A))$ or, equivalently, $\cup_{\lambda>0}\lambda(\mathrm{pr}_1(\mathrm{dom}(\varphi_T)) - \mathrm{Im}(A))$ is a closed linear subspace. This is actually the same with $\cup_{\lambda>0}\lambda\big(\mathrm{dom}(\varphi_T) - \mathrm{Im}(A) \times Y^*\big)$ being a closed linear subspace,

and so, taking into account that $B = A \times \mathrm{id}_{Y^*}$, $0 \in^{ic} (\mathrm{dom}(\varphi_T) - \mathrm{Im}(B))$. This yields, by Theorem 2.3.8(vii) in [25],

$$(\varphi_T \circ B)^*(w^*, Aw) = \min_{(y^*,y)\in Y^*\times Y} \{\varphi_T^*(y^*, y) : B^*(y^*, y) = (w^*, Aw)\},$$

which is equivalent to (CQ). Therefore $(CQ_Z) \Rightarrow (CQ)$. A counterexample to show that it is possible to have (CQ) satisfied and (CQ_Z) violated is given later.

Remark 4. The maximal monotonicity of T_A is valid also when imposing the constraint qualification

$$(\widetilde{CQ}) \qquad A^* \times \mathrm{id}_Y \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(\varphi_T^*)) \text{ is closed.}$$

The only difference in the proof is that we use Corollary 1(i) instead of Proposition 1. One may notice that we have $(CQ_Z) \Rightarrow (\widetilde{CQ}) \Rightarrow (CQ)$; i.e., $(\widetilde{CQ})$ is still weaker than (CQ_Z).

The remaining part of the section is dedicated to the proof of the fact that (CQ) is indeed weaker than (CQ_Z).

Example 1. Let $X = \mathbb{R}$ and $Y = \mathbb{R} \times \mathbb{R}$. Then $X^* = \mathbb{R}$ and $Y^* = \mathbb{R} \times \mathbb{R}$. Consider the operator $T : \mathbb{R} \times \mathbb{R} \to 2^{\mathbb{R}\times\mathbb{R}}$ defined by

$$T(x, y) = \begin{cases} (-\infty, 0] \times \{0\} & \text{if } x = 0,\ y < 0, \\ (-\infty, 0] \times [0, +\infty) & \text{if } x = y = 0, \\ \{x\} \times \{0\} & \text{if } x > 0,\ y < 0, \\ \{x\} \times [0, +\infty) & \text{if } x > 0,\ y = 0, \\ \emptyset & \text{otherwise.} \end{cases}$$

It is not difficult to notice that, considering the following proper, convex, and lower semicontinuous functions $f, g : \mathbb{R} \to \overline{\mathbb{R}}$, $f(x) = (1/2)x^2 + \delta_{[0,+\infty)}(x)$, and $g = \delta_{(-\infty,0]}$, for any $(x, y) \in \mathbb{R} \times \mathbb{R}$ we have $T(x, y) = \big(\partial f(x), \partial g(y)\big)$, and thus T is a maximal monotone operator. Taking $A : \mathbb{R} \to \mathbb{R} \times \mathbb{R}$, $Ax = (x, x)$, one gets, for any $x \in \mathbb{R}$,

$$T_A(x) = A^* \circ T \circ A(x) = \partial f(x) + \partial g(x) = \begin{cases} \mathbb{R} & \text{if } x = 0, \\ \emptyset & \text{otherwise,} \end{cases}$$

and thus T_A is a maximal monotone operator, too.

Let us calculate the conjugate of φ_T to see if (CQ) is fulfilled. We have $\forall (x, y, x^*, y^*) \in \mathbb{R} \times \mathbb{R} \times \mathbb{R} \times \mathbb{R}$

$$\varphi_T(x, y, x^*, y^*) = \begin{cases} \left(\frac{x+x^*}{2}\right)^2 & \text{if } x \geq 0,\ x + x^* > 0,\ y \leq 0,\ y^* \geq 0, \\ 0 & \text{if } x \geq 0,\ x + x^* \leq 0,\ y \leq 0,\ y^* \geq 0, \text{ and} \\ +\infty & \text{otherwise,} \end{cases}$$

$$\varphi_T^*(x^*, y^*, x, y) = \begin{cases} x^2 & \text{if } x \geq 0,\ x \geq x^*,\ y^* \geq 0,\ y \leq 0, \\ +\infty & \text{otherwise.} \end{cases}$$

Thus the epigraph of the conjugate is

$$\mathrm{epi}(\varphi_T^*) = \bigcup_{x\geq 0} \Big((-\infty, x] \times [0, +\infty) \times \{x\} \times (-\infty, 0] \times [x^2, +\infty)\Big),$$

and so

$$A^* \times \mathrm{id}_{\mathbb{R}\times\mathbb{R}} \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(\varphi_T^*)) = \mathbb{R} \times \bigcup_{x\geq 0} \Big(\{x\} \times (-\infty, 0] \times [x^2, +\infty)\Big),$$

which is closed; i.e., $(\widetilde{CQ})$ is valid. Thus it is closed regarding the subspace $\mathbb{R} \times \mathrm{Im}(A) \times \mathbb{R} = \mathbb{R} \times \Delta_{\mathbb{R}} \times \mathbb{R}$, too; i.e., (CQ) is satisfied for the chosen T and A. Here we used the notation $\Delta_X = \{(x, x) : x \in X\}$, in case $X = \mathbb{R}$.

Let us calculate now $\cup_{\lambda>0} \lambda(D(T) - \mathrm{Im}(A))$ in order to check the validity of (CQ_Z). It is clear that $D(T) = [0, +\infty) \times (-\infty, 0]$ and $\mathrm{Im}(A) = \Delta_{\mathbb{R}}$. We have $D(T) - \mathrm{Im}(A) = \{[x, +\infty) \times (-\infty, x] : x \in \mathbb{R}\}$, and so

$$\bigcup_{\lambda>0} \lambda(D(T) - \mathrm{Im}(A)) = \{[x, +\infty) \times (-\infty, x] : x \in \mathbb{R}\} = \{(x, y) \in \mathbb{R} : x \geq y\},$$

which is not a subspace, and thus (CQ_Z) is violated. Therefore, even if (CQ_Z) implies (CQ), the reverse implication does not always hold; i.e., (CQ) is indeed weaker than (CQ_Z).

3.2. Maximal monotonicity for the sum of two maximal monotone operators. An important special case of the problem treated in Theorem 1 is the situation when the sum of two maximal monotone operators is maximal monotone. This case is obtained from the general one by taking $Y = X \times X$, $A(x) = (x, x)$ for any $x \in X$ and $T : X \times X \to X^* \times X^*$, $T(x, y) = (T_1(x), T_2(y))$ when $(x, y) \in X \times X$, where T_1 and T_2 are maximal monotone operators on X. It is a simple verification to show that T is maximal monotone. Having these choices, for any $x \in X$ we have $T_A(x) = T_1(x) + T_2(x)$. Moreover, the condition on the domain of φ_T becomes $\mathrm{pr}_1(\mathrm{dom}(\varphi_{T_1})) \cap \mathrm{pr}_1(\mathrm{dom}(\varphi_{T_2})) \neq \emptyset$.

The literature concerning the maximal monotonicity of $T_1 + T_2$ is richer than the one in the more general case. Let us mention here, alongside the papers already cited above, also [3], [20], and [23]. A comprehensive study on this problem is available in [21] (see also [24]), where many sufficient conditions for the maximal monotonicity of the sum of two maximal monotone operators are compared and classified.

Our constraint qualification (CQ) becomes in this special case

(CQ^s) $\{(x^* + y^*, x, y, r) : \varphi^*_{T_1}(x^*, x) + \varphi^*_{T_2}(y^*, y) \leq r\}$ is closed regarding the subspace $X^* \times \Delta_X \times \mathbb{R}$.

Introducing the function (see [23])

$$\rho : X \times X^* \to \overline{\mathbb{R}},\ \rho(v, v^*) = \inf_{x^*, y^* \in X^*} \{\varphi_{T_1}(v, x^*) + \varphi_{T_2}(v, y^*) : x^* + y^* = v^*\},$$

by using Proposition 1, one can show that (CQ^s) is equivalent to

$$\begin{aligned} \rho^*(w^*, w) &= \min_{\substack{x, y \in X, \\ x^*, y^* \in X^*}} \{\varphi^*_{T_1}(x^*, x) + \varphi^*_{T_2}(y^*, y) : x^* + y^* = w^*,\ x = y = w\} \\ &= \min_{\substack{x^*, y^* \in X^*, \\ x^* + y^* = w^*}} \{\varphi^*_{T_1}(x^*, w) + \varphi^*_{T_2}(y^*, w)\}. \end{aligned}$$

In [23] Simons and Zălinescu prove that a sufficient condition for having this equality fulfilled is

$$\bigcup_{\lambda>0} \big(\mathrm{pr}_1(\mathrm{dom}(\varphi_{T_1})) - \mathrm{pr}_1(\mathrm{dom}(\varphi_{T_2}))\big)$$

being a closed linear subspace, which was the weakest constraint qualification guar-

anteeing the maximal monotonicity of $T_1 + T_2$ known so far. Consequently, (CQ) delivers the weakest constraint qualification for the maximal monotonicity of sum of two maximal monotone operators.

THEOREM 2. *Let T_1 and T_2 be maximal monotone operators on X such that $\mathrm{pr}_1(\mathrm{dom}(\varphi_{T_1})) \cap \mathrm{pr}_1(\mathrm{dom}(\varphi_{T_2})) \neq \emptyset$. If (CQ^s) is fulfilled, then $T_1 + T_2$ is a maximal monotone operator on X.*

Remark 5. The other constraint qualification we gave, $(\widetilde{CQ})$, becomes in this case

$$(\widetilde{CQ}^s) \qquad \{(x^* + y^*, x, y, r) : \varphi^*_{T_1}(x^*, x) + \varphi^*_{T_2}(y^*, y) \leq r\} \text{ is closed.}$$

One can prove that $(\widetilde{CQ}^s)$ is weaker than the other constraint qualifications mentioned within this subsection, except (CQ^s), which is implied by it.

Remark 6. One of the reviewers suggested that we try to obtain a constraint qualification for the maximal monotonicity of the precomposition with a linear operator assuming (CQ^s) to be known, by using the approach in [16]. For an appropriate choice of the monotone operators in the sum we have obtained Theorem 1 from Theorem 2. Let us notice that the same applies when using the approach in [9], quite different from the one in [16], for expressing the precomposition via a sum of monotone operators.

4. Brézis–Haraux-type approximation of the range of the subdifferential of the precomposition with a linear operator. Within this part X and Y are considered Banach spaces, unless otherwise specified. Let us mention that, unlike in the previous section, here we do not ask these spaces to be, moreover, reflexive. We rectify, weaken, and generalize a statement due to Riahi [18] concerning the so-called Brézis–Haraux-type approximation of the range of the sum of the subdifferentials of two proper convex lower semicontinuous functions, giving it for the operator T_A introduced in the previous section. Riahi's statement is recovered as a special case, under a weaker sufficient condition than in the original paper.

4.1. Some preliminaries. We need to introduce some notions and to recall some results which are dealt with only within this part. First, we define the so-called monotone operators of dense type, originally introduced by Gossez in [10], of type 3^*, also known as star monotone and of type (BH), and operators of type (NI). Let us stress once again that we work in nonreflexive Banach spaces.

Before this we need to introduce τ_1 as being the weakest topology on X^{**} which renders continuous the following real functions:

$$X^{**} \to \mathbb{R}: \quad x^{**} \mapsto \langle x^{**}, x^* \rangle \quad \forall x^* \in X^*,$$
$$X^{**} \to \mathbb{R}: \quad x^{**} \mapsto \|x^{**}\|.$$

The topology τ considered in $X^{**} \times X^*$ will be the product topology of τ_1 and the strong (norm) topology of X^* (see [10]) .

DEFINITION 5 (cf. [10]). *A monotone operator $T : Y \rightrightarrows Y^*$ is called of* dense type*, provided that the* closure operator $\overline{T} : Y^{**} \rightrightarrows Y^*$ *that is defined as follows:*

$$G(\overline{T}) = \{(x^{**}, x^*) \in Y^{**} \times Y^* : \exists (x_i, x_i^*)_i \in G(T) \text{ with } (\hat{x}_i, x_i^*) \xrightarrow{\tau} (x^{**}, x^*)\}$$

is maximal monotone.

Different from Riahi in [18], where these operators are called *densely maximal monotone*, we decided to call them of *dense type* as originally done by Gossez in [10]. By Lemme 2.1 in the same paper, for a monotone operator $T : Y \rightrightarrows Y^*$ of dense type, one has $(x^{**}, x^*) \in G(\overline{T})$ if and only if $\langle x^{**} - \hat{y},\, x^* - y^* \rangle \geq 0\ \forall (y, y^*) \in G(T)$.

DEFINITION 6 (cf. [6], [14], [18]). *A monotone operator $T : Y \rightrightarrows Y^*$ is called* 3^*-monotone *if $\forall x^* \in R(T)$ and $x \in D(T)$ there is some $\beta(x^*, x) \in \mathbb{R}$ such that* $\inf_{y^* \in T(y)} \langle x^* - y^*,\, x - y \rangle \geq \beta(x^*, x)$.

DEFINITION 7 (cf. [21], [22]). *An operator $T : Y \rightrightarrows Y^*$ is called of* type (NI) *if $\forall (x^{**}, x^*) \in Y^{**} \times Y^*$ one has* $\inf_{y^* \in T(y)} \langle \hat{y} - x^{**},\, y^* - x^* \rangle \leq 0$.

Some necessary results follow.

LEMMA 3 (cf. [18]). *Given the operator $T : Y \rightrightarrows Y^*$ of dense type and the nonempty subset $E \subseteq Y^*$ such that for any $x^* \in E$ there is some $x \in Y$ fulfilling* $\inf_{y^* \in T(y)} \langle y^* - x^*,\, y - x \rangle > -\infty$, *one has $E \subseteq \mathrm{cl}(R(T))$ and $\mathrm{int}(E) \subseteq R(\overline{T})$.*

PROPOSITION 4. *If $T : Y \rightrightarrows Y^*$ is 3^*-monotone and $A : X \to Y$ is a linear continuous mapping such that T_A is of dense type, then*

(i) $A^*(R(T)) \subseteq \mathrm{cl}(R(T_A))$,

(ii) $\mathrm{int}(A^*(R(T))) \subseteq R(\overline{T_A})$.

Proof. As T is 3^*-monotone, we have for any $s \in D(T)$ and any $s^* \in R(T)$ that there is some $\beta(s^*, s) \in \mathbb{R}$ such that $\beta(s^*, s) \leq \inf_{x^* \in T(x)} \langle s^* - x^*,\, s - x \rangle$.

To apply Lemma 3 for $E = A^*(R(T))$ and T_A, we need to verify if they satisfy its hypothesis. Take some $u^* \in A^*(R(T))$, and thus there is an $v^* \in R(T)$ such that $u^* = A^* v^*$. We have for any $u \in X$

$$\inf_{x^* \in T_A(x)} \langle x^* - u^*, x - u \rangle = \inf_{t^* \in T \circ A(x)} \langle A^* t^* - A^* v^*, x - u \rangle$$

$$= \inf_{t^* \in T \circ A(x)} \langle t^* - v^*, A(x - u) \rangle \geq \inf_{t^* \in T(t)} \langle t^* - v^*, t - Au) \rangle \geq \beta(v^*, Au) > -\infty.$$

Having this fulfilled for any u, we apply Lemma 3 which yields (i) and (ii). □

PROPOSITION 5 (cf. [10, Remark 1]). *In reflexive Banach spaces every maximal monotone operator is of dense type and coincides with its closure operator.*

The last result we give here carries the 3^*-monotonicity from T to T_A.

PROPOSITION 6. *If $T : Y \rightrightarrows Y^*$ is 3^*-monotone and $A : X \to Y$ is a linear continuous mapping, then T_A is 3^*-monotone, too.*

Proof. Take $x^* \in R(T_A)$; i.e., there is some $z \in X$ such that $x^* \in A^* \circ T \circ A(z)$. Thus there exists a $z^* \in T \circ A(z)$ satisfying $x^* = A^* z^*$. Clearly, $z^* \in R(T)$. Consider also an $x \in D(T_A)$ and denote $u = Ax \in D(T)$. When $y^* \in T_A(y)$ there is some $t^* \in T \circ A(y)$ such that $y^* = A^* t^*$. We have

$$\begin{aligned} \inf_{y^* \in T_A(y)} \langle x^* - y^*, x - y \rangle &= \inf_{t^* \in T \circ A(y)} \langle A^* z^* - A^* t^*, x - y \rangle \\ &= \inf_{t^* \in T \circ A(y)} \langle z^* - t^*, A(x - y) \rangle \\ &\geq \inf_{t^* \in T(v)} \langle z^* - t^*, u - v \rangle \geq \beta(z^*, u) \in \mathbb{R}, \end{aligned}$$

as T is 3^*-monotone. Therefore T_A is 3^*-monotone, too. □

4.2. Rectifying and extending Riahi's results. We give here the main results in this section concerning the so-called Brézis–Haraux-type approximation (see [21]) of the range of the operator T_A (respectively, of the subdifferential of the precomposition of a linear continuous mapping with a proper convex lower semicontinuous

function). Some results related to them were obtained by Pennanen in [14] but in reflexive spaces.

THEOREM 3. *If $T : Y \rightrightarrows Y^*$ is 3^*-monotone and $A : X \to Y$ is a linear continuous mapping such that T_A is of dense type, then*

(i) $\mathrm{cl}(A^*(R(T))) = \mathrm{cl}(R(T_A))$,

(ii) $\mathrm{int}(R(T_A)) \subseteq \mathrm{int}(A^*(R(T))) \subseteq \mathrm{int}(R(\overline{T_A}))$.

Proof. By Proposition 4(i) we have also $\mathrm{cl}(A^*(R(T))) \subseteq \mathrm{cl}(R(T_A))$ and $\mathrm{int}(A^*(R(T))) \subseteq \mathrm{int}(R(\overline{T_A}))$. Take some $x^* \in R(T_A)$. Then there are some $x \in X$ and $y^* \in T \circ A(x) \subseteq R(T)$ such that $x^* = A^* y^*$. Thus $x^* \in A^*(R(T))$, and so $R(T_A) \subseteq A^*(R(T))$, and so the same inclusion stands also between the closures (respectively, the interiors) of these sets. Relations (i) and (ii) follow immediately by Proposition 4. □

Remark 7. The previous statement generalizes Theorem 1 in [18], which can be obtained for $Y = X \times X$, $Ax = (x, x)$, and $T = (T_1, T_2)$. The next consequence extends Corollary 1 in [18] which arises for the same choice of Y, A, and T.

COROLLARY 2. *Assume X to be, moreover, reflexive and let $T : Y \rightrightarrows Y^*$ be 3^*-monotone and $A : X \to Y$ a linear continuous mapping such that T_A is maximal monotone. Then one has $\mathrm{cl}(A^*(R(T))) = \mathrm{cl}(R(T_A))$ and $\mathrm{int}(R(T_A)) = \mathrm{int}(A^*(R(T)))$.*

Proof. As X is reflexive, Proposition 5 yields that T_A is of dense type and that $\overline{T_A}$ and T_A coincide. We apply Theorem 3, which yields the conclusion. □

The next statement generalizes Corollary 2 in [18], providing, moreover, a weaker constraint qualification under which one can assert the Brézis–Haraux-type approximation of the range of the sum of the subdifferentials of two proper convex lower semicontinuous functions. First, we give the constraint qualification that guarantees our more general result,

$(\overline{CQ})$ $A^* \times \mathrm{id}_{\mathbb{R}}(\mathrm{epi}(f^*))$ is closed in the product topology of $(X^*, w(X^*, X)) \times \mathbb{R}$.

THEOREM 4. *Let the proper convex lower semicontinuous function $f : Y \to \overline{\mathbb{R}}$ and the linear continuous operator $A : X \to Y$ such that $f \circ A$ be proper and assume $(\overline{CQ})$ to be valid. Then one has*

(i) $\mathrm{cl}(A^*(R(\partial f))) = \mathrm{cl}(R(\partial(f \circ A)))$,

(ii) $\mathrm{int}(R(\partial(f \circ A))) \subseteq \mathrm{int}(A^*(R(\partial f))) \subseteq \mathrm{int}(D(\partial(A^* f^*)))$.

Proof. By Corollary 1(ii) we know that $(\overline{CQ})$ implies $A^* \circ \partial f \circ A = \partial(f \circ A)$. Again, $f \circ A$ is proper, convex, and lower semicontinuous, and so by Théoréme 3.1 in [10] we know that $\partial(f \circ A)$ is an operator of dense type, while according to Theorem B in [19] (see also [14], [18]) ∂f is 3^*-monotone. Applying Theorem 3 for $T = \partial f$ we get $\mathrm{cl}(A^*(R(\partial f))) = \mathrm{cl}(R(A^* \circ \partial f \circ A))$, which with $(\overline{CQ})$ yields (i), and $\mathrm{int}(R(A^* \circ \partial f \circ A)) \subseteq \mathrm{int}(A^*(R(\partial f))) \subseteq \mathrm{int}(R(\overline{A^* \circ \partial f \circ A}))$. Using $(\overline{CQ})$ the latter becomes

$$\mathrm{int}(R(\partial(f \circ A))) \subseteq \mathrm{int}(A^*(R(\partial f))) \subseteq \mathrm{int}(R(\overline{\partial(f \circ A)})). \tag{8}$$

As from Corollary 1(i) one may deduce that under $(\overline{CQ})$ $A^* f^* = (f \circ A)^*$, by Théoréme 3.1 in [10] we get $R(\overline{\partial(f \circ A)}) = D(\partial(f \circ A)^*) = D(\partial(A^* f^*))$. Taking this into (8) we get (ii). □

When one takes $Y = X \times X$, $Ax = (x, x)$, and $f(x, y) = g(x) + h(y)$, where $x, y \in X$, the constraint qualification $(\overline{CQ})$ becomes (see [2])

$(\overline{CQ}^s)$ $\mathrm{epi}(g^*) + \mathrm{epi}(h^*)$ is closed in the product topology of $(X^*, w(X^*, X)) \times \mathbb{R}$.

COROLLARY 3. *Let g and h be two proper convex lower semicontinuous functions on the Banach space X with extended real values such that* $\operatorname{dom}(g) \cap \operatorname{dom}(h) \neq \emptyset$. *Assume* $(\overline{CQ}^s)$ *satisfied. Then one has*

(i) $\operatorname{cl}(R(\partial g) + R(\partial h)) = \operatorname{cl}(R(\partial(g+h)))$,

(ii) $\operatorname{int}(R(\partial(g+h))) \subseteq \operatorname{int}(R(\partial g) + R(\partial h)) \subseteq \operatorname{int}(D(\partial(g^* \square h^*)))$.

A similar result has been obtained by Riahi in Corollary 2 in [18]. There he said that under the constraint qualification

$$(\overline{CQ}_R) \qquad \bigcup_{t>0} t(\operatorname{dom}(g) - \operatorname{dom}(h)) \text{ is a closed linear subspace of } X,$$

one gets $\operatorname{cl}(R(\partial g) + R(\partial h)) = \operatorname{cl}(R(\partial(g+h)))$ and $\operatorname{int}(R(\partial g) + R(\partial h)) = \operatorname{int}(D(\partial(g^* \square h^*)))$.

We prove that the latter is not always true when $(\overline{CQ}_R)$ stands. For a proper, convex, and lower semicontinuous function $g : X \to \overline{\mathbb{R}}$ Riahi's relation would become $\operatorname{int}(R(\partial g)) = \operatorname{int}(D(\partial g^*))$, which is equivalent, by Théoréme 3.1 in [10] to

$$\operatorname{int}(R(\partial g)) = \operatorname{int}(R(\overline{\partial g})). \tag{9}$$

From the above mentioned theorem we also have that ∂g is a monotone operator of dense type, and it is also known that it is maximal monotone, too. According to Simons [22] ∂g is also of type (NI). Finally, by Lemme 2.1 in [10] and by Theorem 20 in [22], we get that $\operatorname{int}(R(\overline{\partial g}))$ is convex, and so (9) yields $\operatorname{int}(R(\partial g))$ convex. Unfortunately this is not always true, as Example 2.21 in [17], originally given by Fitzpatrick, shows. Take $X = c_0$, which is a Banach space with the usual supremum norm, and $g(x) = \|x\| + \|x - (1, 0, 0, \dots)\|$, a proper, convex, and continuous function on c_0. Skipping the calculatory details, it follows that $\operatorname{int}(R(\partial g))$ is not convex, unlike $\operatorname{int} R(\overline{\partial g})$. Thus (9) is false and the same happens to Riahi's allegation.

Remark 8. As proven in Proposition 3.1 in [4] (see also [2]), $(\overline{CQ}_R)$ implies $(\overline{CQ}^s)$, but the converse is not true, as shown by Example 3.1 in the same paper. Therefore our Corollary 3 extends, by weakening the constraint qualification, and corrects Corollary 2 in [18].

5. Conclusions. Given a maximal monotone operator T on the reflexive Banach space Y and the linear continuous operator $A : X \to Y$, where X is a reflexive Banach space, too, we give a sufficient condition for the maximal monotonicity of $A^* \circ T \circ A$ weaker than the generalized interior-point regularity conditions known to us from the literature. Moreover, when Y, A, and T are chosen such that the assertion turns into the maximal monotonicity of the sum of two maximal monotone operators on a reflexive Banach space X, we prove that our constraint qualification is actually the weakest condition guaranteeing the mentioned result known to us. In the second part of the paper, where we work in nonreflexive Banach spaces, we rectify and extend a result due to Riahi, giving a weak constraint qualification in order to ensure the so-called Brézis–Haraux-type approximation of the range of $\partial(f \circ A)$, where $f : Y \to \overline{\mathbb{R}}$ is a proper convex lower semicontinuous function. For a special choice of functions we prove that the corrected version of Riahi's results holds under a weaker constraint qualification than required by him.

Acknowledgments. The authors are grateful to the anonymous reviewers for some valuable suggestions which improved the quality of the paper. Moreover, we are thankful to one of them for making us aware of the differences between the classes of monotone operators of *dense type* and of *type* (D).

AN IMPLEMENTABLE ACTIVE-SET ALGORITHM FOR COMPUTING A B-STATIONARY POINT OF A MATHEMATICAL PROGRAM WITH LINEAR COMPLEMENTARITY CONSTRAINTS: ERRATUM*

MASAO FUKUSHIMA† AND PAUL TSENG‡

Abstract. In [M. Fukushima and P. Tseng, *SIAM J. Optim.*, 12 (2002), pp. 724–739], an ϵ-active set algorithm was proposed for solving a mathematical program with a smooth objective function and linear inequality/complementarity constraints. It is asserted therein that, under a uniform LICQ on the ϵ-feasible set, this algorithm generates iterates whose cluster points are B-stationary points of the problem. However, the proof has a gap and shows only that each cluster point is an M-stationary point. We discuss this gap and show that B-stationarity can be achieved if the algorithm is modified and an additional error bound condition holds.

Key words. MPEC, B-stationary point, ϵ-active set, error bound

1. Introduction. In a recent paper by the authors [3], an ϵ-active set algorithm was proposed for solving the following mathematical program with equilibrium constraints (MPEC):

$$\begin{array}{lll} \text{minimize} & f(z) & \\ \text{subject to} & G_i(z) \geq 0, & i = 1, \ldots, m, \\ & H_i(z) \geq 0, & i = 1, \ldots, m, \\ & G_i(z)H_i(z) = 0, & i = 1, \ldots, m, \\ & g_j(z) \leq 0, & j = 1, \ldots, p, \\ & h_l(z) = 0, & l = 1, \ldots, q, \end{array} \tag{1}$$

where f is a real-valued continuously differentiable function on $\Re^n$ and G_i, H_i, g_j, h_l are real-valued *affine* functions on $\Re^n$. In Theorem 4.1(a) of [3], it is asserted that every cluster point of iterates generated by the algorithm is a B-stationary point of (1). However, the proof has a gap and shows only that every cluster point is an M-stationary point. We will discuss this gap and a modified algorithm that achieves B-stationarity under an additional error bound condition.

The gap occurs on [3, page 734] in the line "If $\nu_k \to 0$, then $|\mathcal{K}'| = \infty$, $\delta_k \to 0$, and the updating formula for ϵ_k would imply $\epsilon_k \to 0$, so any cluster point $\bar{z}$ of $\{\hat{z}^k\}_{k \in \mathcal{K}'}$ would be a KKT point of the *relaxed problem* $\mathrm{R}(\bar{z})$, which is a B-stationary point of

MPEC (1) under the uniform LICQ." In particular, we have for all $k \in \mathcal{K}'$ that

$$v_i^k \geq -\nu_k \quad \text{and} \quad w_i^k \geq -\nu_k \quad \forall\, i \in \hat{A}^k \cap \hat{B}^k, \tag{2}$$

where $\hat{A}^k$, $\hat{B}^k$ are given by [3, eq. (7)] and v_i^k, w_i^k are multipliers associated with $\hat{z}^k$ (see [3, eqs. (5), (6)]).[1] Thus, if a subsequence $\{\hat{z}^k\}_{k\in\mathcal{K}''}$ ($\mathcal{K}'' \subseteq \mathcal{K}'$) converges to some $\bar{z}$, then by further passing to a subsequence if necessary, we can assume that the index sets $\hat{A}^k$ and $\hat{B}^k$ are constant (i.e., $\hat{A}^k = \bar{A}$, $\hat{B}^k = \bar{B}$ for some $\bar{A}$, $\bar{B}$) for all $k \in \mathcal{K}''$. Since $\bar{z}$ satisfies the uniform LICQ, $\{(v_i^k)_{i\in\bar{A}}, (w_i^k)_{i\in\bar{B}}\}_{k\in\mathcal{K}''}$ also converges to some $(\bar{v}_i)_{i\in\bar{A}}, (\bar{w}_i)_{i\in\bar{B}}$.[2] By (2),

$$\bar{v}_i \geq 0 \quad \text{and} \quad \bar{w}_i \geq 0 \quad \forall\, i \in \bar{A} \cap \bar{B}.$$

This together with [3, eqs. (5), (6)] implies that $\bar{z}$ is an *M-stationary point* (see [4, 5] and (5) below). If in addition

$$\bar{A} \cap \bar{B} = A_0(\bar{z}) \cap B_0(\bar{z}), \tag{3}$$

then $\bar{z}$ is a B-stationary point of (1). In general, however, we can only assert that $\bar{A} \cap \bar{B} \subseteq A_0(\bar{z}) \cap B_0(\bar{z})$. This is the gap.

2. A modified ϵ-active set algorithm. We now describe a way, based on the active set identification approach of Facchinei, Fischer, and Kanzow [1], to modify the ϵ-active set algorithm so that (3) holds under an additional error bound condition. To simplify the notation, we will consider only the complementarity constraints, i.e., we assume $p = q = 0$ in (1). The general case can be treated analogously. The Lagrangian associated with (1) is

$$L(z, v, w) := f(z) + \sum_{i=1}^{m} (G_i(z)v_i + H_i(z)w_i).$$

We assume that there exists a computable continuous function $R : \Re^n \times \Re^m \times \Re^m \to [0, \infty)$ providing a local Hölder error bound at each M-stationary point $\bar{z}$ that is not B-stationary, i.e., there exist scalars $\tau > 0$, $\gamma > 0$, and $\delta > 0$ (depending on $\bar{z}$) such that

$$\|(z, v, w) - (\bar{z}, \bar{v}, \bar{w})\| \leq \tau R(z, v, w)^\gamma \quad \text{whenever } \|(z, v, w) - (\bar{z}, \bar{v}, \bar{w})\| \leq \delta, \tag{4}$$

where the multiplier vectors $\bar{v}, \bar{w}$ satisfy

$$\nabla_z L(\bar{z}, \bar{v}, \bar{w}) = 0, \ \left\{ \begin{array}{l} \bar{v}_i \perp G_i(\bar{z}) \geq 0 \\ \bar{w}_i \perp H_i(\bar{z}) \geq 0 \end{array} \right\}, \ G_i(\bar{z})H_i(\bar{z}) = 0, \ \left\{ \begin{array}{c} \bar{v}_i\bar{w}_i \geq 0 \\ \bar{v}_i \geq 0 \text{ or } \bar{w}_i \geq 0 \end{array} \right\} \ \forall i. \tag{5}$$

Here, $a \perp b$ means $ab = 0$. Due to uniform LICQ, $\bar{v}, \bar{w}$ are uniquely determined by $\bar{z}$. In fact, (5) characterizes M-stationarity for any $\bar{z} \in \Re^n$. We also assume that

$$R(\bar{z}, \bar{v}, \bar{w}) = 0 \quad \Longleftrightarrow \quad (\bar{z}, \bar{v}, \bar{w}) \text{ satisfies (5)}. \tag{6}$$

[1] Throughout, we use the same notation as [3].

[2] This follows from [3, eq. (6)], $\|r^k\|_1 \leq \delta_k \to 0$ (see [3, eq. (5)]), and the fact that if $b^k = C^k u^k$ for all k and $b^k \to b \in \Re^q$, $C^k \to C \in \Re^{q\times p}$ with C having linearly independent columns, then $u^k \to u \in \Re^p$ with u being the unique solution of $b = Cu$.

The "residual" function $R(z,v,w)$ can be constructed analogous to the NLP and NCP cases [1, 2]. In particular, consider

$$
\begin{aligned}
R(z,v,w) \quad &:= \quad \|\nabla_z L(z,v,w)\| + \sum_{i=1}^{m}\Big(|\min\{G_i(z),|v_i|\}| + |\min\{H_i(z),|w_i|\}| \\
&+ \quad |G_i(z)H_i(z)| + |\min\{0,v_i w_i\}| + |\min\{0,v_i\}\min\{0,w_i\}|\Big).
\end{aligned} \tag{7}
$$

Then, R is continuous and satisfies (6). Arguing as in the proof of Corollary 6.6.4 in [2], we have that the local error bound (4) holds if the M-stationary point $\bar{z}$ is isolated and f and ∇f are continuous and subanalytic (G and H, by being affine, are automatically continuous and subanalytic). A referee suggests that the assumption of $\bar{z}$ being isolated is benign when G and H are affine. In particular, it is readily shown that the M-stationary points of (1) are isolated if f is strictly convex on the null space of the active constraint gradients. Alternatively, it can be shown that the local error bound (4) holds with $\gamma = 1$ if a certain second-order sufficient condition holds at $\bar{z}$. This is a topic for further research.

Let $\theta : (0,\infty) \to (0,\infty)$ be any continuous nondecreasing function satisfying $\lim_{t\downarrow 0} t/\theta(t^\gamma) = 0$ for any $\gamma > 0$. An example is $\theta(t) = -C/\log(\min\{t, 0.9\})$ with $C > 0$. Using (4), (6) and following [1, 2], the function

$$\Theta(z,v,w) := \theta(R(z,v,w))$$

has the active set identification property that, for any M-stationary point $\bar{z}$ that is not B-stationary and corresponding multiplier vectors $\bar{v}, \bar{w}$, we have

$$\lim_{(z,v,w)\to(\bar{z},\bar{v},\bar{w})} \frac{G_i(z)}{\Theta(z,v,w)} = \begin{cases} 0 & \text{if } G_i(\bar{z}) = 0, \\ \infty & \text{if } G_i(\bar{z}) > 0, \end{cases}$$

and similarly with "G_i" replaced by "H_i."

Let us define

$$\bar{A}^k := \left\{ i \in \{1,\dots,m\} : \frac{G_i(\hat{z}^k)}{\Theta(\hat{z}^k, v^k, w^k)} \le 1 \right\},$$

$$\bar{B}^k := \left\{ i \in \{1,\dots,m\} : \frac{H_i(\hat{z}^k)}{\Theta(\hat{z}^k, v^k, w^k)} \le 1 \right\},$$

where the ith component of v^k is v_i^k if $i \in \hat{A}^k$ and is zero otherwise (and w^k is defined analogously). Since $(\hat{z}^k, v^k, w^k)$ satisfies [3, eqs. (4)–(6)], if (2) holds, then $R(\hat{z}^k, v^k, w^k)$ would tend to zero as $\hat{z}^k \to \bar{z}$ and $\epsilon_k, \delta_k, \nu_k$ tend to zero and, for $\hat{z}^k$ sufficiently near $\bar{z}$, we would have (v^k, w^k) sufficiently near $(\bar{v}, \bar{w})$ (due to [3, A2]) and

$$\bar{A}^k = A_0(\bar{z}), \quad \bar{B}^k = B_0(\bar{z}), \tag{8}$$

as well as

$$A_\epsilon(\hat{z}^k) \supseteq \bar{A}^k \supseteq \hat{A}^k, \qquad B_\epsilon(\hat{z}^k) \supseteq \bar{B}^k \supseteq \hat{B}^k, \tag{9}$$

where $\epsilon \ge 0$ is defined as in [3] (see page 727 therein).[3] Let

$$\bar{\epsilon}_k := \max\left\{ \epsilon_k, \max_{i\in\bar{A}^k} G_i(\hat{z}^k), \max_{i\in\bar{B}^k} H_i(\hat{z}^k) \right\}. \tag{10}$$

[3]The first containment in (9) holds whenever $\Theta(\hat{z}^k, v^k, w^k) \le \epsilon$, which in turn holds whenever $R(\hat{z}^k, v^k, w^k)$ is sufficiently small. By (8) and [3, eq. (7)], the second containment in (9) holds whenever $A_0(\bar{z}) \supseteq A_{\epsilon_k}(\hat{z}^k)$, which in turn holds whenever $\hat{z}^k$ is near $\bar{z}$ and ϵ_k is sufficiently small. The other two containments can be argued similarly.

Since $\bar{\epsilon}_k \geq \epsilon_k$, [3, eq. (4)] implies that $\hat{z}^k \in \mathcal{F}_{\bar{\epsilon}_k}[A^k, B^k]$ for all k. In fact, it can be seen that $\hat{z}^k$ remains an approximate KKT point of the subproblem [3, eq. (3)] (in the sense of [3, eqs. (4)–(6)]) when ϵ_k is replaced by $\bar{\epsilon}_k$ and $\hat{A}^k, \hat{B}^k$ are correspondingly replaced by $A_{\bar{\epsilon}_k}(\hat{z}^k), B_{\bar{\epsilon}_k}(\hat{z}^k)$. Thus, we can modify Step 2 of the ϵ-active set algorithm by possibly making this replacement when we are in case (c) and (9) holds.

THE MODIFIED $\boldsymbol{\epsilon}$-ACTIVE SET ALGORITHM FOR MPEC (1).

This is the same as the ϵ-active set algorithm in [3, pp. 730–731], except that when we are in case (c) in Step 2, we do the following: If

$$\text{(9) holds,} \quad \bar{A}^k \cap \bar{B}^k \neq \hat{A}^k \cap \hat{B}^k, \quad \bar{\epsilon}_k < \bar{\epsilon} \tag{11}$$

($\bar{\epsilon}$ is a threshold which initially can be any positive scalar below ϵ), then repeat Step 2 with ϵ_k replaced by $\bar{\epsilon}_k$ (and with $\hat{A}^k$, $\hat{B}^k$ redefined accordingly, i.e., they are replaced by $A_{\bar{\epsilon}_k}(\hat{z}^k), B_{\bar{\epsilon}_k}(\hat{z}^k)$ in Step 2, (9), (11)), and update $\bar{\epsilon} \leftarrow \bar{\epsilon}/2$. Otherwise, if $\epsilon_k \leq \epsilon_{\rm tol}$ and $\nu_k \leq \nu_{\rm tol}$, then terminate; otherwise, determine ν_{k+1} and $\tilde{z}^k$ by [3, eq. (14)], and proceed to Step 3.

If (11) holds, then $\epsilon_k < \bar{\epsilon}_k$,[4] which in turn implies $\bar{A}^k = A_{\bar{\epsilon}_k}(\hat{z}^k)$ and $\bar{B}^k = B_{\bar{\epsilon}_k}(\hat{z}^k)$.[5] Thus, when Step 2 is repeated, the second relation in (11) is violated.

THEOREM 2.1. *Under assumptions* [3, A1–A3], *the following results hold for the sequence* $\{(z^k, \hat{z}^k, \tilde{z}^k, \epsilon_k, \nu_k)\}$ *generated by the modified* ϵ*-active set algorithm, with* $\bar{\mathcal{K}} := \{k : \textit{at iteration } k, \textit{ Step 2 is repeated}\}$.

(a) *Suppose that each M-stationary point* $\bar{z}$ *of MPEC* (1) *that is not B-stationary satisfies* (4), *where* $(\bar{v}, \bar{w})$ *satisfies* (5) *and* R *satisfies* (6). *If* $\epsilon_0 > 0$, $\nu_0 > 0$, $\epsilon_{\rm tol} = \nu_{\rm tol} = 0$, f *is Lipschitz continuous with constant* L *on a set* Z *containing* $\{z^k\}$ *and* $\{\tilde{z}^k\}$, *and* $|\bar{\mathcal{K}}| < \infty$ *(respectively,* $|\bar{\mathcal{K}}| = \infty$*), then* $\epsilon_k \downarrow 0$, $\nu_k \downarrow 0$, *and every cluster point of* $\{\hat{z}^k\}$ *(respectively,* $\{\hat{z}^k\}_{k\in\bar{\mathcal{K}}}$*) is a B-stationary point of MPEC* (1).

(b) *If* $\epsilon_0 = \nu_0 = 0$ *and* f *is quadratic, then there exists a* $\bar{k} \in \{0, 1, \ldots\}$ *such that* $\hat{z}^{\bar{k}}$ *is a B-stationary point of MPEC* (1).

Proof. The first paragraph of the proof is identical to the proof of [3, Thm. 4.1], except we define $\mathcal{K} := \{k :$ We enter Step 3 from case (a) or (b) in Step 2 at iteration $k\}$ and $\mathcal{K}' := \{k :$ We enter Step 3 from case (c) in Step 2 at iteration $k\}$. The proof of (b) is identical to the proof of [3, Thm. 4.1(b)]. We prove (a) below.

(a) Suppose $\nu_k \to 0$. Then $|\mathcal{K}'| = \infty$, $\delta_k \to 0$, and the updating formulas for ϵ_k and $\bar{\epsilon}$ imply $\epsilon_k \to 0$, so any cluster point $\bar{z}$ of $\{\hat{z}^k\}_{k\in\mathcal{K}'}$ is an M-stationary point of MPEC (1). First, suppose $|\bar{\mathcal{K}}| < \infty$, so that $\bar{\epsilon} > 0$ is constant after a while. Let $\{\hat{z}^k\}_{k\in\mathcal{K}''}$ ($\mathcal{K}'' \subseteq \mathcal{K}'$) be any subsequence converging to $\bar{z}$. Since [3, eqs. (4)–(6)] and (2) hold for all $k \in \mathcal{K}''$, we have from [3, A2] and the same argument as in section 1 that $\{(v^k, w^k)\}_{k\in\mathcal{K}''} \to (\bar{v}, \bar{w})$ satisfying (5). By (6), $R(\bar{z}, \bar{v}, \bar{w}) = 0$. Since R is continuous, $\{R(\hat{z}^k, v^k, w^k)\}_{k\in\mathcal{K}''} \to 0$. If $\bar{z}$ is not B-stationary for (1), then the error bound (4) would hold and this would imply that (8) and (9) hold for all $k \in \mathcal{K}''$ sufficiently large. Moreover, $\{\bar{\epsilon}_k\}_{k\in\mathcal{K}''} \to 0$, so that $\bar{\epsilon}_k < \bar{\epsilon}$ for all $k \in \mathcal{K}''$ sufficiently

[4] If $\epsilon_k = \bar{\epsilon}_k$, then (10) and [3, eq. (7)] would imply $\bar{A}^k \subseteq \hat{A}^k$ and $\bar{B}^k \subseteq \hat{B}^k$, so (9) would yield $\bar{A}^k = \hat{A}^k$ and $\bar{B}^k = \hat{B}^k$, contradicting (11).

[5] Why? Since $\epsilon_k < \bar{\epsilon}_k$, we have from (10) and the definition of $\bar{A}^k$ and $\bar{B}^k$ that

$$\bar{\epsilon}_k = \max\left\{\max_{i\in\bar{A}^k} G_i(\hat{z}^k), \max_{i\in\bar{B}^k} H_i(\hat{z}^k)\right\} \leq \Theta(\hat{z}^k, v^k, w^k).$$

Thus, if $i \notin \bar{A}^k$, then $G_i(\hat{z}^k) > \Theta(\hat{z}^k, v^k, w^k) \geq \bar{\epsilon}_k$. By (10), if $i \in \bar{A}^k$, then $G_i(\hat{z}^k) \leq \bar{\epsilon}_k$. This shows that $\bar{A}^k = A_{\bar{\epsilon}_k}(\hat{z}^k)$. An analogous argument shows that $\bar{B}^k = B_{\bar{\epsilon}_k}(\hat{z}^k)$.

large. Thus, at each such iteration $k \in \mathcal{K}''$, we would have upon entering Step 3 that $\bar{A}^k \cap \bar{B}^k = \hat{A}^k \cap \hat{B}^k$ (since (11) must be violated). Then it would follow from (2) and (8) that $\bar{z}$ is a B-stationary point of (1), a contradiction. Second, suppose $|\bar{\mathcal{K}}| = \infty$. Then, as we discussed earlier, for each iteration $k \in \bar{\mathcal{K}}$, the second relation in (11) is violated upon entering Step 3, i.e., $\bar{A}^k \cap \bar{B}^k = \hat{A}^k \cap \hat{B}^k$. Then, an argument similar to the one above shows that every cluster point $\bar{z}$ of $\{\hat{z}^k\}_{k \in \bar{\mathcal{K}}}$ is a B-stationary point of (1).

Suppose instead $\nu_k \not\to 0$, so that $|\mathcal{K}'| < \infty$, $|\mathcal{K}| = \infty$, and $\nu = \lim_{k \to \infty} \nu_k > 0$. The remainder of the proof is identical to the proof of [3, Thm. 4.1(a)], except that, due to ϵ_k being replaced by $\bar{\epsilon}_k$ in Step 2 for all iterations $k \in \bar{\mathcal{K}}$, instead of [3, eq. (22)] we have

$$f(z^{k+1}) \le f(\tilde{z}^k) + 2L\tau m(\epsilon_k - \epsilon_{k+1} + \Delta_k) \quad \forall\, k,$$

where $\Delta_k := \bar{\epsilon}_k$ if $k \in \bar{\mathcal{K}}$ and $\Delta_k := 0$ otherwise. Since (11) holds at each iteration $k \in \bar{\mathcal{K}}$ and $\bar{\epsilon}$ is halved at each such iteration, it follows that $\sum_{k=0}^{\infty} \Delta_k = \sum_{k \in \bar{\mathcal{K}}} \bar{\epsilon}_k < \infty$. Then it can be argued similarly as in the proof of [3, Thm. 4.1(a)] that $\{f(z^k)\}$ converges and so on. □

We illustrate the assumptions of Theorem 2.1 with the following example of (1):

$$\text{minimize} \quad f(z) \quad \text{subject to} \quad z_1 \ge 0,\ z_2 \ge 0,\ z_1 z_2 = 0.$$

This example satisfies assumption [3, A2] for any $\epsilon \ge 0$. If $f(z) = (z_2)^p$ $(p \ge 1)$, then assumption [3, A1] also holds and each M-stationary point, which is of the form $(\bar{z}_1, 0)$ with $\bar{z}_1 \ge 0$, is B-stationary. If $f(z) = z_1^4 + z_2^2 - z_2$, then assumptions [3, A1, A3] also hold and the M-stationary points, $(0,0)$ and $(0, \frac{1}{2})$, are isolated with $(0, \frac{1}{2})$ B-stationary. For R given by (7), the error bound (4) holds at $(0,0)$. However, if $f(z) = z_2^2 - z_2$, then the M-stationary point $\bar{z} = (0,0)$, with multipliers $\bar{v} = 0, \bar{w} = -1$, is not B-stationary and is not isolated. Moreover, for any continuous R satisfying (6), the error bound (4) does not hold at $(0,0)$. This is because, for any fixed $\delta > 0$, $(\delta, 0)$ is M-stationary with multipliers $v = 0, w = -1$, so $R((\delta, x_2), 0, -1) \to R(\delta, 0), 0, -1) = 0$ as $x_2 \to 0$. But $\|((\delta, x_2), 0, -1) - ((0,0), 0, -1)\| \to \delta$ as $x_2 \to 0$.

Acknowledgments. The authors thank Lifeng Chen for notifying them of the gap in the proof of [3, Thm. 4.1]. They also thank two referees for their helpful comments.
